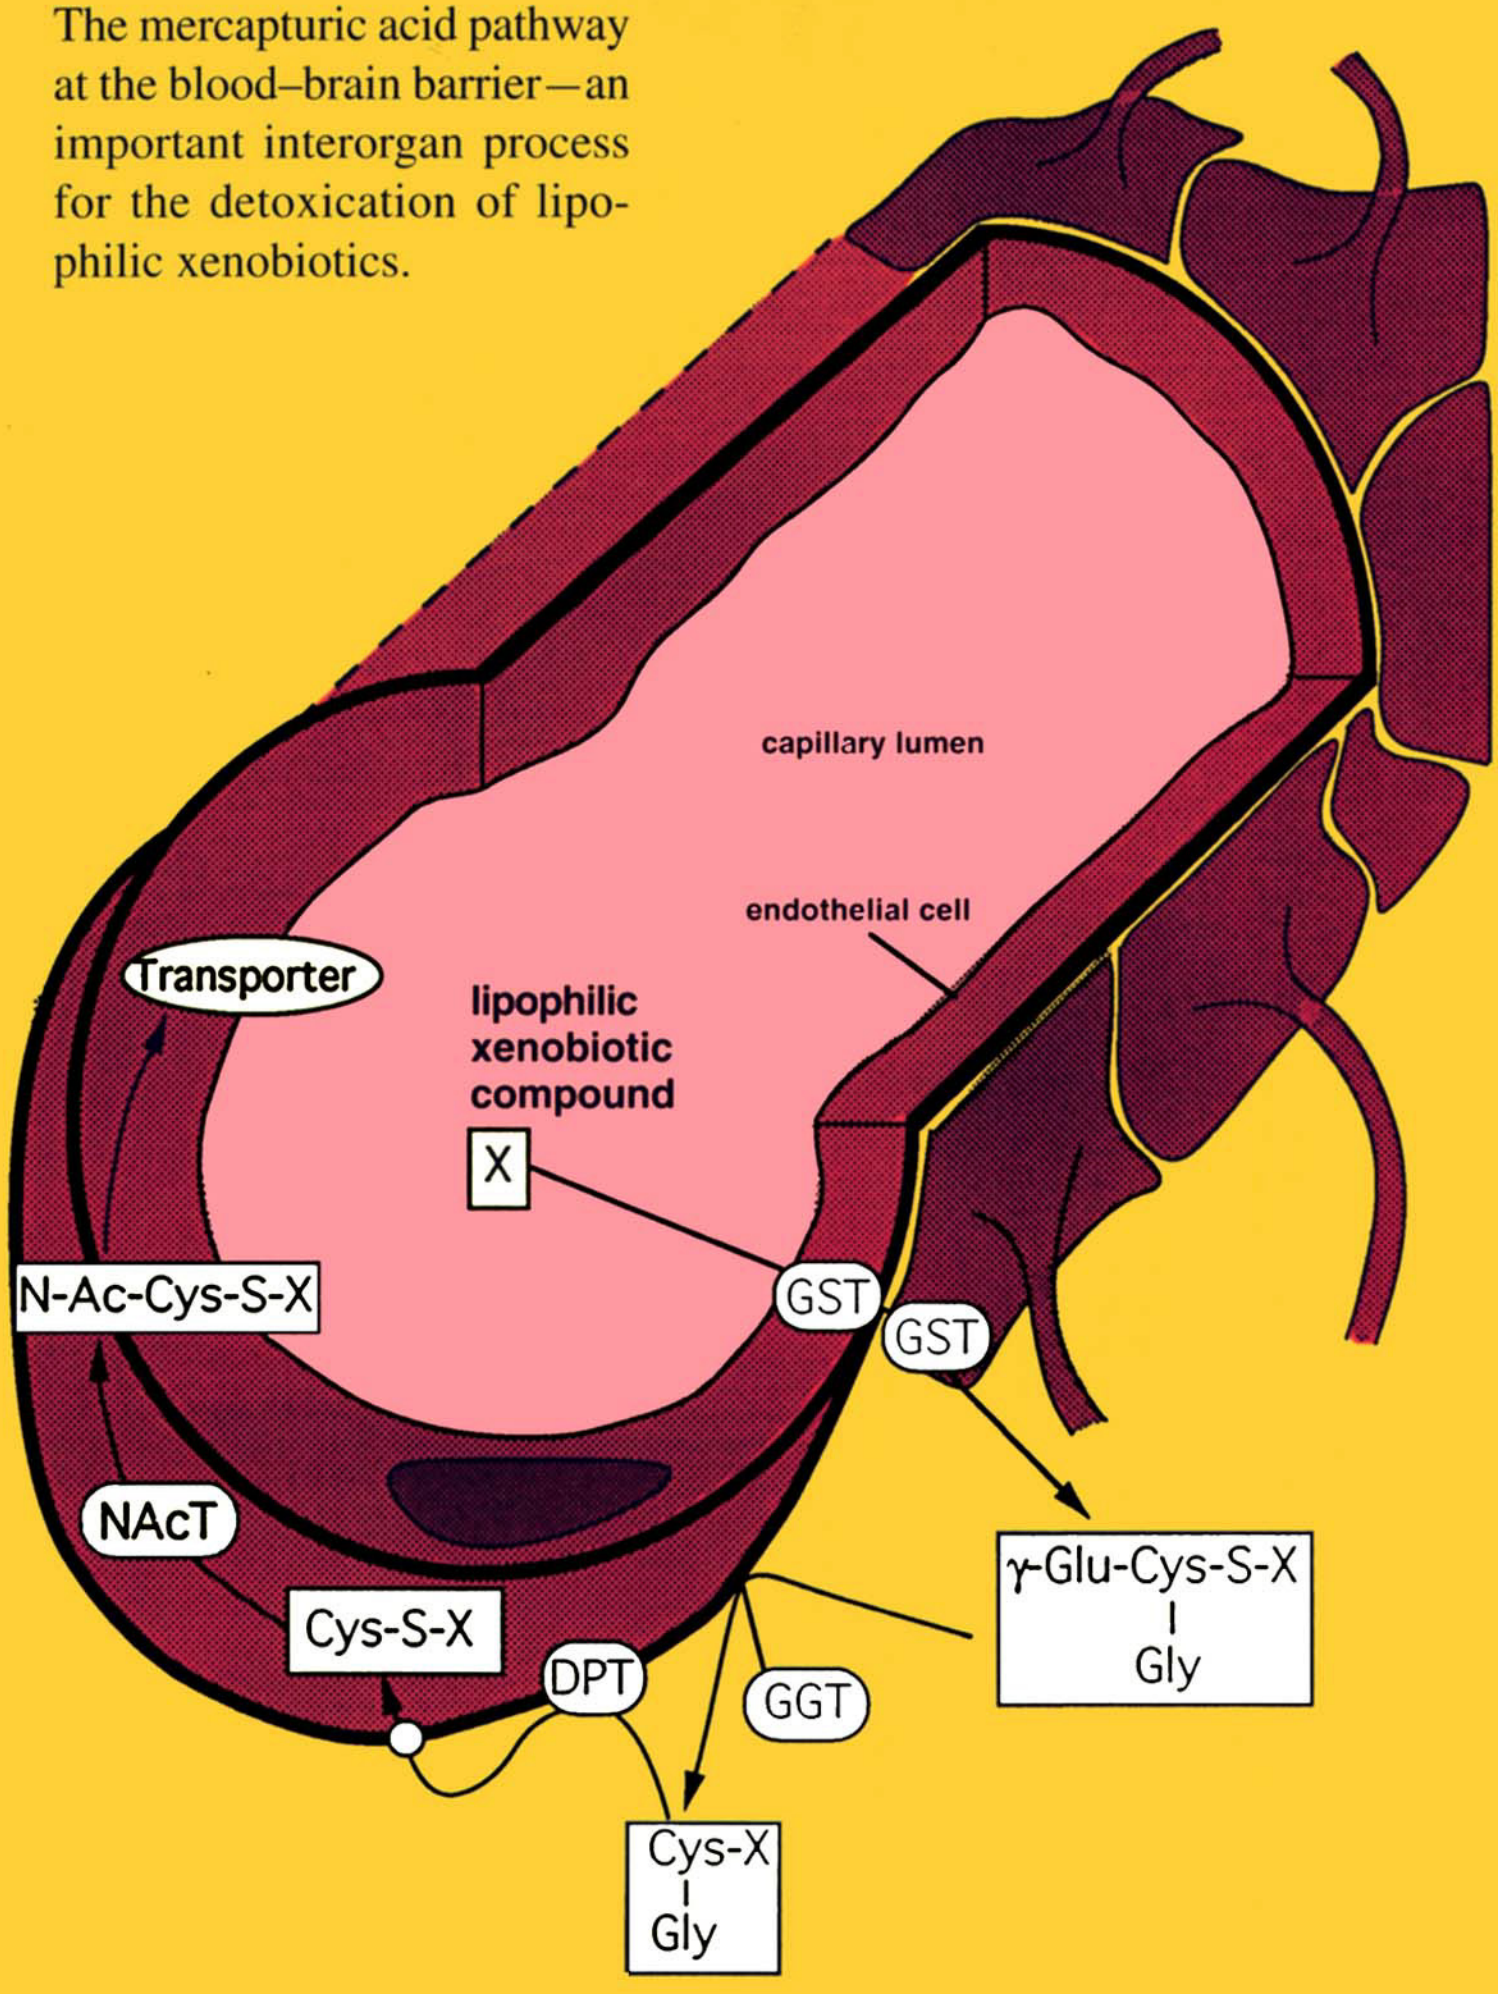
The mercapturic acid pathway at the blood–brain barrier—an important interorgan process for the detoxication of lipophilic xenobiotics.



Transport and Detoxication: Principles, Approaches, and Perspectives for Research on the Blood–Brain Barrier**

Achim Aigner, Sabine Wolf, and Hans Günter Gassen*

The blood–brain barrier is an anatomical constraint that maintains homeostasis within the brain and consists of uniquely structured brain capillaries. In addition to these morphological features, a number of specific proteins and transport systems (which are relevant to pharmaceutical applications) can be described that complement barrier functions and ensure a selective supply of substances from the blood to the brain. The additional role of the blood–brain barrier as a site of active detoxication by metabolizing and thus defending against neurotoxic substances has only become apparent in the past few years. Fundamental to understanding these processes are the principles of detoxication reactions and metabolic pathways of excretory organs, which will be described briefly here. The confirmation of these mechanisms in the brain enhances understanding of the complex protective functions of the blood–brain barrier. Evidently, these detoxication pathways simultaneously produce metabolites with neurotoxic or, in case of leukotriene, blood–brain barrier damaging potential. Finally, a detailed description of the mercapturic acid pathway of detoxication will be used to illustrate how evidence of representative enzymes can be used to distinguish definite functions of particular cell types and marker proteins of the blood–brain barrier.

Keywords: enzyme catalysis leukotrienes · mercapturic acid pathway · metabolism · xenobiotics

1. The Blood–Brain Barrier

In all mammals the circulatory system is the most important transport system of the body. In addition to nutrients, respiratory gases, and metabolites, the cardiovascular system also transports water, electrolytes, acids, bases, hormones, and components of the cellular and humoral immune system and therefore fulfills a wide range of tasks. The term microvasculature describes the tiny, branched vessels of the circulatory system, the arterioles, capillaries, and venoles. Their structure is determined by the function and local requirements of the vessel. Capillaries are the site of substance exchange with surrounding tissues, and hence, they are vitally important. The estimated 40 billion capillaries in the human body cover an area of 600 m^2. Capillaries have a diameter between 3 and 10 μm. The capillary wall consists of a single layer of endothelial cells surrounded by a basement membrane. Based on their ultrastructure, three principle types of capillaries, known as discontinuous, continuous, and fenestrated types, can be discerned. A complete layer is only formed by the continuous type of endothelial cells. Hence, in vessels lined in this way, unrestricted substance exchange with the surroundings is not possible. This type of capillary is found in only a few organs including the brain. In accordance to functional requirements, the endothelial cells of the brain capillaries are highly specialized and form the so-called blood–brain barrier. The blood–brain barrier separates the blood vessels, which supply blood to the brain through a dense three-dimensional network of capillaries, from the interstitium, the direct surrounding of neurons and glial cells.

Maintaining a stable internal milieu (homeostasis) in the neural microenvironment is essential to the perfect functioning of the brain. In this way an optimal environment for synaptic and nonsynaptic communication between neuronal cells is ensured whilst guaranteeing that short-term variations in the composition of the interstitial fluid are maintained as signals. The brain must therefore be protected from metabolic fluctuations in blood composition, and at the same time a contact with blood must be maintained for nutrient supply and waste disposal. This complex task is accomplished by the blood–brain barrier, which has four functions:

1. Protecting the brain from the fluctuating composition of the blood by preventing unspecific passage of substances by means of a complete endothelial cell layer, and consequently, protecting the brain from circulating peripheral neurotransmitters and neuroactive agents.
2. Ensuring the selective supply of substances from the blood to the brain by means of specific transport systems.

3. Metabolizing and retrograde transport of substances to the blood that permeate the blood–brain barrier as a consequence of their chemical properties or accumulate as metabolites in the brain and potentially impair brain function.
4. Restraining ions and peptides, thus assuring additional interneuronal communication.

In contrast, in several regions of the brain neurons react to the presence of hormones circulating in the blood or secrete neuroendocrine hormones directly into the blood. In these cases not separation but rather direct contact between neurons and blood is of functional importance. The hypophysis, hypothalamus, area postrema, epiphysis, and choroid plexus, all situated near the ventricle and therefore known as circumventricular organs, belong to these regions.[1] In order to protect the surrounding nerve tissue despite the absence of the blood–brain barrier, a comparable barrier function is accomplished by special ependymal and glial cells.[2] The blood–liquor barrier is situated in the choroid plexus. Apart from a few exceptions the blood–brain barrier has been verified in all vertebrates and is revealed in a unique organization of brain capillaries.

1.1. Discovery and Morphological Principles of the Blood–Brain Barrier

The existence of a barrier between blood and brain was demonstrated over 100 years ago by Ehrlich in vital stain experiments.[3] In rats, intravenously injected trypan blue dye stained all tissues except the central nervous system. However, the results of this experiment were interpreted by Ehrlich as a lack of important dye-binding substances. When Goldman repeated the experiment in 1909, he discovered that dye injected into the brain parenchyme did not permeate into the blood vessels. The hypothesis whereby astrocyte endfeet (see below) morphologically correspond to the blood–brain barrier was only rectified in the late 1960s after the development of high-resolution techniques. Reese and Karnowski[5] as well as Brightman and Reese[6] produced electron microscope images of animal brain sections (Figure 1). By first injecting with the enzyme horseradish peroxidase, they were able to locate the blood–brain barrier in the cerebral capillary endothelium. A schematic cross- and longitudinal section of a cerebral capillary is shown in Figure 1.

The endothelial cells in brain capillaries are distinguished from other endothelia in the body by a number of morphological and biochemical features. Close cell-to-cell contacts (zonulae occludentes or tight junctions) both within the same cell and

Achim Aigner, born in 1965, studied chemistry at the Technische Hochschule Darmstadt between 1985 and 1991. He completed his PhD in biochemistry in 1995 for research on transport and detoxication processes at the blood–brain barrier conducted in the research group headed by Prof. H. G. Gassen. Since April 1996 he has been conducting postdoctoral research at the Lombardi Cancer Center, Georgetown University, Washington DC under the direction of Prof. A. Wellstein.

Sabine Wolf was born in 1958 and studied chemistry at the Technische Hochschule Darmstadt from 1977 to 1982. She received her PhD in biochemistry in 1986 under the direction of Prof. E. Heidemann. Since 1993 she has been the head of the research project "Transport and Detoxication Processes at the Blood–Brain Barrier" in the research group led by Prof. H. G. Gassen.

Hans Günter Gassen, born in 1938, studied chemistry at the University of Marburg. He gained his PhD in biochemistry (enzymology) and subsequently spent two years in the USA at the Oak Ridge National Laboratories (Biology Division) and three years at the Max Planck Institute for Experimental Medicine in Göttingen. He qualified as a lecturer at the University of Münster and was appointed as a professor at the Technische Hochschule Darmstadt in 1973. In association with the companies Grünenthal, Merck, and Röhm, he founded the research cooperative "Applied Gene Technology" in 1985. He is the author of textbooks and numerous scientific publications.

are formed by fusion of the plasma membrane. An electrical resistance of up to 2000 Ωcm^{-2} reflects the unique complexity of these junctions.[7] Consequently, paracellular diffusion is completely inhibited. Freeze-fracture images indicate that tight junctions form branched ribbons with beadlike structures. Membrane lipids as well as proteins are presumably involved here.

In addition, the small number of pinocytotic vesicles present in the endothelial cells inhibits nonspecific transcellular transport (transcytosis).[8] The large number of mitochondria, which are responsible for cellular energy production, indicate the presence of a many energy-consuming transport mechanisms.

1.2. Pericytes—Another Cell Type in the Blood–Brain Barrier?

Another type of cell, the pericytes, is found on the abluminal surface (the microvasculature surface opposing the blood) situated on the single layer of endothelial cells. Since pericytes are thought to play a significant role in the blood–brain barrier and in the metabolic pathways proposed for the barrier, we describe them in detail in this section. Pericytes are morphologically, biochemically, and physiologically heterogeneous and have not been investigated to the same extent as the endothelial cells.[9] Owing to the lack of a specific cell marker (see below), pericytes are mainly defined by their abluminal situation on the blood vessels.[10] The degree of coverage of the endothelial cells depends on the location of the microvasculature.[9] The findings of in vivo and in vitro experiments carried out by several groups vary to some extent with the organ or species under investigaion and can be summarized as follows:

1. Pericytes are found on capillaries in nearly all organs. However, their distribution is highly variable. They never cover the corresponding vessel completely. The ratio of endothelial cells to pericytes and the area of the endothelial cell actually covered by pericytes seem to be related to the density of interendothelial connections and the blood pressure within the microvasculature. The larger the number of pericytes, the higher the density of the vessel and the higher the local blood pressure.[9] For very dense vessels, very high degrees of pericyte coverage of 0.41 (blood–retina barrier) and 0.22–0.30 (blood–brain barrier) have been found.[11]
2. Pericytes are embedded in the basal lamina which surrounds the endothelial cells abluminally. They are involved in the synthesis and release of components of the basal lamina and extracellular matrix such as collagen[12] and glycosaminoglycans.[13] The basal lamina often fuse to a joint basal lamina within the intracellular space between the endothelial cells and the pericytes.
3. Studies of the ultrastructure verify a high degree of interaction between pericytes and endothelial cells in vivo. Close associations between cells as well as direct contact sites between the two cell types through fenestrations in the basal lamina are evident in transmission electron microscopic studies.[10] Frank et al.[11] presume that the extent of these associations has important consequences for the control of the microvasculature functions. The appearance of functional gap junctions between pericytes and endothelial cells in vivo and in vitro has been described in several papers.[10]
4. In most cases, pericytes have contractile abilities. Early assumptions that blood flow in the capillaries is regulated by pericytic contraction were confirmed in numerous studies revealing the presence of contractile proteins. These include smooth-muscular and nonmuscular actin isotypes, smooth-muscular and nonmuscular myosin, and tropomyosin, as well as vimentin and desmin. Direct evidence for pericyte contractility has yet to be established.[14] Depending on the size of the microvasculature, significantly different quantities of various contractile protein isoforms were found. However, in many respects the pericytes of the brain capillaries appear exceptional. Lower amounts of various contractile proteins and the presence of specific marker proteins such as γ-glutamyl transpeptidase (GGT)[15, 16] and aminopeptidase N[17] in the cell suggest a unique, nearly homogenous population distinct from all other pericytes. In correspondance with pericytes of the blood–retina barrier, they do not control blood pressure, but maintain the respective barrier and stabilize the capillary wall. By covering capillaries with their extensions, the pericytes of the blood–brain barrier mechanically stabilize the vessel and preclude damage from counterpressure exerted by erythrocytes in the blood.
5. Pericytes regulate the proliferation and differentiation of endothelial cells. Perivascular cells appear to play an important role in the early phase of capillary development and influence endothelial cell growth in vivo and in vitro. In studies by Crocker et al.[18] the invasion of the basement membrane by pericytes terminated the growth of newly developed capillaries in a wound-healing experiment in vivo. Clearly pericytes exert a suppressive effect on the proliferation of endothelial cells. Angiogenesis can be visualized as the highly coordinated simultaneous growth of endothelial cells and pericytes.[14]
6. Pericytes play an important role in antigen presentation in the brain. Furthermore, they may possibly contribute to perivascular amyloid deposition in neurodegenerative diseases such as Alzheimer's disease.[19]
7. Pericytes of arterioles, capillaries, and venoles are clearly important in phagocytosis.[20] Although Weibel[21] was only able to detect a few lysosomes, phagokinetic activity was established for pericytes of skin and skeleton muscle.

In reference to the blood–brain barrier, pericytes have a protective role beyond that of purely mechanical stabilization. Thus, it has been established experimentally that when horseradish peroxidase is present in the cerebral interstitium, the enzyme accumulates selectively in the cerebral pericytes.[22] Other studies also demonstrate that under pathological conditions pericytes are capable of taking up proteins from the cerebral interstitium[14] and metabolizing extracellular bioactive proteins.[17] Thus, pericytes form a second line of defense,[17, 23] which, particularly under breakdown conditions or partial disfunctionality of the endothelial blood–brain barrier, helps maintain homeostasis in the brain. In this connection, the presence of γ-glutamyl transpeptidase in cerebral pericytes is of special interest.[15, 16] This enzyme is implicated in glutathione-based detoxication reactions (see Section 3).

1.3. The Significance of Astrocytes

The abluminal surface of cerebral endothelial cells consists of the basal lamina containing pericytes and is surrounded by astrocyte endfeet. Astrocytes belong to the glial cells and also serve as connective tissue within the brain. Furthermore they help maintain homeostasis by regulating the ionic balance of the cerebral interstitial fluid.[24] Although astrocyte endfeet almost completely surround the capillaries, they are not connected by tight cell-to-cell junctions. Hence, they do not form the anatomical basis for the blood–brain barrier. Gaps between astrocytes facilitate the passage of proteins and other polar molecules from the interstitial fluid to the abluminal surface of the endothelial cells and pericytes.[25] Astrocytes play an important part in the development and maintenance of the barrier by inducing blood–brain barrier properties. In vitro studies with astrocyte-conditioned medium or with cocultivated astrocytes have established that under these conditions endothelial cells express endothelial markers for blood–brain barrier features[26] and form complex tight junctions;[27, 28] however, the high electrical resistance established in vivo could not be verified.[29] Recent studies reveal that in addition to the astrocytes, the intraendothelial level of cyclic AMP has a crucial effect on permeability and electrical resistance.[30] Conversely, endothelial cells contribute to the maturation and differentiation of astrocytes, making these less susceptible to cytotoxic factors such as lead.[31]

Since cell-to-cell contact between astrocytes and endothelial cells is not necessary,[32] the induction of blood–brain barrier properties is attributed to soluble factors. However, in situ studies of the blood–brain and blood–retina barriers have indicated that for induction of blood–brain barrier properties the astrocyte endfeet and endothelial cells must be in close proximity in vivo and in vitro.[33, 34]

1.4. Markers for Vascular Cells with Blood–Brain Barrier Properties

The determination of markers generally facilitates the characterization of cell types or cell associations, as well as their state of development and differentiation. Markers are associated with properties of a particular cell or tissue type that result from expression of a specific gene. In the case of the blood–brain barrier these include the particular properties of the cerebral vascular endothelium discussed in the preceeding sections. Endothelial markers differentiate blood vessels and cells from the surrounding tissue. However, markers for blood–brain barrier properties enable a more discriminative study of various blood vessels. Hence only those characteristics can be utilized as markers that are particular to the highly specialized capillaries with blood–brain barrier function. Since the aim is primarily to differentiate between capillaries with and without barrier function, the expression of these markers in other noncapillary cells is of no consequence.

Markers are usually classified into morphological, biochemical, and immunocytochemical types (Table 1). Ultrastructural studies reveal the exceptional morphological features of capillaries with blood–brain barrier properties that distinguish them from other capillaries (see preceeding sections). The cerebral vascular endothelium is a tissue with high metabolic activity. Numerous specific enzyme-catalyzed transport and metabolic pathways contribute to the functioning of the blood–brain barrier. A number of specific marker proteins for the blood–brain barrier have been identified by immunocytochemical methods. However, functions have only been reliably ascertained for a fraction of these. In the meantime, more detailed studies have revealed that not all blood–brain barrier markers fit the strict definition mentioned previously.

1.5. Transport Processes within the Blood–Brain Barrier

As discussed in Section 1.1, the distinct morphology of the endothelial cells in the blood–brain barrier prevents the unspecific passage of substances from the blood. Gases such as O_2 and CO_2, water, and lipophilic substances can pass through the lipid bilayer membrane and enter the brain interstitium transcellularly. Lipophilic properties are usually defined by the oil–water partition coefficient. Several in vitro, in vivo, and in situ techniques for quantifying the passage of substances have been described.[64] The usual indicator for passage is the brain uptake index (BUI). This compares the ratio of the concentration of test substance taken up by the brain and the amount injected luminally with the ratio of the concentration of a reference substance (e.g. ^3H_2O) taken up by the brain and the amount injected luminally. Recent studies illustrate that the ability of substances to diffuse through the blood–brain barrier can be precisely predicted by measuring their surface activity, which takes into account the hydrophobic properties and charged groups of the substance. Three groups of compounds can be identified in this way: a) extremely hydrophobic substances, which do not enter the brain interstitium because they are strongly integrated and therefore accumulate within the endothelial cell membrane, b) relatively hydrophilic substances that are not able to pass through the blood–brain barrier under physiological conditions because they lack of hydrophobic properties, and c) substances that lie between these two extremes and are able to pass through the blood–brain barrier.[65] Complete impermeability is not likely in any case.

The metabolically very active brain must be well-supplied with blood-borne nutrients such as glucose, amino acids, purines, ketone bodies, and choline. Here the blood–brain barrier forms a crucial impediment, and transport across the blood–brain barrier is an important regulatory mechanism for many substrate-limited metabolic pathways in the brain. Selective passage of substances is facilitated through a number of specialized carrier systems and receptor-mediated or adsorption-mediated transcytosis, depending on the type of molecule (Table 2). In the case of the carrier systems it is possible to differentiate between active transport and facilitated diffusion. The latter operates along a concentration gradient and is therefore energy-independent. Active transport operates against a concentration gradient and is therefore an energy-consuming process. A large number of carrier systems are known (Table 2).

Peptides, plasma proteins, and viruses are transferred by receptor-mediated transcytosis. The process can be divided into three events: a) receptor-mediated endocytosis on the luminal

Table 1. Morphological, biochemical, and immunochemical blood–brain barrier (BBB) markers.

Markers	Comments	Refs.
Morphological markers		
close cell-to-cell contacts		[5]
small number of pinocytotic vesicles		[8]
large number of mitochondria		[35]
Biochemical markers		
alkaline phosphatase		[8, 36, 37]
aminopeptidase A capillaries without BBB	low activity also in brain	[38]
aminopeptidase M	activity also in brain capillaries without BBB	[38]
butyrylcholinesterase		[39]
	activity also in fenestrated brain capillaries	[1, 40]
	activity associated with pericytes	[41]
dipeptidylpeptidase IV	very specific; activity only in brain capillaries with BBB	[38]
γ-glutamyl transpeptidase		[42]
	also in epithelial cells of the choroid plexus and in brain capillaries without BBB	[1, 38]
	activity is mainly pericyte-associated	[15, 16]
	not in bird BBB	[43]
	also present in other organ barriers	[44, 45]
Immunocytochemical markers		
endothelial barrier antigen	antibody recognizes protein triplet; particularly specific for endothelial cells in brain capillaries with BBB	[46]
glucose transporter GLUT-1	minor N-glycosylated type	[47–49]
	also in epithelial cells of the choroid plexus	[50]
	transport activity dependent on subcellular distribution	[51, 52]
glycoprotein GP 140	only in pericytes	[53, 54]
insulin receptor	receptor-mediated transcytosis of insulin	[55]
low density lipoprotein	no expression in endothelial receptor cells of peripheral capillaries	[56]
neurothelin/HT 7/OX 45 antigen/1W5 antigen	integral membrane protein in the luminal membrane of the BBB	[57, 58]
	also in other tissues with barrier function, possibly involved in transport, surface recognition, and cell adhesion	[1, 59]
		[1, 59]
P-glycoprotein	no expression in endothelial cells without barrier function; part of multidrug resistance	[60]
transferrin receptor	no expression in endothelial cells of peripheral capillaries	[61]
46 kDa protein/53 kDa and 45 kDa proteins	surface antigens specific for endothelial cells of brain capillaries; possibly a component of tight junctions	[62]
	antibody also recognizes a 200 kDa protein in the choroid plexus	[63]

Table 2. Carrier systems of the blood–brain barrier (LNAA = large neutral amino acids).

Carrier description	Substrates (examples)	Refs.
hexose carrier	glucose, deoxyglucose	[66, 67]
monocarboxylic acid carrier	lactate, pyruvate, ketones bodies	[68]
L-system, LNAA carrier	phenylalanine, leucine	[69, 70]
A-system (only abluminal)	alanine	[71]
$B^{0,+}$-system	phenylalanine	[72]
acidic amino acid carrier	glutamate	[73]
basic amino acid carrier	lysine, ornithine, arginine	[69, 74]
amine carrier	choline	[75]
purine base carrier	adenine, guanine	[76]
nucleoside carrier	adenosine	[76]
thiamine carrier	thiamine	[73]
glutathione carrier	glutathione	[77, 78]
myoinositol carrier	myoinositol	[79]
thyroid hormone carrier	triiodothyronine	[80, 81]

side of the blood–brain barrier, b) diffusion of the peptide or peptide–receptor complex, for example, through the endothelial cytoplasm, and c) receptor-mediated exocytosis on the abluminal side of the blood–brain barrier into the interstitium. Examples of this type of transfer are the transport of insulin[82] and transferrin.[61] The relevant receptors are often used as blood–brain barrier markers (cf. Section 1.3). A comparable process is adsorption-mediated transcytosis, which commences with the adsorption of lectins[83] or polycationic proteins such as cationized albumin,[84] recombinant CD4,[85] and histones[86] onto the luminal membrane.

1.6. Pharmacological Applications: Transport of Drugs across the Blood–Brain Barrier

Some of the previously mentioned transport systems are known to be, or should soon be recognized to be, relevant for the effectiveness of drugs. As a consequence, the development of pharmaceuticals such as proteins, cationized antibodies, and antisense oligonucleotides must also include the development of relevant strategies for in vivo substance transport across the blood–brain barrier. Many cerebral diseases such as infections, microangiopathies, and tumors can only be treated in this manner. However, currently the elucidation of the effects of newly developed and discovered diagnostic and therapeutic substances often takes precedence over the question of their specific transport.

Once the basic requirements have been fulfilled—that an active substance is soluble in blood in a nonionic form, is not enzymatically degraded in blood plasma, and is not bound to plasma proteins—passage across the blood–brain barrier is ensured. The known measures for introducing neuropharmaceuticals into the central nervous system can be divided into three groups: a) invasive or blood–brain barrier opening techniques, b) pharmacological approaches to improve the transport of the substances, and c) physiological approaches relying on chimeral peptides or on cationized antibodies. The first category involves intraventricular infusion of neuropharmaceuticals to bypass the blood–brain barrier, cell therapy, and short-term unspecific opening of the blood–brain barrier. The intraventricular infu-

sion of active substances (that is, direct injection in the brain ventricles) is an invasive strategy with considerable risks. The method is only employed for introducing chemotherapeuticals to the brain surface, since it is bathed in cerebrospinal fluid. A further disadvantage is that rapid renewal of cerebrospinal fluid results in removal of active substances by peripheral blood vessels, even at high concentrations. This contrasts with the very slow penetration by diffusion of the active substance into the parenchyme. The osmotic, biochemical, and pharmaceutical methods for opening the blood–brain barrier have been known for a long time.[87] These are either based on the infusion of hyperosmotic mannitol or arabinose solutions (hyperosmotic shock), the application of substances that increase cerebral endothelial permeability (pharmacological approach), and the infusion of vasoactive substances such as bradykinin or leukotrienes (biochemical strategy). The increase in permeability is accomplished either by damaging the tight junctions through cell shrinkage or by increasing vesicular transport activity through the endothelial cells of the brain capillaries. The protection of the central nervous system from neurotoxic substances and degradation products as well as homeostasic maintenance is lost during the temporary opening of the blood–brain barrier. As a consequence, side effects such as short-term amplification of existing neurological disorders, permanent neurological disorders, and brain edemas have been observed.[87, 88] The risk of permanent damage appears to be very low when treatment is restricted to a few cycles (roughly 10–30 cycles).[89]

Pharmacological approaches to overcoming the blood–brain barrier include lipidization, whereby the lipophilic properties of active substances can be increased by chemical modification (esterification, acetylization of carboxyl, hydroxyl, or amino groups) or by removing quarternary ammonium groups. After the modified pharmaceutical (prodrug) has passed the blood–brain barrier, the lipophilicity-inducing group is cleaved and the active substance released. However, it must be taken into consideration that increasing lipophilicity also a) facilitates undesired, nonselective resorption in other organs, b) reduces the residence time of the substance in the brain due to the increased effluent rates, c) facilitates the hydrolytic release of the active substance in the blood, and d) strengthens bonding to plasma proteins. As a consequence of these limiting factors, only a small number of prodrugs such as the various esters of the weakly neurotoxic chlorambucil can be implemented in practice. In some cases substances have been modified to serve as substrates for a carrier system. An example for such a modification is dopamine (3,4-dihydroxy-β-phenethylamine), an important substance in the treatment of Parkinson's disease. The precursor L-dopa (3,4-dihydroxyphenylalanine) has a very high affinity for the L-system.[67] Additionally, the antitumor agent melphalan, a derivate of phenylalanine also has a high affinity for the same transport system.[90]

The transport of liposomes is a further pharmacological approach. Passage across the blood–brain barrier is probably facilitated by transient pores in the lipid bilayer membrane. The liposome and cell membranes are fused temporarily, thereby forming a pore through which the liposome contents are released into the endothelial cell. This process has only been observed for small molecules and consequently, the size of liposomes usually precludes them from passage. However, an application with citicoline is one example for increasing the effectiveness of therapeutic agents in the brain.[91]

Physiological approaches are based on the use of chimeral peptides and cationized antibodies. The principle behind the application of chimeral peptides is founded on the discovery of receptor- and absorption-mediated specific transcytosis pathways for certain substances. In this case, nontransportable diagnostic or therapeutic agents can be connected to transport vectors through disulfide bridges or by linkage to ligands of the avidin–biotin system.[92] These conjugates can then be transported across the blood–brain barrier. In the brain they are cleaved by disulfide reductases, for example, and the active substance released. Examples of such transport vectors are insulin, insulin-like growth factor, and the monoclonal antibody OX-26 raised against the rat transferrin receptor,[93] as well as cationized albumin,[84, 94] cationized histone, and recombinant CD4.[89] Hydrolysis of the conjugate should take place within the brain. In view of the large number of peptidases in blood plasma and especially in cerebral capillary cells, it is necessary to use peptidase-resistant conjugates. In analogy to albumin, cationized antibodies can cross the blood–brain barrier by absorption-mediated transcytosis. These substances are important diagnostic or, in the case of immunotoxins, therapeutic tools in the brain. The early immunochemical diagnosis of βA4-amyloid deposits, typical for Alzheimer's disease, and prevention of their formation are examples of this type of application.[95]

2. Principles of Detoxication Processes

In nature all living things are constantly exposed to a multitude of potentially harmful substances. Consequently, defense mechanisms exist to prevent uptake of such substances or to modify, degrade, and excrete them after incorporation. The liver is the main site for metabolizing endogenous and exogenous substances in mammals. However, enzymes that facilitate these biotransformations have been detected in kidneys, gut, lungs, skin, heart, and brain. Up to the 1980s the general absence of detoxication mechanisms in the central nervous system was presumed by some authors to indicate a principle difference between the central nervous system (CNS) and the peripheral organs. Protection of the brain was attributed to the purely physical action of the blood–brain barrier. However, it had already been established by this time, that the CNS has enzymatic protective mechanisms beyond those of the blood–brain barrier. The first evidence of these mechanisms published by Cohn et al.[96] referred to one of the most important detoxication systems, cytochrome P_{450}. Since then, these findings have frequently been confirmed by others. By the mid-1980s over 30 enzymatic systems had been established, which were able to metabolize exogenous substances in the brain.[97] However, in view of the low enzyme concentrations in the brain, the investigation of other organs, especially the liver, was usually given precedence.

Two fundamental pathways for eliminating xenobiotics and intracellular metabolites have been described: 1) direct, active exocytosis of a wide range of substances by transmembrane pumps of low specificity (P-glycoproteins, Figure 2, X_A) and

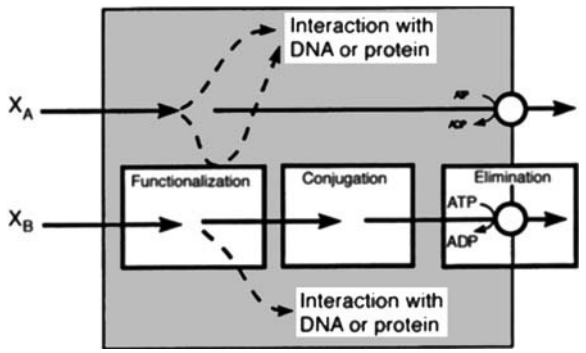

Figure 2. Pathways for eliminating xenobiotics or intracellular metabolites [98].

2) multistage biotransformation of the substance followed by exocytosis of the product (Figure 2, X_A).

P-glycoproteins were first described in studies of multidrug resistance in tumor cells.[99] The large, 140 to 170 kDa plasma membrane proteins consist of two identical halves, each with presumably six transmembrane domains and a single ATP binding site.[100, 101] They belong to the large family of proteins that include ABC (ATP-binding cassette) translocases also found in prokaryotes.[102] P-glycoproteins account for the cellular phenotype of mutidrug resistance, meaning the immunity against chemotherapeutic agents, by facilitating exocytosis of structurally dissimilar, amphiphatic substances. This resistance is either developed from the beginning, meaning it is intrinsic in character, or can be stimulated during chemotherapy by inducing overexpression of P-glycoprotein (acquired resistance).[103] In both cases the effect of the export pump in tumor cells is to lower the intracellular concentration and therefore reduce the effectiveness of a therapeutic agent. This can lead to complete failure of chemotherapy. However, this is presumably rarely due to the activity of P-glycoproteins alone, but is more likely the result of the combined effects of different resistance mechanisms.[103]

P-glycoproteins are encoded in a single gene family comprising three genes in the mouse (mdr1a, mdr1b, mdr2) and two genes in humans (MDR1 and MDR3). Only mdr1a, mdr1b, and MDR1 are associated with the development of multidrug resistance.[104] Functional P-glycoproteins are also found in normal tissue, particularly in three main types of nonmalignant cells: specialized epithelial cells with secretory or excretory functions, trophoblasts of the blastula, and endothelial cells of capillaries with barrier function, for example the blood–brain barrier.[60] In the last case the occurrence of P-glycoproteins indicates that the ATP-dependant transport pump is an operative component of the enzymatic blood–brain barrier,[105] facilitating the retrograde transport of substances from the brain into the blood. This would explain results indicating that the brain is protected from passive passage of certain unpolar xenobiotics even when their concentration in the plasma is up to 15 to 30 times higher.[60]

In fact, P-glycoprotein knock-out mice (mdr1a (−/−)) displayed a higher sensitivity for an administered pesticide or carcinostatic agents than control animals. Additionally, higher concentrations and reduced elimination of the substances were noted in many organs, particularly in the brain.[104] Analogous results were obtained for a large number of toxins and carcinogens derived from plants, fungi, and bacteria. P-glycoprotein is responsible for two effects: the accumulation of toxins is reduced by their export from certain tissues like the brain, and the plasma concentration of these substances is lowered owing to increased excretory rates, probably by stimulated excretion in gall or urine.

New publications reveal that the metabolic processes involved in biotransformations of xenobiotics can be distinguished into three phases[106, 107] (Table 3).

Table 3. Fundamental metabolic processes involved in biotransformation of xenobiotics.

Phase I	functionalization	oxidation, reduction, and aromatization, dealkylation, or hydrolysis of lipophilic substrates to introduce a functional group
Phase II	conjugation	linking the substance with a polar endogenous substrate (amino acid, sulfate, glutathione, or sugar) to increase polarity, reduce physiological, pharmacological, and toxic potential, and facilitate rapid excretion
Phase III	elimination/storage, excretion	via kidney or intestine, or (in plants) compartimentalization and storage in vacuoles or in the cell wall

For most xenobiotics, a number of metabolic pathways operate simultaneously and consequently several products are formed. Which metabolic process becomes operative depends in part upon the following factors:[97] a) the biochemical characteristics of the enzymes involved (K_M and the maximum rate v_{max}) versus substrate concentration, b) the availability of active sites on an enzyme for a particular substrate, especially in the case of compartmentalization and permeability barriers, c) the presence of competitive substrates, d) the availability of coenzymes, cosubstrates, and cofactors, and e) the hormonal activation or inhibition of the enzymes.

As a consequence, the metabolic pathways, the metabolic rates, and the products formed vary between each organ, tissue, and cell type. Table 4 presents some examples of phase I and II reactions involved in detoxication of xenobiotics and the participating enzymes, selected from the multitude of metabolic processes (for instance 27 gene families with over 200 cytochrome P_{450} genes have been identified).

The localization of small quantities of enzymes in the brain is difficult. In spite of this, several studies have revealed the significance of some of the previously mentioned metabolic pathways for the blood–brain barrier. The results show that the activities of a number of enzymes involved in detoxication processes such as NADPH–cytochrome P_{450} reductase, 1-naphthol-glucuronosyltransferase, and epoxide hydrolase were higher in isolated brain capillaries than in brain parenchyme.[110, 111]. By restraining molecules circulating in the blood with potential or actual neuroactivity or a potential for impairing cerebral homeostasis, these enzymes have a protective function within the enzymatic blood–brain barrier.[97] However, toxic metabolites can be produced in the liver, the cerebral endothelium, and in the brain parenchyme itself (Figure 3). For example, a precursor is activated prior to the conversion of codeine to morphine.[112] Furthermore, the enzyme systems located at the

Table 4. Phase I and II reactions.

Enzyme	Reaction(s)	Substrates (examples)	Product(s)
Phase I			
monoamine oxidase	oxidative deamination	1°, 2°, 3° amines, e.g. serotonine, dopamine	aldehydes, H_2O_2, NH_3
cytochrome P_{450}	hydroxylation, N-demethylation, epoxidation	lipids, steroids, polycyclic aromatic hydrocarbons, arachidonic acid	hydroxylated substances, steroids, prostanoids, free radicals
NADPH-cytochrome P_{450} reductase	reduction	cytochrome P_{450}	
epoxide hydrolase	epoxide hydrolysis	epoxides	vicinal diols
Phase II			
UDP-glucuronosyl transferase	glucuronidization	1-naphthol, *p*-nitrophenols	corresp. glucuronic acid conjugates
phenol-sulfo-transferase	sulfoconjugation	phenol derivatives	corresp. sulfates
glutathione *S*-transferase	linkage with glutathione	hydrophobic electrophiles (halides, epoxides, etc.)	corresp. glutathione conjugates
N-acetyl-transferase	N-acetylation	aromatic amines	corresp. acetyl cmpds.

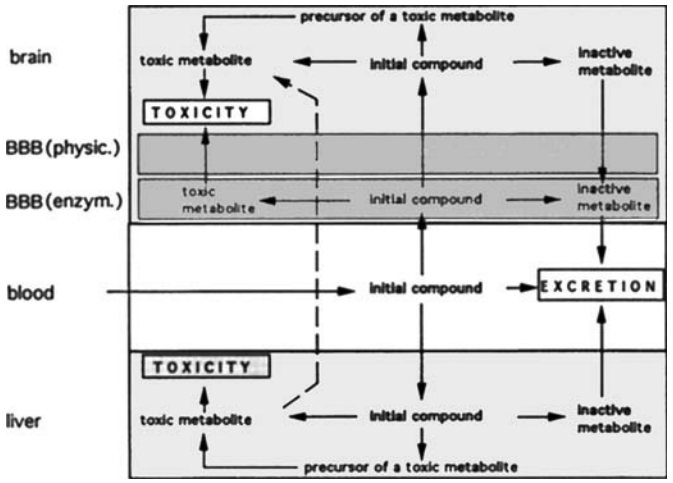

Figure 3. Relationship between biotransformations of lipophilic xenobiotics in brain and liver (adapted from ref. [97]; BBB: blood–brain barrier).

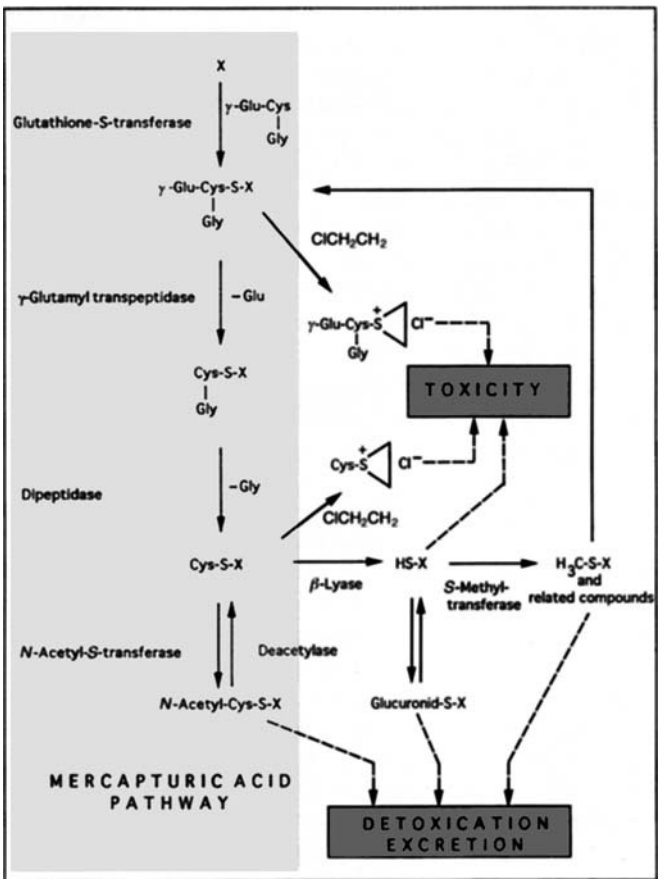

Figure 4. The mercapturic acid pathway of detoxication and known side reactions (adapted from refs. [117, 118]).

blood–brain barrier are rapidly saturated, so that passage of lipophilic substances is not completely inhibited at higher plasma concentrations of the substrates.[97]

Metabolism is often related to an increase in hydrophilicity and the resulting reduction in membrane solubility and permeability. This is advantageous on the luminal side of the blood–brain barrier, but can lead to problems within the brain parenchyme. The reduced permeability across the blood–brain barrier must be compensated by special transport systems. As evident in Figure 3, detoxication reactions are interorganic processes in many cases. This also applies to the glutathione-linked metabolic pathways.

3. Glutathione-Linked Detoxication: The Mercapturic Acid Pathway

The mercapturic acid pathway has long been identified as the most important detoxication process for many xenobiotics and a number of endogenous substances (Figure 4). The enzymes of the mercapturic acid pathway are found mainly in the liver, kidney, bile duct, and small intestine. Depending on the species, these organs contribute in varying degrees to the reactions of the mercapturic acid pathway. The initial step of the mercapturic acid pathway, a phase II reaction, is the intracellular conjugation of a particular substance with glutathione (GSH). The paramount biochemical importance of the tripeptide glutathione (γ-Glu-Cys-Gly) is reflected in its relatively high concentrations of up to 10 mM in mammalian cells and in its mani-

fold functions. Glutathione is the most important intracellular non-protein thiol and exists mainly in reduced form, which can be reversibly oxidized to glutathione disulfide (GSSG). In addition to functioning as a nucleophilic reagent in coupling reactions, glutathione is an important reducing agent for the cell, protecting it from oxidative stress.[113] Furthermore, the tripeptide is implicated in amino acid transport processes.[114] The conjugation of glutathione with xenobiotics and with endogenous toxins is catalyzed by glutathione *S*-transferases, which belong to a protein family of multifunctional enzymes. These mainly cytosolic proteins may also found in the mitochondria and microsomes, and are intracellular and extensively distributed (see Section 3.1). The metabolization of glutathione *S*-conjugates is preceded by transport out of the cell by a specific ATP-dependant transport system.[106] In a reaction catalyzed by the ectoenzyme γ-glutamyl transpeptidase (GGT) and cysteinylglycine dipeptidase, the γ-glutamyl residue and glycine are released and the cysteine *S*-conjugate is obtained. Subsequently, the cysteine *S*-conjugate is transformed intracellularly into *N*-acetyl-cysteine *S*-conjugates (mercapturic acids) with the cysteine *S*-conjugate specific *N*-acetyltransferase.[115] Although actual detoxication is achieved with this reaction step, this enzyme is the least understood and researched in the mercapturic acid pathway. The final products in this pathway, the mercapturic acids, have low toxicity and are excreted mainly in the urine via a probenecid (4-dipropylsulfamoylbenzoic acid) specific transporter for organic anions.[116]

Enzyme activity tests as well as in vivo investigations of routes followed by radioactively labeled xenobiotics have proved the mercapturic acid pathway to be a complex interorgan process. The liver is the main site for the conjugation of glutathione with blood-borne xenobiotics and endogenous toxins. Cleavage of glutamate and glycine and subsequent formation of cysteine *S*-conjugates occurs mainly in the kidneys but also in the bile duct and small intestine. These organs display high enzymatic activities of γ-glutamyl transpeptidase and dipeptidase. Recent studies reveal large species-related discrepancies in the ratio of enzymatic activities between different organs. In a number of mammals metabolization of glutathione *S*-conjugates is also assumed to occur in the liver, the organ in which they are produced. Inhaled substances are presumably conjugated directly in the lungs.[119] In this case the liver seems to be the main site for N-acetylation.[120] This is somewhat surprising since 1) many cysteine *S*-conjugates must be transported back to the liver from the kidneys where they are produced, 2) the mercapturic acids are excreted subsequently mainly in the urine, which implies that they must be transported back to the kidneys, and 3) the kidneys have an *N*-acetyl-*S*-transferase activity exceeding that of the liver.[121]

In fact N-acetylation also occurs in the kidneys. Cysteine *S*-conjugates with a high affinity for *N*-acetyltransferase are probably acetylated in the kidneys. Substrates with a lower affinity are not acetylated here but accumulate mainly in the liver for this last reaction step.[120] To date, the complicated interaction between various organs during metabolization, transport, and excretion of mercapturic acids and their precursors is only insufficiently understood. Detoxication of xenobiotics and endogenous toxins is a function of the mercapturic acid pathway and conjugation with glutathione is usually sufficient to reduce toxicity. However, bioactivation of substances derived from intermediates in the mercapturic acid pathway into mutagenic and/or nephrotoxic metabolites have been observed.[117,122] Several substance-dependant processes are responsible for this phenomenon. Table 5 summarizes the established and presumed metabolic pathways.

The most important reaction is the β-lyase catalyzed metabolism of a number of cysteine *S*-conjugates, producing reactive thiols, ammonia, and pyruvate.[126] This reaction competes with the detoxifying N-acetylation and is known as the β-lyase shunt.[127] The physiological relevance of this metabolic route, established in mammalian liver and kidney as well as in the gastric flora,[118] is not known. The toxic effects of reactive thiols and their only partly identified derivatives, mainly observed in the kidneys, arise from spontaneous reactions with macromolecules such as proteins or DNA. The reactive thiols can be methylated subsequently in a thiol-*S*-methyltransferase-catalyzed reaction, resulting in the formation of methylthio derivatives or their S-oxidized derivatives, which often arise in vivo from many xenobiotics.[128] In contrast, the principle of the mercapturic acid pathway is to increase hydrophilicity of lipophilic xenobiotics, thus promoting excretion. Methylation necessitates further detoxication reactions such as renewed passage through the mercapturic acid pathway.

Mercapturates are not transformed into reactive thiols; however, they can be converted into the relevant cysteine *S*-conjugates by deacetylase-catalyzed cleavage of the N-acetyl group. The conjugates are then available as substrates for β-lyase-catalyzed reaction. Deacetylation is primarily observed in the kidney and to a lesser degree in the liver and other organs. This is consistent with the previously mentioned observation that many xenobiotics are nephrotoxic.

The relative proportions of excreted mercapturates therefore depends not only on *N*-acetyltransferase activity but also on the activities of competing enzymes such as *N*-deacetylase and β-lyase. In addition to the balance between (re-) acetylation and deacetylation, the reactivity of the products, interorgan transport, and the cellular uptake of the intermediates, the species-dependant apparent and actual differences in *N*-acetyltrans-

Table 5. Bioactivation of mercapturic acid pathway intermediates into toxic products.

Xenobiotics	Substrates	Toxic products	Enzyme	Ref.
1,2-dihaloethanes (Cl, Br)	GSH *S*-conjugates	GSH-episulfonium ions	–	[123]
haloalkenes	Cys *S*-conjugates	reactive thiols	β-lyase	[118]
haloalkenes	Cys *S*-conjugates	α-keto acids	β-lyase	[124]
1,2-dihaloethanes (Cl, Br)	Cys *S*-conjugates	Cys-episulfonium ions	–	[123]
trichloroethene	*S*-(1,2-divinyl)cysteine sulfoxide	*S*-(1,2-dichlorovinyl)cysteine	monooxygenase	[125]

ferase activities are important criteria for nephrotoxicity and mutagenicity of a mercapturate and for the detoxication due to the mercapturic acid pathway.

3.1. Glutathione *S*-transferases

Glutathione *S*-transferases (GST, EC 2.5.1.18) participate in protective mechanisms against electrophiles, chemical carcinogens, and oxidative stress. They are also implicated in the acquired chemotherapeutic resistance of cancer cells. As a consequence, glutathione *S*-transferases have become one of the most intensively studied enzymes in recent years. This multienzyme family with wide substrate specificity catalyzes the nucleophilic addition of the thiol group in reduced glutathione to a number of hydrophobic electrophiles such as alkyl and aryl halides, epoxides, organic peroxides, sulfates, quinones, polycyclic aromatic hydrocarbons, and activated alkenes.[129, 130] In addition to these catalytic features, glutathione *S*-transferases have ligand-binding abilities, thereby facilitating intracellular transport of hydrophobic and amphiphatic compounds such as bilirubin, heme, steroids, and bile salts.[131, 132] Most of the cytosolic glutathione *S*-transferases can be subdivided into at least four very distinct species-independant classes (α, μ, π, and θ).[133, 134] Although many homo- and heterodimeric isoforms exist, mixed-class heterodimers and active monomers are unknown. In addition to the four cytosolic classes of enzymes, microsomal and plasma membrane bound glutathione *S*-transferases have been identified in rat liver.[135, 136] In view of their subcellular location, they are assumed to play an important part in protecting the endoplasmic reticulum from the formation of lipid peroxides, as well as in conjugating xenobiotics with glutathione, which remain within the membrane after activation by cytochrome P_{450}.[137, 138] According to a more recent study, homotrimeric microsomal glutathione *S*-transferase is the primary binding site for the bioactive arachidonic acid derivative leukotriene C_4 (LTC_4, see Section 4) in a human cell line. Whether this implies the storage of newly formed LTC_4 or the modulation of glutathione *S*-transferase activity is uncertain.[139] All glutathione *S*-transferases seem to have a two-domain structure.[140] Studies of μ-class isoenzymes reveal that the (larger) domain II determines substrate specificity. This is attributed to the highly variable areas of the primary structure, which in analogy to the immunoglobins are known as variable regions, situated mainly in this domain. A number of domain I residues also contribute to the three-dimensional structure of the substrate-binding site. However, the principle function of these small domains is glutathione conjugation.[141] The distinct disparity between isoenzymic classes with respect to substrate specificity, amino acid sequence, immunological properties, distribution in the cell, and expression patterns during development probably reflect differing biological functions.[142] Many of these points have not been resolved to date.

At least three glutathione *S*-transferases have been established and purified in the human brain. These have different molecular masses, isoelectric points, and enzymatic properties. Presumably they ensure protection of the central nervous system from oxidative stress as well as from toxic xenobiotics. They are not found in other tissues.[143] On the transcription level, several genes for glutathione *S*-transferases have been established in rat brain by expression banks. In view of the hetereogeneity of brain cells, the exact functions of the enzymes have not been determined. At least one of the glutathione *S*-transferases is not found in any other tissue or is only expressed in low levels.[144] In mice one glutathione *S*-transferase was found exclusively in the brain and other tissues rich in lipids with a high oxygen supply. This enzyme is thought to play a key role in the conjugation and/or reduction of cytotoxic compounds resulting from lipid peroxide formation.[145] Immunohistochemical studies by Carder et al.[142] provide evidence for the biological functions of human brain glutathione *S*-transferases and their location in the cell. π-Class isoenzymes were found in membranes separating fluid compartments. Thus the enzymes were established in the pia arachnoidea, choroid plexus, and ependymal cells, in astrocytes and in the vascular endothelium, but not in neurons. Consequently, they can be assigned to the blood–cerebrospinal fluid and blood–brain barrier as well as to membranes separating the interstium from the cerebrospinal fluid. Glutathione *S*-transferases are apparently ideally placed to regulate or prevent neuronal exposure to potentially toxic substances from the blood and the cerebrospinal fluid.

3.2. γ-Glutamyl Transpeptidase

γ-Glutamyl transpeptidase (GGT, EC 2.3.2.2) is an integral membrane protein consisting of two noncovalently linked subunits. The enzyme is found extensively in prokaryotes as well as in mammals and other eukaryotes. Depending on the species, the molecular mass of the enzyme varies between 68 and 95 kDa and reflects different grades of glycosylation.[146] Even within the same tissue several isoforms of the enzyme may exist with different isoelectric points and glycosylation patterns. Recent studies also reveal tissue-dependent expression of various GGT genes.[147] GGT is located on the external surface of the cell and is anchored to the membrane by a single transmembrane domain situated at the amino terminal end of the heavy subunit.[148] GGT catalyzes the transfer of a γ-glutamyl residue from a γ-glutamyl donor peptide or peptide derivative to a large number of acceptors such as amino acids, peptides, and water. In addition to glutathione, probably the most important donor, a large number of natural and synthetic γ-glutamyl compounds are accepted, including S-substituted glutathione derivatives.[149–151]

The relationship between competing transfer reactions (transpeptidation reactions, autotranspeptidation reactions, hydrolysis) is dependent on pH as well as on the nature and concentration of acceptor substrates in the medium. Only contradictory data is available on the relationship between these reactions under physiological conditions, for example in blood plasma.[149, 152] In view of the large number of GGT isoforms, their low donor–substrate specificity, and the competition between the various reaction mechanisms, an exact description of GGT function in a particular tissue is difficult. The participation of GGT in the cyclic metabolism of glutathione in the kidney (γ-glutamyl cycle) has long been postulated (Figure 5). The proposed additional function of the cycle in transporting

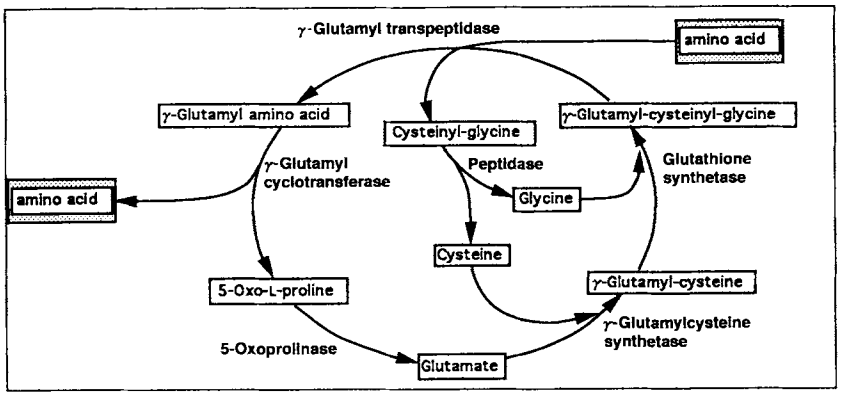

Figure 5. The γ-glutamyl cycle (adapted from ref. [114]).

amino acids from plasma to the cytosol is a subject of debate.[114] The GGT-catalyzed extracellular γ-linkage of glutamate, cleaved from glutathione, with the amino acid to be transported is fundamental to the γ-glutamyl cycle. Basically this is a transpeptidation reaction. Subsequent to transport into the cell the adduct is cleaved, releasing the amino acid. Glutathione is thus regenerated, transferred to the GGT active site, and the cycle completed.

This model has been modified in view of experimental results concerning the stoichiometry of the cycle and the function of γ-glutamyl transpeptidase. Accordingly, GGT is certainly not a transport protein. Similarly, studies on the involvement of γ-glutamyl transpeptidase in other known amino acid transport systems gave contradictory results.[153] In more recent proposals[154] the γ-glutamyl cycle only induces the transport of amino acids when their extracellular concentrations are high and probably involves the intermediate oxoproline as a second messenger. The actual transport occurs with a different transport system having similar substrate specificity.

In addition to participating in the γ-glutamyl cycle, GGT is also involved in the mercapturic acid detoxication pathway and leukotriene metabolism, which is a special case of the mercapturic acid pathway (Section 4). GGTs have been established in a wide range of mammalian organs such as kidney, liver, lungs, and brain, as well as in body fluids. Especially high enzyme activities are found in epithelial cells with secretory or absorptive functions, including cells found in renal tubule brush borders, on the inner surface of the bile duct, in bronchioles, and the intestinal epithelium. High activities are also found in various organ barriers.[153] Early histochemical and biochemical studies of GGT distribution in the brain of many species have revealed regional enzyme heterogeneity. According to these studies, GGT was established in the choroid plexus[155] and in the cerebral capillary epithelium, suggesting that it participates in blood–brain barrier functions and in the transport of amino acids across the barrier.[156–158] A similar role can be envisaged for the GGT found in glial cells. Possibly the enzyme is involved in removing transmitters from the synaptic cleft by transporting them into the glial cells.[158] GGT expression in mouse brain capillaries is correlated with the development of the blood–brain barrier and therefore reflects the state of differentiation of the endothelial cells.[43] However, Wolff et al. established that GGT activities vary in capillaries of different regions of bovine and rat brain.[159] In correspondence with the postulated GGT involvement with the blood–brain barrier, this study reveals low activities in regions without barrier function.

The regulation of GGT activity in brain capillaries is not fully understood. In cell culture experiments with brain capillary endothelial cells, cocultured astrocytes were found to induce GGT expression,[160] thus counteracting dedifferentiation of the dividing endothelial cells.[161] Since astrocytes are a heterogeneous cell type, regional dissimilarities in GGT expression may be related to variable astroglial differentiation and consequently variable induction of endothelial cells by astrocytes.[159] Similarly, the expression of other of endothelial cell properties may be traced back to induction through astrocytes and the metabolic requirements of the particular region of the brain.

In contrast, immunochemical, histochemical, and biochemical studies by Frey et al.[15] and by Risau et al.[16] establish that the greatest GGT activity in brain capillaries is in the abluminally situated pericytes and not in the endothelial cells. In immunofluoresence staining of porcine brain cryotissue sections the stain distribution in capillary longitudinal and cross-sections was asymmetric. Both electron microscope images of brain sections and cell culture experiments confirm that the more intensely stained areas are in fact pericytes. In contrast to earlier studies of the cerebellum,[162] tissue sections reveal an exclusively abluminal GGT localization at subcellular level.[15] Similar to the regional heterogeneity in tissue sections, pericytes also show variable GGT activities and stain intensities in culture.[16] The authors suggest that this may be due to their derivation from different pericyte subpopulations, as well as to growth in an "unnatural environment" without endothelial cells and/or astrocytes. Accordingly, higher GGT expression was noted in pericytes in contact with neighboring endothelial cells or pericytes. In addition it was shown that larger vessels with little or no blood–brain barrier features were also incorporated during the preparation of cerebrovascular cells.

The high concentration of GGT in pericytes is hardly reconcilable with the amino acid transport model. It rather suggests that at the blood–brain barrier, this cell type has protective and detoxicating functions involving the mercapturic acid pathway.[15] Since the GGT content of brain capillary pericytes differ from those of all other tissues, clarification of GGT function at the blood–brain barrier will lead to an understanding of pericyte function in other tissues.

3.3. Cysteine *S*-conjugate Specific *N*-Acetyl-*S*-transferase

Cysteine *S*-conjugate specific *N*-acetyl-*S*-transferase (NAcT, EC 2.3.1.80) is a membrane-bound enzyme catalyzing the last step in the mercapturic acid pathway, the N-acetylation of thioethers. Although it is involved in the detoxication of a large number of reactive thiols, the enzyme has not been investigated very extensively. *N*-acetyl-*S*-transferase is mainly located in the

liver and kidney in rats.[121, 163] Very small amounts of the enzyme were also found in the small intestine.[164] The highest activities were measured in the kidneys, where a distinct correspondence exists between the distribution profiles of *N*-acetyl-*S*-transferase and the ectoenzymes of the mercapturic acid pathway, γ-glutamyl transpeptidase and dipeptidase.[165] In contrast to these enzymes, *N*-acetyl-*S*-transferase is located subcellularly in the liver and kidney on the cytosolic side of the endoplasmic reticulum. The intracellular situation of the enzyme presumably ensures a sufficiently high concentration of the exclusively intracellular cofactor acetyl-CoA, necessary for N-acetylation.

Since the enzyme is membrane-bound and has a high substrate specificity, it can be clearly distinguished from other, better investigated acetyltransferases, which are found mainly in the liver, located in the cytosol or in the nucleus of eukaryotic cells. They include cytosolic arylamine *N*-acetyltransferases (EC 2.3.1.5), which has *N*-hydroxyarylamine *O*-acetyltransferase as well as arylhydroxamic acid *N*,*O*-acetyltransferase activities, nucleus-bound histone-*N*-acetyltransferase, lysosomal α-glucosamide-*N*-acetyltransferase (EC 2.3.1.78) and serotonin-acetyltransferase (EC 2.3.1.87). Cysteine *S*-conjugate specific *N*-acetyl-*S*-transferase only accepts S-substituted L-cysteines or O-substituted analogs (serine derivates). For the most part, free amino acids are not N-acetylated; however, tryptophan and unsubstituted L-cysteine may be N-acetylated to a low extent. The reaction rate intensifies with increased lipophilic properties of the S substituents. In a number of species the enzyme is implicated in the N-acetylation of leukotriene E_4. However, this has not been verified in any case.[166] Based on activity tests[167] we have established *N*-acetyl-*S*-transferase in porcine kidney, liver, and brain. Preparations of cerebral capillaries, choroid plexus, and cultures of cerebral capillary endothelial cells displayed high specific activities. This indicates the significance of the enzyme in regions with barrier properties (blood–brain barrier, blood–liquor barrier).

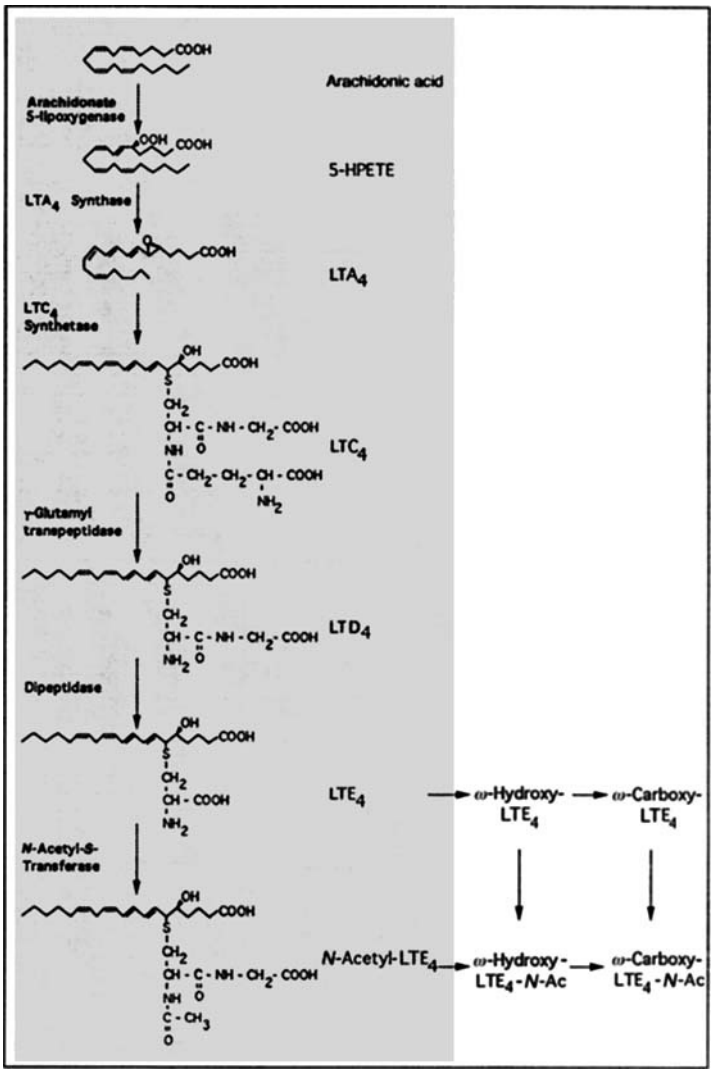

Figure 6. Leukotriene (LT) metabolism; 5-HPETE: 5-hydroperoxyeicosatetraenoic acid.

4. Leukotriene Metabolism

Leukotrienes are a class of biologically active compounds, first described around ten years ago. They have a wide range of functions and effects, depending on the organ and cell type.[168–170] Their name originates from leukocytes, in which they were first discovered, and the three conjugated double bonds (triene unit) common to all leukotrienes. They are all derivatives of arachidonic acid, a polyunsaturated C_{20} fatty acid, which is the basic structure of all leukotrienes. Arachidonic acid is converted into leukotrienes in a series of enzyme-catalyzed reactions largely analogous to the mercapturic acid pathway. Therefore leukotriene metabolism can be perceived as a special case of this detoxication pathway. They are distinguished into classes A to F according to sequence of formation; the subscript indicates the total number of C=C bonds in the basic C_{20} structure.[169] Leukotriene biosynthesis is initiated by the enzyme arachidonate 5-lipoxygenase (Figure 6). Accordingly, the route is often described as the lipoxygenase metabolic pathway.[170–172] The calcium-dependent enzyme converts arachidonic acid into 5-hydroperoxyeicosatetraenoic acid (5-HPETE), which is rapidly reduced to the unstable leukotriene A_4 (LTA_4) by the same enzyme.[173] LTA_4 is then either enzymatically hydrolyzed by a hydrolase to leukotriene B_4 (LTB_4) or nonenzymatically to various compounds.[174] However, should the molecule enter the mercapturic acid pathway, it is conjugated with glutathione and cysteinyl leukotriene C_4 (LTC_4) is formed.[168, 170] In contrast to the mercapturic acid pathway and to earlier opinions this reaction is not catalyzed by a glutathione *S*-transferase but by microsomal LTC_4 synthase.[175, 176] LTC_4 synthase was distinguished from cytosolic and microsomal glutathione *S*-transferase a number of years ago;[177] however, recent studies confirmed that this enzyme can be clearly distinguished by its nucleotide and amino acid sequence as well as substrate specificity.[178, 179] Accordingly, it seems that homodimer LTC_4 synthase is only involved in LTC_4 biosythesis and not in cellular detoxication. LTC_4 is transported out of the cells by means of an ATP-dependent leukotriene export carrier (LTEC).[180, 181] The ectoenzymes γ-glutamyl transpeptidase and dipeptidase catalyze the successive cleavage of the γ-glutamyl moiety and glycine residue from LTC_4, forming leukotriene D_4 (LTD_4) and finally leukotriene E_4 (LTE_4).

The enzymes are presumably identical to those in the mercapturic acid pathway.[168, 169] The three compounds have long been known as the "slow reacting substance of anaphylaxis" (SRS-A) in view of their effect (see below). In analogy to the mercapturic acid pathway, leukotriene E_4 is converted into the biologically largely inactive *N*-acetyl-LTE_4.[182]

The ω-hydroxyl and ω-carboxyl products of LTE_4, *N*-acetyl-LTE_4, and LTB_4 were found in hepatocytes. These are degraded by peroxisomal β-oxidation of the substituent in the ω-position.[174] Reactions yielding other products such as the GGT-catalyzed formation of LTF_4 (γ-glutamyl-LTE_4)[174] have been established in vitro, but not in vivo in an intact organism. The biologically highly active cysteinyl leukotrienes LTC_4, LTD_4, and LTE_4 are rapidly removed from circulating blood in the kidney and in particular in the liver, probably after prior metabolization. For their excretion in bile, leukotrienes and their derivatives, bound to albumin in nanomolar concentrations in the blood, are taken up though the basolateral (sinusoidal) membrane of hepatocytes, then most likely metabolized, and subsequently exported from the cell by an ATP-dependent transport system.[98] The best substrate for the leukotriene export carrier (LTEC) in the biliary membrane is LTC_4. However, the similarly high affinity for LTD_4 and *N*-acetyl-LTE_4, for example, indicates that the attached glutathione residue is not a structural feature that defines substrate specificity.[98] Studies of inherited transport defects in rats have established that, despite similar substrate specifications, distinct leukotriene export carriers exist in different tissues.[183, 184] Competition experiments also reveal that a single carrier exists for all leukotrienes in a particular cell type or tissue.[185] These leukotriene transport systems are clearly distinct from other non-leukotriene transporters such as P-glycoprotein (see Section 2) and the recently discovered ATP-dependent bile salt transporter.[186] Investigations of transfected cells show that leukotriene transport is facilitated by a 190 kDa glycoprotein that is the gene product of the MRP (multidrug resistance associated protein) gene.[187, 188]

Studies of synthetic or biosynthetic leukotrienes have provided detailed information on their biological effects in different tissues and organs. Thus leukotrienes play an important role as endogenous mediators in signal transmission between cells, inflammation, various shock conditions, and allergic reactions as well as in tissue damage, bronchial asthma, and coronary diseases. Cysteinyl leukotrienes known as SRS-A have a strong constrictive effect on the central and peripheral air passages of the lung.[189] This may lead to complete closure of the respiratory tract and secretion of mucus.[190] The increased production of cysteinyl leukotrienes after exposure to diverse allergens substantiates a correlation with allergic reactions.[191, 192] In view of their strong smooth muscle contractile activity,[170, 193] leukotrienes are effective vasoconstrictive agents in the vessels of the heart, lung, kidney, and other tissues. Concentrations in the lower nanomolar range are sufficient for a dose-dependent contraction of vessels and especially of arterioles and postcapillary venoles. Receptors facilitate a direct and specific effect upon the endothelial lining of the vessels. Examples of the indirect consequences of this contraction are negative inotropic effects of the heart in combination with reduced coronary blood flow and a reduced glomerular filtration in the kidney.[169, 194] However, observations in numerous organs indicate that constriction is followed by increased vascular permeability and efflux of plasma and macromolecules.[170, 195] Large regions of the brain are also extensively capable of synthesizing leukotrienes; however, the amount of leukotrienes varies with the region. Thus LTC_4 is mainly formed in the hypothalamus and to a lesser degree in the cerebral cortex and cerebellum.[196, 197] LTC_4 was also established in the cerebrospinal fluid.[198] Although the exact location of leukotriene synthesis is as yet unknown, neurons are considered most likely.

A physiological significant property of leukotrienes in the central nervous system is control of neuronal excitibility, demonstrated in rat cerebellar Purkinje cells.[199] In addition to neuromodulation, leukotrienes are also suggested to be involved in neuroendocrine functions[200] such as the release of luteinizing hormone by the hypophysis frontal lobe of the rat.[196, 201] Since increased leukotriene levels in the brain follow a cerebral ischemia,[202] they have been proposed to be involved in brain damage pathogenesis as a consequence of an ischemia.[202, 203] The initial results of studies on blood–brain barrier disruption or brain edema formation as a consequence of leukotriene vasoconstrictory and permeability effects in the cerebrocapillary system were contradictory. Thus, increased permeability of the blood–brain barrier was detected after an intraparenchymal injection of LTC_4,[203, 204] and leukotrienes were suggested to be responsible for partial destruction of the barrier. However, this effect was only noted for physiologically inconceivable levels of leukotrienes, far exceeding those measured in the cerebral cortex after a temporary ischemia. Mayhan et al.[205] established that low leukotriene concentrations only cause minor cerebral vasoconstriction and minimal disruption of the blood–brain barrier. In contrast, the effects of leukotrienes on noncerebral vessels are more pronounced. Hsu et al.[206] detected no increase in leukotriene levels during temporary ischemia of neonatal porcine brain. According to both groups, leukotrienes are not involved in the breakdown of the blood–brain barrier. This apparent contradiction is resolved by more recent studies on the enzymatic blood–brain barrier.[207, 208] Thus the particular resistance of brain capillaries to leukotriene vasoconstrictory and permeability effects can be explained by GGT-catalyzed metabolism of LTC_4. This takes place in brain capillaries but not in the blood vessels of other organs, thus protecting the cerebral capillary system from LTC_4. Earlier investigations had already established the transformation of LTC_4 into LTD_4 and LTE_4 in brain capillaries and choroid plexus.[209] The susceptibility of brain capillaries to LTC_4 after cerebral ischemia is attributable to a decrease in GGT activity following the ischemia, which was detected by Baba et al.[207] In agreement with this hypothesis, distinct leukotriene effects have been observed in the GGT-deficient blood–tumor barrier of brain tumors.[210]

5. Outlook

One feature of the blood–brain barrier is the incapacity to retain blood-borne lipophilic substances. Because they are soluble in lipids they are able to cross the cerebral capillary endothelial membranes and enter the brain. Consequently, an effective retrograde transport of these substances, possibly after

chemical modification, is necessary to complete barrier functions. Glutathione *S*-transferases and γ-glutamyl transpeptidase have been established in astrocytes, and GST, GGT, and *N*-acetyl-*S*-transferase in the cerebrocapillary endothelium. This indicates that the mercapturic acid pathway is also found in the blood–brain barrier in addition to other transport systems such as the P-glycoprotein (see Section 2). In view of this, the marker enzyme GGT (Figure 7) can be assigned a definite function. According to this model, the mercapturic acid pathway of detoxication is part of the enzymatic blood–brain barrier in the brain. It protects the central nervous system and the blood–brain barrier itself from toxic or otherwise harmful substances by metabolism and transport. Thus lipophilic xenobiotics are conjugated during or immediately following passage through the blood–brain barrier in endothelial cells or astrocyte endfeet. On the abluminal side, they are subsequently converted into the corresponding cysteine *S*-conjugate, a process catalyzed by the enzymes γ-glutamyl transpeptidase and dipeptidase. The crucial step is then the intracellular N-acetylation of the conjugates to form the corresponding mercapturic acids. These form the end products of the detoxication pathway in other organs and transport systems have already been described for them.

The complete metabolic route is characterized by the N-acetylation process and the cysteine *S*-conjugate specific *N*-

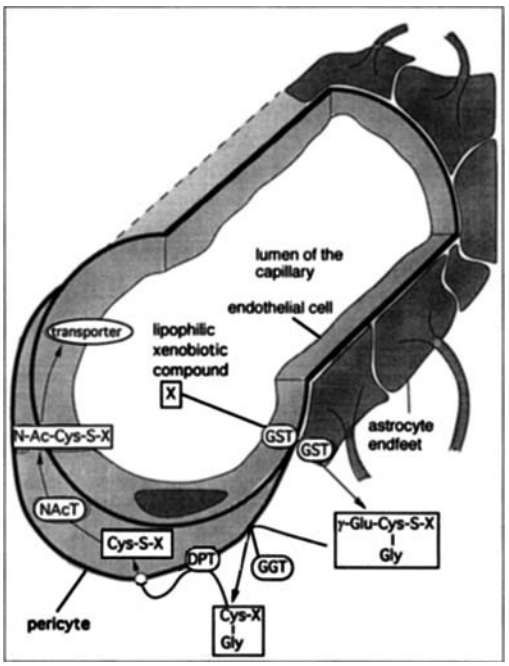

Figure 7. Model of the mercapturic acid pathway at the blood–brain barrier. GST: glutathione *S*-transferase; GGT: γ-glutamyl transpeptidase; DPT: dipeptidase; NAcT: *N*-acetyl-*S*-transferase.

Appendix 1. Glossary of the most important abbreviations and medical terms.

abluminal	the side of the microvasculature not in contact with the blood
amyloid	waxy deposition of proteins formed in the blood vessels under abnormal conditions
astrocytes	star-shaped glial cells
basement membrane	single-layered connective tissue membrane underlying the epithelial and endothelial cells
blood–liquor barrier	barrier between the blood and cerebrospinal fluid
CD4	surface antigen of T-lymphocytes
cerebrospinal fluid (CSF)	includes the lymphlike fluid in the spinal fluid that is secreted by the choroid plexus
endothelium	a type of cells lining blood vessels
ependymal cells	cells lining the internal cavities of the central nervous system
epiphysis	pineal gland; an appendage of the brain
gap junctions	contacts between cells essential to metabolic cooperation; the plasma membranes of these cells are separated by 2 to 4 nm
glial cells	supporting cells in the central nervous system
homeostasis	equilibrium of the physiological functions
interstitium	supporting tissue containing nerves and blood vessels that fills the spaces in or around the parenchyme of an organ
ischemia	local restricted tissue anemia
luminal	the side of the microvasculature in contact with the blood
multidrug resistance associated protein	the membrane protein (P-glycoprotein) that is responsible for the ATP-dependent transport of cell toxins out of the cell; the acquired resistance of tumor cells to drugs in cancer treatment is linked to this protein
parenchyme	the tissue in an organ responsible for the specific function of the organ, not connenctive or supportive tissue
pericytes	cell type associated with the abluminal membrane of the capillaries
choroid plexus	ependymal cells that line the brain cavity; responsible for secretion of cerebrospinal fluid and location of the blood–liquor barrier
Purkinje cells	large nerve cells in the cerebellum
slow reacting substance of anaphylaxis (SRS-A)	mixture of the cysteine-containing leukotrienes LTC_4, LTD_4, and LTE_4
tight junctions	contacts between neighboring epithelial or endothelial cells; the plasma membranes are fused together and intercellular space is eliminated
transcytosis	transcellular transport (absorption at one membrane, transport through the cytosol, and release at the opposite membrane), which can be either specific (receptor-mediated) or unspecific
vasoconstriction	narrowing of the blood vessels by contraction of the smooth muscles in the vasculature
vasoconstrictor	a nerve that induces vasoconstriction

acetyl-*S*-transferase that catalyzes the reaction. Consequently, this enzyme can be used to demonstrate the presence of the mercapturic acid pathway in the blood–brain barrier. In a recent study we purified the enzyme completely for the first time and obtained a polyclonal antiserum by immunization.[211] Through immunofluorescence and enzymatic activity measurements we established cysteine *S*-conjugate specific *N*-acetyl-*S*-transferase specifically in the cerebral capillaries. In addition, especially large amounts of the enzyme were found in pericytes. This indicates that this cell type may be involved in detoxication processes in the blood–brain barrier.

Under certain circumstances leukotrienes are capable of partially destroying the blood–brain barrier. These substances, which are also synthesized in the brain, must consequently be metabolized, biologically inactivated, and exported immediately on arrival at the blood–brain barrier. Recent studies have underlined the importance of GGT activity in protecting the blood–brain barrier from the effect of leukotrienes (see Section 4). In many cases, the LTD_4 produced during this stage has an even higher biological activity than LTC_4,[190, 212, 213] thus necessitating further metabolism. Only after N-acetylation or oxidation of LTE_4 is the substance biologically inactivated. In view of this, *N*-acetyl-*S*-transferase may play a key role in protecting the blood–brain barrier from endogenous leukotrienes. However, to date there is no conclusive evidence that the enzyme is capable of acetylating LTE_4 in vivo.

Early research in this area first resolved the morphological features of the cerebral microcapillaries and therefore the blood–brain barrier. Then the presence of specific transport systems for biochemical compounds was established. The study of enzymatic detoxication pathways from the standpoint of an incomplete physical barrier came later and complements our view of the enzymatic blood–brain barrier. The detection of further detoxicating pathways such as the mercapturic acid pathway at the barrier supplements this understanding and extends our appreciation of the complexities of the blood–brain barrier.

This research was supported through grants from the Max-Buchner-Forschungsstiftung and the Hans-Seidel-Stiftung (A. A.) as well as the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft (Wo569/1-1 and Ga131/1-1).

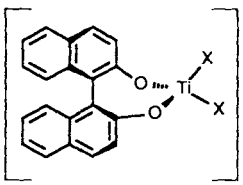
Fluorotitanium Compounds—Novel Catalysts for the Addition of Nucleophiles to Aldehydes

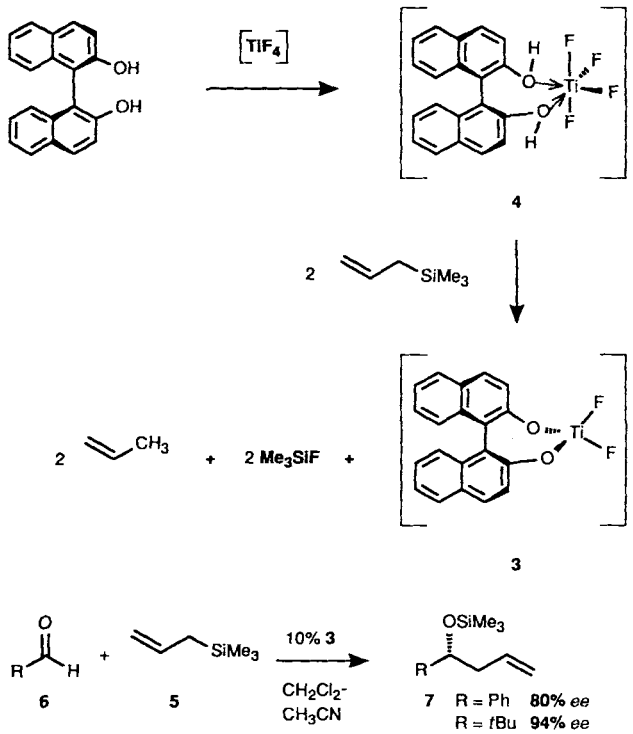
Rudolf O. Duthaler* and Andreas Hafner

Transformations with chiral catalysts lead most efficiently to optically active products. The degree of enantioselectivity rather than the efficiency of the catalytic cycle has up to now been in the center of interest. Catalytic oxidations or C–C bond formations are much more complex processes than catalytic hydrogenations and are still under development. In the case of catalytic additions of dialkylzinc compounds,[1] allylstannanes,[2] allylsilanes,[3] and silyl enol ethers[4] to aldehydes the degree of asymmetric induction is less of a problem than the turnover number and substrate tolerance. Chiral Lewis acids for the enantioselective Mukaiyama reaction have been known for some time already,[4] and recently the binaphtholtitanium complexes **1**[2c–2e] and **2**[2b] have been found to catalyze the addition of allylstannanes to aldehydes quite efficiently.



1 X = *i*PrO Ti-O-Ti bridged oligomer
2 X = Cl
3 X = F Ti-F-Ti bridged oligomer?

Most desirable, however, would be chiral catalysts for the addition of the more readily available and less toxic allylsilanes, but so far the efforts towards an enantioselective variant of the Sakurai–Hosomi reaction have been less successful. Some time ago Ketter and Herrmann[3a] obtained 24% *ee* for the addition of allylsilane to aldehydes catalyzed by the dichlorotitanate **1**. Better results (80% *ee*) have been reported by Mikami, Nakai, and co-workers[3c] for the addition of crotylsilane, also catalyzed by complex **1**. Yamamoto and co-workers[3b] used chiral acyloxy boranes to catalyze the Sakurai–Hosomi reaction. Whereas an excellent value of 96% *ee* was obtained for the addition of 2,3-disubstituted allyl groups, the conversion with parent allylsilane was low (46%) and the asymmetric induction mediocre (55% *ee*). Gauthier and Carreira[5] made a leap forward by using the fluorotitanium binaphthol complex **3**. Catalyst **3** is prepared in situ from the TiF_4–binaphthol adduct **4** on formal HF elimination mediated by allylsilane **5**. The addition of **5** to aldehydes **6** to form **7**, catalyzed by 10% of **3**, proceeds with 61–94% *ee* and good yields (69–93%); the best results are observed for aldehydes with tertiary alkyl residues (Scheme 1).



Scheme 1.

The prerequisites for enantioselective catalysis of the Mukaiyama reaction with chiral metal complexes have been thoroughly analyzed by Hollis and Bosnich[4a] (see also Refs. [4b,c]). They are depicted in Scheme 2 for the Sakurai–Hosomi reaction with a titanium catalyst: 1) the Lewis acid should form a complex with the aldehyde (**8**), rather than being transformed into an allyltitanium compound by reaction with allylsilane **5**. 2) The Ti–O bond of intermediate **9** should be relatively weak, thus enabling direct conversion into the O-silylated adduct **7** with regeneration of catalyst **10** according to the variant Ⓐ. Scheme 2.

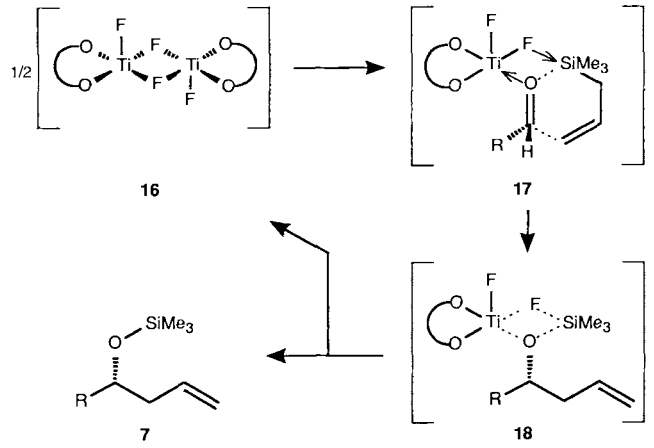
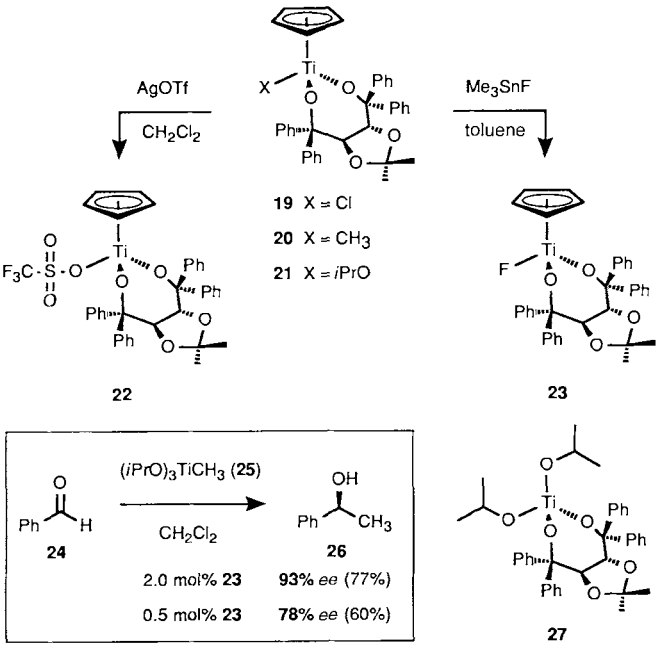
case of pathway Ⓑ a titanated product **11** is formed together with Me_3SiX **12**. When X is CF_3SO_3, **12** is an excellent catalyst for the allylsilylation (Sakurai reaction), which affords racemic product **7**. In most cases this unselective catalysis by **12** is indeed much faster than the metathesis of **11** and **12** to form the desired product **7** and chiral catalyst **10**. We have been able to document such a metathesis by treating the primary product **13** of the allyltitanation of benzaldehyde either with Me_3SiBr or Me_3SiI in toluene to form the silyl ether **14** and the titanium halogenide **15**. In a stepwise manner **15** can be converted back into the allyltitanium reagent by reaction with an allyl Grignard compound to restart the cycle with a further batch of benzaldehyde.[6]

As put forward by Gauthier and Carreira,[5] the special nature of the titanium–fluoride bond is crucial for the catalytic properties of complex **3**. Because of the extreme electronegativity of fluorine the Ti–F bond is highly polar and hence also very strong. A characteristic feature of fluoride ligands, as opposed to chloride and oxide substituents, is the high tendency to bridge metal centers. This has recently been documented by Roesky, Noltemeyer, and co-workers[7] with numerous crystal structure analyses. Quite analogous to the allylstannane addition catalyzed by alkoxide **1**,[2c–2e] the induction observed with complex **3** exceeds the optical purity of the binaphthol ligand.[5] This is explained by aggregate formation (see also Ref. [2d]), and the crystal structure of **1** reveals oligomer formation through Ti-O-Ti bridges.[8] Based on the many structures of titanium fluorides[7] it would be astonishing if the fluoride **3** did not aggregate by Ti-F-Ti bridging. One could therefore envisage, that, starting from dimer **16**, a ternary transition state **17** is responsible for the catalytic Sakurai–Hosomi reaction, in which the electrophilic titanium center activates the aldehyde and the nucleophilic fluoride bridge to silicon increases the reactivity of the allylsilane. It is known that pentacoordinated, negatively charged allyl siliconates add without Lewis acid to aldehydes.[9] The adduct **18** as the primary product could then fragment to the silyl ether **7**, and catalyst **16** would be regenerated (Scheme 3).



Scheme 3.

We had already speculated earlier that a fluoride ligand might add catalytic properties to our chiral dialkoxy cyclopentadienyltitanium complexes. Chlorotitanium-TADDOLate **19**—an excellent template for controlling the stereochemistry of stoichiometric additions, also to chiral aldehydes—could easily be transformed into the relatively inert methyltitanium derivative **20**, isopropoxide **21**, and trifluoromethylsulfonate **22**. However, the preparation of fluoride **23** turned out to be rather tricky.[11] We finally succeeded when a new method developed by Roesky and co-workers[7a,b] appeared, which allows a clean conversion of chloride **19** into **23** with Me_3SnF (Scheme 4).[11] An X-ray



Scheme 4.

analysis revealed that the fluoride **23** is monomeric in the crystal and also nearly congruent with chloride **19**, except for the Ti–F bond (182.5(5) pm), which as expected is shorter than the Ti–Cl bond of **19** (228.4(3) pm).[12] We were, of course, interested in comparing the catalytic properties of **23** with those of triflate **22**. In the presence of **22** allylsilane **5** smoothly adds to benzaldehyde, but the product is racemic. Most probably the catalyst is trimethylsilyl triflate, which is formed according to pathway Ⓑ (Scheme 2, cf. Ref. [4a]). On the contrary, no reaction between benzaldehyde and allylsilane **5** is observed in the presence of fluoride **23**. As we had observed before, all cyclopentadienyltitanium TADDOLates studied catalyzed the conversion of benzaldehyde **24** with salt-free (iPrO)$_3$TiCH$_3$ (**25**) into 2-phenylethanol (**26**).[11] In this case the titanium fluoride effect was indeed very pronounced: at −78 °C 0.5% of **23** afforded 60% of product **26** with 78% *ee* in 17 h; with 2% of **23** the induction is 93% *ee*.

Fluoride **23** thus outperforms the analogous complexes by far, since **26** is obtained in only 40–60% *ee* in the presence of 10% of **19**–**22**.[11] The reaction of **25** with aldehydes can also be catalyzed by titanate **27**. In this case, however, 20% or even stoichiometric amounts of catalyst have been used.[13] For comparison we have tested complex **27** under similar conditions. With 0.5% of **27** only 6% of benzaldehyde **24** was converted into **26**.[11] Originally we also hoped for high versatility and substrate tolerance with fluoride **23**. However, with complex aldehydes such as glyceraldehyde acetonide no conversion was observed.

As exemplified by the reactions of Schemes 1 and 4, fluorotitanium compounds could open new possibilities for metal-catalyzed processes. Their fascinating structural diversity as well as further catalytic possibilities in the field of olefin polymerizations have been illustrated by the pioneering work of Roesky, Noltemeyer and co-workers.[7] Similar properties were also exhibited by the analogous zirconium and hafnium compounds.[7b,i] A binaphtholatezirconium diisopropoxide has already been successfully used for the enantioselective allylstannylation of aldehydes.[2f]

Electron Crystallography—Now a Handy Method

Wilhelm Mertin*

The term electron crystallography denotes the structure analysis of crystalline samples from electron diffraction patterns and electron microscopy images. The possibility of solving crystal structures ab initio by electron crystallography has been discussed several times.[1-4] In physics and materials science the problems associated with electron diffraction that arise because of the strong interaction between electrons and matter, particularly multiple scattering etc. (dynamical effects), have been highlighted and dealt with,[1, 5, 6] while in molecular biology where samples consist of only light elements, the possibilities of kinematical electron diffraction have been exploited[2, 7, 8] based on principles applied in X-ray crystallography.

X-rays interact with shell electrons of atoms, while electrons are deflected mainly by the potential of a nucleus of an atom. Therefore, while ideally X-rays are diffracted only once (kinematical diffraction) in a suitable sample and the diffracted rays are not further modified by additional diffraction in the passage through the crystal, electrons undergo multiple scattering in that crystal. The diffracted beams interfere not only with the central beam but also with each other. This is called dynamical diffraction. The phenomenon requires a much more complicated theoretical treatment[1, 5, 6] than the kinematical case, which is usually the basis for calculations in X-ray crystallography. Nevertheless, many studies have been published in which structures were solved by using quantitative electron diffraction intensities. However, the commonly held view was that dynamical effects were too severe[4] and that the initial phase models had been gained by employing results from corresponding X-ray investigations.

For several years a new generation of electron microscopes has been generally available with a 1–2 Å resolution and an acceleration voltage of 200–400 kV (higher than that of previous instruments). Now rows of atoms viewed end-on can be resolved with high-resolution electron microscopy (HREM). Such electron micrographs can be interpreted directly in terms of the projected crystal structure if they are recorded at an optimal defocus condition (Scherzer focus) and if the object is sufficiently thin.[5, 6, 9] In the course of this development the accumulation of experimental data has led to growing confidence that "quasi kinematical" conditions can be assumed even for inorganic substances, minerals, and ceramics, if the area under investigation is thin enough (weak phase approximation). Based on principles applied in molecular biology, a system of programs has been developed[10] that offers the possibility of evaluating micrographs and electron diffraction patterns on a personal computer and of determining the averaged structure of a single crystal. Other image processing systems also exist.[10]

A recent publication "A crystal structure determined with 0.02 Å accuracy by electron microscopy" by T. E. Weirich et al.[11] demonstrates the possibilities of electron crystallography. The structure of $Ti_{11}Se_4$ was solved and refined by utilizing Fourier transforms of high-resolution micrographs and data from single-crystal electron diffraction patterns.[12]

In a first step an electron microscope acts as a diffractometer.[13] As with X-rays one can register the intensities of the deflected beams; however, one loses the phases φ of these waves. Under conditions that are suitable for imaging a structure in projection, the diffracted intensities are[3] $I(h,k) = F(h,k)F^*(h,k) = |F(h,k)|^2$ and $F(h,k) = |F(h,k)|\exp(i\varphi)$. $|F(h,k)|$ is the magnitude of the structure factor amplitude $F(h,k)$. φ is the resulting phase of the deflected beam in the direction h,k. The origin of a unit cell of a crystal is the reference point from which the phases of all waves originating from atoms are counted, and therefore the positional parameters of the atoms in a unit cell are contained in φ. The different phases relate the different reflections to each other. The advantage of electrons over X-rays is that they can be diverted by electromagnetic lenses. The diffracted beams can be reunited with the primary beam to form an image of the projected structure. Phases *and* amplitudes of the waves are thus utilized. When the weak phase object approximation is valid, the image intensity is directly proportional to the projected potential of the crystal structure.[3] This means in the reverse case that not only amplitudes but also the phases of structure amplitudes can be gained from the computed Fourier transform of a digitized electron microscope image if it is recorded under the right conditions, as mentioned above. But even nonideal images can be computationally improved by correcting for wrong defocus, astigmatism, etc.[12] An important step is the refinement of the origin.[12] The origin of the unit cell of the structure projection is placed so that the experimental phases are most reasonably related by a symmetry as high as possible; this symmetry is then regarded as the symmetry of the structure projection. The symmetry is now imposed on both amplitudes and phases, and a density map is calculated as an inverse Fourier-transformation. This density map should correspond to the projected potential of the crystal structure from which the atomic positions can be determined. Figure 1 depicts how potential maps obtained by crystallographic image processing of a micrograph of $Nb_2W_{15}O_{47}$[14] can vary with the imposed symmetry or by shifting the origin of the unit cell. The correction of the original electron microscopy images and all other computational steps are by no means mere routine. Good electron micrographs and electron diffraction patterns are still the best prerequisites.

T. E. Weirich et al.[11] demonstrated that once the phase model is established the more accurate intensities and amplitudes from electron diffraction patterns can be used to refine the structure to a level that is comparable to that obtained by X-ray methods. In the case of $Ti_{11}Se_4$ the lattice constant in the direction of projection of the structure was conveniently short (b = 3.4481 Å); thus projected atoms did not overlap within the unit cell. Therefore the projection in one direction was suffi-

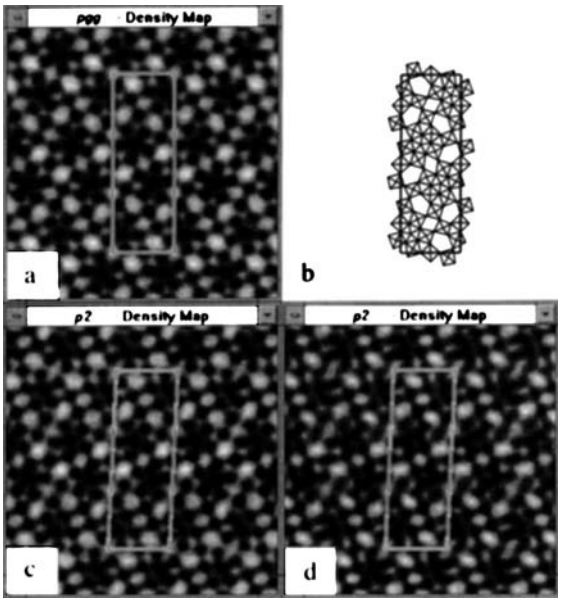

Figure 1. Schematic representation and computed projection maps of $Nb_2W_{15}O_{47}$ calculated for different conditions of symmetry and origin. a) Projection map on (001), black dots represent Nb/W atoms, symmetry *pgg*; mean phase error $\varphi Res = 18.9°$. b) Structure principle [15] of $Nb_2W_{15}O_{47}$ in projection along [001]; lattice parameters: $a = 36.7$, $b = 12.3$, $c = 3.8$ Å. c) *p*2 Symmetry leads to only a slightly worse fit of the data ($\varphi Res = 19.1°$) [12] than the true symmetry *pgg* in a). d) Imposed symmetry *p*2; origin shifted by 3/10 of lattice parameter *a*; mean phase error enlarged to $\varphi Res = 30.9°$.

cient to solve the structure. However, the programm system used[10] also offers the possibility to combine Fourier transforms of crystal projections of different directions; that is to proceed in a way as usually done in X-ray crystallography to solve a three-dimensional structure.

The branch of electron crystallography that cannot always make use of high-resolution electron microscopy images and its Fourier transforms has also advanced rapidly. It has been applied to structures of minerals[6] and especially to the determination of structures of small crystals like those often encountered for organic molecules and polymers which, in addition, are sensitive to radiation damage.[3, 16] Direct methods, like those known from X-ray crystallography, the maximum entropy method, and other likelihood ranking methods have been applied successfully to the elucidation of structures.

Electron crystallography is valuable addition to the tools available for solving crystal structures. Although the interaction of electrons with crystalline material is very complicated and theoretical concerns are justified, the method should be further tested to establish the range of its applicability and to work out how the problems associated with it can be solved. Crystal structures should be solved by using data from different projections. A long-term goal would be the three-dimensional reconstruction of an inorganic real crystal volume.[17] Materials that, for example, are very sensitive to radiation damage, oxygen, and moisture, or easily undergo phase changes during the preparation of the sample for electron microscopy are difficult to investigate especially since the very thin transparent areas of a sample should remain intact. For very small crystals, however, electron crystallography is the method of choice. Particularly in combination with X-ray, image simulation, and crystallographic image processing (CIP) methods, it can be a valuable tool. Even micrographs whose resolution is not particularly high can be used to obtain phase information on sublattices, for example, when strongly scattering building elements of a structure are present. A modern computer, simple digitizing equipment (e.g. a CCD camera and a frame grabber) are requirements which make the method accessible to nearly every laboratory. Of course, one also needs to have access to a high-resolution electron microscope, but the number of these instruments available is increasing all the time.

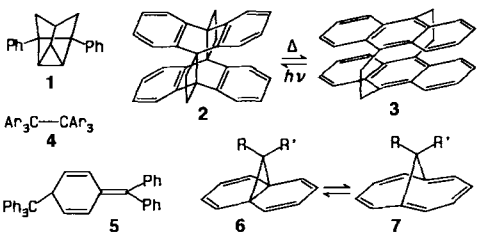
Overlong C–C Single Bonds

Gerd Kaupp* and Jürgen Boy

Covalent C–C single bonds are typically 1.54 Å long. This fact has been confirmed over and over again by X-ray crystal structure analyses (Cambridge Database, Ian Castleden) and other techniques. Larger deviations from the standard value are observed only in structures having exceptional ring strain, steric congestion, or electronic peculiarities. Numerous efforts have been directed at finding very long C–C single bonds. Thus, semiempirical calculations of the polycycle **1**[1] predicted a particularly long diphenyl-substituted bond (PM3 1.642 Å; MNDO 1.652 Å); however, it did not appear worthwhile to conduct an X-ray structure analysis, as much longer C–C single bonds had already been described. A presumed world record was the length of the central bonds in the photoisomer **2** of [2.2]tetrabenzoparacyclophane **3**, which was determined by an X-ray analysis and reported by Ehrenberg as 1.77 Å.[2] However, in this study no evident means of avoiding the thermal reaction leading to the golden yellow isomer **3** were taken.[1b, 3]

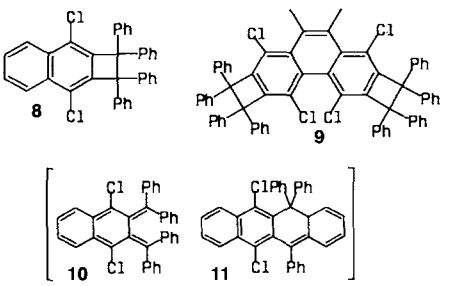


Furthermore, semiempirical calculations indicated considerably shorter central bond lengths for **2**.[4] Thus, it was concluded that Ehrenberg had investigated a mixture of **2** and **3** which had formed in a topotactic reaction.[1b, 3] Consequently, a neutron diffraction analysis using a very large single crystal of **2** (the crystal did not stay completely colorless even though it was continuously irradiated with filtered laboratory light)[4] exhibited central C–C bond lengths of 1.64(1) Å ($R_w = 0.072$; $R = 0.095$) in perfect agreement with the semiempirical MNDO calculation ($d = 1.63$ Å).[4] Later on, based on these experiences the research groups of Ogawa[5] and Siegel[6] measured bond lengths of 1.663(4) and 1.648(3) Å ($R_w = 0.069$, $R = 0.055$ and $R = 0.053$, $wR = 0.0725$, respectively) in X-ray diffraction studies using much smaller crystals of **2**. Both groups reported crystal data of **3**.[5] Ab initio calculations of **2** gave central bond lengths ranging from 1.635 to 1.673 Å.[6]

The history of the reported bond lengths in hexaarylethanes is a true odyssey. First of all, the structure of the basic compound **4** (Ar = C_6H_5) had to be changed into **5**,[7] a fact that was not always acknowledged until 1987.[8] Force field and MNDO calculations indicated a long central bond in **4** (Ar = C_6H_5: 1.60–1.64 Å and 1.68 Å),[9] values which are not very far off from that measured in **5** (1.589 Å).[10] Nevertheless, Rieker and co-workers reported an exceedingly short distance of only 1.47(2) Å in the X-ray structure determination of a genuine (substituted) derivative of hexaarylethane **4**.[11] However, after an extended debate Mislow and co-workers corrected this value to 1.67 Å (**4**, Ar = 3,5-di-*tert*-butyl-phenyl).[12]

Bisnorcaradienes **6** were further candidates for overlong C–C bonds. Apparently, the very long central C–C distances found in X-ray structural analyses of **6** (R, R' = CH_3: 1.826 and 1.770 Å; R = CH_3, R' = CN: 1.850 and 1.783, as well as 1.712 and 1.636 Å)[13] were not reliably interpreted. The early objection of a referee that **6** and **7** might coexist was initially answered with a claim of "normal" thermal parameters.[14] Later,[15] however, the three-membered ring carbons were found to be more mobile, but the irregularities in the U_{ij} values seemed not to merit further investigations. The concept of "fluxional" systems[16] was introduced, but ab initio calculations did not lead to a convincing solution to the problem.[13] Thus, several of the cited species were assumed to be on the annulene side of the **6**⇌**7** equilibrium, and if indeed long central C–C bonds were present, they would be weak and labile.[13] As the refined structure model is not perfect even at −100 °C,[16] it must be concluded that the reported temperature factors are not normal and that an unrecognized structural disorder gave rise to averaged values from coexisting fractions of **6** and **7**. In the meantime, the positions of the equilibria can be derived from ^{13}C solid-state NMR spectra.[17]

Overlong C–C single bonds ($d > 1.7$ Å) can be determined unequivocally in stable molecules, and recently Toda, Goldberg, and co-workers reported C(sp^3)–C(sp^3) bond lengths of 1.720(4) Å in **8** and 1.710(5) as well as 1.724(5) Å in **9**.[18] Compounds **8** and **9** are easily synthesized.[19] In contrast to the



apparently labile, parent compound tetraphenylbenzocyclobutene,[20] **8** and **9** do not spontaneously isomerize to give *o*-quinodimethanes (such as **10**) or their products of cyclization (such as **11**), but are remarkably stable. Compounds **8** and **9**, which display overlong, sterically congested benzocyclobutene bonds with four phenyl groups, were characterized by standard X-ray diffraction techniques at room temperature. The struc-

tures were refined to give R-values of 0.0480 and 0.0610, respectively. Compound **8** crystallized without solvent. However, the crystals of **9** contained 1.5 equivalents of disordered toluene. Nevertheless, the refinement converged rather well at 6.1%. Therefore, despite its remarkable unsymmetry, the structure of **9** also appears reliable, even though no reasonable crystal field analysis could be conducted to clarifying this point, owing to the disorder. The average of 1.717 Å should be a good value for both of the overlong bonds of **9**. Thus, exceedingly long tetraphenyldihydrocyclobutaarene bonds ($d > 1.7$ Å) have been unequivocally detected in both **8** and **9**. Compounds **8** and **9** are colorless both in the crystalline state and in solution.

It appears important to test the performance of usually reliable semiempirical methods like PM3 (SPARTAN 4.1) in duplicating the overlong tetraphenyldihydrocyclobutaarene bonds. A bond length of 1.671 Å is calculated for **8** (MNDO gives 1.676 Å; semiempirical values of 1.670–1.684 Å are cited in ref. [18]). The calculations show that the PM3 method underestimates the bond length of **8** by the remarkable value of 0.050 Å. This deviation cannot be accounted for by the chlorine atoms in **8** alone; when they are replaced with H atoms PM3 calculations predict a larger bond length, though it is still too small (1.684 Å). Apparently, special bonding effects exist that are not suitably or exhaustively covered by the present empirical PM3 parameters. Meanwhile, the computed results may serve as an additional support for the molecular structure of **8** and **9** exhibiting overlong C–C single bonds ($d = 1.720$ and 1.717 Å, respectively). It would be highly desirable to know if additions to these compounds are enhanced.

The tetraphenyldihydrocyclobutaarenes **8** and **9** contain undoubtedly the longest C–C single bonds reliably determined to date. These compounds are of utmost importance for our understanding of chemical bonding. All available theoretical concepts of steric effects (for example overcrowding, angular strain, ring strain, bent bonds) and electronic effects (for example C–C hyperconjugation, $\sigma-\pi$ interactions, σ overlap of p orbitals, homoconjugation, through-space and through-bond interactions, charge density, hybridization) should be tried on them and additional measurements (most importantly electron density maps, photoelectron spectra, laser photolyses, etc.) performed. The significance of the common heuristic bonding effects such as isolated steric and electronic effects, which are so important for the theoretical understanding, ought to be tested. "Comprehensive" semiempirical calculations, which are performed easily and rapidly, appear helpful for the systematic search of the structural requirements for extralong single bonds, even though the present parameters are not completely suitable for such extreme cases. One can then deduce which compounds would be the most interesting to synthesize and study. Thus, PM3 was used to calculate the long bonds of 1,1,2,2-tetraphenylcyclobutane[21] (1.610 Å), of 3,3,4,4-tetraphenylcyclobutene (1.651 Å), and of tetraphenylbenzocyclobutene[20] (1.678 Å) (cf. **1**: 1.642 Å). These bonds are expected to be markedly longer in reality. Continued activities will almost certainly result in a race for the longest C–C single bond and hopefully not be bogged down by questions of definition. Thus, one should not claim that a single bond exists when, for instance, two tri-*tert*-butylmethyl radicals interact at the (PM3) minimum separation of 4.66 Å. Even if these radicals were held permanently fixed in a matrix at the calculated minimum distance, this situation would not correspond to a hexa-*tert*-butylethane, but would still be the intermolecular interaction of two radicals. Furthermore, a distinction has to be made between C–C single bonds and electron-deficient or electron-excessive multicenter bonds. Common examples are bridged nonclassical carbocations (high-level calculations)[22] and $\pi^- - \pi^-$ complexes (X-ray structural data).[23] Of course, in this connection the lowest "nonbonding" C–C distance is also of interest; it was measured to be 1.80 Å in 1-iodobicyclo-[1.1.1]pentane-3-(1-pyridinium) iodide.[24]

Continued research on extralong C–C single bonds should yield further theoretical conclusions on chemical bonding.

Organometallic Chemistry of $[W_2(OCH_2tBu)_8]$**

Malcolm H. Chisholm,* Kirsten Folting, Matthew A. Lynn, William E. Streib, and Darin B. Tiedtke

Dedicated to Professor Walter Siebert on the occasion of his 60th birthday

The triple bond in $[W_2(OR)_6]$ compounds has provided access to extensive organometallic and coordination chemistry.[1] The recent preparation of $[W_2(OCH_2tBu)_8]$[2] has allowed us to examine the chemistry derived from a d^2–d^2 $(W{\equiv}W)^{8+}$ center, and herein we describe some preliminary findings. These are of interest in their own right and make a fascinating comparison with the chemistry already established for $[W_2(OR)_6]$ complexes and other species with M≡M bonds such as "$Os_2(CO)_8$"[3] and $[Cp^*_2Re_2(CO)_4]$.[4] Several of the findings described herein are summarized in Scheme 1. The new compounds have been fully characterized and only selected data are given in the text and footnotes.

$[W_2(OCH_2tBu)_8]$ is believed to be a polymer containing alkoxide-bridged $(W{\equiv}W)^{8+}$ units in the solid state and is insoluble in hydrocarbon solvents.[2] It does, however, readily dissolve in the presence of a Lewis base such as pyridine (py) to form $[W_2(OCH_2tBu)_8(py)]$. When a suspension of $[W_2(OCH_2tBu)_8]_n$ in toluene is allowed to react with KH in the presence of [18]crown-6, the $[W_2(OCH_2tBu)_8(\mu\text{-}H)]^-$ ion is formed: (^{1}H NMR: $\delta = 9.8$ ($W_2(\mu$-H), $^1J(^{183}W,H) = 119$ Hz, $I = 24\%$)).

The addition of ethyne to $[W_2(OCH_2tBu)_8]_n$ in toluene yields a 1:1 adduct, **1**, whose structure is shown in Figure 1.[5] The solid-state structure provides a rare example of an organometallic compound with a bridging alkyne ligand that is neither perpendicular nor parallel to the M–M bond.[6] By analogy with the chemistry of "$Os_2(CO)_8$" we might have anticipated a parallel structure: a dimetallacyclobutene. Indeed, simple calculations (EHMO and Fenske–Hall) based on $[W_2(OH)_8(C_2H_2)]$ with a $W_2(OH)_8$ skeleton taken from the observed structure suggest that by using the sum of the energies of the occupied orbitals, which was employed by Calhorda and Hoffmann to explain the bonding in the model complex $[W_2(NH_2)_2Cl_6(C_2H_2)]^{2-}$, the parallel structure is favored.[7] However, ab initio calculations (Gaussian 92 RHF)[8] on $[W_2(OH)_8(C_2H_2)]$ reveal an optimized geometry with the C–C vector at an angle of 67° to the W–W axis, which is in good agreement with the observed structure. Calculations employing the Fenske–Hall method show that the HOMO–LUMO gap is maximized at a dihedral angle of approximately 50°, thereby suggesting a second-order Jahn–Teller distortion is responsible for the observed structure. Full details of the calculations will be reported later. In any case, the distortion of the μ-ethyne from perpendicular or parallel appears to be electronic in nature rather than due to steric constraints imposed by the alkoxide ligands, though the potential energy surface is rather flat. The latter is confirmed experimentally since the ethynyl carbon atoms in the $^{13}C_2H_2$ isotopomer show only *one* ^{183}W–^{13}C coupling constant in the $^{13}C\{^1H\}$ NMR spectrum: $\delta = 191$, $^1J(^{183}W,^{13}C) = 57$ Hz, $I = 25\%$ even at -80 °C in [D_8]toluene. Experimentally we cannot, therefore, distinguish between a rapid interconversion of the μ-perpendicular and μ-parallel alkyne isomers and a dynamic process in which the twisted μ-alkyne oscillates about a symmetric μ-perpendicular position.

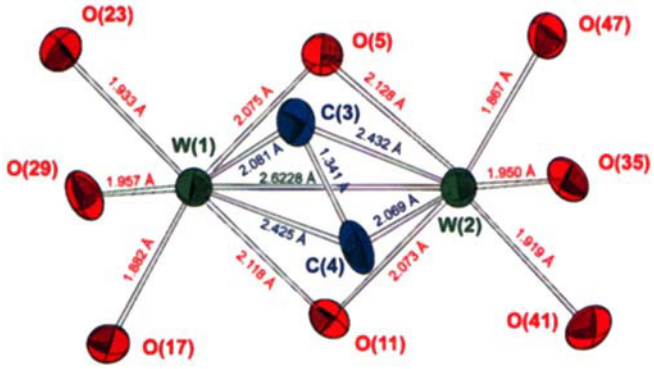

Figure 1. An ORTEP drawing of the central $W_2(O)_8(\mu\text{-}C_2)$ unit of **1**, showing the pseudo confacial bioctahedral geometry and the twisted μ-ethyne moiety. The standard deviations for the distances [Å] shown are (3) to the last significant figure.

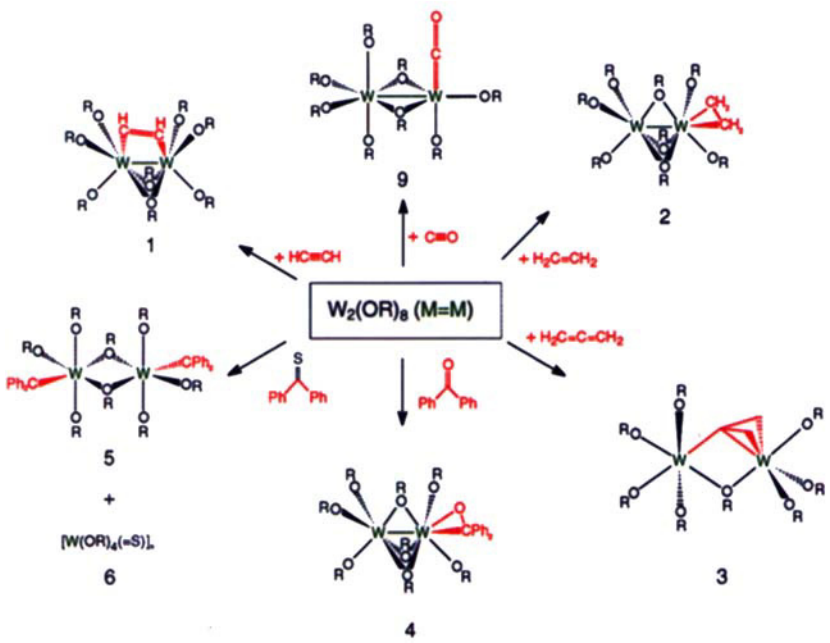

Scheme 1. Summary of the reactions of $[W_2(OR)_8]$. R = CH_2tBu.

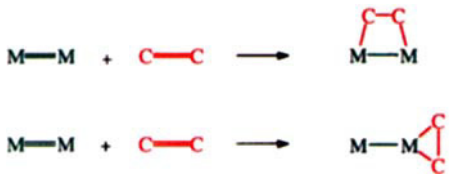
The addition of ethene in toluene to give green solutions and a similarly colored crystalline compound. Crystals suitable for X-ray analysis have not yet been obtained but the NMR data leave little ambiguity concerning the nature of the 1:1 adduct $[W_2(OCH_2tBu)_8(\mu^2\text{-}C_2H_4)]$ (**2**). In contrast to "$Os_2(CO)_8$", which forms a dimetallacyclobutane upon reaction with ethene,[3] the structure of **2** may be described as a confacial bioctahedron, in which the η^2-C_2H_4 unit occupies a terminal site. Thus, addition occurs according to Equation (b) and not by Equation (a). Compound **2** possesses eight inequivalent

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3601-0052 $ 15.00+.25/0



OCH_2tBu ligands, which leads to sixteen doublets in the OCH_2 region of the ^1H NMR spectrum, and eight OCH_2 carbon resonances are observed in the $^{13}C\{^1H\}$ NMR spectrum. Similarly, the η^2-C_2H_4 ligand gives rise to four multiplets in the ^1H NMR spectrum, while the $^{13}C\{^1H\}$ NMR data of the $^{13}C_2H_4$-labeled compound show two signals for inequivalent carbon atoms at $\delta = 55$ and 65 with $^1J(^{13}C,^{13}C) = 31$ Hz. This C–C coupling constant is significantly smaller than the value observed for free ethene (67 Hz), and is consistent with the formation of a metallacyclopropane upon coordination of ethene. The W–W bond is therefore oxidized by two electrons as depicted in Equation (b). The rigid structure on the NMR time-scale arises from the mutual competition of M–M and M $d\pi$-C_2 π^* bonding which use different metal t_{2g}-type orbitals.

Allene and $[W_2(OCH_2tBu)_8]_n$ also form a 1:1 adduct in hydrocarbon solvents from which orange crystals of $[W_2(OCH_2tBu)_8(\mu\text{-}\eta^1,\eta^3\text{-}C_3H_4)]$ (**3**) are obtained.[5] The molecular structure of **3** in the solid-state is shown in Figure 2. The geometry about W(1) may be viewed as octahedral, while that about W(2) may be described as a distorted trigonal bipyramid in which the η^3-C_3 unit occupies a single equatorial site with the methylene units lying slightly above the trigonal plane. When the orange crystals are dissolved in hydrocarbon solvents, green solutions are obtained whose NMR data are very complex and are quite inconsistent with the structure shown in Figure 2. Thus the 1:1

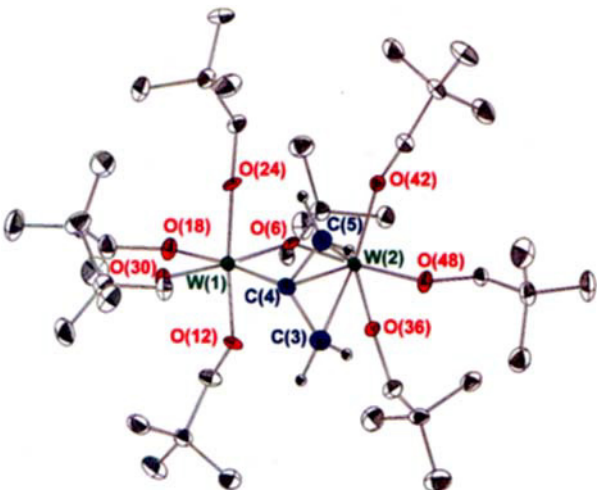


Figure 2. An ORTEP drawing of **3**, showing the pseudo-octahedral geometry at W(1) and the pseudo-trigonal-bipyramidal geometry at W(2) (O(6)-W(2)-O(48) 167.4(2)°). Selected distances [Å] and angles [°]: W(1)–W(2) 2.97(1), W(1)–C(4) 2.11(1), W(2)–C(4) 2.25(1), W(2)–C(3) 2.35 (1), W(2)–C(5) 2.27(1); C(3)-C(4)-C(5) 108.7(6).

allene adduct **3** must exist in equilibrium with another isomer (or isomers), one of which is believed to be analogous to the η^2-ethene adduct described previously.

Benzophenone and $[W_2(OCH_2tBu)_8]_n$ react to give a 1:1 adduct, **4**, whose structure is proposed (based on spectroscopic properties) to be analogous to the fully characterized compound $[W_2(O\text{-}c\text{-}C_5H_9)_8(\eta^2\text{-}OC_5H_8)]$.[9] Specifically for **4**, there are eight inequivalent OCH_2tBu ligands, and the η^2-$O^{13}CPh_2$ carbon resonance occurs at $\delta = 100$ with $^1J(^{183}W,^{13}C) = 47$ Hz, $I = 14\%$.

In the related reaction with thiobenzophenone the C=S bond is cleaved rapidly, leading to the products $[\{W(=CPh_2)(OCH_2tBu)_3(\mu\text{-}OCH_2tBu_3)\}_2]$ (**5**) and $[\{W=S(OCH_2tBu)_4\}_n]$ (**6**). The presence of the terminal alkylidene is evident from the reaction involving $Ph_2{}^{13}C=S$, which yields $W=^{13}CPh_2$ with a chemical shift of $\delta = 261$ and $^1J(^{183}W,^{13}C) = 259$ Hz, $I = 14\%$. The structure of **5** is based on an edge-shared bioctahedron. The addition of EtOH to **5** led to the ethoxide complex $[\{W=CPh_2(OEt)_2(OCH_2tBu)(\mu\text{-}OEt)\}_2]$, which was crystallographically characterized[5] and shown to have this structure. Although the structure of $[W=S(OtBu)_4]$ is known,[10] we attempted an independent preparation of **6** by treating $[W_2(OCH_2tBu)_8]_n$ with elemental sulfur. While **6** is indeed formed in this reaction in hydrocarbon solvents, a blue intermediate $[W_2(\mu\text{-}S)(OCH_2tBu)_8]$ (**7**) was identified and crystallographically characterized (Figure 3). The molecular structure of **7** can be described as a face-centered bioctahedron with a symmetric W–S bridge and a W–W single bond (2.628 Å).

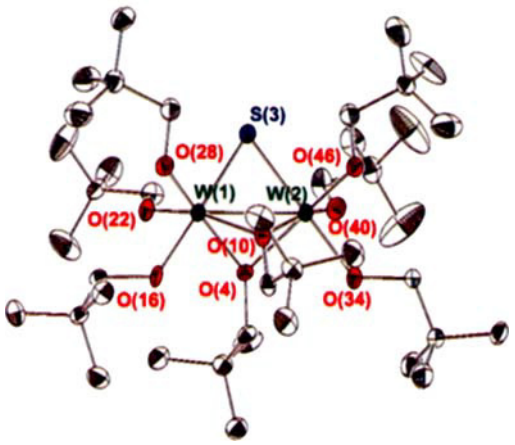

Figure 3. An ORTEP drawing of **7**, showing the confacial W_2O_8S core. Selected distances [Å] and angles [°]: W–W 2.628(1), W(1)–S(3) 2.356(2), W(2)–S(3) 2.355(2); W(1)-S(3)-W(2) 67.82(5).

An oxo analog of **7**, namely $[W_2(\mu\text{-}O)(OCH_2tBu)_8]$ (**8**), has been synthesized and characterized[5] as a purple, hydrocarbon-soluble, crystalline solid from the reaction between $[W_2(OCH_2tBu)_8]$ and pyridine *N*-oxide in toluene. The W–W distance of 2.55 Å in **8** is notably shorter than that in **7** and reflects the fact that the W–μ-O distances (av 1.95(1) Å) are much shorter than the W–μ-S distances (av 2.35(1) Å). The reaction of **8** with O_2 yields $[W=O(OCH_2tBu)_4]$.

$[W_2(OCH_2tBu)_8]_n$ and carbon monoxide react in hydrocarbon solvents to form a 1:1 adduct. The proposed structure of $[W_2(OCH_2tBu)_8(CO)]$ (**9**) is shown in Scheme 1 and a simple orbital interaction diagram is given in Scheme 2. In contrast to $[W_2(OR)_6]$ complexes, the formation of a terminal carbonyl with ketene-like character is quite striking: $\delta = 323$ for ^{13}CO with $^1J(^{183}W,^{13}C) = 220$ Hz, $I = 14\%$; $\tilde{\nu}(^{13}CO) = 1817$ cm^{-1}. The proposed structure of this monocarbonyl adduct allows the partitioning of electrons between the two tungsten atoms such that the W atom bearing the CO ligand is a d^4 pseudo-trigonal bipyramidal metal center. Thus, as shown in Scheme 2, the $(d_{xz}, d_{yz})^4$ orbitals may back-bond to the CO π^* ligand and at the same time they may mix with the formally vacant t_{2g} orbitals of like symmetry at the other metal center. In the absence of accu-

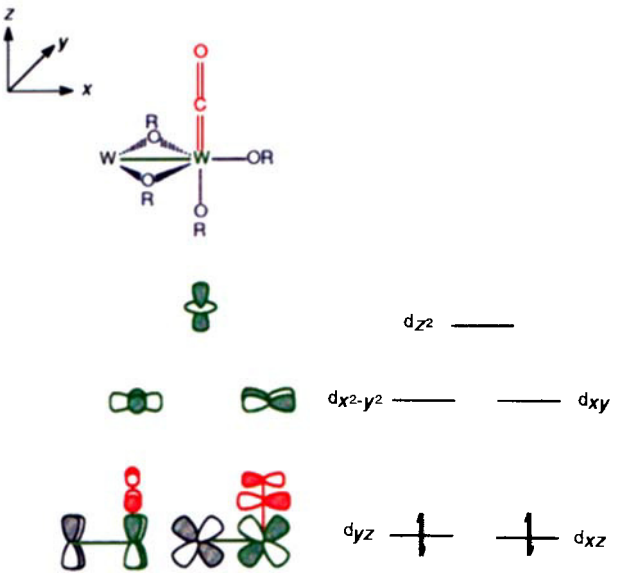

Scheme 2. Orbital scheme of **9**.

rate data for the W–W distance, the relative importance of the Wdπ-Wdπ bonding cannot be determined.

In summary, our preliminary investigation of the chemistry of the W=W bond in $[W_2(OCH_2tBu)_8]$ reveals some fascinating chemistry that is notably different from that established for other M=M bonded complexes[3, 4] and for related d^3–d^3 $(W \equiv W)^{6+}$-containing compounds supported by alkoxide ligands.[1]

Experimental Section

1: Ethyne (0.225 mmol) was added by using a calibrated gas manifold to a suspension of $[W_2(OCH_2tBu)_8]$ (120 mg, 0.113 mmol) in dry, degassed hexanes (10 mL) at −196 °C. Recrystallization in dry, degassed toluene afforded X-ray quality dark red crystals of **1** in 86% yield. $^{13}C\{^1H\}$ NMR (125 MHz, C_7D_8, 24 °C): $\delta = 191$ ($^1J(^{183}W,^{13}C) = 56$ Hz (25%)).

2: Ethene (0.103 mmol) was added to a suspension of $[W_2(OCH_2tBu)_8]$ (100 mg, 9.39×10^{-2} mmol) in dry, degassed hexanes (10 mL) at −196 °C by using a calibrated gas manifold. Recrystallization in dry, degassed toluene gave dark green crystals of **2** in 78% yield. ^1H NMR (500 MHz, C_7D_8, −65 °C): $\delta = 5.3$–3.3 16 doublets (1H per doublet), 1.48 (9H), 1.30 (9H), 1.20 (9H), 1.26 (9H), 1.09 (18H), 0.90 (9H), 0.88 (9H); $^{13}C\{^1H\}$ NMR (125 MHz, C_7D_8, −65 °C): $\delta = 64.3$, 55.1 ($H_2C{=}CH_2$, $^1J(^{13}C,^{13}C) = 31$ Hz), 36.1, 35.3, 35.0, 34.7, 34.5, 34.4, 33.5, 33.3 (CH_2), 28.5, 27.9, 27.7, 27.6, 27.5, 27.3, 26.7 ($C(CH_3)_3$).

3: Allene (0.129 mmol) was added to a suspension of $[W_2(OCH_2tBu)_8]$ (125 mg, 0.117 mmol) in dry, degassed hexanes (10 mL) at −196 °C by using a calibrated gas manifold. Upon warming to 23 °C, the solution became deep green. Crystallization in hexanes gave X-ray quality pale orange crystals of **3** in 82% yield.

4: $[W_2(OCH_2tBu)_8]$ (100 mg, 9.39×10^{-2} mmol) and benzophenone (34 mg, 0.19 mmol) were dissolved in dry, degassed hexanes (10 mL) at 24 °C to give a forest green solution. Crystallization in Et_2O gave crystals of **4** in 79% yield. $^{13}C\{^1H\}$ NMR (125 MHz, C_7D_8, 24 °C): $\delta = 100$ (Ph-C(O)-Ph, $^1J(^{183}W,^{13}C) = 47$ Hz (14%)).

5 and **6**: $[W_2(OCH_2tBu)_8]$ (150 mg, 0.141 mmol) and thiobenzophenone (56 mg, 0.28 mmol) were dissolved in dry, degassed hexanes (10 mL) at 24 °C to give a brown solution. $^{13}C\{^1H\}$ NMR (125 MHz, C_7D_8, 24 °C): $\delta = 263$ ($W{=}CPh_2$, $^1J(^{183}W,^{13}C) = 259$ Hz (14%)). Compounds **5** and **6** cocrystallize in hexanes. Compound **6** can be prepared independently [10] and identified spectroscopically. Addition of ethanol to **5** resulted in the formation of the mixed alkoxide complex, $[\{W{=}CPh_2(OEt)_2(OCH_2tBu)(\mu\text{-}OEt)\}_2]$ which was identified crystallographically [5].

7: $[W_2(OCH_2tBu)_8]$ (100 mg, 9.39×10^{-2} mmol) and elemental sulfur (3.0 mg, 1.2×10^{-2} mmol) were dissolved in dry, degassed hexanes (10 mL) at 24 °C to give a brown solution. Crystallization from hexanes gave X-ray quality pale blue crystals of **7** in 78% yield.

8: $[W_2(OCH_2tBu)_8]$ (120 mg, 0.113 mmol) and pyridine *N*-oxide (10.7 mg, 0.113 mmol) were dissolved in dry, degassed toluene (10 mL) at 24 °C to give a purple solution. Crystallization from toluene gave X-ray quality purple crystals of **8** in 87% yield.

9: Carbon monoxide (0.103 mmol) was added to a suspension of $[W_2(OCH_2tBu)_8]$ (100 mg, 9.39×10^{-2} mmol) in dry, degassed hexanes (10 mL) at −196 °C by using a calibrated gas manifold. Recrystallization in dry, degassed Et_2O gave dark red crystals of **9** in 81% yield. $^{13}C\{^1H\}$ NMR (125 MHz, C_7D_8, −65 °C): $\delta = 320$ (CO, $^1J(^{183}W,^{13}C) = 227$ Hz (14%)), 35.4, 35.1, 35.0, 34.8, 34.5, 34.1 (CH_2, in relative ratios of 1:2:1:1:1:2), 28.0, 27.4, 27.2, 27.0, 26.8 ($C(CH_3)_3$, in a 1:1:2:2:2 ratio). IR: $\tilde{\nu}(^{13}CO) = 1817\ cm^{-1}$, $\tilde{\nu}(^{13}C^{18}O) = 1770\ cm^{-1}$.

[5] Summary of the crystal data for **1**: $M_r = 1090.85$, monoclinic, space group $P2_1/a$, $a = 18.836(4)$, $b = 11.518(2)$, $c = 23.620(5)$ Å, $\beta = 99.87(5)°$, $V = 5048.33$ Å^3, $\rho_{calcd} = 1.435\ g\,cm^{-3}$. The structure was solved by using a combination of direct methods (MULTAN78) and Fourier techniques. The positions of the tungsten atoms were obtained from an initial E-map. The positions of the remaining non-hydrogen atoms were obtained from subsequent iterations of least-squares refinement followed by a difference Fourier calculation. Hydrogen atoms were included in fixed, calculated positions with thermal parameters fixed at one plus the isotropic thermal parameter of the carbon atom to which it was bonded. The final $R(F)$ was 0.0651 for the 470 total variables and 7250 reflections considered observed. Summary of the crystal data for **3**: $M_r = 1104.88$, triclinic, space group $P\bar{1}$, $a = 19.620(3)$, $b = 18.252(3)$, $c = 15.179(3)$ Å, $\alpha = 92.20(2)$, $\beta = 113.17(2)$, $\gamma = 93.03(2)°$, $V = 5068.27$ Å^3, $\rho_{calcd} = 1.448\ g\,cm^{-3}$. The final $R(F)$ was 0.0256 for the 479 total variables and 5856 reflections considered observed. Summary of the crystal data for $[\{W{=}CPh_2(OEt)_2\text{-}(OCH_2tBu)(\mu\text{-}OEt)\}_2]$. $M_r = 1329.06$, triclinic, space group $P\bar{1}$, $a = 12.408(4)$, $b = 13.295(4)$, $c = 9.453(3)$ Å, $\alpha = 93.86(2)$, $\beta = 94.34(2)$, $\gamma = 69.91(1)°$, $V = 1459.02$ Å^3, $\rho_{calcd} = 1.513\ g\,cm^{-3}$. The final $R(F)$ was 0.0408 for the 335 total variables and 4717 reflections considered observed. Summary of the crystal data for **7**. $M_r = 1096.88$, triclinic, space group $P\bar{1}$, $a = 14.755(6)$, $b = 14.888(6)$, $c = 12.172(5)$ Å, $\alpha = 92.20(2)$, $\beta = 113.17(2)$, $\gamma = 113.17(2)°$, $V = 2449.60$ Å^3, $\rho_{calcd} = 1.487\ g\,cm^{-3}$. The final $R(F)$ was 0.0294 for the 461 total variables and 5524 reflections considered observed. Summary of the crystal data for **8**. $M_r = 1080.81$, triclinic, space group $P\bar{1}$, $a = 12.221(1)$, $b = 19.820(2)$, $c = 11.593(1)$ Å, $\alpha = 91.56(1)$, $\beta = 111.49(1)$, $\gamma = 72.05(1)°$, $V = 2474.00$ Å^3, $\rho_{calcd} = 1.451\ g\,cm^{-3}$. The final $R(F)$ was 0.0228 for the 461 total variables and 6890 reflections considered observed. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-59380.

Molecular Self-Assembly to Give the Antiferromagnetic Cage Compound $[\{CpFe(CO)_2(Mes)PO_2\}_4\{MesPO_3Fe_2(OH)Cl\}_2]$**

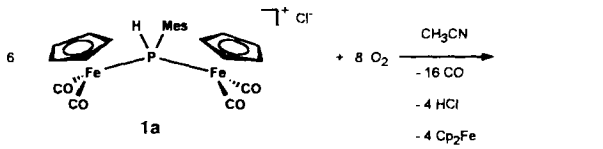
Ingo-Peter Lorenz,* Wolfgang Pohl, and Heinrich Nöth

Dedicated to Professor Joachim Strähle on the occasion of his 60th birthday

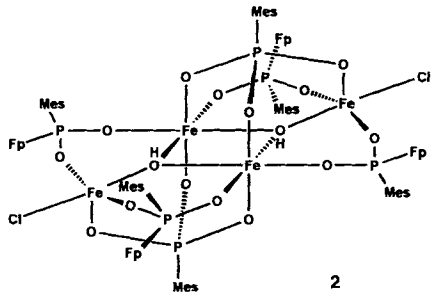
The basis of chemical research is the planning and execution of rational syntheses of interesting materials with defined functionality. However, many reactions don't yield the desired product but often lead to surprising novel compounds. In the construction of structures of high complexity from simple building blocks chance frequently plays the role of the architect. The self-assembly of chemical systems is particularly appealing, and recently Müller et al. synthesized an unusually large host–guest complex from a solution containing eight components; one of which was a phosphonate.[1] We report here on a very simple and surprising oxidative conversion of a diorganometalated phosphonium salt with two iron(II) centers to a molecule containing eight iron centers (four Fe^{II} and four Fe^{III}) that are held together by two tridentate phosphonato and four bidentate phosphinato ligands.

In our investigations on organometalated phosphorus compounds,[2] which obey the isolobal principle, we have prepared the P-H functional diferriophosphonium salt **1a** via the non-isolable intermediate $[\{CpFe(CO)_2\}_2PClR]Cl$ (**1'a**) (R = mesityl (Mes)) by using $[\{CpFe(CO)_2\}_2]$ (= Fp_2) and $RPCl_2$.[3] Exposure of a solution of **1a** in acetonitrile or acetone to aerial oxidation afforded yellow crystals of **2** (R = Mes) reproducibly [Eq. (a)]; ferrocene forms as a by-product. In case of R = Me, *i*Pr, Ph, the corresponding P–Cl functional diferriophosphonium salts can be isolated and characterized;[3] their P–Cl function can be subsequently modified.[4]

The simple aerial oxidation of **1a** has radical consequences: Some of the iron(II) centers of **1a** are completely oxidatively



(a)



decarbonylated to iron(III) centers with concomitant loss of the Cp ligand. The phosphorus centers are oxidized to phosphinato ($Fp(Mes)PO_2^-$) and phosphonato ($MesPO_3^{2-}$) ligands. Surprisingly a neutral polyhedron framework formed consisting of four iron(III) and six phosphorus centers, which are connected through O bridges. To each phosphorus atom a Mes group is bound, to four of them a $CpFe(CO)_2$ fragment is also attached (two $MesPO_3^{2-}$ and four $Fp(Mes)PO_2^-$).

The analytical and spectroscopic characterization of **2** does not give any useful indications toward the composition and structure. The IR spectrum (solid/KBr) of **2** shows absorptions for mesityl and Cp ligands, two strong absorptions for ν(CO) at 2028 and 1980 cm^{-1}, and surprisingly two additional absorptions for $\nu(PO_n)$ at 1059 and 974 cm^{-1} as well as a weak absorption for ν(OH) at 3559 cm^{-1}. The $^{31}P\{^1H\}$ NMR spectrum (in $[D_6]$DMSO) shows two broad signals at $\delta = 138.4$ and 15.3 in a 1:2 ratio. The ^1H NMR spectrum (in $[D_6]$DMSO) reveals slightly broadened signals at $\delta = 5.3$ (for Cp, s) as well as at 7.3, 2.2, 2.1 (for Mes, each s); the signals of the protons of the μ_3-OH groups were not observed (see below). The highest mass detected by FAB mass spectrometry appeared at m/z 2090, which is assumed to be the chloride-free fragment $[M - 2Cl]^+$; in contrast, the elemental analysis reveals the presence of a chloride-containing species.

The structure and composition of **2** was clarified by a single-crystal X-ray structure analysis (Figure 1).[5] It shows there

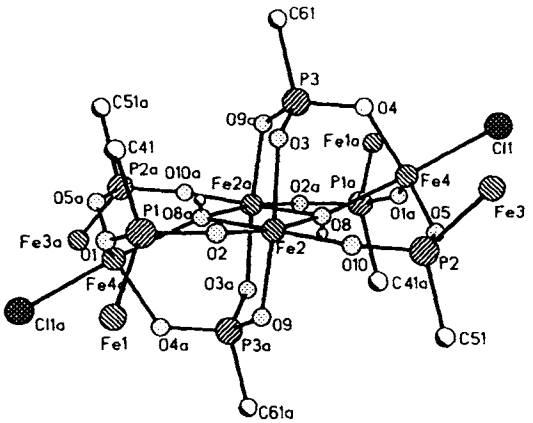


Figure 1. Molecular structure of **2** in the crystal. The mesityl groups (with exception of the *ipso*-C atoms) and the ligands Cp and CO at the iron atoms were omitted for clarity. Selected bond lengths [Å] and angles [°]: Fe2–O2 1.929(6), Fe2–O10 1.932(6), Fe2–O3 2.008(7), Fe2–O9 2.015(7), Fe2–O8 2.123(7), Fe4–O8 2.168(7), Fe4–O1a 1.883(7), Fe4–O4 1.908(7), Fe4–O5 1.884(7), Fe4–Cl1 2.346(7), P3–O_n 1.534(7)–1.546(7), P2–O_n 1.544(7)–1.561(7), P2–Fe3 2.261(3); O2-Fe2-O10 95.6(3), O8-Fe2-O8a 81.7(2), Fe2-O8-Fe2a 98.3(3), Fe2-O8-Fe4 123.0(3), P3-O_n-Fe_n 124.5(4)-127.6(4), P2-O_n-Fe_n 136.0(4)-142.0(4).

is a central cage framework consisting of two edge-sharing $FeO_4(OH)$ octahedrons, which are connected through the common μ_3-OH bridges to two further, trigonal-bipyramidal-configurated iron centers. These trigonal bipyramids are mostly O-coordinated with one apical chloro ligand ($FeO_3(OH)Cl$). Compound **2** has a crystallographically-imposed inversion center. All O bridges stem from tetrahedrally coordinated phosphorus ligands, two μ_3-$MesPO_3^{2-}$ and four μ_2-$Fp(Mes)PO_2^-$ ligands. These together with the two chloride and two hydroxide ions provide 12 negative charges and act, with the exception of the Cl^- ion, as bridging ligands for the four Fe^{III} centers.

[**] We thank the Fonds der Chemischen Industrie for financial support, the Freistaat Bayern for a doctoral grant for W. P., and Prof. Dr. G. Pausewang, Universität Tübingen, for the magnetic measurements.

Depending on the donor ligand the average Fe–O distances in the double octahedron are about 1.93 Å (FpP(Mes)O_2), 2.011(7) Å (MesPO_3), and 2.123(7) Å (μ_3-OH). The equatorial angles O2-Fe2-O10 and O8-Fe2-O8a were determined to be 98.9(3) and 81.7(2)°, respectively. The atoms Fe2, O8, Fe2a and O8a lie in one plane and form a rhombus with the acute angle at the iron atoms; thus, a bonding interaction between Fe2 and Fe2a is not possible (distance Fe2–Fe2a = 3.212 Å). The trigonal-bipyramidal coordination of Fe4 is slightly distorted. The longest Fe–O distance in **2** was determined for Fe4–O8(apical) to be 2.168(7) Å, the shortest for Fe4–O_n (equatorial) to be about 1.895 Å. The equatorial bridges O4, O5, and O1a are bent slightly out of the ideal plane. The Fe4–Cl1 distance is 2.346(3) Å. The bond angles at the O bridges lie between 124.5(4) and 146.7(4)°, those at the P atoms (103.8(4)–113.1(3)°) have values close to the tetrahedron angle. The sum of angles Fe-O-Fe at the trigonal-pyramidal μ_3-OH bridges is 345.3°; the μ_3-OH hyrogen atom does not participate in any hydrogen bonding.

Temperature-dependent magnetic measurements for **2** revealed antiferromagnetic behavior with a Neél temperature of 40 K; the bond lengths (Fe–O) and angles (Fe-O-Fe) of the four central Fe^{III} ions (Fe2, Fe2a, Fe4, Fe4a) allow superexchange and spin orientation. At 300 K the μ_{eff} value was 5.48 BM.[6]

The mild aerial oxidation of the diferriophosphonium salt **1a** leads to many (sometimes drastic) changes in the functionality at both the iron and phosphorus atoms: We find both retention and elimination of the $CpFe(CO)_2$ groups as well as complete oxidation to give iron(III) centers, and oxidation of the phosphonium building blocks to give μ_2-phosphinato and μ_3-phosphonato ligands. This wide palette of new building blocks finally readily combines to form **2**. The new molecular framework of **2** is illustrated by the polyhedral representation in Figure 2. The structure contains a central double octahedron $(FeO_4(OH))_2$, two trigonal bipyramids (FeO_3(OH)Cl), and six tetrahedrons (four Fp(Mes)PO_2 and two MesPO_3). Compound **2** is an example for the unusual combination of classic (in the core) and organometallic complex chemistry (at the periphery). We are currently investigating similar organometalated sulfonium salts,[7] which also may be converted to similar coordination polyhedrons with sulfenato, sulfinato, and sulfonato ligands by aerial oxidation.

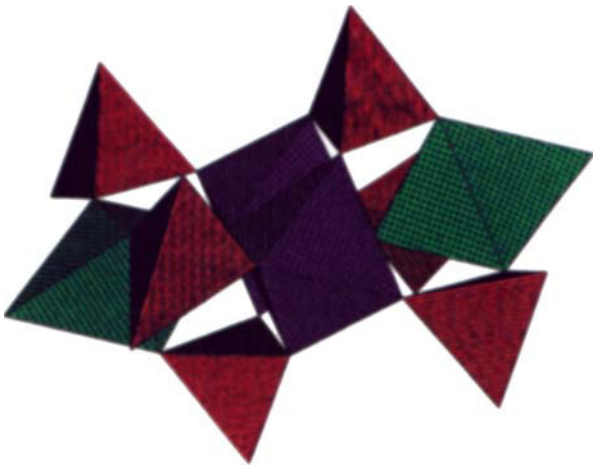

Figure 2. Polyhedral representation of **2**, consisting of two edge-shared octahedrons ($[FeO_4(OH)]_2$), two trigonal bipyramids (FeO_3(OH)Cl), and six tetrahedrons (four Fp(Mes)PO_2 and two MesPO_3).

Experimental Section

Synthesis of **1a** see reference [3].

2: **1a** (200 mg, 0.37 mmol) was dissolved in acetonitrile (12 mL) and this solution was exposed to air for three days. Small yellow crystals formed on the inside glass surface. They were collected and washed with acetone. Yield: 30 mg (22.4%). Additional quantities of **2** remained in the mother liquor; however, these could not be isolated in a pure form; correct elemental analysis. Compound **2** is soluble only in dimethyl sulfoxide (DMSO).

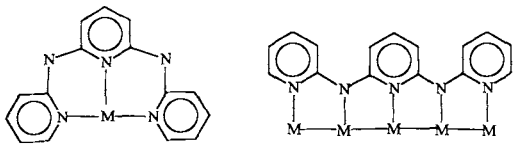
(α-pyridyl)amido ligand have been reported.[4, 5] In order to achieve a further extension to pentanuclear metal complexes a new ligand, *N*,*N*′-bis(α-pyridyl)-2,6-diaminopyridine (the common name in our system is tripyridyldiamine abbreviated as H_2tpda), was synthesized. It was found that the ligand can bind metal ions in two conformations, the *anti*–*anti*–*anti*–*anti* form **I** and the *syn*–*syn*–*syn*–*syn* form **II**.



I **II**

In **I** the ligand is tridentate and coordinates to metal ion through the nitrogen atoms of pyridine moieties. The ligand can be either neutral or dianionic. $[Co^{II}(H_2tpda)Cl_2]$ illustrates this coordination mode. In **II** the ligands have been deprotonated and act as bridging pentadentate ligands. The unprecedented linear pentanuclear nickel(II) and cobalt(II) complexes ($[M_5(\mu_5\text{-tpda})_4X_2]$, M = Ni, X = Cl, and M = Co, X = NCS) are reported here.

The ligand was synthesized by treating 2.5 equivalents of 2-bromopyridine with 1 equivalent of 2,6-diaminopyridine under basic conditions. Remaining 2,6-diaminopyridine and *N*-(α-pyridyl)-2,6-diaminopyridine were washed away with water. The crude product of *N*,*N*′-bis(2-pyridyl)-2,6-diaminopyridine was recrystallized from dichloromethane and methanol. The cobalt complex of type **I** was synthesized by treating equimolar amounts of $CoCl_2 \cdot 6H_2O$ with H_2tpda in dichloromethane. The crystal structure of the neutral complex $[Co(H_2tpda)Cl_2]$ reveals that the coordination geometry around the cobalt(II) ion is trigonal bipyramidal with two chloride ions and the nitrogen atom of the central pyridine as the basal plane and two nitrogen atoms of the terminal pyridine group as the apex. The ligand H_2tpda is planar and coordinates to cobalt ion in *anti*–*anti*–*anti*–*anti* conformation.

The pentanuclear cobalt(II) complex was synthesized similarly to the trinuclear metal complex.[4–7] It was characterized by various spectroscopic methods, in particular mass spectrometry (FAB) and X-ray diffraction. The parent peak of $[Co_5(\mu_5\text{-tpda})_4(NCS)_2]$ is clearly assigned and peaks of the fragments of $[Co_5(\mu\text{-tpda})_4(NCS)]$, $[Co_5(\mu\text{-tpda})_4]$, $[Co_4(\mu\text{-tpda})_3(NCS)]$, $[Co_4(\mu\text{-tpda})_3]$, and $[Co_3(\mu\text{-tpda})_3]$ are observed. The structure of the complex, obtained by X-ray single crystal diffraction study, has several uncommon features (Figure 1). First, the pentacobalt metal chain is helically wrapped by four *syn*–*syn*–*syn*–*syn* type ligands. The complex exhibits approximate D_4 symmetry. Secondly, the five cobalt(II) ions are collinear, linked by multicentered Co–Co σ bonding. The Co–Co distances are 2.277(2), 2.232(2), 2.229(2), and 2.274(2) Å, which are comparable with those of dinuclear cobalt complexes.[8] The preliminary MO analyses indicate there are two σ bonds among five cobalt(II) ions, and the HOMO is of nonbonding character and singly occupied. The average Co1–N(py) (1.97(1)), Co2–N(amido) (1.90(1)), Co3–N(py) (1.93(1)), Co4–N(amido) (1.90(1)), and Co5–N(py) distances (1.97(1) Å) are consistent with a low spin state for the cobalt(II) ion ($\mu = 1.9\ \mu_B$ and temperature-independent). Thirdly, the negative charges of the anionic ligand are delocalized on the five nitrogen atoms of the ligand. The observed bond pattern is qualitatively consistent with the delocalization model.

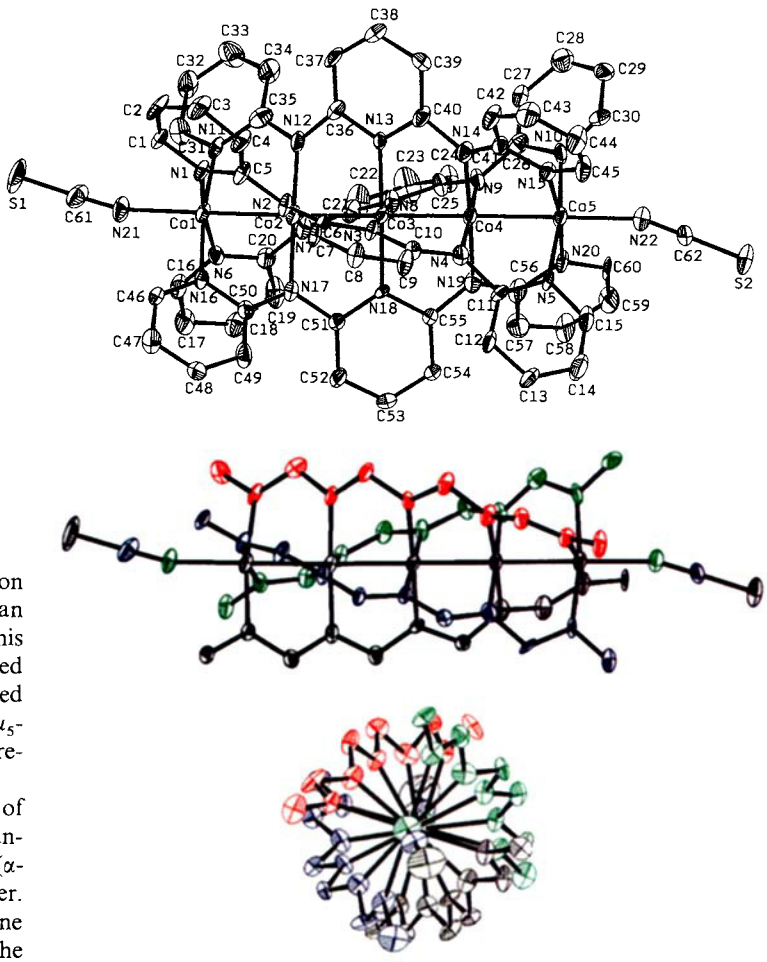


Figure 1. Top: Crystal structure of $[Co_5(\mu_5\text{-tpda})_4(NCS)_2]$ (ORTEP view). Pertinent bond lengths (Å) and angles (°): Co1–Co2 2.277(2), Co2–Co3 2.232(2), Co3–Co4 2.229(2), Co4–Co5 2.274(2), Co1–N21 2.07(1), Co1–N(py) (averaged) 1.97(1), Co2–N (averaged) 1.90(1), Co3–N (averaged) 1.93(1), Co4–N (averaged) 1.90(1), Co5–N(py) (averaged) 1.97(1), Co5–N22 2.06(1), N21-Co1-Co2 178.8(3), Co1-Co2-Co3 178.7(1), Co2-Co3-Co4 179.9(1), Co3-Co4-Co5 178.8(1), Co4-Co5-N22 179.3(3), N(py)-Co1-Co2 (averaged) 86(1), N-Co2-Co3 (averaged) 89(1), N-Co3-Co4 (averaged) 90(1), N-Co4-Co3 (averaged) 89(1), N(py)-Co5-Co4 (averaged) 86(1). Center: Illustration of the helical ligands wrapped around the linear metal chain (along the metal chain axis). The three carbon atoms of pyridine rings are omitted for clarity. Bottom: Another illustration down the metal chain axis.

The pentanuclear nickel(II) complex has also been synthesized similarly to the trinuclear metal complexes.[4–7] The parent peak of $[Ni_5(\mu_5\text{-tpda})_4Cl_2]$ is clearly assigned, and peaks of the $[Ni_4(\mu\text{-tpda})_3]$ and $[Ni_5(\mu\text{-tpda})_4Cl]$ fragments are also observed. The single-crystal X-ray diffraction study of $[Ni^{II}_5(\mu_5\text{-tpda})_4Cl_2]$ reveals that the asymmetric unit contains half of the complex and two dichloromethane molecules. The complex is located at the crystallographic center of inversion. The atomic positions are averaged, because right-turn and left-turn helical complexes are disordered in the crystal. Eight nitrogen atoms from amido groups that are coordinated to nickel ions (Ni2, occupancy factor 0.5) and the α-carbon atoms of the pyridyl groups have high anisotropic thermal parameters. One of the helical forms is shown in Figure 2. The pentanuclear

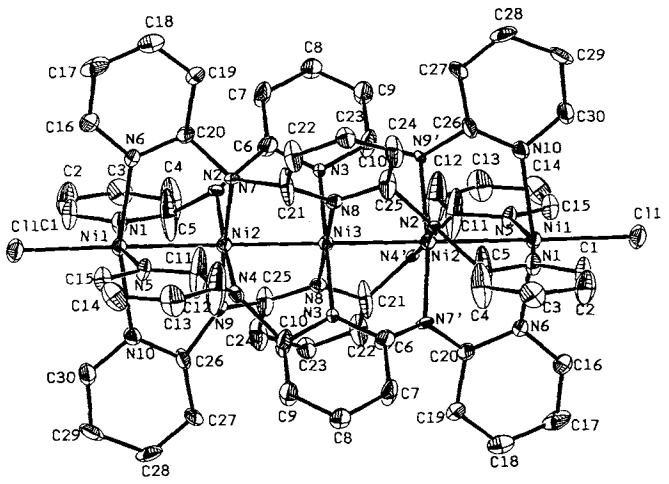

Figure 2. Crystal structure of $[Ni_5(\mu_5\text{-tpda})_4Cl_2]$ (ORTEP view). Pertinent bond lengths (Å) and angles (°): Ni1–Cl 2.346(3), Ni1–Ni2 2.385(2), Ni2–Ni3 2.305(1), Ni1–N (averaged) 2.111(9), Ni2–N (averaged) 1.897(15), Ni3–N 1.904(8), Cl-Ni1-Ni2 179.1(1), Ni1-Ni2-Ni3 179.5(1), Ni2-Ni3-Ni2 180, N-Ni3-N2 (averaged) 90, N-Ni2-Ni3 (averaged) 88(1), N-Ni1-Ni2 (averaged) 82(1).

linear metal chain is helically wrapped by four *syn–syn–syn–syn* type ligands. The five nickel ions and two chloride ions are collinear (Cl-Ni1-Ni2 179.1(1)°, Ni1-Ni2-Ni3 179.5(1)°, and Ni2-Ni3-Ni2′ 180°). The Ni–Ni distances are very short (Ni1–Ni2 2.385(2); Ni2–Ni3 2.306(2) Å). The latter is the shortest known Ni–Ni distance.[9–11] According to MO analyses, no bonding interactions exist between the nickel ions, which is consistent with the magnetic data (see below).

The average Ni2–N (1.897(15) Å) and Ni3–N distances (1.904(8) Å) are short, consistent with a square-planar, diamagnetic arrangement of nickel(II) ions. The terminal Ni^{II} ions (Ni1) are in a square-pyramidal environment and exhibit a long Ni1–Cl bond (2.346(3) Å) and long Ni1–N bonds (av. 2.111(9) Å), consistent with high-spin nickel(II) ions ($S = 1$, $\mu = 2.8\ \mu_B$). A temperature-dependent magnetic study of the complex (Figure 3) indicates the antiferromagnetic interaction of terminal high-spin nickel ions with $J = -14.6\ cm^{-1}$. This interaction is one order of magnitude smaller than those of similar trinuclear nickel(II) complexes.[7, 12]

Attempts to isolate other linear pentanuclear metal complexes and demonstration of their potential application as molecular wires are under way.

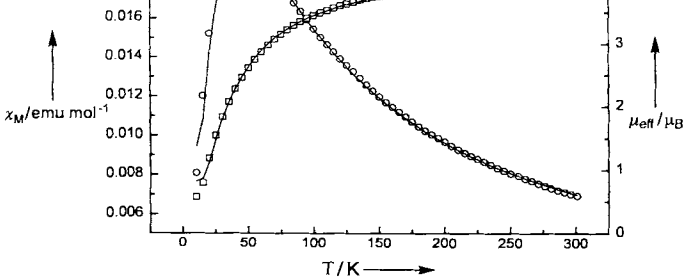

Figure 3. Magnetic data for $[Ni_5(\mu_5\text{-tpda})_4Cl_2]$. Solid curves represent calculation based on the equation $\xi_M = C(2e^{2x} + 10e^{6x})/(1 + 3e^{2x} + 5e^{6x})$, $C = Ng^2\beta^2/kT$, $x = J/kT$, $\mathcal{H} = -2JS_1 \cdot S_5$ ($S_2 = S_3 = S_4 = 0$, $S_1 = S_5 = 1$) and $\mu_{eff} = 2.84(\xi_M T)^{1/2}$. ○ is the observed χ_M and □ the observed μ_{eff}.

Experimental Section

H_2tpda: Under a nitrogen atmosphere 2-bromopyridine (36 mL) was added to a solution of 2,6-diaminopyridine (10 g, 0.09 mol) and *t*BuOK (30.24 g, 0.27 mol) in THF (150 mL). The reaction mixture was heated under reflux for 24 h. After cooling to room temperature, the solvent was removed by rotary evaporator. Then the mixture was extracted with dichloromethane, and the solvent removed under reduced pressure. Unchanged 2,6-diaminopyridine and *N*-(α-pyridyl)-2,6-diaminopyridine were rinsed away with water. The crude product of *N*,*N*′-bis(2-pyridyl)-2,6-diaminopyridine was recrystallized from dichloromethane and hexane(Yield 26%). IR (KBr) $\tilde{\nu} = 3442, 3180\ cm^{-1}$ (NH). UV/Vis (CH_2Cl_2): λ_{max} (ε) = 268 (3.76×10^3), 321 nm (4.13×10^3). MS (FAB): *m*/*z* (%) 264 (60) $[M+1]^+$, 186 (100) $[C_{10}N_4H_9]^+$, 77 (20) $[C_5H_5N]^+$.

$[Co(H_2tpda)Cl_2]$: $CoCl_2 \cdot 6H_2O$ (23 mg, 0.09 mmol) was added to a solution of H_2tpda (25 mg, 0.09 mmol) in CH_2Cl_2 (30 mL). The yellow solution was stirred for 6 h. A green precipitate was formed, filtered off, washed with ether, and air-dried. Green prismatic crystals were formed by slow diffusion of diethyl ether into a CH_3CN/DMF solution of the compound (yield 70%). IR (KBr): $\tilde{\nu} = 3397, 3316, 3203\ cm^{-1}$ (NH). UV/Vis (DMF) λ_{max} (ε) = 330 (3.34×10^4). MS (FAB): *m*/*z* (%) 321 (40) $[M - Cl]^+$.

$[Co_5(\mu_5\text{-tpda})_4(SCN)_2]$: $CoCl_2 \cdot 6H_2O$ (0.936 g, 4 mmol) and H_2tpda (1.02 g, 4 mmol) were placed in an Erlenmeyer flask, and naphthalene (7.2 g) was added. The mixture was heated (about 160–180 °C) for 10 min to remove water. Then *n*-butanol (3 mL) was added to the heated mixture, and heating was continued until the *n*-butanol had almost completely evaporated. A solution of potassium *n*-butoxide (0.88 g, 8 mmol) *n*-butanol (20 mL) was added dropwise. Heating was continued until the remaining *n*-butanol had evaporated completely, after which an excess of sodium thiocyanate (1.0 g) was added. After the mixture had cooled, *n*-hexane was added to wash out naphthalene. The remaining solid was extracted with CH_2Cl_2 and recrystallized from CH_2Cl_2/*n*-hexane solution. Deep brown crystals were obtained (yield 5%). IR (KBr) $\tilde{\nu} = 2058$ (CN), 1594, 1565, 1536 (C=C). UV/Vis (CH_2Cl_2) λ_{max} (ε) = 279 (1.13×10^5), 338 (6.21×10^4), 393 (5.84×10^4), 513 (9.75×10^3), 725 cm^{-1} (1.01×10^3). MS (FAB): *m*/*z* (%) 1455 (2) $[M]^+$, 1397 (4) $[M - SCN]^+$, 1339 (1) $[Co_5(\mu\text{-tpda})_4]^+$, 1077 (6) $[Co_4(\mu\text{-tpda})_3SCN]^+$, 1019 (4) $[Co_4(\mu\text{-tpda})_3]^+$.

$[Ni_5(\mu_5\text{-tpda})_4Cl_2]$: $NiCl_2 \cdot 6H_2O$ (0.948 g, 4 mmol) and H_2tpda (1.02 g, 4 mmol) were placed in an Erlenmeyer flask, and naphthalene (7.2 g) was added. The mixture was heated (about 160–180°) for 10 min to remove water. Then *n*-butanol (3 mL) was added to the heated mixture, and heating was continued until the *n*-butanol had almost completely evaporated. A solution of potassium *n*-butoxide (0.88 g, 8 mmol, in 20 mL *n*-butanol) was added dropwise. Heating was continued until the remaining *n*-butanol had evaporated completely. After the mixture had cooled, *n*-hexane was added to wash out naphthalene. The remaining solid was extracted with CH_2Cl_2 and recrystallized from CH_2Cl_2/*n*-hexane solution. Deep purple crystals were obtained (yield 50%). IR (KBr) $\tilde{\nu} = 1591, 1562, 1541\ cm^{-1}$ (C=C). UV/Vis (CH_2Cl_2) λ_{max} (ε) = 253(1.02×10^5), 293(1.28×10^5), 373(1.55×10^5), 592 nm (1.28×10^4). MS (FAB): *m*/*z* (%) 1408 (4) $[M]^+$, 1373 (3), $[M - Cl]^+$, 1017 (10) $[Ni_4(\mu\text{-tpda})_3]^+$, 698 (10) $[Ni_3(\mu\text{-tpda})_2]^+$.

Crystal data for $[Co^{II}(H_2tpda)Cl_2]$: Monoclinic, space group $C2/c$, $a = 7.482(1)$, $b = 17.172(3)$, $c = 12.833(1)$ Å, $\beta = 104.1(1)°$, $V = 1598.8(4)$ Å^3, $\rho = 1.633\ g\,cm^{-3}$, $Z = 4$; CAD4 diffractometer with graphite-monochromated $Mo_{K\alpha}$ radiation, Ψ-scan absorption correction (0.91–1.00); of 1406 unique reflections ($2\theta < 50°$) measured, 1125 with $I > 2\sigma(I)$ were used in the refinement. $R = 0.027$, $Rw = 0.026$ (133 variables).

Crystal data for $[Ni^{II}_5(\mu_5\text{-tpda})_4Cl_2](CH_2Cl_2)_4$: Monoclinic, space group $P2_1/n$, $a = 13.416(3)$, $b = 16.894(3)$, $c = 15.8807(4)$ Å, $\beta = 92.54(2)°$, $V = 3578(1)$ Å^3, $\rho = 1.623\ g\,cm^{-3}$, $Z = 4$; Ψ-scan absorption correction (0.92–1.00); of 6280 unique reflections ($2\theta < 50°$) measured, 3188 with $I > 2\sigma(I)$ were used in the refinement. $R = 0.072$, $Rw = 0.071$ (485 variables).

Crystal data for $[Co^{II}_5(\mu_5\text{-tpda})_4(SCN)_2] \cdot CH_2Cl_2 \cdot (C_2H_5O)_{0.5} \cdot (H_2O)_{0.5}$: Triclinic, space group $P\bar{1}$, $a = 11.802(1)$, $b = 14.631(7)$, $c = 20.184(4)$ Å, $\alpha = 73.42(3)$, $\beta = 77.77(1)$, $g = 87.56(3)°$, $V = 3264(2)$ Å^3, $\rho = 1.615\ g\,cm^{-3}$, $Z = 2$; Ψ-scan absorption correction (0.83–1.00); of 8645 unique reflections ($2\theta < 45°$) measured, 3400 with $I > 2\sigma(I)$ were used in the refinement. $R = 0.049$, $Rw = 0.046$ (847 variables).

Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-145. An Interwoven Supramolecular Cage**

Peter R. Ashton, Andrew N. Collins, Matthew C. T. Fyfe, Peter T. Glink, Stephan Menzer, J. Fraser Stoddart,* and David J. Williams

Dedicated to Professor Vincenzo Balzani on the occasion of his 60th birthday

In recent times, supramolecular, noncovalent synthesis[1] has provided the chemist convenient access to some remarkable superstructures, many of which are produced with a high degree of architectural control and have the potential to perform specific functions. One of the most challenging domains within this field of endeavor involves self-assembling[2] discrete supramolecular cages that are held together by intermolecular interactions[3] and can act as synthetic receptors. However, none of the systems reported to date involve interlocked or interwoven structures.[4] We have designed such a system (Scheme 1), which relies upon the simultaneous threading of two secondary dialkylammonium ions through the cavity of a ditopic crown ether, namely bis-*p*-phenylene[34]crown-10 (BPP34C10).[5] The trifurcated trisammonium ion $[\mathbf{1}\text{-}H_3]^{3+}$ has three secondary ammonium centers in branches radiating from a central polyaromatic core. Each branch can insert itself through the cavity of a BPP34C10 molecule, but then utilizes only half of the potential receptor sites. The vacant receptor sites remaining in each of the cavities of the three macrocyclic polyethers are then free to accept another branch from a second trication, which leads to a cagelike supermolecule. Here we report the synthesis of the trifurcated trisammonium salt $\mathbf{1}\text{-}H_3\cdot 3PF_6$ and the self-assembly of a five-component interwoven supramolecular cage in the solid state from the $[\mathbf{1}\text{-}H_3]^{3+}$ ion and BPP34C10.

The trisammonium ion $[\mathbf{1}\text{-}H_3]^{3+}$ was prepared as its hexafluorophosphate salt in good overall yield: condensation of 1,3,5-tris(4-formylphenyl)benzene[6] with benzylamine, followed by reduction of the resultant trisaldimine, gave the trifurcated trisamine 1,3,5-tris[(4-benzylaminomethyl)phenyl]-benzene, which afforded $\mathbf{1}\text{-}H_3\cdot 3PF_6$ after treatment with hydrochloric acid and counterion exchange from chloride to hexafluorophosphate.

Single crystals suitable for X-ray analysis were obtained when a $MeNO_2$ solution containing BPP34C10 (3 equiv) and $\mathbf{1}\text{-}H_3\cdot 3PF_6$ (2 equiv) was layered with Et_2O. Gratifyingly, the crystallographic analysis of one of these crystals (Figure 1) reveals[7] the formation of a highly symmetrical cagelike superstructure in which two $[\mathbf{1}\text{-}H_3]^{3+}$ ions are threaded through three BPP34C10 macrocycles.[8] The supermolecule has D_3 symmetry, and the principal axis passes through the centers of the two 1,3,5-triarylbenzene rings,[7] which have a mean interplanar separation of about 4.0 Å (Figure 2). The three *para*-phenylene rings of each trication are rotated by about 37° out of the plane

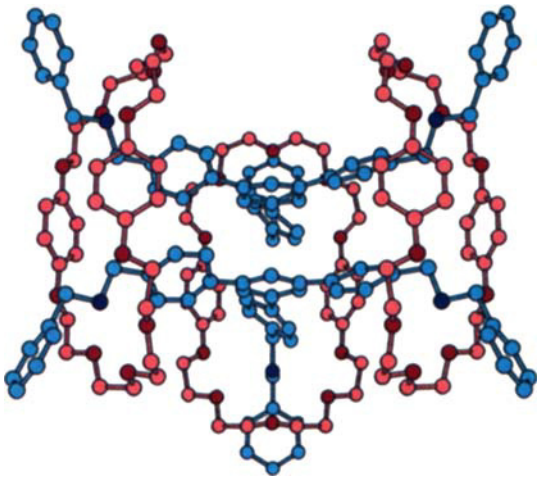

Figure 1. Ball-and-stick representation of the $[(BPP34C10)_3 \cdot (\mathbf{1}\text{-}H_3)_2]^{6+}$ supermolecule in the solid state. Red: BPP34C10 components; blue: $[\mathbf{1}\text{-}H_3]^{3+}$ ions.

of the central benzenoid ring to produce a propellerlike geometry. In addition to this twisting, there is a slight "dishing" of these three rings away from the center of the supermolecule: the centroids of overlapping *para*-phenylene rings are separated by about 4.6 Å. The threading geometries of pairs of benzylammonium subunits through the BPP34C10 ring are highly reminiscent of those observed[5a–c] for the 2:2 complex formed between α,α′-bis(benzylammonium)-*p*-xylene bis(hexafluorophosphate) and BPP34C10. The nonbonded intraannular N···N distance is about 7.5 Å. The planes of the two hydroquinone rings are tilted inwards by about 20° from a parallel alignment; their centroid–centroid separation is 6.6 Å. The supermolecule is stabilized by nearly linear $[N^+ - H \cdots O]$ hydrogen bonds between the NH_2^+ centers and the β-oxygen atoms of each polyether linkage ($[N \cdots O]$, $[H \cdots O]$ distances 3.02, 2.06 Å; $[N - H \cdots O]$ angle 176°). Adjacent supermolecules are rotated by 60° with respect to each other about their C_3 axes to form a partially interleaved assemblage (Figure 3), within which the separation between the nearest intercomplex 1,3,5-triarylbenzene rings is 12.9 Å.

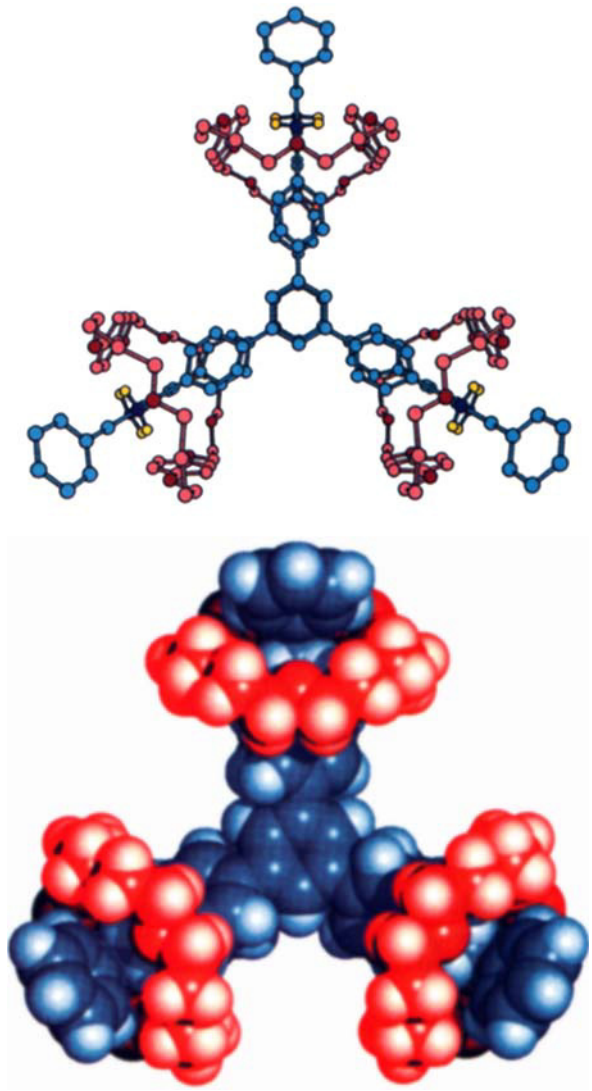

Figure 2. Top view of the five-component $[(BPP34C10)_3 \cdot (\mathbf{1}\text{-}H_3)_2]^{6+}$ supermolecule. Top: Ball-and-stick representation. Bottom: Space-filling representation. Red: BPP34C10 molecules; blue: $[\mathbf{1}\text{-}H_3]^{3+}$ ions.

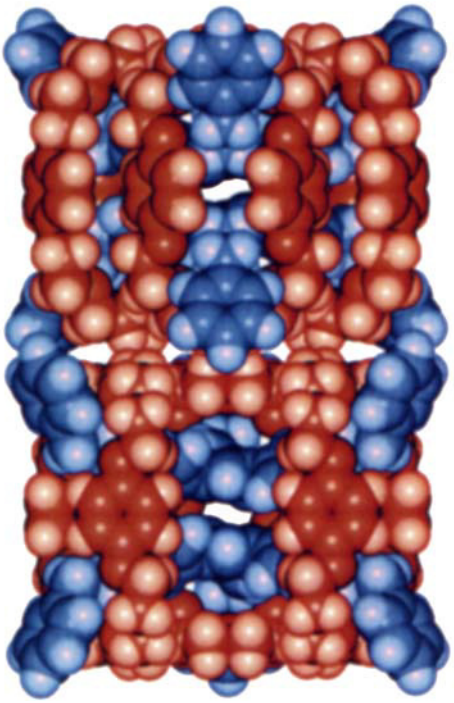

Figure 3. Space-filling representation of part of the interleaved array produced by the $[(BPP34C10)_3 \cdot (\mathbf{1}\text{-}H_3)_2]^{6+}$ supermolecule. Red: BPP34C10 molecules; blue: $[\mathbf{1}\text{-}H_3]^{3+}$ ions.

We believe that this remarkable [3+2] self-assembly process is favored[9] for several reasons. Firstly, the principle of maximal site occupancy dictates[9] that the system progresses toward the species in which the maximum number of cationic centers within the $[\mathbf{1}\text{-}H_3]^{3+}$ trication, in addition to the receptor sites supplied by the macrocyclic polyether, are occupied. The $[(BPP34C10)_3 \cdot (\mathbf{1}\text{-}H_3)_2]^{6+}$ supermolecule is a closed architecture: the binding sites of its constituents are completely occupied, with the result that the greatest number of hydrogen bonds are formed—thus, the supermolecule attains the thermodynamically most stable state. Secondly, entropic factors[9] dictate that the maximum number of supramolecular entities should be formed. The formation of a porous, three-dimensional, supramolecular array could also have been envisaged in the solid

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3601-0060 $ 15.00+.25/0

state: this would have occurred if the BPP34C10 "connectors" had linked each $[\mathbf{1}\text{-}H_3]^{3+}$ trication noncovalently to three different trications. The resulting superstructure—commensurate with a single "supermolecule"—would display a considerable entropy loss relative to a system comprising a large number of small, discrete supermolecules. Furthermore, the five-component cage supermolecule retains both translational and rotational entropy, whereas in the hypothetical polymeric supramolecular array, loss of these degrees of freedom amounts to a sizeable entropy deprivation. Finally, $\pi-\pi$ stacking interactions between the 1,3,5-triarylbenzene subunits—although probably quite weak at a distance of 4 Å—increase the stability of the [3+2] cage supermolecule. These energetically favorable interactions would not be present in the open supramolecular array.

The formation of the $[(BPP34C10)_3\cdot(\mathbf{1}\text{-}H_3)_2]^{6+}$ supermolecule constitutes a notable example of molecular programming[10] in which the set of commands for the assembly of the supramolecular species is stored in the covalent framework of its molecular precursors. In this case, the information in the "program" is provided by the number and nature of each molecular component's binding sites: the $[\mathbf{1}\text{-}H_3]^{3+}$ ion possesses three ammonium centers located at the corners of a triangle and can therefore accommodate the binding of three complementary receptors, while the ditopic crown ether BPP34C10 possesses two recognition sites positioned within the same macrocyclic cavity, both of which can bind[5] a cationic ammonium center. The operation of the program through an algorithm based on hydrogen bonding and $\pi-\pi$ stacking leads to the desired cage-like supermolecule.

The constituents of this multicomponent self-assembly process should be able to be easily modified to yield cages of different shape and size. Although the cage presented here is too small to incorporate guests, one can envisage using even larger ditopic crown ethers[11] in order to increase the size of the cavity within the cage and so afford self-assembled hosts capable of binding small guests within their voids.

Experimental Section

1-$H_3\cdot 3PF_6$: A mixture of 1,3,5-tris(4-formylphenyl)benzene (730 mg, 1.87 mmol) and $PhCH_2NH_2$ (603 mg, 5.62 mmol) in PhMe (125 mL) was heated under reflux for 14 h; the H_2O produced was collected in a Dean-Stark separator. The solution was filtered while hot, and the solvent evaporated off under reduced pressure to give 1,3,5-tris[(4-benzyliminomethyl)phenyl]benzene (1.19 g, 97%) as an off-white solid. ^{1}H NMR (300 MHz, $CDCl_3$, 20 °C): $\delta = 4.85$ (s, 6H), 7.24–7.36 (m, 15H), 7.74 (d, $J = 8$ Hz, 6H), 7.82 (s, 3H), 7.89 (d, $J = 8$ Hz, 6H), 8.45 (s, 3H). This solid (326 mg, 0.5 mmol) was dissolved in a 5/3 mixture of THF and MeOH (16 mL). $NaBH_4$ (197 mg, 5.2 mmol) was added and the solution was heated at reflux with stirring for 16 h. Upon cooling, the reaction mixture was treated with 12 N HCl to adjust the pH to 1. The solution was concentrated in vacuo, and the residue was partitioned between 1 N NaOH (60 mL) and CH_2Cl_2 (100 mL). The aqueous layer was extracted further with CH_2Cl_2 (3 × 100 mL). The combined organic extracts were washed with a 10% aqueous Na_2CO_3 solution (100 mL) and H_2O (100 mL), and then dried (K_2CO_3). Filtration and solvent evaporation gave 1,3,5-tris[(4-benzylaminomethyl)phenyl]benzene (329 mg, 100%) as a yellow oil. ^{1}H NMR (300 MHz, $CDCl_3$, 20 °C): $\delta = 3.84$ (s, 6H), 3.87 (s, 6H), 7.21–7.39 (m, 15H), 7.44 (d, $J = 8$ Hz, 6H), 7.65 (d, $J = 8$ Hz, 6H), 7.75 (s, 3H). This oil was dissolved in a THF/MeOH/EtOH solution (2/5/5, 60 mL). Then 4 N HCl was added with stirring to alter the pH to 1. After 2.5 h the solution was filtered and concentrated to give a white solid, which was washed with Et_2O (50 mL), before being dissolved in hot H_2O (210 mL). A white solid precipitated out of solution when a concentrated aqueous solution of NH_4PF_6 was added to the hot aqueous trisammonium salt solution. The resulting suspension was extracted with $MeNO_2$ (200 mL, followed by 3 × 100 mL). After the combined $MeNO_2$ extracts had been washed with H_2O (2 × 50 mL), the solvents were evaporated off under reduced pressure to give the trisammonium salt **1**-$H_3\cdot 3PF_6$ as an off-white solid (525 mg, 96%, m.p. 139 °C with decomp.); ^{1}H NMR (300 MHz, CD_3CN, 20 °C): $\delta = 4.29$ (s, 6H), 4.32 (s, 6H), 7.05 (br s, 6H), 7.44–7.56 (m, 15H), 7.61 (d, $J = 8$ Hz, 6H), 7.92 (d, $J = 8$ Hz, 6H), 7.97 (s, 3H); ^{13}C NMR (75.5 MHz, CD_3CN, 20 °C): $\delta = 52.1$, 52.6, 126.3, 128.9, 130.1, 130.8, 130.9, 131.2, 131.3, 131.8, 142.4, 142.6. Analysis: found: C 52.17, H 4.42, N 3.81%; calcd for $C_{48}H_{48}F_{18}N_3P_3$: C 52.33, H 4.39, N 3.81%; MS (LSI): *m/z*: 810 $[(M - PF_6 - HPF_6)^+]$.

[7] Crystal data for $[(BPP34C10)_3\cdot(\mathbf{1}\text{-}H_3)_2][PF_6]_6$: hexagonal, space group $P6_3/mcm$, $a = b = 19.212(1)$, $c = 33.876(7)$ Å, $V = 10829$ Å^3, $Z = 2$, $\rho_{calcd} = 1.164$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 12.5$ cm^{-1}, $T = 293$ K. The 2643 independent reflections were measured on a Siemens P4 rotating anode diffractometer with graphite monochromated $Cu_{K\alpha}$ radiation and ω scans. Of these, only 1150 had $I_0 > 2\sigma(I_0)$ and were considered to be observed. The initial superstructural model was obtained by direct methods and the non-hydrogen atoms were refined anisotropically with F^2 data to give $R_1 = 0.1891$, $wR_2 = 0.4692$. The six PF_6^- anions are disordered and distributed over 24 partial occupancy positions and the *para*-phenylene rings have two alternative tilt orientations, each of 50% occupancy. These latter factors are the principal reasons for the high final value of R_1. The space group in which the superstructure was solved and refined requires the [3+2] supermolecule to have D_{3h} symmetry and the *para*-phenylene rings have two superimposed twist orientations (vide supra). This disorder can be explained readily in terms of an approximately even number of right-handed and left-handed propeller species of each trication in the crystal. However, the D_{3h} symmetry requirements necessitate pairs of adjacent trications within each supermolecule to be tilted toward each other, providing unacceptable [C–H···H–C] contacts between adjacent *para*-phenylene rings. The true molecular symmetry is thus incompatible with the symmetry requirement of the space group. Desymmetrization to space groups not requiring the horizontal and vertical mirror planes associated with D_{3h} symmetry resulted in highly unstable, nonconvergent refinements with substantially higher values for R_1. The SHELXTL package (version 5.03) was used for all computations. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-140. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: Int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

[8] Unfortunately our attempts to characterize a self-assembled [3+2] species in the solution and "gas" phases have not yet met with success. (Similar difficulties have been encountered in the characterization of the four-component

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3601-0061 $ 15.00+.25/0

supermolecule formed between α,α'-bis(benzylammonium)-*p*-xylene bis(hexafluorophosphate) and BPP34C10 [5a, 5b].) The ^{1}H NMR spectrum (300 MHz) of a 3:2 molar ratio of BPP34C10 and **1**-$H_3\cdot 3PF_6$ in CD_2Cl_2/CD_3CN (4:1) at 20 °C showed several broad, featureless peaks, indicating that aggregation occurs in solution; however, no signals associated with the cage supermolecule could be identified. Liquid secondary ion mass spectrometry (LSIMS; VG Zabspec mass spectrometer equipped with a cesium ion source, *meta*-nitrobenzyl alcohol matrix) was employed for the characterization of the aggregate in the "gas phase"—no peaks corresponding to the [3 + 2] supermolecule were observed. Nevertheless, peaks at *m/z* 2595, 2449, and 2303 were detected, corresponding to the species $[BPP34C10\cdot(\mathbf{1}\text{-}H_3)_2][PF_6]_6$, with the loss of one, two, and three PF_6^- counterions, respectively.

[9] Similar arguments have been used by Lehn and co-workers to explain self-recognition processes involving metal-ligand interactions in helicate self-assembly: R. Krämer, J.-M. Lehn, A. Marquis-Rigault, *Proc. Natl. Acad. Sci. USA* **1993**, *90*, 5394–5398. We note that in this seminal paper the authors remark that, "These considerations also apply to systems where binding involves interactions other than metal coordination such as hydrogen bonding or donor–acceptor forces."

[11] A suitable crown ether could be 1,4,7,10,13,26,29,32,35,38-decaoxa[13.0.13.0]-paracyclophane where the hydroquinone rings of BPP34C10 are replaced by 4,4'-dioxybiphenyl units. See P. R. Ashton, D. Joachimi, N. Spencer, J. F. Stoddart, C. Tschierske, A. J. P. White, D. J. Williams, K. Zab, *Angew. Chem.* **1994**, *106*, 1563–1566; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 1503–1506.

$In_4S[C(SiMe_3)_3]_4$: An Organoindium Compound with an In_4S Core Isovalence Electronic to Pentahydro-*closo*-pentaborate(2−)**

Werner Uhl,* Rene Graupner, Wolfgang Hiller, and Markus Neumayer

Novel and unprecedented organoelement cluster compounds of the heavier elements of the third main group aluminum, gallium, and indium were reported recently.[1–8] Some derivatives like $[Al(C_5Me_5)]_4$,[1] $K_2[Al_{12}iBu_{12}]$,[2] $[Ga\text{–}C(SiMe_3)_3]_4$,[3] and $[In\text{–}C(SiMe_3)_3]_4$[4, 5] were verified by crystal structure determinations, others like $[Al\text{–}Si(CMe_3)_3]_4$,[6] $[Al\text{–}CH_2CMe_3]_4$,[7] and $[Ga\text{–}CH_2CMe_3]_n$[8] by specific reactions, theoretical investigations, or further characterization. A few sterically highly shielded cyclopentadienides of the monovalent elements indium and thallium show a pseudodimeric or a pseudohexameric arrangement of the metal atoms; however, long distances between the atoms of the clusters confirm only a weak element–element bonding interaction,[9] the significance of which has been controversial.[10] Aluminum(I) and gallium(I) compounds were recently described in a concise survey by Schnöckel et al.[11] The cluster compounds cited above have already been employed in the syntheses of numerous further products with hitherto unknown molecular structures.[8, 11–13] At present we are interested in the chemical behavior of the tetrahedral cluster compound $In_4[C(SiMe_3)_3]_4$ **1**,[4, 12, 13] which is obtained in high yield by treatment of InBr with $LiC(SiMe_3)_3\cdot 2THF$.[4, 5] The reactions of **1** with an excess of elemental sulfur, selenium, or tellurium give $In_4X_4[C(SiMe_3)_3]_4$ derivatives that exhibit a In_4X_4 heterocubane framework.[4, 13] Because of the easy insertion of four sulfur atoms under mild conditions, we hoped to synthesize compounds with the composition $In_4S_{4-x}[C(SiMe_3)_3]_4$ ($x = 1$ to 3) by the reaction of elemental sulfur with an excess of **1**; unlike the heterocubane molecules such derivatives would still contain indium atoms in an unusual low formal oxidation state.

However, elemental sulfur proved to be unsuitable for the syntheses of these compounds, because regardless of the reaction conditions only mixtures of $In_4S_4[C(SiMe_3)_3]_4$ and the starting compound **1** were formed. As a very mild reagent for the transfer of sulfur atoms we finally used propylene sulfide, which, however, required extensive optimization of the reaction. A colorless solid precipitated from the reaction solution that could not be further characterized because of the small amounts formed; in addition, the In_4S_4 derivative is partially formed from the beginning of the reaction by the complete sulfurization of **1**. Nevertheless we found an easy and reproducible method for the syntheses of a further compound (**2**): A solution of **1** in hexane was treated with a small excess of propylene sulfide and heated to 60 °C for 90 minutes. ^{1}H NMR spectra recorded to monitor the reaction reveal the formation of a mixture of **1** ($\delta = 0.447$), $In_4S_4R_4$ ($\delta = 0.443$), and the new product **2** ($\delta = 0.455$). Subsequently, additional propylene sulfide was added in portions, and each time the mixture was heated to 60 °C for 90 minutes, until **1** was completely consumed; the color of the solution changed from violet to red. The addition of the propylene sulfide in small portions gave a better result than the addition of a large excess of the reagent at the beginning of the reaction. Compound **2** and $In_4S_4[C(SiMe_3)_3]_4$ are present in a molar ratio of about 0.6 to 0.4 (NMR spectroscopy), and **2** crystallizes almost quantitatively from a solution in pentane as the less soluble component. The reaction is summarized in Equation (a).

$$\underset{\mathbf{1}}{In_4[C(SiMe_3)_3]_4} + H_3C\text{–}HC(\diagup S\diagdown)CH_2 \longrightarrow \underset{\mathbf{2}}{In_4S[C(SiMe_3)_3]_4} + H_3C\text{–}CH{=}CH_2 \qquad (a)$$

The deep red compound **2** is isolated in 44% yield (based on **1**). According to elemental analysis the In:S ratio is 4:1, and the molar mass determined cryoscopically in benzene shows that **2** exists in the undissociated form. Single crystals of **2** were obtained from solutions of the compound in diisopropyl ether; they exhibit the same cell dimensions and space group as the starting compound **1**; however, one face of the In_4 tetrahedron is capped by a sulfur atom leading to the formation of a trigonal In_4S bipyramid (Figure 1).

The addition of the four-electron donor atom sulfur to the molecular core of **1** makes compound **2** isovalence electronic to the hitherto unknown compounds pentahydro-*closo*-pentaborate(2−) $[B_5H_5]^{2-}$ and thia-*closo*-pentaborane(4) B_4H_4S[15] as well as to the isolated and completely characterized 1,5-dicarba-*closo*-pentaborane(5) $B_3C_2H_5$.[15] Almost identical structural parameters were observed or calculated for all three boron derivatives; the B–B distances to the axial atoms were appropriate for single bonds, the B–B distances in the equatorial plane

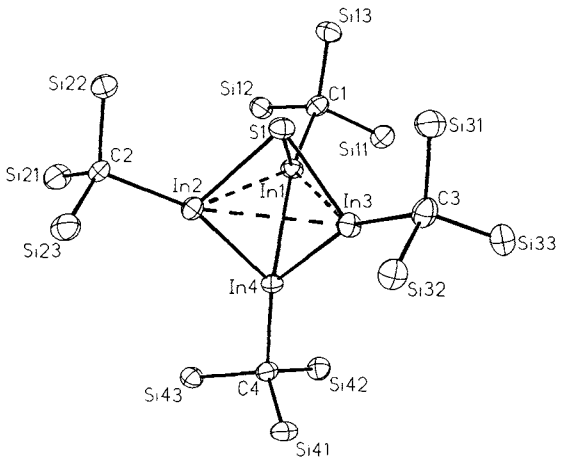

Figure 1. Molecular structure of **2**; methyl groups are omitted for clarity, the long In–In distances in the equatorial plane are indicated by broken lines. Important bond lengths [pm] and angles [°]: In1–S1 257.6(2), In2–S1 260.7(2), In3–S1 258.9(2), In1–In4 283.0(1), In2–In4 283.3(1), In3–In4 285.0(1), In1–In2 338.4(1), In1–In3 336.2(1). In2–In3 341.42(9), In1–C1 221.1(8), In2–C2 223.9(7), In3–C3 223.0(8), In4–C4 225.7(7); In1-S1-In2 81.51(6), In1-S1-In3 81.21(6), In2-S1-In3 82.15(6), In1-In4-In2 73.37(3), In1-In4-In3 72.57(3), In2-In4-In3 73.85(3), S1-In1-In4 87.90(6), S1-In2-In4 87.23(5), S1-In3-In4 87.22(5).

were considerably longer ($[B_5H_5]^{2-}$: $B_{eq}-B_{ax}$ 168.1, $B_{eq}-B_{eq}$ 187.4 pm; B_4H_4S: $B_{eq}-B_{ax}$ 165.1, $B_{eq}-B_{eq}$ 192.3 pm; $B_3C_2H_5$: B–C 155.6, B–B 185.3 pm).[15] The corresponding parameters for **2** are quite similar: The average In–In distance to the axial In atom In4 is 283.8 pm, and thus lies in the range of In–In single bonds in organoelement derivatives;[6, 16] it is 16 pm shorter than the average In–In distance in tetraindane(4) **1**.[4] In contrast, the equatorial In–In distances are significantly longer (338.7 pm); they lie between the value found in **1** (300.2 pm) and that found in In^I derivatives with sterically demanding cyclopentadienyl groups (> 360 pm)[9] and only negligible In–In interactions. Thus, **2** can be described as the first organoindium analog of the *closo*-borate ions, even if a classical description of the bonding with localized bonds and a hyperconjugative electron transfer from the α-C–Si bonds to the unsaturated In atoms should not be ruled out completely. An approach towards the classical, localized bonding model with a significant lengthening of the equatorial B–B distance to 197 pm[17] is observed in 1,5-dicarbapentaborane(5) on substitution of hydrogen atoms by amino groups. The latter reduce the participation of the B atoms in delocalized multicenter bonding through a π interaction with their lone pair of electrons.

The In–S bond lengths in **2** (259.1 pm) are slightly longer than those in the In_4S_4 heterocubane (254.9 pm),[13] which might be caused by the lower oxidation states of the In atoms; they still lie in the range normally associated with three-coordinate sulfur atoms.[18] The equatorial In–C bonds are shorter (av 222.7 pm) than the axial In–C bond (225.7 pm). Inside the In_4S bipyramid the angles are more acute at the axial In atom In4 (73.26°) than at the sulfur atom S1 (81.62°); in the In_3 plane angles of between 59.3 and 60.8° are observed.

Chemically nonequivalent equatorial and axial $C(SiMe_3)_3$ groups are present in the molecular structure of **2** in the solid state; however, only one sharp singlet is observed for the $SiMe_3$ atoms in both the ^1H and ^{13}C NMR spectra at room temperature. The spectra remain unchanged on cooling a solution of **2** in [D$_8$]toluene to −70 °C. Compound **2** decomposes slowly in polar solvents; thus, solvent-dependent NMR spectra could not easily be recorded. Only in [D_{10}]diethyl ether were we able to obtain additonal temperature-dependent ^1H NMR spectra without significant decomposition. These spectra show a splitting of the resonance of the $SiMe_3$ group below −10 °C into two very narrow signals at $\delta = 0.34$ and 0.33 with an intensity ratio of 3:1. These observations possibly indicate a fast equilibration of the position of the sulfur atom over all four faces of the In_4 tetrahedron in solution at room temperature. The spectroscopic data of **1** and **2** are very similar, and the differentiation between **1** and **2** is most apparent from the UV/Vis spectra, in which an absorption at 490 nm (shoulder at 570 nm)[4, 5] is observed for **1**, while the most bathochromically shifted absorption of **2** occurs at only 400 nm.

Experimental Section

A solution of propylene sulfide (7 mL, 0.065 M solution in toluene) was added to a solution of **1** (0.489 g, 0.35 mmol) in hexane (50 mL). The mixture was heated to 60 °C for 90 min, and the reaction monitored by NMR spectroscopy. Additional amounts of the solution of propylene sulfide was added (7 + 3 mL) and the mixture was heated each time to 60 °C for 90 min, until **1** was completely consumed. The solvent was evaporated under vacuum, and the residue was dissolved in a small volume of pentane and filtered. Compound **2** crystallized on cooling to −30 °C. Yield: 0.22 g (44%); red, slightly air-sensitive crystals. Decomposition at 170 °C (under argon). Molar mass (determined cryoscopically in benzene) [g mol^{-1}]: found 1335; calcd 1417.66. ^1H NMR (C_6D_6): $\delta = 0.455$; ^{13}C NMR (C_6D_6): $\delta = 6.95$ ($SiMe_3$), α-C atom not detected. IR (Nujol, CsBr): $\tilde{\nu}$ [cm^{-1}] = 1327 w, 1289 w, 1252 vs δCH$_3$; 1190 vw, 1167 w, 1127 w, 1111 w, 1015 m (diisopropyl ether); 856 vs, 839 vs, 774 s, 723 m ρCH$_3$(Si); 673 vs, 648 vs ν_{as}SiC; 615 m ν_sSiC; 583 vs νIn$_4$C$_4$; 517 vw, 473 w, 448 vw νInC; 361 w, 311 m δSiC, νInS. UV/Vis (pentane): λ_{max} [nm] (lgε) = 250 (4.5), 400 (3.8).

onal bipyramid could be refined with an occupancy factor of 0.08. The second position of the cluster can be explained by a rotation of the molecule and formally by the occupation of another face of the In_4 tetrahedron; its In atoms exhibit normal distances to quarternary C atoms, so that the rest of the molecular structure seems to be little influenced by the disorder. $Tl^I[C(SiMe_3)_3]$—An Alkylthallium(I) Compound with a Distorted Tetrahedron of Tl Atoms in the Solid State**

Werner Uhl,* Sven Uwe Keimling,
Karl Wilhelm Klinkhammer, and Wolfgang Schwarz

Tetrahedral clusters with monovalent elements of the third main group are at the center of current research in the field of organoelement chemistry that has already produced remarkable novel compounds: $B_4(CMe_3)_4$,[1] $Al_4Cp^*_4$ ($Cp^* = C_5Me_5$),[2] $Al_4(CH_2CMe_3)_4$,[3] $Al_4[Si(CMe_3)_3]_4$,[4] $Ga_4[C(SiMe_3)_3]_4$,[5] and $In_4[C(SiMe_3)_3]_4$.[6, 7] In addition to the preparative aspects, the chemical bonding has been investigated by theoretical studies.[8] Corresponding thallium compounds are up to now unknown. Cyclopentadienides of monovalent thallium preferably form cyclopentadienyl-bridged oligomers and polymers;[9, 10] a pseudodimer was obtained with the sterically demanding pentabenzylcyclopentadienyl ligand, in which the Tl atoms, although they approach each other, show only a weak Tl–Tl interaction with a long Tl–Tl distance.[11, 12]

Initially we tried to synthesize an alkylthallium(I) derivative in an analogous way to the corresponding indium compound by treating freshly sublimed TlBr with the THF adduct of $LiC(SiMe_3)_3$.[13] However, we obtained $HC(SiMe_3)_3$ as the main product; the brief appearance of a red color possibly indicates the formation of an alkylthallium compound. In contrast, in addition to insoluble lithium cyclopentadienide, deep red-violet, almost black crystals of the alkylthallium(I) compound **1**, were obtained from cyclopentadienylthallium(I) and the organolithium compound in toluene under mild conditions, followed by rapid workup [Eq. (a)]. The product **1** decomposes at 65 °C,

$$TlC_5H_5 + LiC(SiMe_3)_3 \cdot 2THF \longrightarrow Tl[C(SiMe_3)_3] + LiC_5H_5 + 2\,THF \quad (a)$$

1

and thallium deposits even at −50 °C from the red-violet solutions in pentane. The organothallium compound is thus considerably less stable than the corresponding gallium[5] and indium derivatives.[7] According to the cryoscopic determination of the molar mass, **1** is present as a monomer in benzene, whereas the indium analog remains tetrameric in solution.[7] Because of the steric demand of the voluminous substituents and the shorter element–element distances than in the tetraindium derivative, the gallium compound forms monomers on increasing the dilution of its solutions in benzene.[5] In the ^1H and ^{13}C NMR spectra of **1** singlets are observed for the $SiMe_3$ groups regardless of the temperature, and the most bathochromically shifted absorption band in the UV/Vis spectra appears similarly as for the In_4 derivative at 515 nm.

The crystal structure analysis of **1** (Figure 1)[14] reveals a tetramer, in which the thallium atoms are in a distorted tetrahedral arrangement with remarkably different Tl–Tl distances.

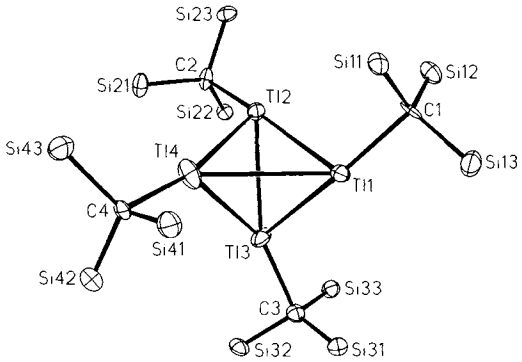

Figure 1. Molecular structure of **1**; methyl groups are omitted for clarity. Important bond lengths [pm] and angles [°]: Tl1–Tl2 332.2(1), Tl1–Tl3 335.1(1), Tl2–Tl3 333.1(1), Tl1–Tl4 362.7(1), Tl2–Tl4 346.1(1), Tl3–Tl4 363.8(1), Tl1–C1 238(1), Tl2–C2 238(1), Tl3–C3 238(1), Tl4–C4 233(1); Tl2-Tl1-Tl3 59.89(2), Tl2-Tl1-Tl4 59.54(2), Tl3-Tl1-Tl4 62.69(2), Tl1-Tl2-Tl3 60.50(2), Tl1-Tl2-Tl4 64.62(2), Tl3-Tl2-Tl4 64.74(2), Tl1-Tl3-Tl2 59.62(2), Tl1-Tl3-Tl4 62.37(2), Tl2-Tl3-Tl4 59.35(2), Tl1-Tl4-Tl2 55.84(2), Tl1-Tl4-Tl3 54.94(2), Tl2-Tl4-Tl3 55.91(2).

