[a] CH_2Cl_2. [b] CH_3CN.

step also disappears, and in all cases a new cathodic wave appears in the potential range between 0.18 and 0.24 V (Figure 3). Increasing the concentration of the redox system at a given temperature produces analogous phenomena (Figure 1c).

A qualitative analysis of these results indicates a reversible reaction after the first redox step. At low scan rates ($v = 0.1$ Vs^{-1}), the successive reaction linked to the charge transfer attains thermodynamic equilibrium. In other words, although the radical cation produced at the electrode undergoes a fast dimerization on the time scale of the experiment, the resulting product of the successive reaction reacts immediately at a lower reverse rate to again form the radical cation, which in the voltammetric reverse scan is reduced to the neutral species. As the scan rate increases, the influence of the slower reverse reaction diminishes, and the radical cation ceases to be regenerated on the experimental time scale. Consistent with this, in the voltammetric experiment the signal for the reduction of the radical cation diminishes, and a new cathodic wave for the reduction of the product of the successive reaction appears. Finally, at high scan rates the time scale becomes so short that the radical cation can no longer react within it, and in the cyclic voltammogram the waves of the $A/A^{\bullet+}$ and $A^{\bullet+}/A^{2+}$ pairs approach those of pure redox processes.

The strong concentration dependence of voltammetric signals, leads one to conclude that the charge transfer is followed by a second-order reaction, which is a dimerization process. Raising the concentration of the redox-active species increases the rate of the coupling reaction between the radical ions without affecting the kinetics of the first-order reverse reaction. The transition from a thermodynamically to a kinetically controlled reaction in turn determines that the dimerization reaction dominates. In the cyclic voltammogram, the waves signalling the reduction of the radical cation or its oxidation to the dication diminish or even disappear completely.

The experimental results obtained by lowering the temperature confirm the mechanism proposed for room temperature conditions. Owing to negative reaction enthalpy and the fading influence of reaction entropy, the equilibrium shifts towards the dimeric dication as the temperature decreases. The dimeric dication therefore decays more slowly, and as a result, the reaction is kinetically controlled even at low scan rates. In the voltammetric reverse scan, the signal for the reduction of the dimeric successive product is particularly strong. So far, it has not been possible to determine whether this reduction process follows an EEC or an ECE mechanism.

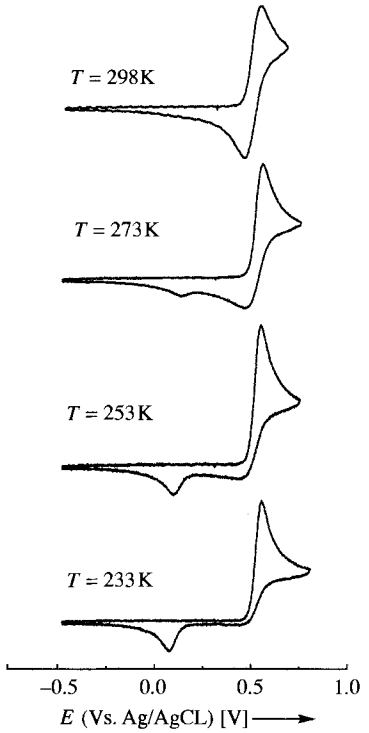

Figure 3. Cyclic voltammogram of **2** in CH_2Cl_2/(0.1 M $TBAPF_6$) $c = 4.5 \times 10^{-4}$ mol L^{-1} at various temperatures, $v = 0.05$ Vs^{-1}.

Quantitative evaluation of the voltammetric data confirm the qualitative picture. The rate constants and equilibrium constants of the chemical reaction were all calculated from working curves[21, 22] and digital simulations[23] in the temperature range between 298 K and 233 K. The results of the evaluation, including the activation and thermodynamic reaction parameters, are summarized in Tables 2 and 3. The quantitative analysis provides unequivocal proof for the dimerization of radical cations (RR coupling), but not for the often postulated, irreversible coupling between radical cations and neutral species (RS coupling).[24]

Particularly striking is the weak temperature dependence of the rate constants for the dimerization, which result in values of the activation enthalpy that are close to zero or even negative. Reactions involving apparently negative activation energies have already been described.[25–27] To interpret them, one assumes a rapid initial equilibrium reaction with a negative standard reaction enthalpy larger than the activation energy of the dimerization itself.[25, 26] In the current case though, it is unclear which process could make a sufficiently large negative contribution. Diffusion-controlled processes between similarly charged particles can also cause relatively low rate constants despite the low activation parameters measured a number of times for dimerizations of radical ions.[27] One can obtain quantitative results with the Debye–Smoluchowski theory.[28] However, further theoretical and experimental work is needed to clarify details of the elementary steps.

So far, all reports of intermolecular reactions between radical cations of conjugated systems postulate the formation of π-mers. The distance dependence of the bonding interactions in the cases of Wursters blue[29] and viologenes[30] may indicate the existence of such complexes. Moreover, the lack of any electrochemical findings for a successive reaction was interpreted as a rapid equilibrium reaction with low reaction energies. The only X-ray structure analysis of an end-capped thiophene does not provide any information about the formation of π-mers[31] or σ bonds.

In most cases the charge transfer bands one would expect were not observed in the UV/Vis spectra of the radical cations of oligomeric thiophenes and pyrroles.[32] To explain this, it was assumed that π-mers are not easily polarizable.[19] Nor did we find any charge-transfer bands in the UV/Vis spectra of the radical cations of **1** and **2** (Figure 4). Rather, the bands that can be attributed to the dimer all have shorter wavelengths than the monomer. The combination of the very large reaction enthalpies (not bonding enthalpies) of between −60 and −90 kJ mol^{-1} for the formation of the dimers, the very similar rate constants of **1** and **2** (despite differences in steric hindrance), and the continued coulombic repulsion speak against a simple charge-transfer interaction.

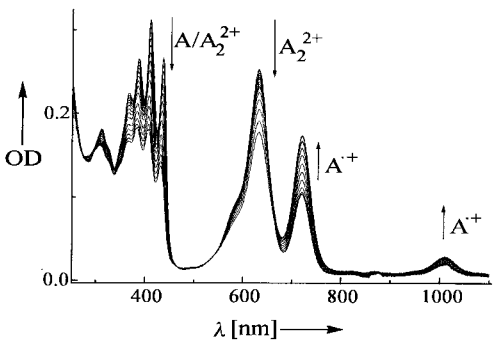

Figure 4. Absorption spectra of $\mathbf{1}^{\cdot+}$ and its dimer in CH_2Cl_2; temperature varies from $T = 233$ to 273 K (arrows). Oxidation medium $FeCl_3$, not completely converted. OD: optical density.

Although the coulombic repulsion in the gas phase is fully effective, AM1 calculations assuming a benzylic σ bond between two charged monomer chains indicate that such a system is about 160 kJ mol^{-1} more stable than the pure π complex.

In the case of 4,4′-dimethoxystilbene, the smallest unit of the structurally related diphenylpolyenes and phenylenevinylenes, whose radical cations also dimerize reversibly at a benzylic position,[33] the product of coupling after the addition of water could be isolated as a derivative of tetrahydrofuran.[34] Effenberger's studies of dimeric σ complexes of 2,4,6-tripyrrolidinobenzene derivatives also indicate a dimerization of radical cations.[35]

All these findings lead to the conclusion that a σ bond forms between the two charged monomers, analogous to the reversible dimerization of radical anions.[21, 27, 36] The possible formation of σ bonds between radical cations of oligomeric thiophene derivatives has also attracted the interest of other authors.[37]

The number of oligomeric systems known to exhibit this behavior has risen substantially in the interim. Besides oligoenes, oligomeric thiophenes,[38] oligophenylenevinylenes,[39] and 2,3,7,8-tetramethoxythianthrene[40] also dimerize. Very recently, high resolution ^{13}C NMR investigations proved the reversible dimerization of [60]fullerene radical anions by the formation of a σ bond between two C_{60} units.[41] This process had been previously postulated.[42–44] A general reaction principle for radical (cat)ions seems to have been discovered. So far, most of the experimental evidence comes from conjugated chainlike oligomers. The structure of the system and the environmental influences determine the equilibrium and kinetics of such reactions. Applying these results to the properties of conducting polymers opens up new perspectives for interpreting charge storage and conductivity. Contrary to the predictions of the bipolaron model, the energetic stabilization of such systems depends not on lattice relaxation after distortion of the geometry of the chain segment by a polaron or bipolaron, but results from the intermolecular coupling of two π-radical centers to form a σ bond. In the case of polymers, this produces a network. As experiments prove, the latter process produces a marked stabilization (Table 3) and, in addition, results in localized charges. This explains the marked hysteresis between charging and discharging and the low conductivity at low charging levels.

Experimental Section

The cyclic voltammetric experiment was performed with a three-electrode arrangement: a platinum disk electrode $d = 1$ mm (or 0.5 mm/0.1 mm) as working electrode, platinum wire as the counter electrode and an Ag/AgCl reference electrode. The potentials were determined relative to the ferrocene/ferrocinium redox pair. Solutions of 0.1 M nBu$_4$NPF$_6$ (TBAPF$_6$) in dichloromethane or acetonitrile were used as electrolytes. The UV/Vis spectra were recorded in dichloromethane solutions; the oxidation of the diphenylpolyene was performed in a $FeCl_3/CH_2Cl_2$ solution.

[22] Digital simulations were used to obtain the working curves for a reversible dimerization reaction. The technical necessity for electrodes with different radii caused problems in evaluation, because it was not possible to give due consideration to the influence of the electrode size on the resulting diffusion field (for example, hemispherical mass transport) and, thus, the form and size of the voltammetric signal. The rate constants and the activation parameters therefore have a margin of error of at least ±20%.

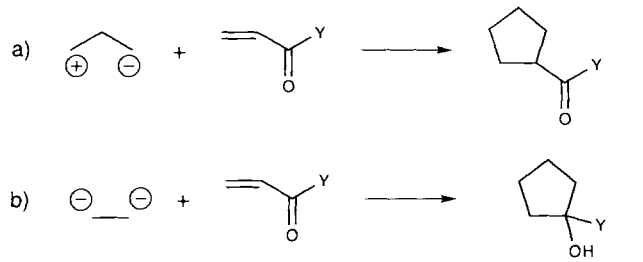
A Novel [3+2] Annelation between *ortho*-Carboranyltrimethylsilane and Conjugated Carbonyl Compounds

Hiroyuki Nakamura, Kouichi Aoyagi, Bakthan Singaram, Jianping Cai, Hisao Nemoto, and Yoshinori Yamamoto*

The most efficient method for the construction of five-membered carbocyclic rings is a [3+2] annulation process.[1] Perhaps the most widely utilized strategy in this regard is one in which dipolar C_3 units are utilized in conjunction with electron-deficient olefins (dipolar C_2 synthons) to achieve [3+2] annulation (Scheme 1a).[1, 2] However, [3+2] annulation between dianionic C_2 and dicationic C_3 building blocks are less common than dipolar annulations.[3] This approach has been used to investigate the coupling of the 1,3-dihalides or β-haloesters with the doubly charged succinate anions[4] or tetraethoxycarbonylethyl anions.[5] We report here that [3+2] annulation between dianionic C_2 units and α,β-unsaturated ketones and aldehydes (dicationic C_3 synthons) gives the corresponding five-membered carbocycles (Scheme 1b).



Scheme 1. [2+3] annulation of dipolar C_3 and C_2 building blocks (a) and of dianionic C_2 and dicationic C_3 building blocks (b).

The TBAF-mediated (TBAF = tetrabutylammonium fluoride) reaction of 1,2-dicarba-*closo*-dodecaboran(12)-1-trimethylsilane (**1**)[6] with enones and enals **2** gave the five-membered carbocyclic compounds **3** in good yields (Tables 1 and 2).[7, 8] The cycloaddition of **1** to form crotonaldehyde **2a** proceeded smoothly at 25 °C in the presence of three equivalents of TBAF, giving **3a** in 83% yield with a 58:42 mixture of *syn* and *anti* diastereoisomers (entry 1, Table 1). The use of catalytic amounts of TBAF gave a lower chemical yield. The *syn* configuration of the major diastereoisomer of **3a** was confirmed unambiguously by X-ray analysis (Figure 1). The reaction of 2-methylpropenal **2b** gave **3b** in 48% yield with a *syn*/*anti* ratio of 17/83 (entry 2). The stereochemistry of the major isomer of **3b**

Table 1. Reaction of **1** with **2** [a].

Entry	Enones and Enals		Product [b]		Yield [%]	d.r. [c] (*syn*:*anti*)
1		**2a**		**3a**	83	58:42
2		**2b**		**3b**	48	17:83
3		**2c**		**3c**	77	–
4		**2d**		**3d**	81	[d]
5		**2e**		**3e**	76 [e]	56:44
6		**2f**		**3f**	74	–
7		**2g**		**3g**	52	40:60
8		**2h**		**3h**	35 [f]	21:79
9		**2i**		**4**	39	–

[a] Typical method: To a solution of **1** (1 equiv) and **2a** (1.1 equiv) in THF was added TBAF (3 equiv) at room temperature under argon, and the mixture was stirred for 10 min. The reaction was stopped by addition of water, and the solution extracted with diethyl ether. The solvent was removed under vacuum, and the residue purified by column chromatography over silica gel (hexane/AcOEt, 10/1). [b] For compounds for which the configuration could be determined without doubt the major diastereomer is shown. [c] The diastereomer ratio was determined by ^{1}H NMR spectroscopy, and the configuration of the products by X-ray crystallography (**3a**), NOE NMR spectroscopy (**3b** and **3g**), or by comparison with the configurations of **3a** (**3e**) and **3g** (**3h**). [d] Three diastereomers were obtained in the ratio 55:34:11; their configurations were not determined. [e] Duration of the reaction: 35 min. [f] The reaction was sluggish, and after 16 h the product was obtained in 35% yield.

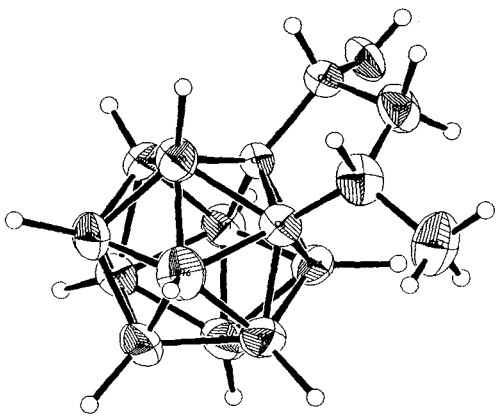

Figure 1. Crystal structure of the cyclic adduct **3a**.

was determined by NOE experiments. Since NOEs were observed between CH_3 protons and H^b but not between H^b and H^a, the configuration of the major isomer was *anti*. The stereochemistry of the minor isomer (*syn*) was also determined by

NOE experiments. The yields in the reactions with 3-substituted aldehydes (**2a** and **2c–e**) were higher than those with 3-unsubstituted aldehyde (**2b**), as shown in Table 1 entries 1–5. The diastereoisomer ratio of **3d** was determined by 400 Hz ^{1}H NMR spectroscopy, but the stereochemistry of those isomers was not determined. Even α,β-unsaturated ketones reacted with **1** under the same reaction conditions as above to afford the cyclic adducts in good to acceptable yields (entries 6-8). The reaction of **1** with **2g** gave **3g** in 52% yield with a *syn*/*anti* ratio of 40/60. NOEs were observed between H^a and H^b, and between H^c and protons of CH_3 attached to the OH-substituted C atom of **3g**, thus indicating that the configuration of the major isomer was *anti* (see **3g**). However, a phenyl group at the γ-position of the enone led to higher diastereoselectivity (*syn*/*anti* = 21/79, entry 8), although the substituent groups at the γ-position of enals did not affect the diastereoselectivity (entries 1 and 5). Cyclohexenone **2i**, which has a fixed s-*trans* enone configuration, gave the corresponding 1,4-addition compound **4** in 39% yield instead of affording the expected annulation product (entry 9).

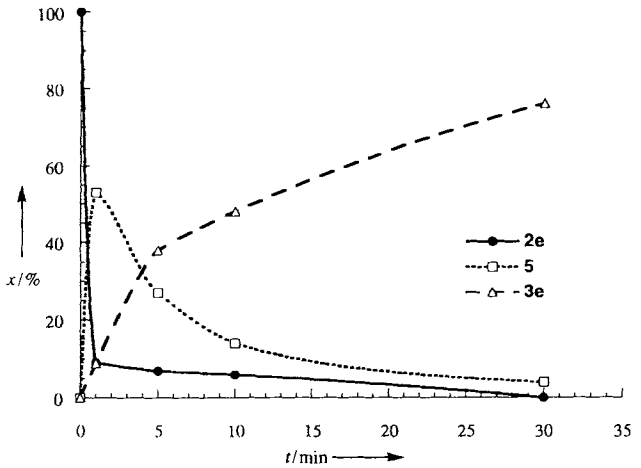

Figure 2. Concentrations of **3e** and **5** with time during the reaction of **1** and **2e** catalyzed by TBAF in THF. The amount of product x (yields) were determined by ^{1}H NMR spectroscopy.

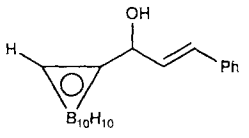

5

To clarify the mechanism of this unique annulation reaction, we monitored the reaction of **1** with cinnamaldehyde **2e** (Figure 2). Within a minute after the addition of TBAF, the 1,2-adduct **5** and the cyclic adduct **3e** were produced in 53% and 9% yield, respectively. The yield of **5** gradually decreased and the yield of **3e** increased as the reaction progressed. After 30 min, the yield of the cyclic product **3e** was 76%, the starting enal **2e** was consumed completely, and very small amounts of the 1,2-adduct **5** were present.

Based upon this observation, it was thought that the [3+2] annulation proceeded through kinetically controlled 1,2-addition followed by the cyclization process. Actually, when **6**[9] was treated with TBAF, **3a** was obtained in 18% yield along with the formation of desilylated product **7** in 58% yield. According to

6 18% **7** 58%

a possible mechanism for this unprecedented annulation reaction (Scheme 2), the reaction of **1** with TBAF gives an anionic intermediate **8**, which undergoes addition to **2** either in 1,2- or 1,4-manner to give the 1,2-adduct **9** or 1,4-adduct **10** that are in equilibrium. The formation of **9** is postulated to be a kinetically controlled process, as is apparent from the result of Figure 2. The thermodynamically favored **10** undergoes proton exchange to afford the 1,2-carborane anion **11**, which gives **3** by intramolecular ring closure.[10] In the case of cyclohexenone, the enolate generated by the 1,4-addition may abstract a proton from the carborane cage, but the carbonyl group cannot approach the resulting carboranyl anion for geometric reasons, and thus no annulation takes place with **2i**.

We are actively investigating the scope and limitation of this novel annulation reaction, which is synthetically useful for providing biologically active carborane derivatives for boron neutron capture therapy.[11]

[6] Preparation of **1**: To a stirred solution of 1,2-dicarbadodecaborane (0.72 g, 5 mmol) dissolved in dry THF (50 mL) at −78 °C was added dropwise a solution of *n*BuLi in hexane (1.6 mol dm^{-3}, 3.13 mL, 5 mmol). After the mixture had been stirred for 30 min at −78 °C, trimethylsilyl chloride (0.67 mL, 5.28 mmol) was added dropwise. The solution was stirred for 1 h and then warmed to ambient temperature. The reaction was quenched with water, extracted with diethyl ether, and dried over anhydrous magnesium sulfate. The solvent was evaporated off, and the residue purified by short column chromatography on silica gel with hexane as eluent to give **1** as a white solid in 86% yield (0.93 g, 4.3 mmol). In this case, bis(trimethylsilyl)-substituted carborane was not obtained. The use of a dilute solution of lithium carborane is essential to obtain the monosilylated carborane derivative selectively.

[7] In the case of addition of carboranyltributylstannane to cinnamaldehyde catalyzed by palladium, only 1,2-adduct was obtained: H. Nakamura, N. Sadayori, M. Sekido, Y. Yamamoto, *J. Chem. Soc. Chem. Commun.* **1994**, 2581.

[8] The addition of **1** to aromatic and aliphatic aldehydes promoted by TBAF gave 1,2-adducts in good to high yields: J. Cai, H. Nemoto, H. Nakamura, B. Singaram, Y. Yamamoto, *Chem. Lett.* **1996**, 791.

[9] Silyl ether **6** was easily prepared by 1,2-addition of 1-lithio-1,2-dicarba-*closo*-dodecaborane(12) to crotonaldehyde in THF.

[10] The mechanism of this reaction involving a 1,4-addition–proton exchange–addition sequence is quite similar to that of 2,3-bis(phenylsulfonyl)-1,3-butadiene to activated methylenes: A. Padwa, S. S. Murphree, Z. Ni, S. H. Watterson, *J. Org. Chem.* **1996**, *61*, 3829.

Molecular Cubic Hyperpolarizabilities of Systematically Varied (Triphenylphosphane)-gold–σ-Arylalkynyl Complexes**

Ian R. Whittall, Mark G. Humphrey,* Marek Samoc, and Barry Luther-Davies

Dedicated to Professor G. Erker on the occasion of his 50th birthday

The nonlinear optical (NLO) responses of organometallic compounds have been the subject of many reports recently,[1, 2] but most such studies have considered quadratic optical nonlinearities.[3] Cubic nonlinearities are comparatively little explored; in particular, few studies probing structure–property relationships, necessary for rational materials improvement, have been promulgated.[4] We have commenced a detailed investigation of the NLO behavior of organometallic compounds and have recently reported cubic hyperpolarizabilities of (cyclopentadienyl)bis(phosphane)ruthenium complexes containing σ-arylalkynyl ligands.[4c] Phosphane variation (replacing PPh_3 by PMe_3) was found to have little impact on measured nonlinearity, whereas chain lengthening of the aryl substituent of the alkynyl ligand (from 4-nitrophenyl to (*E*)-4,4′-nitrostilbenyl) led to a substantial increase in nonlinear response. However, the dispersion effect of two-photon states contributed significantly to measured nonlinearities, precluding a detailed investigation of the effect of structural variation on the merit of the nonlinear optical properties; a key factor in this context is the presence of optical absorption maxima to low energy of 2ω (ω = irradiating laser frequency, corresponding to the wavelength of 800 nm in our experiments). We therefore sought a systematically variable series of alkynylmetal complexes, which will minimize two-photon effects at 800 nm. We report herein the results of studies on the third-order hyperpolarizabilities of some alkynyl(triphenylphosphane)gold complexes; unlike the ruthenium examples investigated in our earlier work, the energies of the linear optical absorption maxima for all the gold complexes are higher than 2ω, which reduces problems arising from two-photon states and permits comment on the effect of alkynyl ligand variation on cubic NLO merit.

The complexes studied (Scheme 1) were synthesized by published procedures,[3b, 5] and third-order nonlinearities evaluated by the Z-scan technique;[6] although Z-scan does not provide information on the temporal behavior of the NLO response, an electronic origin for cubic nonlinearities in alkynylmetal complexes has been demonstrated previously.[4c] Results of measurements are given in Table 1; the cubic nonlinearities of **1** and **2** could not be determined accurately, only an upper bound for the nonlinearity being obtained. A number of conclusions from comparisons across these data can be made. Replacement of 4-H by 4-NO_2 in proceeding from **2** to **3** results in a substantial increase in nonlinearity; unlike all related nitro-containing alkynylruthenium complexes for which negative nonlinearities were obtained,[4c] γ values for all nitro-containing alkynylgold complexes considered here are positive, consistent with greatly diminished two-photon dispersion. (It should be emphasized, though, that the presence of imaginary components in the γ values for **3**–**8**—associated with nonlinear absorption—suggests that electronic resonance enhancement still exists though diminished with respect to the ruthenium complexes.) Chain lengthening of the alkynyl chromophore leads to a dramatic increase in nonlinearity, as shown by the significantly larger nonlinearities for **4**–**7** than for **3**. The present data permit evaluation of the merit of the linking unit: the ene-linkage **5** and yne-linkage **7** are much more effective than the biphenyl linkage **4**, torsional effects at polyphenyl groups probably leading to difficulty in enforcing coplanarity of rings and efficient π delocalization. The effect of stereochemistry of the bridging unit in ene-linked complexes has also been probed: γ for the *E* complex **5** is about three times larger than that for the *Z* complex **6**. Although the π system is the same length for **5** and **6**, the *E* geometry leads to a greater charge separation for the important metal-to-ligand charge transfer (MLCT) transition. The difference in ground and excited state dipole moment is an important contributor to one of three terms influencing γ in the three-level model derived from perturbation theory,[7] but the validity of this model for organometallic complexes of the type considered here is unclear. Contributions from the oscillator strength (that of **5** is twice that of **6**) may also be important. We have also probed the effect of varying the bridging atom, by replacing CH in **5** by N to afford **8**. Surprisingly, there is an order of magnitude difference in γ between **5** and **8**, consistent with diminished electron delocaliza-

Table 1. Linear optical and cubic nonlinear optical response parameters for complexes **1**–**8** [a].

tion caused by electronegative atoms in the π system. There are broad similarities in relative efficiency for γ with that for β (for which the series $\mathbf{1}<\mathbf{2}<\mathbf{3}<\mathbf{4}<\mathbf{6}\approx\mathbf{7}<\mathbf{8}<\mathbf{5}$ was obtained from hyper-Rayleigh scattering measurements at 1064 nm),[3b] consistent with a "cascade" effect, although the relative ordering is not identical; significant differences in chromophore NLO efficiency between quadratic and cubic responses for this series of complexes are the small γ for the imino-linked **8** relative to its high β value, and the large γ for the yne-linked **7** in contrast to its more modest β value. Complex **8** is the only one in this series for which the imaginary part of γ is larger than the real part, suggesting proximity of 2ω to the two-photon absorption peak and strong dispersion effects—possibly resulting in a diminished real part of γ. The disparity of the results for **7** suggests that different alkynyl ligands may be required for optimization of quadratic and cubic NLO efficiencies in organometallic complexes.

The effect of the ligated metal upon β and γ values differs. Quadratic nonlinearities for alkynyl(cyclopentadienyl)bis(triphenylphosphane)ruthenium complexes are three to five times larger than those for the corresponding alkynyl(triphenylphosphane)gold complexes,[3b] consistent with the fact that the 18-electron, more easily oxidizable ligated ruthenium(II) center is a better donor than the 14-electron, less readily oxidizable ligated gold(I) center. In contrast, cubic nonlinearities for the "extended chain" alkynyl(triphenylphosphane)gold complexes **5** and **7** are, in absolute terms, two to three times larger than those for the (cyclopentadienyl)bis(triphenylphosphane)ruthenium analogues, despite both the nominally greater delocalization (and hence polarization) possibilities due to the cyclopentadienyl group and additional triphenylphosphane ligand and the substantial dispersion enhancement of the Ru complex. This suggests that different ligated metals may be required to optimize quadratic and cubic NLO efficiencies in organometallic complexes.

Data from investigations of the cubic molecular optical nonlinearities of organometallic complexes have been summarized.[2, 4] The largest reported nonlinearities (up to 4933×10^{-36} esu) are for oligomeric systems,[8] and it is generally accepted that chain lengthening by oligomerization and polymerization leads to an increase in γ value. The nonlinearities of **5** and **7** are the largest yet for a monomeric organometallic compound and approach the largest values known for oligomeric organometallic systems. The presence of the metal atom terminating the alkynyl ligand in these organometallic chromophores is critical for their NLO response—precursor acetylenes have nonlinearities not significantly different from that of the solvent—but it is possible that *one metal may suffice*. (Alkynyl)-metal oligomers and polymers are currently attracting a great deal of attention because of their potential NLO performance,[9] but it is possible that metal-capped organic oligomers or polymers may also be worthy of study.