An average Tl–Tl distance of 333.5 pm is observed in the plane (Tl1,Tl2,Tl3), but the distances to the atom Tl4 are significantly longer (346.1–363.8 pm), and lie in the range of weak interactions in pentabenzylcyclopentadienylthallium(I);[11] the significance of these interactions has been discussed controversially.[12] A length of approximately 294 pm was established for a Tl–Tl single bond;[4, 15] thus even the shortest Tl–Tl distance in **1** is 13% longer than this value. In contrast, in the analogous compounds with Ga_4 and In_4 tetrahedra we observed almost indistinguishable Ga–Ga and In–In distances, respectively, which are less than 6% longer than the respective single bonds in organoelement compounds. Intermetallic phases with Tl clusters show Tl–Tl distances of greater than 300 pm.[16]

In contrast to the Ga_4 and In_4 compounds, in the Tl_4 cluster the E–C vectors (E = Tl) do not point away from the center of the terahedron, but rather a paddle wheel arrangement of the substituents is observed; thus, the deviation from the ideal arrangement on projection on a triangular face of the cluster is close to 35°, and one almost linear Tl-Tl-C group (155 to 174°)

results for each Tl atom. For Tl4 the shortest Tl–Tl distance in the cluster is part of this approximately linear arrangement (Tl2-Tl4-C4 169.1°). The triangle Tl1, Tl2, Tl3 can be compared with a recently calculated triplumbane $(H_2Pb)_3$, for which a paddle wheel arrangement of the substituents with Pb–Pb distances longer than a Pb–Pb single bond was obtained as the energy minimum.[17] The bonding in this triangle is best described similarly to that in tetrakis[bis(trimethylsilyl)methyl]distannene from Lappert et al.[18] by a Lewis acid–base interaction between three plumbanediyl (H_2Pb) or thalliumdiyl (RTl) fragments through their lone pair of electrons and their empty p orbital, which in contrast to the dimeric Sn compound with a nonclassical Sn–Sn double bond results in a cyclic trimer. The atom Tl4 is located above the Tl_3 triangle with, however, significantly longer Tl–Tl distances, which might indicate only very weak Tl–Tl bonding interactions. Thus, in addition to the cryoscopically determined molar mass of **1** in solution, the crystal structure analysis clearly confirms weaker element–element bonding than in the analogs with the lighter elements Ga and In. The Tl–C bond lengths of 238 pm (to Tl1, Tl2 and Tl3) and 233 pm (Tl4–C4) are longer than the values in compounds with trivalent Tl atoms (av 215 pm).[19]

Experimental Section

A solution of $LiC(SiMe_3)_3 \cdot 2THF$ (2.13 g, 5.58 mmol) [13] in toluene (25 mL) was added dropwise to a cooled (−40 °C) suspension of sublimed cyclopentadienylthallium(I) (1.58 g, 5.87 mmol) in toluene (25 mL) under argon. The solution was slowly allowed to warm to 0 °C and the solvent rapidly evaporated at room temperature. The residue was treated with pentane (10 mL) and filtered. The red-violet filtrate was evaporated to dryness, diisopropyl ether was added, and the solution quickly cooled to −50 °C. Compound **1** crystallized as pyrophoric, extremely sensitive, almost black crystals, which appeared deep red-violet in thin layers. Yield: 1.58 g (65%). Decomposition at 65 °C (under argon). Molar mass (determined cryoscopically in benzene) [g mol^{-1}]: found 413; calcd 435.96 (for the monomer). ^{1}H NMR (C_6D_6): $\delta = 0.13$; ^{13}C NMR (C_6D_6): $\delta = 6.6$ ($SiMe_3$), 30.5 (TlC). IR (Nujol; CsBr): $\tilde{\nu}$ [cm^{-1}] = 1250 m δCH_3; 1169 w, 1113 vw, 1093 vw, 1044 w, 1009 m; 883 vs, 850 vs, 766 s, 745 m, 723 s $\rho CH_3(Si)$; 673 s, 665 s $\nu_{as}SiC$; 640 m, 611 m ν_sSiC; 525 vs, 465 m νTl_4C_4; 363 w, 312 w δSiC. UV/Vis (pentane): λ_{max} [nm] (lgε) = 215 (3.7), 245 (3.8), 320 (sh, 3.0), 380 (sh, 2.7), 515 (2.7).

"Redox-Switch" Catalysis of C–C Bond Formation with H_2: One-Electron Reduction of the Trityl Cation**

Robert T. Hembre* and J. Scott McQueen

The use of H_2 as a reducing agent in electron transfer is nearly unknown,[1] but we have discovered a metal hydride, [Cp*(dppf)RuH] (**1**, dppf = 1,1′-bis(diphenylphosphino)ferrocene), that is a unique catalyst for one-electron reductions of the ferrocinium ion or methylviologen with H_2.[3] Further study of the activation of H_2 by **1** has revealed unprecedented coupling of a carbon–carbon bond-forming reaction to H_2 oxidation: the trityl cation is reduced by H_2, in the presence of a base (tetramethylpiperidine (TMP)) yielding the dimer of the triphenylmethyl radical known as "Gomberg's dimer" [Eq. (a)].[4]

[**] We are grateful to Nebraska NSF-EPSCoR Program (OSR-9255225) for their support of this research, to Jody Redepenning and Mike Anderson for electrochemical measurements and expertise, and to Boulder Scientific Co. (Mead, CO) for a generous gift of C_5Me_5H.

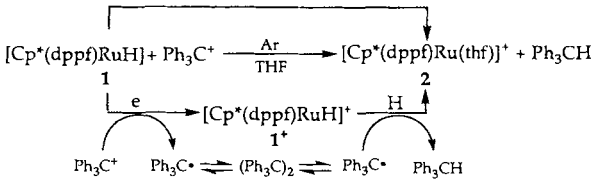
This discovery was a surprise, because we first examined stoichiometric reactions of **1** with the trityl cation that yield only triphenylmethane and the cationic ruthenium(II) derivative, $[Cp^*(dppf)Ru(thf)]^+$ (**2**), by a hydride transfer [Eq. (b)]. As a

$$[Cp^*(dppf)RuH] + Ph_3C^+ \xrightarrow[THF]{} [Cp^*(dppf)Ru(thf)]^+ + Ph_3CH \quad (b)$$

1 **2**

test of single- vs. multi-step hydride transfer in reaction (b), ratios of $\mathbf{1}:Ph_3C^+$ were varied from 3.0 to 0.33.[5] In every case only **2** and triphenylmethane were produced.

To explain the production of Gomberg's dimer in the catalytic reduction [Eq. (a)] and its absence in reaction (b), separate reactions of the ruthenium(II) hydride **1** and its ruthenium(III) counterpart $\mathbf{1}^+$[3] with Gomberg's dimer[8] were investigated. The first combination gave no reaction, but the second yielded a rapid and clean production of triphenylmethane and **2**.[9] Thus, it is possible that the apparently concerted hydride transfer of reaction (b) is a two-step process in which the trityl radical is produced from the trityl cation by an initial one-electron oxidation of **1**[10] followed by a selective H-atom transfer from $\mathbf{1}^+$ to the trityl radical yielding triphenylmethane and **2**. This eH mechanism (electron transfer/H-atom transfer) appears "concerted" because $\mathbf{1}^+$ is unusually stable and reacts selectively with the trityl radical, even in the presence of excess **1** (Scheme 1).[11]



Scheme 1. Single-step and eH mechanisms for hydride transfer from **1** to the trityl cation [Eq. (b)]. Ar = under argon atmosphere.

In this case distinguishing a concerted hydride transfer mechanism from its eH alternative requires a trapping agent that reacts with $\mathbf{1}^+$ and $Ph_3C^\bullet$ at a rate competitive with their combination, but the trap must not react with **1** or Ph_3C^+. These requirements are fulfilled by $[BrMn(CO)_5]$.[14] It is unreactive with **1** or Ph_3C^+ and effectively converts $\mathbf{1}^+$ and $Ph_3C^\bullet$ into their respective bromides. Thus, in the presence of 4.4 equivalents of $[BrMn(CO)_5]$ (7.2×10^{-2} M) the reaction between **1** and Ph_3C^+ yields Ph_3CBr and other "LRuBr products" [Eq. (c)].[17] If the

$$\mathbf{1} + (Ph_3C)BF_4 \xrightarrow[THF]{[BrMn(CO)_5]} Ph_3CH + Ph_3CBr + [LRu(THF)]^+ + (LRuBr\ products) \quad (c)$$

reaction were truly concerted these additional products from reaction of intermediates with $[BrMn(CO)_5]$ would not appear. The hydride transfer of reaction (b) is thus revealed as a more complex eH process, a conclusion more readily reconciled with the products of catalytic reduction with H_2 [Eq. (a)].

Stoichiometric reaction between H_2 and the cation **2** at 70 °C in the presence of TMP yields **1** and in the absence of TMP produces the ruthenium(IV) dihydride $[Cp^*(dppf)RuH_2]^+$ (**3**, Eq. (d)). Complex **3** is recognized as a *trans*-dihydride by the

$$\mathbf{2} + H_2 \xrightarrow{THF} [Cp^*(dppf)Ru(H)_2]^+ \xrightarrow{TMP} \mathbf{1} + [HTMP]^+ \quad (d)$$

3

^1H NMR spectrum of its dppf ligand.[19] Its acidity may be estimated from the correlation reported by Morris and Jia of the pK_a of cationic dihydrides with the oxidation potential of their conjugate base monohydrides.[21] For **1** not only a first, but also a second oxidation is electrochemically reversible (see E_1 and E_2 in Scheme 2)[3] so that the acidity of **3** ($pK_a \approx 12$) can be estimated based on E_1. Under the conditions of catalysis TMP fully deprotonates **3** in THF [Eq. (d)].

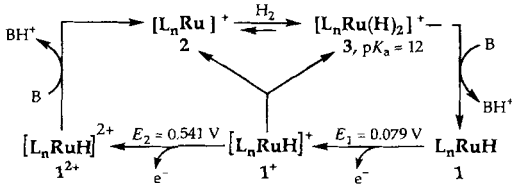
The reversibility of H_2 addition to **2** is demonstrated by its displacement upon reaction of **3** with CO to yield the ruthenium(II) carbonyl $[Cp^*(dppf)Ru(CO)]^+$ (**4**, Eq. (e)). Further

$$3 + CO \xrightarrow[THF]{-H_2} \underset{\mathbf{4},\ \tilde{\nu}_{CO} = 1949\ cm^{-1}}{[Cp^*(dppf)Ru(CO)]^+} \underset{[Cp_2Co]}{\overset{(NAr_3)X}{\rightleftharpoons}} \underset{\tilde{\nu}_{CO} = 1958\ cm^{-1}}{[Cp^*(dppf)Ru(CO)]^{2+}} \quad (e)$$

1 atm

oxidation of **4** with $[N(C_6H_4Br)_3]SbCl_6$ ($(NAr_3)X$) yields a species with an infrared CO stretching band at 1958 cm^{-1}, only 9 cm^{-1} above that of **4** (a similar shift was reported by Wrighton for the iron-centered oxidation of $[(dppf)Re(CO)_3Cl]$).[22] Treatment of this oxidized species with cobaltocene cleanly regenerates **4**. Similar oxidation of **3** produces a derivative with two broadened bands in its ^1H NMR at $\delta = -2.0$ and -8.0 that is converted back into **3** by one equivalent of cobaltocene. Cyclic voltammograms of **3** show a single reversible oxidation at 1.08 V vs. NHE,[23] attributed to the Fe^{III}/Fe^{II} couple of the dppf ligand.[24]

To account for the accumulation of Gomberg's dimer along with triphenylmethane in the reduction of the trityl cation with H_2 [Eq. (a)] we propose the following catalytic cycle (Scheme 2).



Scheme 2. Proposed catalytic cycle for activation of hydrogen and redox-switch catalysis by **1** (L_n = Cp*(dppf)).

We assume that reaction (d) accounts for the activation of H_2 (in THF at 1 atm H_2, 70 °C, $c(\mathbf{1}) = 1.2 \times 10^{-4}$ M) and that an electron transfer from **1** to Ph_3C^+ yields $\mathbf{1}^+$ and $Ph_3C^\bullet$. If true, then $\mathbf{1}^+$ must be converted into **2** by a path alternative to, and competitive with, H-atom abstraction by $Ph_3C^\bullet$ [as in Eq. (b)]. Three options may be considered. First, disproportionation of $\mathbf{1}^+$ occurs at ambient temperature yielding **2** and **3**,[3] as depicted in Scheme 2. Although the concentration of $\mathbf{1}^+$ must be low under catalytic conditions, this reaction mode is, in principle, active. Ion $\mathbf{1}^+$ may also be converted into **2** by two-step sequences. Either oxidation ($\mathbf{1}^+ \rightarrow \mathbf{1}^{2+}$)/deprotonation ($\mathbf{1}^{2+} \rightarrow \mathbf{2}$), or inversely, deprotonation ($\mathbf{1}^+ \rightarrow L_nRu$)/oxidation ($L_nRu \rightarrow \mathbf{2}$). We favor the former of these (Scheme 2) as cyclic voltammetry has shown the formation of $\mathbf{1}^{2+}$ is viable on an electrochemical time scale,[3] and preliminary kinetic studies show that the disproportionation of $\mathbf{1}^+$ is not influenced by TMP.[25] Studies of the disproportionation and acidity of $\mathbf{1}^+$ (and $\mathbf{1}^{2+}$) to distinguish the active mechanism of this catalysis are in progress.

In summary, one-electron reduction of the trityl cation with H_2 is catalyzed by the ruthenium hydride **1**. This catalysis is proposed to occur with the 17-electron ruthenium(III) hydride

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3601-0066 $ 15.00+.25/0 Angew. Chem. Int. Ed. Engl. 1997, 36, No. 1/2

1^+ as a key intermediate. Preference for electron transfer over hydride transfer in the reaction of **1** with the trityl cation is revealed by competitive atom-transfer trapping of 1^+ with $[BrMn(CO)_5]$. These experiments establish a two-step eH mechanism rather than a concerted hydride transfer for the reaction of **1** with the trityl cation. Under the conditions of reduction with H_2 eH hydride transfer is interrupted, which results instead in the accumulation of Gomberg's dimer derived from one-electron reduction of the trityl cation.

Due to the role of **1** in converting H_2, a two-electron reducing agent, into a reductant for two one-electron steps, we refer to it as a "redox-switch" catalyst. Further studies of this unprecedented transfer of electrons from the H–H bond of hydrogen to C–C bonds by one-electron reduction of carbenium ions are in progress.

[5] If hydride abstraction by Ph_3C^+ occurs by initial one-electron oxidation, the resulting odd-electron metal hydride, a "radical cation", may be reactive in side reactions. For instance, oxidation of $[Cp(PMe_3)_2RuH]$ yields $[Cp(PMe_3)_2RuH]^+$ which is relatively acidic and protonates its parent hydride yielding $[Cp(PMe_3)_2Ru(H_2)]^+$ [6]. Such proton transfers can compete with the H-atom transfer required to convert $Ph_3C^\cdot$ into Ph_3CH by an eH mechanism. Thus, an eH hydride transfer can yield products in relative amounts that depend on the ratio of the trityl cation to the metal hydride. We have reported such variations in the reaction of [Cp*(dppm)RuH] with the trityl cation (dppm = bisdiphenylphosphinomethane) [7]. The products of a single-step hydride transfer are, on the other hand, insensitive to this ratio.

[25] The ratio of triphenylmethane to Gomberg's dimer produced under catalytic conditions is dependent on the concentration of TMP. An increase the amount of TMP from one to five equivalents increases the yield of Gomberg's dimer from 30 to 70%. This could be explained if deprotonation of $1^\cdot$ competes with H-atom transfer. However, a study of the rate of disproportionation of 1^+ ($k = 3.5 \times 10^{-2} M^{-1} s^{-1}$ at 23 °C) [3] monitored by its electronic spectrum shows no influence of TMP. This implies that TMP does not deprotonate 1^+.

New Cage Compounds: Preparation and Characterization of Chiral C_3-Symmetric Macrobicyclic Tris(phosphazides)**

Mateo Alajarín,* Pedro Molina,
Antonia López-Lázaro, and Concepción Foces-Foces*

The formation of medium and large ring systems is a permanent challenge for synthetic chemists, as special skills are usually required for the cyclization, although self-assembly and preorganization of the reactants can minimize undesirable oligomerizations. Phosphorus-containing macrocycles are now well-documented, but those with intracyclic P–N units are scarce.[1] Macrocyclization reactions involving P–N bond formation have been rarely explored.[1c]

$CH_3C(CH_2PPh_2)_3$ (triphos), the most widely investigated tripodal polyphosphane, is an excellent ligand of increasing significance in coordination chemistry.[2] However, little is known about the chemistry of triphos other than its extraordinary coordinating ability, and no reactions with azides have been reported.

Tris(azide) **1** was prepared by standard chemistry starting from bis(*o*-azidobenzyl)amine[3] and *o*-azidobenzyl chloride.[4] The reaction of equimolar amounts of **1** and triphos at room temperature provided microcrystalline **2** in 66% yield [Eq. (a)].

In the $^{31}P\{^1H\}$ NMR spectrum of **2** ($CDCl_3$) the singlet at $\delta = 1.34$ is in the range[5] typical for phosphazides[6] 25–30 ppm downfield relative to the resonance of the phosphane counterpart (triphos $\delta = -27.3$),[7] which reflects the high symmetry of **2** (probably C_3). The same holds for the ^1H and $^{13}C\{^1H\}$ NMR spectra, where only one set of signals is present (Table 1). The

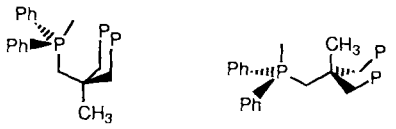
[a] The new compounds gave satisfactory C,H,N elemental analyses; H,H-COSY experiments and high-resolution $^{13}C\{^1H\}$ NMR spectra were used for accurate assignments.

diastereotopicity of the methylene protons in the CH_2-P and CH_2-N groups speaks for intrinsic chirality and therefore for the helical or propellerlike shape of the molecule. Particularly noteworthy is the chemical shift of the CH_3 protons ($\delta = -0.12$, broad singlet), which is 1.07 ppm upfield relative to the analogous signal in the phosphane[7] and far away from the signals of most of the known triphos transition metal complexes, which lie in the range $\delta = 1.12$–2.09.[8] Also, the shifts of the CH_2-P protons ($\delta = 3.92$ and 4.24) are notably different from those in the phosphane ($\delta = 2.48$)[7] and its complexes ($\delta = 2.06$–2.78).[8] These data raised the question of the conformation of the triphos fragment in compound **2**. Does it have the CH_3-*out* conformation found in all the known triphos complexes in which the ligand is coordinated in an η^3 fashion, the previously not reported CH_3-*in* conformation (Scheme 1), or some other conformation imposed by the particular topology of the molecule?[9]

In this context, we observed that, like the methyl protons, the CH_3 carbon atom of **2** is also shielded (broad singlet at $\delta = 26.36$; $\delta = 29.5$ and 36–40 in the phosphane and its complexes, respectively)[7, 8]. In the ^{13}C NMR spectrum the two diastereotopic phenyl rings linked to each phosphorus atom appear to be magnetically inequivalent with notable differences in the coupling constants $^1J(C,P)$ for the two *ipso* carbon atoms (83.2 and 104.5 Hz). This unusual fact probably reflects a not exactly tetrahedral environment at the phosphorus atoms.



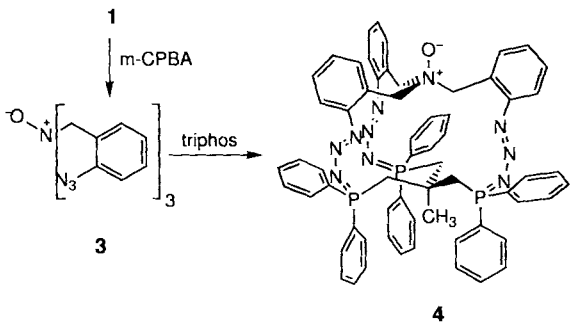
CH_3-*out* CH_3-*in*

Scheme 1. The two known conformations of triphos depicting the position of the CH_3 group

Since the NMR spectra did not change when the sample was cooled to 203 K, significant dynamic processes for compound **2** at room temperature can be excluded. Because of the chemical instability of this tris(phosphazide) its apparent conformational rigidity could not be evaluated by high-temperature NMR experiments. In $CDCl_3$ **2** decomposed totally in 24 h at 298 K and in 2 h at 323 K, giving an intractable mixture.

All this data indicate unequivocally that compound **2** is a tris(phosphazide). Phosphazides typically lose dinitrogen at ambient or even lower temperature to produce λ^5-phosphazenes,[10] although some phosphazides have been isolated.[10b] The X-ray structural data of six phosphazides[11] showed as common features the essentially zwitterionic character of the PN_3 framework ($P^+-N=N-N^-$) and the *E* configuration of the central N=N bond. Attempts to build reasonable molecular models of tris(phosphazide) **2** with (*E*)-PN_3 frameworks, with four possible combinations of the conformations around the bridgehead N and quaternary sp^3 carbon atoms (N lone pair *in* or *out*, CH_3 *in* or *out*), gave highly strained structures. Unfortunately, we were unable to obtain a crystalline sample of **2** suitable for X-ray structure determination.

We reasoned that the lability of **2** in solution could result from the initial dissociation of one PN_3 arm into phosphane and azide,[12] and that this dissociation could be facilitated by the inversion of the configuration at the bridgehead N atom. To suppress this inversion we decided to prepare similar tris(phosphazides) in which that N atom is quaternized. Derivatization of **2** by protonation with acids or methylation with methyl iodide, triflate, or tetrafluoroborate gave only intractable complex mixtures. Although tris(azide) **1** was easily protonated and methylated, the resulting ammonium salts did not react efficiently with triphos. Finally reaction of the tertiary amine N-oxide **3**, easily prepared from **1** by the action of *m*CPBA,[13] with triphos provided the macrobicyclic tris(phosphazide) **4** [Eq. (b)].



(b)

Compound **4** was stable in $CDCl_3$ solution for several days at room temperature without noticeable decomposition, and its analytical and spectroscopic data (Table 1) are in agreement with the proposed structure and very similar to those obtained for the tris(phosphazide) **2**. Suitable crystals of **4** now allowed an X-ray structure analysis.[14]

Two perspective views of the molecular structure of **4** are shown in Figure 1. The molecule is located on a threefold crystallographic axis passing through O1, N2, C15, and C16, and its propellerlike shape is clearly apparent when the molecule is viewed along this axis (Fig. 1b). Both O1 and C16 are located outside the cavity of the macrobicycle. The PN_3 fragment presents a *Z* configuration with respect to the central N–N bond

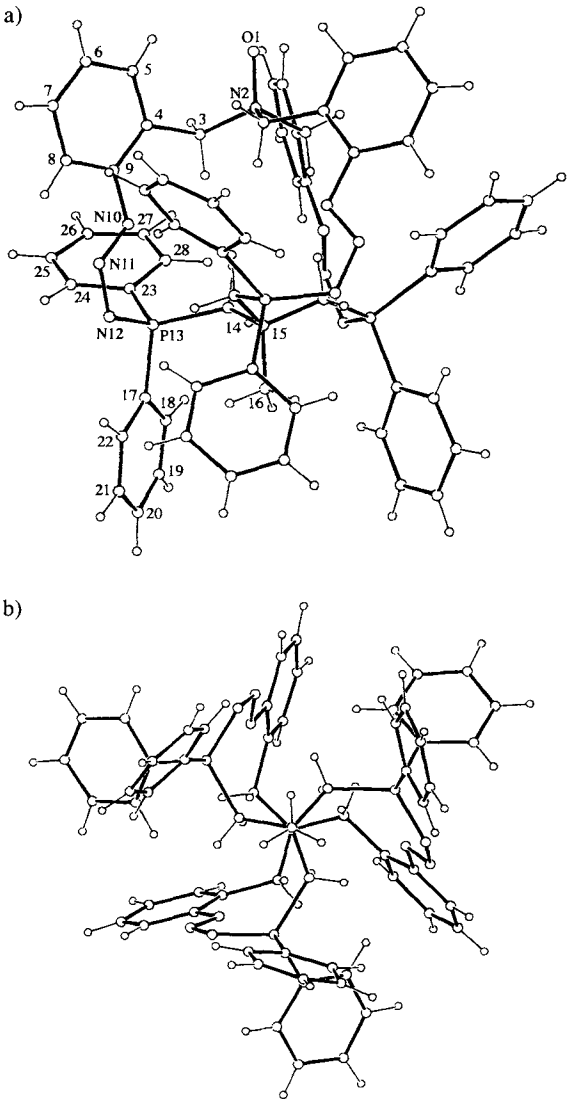


Figure 1. a) Molecular structure of **4**. Selected interatomic distances [Å] and angles [°]: O1–N2 1.344(15), N2–C3 1.519(11), N10–N11 1.257(12), N11–N12 1.340(11), N12–P13 1.640(8), P13–C14 1.810(11), P13–C17 1.791(10), P13–C23 1.799(8), N10–P13 2.714(7); O1-N2-C3 110.2(3), C9-N10-N11 114.7(7), N10-N11-N12 117.5(8), C14-P13-C17/C23/N12 108.5(5)/105.2(4)/119.9(4), C17-P13-C23/N12 106.1(4)/102.0(4), N10-P13-C14/C17/C23 88.5(3)/156.6(4)/83.8(3). b) A perspective view as projected along the threefold axis.

[N10-N11-N12-P13 = −7.5(11)°] in contrast to the *E* configuration observed in all the previously reported phosphazides.[11] There is extensive electronic delocalization in the P-N-N-N fragment and the distances compare fairly well with the average values of 1.630(1), 1.341(1), and 1.273(1) Å for the analogous *E*-phosphazides; the lengths of the N12–P13 and N11–N12 bonds are between those of single and double bonds [1.697(15), 1.582(19) Å for N–P bonds in phosphazenes, and 1.401(18), 1.245(9) Å for N–N bonds].[18] The environment of the phosphorus atom can be described as a tetrahedron distorted toward a trigonal bipyramid with N10 and C17 in axial positions (Fig. 1a). The P13···N10 distance is within the range of 2.592(7)–2.741(7) Å reported for related compounds that are intermediate to open-chain betaines and cyclic 1,3,2-diazaphosphetidines.[19] The hydrogen atoms of the C16 methyl group are 1.49 and 3.13 Å away from the C17–C22 and C23–C28 planes, respectively; the distances to the respective centroids are 3.51 and 6.19 Å.

Tris(phosphazide) **4** is notably more stable than **2** and is unchanged after several weeks in $CDCl_3$ solution at 298 K and also after mild heating (6 h, 334 K, $CDCl_3$). High-temperature ^1H NMR experiments ($CDCl_3$, from 298 to 330 K) showed no appreciable changes in the normal spectrum of **4**. Thus, in this range of temperatures the chiral, C_3-symmetric structure is rigid and does not isomerize via labile conformations with C_1 symmetry.

Experimental Section

General synthesis of **2** and **4**: Two solutions of the corresponding tris(azide) (10 mL, 1.5 mmol, 0.15 M in diethyl ether for **1**, and in dichloromethane for **3**) and triphos (10 mL, 1.5 mmol, 0.15 M in diethyl ether) were simultaneously added under nitrogen at room temperature over 30 min and with stirring, to a round-bottom flask containing 15 mL of diethyl ether. The resulting mixture was then stirred overnight, the precipitated pale yellow solid was filtered and dried under vacuum to give compounds **2** and **4** in 66 and 85% yield, respectively.

[14] Crystals of **4** were obtained by slow diffusion of ether into a solution of the compound in $CDCl_3$. Crystal data for **4**: $C_{62}H_{57}N_{10}OP_3 \cdot 2H_2O$, yellow crystal of dimensions $0.37 \times 0.37 \times 0.27$ mm, rhombohedral, $R\bar{3}$, $a = b = 15.0677(7)$, $c = 48.7214(49)$ Å, $\alpha = \beta = 90$, $\gamma = 120°$, $V = 9579(1)$ Å^3, $\rho_{calcd} = 1.102$ g cm^{-3}, $Z = 6$, $\mu = 12.22$ cm^{-1}, 2328 independent reflections, $R(Rw) = 0.105(0.103)$ for 1309 [$I > 2\sigma(I)$] observed reflections. Maximum final difference Fourier peak 0.83 e Å^{-3}. Seifert XRD3000-S, four-circle diffractometer, $Cu_{K\alpha}$ radiation, graphite monochromator, $\omega/2\theta$ scan, $\theta_{max} = 60°$. Two set of data were collected due to the instability of the crystal, and although the present set was recorded more quickly the decay factor was 7%. Semiempirical Ψ-scan absorption correction was applied. Refinement on F_0 with full matrix. The structure was solved by direct methods [15] and the molecule was located on a threefold crystallographic axis. An anisotropic thermal model was used for the non-hydrogen atoms, while the thermal and positional parameters for H atoms, which were obtained unambiguously from difference Fourier synthesis, were kept fixed during the last cycles of refinement. The water molecules appear to be disordered and the hydrogen atoms of the water molecule situated on the threefold axis could not be located. Moreover, in spite of the high displacement parameters of the C17–C22 atoms no disorder model could be obtained. The weighting scheme was established as to give no trends in $<\omega\Delta^2F>$ versus $<F_0>$ and $<\sin\theta/\lambda>$. The poor quality of the data could be a consequence of the disorder problems (low value of the total packing coefficient, 0.60), which did not allow any improvement of the R factor in the refinement process. Most of the calculations were performed using the XTAL System [16] on a VAX6410 computer. The atomic scattering factors were taken from ref. [17]. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-135. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ (UK) (fax: Int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

$[(\eta^5\text{-}C_5Me_5)Al\text{–}Fe(CO)_4]$—Synthesis, Structure, and Bonding

Jurij Weiss, Dana Stetzkamp, Bernhard Nuber, Roland A. Fischer,* Christian Boehme, and Gernot Frenking*

The series of surprisingly stable subvalent halides and organometallic compounds of aluminum and gallium has extended over the last few years to include several interesting compounds that open up promising perspectives as starting materials for preparative purposes.[1] For instance the fascinating tetrahedral compound $[(Cp^*Al)_4]$,[2] its alkyl congeners $(RE)_4$ and $R_2E\text{–}ER_2$ ($R = (Me_3Si)_2CH$, $(Me_3Si)_3C$; E = Al, Ga, In),[3] and $[R_2Al\text{–}AlR_2]^-$ ($R = (Me_3Si)_2CH$, 2,4,6-$iPr_3C_6H_2$)[3] are examples for Al–Al π bonding. Carbonylmetal complexes with donor-stabilized Al^I and Ga^I fragments such as $(CO)_5Cr\text{–}Ga(C_2H_5)L_2$ (L_2 = tmeda) are also of interest, since they are suitable volatile precursors for the deposition of intermetallic phases (e.g. CrGa) by chemical vapor deposition.[4a] Analogous complexes with donor-free aluminum centers are very rare, and only two examples are known: $[(Cp^*Al)_2(CpNi)_2]$[4b] and $[\{EtAl\text{–}CoCp^*(\eta^2\text{-}C_2H_4)\}_2]$,[4c] *in which the* RAl^I fragments have been described as CO-analogous two-electron bridging ligands. However, no quantum theoretical investigations of the bonding in these species have been carried out. Therefore, with this aim in mind, our interest was directed to the synthesis of a most simple structured model complex in which one donor-free RAl^I unit is terminally bound to a transition metal fragment.

Treatment of a solution of $[\{Cp^*AlCl_2\}_2]$[5] in toluene with an excess of solid $K_2Fe(CO)_4$ [Eq. (1)] gave a reaction mixture

$$[(Cp^*AlCl_2)_2] + 2K_2[Fe(CO)]_4 \longrightarrow \underset{\mathbf{1}}{2[Cp^*Al\text{–}Fe(CO)_4]} + 4KCL \qquad (1)$$

whose IR spectrum, recorded after a short reaction time, exhibits the typical ν(CO) pattern for a pseudo-C_{3v}-symmetric $[LM(CO)_4]$ complex. If the reaction is stopped at this stage, and the reaction solution is filtered and concentrated, complex **1** is obtained as colorless cubes in 10–20% yield by crystallization at −30 °C over several weeks. Attempts to increase the yield of **1** by employing other reaction media (THF, Et_2O, CH_2Cl_2), phase-transfer reagents ($[R_4N](PF_6)$; dibenzo-[18]crown-6), ultrasound, or higher temperature, have so far been unsuccessful.

The position of the ^{27}Al NMR signal at $\delta = -0.4$ ($w_{1/2} = 2600$ Hz) indicates that **1** differs considerably from donor-stabilized complexes of the type $[L_2Al(R)\text{–}M(CO)_n]$[4a] and resembles more closely the tetramer $[(Cp^*Al)_4]$[2] whose Al nuclei are comparably shielded.[6] The single-crystal X-ray diffraction study[7] reveals that the Cp*Al unit is indeed terminally bound (apical position) to the 16-electron $Fe(CO)_4$ fragment. The Al–Fe bond (223.1(3) pm) in **1** is significantly shorter than the Al–Fe bonds in typical Al^{III} complexes such as $[(^iBu)\{Me_2N(CH_2)_3\}Al\text{–}FeCp(CO)_2]$ (245.6(1) pm)[4d] and the Lewis acid/base adduct $[(Ph)_3Al\text{–}FeCp(CO)_2]^-$ (251.0(2) pm).[4e] In alloys (e.g. Al_3Fe[4f]) the average Al–Fe distance (255 pm) is about 32 pm longer than in **1**. However, Al–M distances similar to those in **1** are found in multinuclear complexes with donor-free Al centers such as $[(NiCp)_2(Cp^*Al)_2]$[4e] (228 pm) and $[\{EtAl\text{–}CoCp^*(\eta^2\text{-}C_2H_4)\}_2]$[4f] (233 pm). The Al1-Fe1-C13 (87.8(3)°) and Al1-Fe1-C14 (82.1(2)°) angles (Fe–C14a is symmetrically equivalent; for atom numbering see Figure 1) are consistent with a weakly developed umbrella effect.[8] The Al1-Fe1-C12 angle (172.4(3)°) is close to the ideal value of 180° for a trigonal-bipyramidal coordinated Fe center. The average Al–C(Cp) distance (214.7 pm) is shorter than that in the Ni_2Al_2 complex (225.3 pm) mentioned above; a value of 233.4 pm was found for the $[(Cp^*Al)_4]$ tetramer. Evidently, **1** exhibits a more pronounced charge polarization $Al^{\delta+}\text{–}Cp^{\delta-}$. However, an extreme description as a contact ion pair $[Cp^*Al]^{2+}[Fe(CO)_4]^{2-}$ can be ruled out on the basis of the position of the ν(CO) IR absorption bands (> 1900 cm^{-1}) and the fact that Fe–Al coordination is preferred over isocarbonyl bridging Fe-C-O-Al.

Further information about the bonding was provided by quantum theoretical calculations using density functional theory in conjunction with relativistic pseudopotentials at Fe[9] on the model compound $[(\eta^5\text{-}Cp)Al\text{–}Fe(CO)_4]$ (**1a**, substitution of Cp* by Cp (C_5H_5)). The theoretical data for **1a** (Figure 2)

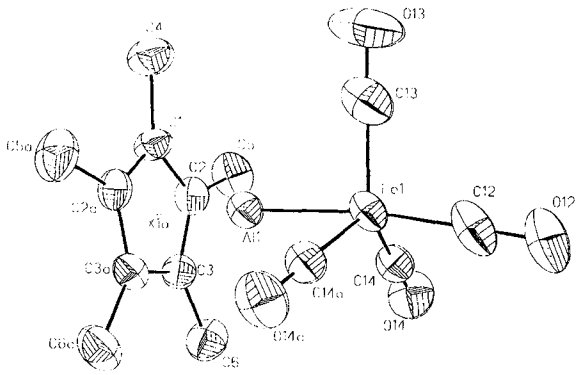

Figure 1. Molecular structure of **1** in the solid state (ORTEP, thermal ellipsoids with 50% probability). Selected bond lengths [pm] and angles [°]: Fe1–C12 179.6(10), Fe1–C13 176.8(11), Fe1–C14 176.5(5), Fe1–Al1 223.1(3), Al1–C1 214.9(8), Al1–C2 214.0(5), Al1–C3 215.3(5); Al1-Fe1-C12 172.4(3), Al1-Fe1-C13 87.8(3), Al1-Fe1-C14 82.1(2), Cp-Al-Fe 176.

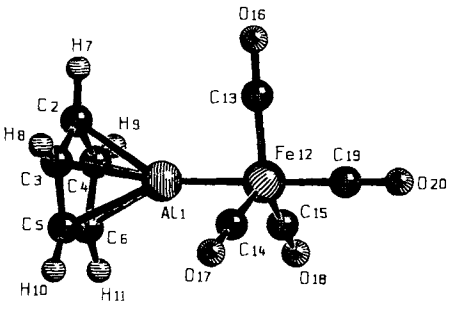

Figure 2. The DFT-optimized structure of **1a** (C_s). Selected bond lengths [pm] and angles [°]: Fe–C19 177.7, Fe–C13 177.9, Fe–C14/15 177.9, Fe–Al 224.3, Al–C2 224.0, Al–C3/4 224.1, Al–C5/6 224.4; Al-Fe-C19 179.5, Al-Fe-C13 84.7, Al-Fe-C14/15 85.2.

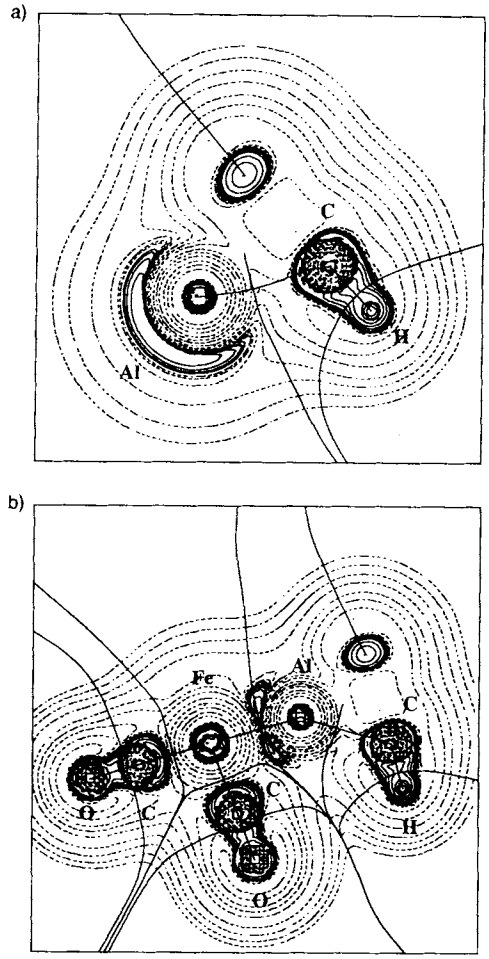

Figure 3. Laplacian distribution of the electron density of a) CpAl in the Al-C-H plane and b) **1a** in the Fe-Al-C plane. Dashed lines show areas with electron depletion at ($\nabla^2\rho(r)>0$), while solid lines represent areas with electron concentration ($\nabla\rho(r)<0$). Solid lines connecting atomic nuclei symbolize bonding paths; those that separate atomic nuclei from each other, show the zero-flux surfaces of the atoms in the molecules.

shows a very good agreement with the experimentally determined structural parameters of **1** (Figure 1) . The calculated Al–C bond lengths in **1a** (224.0–224.4 pm) are somewhat longer than the Al–C bond lengths in **1** (214.0–215.3 pm), since the donor effect of Cp in **1a** is weaker than that of Cp* in **1**.

The analysis of the electronic structure shows that **1a** can clearly be described as a donor–acceptor complex; the CpAl fragment serves as the donor through the lone pair of electrons at Al. Figure 3 shows the Laplacian distribution of the electron density[10] for the free CpAl fragment and the complex **1a**. The free CpAl fragment (Figure 3a) has an area of electron concentration at Al ($\nabla^2\rho(r)>0$, solid lines) on the side pointing away from the Cp ligand, which is attributed to electron density of the lone pair of electrons. In contrast, the on side of Al pointing toward the Cp fragment is a region of electron depletion ($\nabla^2\rho(r)$, dashed lines). The AlCp fragment can be clearly described as an ionic compound Al^+Cp^-. The charge distribution calculations (NBO method[11]) give a positive partial charge of +0.61 for Al in the free AlCp fragment.

The Laplacian distribution of the electron density of **1a** reveals that the formation of the Al–Fe bond results in a clear distortion of the electron density at Al (Figure 3b). Inspection of the fragment orbital interactions between the fragments AlCp and $Fe(CO)_4$ by the charge density analysis (CDA) method[12] supports the designation of **1a** as a [CpAl–$Fe(CO)_4$] donor–acceptor complex. The mixing of the occupied orbitals of the CpAl fragment with the unoccupied MOs of the $Fe(CO)_4$ fragment provides 0.61 electrons for the donor bonding, whereas for the back donation (CpAl←$Fe(CO)_4$) only 0.19 electrons were calculated. The electron donation (CpAl → $Fe(CO)_4$) occurs almost exclusively from one orbital (MO 58), which donates 0.59 electrons. The shape of the orbital depicted in Figure 4 demonstrates the donor–acceptor character of the Al–Fe bond. The Al–Fe bond in **1a** has a higher ionic character than the Fe–CO bonds. This is derived from the partial charges, which according to NBO calculations are +1.21 for Al, −0.57 for Fe, and be-

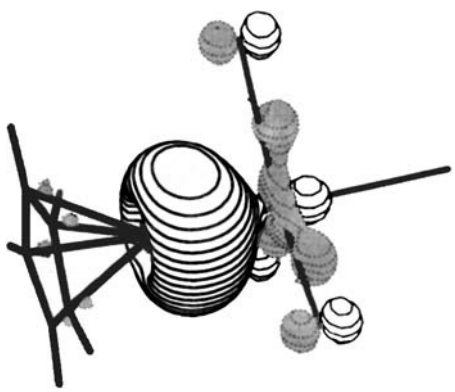

Figure 4. Graphic representation of the molecular orbital 58 of **1a**, which, according to CDA results [12], is the orbital with the large share of the electron donation [CpAl → $Fe(CO)_4$].

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997* *0570-0833/97/3601-0071 $ 15.00+.25/0*

tween −0.06 (equatorial CO) and +0.05 (axial CO) for C. The partial charges give an overall donation of 0.70 electrons from the AlCp fragment to the $Fe(CO)_4$ fragment. This electron donation almost exclusively originates from the electron density at the Al center, whose positive charge of +0.61 in free AlCp is raised to +1.21 in **1a**.

Density functional theory calculations on the complex **1a** and the CpAl and $Fe(CO)_4$ fragments yielded an Al–Fe bond strength of 52.7 kcal mol^{-1}. At the same level of theory, the dissociation energy of CO in $Fe(CO)_5$ is calculated to be 47.9 kcal mol^{-1}; the experimental value is 41 ± 2 kcal mol^{-1}.[13] The theoretical value of D_e = 52.7 kcal mol^{-1} for the Al–Fe bond thus seems to be overestimated by approximately 7 kcal mol^{-1}. However, since the Cp*Al fragment is a better donor than CpAl, the Al–Fe bond strength in **1** can be estimated to be about 50 kcal mol^{-1}; thus, corresponding to a quite strong complex bond.

Experimental Section

1: A sample of $K_2[Fe(CO)_4]$ (984 mg, 4 mmol) [19] was suspended in toluene (25 mL) at −78 °C. At this temperature, a solution of $[\{Cp^*AlCl_2\}_2]$ (466 mg, 2 mmol) [5] in toluene (25 mL) at −78 °C was quickly added in one portion with vigorous stirring. The reaction mixture was allowed to warm up to room temperature and stirred for 2 h, filtered, and the filtrate concentrated to about 20 mL, over which *n*-pentane (10 mL) was layered. The product **1** crystallized after several weeks at −78 °C. Yield: about 100 mg (15%). ^{1}H NMR (399.78 MHz, C_6D_6, 298 K): δ = 1.56 (s, 15H, Cp*); $^{13}C\{^1H\}$ NMR (100.5 MHz, C_6D_6, 298 K): δ = 116.5 (Cp*), 6.6 (Cp*); $^{27}Al\{^1H\}$ NMR (104.14 MHz, C_6D_6, 298 K): δ = −0.4 ($w_{1/2}$ = 2600 Hz). IR (toluene): $\tilde{\nu}$(CO) [cm^{-1}] = 2024 s, 1948 m, 1903 vs ν(CO); correct elemental analysis.

Relative Configuration and Synthesis of a New C-4 Branched Sugar, a Component of the Lipooligosaccharide LOS-III from *Mycobacterium gastri*

Jacques Longépé, Jacques Prandi,* and Jean-Marie Beau

C-4 Branched chain sugars have been found to be important components of cell wall lipopolysaccharides in various bacteria and mycobacteria.[1, 2] Recently, a new 3,6-dideoxy-4-*C*-(1,3-dimethoxy-4,5,6,7-tetrahydroxyheptyl)-α-*xylo*-hexopyranoside was described as the distal sugar in the highly antigenic lipooligosaccharide LOS-III (Figure 1) isolated from *Mycobacterium gastri*.[3, 4] This LOS-III was shown to be a permanent marker of *M. gastri* and could be used to distinguish this species of mycobacteria from the closely related opportunistic pathogen

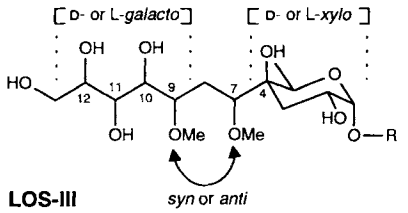

Figure 1. Gross structure of LOS-III from *Mycobacterium gastri*. R = oligosaccharide fatty acids.

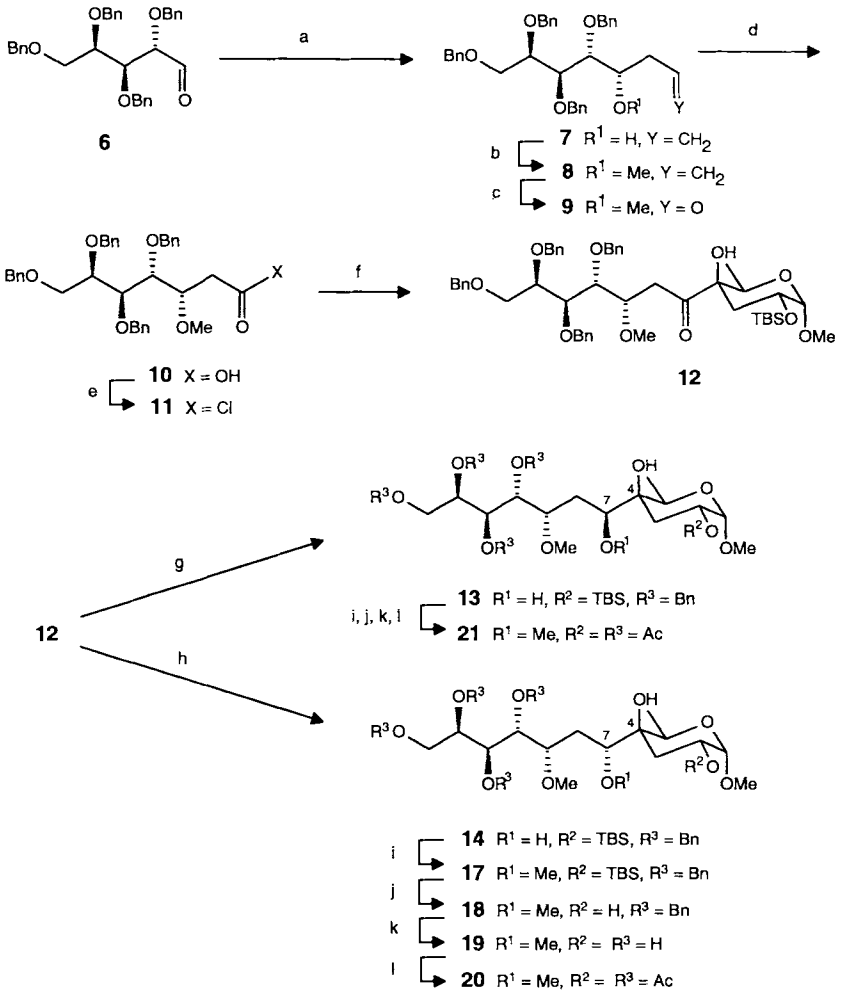
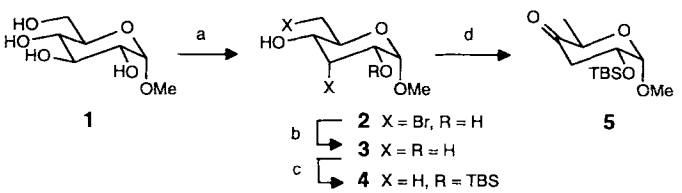
M. kansasii[3] involved in mycobacterial infection of immunodeprived hosts.[5] However, the natural product was isolated in very small amounts and although the gross structure could be established by a combination of NMR experiments and mass spectroscopic data,[3] the complete relative configuration of this new branched sugar remained unknown. In light of the biological significance of this compound as part of the epitope of LOS-III and its potential importance for the serological characterization of mycobacterial infection, we decided to establish its complete structure and to develop a general synthetic access to C-4 branched sugars.[6]

Analysis of the ^{1}H NMR data of the peracetylated LOS-III in solution[4] and comparison to that of the alditols peracetates[7] gave a splitting pattern typical of the 9,10-*syn*, 10,11-*anti*, and 11,12-*syn* arrangement, that is, the relative *galacto* configuration for the C-9 through C-12 asymmetric centers[8] of the side chain (Figure 1). The 7,9-dimethoxy function was not assigned, as the analysis of the proton–proton coupling constants for the 7,9-*syn* and -*anti* diastereoisomers on these centers was inconclusive. Furthermore, the series (D or L) of the cyclic 3,6-dideoxy moiety could not be correlated with the absolute configurations of the side chain; thus, four diastereoisomeric compounds had to be made.



Scheme 2. Synthesis of compounds **20** and **21**. a) AllylTMS, $TiCl_4$, −100 °C, CH_2Cl_2, 59%, 13:1; b) NaH, MeI, THF, 0 °C, 80%; c) O_3, CH_2Cl_2, −78 °C, then PPh_3, 78%; d) CrO_3, H_2SO_4, acetone, 85%; e) $(COCl)_2$, pyridine, CH_2Cl_2, 0 °C; f) 1.3 equiv **11**, 1.0 equiv **5**, SmI_2, THP, room temperature, 58%; g) $NaBH_4$, MeOH, 0 °C, 72%, 18:1; h) TMSOTf, pyridine, CH_2Cl_2, 0 °C, 91%; Red-Al, toluene, 0 °C, 70%, 100:1; i) Me_2SO_4, NaOH, hexane, nBu_4NI, 0 °C, 81%; j) HCl, MeOH, room temperature, 91%; k) H_2, 10% Pd/C, EtOAc/MeOH, room temperature, 82%; l) Ac_2O, pyridine, 80 °C, 87%.

For a general route to C-4 branched sugars, disconnection between C-4 and C-7 was obvious; formation of this bond from a cyclic ketone such as **5** (see Scheme 1) and a suitable seven-carbon side chain precursor was pinpointed as the strategic step. For this, we capitalized on the recently reported samarium diiodide promoted coupling reaction of ketones with acid chlorides,[9] which would introduce the side chain and an oxygenated functionality at C-7.[10] The cyclic dideoxy sugar would then be used as a control element for the reduction of the C-7 keto group to any of the desired epimers.[11] We considered D- and L-lyxose as the most appealing starting materials for easy availability of the seven-carbon side chain in either enantiomerically pure form.



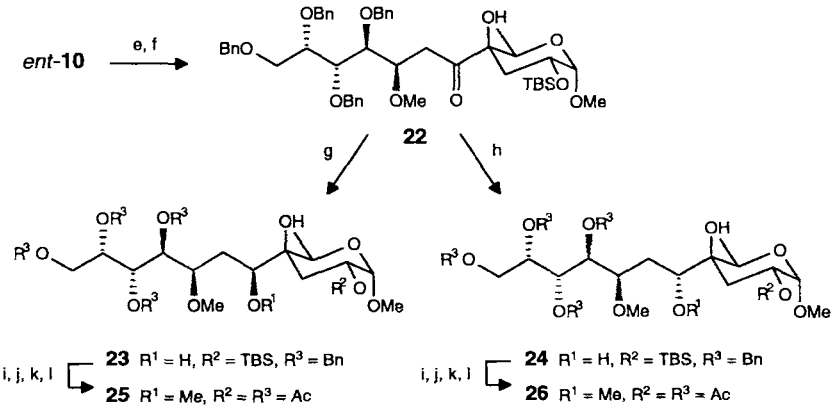
Scheme 1. Elaboration of methyl α-D-glucopyranoside **1** to the coupling partner **5**. a) PPh_3, tribromoimidazole, toluene, reflux; b) H_2, Pd/C or Bu_3SnH, AIBN, 58–61% over two steps; c) TBSCl, imidazole, DMF, −17 °C, 73%; d) PCC, AcONa, CH_2Cl_2, 92%.

Construction of the cyclic ketone **5** started from methyl α-D-glucopyranoside **1**. Dibromination under Garegg's conditions[12] and bromide reduction (H_2, Pd/C or Bu_3SnH, azobisisobutyronitrile (AIBN)) gave diol **3** in 58–61% yield[13] (Scheme 1). Position 2 of **3** was then selectively protected as a *tert*-butyldimethylsilyl (TBS) ether (TBSCl, imidazole, DMF, −17 °C, 73%) before oxidation of the hydroxyl group in **4** with pyridinium chlorochromate (PCC) in buffered dichloromethane,[14] which gave a 92% yield of the desired ketone **5**. The overall yield for the sequence from **1** was 40%.

Compound **6**, the perbenzylated open-chain form of D-lyxose was available in 77% overall yield from the free sugar in three steps: formation of the diethyldithioacetal derivative,[15] benzylation (NaH, BnBr, DMF), and hydrolysis of the thioacetal catalyzed by mercuric chloride.[16] Titanium tetrachloride mediated, chelate-controlled addition of allyltrimethylsilane[17] to aldehyde **6** at −100 °C in dichloromethane gave the *galacto* alcohol **7** in 58% yield and 13:1 diastereoselectivity (Scheme 2). Methylation (NaH, CH_3I, 80%) and ozonolysis gave the aldehyde **9** in 78% yield. Final oxidation of this aldehyde under Jones's conditions[18] gave the required heptanecarboxylic acid

10 in 85% yield. The very same sequence of reactions carried out from *ent*-**6**,[19] the enantiomer of **6**, delivered the enantiomeric carboxylic acid *ent*-**10** in a comparable overall yield.

Treatment of ketone **5** at 25 °C with a solution of freshly prepared acid chloride **11** (1.3 equiv) in tetrahydropyran (THP) with an excess of samarium diiodide for ten minutes[9] provided the coupling product **12** in 58% yield in a diastereoisomeric ratio of 5:1. Although we were not able at this stage to prove the equatorial orientation of the side chain in the major product, the preferential equatorial attack of an organosamarium species on a conformationally rigid cyclohexanone[10] had been described previously, and this point was unambiguously confirmed after reduction of ketone **12**.



Scheme 3. Synthesis of compounds **25** and **26**. Reagents as for Scheme 2; yields are similar.

The 7,9-*anti* system was selectively obtained by sodium borohydride reduction of **12** in methanol at 0 °C, which gave diols **13** and **14** (72% yield) in an isomeric ratio of 18:1. The configurations at C-4 and C-7 of the major product **13** were deduced from the NOESY spectrum of **15**, the 4,7-isopropylidene derivative of **13** (Figure 2). First, the NOE connectivity between H-5 and H-8

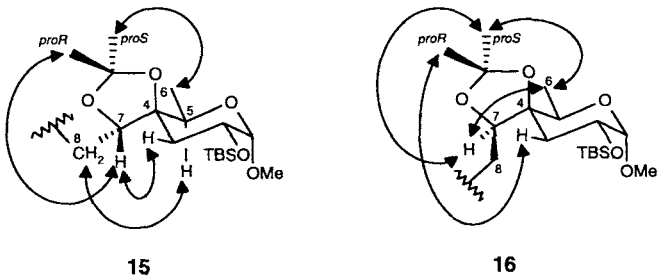


Figure 2. Selected NOEs observed for **15** and **16**. (NOESY, 250 MHz, 25 °C, $CDCl_3$).

is only compatible with an equatorial orientation of the side chain in **15** (and **13**), leading to the *S* configuration at C-4 in **13**. Next, strong NOE correlations of H-6 with the *proS* isopropylidene methyl group, and of H-7 with the *proR* methyl group and with H-3(equatorial) clearly put H-7 and H-6 on opposite faces of the 1,3-dioxolane ring. The *S* configuration at the C-7 center of **15** (and **13**) then follows. The 7*R* isomer **14**, the minor isomer isolated from the $NaBH_4$ reduction, was selectively obtained from ketone **12** after protection of the tertiary alcohol as a trimethylsilyl ether (trimethylsilyl trifluoromethanesulfonate (TMSOTf), pyridine, 91%) and reduction of the carbonyl double bond with Red-Al (toluene, 0 °C, 70%).[11] Very high selectivity was observed (100:1) and the configuration of the major diol **14** was again deduced after ketalization to give the 4,7-isopropylidene derivative **16**. NOE contacts of the *proS* isopropylidene methyl group with H-6 and H-7 (Figure 2) established the *cis* relationship of these groups in the dioxolane ring in **16** and thus the *R* configuration for the C-7 center of **16** and **14**.

The conclusion of the synthesis was straightforward. Treatment of diol **14** at 0 °C with NaOH and dimethyl sulfate in large excess under phase-transfer conditions[20] resulted in clean methylation of the secondary 7-hydroxyl, and the tertiary alcohol **17** was obtained in a rewarding 81% yield. Cleavage of the silyl ether and hydrogenolysis of the benzyl ethers gave the final methyl glycoside **19**, which was acetylated to **20**. The same sequence of reactions carried out from **13** delivered the diastereoisomer **21** in a similar overall yield.

Using the same chemistry, ketone **22** was obtained by SmI_2-promoted condensation of the acid chloride derived from *ent*-**10** with the ketone **5** (Scheme 3). Reduction of the keto group in **22** with sodium borohydride gave selectively the 7*S* product **23** (61% yield, isomeric ratio **23**:**24** = 8:1), while the 7*R* isomer **24** was obtained after the TMS protection/Red-Al reduction sequence (67% yield, only one isomer was isolated). These stereochemical results, deduced from NOESY experiments on the 4,7-isopropylidene derivatives of **23** and **24** as above, clearly indicate that reduction of the ketone in **12** and **22** was mostly controlled by the asymmetric centers of the adjacent ring and not by the C-9 substituent. Diols **23** and **24** were then converted into the final compounds **25** and **26** according to the previously described chemistry.

The ^1H NMR spectra of the four diastereoisomers **20**, **21**, **25**, and **26** were recorded in $CDCl_3$ solution at 25 °C and carefully compared with the reported data for this sugar in the peracetylated LOS-III.[4] The ^1H NMR data of compound **20**,[21] in particular for the crucial C-7 to C-10 fragments, gave the best match (Table 1).

The relative configurations of **19** and of the distal C-4 branched sugar of the LOS-III of *M. gastri* were then established to be 2*R**, 4*R**, 5*R**, 7*R**, 9*S**, 10*S**, 11*S**, 12*R**. This sugar, according to the systematic nomenclature, is 3,6-dideoxy-

5,7-di-*O*-methyl-4-*C*-[(*R*)-1-hydroxyethyl)]-D-*lyxo*-D-*allo*-undecose or its enantiomer and exists as the pyranose form in the natural product. Further biochemical experiments are underway to define the absolute configuration of this novel sugar, which has not yet been isolated from the entire lipooligosaccharide LOS-III available in only minute amounts from the natural source.

This synthetic methodology, selective and high-yielding, makes the other known C-4 branched sugars[1, 2] readily accessible and could be of interest for the elaboration of other C-branched carbohydrates.[6]

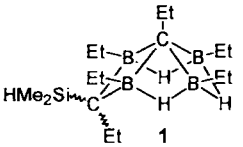
The First 2-Carba-*nido*-pentaborane(8) Derivative; Structure of Sodium Hexaethyl-2,4-Dicarba-*nido*-hexaborate(1 −)

Bernd Wrackmeyer,* Hans-Jörg Schanz, and Wolfgang Milius

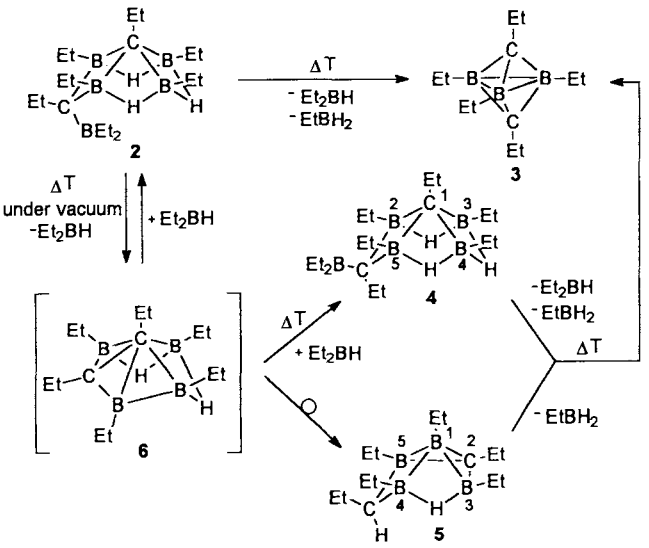
Dedicated to Professor Walter Siebert on the occasion of his 60th birthday

C,B-alkylated carboranes were synthesized in the 1960s, shortly after the beginning of carborane chemistry.[1, 2] A reinvestigation of some of these reactions is promising since mechanistic details may be revealed, and there is the possibility of detecting or even isolating potential intermediates with new carborane structures.[3–6] Furthermore, peralkylated polyboranes and also carboranes are of interest because of their greatly enhanced thermal stability over the partially alkylated derivatives or the parent compounds.[1, 4]



1

Recently we reported on a route to 1-carba-*arachno*-pentaborane(10) derivatives **1**,[5a] and the key position of the analogous carborane **2** on the way to pentaethyl-1,5-dicarba-*closo*-pentaborane(5) (**3**) was shown (Scheme 1).[6] This transformation of the *arachno*- to the *closo*-carborane should be accompanied by the formation of other carboranes, possibly with *nido* structures. Although the existence of compounds with a *nido* structure in the reaction mixture was proposed,[6] their composition and structure remained undefined. It has now proved possible to separate and isolate two intermediates in this rearrangement: the 1-carba-*arachno*-pentaborane(10) **4**, the *syn* isomer of **2**, and the new 2-carba-*nido*-pentaborane(8) derivative **5**, the first representative of this class of compounds. The proposed structures of **4** and **5** are deduced from the sets of ^1H, ^{11}B, and



Scheme 1.

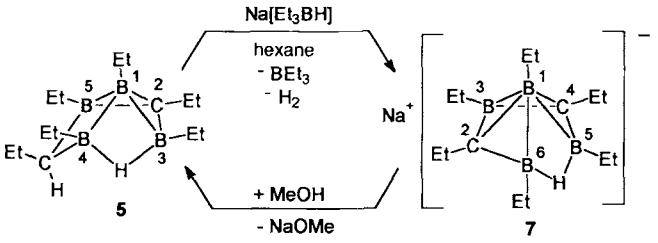
^{13}C NMR spectroscopic data (see Experimental Section), and the NMR signals were assigned as described previously for **1**.[5a]

The formation of **5** from **2** can be explained by intramolecular elimination of "Et_2BH";[7] the carbon atom in the bridge thereby becomes integrated in the carborane cage. There is no NMR spectroscopic evidence for the existence of a long-lived 1,2-dicarba-*nido*-hexaborane(8) derivative **6** as the primary product after the liberation of "Et_2BH". Assuming that **6** is an unstable intermediate, the carborane **5** is formed when the carbon atom in the unfavorable apical position[8] migrates to the bridging position, and accepts a hydrogen atom that had been located previously in a B-H-B bridge, and one of the boron atoms takes over the apical position, which is in agreement with the selective formation of the *anti* isomer of **5**. Under the experimental conditions, these processes are accompanied by the isomerization of **2** to **4**, since the short-lived intermediate **6** may react with "Et_2BH" to give either **2** or **4**. In freshly prepared samples of **2**, the *syn* isomer **4** is not present to an appreciable extent (< 3%). If these samples are kept at room temperature for a prolonged period (several days), the amount of **4** increases slowly, and the formation of **3** becomes apparent; however, ^{11}B NMR spectra do not indicate the presence of a significant amount of **5**. The intramolecular elimination of "Et_2BH" in **4** is sterically hindered, and, therefore, **4** is not readily converted into **5**. Further heating of **4** or **5**, or of a mixture of both, leads finally to the *closo*-carborane **3**.[6] The proposed structure of **5** also indicates that elimination of "$EtBH_2$", as the next step upon further heating, provides a straightforward route to **3**.

The carborane **5** can be deprotonated by reaction with $Na[BEt_3H]$ in hexane to give the sodium hexaethyl-2,4-dicarba-*nido*-hexaborate(1 −) **7**, in which the bridging sp^3-hybridized carbon atom in **5** has become part of the carborane framework (Scheme 2). The parent anion $[2,4\text{-}C_2B_4H_7]^-$ was prepared by



Scheme 2.

other methods, but its structure was not confirmed and its chemistry has not been studied.[9] The reaction of **7** with methanol leads to reformation of **5**, and the reaction with deuterated methanol gives **5** with a C(Et)D bridge; the B-H-B bridge remains unaffected. To the best of our knowledge, this is the first example of the reversible integration of a carbon atom into a carborane cage.

The sodium salt **7** crystallizes as a dimer from toluene solutions. The molecular structure of **7** (Figure 1) was determined by X-ray structure analysis.[10] The structure differs markedly from that of $\{Na(thf)[2,3\text{-}(Me_3Si)_2\text{-}2,3\text{-}C_2B_4H_5]\}_2$,[11] since the dimer of **7** crystallizes without solvent, and the presence of the ethyl groups has an important influence. Both sodium atoms [d_{Na-Na} = 348.0(2) pm] are embedded and shielded in the cavity formed by the ethyl groups. There are numerous short Na−H (in particular to the hydrogen atoms of C(14)), Na−C, and Na−B contacts; the B(5)-H-B(6) hydrogen atom is not involved.

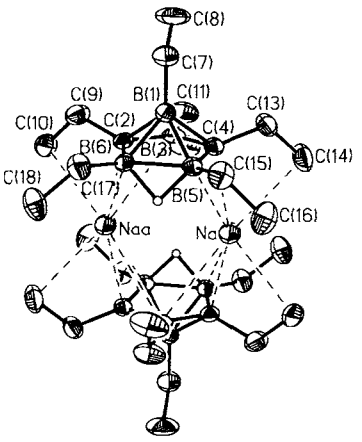


Figure 1. Molecular structure of **7** (dimer) in the crystal. Selected bond lengths [pm] and angles [°]: Na−Naa 348.0(2), Na−B(3) 313.0(3), Na−B(5) 289.6(3), Na−C(4) 251.3(3), Na−C(14) 287.7(4), B(1)−B(3) 182.6(4), B(1)−B(5) 174.2(4), B(1)−B(6) 174.9(4), B(1)−C(2) 170.2(3), B(1)−C(4) 170.7(4), C(2)−B(3) 154.3(4), C(2)−B(6) 157.2(4), C(4)−B(5) 155.7(4); C(2)-B(3)-C(4) 106.7(2), B(3)-C(2)-B(6) 113.8(2), C(2)-B(6)-B(5) 102.2(2), C(4)-B(5)-B(6) 103.6(2), C(2)-B(1)-B(3) 51.7(2), C(2)-B(1)-C(4) 93.8(2), C(2)-B(1)-B(5) 99.1(2), C(2)-B(1)-B(6) 54.2(1), B(1)-C(7)-C(8) 115.2(2), B(3)-C(11)-C(12) 114.1(3), B(5)-C(15)-C(16) 115.4(2), B(6)-C(17)-C(18) 116.2, C(2)-C(9)-C(10) 114.3(2), C(4)-C(13)-C(14) 115.3(2).

The investigation of the route to the *closo*-carborane **3** has not only revealed the existence of new carboranes as reasonably stable intermediates such as **2**, **4**, and **5**, but has also opened the access to the new anion $[Et_6\text{-}nido\text{-}2,4\text{-}C_2B_4H]^-$ as the sodium salt **7**, which may have considerable synthetic potential in reacions with electrophiles.

Experimental Section

5 and **4**: Carborane **2** [6] (3.217 g, 10.25 mmol) was heated at 85 °C for 2 h in vacuo. The yellowish, viscous residue (1.995 g, 62%) was identified as compound **4** (> 80% pure as shown by NMR spectra). Redistillation of the condensed product gave **5** (0.772 g, 31%; < 90% pure according to NMR spectra) as a colorless liquid, b. p. 79–81 °C/10^{-4} Torr. **4**: IR: ν(BHB): 2100 cm^{-1}. ^1H NMR (250 MHz, 25 °C, CD_2Cl_2): δ = −1.34 (broad, 1H, B(3)-H-B(4)), 0.26 (broad, 2H, B(2)-H-B(3), B(4)-H-B(5)); 1.77 q, 1.15 t (5H, C(1)-Et), 1.29 q, 1.37 t (5H, μ-C-Et), 0.69 (m), 086 (m), 0.62 (t), 0.90 t, (20H, B(2,3,4,5)-Et), 0.99 m, 1.05 t (10H, μ-C-BEt_2); ^{11}B NMR (80.3 MHz, 25 °C, CD_2Cl_2): δ = −12.1 (B(3,4)), 13.3 (B(2,5)), 82.9 (μ-C-BEt_2); ^{13}C NMR (62.9 MHz, −60 °C, CD_2Cl_2): δ = 7.8 (broad, C(1)), 17.2 (broad, μ-C) 17.5, 13.9 (C(1)-Et), 31.5, 16.0 (μ-C-Et), 2.3 (broad), 8.2 (broad), 12.3, 13.4 (B(2,3,4,5)-Et), 18.5 (broad), 8.9 (μ-C-BEt_2).

5: ^1H NMR (250 MHz, 25 °C, [D_8]toluene): δ = −2.15 (broad, 1H, B(3)-H-B(4)), −1.47 m, 1.88 m, 2.20 m, 1.06 m [6H, μ-CHEt]; 0.02 m, 0.52 t (5H, B(1)-Et), 1.00 m, 0.73 t (5H, B(5)-Et), 0.52 m, 1.36 t (5H, C(2)-Et), 1.01 m, 1.09 t, 1.01 m, 1.19 t (10H, B(3,4)-Et); ^{11}B NMR (80.3 MHz, 25 °C, [D_8]toluene): δ = −27.8 (B(1)), 17.8, 12.3 (B(3,4)), 39.6 (B(5)); ^{13}C NMR (62.9 MHz, −40 °C, [D_8]toluene): δ = 91.5 (broad, C(2)), 41.3 (broad, μ-C ($^1J(^{13}C,^1H)$ = 100.0 Hz)), 0.4 (broad), 12.0 (B(1)-Et), 5.9 (broad), 16.0 (B(5)-Et), 17.0, 18.2 (C(2)-Et), 4.5 (broad), 13.7, 5.9 (broad), 13.7 (B(3,4)-Et), 21.8, 11.5 (μ-C-Et).

7: A solution of $Na[BEt_3H]$ in hexane (6.02 M, 0.14 mL, 0.84 mmol) was added to a stirred solution of **5** (0.204 g, 0.836 mmol) in hexane (5 mL). H_2 was liberated, and after 10 min all volatile material was removed in vacuo. The colorless solid was dissolved in toluene, and upon cooling at −20 °C compound **7** crystallized (m.p. > 125 °C (decomp)) in almost quantitative yield. ^1H NMR (250 MHz, 25 °C, [D_8]toluene): δ = −3.39 (broad, 1H, B(5)-H-B(6)), 0.65 m, 1.12 t (5H, B(1)-Et), 2.12 m, 1.85 m, 0.92 m (10H, C(2,4)-Et), 0.16 m, 0.76 t (5H, B(3)-Et), 0.37 m, 1.04 m (10H, B(5,6)-Et); ^{11}B NMR (80.3 MHz, 25 °C, [D_8]toluene): δ = −39.1 (B(1)), 10.3 (B(5,6)), 28.9 (B(3)); ^{13}C NMR (75.5 MHz, −30 °C, [D_8]toluene): δ = 86.5 (broad, C(2,4)), 21.8, 20.0 (C(2,4)-Et), 5.5 (broad), 13.1 (B(1)-Et), 6.3 (broad), 14.6 (B(3)-Et), 8.6 (broad), 15.7 (B(5,6)-Et).

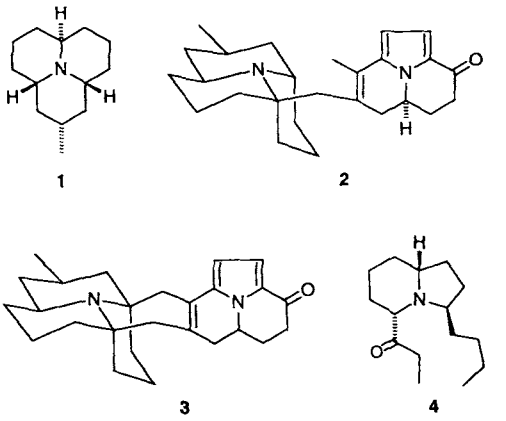
Myrmicarin 663: A New Decacyclic Alkaloid from Ants**

Frank Schröder, Volker Sinnwell, Horst Baumann, Manfred Kaib, and Wittko Francke*

Dedicated to Professor Jerrold Meinwald on the occasion of his 70th birthday

Alkaloids with unbranched carbon skeletons, which are derived from the acetate pool, are widespread among the plant and animal kingdoms. Whereas the ladybird alkaloid precoccinellin (**1**), which consists of a single unbranched chain, was discovered some time ago,[1] only recently have the more complex structures **2** and **3** been described.[2] They may be regarded as "dimers" of precoccinellin (**1**). So far, a large variety of monocyclic and bicyclic alkaloids typically bearing 13 or 15 carbon atoms has been identified in ants.[3] We now report on the isolation and identification of a new decacyclic alkaloid, myrmicarin 663, made up of three unbranched chains of 15 carbon atoms each. Myrmicarin 663 may be regarded as a "trimer" of a disubstituted indolizidine like **4**, previously identified from the African ant, *Myrmicaria eumenoides*.[4]



Ants of the genus *Myrmicaria* have an exceptionally large poison gland reservoir, which can contain up to 0.5 μL of a lipophilic secretion.[5] Apart from a group of simple monoterpene hydrocarbons, GC/MS analysis of the secretion from the species *Myrmicaria striata* revealed a new alkaloid of very low volatility as the main component. The compound is highly temperature- and air-sensitive. Since a sample of pure alkaloid showed more than 50% decomposition within 2 h when stored under air, all isolation steps and the identification procedure had to be carried out strictly under argon.

The molecular weight ($M_r = 663$) of the alkaloid was determined by CI mass spectroscopy. Apart from an intense molecular ion for $C_{45}H_{65}N_3O$ (myrmicarin 663), high-resolution EI mass spectrometry showed two diagnostic peaks corresponding to loss of C_3H_5O (m/z 606; base peak) and C_2H_5 (m/z 634). Isolation of the alkaloid could be accomplished either by column chromatography on neutral alumina or by extraction of a pentane solution of the secretion with hydrochloric acid. From more than 300 poison gland reservoirs, 14 mg of myrmicarin 663 was isolated as a viscous oil of 95% purity (NMR).

Strong IR bands at 1712 cm^{-1} and 1651 cm^{-1} indicated the presence of carbonyl and enamine functions. Hydrogenation resulted in a mixture of compounds with $M_r = 671$, corresponding to the hydrogenation of four double bonds. Thus, assuming the presence of four C–C double bonds and one carbonyl group, the fifteen double bond equivalents implied by the molecular formula suggested a decacyclic structure.

To obtain more detailed structural information, a sample of pure myrmicarin 663 was analyzed by NMR spectroscopy (Figure 1). Apart from the signals of a single proton at $\delta = 4.21$ and a multiplett appearing at $\delta = 3.3$–3.5, the one-dimensional ^{1}H NMR spectrum exclusively showed severely overlapping signals of aliphatic protons. Six methyl, eighteen methylene, and eleven methine groups could be assigned from ^{13}C NMR and (^{13}C,^{1}H) correlation experiments. Furthermore, the presence of ten quaternary carbon atoms was established, including seven carbon atoms appearing in the olefinic region and a carbonyl carbon atom at $\delta = 211.5$ (Table 1). The 65 protons were assigned to four larger spin systems (**I**–**IV** in Scheme 1) and three isolated ethyl groups (see Table 2) by phase-sensitive DQ (^{1}H,^{1}H) COSY experiments. Spin systems **I** and **II** are linked by small, long-range couplings of 1–3 Hz between the protons at C-6 and C-22. Because of the small difference between the chemical shift values of the protons 20-H and 21-H, the vicinal coup-

1′-CH_2CH_3	16.39	1′-CH_2CH_3

ling $J_{20,21}$ in spin system **II** could not be directly detected in (^{1}H,^{1}H) COSY spectra. Therefore, a two-step RELAY experiment was performed,[6] which showed a crosspeak between 20-H and 22-H_c corresponding to magnetization transfer from 20-H via 21-H to 22-H_c. The connection of the two methine groups at positions 20 and 21 is further corroborated by (^{13}C,^{1}H) long-range correlations of the carbon atoms C-19, C-20, C-21, and C-22 in HMBC spectra (Table 1).

As a next step, the four ^{1}H spin systems were combined according to the information from long-range correlation signals of the quaternary carbons, which resulted in the decacyclic structure shown in Scheme 1. The structure of the tricyclic subunit followed from HMBC signals of C-2′/C-2a′ and C-1′/C-7a′ with 3′-H/4′-H and 6′-H/7′-H, respectively. Analogously, the linkage of spin systems **II** and **III** resulted from correlation signals of the bridgehead atoms C-8, C-13, and C-14. Furthermore, the observation of crosspeaks between C-7 and 6-H, 9-H, 20-H, and 22-H, as well as between C-23 and 6-H and 22-H enabled us to connect spin systems **I** with **II** and **III**. The positions of the three nitrogen atoms could be deduced from the chemical shift values of the attached carbons and corresponding protons as well as from a number of (^{13}C,^{1}H) long-range correlations via nitrogen, for example, from C-5 to 1-H, C-14 to 18-H, or C-23 to 1-H and 4-H. Thus, myrmicarin 663 consists of two oligocyclic subunits, a hexahydropyrrolo[2,1,5-*c*,*d*]indolizine and an entirely new heptacyclic system. Long-range correlation signals observed for the proton 12-H of the heptacycle with C-1′, C-2′, and C-2a′ in the pyrrole ring of the tricycle finally revealed that the two subunits are connected through C-12 and C-2′. Extraordinarily high chemical shift values are shown by carbon atoms C-9 through C-13, which are not bonded to a heteroatom. Like in certain steroids that bear an additional 5-membered ring fused to the D-ring of the steroid skele-

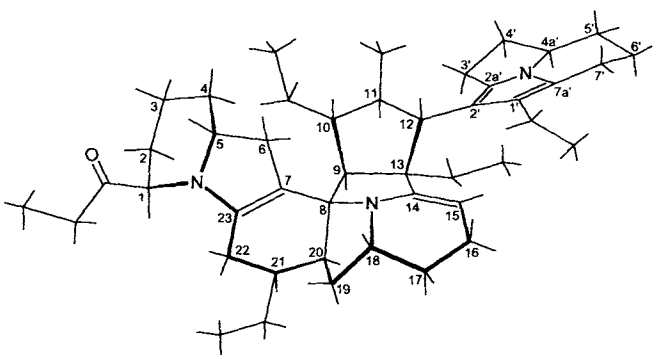
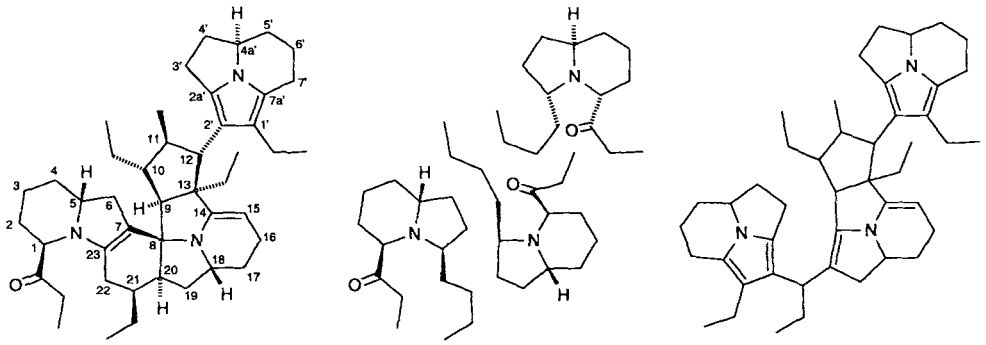
[a] The crosspeak volume of aliphatic geminal proton pairs (corresponding to an interatomic distance of 178 pm) was used as the reference standard (100%): $V^s > 25\%$, $25\% > V^m > 10\%$, $V^w < 10\%$. The subscripts c for *cis* and t for *trans* for the protons refer to their position relative to 1-H in the heptacycle or to 4a′-H in the tricycle.

ton,[7] chemical shift values up to $\delta = 60$ are observed for carbon atoms of aliphatic methine groups.

The relative configuration of myrmicarin 663 was determined by NOE effects (phase-sensitive 2D NOESY experiments) and the ^{1}H coupling constants (Table 2). Due to the high complexity of the spin systems and considerable overlap in the aliphatic regions, especially small coupling constants could not always be directly extracted from DQ (^{1}H,^{1}H) COSY spectra. In these cases, accurate values for the ^{1}H couplings were obtained by additional evaluation of E. COSY spectra.[8] An impression of the huge number of observable NOE effects is given by the spectrum displayed in Figure 1. The NOE effects were classified into strong (s), medium (m) and weak (w) relative to the crosspeak volume of geminal proton pairs (for details see footnote [a] of Table 2). Starting with the strong NOE effect observed for 9-H and 20-H, which indicated *cis* orientation of these protons, and setting the configuration of C-8 arbitrarily to (*R*), we finally arrived at the structure shown in Scheme 2. The configurations at C-10, C-13, and C-21 followed directly from the NOE effect of the methyl groups 10-CH_2CH_3 and 13-CH_2CH_3 with 9-H, 20-H, and 21-H, whereas those of C-11 and C-12 are determined from the NOE effects 10-H/12-H, 10-H/11-CH_3, and 10-CH_2CH_3/11-H. As there is no positive NOE 11-H/12-H, the large coupling $J_{11,12}$ indicated a 1,2-*trans* diaxial configuration of these protons, which corroborated the assignments given for C-11 and C-12. Furthermore, the relative configuration of these stereogenic centers is confirmed by NOE effects between 6-H_c and the protons of the "upper face" of the G-ring (10-H, 11-CH_3, and 12-H). The configuration at C-5 followed from observation of the NOE effects 4-H_c/11-CH_3 and 4-H_c/6-H_c, as well as from the coupling constants and internal NOE effects of the protons of the A-ring, which suggested a slightly twisted chair conformation for this ring, thus indicating an 1,2-*trans* diaxial configuration of 4-H_c and 5-H. Analogously, the assignment of an axial position for the propionyl side chain at C-1 resulted from the small coupling constants of 1-H and from the NOE effect between one of the protons of 1-$COCH_2$ and 5-H. Finally, the configuration at C-18 followed from the NOE 6-H_t/18-H and from the coupling constants and internal NOE effects of spin system **II**.



Scheme 2. Relative configuration in myrmicarin 663. For clarity the positions of a few substructures have been slightly changed from those in the energetically most favorable conformation.



Scheme 3. Structural relationships between myrmicarin 237A (constructed from one unbranched chain of 15 carbon atoms) and the "trimers" myrmicarin 663 and myrmicarin 645. The central eight carbon atoms of each of the carbon C_{15}-chains form indolizine subunits. Carbon–carbon bonds appear only between certain carbon atoms of the C_{15} chains.

To determine the relative configuration at C-4a′ in the tricyclic subunit, first of all the torsion angle about the 12-2′ bond (11-12-2′-1′) had to be considered. Molecular modeling (SYBYL, Tripos inc.) yielded two energetic minima at 131° (70 kcal mol^{-1}) and 312° (72 kcal mol^{-1}) separated by a rotational barrier of about 30 kcal mol^{-1}. As evident from the NOE effects 11-H/3′-H_t, 11-CH_3/3′-H_t and 13-CH_2CH_3/3′-H_c, as well as 12-H/1′-CH_2CH_3, myrmicarin 663 exists in a conformation that corresponds to the more stable minimum of the model. On the basis of this information, the coupling constants and internal NOE effects of spin system **IV** indicated that 3′-H_t is *trans* to 4a′-H, which corresponds to an (*R**) configuration at C-4a′.

Thus, the constitution and relative configuration of the new alkaloid from *Myrmicaria* are established. Attempts to crystallize myrmicarin 663 or a suitable derivative for determination of the absolute configuration by single-crystal X-ray diffraction analysis have not yet been successful.

Myrmicarin 663 is the first example of a new class of alkaloids consisting of condensed indolizine subsystems. Scheme 3 shows the close relationship between the simple indolizine alkaloid myrmicarin 237A from *M.eumenoides*[4] and myrmicarin 663 from *M.striata*. Thus, myrmicarin 663 can be regarded to consist of three unbranched C_{15}-chains. In addition to myrmicarin 663, the poison gland secretion of *M. striata* contains traces (1%) of a structurally related alkaloid with $M_r = 645$ ($C_{45}H_{63}N_3$, "mymicarin 645") showing ^{1}H-spin systems that are consistent with the structure given in Scheme 3. Due to the sensitivity of myrmicarin 645 and the small amounts available (50 μg), heteronuclear NMR experiments could not be performed.

The accumulation of enamine moieties in the considerably strained structures of myrmicarin 663 and myrmicarin 645 may account for their high temperature- and air-sensitivity. In view of this lability, it seemed to be necessary to confirm that no structural alterations had occurred during isolation. For this purpose, a sample of freshly collected poison gland secretion was submitted to NMR analysis without any purification or workup. Due to the comparatively simple composition of the ants' secretion, the characteristic signals of the monoterpene hydrocarbons as well as those of myrmicarin 663 could be directly identified in the DQ (^{1}H,^{1}H) COSY spectrum. Furthermore, no additional components with a comparable concentration were detected. The signals of myrmicarin 645 could not be detected in these experiments. possibly due to the very low concentration of this alkaloid.

Similar to myrmicarin 237A,[4] myrmicarin 663 acts as a poison on prey such as termites. The secretion is applied topically by the sting apparatus, which is modified to a brush- or spatulumlike organ.[5] The presence of monoterpenes is crucial for the activity of the secretion, since it lowers its viscosity and improves the spreading properties. Similar alkaloids with related structures comprising one or two unbranched C_{15}-chains occur in other *Myrmicaria* species and have analogous functions.[9, 10]

Microporous Magnesium Aluminophosphate STA-1: Synthesis with a Rationally Designed Template and Structure Elucidation by Microcrystal Diffraction**

Graham W. Noble, Paul A. Wright,* Philip Lightfoot, Russell E. Morris, Kelly J. Hudson, Åke Kvick, and Heinz Graafsma

The synthesis of novel microporous materials has over the last twenty years or so depended on the innovative use of commercially available organic bases as templates. It has more recently become clear that customized laboratory synthesis of potential templates, in high yield and from readily available precursors, offers an alternative approach.[1-3] Desired pore sizes and connectivities in zeolites may be targeted, and template molecules can be designed that, if incorporated during a synthesis (and subsequently removed), must give the required features. The structures of new microporous solids have been analyzed by single-crystal X-ray crystallography or, for materials available only as powders, ab initio from powder diffraction data or by a combination of electron microscopy and molecular modeling. The recent development of microcrystal diffraction at synchrotron X-ray sources redefines the boundary between these categories. Harding et al. have shown the feasibility of the method by solving known microporous structures and structures related to known frameworks[4, 5] by diffraction experiments on crystals of volumes as small as 10^4 μm^3 with synchrotron X-ray sources in combination with area detectors.

In this paper we report the synthesis of a homologous family of diammonium templates and their use as templates for aluminophosphate-based microporous solids including the novel solids STA-1 and STA-2 (University of *St. A*ndrews). The chosen template cations are linear diquinuclidinium ions of the form $[(C_7H_{13}N)-(CH_2)_n-(NC_7H_{13})]^{2+}$ and were chosen because they possess features of flexibility, charge, and bulky end groups likely to form structures with interconnected pore space. Their use in the synthesis of aluminosilicate zeolites has been reported, and the small pore SSZ-16 has been prepared from templates with an interconnecting group of four methylene units between the quinuclidine units.[1] Among the solid products we synthesized, STA-1 forms as crystals that are not amenable to conventional single-crystal analysis. We report here its structure solution by microcrystal diffraction of synchrotron radiation.

Diquinuclidinium ions were found to be excellent templates for the formation of microporous magnesium aluminophosphate solids. At $n = 3$ (n is the number of carbons in the methylene chain) the erionite isotype MgAPO-17 is formed (the template is of exactly the right size to fit into the cages in the structure in the same way as hexamethonium ions[6]). At $n = 4$ and 5 the product is the novel STA-2 (structure unknown), and longer templates (n from 6 to 10) direct the formation of the one-dimensional, large-pore aluminophosphates MAPO-36 and MAPO-5. STA-1 occurs either phase pure or cocrystallized with MAPO-5 for $n = 7$, 8, and 9, in the form of tetragonal bipyramids truncated on (001) with equatorial base dimensions varying from a few μm to 30–40 μm. Where it occurs with MAPO-5, it can readily be separated due to its lower density. Energy dispersive X-ray diffraction (EDX) and thermogravimetric analysis (TGA) of the sample indicate the composition $Mg_{0.18}Al_{0.82}PO_4 \cdot R_{0.094} \cdot 0.22H_2O$ (R = diquinuclidinium template).

The X-ray powder diffraction pattern recorded at room temperature of the as-prepared STA-1 (Figure 1) was indexed on a tetragonal cell, $a = 13.810$, $c = 21.969$ Å, with a symmetry close

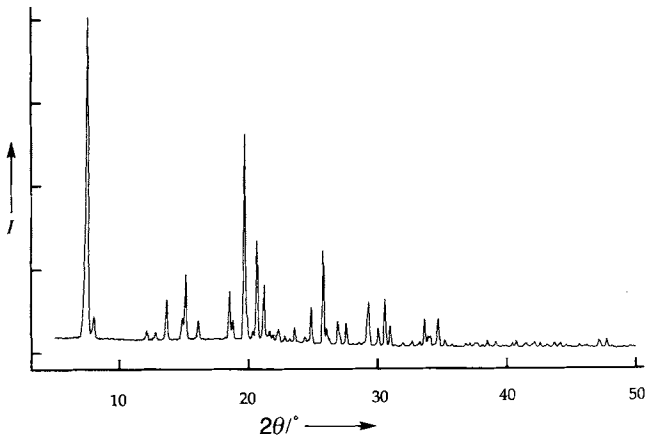

Figure 1. Powder diffraction pattern of the as-prepared magnesium aluminophosphate STA-1, with $Cu_{K\alpha_1}$ radiation, $\lambda = 1.54056$ Å.

to body-centered but violated by weak reflections. From density measurements and TGA the unit cell framework composition $T_{56}O_{112}$ (T = Mg, Al, P) was established. The solid-state MAS-NMR spectrum (MAS = magic angle spinning) indicates that the aluminum ($\delta = 39.3$) and the phosphorus atoms ($\delta = -15.3$(w), -19.3(s), -23.0(s), -26.0(w)) are both tetrahedrally coordinated, and the chemical shifts of the phosphorus signals are consistent with the incorporation of magnesium into the framework. ^{13}C MAS-NMR investigations confirm that the template remains intact during synthesis. Attempts to solve the structure ab initio from the powder diffraction data were unsuccessful. Crystals of STA-1 prepared from the heptamethylene diquinuclidinium template were therefore examined at the European Synchrotron Radiation Facility, Grenoble (for details of the structure solution, see the experimental section) Calcination of the material at 550 °C for eight hours in a stream of air results in a major loss of crystallinity.

Although the asymmetric unit of STA-1 consists of two four-rings joined to each other through only three of the four vertices, (Figure 2a), the framework may best be thought of as being made up of two different kinds of structural building units (Figures 2b and 2c), each possessing $\bar{4}m$ symmetry, which are linked through a shared face, or four-ring, as illustrated in Figure 2d. The units depicted in Figure 2b may also be viewed as being fused together through shared edges of four subunits containing four- and six-rings (Figure 2e) of the type that occur in chains in the recently observed aluminophosphate-based solids SAPO-40[7] and UiO-7.[8] The arrangement in the unit cell is illustrated in Figure 3. The building units are arranged in a body-centered array. Strict alternation of aluminum (and magnesium) with

[**] We thank the University of St. Andrews (GWN), the Nuffield Foundation (PAW) and the Royal Society of Edinburgh (REM) for financial support, the ESRF for synchrotron beam time, and the EPSRC Solid State NMR service at UMIST, and in particular Miss B. E. Gore, for the MAS-NMR spectra.

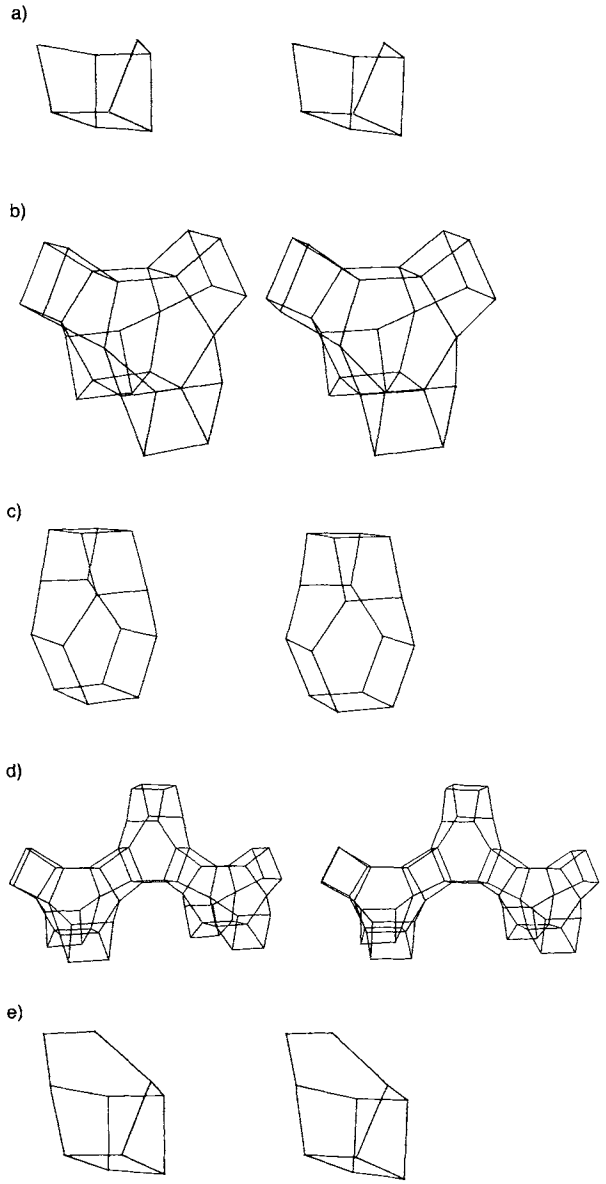

Figure 2. Crystal structure of STA-1: Stereopairs of the asymmetric unit (a) and the secondary building units (b, c) The linkage of two units of type b) to one of type c) is indicated in (d). In the structure four units of type (b) would be joined through shared four-rings to one of type (c). The building unit (b) may also be thought of as being made up of four subunits of type (e) fused together. For simplicity the oxygen atoms are omitted.

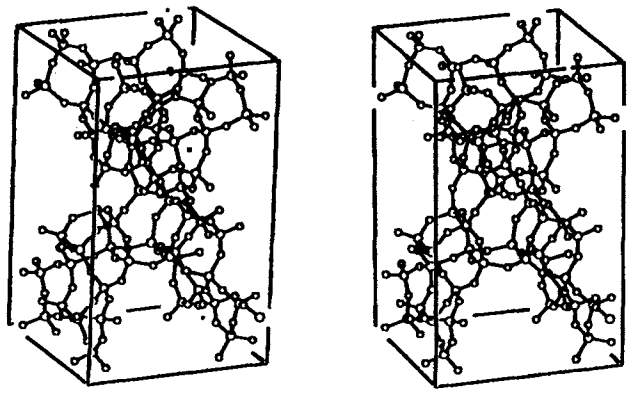

Figure 3. Arrangement of secondary building units within the unit cell. The body-centered symmetry of the arrangement of structural units is broken by the ordering of Al (or magnesium) and phosphorus atoms in the aluminophosphate structure.

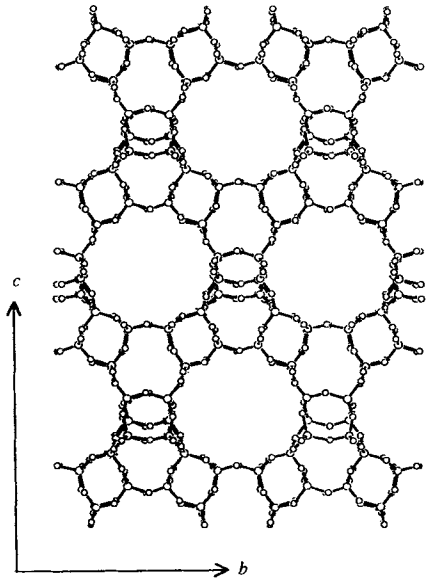

Figure 4. Crystal structure of STA-1: A projection of the structure onto the (100) plane, showing the 12-ring openings to the channels. These intersect another set of channels running parallel to [010] in 12-ring openings. Oxygen atoms are included in the figure.

phosphorus atoms in the tetrahedral cation sites lowers the symmetry to primitive. The structure has large-pore channels, bounded by 12-rings, that run parallel to both [100] and [010], but are offset in the z direction. A projection along [100] is shown in Figure 4. These channel systems are linked in the z direction to form large cavities, so that the connectivity is three-dimensional, although the channel pathway in this direction is not straight.

STA-1 has a very low framework density (13.4 tetrahedra per 1000 Å^3 at room temperature) that is only a little greater than that of the least dense aluminophosphate-based solids AlPO-50 (12.5 tetrahedra per 1000 Å^3) and AlPO-37 (12.7) and less than AlPO-46 (13.7), DAF-1 (14.1), and VPI-5 (14.2).[9]

The synthesis and structure solution of STA-1 underlines both the potential of rational template design for the preparation of novel microporous solids and also the power of modern synchrotron crystallographic facilities. The clearcut dependence of the crystallization field of STA-1 on the length of the oligomethylene chain linking the diquinuclidinium end groups suggests that the template is able to find a very specific and energetically favorable site next to the framework. This approach, by which a "supramolecular" template of desired shape can be built from readily available compounds, should be of wide applicability for the synthesis of microporous solids. The structure solution of STA-1 is, to our knowledge, the first of a completely novel framework that uses microcrystal diffraction at a synchrotron source, although successful solution of structures closely related to those solved by other methods has already been achieved. The power of the technique is such that crystals of microporous solids that are much smaller than those of STA-1 can readily be studied.[12]

Experimental Section

A family of diquinuclidinium templates of the general formula $[(C_7H_{13}N)-(CH_2)_n-(NC_7H_{13})]Br_2$, $n = 3-10$, was prepared by the reaction of quinuclidine with α,ω-dibromoalkanes (2:1) in ethanol at 70 °C for 72 h. The diquinuclidinium bromides

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3601-0082 $ 15.00+.25/0

were washed with cold ethyl acetate and dried. ^{13}C NMR spectra of the products in solution in D_2O were recorded. The bromides were converted into hydroxides with Ag_2O to produce mildly acidic or neutral gels. These were prepared by the addition of aluminum hydroxide hydrate ($Al(OH)_3 \cdot x H_2O$, Aldrich), magnesium acetate tetrahydrate, orthophosphoric acid, and the diquinuclidinium hydroxide to distilled water in the molar ratio of 0.9:0.1:1.0:0.4:40. The gels were heated without stirring at 190 °C for 48 h in a stainless steel, PTFE-lined autoclave. The MgAPOs were characterized by X-ray powder diffraction with a STOE STADIP automated diffractometer and analyzed thermogravimetrically. The density of STA-1 was determined with the aid of a variable mixture of diiodomethane (3.325 g cm^{-3}) and 1-bromobutane (1.276 g cm^{-3}). ^{31}P, ^{27}Al and ^{13}C MAS-NMR spectra were obtained with a Bruker 400 MSL spectrometer. The ^{13}C NMR spectrum of the template within STA-1 in the solid state (δ = 65.4, 56.1, and a broad envelope of peaks between 30 and 20, maximum at 24.5, for the n = 8 template) corresponded closely with that in solution with higher resolution (δ = 64.31, 54.64, 27.73, 25.51, 23.40, 21.36, 19.10). Chemical analysis was performed by EDX of X-rays emitted in an electron microscope.

Single-crystal diffraction data were collected on the Materials Science Beamline (ID-11, BL2) at the ESRF, Grenoble [10]. A crystal of approximate dimensions 30 × 30 × 30 μm was glued to a fine glass fiber and mounted on the three-circle fixed kappa Siemens diffractometer fitted with a Siemens SMART CCD detector and cooled to 200 K. The wavelength was calibrated prior to the experiment as 0.484 Å. Individual frames (1250) were collected at ω intervals of 0.1°, during which the detector covered 8° < 2θ < 28°, corresponding to a d-spacing range 1.000 < d < 3.469 Å. Normalization and integration of the data carried out with Siemens SAINT software gave refined lattice parameters of a = 13.620(4) and c = 21.649(5) Å for 411 contributing reflections. A total of 2097 reflections were processed, of which 954 were unique and 845 considered observed ($I > 3\sigma(I)$). The space group was identified as $P\bar{4}n2$ from the systematic absences and intensity statistics. The framework structure was solved with SIR92 and refined with the teXsan suite [11] to final agreement factors R = 0.059, Rw = 0.076. The positions of the template molecules could not be determined from the single crystal data, presumably due to disorder, and the simulated powder diffraction pattern calculated from the single-crystal data closely matched the observed pattern measured over the same range, although the intensities of reflections with higher d-spacings were very different, due to the presence of extra-framework scattering. Atomic coordinates of STA-1 are given in Table 1. At 200 K the structure has a cell volume of 4016 Å and a calculated density, including template molecules and water, of 1.815 g cm^{-3}. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-405444.

Probing Gaseous Ion–Molecule Complexes with Chiral Agents: The Reaction of Arenium Ions with (*R*)-(−)-*s*-Butyl Chloride**

Massimiliano Aschi, Fulvio Cacace,* and Anna Troiani

Gaseous ion-neutral complexes (INC) are currently the focus of active interest, owing to the increasing recognition of their role in a variety of ionic processes.[1, 2] Crucial questions concern the chemical identity and the relative spatial arrangement of the reactants confined in the complex, two features of paramount importance to assess the kinetic and mechanistic role of the INC. Direct experimental information on these points is very scarce, which accounts for the recourse to theoretical approaches in systems of particular interest.[3, 4]

We report here the first use of a chiral reagent in the characterization of gaseous INCs. A class of aromatic substitutions that do not conform to the conventional mechanism but follow the route delineated in Equation (a), in which ArH_2^+ denotes the

$$ArH_2^+ + P \longrightarrow \underset{\text{INC 1}}{[ArH_2^+, P]} \xrightarrow[\text{transfer}]{H^+} \underset{\text{INC 2}}{[ArH, E^+]} \longrightarrow \underset{\sigma\text{-Complex}}{ArHE^+} \qquad \text{(a)}$$

arenium ions and P a proelectrophile, that is, a neutral molecule whose protonation within the complex generates the electrophile E^+, have been studied. The quite general reaction has been nicknamed a 'Crafts–Friedel' reaction in the specific case of alkylation to underline the exchange of roles relative to the conventional course.[5–7] Among other examples, aromatic *s*-butylation has been demonstrated to occur according to sequence (a) within the INC formed upon addition of the benzenium ion to *s*-butyl chloride. Fourier-transform ion-cyclotron resonance (FT-ICR) mass spectrometry shows that the alkylation takes place at 300 K with a rate constant of about 5×10^{-11} cm^3 s^{-1} per molecule, corresponding to a collision

efficiency of about 2.5%. In these low-pressure experiments the $C_{10}H_{15}^+$ ion ($m/z = 135$), that is, protonated *s*-butylbenzene, is accompanied by minor fragments, namely, the $C_4H_9^+$ ($m/z = 57$) and the $C_{10}H_{13}^+$ ions ($m/z = 133$).[7] The FT-ICR results provide no information on the electrophile responsible for the intracomplex alkylation—which could be either a halonium (INC **2a**) or a carbenium ion (INC **2b**)—nor on its relative

$[C_6H_6, s\text{-}C_4H_9ClH^+]$ $[C_6H_6, s\text{-}C_4H_9^+, HCl]$

spatial juxtaposition with the arene. In particular this concerns the mechanistically relevant question whether the complex has a definite structure, that is whether the arene and the electrophile are in a fixed geometrical arrangement.

In radiolytic experiments mixtures containing CD_4 as the bulk component are irradiated together with traces of $^{12}C_6H_6$[8] and (*R*)-(−)-*s*-butyl chloride (Table 1). Ionization of CD_4 gives

Table 1. Aromatic alkylation in the gaseous complexes formed upon addition of $C_6DH_6^+$ and $CH_3C_6H_6^+$ ions to (*R*)-(−)-*s*-butyl chloride.

$C_nD_5^+$ ions ($n = 1, 2$), which undergo exothermic deuteron transfer to C_6H_6 to give $C_6DH_6^+$ ions. Following collisional thermalization and intramolecular isotopic randomization, the benzenium ions interact with *s*-C_4H_9Cl promoting sequence (a) whose product, the *s*-$C_4H_9C_6DH_5^+$ ion, is deprotonated by a gaseous base, eventually yielding *s*-$C_4H_9C_6DH_4$.[9] It should be noted that conventional alkylation promoted by deuteron transfer to *s*-butyl chloride [Eq. (b)] does occur as well, but yields

$$C_nD_5^+ + s\text{-}C_4H_9Cl \longrightarrow C_nD_4 + DCl + s\text{-}C_4H_9^+ \xrightarrow{+C_6H_6} s\text{-}C_4H_9C_6H_6^+ \quad (b)$$

unlabeled *s*-butylbenzene. The neutral products have been analyzed by GC-MS on a capillary column coated with a chiral stationary phase. The results, illustrated in Table 1, show that sequence (a) is moderately efficient, characterized by a *s*-$C_4H_9C_6DH_4$ G_{+M} value of 0.12. This corresponds to a 10% abundance of deuterated molecules in the *s*-butylbenzene formed, which allows reliable enantiomeric analysis. The paramount result is that complete racemization is observed, as illustrated in the typical chromatogram of Figure 1. In an ancillary experiment methylbenzenium ions were formed by methylation of C_6H_6 with $(CH_3)_2F^+$ ions, generated by irradiating CH_3F.[9] The yields of *s*-$C_4H_9C_6H_4CH_3$ isomers from $CH_3C_6H_6^+$ are much lower than those of *s*-$C_4H_9C_6DH_4$ from $C_6DH_6^+$, owing to the higher basicity of $CH_3C_6H_5$ than of C_6DH_5, which makes intracomplex proton transfer energetically more unfavorable. Nevertheless, also in this case the enantiomeric analysis of the *meta* and *para* isomers, the only ones amenable to chiral resolution by the column employed, show complete racemization (Figure 2).

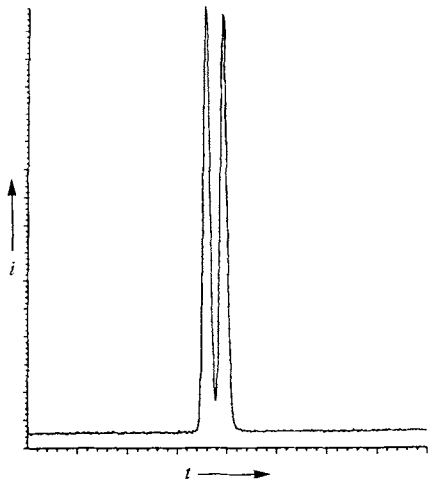

Figure 1. Enantiomeric resolution by GC/MS of racemic *s*-$C_4H_9C_6DH_4$ from the reaction of $C_6DH_6^+$ with (*R*)-(−)-*s*-C_4H_9Cl. Time profile of the intensity of the molecular ion at $m/z = 135$.

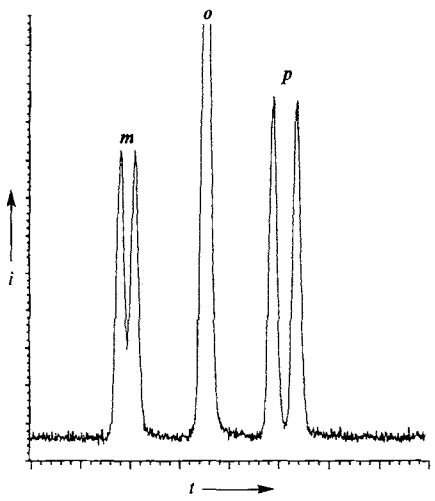

Figure 2. Partial enantiomeric separation by GC/MS of the $CH_3C_6H_4$-*s*-C_4H_9 isomers from the reaction of $C_7H_9^+$ with (*R*)-(−)-*s*-C_4H_9Cl. Time profile of the intensity of the molecular ion at $m/z = 148$.

The result elucidates the nature of the electrophilic reagent: the nucleophilic attack of the arene on optically active *s*-$C_4H_9ClH^+$ would be expected to be stereoselective and to lead to inversion rather than to the observed racemization.

A recent theoretical analysis of the other candidate, the *s*-butyl cation, is consistent with the results of NMR, ESCA,[10–13] and solvolytic studies[14] and has identified several species of comparable stability, namely, a *cis* and *trans* H-bridged ion, a CH_3-bridged ion, and two classical ions whose energies are very close (within a 2.3 kcal mol^{-1} range).[15] Interconversion of relevant structures, allowed by the relatively flat energy hypersurface of this region of the *s*-$C_4H_9^+$ system, and possibly catalyzed by the neutrals present in the complex, may well account per se for the observed racemization. Even if one assumes that differential solvation effects stabilize the classical *s*-butyl cation within the INC, racemization can occur as well, provided that internal rotation of the electrophile with respect to the arene is allowed. In summary, the results deny any role for *s*-$C_4H_9ClH^+$ and identify *s*-$C_4H_9^+$ as the electrophile responsible for the intracomplex alkylation.

Another relevant point concerns the spatial correlation of the reactants. Should the electrophile be generated in a fixed geo-

metrical position relative to the aromatic ring ("structured" complex) and retain the position until substitution takes place, for example according to a concerted mechanism, pronounced stereoselectivity would be expected in contrast to the experimental results. Instead, the picture emerging from the present study is consistent with a model in which the reagents confined in INC **2b** are not constrained in a fixed geometrical arrangement ("loose" complex).

Despite its preliminary nature, this study shows that the use of chiral reagents can probe gaseous INCs, in particular with regard to the identity of the reacting species and the structure of the complex ("loose" vs "structured"). Further work along these lines is in progress, and the results will be reported in a full paper.

Experimental Procedure

All reagents were obtained from commercial sources or prepared according to standard procedures. CD_4 (99 atom% *D*) and $^{12}C_6H_6$ (99.9 atom% ^{12}C) were purchased from Cambridge Isotope Laboratories. *R*-(−)-*s*-butyl chloride was prepared from *S*-(+)-*s*-butanol (Aldrich) [16, 17] and its enantiomeric purity was checked by GC with the same column employed for the analysis of the radiolytic products (25-m long, 0.25 mm i.d. fused-silica capillary column coated with DACTBS-Beta-CDX chiral phase from Mega). The radiolysis was performed at 25 °C in a commercial γ-irradiation facility to a total dose of 2.5×10^4 Gy.

On the Mobility of Trivalent Ions: Pr^{3+} in Pr^{3+}-β''-Al_2O_3**

Joachim Köhler and Werner Urland*

A growing number of reports on ion-conducting systems with trivalent ions as mobile charge carriers were published recently.[1–3] Indications for charge transport processes of that kind were found particularly in the lanthanide ion exchanged Na^+-β''-aluminas Na^+/Ln^{3+}-β''-Al_2O_3 (Ln = La,[4] Pr,[1, 5, 6, 7] Gd,[3] Ho[2]), as well as in rare earth tungstates, for example $Sc_2(WO_4)_3$.[8]

From electrostatic considerations ions with a low charge are especially suitable for the transport of ionic current. Accordingly, numerous cationic ion-conducting systems with monovalent ions exist (for example α-AgI, Na^+-β''-Al_2O_3, and Li_3N). In contrast, only few compounds containing mobile divalent cations (for example M^{2+}-β''-Al_2O_3 where M = Ca, Sr, Pb) or trivalent charge carriers are known. Within these systems the ion transport is hindered by strong coulombic interactions between the polyvalent ions and the surrounding host lattice. In this report we present temperature-dependent, single-crystal X-ray diffraction[9] that confirms and substantiates the results concerning ion conduction by mobile trivalent cations obtained from impedance spectroscopic measurements on the Na^+/Pr^{3+}-β''-Al_2O_3[1, 6] system.

Generally, the composition of the Mg^{2+}-stabilized superionic conductor Na^+-β''-Al_2O_3 is given by the formula $Na_{1+x}Mg_xAl_{11-x}O_{17}$ ($x = 0.24$–0.70). The layered crystal structure[10] consists of alternating sequences of close-packed spinel block layers and the "conduction planes" with loosely packed oxygen layers (three-quarters of the oxygen positions remain unoccupied). The spinel blocks are interconnected by covalent Al-O-Al bonds as well as by coulombic attractive forces between the Na^+ ions (which are located exclusively within the conduction planes) to adjacent oxygen ions. The lowered oxygen occupation facilitates a comparatively easy Na^+ migration generating the two-dimensional ionic conductivity. Due to the high mobility the Na^+ ions can be replaced by other mono-, di-, and trivalent cations, particularly by lanthanide ions (for example $Na_{1+x-y}Ln_{y/3}Mg_xAl_{11-x}O_{17}$).[11, 12] These alumina compounds offer an easy opportunity to vary the conducting ion within an ion-conducting system and to investigate the dependence of the ionic conductivity on the type and concentration of the charge carrier.

An idealized representation of a conduction plane in Na^+-β''-Al_2O_3 (*ab*-plane) is given in Figure 1. Two different crystallographic positions within the planes are available to the cations: the Beevers–Ross (BR) position (C_{3v} symmetry) with a triply capped tetrahedron (4 + 3 coordination) and the eight-coordinate "mid-oxygen" (mO) position (C_{2h} symmetry, doubly capped octahedron). The height H_L of the conduction layers (extension in *c* direction) is determined through coulombic interactions by the type (size and charge) and concentration of the cations located within these planes. H_L decreases with increasing cation concentration as demonstrated recently by X-ray diffraction studies on Na^+-β''-Al_2O_3[6, 13] and Pr^{3+}-β''-Al_2O_3.[14] In turn H_L influences the cation distribution within the planes as

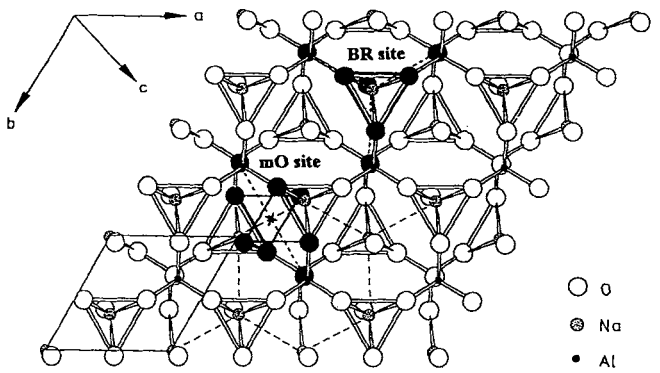

Figure 1. Idealized representation of a conduction plane in Na^+-β''-Al_2O_3 ($R\bar{3}m$, $Z = 3$) with the adjoining oxygen layers of the adjacent spinel blocks. Corresponding to the hypothetical composition $Na_2MgAl_{10}O_{17}$ the BR sites are fully occupied by Na^+ ions. The coordination spheres of a BR and an mO site are displayed as black circles. The dashed lines indicate possible pathways of the Na^+ ions. The hexagonal unit cell is represented by solid lines.

well as the ionic conduction behavior.[14, 15] The ion transport in the conduction layers is achieved by migration of mobile charge carriers between nonequivalent sites (see conduction pathways in Figure 1). In the fully exchanged Na^+/Pr^{3+}-β''-Al_2O_3 crystal[16] with the composition $Na_{0.01}Pr_{0.53}Mg_{0.72}Al_{10.33}O_{17}$ (degree of exchange $\xi = 99\%$)[17] Pr^{3+} ions, nearly exclusively, are available for the current transport. Raising the temperature is expected to increase the mobility of these cations. The migration should be detectable from the difference in site occupations in X-ray crystal structure investigations.

The most important result of these measurements is given in Figure 2.[18] The dependence of the fraction of the Pr^{3+} ions occupying BR sites ($x_{BR}(Pr^{3+})$) on temperature is depicted. At

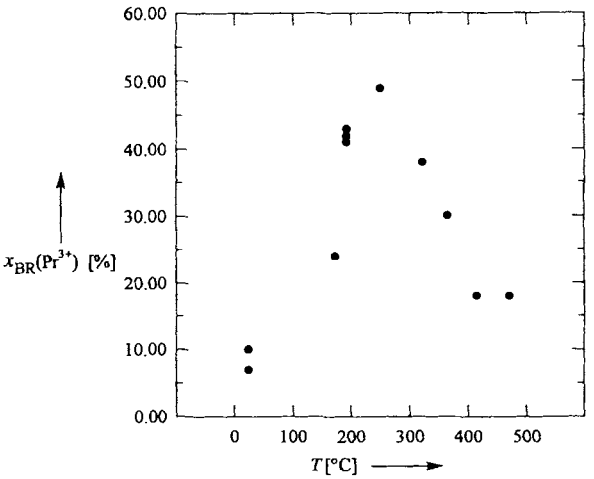

Figure 2. Dependence of the percentage BR site occupation (x_{BR}) with Pr^{3+} ions on temperature in $Na_{0.01}Pr_{0.53}Mg_{0.72}Al_{10.33}O_{17}$.

room temperature 7–10% of the cations are in BR and 90–93% in mO positions. This ratio agrees well with the results of calculations based on the crystal composition.[6, 14] Increased temperature leads to elevated BR occupations. Even at 180 °C about 25% of the Pr^{3+} ions occupy BR sites, whereas at 250 °C the two positions are occupied nearly equally. However, a further temperature increase leads to a redistribution of the Pr^{3+} ions into the mO sites again. At temperatures above 400 °C the occupation ratio (x_{BR}:x_{mO}) amounts to 17:83 for the two crystallographic positions.

These results indicate considerable Pr^{3+} mobility at elevated temperatures. The activation energy E_a required for every site exchange process differs for the two sites: it is significantly larger for departure from the BR sites than for departure from the mO sites ($E_a(BR) > E_a(mO)$). The Pr^{3+} ions are able to leave the mO sites at comparatively low temperatures ($T < 180$ °C). In contrast, the thermal energy is not sufficient in the temperature range $25 < T < 250$ °C to facilitate the migration from the BR into mO sites. Consequently, the Pr^{3+} ions accumulate in the BR positions with lower coordination number. Only above 250 °C (the so-called transition temperature T_t) are the Pr^{3+} ions in BR sites sufficiently thermally activated to overcome the potential barriers to migrate from BR into mO positions. Therefore, the percentage BR occupation $x_{BR}(Pr^{3+})$ is lowered in the temperature range $250 < T < 400$ °C from 50% to 17% at temperatures above 400 °C. This behavior differs significantly from temperature-induced site exchange processes in some spinels in which no ionic conductivity is observed.

On cooling the system slowly from 250 °C to room temperature the original cation distribution (x_{BR}:x_{mO} = 7:93) is not restored. The fraction of Pr^{3+} ions occupying BR sites are rather trapped within these positions. The required activation energy for leaving the BR sites is no longer provided thermally. About 50% of all Pr^{3+} ions are found within the BR positions after cooling (not shown in Figure 2).

All of the results presented here agree very well with data obtained from impedance spectroscopic measurements on Na^+/Pr^{3+}-β''-Al_2O_3 crystals.[1, 6, 7] Figure 3 shows the conductivity

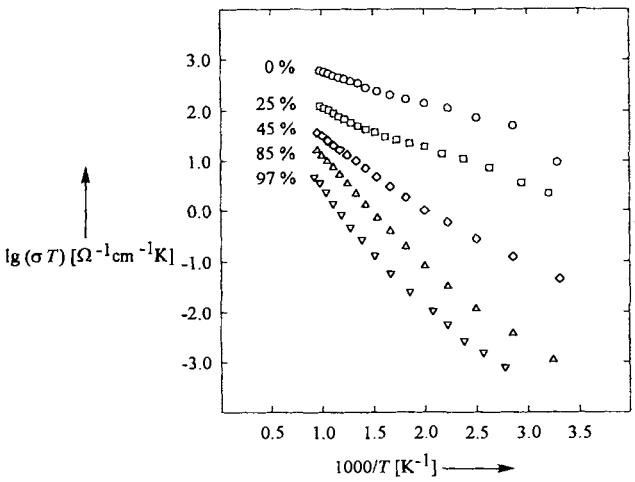

Figure 3. Arrhenius plot of Na^+/Pr^{3+}-β''-Al_2O_3 crystals differing in degree of exchange.

data in form of an Arrhenius diagram for selected Na^+/Pr^{3+}-β''-Al_2O_3 crystals with different degrees of exchange.[1] Two temperature regions are distinguishable and can be interpreted as follows: At low temperatures the conductivity is generated by the mobility of unexchanged Na^+ ions, whereas the steeper conductivity curve in the higher temperature region is due to the enhanced mobility of the Pr^{3+} ions.[1, 6] The start of the increased Pr^{3+} mobility is deduced from the Arrhenius plots of all investigated Na^+/Pr^{3+}-β''-Al_2O_3 crystals to be 290 ± 40 °C (by determining the intersection of the two straight lines obtained by the extrapolation of the experimental data within the upper and lower temperature range).[6, 15] Exactly in this tem-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3601-0086 $ 15.00+.25/0

perature region the migration of the Pr^{3+} ions from BR into mO sites sets in, as mentioned above.

The ionic conduction behavior of Na^+/Pr^{3+}-β''-Al_2O_3 can therefore be described as follows: At temperatures below 250 °C an exchange of sites (from mO into BR positions) is only possible for those Pr^{3+} ions occupying mO positions, but a further migration from the BR sites with lower coordination number is not possible. Despite this partial mobility a continous current is not detectable, because the ions trapped within the BR positions interrupt the current transport. The observed conductivities at these low temperatures are caused by residual, unexchanged Na^+ ions, which are able to pass through both sites without any hindrance. Only above 250 °C are the Pr^{3+} ions completely mobile. These trivalent cations are now able to overcome all potential barriers along the conduction pathways. Consequently, ion transport is detectable, and an increase in ionic conductivity occurs (cf. Figure 3).

The above-mentioned transition temperature ($T_t = 250$ °C) only holds for Na^+/Pr^{3+}-β''-Al_2O_3 crystals with the composition $Na_{0.01}Pr_{0.53}Mg_{0.72}Al_{10.33}O_{17}$ because of the pronounced dependence of the height H_L of the conduction layers on the cation concentration.[14] For steric reasons the extension of H_L in turn influences the size of the potential barrier that must be overcome by ions leaving BR sites. Appropriate experiments to investigate quantitatively the correlation of the cation concentration with the transition temperature are under way.

Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository numbers CSD-405335 (crystal a), CSD-405334 (crystal b) and CSD-405333 (crystal c).

Atom-Bridged Intermediates in N- and P-Atom Transfer Reactions**

Marc J. A. Johnson, P. Mae Lee, Aaron L. Odom, William M. Davis, and Christopher C. Cummins*

Complete intermetal N-atom transfer reactions constitute highly economical three-electron redox processes.[1] A seminal reaction of this type is the reduction of [NMn(TTP)] (TTP = *meso*-tetrakis(4-tolyl)porphyrin) by [Cr(TTP)] to give [Mn(TTP)] and [NCr(TTP)].[1] Certain quasi-degenerate intermetal N-atom transfer reactions have been subjected to kinetic studies to delineate energetic parameters innate to the atom-transfer event.[2] Evidence has been amassed regarding the role of N-atom-bridged species as intermediates in N-atom transfer reactions, but until now such intermediates have eluded characterization.[2]

It was found recently[3] that the three-coordinate molybdenum(III) complex **1**[3–7] effects N-atom abstraction from the nitrido complex **2**[8] to give **3** [3–5, 7] and (under argon) 0.5 equiv-

alents **4**[9, 10] or (under 1 atm dinitrogen) predominantly **2**. Products **4** and **2** appear to result from dimerization and dinitrogen cleavage,[5, 7] respectively, stemming from transient **5**, which was not observed. During N-atom abstraction from **2** by **1**, a blue color was observed that was tentatively attributed to the intermediate complex **6**.[3] Here we report that in a closely related reaction system, the teal N-atom bridged species **7** (R = $C(CD_3)_2CH_3$, Ar_F = 4-C_6H_4F, [Eq. (1)]) produced upon

(1)

mixing equimolar quantities of **8** and **9** is relatively robust in solution (toluene or ether) at low temperatures (ca. $-20\,^{\circ}C$ or below).

An ORTEP drawing of the structure of **7** is presented in Figure 1.[11] Salient features of the structure are a linear μ-nitrido bridge[12,13] and crystallographic threefold symmetry

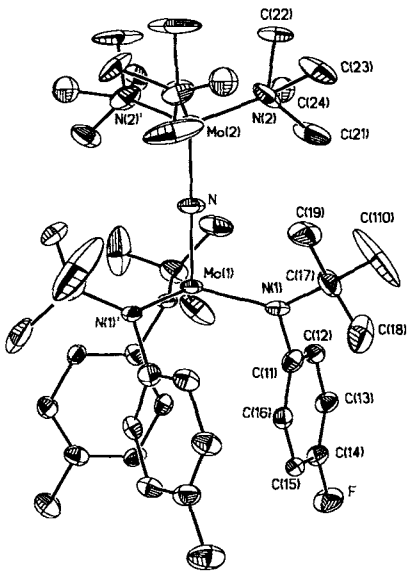

Figure 1. Crystal structure of **7** (ORTEP diagram). For a discussion of the disordered NMe_2 groups see ref. [11] and text. Selected bond lengths [Å] and angles [°]: Mo(1)–N 1.82(4), Mo(1)–N(1) 1.977(10), Mo(2)–N 1.83(4), Mo(2)–N(2) 1.969(13), N(2)–C(22) 1.36(4), N(2)–C(24) 1.39(5), N(2)–C(21) 1.42(4), N(2)–C(23) 1.50(5); N-Mo(1)-N(1) 103.9(3), N(1)'-Mo(1)-N(1) 114.4(2), N-Mo(2)-N(2) 108.9(4), N(2)'-Mo(2)-N(2) 110.0(4), Mo(1)-N-Mo(2) 180.0.

about the Mo(μ-N)Mo axis. Disorder of the $(Me_2N)_3Mo$ moiety about the threefold axis was accounted for by a model in which one dimethylamido group is oriented with its NC_2 plane perpendicular to the molecular threefold axis, and the other two NMe_2 groups adopt a parallel orientation thereto.[11] In this model, although each molecule of **7** conforms to C_1 point symmetry, three equally probable orientations of **7** in the unit cell result in crystallographic threefold symmetry and the observed disorder. Observation of the C_1-symmetric structure of **7** as opposed to an alternative C_3-symmetric structure can be attributed to a Jahn–Teller distortion for this $(1\pi_u)^4(1\pi_g)^3$ system. Although the μ-nitrido nitrogen atom appears to be symmetrically disposed between the inequivalent Mo centers, relatively high esd's associated with this atom prohibit a firm conclusion in this regard.[11] The C_3-symmetric conformation of the Mo(NRAr$_F$)$_3$ moiety in **7** is as observed previously for several [XM(NRAr)$_3$] molecules;[6,14,15] the apical group X is commonly located in the pocket presented by the three groups R, and the three aryl groups pack tightly in a trigonal construction that protects the opposite hemisphere of the complex. Conversion of **7** to the putative transient **10** and the terminal nitrido complex **11** represents the complete intermetal N-atom transfer process for this reaction system. Thermal transformations of **7** are currently under scrutiny.

"[Mo(NMe$_2$)$_3$]" **10**

[NMo(NRAr$_F$)$_3$] **11**

Evidence for complete N-atom transfer was obtained in a related system as follows: a single crystal obtained by cooling a solution in which equimolar quantities of **8** and **12**[7] had been

[Mo(N*t*BuPh)$_3$] **12**

[Mo$_2$(NMe$_2$)$_6$] **13**

[(Me$_2$N)$_3$Mo(μ-N)Mo(NMe$_2$)$_3$] **14**

combined at 28 °C was studied by X-ray crystallography and found to contain a 1:1 mixture of known dimer **13**[16–18] and the symmetrical μ-nitrido complex **14** (Figure 2).[19] The structure of dimer **13** is as reported previously.[17] More intriguing is the structure of μ-nitrido-bridged complex **14**, which may be considered the product of reaction between transient **10** and the terminal nitrido complex **8** (Scheme 1). The μ-nitrido nitrogen atom in **14** resides at a crystallographic inversion center, which when combined with the absence of a crystallographic threefold axis along the linear Mo(μ-N)Mo vector leads to the point group assignment C_i for the molecular complex **14**. In principle less-favored for **14** would be more symmetrical S_6 and D_{3d} structures, invoking the Jahn–Teller theorem for $(1\pi_u)^4(1\pi_g)^3$ **14** as for **7** above. The unique Mo-μ-N distance in **14** corresponds approximately to bond order two. The geometry at molybdenum is pseudotetrahedral. From a chemical point of view **14** is probably best regarded as a source of putative transient **10**, since disintegration of either Mo-μ-N linkage would produce **10** along with the terminal nitrido complex **8**. Dimerization of **10**, in which the Mo center is three-coordinate, would produce **13** (Scheme 1).

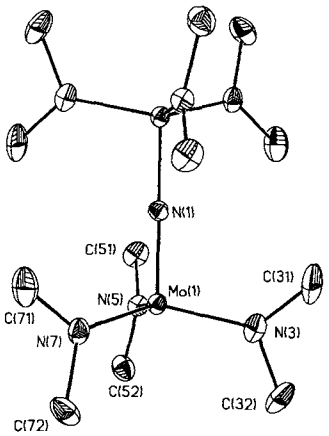

Figure 2. Crystal structure of **14** (ORTEP diagram). Selected bond lengths [Å] and angles [°]: Mo(1)–N(1) 1.7990(8), Mo(1)–N(3) 1.948(9), Mo(1)–N(5) 1.953(8), Mo(1)-N(7) 1.955(8); N(1)-Mo(1)-N(3) 100.1(3), N(1)-Mo(1)-N(5) 99.4(2), N(3)-Mo(1)-N(5) 116.6(4), N(1)-Mo(1)-N(7) 100.0(3), N(3)-Mo(1)-N(7) 117.3(4), N(5)-Mo(1)-N(7) 117.6(3).

The symmetrical μ-nitrido complex **14** was isolated in pure form by treatment of **12** with two equivalents of **8** (see Experimental Section). Complex **14** exhibits a single broad ^{1}H NMR signal at about $\delta = 7$ in C_7D_8 at 22 °C, and the compound transforms smoothly to give a mixture of dimer **13** and the terminal nitrido complex **8** upon stirring under N_2 (1 atm) at 28 °C for 90 min, as assayed by ^{1}H and ^{13}C NMR spectroscopies.

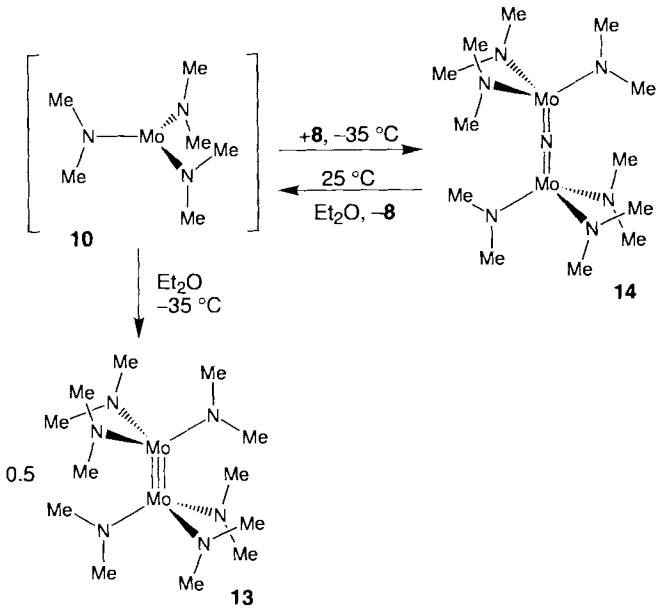


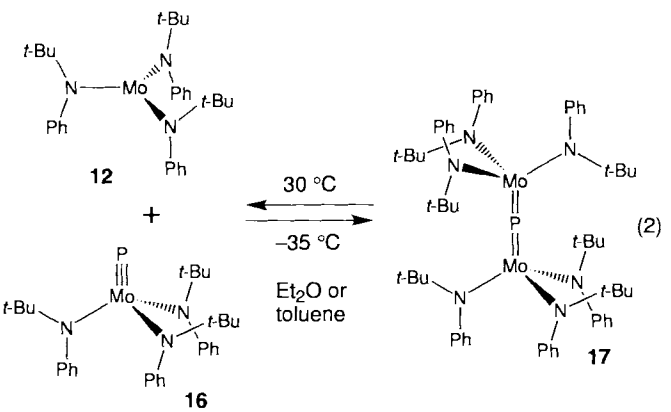
Scheme 1. Possible reactions involving the participation of the putative transient **10**.

Robust terminal phosphido (P^{3-}) complexes were discovered recently.[6, 20, 21] One might suspect that these heavy analogues of terminal nitrido complexes are equipped to engage in intermetal P-atom transfer processes. Accordingly, we find that mixing equimolar quantities of **15**[6] and **12**[7] in toluene leads to

$[PMo(NRAr)_3]$ **15**

$[PMo(NtBuPh)_3]$ **16**

reversible P-atom transfer at 25 °C; ^{31}P NMR signals were observed at $\delta = 1216$ and 1226 for terminal phosphido complexes **15** and **16**, respectively. Cooling an equimolar mixture of **12** and **16** in toluene to −35 °C elicits a color change from red-brown to purple [Eq. (2)] that is reversible upon repeated warming and



cooling cycles. The purple color is attributed to the symmetrical bridging phosphido[22] complex **17**, which has been isolated and characterized by X-ray crystallography (Figure 3).[23]

Complex **17** possesses C_i symmetry in the crystal, reminiscent of the structure of the μ-nitrido complex **14**. In fact, the description of **14** given above applies in many respects to **17**. The disposition of planar NC_2 fragments relative to the linear Mo-(μ-E)Mo (E = N or P) core is very similar in the two complexes. Two molybdenum atoms at 2.2430(6) Å flank the symmetrically bridging phosphorus atom in **17**; the Mo–P distances in **15** and

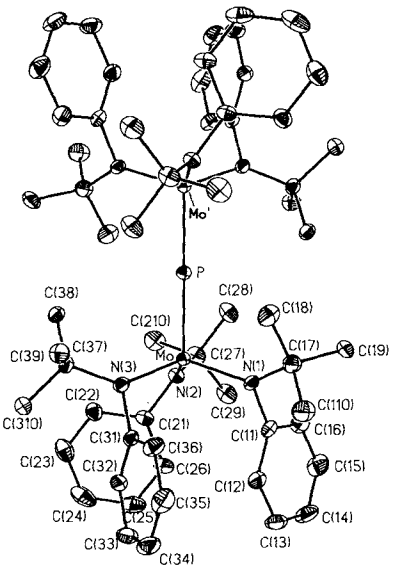


Figure 3. Crystal structure of **17** (ORTEP diagram). Selected bond lengths [Å] and angles [°]: Mo–N(1) 1.990(6), Mo–N(2) 1.992(6), Mo–N(3) 1.993(6), Mo–P 2.2430(6); N(1)-Mo-N(2) 113.8(2), N(1)-Mo-N(3) 110.6(2), N(2)-Mo-N(3) 112.4(2), N(1)-Mo-P 106.2(2), N(2)-Mo-P 106.2(2), N(3)-Mo-P 107.2(2), Mo'-P-Mo 180.0.

16 are 2.119(4) and 2.111(2) Å, respectively. Based on the Mo–P distances in **17** and on the probable electronic configuration of its Mo(μ-P)Mo π system, specifically $(1\pi_u)^4(1\pi_g)^3$, a Mo–P bond order of two follows for the complex. Metrical parameters for **17**, apart from those associated with the phosphorus atom, indicate that little reorganization takes place during its formation.

The findings communicated here conclusively implicate atom-bridged species as intermediates in intermetal N- and P-atom transfer reactions involving the Mo^{III}/Mo^{VI} redox couple. Energetic parameters pertaining to these overtly simple transformations are now open for inquiry. Especially appealing is the synthetic utility these transformations may offer in generating reactive transients such as the putative monomer $[Mo(NMe_2)_3]$ (**10**).

Experimental Section

General: All manipulations were performed in a Vacuum Atmospheres glovebox under an atmosphere of dry nitrogen unless otherwise indicated. Solvents were freed from air and moisture by using standard procedures.

7: **8** (120.7 mg, 0.4984 mmol) and **9** (301.3 mg, 0.4918 mmol) were mixed as solids in a 20 mL scintillation vial. To the mixture was added ether (20 mL) at 28 °C, while stirring vigorously. After about 10 s, the resulting dark blue-green homogeneous solution was placed in a freezer (− 35 °C). Over a period of 4 h, dark green crystals and powder separated from the solution. The solid product was collected by filtration on a sintered glass frit and dried in vacuo (309.4 mg, 0.3619 mmol, 73.59%). ^2H NMR (46 MHz, C_7H_8, 22 °C): $\delta = 5.49$ ($\Delta\nu_{1/2} = 14$ Hz); ^{19}F NMR (282 MHz, C_7D_8, 22 °C): $\delta = -113.0$ ($\Delta\nu_{1/2} = 160$ Hz). μ_{eff} (SQUID, 5–300 K): 1.56 μ_B. Anal. calcd for $C_{36}H_{39}D_{18}F_3N_7Mo_2$: C 50.58, H 6.72, N 11.47; found: C 50.74; H 6.62, N 11.50.

8: Colorless needles of **2** (2.59 g, 7.87 mmol) were slurried in toluene (50 mL). Yellow-gold $[Ti(NMe_2)_4]$ (1.33 g, 5.93 mmol, 0.754 equiv) was added and rinsed in with additional toluene (10 mL). The reaction mixture acquired a light orange color and became homogeneous in less than 5 min. The color faded to pale yellow during the next several minutes, and the reaction solution was stirred for a total of 3 h. A ^1H NMR spectrum (C_6D_6) of an aliquot exhibited singlets for $[Ti(O\text{-}tBu)_4]$ and **8** at $\delta = 1.35$ and 3.29, respectively. The reaction mixture was placed in the freezer (− 35 °C), whereupon pale-yellow crystals formed. The crystals were isolated by filtration on a sintered glass frit, washed with pentane, and dried in vacuo (two crops: 1.53 g and 0.1576 g, 6.97 mmol, 88.6%). ^1H NMR (300 MHz, C_6D_6, 23 °C): $\delta = 3.293$ (s); ^{13}C NMR (75 MHz, C_6D_6, 23 °C): $\delta = 51.19$ (q, $J = 134$ Hz). Anal. calcd for $C_6H_{18}N_4Mo$: C 29.76, H 7.49, N 23.13; found: C 29.44, H 7.50, N 23.02.

9: White $[Li(NRAr_F)(OEt_2)]$ was prepared according to the published procedure for $[Li(NRAr)(OEt_2)]$, substituting 4-fluoroaniline for 3,5-dimethylaniline. A solution

of [Li(NRAr$_F$)(OEt$_2$)] (5.10 g, 20.1 mmol, 2.01 equiv) in diethyl ether (160 mL) was chilled until frozen, and then allowed to thaw at 28 °C. To the thawing mixture was added [MoCl$_3$(thf)$_3$] [24–26] (4.20 g, 10.0 mmol). The resulting orange suspension was stirred and, after 30 min, rapidly acquired a brown color. ^{2}H NMR spectra indicated an extent of reaction of 70% after 90 min, and greater than 80% after 2 h. The mixture was filtered through Celite on a frit after 3 h, and all volatile matter was removed from the filtrate. The crude dark brown powder was dissolved in diethyl ether (12 mL), and the solution was sparged with argon prior to storage in a tightly capped vessel at −35 °C overnight. Green-tinted yellow-brown powder was isolated by filtration on a sintered glass frit (two crops, 2.16 g, 3.53 mmol, 52.5%). M.p. 130–132 °C (decomp). ^{1}H NMR (300 MHz, C_6D_6, 23 °C): δ = 68.88 (v br s, 9H, $C(CD_3)_2CH_3$, $\Delta\nu_{1/2}$ = 900 Hz), 22.75 (br s, 6H, *meta*-C_6H_4F, $\Delta\nu_{1/2}$ = 130 Hz), −27.31 (v br s, 6H, *ortho*-C_6H_4F, $\Delta\nu_{1/2}$ = 530 Hz); ^{2}H NMR (46 MHz, Et_2O, 22 °C): δ = 69.37 ($\Delta\nu_{1/2}$ = 36 Hz); ^{19}F NMR (282 MHz, C_6D_6, 22 °C): δ = 24.76 ($\Delta\nu_{1/2}$ = 600 Hz). μ_{eff} (Evans' method, 300 MHz, C_6D_6, 21.0 °C) = 3.74 μ_B. Anal. calcd for $C_{30}H_{21}D_{18}F_3N_3Mo$: C 58.81, H 6.42, N 6.86; found: C 58.80, H 6.61, N 6.72.

11: Dark yellow powdery [Mo(NRAr$_F$)$_3$] (111.3 mg, 0.1817 mmol) was dissolved in diethyl ether (5 mL), producing a clear orange solution, to which was added neat pale yellow mesityl azide [27] (38 μL, 0.26 mmol, 1.4 equiv). The reaction mixture rapidly acquired an intense purple color, and vigorous effervescence occurred for approximately 15 s, during which time the solution became dark forest green. The mixture was stirred for a further 4 h, then solvent was removed in vacuo. The resulting dark green solid was dissolved in hexamethyldisiloxane (ca. 8 mL) and cooled to −35 °C. Fine off-white crystals formed (two crops, 74.3 mg, 0.119 mmol, 65.2%). ^{1}H NMR (499.7 MHz, $CDCl_3$, 22 °C): δ = 6.70 (pseudo triplet, 2H, *meta*), 5.97 (br dd, 2H, *ortho*), 1.36 (s, 3H, $C(CD_3)_2CH_3$); ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$, 23 °C): δ = 160.67 (d, J(C,F) = 246.0 Hz, *para*), 146.08 (s, *ipso*), 131.50 (d, J(C,F) = 8.1 Hz, *ortho*), 114.75 (d, J(C,F) = 21.8 Hz, *meta*), 61.34 (m, $C(CD_3)_2CH_3$), 32.68 (s, $C(CD_3)_2CH_3$), 32.16 (m, $C(CD_3)_2CH_3$); ^{13}C NMR (75 MHz, $CDCl_3$, 23 °C): δ = 160.67 (d m, *para*), 146.08 (t, *ipso*), 131.50 (doublet of pseudo triplets, *ortho*), 114.71 (ddd, *meta*), 61.34 (br, $C(CD_3)_2CH_3$), 32.66 (q, $C(CD_3)_2CH_3$), ca. 32.15 (m, $C(CD_3)_2CH_3$). Anal. calcd for $C_{30}H_{21}D_{18}F_3N_4Mo$: C 57.50, H 6.27, N 8.94; found: C 57.21, H 6.21, N 8.80.

14: A dark orange-brown solution of **12** (101.9 mg, 0.1885 mmol) in diethyl ether (2 mL) was added to a yellow solution of **8** (90.8 mg, 0.375 mmol, 1.99 equiv) in diethyl ether (6 mL) at 28 °C. The resulting dark teal mixture was stirred rapidly and sparged with argon for 30 s before the vial was capped tightly, taped, and placed in a freezer at −35 °C. Large black blocks formed at the bottom of the vial over several hours; an orange plate of [NMo(N*t*BuPh)$_3$] (**18**) formed on the side of the vial above the surface of the dark teal mother liquor. The solution was decanted and the crystals were dried under vacuum. The single crystal of **18** remained apart from the dark blocks, which are presumed to consist largely of **14** (50.1 mg, 0.1864 mmol, 57.1%); neither **8** nor **13** was observed in the ^{1}H NMR spectrum of the isolated product. ^{1}H NMR (500 MHz, C_7D_8, 22 °C): δ = 7.13 ($\Delta\nu_{1/2}$ = 74 Hz). Anal. calcd for $C_{12}H_{36}N_7Mo_2$: C 30.64, H 7.71, N 20.85; found: C 31.69, H 7.38, N 20.79. Chemical characterization: dark shiny crystals of **14** (40.2 mg, 0.0855 mmol) were placed in a small glass vessel to which just-melted ether was added. The vessel was sealed under nitrogen and allowed to warm to 28 °C while the mixture was stirred. The initially dark teal solution acquired a green hue over about 5 min, and became brown within 90 min, at which point volatile material was removed. ^{1}H and ^{13}C{^{1}H} NMR spectra indicated the presence of **13** and **8** in a 1:4 mole ratio as follows: ^{1}H NMR (300 MHz, C_6D_6, 23 °C): δ = 3.42 (br s, **13**), 3.29 (s, **8**); ^{13}C{^{1}H} NMR (75 MHz, C_6D_6, 40.3 °C): δ = 51.15 (**8**), 49.72 (br, **13**). No signals attributable to (N*t*BuPh)-containing compounds were observed.

14: Preparation of 1:1 co-crystal with **13**. Orange **12** (242.1 mg, 0.4478 mmol) and pale yellow **8** (108.1 mg, 0.4464 mmol) were combined in a 20 mL scintillation vial, and diethyl ether (6 mL) was added at 28 °C. The mixture was agitated until it became homogeneous and dark teal in color (ca. 45 s). The vial was then capped and stored for 5 d at −35 °C. Crystals of two morphologies separated from the solution: a) large clear pale orange crystals characteristic of **18**, and b) small, dark green blocks. A crystal of type b was investigated by X-ray diffraction and found to be a 1:1 cocrystal of **14** and **13**.

17: Yellow crystals of **16** (108.0 mg, 0.189 mmol) and wine-red crystals of **12** [7] (102.3 mg, 0.189 mmol) were added to ether (10 mL, argon-sparged) in a 20 mL scintillation vial, and the vial was tightly capped after sparging the mixture with argon. The mixture was warmed to 28 °C to ensure complete dissolution of the complexes. The vial was then placed in a freezer (−35 °C), whereupon the solution adopted an intense purple color. Crystals of dark purple **17** formed over several hours (158.9 mg, 75.6%). Crystals suitable for a single-crystal X-ray diffraction study were obtained by recrystallization from argon-sparged ether by slow cooling to −35 °C in an insulated vessel. ^{1}H NMR (300 MHz, C_7D_8, −40 °C): δ = 14.20 ($\Delta\nu_{1/2}$ = 75 Hz, 6H, C_6H_5), 13.95 ($\Delta\nu_{1/2}$ = 35 Hz, 6H, C_6H_5), 8.95 ($\Delta\nu_{1/2}$ = 17 Hz, 6H, C_6H_5), 8.65 ($\Delta\nu_{1/2}$ = 36 Hz, 54H, $C(CH_3)_3$), 6.10 ($\Delta\nu_{1/2}$ = 21 Hz, 6H, C_6H_5), 4.84 ($\Delta\nu_{1/2}$ = 36 Hz, 6H, C_6H_5). μ_{eff} (Evans' method, 300 MHz, C_7D_8, −76 °C) = 2.08 μ_B, μ_{eff} (SQUID, 5–300 K) = 1.75 μ_B.

[11] X-ray crystal structure of **7**. A batch of crystals grown from ether was coated with Paratone-N oil (Exxon). A black parallelepiped of approximate dimensions 0.40 × 0.40 × 0.12 mm was selected. Crystal data: a = 16.0996(10), c = 13.5646(9) Å, V = 3044.9(3) Å^3, Z = 3, space group $R\bar{3}$, μ = 0.664 mm^{-1}, ρ_{calcd} = 1.369 g cm^{-3}, F(000) = 1299. Data collection was carried out on a Siemens Platform goniometer with a CCD detector at 188(2) K using $Mo_{K\alpha}$ radiation (λ = 0.71073 Å). 4238 reflections were collected over the range $-17 \le h \le 16$, $-17 \le k \le 17$, and $-8 \le l \le 15$, of which 1604 were unique (R_{int} = 0.1218). The extinction coefficient was 0.0029(6). The structure was solved by direct methods in conjunction with standard difference Fourier techniques. Least squares refinement based upon F^2 converged with residuals of R_1 = 0.0692 and wR_2 = 0.1741, and GOF = 1.210 based upon $I > 2\sigma(I)$. The dimethylamido substituent has a rotational disorder. Occupancy refinement gave values close to 0.67 and 0.33 for the nitrogen trigonal plane approximately parallel and perpendicular to the crystallographic threefold axis, respectively. For final refinement the occupancies were set to these values. All non-hydrogen atoms with the exception of those involved in the disorder (C21, C22, C23, and C24) were refined anisotropically and hydrogen atoms were placed in calculated (d(C–H) = 0.96 Å) positions. The largest peak and hole in the final difference map were 0.992 and −0.966 e Å^{-3}, respectively [28].

Insertion of Functional Groups into Square-Planar Units: A New Construction Principle for Open Microporous Framework Structures

Michael Schindler* and Werner H. Baur*

Currently 98 different topologies of microporous frameworks are known,[1] most of which are based on variously bridged coordination tetrahedra of oxygen atoms around aluminum, phosphorus, and silicon centers. Much current synthetic work involving related phases is devoted to incorporating reactive transition metals into these frameworks and to devising compounds with larger pores accessible to larger molecules. The aim of this work is to increase the potential usefulness of such microporous compounds for catalytic applications.

Recently three phases were synthesized that combine the presence of a reactive transition metal with an accessible pore space; these phases are thermally reasonably stable, re- and dehydrate reversibly, and are capable of exchanging cations located in the pore space: Frankfurt vanadium phosphate one (FVP-1) **1**[2] (with $2.8 \le v \le 4.0$, $-0.1 \le w \le 1.1$, $0 \le x \le 0.2$, $0 \le y \le 2.1$, and $7 \le z \le 10$) as well as compounds **2**[3] and **3**.[3] At first sight the

$Na_v[\{(V^{4+}_{4-w}V^{5+}_{1+w})O_9\}(PO_4)_2]\cdot(PO_4)_x\cdot(OH)_y\cdot zH_2O$ **1**

$[HN(CH_2CH_2)_3NH]K_{1.35}[V_5O_9(PO_4)_2]\cdot xH_2O$ **2**

$Cs_3[V_5O_9(PO_4)_2]\cdot xH_2O$ **3**

architecture of these compounds seems to be based on different principles from those applicable to zeolite frameworks. However, on closer inspection it appears that different chemical compositions require an extension of these principles.

The exciting chemistry and topology of the bonding arrangements in vanadates and related materials has merited two recent reviews.[4] While many of these phases are based on the principle of heteropolyions of the Keggin type,[5] (i.e. these clusters do not form strong bonds outside the molecule) the units of **1**–**3** are what we denote as anti-Keggin groups (composition $[(V^{4+}_{4-w}V^{5+}_{1+w})O_9](PO_4)_2$, with $-0.1 \le w \le 1.1$),[2] in which the phosphate tetrahedra are outside of the shells of vanadium coordination polyhedra and are, therefore, able to form bridges between neighboring groups. Each of these $V_5O_9(PO_4)_2$ (or $V_5P_2O_{17}$) groups is composed of five square-pyramidally O-coordinated V atoms and four PO_4 groups (Figure 1). The central

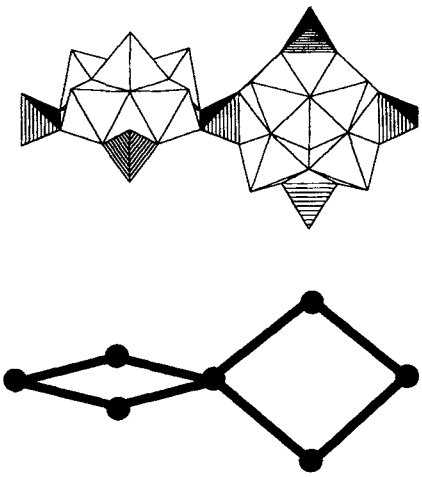

Figure 1. Two bridged spiked helmet $V_5O_9(PO_4)_2$ units (top) as well as two joined square-planar building blocks (bottom), which could, for example, represent two single four-rings (S4R) or two square-planar coordination polyhedra of O around Nb. The circles denote the connectors to neighboring groups. An individual $V_5O_9(PO_4)_2$ group consists of four connectors, in this case phosphate tetrahedra, and a central square-pyramidal coordination around V^{5+}, which shares all its basal edges with the surrounding square-pyramidal coordination polyhedron around V^{4+}. The symmetry of one spiked helmet $V_5O_9(PO_4)_2$ unit is $4mm$.

vanadyl oxygen atom is bonded to a V^{5+} ion, its position on the hemispherical-shaped group is reminiscent of the spike on a spiked helmet.[2] However, in a topological sense the vanadium coordination polyhedra are only decoration. The active parts of the group are the phosphate tetrahedra that connect the planar square groups at their corners after twists of about 90° (Figure 1). Thus, we must initially consider nets composed of square-planar groupings.

As far as we know, nets of bonds have not been studied from this viewpoint. However, studies by Wells[6] and Smith[7] include useful information on this topic. We consider our basic building units to be four-connected square-planar groups, which can differ considerably in terms of their chemistry and size. Thus, the planar four-coordinations of oxygen atoms around Nb (and Nb around O) yield in one topology the NbO crystal structure type[8] (Figure 2a and Table 1), and single four-rings (S4R) of silicate tetrahedra $Si_4O_4O_{8/2}$ yield within the NbO framework the crystal structure of the zeolite sodalite[9] (Figure 2b and Table 1). By connecting the squares we can obtain either the framework of **1** (and **3**) with the spiked helmet unit as the building block (Figure 2c, Table 1) or the framework of **4**[10] (not illustrated) with the square-planar $Mo_4O_8(PO_4)_2$ group as the building block. The central part of this group

$[(CH_3)_4N]_{1.3}(H_3O)_{0.7}[Mo_4O_8(PO_4)_2]\cdot 2H_2O$ **4**

consists of a $Mo_4O_8^{4+}$ cube with four molybdenyl (Mo=O) groups and two Mo–Mo bonds; that is, it is chemically completely different from the vanadium phosphate groups in **1** and **3** but the connectivity properties of both groups are identical. Thus, we know four frameworks, which are constructed by con-

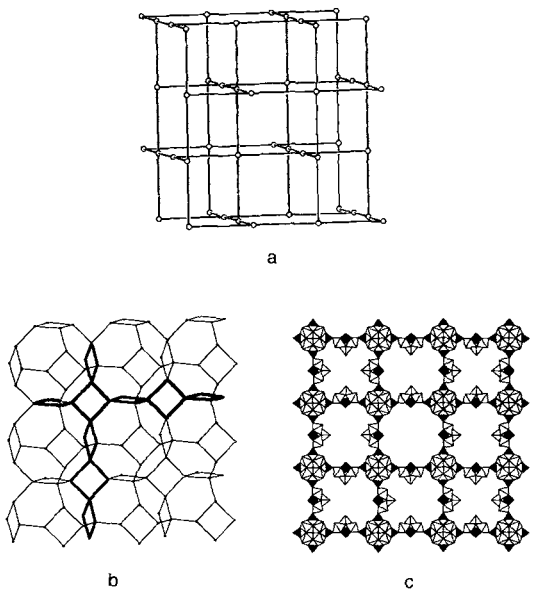

Figure 2. The underlying nets of the αSOD topologies (viewed approximately parallel to [001]): a) NbO-type: Nb and O are represented by circles of the same size; b) sodalite: the tetrahedral centers are indicated by small circles, two of the twisted ts chains are highlighted; c) polyhedral representation of the framework of **1**: the spiked helmet $V_5O_9(PO_4)_2$ units are shown in one of their possible orientations.

Table 1. Frameworks classified as belonging to the αSOD, αRHO, and αMER general topologies of connecting square-planar building units. The chemical compositions apply only to the frameworks themselves, not to the pore contents of the corresponding compounds. Compound **3**, the ordered counterpart of **1**, belongs also to the αSOD type of net, but crystallizes in the space group $Fd\bar{3}m$.

	αSOD	αRHO	αMER
framework	Nb_3O_3	?	?
cell constants [Å]	4.21		
FD [a]	40.2		
space group	$Pm\bar{3}m$		
framework	sodalite	zeolite rho	zeolite W
composition	$Al_6Si_6O_{24}$	$Al_{12}Si_{36}O_{96}$	$Al_{10}Si_{22}O_{64}$
cell constants [Å]	8.87	14.66	14.09, 14.20, 10.04
FD [a]	17.0	15.2	15.9
space group	$P\bar{4}3n$	$I\bar{4}3m$	$Immm$
framework	**1**	**2**	(hypothetical)
composition	$V_{30}P_{12}O_{102}$	$V_{120}P_{48}O_{408}$	$V_{80}P_{32}O_{272}$
cell constants [Å]	16.03	26.25	25.5, 25.5, 18.1
FD [a]	10.2	9.3	9.5
space group	$Im\bar{3}m$	$I\bar{4}3m$	$I4mm$

[a] FD = number of cations per 1000 Å^3.

nections of square-planar units, that are based on an α-type sodalite framework. Therefore, we adopted the code αSOD, in order to distinguish it from the symbol for SOD type topology employed for zeolites.[1] The topological relationship between the NbO-type and the SOD-type nets[1] had already been recognized by Wells (see p. 29 in reference [6]). A necessary, but possibly insufficient condition for a zeolite framework to be the basis of a net composed of square units is the presence of infinite chains of four-rings within the three-dimensional nets. These are obtained by extending the dimers given in Figure 1 into chains (Figure 2b). Smith calls these the ts chains.[7] They occur in a number of frameworks derived from the planar 4.8^2 net.[7]

The same type of relationship that was recognized between the SOD-type net[1] and the $V_5O_9(PO_4)_2$ framework of **1** exists between the net of zeolite rho[11] and the $V_5O_9(PO_4)_2$ framework of **2**[3] (Table 1, Figure 3): the S4R of (Si,Al)-tetrahedra are replaced by the spiked helmet $V_5O_9(PO_4)_2$ groups. The relationship can be pictured by realizing that four $V_5O_9(PO_4)_2$ units replace each double eight-ring (D8R) of (Si,Al)-tetrahedra in zeolite rho (Figure 3b). The comparison of the unit cell lengths of the vanadium phosphates and the aluminosilicates shows that the linear dimensions of the square-planar $V_5O_9(PO_4)_2$ unit are about 1.8 times larger than those of a S4R $Si_4O_4O_{8/2}$ unit; thus, their pore space is larger. The framework density of zeolites is expressed as the number of tetrahedral cations per 1000 Å^3. The number of V and P atoms per 1000 Å^3 is only 60% of the number of Al and Si atoms per 1000 Å^3 for the αSOD and the αRHO net types (Table 1). However, these numbers cannot be compared directly, because in the aluminosilicates there are two O atoms per cation, while in the vanadium phosphates there are 2.43 O atoms per cation. The most open fully crosslinked (Si,Al)-framework observed so far is that of the zeolite faujasite[12] with 12.5 (Si,Al) atoms per 1000 Å^3; thus, it is denser than the frameworks of **1** and **3**.

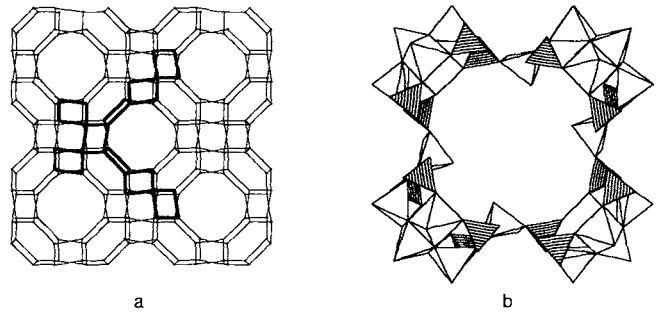

Figure 3. a) The underlying net of αRHO topology (viewed approximately parallel to [100]) for zeolite rho: two of the ts chains are highlighted; b) a ring of four spiked helmet $V_5O_9(PO_4)_2$ units in **2**, which is equivalent to a double eight-ring (D8R) in zeolite rho.

One hypothetical example of a vanadium phosphate net based on the MER topology of the zeolite merlinoite (zeolite W[13]) is presented in Figure 4 and in Table 1. Many more such hypothetical vanadium phosphate frameworks can be derived from zeolite-type nets by replacing the S4R of tetrahedra by square units.

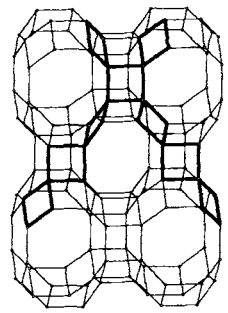

Figure 4. The net of αMER topology (viewed parallel to [001]) for zeolite W; two of the ts chains are highlighted.

A fascinating aspect of the αSOD frameworks of Nb_3O_3, sodalite, and **1** is that in each case the same topology is generated, however, by groups of radically different geometries, sizes, and compositions. They have in common an overall four-connected square-planar geometry with an approximate 90° twist at the nodes. In terms of the geometry of the immediate surroundings of the individual coordination polyhedra they differ too; thus the coordination sequences used to distinguish between tetrahedral frameworks[1] are different for Nb_3O_3, sodalite, and **1**.

The analogy between the more complex α-type nets and the zeolite nets is most apparent in that both nets are of an AB_2 type. In zeolites, A are four-coordinate and B two-coordinate atoms, whereas in the α-type nets, A and B each represent groups of atoms (**1**: A = V_5O_9, B = PO_4). This opens the way to interpret other framework structures without square units in an analogous way—like, for instance, the sulfides of Sn, Ge, and

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3601-0092 $ 15.00+.25/0

Sb[14] studied recently. An example of a structure built from tetrahedral units is the Ge_4MnS_{10} framework in $[(CH_3)_4N]_2$-Ge_4MnS_{10},[15] which is identical to the framework of cristobalite,[16] if one substitutes MnS_4 for one half of the SiO_4 groups, and the adamantane-shaped Ge_4S_{10} group for the other half. Furthermore, starting from the ReO_3-type[17] (AB_3) we can view the framework of pharmacosiderite, $KFe_4(OH)_4$-$(AsO_4)_3 \cdot 6H_2O$, and its many isostructural compounds as examples of structures built from octahedral units. It consists of A groups $[M(O,OH)]_4$ (with M = Fe, Al, Ge, Mo and other cations in octahedral coordinations) made up of four fused octahedra tetrahedrally arranged, and of 6/2 tetrahedral B groups TO_4 (with T = As, P, Ge and others[18]) surrounding it octahedrally. Even $Na_3Zn_4O(PO_4)_3 \cdot 6H_2O$[19] belongs to this series because four fused Zn coordination tetrahedra around a central oxygen atom replace the four octahedra of the pharmacosiderite framework.

In terms of new microporous materials it is important to find more open frameworks by searching for additional square-planar four-connected groups analogous to the $V_5O_9(PO_4)_2$ and $Mo_4O_8(PO_4)_2$ units, and possibly larger ones, and to synthesize frameworks along the principles described here. Such materials could be particularly useful if they contained reactive transition elements, such as the V^{4+}/V^{5+} pair.[20] The new construction principle is important: the inert tetrahedral phosphate groups bridge the potentially reactive square-planar groupings. This role of the phosphate groups could be played by other tetrahedral anions, and the central square-planar Mo_4O_8 and V_5O_9 units could be replaced by other groups. The nets composed of square-planar units that have been introduced here are thus potential carriers of arbitrary functional groups.

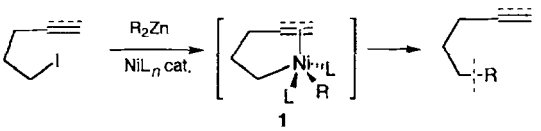
New Nickel-Catalyzed Carbozincation of Alkynes: A Short Synthesis of (*Z*)-Tamoxifen**

Thomas Stüdemann and Paul Knochel*

Dedicated to Professor Waldemar Adam on the occasion of his 60th birthday

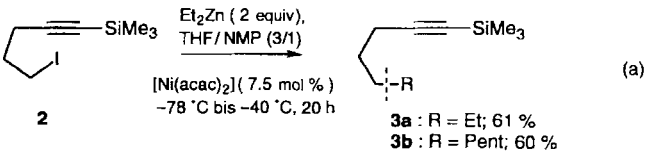
The coordination of a double bond to a transition metal center strongly modifies the reactivity of the metal fragment *and* that of the coordinated olefin.[1] This olefin activation is of great importance for applications in organic synthesis, since it allows the formation of new carbon–carbon bonds between unfunctionalized unsaturated molecules.[2] Recently, we have shown that the coordination of a double bond to a dialkylnickel(II) complex considerably facilitates the reductive elimination of the organic ligands, making efficient nickel-catalyzed cross-coupling reactions between sp^3-hybridized C centers possible for the first time.[3] Here we report our attempts to extend this reaction to alkynyl iodides (Scheme 1), which led to the discovery of a highly stereoselective nickel-catalyzed carbozincation of alkynes.



1

Scheme 1. Nickel-catalyzed cross-coupling of alkenyl and alkynyl iodides with dialkylzinc compounds.

Our first experiments involved the treatment of trimethylsilylpentyne **2** with two dialkylzinc compounds, diethylzinc (Et_2Zn) and dipentylzinc ($Pent_2Zn$). Like the corresponding alkenyl iodide, **2** undergoes smooth cross-coupling with Et_2Zn and $Pent_2Zn$ in THF/NMP (3/1) in the presence of a catalytic amount of $[Ni(acac)_2]$ (7.5 mol%, acac = acetylacetonate; −40 °C, 20 h) to give the desired cross-coupling products **3a** and **3b** in 60 and 61% isolated yield, respectively [Eq. (a)]. The coordination of the triple bond lowers the electron



2

3a : R = Et; 61 %
3b : R = Pent; 60 %

(a)

density at the metal center (intermediate **1** in Scheme 1) and facilitates the cross-coupling reaction.[3, 4]

In contrast, iodohexynes such as **4a** that bear a more reactive terminal alkyne group undergo tandem addition to the triple bond, followed by coupling with the R group of R_2Zn, to afford *exo*-alkylidenecyclopentanes **5**. The reaction of **4a** with $Pent_2Zn$ or di(4-chlorobutyl)zinc in the presence of $[Ni(acac)_2]$ (7.5 mol%) furnishes cyclopentanes **5a** (65%) and **5b** (68%) [Eq. (b)]. To determine the stereochemistry of the addition to

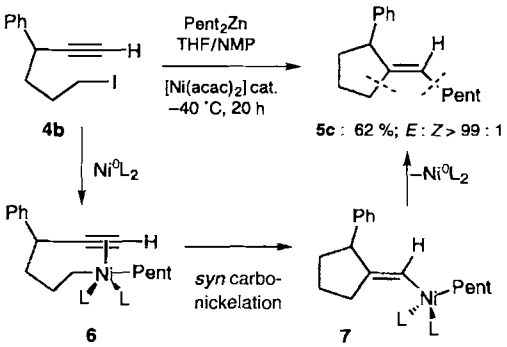
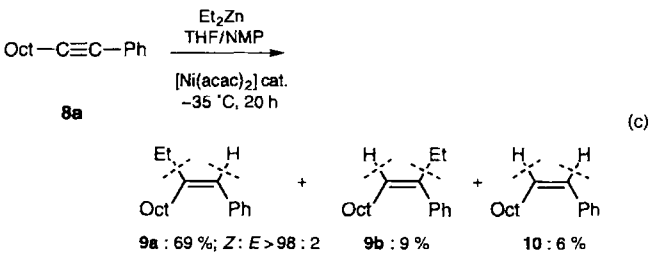
(b)

the triple bond (*syn* or *anti*), the phenyl-substituted alkyne **4b** was treated with $Pent_2Zn$ (7.5 mol% [Ni(acac)$_2$]; THF/NMP, −40 °C, 20 h). This led almost exclusively to the (*E*) stereoisomer **5c** (*E*:*Z* > 99:1), which indicates a *syn* addition to the triple bond. This result allows us to postulate the following mechanism for this cyclization reaction. The insertion of in-situ-generated nickel(0) into the carbon–iodine bond of **4b** followed by transmetalation with $Pent_2Zn$ affords the nickel(II) complex **6**, which effected *syn* carbonickelation of the alkyne and formation of the alkenyl alkyl nickel(II) complex **7**. Reductive elimination[5] then leads to the (*E*)-*exo*-alkylidenecyclopentane **5c** (Scheme 2).



Scheme 2. Mechanism of the nickel-catalyzed cyclization of **4b** to **5c**.

The *syn* stereoselectivity of the carbonickelation encouraged us to examine the intermolecular version of this reaction. Whereas internal dialkylacetylenes display moderate reactivity, the intermolecular carbozincation of internal phenylacetylenes[6] proceeds with good to excellent regioselectivity and almost complete *syn* stereoselectivity. Thus, the reaction of 1-phenyl-1-decyne (**8a**) with Et_2Zn in THF/NMP in the presence of [Ni(acac)$_2$] (25 mol%) at −35 °C for 20 h affords the *syn*-ethylated products **9a** (*Z*:*E* > 98:2) and **9b** in an 88:12 ratio (78% yield) and the hydrometalated product **10** in 6% yield [Eq. (c)]. With phenylacetylenes bearing smaller alkyl groups in



(c)

the 2-position, far better regioselectivities are obtained (Table 1). Varying the reaction conditions (solvent, temperature) and the catalyst ($NiCl_2$, [Ni(cod)$_2$]) did not lead to a dramatic improvement in the regioselectivity. Moreover, the hydrometalation product of type **10** was observed only with Et_2Zn. In the case of more reactive acetylenes such as 1,2-

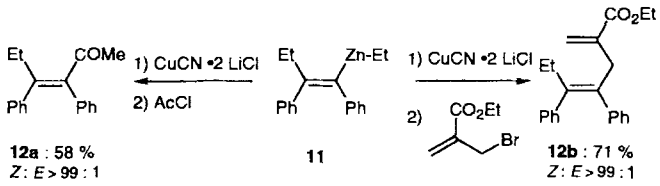
[a] Yields of analytically pure isolated products. [b] Only the regioisomer depicted is obtained. [c] The hydrometalation product (*Z*)-stilbene was obtained in 2% yield.

diphenylacetylene (**8d**), it is formed in less than 2% yield. Interestingly, with 2-trimethylsilyl-1-phenylacetylene (**8e**), the opposite regioselectivity of the carbozincation is observed (nos. 6 and 7 in Table 1). The addition of dimethylzinc to the silylated acetylene **8e** also gives the desired *syn*-addition product with high stereoselectivity (*E*:*Z* = 2:98; 64% yield).[7] The trisubstituted alkenylzincs obtained by nickel-catalyzed carbozincation can be trapped with several electrophiles to give tetrasubstituted olefins with high stereoselectivity. Thus, the addition of Et_2Zn to 1,2-diphenylacetylene (**8d**) in the presence of [Ni(acac)$_2$] (THF/NMP; −35 °C, 3 h) furnishes the (*E*)-alkenylethylzinc **11** (no. 4 in Table 1), which in the presence of CuCN·2 LiCl[8] reacts with acetyl chloride (−10 °C, 10 h) or ethyl (α-bromomethyl)acrylate[9] (−10 °C, 1 h) to give the tetrasubstituted olefins **12a** and **12b** in 58% and 71% yield, respectively.



Scheme 3. Synthesis of the tetrasubstituted alkenes **12a** and **12b** from the alkenylzinc compound **11**.

The reaction with diphenylzinc[10] proceeds even more readily. Addition to 1-phenyl-1-butyne (**8c**) (THF, −35 °C, 3 h) and subsequent iodolysis gives the pure (*Z*)-alkene **13** in 88% yield (*Z*:*E* > 99:1, Scheme 4). This adduct has been converted in one step into (*Z*)-tamoxifen (**14**), an anti-estrogenic anticancer drug that is effective for the treatment of metastatic breast cancer.[11] Thus, the reaction of **13** with the arylzinc bromide **15** in the presence of [Pd(dba)$_2$] (4 mol%; dba = dibenzylideneacetone) and PPh_3 (16 mol%) in THF (55 °C, 10 h) provides (*Z*)-tamoxifen (**14**) in 75% yield (*Z*:*E* > 99:1).

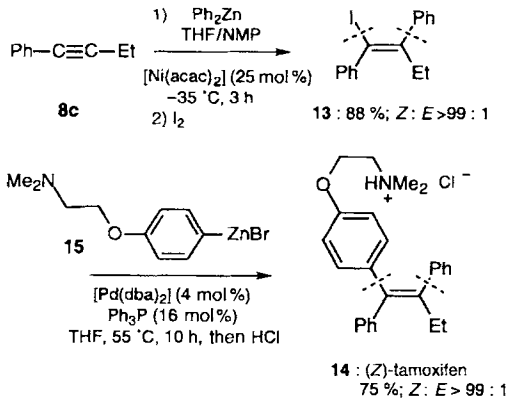

Scheme 4. Synthesis of (*Z*)-tamoxifen (**14**).

In summary, we have reported a new intramolecular *syn* carbonickelation leading to alkylated *exo*-alkylidenecyclopentane derivatives, as well as an intermolecular carbozincation of substituted phenylacetylenes that allows stereoselective (>98% *syn* addition) synthesis of tri- and tetrasubstituted phenylalkenes.

Experimental Procedures

(**12b**): [Ni(acac)$_2$] (320 mg, 1.25 mmol, 25 mol%) and **8d** (0.89 g, 5 mmol, 1 equiv) were dissolved in THF (3.75 mL) and NMP (1.25 mL) at −40 °C under argon. Diethylzinc (1.0 mL, 10 mmol, 2 equiv) was carefully added via syringe at −78 °C. The reaction mixture was allowed to warm to −35 °C and stirred for 2.5 h. Meanwhile a mixture of CuCN (1.79 g, 20 mmol, 4 equiv) and LiCl (1.69 g, 40 mmol, 8 equiv) was dried in vacuo at 130 °C for 2 h and then dissolved in THF (10 mL). The solution was cooled to −60 °C and added by syringe to the reaction mixture at −78 °C. The resulting dark solution was warmed to 0 °C for a few minutes and then again cooled to −78 °C. Ethyl (α-bromomethyl)acrylate[9] (4.82 g, 25 mmol, 5 equiv) was added, and the reaction mixture warmed to 25 °C and worked up. The crude product was purified by flash-chromatography (hexanes/ether 20/1), affording the ester **12b** (1.13 g, 3.53 mmol, 71% yield; *Z*:*E*>99:1) as a white powder.

(**5c**): [Ni(acac)$_2$] (96 mg, 0.37 mmol, 7 mol%) was dissolved in THF (3.75 mL) and NMP (1.25 mL) at −40 °C under argon, and 1-iodo-4-phenyl-5-hexyne (**4b**) (1.41 g, 5 mmol, 1 equiv) was added. At ≅78 °C, $Pent_2Zn$ (2.0 mL, 10 mmol, 2 equiv) was carefully added by syringe. The reaction mixture was stirred for 30 h at −40 °C. After the usual workup, the solvents were distilled off, and the crude residue was purified by chromatography (hexanes) to give the cyclized product **5c** (0.74 g, 3.24 mmol, 65% yield; *E*:*Z*>99:1) as a colorless oil.

Hydroxyamines as a New Motif for the Molecular Recognition of Phosphodiesters: Implications for Aminoglycoside–RNA Interactions**

Martin Hendrix, Phil B. Alper, E. Scott Priestley, and Chi-Huey Wong*

The molecular recognition of phosphodiesters has received much attention due to their biological importance. In protein–nucleic acid complexes, binding of the phosphodiester backbone is often achieved through a dense network of hydrogen bonding frequently involving a bidentate interaction with the guanidinium group of arginine.[1, 2] In order to identify the underlying principles of phosphodiester recognition in biological systems, various phosphate receptor models have been developed, including synthetic receptors incorporating guanidinium moieties,[3] linear and macrocyclic polyamines,[4] ureas,[5] amidines,[6] aminopyridines,[7] porphyrins,[8, 9] and uranyl complexes.[10]

Aminoglycoside antibiotics[11] have been shown to directly interact with a number of RNA sequences[12] including two important HIV regulatory domains, RRE[13] and TAR.[14] We speculated that the hydroxyamine substructures often found in these molecules may play an important role in recognition. A typical member of the class, neomycin B (**1**, Scheme 1), has a number of different 1,2- and 1,3-hydroxyamine substructures. We therefore prepared the model compounds **2**–**5** to first evaluate their individual binding capacities to dimethylphosphate as a model phosphodiester. To compare our results for phosphodiester binding by hydroxyamines we chose the well-characterized bicyclic guanidine **6**, since it has been used as a standard model for phosphate recognition.[3a] Compound **6** is symmetrical and presents only one hydrogen bond donor, unlike arginine, which has two, allowing straightforward interpretation of spectroscopically derived binding data.

1,3-Hydroxyamines **2**–**4**[15] were synthesized conveniently from the respective diol precursors via cyclic sulfate[16] intermediates as shown in Scheme 2. The *galacto*-configured hydroxyamine **4** was designed to mimic the 4‴, 6‴-hydroxyamine substructure found in the L-*ido* ring of neomycin B, which exists in a triaxial $^4C_1$ chair conformation as shown in Scheme 1.[17]

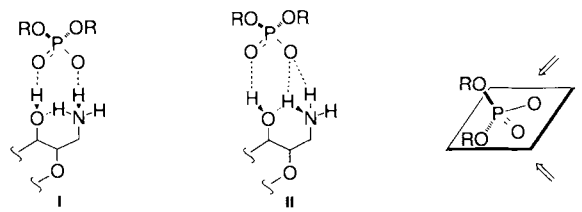
[a] NMR dilution experiments with the preformed 1:1 salt complexes were performed in [D_6]DMSO at 293 ± 1 K. [b] calculated maximum shift at full complexation.

While the absolute configuration of the hydroxyamine substructure in **4** is enantiomeric to that of L-idose, the relative orientation of the equatorial aminomethyl and the axial hydroxyl groups is the same and therefore their interactions with achiral compounds will be equivalent.

To determine binding constants we prepared defined 1:1 salt complexes and measured their dissociation upon stepwise dilution in [D_6]DMSO by following the ^{1}H NMR shifts of the NH and OH signals. The chemical shift values of the totally uncomplexed state (δ_0) and the fully complexed state (δ_∞) and the stability constant K_a were subsequently determined by curve fitting. This procedure has the advantage that it does not rely on experimentally determined values of δ_0, which require separate measurements with a noncomplexing counterion that may nonetheless have some residual binding affinity.[18] Table 1 shows the results of dilution experiments with chloride and phosphodiester counterions for compounds **2**–**6**.[19] In all cases, data could be fitted to a 1:1 binding isotherm. Importantly, the *gluco*-configured 1,3-hydroxyamine **2** binds dimethylphosphate with higher affinity than bicyclic guanidine **6**. In contrast, the *galacto* epimer **4** shows reduced binding. The 1,2-*trans*-hydroxyamine **5** binds dimethylphosphate with lower affinity than either **2** or **6**, but is still superior to **4**. All three hydroxyamines show substantial selectivity for dimethylphosphate over chloride (Table 1), suggesting the involvement of hydrogen bonds in addition to ionic contributions, which are typically somewhat larger for the more localized charge of protonated amines.[3c] Evidence for the involvement of a bidentate[20] mode of recognition for **2** was provided by the large downfield shift of its OH resonance upon complexation ($\Delta\delta_{max}$ = 0.84). A smaller shift of the OH signal was seen in **5** ($\Delta\delta_{max}$ = 0.56) and in **4** ($\Delta\delta_{max}$ = 0.38). This order mirrors the order of binding affinities and is consistent with the interpretation that differential involvement of the hydroxyl group in hydrogen bonding accounts for the energetic differences in complexation.

A structural model for the interaction of 1,3-hydroxyamines with phosphodiesters could include either two (**I**) or three (**II**)

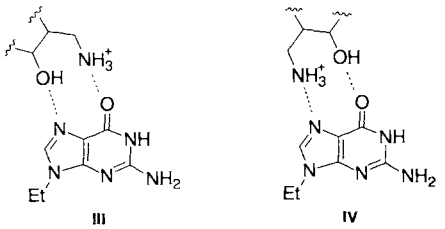


hydrogen bonds. In the latter arrangement the hydrogen bonds are formed simultaneously above and below the OPO plane, which is common for coordination of phosphates in biological systems.[21] Results obtained with compound **3**, which features one more benzyl substituent than **2**, are consistent with this model. The intrinsic ion binding capability of **3** is reduced by this substitution as can be seen from its chloride binding ability, which is less than that of **2**, **4**, and **5**. This may be due to added steric bulk and higher basicity of the secondary amine, which decreases its hydrogen bonding donor strength. However, the selectivity for dimethylphosphate over chloride is only slightly diminished (sevenfold vs. tenfold for **2**), suggesting that the principal hydrogen bonding network involved in recognition is still intact. The clear difference in the phosphate recognition abilities of **2** and **4** is interesting. Careful analysis of the coupling constants $J_{5,6a}$ and $J_{5,6b}$ in **2** indicates that in the uncomplexed state a single rotamer around the C5–C6 bond dominates

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3601-0096 $ 15.00+.25/0 Angew. Chem. Int. Ed. Engl. 1997, 36, No. 1/2

($J_{5,6a} \leq 2$, $J_{5,6b} = 8-9$ Hz), which does not change significantly upon binding of the phosphodiester. This contrasts with *galacto* epimer **4**, which in the uncomplexed state ($J_{5,6a} = 4.5$, $J_{5,6b} = 8.5$ Hz at 17% complexation) is probably an equilibrium mixture of two rotamers. Upon complexation of dimethylphosphate the molecule rearranges and the torsional angle for the C5–C6 bond changes ($J_{5,6a} \approx J_{5,6b} = 6.5$ Hz at 65% complexation). Thus it is likely that **2** is perfectly preorganized for binding of phosphodiesters, while **4** must undergo rearrangement, accounting for its reduced binding affinity.

The results from the phosphodiester binding studies suggest that hydroxyamines share some of the molecular recognition properties of guanidines, and it is known that in protein–nucleic acid complexes the guanidinium group of arginine frequently makes contact to the Hoogsten face of guanosine.[22] When 9-ethylguanine was titrated with **4**, a downfield shift of the H8 signal due to hydroxyamine binding was indeed observed. Possible complex structures as shown in **III** and **IV** are therefore proposed.



III

IV

To investigate whether 1,3-hydroxyamine substructures may be involved in binding in aqueous solution, we turned our attention to the binding of neamine (**12**), a pseudodisaccharide substructure commonly found in a wide range of aminoglycoside antibiotics. However, initial studies with dimethylphosphate in water showed no detectable binding in the concentration ranges accessible by NMR. This may not be surprising since ionic and hydrogen bonding interactions are severely reduced in water. These weak forces may, however, be enhanced by increasing the charge of the interacting species. In fact, many recognition events involving nucleic acids—including those by aminoglycosides—are likely to have a strong contribution from their polyionic character. We therefore turned our attention to the binding of sulfate, as it is a tetrahedral oxyanion similar to phosphate and its double negative charge mimics the effect of a polyanion. Furthermore, it has a defined ionization state. Since the ^{1}H NMR spectra of aminoglycosides are highly dependent on pH, and even minor pH changes can outweigh any small complexation-induced shifts, we performed binding studies at low pH, where neamine is fully protonated. Upon addition of sodium sulfate to a solution of neamine·4HCl at pH 3.5, only small changes were observed in the ^{1}H NMR spectrum and their interpretation was complicated by severe overlap of signals. Analysis of ^{13}C NMR spectra provided a clearer picture (Figure 1). Signals for all carbons were assigned unambigously through 2D COSY and NOESY spectra and were in full agreement with the assignments made earlier[23] based on comparison of chemical shift values with model compounds. By following the shift of the C1′ signal, an apparent binding constant $K_{app} = 294 \pm 26\ \text{M}^{-1}$ was calculated for the competitive binding of sulfate over chloride through curve-fitting procedures.[24] In-

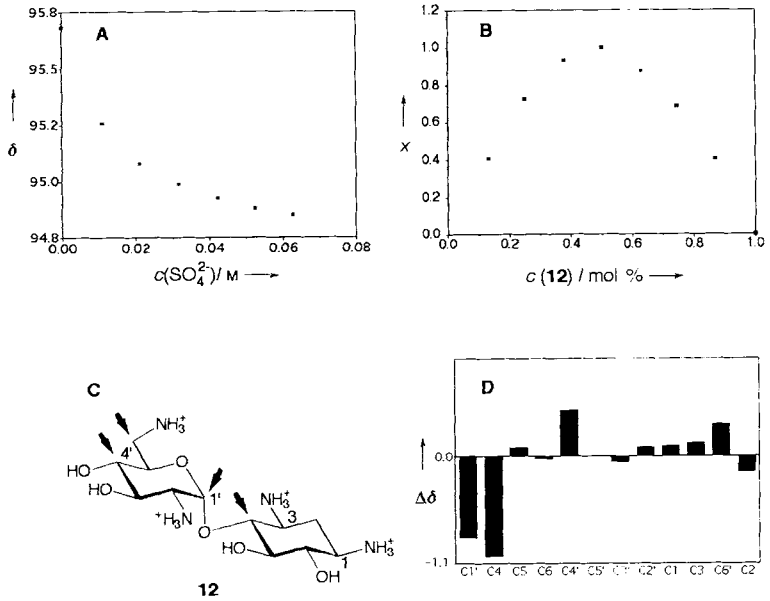


Figure 1. Titration of neamine (**12**) with sodium sulfate at pH 3.5. A) ^{13}C NMR titration curve (C1′ signal). B) Job plot; x = amount [%] of complex formation. C) Structure of neamine indicating the C atoms having the maximum observed shifts. D) Maximum observed shifts of the ^{13}C NMR signals.

vestigation of the binding stoichiometry by the method of Job[25] revealed the predominant existence of a 1:1 complex with only minor contributions from two sulfates binding simultaneously. Tabulation of the maximum observed shifts $\Delta\delta_{max}$ provides an interesting picture: significant changes are seen for the C4, C1′, C4′, and C6′ signals. The changes for the C4 and C1′ signals are opposite in sign to all other shifts and can be interpreted as resulting from a change in glycosidic torsion angles[26] due to altered electrostatic repulsion after complexation of sulfate. The changes for the C4′ and C6′ signals are indicative of binding at the respective sites. In particular, C4′ is the only hydroxyl-substituted carbon showing a large shift. These observations provide clear evidence for anion recognition by a 1,3-hydroxyamine substructure in water.[27] Thus, the selectivity found in aqueous solution is in full agreement with the order of binding affinities determined in the model compounds.

In conclusion, we have identified 1,3-hydroxyamines commonly found in aminoglycoside antibiotics as a new recognition motif for the complexation of phosphodiesters and probably the Hoogsten face of guanosine. This core structure should find useful applications in many molecular recognition systems in which the complexation of phosphodiesters is desired. Work is in progress to combine hydroxyamines with other nucleic acid binding motifs to generate molecules targeting specific nucleic acid sequences.

[27] Preliminary results obtained with derivatives of neomycin B suggest that both the 6′ and 6‴ amino groups are involved in the binding of RRE. Acylating these groups sharply reduces their affinity (K_i > 0.1 mM) in a filter binding assay: T. J. Daly, R. C. Doten, P. Rennert, M. Auer, H. Jaksche, A. Donner, G. Fisk, J. R. Rusche, *Biochemistry* **1993**, *32*, 10497.

A Straightforward Access to α-Functional Phospholide Ions

Serge Holand, Muriel Jeanjean, and François Mathey*

Despite their highly delocalized electronic structure,[1, 2] phospholide ions are functionalized exclusively at the phosphorus atom.[3] To develop the chemistry at the carbon atoms of the ring and to assemble porphyrin-like arrays based upon this heteroatomic unit, we need a straightforward access to functional phospholides. Previous attempts to synthesize such derivatives lacked the necessary simplicity and generality.[4] Perhaps the most characteristic feature of phospholes is their easy interconversion of 1*H*- into 2*H*-phosphole derivatives through [1,5] sigmatropic shifts of the phosphorus substituents.[5, 6] The 2*H*-phospholes generated by these shifts tend to dimerize by [4 + 2] cycloaddition, but this dimerization is known to be reversible.[5a] We reasoned that the treatment of these [4 + 2] dimers with a base, at a temperature high enough to establish the monomer–dimer equilibrium, could yield the corresponding phospholide ions. To check the feasibility of this crucial step, we heated the well-defined [4 + 2] dimer of 3,4-dimethyl-2*H*-phosphole **1**[7] with a variety of bases. Potassium *tert*-butoxide appeared to be the reagent of choice.

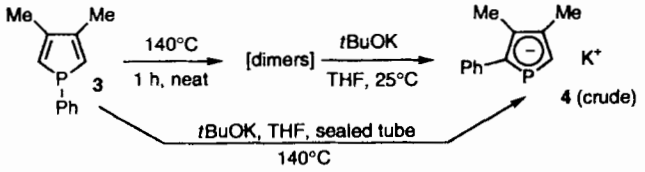
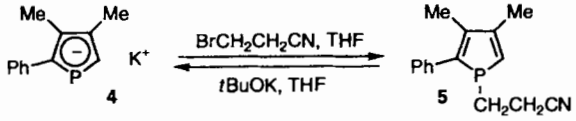
In fact, the reaction takes place almost instantaneously at room temperature. The monitoring of the reaction mixture by ^{31}P NMR spectroscopy indicated a quantitative conversion of **1** ($\delta = -24$ and -63, $^1J(P,P) = 185$ Hz) into **2** ($\delta = +64$). Thus, it appeared to be possible prepare α-functional phospholides by combining a [1,5] shift of the functionality from the P atom to the C2 atom, followed by an aromatization of the resulting dimers by *t*BuOK. We tested the practical feasibility of this strategy on the 1-phenylphosphole derivative **3**.

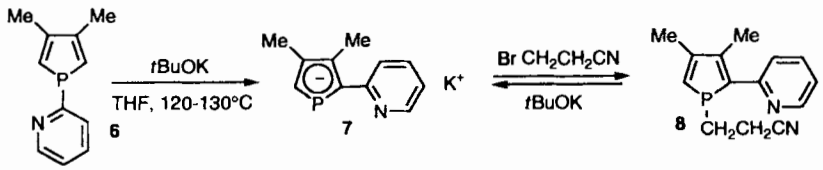
When **3** is heated to 140 °C a complex mixture of isomeric dimers is produced. At 160 °C these transform into the thermodynamically favored species ($\delta(^{31}P) = -30$ and $+37$, $^1J(P,P) = 198$ Hz) whose conversion into anion **4** appears to be difficult.



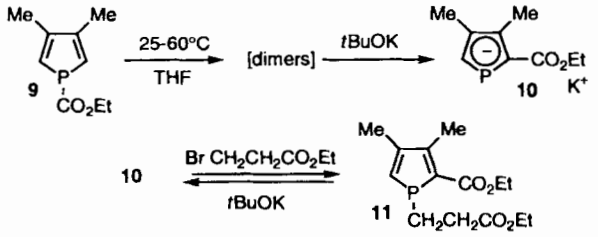
Finally, it proved simpler and more efficient to react **3** directly with *t*BuOK at 140 °C in THF under pressure. The alcoholate does not react with **3** but deprotonates its 2*H*-isomer spontaneously to give **4**. The crude phospholide was purified by alkylation/dealkylation; the purification was carried out on phosphole **5**.



Since we now had an effective route to α-substituted phospholides available, we decided to check its applicability to the synthesis of functional phosphole derivatives. By using an overall scheme similar to that used for the preparation and purification of the anion **4**, we obtained the 2-(2-pyridyl)phospholide **7**. 1-(2-Pyridyl)phosphole **6** was prepared by reacting the anion **2** with 2-bromopyridine in the presence of CuI as catalyst.



In a further experiment, the lithium salt of **2** was treated with ethyl chloroformate to give phosphole **9**, which spontaneously formed a mixture of 2*H*-phosphole dimers between 25 and 60 °C. Their deprotonation with *t*BuOK yielded the 2-(ethoxycarbonyl)phospholide **10**.



Anion **10** can be purified by alkylation/dealkylation or used directly to prepare the difunctional anion **13**. Each of these new phospholide ions was characterized by negative ion mass spectrometry (M^-, 100%) and by ^1H, ^{13}C, and ^{31}P NMR spectroscopy. For NMR studies, the anions **4**, **7**, **10**, and **13** were generated in C_4D_8O by dealkylation of phospholes **5**, **8**, **11**, and **14** respectively. The ^{13}C and ^{31}P data are collected in Table 1. The numerous possible applications of this synthetic strategy are currently under investigation.

Experimental Section

All reactions were performed under nitrogen using solvents purified and dried by standard methods. The ^{13}C NMR coupling constants *J*, refer to ^{13}C, ^{31}P couplings.

5 (and **4**): a) Phosphole **3** [8] (20 mmol) was heated for 1 h at 140 °C to give a mixture of dimers, which were characterized by ^{31}P NMR spectra (81.0 MHz, THF, H_3PO_4): δ between -44 and $+36$; 15–20 doublets with varying intensities, $^1J(P,P)$ values of about 200 Hz. The mixture was dissolved in THF (15 mL), and *t*BuOK (1.2 equiv) was added at room temperature to give **4** ($\delta(^{31}P) = 71.5$) and by-products; weak signals between $\delta = -31$ and $+36$). The solution was cooled at 0 °C, and $BrCH_2CH_2CN$ (1.2 equiv) was then added. After 15 min, the solvent was vacuum distilled and the residue chromatographed on silica gel (hexane:CH_2Cl_2 1:1); yield 65% of pure **5**. b) A mixture of **3** (20 mmol) and *t*BuOK (1.2 equiv) in THF (20 mL) was heated in a sealed tube (or an autoclave) for 1 h at 140 °C. The resulting impure anion was then treated with $BrCH_2CH_2CN$ and purified as indicated above; yield 70%. **5**: negative ion MS (NH_3, 70 eV): *m/z* (%): 242 (100) [M^-]; ^{31}P NMR ($CDCl_3$): $\delta = -1.4$; ^1H NMR (200 MHz, $CDCl_3$, TMS): $\delta = 1.74$–2.06 (m, 4H, CH_2CH_2), 2.11 (d, $^4J(H,P) = 3$ Hz, 3H, CH_3); 2.15 (dd. $^4J(H,P) = 1.3$ Hz, $^4J(H,P) = 3.0$ Hz, CH_3), 6.30 (d, $^2J(H,P) = 39.4$ Hz, 1H, =CH), 7.34 (m, 5H, C_6H_5); ^{13}C NMR (50.0 MHz, $CDCl_3$): $\delta = 12.55$ (s, CH_2-CN), 14.65 (s, CH_3), 18.68 (d, $^3J = 2.6$ Hz, CH_3), 19.23 (d, $^1J = 24.7$ Hz, CH_2P), 119.73 (d, $^3J = 6.1$ Hz, CN), 124.25 (d, $^1J = 4.0$ Hz, C5), 143.23 (d, $^2J = 12.7$ Hz, C3 or C4), 144.24 (s, C4 or C3), 153.15 (d, $^1J = 6.1$ Hz, C2), C_6H_5: 126.71 (s), 128.66 (s), 128.89 (s), and 136.60 (d, $^2J = 18.2$ Hz, *ipso*-C).

4: Phosphole **5** (0.125 g, 0.52 mmol) in [D_8]THF (1 mL) was treated with *t*BuOK (0.07 g, 0.62 mmol) at room temperature. The pale brown reaction mixture was filtered through dry Celite to give a clear solution of **4**.

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997* *0570-0833/97/3601-0099 $ 15.00+.25/0*

6: A mixture of phospholyllithium [9] (0.532 mmol), 2-bromopyridine (9.8 g, 0.62 mmol) and CuI (0.5 g, 2.6 mmol) was heated to reflux for 3 h. After the mixture had cooled, it was poured into iced water, extracted with CH_2Cl_2, and treated as dscribed above. Chromatography on alumina (CH_2Cl_2) gave 8.0 g of a light yellow liquid; yield 80%. MS: *m/z* (%): 189 (100) [M^+]; ^{31}P NMR ($CDCl_3$): $\delta = 1.8$; ^{1}H NMR ($CDCl_3$): $\delta = 2.11$ (dd, ^4J(H,H) = 0.7 Hz, ^4J(H,P) = 3.0 Hz, 6H, CH_3), 6.53 (d, ^2J(H,P) = 37.9, 2H, =CH), 7.09–8.58 (aromatic H); ^{13}C NMR ($CDCl_3$): $\delta = 17.83$ (d, $^3J = 3.1$ Hz, CH_3), 126.93 (d, $^1J = 13.5$ Hz; C2 and C5), 149.96 (d, $^2J = 7.4$ Hz, C3 and C4), aromatic C: 122.16 (s), 126.71 (s), 135.70 (s), 150.04 (d, $^1J = 7.5$ Hz, *ipso*-C), and 150.20 (d, $^2J = 13.7$ Hz, C3').

8: Impure **7** was generated from **6** either from its dimers (1 h at 130 °C) or directly by heating with *t*BuOK (1 h, 120–130 °C) as described for **4**. Reaction with $BrCH_2CH_2CN$ followed by chromatography on alumina (CH_2Cl_2) gave **8** with 66% yield. MS: *m/z* (%): 242 (80) [$M^+ + 1$]; ^{31}P NMR ($CDCl_3$): $\delta = 1.8$; ^{1}H NMR ($CDCl_3$): $\delta = 2.02$ (m, 2H, CH_2CN), 2.15 (partially masked, CH_2P) and 2.16 (dd, ^4J(H,H) = 0.7 Hz, ^4J(H,P) = 3.4 Hz, CH_3), 2.28 (d, ^4J(H,P) = 3.3 Hz, 3H, CH_3), 6.42 (d, ^2J(H,P) = 38.4 Hz, 1H, =CH), 7.11–8.62 (aromatic H); ^{13}C NMR ($CDCl_3$): $\delta = 12.98$ (s, CH_2CN), 15.30 (s, CH_3), 18.53 (s, CH_3), 19.12 (d, $^1J = 26.0$, CH_2P), 119.82 (d, $^3J = 4.7$ Hz, CN), 126.85 (d, $^1J = 4.5$ Hz, C5), 143.48 (s, C2), 146.42 (d, $^2J = 12.1$ Hz, C4), 152.37 (d, $^2J = 6.1$ Hz, C3), aromatic C: 120.99(s), 122.68 (d, $J = 6.1$ Hz), 136.28(s), 149.78(s) and 155.44 (d, $^2J = 16.8$ Hz, *ipso*-C).

7: The pure anion **7** was obtained by reacting **8** with *t*BuOK (1.2 equiv) in [D_8]THF. Negative ion MS: *m/z* (%): 188 (100) [M^-]. For ^{31}P and ^{13}C NMR data see Table 1.

9: $ClCO_2Et$ (0.63 mmol) was slowly added to a solution of phospholyllithium [9] (0.532 mmol) in THF (200 mL) at 0 °C, and the mixture was stirred for 15 min at room temperature. The solvent was then removed in vacuo (bath temperature below 30 °C), and the residue was chromatographed on silica gel. Elution with toluene gave a fraction of pure phosphole **9**: yield 25%. MS: *m/z* (%): 185 (100) [$M^+ + 1$]; ^{31}P NMR ($CDCl_3$): $\delta = -0.6$; ^{1}H NMR ($CDCl_3$): $\delta = 1.25$ (t, ^2J(H,H) = 7.1 Hz, 3H, CH_3-CH_2), 2.11 (dd, ^4J(H,H) = 0.8 Hz, ^4J(H,P) = 2.8 Hz, 6H, CH_3), 4.16 (m, 2H, OCH_2), 6.27 (d, ^2J(H,P) = 38.6 Hz, 2H, =CH); ^{13}C NMR ($CDCl_3$): $\delta = 14.82$ (s, CH_3-CH_2), 17.56 (s, CH_3), 61.53 (s, OCH_2), 121.66 (s, =CH), 151.01 (s, =*C*-CH_3), 175.53 (d, $^1J = 16.2$ Hz, CO). Pure **9** was followed by a mixture of **9** and its dimers, yield 60%; same mass spectrum as pure **9**; ^{31}P NMR ($CDCl_3$): $\delta = -50$ to +90; more than 20 singlets or doublets (J(P,P) between 135 and 190 Hz).

11: A solution of **9** (and/or its dimers) in THF was heated for 30 min at 60 °C. After the mixture had been cooled to 0 °C, *t*BuOK (1.2 equiv) was added, followed by $BrCH_2CH_2CO_2Et$ (1.2 equiv). The solvent was distilled and the residue chromatographed on florisil (hexane: CH_2Cl_2 1:1), yield 55%. MS: *m/z* (%): 284(65) [M^+]; ^{31}P NMR ($CDCl_3$): $\delta = 3.9$; ^{1}H NMR ($CDCl_3$): δ (selected) = 2.09 (partially masked m, CH_2CN) and 2.12 (dd, ^4J(H,H) = 1.1 Hz, ^4J(H,P) = 3.2 Hz, CH_3), 2.26 (m, 2H, CH_2P), 2.43 (d, ^4J(H,P) = 4.8 Hz, 3H, CH_3), 6.55 (d, $^2J = 36.4$ Hz, 1H, =CH); ^{13}C NMR ($CDCl_3$): δ (selected) = 16.03 (s, CH_3), 18.27 (d, $^3J = 2.4$ Hz, CH_3), 18.76 (d, $^1J = 21.82$ Hz, CH_2P), 30.70 (s, CH_2-CO), 132.32 (s, C2), 135.05 (d, $^1J = 4.6$ Hz, C5), 150.39 (d, $^2J = 4.6$ Hz, C4 or C3), 159.96 (d, $^2J = 12.3$ Hz, C3 or C4), 165.58 (d, $^2J = 19.7$ Hz, *C*O-C2), 179.13 (d, $^3J = 5.0$ Hz, *C*O-CH_2).

10: **10** was prepared analogously to **4**. ^{1}H NMR ([D_8]THF): $\delta = 1.22$ (poorly resolved t, ^3J(H,H) = 7.0 Hz, 3H, CH_3CH_2), 2.02 (s, 3H, CH_3), 1.24 (s, 3H, CH_3), 4.07 (poorly resolved q, ^3J(H,H) ≈ 7 Hz, 2H, OCH_2), 6.80 (d, ^2J(H,P) = 39.4 Hz, 1H, =CH). For ^{31}P and ^{13}C NMR data, see Table 1.

14: $ClCO_2Et$ (1.1 equiv) was added dropwise to a solution of anion **10** (0.45 mmol) in THF (100 mL) at 0 °C. After 15 min at room temperature, the resulting phosphole **12** (^{31}P NMR: $\delta = 5.1$) was heated to reflux for 1 h to give the corresponding dimers (^{31}P NMR: signals between $\delta = -40$ and +40). The mixture was then cooled at 0 °C, and *t*BuOK (1.2 equiv) was added, followed by $BrCH_2CH_2CN$ (1.2 equiv). After vacuum distillation of the solvent, the residue was chromatographed on silica gel (CH_2Cl_2). Yield 8.3g (60%) of pale yellow crystals, m.p. 78 °C (hexane). MS: *m/z* (%): 309 (75) [M^+]; ^{31}P NMR ($CDCl_3$): $\delta = 10.0$; ^{1}H NMR ($CDCl_3$): $\delta = 1.36$ (t, ^3J(H,H) = 7.1 Hz, 3H, CH_3CH_2), 2.11 (A_2B_2X, ^3J(H,H) = 6.9 Hz, CH_2CN), 2.48 (d, ^4J(H,P) = 5.3 Hz, CH_3) 2.49 (A_2B_2X, CH_2P), 4.30 (m, 2H, OCH_2); ^{13}C NMR ($CDCl_3$): $\delta = 13.71$ (s, CH_2CN), 14.36 (s, CH_3-CH_2), 15.85 (s, CH_3), 20.22 (d, $^1J = 30.5$ Hz, CH_2P), 60.82 (s, OCH_2), 119.07 (d, $^3J = 5.7$ Hz, CN), 134.96 (d, $^2J = 3.0$ Hz, C3 and C4), 159.71 (d, $^1J = 9.8$ Hz, C2 and C5), 164.60 (d, $^2J = 19.3$ Hz, CO).