Experimental Section

Measurements were performed at 800 nm with a system consisting of a Coherent Mira Ar-pumped Ti-sapphire laser that generates a mode-locked train of approximately 100 fs pulses and a Ti-sapphire regenerative amplifier pumped with a frequency-doubled, Q-switched pulsed YAG laser (Spectra Physics GCR) at 30 Hz and employing chirped pulse amplification. THF solutions were examined in a glass cell with a 0.1 cm path length. The Z-scans were recorded at two concentrations for each compound, and the real and imaginary part of the nonlinear phase change determined by numerical fitting.[6] The real and imaginary part of the hyperpolarizability of the solute was then calculated assuming linear concentration dependence. The nonlinearities and light intensities were calibrated against measurements of a 1 mm thick silica plate for which the nonlinear refractive index $n_2 = 3\times10^{-16}\ \mathrm{cm^2\,W^{-1}}$ was assumed.

First Examples of a Claisen Rearrangement Stereocontrolled by a Sulfinyl Group: Synthesis of Novel α-Sulfinyl Dithioesters

Carole Alayrac, Christophe Fromont, Patrick Metzner,* and Nguyen Trong Anh

Sulfoxides are very useful chiral auxiliaries in asymmetric synthesis.[1, 2] The efficient control of the stereochemistry in the Diels–Alder reactions[3] with unsaturated sulfoxides as chiral dienophiles prompted us to consider the sulfinyl moiety as an auxiliary for asymmetric [3,3] sigmatropic shifts.[4] Induction by an asymmetric carbon center located outside the sigmatropic framework has been previously demonstrated,[5, 6] but the use of a stereogenic sulfur center is unprecedented. However, we were concerned about a subsequent β-elimination of the sulfinyl group[7] from the expected γ-unsaturated α-sulfinyl carbonyl compounds. We therefore chose to perform the Claisen rearrangements with the thiocarbonyl analogues. This transposition occurs at much lower temperatures than for the oxygen analogues—usually at room temperature and in neutral medium.[8, 9] Further interest in this reaction arises because the thiocarbonyl functional group can be converted into sulfur-free functional groups such as carbonyl or alkoxycarbonyl groups.[8, 10] We report here the first examples of asymmetric thio-Claisen rearrangements directed by a sulfinyl group.

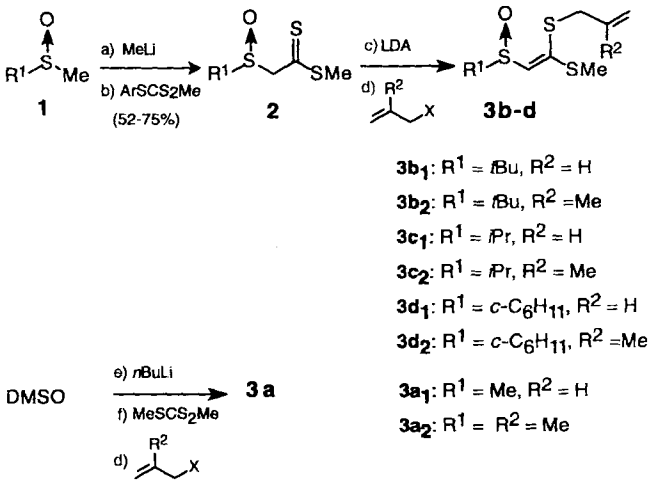
The substrates of the rearrangement are ketene dithioacetals containing a sulfinyl group at the double bond. They were readily prepared from 2-sulfinylethanedithioates. The synthetic utility of α-sulfinyl ketones and esters has been reviewed.[1a, 1d] These molecules, for example, provide very high asymmetric induction in carbonyl reductions[1a, 1b] and in aldol-type condensations.[11] In contrast, molecules bearing a sulfinyl group adjacent to a thiocarbonyl function have so far received little attention.[12, 13] We chose to study four different alkylsulfinyl groups with varied steric hindrance (R^1 = methyl, isopropyl, cyclohexyl, *tert*-butyl) and work exclusively with racemic compounds.

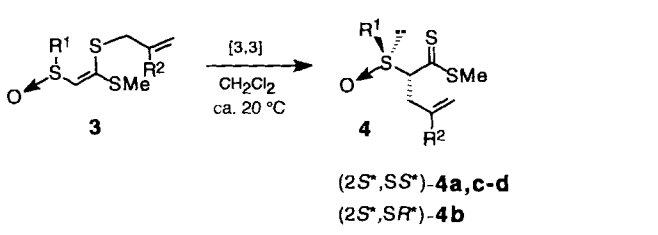
The α-sulfinyl dithioesters **2** were prepared by adding methyl 4-fluorophenyltrithiocarbonate to lithiated alkyl methyl sulfoxides **1** in tetrahydrofuran at −40 °C (Scheme 1). Deprotonation



Scheme 1. Preparation of compounds **3a–d**. **1**, **2**: **a**, R^1 = Me, **b**, R^1 = *t*Bu, **c**, R^1 = *i*Pr, **d**, R^1 = *c*-C_6H_{11}; Ar = 4-fluorophenyl; X = Br, I.

of **2** by lithium diisopropylamide (LDA) was quantitative and predominantly led to the *cis* enethiolate[2, 8, 14] (isomeric ratio >9:1).[15] The *cis* enethiolization is typical of thiocarbonyl compounds[8] and contrasts the *trans* enolization of esters and ketones (under aprotic conditions). It is most probably increased for **2** by the assistance of lithium coordination to the sulfinyl oxygen atom. Enethiolates are ambident nucleophiles that react through the sulfur termini with alkyl halides. Thus, ketene dithioacetals **3** were obtained by S-allylation of the enethiolates resulting from deprotonation of **2**. As the dithioester **2a** (R^1 = Me) is not stable, the corresponding ketene dithioacetals were prepared in a single step from dimethylsulfoxide (DMSO) by using the method applied by Yokoyama et al.[12] (Scheme 1).

Ketene dithioacetals **3** readily rearrange at room temperature into γ-unsaturated α-sulfinyl dithioesters **4** (Scheme 2). The reaction times range from 5 to 45 hours according to the nature of R^1. The crude yields are greater than 90%. The yields after purification by chromatography on silica gel are lower due to a partial decomposition of the product. However, as the purity of crude dithioesters **4** is satisfactory, no purification is necessary to carry out the next step.



Scheme 2. Claisen rearrangement of compounds **3**. For groups R^1 and R^2 see Table 1.

The diastereomeric ratio was determined by measuring the integrals of ^{1}H NMR signals of the MeS group of each isomer (Table 1).[16] This demonstrated that the asymmetric induction

[a] The rearrangements were performed at room temperature in CH_2Cl_2 and monitored by ^{1}H NMR spectroscopy and thin-layer chromatography. [b] Diastereomeric ratio according to ^{1}H NMR analysis. Only compounds **4a$_1$** and **4a$_2$** underwent significant isomerization on silica gel. [c] Yield of isolated product.

of sulfoxides was extremely effective: in all cases a very high diastereoselectivity was measured (diastereomeric ratio >93:7). Interestingly, the steric demand of R^1 seems to have little influence on the selectivity. We could also demonstrate that the rearrangement does not proceed under thermodynamic control. Indeed the dithioesters **4c** isomerize on treatment with triethylamine at room temperature, and the ratio at equilibrium is 4:1. The configuration of the major diastereomer of dithioester **4a$_2$** (R^1 = R^2 = Me) has been assigned as (2*S**,S*S**) by X-ray crystallography.[17] According to similar trends observed in ^{1}H NMR spectra, the same configuration can be empirically assigned to the major isomers of the other Claisen rearrangement products.[18]

To rationalize our results, we suggest a model that is a natural extension of the Felkin one. Since the main physical phenomenon in a reaction between ions is electron transfer from the nucleophile to the electrophile, in nucleophilic (electrophilic) additions, the best acceptor (donor) should be placed *anti* to the incoming nucleophile (electrophile).[19] In the present case, the lone pair of electrons of the sulfinyl group of **3** is the best electron donor. Consequently the attack of the allylic chain should occur *anti* to this lone pair of electrons.[20] Thus, two transition states derived from the conformers **A** and **B** are conceivable for the major (*Z*) ketene dithioacetal **3** (Scheme 3). The former (**A**) is more favored as the alkyl group R^1 is bulkier than the oxygen atom. This is in agreement with the observed stereochemistry (2*S**,S*S**). Moreover, in model **A**, the R^1 group occupies an outside position, which may explain the slight influence of its size on the observed selectivity. The same model applied to the minor (*E*) isomer leads to the same (2*S**,S*S**) diastereomer.[21] Calculations are underway to evaluate the reliability of this model.

In conclusion, we have described a new method for asymmetric C–C bond formation in acyclic compounds. The Claisen rearrangement of ketene dithioacetals bearing a sulfinyl group requires mild conditions and is highly diastereoselective. Furthermore, no elimination of the sulfinyl group was observed. Scheme 3. Considerations of the stereochemical course of the Claisen rearrangement of compounds **3**.

contrast the rearrangement products in the oxygen series could not be isolated because higher temperatures were necessary for the Claisen rearrangement.[7] To the best of our knowledge the reaction presented here is the first [3,3] rearrangement directed by a sulfinyl group. Application of this method to enantiopure substrates and elaboration of carbon chains bearing three contiguous stereogenic centres are in progress.

Experimental Section

Sulfoxides **1** were prepared in two steps from the corresponding thiols according to known procedures [22].

2d: MeLi (9.0 mL of a 1.6 N solution in ethyl ether, 14.4 mmol) was added dropwise to a solution of **1d** (2.24 g, 14.4 mmol) in THF (60 mL) at $-40\,^{\circ}C$. The reaction mixture was stirred for 40 min at $-30\,^{\circ}C$ then cooled to $-40\,^{\circ}C$, and a solution of methyl 4-fluorophenyltrithiocarbonate (1.57 g, 7.2 mmol) in THF (6 mL) was added. The resulting mixture was stirred for 1 h at $-20\,^{\circ}C$ then allowed to warm up to $0\,^{\circ}C$. It was worked up by addition of saturated aqueous NH_4Cl solution (20 mL), followed by extraction with CH_2Cl_2 (3×30 mL). The combined organic layers were washed with brine, dried over $MgSO_4$, and then concentrated to dryness. Purification of the residue by column chromatography (silica gel, petroleum ether/ethyl acetate 1:1) afforded 0.93 g of dithioester **2d** (55%). **2d**: Orange solid, m.p. 43 °C; ^1H NMR ($CDCl_3$, 250 MHz): $\delta = 1.18-2.15$ (m, 10H), 2.70 (s, 3H), 2.75 (tt, $J = 3.6$, 11.5 Hz, 1H), 4.32 and 4.37 (AB, $J_{AB} = 12.5$ Hz, 2H); ^{13}C NMR ($CDCl_3$, 62 MHz): $\delta = 21.1$, 24.0, 25.2, 25.5, 25.6, 26.9, 58.5, 68.8, 222.8; IR (NaCl): $\tilde{\nu} = 3424$, 2930, 2852, 1648, 1448, 1414, 1264, 1202, 1124, 1054, 970, 730 cm^{-1}; MS: *m/z* (%): 236 (0.8) [M^+], 106 (18), 91 (14), 84 (12), 83 (15), 81 (7), 73 (32), 61 (59), 59 (31), 58 (67), 55 (96), 48 (11), 47 (28), 45 (42), 43 (33), 41 (100); elemental analysis calcd for $C_9H_{16}OS_3$: C 45.72, H 6.82, S 40.69; found: C 45.80, H 6.86, S 40.39.

3d$_1$: A solution of **2d** (342 mg, 1.45 mmol) in THF (5 mL) was added to a solution of LDA (1.57 mmol) in THF [5.2 mL, freshly prepared from *n*BuLi (1 mL of a 1.6 N solution in hexane) and diisopropylamine (0.25 mL)] at $-40\,^{\circ}C$. After the solution had been stirred for 40 min at $-30\,^{\circ}C$, it was cooled to $-40\,^{\circ}C$ and allyl bromide (0.16 mL, 1.9 mmol) was added. The reaction mixture was allowed to warm to $0\,^{\circ}C$ over 1.5 h then treated with saturated aqueous NH_4Cl solution (10 mL). The product was extracted with CH_2Cl_2 (3×10 mL); the combined organic layers were washed with brine, dried over $MgSO_4$, and then concentrated to dryness for analysis. The crude product was obtained with quantitative yield (400 mg). **3d$_1$**: Signals of the major isomer (*Z*) that were clearly identified; ^1H NMR ($CDCl_3$, 250 MHz): $\delta = 2.10-2.15$ (m, 1H), 2.42 (s, 3H), 3.48 and 3.68 (AB signals of an ABX system, $J_{AB} = 13.4$ Hz, $J_{AX} = 7.9$ Hz, $J_{BX} = 7.0$ Hz, 2H), 5.14–5.27 (m, 2H), 5.80–5.92 (m, 1H), 6.09 (s, 1H); signals of minor isomer (*E*) that were clearly identified; ^1H NMR ($CDCl_3$): $\delta = 2.09-2.14$ (m, 1H), 2.45 (s, 3H), 3.52 (dd, $J = 1.1$, 6.7 Hz, 2H), 5.22 (dd, $J = 1.0$, 10.0 Hz, 1H), 5.27–5.35 (m, 1H), 5.84 (ddt, $J = 6.7$, 10.0, 17.0 Hz, 1H), 6.19 (s, 1H).

4d$_1$: Claisen rearrangement of **3d$_1$** (80 mg, 0.29 mmol) was carried out in CH_2Cl_2 (3 mL) at room temperature and monitored by thin-layer chromatography. It was complete after 20 h. The solution was then concentrated to dryness. The ^1H NMR spectrum showed that the ratio of the two diastereomers was 95:5. Purification of the residue by column chromatography (silica gel, petroleum ether/ethyl acetate 7/3) afforded 38 mg of dithioester **4d$_1$** (47%, ratio of diastereomers = 93:7). **4d$_1$**: Orange solid, m.p. 37 °C; ^1H NMR ($CDCl_3$, 250 MHz): $\delta = 1.25-2.03$ (m, 10H), 2.56 (tt, $J = 3.6$, 12.0 Hz, 1H), 2.68 (s, 3H), 3.00–3.06 (m, 2H), 4.39 (dd, $J = 4.6$, 10.2 Hz, 1H), 5.05–5.17 (m, 2H), 5.62–5.78 (m, 1H); ^{13}C NMR ($CDCl_3$, 62 MHz): $\delta = 19.8$, 21.9, 25.3, 25.4, 26.0, 28.5, 36.5, 55.4, 76.3, 118.8, 132.5, 228.5; IR (NaCl): $\tilde{\nu} = 2930$, 2854, 1450, 1418, 1054, 992, 946, 920 cm^{-1}; MS: *m/z* (%): 276 (0.5) [M^+], 91 (18), 83 (52), 82 (10), 81 (27), 55 (100), 47 (17), 43 (19), 41 (89); elemental analysis calcd. for $C_{12}H_{20}OS_3$: C 52.13, H 7.29, S 34.79; found: C 52.07, H 7.20, S 34.60; ^1H NMR signal of the minor isomer ($CDCl_3$): $\delta = 2.70$ (s, 3H).

[14] The designation *cis* refers to the relationship between the sulfinyl and the SLi groups.

[15] In previous work from our laboratories, we have demonstrated that enethiolate alkylation proceeded with complete retention of configuration [23]. The configurations of ketene dithioacetals were assigned based on the results of NOE difference studies, which were carried out on the corresponding *S*-benzyl ketene dithioacetals.

[16] In order to determine the ^1H NMR signals corresponding to the minor isomer, compounds **4** were submitted to a deprotonation/protonation sequence with different bases (NEt_3, NaH). Once we had the reference spectrum of the minor isomer, it was possible to evaluate the isomeric ratio of crude compounds **4** by expanding the area containing the ^1H NMR signals of the MeS groups and by measuring the integrals of both singlets.

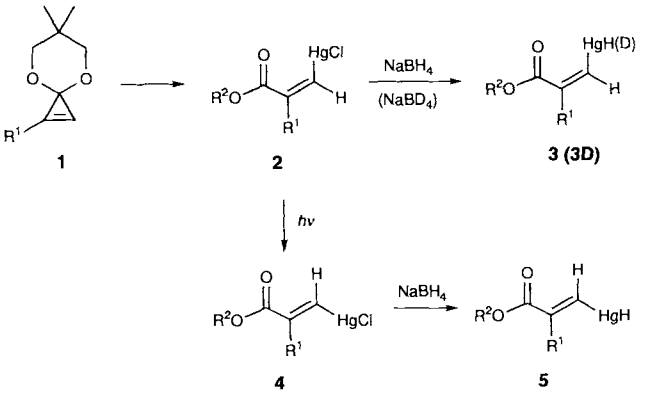
Unusually Stable Organomercury Hydrides and Radicals**

Eiichi Nakamura,* Yong Yu, Seiji Mori, and Shigeru Yamago

There is growing interest in the characterization of organomercury hydrides,[1] which have been elusive species until very recently. Hydride reduction of organomercury chlorides is an important method for generating carbon radicals.[2] The reaction is considered to proceed in three steps: formation of an organomercury hydride, homolysis of the Hg–H bond, and immediate decomposition of the transient organomercury radical.[3] However, experimental evidence for this proposed mechanism has been rather scant. A few alkylmercury hydrides were recently isolated and proved to be very unstable.[1f] The second intermediate, an organomercury radical, has still remained elusive, and no direct proof of its existence has been obtained. Here we report on the synthesis of the unusually stable organomercury hydrides **3** and deuterides **3D**, which are much more stable than the mercury hydrides described so far. Furthermore, these hydrides generate the organomercury radicals **6**, which are stable enough to be trapped intermolecularly.

The reaction of cyclopropenone acetal **1a**[4] with $Hg(OAc)_2$, followed by treatment with a saturated NaCl solution, stereospecifically produced the (*Z*)-olefinic mercury chloride **2ax** in 92% yield. The mercury chlorides **2** with different R^2 groups could also be prepared.[5] Stereospecific conversion of the mercury chlorides to the hydrides **3ay** and **3az** was then achieved



1 **2** **3 (3D)** **4** **5**

b; $R^1 = H$ **y**; $R^2 = CH_3$
z; $R^2 = p\text{-}NO_2C_6H_4$

with $NaBH_4$ at 0 °C. The same procedure was applied to the unsubstituted cyclopropene **1b** to produce the acrylate derivatives **3by** and **3bz** in 70–80% yield. Photolysis of the (*Z*) methyl ester **2ay** affords the (*E*) isomer **4ay** (28% yield, 60% recovery of **2ay**), which was reduced to provide the (*E*)-olefinic mercury hydride **5ay** in 78% yield.

The hydridomercury acrylate derivatives **3** and **5** are stable, colorless solids. The stability increases from the methyl ester **3ay** (half-life $t_{1/2} = 34$ h at 75 °C in C_6D_6) to the *p*-nitrophenyl ester **3az** ($t_{1/2} = 74$ h at 75 °C in C_6D_6). The *p*-nitrophenyl esters **3az** and **3bz** remain unchanged for many weeks as a solid at 4 °C and in benzene solution at 25 °C. The hydride **3z** decomposes with a first-order rate constant of $k = 2.6 \times 10^{-6}\ s^{-1}$ at 75 °C in degassed C_6D_6. The corresponding deuteride **3D-az** is much longer lived ($k = 9.6 \times 10^{-7}\ s^{-1}$, $t_{1/2} = 201$ h at 75 °C in degassed C_6D_6).[6] The remarkable stability of **3** is in sharp contrast to the instability of previously known RHgH compounds ($t_{1/2} = 100$ min at 20 °C for CH_3HgH in benzene).[1f,g] Some spectral properties correlate with the stability of the compounds. The IR stretching frequency (KBr) of the Hg–H bond increases from the methyl ester **3ay** (1969 cm^{-1}) to the *p*-nitrophenyl ester **3az** (1983 cm^{-1}). The Hg–H coupling constant in the NMR experiment increases from 3118.3 Hz for **3ay** to 3218.0 Hz for **3az**. The substituent R^1 (Et, H) does not significantly affect the stability of the hydrides. The *Z* and *E* isomers of the methyl esters **3ay** and **5ay** are of comparable stability ($t_{1/2} = 34$ h and 23 h, respectively, at 75 °C in degassed C_6D_6). This indicates that coordinative interaction between the ester and the mercury atom is not very important for the stability of the hydrides. In line with this observation is the fact that reduction of 2-(ethoxycarbonyl)ethylmercury(II) chloride[7] with $NaBH_4$ does not give the corresponding isolable mercury hydride, which would be a saturated analog of **3ay**.

Thermolysis of **3ay** and **3az** nearly exclusively produces the divinylmercury compound **8** (90–100% yield) and metallic mercury. Only traces of the normal reductive elimination products **11** (Scheme 1) could be found. Formation of **8** suggests intervention by the dimer **7**, hence implying that **6** is long-lived enough to be chemically trapped. Indeed, when **3ay** was treated with the halogenating agents NCS, Cl_3CBr, CCl_4, and *t*BuBr (listed in order of decreasing halogen donating ability[8]), the halogenated products **9ay** (X = Cl, Br) were formed in 90, 76, 23, and 6% yield, respectively. Addition of hydroquinone (11 mol%) to the reaction mixture resulted in a decrease in the rate of halogenation with Cl_3CBr and formation of the dimer **8ay** (**8ay**: 44%; **9ay**: 51% yield). Use of an inferior radical acceptor, such as

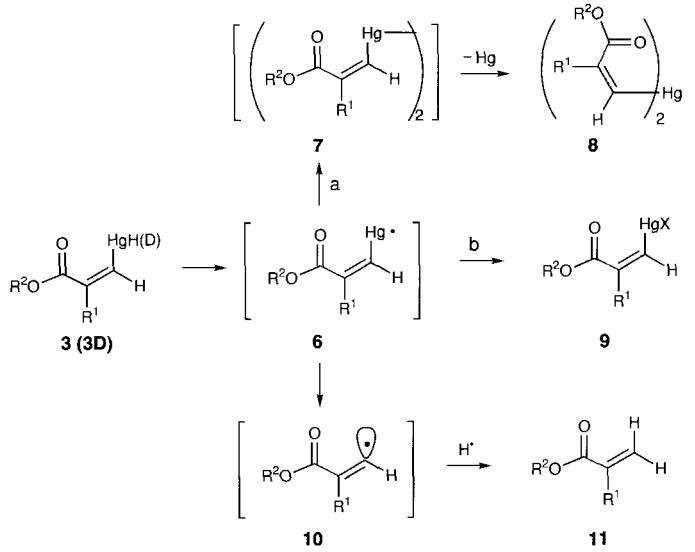
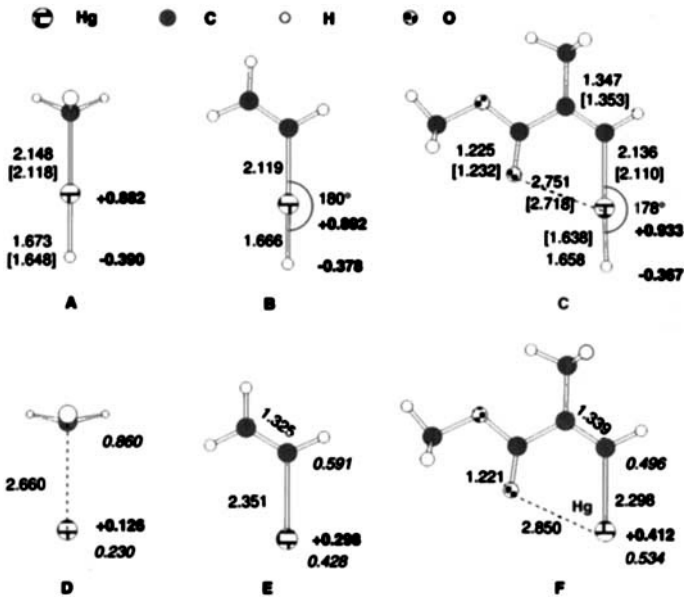


Scheme 1. Thermolysis and trapping of organomercury radicals. All reactions (in C_6D_6) proceeded with complete retention of the olefin geometry: a) 75 °C in C_6D_6. b) NCS (3 equiv, 25 °C, 90%), Cl_3CBr (13 equiv, 50 °C, 76% accompanied by 17% of **8**), CCl_4 (10 equiv, 50 °C, 23% accompanied by 3% of **8** and 73% of **11**), *t*BuBr (13 equiv, 50 °C, 6% accompanied by 29% of **8** and 64% of **11**).

benzylidene malononitrile, resulted in recovery of the trap[1f] and quantitative formation of **8ay**. Notably, we found no evidence that the vinyl radical **10** could be trapped (< 3%).

What is the origin of the stability of the hydride **3** and the radical **6**? Since little information on the structures and properties of organomercury hydrides and radicals is available in the literature, we carried out quantum mechanical calculations at the electron correlated levels.[9-11] 2-Methoxycarbonyl-(*Z*)-propenylhydridomercury(II) (**C**, C_s symmetry) served as a hydride model. Methylhydridomercury(II) CH_3HgH (**A**, C_{3v} symmetry) and ethenylhydridomercury(II) $CH_2{=}CHHgH$ (**B**, C_s symmetry) served as references. We also examined the corresponding radical models, **D**, **E**, and **F** (Scheme 2).



Scheme 2. Stuctures of CH_3HgH (**A**), ethenylmercury hydride (**B**), 2-methoxycarbonylethenyl-(*Z*)-hydridomercury(II) (**C**), and the corresponding mercury radicals (**D**, **E**, and **F**) optimized at the B3LYP/6-31G(d,p)-SKBJ RECP level. Bond lengths [Å] (B3LYP level; numbers in brackets: MP2 level). Natural charges (B3LYP) are in bold, and atomic spin densities (B3LYP) are in italics.

Table 1. Bond dissociation energies for **A**–**F**. The pertinent bond is indicated by a hyphen. Energies are given in kcal mol^{-1} at the 6-31G(d,p)-SKBJ RECP level.

Species	B3LYP	CCSD(T)//B3LYP
CH_3Hg-H (**A**)	70.3	71.5
CH_3-HgH (**A**)	65.2	63.2
$CH_3-Hg^{\bullet}$ (**D**)	1.5	0.4
$CH_2CHHg-H$ (**B**)	71.8	
$CH_2CH-HgH$ (**B**)	72.9	
$CH_2CH-Hg^{\bullet}$ (**E**)	5.6	
$CH_3OOCCCH_2CHHg-H$ (**C**)	76.2	
$CH_3OOCCCH_2CH-HgH$ (**C**)	79.3	
$CH_3OOCCCH_2CH-Hg^{\bullet}$ (**F**)	9.8	

C–Hg and O–Hg distances in **C** calculated at the MP2 and B3LYP[12] levels show good agreement with those from the X-ray structure of (Z)-$(C_6H_5COCH{=}CH)_2Hg$.[13] Characteristic is the linear arrangement of the C-Hg-H unit, which is bent by 2° due to the influence of the neighboring oxygen atom. The good agreement between calculated (for the monomer model) and experimental values of Hg–H IR frequencies (KBr)[14] suggests that there is very little intermolecular association in **3** in the solid state.

The Hg–H bond lengths and the bond dissociation energies (BDE, Table 1) for **A**–**C** correspond with the much higher stability of the mercury hydrides **3** than alkyl mercury hydrides. Thus, the Hg–H bond progressively shortens upon going from **A** (1.673 Å) to **B** (1.666 Å) to **C** (1.658 Å). The calculated IR frequencies also show the same trend and agree well with the experimental values.[14] The Hg–H BDE (Table 1) increases from **A** to **B** by 1.5 kcal mol^{-1} and from **A** to **C** by 5.9 kcal mol^{-1}.[15] Furthermore, the electron densities on the hydride and Hg atom (natural charges) progressively decrease from **A** to **B** to **C**. Therefore, the stability of **3** must arise largely from the large electron-accepting ability of the acrylic acid moiety.