13: The pure anion was obtained by reacting **14** with *t*BuOK (1.2 equiv) in a mixture of [D_8]THF and $HCONMe_2$ (1/1). Negative ion MS: *m/z* (%) = 255 (100) [M^-]. For ^{31}P and ^{13}C NMR, see Table 1.

The First Large-Pore Vanadosilicate Framework Containing Hexacoordinated Vanadium**

João Rocha,* Paula Brandão, Zhi Lin, Michael W. Anderson, Viveka Alfredsson, and Osamu Terasaki

Dedicated to Professor Júlio Pedrosa

Unlike other zeolite-type solids, microporous titanosilicates (known as ETS) contain hexacoordinated framework atoms. We have recently solved the structure of ETS-10 (Figure 1), the most prominent member of this new family.[1, 2] The material has a framework consisting of "TiO_2" rods, which run in two orthogonal directions, surrounded by tetrahedral silicate units. The pore structure consists of 12-, 7-, 5-, and 3-membered rings and has a three-dimensional, wide-pore channel system whose minimum diameter is defined by 12-membered ring apertures. The disorder arises from structural faulting along planes parallel to the direction of the 12-membered ring channels, and it is possible to describe the structure in terms of an intergrowth of two ordered polymorphs with tetragonal and monoclinic sym-

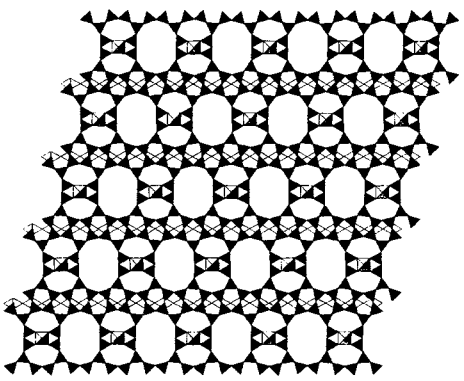

Figure 1. Polyhedral representation of ETS-10 polymorph B viewed along [100] or [0$\bar{1}$0] showing the tetrahedral silicon atoms (black) and the chains of octahedral titanium atoms (gray). The novel microporous vanadosilicate AM-6 has a similar structure in which hexacoordinated Ti^{4+} ions are replaced by V^{4+} ions (and probably also V^{5+} ions).

metry, respectively. Since ETS-10 contains corner-sharing TiO_6 octahedra and corner-sharing SiO_4 tetrahedra for every titanium atom in the framework, the associated charge is -2. This charge is compensated by cations not in the framework (usually Na^+ and K^+). The formula of anhydrous ETS-10 is $M^{m+}_{2/m})TiSi_5O_{13}$, where M is a cation with charge m. The cation density in ETS-10 is, therefore, approximately equivalent to that in a zeolite with Si/Al = 2.5, for example zeolite Y. We have also reported on the isomorphous substitution of silicon in ETS-10 by aluminium and gallium.[3, 4]

As a result of a systematic study aimed at replacing selectively some titanium atoms by vanadium atoms in the framework of ETS-10, we prepared a pale green vanadosilicate (containing *no* titanium) with the structure of ETS-10. Vanadium has already been introduced in the framework of certain zeolites in small amounts. However, to the best of our knowledge, cavansite and pentagonite, dimorphs of the mineral $Ca(VO)(Si_4O_{10})\cdot 4H_2O$ (Malheur County, Oregon), are the only microporous framework solids known to contain stoichiometric amounts of vanadium.[5, 6] The framework of cavansite is formed by silicate layers of four- and eight-membered rings of tetrahedra connected vertically by V^{4+} cations that are in a square-pyramidal coordination. Replacement of the VO_5 group by two bridging oxygens would produce a tetrahedral framework topologically identical to that of zeolite gismondine. The Ca cations and the water molecules reside in the channels formed by the eight-membered rings and between the SiO_2 layers. Cavansite has channels running parallel to the c direction with a free diameter of only 3.3 Å in the hydrated state.[5, 6] Hence, both cavansite and pentagonite are likely to behave (at best) as small-pore materials.

In this paper we report the synthesis and structural characterization of the novel large-pore vanadosilicate containing hexacoordinated vanadium and possessing a structure similar to that of ETS-10. We have named this material AM-6 (*A*veiro–*M*anchester).

Nitrogen adsorption isotherms on ETS-10 and AM-6 (not shown) are both rectilinear, characteristic of microporous materials, with maximum uptakes of about 0.12 and 0.15 $g_{nitrogen}$ per $g_{adsorbant}$, respectively. Thermogravimetric analysis gives a weight loss (water) at 50 and 400 °C of about 13%, similar to that measured for ETS-10. Our best AM-6 sample seems to be a pure phase. Scanning electron microscopy (not shown) indicates that this material contains only a very small amount of quartz as impurity. The cuboid AM-6 crystals are similar to ETS-10 crystals, with a particle size of around 1 to 3 μm. Figure 2 shows high-resolution electron micrographs obtained on a JEM microscope operated at 1.25 MeV. Because AM-6 is much less stable than ETS-10 in the electron beam, the images are of a somewhat lower quality than those given for ETS-10.[1, 2] Despite this there can be no doubt from Figure 2 that AM-6 is indeed a wide-pore material with a structure closely related to that of ETS-10. Detailed analysis of the micrographs suggests that the stacking disorder is similar in both materials.

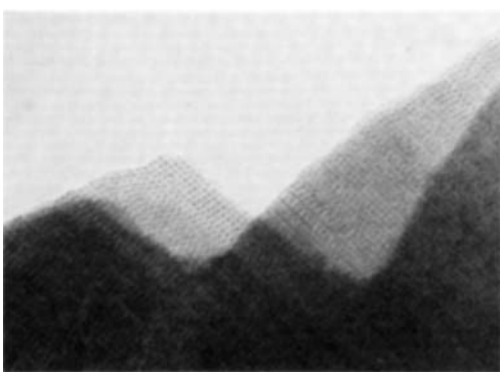

Figure 2. High-resolution electron micrograph of microporous vanadosilicate AM-6 viewed along a direction perpendicular to the z axis.

The powder X-ray diffraction (XRD) patterns of ETS-10 and AM-6 shown in Figure 3 further confirm that the two solids have very similar structures. The strongest AM-6 reflection appears at a d-spacing (3.599 Å) slightly lower than that of ETS-10 (3.614 Å), but this is not altogether unexpected since V^{4+} and V^{5+} ions are slightly smaller than Ti^{4+} ions.

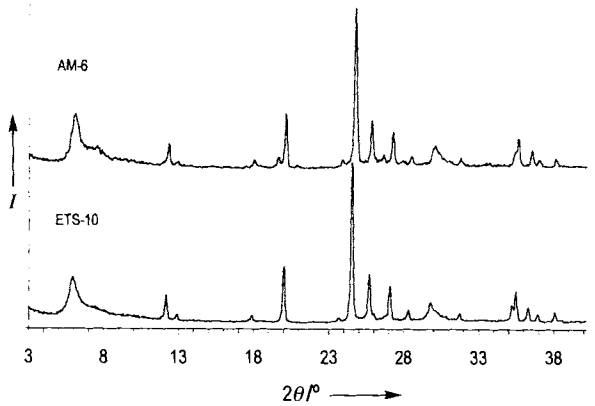

Figure 3. Powder XRD patterns of ETS-10 and microporous vanadosilicate AM-6. I = intensity (arbitrary units).

The Raman spectra of ETS-10 and AM-6 are shown in Figure 4. The former displays a strong band at about 730 cm^{-1} associated with the TiO_6 octahedra,[7] whereas AM-6 gives a strong, sharp signal at 870 cm^{-1}. Octahedrally coordinated vanadate species are usually not symmetric, and in general their Raman bands can not be used to fingerprint their structures. For an ideal VO_6 octahedron the highest frequency stretching bands are estimated to occur as low as 607 cm^{-1}.[8] However, in practice the bands appear at much higher frequency. For example, one of the most regular VO_6 octahedral structures known is contained within the decavanadate ion in $Na_6V_{10}O_{28}\cdot 18H_2O$; the highest stretching frequency from this structure appears at 830 cm^{-1}.[8] We assign the AM-6 band at 870 cm^{-1} to relatively undistorted VO_6 octahedra. Since the

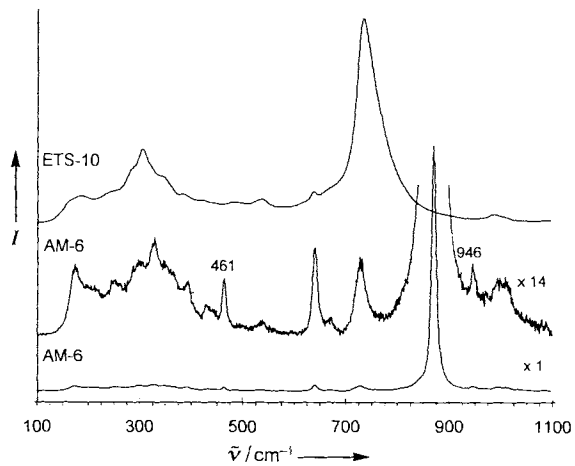

Figure 4. Stokes-shifted Raman spectra of ETS-10 and microporous vanadosilicate AM-6, measured at room temperature, with 1 cm^{-1} resolution (Renishaw Raman imaging microscope 2000 model fitted with a Spectra Physics 127 HeNe laser for excitation at 632.8 nm; 25 mW power at the source). I = intensity (arbitrary units).

Raman spectra do not display the characteristic bands at 994, 701, 526, and 481 cm^{-1}, our AM-6 samples do not seem to contain any V_2O_5. The structure of AM-6 may only contain (short) terminal V=O bonds in defect sites or on the surface of crystallites. Accordingly, the main AM-6 band is seen at 870 cm^{-1}, whereas the Raman bands associated with V=O bonds usually appear at 900–1000 cm^{-1}.[8] Close inspection of the spectrum of AM-6 reveals the presence of a weak band (not seen for ETS-10) at 946 cm^{-1}, which is perhaps due to a relatively small number of V=O bonds in the environments mentioned above. In the spectral range 100 to 700 cm^{-1} most AM-6 bands are also exhibited by ETS-10. However, the bands of the former are much weaker and seem to appear at slightly different frequencies. The band at 461 cm^{-1} is not seen in the spectrum of ETS-10.

The room-temperature electron paramagnetic resonance spectrum of AM-6 (not shown) displays a single, relatively broad resonance (peak-to-peak width about 53 G) centered at $g = 1.9545$ and lacking hyperfine structure, which indicates, the presence of (nonisolated) V^{4+} in dipolar interaction with other V^{4+} ions. Although we were unable to observe any ^{51}V magic-angle spinning (MAS) solid-state NMR signals from the samples prepared so far, the framework of AM-6 probably also contains V^{5+} ions. Indeed, the presence of paramagnetic V^{4+} may render the V^{5+} signal too broad to be detected. On the other hand, preliminary experiments show that upon calcination in oxygen (or air) at 400 °C AM-6 turns from faint green to white and gives a broad ^{51}V MAS NMR signal at $\delta = -566$ (relative to $VOCl_3$). However, powder XRD (not shown) suggests that the AM-6 structure has partially collapsed. At 450 °C the sample is completely amorphous. Hence, we can not draw any conclusions about the coordination of vanadium in AM-6 based on the NMR results.

In conclusion, the novel large-pore vanadosilicate possesses a structure similar to that of ETS-10. The presence of stoichiometric amounts of vanadium in the framework of AM-6 gives this material a great potencial for applications as a catalyst, sorbate, or functional material.

Experimental Section

Synthesis of microporous vanadosilicate AM-6: An alkaline solution was made by mixing sodium silicate (6.26 g; Na_2O 8 wt%, SiO_2 27 wt%), H_2O (8.03 g), NaOH (0.20 g), KCl (0.99 g), and NaCl (3.08 g). A second solution was made by mixing H_2O (7.60 g) with $VOSO_4 \cdot 5H_2O$ (1.50 g). These two solutions were combined, seeded with 0.10 g ETS-10, and stirred thoroughly. The gel ($Na_2O:K_2O:SiO_2:V_2O_5:H_2O$ composition of 1.0:0.23:0.97:0.10:30) was heated in an autoclave under autogeneous pressure for 3 days at 230 °C. The crystalline product was cooled down to room temperature, filtered, washed with distilled water, and dried at 120 °C. Energy-dispersive absorption of X-rays by single crystals and bulk chemical analysis yield Si/V molar ratios of about 4.9 and 5.4, respectively.

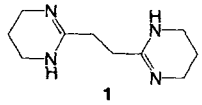
The Simultaneous Use of H-Bonding and Coulomb Interactions for the Self-Assembly of Fumaric Acid and Cyclic Bisamidine into One- and Two-Dimensional Molecular Networks**

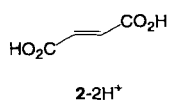
Olivier Félix, Mir Wais Hosseini,* André De Cian, and Jean Fischer

Molecular solids are defined by the chemical nature of their molecular components and by their interactions in the crystalline phase. Whereas molecular chemistry deals with the design and the synthesis of the individual units, their assembly into a solid is governed by concepts of supramolecular chemistry.[1, 2] Although tremendous progress has been achieved by molecular chemistry in terms of planning the synthesis of desired structures and properties, the supramolecular design and synthesis of solid materials still remain great challenges.[3] By using both molecular and supramolecular concepts, the manufacture of strictly programmed and controlled solids can be envisaged through the self-assembly[4] of structurally defined and energetically programmed tectons.[5] In principle, any type of weak intermolecular interactions may be used to construct molecular solids. Although a structurally characterized α-network based on van der Waals interactions has been recently reported,[6] the majority of examples deals with hydrogen bonding.[7] Furthermore, most cases so far describe nonionic hydrogen-bonding patterns. Although one-dimensional molecular cocrystals are rather common,[1, 8, 9b] the synthesis of two-dimensional β-networks[9c, 10] and three-dimensional γ-networks[5, 11] is under intensive investigation.

Our approach to organic crystal engineering was based on the simultaneous use of directional hydrogen bonding and less directional electrostatic interactions between complementary units. Our first attempt aimed at assembling an α-network from centrosymmetric dicationic molecular tectons[9a] such as **1**-2H$^+$ with dianionic modules such as iso- and terephthalate dianions.[9b] The extension from α- to β-networks requires the interconnection of individual rods or ribbons. To achieve this with a two-component system, another dimension could be added within the structure of the building blocks, for example by using an sp^3 center such as phosphates instead of sp^2 carboxylate units.[9c] Another possibility may be to increase in the number of constituents. Most examples deal with two-component cocrystals. We describe here the formation of an α-network by using a two-component system and its extension to a β-network by interconnecting α-networks by a third component (Figure 1c).



1



2-2H$^+$

We have previously demonstrated[9] that amidines such as **1**[12] were interesting tectons for crystal engineering. Indeed, due to the conjugation of the amidine group, the diprotonated

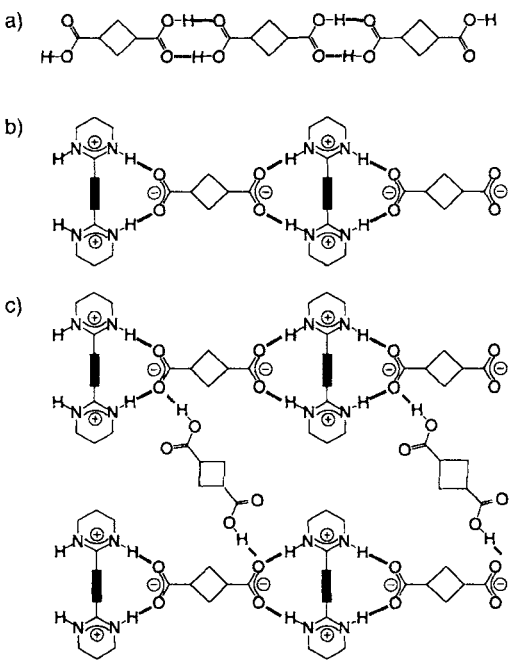

Figure 1. Schematic representations of α-networks that use intermolecular hydrogen bonding a) between dicarboxylic acids and b) between dicarboxylate dianions and dicationic organic connectors, as well as c) of a β-network formed by interconnection of α-networks. The squares represent spacers.

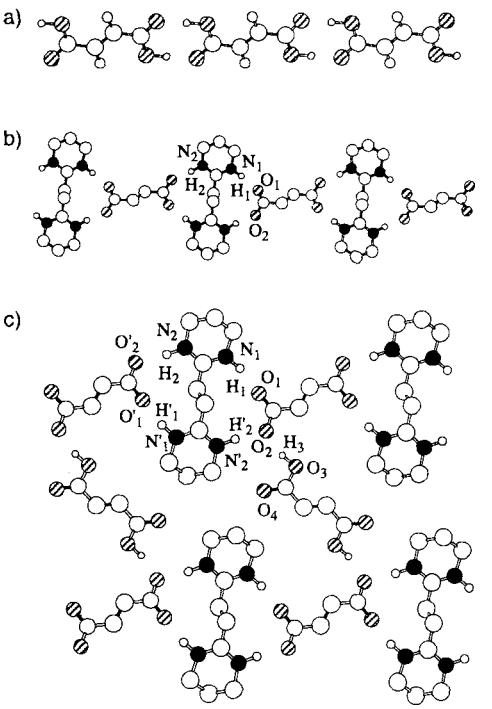

Figure 2. X-ray structures [15] of α-networks formed a) by fumaric acid and b) by the fumarate dianion 2^{2-} and the dicationic module 1-2H$^+$, as well as c) the structural analysis of a β-network formed by interconnection of α-networks by fumaric acid groups 2-2H$^+$. For bond lengths and angles see text.

1-2H$^+$ dication possesses four N–H acidic protons pointing outward and thus capable of acting as donor for four hydrogen bonds. As the complementary anionic tecton, fumarate dianions 2^{2-} bearing two negative charges distributed over four oxygen atoms and thus capable of accepting at least four hydrogen bonds was chosen (Figure 1a and b).

The mixing of the free base **1** with fumaric acid 2-2H$^+$ in different ratios in a water/ethanol mixed solvent gave two distinct types of cocrystals.

As predicted and previously observed for 1/1 cocrystals of **1** and tere- or isophthalic acids,[9b] infinite linear chains (one-dimensional α-network) exclusively composed of the 1-2H$^+$ dication and the 2^{2-} dianion interconnected in the solid state through strong hydrogen bonds were obtained (Figure 2b).[13a] The analysis of the unit cells revealed the following features: a) Due to the *trans* conformation of the ethylene chains connecting the two amidines, the N1, N2, C1 and N′1, N′2, C′1 planes are almost parallel but not coplanar. The two carboxylate groups of 2^{2-}, however, are essentially coplanar. b) All four acidic protons are localized on **1** with an average N–H distance of about 1.01 Å. c) The dications 1-2H$^+$ and fumarate dianions 2^{2-} are connected symmetrically through four strong hydrogen bonds[14] with an average N···O distance of about 2.72 Å and an NH···O distance of about 1.72 Å. The average NHO angle is about 172°. The lattice analysis revealed that the infinite linear chains (Figure 2b) are discrete without any specific interactions between them.

Fumaric acid has been shown to crystallize in an α and a β form.[15] In both cases, as often observed for dicarboxylic acids, a one-dimensional α-network results from intermolecular hydrogen bonding between units (Figure 1a and 2a). The α-network formed from 1-2H$^+$ and 2^{2-} may be considered either as an infinite anionic chain of fumarate 2^{2-} ions interconnected in a linear fashion by dications 2-2H$^+$, or conversely as an infinite cationic chain of 1-2H$^+$ ions interconnected by 2^{2-} dianions (Figure 2b).

Whereas for the 1/1 cocrystals of **1** and 2-2H$^+$ only a one-dimensional α-network composed of 1-2H$^+$ and 2^{2-} units could be observed, for the 1/2 cocrystals the X-ray analysis[13b] revealed the presence of a two-dimensional β-network in which the dicationic bisamidinium units 1-2H$^+$, as in the case of 1/1 cocrystals, were connected to each other through the dianionic fumarate 2^{2-} and the resulting one dimensional α-networks in turn were connected through hydrogen bonding by fumaric acid 2-2H$^+$ moieties (Figures 1c and 2c).[13c] The simultaneous presence of fumarate 2^{2-} ions and fumaric acid 2-2H$^+$ is supported by two sets of C–O distances ($d_{C\sim O1} = 1.24$ Å, $d_{C\sim O2} = 1.27$ Å (CO^-) for 2^{2-} and $d_{C-O3} = 1.31$ Å (C-O3H3), $d_{C\sim O4} = 1.21$ Å (C=O4) for 2-2H$^+$). Whereas the O4 oxygen is not hydrogen bonded, the O3 oxygen connects the α-networks through the H3 proton. The α-network of the 1/2 cocrystals is rather similar to the one of the 1/1 cocrystals. Both the conformations of the two components 1-2H$^+$ and 2^{2-} in each cocrystal and the hydrogen-bonding pattern connecting the cationic and anionic units are the same; however, the hydrogen-bonding pattern is less symmetrical in the 1/2 cocrystals than in the 1/1 cocrystals. In contrast to the latter in which the N–O bond lengths were almost the same, for the 1/2 cocrystals one rather short ($d_{N1\sim O1} = 2.76$ Å) and one longer ($d_{N'2\sim O2} = 2.86$ Å) N–O distance were observed. Furthermore, the N1H1O1 (159.7°) and the N′2H′2O2 angles (175.3°) are distinctly different. Thus the α-networks are indeed linked by strong hydrogen bonding through H_3 between fumarate dianions 2^{2-} and fumaric acid 2-2H$^+$ ($d_{O2-O3} = 2.54$ Å, $d_{O2-H3} = 1.60$ Å; O2H3O3 angle: 162°). The N′2O2O3 angle of 113.2° and the H′2O2H3 angle of 108.5° indicated a rather perfect arrangement of hydrogen-bond donors and acceptors. The β-network thus obtained may be described either as α-networks composed of 1-2H$^+$ and 2^{2-} units interconnected by fumaric acid 2-2H$^+$, or as α-networks, based on hydrogen-bonded fumarate 2^{2-} and fumaric

acids **2**-2H$^+$, interconnected by the dicationic **2**-2H$^+$ units (Figure 2c).

In conclusion, the following points may be emphasized: 1) compound **1**-2H$^+$, which as dicationic building block is capable of acting as H-donor for four H-bonds, is well suited for hydrogen bonding to two dicarboxylate ions; 2) through both electrostatic interactions and directionally controlled H-bonding, positive and negative units may be assembled in the solid state into an α-network with predictable structures; and 3) by varying the ratio of the two components, β-networks or layered structures may be generated by interconnection of α-networks.

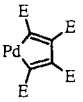
Preparation of Enantiomerically Pure 5-Palladatricyclo[4.1.0.0^{2,4}]heptanes and Conversion into Enantiomerically Pure Complexes with Helical Chirality at Palladium**

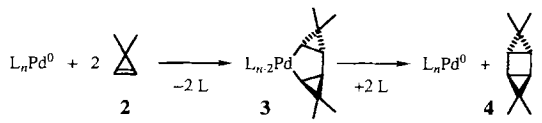
A. Stephen K. Hashmi,* Frank Naumann, Ralf Probst, and Jan W. Bats

In 1971 Maitlis observed the formation of stable palladoles **1** from Pd^0 compounds and acetylenedicarboxylates.[1] In the following years the chemistry of these compounds was intensively investigated by several groups.[2] Of special significance for organic chemists was the subsequent observation made by Trost and Tanoury in 1987[3a] that palladoles are cycloisomerization catalysts facilitating unique, synthetically very interesting reactions (enyne metathesis and related conversions). In some of these cycloisomerization reactions racemic products with one or more stereocenters are formed from achiral starting compounds.[3] While the diastereoselectivity of these reactions with regard to stereocenters already existing in the starting material has been investigated, so far no chiral catalyst has been found that enables an asymmetric induction.[4] Our aim is the synthesis of chiral catalysts with palladole-like structure for the enantioselective variants of the reactions mentioned above. We were encouraged by successful applications of achiral palladacycles with carbon ligands as catalysts for Heck and cross-coupling reactions.[5]



1

To bring the chiral information as close as possible to the metal center, we planned to utilize cyclopropanes as homoolefins. Binger et al. showed that Pd^0 complexes of cyclopropenes **2** without substituents at the 1- and 2-positions dimerize to give tricyclo[3.1.0.0^{2,4}]hexanes **4**.[6a,b,f] In the presence of



2 **3** **4**

stabilizing ligands the presumed intermediates, 5-palladatricyclo[4.1.0.0^{2,4}]heptanes **3** (PTHs), could be obtained as stable compounds.[7] The complexes have the C_2 symmetry shown; C_s-symmetrical compounds were observed as side products only in the case of the analogous nickel complexes. It was also known that cyclopropenes can be opened by transition metals to give vinylcarbene complexes[6f,8] and that the 1,2-disubstituted cyclopropenes investigated previously formed no PTHs.[9]

In analogy to Maitlis's palladoles we hoped to be able to isolate the PTHs formed from ester-substituted cyclopropenes without additional stabilizing ligands. The 1,2-dicarboxyalkyl-3,3-dimethylcyclopropenes **5** we needed were readily accessible based on the work of Franck-Neumann.[10] From $[Pd_2(dba)_3] \cdot CHCl_3$ (dba = dibenzylideneacetone) and **5** we obtained the PTH *rac*-**7** in 92% yield (Scheme 1). The yellow compound was

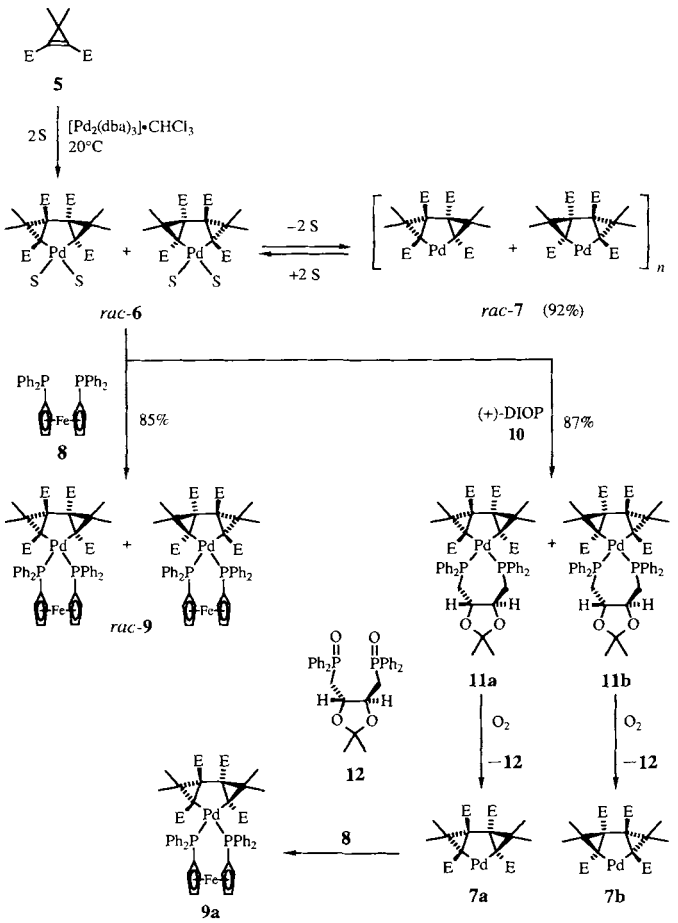

Scheme 1. Synthesis and reactions of *rac*-**6**/*rac*-**7**. E = CO_2Me, S = acetone.

purified by column chromatography and could be stored for months without detectable decomposition.[11] We assume that *rac*-**7** has a polymeric structure analogous to **1**, in which both free coordination sites of palladium are occupied by the carbonyl groups of carboxylic esters of neighboring PTHs.[1] The good solubility of **7** in acetone may be explained by the disruption of the polymeric structure and formation of the monomeric complex **6**. We could not detect products with three or four cyclopropyl units like those described by Binger et al. for the reaction of **2** with Pd^0 compounds.[6, 7]

Now the question arose whether *rac*-**7** has the C_2 symmetry necessary for a chiral compound in this case or C_s symmetry. Complexation of *rac*-**7** with 1,1′-bis(diphenylphosphanyl)ferrocene (**8**) yielded the crystalline compound *rac*-**9**. The X-ray structure analysis of *rac*-**9** proved the constitution and the *anti* arrangement of the two cyclopropane rings of **7**.[12] The C_2 symmetry was proven even more quickly by coordination to the bidentate, C_2-symmetrical, chiral ligand (+)-2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(diphenylphosphanyl)butane ((+)-DIOP, **10**). Two diastereomeric complexes **11a** and **11b** were formed, which were easily separated by HPLC. If **6** were to have a C_s-symmetrical arrangement, one would expect only one product. This separation of the racemic PTHs has the advantage that both enantiomers of **7** are equally accessible. The disadvantage is that the coordination sites for the substrate are blocked by the bidentate diphosphane. To prepare a potential catalyst, the (+)-DIOP ligand must be removed from **11**, for example by oxidation with air.[13] Thus enantiomerically pure **7** and the chiral bis(phosphanoxide) **12** were obtained.[12, 14, 15]

Since the relative configurations of the two diastereomers of **11** had not been assigned yet, the complex **9a** was formed from the **7a** synthesized from **11a** (Table 1) and again investigated by X-ray structure analysis (Figure 1).[12] The absolute configuration was assigned by the anomalous dispersion effect[12] as (1*R*,2*R*,4*R*,6*R*). We were surprised that **9a** does not have the square-planar coordination environment at the Pd center one would expect for the formal oxidation state of +II. The C-Pd-C and the P-Pd-P planes are tilted towards each other. The phosphane ligand is shifted towards the side where the cyclopropane ring is bent back and thus points away from the ester group. This interaction should be utilized later for the transfer of chirality to the substrate of catalytic reactions. The similarity of the structures of *rac*-**9** and **9a** prove that the tilt is essentially an intramolecular effect and not a stacking effect. The deviation from square-planar geometry is 28.4(1)° in the first case and even 30.4(2)° in the second case! As a result, not only are the four carbons of palladacycle **9** chiral centers, but also the metal center defines helical chirality in the complex.[16] Thus the tricyclo[4.1.0.$0^{2,4}$]heptane framework is composed exclusively of quarternary carbon atoms, only two of which are not stereo-

centers. To our knowledge **9a** is the first example of a enantiomerically pure palladacyclopentane showing helical chirality at palladium.[17]

The X-ray analyses of *rac*-**9** and **9a** show that the two structures are almost superimposable. Complex **9a** is exactly C_2-symmetrical (axis through Fe and Pd), *rac*-**9** has close to C_2 symmetry. The angle between the planes of the cyclopentadienyl rings of the ferrocene subunit is 4°. The Pd–C bond lengths correspond to known values for related compounds. The Pd–P bond lengths of 2.39 Å are significantly longer than those in other Pd^{II} complexes of **8**.[18] This could explain why the bidentate ligands can be removed so easily.

Although the diastereomers **11a** and **11b** can be separated by HPLC, the detour of complex formation with chiral phosphanes, separation, and subsequent decomplexation might be avoided by the installation of chiral substituents in the cyclopropenes. Then instead of the enantiomers **7a** and **7b**, two HPLC-separable diastereomeres would form. In future investigations we plan to employ cyclopropenecarboxylic esters prepared from chiral alcohols.

Experimental Section

rac-**7**: A solution of **5** (400 mg, 2.17 mmol) in 20 mL of acetone was added to a well-stirred suspension of $[Pd_2(dba)_3]\cdot CHCl_3$ (400 mg, 386 μmol) in 100 mL of acetone at room temperature. The $[Pd_2(dba)_3]\cdot CHCl_3$ completely dissolved within 3 h, and the dark violet reaction mixture turned yellow. After 12 h the solvent was removed in vacuo, and the residue was purified by chromatography on silica gel eluting with acetone/*n*-hexane (3/2) to give *rac*-**7** as a yellow solid (337 mg, 92%).

[4] So far only palladoles are known to catalyze enyne metathesis and related reactions; diphosphanes inhibit these reactions. Thus it is not possible to use one of the numerous known chiral, nonracemic diphosphane ligands, as recently described for the first time for enyne cycloisomerisation (A. Goeke, M. Sawamura, R. Kuwano, Y. Ito, *Angew. Chem.* **1996**, *108*, 686–687; *Angew. Chem. Int. Ed. Engl.* **1996**, *35*, 662–663).

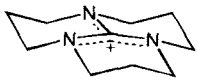
Geometry-Tunable Lewis Acidity of Amidinium Cations and Its Relevance to Redox Reactions of the Thauer Metal-Free Hydrogenase: A Theoretical Study**

Jerzy Cioslowski* and Gernot Boche*

Dedicated to Professor Waldemar Adam on the occasion of his 60th birthday

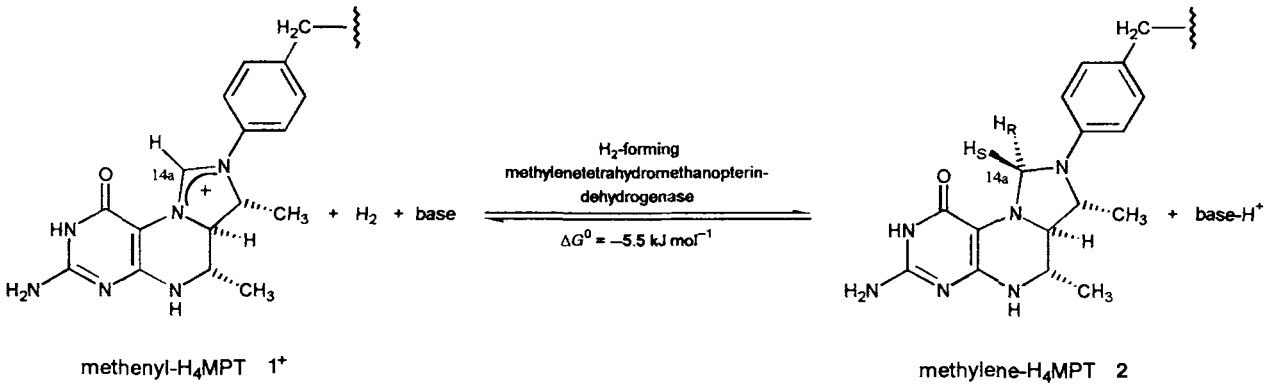
Some years ago R. K. Thauer et al. made the astonishing discovery of a metal-free hydrogenase.[1] When bound to an enzyme, N^5,N^{10}-methenyltetrahydromethanopterin (methenyl-H_4MPT $\mathbf{1}^+$), which is an amidinium ion, reacts reversibly with dihydrogen to yield N^5,N^{10}-methylenetetrahydromethanopterin (methylene-H_4MPT **2**) and a proton. Since all other presently known hydrogenases activate dihydrogen H_2 by the formation of an M–H_2 complex (where either Ni or Fe/S serves as the metal M),[2] this redox process must proceed by a completely new mechanism. Such a mechanism, proposed by Berkessel and Thauer,[3] is shown in Scheme 1. For the reverse reaction ($\mathbf{2} + H^+ \rightarrow \mathbf{1}^+ + H_2$), which undoubtedly benefits from the resonance stabilization of the planar amidinium ion $\mathbf{1}^+$, the experimental findings are in agreement with H_R of **2** being transferred to H^+ as a hydride H_R^-.[4, 5] The feasibility of such a hybride transfer is corroborated by an analogous reaction in which the protonation of a structurally related orthoamide produces the guanidinium ion $\mathbf{3}^+$ and H_2 (HCl or HBF_4, 110 °C, 23 h).[6]



$\mathbf{3}^+$

On the other hand, the reaction of $\mathbf{3}^+$ with H_2 to give the orthoamide and H^+ is not observed. Likewise, amidinium ions have never been reported to react with H_2. It is therefore clear that the enzyme-bound $\mathbf{1}^+$ must be somehow destabilized and thereby have its Lewis acidity increased for the reaction with H_2. According to the mechanism proposed by Berkessel and Thauer,[3] this destabilization is achieved by bending the cationic carbon C14a in $\mathbf{1}^+$ out of the plane of the other four atoms present in the five-membered ring. Such bending decreases the delocalization of the nitrogen lone pairs into the empty p_z orbital of this carbon. Consequently, the enzyme-bound $\mathbf{1}^+$ should behave more like conventional carbocations and react like they do with H_2.[7] Correspondingly, the enzyme-bound **2** is known to exchange protons with the solvent H_2O,[4, 5] in analogy with the protonation (deuteration) of C–H bonds with very strong acids that results in the $H^+(D^+)$-exchange with or without the formation of carbocations.[8, 9]

One readily concludes from this discussion that the plausibility of the Berkessel–Thauer mechanism hinges upon the right balance of the Lewis acidity of $\mathbf{1}^+$ and the acidity of the proton H^+ or, more precisely, its base-bound equivalent base–H^+ (Scheme 1). For an enzyme reaction in water, water can be the base to give H_3O^+. It is, however, also likely (and even indicated by the structure of $\mathbf{1}^+$) that protonation of an amine (general formula R_3N) to R_3NH^+ might be relevant. Therefore, in order to establish the feasibility of this mechanism, we have carried out rigorous calculations[10] first on the energetics of model reactions (1) and (2), in which solvation of H^+ by a base is not taken into account—as originally formulated[3] (Table 1). Secondly, the influence of the solvent water H_2O on the reaction energetics was assessed by investigating the analogous transformations (3) and (4).[11] Thirdly, we calculated the energetics of the reactions (5) and (6), in which NH_3 (also solvated in water[11]) serves as a model for amine bases.



Scheme 1. The reversible redox reaction of the Thauer metal-free hydrogenase (the complete structural formulas are given in ref. [4]).

Like the enzyme-free $\mathbf{1}^+$, the planar model amidinium ion $\mathbf{4}^+$ is stabilized by delocalization of the lone pairs of two nitrogens into the p_z orbital of the carbon atom they flank. The parallel orientation of these three orbitals, however, is impossible in the bicyclic amidinium ion $\mathbf{6}^+$, making it an appropriate model to study the possible bending of the enzyme-bound $\mathbf{1}^+$. Interestingly, the plane A of the N-CH^+-N moiety in $\mathbf{6}^+$ does not dissect the angle between the planes B and C of the two N-CH_2-CH_2-N chains. Consequently, $\mathbf{6}^+$ has C_s rather than C_{2v} symmetry. This decrease in symmetry reflects the trade-off between electron delocalization, which favors a coplanar arrangement of the planes A and B, and strain, which is minimized when the inclina-

$4^+ + H_2$	→	$5 + H^+$	244	(1)
$6^+ + H_2$	→	$7 + H^+$	149	(2)
$4^+ + H_2 + H_2O$	→	$5 + H_3O^+$	33	(3)
$6^+ + H_2 + H_2O$	→	$7 + H_3O^+$	−57	(4)
$4 + H_2 + NH_3$	→	$5 + NH_4^+$	4	(5)
$6^+ + H_2 + NH_3$	→	$7 + NH_4^+$	−87	(6)

tion angle of A with respect to B is the same as that of A with respect to C. The actual energy minimum for 6^+ is attained at the inclination angles $\varphi_{AB} = 30.2°$ and $\varphi_{AC} = 67.7°$. In contrast, the optimized geometry of the bicyclic (bent) aminal **7** exhibits C_{2v} symmetry, reflecting the lack of electron delocalization in this species. For the same reason, the aminal **5** assumes a twisted conformation with C_1 symmetry (note the lowering from C_2 symmetry that is due to the coupling between ring puckering and the rotation of the methyl groups).

The base-free reactions (1) and (2) are predicted to be highly endothermic by 244 and 149 kcal mol^{-1}, respectively.[12] Thus, neither the planar 4^+ nor the bent 6^+ is expected to react with H_2 in the absence of a suitable proton acceptor. However, the addition of a base alters the energetic balances of these reactions dramatically.[13] Indeed, whereas the reaction of planar 4^+ with H_2 and H_2O (reaction (3)) is still endothermic by 33 kcal mol^{-1}, the analogous transformation of the bent 6^+ (reaction (4)) is exothermic by 57 kcal mol^{-1}. From these two numbers one immediately concludes that the reaction of an amidinium ion with H_2 and H_2O to give an aminal and H_3O^+ can be made thermoneutral by deforming the five-membered rings of the amidinium ion and the aminal from planarity. A crude estimate[14] yields the value of 18° for the angle of inclination between the N-CH$^+$-N (N-CH$_2$-N) and N-C-C-N planes of the five-membered rings in 1^+ (**2**) necessary to make the redox reaction $1^+ + H_2 + H_2O \rightleftharpoons 2 + H_3O^+$ reversible.

With the model base NH_3, the reaction of the planar amidinium ion 4^+ (reaction (5)) is endothermic by only 4 kcal mol^{-1}, while the transformation of its bent analogue 6^+ (reaction (6)) is exothermic by 87 kcal mol^{-1}. Thus, the bending angle in 1^+ (**2**) required to make the process $1^+ + H_2 + NH_3 \rightleftharpoons 2 + NH_4^+$ thermoneutral is estimated[14] at only 6°.[15]

The present study establishes the thermodynamic feasibility of the Berkessel–Thauer mechanism in the presence of a base.[3] It should be emphasized that the enzyme reactions studied here are possible only because of the interplay of several factors that balance the Lewis acidity of 1^+ with the basicity of the model proton acceptors H_2O and NH_3. Although the inductive effects of the nitrogen atoms of the amidinium ion moiety in 1^+ bring the Lewis acidity of 1^+ into the right range (compare the Lewis acidities of 6^+ and CH_3^+),[10, 12] it is the bending that provides the necessary fine-tuning. The bending, especially by the angle of 6° estimated for 1^+ (**2**) from the reactions of 4^+ (6^+) with H_2 and NH_3 as a model for an amine base, should not be excessively difficult to attain in the enzyme. One should also point out that the present calculations do not address the question of the reaction kinetics, in other words the activation energy. This energy is expected to be very sensitive to the molecular environment around the reaction center, which cannot be modeled without a detailed knowledge of the enzyme structure.

[10] All the data reported here were obtained at the BLYP/6-311G(2d,2p) level of theory. The adequacy of such a treatment for the reactions between carbocations and H_2 is demonstrated by the following predictions for the energy of the process $CH_3^+ + H_2 \rightarrow CH_4 + H^+$ (at 0 K): 88.3 (G1), 88.5 (G2), 88.9 (G2MP2), 86.2 (CBS-4), and 88.3 kcal mol^{-1} (the present calculations). For a recent comparison of the high-accuracy G1, G2, G2MP2, and CBS-4 methods see: J. W. Ochterski, G. A. Petersson, K. B. Wiberg, *J. Am. Chem. Soc.* **1995**,

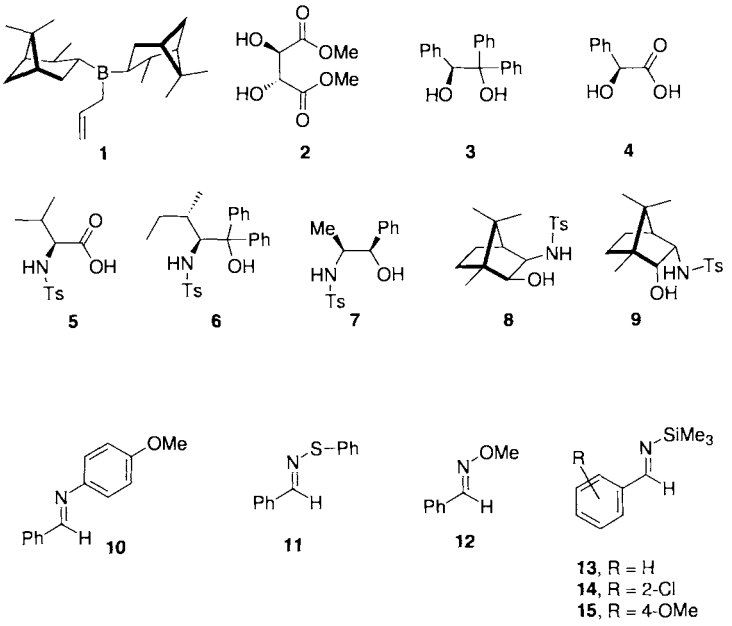
[11] The solvent effects were modeled with the SCI-PCM (Self-Consistent Isodensity Polarized Continuum Model) formalism using the dielectric constant of 80 and the default isodensity value. All geometries were fully optimized in the presence of the reaction field of the solvent. The calculations were carried out with the GAUSSIAN 94 suite of programs: GAUSSIAN 94; M. J. Frisch, G. W. Trucks, H. B. Schlegel, P. M. W. Gill, B. G. Johnson, M. A. Robb, J. R. Cheeseman, T. Keith, G. A. Petersson, J. A. Montgomery, K. Raghavachari, M. A. Al-Laham, V. G. Zakrzewski, J. V. Ortiz, J. B. Foresman, J. Cioslowski, B. B. Stefanov, A. Nanayakkara, M. Challacombe, C. Y. Peng, P. Y. Ayala, W. Chen, M. W. Wong, J. L. Andres, E. S. Replogle, R. Gomperts, R. L. Martin, D. J. Fox, J. S. Binkley, D. J. Defrees, J. Baker, J. P. Stewart, M. Head-Gordon, C. Gonzalez, J. A. Pople, Gaussian, Inc., Pittsburgh, PA, **1995**.

[12] These numbers do not include ZPE corrections, which are found to be small (ca. 2 kcal mol^{-1}) for the reaction $CH_3^+ + H_2 \rightarrow CH_4 + H^+$. Moreover, the values of $\Delta E°$ at 0 K, ΔE^c, ΔH^c, and $\Delta G°$ for this process are predicted to be very similar (88.5, 87.9, 87.9, and 89.5 kcal mol^{-1}, respectively, at the G2 level of theory), indicating that energy differences can be used directly to estimate the directions of the reactions involving the model cations 4^+ and 6^+.

[13] A recent account on the significance of the stabilization of localized charges in enzymatic reactions other than that of H^+ has been given by J. A. Gerlt, P. G. Gassman, *Biochemistry*, **1993**, *32*, 11943–11952; see also G. L. Kenyon, J. A. Gerlt, G. A. Petsko, J. W. Kozarich, *Acc. Chem. Res.* **1995**, *28*, 178–180, and the references therein.

[14] This estimate is obtained as follows: To the first degree of approximation, the Lewis acidity of $\mathbf{1}^+$ and thus the energy ΔE of the reaction $\mathbf{1}^+ + H_2 + H_2O \rightarrow \mathbf{2} + H_3O^+$ is related to the bending φ of the five-membered ring. Assuming that all other factors are equal, the dependence of ΔE on φ can be derived from the energies of the reactions involving $\mathbf{4}^+$ and $\mathbf{6}^+$. Since ΔE is an even function of φ, the proper interpolating function is $\Delta E(\varphi) \approx A + B(1 - \cos\varphi)$, with $A = 33$ kcal mol^{-1} and $B = -671$ kcal mol^{-1}. Setting $\Delta E(\varphi) = 0$ produces the value quoted in the text.

[15] The difference calculated for H_2O and NH_3 as bases corresponds to the experimental observation that the enzymatic reaction $\mathbf{1}^+ + H_2 \rightarrow \mathbf{2} + H^+$ is more exergonic if the concentration of H^+ is lowered (higher pH value): R. K. Thauer, private communication, August 21, **1996**. The different effects of a model oxygen (H_2O) and a model nitrogen base (NH_3) might also be of interest in considerations concerning the transition state of the reaction of this hydrogenase.



Enantioselective Synthesis of Homoallylamines by Nucleophilic Addition of Chirally Modified Allylboron Reagents to Imines**

Shinichi Itsuno,* Katsuhiro Watanabe, Koichi Ito, Ashraf A. El-Shehawy, and Ali A. Sarhan

The reactions of allylboron reagents with imine derivatives are of considerable interest in the context of the acyclic stereoselective synthesis of amines.[1] Hence, in recent years, some diastereoselective allylborations of enantiomerically pure imines have been developed to give chiral amines.[2] Although the enantioselective addition of chirally modified allylmetals to aldehydes has been studied extensively,[3] few examples have been reported on the same reaction with imine derivatives. In connection with our ongoing studies on asymmetric synthesis of optically active amines[4] by asymmetric addition to the C=N bond of prochiral imines, we were interested in developing further the enantioselective allylboration of imines as a route to optically active homoallylamines. The resulting enantiomerically enriched homoallylamines are of premier importance as substructures of numerous biologically active natural products as well as building blocks for β-lactam synthesis.[2c, 5] We have now been able to show that allylborations of this kind are feasible and result in good enantiomeric excesses when chiral *B*-allyloxazaborolidines are used as the allylboration agents.

The imines chosen for this study include the N-masked imines with a labile N–X bond such as oxime ethers, sulfenimines, and *N*-trimethylsilylimines, since the reaction of N-unsubstituted aldimines is not practical due to their inherent instability. Initially, we investigated the reaction of triallylborane with an *N*-arylbenzaldimine **10**; the corresponding secondary homoallylamine was obtained with triallylborane in 55% yield after 16 h at room temperature. Then we examined chirally modified allylborane **1**[6] for allylboration of **10** and found that the chiral amine was obtained in 22% *ee*. Results of reactions of **1** with several representative prochiral imines are summarized in Table 1.

Table 1. Asymmetric allylation of imines with **1** in THF.

Imine	T [°C]	Homoallylamine		
		Yield [%] (t [h])	*ee* [%] [a]	Config. [b]
10	RT	22 (3)	22	–
11	RT	92 (30)	32	*S*
11	−78	36 (30)	79	*S*
12	70	36 (32) [c]	26	*S* [d]
12	0	46 (120) [c]	63	*S* [d]
13	−78	70 (3)	73 [e]	*S*

[a] Determined by HPLC using a chiral stationary phase (Daicel Chiralcel OD-H; hexane/*i*PrOH/Et_2NH 90/10/0.1). [b] Determined by comparison of the optical rotation with the literature value [2b]. [c] The corresponding methoxyamine was obtained. [d] Configuration of the free amine. [e] Diethyl ether used as solvent.

Wuts and Jung reported that the addition of allylboronates to aryl sulfenimines in refluxing toluene provided sulfenamides.[7] We have found that sulfenimine **11** was asymmetrically allylated with **1** at room temperature to give primary homoallylamine in 92% yield with 32% *ee*. At −78 °C much higher enantioselectivity (79% *ee*) was obtained with this reagent even though the reaction is slow. Oxime ethers are also known to react with allylboronates to give *N*-alkoxyamines.[8] When chiral allylborane **1** was employed for allylboration of **12**, the corresponding methoxyamine was obtained in 36% yield at 70 °C with 26% *ee*. At 0 °C the same product was obtained in 46% yield with 63% *ee* after 120 h. No reaction occurred at −78 °C within three days.

In an effort to increase the reactivity of aldimines in allylborations, *N*-trimethylsilylimine derivatives were prepared. These imines were found to be quite reactive to triallylborane to afford the homoallylamine in quantitative yield after 1 h at 0 °C. This result encouraged us to choose this substrate for the asymmetric allylboration reaction. By using **1**, the imine **13** was allylated smoothly even at −78 °C to afford the homoallylamine with

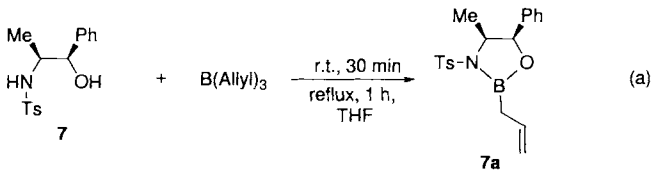
[a] Reactions conducted at −78 °C for 3 h. [b] Determined by HPLC using a chiral stationary phase (Daicel Chiralcel OD-H; hexane/*i*PrOH/Et_2NH 90/10/0.1). [c] Determined by comparison of the optical rotation with the literature value [2b]. [d] Diethyl ether used as solvent.

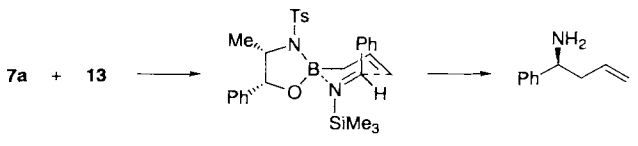
73 % *ee*. Then we examined the enantioselective allylboration of several *N*-trimethylsilylimines[9] with chirally modified allylboron reagents. The results are summarized in Table 2.

A variety of chiral modifiers, including chiral diols **2** and **3**, chiral hydroxy acid **4**, *N*-sulfonylated amino acid **5**, and *N*-sulfonylamino alcohols **6**, **7**, **8**,[10] and **9** were evaluated for their efficiency in enantioselective allylboration reactions. To prepare the allylboration reagents, triallylborane[11] (1 equiv) was allowed to react with the appropriate chiral modifier [Eq. (a)] in



(a)

tetrahydrofuran. In the enantioselective allylboration reaction, 1.25 equivalents of the chirally modified allylboron reagent in tetrahydrofuran were treated with a silylimine at −78 °C, affording the homoallylamines after the usual workup procedure. The enantioselective allylboration using **1** and **8a** with a series of *N*-trimethylsilylimines was investigated. Other reagents were also used for the allylation of **13**, and the best result (92 % *ee*) was obtained with *B*-allyloxazaborolidine **7a** derived from (−)-norephedrine (Table 2). To our knowledge, this is the highest selectivity obtained in the enantioselective allylation of imines. The chiral ligand **7** could be prepared easily and efficiently from norephedrine on a large scale. The observed absolute configuration of the major enantiomers of the homoallylamine from **7a** can be explained on the basis of a transition state with optimum stereoelectronics and minimum steric repulsion as shown in Scheme 1. The steric repulsion between the bulky trimethylsilyl and toluenesulfonyl groups seems to be very important. *N*-Sulfonylamino alcohol **8** derived from D-camphor is also an efficient chiral ligand for allylboron, and **8a** gives the (*S*)-amine in



Scheme 1. Asymmetric allylation of **13** with *B*-allyloxazaborolidine **7a**

high enantiomeric excess. The *endo* isomer **9a** was then prepared and used to give the product having the reversed stereoselectivity, as expected from the results of other asymmetric reactions using *endo* and *exo* camphor derivatives as chiral auxiliaries.[12] Chiral modifiers **2**–**9** used in this study were easily recovered and recycled.

In conclusion, the *B*-allyloxazaborolidine **7a** is the most highly enantioselective reagent for the allylation of imines reported to date. It is easily prepared and consequently is well-suited for general use in organic synthesis. The development of catalytic allylation of imines is now in progress.

Experimental Section

Asymmetric allylboration of **13** with **8a**: To a THF (5 mL) solution of $BF_3 \cdot Et_2O$ (0.61 mL, 5 mmol) under N_2 was added a THF solution of allylmagnesium chloride (15 mmol, 1.2 M) at 0 °C. After it had been stirred at room temperature for 30 min, the triallylborane solution generated was added dropwise to a THF (20 mL) solution of **8** (5 mmol, 1.62 g) and triethylamine (50 mL) in another flask. The reaction mixture was stirred at room temperature for 30 min and heated at reflux for 1 h to complete the formation of the chirally modified allylboron reagent. The solvent was removed in vacuo and the resulting solid dissolved in dry ether (20 mL). To this solution was added **13** (4 mmol, 0.71 g) in ether (2 mL) at −78 °C. The reaction mixture was maintained at −78 °C for 3 h after which 1 N HCl was added and the organic phase was separated and concentrated to dryness. After recrystallization of the residue, the chiral ligand **8** was recovered in 85 % yield. The aqueous phase was neutralized and extracted with ether. The combined ether layers were dried over $MgSO_4$ and concentrated to dryness. Chromatography gave 1-phenyl-3-butenamine as a colorless liquid (0.53 g, 90 % yield, 89 % *ee* (*S*)) [13]. The enantiomeric excess was determined by HPLC using Chiralcel OD-H. The configuration of the product amine was determined by measurement of the optical rotation and comparison with the literature value [2b].

Assembly of Novel DNA Cycles with Rigid Tetrahedral Linkers**

Jufang Shi and Donald E. Bergstrom*

The chemical synthesis of components for the assembly of supramolecular structures is likely to play a significant role in the field of molecular nanotechnology.[1] Assembly of complex and highly differentiated supramolecular structures presents a formidable task for synthetic chemists. If each unique component of a supramolecular assembly is to be positioned at a precise location in order to create devices capable of complex functions at the molecular level, it will be necessary to construct each component with unique recognition elements as a code for self-assembly. Association of the natural nucleic acid components adenine (A) with uracil (U) or thymine (T), and cytosine (C) with guanine (G) provides a precise and well-defined code for molecular recognition. Sequences of the bases as components of DNA and RNA associate through duplex formation with high specificity. DNA and its structural analogues are attractive as components for the coded self-assembly of molecular devices because 1) they can be fabricated readily on automated synthesizers; 2) bases can be modified by chromophores, fluorophores, redox-active groups, metal-complexing ligands, and other useful moieties without compromising base-pairing properties; 3) sequences can be designed to bind to specific proteins, which in turn could be structurally modified to function as molecular electronic/photonic components; and 4) self-assembly can occur under mild conditions to give well-defined structures.

Seeman and co-workers have elegantly demonstrated the capacity of DNA for the construction of geometrical objects, including a cube and a truncated octahedron by a combination of enzymatic and synthetic techniques.[2, 3] The polynucleotide strands totally define the structures, serving both as edges and vertices. By clever use of restriction enzymes and DNA ligase completely closed structures are obtained. Potential uses of DNA-based assemblies for applications in nanotechnology have been described.[4–7]

In a strategy complementary to that devised by Seeman and co-workers we have designed DNA-containing subunits in which the DNA functions as connectors between rigid vertices. The vertices were designed such that up to four oligonucleotide arms are attached through rigid spacers to a single tetrahedral hub. In principal one could construct the hubs (or vertices) with different numbers of arms each containing different oligonucleotide sequences as a means to direct the construction of unique supramolecular assemblies. A similar concept, but using shorter spacers has been recently outlined by Stephan Jordan in collaboration with von Kiedrowski.[8]

For proof of concept we chose a simple two-arm vertex consisting of two *p*-(2-hydroxyethyl)phenylethynylphenyl spacers attached to a single tetrahedral carbon atom (Figure 1). As described below we have been able to demonstrate that oligonucleotide-conjugated vertices will self-assemble by hybridization into a series of discrete cyclic supramolecular structures, which

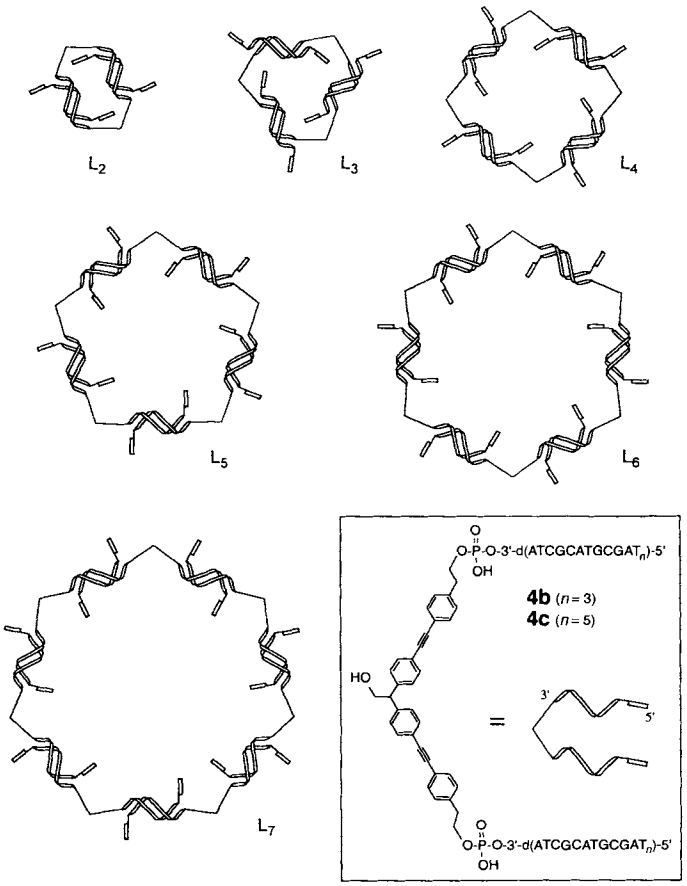

Figure 1. Self-assembly of DNA cycles based on a rigid vertices attached to two self-complementary oligonucleotides. The nonhybridized thymidine units at the 5'-ends of the oligonucleotides are symbolized by small rectangles.

can be separated by gel electrophoresis under nondenaturing conditions. Other synthetic DNA cycles have been constructed but they differ significantly in both structure and concept.[9–11]

In order to construct vertices containing two oligonucleotide arms it was necessary to design a precursor that could be attached to a controlled pore glass (CPG) solid support while leaving two free aliphatic hydroxyl groups for oligonucleotide extension. Compound **1**,[12] which contains two side chains terminating in trityl-protected alcohols and a third short arm attached to the central carbon atom, appeared ideally suited for this application. Compound **1** was allowed to react with oxalyl chloride (1 equiv) to yield intermediate **2**, which was subsequently coupled to long-chain aminoalkyl controlled-pore glass (LCAA-CPG) in situ (Figure 2). A similar strategy was reported for the synthesis of a variety of base-sensitive oligonucleotide derivatives.[13]

Three different oligonucleotide sequences were constructed on the two-arm linker derivatized LCAA-CPG by means of standard phosphoramidite chemistry on an automated synthesizer. Two modifications in the standard protocol were necessary to optimize the yield of the oligonucleotide conjugates. The reaction time of the first detritylation step was increased to insure complete cleavage of the more stable phenethyl trityl ethers, and the reaction time of the first phosphoramidite coupling step was increased. In subsequent cycles the trityl release was consistent and the overall yield varied ranged from 70 to 95%. The oligonucleotide conjugates were cleaved smoothly from the solid support under standard conditions (see Experimental Section).

[**] This work was supported in part by a grant from the National Institutes of Health (RO1-AI36601). The assistance of Norman Gerry (HPLC, gel electrophoresis, and phosphorimaging) is gratefully acknowledged.

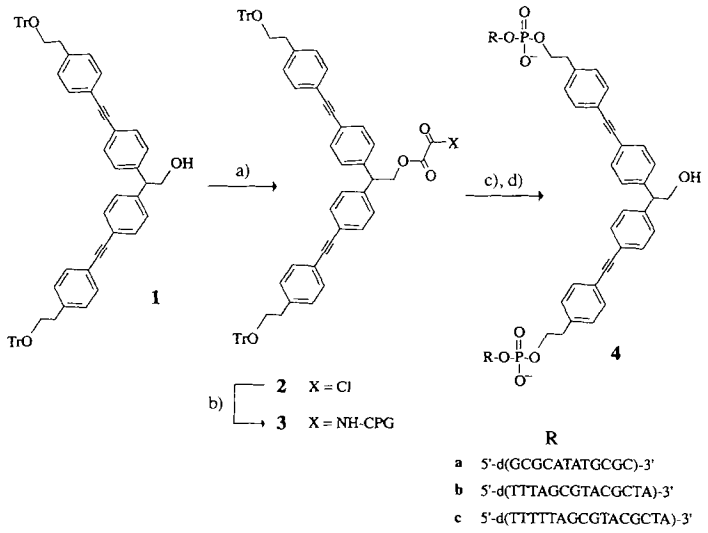

Figure 2. Synthesis of conjugates **4a–c**. a) Oxalyl chloride, tetrazole, pyridine; b) CPG-NH_2; c) sequential addition of nucleoside phosphoramidites; d) NH_4OH, 55 °C, 5–8 h.

The solutions containing oligonucleotide conjugates **4a–4c** were treated with concentrated NH_4OH to remove the protecting groups, and then diluted with H_2O and lyophilized. The crude products were purified directly by polyacrylamide gel electrophoresis (PAGE). Typically the major band (see Experimental Section for method of detection) corresponded to the desired conjugates; for a two-arm 12-mer (24 nt) that band was just below that of xylyl-cyanol (XC, 20% denatured PAGE, corresponding to approximately a 28-mer) while bands of the two-arm 14- and 16-mers (28 and 32 nt) ran above that of XC. After denaturing gel electrophoresis, the desired bands were cut and eluted in H_2O, desalted either by C18 reverse-phase chromatography or filtration to yield pure products. The structures of the conjugates were confirmed by matrix-assisted laser desorption ionization (MALDI) mass spectrometry.[14]

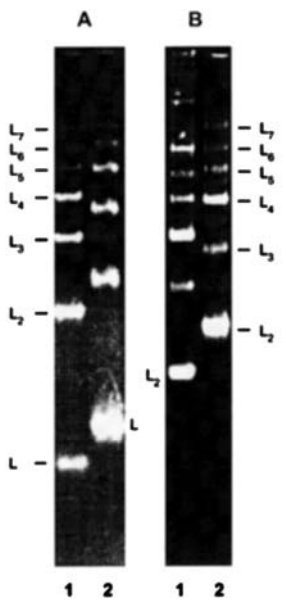

Figure 3. Polyacrylamide gel electrophoresis (PAGE; 20%, native). **A**: Zn buffer, 4 °C, 3 h; **B**: TAE-Mg buffer, 4 °C, 40 h. Lanes 1 and 2: conjugates **4b** and **4c**, respectively. Bands in the gel corresponding to cycles L_2–L_7 (see Figure 1) are indicated.

Native PAGE was used to characterize the hybridized products from the oligonucleotide conjugates. The purified two-arm self-complementary oligonucleotide conjugates **4a–4c** formed distinct "ladders" of bands, which ranged in size continuously from 24 base-pairs to 98 base-pairs. Conjugate **4b**, which consists of a 12-mer self-complementary oligonucleotide segment to which two additional thymine (T) residues were attached, gave a relatively clean "ladder", in which at least eight bands are clearly discernible (Figure 3). Conjugate **4c** with four extra T residues generally gave slightly more diffuse bands, with more of the monomer and less of the higher order structures.

Oligonucleotide concentration, temperature, cation, and ionic strength were varied to find the optimum hybridization conditions. The most consistent results were obtained with relatively short hybridization times (3 h) and a buffer consisting of 12.5 mM $ZnCl_2$ and 50 mM 2-[4-(hydroxyethyl)piperazine-1-yl]-ethanesulfonic acid (HEPES). Similar results were obtained with a buffer composed of 50 mM tris(hydroxymethyl)aminomethane (Tris), 10 mM $MgCl_2$, and 100 mM NaCl. A TAE-Mg buffer solution (40 mM Tris-acetate pH 8.0, 20 mM NaOAc, 2 mM ethylenediaminetetraacetate (EDTA), 12.5 mM Mg$(OAc)_2$), which has been employed by others to favor hybridization, required significantly longer hybridization times and gave gels with bands that were more inconsistent in relative intensity.[15] At lower oligonucleotide concentration the amount of dimer was increased relative to the amount of the higher order structures, while at higher concentration less distinct bands corresponding to higher order structures were observed. Longer hybridization times also led to increasing amounts of higher order structures. A plot of gel migration distance (Figure 4) versus cycle size for oligonucleotide conjugates **4b** and **4c** is shown in Figure 4.

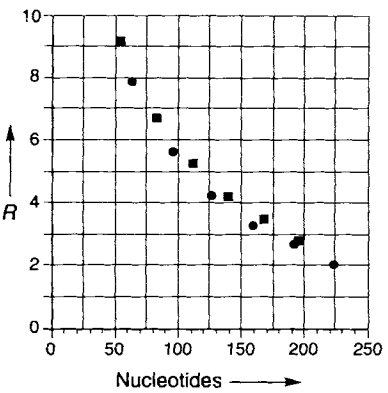

Figure 4. Plot of relative gel migration distance R (see Figure 3) versus cycle size for conjugates **4b** (■) and **4c** (●).

In summary we have shown that the attachment of short DNA sequences to rigid hydrocarbon spacers allows the self-assembly of a set of cyclic DNA varying continuously in size from dimer to beyond heptamer. Cycle formation is not hindered by the extension of the oligonucleotide arms (**4b** and **4c** have two and four additional dangling T residues). This indicates that the cycles, once suitably stabilized by covalent crosslinking, could potentially be used as modules for the assembly of higher order structures. Efforts in this direction are underway.

Experimental Section

3: Oxalyl chloride (25 μL, 0.05 mM) was added to a solution of 1,2,4-triazole (20 mg, 0.29 mM) in acetonitrile (1 mL). The small amount of precipitate that formed disappeared after addition of pyridine (25 μL). A solution of vertex **1** (48.5 mg, 0.05 mM) in acetonitrile (250 μL) and pyridine (25 μL) was added, the mixture stirred for 1 h, and then LCAA-CPG (500 mg) was added. The mixture was allowed to stand for 15 min. Then the liquid was removed and the solid was washed with acetonitrile, dry methanol, acetonitrile, and a 1:1 mixture of dimethylaminopyridine (0.3 M) and acetic anhydride in THF. Unreacted **1** was recovered by chromatography (silica gel 60 PF254 containing gypsum; chromatotron (Harrison Research)). The support was then washed with anhydrous DMF and anhydrous ether, and then air-dried before it was loaded onto an ABI DNA synthesis column. The loading yield was determined by carrying out a standard oligonucleotide synthesis using phosphoramidite chemistry with the derivatized CPG as described above. Coupling yields were measured from the effluent after detritylation (dimethoxytrityl (DMTr) cation) by using the standard protocol. The effluent from the detritylation following the first phosphoramidite coupling from 7.5 mg solid support showed 0.95 A_{260} (30 mL dilution), which corresponded to a loading of 54 μmol g^{-1} DMTr. Since each linker has two hydroxyl groups, the actual loading of the linker was 27 μmol g^{-1}.

Oligonucleotide synthesis: The oligonucleotide conjugates were synthesized on an Applied Biosystem 381A synthesizer (0.2 μmol scale, pulsed-delivery cycle in the "trityl off" and "manual cleavage" mode). The syntheses were evaluated by UV spectroscopic quantitation of trityl cation released during the trichloroacetic acid

treatment step. The reaction time of the detritylation was extended by 4 min, that of the first phosphoramidite coupling by 5 min.

Standard cleavage conditions (conc. NH_4OH, room temperature, 5–20 min) were employed to liberate the oligomer conjugates from the solid support. Deprotection was accomplished by treatment with conc. NH_4OH at 55 °C for 5–8 h. The oligonucleotide conjugate solutions were then diluted with fivefold deionized H_2O, frozen in dry ice/acetone, and lyophilized. The lyophilized oligomer conjugates were redissolved in aqueous solution and the amount of material quantitated by the UV absorbance at $\lambda = 260$ nm. The oligomer conjugates were purified by PAGE (15 or 20%) under denaturing conditions (8.3 M urea). Following electrophoresis the gels were covered with plastic wrap and illuminated with a hand-held UV lamp; the shadow on a fluorescent TLC plate (Merck, EM Sciences) was photographed. Subsequently, the oligomers were extracted from the crushed gel by autoclaved H_2O at room temperature overnight, and subsequently desalted either by reverse-phase chromatography (C18 SEP-PAK) or by centrifugal concentration using an Amicon Centricon-SR3 (3000 MW cutoff) Concentrator. The solutions of purified oligomer conjugates were diluted with fivefold deionized H_2O, separated into aliquots (0.1 OD per aliquot), frozen, lyophilized, and stored in the dark at −20 °C. MALDI-TOF MS analysis was carried out on a PerSeptives Voyager Biospectrometry Workstation. Samples were prepared for mass spectrometric analysis by combining 5–30 pm of oligonucleotide with 0.5 μL of a matrix solution containing 0.0184 M ammonium citrate, 0.0338 M picolinic acid, and 0.279 M 3-hydroxypicolinic acid: **4b**: calcd: 9136 [$M+1$], found: 9131; **4c**: calcd 10360 [$M+1$], found: 10360.

Hybridization and characterization of oligonucleotide conjugates: A solution of the oligonucleotide conjugates (0.05 OD) in 15–30 μL of hybridization buffer (Zn buffer: 12.5 mM $ZnCl_2$, 50 mM HEPES; TMS buffer: 50 mM Tris, 10 mM $MgCl_2$, 100 mM NaCl; TAE-Mg buffer: 40 mM Tris-acetate, 20 mM NaOAc, 2 mM EDTA, 12.5 mM $MgCl_2$) was allowed to hybridize at three different temperatures (4, 24, and 50 °C) and varying times (from 10 min to >24 h). The effect of concentration on hybridization was examined by dissolving 0.05 OD units of the oligonucleotide conjugate in varying amounts of TAE-Mg buffer (12.2, 36.6, and 244 μL) and by comparing the PAGE results.

Native PAGE: In most cases 15 or 20% native polyacrylamide gels (15 × 17 cm) were cast, allowed to polymerize for at least 45 min (not more than 2 h), and then subjected to electrophoresis for 30 min before the samples were loaded. The gels were electrophoresed for 8–12 h at 8–10 Vcm^{-1} in TBE buffer (89 mM Tris, 89 mM boric acid, 2.5 mM Na_2EDTA, adjusted to pH 8.0 with conc. HCl) at 4 °C. The migration distances were measured from the respective loading wells for each lane by means of an ethidium bromide stained transilluminating photograph (7.5 × 10 cm).

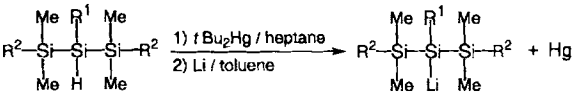
[Me(PhMe$_2$Si)$_2$SiLi] and [Ph(Me$_3$Si)$_2$SiLi]: Preparation, Characterization, and Evidence for an Intramolecular Li–Ph Interaction**

Akira Sekiguchi,* Masato Nanjo, Chizuko Kabuto, and Hideki Sakurai*

Despite numerous reports on syntheses of lithiosilanes far less attention has been devoted to their structures in the solid state.[1] Up to now, a few crystal structures of lithiosilanes containing chelating solvents[2] and only two examples of unsolvated hexameric lithiosilanes Me_3SiLi[3] and tetrameric Me_5Si_2Li,[4] have been reported. We report here on the isolation and characterization of the first unsolvated dimeric lithiosilanes, **1a** and **1b**. The evidence for an intramolecular lithium–phenyl interaction is also described.

Bis(1,3-diphenylpentamethyltrisilyl)mercury was treated with lithium metal in toluene to give yellow crystals of **1a** [Eq. (a)].[5] By the same procedure, **1b** was also obtained as yellow crystals.[6]



1a: R^1 = Me, R^2 = Ph
1b: R^1 = Ph, R^2 = Me

Lithiosilane **1a** is dimeric in the solid state and its molecular structure has a crystallographic inversion center (Figure 1).[7] The two lithium and two anionic silicon centers constitute a planar four-membered ring with Li–Si distances of 2.664(5) and 2.778(7) Å, a Li–Si–Li bond angle of 58.1(2)°, and a Li–Li distance of 2.65(1) Å. The two Si2–Si bond lengths are 2.336(1) and 2.361(1) Å. The Si2–CH_3 bond length of 1.923(4) Å is considerably longer than normal (1.88 Å) due to the negative charge on the silicon center. The bond angles around the anionic silicon are highly contracted (sum of the angles: 312.1(1)°). The most striking point of the structure is that each lithium atom is surrounded by the four phenyl groups. Li1 and Li1′ are not located directly over the centers of the benzene rings, but are in rather close contact with the *ipso* and *ortho* carbon atoms. These Li–C distances (e.g. Li1′–C12 2.348(6), Li1′–C13 2.483(7), Li1′-C17 2.730(8) Å) are typical for π-complexed organolithiums.[8] Such interactions are apparently caused by electrostatic attraction between the lithium ion and the benzene rings.

The dimeric structure of lithiosilane **1b** was also established by X-ray diffraction (Figure 2).[7] The structural parameters are

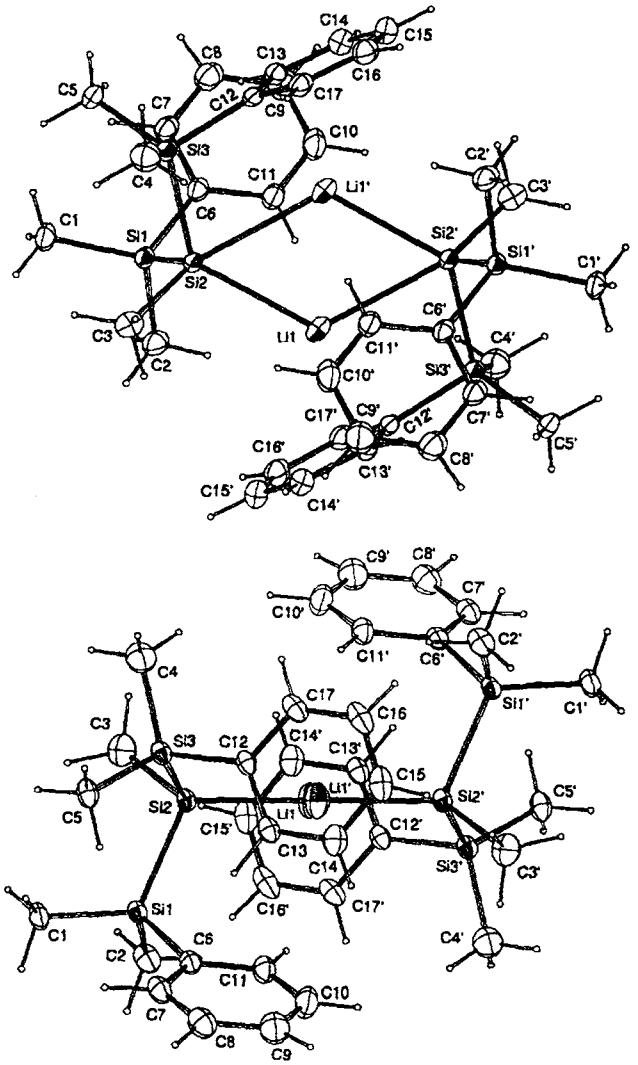

Figure 1. ORTEP representation of the X-ray crystal structure of **1a**. Top: top view; bottom: side view. Selected distances [Å]: Si1-Si2 2.336(1), Si2-Si3 2.361(1), Si2-C3 1.923(4), Si2-Li1 2.664(5), Si2-Li1′ 2.778(7), Li1-Li1′ 2.645(10). Selected bond angles [°]: Si1-Si2-Si3 103.6(0), Si1-Si2-C3 103.8(1), Si3-Si2-C3 104.7(1), Li1-Si2-Li1′ 58.1(2).

quite similar to those of **1a**. A planar four-membered ring is made up of two lithium atoms and two anionic silicon centers with Li–Si distances of 2.63(1) and 2.78(1) Å and a Li–Si–Li bond angle of 68.3(3)°. The Li–Li distance in **1b** (3.03(1) Å) is longer than that in **1a**, probably for geometric reasons and because the electrostatic repulsion between the electropositive lithium centers is increased since only two benzene rings serve as electron donors. As in **1a**, the two lithium atoms are associated with the two phenyl groups. The distances between Li1 and Li1′ and the *ipso* and *ortho* carbons of the benzene rings range from 2.36(1) to 3.17(1) Å.

The chemical shifts in the ^{7}Li NMR spectra provide a useful probe for evaluating the interaction between the lithium and benzene rings. The ^{7}Li NMR signal of **1a** is shifted significantly to upper field, $\delta = -0.54$ in [D$_8$]toluene and $\delta = -0.36$ in [D$_{12}$]cyclohexane, because of the shielding effect of the phenyl groups.[9] However, the ^{7}Li NMR signal is observed at $\delta = 0.58$ for a solution of **1a** in [D$_8$]THF,[10] indicating that the dimeric structure of **1a** is destroyed completely by complexation with THF. Consequently, the lithium atom can be no longer shielded by the phenyl groups. Lithiosilane **1b** provided similar

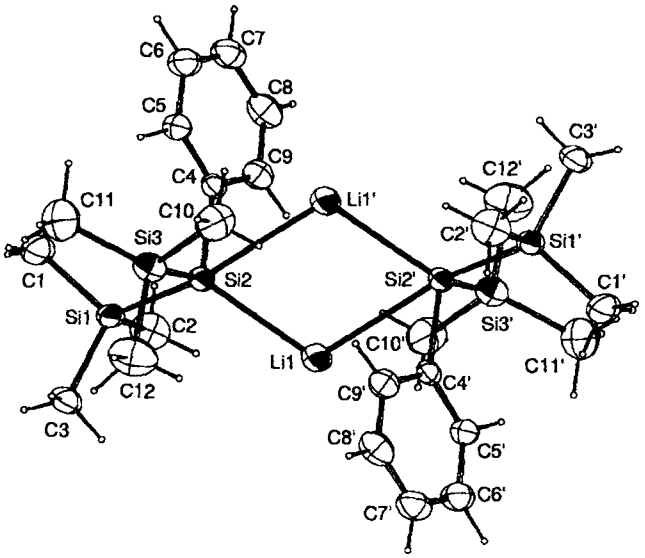

Figure 2. ORTEP representation of the X-ray crystal structure of **1b**. Selected distances [Å]: Si1-Si2 2.343(2), Si2-Si3 2.346(2), Si2-C4 1.939(6), Si2-Li1 2.630(12), Si2-Li1′ 2.775(11), Li1-Li1′ 3.034(14). Selected bond angles [°]: Si1-Si2-Si3 107.6(1), Si1-Si2-C4 97.3(2), Si3-Si2-C4 107.3(2), Li1-Si2-Li1′ 68.3(3).

^{7}Li NMR spectra: $\delta = -0.42$ in [D$_8$]toluene, $\delta = -0.97$ in [D$_{12}$]cyclohexane, and $\delta = 0.69$ in [D$_8$]THF.

The lithium–phenyl interaction is an important feature in the molecular structures of **1a** and **1b** as evident in the crystal structures and NMR studies.[11] Such electrostatic interactions stabilize unsolvated lithiosilanes. The best organic group to interact with the electron-deficient lithium atom could be a phenyl group as a π-base. Obviously, no analogous interactions can be found in [Ph$_3$SiLi(thf)$_3$][2c] and [(thf)$_3$Li(SiPh$_2$)$_4$Li(thf)$_3$][2e] because of the strong Li–THF coordination.

Experimental Section

1a: A mixture of *t*Bu$_2$Hg (3.14 g, 10.0 mmol) and Me(PhMe$_2$Si)$_2$SiH (6.30 g, 20.0 mmol) in heptane (50 mL) was heated at 85 °C for 86 h under argon. The solution turned to yellow due to the formation of [Si(SiMe$_2$Ph)$_2$Me]$_2$Hg. The solvent was removed in vacuo, and then lithium wire (ca. 1 g) and toluene (50 mL) were introduced. The mixture was stirred for 180 h. After removal of the resulting Hg and unreacted Li, the solvent was evaporated in vacuo to give yellow crystals of **1a** (4.52 g, 71 %). ^{1}H NMR ([D$_8$]toluene, TMS): $\delta = 0.23$ (s, 3H, SiMe), 0.47 (s, 6H, Ph*Me*MeSi), 0.53 (s, 6H, PhMe*Me*Si), 7.04–7.08 (m, 2H, ArH), 7.11–7.20 (m, 4H, ArH), 7.36–7.40 (m, 4H, ArH); ^{13}C{^{1}H} NMR ([D$_8$]toluene, TMS): $\delta = -11.1$, 0.16 (Ph*Me*MeSi), 0.25 (PhMe*Me*Si), 128.5, 129.4, 133.0, 147.2; ^{29}Si{^{1}H} NMR ([D$_8$]toluene, TMS): $\delta = -123.3$ (m), −9.7; ^{7}Li{^{1}H} NMR ([D$_8$]toluene, LiCl in MeOH, external): $\delta = -0.54$.

Thermal Decomposition of $[(\eta^5\text{-}C_5Me_5)TiMe_3]$: Synthesis and Structure of the Methylidyne Cubane $[\{(\eta^5\text{-}C_5Me_5)Ti\}_4(\mu_3\text{-}CH)_4]$**

Román Andrés, Pilar Gómez-Sal, Ernesto de Jesús, Avelino Martín, Miguel Mena,* and Carlos Yélamos

Organometallic compounds and metal alkoxides may be converted by controlled thermolysis into a range of useful materials of high purity or specific morphology (for electronic and optical applications), high strength, and/or high-temperature stability (for structural or refractory usage). The factors that determine the stabilities, the mode of the hydrocarbon eliminations, and the steps involved in the conversion of these precursors have become the focus of numerous practical and theoretical investigations.[1]

In our studies on the stability of the metal–carbon bonds in monopentamethylcyclopentadienyl complexes of group 4, we discovered that thermolysis of the trinuclear compounds $[\{(\eta^5\text{-}C_5Me_5)Ti(\mu\text{-}O)(CH_2R)\}_3]$ (R = H, Me) cleanly gave d^0 μ_3-alkylidyne derivatives $[\{(\eta^5\text{-}C_5Me_5)Ti(\mu\text{-}O)\}_3(\mu_3\text{-}CR)]$ and the corresponding alkanes CH_3R.[2] Here we report on the thermolysis of the mononuclear titanium derivative $[(\eta^5\text{-}C_5Me_5)TiMe_3]$ **1**[3] in toluene at $\geq 95\,°C$, which under methane elimination gives the titanium cubane $[\{(\eta^5\text{-}C_5Me_5)Ti\}_4(\mu_3\text{-}CH)_4]$ **2** [Eq. (a)] in high yield. This transformation was monitored by ^{1}H NMR spectroscopy and no intermediates were detected.

$$\underset{\mathbf{1}}{4\,[Cp^*TiMe_3]} \xrightarrow[-8\,CH_4]{\geq 95\ C/\text{toluene}} \underset{\mathbf{2}}{[(Cp^*Ti)_4(\mu_3\text{-}CH)_4]} \qquad \text{(a)}$$

$Cp^* = \eta^5\text{-}C_5Me_5$

Compound **2** is a dark brown crystalline solid, which is thermally very stable; in solution in benzene and toluene no decomposition was observed even after several days at temperatures above 200 °C. Elemental analyses and NMR spectroscopic data are consistent with a $[(\eta^5\text{-}C_5Me_5)Ti(CH)]$ stoichiometry and a highly symmetric structure in solution. The methylidyne groups appear as a singlet at $\delta = 17.75$ in the ^{1}H NMR spectrum, and the ^{13}C NMR signal of these ligands occurs at the very low field ($\delta = 490.8$), which is unprecedented for diamagnetic compounds. The IR spectrum shows a strong absorption at 583 cm^{-1}, which we tentatively assign to the metal–carbon-(methylidyne) bonds.[4]

The X-ray structure analysis of single crystals of **2** (obtained by slow cooling of a solution of **2** in hexane) reveals that the structure (Figure 1)[5] consists of an almost perfect Ti_4C_4 cube,

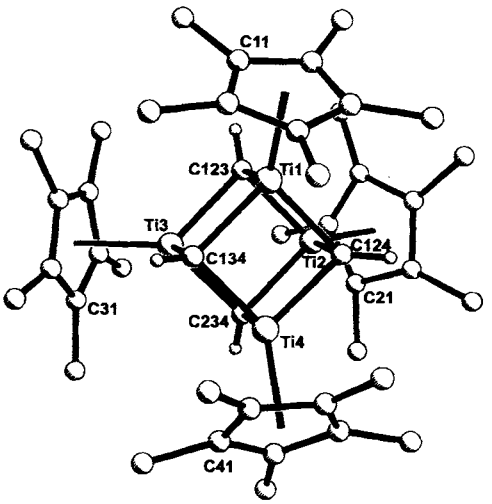

Figure 1. Molecular structure of **2**. Selected average bond lengths [Å] and angles [°]: Ti–C 2.052(7), Ti–Cp* 2.069; Ti···Ti 2.893(2), HC···CH 2.91(1); Cp*-Ti-C 125.0, HC-Ti-CH 90.3(3), Ti-C-Ti 89.7(3). Cp* denotes to the center of the C_5Me_5 ring.

in which, similar to the Ti_4N_4 core in the nitride $[\{(\eta^5\text{-}C_5Me_5)Ti\}_4(\mu_3\text{-}N)_4]$, the Ti-C-Ti and C-Ti-C angles are close to 90°.[6] The Ti_4C_4 core of **2** shows the same structural disposition as the face-centered cubic lattice of TiC.[7] Furthermore, this core is the smallest cubic crystallite structure ($2 \times 2 \times 2$) proposed for a gas-phase-generated transition metal–carbon cluster.[8] To our knowledge, compound **2** is the first structurally characterized tetranuclear cubane-like alkylidyne complex with transition metal centers. The Ti–CH bond bonds in **2** [av 2.052(7) Å] are slightly shorter than those in alkyltitanium complexes with Ti–C(sp^3) bonds such as $[(\eta^5\text{-}C_5Me_5)TiMe_3]$ (av 2.10 Å),[9] $[\{(\eta^5\text{-}C_5Me_5)TiMe\}_3(\mu\text{-}O)_3]$ (av 2.09 Å),[10] $[\{(\eta^5\text{-}C_5Me_5)_4Ti_4Me_2\}(\mu\text{-}O)_5]$ (2.11 Å),[11] and the μ_3-alkylidyne derivative $[\{(\eta^5\text{-}C_5Me_5)Ti(\mu\text{-}O)\}_3(\mu_3\text{-}CMe)]$ (av 2.11 Å).[2a]

[**] This work was supported by the Spanish Dirección General de Investigación Científica y Técnica (DIGICYT) (PB93-0476) and the Universidad de Alcalá.

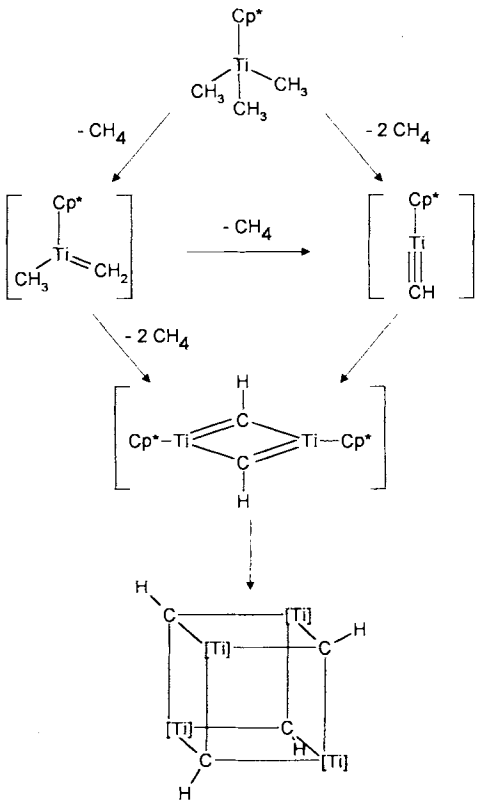
The metal centers are very close to each other (av 2.893(2) Å) and are arranged tetrahedrally; a μ_3-methylidyne group is situated above each face, and a η^5-C_5Me_5 ligand is attached to each titanium atom.

Extended Hückel molecular orbital (EHMO) calculations have been carried out for the hypothetical analogue of **2**, $[\{(\eta^5\text{-}C_5H_5)Ti\}_4(\mu_3\text{-}CH)_4]$, and its related nitride $[\{(\eta^5\text{-}C_5H_5)Ti\}_4(\mu_3\text{-}N)_4]$ to analyze the interaction between $\{(\eta^5\text{-}C_5H_5)Ti\}_4$ and $(\mu_3\text{-ligand})_4$ fragments. The interaction schemes[12] are similar to those reported for $[\{(\eta^5\text{-}C_5H_5)Cr\}_4(\mu_3\text{-}O)_4]$.[13] The frontier orbitals are mainly d metal centered, and those of lowest energy have e, a_1, and t_2 symmetry. These orbitals are empty in the titanium(IV) cubanes; therefore, no significant distortion is expected for the Ti_4 tetrahedra in agreement with the X-ray structure analysis: the Ti···Ti distances range between 2.873 and 2.941 Å in **2**, and between 2.782 and 2.793 Å in $[\{(\eta^5\text{-}C_5Me_5)Ti\}_4(\mu_3\text{-}N)_4]$.[6]

The thermal decomposition of **1** in [D$_6$]benzene at 96 °C follows first-order kinetics and proceeds 2.7 times faster than that of $[(\eta^5\text{-}C_5Me_5)Ti(CD_3)_3]$ ([D$_3$]-**1**),[14] suggesting that the first and rate-determining step of this process could be the intramolecular activation of at least one C–H bond in one of the methyl groups bonded to titanium. When the labeled derivative $[(\eta^5\text{-}C_5Me_5)Ti(^{13}CH_3)_3]$ ([^{13}C]-**1**) (33% ^{13}C) was used, the products obtained were exclusively $[\{(\eta^5\text{-}C_5Me_5)Ti\}_4(\mu_3\text{-}^{13}CH)_4]$ ([^{13}C]-**2**) and methane, both of which contained 33% ^{13}C as established by ^{1}H NMR spectroscopy. This indicated that the methylidyne groups in **2** arise from the methyl groups directly bonded to titanium in the starting reagent **1**.

These results reveal that the thermal decomposition of **1** could initially lead to the methylene intermediate $[(\eta^5\text{-}C_5Me_5)Ti(=CH_2)Me]$ (Scheme 1). This species would be similar to the methylenetitanocene proposed by Bercaw et al.[15] as an intermediate in the thermal decomposition of $[(\eta^5\text{-}C_5Me_5)_2TiMe_2]$ and to those compounds synthesized by treating titanocene metallacyclobutanes with phosphanes by Grubbs et al.[16] This methylene intermediate could dimerize through intermolecular C–H activations to give a μ_2-alkylidyne species,[17] and subsequently react to afford **2**.

However, we can not exclude a pathway in which the tetramerization of the mononuclear methylidyne intermediate $[(\eta^5\text{-}C_5Me_5)Ti{\equiv}CH]$ could give the final product **2**, similarly to the cyclotetramerization of phospha- and arsaalkynes to produce tetraphospha- and tetraarsacubanes, respectively.[18]



Scheme 1. [Ti] = $(\eta^5$-$C_5Me_5)$Ti.

Experimental Section

2: A solution of **1** (1.10 g, 4.82 mmol) in toluene (or hexane) (60 mL) was transferred by cannula to a Carius tube (volume 120 mL), cooled to −78 °C, and flame-sealed. This tube was heated for 24 h at 120 °C; this resulted in a brown solution, which afforded dark brown crystals of **2** at room temperature. Yield: 0.70 g (74%). Satisfactory elemental analysis. ^{1}H NMR (500 MHz, $C_6D_5CD_3$, 25 °C, TMS): δ = 1.89 (s, 15H, C_5Me_5), 17.75 (s, 1H, CH); ^{13}C{^{1}H} NMR (125 MHz, $C_6D_5CD_3$, 25 °C, TMS): δ = 12.2 ($C_5\mathit{Me}_5$), 119.9 (C_5Me_5), 490.8 (CH); IR (KBr): ν[cm^{-1}] = 2904 vs, 2719 w, 1488 w, 1432 s, 1371 s, 1240 m, 1159 m, 1100 w, 1022 m, 790 s, 729 w, 583 vs, 504 s, 411 s.

[D$_4$]-**2** [IR (KBr): ν(C–D) = 2138 cm^{-1}; ^{2}H NMR (76 MHz, $C_6H_5CH_3$, 25 °C, C_6D_6): δ = 17.85] and [^{13}C]-**2** (33% ^{13}C)[^1J(C,H) = 122.0 Hz for the methylidyne groups] were prepared analogously to **2** from [D$_3$]-**1** and [^{13}C]-**1** (33% ^{13}C), respectively.

[5] Crystal structure analysis of **2**: $C_{44}H_{64}Ti_4$, M_r = 784.55, triclinic, space group $P\bar{1}$, a = 11.114(2), b = 11.180(2), c = 18.553(4) Å, α = 83.80(1), β = 83.61(1), γ = 66.54(1)°, V = 2096.5(7) Å^3, Z = 2, ρ_{calcd} = 1.243 g cm^{-3}; F(000) = 832, λ = 0.71065 Å, $\mu(Mo_{K\alpha})$ = 0.762 mm^{-1}. The data were collected on an Enraf Nonius CAD4 diffractometer. Intensity measurements were performed by ω-θ scans in the range $2° < 2\theta < 50°$ at 19 °C on a crystal of dimensions 0.43 × 0.37 × 0.32 mm. Of the 7916 measured reflections, 7359 were independent; largest minimum and maximum in the final difference Fourier synthesis: −0.647 and 0.932 e Å^{-3}, $R1$ = 0.091 and $wR2$ = 0.242 (for 5289 reflections with $F > 4\sigma(F)$). The values of $R1$ and $wR2$ are defined as follows $R1 = \sum||F_o| - |F_c||/\sum|F_o|$; $wR2 = \{[\sum w(F_o^2 - F_c^2)^2]\ /[\sum w(F_o^2)^2]\}^{1/2}$. The structure was solved by direct methods (SHELXS-90) and refined by least-squares against F^2 (SHELXL-93). The molecule showed disorder in one of the four pentamethylcyclopentadienyl ligands (each carbon atom with two sites and 50% occupancy). The hydrogen atoms were positioned geometrically and refined by using a riding model. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-130. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: Int. code +(1223) 336-033; e-mail: deposit@chemcrys.cam.ac.uk).

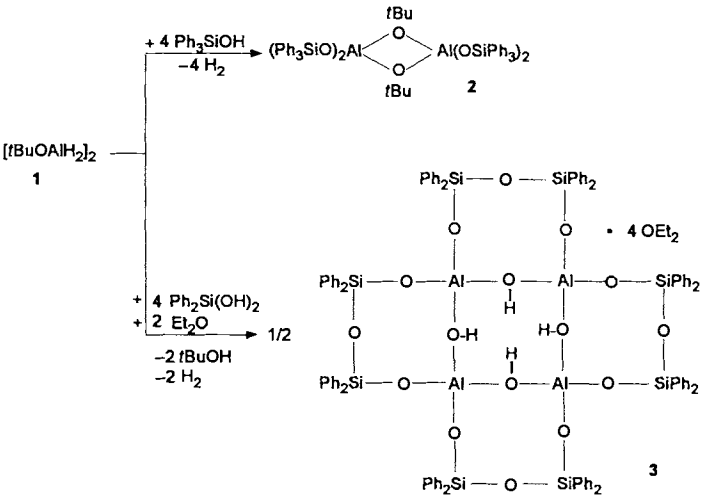

Scheme 1.

An $Al_4(OH)_4$ Eight-Membered Ring in a Molecular Aluminopolysiloxane and Its Behavior with Bases**

Michael Veith,* Maria Jarczyk, and Volker Huch

Dedicated to Professor Roger Blachnik on the occasion of his 60th birthday

In the last few years many research groups, especially that of H. W. Roesky, have shown that aluminopolysiloxanes that are soluble in organic solvents are surprisingly simple to synthesize.[1, 2] The compounds known to date have a polycyclic framework consisting of Al, Si, and O; the silicon atoms bear a further organic or amine ligand. A molecular sodium aluminosilicate has also been synthesized and characterized.[1]

We recently reported the structure of *tert*-butoxyaluminum hydride (**1**).[3] Herein we describe related aluminopolysiloxanes, which we obtained while investigating the reactivity of **1** with triphenylsilanol and diphenylsilanediol. Surprisingly, the reaction with diphenylsilanediol results in an aluminosiloxane that contains a central Al_4O_4 ring. To our knowledge, a structural unit of this type had hitherto not been detected in natural aluminosilicates.

The alkoxydihydride **1** reacts with Ph_3SiOH with elimination of hydrogen to provide the aluminum alkoxydisilanolate **2** in nearly quantitative yield (Scheme 1).[4] According to the X-ray structure analysis[5] the molecule is dimeric with distorted tetrahedral coordination at aluminum and a central, planar Al_2O_2 four-membered ring (point symmetry C_i, Figure 1). As expected, the oxygen atoms of the *tert*-butoxy ligands function as bridging atoms between the aluminum atoms, whereas the triphenylsilanolate groups are terminally bound. The large

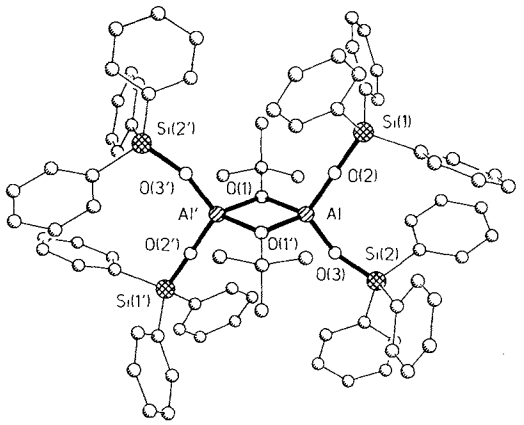

Figure 1. Ball-and-stick representation of **2** in the crystal [5]. Important bond lengths [Å] and angles [°]: Al-O(1) 1.827(2), Al-O(1') 1.824(2), Al-O(2) 1.686(3), Al-O(3) 1.694(3), Si(1)-O(2) 1.607(3), Si(2)-O(3) 1.620(3); O(1)-Al-O(1') 81.0(1), O(1)-Al-O(2) 112.4(1), O(1)-Al-O(3) 115.7(1), Al-O(1)-Al' 99.0(1), Si(1)-O(2)-Al 177.6(2), Si(2)-O(3)-Al 153.5(2).

Si-O-Al angles (Si(2)-O(3)-Al 153.5(2), Si(1)-O(2)-Al 177.6(2)°) are typical for sterically demanding R-O-Al ligands.[6]

Treatment of **1** with two equivalents of $Ph_2Si(OH)_2$ in diethyl ether (Scheme 1) led to the crystalline compound **3** in acceptable yield. In addition to the evolution of hydrogen, the formation of *tert*-butanol is detected by ^1H NMR spectroscopy. The ^{27}Al and ^{29}Si NMR spectra of **3** each show one signal. The ^1H NMR spectrum displays a sharp singlet at $\delta = 6.17$ for an OH group. Accordingly, the solid-state IR spectrum of **3** contains an unusually narrow band at 3619 cm^{-1} accompanied by a less intense band at 3560 cm^{-1}. Both bands are assigned to O–H stretches; the splitting of the signals can be explained by the crystal structure (see below). The $OSi(Ph_2)OSi(Ph_2)O$ units present in the molecule can be attributed to the Lewis acid catalyzed condensation of $Ph_2Si(OH)_2$ monomers. Although the reactions of $Ph_2Si(OH)_2$ with trialkylalanes could lead to OAlOAlOSi chains or $Al_2Si_2O_4$ rings, no such observation was made.[7]

As seen in the crystal structure analysis,[5] **3** is an isolated aluminopolysiloxane, which crystallizes with four molecules of ether (Figure 2). There is an $Al_4(OH)_4$ eight-membered ring in the center of the structure; the Al(OH)Al edges are spanned by four disiloxane bridges. This results in a framework of five annelated eight-membered rings, and the molecule has approxi-

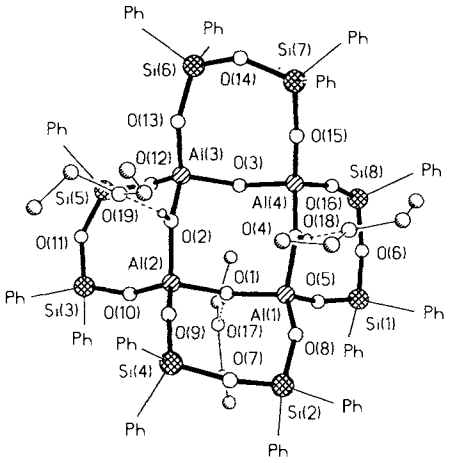

Figure 2. Ball-and-stick representation of **3** in the crystal [5]. For clarity, the phenyl groups are indicated by Ph. The fourth diethyl ether molecule is a space filler between the molecules and does not interact with the OH groups. Important bond lengths [Å] and angles [°]: Al(1)-O(1) 1.797(3), Al(1)-O(4) 1.802(3), Al(2)-O(1) 1.796(3), Al(2)-O(2) 1.806(3), Al(3)-O(2) 1.789(1), Al(3)-O(3) 1.807(3), Al(4)-O(3) 1.814(3), Al(4)-O(4) 1.787(3); mean values: Si-O_{Al} 1.604(3), Si-O_{Si} 1.631(3); Si-O-Si 144.8(2), Si-O-Al 157.6(2), Al-O_{Si} 1.698(3), Al-O-Al 130.8.

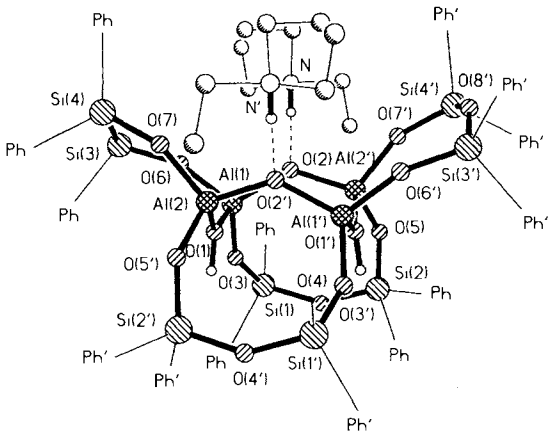

Figure 3. Ball-and-stick representation of **4** in the crystal [5]. The view is orthogonal to that in Figure 2. Important bond lengths [Å] and angles [°]: Al(1)-O(1) 1.820(4), Al(2)-O(1) 1.829(4), Al(1)-O(2) 1.733(3), Al(1)-O(3) 1.727(3), Al(1)-O(6) 1.727(3), Al(2)-O(2') 1.724(3), Al(2)-O(5') 1.722(3), Al(2)-O(7) 1.715(3); Al(1)-O(1)-Al(2) 134.6(3), Al(1)-O(2)-Al(2') 130.5(2); mean values: Si-O_{Al} 1.604(4), Si-O_{Si} 1.625(5); Si-O-Si 147.2(3), Si-O-Al 149.5(3).

mately S_4 point symmetry. The annelated rings form an average angle of 131.5° (O–Al···Al) with the central four-membered Al_4 ring. The S_4 symmetry is disrupted because only three of the four molecules of diethyl ether are coordinated through their oxygen atoms to the hydrogen atoms of the central OH groups in the $Al_4(OH)_4$ unit. The fourth diethyl ether molecule acts only as a space filler in the van der Waals lattice. The coordination of the ether molecules is indirect evidence of the presence of OH groups in the central eight-membered ring; the O–O distances of the O–H···O bridges lie in the range of 2.60–2.70 Å, and indicate strong hydrogen bonding.[8] The Al-O-Al bridges are virtually symmetrical (Al–O 1.787(3)–1.814(3) Å), and, as expected, the other distances in the side rings are homogeneous.[1, 2] The Al–O(H) distances (av 1.800 Å) are 0.1 Å longer than the other Al–O distances in **3** (1.698 Å).

Why are only three of the four ether molecules directly coordinated to the $Al_4(OH)_4$ unit? An exact analysis of the distances between atoms not directly bonded to one another shows that there is not enough space for another ether molecule to approach the free OH group. Evidently coordination of the fourth ether molecule would require distortion of the $[(Ph_2Si)_2O_3]_4$-$Al_4(OH)_4$ polycycle; hence, two $(Ph_2Si)_2O_3Al_2OH$ wings would come closer together and result in considerable steric hindrance.

To confirm this theory, we treated the ether adduct **3** with triethylamine; this is more sterically demanding and a stronger base than diethyl ether [Eq. (1)].

$$[(Ph_2Si)_2O_3]_4Al_4(OH)_4 \cdot 4Et_2O + 2Et_3N \longrightarrow [\{(Ph_2Si)_2O_3\}_4Al_4O_2(OH)_2]^{2-} \cdot 2HNEt_3^+ + 4OEt_2 \quad (1)$$

Regardless of the reaction stoichiometry, only two equivalents of triethylamine react with **3** under complete substitution or loss of the ether molecules to form the amine adduct **4**.[9] This crystallizes from the toluene solution and can be isolated almost quantitatively.

The crystal structures of **3** and **4** (Figure 3)[5] differ in the number of coordinated donor molecules; the aluminosiloxane units are basically the same. Molecule **4** has C_2 point symmetry; the twofold axis is perpendicular to the central Al_4O_4 eight-membered ring. The hypothesis presented above that coordination of base molecules to the hydrogen atoms of the OH groups influences the annelated $Si_2O_4Al_2$ rings is clearly confirmed. The best-fit plane for the $Si_2O_4Al_2$ eight-membered rings adjacent to the coordinated OH groups forms an average angle of 120.6° to the central Al_4O_4 ring, whereas the the other two $Si_2O_4Al_2$ rings form an angle of 138.2°. The access to OH groups that are not coordinated to amine molecules is threrefore hindered. The host–guest principle for more than two Et_3N molecules does not work because of the "closing of the $Si_2O_4Al_2$ rings".

The higher basicity of the nitrogen atom in triethylamine compared to that of the oxygen atom in diethyl ether, also has an influence on the bonding in the central $Al_4(OH)_4$ ring. Hence, the bonds to O(1) (Al(2)–O(1) 1.829(4), Al(1)–O(1) 1.820(4) Å) differ from those to O(2) (Al(1)–O(2) 1.733(3), Al(2)–O(2') 1.724(3) Å). The latter are 0.1 Å shorter than a normal AlO(H)Al bridge, which leads to the conclusion that the hydrogen atom is in fact bound to Et_3N and an AlO^-Al bridge is present instead of an AlO(H)Al bridge. Therefore, **4** is best described, at least in the crystal, as an ion pair of the form $[(Ph_2Si)_8Al_4O_{14}(OH)_2]^{2-} \cdot 2HNEt_3^+$ (a detailed analysis of solution and solid-state NMR spectra of **4** in comparision to that of $Et_3NH^+Cl^-$ indicates that an ion pair also exists in solution). The O(2)–N bond length is 2.72 Å and is thus slightly longer than the O–O bond length between the ether molecules and the OH groups in **3**.[8] The solid-state IR spectrum of **4** only shows one broad OH band at 3550 cm^{-1}, whereas the N–H stretches attributed to Et_3NH^+ are possibly hidden by C–H vibrations.

A Complex Catalytic Cycle Leading to a Regioselective Synthesis of *o,o'*-Disubstituted Vinylarenes**

Marta Catellani,* Franco Frignani, and Armando Rangoni

The ability to catalyze multistep processes is one of the most interesting features of transition metal reactivity. In particular palladium-catalyzed sequential reactions have been the object of much work.[1] The present synthesis, consisting of the regioselective functionalization of aromatic compounds at the 1, 2, and 3 positions, is based on the different reactivity of palladium(0), (II), and (IV) species formed along a catalytic sequence.

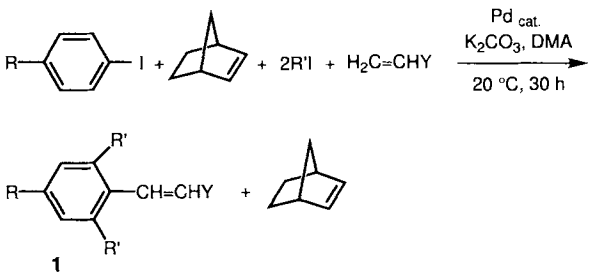
[**] This work was supported by the Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MURST, Roma), and the Consiglio Nazionale delle Ricerche (CNR, Roma). Mass and NMR facilities were provided by Centro Interfacoltà dell'Università di Parma.

The overall process comprises the reaction of an iodoarene, a strained olefin such as norbornene, an aliphatic iodide, and a terminal olefin as shown in Scheme 1. The catalyst can be introduced in the form of any of the palladium intermediates (or their precursors) shown in Scheme 2. The strained olefin is essential for the reaction to occur, although it is expelled towards the end of the catalytic process, like a sort of scaffold to be removed after the building of the molecule is complete. It thus behaves as a catalyst, although an excess is necessary to push the reaction toward the desired species. To stress this behavior norbornene has been placed in both terms of the equation reported in Scheme 1. In a typical example iodobenzene, norbornene,



1

Scheme 1. Palladium-catalyzed synthesis of *o,o'*-dialkylvinylarenes.

n-butyl iodide, and methyl acrylate underwent reaction in dimethylacetamide (DMA) at 20 °C for 30 h with *cis,exo*-2-phenylnorbornylpalladium chloride (PNP) dimer[2] as precursor of the monomeric catalyst (2.5×10^{-3} M). A 10:1 molar ratio of both iodobenzene and norbornene to palladium was used, and a 50% molar excess of methyl acrylate and a large excess of *n*-butyl iodide (100%) and of K_2CO_3 were used. After conventional treatment an unexpectedly high yield of methyl (*E*)-2,6-di-*n*-butylcinnamate (93% based on the arene) was obtained; the excess starting aliphatic halide was recovered mostly as such and in part as dialkyl carbonate. The catalyst efficiency is unchanged for about ten cycles and has not been optimized. The temperature was raised to 50 °C without large variations in yields and conversions. Beyond 50 °C the selectivity began to decrease remarkably as expected in view of the competition among the reactants. Other catalysts such as Pd^0 complexes and palladium acetate (which is reduced to Pd^0 under the reaction conditions) can also be used provided that the molar ratios of the reagents are properly adjusted. So far, however, the best results have been obtained with the above mentioned PNP dimer.

The reaction has general character: substituted aromatic iodides, primary aliphatic iodides and terminal olefins bearing either electron-withdrawing or electron-releasing groups can be used. The examples reported in Table 1 show the potential of the present reaction. The building blocks of the final product, the iodoarenes, iodoalkanes, and olefins can be widely varied, which makes the method extremely versatile for the preparation of 1,2,3-trisubstituted arenes not easily accessible by conventional methods with complete regioselectivity. As can be seen in Table 1 selectivities are very high, while conversions vary depending on the type of terminal olefin used.

All new compounds reported in Table 1 were fully characterized by ^{1}H, ^{13}C, ^{1}H–^{1}H and ^{13}C–^{1}H correlation NMR spectroscopy, IR spectroscopy, and mass spectrometry (Table 2). In the ^{1}H NMR spectra of compounds **1** (R = H) the aromatic protons form an AB_2 system as expected for a 1,2,3-trisubstituted structure, while a singlet is observed for compounds **1d** and **1e**.

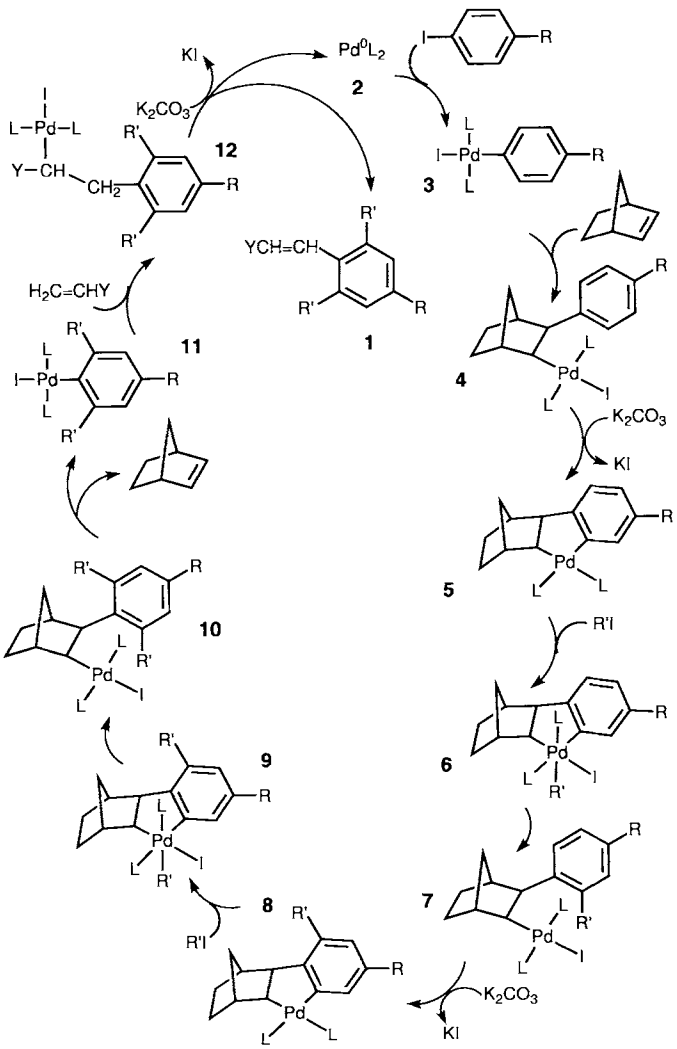
[a] Molar ratio of the reagents 1:4:1:1.5:3; the ratio of the PNP dimer to the aromatic iodide was 0.05:1 (20 °C, 30 h, DMA as solvent, N_2 atmosphere). [b] **1a–g** are *E* stereoisomers. [c] On the aryl iodide by GLC. [d] Based on the isolated product. [e] As expected another 10% of **1a**, corresponding to the reaction of the phenyl group of the catalyst is also obtained. [f] Hydrogenated compound from a mixture of linear unsaturated products.

The four organic reactants shown in Scheme 1 can interact selectively in the coordination sphere of the palladium complexes, as was established by experimental observations on the behavior of palladium(0), (II), and (IV) species for a series of steps that are depicted in the simplified Scheme 2 (dissociation, ligand



Scheme 2. Proposed catalytic cycle showing the course of aromatic functionalization through palladium complexes in different oxidation states (L = DMA, olefin; for R, R′, Y as in Table 1).

Table 2. Selected spectroscopic data for compounds **1a–1g** and **1h**-H_2 [a].

[a] All NMR spectra were recordered in $CDCl_3$ at 20 °C; ^{1}H NMR: 300.1 MHz (400.1 MHz for **1c** only), ^{13}C NMR: 75.4 MHz; the solvent was used as internal standard. * indicates interchangeable assignments.

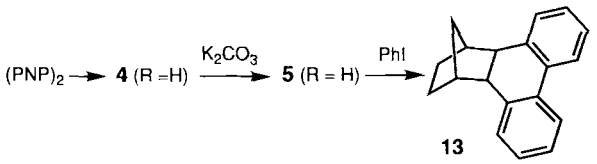
replacement, and rearrangement steps involved in the evolution from one complex to the next are omitted).

In particular the following points have been examined: a) $Pd^0 \rightarrow Pd^{II}$ (**2** → **5**): It is well known that palladium(0) complexes with several types of ligands (mainly tertiary phosphanes) undergo oxidative addition of aryl iodides at room temperature to give **3**.[3] Arylpalladium iodide **3** inserts norbornene giving **4** (*cis,exo*),[2, 4] which rather than undergoing a difficult β-hydrogen elimination[5] forms metallacycle **5** even at low temperature.[6, 7] The present catalytic cycle requires weak ligands such as the DMA used as solvent, however, to prevent too strong

stabilization of some intermediates. It has also been reported that oxidative addition occurs in dimethylformamide (DMF) under mild conditions (for example, in the course of the Heck reaction).[8] Both in DMF and in DMA at 20 °C and in the presence of K_2CO_3, complex **4** (R = H), formed from complex **3** (R = H) by norbornene insertion, reacted to give **5** (R = H), which could be isolated by addition of 1,9-phenanthroline (52% yield).[6a] We ascertained that norbornene exclusively was inserted into complex **3** even if a terminal olefin was present in large excess. As mentioned above catalyst **4** was introduced as a precursor, the PNP dimer. This species proved to be quite convenient because it contains no undesired ligands and is prone to opening of the halide bridge to give the monomeric form. We also observed that in the presence of an excess of *n*-butyl iodide no oxidative addition of the iodide to the palladium(0) species **2** or to the palladium(II) species **3** and **4** occurred, but the reaction proceeded further after the formation of **5** as shown below.

b) $Pd^{II} \rightarrow Pd^{IV} \rightarrow Pd^{II}$ (**6** → **10**): As we proved in earlier papers,[6a, 10e, 9] complex **5** (L = phenanthroline) is able to undergo oxidative addition of some reactive organic halides such as methyl, allyl, and benzyl halides to form a palladium(IV) complex of type **6**,[10] which undergoes reductive elimination to form **7**.[9] This process readily occurs even at low temperature (−20 °C). Under these conditions other aliphatic iodides are not reactive, but in the absence of phenanthroline and in DMA as solvent they react readily at room temperature. The new metallacycle **8** is formed in the same way as **5** and undergoes a new oxidative addition of the aliphatic halide to afford first the palladium(IV) complex **9** and then the reductive elimination product **10**.[11]

On the other hand, palladium(II) complexes have also been proposed to be involved in reactions with aromatic iodides.[12] Since they are present in the reaction mixture we checked their reactivity using as example metallacycle **5** (R = H, L = DMA), prepared in situ from the precursor of complex **4** (R = H, the PNP dimer), in the presence of K_2CO_3. The addition of iodobenzene gave compound **13** in 72% yield (Scheme 3).[12a]



Scheme 3. Reaction of iodobenzene with metallacycle 5 (R = H) at 20 °C for 6 h.

Aliphatic iodides, however, are strongly preferred to aromatic iodides. In fact, the same metallacycle **5** (R = H, L = DMA), formed in situ as above under the reaction conditions of our process, gave **1** exclusively even in the presence of iodobenzene, thus showing that under our reaction conditions aliphatic iodides are much more reactive than aromatic iodides.

Another aspect worth noting is that β-H elimination to give an olefin, which is a known feature of the alkylpalladium(II) complexes,[13] does not occur with alkylpalladium(IV) iodides **6** and **9**, which instead transfer the alkyl group as such to the arene to form complexes **7** and **10**, respectively.

c) $Pd^{II} \rightarrow Pd^{0}$ (**11** → **12**): We have previously shown[11] that complex **11** is formed by norbornene expulsion from its precursor **10**. C–C bond cleavage is thus implicated.[14] We have now found that complex **11** still is able to insert an olefin: as shown in Table 1 besides methyl acrylate, methyl vinyl ketone, styrene, and 1-octene form **12** and undergo β-H elimination to the *o,o'*-dialkylsubstituted vinylarene **1** in a Heck type reaction (conversions reflect the higher reactivity of olefins bearing electron-withdrawing substituents).[15] Thus the situation in the last steps of the cycle turns out to be opposite to that observed in the initial insertion step, in which norbornene was strongly preferred to terminal olefins. The latter are now inserted exclusively in place of norbornene. The reversed trend is ascribed to the steric effect of the *ortho* alkyl groups. A steric effect also appears to be responsible for the attack by the aryl group on the terminal position of the olefin in the step from **11** to **12**. The *E* isomers are formed predominantly.

The above observations offer the basis for a catalytic cycle as shown in Scheme 2, in which conditions have been kept constant for sake of comparison. The relative amounts of each substrate have to be properly balanced, however, for efficient catalytic operation. Thus in the formation of **1a** (Scheme 1) a large excess of methyl acrylate (twice the stoichiometric amount) led to a much lower yield (25%), probably owing to stabilization of a Pd^0 complex. Furthermore some substrates such as benzyl and allyl halides are not suitable for a catalytic cycle, because their complexes are too stable.

In spite of the complex mechanism the present synthesis is quite simple and straightforward from the synthetic point of view. It is rather surprising that the sequence of steps shown occurs under mild conditions, but even more surprising is the fact that a precise molecular recognition of the substrates by the catalyst occurs even in the presence of similar classes of compounds such as aromatic and aliphatic iodides or norbornene and olefins. This is essentially due to the different properties of the metal in different oxidation states and to the steric effects of palladium-bonded substrates.

Experimental Section

The general procedure is illustrated for the case of iodobenzene, *n*-butyl iodide, norbornene, and methyl acrylate. Under nitrogen *cis,exo*-2-phenylnorbornylpalladium chloride (PNP) dimer (11 mg, 0.017 mmol) and K_2CO_3 (146 mg, 1.05 mmol) are placed in a Schlenk-type flask. A solution containing iodobenzene (71 mg, 0.35 mmol), *n*-butyl iodide (258 mg, 1.40 mmol), norbornene (30 mg, 0.32 mmol) and methyl acrylate (45 mg, 0.52 mmol) in DMA (7.0 mL) is then added. After the mixture has been stirred at 20 °C for 30 h, 5% H_2SO_4 is added, and the organic part is extracted with CH_2Cl_2, and dried. Concentration to dryness gives almost pure product. Flash chromatography on silica with hexane/ethyl acetate (9/1) as the eluent affords pure methyl 2,6-di-*n*-butylcinnamate (*E*)-**1a** (98 mg) in 93% yield based on the arene (including the phenyl group contained in the catalyst). GC analysis (SE 30 column) of the volatiles removed under vacuum and trapped at −196 °C shows that most of the norbornene is recovered, as well as 49% of the unchanged *n*-butyl iodide along with 23% of the di-*n*-butyl carbonate.

5 (R = H, L = 1,9-phenanthroline, phen): PNP dimer (50 mg, 0.08 mmol) and K_2CO_3 (22 mg, 0.16 mmol) in DMA (3 mL) are stirred under nitrogen at 20 °C for 5h. 1,9-Phenanthroline (29 mg, 0.16 mmol) is then added, and stirring is continued for further 10 min. The solvent is removed under vacuum, the residue taken up in CH_2Cl_2, and the resulting suspension filtered through Celite. Recrystallization from a mixture of CH_2Cl_2 and hexane yields the desired product (38 mg, 52%) [6a].

13: To PNP dimer (44 mg, 0.07 mmol) and K_2CO_3 (21 mg, 0.015 mmol) a solution of iodobenzene (28 mg, 0.14 mmol) in DMA (2 mL) is added under nitrogen, and the resulting solution is stirred at 20 °C for 6 h. After conventional treatment and subsequent column chromatography on silica (hexane/ethyl acetate 98/2) compound **13** [12a] (25 mg, 72%) is obtained.

Unconventional Amphiphilic Polymers Based on Chiral Polyethylene Oxides**

Henk M. Janssen, Emiel Peeters, Marga F. van Zundert, Marcel H. P. van Genderen, and E. W. Meijer*

In recent years the coiled-coil superstructure of α-helical polymers has received enormous attention.[1] Not only naturally occurring proteins[2] but also synthetic, designed polypeptides[3] have been investigated in order to distinguish between the different factors that are involved in the formation of coiled coils. It is now generally accepted that the most important characteristic of polypeptides that form coiled coils is the regular repeat of hydrophobic amino acids in a hydrophilic sequence. This is expressed in a $[PAPPAPP]_n$ primary structure, in which P stands for a polar residue and A stands for an apolar residue (typically leucine). The repeat of polar and apolar residues gives rise to a hydrophobic ribbon on the α-helix of the polypeptide, which causes dimerization of two amphiphilic α-helices in water into a coiled coil with the leucine-zipper motif.[4] Despite numerous studies of synthetic amphiphilic polymers[5] and polymer complexes,[6] this special type of ribbon amphiphiles has never been addressed. Here we present the synthesis and properties of the first potential ribbon-type amphiphilic polymers based on chiral modified polyethylene oxides (PEOs). These polymers, as given in Figure 1, can provide the link between "complicated" biological systems and "simple" synthetic systems.[7]

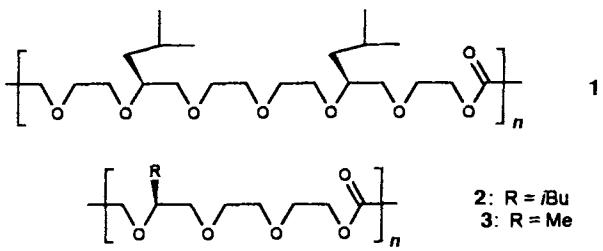

Figure 1. Designed synthetic coiled-coil analogues based on PEO. Isobutyl and methyl side groups are chosen in analogy to the leucine moiety in peptides that form coiled-coil structures and the methyl side group in PEO/PPO/PEO block-copolymers, respectively.

The choice of PEO-based target polymers **1**–**3** (for synthetic feasibility we introduced an ester functionality in the backbone) is inspired by the solubility of PEO in water and its 7_2-helical conformation in dilute aqueous solutions.[8] In contrast, polypropylene oxide (PPO) and polybutylene oxide (PBO) are insoluble in water, while both PEO/PPO/PEO and PEO/PBO/PEO block-copolymers show distinct amphiphilic behavior.[9] Therefore, the stereospecific placement of isobutyl side chains at every second and fifth unit of a seven-unit repeat of PEO, as shown in polymer **1**, results in a synthetic analogue for coiled-coil forming polypeptides, in the sense that the design of the primary structure is identical. Polymers **2** and **3** have

also been synthesized, both of which have a [PPAP'] repeat in the primary structure. This repeat resembles the [PAPPAPP'] repeat in **1**.

Polymer **1** was obtained by the ring-opening polymerization of the 2-oxo[21]crown-7 **4**. The synthesis of optically pure **4** is outlined in Scheme 1.[10] (*S*)-Leucine, the starting compound, is the basis for the chiral, apolar residue in the final monomer. A short reaction sequence, including protection and deprotection steps and Williamson syntheses with glycol compounds, provided the ω-hydroxycarboxylic acid precursor of **4**. Subsequent cyclization using a modification of a procedure reported by Corey and Nicolaou gave **4** in 50% yield.[11]

Both 2-oxo[12]crown-4 monomers **5** and **6** (Figure 2) were synthesized in analogy to **4**.[10] Cyclization affording **5** and **6** was achieved in high yields by heating the α-hydroxycarboxylic acid precursors in a Kugelrohr apparatus in the presence of $CoCl_2$ at 250 °C and ≈ 5 mbar.[12] The distillate was purified by column chromatography with alumina giving **5** and **6** in yields of 72 and 56%, respectively. The optically pure, oxocrown ethers **4**–**6** were characterized by ^1H and ^{13}C NMR spectroscopy, mass spectrometry, and chromatography (HPLC with a chiral stationary phase); all data are in agreement with the proposed structures.

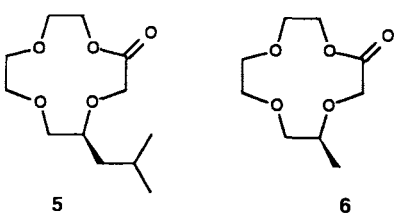

Figure 2. Substituted 2-oxocrown ethers **5** and **6**.

Stannous octanoate ($SnOct_2$) catalyzed polymerization[13] of the monomers **4**–**6** yielded polymers **1**–**3**. The reactions were carried out at 130 °C with monomer/$SnOct_2$ molar ratios of 20/1 and without any solvent. Polymers **1**–**3** were isolated as sticky, viscous oils by precipitation in hexane and/or ether and are soluble in a wide variety of solvents such as acetonitrile, ethyl acetate, THF, and methanol. All spectroscopic data of the polymers are in full agreement with the structures assigned. Selected physical and spectroscopic data for **1**–**3** are given in Table 1.

The behavior of the polymers was studied in water and in aqueous solvent mixtures. Solutions of **1**–**3** in water were transparent only at low concentrations (<0.0005, <0.1, and <1 mg mL^{-1} for **1**, **2**, and **3**, respectively). At higher concentrations of approximately 10 mg mL^{-1}, stable turbid solutions were obtained. A critical association concentration of approximately 3×10^{-6} M was measured for polymer **2** by application of pyrene-probe luminescence techniques.[14] This result implies that these newly designed polymers have a truly amphiphilic character. Transmission electron microscopy (TEM) studies of samples from both the dilute transparent and the concentrated turbid solutions did, however, not show any organized structures.

Table 1. Selected physical and spectroscopic data for **1**–**3**.

1: ^1H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 4.3$ (m, 2H; CH_2CH_2CO), 4.2 (s, 2H; $COCH_2O$), 3.9–3.5 (m, 20H; further backbone protons), 1.75 (m, 2H; $CH_2CH(CH_3)_2$), 1.45 (m, 2H; $CH'H''CH(CH_3)_2$), 1.25 (m, 2H; $CH'H''CH(CH_3)_2$), 0.90 (m, 12H; $4 \times CH_3$); ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C): $\delta = 170.5$ (CO), 77.6, 77.5, 74.5, 74.2, 71.3, 70.9, 70.8, 70.6, 69.4(2), 69.1, 68.5, 63.7 (backbone carbons), 41.2, 41.1, 24.5(2), 23.3(2), 22.4, 22.3 (isobutyl carbons); GPC [a]: $M_n = 5.2$ kg mol^{-1}, $M_w = 9.0$ kg mol^{-1}, $D = 1.7$.

2: ^1H NMR (400 MHz, CD_3CN, 25 °C): $\delta = 4.2$ (m, 4H: CH_2CH_2-CO and $COCH_2O$), 3.7–3.4 (m, 9H; further backbone protons), 1.75 (m, 1H; $CH_2CH(CH_3)_2$), 1.4 (ddd, $^2J(H,H) = 13.9$ Hz, $^3J(H,H) = 8.1$ Hz, $^3J(H,H) = 5.9$ Hz, 1H; $CH'H''CH(CH_3)_2$), 1.25 (ddd, $^2J(H,H) = 13.9$ Hz, $^3J(H,H) = 8.1$ Hz, $^3J(H,H) = 4.8$ Hz, 1H; $CH'H''CH(CH_3)_2$), 0.9 (d, $^3J(H,H) = 6.6$ Hz, 3H; CH_3'), 0.88 (d, $^3J(H,H) = 6.6$ Hz, 3H; CH_3''); ^{13}C NMR (100 MHz, CD_3CN, 25 °C): $\delta = 171.5$ (CO), 78.3, 74.9, 71.2, 71.0, 69.5, 68.0, 64.4 (backbone carbons), 41.6, 25.1, 23.5, 22.7 (isobutyl carbons); GPC [a]: $M_n = 7.3$ kg mol^{-1}, $M_w = 17.3$ kg mol^{-1}, $D = 2.4$.

3: ^1H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 4.3$ (m, 2H; CH_2CH_2CO), 4.25 (s, 2H; $COCH_2O$), 3.8–3.45 (m, 9H; further backbone protons), 1.2 (d, $^3J(H,H) = 6.6$ Hz, 3H; CH_3); ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C): $\delta = 170.5$ (CO), 75.1 (2), 70.3, 70.1, 68.6, 66.6, 63.3 (backbone carbons), 16.6 (methyl carbon); GPC [a]: $M_n = 3.7$ kg mol^{-1}, $M_w = 7.4$ kg mol^{-1}, $D = 2.0$.

We used optical rotatory dispersion (ORD) spectroscopy to investigate the possible conformational changes of the polymers upon the addition of water to THF solutions, prior to phase separation. All polymers showed the same trend: increasing the water content induced a less negative specific rotation. The effect was most striking for the methyl-substituted polymer **3**: an inversion of optical rotation was observed (Figure 3). The

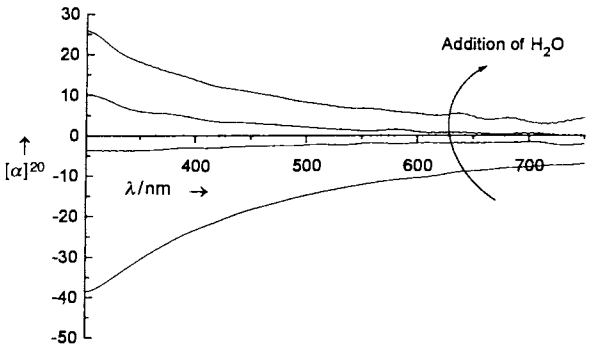

Figure 3. ORD spectra of polymer **3** in THF and THF/water mixtures. $[\alpha]^{20}$ in degrees vs wavelength in nm. Concentrations of **3**: 10–20 mg mL^{-1}; water content: 0, 18, 32, and 47%.

isobutyl-substituted polymers **1** and **2** show phase separation before inversion of optical rotation can occur. The observed inversion is seldomly seen for polymers and has always been related to a well-defined ordering process of the polymers.[15] Here, we propose that the inversion in optical rotation is caused by a distinct conformational transition. However, it is not possible to attribute the effects found in these experiments to the formation of a 7_2-helical conformation and subsequent association of the chiral substituted polyethylene oxides.

Indications for the nature of the conformational transition were found by studying the complexation of the polymers with cations in solution. Oligoethylene glycols form helical structures upon complexation with a variety of cations in the solid state.[16] The "monomeric" precursor of polymer **1**, compound **7** in Scheme 1, formed a 1:1 complex with KSCN in methanol.[17] A titration experiment monitored with ORD showed an inversion of optical rotation as a result of the complexation process (Figure 4). A similar result, inversion of optical rotation, was obtained when polymer **2** was titrated with KSCN. We interpret these inversions as the result of a conformation change from a random coil to a helical conformation, assuming that the behavior of the complexes in the solid state and in solution is similar.

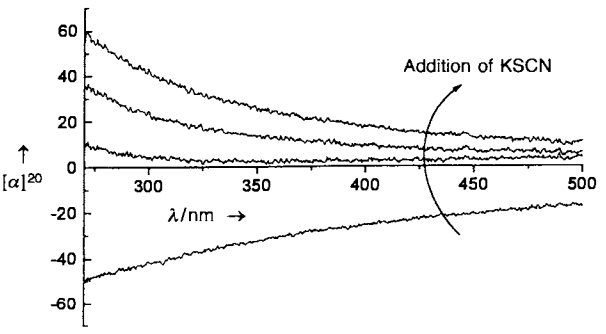

Figure 4. KSCN titration of a methanolic solution of **7** monitored by ORD spectroscopy. $[\alpha]^{20}$ in degrees vs wavelength in nm. Concentration of **7**: 8.3 mg mL^{-1}; equivalents of KSCN added: 0, 1.7, 4.0, and 10.9 equiv.

Consequently, we propose that the transitions in the ORD spectra of polymers **1**–**3** induced by increasing water content (see Figure 3) should also be interpreted as transitions from a random coil to a helical conformation.[18]

In summary, a new class of synthetic amphiphilic polymers has been synthesized and characterized. Further studies are in progress to determine how polymers **1**–**3** associate in aqueous solutions and whether the proposed random coil to helix transition is accompanied by the formation of coiled coils.

Immunization of Mice with a Fully Synthetic Globo H Antigen Results in Antibodies against Human Cancer Cells: A Combined Chemical—Immunological Approach to the Fashioning of an Anticancer Vaccine

Govindaswami Ragupathi, Tae Kyo Park, Shengle Zhang, In Jong Kim, Linda Graber, Sucharita Adluri, Kenneth O. Lloyd, Samuel J. Danishefsky,* and Philip O. Livingston

Mobilization of the unsurpassed resourcefulness and ingenuity of the human immune system to do battle against cancer is an enduring hope.[1] Perhaps the ideal approach would be through a vaccine that would educate the immune apparatus to provide surveillance against a particular tumor-associated antigen or even a range of such signature antigens.[1, 2] Success along these lines would require proper identification of antigens and their presentation to patients in an effective immunostimulating context. Based on this principle, a number of completely synthetic vaccines have been prepared.[3] A construct containing a synthetic T-antigen disaccharide covalently attached to a carrier protein is of particular interest since a specific immune response in human cancer patients was observed.[4]

We started from the known tendency of transformed cells to express on their surfaces rather selective carbohydrate constellations in the form of glycoproteins or glycolipids. In principle, it should be possible to key the human immune system to identify the presence of such carbohydrate antigens. Toward this goal, we have merged the resources of chemistry and immunology. In describing our program we begin with the chemical synthesis of the carbohydrate sector. We made full use of the logic of glycal assembly[5] to obtain the complex carbohydrate moiety in homogeneous form. A spacer region was then inserted in a structurally defined way with a linkage arm for conjugation to carrier protein.[6] The extent of the conjugation is determined. The structurally defined protein–spacer-conjugated carbohydrate was administered to a mouse along with an appropriate immunoadjuvant (Figure 1). We demonstrate here that one such

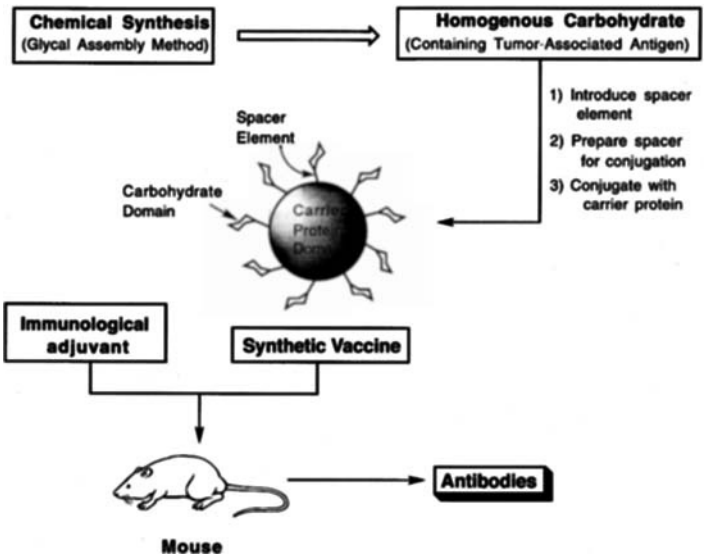

Figure 1. General strategy for the preparation of carbohydrate-based antitumor vaccines.

synthetic vaccine immunoconjugate combination activates the immune system of a mouse to produce antibodies that bind to human cancer cells expressing the epitope around which the carbohydrate region was fashioned.

The breast tumor glycolipid associated antigen **2** isolated by Hakomori and co-workers from MCF-7 cells, and termed globo H, constituted a promising possibility for exploration.[7] Early studies in this area were facilitated by the immunocharacterization of the antigen by the murine monoclonal antibody MBr1.[8] Previously, we had described the total synthesis of the hexacyclic globo H glycal **1** by the method of glycal assembly (Scheme 1).[9] This system was carried forward to reach antigen **2**, whose structure assignment was verified by unambiguous spectroscopic corroboration through this synthesis. Furthermore, the synthetic compound **2** did, indeed, bind to the murine monoclonal antibody (mAb) MBr1 and inhibited its binding to MCF-7 cells as measured by flow cytometry.[10]

We then built upon the logic of our synthesis to prepare congeners of the compound and to use them to map the structural requirements for binding to the mAb MBr1. Thus, allyl glycoside **3**, corresponding in its epitope region to **2**, was found to bind well (Figure 2).[10] These studies also revealed that for this monoclonal antibody both the fucose appendage[10, 11] (compound **4** is not bound) and the β-glycoside linkage between the C and D sectors are critical. Compound **5** containing an α linkage at this locus is only weakly bound. Both the A ring and the AB sector can be deleted (see compounds **6** and **7**, respectively). The β linkage of the glycosidic bond between the B and C rings is not of large effect (see compound **8**, which is well recognized).

As previously reported, the double bond at the reducing end of globo H glycal was used as the access point to reach the fully deprotected allyl glycoside **3**.[9a] We proceeded as follows. Ozonolysis of **3** was followed by reductive amination[12a,b] with carrier protein keyhole lympet hemocyanin (KLH) (see **9**) and with bovine serum albumin (BSA) (see **10**). In the case of the KLH conjugate, we introduced about 150 carbohydrate units per protein.[12c] Similarly, carbohydrate:protein analyses revealed the presence of 17 carbohydrate units in **10**. Systems **9** and **10** (of defined carbohydrate structure) were the starting points for immunological investigations (see Scheme 1).

Groups of mice (female CB6F1 mice, Jackson Laboratory, Bar Harbor, ME, USA) were immunized subcutaneously with either construct **9** or **10**, which were derived from conjugation of **3** with KLH and BSA, respectively. Each vaccination (after weeks 0, 1, 2, 7, 20, and 35) contained 10 μg of the synthetically derived epitope and 10 μg of the immunological adjuvant QS-21. Mice were bled 10 days after the third, fourth, fifth, and sixth vaccinations. Control vaccinations were conducted with phosphate-buffered saline (PBS), and **2** with QS-21.

Serological responses were analyzed by several methods. An enzyme-linked immunosorbent assay (ELISA) was used to determine the titer of antibodies against globo H ceramide (**2**), as described previously.[13] Cell surface reactivity of these antibodies was assayed by flow cytometry and immune adherence (IA) assays[14,15] on globo H positive MCF-7 cells and as a control, with globo H negative B78.2 melanoma cells. The ability of these sera to mediate complement lysis was assessed by a europium-release complement-dependent cytotoxicity assay against MCF-7 cells.[14]

The globo H-KLH (system **9**) vaccine, coadministered with QS-21, induced higher titer IgM and IgG than the globo H-BSA vaccine plus QS-21. The time course of the induction of IgM and IgG antibodies in five mice by the globo H-KLH vaccine is shown in Figure 3. IgM antibody titers generally remained higher than IgG titers, even after the three booster vaccinations. In general, titers were not higher after the booster immunizations than after the initial immunizations. No detectable anti-globo H antibodies were observed with the control vaccines described above.

A potentially critical finding was that anti-globo H IgM antibodies showed clear reactivity with MCF-7 breast cancer cells by flow cytometry (Figure 4) and, in a control experiment, failed

to react with globo H-negative B78.2 melanoma cells. Furthermore, antibodies induced by globo H-KLH reacted more strongly than antibodies induced by globo H-BSA. Similarly, cell surface reactivity of the anti-globo H IgM antibody was confirmed by immune adherence methods. This assay revealed that anti-globo H titers increased from 0 to 1/360 after immunization with globo H-KLH (**9**) and to 1/160 after immunization with globo H-BSA (**10**).

These antibodies were also highly effective at inducing complement-mediated cytotoxicity. In background experiments, antisera without complement, or complement without sera as well as complement with sera arising from control vaccines, failed to lyse. At a serum dilution of 1:10 in the presence of human complement, the percentage lysis with antibody induced by globo H-KLH (**9**) conjugate was 48%. Lysis induced by the globo H-BSA vaccine (**10**) was 39%. By way of reference, maximal complement-induced cytotoxicity with monoclonal antibody MBr1 was 72%.

As an indication of specificity, we conducted assays with compounds **2**–**8** to determine their ability to inhibit the binding of the antisera to the fully synthetic globo H antigen **2** (Figure 5). Of these probe compounds, only the full globo H hexasaccharide (compound **2**) manifested complete inhibition. Partial inhibition resulted from truncated globo H compounds, but not with unrelated compounds such as ganglioside GD3. These findings are consistent with a polyclonal serological response in which different antibodies react with different portions of compound **2**.

Finally, ELISAs were also performed with sera that had been absorbed by incubation with MCF-7 or B78.2 cells. For this assay 5×10^5 cells were incubated with sera for 1 h and the cells removed by centrifugation. In this experiment more than 50% of the ELISA reactivity against globo H-ceramide was lost following incubation with MCF-7 cells. By contrast, no decrease in the activity was observed following incubation with globo H-negative B78.2 melanoma cells (Figure 6).

SSEA: state-specific embryonic antigen or desfucosylpentasaccharide.

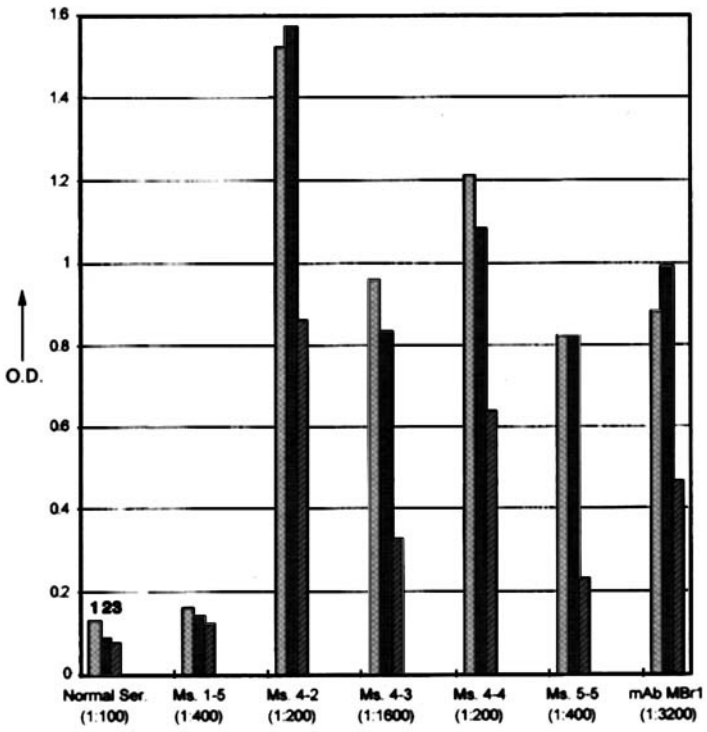

Figure 6. Absorption analysis of globo H antisera with MCF-7 and B78.2 cells. O. D. (optical density) at 405 nm; 1: no cells, 2: B78.2 (negative control), 3: MCF-7. Ratios given refer to the dilution of serum used for analysis. Ms: mouse serum. Ms. 1-5 vaccinated with PBS; Ms. 4-2, 4-3, and 4-4 vaccinated with globo H-KLH (**9**); Ms. 5-5 vaccinated with globo H-BSA (**10**).

These experiments demonstrate that the response was polyclonal with antibody subpopulations recognizing, in varying degrees, several different globo H epitopes present in probe structures **2**–**8**. As with monoclonal antibody MBr1, the fucose terminus of the saccharide was especially important for antibody recognition (see Figure 5, compound **4**, for the consequence of deletion of the fucose residue). Furthermore, globo H epitopes expressed on the MCF-7 cell surface are readily recognized by the induced antibodies, resulting in complement activation and lysis of globo H-positive tumor cells.

This report confirms the immunogenicity of the most complex, but rigorously defined synthetic carbohydrate antigen yet evaluated. It provides a basis for the synthesis and examination of other vaccines of complex carbohydrates. Based on these results, we plan to initiate clinical trials with the globo H-KLH plus QS-21 vaccine in patients with demonstratable globo H-positive cancers. Other constructs, assembled through the same logic, are at various stages of preclinical assessment and early indications are encouraging.[16]

Detection and Characterization of a Pre-Reactive Complex in a Mixture of Water and Fluorine: Rotational Spectrum of $H_2O\cdots F_2$**

Stephen A. Cooke, Gina Cotti, John H. Holloway, and Anthony C. Legon*

The vigorous reaction of water with fluorine has long fascinated chemists. Moissan, who first isolated fluorine in 1886, showed in 1900[1] that bubbling the gas through water produced oxygen and a substance of great oxidizing strength. Subsequently, it was demonstrated[2] that the reaction gives rise to HF, H_2O_2, O_2, and OF_2 and is evidently complicated. Investigations of the fluorination of ice revealed[3] that the highly reactive hypofluorous acid, HOF, is present as a steady-state intermediate, formed in the reaction (a). Not only does HOF decompose

$$F_2 + H_2O \overset{-40\ ^\circ C}{\rightleftharpoons} HOF + HF \qquad (a)$$

spontaneously to give HF and oxygen at room temperature but it also reacts rapidly with water to yield HF, H_2O_2, and O_2. Moreover, it reacts with fluorine in the presence of water to form OF_2 [Eq. (b)], as well as with HF by the reverse of (a).

$$HOF + F_2 \xrightarrow{H_2O} OF_2 + HF \qquad (b)$$

In view of the interest in the H_2O/F_2 reaction, a significant challenge for chemists is to isolate and characterize any molecular complex formed by H_2O and F_2 prior to reaction (a). Such a complex may be described as a pre-reactive intermediate because, presumably, it has only transient existence between encounter of the components and their chemical reaction.

We report herein on the first experimental identification of a pre-reactive complex $H_2O\cdots F_2$. A detailed characterization of this species was achieved through its rotational spectrum, as observed with a pulsed-nozzle, Fourier-transform microwave spectrometer,[4] modified to satisfy three conditions. These were: to avoid premature mixing of H_2O and F_2, to ensure that when the components did encounter each other they interacted in the absence of surfaces thereby avoiding heterogeneous reactions and, finally, to ensure that complexes so formed attained very low rotational/vibrational temperatures and collisionless expansion rapidly enough to preclude any homogeneous reaction, either bimolecular or unimolecular.

The device used to secure these conditions was a fast-mixing nozzle,[5] which consists essentially of a pair of concentric, nearly coterminal tubes. Water vapor issued continuously from the inner tube, while a mixture of F_2 in Ar was pulsed down the outer tube. The components mixed only as they emerged into the vacuum chamber of the spectrometer and were then travelling at supersonic speed away from the nozzle surfaces. The $H_2O\cdots F_2$ complexes formed in three-body collisions within about 1 μs of mixing were in collisionless expansion after about 10 μs.[6] Their rotational spectrum was then observed by interrogating the collision-free, concentric gas flow with pulses of microwave radiation.

Ground-state rotational spectra of the three isotopomers $H_2{}^{16}O\cdots F_2$, $H_2{}^{18}O\cdots F_2$, and $D_2{}^{16}O\cdots F_2$ thereby detected were characteristic of a nearly prolate, asymmetric rotor of large A_0 value, and exhibited the *a*-type transitions $2_{12}\leftarrow 1_{11}$, $2_{02}\leftarrow 1_{01}$, $2_{11}\leftarrow 1_{10}$, $3_{13}\leftarrow 2_{12}$, $3_{03}\leftarrow 2_{02}$, and $3_{12}\leftarrow 2_{11}$ in the frequency range 6–18 GHz. Each transition carried partially resolved hyperfine structure arising from coupling of the F and H/D nuclear spins to the molecular rotation and extending over a few tens of kilohertz. This restricted frequency measurements to an accuracy of about 5 kHz. Analysis of observed frequencies by using a Hamiltonian appropriate to the Watson A reduction[7] gave the rotational constants B_0 and C_0, and the centrifugal distortion constants Δ_J and Δ_{JK} recorded in Table 1. The

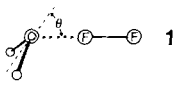
Table 1. Ground-state spectroscopic constants of three isotopomers of $H_2O\cdots F_2$.

	$H_2{}^{16}O\cdots F_2$	$H_2{}^{18}O\cdots F_2$	$D_2{}^{16}O\cdots F_2$
A_0 [MHz] [a]	(428920)	(428920)	(214625)
B_0 [MHz]	2988.086(1)	2816.183(2)	2751.650(2)
C_0 [MHz]	2958.280(1)	2789.767(2)	2707.633(2)
Δ_J [kHz]	20.22(6)	18.2(1)	16.5(1)
Δ_{JK} [MHz]	3.7210(7)	3.269(1)	3.770(1)

[a] A_0 was preset to the value predicted from the model **1** with $\theta = 0$ while the values of the centrifugal distortion constants Δ_K, δ_J, and δ_K were fixed at zero. See text for discussion.

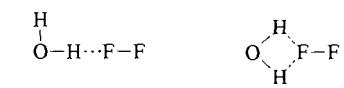
effective independence of the observed frequencies of A_0, Δ_K, δ_J, and δ_K dictated that A_0 should be pre-set to its value calculated from the determined geometry (see below), while the values of the remaining constants were held at zero.

Several arguments based on the form of the observed spectrum, the magnitudes of the derived spectroscopic constants, and the effects of isotopic substitution on both show that the complex has an equilibrium geometry of the type **1** but is subject to the following constraints: either $\theta = 0$ (planar, C_{2v}) or θ is nonzero (pyramidal, C_s) but with a potential energy barrier to the planar conformation so low that the configuration at oxygen is rapidly inverting. The latter geometry is referred to as effectively planar.



1

First, the changes in B_0 and C_0 on isotopic substitution of ^{18}O and D_2 to give $H_2{}^{18}O\cdots F_2$ and $D_2{}^{16}O\cdots F_2$, respectively, are consistent only with the order $H_2O\cdots F-F$ of the nuclei; structures like those shown in Scheme 1 are ruled out.



Scheme 1. Theoretically conceivable geometries of $H_2O\cdots F_2$ adducts with hydrogen bonds.

Second, there is evidence of a nuclear spin statistical weight difference between the spectra of $H_2O\cdots F_2$ and $D_2O\cdots F_2$ consistent with either a planar or effectively planar geometry of the type **1**. For such a geometry, a rotation C_2^a applied to $H_2O\cdots F_2$ exchanges a pair of equivalent protons ($I = 1/2$). Standard arguments based on Fermi–Dirac statistics then require, for example, that the transitions $2_{12}\leftarrow 1_{11}$ and $2_{11}\leftarrow 1_{10}$ in the vibrational ground state have a nuclear spin statistical weight of 3, while the transition $2_{02}\leftarrow 1_{01}$ has a weight of 1. In $D_2O\cdots F_2$, the weight ratio is reversed to 1:2 in favor of the $2_{02}\leftarrow 1_{01}$ transition because D nuclei are bosons with $I = 1$. Superimposed on these weightings is the loss

of intensity of the $K_{-1} = 1$ transitions resulting from their depleted Boltzmann population at the end of the supersonic expansion. This effect will be more serious for $H_2O\cdots F_2$ than $D_2O\cdots F_2$ because $K_{-1} = 1$ levels are higher in energy by $h(A - B)$ than $K_{-1} = 0$ levels of the same J, and A is predicted to be a factor of two larger for $H_2O\cdots F_2$, according to the planar model. Hence, in the absence of nuclear spin statistics, the relative intensity R of $K_{-1} = 0$ to $K_{-1} = 1$ transitions of a given J should be greater for $H_2O\cdots F_2$. In fact, the observed values are $R \approx 2$ and 5 for $H_2O\cdots F_2$ and $D_2O\cdots HF$, respectively, establishing the presence of the nuclear spin statistics. It is worth noting that the very observation of $K_{-1} = 1$ transitions with appreciable intensity for $H_2Y\cdots HX$ (Y = O or S, X = F, Cl, or CN) molecules formed in a supersonic expansion is a hallmark of a planar/effectively planar geometry and occurs for all complexes with Y = O so far investigated.[8] On the other hand, for $H_2S\cdots HX$ complexes, all of which are rigidly pyramidal at S and noninverting in the zero-point state, $K_{-1} = 1$ transitions are very weak or unobservable.[9] Reasons for the strong rotational cooling of $K_{-1} = 1$ states in $H_2S\cdots HX$ have been discussed.[10]

The third observation consistent with a planar or effectively planar geometry of the type **1** concerns the values of $B_0 - C_0$. The maximum value of $B - C$ for **1** occurs at $\theta = 0$. Such a planar model, in which the geometries of H_2O and F_2 are assumed unperturbed and $r(O\cdots F) = 2.72$ Å (see below), predicts $B - C$ values of 20.8, 18.5, and 34.3 MHz for $H_2{}^{16}O\cdots F_2$, $H_2{}^{18}O\cdots F_2$, and $D_2{}^{16}O\cdots F_2$, respectively. These values are systematically smaller than the observed values 29.8, 26.4, and 44.0 MHz, respectively, no doubt as a result of the contribution of the low frequency intermolecular vibrations to the zero-point moments of inertia, especially the motion that takes the H atoms out of the plane. Such behavior is also observed in $H_2O\cdots HF$[11] and $H_2O\cdots HCN$,[8] both of which have effectively planar geometries of the type **1**.

A least-squares fit of the rotational constants B_0 and C_0 for the three isotopomers given in Table 1 under the constraints $\theta = 0$ and unperturbed geometries for H_2O and F_2 gives $r(O\cdots F) = 2.719(4)$ Å for model **1**. The assumption of unperturbed geometries is justified by the very weak binding of the complex, as measured by the intermolecular stretching force constants k_σ. For **1** with $\theta = 0$ and rigid subunits, Millen[12] has given a simple expression that relates k_σ to Δ_J. The results for the three isotopomers $H_2{}^{16}O\cdots F_2$, $H_2{}^{18}O\cdots F_2$, and $D_2{}^{16}O\cdots F_2$ are included in the range $k_\sigma = 3.63(7)$ N m^{-1}. This should be compared with $k_\sigma = 1.4$[13] and 24.9 N m^{-1}[14] for $Ar\cdots HF$ and $H_2O\cdots HF$, respectively.

Experimental Section

Rotational spectra of $H_2O\cdots F_2$ were observed by using a pulsed-nozzle, Fourier-transform microwave spectrometer[4] equipped with a fast-mixing nozzle [5]. A mixture composed of approximately 2% of fluorine (99.8% pure; Distillers M. G.) in argon was pulsed through the outer of the two concentric tubes of the nozzle at a rate of 2 Hz from a stagnation pressure of 3 bar. At the exit into the vacuum chamber of the spectrometer the pulses met water vapor issuing continuously from the coterminal inner 0.3 mm diameter glass tube. The water vapor flow rate was the maximum possible from a sample of the liquid at room temperature. The rotational spectrum of gas pulses so produced was recorded in the usual way in the frequency range 6–18 GHz. For $H_2{}^{18}O\cdots F_2$ and $D_2{}^{16}O\cdots F_2$, samples of isotopically enriched water ($H_2{}^{18}O$, 98 atom%; Amersham International plc) and D_2O, (99.9 atom%, Fluorochem Ltd.) were employed.

Tuning the Structure and Reactivity of the $[Cu_2(\mu\text{-}O)_2]^{2+}$ Core: Characterization of a New Bis(μ-oxo)dicopper Complex Stabilized by a Sterically Hindered Dinucleating Bis(triazacyclononane) Ligand**

Samiran Mahapatra, Victor G. Young, Jr., Susan Kaderli, Andreas D. Zuberbühler,* and William B. Tolman*

An important objective in continuing efforts to understand the fundamental chemistry involved in oxidase and oxygenase reactions of synthetic and biological copper-containing catalysts is the synthesis, structural elucidation, and characterization of the reactivity of copper–dioxygen complexes resulting from the reaction of O_2 with Cu^I precursors.[1] The few such compounds that have had their structures determined unequivocably by X-ray crystallography display a variety of core geometries (Figure 1) that differ as an apparent result of the divergent nature of the supporting multidentate ligands, among other factors.[2, 3] How supporting ligand topology influences the structure and reactivity of copper–dioxygen complexes is an important issue in contemporary research that has implications in understanding metalloenzymes and other catalysts.

[**] This work was supported by grants from the National Institutes of Health (GM47365 to W. B. T.), the National Science Foundation (National Young Investigator Award to W. B. T. and CHE-9413114 for partial support of the X-ray diffractometer), the Alfred P. Sloan and Camille and Henry Dreyfus Foundations (W. B. T.), Unilever Corporation (W. B. T.), and the Swiss National Science Foundation (A. D. Z.). We thank Jason A. Halfen for his assistance with the X-ray crystal structure determination and Elizabeth C. Wilkinson and Professor Lawrence Que, Jr., for resonance Raman spectroscopic measurements.

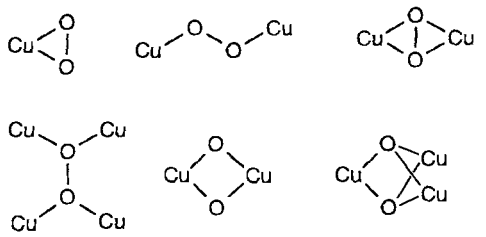

Figure 1. Core geometries of copper–dioxygen complexes that have been structurally characterized by X-ray crystallography (ref. [2,3a]).

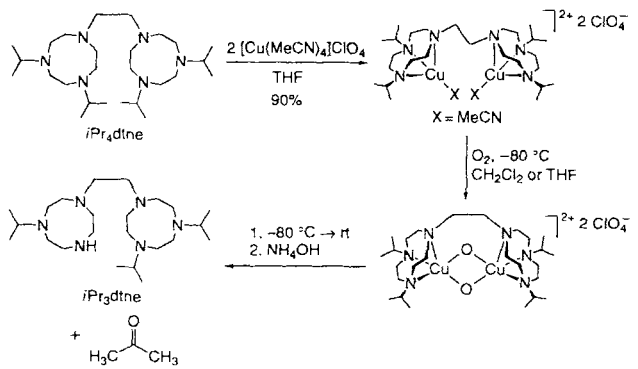
We recently reported that low-temperature oxygenation of Cu^{I} complexes of hindered *N,N′,N″*-trisubstituted 1,4,7-triazacyclononane derivatives generates isomeric (μ-η^2:η^2-peroxo)- and/or bis(μ-oxo)dicopper complexes.[3] Spectroscopic and X-ray crystallographic analysis of one of the latter species confirmed the presence of a planar $Cu_2(\mu\text{-}O)_2$ rhomb with short Cu–O (1.8 Å) and Cu···Cu (2.8 Å) distances, a novel structure in copper chemistry.[3a–c] These complexes are highly reactive monooxygenase models; they decompose through a first-order, intramolecular N-dealkylation reaction that involves rate-determining ligand substituent α-C–H bond scission by the intact $[Cu_2(\mu\text{-}O)_2]^{2+}$ unit.[4] Here we describe the X-ray crystal structure analysis of a new bis(μ-oxo)dicopper complex that reveals significant structural perturbations of the core arising from constraints imposed by a modified hexadentate supporting ligand. Attenuation of the monooxygenase reactivity of the core accompanies these geometric changes, thus illustrating how ancillary ligand properties may influence the structure and function of copper–dioxygen complexes.

Oxygenation of the dicopper(I) complex of 1,2-bis(4,7-diisopropyl-1,4,7-triaza-1-cyclononyl)ethane (*i*Pr$_4$dtne), a sterically hindered variant of a known ligand,[5] in CH_2Cl_2 or THF at −80 °C proceeded with 2:1 Cu:O_2 stoichiometry to yield an orange-brown solution with UV/Vis and Raman spectroscopic properties diagnostic for the bis(μ-oxo)dicopper core (Scheme 1).[6] There was no evidence in either solvent for the



Scheme 1. RT = room temperature.

corresponding μ-η^2:η^2-peroxo isomer. A formulation [(*i*Pr$_4$-dtne)$Cu_2(\mu\text{-}O)_2$]$^{2+}$ for the complex in solution was supported by electrospray ionization mass spectrometry at −40 °C: for the compound having perdeuterated isopropyl substituents a peak envelope at *m/z* 739 with an isotope pattern consistent with {[([D$_{28}$]*i*Pr$_4$dtne)$Cu_2(\mu\text{-}O)_2$](ClO$_4$)}$^+$ was observed. Crystals suitable for X-ray structure analysis were grown by allowing a solution of the deuterated complex (with SbF_6^- counterions) in CH_2Cl_2/acetone (1:1) to stand at −80 °C.[7] A view of the dicationic fragment is presented in Figure 2, and the $[Cu_2(\mu\text{-}O)_2]^{2+}$ core is compared to that of the previously reported[3a,c] complex [([D$_{21}$]L^{Bn3}Cu)$_2(\mu\text{-}O)_2$](SbF$_6$)$_2$ (L^{Bn3} = 1,4,7-tribenzyl-1,4,7-triazacyclononane) in Figure 3.

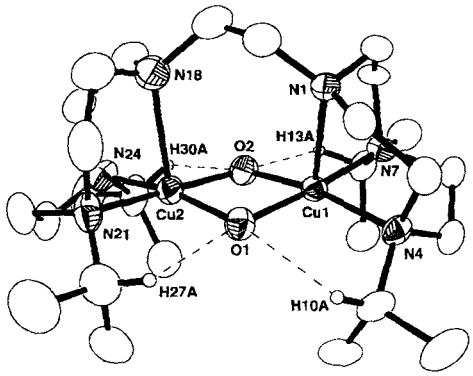


Figure 2. X-ray crystal structure of the cationic fragment of [([D$_{28}$]*i*Pr$_4$dtne)Cu_2-$(\mu\text{-}O)_2$](SbF$_6$)$_2$·3CH_2Cl_2 (50% ellipsoids, all hydrogen atoms except those labeled omitted for clarity). The dashed lines indicate hydrogen-bonding interactions characterized by the following distances [Å] (calculated by fixing the C–H bonds to 1.08 Å): O1–H27A 2.33, O1–H10A 2.58, O2–H30A 2.57, O2–H13A 2.34.

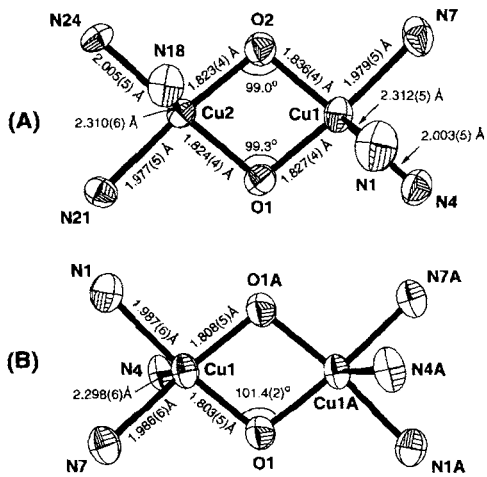

Figure 3. Drawings of the copper coordination spheres with selected bond lengths and angles noted for the cationic fragments in (A) [([D$_{28}$]*i*Pr$_4$dtne)$Cu_2(\mu$-$O)_2$](SbF$_6$)$_2$ and (B) [([D$_{21}$]L^{Bn3}Cu)$_2(\mu\text{-}O)_2$](SbF$_6$)$_2$ (ref. [3a]).

The two bis(μ-oxo)dicopper complexes are characterized by similarly short Cu···Cu distances (2.783(1) Å vs. 2.794(2) Å for the cores supported by [D$_{28}$]*i*Pr$_4$dtne and [D$_{21}$]L^{Bn3}, respectively), long O···O distances indicative of dioxygen O–O bond scission (2.351(2) Å vs. 2.287(2) Å), and analogous hydrogen-bonding interactions between the bridging oxygen atoms and the respective isopropylmethine or benzylic C–H bonds of the equatorial substituents (see caption to Figure 2). However, there are also significant differences between the structures that can be attributed to the presence or absence of the ethylene linker between the macrocyclic ligands. The ethylene tether forces the axial N-donor atoms to adopt a *syn* (distorted from eclipsed by 22.7(2)°) rather than an *anti* conformation. In addition, the Cu_2O_2 rhomb is strictly planar in the [D$_{21}$]L^{Bn3} structure but it is puckered in the [D$_{28}$]*i*Pr$_4$dtne case (dihedral angles between O-Cu-O and Cu-O-Cu planes are 12.0° and 14.2°, respectively). In spite of this puckering, the Cu···Cu distance is not shortened in the [D$_{28}$]*i*Pr$_4$dtne structure because the Cu–O bonds are slightly lengthened (av Cu–O = 1.83 Å vs. 1.80 Å for

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3601-0131 $ 15.00+.25/0

$[D_{28}]i\mathrm{Pr}_4$dtne and $[D_{21}]L^{Bn3}$, respectively). Overall, the geometric distortion of the Cu_2O_2 unit induced by the ethylene linker is analogous to those previously noted for $Mn_2(\mu\text{-}O)_2$ complexes that have an additional bridging ligand.[8]

Stopped-flow kinetics data[9] for the oxygenation reaction collected between -75 and $+25\,^{\circ}C$ for the $i\mathrm{Pr}_4$dtne case in acetone indicate that it is second order overall (first order in the concentrations of the dicopper(I) complex and O_2) with the following activation parameters: $\Delta H^{\ddagger} = 9.41(5)\ \mathrm{kcal\,mol^{-1}}$ and $\Delta S^{\ddagger} = -7.6(2)\ \mathrm{cal\,K^{-1}\,mol^{-1}}$. Formation of $[(i\mathrm{Pr}_4\mathrm{dtne})Cu_2(\mu\text{-}O)_2](ClO_4)_2$ is essentially complete at all temperatures; there is no evidence for intermediates or relevant steady-state species. These results are consistent with initial formation of a monocopper–dioxygen adduct as the rate-determining step followed by rapid formation of a binuclear species and O–O bond scission to yield the bis(μ-oxo)dicopper core. In a slower subsequent transformation, the bis(μ-oxo)dicopper product decomposes through regiospecific oxidative cleavage of an isopropyl substituent in a clean monooxygenase reaction; no scission of the ethylene linker was observed (Scheme 1). Kinetics data obtained for the decay of the complexes ligated by $i\mathrm{Pr}_4$dtne and $[D_{28}]i\mathrm{Pr}_4$dtne indicate that, like the L^{Bn3} and L^{iPr3}-capped analogs,[4] the N-dealkylation reaction exhibits a first-order dependence on the concentration of the bis(μ-oxo)dicopper complex and involves rate-controlling C–H bond cleavage characterized by a large primary kinetic deuterium isotope effect: $\mathrm{KIE} = k_H/k_D\,(-40\,^{\circ}C) = 40(4)$. Activation parameters are: $\Delta H_H^{\ddagger} = 13.5(5)\ \mathrm{kcal\,mol^{-1}}$, $\Delta H_D^{\ddagger} = 16.3(5)\ \mathrm{kcal\,mol^{-1}}$, $\Delta S_H^{\ddagger} = -14(2)\ \mathrm{cal\,K^{-1}\,mol^{-1}}$, and $\Delta S_D^{\ddagger} = -10(2)\ \mathrm{cal\,K^{-1}\,mol^{-1}}$. Also like the L^{R3} complexes, the temperature dependence of the KIE is consistent with a tunneling contribution to the reaction rate, as shown by the difference in activation enthalpies $\Delta\Delta H_{D-H}^{\ddagger} = \Delta H_D^{\ddagger} - \Delta H_H^{\ddagger} = 2.8\ \mathrm{kcal\,mol^{-1}}$ that is greater than the zero-point energy difference of a C–H bond ($\approx 1.4\ \mathrm{kcal\,mol^{-1}}$) and the ratio of Arrhenius A values $A_H/A_D = 0.10(5)$ that is less than 0.5.[10] However, the rate of the reaction for the $i\mathrm{Pr}_4$dtne complex [k_{obs} $(-30\,^{\circ}C) = 7.8(1)\times10^{-4}\,s^{-1}$] is about 10–20 times slower than for the L^{R3} congeners [k_{obs} $(-30\,^{\circ}C) = 7.0\times10^{-3}\,s^{-1}$ (L^{iPr3}) or $1.6\times10^{-2}\,s^{-1}$ (L^{Bn3})].[3,4] The combined data are consistent with a pathway for the decay of $[(i\mathrm{Pr}_4\mathrm{dtne})Cu_2(\mu\text{-}O)_2](ClO_4)_2$ in which intramolecular cleavage of a C–H bond of an equatorially disposed isopropyl ligand substituent is the rate-determining step. Apparently, the analogous C–H bonds in the ethylene linker are inaccessible to the $[Cu_2(\mu\text{-}O)_2]^{2+}$ core, consistent with their disposition in the X-ray structure. The slowed rate compared to that of the L^{R3}-capped complexes may be attributed to the $i\mathrm{Pr}_4$dtne ligand causing enhanced stability of the core and/or strain in the transition state structure.

In summary, multiple effects on the structure and reactivity of the bis(μ-oxo)dicopper core may be traced to the constraints imposed by the ethylene tether between the macrocyclic N-donor caps. Prevention of the formation of the (μ-η^2:η^2-peroxo)dicopper form (characterized by a Cu···Cu distance of ca. 3.5 Å) by the short linker illustrates one way the relative stabilities of the isomeric μ-η^2:η^2-peroxo and bis(μ-oxo) cores—which have a low kinetic barrier for interconversion[3a]—may be controlled. The short linker also induces puckering of the $[Cu_2(\mu\text{-}O)_2]^{2+}$ unit, a structural distortion akin to ones previously noted for bis(μ-oxo)dimanganese[8] and (μ-peroxo)dicopper systems[11] with additional bridging ligands. Finally, a slowed rate of C–H bond activation in the linked system implicates reactivity consequences arising from the geometric distortions, a potentially general relationship between structure and function.

Experimental Section

$i\mathrm{Pr}_4$dtne: 1,4-diisopropyl-1,4,7-triazacyclononane [12] (0.30 g, 1.40 mmol), $ClCH_2CH_2Cl$ (0.07 g, 0.70 mmol), Na_2CO_3 ($\approx$1.0 g), and Bu_4NBr ($\approx$0.01 g) were heated to reflux in CH_3CN (15 mL) under an N_2 atmosphere for 12 h. After cooling to room temperature, the mixture was filtered, washed with $CHCl_3$, and the combined filtrates dried with anhydrous $MgSO_4$. Removal of solvent under reduced pressure afforded the product as a colorless, viscous oil (0.27 g, 85%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ = 2.92–2.84 (m, 12H), 2.66–2.63 (m, 12H), 2.53 (s, 8H), 0.95 (d, J = 6.5 Hz, 24H); $^{13}C\{^1H\}$ NMR ($CDCl_3$, 125 MHz): δ = 56.5, 55.8, 54.8, 52.9, 52.7, 18.3; LREI-MS m/z (rel intensity): 452.4 (2, M^+), 354.3 (20, $[M-2i\mathrm{Pr},-\mathrm{Me}]^+$), 226.2 (100, $[M-i\mathrm{Pr}_2\mathrm{tacn},-CH_2]^+$) (tacn = 1,4,7-triazacyclononane). Correct C,H,N analysis. The ligand $[D_{28}]i\mathrm{Pr}_4$dtne (perdeuterated iPr substituents) was synthesized similarly from $[D_{14}]$-1,4-diisopropyl-1,4,7-triazacyclononane. Deuterium content: 99% (determined by integration of the residual proton signals).

$[(i\mathrm{Pr}_4\mathrm{dtne})Cu_2(CH_3CN)_2](ClO_4)_2$: In a glove box, solid $[Cu(CH_3CN)_4]ClO_4$ (0.26 g, 0.80 mmol) was added to a stirred solution of $i\mathrm{Pr}_4$dtne (0.18 g, 0.40 mmol) in THF (5 mL). After stirring the mixture for 10 min, Et_2O ($\approx$5 mL) was added to the light yellow solution. An off-white precipitate formed and was collected, washed with Et_2O, and dried under a stream of N_2. Recrystallization of this solid from THF/Et_2O yielded the complex as off-white microcrystals (0.30 g, 87%). ^{1}H NMR (CD_2Cl_2, 500 MHz): δ = 3.18 (s, 4H), 3.15 (sept, J = 6.5 Hz, 4H), 2.96–2.77 (m, 16H), 2.67–2.55 (m, 8H), 2.30 (s, br, 6H), 1.26 (d, J = 6.5 Hz, 12H), 1.24 (d, J = 6.5 Hz, 12H); $^{13}C\{^1H\}$ NMR (CD_2Cl_2, 125 MHz): δ = 58.9, 57.9, 54.9, 50.4, 50.2, 19.9, 19.0; FTIR (KBr) $\tilde{\nu}[\mathrm{cm^{-1}}]$ = 2253 (C$\equiv$N), 1093 (ClO_4^-), 624 (ClO_4^-). Correct C,H,N analysis.

$[(i\mathrm{Pr}_4\mathrm{dtne})Cu_2(\mu\text{-}O)_2](ClO_4)_2$: Dry O_2 was bubbled through a solution of $[(i\mathrm{Pr}_4\mathrm{dtne})Cu_2(CH_3CN)_2](ClO_4)_2$ (0.20 g, 0.23 mmol) or its analog derived from $[D_{28}]i\mathrm{Pr}_4$dtne in CH_2Cl_2 (10 mL) at $-80\,^{\circ}C$ for 15 min, yielding a deep orange-brown solution of the complex that was immediately subjected to spectroscopic characterization.

Ligand recovery experiment: Warming of a solution of $[(i\mathrm{Pr}_4\mathrm{dtne})Cu_2(\mu\text{-}O)_2](ClO_4)_2$ [generated from 0.080 g (0.093 mmol) of the copper(I) complex] in CH_2Cl_2 (5 mL) to room temperature yielded a blue-green solution. Aqueous NH_4OH (5 mL) was added and the mixture was extracted with CH_2Cl_2 (3 × 5 mL). Removal of solvent from the extracts yielded $i\mathrm{Pr}_3$dtne as an oil (0.035 g, 92%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ = 2.89–2.84 (m, 7H), 2.69–2.60 (m, 12H), 2.56–2.50 (m, 8H), 0.98 (d, J = 6.5 Hz, 6H), 0.94 (d, J = 6.5 Hz, 12H); ^{13}C NMR ($CDCl_3$, 125 MHz): δ = 56.6, 56.0, 55.7, 54.8, 54.5, 53.2, 52.8, 52.7, 18.7, 18.3. LREI-MS m/z (rel intensity) 410.3 (2, M^+), 312.2 (25, $[M-2i\mathrm{Pr},-\mathrm{Me}]^+$), 226.2 (100, $[M-i\mathrm{Prtacn},-CH_2]^+$). Coproduct [$D_6$]acetone was identified by GC/MS analysis of the solution (after silica gel filtration) resulting from decomposition of the deuterated analog in THF.

Synthesis and Structure of the First Molecular Thulium(II) Complex: $[TmI_2(MeOCH_2CH_2OMe)_3]$**

Mikhail N. Bochkarev,* Igor L. Fedushkin, Anatoly A. Fagin, Tatyana V. Petrovskaya, Joseph W. Ziller, Randy N. R. Broomhall-Dillard, and William J. Evans*

A significant part of the emerging importance of 4f element chemistry involves complexes in which the lanthanide metal is in the +II oxidation state.[1] For example, $[SmI_2(thf)_x]$ is now a frequently used reducing reagent in organic synthesis,[2] the solvated metallocenes $[(C_5R_5)_2LnL_x]$ (Ln = Sm, Eu, Yb; R = Me, H; L = ethers) display an extensive and often unique organometallic chemistry,[3] the unsolvated metallocenes $[(C_5Me_5)_2Ln]$[4] have stimulated theoretical studies[5] due to their unusual bent structure, and divalent chalcogenide complexes are of interest as precursors to materials with interesting optical, electronic, and magnetic properties.[6]

To date this important divalent 4f element chemistry has involved only three metals, Sm^{II}, Eu^{II}, and Yb^{II}. Divalent ions can be formed for all of the metals in the 4f series by high-temperature reduction of the halides with the metal[7] or by radiolysis of trivalent metal ions trapped in crystalline lattices,[8] but these insoluble and dilute systems are generally only characterized by spectroscopic means. The large reduction potentials[9] (-2.3 to -2.9 V Ln^{III}/Ln^{II}) for 4f elements other than Eu, Yb, and Sm make these other divalent metals difficult to isolate as molecular species. Two exceptions are in the literature $[\{K(monoglyme)\}_2\{(C_8H_8)_2Ce\}]$[10] (monoglyme = diethyleneglycolmonoethyl ether) and $[\{(C_5Me_5)_2NdCl_2\}\{K(thf)_n\}_2]$,[11] but neither of these species have been fully characterized by X-ray crystallography.

We report here the first crystal structure analysis of a molecular complex of a divalent 4f element other than Eu, Sm, and Yb. This was done with thulium, which has the most stable divalent oxidation state after Eu, Yb, and Sm ($Tm^{III}/Tm^{II} = -2.3$ V vs NHE).[9a] The thulium diiodide **1** (dme = dimethoxyethane), was synthesized by reduction of TmI_3 with

$[TmI_2(dme)_3]$ **1**

thulium metal in refluxing DME. Repeated treatment of the solid reactants with DME, followed by removal of DME under vacuum ultimately gave a 54% yield of **1** as an air-sensitive malachite-green crystalline solid. In the solid state and in solution, **1** slowly decomposes at room temperature to give a colorless solid and gaseous products. Decomposition is noticeably accelerated by sunlight which will completely decolorize a 1 mM solution of **1** in one hour.

Elemental analysis on **1** was consistent with three DME molecules per TmI_2 unit. This was confirmed by an X-ray crystal structure analysis (Figure 1).[12] The unit cell contains two independent molecules that have similar bonding parameters.

The thulium atom in $[TmI_2(dme)_3]$ (**1**) is seven-coordinate; two DME ligands are chelating and one is monodentate. This is a rare example of a complex containing a monodenate DME

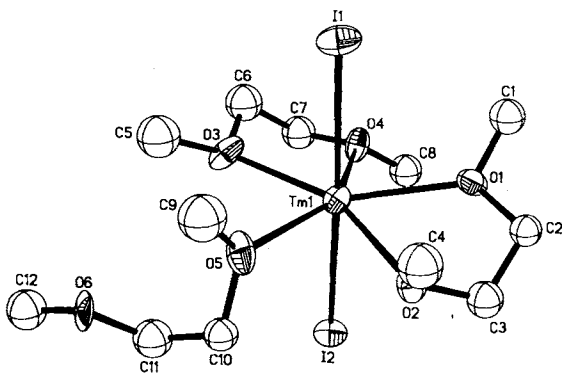

Figure 1. Thermal ellipsoid plot of one of the independent $[TmI_2(dme)_3]$ molecules in the unit cell of **1** (ellipsoids drawn at the 50% probability level). Selected bond lengths [Å] and angles [°]: Tm1–O5 2.47(2), Tm1–O1 2.48(2), Tm1–O2 2.489(14), Tm1–O3 2.50(2), Tm1–O4 2.50(2), Tm1–I1 3.141(2), Tm1–I2 3.186(2); O5-Tm1-O2 73.3(5), O1-Tm1-O2 65.8(5), O5-Tm1-O3 80.1(5), O1-Tm1-O4 75.9(5), O3-Tm1-O4 67.9(5), O5-Tm1-I1 92.3(4), O1-Tm1-I1 83.4(4), O3-Tm1-I1 83.8(4), O4-Tm1-I1 91.8(4), O5-Tm1-I2 91.2(4), O1-Tm1-I2 97.7(4), O2-Tm1-I2 84.6(4), O3-Tm1-I2 91.5(4), O4-Tm1-I2 82.4(4), I1-Tm1-I2 173.68(6).

ligand.[13] The pentagonal-bipyramidal structure of **1** is similar to those of the solvated divalent samarium diiodide complexes **2**–**4**.[14] In all of these complexes, the halide ligands are in the

$[SmI_2(thf)_5]$ **2** $[SmI_2(dme)(thf)_3]$ **3** $[SmI_2(dme)_2(thf)]$ **4**

axial positions and oxygen donor atoms are at the equatorial sites. The average I-Tm-I angle (174.3(5)°) in **1** is similar to the I-Sm-I angles in **3** and **4** (178.8(1)°). The I-Tm-O angles range from 79.7(4) to 102.8(3)° and thus deviate from the angle expected in a perfect pentagonal bipyramid (90°). The corresponding I-Sm-O angles in **3** and **4** range from 79.2(1) to 100.6(1)°. The range of O-Tm-O angles for adjacent donor atoms (65.8(3)–80.5(5)°) is also similar to the corresponding range of O-Sm-O angles (63.6(1)-80.2(2)°) in **3** and **4**, and differs from the ideal angle of 72° because some of these angles involve a single chelating ligand and some are between ligands.

Previous data[14, 15] suggested that $[LnZ_2(solvate)_x]$ complexes, in which Z is an anionic ligand, favored $x = 5$ and a pentagonal-bipyramidal structure. The structure of **1** strongly supports these findings, since one DME molecule remains monodentate rather than binding as a bidentate ligand to form an eight-coordinate complex. Another alternative which is not observed is a six-coordinate bis(dme) complex.

In comparison with the metal–iodide distances in the samarium(II) complexes **3** and **4**, the average Tm–I distance (3.16(2) Å) in **1** is in the range expected for a Tm^{II} complex. The Sm–I distances in **3** and **4** are 3.231(1)–3.246(1) Å, and the ionic radius of samarium is about 0.13 Å larger than that of thulium.[16] The range of Tm–O distances (2.456(13)–2.546(14) Å) for the two independent molecules in the unit cell is wider than the range observed for Sm^{II}–O(dme) distances (2.595(5)–2.646(4) Å) in **3** and **4**, but again these distances are consistent with the presence of Tm^{II} after the difference in radius (0.13 Å) is taken into consideration.

The Tm^{II}–O distances in **1** are significantly different from the distances found in Tm^{III} complexes. For example, Tm^{III}–O(thf) distances of 2.353(3) and 2.315(3) Å have been reported in eight-coordinate $[(C_8H_8)Tm\{PhC(NSiMe_3)_2\}(thf)]$[17] and five-coordinate $[Tm\{P(SiMe_3)_2\}_3(thf)_2]$,[18] respectively. No Tm^{III}–I distances are available for comparison, but Tm^{III}–Cl distances ranging from 2.585(4) to 2.667(2) Å are found in the eight-coordinate complexes $[TmCl_2(OH_2)_2([12]crown-4)]Cl$[19] and $[TmCl(terpy)(OH_2)_4]Cl_2 \cdot 3H_2O$ (terpy = 2,2′:6′,2″-terpyridine).[20] Assuming that metal–chloride distances are typically 0.31–0.42 Å shorter than metal–iodide distances,[16, 21] analogous Tm^{III}–I distances would be in the range 2.89–3.09 Å which is substantially shorter than those observed in **1**.

The UV/Vis spectrum of **1** is similar to that of a solution of TmI_2 in THF prepared by heating TmI_3 with thulium metal in a welded tantalum crucible under argon at 800 °C.[22] The measured effective magnetic moment of **1** (4.53 μ_B (293 K)) matches the value of 4.5 μ_B calculated for a $4f^{13}$ electron configuration[23] and found for isoelectronic Yb^{III} complexes.[24] This value differs significantly from Tm^{III} magnetic moments which are typically 7.1–7.5 μ_B.[24]

These data unequivocally establish the existence of a new soluble divalent 4f element system whose chemistry can be explored. The high reactivity of this complex suggests that a rich chemistry can be developed.

Experimental Section

All manipulations were carried out under the exclusion of oxygen and moisture using vacuum line techniques. Thulium filings (6.2 g, 36 mmol), iodine (5.0 g, 19.7 mmol), and DME (20 mL) were stirred for 48 h under vacuum at room temperature. The TmI_3 that precipitated was washed with DME (5 × 70 mL) to remove unconverted iodine. The remaining mixture of Tm and TmI_3 was treated with DME (80 mL), and the mixture was heated to reflux and stirred until the solution turned green (approximately 30–45 minutes). The green solution was decanted from the solid Tm/TmI_3 mixture. DME was transferred from the solution by condensation under vacuum back to the remaining Tm and TmI_3. The mixture was again heated to reflux and stirred until the solution turned green. The operation was repeated six times. Final removal of solvent from the deep green solution by condensation under vacuum at room temperature produced malachite-green crystalline solids which were recrystallized from DME at −10 °C to yield **1** (7.3 g, 54%). X-ray quality crystals were grown from DME at −38 °C. The crystals decompose without melting on heating at 100 °C and are soluble in DME to the extent of 0.1 g mL^{-1}. IR (KBr): $\tilde{\nu}$ = 2929 s, 2879 m, 2829 w, 1453 s, 1409 w, 1364 w, 1284 w, 1239 w, 1189 m, 1095 s, 1055 s, 1030 s, 861 s, 811 w, 547 w, 482 w cm^{-1}. UV/Vis (1.15×10^{-3} M in DME, 20 °C, $\lambda_{max}(\varepsilon)$): 298 (700), 416 (250) , 562 (90), 624 (80) nm. Anal. calcd for $C_{12}H_{30}O_6I_2Tm$: I 36.62, Tm 24.37; found: I 36.28, Tm 23.58. Magnetic susceptibility (293 K) $\chi_M = 8741 \times 10^{-6}$, $\mu_{eff} = 4.5\ \mu_B$.

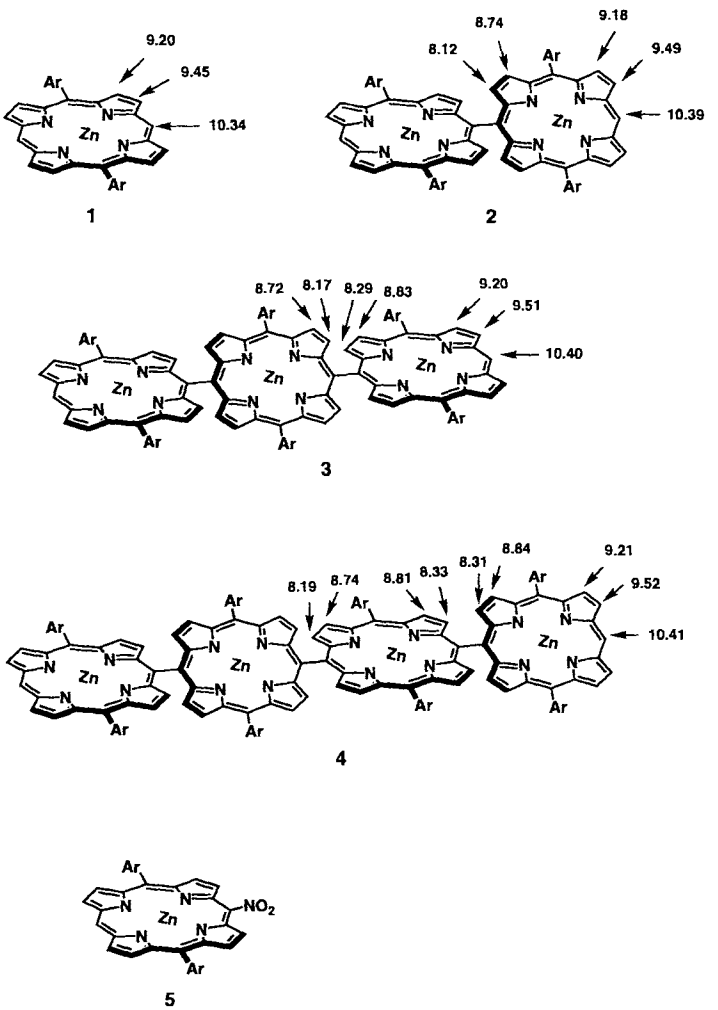
meso,meso-Linked Porphyrin Arrays**

Atsuhiro Osuka* and Hitoshi Shimidzu

Owing to the central importance of multiporphyrin assemblies in photosynthetic reaction centers and light-harvesting antenna complexes, considerable attention has been focused on the development of covalently linked porphyrin arrays as effective biomimetic models. Systematic studies on these models will aid also in the development of new photonic materials and molecular devices.[1–6] In these model studies a variety of bridges that connect porphyrin chromophores have been examined in their abilities to facilitate electron and photon connectivity or to perturb the spectral properties of the porphyrin chromophores. As an extension, a bridgeless, directly coupled porphyrin array may be a fascinating, ultimate candidate for exploring novel connectivity.

Here we report on a novel, very facile oxidative coupling reaction of zinc(II) 5,15-di(3,5-di-*tert*-butylphenyl)porphyrin (**1**) to give porphyrin dimer **2** and porphyrin trimer **3** as the first example of *meso,meso*-coupled multiporphyrins. Treatment of a chloroform solution of **1** with $AgPF_6$ (0.5 equiv) dissolved in acetonitrile for 5 h gave **2** and **3**; NMR analysis revealed the distribution of products: **1** (47%), **2** (27%), and **3** (4%). Although these products were difficult to separate over standard silica gel columns, they were separated by size exclusion chromatography,[7] by which the products are eluted in the order of molecular weight: first, higher oligomers and trace amounts of tetramer **4** > **3** > **2** > **1**. The yields of isolated compounds were 25% for **2** and 4% for **3**, based on the amount of **1** used. Reaction of **2** under analogous conditions (0.5 equiv $AgPF_6$) gave **4** in 23% yield. The regioselectivty of the coupling was quite high.[8]

Compounds **2**–**4** were fully characterized by ^1H NMR spectroscopy (500 MHz) and FAB mass spectrometry. ^1H NMR analysis revealed the presence of one *meso*- and two, four, six, and eight β-protons in **1**–**4**, respectively (Scheme 1). In the spectrum of **2** the signals of the inner β-protons are shifted upfield by $\Delta\delta = 1.33$ and 0.46 ppm relative to those of **1**, reflecting the ring current effect of the second porphyrin ring, while the signals of the outer β-protons appear nearly at the same chemical shifts. Similar features are observed for **3** and **4**. These data, analyzed in terms of the ring current model, suggest an approximate perpendicular arrangement of the neighboring porphyrins.



Scheme 1. Structures of **1**–**5**. NMR chemical shifts of the *meso*- and β-protons ($CDCl_3$) are indicated. Ar = 3,5-$tBu_2C_6H_3$.

$AgClO_4$ and $AgBF_4$ were similarly effective in this coupling, but the use of $AgNO_2$ led to *meso*-nitration, giving **5** almost quantitatively. The coupling reaction was accelerated by addition of I_2; under these conditions the reaction was complete within 5–10 min.[9] In the I_2-promoted reactions use of one or more equivalents of the Ag^I salt and I_2 led to lower yields of **2** and **3**, under otherwise the same reaction conditions.[10] Most probably, the initial generation of radical cation $\mathbf{1}^{\bullet+}$ followed by nucleophilic attack by a molecule of neutral **1** results in the formation of **2**, in analogy to the related *meso*-substitution reaction of porphyrins.[11] Thus, the nitrite ion traps $\mathbf{1}^{\bullet+}$ to give **5** in the reaction of $AgNO_2$, and an excess of strong oxidant (I_2/Ag^I salt) converts a large portion of **1** to $\mathbf{1}^{\bullet+}$, thereby suppressing the formation of **2**. The concurrent formation of **2** and **3** can be explained by the fact that **1** and **2** have nearly the same oxidation potentials.[12, 13] Consistent with this mechanism, treatment of a chloroform solution of **1** with tris(4-bromophenyl)aminium hexachloroantimonate, a typical one-electron oxidizing agent, provided **2** (8%) and **3** (2%).

[**] This work was supported by the Ministry of Education, Science, Sports and Culture of Japan (Grants-in-Aid for Scientific Research No. 07228232 (Priority Research Area "Photoreaction Dynamics") and No. 07454249) and by the Ogasawara Foundation for the Promotion of Science and Engineering.

The one-electron oxidation reactions of metalloporphyrins have been extensively studied in view of their important roles in electron transfer and oxidation processes in biological systems.[14] Interestingly, cations such as $[Mg(oep)]^+$ and $[Zn(oep)]^+$ (oep 0 2,3,7,8,12,13,17,18-octaethylporphyrin dianion) were reported to dimerize at low temperature,[15] and later the structure of a dimeric product, $[\{Zn(oep)\}_2]$, was determined by X-ray analysis to be a noncovalently bound, stacked dimer.[16] In a few examples the formation of bis(tetrapyrroles) (from 5,15-dioxoporphodimethene and oxophlorin (2-hydroxyporphyrin)) with similar direct *meso,meso* linkage have been reported upon oxidation of [Zn(oep)] with $Tl(OTf)_3$[17] and on one-electron oxidation of *meso*-hydroxyl-substituted $[Ni^{II}(oep)]$.[18] However, **2**–**4** are the first examples of *meso,meso*-coupled arrays of the porphyrin chromophore.

The *meso*-positions of porphyrins have been known to be the most reactive centers towards both electrophilic and nucleophilic reagents,[19] but these reactivities are usually masked in tpp (tpp = tetraphenylporphyrin) and oep derivatives because of the *ipso*-phenyl groups in the former and the severe steric congestion due to the neighboring β-ethyl substituents in the latter. In this respect, 5,15-diarylporphyrins, which lack β-pyrrolic substituents, are good substrates for exploring the intrinsic high reactivity of the *meso*-position, particularly towards sterically demanding reagents.[20] It seems probable that steric congestion around the *meso,meso* linkage in the previously studied bis(tetrapyrroles)[17, 18] suppresses the formation of *meso,meso*-linked porphyrins, in which the planarity of porphyrin would increase the steric hindrance. In this regard, **1** is also a good substrate for this coupling.

As shown in Figure 1, the direct *meso,meso* connectivity in **2**–**4** results in large excitonic splitting in the Soret bands (S_2 state), but the spectral changes in the Q-band region (S_1 state)

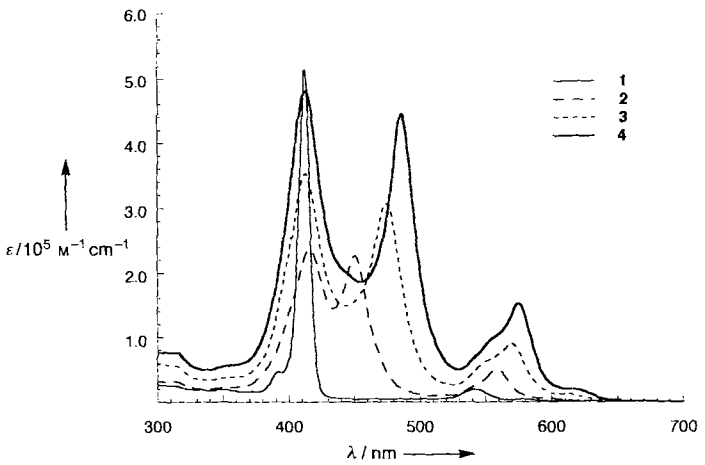

Figure 1. Absorption spectra of **1**–**4** in THF ($c = 1.0 \times 10^{-6}$ M)

are rather modest. When the exciton splitting energies in the Soret bands, ΔE, were plotted versus $2\cos[\pi/(N+1)]$,[21] we obtained a line with a slope of $E_0 = 2100\ cm^{-1}$. This value, which corresponds to the exciton coupling energy between the neighboring porphyrins, is certainly larger than that found for 1,4-phenylene-bridged linear porphyrin arrays (ca. $800\ cm^{-1}$)[22] but seems to be small considering the direct linkage of the porphyrin π-systems. The fluorescence emission spectrum of **1** displays two bands (584 and 634 nm), which are characteristic of a zinc porphyrin monomer; the spectra of **2**–**4** exhibit slightly broadened emissions with peak maxima of 613, 626, and 633 nm, respectively. The fluorescence quantum yields of **1**–**4** determined in THF relative to Zntpp (0.03)[23] are 0.036, 0.025, 0.036, and 0.033, respectively. The symmetric structural feature **2** is reminiscent of that of 9,9′-bianthryl, which undergoes solvent-induced symmetry breaking, thereby promoting the population of the charge transfer states.[24] But significant reduction of the fluorescence quantum yield was not observed for **2**–**4** even in polar solvents such as DMF and acetonitrile. We interpret the observed small electronic interactions in the ground and S_1 states as evidence that the porphyrins in **2**–**4** lie approximately orthogonal to each other, in line with the results of the ^1H NMR analyses.

In summary, the Ag^I-promoted oxidative coupling of zinc(II) 5,15-diarylporphyrins provides an easy entry to a new class of *meso,meso*-linked multiporphyrin arrays, which will offer new opportunities for studying the electronic interactions in porphyrin arrays with direct links, and for exploring intramolecular, long-range electron- and energy-transfer systems across these directly linked porphyrin arrays.

Experimental Section

To a solution of **1** (60 mg, 80 mmol) in 40 mL of $CHCl_3$ was added all at once a solution of $AgPF_6$ (10.3 mg, 40 mmol) in acetonitrile. The reaction mixture protected from light and stirred at room temperature for 5 h. The mixture was filtered, diluted with water, and extracted with $CHCl_3$. The organic layer was removed, washed with water, and dried over anhydrous Na_2SO_4. A saturated solution of $Zn(OAc)_2$ in methanol (1 mL) was added, and the resulting solution was refluxed for 1 h, diluted with water, and extracted with $CHCl_3$. The organic layer was removed and dried over Na_2SO_4. The product mixture was separated by preparative size exclusion chromatography (BioRad Bio-Beads SX-1 packed in benzene in a 4.8×60 cm gravity-flow column; flow rate 4 mL min^{-1}). Elution with benzene yielded four major fractions in the following order: higher oligomers along with a trace amount of tetramer **4**, trimer **3**, dimer **2**, and the starting monomer **1**. Because separation of **3** and **2** was difficult, chromatographic separations were repeated on the same column. UV spectroscopy was very effective in checking the fractions. The trimer **3** (2.4 mg, 4%) and the dimer **2** (15 mg, 25%) were obtained in pure form from the second and the third fractions, respectively, and the starting monomer **1** (20 mg, 33%) was recovered from the fourth fraction. The tetramer **4** was prepared in 23% yield from the analogous reaction of **2** (45 mg, 30 mmol) in 60 mL of $CHCl_3$.

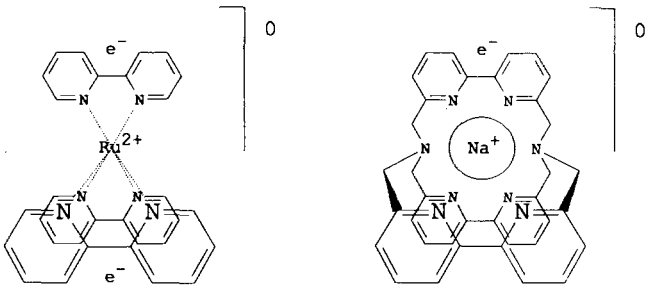
X-ray Structure of $[Ru(bpy)_3]^0$: An Expanded Atom or a New Electride?**

Eduardo E. Pérez-Cordero, Charles Campana, and Luis Echegoyen*

Dedicated to Professor Waldemar Adam on the occasion of his 60th birthday

We recently prepared and chemically characterized single crystals of electroneutral $[M(bpy)_3]^0$ complexes (where bpy is 2,2′-bipyridine and M is Fe, Ru, and Os).[1] These materials had been previously reported as powders.[2] Herein we present the X-ray crystal structure characterization of the $[Ru(bpy)_3]^0$ complex; the transport and magnetic properties of this material have been previously discussed.[3]

The compound $[Ru(bpy)_3]^0$ (**1**) is conceptually similar to the first crystalline cryptatium (**2**), which was described in 1991.[4]



1 **2**

For the latter neutral, "expanded-atom" type species **2**, formed by reductive electrocrystallization of sodium tris(bipyridine) cryptate, the crystal structure analysis provides clear evidence that the unpaired electron density is mainly localized on only one of the bpy subunits.[4] This observation is consistent with MO calculations for bpy, which show that the LUMO (2,2′-bond) is bonding and thus that its occupation by an added electron would tend to flatten the bpy subunit.[5] Both compounds may be compared, at least conceptually, to endohedral fullerenes, since in all three cases there are central metal cations surrounded by organic ligands that effectively delocalize the negative charge to afford overall electroneutral species.[6]

$[Ru(bpy)_3](PF_6)_2$ and $[Ru(bpy)_3](PF_6)_3$ were recently structurally characterized.[7a] The latter was the first report of the structure of the Ru^{3+} complex, while the structure of the Ru^{2+} complex had been described before (see citation in reference [6]). The results presented here for **1** are mainly compared to those for $[Ru(bpy)_3]^{2+}$.[7a]

We gratefully acknowledge Prof. H. B. Bürgi (Laboratorium für Kristallographie, Universität Bern) for the help offered during the reviewing stages of this work.

As described previously,[1] crystals of **1** were grown on a Pt cathode from a 1 mM solution of the Ru^{2+} complex in acetonitrile containing 0.1 M tetrabutylammonium hexafluorophosphate. The process was conducted under strict exclusion of air (10^{-6} Torr) after the solution had been frozen in liquid nitrogen. The electrocrystallization was done using a two-electrode configuration at constant current (11 $\mu A cm^{-2}$). After shiny needles had grown, dry Ar gas was allowed to enter, and the crystals were removed from the solution and stored under vacuum.