Similar substitutent effects were also observed for the organomercury radicals **D**, **E**, and **F**. The Hg–C bond in **D** is decidedly longer than that in **A** (24%), while that in **F** is only 7.5% longer than that in **C**. The ethenylmercury radical **E** showed an intermediate value of 11% elongation. The methyl group in **D** is flattened, and the atomic spin density is concentrated on the methyl carbon atom (0.860). The natural charge of Hg in **D** is only +0.126 (+ 0.882 in **A**). All of these properties indicate that **D** possesses the characteristics expected for a complex between $CH_3^{\bullet}$ and Hg^0 rather than $CH_3Hg^{\bullet}$. On the other hand, the C–Hg bond in **F** (2.298 Å) is much shorter than in the other radicals, and the vinyl moiety retains its sp^2 geometry. The mercury atom bears higher spin density (0.534) and is more positively charged (+ 0.412). In agreement with these data, the BDE for the C–Hg bonds in **D** (Table 1) is extremely small (1.5 kcal mol^{-1} at B3LYP and 0.4 kcal mol^{-1} at CCSD(T)[16]//B3LYP; 9.8 kcal mol^{-1} for **F**). Therefore, the commonly accepted instability of **D** must be valid.[2, 3] The radical **F** is expected to be much more stable and have a lifetime long enough to be trapped intermolecularly, as found experimentally.

We have prepared unusually stable mercury hydrides, which in turn give rise to unusually stable organomercury radicals. The experimental and calculated physical data indicate that the stability is due to the electron-withdrawing effects of the acrylic acid moiety. In light of the linear H-Hg-C arrangement, the stabilization of the mercury hydride can be viewed as the "trans effect"[17] of the electron-withdrawing organic group. This will probably prove to be a general feature in mercury hydride chemistry.

[5] The ester **2a** was first hydrolyzed with KOH (1.5 equiv) in 95% ethanol (yield 94%). Esterification either directly (R^2OH, DCC/DMAP in CH_2Cl_2, 56% for CH_3OH and 67% for p-$NO_2C_6H_4OH$) or via the acid chloride ($(COCl)_2$/cat. DMF, R^2OH/pyridine, 71% for CH_3OH) afforded **2ay** and **2az**.

[6] Thermolysis reactions were carried out in a vacuum-sealed Pyrex NMR tube previously washed with HNO_3, NH_4OH, and bis(trimethylsilyl)acetamide (14 h). The reaction mixture was thoroughly degassed by several freeze/thaw cycles. The hydrides are rather sensitive to acidic impurity, which generates 2-ethylacrylate by protonolysis of the Hg–H bonds (for example, the deuteride **3D-ay** reacts with CF_3COOH at 50 °C to quantitatively afford the protonolysis product **11** in 20 min). Thus, the rate measurements are always slightly dependent on reaction conditions. This is probably the reason why analytically pure samples have not yet been made.

[14] The following Hg–H frequencies were calculated for structures at the MP2/6-31G(d,p)-SKBJ RECP] HF level: **A**: 1975 cm^{-1}, **C**: 2004 cm^{-1}. Experimental values [1h]; CH_3HgH, 1940 cm^{-1}; **3az**: 1983 cm^{-1}.

[15] A referee pointed out that the estimated activation energy of CH_3HgH decomposition (ca. 23 kcal mol^{-1}) is much lower than the calculated BDE (70–71 kcal mol^{-1}). We suggest that decomposition of CH_3HgH proceeds by a radical chain reaction involving bimolecular hydrogen abstraction (for instance, by $CH_3^{\bullet}$). Hence, the activation energy of CH_3HgH decomposition is related to but not the same as the BDE, which is a measure of the stability of a single isolated molecule.

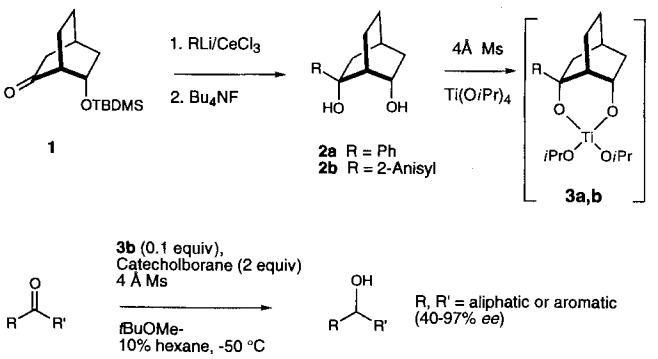
New Ligands for the Titanium(IV)-Induced Asymmetric Reduction of Ketones with Catecholborane**

Fredrik Almqvist, Lillemor Torstensson, Anette Gudmundsson, and Torbjörn Frejd*

Enantioselective reduction of ketones[1] is an important reaction because the resulting optically active alcohols may be used in many syntheses of complex target molecules. Particularly attractive reduction methods are those that can be performed at ambient conditions and that require only catalytic amounts of the chiral inductor, such as borane reductions either in the presence of oxazaborolidines[2–9] or titanium TADDOLates.[10, 11] During work with optically active bicyclo[2.2.2]octane derivatives, we became interested in the development of these compounds into new, chiral bidentate ligands. Herein, we report on our results with (1*R*, 2*R*, 4*S*, 6*S*)-2-phenylbicyclo[2.2.2]octane-2,6-diol (**2a**) and (1*R*, 2*R*, 4*S*, 6*S*)-2-(2-anisyl)bicyclo-[2.2.2]octane-2,5-diol (**2b**) in the Ti^{IV}-catalyzed reduction of ketones with catecholborane. We also suggest that diols based on the bicyclo[2.2.2]octane framework are named BODOLs (*bi*cyclo[2.2.2]octane*diol*s).

BODOLs **2a** and **2b** (Scheme 1) of high enantiomeric purity (≥98%) were synthesized simply by addition of the corresponding RLi/$CeCl_3$ reagent[12, 13] to the O-TBDMS protected



Scheme 1. Synthesis of the Ti-BODOL complexes **3a** and **3b** and their application in the reduction of ketones with catecholborane. Ms = molecular sieves.

(TBDMS = *tert*-butyldimethylsilyl) optically active hydroxy ketone **1**,[14] followed by deprotection. The catalysts **3a** and **3b** were then prepared by mixing the BODOLs with $Ti(OiPr)_4$ in a 1.2:1 ratio in the presence of molecular sieves (Union Carbide Type A, 4 Å) at 0 °C, and then keeping the mixture at room temperature overnight. A small excess of the BODOLs was used to consume all $Ti(OiPr)_4$, thus avoiding reduction by complexation of the ketones with this achiral Lewis acid. In order to make this ligand exchange effective it was important to activate the powdered molecular sieves at 400 °C for 5–7 h. Very extended times at this temperature resulted in inactive molecular sieves, and heating at lower temperatures (100–300 °C) was not sufficient. We recommend that the amount of the molecular sieves be

maintained at a certain level (11 to 36 g per mmol of the BODOL).

Recently, Lindsley and DiMare demonstrated that a titanium TADDOLate based on tartrate was effective as a catalyst (0.05 equiv) in the asymmetric reduction of acetophenone with BH_3·THF (24% *ee*).[10] Higher enantiomeric excesses (up to 84%) were later obtained by Giffels et al. by using catecholborane and a titanium TADDOLate based on a bicyclic framework.[11] Thus, it seemed appropriate to test our catalysts **3a** and **3b** in this type of reaction, as exemplified in Scheme 1. Our results are summarized in Table 1. The absolute configuration

Table 1. Asymmetric reduction of ketones with catecholborane in the presence of about 0.1 equiv of **3a** or **3b** [a].

Entry	Starting material	Catalyst	Yield of alcohol [%]	*ee* [%]	Reaction time [h]
1	acetophenone	**3a**	47	89 (*R*)	7.5
2		**3b**	>97	97 (*R*)	4.5
3	propiophenone	**3a**	<40	<15	5
4		**3b**	48	76	10
5	octan-3-one	**3a**	46	23	7.5
6		**3b**	81	40	5
7	hept-6-yn-2-one	**3a**	97	60 (*R*)	7.5
8		**3b**	>98	83 (*R*)	5
9	octan-2-one	**3a**	>97	62–75	2.5–5
10		**3b**	>98	79	5
11	hexan-2-one	**3a**	>98	66	4
12		**3b**	>98	75	4.5
13	2-methylcyclohexanone	**3a**	67/28 [b]	25; 35 [c]	3
14		**3b**	63/37 [b]	45; 74 [c]	9.5

[a] Yields and enantiomeric excesses (*ee*) were determined by chiral phase GC analysis. [b] *trans*/*cis* ratio. [c] *ee* of the *trans* or *cis* isomer.

of the alcohols produced was checked in the reductions of acetophenone and hept-6-yn-2-one. Thus, the (+)-forms of the BODOLs both gave the corresponding alcohols with *R* configuration (entries 1, 2, 7, and 8). The highest enantiomeric excess (97%) was reached in the reduction of acetophenone in the presence of **3b** (entry 2), but perhaps more interesting are the fairly high enantiomeric excesses (75–83%) obtained with the linear methyl ketones with catalyst **3b** (entries 8, 10, 12). These values are among the highest hitherto recorded for this type of ketones. In comparison, the use of the titanium TADDOLates gave only 34% *ee* in the reduction of 2-octanone.[11] Propiophenone gave a low enantiomeric excess with catalyst **3a** but reached a much higher level with **3b**, although in both cases the chemical yields were only moderate (entries 3 and 4). Also the enantiomeric excesses in the reductions of octan-3-one (entries 5 and 6) are low, but the increase from 23 to 40% *ee* in going from **3a** to **3b** indicates that the ligand system may be adjusted to bring these values up to useful levels. It is encouraging that the chemical yield obtained in this case by using **3b** is 81%. Although the reduction of 2-methylcyclohexanone (entries 13 and 14) was not particularly diastereoselective, the excess of the *cis* isomer (the racemate was prepared according to ref. [15]) was fairly high (74%) when **3b** was used as the catalyst (entry 14). In all cases tested catalyst **3a** gave lower enantiomeric excesses than **3b**. In the absence of a Lewis acid the ketones were not reduced at the low temperatures applied.

The structures of **3a** and **3b** have not yet been determined, and the formula shown in Scheme 1 only indicates the approximate stoichiometry. The exact nature of the active catalyst is difficult to assess with certainty, as has been experienced for other similar systems.[10,16–18] However, **2a** and **2b**, as bidentate ligands, must form six-membered rings with titanium, in contrast to the seven-membered titanium TADDOLates, and also **3a** and **3b** are C_1 symmetric, while the TADDOLates used by Lindsley and DiMare[10] as well as by Giffels et al.[11] are C_2 symmetric.

Experimental Section

2a: A solution of ketone **1** [14] (1.00 g, 3.94 mmol) in THF (2.5 mL) was added dropwise to a mixture of phenyllithium (10.1 mmol) and $CeCl_3$ (13.1 mmol) [13] in THF (30 mL) at −78 °C. The reaction mixture was allowed to warm to room temperature overnight and then quenched with saturated NH_4Cl solution at 0 °C. After standard workup, including filtration through a short pad of silica gel, the crude half-protected diol was deprotected at 0 °C by using tetrabutyl ammonium fluoride (1 M in THF, 6 mL, 6 mmol) in THF (65 mL). Crystalline **2a** (817 mg, 95%) was obtained after chromatography (SiO_2, heptane/ethyl acetate 2:1, $R_f = 0.19$); m.p. 84–87 °C; $[\alpha]_D^{22} = +71$ ($c = 2.2$ in $CHCl_3$); IR (KBr): $\tilde{\nu}$ = 3100–3500, 2940, 2860, 1490, 1450, 1060 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$): δ = 7.55 (m, 2H), 7.37 (m, 2H), 7.28 (m, 1H), 3.98 (m, 1H), 3.90 (d, J = 8.7 Hz, 1H), 3.32 (s, 1H), 2.45 (dm, J = 14.3 Hz, 1H), 2.22 (m, 1H), 2.06 (m, 1H), 2.00 (m, 1H), 1.95 (dm, J = 14.3 Hz, 1H), 1.68 (dm, J = 13.6 Hz, 1H), 1.23–1.38 (m, 4H); anal. calcd. for $C_{14}H_{18}O_2$: C 77.03; H 8.31, found: C 77.3; H 8.3.

2b: The preparation was analogous to that for **2a** but with 2-anisyllithium [19] instead of phenyllithium. Yield 90%; m.p. 74–78 °C; $[\alpha]_D^{22} = +46$ ($c = 0.68$ in $CHCl_3$); IR (KBr): $\tilde{\nu}$ = 3555, 3500, 3070, 2935, 1595, 1580, 760 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$): δ = 7.27 (m, 2H), 6.97 (m, 2H), 4.59 (s, 1H), 4.36 (d, J = 9.8 Hz, 1H), 3.92 (s, 3H), 3.92 (m, 1H), 2.45 (m, 1H), 2.17–2.26 (m, 3H), 1.93 (m, 1H), 1.72 (dm, J = 13.5 Hz, 1H), 1.28–1.49(m, 4H); HRMS: calcd. for $C_{15}H_{20}O_3$ 248.1412, found 248.1414.

General procedure for the reduction of the ketones:
$Ti(OiPr)_4$ (0.18 mL, 0.064 M in *t*BuOMe, 0.012 mmol) was added to a mixture of diol (0.014 mmol) and powdered molecular sieves (500 mg, 4 Å) in *t*BuOMe (2.6 mL) at 0 °C. The resultant slurry was kept at room temperature overnight, whereafter the ketone (0.115 mmol) and hexane (0.29 mL) were added. After 30 min at room temperature this mixture was cooled to −50 °C (−40 °C for propiophenone), followed by addition of catecholborane (0.23 mL, 1 M in THF, 0.23 mmol). The progress of the reaction was monitored by GC analysis (Supelco SPB-5), and after consumption of all of the starting material 1 M HCl (2 mL) was added. The aqueous phase was extracted with ethyl acetate, and the combined organic phases were washed with 1 M NaOH and dried. Normal phase (Supelco SPB-5) and chiral phase (ALPHA-DEX 120) GC analyses were done on these extracts. The results are summarized in Table 1.

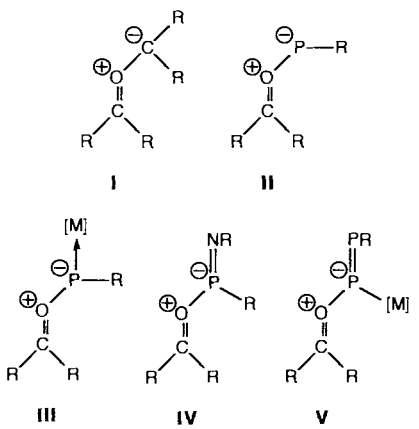
Unexpected Intramolecular Reactions of Intermediate Phosphacarbonyl Ylide Tungsten Complexes**

Rainer Streubel,* Annette Ostrowski, Hendrik Wilkens, Frank Ruthe, Jörg Jeske, and Peter G. Jones

Carbonyl ylides (**I**; Scheme 1) can be obtained by reactions of carbenes and carbenoids with aldehydes and ketones[1, 2] or by electrocyclic ring opening of oxiranes.[3] As 1,3-dipoles[4] they are mechanistically and preparatively of interest for heterocycle syntheses, and can be detected by intra- and intermolecular trapping reactions.[2] In reactions of carbonyl compounds with organophosphorus carbene analogues, such as phosphanediyls, electrophilic, terminal phosphanediyl metal complexes,[5] iminophosphanes,[6] or metallodiphosphenes,[7] the formation of phosphorus analogues (**II**–**V**) of carbonyl ylides has not yet

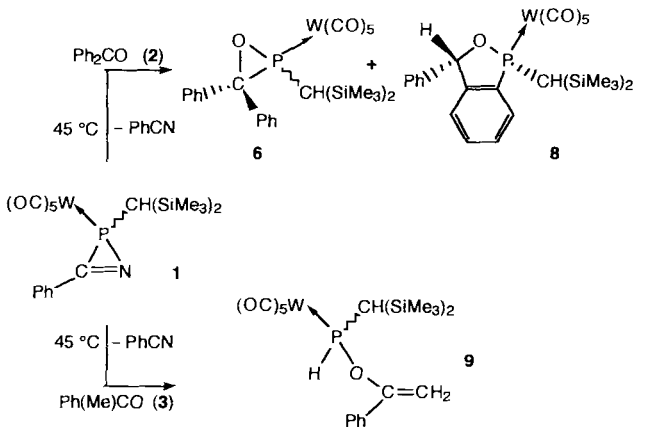


Scheme 1. Carbonyl ylides (**I**) and organophosphorus analogues (**II**–**V**) (R = alkyl, aryl; [M] = metal complex fragment).

been proved; thus, the course of the oxaphosphirane ring closure has not yet been elucidated. We recently reported the synthesis of an oxaphosphirane tungsten complex,[8, 9] and postulated a terminal phosphanediyl tungsten complex with benzaldehyde as an intermediate to rationalize the reaction.[10] Although a publication by Mathey et al. on Lewis acid/Lewis base adducts of electrophilic, terminal phosphanediyl tungsten complexes with phosphanes and amines has appeared,[11] the reactions of these carbene analogues with carbonyls remain unexplained, as do those with imines, which proceed under the formation of three-membered heterocycles.[12]

In order to investigate the course of the oxaphosphirane ring formation more closely, and to enable a comparison with the formation of azaphosphiridines, we have thermolyzed a 2*H*-azaphosphirene tungsten complex in the presence of benzophenone, acetophenone, and (*E*)-*N*-methyl(benzylidene)amine. Here we describe the new, and in some cases novel, complexes resulting from these reactions, and also report the first unambiguous evidence for a phosphacarbonyl ylide complex in the oxaphosphirane ring formation.

The thermolysis of the 2*H*-azaphosphirene tungsten complex **1**[13] in toluene at 45 °C in the presence of benzophenone (**2**) or acetophenone (**3**) takes an unexpected course in both cases. With benzophenone, the products are benzonitrile,[14] the oxaphosphirane tungsten complex **6**, and the benz[*c*]-1,2-oxaphospholane tungsten complex **8**. With acetophenone, the only product formed apart from benzonitrile[14] is the tungsten complex **9**, which bears a P–H function (Scheme 2). The products **8** and **9** can be readily separated by low-temperature chromatography and crystallization, whereas the oxaphosphirane tungsten complex **6** can only be obtained in reduced yield and is contaminated with 5–10% **8**. The suggested constitutions of compounds **6**, **8**, **9** are based on their NMR spectroscopic, (Table 1) IR, and MS data,[15] and are confirmed for **8** and **9** in the solid state by single-crystal X-ray structure analyses.[16, 17]



Scheme 2. Thermolysis of **1** in the presence of benzophenone (**2**) and acetophenone (**3**).

[**] Chemistry of 2*H*-azaphosphirene Complexes, Part 5. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 4: A. Ostrowski, J. Jeske, P. G. Jones, R. Streubel, *J. Chem. Soc. Chem. Commun.* **1995**, 2507.

It is noteworthy that the double phenyl substitution in the oxaphosphirane tungsten complex **6** leads to a significantly low-field-shifted resonance signal of the atoms of the three-membered ring, compared to those of the corresponding atoms in **10**[8] (**6**: $\delta^{31}P = 52.2$, $^1J(^{31}P,^{183}W) = 306.4$ Hz; $\delta^{13}C = 71.7$, $J(^{13}C,^{31}P) = 19.7$ Hz vs. **10**: $\delta^{31}P = 40.4$, $^1J(^{31}P,^{183}W) =$ 308.2 Hz; $\delta^{13}C = 59.7$, $J(^{13}C,^{31}P) = 27.3$ Hz). The presence of the 1,2-oxaphospholane ring in **8** is demonstrated, for example, by the ^{31}P resonance signal ($\delta = 140.4$, $^1J(^{31}P,^{183}W) = 273.5$ Hz), the ^{13}C resonance signal of the carbon atom directly bonded to oxygen ($\delta = 86.0$; $J(^{13}C,^{31}P) = 7.5$ Hz), and the presence of the signals of the arene unit. A remarkable spectroscopic feature of complex **9** is the ^{31}P resonance signal ($\delta = 95.4$, $^1J(^{31}P,^1H) = 329.2$, $^1J(^{31}P,^{183}W) = 276.5$ Hz) and also both resonance signals of the ethylene moiety in the ^{13}C NMR spectrum ($\delta = 95.1$ (d, $^3J(^{13}C,^{31}P) = 11.1$ Hz, $C{=}CH_2$); $\delta = 156.7$ (d, $^2J(^{13}C,^{31}P) = 9.1$ Hz, O-C=C)).

[{Ph(H)C–O–PCH(SiMe$_3$)$_2$}W(CO)$_5$] **10**

The molecular structures of compounds **8** (Figure 1) and **9** (Figure 2) in the crystal show some characteristic features. Compound **8** displays the typical envelope conformation of the 1,2-oxaphospholane unit (cf. [18]); the O atom lies 30 pm out of the P-C6-C7-C8 plane, and the tungsten atom adopts a distorted octahedral coordination with appreciably different C4-W-P and C3-W-P bond angles of 86.76(11) and 96.86(10)°, respectively. Compounds **8** and **9** display almost identical bond lengths at phosphorus, but a significant difference in the O6–C6 distances (146.3(4) vs. 139.0(4) pm).

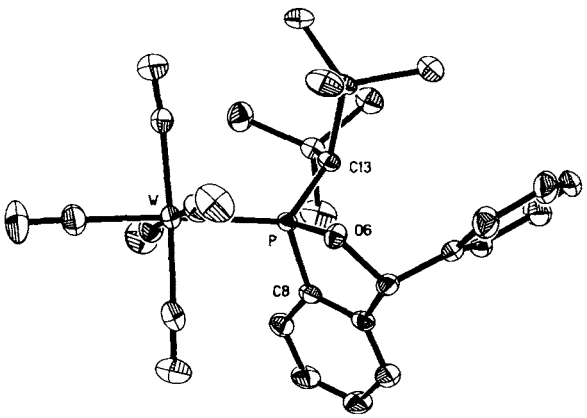

Figure 1. Molecular structure of **8** in the crystal (ellipsoids represent 50% probability levels; hydrogen atoms omitted for clarity). Selected bond lengths [pm] and angles [°]: P–W 249.17(10), P–C13 182.2(6), P–O6 164.1(2), P–C8 182.2(6); C8-P-O6 91.42(18), W-P-C13 125.21(12), W-P-O6 111.66(9), W-P-C8 114.14(11), C13-P-C8 106.0(2), C13-P-O6 102.74(14).

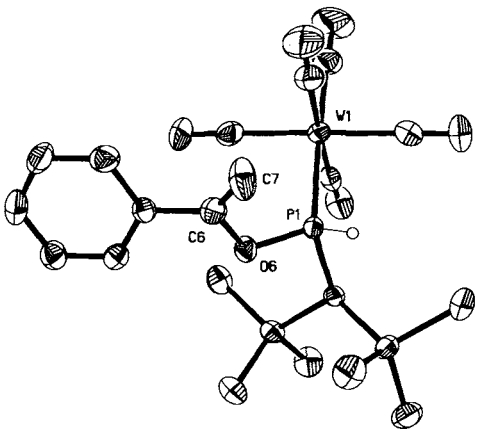

Figure 2. Molecular structure of **9** in the crystal (ellipsoids represent 50% probability levels; hydrogen atoms omitted for clarity). Selected bond lengths [pm] and angles [°]: P1–W1 248.18(9), P1–C14 181.1(3), P1–O6 164.5(2), O6–C6 139.0(4), C6–C7 131.6(5), O6-P1-C14 100.45(14), O6-P1-W1 118.9(9), C14-P1-W1 120.40(12).

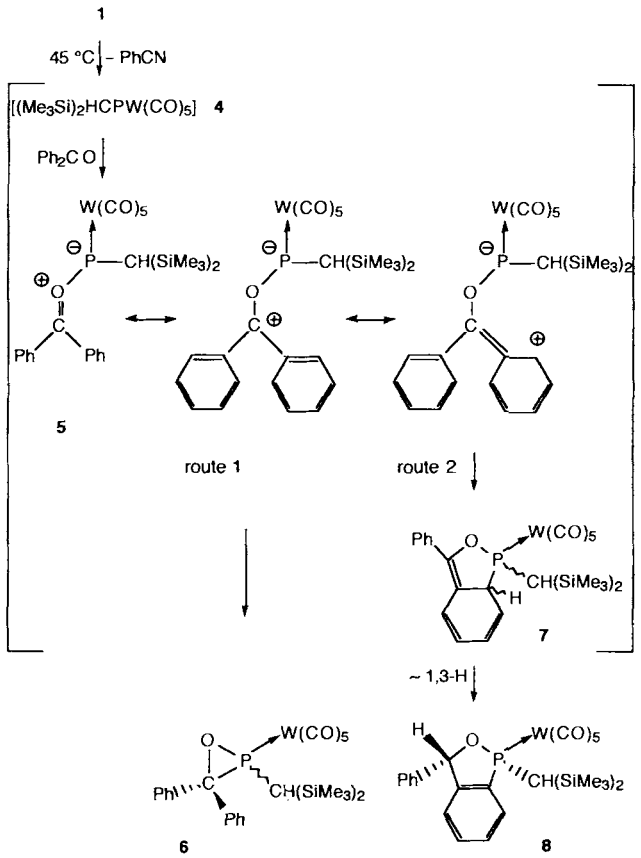
In order to throw more light on the mechanism of the cyclizations, we have investigated the influence of the following reaction conditions on the product ratio of **6** to **8** by using ^{31}P NMR spectroscopy: 1) the concentration of benzophenone (2 to 30 mmol), 2) the temperature (40 to 60 °C), 3) the reaction time (10 to 50 h). In fact, the product ratio of 1:1.7 **6**:**8** remained essentially constant, not significantly influenced by any of the above-mentioned parameters; the values varied between 1:1.6 and 1:1.8. Furthermore, warming **6** and **8** in toluene at 45 °C showed no interconversion of the oxaphosphirane to the oxaphospholane ring or vice versa (^{31}P NMR spectroscopy). These observations lead us to postulate the carbonyl ylide-analogous intermediate **5** as the common precursor of compounds **7** and **8**. The formation of **5** can be explained by a Lewis acid/Lewis base reaction of the transiently formed electrophilic phosphanediyl tungsten complex **4** with benzophenone,[19] and the remaining steps of the reaction can be described in terms of two routes (Scheme 3). Route 1 provides the oxaphosphirane tungsten complex **6** by a 1,3 ring closure; whereas a 1,5 ring closure by nucleophilic attack of the phosphorus atom on the allyl-cationic *ortho*-phenyl carbon atom of **5** leads to the further intermediate **7** (route 2). An immediate 1,3 hydrogen shift and subsequent rearomatization leads to the formation of the benz-[*c*]-1,2-oxaphospholane tungsten complex **8**. This suggestion would also be essentially consistent with the product ratio of about 1:1.7, but would not explain the deviation from the ideal



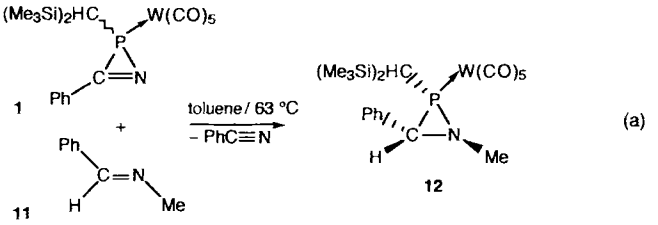
Scheme 3. Postulated reaction course for the formation of the three- and five-membered rings of the complexes **6** and **8**, respectively.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3604-0379 $ 15.00+.25 0

ratio of 1:2, since a priori each phenyl ring of the benzophenone can form part of an allyl cation system.

With acetophenone, compound **9** is formed rather than the corresponding oxaphosphirane- or benz[*c*]-1,2-oxaphospholane tungsten complex; this could be caused by a rapid rearrangement of a compound analogous to the intermediate **5**, involving migration of a hydrogen atom of the methyl group to the phosphorus (cf. ref. [20]).