A stereoview of the structure of two $[Ru(bpy)_3]^0$ units along the C_3 axis, together with the numbering scheme is shown in Figure 1.[8] There are two crystallographically independent

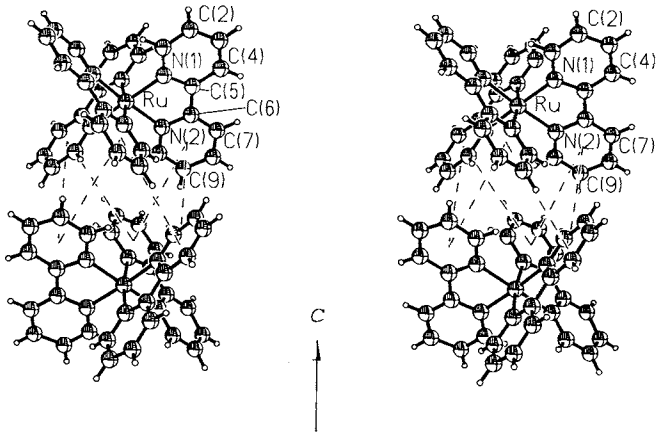

Figure 1. Stereoview of two $[Ru(bpy)_3]^0$ units in crystals of **1** (program SHELYTL XP [9]). Dotted lines highlight potential CH – π interactions. Although distances are reasonable for these interactions, the relative orientations are not optimal; see text for more details.

$[Ru(bpy)_3]^0$ units in the lattice, Ru(A) and Ru(B) (see Figure 3); however, intrinsic differences between these are relatively small. Selected bond lengths and angles are summarized in Table 1.[10]

Table 1. Selected bond lengths [Å] and angles [°] for **1** [a].

Parameter	Site A	Site B
Ru–N(1)	2.044(2)	2.041(2)
Ru–N(2)	2.059(2)	2.041(2)
N(1)–C(5)	1.381(4)	1.385(4)
N(2)–C(6)	1.380(3)	1.385(4)
C(5)–C(6)	1.448(4)	1.431(5)
N(1)-Ru-N(2)	78.92(9)	79.80(13)

[a] Numbers in parentheses are estimated standard deviations in the least significant digits.

The three bpy ligands are equivalent and almost perfectly planar: dihedral angles between pyridine rings are 2.8 and 6.7° for ligands in crystallographic sites A and B, respectively. The molecular structure exhibits only minor deviations from ideal octahedral coordination geometry. Thus, the main conclusion derived from the intrinsic structure of each $[Ru(bpy)_3]^0$ unit is that they closely resemble that of the precursor $[Ru(bpy)_3]^{2+}$.[7] Interestingly, if all of the distances are taken into consideration, the structure of $[Ru(bpy)_3]^0$ more closely resembles that of the complex cation $[Ru(bpy)_3]^{3+}$. Thus, we can conclude from these structural similarities that the structures are not particularly sensitive to the total electronic density. Small but perhaps significant differences between the structures of $[Ru(bpy)_3]^{2+}$ and $[Ru(bpy)_3]^0$ occur in the Ru–N and C(5)–C(6) distances: Ru–N bond lengths of 2.053–2.056 Å and C(5)–C(6) bond lengths of 1.476–1.482 Å have been reported for the unreduced complex,[7] while the ranges of bond lengths observed here for the reduced complex are 2.041–2.059 Å and 1.431–1.448 Å, respectively. The shortening of the C(5)–C(6) bond could indicate some electron localization on the bpy ligands.[4, 7a]

In contrast to these small molecular structural differences, analysis of the molecular packing reveals profound differences with respect to the crystalline structure of the parent complex $[Ru(bpy)_3](PF_6)_2$. Figure 2a shows the arrangement of the Ru atoms in the crystal structure of **1**. Six molecules form a hexagonal "pseudo plane" perpendicular to the C_3 axis; the molecules are slightly displaced above and below this plane (by 0.216 Å). The distances between the six Ru centers are 9.572 Å. Above and below this plane there are similar "pseudo hexagons". Because of *c* glide planes, the chirality alternates as one moves along the C_3 axis. This is consistent with the results of the X-ray structure analysis of $[Ru(bpy)_3]^{2+}$.[7] However, in the latter the Ru–Ru distances (8.11 Å) along this axis are longer than those in **1** (7.722 Å).[7a]

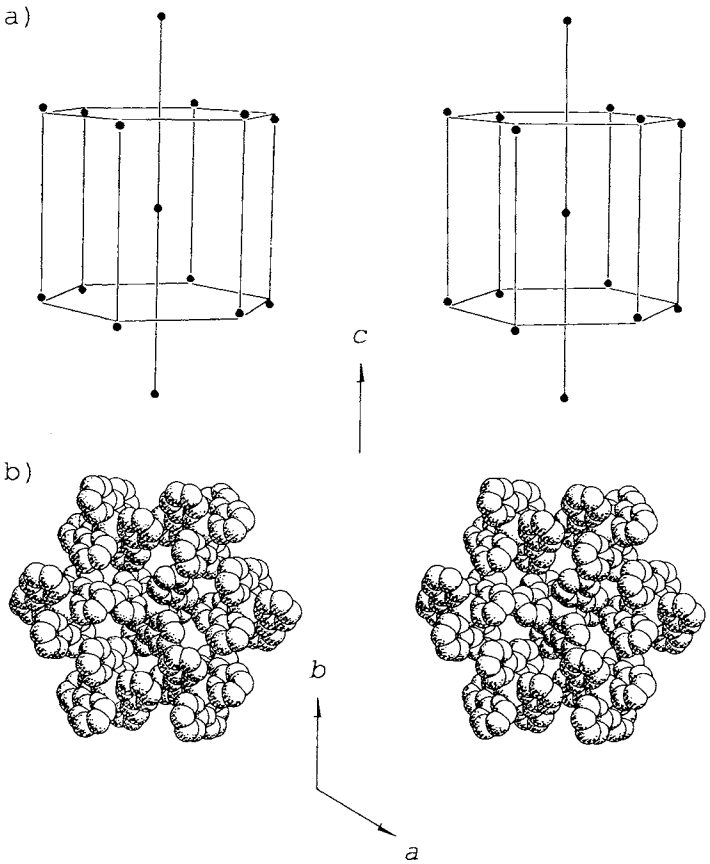

Figure 2. a) Stereoview of the positions of 15 Ru centers in the lattice of **1**, providing a representation of the packing structure. "Pseudo hexagonal" planes are evident, as well as the central stack, which is offset by *c*/2 relative to the units in the hexagonal arrangements. In this representation there is a twofold elongation along the *c* axis, but not along the other axes, in order to accentuate the structural features described in the text. b) Stereoview of the van der Waals surfaces of a group of seven $[Ru(bpy)_3]^0$ units from a pseudo hexagon and the central stack. Intermolecular π–π contacts are clearly evident along the hexagonal system, however, these are not very extensive nor optimal; see text for more details.

Down the middle of these hexagonal structures there are stacks of $[Ru(bpy)_3]^0$ units, which again exhibit alternating

chirality. These stacks are offset by 3.861 Å relative to the hexagonal average planes (Figure 2a). The closest Ru–Ru distances between these stacks and the pseudo hexagon are 10.233 and 10.395 Å.

In $[Ru(bpy)_3](PF_6)_2$ two PF_6^- ions per complex occupy interstitial positions.[6] These anions do not inhibit intermolecular interactions between complex isomers along C_3, but they do prevent short intermolecular contacts between the complex molecules in the *a*, *b* plane.[7] The opposite situation is true for the electrocrystallized material **1**. Figure 2b shows a stereoview of the van der Waals surface of one of the hexagonal units. The interplanar distance observed between bpy units in adjacent complexes around the hexagon is 3.26 Å; that is, optimal for π-π stacking. Owing to the $\bar{3}$ axis, the three units that sit slightly above the hexagonal plane have the same chirality, but opposite to that of the three units that sit slightly below the plane. In the unreduced complex, the pseudo layers perpendicular to the C_3 axis are composed of units with uniform chirality.

The dotted lines in Figure 1 connect the centers of the vicinal pyridine rings in two consecutively stacked $[Ru(bpy)_3]^0$ units. These stacks, which are composed of alternating enantiomeric molecules, show a reasonable complementary fit if CH-π interactions are invoked; the centroid-to-centroid distances oscillate between 5.128 and 5.368 Å.[11]

The most important issue that needs to be addressed after presenting the detailed analysis of the structure and packing of **1** concerns the location of the additional electron density. $[Ru(bpy)_3]^0$ contains two more electrons than the starting material $[Ru(bpy)_3]^{2+}$, yet no significant distortion of the intrinsic geometry around the central Ru atom occurs. Based on all previous electrochemical observations of $[Ru(bpy)_3]^{2+}$ as well as on its electronic properties, localization of the electron density on the ligands was expected.[2, 5, 12] However, if the additional electron density is mainly localized on bpy-like orbitals, a distorted $[Ru(bpy)_3]^0$ structure would be expected, in which two of the ligands should show different properties than the third ligand. Such a situation was observed for cryptatium.[4] A similar distortion was observed for a reduced, binaphthyridineruthenium complex, $[Ru(binaphthyridine)_3](PF_6)_2$.[13] Reduction with one electron leads to a crystalline material, $[Ru(binaphthyridine)_3](PF_6)$, the geometry of which is very distorted relative to that of the unreduced complex. Thus, these two cases exhibit considerable distortions upon reduction; however, this is not the case for $[Ru(bpy)_3]^0$.

There are three ways to explain why **1** behaves differently from cryptatium and $[Ru(binaphthyridine)_3](PF_6)$. One is to assume that the two additional electrons are delocalized in an orbital that contains equal contributions from the three ligands. If this is true, the material fits well the description of an "expanded atom" in which a symmetrically reduced ligand environment surrounds the central metal ion.

Another possible interpretation is that if the electrons are localized on two ligands, a disordered structure in which the unreduced ligand is randomly distributed over the three positions would average the observed coordinates. The disorder would result in only small increases of the anisotropic displacement parameters ($\Delta^2/4 < 0.001$ Å) since Δ values (the difference between bond lengths in bpy and $(bpy)^-$ taken from reference [4]) are small. A third possible explanation is that the electrons occupy, at least partially, some lattice sites. In this case the crystalline material could be formally described, at least partially, as an electride.[14, 15]

Analysis of the crystal packing of $[Ru(bpy)_3]^0$ (**1**) reveals the presence of two cavities per Ru atom, in which, like in electrides, there could be electron density.[14, 15] The positions of the intermolecular spaces, which are essentially empty cavities in the lattice structure, can be easily appreciated from Figure 3. They approximately correspond to the positions where the PF_6^- ions are found in the structure of $[Ru(bpy)_3](PF_6)_2$.[7] These cavities are connected by channels that seem to run in a somewhat twisted fashion along the C_3 axis.

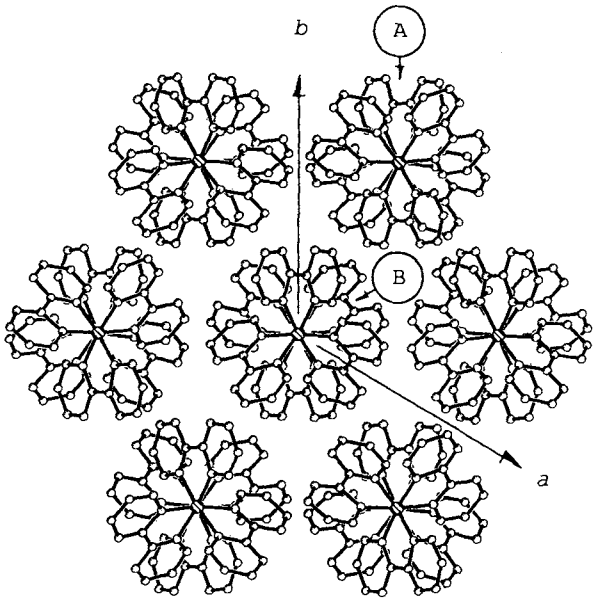

Figure 3. Projection of the lattice structure of **1** along the C_3 axis; the hydrogen atoms are omitted for clarity. The central stack is surrounded by six intermolecular spaces, which correspond approximately to the positions of the PF_6^- ions in the $[Ru(bpy)_3](PF_6)_2$ structure. These spaces contain cavities in which lattice electrons could probably be localized, at least partially.

Based on the available data it is impossible at the present time to ascertain unequivocally which of these interpretations is correct. It is possible that **1** has some of the extra electron density delocalized between the bpy ligands and the lattice cavities, and that the delocalization over the complex molecules is nearly perfectly symmetric. This and many other questions about the nature and properties of this material are currently under investigation.

[8] X-ray structure determination of **1**: A dark blue hexagonal needlelike crystal of approximate dimensions 0.10 × 0.10 × 0.30 mm was coated with Paratone-N oil under an argon atmosphere and immediately placed in a cold nitrogen stream at 153 K on the X-ray diffractometer. The X-ray intensity data were collected on a standard Siemens SMART CCD area detector system equipped

with a normal focus molybdenum-target X-ray tube operated at 2.0 kW (50 kV, 40 mA) [9]. A total of 1321 frames of data were collected using a narrow-frame method with scan widths of 0.3° in ω and exposure times of 30 sec per frame using a crystal-to-detector distance of 6.015 cm (maximum 2θ angle 51.62°). The total data collection time was approximately 13 h. Frames were integrated with the Siemens SAINT program to yield a total of 14059 reflections, of which 2213 were independent ($R_{int} = 0.0307$, Laue symmetry $6/mmm$, $R_{sig} = 0.0179$) and 1993 were above $4\sigma(F)$. The unit cell parameters (at 153 K) of $a = b = 16.5617(2)$, $c = 15.4433(2)$ Å were based upon least-squares refinement of the three-dimensional centroids of 8192 reflections. The cell volume and density were 3668 Å^3 and 1.547 g cm^{-3}, respectively. By assuming a merohedrally twinned trigonal specimen, twinning law $(0\ -1\ 0\ -1\ 0\ 0\ 0\ 0\ -1)$ and space group $P\bar{3}c1$, Ru of position A is found at (1/3, 2/3, z) (site simmetry $C_3\bar{3}$) and Ru of position B at (0, 0, 1/4) (site symmetry $D_3\bar{3}2$) with a twin population of 0.501(3). The refinement of coordinates and anisotropic displacement parameters converged at $R_1 = 0.0250$, GOOF = 1.144 ($\omega = 1/(\sigma^2(F_o^2) + (0.0090\,P)^2 + 3.0338\,P)$, where $P = (F_o^2 + 2F_c^2)/3$) for 1993 observations and 181 parameters (hydrogen atoms in calculated positions, d(C–H) = 0.95 Å).

Synthesis, Structure, High-Resolution Spectroscopy, and Laser Chemistry of Fluorooxirane and 2,2-[$^2H_2$]-Fluorooxirane**

Hans Hollenstein, David Luckhaus, Jörg Pochert, Martin Quack,* and Georg Seyfang

Dedicated to Professor Edgar Heilbronner on the occasion of his 75th birthday

Fundamental questions concerning symmetry, structure, and dynamics of chiral molecules beyond classical structural concepts[1] may in future be answered by spectroscopy and laser chemical investigations.[2] For this purpose, small chiral molecules that can be investigated by reaction dynamics and by gas-phase IR and UV spectroscopy with rotational resolution have to be found. Only few examples of this type have been reported, for instance CHBrClF[3] or the substituted thiiran-1-oxides.[4]

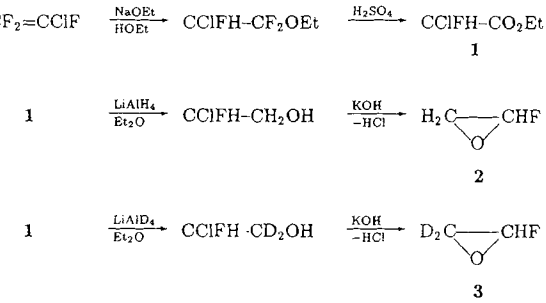
Fluorinated oxiranes are suitable candidates for such investigations because of the small and rigid ring structure and their strong infrared absorptions in the range of the CO_2 laser. Some work on the influence of substituents on the ring structure of highly fluorinated oxiranes has been reported,[5–8] but up to now monofluoroxirane has neither been prepared nor otherwise experimentally investigated. Two publications describe theoretical computations of the molecular structure of the monofluoroxirane.[9, 10] The anticipated shortening of the C–O bond at the fluorinated carbon atoms relative to the C–O bond length at the CH_2 carbon suggests the formation of a C–O double bond at the CHF side of the ring upon elimination of hydrogen fluoride. Both the structure and the proposed decomposition pathway have to be verified by experiment. We have found remarkably diverse phenomena in experiments with isotopic labeling. Furthermore, fluorooxirane should also be important in the chemical activation of fluoroethylene with oxygen atoms (^1D oder ^3P).[11] In a general context, the calculation of the circular dichroism of substituted oxiranes,[12] the stereomutation at the carbon atom,[13] and parity selection[14] are of interest.

Fluorooxirane **2** and 2,2-[$^2H_2$]-fluorooxirane **3** have been prepared according to Scheme 1, starting from chlorotrifluoroethylene. The preparation of the ester[15] and its reduction to the optically active (–)-alcohol following the diastereoisomer separation of chlorofluoroacetic acid have been reported.[16]



Scheme 1.

The last step is performed in analogy to the reaction of 2-chloroethanol with potassium hydroxide to yield the unsubstituted oxirane already reported by Wurtz.[17] For the doubly deuterated isotopomer the ester **1** is reduced with lithium aluminium deuteride. The isotopic purity of the CD_2 groups of the alcohol and the oxirane has been checked by infrared and mass spectroscopy to be at least 99%.

Figure 1 shows the gas-phase infrared spectra of **2** and **3** in the region important for CO_2-laser excitation. For the normal mode assignment of the fundamentals and to characterize the compounds, the equilibrium geometry and the infrared spectra have been calculated ab initio (Gaussian'94, MP2) with basis sets of increasing size up to triple-zeta with additional polarization functions (C,F,O: 5s4p2d; H: 3s3p[19]). The experimental and ab initio wavenumbers in Table 1 show differences of the order of a few percent. The sequences of strong and weak absorptions are identical for experiment and ab initio theory. The strongest absorptions are due to the C–F chromophore at 1100 (**3**) and 1125 cm^{-1} (**2**).

The rotational structure of the vibrational bands has been resolved in the spectra recorded on our BOMEM-DA002 Fourier-transform infrared spectrometer with an instrumental bandwidth of 0.004 cm^{-1} (FWHM, apodized). In an iterative

[a] $G = \int \sigma(\tilde{\nu})\, d\ln\tilde{\nu}$ where σ represents the absorption cross-section. Range of integration for overlapping bands [cm^{-1}]: [b] 2961–3134. [c] 1078–1177. [d] 1020–1190. [e] 760–847. The values $\tilde{\nu}_{exp}$ represent the approximate band positions, except for the fundamentals analyzed in Table 2. The assignments of local symmetry coordinates are given in the last column. δ represents a deformation and ν a stretching vibration.

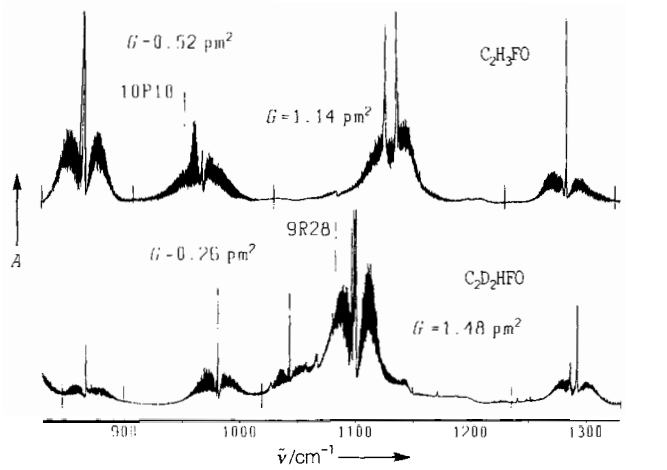

Figure 1. Gas-phase infrared spectra of **2** and **3** in the spectral region of the emissions of the CO_2 laser. Experimental conditions: 9 mbar **3** and 5 mbar **2**, pathlength 18 cm. Resolution: 0.1 cm^{-1}. The positions of the laser frequencies used for excitation and the integration ranges for the evaluation of the integrated band strengths G are indicated by lines. The maximum values of the absorbance ($A = \ln I_0/I$) are close to 4 for **3** and 1 for **2**.

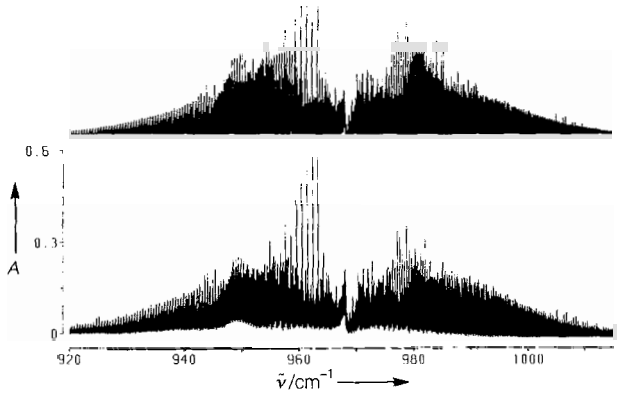

Figure 2. Experimental (bottom) and simulated rovibrational structure (top) of the 968 cm^{-1} band of **2** (parameters from Table 2). Experimental conditions: 5 mbar **2**, pathlength 18 cm, resolution 0.004 cm^{-1}.

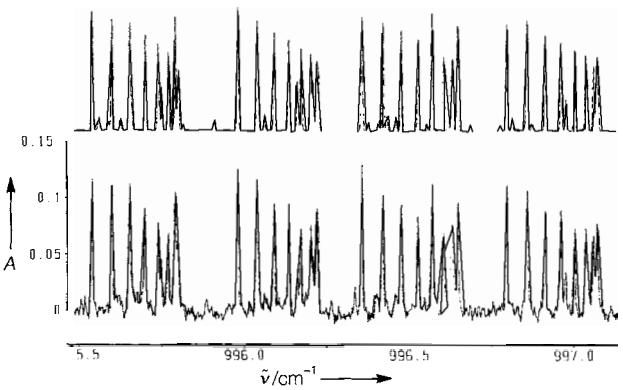

Figure 3. Detail of Figure 2, showing the perfect agreement of experimental (bottom) and simulated rovibrational structure (top).

procedure,[20] the simulated rovibrational structure was fitted to experiment (Figures 2 and 3). The rotational and centrifugal distortion constants of both fluorooxiranes were determined. The vibrational ground-state constants were determined by a separate fit to combination differences. The good correspondence between calculated and experimental rotational constants provides evidence for the identity and the structure of the prepared molecules. Although this type of proof is rather usual for the identification of unstable species, for example in radioastronomy,[21] it can also be applied in exceptional cases for the characterization of newly synthesized compounds.[22] Table 2 lists the calculated and experimentally determined parameters. For the determination of the experimentally improved r_0-structure, the ab initio geometry is used as a starting point, and the bond lengths and bond angles of the heavy atoms (C,O,F) are fitted to the experimental rotational constants. The C–H distances are taken from the correlation between stretching frequency and bond length[23] and the angles from the ab initio calculation (MP2/TZ2P). An additional investigation of the effect of H/D substitution on the rotational constants showed that the chosen r_0 CH/D bond lengths are optimal with respect to the deviation between experimental and calculated rotational constants. The resulting structure is shown in Figure 4. While the CH and CD r_0 structures are slightly different in general,[24] this is not important at the level of accuracy achieved here.

When irradiated at small pressures in the gas phase with infrared laser light, fluorooxirane decomposes unimolecularly after

[a] All values (except N_{data}) are given in cm^{-1}. Rotational constants calculated ab initio are given in cm^{-1}: for **2** $A_e = 0.670755$, $B_e = 0.245158$, $C_e = 0.213635$; for **3**: $A_e = 0.584162$, $B_e = 0.227693$, $C_e = 0.197700$. Combination differences: [b] 2010 from the analyses of v_{11} and 407 from v_{12}. [c] 1119 from v_9 and 1181 from v_7. d_{rms} represents the root mean square of the deviation between calculated and experimental frequencies (N_{data}). See ref. [20] for the definition of the parameters and for the numerical procedure.

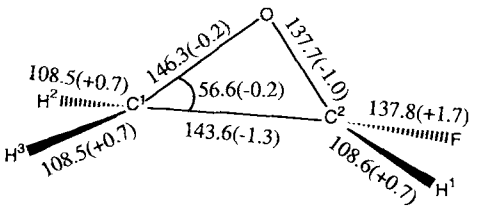

Figure 4. Structural parameters of the fluorooxiranes. The bond lengths [pm] and angles [°] are obtained by fitting the coordinates of he heavy atoms to the experimental rotational constants. The deviations ($r_{fit} - r_{ai}$) between the fitted and the pure ab initio structure are given in parentheses. An estimation of the errors of the fitted structure can be made by a sensitivity analysis of the fitted coordinates. The uncertainty in the bond distances is of the order of 2 pm; for the bond angles it is about 2°. Additional bond angles in degrees: $H^2C^1H^3 = 117.6\ (\pm 0)$, $H^1C^2F = 110.8\ (+0.3)$, $FC^2O = 114.6\ (-0.9)$, $C^1C^2F = 118.7\ (+0.2)$, $C^1C^2H^1 = 117.7\ (\pm 0)$, $C^2C^1H^2 = 120.8\ (\pm 0)$, $C^2C^1H^3 = 124.5\ (\pm 0)$, $H^2C^1O = 114.9\ (+0.1)$. The angle between the CCO and the $H^2C^1H^3$ planes is 90.9 (± 0)° with respect to H^2. The angle between the CCO and the H^1C^2F planes is 88.8 (+ 0.5)° with respect to F. H^3 is oriented *trans* to F.

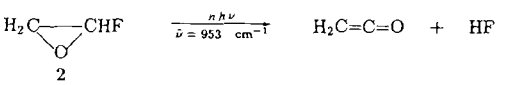
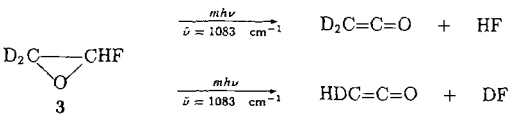
absorption of about $n = 27$ photons ($\tilde{\nu} = 952.9\ cm^{-1}$) to give ketene and hydrogen fluoride (Scheme 2). The position of the exciting laser line with respect to the band center is rather similar for both the deuterated (excitation: 1083.5 cm^{-1}, m = 24 photons; band center: 1100 cm^{-1}) and the nondeuterated compound (excitation: 952.3 cm^{-1}, band center: 968 cm^{-1}).



Scheme 2.

Because of the higher band strength G of the excited vibration, the process of excitation is more efficient for the deuterated isotopomer (Figure 1, Table 1) than for the nondeuterated compound. This results in higher yields for the laser chemical reaction in the case of the 2,2-[$^2H_2$]-fluoroxirane. The infrared spectra of the product mixture shows clearly the strong absorption at 2130 cm^{-1}, which is characteristic for ketene,[25] and can be represented by the superposition of the spectra of the ketene, which we prepared separately by published methods,[26] and the reactant. The reaction product hydrogen fluoride reacts with the walls of the glass cells used in the experiments. The very large isotope shifts in the infrared spectrum would offer excellent H/D isotopomer selectivities, although for large-scale hydrogen isotope separation simpler compounds are known to be useful.[18] The monodeuterated fluorooxirane HDCOCHF is present as a *cis-trans* diastereoisomer pair, which should be also separable quite easily by laser chemistry.[27] Chiral selection by infrared laser chemistry with circularly polarized light should be possible in principle, but has not yet been reported. However, mode selectivity, which could be tested for by irradiating D_2COCHF near 980 cm^{-1} and near 1080 cm^{-1}, is not expected under our experimental conditions.[18]

As the reaction products of an $\alpha\alpha$ (HF + [$^2H_2$]-ketene) and an $\alpha\beta$ (DF + [$^2H_1$]-ketene) elimination are different (Scheme 3),



Scheme 3.

the laser chemistry of the 2,2-[$^2H_2$]-fluorooxirane gives insight into the mechanism of hydrogen fluoride elimination. Because of a lack of information about the rovibrational parameters of the 2130 cm^{-1} absorption of ketene, the high resolution IR spectrum gives only a hint that both the deuterated and the doubly deuterated ketene are present in the reaction mixture. The mass spectrometric analyses yield a ratio of 2.7 to 1 for the molecular ions of [$^2H_2$]-ketene and [$^2H_1$]-ketene, whereas their fragment ions CD_2 and CHD show a shifted ratio of 1.3 to 1, due to isotope effects. From these results we conclude that at least two different mechanisms for the elimination of hydrogen fluoride from the fluorooxirane operate, and that the one leading to HF and the doubly deuterated ketene is clearly favored. This preference is in agreement with our expectations from the structure–reactivity relationship discussed at the beginning.

Ab initio calculations[28] on the transition states, products, and reaction pathways of the fluorooxirane show a manifold of possible reactions like the thermodynamically favored dissociation to CO and CH_3F, the rearrangement to fluoroacetaldehyde or acetyl fluoride followed by HF elimination, as well as the concerted $\alpha\beta$ and the $\alpha\alpha$ elimination of HF. The latter reaction is followed by ring opening of oxiranylidene to yield ketene. The experimental facts suggest that the last two mechanisms are reasonable, because no additional product beyond ketene and hydrogen fluoride is observed in the experiments. For a quantitatively correct description, the reaction threshold of the $\alpha\alpha$ elimination is fitted to the experimental branching ratio. The

experimental laser-chemical yields P_{app}, which correspond approximately to the fraction of molecules dissociated in one laser shot in the effectively irradiated volume (for exact definition see Ref. [29]) are analyzed quantitatively by means of a complete simulation of the reaction (Figure 5) in terms of the non-

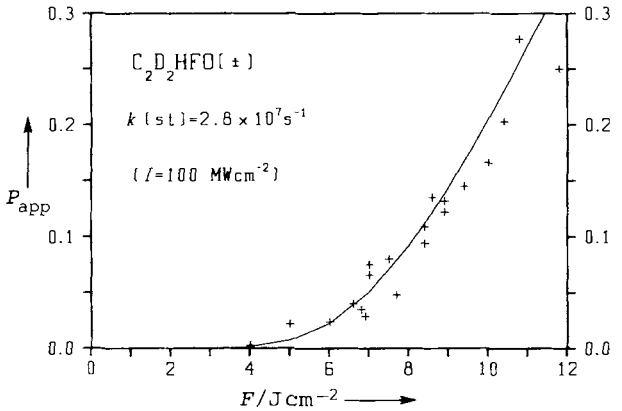

Figure 5. Reaction yield P_{app} (defined according to Ref. [29]) of the laser-chemical reaction of **3** as a function of laser fluence on excitation with the laser line 9R28 (1083.5 cm^{-1}). The solid curve represents the calculated reaction yield. A rate constant of k(st) = 2.8×10^7 s^{-1} at a laser intensity of 100 MWcm^{-2} is determined by fitting the coupling width DV = 160 cm^{-1} to the experimental data. The reaction threshold of the $\alpha\beta$ channel is calculated ab initio to be 304.0 kJmol^{-1}, including zero point corrections. The threshold of the $\alpha\alpha$ elimination was adjusted, starting from the ab initio value until the experimental branching ratio of $\alpha\alpha:\alpha\beta \approx 2:1$ was reached (final value also 304.0 kJmol^{-1}). This turned out to be only slightly fluence (F) dependent ($F = \int I dt$ with laser intensity I).

linear case B/C master equation with respect to the spatial and temporal beam profile in the reaction cell and statistical specific rate constants.[30] A laser chemical rate constant for the decomposition of $k(\mathrm{st}) = 2.8 \times 10^7\ \mathrm{s}^{-1}$ at a laser intensity of 100 MWcm^{-2}, where the intensity proportional region is almost reached, is derived. The calculated branching ratio depends only slightly on the laser fluence ($\alpha\alpha/\alpha\beta = 2 \pm 0.3$). Thus we have opened the route to the laser chemistry of the fluorooxiranes qualitatively and quantitatively for the first time.

Experimental section

Chlorotrifluoroethylene is obtained from Aldrich (29,516-7). 2-chloro, 2-fluoroethanol (5 g) is heated to 80 °C, and 4 KOH pellets are added. The apparatus is closed, and the produced gas is trapped at −78 °C. The trap is warmed to room temperature, and the evolving gas condensed in a glass finger on a vacuum line. The yield of **2** or **3** is 15%. The vapor pressure is more than 250 mbar at 20 °C. The compounds can be stored in liquid nitrogen for several days and are stable under gas-phase conditions. MS (C_2H_3FO, 70 eV): *m/z* 62, 44, 42, 33, 32, 31, 29 (100%), 28, 18, 17, 16, 15; MS (C_2D_2HFO, 70 eV): *m/z* 64, 45, 33, 31, 30 (100%), 29, 17, 16. The mass spectra have been recorded on a Alkaid quadrupole spectrometer, the FTIR spectra with our BOMEM DA002 spectrometer (see Ref. [31] and references therein for experimental details). The product analysis has been carried out on a Perkin-Elmer 983 G grating spectrometer. For the laser chemistry, a Lumonics TEA 103-2 CO_2 Laser with multimode pulses of 100 ns duration [32] was available. The pressure in these experiments was 1 mbar fluoroxirane and 10 mbar nitrogen.

Ene Reactions of Alkynes for the Stereoselective Synthesis of Allylamines**

Armin R. Ofial and Herbert Mayr*

Dedicated to Professor Rolf Gleiter on the occasion of his 60th birthday

Reactions of terminal acetylenes with formaldehyde and secondary amines yielding propargylamines through the intermediacy of iminium ions were first reported by Mannich in the 1930s (Scheme 1).[1] Later it was found that these reactions are often

$$R_2NH + HCHO + H{-}C{\equiv}C{-}R' \longrightarrow R_2N{-}CH_2{-}C{\equiv}C{-}R'$$

Scheme 1. Synthesis of a propargylamine from a secondary amine, formaldehyde, and a terminal acetylene.

promoted by the addition of copper salts.[2] Dialkyl-substituted acetylenes undergo intramolecular reactions with in situ generated iminium ions only with the assistance of external nucleophiles such as I^-.[3] Nucleophilic assistance is not needed for the aminomethylations of the more reactive propargylsilanes,

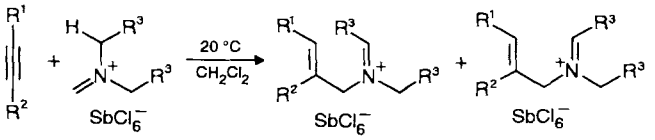
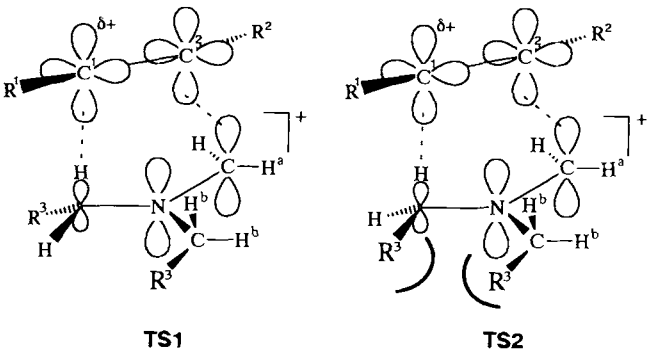
which undergo S_E2' reactions to give homoallenylamines under classical Mannich conditions.[4, 5]

We now report on a new type of reaction of iminium ions with alkynes which occurs when nonnucleophilic counterions[6] are employed in inert solvents. When the iminium hexachloroantimonates (**2a–c**)-$SbCl_6^-$ are combined with alkynes **1a–h** in dichloromethane, ene reactions with inverse electron demand[7, 8] give high yields of the *N*-alkyl-*N*-allylalkylideneammonium salts (**3a–k**)-$SbCl_6^-$ (Table 1).



1 **2**-$SbCl_6^-$ (*Z*)-**3**-$SbCl_6^-$ (*E*)-**3**-$SbCl_6^-$

2a (R^3 = Me)
2b (R^3 = *i*Pr)
2c (R^3 = -CH_2-)



TS1 **TS2**

Figure 1. Transition states **TS1** and **TS2** of the alkyne–iminium ene reaction.

The constitutions of the products can be rationalized by either stepwise or concerted ene reactions with a transition state in which the formation of the C–C bond is more advanced than the formation of the C–H bond (Figure 1). Since there is at least a partial positive charge at C-1 in the transition state, phenyl, trimethylsilylmethyl, alkenyl, and alkyl groups are preferred in the position R^1, while trimethylsilyl assumes the position R^2 and thus stabilizes the positive charge (β-silyl-effect[9]). In both mechanisms the hydrogen transfer occurs intramolecularly, resulting in the stereoselective formation of the new C=C bond. In the products the substituents R^1 and R^2 are exclusively in *cis* position (>97%, NMR). In most cases the resulting reaction products are mixtures of (*E*) and (*Z*) isomers with respect to the configuration of the C=N bond. The ratios of the stereoisomers can be rationalized by the transition states **TS1** and **TS2** shown in Figure 1. With the assumption that H^a and H^b are eclipsed in the most favorable conformation,[10] an unfavorable steric interaction of the R^3 groups can only be avoided in the transition state **TS1**. The stereoisomer arising from **TS1** is always preferred (Table 1), and this preference increases with the size of R^3 (cf. entries 1/2 and 7/8).

Alkynes with R^2 = $SiMe_3$ and R^1 = phenyl, vinyl, alkyl, or trimethylsilyl react smoothly. In contrast, terminal alkynes (R^2 = H) react only when R^1 is a strong electron donor such as phenyl, trimethylsilylmethyl, or propen-2-yl, while 1-hexyne does not react. Attempts to combine 1-phenylpropyne, diphenyl-acetylene, 3-hexyne, trimethylsilylacetylene, and 1,3-bis(trimethylsilyl)-3-methyl-1-butyne with **2a**-$SbCl_6^-$ under the conditions described were not successful. In these cases only the iminium salt **2a**-$SbCl_6^-$ was recovered in 77–94% yield after two to three days (diphenylacetylene: 2.5 h).

As discussed in the introduction, the ene reactions reported here were not observed when the iminium ions were generated in situ from formaldehyde and secondary amines. When the preformed iminium chloride **2a**-Cl^-[11] was combined with phenylacetylene (**1b**) or 2-methyl-1-buten-3-yne (**1g**) in dichloromethane, we also exclusively isolated the expected aminomethylated alkynes after aqueous workup. This observation again stresses the necessity to employ nonnucleophilic counterions.

Table 1. Products of the ene reaction of **1** and **2**.

Entry	**1**	R^1	R^2	**2**	*t* [h]	Yield [%]	Ene product **3** (*Z*:*E*) [a]
1	**1a**	Ph	$SiMe_3$	**2a**	19	91	 **3a** (70:30)
2	**1a**	Ph	$SiMe_3$	**2b**	1	81	 **3b** (>95:5)
3	**1a**	Ph	$SiMe_3$	**2c**	1	70	 **3c**
4	**1b**	Ph	H	**2a**	44	81	 **3d** (75:25)
5	**1c**	Me	$SiMe_3$	**2a**	40	71	 **3e** (70:30)
6	**1d**	Bu	$SiMe_3$	**2a**	19	90	 **3f** (80:20)
7	**1e**	$SiMe_3$	$SiMe_3$	**2a**	24	83	 **3g** (70:30)
8	**1e**	$SiMe_3$	$SiMe_3$	**2b**	26	78	 **3h** (92:8)
9	**1f**	CH_2SiMe_3	H	**2a**	1	86	 **3i** (63:37)
10	**1g**	$C(CH_3)=CH_2$	H	**2a**	120	68	 **3j** (68:32)
11	**1h**	$CH=CH_2$	$SiMe_3$	**2a**	19	87	 **3k** (76:24)

[a] (*Z*) and (*E*) refer to the configuration of the C=N bond. The ratio of the stereoisomers was determined by ^1H NMR spectroscopy. The position of the waved line indicates the configuration of the preferred (*Z*) isomer.

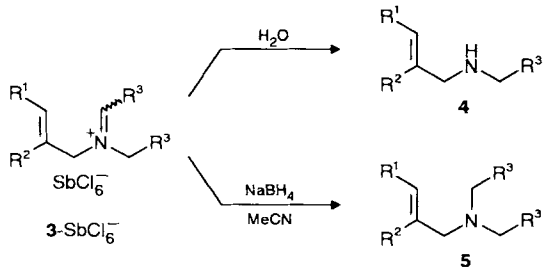
Though the examples in Table 1 demonstrate that *N*-allyliminium ions with a wide range of substitution patterns are accessible by ene reactions of alkynes with iminium salts, the scope and limitation of this method is yet not clear. Since the iminium ions **3** can easily be transformed into the secondary and tertiary amines **4** and **5**, respectively, which incorporate useful functionalities, the reaction products generated by this method should be useful building blocks, especially for the synthesis of alkaloids.



Experimental Section

All reactions were performed in Schlenk tubes under anhydrous conditions. The iminium salts **2**-$SbCl_6^-$ were generated in dichloromethane from the corresponding formaldehyde-*N*,*O*-acetals [11a] by successive addition of chlorotrimethylsilane [11c] and antimony(v) chloride [12] without isolation of the intermediate hygroscopic iminium chlorides **2**-Cl^-.

3-$SbCl_6^-$: Two equivalents of alkyne **1** [13] was added to a suspension of **2**-$SbCl_6^-$ in dichloromethane (5 mL per mmol) at room temperature. After dissolution of the iminium salt stirring was continued for 30 min. The volatile components were removed in vacuo to yield mixtures of the diastereomeric salts **3**-$SbCl_6^-$, which were obtained as analytically pure compounds by washing with a dichloromethane/diethyl ether mixture (1:1).

(*E*)-3-Ethylamino-1-phenylpropene (**4d**) [14]: A solution of **2a**-$(Sn_2Cl_{10}^{2-})_{0.5}$ (7.0 mmol) in CH_2Cl_2 (20 mL) was combined with three equivalents of **1b**. After 48 h the solution was concentrated to one-third of its original volume and stirred with saturated aqueous K_2CO_3 solution for 30 min at 0 °C. The aqueous layer was extracted with diethyl ether (2 × 20 mL), and the combined organic fractions were washed with water (20 mL) and dried over $MgSO_4$. The solvent was removed to yield an oil which was purified by Kugelrohr distillation (115 °C/10^{-2} mbar): 0.62 g **4d** (53%).

[14] S. Rehn, Diploma Thesis, Universität München, **1996**. If the isolation of the iminium ions **3** is not intended, it is advantageous to employ the more soluble iminium salts **2**-$(Sn_2Cl_{10}^{2-})_{0.5}$, which can be generated in solution in analogy to the corresponding hexachloroantimonates.

Synthesis and Isolation of a Homodimer of Cadmium Selenide Nanocrystals**

Xiaogang Peng, Troy E. Wilson, A. Paul Alivisatos,* and Peter G. Schultz*

Inorganic nanocrystals provide an opportunity to observe the evolution of fundamental properties from isolated atoms to a bulk solid.[1] Research in this area has recently expanded beyond studies of isolated nanoparticles to include investigations of the properties of coupled quantum dot systems.[2–6] However, continued progress toward understanding the collective behavior of coupled nanoparticles will likely require the development of reliable synthetic methods for the assembly and organization of ligand-stabilized nanoparticles. A variety of strategies to organize inorganic nanoparticles, including the use of co-colloidal suspensions,[3] chemical cross-linking,[4] the preparation of organic monolayers,[5] and crystallization[6] have been described. We investigated wet-chemical methods for the synthesis and characterization of higher order structures of metal and semiconductor nanoparticles and describe herein the successful preparation and isolation of a linked homodimer of cadmium selenide (CdSe) nanocrystals. Compared to our other method—the organization of nanocrystal molecules using DNA[7]—these efforts hold the prospect of preparing nanocrystal aggregates by wet-chemical methods in which the interactions between particles are controlled by the length and composition of organic linkers or "bonds".

[14] S. Rehn, Diploma Thesis, Universität München, **1996**. If the isolation of the iminium ions **3** is not intended, it is advantageous to employ the more soluble iminium salts **2**-$(Sn_2Cl_{10}^{2-})_{0.5}$, which can be generated in solution in analogy to the corresponding hexachloroantimonates.

Synthesis and Isolation of a Homodimer of Cadmium Selenide Nanocrystals**

Xiaogang Peng, Troy E. Wilson, A. Paul Alivisatos,* and Peter G. Schultz*

Inorganic nanocrystals provide an opportunity to observe the evolution of fundamental properties from isolated atoms to a bulk solid.[1] Research in this area has recently expanded beyond studies of isolated nanoparticles to include investigations of the properties of coupled quantum dot systems.[2–6] However, continued progress toward understanding the collective behavior of coupled nanoparticles will likely require the development of reliable synthetic methods for the assembly and organization of ligand-stabilized nanoparticles. A variety of strategies to organize inorganic nanoparticles, including the use of co-colloidal suspensions,[3] chemical cross-linking,[4] the preparation of organic monolayers,[5] and crystallization[6] have been described. We investigated wet-chemical methods for the synthesis and characterization of higher order structures of metal and semiconductor nanoparticles and describe herein the successful preparation and isolation of a linked homodimer of cadmium selenide (CdSe) nanocrystals. Compared to our other method—the organization of nanocrystal molecules using DNA[7]—these efforts hold the prospect of preparing nanocrystal aggregates by wet-chemical methods in which the interactions between particles are controlled by the length and composition of organic linkers or "bonds".

Several authors have reported the cross-linking of inorganic nanoparticles by organic ligands.[4] Transmission electron microscopy (TEM) images in those papers suggest that the resulting products consist of aggregates containing different numbers of particles.[3b, 4] We extend these prior studies by demonstrating the isolation of a specific, stable "nanocrystal molecule." The isolation of a specific nanocrystal molecule from a complex mixture requires that the starting nanocrystalline "reagents" be mondisperse, a condition which has been satisfied by several recently reported preparations.[6d, 8] CdSe nanocrystals are one of the better characterized systems and was chosen for that reason.

Monodisperse and highly crystalline CdSe nanocrystals, passivated with trioctylphosphane oxide (TOPO), were synthesized on a gram scale by a high-temperature procedure.[8b, 8c] The CdSe–TOPO nanocrystals dissolve without decomposition in nonpolar solvents such as toluene. However, TOPO molecules are not strongly bound to the nanocrystals and can be washed away by polar solvents like methanol.[8b] Since the chemical processing steps involved in linking and purifying aggregates of CdSe nanocrystals required a robust ligand shell, the binding of other ligands to CdSe was investigated (phenols, carboxylic acids, amines, hydrazines, acyl hydrazides, phosphanes, thiols, and thiol acids). Treatment of CdSe–TOPO with thiols (or acyl hydrazides) with a polar end group at elevated temperatures afforded a uniform surface coverage of ligands on CdSe nanoparticles (Figure 1). The resulting thiol-coated CdSe nanocrystals were stable and soluble in water and methanol, and somewhat soluble in ethanol, dimethylsulfoxide, and dimethylformamide. The hydrazide-coated nanocrystals were soluble and stable in those solvents under basic conditions, but decomposed gradually in water. Thiol-coated CdSe nanocrystals are sensitive to photooxidation.

Thiol-passivated semiconductor particles (CdSe-**1**) were cross-linked by the addition of a bis(acyl hydrazide) **2** at elevated temperature and high pH (Figure 1). Insoluble aggregates were removed by centrifugation, and the mixture was further purified by size-selective precipitation to afford the homodimeric product CdSe-**3**, which was isolated as a redissolvable powder. The CdSe-**3** homodimers were characterized by TEM and compared to their monomeric precursors. Micrographs of the CdSe monomers, the crude coupling mixture, and CdSe-**3** homodimers purified by size-selective precipitation are shown in Figure 2. The middle panel (B) shows a crude coupling mixture obtained after cross-linking and centrifugation. The highest molecular weight aggregates have been removed by centrifugation leaving a distribution of aggregates consisting primarily of dimers, trimers, and several multimers. The bottom panel (C) shows the improvement in purity after repeated size-selective precipitation with a $MeOH-Et_2O$ cosolvent system. The size-selective precipitation procedure yielded samples highly enriched in homodimer CdSe-**3** with a monomer:dimer:trimer ratio of approximately 2:7:1. The center-to-center interparticle distance in the CdSe-**3** samples (Figure 2C) shows a reproducible separation equal to approximately one fourth of the particle diameter. This distance is consistent with the physical dimensions of the rigid bis(acyl hydrazide) cross-linking agent **2** obtained from molecular modeling.

The TEM images of the unpurified CdSe aggregates (Figure 2B) may appear qualitatively similar to earlier reports of co-colloidal systems[3] and aggregates prepared with small molecule cross-linking reagents.[4] However, as indicated in Figure 2C,

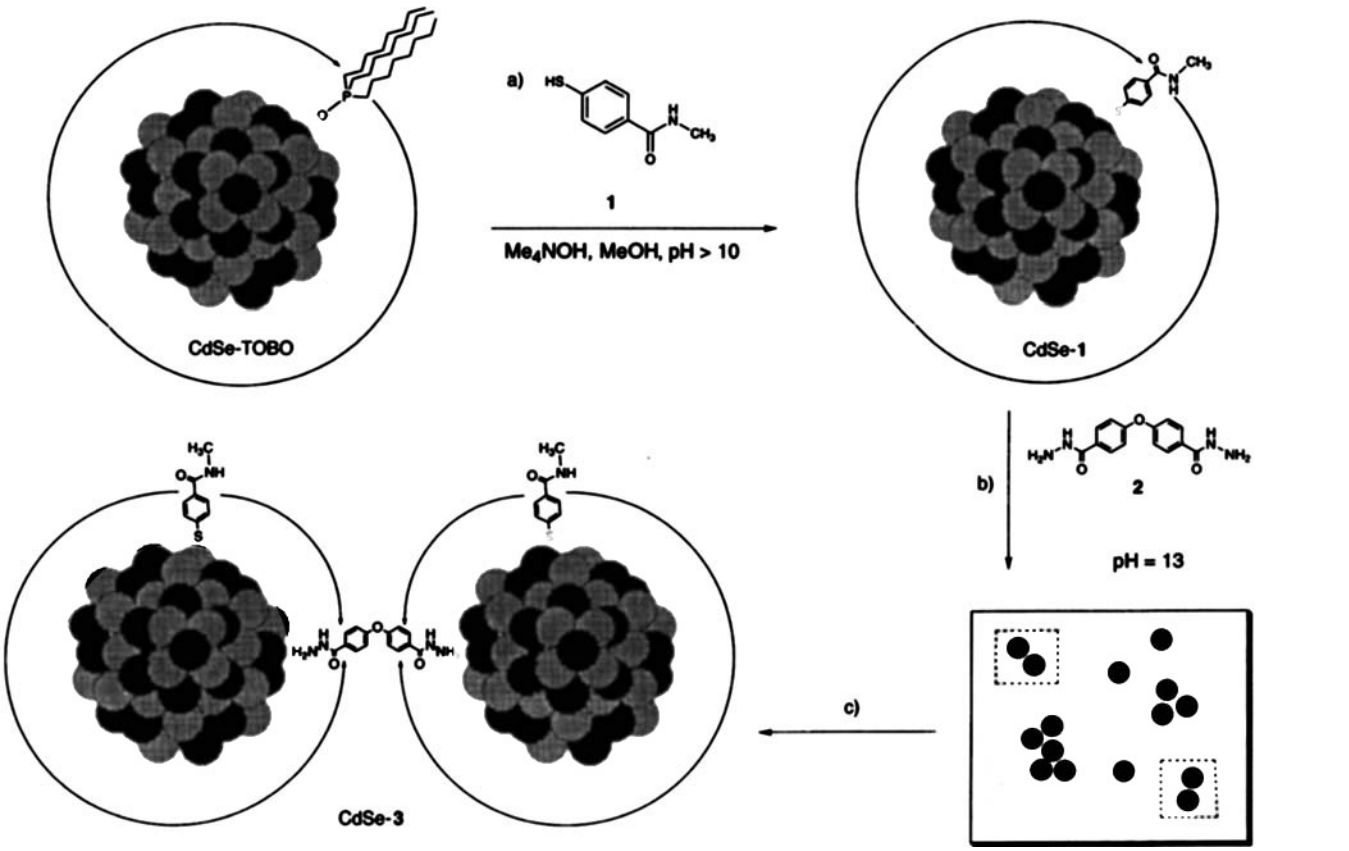

Figure 1. Schematic preparation of homodimers of CdSe nanocrystals: a) passivation with *N*-methyl-4-sulfanylbenzamide (MBAA) **1**, b) cross-linkage through addition of bis(acyl hydrazide) **2**, and c) size-selective precipitation at pH > 10.

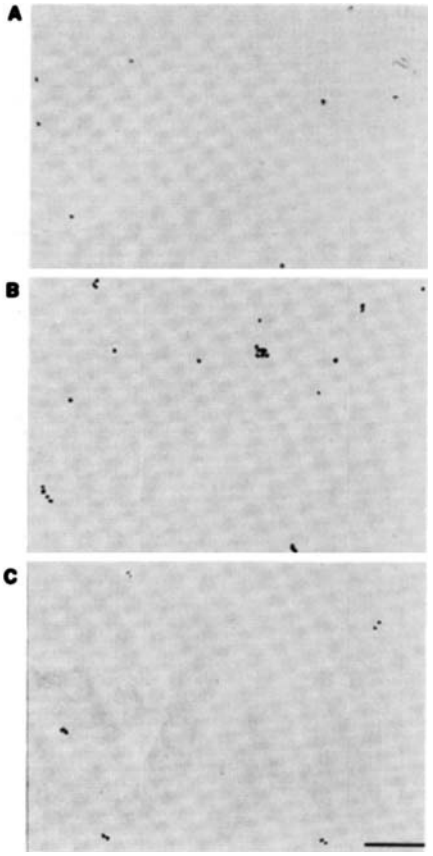

Figure 2. TEM images of 4.0 nm (CdSe) nanoparticles on an amorphous carbon substrate. A) Monomeric CdSe particles passivated with sulfanylarene **1**, B) aggregates of CdSe nanoparticles that have been cross-linked with bis(acyl hydrazide) **2** and purified by centrifugation, C) an enriched sample of cross-linked CdSe-**3** particles that have been purified to near homogeneity by repeated size-selective precipitation. Scale bar in C represents 50 nm.

the CdSe-**3** homodimers can be isolated as discrete, homogeneous, and soluble "nanomolecules".[9] By judicious choice of the structural and electronic properties of the linker (with respect to distance, excited state energy, and bond order), it should be possible to modulate interactions between a variety of semiconducting, metallic, or insulating nanoparticle dimers. Efforts to extend these results to other inorganic materials as well as studies of the physical properties of the homodimers are under way.

Experimental Section

1: 4-(Methylthio)benzoic acid was treated with thionyl chloride in dichloroethane at reflux, followed by reaction with an excess of *N*-methylamine in THF. The resulting aryl methyl sulfide was converted into the corresponding sulfanylbenzamide **1** [10]. Compound **2** was prepared by hydrazinolysis of 4,4'-oxybis(methyl benzoate) at 65 °C in a 50% solution of hydrazine in MeOH followed by recrystallization from EtOAc. Compounds **1** and **2** gave satisfactory spectroscopic and analytical data.

CdSe-**1**: The CdSe nanocrystals used in this study were characterized by UV/Vis spectroscopy, X-ray photoelectron spectroscopy, transmission electron microscopy, and X-ray diffraction. CdSe nanocrystals passivated with ligand **1** were prepared by addition of 2 equiv **1** (based on particle size and quantity of the not quite monodisperse nanocrystals) and TOPO–CdSe (30 mg) to MeOH (20 mL) under argon. The pH was adjusted to 10 by addition of tetramethylammonium hydroxide, and the reaction mixture was heated (57 °C) for six hours. The thiol-passivated CdSe nanoparticles were purified by several cycles of precipitation with THF followed by dissolution in MeOH. The extent of ligand substitution and degree of surface coverage were determined by ^{1}H NMR spectroscopy and elemental analysis of the passivated particles, which are stable for several weeks in the solid state and in solution in the absence of light and oxygen.

CdSe-**1**: A sample of CdSe-**1** was dissolved in MeOH under argon. The pH was adjusted to 13 by the addition of tetramethylammonium hydroxide, **2** (0.5 equiv) was added, and the reaction mixture was heated (57 °C) for 12 hours, then cooled to ambient temperature, and the precipitate was removed by centrifugation. An approximately 0.5 M solution of Et_3N in Et_2O was added to the supernatant until it became turbid. The resulting precipitated particles were removed by centrifugation and redissolved in methanol containing tetramethylammonium hydroxide (pH 10) and approximately 0.2 M of **1**. A Jeol-100CX TEM Instrument, operating at 80 kV, was used to image samples of the CdSe-**3** homodimer. Dilute methanolic samples of the CdSe-**3** homodimer were applied to 400-mesh, carbon-coated copper grids that had been glow-discharged for 30 s in an argon plasma at approximately 50 mTorr.

vated functionality into physical signals provides the basis for molecular electronic systems. For example, the electrically induced translocation of a bipyridinium cyclophane electron acceptor between the benzidine and bisphenol electron donor sites within a supramolecular "wire assembly" could be an element of a molecular electronic system.[3] Photonic or optical triggering of molecular functions and transduction of the light-activated chemical functionality into a physical signal are the basic features of molecular optoelectronics.[4, 5] Reversible photochemical isomerization to redox-active states enables the transduction of recorded optical signals into electrochemical signals.[6, 7] For example, ethylenebis(hydroxythiophene) undergoes reversible photoisomerism, and upon light-induced electrocyclization, a hydroquinoid, redox-active state is generated that enables electrochemical readout of the recorded optical signal.[8] Supramolecular donor–acceptor complexes formed between xanthene dyes and *N*,*N*′-dialkyl-4,4′-bipyridinium salts have been characterized in detail.[9] In a preliminary study, we demonstrated that in the presence of a photoisomerizable bipyridiniomethylazobenzene diad the formation of the supramolecular donor–acceptor complex is controlled by light and is dominated by the isomer state of the electron acceptor.[10] To design molecular electronic or optoelectronic devices, integration of a signal-triggered molecular assembly with a transducing element is essential.[11] For example, a photoisomerizable phenoxynaphthacenequinone monolayer, assembled onto an electrode, allowed the transduction of optical signals recorded by the monolayer into amperometric signals.[11b] Similarly, functionalization of a gold electrode with an eosin monolayer yields an active interface for the transduction of the photochemically induced formation of the donor–acceptor complex with a bipyridiniomethylazobenzene diad at the electrode surface into electrochemical signals.[12] Here we report on the light-controlled formation of supramolecular complexes between eosin (**1a**) and 3,3′-bis(pyridiniomethyl)azobenzene (**2**) or 4,4′-bis(pyridiniomethyl)azobenzene (**3**). We found that photoinduced formation and dissociation of the resulting supramolecular complexes is transduced in solutions into optical signals. By the assembly of an eosin monolayer on a piezoelectric crystal, the light-activated formation and dissociation of the supramolecular complexes is transduced.

The bis(pyridiniomethyl)azobenzene salts **2** and **3** form 1:1 donor–acceptor complexes with eosin (**1a**). Figure 1 shows the

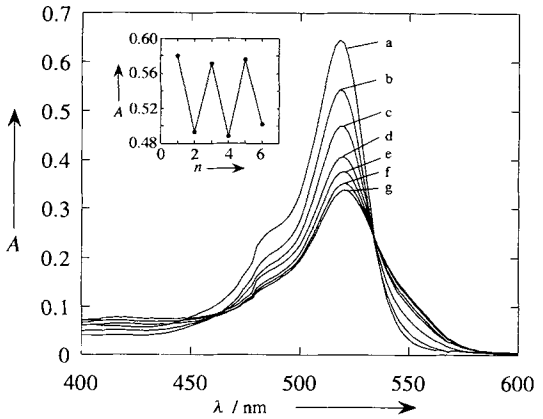

Figure 1. Changes in the absorbance A of eosin (**1a**) (1×10^{-5} M) at different concentrations of (*E*)-**2**: a) 0 M, b) 6.6×10^{-6} M, c) 1.32×10^{-5} M, d) 1.96×10^{-5} M, e) 2.6×10^{-5} M, f) 3.2×10^{-5} M, g) 3.85×10^{-5} M. Inset: Periodic light-stimulated decomplexation and complexation of (*Z*)-**2** and (*E*)-**2**, respectively, with eosin (**1a**); [**1a**] = 1×10^{-5} M; [(*E*)-**2**] = 8×10^{-5} M. The (*Z*)-**2** state was generated by irradiation of the system at $\lambda = 355$ nm, the (*E*)-**2** state at $\lambda > 420$ nm. Changes in the absorbance of the chromophore as a result of complex formation or dissociation were followed at $\lambda = 520$ nm.

changes in the absorbance of eosin upon addition of (*E*)-**2**. The association constant of the complex was evaluated from the spectral changes of the eosin chromophore at different concentrations of (*E*)-**2** by using the Benesi–Hildebrand relation.[13] Analogous spectroscopic analyses provided the association constants of the eosin complexes of (*Z*)-**2**, (*E*)-**3**, and (*Z*)-**3** (Table 1). The affinities of (*E*) isomers of **2** and **3** for the formation of the supramolecular complex with eosin are substantially higher than those of the (*Z*) isomers.[14] From Figure 1 it is also evident that the formation of the supramolecular complexes between the pyridinium salts and eosin is accompanied by a change in the chromophore absorbance. For example, the extinction coefficient of **1a**, $\varepsilon_{520} = 83000\ \text{M}^{-1}\text{cm}^{-1}$, is changed upon complexation with (*E*)-**2** to $\varepsilon_{520} = 28000\ \text{M}^{-1}\text{cm}^{-1}$. This enables the formation of the complex with the (*E*) isomer of

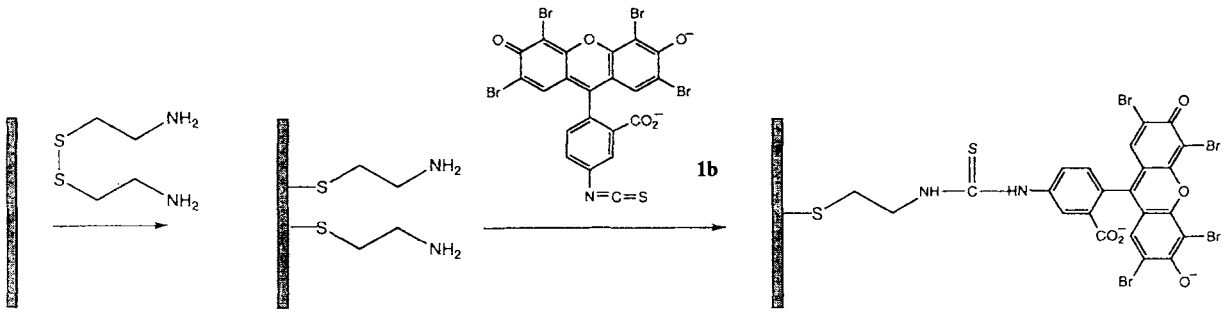

Scheme 1. Assembly of an eosin monolayer on a gold surface.

2 or **3** and its dissociation upon photoisomerization of the acceptors to the (*Z*) state to be transduced into optical signals.

In the presence of (*Z*)-**2** a high absorbance for **1a** is observed, implying that the two components exhibit only weak mutual recognition and are essentially separated. Upon photoisomerization to (*E*)-**2** ($\lambda > 420$ nm), a lower absorbance is observed, indicating the formation of a complex between (*E*)-**2** and **1a**. Further photoisomerization of (*E*)-**2** to (*Z*)-**2** ($\lambda = 355$ nm) regenerates the high absorbance. By cyclic photoisomerization of the acceptor between states (*Z*)-**2** and (*E*)-**2**, reversible high and low absorbance of the systems is observed, respectively (Figure 1, inset). The photoinduced formation and dissociation of the complex between eosin and **3** was similarly transduced into optical signals.

The light-induced formation and dissociation of the supramolecular complexes between eosin (**1a**) and the photoisomerizable electron acceptors were further transduced into microgravimetric responses by using a quartz crystal microbalance.[15] An eosin monolayer was assembled onto the gold electrodes associated with a quartz crystal (9 MHz), as outlined in Scheme 1. Figure 2 shows the frequency changes (Δf) of the

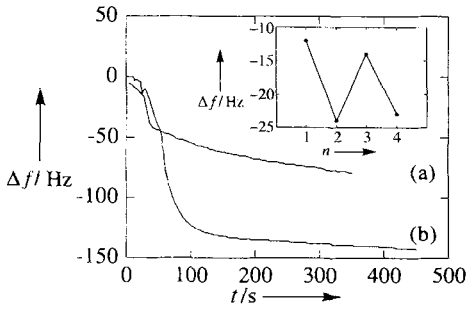

Figure 2. Changes in the frequency of the eosin-modified quartz crystal in the presence of: a) (*Z*)-**2** (2.94×10^{-4} M) and b) (*E*)-**2** (2.94×10^{-4} M). Inset: Reversible changes in the frequency of the eosin-modified quartz crystal upon photoisomerization of the diad between states (*Z*)-**2** and (*E*)-**2**. All experiments were performed in a pure aqueous environment.

monolayer-modified crystal upon interaction with (*Z*)-**2** and with (*E*)-**2**. With (*E*)-**2** [curve (b)] a large decrease in frequency is observed, implying the association of (*E*)-**2** to the monolayer. Interaction of (*Z*)-**2** with the modified crystal results in a substantially smaller change in frequency [curve (a)], implying that (*Z*)-**2** has low affinity for the eosin monolayer. Control experiments revealed that neither (*E*)-**2** nor (*Z*)-**2** adsorbs to bare gold electrodes associated with the quartz crystals ($\Delta f = \pm 2$ Hz). Thus, the changes in the frequency of the crystal originate from the formation of tight and weak donor–acceptor complexes between the eosin monolayer and (*E*)-**2** and (*Z*)-**2**, respectively. Similar results are observed for the microgravimetric analyses of the interactions of (*E*)-**3** and (*Z*)-**3** with the eosin-modified monolayer assembled on the crystal (Table 1). The coverages of the monolayer by the electron–acceptor photoisomers were calculated by using the Sauerbrey equation [Eq. (a)] and are also included in Table 1.

$$\Delta f = (-2.3 \times 10^{-6}) f_0^2 \frac{\Delta m}{A} \qquad \text{(a)}$$

By reversible photoisomerization of the electron acceptors between the (*E*) and (*Z*) states, the formation and dissociation of the complexes at the eosin monolayer were transduced into a cyclic microgravimetric response (Figure 2, inset). With (*Z*)-**2** a small change in frequency is observed, indicating the weak association of the electron acceptor to the monolayer. Photoisomerization of (*Z*)-**2** to (*E*)-**2** ($\lambda > 420$ nm) results in a large change in the frequency of the crystal, indicating the formation of the supramolecular complex at the monolayer. By further photoisomerization of the electron acceptor between states (*E*)-**2** and (*Z*)-**2**, reversible large and small changes in the frequency of the crystal are observed. The reversible photostimulated formation and dissociation of the complex between **3** and the eosin monolayer were analyzed analogously by microgravimetric, quartz crystal microbalance experiments.

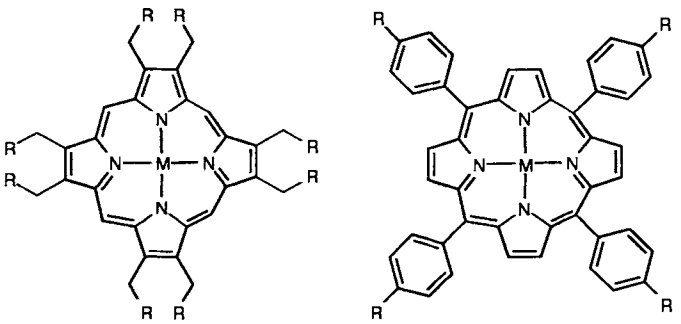
Low-Melting, Liquid-Crystalline Metalloporphyrins**

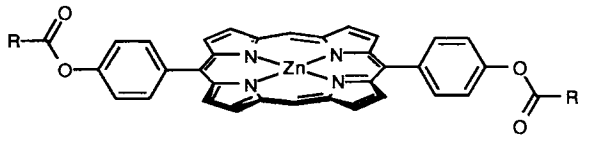
Qing Min Wang and Duncan W. Bruce*

The inherent disklike shape of the porphyrin moiety led to initial work on liquid crystal porphyrins, which centered on peripherally octasubstituted systems (Scheme 1, left) that show columnar mesophases.[1] Later work on columnar systems by Shimizu and co-workers (Scheme 1, right) concentrated on

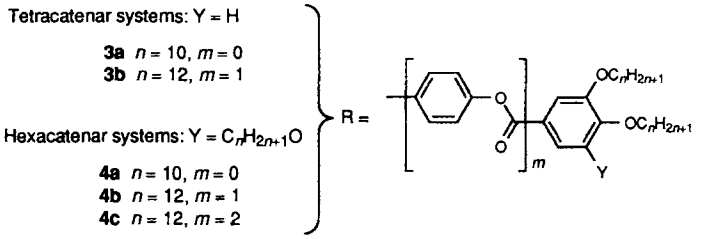


Scheme 1. Porphyrins that form columnar mesophases.

meso-tetrasubstituted porphyrins, which showed lamellocolumnar phases.[2] More recently, we became interested in trying to construct porphyrins that were extended in a more linear fashion, which we reasoned should lead to materials showing mesophases normally characteristic of rodlike (calamitic) molecules. Thus, we showed that zinc 5,15-di(alkoxyphenyl)-porphyrins (**1a**) exhibited crystal smectic mesophases,[3] while the more extended zinc 5,15-di(4-(4-alkoxybenzoyloxy)phenyl)-(**1b**) and zinc 5,15-di(4-(4-alkylcyclohexanoyloxy)phenyl)porphyrins (**1c**) gave rise to nematic and smectic A mesophases,

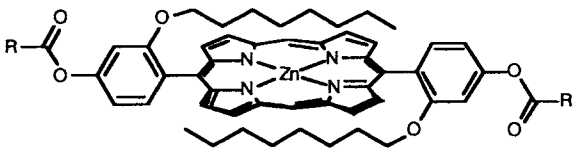


1a R = C_nH_{2n+1}
1b R = $C_nH_{2n+1}O$–C_6H_4–CO
1c R = C_7H_{15}–C_6H_{10}–CO

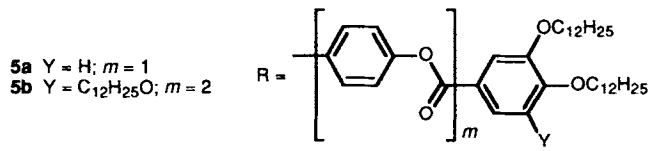


respectively.[4] Thus, by appropriate substitution of the porphyrin skeleton, control can be exerted over the molecular organization to lead either to columnar or calamitic mesophases.

However, the transition temperatures of the nematic and smectic A porphyrins were rather high (>300 °C), and we became interested in strategies to reduce these temperatures. Reduction of the transition temperatures is, of course, important both from the point of view of allowing in-depth physical studies, and for looking at potential applications (that is, having processable materials). In one approach[5] we had introduced lateral chains that folded over the faces of the porphyrin, acting as "lubrication", hence reducing intermolecular electrostatic interactions[6] and leading to lower melting and lower clearing materials (**2**). For example, **2a** (α,β-atropisomer, $n = 7$) melts at



2a R = $C_nH_{2n+1}O$–C_6H_4–CO
2b R = C_7H_{15}–C_6H_{10}–CO



141 °C to a nematic phase, which clears at 177 °C, whereas the parent porphyrin, **1b** ($n = 7$) melts into a nematic phase at 305 °C and clears with decomposition at 433 °C. In this paper, we describe another strategy, namely the synthesis of metalloporphyrins with several terminal alkyl chains (polycatenar[7]), which leads to materials with reduced melting points, and to another method of controlling the aggregation behavior of metalloporphyrins in mesophases. We also report that the combination of the "lubricating" and the polycatenar approach results in porphyrins with very low melting points.

[**] This work was supported by a Sino-British Friendship Scholarship to Q. M. W.

The basic starting materials in this study were zinc 5,15-di(4-hydroxyphenyl)porphyrin and zinc 5,15-di(4-hydroxy-2-octyloxyphenyl)porphyrin, obtained from dipyrromethane[8] and 4-hydroxybenzaldehyde or 4-hydroxy-2-octyloxybenzaldehyde, respectively, as described previously.[4, 5] These were then treated with two equivalents of the appropriate benzoic acids in the presence of 4-(*N*,*N*-dimethylamino)pyridine and dicyclohexylcarbodiimide to give diesterified porphyrins.

The results obtained were at first sight a little disappointing in that only two of the seven new porphyrins were mesomorphic. The five-ring (four peripheral phenyl rings plus the porphyrin), tetracatenar material (**3a**) showed no mesophase at all, although its melting point was some 50 °C lower than that of a typical parent porphyrin with only one alkoxy chain at each end. Clearly here, the mesophase had been severely destabilized by the addition of the two terminal chains in the 3- and 3′- positions. The seven ring compound (**3b**) was mesomorphic and showed a smectic C and nematic phase. In principle, with dodecyloxy chains such a tetracatenar material would have been expected to show a columnar mesophase, in common with other tetracatenar materials. However, some studies have shown that columnar mesophases only arise when the molecular mass of the chain portion of the molecule is at least 50% of the total molecular mass.[9] In addition, there are few, if any, seven-ring tetracatenar mesogens for coomparison.

The hexacatenar materials are also rather devoid of mesomorphism, and both the five- (**4a**) and seven-ring (**4b**) systems were nonmesomorphic, although each showed several crystal modifications and much reduced melting points. However, the remarkable nine-ring material (**4c**) was in fact mesomorphic, forming a columnar mesophase between 188 and 288 °C. Given the very high molecular mass of this last porphyrin, this melting point is very low.

The most interesting porphyrins were obtained when the polycatenar strategy was combined with the approach in which lateral chains were used to lubricate the faces of the porphyrins.[5] The lateral chains act to prevent intermolecular $\pi-\pi$ interactions, so reducing both the melting and clearing point of the porphyrins.

The combination of the two approaches leads to the materials **5**, whose mesomorphic behavior is summarized in Table 1. Thus, **5a** melts into a nematic phase at 133 °C, clearing at 169 °C. The related parent with no lateral chains (**3b**) forms smectic C and nematic phases between 276 and 321 °C. Thus, the melting point has been reduced by 140 °C and the clearing point by 150 °C, while the smectic phase is suppressed. However, the massive nine-ring, hexacatenar porphyrin with lateral chains (**5b**) melts at only 50 °C into a nematic phase, clearing at 153 °C. Reductions in the melting and clearing points relative to the parent without a lateral chain (**4c**) were 138 and 135 °C, respectively, similar to the reductions observed for **5a**/**3b**. In this case, the columnar mesophase has been replaced by a fluid, nematic phase, and the melting point has been reduced to almost room-temperature—quite a drop from the first nematic porphyrins we reported with melting points in excess of 300 °C.[4]

It is interesting to note that in compounds **5**, there is no evidence for any complicating factors arising from atropisomerism. For related compounds, we were able to see clear evidence for transformations of one isomer into another by differential scanning calorimetry (DSC).[5b] The isomers were readily identified as the anisotropy of the α,β-isomer led to mesomorphic materials, while the greatly reduced anisotropy of the α,α-isomer precluded mesomorphism. Thus, although the ^{1}H NMR spectrum of **5a** showed some evidence of both α,α- and α,β-isomers in solution, the former obviously transformed easily into the latter on heating, as the material behaved as a pure compound. For **5b**, NMR showed only one isomer.

Table 1. Transition temperatures of the new porphyrins **3**–**5**.

Porphyrin	Transition [a]	T[°C]	ΔH[kJ mol^{-1}]	ΔS[J K^{-1} mol^{-1}]
3a	Cry-I	251	53.0	101
3b	Cry_1-Cry_2	138	2.4	6
	Cry_2-S_C	276	35.3	64
	S_C-N	287	2.0	4
	N-I [b]	321	–	
4a	Cry_1-Cry_2	58	3.1	9
	Cry_2-Cry_3	88	1.5	4
	Cry_3-Cry_4	120	5.0	13

	N-I	169	1.6	4
5b	Cry-N	50	48.6	150
	N-I	153	0.7	2

[a] Abbreviations: Cry = crystalline phase, I = isotropic phase, S_C = smectic C phase, N = nematic phase, ϕ = columnar phase. The exact symmetry of the columnar mesophases has not yet been determined, although microscopy implies that it is hexagonal. [b] Decomposition occurred around T_{NI}. Thus, the TNI was obtained from microscopic observation. [c] The thermal data were obtained from the second heating. On the first heating, DSC thermogram was complicated by the phase transition from the α,α- to the α,β-atropisomer. However, on the second heating, the compound existed in the form of α,β-atropisomer.

The new strategy for the reduction of melting points in calamitic metalloporphyrins, namely the formation of polycatenar derivatives, leads on combination with the use of lateral chains to very low melting materials indeed. We are also able to control the nature of the mesophase formed in 5,15-disubstituted porphyrins by the use of the appropriate molecular design strategy, which is of particular significance for the design of materials with biaxial nematic mesophases. Materials with this phase have been postulated for molecules possessed of both rodlike and disklike features.[1] This work now provides us with materials whose potential biaxial properties can readily be evaluated, and we anticipate the results of these studies with great interest.

Experimental Section

The target porphyrins were prepared by a standard esterification between the appropriate carboxylic acid and zinc 5,15-di(4-hydroxyphenyl)porphyrin or zinc 5,15-di(4-hydroxy-2-octyloxyphenyl)porphyrin [5] with 4-(*N*,*N*-dimethylamino)pyridine (DMAP) and dicyclohexylcarbodiimide (DCC). The porphyrins were purified by flash chromatography and crystallization. Satisfactory spectroscopic and analytical data were obtained for all new compounds. Mesophases were characterized by optical microscopy (Zeiss Labpol equipped with a Linkam PR 600 controller and TH600 hot stage) and differential scanning calorimetry (Perkin Elmer DSC7).

4-(3,4-Di(dodecyloxy)benzoyloxy)benzoic acid: 3,4-Di(dodecyloxy)benzoic acid (1 g, 2.0 mmol), benzyl 4-hydroxybenzoate (0.5 g, 2.0 mmol), and DMAP (0.1 g, 1 mmol) were dissolved in a mixture of dichloromethane (30 mL) and THF (20 mL). To this solution, DCC (0.4 g, 2.0 mmol) and activated molecular sieves (4 or 5 Å, 2–3 g) were added. The mixture was stirred overnight at room temperature. The reaction solution was then filtered. On evaporation of solvents and crystallization from absolute ethanol, the pure product was obtained as a colorless, crystalline material (1.2 g, 80%). This compound (1.1 g, 1.6 mmol) was dissolved in freshly

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997* *0570-0833/97/3601-0151 $ 15.00+.25/0*

distilled THF. Palladium on charcoal (10%, 160 mg) was added. The solution was stirred at room temperature under 1 atm of H_2 for 3 h and then filtered through a pad of Celite to give a colorless solution. On evaporation of solvent and crystallization from absolute ethanol, the pure product was obtained as a colorless crystalline material (0.73 g, 73%). M.p. 147 °C. ^{1}H NMR (250 MHz, $CDCl_3$): $\delta = 0.87$ (t, 6H, $2CH_3$), 1.26 (m, 32H, $16CH_2$), 1.48 (m, 4H, $2CH_2$), 1.84 (m, 4H, $2CH_2$), 4.07 (m, 4H, $2OCH_2$), 6.93 (d, 1H, $J = 8.0$ Hz), 7.33 and 8.20 (m, 4H, benzene ring, AA'XX', $J_{AX} = 9$ Hz), 7.65 (d, 1H, $J = 2$ Hz), 7.82 (dd, 1H, $J = 8$, $J' = 2$ Hz). Elemental analysis (%): found: C 74.8, H 9.6; required for $C_{38}H_{58}O_6$: C 74.7, H 9.6.

4-(3,4,5-Tri(dodecyloxy)benzoyloxy)benzoic acid: The synthesis was as above, starting with 3,4,5-tridodecyloxybenzoic acid. Yields: esterification: 92%; hydrogenolysis: 75%. M.p. 92 °C. ^{1}H NMR (250 MHz, $CDCl_3$): $\delta = 0.87$ (m, 9H, $3CH_3$), 1.26 (m, 48H, $24CH_2$), 1.49 (m, 6H, $3CH_2$), 1.83 (m, 6H, $3CH_2$), 4.04 (m, 6H, $3OCH_2$), 7.40 (s, 2H, benzene ring), 7.32 and 8.20 (m, 4H, benzene ring, AA'XX', $J_{AX} = 9$ Hz). Elemental analysis (%): found C 75.7, H 10.9; required for $C_{50}H_{82}O_7$: C 75.5, H 10.4.

4-(3,4,5-Tri(dodecyloxy)benzoyloxy)benzoyloxybenzoic acid: The synthesis was as above, starting with 3,4,5-tridodecyloxybenzoic acid; esterification/hydrogenolysis was repeated to obtain this compound. Yields: esterification: 97%; hydrogenolysis: 86%. M.p. 90 °C. ^{1}H NMR (250 MHz, $CDCl_3$): $\delta = 0.87$ (m, 9H, $3CH_3$), 1.26 (m, 48H, $24CH_2$), 1.49 (m, 6H, $3CH_2$), 1.84 (m, 6H, $3CH_2$), 4.05 (m, 6H, $3OCH_2$), 7.41 (s, 2H, benzene ring), 7.35, 7.38, 8.21, 8.29 (m, 8H, two benzene rings, two AA'XX' systems, $J_{AX} = 9$ Hz). Elemental analysis (%): found C 74.8, H 9.6; required for $C_{57}H_{86}O_9$: C 74.8, H 9.5.

Porphyrin **3a**: $\delta = 0.90$ (t, 12H, $4CH_3$), 1.25–1.54 (m, 56H, $28CH_2$), 1.94 (m, 8H, $4CH_2$), 4.17 (m, 8H, $4OCH_2$), 7.05 (d, 2H, $J = 8.5$ Hz), 7.65 and 8.34 (m, 8H, two inner benzene rings, AA'XX', $J = 8.5$ Hz), 7.88 (d, 2H, $J = 2$ Hz), 8.04 (dd, 2H, $J = 8.5$, $J' = 2$ Hz), 9.24 and 9.49 (d, 8H, 8βH, AB, $J = 5$ Hz), 10.39 (s, 2H, 2*meso*-H). Yield 30%. UV/Vis (CH_2Cl_2): $\lambda_{max} = 411.1$, 539.3, 574.4 nm. C,H,N analysis: found(calcd): C 74.2(74.3), H 7.8(7.8), N 3.9(4.0). FAB-MS (positive ions): *m/z*: 1391 [M^+] (calcd: 1391.22).

Porphyrin **3b**: $\delta = 0.89$ (t, 12H, $4CH_3$), 1.20–1.50 (m, 72H, $36CH_2$), 1.88 (m, 8H, $4CH_2$), 4.10 (m, 8H, $4OCH_2$), 6.97 (d, 2H, $J = 8.5$ Hz), 7.49 and 8.34 (m, 8H, two inner benzene rings, AA'XX', $J = 8.5$ Hz), 7.69 and 8.50 (m, 8H, two middle benzene rings, AA'XX', $J = 8.5$ Hz), 7.71 (d, 2H, $J = 2$ Hz), 7.88 (dd, 2H, $J = 8.5$, $J' = 2$ Hz), 9.21 and 9.47 (d, 8H, 8βH, AB, $J = 4.6$ Hz), 10.35 (s, 2H, 2*meso*-H). Yield 61%. UV/Vis (CH_2Cl_2): $\lambda_{max} = 410.5$, 538.9, 574.4 nm. C,H,N analysis: found(calcd): C 74.2(74.4), H 7.7(7.6), N 2.9(3.2). FAB-MS (positive ions): *m/z*: 1743 [M^+] (calcd: 1743.66).

Porphyrin **4a**: $\delta = 0.90$ (t, 18H, $6CH_3$), 1.20–1.52 (m, 84H, $42CH_2$), 1.88 (m, 12H, $6CH_2$), 4.15 (m, 12H, $6OCH_2$), 7.62 (s, 4H), 7.65 and 8.33 (m, 8H, two inner benzene rings, AA'XX', $J = 8.5$ Hz), 9.21 and 9.49 (d, 8H, 8βH, AB, $J = 4.6$ Hz), 10.37 (s, 2H, 2*meso*-H). Yield 51%. UV/Vis (CH_2Cl_2): $\lambda_{max} = 410.6$, 539.2, 574.4 nm. C,H,N analysis: found(calcd): C 74.5(74.7), H 9.0(8.8), N 3.2(3.3). FAB-MS (positive ions): *m/z*: 1703 [M^+] (calcd: 1703.6).

Porphyrin **4b**: $\delta = 0.82$ (t, 18H, $6CH_3$), 1.16–1.46 (m, 108H, $54CH_2$), 1.76 (m, 12H, $6CH_2$), 4.03 (t, 12H, $6OCH_2$), 7.40 (s, 4H), 7.42 and 8.28 (m, 8H, two inner benzene rings, AA'XX', $J = 8.2$ Hz), 7.63 and 8.44 (m, 8H, two middle benzene rings, AA'XX', $J = 8.5$ Hz), 9.16 and 9.43 (d, 8H, 8βH, AB, $J = 4.6$ Hz), 10.31 (s, 2H, 2*meso*-H). Yield 56%. UV/Vis (CH_2Cl_2): $\lambda_{max} = 410.7$, 539.2, 574.4 nm. C,H,N analysis: found(calcd): C 75.0(75.1), H 8.5(8.5), N 2.6(2.7). FAB-MS (positive ions): *m/z*: 2111 [$(M-1)^+$] (calcd: 2112.3).

Porphyrin **4c**: $\delta = 0.88$ (t, 18H, $6CH_3$), 1.22–1.52 (m, 108H, $54CH_2$), 1.82 (m, 12H, $6CH_2$), 4.07 (t, 12H, $6OCH_2$), 7.43 (s, 4H), 7.41, 7.52, 7.69, 8.35, 8.36, 8.52 (m, 24H, six benzene rings, three AA'XX' systems, $J = 8.2$–8.9 Hz), 9.22 and 9.49 (d, 8H, 8βH, AB, $J = 4.6$ Hz), 10.37 (s, 2H, 2*meso*-H). Yield 55%. UV/Vis (CH_2Cl_2): $\lambda_{max} = 410.4$, 538.5, 574.8 nm. C,H,N analysis: found(calcd): C 74.0(74.5), H 8.0(8.1), N 2.3(2.4). FAB-MS (positive ions): *m/z*: 2351 [$(M-1)^+$] (calcd: 2352.52).

Porphyrin **5a**: $\delta = 0.32$ (m, protons of the terminal methyl groups of the lateral side chains), 0.36–1.06 (m, 36H, $4CH_3 + 12CH_2$ in the lateral chains), 1.22–1.52 (m, 72H, $36CH_2$), 1.89 (m, 8H, $4CH_2$), 3.91 (t with tiny couplings, 4H, $2OCH_2$ in the lateral chains), 4.11 (m, 8H, $4OCH_2$), 6.98 (d, 2H, $J = 8.6$ Hz), 7.26 (m, overlapped with the $CHCl_3$ signal, 2H), 7.31 (d, 2H, $J = 2.2$ Hz), 7.49 and 8.49 (m, 8H, two middle benzene rings, AA'XX', $J = 8.5$ Hz), 7.72 (d, 2H, $J = 2.1$ Hz), 7.89 (dd, 2H, $J = 8.6$, $J' = 2.1$ Hz), 8.12 and 8.15 (d in two sets, 2H, $J = 7.6$ Hz), 9.15 (d in two sets, 4H, 4βH, AB, $J = 4.6$ Hz), 9.42 (d, 4H, 4βH, AB, $J = 4.6$ Hz), 10.29 (s, 2H, 2*meso*-H). Yield 61%. UV/Vis (CH_2Cl_2): $\lambda_{max} = 410.4$, 538.5, 573.7 nm. C,H,N analysis: found(calcd): C 74.0(74.5), H 8.4(8.3), N 2.7(2.8). FAB-MS (positive ions): *m/z*: 1999 [$(M-1)^+$] (calcd: 2000.09).

Porphyrin **5b**: $\delta = 0.33$ (m, protons of the terminal methyl groups of the lateral side chains), 0.36–1.08 (m, 42H, $6CH_3 + 12CH_2$ in the lateral chains), 1.27 (m, 96H, $48CH_2$), 1.51 (m, 12H, $6CH_2$), 1.82 (m, 12H, $6CH_2$), 3.91 (t, 4H, $2OCH_2$ in the lateral chains), 4.07 (m, 12H, $6OCH_2$), 7.26 (m, overlapped with the $CHCl_3$ signal, 2H), 7.31 (d, 2H, $J = 1.9$ Hz), 7.43 (s, 4H), 7.41, 7.51, 8.36, 8.51 (m, 16H, four middle benzene rings, two AA'XX' systems, $J = 8.9$ Hz), 8.12 and 8.15 (d in two sets, 2H, $J = 7.3$ Hz), 9.14 (d in two sets, 4H, 4βH, AB, $J = 4.6$ Hz), 9.42 (d, 4H, 4βH, AB, $J = 4.6$ Hz), 10.28 (s, 2H, 2*meso*-H). Yield 55%. UV/Vis (CH_2Cl_2): $\lambda_{max} = 410.9$, 539.2, 574.4 nm. C,H,N analysis: found(calcd): C 74.1(74.6), H 8.5(8.5), N 2.4(2.2). FAB-MS (positive ions): *m/z*: 2609 [M^+] (calcd: 2608.95).

Valence-Delocalized and Valence-Trapped $Fe^{II}Fe^{III}$ Complexes: Drastic Influence of the Ligands

Sujit K. Dutta, Jürgen Ensling, Rüdiger Werner, Ulrich Flörke, Wolfgang Haase, Philipp Gütlich, and Kamalaksha Nag*

Complexes with metal ions in mixed oxidation states play important roles in materials and biology.[1] The valence-trapped $Fe^{II}Fe^{III}$ units are known to occur in the diiron proteins hemerythrin, methane monoxygenase, and purple acid phosphatase, in which the two high-spin metal centers are antiferromagnetically coupled with an $S = 1/2$ ground state.[2] By contrast, the presence of a valence-delocalized $[Fe_2]^V$ unit with $S = 9/2$ spin ground state has been implicated[3] in iron–sulfur proteins containing $[Fe_2S_2]$, $[Fe_3S_4]$ and $[Fe_4S_4]^{3-}$ cores. The domineering influence of double exchange,[4] that is, the interplay of electron transfer and electron coupling, on electronic and magnetic properties of valence-delocalized species has been underscored by several theoretical studies.[5]

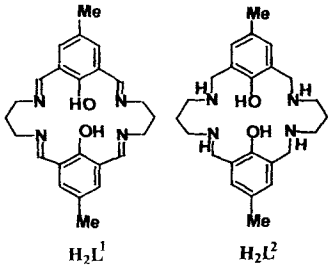
Although a few valence-locked binuclear $Fe^{II}Fe^{III}$ complexes have been structurally characterized,[6] fully delocalized compounds are rare.[7] $[L_2Fe_2(\mu\text{-}OH)_3](ClO_4)_2\cdot 2H_2O$[8] (L = *N*,*N*′,*N*″-trimethyl-1,4,7-triazacyclononane) seems to be the only compound belonging to the Robin–Day class III system that exhibits double exchange with an $S = 9/2$ spin ground state.

We report here the synthesis of a novel valence-delocalized diiron complex **1** derived from the tetraiminodiphenol macrocyclic ligand H_2L^1 and a valence-trapped dissymetric complex **2** obtained from the related tetraaminodiphenol macrocyclic ligand H_2L^2.

$[L^1Fe_2(\mu\text{-}OAc)_2](ClO_4)$ **1**

$[L^2Fe_2(\mu\text{-}OAc)(OAC)(H_2O)](ClO_4)\cdot 2H_2O$ **2**



The electronic spectrum of **1** shows a phenolate → $[Fe_2]^V$ charge transfer (CT) transition at 480 nm (ε = 2300 $M^{-1}cm^{-1}$ in MeCN) and an intervalence transfer transition (IT) at 1060 nm. The peak of the IT band ($\tilde{\nu}_{max} = 9430\ cm^{-1}$), its width at half height ($\Delta\tilde{\nu}_{1/2} = 3980\ cm^{-1}$) and intensity ($\varepsilon = 1250\ M^{-1}cm^{-1}$) all remain unchanged in a number of solvents (MeCN, $MeNO_2$, $EtNO_2$, $PhNO_2$, or Me_2CO), which indicates that **1** belongs to the class III system. Further, the value of $\tilde{\nu}_{1/2}$ predicted by Hush's relation[9] for a class II compound is appreciably larger (4670 cm^{-1}). Accordingly, the degree of electron coupling ($H_{AB} = \tilde{\nu}_{max}/2$)[9] and double exchange parameter ($|B| = \tilde{\nu}_{max}/10$)[8] for **1** are estimated to be 4715 and 943 cm^{-1}, respectively. Complex **2** also exhibits the phenolate → Fe^{III} CT band at 510 nm ($\varepsilon = 2600\ M^{-1}cm^{-1}$ in MeCN) and an IT band between 1110 and 1160 nm; however, the peak position and intensity ($\varepsilon = 560-640\ M^{-1}cm^{-1}$) of the latter are strongly solvent-dependent[10] (MeOH, EtOH, MeCN, $MeNO_2$, or Me_2SO). In keeping with the class II character,[9] the observed bandwidth of **2** (4620 cm^{-1} in $MeNO_2$) agrees well with the predicted value (4560 cm^{-1}). The electron coupling H_{AB} in **2**, as estimated by Equation (a) if the intra-

$$H_{AB} = [2.06\times 10^{-2}\ (\varepsilon\Delta\tilde{\nu}_{1/2}\tilde{\nu}_{max})^{1/2}]/r \qquad (a)$$

molecular metal–metal distance r is assumed to be about 3.03 Å, ranges from 1050 to 1200 cm^{-1}. Thus, H_{AB} in **1** is considerably greater than in **2**, and it appears that the difference between the two compounds is largely due to a modulation in H_{AB}.

From the infrared spectra of **1** and **2** useful information regarding the nature of acetate binding has been obtained. Complex **1** exhibits $\nu_{as}(CO_2^-)$ and $\nu_s(CO_2^-)$ vibrations at 1556 and 1409 cm^{-1}, respectively, which indicate that the two acetates are bridged in the same way. On the other hand, the single $\nu_{as}(CO_2^-)$ vibration at 1558 cm^{-1} but two $\nu_s(CO_2^-)$ vibrations at 1446 and 1402 cm^{-1} for **2** suggest the presence of both bridging and unidentate acetate ligands. We earlier reported[11] that in the heterobimetallic complex **3** three such bands are observed at

$[L^2Fe^{III}Ni^{II}(\mu\text{-}OAC)(OAC)(H_2O)](ClO_4)\cdot 2H_2O$ **3**

1575, 1430, and 1390 cm^{-1}. Furthermore, the crystal structure of **3** has shown[11] that, apart from the carboxylate bridge, one of the apical positions of Fe^{III} is occupied by the water molecule and that of Ni^{II} by the unidentate acetate ligand, and the Fe···Ni distance is 3.03 Å. Although we have not yet been able to determine the structure of **2**, it presumably has a structure similar to that of **3**.

The crystal structure of **1** has been determined.[12] The complex cation, shown in Figure 1, has a centrosymmetric structure;

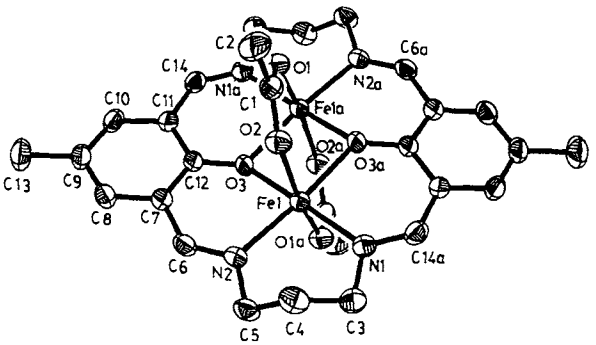


Figure 1. Structure of the cation in **1** (ORTEP representation). Selected bond lengths [Å] and angles [°]: Fe1–O3 2.028(2), Fe1–O3a 2.036(2), Fe1–O2 2.047(2), Fe1–O1a 2.061(2), Fe1–N1 2.139(2), Fe1–N2 2.142(2), Fe1···Fe1a 2.7414(8); O3-Fe1-O3a 95.17(6), N1-Fe1-N2 95.17(8), O3-Fe1-N1 175.45(8), O3a-Fe1-N2 171.27(8), Fe1-O3-Fe1a 84.83(6).

the center of inversion is at the middle of the $Fe_2(\mu\text{-}O)_2$ plane. Although the crystallographic symmetry in **1** indicates that the iron sites are equivalent and the compound is valence-delocalized, the possibility of a static disordering due to the superposition of an equal number of valence-trapped $Fe^{II}Fe^{III}$ and $Fe^{III}Fe^{II}$ cations or a dynamic disordering due to rapid electron transfer between the metal centers can not be ruled out.[13] Indeed, from a detailed analysis of anisotropic thermal parameters in $[(phen)_2Mn^{IV}(\mu\text{-}O)_2Mn^{III}(phen)_2](PF_6)_3\cdot MeCN$ (phen = 1,10-phenanthroline) it has been shown[13] that the two Mn ions are not chemically equivalent, even though they are related by a twofold rotation axis. In a $Fe^{III}Fe^{II}$ compound no significant Jahn–Teller distortion is expected for high-spin Fe^{III} (d^5 configuration) or Fe^{II} (d^6 configuration) ions. The small difference observed between the axial Fe–O bonds (average 2.054(7) Å) and equatorial Fe–O bonds (average 2.032(4) Å) is due to the different ligand donors. Clearly, when Jahn–Teller distortion is absent and the axial and equatorial ligands are different, it is not easy to establish unequivocally electron delocalization in a mixed-valence species from crystal structure alone. In our case, however, the vibrational behavior speaks against a possible disorder.

Variable-temperature Mössbauer spectra of **1** and **2** are shown in Figures 2 and 3, and the results are summarized in Table 1. A single quadrupole doublet observed for **1** at 293 K

Table 1. Mössbauer parameters for the complexes **1**–**3**.

Complex	T [K]	δ [$mm\,s^{-1}$] [a]	ΔE_Q [$mm\,s^{-1}$] [b]	Γ [$mm\,s^{-1}$] [c]	H [T] [d]

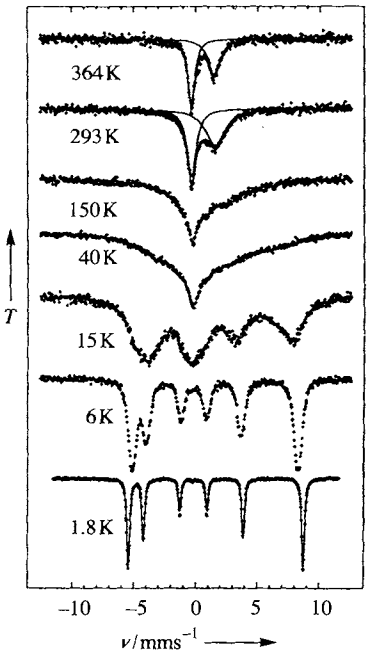

Figure 2. Mössbauer spectra of **1** (polycrystalline form) at the indicated temperatures. The solid lines represent the simulated spectra. T = relative transmission.

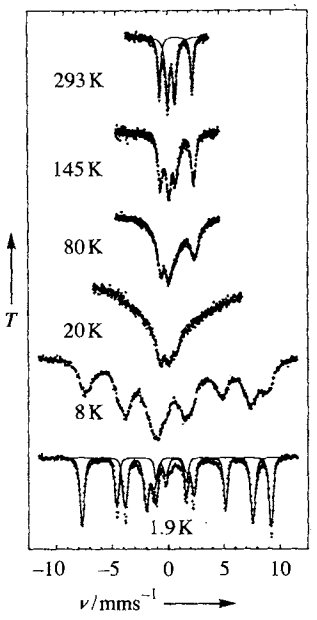

Figure 3. Mössbauer spectra of **2** (polycrystalline form) at the indicated temperatures. The solid lines represent the simulated spectra. T = relative transmission.

(and 364 K) has the δ and ΔE_Q values intermediate between those of high-spin $Fe^{III}Fe^{III}$ and $Fe^{II}Fe^{II}$ compounds with similar coordination environment. At lower temperatures line broadening occurs due to paramagnetic relaxation, and below 10 K easy orientation of the internal magnetic field relative to the principal axes of the electric field gradient (efg) removes degeneracy of the spin levels to give rise to six allowed ($\Delta m = \pm 1$) and two nominal, weakly allowed transitions ($\Delta m = \pm 2$) for the two equivalent $Fe^{2.5+}$ centers (Figure 2). Thus, over the entire temperature range, 1.8–364 K, the electron delocalization rate in **1** is faster than 10^{-7} s (Mössbauer timescale). By contrast, the Mössbauer spectrum of **2** at 293 K (Figure 3) exhibits two doublets for the discrete Fe^{II} and Fe^{III} sites, each of which split at 1.9 K to show their typical magnetic hyperfine features. The direction of the internal magnetic field at the $Fe^{2.5+}$ center of **1** and Fe^{2+} center of **2** turns out to be almost parallel to the principal axis of the efg tensor, the asymmetry parameter η being 0.1 and 0.5, respectively. From Table 1 it is evident that the δ and ΔE_Q values for the Fe^{III} center in **2** are greater than those in **3**, which emphasizes the weak electron coupling in **2**.

Magnetic susceptibilities of **1** and **2** have been measured in paraffin matrices in the range 4.5–300 K. As shown in Figure 4, the temperature dependence of the effective magnetic moments (μ_{eff}) of **2** can be fitted with the Heisenberg–Dirac–Van Vleck model ($\mathcal{H} = -2JS_1S_2$) with $J = 17(1)\ cm^{-1}$ and $g = 1.98(2)$. Ferromagnetic $Fe^{II}Fe^{III}$ systems are sparse.[6f] In the case of **1**, the μ_{eff} values remained practically constant [9.98(6) μ_B] from 300 to 70 K indicating a spin state of $S = 9/2$ ($\mu_{eff} = 9.95\ \mu_B$, $g = 2.00$). With further lowering of temperature the magnetic moment slowly increased to reach a peak (10.22 μ_B) at about 30 K and then rapidly decreased (9.24 μ_B) at 4.5 K.

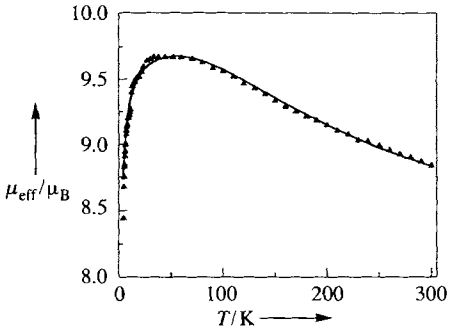

Figure 4. Experimental (▲) and theoretical (—) temperature dependence of effective magnetic moment (μ_{eff}) for **2** in paraffin matrix.

The electrochemical (cyclic voltammetry and differential pulse voltammetry) measurements of **1** in $MeNO_2$ have revealed that the reduction to $[Fe^{II}Fe^{II}]$ takes place reversibly ($E_{1/2} = -0.27$ V vs. Ag/AgCl), while the oxidation to $[Fe^{III}Fe^{III}]$ occurs irreversibly ($E_{pa} = 0.60$ V). For **2**, however, both the electron transfer processes are quasi-reversible ($E = -0.48$ V, $E = 0.44$ V). The large magnitude of the comproportionation constant ($K_c = 3.6 \times 10^{15}$) signifies considerable stability of the mixed-valence species over the isovalent species.

Experimental Section

1: $Pb(OAc)_2 \cdot 3H_2O$ (0.76 g, 2 mmol) and $Pb(NO_3)_2$ (0.66 g, 2 mmol) were dissolved in DMF (10 mL) and mixed with a solution of 2,6-diformyl-4-methylphenol (1.3 g, 8 mmol) in MeOH (60 mL). To the solution heated at reflux 1,3-diaminopropane (0.59 g, 8 mmol) diluted with MeOH (10 mL) was added. $[Pb(L^1H_2(NO_3)_2] \cdot 2H_2O$ [14], deposited as yellow crystals, were filtered off after 2 h (yield: 2.5 g, 80%). This compound (1.53 g, 2 mmol) was suspended in MeOH (100 mL) and stirred with $FeCl_3 \cdot 6H_2O$ (0.54 g, 2 mmol). Precipitated $PbCl_2$ was removed, and the filtrate, to which $NaClO_4$ (2 g) was added, was concentrated to obtain $[Fe(L^1H_2)(H_2O)Cl](ClO_4)_2 \cdot 2H_2O$ (yield: 1.2 g, 75%). The latter (0.74 g, 1 mmol) dissolved in MeCN (40 mL) was treated under N_2 with $Fe(ClO_4)_2 \cdot 6H_2O$ (0.36 g, 1 mmol) and NaOAc (0.49 g, 6 mmol). On slow addition of EtOH (60 mL) bright red crystals of **1** deposited, which were collected by filtration and recrystallized from MeCN/MeOH (1/2); yield: 0.58 g (80%). $C_{28}H_{32}ClN_4O_{10}Fe_2$; elemental analysis: found C 46.02, H 4.51, N 7.58, Fe 15.14%; calcd. C 45.92, H 4.37, N 7.65, Fe 15.26%. IR (KBr): $\tilde{\nu}$ = 1628s ν(C=N), 1556m $\nu_{as}(CO_2^-)$, 1409m $\nu_s(CO_2^-)$, 1090s, 620m $\nu(ClO_4^-)$ cm^{-1}; UV/Vis ($MeNO_2$): λ_{max} (ε) = 370 (9980), 480 (2300), 1060 nm ($1250\ M^{-1}cm^{-1}$).

2: $[Fe_2(L^2H)_2(\mu\text{-}OH)_2](ClO_4)_2$ [15] (0.58 g, 0.5 mmol) was dissolved in a mixture of MeCN (25 mL) and EtOH (60 mL), to which a solution of NaOAc (0.33 g, 4 mmol) in MeOH (20 mL) had been added. The solution was then treated under N_2 with $Fe(ClO_4)_2 \cdot 6H_2O$ (0.36 g, 1 mmol), and the bulk of the solvent (about 100 mL) removed in a stream of N_2. Cooling at −10 °C afforded blue-violet crystals of **2** (yield: 0.60 g, 75%). $C_{28}H_{46}ClN_4O_{13}Fe_2$; elemental analysis: found C 42.58, H 5.75, N 6.92, Fe 14.22%; calcd. C 42.33, H 5.80, N 7.05, Fe 14.11%. IR (KBr): $\tilde{\nu}$ = 3400br ν(OH), 3245m ν(NH), 1558m $\nu_{as}(CO_2^-)$, 1446m, 1402m $\nu_s(CO_2^-)$, 1095s, 621m $\nu(ClO_4^-)$ cm^{-1}; UV/Vis ($MeNO_2$), λ_{max} (ε) = 285 (8650), 325sh (3000), 510 (2600), 1160 nm ($640\ M^{-1}cm^{-1}$).

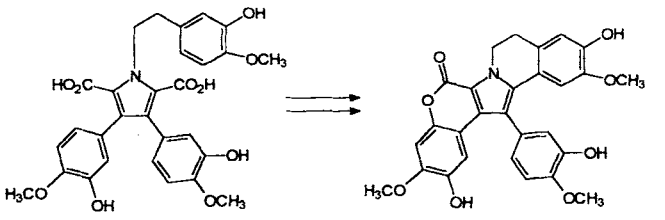
Biomimetic Synthesis of Lamellarin G Trimethyl Ether**

Alexander Heim, Andreas Terpin, and Wolfgang Steglich*

Lamellarin G (**2**) belongs to a group of marine natural products that contain a 5-oxa-6b-aza-dibenzo[*a*,*i*]fluoren-6-one skeleton. Up to now, 16 members of this class of alkaloids are known from ascidians and prosobranch molluscs.[1] Some of



1 **2**

these compounds inhibit cell division [1a] or show cytotoxic and immunomodulatory activity.[1c] However, hitherto, no synthesis of this type of compound has been published.

Biogenetically, compounds like lamellarin G (**2**) can be derived from 3,4-diaryl-1-(2-arylethyl)-2,5-pyrrole dicarboxylic acids (e. g. **1**) by two consecutive oxidative cyclizations. Since compounds of type **1** can be easily obtained from 3-arylpyruvic acids,[2, 3] we tried to use a suitable pyrrole dicarboxylic acid for the synthesis of lamellarin G trimethyl ether (**8**). The key step in our one-pot synthesis is the oxidative coupling of two molecules of 3-(3,4-dimethoxyphenyl)pyruvic acid (**3**) to give the 1,4-diketone **4**, which was not isolated but allowed to react directly with the 2-phenylethylamine **5** to form the pyrrole dicarboxylic acid **6** in 62% yield (Scheme 1).

Treatment of **6** in refluxing ethyl acetate with one equivalent of lead(IV) acetate afforded lactone **7** in 71% yield.[4] Interestingly, only one regioisomer was obtained, which showed two singlets for the coumarin protons at $\delta = 6.38$ and 6.61 in the ^1H NMR spectrum in accord with the proposed structure. In addi-

[**] Alkaloids from Marine Organisms, Part 2. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 1: ref. [3].

tion, one of the methoxy resonances was shifted upfield to $\delta = 3.28$ as a result of shielding of the methoxy group by the neighboring phenyl ring.[1b] This group occupies a nearly orthogonal position, which would also explain the absence of dilactone formation after closure of the first lactone ring.

In the final synthetic step an intramolecular Pd-catalyzed Heck reaction was applied for the formation of the isoquinoline ring. This reaction afforded lamellarin G trimethyl ether (**8**) in 74% yield. To our knowledge, this is the first example of a Heck reaction in which after oxidative addition, the Pd^{II} intermediate fragments by elimination of CO_2. This method delivers the cyclization product **8** in higher yields than the conventional Heck reaction with the free pyrrole obtained by decarboxylation of **7**.

This short sequence (three steps) affords lamellarin G trimethyl ether (**8**) in 33% overall yield. Application of our method to the synthesis of other lamellarins, especially to those with unsymmetrically substituted aryl groups, is in progress. Since lamellarins of type **2** are easily dehydrogenated to the corresponding dihydroisoquinoline derivatives[1c] by action of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ), compounds of the latter type can also be obtained by our procedure.

Experimental Section

6: *n*BuLi (3.56 mL of a 2.5 M solution in hexane, 2.0 equiv) was added dropwise to a stirred solution 3-(3,4-dimethoxyphenyl)pyruvic acid (**3**) (1.0 g, 4.46 mmol) in dry THF (80 mL) at −78 °C. After the mixture had been stirred for 20 min, a solution of iodine (0.56 g, 2.23 mmol, 0.5 equiv) in THF (20 mL) was added dropwise. The reaction mixture was allowed to warm up to room temperature, stirred for another hour, and then 2-(2-bromo-4,5-dimethoxyphenyl)ethylammonium bromide [6] (**5**) (1.0 g, 2.93 mmol) was added and the resulting solution was stirred for 12 h over molecular sieves (4 Å). The cloudy solution was quenched with 2 M NaOH. The layers were separated, the aqueous phase was washed with ethyl acetate (3 × 30 mL), acidified with concentrated HCl to pH 4, and extracted with ethyl acetate (3 × 30 cm^3). The combined organic layers were dried (Na_2SO_4), filtered, and the organic solvent was removed in vacuo to give 1.9 g of crude material, which was recrystallized from methanol to yield **6** as a yellowish powder (1.39 g, 62%). M.p. 201 °C; UV/Vis (CH_3OH): λ_{max} (qualitative, nm) = 208, 288; ^1H NMR (300.13 MHz, [D$_6$]DMSO): δ = 10.77 (s, br., 2H), 7.06 (s, 1H), 6.74 (d, ^3J = 7.9 Hz, 2H), 6.61 (s, 1H), 6.51 (m, 4H), 4.89 (t, ^3J = 6.5 Hz, 2H), 3.73 (s, 3H), 3.69 (s, 3H), 3.67 (s, 6H), 3.51 (s, 6H), 3.06 (t, ^3J = 6.7 Hz, 2H); ^{13}C NMR (75.47 MHz, [D$_6$]DMSO): δ = 162.66 (2 COOH), 148.56 (C-OCH_3), 148.37 (C-OCH_3), 147.50 (2 C-OCH_3), 147.44 (2 C-OCH_3), 129.48 (2 quart. C), 129.26 (quart. C), 127.18 (2 quart. C), 124.77 (2 quart. C), 122.80 (2 CH), 115.71 (quart. C), 114.84 (2 CH), 113.82 (CH), 113.75 (CH), 110.88 (2 CH), 56.08 (OCH_3), 55.52 (OCH_3), 55.47 (2 OCH_3), 55.34 (2 OCH_3), 45.88 (N-CH_2), 37.57 (CH_2); IR (KBr): $\tilde{\nu}$ (cm^{-1}) = 3412 (m, br.), 2998 (w), 2937 (m, br.), 1714 (s), 1671 (m), 1350 (m), 1510 (m, br.), 1465 (m), 1440 (m), 1426 (m), 1385 (w), 1347 (m), 1256 (s), 1231 (m), 1218 (w), 1192 (m), 1165 (w), 1028 (m); MS (EI, 70 eV) *m/z* (%) = 671 (0.63) [M^+(^{81}Br)], 669 (0.59) [M^+(^{79}Br)], 627 (2) [M^+(^{81}Br) − CO_2], 625 (2) [M^+(^{79}Br) − CO_2], 583 (10) [M^+(^{81}Br) − 2 CO_2], 581 (10) [M^+(^{79}Br) − 2 CO_2], 503 (29) [583 − Br], 502 (100) [581 − Br]; elemental analysis calcd for $C_{32}H_{32}NO_{10}Br$ (670.51): C 57.32, H 4.81, N 2.08, Br 11.91; found C 57.16, H 4.88, N 2.09, Br 11.88.

7: **6** (130 mg, 0.19 mmol) was heated to reflux with lead(IV) acetate (84.2 mg, 0.19 mmol) in ethyl acetate (40 mL) for 1 h, and the solution turned to light yellow. The reaction was monitored by TLC. In the case of incomplete conversion, further $Pb(OAc)_4$ was added and the reaction time was prolonged until the reaction had reached completion. The reaction mixture was allowed to cool to room temperature, filtered, washed with 20% citric acid, and dried (Na_2SO_4). The solvent was removed and the crude product was recrystallized from methanol to yield **7** (90 mg, 71%) as a yellow powder. M.p. 297 °C; UV/Vis (CH_3OH): λ_{max} (qualitative, nm) = 206, 288, 326; ^1H NMR (600.13 MHz, [D$_6$]DMSO): δ = 12.42 (s, br, 1H), 7.06 (d, ^3J = 8.1 Hz, 1H), 7.03 (s, 2H), 6.85 (s, 1H), 6.83 (d, ^3J = 8.1 Hz, 1H), 6.61 (s, 1H), 6.38 (s, 1H), 5.08 (t, ^3J = 6.4 Hz, 2H), 3.79 (s, 3H), 3.77 (s, 3H), 3.71 (s, 3H), 3.71 (s, 3H), 3.57 (s, 3H), 3.28 (s, 3H), 3.11 (d, 2H); ^{13}C NMR (150.92 [D$_6$]DMSO): δ = 174.66 (COOH), 161.64 (-COO-), 154.35 (*C*-OCO), 149.18 (*C*-OCH_3), 148.75 (*C*-OCH_3), 148.60 (*C*-OCH_3), 148.52 (*C*-OCH_3), 148.26 (*C*-OCH_3), 145.68 (*C*-OCH_3), 145.41 (quart. Synthesis and Coordination Chemistry of Fluorine-Containing Cages**

Herbert Plenio,* Ralph Diodone, and Dirk Badura

Following a structural data bank survey in the early 1980s Glusker, Murray-Rust et al.[1a] proposed that in the solid state, covalently bonded fluorine can function as a donor to hard acceptors such as alkali and alkaline earth metal ions.[1] We recently demonstrated that this proposal is correct, since an interaction occurs not just in the solid state, but also in solution and that the contacts between the metal ion and fluorine result

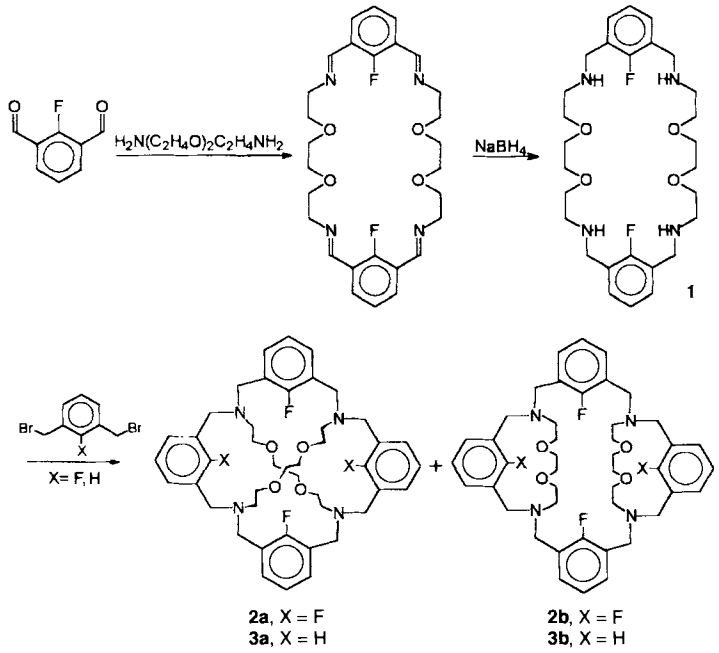
in a significant stabilization of the complexes.[2, 3] To date, all the ligands we have prepared contain only one fluorine atom capable of coordinating to a metal center; the other metal coordination sites are occupied by oxygen donor functions. If the concept of covalently bonded fluorine atoms functioning as a donor to metal centers is correct, it implies that it should be possible with the appropriate ligands to synthesize metal complexes in which the coordination sphere of the metal ion is dominated by fluorine donor atoms. In such complexes the metal–fluorine interactions should contribute significantly to the overall stability of the complex. Macrocyclic ligands appear to offer the best opportunity to achieve the aforementioned goals, and we report herein on the synthesis of such ligands as well as on the structure of a Cs^+ complex.

A novel cage compound can be readily synthesized in three steps from 2-fluoro-isophtaldialdehyde[4] and 1,8-diamino-3,6-dioxaoctane (Scheme 1). Condensation of dialdehyde and diamine results in the formation of the (2 + 2) addition product



Scheme 1. Synthesis of the fluorine-containing cage compounds **2** and **3**.

(together with some polymeric material), which, after reduction with $NaBH_4$ gives the tetraamine **1** in near quantitative yield. In contrast, the corresponding fluorine-free crown ether cannot be prepared from isophtaldialdehyde; regardless of the reaction conditions only polymeric condensation products are obtained. In the last synthetic step the tetraamine **1** is treated under high dilution conditions with 1,3-bis(bromomethyl)-2-fluorobenzene,[5] which results in the cross product **2a** and the parallel-product **2b** in equal yield (both 20%).[6] The separation of the two isomers is very simple since **2b** can be extracted with petroleum ether. Analogously, reaction of **1** with 1,3-bis(bromomethyl)benzene affords the ligands **3a** and **3b**.

In order to determine the metal–fluorine distances, a single-crystal X-ray structure analysis of $(Cs^+ \cdot \mathbf{2a})(CF_3SO_3^-)$ (Figure 1) was carried out.[7] The most remarkable feature of this structure is the $F_4O_3N_1$ coordination sphere of Cs^+. All four fluorine atoms are coordinated to the Cs^+ ion; however, the Cs(1)–O(1) separation of 473.8 pm is too large to imply any significant interaction. Investigation of the Cs^+ ion bonding

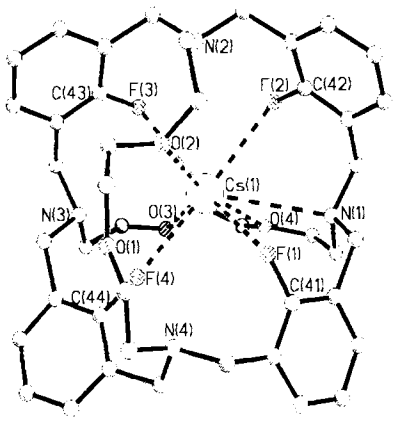


Figure 1. Crystal structure of the complex cation of $(Cs^+ \cdot \mathbf{2a})(CF_3SO_3^-)$ (H atoms are omitted for clarity). Selected bond lengths [pm] and angles [°]: Cs(1)–F(4) 284.3(3), Cs(1)–F(2) 304.7(3), Cs(1)–O(2) 305.4(3), Cs(1)–F(3) 308.2(2), Cs(1)–O(4) 311.0(3), Cs(1)–O(3) 322.2(3), Cs(1)–F(1) 337.3(3), Cs(1)–N(1) 344.6(4), F(1)–C(41) 135.5(5), F(2)–C(42) 136.9(6), F(3)–C(43) 135.9(5), F(4)–C(44) 135.0(4); C(41)-F(1)-Cs(1) 111.8(2), C(42)-F(2)-Cs(1) 108.4(2), C(43)-F(3)-Cs(1) 112.1(2), C(44)-F(4)-Cs(1) 161.0(2).

shows three of the four shortest metal–ligand interactions (including the two shortest) to be Cs–F bonds. The Cs(1)–F(4) distance (284.3(2) pm) is more than 20 pm shorter than the next shortest Cs–F distance (Cs(1)–F(2) 304.7(3) pm). This is a remarkable result, since as far as we know there are only six reported structures in which a Cs–F separation of less than 330 pm is found[8] (the shortest distance is 309.5 pm[8d, 9]). The significance of this close Cs(1)–F(4) contact is highlighted by comparisons to substances containing Cs–O bonds. We are aware of only four structures in which Cs–O separations of less than 300 pm are reported,[10] of these the shortest Cs–O distance is 285.5 pm,[10b] which is thus only slightly longer than the Cs(1)–F(4) bond described here.

The contribution of each donor function to the overall bonding of a metal ion can be assessed by means of the Shannon–Brown valence bond sums s.[11] For $Cs^+ \cdot \mathbf{2a}$ it is calculated that $s(F) = 0.065 + 0.127 + 0.118 + 0.20 = 0.51$ [for F(1) + F(2) + F(3) + F(4)] and $s = 0.17 + 0.151 + 0.119 = 0.44$ [for O(2) + O(3) + O(4)] and $s = 0.08$ [for N(1)] with $\sum s = 1.03$,[12] thus demonstrating that the bonding contribution from F coordination is significantly greater than that resulting from O coordination.

Furthermore, it is noteworthy that the extremely short Cs(1)–F(4) bond is characterized by an almost linear coordination of the metal ion [Cs(1)-F(4)-C(44) 161.0(2)°]. In the metal complexes of the partially fluorinated macrocycles previously described this has not been observed; the typical M^+-F-C bond angles lie in the range 80–110°, the angles around the other fluorine atoms F(1), F(2), and F(3) in $Cs^+ \cdot \mathbf{2a}$ are towards the higher end of this range.

Owing to the short Cs^+–F contacts in the solid state, a ^{133}Cs–^{19}F coupling was expected in the NMR spectrum.[13] The ^{19}F NMR spectrum of $(Cs^+ \cdot \mathbf{2a})(CF_3SO_3^-)$ displays a broad singlet at room temperature. This signal splits into two when the temperature is reduced to 223 K, and at 203 K a complicated pattern of at least eight different, very broad ($\nu_{1/2} = 50$–150 Hz) signals is observed; thus it is not possible to detect a ^{133}Cs–^{19}F coupling (Figure 2). The ^{19}F NMR chemical shifts (in [D_5]pyridine) for the different metal complexes of **2a** are very characteristic: $\delta = -119.33$ (free ligand), -119.34 (Li^+), -119.36 (Na^+), -123.46 (K^+), -122.16 (Rb^+), and -118.02 (Cs^+).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3601-0157 $ 15.00+.25/0

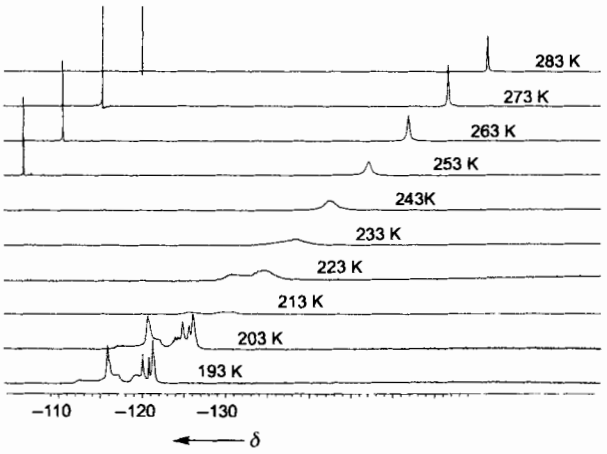

Figure 2. ^{19}F NMR spectra of $(Cs^+ \cdot \mathbf{2a})(CF_3SO_3^-)$ at different temperatures in $[D_6]$acetone (top left: signals for $(CF_3SO_3^-)$).

In order to better assess the role of fluorine as a donor, stability constants were determined for the complexes of **2a** with picrate extraction experiments: $\log K(M+) = 4.91$ (Li^+), 5.68 (Na^+), 5.48 (K^+), 5.72 (Rb^+), 5.62 (Cs^+). The narrow range of values obtained was unexpected, since with the exception of the Li^+ complex, all the complexes are more or less equally stable.

In summary, a single-crystal X-ray structure analysis of $(Cs^+ \cdot \mathbf{2a})(CF_3SO_3^-$ shows that all four fluorine atoms of the ligand are coordinated to the Cs^+ ion. This demonstrates how important fluorine donation is in stabilizing the bonding of the Cs^+ ion in this ligand. The $F_4O_3N_1$ coordination of the cation demonstrates that under favorable conditions, fluorine can play a more important role than oxygen in the coordination of metal ions. This suggests the possibility of preparing complexes in which metal ions are coordinated solely to fluorine centers.

Experimental Section

All NMR spectra were measured in $CDCl_3$ unless otherwise stated.

1: A solution of 2-fluoroisophtaldialdehyde (2.16 g, 14.2 mmol) in CH_3CN (100 mL) was added dropwise to 1,8-diamino-3,6-dioxaoctane (2.10 g, 14.2 mmol) in CH_3CN (700 mL), and the solution was stirred at room temperature for 17 h. The colorless precipitate was collected by filtration, dried under vacuum on an oil pump, and used without further purification. Crude yield: 3.15 g (5.96 mmol, 84%); MS: *m/z* (%): 528 (M^+, 100%); ^1H NMR: $\delta = 3.63$ (s, 8H, NCH_2), 3.75 (s, 16H, OCH_2), 7.14 (t, $J = 7.7$ Hz, 2H, ArH), 7.97 (t, $J = 7.3$ Hz, 4H, ArH), 8.50 (s, 2H, ArH); ^{19}F NMR: $\delta = -131.99$ (t, $J = 6.9$ Hz). The tetraimine was suspended in ethanol (200 mL), $NaBH_4$ (3.25 g, 85.9 mmol) was added, and the mixture stirred at room temperature for 12 h. The solvent was removed and the colorless residue hydrolyzed with H_2O (80 mL). The aqueous layer was extracted with CH_2Cl_2, the organic phases collected, dried with $MgSO_4$. The solvents were removed and the product was dried under vacuum on an oil pump. Yield: 2.12 g (3.95 mmol, 56%). m.p. 86 °C, MS: *m/z* (%): 537 (M^+, 34%). ^1H NMR: $\delta = 1.84$ (s, 4H, NH), 2.78 (t, $J = 5.1$ Hz, 8H, NCH_2), 3.60 (m, 16H, OCH_2), 3.80 (s, 8H, $(ArCH_2)$, 6.98 (t, $J = 7.5$ Hz, 2H, ArH), 7.21 (t, $J = 7.3$ Hz, 4H, ArH); ^{13}C NMR: $\delta = 47.12$ (d, $J(C,F) = 3.9$ Hz), 48.61, 70.31, 70.47, 123.42 (d, $J(C,F) = 4.0$ Hz), 127.08 (d, $J(C,F) = 16.2$ Hz), 128.87 (d, $J(C,F) = 4.9$ Hz), 159.43 (d, $^1J(C,F) = 245.7$ Hz); ^{19}F NMR: $\delta = -126.55$ (t, $J = 6.9$ Hz).

2a, **2b**: To a stirred solution of K_2CO_3 (0.95 g, 6.87 mmol) and KCF_3SO_3 (0.27 g, 1.43 mmol) in CH_3CN (1000 mL) under reflux, solutions of 1,3-bis(bromomethyl)-2-fluorobenzene (0.79 g, 2.80 mmol) in CH_3CN (50 mL) and $F_2N_4O_4$ (0.75 g, 1.40 mmol) in CH_3CN (50 mL) were slowly added simultaneously (ca. 3 mL h^{-1}). Afterwards the solution was heated to reflux for 1 h before the solvents were removed. The residue was extracted with CH_2Cl_2, the organic layer washed with water, collected, dried over $MgSO_4$, and the solvents removed. The residue was chromatographed on a silica column (cyclohexane/$HNEt_2$, 20/1; fractions between $R_f = 0.2-0.1$). After removal of the solvent the solid was extracted with boiling 60/70 petroleum ether; the solution contained **2b**, whereas **2a** remained as an insoluble residue, which was recrystallized from ethyl acetate. **2a**: Yield: 0.22 g (0.28 mmol, 20%), m.p. 182 °C. MS: *m/z* (%): 777 (M^+, 25%). ^1H NMR: $\delta = 2.57$ (t, $J = 5.4$ Hz, 4H, NCH_2), 3.18 (s, 4H, OC_2H_4O), 3.25 (t, $J = 5.4$ Hz, CH_2O), 3.54 (d, $J = 12.9$ Hz, 4H, $ArCH_2$) 3.73 (d, $J = 12.9$ Hz, 4H, $ArCH_2$), 6.93 (t, $J = 7.5$ Hz, 4H, ArH), 7.15 (t, $J = 7.3$ Hz, 8H, ArH); ^{13}C NMR: $\delta = 52.38$, 52.57, 69.21, 69.84, 122.73, 126.09 (d, $J(C,F) = 15.3$ Hz), 130.38 (d, $J(C,F) = 4.4$ Hz), 160.92 (d, $^1J(C,F) = 258.1$ Hz); ^{19}F NMR: $\delta = -120.09$ (br, s).

Recrystallization of **2b** from ethyl acetate gave fine colorless crystals. **2b**: Yield: 0.20 g (0.26 mmol, 19%), m.p. 224 °C, MS: *m/z* (%): 777 (M^+, 17%). ^1H NMR: $\delta = 2.74$ (b, 4H, NCH_2), 3.24 (sb, 4H, CH_2O), 3.48 (t, $J = 4.2$ Hz, OCH_2), 3.53 (s, 4H, $ArCH_2$), 3.67 (sb, 4H, $ArCH_2$), 6.83 (t, $J = 7.5$ Hz, 1H, ArH), 6.96 (t, $J = 7.5$ Hz, 1H, ArH), 7.07 (t, $J = 7.1$ Hz, 2H, ArH), 7.30 (t, $J = 7.1$ Hz, 2H, ArH); ^{13}C NMR: $\delta = 50.23$, 53.73, 55.21, 67.38, 70.38, 122.29 (d, $J(C,F) = 4.3$ Hz), 123.19 (d, $J(C,F) = 4.1$ Hz), 126.08 (d, $J(C,F) = 14.9$ Hz), 126.86 (d, $J(C,F) = 13.8$ Hz), 129.03 (d, $J(C,F) = 4.7$ Hz), 130.72 (d, $J(C,F) = 4.7$ Hz), 159.84 (d, $J(C,F) = 252.1$ Hz), 160.54 (d, $^1J(C,F) = 249.8$ Hz); ^{19}F NMR: $\delta = -121.39$ (vb, 2F), −119.97 (s, 2F).

$(Cs^+ \cdot \mathbf{2a})(CF_3SO_3^-)$: Equimolar amounts of $CsCF_3SO_3$ and **2a** were dissolved in acetone, and the solvent was removed under vacuum. Single crystals of $(Cs^+ \cdot \mathbf{2a})(CF_3SO_3^-)$ were obtained by recrystallization of the complex from ethyl acetate. ^1H NMR ($[D_5]$pyridine): $\delta = 2.62$ (t, $J = 4.6$ Hz, NCH_2, 8H), 3.32 (s, 8H), 3.41–3.64 (m, 24H), 7.18 (t, $J = 7.3$ Hz, ArH, 4H), 7.31 (t, $J = 7.3$ Hz, ArH, 8H); ^{13}C NMR ($[D_5]$pyridine): $\delta = 53.91$, 54.56, 69.18, 70.53, 124.39 (d, $J(C,F) = 4$ Hz), 125.57 (d, $J = 16$ Hz), 132.85 (d, $J(C,F) = 5$ Hz), 160.04 (d, $^1J(C,F) = 245$ Hz).

^{19}F NMR spectra of the complexes with the other metal ions were determined in solutions of the ligand in $[D_5]$pyridine, which had been treated with an excess of metal triflate.

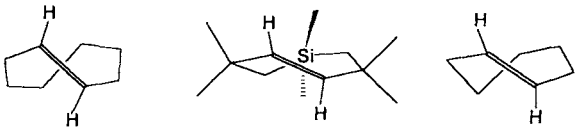
A Stable Hetero-*trans*-cyclopentene**

Adolf Krebs,* Karl-Ingo Pforr, Walter Raffay, Bernd Thölke, Wilfried A. König,* Ingo Hardt, and Roland Boese*

Trans-cyclooctene **1** is the smallest unsubstituted *trans*-cycloalkene that is stable at room temperature.[1] *Trans*-cycloheptene **2** can be generated at low temperatures, observed by spectroscopy, and trapped; however, it rapidly isomerizes at room temperature to give *cis*-cycloheptene.[2] *Trans*-cycloheptenes that are isolable at room temperature can be obtained if one methylene group in **2** is replaced by a larger heteroatom, and thus the ring strain is reduced.[3] Moreover, introduction of four methyl groups in the allylic positions should decrease the tendency towards dimerization[3] and increase the barrier to *trans*–*cis* isomerization.



1 **3** **2**

Therefore, we synthesized *trans*-1,1,3,3,6,6-hexamethyl-1-sila-4-cycloheptene **3** by the following route (Scheme 1): Treatment of the commercially available bromoalcohol **4** with $(CH_3)_2SiCl_2$ afforded the dibromosiloxane **5**, which on reaction with lithium yields the diol **6**.[4] After oxidation to give the dicarboxylic acid[5] and its esterification, the seven-membered ring is closed by an acyloin condensation. Reduction of the silylated acyloin **7** with $LiAlH_4$ gave the *trans*-1,2-diol **8**, whereas direct reduction of the unsilylated acyloin with $LiAlH_4$ yielded only the corresponding *cis*-diol. Corey–Winter elimination of the thiocarbonate **9** under carefully controlled conditions afforded the *trans*-cycloalkene **3**.[6]

Compound **3** is a liquid at room temperature, but crystallizes at lower temperatures; therefore it was possible to carry out an X-ray structure analysis at −148 °C.[7] In these crystals **3** has C_1 symmetry. Remarkable is the C–C=C–C torsion angle of only 130.97°; it is nearly 9° smaller than in the corresponding carbocyclic eight-membered ring derivative, *trans*-3,3,8,8-tetramethyl-1-cyclooctene (139.68°).[8] Thus, of the nonbridged *trans*-cycloalkenes that are isolable at room temperature **3** exhibits the largest deformation of the double bond. In contrast, the H–C=C–H torsion angle in **3** (173.1°) and the C–C=C angles (121°) do not differ very much from normal values. The C_1 symmetry of **3** and the large twist of the double bond are clearly evident in Figure 1. The length of the C–C double bond is, despite of the large ring strain, normal (133 pm), whereas the Si–C2(C7) (191 pm) and the C2–C3 (C6–C7) bonds (156 pm) are lengthened considerably. Ab initio calculations for **3** with the program GAUSSIAN 92[9] at the 6-31G** level gave struc-

tural parameters that were consistent with the experimental ones.

The *trans*-silacycloheptene **3** is quite stable thermally (the half life at 123 °C is about 5.7 d); under these conditions it isomerizes to the corresponding *cis* compound. With oxygen **3** reacts slowly. The ^{1}H NMR spectrum (250 MHz) shows two singlets for the methyl groups at carbon, one singlet for the methyl groups at silicon, one singlet for the olefinic protons, and an AB system for the methylene groups; at higher (up to 100 °C) and lower (−90 °C) temperatures the ^{1}H NMR spectrum does not change. The fact that only one signal is observed for the methyl groups at silicon even at low temperatures, indicates that the barrier to inversion of the $Si(CH_3)_2$ group is low. On the other hand, the ^{1}H NMR spectrum proves that **3** is chiral and has a high barrier to racemization. An experimental determination of the barrier to racemization is not possible, because **3** isomerizes faster to the corresponding *cis* compound. The enantiomers of **3** were separated by gas chromatography on a capillary column, which was coated with the chiral phase 2,6-dimethyl-3-pentyl-β-cyclodextrin.[10] Preparative separations[11] yielded fractions with an enantiomeric excess of 58%; by extrapolation a specific rotation of $[\alpha]_{589}^{20} = -296$ was calculated for the pure (−)-enantiomer.

In the reaction with phenylazide, a sterically not demanding 1,3-dipole, **3** is significantly more reactive than *trans*-cyclooctene **1**: compound **3** adds phenylazide about 160 times faster than **1**.[12] Furan reacts with **3** in a Diels–Alder addition.

To the best of our knowledge **3** is the most strained non-bridged *trans*-cycloalkene that can be isolated in pure form at room temperature. Its relatively high kinetic stability suggests that even more strained *trans*-cycloalkenes of similar substitution pattern can be isolated.

Aggregation and Redox-Disproportionation in Tripodal Indium and Thallium Amides: First Characterization of Mixed-Valent M^I/M^{II} Compounds (M = In, Tl)**

Konrad W. Hellmann, Lutz H. Gade,* Alexander Steiner, Dietmar Stalke, and Frank Möller

Dedicated to Wilhelm Gade on the occasion of his 70th birthday

The heavy post transition metals (groups 11–15) display forms of intra- and intermolecular interactions that lie beyond the established paradigms of chemical bonding. The nature of the attractive interaction between formally closed-shell heavy metal atoms with d^{10} or $d^{10}s^2$ configurations has been the subject of several systematic investigations during the past decade.[1–3] Most recently the forms of aggregation observed in the solid-state structures of Tl^I compounds has been the focus of research efforts.[4, 5] Thus, in contrast to the structural patterns displayed by molecular alkali metal compounds in which electrostatic ligand–metal interactions dominate, the analogous derivatives of the heavy monovalent group 13 metals are expected to display different forms of aggregation which are in part based upon weak metal–metal attractions.

Among the examples of $Tl^I \cdots Tl^I$ interactions we note that such aggregation by metal atoms has been reported recently by Veith et al. for the dimeric thallium amide $[CH_3Si\{N(Tl)tBu\}_3]_2$.[6] The tripodal amido ligands of the type $[CH_3C(CH_2NR)_3]^{3-}$ introduced by us[7] provided the opportunity to study this aspect more closely, particularly in light of the restrictions on the conformational space enforced by the ligand

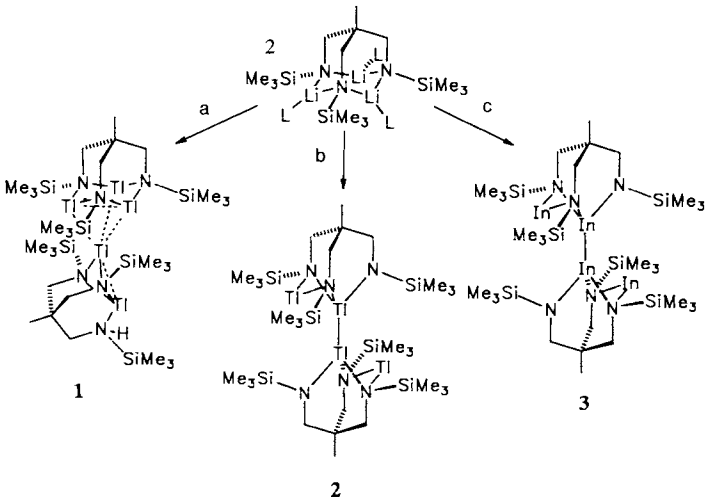
framework. Moreover, the nature of previously observed redox disproportionations involving Tl^I and In^I was of particular interest. To this end, transmetalations of the previously characterized tripodal lithium amides $[H_3CC\{CH_2N(Li)SiMe_3\}_3]_2$[7] with TlCl and InCl were carried out (Scheme 1).



Scheme 1. The metal exchange reactions and redox disproportionations that generate compounds **1**–**3**; L = coordinated solvent: dioxane or thf; a) TlCl/dioxane, 3 h; b) TlCl/thf, 3 d; c) InCl/dioxane, 1 h.

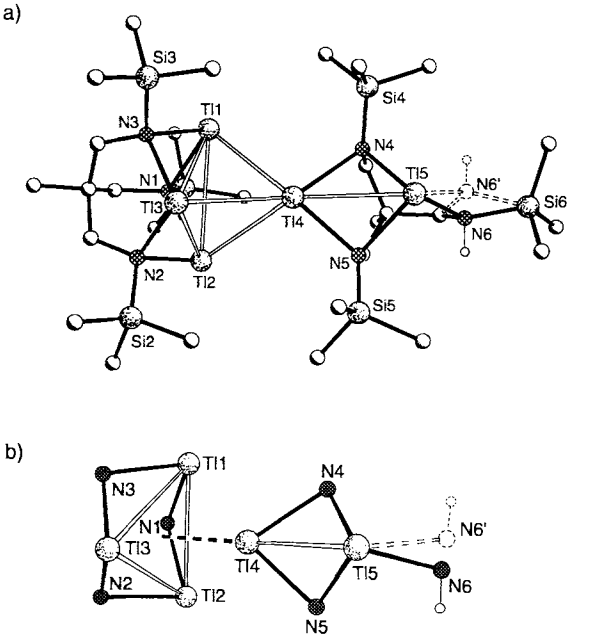


Figure 1. a) Molecular structure of **1** in the solid state and b) the thallium–nitrogen core of **1**; selected bond lengths [Å] and angles [°] (those marked with an asterisk are average values): Tl1–Tl2 3.707(3), Tl1–Tl3 3.837(3), Tl2–Tl3 3.756(3), Tl4–Tl1 3.409(3), Tl4–Tl2 3.541(3), Tl4–Tl3 3.479(3), Tl4–Tl5 3.403(3), Tl–N 2.43* (2.39(1)–2.49(1)), Tl5–N6 2.62(2); Tl1-Tl4-Tl5 142.20(5), Tl2-Tl4-Tl5 148.99(3), Tl3-Tl4-Tl5 131.31(6), Tl4-Tl5-N6 109.1(7).

When a solution of $[H_3CC\{CH_2N(Li)SiMe_3\}_3(dioxane)_3]$[8] was stirred with TlCl in dioxane for 3 h thallium metal precipitated; work up of the supernatant deep red solution afforded a red solid in 65–70% yield the analytical data, in particular the Tl analysis, of which were consistent with its formulation as $[\{H_3CC(CH_2NSiMe_3)_3\}_2(H)Tl_5]$. A complete metal exchange had thus not taken place, and the presence of a ν(N–H) band in the IR spectrum of the material (3338 cm^{-1}) indicated that at least one of the amido functions had been converted to an NH-amino function. The ^1H NMR spectra recorded between 290 and 190 K were consistent with the presence of two different species both of which apparently undergo several exchange processes.[9] The nature of the reaction product could only be determined by single-crystal X-ray structure analysis (Figure 1), which confirmed the above-mentioned characteristics and established its formulation as $[\{H_3CC(CH_2NSiMe_3)_3\}_2(H)Tl_5]$ (**1**).[10]

The thallium amide **1** proved to have a very intriguing solid-state structure in which a trimetalated and a dimetalated fragment aggregate in a cluster-type fashion. The central structural unit is the Tl_5 "core", which adopts the geometry of a spiked tetrahedron with Tl4 linking the units of the aggregate. The nitrogen-donor function at N6 is converted to an amino function, as evidenced by the Tl–N distance d(Tl5–N6) = 2.62(3) Å), which is larger than those in the amidothallium units [d_{av}(Tl–amido-N) = 2.43 Å], and the slight pyramidalization of N6 [N6 is located 0.29 Å below the plane defined by the three neigboring atoms]. It should be noted that the expected orientation of the lone pair of electrons at Tl4 (if at all stereochemically active[11]) is towards the metal triangle defined by Tl1–Tl3 (Figure 1b). There are four amido-bridged Tl–Tl contacts [Tl1–Tl2, Tl2–Tl3, Tl1–Tl3, d(Tl–Tl) = 3.7–3.8 Å; Tl4–Tl5 d(Tl–Tl) = 3.403(3) Å] and three unsupported metal–metal contacts [Tl1–Tl4 3.409(3), Tl2–Tl4 3.541(2), Tl3–Tl4 3.479(3) Å], which are close to the shortest Tl–Tl distances in α-thallium metal (3.408 and 3.457 Å).[12] Such short metal–metal contacts have been previously noted for several Tl^I compounds[13] (as well as for other closed-shell heavy metal species) and their nature has been the subject of some debate during the past five years.[5, 14] In view of the structure of the Tl_5 aggregate in **1**, it is fair to assume a weak attractive interaction, most probably primarily dispersive in nature, a notion which would be compatible with the theoretical explanations put forward to date.

The precipitation of Tl metal in the course of the transmetalation, and the observation that a complete thermal demetalation with concomitant generation of the free amine $H_3CC(CH_2NHSiMe_3)_3$ could be achieved, suggested that a Tl^{II}-radical species, which was generated in the redox disproportionation of Tl^I, abstracted a hydrogen atom from the solvent, generating the partially "protonated" amide **1**.[15] This notion of the presence of Tl^{II} species found additional support through the isolation and complete characterization of a minor component **2** (5–10%) in these reaction mixtures. Compound **2** could be selectively generated (in ca. 30–35% yield) when THF was used as the reaction medium and the transmetalation was stopped after the reaction had been allowed to stir for three days.

The analytical data of the deep yellow, highly crystalline solid were consistent with its formulation as $[H_3CC(CH_2NSiMe_3)_3Tl_2]_n$.[9] Since no ν(N–H) bands were observed in the IR spectrum, and in view of its diamagnetism, compound **2** was formulated as a mixed-valent Tl^I/Tl^{II} amide containing a covalent Tl–Tl bond: $[H_3C\text{-}C(CH_2NSiMe_3)_3Tl_2]_2$ (Scheme 1). This proposed structure of **2** was confirmed by the results of a single-crystal X-ray diffraction study (Figure 2).[10]

The structural center piece is the directly metal–metal bonded Tl_2^{4+} fragment, which is effectively shielded by the ligand framework and the peripheral N-bonded $SiMe_3$ groups. The Tl–Tl distance of 2.734(2) Å is remarkably short in comparison to those in the two previously reported compounds with Tl–Tl bonds $[\{(Me_3Si)_3Si\}_2Tl\text{-}Tl\{Si(SiMe_3)_3\}_2]$ (d(Tl–Tl) = 2.9142(5) Å; Klinkhammer et al.[16]) and $[\{(tBu)_3Si\}_2Tl$-

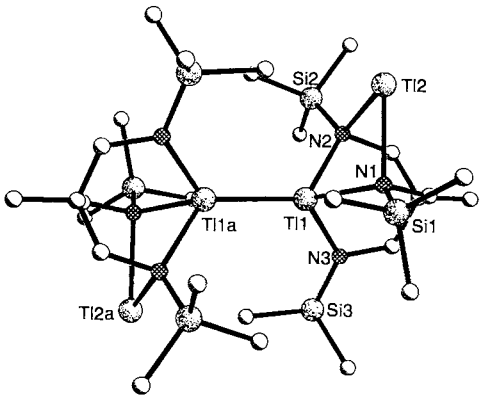

Figure 2. Molecular structure of **2** in the solid state; selected bond lengths [Å] and angles [°] Tl1–Tl1a 2.734(2), Tl1–N1 2.29(1), Tl1–N2 2.28(1), Tl1–N3 2.14(1), Tl2–N1 2.50(1), Tl2–N2 2.54(1), Tl1···Tl2 3.539(1); N1-Tl1-N2 78.9(4), N1-Tl2-N2 70.3(4), N1-Tl1-N3 93.5(5), N2-Tl1-N3 93.4(5), Tl2···Tl1-Tl1a 113.58(4); selected bond lengths [Å] and angles [°] for the isostructural indium complex **3**: In1–In1a 2.8067(9), In1–N1 2.197(9), In1–N2 2.221(5), In1–N3 2.080(4), In2–N1 2.441(5), In2–N2 2.418(8); N1-In1-N2 80.1(3), N1-In2-N2 71.6(2), N1-In1-N3 96.1(3), N2-In1-N3 96.3(2). There are no close intermolecular M···M distances (M > 4 Å) in both crystal structures.

$Tl\{Si(tBu)_3\}_2]$ (d(Tl–Tl) = 2.966(2) Å; Wiberg et al.[17]), as well as the value of 2.840(3) Å found by Dronskowski and Simon for the Tl_2^{4+} ions in the solid-state structure of $Tl_{0.8}Sn_{0.6}Mo_7O_{11}$.[18] The length of the metal–metal bond in **2** is close to that recently calculated at the HF-SCF level for D_{2d}-Tl_2H_4 by Treboux and Barthelat (2.775 Å);[5] however, such comparisons should be treated with care in view of the well-known wide variations of covalent M–M bond lengths in heavy metal chemistry and their dependence upon the sets of ligands associated with them. The large body of data obtained for the isoelectronic "neighbor" in the periodic table, Hg_2^{2+}, serves as a caveat in this context![19]

As Schnöckel et al. have recently pointed out in a review,[20] thallium is the only group 13 metal for which an "ethane-analogue" of the form $[X_2(D)E–E(D)X_2]$ (X = anionic ligand, D = neutral donor ligand, E = group 13 element in the formal oxidation state +II) could not be characterized to date. Compound **2** is closely related to this missing link in the structural systematics of the divalent elements of this group.

The indium(I/II) analogue of **2**, $[H_3CC(CH_2NSiMe_3)_3In_2]_2$ (**3**), was isolated as a yellow solid by carrying out the transmetalation in dioxane under similar reaction conditions. The proposed structure (Scheme 1) was initially based on the observed resonance pattern in the ^1H and ^{13}C NMR spectra,[9] the analytical data, and the fact that the isolated solid was crystallographically isomorphous to **2**. This was confirmed by a single-crystal X-ray structure analysis.[10] As in **2** the In^I atoms in **3** occupy exposed, peripheral positions bridging two amido-N atoms, while the In_2^{4+} unit occupies the central binding sites of the two tripodal amido ligands. That both compounds **2** and **3** are indeed to be viewed as mixed-valent species may be inferred from the different amido-N–metal bond lengths of the central M_2^{4+} unit, which are shorter than the M–N distances to the M^I centers (**2**: $d_{av}(Tl^{II}–N)$ = 2.24, $d_{av}(Tl^{I}–N)$ = 2.52 Å; **3**: $d_{av}(In^{II}–N)$ = 2.17, $d_{av}(In^{I}–N)$ = 2.43 Å). The metal–metal bond length of 2.807(1) Å is greater than the Tl1–Tl1a distance in **2** but lies in the range previously found for covalent In–In bonds by Uhl and others.[21] The efficient shielding of the metal–metal bond in **3** is reflected in the complete inertness of this compound towards isocyanides and heteroallenes, which were found to insert into In–In bonds in related compounds.[22]

Experimental Section

*n*BuLi (3.60 mL, 9.00 mmol of a 2.5 M solution in hexanes) was added to a solution of $H_3CC(CH_2NHSiMe_3)_3$ (1.0 g, 3.00 mmol) in dioxane (30 mL; **1**, **3**) or THF (30 mL; **2**) at 0 °C (– 35 °C for **2**). The mixture was allowed to warm up to ambient temperature and stirred for 1 h. After renewed cooling to 0 °C (– 35 °C for **2**), solid TlCl (2.16 g, 9.00 mmol; InCl for **3**) was added. An immediate color change to dark brown was observed for **3**. After the mixture had been stirred for a further 3 h (3 d for **2**), the solvent was removed in vacuo and the residue was extracted with toluene (20 mL). After centrifugation the red (**1**), yellow (**2**), or red-brown (**3**) toluene solution was concentrated to 8 mL (**1**) or 5 mL (**2**, **3**) and stored at – 35 °C. Over a period of several days **1** crystallized as red, **2** and **3** as yellow solids. Yield: **1**: 1.76 g (70%); **2**: 0.78 g (35%); **3**: 0.67 g (40%).

Laser Chemistry in Suspensions: New Products and Unique Reaction Conditions for the Carbon–Steam Reaction**

Huxiong Chen, Thomas McGrath, and Gerald J. Diebold*

Small particles can have sufficiently large optical absorption cross sections[1, 2] that on irradiation of a suspension by a laser pulse with a few hundred mJ of energy, extremely high temperatures are produced in spite of the strong influence of heat diffusion into the surrounding fluid. We describe here the chemical reactions that take place in suspensions of carbon black in water irradiated by the output of a Q-switched laser and the morphological changes that take place in the particles as they are consumed.

Perhaps the most striking feature of the laser-initiated reaction of carbon black with water is the transformation of the optical absorption of the suspension after several minutes of irradiation: a few mL of a suspension of carbon black in water that is originally completely opaque to the eye becomes almost completely transparent after irradiation with 6000 shots of 1.06 μm radiation from a Q-switched Nd:YAG laser. The suspensions are made by adding dry carbon particulate 25 nm in diameter[3] at a concentration of 200 mg L^{-1} to distilled water in a glass beaker, which is then placed in an ultrasonic bath for approximately 30 s to disperse the particles. A portion of the suspension, 7.5 mL, is drawn into a glass hypodermic syringe fitted at the end with a rubber septum. The laser produces 700 mJ in a pulse 16 ns in length and is fired at 10 Hz, irradiating a spot approximately 1 cm in diameter on the side of the syringe. After several laser shots, hundreds of extremely fine bubbles can be seen rising to the surface of the liquid.[4] After 10 min of irradiation the suspension appears almost completely transparent, with a slight tint of gray, and approximately 1 cm^3 of gas has collected at the top of the syringe. Over the course of several days, a precipitate slowly forms in the suspension.[5]

Dynamic light scattering experiments showed that before irradiation the particles (25 nm in diameter) are agglomerated in large groups[6] with a mean hydrodynamic diameter of 500 nm. Light scattering measurements showed a significant reduction in the agglomerated particle diameters as a result of the laser irradiation. Although some carbon in the solution is consumed, the predominant factor in changing the optical absorption of the suspension according to Mie theory[1, 2] is the reduction in size of the particulates by the action of the laser.

The gas above the suspension was sampled through the septum and analyzed by gas chromatography with flame ionization and thermal conductivity detection. The gases detected in the chromatographs followed by their volume per unit mass of carbon in the suspension were determined to be CO (630 mL g^{-1}), H_2 (260 mL g^{-1}), C_2H_2 (20 mL g^{-1}), CH_4 (8.9 mL g^{-1}), and C_2H_4 (2.8 mL g^{-1}). Also found were O_2, N_2, and small amounts of CO_2 and C_2H_6. The production of CO, H_2, and

Suuberg, Prof. D. Sweigart, and Prof. W. Suggs for a number of enlightening discussions, and to Dr. T. Sun, Dr. M. Antxustegi, and D. Walther for performing measurements.

CO_2 can be ascribed to the well-known carbon–steam and shift reactions (a) and (b), respectively, which are the primary reac-

$$C + H_2O \longrightarrow H_2 + CO \quad (a)$$

$$CO + H_2O \longrightarrow H_2 + CO_2 \quad (b)$$

tions in coal gasification.[7] Small amounts of CH_4 are known to be produced in reactors containing carbon and steam at high pressures;[7] C_2H_2 and C_2H_4 are not normally reported as reaction products.[8]

Unfortunately, the purity of the carbon black used in the experiments was not sufficiently high to rule out the possibility that the hydrocarbons detected were simply desorbed from the interior of the particles as a result of the high temperatures produced by the absorption of laser radiation. That is, a standard chemical analysis[5] of the carbon black showed the original sample contains H (0.30 wt%), N (0.39 wt%), and O (2.20 wt%); the amount of H in the carbon black is thus at least enough to account for all of the hydrocarbons detected by gas chromatography. An experiment in which the carbon black was prepared in deuterated water and the gas products were analyzed by gas chromatography/mass spectrometry (GC-MS) was carried out to investigate the possibility of simple desorption of existing hydrocarbons from the carbon black. Although all of the acetylene detected in the mass spectrometer[9] appeared as C_2D_2, which strongly argues against simple desorption as the mechanism for producing acetylene in the gas bubble, this result could be explained as well by H/D scrambling following desorption at high temperatures.

Finally, a sample of graphite powder with particles 1 μm in diameter that was analyzed[10] to contain 0.0038 wt% H was prepared as a somewhat unstable suspension and irradiated as described above. Chromatographic analysis showed the H content of the hydrocarbons over the suspension to exceed that in the graphite powder by a factor of 200, confirming chemical reaction as the source of the hydrocarbons.

In the course of carrying out experiments with different size particles, it was found that the production of hydrocarbons varied with particle diameter. The data in Figures 1 and 2 show that the production of all gases when normalized to the mass of C in the suspension increases with increasing particle diameter.

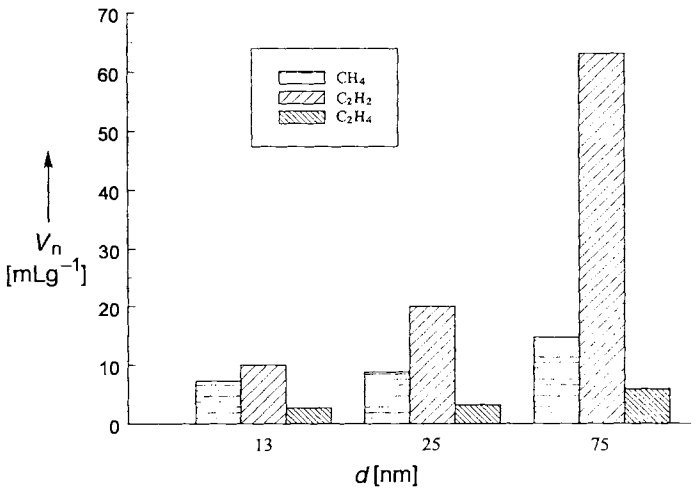

Figure 1. Composition of the hydrocarbons in the gas above the irradiated suspension (normalized volumes V_n in milliliters of gas per gram of carbon) versus particle diameter d. The suspensions were made with 200 mg of carbon per liter and were irradiated by a 700 mJ laser beam under identical conditions. The particle sizes refer to the unagglomerated particle diameters.

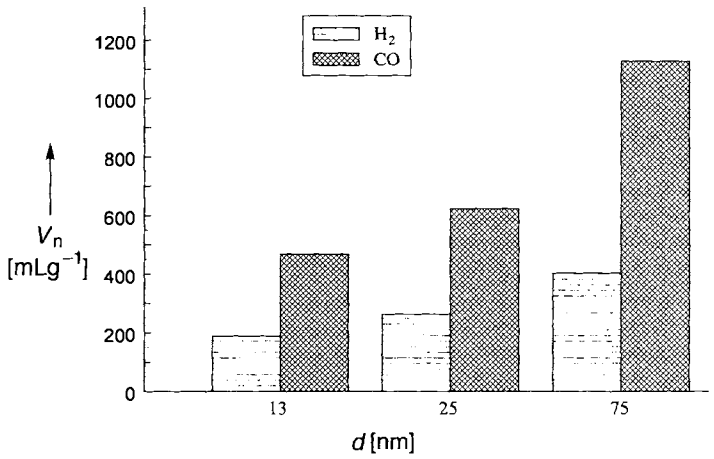

Figure 2. H_2 and CO content of the evolved gas in milliliters of gas per gram of carbon in the suspension versus particle diameter as in Figure 1.

The optical absorption of suspensions after irradiation was found to decrease with increasing particle diameter, indicating a higher total consumption of C in suspensions of the large-diameter particles. A rudimentary calculation of the temperature profile of a small, uniformly heated sphere in a heat conducting medium shows that the surface of a sphere is driven to higher temperatures, the larger its diameter.[11] Since C_2H_2 is more stable than other hydrocarbons at temperatures higher than 1350 °C,[8] the trend of increasing relative C_2H_2 production with an increase in particle diameter shown in Figure 1 provides some evidence for the hypothesis of surface temperatures that increase with increasing particle diameter. A process whereby reduction of the particle diameter through reaction to a point at which its thermal inertia is so small that its temperature rise is limited and no further reaction follows on subsequent absorption of radiation is consistent with the findings that for suspensions initially made of large particles the gas volume is greater than and the postirradiation optical density less than that of suspensions initially made of small particles.

The data in Figure 2 show, irrespective of particle size, that the CO:H_2 ratio in the reaction products is consistently higher than the 1:1 ratio dictated by reaction (a). An experiment was performed with carbon particles 25 nm in diameter in ^{18}O-enriched water to investigate the possibility that part of the CO arises from sources other than chemical reaction. The results of the GC-MS analysis showed significant dilution of the ^{18}O in the CO and CO_2; the O in the original carbon black sample is the likely source[12] of the ^{16}O.

Aside from chemical reaction, two salient features of the interaction of high-power laser radiation with carbon suspensions are the generation of an audible sound wave above suspensions open to the atmosphere,[13] and the production of diffuse white light along the path of the exciting laser beam.[14] Experiments with a photomultiplier positioned to view the irradiated region of a cell showed that the radiation was coincident with the 16 ns laser pulse to within the time resolution of the phototube.[15] Since reaction rates are typically a strong function of temperature, it is expected that the products are formed predominantly during the 16 ns period in which light is emitted from the suspension. Although there appears to be no calculations of the time profile of the pressure around laser-heated particles, the qualitative behavior of the "giant" photoacoustic effect[13] together with the empirically determined dependence of CH_4 production on pressure points to the generation of high pressures at the surfaces of the particles.

The question of the morphogenesis of the carbon particles under laser irradiation was investigated by examining the particles after various irradiation times using a transmission electron microscope.[16] Samples of a few μL of an irradiated suspension were placed on a standard graphite-coated electron microscope grid and left to dry. Figure 3 shows a micrograph of

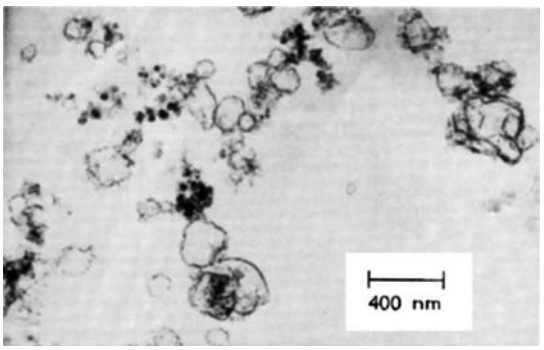

Figure 3. Electron micrograph of a sample after 15 laser shots showing the large-diameter structures generated by laser irradiation of a suspension of carbon black particles 25 nm in diameter. Several agglomerates consisting of particles 25 nm in diameter can be seen, as are typically found in micrographs taken before irradiation.

a sample of a suspension that had been irradiated for 15 shots. The figure shows agglomerates made up of particles 25 nm in diameter as they are typically seen in the initial suspension. As the irradiation proceeds, the large, nearly spherical structures[17] shown in Figure 3 appear as the number of agglomerates of small particles decreases. The uniform spatial profile of the original, 25 nm diameter spherical particles in the micrograph can be contrasted with the shell-like structure of the large particles. Large structures with diameters ranging up to 400 nm in which a dense shell surrounds a lower density core have been found by both transmission and scanning electron microscopy.

The conditions produced by the laser irradiation of carbon particles[18] can be likened to those found in intense sound beams where short bursts of high temperature and pressure likewise initiate chemical reactions.[19] While the laser method is somewhat more restricted than the sonochemical one in that it requires an optical absorber, it should be applicable to any suspension[20] for which an absorption of the particles can be matched to the wavelength of a laser. Since the power of the laser together with the rate of heat conduction from the particle surface by the surrounding fluid determines the amount of reaction and governs the rise and fall of the state variables near the particles, manipulation of the laser power and pulselength provides a somewhat unconventional, but straightforward means of controlling the conditions under which the reactions take place. The facile production of hydrocarbons, in particular, acetylene and ethylene, in aqueous carbon suspensions points to unique reaction conditions at the carbon–water interface characterized by high temperatures and pressures of extremely short duration and a chemical environment rich in carbon.

[3] The carbon particles, kindly donated by Cabot Inc. ("Black Pearls" 1300, 470, and 130) have individual particle diameters specified as 13, 25, and 75 nm, and agglomerate diameters of 36, 94, and 236 nm, respectively.
[4] The evolution of gas from laser-irradiated carbon black has been reported by K. J. McEwan, P. A. Madden, *J. Chem. Phys.* **1992**, *97*, 8748–8759 in conjunction with transient gratings. For work on optical limiting see also K. M. Nashold, D. P. Walter, *J. Opt. Soc. Am. B* **1995**, *12*, 1228–1237, and references therein.
[5] Standard oxidative elemental analysis of the C, H, N, and O content of the carbon black was performed by National Chemical Consulting, Tenafly, NJ (USA). The precipitate was found to contain C (71.59 wt%), H (3.01 wt%), N (1.62 wt%), and O (21.23 wt%).
[6] Transmission electron microscopy confirmed the agglomeration of the 25 nm particles into large groups in aqueous solution (see ref. [16]). The suspensions of carbon in water were stable for several hours. Surfactants can be used to stabilize the suspensions in water to form India inks, which qualitatively act the same as the carbon black suspensions when irradiated; however, inks were not used in these experiments in order to limit extraneous sources of H or O.
[7] C. G. von Fredersdorff, M. A. Elliott in *Chemistry of Coal Utilization, Supplementary Volume*, Wiley, New York, **1963**. The actual species involved in the reactions may include reactive clusters of carbon, for example, C_2–C_{200}. See S. H. Yang, C. L. Pettiette, J. Conceicao, O. Cheshnovsky, R. E. Smalley, *Chem. Phys. Lett.* **1987**, *139*, 223–238; E. A. Rohlfing, D. M. Cox, A. Kaldor, *J. Chem. Phys.* **1984**, *81*, 3322–3330; D. W. Arnold, S. E. Bradforth, T. N. Kitsopoulos, D. M. Neumark, *J. Chem. Phys.* **1991**, *95*, 8753–8764.
[8] C_2H_2 is found in the quenched, high-temperature plasma pyrolysis of coal; unlike the carbon used here, coal is rich in a variety of hydrocarbons. See N. Berkowitz, *An Introduction to Coal Technology*, Academic Press, New York, **1994**, Section 6.7.
[9] No undeuterated acetylene could be detected in the mass spectra within the detection limits (estimated to be less than 1% of the peak amplitude of the deuterated acetylene). Signals for C_2D_4 and C_2D_6 were found, with additional small peaks near the characteristic peaks for these species; however, the spectra were not consistent with either the purely or singly hydrogenated analogues of these species.
[10] The ultrasensitive analysis of the graphite for hydrogen (by chromatographic methods) was carried out by LECO Inc., Midland, MI (USA). Although the aqueous suspension of graphite powder produced gases on irradiation by the laser, the quality of the suspension was so poor that comparison of composition of the gas with that of the suspensions of carbon black, as shown in Figures 1 and 2, was judged to be inappropriate. In addition, these particles are a bit too large (1 μm diameter) to be considered within the Rayleigh limit discussed in ref. [11].
[11] Particles whose radii are small compared with the wavelength of the exciting radiation (the Rayleigh limit), in the absence of any cooling mechanism, reach the same final temperature irrespective of particle diameter. The calculation of the temperature with heat diffusion is based on Equation 10.2.6 in H. S. Carslaw, J. C. Jaeger, *Conduction of Heat in Solids*, 2nd ed. Oxford University Press, New York, **1956**, for a sphere with the same diffusivity as the surrounding material. In addition to heat conduction, several other heat loss mechanisms can be operative, including phase changes, chemical reaction, and radiation. However, for any loss mechanism dependent on surface area, the increase in the thermal inertia of a sphere with increasing radius (but still within the Rayleigh limit) argues for a higher average surface temperature for large particles, as well.
[12] Temperature-programmed desorption of dry carbon black with particles 25 nm in diameter from 30 to 1250 °C showed that gas with a charge-to-mass ratio of 28 was evolved. This finding is consistent with the observed dilution of the ^{18}O signal in the CO.
[13] See H. X. Chen, G. J. Diebold, *Science* **1995**, *270*, 963–966. The sound waves can be strong enough to fracture the glass wall of the syringe at the concentrations and power levels used here.
[14] In studies of optical limiting in carbon black suspensions, light emission is observed. See, for instance, K. Mansour, M. J. Soileau, E. W. Van Stryland, *J Opt. Soc. Am.* **1992**, *9*, 1100–1109; with regards to light emission and ionization, see also W. Robers, H. Schroder, K. L. Kompa, R. Niessner, *Z. Physikalische Chem.* **1988**, *159*, 129–148.
[15] The width of the white light pulse was found to be identical to that of the laser to within the time resolution of the apparatus. A 1P28 photomultiplier with a risetime of 2.2 ns and an oscilloscope with a 350 MHz bandwidth were used here.
[16] The results from transmission electron microscopy are somewhat at odds with those of light scattering. After 10 min of irradiation, no particulate matter could be found by the former technique, while the latter showed particles with a hydrodynamic diameter of 100 nm. We attribute this disparity to the drying that is required to prepare a sample for electron microscopy, which may cause

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3601-0165 $ 15.00+.25/0

the formation of precipitates. Note that extraction of the particle diameters from the light scattering data presumes the existence of spherical particles only, which appears to make the agglomeration diameters somewhat larger than those determined by electron microscopy.

[17] Smaller, but somewhat similar structures have been reported in the laser irradiation of soot in flames. See R. L. Vander Wal, M. Y. Choe, K. O. Lee, *Combustion Flame* **1995**, *102*, 200–294.

[18] Absorbing solids also can undergo chemical reactions when driven to high temperatures with a laser. See S. Mohr, H. Muller-Bbuschbaum, *Angew. Chem.* **1995**, *107*, 671–677; *Angew. Chem. Int. Ed. Engl.* **1995** *34*, 634–640.

[20] Preliminary experiments with lampblack in toluene give a number of products incuding C_2H_2 and C_2H_4, products not seen in the sonolysis on toluene [19].

Total Synthesis of Epothilone A: The Olefin Metathesis Approach**

Zhen Yang, Yun He, Dionisios Vourloumis, Hans Vallberg, and K. C. Nicolaou*

Dedicated to Professor Thomas J. Katz on the occasion of his 60th birthday

Epothilone A (**1**)[1,2] is an exciting new natural product, isolated from the myxobacteria *Sorangium cellulosum* strain 90, with novel molecular architecture, important biological properties, and an intriguing mechanism of action. Amongst its biological properties are potent antifungal and selective cytotoxic activities.[1–4] Its mechanism of action against tumor cells has been attributed to the binding and stabilization of microtubules,[4] and in that respect it resembles taxol.[5] Following our recent report[6] on a metathesis-based approach[7] towards this class of compounds, we now disclose the total synthesis of epothilone A (**1**) by this novel strategy.

Figure 1 shows the strategic bond disconnections that led to the convergent strategy utilized in this synthesis. The plan calls

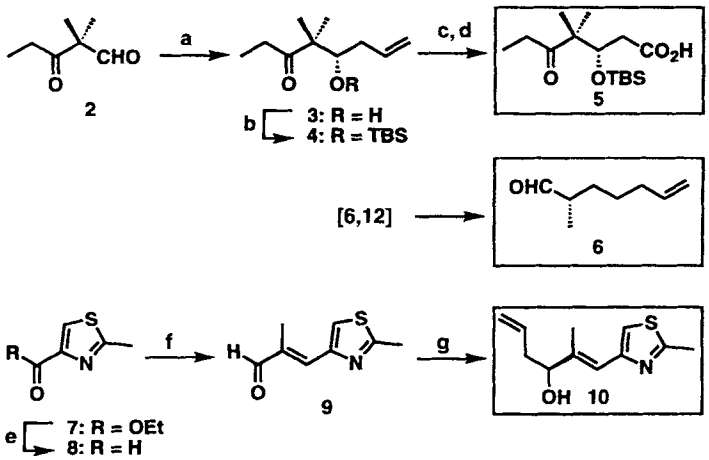
for the construction of the three key building blocks **5**, **6**, and **10** (Scheme 1), their union and elaboration to the 16-membered macrocycle, and final epoxidation. For the present approach, the olefin metathesis step and the selective epoxidation of the $\Delta^{12,13}$-double bond in the final step were considered, at the outset, both risky and crucial.

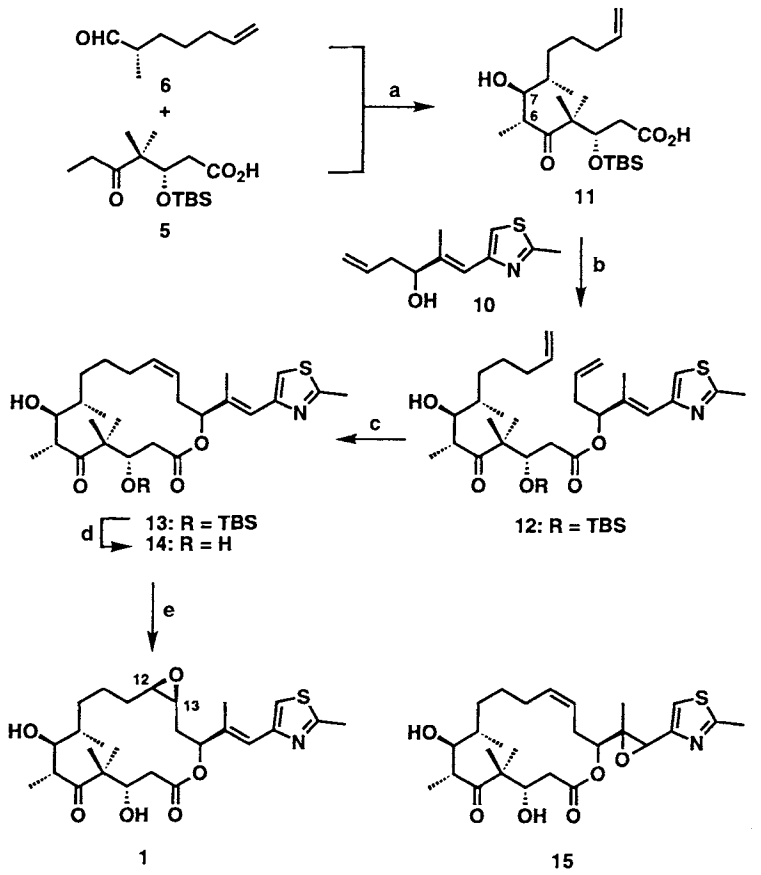


Scheme 1. Synthesis of building blocks **5**, **6**, and **10**. a) 1.1 equiv (+)-$Ipc_2B(allyl)$, Et_2O/pentane, −100 °C, 0.5 h, 74%; b) 1.1 equiv TBSOTf, 1.2 equiv 2,6-lutidine, CH_2Cl_2, 25 °C, 1 h, 98%; c) O_3, CH_2Cl_2, −78 °C, 0.5 h, then excess Ph_3P, −78 → 25 °C, 1 h, 82%; d) 3 equiv $NaClO_2$, 4 equiv 2-methyl-2-butene, 1.5 equiv NaH_2PO_4, *t*BuOH:H_2O 5:1, 25 °C, 2 h, 93%; e) 1.1 equiv DIBAl-H, CH_2Cl_2, −78 °C, 0.5 h, 90%; f) 1.1 equiv Ph_3P=C(Me)CHO, benzene, 80 °C, 1 h, 90%; g) 1.1 equiv (+)-$Ipc_2B(allyl)$, Et_2O/pentane, −100 °C, 0.5 h, 96%. TBS = *tert*-butyldimethylsilyl; $Ipc_2B(allyl)$ = diisopinocampheylallylborane.

Scheme 1 summarizes the construction of the key building blocks **5**, **6**, and **10**. The synthesis of carboxylic acid **5** commenced with the known ketoaldehyde **2**,[8] which reacted selectively with Brown's allyl isopinocampheyl borane reagent [(+)-$Ipc_2B(allyl)$][9] in ether/pentane at −100 °C to afford alcohol **3**[10] in 74% yield. Protection of this alcohol with TBSOTf-2,6-lutidine afforded the silyl ether **4** in 98% yield. Ozonolytic cleavage of the double bond in **4** followed by $NaClO_2$ oxidation of the resulting aldehyde gave the targeted carboxylic acid **5** in 75% yield. The preparation of the heterocyclic component **10** was carried out from the known thiazole ester **7**[11] by a) reduction to the corresponding aldehyde (**8**) with Dibal-H (90% yield), b) Wittig reaction with Ph_3P=C(Me)CHO to afford the conjugated aldehyde **9** (90% yield), and c) condensation of **9** with (+)-$Ipc_2B(allyl)$ in ether/pentane at −100 °C (96% yield).[10]

Having secured the requisite building blocks, we then turned our attention to their coupling and further elaboration. Scheme 2 depicts these final stages of the present total synthesis of epothilone A (**1**). Condensation of the dianion of **5** (2.2 equiv of LDA, THF, −78 to −40 °C) with aldehyde **6**[6,12] (1.2 equiv) at −78 to −40 °C resulted in the formation of the desired aldol product (**11**) as the major isomer, together with its 6*S*,7*R*-diastereomer in high yield and approximately a 2:1 ratio. Esterification of this mixture with the hydroxy component **10** (2.0 equiv) proceeded in the presence of DCC and 4-DMAP in toluene at 25 °C to afford compound **12** and its 6*S*,7*R*-diastereomer in 70% overall yield[13] from ketoacid **5**. The two isomers were chromatographically separated [silica gel, ethyl acetate:hexane (1:5), R_f = 0.29 (**12**, 45% overall yield from **5**), 0.24 (6*S*,7*R*-diastereomer of **12**, 25% yield from **5**)], and the major product (**12**) was taken forward in the synthesis as a pure

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/0166-3124 $ 15.00+.25/0



Scheme 2. Synthesis of epothilone A (**1**): a) 2.2 equiv LDA, THF, $-78 \rightarrow -40\,^{\circ}C$, 0.5 h, then 1.2 equiv **6** in THF, $-78 \rightarrow -40\,^{\circ}C$, 0.5 h, high yield of **11** and its (6*S*,7*R*)-diastereomer; b) 2.0 equiv **10**, 1.5 equiv DCC, 1.5 equiv 4-DMAP, toluene, 25 °C, 12 h, **12** (45% overall yield from **5**) and (6*S*,7*R*)-diastereomer of **12** (25% overall yield from **5**); c) **12** (0.006 M in CH_2Cl_2), 15 mol% $[RuCl_2(=CHPh)(PCy_3)_2]$ cat., 25 °C, 8 h, 50% plus $\Delta^{12,13}$-*trans*-isomer of **13** (35%); d) CF_3COOH (20 vol.%), CH_2Cl_2, 0 °C, 4 h, 98%; e) 1.1 equiv *m*CPBA, benzene, 0 °C, 20 h, **1** (55%) and 12α,13α-epoxide (20%) plus regioisomeric epoxide **15** (20%); LDA = lithium diisopropylamide, DCC = dicyclohexylcarbodiimide, 4-DMAP = 4-dimethylaminopyridine.

isomer. Its structure was eventually confirmed by conversion into epothilone A (**1**). The olefin metathesis reaction of **12** proceeded smoothly in the presence of $[RuCl_2(=CHPh)(PCy_3)_2]$ catalyst[14] in dilute CH_2Cl_2 solution at 25 °C to afford, in 50% yield, the *Z*-olefin **13**,[15] together with its *E*-isomer (35%).[15] After chromatographic purification [silical gel, benzene:ethyl acetate:hexane (2:1:2), $R_f = 0.21$ (*Z*-isomer), 0.45 (*E*-isomer)], the silyl group was removed from macrocycle **13** by exposure to CF_3COOH in CH_2Cl_2 at 0 °C to afford the dihydroxy lactone **14** in 98% yield. Finally, selective epoxidation of the $\Delta^{12,13}$-double bond of **14** was effected with *m*CPBA in CH_2Cl_2 at 0 °C to afford epothilone A (**1**) in 55% yield [silica gel, methanol: CH_2Cl_2 (1:20), $R_f = 0.23$], together with its 12α,13α-epoxide isomer [20% yield, silica gel, methanol:CH_2Cl_2 (1:20), $R_f = 0.16$] and its regioisomer **15** [20% yield, silica gel, methanol:CH_2Cl_2 (1:20), $R_f = 0.22$, stereochemistry unassigned]. Chromatographically purified synthetic epothilone A (**1**) exhibited identical properties (^1H and ^{13}C NMR, mass spectrum, $[\alpha]_D$, TLC and HPLC) to those of an authentic natural sample (Table 1).[16]

The reported total synthesis[17] demonstrates the power of the olefin metathesis reaction in complex molecule construction and renders epothilone A (**1**) readily accessible. Most importantly, its brevity, convergent nature, and flexibility should allow the generation of a diverse epothilone library for further biological investigations. In addition to the olefin metathesis approach reported herein, Figure 1 points to at least two more, distinctly different approaches[18] to epothilones: a) a macrolactonization approach and b) an approach in which an intramolecular aldol reaction may play the crucial role of constructing the macrocyclic skeleton. These and other strategies towards these compounds are currently under investigation in these laboratories.

Table 1. Selected physical properties of compounds **1**, **12**, and **13**.

12: $R_f = 0.29$ (silica gel, ethyl acetate:hexane 1:5); $[\alpha]_D = -53.4$ ($c = 1.0$, MeOH); IR (film): 3508 (br., OH), 1736 (C(O)O), 1690 (COC), 1650 cm^{-1} (CH=CHCO); ^1H NMR (500 MHz, $CDCl_3$): $\delta = 6.93$ (s, 1H, −C=CHS−), 6.47 (s, 1H, −C=CH−C=), 5.81–5.72 (m, 1H, $CH=CH_2$), 5.73–5.65 (m, 1H, $-CHCH_2-$), 5.27 (dd, 1H, $J_1 = 7.0$, $J_2 = 6.5$ Hz, −OCH−), 5.06 (dd, 2H, $J_1 = 17.5$, $J_2 = 10.0$ Hz, $CH=CH_2$), 4.92 (dd, 2H, $J_1 = 17.0$, $J_2 = 10.5$ Hz, $CH=CH_2$), 4.39 (dd, 1H, $J_1 = 4.0$, $J_2 = 6.0$ Hz, $-(CH_3)_2CCH-$), 3.42 (bs, 1H, OH), 3.28 (q, 1H, $J = 7.0$ Hz, $-CH(CH_3)C(O)-$), 3.24 (d, 1H, $J = 9.5$ Hz, CH(OH)), 2.67 (s, 3H, $-SC(CH_3)=N-$), 2.54 2.43 (m, 2H), 2.43 (dd, 1H, $J_1 = 4.0$, $J_2 = 10.0$ Hz, $-CH_2COO-$), 2.31 (dd, 1H, $J_1 = 6.0$, $J_2 = 10.0$ Hz, $-CH_2COO-$), 2.04 (s, 3H, $-C(CH_3)=C-$), 1.95 (m, 2H, $-CH_2CH=CH_2$), 1.75–1.65 (m, 1H), 1.48–1.43 (m, 1H), 1.43–1.36 (m, 1H), 1.22–1.10 (m, 2H), 1.17 (s, 3H, $-C(CH_3)_2-$), 1.09 (s, 3H, $-C(CH_3)_2-$), 1.01 (d, 3H, $J = 6.5$ Hz, C(O)CH(CH_3)−), 0.86 (s, 9H, $SiC(CH_3)_3(CH_3)_2$), 0.81 (d, 3H, $J = 7.0$ Hz, $-C(OH)CH(CH_3)-$), 0.09 (s, 3H, $SiC(CH_3)_3(CH_3)_2$), 0.04 (s, 3H, $SiC(CH_3)_3(CH_3)_2$); ^{13}C NMR (125 MHz, $CDCl_3$): $\delta = 221.8$, 170.9, 164.6, 152.4, 139.0, 136.6, 133.2, 121.0, 117.8, 116.4, 114.1, 78.8, 74.5, 73.4, 53.9, 41.2, 40.1, 37.4, 35.4, 34.1, 32.3, 26.0, 25.9, 21.9, 19.9, 19.2, 18.1, 15.2, 14.6, 9.7, −4.3, −4.9; HRMS calcd for $C_{34}H_{57}NO_5SSi$ ($[M + Cs]^+$): 752.2781, found: 752.2760.

13: $R_f = 0.21$ (silica gel, ethyl acetate:benzene:hexane 1:2:2); $[\alpha]_D = -97$ ($c = 0.2$, MeOH); IR (film): 3456 (br., OH), 1739 (C(O)O), 1692 (COC); ^1H NMR (500 MHz, $CDCl_3$): $\delta = 6.94$ (s, 1H, −C=CHS−), 6.56 (s, 1H, −C=CHC=), 5.45 (dd, 1H, $J_1 = 10.5$, $J_2 = 3.0$ Hz, $-CH=CHCH_2-$), 5.35 (m, 1H, $-CH=CHCH_2-$), 5.02 (d, 1H, $J = 10.0$ Hz, −OCH−), 4.06 (dd, 1H, $J_1 = 7.0$, $J_2 = 5.5$ Hz, $-C(CH_3)_2CH-$), 3.94 (bt, 1H, $-CH(OH)-$), 3.05 (dq, 1H, $J_1 = 3.0$, $J_2 = 6.5$ Hz, $-C(O)CH(CH_3)-$), 3.00 (bs, 1H, OH), 2.82–2.78 (m, 2H), 2.78–2.69 (m, 1H), 2.71 (s, 3H, $-SC(CH_3)=N-$), 2.40–2.30 (m, 1H), 2.10 (s, 3H, $C(CH_3)=CHC=$), 2.10–2.00 (m, 1H), 1.99–1.90 (m, 1H), 1.75–1.65 (m, 1H), 1.70–1.50 (m, 2H), 1.45–1.35 (m, 1H), 1.21 (m, 1H, $-CH(CH_3)CH_2CH_2-$), 1.17 (s, 6H, $-C(CH_3)_2-$), 1.14 (d, 3H, $J = 5.0$ Hz, $-C(O)CH(CH_3)-$), 1.02 (d, 3H, $J = 5.0$ Hz, $-CH(CH_3)-$), 0.82 (s, 9H, $SiC(CH_3)_3(CH_3)_2$), 0.12 (s, 3H, $SiC(CH_3)_3(CH_3)_2$), 0.05 (s, 3H, $SiC(CH_3)_3(CH_3)_2$); ^{13}C NMR (125 MHz, $CDCl_3$): $\delta = 218.1$, 170.9, 164.7, 138.2, 134.7, 124.0, 119.6, 119.4, 116.0, 79.0, 76.3, 73.2, 53.5, 43.0, 39.1, 38.8, 33.6, 31.9, 28.4, 27.8, 26.1, 24.8, 22.9, 19.2, 18.6, 16.5, 15.3, 14.1, −3.6, −5.5; HRMS calcd for $C_{32}H_{53}NO_5SSi$ ($M + Cs^+$): 724.2468, found: 724.2479.

1: $R_f = 0.23$ (silica gel, MeOH:CH_2Cl_2 1:2); HPLC (Watman EOC, C-18, 4 m, 108 × 4.6 mm column, solvent: gradient: 0 → 20 min, 30 → 80% MeOH in H_2O, $R_t = 14.8$ min; $[\alpha]_D = -45.0$ ($c = 0.02$, MeOH); ^1H NMR (500 MHz, C_6D_6): $\delta = 6.78$ (s, 1H, −C=CHS), 6.52 (s, 1H, −C=CHC=), 5.52 (dd, 1H, $J_1 = 6.0$, $J_2 = 2.0$ Hz, OCH), 4.24 (d, 1H, $J = 10.0$ Hz, CH(OH)), 3.86 (m, 1H, CH(OH)), 3.81 (bs, 1H, OH), 3.10 (m, 1H, CH_2CHO), 2.84 (m, 1H, C(O)CH), 2.67 (m, 1H, CH_2CHO), 2.49 (dd, 1H, $J_1 = 11.0$, $J_2 = 14.5$ Hz, $-OOCCH_2$), 2.27 (s, 3H, $-SC(CH_3)=N$), 2.24 (dd, 1H, $J_1 = 14.5$, $J_2 = 3.5$ Hz, $OOCCH_2$), 2.11 (s, 3H, $-C(CH_3)=$), 1.92 (m, 1H, CH_2CHO), 1.84 (m, 1H, CH_2CHO), 1.74 (m, 1H), 1.57 (m, 1H), 1.27–1.42 (m, 5H), 1.11 (d, 3H, $J = 7.0$ Hz, C(O)CH(CH_3)), 1.09 (s, 3H, $C(CH_3)_2$), 1.03 (s, 3H, $C(CH_3)_2$), 1.01 (s, 3H, $CH(CH_3)$); ^{13}C NMR (125 MHz, C_6D_6): $\delta = 218.7$, 169.9, 164.1, 152.6, 137.2, 119.5, 119.3, 76.3, 74.8, 73.1, 56.9, 53.9, 52.6, 43.4, 38.8, 36.0, 31.4, 30.0, 27.0, 23.6, 20.8, 20.2, 18.4, 17.0, 15.4, 14.3; HRMS calcd for $C_{26}H_{39}NO_6S$ ($M + Cs^+$): 626.1552, found: 626.1551.

EVENTS

The eighth international symposium on inorganic ring systems will be held in Loughborough in August 1997. Invited speakers include: H. Nöth, M. F. Hawthorne, K. Wade, P. Power, D. Tilley, F. Feher, R. C. Haushalter, D. Fenske, A. Haas.

Contributed lectures and posters will be accepted on any aspect of inorganic rings, cages, including the interface with solid state chemistry.

Reduced registrations will be offered to students. Bursaries are available for younger participants.

Requests for further details should be sent to:

J D Woollins, Dept of Chemistry, Loughborough University, Loughborough, Leics. LE11 3TU, UK. e-mail: j.d.woollins@lboro.ac.uk http://www.lboro.ac.uk/departments/cm/iris1.html

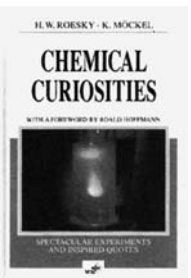
Seeing Is Believing

Spectacular Experiments and Inspired Quotes. Chemical Curiosities. By *H. W. Roesky* and *K. Möckel*. VCH Verlagsgesellschaft, Weinheim, 1996. 339 pp., hardcover DM 68.00.—ISBN 3-527-29414-7

This multifaceted description of some 124 demonstrations in chemistry is indeed a pleasure to read as one might read a volume of short stories. Its brief (about two pages per experiment), but detailed and adequate directions usually include sections on safety precautions, the apparatus, chemicals, the procedure, an explanation of the phenomenon, waste disposal, and references. The 37 color figures are beautifully made, and add greatly to the delight of the reader.



But there is much more: almost all of the 124 descriptions are prefaced by remarkably appropriate quotes and bits of history (including alchemy) attributed to scientists, philosophers, artists, poets, writers, and others.

Of course Goethe heads the list, while others span the time from Lucretius to Einstein, Linus Pauling, and on into the present. These introductory quotes and remarks provide continuity throughout the experiments and the progress of the book, and link to relationship between the humanities and the science described here.

For example, the quotations approach their zenith in Chapter 23 (The Thermite Process, for which extreme caution is advised). The three quotations are as follows:

From Douglas Adams: *There is a theory that when someone finds out precisely why the universe exists, and for what purpose, it will disappear on the spot and be replaced by something more bizarre and inconceivable.*

There is another theory according to which that has already occurred.

From Justus Liebig: *Measured against that which we desire, our knowledge and understanding are clearly limited, and if in this context we wish to regard ourselves as children, then we know as well that we are growing.*

From Yogi Berra: *I don't want to make the wrong mistake.*

Also preceding this thermite experiment are excerpts of publications and letters that illuminate Friedrich Wöhler's discovery of aluminum and the subsequent controversy with Henri Sainte-Claire Deville. This matter was handled by Wöhler in a gentlemanly way, an example for our times.

As a personal note, I was surprised at how many of these experiments I did in my youth in the years after I had been given a chemistry set when I was eleven years old, and especially after I had greatly augmented this original supply of chemicals and apparatus. Also, I was reminded of many demonstration experiments from in my undergraduate chemistry courses. However, times have changed: chemistry sets are less interesting (and less hazardous), and demonstration experiments in courses occur less frequently.

I hope that a book such as this one may reawaken or strengthen interest in these striking experiments that illustrate many of the ideas of chemistry. The emphasis on chemical reactions is a reminder that chemistry is unique among the sciences in the extent to which it creates its own new substances and to which it exhibits a special logic for syntheses and transformations of these substances.

The Foreword by Roald Hoffmann sets the stage and invites you to try these demonstrations, and he comments: "The remarkable achievement of Herbert Roesky's and Klaus Möckel's book is the linkage it achieves between the world of the human spirit, expressed in literature and historical continuity, and the art of chemical demonstration".

Qu'est-ce que l'alchimie? By *P. Laszlo*. Hachette, Paris, 1996. 144 pp., paperback Ffr 59.00.—ISBN 2-01-235190-5

This little book is one in a popular scientific series entitled *Questions de Science*. It is certainly not intended to be a history of alchemy, especially since the author admits in the introduction that he does not really understand the texts of the alchemists. The discussion is based on secondary literature, about half of which belongs to the fields of the esoteric and of depth psychology. The author leads us from the ancient world, via the Middle Ages and the Renaissance, up to the 17th and 18th centuries. These wanderings are described in a conversational style, and although the discussion takes account of the results of recent historical research, it lacks any in-depth analysis or serious evaluation. Errors such as citing Robert Boyle's work *The Sceptical Chymist* with an incorrect title and the wrong year of publication (p. 104) are among the least annoying faults. A more serious shortcoming is the neglect of some central elements of alchemy, such as its background of natural philosophy, its tradition of practical metallurgy, and its rich imagery. Important historical differences become blurred when, for example, the concepts of yin and yang, sulfur and mercurius, acid and base, anion and cation, or electrophilicity and nucleophilicity, become lumped together in a sort of universal complementarity principle. When, in the last chapter, the discussion spans the range from Mary Shelley's *Frankenstein* via Jules Verne to Ernst Jünger, one suspects that any hope of arriving at a histor-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

ically based view of alchemy has disappeared. Included as an appendix is the text of an interview, in which the series editor Dominique Lecourt talked to the author; this is a plea to the effect that even modern scientists should give some attention to earlier and quite different forms of knowledge. However, I am not convinced that this book will achieve that goal.

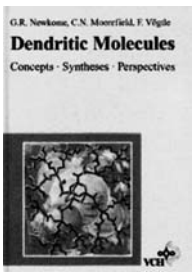
Dendritic Molecules. By *G. R. Newkome, C. N. Moorefield,* and *F. Vogtle.* VCH Verlagsgesellschaft, Weinheim, 1996. 261 pp., hardcover $ 140.00.—ISBN 3-527-29325-6

The authors of this first book to be totally devoted to dendritic molecules have themselves previously contributed important seminal papers to the rapidly developing field of these highly branched molecules emanating from a central core. This comprehensive book on concepts, synthesis, and future perspectives of dendrimers is an excellent overview, describing essentially all the published work up to early 1996. In its approximately 250 pages the book contains detailed information on all the known synthetic schemes and dendrimers, using a very clear "Beilstein-type" subdivision, as well as an informative introduction for those not (yet) active in the field of dendrimers. Research in this field now involves a rapidly increasing number of groups in chemistry, physics, and bio-related disciplines. New discoveries in synthesis, characterization, properties, and applications are reported almost every week. Therefore, we often have to reconsider our ideas, insights, and concepts. As the authors write in their preface, " there is little doubt in our minds that the surface of this topic has just been scratched". In view of this, the authors have rightly decided to focus their book on a state-of-the-art description of the research performed so far, without trying to define the scope and limitations of dendrimers or to discuss different conceptual aspects in detail. With an astonishing accuracy and a very elegant subdivision, all dendrimers that have been synthesized up to early 1996 are discussed and presented in the many figures and schemes, with space-consuming, but esthetically pleasing representations of the molecules.



The book starts with an excellent introductory chapter by W. L. Mattice on the masses, sizes, and shapes of macromolecules from multifunctional monomers. Since many researchers interested in dendrimers have had their training in organic chemistry, they will be very pleased with this chapter on some basic aspects of polymers. Molecular weight distributions, branching, radius of gyration, shape analysis, and a number of other important features of macromolecules are introduced. Although these aspects are all very crucial to the understanding of the properties of dendrimers, the topics of Chapter 1 are not really used in the following chapters. In Chapter 2, both the historical perspectives of dendrimers and the fractal geometry of macromolecules in general and of dendrimers in particular are discussed. Obviously, an account of the history of the development of a new field, written by scientists who were and are still involved themselves, is always colored with some personal preferences. Despite this, the reconstruction of events in the development of dendrimers as given here is reasonably objective. Chapter 3 discusses the nomenclature of dendrimers as proposed some time ago by the same authors. The names are very useful for IUPAC, but they use almost as much space as the structures of the molecules in the many figures of the book. Thus, for dendrimers one still awaits a proposal for a concise nomenclature and more compact structural schemes.

The appetite of the more knowledgeable reader begins to be stimulated in Chapters 4–6, in which the different synthetic methodologies are described in 133 pages. As well as following the well-known division into the divergent (Chapter 4), convergent (Chapter 5), and one-step or hyperbranched (Chapter 6) procedures, the authors subdivide each chapter systematically according to branching and connectivity, thus making the book very useful as a reference source. For most of the dendrimers, a complete synthetic scheme is given, while some details of the properties are discussed. All dendrimers given in the figures are presented in their perfect, defect-free structure. However, many samples, especially those obtained from the divergent procedures, will contain structures with statistical errors as a result of the repetitive synthetic schemes. Unfortunately, the treatment of this topic is very limited as a consequence of the many omissions in the original papers chosen for reviewing. Nevertheless, Chapters 4–6 provide an excellent insight into the different synthetic methodologies of dendritic molecules.

Chiral dendritic macromolecules (Chapter 7) and dendrimers containing metal sites (Chapter 8) are discussed as special topics. Although there is some overlapping with the earlier chapters, these dedicated chapters nicely illustrate those areas that deserve special attention and are generally accepted as being very important, both conceptually and with respect to possible applications in catalysis and in the pharmaceutical or medical sciences. In Chapter 9 the concepts of dendritic assemblies and dendritic networks are discussed. The authors predict that these higher-order architectures will contribute to the field of nanotechnology and supramolecular materials, and it is clear that considerable progress is being made through the stimulus of making the connection with topological dendrimers.

Early work on dendrimers led to speculations about possible applications, and recent developments hold out prospects for future discoveries and uses. Therefore, the book ends with a very useful chapter listing illustrative references to papers and patents describing applications, as well as an appendix listing earlier reviews on dendrimers.

Overall, this book is required reading for research scientists active in the field and for those interested in joining the dendrimer community. They will appreciate the accuracy of this overview of dendrimers, and the book will become a major reference source. Furthermore, the topic of dendrimers is of broad general interest, and therefore the book is highly recommended for all chemistry libraries.

The Responsible Conduct of Research. By *Doré Beach.* VCH Verlagsgesellschaft, Weinheim, 1996. 162 pp., paperback DM 48.00.—ISBN 3-527-29333-7

Doesn't it make sense, in the interests of scientific advancement, that one should (for instance) supply a library with the coordinates of the atoms of a protein whose structure one has determined, so that others might use them? Or that one doesn't rush into print in a quicker publishing journal a synthesis of a prized target molecule the moment one has learned from a refereee in a "slower" journal that

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3601-0170 $ 15.00+.25/0

someone else has completed such a synthesis?

Such unethical but not illegal actions happen. They are rare (still more rare is real fraud), but they happen. Interesting is the implicit hubris of the way in which I asked the question—"Doesn't it make sense?"—thus in a way assuming that ethics is logic.

Ethics is not logic. And scientists are not born with ethics (nor with logic for that matter). Science is an eminently successful social structure for inquiry, done by curious, intelligent, but fallible people, who need all the help they can get in learning ethical behavior—from their parents, friends, religious counselors, teachers, books. And who need to talk to each other, not so much of moral principles but of specifics, often unpleasant. Non-trivial ethical problems involve the collision of obvious goods of different people. So ethics is inevitably shaped in dialogue with others.

In response to journalistic exposure and governmental concern (most scientists think both overdone, if not malicious) about prominent cases of misconduct in science, we now at last have several carefully reasoned reports on ethics and responsible conduct in science, governmental mandates (in some fields) for structured instruction, and some books for the scientist.

The book by Doré Beach and associates indeed addresses most of the important ethical issues in scientific research. It does so in a way that I find partially unsatisfactory, but before I get to that let me say what is in this book.

The book contains ten appropriately brief chapters, covering subjects ranging from a definition of ethics and a brief sketch of its place in philosophy, through ethical issues in publication and the legalities of intellectual property protection, on to a discussion of misconduct. Given the short, readable format, the coverage is comprehensive—the only serious omission in my view is the absence of a discussion of the contentious, but very much ethically founded, issues of animal rights and animal testing.

Five of the ten chapters are written by Dr. Beach, who is the Director of Responsible Conduct of Research and Applied Ethics at the University of South Florida. The other five chapters were written by her colleagues, mostly in administration or the "Division of Sponsored Research" (the people who help you get research grants). The orientation of the book is understandably very American.

Each chapter ends with one or more case studies. These are detailed, realistic, and often fascinating. And each is accompanied by some questions aimed at guiding discussion.

The book is intended for the practicing researcher with perhaps more emphasis on university than on industry. Amusingly, there is a glossary of philosophical terms (including words such as "duty" or "truth"!), but none of the technical terms around patent law.

The book is balanced in tone, a real virtue. With this subject, one could easily turn polemical or defensive, or overly preachy (as I am when I write about ethics). It is understandable that a multi-author book might be uneven in style, even when obviously edited for coherence (as the consistent case study format suggests). So why do I come away partially unsatisfied?

Something to get out of the way first, a bad beginning. A book that discusses, inter alia, ethical problems of authorship, should leave us with a clean feeling about its own authorship. Half the book is written by Beach, half by her colleagues. Their names appear in the Table of Contents but not on the book cover or title page. It could have been done better.

Beach's own writing is uneven. At times she is authoritative, as in the discussion of ethics within philosophy, and the important focus on the Nuremberg code of ethics of experimentation on human subjects. It is good to be reminded that the ideas of informed consent and risk/benefit analysis derive from that 1946 code. And that for 20 years the US failed to implement guidelines for American researchers to adhere to this code.

At times, however, the author just lapses into making lists or chronologies, often taking the list from a (properly credited) US agency report. The bolder task of pointing out the inconsistencies in these lists and of criticizing them—be they of ethical practices in data "management" or what constitutes safe chemical practice—is avoided.

Beach argues (and I agree) that ethical behavior is shaped by casuistry (particular case analysis, not the other meaning of the word), or what I would call situation ethics—a free dialogue by concerned people around a specific issue. This is the rationale for this book's Case Studies with their "Questions for Discussion." What I just longed for after a while was a verbatim account of the discussion of a case. Providing not an answer for all time, but the arguments (logical or not) of various sides. Interesting (problematic) ethical questions are those in which agreed-on goods collide—for example, the banning of thalidomide vs. the efficacy of thalidomide for leprosy and maybe AIDS. I wanted to read how intelligent but impassioned people argued such a case, and I wanted to see how someone trained in ethics, while not resolving the problem, might at least steer the discussion in a productive way.

I found traces of this in the text, in Beach's discussion of David Keen's bullets that would pierce bullet-proof vests and shred flesh. And I found a good bit along these lines in the best written chapter in the book, by Lawrence R. Oremland, on intellectual property rights. He intrudes into his cases, in just the direction I wanted. And Oremland has an account of "The Texaco Case" that will make you think twice about copying for your files eight articles from the *Journal of Catalysis*!

In a way ethics is like science, and unlike law or politics. Faced with a difficult (and therefore interesting) question with seemingly irreconcilable arguments, science can say "I'm not yet sure who is right; come back and ask me next year." And ethical discourse will guide you to see the validity of the side you are not on, the moral claims of the various positions. But the law doesn't have the luxury of just describing anguished alternatives, or waiting. It must decide—"guilty," or "not guilty." And politicians all the time make compromises between irreconcilable interests; the compromises you and I hate to make. I respect both judges and politicians for that.

Acceptor-substituted enynes **A** (Acc = acceptor substituent) can undergo 1,4- and 1,6-additions with organocuprates. For the 1,6-addition product subsequent reactions at C-2 and C-4 are possible. Examples are given in the following article.

Regio- and Stereoselective Syntheses with Organocopper Reagents

Norbert Krause* and Andreas Gerold

Dedicated to Professor Klaus Hafner on the occasion of his 70th birthday

Of all of the organometallic reagents currently used to form carbon–carbon bonds, organocopper reagents rank amongst the most important. Interest in these reagents centers not only on their regioselectivity, but also increasingly on their application in stereoselective transformations (principally Michael additions and S_N2' reactions); the use of suitable substrates or chirally modified cuprates can lead to highly diastereo- and enantioselective reactions. Simultaneously, extensions of methods for the preparation and application of these reagents (for example functionalized organocopper species and Lewis acid catalysis, respectively) have opened up new horizons for organocopper reagents. Mechanistically, the reactions are well-documented and understood, but this aspect of the subject has not kept pace with the many rapid developments in preparative chemistry. Organocopper reagents have proved to be indispensable in the synthesis of complex natural products and pharmaceuticals, chiral auxiliaries, and molecules with interesting structural features. In this review we will discuss some of the more recent important developments in this area; the organization will follow the type of selectivity (regio-, diastereo-, and enantioselectivity).

Keywords: chirality · catalysis · copper reagents · synthetic methods

1. Introduction

The element copper is one of the metals that has been known since ancient times. It occurs widely, can be easily won from its salts and further worked, and continues to fascinate humans with its unique color. It is only natural that copper and its salts have had a place on the chemist's workbench for many years, and there is no lack of established reactions in organic chemistry relying on this element: the Sandmeyer reaction, the Ullmann coupling,[1] and coupling reactions of alkynes (the Stephens–Castro, Glaser, Eglinton, and Cadiot–Chodkiewicz reactions[2]). This group also includes the 1,4-addition of Grignard reagents to enones catalyzed by copper(I) salts, which was discovered by Kharash.[3]

Although organocopper reagents are undoubtedly important participants in a wide range of these reactions, interest in the targeted preparation and preparative application of these reagents has been remarkably limited. The first detailed investigation of phenylcopper (prepared by transmetalation of phenylmagnesium iodide with copper(I) chloride), carried out by Gilman et al. in 1936,[4] shows clearly the ground for this: Such monoorganocopper reagents have very limited thermal stability and only moderate reactivity. In 1952 Gilman made an important breakthrough—namely the first preparation of an organocuprate, lithium dimethylcuprate, by the reaction of the poorly soluble, unreactive, and explosive methylcopper (formed from equimolar amounts of MeLi and CuCl) with a second equivalent of MeLi [Eq. (1)].[5] This reagent is readily soluble in

$$CuX \xrightarrow[-LiX]{MeLi} MeCu \xrightarrow{MeLi} Li[CuMe_2] \qquad (1)$$

diethyl ether and THF and is (in comparison with methylcopper) highly reactive towards a wide variety of electrophiles. The basis of its reactivity was demonstrated in later investigations to be the optimal combination of the soft, nucleophilic copper and the hard, electrophilic lithium. Cuprates of the type $Li[CuR_2]$ are referred to as Gilman reagents in honor of this pioneering work.

Early investigations into the reactivity of organocuprates by House et al. and Corey et al. clearly showed that these reagents are particularly well-suited for substitution reactions on an extremely wide range of saturated (haloalkanes, acid chlorides, oxiranes) and unsaturated electrophiles (allylic and propargylic derivatives) as well as for 1,4-additions to α,β-unsaturated carbonyl compounds; these advances were summarized by Posner.[6, 7] The third important type of reaction is carbocupration, the addition of organocopper species to nonactivated alkynes. Even in this early phase of development, organocopper reagents were used to solve synthetic problems that often had no other solution. One example is found in the first total synthesis of the cecropia juvenile hormone **6** by Corey et al.[8] in 1968 (Scheme 1). At this time no viable method for the stereoselective

preparation of trisubstituted alkenes existed; the target molecule contained two such fragments, both of which were constructed from iodoalkenes and cuprate reagents by substitution with retention of configuration.

Of course, this synthetic problem can now be solved more elegantly in a variety of ways, and the demands on reagents have changed substantially. Nevertheless, organocopper reagents are particularly well-suited to the most important challenge in modern synthetic chemistry—the efficient and selective formation of carbon–carbon bonds. They are amongst the most popular organometallic reagents, and many total syntheses of complex target molecules rely on the use of at least one copper-mediated carbon–carbon bond forming reaction.[9] This review highlights some of the most important advances in this area from the last few years, with an emphasis on methodological extensions in the preparation and transformations of organocopper reagents and on their application in regio- and stereoselective syntheses of natural products and pharmaceuticals, chiral auxiliaries, and target molecules with interesting structures. In contrast to previous reviews[6, 7, 9] this article is organized according to the type of selectivity (regio-, diastereo-, and enantioselectivity) and not according to reaction type.

2. Preparation and Structures

2.1. Further Developments in Methods of Preparation

By far the most important means of preparing an organocopper reagent remains the transmetalation of an organometallic reagent with a copper salt. Practically all copper(I) salts can be used for this purpose; particularly commonly used are the halides CuI and $CuBr \cdot SMe_2$ and copper(I) cyanide. Diethyl ether, THF, and dimethyl sulfide are suitable solvents for the preparation and reactions of organocopper reagents RCu and cuprates $Li[CuR_2]$. By variation of the stoichiometry of the reactants, reagents with the composition $Li_2[CuR_3]$, $Li[Cu_2R_3]$, and $Li_2[Cu_3R_5]$ can be obtained, which, according to NMR spectroscopic investigations (Section 2.2), are discrete cuprate species (Table 1).

Table 1. Overview of the different types of organocopper reagents (Th = thienyl).

Monoorganocopper compound	RCu	
homocuprates	$Li[CuR_2]$ $Li_2[CuR_3]$,$Li[Cu_2R_3]$, $Li[Cu_3R_5]$	Gilman cuprates
heterocuprates	Li[CuR(OR')] Li[CuR(SR')] Li[CuR(NR'_2)] Li[CuR(PR'_3)] Li[CuR(2-Th)]	alkoxycuprates thiolatocuprates amidocuprates phosphidocuprates thienylcuprates
cyanocuprates	Li[CuR(CN)] $Li_2[CuR_2(CN)]$	"lower order" cyanocuprates "higher order" cyanocuprates
silylcuprates	$Li[Cu(SiR_3)_2]$, Li[CuR'(SiR_3)]	
stannylcuprates	$Li[Cu(SnR_3)_2]$, Li[CuR'(SnR_3)]	

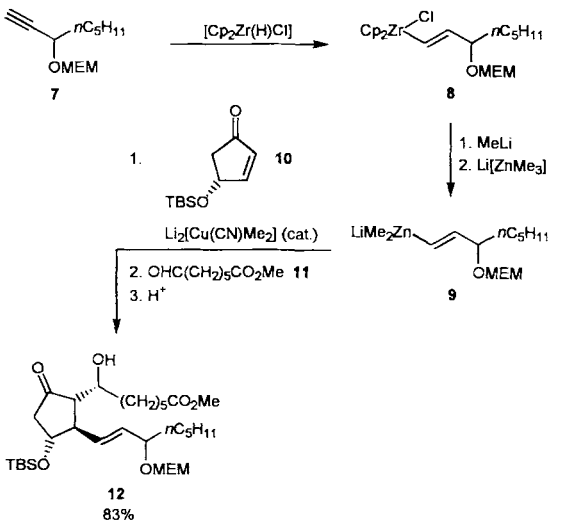
Since generally only one of the two R groups in a cuprate of the stoichiometry $Li[CuR_2]$ can be introduced into a substrate, mixed cuprates of the type $Li[CuR_tR_r]$ have been used, in which R_t is an easily transferred ligand and R_r is a tightly held, "residual", nontransferable "dummy ligand".[9] Commonly used dummy ligands are the cheap and easily accessible alkynyl,

Norbert Krause was born in 1959 in Wolfsburg, Germany, studied chemistry from 1979 to 1984 at the Technical University of Braunschweig, and obtained his doctorate in 1986 under the supervision of H. Hopf for research on sterically and electronically modified retinoids. He then completed one-year postdoctoral appointments with D. Seebach (ETH Zürich, Switzerland) and M. Saunders (Yale University, New Haven, USA). In 1993 he obtained his "habilitation" in organic chemistry in the group of K. Hafner at the Technische Hochschule Darmstadt. He joined the faculty at the University of Bonn in 1994. His research focuses on the development, application, and mechanistic understanding of organometallic reactions and on regio- and stereoselective protonation reactions. This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft, and has been recognized through the award of the Heinz-Maier-Leibnitz prize (1991), the ADUC annual prize for lecturers (1993), and a Heisenberg stipend (1994).

thienyl, alkoxy, thiolato, amido, and phosphane groups (Table 1).[9] By transmetalation, silyl-[10] and stannylcuprates[11] and mixed reagents with one silyl or stannyl group and a carbon-based group can also be prepared; in the latter case, the carbon-based group functions as the dummy ligand, and the silyl or stannyl group is transferred preferentially to the substrate.[10, 11]

A disadvantage of the classical method of preparation is that the organolithium and Grignard reagents required are too basic and nucleophilic to be compatible with most functional groups. This method can therefore provide only cuprates containing simple, unfunctionalized groups. One solution to this problem is conducting the transmetalation reaction with less reactive organometallics. In principle, all metals less electronegative than copper can be used.[12] Organotitanium,[13] -zirconium,[14] -aluminum,[15] -tin,[16] and -zinc compounds[17, 18] have proved to be particularly useful in this context; not only can they be converted into organocopper reagents by reaction with an equimolar amount of a copper(I) salt, but they can also serve in catalytic systems in direct combination with an electrophile.

The synthesis of prostaglandin **12**[14f] (Scheme 2), in which three transmetalation steps are conducted with four different



Scheme 2. Synthesis of prostaglandin **12** (MEM = methoxyethoxymethyl, TBS = *tert*-butyldimethylsilyl).

metals, is a prominent example of how complex reactions can be performed with this method in one pot without isolation of the intermediates. The starting point is the alkyne **7**, an unlikely precursor for a cuprate, which is converted by hydrozirconation with the Schwartz reagent $[Cp_2Zr(H)Cl]$ into the vinylzirconocene **8**. Methylation with MeLi and transmetalation with lithium trimethylzincate leads to the organozincate **9**. In the presence of catalytic quantities of the cuprate $Li_2[Cu(CN)Me_2]$, **9** undergoes a diastereoselective 1,4-addition to the chiral enone **10**. In this step, addition of a mixed cuprate presumably leads to a copper or lithium enolate, which is converted into the corresponding zinc enolate by transmetalation with **9**. The reaction of this species with the formyl ester **11** also takes place diastereoselectively with formation of the product **12**. Thus the reaction is conducted under catalytic conditions with regard to copper, and another particularly advantageous aspect is the trapping of the electrophile with a zinc enolate. Such an enolate is significantly more reactive than the corresponding copper and lithium enolates formed in stoichiometric cuprate additions.

Organozinc reagents FG–RZnI (FG–R: alkyl group R substituted with a functional group FG) are particularly well-suited to the preparation of functionalized cuprates. These reagents can be prepared directly from activated zinc and iodoalkanes (or from alkenes by hydroboration and transmetalation).[17, 18] The very thorough work of Knochel et al.[18] showed that the transmetalation of these reagents with the THF-soluble complex CuCN·2 LiCl leads to the corresponding cuprates of the stoichiometry FG–RCu(CN)ZnI [Eq. (2)]. These reagents may

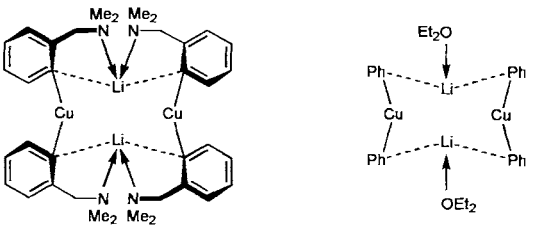
bear a variety of functional groups, for example keto, ester, cyano, and sulfonyl groups, as well as contain epoxides and halogens. They undergo the normal addition and substitution reactions with tolerance of the functional group FG.

An alternative approach to this type of functionalized organocopper reagent is the direct synthesis using the highly reactive Rieke copper,[19] which is obtained by reducing copper salts (e.g. CuCN·2 LiCl) with naphthalene–lithium. Subsequent reaction with functionalized alkanes FG–RX yields the corresponding organocopper reagent FG–RCu [Eq. (3)]. A

wide variety of functional groups are tolerated in this case too, and the reagents can be used in addition and substitution reactions with, for example, haloalkanes, oxiranes, enones, and acid chlorides.

2.2. Structures in the Solid State and in Solution

The solid-state structures of organocopper reagents have been intensively investigated in the last decade.[20] While monoorganocopper reagents such as methylcopper (a yellow solid) frequently form polymeric chain structures and are thus poorly soluble, cuprates generally exist as discrete aggregates, which are amenable to characterization by X-ray crystal structure analysis. The first cuprate to be investigated in this way was the compound $Li_2[Cu_2(2\text{-}Me_2NCH_2C_6H_4)_4]$ (Scheme 3, left), which was shown to be a dimer by van Koten et al.[21]



Scheme 3. Solid-state structures of organocuprates.

The arylcuprate contains two practically linear Ar_2Cu^- units which are linked through two Li^+ ions by ionic interactions. Intramolecular coordination with the dimethylamino groups, which are perfectly positioned for this purpose, allows the Li ions to achieve the coordination number 4. This motif of dimeric aggregates is found in many solid-state structures of organocuprates, for example the lithium diphenylcuprate $Li_2[Cu_2Ph_4(Et_2O)_2]$[22] (Scheme 3, right) and the only alkylcuprate for which an X-ray crystal structure exists, $[Li_2[Cu_2(Me_3SiCH_2)_4(Me_2S)_2]$.[23] In both these compounds the free coordination sites of the lithium ions are occupied by solvent molecules. These solid-state structures, as well as theoretical studies,[24] confirm the picture of cuprates of the formula $Li[CuR_2]$ as consisting of an anionic, nucleophilic R_2Cu^- species and an electrophilic Li^+ ion; this is of significance in understanding the mechanisms of the reactions that these compounds undergo (Section 6).

The most relevant parameter for the practical application of these reagents is, however, their structure in solution. Determination of the degree of association of lithium dimethylcuprate by ebullioscopy and vapor pressure measurements indicated that this species exists as a dimer in ethereal solutions. The structure of this dimer may well bear similarities to the solid-state structure.[25] However, NMR spectroscopic investigations indicate that cuprates are typically dynamic species in solution and that equilibria between different copper species are common.[25,26] Thus, lithium dimethylcuprate in THF exists in equilibrium with MeLi and $Li[Cu_2Me_3]$ [Eq. (4)], although only when the LiI formed during the preparation of the cuprate has been removed.[26b] In the presence of the lithium salt or in diethyl ether this equilibrium cannot be detected, and $Li[CuMe_2]$ exists as the only stable species. Exchange of alkyl groups between two different cuprates can also take place; thus in a mixture of $Li[CuMe_2]$ and $Li[Cu\textit{n}Bu_2]$ the predominant species is the mixed cuprate $Li[CuMe(\textit{n}Bu)]$ [Eq. (5)].[26c] The example

$$Li_2[(CuMe_2)_2] \rightleftharpoons MeLi + Li[Cu_2Me_3] \quad (4)$$

$$Li[CuMe_2] + Li[Cu\textit{n}Bu_2] \rightleftharpoons 2\ Li[Cu\textit{n}BuMe] \quad (5)$$

$$Li[CuPh_2] + LiI \rightleftharpoons Li_2[CuIPh_2] \quad (6)$$

of lithium diphenylcuprate makes it clear that the lithium salt formed during the preparation of the organocopper reagent can also directly affect its dynamics. The NMR spectra measured in dimethyl sulfide indicate an equilibrium between the species $Li[CuPh_2]$ and $Li_2[CuIPh_2]$ [Eq. (6)].[26d]

2.3. Cyanocuprates: A Special Case

About 15 years ago Lipshutz et al. introduced copper(I) cyanide as a source of copper in organocuprate chemistry.[9e,f,h] The cyanocuprates formed by transmetalation of organolithium species with CuCN differ dramatically from the Gilman cuprates, both in terms of stability and reactivity. Thus, the reaction of two equivalents of *t*BuLi with one equivalent of CuCN in diethyl ether or THF leads to clear solutions of the cuprate that are stable below $-30\,^\circ C$, while the corresponding Gilman cuprate formed from CuI under the same conditions decomposes to form a black suspension. Like the Gilman cuprates, the cyanocuprates take part in addition and substitution reactions with saturated and unsaturated electrophiles, although they are often significantly more reactive. This observation and early spectroscopic studies[27] led to the postulate that the cyano group is bound to the copper atom. Accordingly, the reaction of the copper salt with one equivalent of RLi leads to the copper species Li[CuR(CN)] [Eq. (7)], desig-

$$CuCN \xrightarrow{RLi} Li[CuR(CN)] \xrightarrow{RLi} Li_2[CuR_2(CN)] \quad (7)$$

nated as a lower order cyanocuprate; this monoanion ($[CuR(CN)]^- + Li^+$) has the composition $Li[CuR_tR_r]$, in which the cyano group assumes the role of the dummy ligand R_r. The addition of a second equivalent of RLi yields the cuprate $Li_2[CuR_2(CN)]$, which is composed of a dianion ($[CuR_2(CN)]_2^- + 2Li^+$) with three organic groups bound to the copper. Lipshutz designated these reagents as higher order cyanocuprates.[9e,f,h]

Since crystals suitable for X-ray studies could not be obtained for either type of cyanocuprate, the solid-state structures of these reagents are not yet known. Structural investigations in solution by NMR,[28] EXAFS (Extended X-ray Absorption Fine Structure), and XANES (X-ray Absorption Near-Edge Structure) spectroscopy[29] confirmed the composition Li[CuR(CN)] with the cyano group bound to the copper in the lower order cyanocuprates. Thus, Bertz[28] found that in the ^{13}C NMR spectrum of $Li[Cu(^{13}CN)Me]$, the cuprate formed from the reaction of ^{13}C-labeled copper cyanide with MeLi, the methyl resonance is coupled ($J = 22$ Hz) to the CN resonance. This confirms beyond doubt that the methyl and the cyano groups are both bound to the copper atom.

In contrast, the existence of higher order cyanocuprates $Li[CuR_2(CN)]$ is still controversial. Bertz et al.[30] observed identical chemical shifts in the ^{13}C NMR spectra of a variety of cuprates prepared from CuI and CuCN, while Lipshutz et al.[31] reported different chemical shifts for $Li[CuMe_2]$ (from CuI) and $Li_2[CuMe_2(CN)]$ (from CuCN). In the corresponding cuprates prepared from ^{13}C-labeled copper cyanide no coupling was observed between the alkyl groups and the cyano group.[28] In another NMR spectroscopic study, Oehlschlager et al.[32] proposed an equilibrium between the higher order species $Li_2[Cu(CN)Me_2]$ and $Li[CuMe_2] + LiCN$, formed in the reaction between MeLi and CuCN in THF. This equilibrium can be shifted to the right by addition of hexamethylphosphoric triamide (HMPA) [Eq. (8)]. Additionally, when chlorotrimethyl-

$$Li_2[Cu(CN)Me_2] \xrightleftharpoons{HMPA} Li[CuMe_2] + LiCN \quad (8)$$

silane is added to $Li_2[Cu(CN)Me_2]$ both the Gilman cuprate $Li[CuMe_2]$ and Me_3SiCN can be detected by NMR.[33] Further spectroscopic studies by Lipshutz et al.[34] on this system led to the postulate that the cyano group is bound to the copper as a π-ligand.

Ab initio calculations for $Li_2[Cu(CN)Me_2]$ yielded a cuprate without a Cu–CN bond; in the most stable structure the

cyanide ion is bound to the lithium ions.[35] EXAFS and XANES spectroscopic investigations of the cuprates formed from two equivalents of MeLi or *n*BuLi and one equivalent of CuCN are in agreement with this result; in both cases the majority of Cu atoms (>90%) have no coordinated cyanide.[29] Additionally, recently completed cryoscopic measurements of the degree of association of a range of cuprates in THF confirm the structural complexity of these reagents: whereas the "lower order" cyanocuprates exist either as monomers (Li[Cu*t*Bu(CN)]) or dimers (Li[CuPh(CN)]), studies of "higher order" cyanocuprates hinted at the existence of equilibria between different species.[36]

The discrepancies between the various spectroscopic results cannot be explained convincingly without further data (preferably solid-state structures). It is, however, conceivable that the thermodynamically most stable species is not the kinetically most active; in other words, the system $Li[CuR_2] + LiCN$ could generate small amounts of the higher order cyanocuprate $Li_2[Cu(CN)R_2]$ [see Eq. (8)], which might be responsible for the high reactivity of these reagents (compared to the Gilman reagents).

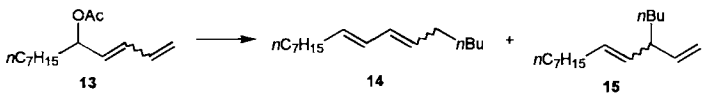
3. Regioselective Reactions

Organocopper reagents are particularly well-suited for regioselective reactions with ambident electrophiles, and the fundamental studies have already been thoroughly reviewed.[6, 7, 9] Thus, substitution reactions of unsymmetrical oxiranes take place regioselectively on the less substituted carbon atom of the epoxide ring, and allylic and propargylic electrophiles (halides, acetates, phosphates, etc.) are typically attached at the γ-C atom (along the lines of an S_N2' reaction with allylic rearrangement). The corresponding S_N2 reactions at the α-carbon are possible by means of Pd^0- and Ni^0-catalyzed reactions with organozinc reagents.[17b, 18] The addition of organocopper compounds to α,β-unsaturated carbonyl compounds also proceeds regioselectively at the β-C atom (i.e. 1,4-addition). As will be discussed in Sections 4 and 5, these C–C bond forming reactions can be carried out with a high degree of stereoselectivity, making them extremely useful synthetic transformations.

Nevertheless, not all aspects of organocopper reagents in regioselective reactions have been explored. There have been indications in the last few years that the regioselectivity of reactions involving ambident substrates with extended multiple bond systems (in other words, with more than two reactive positions) can also be controlled. Indeed, this is true not only for substitutions (1,5-substitutions), but also for additions (1,6- and 1,8-additions, etc.). These unusual reaction types not only open up novel entries to interesting target molecules but also provide deeper insight into the mechanisms of copper-mediated bond formation (see Section 6.).

3.1. 1,5-Substitutions

Dienyl acetates of type **13** can, in principle, be substituted at the α-, γ-, or ε-carbon atoms. While the direct S_N2 reaction at the α-position does not take place in the reaction with organocopper reagents, Utimoto et al.[37] found that the ratio of the γ- and ε-substituted products is strongly dependent on the reaction conditions (Scheme 4). When the conversion is carried out in THF with *n*BuMgBr and catalytic quantities of copper(I)

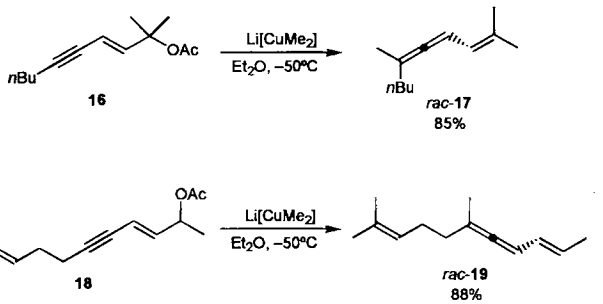


*n*BuMgBr (1.5 equiv), CuI (0.3 equiv), THF: > 99 : < 1 (83%)
*n*BuMgBr (1.5 equiv), CuI (1.5 equiv), Et_2O: 8 : 94 (63%)

Scheme 4. Substitution reactions of dienyl acetate **13**.

iodide, the conjugated diene **14** is formed exclusively (predominantly the (*E*,*E*) isomer); that is, the reaction takes place at the ε-position as a 1,5-substitution. With stoichiometric quantities of the copper salt and diethyl ether as solvent the product spectrum shifts in favor of the S_N2' reaction, giving the (1,3)-substitution product **15**, which, in the best case, was obtained with a regioselectivity of 94%, again predominantly as the (*E*) isomer. The dependence of the reaction course on the *n*BuMgBr:CuI ratio gives credence to the postulate that different organocopper species are responsible for the formation of the regioisomeric products. With equimolar amounts of Grignard reagent and copper salt the probable copper species is the monoalkylcopper compound *n*BuCu·MgBr, which leads to **15**. In contrast, an excess of Grignard reagent should lead to the magnesium cuprate $nBu_2CuMgBr$ as the active species, which gives the 1,5-substitution product **14**.

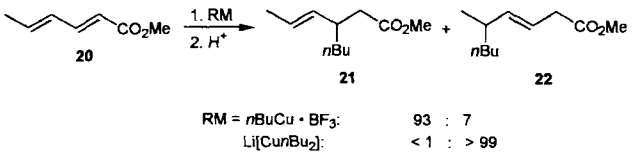
Analogous 1,5-substitution reactions are also possible with conjugated enyne acetates.[38] Thus, substrate **16** reacts regioselectively at the triple bond with lithium dimethylcuprate in diethyl ether to give the vinylallene *rac*-**17** (Scheme 5). The corresponding reaction of enyne **18** leads to the 1,5-substitution product *rac*-**19** in good yield. Such vinylallenes are useful diene components in Diels–Alder reactions.



Scheme 5. 1,5-Substitutions of enyne acetates.

3.2. 1,6-Additions

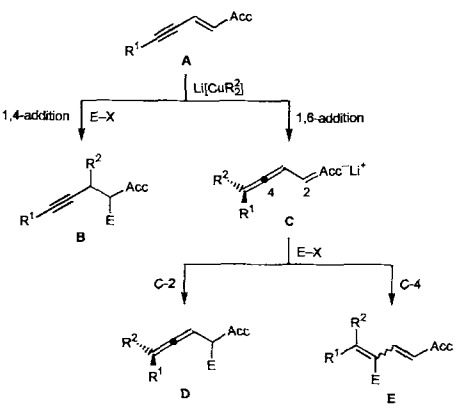
Addition reactions of organocopper reagents to Michael acceptors with an extended multiple bond system were first demonstrated by Yamamoto et al.[39] with the example of methyl sorbate (**20**). In this case, the regioselectivity depends on the copper reagent used (Scheme 6). While the combination of



Scheme 6. Regioselectivity in additions to methyl sorbate (**20**).

n-butylcopper and the Lewis acid boron trifluoride leads to the 1,4-adduct **21** as the major product, the use of the Gilman cuprate Li[Cu*n*Bu$_2$] yields exclusively the 1,6-addition product **22**. Addition of the Lewis acid $BF_3 \cdot Et_2O$ dramatically increases the reactivity of the monoorganocopper compound; the synthetically very useful organocopper compounds $RCu \cdot BF_3$ have been named Yamamoto reagents.[9d]

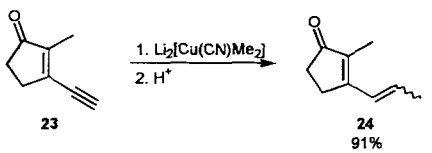
Different types of Michael acceptors can be obtained by the inclusion of triple bonds. Particularly interesting are substrates in which one or more double bonds are situated between the triple bond and the acceptor group. If, for example, the acceptor-substituted enyne **A** is treated with a cuprate Li[CuR$_2^2$] and an electrophile EX, then the cuprate can add in either a 1,4- (→ **B**) or 1,6-fashion (→ **C**) (Scheme 7). The ambident allenyl



Scheme 7. Regioselectivity in the additions of cuprates to acceptor-substituted enynes **A** (Acc = acceptor substituent).

enolate **C**, formed in the second case, can react with the electrophile at either C-2 (→ **D**) or at C-4 (→ **E**).

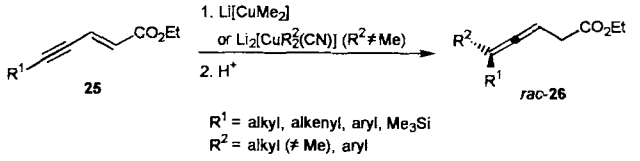
Preliminary investigations by Hulce et al.[40] into cyclic enynones of type **23** (Scheme 8) showed that both parts of the reaction proceed regioselectively in the majority of cases.



Scheme 8. 1,6-Addition to enynone **23**.

The cuprate attacks the triple bond in a 1,6-addition and the allenyl enolate is protonated at C-4 with formation of the diene **24**.

More interesting synthetically would be the possibility of shifting the regioselectivity of the electrophilic quenching reaction towards formation of allene **D**, since the number of synthetic methods for the preparation of functionalized allenes is limited.[41] Furthermore, a stereoselective reaction of this type would open up a route to these axially chiral compounds in enantiomerically enriched or pure form. Indeed, Gilman cuprates (Li[CuMe$_2$]) and cyanocuprates (Li$_2$[CuR$_2$(CN)], R ≠ Me) in diethyl ether react regioselectively with variously substituted Michael acceptors of type **25** in a 1,6-fashion (Scheme 9). Proto-



Scheme 9. Synthesis of β-allenyl carboxylates *rac*-**26** by the 1,6-addition of cuprates.

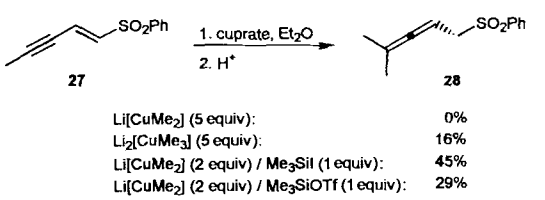
nation with dilute sulfuric acid gives the β-allenyl carboxylates *rac*-**26** with alkyl, alkenyl, aryl, and silyl substituents in good yield.[42]

The 1,6-addition of cuprates to acceptor-substituted enynes has been intensively investigated in the last five years and has proved to be a valuable, widely applicable synthetic method for the preparation of functionalized allenes. The important aspects of this reaction are discussed in the following sections.

3.2.1. *Regioselectivity of Cuprate Additions*

The regioselectivity of the addition of copper reagents with the composition Li[CuR$_2$] or Li$_2$[CuR$_2$(CN)] to enynes **A** is hardly influenced by the nature of the acceptor substituent. Enynes containing ester, thioester, lactone, and dioxanone as well as keto, sulfonyl, sulfinyl, cyano, and oxazolidino groups react in a 1,6-manner to give the corresponding functionalized allenes.[42–45] Only 1-nitro-1-en-3-ynes are attacked at the C=C double bond with the formation of 1,4-adducts.[45] The differences in reactivity that appear can be described qualitatively by the following reactivity scale: Acceptor (Acc) = NO_2 > COR, CO_2R, COSR > CN, SO_3R, oxazolidino > SO_2R > SOR ≫ $CONR_2$.

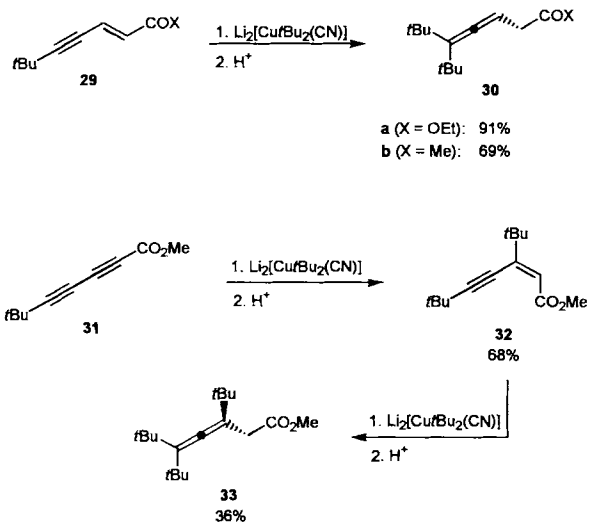
To achieve acceptable yields with the less reactive Michael acceptors, it is often necessary to use more reactive organocopper reagents or Lewis acid catalysis (the effect of Lewis acids in increasing the reactivity and selectivity of cuprates in 1,4-additions has already been thoroughly documented[9]). Thus, the reaction of enynesulfone **27** with five equivalents of Li[CuMe$_2$] alone gave no trace of addition product, whereas the analogous reaction with Li$_2$[CuMe$_3$] provided allene **28** in 16% yield (Scheme 10). With two equivalents of Li[CuMe$_2$] in the presence



Scheme 10. Optimization of the synthesis of allenylsulfone **28**.

of one equivalent of iodotrimethylsilane (Me_3SiI) the yield of **28** increased to 45%, while with Me_3SiOTf the allene was isolated in 29% yield.[45] Only amides fail to form 1,6-adducts under these conditions.

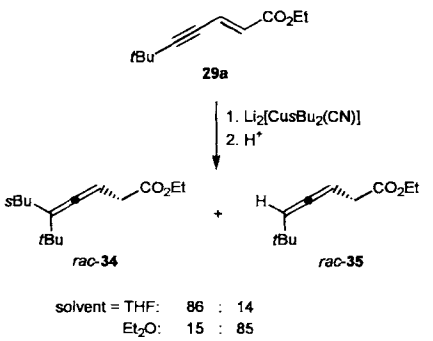
Remarkably, the regioselectivity of the cuprate addition to acceptor-substituted enynes is insensitive to the steric properties of the substrate. Enynes with *tert*-butyl substituents at the triple bond undergo 1,6-addition, even when the cuprate itself is sterically demanding. The reaction is therefore suitable for the preparation of sterically encumbered allenes, for example compounds of type **30** and **33**, which contain geminal *tert*-butyl groups (Scheme 11).[43] Since enyne **32**, the precursor to allene



Scheme 11. Preparation of sterically encumbered allenes by 1,4- and 1,6-addition of cuprates.

33, is prepared by a cuprate addition to diyne ester **31**, a combination of 1,4- and 1,6-additions succeeds in incorporating two groups derived from cuprates into the allene.

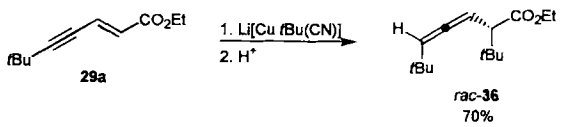
In contrast to the substrate, the organocuprate has a pronounced influence on the regioselectivity of the addition to acceptor-substituted enynes. While the Gilman cuprate Li[$CuMe_2$] and the cyanocuprates $Li_2[CuR_2(CN)]$ (R ≠ Me) add regioselectively in a 1,6-manner,[46] silylcuprates of the composition $Li[Cu(R_3Si)_2]$ and the reagent combination RCu/Me_3SiI[47] both lead to 1,4-adducts. The behavior of the cyanocuprate $Li_2[CusBu_2(CN)]$ towards 2-en-4-ynoates (e.g. **29a**, Scheme 12) is particularly unusual: the reaction is very



Scheme 12. 1,6-Reduction of enyne **29a**.

solvent sensitive. In THF the 1,6-adduct *rac*-**34** is obtained as the major product, whereas in diethyl ether the 1,6-reduction product *rac*-**35** is the main component of the product mixture.[48] A satisfactory mechanistic explanation has not yet been put forward.

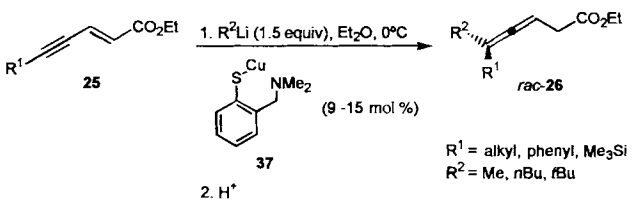
Lower order cyanocuprates Li[CuR(CN)] do not generally react with acceptor-substituted enynes. An exception is the cuprate Li[Cu*t*Bu(CN)], which undergoes *anti*-Michael additions with 2-en-4-ynoates and nitriles; thus, the substrate **29a** is converted into the allene *rac*-**36**, as a mixture of diastereomers, with the *tert*-butyl group at C-2 (Scheme 13).[49] Like the 1,6-reduction, the mechanistic aspects of this very unusual reaction are unknown; radical intermediates and electron transfer steps have not been found.



Scheme 13. *anti*-Michael addition of Li[Cu*t*Bu(CN)] to enynoate **29a**.

3.2.2. Copper-Catalyzed 1,6-Additions

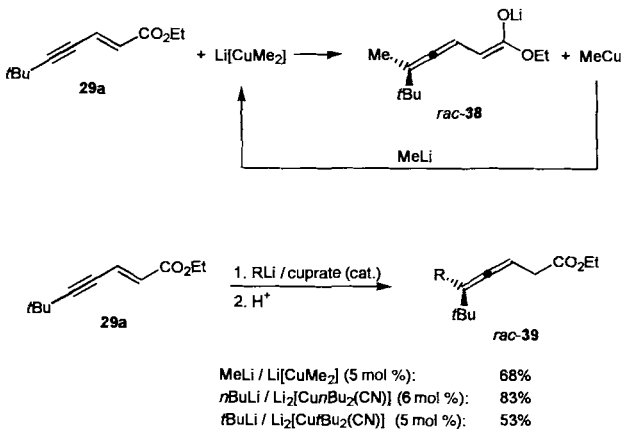
In analogy to the Kharasch method[3] mentioned in the introduction, the 1,6-addition to acceptor-substituted enynes can also take be conducted under catalytic conditions.[50] The advantages are the very efficient utilization of the organometallic reagent and the reduced amount of metal salts generated as waste. Nevertheless, one cannot use just about every copper(I) salt as is the case with the 1,4-addition. Rather, only carefully controlled reaction conditions will lead to the 1,6-adduct as the major product. Thus, the catalyst must be the copper arylthiolate **37** developed by van Koten et al.,[51] and the substrate and the nucleophilic organolithium reagent must be added simultaneously and dropwise to a suspension of the catalyst in diethyl ether at a temperature of 0 °C (Scheme 14).[50] Under these con-



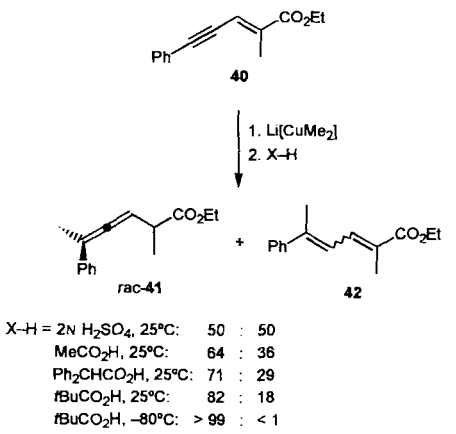
Scheme 14. 1,6-Addition of organolithium reagents to 2-en-4-ynoates catalyzed by copper arylthiolate **37**.

ditions variously substituted β-allenylcarboxylates *rac*-**26** are obtained with yields comparable to those of the stoichiometric cases. Other copper(I) salts and the use of Grignard reagents as the nucleophile lead to very low yields of 1,6-addition products.

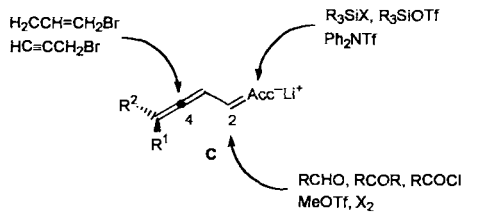
A second possible catalytic version of the reaction arises from the observation that the products of the (stoichiometric) 1,6-addition, the allenyl enolate and the organocopper compound, are formed as independent species. Thus, treatment of the enynoate **29a** with Li[$CuMe_2$] in diethyl ether yields poorly soluble methylcopper as a yellow precipitate, while the allenyl enolate *rac*-**38** remains in solution (Scheme 15). It should therefore be



Scheme 15. 1,6-Additions of organolithium reagents to enyne **29a** catalyzed by monoorganocopper compounds or lower order cyanocuprates.



Scheme 16. Regioselectivity in the protonation of an allenyl enolate.



Scheme 17. Regioselectivity in the reaction of allenyl enolates with electrophiles (Acc = acceptor substituent, Tf = trifluoromethanesulfonate, X = halogen).

possible to regenerate the cuprate by addition of one equivalent of MeLi such that it reacts with a further equivalent of the Michael acceptor. This procedure can, in principle, be repeated infinitely. The reaction can be conducted in a continuous mode by adding the substrate and the organolithium reagent simultaneously to a solution of the cuprate. In this way 5 mol% of the Gilman cuprate $Li[CuMe_2]$ or the cyanocuprates $Li_2[Cu\mathit{n}Bu_2(CN)]$ or $Li_2[Cu\mathit{t}Bu_2(CN)]$ catalyze the formation of allenes *rac*-**39** in yields of 53–83%.[52] This catalytic 1,6-addition is analogous to that in Scheme 14, and simple monoalkylcopper compounds (MeCu) or lower order cyanocuprates Li[CuR(CN)] are used as catalysts in place of the copper arylthiolate **37**.

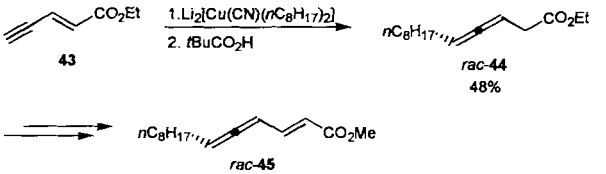
3.2.3. *Regioselectivity of the Electrophilic Trapping Reaction*

A precondition for the successful preparation of allenes by 1,6-addition (Scheme 7) is that the allenyl enolate **C** reacts regioselectively with an electrophile at C-2 with formation of the allene **D** (or at the enolate oxygen atom to give the allenylketene acetal). The regioselectivity of the simplest trapping reaction, protonation of the allenyl enolate, depends on the steric and electronic properties of the substrate and of the reagent used for the protonation.[42–45] Thus, sterically demanding groups on C-5 of the enolate promote the formation of allene **D** because protonation at C-4 is sterically hindered (Scheme 11). However, with a substituent at C-2 of the enolate, mixtures of allenes **D** and conjugated dienes **E** are formed, since now protonation at C-2 is sterically hindered. In the case of ester enolates this problem can be solved by using a different proton source. The allene:diene ratio resulting from protonation with weak organic acids such as acetic acid and diphenylacetic acid is higher than that obtained with dilute sulfuric acid (Scheme 16). The optimal proton source to conquer this problem of regioselectivity has been found to be pivalic acid (2,2-dimethylpropionic acid). At room temperature an allene:diene ratio of 82:18 is observed, and at −80 °C only the allene *rac*-**41** is formed.[42]

In contrast to protonation, the regioselectivity of the reaction of other electrophiles with allenyl enolates is independent of the steric and electronic properties of the reaction partners (Scheme 17).[45, 50, 53] Hard electrophiles such as silyl halides and triflates react at the enolate oxygen atom to form allenylketene acetals, while soft electrophiles such as carbonyl compounds attack at C-2. Only allylic and propargylic halides react regioselectively at C-4 of the allenyl enolate to give substituted dienes of type **E**; these reactions may also proceed via allenes **D**, which may then undergo a (metal-catalyzed?) Cope rearrangement to give dienes **E**.

3.2.4. *Preparative Applications*

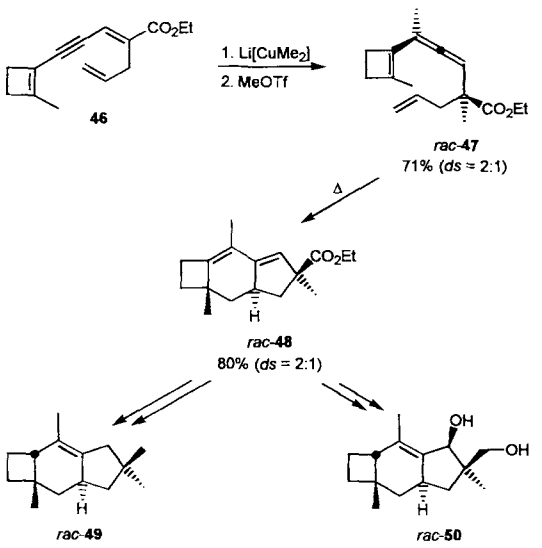
The synthesis of allenes by 1,6-addition of organocopper reagents to acceptor-substituted enynes has already found a wide range of preparative applications. In addition to sterically encumbered allenes (Scheme 11)[43] and simple terpenes such as pseudoionone,[42] allenic natural products have been prepared by this method (Scheme 18).[38] Thus, 1,6-addition of lithium



Scheme 18. Preparation of the insect pheromone *rac*-**45**.

di-*n*-octylcyanocuprate to the Michael acceptor **43**, followed by regioselective protonation with pivalic acid, yields the allene *rac*-**44**, which can be converted into the insect pheromone methyl 2,4,5-tetradecatrienoate (*rac*-**45**) by a known approach.[54]

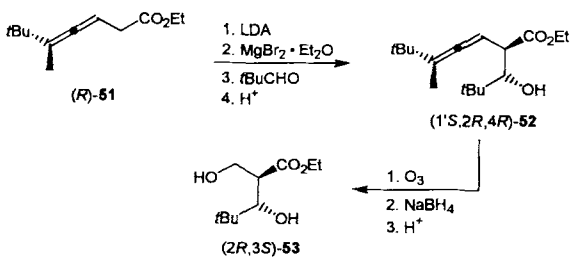
A further application of 1,6-addition in natural product synthesis relies on vinylallenes as diene components in the Diels–Alder reaction.[55] The synthesis of the fungal metabolite (+)-sterpurene (*rac*-**49**),[56] shown in Scheme 19, starts from



Scheme 19. Preparation of (±)-sterpurene (*rac*-**49**) and the dihydroxylated derivative *rac*-**50** (Tf = trifluoromethanesulfonate).

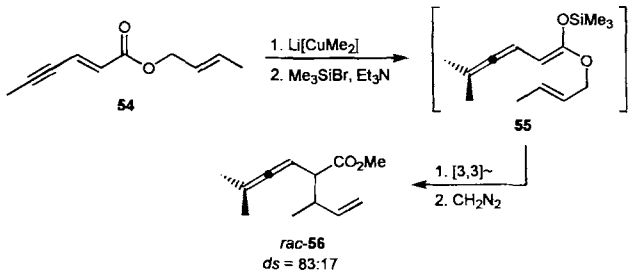
the substituted 2-en-4-ynoate **46** which undergoes 1,6-addition of lithium dimethylcuprate and regioselective trapping with methyl triflate to afford the vinylallene *rac*-**47**. A short period of heating in toluene is sufficient to convert *rac*-**47** into the tricyclic *rac*-**48**; the advantageous positioning of the diene and dienophile is reflected in the extremely low activation barrier for this nonactivated [4 + 2]cycloaddition, and also defines the relative configuration of the two new stereogenic centers. The ester *rac*-**48** can be converted into the natural product *rac*-**49** in a few steps and also into several oxygenated metabolites such as *rac*-**50**.

The intramolecular Diels–Alder reaction of the vinylallene *rac*-**47** to give *rac*-**48** is an example of how axially chiral allenes, accessible through 1,6-addition, can be utilized to form new stereogenic centers selectively. This is also possible by functionalizing chiral allenyl enolates **C** at C-2 (Scheme 7). The aldol reaction[57] and the Ireland–Claisen rearrangement[58] are particularly well-suited for this purpose. For example, the magnesium enolate formed from the chiral β-allenic ester (*R*)-**51** by deprotonation and transmetalation undergoes aldol reactions with good simple diastereoselectivity and diastereofacial selectivity; chirality is transferred from the chirality axis of the allene to the stereogenic centers generated in the aldol adduct (Scheme 20).[57] This chirality transfer has been used in the preparation of the enantiomerically pure, highly functionalized synthetic building block (2*R*,3*S*)-**53**, which is obtained from the aldol adduct (1′*S*,2*R*,4*R*)-**52** by ozonolysis.



Scheme 20. Chirality transfer in the aldol reaction of a chiral allenyl enolate.

Ireland–Claisen rearrangements of allenylketene acetals, which are accessible by 1,6-addition of cuprates to suitable allyl 2-en-4-ynoates (e.g. **54**), followed by trapping with silyl halides, also proceed with good simple diastereoselectivity and diastereofacial selectivity. An example is provided by the rearrangement of the ketene acetal **55**, which delivers the β-allenic ester *rac*-**56** with a diastereoselectivity of 83:17 (Scheme 21).[58, 59]

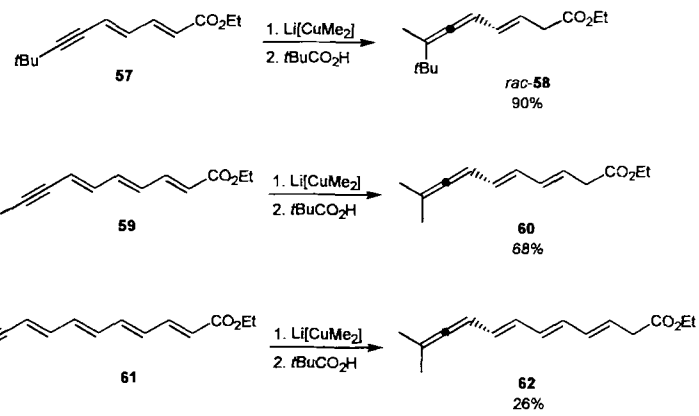


Scheme 21. Ireland–Claisen rearrangement of allenylketene acetal **55**.

3.3. 1,8-, 1,10-, and 1,12-Additions

When one considers the high regioselectivity of the addition of organocuprates to acceptor-substituted enynes, it is natural to ask whether the preference of these reagents for triple bonds persists when the distance between the acceptor group and the triple bond is increased by the introduction of further C=C bonds. The number of possible regioisomeric products increases with the increasing length of the Michael acceptor. Thus, the 2,4-dien-6-ynoate **57** can be attacked by an organocopper reagent at C-3, C-5, or C-7. The last possibility leads to a vinylogous allenyl enolate having four reactive positions (enolate oxygen, C-2, C-4, C-6). Therefore the high regioselectivity of the reaction of **57** with lithium dimethylcuprate is particularly remarkable.[60] The cuprate attacks the triple bond exclusively and protonation with pivalic acid occurs at C-2 of the enolate, giving the 1,8-adduct *rac*-**58** as the only isolable regioisomer in a yield of 90% (Scheme 22). This vinylallene is well-suited as a diene in regio- and stereoselective Diels–Alder reactions.[60]

The trienynoate **59** reacts analogously in a 1,10-fashion to give the allene **60** (68% yield), and one obtains the 1,12-adduct



Scheme 22. 1,8-, 1,10-, and 1,12-addition of cuprates to acetylenic Michael acceptors.

62 from the Michael acceptor **61**, which contains four (!) double bonds between the triple bond and the acceptor substituent (Scheme 22).[60] Here we have reached the limit, and the yield sinks to 26%. This has probably less to do with reduced regioselectivity (**62** is the only isolable reaction product, apart from polymeric compounds) but with the reduced thermal stability of the addition products with increasing length of the conjugated π-system.

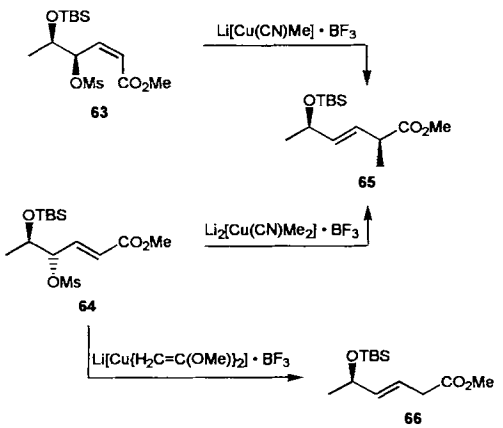
These reactions and those of the substrates **31** and **46** make clear that Michael acceptors containing any combination of double and triple bonds undergo regioselective addition reactions with organocopper reagents. The following rule holds: *Michael acceptors with any given arrangement of conjugated double and triple bonds react regioselectively with organocuprates at the triple bond closest to the acceptor substituent.*

4. Diastereoselective Reactions

4.1. Substitutions

Substitution reactions of chiral electrophiles with organocopper reagents generally display high diastereoselectivity. Well-documented examples of this are the substitutions of alkyl halides, tosylates, acetates, and oxiranes, which proceed with inversion of configuration.[9] Allylic and propargylic electrophiles react similarly, leading to products derived from regio- and *anti*-diastereoselective S_N2' reactions. Since these chiral substrates are readily available in enantiomerically pure form (for example by enantioselective reduction of carbonyl compounds[61]), such substitution reactions are particularly suitable for the preparation of stereochemically defined target molecules. This is demonstrated by some representative examples from the more recent literature.

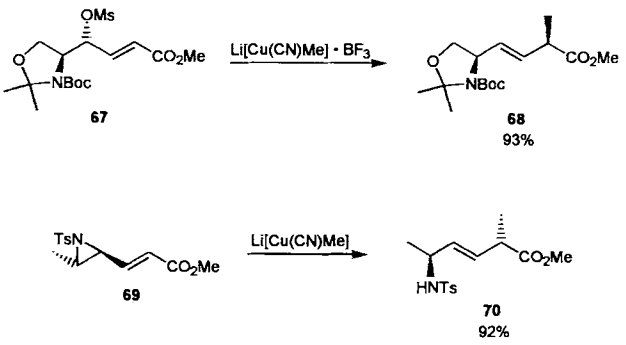
Ibuka, Yamamoto, et al.[62] thoroughly investigated the possibilities of 1,2- and 1,3-induction in S_N2' reactions of chiral γ-mesyloxyenoates and related compounds. For instance, substrates **63** and **64** both react with cyanocuprates in the presence of boron trifluoride to give the *anti*-S_N2' reaction product **65** (Scheme 23). 1,4-Adducts are not formed, and the second stereogenic center at the δ-atom does not influence the stereochemical course of the reaction. In some cases the reduction



Scheme 23. Diastereoselective S_N2' reactions of chiral γ-mesyloxyenoates (Ms = mesyl, TBS = *tert*-butyldimethylsilyl).

product **66** is formed, which can also arise by selective conversion of **64** with alkenylcuprates.

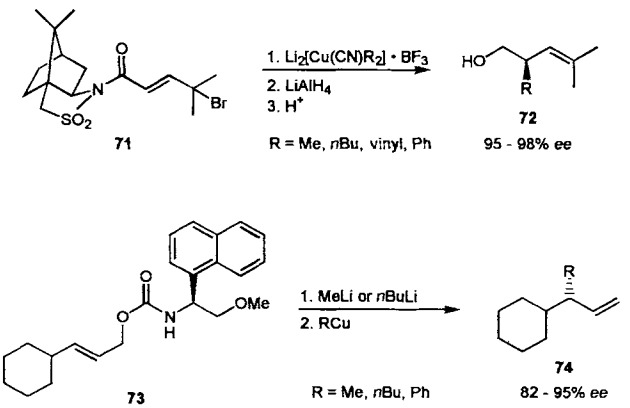
Analogous reactions are found with 4,5-epoxyenoates[62a] and substrates of type **67** and **69** containing a nitrogen functionality (Scheme 26).[62a, c, f] The latter are of particular interest,



Scheme 24. Synthesis of dipeptide isosteres (Boc = *tert*-butoxycarbonyl, Ms = mesyl, Ts = tosyl).

since the S_N2' reaction produces dipeptide isosteres (e.g. **68** and **70**). These compounds are potential protease inhibitors, in which the amide bond of the corresponding dipeptide is replaced by a topologically very similar, but nonpolar and biochemically nondegradable, C=C bond.

Chiral allylic electrophiles, in which the stereogenic center is not situated at the γ-C atom, can also take part in stereoselective S_N2' reactions with organocopper reagents.[63-65] Bloch et al.[64] demonstrated that the chiral sultam **71** undergoes highly selective substitution reactions with cyanocuprates $Li_2[CuR_2(CN)]\cdot BF_3$. Reductive cleavage of the sultam group provides practically enantiomerically pure homoallylic alcohols **72** (Scheme 25). Denmark et al.[65] observed a case of "remote

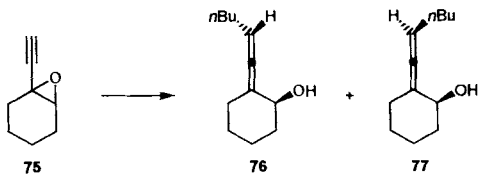


Scheme 25. Stereoselective S_N2' reactions of chiral allylic electrophiles.

stereocontrol" in the substitution reactions of the chiral carbamate **73** (Scheme 25). Deprotonation and treatment with organocopper compounds delivered the alkene **74** with selectivities of up to 95% *ee*.

The diastereoselective substitution of chiral propargylic derivatives with organocopper species is the most important method for the stereoselective preparation of chiral al-

lenes.[41, 57] The possibilities of stereocontrol in these transformations have been thoroughly investigated by Alexakis et al.[66] Studies with propargyl ethers and propargyl oxiranes indicate that the stereochemical course of the reaction is strongly dependent on the composition of the reagent (Scheme 26). The reac-



*n*BuMgBr / CuBr · 2 nBu$_3$P (5 mol %): > 99 : < 1
*n*BuMgCl / Me$_3$SiCl / CuBr (5 mol %): 10 : 90

Scheme 26. Diastereoselectivity in S_N2' reactions of propargyl oxirane **75**.

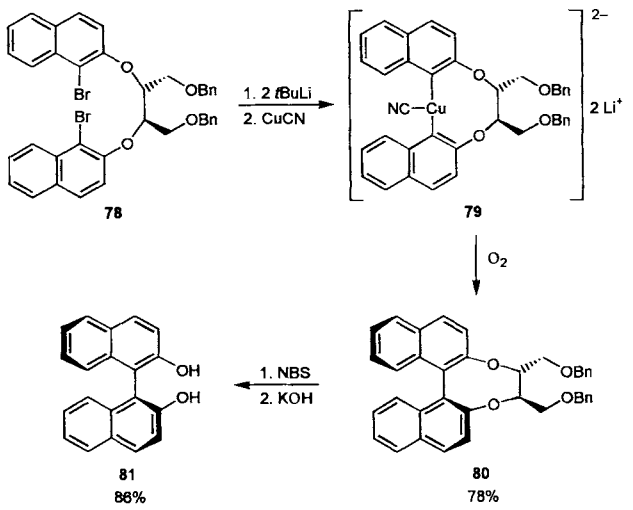
tion of epoxide **75** and *n*BuMgBr in the presence of catalytic amounts of CuBr·2nBu$_3$P affords the *anti* substitution product **76**, while the same conversion with *n*BuMgCl/CuBr (cat.)/Me$_3$SiCl, produces the *syn* isomer **77** with a diastereoselectivity of 90%. These reactions proceed, in all probability, by means of an addition–elimination mechanism. In some cases the alkenylcopper compounds that occur as intermediates can be trapped by electrophiles.[66]

Another example of copper-mediated substitution reactions is the Ullmann coupling, in which biaryls are formed by treatment of haloarenes with copper powder or copper(I) triflate.[1] However, this method is not suitable for the preparation of unsymmetrical biaryls Ar–Ar', since the coupling of two different aryl halides delivers a statistical mixture of the three possible reaction products. Lipshutz et al.[67] solved this problem by oxidizing mixed diarylcuprates of the (presumed) composition Li$_2$[CuArAr'(CN)] [Eq. (9)]. These cuprates are obtained by

$$\mathrm{CuCN} \xrightarrow{\mathrm{ArLi}} \mathrm{Li[CuAr(CN)]} \xrightarrow[-125\,^\circ\mathrm{C}]{\mathrm{Ar'Li}} \mathrm{Li_2[CuArAr'(CN)]} \xrightarrow[-125\,^\circ\mathrm{C}]{\mathrm{O_2}} \mathrm{Ar\text{–}Ar'} \quad (9)$$

treating CuCN successively with one equivalent each of ArLi and Ar'Li; it is essential that the addition of the second aryllithium compound and the subsequent oxidation with oxygen are carried out at the lowest possible temperature in order to avoid exchange reactions leading to symmetrical cuprates Li$_2$[CuAr$_2$(CN)] and Li$_2$[CuAr'$_2$(CN)], from which symmetrical biaryls are produced. Suitable aryl groups include phenyl and naphthyl, as well as heteroaryls such as thiophenes, benzothiazoles, and pyridines.[67]

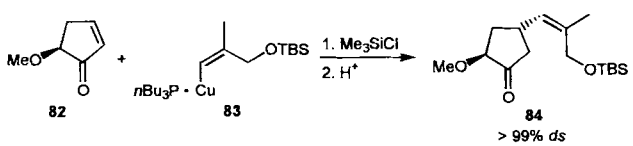
Two arenes can also be coupled with diastereoselectivity by taking advantage of a chiral bridge. This principle has led to an elegant synthesis of the important chiral auxiliary (*S*)-2,2'-binaphthol (**81**) (Scheme 27).[68] The bridge used in the starting material **78** is easily accessible from (*S*,*S*)-tartaric acid. Double exchange of bromine for lithium, followed by transmetalation with copper(I) cyanide gives the cuprate **79**, which can be converted to the enantiomerically pure target molecule by oxidation to **80** and then cleavage of the bridge.



Scheme 27. Preparation of (*S*)-2,2'-binaphthol (**81**) by oxidation of cuprate **79** (Bn = benzyl, NBS = *N*-bromosuccinimide).

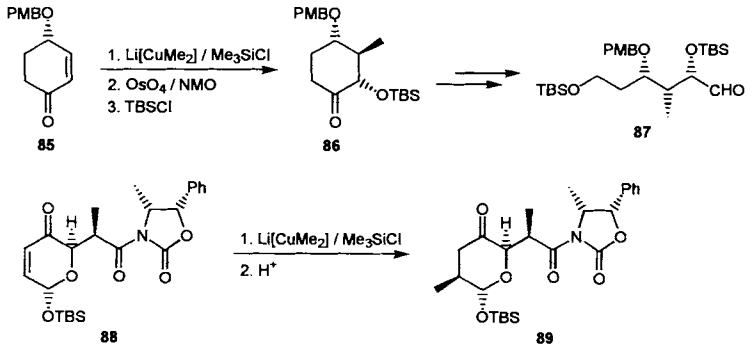
4.2. Michael Additions

The synthetic potential of the diastereoselective additions of organocopper reagents to Michael acceptors has been thoroughly summarized in two reviews which appeared a few years ago.[69] New results in this area include methodological extensions of the reaction, the use of novel substrate types (for example chiral metal complexes), and the synthesis of natural products and (potential) pharmaceuticals. The diastereoselectivity of the 1,4-addition of cuprates to cyclic Michael acceptors is, as a rule, easier to control than the corresponding reaction with acyclic substrates. Not surprisingly, many preparative applications of this technique therefore use chiral cyclic enones. The classical area of application is the synthesis of prostaglandins (see Scheme 2);[9, 70] in such cases the prostaglandin skeleton (e.g. **12**) is formed directly in a one-pot reaction by *anti*-diastereoselective cuprate addition to a chiral cyclopentenone of type **10**, followed by a trapping reaction (also *anti*-stereoselective). This method is suitable for the preparation of other classes of natural products as well. For instance, a key intermediate in a synthesis of the macrocyclic antibiotic (+)-hitachimycin is fragment **84**, which is obtained by diastereoselective 1,4-addition of the organocopper compound **83** to the chiral enone **82** (Scheme 28).[71]



Scheme 28. Diastereoselective 1,4-addition to the chiral enone **82** (TBS = *tert*-butyldimethylsilyl).

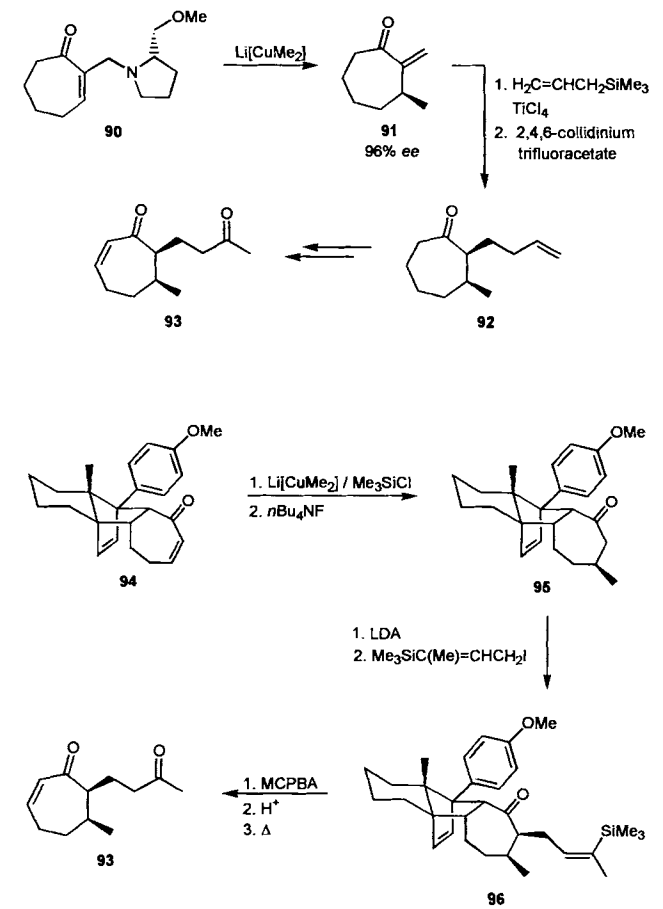
Diastereoselective cuprate additions to chiral 4-alkoxy-2-cyclohexenones are the key steps in the syntheses of other natural products (Scheme 29). As an example, the 1,4-addition of lithium dimethylcuprate to enone **85**, followed by oxidative trapping, gives ketone **86**, which is converted in a few steps into **87**, a fragment of the immunosuppressant FK-506.[72] Analogous-



Scheme 29. Diastereoselective 1,4-additions of cuprates to chiral 4-alkoxy-2-cyclohexenones (NMO = *N*-methylmorpholine-*N*-oxide, PMB = *p*-methoxybenzyl, TBS = *tert*-butyldimethylsilyl).

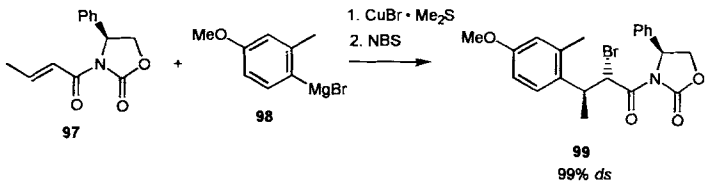
ly, the conversion of the highly functionalized substrate **88** leads to the 1,4-adduct **89**, with stereocontrol arising from the silyloxy group. This adduct is an intermediate in the synthesis of the antibiotic (+)-macbecin I.[73] These transformations are additional examples of the well-documented influence of additives on the stereochemical course of cuprate additions,[9, 69] since high *anti*-diastereoselectivities are only achieved in the presence of chlorotrimethylsilane.

Of the numerous other such examples,[9, 69] we highlight two elegant stereoselective syntheses of the natural product (+)-clavularin A (**93**) (Scheme 30). Building on their earlier work on the preparation of stereochemically pure 2-*exo*-methylenecycloalkanones,[74] Tamura et al.[75] employed product **91**, derived from addition of Li[CuMe$_2$] to enone **90** and subsequent elimination of the chiral auxiliary, as an intermediate in the preparation of the target molecule. A Sakurai reaction and *cis*-diastereoselective protonation with 2,4,6-collidinium trifluoroacetate led to the ketone **92**, which was converted into the natural product **93** by the introduction of the endocyclic double bond and oxidation. In an alternative synthesis Winterfeldt et al.[76] started with the polycycle **94**; in this case the attack of the cuprate took place exclusively on the convex side of the molecule on steric grounds, forming the adduct **95**. Diastereoselective allylation, oxidation, and thermal retro-Diels–Alder reaction led to the target molecule **93** via the intermediate **96**.



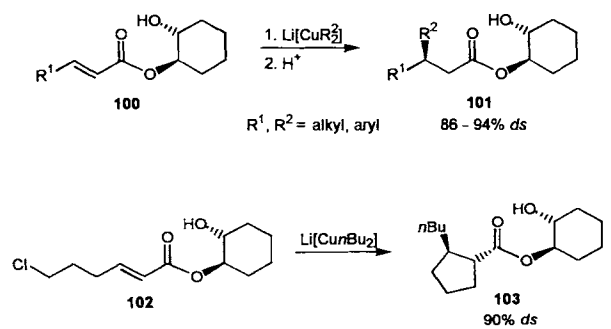
Scheme 30. Two syntheses of the natural product (+)-clavularin A (**93**; MCPBA = *m*-chloroperbenzoic acid).

Such high diastereoselectivities cannot be achieved so readily with chiral acyclic Michael acceptors due to their greater conformational flexibility.[9, 62a, 69, 77] Conformational fixing of the substrate is required, either by using chiral auxiliaries with bulky blocking substituents or through π-stacking;[78] examples of this are α,β-unsaturated esters derived from 8-phenylmethanol and from chiral camphor derivatives.[9, 69, 78–80] Other Michael acceptors belonging to this class are chiral *N*-crotyloxazolidinones such as **97** (Scheme 31).[81] This compound undergoes a highly diastereoselective 1,4-addition with the organocopper reagent derived from the Grignard reagent **98** and CuBr·Me$_2$S. The intermediate enolate can be protonated or, as in Scheme 31, brominated to give **99**. This route allows easy access to the corresponding diastereomerically and enantiomerically pure α-amino acid derivatives.



Scheme 31. Diastereoselective Michael addition to *N*-crotyloxazolidinone **97** (NBS = *N*-bromosuccinimide).

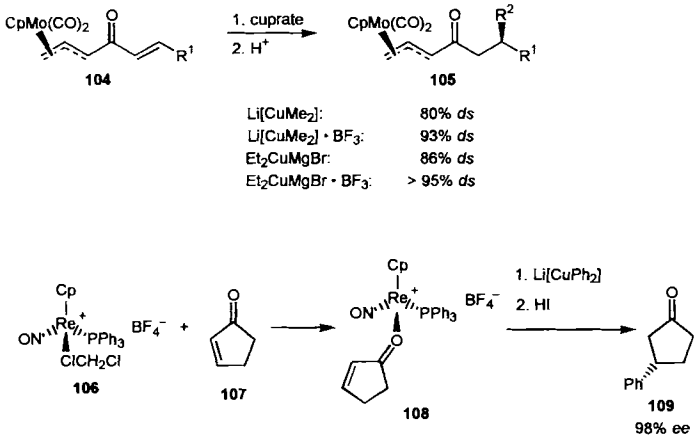
Similarly high diastereoselectivities are achieved in the iodotrimethylsilane-induced addition of organocopper reagents to chiral α,β-unsaturated amides and imides.[82] A further chiral auxiliary suitable for this reaction is the C_2-symmetrical *trans*-1,2-cyclohexanediol (Scheme 32).[83] For example, the reaction of ester **100** with Gilman cuprates yields the adducts **101** with



Scheme 32. Diastereoselective 1,4-additions to chiral α,β-unsaturated esters.

diastereoselectivities of 86–94% *ds*, and the halogenated derivative **102** gives the product **103** with 90% *ds* after cuprate addition and subsequent cyclization. In contrast, 1,4-additions of cuprates to α,β-unsaturated binaphthyl esters proceed with rather low diastereoselectivities.[84]

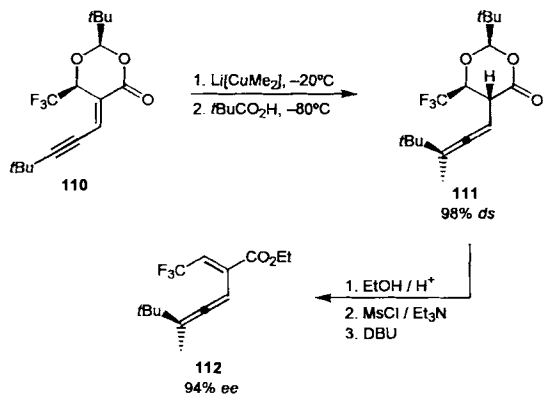
Chiral metal complexes have also been employed successfully as Michael acceptors in diastereoselective cuprate additions (Scheme 33). While, in the case of a chiral arylchromium com-



Scheme 33. Diastereoselective addition of cuprates to chiral metal complexes.

plex, the use of a chiral organocopper reagent in the form of a "matched pair" is required to achieve high diastereoselectivity,[85] the π-allylmolybdenum compound **104** reacts with simple Gilman cuprates to give the 1,4-adducts **105** in good to very good stereoselectivities.[86] Planar-chiral η^3-allyliron complexes are also suitable for such conversions.[87] In an alternative approach Gladysz et al.[88] relied on the chiral Lewis acid **106**, which, in a simple example, forms a complex (**108**) with enone **107**; the chiral ketone **109** can be obtained by 1,4-addition of cuprate to **108** and removal of the Lewis acid. Enantioselectivities of up to 98% *ee* can be achieved with this method.

Translation of these results to the 1,6-addition of cuprates to acceptor-substituted enynes is problematic owing to the even greater conformational mobility of the substrates. It is therefore no surprise that 1,6-additions to acyclic chiral 2-en-4-ynoates proceed only with very low diastereoselectivities. The chiral 5-alkynylidene-1,3-dioxan-4-ones of the type **110** are much better



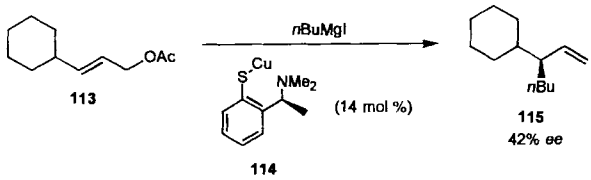
Scheme 34. Diastereoselective 1,6-addition of a cuprate to the chiral dioxanone **110** (Ms = mesyl, DBU = 1,8-diazobicyclo[5.4.0]undec-7-ene).

suited for this reaction, since the equatorial *tert*-butyl group forces the molecule to adopt a very rigid conformation and the trifluoromethyl group protects the top face of the enyne unit, making the preferred point of attack the underside of the molecule (Scheme 34). Consequently, reaction with lithium dimethylcuprate and pivalic acid gives the allene **111** with a diastereoselectivity of 98% *ds*. The stereochemical information generated in this step remains intact even after the further conversion of **111** into the chiral vinylallene **112**.[89, 90]

5. Enantioselective Reactions

5.1. Substitutions

Enantioselective substitution reactions of prochiral electrophiles with chiral organocopper reagents have not been investigated very thoroughly. This is largely because enantiomerically pure or enriched substitution products are easily accessible by the reaction of chiral substrates with achiral organocopper reagents.[9] Bäckvall, van Koten, et al.[91] have described an example of an enantioselective S_N2' reaction catalyzed by a chiral organocopper reagent (Scheme 35). Allylic acetate **113** reacts with *n*-butylmagnesium iodide in the presence of 14 mol% of the chiral copper arylthiolate **114**, giving the product **115** with 42% *ee*.

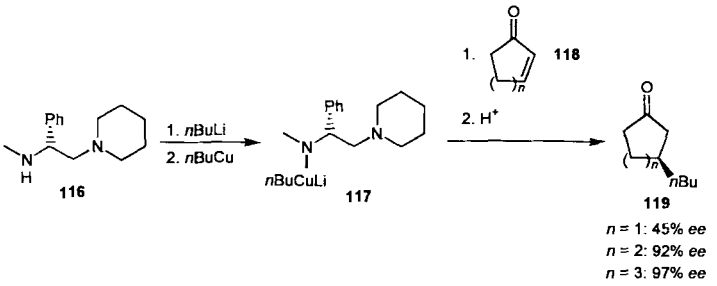


Scheme 35. Enantioselective S_N2' reaction catalyzed by the copper arylthiolate complex **114**.

5.2. Michael Additions

Enantioselective 1,4-additions of chirally modified organocopper reagents to achiral Michael acceptors have been investigated intensively in the last ten years.[9, 69] As the contributions from the groups of Bertz, Corey, Dieter, Rossiter, and Tanaka show, reagents of the stoichiometry Li[CuR(L*)] are particularly well-suited for this application when the chiral nontransferrable ligand L* controls the stereochemical course of the transfer of the group R to the substrate. The chiral ligands L* are predominantly alcoholates and amides.[69] The dynamic behavior of the organocopper species in solution has presented difficulties (Section 2.2); in many cases the reagents Li[CuR(L*)] deliver only very modest enantioselectivities. This may well be due to equilibria with achiral, but more active cuprate species (such as homocuprates of the composition $Li[CuR_2]$), which form racemic 1,4-adducts.

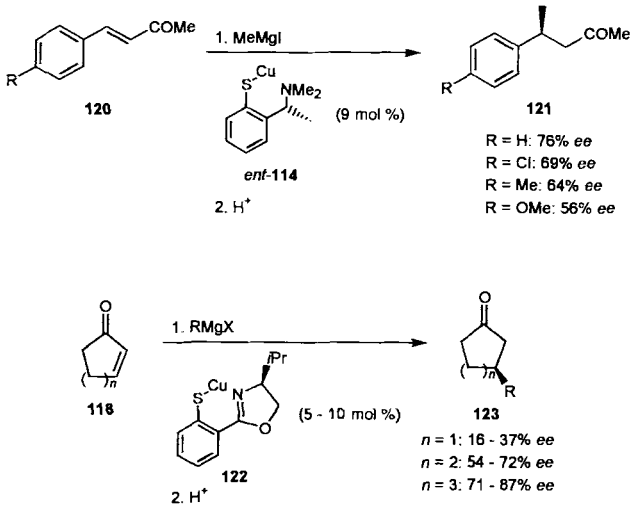
The most recent work in this area has focused on the development of efficient chiral ligands[92, 93] and catalytic reactions.[94–96] Thorough investigations into the enantioselective 1,4-addition of chiral amidocuprates have been carried out by Rossiter et al.,[93] who found that cuprates of the type **117** are the most selective (Scheme 36). These species are formed by



Scheme 36. Enantioselective 1,4-additions of the chiral amidocuprate **117**.

deprotonation of (*S*)-*N*-methyl-1-phenyl-2-(1-piperidinyl)-ethanamine ((*S*)-MAPP, **116**) and subsequent reaction with organocopper compounds. Addition of **117** to cyclic enones **118** yields the adducts **119** with enantioselectivities of 45–97% *ee*.

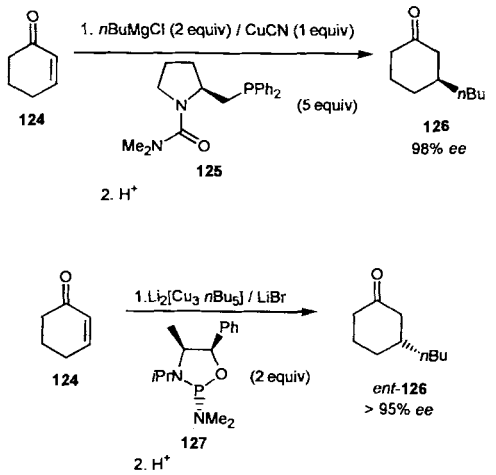
Selectivities of this magnitude have also now been achieved by the 1,4-addition of Grignard reagents to enones in the presence of chiral copper catalysts (Scheme 37). Thus, the reaction of



Scheme 37. Enantioselective 1,4-addition of Grignard reagents, catalyzed by the chiral copper thiolates *ent*-**114** and **122**.

substituted benzylideneacetones **120** with methylmagnesium iodide and catalytic quantities of the copper arylthiolate *ent*-**114**, developed by van Koten et al.,[95] yields the adducts **121** in 56–76% *ee*. Pfaltz et al.[96] made use of the structurally related **122** to catalyze the enantioselective 1,4-addition of a range of different alkylmagnesium halides to cyclic enones **118**; the resulting adducts **123** were obtained with selectivities of up to 87% *ee*. In both cases, complex nonlinear relationships observed between the enantiomeric excesses of the catalysts and the adducts led to the conclusion that several reaction paths involving more than one organocopper species all lead to the product. Remarkable substrate specificity is also apparent, since the catalyst *ent*-**114** is as unsuitable for enantioselective additions to cyclic enones as compound **122** is for acyclic substrates.

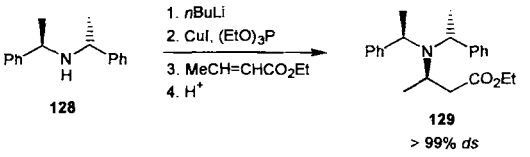
The preparation of chiral organocopper reagents does not require that the chiral auxiliary be bound to the copper center in the form of an anionic ligand. In several cases the addition of neutral, chiral compounds as "cosolvents" to the reaction medium is sufficient to induce the formation of enantiomerically pure or enriched 1,4-additions products.[69] These reactions may well proceed via chiral copper species, in which the chiral, neutral ligand takes the place of a solvent molecule that is normally bound to the copper. Thus, Tomioka et al.[97] obtained the adduct **126** with 98% *ee* by treating 2-cyclohexenone (**124**) with *n*BuMgBr/CuCN in the presence of two equivalents of the chiral amidophosphane **125** (Scheme 38). In related work



Scheme 38. Enantioselective 1,4-additions in the presence of chiral neutral ligands.

Alexakis et al.[98] utilized heterocycles of the type **127** as chiral ligands in the enantioselective 1,4-addition of cuprates of the stoichiometry $Li_2[Cu_3R_5]$ to enones and unsaturated lactones; 2-cyclohexenone (**124**) yielded the adduct *ent*-**126** with >95% *ee* under these conditions. For reasons that are not yet clear, the addition of excess lithium bromide was required to achieve such high stereoselectivity.

The third possible means of carrying out stereoselective 1,4-additions of cuprate relies on organocopper reagents carrying chiral transferrable groups. Several examples of the transfer of chiral groups to Michael acceptors with the help of the corresponding cuprate have already been documented.[69] This approach has been extended more recently by enantioselective addition reactions of chiral amidocuprates (Scheme 39). Thus, the

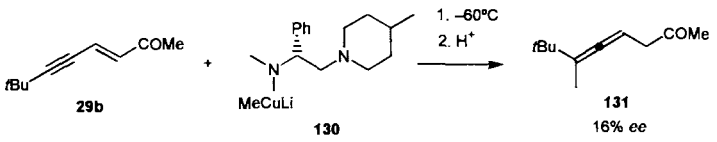


Scheme 39. 1,4-Addition of an amidocuprate.

diastereo- and enantiomerically pure β-amino acid derivative **129** is accessible from ethyl crotonate by the 1,4-addition the amidocuprate species derived from amine **128** by deprotonation and transmetalation.[99]

As was the case with the diastereoselective variants (Section 4.2.), enantioselective 1,6-additions of chirally modified cuprates to acceptor-substituted enynes are difficult to devise; heterocuprates are often not reactive enough towards these Michael acceptors and the substrates display high conforma-

tional flexibility. Only very recently was the first significant success in this area achieved with the chiral amidocuprate previously described by Rossiter et al.[93] (Scheme 40). Thus, the 1,6-addition of cuprate **130** to enynone **29b** yields the axially chiral allene **131** in 16% *ee*.[100] Although this enantioselectivity is obviously far too low to be of synthetic utility, it may well be optimized by suitable choice of substrates and ligands.

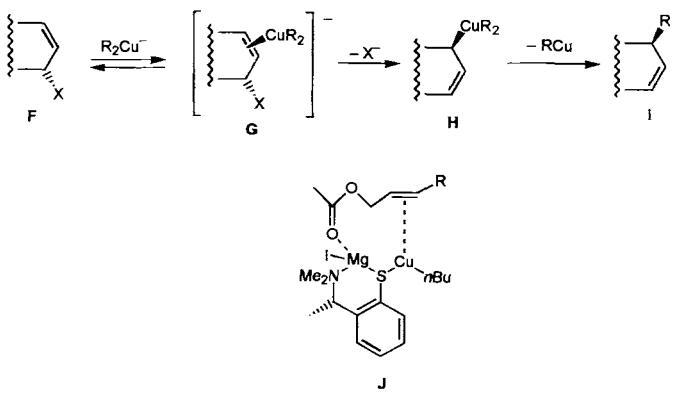


Scheme 40. Enantioselective 1,6-addition of the chiral amidocuprate **130**.

6. Mechanistic Investigations

A good understanding of the mechanistic course of the reactions of organocopper compounds is a prerequisite for "fine-tuning" the regio- and stereoselectivity of the reagents by the choice of suitable reaction conditions (solvent, stoichiometry, ligands, etc.). There has, therefore, been no lack of effort to clarify the mechanism of addition and substitution reactions of organocopper reactions. Indirect methods, for example the investigation of stereochemical details, as well as direct techniques, such as kinetic measurements and the detection of reactive intermediates by NMR spectroscopy, have been used. S_N2' reactions and Michael additions proved to be mechanistically very closely related. In fact, Michael reactions can be considered as substitution reactions in which a bonding electron pair functions as the leaving group.

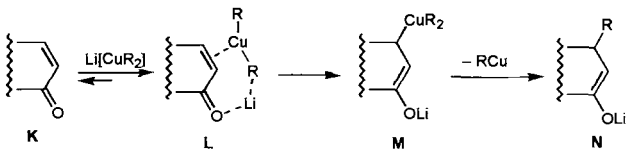
As has been discussed in Sections 3 and 4, most reactions of allylic electrophiles with organocopper reagents are regioselective (in the sense of an S_N2' reaction) and *anti*-diastereoselective under both stoichiometric and catalytic conditions. The reactions proceed presumably via π-complexes of type **G**, in which the cuprate fragment is bound *anti* to the leaving group X on electronic and steric grounds (Scheme 41).[9, 101] In the rate-determining step the σ-copper(III) species **H** is formed; subsequent reductive elimination of alkylcopper with retention of configuration leads to the *anti*-S_N2' product **I**. The loss of regioselectivity observed in some cases can be rationalized by the assumption



Scheme 41. Postulated mechanism of the S_N2' reaction of allylic electrophiles.

that **H** isomerizes via π-allylcopper complexes. Intermediates (e.g. **J**) corresponding to the π-complex **G** have also recently been proposed for S_N2' reactions catalyzed by the copper arylthiolates **37** and **114** (Schemes 14 and 35, respectively).[91, 101] An analogous picture has also been assumed for reactions with propargylic electrophiles.[9, 66]

Thorough NMR spectroscopic investigations of the mechanism of the 1,4-addition to enones and enoates have been carried out by Ullenius et al.,[102] Bertz et al.,[103] Oehlschlager et al.,[104] and Smith et al.[105] In all of these studies the π-complex **L** was found as a stable intermediate in solution at low temperatures; recently, a corresponding π-complex was also detected as an intermediate in the 1,4-addition of cuprates to acetylenic esters.[106] Here, in analogy to the intermediates **G** and **J**, there is also an apparent interaction between the π-system of the C=C bond and the nucleophilic copper atom (Scheme 42), which can

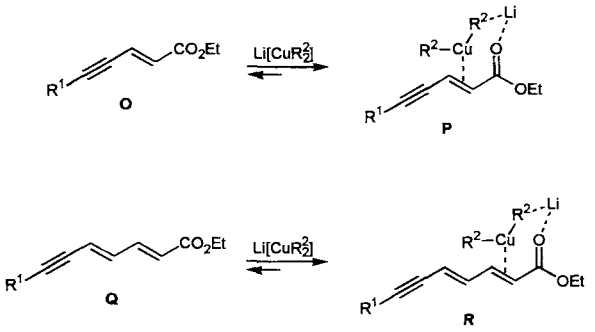


Scheme 42. Postulated mechanism of the 1,4-addition of cuprates to enones and enoates.

be considered as a soft–soft interaction according to the HSAB principle (HSAB = Hard and Soft Acids and Bases[107]). As is the case with **J**, a second interaction is observed in **L** between the hard lithium ion of the cuprate and the hard carbonyl oxygen. The 1,4-addition could then proceed by intramolecular rearrangement via the copper(III) species **M**, which is analogous to the intermediate **H** postulated for S_N2' reactions. Reductive elimination of RCu from **M** would then give the enolate **N**. Kinetic investigations are consistent with this model.[108] An alternative mechanistic scenario involves the formation of a 1,2-adduct of the cuprate and the C=C double bond of the Michael acceptor.[109]

Thus, the proposed mechanisms for addition and substitution reactions resemble each other to a considerable degree, and the similarity of the postulated (**J**) and experimentally detected (**L**) π-complexes is intriguing. Analogous structures have been put forward for the intermediates in enantioselective 1,4-additions of chirally modified organocopper reagents.[93, 95] However, the existence of the copper(III) species **H** and **M** is controversial. These intermediates have not yet been detected experimentally,[110] and theoretical calculations both support[111] and refute[112] the participation of copper(III) compounds in the reactions of organocuprates.

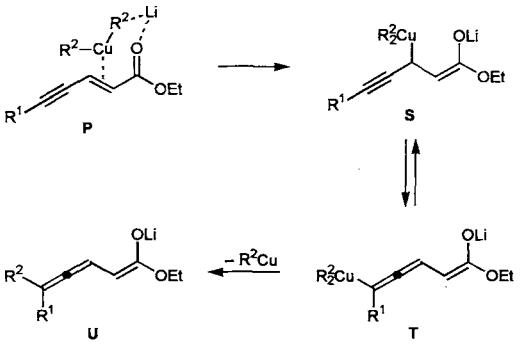
Kinetic and NMR spectroscopic investigations have recently allowed more profound mechanistic insights into the 1,6-addition of organocuprates to acceptor-substituted enynes (and 1,8-additions to dienynes). These substrates not only offer a larger number of possible regioisomeric products than the simpler enones (Section 3.2), but the potential number of possible regioisomeric intermediates is also greater. Thus, a cuprate could coordinate to the C–C double bond or the triple bond of the enyne **O**, whereas the dienyne **Q** offers three corresponding positions (Scheme 43). The ^{13}C NMR spectra of the π-complex-



Scheme 43. Formation of π-complexes in the 1,6- and 1,8-additions of cuprates to acetylenic Michael acceptors.

es **P** and **R** indicate that in both cases the cuprate is coordinated to the double bond neighboring the ester group.[113] Li–O interactions are also evident like those observed for the π-complex **L**. The $^{13}C,^{13}C$ coupling constants were determined with ^{13}C-labeled substrates, and the cuprate in **P** was found not to interact with the triple bond.[114] Furthermore, couplings between the labeled Michael acceptor and the copper- or lithium-bound alkyl group could be observed in some cases, giving the first hints regarding the structure of the metal-containing part of the cuprate π-complexes.[114, 115]

The major mechanistic difference between the 1,4-addition of cuprates to enones and the 1,6-addition to acceptor-substituted enynes is that, in the first case, both the π-complexation and the transfer of the organic group take place on the C=C bond, while the corresponding positions are different in the second case (naturally, this also holds for 1,8-additions to the 2,4-dien-6-ynoates **Q**). How is it then that 1,6-addition products are formed from the π-complex **P**? A mechanistic model in agreement with the currently available experimental data[113–115] is represented in Scheme 44. The rate-determining step is the intramolecular rearrangement of the π-complex **P** to form the intermediate **S** (corresponding to the copper species **M**), which is in equilibrium with the allenylcopper compound **T**. Reductive elimination of R^2Cu then leads to the allenyl enolate **U**.



Scheme 44. Postulated mechanism of the 1,6-addition of cuprate to acceptor-substituted enynes.

One explanation of the exclusive formation of the 1,6-adduct is that the equilibrium lies very much in favor of the intermediate **T**; alternatively, the reductive elimination of R^2Cu from **T** is much more rapid than that from **S**. Similar mechanisms can be formulated for the 1,8-, 1,10-, and 1,12-additions of cuprates to acetylenic Michael acceptors (Section 3.2). These mechanisms require two, three, and four rearrangement steps, respectively, of the type **S** → **T** in order to reach the desired copper compound.

7. Summary and Outlook

Organocopper reagents have been utilized with great success in organic synthesis in the last 30 years. The more recent examples discussed in this review document the excellent performance of these organometallic compounds in regio- and stereoselective transformations. Significant new developments include the extension of the Michael addition to 1,6-, 1,8-, 1,10-, and 1,12-additions to acetylenic substrates and the realization of highly diastereoselective substitution and addition reactions. In contrast, the addition of chirally modified organocopper reagents to achiral acceptors is highly enantioselective only in exceptional cases, and the various reagents are each applicable to only a few substrates. The further development of enantioselective transformations and of the mechanistic understanding of these reactions should be the emphasis of future research in this area.

Our work on the addition of cuprates to extended Michael acceptors was sponsored by the Deutsche Forschungsgemeinschaft, the Volkswagen-Stiftung, the Fonds der Chemischen Industrie, the Dr.-Otto-Röhm-Gedächtnisstiftung, the European Community, and the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen. We would also like to thank all our co-workers, whose names are listed in the references, for their contributions.

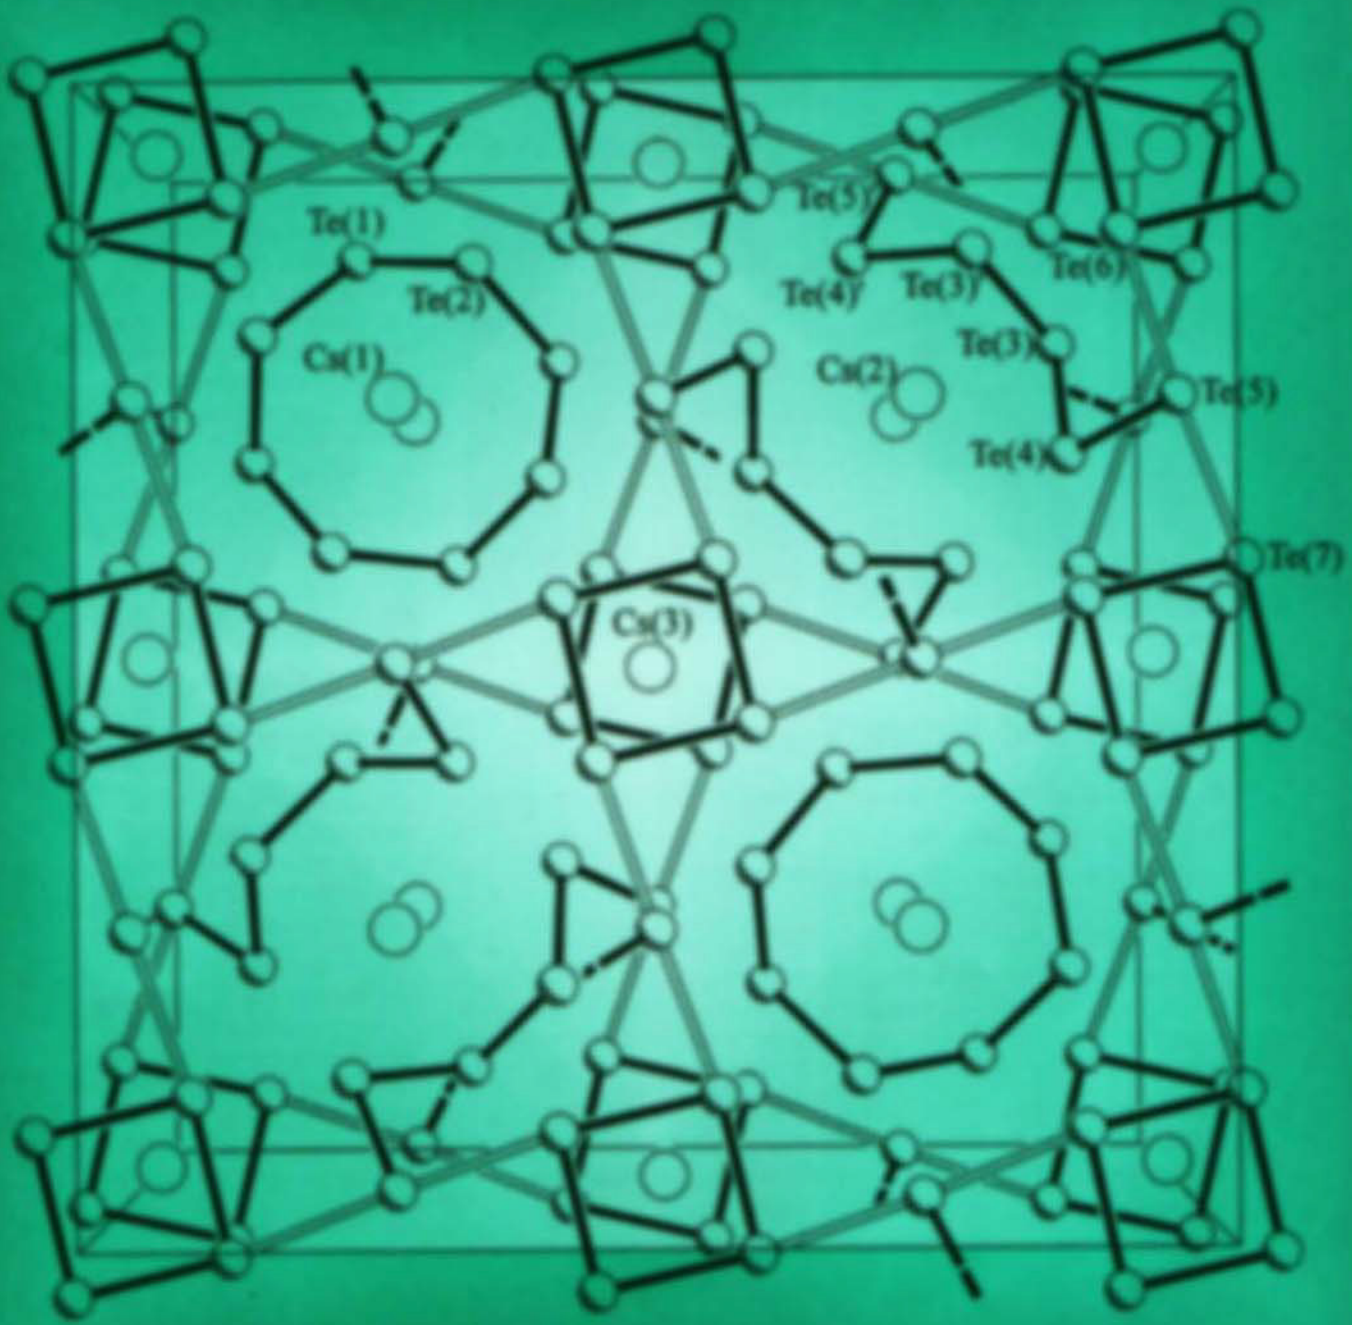
The metastable phase Cs_4Te_{28} was obtained under methanolothermal conditions (superheated methanol, 180°C).



Apart from Te_4 crown molecules and an incomplete $^2_\infty[Te_6^{2-}]$ sheet anion, the crystal contains — when secondary Te···Te interactions (depicted as open bonds) are ignored — two further unique structural entities: Te_5^{2-} chains and uncharged Te_4 squares.

Solventothermal Synthesis of Solid-State Chalcogenidometalates

William S. Sheldrick* and Michael Wachhold

Development of solventothermal methods in the intermediate-temperature (100–600 °C) range has been motivated by current interest in the design of solid-state compounds with open framework structures. The preparation of nanoporous chalcogenidometalates by this technique is particularly promising, as a combination of the typical ion-exchanging and catalytic features of zeolite-like phases with the unique optoelectronic properties of transition metal and group 13–16 chalcogenides could afford novel multifunctional materials. Superheated strongly polarizing solvents such as water, methanol, and amines at temperatures in the range 110–200 °C provide reaction conditions adequate to greatly enhance solubility, diffusion, and crystallization but still mild enough to leave molecular building blocks such as chains and rings intact to participate in the formation of polymeric anions. Such intermediate temperatures often allow the isolation of metastable solid-state compounds and thermodynamically stable phases that decompose at higher temperatures. The dimensionality and pore size of the anion network can be influenced by the choice of a suitable structure-directing alkali metal or alkylammonium cation. Methanolothermal conditions have been found to be particularly suitable for the preparation of selenido- and telluridometalates, and have afforded a new class of very tellurium-rich alkali metal tellurides such as $RbTe_6$ and Cs_3Te_{22}. This article presents a comprehensive review of the application of mild solventothermal techniques to the preparation of heavier group 14–16 and transition metal chalcogenidometalates.

Keywords: chalcogens · methanol · nanostructures · polychalcogenides · solventothermal synthesis

1. Introduction

Solid-state synthetic techniques have often involved solid–solid reactions at temperatures (typically >600 °C) high enough to allow adequate diffusion of atoms or ions to the site of product formation. Such experimental conditions lead almost invariably to thermodynamically stable phases with simple lattice structures of high density and high symmetry. High-temperature diffusion control also leads to drastic restrictions in the number and complexity of the structural building blocks available for the construction of solid-state frameworks. In many cases these units are limited to the individual atoms themselves.

In contrast to the results of such classical ceramic synthetic methods, the products of molecular chemistry are characterized by a high degree of predictability, as a result of fundamental differences in the reaction conditions involved. First, diffusion control is removed by use of a suitable solvent, which allows intimate mixing of the starting materials. Second, the employment of relatively low temperatures restricts the reaction to one or more functional groups and leaves the majority of the chemical bonds intact. Technological interest in the design of solid-state phases with tailor-made properties has stimulated research into solid-state synthetic methods at intermediate temperatures (100–600 °C), including molten flux and solventothermal techniques,[1] both of which involve solubilization of inorganic starting materials such as metals, chalcogenides, and silicates. Such compounds exhibit infinite networks of atoms linked together by strong covalent or ionic bonds and tend to be effectively insoluble in common solvents at ambient temperature. However, their solubility may be considerably increased by employing a strongly polarizing medium such as a molten salt (molten flux method, 200–600 °C) or a molecular solvent (solventothermal method, 100–400 °C) at elevated temperature. The reaction conditions applied in both methods are adequate to greatly enhance diffusion but still mild enough to leave molecular entities such as chains and rings intact to participate in the formation of solid-state phases. The effective removal of diffusion control tends to afford open crystalline structures of relatively low density and symmetry, often with a number of individual building units. Use of intermediate temperatures can be conducive to the kinetic trapping of metastable nanoporous materials that exhibit interesting molecular sieving, catalytic, ion exchange, and electrical properties.[1b, 2] In particular cases, it can also allow the preparation of thermodynamically stable compounds that are inaccessible by the ceramic method owing to their decompo-

sition at higher temperatures. The pioneering work of Rabenau and Rau from the 1960s to the 1980s demonstrated the scope of the hydrothermal method for the synthesis of a vast range of solid-state compounds such as oxides, sulfides, and halides.[3]

Such "chimie douce" approaches are now beginning to open the door to a new field of mechanistic solid-state chemistry, which has the long-range goal of using molecular building blocks to prepare novel materials of designed structure. One of the most promising current areas of interest is the synthesis of solid-state ternary and quarternary chalcogenidometalates, and a series of reviews on this topic by Kanatzidis et al.[4a-d] have appeared in which a particular emphasis was placed on the molten flux technique. Other recent review articles have dealt with soluble complexes containing chalcogenido ligands.[4e-k] The past 10 years have also witnessed a growing interest in hydrothermal and other solventothermal methods, much of which has been motivated by the technological potential of materials containing regularly spaced pores and cavities. Synthetic strategies for the design of such nanoporous structures have generally concentrated on the substitution of Al and Si atoms in the aluminosilicate frameworks of zeolites by main group elements and transition metals.[2c] The size and shape of the molecular-dimension channels can be influenced by the addition of structure-directing agents such as organic amines and alkylammonium cations, which are enclosed by the anionic framework in the final structure. Despite the importance of chalcogenides in optoelectronic devices, relatively few attempts have been undertaken to introduce the properties of such materials into zeotype compounds by replacing framework O atoms with the heavier congeners S, Se, and Te. However, the potential of mild solventothermal techniques for the design of such compounds with the heavier group 14 and 15 elements (Ge, Sn, As, Sb), has become apparent in the past few years. The participation of water in hydrolysis reactions in basic solutions often limits the use of the solventothermal method in this medium for the metals Sn and Sb to the preparation of new oxo- and thiometalates. However, this restriction can be removed by employing methanolothermal conditions, which have afforded an extensive range of new alkali metal chalcogenidometalates of group 14 and 15 elements at relatively low temperatures (110–220 °C). Examples of the potential of this approach to solid-state design are also provided by the recent syntheses of compounds such as $RbTe_6$ and Cs_3Te_{22} (Figures 1a, b), which represent the first members of a new class of very tellurium-rich tellurides.[5] This article focusses on soft solventothermal techniques for the preparation of solid-state chalco-

William S. Sheldrick was born in 1945 in Huddersfield, UK, and studied chemistry at the University of Cambridge, where he received his Ph.D. in 1969. After a period of two years with an Alexander von Humboldt Scholarship at the Technical University of Braunschweig, he took up a position at the Gesellschaft für Biotechnologische Forschung in 1973. He completed his Habilitation in 1976 and moved to the University of Kaiserslautern as Professor of Inorganic Chemistry in 1983. The appointment to his present Full Professorship at the Ruhr-Universität of Bochum followed in 1989. His research interests, as documented in more than 360 publications, include the analytical coordination chemistry of nucleotides and peptides, bioorganometallic chemistry, and structural aspects of heavier group 14–16 elements.

M. Wachhold

Michael Wachhold was born in Witten, Germany, in 1968 and studied chemistry at the Ruhr-Universität of Bochum from 1989 to 1994. In his dissertation, which he started in mid-1994, he has investigated the synthesis of novel group 15 and 16 chalcogenidometalates under methanolothermal conditions.

genidometalates and reviews the structures of polymeric anions obtained in this manner for heavier group 14–16 elements and transition metals. Compounds synthesized by other approaches are only included when required for comparison.

2. Solventothermal Synthesis

2.1. Reaction Types

Hydrothermal chemistry at near- and supercritical conditions (H_2O, $T_c = 374.1\,^{\circ}C$, $p_c = 221.2$ bar) was originally a domain of geochemists and mineralogists, whose main interest lay in simulating mineral formation. In fact, solventothermal syntheses may be regarded as a special case of a chemical transport reaction,[12] and the potential of this technique[3] for preparative solid-state chemistry was discussed in 1985 in the now classic review article of Rabenau.[3a] A trend to considerably milder conditions (100–200 °C) has become increasingly apparent over the past two decades. At the low pressures involved (< 30 bar), solventothermal syntheses can generally be performed in a simple manner in sealed glass tubes, which offer the important advantage of allowing direct visual control of the progress of the reaction. Typical reaction conditions that have been employed for the preparation of group 14–15 chalcogenidometalates are summarized in Table 1. Pioneer work in this field was performed by H. Schäfer and co-workers in the period 1972–1985. They prepared a series of alkali (and alkaline earth) metal thioantimonates(III)[6, 13, 14] by dissolving Sb_2S_3 in aqueous A_2S/ASH solutions (A = Na, K, Rb, Cs) at 120–180 °C. The viscosity of water decreases from $1.002 \times 10^{-3}\,kg\,m^{-1}\,s^{-1}$ at 20 °C and 1 bar to $0.137 \times 10^{-3}\,kg\,m^{-1}\,s^{-1}$ at 200 °C and 100 bar,[15] a change that has a significant effect on solvent properties. Diffusion processes for molecules and ions are more rapid,[15b] leading to an acceleration in both solubilization of the starting compounds and subsequent crystal growth.[16] A minimum solubility of 2–5% has been established as being necessary for reactants in hydrothermal synthesis.[16b] However, solubility of inorganic components may often be enhanced by addition of a mineralizer,[16] compounds which are complexing agents that effectively transport ions from the starting material to the site of product crystallization. A typical example is provided by the A_2S/ASH components of reaction type 1a (Table 1), which produce an alkaline aqueous solution capable of dissolving Sb_2S_3 to afford thioantimonate(III) anions such as SbS_3^{3-}. Many inorganic ions including OH^-, Cl^-, S_x^{2-}, Se_x^{2-}, and NH_4^+ are effective mineralizers.[16]

We have found that alkali metal carbonates are particularly useful for the solubilization of sulfides, selenides, and (to a lesser extent) tellurides of group 14/15 elements (reaction types 1b,c, Table 1). Aqueous or methanolic solutions of A_2CO_3 can also induce disproportionation of S, Se, and Te to oxoanions and polychalcogenides E_x^{2-}, thereby providing a convenient source of the latter species. Potential redox equilibria such as (a) will be driven to the right under solventothermal conditions by the development of CO_2.

$$3CO_3^{2-} + 2(n+1)S \rightleftharpoons 2S_n^{2-} + S_2O_3^{2-} + 3CO_2(g) \qquad (a)$$

The formation of thiosulfates in alkaline S/H_2O systems is well documented.[17] An example for the preparative application of such a disproportionation for selenium[17e,f] is provided by the methanolothermal synthesis of Cs_4Se_{16} (Figure 2) by reaction of Cs_2CO_3 with Se at 160 °C.[18] The additional presence of Ge or Sn leads to formation of selenidogermanates(IV) or selenidostannates(IV), respectively, at 160–190 °C (reaction type 1d, Table 1); access to the analogous telluridometalates can be achieved by substitution of Se for Te. Under similar methanolothermal conditions reaction of Cs_2CO_3 and Te alone affords the known tellurides Cs_2Te_3 and Cs_2Te_5.[19] Direct reaction of Ag with S in methanolic Cs_2CO_3 solution has also been

employed to synthesize the novel thioargentates(I), $RbAg_5S_3$ and $CsAg_7S_4$ (reaction type 2g, Table 2). In an alternative approach to in situ generation of polychalcogenido solutions E_x^{2-}, alkali metal salts Na_2E_x and K_2E_x (E = S, Se) have also been used directly as mineralizers/chalcogen source for the preparation of transition metal chalcogenidometalates (reaction types 2a–c, e, f, h in Table 2). The structures of the polymeric anions obtained by the reaction types summarized in Tables 1 and 2 will be influenced by the interplay of a range of variables such as the starting composition A:M:E, the physical and chemical properties of the reaction medium, reaction temperature, reaction time, pH, and oxidation potential of the solution, and size and shape of the cation. These and other factors will now be discussed in detail in the Sections 2.2–2.7.

2.2. Solvent Properties

Water has traditionally been the medium of choice for solventothermal reactions. However, alkali metal and quarternary phosphonium or ammonium polychalcogenides are quite soluble not only in water but also in a range of polar organic solvents such as methanol, amines, and *N*,*N*-dimethylformamide (DMF). The aprotic character of DMF leads to a marked increase in the activity of anionic species such as E_x^{2-}, which is responsible for moving equilibria between insoluble solid-state chalcogenidometalates and soluble discrete metal chalcogenide clusters towards the latter.[4i] Such anions have often been isolated from DMF solutions by employing suitably large counterions.[4e–k] Other aprotic solvents such as tetrahydrofuran and acetonitrile have also been used as a reaction medium for these purposes. A considerably lower solubility of the components is generally desirable for solventothermal techniques; the molecular building blocks should be easily removable from solution by their participation in the construction of polymeric anions at the site of crystallization. In addition to water, methanol and less frequently ethylenediamine (en) have been employed in the solventothermal synthesis of such solid-state chalcogenidometalates (Tables 1 and 2). A number of alkali metal tellurides have been prepared by ammonothermal synthesis.[3, 26] Important physical parameters for these solvents are listed in Table 3.

Table 3. Physical parameters of important solvents [3, 27].

Solvent	H_2O	CH_3OH	en	NH_3
melting point T_{mp} [°C]	0.0	−97.7	11.3	−78.0
boiling point T_{bp} [°C]	100.0	64.5	116.9	−33.45
critical temperature T_c [°C]	374.1	240	318	132.3
critical pressure p_c [bar]	221.2	81	61.5	111
dielectric constant ε_r (25 °C)	78.30	32.66	12.9	16.9
dipole moment μ [10^{-30} Cm]	6.17	5.7	6.3	4.90

The solventothermal construction of polymeric chalcogenidometalates proceeds through a cation-directed condensation of anionic building units such as ME_4^{4-} (group 14), ME_3^{3-} (group 15), E_x^{2-} chains, and E_n rings at the site of crystallization. It is apparent that solvent properties such as polarity, ability to donate or accept lone pairs of electrons, softness, self-cohesiveness, and viscosity will strongly influence the solubility and transport behavior of the ions involved in such heterogenous liquid–solid reactions. Both the kinetics and thermodynamics

of compound formation will be governed by the removal of the solvation shell; this desolvation is a prerequisite for anion condensation and crystal lattice construction. Dielectric constants ε_r and dipole moments μ have often been used in the quantitative characterization of solvent polarity. In fact, this term is generally used to describe the overall solvation ability of a solvent, a property that is dependent on the interplay of all molecular properties, which influence the interactions between solvent and solute molecules or ions. Empirical normalized parameters E_T^N, whose values are based on measurements of the charge-transfer band shift for solvatochromic dyes, have been shown to provide a good estimate of solvent polarity.[27] The derived values of E_T^N (H_2O: 1.000; MeOH: 0.762; en: 0.349) suggest that methanol will exhibit a polarity closer to that of water than would be predicted on the basis of their respective dielectric constants. Furthermore, several potential advantages are apparent for methanol as a reaction and crystallization medium for the solventothermal synthesis of chalcogenidometalates:

1) The lower critical temperature T_c: Since the critical temperature of methanol (240 °C) is much lower than that of water (374 °C), the diffusion of ions in methanol at the intermediate temperatures typically employed (100–200 °C) will be considerably more rapid because of its markedly lower viscosity. This leads to an acceleration in the solubilization of starting materials and in subsequent crystal growth.
2) The lower Gibbs energy of solvation $-\Delta G^\circ_{solv}$ for alkali metal cations: The molar Gibbs energy of solution ΔG°_{soln} for a compound is given by the sum of ΔG°_{solv} and the lattice energy ΔG°_{latt}. Conductance data indicate that the solvation numbers (e.g. Li^+: 7 in MeOH, 21 in H_2O) are generally much higher for individual ions in water (W) than in methanol (S). In particular, $-\Delta G^\circ_{solv}$ values are considerably smaller for alkali metal cations in methanol, thereby favoring crystallization of their salts from this reaction medium. A quantitative measure of this difference is provided by the standard molar Gibbs energy of transfer ΔG°_{tr} (W → S) for specific cations between the two solvents (e.g. 8.2–9.6 kJ mol^{-1} for the alkali metal cations Na, K, Rb, Cs).[28a]
3) Acid–base behavior: Hydrolysis reactions restrict the use of water as a reaction medium in the solventothermal synthesis of chalcogenidometalates. For instance, selenido- and telluridometalates with M = Sn, Sb decompose on contact with water as do alkali metal polytellurides such as Cs_3Te_{22} and $RbTe_6$. The tendency of methanol to self-ionize is significantly less than that of water [pK_{auto} (MeOH) $-$ pK_{auto} (H_2O) = 3.2],[27] thus the participation of methanol in solvolysis reactions is less pronounced. It therefore provides a more suitable amphiprotic polar solvent for the synthesis of selenium- and tellurium-containing polyanions. As a very hard molecule with respect to both its acidic and basic properties (HSAB concept),[29] water is an excellent solvent for hard ions such as alkali metal cations and OH^-. The hardness of water is reduced by introducing alkyl substituents; thus, in some cases methanol can be a better solvent for softer chalcogen-containing anions. For instance, whereas alkali metal oxalates are effectively insoluble in methanol, the corresponding bis(thiooxalate) salts are quite soluble. On the Marcus scale of solvent softness,[28b] the μ value is 0.02 for methanol. This value is based on the difference between the mean standard molar Gibbs energies of transfer ΔG°_{tr} (W → S) of hard Na^+ and K^+ ions from water to methanol and the corresponding transfer energy for soft Ag^+ ions.
4) The reduced tendency to cocrystallize: As a result of its reduced ability to solvate ions or participate in hydrogen bonds and also on account of its increased size, methanol is much less likely to cocrystallize than water. This means that methanolothermal conditions are better suited for the preparation of solvent-free phases. Water exhibits a high proclivity to occupy vacant sites in alkali metal coordination spheres; thus, hydrothermal conditions frequently lead to the formation of hydrates (see Table 1 for examples). A recent analysis of 9464 organic crystal structures in 1988 has shown that for reactions carried out in the respective solvents 61.4% of these compounds contain H_2O molecules, but only 4.1% MeOH molecules.[30]

Solventothermal syntheses in the protophilic solvent ethylendiamine (en) have generally been performed under supercritical conditions,[11, 24] and are rather limited in number. The bidentate ligand ethylendiamine will, of course, readily chelate divalent alkaline earth or transition metal cations, generating, thereby, large doubly charged counterions when such species are employed as cation sources, for example $[Ca(en)_4]As_2Se_7$[4k] and $[Fe(en)_3]Hg_2Te_9$.[25]

2.3. Speciation

Solubilization of sulfides and selenides ME_2 of the group 14 elements Ge and Sn provides monomeric species ME_4^{4-}, which readily condense to afford oligomeric anions with the general formulation $M_mE_n^{(2n-4m)-}$, in which individual ME_4 tetrahedra are linked through shared chalcogen atoms. Krebs[31] has investigated the pH dependence of anions such as $M_2E_7^{6-}$, $M_2E_6^{4-}$, $M_4E_{10}^{4-}$, and $M_8E_{19}^{6-}$, and has demonstrated that a higher degree of condensation m/n may be achieved by lowering the pH value. For instance, whereas corner- and edge-bridged dimeric species $Ge_2Se_7^{6-}$ and $Ge_2Se_6^{4-}$ can only exist in alkaline solution, adamantane-like anions $Ge_4Se_{10}^{4-}$ are observed in the wide pH range 3–11. Such condensed anions are also formed under soft solventothermal conditions and have often been isolated from methanolic solutions. For instance $Rb_4Sn_2Se_6$,[32] $Cs_4Sn_2Se_6$,[8c] and $[enH_2]Sn_2Se_6 \cdot 2en$[33] all contain edge-bridged $[Sn_2Se_6]^{4-}$ dimers (Figure 3a). This anionic species is extended by a further edge-bridged $SnSe_4$ tetrahedron in the unique tritetrahedral $[Se_3Se_8]^{4-}$ anion of $K_4Sn_3Se_8$[9b] (Figure 3b). Examples of adamantane-like $[Ge_4Se_{10}]^{4-}$ anions are provided by $Rb_4Ge_4Se_{10} \cdot MeOH$ [34] and $Cs_4Ge_4Se_{10} \cdot 2MeOH$[9a] (Figure 3c).

Group 15 element sulfides M_2S_3 (M = As, Sb) dissolve in aqueous alkaline solution to afford thiometalates(III) of the type ME_3^{3-} together with oxo- and oxothioanions. UV/Vis studies[35] have indicated that such monomeric AsS_3^{3-} ions will readily condense in solution to afford the cyclic species $[As_3S_6]^{3-}$, which can be isolated from an ethylenediamine solution at room temperature in the form of salts such as $[enH_2]_3(As_3S_6)_2 \cdot 6en$[36] and $[Ba(en)_4]_3(As_3S_6)_2$.[37] The As_3S_3 six-membered rings exhibit a chair conformation; the terminal

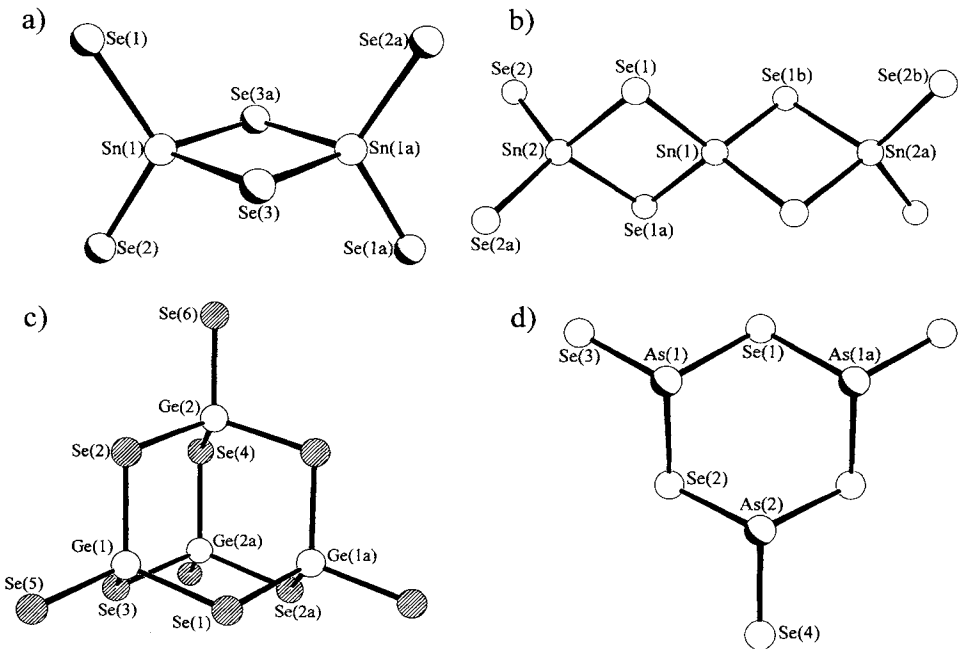

Figure 3. Discrete selenidometalate anions of group 14 and 15: a) $[Sn_2Se_6]^{4-}$ in $Rb_4Sn_2Se_6$ [32] and $Cs_4Sn_2Se_6$ [8c]; b) $[Sn_3Se_8]^{4-}$ in $K_4Sn_3Se_8$ [9b]; c) $[Ge_4Se_{10}]^{4-}$ in $Cs_4Ge_4Se_{10}\cdot 2CH_3OH$ [9a]; d) $[As_3Se_6]^{3-}$ in $[Sr(en)_4]_2(As_3Se_6)Cl$ [38].

S atoms adopt the equatorial sites. A similar structure is also observed for the analogous $[As_3Se_6]^{3-}$ ion in $[Sr(en)_4]_2(As_3Se_6)Cl$[38] (Figure 3d). Electrospray mass spectrometric measurements on the K^+/Sb/Se system in DMF confirm the presence of Zintl ions such as $SbSe_3^{3-}$, $Sb_2Se_5^{4-}$, $Sb_3Se_7^{5-}$, $Sb_4Se_9^{6-}$, $Sb_6Se_{12}^{6-}$, and $Sb_8Se_{15}^{6-}$.[39a]

Condensation of ME_4^{4-} (M = Sn) and ME_3^{3-} (M = As, Sb) species under soft solventothermal conditions in the presence of alkali metal, quarternary phosphonium, or ammonium cations can afford a wide variety of polymeric anions with chain, sheet, or framework structures (reaction types 1a–c,e,f). The ability of the heavier elements Sn and Sb to extent their coordination numbers above 4 and 3, respectively, (as observed in their isolated anions) leads to new structural motifs in the polymeric chalcogenidometalates (see Sections 3.2 and 3.3). In contrast to Sb^{III}, As^{III} exhibits only a weak tendency to extend its coordination number (to 4) so that the solution species remain recognizable as molecular building blocks in the solid-state structure. For instance, $Rb_2As_8S_{13}\cdot H_2O$[40] contains cyclic As_3S_6 units, which are linked together by edge-bridged As_2S_5 fragments into a double chain as depicted in Figure 4. In the compounds

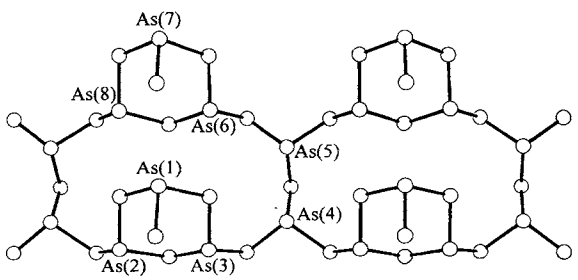

Figure 4. a) $^1_\infty[As_8S_{13}^{2-}]$ double chain in $Rb_2As_8S_{13}\cdot H_2O$ [40], formed by condensation of $[As_3S_6]^{3-}$ six-membered rings and AsS_3^{3-} pseudo-tetrahedra.

$AAsSe_2$ (A = K, Rb, Cs[8a]) individual pseudo-tetrahedral $AsSe_3$ building blocks are connected through two common corners to give an infinite chain $^1_\infty[AsSe_2^-]$.

A number of the reaction types summarized in Tables 1 and 2 use alkali metal polychalcogenides; these are well-known to form chain fragments E_x^{2-} of various lengths x in solution, and are present in dynamic equilibrium with one another. Larger chains can exist in significant concentrations at the relatively low temperatures (100–200 °C) employed for mild solventothermal syntheses but these are unstable with respect to disproportion reactions of type (b) at higher temperatures.

$$E_x^{2-} \rightleftharpoons E_{x-n}^{2-} + nE \qquad (b)$$

The ability to form chains and the tendency to adopt coordination numbers above 2 increase for the chalcogens in the order S < Se < Te. This behavior is reflected in the frequency of the occurence of E_x ($x \geq 2$) building units in chalcogenidometalates obtained by solventothermal techniques.

Speciation analysis for polychalcogenides in solution (H_2O, alcohols, NH_3, DMF) has been performed by a variety of physical methods including UV/Vis absorption spectroscopy, Raman spectroscopy,[41] ^{77}Se, ^{123}Te, and ^{125}Te NMR spectroscopy,[42] electron spin resonance,[42] and electrospray mass spectrometry.[39]

The solutions of alkali metal polysulfides have been investigated by UV/Vis and Raman spectroscopy.[41,43] All species S_x^{2-} in the range $x = 1-5$ are present in aqueous solution.[43c] Lelieur et al[41] have also identified the S_6^{2-} ion in a solution of Li_2S_x in liquid ammonia, and have established that dissociation of this ion to $S_3^{\bullet-}$ radicals can occur, giving rise to a characteristic absorption band at 610 nm. ^{77}Se NMR spectroscopy is well suited to probe individual selenium atoms of a Se_x^{2-} chain, as it offers the advantage of a wide chemical shift range (ca. 3000 ppm). The absence of ^{77}Se NMR signals for solutions of polyselenides in DMF was interpreted as indicating the presence of paramagnetic radical ions at room temperature.[4g] However, Cusick and Dance[44] have since demonstrated that satisfactory spectra may be obtained at about 240 K. The chemical shift δ_{Se} of a selenium atom in a particular Se_x^{2-} ion is dependent on the distance [$\delta_{Se}(\gamma) > \delta_{Se}(\beta) > \delta_{Se}(\alpha)$] from the chain end ($\alpha$ position), and lies in the range $\delta = 192-860$ ($\delta(Me_2Se) = 0$). All ions Se_x^{2-} with $x = 3-6$ have been detected in DMF but interestingly no NMR spectroscopic evidence was obtained for the presence of Se_2^{2-} in this or other solutions (H_2O, C_2H_5OH). This dumbbell ion is believed to disproportionate to give Se^{2-} and Se in DMF. The spirocyclic anion $[Se(Se_5)_2]^{2-}$, which may be crystallized as $[Ph_4P]_2Se_{11}$,[45] is formed from Se_x^{2-} solutions in the presence of suitable oxidants (e.g. NO_3^-) in DMF; only

one ^{77}Se resonance is observed at $\delta = 720$, which is indicative of a rapid exchange mechanism.[44] In contrast to these findings, Licht and Forouzan assigned an absorption peak at 431 nm in an aqueous K_2Se_x solution to Se_2^{2-}.[46] Their UV/Vis speciation analysis excluded the presence of Se_x^{2-} ions with $x > 4$, and provided the species distribution diagram presented in Figure 5.

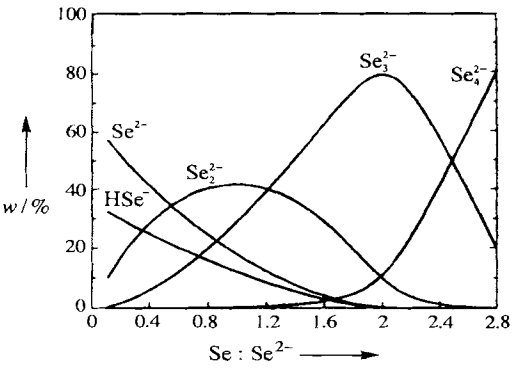

Figure 5. Dependence of the proportion w of the Se_x^{2-} species as well as HSe^- in a 1 M K_2Se/KOH solution on the amount of added Se [46]. The solution is saturated at a $Se:Se^{2-}$ ratio of 2.8:1.

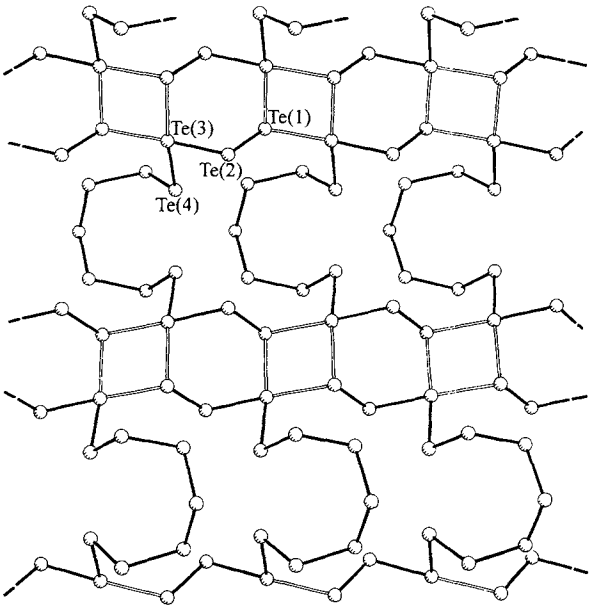

Figure 6. Structure of the Te_{13}^{2-} ion in Cs_2Te_{13} [5b]; the secondary Te···Te interactions (>3.18 Å) are indicated by open bonds. Selected bond lengths [Å]: Te(1)–Te(2) 2.763(2), Te(2)–Te(3) 2.896(2), Te(3)–Te(4) 2.910(2).

Homo- and heteropolychalcogenide ions E_x^{2-} (E = Se and/or Te, $x = 2-4$) have been characterized by ^{77}Se, ^{123}Te, and ^{125}Te NMR spectroscopy in ethylenediamine or liquid NH_3, with alkali metal counterions in the presence or absence of [2.2.2]cryptand.[47] With the exception of the pseudo-tetrahedral $TeSe_3^{2-}$ ion, all polychalcogenido anions exhibit chain structures. However, UV/Vis speciation analyses of A_2E (A = Na, K) solutions in liquid NH_3 provided no evidence for Te_4^{2-} (or higher polytellurides).[48]

As negative charge is effectively localized on the terminal atoms of E_x^{2-} chains, internal chalcogen atoms whose formal charge is near zero will not generally be expected to participate in bonding interactions with metal atoms of chalcogenidometalates. The molten flux method has proved to be the method of choice for the synthesis of open nanoporous structures with long terminal or bridging E_x^{2-} building blocks ($x \geq 3$).[4a–d] Representative examples are provided by the terminal Se_5^{2-} chains in K_3AuSe_{13} and the bridging Se_5^{2-} fragments in $KAuSe_5$.[49] Bridging S_5^{2-} units are found in $CsSbS_6$,[50] chelating S_4^{2-} and S_6^{2-} ligands in Cs_2SnS_{14}.[51] In contrast, solventothermal techniques for group 14 and 15 elements generally yield chalcogenidometalates composed of exclusively corner- or edge-bridged ME_x ($x = 3-6$) polyhedra. Examples of E_x^{2-} chains are restricted to $x = 2$; as exemplified by the Se_2 units in $Cs_2Sb_4Se_8$[52] or E_2 fragments in $Cs_4As_2Te_6$[58] and compounds of the type A_2ME_4 (A = K–Cs; M = Ge, Sn; E = Se, Te).[9c, 34] However, the Se_{16}^{4-} ion of the methanolothermal polyselenide Cs_4Se_{16} can be regarded as containing an Se_6 ring and two Se_5^{2-} chains as molecular building blocks (Figure 2),[18] and effectively discrete Te_{13}^{2-} and Te_6^{2-} chains are found in the polytellurides Cs_2Te_{13} (Figure 6) and Cs_4Te_{28}.[5c] $K_4V_2O_2Se_{10} \cdot 2MeOH$ and $K_4V_2O_2Se_8 \cdot 0.65\,MeOH$[20a] contain chelating Se_4^{2-} ligands, K_2PdSe_{10}[22a] bridging Se_4^{2-} and Se_6^{2-} chains (reaction types 2a,e in Table 2).

2.4. Redox Equilibria

The oxidizing power of chalcogens and polychalcogenide anions can be used to solubilize both main group and transition metals in superheated water and methanol. The group 14 metals Ge and Sn invariably possess their highest oxidation state (+ IV) in phases isolated from their methanolothermal reaction with Se or Te in the presence of alkali metal carbonates (reaction type 1d, Table 1). Likewise anhydrous selenidoarsenates(V) and -antimonates(V) of the type A_3MSe_4 (A = Rb, Cs; M = As, Sb) may be prepared in high yield by treatment of M_2Se_3 with Se in a methanolic A_2CO_3 solution at 180–200 °C.[53] The analogous telluridometalates(V) cannot be obtained in this manner and appear to be unknown.[4k] We have occasionally isolated compounds containing discrete ME_4^{3-} anions (M = As, Sb; E = S, Se) in low yield (<5%) from hydro- and methanolothermal reactions between A_2CO_3 and M_2E_3 in the absence of elemental chalcogen E as an oxidizing agent.[37, 54] For instance, both Rb_3SbSe_4[53] and the known polyselenide Rb_2Se_5[55] can be obtained in low yield when Rb_2CO_3 and Sb_2Se_3 are heated in water at 65 °C.[37] The analogous hydrothermal reaction of Cs_2CO_3 and Sb_2Se_3 at 115 °C affords the oxidation product $Cs_2Sb_4Se_8$, in which $^1_\infty[Sb_2Se_4^{2-}]$ chains are linked into infinite sheets $^2_\infty[Sb_4Se_8^{2-}]$ through direct Se–Se bonds (Figure 7).[52]

The isolation of such a variety of oxidation products indicates that redox equilibria for group 15 M/E solventothermal systems may often be quite complex. Redox reactions can, of course, be promoted by the formation of products of low solubility such as polymeric chalcogenidometalates(III), which will remove particular anions from solution. For instance, Kaub[37] has demonstrated that compounds of the type $A_2As_8S_{13} \cdot xH_2O$ (A = K, Rb, NH_4; $x = 1$;[40] A = Cs; $x = 0$[7a]), which can be obtained as major products of the hydrothermal reaction of A_2CO_3 with

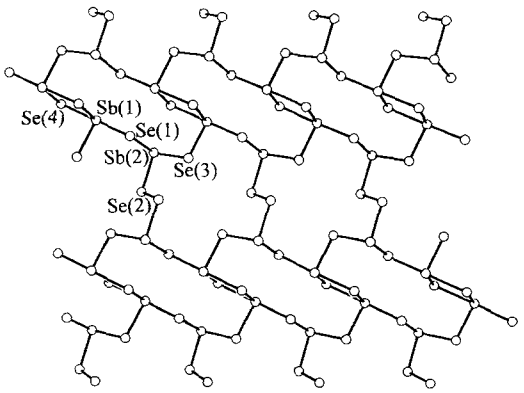

Figure 7. Structure of the polyanion $^2_\infty[Sb_4Se_8^{2-}]$ in $A_2Sb_4Se_8$ (A = K, Rb [83], Cs [52]).

As_2S_3 at 180–220 °C, may also be isolated in low yield by employing As_4S_4 (realgar) or As_2S_5 instead of As_2S_3. The relative stability of ME_4^{3-} ions increases with pH value of the solution and decreases with the atomic number of the elements M and E. Formation of chalcogen-containing anions with either pentavalent group 15 elements M^V or of direct E–E bonds by solventothermal reaction of M_2E_3 with A_2CO_3 requires simultaneous reduction of M^{III} or the solvent. Low yields have prevented a full investigation of redox equilibria for Sb_2E_3 but products of both such reduction processes have been characterized[56] by X-ray structural analysis for As_2S_3. For instance, the methanolothermal reaction of Rb_2CO_3 with As_2S_3 at 130–180 °C affords $RbAsS_2$ with $^1_\infty[AsS_2^-]$ chains and $Rb_2As_4S_6 \cdot As_4S_3$, which contains cagelike As_4S_3 molecules and discrete $As_4S_6^{2-}$ ions.[57b] The ions are presumably derived from realgar[57a] by nucleophilic attack of S^{2-} ions at the two As atoms of an As–As bond cleaved in the course of the reaction. Reaction of Cs_2CO_3 with As_2S_3 under analogous conditions provides not only $Cs_2As_8S_{13}$[7a] with $^2_\infty[As_8S_{13}^{2-}]$ sheets but also $Cs_2[As(OMe)S_3]$ and $Cs_2[As(Me)S_3]$ with two novel tetrahedral thioarsenate(v) anions. The formation of $[As(Me)S_3]^{2-}$ requires methanol reduction in a reaction such as (c).

$$AsS_3^{3-} + MeOH \rightleftharpoons As(Me)S_3^{2-} + OH^- \quad (c)$$

The tendency of As to form neutral or anionic chalcogenides[4k] with direct As–As bonds is well-known, and it is not surprising that As_4S_4 and As_4Se_4 are often observed as by-products of hydro- or methanolothermal reactions of As_2S_3 or As_2Se_3, respectively. This facile reduction opens a novel solventothermal route to phases with E_x building blocks, which was first employed more than 10 years ago in the preparation of the compounds $AAsSe_3 \cdot xH_2O$ (A = K, $x = 1$; A = Rb, Cs, $x = 0.5$),[7b] in which pseudo-$AsSe_3$ tetrahedra are connected into infinite chains by Se–Se bonds. However, it is only in the past two years, through extension of the methanolothermal methodology to tellurides (reaction types 1c and 1d in Table 1), that the full synthetic potential of such redox equilibria for the design of novel solid-state phases has become apparent. Fine control of redox and temperature conditions has allowed us to prepare a new family of tellurium-rich tellurides A_xTe_y with $x/y < 1/4$ (Section 3.1). For instance, the related novel phases Cs_2Te_{13} (Figure 6), Cs_4Te_{28}, and Cs_3Te_{22} (see Figures 1, 14) may be obtained together with the known telluride Cs_2Te_5[19b] by reaction of Cs_2CO_3 with As_2Te_3 in methanol in the temperature regions 150–160, 170–180, and 190–200 °C, respectively.[5b,c] An As^{II} redox product $Cs_4As_2Te_6$, in which the discrete $As_2Te_6^{4-}$ ions contain pseudo-tetrahedral As(As)(Te_2)(Te) units with a common As–As bond, can be isolated at lower temperature (145 °C).[58] Interestingly, a solventothermal redox reaction was also employed in the recent preparation[59] of $[Cr(en)_3]Te_6$ by decarbonylation of $[Cr(CO)_6]$ in ethylenediamine in the presence of an alloy of nominal composition $BaAs_4Te_4$. The unrelated Te_6^- ion is present in $RbTe_6$, which is obtained by methanolothermal reaction of Rb_2CO_3 with Te and Ge (as reducing agent) at 160 °C.[5a]

The very low solubility of As_2Te_3 and Cs_xTe_y ($x/y < 1/4$) in methanol in the temperature range 145–200 °C leads to the immediate crystallization of the tellurium-rich tellurides at the site of the Te_x^{2-} formation on the surface of As_2Te_3 (see Section 3.1). This observation prompted us to investigate the methanolothermal reaction of group 15 tellurides M_2Te_3 (M = As, Sb, Bi) with Cs_2CO_3 in the presence of Se, in the hope of preparing novel mixed chalcogenides under such conditions. Our exploratory synthetic studies[60] have been rewarded for Sb_2Te_3 by the isolation of $Cs_4Te_{9.8}Se_{13.2}$, which contains both novel Te_3Se_3 six-membered rings with alternating chalcogen atoms (besides other disordered $Te_{6-x}Se_x$ rings) and pyramidal $TeSe_3^{2-}$ ions. The very low release velocity of tellurium for Bi_2Te_3 leads to formation of the selenium-rich phases $Cs_2Te_2Se_6$ (Figure 8) and Cs_4TeSe_{15}, which are isostructural to Cs_2Te_8[61] and Cs_4Se_{16},[18] respectively (Figure 2); the Te atoms occupy the tri- and tetracoordinated chalcogen sites of the latter phases (Section 3.1).

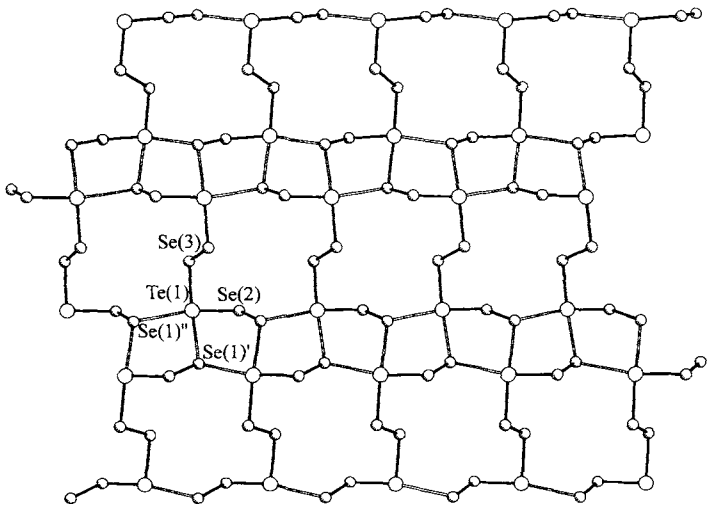

Figure 8. Structure of the $^2_\infty[Te_2Se_6^{2-}]$ anion in $Cs_2Te_2Se_6$ [60]; the long Te···Se interactions (> 2.91 Å) are depicted as open bonds. Selected bond lengths [Å]: Te–Se(1)' 2.923(2), Te–Se(2) 2.600(2), Te–Se(3) 2.717(2), Te–Se(1)'' 3.243(2).

2.5. In Situ Generation of Cations

Organic amines and alkylammonium cations such as R_4N^+ (R = Me, Et, *n*Pr) or $[enH_2]^{2+}$ are of considerable current interest as structure-directing agents in the synthesis of nanoporous materials.[2a,62] For instance ethylenediamine has been em-

ployed in the solventothermal preparation of $^1_\infty[Sb_8S_{13}^{2-}]$ double chains and $^2_\infty[Sn_3Se_7^{2-}]$ sheets in the compounds $[enH_2]$-Sb_8S_{13}[63a] and $[enH_2]Sn_3Se_7 \cdot 0.5en$.[33] The solvents ($H_2O$ and MeOH, respectively) provide the proton source for the required in situ generation of $[enH_2]^{2+}$ ions. An interesting strategy for the investigation of templating mechanisms (Section 2.7) has been developed by Parise and co-workers, who have synthesized a series of polymeric group 14 and 15 chalcogenidometalates with small alkylammonium counterions, provided, in some cases, by the decomposition of larger organic amines and $[R_4N]^+$ ions under mild hydrothermal conditions. For instance, triethylenetetramine, $C_6H_{18}N_4$, has been used in this way to generate the piperazinium ion $[pipzH_2]^{2+}$ in $[pipzH_2]Sb_4S_7$[64] and the trimethylammonium ion in $[Me_3NH]_4[Sn_{10}O_4S_{18}]$.[65] Solvent participation (Section 2.6) is required for the formation of the anionic framework in the latter, which consists of corner-linked supertetrahedral $[Sn_{10}O_4S_{20}]^{8-}$ building units, previously isolated as discrete anions in $Cs_8Sn_{10}O_4S_{20} \cdot 13H_2O$ from thiostannate(IV) solutions at pH = 3.[66] The counterion of this phase has also been obtained in $[Me_3NH][nPr_4N]Sn_4S_9$ by breakdown of the $[nPr_4N]^+$ ion at 150 °C.[67] Controlled variation of the temperature range, starting composition, and reaction time has allowed the isolation of $[Me_4N]_2Sn_3S_7 \cdot H_2O$, $[Me_3NH]_2Sn_3S_7 \cdot 0.72H_2O$, and a third compound containing $^2_\infty[Sn_{20}O_8S_{37}^{10-}]$ sheets with three-connected $[Sn_{10}O_4S_{20}]^{8-}$ clusters from the $(Me_4N)OH/SnS_2/S$ hydrothermal system.[68] Although satisfactory resolution of the counterions was not possible for the mixed oxothiostannate(IV), $[Me_2NH_2]^{2+}$ ions were proposed on the basis of difference syntheses.[68c] The observed sequence of compounds formed during the reaction suggests that development of the $[Sn_{10}O_4S_{20}]^{8-}$ supertetrahedral units must involve initial crystallization of $^2_\infty[Sn_3S_7^{2-}]$ sheets, and is accompanied by progressive decomposition of the original $[Me_4N]^+$ ions.

The potential of in situ generation of cations under solventothermal conditions is also illustrated by the reaction of $SnSe_2$ with Se in a $MeCN/H_2O$ mixture at 145 °C, which leads to formation of $[CH_3C(NH_2)_2]_2Sn_2Se_5$ (Figure 9), a selenidostannate(IV), in which $SnSe_4$ tetrahedra are connected by alternating edges and corners into a $^1_\infty[Sn_2Se_5^{2-}]$ chain.[69] The amidinium cation is formed by reaction of the component solvents with one another.

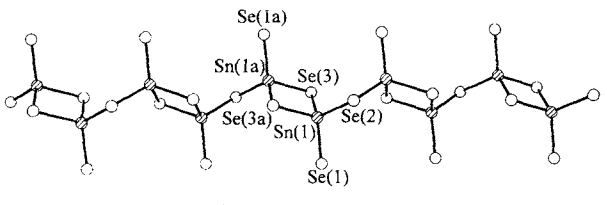

Figure 9. The chain anion $^1_\infty[Sn_2Se_5^{2-}]$ in $[CH_3C(NH_2)_2]_2Sn_2Se_5$ [69].

A remarkable example of cation decomposition has recently been reported; it leads to the isolation of the novel highly charged $[C_2S_6]^{6-}$ ligand in the complex anions α- and β-$[Pd_6(C_2S_6)(S_3)_6]^{6-}$ and $[Pd_6(C_2S_6)(S_3)_4(S_4)_2]^{6-}$.[70a] During attempts to extend reaction type 2e (Table 2) to the preparation of K_2PdS_{10}, the methanolothermal reaction of Na_2PdCl_4, Na_2S_4, and $[(CH_3)N(CH_2CH_2)_3N(CH_3)]I_2$ in a 1:3:1 ratio was investigated at 110 °C. Cation decomposition affords Na_3-$[(CH_3)N(CH_2CH_2)_3N]_3[Pd_6(C_2S_6)(S_3)_6] \cdot 3MeOH$, in which the $[C_2S_6]^{6-}$ ligand connects six square-planar Pd^{II} centers to generate an anion with idealized D_{3d} symmetry. The ethane-like ligand is believed to originate from the liberated methyl group of the starting cation; however, participation of the ethylene groups cannot be ruled out.

$Na_2[(CH_3)N(CH_2CH_2)_3N]_4[Pd_6(C_2S_6)(S_3)_4(S_4)_2] \cdot MeOH$ is formed under similar conditions at 80 °C by using $PdCl_2$ instead of Na_2PdCl_4.[70a] In the anion in this compound and in β-$[Pd_6(C_2S_6)(S_3)_6]^{6-}$, which is present in $K_4[(CH_3)_3NCH_2CH_2$-$N(CH_3)_2]_2[Pd_6(C_2S_6)(S_3)_6]$, the $[C_2S_6]^{6-}$ ions connect two trinuclear Pd^{II} fragments.

2.6. Solvent Participation

In contrast to products of hydrothermal syntheses, which regularly contain water molecules in the cation coordination sphere and/or as part of a hydrogen-bonding network, relatively few examples of cocrystallization have been reported for reactions in superheated methanol (Section 2.2). These are restricted to compounds containing larger discrete anions, in which methanol O atoms are required to complete the cation coordination spheres, for example in $Cs_4Ge_4Se_{10} \cdot 2MeOH$[9a] and $Rb_4Ge_4Se_{10} \cdot MeOH$.[34]

Participation of solvent water in the formation of mixed oxothiostannates(IV) has already been discussed in Section 2.5. Such product solvolysis has not been observed for chalcogenidostannates(IV) prepared under methanolothermal conditions. However, this solvent does provide the source of the *cis*-terminal oxygen atoms in the dimeric oxoselenidovanadates(V) $[V_2O_2Se_{10}]^{4-}$ and $[V_2O_2Se_8]^{4-}$, which are prepared by reaction of vanadium with K_2Se_4 at 135 °C.[20a] The strong affinity of vanadium ions for oxygen leads to exclusive formation of oxovanadates under analogous hydrothermal conditions. Methylation of the Te^{2-} ion occurs[70b] in the reaction of $M_3(CO)_{12}$ (M = Fe, Ru) with Na_2Te_2 in MeOH at 80–110 °C, it leads to the formation of cluster anions of the type $[M_4(Te_2)_2$-$(Te)_2(TeMe)_2(CO)_8]^{2-}$.

Generation of large counterions such as $[Ca(en)_4]^{2+}$ and $[Fe(en)_3]^{2+}$ in ethylenediamine was mentioned in Section 2.2. A unique application of ethylenediamine chelation is provided by the stabilization of the $SnSe_2$ chain in $^1_\infty[2SnSe_2 \cdot en]$ (Figure 10), which was prepared by methanolothermal reaction of $SnSe_2$ and en at 160 °C.[33]

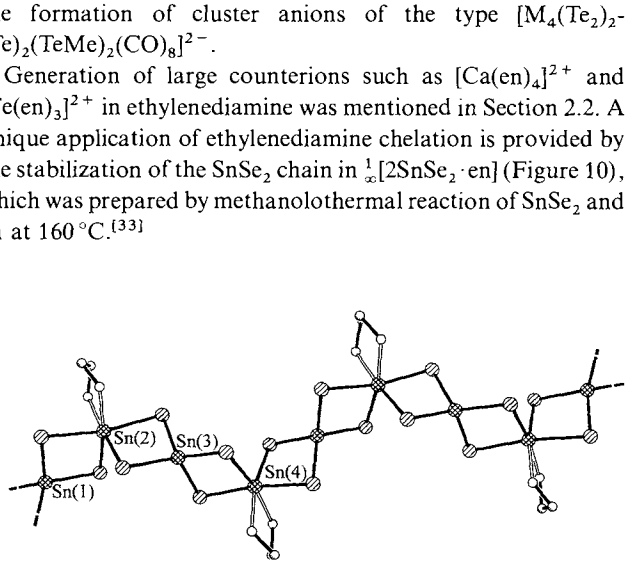

Figure 10. The $SnSe_2$ chain stabilized by ethylendiamine coordination in $^1_\infty[2SnSe_2 \cdot en]$ [33].

2.7. Structure-Directing Agents

Alkylammonium ions, amines, and alkali metal cations have often been used to direct the hydrothermal assembly of zeolite structures containing regularly spaced pores and channels. The size of these cavities generally reflects the geometry of the added organic molecules or (hydrated) alkali metal cations, an observation that is suggestive of a templating mechanism. However the organization processes behind the self-assembly of complex frameworks from simple building units are still not well understood. A particular template can often generate a number of different anionic structures, but alternatively one particular network may often be obtained with different structure-directing cations. Both space-filling and charge-compensation effects appear to play an important role in templating mechanisms. The influence of parameters such as cation size and geometry on the connectivity of individual molecular building units can be studied for compounds of invariant stoichiometry $A_xM_yE_z$; this will be considered in more detail in Section 3. An instructive example is provided by the anionic structures of $A_2As_8S_{13}\cdot H_2O$ (A = K, Rb, NH_4)[40] and $Cs_2As_8S_{13}$,[7a] which are depicted in Figures 4 and 11. Condensation of $As_3S_6^{3-}$ six-membered rings

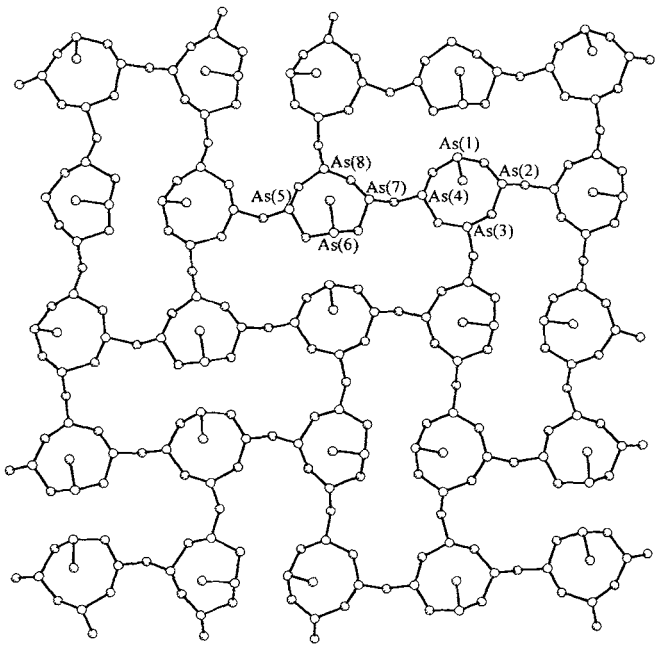

Figure 11. Structure of the $^2_\infty[As_8S_{13}^{2-}]$ sheet in $Cs_2As_8S_{13}$ [7a].

and AsS_3^{3-} pseudo-tetrahedra, which are present in aqueous solution, leads to formation of $^1_\infty[As_8S_{13}^{2-}]$ double chains for the cations K^+, Rb^+, and NH_4^+. Such M_3E_3 building blocks are also a common feature of the polymeric thio and selenido anions of the heavier homologue Sb^{III}, and an identical structural motif has been found in $[enH_2]Sb_8S_{13}$[63a] and the mineral gerstleyite $Na_2(Sb_{0.9}As_{0.1})_8S_{13}\cdot 2H_2O$.[63c] In contrast, the templating effect of the larger Cs^+ ions leads to the generation of $As_4S_8^{4-}$ eight-membered rings under hydrothermal conditions. These rings are of suitable size to allow the simultaneous coordination of the alkali metal by four endocyclic sulfur atoms. These building units now possess three terminal S atoms for connectivity purposes and condense into $^2_\infty[As_8S_{13}^{2-}]$ layers containing both As_4S_4 and $As_{14}S_{14}$ rings. The structural diversity of the group 14 and 15 chalcogenidometalates increases dramatically on going from Ge^{IV} and As^{III} to the heavier homologues Sn^{IV} and Sb^{III}, which can exhibit coordination numbers higher than their nominal valency. For instance the cation-dependent incorporation of pseudo-SbS_3 tetrahedra and pseudo-SbS_4 trigonal bipyramids in differing ratios (4:0, 3:1, 2:2, 0:4) has led to the observation of no fewer than seven different structural motifs for anions of the formula type $Sb_4S_7^{2-}$ (see Table 6).

Kanatzidis has recently commented on a correlation between counterion size and coordination number for related group 11 chalcogenidometalates of the type AME_x (M = Cu, Ag; E = S, Se; $x = 4-6$) with chain structures.[4c] For large cations such as $[Ph_4P]^+$, the chains unfold and the metal atom assumes the lower coordination number of 3. Smaller cations such as K^+ and $[Me_4N]^+$ generate more compact chain structures with tetrahedral coordination of M. A general tendency of smaller cations to stabilize transition metal chalcogenidometalate anions of higher dimensionality was also proposed.[4c]

A similar correlation between cation size and dimensionality is also apparent for group 14 and 15 chalcogenidometalates prepared by solventothermal techniques. Whereas $K_2Sb_4S_7$,[13c] $A_2Sb_4S_7\cdot H_2O$ (A = K, Rb),[13d, 14a, e] and $Rb_2Sn_2Se_5$[71a] all contain three-dimensional framework anions, only chain and sheet anions have been obtained under such conditions for Cs^+ and larger alkylammonium ions (see Tables 6 and 7). For instance, $Cs_2Sb_4S_7$[6b] and $[pipzH_2]Sb_4S_7$[64] both contain one-dimensional polymeric anions. However, the frequent presence of water molecules in the alkali metal coordination sphere prevents the prediction of dimensionality for hydrothermal phases. Although a general correlation between cation size and the coordination number of anion polyhedra is not apparent for group 14 and 15 chalcogenidometalates, it is possible to discern a trend for compounds of the formula type $A_2Sb_4S_7$. In contrast to the three-dimensional framework structures of $K_2Sb_4S_7$ and $A_2Sb_4S_7\cdot H_2O$ (A = K, Rb), which contain SbS_3 and SbS_4 polyhedra in a 2:2 ratio, the former pseudo-tetrahedral units predominate for the larger cation in $Cs_2Sb_4S_7$[6b] (3:1), and are found exclusively in $(NH_4)_2Sb_4S_7$[14e] and $[pipzH_2]Sb_4S_7$.[64] The unusual fourfold coordination of a bridging sulfur atom is responsible for the formation of $^2_\infty[Sb_4S_7^{2-}]$ sheets, which contain only pseudo-SbS_4 trigonal bipyramids (Figure 12) in $Rb_2Sb_4S_7$.[71b]

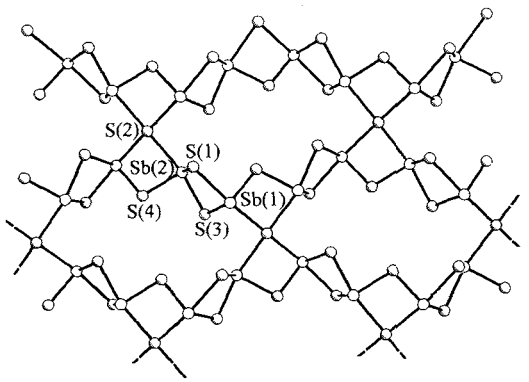

Figure 12. $^2_\infty[Sb_4S_7^{2-}]$ sheets in $Rb_2Sb_4S_7$ [71b] containing individual $^1_\infty[SbS_2^-]$ chains connected by square-planar S atoms.

A unique mechanistic insight into template-directed structural preassembly for solid-state synthesis in superheated fluids is provided by the series of metastable tellurium-rich tellurides Cs_2Te_{13}, Cs_4Te_{28}, and Cs_3Te_{22};[5b, 5c] this is considered in detail in the Section 3. The templating effect of the Cs(2) atom on the central crownlike Te_7 unit of a Te_{13}^{2-} ion in Cs_2Te_{13}, the first member of the above-mentioned series, is demonstrated in Figure 13.

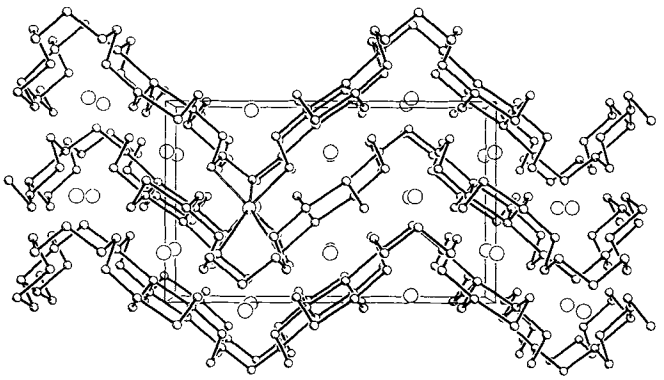

Figure 13. Undulating layers of Cs_2Te_{13} [5c] perpendicular to [100] with Cs(2)···Te interactions to the central crownlike Te_7 unit.

3. Chalcogenidometalates of Groups 14–16

3.1. Group 16 (Se and Te)

Chainlike polyselenides Se_x^{2-} have been isolated with large counterions for $x = 2-9$,[73] analogous polytellurides Te_x^{2-} for $x = 2-5$ [74] and $x = 12$,[75] 13.[5c] The ability of Se to extend its coordination number beyond 2, though markedly less pronounced than for its heavier homologue, leads to the formation of bicyclic anions for $x > 9$ in the compounds $[Ph_3PNPPh_3]_2Se_{10}\cdot DMF$,[76a] $[Ph_4P]_2Se_{11}$,[45] and $[nPr_4N]_2Se_{11}$.[76b] With the exception of Cs_4Se_{16}, all known alkali metal selenides A_2Se_x ($x \geq 5$)[77] exhibit isolated acyclic anions, for example Rb_2Se_5 [55] and Cs_2Se_5.[77] Cs_4Se_{16} (Figure 2) contains a central square-planar Se atom with a severe e_u distortion.[18] If the long Se(4)–Se(5) distances of 2.989(4) Å are ignored, the structure consists of a neutral Se_6 ring, and two Se_5^{2-} chain ions. The formation of isolated selenium rings under solventothermal conditions has also been reported for $Rb_3AsSe_4\cdot 2Se_6$[78] and $[\{(NH_4)_2Mo_3S_{11.72}Se_{1.28}\}_2\cdot Se_{12}]$;[21] the neutral Se_{12} units of the latter compound provide the largest known ring system for this element.

In contrast to the analogous compounds of the lighter homologues S and Se, alkali metal polytellurides A_xTe_y ($x/y \geq 1/4$),[26] some of which can be prepared by ammonothermal synthesis under supercritical conditions (e.g. A_2Te_3, A_2Te_5; A = Rb, Cs [19, 79]), have been found to exhibit a variety of formula types (x/y = 5/3, 2/1, 1/1, 2/3, 2/5, 1/3, 1/4) and structural motifs. On the basis of the Zintl–Klemm concept, the valence electrons of the alkali metal cations may be regarded as being fully transferred to the anion structure of the more electronegative partner Te. Isolated anions are observed for $x/y \geq 2/3$, polymeric chainlike and layer anions for $x/y \leq 2/5$.[26] Characteristic building blocks for the latter polyanions are linear $TeTe_2$, T-shaped $TeTe_3$ (e.g. $^2_\infty[TeTe_3^-]$ sheets in Cs_2Te_8[61]), and square-planar $TeTe_4$ units (e.g. $^1_\infty[TeTe_4^{2-}]$ chains in A_2Te_5, A = Rb, Cs [19b, 79]). The latter unit is also found in the isolated bicyclic $[Te(Te_3)(Te_4)]^{2-}$ anion of $[K([15]\text{-crown-}5)_2]_2Te_8$.[81]

The potential applications of main group tellurides such as SnTe, Sb_2Te_3, and Bi_2Te_3 as semiconductors in optoelectronic devices have led to a growing interest in the synthesis and properties of such tellurium compounds.[26, 75a, 80] Current technology for the industrial-scale preparation of tellurides includes high-temperature solid-solid reactions, chemical vapour deposition from organometallic precursors (MOCVD) and aqueous precipitation. The development of alternative synthetic routes has provided a major focus of recent work. Methanolothermal reaction conditions have allowed the synthesis of a new class of tellurium-rich alkali metal tellurides with $x/y \leq 1/6$ (Table 4),

Table 4. Alkali metal polyselenides and alkali metal polytellurides prepared under methanolothermal conditions.

A_xSe_y	$A_xSe_yTe_z$	A_xTe_y
Cs_4Se_{16} [18]	Cs_4TeSe_{15} [60]	$RbTe_6$ [5a]
	$Cs_2Te_2Se_6$ [60]	Cs_2Te_{13} [5c]
	$Cs_4Te_{9.8}Se_{13.2}$ [60] [a]	Cs_4Te_{28} [5c]
		Cs_3Te_{22} [5b]

[a] $Cs_4[TeSe_3]_2\cdot Te_3Se_3\cdot 1.5Te_{3.2}Se_{2.8}$ with a Se/Te disorder in the second six-membered ring.

for instance $RbTe_6$ with $^2_\infty[Te_6^-]$ sheet anions, in which chair-shaped Te_6 rings (Figure 1a) are connected through four longer Te–Te bonds.[5a] The axial Te–Te bonds of the resulting T-shaped $TeTe_3$ units exhibit distances of 3.195(3) and 3.214(3) Å typical for secondary interactions,[26] and much longer than the associated equatorial distances of 2.777(3) and 2.789(2) Å. If these longer bonds are neglected, the anion layers contain Te_3 groups with a formal charge of −0.5. In contrast to these $^2_\infty[Te_6^-]$ sheets in $RbTe_6$, it is possible to describe the bonding in the $^2_\infty[Te_6^{3-}]$ ion of $[Cr(en)_3]Te_6$[59] in a conventional manner. If only Te–Te distances less than 3.12 Å are considered, the polyanion consists of isolated Te_4^{2-} chains, the terminal atoms of which participate in secondary bonded Te_3 rings.

By using a similar approach (Te–Te distances < 3.17 Å), the anion structure in Cs_2Te_{13}[5c] may be described as an isolated Te_{13}^{2-} chain (Figure 6) that is stabilized by the templating effect of a coordinated Cs atom (Figure 13). The structurally related Te_{12}^{2-} ion in $[Et_4N]_2Te_{12}$ was prepared by cathodic dissolution of an $SbTe_{10}$ alloy electrode in a solution of $[Et_4N]I$ in ethylenediamine.[75] The long chains in these structures are both connected into undulating sheets through secondary interactions, which in the case of Cs_2Te_{13} (Te···Te distances 3.181(2), 3.261(2) Å) lead to a ladder of Te_4 rectangles and Te_6 rings. Cleavage of the symmetry-related Te(3)–Te(4) bonds in this compound, and addition of a Te atom to the liberated Te_7 fragment affords the isolated crown-shaped Te_8 rings (Figure 14), which was first observed in Cs_3Te_{22}.[5b] Rearrangement of the remaining $^1_\infty[Te_6^{2-}]$ chains into the unique thinned 4^4 net with Te_4 and Te_{12} squares (Figure 1a) that separates Te_8 rings in Cs_3Te_{22}, can theoretically be achieved on one-electron reduction by cleavage of the old Te(1)–Te(2) bonds and formation of new Te(1)–Te(2)

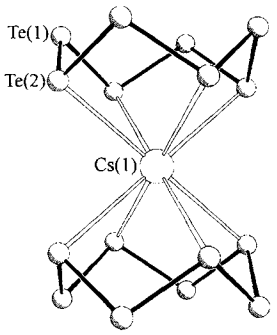

Figure 14. Eightfold coordination of a Cs atom by two Te_8 rings in Cs_3Te_{22} [5b]; average bonding parameters are Te–Te 2.80(2) Å and Te-Te-Te 100.0(16)°.

bonds between the remaining Te_4 rings of the original adjacent ladders. Extended Hückel calculations for this "strange yet simple"[82a] planar $^2_\infty[Te_6^{3-}]$ ion have yielded atomic charges of -1.065 for the linear Te atoms and -0.218 for the participating atoms of the Te_4 squares. The Te–Te bonds are weak (distances Te(3)–Te(3) 3.003(2), Te(3)–Te(4) 3.077(1) Å), and all Te atoms in the net are hypervalent. In the band structure diagram, band 20, which is only half occupied in the $^2_\infty[Te_6^{3-}]$ sheet, crosses the Fermi level around X (Figure 15); a gap of about 2 eV is found above this band and as a consequence of its being half-filled, the phase Cs_3Te_{22} should be metallic. The Fermi surface of the $^2_\infty[Te_6^{3-}]$ layer is almost perfectly nested with the result that there could be an associated charge density wave instability, which would be responsible for a metal-to-insulator transition.[82b,d]

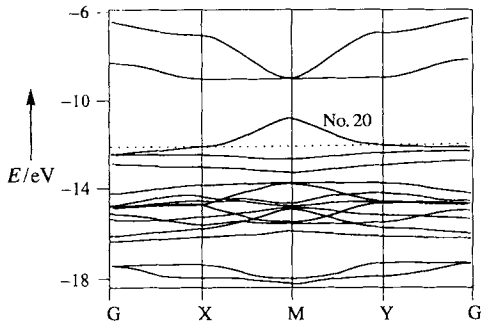

Figure 15. Band structure for the $^2_\infty[Te_6^{3-}]$ sheet in Cs_3Te_{22} [82a-b]; the Fermi level is indicated by the dotted line.

An intermediate metastable phase Cs_4Te_{28}[5c] can be synthesized in superheated methanol at a temperature 20 °C higher than that used to prepare Cs_2Te_{13}. Whereas isolated Te_8 crowns can once again readily be identified in this structure (Figure 16), the formation of a $^2_\infty[Te_6^{2-}]$ sheet anion remains incomplete. When Te···Te secondary bonds longer than 3.15 Å (open bonds in Figure 16) are neglected, the crystal lattice of Cs_4Te_{28} contains two further unique structural entities: Te_6^{2-} chains and uncharged Te_4 squares. These are linked together through long Te(5)···Te(6) (3.153(2) Å) and Te(5)···Te(7) (3.194(2) Å) contacts into a $^3_\infty[Te_{20}^{4-}]$ framework. The Te–Te bonds of the four-membered rings (2.911(2), 2.955(2) Å) are markedly shorter than those in Cs_3Te_{22} (3.003(1)Å), indicating that these entities can be considered to be effectively neutral; the negative charge is mainly localized on the terminal Te(5) atoms of the Te_6^{2-} chains. Opposite central Te_4 units of neighboring Te_6^{2-} chains adopt conformations that readily allow the formation of new crown-shaped Te_8 rings on addition of a further electron by shortening of the Te(4)···Te(4) interactions (3.442(2) Å) and cleavage of the Te(4)–Te(5) bonds.

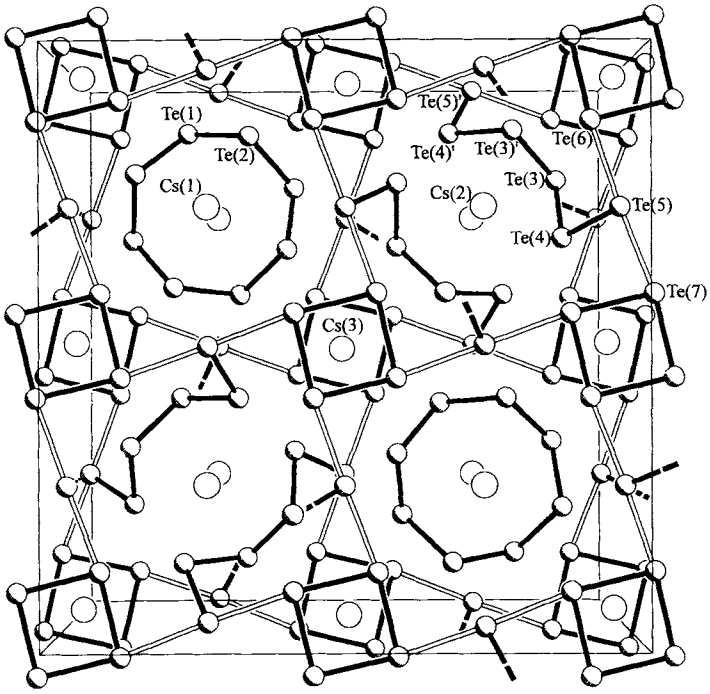

Figure 16. Structure of Cs_4Te_{28} [5c]; selected bond lengths [Å]: Te(1)–Te(2) 2.778(2), Te(1)–Te(2)' 2.829(2), Te(3)–Te(3)' 2.788(3), Te(3)–Te(4) 2.774(2), Te(4)–Te(5) 2.797(2).

The methanolothermal technique has also successfully been employed to synthesize the selenidotellurates $Cs_4Te_{9.8}Se_{13.2}$, $Cs_2Te_2Se_6$ (Figure 8), and Cs_4TeSe_{15}.[60] Replacement of Se(4) in Cs_4Se_{16} (Figure 2) by a Te atom in Cs_4TeSe_{15} leads to a marked reduction in the degree of distortion of the central square-planar unit of the anion, a finding that is in accordance with the increased tendency of Te to exhibit higher coordination numbers. The difference between opposite X–Se distances is 0.564 Å in Cs_4Se_{16} but only 0.360 Å in Cs_4TeSe_{15} (corresponding bond lengths Te(4)–Se(3) 2.602(3), Te(4)–Se(5) 2.962(4) Å). In nondisordered Se/Te rings, the chalcogen atoms are sited so that the Te atoms adopt positions with the shortest secondary interactions to neighboring anions, a preference that should lead to a range of novel selenidotellurates.[60]

3.2. Group 15 (As and Sb)

In contrast to its heavier homologue, the tendency of trivalent As to extend its coordination number beyond 3 in the thio- and selenidoarsenates(III) is relatively weak. However, the possibility of participating in secondary As···S interactions does lead the free terminal S atoms in the polymeric anions of $A_2As_8S_{13}\cdot H_2O$ (A = K, Rb, NH_4)[40] and $Cs_2As_8S_{13}$[7a] to adopt unusual axial sites relative to their respective As_3S_3 and As_4S_4 rings (Figures 4 and 11). For instance, the relevant As···S contacts in $Rb_2As_8S_{13}\cdot H_2O$ lie in the range 2.92–3.03 Å and are consequently much shorter than the sum of the van der Waals radii of As and S (3.65 Å, Pauling). If the weak As···S contacts to the axial S atom are taken into consideration, a semicube As_3S_4 is formed, which is analogous to the Sn_3E_4 building blocks frequently observed in thio- and selenidostannates(IV) (Section

tion 3.3). The effective restriction of the available building units to the pseudo-AsE_3 tetrahedron leads to a paucity in the formula and structural types observed for the ternary thio- and selenidoarsenates(III) (Table 5). The structural motifs are limited

Table 5. Ternary alkali metal thio- and selenidoarsenates(III) prepared under solvatothermal conditions.

Chalcogen	S		Se	
Solvent	H_2O	CH_3OH	H_2O	CH_3OH
K^+	$K_2As_8S_{13}\cdot H_2O$ [40]		$KAsSe_3\cdot H_2O$ [7b]	$KAsSe_2$ [8a]
Rb^+	$Rb_2As_8S_{13}\cdot H_2O$ [40]	$RbAsS_2$ [56]	$RbAsSe_3\cdot 0.5H_2O$ [7b]	$RbAsSe_2$ [8a]
Cs^+	$Cs_2As_8S_{13}$ [7a]	$Cs_2As_8S_{13}$ [56]	$CsAsSe_3\cdot 0.5H_2O$ [7b]	$CsAsSe_2$ [8a]

to corner- or Se–Se-bridged chains $^1_\infty[AsE_2^-]$ and $^1_\infty[AsSe_3^-]$, and the one- and two-dimensional anions of the type $^n_\infty[As_8S_{13}^{2-}]$. However it has very recently been demonstrated that $[As_xS_y]^{(2y-3x)-}$ building blocks formed by the condensation of invidual pseudo-AsS_3 tetrahedra can be incorporated under hydrothermal conditions into novel polymeric anions containing elements such as In^{III}, Bi^{III}, Ni^{II}, Pt^{II}, Ag^I, and Hg^{II} (reaction type 1e, Table 1).[10] Chainlike units such as $[As_3S_7]^{5-}$, $[As_4S_9]^{6-}$, and $[As_3S_6]_n^{3n-}$ are found in the anionic structures of $[Ph_4P]_2[InAs_3S_7]$ and $K_2[Ag_6(AsS_3)(As_3S_7)]$ (= $K[Ag_3As_2S_5]$), $[Ph_4P]_2[Hg_2As_4S_9]$, and $[Me_4N][HgAs_3S_6]$, and cyclic $[As_3S_6]^{3-}$ fragments in the layered anions of $[Me_4N]_2$-$Rb[BiAs_6S_{12}]$. The solventothermal design of such M/As/E covalent frameworks should provide an exciting synthetic challenge for the coming years.[10]

The availability of pseudo-SbE_4 trigonal bipyramids and (in rare examples) pseudo-SbS_5 octahedra in addition to pseudo-SbE_3 tetrahedra as molecular building units leads to a fascinating diversity in the cation-controlled structural motifs in the thio- and selenidoantimonates(III) (Table 6). Four- and six-membered Sb_2E_2 and Sb_3E_3 ring systems are frequently observed as connecting units. Solventothermal conditions have afforded the following formula types with monovalent cations.

Table 6. Ternary alkali metal and alkaline earth metal thio- and selenidoantimonates(III) prepared under solvatothermal conditons [a].

Chalcogen	S		Se
Solvent	H_2O	CH_3OH	CH_3OH [b]
Na^+	β-$NaSbS_2$ [13a]		
K^+	$K_3SbS_3\cdot 3Sb_2O_3$ [13e]	$KSbS_2$ [56, 13b]	$KSbSe_2$ [56, 13f]
	$KSbS_2$ [13b]		$K_2Sb_4Se_8$ [83]
	$K_2Sb_4S_7$ [13c]		
	$K_2Sb_4S_7\cdot H_2O$ [13d]		
Rb^+	$RbSb_3S_5\cdot H_2O$ [6a]	$Rb_2Sb_4S_7$ [71b]	$RbSb_3Se_5$ [84]
	$Rb_2Sb_4S_7\cdot H_2O$ [13d, 14a]		$Rb_2Sb_4Se_8$ [83]
Cs^+	$Cs_2Sb_4S_7$ [6b]	$Cs_3Sb_5S_9$ [8b]	$CsSbSe_2$ [56, 85]
	$Cs_2Sb_8S_{13}$ [6c]		$Cs_3Sb_5Se_9$ [8b]
	$Cs_3Sb_5S_9\cdot 0.6H_2O$ [86a]		
Sr^{2+}	$Sr_2Sb_2S_5\cdot 15H_2O$ [14b]		
	$Sr_2Sb_4S_7\cdot 6H_2O$ [14c]		

[a] The following thioantimonates(III) with NH_4^+ or organic ammonium ions have been prepared under hydrothermal conditions: NH_4SbS_2[14d], $[Me_4N]Sb_3S_5$ [87], $[nPr_4N]Sb_3S_5$ [64], $(NH_4)_2Sb_4S_7$ [14e], $[pipzH_2]Sb_4S_7$ [64] (pipz = piperazine), $[enH_2]Sb_8S_{13}$ [63a], $[C_4H_{10}N]_2Sb_8S_{13}\cdot 0.15H_2O$ [63b], $[CH_3NH_3]_2Sb_8S_{13}$ [88a, b], $[H_3N(CH_2)_3NH_3]Sb_{10}S_{16}$ [88c]. [b] $Na_3SbSe_3\cdot 3Sb_2O_3\cdot 0.5Sb(OH)_3$ [88d] as well as several compounds with similar compositions [88e–h] and $Cs_2Sb_4Se_8$ [52] have been prepared under hydrothermal conditions.

- $ASbE_2$: sheets: β-$NaSbS_2$; chains: $KSbE_2$ (E = S, Se), NH_4SbS_2
- $A_2Sb_4Se_8$: sheets with Se–Se bridges, (A = K, Rb, Cs)
- ASb_3E_5: three-dimensional framework: $[Me_4N]Sb_3S_5$: sheets: $RbSb_3S_5\cdot H_2O$, $RbSb_3Se_5$; chains: $[nPr_4N]Sb_3S_5$
- $A_2Sb_4S_7\cdot xH_2O$: three-dimensional frameworks: $K_2Sb_4S_7$, $A_2Sb_4S_7\cdot H_2O$ (A = K, Rb); sheets: $Rb_2Sb_4S_7$; chains: $Cs_2Sb_4S_7$, $(NH_4)_2Sb_4S_7$
- $Cs_3Sb_5E_9\cdot xH_2O$: sheets: $Cs_3Sb_5E_9$ (E = S, Se), $Cs_3Sb_5S_9\cdot 0.62H_2O$
- $A_2Sb_8S_{13}$: three-dimensional framework: $[CH_3NH_3]_2$-Sb_8S_{13}; sheets: $Cs_2Sb_8S_{13}$

All listed examples exhibit different cation-controlled structure types. In view of the range of longer Sb–E distances typically observed in such compounds, assignment of dimensionality will always remain somewhat arbitrary. The presence of solvent water molecules in the crystal lattice can have a profound effect on the structure adopted by a particular formula type. Whereas $Cs_3Sb_5S_9$ ($C2/m$) and $Cs_3Sb_5S_9\cdot 0.62H_2O$ ($P\bar{1}$) exhibit different space groups but the same anionic structure, different connectivities are found for the pseudo-SbE_3 tetrahedra ($\times 1$) and pseudo-SbE_4 trigonal bipyramids ($\times 2$) in $RbSb_3S_5\cdot H_2O$ and $RbSb_3Se_5$ (Figure 17). In contrast to the former

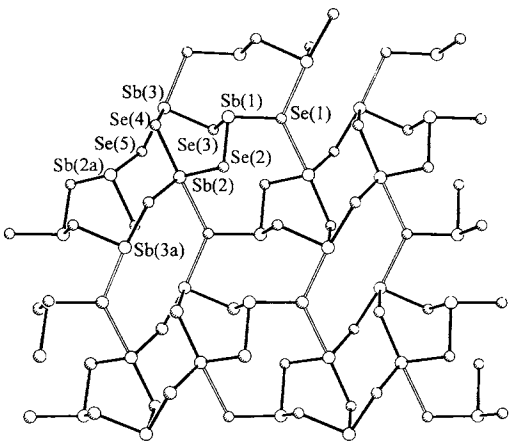

Figure 17. The anion sheet $^2_\infty[Sb_3Se_5^-]$ in $RbSb_3Se_5$ [84] with pseudo-$SbSe_3$ tetrahedra and pseudo-$SbSe_4$ trigonal bipyramids; selected bond lengths [Å]: Se(1)···Sb(2) 3.055(2), Se(1)···Sb(3) 3.103(2) (depicted as open bonds).

phase, in which all Sb atoms participate in Sb_2S_2 rings, five-connected cyclic Sb_3Se_3 fragments provide the building units for the anion sheets in $RbSb_3Se_5$.[84] The introduction of a water molecule has an even more dramatic effect for $Rb_2Sb_4S_7$. Whereas the methanolothermal anhydrous phase (ρ = 3.97 g cm^{-3}) contains dense $^2_\infty[Sb_4S_7^{2-}]$ sheets with exclusively pseudo-SbS_4 trigonal bipyramids (Figure 12), $Rb_2Sb_4S_7\cdot H_2O$ (ρ = 3.67 g cm^{-3}) exhibits a much more open sheet structure (two pseudo-SbS_3 tetrahedra, two pseudo-SbS_4 trigonal bipyramids), in which both Sb_2S_2 and Sb_3S_3 rings participate. Methanolothermal conditions provide a synthetic route not only to anhydrous thioantimonates(III) but also to the corresponding selenidoantimonates(III), which have not been prepared in superheated water.

3.3. Group 14 (Ge and Sn)

The development of nanoporous structures containing exlusively GeE_x polyhedra is hampered by the restriction of the available building blocks to the GeE_4 tetrahedron for S and its heavier homologues. Mild hydro- and methanolothermal conditions have yielded the isolated adamantane-like anions $[Ge_4E_{10}]^{4-}$ in $[Me_4N]_4[Ge_4S_{10}]$,[89a] and $Rb_4Ge_4Se_{10}\cdot MeOH$[34] and $Cs_4Ge_4Se_{10}\cdot 2MeOH$,[9a] respectively. The methanolothermal technique has also afforded the novel cyclic $[Ge_2Se_8]^{4-}$ ions in $Cs_4Ge_2Se_8$[9a] and a family of compounds belonging to the formula type A_2GeE_4 (A = K, Rb, Cs; E = Se, Te) with chains of E–E-connected GeE_4 tetrahedra.[34] An interesting example for the incorporation of $[Ge_4S_{10}]^{4-}$ cages into a three-dimensional framework is provided by treatment of $[Me_4N]_4[Ge_4S_{10}]$ with an aqueous solution of $[Mn(CH_3COO)_2]$ at room temperature, which affords yellow crystals of the polymeric compound $[Me_4N]_2[MnGe_4S_{10}]$ within 24 h.[89b] The corner linkage of adamantane-like units and MnS_4 tetrahedra generates a nanoporous system of intersecting channels occupied by $[Me_4N]^+$ ions. The same compound was also synthesized by Achak et al.[89c] by direct hydrothermal synthesis from GeS_2, $Mn(CH_3COO)_2$, and $(Me_4N)Cl$ at 140 °C for 48 h. The potential of this approach to the self-assembly of mixed main group element/transition metal thiometalates from molecular precursors should be appreciable as indicated by the recent preparation of similar open-framework structures in $[Et_4N][CuGe_2S_5]$,[89d] $[Me_4N]_6[(Cu_{0.44}Ge_{0.56}S_{2.23})_4(Ge_4S_8)_3]$,[89e] $Cs_2[FeGe_4S_{10}]\cdot xH_2O$, $[Me_4N][FeGe_4S_{10}]$,[89f] and $[C_6H_{13}N_2]_2[H_3O][AgGe_4S_{10}]\cdot xH_2O$.[89g] Replacement of the divalent metal ions by dimeric group 11 cations Cu_2^{2+}, Ag_2^{2+}, and Au_2^{2+} has also been reported.[72] $Cs_2[FeGe_4S_{10}]\cdot xH_2O$ loses physisorbed and chemisorbed water molecules at 116 °C and 188 °C, respectively, but the three-dimensional anion framework is stable up to 630 °C under vacuum. Thus, this compound provides an encouraging example for the development of sulfide-based materials. Condensation of $[Ge_4S_{10}]^{4-}$ anions to an infinite $^1_\infty[Ge_4S_9^{2-}]$ chain has been achieved in $[(C_3H_7)_2NH_2][(C_3H_7)NH_2(C_2H_5)]Ge_4S_9$, which was prepared under hydrothermal conditions at 125 °C.[89h] An interesting contrast to the self-assembly of $^3_\infty[MGe_4S_{10}^{2-}]$ frameworks discussed above is provided by the hydrothermal reaction of GeS_2, $Ni(OAc)_2\cdot 4H_2O$, and $[Et_4N]HCO_3$ at 120 °C and at an initial pH value of 7.3 which yields a novel Ni-S molecular cluster $[Ni_{12}(S_2)_6S_8]^{3-}$ without Ge.[89i]

The ability of Sn^{IV} to extend its coordination number to 5 in SnE_5 trigonal bipyramids (E = S, Se) and to 6 in SnS_6 octahedra allows the formation of a variety of two- and three-dimensional anionic structures for the chalcogenidostannates(IV) with E = S, Se. The following formula types have been obtained for monovalent cations (see also Table 7) under solventothermal conditions.

- $Rb_2Sn_2Se_5$: three-dimensional framework (isostructural with $Tl_2Sn_2S_5$[90a] and $K_2Sn_2E_5$ (E = S, Se) [90b])
- $A_2Sn_3E_7\cdot xH_2O$: sheets: $Cs_2Sn_3Se_7$, $[Me_3NH]_2Sn_3S_7\cdot 0.72H_2O$, $[Me_4N]_2Sn_3S_7\cdot H_2O$, etc.; double chains (A = K, E = S, $x = 1$; A = Rb, E = S, $x = 2$)
- $A_2Sn_4S_9$: sheets: $[nPr_4N]_2Sn_4S_9$, $[tBu_4N]_2Sn_4S_9$
- $Cs_4Sn_5S_{12}\cdot 2H_2O$: sheets

Table 7. Alkali metal and other chalcogenidostannates(IV) prepared under solvatothermal conditions.

Chalcogen Solvent	S (H_2O)	Se CH_3OH	Te CH_3OH
K^+	$K_2Sn_3S_7\cdot H_2O$ [69]	$K_4Sn_3Se_8$ [9b]	K_2SnTe_5 [69, 91]
Rb^+	$Rb_2Sn_3S_7\cdot 2H_2O$ [32]	$Rb_2Sn_2Se_5$ [71a] $Rb_4Sn_2Se_6$ [32]	$Rb_{4+x}Sn_4Te_{17}$ [92a]
Cs^+	$Cs_4Sn_5S_{12}\cdot 2H_2O$ [7c]	$Cs_4Sn_2Se_6$ [8c] $Cs_2Sn_3Se_7$ [92b]	Cs_2SnTe_4 [9c]
other cations	$[Me_3NH]_2Sn_3S_7\cdot 0.72H_2O$ [68b] $[Me_4N]_2Sn_3S_7\cdot H_2O$ [68a] $R_2Sn_3S_7\cdot xH_2O$, $RR'Sn_3S_7\cdot xH_2O$ [93] [a] $[nPr_4N]_2Sn_4S_9$, $[tBu_4N]_2Sn_4S_9$ [67, 93b] $[Me_3NH][nPr_4N]Sn_4S_9$ [67] $[N_2C_4H_{11}]_2[N_4C_{10}H_{24}]Sn_5S_{12}$ [94]	$[MeC(NH_2)_2]_2Sn_2Se_5$ [69] $[enH_2]_2Sn_2Se_6\cdot en$ [33] $[enH_2]Sn_3Se_7\cdot 0.5en$ [33] $[Me_2NH_2]Sn_3Se_7$ [92c] $[Me_4N]_2Sn_3Se_7\cdot xH_2O$ [93c, d] [b]	

[a] This formula type is observed for a range of alkylammonium ions, for example: R = $[Et_4N]$, $[nPr_3NH]$, $[tBuNH_3]$; RR' = $[NH_4][Et_4N]$ [93c]. [b] A number of isostructural mixed thioselenidostannates $[Me_4N]_2[Sn_3S_{7-x}Se_x]\cdot xH_2O$ ($x = 1.5$–2.5) are known [93d].

Methanolothermal conditions allow synthetic access to selenido- and telluridostannates(IV) but not to the thiostannate(IV). The isostructural thiostannates(IV) $K_2Sn_3S_7\cdot H_2O$[69] and $Rb_2Sn_3S_7\cdot 2H_2O$[32] contain double chains in which individual $^1_\infty[SnS_3^{2-}]$ polyanions are connected through corner-bridged ditetrahedral $[Sn_2S_6]^{4-}$ units. Edge-bridged SnS_6 octahedra provide the building blocks for the $^1_\infty[SnS_3^{2-}]$ chains, which themselves can be regarded as a section of the dense-packed layers of berndtite SnS_2.[95a] A series of compounds $A_2Sn_3S_7\cdot xH_2O$ with larger alkylammonium ions[72, 93] all contain sheet anions $^2_\infty[Sn_3S_7^{2-}]$ with a structure similar to that first observed for $Cs_2Sn_3Se_7$[92b] (Figure 18) and $[enH_2]Sn_3Se_7\cdot$

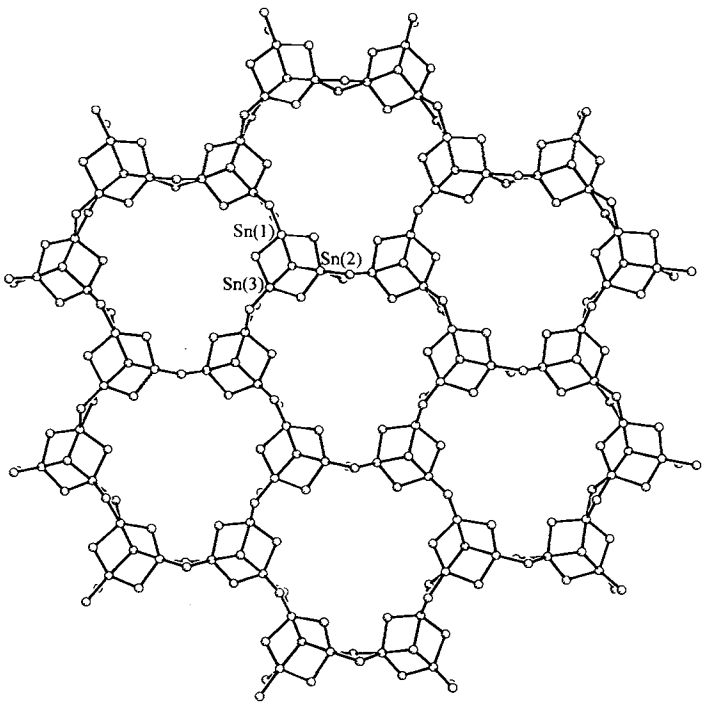

Figure 18. $^2_\infty[Sn_3Se_7^{2-}]$ polyanion with a 6^3 net in $Cs_2Sn_3Se_7$ [92b].

0.5 en.[33] These thiostannates(IV) belong to a family of related anions with accommodating molecular-dimension pores, all of which display Sn_3S_4 semicubes as characteristic molecular building units. The basic 6^3 net for the $^2_\infty[Sn_3S_7^{2-}]$ ions consists of edge-bridged Sn_3S_{10} fragments that contain trigonal SnS_5 bipyramids. Condensation of pairs of opposite semicubes leads to formation of edge-bridged Sn_5S_{16} units with a common central octahedral Sn^{IV} atom, as found in $Cs_4Sn_5S_{12}\cdot 2H_2O$[7c] (Figure 19) and $[N_2C_4H_{11}]_2[N_4C_{10}H_{24}]Sn_5S_{12}$.[94] This reduces

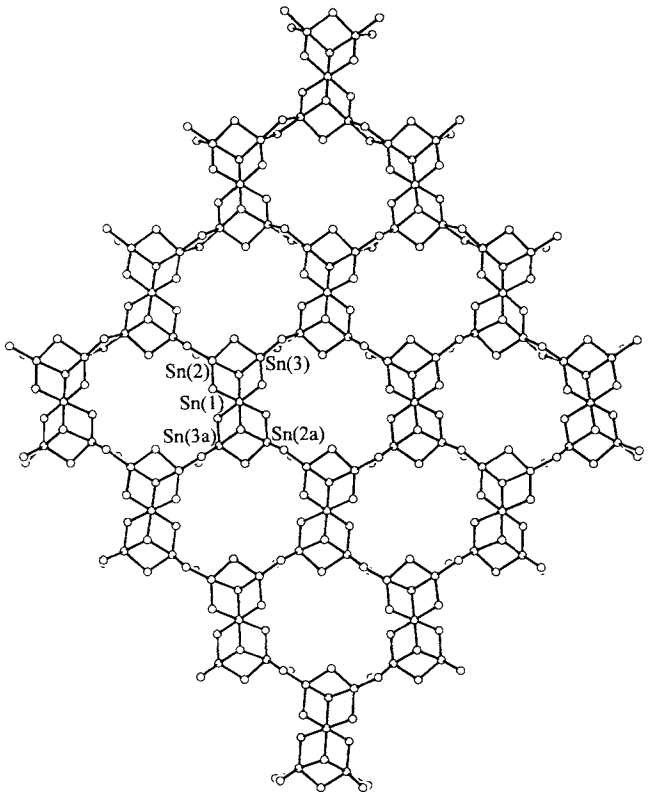

Figure 19. The anion sheet $^2_\infty[Sn_5S_{12}^{4-}]$ in $Cs_4Sn_5S_{12}\cdot 2H_2O$ [7c]; the Sn_3S_4 semicubes are linked through the common octahedrally coordinated Sn(1) atom.

the number of ring atoms from 24 to 20 and changes the ring shape from hexagonal to effectively elliptical. Very large cations lead to 32-membered rings as found in $[n\mathrm{Pr}_4\mathrm{N}]_2Sn_4S_9$, $[t\mathrm{Bu}_4\mathrm{N}]_2Sn_4S_9$, and $[\mathrm{Me}_3\mathrm{NH}][n\mathrm{Pr}_4\mathrm{N}]Sn_4S_9$, in which Sn_6S_{18} fragments of the $^2_\infty[Sn_3S_7^{2-}]$ anions (two edge-bridged Sn_3S_{10} units) are linked through edge-bridged SnS_4 tetrahedra.[67, 93] Any envisaged application of such synthetic zeolites will require template removal with retention of framework integrity. Recent thermochemical studies on $[Et_4N]_2Sn_3S_7$ and $[n\mathrm{Pr}_4\mathrm{N}]_2Sn_4S_9$ have demonstrated that the thermal stability range (20–200 °C) for this class of nanoporous thiostannates(IV) is more restricted than that of oxide-based zeolites.[93] At temperatures above 200 °C, reaction of chemisorbed water and template cations with the anion layer leads to solid-state reconstruction, first to the dense packed layers of SnS_2[95a] and then to SnS [95b] and Sn_2S_3.[95c] Preliminary investigations indicate that alkali metals and alkaline earth metals as well as some transition metal ions can replace the $[Me_4N]^+$ ions in $[Me_4N]_2Sn_3S_7\cdot H_2O$; the integrity of the framework was confirmed by X-ray powder analysis.[68a] The bulk crystalline nanoporosity of these sheet structures has been shown to be reflected in their material surfaces, as studied by atomic force microscopy.[96]

The recent extension of the methanolothermal technique to telluridostannates(IV) has led to the preparation of the known phase K_2SnTe_5[91] and two novel compounds $Rb_{4+x}Sn_4Te_{17}$ ($0\le x\le 1$)[82d, 92a] and Cs_2SnTe_4.[9c] K_2SnTe_5 and Cs_2SnTe_4 contain infinite chain anions in which $SnTe_4$ tetrahedra are linked by edge-bridged square-planar $TeTe_4$ units and Te–Te bonds, respectively. The square-planar $TeTe_4$ building blocks are also found in the unique three-dimensional framework structure of $Rb_{4+x}Sn_4Te_{17}$ (Figure 20), in which planar thinned 4^4 nets with Te_{12} squares are connected through Sn_2Te_6 spacers. Extended Hückel calculations[82d, 97] indicate that the tellurium layers do not communicate electronically through these ditetrahedral groups.

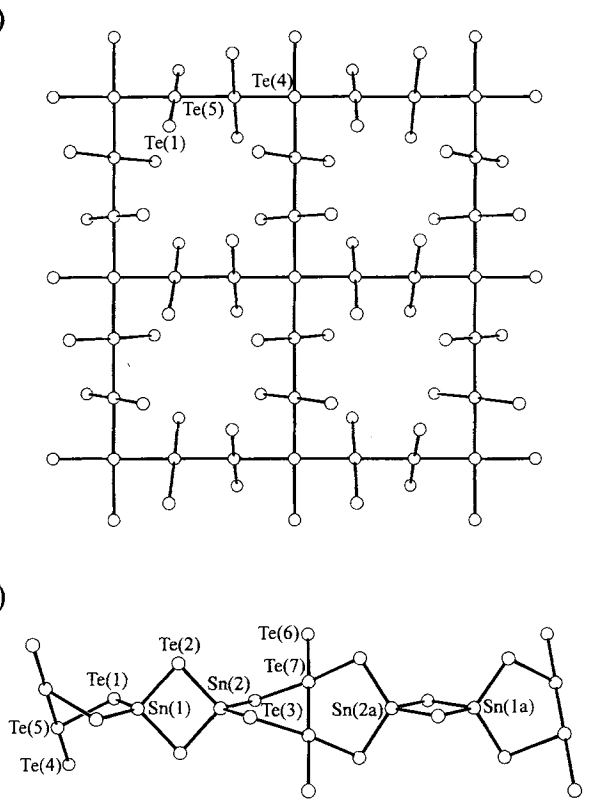

Figure 20. a) Planar, thinned 4^4 tellurium nets in $Rb_{4+x}Sn_4Te_{17}$ ($0\le x\le 1$) [92a]; b) Sn_2Te_6 connecting spacers [Sn(1), Sn(2), Te(1)–Te(3)] between the tellurium layers [Te(4), Te(5) and Te(6), Te(7)].

4. Transition Metal Chalcogenidometalates

Solventothermal reaction conditions that have been employed for the preparation of chalcogenidometalates from groups 4–12 are summarized in Table 2. With the exception of $K_2Mo_3Se_{18}$, this synthetic approach has only afforded polymeric anion structures for the elements Pd, Cu, and Ag from groups 10 and 11. Despite this restriction, the characterized phases have been found to exhibit a remarkable range of formula and structure types:

- chains: $K_2Mo_3Se_{18}$,[20c] α-$CsCuSe_4$,[4a, 23a] α-$CsCu(S_xSe_{4-x})$,[23e] $CsCu(S_xSe_{6-x})$,[23e] $CsCuS_6$[23f]
- sheets: $CsCu_4Se_3$[23a]
- three-dimensional frameworks: $RbAg_5S_3$, $CsAg_7S_4$,[24a] $A_2Ag_6S_4$ (A = Na, K),[24b] $K_2Ag_{12}Se_7$[24c]
- interpenetrating three-dimensional frameworks K_2PdSe_{10}[22a]

Unlike the selenidometalates prepared by methanolothermal reactions for group 14 and 15 elements, several of these compounds contain larger Se_x^{2-} chains ($x = 3$, 4, 6) as molecular building units. $CsCuSe_4$,[23a] for instance, which crystallizes in the $(NH_4)CuS_4$ structure type,[98] consists of $^1_\infty[CuSe_4^-]$ chains in which Cu^I atoms are tetrahedrally coordinated by three selenium atoms belonging to an Se_4^{2-} chain, which itself bridges three symmetry-equivalent copper centers. The first example of a polymeric selenidomolybdate was established with $K_2Mo_3Se_{18}$,[20c] which exhibits no less than four different (poly-)selenides (Se^{2-}, Se_2^{2-}, Se_3^{2-}, and Se_4^{2-}), despite the use of the defined compound K_2Se_4 as a starting material. This unique phase contains individual $[Mo_3(\mu\text{-}Se_2)_3(\mu_3\text{-}Se)]^{4+}$ clusters with approximately threefold symmetry, which are cross-linked into zigzag chains by two bridging Se_4^{2-} ligands between two of the three molybdenium atoms. The third Mo atom is coordinated by adjacent Se atoms of a triselenide chain, whose remaining member participates in weak secondary Se···Se bonding (av 3.15 Å) to a triangle of diselenide Se atoms of the $[Mo_3Se_7]^{4+}$ cluster of a neighboring $^1_\infty[Mo_3Se_{18}^{2-}]$ chain. Minor variations in the quantities of reagents and solvent can lead to the isolation of other phases under the mild hydrothermal conditions required for reaction type 2b (see Table 2).[20c] For instance, an increase in the K_2Se_4:Mo ratio from 3:2 to 2:1 accompanied by a 50% increase in the volume of water used (0.3 mL instead of 0.2 mL) affords $K_{12}Mo_{12}Se_{56}$,[20b] in which four $[Mo_3Se_{14}]^{3-}$ clusters are linked together into the cyclic anion $[Mo_{12}Se_{56}]^{12-}$ by bridging Se_3^{2-} ligands.

A third example of a hydrothermal phase containing longer Se_x^{2-} chains is provided by K_2PdSe_{10}, the first chalcogenidometalate to feature isolated interpenetrating frameworks.[22a] These independent anionic three-dimensional structures are built up in a diamondlike fashion from square-planar $[Pd(Se_4)_4]^{6-}$ and $[Pd(Se_6)_4]^{6-}$ building units connected together through common Se_4^{2-} and Se_6^{2-} units respectively. Unlike other rare examples of interpenetrating frameworks,[99] the three-dimensional anion motifs in K_2PdSe_{10} are both chemically and structurally inequivalent. Their coexistence in the same crystal lattice illustrates the conformational flexibility of polychalcogenide ligands by demonstrating the ability of Se_x^{2-} chains of different length (in this case $x = 4$ or 6) to bridge an array of equally spaced Pd atoms.

All polychalcogenide phases ($x \geq 2$) in Table 2 have been prepared under mild solventothermal conditions (110–170 °C). As would be predicted, the more stringent thermal regime (300–340 °C) required for synthetic work in supercritical ethylenediamine is found to afford only simple chalcogenide ions E^{2-} for the construction of new compounds. Kolis et al. have prepared a series of thio- and selenidoargentates(I), $RbAg_5S_3$, $CsAg_7S_4$,[24a] and $K_2Ag_{12}Se_7$[24c] with open channels under such conditions; Figure 21 depicts the porous self-supporting Ag–S framework structure of $CsAg_7S_4$. Supercritical ethylenediamine was also employed for the synthesis of the isostructural phases $A_2Ag_6S_4$ (A = Na, K),[24b] which contain Ag_6 octahedra capped on four opposite faces by S atoms and linked together into a three-dimensional framework on all the uncapped faces by longer Ag–Ag distances of 3.331(1) Å.

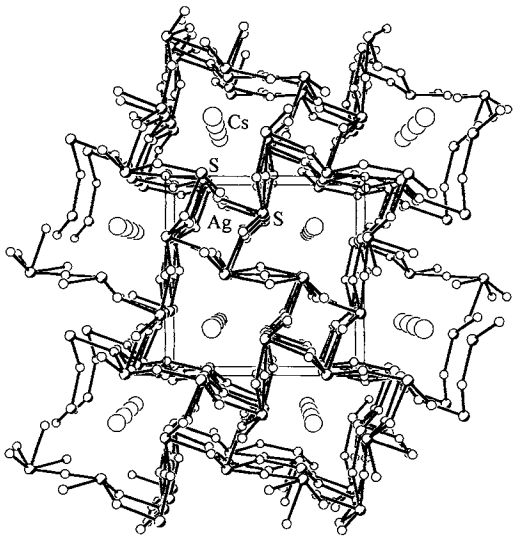

Figure 21. The porous framework structure of $CsAg_7S_4$ showing the atom labeling [24a].

The suitability of solventothermal reaction conditions for the preparation of chalcogenide complexes by oxidative decarbonylation of transition metal carbonyl compounds has recently been demonstrated for ethylenediamine,[100] MeOH,[70b, 101, 102b] and H_2O.[102]

5. Summary and Outlook

The original motivation for the development of new solventothermal techniques in the intermediate-temperature range (100–600 °C) was stimulated by the goal of introducing a degree of mechanistic control to the synthesis of solid-state chalcogenidometalates. As reviewed in the current article, a series of guidelines for the use of molecular building blocks in the design of such anion networks is now beginning to emerge. Although the choice of solvent, thermal regime, and the templating influence of counterion size and charge are of paramount importance, variation of other factors such as the solution oxidation potential or basicity, the molar ratio of the starting materials, and the reaction time can also exert a decisive influence on the adoption of a particular structure or formula type. The relatively high polarity of methanol, coupled with its low viscosity in comparison to water, smaller typical energies of solvation and reduced Brønsted acidity, have led to increased interest in the use of this reaction medium for solventothermal syntheses in the temperature range 110–200 °C. Methanolothermal conditions usually afford solvent-free phases and have been found to be generally more suitable for the preparation of selenido- and telluridometalates of groups 14–16. Extension of the soft solventothermal approach to group 13 chalcogenidometalates (Ga, In, Tl) should be possible and, indeed, the first examples of hydrothermally synthesized In and Tl compounds have recently been published.[103] The thermal instability of molecular building units such as E_x^{2-} chains or E_n ($n = 4$, 6, 8) and $[M_3E_6]^{3-}$

(M = As, Sb) rings generally restricts the use of the soft solventothermal method to temperatures below 200 °C for this class of solid-state compounds. The significance of kinetic control in the isolation of metastable phases is illustrated by the recent synthesis of three mechanistically related tellurium-rich tellurides Cs_2Te_{13}, Cs_4Te_{28},[5c] and Cs_3Te_{22}[5b] in superheated methanol in the narrow temperature range 150–200 °C.

Alkali metal and alkylammonium ions can be used to control the solventothermal assembly of polymeric anion networks, in which the dimensions of resulting channels and cavities are often found to reflect the geometry and size of such structure-directing agents. Whereas smaller cations such as K^+ and Rb^+ are more likely to generate three-dimensional framework structures, larger cations such as Cs^+ and R_4N^+ are likely to give layered or chain polyanions. However, despite this correlation between anion dimensionality and cation size, it is not generally possible to predict which formula or structure type will be produced by use of a particular structure-directing cation. An exception to this observation is provided by the related layered thiostannates(IV) with the formula types $A_4Sn_5S_{12}$, $A_2Sn_3S_7$, and $A_2Sn_4S_9$, all of which contain Sn_3S_4 semicubes as characteristic building units. The ring size of their 6^3 nets increases from 20 through 24 to 32 atoms for the cation series Cs^+, Et_4N^+, and nPr_4N^+.