Thermolysis of the 2*H*-azaphosphirene tungsten complex **1** in toluene at 63 °C in the presence of (*E*)-*N*-methyl(benzylidene)-amine (**11**) leads to the azaphosphiridine tungsten complex **12**, benzonitrile,[14] and about 5% of an inseparable by-product[21] [Eq. (a)].



The assumption that the terminal phosphanediyl tungsten complex **4** undergoes a [1,2] addition to the C–N double bond of **11**, is also plausible for the formation of complex **12**, since, for example, five-membered heterocycles were not observed as products of a phosphanitrile ylide (cf. ref. [8]). The constitution of the azaphosphiridine tungsten complex **12** is shown unambiguously by the NMR spectroscopic details (Table 1) and the mass spectrometric data.[22] In comparison to the ^{31}P resonance signal of noncomplexed azaphosphiridines,[23] that of **12** ($\delta = -37.3$, $^1J(^{31}P,^{183}W) = 269.1$ Hz) is shifted to low field by $\Delta\delta \approx 30$. This effect of a metal complex fragment on the ^{31}P resonance signal of phosphorus atoms in three-membered heterocycles has already been observed for other, related classes of compounds.[24] Since the stereochemical arrangement of the ring substituents in **12** was not unambiguous from the spectra, and because no solid-state structural data were known for the azaphosphiridine ring system, we were particularly interested in an X-ray structure analysis of compound **12**. The results[25] (Figure 3) confirm the structural relationship of **12** to the oxaphosphirane tungsten complex **10** that we had described previously.[8] The formal replacement of the oxygen atom by an *N*-methyl fragment leads to an increase in the bond lengths of the three-membered ring, by which the bond lengths become more nearly equal. There is a marked increase in the exocyclic angle W-P-C14 (126.06(12)°) compared to the corresponding angle in **10** (121.4(2)°),[8] whereas the endocyclic ring angles C6-P-N or C6-P-O of 48.9(2)° and 50.3(3)°,[8] respectively, remain roughly constant; this is consistent with a reduction of steric strain. Particularly interesting is the arrangement of the ring substituents. Future studies will investigate whether this stereochemistry indicates a concerted [2 + 1] cycloaddition of the *E* isomer **11** with the phosphanediyl tungsten complex **4** or a two-step reaction of the *Z* isomer of **11** with **4** analogous to that described in Scheme 3.

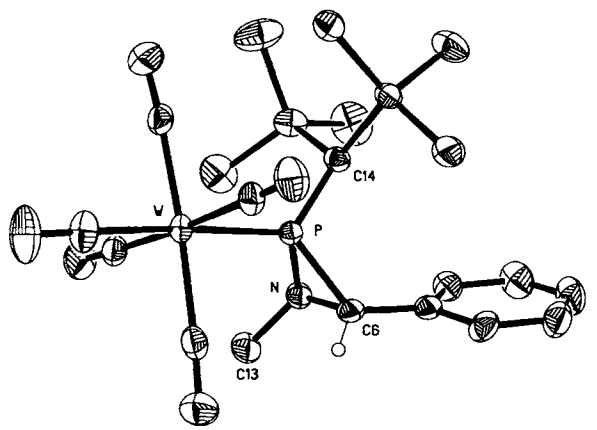


Figure 3. Molecular structure of **12** in the crystal (ellipsoids represent 50% probability levels; hydrogen atoms omitted for clarity). Selected bond lengths [pm] and angles [°]: W-P 249.64(10), P-C14 180.8(4), P-C6 183.5(4), C6-N 147.8(5), P-N 172.8(3); W-P-C14 126.06(12), W-P-C6 108.7(2), W-P-N 123.04(11), C6-P-C14 121.31(12), C6-P-N 48.9(2), P-C6-N 61.8(2), P-N-C6 69.3(2).

Experimental Section

6 and **8**: A solution of **1** (1.36 g, 2 mmol) in toluene (12 mL) was treated with benzophenone (**2**) (4.91 g, 27 mmol) under nitrogen at room temperature and stirred for 43 h at 45 °C (monitored by ^{31}P NMR spectroscopy). The yellow reaction mixture was evaporated to dryness under reduced pressure and dissolved in pentane. Excess benzophenone was removed by crystallization at −60 °C and filtration. The products were separated by two column chromatography runs on silica gel (−20 °C, 1. hexane/Et_2O (97.5:2.5) and 2. hexane/toluene (8:2)). The eluates were evaporated to about 5 mL under reduced pressure and cooled to −30 °C. The resulting solids (**6**,**8**) were washed with a little pentane and freed of remaining solvent traces in vacuo (ca. 10^{-3} mbar). Crystallization from pentane at +6 °C gave yellow crystals of **8**. **6**: colorless powder, yield: 0.05 g (0.07 mmol; 4%), m.p. 113 °C (decomp); **8**: light yellow powder, yield: 0.58 g (0.8 mmol; 42%), m.p. 136 °C (decomp).

9: **1** (0.62 g, 1 mmol) in toluene (5 mL) was treated with acetophenone (3 g, 25 mmol); the mixture was stirred for 21 h at 45 °C. The yellow solution was evaporated to dryness under reduced pressure, and the residue subjected to column chromatography on silica gel (−15 °C, hexane/Et_2O). After the volume of the eluate had been reduced, **9** was obtained as a yellow powder. Crystallization from pentane at +6 °C gave yellow crystals of **9**, yield: 0.43 g (0.68 mmol; 68%), m.p. 74 °C (decomp).

12: **1** (0.62 g, 1 mmol) was dissolved in toluene (3 mL) and treated with (*E*)-*N*-methyl(benzylidene)amine (**11**) (2.7 mL, 24 mmol). The mixture was stirred for 8 h at 63 °C and then evaporated to dryness in vacuo. The residue was subjected to column chromatography on silica gel (−15 °C, hexane/Et_2O). After the volume of the eluate had been reduced, a yellow oil was obtained, from which **12** formed as a yellow solid. This was washed with a little cold pentane and recrystallized from pentane at −30 °C in the form of light yellow crystals: yield: 0.16 g (0.26 mmol; 26%), m.p. 136 °C (decomp).

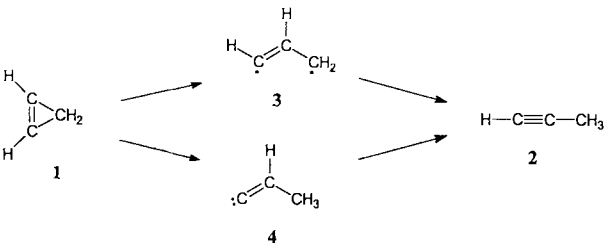
Direct Study of a Nondegenerate Cyclopropene-to-Cyclopropene Isomerization**

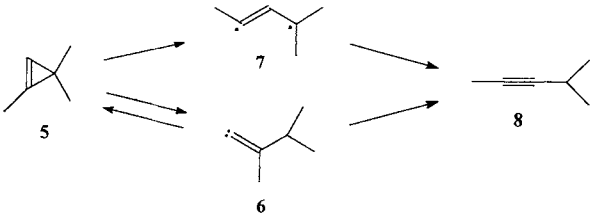
Henning Hopf,* Wilhelm Graf von der Schulenburg, and Robin Walsh*

Until 1989 the mechanism of the thermal isomerization of cyclopropene (**1**) to propyne (**2**) was thought to proceed via the propene-1,3-diyl (**3**) intermediate formed by ring opening of **1**. A subsequent 2,3 hydrogen-shift results in **2**.[1] In that year, Yoshimine et al.[2] proposed a different mechanism on the basis of ab initio calculations at the SDQCI(DZP) and MRCI*(DZP) levels. They suggested a propenylidene (**4**) intermediate, which is formed by ring opening with a synchronous 1,3 H-transfer. This is then followed by a 2,1 H-shift.



At that time, existing experimental studies were unable to distinguish between these alternatives. However, in 1992 Walsh et al.[3] found that alkyne formation was 18 times slower for 1,3,3-trimethylcyclopropene (**5**) than for 3,3-dimethylcyclopropene. They argued that this is due to the 2-methyl-2-isopropylvinylidene intermediate (**6**, formed from **5**), which is an analogue of **4** (formed from **1**).

The reason why **6**, rather than *trans*-4-methylpent-2-ene-2,4-diyl (**7**), can lead to a rate reduction is provided by the second step of the isomerization (**6** → **8**), which involves an alkyl



(methyl or isopropyl) rather than an H-shift. The expected lower rate of the alkyl shift makes the second step rate-determining.[3] This slows the overall reaction and implies reversibility of the first step (**5** → **6**). We have recently confirmed[4] the generality of the mechanism of alkyne formation from cyclopropene via a

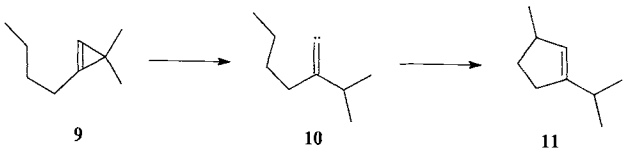
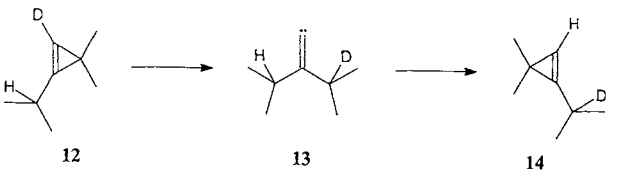
vinylidene intermediate by the intramolecular trapping of the alkyl vinylidene **10**, which is formed in the conversion of cyclopropene **9** into cyclopentene **11**.



9 **10** **11**

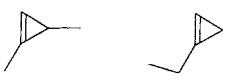
Likhotvorik et al.[5] have found evidence for a vinylidene intermediate in an elegant deuterium-scrambling experiment. Although the product yields are very low (0.5% of **14** for 90% conversion of **12**), this result offers direct confirmation of the



12 **13** **14**

reversibility of cyclopropene ring opening. We have found further suggestive evidence for this process in a pyrolytic kinetic study of a series of 1-alkyl-3,3-dimethylcyclopropenes.[6] In this case, the probable isomeric cyclopropenes were formed in only 2–3% yields and were unstable under pyrolytic conditions.

To provide more concrete evidence for the reversibility of the initial ring-opening step, we looked for a derivative of 1-alkylcyclopropene for which higher yields of an alternative, isomeric cyclopropene are formed during decomposition. 1,3-Dimethylcyclopropene (**15**) and 1-ethylcyclopropene (**16**) have been prepared by published procedures,[7, 8] and the kinetics of their pyrolyses investigated.



15 **16**

To avoid losses by oligomerization, both compounds were stored at low temperatures (−26 °C) until shortly prior to the kinetic investigations. Gas phase kinetic studies were carried out in a pyrex vessel immersed in a stirred molten salt thermostat (static method). The temperature was controlled to ±0.1 K. The gaseous mixtures investigated contained 2.0±0.2% each of reactant (**15** or **16**) and pentane (internal standard) diluted in nitrogen. Six to eight runs were carried out at a total pressure of 50 Torr of reactant mixture for times that provided between 10 and 90% conversions at each of five temperatures (**15**: 482–522 K, **16**: 472–512 K). Products were quantitatively analyzed by GC (FID detector, electronic signal integration) on a packed β,β-oxydipropionitrile (ODPN) column at 40 °C. This resulted in a full separation of the products. Two examples of the chromatograms are shown in Figure 1. Pent-2-yne (**17**), (*E*)-penta-1,3-diene (**18**), (*Z*)-penta-1,3-diene (**19**), penta-2,3-diene (**20**), and penta-1,2-diene (**21**) were identified by NMR spectroscopy, and their column retention times compared with authentic samples. The C_5H_8 isomers were completely recovered (100±2% relative to *n*-pentane added). Figure 2 shows the time evolution curve for the decompositions of **16**; a similar graph was obtained for the pyrolysis of the isomer **15**.

The chromatograms clearly show formation of **16** from **15** and vice versa. The product evolution curves indicate that each isomer has intermediate character when formed from the other.

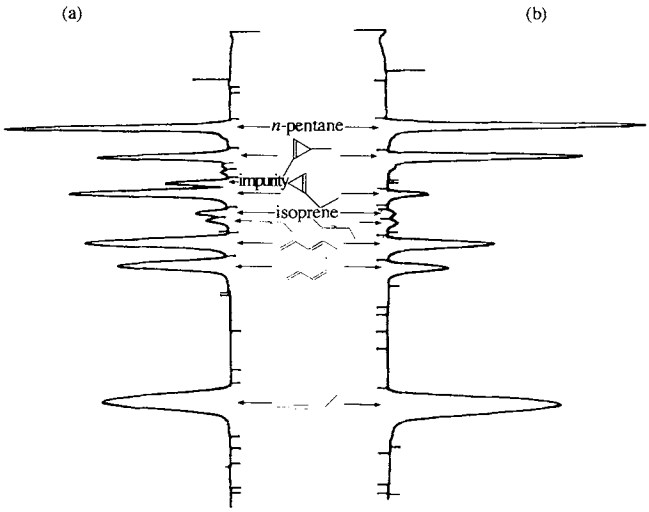


Figure 1. Gas chromatograms of cyclopropene pyrolysis product mixtures (ODPN column, 40°C): a) pyrolysis products of **16**, 198.7 °C, 600 min; b) pyrolysis products of **15**, 208.4 °C, 480 min.

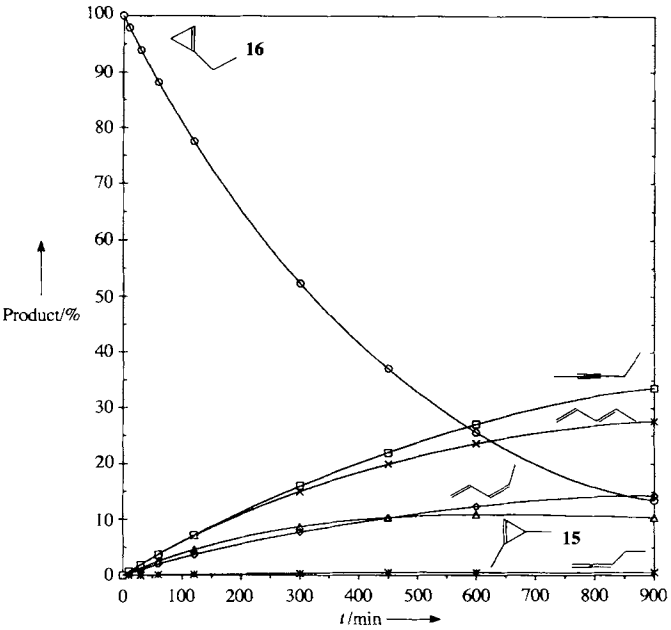

Figure 2. Product time evolution curves for the decomposition of **16** at 198.7 °C.