In the past decade, solventothermal work on chalcogenidometalates has concentrated on development of the method and classification of structure types. However, an increased emphasis on the designed construction of materials with potentially useful ion exchange, catalytic, optical, and semiconducting properties has become apparent in the last few years and it can be assumed that this will continue to gain momentum in the immediate future. In particular, a rapid development of mild solventothermal techniques for the synthesis of mixed chalcogenide-based frameworks[8,9] such as $^3_\infty[MnGe_4S_{10}^{2-}]$ by cation-directed self-assembly from molecular precursors can be expected. The recent observation of charge density wave instabilities for the tellurium layers of $K_{0.33}Ba_{0.67}AgTe_2$[10a] also points to the exciting promise of telluride systems in the search for unusual materials.

We would like to thank those co-workers directly involved in the development of our own research in this field, in particular Dr. Jürgen Kaub, Dr. Hans-Joachim Häusler, Dr. Hans Georg Braunbeck, and Dr. Bernhard Schaaf. We are also indebted to Dr. E. Canadell, and Professors P. K. Dorhout and M. G. Kanatzidis for allowing us to cite their unpublished work.

New Strategies to α-Alkylated α-Amino Acids

Thomas Wirth*

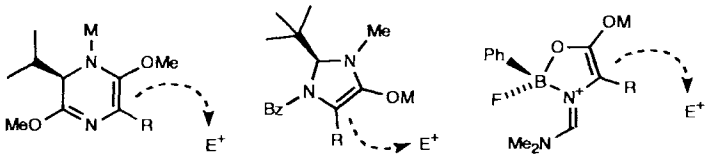
Nonproteinogenic α-alkylated α-amino acids play an important role in natural products and for biological investigations. Because of the tetrasubstituted asymmetric carbon atom they possess a high stability at the stereogenic center. They exert a remarkable influence on the conformation of peptides into which they are incorporated.[1] They can therefore be used for the investigation of enzymatic mechanisms and as enzyme inhibitors. Furthermore, they are interesting building units for the synthesis of natural products, which has already been demonstrated by several impressive examples.[2]

In 1872 the simplest α,α-disubstituted amino acid (2-aminoisobutyric acid, Aib) was described.[3] In 1908 the first optically active representative of this class of compounds, (*R*)-2-ethylalanine (D-isovaline), was isolated by microbial racemic resolution.[4] Synthetic chemists have therefore been interested in the enantiopure synthesis of α-alkylated α-amino acids for some time. Their powerful methods for the construction of chiral α-amino acids can in some cases also be used for the synthesis of the α-alkylated derivatives.

In most of the procedures the stereogenic center is constructed by alkylation of chiral, nonracemic enolates. The established methods, which were reviewed several times,[5] are mentioned only briefly here.

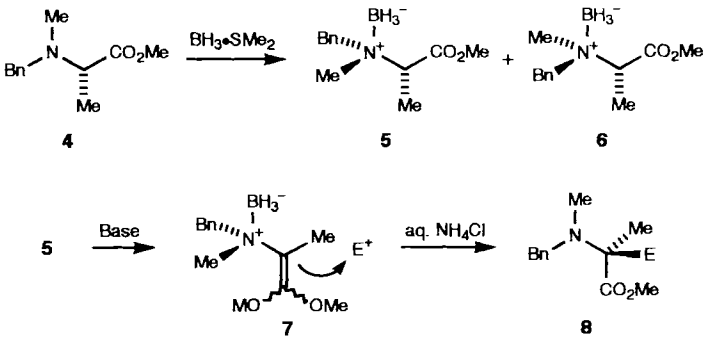
One of the classics is the Schöllkopf synthesis via bislactim ethers.[6] The chirality of an amino acid, mostly valine, is used to create a second stereogenic center by the addition of an electrophile to the deprotonated bislactim ether **1**. Acidic cleavage of the bislactim ether makes it possible to synthesize a variety of natural and unnatural amino acids in high yields and good optical purities.

The Seebach method likewise employs a chiral, cyclic enolate **2** (Bz = benzoyl).[7] The required imidazolidinones are synthesized by condensation of the corresponding amides with pivalaldehyde. The *tert*-butyl group directs the electrophile in a 1,3-induction and determines the configuration of the new stereogenic center. Deprotonated oxazaborolidinones **3** can also serve as chiral equivalents of amino acid enolates.[8] Starting from amino acids, these compounds can be prepared in a few steps in enantiomerically pure form. As in the Seebach method, the chirality of the amino acid is used to control the stereochemistry of a second center, which then directs the attack of the electrophile at the enolate.



1 **2** **3**

An interesting version of this concept was published recently.[9] After reaction of the alanine ester **4** with borane, the mixture of the diastereomers **5** and **6** could be separated (Scheme 1).



Scheme 1. Synthesis of α,α-substituted amino acids from α-methylated amino acids (Bn = Benzyl).

The stereogenic nitrogen atom directs the attack of the electrophile at the enolate. The direction of the attack can be explained by the Felkin–Anh model, because the electrophile approaches *anti* to the largest (benzyl) substituent. The enolate shown in **7** should be preferred because of the repulsion of the boron and the carboxy group. The boron is removed by aqueous workup, and the α-methylated amino acid **8** is obtained in enantiomeric purities of up to 82%.

The chirality of the phenylalanine derivative **9** is used for a direct, asymmetric α-alkylation (Scheme 2).[10] After treatment with base and reaction with an electrophile the α-alkylated amino acid **10** is obtained in up to 88% *ee*. It is not clear yet whether the deprotonated species is an enolate with a stereogenic nitrogen atom (**11**) or a chiral, α-metalated compound (**12**). The protecting groups on the nitrogen seem to play an important role. It is not yet possible to alkylate other phenylalanine derivatives by means of this reaction.

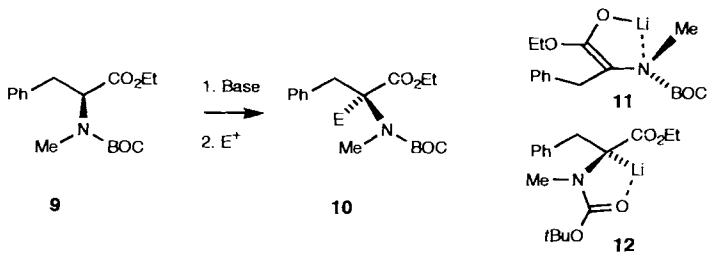
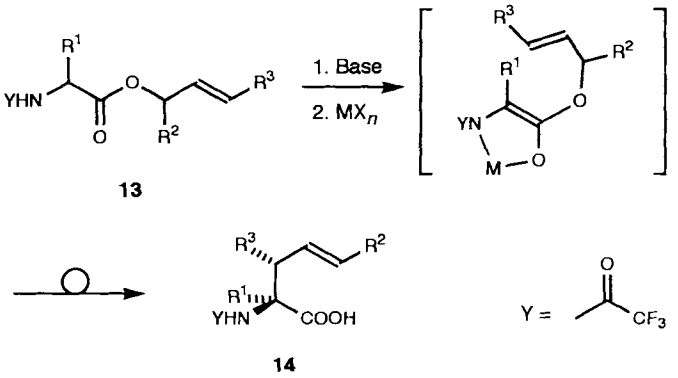


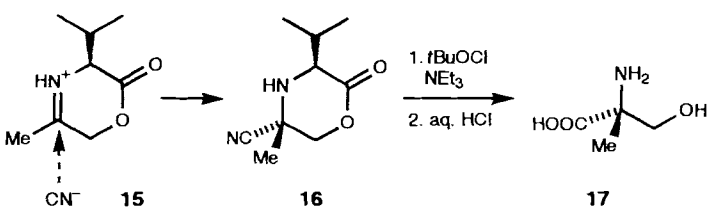
Scheme 2. Asymmetric α-alkylation of a substituted phenylalanine (BOC = *tert*-butoxycarbonyl).

A fast access to α-alkylated amino acids is also possible by the Claisen rearrangement of chelated enolates.[11] Esters of type **13** rearrange after treatment with base and chelation with a metal salt. The products **14** are obtained in good yields and with diastereoselectivities of up to 96% (Scheme 3).



Scheme 3. α-Alkylated amino acids by Claisen rearrangement.

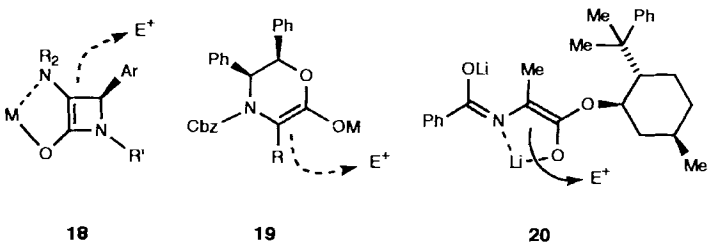
The amino acid synthesis of Strecker has been known since 1850.[12] Asymmetric versions of this synthesis start with chiral amines, which are condensed with carbonyl compounds to form imines. Addition of hydrogen cyanide and subsequent hydrolysis of the amino nitriles yields the amino acids. When ketones are used for the condensation, α-alkylated amino acids are obtained in high yields and good optical purities.[13] A new variant of this reaction reported recently employs valine to build a cyclic imine.[14a, b] The cyclic imine **15** is obtained by condensation of hydroxyacetone with valine, which reacts with cyanide to yield amino nitrile **16**. With *tert*-butyl hypochlorite and triethylamine an imine is formed, which gives after acidic hydrolysis enantiopure α-methylserine **17** in an overall yield of about 55% (Scheme 4). Because of the intramolecular protection of the hydroxy group this method allows a rapid and efficient access to hydroxy amino acids. Two alternative methods to synthesize optically active α-methylserine derivatives were reported recently.[14c, d]



Scheme 4. Asymmetric variant of the amino acid synthesis according to Strecker.

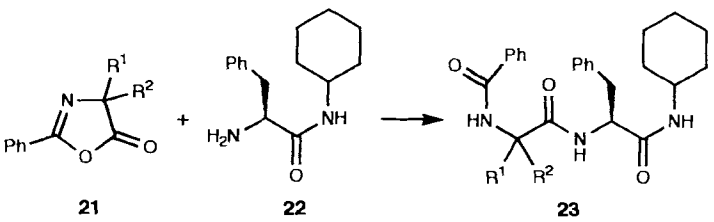
β-Lactams are also suitable intermediates on route to α,α-disubstituted amino acids.[15] In a 1,2-induction the chiral center in **18** is created. After reductive cleavage of the C–N bond enantiomerically pure α-alkylated amino acids are obtained. Two directing stereogenic centers are found in oxazinones **19** (Cbz = carbobenyzloxy), which can also be used advantageously in the synthesis of disubstituted amino acids.[16] However, during the reductive liberation of the amino acids the chiral auxiliary is destroyed.

Another conventional approach, the addition of electrophiles to enolates of chiral esters, has been applied successfully by several groups. The 8-phenylmenthol ester of *N*-benzoyl alanine can be deprotonated twice (**20**), and after addition of various



electrophiles, α-methylated derivatives are obtained. After cleavage of the chiral auxiliary they can be transformed into the enantiomerically pure α-methylated amino acids.[17]

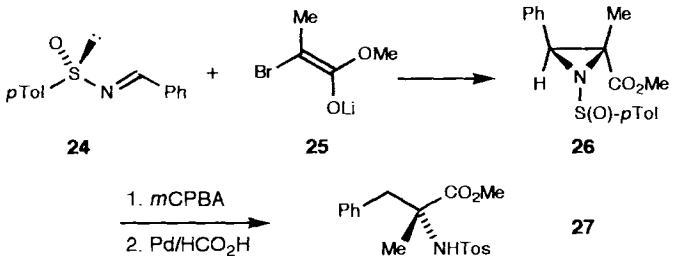
With racemic α-alkylated amino acids an enzymatic racemate resolution is possible. Different microorganisms have been applied, and the products are obtained in very high enantiomeric purities. Because α-alkylated amino acids are used as building blocks for different active substances, methods for the synthesis of large quantities have been developed, especially in industry.[18] Other effective racemic resolution techniques have been described recently. Disubstituted azlactones of type **21** can react with the phenylalanine derivative **22**.[19] The diastereomers of the protected dipeptide **23** are then separated. The easy access of compounds **21**, together with the optimized reagent **22**, ensures that the method is powerful for the synthesis of optically pure α,α-disubstituted amino acids (Scheme 5).



Scheme 5. Synthesis of optically pure α,α-disubstituted amino acids by treatment of racemic azlactones **21** with **22** and subsequent diastereomer separation of **23**.

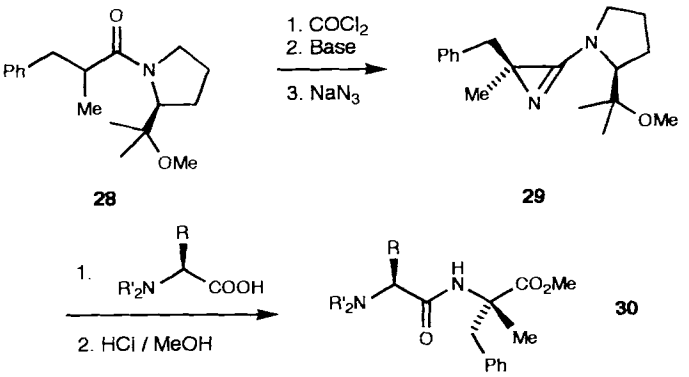
Nitrogen heterocycles like azirines and aziridines are also used effectively as building blocks for the synthesis of α,α-disubstituted amino acids. The aziridine derivative **26** is prepared in optically pure form by addition of the lithium enolate **25** to the chiral sulfinimide **24** (Scheme 6).[20] After oxidation of the sulfoxide to the sulfone and subsequent hydration, the α-methylated phenylalanine derivative **27** is obtained in good overall yield.

The introduction of α,α-disubstituted amino acids into peptides is sometimes troublesome. A recent, easy access to enan-



Scheme 6. Aziridines as intermediates in the synthesis of α,α-disubstituted amino acids (*p*Tol: *p*-tolyl, Tos: *p*-toluenesulfonyl).

tiomerically pure 3-amino-2*H*-azirines[5b, 21] offers an elegant way for the incorporation of α,α-disubstituted amino acids into peptides. The amide **28** is treated with phosgene and a base to yield a ketene iminium salt, which then reacts with sodium azide to afford azirine **29** with loss of nitrogen (Scheme 7). Because of



Scheme 7. Incorporation of α,α-disubstituted amino acids into peptides on treatment of diastereomerically pure 3-amino-2*H*-azirines **29** with an amino acid and scission of the chiral residue.

the chiral substituent a separation of the diastereomers is possible only one diastereomer shown there). After reaction with the carboxylic group of an amino acid and acidic cleavage of the chiral auxiliary the dipeptide **30** is obtained.

Stoichiometric amounts of (sometimes cheap) chiral reagents have to be used for most of the synthetic methods presented herein. One can anticipate reactions in which only catalytic amounts of chiral auxiliaries are necessary for the synthesis of enantiomerically pure α-alkylated amino acids.

Phosphinidine-Bridged Silver Clusters**

Dieter Fenske* and Falk Simon

Dedicated to Professor Walter Siebert on the occasion of his 60th birthday

A large number of metal-rich cluster compounds have been synthesized from the reaction of phosphane complexes of transition metal halides with silyl derivatives of the elements of group 15 and 16.[1] The driving force of the reaction is the elimination of $SiMe_3Cl$; cluster formation is facilitated by the shielding effect of the phosphane ligands. The steric demands of the phosphane ligands also influence the size and structure of the cluster.

The reaction of phosphane complexes of copper halides with silylphosphanes, R_2PSiMe_3, $RP(SiMe_3)_2$, and $P(SiMe_3)_3$ (R = organic group) affords cluster compounds that contain phosphido, phosphinidine, and P^{3-} bridges, respectively.[2] Recently the compound $[Cu_{96}P_{30}\{P(SiMe_3)_2\}_6(PEt_3)_{18}]$ was prepared by this method.[3] In contrast, analogous reactions of AgCl–phosphane complexes with Ph_2PSiMe_3 lead to the formation of multinuclear silver complexes,[4, 5] which contain ring structures from Ag and P atoms or polymeric chain structures. Examples of such structures are summarized in Scheme 1. The

$[Ag_3(PPh_2)_3(PR_3)_3]$, $PR_3 = PnBu_2tBu$, $PiPr_3$

$[Ag_4(PPh_2)_4(PR_3)_4]$, $PR_3 = PMeEt_2$, $PMenPr_2$, $PnPr_3$

$[Ag_4(PPh_2)_4(PEt_3)_4]_n$

$[Ag_6(PPh_2)_6(PtBu_3)_2]$

Scheme 1. Examples for ring-shaped or polymeric Ag–P complexes.

steric influence of the phenyl groups and the diphenylphosphido bridging ligands is such that it stabilizes the cluster and at the same time prevents the formation of bigger clusters. Bimetal clusters in which one component is silver have been known for some time, and examples include $[Ag_{13}Fe_8(CO)_{32}]^{4-}$,[6] $[Ag_6\{Fe(CO)_4\}_3\{(Ph_2P)_3CH\}]$,[7] and $[Ag_3M_3(CO)_{12}(dmpe)_3]$ (M = Nb, Ta; dmpe = 1,2-ethanediylbis(dimethylphosphane).[8] Furthermore, a series of Ag–Au heterometallic clusters exists such as $[Au_{18}Ag_{20}Cl_{14}(PTol_3)_{12}]$ (Tol = MeC_6H_4) and $[Au_{13}Ag_{12}Br_8(PPh_3)_{10}](SbF_6)$.[9]

Herein we report on the reactions of AgCl with $PhP(SiMe_3)_2$ in the presence of tertiary phosphanes PR_3, which provides access to phosphinidine-bridged silver clusters. In organic solvents these reactions initially form yellow solutions, which within a few minutes turn dark red. When PMe_3, $PMeEt_2$, $PMenPr_2$, and PEt_3 are used as the tertiary phosphane, a red powder is formed after a short time and the solution turns colorless. For $PR_3 = PnBu_2tBu$ and PEt_2Ph, a red powder is formed when the volume of solvent is reduced, and the remaining red oil is redissolved in diethyl ether, toluene, or pentane. Crystalline products were only obtained from reactions carried out in the presence of $PnPr_3$ in pentane or heptane as the solvent. Variation of the stoichiometric ratios of the starting materials (Scheme 2) afforded the compounds **1**–**3**, which were characterized by X-ray crystal structure analysis.[10]

$$AgCl + m\,PnPr_3 + n\,PhP(SiMe_3)_2 \xrightarrow[n=0.5]{m=1} [Ag_{18}(PPh)_8(PhPSiMe_3)_2(PnPr_3)_8]\ \mathbf{1}$$

$$\xrightarrow[T=-28°C]{m=n=0.4} [Ag_{45}(PPh)_{18}(PhPSiMe_3)_2Cl_7(PnPr_3)_{12}]\ \mathbf{2}$$

$$\xrightarrow[T=2°C]{m=n=0.4} [Ag_{50}(PPh)_{20}Cl_7P(PnPr_3)_{13}]\ \mathbf{3}$$

Scheme 2. Synthesis of the Ag–P complexes **1**–**3**.

The molecular structure of **1** is shown in Figure 1. Compound **1** crystallizes from heptane as thin red platelets with monoclinic habit. The Ag_{18} polyhedron ($\bar{1}$ symmetry) consists of two trigonal prisms of silver atoms (Ag1, Ag2, Ag1′, Ag2′, Ag3, Ag4 and

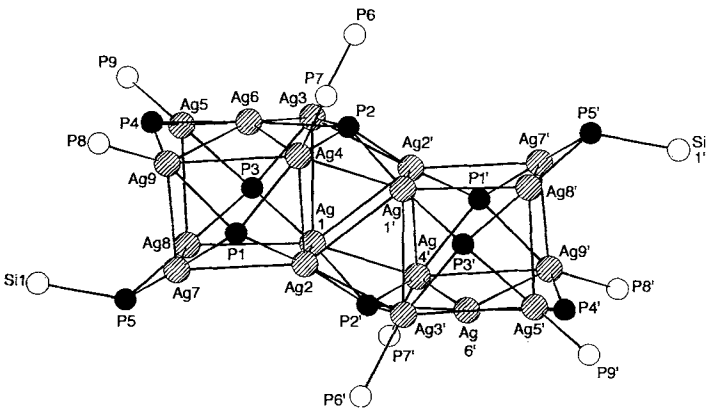

Figure 1. Molecular structure of **1** in the crystal (C and H atoms are omitted). Ag–Ag distances are drawn in up to 330 pm. Selected bond lengths [pm] (±0.1 pm): Ag1–Ag2 300.9, Ag1–Ag3 318.0, Ag1–Ag4 289.1, Ag1–Ag8 311.3, Ag1–Ag2′ 313.9, Ag2–Ag3′ 291.9, Ag2–Ag4 314.6, Ag2–Ag7 317.7, Ag3–Ag5 324.4, Ag3–Ag6 291.9, Ag4–Ag6 288.6, Ag4–Ag9 328.6, Ag5–Ag6 301.9, Ag5–Ag8 301.4, Ag6–Ag9 306.1, Ag7–Ag8 316.2, Ag7–Ag9 295.9.

Ag1, Ag2, Ag1′, Ag2′, Ag3′, Ag4′) that are connected to each other through a common surface (Ag1, Ag2, Ag1′, Ag2′). Cubes (Ag5, Ag7, Ag8, Ag9 and Ag5′, Ag7′, Ag8′, Ag9′) are condensed onto the surfaces formed by Ag1–Ag4 and Ag1′–Ag4′, respectively. One of the cube faces in each case is bridged by a silver atom (Ag6 and Ag6′, respectively), which at the same time caps the prism edge (Ag3, Ag4 and Ag3′, Ag4′, respectively). This causes a distortion of the prisms and the cubes. The Ag–Ag distances lie in the range 288.6(1)–328.6(1) pm, and the P atoms of the bridging ligands (PPh and $PSiMe_3$) function as μ_2-(P5), μ_3-(P4), μ_4-(P1, P3), and μ_5-(P2) bridges. The terminal-bound $PnPr_3$ ligands (P6–P9) are all coordinated to silver atoms at the surface of the cube that is capped by Ag6. This is thereby sterically shielded. The Ag–P distances observed for the bridging P atoms lie in the range 240.8(2)–275.9(2) pm, whereas those of the $Ag-P_{terminal}$ are 245.3(2)–246.8 (2) pm. Compound **1** still contains a reactive $SiMe_3$ group coordinated to P5, which could conceivably lead to further cluster formation. Thus, the reaction with a different stoichiometric ratio of the phosphorus compounds ($m = n = 0.4$) in pentane gave dark red needles of **2**, after the reaction mixture had been kept at −28 °C for two days. The crystal structure analysis of **2** is problematic. On the one hand, some of the carbon atoms bound to the phosphane ligands cannot be localized and on the other, the atoms that are in the center of the cluster are disordered. The molecular structure of **2** is shown in Figure 2. The metal shell of the torus-shaped

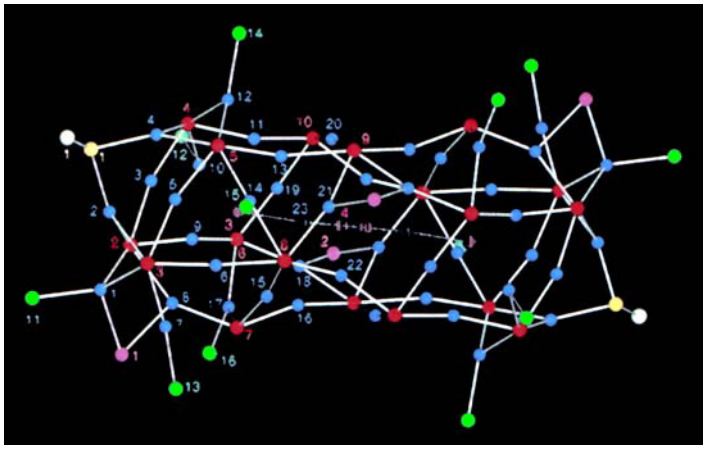

Figure 2. Molecular structure of **2** in the crystal (C and H atoms are omitted). Ag: blue; P atoms of the PPh ligands: red; P atoms of the $PhPSiMe_3$ ligands: yellow; Si: gray; Cl: purple; P atoms of the $PnPr_3$ ligand: green. All the atoms shown are labeled with numbers only, which can be assigned to the corresponding elements through the color-coded atoms. In the figure only one set of symmetry-equivalent atoms are shown.

cluster ($\bar{1}$ symmetry) contains 44 silver atoms. The coordinated PPh_3 ligands can be differentiated between μ_4-(P6, P7, P10) and μ_5-(P2, P3, P4, P5, P8, P9) bridges (Ag–P: 237.7(10)–278.4(12) pm). Cl1, Cl2, and the phosphorus atom of the PhP-$SiMe_3$ group act as μ_2 bridges (Ag–Cl: 263.2(9)–274.8(9) pm, Ag–P: 241.0(13) and 243.7(13) pm). The metal framework is sterically shielded by the phenyl groups of the bridging ligands as well as by the 12 terminal $PnPr_3$ ligands (P11–P16), which are bound to the silver atoms Ag1, Ag7, Ag10, Ag12, Ag14, and Ag17 (239.0(20)–248.3(11) pm).

Inside the torus-shaped cluster **2** are found the chlorine atoms Cl3 and Cl4 (and symmetry equivalents) and Ag23 and Ag23′; however, the positions of Ag23 and Cl4 can only be meaningfully refined with half occupation. The Ag23–Cl3 bond length is 229.3(12) pm, and that for Ag23–Cl4′ is 234.0(20) pm. All other distances to Cl3 and Cl4 are significantly longer (>290 pm). If the overall charge of **2** is considered under the assumption that the ligands are as follows, PPh^{2-}, $PSiMe_3^-$, and Cl^-, one concludes that the silver atoms, like in **1**, are in the oxidation state +1.

The metal atom framework of **2** is highlighted in Figure 3. Accordingly, **2** is built up from Ag five-membered rings that share corners. These five-membered rings are μ_5-bridged by the P atoms of the PPh groups. Through the linking of three of the Ag_5 rings at the corners, Ag triangles are formed. For example,

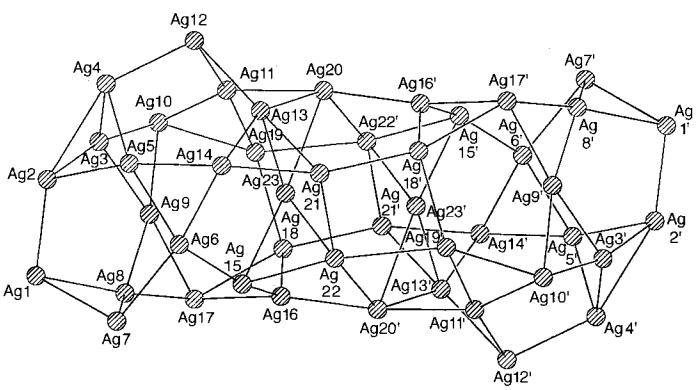

Figure 3. Metal framework of **2** in the same orientation as in Figure 2. Ag–Ag distances are drawn up to 330 pm [13].

the Ag_5 ring made up from Ag1, Ag2, Ag5, Ag6 and Ag7 is condensed with two further rings (Ag5, Ag4, Ag12, Ag13, Ag14 and Ag6, Ag14, Ag21, Ag22, Ag15), which have Ag14 as a common atom. Through this a triangle of silver atoms is formed (Ag5, Ag14, Ag6), which for steric reasons is not bridged.

The shortest Ag–Ag distance is 275.8(5) pm (Ag5–Ag6 and Ag6–Ag15); the majority of other Ag–Ag distances lie in the range 290–300 pm. The relatively short Ag–Ag distances are not attributed to a metal–metal bond, but to the effect of the bridging PPh^{2-} ligands. However, the d^{10}–d^{10} dispersion interaction could help to stabilize the cluster.

If the same reaction conditions are applied as for the synthesis of **2** but the solution is stored at a higher temperature (2 °C), dark red needles of **3** are obtained after two days. The molecular structure of **3** is shown in Figure 4. Compound **3** contains 50 silver atoms, two of which (Ag20 and Ag35) are found inside the cluster. The 20 PhP ligands function as μ_4-(P1, P4, P7, P9, P10,

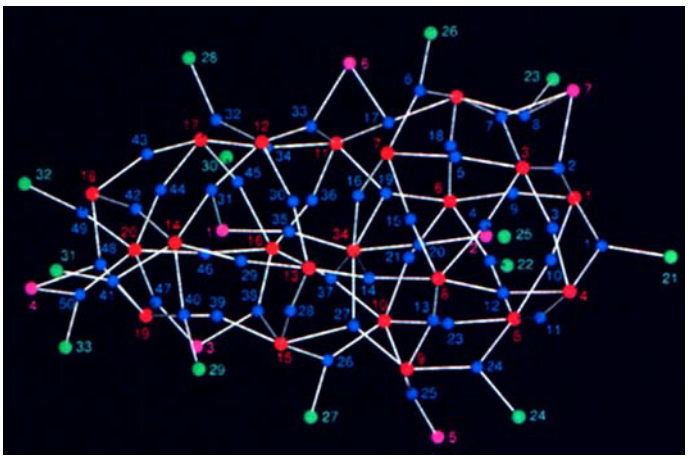

Figure 4. Molecular structure of **3** in the crystal (C and H atoms are omitted). Ag: blue; P atoms of the PPh ligands: red; P^{3-} (P34): red; Cl: purple; P atoms of the $PnPr_3$ ligand: green. All the atoms shown are labeled with numbers only, which can be assigned to the corresponding elements through the color-coded atoms.

P11, P12, P13, P18) or μ_5-(P2, P3, P5, P6, P8, P14, P15, P16, P17, P19, P20) bridges (Ag–P: 236.9(13)–283.0(20) pm). Furthermore, **3** contains seven Cl ligands; Cl7 bridges between three silver atoms at distances of 279.0(20)–283.1(13) pm. The three chlorine atoms Cl3, Cl4, and Cl6 act as μ_2 bridges between two silver atoms (Ag–Cl: 258.4(12)–277.3(11) pm). Taking into account the charge balance and the bond lengths one must assume that inside the cluster there are two Cl^- ions (Cl1, Cl2) and a P^{3-} ligand (P34); Cl1–Ag35 241.8(13) pm and Cl2–Ag20 240.1(14) pm. The distances to other Ag atoms are larger than 293 pm. This shows that Cl1 and Cl2 are essentially bound through ionic interactions.

Between Ag20 and Ag35 lies a P^{3-} ion, which is situated in the center of a strongly distorted pentagonal bipyramid of silver atoms (Ag19, Ag16, Ag14, Ag27, Ag37, Ag35, and Ag20). The shortest distances from P34 are to the atoms Ag20 and Ag35 (241.8(14) and 243.2(14) pm, respectively). The five other Ag–P distances range between 255.9(12) and 277.3(11) pm. Ag20 is surrounded by six silver atoms at distances between 288.3(4) and 324.9(4) pm; the five silver atoms around Ag35 lie slightly further away (303.3(6)–342.7(8) pm). The cluster is shielded by the 20 phenyl groups of the bridging ligands and by the 13 $PnPr_3$

(P21–P33) ligands coordinated terminally to silver atoms. The $Ag-P_{terminal}$ bond lengths lie in the range 240.2(14)–249.0(14) pm.

If one considers only the metal framework of **3** (Figure 5) it can be seen that, as in **2**, the metal cage is made up of five-membered rings of silver atoms. The Ag_5 rings are bridged by the P atoms of the PPh ligands. Here again from the charge balance the silver atoms are in the oxidation state +1.

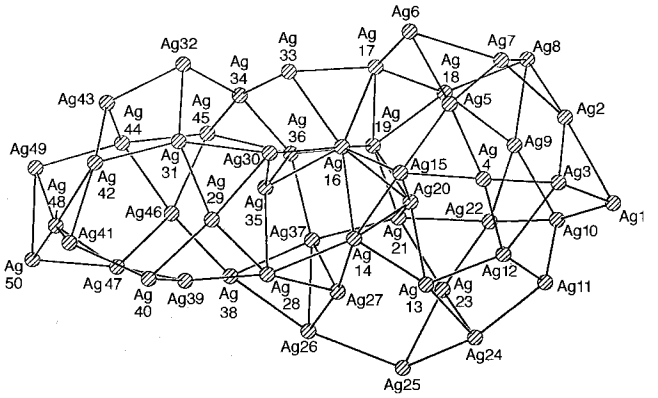

Figure 5. Metal framework of **3** in the same orientation as in Figure 4. Ag–Ag distances are drawn up to 330 pm [14].

If the concentration of the silylphosphane ($n = 0.1$) is further reduced, colorless platelets of $[Ag(PnPr_3)Cl]_4$ crystallize out of the dark red solution after a few days. This is a tetrameric silver chloride phosphane complex with a heterocubane structure. Examples of this structure type with other tertiary phosphanes are known.[11]

NMR spectrospcopic investigations of the compounds **1–3** could not be performed due to their insolubility. The IR spectra of **1–3** show the charactcristic bands for the phenyl groups (1800–2200 cm^{-1}), as well as the aromatic C–H band at 3050 cm^{-1}. The aliphatic C–H bands of the tertiary phosphanes appear between 2800 and 3000 cm^{-1}. P–H bands could not be identified.

Investigations on the reaction of AgCl and $[PMe_3AuCl]$ with the homologous $PhP(SiMe_3)_2$ arsenic compound, $PhAs(SiMe_3)_2$, show that this method can be applied to synthesize arsinidine-bridged silver and gold clusters. To date the compounds given in Scheme 3 have been isolated and structurally characterized.[12]

$[Ag_{14}(AsPh)_6Cl_2(PR_3)_8]$, $PR_3 = PMenPr_2$, $PnPr_3$, PEt_3

$[M_4(As_4Ph_4)_2(PR_3)_4]$, M = Ag: $PR_3 = PEt_3$, $PnPr_3$

$[Au_{10}(AsPh)_4(PhAsSiMe_3)_2(PnPr_3)_6]$

Scheme 3. Arsinidine-bridged silver and gold clusters that were prepared analogously to the clusters **1–3**.

Experimental Section

1: $PhP(SiMe_3)_2$ (0.43 mL, 1.15 mmol) was added to a solution of AgCl (0.43 g, 3 mmol) and $PnPr_3$ (0.59 mL, 3 mmol) in heptane (75 mL) at room temperature, upon which the solution turned dark red. After 30 minutes the solution was reduced to a third of the volume. Red, very thin platelets of **1** and a red powder were formed at −24 °C after several weeks (yield: 52%).

2, 3: AgCl (0.42 g, 2.93 mmol) and $PnPr_3$ (0.23 mL, 1.17 mmol) were suspended in pentane (25 mL). After two hours $PhP(SiMe_3)_2$ (0.33 mL, 1.17 mmol) was added to the white suspension, whereupon the reaction mixture turned from yellow through orange to dark red within a few minutes. At −28 °C dark red needles of **2** crystallized from the solution after a few days. Crystals of **3** were afforded at 2 °C (yields: **2**: 60%, **3**: 46%).

The positions of the H atoms were calculated for idealized positions); $R_1 = 0.053$. **2**: triclinic, $P\bar{1}$ (no. 2); lattice constants (200 K): $a = 19.920(5)$, $b = 22.478(8)$, $c = 24.422(11)$ Å, $\alpha = 84.03(2)$, $\beta = 70.10(2)$, $\gamma = 64.73(2)^\circ$, $V = 9287(6)$ Å^3; $Z = 1$; $\mu(Mo_{K\alpha}) = 25.34$ cm^{-1}; $2\theta_{max} = 45.0^\circ$; 42711 reflections measured, of which 22942 were independent; max. residual electron density 1.40 e Å^{-3}; 714 parameters (Ag, P and Cl anisotropic, Si and C isotropic. Ag23 and Cl have half occupancy). The phenyl groups were refined as rigid groups (C–C bond length 1.39 Å, C-C-C bond angle 120°). The propyl groups were strongly disordered, and it was not possible to localize some of the C atoms and others could only be refined with occupancy less than 1. The positions of the H atoms of the phenyl groups were calculated; $R_1 = 0.124$. **3**: triclinic, $P\bar{1}$ (no. 2); lattice constants (160 K): $a = 21.777(6)$, $b = 27.219(7)$, $c = 31.207(10)$ Å, $\alpha = 87.52(3)$, $\beta = 85.82(2)$, $\gamma = 79.75(3)^\circ$; $V = 18146(14)$ Å^3; $Z = 2$; $\mu(Mo_{K\alpha}) = 28.63$ cm^{-1}; $2\theta_{max} = 45.0^\circ$; 69085 reflections measured of which 43315 were independent; max. residual electron density 1.24 e Å^{-3}; 1576 parameters (Ag, P and Cl anisotropic, C isotropic). The phenyl groups were refined as rigid groups (C–C bond length 1.39 Å, C-C-C bond angle 120°). The propyl groups were partly disordered. The positions of the H atoms of the phenyl groups were calculated. One molecule of **3** crystallizes with 1.5 molecules of pentane in the asymmetric unit; $R_1 = 0.124$. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository numbers CSD-405276, CSD-405277, and CSD-405778.

$[(HgPtBu)_4]_3$—Synthesis, Structure, and Bonding**

Reinhart Ahlrichs,* Malte von Arnim, Jan Eisenmann, and Dieter Fenske*

Dedicated to Professor Günter Schmid on the occasion of his 60th birthday

Phosphane complexes of transition metal chlorides react with silylated phosphanes under the elimination of $SiMe_3Cl$ to from phosphido- and phosphinidine-bridged metal clusters.[1] Recently we showed that the reaction of $ZnCl_2$ or $CdCl_2$ with Ph_2PSiMe_3 in the presence of PR_3 affords phosphido-bridged cluster compounds $[M_4(PPh_2)_4Cl_4(PR_3)_2]$ (M = Zn, Cd; R = aryl, alkyl).[2] The reaction of mercury chloride with $RP(SiMe_3)_2$ in the presence of PR_3 (R = Ph, *t*Bu), however, only results in the formation of elemental mercury and organo-substituted oligophosphorus compounds.

Iron–mercury compounds $[Fe(CO)_4(HgX)_2]$ (X = halogen, OAc) are less strongly oxidizing than mercury chloride.[3] Thus, treatment of $[Fe(CO)_4(HgOAc)_2]$ with one equivalent of $tBuP(SiMe_3)_2$ in toluene results in a yellow-orange solution from which orange crystals of $[(HgPtBu)_4]_3$ (**1**)[4] were obtained within 24 hours [Eq. (a)].

$$[Fe(CO)_4(HgOAc)_2] + tBuP(SiMe_3)_2 \longrightarrow \underset{\mathbf{1}}{[(HgPtBu)_4]_3} \qquad (a)$$

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 195).

The IR spectrum shows the characteristic bands for the P*t*Bu ligands. The compound is not soluble in organic solvents, and thus, ^1H and ^{31}P NMR spectra were not recorded. We have found no indications for the formation of other oligomers. Compound **1** is evidently not stable in the gas phase: only fragments of the molecular ion are observed in the mass spectrum. Above 200 °C, **1** decomposes to form Hg and $(PtBu)_3$.

Compound **1** crystallizes in the space group $P6_3/m$ and, according to the X-ray structure analysis, can be described as as a trimer of $[(HgtBuP)_4]$ units. Within the $(HgP)_4$ eight-membered rings in **1** (e.g. Hg1, P1, Hg2, P3, Hg2C, P1C, Hg1C, P2) the mercury–phosphorus bond lengths lie in the range 242.0(5)–244.8(4) pm, and the mercury atoms are almost linearly coordinated by two P*t*Bu ligands (P-Hg-P: 170.8(2)–174.8(2) °) (Figure 1). The bond angles at the phosphorus atoms deviate only very slightly from 90° (86.8(2)–93.4(2)°). Thus, the mercury atoms are located in the middle of the edges of a rectangle of phosphorus atoms. For the compound $[Cp'Mn(CO)_2Hg]_4$ synthesized by Gäde and Weiss,[5] a secondary attractive interaction between the Hg^{II} atoms was postulated because of the nonlinearity of the Mn-Hg-Mn (157.2°) arrangement and the very short Hg···Hg distances (289 pm). In contrast to this the Hg···Hg distances in **1** within the $(HgP)_4$ eight-membered ring lie between 333.0(1) and 356.4(1) pm, so that the attractive d^{10}–d^{10} interaction can have no significant influence on the structure.

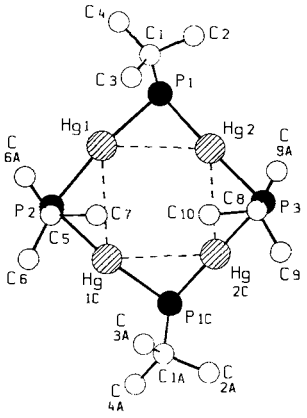

Figure 1. Structure of a $(HgPtBu)_4$ unit in **1**. Selected bond lengths [pm] and angles [°]: Hg1–P1 242.2(4), Hg1–P2 244.8(4), Hg2–P1 242.0(4), Hg2–P3 242.4(4), Hg1–Hg1C 356.4(1), Hg2–Hg2C 333.0(1), Hg1–Hg2 341.6(1); P1-Hg1-P2 170.8(2), P1-Hg2-P3 174.8(2), Hg1-P1-Hg2 89.7(2) Hg1-P2-Hg1C 93.4(2), Hg2-P3-Hg2C 86.8(2).

Figure 2 illustrates the way in which the three molecules of $[(HgtBuP)_4]$ build up to form a trimer. As a result of the crystal symmetry, this structure shows C_{3h} symmetry, and a trigonal prism of six mercury atoms (Hg1–Hg1E) is formed. The dotted lines between the Hg atoms in Figures 1 and 2 have been drawn in to help clarify the coordination environment and are not meant to represent bonds. Just as in the $[(HgtBuP)_4]$ units,

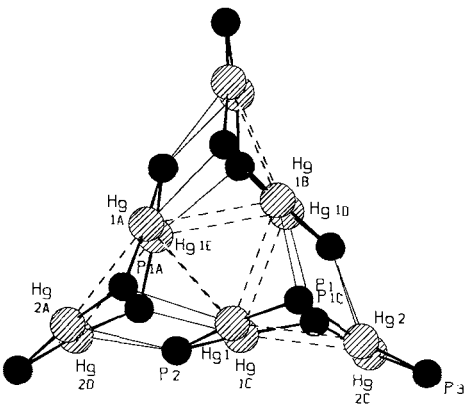

Figure 2. Molecular structure of **1** in the crystal. Selected bond lengths [pm]: Hg1–P1A 326.3(4), Hg2A–P2 326.6(5), Hg2D–P2 326.6(5), Hg1–Hg1A 350.5(1), Hg1–Hg1B 350.5(1).

the Hg–Hg interaction within the trimer is only very weak (Hg1–Hg1A: 350.5(1), Hg1–Hg1B: 350.4(1), Hg1–Hg1C: 356.4(1) pm).

The shortest intermolecular Hg–P distances are 326.3(4) (Hg1–P1A) and 326.6(5) pm (Hg2A–P2), and therefore lie within the sum of the van der Waals radii (335 pm).[6] Thus six P*t*Bu groups (P1 and symmetry equivalents) act as threefold bridges over the triangular edges of the trigonal prism between two inner (Hg1) and one outer (Hg2) mercury atoms. Three further phosphinidine ligands (P2, P2A, P2B) act as μ_4 ligands bridging the prism edges between the triangles, and undergo van der Waals interactions to two external mercury atoms. The phosphorus atoms P3, P3A, and P3B are μ_2-bridging in the dodecamer and show no intermolecular interactions.

Calculations of the electronic structure were performed with the program system TURBOMOLE at SCF, DFT, and MP2 levels.[7]

As the DFT and SCF calculations give almost identical results for the structure parameters and reaction energies, only the SCF results will be discussed here. In order to save on the calculation time, $(HgPR)_n$ with $n = 2-6$, 8, and 12 was computed for R = Me instead of R = *t*Bu.

The most important results of the SCF calculations are summarized in Figure 3 and Table 1. For $(HgPR)_n$ with $n \leq 6$, the energetically stable structures are always $(HgP)_n$ rings. Mercury adopts the preferred almost linear coordination (173° to 179°);

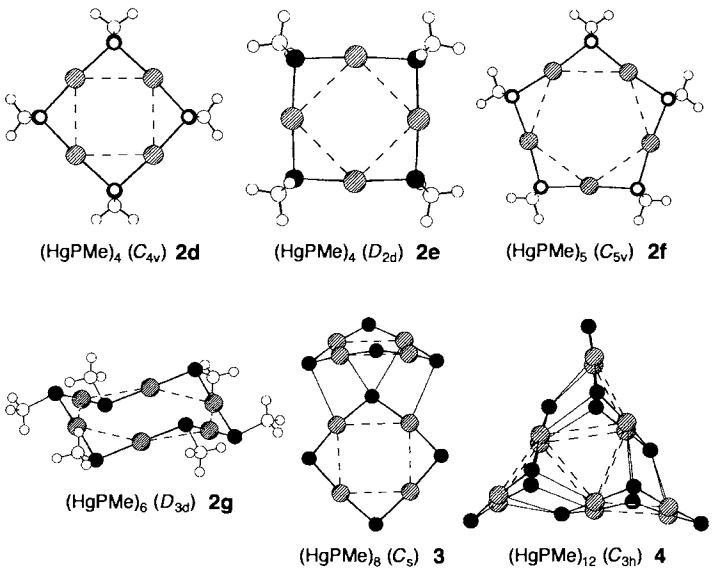

Figure 3. Molecular structures of the calculated clusters $(HgPMe)_n$. Hg: striped, P: black, C: large open circles, H: small open circles.

Table 1. Energetics and important structure constants of the cluster $(HgPMe)_n$ from SCF calculations [a].

n	Compd.	*G*	Hg–P	P-Hg-P	Hg-P-Hg	ΔE
2	**2a**	C_{2v}	265	112	68	133.7
2	**2b**	C_{2h}	264	112	68	133.6
3	**2c**	C_{3v}	254	156	84	27
4	**2d**	C_{4v}	250	174	94	0.0
4	**2e**	D_{2d}	250	175	94	−1.7
5	**2f**	C_{5v}	249	173	102	−3.3
6	**2g**	D_{3d}	249	177	101	−5.2
8	**3**	C_s	250–252	169–173	90–95	−16.5
12	**4**	C_{3h}	249–251	168–172	92–97	−36.0

[a] *G* = point group symmetry; distances [pm], angles [°], $\Delta E = E_{SCF}[(HgPMe)_n] - E_{SCF}[(HgPMe)]$ in kJ mol^{-1}.

the Hg-P-Hg angles lie between 94° and 102°. These characteristics are revealed in the relative stability of the tetramer $(HgPR)_4$ (**2d**), as opposed to the taut trimer $(HgPR)_3$ (**2c**), as well as the slightly higher stability of the pentamer **2f** and the hexamer **2g**. The hexamer clearly shows a corrugated $(HgP)_6$ ring with Hg-P-Hg angles of 101°. For the organic groups R, a *trans* position is energetically weakly favored by about 1.7 kJ mol^{-1} over the *cis* position.[8] The *trans* isomers are not particularly suited for the formation of intermolecular complexes due to the good steric shielding.

The calculated bond lengths in **2d** to **2g** show no significant variation: Hg–P: 250(±1) pm, P–C: 189(±0.5) pm. The same values were calculated for clusters of two (**3**) and three (**4**) tetramers, which indicates relatively small intermolecular interactions between the tetramers. Energetically stable structures other than those shown in Figure 3 were not found.

The calculated P–C distances and the bond angles in the $(HgP)_4$ rings in **2d** (P–C 189 pm) correlate very well with those from the crystal structure analysis of **1** (P–C 188–194 pm). The calculated Hg–P distances (251 pm) are, however, about 8 pm longer than those of the crystal (242–245 pm). This discrepancy is not unexpected: the attractive dispersion interaction between the $5d^{10}$ subshell of Hg and the valence electrons of PR leads to shorter bond lengths, which is typical for elements from groups 11 and 12.[9] Dispersion interactions are not included in the SCF and DFT calculations; however in the MP2 approximation a good estimation is described. MP2 calculations give Hg–P = 241 pm for the tetramer **2d**, which is in agreement with the values from the X-ray crystal structure analysis (242–245 pm).

For the dimer of the tetramer **2d**, intermolecular interactions lead to the structure **3**, which has a bonding energy of −16.5 kJ mol^{-1} relative to the tetramer with C_{4v} symmetry. The relative positions of the basic units is very similar in the trimer of tetramers **2d**, so that the electrostatic and dispersion forces responsible in **4** are optimized. The intermolecular Hg–P distances in the SCF calculation were maintained at 366–373 pm, 50 pm bigger than in the crystal. This considerable discrepancy results from the fact that the SCF approximation does not take into account the attractive dispersion forces, and furthermore that the potential well is very flat.

Experimental Section

To a suspension of $[Fe(CO)_4(HgOAc)_2]$ (0.34 g, 0.5 mmol) in toluene (20 mL), *t*BuP$(SiMe_3)_2$ (0.12 mL, 0.49 mmol) was added. An orange solution was immediately formed, from which, in addition to a yellow powder, orange needles of **1** crystallized (yield 40%). The yellow powder was analytically identical to **1**.

Enantioselective Hydrogen Transfer from a Chiral Tin Hydride to a Prochiral Carbon-Centered Radical

Michael Blumenstein, Kay Schwarzkopf, and Jürgen O. Metzger*

Radical reactions can proceed with high stereoselectivities.[1] Enantioselective radical reactions, however, continue to be a challenging concept. Currently, this problem is being explored by using two principally different approaches [Eqs. (1), (2)]. In analogy to carbanion chemistry, a chiral auxiliary can be attached to an existing radical to control the configuration of the new stereogenic center [Eq. (1)].[1b] The chiral auxiliary used in this approach does not have to be covalently bound to the radical. Murakata et al., for instance, reported the enantioselective radical reduction of an α-iodolactone with tributyltin hydride in the presence of stoichiometric amounts of a chiral

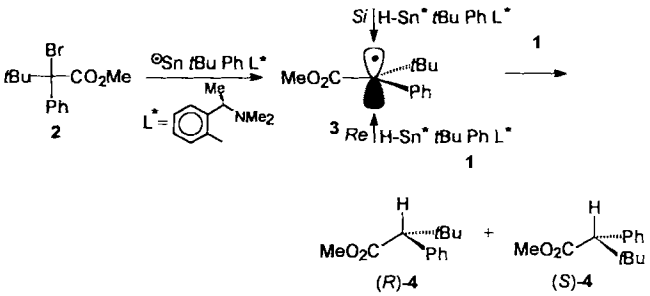
amine and a Lewis acid. In this case, the hydrogen atom is transferred to a chiral radical, which is formed in situ by complexation to the chiral auxiliary.[2] Analogous enantioselective hydrogen transfers[3] as well as intra-[4] and intermolecular[5] additions have also been reported. The prerequisite for such enantioselective reactions is that the substrate contains suitable coordination sites for the chiral auxiliary. These are not required for reactions in which, according to Equation (2), a chiral reagent distinguishes between enantiotopic faces of a radical in diastereomeric transition states.[6]

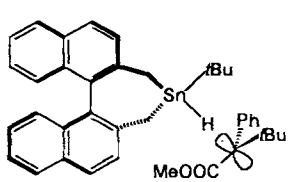
Tin hydrides that contain chiral ligands are hydrogen donors which, in principle, can trap prochiral radicals enantioselectively.[7] Since the chirality of these tin compounds is maintained under conditions of a radical chain reaction,[8] catalytic enantioselective transformations appear feasible.

We have demonstrated that chiral tin hydrides such as **1** reduce the α-bromoester **2** enantioselectively to the ester **4** via the prochiral radical **3** with enantiomeric excesses of up to 25%.[9]



Although the enantioselectivity was low due to the fact that **1** was used as a diastereomeric mixture, the outcome clearly showed for the first time that enantioselective radical transfers of hydrogen atoms according to Equation (2) are possible,[10] and furthermore that high and synthetically useful enantioselectivities can be achieved when suitable, sterically uniform tin hydrides are employed.

Chiral C_2-symmetric tin hydrides are hitherto unknown. However, three 2,2′-dimethyl-1,1′-binaphthyl-substituted tin compounds have been described[11] that could potentially be used as precursors for the synthesis of such a hydride. To explore this possibility, we used MOPAC[12]/PM3 to calculate the structure of the tin hydride (*R*)-**5**, which contains a C_2-symmetric substituent and a rigid conformation with respect to the stannepine ring. Based on steric effects, in the transition state of the H-transfer, in which the donor, hydrogen, and acceptor atoms assume a linear arrangement (Sn···H···C), (*R*)-**5** should be able to distinguish between the enantiotopic faces of a prochiral radical such as **3** (Scheme 1). In this transition state, the small substituent S at the radical center is presumably oriented beneath the binaphthyl substituent, the medium-sized substituent M is oriented to the back, and the large substituent L is oriented to the front in the least sterically hindered space. Based on this model, the selective formation of (*S*)-**4** is expected upon reduction of the α-bromoester **2** via radical **3** (S = COOMe, M = Ph, L = *t*Bu).



(*R*)-**5** **3**

Scheme 1. Preferred approach of radical **3** to the tin hydride (*R*)-**5**.

We now report on the synthesis of both enantiomers (*R*)- and (*S*)-**5** of the first chiral tin hydride containing a C_2-symmet-

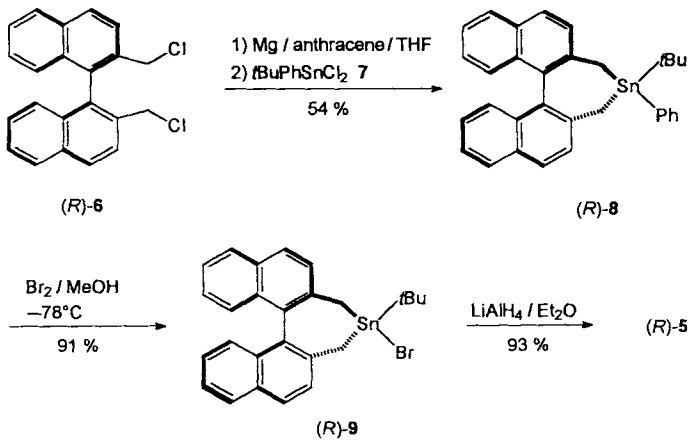
ric binaphthyl substituent,[13] and their application in the enantioselective reduction of the α-bromoester **2**. Furthermore, we demonstrate for the first time that these enantioselective reductions can also be performed with catalytic amounts of the respective chiral tin hydride.

The tin hydrides (*R*)-**5** and (*S*)-**5** were prepared in three steps starting from (*R*)- and (*S*)-2,2′-bis(chloromethyl)-1,1′-binaphthyl **6**, respectively.[14] Compound **6** was first allowed to react with magnesium–anthracene to give the di-Grignard compound, which, upon treatment with *tert*-butylphenyltin dichloride (**7**), afforded stannepine **8**.[14] Bromination to bromostannepine **9** and subsequent reduction with lithium aluminum



hydride gave **5** in an overall yield of 46%. This sequence can be used for a wide variety of different alkyl substituents at the tin atom. In an inert gas atmosphere, the solid tin hydride **5** can be stored for several weeks at room temperature without notable decomposition.

The reduction of the bromoester **2** proceeded smoothly. Only at −78 °C did it become necessary to add triethylborane as an initiator (Table 1).[15] The reaction of (*R*)-**5** at −78 °C led to the reduction product in a ratio of [(*S*)-**4**]:[(*R*)-**4**] = 76:24 (52% *ee*) (Table 1, entry 1). More significantly, the major and minor enantiomers of this reaction could be determined a priori by a simple examination of the steric interactions present in the transition state (Scheme 1). The selectivity decreases with increasing temperatures and was found to be 66:34 (32% *ee*) at −10 °C (entry 2), and 64:36 (28% *ee*) at 24 °C (entry 4). The enantiomeric tin hydride (*S*)-**5** reduces **2** with reversed selectivity (entry 3). A kinetic resolution of **2** was not observed.

Table 1. Enantioselectivity of the reduction of **2** with **5** [a].

2 **4**

Entry	H-donor	*T* [°C]	Yield [%]	[(*S*)-**4**]:[(*R*)-**4**]
1	(*R*)-**5**	−78 [b]	93 [d]	76:24
2	(*R*)-**5**	−10	94 [d]	66:34
3	(*S*)-**5**	−15	96 [d]	32:68
4	(*R*)-**5**	24	97 [d]	64:36
5	$NaB(CN)H_3$, (*R*)-**9** [c]	24	98 [e]	63:37

[a] See *Experimental Section* for reaction conditions. [b] Addition of an equimolar amount of Et_3B as an initiator [15]. [c] See *Experimental Section* for catalytic reaction conditions. [d] Based on **5**. [e] Based on **2**.

In general, reductions with tin hydrides can also be performed catalytically; the tin hydride reducing agent can be regenerated by the addition of sodium cyanoborohydride.[16] Particularly noteworthy is the observation that the enantioselective reductions discussed herein proceed with the same selectivities when the catalytic variant is used (entry 5) in which **5** is formed in situ from tin bromide **9**.

Experimental Section

Reduction of **2**: **2** (7 mg, 0.16 mmol), dodecane (3.6 mg, 0.02 mmol) as internal standard, and **5** (30–40 mg, 0.07–0.09 mmol) were stirred for 13–25 h in diethyl ether (5 mL) under argon at the temperatures listed in Table 1. Triethylborane (1 equiv in hexane) was added at −78 °C (entry 1). For entry 5, **9** (1 mg) and $NaB(CN)H_3$ (30 mg, 0.48 mmol) were used. After a saturated NH_4Cl solution had been added, the mixture was dried over $MgSO_4$ and filtered through silica gel. The reaction product was analyzed by using a 25 m heptakis(2,6-di-*O*-pentyl)-β-cyclodextrin-OV1701 capillary (temperature program: 90 °C (5 min), 0.2 degrees per min, 100 °C (5 min): (*S*)-**4**: 25.44 min, (*R*)-**4**: 26.04 min).

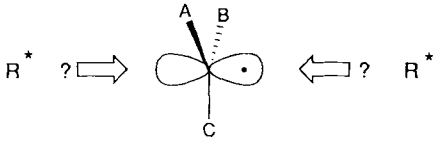
A Totally Radical Approach to the Control of Stereochemistry: Coupling of Prochiral Radicals with Chiral Nitroxyl Radicals**

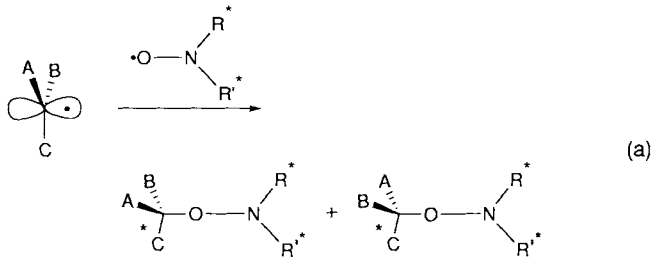
Rebecca Braslau,* Leland C. Burrill II, Lara K. Mahal, and Todd Wedeking

The development of new, selective methods for preparing optically pure compounds is a major challenge facing organic chemists. The control of stereochemistry in reactions with free radical intermediates has been successfully approached by using relative diastereoselectivity. Extension to the control of absolute stereochemistry has been effected with temporarily appended chiral auxiliaries.[1] A more elegant approach is that of enantioselectivity,[2] in which a prochiral radical[3,4] containing no preexisting stereogenic centers reacts with a noncovalently bonded optically active reagent to form a new stereogenic center selectively. We have initiated a research program to study the ability of nonbonded optically active reagents to discriminate between the two faces of a prochiral radical (Scheme 1). Nitroxyl radicals



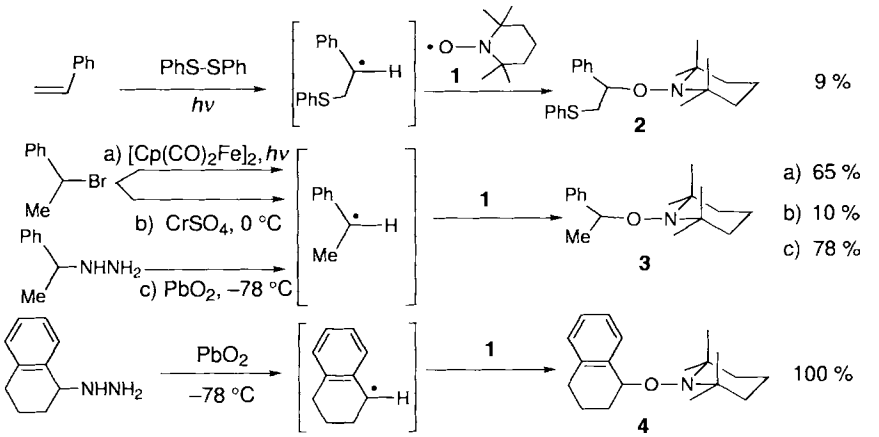
Scheme 1. Optically active reagent R* approaching the two enantiotopic faces of a prochiral carbon radical.

are persistent species[5] and are highly effective traps for carbon radicals.[6] Herein, we demonstrate stereoselectivity in the coupling of optically active nitroxyl radicals with transient prochiral carbon radicals [Eq. (a)].[7]



(a)

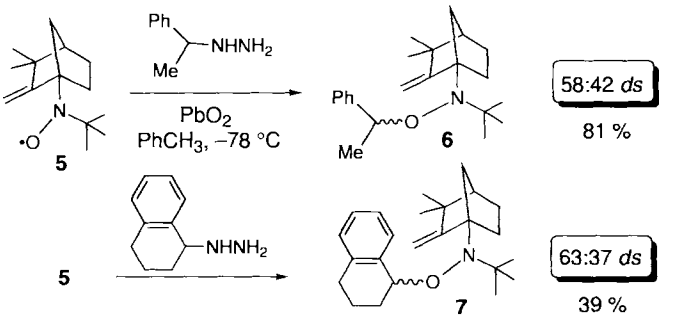
Strategies for radical coupling required stoichiometric carbon radical generation in the presence of the nitroxyl functionality. We first used achiral 2,2,6,6-tetramethylpiperidin-1-oxyl (TEMPO, **1**) as a model. In Scheme 2, addition of thiol radicals



Scheme 2. Generation of prochiral radicals and trapping with TEMPO (**1**).

to styrene, photolysis of an organohalide with dicarbonyl(η^5-cyclopentadienyl)iron dimer,[8] and treatment of alkyl halides with chromium(II)[9] produced the TEMPO trapping products in poor to acceptable yields. Much cleaner results were obtained under mild oxidative conditions with lead dioxide and alkyl hydrazines[10] in toluene at $-78\,^{\circ}C$.

The first chiral nitroxyl radical examined was Rassat's camphor-derived **5** (Scheme 3),[11] which coupled with 1-phenethyl



Scheme 3. Stereoselectivity in the coupling of prochiral carbon radicals with nitroxyl radical **5**.

radical at $-78\,^{\circ}C$ with a diastereoselectivity of 58:42. The tetralinyl radical proved somewhat more discriminating, providing a 63:37 ratio of diastereomers.[12] An inherent drawback of radical **5** for this study is its conformational mobility. Much more advantageous would be a conformationally restrained nitroxyl radical in a stereochemically rigid environment.

We thus turned to the steroidal doxyl radical **11**.[13] First 1-phenethyl radical was coupled to a model compound, the doxyl radical **8** derived from cyclohexanone (Scheme 4). The chromatographically pure coupling product **9** was obtained; however, the ^1H and ^{13}C NMR spectra showed duplicate resonances. In contrast, the ^1H and ^{13}C NMR spectra of the re-

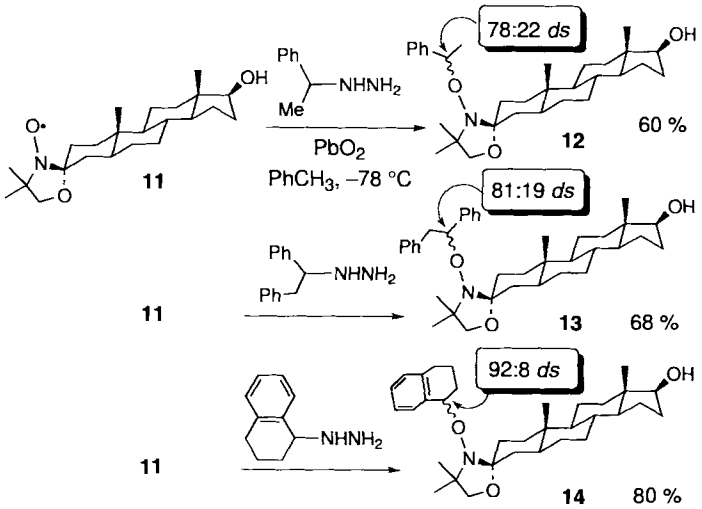
duced hydroxyl amine **10** were single sets of peaks. This implies that the nitrogen atom in compound **9** behaves as a stereogenic center on the NMR timescale, resulting in transient diastereomers.[14]

The key coupling reaction with chiral doxyl radical **11** proceeded smoothly (Scheme 5). The NMR spectra of the isolated



Scheme 5. Stereoselectivity in the coupling of prochiral carbon radicals with nitroxyl radical **11**.

products were extremely complex due to nitrogen inversion, as observed in the doxyl **8** model system. The product ratios were ultimately evaluated by HPLC and ranged from 78:22 to 92:8.[15]

Secondary benzylic radicals react with TEMPO approximately ten times slower than nonstabilized alkyl radicals.[16] The diastereomer ratios could result from reversible cleavage in a thermodynamic equilibration.[17] A few stabilized tertiary radicals have been shown to couple with nitroxyl radicals reversibly;[18] prolonged heating results in disproportionation to give olefin and hydroxyl amine. To test the thermal stability of our products, model coupling adduct **9** was heated in deoxygenated $CDCl_3$ at 50 °C for several days: no evidence of styrene formation could be detected, and the sample remained completely intact. Furthermore, addition of thiophenol did not result in the formation of 1-phenylethane. This suggests that these nitroxyl coupling products are formed under kinetic control.

In summary, we have demonstrated several examples of a chiral nonbonded reagent distinguishing between the two prochiral faces of a carbon radical.

Experimental Section

6: Hydrazine (935 mg, 29 mmol) was added to (1-bromoethyl)benzene (270 mg, 1.45 mmol) and sonnicated for 30 min. The reaction mixture was diluted with 15 mL diethyl ether, the layers separated, and the hydrazine layer washed with diethyl ether (5 mL). The combined organic layer was washed with 10% aqueous KOH (5 mL) followed by aqueous saturated sodium chloride solution (5 mL) and dried over magnesium sulfate. The solvent was removed in vacuo yielding 180.4 mg of 1-phenylethyl hydrazine as a viscous oil. In a separate flask, lead dioxide (211.3 mg, 0.883 mmol) and D,L-camphenyl-1-*t*-butylnitroxide (98.1 mg, 0.441 mmol) were suspended in 0.75 mL toluene and sonnicated for 30 min. The nitroxyl mixture was cooled to −78 °C, and the 1-phenylethyl hydrazine suspended in toluene (0.5 mL) was added by cannula in portions. An additional 0.75 mL of toluene was added to the hydrazine flask and again cannulated into the suspension at −78 °C. The reaction mixture was allowed to stir overnight while slowly warming to room temperature. The mixture was diluted with diethyl ether (10 mL) and filtered through celite, and the celite washed with diethyl ether (20 mL). The solvent was removed in vacuo to give 196.1 mg of a yellow oil. Purification by flash chromatography (95:5 hexane:ethyl acetate) afforded 125.5 mg (81% yield) of the major and minor diastereomers as an inseparable mixture in a 1.4:1 ratio (by 500 MHz ^{1}H NMR spectroscopy, C_6D_6). An additional 9.5 mg of impure product of the same diastereomeric ratio was obtained (approximately 6%). IR($CDCl_3$) $\tilde{\nu}$ = 3070, 2949 (br), 1458, 1365, 1066 cm^{-1}; ^{1}H NMR (500 MHz, C_6D_6, 25 °C, TMS, major (**a**) and minor (**b**) diastereomers): δ = 7.24-7.42 (m, 10H), 5.31 (**a**, s, 1H), 5.23 (**b**, q, 1H, ^3J(H,H) = 6.5 Hz), 4.76 (**b**, q, 1H, ^3J(H,H) = 6.5 Hz), 4.75 (**a**, s, 1H), 4.76 (**b**, q, 1H, ^3J(H,H) = 6.5 Hz), 4.75 (**a**, s, 1H), 4.68 (**b**, s, 1H), 2.54–2.60 (m, 1H), 2.02–2.12 (m, 3H), 1.86 (**a**, br s, 1H), 1.76 (**b**, br s, 1H), 1.69 (**a**, br s, 1H), 1.67 (**b**, br s, 1H), 1.59 (**b**, d, 3H, ^3J(H,H) = 6.5 Hz), 1.51 (**a**, d, 3H, ^3J(H,H) = 6.5 Hz), 1.30–1.62 (m, 5H), 1.34–1.35 (m, 1H), 1.28 (**b**, s, 9H), 1.15 (**a**, s, 3H), 1.07 (**b**, s, 3H), 1.05 (**b**, s, 3H), 1.04 (**a**, s, 12H); ^{13}C NMR (APT; 63 MHz, $CDCl_3$, 25 °C) major diastereomer: δ = 167.5 (s), 143.7 (s), 128.1 (d), 127.6 (d), 127.3 (d), 101.5 (t), 81.8 (d), 78.5 (s), 62.1 (s), 45.3 (d), 42.0 (s), 39.8 (t), 36.1 (t), 29.5 (q), 26.6(q), 23.5 (t), 21.5 (q); minor diastereomer: δ = 167.5 (s), 143.7 (s), 128.1 (d), 127.6 (d), 127.2 (d), 101.5 (t), 80.9 (d), 78.6 (s), 61.8 (s), 45.2 (d), 42.0 (s), 39.6 (t), 35.5 (t), 29.3 (q), 26.6 (q), 23.2 (t), 21.9 (q); Analysis calcd for $C_{22}H_{33}NO$: C 80.68, H 10.16, N 4.28; found: C 80.59, H 10.14, N 4.12.

Cyclic and Cubic Organophosphonates of Gallium and Their Relationship to Structural Motifs in Gallophosphate Molecular Sieves**

Mark R. Mason,* Mark S. Mashuta, and John F. Richardson

The synthesis of the large-pore molecular sieve cloverite[1] has sparked the search for new gallophosphate ($GaPO_4$) materials with potential catalytic and sorptive properties. This effort has resulted in the preparation of several unique $GaPO_4$ phases having diverse structures with no aluminophosphate or aluminosilicate counterpart.[2-5] The use of fluoride as a mineralizing agent has been instrumental for the synthesis of several of these phases. Incorporation of fluoride in the resulting product has led to secondary building units (SBUs)[6] that contain μ_2-F bridges between gallium atoms,[7,8] as well as encapsulated fluoride in double four-rings (D4Rs) as found in cloverite, ULM-5,[9] and gallophosphate-A.[10] Although it was initially thought that fluoride has a strong propensity to form D4R structures in $GaPO_4$ phases, the finding of SBUs with μ_2-F bridges and the finding that fluoride is not always incorporated into the final $GaPO_4$ product[11] raises interesting questions concerning the role of fluoride as a template and the potential diversity of undiscovered structural motifs in the fluoride/$GaPO_4$ system.

We have initiated the synthesis of derivatives of gallophosphate SBUs that are soluble in organic solvents in order to probe interactions with fluoride and to employ the derivatives as potential precursors to new $GaPO_4$ materials. Our initial target molecules were those with a cubic $Ga_4P_4O_{12}$ core analogous to the D4Rs in cloverite, ULM-5, and gallophosphate-A. The targeted $Ga_4P_4O_{12}$ core is isoelectronic and structurally related to the Si_8O_{12} core of the octameric silasesquioxanes $[RSiO_{1.5}]_8$,[12,13] and structurally related to the $Al_4Si_4O_{12}$ and $Ga_4Si_4O_{12}$ cores of soluble aluminosiloxanes,[14,15] aluminosilicates,[15] and gallosiloxanes,[16] which have been introduced by Roesky et al. as models of, and potential precursors to, zeolitic materials. The $Ga_4P_4O_{12}$ core is also analogous to the $Al_4P_4O_{12}$ cores of aluminophosphates[17] and aluminophosphonates[18,19] that are soluble in organic solvents. We report here on the synthesis and characterization of the cyclic gallophosphonate **1** and the first gallophosphate D4R derivative **2**.

$[t\mathrm{Bu_2Ga}(\mu_2\text{-}\mathrm{O_2P(OH)Ph})]_2$ **1**

$[t\mathrm{BuGa}(\mu_3\text{-}\mathrm{O_3PPh})]_4$ **2**

Equimolar reaction of $t\mathrm{Bu_3Ga}$ and phenylphosphonic acid readily yields compound **1** as a white crystalline solid in 79% yield. The ^{1}H NMR spectrum for **1** shows a 2:1 ratio of *tert*-butyl to phenyl substituents consistent with the formula $[t\mathrm{Bu_2Ga}(\mu_2\text{-}\mathrm{O_2P(OH)Ph})]_n$. The presence of unconverted hydroxyl substituents on phosphorus is confirmed by a broad OH resonance centered at $\delta = 8.00$ in the ^{1}H NMR spectrum, as well as a broad intense O–H stretch centered at 3300 cm^{-1} in the IR spectrum. Elemental analysis is also consistent with the formulation $[t\mathrm{Bu_2Ga}(\mu_2\text{-}\mathrm{O_2P(OH)Ph})]_n$, and high-resolution mass spectrometry confirms a dimeric species ($n = 2$) in the gas phase. Dimeric structures with eight-membered $Ga_2P_2O_4$ rings have previously been proposed for phosphinates of gallium, $[\mathrm{R_2Ga}(\mu_2\text{-}\mathrm{O_2PR'_2})]_2$ (R = Me, Et; R' = Me, Ph, F, Cl), on the basis of spectroscopic data,[20-23] and confirmed in the solid state by X-ray crystallography for $[t\mathrm{Bu_2Ga}(\mu_2\text{-}\mathrm{O_2PPh_2})]_2$[24] and $[(\mathrm{CH_3})_2\mathrm{Ga}(\mu_2\text{-}\mathrm{O_2PPh_2})]_2$.[25]

The molecular structure of **1** is shown in Figure 1. The centrosymmetric $Ga_2P_2O_4$ ring comprises two μ_2-η^2-$\mathrm{O_2P(OH)Ph}$ units bridging distorted tetrahedral gallium centers. All angles

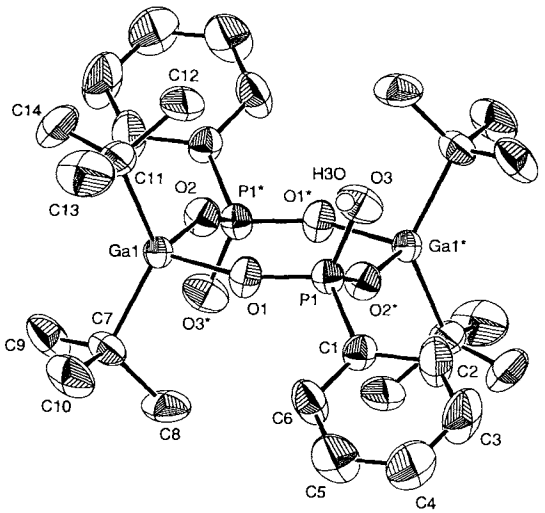

Figure 1. Crystal structure of **1** (ORTEP drawing). Thermal ellipsoids are drawn at the 50% probability level, and hydrogen atoms, except for hydroxyl hydrogens, are omitted for clarity. Selected bond lengths [Å] and angles [°]: Ga1–O1 1.944(4), Ga1–O2 1.917(4), P1–O1 1.490(4), P1–O2* 1.483(4), P1-O3 1.556(5); O1-Ga1-O2 102.8(2), C7-Ga1-C11 130.2(3), O1-P1-O2* 115.4(3), O1-P1-O3 111.0(3), Ga1-O1-P1 142.3(3), Ga1-O2-P1* 157.8(3).

at gallium lie between 102.6(3) and 107.7(2)° except for the large C-Ga-C angle of 130.2(3)°. Gallium–oxygen distances (1.944(4), 1.917(4) Å) and intra-ring P–O distances (1.483(4), 1.490(4) Å) are comparable to those in the related heterocycles $[t\mathrm{Bu_2Ga}(\mu_2\text{-}\mathrm{O_2PPh_2})]_2$ (Ga–O 1.950(8), 1.969(7) Å; P–O 1.485(8), 1.497(8) Å) and $[(\mathrm{CH_3})_2\mathrm{Ga}(\mu_2\text{-}\mathrm{O_2PPh_2})]_2$ (Ga–O 1.9384(12), 1.9295(12) Å; P–O 1.5204(12), 1.5095(12) Å).

The most intriguing structural feature for **1** is the *trans* orientation of the hydroxyl substituents at phosphorus in the solid state despite the observation of a 50/50 mixture of *cis* and *trans* isomers in solution by multinuclear (^{1}H, ^{13}C, ^{31}P) NMR spectroscopy. To explain this observation, we suggest a *cis*–*trans* equilibrium in solution with preferential crystallization of the *trans* isomer. This proposal is consistent with the thermolysis of **1** in solution, which results in the high-yield fusion of two $Ga_2P_2O_4$ rings to form the cubic $Ga_4P_4O_{12}$ core of **2**, as described below. The high yield observed is consistent with a *cis*–*trans* isomerization; however, only the *cis* isomer converts to the cubic compound **2**. The *trans* isomer should yield only polymeric products. Further details of the proposed isomerization of **1** and related compounds are under investigation.

The thermolysis of **1** in diglyme under reflux yields **2** as a crystalline white precipitate in 88% yield. Thermolysis in lower boiling solvents such as toluene or xylene is precluded by the thermal stability of **1**. Compound **2** exhibits a 1:1 ratio of *tert*-butyl to phenyl substituents by ^{1}H NMR spectroscopy. Both ^{1}H NMR and IR spectroscopic data confirm the absence of

hydroxyl substituents on phosphorus. Multinuclear NMR spectrospcopic data show **2** to be highly symmetric. These data and elemental analyses are consistent with the formulation $[t\mathrm{BuGa}(\mu_3\text{-}\mathrm{O_3PPh})]_n$. Mass spectrometric data confirm that **2** is a tetramer ($n = 4$) in the gas phase, and all evidence suggests that **2** remains a tetramer in solution.

The tetrameric structure of **2** has also been confirmed in the solid state by X-ray crystallography. The triclinic unit cell contains two independent molecules of the complex, each with the same overall geometry, but with slight variations in bond lengths and angles. One of the independent molecules exhibits greater distortions than the other,[26] but average distances and angles for the two molecules are comparable. The following discussion of the molecular structure is limited to the structural parameters of the least distorted molecule (Figure 2).

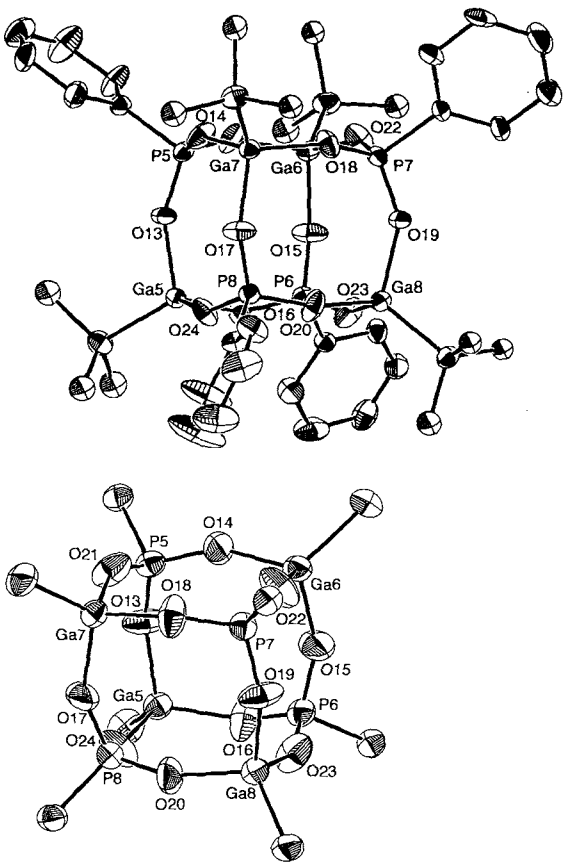

Figure 2. Top: Crystal structure of one of the independent molecules of **2** (ORTEP drawing). Bottom: $Ga_4P_4O_{12}$ core of **2** with only *ipso* carbon atoms shown for clarity. Thermal ellipsoids are drawn at the 40% (top) and 50% (bottom) probability levels. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Ga8–O19 1.852(7), Ga8–O20 1.827(7), Ga8–O23 1.827(7), P7–O18 1.493(7), P7–O19 1.486(7), P7–O22 1.495(8); O19-Ga8-O20 103.4(4), O19-Ga8-O23 104.5(4), O20-Ga8-O23 103.7(4), Ga8-O19-P7 146.8(5), Ga8-O23-P6 151.1(5), Ga8-O20-P8 155.6(6), O18-P7-O19 112.4(5), O18-P7-O22 112.4(5), O19-P7-O22 112.0(5).

The structure of **2** is composed of a cubic $Ga_4P_4O_{12}$ core in which gallium and phosphorus atoms occupy vertex positions, and μ_2-oxo bridges form along the edges. This core is analogous to the D4R building blocks in cloverite, ULM-5, and gallophosphate-A. Gallium and phosphorus atoms reside in distorted tetrahedral environments; the angles at gallium and phosphorus range from 102.1(4)–116.5(5)° and 105.8(5)–113.1(6)°, respectively. Phosphorus–oxygen distances (1.478(8)–1.512(8) Å) are normal by comparison to those in **1**, those in the related heterocycles noted above, and those in gallophosphate materials. Gallium–oxygen distances (1.827(7)–1.858(7) Å; av 1.84 Å) are significantly shorter than those in **1**, $[(CH_3)_2\mathrm{Ga}(\mu_2\text{-}\mathrm{O_2PPh_2})]_2$, and $[t\mathrm{Bu_2Ga}(\mu_2\text{-}\mathrm{O_2PPh_2})]_2$ (av 1.93, 1.93, and 1.96 Å, respectively), but are in the range observed for four-coordinate gallium in gallophosphates.

The comparison of **2** with the D4Rs in cloverite reveals that the two have comparable Ga–O and P–O distances, but the D4R of cloverite has smaller P-O-Ga angles (132.9–141.3°) and larger O-Ga-O angles (114.7–121.3°) than those in **2** (146.8(5)–155.6(6) and 102.1(4)–104.8(4)°, respectively). The larger O-Ga-O angles in cloverite can be attributed to the encapsulated fluoride ion, which forces a trigonal-bipyramidal coordination at gallium in which three μ_2-oxo ligands are situated in the equatorial plane. On average, intracage diagonal Ga–P distances are somewhat shorter in cloverite (5.42 Å) than in **2** (5.58 Å). The shorter distances arise from slight inward puckering of the gallium atoms to maximize bonding with the encapsulated fluoride ion. The overall similarities of the cage unit and the inner dimensions of the $Ga_4P_4O_{12}$ core of **2** with that of the D4Rs of cloverite suggests that encapsulation of fluoride in **2** should be feasible. Efforts to affect this encapsulation are currently in progress.

Experimental Section

All reactions were performed in an atmosphere of purified nitrogen by using standard Schlenk line techniques. Low-resolution mass spectra *m/z* values are reported for the predominant peak within the isotope pattern.

1: A solution of $\mathrm{PhP(O)(OH)_2}$ (1.58 g, 10.0 mmol) in THF (15 mL) was added dropwise to a stirred solution of $t\mathrm{Bu_3Ga}$ [27] (2.41 g, 10.0 mmol) in toluene (25 mL) and THF (5 mL). The resulting clear solution was heated to reflux for 1.5 h. The volume of the solution was reduced in vacuo and the solution was cooled at −20 °C overnight to produce clear, colorless crystals of **1**. The crystalline product became white upon isolation by filtration and brief drying in vacuo. The filtrate was concentrated and cooled to yield a second batch of product. Yield of **1** as a disolvate: 3.25 g (3.93 mmol, 79%). ^{1}H NMR (500 MHz, $CDCl_3$, TMS): $\delta = 8.00$ (br, 2H, OH), 7.84 (m, 4H, *ortho*), 7.45 (m, 2H, *para*), 7.41 (m, 4H, *meta*), 3.58 (m, 8H, OCH_2, (THF)), 1.73 (m, 8H, CH_2CH_2, (THF)), 1.16 (s, 9H, *t*Bu, *cis* isomer), 1.01 (s, 18H, *t*Bu, *trans* isomer), 0.88 (s, 9H, *t*Bu, *cis* isomer); ^{13}C{^{1}H} NMR (125.5 MHz, $CDCl_3$, TMS): $\delta = 132.98$ (d, ^1J(P,C) = 196.9 Hz, *ipso*), 132.60 (d, ^1J(P,C) = 198.0 Hz, *ipso*), 131.30 (br, *para*), 131.22 (br, *para*), 131.07 (d, ^2J(P,C) = 10.2 Hz, *ortho*), 128.07 (d, ^3J(P,C) = 15.2 Hz, *meta*), 128.04 (d, ^3J(P,C) = 15.2 Hz, *meta*), 67.79 (s, OCH_2, (THF)), 29.83 (s, CH_3), 29.78 (s, CH_3), 29.71 (s, CH_3), 25.32 (s, CH_2CH_2, (THF)), 22.83 (s, $C(CH_3)_3$), 22.72 (s, $C(CH_3)_3$); ^{31}P{^{1}H} NMR (121.5 MHz, $CDCl_3$, 85% H_3PO_4): $\delta = 7.1$ (s), 6.8 (s). MS (EI): *m/z* (%): 625 (40) [$M^+ - t$Bu], 567 (100) [$M^+ - t$Bu − *t*BuH]. HR-MS (EI): *m/z* for $C_{24}H_{39}O_6{}^{69}Ga_2P_2$ [$M^+ - t$Bu]: 623.0765 (calcd 623.0734). Anal. calcd for $C_{36}H_{64}O_8Ga_2P_2$: C 52.33, H 7.81, P 7.50; found: C 52.02, H 7.80, P 7.63.

2: A solution of **1** (2.25 g, 2.72 mmol) in diglyme (50 mL) was heated to reflux for 6 h during which time a white precipitate formed. Precipitation of the product was completed by cooling (−20 °C) the solution for one day. The white product was isolated by filtration, washed with diethyl ether (2 × 20 mL), and dried in vacuo. Yield of **2**: 1.36 g (1.20 mmol, 88%). Colorless, cubic crystals for X-ray analysis were grown from a slowly cooled hot diglyme solution. ^{1}H NMR (500 MHz, $CDCl_3$, TMS): $\delta = 7.82$ (dd, ^3J(P,H) = 14.3, ^3J(H,H) = 7.0 Hz, 2H, *ortho*), 7.48 (td, ^3J(H,H) = 7.4, ^5J(P,H) = 1.4 Hz, 1H, *para*), 7.43 (m, 2H, *meta*), 1.02 (s, 9H, CH_3); ^{13}C{^{1}H} NMR (125.5 MHz, $CDCl_3$, TMS): $\delta = 132.87$ (d, ^1J(P,C) = 212.2 Hz, *ipso*), 130.98 (br, *para*), 130.51 (d, ^2J(P,C) = 10.2 Hz, *ortho*), 127.96 (br, *meta*), 28.79 (q, ^4J(P,C) = 13.2 Hz, CH_3), 21.62 (br, $C(CH_3)_3$); ^{31}P{^{1}H} NMR (121.5 MHz, $CDCl_3$, 85% H_3PO_4): $\delta = 3.2$ (s). MS (EI): *m/z* (%): 1075 (100) [$M^+ - t$Bu]. Anal. calcd for $C_{40}H_{56}O_{12}Ga_4P_4$: C 42.45, H 4.99, P 10.95, Ga 24.64; found: C 42.38, H 5.06, P 10.84, Ga 24.96.

Crystal structure data for **1**: $C_{36}H_{64}O_8Ga_2P_2$, monoclinic, $C2/c$ (no.15), $a = 20.234(7)$, $b = 13.554(3)$, $c = 16.437(4)$ Å, $\beta = 95.52(3)°$, $V = 4486(1)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.22$ g cm^{-3}, $T = 295$ K. All measurements were made on an Enraf-Nonius CAD4 diffractometer with graphite-monochromated $Mo_{K\alpha}$ radiation. Calculations were performed by utilizing the teXsan [28] crystallographic software package. The structure was solved by direct methods (SIR-92) and expanded by using fourier techniques. The disordered THF solvate molecule was modeled by using isotropically refined non-hydrogen atoms. Hydrogen atoms were located by difference maps and includes but not refined. Of 3310 data collected (*maximum* $2\theta = 46°$, $Mo_{K\alpha}$, $\mu = 13.13$ cm^{-1}), 3228 were unique. The final residuals for 173 parameters refined against 2890 unique data with $I > 3\sigma(I)$ were $R = 0.054$ and $R_w = 0.065$.

Crystal structure data for **2**: $C_{40}H_{56}O_{12}Ga_4P_4$, triclinic, $P\bar{1}$ (no. 2), $a = 15.647(2)$, $b = 22.325(3)$, $c = 14.852(4)$ Å, $\alpha = 94.91(2)$, $\beta = 90.17(2)$, $\gamma = 83.53(1)°$, $V = 5136(1)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.463$ g cm^{-3}, $T = 296$ K. Instrumentation and software were as noted for **1**. The structure was solved by Patterson methods and expanded by using fourier techniques. Hydrogen atoms were included but not refined. Of 18771 data collected (maximum $2\theta = 50°$, $Mo_{K\alpha}$, $\mu = 22.52$ cm^{-1}), 18033 were unique. The final residuals for 1082 parameters refined against 8078 unique data with $I > 3\sigma(I)$ were $R = 0.053$ and $R_w = 0.054$. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100024. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: Int. code +(1223) 336-033; e-mail deposit@chemcrys.cam.ac.uk).

A Cage Molecule with a Cubanoid P_4B_4 Framework: $tBu_4P_4Ph_4B_4O_{12}$—A Structural Analogue of the Isovalence Electronic Organosilasesquioxanes $R_8Si_8O_{12}$

Klaus Diemert, Ulli Englert, Wilhelm Kuchen,* and Frank Sandt

Whereas a large number of oligomeric compounds with a Si-O-Si framework is known, to our knowledge no materials have hitherto been reported, which instead contain isovalence electronic P-O-B groupings. Such materials could, however, provide information as to whether substitution of this kind leads to structures that are analogous to those of the Si–O compounds, as is the case for the solids SiO_2 and BPO_4, and as to how this substitution influences the physical and chemical properties of the substances. We have now found a way to couple P-O-B bonds under mild conditions; this has afforded the title compound **1**, and possibly will facilitate the access to other compounds from this class of substances.

Prior to this was our finding that phosphonic silyl esters $RP(O)(OSiMe_3)_2$ react smoothly with phosphonic dichlorides $RP(O)Cl_2$ under elimination of Me_3SiCl to give phosphonic anhydrides $[RP(O)-O]_n$, for which we postulated ring structures. For the substituents R = *tert*-butyl, 2-methylphenyl, and 2,4,6-trimethylphenyl, we obtained trimers, among which the *tert*-butyl compound is remarkably stable to hydrolysis. Therefore, not only was it possible to follow its stepwise degradation via the corresponding tri- and diphosphonic acids to the phosphonic acid, but the intermediates could be isolated as such or as salts.[1, 2]

We have now treated the *tert*-butylphosphonic bis(trimethylsilyl ester) with $PBCl_2$ in toluene according to Equation (a) and obtained the mixed anhydride **1**, which forms colorless, moisture-sensitive needles that melt above 300 °C with decomposition and dissolve readily in benzene, toluene, and chlorohydrocarbons.

$$4\,t\mathrm{BuP(O)(OSiMe_3)_2} + 4\,\mathrm{PhBCl_2} \xrightarrow{-\mathrm{Me_3SiCl}} \underset{\mathbf{1}}{t\mathrm{Bu_4P_4Ph_4B_4O_{12}}} \qquad \text{(a)}$$

According to the crystal structure analysis,[3] **1** did not have the 16-membered ring structure $[P(t\mathrm{Bu})(O)-O-B(Ph)-O]_4$ which we had initially expected. Instead **1** revealed a cage structure with a cubane framework, the corners of which are occupied alternately by P and B atoms. The 12 O atoms are located approximately in the middle of the edges. Thus, each P and each B atom is tetrahedrally coordinated by the respective organic group and three O atoms (Figure 1). In the crystal lattice the centers of gravity of each molecule occupies the corner or center of slightly distorted cubooctahedra. Figure 2 shows the central $P_4B_4O_{12}$ framework of a molecule surrounded by the center of gravity of each its twelve neighboring molecules.

The phosphorus–oxygen and boron–oxygen bonds in **1** are largely equivalent. The average P–O distance of 1.502 Å (12 values, 1.486(3)–1.516(3) Å) lies in the range typical for partial

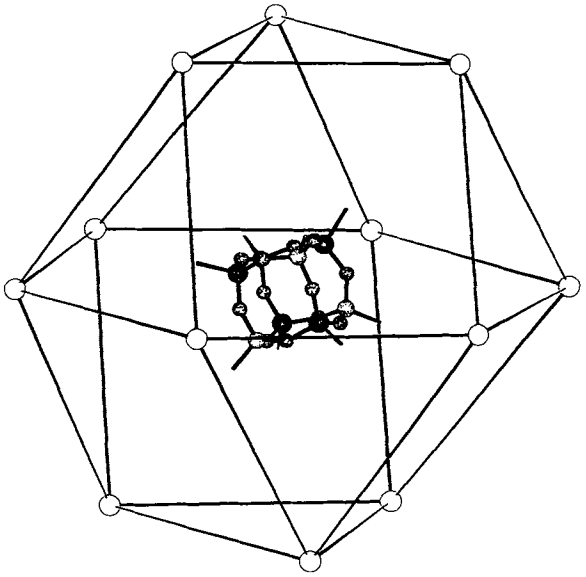

Figure 2. Arrangement of the molecules of **1** in the crystal lattice, showing the cubane-analogous framework of a central molecule and its cubooctahedral environment of neighboring molecules, which are abstracted to their centers of gravity.

multiple bonds.[6] The valence angle at the edge-bridging oxygen atoms (ca. 147°) is also indicative of multiple bonding contributions. In agreement with this are the slightly widened O-P-O bond angles. The B–O bond length (av. 1.464 Å; 12 values, 1.450(5)–1.472(5) Å) lies in the same range as that for borate ions with tetracoordinate boron.[6]

The molecules of **1** occupy the general positions in the "antimorphous"[7] space group $P2_1/n$, which is most common for van der Waals crystals, and thus show crystallographic C_1 symmetry. As a result of the nonpolar periphery, there are no directed interactions that determine the packing in the crystal lattice: the shortest intermolecular distances lie in the range of typical van der Waals contacts (ca. 2.4 Å for H–H and ca. 2.9 Å for C–C interactions). The decisive argument for the nature of the packing is thus space-filling. Since the shape of the molecule shows no pronounced anisotropy, a slightly distorted cubooctahedral arrangement of twelve nearest neighbors about each molecule can be achieved following the cubic close packing.

Schematically, the formation of the cubane framework in **1** can be explained by either the above-mentioned 16-membered ring in the saddle conformation closing to give the cubane by generation of P(O) → B bonds or by two eight-membered rings with *syn*-positioned P(O) groups combining in the same way with their faces parallel. In this way the boron atoms achieve tetrahedral coordination.

A structure analogous to that of **1** is found in the $R_8Si_8O_{12}$ (R = H, alkyl, aryl) compounds, whose cubane framework possesses the structure element Si-O-Si isovalence electronic with P-O-B.[9] Most of these compounds also show characteristically high melting or decomposition temperatures and are often relatively soluble in organic solvents.[10] In contrast to **1**, however, they are very stable to hydrolysis. The cubic Si_8O_{12} unit corresponds to the smallest known cage in zeolites, and cubooctahedra are an additional structural feature of this class of substances.

Experimental Section

The synthesis and handling of the following substances was carried out under strict exclusion of moisture.

*t*BuP(O)$(OSiMe_3)_2$: In accord with the procedure in reference [11], NaI (580 mmol) was dried under vacuum at 80 °C for 8 h, and after addition of MeCN (290 mL), the solution was treated with *t*BuP(O)$(OEt)_2$ (290 mmol). Then Me_3SiCl (580 mmol) was added dropwise under stirring, and the mixture was warmed to 40 °C for about 30 min. After the reaction mixture had been filtered, the silyl ester was obtained by distillation as a colorless, hydrolysis-sensitive liquid. B.p. 59 °C (0.04 Torr); yield 52%; elemental analysis calcd. for $C_{10}H_{27}O_3PSi_2$ (M_r = 282.5): C 42.52, H 9.63; found: C 42.52, H 9.40; ^{31}P NMR (200 MHz, liquid, 85% H_3PO_4): δ = 19.3 (s); ^1H NMR (200 MHz, C_6D_6, TMS): δ = 0.81 (s, $SiMe_3$), 1.02 (d, $^3J(P,H)$ = 17.0 Hz; *t*Bu).

1: A solution of $PhBCl_2$ (10 mmol) in toluene (10 mL) was added dropwise over an hour to a heated solution of *t*BuP(O)$(OSiMe_3)_2$ (10 mmol) in toluene (10 mL); the Me_3SiCl that formed and small amounts of toluene were continually distilled off. At the end of the addition, the mixture was heated until the distillate consisted exclusively of toluene. After cooling, the turbid solution was filtered through a membrane filter (Schleicher & Schüll, RC 60, 1 μm) and the clear filtrate was concentrated under vacuum. The residue was dissolved in a little toluene, and the resulting solution was layered very carefully with ligroin (100–140 °C). After the mixture had been allowed to stand at room temperature for several days, **1** precipitated as colorless, moisture-sensitive needles that melt under decomposition between 300 and 310 °C. Yield ca. 14%; elemental analysis calcd for $C_{40}H_{56}B_4O_{12}P_4$ (M_r = 896.0): C 53.62, H 6.30, P 13.38, B 4.83; found: C 53.39, H 6.20, P 13.30, B 4.72; M_r (cryoscopic in C_6H_6): 869 (0.066 molal), 882 (0.124 molal); ^{31}P NMR (200 MHz, C_6D_6, 85% H_3PO_4): δ = 9.31 (s); ^1H NMR (200 MHz, C_6D_6, TMS): δ = 1.30 (d, $^3J(P,H)$ = 18.8 Hz, *t*Bu), 7.70 and 8.20 (m, Ph); DCI-MS (NH_3): *m/z* (%): 897 (100, $[(M + H)^+]$), 914 (8, $[(M + NH_4)^+]$).

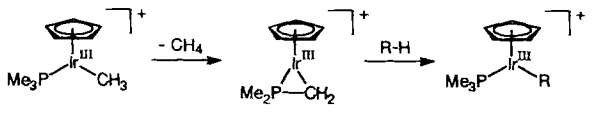
Direct Observation of a Dissociative Mechanism for C–H Activation by a Cationic Iridium(III) Complex**

Christian Hinderling, Dietmar A. Plattner,* and Peter Chen*

We report the direct, mass spectrometric observation of the reactants, reactive intermediates, and products in the C–H activation reaction by $[CpIr(PMe_3)CH_3]^+$ (**1**) in the gas phase by tandem mass spectrometry of ions produced by electrospray ionization. The reaction of the unsolvated cationic Ir^{III} complex[1] with pentane, cyclohexane, and benzene is found to proceed by a dissociative mechanism through 16-electron Ir^{III} intermediates rather than the associative mechanism through an 18-electron Ir^{V} species proposed for the analogous $[Cp^*Ir(PMe_3)(CH_3)(CH_2Cl_2)]^+$ ($Cp^* = C_5Me_5$) complex in solution.[2,14] In addition, an isotope scrambling experiment points to the existence of an intermediate or transition state isomeric with **3** (R = Ph), presumably with a π-bound structure.



1 **2** **3**

Cation **1** was prepared in the gas phase by electrospray of CH_2Cl_2 or $CHCl_3$ solutions of the $[CpIr(PMe_3)(CH_3)(N{\equiv}CCH_3)]^+ ClO_4^-$ salt (**4**). $[CpIr(PMe_3)(I)_2]$ was synthesized as described by Heinekey et al.[3] and then alkylated[4] with CH_3MgCl to produce $[CpIr(PMe_3)(CH_3)I]$ (**5**). The structure of **5**, the last synthetic intermediate isolated in pure form, was confirmed by X-ray crystallography (Figure 1).[5] Complex **4** was then prepared in situ by treatment of **5** with $AgClO_4$ in CH_3CN.

The slightly modified Finnigan MAT TSQ7000 electrospray tandem mass spectrometer was set up with an octopole, quadrupole, octopole, quadrupole (O1/Q1/O2/Q2) configuration, similar to the guided ion beam instruments pioneered by Armentrout,[6] but with an electrospray ion source[7] instead of a conventional ion source. The extent of desolvation and collisional activation prior to thermalization, reaction, and/or analysis was controlled by the tube lens potential in the electrospray source, which typically ranged from 35 V (mild conditions) to 60 V (harsh conditions). The first octopole was fitted with an open cylindrical sheath around the rods into which a collision gas could be bled for thermalization or reaction at pressures up to 20 mTorr. Control experiments have found that about 10 mTorr N_2 in O1 are sufficient for thermalization of ions produced by the electrospray source to the manifold temperature (70 °C). The second octopole was operated as a conventional collision-induced dissociation (CID) cell and run as specified in the commercial instrument for MS/MS experiments. Further details of the instrument will be described in a forthcoming report. General methods for the mass spectrometric investigation of organometallic ions have been recently reviewed from the standpoint of reactivity[8] and thermochemistry.[9]

Electrospray of **4** under mild desolvation conditions easily produced the unfragmented cation.[10] A slight increase in the tube lens potential (slightly higher collision energies in the desolvation region of the source) led to complete loss of the acetonitrile ligand, leaving predominantly bare, unsolvated **1**, with only minor amounts of **2**. Introduction of about 10 mTorr partial pressure of either pentane or benzene with the N_2 buffer gas into the O1 region resulted in complete depletion of **2**, accompanied by the appearance of a commensurate amount of **3**. The absence of change in the signal from **1** indicates a much lower reactivity of **1**, relative to **2**, with regard to addition to a C–H bond. Application of a slightly greater tube lens potential in the source resulted in the loss of CH_4 from **1**, producing predominantly **2**. Introduction of pentane, $[D_{12}]$cyclohexane, benzene, or $[D_6]$benzene to the O1 region under conditions in which **2** was formed resulted in production of the corresponding **3**. In a second experiment, mass selection of **1** by Q1, followed by collision of the ions with hydrocarbons in O2, produced no reaction until collision energies were high enough to produce **2**, at which point ions of a mass corresponding to **3** simultaneously appeared. Further highlighting the difference in reactivity between **1** and **2**, a comparable experiment with a higher tube lens potential in the source produced **2**, which was thermalized in O1, mass-selected in Q1, and then allowed to collide with the hydrocarbons in O2; **3** was readily produced, even at low collision energy. In a last set of experiments, production of **3** from **2** and pentane, $[D_{12}]$-cyclohexane, or $[D_6]$benzene in the O1 region, followed by mass-selection of **3** in Q1, and finally CID in O2, resulted in the loss of hydrocarbon fragments from **3**. For **3** produced from **2** and pentane, pentene was lost upon CID, presumably leaving the

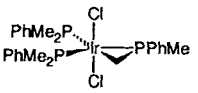
iridium hydride **3** (R = H). Similarly, the adduct from $[D_{12}]$cyclohexane lost cyclohexene, and two deuterium atoms remained in **2**. Lastly, CID of **3**, produced from **2** and $[D_6]$benzene, regenerated **2** with the unambiguous incorporation of up to five deuterium atoms. A mass peak corresponding to **2** with six deuterium atoms appeared at the limits of detection sensitivity. For substantially higher collision energies at which the phosphane ligand was also lost, the deuterium labels were expelled with the phosphane.

The analogous $[Cp^*Ir(PMe_3)(CH_3)(CH_2Cl_2)]^+$ complex reported by Arndtsen and Bergman[2, 11] reacts with the C–H bond in alkanes below room temperature without the need for prior thermal or photochemical activation.[12] The remarkable reactivity of the complex was attributed to the facile loss of the weakly bound CH_2Cl_2 ligand. Two mechanisms for the resulting σ-bond metathesis reaction were proposed: 1) oxidative addition of the 16-electron Ir^{III} complex to the C–H bond, forming an 18-electron Ir^{V} intermediate, followed by reductive elimination, or 2) concerted, four-center metathesis of the M–CH_3 and R–H bond. The former mechanism finds precedent in the low oxidation state, late transition metal complexes such as Bergman's Ir(I) complexes,[12] while the latter mechanism is found to occur for electropositive early transition metals, lanthanides, and actinides.[13] A computational study using density-functional theory compared the two processes for the cationic Ir^{III} complexes and concluded that the associative mechanism through an Ir^{V} intermediate was preferred.[14] The mass spectrometric results reported here clearly show that a third mechanism, a dissociative mechanism in which the metal is in oxidation state +III in all detectable intermediates, operates in the case of complex **1**.



6

The proposed structure of **2** finds precedent in the X-ray structure of complexes such as **6**, a neutral Ir^{III} complex.[15] Metallophosphacyclopropanes are also known for Mn,[16] Mo,[17] Co,[18] Fe,[19] Ni,[20] Re,[21] Ru,[22] and other Ir complexes.[23] The $[Cp^*Re(CO)(PMe_3)]$ complex undergoes a cyclometalation reaction to form an isolable rhenium metallophosphacyclopropane,[21] which can then undergo a facile reaction with methane or benzene in which C–H insertion occurs concomitantly with ring opening. However, it could not be determined whether the reactive species was in fact the metallophosphacyclopropane or the isomeric $[Cp^*Re(CO)(PMe_3)]$ in equilibrium with it. The absence of a hydrido ligand in **2** precludes the possibility of an isomeric ring-opened structure in equilibrium with **2** for the present case. We presume that the greater reactivity of **2** versus that of **1** has its origin in a combination of better steric access to the metal center and relief of strain, although an electronic reason cannot be ruled out. While neither the present evidence nor the reported reactivity in solution can confirm or reject a dissociative mechanism for the solution-phase reactions by analogs of **1**, the high oxidation state of the Ir^{III} complexes may contribute to the sluggishness of the oxidative addition in general. The absence of even a weakly bound solvent molecule and the use of Cp instead of the more electron-donating Cp* may further add to the electron deficiency of **1** relative to its analogs in solution. These issues should be settled by further studies. In particular, the determination of activation energies and reaction heats by quantitative CID threshold measurements is underway. In this way we should be able to map out the potential surface for the C–H activation by a technique that we hope will be generally applicable to organometallic reactions.

A final point may be made from the isotopic scrambling in the CID of **3**. The loss of $C_6H_nD_{6-n}$ ($n = 0-6$) upon collisional activation of the adduct of **2** and C_6D_6 clearly indicates that, prior to dissociation, reversible exchange of hydrogen atoms (deuterium atoms) between the phenyl moiety and the methyl groups on the phosphane can occur. The absence of comparable scrambling in the deuterated cyclohexane experiments rules out a long-lived, reversibly formed σ-complex with an agostic bond as the intermediate or transition state through which scrambling occurs in the experiment with deuterated benzene. One would presume, therefore, that the intermediate or transition state has a π-bound structure.

A mechanistic study of C–H activation by cationic Ir^{III} complexes by electrospray tandem mass spectrometry yields the unexpected result that neither the oxidative addition–elimination nor the concerted σ-bond metathesis mechanism is operative. An elimination–addition mechanism through Ir^{III} intermediates is observed and confirmed by isotopic labeling. Quantitative studies on the reaction energetics are underway.

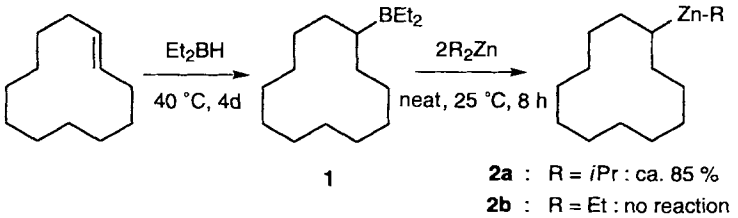
Stereoselective Preparation and Reactions of Cycloalkylzinc Compounds**

Laurent Micouin, Martin Oestreich, and Paul Knochel*

The preparation of chiral organometallic compounds with secondary alkyl substituents has been actively investigated over the past two decades. In the most successful studies the corresponding organolithium compounds[1, 2] were prepared bearing a heteroatom in α-position to the carbon–lithium bond, which ensures that these reagents can be handled easily and are configurationally stable. In contrast, organometallics having a more covalent carbon–metal bond display higher configurational stability even in the absence of an α-heteroatom, and it has been shown[3] that organozinc halides are configurationally stable over a wide temperature range.

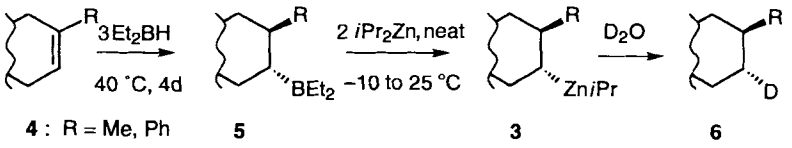
Unfortunately, a general method was not available previously for converting a chiral precursor stereoselectively into a chiral organozinc species. Thus, zinc metal inserts into stereochemically pure, secondary alkyl iodides by a radical mechanism and a mixture of stereoisomeric organozinc derivatives usually results.[3, 4] Recently we have found that organoboranes obtained by the hydroboration of alkenes can be converted to diorganozinc derivatives by treatment with diethylzinc (Et_2Zn). Although fast with primary organoboranes, this exchange is sluggish with secondary organoboranes and not stereoselective.[4, 5] Thus, the reaction of diastereomerically pure *trans*-2-diethylboryl-1-methylcyclohexane with Et_2Zn (large excess, neat, 25 °C, 40 h) produces a 1:2 mixture of *cis*- and *trans*-2-methylcyclohexylzinc derivatives in moderate yield.

We report herein that the boron–zinc exchange reaction is dramatically accelerated when diisopropylzinc (iPr_2Zn)[6] is used instead of Et_2Zn and that this experimental procedure results in the first preparation of stereochemically pure, cycloorganozinc species which react with several classes of electrophiles with retention of configuration. Thus, the reaction of diethylborylcyclododecane (**1**) with iPr_2Zn (2 equiv, neat, 25 °C, 8 h) gave the mixed isopropylcyclododecylzinc (**2a**) in about 85% yield (as determined by iododolysis experiments). When Et_2Zn was used instead of iPr_2Zn, the corresponding zinc reagent **2b** did not form under the same experimental conditions (Scheme 1).



Scheme 1.

With iPr_2Zn we could generate diastereomerically pure cycloorganozinc compounds of type **3** for the first time starting from the corresponding olefin of type **4**. The hydroboration of **4** with diethylborane (3 equiv, 40 °C, 90 h) produced the *trans*-diethylborylcycloalkane (**5**) (>99% *trans*). The reaction of **5** with iPr_2Zn (2 equiv) furnished as expected the desired zinc reagent **3**, which was quenched with D_2O in THF at −78 °C to provide the *trans*-monodeuterated products **6** (Scheme 2, Table 1).[7]



Scheme 2.

Table 1. Yields of **6** as well as conditions of the boron–zinc exchange.

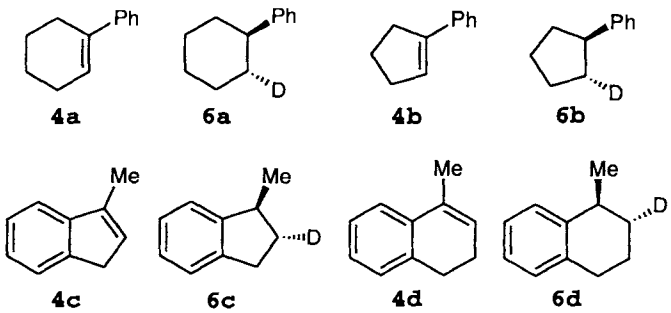
[a] Temperature and time required for the boron–zinc exchange reaction. [b] The *trans*:*cis* ratio was determined by ^2H NMR spectroscopy. [c] Overall yield (based on the olefin **4**) of analytically pure products.



Phenylcyclohexene **4a** was converted by this sequence into pure *trans*-2-deuterio-1-phenylcyclohexane (**6a**), showing that the boron–zinc exchange and deuterolysis proceed with retention of configuration (Table 1, entry 1). Treatment of *trans*-isopropyl-(2-phenylcyclohexyl)zinc (**3a**) with CuCN·2LiCl[8] afforded an intermediate zinc–copper species which was deuterated to give **6a** with the same stereoselectivity. This implies that the zinc–copper transmetalation and deuterolysis of a zinc–copper reagent also occurs with retention of configuration. In the case of the conformationally flexible cyclopentane system, the stereoselectivity of the boron–zinc exchange was found to depend on the reaction temperature. Thus, by performing this reaction with *trans*-2-diethylboryl-1-phenylcyclopentane (**5b**) at 25 °C, we obtained **6b** in a *trans*:*cis* ratio of 87:13 after deuterolysis; however, when the same reaction was performed at −10 °C the *trans*:*cis* ratio was 98:2 (Table 1, entries 2 and 3). A similar result was obtained for 1-methylindene (**4c**) (entries 4 and 5). Interestingly, the deuterolysis of a secondary zinc reagent like *trans*-isopropyl-(2-phenylcyclopentyl)zinc (**3b**), which was stored for one week at 5 °C, proceeded with the same

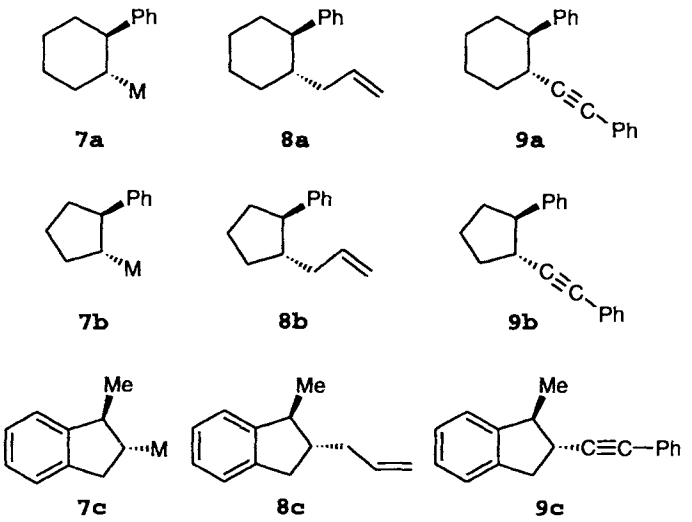
[a] M = Cu(CN)Zn*i*Pr. [b] The *trans*:*cis* ratio was determined by GC analysis and a ^{13}C NMR spectroscopy of the crude reaction mixture. [c] Overall yields (based on the olefin **4**) of analytically pure products.



The degree of configuration retention depends critically on the reaction conditions. When the alkynylation was conducted at temperatures above −50 °C, significant epimerization was observed. Although the *trans*-isopropyl-(2-phenylcyclohexyl)-zinc (**3a**) and its zinc–copper derivative are less sensitive to the reaction conditions used, it was noticed with **3b** that the presence of an extra equivalent of zinc bromide leads to extensive isomerization. The allylated product **8b** (Table 2, entry 3) was obtained with a 66:34 *trans*:*cis* ratio, in strong contrast with results obtained without zinc bromide (*trans*:*cis* ratio of 95:5).

We have described a new method for preparing stereoselectively chiral non-heteroatom stabilized cycloorganozinc compounds. We have demonstrated that these reagents react stereoselectively with several carbon electrophiles (allylation, alkynylation) in the presence of CuCN·2 LiCl. Extension of this reaction to the preparation of diastereomerically pure aliphatic organozinc compounds as well as the study of the stereoselectivity of the trapping reactions of these organometallics are currently underway.

Experimental Section

Typical procedure: **9b**: A 50 mL, two-necked flask equipped with a rubber septum and an argon inlet was charged with the olefin **4b** (649 mg, 4.50 mmol). After the olefin had been degassed, diethylborane (prepared from triethylborane and borane/methyl sulfide complex (1.32 g, 13.5 mmol, 3 equiv)) was added dropwise by syringe at 25 °C. The resulting mixture was stirred for 4 d at 40 °C. Excess diethylborane was removed by distillation (25 °C, 2 h). *i*Pr$_2$Zn (1.36 g, 9.00 mmol, 2 equiv) was carefully added by syringe at 25 °C. The reaction mixture was immediately cooled to −10 °C and kept at this temperature for 10 h with exclusion of light. Meanwhile a mixture of CuCN (806 mg, 9.00 mmol, 2 equiv) and LiCl (763 mg, 18.0 mmol, 4 equiv) was dried in vacuo (130 °C, 3 h). The copper and lithium salts were dissolved in dry THF (9 mL) and the solution cooled to −78 °C. Then excess *i*Pr$_2$Zn was removed by distillation (25 °C, 1 h); the flask was covered with aluminum foil to exclude light. The flask was equipped with an internal thermometer and the organozinc compound was diluted with dry THF (2 mL) and cooled to −78 °C. The previously prepared CuCN·2 LiCl solution was added. The reaction mixture was stirred at −78 °C for 15 min, and 2-bromo-1-phenylacetylene (1.63 g, 9.00 mmol, 2 equiv) in dry THF (5 mL) was added dropwise within 20 min while the temperature of the reaction mixture was kept below −70 °C. The reaction mixture was warmed up to 25 °C and worked up as usual. The crude product was purified by flash chromatography (hexanes), affording the compound **9b** (459 mg, 1.82 mmol, 41 % yield) as a pale yellow liquid.

An Acentric, Three-Dimensional Coordination Polymer: Synthesis and Structure of $[Cu(pyrimidine)_2]BF_4$**

Steven W. Keller*

Crystal engineering[1] is a burgeoning field that offers hope of rationally designing extended solids by linking together molecular building blocks having specific functionality and geometry. Molecular species that remain intact when solubilized in organic or aqueous solvents at room temperature can then be "snapped together" in predictable ways, forming a tremendous variety of metastable structures, which may find uses in catalysis, nonlinear optics, and molecular electronics.

Initial successes came from the use of noncovalent intermolecular interactions, such as electrostatic attraction[2] and hydrogen bonding.[3] The work of Fischer et al. with organometallic moieties[4] hinted to the added directional control and increased bond strength possible with coordinate covalent bonds, and has led to the increased popularity of metal cations as building blocks.[1b, 5] Learning from Nature's example, and taking advantage of the well-defined coordination geometries around metal centers, several groups succeeded in mimicking the structures of simple minerals such as perovskite,[6] rutile,[7] and PtS,[8] by replacing the monatomic anions (O^{2-} and S^{2-}) with polyfunctional, polyatomic neutral, or anionic ligands. Even more elaborate coordination polymers have been prepared containing large voids and channels,[9] as well as complicated interpenetrating networks having no mineral analog.

Silicates, including quartz (piezoelectrics), clays (ion exchangers for water softening), and zeolites (heterogeneous catalysts), comprise a technologically important class of minerals that has not been explored in the area of coordination polymers. The variety of structures and properties belies the similarity of the structural building blocks in these materials; the silicon atoms are found tetrahedrally coordinated by oxygen atoms almost exclusively. The structural differences arise from the variety of ways in which the tetrahedra can be fused together. The coordination chemistry of monovalent copper is often characterized by a tetrahedral ligand environment,[10] and indeed, several coordination polymers with copper(I) centers have been reported, which preserve that coordination in the solid state. However, in previous examples the metal centers are bridged with linear rods[11] or tetrahedral ligands,[12] both of which form diamondoid networks with varying degrees of interpenetration. In silicates such as quartz and zeolites, however, the Si-O-M (M = Si or Al) angle is about 145°, intermediate between those for linear and tetrahedral geometry. Here we report the crystal growth and structural characterization of $[Cu(pyrimidine)_2]BF_4$, in which a nonchelating, bent bridging ligand (pyrimidine) knits together an acentric, three-dimensional framework of tetrahedral copper(I) centers.

Crystals of $[Cu(pyrimidine)_2]BF_4$ suitable for single-crystal X-ray diffraction[13] were prepared by slowly diffusing tetrahydrofuran into a solution of $[Cu(CH_3CN)_4]BF_4$ and pyrimidine in nitrobenzene/acetonitrile. The unit cell contains two independent copper centers, each coordinated in a slightly distorted tetrahedral geometry by four nitrogen atoms from four different pyrimidine molecules. Each of the pyrimidine ligands bridges two copper(I) ions; the shortest Cu(1)–Cu(2) distance is 6.02 Å. This bidentate, nonchelating coordination leads to the three-dimensional framework shown in Figure 1. The tetrafluoroborate ions are located adjacent to the framework, and each is anchored to the framework through short $F\cdots H-C_{ring}$ hydrogen bonds (2.313 Å and 2.422 Å).

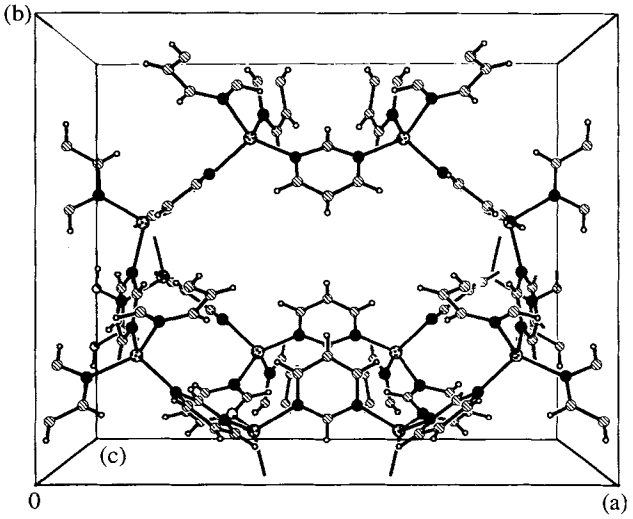

Figure 1. Structure of the framework unit cell of $[Cu(pyrimidine)_2]BF_4$ (view down the *c* axis). Copper atoms: large dotted circles, nitrogen atoms: darkly shaded atoms, carbon atoms: hatched circles, hydrogen atoms: open circles. The anions are omitted for clarity.

A further illustration of the connectivity of this coordination polymer can be gleaned by representing the centroids of the pyrimidine rings as the vertices of distorted tetrahedra that have the copper atoms at their center. This corner-shared network (Figure 2a) consists of eight-rings of tetrahedra connected together with four-rings to form elliptical channels (perpendicular to the plane of the paper). The structure is not related to any of the polymorphs of SiO_2, (quartz, cristobalite, etc.), as none have larger than six-rings. However, the feldspars (a family of aluminosilicate minerals that comprise nearly 60% of the earth's crust), do have elliptical eight-rings interconnected by four-rings,[14] albeit in a slightly different orientation (Figure 2b). In Figure 2b only one layer of the feldspar structure

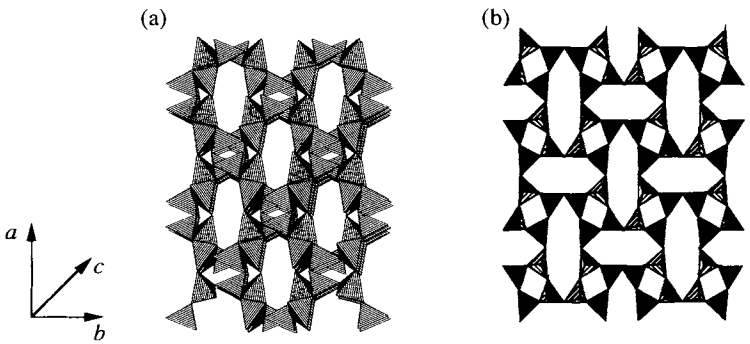

Figure 2. a) Polyhedral packing diagram of $[Cu(pyrimidine)_2]BF_4$. The centroids of the pyrimidine rings are defined as the vertices of the polyhedra. The copper(I) cations (located at the center of each tetrahedron), are omitted, as are the anions, for clarity. b) Schematic view of the feldspar structure viewed down the *a* axis. The large cations (Na, K, Ca, or Ba) reside in the eight-ring voids.

is shown; neighboring layers are offset such that the "channels" are almost completely constricted, and therefore there is no void space in these structures. In the majority of these minerals, isomorphous substitution of one quarter of the SiO_4 tetrahedra by AlO_4 tetrahedra requires incorporation of extra-framework alkali metal cations for charge balance (e.g. orthoclase: $KAlSi_3O_8$); these reside in the eight-ring voids (Figure 2b). $[Cu(pyrimidine)_2]BF_4$, which has a 1:1 ratio of framework cations (copper(I)) to extra-framework (BF_4^-) ions, can therefore be regarded, at least in a topological sense, as a "stuffed" feldspar derivative, to accentuate the presence of additional charge balancing ions, as in "stuffed" quartz structures (e.g. $LiAlSiO_4$ and $Mg[Al_2Si_3O_{10}]$).[15]

In terms of intracrystalline pore volume, the framework accounts only for approximately 70% of the total volume of the unit cell, taking 19 Å^3 as the volume for all non-hydrogen atoms. By including the anions the volume accounted for increases to 90%, leaving about 10% available for disordered solvent molecules. Inspection of difference Fourier peaks did not yield discernible chemical species, and apparently the included solvent is almost liquidlike within the cavities formed by the framework as has been seen previously.[12] NMR spectra of several single crystals dissolved in [D_6]DMSO revealed the presence of both nitrobenzene and THF (in approximately 1:2 stoichiometry with pyrimidine).

Remarkably, although the space group is not chiral, neither is it centrosymmetric; therefore, mimicry of some of the unique physical properties of quartz such as piezoelectricity or nonlinear optical behavior remains possible. Current investigations are aimed at increasing the volume of the channels, while maintaining the acentric environment, by lengthening the spacer ligands that connect the metal centers. In addition, we hope to explore the use of various anions that may act as templates, analogous to those used in hydrothermal zeolite syntheses, to produce different crystal structures from identical building blocks, simply by connecting them in different ways.

Experimental Section

To a solution of $[Cu(CH_3CN)_4]BF_4$ (0.032 g, 0.1 mmol) [16] in nitrobenzene (3 mL) and acetonitrile (0.5 mL) was added pyrimidine (0.132 g 1.7 mmol). Tetrahydrofuran was allowed to diffuse slowly into the solution, resulting in the formation of yellow needle-shaped crystals after several days.

[13] Yellow single crystals of $[Cu(pyrimidine)_2]BF_4 \cdot n$ solvent were mounted with epoxy resin in a glass capillary, and diffraction data was collected at room temperature using a Siemens SMART system equipped with a CCD area detector. Crystal data: Orthorhombic, space group $Cmc2_1$ with $a = 20.417(1)$, $b = 16.598(1)$ and $c = 15.912(1)$ Å, $V = 5392.3(6)$ Å^3, $\rho_{calcd} = 1.717$ g cm^{-1}, and $\mu(Mo_{K\alpha}) = 1.683$ mm^{-1}. A full hemisphere of data was collected, yielding 5838 independent reflections, which were corrected for absorption using simulated Ψ scans. The structure was solved by direct methods (G. M. Sheldrick, SHELXS-90, program for structure solution, University of Göttingen, Germany, **1991**), and refined by using a full-matrix least-squares treatment on F^2 (G. M. Sheldrick, SHELXL-93, program for structure refinement, University of Göttingen, Germany, **1994**). The space group was originally designated as $Cmc2_1$ on statistical grounds, and the structure solved adequately. To search for possible missed symmetry elements, the program MISSYM (Y. LePage, *J. Appl. Cryst.* **1988**, *21*, 983) was employed, and no additional symmetry operations were detected. All of the framework atoms were located and refined before inclusion of the BF_4^- ions. Anisotropic thermal parameters were assigned to all non-hydrogen atoms. No discernible chemical species could be identified in the residual electron density peaks. The chosen model assigned the six largest peaks (1.0–1.2 e Å^{-3}) as carbon atoms; after isotropic refinement, each of their site occupancies lowered to about 0.25, in qualitative agreement with the NMR spectroscopic results. Final R_1 [$I > 2\sigma(I)$] = 0.0849 for 341 parameters. Further details of the crystal structure investigation may be obtained from the Fachinformationszenrium Karlsrule, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-405495.

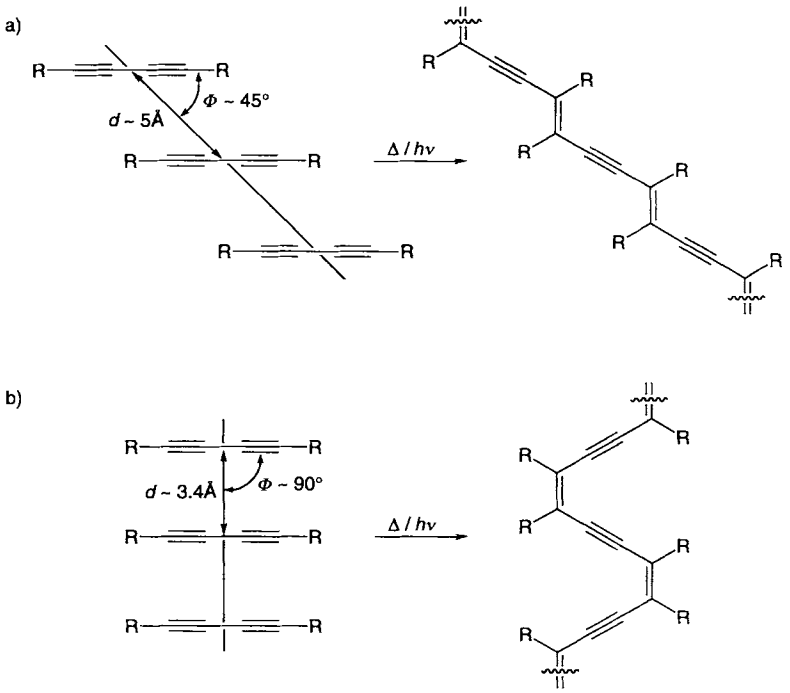
macrocycles in solution has been attributed to arene–arene interactions,[6, 7] as has the liquid-crystalline behavior of some arene-containing molecules.[8] In addition, arene–arene interactions are important in molecular recognition events[9–11] and have been shown to influence selectivity in both solution-phase[12, 13] and solid-state recognition events.[14]

Although a considerable amount of work concerning the stacking of aromatic rings has concentrated on phenyl–phenyl interactions, there is a growing interest in the interactions of phenyl and perfluorophenyl groups.[15–17] Patrick and Prosser first recognized that a 1:1 mixture of benzene (m.p. = 5.5 °C) and hexafluorobenzene (m.p. = 4 °C) forms a complex, which melts at 24 °C.[18] Although pure benzene adopts an edge-to-face structure in the solid-state,[19] it has been determined that the structure of the lowest temperature phase of the benzene/hexafluorobenzene material consists of stacks of alternating molecules.[15, 20, 21] This stacking arrangement is thought to result from the minimization of electrostatic repulsions and the maximization of electrostatic attractions between the molecules, not from charge-transfer interactions.[15, 22, 23] The electrostatic potential map of benzene[24] reveals concentrations of negative potential above and below the molecular plane, and a ring of positive potential in the plane focused on the hydrogens. Hexafluorobenzene possesses the reverse charge distribution. Stated differently, both benzene and hexafluorobenzene have large molecular quadrupole moments that are similar in magnitude, yet opposite in sign.[15] Further support for the importance of electrostatics in such interactions comes from Cozzi and Siegel's elegant studies of rotational barriers in 1,8-diarylnaphthalenes[25, 26] and from recent theoretical studies.[27, 28]



Scheme 1. a) Commonly observed diyne polymerization to yield a *trans*-polybutadiyne. b) Unprecedented synthesis of a *cis*-polybutadiyne.

The identification and detailed understanding of commonly observed interactions in molecular crystals is a prerequisite to the advancement of the field of crystal engineering.[29, 30] In addition, these interactions, which generate structures that were recently termed "supramolecular synthons",[31] are crucial to the topochemical reactivity of molecules in the crystalline state. For example, the control of crystal architectures is extremely important in solid-state butadiyne polymerizations,[32–34] where subtle changes in monomer substitution can dramatically alter monomer packing, and hence reactivity. We report here the utilization of specific phenyl–perfluorophenyl stacking interactions to align diyne molecules for reaction in the crystalline state.

It is well established that a prerequisite for efficient topochemical polymerization of 1,3-diynes is the tilted stacking of the monomers, with a distance d between the diyne centers of about 4.7–5.2 Å, and an angle Φ between the molecular and stacking axes of about 45° (Scheme 1a).[35, 36] Hydrogen-bonding and/or the slipped face-to-face stacking of aromatic groups are commonly observed orientational interactions in crystals that undergo polymerization, but it should be noted that subtle changes in the structure of the monomer often result in inactive materials. Polymerization in these systems, typically indicated by a color change, can be induced by exposure to heat, UV-light, γ-rays, or by the application of pressure to the crystal. After initiation, perhaps involving a diradical cumulene, propagation through the molecular stacks by a 1,4-addition process produces a conjugated enyne polymer, with the olefins of the polymer in a *trans* configuration. Interestingly, there are no reported examples of *cis* polymers in which the diacetylene monomers are packed in a ladder-type structure ($\Phi = 90°$) (Scheme 1b).[37] Using the observed bond distances from the existing *trans* enyne polymers,[36] we calculated that the optimal diacetylene separation for such a polymerization should be approximately 3.4 Å. Since the observed interplanar distances between hexafluorobenzene and various aromatic hydrocarbons range from 3.4–3.6 Å,[38] we hypothesized that appropriately fluorinated diphenyldiacetylenes might stack in the required geometry for a *cis*-specific polymerization. Such materials should have new and interesting properties, and might undergo cascade radical cyclizations to yield graphite-like ribbon-type polymers.[39, 40]

Diphenylbutadiyne (**1**)[41] and decafluorodiphenylbutadiyne (**2**)[42] are colorless, crystalline compounds. Diacetylene **1** is known to be completely photostable,[43] and we found that **2** produces only traces (<4%) of a violet polymeric material upon UV irradiation, which implies a slight degree of polymerization. Although X-ray structural data for **2** are not available, **1** packs in a highly slanted manner (d = 6.0 Å, and $\Phi = 51°$),[44] consistent with the observed lack of photoreactivity.[43] Co crystallization of **1** and **2** from ethanol gave long needles of a colorless, crystalline material (**1**·**2**) that melted at 152 °C (the melting points of **1** and **2** are 87 °C and 114 °C, respectively). X-ray structural analysis[45] of the **1**·**2** cocrystal revealed that the diacetylenes pack alternately in well-ordered stacked columns (Figure 1a), analogous to the benzene/hexafluorobenzene complex.[46] The carbon frameworks of **1** and **2** are virtually identical to that determined for **1**.[44] The diyne–diyne separation d is 3.69 Å, and the mean angle Φ is 75.1° (Figure 1b). The mean distance between reactive carbon atoms is 3.69 Å, well within the distance of 4 Å found to be necessary in other diyne polymerizations.

We anticipated that the related compound 2,3,4,5,6-pentafluorodiphenyldiacetylene (**3**) might stack in a similar manner and thus also adopt the arrangement required for a *cis* polymerization.[47] Diyne **3** was synthesized by an Eglinton coupling[41]

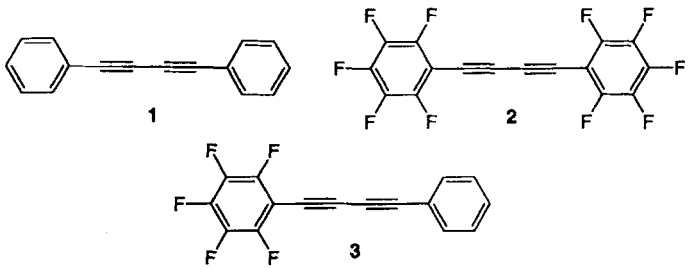
of phenylethyne and pentafluorophenylethyne and was purified from the homocoupled products (**1** and **2**) by column chromatography.



1 **2** **3**

Single crystal X-ray structural analysis of **3** revealed an array of stacked columns similar to **1·2**, in which the diynes were packed in a head-to-tail fashion.[48] However, in contrast to **1·2**, the molecules of **3** are slightly staggered in directions perpendicular to the stacking axis (Figure 2a). Bond distances and

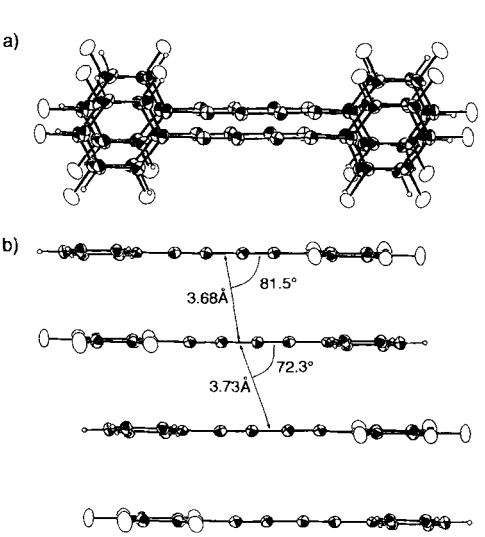


Figure 2. Molecular structure of the **3** in the crystal (ORTEP, 50% probability thermal ellipsoids; hydrogen atoms are shown as spheres at one-tenth scale). a) View along the diyne stacking axis (*b* axis). b) View parallel to the least-squares plane of **3**.

angles were comparable in all cases to those found in the structure of **1·2**. The center-to-center distances of the diynes ($d = 3.68$ Å, 3.73 Å) are again within the range expected of a reactive crystal. The angles Φ are 81.5° and 72.3°, creating a slight zig-zag type displacement of the diyne axes (Figure 2b).

Preliminary results reveal that a solid-state, photochemically-induced polymerization does occur in both crystals **1·2** and **3**. Photolysis of the **1·2** complex resulted in the immediate shattering of the crystal and the eventual formation of a dark red-brown powder. After irradiating with UV light for 18 h, the unchanged monomer was removed by sublimination revealing an 18% conversion of the diynes. Crystals of **3** produced a rust-colored polymeric material in 16% yield upon irradiation for 18 h. Reaction of finely dispersed samples of **1·2** for 24 h produced polymer in 50% yield. The polymerization kinetics of a sample of **1·2** revealed that, unlike many other diyne polymerizations, this reaction has no initiation period.[36]

The occurrence of a photochemically induced polymerization of **1·2** and **3** was confirmed by fast-atom bombardment mass spectroscopy (FAB-MS) of the photolysis product.[49] Peaks corresponding to the alternating oligomers[50] (up to six units) of **1** and **2** are present in the mass spectrum. In addition, gel-permeation and thin-layer chromatography of the product revealed the presence of oligomers. Conversion to high polymer is presumably limited by the spacing of the monomer (3.69 Å, ideal = 3.4 Å) and the slight tilt of the diyne stack (75.1°, ideal = 90°); at some point during the polymerization the distance between the propagating species and the next monomer unit is too great, and termination of chain propagation results. Although the monomers appear to be arranged as necessary for a *cis*-specific polymerization, further studies will be necessary to determine the structure of the polymer unambiguously.[51]

The current results indicate that the alternating, stacked phenyl–perfluorophenyl arrangement first seen in benzene/hexafluorobenzene may be a fairly general supramolecular motif. In diyne systems such intermolecular arene–arene associations orient the reactive diyne units in a manner that is compatible with solid-state photopolymerization. The diphenylbutadiynes investigated here are structurally among the simplest diynes that undergo a polymerization reaction, and are packed in the crystal to yield novel alternating copolymers (poly(**1·2**)) and regioregular, head-to-tail homopolymers (poly(**3**)). Due to the ease of incorporating phenyl and perfluorophenyl groups into molecules, this supramolecular synthon might facilitate a wide array of new developments in chemistry and biology where control of the relative orientation of molecular groups is important.

Experimental Section

3: Phenylacetylene (2.79 g, 27.3 mmol) and pentafluorophenylacetylene [42] (1.00 g, 5.2 mmol) were added to a suspension of copper(II) acetate (11.0 g, 60.6 mmol) in pyridine/methanol (1/1, 40 mL). After 24 h, the reaction mixture was diluted with 1 M HCl (100 mL) and extracted with diethyl ether (3 × 100 mL). The organic phase was dried (Na_2SO_4) and concentrated, and the residue was purified by flash chromatography (SiO_2; eluent: hexanes) to afford 0.40 g (26%) of **3**: m.p. 124 °C; ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 7.37$ (m, 3H, *m,p*-ArH), 7.55 (m, 2H, *o*-ArH); ^{13}C{^{1}H} NMR (75.4 MHz, $CDCl_3$): $\delta = 64.56$ (br), 72.73, 85.07, 85.32 (br), 120.62, 128.55, 130.00, 132.67, and a series of broad multiplets between 135 and 150; ^{19}F NMR (470.6 MHz, $CDCl_3$, $CFCl_3$): $\delta = -161.6$ (m, *m*-ArF), −150.8 (m, *p*-ArF), −135.0 (m, *o*-ArF). Polymerization reactions were carried out in quartz reaction tubes under argon with a quartz-jacketed 450 W Hanovia medium-pressure mercury vapor lamp at ambient temperature.

[51] We have tentatively ruled out a possible ladder structure (see ref. [35]), as the UV/Vis spectrum of the polymers are significantly different than that of the model compound decaphenylanthracene (ref. [40]).

Five-Coordinate Sulfur in a Polymeric Copper(I) Thiolate Complex**

Richard V. Parish,* Zahra Salehi, and Robin G. Pritchard

Metal thiolate complexes show remarkable diversity of structure. In the case of copper(I) derivatives, these range from simple anions with two- and three-coordination for the copper atom, through rings and cages, to complicated clusters.[1] Such materials are studied both in their own right and as possible models for naturally occurring copper-containing proteins. In the case of copper(I) complexes the range of structures arises from the ability of both the metal and sulfur atoms to adopt various coordination modes. Copper(I) can be two-, three-, or four-coordinate, while the thiolate sulfur atom can bind to one, two, or three metal atoms. The most common structural unit in the known thiolates is a three-coordinate copper atom bonded to μ_2-bridging thiolates. Despite the wide range of stoichiometries and structures now known, the SR:Cu ratio is never less than 1 for simple monothiolate ligands; μ_2-thiolate bridging between metal atoms is far more common than μ_3 bridging, while symmetrical μ_4-bridging is unknown. We now report a novel compound in which SR:Cu < 0.5, and in which the thiolate sul-

fur atom simultaneously bridges four equivalent metal atoms. It represents a new and beautiful structure type.

Conductivity and pH measurements show that when solid CuCl is added to an aqueous solution of cysteamine hydrochloride ($HSCH_2CH_2NH_3^+Cl^-$), one mole of H^+ is liberated for each mole of Cu^+ added, but no additional Cl^- goes into solution. This is in agreement with previous pH studies and shows that the zwitterion $^-SCH_2CH_2NH_3^+$ is acting as a neutral ligand to form a 1:1 complex.[2] When solutions with a metal-to-ligand ratio of about 1:4 were allowed to stand (approximate pH 1.9),[3] colorless, needle-shaped crystals suitable for X-ray analysis were slowly deposited.

The crystallographic analysis[4] showed a complex polymeric structure of composition $[Cu_{13}Cl_{13}(SR)_6 \cdot H_2O]_n$ ($R = CH_2CH_2NH_3$). The basic unit is a centrosymmetric Cu_{12} cubo-octahedron. A regular octahedron of sulfur atoms, bearing organic chains pointing outwards, has each edge bridged by a CuCl unit (Figure 1, top). There are thus three mutually perpendicular, planar, eight-membered $[(CuCl)(\mu_2\text{-}SR)]_4$ rings intersecting at the sulfur atoms, giving a gimbal-like "Atlas-sphere" configuration (Figure 2a).

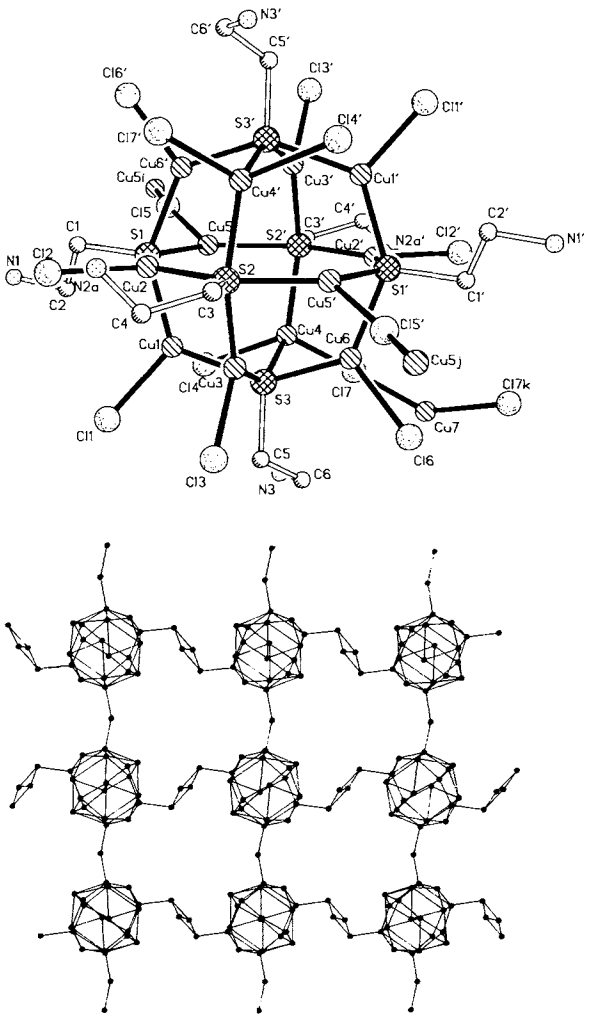

Figure 1. Top: Structure of the basic $Cu_{13}Cl_{13}(SR)_6$ unit; hydrogen atoms are omitted for clarity. There is a center of symmetry at the center of the S_6 cage. Bottom: The layers of clusters forming sheets linked through Cl5 in one direction (Cu5-Cl5-Cu5') and Cl7 in the other, the latter via Cu7 (Cu4-Cl7-Cu7-Cl7'-Cu4'); H_2O molecules, the $CH_2CH_2NH_3^+$ ions, and the cluster-bound Cl atoms are omitted for clarity. The bridging Cu7 is disordered between the two positions shown, which span a center of symmetry.

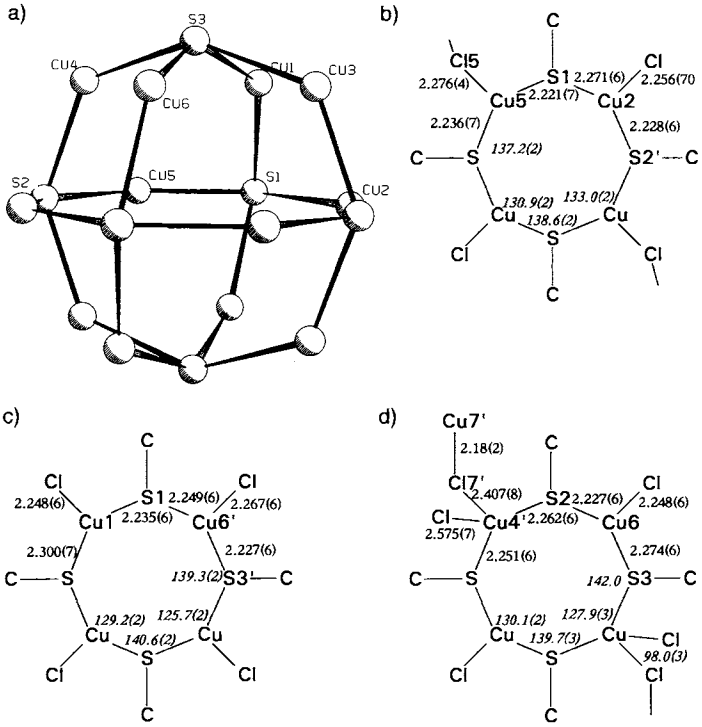

Figure 2. Schematic diagrams of the Cu–S framework. a) The "Atlas-sphere" comprising three rings. b)–d) The three individual $[SCuCl]_4$ rings, showing important bond distances and angles (in italics). The mean deviations of atoms from the planes of the rings: b) 0.023 Å; c) 0.025 Å; d) 0.116 Å. Dihedral angles: b), c) 94.16°; b), d) 90.11°; c), d) 91.41°.

The $Cu_{12}Cl_{12}(SR)_6$ clusters are linked to form two-dimensional sheets with different linkages in the two directions (Figure 1, bottom). Parallel to the *c* axis, chloride ligands (Cl 5) bridge directly between two copper atoms of different clusters (Cu 5, Cu 5j).[5] Perpendicular to this direction, along the *a* axis, the link is formed by a $CuCl_2$ unit (Cl7 Cu7 Cl7k), the chlorides of which are also coordinated to cluster copper atoms Cu4 and Cu4'. Thus, Cu4 is four-coordinate and approximately tetrahedral, while the remaining copper atoms of the cluster are accurately planar and three-coordinate. The coordination of Cu7 is nonlinear (Cl-Cu-Cl 144°) because of an interaction with Cl2 atoms in adjacent layers [2.78(1) Å].

The Cu–S bonds are all similar in length (2.221–2.300 Å, average 2.248 Å) and lie in the normal range for Cu^I–SR involving three-coordinate copper.[1, 6] The two bonds to the four-coordinate Cu4 are only slightly longer (average 2.256 Å). The Cu4–Cl bonds (2.407, 2.575 Å) are significantly longer than those of the other copper atoms (average 2.249 Å). The water molecules are not coordinated to copper, but are hydrogen bonded to the NH_3^+ ions.

The most interesting aspect of this structure is the unique four-way bridging of the thiolate sulfur atoms: each atom is common to two eight-membered rings and is bonded to four equivalent copper atoms and a carbon atom. As far as we are aware, there is only one other known compound that has a thiolate sulfur atom bonded to four metal atoms: *tert*-butylthiolato(methyl)zinc.[7] This pentameric compound has a distorted cubane structure in which one sulfur atom makes contacts with four zinc atoms. The cubane Zn–S bonds (involving four-coordinate zinc) are longer even than the Cu4–S bonds seen here, averaging 2.435 Å, whereas those in the SZn_4 unit are very long and nonequivalent (two at 2.514(8) Å, and two at

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3603-0252 $ 15.00+.25/0

2.982(8) Å). This clearly represents an entirely different bonding system from the one discussed here.

Evidently, the bonding of the thiolate sulfur to four equivalent copper atoms is electron-deficient, since RS^- has only three lone pairs in addition to the C–S bond pair. The copper atoms are sufficiently separated that the cluster may be described in terms of noninteracting square-pyramidal $CSCu_4$ units. This geometry favors the bonding, since two of the copper atoms can interact with the sulfur p_x orbital (the S–C axis is the z direction), and the other two with p_y. All four copper atoms can interact with an inward-pointing sp_z hybrid. It is thus possible to accommodate the four available electron pairs in bonding molecular orbitals (Figure 3), the next highest orbital being

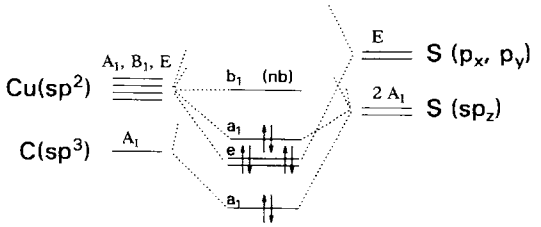

Figure 3. Schematic molecular orbital diagram for the $CSCu_4$ unit. Symmetry labels correspond to idealized C_{4v} symmetry.

nonbonding (or slightly antibonding, to the extent that the copper orbitals overlap). Inclusion of the sulfur $d_{x^2-y^2}$ orbital might stabilize the b_1 orbital slightly, but would provide no additional bonding electrons. The bond lengths indicate that this six-center, eight-electron system is tightly bound.

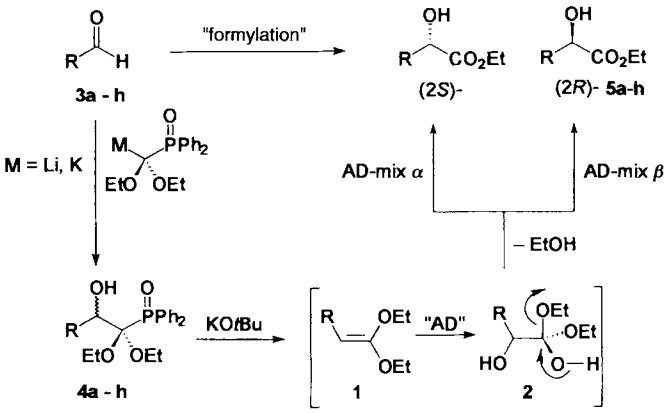
A New Asymmetric Formylation of Aldehydes**

Andreas Kirschning,* Gerald Dräger, and Alexander Jung

Formylation of aldehydes is of major importance in synthesis.[1] The formyl anion is typically employed in a masked form; thus masked α-hydroxy aldehydes, carboxylic acids, or esters are formed, which subsequently have to be unmasked. The most commonly applied formylating agents are heteroatom-stabilized (often sulfur-stabilized) carbanions. Control of the configuration of the newly formed stereogenic center at C-2 has been achieved either by an α-positioned chiral center in the substrate[2, 3] or by chiral auxiliaries in the carbanion.[4] In the latter case achiral aldehydes may be used but liberation of the carbonyl group is often accompanied with irreversible loss of the chiral auxiliary.[5]

In contrast, our strategy uses a formyl anion equivalent that homologates aldehydes in the primary step in such a way that prochirality at the former aldehyde carbon atom is retained. Then the hydroxy group at C-2 is enantioselectively introduced and the masked formyl group at C-1 liberated simultaneously. Ketene *O,O*-acetals **1** are ideal for this new formylation strategy, because they can be prepared from aldehydes in the Horner-Wittig reaction,[6] and they give intermediate diols **2** in the Sharpless asymmetric dihydroxylation (AD)[7] that spontaneously collapse to α-hydroxy carboxylates (Scheme 1).



Scheme 1. Asymmetric formylation of aldehydes via ketene *O,O*-acetals.

In order to carry out this formylation sequence most efficiently, the Horner–Wittig step had to be optimized. Quantitative formation of the metalated diethoxymethyl diphenyl phosphine oxide[8] was best achieved by use of lithium diisopropylamide (LDA) or potassium diisopropylamide (KDA) in THF. In contrast to earlier reports by van der Gen et al.,[9] a minimum deprotonation time of two hours and a temperature of −110 °C is important. Under these conditions the dark red anion is quantitatively generated. Use of complexating agents like HMPA or crown ethers did not result in improved yields.[10] Addition of aldehydes **3a–h** afforded stable phosphine oxides **4a–h** after

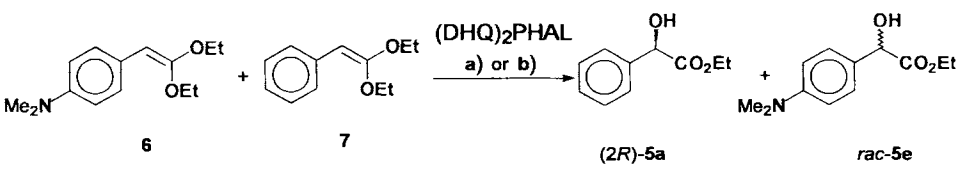
[g] Reduced yield due to volatile ketene acetal. [h] Determined from ^{1}H NMR spectra.

aqueous workup. These phosphine oxides could be chromatographed on silica gel and fully characterized or used directly for the next step (Table 1). In some cases the potassium salt of diethoxymethyl diphenyl phosphine oxide reacted more efficiently. The yields of the isolated products were considerably reduced for enolizable aldehydes like **3g** and **3h**. In the following the corresponding ketene acetals **1** were liberated by KO*t*Bu-promoted elimination.[11] After concentration of the reaction mixture at 0 °C the crude product was enantioselectively oxidized to afford the α-hydroxy carboxylates **5a–h** in moderate to good overall yield (Table 1).[12] In most cases ketene acetal formation and the following asymmetric dihydroxylation process proceeds almost quantitatively. Under the phase-transfer conditions employed, proton-induced hydrolysis of the ketene acetals to the corresponding carboxylates did not occur. However, oxidation is best performed in an inverse manner by adding the precooled AD-mixture to **1**.

Except for 4-dimethylaminobenzaldehyde (**3e**), all aldehydes were formylated with a high degree of enantioselectivity. The lower *ee* values for dihydrochinin (DHQ) ligands than for dihydrochinidin (DHQD) ligands is a phenomenon often observed for the AD-process.[13] The formation of racemate **5e** may be caused by competition between the amino group in **6** and the chiral ligand for the binding site of the osmium complex. To test this hypothesis, a mixture of ketene acetals **6** and **7** were oxidized under AD-conditions, and in a second experiment **6** was oxidized first and ketene acetal **7** added after complete transformation (Scheme 2). Again the *ee* values of the oxidation products for both experiments scarcely differed from those obtained under standard conditions (racemate for **5e** and >99 and 95.1% *ee*, respectively for **5a**). Therefore the amino group of neither the ketene acetal **6** nor the product **5e** deactivates the chiral catalyst. Probably either the polarity of the dimethylamino group in **6** prevents binding of the chiral ligand to the osmate complex or (more likely) **5e** undergoes rapid racemization. In fact, when the *ee* of **5b** was redetermined after three months of storage at −10 °C the value had dropped from 93% down to 83%.

In summary, we present a new asymmetric formylation method for aldehydes that affords α-hydroxy carboxylates with high enantiomeric purity. Unlike common one-carbon homologations of aldehydes, we utilize prochiral ketene *O,O*-acetals as intermediates. In view of new chiral ligands for the AD-process that have recently been disclosed by Sharpless and co-workers,[13, 14] this process may be improved further.



Scheme 2. AD competition experiment with ketene acetals **6** and **7**: a) **6**, 3h, 0 °C, then addition of **7**, 12h, 0 °C; b) **6**, **7**, 12h, 0 °C.

Experimental Section

4: To a solution of LDA or KDA [15] (1.1 mmol) in dried THF (15 mL) under nitrogen at −110 °C was added diethoxymethyl diphenyl phosphine oxide (0.35 g, 1.2 mmol) in dried THF (2 mL) over a period of 30 min. After 1.5 h at ambient temperature freshly purified aldehyde **3** (1.0 mmol) in dried THF (2 mL) was added to the dark red solution. The reaction mixture decolorized immediately, was hydrolyzed after 15 min with water (4 mL) and allowed to warm to room temperature. After addition of brine (10 mL) and dichloromethane (10 mL) the layers were separated. The aqueous phase was washed with dichloromethane (5 ×), and the combined organic extracts were dried ($MgSO_4$) and concentrated in vacuo. The crude product can either be purified by column chromatography on silica gel or can be used directly for the next reaction. In this case, traces of water were removed by codistillation with toluene prior to use.

5: The adduct **4** (1 mmol) was dissolved in dried THF (15 mL) under nitrogen and treated with freshly sublimed potassium *tert*-butoxide (12.3 mg, 1.1 mmol) in THF (2 mL) at 0 °C. After 15 min the solution was concentrated under reduced pressure (with cooling in an ice bath) to a volume of appoximately 1 mL. A suspension of "AD-mix" (1.4 g; that

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3603-0254 $ 15.00+.25/0

is, 1 mol% $(DHQ)_2$-PHAL for AD-mix-α or $(DHQD)_2$-PHAL for AD-mix-β) in water (5 mL) and *tert*-butanol (5 mL) was prepared at room temperature, cooled to 0 °C, and added to the precooled ketene acetal. After addition of methanesulfonamide (95 mg, 1.02 mmol) the suspension was vigorously stirred overnight at 0 °C and reduced with sodium sulfite (1.5 g). Stirring was continued for 30 min at 0 °C and after an additional 15 min at room temperature water (5 mL) and dichloromethane (20 mL) were added. The aqueous layer was extracted with dichloromethane (5 ×), and the combined organic extracts were dried ($MgSO_4$), concentrated under reduced pressure, and purified by column chromatography on silica gel.

Conditions for the determination of the enantiomeric excesses of the α-hydroxycarboxylates **5** by GC analysis on a chiral heptakis(2,6-di-*O*-methyl-3-*O*-pentyl)-β-cyclodextrin column (all isothermal with a flow rate of 1.5 mL min^{-1}): **5a**: 100 °C, 52.7 min (2*S*), 48.6 min (2*R*); **5c**: 115 °C, 104.1 min (2*S*), 98.6 min (2*R*); **5d**: 131 °C, 52.1 min (2*S*), 47.9 min (2*R*); **5e**: 145 °C, 64.7 min (2*S*), 62.3 min (2*R*); **5f**: 107 °C, 42.8 min (2*S*), 41.0 min (2*R*); **5g**: 65 °C, 38.7 min (2*S*), 36.7 min (2*R*).
The absolute configuration was deduced from comparison of CD-spectra with those of authentic (2*R*)-**5a** (positive Cotton-effect for (2*S*)-**5a**–**h**; negative Cotton-effect for (2*R*)-**5a**–**h**) with authentic (2*R*)-**5a**).

Constitution of the Iodyl Cation**

Martin Jansen* and Ralph Müller

The syntheses and crystal chemistry of ternary oxides can be categorized into three classes depending on the oxide basicity or the acidity of the appropriate binary components.[1] The largest group of ternary oxides consists of binary components with strongly different oxide basicities. As a rule these contain complex anions (e.g. in $K_6[Co_2O_7]$) that are formed through O^{2-} transfer.[2] Combinations of binary oxides with similar basicities (e.g. $MgAl_2O_4$) often are referred to as double oxides. The investigation of ternary oxides of nonmetals, of which both components preferably act as acids with other oxides as in systems containing iodine oxides, has more or less been neglected until recently. Although a large number of such phases have been identified through their "fingerprints", mainly with vibrational spectra, their composition and constitution have, as a rule, not been reliably clarified. This fact applies especially to cases where iodine oxide appears as oxide base and crystallochemically takes over the cationic function. Of these ternary oxides, mainly known as iodosyl and iodyl compounds, only the crystal structure of $(IO)_2SO_4$ or $I_2O_3 \cdot SO_3$ could be substantiated until recently.[3] The polymeric and mixed valency $I_3O_6^+$ cation in $(I_3O_6)HSO_4$ has now also been elucidated.[4] The details given on the iodyl cation IO_2^+ are contradictory and generally lack a reliable experimental basis.[5] The iodyl cation is reported to exist as a monomer in solutions.[6] A polymeric constitution similar to the structure of solid selenium(IV) oxide has been suggested for the solid state.[7] This unsatisfactory state of iodine–oxygen chemistry is mainly caused by the unusually large variety of compounds within these systems, which makes it a laborious task to prepare single-phase products.[8] Furthermore, the preparation of crystals is impeded by the polymeric nature and thermal lability of the iodine–oxygen compounds.

If the reaction parameters of the system $I_2O_5/SO_3/H_2O$ (beside concentration and temperature, the time required for the establishment of equilibrium is a critical factor) are adjusted in such a way that $(IO_2)_2S_2O_7$ is the first phase to exceed its solubility product, it precipitates as a coarse crystalline product.

The analysis of the crystal structure contradicts all earlier suggestions for the structure of the iodyl cation,[9] and reveals it to be a dimer $I_2O_4^{2+}$ (Figure 1). The variation of I–O bond lengths within this unit is remarkable. The two shortest I–O distances and the asymmetrical I-O-I bridges suggest a monomeric, angular IO_2^+ (bond angle at iodine: 98°, isoelectronic with SO_2). If not examined in detail the dimensions of the $S_2O_7^{2-}$ anion do not present any peculiarities.

This rigorous description as an ionic crystal of $I_2O_4^{2+}$ cations and

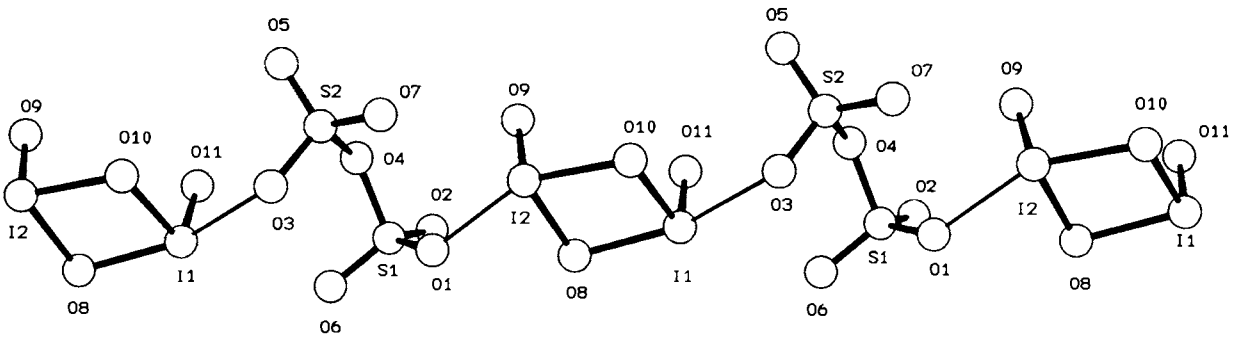

Figure 2. Chains of $I_2O_4^{2+}$ and $S_2O_7^{2-}$ in $(IO_2)_2S_2O_7$. Selected bond lengths [pm] and angles [°]: I1–O3 224.2(8), I2–O1 224.0(9), S1–O1 148.4(25), S1–O2 144.0(27), S1–O4 161.7(24), S1–O6 142.6(19), S2–O3 148.2(28), S2–O4 163.9(26), S2–O5 143.1(24), S2–O7 142.7(18); O1-S1-O2 113.0(9), O1-S1-O6 111.0(10),O1-S1-O4 104.7(11), O2-S1-O4 101.2(9), O2-S1-O6 117.7(13), O4-S1-O6 107.9(10), O3-S2-O4 104.8(12), O3-S2-O5 113.4(9), O3-S2-O7 111.0(7), O4-S2-O5 101.7(8), O4-S2-O7 106.7(9), O5-S2-O7 118.1(12).

$S_2O_7^{2-}$ anions is reasonable and allows a quick classification, but does not fully regard the actual bonding. The shortest bond between a terminal oxygen atom of the disulfate group (O3 and O1) and iodine (224 pm) exceeds the longest intraionic distances within the I_2O_4 group only by 11% and is therefore to be classified as clearly binding. The next largest interionic contacts are longer than 260 pm and therefore only to be considered as, at best, weakly binding. A chainlike polymer is created by the described strong interionic linkages, in which $I_2O_4^{2+}$ and $S_2O_7^{2-}$ units alternate (Figure 2).

The coordination number of iodine naturally varies with the arbitrarily chosen effective radius r. Remarkably, however, each of the resulting different coordination polyhedra can be interpreted according to the valence electron pair repulsion concept:[10] For $r<190$ pm the units are pseudo-trigonal-planar IO_2^+ groups, for $190<r<200$ pm they are $I_2O_4^{2+}$ dimers with pseudo-tetrahedrally coordinated iodine, and finally for $200<r<225$ pm a pseudo-trigonal bipyramidal environment can be assigned.

A description of the crystal structure of $I_2S_2O_{11}$ as an one-dimensional polymer clearly emphasizes its ternary nonmetal oxide character comprising I_2O_5 and SO_3. The difference in the oxide acidity between the binary components does not suffice to effect a complete transfer of O^{2-} ions with formation of complex ions. Nevertheless, the relative oxide acidities of I_2O_5 and SO_3 can be measured from the extent of the transfer of O1 and O3 from iodine to sulfur and is even quantifiable through the partial valence sums of oxygen or iodine and sulfur:[11] the valence sums of O1 and O3 meet the expectations of 1.99 and 1.98; S^{VI} contributes 3/4 and I^V the smaller share of 1/4 to these sums.

Experimental Section

Preparation of $(IO_2)_2S_2O_7$: iodic acid (5 mmol, purum p.a. > 99%, Fluka) is dissolved in oleum (100 mmol, purum p.a., Riedl-de-Haën; about 20% SO_3) under purified dry argon. Within 1 h the reaction mixture is heated to 195 °C and stirred for an additional 30 min. For crystallization the product is cooled to room temperature over 2 h. The colorless crystals were washed with trifluoroacetic acid (freshly distilled over P_4O_{10}) and dried under vacuum.

Selective Ring-Opening Olefin Metathesis of Functionalized Monosubstituted Olefins

Matthias F. Schneider, Norbert Lucas, Janna Velder, and Siegfried Blechert*

Olefin metathesis has been increasing in importance recently.[1] New catalysts such as Grubb's ruthenium catalyst[2] $[Cl_2(Cy_3P)_2Ru{=}CHPh]$ (= [Ru]); Cy = cyclohexyl) and Schrock's molybdenum catalyst[3] $[PhMe_2CCH{=}Mo{=}N(2,6\text{-}iPr_2C_6H_3)(OCMe(CF_3)_2)_2]$ (= [Mo]) have imparted significant impetus to this C–C bond forming method. Many reports have been published on the subject of ring-closing metathesis, either with the formation of relatively strained ring systems or macrocycles.[4] Selective crossed olefin metathesis reactions in the presence of functional groups are, on the other hand, much less well documented: high selectivities have only been reported in the cases of styrene,[5] acrylonitrile,[6] and allylsilanes[7] with the relatively inaccessible, expensive, and very air sensitive molybdenum catalyst, and the high selectivities have been explained on the basis of electronic effects. One of the two olefins was always present in a twofold excess.

We recently reported a combination of ring-opening metathesis and selective cross-coupling.[8] Thus, strained norbornenes were treated with a symmetrically disubstituted olefin, which was present in large excess to suppress the self-metathesis of the norbornenes. Surprisingly, the self-metathesis hardly occurred with monosubstituted olefins, and high selectivities and yields could be achieved even with a 1:1 ratio of the two olefins. To the best of our knowledge, selective cross-couplings with the easily accessible and relatively stable ruthenium catalyst have not been reported. For example, treatment of the polymerization-active[9] dicyclopentadiene **1** (1 g in 50 mL CH_2Cl_2) with one equivalent of allyltrimethylsilane **10a** and only 0.07 mol% [Ru] affords a 3:1 mixture of the two regioisomeric ring-opening products **2a** and **2a'** in 94% yield in only 15 min at room temperature (Table 1). This is, as far as we are aware, the highest turnover number ever reported for Grubb's ruthenium catalyst.

Table 1. Results of the ring-opening metathesis of strained olefins with monosubstituted alkenes (Boc = *tert*-butoxycarbonyl, TBDMS = *tert*-butyldimethylsilyl).

Starting material	Product	Equiv **10**	Catalyst (mol%); Duration [h]	*E*:*Z*
1	**2a**:**2a'** (3:1)	1.0 **10a**	[Ru] (0.07); 0.25	5:1 (**2a**)
3	**11**	1.0 **10a**	[Ru] (5); 3.5	2:1
4	**12a**	1.2 **10a**	[Ru] (5); 1.5	1:5

5	**13a**	1.5 **10c**	[Mo] (7); 3	2:1
5	**13b** [a]	1.5 **10d**	[Mo] (5); 3	1:6
6	**14**	1.2 **10e**	[Ru] (5); 1	1:3
7	**15**	1.5 **10f**	[Ru] (7); 16	1:2
8	**16** [b,c]	1.5 **10a**	[Ru] (2); 2	1:1
9	**17a** [b]	1.5 **10a**	[Ru] (5); 20	1:1.5
9	**17b** [b]	5 **10b**	[Ru] (5); 20	1:1.5

[a] The compound is unstable; the yield was therefore determined by ^1H NMR spectroscopy. The complete characterization was performed on the diester. [b] Because of the volatility of the product the yield was determined by gas chromatography (heptadecane als internal standard). [c] The reaction was performed in dichlormethane under reflux.

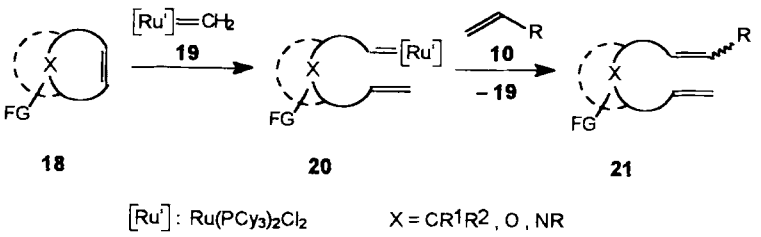
This atom-efficient synthesis[10] is also remarkable for its regioselectivity. According to the Chauvin mechanism,[11] cycloaddition of a carbene complex to an olefin results in the formation of a metallocyclobutane, whose cycloreversion leads to ring opening. The regioselectivity is thus presumably due to steric effects in the cycloaddition. The major isomer **2a** is present as an *E*/*Z* mixture (5:1); the ^{1}H NMR spectrum of **2a'** displays signals due to the *E* isomer only. The *E*/*Z* selectivities, which vary dramatically (from 5:1 to 1:6), cannot at the moment be predicted. If the cycloreversion proceeds in a concerted manner, the stereochemistry of the olefin can be determined from the relative configuration of the metallacyclobutane and is probably also dictated by the cycloaddition. Directing effects are currently being investigated (Scheme 1).

In order to determine the extent of the utility of the ring opening, we have used monosubstituted olefins with strained rings for cross-coupling experiments (Table 1). Since regioselective ring openings are, in principle, possible (see **2a**, **2a'**), the *N*-BOC-acylated lactam **3** was treated with one equivalent of the allyltrimethylsilane **10a**. This novel route to monosubstituted 3,5-pyrrolidinones yields only one regioisomer (**11**) in acceptable yield. In this case, too, we favor steric control, although complexation cannot be ruled out altogether. The reaction with **4** is a good example of directing effects in relation to the *E*/*Z* ratio. The disilylderivative yields predominantly the *Z* isomer, whereas the corresponding diol leads preferentially to the *E* isomer. The high selectivity and the excellent yield of this cross-coupling is not, as assumed in in other cases,[7] due to the β-effect of the silicon. The dimethylpentene **10b** reacts in a similar manner (see **12a,b** in Table 1). As expected, the ring opening is also successful with other monosubstituted olefins. Since allylstannanes should offer a range of further reactions and metathesis products of this nature have never been described, we also attempted reactions with **10c**. Olefin metathesis does not take place with the ruthenium catalyst; however, they do take place smoothly with the molybdenum catalyst. The acrylonitrile **10d** behaves analogously. On the other hand, reaction of the allyl cyanide **10e** proceeds readily with the ruthenium catalyst. Notable is the ring opening of the diol **7** with the allyl acetate **10f**, which is only possible with the ruthenium catalyst, because the molybdenum catalyst cannot tolerate free alcohols and allyl acetates. Nevertheless, the required amount of catalyst is significantly larger. This quantity appears to be dependent on the type of functional groups and the scale of the reaction. Since the reaction succeeds with olefins containing a variety of functional groups, the method appears to be generally applicable. Sterically demanding olefins, however, provide a problem: attempted coupling reactions with vinylsilanes gave yields of less than 10%. Preliminary reactions with 1,1-disubstituted olefins such as 4-benzyloxy-2-methyl-1-butene were unsuccessful. Ring openings are not restricted just to norbornenes: recently we also converted 3.3.0-bicyclooctenes of type **2** into cyclopentanes (Table 1).

Crossed olefin metatheses with monosubstituted olefins could provide an exciting route to unsymmetric acyclic diolefins. Since ring strain is required as a driving force for the reaction, cyclobutenes and cyclooctenes should be suitable. This is confirmed by examples **8** and **9**. The conversion of cyclooctene **8** with 1.5 equivalents of the allyltrimethylsilane **10a**, however, also formed oligomeric by-products, whereas the analogous opening of **9** proceeded in very good yield. We rationalize this behavior in terms of the predominantly sterically derived differences in metathesis reactivity between the ring-opened products **16** and **17**: the product **16** can compete with the monosubstituted olefin, whereas **17** cannot.

Several mechanisms are possible for the ring opening. Due to the high selectivity of the cross-coupling (even with equivalent quantities of reagents) we prefer the reaction sequence represented in Scheme 1, particularly for bicyclic olefins. We presume that the methylene complex **19**, formed in an initiated process (Scheme 1), which displays a high metathesis activity,[12] is



Scheme 1. Postulated mechanism for selective crossed ring-opening metathesis (FG = functional group, Cy = cyclohexyl).

added preferentially to the strained double bond of the cycloolefin **18**, due to less steric hindrance. The carbene complex **20**, formed in the ring opening, then reacts selectively (again on steric grounds) with the monosubstituted olefin **10**. The atom-economical cross-coupling is completed by reformation of the catalytically active methylene complex **19**.

Experimental Section

All metatheses were carried out under argon, and when not otherwise indicated, at room temperature. The synthesis of **11** represents a typical synthetic procedure: **10a** (27.3 mg, 0.239 mmol) and **3** (50 mg, 0.239 mmol) were added to CH_2Cl_2 (10 mL). [Ru] (9.8 mg, 11.9 μmol, 5 mol%) in CH_2Cl_2 (3.4 mL) was then added. This was then stirred at room temperature for 3.5 h. After conversion was complete, the solvent was removed under reduced pressure. The crude product was purified by column chromatography (silica gel deactivated with MeOH, *tert*-butyl methyl ether:petroleum ether = 1:9). Yield: 64 mg (0.198 mmol, 83%) **11** as a pale yellow oil.

All new compounds were unambiguously characterized spectroscopically. Confirmation of their structure was carried out by two dimensional NMR spectroscopy and NOE experiments. Selected spectroscopic data for **11**: summated ^{1}H NMR spectrum (400 MHz, $CDCl_3$): δ = 5.98–5.85 (33% 1H, m), 5.78 (66% 1H, ddd, J = 17, 10, 7.5 Hz), 5.69–5.61 (33% 1H, m), 5.57 (66% 1H, dt, J = 15, 8 Hz), 5.27 (66% 1H, ddt, J = 15, 7, 1 Hz), 5.32–5.10 (33% 1H + 2H, m), 4.44 (66% 1H, ddd, J = 15, 7.5, 7.5 Hz), 4.38 (33% 1H, ddd, J = 15, 7.5, 7.5 Hz), 3.19 (33% 1H, m), 3.11 (66% 1H, ddd, J = 15, 7.5, 7.5 Hz), 2.48–2.31 (1H, m), 1.80–1.55 (1H, m), 1.51–1.40 (2H, m), 1.47 (9H, s), 0.02 (22% 9H, s), 0.00 (11% 9H, s), −0.02 (66% 9H, s); *E*-**11**: ^{13}C NMR (50.32 MHz, $CDCl_3$): δ = 174.7 (C), 149.9 (C), 138.8 (CH), 130.5 (CH), 124.0 (CH), 115.6 (CH_2), 82.8 (C), 58.7 (CH), 46.1 (CH), 31.9 (CH_2), 27.9 (CH_3), 23.0 (CH_2), −2.1 (CH_3); *Z*-**11**: ^{13}C NMR (50.32 MHz, $CDCl_3$): δ = 173.9 (C), 149.8 (C), 138.5 (CH), 130.8 (CH), 128.5 (CH), 115.9 (CH_2), 82.4 (C), 58.6 (CH), 46.2 (CH), 32.5 (CH_2), 27.9 (CH_3), 22.5 (CH_2), −1.8 (CH_3); IR (CCl_4): $\tilde{\nu}$ = 2957, 1749, 1724, 1299, 1249, 1155, 854 cm^{-1}; MS: *m*/*z* (%) = 267 (22) [$M^+ - C_4H_8$], 222 (8), 208 (17), 199 (7), 181 (29), 162 (17), 140 (9), 122 (6), 91 (20), 79 (26), 73 (81), 57 (100), 41 (22), 29 (9); HR-MS calcd for $C_{13}H_{21}NO_3Si$ [$M^+ - C_4H_8$]: 267.1291; found: 267.1291.

New Supramolecular Complex of C_{60} Based on Calix[5]arene—Its Structure in the Crystal and in Solution

Takeharu Haino, Manabu Yanase, and Yoshimasa Fukazawa*

Buckminsterfullerene and its related fullerenes have generated a rapidly growing and active research area.[1] The former is one of the most impressive molecules because of its cagelike, truncated icosahedral structure. This molecule, a weak electron-acceptor, forms clathrates in the solid state.[2] The selective formation of a clathrate from C_{60} and calix[8]arenes was excellently utilized for the separation of C_{60} and C_{70}.[3] Supramolecular complexes of C_{60} in solution are limited in the aqueous system,[4] though extremely weak charge transfer (CT) complexes[5] are known in organic solvents. Quite recently weak inclusion complexes of C_{60} and calix[6]arenes have been reported.[6] Because of the smooth and dense surface of C_{60}, it can be bound through an accumulation of weak van der Waals interactions, even in organic solvents, if a host with a suitably complementary shape is selected. In this paper we report the binding of calix[5]arene[7] receptors to C_{60} in organic solvents and the crystal structure of the inclusion complex.

A color change (purple → pale yellow) was observed in the solution of C_{60} upon addition of the receptor (**1**). The intensity of the shoulder in the guest's absorption band in the 400-470 nm region increased (Figure 1) with the addition of the receptor (**1**).

The isosbestic point at 478 nm as well as a Job's plot provided evidence for a 1:1 complex in solution.[8] The association constant of the complexes (Table 1) determined by the Benesi–Hildebrand method confirmed a 1:1 stoichiometry for the host–guest complexes in all cases. To our knowledge the association constant of **1** with C_{60} ($2.1 \pm 0.1 \times 10^3$ dm^3 mol^{-1}) is the largest yet reported for organic solvents.

Table 1. Association constants [dm^3 mol^{-1}] obtained by titration of **1**–**3** with C_{60} at 298 K (λ = 430–440 nm).

	Toluene	Benzene	CS_2	*o*-Dichlorobenzene
1	2120 ± 110	1840 ± 130	660 ± 30	308 ± 41
2	1673 ± 70	1507 ± 84	600 ± 3	277 ± 14
3	588 ± 70	459 ± 74	284 ± 70	207 ± 11

The association constants are solvent dependent. The solubility of the guest increases along the series benzene, toluene, CS_2, and *o*-dichlorobenzene. The more weakly solvated guest is more strongly bound in the host. The Gibbs energies of complexation plotted against the logarithm of guest solubility (mg mL^{-1})[1a] gave good linear relationships (correlation coefficients R^2: **1** 0.943; **2** 0.952; **3** 0.845). Thus, complex formation competes against the solvation of the guest in these apolar solvents.

The association constants are also dependent on the substituents of the host ($K_a(\mathbf{1}) > K_a(\mathbf{2}) > K_a(\mathbf{3})$ in every solvent). Since the guest molecule is a weak electron-acceptor, charge-transfer type interaction may play a role in the complexation. To examine this idea, the HOMO energies of the host (**1** −8.819, **2** −8.843, **3** −8.875 eV) were evaluated with PM3 MO calculations. The plot of HOMO energies against the Gibbs energies gave a good linear relationship in every solvent (average correlation coefficient for 4 solvents: $R^2 = 0.925 \pm 0.032$).

Van der Waals interactions between the host and guest are also operative, since the host with the substituent of the highest polarizability (X = I) binds the guest most strongly. The magnitude of the van der Waals interaction was estimated by means of molecular mechanics calculations (with the program AMBER*,

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3603-0259 $ 15.00+.25/0

implemented in MacroModel V.5.0).[9] The relative steric energies of association are -3.51 kcal mol^{-1} (**1**), -2.33 kcal mol^{-1} (**2**), and 0.0 kcal mol^{-1} (**3**). A plot of the Gibbs energies of the complexation versus the relative steric energies gave an excellent correlation in every solvent ($R^2 = 0.951$ (toluene), 0.961 (benzene), 0.975 (CS_2), and 0.998 (*o*-dichlorobenzene)). We therefore conclude that the van der Waals interactions between host and guest play an important role in these complexations.

Slow concentration of a solution of **1** and an equimolar amount of the guest molecule in CS_2 gave purple prisms of the inclusion complex. The X-ray crystallographic analysis[10] provided an unexpected result: the ratio of the host and C_{60} was 2:1 in the solid state! The guest molecule is encapsulated within a cavity composed of the two host molecules (Figure 2). Due to

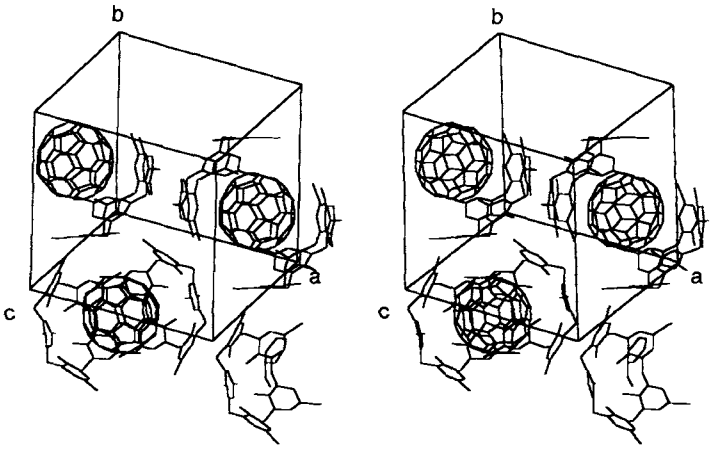

Figure 2. A stereoscopic view of the crystal packing of 1:2 complex of C_{60} with **1**.

the positional disorder of the two iodine atoms over the *para* positions of the five phenols, this $C_{60}\cdot(\mathbf{1})_2$ complex has pseudo D_{5d} symmetry in the solid state. Judging from the symmetry, there are only four nonequivalent carbons for the guest molecule. In this complex, there are altogether 144 short interatomic distances (<4.0 Å) between the sp^2 carbons in the guest and two hosts, which suggests a strong binding of this complex.[11]

A complexation-induced upfield shift of ^{13}C NMR signals[12] for the guest can be observed if the structure of the 1:1 complex in solution is similar to that of C_{60} in the solid state. Based on the X-ray structure of $C_{60}\cdot(\mathbf{1})_2$, we evaluated the local anisotropic contributions of the five benzene rings of calix[5]arenes upon the ^{13}C chemical shifts for the included C_{60} by our ring current method[13]. The symmetry of the inclusion complex was reduced to C_{5v} and the number of nonequivalent carbon atoms of C_{60} increased from 4 to 8 when one of the host molecules was eliminated. The complexation-induced chemical shifts of these eight different carbons (the number of carbon atoms in each environment is given in parentheses) were estimated: $\delta = 2.83$ (5), 2.61 (5), 1.56 (10), 0.79 (10), 0.50 (10), 0.38 (10), 0.33 (5), 0.31 (5): the average of 60 carbons is $\delta = 1.044$.

The observed complexation-induced shift $\Delta\delta$ of C_{60} is 0.35, when the equimolar amount of the guest (1.74×10^{-3} mol dm^{-3}) and host (1.75×10^{-3} mol dm^{-3}) are present in CS_2. Judging from the association constant, 41 % of the guest is bound by the host in the solution. The calculated shift $\Delta\delta$ induced by the complexation of the guest molecule is thus 0.43. The good agreement of the observed and calculated induced shifts supports our assumed inclusion structure in solution. Of course, a rapid association–dissociation equilibrium makes all the carbon atoms of the molecule equivalent in solution.

In summary, the structure of the complex in solution was disclosed by the ring current method based on X-ray crystallographic analysis. The experiments presented here have shown that van der Waals interactions between the host and guest play an important role in the complexation in solution.

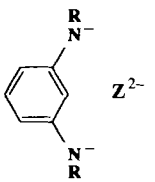
A Dinuclear Tin(II) Amide, a *meta*-Stannylaminocyclophane and Its Orthostannylated Derivative, a Dimeric Trinuclear Tin(II) Cluster**

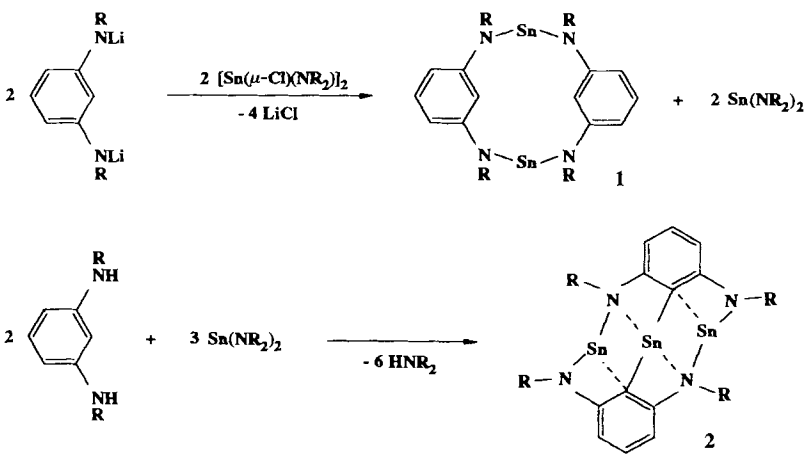
Holger Braunschweig, Christian Drost, Peter B. Hitchcock, Michael F. Lappert,* and Luc J.-M. Pierssens

Trimethylsilylamido ligands such as $Sn(NR_2)_2$ ($R = SiMe_3$)[1] and $Sn(NR_2)(2,6\text{-}tBu_2\text{-}4\text{-}Me\text{-}C_6H_2O)$[2] have played a pivotal role in the study and structural characterization of divalent tin compounds. In 1994 we drew attention to the ligands 1,4-$(R\bar{N})_2C_6H_4$ ($\mathbf{X}^{2-}$) and *trans*-1,4-$(R\bar{N})_2C_6H_{10}$, which provided the first dinuclear divalent tin compounds, 1,4-$(R_2NSnNR)_2C_6H_4$ and *trans*-1,4-$(R_2NSnNR)_2C_6H_{10}$, respectively.[3] The 1,2-isomer $\mathbf{Y}^{2-}$ of the former bisamido ligand had been employed previously as a bridging moiety in $[Mg\{1,2\text{-}(RN)_2C_6H_4\}(OEt_2)]_2$,[4] or as a chelate in M[1,2-$(RN)_2C_6H_4$] (M = Ge,[5] Sn[6]).

Herein we discuss a new bisamido ligand ($\mathbf{Z}^{2-}$), the 1,3-isomer of $\mathbf{X}^{2-}$ and $\mathbf{Y}^{2-}$ ($R = SiMe_3$), which we believe will find a useful place in coordination chemistry, and report on 1) the synthesis of a novel, dinuclear, divalent tin(II) complex, the *meta*-bis(stannylamino)cyclophane **1**, 2) the trinuclear tin(II) cluster compound **2** (a loosely bonded dimer in the crystal), formally an orthostannylated derivative of **1**, and 3) structural details for **1** and **2**, both in the crystalline state and in solution in benzene.



Treatment of the *N,N'*-dilithio derivative of the ligand $\mathbf{Z}^{2-}$ with an equimolar amount of $[Sn(\mu\text{-}Cl)(NR_2)]_2$[7] gave dark red crystals of **1** and $Sn(NR_2)_2$; while orange crystals of **2** were obtained from 1,3-$[R(H)N]_2C_6H_4$ (2 mol) and $Sn(NR_2)_2$ (3 mol) (Scheme 1, Table 1).



Scheme 1. Synthesis of the *meta*-bis(stannylamino)cyclophane **1** and of the Sn^{II} cluster **2** ($R = SiMe_3$).

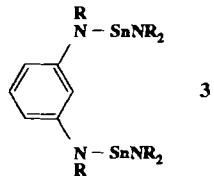
Table 1. Selected analytical and spectroscopic data for **1** and **2** at 298 K in C_6D_6 (^1H) or $PhMe/C_6D_6$. ^1H NMR: 250 MHz; $^{13}C\{^1H\}$ NMR: 62.86 MHz; $^{119}Sn\{^1H\}$ NMR: 186.42 MHz; $^{29}Si\{^1H\}$ NMR: 99.33 MHz; ^{15}N NMR INEPT from ^1H NMR at 500 MHz [a].

1: Dark red; 66% yield; m. p. ca. 120 °C (decomp); δ $^{119}Sn\{^1H\}$ NMR: $\delta = 505$; ^1H NMR: $\delta = 0.27$ (s, 18H, CH_3, $SiMe_3$), 5.56 (t, 1H, arom. CH, $^4J = 2.1$ Hz), 6.00 (dd, 2H, arom. CH, $^4J = 2.2$, $^3J = 7.7$ Hz), 6.81 (t, 1H, arom. CH, $^3J = 7.7$ Hz); $^{13}C\{^1H\}$ NMR: $\delta = 2.49$ (CH_3), 107.29 (C3 and C5, C_6H_4), 121.67 (C1, C_6H_4), 148.55 (C2 and C6, C_6H_4), 151.78 (C4, C_6H_4); EI-MS: *m/z*: 738 (M^+, 56%).

2: Orange; 75% yield; m. p. ca. 295 °C (decomp); sublimation at 5×10^{-6} Torr with bath at 190 °C; $^{119}Sn\{^1H\}$ NMR: $\delta = -888$ (1Sn, $^1J(^{119}Sn,^{119/117}Sn) = 254$ Hz), -501 (2Sn, $^1J(^{119}Sn,^{119/117}Sn) = 250$, $^1J(^{119}Sn,^{117}Sn) = 600$ Hz); ^1H NMR: $\delta = 0.33$ (s, 9H, CH_3, $SiMe_3$), 0.39 (s, 9H, CH_3, $SiMe_3$), 6.33 (d, 1H, arom. CH, $^3J = 8.2$ Hz), 6.33 (d, 1H, arom. CH, $^3J = 7.5$ Hz), 7.23 (t, 1H, arom. CH, $^3J = 8$ Hz); $^{13}C\{^1H\}$ NMR: $\delta = 1.47$ (CH_3), 3.25 (CH_3), 109.75, 109.97 (C3 and C5, C_6H_3), 115.63 (C1, C_6H_3, $^1J(^{13}C,^{119}Sn) = 100$, 198 Hz), 137.76 (C4, C_6H_3), 163.85, 165.03 (C2 and C6, C_6H_3); $^{29}Si\{^1H\}$ NMR: $\delta = 0.59$, 8.05; $^{15}N\{^1H\}$ NMR: $\delta = -245.5$, -234.3; EI-MS: *m/z* = 854 (M^+, 70%).

[a] $^{119}Sn\{^1H\}$ NMR values for $Sn[N(SiMe_3)_2]_2$: $\delta = +776$ at 283 K; for $[Sn(\mu\text{-}Cl)\{N(SiMe_3)_2\}]_2$: $\delta = +138$.

To test whether **1** was an intermediate in the formation of **2** from $\mathbf{ZH}_2$ and $Sn(NR_2)_2$, two $^{119}Sn\{^1H\}$ NMR spectroscopic experiments were carried out. In the first, **1** was mixed with an excess of $Sn(NR_2)_2$ in $PhMe/C_6D_6$ at ambient temperature. After 24 h, three signals were recorded: a quintet centered at $\delta = 774$, due to $Sn(NR_2)_2$, a singlet at $\delta = 506$, due to **1**, and a singlet at $\delta = 586.6$ attributed to the stannylene **3**; the latter two were of comparable intensity. In the second experiment, $\mathbf{ZH}_2$ was mixed with an equimolar amount of $Sn(NR_2)_2$ under similar conditions; the same three signals were observed, although that at $\delta = 586.1$ was accompanied by a signal of roughly equal intensity at $\delta = 596.9$. In the two experiments, the signals at $\delta \approx 590$ had the appearance of quintets, as expected for $^1J(^{119}Sn,^{14}N)$ coupling to two equivalent nitrogen atoms. We conclude that **3** and not **1** is an intermediate in the formation of **2** from $\mathbf{ZH}_2$ and $Sn(NR_2)_2$, and that **3** may have the structure shown and thus may exist in two stereoisomeric forms.



3

Evidently, formation of **2** involves an unprecedented stannylation of the 2-position of a substituted 1,3-diaminobenzene. It is well known that lithiation of an aminobenzene is directed to the *ortho*-position, which is due in part to the increased kinetic acidity in this position as a consequence of the (– I) effect of the electronegative nitrogen atom; an *N*-stannyl substituent, such as that in **3**, would further enhance the (– I) effect. A contributory, and perhaps dominant effect is the capacity of neighboring nitrogen atoms to complex the lithium atom and hence direct it into the 2-position; divalent tin in $Sn(NR_2)_2$ has a low-lying vacant orbital and hence may act as a Lewis acid site.

The crystalline *meta*-bis(stannylamino)cyclophane **1** is a centrosymmetric molecule (Figure 1).[8] The unit cell contains two independent molecules of essentially the same geometry; only bonds and angles for one of the two molecules are discussed. The phenylene rings, which are related by an inversion center, are necessarily parallel (their planes are separated by 3.1 Å), but

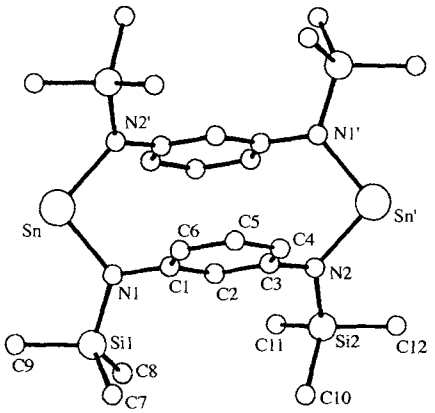

Figure 1. Crystal structure and atom labeling scheme of **1**. Selected bond lengths [Å] and angles [°] for one of the two independent molecules: Sn–N1 2.066(7), Sn–N2′ 2.069(9), Si1–N1 1.732(9), Si2–N2 1.754(7), N1–C1 1.432(13), N2–C3 1.397(13); N1-Sn-N2′ 98.3(3), Sn-N1-C1 120.4(6), Sn-N1-Si1 122.2(5), N1-C1-C2 122.1(8).

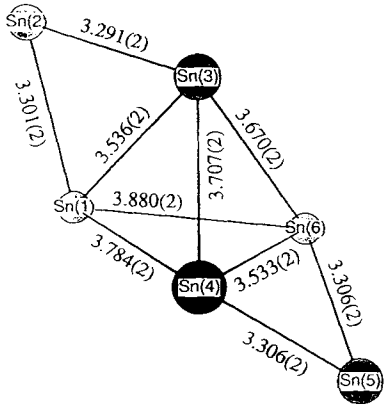

Figure 3. The Sn ··· Sn distances and atom labeling scheme of the Sn_6 skeleton $(\mathbf{2})_2$.

show a sideways displacement such that the angle between the N1-N2-N1′-N2′ and C1-C2-C3-C4-C5-C6 planes is 74°. Each two-coordinate tin atom has a V-shaped relationship to its two nitrogen atom nearest neighbors; the Sn–N bond lengths are 2.066(7) and 2.069(9) Å, and the N-Sn-N′ angle is 98.3(3)°. These values are comparable to the corresponding bond lengths and angles in $Sn[N(SiMe_3)_2]_2$[1b] (2.096(1) and 2.088(6) Å and 104.7(2)°) and in 1,4-$[N(R)Sn(NR_2)]_2C_6H_4$ (2.066(6) and 2.082(7) Å and 101.8(3)°).[3]

The crystalline trinuclear cluster **2** has a nearly equilateral triangular Sn_3 skeleton (Figure 2), which is closely associated with a neighboring Sn_3 unit (Figure 3).[8] The Sn ··· Sn contacts may be compared with 1) the Sn–Sn bond length in tetrahedral tin (2.810 Å), 2) the Sn ··· Sn contacts in polyhedral tin clusters such as penta[1.1.1.]propellane $Sn_5(2,6\text{-}i\text{Pr}_2C_6H_3)_6$ (**A**) (mean Sn_{br}–Sn_{bh} 2.858, Sn_{bh}–Sn_{bh} 3.367 Å (br = bridging, bh = bridgehead)),[9] and 3) the Sn ··· Sn contacts in iminostannylene

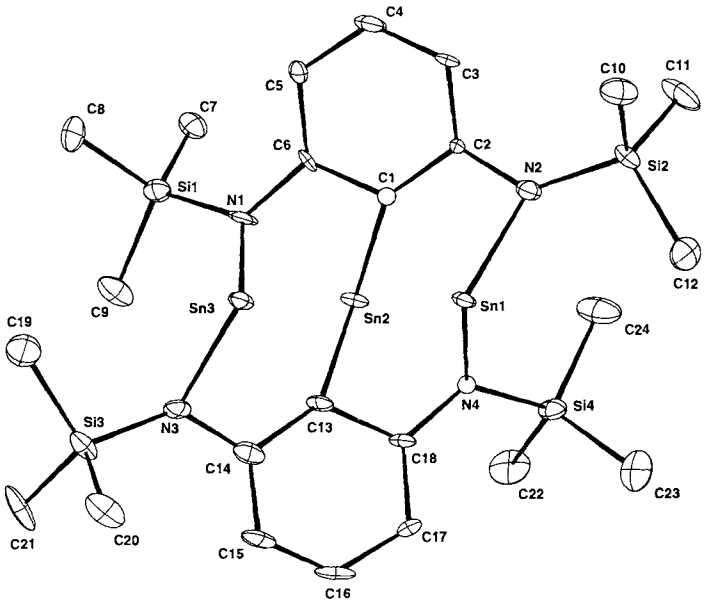

Figure 2. Crystal structure and atom labeling scheme of **2**. Selected bond lengths [Å] and angles [°]: Sn1–N2 2.160(13), Sn1–N4 2.212(13), Sn2–N4 2.483(12), Sn1–C1 2.45(2), Sn2–C1 2.31(2), Sn3–C13 2.42(2), C6–C1 1.39(2), C1–C2 1.41(2), C3–C4 1.37(2); N2-Sn1-N4 104.0(5), N2-Sn1-C1 60.6(5), C1-Sn2-C13 98.7(5), N4-Sn1-C1 90.7(5), Sn2-C1-Sn1 87.9(5), N2-C2-C1 114.4(13), C1-C6-N1 114.6(13), N2-C2-C3 125.9(14).

$[Sn(N\text{t}Bu)]_4$ (**B**) (3.321–3.348 Å);[10] in **A** and **B** and related compounds the longer contacts are regarded as implying little or no bonding interaction.[9–11] The central tin atom Sn2 forms bonds to the 2-phenylene carbon atoms C1 and C13 (mean Sn–C 2.31(2) Å), comparable in length to those in Sn[2,4,6-$t\text{Bu}_3C_6H_2]_2$[12] (mean Sn–C 2.261(4) Å); the other two tin atoms (Sn1 and Sn3) of the Sn_3 unit form somewhat longer contacts to C1 and C13 (mean 2.44(2) Å), respectively. The Sn1–N2 and Sn3–N3 bonds have mean lengths of 2.15(1) Å, while those for Sn1–N4 and Sn3–N1 have mean lengths of 2.22(1) Å; Sn2 also has close contacts to N1 and N4 (2.426(14) and 2.483(12) Å, respectively).

Whereas a solution of **1** in $PhMe/C_6D_6$ is highly symmetrical, the $^{29}Si\{^1H\}$ and $^{15}N\{^1H\}$ NMR spectra (Table 1) reveal that the two trimethylsilylamido groups in **2** are magnetically inequivalent. Furthermore, the ^1H and $^{13}C\{^1H\}$ NMR spectra (Table 1) show that the symmetry is not retained within the aromatic ring.

The reactions of the ligand 1,3-$(R\bar{N})_2C_6H_4$ to give the highly novel complexes **1** and **2**, are being extended to other divalent elements and to heterometallic analogues. The metalation of arenes has previously been reported for lithium, mercury(II), boron ($BCl_3/AlCl_3$), thallium(III), lead(IV), antimony(V) $[(SbF_5)_2]$, tellurium(IV) (e.g. $TeCl_4$ + PhOMe), and some noble metals[13] such as gold(III). For metals of variable oxidation state, these reactions proceed through a higher oxidation state complex; therefore, the present stannylation by a tin(II) amide to give **2** is especially noteworthy and is likely to have further implications.

Experimental Section

1: *n*BuLi (8 mL of a 1.6 M solution in *n*-hexane, 12.69 mmol) was added to a stirred solution of 1,3-$[H(SiMe_3)N]_2C_6H_4$ [14] (1.6 g. 6.35 mmol) in *n*-hexane (100 mL). The solution was gently heated to reflux for 1 h, then cooled to room temperature. $[Sn(\mu\text{-Cl})\{N(SiMe_3)_2\}]_2$ [7] (4.0 g. 6.35 mmol) was added, and the mixture was stirred for 12 h at 25 °C and then at about 60 °C for 1 h. The precipitate was filtered off, and the filtrate was concentrated to about 40 mL in vacuo and cooled to −30 °C to afford dark red crystals of **1** (1.50 g. 66%); correct elemental analysis.

2: 1,3-$[H(SiMe_3)N]_2C_6H_4$ [14] (2.0 g. 7.75 mmol) in *n*-hexane (70 mL) was added dropwise to a solution of $Sn[N(SiMe_3)_2]_2$ [1] (5.1 g. 11.6 mmol) in *n*-hexane (40 mL) at about 25 °C. The reaction mixture was stirred overnight. Volatiles were removed in vacuo to yield an orange solid, which was extracted with toluene (40 mL). Filtration to remove a slight cloudiness, followed by concentration of the filtrate in vacuo, and cooling at −5 °C, yielded orange crystals of **2** (2.6 g. 75%); correct elemental analysis.

Highly Selective Allylic Alkylation with a Carbon Nucleophile at the More Substituted Allylic Terminus Catalyzed by an Iridium Complex: An Efficient Method for Constructing Quaternary Carbon Centers**

Ryo Takeuchi* and Mikihiro Kashio

Iridium complexes have been studied as models for intermediates in catalytic reactions. For example, the oxidative addition reaction of $[IrCl(CO)(PPh_3)_3]$ is well known.[1] Since Crabtree reported that a cationic iridium complex is a highly active catalyst for hydrogenation of alkenes,[2] iridium complexes have received much attention as potential hydrogenation catalysts. Recently an iridium complex catalyzed asymmetric hydrogenation was reported.[3] In contrast, the development of carbon–carbon bond forming reactions catalyzed by iridium complexes lags far behind.[4] Synthetically useful stereo- and regiocontrolled carbon–carbon bond forming reactions are unexplored. We report here on highly selective allylic alkylations with carbon nucleophiles that are catalyzed by an iridium complex [Eq. (a)].

Transition metal complex catalyzed allylic alkylation with carbon nucleophiles is an essential method for constructing complex organic molecules. Palladium,[5] nickel,[6] molybdenum,[7] iron,[8] tungsten,[9] and ruthenium[10] complexes can serve as catalysts. Oxidative addition of the allylic substrate to a low-valent transition metal complex produces a π-allyl complex, which is then attacked by the nucleophile to give the final product. The control of regioselectivity in this reaction is important. One of the most extensively studied transition metals in allylic alkylation is palladium. Generally palladium complexes direct attack at the less substituted allylic terminus. In contrast, molybdenum, tungsten, and ruthenium complexes tend to lead to preferential attack at the more substituted allylic terminus. Complete regiocontrol of the nucleophilic attack at the more substituted allylic terminus is a challenging problem.

The reaction of (*E*)-2-hexenyl acetate (**1a**, X = Ac) with diethyl malonate anion in the presence of $[Ir(cod)Cl]_2$ gave a mixture of **2a** and **3a**. Product **2a** arose from alkylation at the more substituted allylic terminus and **3a** from alkylation at the less substituted allylic terminus. The addition of phosphorus ligands had a significant effect on the selectivity and yield of products. The results are summarized in Table 1. $P(OPh)_3$ was found to be the most effective ligand. The reaction was complete in three hours at room temperature to give an excellent yield of products. Compound **2a** was obtained in 96% selectivity (entry 1); the alkylation was highly selective at the more substituted allylic terminus. The reaction using $P(OEt)_3$ as a ligand gave a comparable yield of products with much less selectivity (entry 2). When a more electron-donating phosphorus ligand such as PPh_3 and $P(nBu)_3$ was used, products were obtained in poor yields (entries 4 and 5).

Table 1. Effect of the phosphorus ligand on the iridium complex catalyzed allylic alkylation of **1a**, X = Ac, with the anion of diethyl malonate [a].

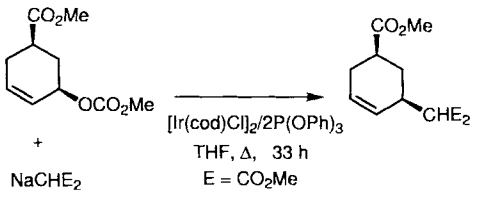
[a] A mixture of **1** (2 mmol), nucleophile (4 mmol), $[Ir(cod)Cl]_2$ (0.04 mmol), $P(OPh)_3$ (0.16 mmol), and THF (10 mL) was stirred under Ar at room temperature. [b] Yield of isolated product. [c] Determined by gas chromatography. [d] Heated at reflux. [e] 6 mmol Nucleophile. [f] 1:1 Mixture of diastereomers. [g] 0.08 mmol $[Ir(cod)Cl]_2$, 0.32 mmol $P(OPh)_3$.

more substituted allylic terminus occurred with high regioselectivity. The reactions proceeded smoothly at room temperature except in the case of allylic alcohol **1a**, X = H. The sodium salt of ethyl acetoacetate also could be used as carbon nucleophile (entry 2). The reactivity of carbonate **1a**, X = CO_2Me (entry 4), was comparable to that of acetate **1a**, X = Ac (entry 1). Allylic esters are generally used as substrates because of their high reactivity in oxidative additions with low-valent transition metal complexes. The palladium complex catalyzed reaction of allylic alcohols with carbon nucleophiles is reported to be nonregioselective and requires extreme reaction conditions.[11] With iridium catalysis, allylic alcohol **1a**, X = H, underwent regioselective alkylation at the more substituted allylic terminus under mild conditions (entry 5). The reaction of 1-hexen-3-yl acetate, a regioisomer of **1a**, X = Ac, gave products **2a** and **3a** in 85% yield under the same reaction conditions with a ratio of 95:5. The results strongly suggest the intermediacy of a π-allyl iridium complex. Acetates **1b** and **1c** were readily alkylated at the more substituted allylic terminus (entries 6 and 7). 3-Methyl-2-butenyl acetate failed to react. The replacement of the acetyl leaving group with a trifluoroacetyl group enhanced the reactivity of the allylic substrate considerably. Product **2d** was obtained with 95% selectivity (entry 8). The most unique aspect of the iridium complex catalyzed reactions is demonstrated in the reactions of **1e**–**1g**. Regiospecific alkylation at the tertiary allylic terminus resulted in the construction of a quaternary carbon center (entries 9–14), a feature in numerous natural products.

The regioselectivity of the allylic alkylation is controlled by three factors: 1) the steric interaction between the incoming nucleophile and allylic terminus, 2) the charge distribution of the π-allyl ligand on the metal center, and 3) the stability of the resulting alkene–metal complex as the initial product. The results described here indicate that the first is not important. With regards to the third factor, it is clear that nucleophilic attack at the more substituted allylic terminus results in formation of the more stable terminal alkene complex[12] as the initial product. $P(OPh)_3$ plays a crucial role with regards to the second factor. Since it is a better π-acceptor,[13] it promotes carbonium ion character at the more substituted allylic terminus in the π-allyl complex[14] and directs the nucleophilic attack to this position. In agreement with this, when a ligand with weaker acceptor properties was used such as $P(OEt)_3$, the reaction was much less selective (Table 1, entry 2).

The stereochemistry of the reaction was also examined. (*Z*)-5-(Methoxycarbonyl)-2-cyclohexen-1-yl methyl carbonate was treated with the sodium salt of dimethyl malonate [Eq. (b)].



(b)

Unlike the reactions with acyclic systems, this reaction was quite sluggish and did not go to completion. The product was obtained in 37% yield; the starting material was recovered in 40% yield. The product with net retention of configuration was obtained exclusively, which suggests that the reaction proceeds by a double inversion mechanism.[15, 16]

In conclusion, iridium complexes were found to be new and efficient catalysts for the allylic alkylation of acyclic systems. The regioselectivity is opposite to that achieved with palladium catalysts. Currently we are testing synthetic applications of this reaction in asymmetric synthesis.

Experimental Section

Table 2, entry 13: A solution of **1g** (393 mg, 2.0 mmol), $P(OPh)_3$ (49.6 mg, 0.16 mmol), and $[Ir(cod)Cl]_2$ (26.9 mg, 0.04 mmol) was stirred in 5.0 mL of THF under Ar atmosphere. In a separate flask, diethyl malonate (961 mg, 6.0 mmol) was added to a slurry of sodium hydride (144 mg, 6.0 mmol) in 5.0 mL of THF. The resulting clear solution was added to the first solution by syringe, and the mixture was stirred at room temperature for 18 h. The progress of the reaction was monitored by gas chromatography. After complete consumption of **1g** the reaction mixture was partitioned between ether and water. The organic layer was separated and the aqueous layer was extracted with ether. The combined organic layers were concentrated in vacuo. The residue was purified by column chromatography (*n*-hexane/ethyl acetate 98/2) to give **3g** (505 mg, 85%).

Dihydrogen Formation in a Trihydride Metallocene and Its Elimination, Both Assisted by Lewis Acids: The $[Cp_2NbH_3]+BH_3$ System**

Santiago Camanyes, Feliu Maseras, Miquel Moreno, Agustí Lledós,* José M. Lluch,* and Juan Bertrán

Before 1984 hydrogen coordination to a transition metal was assumed to involve breaking of the H–H bond to produce two separate hydride ligands.[1] Nowadays the existence of coordinated molecular hydrogen in certain transition metal complexes is well established.[2] The number of new dihydrogen complexes discovered has not ceased to grow, and the reinvestigation of polyhydride systems is opening new routes to dihydrogen complexes. These two structures are indeed closely related.[3] It has been shown that trihydride metallocene complexes possess a thermally accessible dihydrogen state.[4] The presence of such a state has been used to explain the abnormally large and temperature-dependent NMR J_{HH} coupling constants, a phenomenon associated with the quantum mechanical exchange of a pair of hydrides.[4, 5] Recent studies have revealed that the replacement of one hydride by a π-acceptor ligand in niobocene and tantalocene trihydride complexes enables the observation and characterization of the first stable dihydrogen complexes of Group 5.[6] It has been suggested that the formation of an adduct between the trihydride complex and a Lewis acid could similarly stabilize the dihydrogen species by decreasing the electron density around the metal.[7] These arguments have been used to explain the exchange couplings observed in Lewis acid adducts of niobocene trihydrides.[7, 8]

The most common reaction exhibited by these trihydride species is the loss of molecular hydrogen on heating.[9] It is interesting to note that addition of a HBR_2 Lewis acid clearly lowers the temperature for hydrogen evolution.[10] In this communication we present, for the first time, ab initio DFT calculations indicating that the formation of an adduct between a trihydride complex and a Lewis acid converts the dihydrogen structure into a stable complex and, in addition, so assists the loss of molecular hydrogen that it becomes quite easy. To this end we have performed an ab initio density functional theory[11] (DFT) study on the $[Cp_2NbH_3]+BH_3$ system.[12–17] BH_3 has been chosen as the simplest model of a Lewis acid.

Figure 1. Energies [kcal mol^{-1}] of the stationary points located. Compounds **1**, **2a**, **2b**, and **4** correspond to minimum energy structures; **3** is a transition state.

In Figure 1 the energies of all the stationary points (that is, points of zero gradient) are presented schematically. The corresponding geometries are sketched in Figure 2. Structure **1** is for the $[Cp_2NbH_3]$ trihydride.

BH_3 can interact with any of the three hydrides of $[Cp_2NbH_3]$. This interaction leads to two different minimum energy adducts (**2a** and **2b**). Geometrical analysis of **2a** shows a strong interaction between the BH_3 and the central hydride that lengthens the distance between Nb and the central H by 0.08 Å with respect to that in **1**. Furthermore, the BH_3 fragment, which is planar when isolated, has already adopted a nonplanar geometry that begins to resemble the tetrahedral BH_4^- anion. This affinity of the Lewis acids for the hydride ligands of metallocene complexes had already been observed experimentally for $[Cp_2MH_3]$ (M = Nb, Ta)[18a] and $[Cp_2Nb(CO)H]$.[18b] Adduct **2a** involves a strong interaction between the two fragments as indicated by the large stabilization of this complex with respect to the separated partners (14.6 kcal mol^{-1}, see Figure 1). However, this interaction is weaker than that between NH_3 and BH_3, which is 32.4 kcal mol^{-1} at our level of calculation. For comparison, an

ab initio MP2 calculation with a triple-ζ, double-polarized basis set gives a value of 30.7 kcal mol^{-1}[19] for the dissociation energy of the NH_3-BH_3 complex, whereas the approximate experimental value is 31.1 kcal mol^{-1}.[20]

Very interestingly, the interaction of BH_3 with a lateral hydride leads to the formation of dihydrogen complex **2b**. The energy of this structure is only 3.3 kcal mol^{-1} above that of the trihydride **2a**. The formation of this stable η^2-H_2 complex can be attributed to the lower electron density at the niobium metal caused by the presence of the Lewis acid attached to one of its hydride ligands. When two of the hydrogen atoms are fixed in the same positions as dihydrogen in **2b** and geometry of **1** is optimized, the energy is 6.7 kcal mol^{-1} higher than the trihydride minimum. Since attempts of optimization starting from this constrained structure always revert to the original trihydride complex **1**, the stabilizing role of the Lewis acid on the dihydrogen complex is confirmed.

The structures of **2a** and **2b** are similar to those of the recently isolated $[Cp_2NbH_2L]^+$ (L = $P(OEt)_3$, PMe_2Ph) and $[Cp_2TaH_2(CO)]^+$ species in which both a transoid dihydride and a cisoid dihydrogen isomer have been shown to exist.[6]

The existence of the dihydrogen structure **2b** led us to postulate that addition of a Lewis acid could facilitate the elimination of molecular hydrogen from the original trihydride complex. We indeed succeded in locating a transition state **3**, which corresponds to the elimination of H_2 from the dihydrogen complex **2b**. This transition state is 11.7 kcal mol^{-1} above the dihydrogen minimum **2b** and 15.0 kcal mol^{-1} above the most stable trihydride complex **2a**. However, as seen in Figure 1, this transition state is only 0.4 kcal mol^{-1} above the separated $[Cp_2NbH_3]$ and BH_3. This result is consistent with the experimental fact that a Lewis acid lowers the temperature at which molecular hydrogen is eliminated.[10] In comparison, direct molecular hydrogen elimination from the trihydride complex **1** to give the coordinatively unsaturated $[Cp_2NbH]$ complex implies a monotonous energy increase of 30.8 kcal mol^{-1}. The geometry of transition state **3** is also depicted in Figure 2. Analysis of this geometry explains why the molecular hydrogen elimination is facilitated by the presence of the BH_3 fragment. The H_2 molecule being eliminated is almost completely formed in this transition state (the H–H distance is 0.754 Å, close to the value of the free hydrogen molecule), and it is already far away from the rest of the molecule (the Nb–H distances are 2.410 and 2.660 Å). To compensate for this loss of hydrogen, a new bond between the metal and one of the hydrogen atoms of the BH_3 molecule (H4) is forming (the Nb–H4 distance is 2.713 Å). The main components of the transition vector also point to this mechanism in which elimination of the dihydrogen molecule is coupled to motion of the H1–BH_3 fragment which reorganizes in order to form a tetrahydroborate ligand coordinated in a η^2 way to the niobium.

The final product of this reaction (**4**) confirms the formation of the η^2-BH_4 complex. Its geometry (Figure 2) reproduces the coordination pattern observed in an X-ray study of this complex performed several years ago.[21] It is also very close to the X-ray structure of $[Cp_2Nb\{BH_2(C_8H_{14})\}]$ prepared by addition of 9-borabicyclenonane to $[Cp_2NbH_3]$.[10] The presence of a HBR_2 Lewis acid allows the final product to remain coordinatively saturated; consequently, the global reaction is now highly exothermic.

To summarize, we have shown that interaction between a Lewis acid and a trihydride metallocene complex stabilizes the dihydrogen structure and facilitates molecular hydrogen elimination. This result could be very interesting for the study of the storage and elimination of H_2 in transition metal complexes. Finally although the BH_3 molecule is a very crude model of a Lewis acid, we believe that these conclusions can be generalized. Additional theoretical work with a set of more realistic Lewis acids is presently in progress in our laboratory.

[12] Calculations have been carried out with the GAUSSIAN 94 series of programs [13] using the DFT methodology with the nonlocal B3LYP functional [14]. This computational method has been proved to yield satisfactory results in the case of $[Cp_2MH_3]$ complexes (M = Nb, Ta) [4c]. The geometry optimization of the Cp rings was always restricted to a local C_{5v} symmetry. The stationary points were located with the Schlegel gradient minimization algorithm [15]. If the approximate derivative matrix is forced to contain zero or a single negative eigenvalue, the optimization converges to a minimum or a transition state, respectively.

[16] An effective core potential operator (ECP) has been used to replace 28 core electrons of niobium [17a]. The basis set used for the metal was that associated with the pseudopotential [17a] with a standard valence double-ζ LANL2DZ contraction [13]. The 6-31G(d,p) basis set was used for the boron and hydrogen atoms of the BH_3 group, and for the hydrogen atoms directly attached to the metal [17b,c,d]. The double-ζ 6-31G valence basis set was used for the C and H atoms of the Cp ligands [17e].

Defining the Conformation of Lewis Acid/Lewis Base Complexes: Crystallographic Evidence for Simultaneous σ and π Donation by a Carbonyl Group to a Divalent Boron Lewis Acid**

Michael C. Amendola, Kenneth E. Stockman, Diego A. Hoic, William M. Davis, and Gregory C. Fu*

Because Lewis acids are extraordinarily versatile catalysts,[1] a great deal of effort has been devoted to the development of *chiral* Lewis acid catalysts.[2, 3] Defining the conformation about the dative bond between substrate and Lewis acid is one of the important issues faced in the design of an effective catalyst (for example, see **A**).[4, 5] Several successful strategies for restricting this rotational degree of freedom, typically through a two-point interaction between reactant and catalyst, have been described.[6, 7]

A

Our approach to addressing this conformational issue focuses on the development of Lewis acids that bear both an empty σ-symmetry and an empty π-symmetry orbital (Figure 1). These

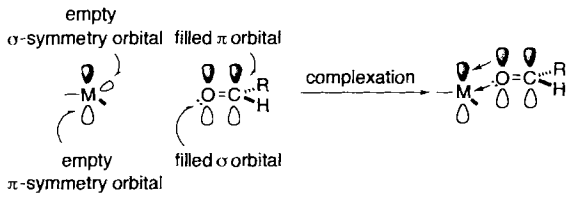

Figure 1. Simultaneous σ and π donation by a carbonyl group to a divalent Lewis acid.

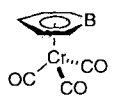
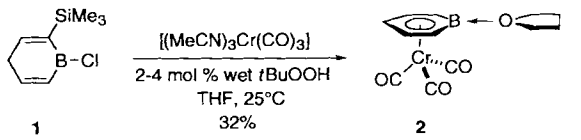
vacant orbitals can simultaneously accept electron density from an oxygen lone pair and from the π system of a carbonyl group.[8] The distinguishing feature of this approach is the π-symmetry interaction, which at once organizes the donor–acceptor complex and activates the substrate toward nucleophilic addition.[9] In this report we provide structural data[10] that suggests that a π interaction of the type illustrated in Figure 1 can indeed define the conformation of a complex formed between a carbonyl compound and a Lewis acid.



B

The [(η^6-borabenzene)Cr(CO)$_3$] framework (**B**) seemed well-suited for our initial studies, since the divalent boron atom bears both an empty σ-symmetry orbital and an empty, relatively low-lying π-symmetry orbital, the π* orbital of the aromatic ring;[11, 12] complexing borabenzene to Cr(CO)$_3$, a powerful electron-withdrawing group, should significantly lower the energy of the π* orbital of [(η^6-borabenzene)Cr(CO)$_3$] below that of borabenzene itself.[13] Treatment of boracycle **1**[14] with [(MeCN)$_3$Cr(CO)$_3$] in THF affords air- and moisture-sensitive [(η^6-borabenzene–THF)Cr(CO)$_3$] (**2**) [Eq. (a)].[15] An



(a)

1 **2**

X-ray diffraction study of **2** reveals that the THF binds to the boron atom with a slightly distorted trigonal-planar geometry at oxygen (∢B-O4-C4 + ∢B-O4-C7 + ∢C4-O4-C7 = 356°; Figure 2 top and Table 1).[16] The B–O bond in **2** (1.467 Å) is

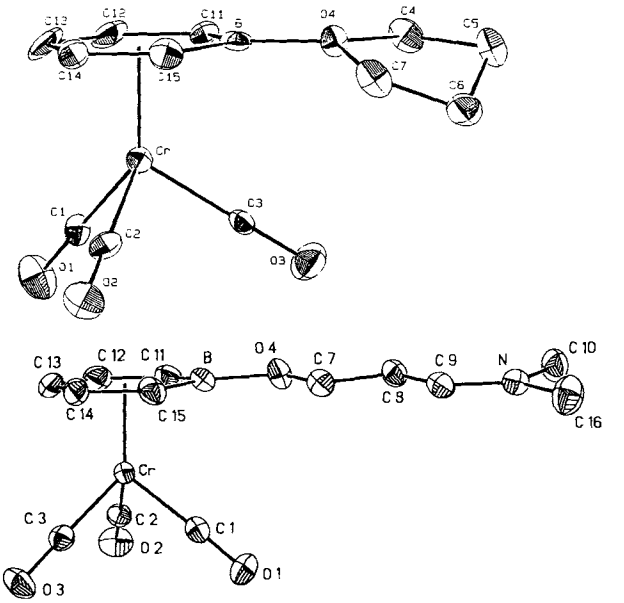


Figure 2. X-ray structure analyses of **2** (top) and **3** (bottom); ORTEP representations with thermal ellipsoids drawn at the 35% probability level.

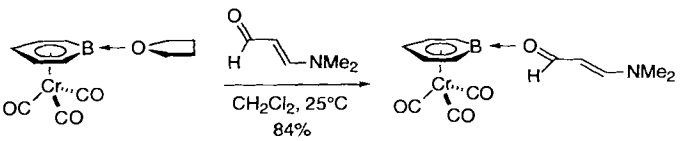
markedly shorter than that observed in any other boron-based THF complex (1.51–1.59 Å).[17, 18] The structure is consistent with donation from a filled π-symmetry oxygen orbital to an empty π-symmetry borabenzene orbital.

Complex **2** reacts with 3-(dimethylamino)acrolein to provide [η^6-borabenzene-(3-(dimethylamino)acrolein)]Cr(CO)$_3$] (**3**) [Eq. (b)].[19] The crystal structure of **3** (Figure 2 bottom,



(b)

2 **3**

Table 1)[20, 21] displays the following features, each of which is typical for Lewis acid/aldehyde complexes:[4] 1) the Lewis-acidic atom lies in the plane of the carbonyl group (∢B-O4-C7-C8 = −176°); 2) the Lewis acid binds *syn* to the hydrogen of the aldehyde, rather than *syn* to the carbon substituent;[22, 23] and 3) the Lewis acid-oxygen-carbon angle is roughly 120° (∢B-O4-C7 = 123°).

[a] The sign of the torsion angle is positive if, when on looking from atom 2 to atom 3, a clockwise motion of atom 1 would superimpose it on atom 4.

The most noteworthy feature of the crystal structure of complex **3** is the coplanarity of the borabenzene ring and the α,β-unsaturated aldehyde (Figure 2 bottom; root mean square distance = 0.05 Å from the plane defined by the 13 non-hydrogen atoms), a conformation that allows interaction between π-symmetry orbitals of the two fragments (Figure 1). The bond lengths in **3** are indicative of an unusually strong interaction between the Lewis acid and the carbonyl group. As in the case of THF adduct **2**, the B–O length in **3** (1.451 Å) is extremely short for a dative bond, approaching the 1.400 Å value found for the covalent B–O bond of Na[(η^6-borabenzene-OMe)Cr(CO)$_3$].[24] In contrast, all other B–O distances for complexes between boron Lewis acids and carbonyl compounds fall in the 1.49–1.59 Å range.[25, 26] The C=O and $C_{carbonyl}$–C_α bonds in **3** have comparable lengths, suggesting that the π electrons of 3-(dimethylamino)acrolein are delocalized effectively upon complexation to [(η^6-borabenzene)Cr(CO)$_3$] (Table 2[27]).

Table 2. Bond lengths [Å] in bound and free 3-aminoacroleins.

Parameter	**3**	free 3-aminoacrolein
B–O	1.451(5)	–
C=O	1.316(4)	1.23
$C_{carbonyl}$–C_α	1.345(5)	1.41

NMR data are also indicative of a strong interaction between the Lewis acid and the Lewis base components of adduct **3**. As illustrated in Figure 3, the ^{1}H and ^{13}C NMR resonances of 3-(dimethylamino)acrolein are shifted significantly downfield upon binding to boron.[28–30]

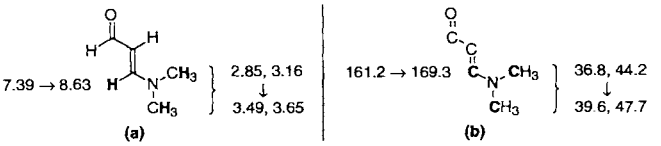

Figure 3. NMR chemical shifts [δ] of 3-(dimethylamino)acrolein and complex **3**. a) ^{1}H NMR data (free → complexed aldehyde); b) ^{13}C NMR data (free → complexed aldehyde).

This structural study provides the first experimental support for the suggestion that donation of electron density simultaneously by a lone pair and by the π system of a carbonyl group to a Lewis acid can organize the resulting complex.[31] In contrast to some of the previous strategies for defining the conformation of Lewis acid/Lewis base adducts, this approach does not require a two-point interaction between the two components. Our current efforts are directed toward developing chiral catalysts based on the [(η^6-borabenzene)Cr(CO)$_3$] framework.

Experimental Section

Reactions were carried out under an atmosphere of nitrogen in oven-dried glassware inside a Vacuum Atmospheres HE-43-2 glove box.

2: This reaction is sensitive to the amount of wet *t*BuOOH used, and the optimum stoichiometry varies with the batch of boracycle **1**. Therefore, to determine the appropriate stoichiometry of wet *t*BuOOH to employ for a given batch of **1**, three reactions were routinely set up side-by-side, wherein *t*BuOOH (1.0 μL, 2.0 μL, or 3.0 μL; 70% in H_2O) was added to a solution of boracycle **1** (50 mg, 0.27 mmol) in 1.5 mL of THF at room temperature. The resulting solutions were immediately added to vials containing [(MeCN)$_3$Cr(CO)$_3$] (70 mg, 0.27 mmol). The vials were then capped and shaken vigorously until most of the [(MeCN)$_3$Cr(CO)$_3$] had dissolved (ca. 2 min). The reaction mixtures were allowed to stand at room temperature for 10 min (during which time the yellow product may begin to precipitate), and then they were cooled to −35 °C. (If too little (dark purple-brown reaction mixture) or too much (yellow-orange reaction mixture) *t*BuOOH was present, then no product precipitated from solution; a successful reaction maintained a yellow-brown color, from which complex **2** precipitated as a yellow-brown solid.) The supernatant of the successful reaction was removed by pipet, and unreacted [(MeCN)$_3$Cr(CO)$_3$] was removed by washing the remaining solid with Et_2O until the washings were colorless. The resulting yellow-brown solid turned yellow upon washing with THF (3 × 1 mL). The Et_2O and THF washings were added to the supernatant and cooled to −35 °C, thereby providing a second crop of crystals. Combining the two crops afforded THF adduct **2** in 30% yield. Once the optimum stoichiometry of wet *t*BuOOH had been determined by this procedure, the successful reaction could be scaled up; scaling this process up by a factor of four reproducibly furnished **2** in 30–35% yield. ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 5.57 (approx. t, 2H, J = 7.2 Hz), 4.94 (t, 1H, J = 6 Hz), 4.88–4.84 (br. m, 4H), 3.91 (d, 2H, J = 9.9 Hz), 2.43–2.39 (br. m, 4H); ^{13}C NMR (75 MHz, CD_2Cl_2): δ = 238.0, 105.5, 84.0, 80.2, 77 (br.), 25.6; ^{11}B NMR (96 MHz, CD_2Cl_2): δ = 28.5; FTIR (THF): $\tilde{\nu}$ [cm^{-1}] = 2926, 2681, 1967, 1932, 1846, 1829, 1460; HRMS calcd for $C_{12}H_{13}BCrO_4$: 284.0312; found: 284.0311.

3: Neat 3-(dimethylamino)acrolein (65 mg, 0.66 mmol) was added to a solution of **2** (50 mg, 0.18 mmol) in 2.0 mL of CH_2Cl_2 at room temperature. After standing for 10 min at room temperature, the solution was cooled to −35 °C overnight, during which time **3** crystallized as orange microcrystals. The supernatant was decanted, and the solid was washed with hexane and then dried, affording 57 mg (84%) of

pure **3**. Compound **3** decomposes at $-35\,^{\circ}C$ over a period of months. ^1H NMR (300 MHz, [D$_7$]DMF): $\delta = 8.63$ (d, 1H, $J = 6.9$ Hz), 8.46 (d, 1H, $J = 6.6$ Hz), 6.39 (approx. t, 1H, $J = 6.6$ Hz), 5.34 (dd, 2H, $J = 5.4$, 3.6 Hz), 4.86 (t, 1H, $J = 3.6$ Hz), 3.89 (d, 2H, $J = 5.1$ Hz), 3.65 (s, 3H), 3.49 (s, 3H); ^{13}C NMR (75 MHz, [D$_7$]DMF): $\delta = 239.1$, 177.1, 169.3, 106.1, 103.3, 82.1, 80 (br.), 47.7, 39.6; ^{11}B NMR (96 MHz, [D$_7$]DMF): $\delta = 28.8$; FTIR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}]: 1922, 1821, 1649, 1605; analysis calcd for $C_{13}H_{14}BCrNO_4$: C 50.15, H 4.54, N 4.50; found: C 50.13, H 4.55, N 4.36; HRMS calcd for $C_{13}H_{14}BCrNO_4$: 311.0421; found: 311.0422.

A Tandem Approach to Graft and Dendritic Graft Copolymers Based on "Living" Free Radical Polymerizations**

Robert B. Grubbs, Craig J. Hawker,* Julian Dao, and Jean M. J. Fréchet*

Interest in the accurate control of macromolecular architecture, an increasingly important theme in polymer science, is being driven by the desire to prepare advanced materials with new and/or improved properties.[1] Two methods commonly used to achieve these goals are the introduction of branching to the polymer backbone and the formation of block copolymers between otherwise incompatible materials. Dendrimers provide dramatic examples of the effect of branching on macromolecular structures and properties, as a number of their physical properties differ distinctly from those of normal linear polymers. Similarly, the unique features of block, graft, and star copolymers have been well-documented.[2]

Regularly branched dendrimers have previously been prepared only through lengthy multistep syntheses, which has limited their availability.[3] Several similar though structurally less perfect classes of three-dimensional polymers have been studied in the hope that their properties might approximate those of dendrimers. Among these systems are hyperbranched[4] and dendritic graft (dendrigraft) macromolecules,[5] also known as combburst or arborescent graft polymers. Preparations of the these dendrigraft systems are of special interest as they typically utilize commercially available monomers to produce exceptionally large and highly branched structures in only a limited number of steps. Pioneering efforts toward the realization of these dendrigraft macromolecules have employed "living" anionic[6] and cationic polymerizations[7]—methods that are frequently used to prepare block copolymers.

To extend the range of monomers that may be used as well as macromolecular architectures that may be obtained we have examined the use of "living" free radical polymerizations for the preparation of novel graft and dendrigraft systems. The synthesis is based on a sequential two-step free radical approach in which an initial nitroxide-mediated "living" free radical polymerization[8, 9] is followed by "living" atom transfer radical polymerization (ATRP)[10] to yield graft and dendrigraft products. These two processes can be combined owing to their inherent chemical differences. While nitroxide-mediated polymerizations are thermally activated at temperatures of approximately 125 °C and need no added reagents for growth, the ATRP procedure requires the addition of a $Cu^{I}Cl$/2,2′-bipyridine complex to the reaction mixture in order for polymerization to proceed. Therefore, a linear backbone incorporating latent ATRP-initiating sites may be grown by nitroxide-mediated "living" free radical polymerization. Subsequently, without further chemical modification, the growth of grafted chains may be initiated by the addition of a $Cu^{I}Cl$/2,2′-bipyridine complex. Such a tandem approach thus readily allows the synthesis of a variety of branched macromolecular architectures with a broad range of chemical compositions in only two steps.

This strategy is illustrated in Figure 1, where the nitroxide-mediated "living" free radical polymerization of a 19:1 mixture of styrene and *p*-(4′-chloromethylbenzyloxymethyl)styrene (**1**),

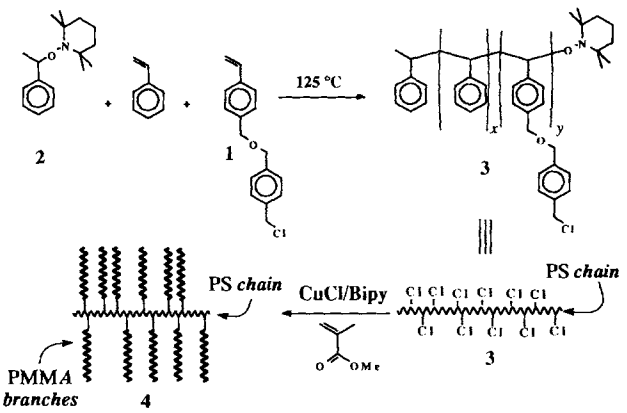

Figure 1. Preparation of a graft copolymer by two consecutive "living" polymerizations. Structures **3** and **4** are shown schematically. Bipy = 2,2′-bipyridine derivative (see also Tables 1 and 2); PS = polystyrene; PMMA = poly(methyl methacrylate).

initiated by **2**, produces the linear polymer **3**. As detailed previously,[8] both the molecular weight of **3** ($M_n = 16300$, $M_w/M_n = 1.14$) and its composition can be controlled accurately by regulating the molar ratio of monomer to initiator,[11] and the "living" free radical approach is tolerant of the reactive functionality in monomer **1**.[12]

The chloromethyl groups incorporated in the polymer **3** in the first step of the synthesis may now be used as graft-initiating sites for the ATRP-based polymerization of acrylic or styrenic monomers. Accordingly, polymerization of methyl methacrylate and **3** in the presence of $Cu^{I}Cl$ and 4,4′-dinonylbipyridine at 115 °C for 48 hours was found to give the block copolymer **4h** in 75% yield after purification (Table 1). Analysis by gel permeation chromatography (GPC) indicated that the polydispersity

of **4** increased only slightly ($M_w/M_n = 1.28$), while the molecular weight increased substantially ($M_n = 119000$) from that of the starting backbone polymer **3**. The molecular weight of copolymer **4l** determined[13] by multiangle laser light scattering (MALLS) is $M_w = 214000$, a value that is supported by comparative NMR measurements ($M_n = 205000$). It is noteworthy that a range of well-defined structures such as **4** may be obtained in two easy-to-conduct reactions under mild conditions (Table 1). In agreement with several recent reports for linear polymerizations, the use of alkylated bipyridines resulted in a marked decrease in the polydispersity of the graft systems.[10c, d]

The deliberate incorporation of a benzyl ether group into the chloromethyl monomer **1** allows the polydispersity and molecular weight of the grafted chains to be elucidated by cleavage of the graft branches with trimethylsilyl iodide (TMSI).[14] For example, the starting material **4e** contains polystyrene grafts connected to a polystyrene backbone by cleavable benzyl ether linkages (Table 1). Reaction of this polymer with TMSI resulted in a dramatic reduction in molecular weight; the cleaved product has a narrow, unimodal molecular weight distribution ($M_n = 15000$, $M_w/M_n = 1.29$). This result is in good agreement with the predicted graft molecular weight of 17000 and confirms the formation of a graft structure in which the molecular weight and polydispersity of the grafted arms can be controlled.

The potential to perform a series of "living" free radical polymerizations is also the key to the synthesis of more complex macromolecular architectures such as dendrigraft macromolecules. The synthesis of these novel polymers again utilizes low-polydispersity chloromethylated linear polystyrene as the starting material. The first reaction carried out on the pendant chloromethyl groups is their nucleophilic displacement by the sodium salt of the initiator **5** to yield the TEMPO-functionalized linear polymer **6** (TEMPO = 2,2,6,6-tetramethylpiperidine-*N*-oxide; Figure 2). Nitroxide-mediated polymerization of a 19:1 amixture of styrene and chloromethylated monomer **1** using the TEMPO-functionalized **6** as a polymeric initiator then afforded the chloromethyl-functionalized graft copolymer **7** in 71% yield after purification. A small amount (roughly 1–2%) of lower molecular weight (≈ 10000 amu) impurity resulting from a competing autopolymerization process was easily removed from graft copolymer **7** by precipitation.[15]

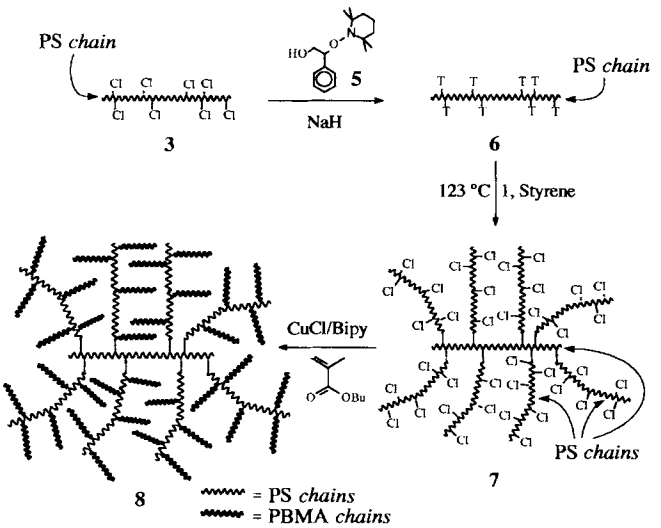

Figure 2. Preparation of a dendrigraft copolymer by three consecutive "living" polymerizations. The letter T in structure **7** represents the TEMPO group introduced by reaction of the chloride groups of **3** with the anion of **6**. PMBA = poly(*n*-butyl methacrylate).

Owing to the chloromethyl groups on the grafts of polymer **7**, this comb polymer can be readily used as a complex polymeric initiator for the synthesis of more highly branched dendrigraft macromolecules through ATRP (Table 2). For example, the reaction of **7** with *n*-butyl methacrylate and Cu^{I}Cl/4,4′-dinonylbipyridine at 115 °C affords the dendrigraft macromolecule **8k** in 58% yield after purification. The block copolymeric nature of dendrigraft **8** was demonstrated in its ^{1}H and ^{13}C NMR spectra, which showed resonances for both the polystyrene chains and the poly(*n*-butyl methacrylate) chains, and by differential scanning calorimetry, which revealed glass transition temperatures at 30 °C and 100 °C, correlating with phase-separated poly(*n*-butyl methacrylate) and polystyrene domains. A comparison of size exclusion chromatography (SEC) traces (Figure 3) for the linear **3**, graft **7**, and dendrigraft **8h** macromolecules also supports the synthetic strategy and the structure proposed for macromolecule **8**. As expected, the molecular weight increased dramatically with each of the two branching steps, while the polydispersity increased only slightly[16] from $M_w/M_n = 1.14$ for the linear polymer **3** to $M_w/M_n = 1.38$ for dendrigraft macro-

Table 2. Synthesis of dendrigraft polymers **8** [a].

molecule **8h** (Table 2). As can be seen in Figure 3, each of the grafting steps appears to be very efficient; the three distribution curves are well-separated and have regular shapes with little overlap. MALLS studies of dendrigraft **8h** give an actual molecular weight ($M_w = 1\,140\,000$) much higher than that measured by SEC ($M_w = 480\,000$), indicating that these macromolecules are highly branched structures that adopt more globular conformations in solution than their linear analogs.

As detailed in Table 2, the use of alkylated bipyridine derivatives was again observed to give products of lower relative polydispersity. However, when the reactions were conducted at higher temperatures and for extended times, insoluble crosslinked materials formed in every case. Presumably, this crosslinking is due to coupling side reactions of some of the numerous growing radical chain ends. While the occurrence of such coupling reactions is only negligible during the synthesis of linear polymers[8–10] or moderately branched star systems[17] by "living" free radical procedures, the presence of a large number of radical centers on the same macromolecule in these dendrigraft polymers greatly increases the probability of crosslinking. For example, the graft copolymer **7** has approximately 50 initiating sites per molecule, while its linear precursor **3** has less than 10.

In conclusion, a novel tandem approach based on "living" free radical polymerizations has been demonstrated to be a viable technique for the synthesis of a wide range of graft and dendritic graft polymers. Complex architectures can be prepared in a few steps from commercially available monomers, and the compatibility of "living" free radical polymerizations with a variety of reactive groups suggests that a range of functionalities may be readily incorporated into such structures. The molecular weight of the grafted chains is controlled by the amount of monomer added, while low polydispersity is maintained in both graft and dendrigraft systems.

Experimental Section

1: A mixture of 4-hydroxymethylstyrene [18] (13.4 g, 100 mmol) and NaH (4.4 g, 60% dispersion in oil, 110 mmol) in anhydrous THF (100 mL) was stirred under Ar at room temperature (RT) for 15 min. A solution of α,α'-4-dichloro-*p*-xylene (35.0 g, 200 mmol) in anhydrous THF (100 mL) was then added dropwise. The reaction mixture was heated at reflux under Ar for 18 h, cooled, and concentrated to dryness. The residue was then partitioned between CH_2Cl_2 (200 mL) and water (200 mL), and the aqueous layer extracted with CH_2Cl_2 (2 × 100 mL). The combined organic layers were dried and concentrated to dryness. The crude product was purified by flash chromatography, eluting with pure hexane and gradually increasing to CH_2Cl_2/hexane (2/3), to afford **1** as a yellowish solid. Yield 73%; ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 4.53$ (s, 4H, CH_2O), 4.58 (s, 2H, CH_2Cl), 5.21 (d, $J = 6$ Hz, 1H, =C*H*H), 5.74 (d, $J = 9$ Hz, 1H, =CH*H*), 6.70 (dd, $J = 6$, 9 Hz, 1H, =CH), 7.25–7.52 (m, 8H, ArH); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 46.13$, 71.70, 72.11, 113.94, 126.38, 127.46, 127.70, 128.78, 136.64, 136.92, 137.14, 137.86, 138.74; MS (EI): *m/z*: 272:274 (3:1).

Chloromethyl-functionalized polymer **3**: A mixture of styrene (18.7 g, 180 mmol), **1** (5.45 g, 20 mmol), and the initiator **2** (261 mg, 1.0 mmol) was stirred at 125 °C under Ar for 30 h. The crude product was dissolved in CH_2Cl_2 (50 mL) and precipitated twice by addition to hexanes (2 L) to give the chloromethyl-functionalized polymer **3** as a white solid (19.7 g, 81%); ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.20$–2.05 (br. m, aliphatic protons), 4.40 (br. s, CH_2O), 4.51 (s, CH_2Cl), 6.30–7.05 (br. m, aromatic protons), 7.25–7.52 (br. s, ArH); $M_n = 16\,500$, $M_w/M_n = 1.14$.

TEMPO-functionalized polymer **6**: To a solution of the hydroxy-functionalized initiator **5** [17a] (2.0 g, 7.2 mmol) in anhydrous THF (30 mL) was added NaH (300 mg, 60% dispersion in oil, 7.5 mmol), and the reaction mixture was stirred at RT under Ar for 30 min. A solution of the chloromethyl polymer **3** (4.8 g, 2.4 mmol equiv) in anhydrous THF (15 mL) was then added dropwise and the reaction mixture heated at reflux under Ar for 12 h, cooled, and concentrated to dryness. The residue was redissolved in CH_2Cl_2 (200 mL), washed with water (3 × 50 mL), dried, and concentrated to dryness. The crude product was purified twice by precipitation from a solution in CH_2Cl_2 (50 mL) by addition to methanol (1 L) to give the TEMPO-functionalized polymer **6** as a white solid (4.6 g, 87%); ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 0.6$ (br. s, TEMPO-CH_3), 1.00–2.05 (br. m, aliphatic and TEMPO protons), 3.62, 3.90, and 4.80 (each AB pattern, TEMPO fragment), 4.36 (br. s, 3 × CH_2O), 6.30–7.05 (br. m, aromatic protons), 7.25–7.52 (br. s, TEMPO fragment); $M_n = 17\,000$, $M_w/M_n = 1.17$.

Chloromethyl graft polymer **7**: A mixture of styrene (18.7 g, 180 mmol), **1** (5.45 g, 20 mmol), and the TEMPO-functionalized linear polymer **6** (2.0 g, 1.0 mmol equiv) was stirred at 125 °C under argon for 30 h. The crude product was dissolved in CH_2Cl_2 (50 mL) and precipitated by addition to hexanes (2 L), isopropyl alcohol/acetone (1/3, 1.5 L), and hexanes (1.5 L) to give the chloromethyl-functionalized graft polymer **7** as a white solid (18.6 g, 71%); ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.20$–2.05 (br. m, aliphatic protons), 4.40 (br. s, CH_2O), 4.51 (s, CH_2Cl), 6.30–7.05 (br. m, aromatic protons), 7.25–7.52 (br. s, ArH); SEC: $M_n = 84\,000$, $M_w/M_n = 1.24$; MALLS: $M_w = 155\,000$; $dn/dc = 0.2869$.

General procedure for ATRP graft copolymerizations: To a mixture of copper(I) chloride (65 mg, 1.0 mmol), 4,4′-dinonylbipyridine [10c] (808 mg, 2.0 mmol), and the chloromethyl-functionalized polymer (2.0 g, 1.0 mmol equiv) was added the desired monomer (200 mmol); the reaction mixture was heated at 125 °C under Ar. After the appropriate amount of time the reaction mixture was dissolved in THF, filtered through a short plug of alumina, concentrated under vacuum, and precipitated by addition to methanol (2 L), isopropyl alcohol/acetone (1/3, 1.5 L), and methanol (2 L) to give the grafted copolymer as a white solid.

The Xe_2^+ Ion—Preparation and Structure

Thomas Drews and Konrad Seppelt*

Xenon forms stable bonds with fluorine. Starting from the three binary fluorides XeF_2, XeF_4, and XeF_6, compounds with real xenon–oxygen, xenon–nitrogen,[1] and finally even xenon–carbon[2] bonds have been synthesized. Furthermore, weak bonds between Cl^- and XeO_3 are observed in $Cs_9(XeO_3)Cl_2)_4Cl$.[3] With this, the chemistry of xenon in the condensed phase is circumscribed. The noble gas krypton forms only one binary fluoride, the metastable KrF_2, and there exists NMR spectroscopic evidence of short-lived $Kr(OTeF_5)_2$.[4]

Stein et al. have shown that $XeF^+Sb_2F_{11}^-$ can be reduced to Xe_2^+ with a variety of reducing agents, and most simply by elemental xenon itself.[5] The existence of Xe_2^+ was concluded based on the UV/Vis, Raman, and in particular, ESR spectra of the dark green solutions. The entire subject is somewhat mysterious: In this reaction elemental xenon has to be spontaneously, rapidly, and reversibly oxidized at temperatures below $-20\,^\circ C$, and the product should contain a cation with a xenon–xenon bond.

We tried to react yellow $XeF^+Sb_2F_{12}^-$ under a Xe atmosphere in the presence of an excess of pure (HF-free) SbF_5, as described by Stein. However, we observed no reaction. Only after addition of anhydrous HF were the described dark green solutions formed. The dark green color disappears and reappears upon pumping off and addition of xenon. The reaction works only in presence of "magic" acid HF/SbF_5. By slow cooling $HF_2^+Sb_2F_{11}^-$,[6] $H_2F_3^+Sb_2F_{11}^-$ (both colorless),[7] and $XeF^+ \cdot HF \cdot Sb_2F_{11}^-$ (yellow) could be crystallized; however, these findings do not hint at possible intermediates in the reaction between XeF^+ and Xe. At about $-30\,^\circ C$ a dark green compound crystallizes, which, according to the single-crystal structure analysis, has the formula $Xe_2^+Sb_4F_{21}^-$ (Figure 1). Apart from dark red $Xe(OTeF_5)_6$[8] this is the only other deeply colored xenon compound and indeed contains the dixenon radical cation.

In the crystal, there are many contacts, although weak (>322 pm), between the xenon atoms and the fluorine atoms of surrounding anions. The xenon–xenon bond length is surprisingly long (308.7(1) pm) and is not surpassed in length in main group chemistry by any other element–element bond. Only among transition metal compounds are metal–metal bond lengths of this size observed, for example in $Re_2(CO)_{10}$ (Re–Re 304.1(1) pm).[9] This unique xenon–xenon bond must be considered weak. Theoretical calculations on the ground state of the gaseous Xe_2^+ ion resulted in bond lengths between 317 and 327 pm.[10] The discrepancy between the calculated and experimental values is all the more serious, since for the condensed state an—even if small—bond lengthening should be expected. Dimer noble gas cations in the gas phase were first detected in 1951 in collision reactions between excited noble gas atoms.[11] High-resolution photoelectron spectroscopy of noble gas dimers gave dissociation energies of 1.15(1) (Ne_2^+), 1.207(5) (Ar_2^+), 1.151(3) (Kr_2^+), and 0.975 eV (Xe_2^+) in the $A^2\Sigma'_{1/2u}$ ground state.[12] Only the weakest bonded dixenon ion can be isolated in the form of a salt, because electron and fluoride ion affinities of the other noble gas cations are too high. Xe_2^+ is isoelectronic with I_2^-, which has been observed in alkali iodide glasses, in aqueous alkaline solutions,[13] and in the matrix,[14] and is also dark green.

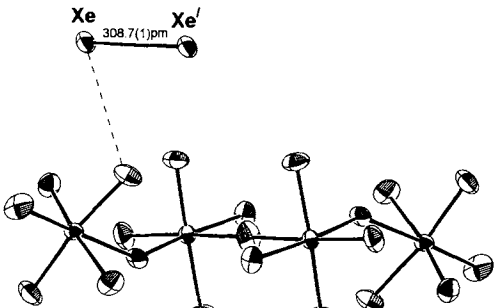

Figure 1. The structure of Xe_2^+ in the crystal (ORTEP plot, ellipsoids with 50% probability). One formula unit is shown. The shortest contact between cation and anion (322.6 pm) is shown as a dashed line. Other slightly longer contacts are also observed.

It is noteworthy that the tetrameric fluoroantimonate $Sb_4F_{21}^-$ acts as the anion; this anion is observed here for the first time. In the sequence $O_2^+SbF_6^-$, $XeF^+Sb_2F_{11}^-$, $Br_2^+Sb_3F_{16}^-$, and $Xe_2^+Sb_4F_{21}^-$ the increased fluoride ion affinity of the parent Lewis acids SbF_5, Sb_2F_{10}, Sb_3F_{15}, and Sb_4F_{20}, respectively, may be necessary to overcome the increased fluoride affinity of the cations.

What is the role of the "magic" acid in the reversible formation of Xe_2^+? After all, HF/SbF_5 is considered to be the strongest Brønsted acid known.[15] Activation of xenon by intermediate formation of HXe^+ is unlikely. The ^{129}Xe NMR spectrum of elemental xenon is strongly dependent on the solvent: The signal of xenon in H_2O is shifted with respect to that of xenon in $CFCl_3$ by $\Delta\delta = -10$, that of xenon in HF/SbF_5 by $\Delta\delta = -100$. The direction and size of the chemical shift do not indicate a notable amount of HXe^+ in the equilibrium, and no $^{129}Xe-^1H$ coupling is observed. In a $Xe/HF/SbF_5$ system even under xenon pressure no band is observed in the IR spectrum that could be assigned to a $H-Xe^+$ stretching frequency.[16] These observations are in accord with the small proton affinity of xenon in the gas phase (114.2 kcal mol^{-1}),[17] although according to Olah the HF/SbF_5-catalyzed H/D exchange between H_2 and D_2 is weakly inhibited by xenon.[18] However, there is a detectable influence of the HF/SbF_5 acid on the oxidizing agent XeF^+. XeF_2 and anhydrous HF do not exchange their fluorine atoms on the NMR time scale. Addition of SbF_5 not only leads to formation of XeF^+,[19] but also to exchange of the last xenon-bonded fluorine atom with the solvent, whereas the signals of the fluorine atoms of the different anions in solution (mainly SbF_6^- and $Sb_2F_{11}^-$) remain separated from those of the solvent in the ^{19}F NMR spectrum. These solutions lead to $XeF(HF)^+Sb_2F_{11}^-$ after crystallization (Figure 2). The cation can be considered as XeF^+ solvated by HF, or as protonated XeF_2. Since in solutions of $XeF^+(HF)$ all xenon-bonded fluorine atoms exchange with the solvent even at $-90\,^\circ C$, it cannot be excluded that double protonation of XeF_2 occurs to a small extent, and that the ion $XeF_2H_2^{2+}$ ($= Xe^{2+}(HF)_2$) is the acting oxidizing agent in the system $Xe/XeF_2/SbF_5/HF$. The overall reaction can therefore be formulated: $XeF^+ + 3Xe + H^+ \rightarrow 2Xe_2^+ + HF$, but the nature of other necessary intermediates remain unknown.

Experimental Section

$Xe_2^+Sb_{11}F_{21}^-$: $XeF^+Sb_2F_{11}^-$ (195 mg) [19] and SbF_5 (1.4 g) were placed into a perfluoropoly(ethenepropoxyethene) tube under exclusion of moisture (glove box <0.1 ppm H_2O), and anhydrous HF (100 mg) was condensed into it by using a metal vacuum line. Subsequently, xenon (1 g) was condensed into the tube at $-196\,^\circ C$, and the tube was sealed. The tube was slowly warmed to $0\,^\circ C$ (pressure!) to give a dark green solution. Subsequent slow cooling to $-30\,^\circ C$ resulted in complete crystallization. Under a microscope and with the aid of a special cooling

Regio- and Stereocontrolled Conjugate Radical Addition to a Desymmetrized Fumarate Derivative: An Efficient Synthesis of (−)-Nephrosteranic Acid and (−)-Roccellaric Acid**

Mukund P. Sibi* and Jianguo Ji

The readily available, simple four-carbon dicarboxylic acids, succinic, fumaric, and maleic acids, serve as important building blocks in organic chemistry. Succinates with dissimilar substituents on the carbon backbone have received attention because of their potential use as components in the development of metalloproteinase inhibitors.[1] We have recently reported highly selective radical conjugate reactions.[2] We surmised that regio- and stereocontrolled radical additions to differentially protected fumarates[3] could be used to prepare functionalized succinates (Scheme 1). In step 1, the remote chiral center is established through a regio- and stereoselective radical addition to the fumarate **1** (X_c = chiral auxiliary). In step 2, the chiral auxiliary controls the regio- and stereochemistry in the introduction of the second substituent by an aldol process. Thus, a single chiral center

in the auxiliary facilitates the sequential introduction of multiple stereocenters with both regio- and stereocontrol.

Trisubstituted butyrolactone natural products have kindled much interest recently because of their wide range of biological activity.[4] Nephrosteranic acid (**4**), roccellaric acid (**5**), and methylenolactocin (**6**), differentially functionalized succinates, are three examples of such butyrolactones. We describe here the selective functionalization outlined in Scheme 1 and apply it in the highly efficient synthesis of **4** and **5**.

Lewis acid mediated addition[5] of isopropyl radical to the desymmetrized fumarate **7**[6] was initially evaluated to establish optimal reaction conditions (Table 1). The auxiliary of choice was the oxazolidinone derived from diphenylalanine[7] since it had shown the best characteristics in our earlier work. Several

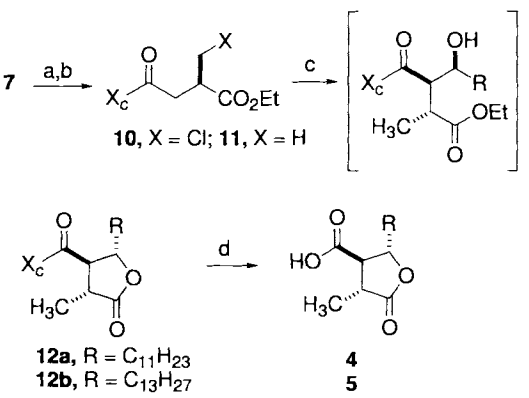
[a] See *Experimental Section* for reaction conditions. [b] Yields of isolated products. [c] Determined from the 400 MHz ^{1}H NMR spectrum of the crude reaction mixture.

trends are evident (Table 1). The conjugate addition reaction proceeds in excellent yields. High regio- and diastereoselectivity is observed with lanthanide and other selected Lewis acids (entries 6, 7, 9, 10, 12, and 13), but the reaction is essentially nonselective in the absence of a Lewis acid (entry 1).[8] Of the Lewis acids examined,[9] yttrium, samarium, thulium, lutetium, and erbium triflates gave the best selectivity (entries 6, 7, 10, 12, and 13). The high regio- and stereoselectivity observed in the radical reactions are of significance because addition of copper reagents to **7** leads to olefin reduction products or cleavage of the auxiliary.[10] Stoichiometric amounts of Lewis acid were required for high selectivity (entries 13, 15). Whereas excess erbium triflate led to a small enhancement in diastereoselectivity (entries 13, 14), excess samarium triflate greatly lowered both regio- and diastereoselectivity (entries 7, 8).

These results indicate that a chelating Lewis acid is required for high selectivity (entries 10, 13, 2). The Lewis acid selectively coordinates to the imide group and activates the substrate for conjugate addition β to the imide carbonyl, resulting in high regioselectivity. Chelation to the Lewis acid also locks the substrate in an *s-cis* conformation and the isopropyl radical approaches from the face opposite to the bulky diphenylmethyl substituent, providing high diastereoselectivity. We have previously established that radical addition to crotonates and cinnamates can be accomplished with substoichiometric amounts of Lewis acid with minimal change in yield and selectivity.[2a] However, with the more reactive fumarate **7**, radical addition to the uncomplexed substrate presumably competes effectively (entry 1) with that to the Lewis acid/substrate complex (entry 15), leading to lower selectivity. The dependence of regio- and diastereoselectivity with variation in chelating Lewis acids remains unexplained.

Having established that regio- and stereocontrolled radical addition to **7** was feasible, we turned our attention to the synthesis of the nephrosteranic and roccellaric acids. This required the addition of methyl radical to **7** followed by *syn*-selective aldol reaction at the methylene group α to the carbonyl of the chiral auxiliary. Addition of methyl radical to **7** using methyl iodide and tributyltin hydride gave mostly the starting material.[11] The successful installation of the methyl group was achieved in two steps (Scheme 2). Addition of chloromethyl radical to **7**



Scheme 2. a) $Sm(OTf)_3$, $ClCH_2I$, Bu_3SnH, Et_3B/O_2, CH_2Cl_2/THF, 1 h, –78 °C, 91% (>100:1); b) Bu_3SnH, AIBN, toluene, reflux, 12 h, 76%; c) Bu_2BOTf, CH_2Cl_2, Et_3N, –78 → 0 °C, RCHO, 12 h, **12a**: 84%, **12b**: 65%; d) LiOH, H_2O_2, THF/H_2O, room temperature, **4**: 92%, **5**: 94%. X_c = chiral auxiliary, AIBN = α,α'-azobisisobutyronitrile, Tf = trifluoromethanesulfonate.

($ClCH_2I/Bu_3SnH$) in the presence of samarium triflate gave **10** as a single regio- and diastereomer in 91% yield. Surprisingly, when erbium triflate was employed lower diastereoselectivity (10:1) resulted. Reductive elimination of the chlorine substituent in **10** using freshly distilled Bu_3SnH gave **11**.[12] We have recently shown that differentially protected succinates undergo aldol reactions in a highly regio- and stereoselective manner.[13] Treatment of **11** with dibutylboron triflate and triethylamine[14] followed by quenching of the boron enolate with lauraldehyde and myristylaldehyde gave the lactones **12a** and **12b**, respectively. Both aldol reactions were >98% *syn*-selective as evidenced by the NMR spectra of the crude products. Selective removal of the chiral auxiliary from **12a** gave nephrosteranic acid (**4**) in 92% yield, and a similar sequence starting with **12b** gave roccellaric acid (**5**) in 94% yield.[15] The overall yields for

nephrosteranic[16] and roccellaric acids[17] were 53 and 42%, respectively, over four synthetic steps from **7**.

In conclusion, we have described a highly regio- and stereoselective method for the addition of radicals to a desymmetrized fumarate. The application of this method in the efficient total synthesis of the butyrolactone natural products nephrosteranic and roccellaric acids has also been demonstrated. The present methodology alleviates some of the problems encountered in our alternate approach to these natural products.[18] Extension to enantioselective radical additions, the synthesis of more complex natural products, and development of tandem addition protocols are underway in our laboratory.

Experimental Section

Typical procedure: To a solution of **7** (37.9 mg, 0.1 mmol) and $Sm(OTf)_3$ (59.7 mg, 0.1 mmol) in CH_2Cl_2 (2 mL) and THF (0.5 mL) in a flame-dried flask under N_2, was added *i*PrI (85 mg, 0.5 mmol) and Bu_3SnH (58 μL, 0.2 mmol) at $-78\,^{\circ}C$. Triethylborane (1 M in hexane; 0.2 mL, 0.2 mmol) was then added. Oxygen (5 mL) was finally added by syringe over 10 min. The reaction mixture was stirred at $-78\,^{\circ}C$ for 1 h. After the reaction was complete the mixture was diluted with Et_2O (15 mL), washed with 10% HCl (2 × 2 mL), and brine (3 × 2 mL), and the organic layer was dried over $MgSO_4$. The residue was purified by chromatography on silica gel (hexane/ethyl acetate 4/1) to give the pure product **8** (40 mg, 95%). M.p. 134–135 °C; $R_f = 0.55$ (hexane/ethyl acetate 7/3); ^1H NMR (400 MHz, $CDCl_3$): $\delta = 7.35-7.20$ (m, 6H), 7.12–7.06 (m, 4H), 5.27 (ddd, $J = 8.0$, 5.6, 2.7 Hz, 1H), 4.68 (d, $J = 5.6$ Hz, 1H), 4.43 (t, $J = 9.4$ Hz, 1H), 4.37 (dd, $J = 9.1$, 2.7 Hz, 1H), 4.18–4.08 (m, 2H), 3.34 (dd, $J = 18.5$, 11.6 Hz, 1H), 2.74 (dd, $J = 18.3$, 3.0 Hz, 1H), 2.67 (ddd, $J = 11.6$, 5.4, 3.2 Hz, 1H), 1.98 (m, 1H), 1.25 (t, $J = 7.2$ Hz, 3H), 0.95 (d, $J = 5.1$ Hz, 3H), 0.93 (d, $J = 5.4$ Hz, 3H); ^{13}C NMR (100 MHz, $CDCl_3$): $\delta = 174.8$, 172.7, 153.1, 140.2, 138.2, 129.8, 128.8, 128.7, 128.3, 127.7, 127.0, 64.1, 60.7, 56.7, 49.8, 44.7, 31.0, 29.6, 20.9, 17.8, 14.4; $[\alpha]_D^{26} = -106.58$ ($c = 0.380$ in CH_2Cl_2); Analysis calcd for $C_{25}H_{29}NO_5$: C 70.90, H 6.90, N 3.31; found: C 71.10, H 6.59, N 3.51.

[6] Substrate **7** was prepared in 87% yield by acylation of the chiral auxiliary with the acid chloride derived from commercially available monoethyl fumaric acid.

[7] For the preparation of the oxazolidinone derived from diphenylalanine see: M. P. Sibi, P. K. Deshpande, A. J. La Loggia, J. W. Christensen, *Tetrahedron Lett.* **1995**, *36*, 8961.

[8] The regioselectivity in the radical addition experiments was determined by NMR analysis of the reaction mixture. Authentic samples of the racemic regio- and diastereomeric (1:1) monoethyl succinic acids were prepared by independent synthesis (ref. [3b]) and the chiral auxiliary introduced by standard techniques. The 400 MHz NMR spectra of the four regio- and diastereomeric products show well-separated signals for the methylene protons, which allowed unambiguous determination of product ratios.

[9] Other lanthanide Lewis acids ($La(OTf)_3$, $Gd(OTf)_3$, $Pr(OTf)_3$, $Tb(OTf)_3$, $Eu(OTf)_3$) were also evaluated but they showed inferior selectivity.

[10] Several reaction conditions were tested: *i*PrMgBr, $CuBr \cdot SMe_2$, $-78\,^{\circ}C$; MeMgBr, $CuBr \cdot SMe_2$; MeMgBr, CuCN; MeLi, CuCN.

[11] Minor amounts of ethyl radical addition (from triethylborane) were also observed.

[12] Older batches of tributyltin hydride led to some epimerization.

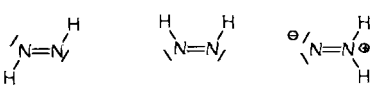
Direct Proof of *trans*-Diazene in Solution by Trapping and Isolation of the Trapping Products**

Dieter Sellmann* and Andreas Hennige

More than a century after the existence of diazene (N_2H_2) was first postulated,[1] the structure and reactivity of this tetraatomic molecule is still controversial. Diazene, occasionally also still termed diimine or diimide, is the parent molecule of all azo compounds. It is extremely unstable in free state ($\Delta H^0_{f(298)} = 212.3 \pm 8.4$ kJ mol^{-1}),[2] has been postulated as a metal-bound intermediate in enzymatic N_2 fixation,[3] and can be stabilized through coordination to metals in mono- and dinuclear complexes.[4] The existence of N_2H_2 in the gas phase under reduced pressure,[5] in the solid state at temperatures lower than $-165\,^{\circ}C$,[6] and in X-ray crystallographically characterized complexes[4] is irrefutable. In these complexes, N_2H_2 exhibits without exception the *trans* structure **A**. From spectroscopic investigations the same structure is concluded for uncomplexed diazene in the gaseous and solid states.[5, 6]



A **B** **C**

In contrast, diazene in solution still is an enigmatic species. Only indirect proof exists for its structure and strictly speaking even for its existence in solution. Mainly the characterization of reaction products serves as indirect evidence that, for example,

[**] Transition metal complexes with sulfur Ligands, Part 121. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 120: D. Sellmann, T. Becker, F. Knoch, *Chem. Eur. J.* **1996**, *2*, 1092–1098.

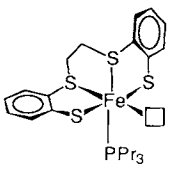
the air oxidation of N_2H_4, the acid hydrolysis of $K_2N_2(CO_2)_2$, or the thermolysis of benzenesulfonic acid hydrazide ($C_6H_5SO_2N_2H_3$) yield diazene as transient species, which disproportionates [Eq. (a)], decomposes [Eq. (b)], or hydrogenates π bonds of the type RC≡CR, $R_2C{=}CR_2$, or RN=NR [Eq. (c)].

$$2\ N_2H_2 \longrightarrow N_2 + N_2H_4 \quad (a)$$

$$N_2H_2 \longrightarrow N_2 + H_2 \quad (b)$$

$$N_2H_2 + R_2C{=}CR_2 \longrightarrow N_2 + \textit{cis}\text{-}R_2HC{-}CHR_2 \quad (c)$$

Because these hydrogenations always occur stereoselectively to give *cis* products, the *cis* structure **B** or the *iso*-diazene structure **C** ("aminonitrene") have been postulated for diazene in solution.[7–9] These transient species have never yet been detected directly in the form of isolable adducts. All attempts to trap *trans*-, *cis*-, or *iso*-diazene as, for example, hetero-Diels–Alder adducts or N_2H_2 complexes remained unsuccessful. In addition, results of theoretical calculations indicate that *trans*-N_2H_2 is the most stable isomer.[10] Thus the appearance of *cis*- or *iso*-diazene in solution implies that isomerization processes have to take place.



1

The first direct proof of diazene in solution has now been obtained through coordination of N_2H_2 to [Fe(PPr$_3$)(**S$_4$**)] fragment **1** (**S$_4$** = 1,2-bis(2-sulfanylphenylthio)-ethane dianion; □ = free coordination site). N_2H_2 was generated by two independent methods and trapped in the form of the fully characterized diazene complex [μ-N_2H_2{Fe(PPr$_3$)(**S$_4$**)}$_2$] (**2**). In the first case, benzenesulfonic acid hydrazide was thermolyzed. The evolved gas was swept by a stream of argon into a solution of the [Fe(PPr$_3$)(**S$_4$**)] fragment in THF/MeOH [Eq. (d)]. In the second case, solid $K_2N_2(CO_2)_2$ was added to a solution of the [Fe(PPr$_3$)(**S$_4$**)] fragment, and the resulting suspension was acidified with acetic acid [Eq. (e)]. In both experiments, the color of the

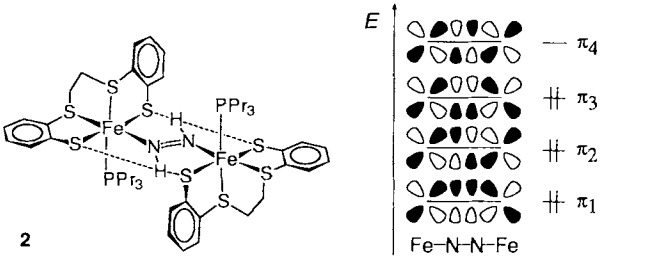
$$[Fe(PPr_3)(\mathbf{S_4})] \xrightarrow[THF/MeOH]{\text{thermolysis gases of } PhSO_2N_2H_3} [\mu\text{-}N_2H_2\{Fe(PPr_3)(\mathbf{S_4})\}_2] \quad (d)$$

2

$$[Fe(PPr_3)(\mathbf{S_4})] + K_2N_2(CO_2)_2 \xrightarrow[THF/MeOH]{HOAc} [\mu\text{-}N_2H_2\{Fe(PPr_3)(\mathbf{S_4})\}_2] \quad (e)$$

2

[Fe(PPr$_3$)(**S$_4$**)] solutions turned from olive-green to dark blue. Subsequently the diazene complex **2** was isolated in high yields. Complex **2** had recently been synthesized through oxidation of the hydrazine complex [Fe(N_2H_4)(PPr$_3$)(**S$_4$**)][11] and is the first N_2H_2 complex that could be obtained in larger amounts of up to 10 g. The X-ray structure analysis proved its *trans* structure (Scheme 1).



2

Scheme 1. Left: Schematic representation of the structure of **2**; right: the π_1–π_4 molecular orbitals of the 4c-6e π system of the [Fe–NH=NH–Fe] chromophore in **2**.

In **2**, a *trans*-diazene ligand bridges two enantiomeric fragments. The N_2H_2 ligand is stabilized by steric shielding, and in particular by a 4-center, 6-electron (4c-6e) π system in the Fe–NH=NH–Fe core and bifurcated N-H···(S)$_2$-bridges.[11] The dark blue color (λ_{max} (ε) = 623 nm (11800)) of **2**, which is a convenient probe for recognizing the formation of **2**, can be assigned to the π_3-π_4 transitions in the 4c-6e π system of the Fe–NH=NH–Fe chromophore. In addition to the σ bonds four localized π molecular orbitals result from the combination of two occupied Fe d orbitals and the diazene π orbitals. Three of these π orbitals are occupied. Thus one bonding π interaction results between the N atoms, and the NN bond of the coordinated N_2H_2 exhibits double bond character like the NN bond of free N_2H_2. Accordingly, the coordinated diazene in **1** shows molecular parameters (r(NN) = 128.8 ± 1.5 pm, δ(NNH) = 105.4°), which are virtually identical to those calculated for free gaseous *trans*-diazene (r(NN) = 126.6 pm, δ(NNH) = 105.4°).[10]

The results show for the first time that N_2H_2 in solution can be trapped through formation of stable adducts. The trapped N_2H_2 proves to be *trans*-diazene. No evidence for the existence of *cis*- or *iso*-diazene in solution could be obtained. The results cannot rule out that *cis*- or *iso*-diazene may nevertheless occur in solution. However, *trans*-diazene was the only N_2H_2 isomer for which positive evidence could be found in the gas phase, in the solid state, and now in solution. Recent UV-spectroscopic investigations also conclude that *trans*-N_2H_2 is the only detectable diazene isomer that forms in the acid hydrolysis of $K_2N_2(CO_2)_2$ in aqueous phase.[12] Thus the question arises whether the existence of *cis*-diazene (or even *iso*-diazene) really has to be postulated in order to explain the stereoselective *cis* hydrogenations of π bonds by N_2H_2. The majority of theoretical calculations assume *cis*-diazene and pericyclic transition states for these hydrogenations; however, the calculations also show that *cis*- and *iso*-diazene are about 20 kJ mol^{-1} and 105 kJ mol^{-1} higher in energy than *trans*-N_2H_2.[10]

The assumption of *cis*-diazene thus always requires an uphill *trans* → *cis* isomerization process and generates a "mechanistic dilemma".[13] One intriguing proposal for the *trans* → *cis* isomerization suggests Bronsted base catalyzed protonation–deprotonation reactions of N_2H_2.[14] The diazene NH bonds, whose expected relatively high acidity has been proved experimentally for [μ-N_2H_2{Cr(CO)$_5$}$_2$][15] and complex **2**, should favor this isomerization. However, *trans* → *cis* conversion remains an uphill process, and it must be emphasized that π bonds may also be hydrogenated by *trans*-N_2H_2 by rapid multistep mechanisms.[16, 17] In conclusion, the experiments and results described here cast serious doubts on the as yet merely postulated *cis* structure of diazene in solution.

Experimental Section

Unless stated otherwise, all procedures were carried out under an inert atmosphere (argon) at room temperature with standard Schlenk techniques. Solvents were dried, distilled, and saturated with argon before use. $K_2N_2(CO_2)_2$ was prepared as described in the literature [1]. Acetic acid (0.2 M) was saturated with argon. **Warning:** At temperatures above 135 °C benzenesulfonic acid hydrazide may explode!

Synthesis of **2** with benzenesulfonic acid hydrazide as the diazene source: The experiment was carried out in an all-glass apparatus. Thermolysis and absorption flasks were connected by a glass tube (length: 1 m, inner diameter: 7 mm) with integrated condenser which was cooled to −78 °C.

[Fe(PPr$_3$)(**S$_4$**)] : *n*-BuLi in *n*-hexane (2.5 M; 0.4 mL, 1 mmol) was added to a solution of **S$_4$**-H_2 (155 mg, 0.5 mmol) in THF (25 mL) at −78 °C. The mixture was warmed to room temperature and combined with a solution of $FeCl_2 \cdot 4H_2O$ (100 mg, 0.5 mmol) in MeOH (25 mL) to give a deep red solution, whose color changed upon addition of PPr$_3$ (0.1 mL, 0.5 mmol) to olive-green. This solution was filtered directly into the absorption flask.

$[\mu\text{-}N_2H_2\{Fe(PPr_3)(S_4)\}_2]$ (**2**): In the thermolysis flask benzenesulfonic acid hydrazide (approximately 5 g, m.p. 105 °C) was cautiously heated to 120 °C, during the course of which an increasing evolution of gas was observed. When a temperature of 110 °C was reached a vigorous stream of argon was passed through the apparatus into the absorption flask containing $[Fe(PPr_3)(S_4)]$. The color of the absorption solution immediately changed to green-blue, and the blue color became more intense over 30 min. Removal of all volatile components from this blue solution yielded a dark blue residue. Recrystallization of this residue from a solution (20 mL) in THF that was layered with 30 mL of MeOH and stored at −22 °C yielded dark violet crystals, which were collected after 4 days, washed with MeOH (20 mL) and *n*-hexane (5 mL), and dried in vacuo (100 mg, 37% based on $[Fe(PPr_3)(S_4)]$). ^1H NMR (270 MHz, CD_2Cl_2): $\delta = 0.9$ (m, 18H; CH_3), 1.2–1.6 (m, 24H; CH_2), 1.6–3.0 (m, 8H; C_2H_4), 6.6–7.6 (m, 16H; C_6H_4), 15.2, 15.5 (2s, 2H, N_2H_2); UV/Vis (CH_2Cl_2): λ_{max} (ε) = 623 (11800); elemental analysis $C_{46}H_{68}Fe_2N_2P_2S_8$: calcd C 51.20, H 6.35, N 2.60, S 23.77; found C 51.26, H 6.39, N 2.54, S 23.78.

Synthesis of **2** with $K_2N_2(CO_2)_2$ as the diazene source: $[Fe(PPr_3)(S_4)]$ was synthesized in an analogous way from H_2-S_4 (310 mg, 1 mmol) in THF (20 mL), *n*-BuLi in *n*-hexane (2.5 M; 0.8 mL, 2 mmol), $FeCl_2 \cdot 4H_2O$ (199 mg, 1 mmol) in MeOH (10 mL), and of PPr_3 (0.2 mL, 1 mmol). The resulting olive-green solution was filtered, and solid $K_2N_2(CO_2)_2$ (500 mg, 2.5 mmol) was added to the filtrate. To the resulting suspension, 0.2 M acetic acid (5 mL, 1 mmol) was added dropwise. Instantly, gas evolved and the solution turned deep blue. Removal of all volatile compounds from this solution yielded a dark blue residue. It was recrystallized from a solution in THF (30 mL) that was layered with MeOH (40 mL) and stored at −22 °C. Dark violet crystals were collected after 5 days, washed with MeOH (20 mL) and *n*-hexane (5 mL), and dried in vacuo (420 mg, 78% based on $[Fe(PPr_3)(S_4)]$). Elemental analysis $C_{46}H_{68}Fe_2N_2P_2S_8$: calcd C 51.20, H 6.35, N 2.60, S 23.77; found C 51.39, H 6.40, N 2.46, S 23.98.

Alkali Metal Complexes of *o,o'*-(Tetraethyleneglycoldiyl)-(*Z*)-stilbene: One Common Ligand Conformation for Li, Na, K, and Rb Ions

Andreas Merz,* Thomas Futterer, Johann Lex,* and Halina Inerowicz

Alkali metal complexes of crown ethers are classical examples of supramolecular structures.[1] [18]Crown-6 shows a distinct selectivity for the potassium ion, which fits the cavity particularly well,[2] but also forms stable complexes with the other alkali metal ions. The typical D_{3d} crown structure is realized in the potassium complex.[3] The same ligand conformation is found in the Li, Rb, and Cs complexes, but the larger ions are located outside the mean coronand plane in anion-bridged $[ML]_2$-type complexes.[3] In contrast, Li coordinates to only three oxygen atoms; a water molecule fills the empty cavity space.[3] In the Na complex five donor atoms are used in an altered ligand conformation.[3]

Here we report on alkali metal complexes of the coronand **1**,[4] whose remarkable tendency towards complex formation had already been useful in the separation of the diastereomers **1** and **1a**.[4] The structure of **1a** in the crystal,[5] which has an

almost planar arrangement of the *E*-stilbene unit, is compact and the oligoethyleneoxy part of the structure resembles free [18]crown-6.[3] In order to obtain an open conformation suitable for complexation, the two phenylene rings would have to be rotated by about 60° and 120° out of the plane of the double bond. As a consequence the π electrons of the double bond would then point into the cavity—an unfavorable situation. In

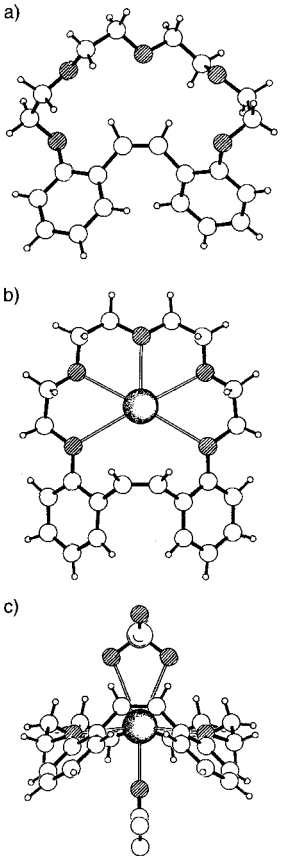

Figure 1. a) Crystal structure of **1**. b), c) Crystal structure of **4**: top projection (b) with counterion and coordinating acetone omitted for clarity, front projection (c) with hydrogen atoms of solvent omitted for clarity.

contrast the approximately C_2 symmetric **1**, which has a pseudo C_2 axis that passes through the center of the double bond and O7 (Figure 1a), already possesses a cavity marked by the unilateral triangle O1-O7-O13. The conformation of the crown ether bridge can be changed by rotation of the phenylene rings abount the bonds to the double bonds (C19–C20 and C21–C22). Thus, these two bonds are hinges by which the distance between O1 and O13 can be adjusted. In this way, in the crystalline alkali perchlorate complexes **2**–**5**,[6] *one common ligand conformation for all cations* with C_s symmetry is achieved.

All four complexes crystallize in the orthorhombic space group $Cmc2_1$ and possess a symmetry plane that bisects the double bond, O7, and the axial ligands. In Figures 1b and c this structure is represented by the potassium complex **4**. The *anti* rotation of the phenylene groups produces an arrangement of the five oxygen atoms that appears like an "amputated" [18]crown-6 with a missing $-(CH_2)_2$-O-$(CH_2)_2$- link. The stilbene double bond is located well outside the average plane of the oxygen atoms, and together with the phenylene rings it forms a roof under which a solvent molecule (**2**: THF; **3**, **4**, **5**: acetone) is arranged with the oxygen atom pointing towards the central cation. At the opposite face the perchlorate anion coordinates through one (**2**) or two oxygen atoms (**3**–**5**).

The structural differences between **2**–**5** are mainly with regard to the positions of the cations in the cavity formed by the five oxygen atoms of the macrocycle and consequently also the positions of the respective axial ligands. All four cations coordinate most strongly at O4, O7, and O10, an approach towards the stilbene double bond is avoided. In the complexes **2** and **3** the M–O1 and M–O13 distances are quite large, and the lithium ion coordinates exclusively at O4, O7, and O10. Only the larger cations have contacts to the oxygen atoms O1 and O13 (Figure 2). Although π-electron density of the double bond is directed towards the center of the crown (Figure 1c), the distance of the rubidium cation to the center of the double bond is still 3.21 Å.

The structures of **4** and **5** with the large cations are quite similar; the cations lie in an almost central location, and the five M–O distances are relatively uniform (Table 1). In comparison to the distances in the corresponding [18]crown-6 complexes, all the distances between the cation and O7 in compounds **2**–**5** are significantly smaller, those to the other oxygen atoms, with exception of **4** are greater, some of them distinctly. The closest similarities are seen in the sodium complexes.

The only structural parameters in the ligands that steadily change with increasing ionic radii are the distances O4–O10

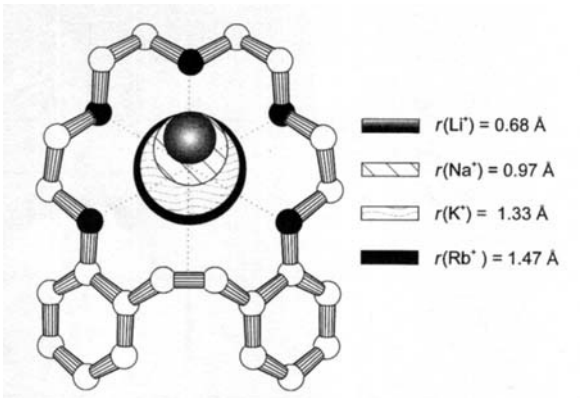

Figure 2. Position and size (Pauling radii) of the cations in the complexes **2**–**5**. The geometry of the ligand corresponds to that of the crystal structure of **2**.

(4.76→4.93 Å) and, consequently, the torsion angles of the phenylene rings at the double bond (55.84 → 59.35°). With CsI a crystalline complex **6** was obtained, which according to elemental analysis is of the ML_2 type.[7] This is also supported by the absence of solvent molecules in **6**. Presumably, the ligand also adopts the shown conformation in this case.[8]

The reason for these strikingly similar structures certainly is the strong coordination at O4, O7, and O10, which even for the small lithium ion affords the symmetric rooflike conformation of the stilbene unit. This interpretation is confirmed by the stability constants of **2**–**6**, which were determined in nitromethane (see below) by conductivity titration.[9] Surprisingly, in spite of the relatively large cavity the *lithium ion* in **2** forms the most stable complex. The complex stabilty then decreases steadily with increasing size of the cations ($\lg[K_{ass}]$ **2**: >6.0; **3**: 4.92 ± 0.01, **4**: 4.25 ± 0.01, **5**: 3.49 ± 0.01, **6**: 2.70 ± 0.01).[10] This experimental result can be explained by the unfavorable interaction between the "hard" alkali cations and the "soft" π bond of the double bond, which becomes more effective the closer the cation approaches the stilbene unit.

^{1}H NMR measurements show that the structures found in the crystals also dominate in the conceivable association and conformational equilibria in solution (Figure 3). For this purpose the highly polar (DK = 36)[11] yet weakly coordinating (DN = 2.7)[11] solvent CD_3NO_2 was used, which is particularly suitable for studying labile complexes.[12] Crown ether complexes exhibit greater association constants and slower decomplexation kinetics in nitromethane than in other solvents.[14] The observed cation-induced chemical shifts in the aliphatic region correspond very well to the respective structural features in the crystal, in terms of the comparison among **2**–**6** and with **1**. Particu-

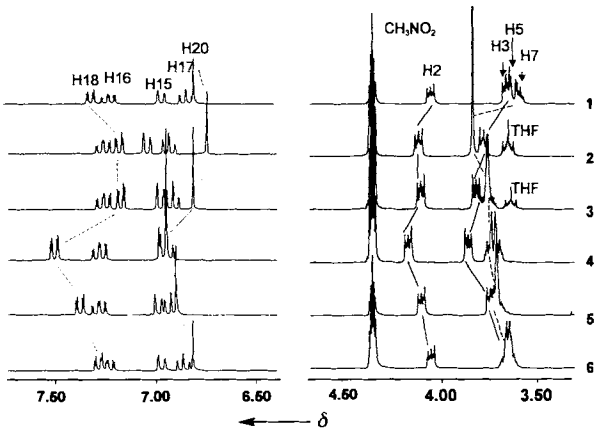

Figure 3. ^{1}H NMR spectra (250 MHz) of **1** and **2**–**6** in CD_3NO_2 (standard: TMS).

larly noteworthy are the proton groups H5, H6, which in the lithium complex **2** are degenerated to give a pseudo singlet and shifted downfield by $\Delta\delta = 0.2$ with respect to **1**. The high-field shifts of the H18,23 and H20,21 signals in **2** with respect to those in **1** result exclusively from anisotropy changes in the stilbene part of the molecule. Therefore, **2** constitutes a reference for the spectra of **3**–**6**. The largest low-field shifts are observed in the potassium complex **4**. The decrease of this effect for **5** and **6** may be explained by the decreasing electronegativities of the cations and the smaller association constants.

An important result of this work is the characteristic change of the stilbene conformation induced by the inclusion of cations in **1**. As a result of this effect the photodynamic *E*/*Z* equilibrium or the extent of the photooxidative phenanthrene cyclization of the stilbene moiety could be influenced in the presence of suitable cations. Further investigations on similar molecules with more extended aromatic π-electron systems are under way.

Experimental Section

The crystalline complexes **2**–**5** were prepared by combining equimolar amounts of **1** and the appropriate metal perchlorate in acetone (**3**, **4**, **5**) or THF (**2**, **3** [4]). Varying amounts of water were added and the solutions were cooled when necessary; for melting points see ref. [6]. Similarly, **6**, m.p. 57 °C, was prepared from **1** and CsI and crystallized in CH_3OH. The complexes were further characterized by correct elemental analysis, ^{1}H NMR (Figure 3), and IR spectra. In the FAB mass spectra, the $(1 + M)^+$ peaks were found throughout, additionally, for **6** a $[2 \times 1 + Cs]^+$ peak (2%) was observed. The conductivity titrations were performed in a Philips PW 9550/60 cell at 298 ± 0.05 K with a Philips PW 9527 conductivity meter [9].

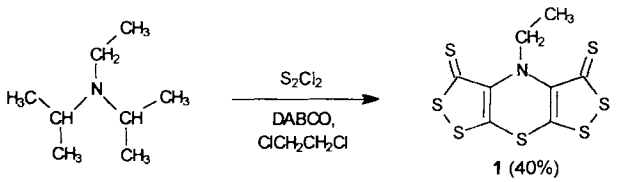
From Hünig's Base to Bis([1,2]dithiolo)-[1,4]thiazines in One Pot: The Fast Route to Highly Sulfurated Heterocycles**

Carlos F. Marcos, Cecilia Polo, Oleg A. Rakitin, Charles W. Rees,* and Tomás Torroba*

Dedicated to Professor Siegfried Hünig on the occasion of his 75th birthday

The chemistry of sulfur-containing heterocycles such as thiophenes and 1,3-dithioles has been extensively studied since the discovery of their superconductivity[1] and optical and electronic switching properties.[2] Polysulfur–nitrogen heterocycles may be even better candidates, but few practical syntheses can be performed on a multigram scale. We have been studying the reactions of cyclic oximes with disulfur dichloride (sulfur monochloride), S_2Cl_2, in the presence of *N*-ethyldiisopropyl amine (Hünig's base) to produce suitable materials for electronic and/or optical applications, and have discovered a useful route to cyclopenta- and cyclohepta-1,2,3-dithiazoles,[3] and some new heterocyclic pseudoazulenes.[4] Several products from these reactions showed birefringence upon melting in a hot-stage polarizing microscope[5] and this, together with the π-excessive nature of the sulfur–nitrogen rings has motivated the development of a new family of liquid-crystalline materials. A striking feature of these S_2Cl_2 reactions is the dependence of the nature of the products and their yields upon the experimental conditions. The best results were obtained when the reactions were conducted with a lengthy induction period (about 3 d) at 4 °C, in THF as solvent, and then heated at reflux for up to three hours. When we tried to shorten the induction period by performing the reactions at room temperature, we obtained an entirely new set of products, as shown by TLC. Furthermore we observed the same products from different starting oximes, indicating that the new products arose from a reaction between S_2Cl_2 and the "inert" Hünig's base. We now describe this reaction which affords, in one pot, the first three examples of a new multisulfur–nitrogen tricyclic system resulting from a multistage reaction sequence, the conditions that favor formation of each product, and a possible mechanistic explanation.

Hünig's base was treated with an excess of S_2Cl_2 in 1,2-dichloroethane in the presence of 1,4-diazabicyclo[2.2.2]octane (DABCO) for three days at room temperature and the mixture was then heated at reflux for two hours. After purification by chromatography compound **1** (m.p. 202–203 °C, 40% yield) was obtained as black needles with a striking metallic luster. The mass spectrum of **1** supported the molecular formula $C_8H_5NS_7$,

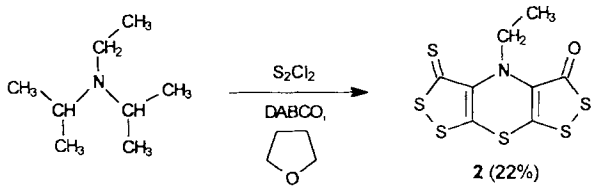


1 (40%)

which was also confirmed by HRMS and microanalysis; the ^{1}H NMR spectrum indicated that the *N*-ethyl group was still present. Thus all the C–H bonds of the two isopropyl groups had been cleaved, and these groups had presumably been fully sulfurated ($EtNC_6H_{14} \rightarrow EtNC_6S_7$). If the carbon connectivity of Hünig's base is retained, only a few reasonable structures are possible for the product. The spectroscopic data all pointed to what we considered to be the most stable possible product **1**, and this was confirmed by X-ray crystallography.[6]

In this one-pot conversion of Hünig's base into **1** the 14 isopropyl C–H bonds have been replaced by 10 C–S bonds and two C–C double bonds, whilst the ethyl group has been untouched. This provides a striking example of high selectivity between primary and secondary N-alkyl groups in a competitive reaction.

By variation of the solvent and reflux time, other derivatives of the bis(dithiolo)thiazine ring system could be obtained. Thus replacement of 1,2-dichloroethane by THF led to the formation of a small amount of compound **1** (25%) together with the new red compound **2** ($C_8H_5NOS_6$, m.p. 179–181 °C, 22% yield).



2 (22%)
+
1 (25%) + **3** (3%)

Mass spectrometry and microanalysis showed that one sulfur atom in **1** had been replaced by an oxygen atom in compound **2**, which had a carbonyl absorption at 1660 cm^{-1} in its IR spectrum. Signals for the N-ethyl group were observed in the ^{1}H NMR spectrum and in the ^{13}C NMR spectrum, which also displayed the signals of six quaternary carbon atoms, proving that **2** does not have a symmetrical structure but rather a 3-oxo-5-thione structure. In addition, minor amounts of the orange product **3** ($C_8H_5NO_2S_5$, m.p. 191–193 °C, 3% yield) were obtained, in which two sulfur atoms in **1** are replaced by two oxygen atoms. Again the N-ethyl group was intact and the ^{13}C NMR spectrum now showed signals for three quaternary carbon atoms, indicating a symmetrical 3,5-dione structure. The source of the oxygen atoms in **2** and **3**, which both formed in THF but not in 1,2-dichloroethane, appears to be the solvent. The reaction was repeated several times in carefully dried THF under dry nitrogen, and compounds **1** and **2** always formed in comparable yields. Under the reaction conditions described, S_2Cl_2 reacts with THF to give 4-chlorobut-1-ene (confirmed by GC-MS), presumably by ring opening to 4-chlorobutanol and dehydration; the alcohol or the water formed could then be the oxygen nucleophile.

Application of the nitrile oxide method for converting thiocarbonyl into carbonyl groups[7] readily gave the minor product **3** in 90% yield from **1** and in 95% from **2**. Solutions of the

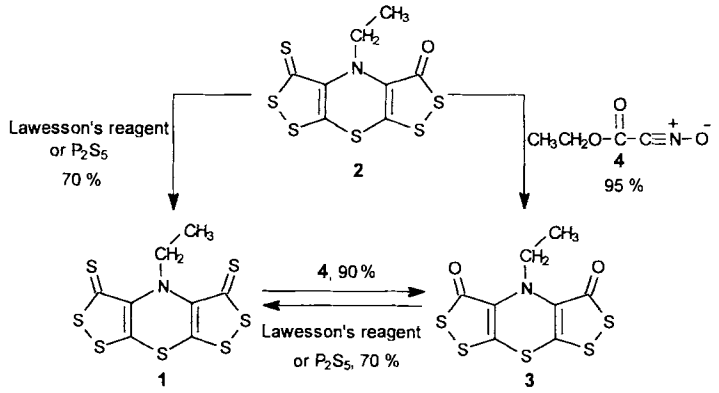
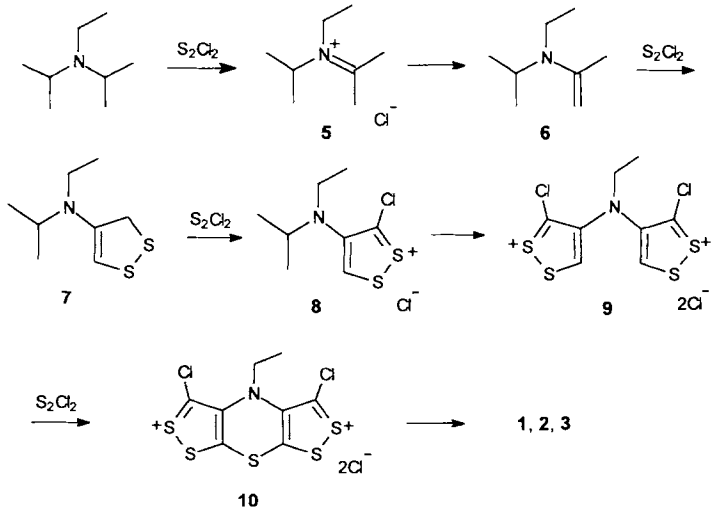
Williams for the X-ray structure determination.



substrates in THF were treated at 0 °C for 15 min with an excess of the nitrile oxide **4** generated from ethyl chlorooximidoacetate and triethylamine. The reverse reactions, thiation of **2** and of **3**, were also readily achieved in about 70% yield by heating with Lawesson's reagent or phosphorus pentasulfide in THF for five hours. However, it was more difficult to convert the symmetrical compounds **1** and **3** into the unsymmetrical 3-oxo-5-thione **2**, and the only satisfactory way to obtain **2** was by the reaction of Hünig's base with S_2Cl_2 in THF with or without DABCO.

It is remarkable that **2** was the major product when Hünig's base was stirred in THF for three days with one equivalent of S_2Cl_2, without DABCO, and then refluxed for 5.5 h. Whilst the precise stoichiometry of this complex reaction is not known, we assume that in the absence of DABCO, Hünig's base is both the reactant and the base that neutralizes the hydrogen chloride formed. Since 14 C–H bonds are broken, up to 14 mol of HCl could be formed, and if the base hydrochloride does not react with S_2Cl_2, then 15 mol of Hünig's base should give 1 mol of product. On this basis the yield of **2** is 82%.

We propose that the first step in these reactions is oxidation of an isopropyl group in Hünig's base by S_2Cl_2 (or its more reactive complex with DABCO) to give the stable iminium ion **5**, as in the oxidation of tertiary amines generally.[8] In agreement with this, electron-withdrawing substituents on nitrogen (as in *N*,*N*-diisopropylacetamide or *N*,*N*-diisopropylcyanamide) suppress the reaction with S_2Cl_2 even under more vigorous conditions. Deprotonation of iminium ion **5** gives enamine **6**, which reacts with S_2Cl_2 (or its DABCO complex) to give the 1,2-dithiole **7**. In turn, **7** would be expected to react further with S_2Cl_2 to give the chlorodithiolium salt **8**. The dithiolium ring in this compound is expected to be stable and the whole sequence could then be repeated to transform the other isopropyl group similarly, giving the bis(dithiolium) salt **9**. This could cyclize to form the tricyclic species **10**, the key intermediate that reacts with sulfur and oxygen nucleophiles to form the three products identified. The isolated compounds **1** and **2** are perfectly stable in boiling aqueous THF in the presence of acidic amberlite IR-120H resin, which implies that the oxo groups in **2** and **3** are not formed from the thione groups during the reaction or on workup. Under milder conditions we have been able to isolate some intermediate salts, including a pale green solid which could be **9** and a deep green solid which could be **10**; both of these compounds are under investigation.



Whatever the precise mechanism, the transformation of Hünig's base into the bis([1,2]dithiolo)[1,4]thiazines must require some 15 or so separate steps, which must therefore proceed in an average yield of about 94% (for a 40% yield of **1**).

In summary, we have shown that Hünig's base is readily and extensively transformed in a one-pot process to give the first three examples (**1**–**3**) of the new bis[1,2]dithiolo[1,4]thiazine ring system. Because of the high reactivity of S_2Cl_2 and its complex with DABCO, the reaction conditions are very mild, in striking contrast to the very vigorous conditions typically required for the formation of 1,2-dithiolo-3-thiones (heating organic substrates with sulfur).[9] Surprisingly, S_2Cl_2 does not appear to have been used before for the synthesis of 1,2-dithioles.

Experimental Section

1: Disulfur dichloride (4.6 mL, 57.6 mmol) was added dropwise to a solution of *N*-ethyldiisopropylamine (1.0 mL, 5.76 mmol) and DABCO (6.44 g, 57.6 mmol) in dichloroethane (100 mL) at −40 °C. The mixture was stirred for 15 min at −40°, for 3 d at room temperature, and then for 2 h at reflux. The reaction mixture was filtered through celite and the solvent removed under reduced pressure. The residue was subjected to medium-pressure liquid chromatography (MPLC) (Silicagel Merck 60, petroleum ether → CH_2Cl_2). Yield: 0.78 g, (40%).

Typical procedure for the reaction of **2** or **3**: A solution of **2** (0.19 g, 0.59 mmol) or **3** (0.18 g, 0.59 mmol) and Lawesson's reagent (1 g, 2.47 mmol) in anhydrous THF (50 mL) was heated at reflux under N_2 for 5 h; the transformation was followed by TLC. The solvent was removed under reduced pressure and the crude product purified by MPLC. Yield: 140 mg (70%); black metallic needles (petroleum ether/CH_2Cl_2), m.p. 202–203 °C (decomp); MS (EI, 70 eV): *m/z* (%): 339 (6) [M^+], 307 (22) [$M^+ - S$], 274 (9) [$M^+ - S_2H$], 247 (7) [$M^+ - S_2 - C_2H_5 + 1$], 174 (6) [$M^+ - C_3S_3 - C_2H_5$], 160 (7) [$M^+ - C_3S_3 - NC_2H_5$], 126 (8) [$M^+ - C_3S_4 - NC_2H_5$], 112 (23) [$M^+ - C_2S_5 - NC_2H_5$], 100 (38) [$M^+ - C_3S_5 - NC_2H_5$], 76 (52) [$M^+ - C_3S_5 - NC_2H_5$]; HRMS: calcd 338.8467, found 338.8450; IR (CCl_4): $\tilde{\nu}$ = 2964, 1551, 1314, 1254, 1057, 1000 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$): δ = 1.34 (t, J = 7.4 Hz, 3H, CH_3), 4.11 (q, J = 7.4 Hz, 2H, CH_2); ^{13}C NMR (100 MHz, [D_5]pyridine): δ = 14.12 (CH_3, DEPT), 44.07 (CH_2, DEPT), 148.65 and 158.75 (quaternary C), 201.55 (C=S); Elemental analysis calcd for $C_8H_5NS_7$: C 28.30, H 1.48, N 4.12; found: C 28.02, H 1.18, N 3.96.

2: Disulfur dichloride (4.8 mL, 60 mmol) was added dropwise to a solution of *N*-ethyldiisopropylamine (10.4 mL, 60 mmol) in THF (100 mL) at −40 °C. The mixture was stirred for 15 min at −40 °C, for 3 d at room temperature, and then for 5.5 h at reflux. The reaction mixture was filtered through celite and the solvent removed under reduced pressure. The residue was subjected to MPLC (Silicagel Merck 60, petroleum ether to CH_2Cl_2). Yield 1.06 g (82%) (based on 1/15 of the starting amine); red needles (petroleum ether/CH_2Cl_2); m.p. 179–181 °C (decomp); MS (EI, 70 eV): *m/z* (%): 323 (4) [M^+], 291 (100) [$M^+ - S$], 276 (18) [$M^+ - S - CH_3$], 263 (13) [$M^+ - S - CO$], 231 (23) [$M^+ - S_2CO$], 198 (9) [$M^+ - S_3 - C_2H_5$], 160 (11) [$M^+ - C_2S_3 - NC_2H_5$], 126 (12) [$M^+ - C_2S_4O - C_2H_5$], 112 (27) [$M^+ - C_2S_4O - NC_2H_5$], 100 (29) [$M^+ - C_3S_4O - NC_2H_5$]; HRMS: calcd 322.8695, found 322.8671; IR (CCl_4): $\tilde{\nu}$ = 2922, 1660 (C=O), 1633, 1287 (C=S), 1080, 1009 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$): δ = 1.33 (t, J = 7.2 Hz, 3H, CH_3), 3.96 (q, J = 7.2 Hz, 2H, CH_2); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 14.42 (CH_3, DEPT), 42.97 (CH_2, DEPT), 137.46, 148.10, 148.18, and 155.24 (quaternary C), 182.29 (C=O), 201.81 (C=S); Elemental analysis calcd for $C_8H_5NOS_6$: C 29.72, H 1.55, N 4.33; found: C 29.78, H 1.57, N 4.31.

3: Triethylamine (0.42 mL, 3.0 mmol) was added dropwise to a solution of **1** (0.2 g, 0.59 mmol) and ethyl chlorooximidoacetate (0.36 g, 2.4 mmol) in dry THF (10 mL) at 0 °C. The mixture was stirred for 15 min at 0 °C and a further 15 min at room temperature. The reaction mixture was filtered through celite and the solvent removed under reduced pressure. The residue was subjected to MPLC (Silicagel

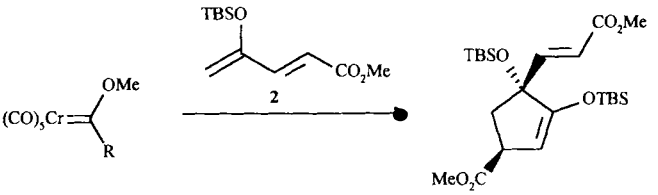
New Surprises with Fischer Carbene Complexes: Formal [3 + 2] Cycloadditions with and without Preceding Carbene–Ligand Metathesis**

Matthias Hoffmann, Matthias Buchert, and Hans-Ulrich Reissig*

Dedicated to Professor Roland Mayer on the occasion of his 70th birthday

Fischer carbene complexes have proved to be versatile and interesting building blocks in organic synthesis.[1] Widely applicable procedures have been developed based on their initially surprising reactions with unsaturated substrates such as alkenes, alkynes, nitriles, isonitriles, and imines. Thermal reactions of carbene chromium complexes **1** with dienes provide the expected cyclopropane derivatives with high regio- and periselectivity.[2] When α,β-unsaturated carbene complexes such as **1c** and **1d** are employed, the initially formed cyclopropane products rearrange to give cycloheptadienes.[3] We have now found a new unexpected reaction sequence with dienes **2** and **4**: a carbene metathesis is followed by a formal [3+2]cycloaddition of the newly generated carbene ligands to dienes **2** and **4** to furnish highly functionalized alkenyl siloxycyclopentene derivatives **3** and **5**, respectively.

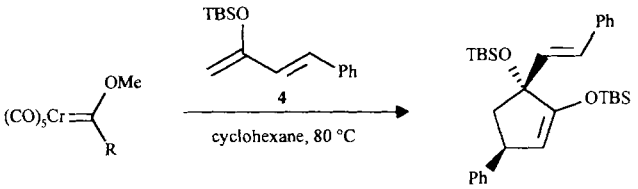


1a	R = Ph	1,2-dichloroethane, 80 °C, 8 h	**3** 99 %
		cyclohexane, 80 °C, 36 h	**3** 39 %
1b	R = Me	cyclohexane, 80 °C, 18 h	**3** 17 %

TBS = tBuMe$_2$Si

By heating complex **1a** with three equivalents of methyl 4-(*tert*-butyldimethylsiloxy)-2,4-pentadienecarboxylate (**2**)[4] in 1,2-dichloroethane or cyclohexane, cyclopentene derivative **3** (diastereomeric ratio >95:5) was obtained in nearly quantitative yield after chromatographic workup. The product was also formed when **2** was treated with the less reactive methyl-substituted carbene complex **1b** (17% yield, one diastereomer (>90%)). Based on its ^1H NMR spectrum, a byproduct from the reaction of **1a** with **2** was identifed as 1-methoxy-1-phenylethene (**8**).

Similar results were obtained from the reactions of siloxybutadiene **4** with complexes **1a** and **1b**. Both carbene complexes furnished the corresponding siloxycyclopentene **5** as a diastereomerically pure product. As in the previous case, the more reactive complex **1a** gave higher yields than **1b**. The constitution and relative configuration of the unexpected products **3** and **5**,



1a	R = Ph	17 h	**5** 99 %
1b	R = Me	8 h	**5** 59 %

which do not incorporate the carbene ligand of the starting material, were determined by 1D- and 2D-INADEQUATE NMR spectra, which established the connectivity, and by 2D-NOESY NMR spectra.[5]

These results can be explained by postulating the formation of new α,β-unsaturated carbene complexes from complexes **1a** and **1b** by an initial carbene ligand metathesis.[6] Accordingly, the highly reactive donor–acceptor-substituted carbene complex **7** and enol ether **8** (which was indeed found) should be formed

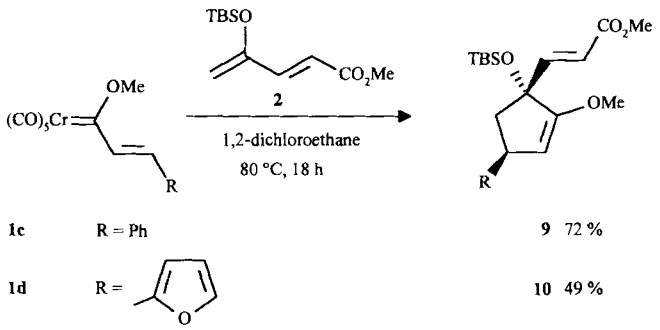
from **1a** and **2** via chromacyclobutane **6**. The further reaction of **7** with **2** to give product **3** will be discussed below.

The postulated formation of the α,β-unsaturated carbene complex **7** led us to conduct experiments with isolable complexes of this type. Indeed, the corresponding alkenyl-substituted methoxycyclopentene derivatives **9** and **10** were obtained

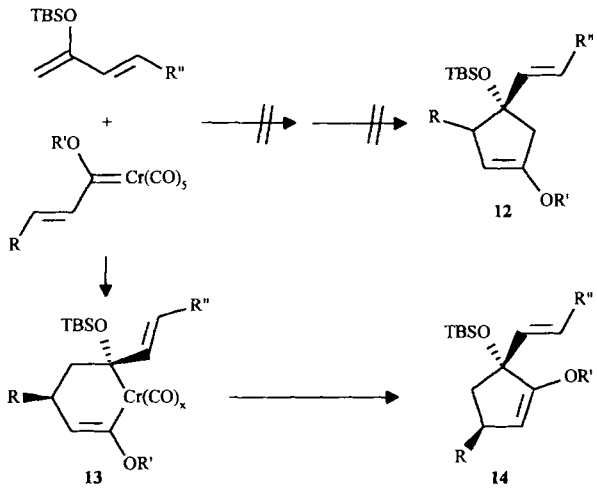


from thermal reaction of **1c** and **1d**,[7] respectively, with siloxydiene **2**, in these cases without preceding carbene metathesis. In contrast, the same reactions carried out with diene **4** furnished only cycloheptadienes.[8] Similarly, the reaction with the electron-rich 1-methoxy-3-siloxy-1,3-butadiene (Danishefsky diene) gave the "normal" seven-membered ring products.[8]

The simplest way to explain the surprising formation of cyclopentenes **3**, **5**, **9**, and **10** from α,β-unsaturated carbene complexes is the [3+2]cycloaddition of the carbene ligand to the electron-rich terminal double bond of siloxydienes **2** and **4**. Formal [3+2]cycloadditions of α,β-unsaturated carbene complexes to *electron-poor* olefins have been reported recently.[9] In these reactions with only low diastereoselectivities, a competition of the cyclopropane-forming [2+1]cycloaddition and the [3+2]cycloaddition was observed, strongly depending on substituents and the donor ability of the solvent. A mechanism[10] similar to that discussed there should provide regioisomeric products **12** for the new reaction, and therefore a different mechanism has to be considered.

In our opinion, the [4+2]cycloaddition of the electron-poor chromadiene system[11] as the 4π component and the terminal double bond of the siloxydienes as the dienophile is the most probable explanation.[12] The regio- and *endo*-selectively formed chromacyclohexene intermediate **13** would then lead to cyclopentene **14** by reductive elimination of the metal fragment with retention of configuration; **14** exhibits the connectivity of atoms and configuration found experimentally. Examples for this postulated Diels–Alder reaction with a metalladiene component are rare but not unknown.[13]

Although we do not yet understand the effects of substituents in the reactions of unsaturated carbene complexes with dienes in detail, the formal [3+2]cycloaddition described here may be of preparative interest due to the high functionality of the formed



cyclopentenes.[14] When combined with an initial carbene ligand metathesis, this transformation is the first example of a previously unknown dimerization of dienes with fragmentation of methylene.

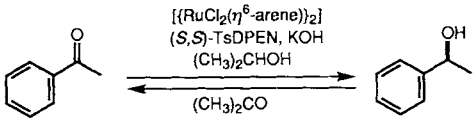
The Catalyst Precursor, Catalyst, and Intermediate in the Ru^{II}-Promoted Asymmetric Hydrogen Transfer between Alcohols and Ketones**

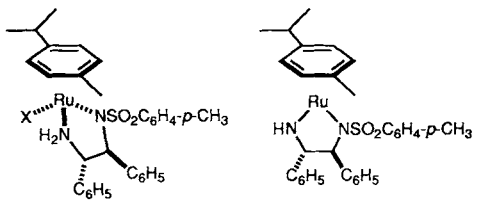
Karl-Josef Haack, Shohei Hashiguchi, Akio Fujii, Takao Ikariya, and Ryoji Noyori*

Well-designed chiral Ru^{II}–arene complexes catalyze the asymmetric transfer hydrogenation of ketones or imines with stable organic hydrogen donors such as 2-propanol[1, 2] and formic acid.[3] In these reactions certain derivatives of 1,2-diamines and β-amino alcohols can serve as excellent chiral modifiers and lead to high reactivity and enantioselectivity. For example, when a 0.1 M solution of acetophenone in 2-propanol containing $[\{RuCl_2(\eta^6\text{-arene})\}_2]$, (1*S*,2*S*)-*N*-*p*-toluenesulfonyl-1,2-diphenylethylenediamine ((*S*,*S*)-TsDPEN), and KOH (ketone:Ru:diamine:KOH = 200:1:1:2 molar ratio) was allowed to stand at 28 °C for 10 h, (*S*)-1-phenylethanol was obtained in up to 97% *ee* and in 98% yield [Eq. (a)].[1a] We here disclose the



(a)

molecular structures of a preformed catalyst precursor **1**, the true catalyst **2**, and the reactive intermediate **3** for this asymmetric transfer hydrogenation using 2-propanol. The functions of the added KOH and the NH moiety in the TsDPEN auxiliary



1: X = Cl
3: X = H

2

have also been clarified. Here we describe a very rare catalytic system in asymmetric transformations for which both the true catalyst and the reactive species have been isolated in a pure state.[4] The success can be attributed to the reversible reactions with different but comparable energy profiles.

First, the catalyst precursor **1** was prepared as orange crystals in >90% yield by reacting $[\{RuCl_2(\eta^6\text{-}p\text{-cymene})\}_2]$, (*S*,*S*)-TsDPEN, and KOH (Ru:diamine:KOH = 1:1:1 molar ratio in CH_2Cl_2 at room temperature) or, more effectively, triethylamine (Ru:diamine:NEt_3 = 1:1:2 in 2-propanol at 80 °C). The single-crystal X-ray analysis illustrated in Figure 1 indicates

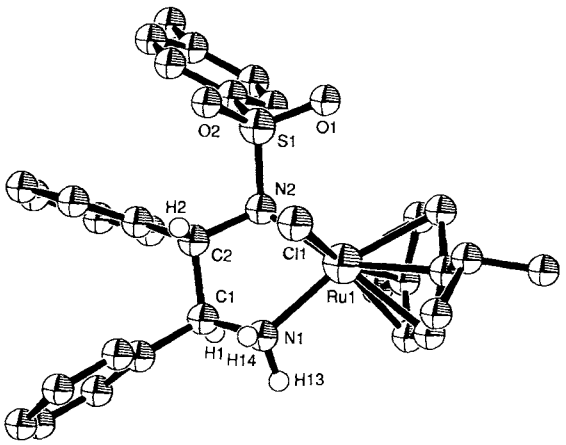


Figure 1. Molecular structure of **1** in the crystal. All hydrogen atoms except for the proton of the amine ligand and those at the carbon atoms in the chelate backbone and one crystal water molecule have been omitted for the sake of clarity. Selected distances [Å] and angles [°]: Ru–Cl 2.435(4), Ru–N1 2.117(9), Ru–N2 2.144(8), RuCl···HN 2.57; N1-Ru-N2 79.4(3), Ru-N1-C1 112.8(7), Ru-N2-C2 111.6(6).

that this 18-electron Ru^{II} complex has a distorted octahedral coordination environment with η^6-arene, amino, sulfonamido, and chloro ligands.[5] The chirality of (*S*,*S*)-TsDPEN forming a δ-configurated five-membered ring determines the (*R*) configuration at the Ru center.[6] Noteworthy is the very short Cl···HN distance of 2.57 Å (expected van der Waals separation, 3.0 Å), which is ascribed to an intramolecular hydrogen bond.[7] The ^{1}H NMR spectrum confirmed that **1** exists as a single diastereomer in $CDCl_3$ solution.

The Ru complex **1**, which catalyzes the asymmetric transfer hydrogenation of acetophenone in 2-propanol containing

KOH, is merely a catalyst precursor. This complex has acidic NH_2 protons as confirmed by rapid H/D exchange with CH_3OD. Complex **1** undergoes facile elimination of HCl probably by a D_{cb} mechanism[8] on treatment with one equivalent of KOH in a CH_2Cl_2 – water two-phase system at room temperature to afford the true catalyst **2** as deep purple crystals in 87% yield. This complex reverts back to **1** upon reaction with triethylammonium chloride. The X-ray crystallographic analysis (Figure 2) reveals that **2** is a monomeric, formally 16-electron neu-

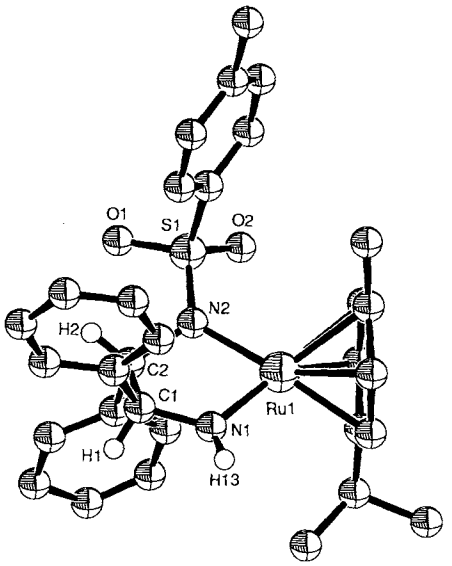

Figure 2. Molecular structure of **2** in the crystal. All hydrogen atoms except for the proton of the amide ligand and those at the carbon atoms in the chelate backbone have been omitted for the sake of clarity. Selected distances [Å] and angles [°]: Ru–N1 1.897(6), Ru–N2 2.065(6), N1–H13 0.88(6); N1-Ru-N2 78.9(2), Ru-N1-C1 121.2(5), Ru-N2-C2 114.9(4).

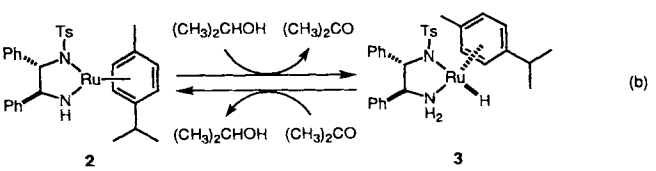
tral Ru^{II} complex with a square-planar geometry;[5, 9] the metal center is coordinated to two anionic nitrogen atoms and to *p*-cymene, which acts as a bis(three-electron) donor (neutral formalism). The basic skeleton (substituents on the nitrogens and arene neglected) has a mirror plane and the face of the arene ligand is perpendicular to the N1-Ru-N2 plane. Both N1 and N2 have planar geometry. Most notably, the N1–Ru bond (1.897 Å) is shorter than the N–Ru single bond in a Ru^{II}–anilide (2.01–2.16 Å)[10] but longer than the distance in a Ru^{II}–imide complex (1.75 Å) for which an N–Ru triple bond may be assumed.[11] This finding implies significant double bond character for the N1–Ru bond in **2**.[12] The N2–Ru bond in **2** (2.065 Å) is shorter than that in **1** (2.144 Å but substantially longer than the N1–Ru bond in **2** owing to the electronegative tosyl substituent.

Because of the unique nature of the Ru–N1 bond, **2** shows distinct dehydrogenative activity for methanol, ethanol, and 2-propanol. For instance, when the purple complex **2** was treated with 2-propanol at room temperature in the *absence of base*, rapid elimination of acetone took place to produce the yellow ruthenium hydride species **3**, which gives rise to a ^{1}H NMR signal at $\delta = -5.47$ in [D_8]toluene [Eq. (b)]. The kinetically



(b)

controlled reaction was highly stereoselective giving the (*R*)-configurated, octahedral Ru^{II} complex,[6] whereas its diastereomer was formed in <1% yield according to ^{1}H NMR spectroscopy. The major stereoisomer **3** was isolated as the hydrate in 70% yield as yellow needles by recrystallization from wet CH_3OH. When the purple complex **2** was mixed with *tert*-butyl alcohol neither the color nor the ^{1}H NMR spectrum changed. The Ru complex **3** was also obtained by reaction of **2** and molecular hydrogen in toluene at room temperature, but only at 80 atm. The single-crystal X-ray analysis indicates that this ruthenium hydride is structurally similar to the chloride complex **1** except for the orientation of the tosyl substituent (Figure 3).[5] The distorted octahedral complex possesses a δ-configurated, five-membered chelate ring (N1–Ru 2.110 Å,

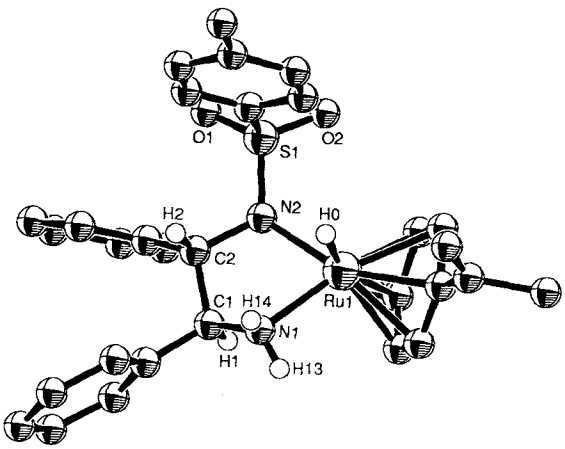


Figure 3. Molecular structure of **3** in the crystal. All hydrogen atoms except for the hydride at ruthenium, the two protons of the amine ligand, and those at the carbon atoms in the chelate backbone, as well as two water molecules in the lattice have been omitted for the sake of clarity. Selected distances [Å] and bond angles [°]: Ru–H0 1.40(1), Ru–N1 2.110(1), Ru–N2 2.139(9), N1–H13 0.90(1), N1–H14 0.7(1), RuH0···H14N1 2.29; N1-Ru-N2 78.3(4), Ru-N1-C1 108.7(7), Ru-N2-C2 113.0(7).

N2–Ru 2.139 Å), an η^6-arene ligand, and a hydrido ligand (Ru–H 1.40 Å). The distance between H0 on Ru and H14 on N1 is short (2.29 Å; van der Waals separation 2.4 Å), indicating a possible hydrogen bonding interaction.[13] One water molecule is hydrogen bonded to H14 on N1, while the second water molecule within the lattice is disordered. Treatment of **3** with a tenfold excess of acetone led instantaneously to the 16-electron species **2** and 2-propanol [Eq. (b)].

The purple complex **2** indeed catalyzes the asymmetric reduction of acetophenone in 2-propanol without KOH to afford (*S*)-1-phenylethanol in up to 95% *ee*. The yellow hydride **3** behaves in the same manner under catalytic conditions. The catalytic activity and stereoselectivity are identical to those observed with the complex formed in situ.[1a] Thus, under the conditions of Equation (a), KOH is necessary only for the generation of the catalyst **2** via the precursor **1**. The isolation of **3** confirms that the Ru-catalyzed transfer hydrogenation takes place by way of a metal hydride rather than the metal alkoxides presumed for the Meerwein–Ponndorf–Verley type reaction.[14] The extent of the enantioselectivity in the acetophenone reduction is independent of the bulkiness or chirality of the hydrogen donors. Methanol, ethanol, 2-propanol, and (*R*,*S*)-, (*R*)-, and (*S*)-2-butanol all gave (*S*)-1-phenylethanol in the same enantiomeric purity, 95 ± 0.5% *ee*, indicating that **3** is the common intermediate. Reduction of acetophenone with $(CH_3)_2CDOH$ (0.996 D at C2) catalyzed by **2** gave (*S*)-$C_6H_5CD(OH)CH_3$ (0.936 D at

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3603-0286 $ 15.00+.25/0

C1) in 95% *ee* as expected. Experiments using mixtures of $(CH_3)_2CHOH$ and $(CH_3)_2CDOH$ revealed a k_H/k_D value of 1.5 ± 0.1 (^{1}H NMR and GCMS). Because of microscopic reversibility, the (*S,S*)-TsDPEN-based complex **2** dehydrogenates (*S*)-1-phenylethanol in acetone more readily than the (*R*) enantiomer, allowing efficient kinetic resolution of the racemate.[2] Notably, the reductive formation of **3** from **2** is consistently diastereoselective, regardless of the structure of the hydrogen-donating alcohol.

Preliminary kinetic investigations proved the isolated complexes **2** and **3** to be the true catalyst and intermediate, respectively, in the hydrogen transfer reaction following Equation (b). The reaction of $(CD_3)_2CO$ with $(CH_3)_2CHOH$ (0.37 to 1.9 M) and **2** (0.45×10^{-2} to 4.0×10^{-2} M) at 23 °C was monitored by following the disappearance of the methyl resonance of $(CH_3)_2CHOH$ in the ^{1}H NMR spectra. We found that the rate of acetone reduction is first order in $[(CH_3)_2CHOH]$ and first order in [**2**]. By reversing the deuteration, the acetone dependence could be measured. The reduction of $(CH_3)_2CO$ with $(CD_3)_2CHOH$ catalyzed by **3** (or **2**) was found to be zero order in $[(CH_3)_2CO]$ (saturation kinetics) at high concentration (> 0.4 M), thus, $-d[2\text{-propanol}]/dt = k[\mathbf{2}][2\text{-propanol}]$, where $k = 2.5 \times 10^{-3}\ M^{-1} s^{-1}$, whereas at low concentrations of acetone (0.19 to 0.39 M) the rate is first order with respect to $[(CH_3)_2CO]$. These results demonstrate that the reaction of **2** with 2-propanol is the turnover-limiting step in the steady-state hydrogen transfer [Eq. (b)] and that the reverse reaction of **3** with acetone is more facile.

In summary, the Ru-catalyzed hydrogen transfer between alcohols and ketones occurs reversibly and is promoted by the bifunctional metal/ligand catalysts **2** and **3** possibly via a six-membered cyclic transition state.[1d] The interconversion between these 16- and 18-electron Ru complexes takes place by the action of an alcohol or ketone either directly or via a very short-lived intermediate. No other complexes that limit the rates are involved.

Experimental Section

All operations were conducted under an atmosphere of dry argon and standard Schlenk-type glassware was used.

1: A mixture of $[\{RuCl_2(\eta^6\text{-}p\text{-cymene})\}_2]$ [15] (1.53 g, 2.5 mmol), (*S,S*)-TsDPEN [16] (1.83 g, 5.0 mmol), and triethylamine (1.4 mL, 10 mmol) in 2-propanol was heated at 80 °C for 1 h. The orange solution was concentrated and the resulting solid was collected by filtration. The crude compound was washed with a small amount of water and dried under reduced pressure to give complex **1**. Yield 2.99 g (94%). Recrystallization from 99% methanol afforded orange crystals. Decomp > 100 °C; IR (KBr): $\tilde{\nu}$ [cm^{-1}]: 3272, 3219, 3142 (H–N), 3063, 3030 (H–C_{arom}), 2963, 2874 (H–C_{aliph}); FD-MS: m/z (%) = 636 (1) [M^+], 600 (30) [M^+ – HCl], 308 (15), 260 (40), 134 (15), 106 (100); ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): δ = 1.32, 1.34 (each d, ^3J(H,H) = 7 Hz, 3H; $CH(CH_3)_2$), 2.19 (s, 3H; CH_3 in *p*-cymene), 2.28 (s, 3H; CH_3 in *p*-Ts), 3.07 (m, 1H; $CH(CH_3)_2$), 3.26 (m, 1H; NH*H*), 3.54 (m, 1H; *H*CNH_2), 3.66 (d, ^3J(H,H) = 11 Hz, 1H; *H*CN-*p*-Ts), 5.68, 5.70, 5.72, 5.86 (each d, 1H; CH_{arom} in *p*-cymene), 6.61 (m, 1H; NH*H*), 6.29–7.02 (14H; *p*-$CH_3C_6H_4$–$SO_2NCH(C_6H_5)CH(C_6H_5)NH_2$). Anal. calcd. for $C_{31}H_{35}ClN_2O_2RuS$: C 58.53, H 5.54, N 4.40, Cl 5.57, Ru 15.89; found: C 58.37, H 5.44, N 4.36, Cl 5.75, Ru 15.83.

2: A mixture of $[\{RuCl_2(\eta^6\text{-}p\text{-cymene})\}_2]$ [15] (306.2 mg, 0.5 mmol), (*S,S*)-TsDPEN [16] (366.4 mg, 1.0 mmol), and KOH (400 mg, 7.1 mmol) in CH_2Cl_2 (7 mL) was stirred at room temperature for 5 min. On addition of water (7 mL) to the reaction mixture, the color changed from orange to deep purple. The purple organic layer was washed with water (7 mL), dried over CaH_2, and concentrated to dryness to afford deep purple **2** (522 mg, 87% yield). The same complex was prepared by treatment of **1** with one equivalent of KOH in CH_2Cl_2 at room temperature. Decomp > 80 °C; IR (KBr): $\tilde{\nu}$ [cm^{-1}]: 3289 (H–N), 3070, 3017 (H–C_{arom}), 2968, 2920, 2859 (H–C_{aliph}); FD-MS: m/z (%) = 600 (10) [M^+], 305 (5), 260 (25), 134 (20), 106 (100); ^{1}H NMR (400 MHz, [D_8]toluene, 25 °C, TMS): δ = 1.20, 1.25 (each d, ^3J(H,H) = 7 Hz, 3H; $CH(CH_3)_2$), 2.05 (s, 3H; CH_3 in *p*-cymene), 2.22 (s, 3H; CH_3 in *p*-Ts), 2.53 (m, 1H; $CH(CH_3)_2$), 4.08 (d, 1H, ^3J(H,H) = 4.4 Hz, *H*CNH), 4.89 (s, 1H; *H*CN-*p*-Ts), 5.11, 5.27, 5.28, 5.39 (each d, ^3J(H,H) = 6 Hz, 1H; CH_{arom} in *p*-cymene), 6.64 (br. d, 1H; NH), 6.87, 7.67 (each d, ^3J(H,H) = 8 Hz, 2H; CH_{arom} in *p*-Ts), 7.2–7.7 (m, 10H; *p*-TsNCH(C_6H_5)CH(C_6H_5)NH). Anal. calcd. for $C_{31}H_{34}N_2O_2RuS$: C 62.09, H 5.71, N 4.67, Ru 16.85; found: C 62.06, H 5.77, N 4.66, Ru 16.47.

3: The purple complex **2** (600 mg, 1.0 mmol) was dissolved in 2-propanol (10 mL), and the resulting red solution was stirred at room temperature for 15 min. The solvent was then removed under reduced pressure at room temperature to give a brownish yellow compound, which was washed with cold pentane and recrystallized from methanol to provide orange needles (420 mg, 70% yield). Under vacuum at room temperature the needles turned brown. The same compound **3** was obtained by stirring a toluene solution of **2** (600 mg, 1.0 mmol) under 80 atm H_2 in an autoclave at room temperature for 18 h. Decomp > 60 °C; IR (KBr): $\tilde{\nu}$ [cm^{-1}]: 3335, 3317, 3228, 3153 (H–N), 3060, 3025 (H–C_{arom}), 2960, 2917, 2867 (H–C_{aliph}), 1911 (broad, H–Ru); ^{1}H NMR (400 MHz, [D_8]toluene, 25 °C, TMS): δ = –5.47 (s, 1H; RuH), 1.53, 1.59 (each d, ^3J(H,H) = 6 Hz, 3H; $CH(CH_3)_2$), 2.29 (s, 3H; CH_3 in *p*-cymene), 2.45 (s, 3H; CH_3 in *p*-Ts), 2.79 (m, 1H; NH*H*), 2.93 (m, 1H; $CH(CH_3)_2$), 3.80 (d, ^3J(H,H) = 8 Hz, 1H; *H*CN-*p*-Ts), 4.02 (m, 1H; *H*CNH_2), 5.15, 5.19, 5.43, 5.58 (each d, ^3J(H,H) = 6 Hz, 1H; CH_{arom} in *p*-cymene), 5.29 (m, 1H; NH*H*), 6.49, 7.59 (each d, ^3J(H,H) = 8 Hz, 2H; CH_{arom} in Ts), 6.9–7.3 (m, 10H; *p*-TsNCH(C_6H_5)CH(C_6H_5)NH_2). Anal. calcd. for $C_{31}H_{36}N_2O_2RuS$: C 61.88, H 6.02, N 4.66, Ru 16.80; found: C 61.79, H 5.94, N 4.70, Ru 16.56.

Kinetic study: The reaction was initiated by adding 2-propanol to a mixture of acetone and **2** at 23 °C. The total volume was maintained at 0.7 mL. When a small amount of acetone was employed, 2-min sonication was necessary to dissolve **2**. The reaction was monitored at 5-min intervals by measuring the integrals of the methyl proton signals in the ^{1}H NMR spectrum [δ = 1.06 (2-propanol) and 2.04 (acetone)].

The reaction of $(CD_3)_2CO$ and 2-propanol (0.37–1.9 M) with **2** (2.3×10^{-2} M) was monitored over a period of 60 min with 2-propanol conversion in the range of 11 to 20%. The plot of lg(initial rate) versus lg[2-propanol]$_0$ showed a linear dependence, giving n = 1.2 (assumed to be 1, within experimental error). Thus, $-d[2\text{-propanol}]/dt = k_{1obsd}[2\text{-propanol}]$, where $k_{1obsd} = 5.4 \times 10^{-5}\ s^{-1}$ at 23 °C. The reaction of $(CD_3)_2CO$ and 2-propanol (1.87 M) with **2** (0.45×10^{-2} to 4.0×10^{-2} M) was monitored over a period of 60 min with 2-propanol conversion in the range of 6.7 to 28%. The plot of lg(initial rate) versus lg[**2**]$_0$ gave n = 0.8 (assumed to be 1, within experimental error). Thus, $-d[2\text{-propanol}]/dt = k_{2obsd}[\mathbf{2}]$, where $k_{2obsd} = 4.7 \times 10^{-3}\ s^{-1}$ at 23 °C.

The reaction of acetone (0.19–0.39 M) with **2** (1.3×10^{-2} M) in $(CD_3)_2CHOH$ was monitored over a period of 5 min with 2-propanol conversions of up to 40%. The plot of lg(initial rate) versus lg[acetone]$_0$ gave n = 1.0. Thus, $-d[\text{acetone}]/dt = k_{3obsd}[\text{acetone}]$, where $k_{3obsd} = 1.4 \times 10^{-3}\ s^{-1}$ at 23 °C. The initial rate became zero order for acetone concentration > 0.4 M. Thus, $-d[\text{acetone}]/dt = k_{4obsd}$, where $k_{4obsd} = 7.8 \times 10^{-4}\ M\,s^{-1}$.

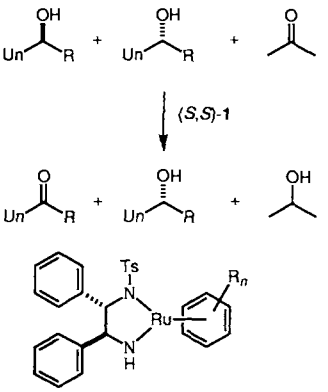
Kinetic Resolution of Racemic Secondary Alcohols by Ru^{II}-Catalyzed Hydrogen Transfer**

Shohei Hashiguchi, Akio Fujii, Karl-Josef Haack, Kazuhiko Matsumura, Takao Ikariya, and Ryoji Noyori*

The recent discovery of highly reactive, chiral metal complexes led to rapid advances in catalytic asymmetric transfer hydrogenation.[1–7] Chiral diamine-based Ru^{II} complexes are particularly efficient catalysts for the enantioselective reduction of prochiral ketones under mild conditions using 2-propanol as a hydrogen source.[1, 3, 4] Since this asymmetric reaction is reversible, the efficiency is highly dependent on the redox properties of the alcohols formed[8] in addition to the chiral recognition capabilities of the catalyst. Therefore, high enantioselectivity is not possible in the preparation of alcohols having a high reduction potential such as 2,3-benzo-2-cyclenols and 1-phenylethanols with an electron-donating group on the aromatic ring.[1] Although this is the greatest flaw of this otherwise attractive asymmetric catalysis, the same tendency provides an opportunity for kinetic resolution of such secondary alcohols. However, this is possible only with a suitable catalyst and under suitable reaction conditions. Here, we report on an example of the direct resolution, without derivatization,[9] of simple racemic alcohols by a purely chemical method,[5c, 10–12] which is a useful complement to the asymmetric reduction of achiral ketones.[1–7]

Excellent kinetic differentiation of enantiomeric alcohols is achieved with the novel purple-colored Ru^{II} complexes (*S,S*)-**1** (Ts = *p*-toluenesulfonyl, see Scheme 1).[3] The kinetic resolution in acetone occurs with the general sense of Equation (a). Thus, when a 2 M solution of racemic 1-phenylethanol (**2a**) in acetone containing (*S,S*)-**1b** (substrate/catalyst molar ratio (S/C) = 500) was left at 28 °C for 30 h, a 97:3 mixture of (*R*)- and (*S*)-**2a** (94% *ee*) was recovered in 51% yield in addition to the acetophenone product in 49% yield. The use of (*S,S*)-**1**, which has a unique 16-electron configuration, is a key reason for the success when the reaction is conducted under nearly neutral conditions. Although treatment of the HCl adduct of **1**, which has an 18-electron configuration,[2] with KOH generates the catalytically active species (*S,S*)-**1** in situ,[1a, 2, 3] excess base



(*S,S*)-**1a**, arene = *p*-cymene
(*S,S*)-**1b**, arene = mesitylene

causes serious side reactions including the aldol reaction of acetone, which hampers the otherwise well-created catalytic cycle.

Some other examples of racemic alcohols resolved in this way are given in Table 1. Most of these alcohols are difficult to obtain in high enantiomeric purity by reduction of the corresponding ketones with 2-propanol.[1] Now, various 1-phenylethanol derivatives **2** having an electron-donating group at the *para* position are available.[13] This method is the first enantioselective approach to **2c**. Polyoxygenated 1-phenylethanols such as **3** can be resolved easily under similar conditions. Resolution

Table 1. Kinetic resolution of alcohols by chiral Ru^{II} complexes in acetone [a].

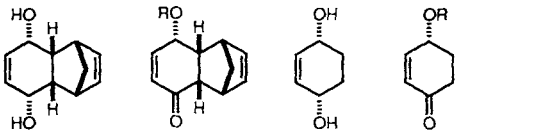
Substr.	Cat.	S/C	Unreacted substrate				
			Time [h]	Recovery [%]	*ee* [%]	Config.	k_f/k_s [b]
2a	(*S,S*)-**1a**	500	36	50	92	*R*	>80
2a	(*S,S*)-**1b**	500	30	51	94	*R*	>100
2b	(*S,S*)-**1a**	500	22	47	92	*R*	>30
2c	(*S,S*)-**1b**	500	30	44	98	*R*	>30
3a	(*S,S*)-**1b**	500	36	47	97	*R*	>50
3b	(*S,S*)-**1b**	500	24	47	97	*R*	>50
4a	(*S,S*)-**1a**	500	6	46	97	*R*	>40
4b	(*S,S*)-**1a**	500	6	49	99	*R*	>50
5	(*S,S*)-**1b**	200	36	51	98	*R*	>100 [c]
6a	(*S,S*)-**1a**	500	4.5	43	93	*R*	14 [c]
6b	(*S,S*)-**1a**	500	5	46	95	*R*	>20 [c]
7	(*S,S*)-**1a**	500	40	49	45	*R*	4

[a] The reaction was carried out at 28 °C in a 2 M acetone solution of the substrate (5–10 mmol). [b] The ratio was estimated based on the final conversion and enantiomeric purity of the recovered alcohol unless otherwise specified. [c] For accuracy, the ratio was determined at 10–20% conversion.

of racemic 1-indanol (**4a**) and 1-tetralol (**4b**) gave the (*R*) enantiomers in 97–99% *ee* at 50–55% conversion. 1-Ferrocenylethanol **5** was also resolved effectively. Reaction of the racemic cyclic allylic alcohols **6a** and **6b** with (*S,S*)-**1a** afforded the slow-reacting (*R*) alcohols in 93 and 95% *ee*, respectively. This is noteworthy because none of the catalytic methods currently available can be used to reduce 2-cyclohexenone or its 3-alkylated derivatives with high enantioselectivity.[14] Unfortunately, the reaction of the flexible allylic alcohol **7** proceeded with only moderate enantioselectivity. Thus, enantiomeric cyclic allylic alcohols are available by means of either resolution by this method or by the Ru(binap)-catalyzed hydrogenation (binap = 1,1′-binaphthalene-2,2′-diyl)bis(diphenylphosphane)) of the corresponding ketones,[11d] although the flexible allylic alcohols are best obtained in high *ee* by means of the Sharpless epoxidation.[11a, b]

The stereochemical outcome of the transfer hydrogenation is very sensitive to both kinetic and thermodynamic factors, because both the hydrogen acceptor and the product are ketones. This simple resolution process benefits from the excellent enantiomer discriminating ability of the ruthenium catalyst **1** and the high reduction potential of the starting alcohols. In the reaction sketched in Equation (a) catalyzed by the (*S,S*) catalyst, an (*S*) alcohol (priority, Un > R) is dehydrogenated more easily than its (*R*) enantiomer. As a consequence of microscopic reversibility, it is the *Si* face of the product ketone that accepts a hydride faster in the same ruthenium template.[1a, 3] In any case, many of the enantiomeric substrates in Table 1 are initially differentiated by a factor of >50,[15] although the reverse process participates to some extent at a later stage of the reaction. ^{1}H NMR analysis revealed that the chiral complex (*S,S*)-**1a** oxidizes (*S*)-**2a** 86 times faster than (*R*)-**2a**.

This procedure is more appealing when applied to the *meso* substrates, because the theoretical yield of the chiral product is 100% rather than 50%. For example, desymmetrization of the unsaturated diol **8** with acetone containing (*S,S*)-**1b** gave **9a** in 96% *ee* and 70% yield. The structure of **9a** was determined after conversion to the acetate **9b**. The hydroxy enone serves as an important building block for the synthesis of various complex compounds.[16] When the *meso*-cyclohexenediol **10** was treated with acetone containing (*S,S*)-**1a**, (*R*)-configurated **11a** was obtained in 87% *ee* and 56% yield. The structure was determined after conversion to the *tert*-butyldimethylsilyl ether **11b**, which is an intermediate in the syntheses of ML-236A[17a] and FK-506.[17b]



8 **9a**: R = H; **9b**: R = CH_3CO **10** **11a**: R = H; **11b**: R = t-$C_4H_9(CH_3)_2Si$

Most chemical asymmetric catalyses developed so far occur in one direction.[18] Hydrogen transfer reaction is characterized by its reversibility, and now both the forward[1] and back reactions, depending on the substrates, are viable as tools for optical resolution. This chemical redox process mimics the biological transformation with oxidoreductases such as horse liver alcohol dehydrogenase with NAD or NADH as the cofactor.[19] The most attractive feature of this ruthenium-catalyzed reaction is the use of acetone and 2-propanol as the inexpensive, well-behaving hydrogen acceptor and donor, respectively.[20] The concomitantly formed product ketones are readily recyclable.

Experimental Section

Kinetic resolution of racemic 1-indanol (**4a**): A mixture of the Ru catalyst (*S,S*)-**1a** [3] (6.0 mg, 10 μmol) and **4a** (671 mg, 5 mmol, 2 M, S/C = 500) in acetone (2.5 mL) was stirred at 28 °C for 6 h under argon and concentrated to dryness under reduced pressure. Chromatographic purification of the residue on silica gel (20 g, hexane/ethyl acetate 3/1 as eluent) gave (*R*)-1-indanol (286 mg, 84%) as colorless crystals. M.p. 71–72 °C; $[\alpha]_D^{24} = -30.1$ ($c = 1.96$, $CHCl_3$) [21]; 97% *ee* determined by HPLC analysis (Chiralcel OB, 2-propanol/hexane 1/9 (0.5 mL min^{-1}), (*S*) isomer 18.6 min, (*R*) isomer 12.9 min).

(*S,S*)-**1b**: This complex was prepared in a similar manner to (*S,S*)-**1a** [3]. Although **1b** is highly moisture-sensitive in solution, it is stable enough to be handled as a solid and can be used in reactions without problems. Crystals suitable for X-ray analysis have not been obtained, but the NMR spectrum was consistent with the assigned structure. ^{1}H NMR (400 MHz, [D$_8$]toluene, 25 °C, TMS): $\delta = 1.91$ (s, 9H; CH_3 in mesitylene), 1.99 (s, 3H; CH_3 in Ts), 3.83 (d, ^3J(H,H) = 4.9 Hz, 1H; *H*CNH), 4.51 (s, 1H; *H*CN-*p*-Ts), 4.95 (s, 3H; CH_{arom} in mesitylene), 5.92 (br. d, 1H; NH), 6.38–7.51 (14H; *p*-$CH_3C_6H_4SO_2N(CH(C_6H_5))_2NH$).

2a: $[\alpha]_D^{23} = +45.2$ ($c = 1.01$, CH_2Cl_2) [22]; 92% *ee* determined by GLC analysis (CP-Cyclodextrin-β-236-M-19, 115 °C, He (2.0 kg cm^{-2}), (*S*) isomer 19.7 min, (*R*) isomer 18.6 min).

2b: $[\alpha]_D^{23} = +48.1$ ($c = 1.04$, $CHCl_3$) [22]; 92% *ee* determined by HPLC analysis (Chiralcel OB, 2-propanol/hexane 1/9 (0.5 mL min^{-1}), (*S*) isomer 26.3 min, (*R*) isomer 34.4 min).

2c: $[\alpha]_D^{23} = +52.0$ ($c = 0.98$, CH_3OH). Since this alcohol is highly acid-sensitive, the value of optical rotation is apt to vary; 98% *ee* determined by HPLC analysis (Chiralcel OD, 2-propanol/hexane/diethylamine 5/95/0.5 (0.5 mL min^{-1}), (*S*) isomer 34.3 min, (*R*) isomer 31.0 min). The absolute configuration was established by the sequence: 1) protection of the hydroxyl group (chloromethyl methyl ether/$(iC_3H_7)_2NC_2H_5$), 2) oxidation of the arene group to a carboxyl group (cat. $RuCl_3$–$NaIO_4$), 3) esterification with diazomethane to form methyl (*R*)-2-methoxymethyloxypropionate. The authentic sample was prepared from the commercially available methyl (*R*)-lactate by methoxymethylation with chloromethyl methyl ether/$(iC_3H_7)_2NC_2H_5$; $[\alpha]_D^{23} = +85.6$ ($c = 1.04$, $CHCl_3$).

3a: $[\alpha]_D^{23} = +43.0$ ($c = 1.00$, $CHCl_3$); 97% *ee* determined by HPLC analysis (Chiralcel OB, 2-propanol/hexane 3/7 (0.5 mL min^{-1}), (*S*) isomer 15.0 min, (*R*) isomer 27.5 min). The absolute configuration was established by the sequence [23]: 1) benzoylation, 2) oxidation of the arene group to a carboxyl group (cat. $RuCl_3$–$NaIO_4$), 3) esterification with diazomethane to form (*R*)-methyl *O*-benzoyllactate.

3b: $[\alpha]_D^{23} = +46.5$ ($c = 1.01$, $CHCl_3$); 97% *ee* determined by HPLC analysis (Chiralcel AS, 2-propanol/hexane 1/4 (0.5 mL min^{-1}), (*S*) isomer 28.6 min, (*R*) isomer 25.0 min). The absolute configuration was established by converting the product alcohol into (*R*)-methyl *O*-benzoyllactate in a similar manner to that for **3a**.

4b: M.p. 40–41 °C; $[\alpha]_D^{23} = -31.6$ ($c = 2.50$, $CHCl_3$) [24]; 99% *ee* determined by HPLC analysis (Chiralcel OB, 2-propanol/hexane = 1/9 (0.5 mL min^{-1}), (*S*) isomer 16.3 min, (*R*) isomer 11.7 min).

5: M.p. 77–78 °C; $[\alpha]_D^{23} = -28.9$ ($c = 1.21$, benzene) [25]; 98% *ee* determined by HPLC analysis (Chiralcel OJ, 2-propanol/hexane 3:97 (0.5 mL min^{-1}), (*S*) isomer 25.7 min, (*R*) isomer 23.3 min).

6a: $[\alpha]_D^{23} = +117.5$ ($c = 1.03$, $CHCl_3$) [26]; 93% *ee* determined by GLC analysis (CP-Cyclodextrin-β-236-M-19, 90 °C, He (2.0 kg cm^{-2}), (*S*) isomer 16.0 min, (*R*) isomer 16.6 min).

6b: $[\alpha]_D^{23} = +92.9$ ($c = 0.99$, $CHCl_3$) [26]; 95% *ee* determined by GLC analysis (CP-Cyclodextrin-β-236-M-19, 100 °C, He (2.0 kg cm^{-2}), (*S*) isomer 16.6 min, (*R*) isomer 18.5 min).

7: $[\alpha]_D^{23} = +16.3$ ($c = 4.98$, $CHCl_3$) [27]; 45% *ee* determined by HPLC analysis (Chiralcel OD, 2-propanol/hexane = 1/9 (0.6 mL min^{-1}), (*S*) isomer 24.0 min, (*R*) isomer 16.8 min).

9b: The reaction of **8** was conducted at a substrate concentration of 0.1 M. M.p. 34–35 °C; $[\alpha]_D^{23} = +238.0$ ($c = 1.00$, $CHCl_3$) [28]; 96% *ee* determined by HPLC analysis (Chiralcel OD, 2-propanol/hexane 3/97 (0.5 mL min^{-1}), (*S*) isomer 28.7 min, (*R*) isomer 30.7 min).

11b: $[\alpha]_D^{23} = +79.8$ ($c = 1.02$, $CHCl_3$) [29]; 87% *ee* determined by HPLC analysis (Chiralcel OD, 2-propanol/hexane 3/97 (0.5 mL min^{-1}), (*S*) isomer 12.1 min, (*R*) isomer 13.3 min).

Determination of the ratio k_f/k_s: Both enantiomers of **2a** (purchased from Wako Pure Chemical Industry, Ltd. (Japan)) were purified by distillation under reduced pressure ((*S*) isomer: 99% *ee*, 99.2% purity; (*R*) isomer: 99% *ee*, >99.5% purity). The reaction was initiated by adding (*S*)- or (*R*)-**2a** to a solution of (*S*,*S*)-**1a** in $(CD_3)_2CO$ (1.0 M, 0.7 mL) at 23 °C. The reaction was monitored by changes in the intensity of the methyl proton signals in the ^1H NMR spectrum [$\delta = 1.40$ (d, $^3J(H,H) = 6.4$ Hz; **2a**) and 2.57 (s; acetophenone)]. In the reaction of the (*S*) isomer, 0.7 mg of (*S*,*S*)-**1a** (1.67×10^{-3} M, S/C = 600) was used, where $k_{f,obsd} = 2.31 \times 10^{-5}$ M^{-1} s^{-1} (10–40 min, 1.3–5.6% conversion). For the (*R*) isomer, 22.0 mg of (*S*,*S*)-**1a** (5.24×10^{-2} M, S/C = 19) was used, where $k_{s,obsd} = 8.46 \times 10^{-6}$ M^{-1} s^{-1} (30–120 min, 2.1–6.6% conversion). Since the reaction rate is first order in the catalyst concentration over the range of the substrate concentration (1 M) [3], the k_f/k_s value is calculated to be 86; both enantiomers are assumed to react by the the same mechanism.

The High Nuclearity Mixed-Metal Cluster Dianions $[Ru_8H_2Cu_7Cl_3(CO)_{24}]^{2-}$ and $[Ru_{12}H_2Cu_6Cl_2(CO)_{34}]^{2-}$**

Michael A. Beswick, Jack Lewis, Paul R. Raithby,* and M. Carmen Ramirez de Arellano

The synthesis of copper-containing clusters is of interest because of the relevance of mixed-copper alloys for use in catalytic processes.[1] The majority of the high nuclearity copper-containing clusters that have been fully characterized involve the combination of copper with main group elements such as selenium and tellurium,[2] and relatively few clusters, which contain more than six metal atoms, have been isolated in which copper combines with transition metal carbonyl fragments. The normal synthetic route for the formation of the mixed transition metal–copper clusters involves the reaction of a mononuclear copper cationic complex with an anionic cluster carbonyl, in which the copper fragment clips on to the periphery of the preformed cluster unit.[3] Condensation reactions between anionic carbonyl clusters and electrophilic mononuclear metal complexes also lead to the formation of large heteronuclear carbonyl clusters.[4–6]

We now report the synthesis and structural characterization of a novel class of mixed-metal ruthenium–copper clusters. Treatment of the monoanion $[Ru_6H(CO)_{18}]^-$ with excess $[Cu(MeCN)_4]^+$ in CH_2Cl_2 in the presence of $[(Ph_3P)_2N]Cl$ under reflux leads after purification by thin-layer chromatography to $[(Ph_3P)_2N]_2[Ru_8H_2Cu_7Cl_3(CO)_{24}]$ (**1**) in 60–70% yield.

After the preliminary characterization of complex **1** by spectroscopy,[7] an X-ray crystal structure analysis was undertaken to establish the geometry of the product. Suitable crystals were grown by the layered diffusion of ethanol into a solution of **1** in CH_2Cl_2.[8] The structure of the dianion (Figure 1 top) may be viewed as two tetraruthenium clusters sandwiching the heptacopper cluster metal core; the metal framework is illustrated in Figure 1 bottom. If the ruthenium tetrahedra are each considered to have a formal 3 − charge, that is $[Ru_4H(CO)_{12}]^{3-}$, each of the seven copper atoms is in a formal +1 oxidation state.

The Cu_7 core geometry may be described as two fused square-based pyramids that share a common triangular face. Three chloro ligands each symmetrically bridge two of the Cu atoms in the core. The remaining Cu atom, Cu(5), which is not involved in the chloro bridges, has no ligand groups attached to it but is coordinated to eight other metal atoms; that is to the other six Cu atoms and Ru(2) and Ru(5). Thus, the immediate environment around Cu(5) is similar to that in metallic copper. The atoms Cu(2) and Cu(6) have seven metal–metal contacts since they are bonded to each other and to six other metals, whereas atoms Cu(1), Cu(3), Cu(4), and Cu(7) have five metal–metal contacts. The individual Cu–Cu contact distances range from 2.513(4) to 2.947(5) Å and do not reflect the idealized mirror symmetry of the cluster core; however, the three chloro-bridged edges are significantly longer (av 2.84 Å) than the other ten edges (av 2.57 Å). Within each Ru_4 tetrahedron the three Ru–Ru edges that are capped by the Cu atoms are significantly longer (av 2.94 Å) than the three that are not capped by the Cu atoms (av 2.81 Å). This may be related to the case of $[H_3Ru_4(CO)_{12}]^-$,[9] in which the Ru–Ru edges that are bridged by the hydride ligands are longer than the other metal–metal edges. The dianion **1** has two asymmetric bridging carbonyl ligands, each Ru_4 unit contains one [C(21)–Ru(8) 2.298(12), C(21)–Ru(2) 1.934(12) Å] and [C(35)–Ru(5) 1.960(12), C(35)–Ru(3) 2.249(12) Å]. The hydride ligands could not be located definitively either from the electron density difference map or from potential energy calculations.[10]

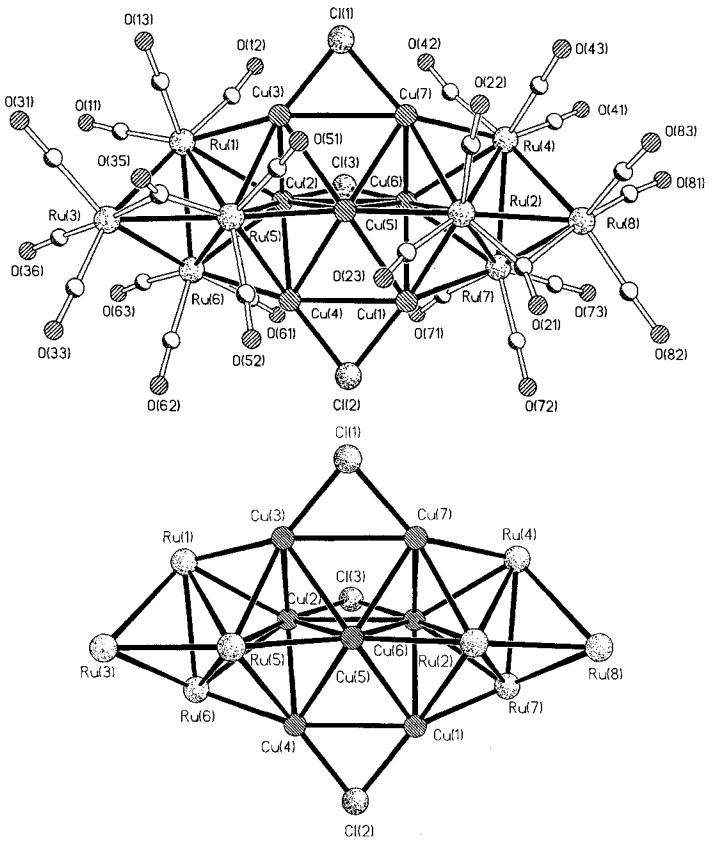

Figure 1. Top: The molecular structure of the dianion $[Ru_8H_2Cu_7Cl_3(CO)_{24}]^{2-}$ of **1** showing the atom numbering scheme. Selected bond lengths [Å]: Ru(1)–Cu(3) 2.616(4), Ru(1)–Cu(2) 2.727(5), Ru(1)–Ru(3) 2.800(5), Ru(1)–Ru(5) 2.905(5), Ru(1)–Ru(6) 2.997(5), Ru(2)–Cu(5) 2.609(4), Ru(2)–Cu(1) 2.622(4), Ru(2)–Cu(7) 2.640(5), Ru(2)–Cu(6) 2.753(5), Ru(2)–Ru(8) 2.817(5), Ru(2)–Ru(4) 2.880(5), Ru(2)–Ru(7) 2.948(5), Ru(3)–Ru(5) 2.825(5), Ru(3)–Ru(6) 2.831(5), Ru(4)–Cu(7) 2.686(5), Ru(4)–Cu(6) 2.754(5), Ru(4)–Ru(8) 2.835(5), Ru(4)–Ru(7) 2.988(5), Ru(5)–Cu(5) 2.590(4), Ru(5)–Cu(4) 2.645(5), Ru(5)–Cu(3) 2.648(5), Ru(5)–Cu(2) 2.745(5), Ru(5)–Ru(6) 2.907(5), Ru(6)–Cu(4) 2.645(5), Ru(6)–Cu(2) 2.679(5), Ru(7)–Cu(1) 2.610(5), Ru(7)–Cu(6) 2.669(5), Ru(7)–Ru(8) 2.778(5), Cu(1)–Cl(2) 2.196(5), Cu(1)–Cu(6) 2.567(5), Cu(1)–Cu(5) 2.617(5), Cu(1)–Cu(4) 2.699(5), Cu(2)–Cl(3) 2.210(5), Cu(2)–Cu(3) 2.513(4), Cu(2)–Cu(4) 2.540(4), Cu(2)–Cu(5) 2.582(5), Cu(2)–Cu(6) 2.947(5), Cu(3)–Cl(1) 2.204(4), Cu(3)–Cu(5) 2.638(5), Cu(3)–Cu(7) 2.886(5), Cu(4)–Cl(2) 2.214(5), Cu(4)–Cu(5) 2.587(5), Cu(5)–Cu(6) 2.518(4), Cu(5)–Cu(7) 2.568(4), Cu(6)–Cl(3) 2.227(5), Cu(6)–Cu(7) 2.525(4), Cu(7)–Cl(1) 2.231(5); bottom: the metal core geometry of **1**.

The structure of **1** is reminiscent of that in $[\{Ru_4H(CO)_{12}B\}_2Cu_4Cl]$, in which two Ru_4B units are fused with a central Cu_4 tetrahedron; this is a rare example of a copper polyhedron forming the central core of a mixed-metal cluster.[11] Interestingly, the copper polyhedron in this example and in **1** has bridging chloro ligands present, which may help to stabilize the copper core against fragmentation.

The nature of the mixed-metal cluster obtained in the reaction is dependent on the solvent used. When $[Ru_6H(CO)_{18}]^-$ is treat-

ed with a large excess of $[Cu(MeCN)_4]^+$ in the presence of $[(Ph_3P)_2N]Cl$ in MeCN, $[(Ph_3P)_2N]_2[Ru_{12}H_2Cu_6Cl_2(CO)_{34}]$ (**2**) was obtained after purification by thin-layer chromatography on silica plates using CH_2Cl_2 as the only eluent. The complex was characterized by spectroscopy,[12] and in order to establish the cluster geometry, by X-ray structure analysis. Suitable crystals were grown by the layered diffusion of ethanol into a solution of the cluster in CH_2Cl_2.[13] The structure of the dianion of **2** is shown in Figure 2 top, the metal framework geometry in Figure 2 bottom.

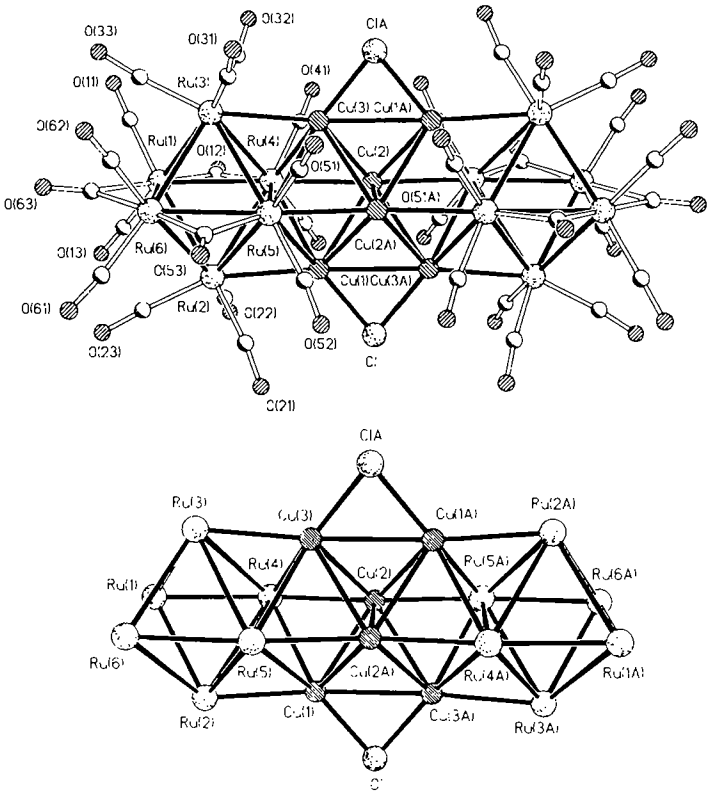

Figure 2. Top: The molecular structure of the dianion $[Ru_{12}H_2Cu_6Cl_2(CO)_{34}]^{2-}$ of **2** showing the atom numbering scheme. Selected bond lengths [Å] and angles [°]: Ru(1)–Ru(6) 2.845(2), Ru(1)–Ru(4) 2.846(2), Ru(1)–Ru(2) 2.848(2), Ru(1)–Ru(3) 2.863(2), Ru(2)–Cu(1) 2.663(2), Ru(2)–Ru(6) 2.883(2), Ru(2)–Ru(4) 2.933(2), Ru(2)–Ru(5) 2.934(2), Ru(3)–Cu(3) 2.636(2), Ru(3)–Ru(6) 2.870(2), Ru(3)–Ru(4) 2.940(2), Ru(3)–Ru(5) 2.963(2), Ru(4)–Cu(2) 2.603(2), Ru(4)–Cu(1) 2.675(2), Ru(4)–Cu(3) 2.719(2), Ru(4)–Ru(5) 3.056(2), Ru(5)–Cu(2a) 2.602(2), Ru(5)–Cu(3) 2.694(2), Ru(5)–Cu(1) 2.715(2), Ru(5)–Ru(6) 2.824(2), Cu(1)–Cl 2.213(4), Cu(1)–Cu(2) 2.619(3), Cu(1)–Cu(2a) 2.668(3), Cu(1)–Cu(3a) 2.768(3), Cu(2)–Cu(2a) 2.472(3), Cu(2)–Cu(3) 2.610(3), Cu(2)–Cu(3a) 2.653(3), Cu(3)–Cl(a) 2.207(4); Cu(3a)-Cl-Cu(1) 77.55(12); bottom: the metal core geometry of **2**.

The structure of the dianion of **2** can be viewed as two hexaruthenium clusters sandwiching the hexacopper cluster metal core; the dianion sits on a crystallographic center of symmetry at the midpoint of the Cu(2)–Cu(2a) bond. The two hexaruthenium units have retained the octahedral metal core geometry in the precursor anion $[Ru_6H(CO)_{18}]^-$, although in this case the hydride ligand is interstitial;[14] in **2** the hydride signal in the ^1H NMR spectrum is at $\delta = -17.8$ indicative of a bridging hydride. There are 17 carbonyl ligands on each of the ruthenium units, 14 are terminal, and three are symmetrically edge-bridging. Each of the two ruthenium octahedra can be viewed as $[Ru_6H(CO)_{17}]^{3-}$, having lost a carbonyl from the original monoanion. The copper core may alternatively be viewed as two tetrahedra fused through a common edge Cu(2)–Cu(2a), which generates two butterfly arrangements Cu(1), Cu(2), Cu(2a), Cu(3) and Cu(1a), Cu(2), Cu(2a), Cu(3a). The two edges Cu(1)–Cu(3a) and Cu(3)–Cu(1a) are each symmetrically bridged by chloride ions. The whole structure can be viewed as the linear condensation of four octahedra, which generates a five-runged ladder type molecule. If each of the ruthenium units donates a 3– charge, as in **1**, each of the six Cu atoms is formally in the +1 oxidation state. As in **1** the Ru–Ru edges that are capped by Cu atoms (av 2.97 Å) are significantly longer than the uncapped edges (av 2.85 Å). Also the Cu–Cu edges bridged by chloro ligands (2.768(3) Å) are longer than the unbridged Cu–Cu edges (av 2.64 Å), and the central Cu(2)–Cu(2a) edge is even shorter at 2.472(3) Å.

Thus, under the appropriate reaction conditions copper cations can form cluster units that will link together anionic transition metal cluster anions to form higher nuclearity mixed-metal clusters. For this process to occur it appears that chloride ions should be available, even if they are abstracted from a chlorinated solvent. The formation of chloro bridges within the copper fragment of the high nuclearity cluster stabilizes the cluster against fragmentation. By varying the reaction conditions and the ruthenium cluster anion used it is possible to synthesize mixed-metal clusters in high yield with specific Ru:Cu ratios. In the case of the anions **1** and **2** the ratios are 8:7 and 2:1, respectively. These clusters may be viewed as precursors to Ru:Cu alloys with specific ratios of the elements.

Experimental Section

1 and **2**: $[(Ph_3P)_2N][Ru_6H(CO)_{18}]$ (100 mg, 0.06 mmol), $[(Ph_3P)_2N]Cl$ (100 mg, 0.17 mmol), and excess $[Cu(MeCN)_4][BF_4]$ (250 mg, 0.80 mmol) in CH_2Cl_2 (MeCN for **2**) (50 mL) were heated under reflux for 4 h. Over this period the solution turned from a bright red to a dark brown. The mixture was filtered hot and the volume reduced to 10 mL under vacuum. The mixture was separated by thin-layer chromatography with CH_2Cl_2 as eluent. In the synthesis of **1** three products were eluted: $[Ru_3(CO)_{12}]$, the starting material $[Ru_6H(CO)_{18}]^-$, and the novel mixed-metal cluster **1** (yield 60–70%, 60 mg); in the synthesis of **2**, **2** was isolated as the only product (yield 70%, 75 mg).

Deposition of Data from X-Ray Structure Analyses

In order to make life easier for authors and referees the Cambridge Crystallographic Data Centre (CCDC) and the Fachinformationszentrum Karlsruhe (FIZ) have unified their procedures for the deposition of data from single-crystal X-ray structure analyses.

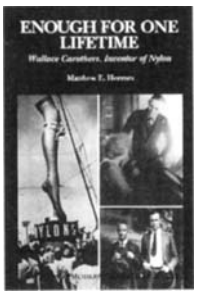
From now on prior to submitting your manuscripts please deposit the data for your compound(s) **electronically** at the appropriate data base, that is, at the CCDC for organic and organometallic compounds and at the FIZ for inorganic compounds. Both data bases will be pleased to provide help (see our *Notice to Authors* in the first issue of this year). In general, you will receive a depository number from the data base within two working days after electronic deposition; please include this number with the appropriate standard text (see our *Notice to Authors*) in your manuscript. This will enable the referees to retrieve the structure data quickly and efficiently if they need this information to reach their decision.

This is now the uniform procedure for manuscripts submitted to the journals *Angewandte Chemie, Chemische Berichte, Chemistry—A European Journal*, and *Liebigs Annalen*.

Mr. Nylon

Enough for One Lifetime. Wallace Carothers, Inventor of Nylon. By *M. E. Hermes*. American Chemical Society, Washington, DC, 1996. 345 pp., hardcover $ 39.95.—ISBN 0-8412-3331-4

This book, in which Matthew E. Hermes describes the life and scientific work of Wallace Carothers, is both important and unusual. The research career of this essential chemist and the story of his discovery of nylon is interesting enough in itself, but the detailed account of his personal life and his unhappy end is fascinating and at the same time thought-provoking. It is a very readable book, espite the author's overemphasis on the personal aspects and on the US context of Carothers' work, while neglecting the ramifications in the international world of science and industry—for example, one would have liked to learn more about the development of polyamide 6 (Perlon) as a competitor to nylon, and about its precursor caprolactam.



The dry facts are as follows. Wallace Hume Carothers, born in 1896 in the mid-western city of Des Moines, was educated at Tarkio College, Missouri and at the University of Illinois, Urbana, where he obtained his Ph.D. in 1924, at a comparatively late age for those times. His supervisor was Roger Adams, the editor of *Organic Syntheses*. The latter series, which consisted of tried and tested synthetic methods, was a direct response to the threat facing the US chemical industry during World War I, which had the effect of cutting off essential supplies of chemicals from Germany. The account of Carothers' time in Urbana reveals how much his subsequent life was influenced by his friendship with James B. Conant, who at that time held the chair of organic chemistry at Harvard University, and later—after World War II—was the US High Commissioner for Germany (not, however, for Europe, as is wrongly stated in the book).

In 1926 Carothers went to Paris, which at that time was the home of the "lost generation" that included Hemingway, Ezra Pound, and Scott Fitzgerald with his wife Zelda. Although these writers were in Paris at different stages of their lives than in Carothers' case, their fates were similar, ending in alcoholism and suicide. Hermes hints at the likely significance of two souvenirs brought back by Carothers from his stay in Paris: a copy of James Joyce's "Ulysses" (banned by the USA authorities at that time), and a slim illustrated volume entitled "21 Ways to Commit Suicide". Carothers appears to have brought back nothing from Paris related to his work in chemistry.

Beginning in the academic year 1926/27, Carothers taught at Harvard University. It was a world that must have seemed very different from the one he was familiar with: "Fight fiercely, Harvard, fight, fight, fight!" (Harvard graduate Tom Lehrer in 1953). Although he had already published quite a number of papers, in 1928 Carothers accepted an invitation to move to DuPont in Wilmington. This was the era of Stine, who placed great emphasis on fundamental research, and Carothers was formally assigned to work on organic chemistry. However, with the agreement of his superiors, Stine and Bolton, he concentrated his main efforts on developing the polymerization section of DuPont's experimental station. Here he worked in the areas of polyesters, vinylacetylenes, chloroprene, synthetic rubbers (DuPrene and Neoprene), "polyalkanes" or ring compounds used in fragrances and flavoring additives, and new developments in important techniques such as molecular distillation. Later he worked under Bolton in his Chemical Department, in an environment clearly orientated towards applied research, and during 1934 and 1935 he carried out his important work on the development of nylon—more precisely, nylon 6-6, the polyamide formed from adipic acid and hexamethylenediamine. Thus he made his lasting contribution to chemical history, and incidentally also helped DuPont to world-wide success and profit.

The above summary, describing what appears from the outside as a very successful life, conceals a darker side to Carothers' personality. Throughout the book there runs the underlying theme of a troubled mind, which Hermes characterizes by the term "abulia". This word appears in few dictionaries, but I eventually found it in Pschyrembel's medical dictionary, where it is described as a loss of willpower and self-control. Carothers began to be aware of his difficulties around the time of his Ph.D. dissertation, when he had a serious alcohol problem (surprisingly, during the time of prohibition in the USA!) and suffered occasional "absences" (brief lapses of awareness). Later on he was subject to sudden disappearances and periods of manic depression, deep melancholy, and neuroses, and was in the habit of always carrying "cyanide pills" with him. Sometimes he would be unable to work, and probably also had difficulties in communicating at a personal level. Hermes presents a depressing, and undoubtedly accurate, picture of Carothers as an introverted scientist who frequently disliked himself, but at the same time appeared to his work colleagues as highly gifted, indeed brilliant, and had no difficulty in communicating on scientific matters. Thus, the supposed victim of "abulia" had two quite different sides to his character: on the one hand the likeable, widely recognized, and intermittently highly productive colleague Carothers (who had published about 50 papers and patents within quite a short time), on the other hand a chemist weakened by periods of illness, apathy, and loss of willpower.

On the basis of the view that "alcoholism was not a congenital disease" (p. 205), the psychiatrist treating Carothers

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

(who, incidentally, also treated Scott Fitzgerald) recommended marriage as an appropriate therapy, and Carothers followed that advice. Whether it was the right advice for such an unhappy man may be doubted even by those of us with no medical knowledge. Against this background, the account of Carothers' unhappy relationships with the girl-friends of his youth, to which Hermes devotes several pages, is easier to understand, and makes an interesting addition to the overall picture. Here, though, and also in other parts of the book, the description seems unnecessarily long. One is aware throughout that this is the work of a scientifically competent author (who has even provided an appendix with chemical formulas). After his active career as a chemist, Hermes took an M. A. degree. He now seems to be now trying (so far unsuccessfully) to arrive at the right compromise between concise scientific writing and an output of flowery, woolly, and often long-winded eulogies more characteristic of students of the humanities. As it turns out, Carothers' (brief) marriage appears not to have been unhappy, despite the fact that Hermes introduces the relevant chapter with a quotation from the *Reader's Digest* of 1935, "Be glad you're neurotic", which seems unnecessarily judgmental and below the belt.

Nevertheless, the last year of Carothers' life was certainly turbulent, and eventually led up to the cataclysm. There was his first appearance on the international conference scene (in Cambridge, England), followed by a week-long disappearance to Paris and the Black Forest, his marriage, election to membership of the US National Academy of Sciences, and his admission to hospital at the request of his wife. His "abulia" is nowadays diagnosed as "neurocirculatory athenia", a severe form of anxiety neurosis.

Wallace Hume Carothers ended his own life on 30 April 1937. However, the two aspects of his life that we now regard as closely associated together are not genius and madness, rather they are genius and alcoholism.

To See the Obvious. (Series: Profiles, Pathways, and Dreams. Series editor: *J. I. Seeman.*) By *A. J. Birch.* American Chemical Society, Washington, DC, 1995. xxviii, 269 pp., hardcover $ 24.95.—ISBN 0-8412-1840-4

The metal–absolute ethanol–liquid ammonia process for the partial dehydrogenation of aromatic systems (with sodium as the most usual metal) was first named by Carl Djerassi and is now universally known as the Birch reduction. This is a versatile and reliable reaction that has been a mainstay of synthetic organic chemists for more than half a century and has facilitated the commercial development of the contraceptive "pill". In fact, as Ralph Raphael stated at a Gordon Research Conference, "the verb 'to birch' no longer means to thrash. No dictionary would be so rash as to put this meaning in first place." This nomenclature accorded Arthur John Birch, the esteemed Australian organic chemist, known as "the grandfather of the contraceptive pill," classic and legendary status and led to the exaggerated rumor that he has been dead for years. Actually, Birch died quite recently—on December 8, 1995. Despite a hospital stay in May 1995 for renal failure, Birch characteristically told *Profiles, Pathways, and Dreams* editor Jeff Seeman, "I just refused to die. I'm very strong minded. Probably too strong-minded," and he completed the page proof corrections for his carefully written autobiography, the 18th in Seeman's series, just after his dismissal from the hospital shortly before his 80th birthday last August.

Admittedly a perfectionist (he destroyed his only copy of his doctoral thesis shortly after obtaining his degree because he regarded the work as "unimaginative potboiling"), Birch spent nearly a decade working on this book. The title is derived from a compliment tendered to him in 1946 by colleague M. A. T. Rogers of Imperial Chemical Industries, Ltd. (ICI), "You are the best person I know for seeing the obvious." Although Birch calls his book "the personal story, over 50 years, of the making of one chemist, embracing general social, political, ethical, and historical aspects of scientific research of technical and philosophical significance, applied in organization and teaching," he does not consider himself the hero: "My 'hero' is organic chemistry in its adolescence up to its present adult status."

Birch was born on August 3, 1915 in Sydney, Australia of a poor family and became interested in science at the age of about ten when he was intrigued by the apparent bending caused by refraction of a stick standing in water. A legacy of £ 100 from his Aunt Maude, who died in 1924, enabled his father to buy him some basic chemical equipment. By the age of 12 he had taught himself organic chemistry from Julius B. Cohen's textbook, and his first home experiments involved steam-distilling leaves and resins of Australian plants and the preparing of ethanol from figs growing in the family garden and converting it to ether and ethyl bromide. He later became interested in natural products chemistry because he was intrigued by the pleasant smells of eucalyptus and wondered what makes the leaves of different trees so different. Beautiful crystals appealed to him aesthetically, so he later usually avoided "messy" technical areas of great biological importance. From his early years he was attracted by "the broad sweep of ideas collected around philosophically defined examples that can be tested experimentally."

Because of his father's illness, Birch was forced to become responsible and to work hard for his own livelihood from the age of 17, which led him to "acquire autonomy and independence, work attitudes that I carried through life despite an inherent dreaminess and laziness and boredom with detail." He attended the University of Sydney during the nadir of the depression (1933–1938), receiving his M. Sc. degree for a study of α-phellandrene and α-thujene. In those days Australian universities did not award doctorates, so he emigrated to England for graduate study. He chose Oxford rather than Imperial College, London "largely because of the reputation of [Sir] Robert Robinson compared with that of Ian Heilbron." After receiving his D. Phil. degree for a study of long-chain fatty acids (1941), he remained at Oxford on an ICI grant, working on synthetic steroids with the aim of assisting fighter pilots through the use of cortical hormones. This led him to devise novel methods of introducing methyl groups and of achieving partial reductions of aromatic systems, resulting in the Birch reduction (1942).

Birch had told Robinson of his work on reductions and had "interpreted his expressed lack of interest as permission to carry on this work." According to 1969 Nobel chemistry laureate Sir Derek H. R. Barton, "Robinson was away from Oxford during much of the war, and when he found out about Birch's work, he was furious. Birch was certainly very seriously considered for a Nobel Prize, but I think that Sir Robert torpedoed it!... Robert Robinson acted on his animosities." Birch

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3603-0296 $ 15.00+.25/0

waxes nostalgic about his days at Oxford's Dyson Perrins Laboratory, and throughout the book he is amazingly frank about Robinson's strengths, weaknesses, and idiosyncrasies: "Robinson and I had a 'friendly enemy' relationship. In a strange way, I was almost his father. He was a childish fellow; I tried to keep him in good humor." Despite Robinson's behavior toward him, in his acknowledgments Birch states, "I wish to express my great admiration and affection for him, despite any remarks I have made to indicate that he was a human being."

In 1942 Birch's mother, who had followed him to England in 1939 (his father had died in 1937), began to suffer from Parkinson's disease. Beginning in 1947 she was cared for by Jessie Williams, a Welsh nurse whom Birch married in October 1948. The couple had three sons and two daughters. In January 1949 Birch moved to Cambridge University (which he compares in some detail with Oxford), where he worked independently as a research fellow on steroid hormone synthesis and natural-product structure determination, with the financial support of 1957 Nobel chemistry laureate Lord Alexander R. Todd, who also provided him with Ph.D. student Herchel Smith. Smith later became a multimillionaire and provided financial support for the "Profiles" series.

Birch's first professorship (that of organic chemistry as well as Department Head) involved his return to his alma mater (University of Sydney, 1952–1955), "a complete innocent in administration, with little teaching experience." He was then called as professor to Manchester University (1956–1967) and to the Australian National University (ANU, 1967–1980), where he and David Craig established the Research School of Chemistry (RSC), of which he served as Dean (1967–1970; 1973–1976). Except for a few examples, such as the synthesis of gabaculine and of isotopically labeled shikimic acid, lack of practical research support during his "retirement" has necessitated his leaving laboratory work to his "very able former collaborators."

Birch relates all these events in his life along with "inside stories," remarkably candid evaluations of himself, colleagues, and friends, as well as his varied research interests and contributions. Characterized by Carl Djerassi as "very imaginative, highly creative" and "a maverick, a lone wolf," Birch describes himself as "a private person ... not an extrovert .... I do what my conscience tells me I must, whatever the personal sacrifice .... I decided in my middle age that I am a rather strange person. I don't behave conventionally. I'm somewhat shy. I'm reluctant to put forward my personal views unless I am compelled to do so. I have never believed in virtue generated solely by self-sacrifice. I do not have broad indiscriminate friendships. Most of my close friendships are notably with my family." Among the many friends and colleagues whom he vividly describes, in addition to Robinson and Todd, are 1975 Nobel chemistry laureate John Warcup ("Kappa") Cornforth, his wife Lady Cornforth (the former Rita Harradence), Herchel Smith, Gilbert Stork, Franz Sondheimer, and Robert B. Woodward.

Birch also devotes four separate chapters to detailed descriptions of his research contributions, which he classifies into "sets"—(1) natural products (chemistry, structural determination, and physical methods); (2) total synthesis, novel methods (including the Birch reduction), reaction mechanisms, regio- and stereospecificity, cortical hormones (he produced the first totally synthetic highly active androgen, which was also the first synthetic structure-specific hormone, published before the natural hormone syntheses of Woodward and of Cornforth and Robinson); (3) biosynthesis, biosynthetic structure determination, alterations of biosynthetic pathways, and his polyketide hypothesis, which evolved into the major theory that now explains the biosynthetic skeletal origins of thousands of natural products; and (4) "superimposed lateral control" of organic synthesis by using transition metal organometallic complexes ("My philosophy is to use the principles by which enzymes work, without trying to imitate the exact practical methods"). These chapters are replete with numerous reaction schemes containing 113 structural formulas.

But in addition to technical details, Birch shares his philosophical reflections on research: "I was never out of my laboratories for long, although not at my bench. I wanted to feel that I was directly involved in the excitement of scientific detail, not just an organizational entrepreneur .... The usual narrow academic approach is the antithesis of genuinely novel research. It is only good for exploiting the known .... After frequent interruptions I returned anew to each scientific problem. This renewal broke vicious circles of thinking, which are the greatest hazards of those scientists who are permitted to revolve in continuously decreasing mental circles within their laboratories. Often their thinking slowly becomes introverted, outdated, and irrelevant .... If people are not allowed to make their own mistakes, they will never make anything worthwhile."

Although Birch devotes a separate 7-page chapter ("Behind Every Successful Man ...") "to look at two women who made possible the beginning and the continuation of my carreer," the portraits of his mother and wife that emerge are unclear and shadowy, and we would have liked to know more about their influence on his life and career. His veneration of the two most important women in his life also seems strangely inconsistent with his oversimplified "politically incorrect" view, expressed elsewhere (p. 233), that "a testosterone factor, involving aggression and egotism, is needed for success ... in a scientific career ... as well as in creative fields like art and music ... at the very highest levels." In our view, lack of an adequate support system for women also contributes to their disproportionately low representation and contributions in these fields.

In a 6-page chapter, "Become a Professor and See the World", Birch discusses his travels, especially in underdeveloped countries, and he relates some amusing jokes and stories about travel difficulties with bureaucracies in socialist countries. He reveals the origin of his beard: "So that I would easily be recognized at foreign airports by people who did not know me." For his "Political and Other Activities" (the title of a 13-page chapter) he received the Companion of the Order of Australia, the highest Australian award, and his activities were so extensive that he became the subject of a Ph.D. thesis in political science at the University of Melbourne.

A unique feature of the book, unprecedented in the series to date, is the inclusion of "Random Conversations with the Editor" (the final and longest—53 pp.—chapter), in interview format. Here Birch addresses important social and human activities of science and of scientists as investigators and as people; creativity and the sources of ideas; motivations for research; the role of teamwork and of women in science; scientific training and attitudes; national versions of chemistry (France, India, United States, Soviet Union and other socialist countries, Switzerland, and Australia); pollution; laboratory design and safety; beauty in science; the rewards of science; and stories about the journal *Tetrahedron*. The book is graced with 45 formal and informal photographs and a caricature of Birch, and it contains 149 references. This intimate and revealing autobiography will appeal to persons interested in organic

The Natural Selection of the Chemical Elements. By *R. J. P. Williams* and *J. J. R. Fraústo da Silva*. Oxford University Press, Oxford, 1996. 646 pp., hardcover £ 75.00. – ISBN 0-19-855843-0

Evolution is a universal process which appears in different forms. One of these is chemical evolution, and in this book R. J. P. Williams and J. J. R. Fraústo da Silva examine the question of how the "selection" aspect of evolution applies to the chemical elements. The elements, either in isolation or in chemical compounds, behave differently towards external influences, and as a result they undergo a form of "selection". Thus, their distribution and function in nature are a consequence of their properties. This relationship, which at first seems trivial, turns out to be remarkably complex when looked at in detail.

Part I of the book consists of seven chapters in which the authors explain the principles governing the natural selection of the chemical elements. First they remind the reader of some basic facts about general, inorganic, and physical chemistry. Then they turn in detail to various aspects of phases and compartmentalization, which are referred to frequently in the later discussions. The interdisciplinary approach and breadth of subject matter that are key characteristics of the book are already evident here. Thus, in the space of only ten pages within a chapter the authors progress from the conventional separation processes of inorganic chemistry to the structures of a sub-unit in a bacterial ribosome and of a DNA–histone octamer complex. Part I ends with a chapter on kinetic control, activation barriers, feedback, and organization.

Part II contains nine chapters dealing with the natural selection of the elements in both living and inanimate systems. We learn that selection can occur by various mechanisms: through the establishment of thermodynamic equilibria, through kinetic trapping, as a consequence of the functional value of a particular element in an organized system (such as a living organism), or lastly by deliberate actions related to the value of a substance for survival, protection, welfare, or pleasure (e.g. in human activities). The reader is also taken on a journey through time, from the origin of our planet and the evolution of organic compounds, to the earliest anaerobic organisms and their possible biochemistry, then to present-day organisms and the effects of human activity on the cycling of the elements. The main emphasis is on chemical elements in living organisms, and the authors link the discussion to their earlier book *The Biological Chemistry of the Elements. The Inorganic Chemistry of Life* (review: *Angew. Chem.* **1993**, *105*, 315; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 300). It is presumably not by chance that the present book has a representation of Botticelli's Venus on the cover, since that is also the logo of the Society of Biological Inorganic Chemistry.

By bringing together knowledge from a variety of disciplines the authors develop many new ideas and concepts, some of which are quite speculative. For example, it is interesting to consider the consequences of changes in the availability of a particular element or compound. Organisms initially treat a new substance as a poison, and they therefore develop internal protective mechanisms. In the course of time these evolve into systems that use the "poison" as a chemical messenger. In the final stage of development the substance becomes incorporated into the organism as a normal constituent. Are we at present seeing the beginning of such a development sequence for aluminum, which is becoming increasingly available to lifeforms as a result of acid rain? Copper, which is now an essential element for all living organisms, was unavailable up to about $2\frac{1}{2}$ billion years ago, as it was locked in the form of sulfides of extremely low solubility. It was not until oxygen began to be produced by photosynthesis that the element became available in a more soluble form, through the conversion of sulfide to sulfate.

The discussions are illustrated by several hundred figures and tables. At the end of each chapter is a list of publications for more advanced study, and a comprehensive index is provided at the end of the book. Only a few errors that I found are worth mentioning. Thus, manganite is MnO(OH), not MnO_2O_3 (Fig. 5.17); in Figure 6.24 the length of the bar is 0.1 micron, not 10 micron; the value given in Figure 7.2 for the pressure at the center of the sun is many orders of magnitude too small; the formula for glutathione in Figure 11.24 is incorrect; Galileo was born in 1564, not 1524 (p. 598). The importance of the book extends well beyond chemistry, as it promotes a view of nature as an interdependent whole, and a respectful attitude towards both living *and* inanimate forms. In this respect it is unfortunate that the readership will probably be essentially limited to graduate chemists with a sound scientific education. However, all those who think that they fit into this category are emphatically recommended to read the book.

The Chemistry of Organophosphorus Compounds. Volume 4. Ter- and Quinquevalent Phosphorus Acids and their Derivatives. (Series: The Chemistry of Functional Groups. Series editors: *S. Patai* and *Z. Rappoport.*). Edited by *F. R. Hartley*. Wiley, Chichester, 1996. 945 pp., hardcover £ 320.00.— ISBN 0-471-95706-2

Volume 4 of *The Chemistry of Organophosphorus Compounds* completes this four-volume work, six years after the first volume appeared. Thus it is now appropriate to evaluate not only this volume but the work as a whole.

In an earlier review (*Angew. Chem. Int. Ed. Engl.*, **1996**, *35*, 667) it was remarked that even after the publication of the first three volumes a clear plan for the overall work was not yet apparent. Now that all four volumes have appeared, this conclusion remains unchanged.

Volume 4 contains ten chapters dealing with important aspects of organophosphorus chemistry. The authors are well-known specialists in their fields. R. S. Edmundson has written no less than five of the chapters (over 600 pages in total). The volume begins with a short chapter by O. Dahl on derivatives of acids containing trivalent phosphorus. This is followed by Edmundson's five chapters, which are concerned with phosphonic and phosphinic acids and their derivatives. In the case of these chapters especially, one would have liked this material to be published sooner. A chapter by E. Breuer treats the related topic of acyl phosphonates.

Next there is a very welcome chapter by R. A. J. O'Hair on mass-spectrometric studies of organophosphorus com-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3603-0298 $ 15.00+.25/0

pounds. Here again one is prompted to ask why chapters of this sort, dealing with physical or other methods of analysis in organophosphorus chemistry, have been scattered through several volumes rather than collected together in a single volume. The following chapters are devoted to the biological activity of phosphonic and phosphinic acids (A. Kalir and H. H. Kalir) and the chemistry of organophosphorus compounds with military applications (R. M. Black and J. M. Harrison); both these are topics without which a work on this subject area would not be complete.

The comments made when reviewing the previous three volumes also apply to Volume 4: here too we have a group of topics of central importance in organophosphorus chemistry, covered by authors who are experts in these areas. Throughout the book there are detailed lists of references giving the reader access to the original literature and to review articles and monographs. In some chapters the references are more up-to-date than in the previous volumes, often extending to very recently published work, and by including "Notes added in proof" it has been possible to update the literature coverage still further. However, a fully comprehensive citation of all published work was apparently not intended.

Regrettably it must again be mentioned, as in previous reviews, that insufficient care has been devoted to the important matter of correctly citing authors' names in the literature references The frequent occurrence of garbled names is annoying. This is especially so when a particular author's name turns up at several places in two, or even three, different versions, which may then appear at different positions in the index of authors. The lack of care is especially obvious in the treatment of names from outside the English-speaking world – for example, an umlaut is almost invariably ignored. With regard to journal names, in a publication of this nature one expects the editors to know, for example, that no journal with the title *Chemische Berichte* existed before 1945. Also a few of the citations turned out to be incorrect when they were checked.

As has already been noted for the preceding three volumes, it must be said again that the work as a whole shows no clearly recognizable plan or systematic arrangement of subject matter. It is not easy to locate information on a specific topic, particularly for the nonspecialist who may not have a very precise idea of what he or she is looking for. It would have been helpful to provide an overall plan for the work, for example by including in Volume 4 a guide to the four volumes, thus making it more user-friendly, especially as the text is closely set with a small typeface.

Despite the above reservations, these four volumes unquestionably provide the most up-to-date and comprehensive treatment of organophosphorus chemistry that is currently available, and they are a valuable addition to the *Chemistry of Functional Groups* series edited by Patai. Every chemist who is interested in any aspect of organophosphorus chemistry needs to have access to them.

Electron Transfer and Radical Processes in Transition-Metal Chemistry. **By** *D. Astruc.* VCH Verlagsgesellschaft, New York, 1995. 630 pp., hardcover DM 225.00/$ 140.00.—ISBN 1-56081-642-2

The intention of Didier Astruc in his book *Electron Transfer and Radical Processes in Transition-Metal Chemistry* is to provide an introduction and overview of electron-transfer reactions and odd-electron transition-metal chemistry for the reader who is relatively unfamiliar with the field. He succeeds in providing an easy-to-read introduction to the majority of important topics in this vast area, but with regard to some topics he falls short of providing a representative sample of the important experiments and ideas in these areas. This is no great surprise considering the enormous breadth of the field he has chosen to review.

Chapter 1 provides a nice overview of some of the basic concepts and theories of electron transfer. This chapter serves as a tutorial for the scientist who is vaguely familiar with the field but wants to learn more about it without being intimidated by its jargon. Chapter 2, which deals with electrochemical techniques for studying the electron transfer properties and reactivities of transition metal complexes, is also nicely done in that it focuses on the methods most frequently used in this area and refers the reader to some of the more sophisticated but less frequently used methods. In this chapter the author has collected relevant examples from existing texts on electrochemistry and presented them in a more reader-friendly manner. In addition, he addresses strengths and limitations of each technique and provides extensive references. Chapter 3, which covers the structures of transition-metal radicals and paramagnetic complexes, is also quite well done. I did not care for Chapter 4, which pertains to the emerging and important area of molecular electronics. In this chapter the referencing is inadequate, and although the author correctly identifies "molecular assembly" as one of the greatest challenges in molecular electronics, he fails to discuss monolayer self-assembly methodology, one of the most important methods for organizing molecules onto device components. The choice of devices and systems for discussion in this area also seems somewhat random. Chapters 5–7, which deal with mechanistic issues involving radical transition metal complexes and the use of transition metal redox equivalents in applications to synthesis and catalysis, are well done with the exception of the section on catalysis of biochemical redox reactions. This section, like the chapter on molecular electronics, is too cursory for the reader to obtain an understanding of the primary issues in these important areas.

Overall, this is a well written book with parts that could be useful in an introductory graduate course that focuses on electron transfer in transition-metal-based systems, providing that the course is supplemented extensively with examples from the literature.

Branched 1-methoxyalkanes have been detected in nature only in spiders. One of their uses may be in species recognition.

The Chemistry of Spider Toxins and Spider Silk

Stefan Schulz

Spiders have a bad reputation because of their predacious and hidden way of life. Nevertheless, they developed a finely tuned system, based on the use of venom and silk, which enabled them to compete successfully in evolution. Only recently has the mystery of the chemistry of their silk and venom begun to unravel, although the first investigations were performed at the beginning of this century and in the fifties. The silk and toxins are made of proteins, but low molecular weight compounds are also present, too. Among these small molecules are compounds not known from any other natural source. For this reason the following article will focus on the structure and function of the low molecular weight components of the silk and the venom.

Keywords: acylpolyamines · lipids · natural products · pheromones · spider toxins

1. Introduction

The relations between human beings and spiders is a special one, which for ages has been based on fear.[1] Of the many examples of this in our culture, one especially impressive is Jeremias Gotthelf's story, "Die schwarze Spinne" ("The Black Spider").[2] On the other hand, the delicate webs and elaborate hunting techniques are also fascinating. Their way of life seems to be very successful, enabling them to survive in all terrestrial ecosystems. In many they are the dominant predatory animals.

Spiders (Araneae) differ from insects in that they have eight legs and a body consisting of two parts. Together with mites and ticks, daddy-long-legs, scorpions, and some other orders they form the large class of arachnida, surpassed in number of species only by insects and fungi. More than 30000 spider species are known. Especially two features are characteristic: they are predatory animals and use chelicera for hunting. This first pair of limbs is located in front of the mouth and contains a poisonous fang, from which the spiders inject a highly effective toxin into the body of their victims. The other feature is the universal use of silk. No other animal order employs it so perfectly. The silk is utilized for many different tasks, for example, in the construction of draglines, hunting webs, protection of eggs or prey, and as building material.

The chemical composition of venom and silk has been under study for some time. The most prominent components of the venom are proteins; the silk is also made of skeletal proteins. During recent years some new constituents, mostly smaller molecules, were identified. This article will focus on these compounds in particular.

2. Spider Venom

On closer examination only a small number of spider species are really dangerous to man. Serious bites are caused often by small inconspicuous spiders such as the black widow (*Latrodectus sp.*). Other dangerous genera are *Atrax*, *Loxosceles*, *Phoneutria*, and *Harpactirella*. The spider venom often creates intense pain, but if treated properly, seldom leads to death.[3]

Since the first investigations by Fischer and Bohn 40 years ago,[4] the toxins of some 90 species have been examined, but only few of them have been characterized chemically. The most prominent components are polypeptides and proteins, which are neurotoxic, cytotoxic, or enzymatically active. Low molecular weight components and inorganic salts are also present.[5] Studies on their structure and mode of action are currently being performed, because they can be used for biochemical research and possibly as treatment for diseases or as insecticides.[6] Only more rarely have the enzymes of the spider venom been investigated. Some of them act hydrolytically and start the digestion of the prey outside the spider's stomach. After some time the spider is able to suck out its prey.[7]

2.1. Proteins as Toxins

Most of proteins and peptides of spider venom characterized so far are neurotoxic. Their structure and mode of action are often species- or genus-specific. Some of the known compounds will be described in this section.

Two similar proteins occur in the black widow spider *Latrodectus mactans*, namely, α-latrotoxin (130 kDa)[8] and α-latroinsectotoxin (120 kDa).[9, 10] Both proteins bind on presynaptic membranes where they form Ca ion channels. This leads to a massive liberation of neurotransmitters from the cell.[9, 11]

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997* *0570-0833/97/3604-0315 $ 15.00+.25/0*

Though these toxins have the same action, each shows a different selectivity. α-Latrotoxin is toxic exclusively for vertebrates,[8] whereas α-latroinsectotoxin affects only insects.[10] Apparently the two toxins bind at different locations of the presynaptic membrane. These neurotoxins have been prepared recently with the aid of insect cells.[12]

Small peptides like robustoxin from the very dangerous Australian funnel web spider *Atrax robustus*, which consists of 42 amino acids, can also elicit increased firing of skeletal motor and autonomic nerves.[13] Robustoxin is liberated from a larger precursor.[14] Additional peptides of this type have been already patented because of their insecticidal properties.[15]

The peptides (agatoxins) isolated from the funnel web spider *Agenelopsis aperta* (Agelenidae) act differently. They block presynaptic Ca channels and thus prevent the liberation of neurotransmitters. The peptide ω-Aga-IVA, which contains 48 amino acids, acts preferentially on channels of the P-type,[16, 17] whereas ω-Aga-IA (66 amino acids) blocks L- and N-type Ca ion channels.[18] The structures of ω-Aga-IVA and the related ω-Aga-IVB in solution were recently published.[19, 20] Both peptides contain a three-stranded, antiparallel β-sheet connected by flexible regions (Figure 1). Four disulfide bridges are present in the molecules. In the vicinity of a random-coil region on the C-terminal end are three positively charged arginine residues. On the basis of this structure a mechanism for the action of the peptide was postulated: The positively charged amino acid residues bind to negatively charged groups of the ion channel,

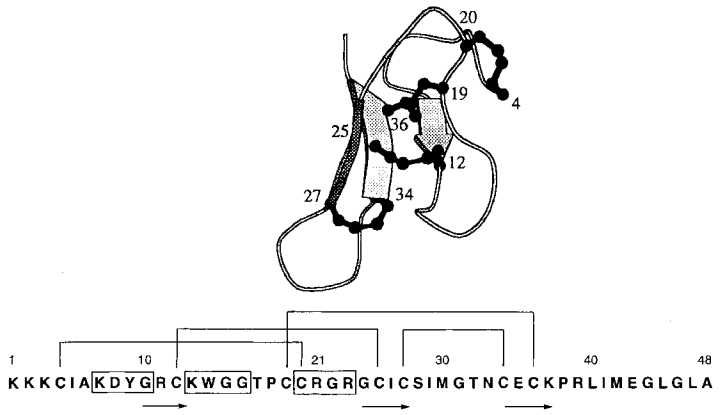

Figure 1. Schematic representation of the structure (top) and the amino acid sequence (bottom) of ω-Aga-IVA [20]. The triple-strand, antiparallel β-sheet is represented by arrows, the three β-turns in the sequence by boxes, and the four disulfide bridges by connecting lines (reproduced with kind permission of the publisher).

which are located near the entrance. The hydrophobic tail of the peptide thus blocks the entrance to the channel.[19]

The peptide μ-Aga-I (36 amino acids, 4 disulfide bridges), which acts specifically at Na ion channels of insects, has a very similar three-dimensional structure, but a completely different sequence of amino acids and mode of action.[21] It alters the release of neurotransmitters from the motoric end plate and leads to repetitive firing of nerve cells, apparently by shifting of the action potential to more negative values.[22] Surprisingly, also the neurotoxic peptides from snails and scorpions possess a similar spatial arrangement, but different primary structures and actions. The peptide SNX-325, which contains 49 amino acids, was isolated from *Segestria florentina* (Segestriidae). It selectively blocks N-type Ca ion channels.[23]

Some of the toxins of the aggressive American banana spider *Phoneutria nigriventer* (PhTx2-5 and PhTx2-6) exhibit a similar action to the μ-agatoxins on Na ion channels, while PhTx3 blocks Ca ion channels.[24] These peptides, some of which are very similar to the agatoxins, contain between 32 and 55 residues.[25] Overall, the amino acid sequences of approximately 35 neurotoxins from 10 species are presently known.[24]

Besides these neurotoxins, a number of enzymes are present in spider toxins. They have been less thoroughly investigated till now. The American *Loxosceles* species (the feared brown recluse spider from North America) possesses a necrosis-producing sphingomyelinase.[26] This enzyme is a phospholipase D, which contrary to phospholipase D from plants selectively cleaves sphingomyelin and thus causes aggregation of blood platelets. It is not known in other animal venoms, but occurs in some bacteria.[27] Other phospholipases,[28] hyaluronidases,[29] collagenases,[30] peptide isomerases,[31] and proteases[32] have been found recently.

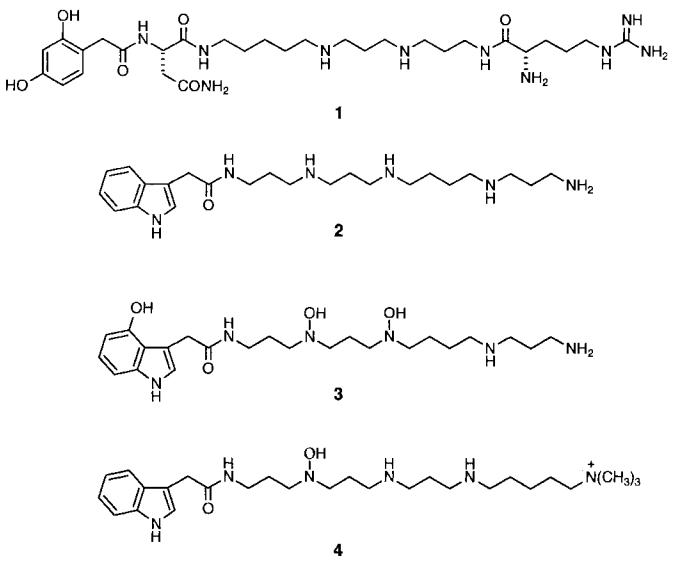
2.2. Low Molecular Weight Components of the Spider Venom

Low molecular weight components (molecular weight below 1000 Da) and inorganic salts have been identified besides proteins and peptides in spider venom.[5] Some of these compounds act as neurotransmitters and increase the effectiveness of the venom. Biogenic amines like 5-methoxy- and 5-hydroxytryptamine (serotonin), histamine, and tyramine as well as the amino acids γ-aminobutyric acid, asparagine, and glutamic acid are known.[33] Citric acid is also present in poison glands[34] and

Stefan Schulz was born in 1957 in Hamburg. He studied Chemistry at the University of Hamburg and completed his dissertation in 1987 in the group of Wittko Francke. He then spent a postdoc fellowship with Jerrold Meinwald at Cornell University. In 1994 he finished his habilitation in Hamburg and was nominated Privatdozent shortly afterwards. His main research area is chemical ecology, especially the chemical communication systems of arachnids and insects. He received the Förderpreis der Greve Stiftung für Wissenschaften awarded by the Joachim Jungius Gesellschaft für Wissenschaften in 1989.

apparently functions as inhibitor of venom phospholipases. The acid binds Ca ions, which are necessary for the action of the enzymes. In this way the self-intoxication of the spider is prevented.[35]

At the beginning of the eighties a new class of compounds was found in spider venom, the acylpolyamines.[36, 37] Free polyamines like spermine were already detected during the fifties in the venom of tarantulas[4], and later in other species.[38] The related acylpolyamines possess an α,ω-diaminopolyazaalkane chain, which consists of one to nine aminopropyl-, aminobutyl-, or aminopentyl units. Sometimes β-alanine or lysine units connected through amide bonds occur in the chain. Some of the N-atoms might be methylated or hydroxylated. The aromatic carboxylic acid is characteristic and bonded through an amide-like linkage to the polyazaalkane chain. So far different hydroxylated benzoic acids, 3-indolylacetic acid, and hydroxylated derivatives, as well as 3-indolyllactic acid have been detected as the lipophilic head groups. The aromatic carboxylic acid and the polyazaalkane chain are constituents of all acylpolyamines. In some compounds the acid and the chain are not connected directly, but by a bridge of one or two of the amino acids asparagine, asparagic acid, ornithine, or ω-methyllysine. The most complex acylpolyamines, for example Arg636 (**1**)[*] (argiotoxin 636, argiopine; Scheme 1) isolated from different

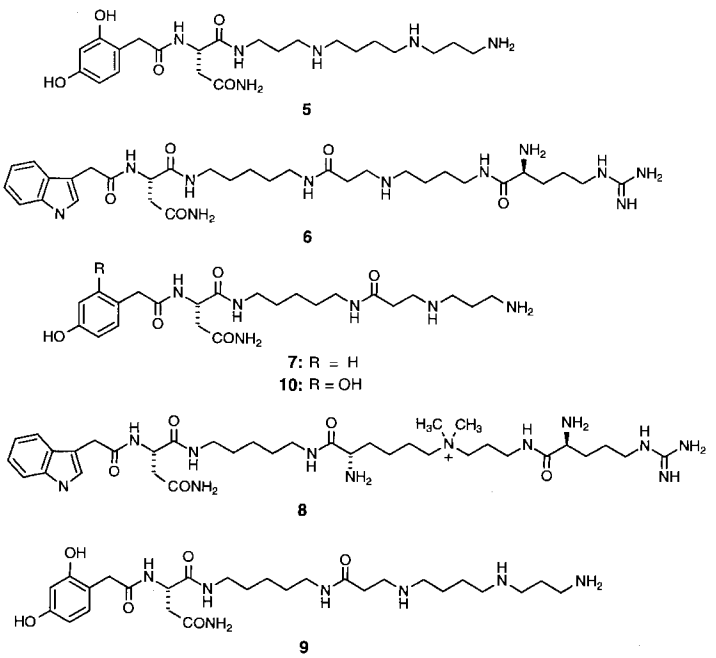


Scheme 1. Argiopine **1** and acylpolyamines of the Agelenidae.

Argiope species, contain a basic amino acid residue at the tail end of the polaazaalkane chain consisting of up to three amino acids. About 70 compounds of this type have been described so far. New review articles describing the structures and synthesis of some representative acylpolyamines,[33, 35, 39] their isolation and analysis,[35] and their biological function[40–42] have been published.

The toxins of the spider families Agelenidae and Araneidae have been investigated most thoroughly. The agelenid toxins represent the simplest acylpolyamines. They are made of the polyazaalkane chain and the aromatic head group, like Agel416 (**2**).[43, 44] Other characteristics of this family are the occasional oxidation of N-atoms in the chain to hydroxyamino groups (Agel464, **3**)[44] and the head groups 4-hydroxybenzoic acid and 2,5-dihydroxybenzoic acid. Sometimes methylated or permethylated derivatives occur, for example Agel 489a (**4**), the structure of which has been revised in 1992.[45] In all, 17 compounds have been isolated to date from the two species *Hololena curta* and *Agenelopsis aperta*. Some of the peptides described in Section 2.1 originate from these species, too.

Most of the known acylpolyamines were isolated from the venom of orb weavers (Araneidae). In these toxins the head group is connected by an amino acid to the polyazaalkane chain, as exemplified by JSTX 1 (**5**) from *Nephila clavata*.[46, 47] In some toxins the basic amino acid arginine or a short peptide with arginine at the amino terminus are additionally bound to the end of the molecule, as in the very well investigated toxin **1**.[37, 47–49] Toxins of the genus *Nephila* very often contain the amino acids β-alanine or lysine in the polyazaalkane chain. Examples are NPTX 10 (**6**)[47] and joramine (**7**)[50, 51] from *Nephila clavata* and Arg743 (pseudoargiopinine 1, **8**) from *Argiope lobata* (Scheme 2).[49, 52] Methylations of N-atoms in the chain occur also (see **8**), but no N-oxidized compounds are known. Almost 40 of such toxin from 7 species have been isolated.



Scheme 2. Acylpolamines of the Araneidae.

Other spider families were only sporadically investigated. The toxins Het389 and Het403 were isolated from tarantulas (*Harpactirella sp.*, Theraphosidae) and *Hebestatis theveniti* (Ctenizidae),[53] while the water spider *Dolomedes okefinokensis* produces the compound CNS 2103.[54] All are very similar to the toxins of the Agelenidae and consist of a unfunctionalized polyazaalkane chain coupled to an aromatic head group.

A special interest in the acylpolyamines arose because of their biological activity, in particular their ability to inhibit Ca ion

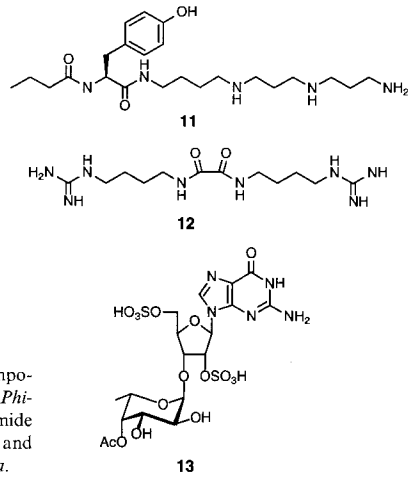
[*] Many acylpolyamines are described by a combination of letters, derived from the species name, and a number that denotes the relative molecular mass. Others possess solely or in addition a trivial name (for example, clavamine), or are denoted in the order of their discovery, e. g. NSTX 1, NSTX 2.

channels. They can selectively block glutamate receptors. Glutamate is a common exciting neurotransmitter in the brain of mammals. Ionotropic glutamate receptors are coupled to an ion channel, which regulates the influx of cations into a cell. Other ionotropic receptors are regulated by serotonin, glycine, or γ-aminobutyric acid. The glutamate receptors can be divided into several subtypes: The NMDA receptor (selective agonist *N*-methyl-D-aspartate) plays a role in some neurological diseases such as stroke, Alzheimer disease, and epilepsy.[55] Spider toxins were the first natural blockers of such receptors. The acylpolyamines may possibly be of therapeutical use[56] or may serve as lead structures for new pharmaceuticals or insecticides.

Not all of the acylpolamines act on the same receptors. The toxins JSTX and NPTX from *Nephila clavata* are effective antagonists of glutamate receptors.[57] JSTX 3 (**9**), a main component of the venom of *Nephila clavata*, is a specific inhibitor of other glutamate receptors, the AMPA (α-amino-3-hydroxy-5-methylisoxazol-4-propionate) and KA (kainic acid, namely 3-carboxymethyl-4-isopropenylproline) receptor channels.[58] The toxin Arg 636 **1**, the best yet investigated, selectively inhibits NMDA receptors. In contrast, other investigators found a selective inhibition of the AMPA and KA receptors by **1**. These partly contradictory results were discussed in detail elsewhere.[40, 42]

All acylpolyamines possess naturally insecticidal properties, because their primary function is paralysis of prey. Ionotropic glutamate receptors are all-important for the signal transduction in the peripheral nerve system of insects. The most important receptor type is selectively stimulated by quisqualic acid (L-α-amino-3,5-dioxo-1,2,4-oxadiazolidin-2-propionic acid, QUIS). Apparently the spiders paralyze the prey by blocking these receptors in the muscles with their venom. Different opinions exist how the toxins actually act on the QUIS receptor: different reports state that the blocking of the receptor is readily reversible, slowly reversible, or essentially irreversible.[40] In addition, not all acylpolyamines show the same effects. Even small structural differences can change their mode of action. Thus, joramine **7** selectively blocks the neuromuscular synapses of lobsters reversibly, while spidamine **10**, different from **7** only in an additional hydroxy group at C2 of the aromatic head group, blocks irreversibly.[51] The additional OH group leads to a totally different conformation of the molecule in solution, as can be seen from the NMR spectrum. Whether this is relevant for the different mode of action is unknown. The most important insecticidal compound from *N. clavata* is clavamine, which is structurally similar to spidamine but contains in addition the tripeptide arginyl-glycyl-alanine at the end of the polyazaalkane chain.[59] Contrary to **7** and **10**, it does not block the excitation route of the lobster synapses.

Acylpolyamines are only known from one source other than spiders: the poison gland of the solitary digger wasp *Philanthus triangulum* (philanthotoxins, PhTx).[60] Besides glutamate receptors, some of the acylpolyamines also inhibit the nicotinic acetylcholine receptors (nAChR). A mode of action for the toxin on the receptor was proposed based on investigations of these receptors with derivatives of the natural PhTX 433 (**11**, Scheme 3) that carry photoaffinity or radioactive labels. The acylpolyamines align in the ion channel with the hydrophobic aromatic head group pointing toward the cell and the polyazaalkane chain blocking the channel (Figure 2). A longer



Scheme 3. PhTx 433 (**11**), component of the venom of the wasp *Philanthus triangulum*, an oxalamide (**12**) from *Plectreurys tristis*, and HF 7 (**13**) from *Hololena curta*.

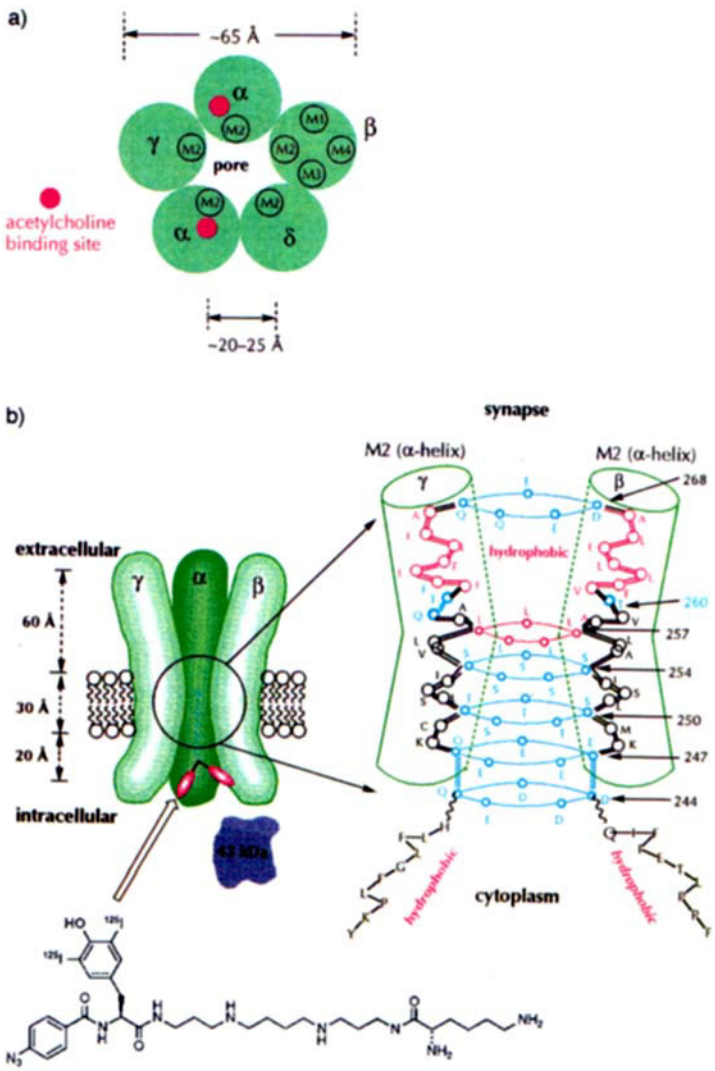


Figure 2. a) The nicotinic acetylcholine receptor (nAChR). Five subunits with four transmembrane segments each (M1–M4) form the ion channel. The ambiphilic helices M2 border the entrance. Acetylcholine opens the channel by binding to positions in the α-subunits (dark points). b) Model for the binding of philanthotoxins to the nAChR. The derivative shown was used for binding studies. It binds at the intracellular side of the channel. The aromatic head group points away from the polyazaalkane chain into the hydrophilic part of the channel. The four blue rings show the hydrophilic region of the five M2 helices. How the toxin reaches this position is unknown (reproduced with kind permission of the publisher) [61].

chain leads to a better binding in the receptor, because more N-atoms are present in the chain to interact electrostatically with the amino acids of the ion channel proteins.[61]

The isolation and structure determination of the acylpolyamines is difficult because the amounts of material available are often small, and complex mixtures of toxins are frequently encountered. Isolations have been successfully performed with reversed phase HPLC. The structure determination is only possible by combination of several techniques. For the elucidation of the first acylpolyamine, Arg636 (**1**), investigations by UV spectroscopy, NMR spectroscopy, mass spectrometry, and an amino acid analysis were necessary.[37, 62] The absolute configuration of the amino acids of the toxins is still not known in many cases.[35] Positions of the N-atoms in the chain can successfully be determined by tandem mass spectrometry. The FAB-MS-MS spectra exhibit fragmentations of the molecular ion that can be explained by breaking of the C–N bonds (Figure 3). This clearly indicates the positions of the N-atoms in the chain, while diagnostic fragments in normal FAB-MS spectra are only visible with low intensity.[54, 63]

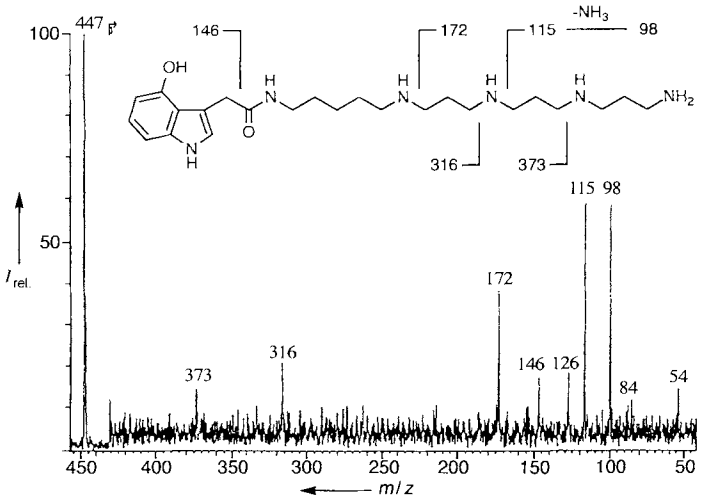

Figure 3. FAB-MS-MS spectrum showing the molecular ion and the fragmentation pattern of CNS 2103 (reprinted from ref. [54] with kind permission from Elsevier Science).

Larger amounts of material than normally available by isolation from natural sources are necessary for the investigation of physiological effects. For this reason, several synthetic approaches to the acylpolyamines have been developed and are reported in detail in some recent reviews.[33, 35, 39] As yet around 25 compounds have been synthesized de novo. Syntheses reported after 1993, conceptionally related to the known ones, are listed in reference [64].

The primitive hunting spider *Plectreurys tristis* does not employ acylpolyamines. Instead, large amounts of bis(agmatin)-oxalamide (**12**) are present besides some peptides. Its structure may be the ancient prototype of the acylpolyamines because of the guanidine end groups and the chainlike backbone. First tests did not show any toxicity against insects and its function remains unclear.[65]

Polyamines are easily protonated under physiological conditions. Thus they can form electrostatic bonds to negatively charged groups in proteins, at least in part the reason for their activity. The compound HF7 **13**, recently isolated from the venom of the agelenid *Hololena curta*, has a totally different structure. This acetylated bissulfate of guanosine fucopyranoside is anionic and the only naturally occurring member of this class of compounds yet discovered.[66] It is also polyvalent, can form mono- or dianions, and blocks Ca ion channels. Simple nucleotides like inosine have been identified from spider venom, too.[67]

3. Spider Silk

All spiders can produce silk, which is used for various tasks. Up to eight types of silk-producing glands are known from some orb weavers. Diverse material is necessary for attachment points, draglines, frames, swathing of prey, cocoons, radial threads, and the glue of the sticky spiral.[68, 69] Since the first analyses by Emil Fischer, who identified seven amino acids in hydrolysates,[70] spider silk was known to consist of proteins. In addition to this proteinogenic frame, some other compounds that are present will be reported in the next sections.

3.1. Structure of the Thread

The silk of spiders is made of keratin, similar to the silk of the silk moth *Bombyx mori*. The α-keratin produced in the silk glands is transformed by pressure into a nematic liquid-crystalline material in the duct of the spinning gland. Directly behind the valve the protein is aligned partially into a β-sheet structure. By this action quasi crystalline regions are embedded into unordered regions.[71] The viscoelastic properties follow from this arrangement: stretching the thread produces a higher state of order. The system can return to its original form on release of the strain because of its high entropy.

The silk possesses a high tensile strength and a good breaking strength. Cracks are absorbed by the crystalline domains, a principle also used in engineering, for example in the use of materials such as glass fiber resins.[72] A tensile strength of $1 \times 10^9\ Nm^{-2}$ (kevlar: $4 \times 10^9\ Nm^{-2}$, rubber $1 \times 10^6\ Nm^{-2}$) and a breaking point energy of $1 \times 10^5\ Jkg^{-1}$ (kevlar $3 \times 10^4\ Jkg^{-1}$, rubber $8 \times 10^4\ Jkg^{-1}$) was measured for the silk of draglines, which is also used for the frames of catching webs.[73] In addition, the silk has a seven times higher elasticity than kevlar. The threads show supercontraction in aqueous media even at room temperature, an unusual property for polymers. The web is always tightened by humidity, because the thread is reduced to 60% of its original dry length.[74]

The catching threads of orb weavers of the genus *Nephila* or the common garden spider *Araneus diadematus* have other properties. This silk is covered with a hygroscopic, viscous, sticky fluid consisting of water, glycoproteins, and other low molecular weight components (see Section 3.2). On uptake of water the thread becomes more elastic and extensible than in the dry state. On its surface the liquid forms small droplets because of the surface tension.[75] This is an important design aspect of the catching system. The sudden impact of prey expands the web without breaking of threads. With decreasing strain the thread

rolls up into the droplets because of the surface tension and slowly returns to its original state. So much energy is absorbed by the net during this process that the prey is not catapulted out but remains attached to the silk. A very strong system results from these viscoelastic properties of the thread and the surface tension of the droplets on its surface.[72]

The silk proteins are mainly made of the amino acids alanine, glycine, and serine, which are accompanied by glutamine, tyrosine, leucine, valine, and proline.[71] They are clearly different from the proteins of the silk of the silk worm, which consists essentially of the three first mentioned amino acids only. Recently the two proteins spidroin I and II (MaSp 1 and MaSp 2) from the dragline of *Nephila clavipes* have been partially characterized by recombinant DNA techniques.[76, 77] Spidroin I has a molecular weight between 275 and 720 kDa,[76] and a repetitive motif, not always strictly followed, consisting of (Gly-Gly-X)$_n$(Ala)$_n$ or (Gly-X-Gly)$_n$(Ala)$_n$. The amino acid X can be glutamine, tyrosine, or leucine.[77] Some disulfide bridges are likely to be present in the molecule.[76] The polyalanine region forms crystalline regions with a β-sheet structure in the polymer. Highly ordered, densely packed regions and less highly ordered regions occur[78] (Figure 4). The crystalline regions are connected by glycine-rich unordered regions in which β-turns are present. The glycine-rich domains also possess regions with a 3_{10}-helix arrangement. These arrangements can lead to intermolecular hydrogen bonds between two protein strands.[79] The protein also carries phosphate groups. *O*-Phosphotyrosine, dihydrogen phosphate, and some other phosphorus-containing compounds were detected in protein hydrolysates.[122] The less well characterized spidroin II possesses a higher proportion of proline and is likely to have properties similar to elastin.[80]

Even at the beginning of the 19th century the physicist Réaumur investigated for the Académie Royale whether commercial production of spider silk in a manner performed for silkworm silk was feasible. This study was based on a dissertation of Bon de Saint-Hilaire on the usefulness of spider silk. Indeed, a pair of gloves was made from silk of *Nephila madagascariensis* for the empress, but the project was not continued, because the cost was 20 times higher than for normal silk.[81] Since then spider silk was used mainly in optical instruments, for instance as the crosshair of telescopic sights. Recently the silk protein genes were cloned and expressed in bacteria, an important step for the production of larger silk quantities.[82] The tensile strength and elasticity makes silk an interesting material, for example, for use as medicinal suture silk or for production of high performance ropes.

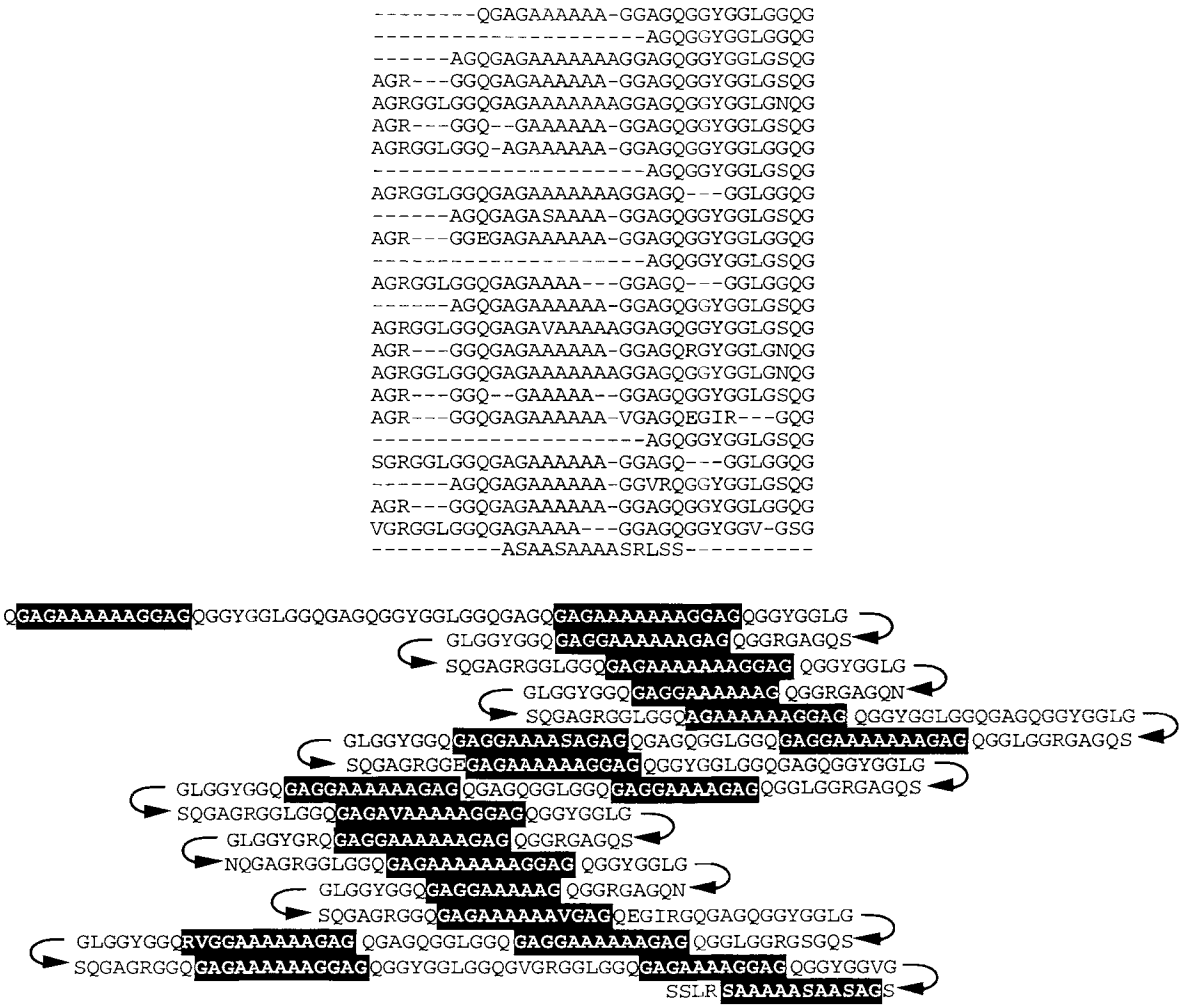

Figure 4. Part of the amino acid sequence of the silk protein of *Nephila clavipes*. The dark regions show the crystalline, alanine-rich β-sheets and the arrows the β-turns (reprinted from ref. [78] with kind permission; Copyright © 1996 American Association for the Advancement of Science).

3.2. The Role of Low Molecular Weight Components for the Function of the Silk

The aqueous coating of the catching threads of orb weavers is essential for the function of the web, as has been explained. First analyses performed as early as the sixties detected high concentrations of γ-aminobutyric acid in this fluid of *Araneus diadematus*. In addition, the amino acids lysine, serine, cystic acid, and a not completely characterized taurine derivative, together with potassium nitrate and potassium dihydrogenphosphate, were identified.[83] New investigations of an aqueous extract of catching threads by ^{1}H NMR spectroscopy showed substantial amounts of the compounds choline, betaine, isethionic acid, *N*-acetyltaurine, and γ-aminobutyric amide, some of which are hygroscopic, to be present. The concentration of the compounds on the thread can reach 2 mol L^{-1}. These concentrated salt solutions, which do not crystallize, reduce the evaporation rate of water from the droplets of the catching thread.[84]

Some of the compounds are known as neurotransmitters. Whether this property helps to overcome the prey is unknown.

Earlier investigations reported that pyrrolidone was present,[85] but it can also be formed during the sample preparation from γ-aminobutyric amide.[86] Both compounds are present in webs of several species belonging to the families Linyphiidae, Arancidae, and Theridiidae, which were investigated carefully.[87] The composition of the water-soluble part of the webs of other orb weavers is rather similar to that of *Araneus diadematus*. Glycine and *N*-acetylputrescine are additional web components.[88]

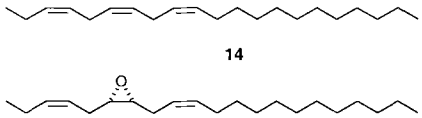
Glycoproteins are present in the salty solution of the droplets. They function as glue and form small nodules around the thread.[89] A preliminary characterization of such a phosphorylated glycoprotein of *Argiope aurantia* showed its relative molecular mass to be 200 kDa. It is composed mainly of glycine, threonine, and proline. The only carbohydrate component identified is *N*-acetylgalactosamine. It is coupled through oxygen to the threonins of the protein, which resembles mucins.[90]

3.3. Semiochemicals

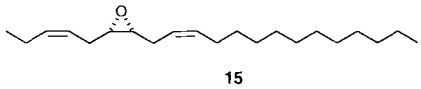
Semiochemicals are used by many spiders for communication. The chemical characterization was achieved recently, although the existence of pheromones[*] or allomones[**] had been proven or postulated for some time. A reason may be the solitary life of spiders. This makes it difficult to keep a larger quantity of animals in the laboratory to get enough material for analysis.

Allomones were identified in the mid eighties in bolas spiders.[91] These unusual araneid spiders build only a single support thread instead of a big orb web. A droplet of glue is positioned at the end of this line. When a moth, attracted by its sexual pheromones emitted by the spider, approaches this droplet the spider swings the line in the direction of the victim to catch it.[92] *Mastophora cornigera* uses as allomones (*Z*)-tetradec-9-enyl acetate, (*Z*)-tetradec-9-enal, and (*Z*)-hexadec-11-enal.[91] These compounds are components of the sexual pheromones of female moths the males of those species are caught by *M. cornigera*.

Mastophora hutchinsoni catches four different species of moth, three of which also use the mentioned aldehydes and acetates. In contrast, the fourth species, *Tetanolita mynesalis* uses a mixture of (*Z*,*Z*,*Z*)-henicosa-3,6,9-triene (**14**) and (6*S*,7*R*)-6,7-epoxy-(*Z*,*Z*)-henicosa-3,9-diene (**15**) as pheromone (Scheme 4).[93] Obviously the spider can synthesize both types



14



15

Scheme 4. Sexual pheromones of the moth *Tetanolita mynesalis*.

pheromones, which are produced by different biosynthetic routes, to enhance their catching success. A direct identification of **14** and **15** in *M. hutchinsoni* is still outstanding. Early juvenile instars of bolas spiders use other so far unknown allomones to catch small flies of the family Psychodidae.[94]

Other genera of the Araneidae also contain species that are specialized in chemical attraction of prey.[92] Single observations suggest that some spiders that spin normal webs to catch prey use allomones to attract the victim, too.[95] Webs of some linyphiids, which are related with the Araneidae, contain (*Z*)-octadec-11-enyl acetate and (*Z*)-tricos-9-ene.[96] These are sexual pheromones of different flies.[97]

The specialized hunting spider *Habronestes bradleyi* (Zoodariidae) uses the chemical communication system of its prey in another way. It locates the very aggressive ant *Iridomyrmex purpureus* by their alarm pheromone 6-methylhept-5-en-2-one (sulcatone), which acts in this case as a kairomone[*].[98]

Several money spiders (Linyphiidae) use pheromones for communication. This family containing very many species builds horizontal webs. Female adults of *Linyphia triangularis* attract males by web-borne pheromones. Upon arrival at the web the male cuts the threads and rolls it up. After finishing this process (in about 15 minutes) it starts courtship behavior, which can last up to five hours.[99] The female now rebuilds its web, which no longer contains pheromones and therefore does not attract males anymore.

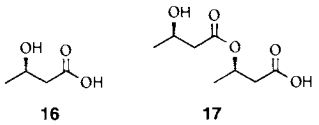
Since the web surface is reduced by the rolling up process, the concentration of the pheromone in the air is reduced. The first male to arrive thus reduces the chance of other males to find the web and to compete for the female.[100] If two males meet at the female web, a fight arises. Any ongoing courtship procedure is aborted.[101]

The web reduction behavior of the males is initiated by (*R*)-3-hydroxybutyric acid (**16**) and its condensation product (*R*,*R*)-3-(3-hydroxybutyryloxy)butyric acid (**17**, a dimer; Scheme 5).[102]

[*] Compounds used for communication between individuals of a species, which elicit a change in behavior.

[**] Compounds used for communication between two different species, which are advantageous for the emitter.

[*] Compounds used for communication between two different species, which are advantageous for the receiver.



16 17

Scheme 5. Sexual pheromones of the spider *Linyphia triangularis*.

The females use the instability of **17**, which is applied to the silk in substantial amounts (up to 5 μg per web) during web construction. The dimer **17** starts to deteriorate autocatalytically under natural conditions because of its acidity. Thus the monomer **16** and crotonic acid are formed. The latter attracts males of another linyphiid, *Neriene montana*.[96] This fine-tuned system offers some advantages for the spiders. The females do not have actively to emit a pheromonal substance from a gland, as is often the case in insects. Instead, formation of the attractive substances is permanently achieved by the autocatalytic deterioration of **17**. In this way the spider is always prepared to catch prey. The female can immediately react and overcome prey the moment it entangles in the web.

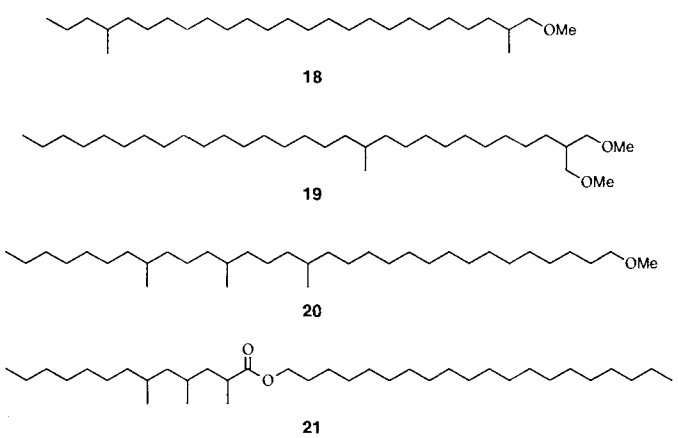
The compounds that evoke the web reduction behavior of the males of *L. triangularis* are also used by a couple of other linyphiids. The compounds **16** and **17** are present in webs of unmated females in at least one American[103] and six European[96] species of the genera *Linyphia*, *Microlinyphia*, and *Neriene*. The habitat of *L. tenuipalpis*, which uses the same pheromone compounds and is sexually active at the same time as *L. triangularis*, partly overlaps with that of this species. Nevertheless, these two species can recognize whether they are in the correct web.[102] This recognition may be achieved by the different composition of web lipids, which is discussed in the following section.

Males but no females of some *Xysticus* species (crab spiders, Thomisidae) are attracted in the field to traps baited with (*E*)-oct-2-enal or (*E*)-dec-2-enal. So far these compounds could not be identified in the females.[104] It remains doubtful whether these compounds are pheromones emitted by the females for attraction of males. Crab spiders wait on leaves or flowers for insects and can adjust their color to match the background. To what extent the aldehydes play a role for the attraction of prey is unknown.

3.4. Lipids

During the pheromone research lipids, which belong to different compound classes, were found on the webs of linyphiids and other spiders. Hydrocarbons predominate. They occur often as main constituents on the cuticle of arthropods.[105] The main compounds of the spider lipids are unbranched, odd-numbered alkanes and even-numbered 2-methylalkanes, for example 2-methyloctacosane. Such compounds are formed biosynthetically by decarboxylation of the appropriate fatty acids, which in turn are formed by condensation of acetyl or malonyl coenzyme A units. From isobutyryl coenzyme A (formed from valine) as starting material, odd-numbered fatty acids with a methyl group at position ($\omega - 1$) are formed, which lead to the corresponding 2-methylalkanes after chain elongation and decarboxylation.[106] These and other branched fatty acids are present in silk lipids. On the silk of *Microlinyphia impigra* 4-methyl-, 13-methyl-, and 14-methylheptadecanoic acids and homologs are present, besides larger amounts of the usual palmitic, stearic, and oleic acids.[96] Low amounts of aldehydes, ketones, fatty acid amides, and wax type esters can be often found, too.

More unusual are methyl ethers present on the spider silk. These are long chain, methyl-branched 1-methoxyalkanes with a chain length from 23 to 37 carbon atoms, a class of compounds identified so far only in spider silk.[107] They form the dominant class of compounds of the linyphiid silk lipids besides alkanes. The main components of all investigated species are odd-numbered, ($\omega - 3$)-branched and even-numbered ($\omega - 2$)-branched ethers and their 2-methyl-branched ethers, for instance 1-methoxy-2,22-dimethylpentacosane (**18**, Scheme 6).



18 19 20 21

Scheme 6. Lipid components of the silk from different spiders.

The hydrocarbons exhibit different branching patterns to the ethers. The biosynthetic pathways to the two compound classes divide quite early. An additional methoxy group is present in some ethers from *Labulla thoracica*. 1-Methoxy-2-(methoxymethyl)-12-methylnonacosane (**19**) and higher methylated homologs form together with 1-methoxyalkanes and hydrocarbons the lipid layer on the silk from this species. A total of more than 100 ethers from 15 species have been identified so far.[96] Species-specific differences in the composition of the lipids can be found mainly in the ethers, while the composition of hydrocarbons and acids is often very similar (Figure 5). Small amounts of the ethers are present on the cuticle of the arachnids, whose main lipidic constituents are hydrocarbons as in insects.

The lipid layer of the webs of *Nephila clavipes* and other *Nephila* species consist of up to 80% of 1-methoxyalkanes.[108] Internally branched ethers dominate, for example 1-methoxy-16,20,24-trimethylhentriacontane (**20**). Three methylene groups are normally present between two methyl side chains. Such orientation is often found in polymethylalkanes from arthropods.[105] The absolute configuration of these compounds remains unclear; no method for separation of enantiomers of chiral, scarcely functionalized, long-chain compounds is yet known. Additional specific compounds of *Nephila* silk, such as the major components tetracosanol, tetracosane-1,3-diol, heptacosa-9,12-diene, and *N*-hydroxyethyloleic amide, are members of other compound classes.

The lipid layer on the web of the daddy-long-legs spider *Pholcus phalangoides* (Pholcidae) does not consist of a complex mixture, but of up to 90% of the branched wax type ester icosyl

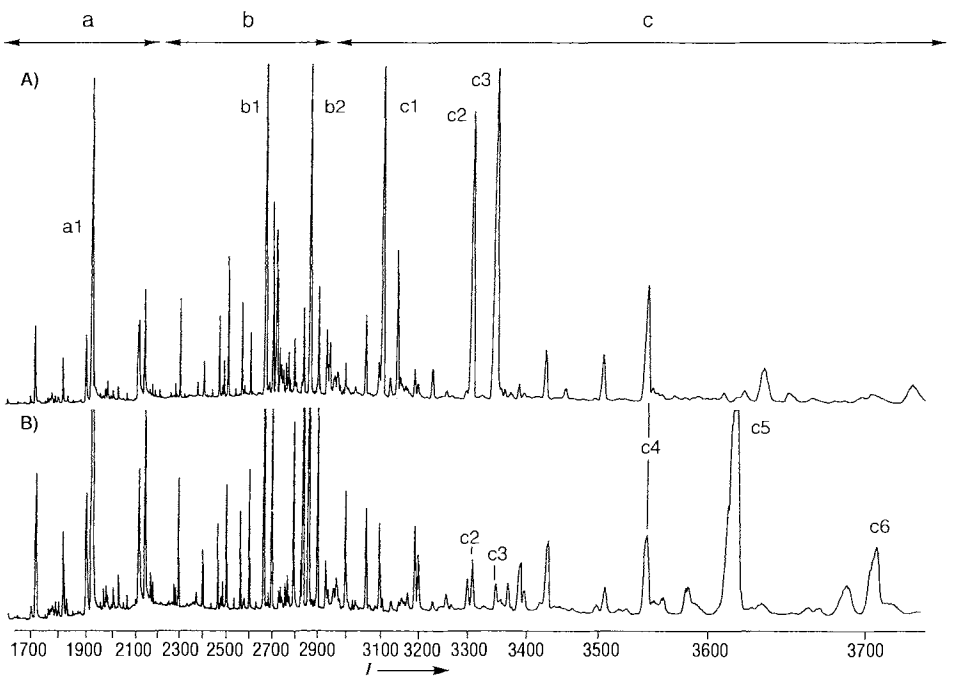


Figure 5. Gas chromatogram of methylated dichloromethane extracts of silk from the linyphiids *Neriene montana* (A) and *Microlinyphia impigra* (B). a: Fatty acid methyl esters, main component methyl palmitate (a1); b: hydrocarbons, main components 2-methylhexacosane (b1) and 2-methyloctacosane (b2); c: methyl ethers. The main components of *N. montana* are the even-numbered, ($\omega - 2$)-branched ethers 1-methoxy-26-methylocatacosane (c1), 1-methoxy-28-methyltriacontane (c2), 1-methoxy-2,28-dimethyltriacontane (c3), and 1-methoxy-2,30-dimethyldotriacontane (c4). *M. impigra* silk contains identical compounds, but also the ($\omega - 3$)-branched ether 1-methoxy-2,30-dimethyltritriacontane (c5) and 1-methoxy-32-methyltetratriacontane (c6). *I* = retention index.

2,4,6-trimethyltridecanoate (**21**), accompanied by low amounts of homologs.[109] Such methyl-branched, waxy esters are typical components of the uropygdial gland of waterfowl and occur in some mammals.[110]

3.4.1. Identification of Silk Lipids

The extractable amounts of silk lipids are very small. A few micrograms per web are normally obtained. The composition of the complex mixtures with up to 150 components can only be determined by gas chromatography and mass spectrometry. While a characterization of hydrocarbons, carboxylic acids, and other lipids can be performed by analysis of their mass spectra, it is difficult for the different methyl ethers, because their spectra can be very similar. The use of gas chromatographic retention indices is a big help. The molecular mass obtained from the mass spectra and incremental calculations allow the determination of the number of methyl branches in the molecule.[107]

Methyl branches at the end of the molecule can be recognized by analysis of the mass spectra.[111] Branching in the middle of the molecule or near the ether group are more difficult to determine unequivocally. The molecular ion easily loses methanol and thus forms an alkene that dominates the mass spectrometric fragmentation. The information on the position of the methoxy group is thus lost, because unspecific fragmentation pathways dominate. The position of methyl groups within the ethers can be deduced from mass spectra of derivatives obtained in microreactions. The oxidation with RuO_4 leads selectively to methyl esters, whose mass spectra clearly show branchings at C2, C3, and C4.[112, 113] Methyl groups in the middle of the chain can be elucidated by transformation of the ethers into cyanides with trimethylsilyl iodide followed by treatment with tetrabutylammonium cyanide.[87] The different mass spectra are shown in Figure 6. The iodides can be transformed into hydrocarbons with lithium aluminum hydride or deuteride, whose identities can be deduced from the branching patterns of their mass spectra.[105] Nevertheless, it must be noted that the presence of natural hydrocarbons in the extract obscure the results obtained by the last method. An unequivocal assignment of the original ether to a detected alkane might not be possible in such a case.

3.4.2. Function of the Lipid Layer

The cuticle of arthropods is covered by a lipid layer, which regulates the water balance of the animals. The main components of this layer are generally long-chain aliphatic hydrocarbons and fatty acids, as well as smaller amounts of waxy esters, long-chain aliphatic alcohols and aldehydes, glycerides, and cholesterol.[114, 115] Similar compounds are present on the spider silk, as discussed in the previous sections. Section 3.2 showed that an optimal water balance is essential for a proper function of the web. The correct water content holds the silk taut and gives it its elastic properties, which are important for prey capture. The thin lipid coating of the silk reduces the required uptake and evaporation of water. The methyl branches of the compounds prohibit the extensive formation of domains formed by unbranched lipids[116] and promote an enhanced mobility of components in the lipid layer. During sudden elongation of the thread, whether it originates in incoming prey or the wind, a uniform covering can be obtained more easily with a mobile oil.

Another function is the protection of the thread—a high performance material—against influences from the environment. Every agressive agent of chemical or biological nature has to penetrate the lipid barrier before reaching the thread. It has long been supposed that the protein-rich silk is chemically protected against the attack of microorganisms.[85] Some of the lipid components may have such an effect. For example, 14-methylhexadecanoic acid is found on the silk beside similar acids and possesses a highly antimicrobial activity.[117] This has been related to its methyl group, which is located at the ($\omega - 2$) position as in some of the methyl ethers.

In linyphiids the lipid layer acts as solvent for the pheromones, too. The polar character of the lipids is enhanced by the introduction of a polar head group like the methoxy group. The association or solution of the polar pheromones is

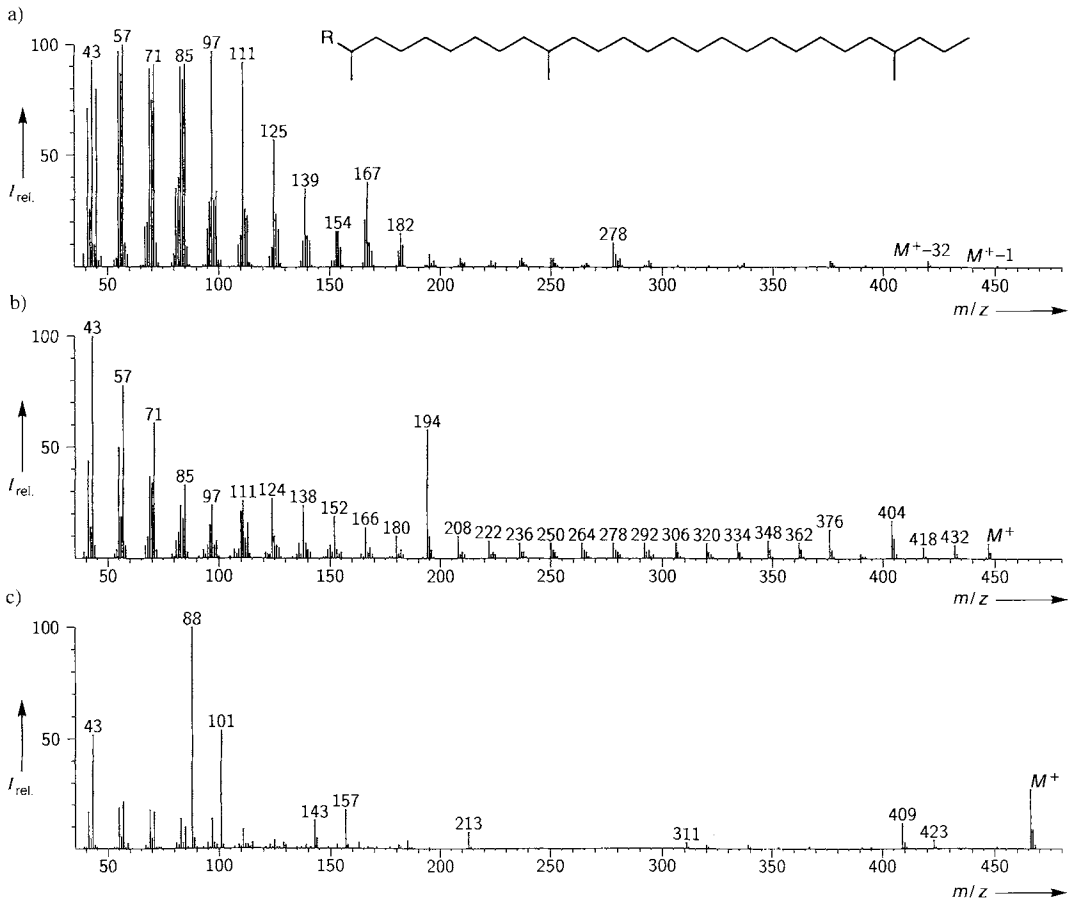

Figure 6. Mass spectra of a) 1-methoxy-2,10,24-trimethylheptacosane (R = CH_2OMe), b) 2,10,24-trimethylheptacosylcyanide (R = CH_2CN), and c) methyl 2,10,24-trimethylheptacosanoate (R = COOMe). The position of the methyl groups at C10 and C24 in spectrum b) can be determined by the intense, CN-containing ions at $m/z = 194$ and 376/404, respectively. The ion pair with $m/z = 88$ and 101 in spectrum c) indicates that the methyl group is located at C2, whereas the ion $m/z = 213$ points to branching at C10. Not all branched methyl esters show such clearly assignable ions [112,113], because they are sometimes overlayed by a unspecific ion series at $m/z = 143 + n \times 56/157 + n \times 56$.

thereby facilitated, and their distribution on the surface of the silk is more regular. This influences the decay rate of the hydroxy acids **16** and **17**. The evaporation rate is reduced, which enables the chemical signal to persist longer.

The information contained in the different composition of the lipids may be used for species recognition. The attracted males come into contact with pheromones on the web, which are embedded in a specific lipid matrix. The correct webs may be recognized by pattern recognition of this matrix. Some insect species can recognize conspecifics or caste members by use of hydrocarbon patterns.[105, 118] Suter et al. showed that the chemical composition of the cuticle, especially the lipid layer, can be used for information transfer. Chemical signals released from the cuticle of the linyphiid *Frontinella pyramitela* modify the behavior of this species and are used for sex recognition.[119] *Argyrodes trigonum* spiders live cleptoparasitic in webs of *F. pyramitela*. Sometimes they feed on their host, but they never attack each other. Such cannibalistic behavior occurs only if the lipids are removed by washing with hexane.[120] This indicates that the lipid layer is used for the recognition of species members. Cuticular extracts of the house spider *Tegenaria atrica*, which lives in house cellars and often evokes fear in the inhabitants because of its size, contains 75 alkanes and carboxylic acids, and their methyl esters. The composition changes with the age of the spiders. These patterns may be responsible for the change that occurs with age in the behavior toward other members of the species, from tolerance to aggression.[121]

The following hypotheses may explain how 1-methoxyalkanes might be used by linyphiids for species recognition: Spider silk from natural sources contains many other components besides the lipids, like plant compounds, remains of the indigestible cuticle of the prey (which are mostly insects), and volatile compounds from the environment. If species recognition were based on hydrocarbon patterns, the inevitable pollution would introduce errors because some compounds might be enriched. The error rate is reduced with spider-specific compounds, because pollution of the webs can not introduce any of these compounds. It seems reasonable to assume that especially the methyl ethers are used for species recognition, because these compounds are known only from spiders.

4. Summary and Outlook

The chemistry of spiders has scarcely been investigated. The results show that they produce unique toxins and lipids not known from other natural sources. Only a few species have been investigated, namely the orb weaver *Nephila* and the funnel web

spiders *Agenelopsis* and *Hololena*, which leaves a broad area open for new investigations. The knowledge of spider chemistry is marginal compared to that of insects. Consequently, it is not surprising that research on new species leads to exciting structures. Many aspects of even the known compounds remain to be elucidated. Especially the interesting chemical ecology of spiders is hardly known. An obstacle to further research on the properties, the functions under natural conditions, and structure determinations is the difficulty in obtaining enough natural material. New results will only be obtained by the development of microchemical methods and the synthesis of the identified compounds. Starting from the materials and compounds described in this paper, new uses will be developed in the future, which could benefit human beings.

I thank Prof. Fritz Vollrath, University of Aarhus, Denmark, and Prof. Wittko Francke, University of Hamburg, Germany, for helpful hints and interesting discussions. I also thank Mirjam Steffensky for the preparation of figures.

Novel High-Performance Ceramics—Amorphous Inorganic Networks from Molecular Precursors

Hans-Peter Baldus and Martin Jansen*

Materials research is an interdisciplinary field in which engineers and physical scientists work together. Since the major binary oxides, nitrides, and carbides, which are currently used as high-performance ceramics, were discovered in the last century, the role of chemistry in the development of materials has become barely noticeable. This has changed only in the recent past as, for example, purity and defined morphology of starting powders were recognized as crucial parameters for enhancing the reliability of ceramic workpieces. While the application of chemical methods led to gradual—though significant—improvements, the true potential of chemistry lies rather in the exploitation of new chemical systems and the development of new preparative routes to already known materials. Such an approach is the preparation of ceramics from molecular or polymeric precursors. Herein we survey the most important contributions to those preparative routes starting from the pioneering work in the 1960s and the 1970s; a certain emphasis is placed on the concepts that we have applied to the preparation of multinary, nonoxide materials and amorphous inorganic networks. The name "amorphous high-performance ceramics" is in fact a contradiction in terms. Such materials are thermodynamically unstable with respect to the transformation or decomposition to crystalline phases, thus excluding their application in sensitive areas at high temperatures. However, the selection of element combinations for which the binding energies are derived from strong, local covalent bonds and which are therefore less dependent on a long-range crystalline order, can yield amorphous materials of remarkable thermal and mechanical durability. This is exemplified by novel quaternary ceramics in the Si/B/N/C system, for which an efficient synthesis, starting from raw materials suitable for industrial production, has been developed. For instance, a material of the composition $SiBN_3C$ remains amorphous up to 1900 °C, which is unique, and, with respect to oxidation, is the most stable nonoxide ceramic known to date. Another advantage of this in several respects unsurpassed material is the simple way, in which the viscosity of the polymeric precursors can be adjusted to various methods of shaping. So far infiltrations and coatings have been realized. Most developed is the preparation of fibers, which in terms of their performance characteristics are significantly better than those currently available.

Keywords: boron · ceramics · nitrides · polymers · silicon

1. Introduction

The class of inorganic, nonmetallic materials has two rather different roots. One origin dates back to the prehistory of mankind. About 8000 years ago, as man settled, he prepared "artificial" materials for the first time by modifying natural raw materials. He formed vessels from clay, which was dried and burned to porous ceramics.[1] Those materials, based on natural resources, were continually improved to their current state with a large range of properties and high-quality standards. Building materials and commodities of the Egyptian and Middle Eastern civilizations,[1a] attic vases,[2] Chinese bone china (since about 700 AD), medieval stoneware, hard porcelain (J. F. Böttcher, Dresden 1709),[3] from which the modern porcelain developed, and the development of many fire-proof items during the appearance of industrial production methods[4] were milestones in this process.

The second root goes back to the beginning of modern chemistry about 200 years ago. This era was characterized by the discovery and classification of many elements up to the creation of the periodic table of the elements. Many of the major binary compounds were prepared and characterized during the same period. Some oxides, nitrides, and carbides had already attracted attention because of their refractory nature; they were mistaken for chemically indecomposable substances, that is, for elements. The first references to currently highly topical materials like Si_3N_4,[5] BN,[6] and α-Al_2O_3[7] were made during

this period. Another important material, SiC, was discovered a hundred years ago.[8] Chemists began to build laboratory equipment, for example, from alumina or zirconium oxide to fulfil their own needs in the field of high-temperature reactions.[9] The impressive work of Otto Ruff, who may be familiar to most as an outstanding fluorine chemist, might be mentioned as an example. He combined basic investigations of chemical and thermal behavior of binary and multicomponent systems with work on the shaping and optimization of the properties of finished workpieces. Even though already published in the 1920s and 1930s,[9a] his publications appear to be up to date in a certain sense with their photographic reproduction of completed workpieces (Figure 1). Despite such sporadical advances into production technology, according to their own traditional understanding the task of chemists seemed to be finished with the provision of the compounds. Apart from some preparative contributions to the field of hard materials,[10] they played hardly any part in the development of high-performance materials. This task passed into the hands of materials scientists and process engineers. However, the potential for the development of further conceivable, suitable compounds has not at all been exhausted, since one needs only consider the relatively small number of mainly binary compounds such as α-Al_2O_3, AlN, BN, and SiC and also Si_3N_4, MgO, ZrO_2, Al_2TiO_5 and B_4C, which were nearly exclusively discussed as the material basis for high-performance ceramics.

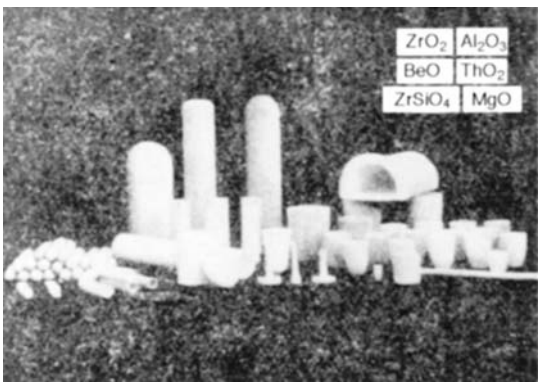

Figure 1. Laboratory equipment made from oxidic ceramics, dated from about 1916.

Nevertheless, it took until the 1980s, when higher expectations in the application potential of ceramic materials led to a more thorough scientific exploration of all steps of production,[11] before chemistry and its methods once more assumed a more important role. First of all, the use of starting powders of well-defined composition, high purity, and optimized particle morphology enabled the failure rate of completed workpieces to be limited. Thus, their performance characteristics approached the intrinsic properties of the material.[12] However, the reverse of the outstanding property profiles of the ceramics caused problems. Low diffusion coefficients and high melting points hampered the densification by sintering and the shaping of workpieces. In this respect a traditional domain of inorganic solid-state chemistry proved useful by providing reactive precursor compounds. In particular, inorganic polymers[13] and the sol–gel process[14] offered new opportunities to cope with the above-mentioned transport problems and with the shaping.

Winter, Verbeek, and Mansmann appeared to be ahead of their time, when they obtained spinnable, inorganic polymers by the aminolysis or ammonolysis of methylchlorosilanes. The pyrolysis of these polymers yielded the first Si/C/N fibers.[15] Without exaggeration this can be regarded as the pioneering work in the field of inorganic precursors for nitridic and carbonitridic ceramics. A similar approach by Yajima et al., in which polycarbosilanes were converted into silicon carbide fiber (with carbon excess, NICALON), acquired commercial significance.[16] For a long time these fibers showed the best properties worldwide. After those, still rather sporadic attempts, the work of Seyferth et al., aimed at the improving the shaping, sintering behavior, and powder morphology of already known systems by the use of molecular and polymeric precursors,[17] triggered worldwide activity, that continues to the present day.

Martin Jansen, born in 1944 on Pellworm, studied chemistry at the Justus-Liebig-Universität Giessen, where he gained his doctorate in 1973 under the supervision of R. Hoppe. After his habilitation in 1978, he was offered and accepted a professorial chair for Inorganic Chemistry at the Universität Hannover. In 1987 he moved to the Rheinische Friedrich Wilhelms Universität in Bonn. His main research interests lie in the field of preparative solid-state chemistry, crystal chemistry, materials research, and the structure–property relationship of solids. Among others, he was awarded the Gottfried Wilhelm Leibniz prize and the Otto Bayer prize.

H.-P. Baldus

M. Jansen

Hans-Peter Baldus, born in 1959 in Kirchen an der Sieg, Germany, studied chemistry in Siegen (diploma 1985) and Osnabrück, where he received his doctorate in 1989 under the supervision of R. Blachnik for work in phosphorus–chalcogen cage compounds. In the same year he joined the main laboratory at Bayer AG and since then his work has focused on the development of new synthetic methods for inorganic solids. His research interests include molecular and solid-state chemistry with a particular emphasis on the development of molecular and polymeric precursors for multinary nonoxidic ceramics.

To date, the area of polymer synthesis has lacked sufficient control of molecular precursors and intermediates, that is, "molecular design". Also the suitability of the precursor methods for the preparation of *new* multinary nitrides, carbides, and carbonitrides had not yet been sufficiently estimated. Herein we report on the preparation of such new materials with significantly improved properties from single-source precursors. The emphasis is on our own contributions, however, a general survey of the current stage of development is also made despite the vast amount of activity in this field.

2. Our Concept for the Production of High-Performance Ceramics

Our approaches are aimed at the widening of the material basis of high-performance ceramics as well as at improving their brittle strength. As mentioned, only a few, mainly binary nitridic and carbidic materials that show significantly better stability at high temperature, hardness and, most of all, temperature shock resistivity than the oxides, have been tested in practical applications. This results in a narrow range of specific properties. The advantages of Si_3N_4, for instance, are its high bending, traction, and wear resistance as well as its relatively high stability against oxidation. A certain weakness lies in its rather low-temperature shock resistivity. BN, on the other hand, shows a high-temperature shock resistivity, but insufficient hardness and oxidation stability.[18]

The transition to the ternary system Si/B/N might give ample room for optimization of these properties. A similar approach, the change from binary to multinary systems, has proved to be successful in designing the properties of oxide ceramics. However, the adaptation of this concept to nitridic materials is hampered by the fact that ternary nonmetal nitrides cannot be prepared by interdiffusion from the binary components because of their low self-diffusion coefficients.

An inherent weakness of nonmetallic inorganic materials is their brittleness. The failure rate can be minimized at the microscopic level by avoiding tension peaks and by limiting the crack propagation. The intrinsic properties of the material are as important with respect to those complex phenomena as the frequency and size of structural flaws. The use of amorphous inorganic networks appeared to be a promising approach to the problem, since all crystalline materials are preferably cleaved along the lowly indexed lattice planes. Amorphous networks have, by definition, no lattice planes. Moreover, they can absorb the fracture energy with the help of dangling bonds that are inevitably present. Admittedly, such materials are not in the global thermodynamic equilibrium state, which might be a disadvantage with respect to the desired thermal and/or mechanical durability. However, amorphous materials of high kinetic stability, and thus durability, should be available by choosing element combinations for which the binding energies are derived predominantly from local covalent bonds (with as little strain as possible), and which are consequently less dependent on long-range order like in ionic crystals.

These requirements can be met by combining second and third row elements of the third to fifth main group including selected early transition metals. The formation of ternary, crystalline phases should be sufficiently hampered by selecting three or more different elements with different, specific coordination numbers and polyhedra. The classic glass preparation methods by melting and quenching to an undercooled melt is usually prevented for nitrides and carbides by the decomposition of at least one component of the desired glass upon melting.

Since melting or solid-state reactions of the binary components are neither suitable for the preparation of multinary, amorphous networks nor for the formation of crystalline nitrides or carbonitrides, only one option was left: the molecular precursor method. The main requirements of single-source precursors are that they must already contain the elements with "cationic" structural chemical function in the same ratios as desired in the final material and that they should show the same structural elements (bridging) as in the proposed crystalline or amorphous material.

In principle, polycondensation and subsequent pyrolysis of the precursors may lead to three classes of products: 1) amorphous networks containing the constituents homogenously dispersed on the atomic level, 2) new, multinary, crystalline phases, and 3) composites of binary or multinary phases. All three product classes are equally attractive for basic research (chemical and structural systematics) and application technology.

3. Molecular Precursors

Apart from molecular precursors of binary nitrides and carbides, here the main emphasis is placed on single-source precursors that offer an access to multinary ceramics. The required precursors must contain two different elements linked by a nitrogen or carbon atom, and the periphery must enable polycondensation by, for example, aminolysis or transamination. In a first step the linkage desired in the final ceramic must be realized. Fortunately, a large stock of chemical tools, developed in basic research, can be used. This is particularly true for the formation of element–nitrogen bonds.[19] The main reactions are presented in Table 1; their advantages and disadvantages are well known. Whereas cheap starting materials can be used for dehydrohalogenations, the separation of the salts, which evolve in stoichiometric amounts, is as time-consuming as it is difficult. The silazane or stannazane eliminations, on the other hand, proceed smoothly and elegantly, since the leaving groups evolve

Table 1. Reactions for forming element–nitrogen bonds.

dehydrohalogenation
$E{-}X + 2\,HNRR' \rightarrow E{-}NRR' + H_2NRR'X$
salt elimination
$E{-}X + LiNRR' \rightarrow E{-}NRR' + LiX$
silazane/stannazane cleavage
$E{-}X + Me_3Si(Sn){-}N(R)M \rightarrow E{-}N(R)M + Me_3Si(Sn)X$
dehydrogenation
$E{-}H + H{-}N(R)M \rightarrow E{-}N(R)M + H_2$
transamination
$E{-}NR_2 + HNR'_2 \rightarrow E{-}NR'_2 + HNR_2$

as volatile compounds. Hydrogen elimination may be a promising technique; however, this requires differently polarized hydrogen–element bonds. At first glance the transamination appears to be a detour, but the element alkylamide can be separated from the salt, which inevitably is formed during the aminolysis of chlorides, by distillation.

Wurtz-analogous dehalogenations can generally be used to form element–carbon bonds. Hydroborations that lead to the formation of boron–carbon bonds are a special case. Generally, the options for establishing element–carbon bonds are much more limited than in the case of nitrogen. It is, however, frequently observed that carbon from substituents is spontaneously incorporated into the inorganic network upon pyrolysis.

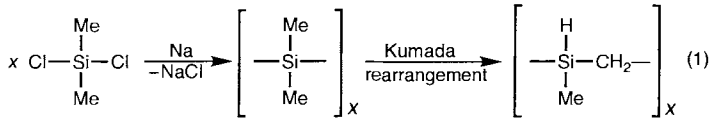
Now it is necessary to select suitable starting materials (Table 2). Since the molecular chemistry of silicon is highly developed (primary materials, intermediates, and waste products of the silicone production), there is ample room for selection. In principle, the situation is equally simple for aluminum, boron, and phosphorus, as they are easily available as binary chlorides.

Table 2. Availability and prices of potential starting materials for carbidic and nitridic ceramics from molecular precursors.

Starting material	Availability [t per a]	Price (ca.) [DM per kg]
hydrogen and carbon compounds		
ammonia	10^8	0.01
methylamine	10^4	1.5
dimethylamine	10^4	1.5
diborane	10^3	500
borane adducts	10^2	500–1000
silanes	10^4	1–30
disilanes	10^4	1–30
carbosilanes	10^1	300–1000
vinylsilanes	10^5	20–30
chlorine compounds		
boron trichloride	5×10^2	30–100
aluminum trichloride	10^5	
titanium tetrachloride	2×10^6	0.5
silicon tetrachloride	10^5	3
chlorosilane ($SiCl_{4-n}Me_n$)	2×10^6	0.5
phosphorus chlorides	4×10^7	1
nitrogen compounds		
silazanes	10^1	300
HMDS	10^3	15
oxygen compounds		
siloxanes	5×10^7	20–30

A selection of reaction sequences that show potential for laboratory and even technical applications includes:

- The reaction sequence applied by Yajima et al., which leads to a polymeric precursor of the NICALON-fiber.[16] Spinnable polycarbosilanes are obtained by a Wurtz-analogous synthesis with subsequent rearrangement [Eq. (1)].



(1)

- The ammonolysis of chlorosilanes yields polysilazanes [Eq. (2)].[17, 20] Seyferth et al. have perfected these precursors

$$H_2SiCl_2 + NH_3 \longrightarrow (—SiH_2—NH—)_x \longrightarrow Si_3N_4 \quad (2)$$

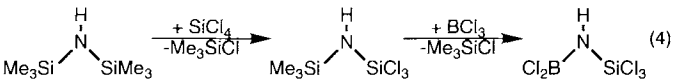
for Si_3N_4 to the stage that they can be employed on an industrial scale.

- The complete aminolysis of $SiCl_4$ with methylamine, followed by distillation of the resulting silazane [Eq. (3a)] and subsequent transamination with ammonia [Eq. (3b)] lead to a silicon imide from which high purity, colorless Si_3N_4 may be obtained.[21] The special advantage of this route over the direct reaction of silicon tetrachloride with ammonia is the fact that the ceramic powder is free of chloride.

$$SiCl_4 + 8\ MeNH_2 \xrightarrow{-4Me\ NH_3Cl} Si(NHMe)_4 \quad (3a)$$

$$3\ Si(NHMe)_4 + 4\ NH_3 \longrightarrow Si_3N_4 + 12\ MeNH_2 \quad (3b)$$

- Starting from hexamethyldisilazane a molecular component containing the function B-N-Si can be prepared in a two-step reaction with almost quantitative yields [Eq. (4)].[22] It is remarkable that hexamethyldisilazane reacts with silicon tetrachloride by the substitution of only one trimethylsilyl group.[19a] The elimination of the second trimethylsilyl group is only achieved by the reaction with boron trichloride,[19b] since it is a stronger Lewis acid than $SiCl_4$. It is possible to reuse the by-product trimethylchlorosilane, for example, for the synthesis of hexamethyldisilazane.



(4)

- Dehydrogenation usually leads directly to a polymeric compound, as shown by the synthesis of precursors of ceramics in the ternary system Si/Al/N [Eq. (5)].[23] The low mass loss makes this method attractive, since during the formation of one Si-N-Al bridge, only one equivalent of hydrogen is released. Furthermore, it is possible to vary the Si/Al ratio over a wide range.

$$3x\ Si(NHMe)_4 + 4x\ AlH_3 \longrightarrow x\ Si_3Al_4(NMe)_{12} + 12x\ H_2 \quad (5)$$

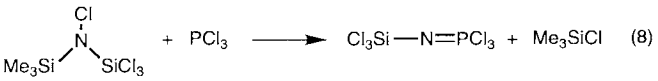
- The coammonolysis of metal alkylamides (of similar ammonolysis speeds)[24] is the equivalent of the well-known sol–gel process, used for the synthesis of ternary oxides. This one-step approach to a polymeric precursor is convincing in its universal applicability. It is used in preference whenever dehydrohalogenations or polycondensations fail, as is the case shown in Equation (6).

$$Si(NHMe)_4 + Ti(NMe_2)_4 \xrightarrow{+NH_3} SiTi(NH)_w(NMe)_x(NHMe)_y(NMe_2)_z \quad (6)$$

- An elegant way to form carbon–boron bonds is hydroboration, the addition of borane at carbon–carbon double bonds. Originally, this method was developed by Riccitiello et al., who used tetravinylsilane as a silicon-containing component.[25] Riedel et al. modified this method by the use of (chloromethyl)vinylsilanes [Eq. (7)].[26]

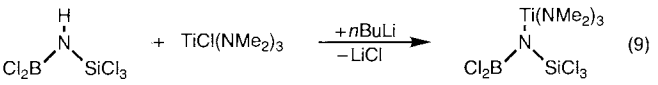
(7)

- The synthesis of a new crystalline ternary nitride, $SiPN_3$, was achieved with a single-source precursor. The precursor can be obtained by an oxidative coupling from hexamethyldisilazane [Eq. (8)].[27]



(8)

- The preparation of single-source precursors of a quaternary material is rather intricate. The simultaneous connection of, for example, main group and transition metals in one molecule overcomes the problems caused by the different ammonolysis speeds of different metal amides. The resulting polymers are, as a rule, homogeneous on the atomic scale [Eq. (9)].[28]



(9)

This selection of the most important syntheses of ceramic precursors is merely a small section of the reactions investigated to date; however, it gives an impression of the opportunities available for a preparative chemist in this field.

4. From the Molecule to the Ceramic Material

In principle, the direct deposition of ceramic materials from the vapor phase by chemical vapor deposition (CVD) is possible by using suitable precursors. However, the low space–time yield limits this technique to the surface finish of completed parts and is thus not considered in this review.[29]

Ceramic materials of macroscopic dimensions (bulk materials, powders, thick layers, fibers) are obtained by the polycondensation or polymerization of single-source precursors and subsequent cleavage (pyrolysis) of volatile parts. The polymer can be prepared by well-defined synthesis steps via oligomeric intermediates or by forming a polymeric network from rapidly progressing sequential hydrolysis or ammonolysis reactions followed by polycondensation of the single-source precursor. Inorganic polymers as intermediates for ceramics have so far been produced exclusively by the second method. Although numerous syntheses of inorganic polymers like the polysilazanes have been described, there are currently no systematic investigations into the determination of reaction mechanisms, the use of alternative polymerization techniques (for example elimination and subsequent polymerization) and into designs to optimize the properties of the final material. This is even more surprising since the step from polymerization to pyrolysis is the key, which decides if this approach can compete with the conventional powder route. A cheap approach to suitable precursor *molecules* has been realized in many cases (see Section 3).

The apparently fascinatingly simple concept of preparing ceramics by the pyrolysis of polymeric precursors, moldable at ambient temperatures, was first suggested by Chantrell and Popper[30] about 30 years ago. The major advantages of this idea are evident: Extremely pure final products can be obtained by purifying the molecular precursors. In principle, the inorganic polymers can easily be shaped, since the vast variety of methods developed for processing organic polymers can be applied. Finally, the properties of the polymers – melting point, solubility etc—as well as the elementary composition of the multicomponent systems are accessible for rough- and fine-tuning.

Besides these advantages there are severe disadvantages. The comparatively low yield of the ceramic final product with respect to the total amount of primary materials, partially obtained by consumptive syntheses, is a disadvantage,[31] particularly from the economic point of view. The pyrolysis of polymeric green parts to bulk materials is very problematic. The organic substituents of the inorganic polymer like polycarbosilanes or polysilazanes are released as gaseous fragments on thermal decomposition. The resulting weight loss and shrinking of the green part is accompanied by a drastic rise of the polymer's molecular weight and viscosity. If a certain limit viscosity is surpassed, the gaseous decomposition products can no longer diffuse unimpeded through the polymer. Consequently, pores and cracks are formed in the green part. Unlike in oxide ceramics, the low self-diffusion coefficient of the resulting ceramic material prevents the curing of the faults by sintering. Thus, in the case of nitridic and carbonitridic ceramics, the structural flaws remain in the ceramic body, leading to a highly porous, brittle bulk material (Figure 2).

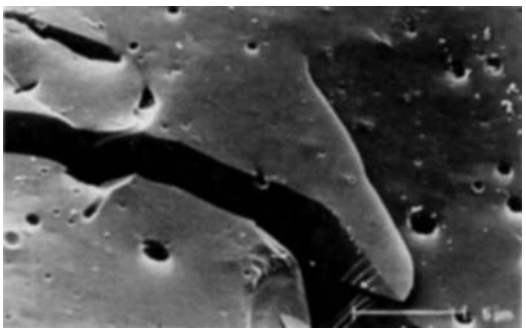


Figure 2. Workpieces made from *N*-methylpolyborosilazane after pyrolysis at 1000 °C.

The most important requirement of an ideal preceramic polymer is directly deduced from these facts: The weight loss on pyrolysis ought to be as low as possible. The (partly incompatible) requirements of a preceramic polymer are:[32]

- high molecular weight (low rate of weight loss on evaporation)
- high portion of cages and rings in the polymeric structure (low portion of volatile fragments)
- viscoelastic properties adjusted to the corresponding shaping method
- residual reactivity to enable curing
- fraction of organic substituents as low as possible, enhancing the ceramic yield
- proper combination of inorganic components, determining the properties of the final ceramic.

It appears reasonable to distinguish the steps of polymerization and pyrolysis conceptually, even though the transition from the molecule to the ceramic via oligomeric and macromolecular intermediates proceeds continuously. Polymeric intermediates are formed in the initial step from molecular precursors, containing either one cationic component or two or more electropositive elements in a specific arrangement (single-source precursor). The former are preferred in the production of binary ceramics, but they can also be used as a route to multicomponent systems by copolymerization. Without doubt this simplifies the procedure by dropping the intermediate step of directed oligomerization. However, up to now this route always results in heterogeneous composites of binary ceramics. Usually this (frequently undesirable) phase separation is already initiated on polymerization as a consequence of the different reaction speeds of the diverse starting molecules. The big advantage of single-source precursors is that they frequently enable the formation of multinary crystalline[27] or amorphous nitrides and carbonitrides with a homogeneous dispersion of the elements on the atomic level.[22]

In both cases the selection of polymerizing reactions is similar, depending on the functional groups. In principle, macromolecular systems are accessible by polymerizations of multiple bond systems, polyadditions, and polycondensations. Polymerizations are of hardly any significance with respect to ceramic synthesis, and polyadditions are rather rarely used; hydroboration is the most common example. Clearly, polycondensation in the shape of "dehalogenizing or dehydrogenating coupling" or "intermolecular deamination/dehydratization" is currently predominant. The ammonolysis of chlorine groups is frequently the initial step to the deamination reaction.

Usually, the further densification of the polymer is achieved thermally; further polycondensation reactions take place, and fragmentation of the released material increases as the temperature rises, marking the transition to "pyrolysis". Temperature, pressure, and atmosphere are the tuning parameters of the pyrolysis. Inert gas (usually Ar or N_2) pyrolyses are distinguished from reaction gas pyrolyses in that in the former case the carrier gas merely removes the volatile decomposition products, whereas in the latter case it takes part in the reaction itself. The major reaction gases are ammonia and nitrogen for nitrides, nitrogen for carbonitrides, and water for oxides. Recently the use of hydrogen as the reaction gas for the synthesis of SiC, which is free of carbon precipitates has been reported.[33] Ammonia is of primary importance in the synthesis of nitrides from carbon-containing precursors, since it removes carbon very efficiently.[34] Apparently NH_3 functions as an aminizing or transaminizing agent, substituting alkylamines and facilitating a better cross-linking of the network. The described processes proceed through numerous, usually metastable and frequently badly defined intermediates. The predominantly kinetic control of the polymerization and the early pyrolysis combined with the many reaction parameters gives many intervention opportunities, which may be used for influencing the viscoelastic properties of the polymer (solubility, meltability, or plasticity).

Only in a few cases have the temperature dependence of the released species and their fragmentation been described in detail, or the solid intermediates been characterized by spectroscopic "fingerprints". However, the data, accumulated so far, reveal a surprisingly universal, well-structured process, which may even be generalized.[35] The major steps of the ceramic formation from the polymer are exemplified in the quarternary system Si/B/N/C .

The single-source precursor $Cl_3SiNHBCl_2$ (TADB = trichlorosilylaminodichloroborane) reacts with methylamine to form an *N*-methylpolyborosilazane. The pyrolysis of this polymer in an inert gas atmosphere yields a ceramic of the approximate composition $SiBN_3C$. Since all polymeric intermediates as well as the final ceramic are amorphous up to 1900 °C, only spectroscopic and thermal methods can be used to characterize the thermal decomposition. Consequently, the pyrolysis of the meltable methylpolyborosilazane has been monitored by combined differential thermal analysis/thermogravimetic analysis/mass spectrometry (DTA/TGA/MS), magic angle spinning (MAS) NMR, and FT/IR spectroscopy.[35] Depending on the temperature, three clearly distinct processes can be distinguished (Figure 3). The polycondensation, accompanied by

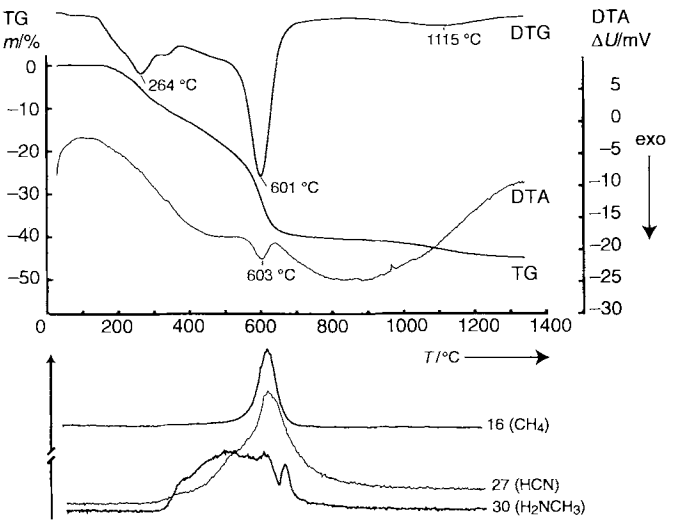

Figure 3. Differential thermal analysis (DTA), thermogravimetry (TG) (*m*: mass loss) and differential thermogravimetry (DTG) of polyborosilazane, and intensity variation of the major gaseous decomposition products; hydrogen and nitrogen are released above 1000 °C.

methylamine elimination, is completed between 200 and 400 °C; the weight loss is about 12%. In the second (pyrolysis) step (ca. 600 °C), mostly methane but also hydrogen, hydrocyan, and some organic fragments are detected by TGA/MS (weight loss ca. 28%). Another inflection point of the TGA plot occurs at about 1100 °C. The weight loss is rather low (about 4%), and is attributed to the loss of residual hydrogen. In addition, some nitrogen is released.

A series of FT/IR spectra has been taken of samples, which were pyrolyzed at temperature intervals of 100 °C between 200 and 1100 °C. Up to 600 °C virtually no significant changes are observed, the characteristic functional groups of the polymer remain the same in this temperature region (Figure 4). Above 600 °C drastic changes take place: The intensity of C–H stretching vibrations decreases dramatically, and instead of numerous sharp absorption lines, broad bands appear in the region for nitrogen–element vibrations. The most significant change is the appearance of an Si–H stretching vibration peak at about

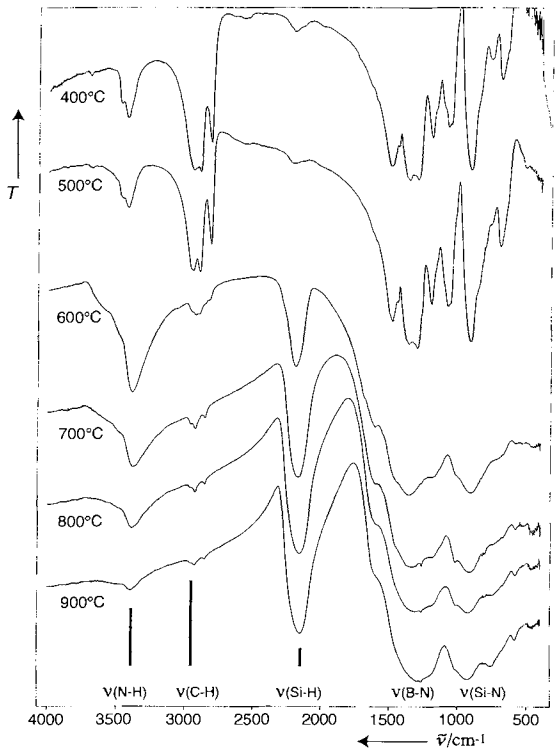

Figure 4. FT-IR spectra of *N*-methylpolyborosilazane, which document the condensation and decomposition behavior.

2200 cm^{-1}. As the pyrolysis proceeds this peak disappears at about 1000 °C, along with all other element–hydrogen vibrations.

The corresponding ^{29}Si MAS NMR spectra show broad signals. The chemical shift changes at about 600 °C from $\delta = -34$ to -41. Remarkably, the half width increases with increasing densification and curing of the network. This can be interpreted in terms of a lower mobility of the silicon atom resulting from the increased cross-branching and/or the larger variance of its chemical environment in the final network. Particularly the second phase of the pyrolysis at 600 °C, which is characterized by the release of methane and ammonia, occurs similarly with other polymers such as the polysilazanes[17] and the polyborosylazanes, which are not produced from single-component precursors.[23, 36] However, the decomposition of hydridopolysilazane does not proceed in such distinct steps but virtually continuously between 200 and 800 °C.[37] The processes during the first step depend on the nature of the polymer; thus, condensations with hydrogen elimination,[37] release of ammonia,[38] or the elimination of trimethylsilyl groups[36a] may occur. In the few cases, where the investigations were extended to temperatures above 1000 °C, hydrogen release was detected at 1100 °C.[36b]

The results from IR spectroscopy vary more strongly. Thus, neither N–H nor C–H stretching vibrations were observed at 550 °C in borazine-modified hydridopolysilazane.[37] Many polymers contain Si–H bonds already at low temperatures, whose absorption may already disappear at 600 °C,[36b, 39] or else, may clearly persist up to 1200 °C.[40]

The increase of the half width of the signals in ^{29}Si NMR spectra with increasing temperature of pyrolysis, appears to be a common property of all pyrolysates.[41]

5. A Survey of Polymer Routes Applicable on an Industrial Scale

A number of excellent reviews[34, 42] on the synthesis, cross-linking, and pyrolysis of preceramic polymers for the formation of silicon carbide, nitride, and carbonitride already exist, and the topic has been treated exhaustively in a recently published paper by Birot et al.[32] For this reason those systems are merely mentioned for completeness. The emphasis here will be placed on heterometallic ceramics, which contain other metallic or half-metallic elements in addition to or instead of silicon. A survey of polymer routes that show potential for practical application is presented in Table 3.

The routes to SiC and Si_3N_4[16, 17] by Yajima et al. and Seyferth et al., respectively, may already be considered as classics. Of the numerous alternatives available for the production of SiC from modified carbosilanes, the approaches by Harrod and Laine et al.[51] as well as by Röwer et al.[52] are highlighted for their advantages for industrial application. The preparation of methylpolysilane from monomethylsilane by dehydrocondensation is attractive for its low weight loss on the way to the polymer.[51] The catalytic disproportionation of chloro(methyl)disilanes is advantageous, since the starting molecules are cheaply available as products of the Rochow–Müller synthesis.[52]

Based on work by Aylett,[53] Seyferth et al.[17, 20] developed storable, low volatile polysilazanes from which Si_3N_4 could be obtained as powders or fibers by pyrolysis in ammonia or hydrazine. An alternative approach from the monomeric precursor $Si(NHCH_3)_4$ yields high purity Si_3N_4 (see Section 3). This process, however, lacks a polymeric intermediate with adjustable options of processing.[21] The pyrolysis of pyridine–borane or piperazine–borane adducts in argon yields borocarbonitrides with graphitelike, turbostratic structure.[54]

Early attempts to obtain heterometallic nitrides and carbonitrides from polymeric precursors started by cross-linking oligomers or monomers that contain the cationic constituents in different molecules or macromolecules. Seyferth et al. polymerized oligomeric cyclohydridosilazanes with borane adducts; thus a Si-N-B linkage is formed under release of hydrogen.[36c, 55] Amorphous Si/B/N/O ceramics with homogeneously distributed elements (though containing oxygen in stoichiometric amounts) are supposed to form from the polycondensate of perhydrosilazane with boron methoxide. At 1800 °C they should decompose to give α-Si_3N_4 and β-Si_3N_4 as well as amorphous BN under massive weight loss and carbon monoxide elimination.[56] According to all current experience these oxidenitrides should be inferior to the purely nitridic and carbonitridic ceramics with respect to their mechanical properties. Polymeric borosilazanes, which may be converted to nitridic or carbonitridic ceramics, depending on the conditions of pyrolysis, are available by the hydroboration of C–C double bonds of a vinylsilazane.[25, 26]

The above-presented approaches to multicomposite ceramics from molecular precursors, which contain the cations in different molecules, have some disadvantages with respect to the efforts to design disordered (amorphous) networks. Thus, the formation of silicon- and boron-enriched domains in the polymer, which favor phase separation on pyrolysis and high-tem-

Table 3. Survey of polymer routes applicable on an industrial scale.

System	Reference	Reaction sequence	Ceramic product

perature applications, cannot be prevented. Therefore, we have preferred single-source precursors right from the beginning. These should contain the cationic constituents already in the ratio and local connectivity, aspired in the amorphous network. We believed the quaternary system Si/B/N/C as well as its ternary subsystems Si/B/N and Si/B/C would be particularly suitable for producing amorphous ceramics resistant to microstructural changes even at top loads, since the bonds between boron and/or silicon and carbon and/or nitrogen, respectively, are expected to show a high degree of covalency. TADB has proved to be particularly efficient and widely applicable, and can be obtained in high yields by only a few synthetic steps. After aminolysis it is polymerized by polycondensation. The B:Si ratio remains exactly 1:1 all the way from the molecule to the ceramic. This is an indication that during the whole process the B-N-Si bridges remain intact. Variation of the molecular component provides access to different compositions as well as to new systems. Examples are compositions with boron/silicon ratios of 1:2[22] or the connection of B, Si, and Ti by one nitrogen atom.[28] Less covalently bonded systems, for example those with Ti or Al, show an increased tendency to precipitate binary components in nanocrystalline form and, furthermore, an increased evaporation loss of these components is observed during the conversion to the ceramic body.

6. Properties, Application Potential, and Industrial Conversion as Exemplified by a Si/B/C/N System from $Cl_3SiNHBCl_2$

The validity of our above concept to improve the properties of nonoxide ceramic systems by the transition to multinary systems and the directed synthesis of amorphous structures shall be demonstrated with the example of ceramics accessible from the single-source precursor $Cl_3SiNHBCl_2$ (TADB). The new class of materials of amorphous silicon boronitrides and carbonitrides offers superior opportunities in technical applications: the starting materials are easily available, the formation can even be controlled on the technical scale, and the products have a unique range of properties.

6.1. Production of the Polymer and of the Ceramic Powder

All starting materials can be produced on an industrial scale (see Table 2). Furthermore, since all steps of synthesis proceed quantitatively and all the by-products (trimethylchlorosilane and methylammonium hydrochloride) up to the polymer are suitable for recycling, the production of this multinary nonoxide ceramic should not be significantly more expensive with respect to the raw materials than the production of a binary nitride like BN. Production on an industrial scale will involve the processes presented in Figure 5. Even though the required technology is, in principle, available, the expenditure involved in construction and optimization should not be underestimated.

Besides the high purity of the polymer, which results from the many purification steps on the way to the oligomer, another advantage lies in the fact that there is no loss of the expensive boron and silicon components all the way from the precursor to the final ceramic. However, as a consequence of this rather positive aspect it is not possible to vary the Si to B ratio, and thus the synthesis of different single-source precursors is required. An idealized mass balance[57] of the formation of

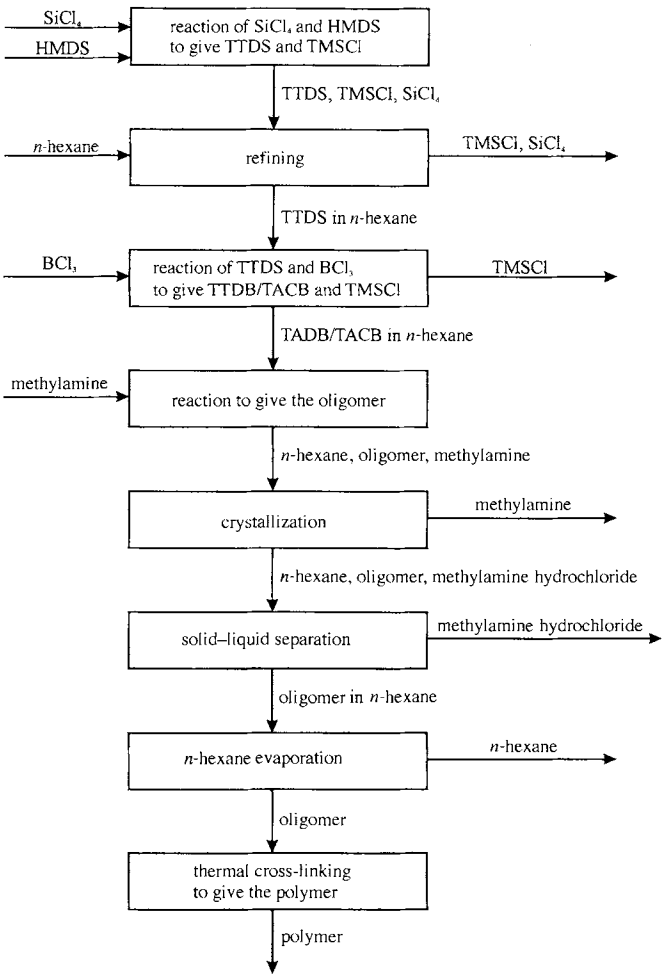

Figure 5. Process for preparing polyborosilazane; HMDS: hexamethyldisilazane, TTDS: trichlorotrimethyldisilazane, TMSCl: trimethylsilyl chloride, TADB: trichlorosilylaminodichloroborane, TACB: bis(trichlorosilylamino)chloroborane.

$Si_3B_3N_7$ and $SiBN_3C$ appears to be quite promising: 8.5 kg primary materials per kg $Si_3B_3N_7$ are required, 6.8 kg by-products can be recycled, and during pyrolysis 0.7 kg are lost. The corresponding figures for $SiBN_3C$ are: 7.0 kg starting materials, 5.3 kg recyclable waste, 0.7 kg loss on pyrolysis. Even though the balance is on the whole quite good, the "ceramic yield" of the last process (pyrolysis of the polymer) reaches 70%, which seems to be too low for the formation of monolithic bulk materials (danger of the formation of macroscopic cracks and pores).

6.2. Properties of the Polymer

The polymerization of the oligomeric *N*-methylborosilazane, which is obtained after ammonolysis, proceeds between 150 and 220 °C with methylamine elimination. The viscosity of the polymer can be adjusted continuously between about 50 mPa s and the unmeltable state. An intermediate degree of cross-linking yields glasslike, soluble and meltable *N*-methylpolyborosilazanes (melting point about 140 °C, viscosity at 180 °C is 60 Pa s, molecular mass of about 20000–30000 g mol^{-1}, glass point 45 °C). They can be converted into a ceramic in yields of 70% (N_2 atmosphere) and 63% (pyrolysis in NH_3), respectively. Polymers with this degree of cross-linking are particularly suitable for the preparation of fibers or as matrix material in carbon fiber reinforced carbon (CFC) and ceramic fiber reinforced ceramic (CMC) composites, because of their meltability. An increased degree of cross-linking (glass temperature >60 °C) results in loss of meltability, but also in higher ceramic yields on pyrolysis (>70%). Highly cross-linked but soluble *N*-methylpolyborosilazanes are particularly suited for processes like coating, which are conducted by using solutions, or the formation of monolithic parts by the polymer route. Qualitative laboratory experiments showed that the conversion of the polymer to the unmeltable duromer proceeds between 210 °C (180 min) and 260 °C (60 min).

The conditions of the prepolymerization (time and temperature) strongly influence the structural and viscose properties of the polymer (Table 4). The variation of the preformation time between 10 and 60 min by 10 minutes (constant temperature of 245 °C) results in dramatic changes of the softening and therefore the spin temperatures, while the weight loss is relatively low with about 2% at the most. The gross composition (C: 27.5%, H: 7.18%, O: 0.7%, N: 38.6%, Cl: 0.06%., B: 6.87%, Si: 17.9%) leads to the empirical formula $Si_2B_2(NH)_2(NHCH_3)_4(NCH_3)_3$.

Table 4. Dependence of spin parameters on thermal pretreatment of polymer (t = duration of pre-cross-linking at 245 °C, T = spin temperature, t_1 = spin duration).

t [min]	$T \pm 10$ [°C]	t_1 [min] at T
10	140	240
20	170	150
30	190	80
35	200	60
40	230	15
50	250	5
60	unspinnable	unspinnable

6.3. Properties of the Ceramic Powder

$Si_3B_3N_7$ or $SiBN_3C$ are available from TADB, depending on the conditions of pyrolysis. The ternary nitride can either be obtained by ammonolysis of the molecular precursor with ammonia in liquid or gaseous phase and subsequent pyrolysis or by pyrolysis of *N*-methylpolyborosilazane (the product of ammonolysis with methylamine) in flowing NH_3 at 1000 °C. Both methods yield amorphous ceramics of the composition $Si_3B_3N_7$ with homogeneously distributed elements; however, particle size distributions and specific surfaces are different. Pyrolysis of *N*-methylpolyborsilazane in nitrogen (heating rate 20 °C to 1800 °C h^{-1}; max. temperature 1650 °C) yields black, amorphous $SiBN_3C$ in ceramic yields of 67%.

Both ceramics are amorphous and show no diffraction phenomena with either X-rays or electron radiation (transmission electron microscopy (TEM), 300 kV). The element distribution is homogeneous down to a lateral resolution of 10 Å. According to ^{29}Si and ^{11}B MAS NMR spectroscopy (Figure 6), silicon and boron reside exclusively in tetrahedral or trigonal-planar nitrogen environments, respectively. ^{13}C MAS NMR spectroscopy of $SiBN_3C$ shows a chemical shift characteristic for sp^2-hybridized carbon. ESCA investigations demonstrate the presence of C–N bonds (Figure 7).

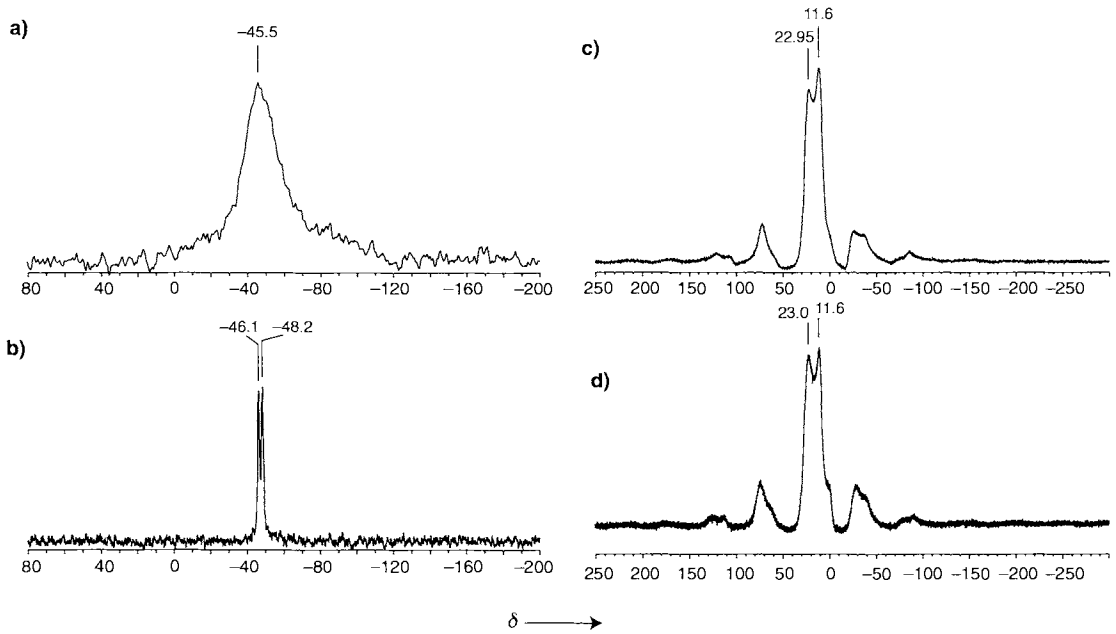

Figure 6. ^{29}Si Magic angle spinning (MAS) NMR spectra of a) $SiBN_3C$ and b) β-Si_3N_4, ^{11}B MAS NMR spectra of c) $SiBN_3C$ and d) h-BN.

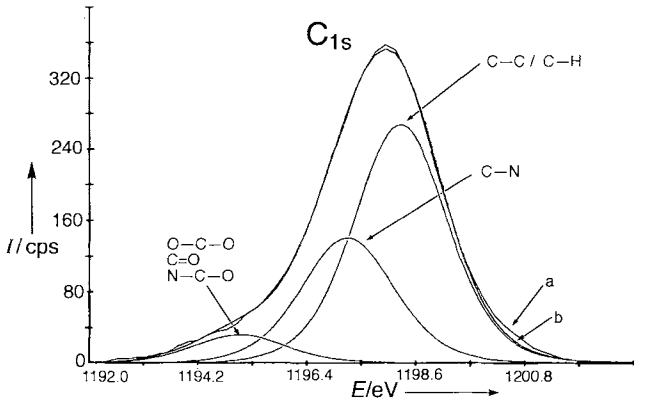

Figure 7. Electron spectroscopy for chemical analysis (ESCA) of C_{1s} in $SiBN_3C$ confirms the presence of C–N linkages (a, experimental plot/b, theoretical plot).

The new amorphous ceramics are distinguished by their unique material properties. Thus, amorphous $Si_3B_3N_7$ has a decomposition temperature more than 150 °C higher than crystalline Si_3N_4 or a Si_3N_4/BN composite (Figure 8). The thermal

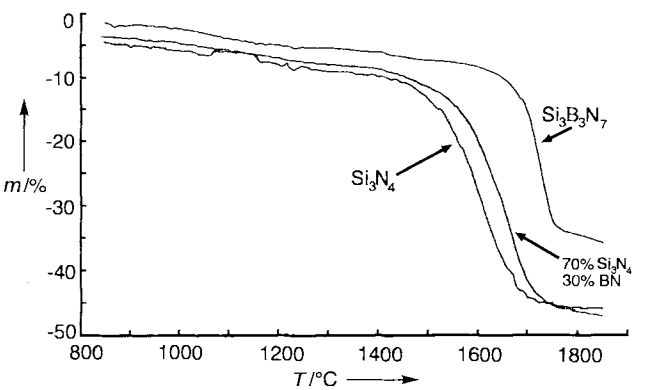

Figure 8. Thermal decomposition of $Si_3B_3N_7$ (amorphous), of α-Si_3N_4, and of a composite of Si_3N_4 and BN; *m*: mass loss.

stability o $SiBN_3C$ is even better. Investigations by X-ray diffraction reveal no indications of decomposition or crystallization in the temperature range between 1400 °C and 1900 °C (Figure 9).

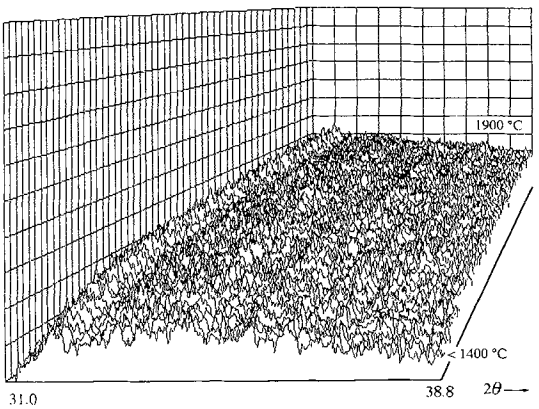

Figure 9. X-ray powder diffraction pattern of $SiBN_3C$ between 1400 and 1900 °C ($Cu_{K\alpha}$ radiation).

This appears to be the limit of the thermal durability of the material. Thus, the amorphous structure is even maintained if it is heated to 1800 °C for longer times under a nitrogen atmosphere (Figure 10). However, if the material is heated to 1940 °C, the release of nanocrystalline silicon nitride is observed (pure Si_3N_4 decomposes already at 1850 °C at 1 bar N_2!) after 60 h. Up to the decomposition at 2000 °C no crystalline BN, SiC, or B_4C can be detected. The complete decomposition into N_2, SiC, and BN takes place at higher temperatures.

In the case of $SiBN_3C$ the oxidation stability, a notorious drawback of other nonoxide ceramics, is remarkably auspicious. The comparison with Si_3N_4 and BN clearly demonstrates its superiority (Figure 11). Isothermal thermogravitic investigations of the weight loss on exposure to air at temperatures between 1520 and 1550 °C (loss of B_2O_3) reveal a parabolic weight

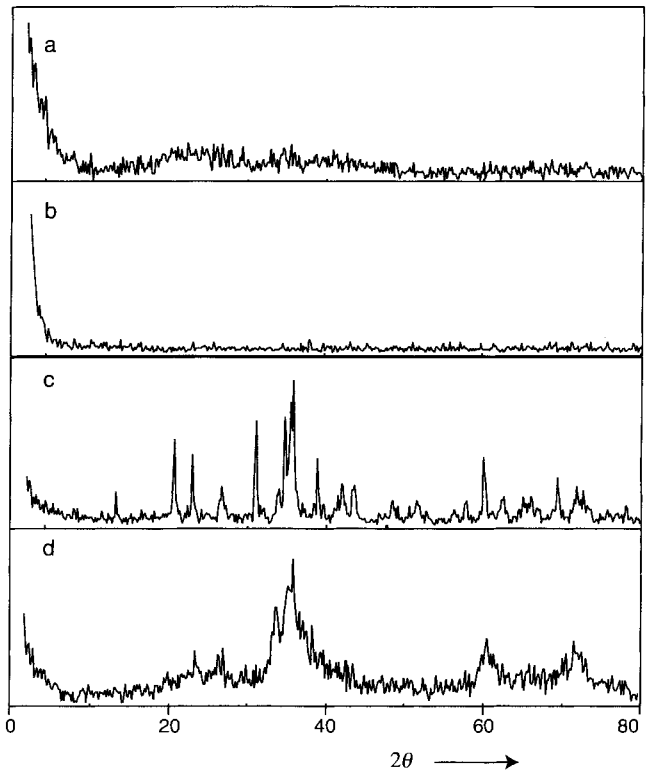

Figure 10. X-ray diffraction pattern of different ceramic materials after temperature stress: a) SiBN(C) [22]/1800 °C—amorphous structure maintained; b) SiBN(C) [22]/1400 °C—completely amorphous; c) SiN(C)/1800 °C—complete crystallization; d) SiN(C)/1400 °C—formation of microcrystalline framework.

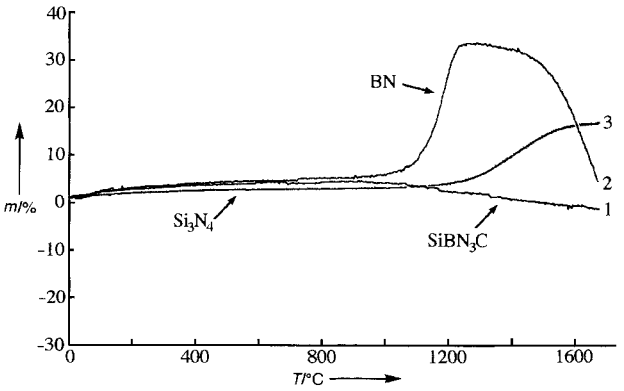

Figure 11. Oxidation behavior of $SiBN_3C$, Si_3N_4, and BN (m: mass loss).

loss, and the overall oxygen content approaches a low limit value. These observations indicate a diffusion-controlled, kinetically strongly impeded oxidation process. Deep profile investigations by secondary neutral particle mass spectroscopy (SNMS) of the surfaces of samples exposed to air at 1520 °C offer an explanation (Figure 12).

The oxygen-containing surface layer is only 1.2 to 1.4 μm thick. The actual surface consists of SiO_2 with some boron and carbon. At deeper levels this changes into a SiBNO phase showing some tendency for boron enrichment, until the bulk composition is assumed. The same double layer structure can be seen in the scanning electron microscope (SEM) images (Figure 13) of $SiBN_3C$, oxidized at 1500 °C for 48 hours.

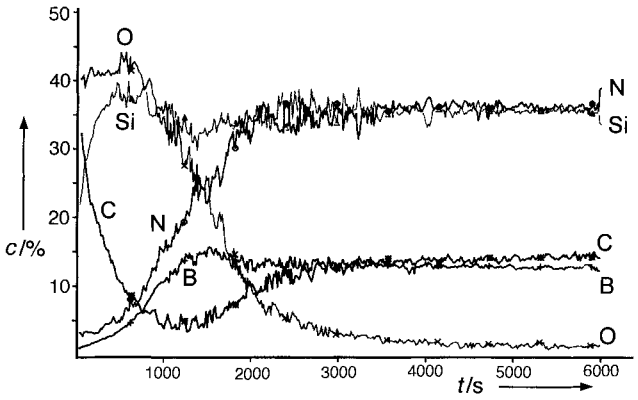

Figure 12. Secondary neutral particle mass spectra of the surface of $SiBN_3C$ powder, oxidized at 1500 °C (a layer of 2 μm has been removed in 3000 s). c = relative concentration.

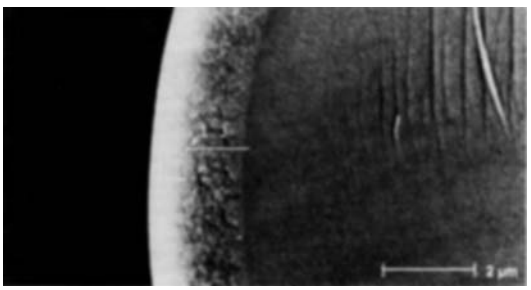

Figure 13. SEM image of $SiBN_3C$ fiber exposed to air at 1500 °C for 50 h; voltage 12.0 kV, magnification 10000 ×.

Up to now, the presented range of properties is unique. The low density and thermal conductivity of the materials are easily explained by their composition and amorphous structure. The high thermal stability and oxidation stability of the thermodynamically metastable SiBNC systems could not be expected in advance. So far, there is no other material besides $SiBN_3C$ that maintains the amorphous state at such high temperatures. The formation of the crystalline state would require multiple cleavage, reorientation, and reconnection of chemical bonds because of the different coordination chemistry of the constituent elements. Since these covalent bonds are very strong, this process is kinetically strongly impeded. This feature is very important for the application of the ceramics, since the mechanical and thus microstructural properties of workpieces that are used in safety relevant applications at high temperatures must not change under working conditions. This applies particularly to ceramic fibers, since they are supposed to work as stabilizing components in critical situations.

6.4. Production and Properties of Bulk Materials

Up to now, large workpieces of sufficient density and thereby mechanical strength could not be obtained from $Si_3B_3N_7$ powders made by the polymer route. In this respect, the high thermal stability results in a low sintering ability. However, the decomposition of the materials into binary components above 1800 °C may be used to produce parts of Si_3N_4/BN composites. The conventional approach starting from coarsely ground Si_3N_4

and BN mixtures has a series of disadvantages. Particularly high quality, dense bulk materials can only be formed by expensive processing methods like hot pressing or hot isostatic pressing.[58] If single phase $Si_3B_3N_7$ powder is used, Si_3N_4/BN composite parts can be formed by sintering in N_2 atmosphere at ambient pressure. Thus a green part that is formed by cold isostatic pressing of a mixture of $Si_3B_3N_7$ and Si_3N_4 (formal BN content: 7 wt%) with a specific surface of 1 $m^2 g^{-1}$ with Al_2O_3 and Y_2O_3 (5 wt% each) as sintering aids yields, upon sintering at 1900 °C and ambient pressure, workpieces that show a bending resistance of about 1000 Mpa and a Vickers' hardness of up to 4 Gpa. These properties are equal or superior to those of workpieces prepared by the more expensive high-pressure sintering method.[59] The microstructure, formed upon sintering, is quite remarkable; for instance, areas that contain nanocrystalline BN particles intragranularly in a Si_3N_4 matrix are found (Figure 14). Such microstructures resemble the micro- and nanocomposites described by Niihara et al.,[58] which are produced by sintering of Si_3N_4 with nanocrystalline BN powders, and which exhibit exceedingly good mechanical properties.

Figure 14. Electron microscope image of a Si_3N_4/BN composite made from $Si_3B_3N_7$ and Si_3N_4. Si_3N_4 and BN crystallites (particle size 400–500 nm) co-exist.

6.5. Ceramic Coatings and Infiltrations

Currently, the occurrence of cracks and pores during the production of larger workpieces from polymeric precursors cannot be prevented. Of course, the resulting difficulties can be avoided by using materials of submillimeter thicknesses. Parts made from graphite, CFC, or carbon fibers are already widely applied. However, the low oxidation stability of carbon limits their suitability for many applications. In order to use carbon-containing materials above the temperature limit of about 500 °C, they are currently preferably coated with multifunctional SiC layers. These are not suitable for long-term application, since crystalline SiC tends to crack on cyclic temperature variation, and is insufficiently stable against oxidation at about 1200 °C. These limitations should be overcome by $SiBN_3C$ coating. Since the thermal coefficients of expansion of $SiBN_3C$ and carbon fibers widely agree, no thermal tension is expected in CFC fibers coated with $SiBN_3C$. Preliminary experiments in this direction are very promising (Figure 15). The potential of SiBNC coatings was recently demonstrated by experiments with carbon fiber reinforced composite materials (C/C and C/SiC). Those with a SiBNC coating

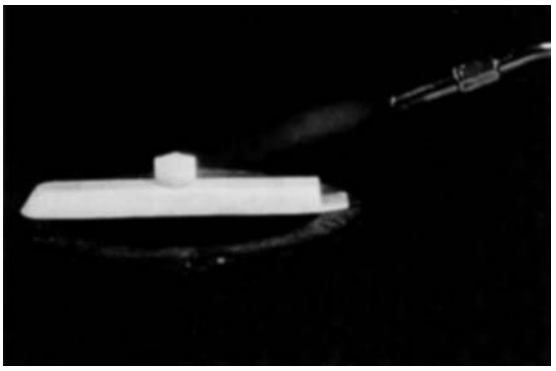

Figure 15. Graphite cube coated with $SiBN_3C$ in oxyhydrogen flame.

showed a superior deflagrating behavior than those with SiC or SiNC coatings.[60]

Polymer infiltration with preceramic polymers (polysilazanes, polycarbosilanes), which are transformed to refractive materials (SiC, SiNC) by pyrolysis is an important method to produce carbon fiber reinforced composites. Compared with other infiltration methods such as chemical vapor infiltration (CVI), polymer infiltration is cheap despite the necessity of several cycles of infiltration and pyrolysis. However, there are some drawbacks regarding the mechanical properties of the resulting parts. The pores and cracks included in the infiltrated part amount to a total porosity of about 10%. Consequently, carbon fiber reinforced composites have to be protected against oxidation at higher temperatures by an outer protective layer. In addition intrinsic oxidation protection is very desirable to improve the long-term oxidation protection even further. The consequences of damage of the outer protective layer would be less severe if every single carbon fiber was separately protected against oxidation. Polyborosilazane-derived $SiBN_3C$ ceramics are particularly well suited for this intrinsic oxidation protection. Such layers operate as crack-free protective coatings, thus ensuring intrinsic oxidation protection in the bulk material. Preliminary experiments indicate that in particular the low-viscous borosilalazane oligomer clearly improves the intrinsic protection against oxidation.

6.6. Ceramic Fibers

Ceramic $SiBN_3C$ fibers can be obtained from meltable *N*-methylpolyborosilazane. Multifilament (up to 200 individual fibers) green fibers are spun from predensified polymers, made unmeltable by curing and finally continuously pyrolyzed to the ceramic state at 1500 °C. The resulting fibers have a very smooth surface and very constant diameter (Figures 16 and 17); their oxygen content is below 1 wt%.

The amorphous state is retained at least up to 1800 °C, and is not subjected to microstructural changes up to this temperature. This results in a remarkably good high-temperature creep-resistance that is at least as good as the currently most creep-resistant SiC fiber (manufacturer: Carborundum). The oxidation stability, which in the important range between 1000 °C and 1500 °C is considerably larger than those of the standard nonoxide materials Si_3N_4 and SiC, is maintained. This is impressively demon-

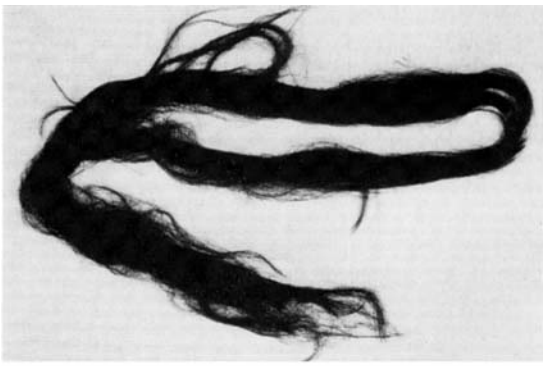

Figure 16. Bundle of $SiBN_3C$ fibers (reduction: 40%).

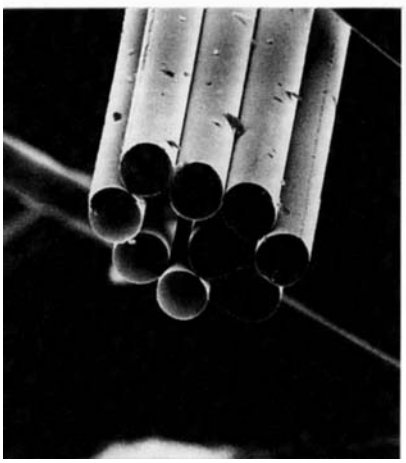

Figure 17. SEM image of $SiBN_3C$ fibers; voltage 25.0 kV, magnification 2250×, 20 μm.

strated by pictures of a ruptured $SiBN_3C$ fiber exposed to air at 1500 °C for 50 hours (Figure 13) and a ruptured Hi-NICALON fiber (SiC) exposed to air at 1500 °C for 15 hours (Figure 18). The SiC fiber developed a thick crystalline crystobalite layer and its tensile strength approaches zero, while the $SiBN_3C$ fiber developed only a thin, crack-free, amorphous SiO_2 layer. The tensile strength of the oxidized fiber is as high as that of the unoxidized one within the experimental error. The tremendous advantage over currently available fibers based on SiC is shown by the comparison of the two most important parameters for high-temperature application creep-resistance and maximum temperature of operation in air. A group of the most important

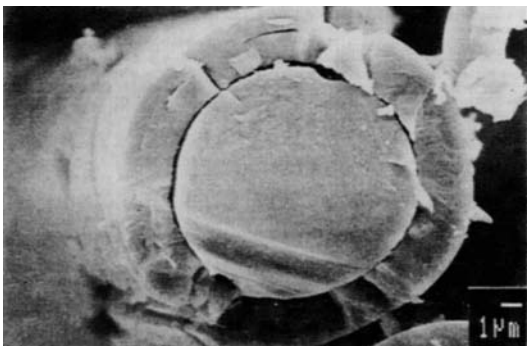

Figure 18. SEM image of Hi-NICALON fiber exposed to air at 1500 °C for 15 h [61].

users (European turbine producers) recently issued very ambitious objectives for third generation fibers. The fibers presented already fulfil all these demands as shown in Table 5.

Up to now, only $SiBN_3C$ fibers obtained by the polymer route from the single-source precursor TADB fulfil the requirements for the technological and economical breakthrough to the third generation ceramic fiber. Even optimized oxide fibers (for example α-Al_2O_3) have insufficient high-temperature stability, for SiC fibers a maximum operating temperature of 1300 °C emerges. Also there are currently no concepts, for example, for the production of single crystalline fibers with directed microstructure, which would be necessary to improve their properties at high temperature. However, it must be taken into account that the processing of fiber matrix composites still requires further research, and that the effects of real combustion chamber atmospheres at elevated pressure and high gas velocities as well as of dynamically changing stress on the material are still unknown.

7. Concluding Remarks

The approach to ceramics from molecular and polymeric precursors has been developed to a promising alternative to the conventional powder route. In some fields such as fibers and coatings, it is even the only option. Herein the major developments of the last 20 years in this field of research have been discussed, and the immense variety of possibilities offered by molecular and polymer chemistry have been made apparent. The history of the material in its molecular and polymer stages

Table 5. Properties of the best, partly currently developed ceramic fibers compared with requirements of potential users (European turbine producers) [61, 62]. RT = room temperature.

Property	Requirement	SiBN(C) [a]	SiC [b]	SiC [c]	SiCTiO [d]
max. operation temperature in air [°C]	1500–2000	1500	1300	1200	1000
tensile strength at RT [GPa]	3.0	3–4	3–4	3	ca. 3.2

influences its properties and structure, despite the relatively simple composition (binary, ternary, or rarely, quarternary compounds) of the ceramic systems and the drastic conditions of the final pyrolysis. For instance, it is possible to determine whether a crystalline or amorphous (glasslike) state is obtained by choosing the appropriate precursor molecules. The first of the three steps —molecular synthesis, polymerization, and pyrolysis—to the ceramic profits from the progress made in molecular chemistry of the main group elements, and is consequently the most advanced. In most cases polymerization and pyrolysis lack a proper description and analysis. To date, these processes are neither understood nor can they be directed.

The application of the numerous alternative approaches to meet the industrial needs helps to separate the wheat from the chaff. Currently, the rationally developed synthesis of the high-temperature stable ceramic in the Si/B/N/C system is one of the most promising concepts. It easily has all the potential for a technical and economic breakthrough:

- The single-source precursor can be produced from industrially available raw materials in few almost quantitative steps. In principle, all by-products evolved up to the beginning of the pyrolysis can be reused.
- The required processing technique is demanding, but available, in principle.
- The single-source precursor can be used in many different ways.
- Composition and viscoelastic properties of the polymer can be varied over a wide range. Thus, all classic processing technologies for polymers can be applied.
- Currently, $SiBN_3C$ is the most oxidation-stable nonoxide ceramic. Under inert conditions it can be thermally charged up to 1900 °C, while remaining amorphous.
- Other promising features of $SiBN_3C$ are the low density ($1.8\,g\,cm^{-1}$), the low thermal coefficient of expansion ($2\times10^{-6}\,K^{-1}$), the low thermal conductivity ($0.4\,Wm^{-1}$ at 1500 °C), the extremely high thermal shock resistivity, the hardness (comparable with alumina), and the high mechanical durability.

Other materials show better results in terms of one or the other of the properties (SiC has a considerably higher decomposition temperature under inert conditions, trivially the oxides are more stable against oxidation); however, up to now, the presented combination of properties in $SiBN_3C$ is unique. Apparently, the components boron (suppresses crystallization) and carbon (increases thermal durability) are present in the ideal ratio. Also, the development of the system was helped by some good fortune, since the high oxidation stability resulting from the formation of the double protective layer was unpredictable. All in all this system shows that the polymer route, though more expensive at first glance, may well compete with the conventional powder technique, if efficient syntheses yield a material with promising properties.

It is very disillusioning for a modern scientist not to know more than the total composition and some macroscopic properties of a new material. After all, he is used to knowing immediately the structural details of a new compound down to the atomic scale. Materials without translational symmetry are equally important as crystalline materials. Thus they deserve to be equally well investigated with respect to their structure and bonding as the latter. This constitutes a further broad, though difficult field for basic research.

We thank the BMBF (project No 40013), Bayer AG, and the Fonds der Chemischen Industrie for their generous support, the project partners and co-workers named in the references for their committed co-operation, and particularly Dipl.-Chem. Hardy Jüngermann, Dipl.-Chem. Matthias Kroschel, and Dipl.-Chem. Utz Müller for their assistance in preparing the manuscript.

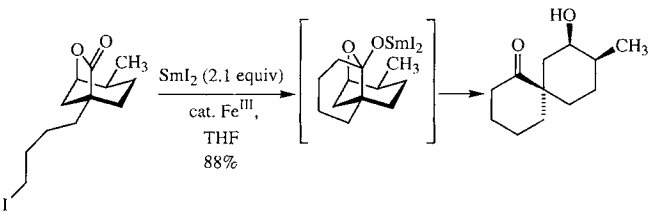
New Sequential Reactions with Single-Electron-Donating Agents

Troels Skrydstrup*

The construction of complex organic compounds by sequential transformations is one of the most impressive and efficient synthetic strategies, which clearly demonstrates the imagination and creativity of synthetic chemists. The advantages of the use of such tandem reactions are many and have been thoroughly discussed by Tietze and Beifuss in a review in 1993.[1] Now through the work of the groups of Molander and Murphy three newly discovered sequential reactions may be added to this growing list of transformations relying on single electron-donating agents such as samarium diiodide and tetrathiofulvalene. These new sequential reactions provide an effective and elegant means to a series of polycyclic compounds.

Of the plethora of contemporary reagents at our disposal for organic synthesis, perhaps the most remarkable is the divalent lanthanide reagent samarium diiodide.[2] This unique, polyvalent reducing agent has been applied to a multitude of important synthetic transformations, which generally proceed with high levels of stereochemical control. The secret to the success of this one-electron-donating agent lies in its intermediate reducing potential: either a radical or a carbanionic reaction may be efficiently performed through the judicious choice of reactants and conditions. As has been demonstrated by several groups, these two reaction types may furthermore be combined in a tandem process known as a radical/polar sequence.[3] Specifically, an initial SmI_2-induced radical cyclization may be succeeded by a second electron transfer from a second equivalent of SmI_2, affording the corresponding organosamarium intermediate with concomitant intermolecular nucleophilic addition or substitution.[3] Radical cyclizations are thereby terminated by the introduction of rather than the loss of functional groups, as is characteristic for cyclizations with tin hydride.

In an extension of this chemistry Molander and Harris have recently demonstrated that SmI_2 may be employed in either an anionic/anionic or an anionic/radical sequential reaction for the stereocontrolled construction of complex bicyclic and tricyclic ring systems, which enhances even further the versatility and possibilities of this reagent.[4, 5] The Molander team, who greatly contributed to the popularity of this reagent over the last decade, had previously observed that nucleophilic acyl substitution reactions proceed exceptionally well to afford cyclic or acyclic ketones (Scheme 1).[6] Considering that SmI_2 promotes Barbier-type cyclization reactions with alkyl halides, it seemed possible to combine these two transformations in a sequential manner. This was exactly the case: when the simple-to-prepare substrates shown in Scheme 2 were subjected to four equivalents of SmI_2 rather than the usual two equivalents, a diverse array of cyclic products formed depending on the substitution pattern of the substrate.[4] In the mechanism proposed for these reactions a tetrahedral intermediate is formed upon nucleophilic addition of an organosamarium species, which is generated upon SmI_2 addition. Liberation of the ketone is then followed by a second intramolecular attack upon reduction of the second alkyl halide side chain. Crucial to the success of some of these reactions is the sequential formation of the organosamarium intermediates, which is controlled by the different rates at which alkyl halides are reduced by SmI_2 ($k_{red(R-I)} > k_{red(R-Cl)}$). When the same halide is employed in the two side chains, it is apparently their length that determines the sequence of attack to the carbonyl functionality. A wide variety of ring systems are accessible by this approach, including seven- and eight-membered rings. Highly impressive are the efficient transformations sketched in the last two examples in Scheme 2. The resulting tricyclic systems are related to certain naturally occurring sesqui- and sesterterpenes.



Scheme 1. SmI_2-induced nucleophilic acyl substitution.

Molander and Harris also demonstrated the efficiency of the SmI_2-promoted anionic/radical sequence as a viable approach to similar ring systems.[5] Basically the same starting materials are exploited again, with one minor but important modification: one of the alkyl halide side chains has been replaced with a side chain containing a double bond. The logic behind these examples is that in the absence of a second alkyl halide reduction step, the intermediate ketone formed after acyl substitution is reduced to the ketyl radical, which attacks the olefin with ring formation. As shown by the examples in Scheme 3, this ap-

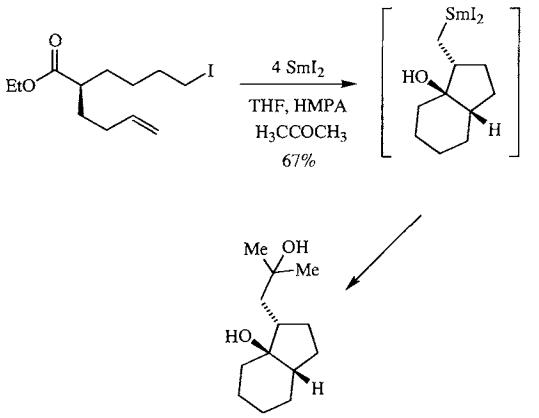
proach also provides an efficient and facile route to numerous substituted carbo- and heterocycles,[2a] and in general proceeds with high diastereoselectivity. This bicyclization process gives the best yields when the substrates bear activating groups on the alkene.

A nice extension of this chemistry to a sequential anionic/radical/anionic sequence was also described.[5] Normally after acyl addition and radical cyclization onto a C=C bond, the newly formed carbon radical is reduced to an organosamarium intermediate, which is subsequently protonated. However, this organosamarium species may be trapped in the presence of a ketone, thus terminating this three-step process (Scheme 4). Until now only a single representative has been reported, but this example certainly suggests the possibility of extending these SmI_2-induced sequential reactions even further.



Scheme 4. An example of a anionic/radical/anionic sequential reaction promoted by SmI_2.

Another impressive array of radical/polar sequential reactions employs an alternative one-electron-donating agent previously not been exploited in organic synthesis, namely tetrathiafulvalene (TTF). In contrast to the traditional radical/polar reactions induced by SmI_2,[3] Murphy and collaborators have demonstrated that radical cyclizations promoted by TTF may be terminated by S_N1-type nucleophilic substitution at the new exocyclic center (Scheme 5).[7] After single-electron reduction of a suitable substrate **A** by TTF and subsequent radical cyclization in analogy to the SmI_2-promoted reactions, the newly formed carbon radical is formally oxidized by combination with the $TTF^{\cdot+}$ radical cation. The carbon radical is not reduced further by a second TTF molecule, as is the case in SmI_2-medi-

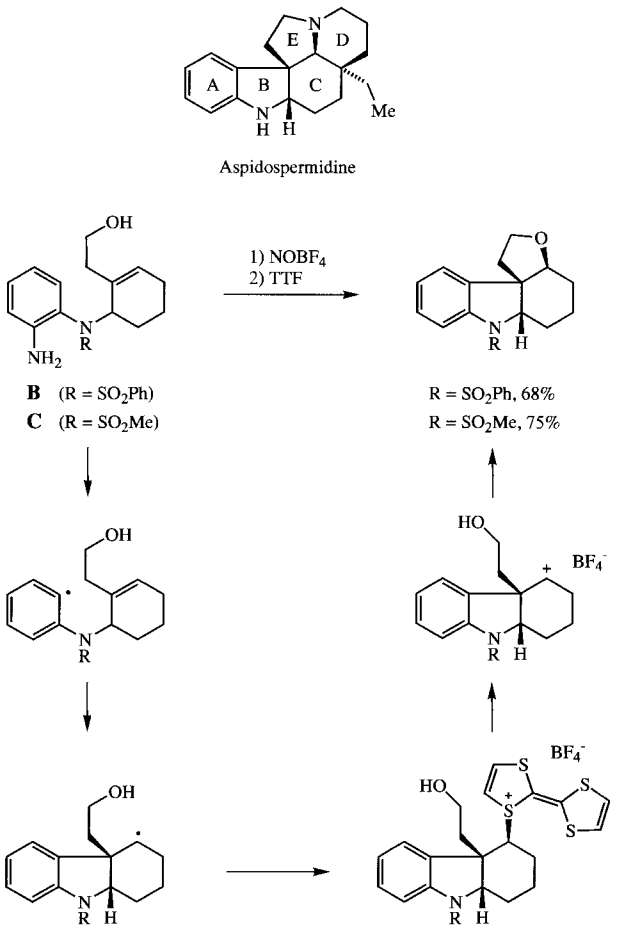

Scheme 6. Degradation of the ABCE tetracyclic substructure of aspidospermidine.

ated reactions, rather the corresponding sulfonium ion forms. Substitution at the sulfonium ion bearing a carbon center with external nucleophiles (for example solvents such as H_2O, MeOH, and CH_3CN) were found to follow S_N1-type kinetics. These reactions have so far been applied only to aryl diazonium salts and are hence restricted to cyclizations of aryl radicals. An intriguing facet of this chemistry is that this radical/polar sequence can be carried out in the presence of a catalytic amount of TTF, because the one-electron-donating agent is regenerated after nucleophilic attack. This reaction is thus clearly distinguished from the samarium(II)-induced reactions, in which two equivalents of the reagent are necessary for the radical/anionic process. Further studies along this line are necessary, since the best yields as well as acceptable reaction times were obtained when one equivalent of TTF was employed.

In a more interesting application of this chemistry, substrates containing internal nucleophiles can be used to construct more complex ring systems.[8] A cunning demonstration of this approach was provided by the Murphy group in their model studies for the preparation of the ABCE tetracyclic substructure of the *Aspidosperma* alkaloids aspidospermidine and strychnine.[9] Diazotization of precursors **B** and **C** and their subsequent reaction with TTF were performed in situ to furnish the desired tetracyclic ring systems in good yields (Scheme 6). Most importantly, the three contiguous stereocenters were formed with complete stereocontrol, affording the all-*cis* product and providing further evidence for the S_N1 reaction with the sulfonium ion intermediate. This radical/polar sequential reaction therefore complements nicely the tandem radical cyclization approach reported by the same group.[10] These new ring-forming methodologies should prove to be a powerful means for the efficient synthesis of complex natural products.

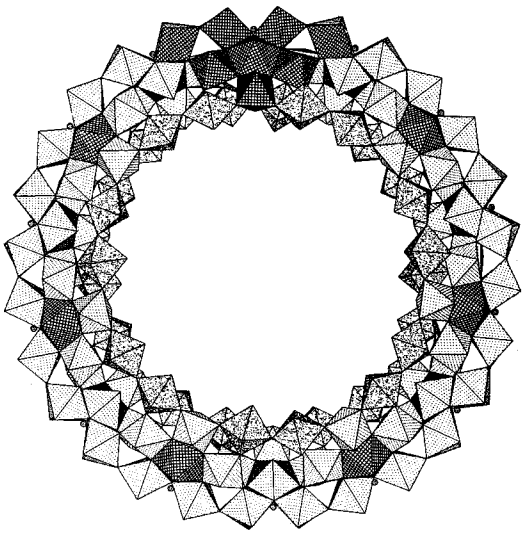
The Fascination of Large Rings: Cyclic Metal Complexes of Polydendate Ligands

Herbert Plenio*

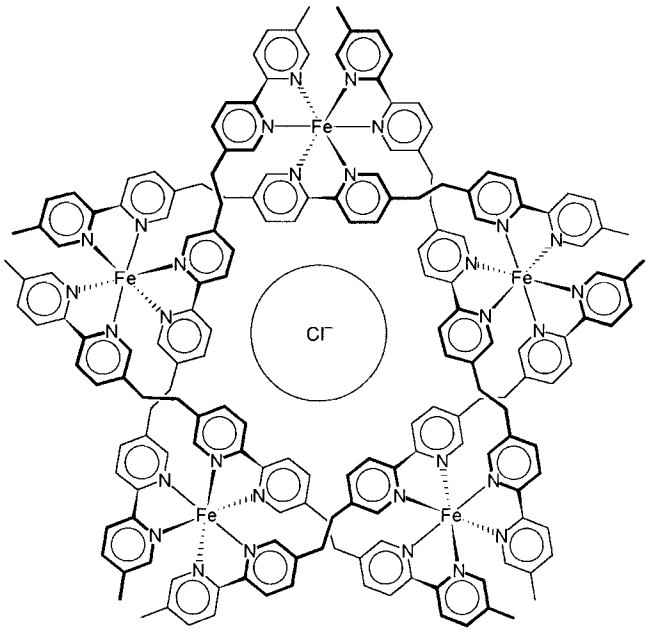
The fascination that cyclic complexes hold for chemists as simple closed systems[1] recently reached a new high point in organic chemistry with the synthesis of olympiadane by Stoddart et al.[2] Over millions of years nature has perfected the tricks of molecular self-assembly to the extent that huge ring structures such as cyclic DNA or the bolaamphiphile components of primitive cell membranes are formed in biological systems "by themselves". In contrast, today's preparative chemists are just beginning to understand the principles that control the construction of complex nonbiological structures from the simplest of building blocks, and recently significant results have been achieved, particularly in the field of coordination chemistry.[3] Herein, several of these unusual cyclic compounds are described, and the factors important in their synthesis are discussed. Along with the aesthetic appeal another striking feature of these complexes is the deceptive simplicity of the syntheses; they are frequently obtained in high yields from one-pot reactions from two or three reagents.

The first example comes from the group of Achim Müller: The reaction of Na_2WO_4, NH_4VO_3, and $NH_2OH \cdot HCl$ in water, weakly acidified with hydrochloric acid, results in the formation of several giant clusters, the largest of which has the composition $(NH_4)_{25\pm5}[Mo_{154}(NO)_{14}O_{420}(OH)_{28}(H_2O)_{70}] \cdot$ ca. $350\ H_2O$.[4] The single-crystal X-ray structure analysis reveals (Scheme 1) the existence of a gaint ring with an external diameter of about 4 nm, which encloses a circular cavity with a diameter of about 2 nm. This cavity has almost the same dimensions as the smaller Mo_{57} clusters, which are formed from the same starting materials under very similar reaction conditions. It is, therefore, plausible to suggest that the small clusters function as templates for the formation of the Mo_{154} ring.[5]



Scheme 1. Structure of the giant molybdenum cluster prepared by Müller et al. [4].

Lehn et al. recently described the reaction of a trimeric bipyridine with $FeCl_2$ in ethyleneglycol at 170 °C, which produces a circular double helicate. The single-crystal X-ray structure analysis of the product, undertaken by Fenske et al., revealed this to have an external diameter of about 2.2 nm (Scheme 2).[6] In the center of the ring is a cavity with a diameter of 0.35 nm into which a chloride ion neatly fits; this ion is believed to be responsible for the formation of the observed pentairon helicate.



Scheme 2. The circular double helix prepared by Lehn et al. [6].

The so-called "molecular squares" also contain large rings. A new example of this class of compounds was recently published by Stang et al. (Scheme 3):[7] The reaction of *trans*-$[(PPh_3)_2Pt(py)(4,4'\text{-biphenyl})Pt(py)(PPh_3)_2^{2+}]$ with *cis*-$[(Ph_2P(CH_2)_3PPh_2)Pt(\text{pyridylacetylene})_2]$ produces, in quantitative yield, a molecular square with sides of 3.0 nm and a maximum intramolecular Pt–Pt separation of 4.3 nm.

Fujita et al. have employed a similar procedure in the high-yield synthesis of a macropolycyclic palladium complex from $[(en)Pd(NO_3)_2]$ and a triazine derivative; the product has a diameter of about 5 nm (Scheme 4).[8] It should be noted that the structures of the complexes prepared by Stang et al. and Ogura et al. have not yet been confirmed by X-ray structure analysis. The growth of suitable, stable single crystals of these giant molecules is a general problem, since the ring-shaped

structure inevitably requires the presence of large cavities in the crystal packing. It is common for solvent molecules to be trapped inside these cavities, which results in structural disorder; however, the loss of this solvent, which often occurs readily, causes the destruction of the crystal.

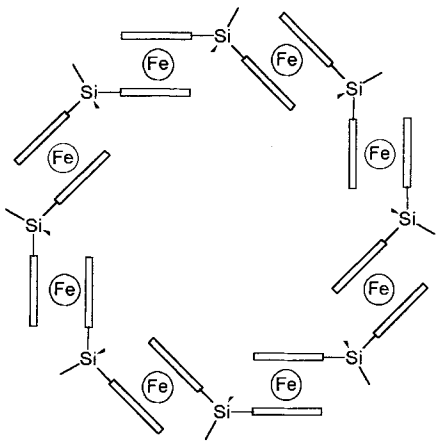
In appreciating the beauty of these compounds an obvious question comes to mind: Why are these particular rings formed? In looking for an answer the first thought to occur is that the key bond formation steps always occur in the coordination sphere of a metal ion. In light of this two further questions that require answers come to mind. 1) What are the differences between the formation of C–C bonds and the formation of coordinate bonds to a metal center? 2) Why does the latter reaction allow the degree of oligomerization to be controlled? One possible explanation is that the formation of a C–C bond typically yields a kinetically stable product, while metal–ligand bonds are frequently labile. This lability makes it possible for a reaction mixture, which initially contains the complete range of possible oligomerization products, to reach "equilibrium" by the formation of a defined ring that, for whatever reason, is energetically preferred. This controlled adjustment of an equilibrium is not possible in a reaction system in which the irreversible formation of kinetically stable bonds occurs.

This notion is supported by the observation by Lehn et al. that during the synthesis of the cyclic helicate in Scheme 2 the "assembly process" can be monitored by ESI mass spectrometry. The reaction of the trimeric bipyridine with $FeCl_2$ initially gives kinetically controlled primary products from which, after a long equilibration period at 175 °C the desired cyclic helicate is formed.[9] This product seems to be favored over the other possible ones by virtue of its ability to encapsulate the chloride ions present in the reaction mixture. This implies that the template principle is another deciding factor in product formation; in accordance with this a component from the reaction mixture acts as a stencil around which the large ring is constructed. This template can be a smaller cluster or a large ion such as chloride.

A third principle controlling the resultant structure appears to be the topolgy of the ligands and metal complexes, which results in geometric restrictions in the coupling of the individual components. In the complexes described by Stang et al. and Fujita et al. (see Scheme 3 and 4, respectively) the 90 ° connectivity of the square–planar *cis*-platinum and *cis*-palladium complexes, respectively, together with the reaction partners, which adopt linear and trigonal-planar arrangements, respectively, controls the geometry of the resulting complexes.

Thus a useful procedure is to reduce the structural units to simple geometric bodies (related to the retrosynthetic synthon) called "tectones".[5] The building of a molecular square thus requires the linking of four linear T_2 tectones (for the sides) and four *cis*-T_2 tectones (for the corners). In the above example these T_2 tectones are derived from the square-planar complexes in which either two *cis* or two *trans* coordination sites are occupied by easily replaceable ligands.

An unusual ferrocene oligomer prepared by Köhler et al.[10] serves as a final example (Scheme 5). It was obtained in low yield



Scheme 5. Ferrocene oligomer prepared by Köhler et al. [10]. In the given projection a second $SiMe_2$ group lies behind each $SiMe_2$ group shown.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3604-0349 $ 15.00+.25/0

from the reaction of double $SiMe_2$-bridged $C_5H_3(SiMe_2)_2$-$C_5H_3^{2-}$ with $FeCl_2$. The X-ray structure analysis of the product reveals a cyclic heptamer with a ring diameter of about 2 nm.[11] It is not easy to explain why this particular oligomer is formed, however, it is again useful to consider the topology of the molecular constituents. The 1,1′,2,2′-binding of the cyclopentadienyl rings by two $SiMe_2$ units hinders the tilting of the rings towards each another. Gokel et al. have described ferrocenes as "molecular ball bearings" because the main degree of freedom is the rotation of the two cyclopentadienyl ligands away from each other; this is largely responsible for preserving the preferred coplanar arrangement of the rings.[12] The reduction in degrees of freedom in both ligands and metallocene can not fully account for the formation of the heptamer (in addition to the polymeric products), but it does focus attention on the course of this unusual ring closure reaction.

To conclude, modern chemistry has virtually solved the problems of stereochemistry and bond formation. The next target is the planned synthesis of large abiotic molecules with defined form and function (molecular devices).[13] Metal complexes will undoubtedly play an important role, since electron transfer processes and unusual magnetic properties can be easily realized by the use of metal-containing molecular building blocks.

The first organometallic derivative of a tellurium allotrope is made up of a folded four-membered ring (viewed from the top) of Te atoms (light brown) to which $Cr(CO)_5$ groups are coordinated in a mutually *trans* fashion (Cr atoms green).

[*cyclo*-$Te_4\{Cr(CO)_5\}_4$] was formed from the niobocene complex [$(C_5Me_5)_2Nb(Te_2H)$], which contains the novel η^2-Te_2H ligand, and [$Cr(CO)_5$(thf)]. Find out more about *cyclo*-tetratellurium on the following pages.

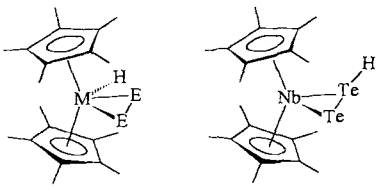
Coordinative Stabilization of *cyclo*-Tetratellurium as $[Te_4\{Cr(CO)_5\}_4]$: The First Organometallic Derivative of a Tellurium Allotrope**

Olivier Blacque, Henri Brunner, Marek M. Kubicki, Bernhard Nuber, Bernhard Stubenhofer, Joachim Wachter,* and Bernd Wrackmeyer

Typical of the inorganic chemistry of tellurium are polytelluride chains, in which higher coordination numbers and hypervalent bonding often play an important role.[1] The ability of polytellurides to act as ligands in transition metal carbonyl complexes has offered interesting, new structural perspectives.[2] Complexes containing cationic ligands such as Te_4^{2+} [3] and η^3-Te_3^{2+} are less numerous,[4] and, to our knowledge, no compounds containing neutral ligands are known. Recently, however, the stabilization of *cyclo*-Te_8 in the layered lattice of Cs_3Te_{22} was realized. [5] This has been recognized as an "important milestone" in the search for allotropic forms of tellurium.[1] We now report on the stabilization of the first molecular derivative of a neutral Te_4-ring, obtained by the elimination of tellurium from $[Cp_2^{(*)}Nb(Te_2H)]$ [**1**, $Cp^{(*)} = C_5Me_5$ (Cp*) or C_5Me_4Et (Cp^x)] under the action of $[Cr(CO)_5(thf)]$.

Complexes **1**, which were synthesized in excellent yields from $[Cp_2^{(*)}NbBH_4]$[6] and elemental Te, not only supply highly reactive tellurium but also contain the novel η^2-Te_2H ligand (**B**). This moiety is different from the ligand combination usually found in niobocene (E = S) and tantalocene dichalcogenides (E = S, Se, Te) of type **A**.[7]

This can be concluded from the ^{1}H NMR spectra of **1**, which exhibit the appropriate signals with ^{125}Te satellites (averaged coupling $J(^{125}Te,^1H) = 115$ Hz) in the region of $\delta = -3.55$. However, a coupling constant of $^1J(^{125}Te,^1H) = 230$ Hz is found in the ^{125}Te NMR spectrum of **1** (Cp*) by means of a ^{1}H–^{125}Te polarization transfer exyperiment ($\delta = -207.9$). This may be due to a rapid, dynamic process in solutions of **1**, by which the H atom migrates between the two Te atoms. The ^{125}Te NMR signal is broad (ca. 60 Hz), not only as a consequence of this dynamic process, but also due to partially relaxed scalar ^{125}Te–^{93}Nb interactions. The ^{93}Nb resonance was not found, probably because of too rapid ^{93}Nb quadrupole relaxation.



A **B**

(M = Nb: E = S; M = Ta: E = S, Se, Te)

[**] This work was supported by the Deutsche Forschungsgemeinschaft. We thank Prof. Dr. G. Huttner (Heidelberg) for support of the structure determination and Dr. E. Keller (Freiburg) for his assistance in producing the colored picture (p. 351).

The H atom in question could not be localized in the X-ray structure analysis of **1** (Cp^x).[8] The Nb and both Te atoms ($d_{Nb-Te} = 2.785(1)$ and $2.958(1)$ Å) form a nearly isosceles triangle, which is approximately bisected by the plane through the cyclopentadienyl centers and the Nb atom. The two Te atoms ($d_{Te1-Te2} = 2.686(2)$ Å) are located at +1.53 and −1.14 Å from this plane. These findings are consistent with the complex type **B** in the solid state.

Precipitation of grey-black tellurium from solutions of **1** can be suppressed with excess $[Cr(CO)_5(thf)]$. Reaction of **1** with four equivalents of $[Cr(CO)_5(thf)]$ in THF in the dark gives the red-brown product **2** after chromatographic workup [Eq. (a)].

$$\underset{\mathbf{1}}{[Cp^*_2Nb(Te_2H)]} + [Cr(CO)_5(thf)] \xrightarrow[20\,^\circ C,\ 12\,h]{THF} \underset{\mathbf{2}}{[Te_4\{Cr(CO)_5\}_4]} \qquad (a)$$

The IR spectrum of **2** exhibits an absorption pattern typical for the $Cr(CO)_5$ fragment ($\tilde{\nu} = 2023$, $1950\ cm^{-1}$) but no more Te–H and C–H bands. The latter would have been expected for addition of $Cr(CO)_5$ to the niobocene dichalcogenide moiety.[9] Complex **2** is soluble in polar solvents such as acetone. The sensitivity of the solutions has so far prevented the acquisition of FD-MS and ^{125}Te NMR spectra.

Single crystals of **2** have been obtained from acetone/CH_2Cl_2/toluene (1/2/1). The X-ray structure analysis[10] shows a folded four-membered ring (dihedral angle Te1-Te2-Te3/Te1-Te2-Te4 = 134.2°) to which all the $Cr(CO)_5$ fragments are *trans*-coordinated (Figure 1). The bonds Te3-Cr3 and Te4-Cr4 form an angle of 68.0 and 64.45°, respectively, with the adjacent triangles. The Te–Te distances (average 2.856(3) Å) are noticeably longer than those in **1** or $[Cp_2^*Ti(\eta^2\text{-}Te_2)]$.[11] The Te-Te-Te angles are 85.3° (mean), and the sum of the angles at the Te atoms is between 294.0° and 302.5°. The atoms at opposite corners of the four-membered ring, for example Te(1) and Te(2), are too far apart for bonding interactions ($d_{Te\cdots Te} = 3.903(2)$ Å).

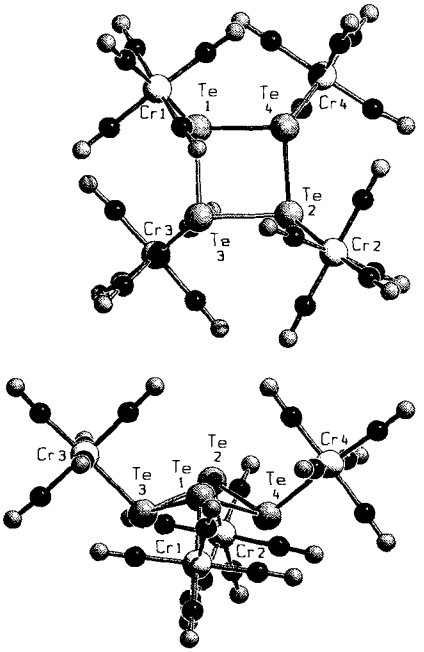

Figure 1. Schakal plot of $[Te_4\{Cr(CO)_5\}_4]$ (**2**) as viewed from the top (top) and side (bottom). Selected distances [Å] and angles [°]: Te1–Te3 2.854(2), Te1–Te4 2.818(2), Te2–Te3 2.895(2), Te2–Te4 2.857(2), Te1–Cr1 2.581(2), Te2–Cr2 2.599(2), Te3–Cr3 2.576 (3), Te4–Cr4 2.592(3), Te1···Te2 3.903, Te3···Te4 3.842; Te3-Te1-Te4 85.3(0), Te3-Te2-Te4 83.8(0), Te1-Te3-Te2 85.5(0), Te1-Te4-Te2 86.9(0), Te3-Te1-Cr1 106.3(1), Te4-Te1-Cr1 103.7(1).

The Cr–Te distances (2.587(3) Å) are about 0.16 Å shorter than those in $[Cr(CO)_5Te_3]^{2-}$[12] or $[Cr(CO)_4Te_4]^{2-}$.[13] No *trans* effect is observed within the CO ligands.

Complex **2** is the first molecular derivative of a tellurium allotrope. Extended Hückel molecular orbital (EHMO) calculations[14] for *cyclo*-Te_4 suggest only small differences (0.2 eV) between the total energies of square-planar (D_{4h}) and butterfly structures (D_{2d}). Thus, the geometry of the *cyclo*-Te_4-derivative **2** in the solid state is determined by the $Cr(CO)_5$ fragments. In contrast, $[\{Cp^*_2Rh_2(\mu\text{-}CH_2)_2\}_2(\mu\text{-}S_4)]^{2+}$, a derivative of *cyclo*-S_4, shows a planar ring conformation.[15]

The niobocene complexes **1** are an as yet unexplored source of highly reactive tellurium. The surprisingly simple coordinative stabilization of *cyclo*-Te_4 by tellurium transfer from labile transition metal tellurides may find broader application in the formation of similar compounds.[16]

Experimental Section

1: Elemental tellurium (642 mg, 5.0 mmol) was added to a green solution of $[Cp^{(*)}_2NbBH_4]$ (2.0 mmol) in THF (50 mL). After 60 h at 60 °C the solvent was removed from the orange-brown suspension, and the residue dissolved in toluene (20 mL) and purified by chromatography (SiO_2, 20 × 5 cm). Complexes **1** ($Cp^{(*)}$) were eluted with toluene as orange bands in 87% yield. Recrystallization from toluene/pentane (2/1) at −20 °C gave up to 82% of crystalline material. **1** (Cp^*): ^{1}H NMR (400 MHz, C_6D_6): $\delta = -3.59$ (t, 1H, averaged coupling $J(^{125}Te,^1H) = 115.4$ Hz), 1.84 (s, 30H); ^{125}Te NMR (157 MHz, C_6D_6): $\delta = -207.9$ ($^1J(^{125}Te,^1H) = 230$ Hz); IR (KBr): $\tilde{\nu} = 1790\ cm^{-1}$ (Te–H). **1** (Cp^x): ^{1}H NMR (400 MHz, C_6D_6): $\delta = -3.55$ (t, 1H, averaged coupling $J(^{125}Te,^1H) = 113.7$ Hz), 0.76 (t, 6H, $^3J = 7.5$ Hz), 1.88 (s, 6H), 1.89 (s, 6H), 1.930 (s, 6H), 1.934 (s, 6H), 2.21 (q, 2H, $^3J = 7.5$ Hz), 2.26 (q, 2H, $^3J = 7.5$ Hz). IR (KBr): $\tilde{\nu} = 1790\ cm^{-1}$ (Te–H). Complexes **1** ($Cp^{(*)}$) gave correct C,H analyses and FD-MS spectra.

2: A solution of **1** ($Cp^{(*)}$) (0.2 mmol) and $Cr(CO)_5$(thf) (4.55 mmol) in THF (100 mL) was stirred for 12 h in the dark at room temperature. The solvent was removed from the brown-violet solution in vacuo. The residue was then dissolved in a mixture of toluene (10 mL) and acetone (5 mL) and purified by chromatography (SiO_2, 20 × 5 cm). An as yet unidentified violet band was eluted with toluene. Subsequent elution with toluene/acetone (1/4) provided a red-brown band containing **2**. After removal of the solvent, the product was dried for 8 h at 80 °C under high vacuum to yield 80 mg (55%) of **2**. Elemental analysis for $C_{20}O_{20}Cr_4Te_4$: calcd C 18.79; found C 19.40.

Palladium Complexes of the New Porphyrin Isomers (*Z*)- and (*E*)-Isoporphycene—Pd^{II}-Induced Cyclization of Tetrapyrrolealdehydes**

Emanuel Vogel,* Martin Bröring, Christoph Erben, Ralf Demuth, Johann Lex, Maja Nendel, and Kendall N. Houk*

Dedicated to Professor Günther Wilke on the occasion of his 70th birthday

Theoretically, porphyrin gives rise to seven structural isomers with an N_4 core, which, in contrast to the parent tetrapyrrolic macrocycle, contain one or two formal double bonds.[1, 2] Thus, in the case of these isomers—to be considered separately from the inverted porphyrins[3] that became known a few years ago—stereoisomerism comes into play; that is, the occurrence of (*Z*)- and (*E*)-isomers is to be reckoned with.

Of the seven (*Z*)-isomers of porphyrin—on which interest was initially focused for obvious geometrical reasons—the three most stable isomers according to theoretical calculations have

been synthesized as octaethyl compounds and other derivatives: the (*Z*)-porphycene **1**,[4] the (*Z*)-hemiporphycene **2**,[5] and the (*Z*)-corrphycene **3**[6] (Scheme 1). The (*Z*)-porphyrin-(3.0.1.0) **4**, for which the name (*Z*)-isoporphycene has been suggested (exchange of both C_2 units in porphycene for one C_1 and one C_3 unit), follows (*Z*)-corrphycene **3** in the stability scale of the (*Z*)-isomers. Since **4** is already 23.6 kcal mol^{-1} higher in energy than porphyrin, the stability limit (or existence limit) of porphyrin structural isomers of this type may have been reached.

	Porphyrin-(2.0.2.0) (*Z*)-Porphycene **1**	Porphyrin-(2.1.1.0) (*Z*)-Hemiporphycene **2**	Porphyrin-(2.1.0.1) (*Z*)-Corrphycene **3**	Porphyrin-(3.0.1.0) (*Z*)-Isoporphycene **4**

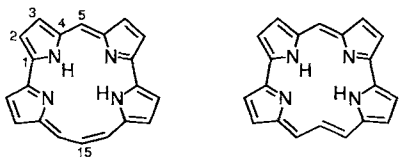
Scheme 1. The (*Z*)-stereoisomers **1**–**4** of the porphyrin structural isomers with a N_4 coordination site, arranged according to increasing relative energy [kcal mol^{-1}] with respect to porphyrin-(1.1.1.1) (calculated according to the PM3 method) [2].

If **4** should prove to be too unstable to be isolable, there might still be a chance that, in analogy to reactive hydrocarbons such as cyclobutadiene and *o*-quinodimethane, it can be obtained in the form of transition metal complexes.

Isoporphycene becomes particularly attractive when one considers that the (*Z*)- and (*E*)-stereoisomers **4** and **5** are predicted to have almost the same relative energies (23.6 and

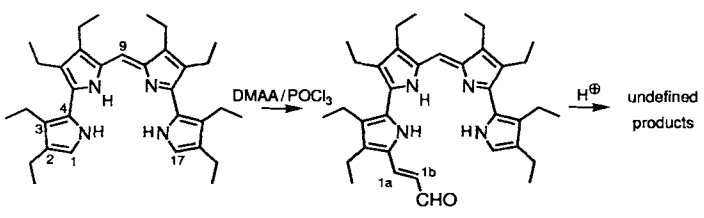


(*Z*)-Isoporphycene **4**

(*E*)-Isoporphycene **5**

23.8 kcal mol^{-1}, respectively, according to PM3). It should, therefore, cause no difficulties to convert one into the other photochemically (*cis* → *trans* isomerization). These considerations allow for a certain flexibility regarding synthesis, because it should be without consequence whether the reaction path is chosen to afford the (*Z*)- or the (*E*)-isomer.

Our concept for the synthesis of the isoporphycenes **4** and **5** in the form of their octaethyl derivatives was to insert a CH–CH=CH bridge into the octaethyltetrapyrrole **6** (considered a suitable starting material) by conversion into the vinyl aldehyde **7** (and/or its (*Z*)-isomer) and subsequent acid-induced cyclization by the MacDonald reaction.[7] While this route has



6 **7**

admittedly not yet led to (*Z*)- and (*E*)-octaethylisoporphycene in the form of free bases, replacement of the acid by Pd^{II} ions has provided access to the palladium complexes of the two stereoisomers described here.

Octaethyltetrapyrrole **6** has already been successfully employed in the synthesis of octaethylisocorrole[8] and can be easily obtained by a variation on a method from Sepulveda-Boza and Breitmaier[9] involving a trifluoroacetic acid induced condensation of tetraethyl-2,2′-bipyrrole[10] with ethyl orthoformate in methanol (room temperature, 6 h, m.p. 155–156 °C, yield 90%; Table 1). By treatment with a moderate excess (1.5-fold) of the vinylogous Vilsmeier reagent 3-(*N*,*N*′-dimethylamino)acrolein (DMAA) [11] and phosphoryl chloride in dichloromethane (0 °C, 3 h) a CH=CH–CHO function was introduced into **6** to form **7**. The isolation of **7** was carried out by adding a 10% aqueous potassium carbonate solution to the reaction mixture and working up in the conventional manner. The residue is then chromatographed on aluminium oxide (activity II–III) with hexane/(ethyl acetate) (3/1). The first fraction, which delivered unchanged starting material **6**, was followed by the reddish black main fraction containing **7** and small amounts of DMAA. The solvent was removed under reduced pressure, and the viscous oily product taken up in methanol. To the resulting solution was added aqueous methanol (50:50) slowly under continuous stirring. Under these conditions the product precipitated in the form of an amorphous solid. According to the ^{1}H NMR spectrum the product consisted of approximately 95% **7** (33% yield, Table 1) and was used without further purification steps as this would have led to high losses.

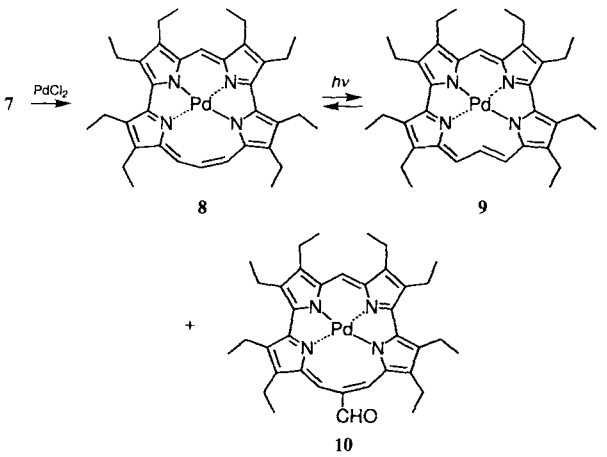
The reaction of **6** with a large excess of DMAA (10-fold) yielded the dialdehyde **15** (see below, Table 1) as the main product. Workup following the same procedure as for **7** proved successful for the isolation of **15**, too. In this case the product was eluted in the third, violet fraction in the chromatography step (the first and second fractions contained **6** (approximately 1%) and **7** (2–5%), respectively). The amorphous product **15** (60% yield) obtained by precipitation was practically pure according to the ^{1}H NMR spectrum and was therefore used without further purification. The aldehydes **7** and **15** have CH=CH coupling constants of 15.6 Hz in the ^{1}H NMR spectra and must accordingly have an (*E*)- and (*E*,*E*)-configuration, respectively.

Attempts to cyclize **7** to form (*Z*)- and/or (*E*)-octaethylisoporphycene in acidic medium were disappointing. Although the reaction conditions were widely varied, defined products could not be obtained. We had hoped to find a way out of this impasse by the use of Cu^{II} ions, because in the case of biladiene-*ac* salts this led to porphyrins through cyclization (mechanism not yet understood).[12] When copper(II) acetate was allowed to react with **7** in methanol at 0 °C, ring closure did indeed take place, although not with the formation of (*Z*)- and/or (*E*)-octaethylisoporphycene. Instead, the copper complex of 9-formyloctaethylisocorrole was formed, in which the metal atom has the formal oxidation state +III (yield 52%).[8] The complex is readily demetalated on reaction with hydrochloric acid, and the ligand is released. As is the case with copper(II) acetate, cobalt(II) chloride also effects the cyclization of aldehyde **7**. The reaction product in this case is the cobalt(III) complex of 9-formylisocorrole.[8]

The breakthrough to the targeted complexes of (*Z*)- and (*E*)-octaethylisoporphycene was finally achieved by the use of palladium(II) chloride as cyclization agent.[13] The reaction of **7** with four equivalents of the palladium reagent in refluxing pyridine (15 h) afforded a product which after removal of the solvent was chromatographed with dichloromethane/hexane (2/1) on silica gel. Two fractions resulted: The first delivered a mixture of the

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3604-0354 $ 15.00+.25/0

palladium complexes of (*Z*)- and (*E*)-octaethylisoporphycene **8** and **9** (yield 3%). The second fraction produced the palladium(II) complex **10** of the (*Z*)-isoporphycene aldehyde as a homogeneous compound (yield 7%, Table 1). The complexes **8** and **9**, which have been only partially separated to date, are readily converted into one another on exposure to light, but not thermally; the composition of the mixture can therefore vary, depending on the light conditions ((*Z*):(*E*) ranges from 40:60 to 50:50). The mixture of **8** and **9** is obtained from hexane/(diethyl ether) (4/1) in the form of violet crystals (needles) in which the components are found in the ratio 45:55 (m.p. 202–203 °C). The aldehyde **10** is likewise obtained in the form of violet needles from methanol/dichloromethane (3/1) (m.p. 284–285 °C). The mechanism of formation of the complex **10**, which contains one "excess" carbon atom, is only speculation at present.



The presence of the palladium complexes **8** and **9** is demonstrated convincingly from their ^{1}H NMR spectra (300 MHz, $CDCl_3$), which show not only the expected splitting patterns, but also chemical shifts for the perimeter protons (with the exception of H15 of the (*E*)-isomer **9**) ($\delta = 9-10$) that are similar to those of the corresponding protons in palladium complexes of porphyrin and known porphyrin isomers (octaethyl derivatives). The extreme upfield shift of the signal of H15 of the (*E*)-isomer ($\delta = -3.26$) is probably mainly due to the anisotropy effect of the diamagnetic ring current. The UV/Vis spectrum of **8**/**9** strikingly resembles that of the palladium complex of octaethylcorrphycene.[14] This is understandable because the three complexes have the same (or approximately the same) symmetry.

It proved to be quite rewarding to subject the palladium complexes **8** and **9** [(*Z*)-octaethylisoporphycenato]palladium(II) and [(*E*)-octaethylisoporphycenato]palladium(II), which formed mixed crystals (statistical incorporation of the isomers in the same ratio as in solution), to an X-ray structure analysis. The ratio of **8** and **9** found by NMR spectroscopy (45:55) was qualitatively confirmed by X-ray studies. The investigations into the structure[15] gave the following results, which are somewhat surprising (Figure 1). The (*Z*)- and (*E*)-isomers **8** and **9** are arranged in the crystal in such a fashion as to permit the determination of the structure of both isomers. It follows from the shape of the thermal ellipsoids and from the observation that the refinement of the site and temperature parameters does not lead to a distortion of the molecular geometry, that the ring frameworks of **8** and **9** have (within the margin of error) identical atomic positions—with the exception of the C_3 segments.

Table 1. Selected physical data for **6**–**10**, **15**, and **18** (^{1}H NMR: 300 MHz; ^{13}C NMR: 75.5 MHz; IR: CsI; UV/Vis: CH_2Cl_2).

Correct elemental analyses for **6**, **8**/**9**, **10**, and **18**.

This conclusion is backed up (inasmuch as comparisons may be drawn) both by the excellent agreement of the structural parameters of the isomers **8** and **9** (Figure 1) and of [15-cyano-(*Z*)-octaethylisoporphycenato]palladium(II).[16] The metalloisoporphycene framework of the (*Z*)-isomer **8** is completely planar, and the H–H distances in the eight-membered palladadiaza ring (partial structure **11**) are very small (<2 Å)—in analogy

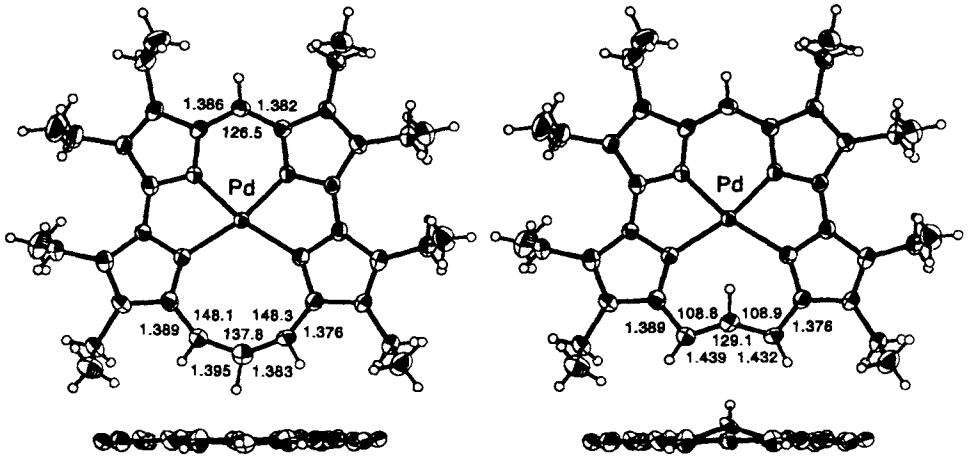

Fig. 1. Structures of **8** and **9** in the crystal (top: views from the top; bottom: views from the side. Ethyl substituents not shown.) Thermal ellipsoids (40% probability) and selected distances [Å] and angles [°] (standard deviations approximately 0.008 Å and 0.5°).

with the relationships in planar, medium-sized rings such as the all-*cis*-cyclononatetraenyl anion **13**.[17] As the hydrogen atoms approach, the C-C-C bond angle on C14 and C16 widens to 148°! The equalization of the bond lengths in the C_3 segment, observed not only in **8** but also in the 15-cyano compound, would suggest the presence of delocalized π bonds. In the case of the (*E*)-isomer **9**, steric interactions cause the central C atom (C15) of the C_3 segment and its inwardly oriented, localizable hydrogen atom (H15) to lie above the plane formed by the other framework atoms (distance of C15 from this plane: 0.44 Å). The distance between H15 and the palladium atom is only 2.38 Å.

The palladadiaza eight-membered rings of **8** and **9** (partial structures **11** and **12**, respectively) deserve attention, because they are prime examples of the analogies that exist between porphyrin and annulene chemistry.[4c, 18] It is clear from Scheme 2 that **11** and **12** are related both geometrically and electronically with the all-*cis*-cyclononatetraenyl anion **13**[17] and the *cis,cis,cis,trans*-cyclononatetraenyl anion **14**.[19] This relationship is manifested in particular in the ^{1}H NMR spectra of the two structure types. It is quite astonishing just how closely the ^{1}H chemical shifts of **11** and **12** that are influenced by ring current effects resemble the corresponding chemical shifts of **13** and **14**, respectively.

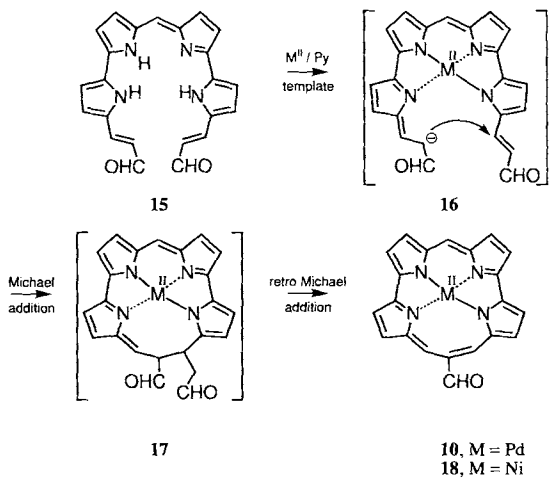
The interesting properties of the palladium isoporphycene complexes prompted us to look for a preparative route to these metalloisoporphycenes and if possible for others. It proved helpful that the reaction of the tetrapyrrolemonoaldehyde **7** with palladium(II) chloride led to a noticeable increase in the yield of **10** when the monoaldehyde that was not purified chromatographically (and contained about 10% of the tetrapyrroledialdehyde **15**) was used. Following up on this finding, the dialdehyde **15** was treated with the palladium reagent (two equivalents) in pyridine under reflux for 15 h, whereupon **10** was formed in 25% yield (Scheme 3). In addition, the metalloisoporphycene cyclization of **15** was no longer palladium(II)-specific, but could also be achieved with nickel(II) (yield of the nickel complex **18** was also 25%) and other transition metal ions (to date only in lower yields, however). There is good reason to assume that the transition-metal-induced cyclization of **15**,



Scheme 3. Template synthesis and assumed mechanism of formation of M^{II} complexes of 15-formyl-(*Z*)-octaethylisoporphycene from **15** (the ethyl substituents on the pyrrole groups are not shown for reasons of clarity).

which forms metallo-(*Z*)-isoporphycene aldehydes (**10**, **18** etc., Table 1), is template-controlled.[20] The incorporation of M^{II} ions into the potentially trianionic **15** in the presence of pyridine furnishes the anionic complex **16**. From a geometrical point of view **16** is favorably arranged to undergo cyclization by intramolecular Michael addition to form **17**. A retro Michael addition of **17**, which is associated with the elimination of a C_2 unit in the form of acetaldehyde, finally leads to the product.

The cyclizations of **15** described here augur well for the development of the metalloisoporphycenes on a broad basis. At the same time, the synthesis of the free isoporphycene ligands comes a step closer, even if these macrocycles should be unstable compounds.[21]

[21] [15-Formyl-(*Z*)-octaethylisoporphycenato]nickel(II) **18** was decarbonylated on reaction with tris(triphenylphosphine)rhodium(I) chloride in boiling benzonitrile to afford [(*Z*)-octaethylisoporphycenato]nickel(II) (**19**). The demetalation of **19** with concentrated sulfuric acid yielded a mixture of products from which one of the two octaethylisoporphycenes was isolated as a relatively stable compound by chromatography with hexane/dichloromethane (2/1) on aluminium oxide (activity II–III). According to the ^{1}H NMR spectrum this was unequivocally the (*E*)-isomer: ^{1}H NMR ([D$_8$]toluene, 90 °C): $\delta = 9.31$ (d, 2H, H-14,16), 9.26 (s, 1H, H-5), 3.79, 3.71, 3.63, 3.48 (all q, 2H, CH_2), 1.71, 1.69, 1.68, 1.60 (all t, 3H, CH_3), 1.57 (br. s, 2H, NH), −1.87 (t, 1H, H-15).

Nickel and Copper Corroles: Well-Known Complexes in a New Light

Stefan Will, Johann Lex, Emanuel Vogel,* Hans Schmickler, Jean-Paul Gisselbrecht, Catherine Haubtmann, Maxime Bernard, and Maurice Gross*

Dedicated to Professor Guy Ourisson on the occasion of his 70th birthday

The discovery of the biologically important metalloporphyrins with tetravalent iron (in the form of hemoproteins),[1] and since then, the successful syntheses of numerous Fe^{IV} complexes with diverse ligands[2] provided the stimulation to study the capability of the potentially trianionic corroles (which for a long time were overshadowed by the porphyrins)[3, 4] to stabilize metal atoms in unusual oxidation states by complexation. This research led to surprising results: iron(III) corroles are oxidized spontaneously by atmospheric oxygen to afford remarkably stable binuclear complexes of the type **1a** with formally tetravalent iron; these can be readily cleaved by acids to form mononuclear Fe^{IV} complexes such as **1b**.[5] Subsequent electrochemical oxidation of **1a**–**1c** yielded iron(IV) π radical cations

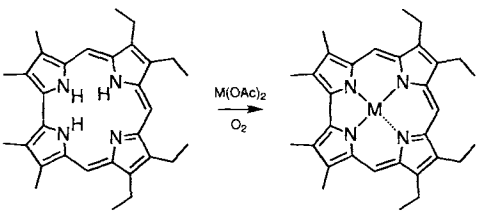
by attack at the corrole ligands. One of these (derived from **1c**) was isolated as a perchlorate, but there was no evidence for the occurrence of iron(v) corroles.[6]

The existence of stable iron(IV) corroles aroused the suspicion that the long-known copper and nickel corroles that were considered as Cu^{II} and Ni^{II} complexes of the type **2**[3b-f] (the tautomeric form of **2** with the hydrogen atom on a *meso*-carbon atom instead of on a nitrogen atom was also taken into consideration) in reality contain the metal ion in the formal oxidation state +III (**3**). As has now been demonstrated on the basis of structure analyses in conjunction with ^{1}H NMR and ESR spectroscopy, and magnetochemical and electrochemical studies, these complexes are indeed of type **3**.

Neutral nickel and copper corroles (in the form of octaalkyl derivatives) were first obtained by A. W. Johnson, the pioneer of corrole chemistry. He described the problem of their constitution as follows: "Unfortunately both the nickel(II) and copper(II) corroles are paramagnetic and n.m.r studies with a view to locating the 'extra' hydrogen have been of no avail."[3e, 7] Apart from arguments based on UV/Vis spectra, the observation that the complexes reacted with bases to form anionic M^{II} corroles provided the major support for their formulation as **2**.[3, 8, 9] This behavior was interpreted as deprotonation.

In order to clarify the constitution of the nickel and copper corroles by structure analyses, the complexes of the octaethylcorrole ligand that proved so useful in the study of the iron corroles were first prepared. However, the poor quality of the crystals prevented analysis. The complexes **5** and **6** of the tetraethyltetramethylcorrole **4** described by Murakami et al. (which were also formulated as M^{II} complexes by the authors)[8] proved suitable. These were synthesized by reaction of the free ligand **4** with the corresponding M^{II} acetates in hot DMF with admission of air (60 °C, 10 min). The nickel corrole **5** (blue-grey, shiny metallic needles from dichloromethane/methanol, yield 53 %, decomposition >200 °C, Table 1), which is only moderately stable in solution, and the more stable copper corrole **6** (red-brown needles from chloroform/hexane, yield 76 %, decomposition >210 °C, Table 1) are identical with the complexes obtained by Murakami et al. by a different route.



4 **5**, M = Ni; **6**, M = Cu

The EI mass spectra of **5** and **6** indicate the presence of nickel and copper corroles with formally trivalent metal centers, as these show the expected molecular ion as the base peak for both compounds. The fact that the IR spectra exhibit no bands for the NH stretching vibration indicates the same. Proof of the molecular structure of the corrole complexes **5** and **6** was delivered by X-ray crystallographic analyses.[10] The crystal structure of **5** (Figure 1) consists of iso-oriented layers of molecular

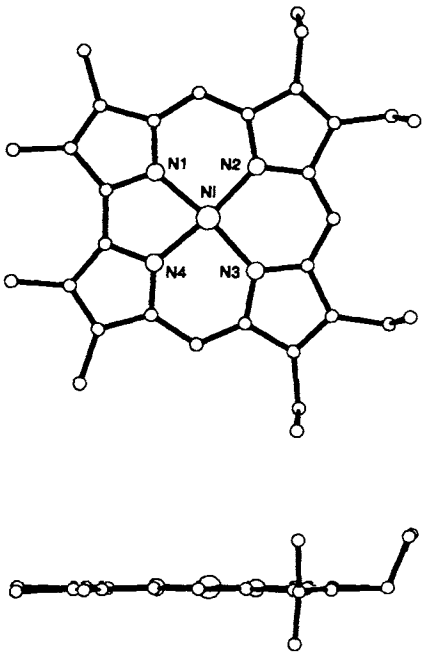

Figure 1. Structure of the nickel corrole **5** in the crystal (top: viewed from the top; bottom: viewed from the side; hydrogen atoms not shown.). Selected bond lengths [Å]: Ni–N1 1.836(3), Ni–N2 1.858(3), Ni–N3 1.859(3), Ni–N4 1.829(3).

units without significant intermolecular interactions. In the case of the copper compound **6**, which was analyzed as dichloromethane solvate **6**·CH_2Cl_2, the single crystal contains two crystallographically independent copper corrole molecules with almost identical structural parameters (Figure 2). As depicted in Figure 2, these two molecules interact with one another to form a π–π dimer[11] (intermolecular Cu–Cu distance 4.721 Å, mean distance between ring planes 3.43 Å). The residual electron density in the structure analyses of **5** and **6** gives no indication of the previously assumed additional hydrogen atom bonded to N or C (the hydrogen atoms H5, H10, H15 in the *meso*- positions were located for both complexes in the electron density map).

The metallocorroles **5** and **6** both contain the metal atom in distorted square-planar coordination in the center of the N_4 cavity. The incorporation of the nickel and copper ions into the nonplanar corrole macrocycle[12] flattens its framework to different degrees. Whereas **5** is totally planar (max. distance Δ_{max} of the C and N atoms from the mean plane of the ring framework: 0.037 Å), the copper corrole molecules in **6**·CH_2Cl_2 take on a slightly corrugated conformation (Δ_{max}: 0.168 Å and 0.215 Å), in which the N_4 core is slightly expanded relative to that in **5**. The bond angles and N–N distances of the corrole framework

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3604-0358 $ 15.00+.25/0

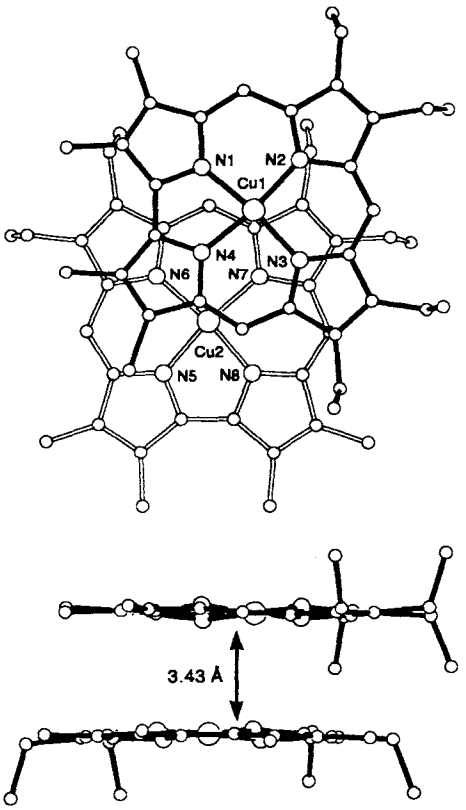

Figure 2. Structure of the two crystallographically independent copper corrole molecules of the solvate $6 \cdot CH_2Cl_2$ in the crystal (top: viewed from the top; bottom: viewed from the side; hydrogen atoms not shown.). Selected distances [Å]: Cu1–N1 1.868(5), Cu1–N2 1.896(5), Cu1–N3 1.885(5), Cu1–N4 1.872(6), Cu2–N5 1.879(6), Cu2–N6 1.880(6), Cu2–N7 1.889(6), Cu2–N8 1.867(6), Cu1···Cu2 4.721.

are changed insignificantly by the incorporation of the metal ion, which serves to underline the relative rigidity of the corrole ligand. Also noteworthy is the fact that the metal–nitrogen bonds in **5** (Ni–N 1.829–1.859 Å) and **6** (Cu–N 1.867–1.896 Å) are shorter than in the corresponding four-coordinate M^{II}-octaethylporphyrinates (Ni–N 1.928–1.958 Å, Cu–N 1.998 Å).[13] In the case of **6** the metal–nitrogen bond lengths lie in a range characteristic for copper(III) complexes with N donor ligands (Cu–N 1.804–1.907 Å)[14] and thus indicate a Cu^{III} center.

Further insight into the nature of the complexes **5** and **6** is provided by ESR and ^{1}H NMR spectra, and by the determination of the magnetic susceptibility on powdered samples in the temperature range 81–293 K.[15] The ESR-active (see below) nickel complex **5** has a weak temperature-dependent effective moment of 1.7 μ_B (293 K) in the solid, which would indicate a complex with a spin ground state $S = 1/2$. That **5** is a paramagnetic compound is confirmed by the ^{1}H NMR spectrum (300 MHz, $CDCl_3$), because, in agreement with earlier reports,[3, 8] only extremely broad signals are found. These findings are not compatible with a Ni^{II} corrole complex (d^8) with square-planar coordination in accordance with the structural formula **2**; such a complex ought to occur in a singlet ground state. The copper complex **6** (ESR-inactive) is effectively diamagnetic in the solid like other square-planar copper(III) compounds.[14] A strong temperature dependence is characteristic of the ^{1}H NMR spectrum of **6** (Figure 3), which was examined in the range 165–406 K (165–298 K in CD_2Cl_2/CS_2, 298–406 K in $C_2D_2Cl_4$). The spectrum of **6** shows two sharp signals

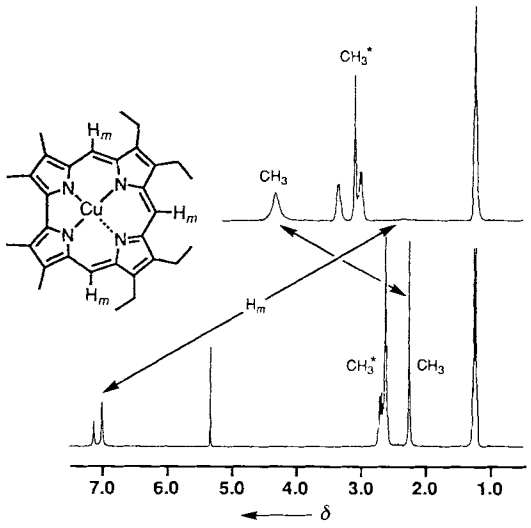

Figure 3. ^{1}H NMR spectra of the copper corrole **6** (300 MHz) at 226 K (CS_2/CD_2Cl_2, bottom) and at 386 K ($C_2D_2Cl_4$, top).

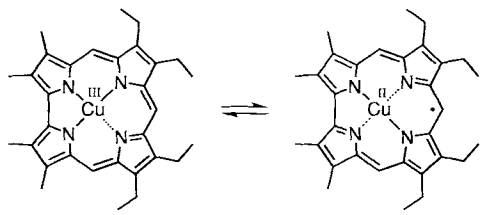
at 226 K (H10, H5, and H15), based on which the compound was identified as a corrole complex with effective C_{2v} symmetry. On raising the temperature line-broadening occurs—an indication of developing paramagnetism—and at the same time the signal of the *meso* protons (no longer resolved) is shifted upfield and the signals of the alkyl protons shifted downfield (see spectrum at 386 K in Figure 3). Above 386 K the broadening of the signals has progressed to such an extent that the signal of the *meso* protons can no longer be detected (aggregation phenomena and interactions with the solvent are negligible as the spectrum is not subject to any significant concentration or solvent influences).

The characteristics of the spectrum of **6** in the temperature range studied—diamagnetic appearance at low temperature, paramagnetic at higher temperature—would suggest that in the case of **6** a rapid equilibrium on the ^{1}H NMR time scale exists between molecules in the diamagnetic Cu^{III} ground state, **6a**, and molecules in a higher energy (paramagnetic) triplet state. In view of the relative ease with which the corrole ligands can be oxidized,[6] it is justifiable to identify the triplet state with π radical cation **6b** of the copper(II) corrole. The presence of a high spin copper(III) corrole, which would also come into consideration, is improbable due to the established square-planar coordination.



6a **6b**

In order to characterize the oxidation state of the nickel corrole **5** more precisely, the compound was examined by ESR methods.[16] The complex **5** has an isotropic ESR signal at $g = 2.01$ (peak–peak distance: 43 G) in the solid and in dichloromethane solution ($T = 298$ K), which is in agreement with a spin ground state $S = 1/2$. At lower temperatures ($T = 200$ K) **5** has an anisotropic spectrum with g values of 2.011 and 1.998, and also considerably smaller line widths

(peak–peak distance: 11 G). A spin quantification resulted in the value of one unpaired electron per molecule. The ESR spectrum of **5** differs significantly from the spectra of the Ni^{III} complexes of porphyrin[17] and other N donor ligands,[18] for which a broad resonance signal at $g = 2.2-2.3$ is typical; however, its g values and line widths compare favorably with that of a π radical cation. Consequently, the nickel complex **5** contains an oxidized corrole ligand and should be formulated as a π radical cation of nickel(II) corrole.

The UV/Vis spectrum of the nickel corrole **5**, which differs considerably from that of copper compound **6**, is also in agreement with the radical character of **5**. Whereas **6** has absorption bands which correspond in position with the Soret and Q bands in the porphyrins, **5** is characterized by a very short-wave UV band and absorptions located in the long-wave region of the spectrum. Similar low-energy electron transitions were determined for several metalloporphyrins oxidized on the ligand.[19]

The reaction of the nickel and copper corroles with bases to form the anionic M^{II} complexes mentioned at the beginning of this paper (previously considered as deprotonation), which led to the conclusion that the starting materials were Ni^{II} and Cu^{II} complexes, must be interpreted as a single-electron reduction according to electrochemical studies.[20] As has been proven coulometrically, **5** and **6** are reversibly reduced in a single-electron step in dichloromethane (0.1 M $TBAPF_6$) at -0.85 and -0.77 V, respectively, (against ferrocene/ferrocenium). Further reductive steps could not be identified up to -2.1 V. The UV/Vis spectra of the reduction products taken after potential-controlled thin layer electrolysis at -1 V (in CH_2Cl_2 with 0.1 M $TBAPF_6$) agree well with the spectra described for anionic nickel and copper corroles.[8]

The results presented here suggest that the recently reported isocorroles[21] can also form complexes with formally trivalent nickel and copper. Indeed, the first copper isocorrole of this type, the electronic fine structure of which is admittedly still in need of clarification, was obtained in connection with our studies on metal complexes of the stereoisomeric isoporphycenes.[22]

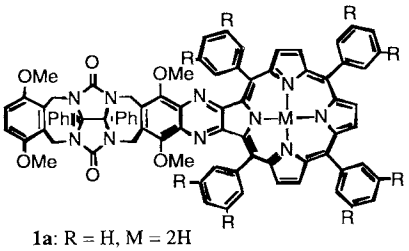
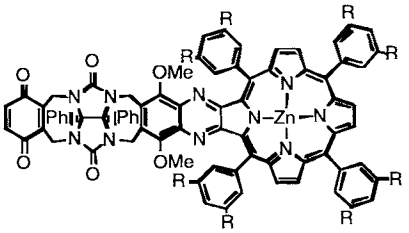
Novel Cleft-Containing Porphyrins as Models for Studying Electron Transfer Processes**

Joost N. H. Reek, Alan E. Rowan, René de Gelder, Paul T. Beurskens, Maxwell J. Crossley, Steven De Feyter, Frans de Schryver, and Roeland J. M. Nolte*

Understanding in detail the mechanism underlying the very efficient conversion of light into chemical energy as displayed by the photosynthetic reaction centers, for example, of the purple photosynthetic bacteria *Rhodopseudomonas viridis* and *Rhodobacter sphaeroides*[1] is of interest with respect to the development of artificial photosynthesis. In recent years the structures of these reaction centers have been elucidated,[1] and in combination with spectroscopic studies on these systems[2] and on model compounds[3] this has led to deeper insight into their working and the importance of specific variables. Until now most model systems described in the literature consist of covalently linked chromophores. Only a few examples have appeared in which a supramolecular approach was followed.[4] Even fewer model systems have been reported that can be used to study the role of intervening aromatic amino acid residues as bridging molecules to enhance the electron transfer over large distances.[5, 6] In the photosynthetic reaction centers of *Rhodopseudomonas viridis* and *Rhodobacter sphaeroides*,[1] the aromatic ring of a tryptophan unit is in van der Waals contact with both the primary acceptor (a bateriochlorophyll) and the quinone and is therefore expected to play an important role in the electron transfer process. To date the model systems designed to study this phenomemon consist of covalently linked chromophores separated by an aromatic spacer. These model systems, however, have several limitations, the most serious one being that electron transfer can and predominantly does occur through the bonds. In this communication we describe novel porphyrin molecules derived from the building block diphenylglycoluril, which contain a substrate binding site and either a donor (**1**) or an acceptor group (**2**). These systems have been developed in order to study the role in the electron transfer process of intervening aromatic molecules that are complexed between the donor and the acceptor.

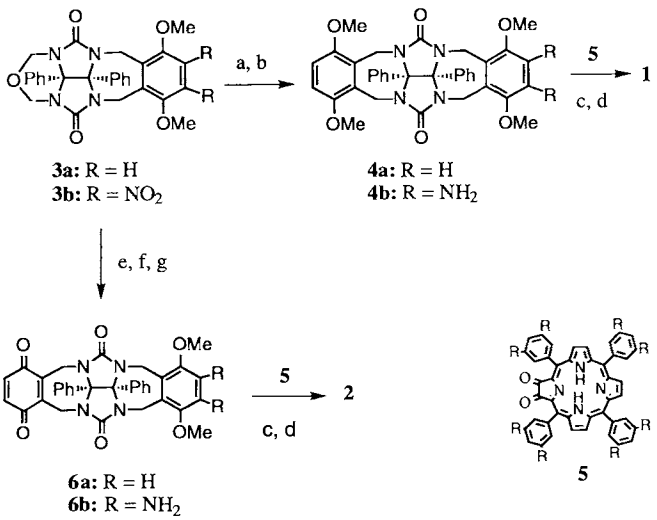


1a: R = H, M = 2H
1b: R = H, M = Zn
1c: R = *t*Bu, M = Zn



2: R = *t*Bu

The synthesis of compound **1a** starts from the diphenylglycoluril derivative **3b**,[7] which was converted in two steps into the diamine functionalized compound **4b** (Scheme 1). First the second *p*-dimethoxybenzene side wall was attached to the molecule. After the reduction of the nitro groups, precursor diamine **4b** was obtained in approximately 50% overall yield. By a simple condensation reaction of **4b** with porphyrin diketone **5**,[8] compound **1a** was prepared in 28% yield (Table 1). Porphyrin **1a** was readily metalated in boiling DMF/toluene by treatment



Scheme 1. a) **3b**, *p*-dimethoxybenzene (1.2 equiv), acetic acid, trifluoroacetic acid, 96% yield; b) triethylammonium formate, Pd/C, THF/MeOH (1/1 v/v), room temperature (RT), 95% yield; c) compound **4b** (or **6b**) and **5** (1 equiv), CH_2Cl_2, molecular sieves, reflux, 45% yield; d) excess $Zn(OAc)_2$, DMF/toluene (1/1 v/v), reflux, 90% yield; e) **3b**, hydroquinone (1.1 equiv), *p*-toluenesulfonic acid, dichloromethane; f) Cu_2Cl_2, pyridine, DMSO, oxygen; g) triethylammonium formate, Pd/C, THF/MeOH (1/1 v/v), RT, 95% yield.

Table 1. Spectroscopic data of **1a**–**1c** and **2**.

1a: ^{1}H NMR ($CDCl_3$): δ = 8.85 and 8.69 (ABq, 4H, J = 5 Hz, pyrrolic β H atoms), 8.68 (s, 2H, pyrrolic β H atoms), 8.21 (m, 8H, 2,6-ArH, porphyrin), 7.84 (m, 8H, 3,5-ArH, porphyrin), 7.76 (m, 4H, 4-ArH, porphyrin), 7.15 (s, 5H, ArH, diphenylglycoluril), 7.12 (s, 5H, ArH, diphenylglycoluril), 6.62 (s, 2H, ArH), 5.90 and 3.89 (ABq, 4H, J = 15.8 Hz, NC*H*HAr), 5.57 and 3.80 (ABq, 4H, J = 15.8 Hz, NC*H*HAr) 3.86 (s, 6H, OMe), 3.75 (s, 6H, OMe), −2.53 (br. s, 2H, NH); FAB-MS (*m*-nitrobenzyl alcohol matrix): *m/z*: 257 $(M + H)^+$

1b: ^{1}H NMR ($CDCl_3$): δ = 8.89 and 8.54 (ABq, 4H, J = 5 Hz, pyrrolic β H atoms), 8.75 (s, 2H, pyrrolic β H atoms), 8.20–8.0 (m, 8H, 2,6-ArH, porphyrin), 7.81–7.72 (m, 12H, 3,5-Ar, H4-ArH, porphyrin), 7.15 (s, 5H, ArH, diphenylglycoluril), 7.14 (s, 5H, ArH, diphenylglycoluril), 6.62 (s, 2H, ArH), 5.92 and 3.98 (ABq, 4H, J = 15.8 Hz, NC*H*HAr), 5.56 and 3.82 (ABq, 4H, J = 15.8 Hz, NC*H*HAr), 3.86 (s, 6H, OMe) 3.72 (s, 6H, OMe); FAB-MS (*m*-nitrobenzyl alcohol matrix): *m/z*: 1321 $(M + H)^+$

1c: ^{1}H NMR ($CDCl_3$): δ = 8.91 and 8.54 (ABq, 4H, J = 5 Hz, pyrrolic β H atoms), 8.85 (s, 2H, pyrrolic β H atoms), 8.12 (s, 2H, ArH, porphyrin), 8.08 (s, 2H, ArH, porphyrin), 8.01 (s, 2H, ArH, porphyrin), 7.86 (s, 2H, ArH, porphyrin), 7.85 (s, 2H, ArH, porphyrin), 7.77 (s, 2H, ArH, porphyrin), 7.10 (m, 10H, ArH, diphenylglycoluril), 6.46 (s, 2H, ArH), 5.90 and 3.93 (ABq, 4H, J = 15.8 Hz, NC*H*HAr), 5.44 and 3.69 (ABq, 4H, J = 15.8 Hz, NC*H*HAr), 3.73 (s, 6H, OMe), 3.62 (s, 6H, OMe), 1.52, 1.50, 1.41 and 1.26 (4s, 72H, CCH_3); FAB-MS (*m*-nitrobenzyl alcohol matrix): *m/z*: 1768 $(M + H)^+$; HR-MS: calcd for $C_{112}H_{123}N_{10}O_6Zn$: 1767.892; found: 1767.882

2: ^{1}H NMR ($CDCl_3$): δ = 8.92 and 8.57 (ABq, 4H, J = 5 Hz, pyrrolic β H atoms), 8.86 (s, 2H, pyrrolic β H atoms), 8.13 (s, 2H, ArH, porphyrin), 8.08 (s, 2H, ArH, porphyrin), 8.02 (s, 2H, ArH, porphyrin), 7.92 (s, 2H, ArH, porphyrin), 7.87 (s, 2H, ArH, porphyrin), 7.77 (s, 2H, ArH, porphyrin), 7.16 (m, 10H, ArH, diphenylglycoluril), 6.57 (s, 2H, quinone), 5.99 and 3.98 (ABq, 4H, $J \approx 15.8$ Hz, NC*H*HAr), 5.49 and 3.72 (ABq, 4H, J = 15.8 Hz, NC*H*HAr) 3.80 (s, 6H, OMe), 1.52, 1.50, 1.41 and 1.26 (4s, 72H, CCH_3); FAB-MS (*m*-nitrobenzyl alcohol matrix): *m/z*: 1738 $(M + H)^+$; HR-MS: calcd for $C_{110}H_{117}N_{10}O_6Zn$: 1737.845; found: 1737.840

with an excess of zinc acetate to yield **1b** in 90% yield. Compound **1c** was obtained analogously. Compound **2** was synthesized by a condensation of diamine **6b** with porphyrin diketone **5**. The former compound was obtained by treating hydroquinone with **3b**. Subsequently the hydroquinone was oxidized to benzoquinone, and the nitro groups reduced to amine functions. Full synthetic details will be described in a forthcoming full paper.[7]

Purple crystals of **1a** suitable for an X-ray structure analysis were grown by slow diffusion of diethyl ether into a chloroform solution of **1a**. The crystal structure of **1a**[9] is monoclinic. The unit cell contains four clip-shaped molecules, which are packed as two dimers (Figure 1a) that are perpendicular to each other. As expected the diphenylglycoluril unit in the X-ray structure of **1a** is quite similar to that in the X-ray structure of **4a**[10] (which was synthesized in an identical manner to **4b**, but from **3a**). The

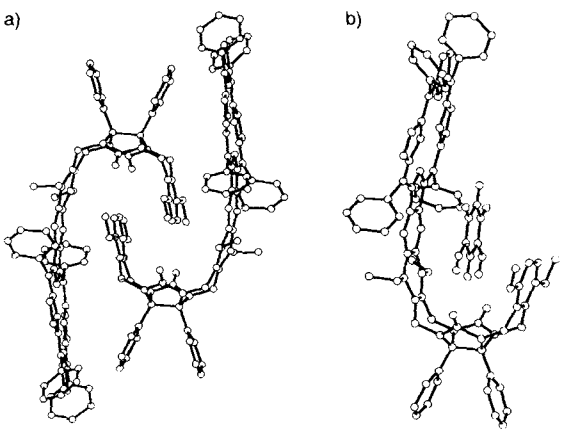

Figure 1. The crystal structure of porphyrin clip **1a** (a) and the structure of the complex between **1a** and a dihydroxybenzene guest molecules as derived from ^{1}H NMR experiments (b). Hydrogen atoms of the clip molecules have been omitted for clarity.

two dimethoxybenzene groups attached to the diphenylglycoluril unit define a tapering cleft with a center-to-center distance of 6.28 Å, which is ideal for forming sandwich complexes with aromatic guest molecules. The twist in the diphenylglycoluril framework of molecule **1a** is somewhat smaller than observed for molecular clip **4a**.[10] The porphyrin wall of **1a** is nonplanar and bends towards the cavity with an out-of-plane angle of 15°, with the result that the porphyrin unit is arranged parallel to the opposite dimethoxybenzene wall. This bending can be attributed to stacking interactions between two molecules in the solid state (Figure 1a). The large porphyrin wall wraps around the back of the diphenylglycoluril part of the molecule and interacts with a phenyl group on the convex side. The dimethoxybenzene wall of one molecule occupies the cleft of its dimeric partner. Although no crystals suitable for X-ray analysis could be grown from **2**, a single molecule of **2** is expected to have approximately the same structure as a single molecule of **1a**.[11] The edge-to-edge distance between the electron donor (zinc porphyrin) and the electron acceptor (benzoquinone) in **2** will be approximately 6.5 Å, and the center-to-center distance 9 Å. This is somewhat smaller than the distance between the bacteriopheophytin and the quinone observed in the X-ray structure of the reaction center of *Rps. viridis* (9.7 Å edge-to-edge and 14.3 Å center-to-center).[1]

Previous work in our group has shown that molecular clips of type **4a** and **6a**[7] bind dihydroxybenzenes and related compounds by hydrogen bonding with the carbonyl functions of the diphenylglycoluril unit and π–π stacking interactions with the aromatic walls of the clip (**4a** + resorcinol, $K_{ass} = 2600\,M^{-1}$).[10] It was also shown that a clip with two functionalized aromatic walls is not capable of binding dihydroxybenzenes.[10, 12] NMR titration experiments[13] with **1a** and the guest hexyl 3,5-dihydroxybenzoate in $CDCl_3$ revealed that the latter molecule is bound in the cleft of the former molecule ($K_{ass} = 120\,M^{-1}$) and that the exchange between the bound and the free guest is fast on the NMR time scale. This guest formed stronger complexes with the host molecules **1b** and **1c** ($K_{ass} = 540\,M^{-1}$), since the metalation of the porphyrins results in more favorable π–π interactions. The binding constants were even larger in CCl_4—which is the solvent used for the fluorescence studies (see below)—because of the larger contribution of the hydrogen bonds to the binding process ($K_{ass} = 2 \times 10^3\,M^{-1}$ for the binding of hexyl 3,5-dihydroxybenzoate in **1c**). Calculations with the Johnson and Bovey tables[14] and the obtained complex-induced shift (CIS) values from the ^{1}H NMR spectra indicated that the guest is complexed in a slightly off-center position between the dimethoxybenzene walls of **1a** (Figure 1b). ^{1}H NMR showed that in the case of **2** the guest molecule is bound in a similar way and hence located between the zinc porphyrin and the quinone function. This host–guest complex was therefore an interesting model for studying the influence of an intervening aromatic guest molecule on the electron transfer process between a porphyrin donor and a quinone acceptor.

Cyclic voltammetric studies of **2** in CH_2Cl_2 revealed that the first oxidation potential of the porphyrin was at 0.30 V and the first reduction potential of the quinone at −0.93 V (potentials vs. an internal ferrocene reference system. According to Marcus theory,[15] the electron transfer process for the donor–acceptor system of molecule **2** should have a low energy barrier in polar solvents and a relatively high energy barrier in apolar solvents. Fluorescence studies with compounds **1** and **2** carried out in different solvents revealed that this was indeed the case (Table 2). In the apolar solvent CCl_4 the fluorescence quantum yields of **1b**, **1c**, and **2** were comparable to that observed for [Zn(tpp)] (TPP = tetraphenylporphyrin), which suggests that

Table 2. Fluorescence quantum yields (ϕ_{em} = 620 nm) of **1b**, **1c**, **2**, and [Zn(tpp)] in various solvents and in the presence of hexyl-3,5-dihydroxybenzoate **7** [a].

Porphyrin	CH_2Cl_2	$CHCl_3$	CCl_4	CCl_4 + 7 [b]
1b	0.016	0.016	0.022	[c]
1c	0.016	0.016	0.020	[c]
2	0.002	0.002	0.020	0.004
[Zn(tpp)]	0.025	–	0.025	0.025

[a] Excitation wavelength 572 nm. [b] An excess (100-fold) of **7** was added. [c] An extra emission band appeared at 680 nm.

almost no electron transfer occurred. In the more polar solvents CH_2Cl_2 and $CHCl_3$ the fluorescence quantum yield of **2** was much lower than those of **1b** and **1c**, which can be explained by a fast electron transfer from the excited porphyrin (570 nm) to the quinone.[16] In line with these experiments, time-resolved single-photon-counting fluorescence (SPC) studies in CCl_4 showed that the decay profiles of **1c** and **2** were virtually the same. The decay profile of **2** in CH_2Cl_2 was different and showed an additional rapid process (52 ps), which was the major contribution (90%) to the fluorescence decay.

In CCl_4 almost no quenching of the fluorescence of **2** due to electron transfer processes was observed. After the addition of hexyl 3,5-dihydroxybenzoate, however, 75% of the intensity was quenched. (A similar effect is expected in CH_2Cl_2; however the binding constant is much lower in this solvent, and the effect cannot be observed). Under the same conditions this quenching was not observed for either [Zn(TPP)], **1b**, or **1c**, and hence this process is likely to be the result of the guest molecule's presence between the donor and acceptor functions of **2**. Further confirmation comes from the quenching of **2**, which is highly dependent upon the guest concentration. The lack of fluorescence quenching for **1b** and **1c** also indicates that the quenching process for **2** is not due to a proton transfer mechanism from the guest to the host, since the most basic sites (the quinoxaline nitrogen atoms) are present in all three molecules. Preliminary SPC measurements indicate that the electron transfer between the porphyrin and the quinone in **2**, responsible for the multiexponential decay of the fluorescence intensity, is substantially faster for the host–guest complex. This is in contrast to a recently constructed porphyrin–quinone system, in which a covalently linked phenyl moiety is positioned between the two chromophores. In this covalently linked system no rate enhancement occurred by through-space electron transfer across the interspaced aromatic moiety.[5] The enhanced electron transfer by the aromatic guest molecule in our system is probably partly a result of a local polarity effect and buttressing or contact effects and partly due to a superexchange mechanism. The latter effect has previously been observed for porphyrin quinone model systems that have aromatic units linking the two chromophores[6] and in solvent-mediated donor–acceptor systems.[17] The addition of hexyl 3,5-dihydroxybenzoate to a solution of **1b** or **1c** in CCl_4 resulted in the appearance of an extra emission band, indicating that the emission process was affected by specific interactions between the host and guest (Table 2). More time-resolved fluorescence studies and transient absorption measurements are in progress to provide a better insight into the mechanisms involved in these new model systems. These results will be presented in a full paper.

[16] The dependence of the fluorescence quantum yield of **2** on solvent and published data on other zinc porphyrin–quinone systems (see ref. [3]) suggest that the fluorescence is quenched by electron transfer from the zinc porphyrin to the quinone, although other mechanisms (energy transfer) cannot yet be ruled out. (The concentrations of host and guest were approximately 0.02 mmol and 1 mmol, respectively. This means that in the experiments approximately 75% of the host molecules bind a guest, and 25% are free).

Reversible Dimerization of Diphenylpolyene Radical Cations: An Alternative to the Bipolaron Model**

Andreas Smie and Jürgen Heinze*

The bipolaron model is the classical model for characterizing the special properties of conducting polymers. Based on the principles of solid-state physics, this model postulates that, on account of lattice distortions, bipolarons will be more stable

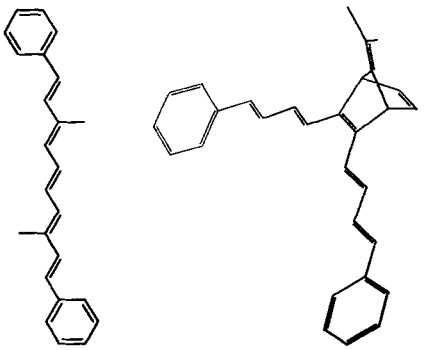
than polarons.[1] Radical ions are the chemical equivalent of polarons, and spin-coupled diionic states are analogous to bipolarons. In applying the bipolaron model to organic conducting polymers, it has been assumed up to now that the formation of polarons caused intramolecular distortion in chainlike conjugated systems. This distortion is accompanied by partial planarization of the chain segments, for example, in the transition from the benzoid to the quinoid structure. The formation of bipolarons is thought to considerably enhance this tendency, resulting in a flattened chain structure that is substantially more stable than two polaron states.

Up to now, experimental research in both physics and chemistry has tried to confirm this model without restrictions. Researchers have either ignored the difficulties, for example, in interpreting redox charging[2] or the memory effect[3] or explained them with the help of theoretical crutches.

In recent years, studies on monodisperse oligomers whose chain length is discretely variable have provided considerable insights into the nature of the corresponding polymer systems.[4-11] This oligomeric approach has significantly improved our understanding of the physical and chemical properties of conducting polymers.

Spectroscopic data published in the past four years prove that intermolecular interactions take place between radical ions of conjugated oligomers.[12-18] For instance, UV/Vis and ESR spectra of the radical cations of some end-capped thiophene,[14-17] pyrrole,[19] and aniline oligomers[20] are concentration- and temperature-dependent. In every case, voltammetric analysis indicated the reversible formation of radical cations without subsequent chemical steps. Accordingly, it was concluded that weakly interacting "π-mers" formed rapidly and also decayed relatively quickly on the time scale of the experiment. Although the formation of π-mers would explain the rapid decrease in spin states during charging, this finding would not affect the underlying assumptions of the bipolaron model and its contradictions.

In this paper, we report on cyclic voltammetric and spectroscopic studies of the oxidation of diphenylpolyenes **1** and **2**. This is the first clear indication that the formation of the radical ions is followed by a rapid reversible dimerization between oligomer chains accompanied by the formation of a σ bond.



1 **2**

In normal voltammetric experiments at room temperature with low scan rates and low concentrations ($c = 10^{-3}$ M), the responses for **1** and **2** were quite normal (Figures 1a,b). Apparently reversible oxidation steps, indicated in the cyclic voltammograms as equivalent anodic and cathodic current waves with a peak separation of ≥ 60 mV, were observed. The slight differences between the peak currents of the first and second redox

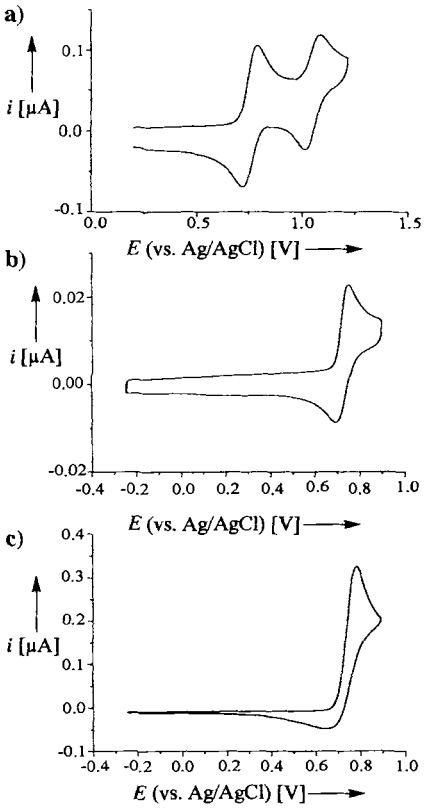


Figure 1. Cyclic voltammogram of **1** in CH_2Cl_2/(0.1 M nBu_4NPF_6 ($TBAPF_6$). a) $T = 273$ K, $v = 0.1$ Vs^{-1}, $c_1 = 5 \times 10^{-5}$ mol L^{-1}, b) $T = 233$ K, $v = 0.02$ Vs^{-1}, $c_1 = 5 \times 10^{-5}$ mol L^{-1}, c) $T = 233$ K, $v = 0.02$ Vs^{-1}, $c_2 = 9.9 \times 10^{-4}$ mol L^{-1}.

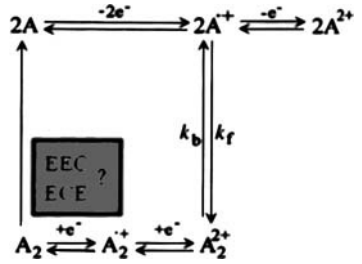
steps, however, indicated that the actual mechanism had to be more complicated.

Further experiments with varying concentrations, scan rates, and temperatures produced marked changes in the voltammograms. Detailed evaluations of the observed phenomena led to the unequivocal conclusion that formation of the radical cations was followed by a reversible dimerization of the species producing a dimeric dication (Scheme 1).



Scheme 1. Mechanism of the oxidation of **1** and **2**. EEC = sequence of reactions: electron transfer, electron transfer, chemical reaction. ECE = sequence of reactions: electron transfer, chemical reaction, electron transfer.

The following findings are proof of this mechanism: In the voltammetric experiment, the peak current ratios i_{pc}/i_{pa} of the waves of the first redox step, which initially were close to 1, decreased as the scan rate increased. In other words, in the reverse scan the corresponding cathodic wave disappears. At the same time, a new cathodic wave appears in the potential range between 0.18 and 0.24 V (Figure 2, Table 2), and the peak current of the second anodic wave, which signals the formation of the monomeric dication, diminishes. If the scan rate is raised above $v = 20$ Vs^{-1}, the peak current ratio of the waves of the first redox process rises again, and the peak current of the second oxidation wave approaches that of the first. At lower temperatures and lower scan rates, the cathodic wave of the first redox