This is clearly seen in Figure 2 where yields of **15** formed from **16** approach 10% of the total mixture (at their maximum). Yields of **16** formed from **15** only reach about 1.1%, but a maximum is nevertheless also clearly visible. The formation of isomeric cyclopropenes and interconversion of **15** and **16** is unambiguously demonstrated by these data.

Rate constants for reactant disappearance were first obtained by a simplified procedure, which neglected reversibility and treated the reaction as first-order. This provided reasonably linear logarithm (% reactant) versus time plots. The temperature dependencies of the obtained rate constants gave the Arrhenius parameters shown in Table 1.

Subsequently, a more complex analysis with the Gear algorithm was undertaken to correlate the time evolution curves with the mechanism shown in Scheme 1. The rate constants were refined for an optimal fit to the analytical data at each temperature. Arrhenius parameters were obtained for all products, but, for reasons of space, only those for the direct transformation

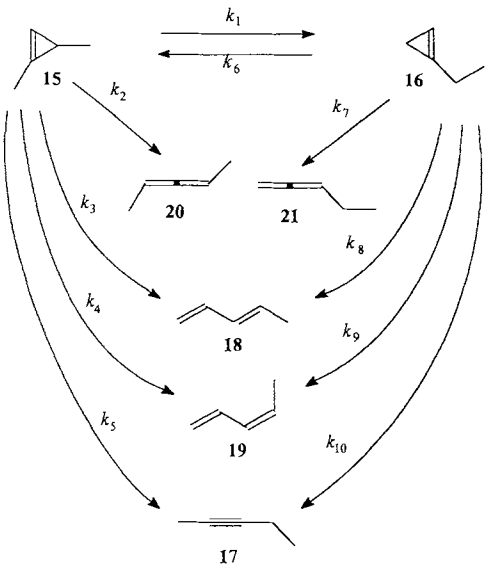
Table 1. Arrhenius parameters for the overall decomposition and selected pathways of 1,3-dimethylcyclopropene (**15**) and 1-ethylcyclopropene (**16**).

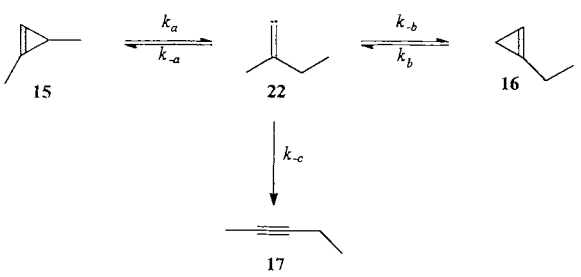
Reaction	lg (A/s^{-1})	E_a/kJ mol^{-1}
 overall decomp.	13.36 ± 0.08	164.0 ± 0.8
	12.29 ± 0.07	166.2 ± 0.6
 overall decomp.	13.36 ± 0.09	160.7 ± 0.9
	12.26 ± 0.06	156.9 ± 0.5
	13.27 ± 0.04	161.6 ± 0.4
	12.85 ± 0.05	158.6 ± 0.5



Scheme 1. Mechanism of the thermal isomerization of **15** and **16**.

15 → **16** are shown in Table 1. Variation of total pressure, alteration of reaction vessel surface-to-volume ratio, and addition of radical inhibitors show that these reactions are truly homogeneous and unimolecular at their high pressure limits.

Apart from providing dramatic support for the importance of vinylidene intermediates in the cyclopropene decomposition process, these results permit a deeper analysis. Scheme 2 shows the mechanistic pathways involving ethylmethylvinylidene (**22**). The elementary constants presented are related to the experimental rate constants[9] and can be analyzed to provide, firstly, the rate constants for the actual ring-opening steps (a) and (b)



Scheme 2. Ethylmethylvinylidene (**22**) as an intermediate in the **15** → **16** interconversion.

and, secondly, the relative rate constants for the ring-closing steps (− a) and (− b) as well as the alkyl migration step (− c) for **22**. Arrhenius parameters for (a) and (b) are given in Table 1.

This analysis shows that ring opening of both **15** and **16** via **22** occurs nearly twice as rapidly as formation of pent-2-yne (**17**). Thus $k_a/k_5 = k_b/k_{10} = 1.712 \pm 0.015$ (values only very slightly temperature-dependent). This helps explain why alkyne formation from 1-alkyl-substituted cyclopropenes is so much slower than for cyclopropenes without 1- or 2- substitution.[3, 6] Furthermore, the relative values of $k_{-a}:k_{-b}:k_{-c}$ are 0.380:0.035:0.585 (almost independent of temperature). Somewhat contrary to our expectations, this result shows that the alkyl migration step (methyl or ethyl) is the most favored for **22**. It also indicates that of the two other steps, by which the vinylidene reverts to cyclopropenes (formally 1,3 H-insertion processes), formation of **15** is favored over that of **16** by a factor of about 11. This outcome is understandable, since it indicates the reasonable preference for secondary over primary C–H insertion. Despite the preference of **22** for alkyl group migration (− c), this study shows that this step must be relatively slow (as proposed[3]). Furthermore, it must have a significant energy barrier to rearrangement, since it is competitive with the C–H insertion processes (− a) and (− b). Yoshimine et al.[2] have calculated that the energy of methylvinylidene (**4**) is approximately 86 kJ mol^{-1} lower than the transition state for rearrangement of cyclopropene **1** → **2**. This value corresponds to the energy barrier for C–H insertion; a thermochemical estimate is about 50 kJ mol^{-1}.[10] Thus, the alkyl migration barrier must be of comparable energy for step (− c) to be competitive. This contrasts with the almost zero energy barrier calculated for the migration of an H atom for **4** → **2** (and for the parent vinylidene[11]).

These findings open the way for obtaining considerable information on the behavior of vinylidenes. These species are of importance in high-temperature pyrolytic processes of unsaturated hydrocarbons,[12–14] including the oligomerization of acetylene leading to polyaromatics.[15] Complete details of these results and a thorough discussion will appear in a full paper.

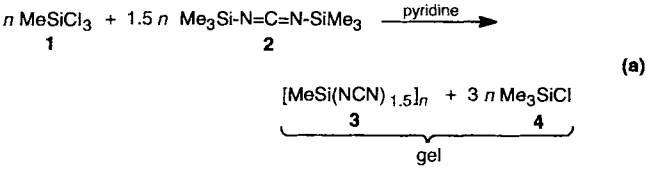
Preparation of Non-Oxidic Silicon Ceramics by an Anhydrous Sol–Gel Process**

Andreas O. Gabriel and Ralf Riedel*

The sol–gel process for the synthesis of oxidic glasses and ceramics has been the subject of intensive investigations in synthetic inorganic chemistry and is used in a wide range of technical applications.[1, 2] However, it was limited hitherto to systems containing oxygen.[2] We now report on the first anhydrous sol–gel process for the synthesis of oxygen-free silicon ceramics.

The reaction of trichloro(methyl)silane (**1**) with the carbodiimide synthetic building block bis(trimethylsilyl)carbodiimide (**2**) and a pyridine catalyst produces a transparent, dimensionally stable gel [Eq. (a)]. The reaction is performed without solvents. The reaction time to the gel point can be altered by varying the amount of pyridine and by changing the reaction temperature (Figure 1). The reaction mixture also gels at room temperature and without pyridine. For example, with 0.25 equiv pyridine (with respect to **1**), the reaction time to the gel point increases from 6 h (reflux temperature) to 24 days (room temperature).



(a)

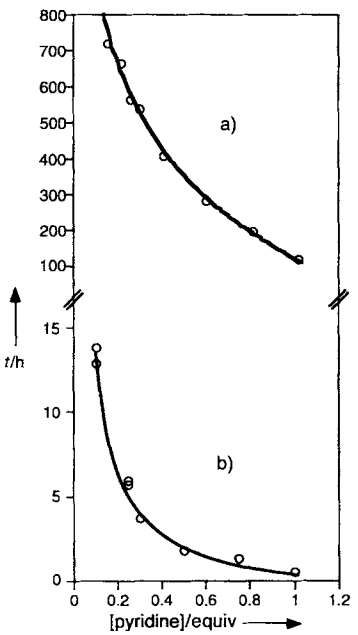


Figure 1. Dependence of the reaction time to the gel point on the pyridine concentration for the reaction of **1** with **2** without solvent a) at room temperature, and b) at reflux temperature.

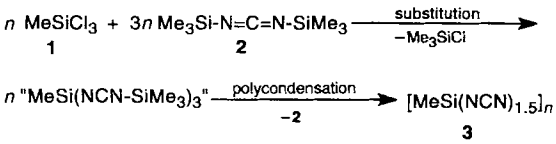
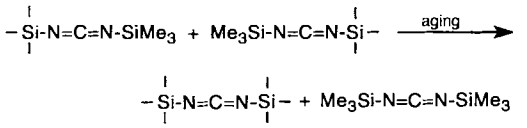
Reaction (a) proceeds completely analogously to the known aqueous sol–gel process; the carbodiimide **2** adopts the role played by water in the substitution and condensation steps [Eq. (b)]. During the aging process, the number of bonds in the gel network is increased by progressive polycondensation. The FT-IR spectra of the nonaged gels reveal the presence of trimethylsilyl end groups; these are no longer detectable by spectroscopy after the aging process [Eq. (c)]. Therefore, the



(b)

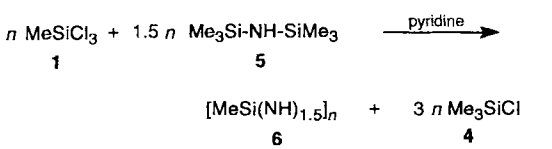


(c)

condensation reactions are not complete at the gel point, but continue during the aging process. The rate of aging is not only a function of the amount of pyridine, but also a function of the temperature: a higher pyridine content and a higher aging temperature (20–45 °C) accelerate further cross-linking. During the aging process there is no phase change to give a crystalline solid. The xerogel **3** obtained after drying (3×10^{-2} mbar, 130 °C) is X-ray amorphous. Furthermore, the in-situ X-ray powder diffractograms do not show any reflections in the temperature range between room temperature and 850 °C which could indicate crystalline phases.

The controlled aging of the gel is characterized by crack-free, three-dimensional shrinkage. Thus, for a pyridine content of 0.3 equiv with respect to **1**, shrinkage is complete after about four weeks. It is irreversible, and the rate of shrinkage is likewise dependent on the temperature and the concentration of catalyst. Immediately after gelation, the gel is transparent. On aging the gel becomes cloudy. On slow evaporation of the liquid phase, it converts into the transparent xerogel **3**. The gel shrinks during the aging process to 25% of the original volume. After the liquid phase was decanted off, and the remaining liquid removed by slow evaporation, the gel shrinks linearly by a further 10%. Measurements of the porosity revealed that the gel is very dense; no micropores could be detected.[3]

In contrast, on treating **1** with hexamethyldisilazane (**5**) there was no gelation, but only precipitation of a solid, **6**[4] [Eq. (d)].



(d)

Thus, the carbodiimide group seems to be the decisive factor in the nonaqueous sol–gel process presented here. The intact carbodiimide groups of **3** were detected by FT-IR spectroscopy ($\tilde{\nu}_{as}$(N=C=N) = 2152 cm^{-1}) and by Raman spectroscopy ($\tilde{\nu}_{s}$(N=C=N) = 1533 cm^{-1}) not only in the freshly prepared gel, but also in the aged gel. This is in agreement with the results from the treatment of **2** with dichloro(dimethyl)silane[5, 6] as

well as tetrachlorosilane.[7] $SiCl_4$ reacts with **2** in an analogous manner to that shown in Equation (a) to give a methyl-free gel of composition SiC_2N_4. After calcination of this xerogel the first crystalline phases in the ternary Si-C-N system could be isolated and characterized.[7]

The thermally induced ceramization of xerogel **3** was investigated by simultaneous thermal analysis (STA) between room temperature and 1500 °C in He. This indicated the yield of ceramic to be 60%. Between 560 and 590 °C a mass loss of 20% was measured, which is accompanied by an exothermic reaction (Figure 2). The decomposition products determined in situ by

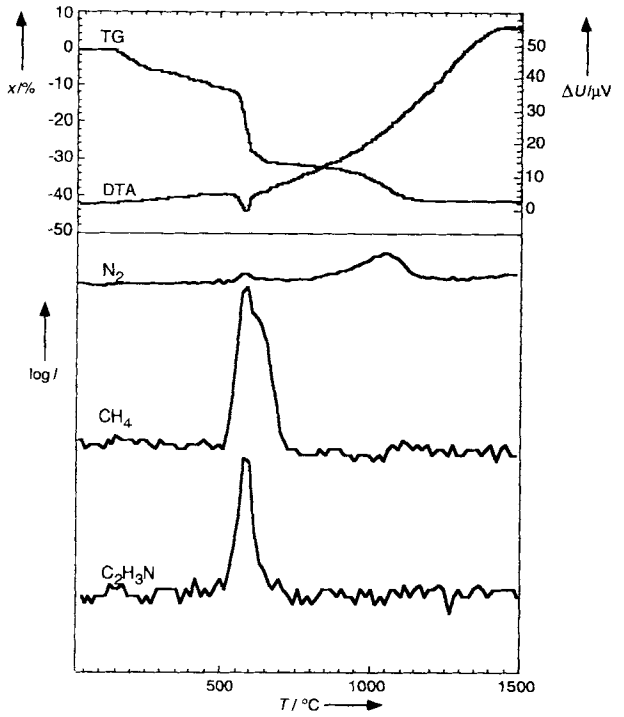

Figure 2. Thermogravimetric (TG) analysis (mass loss x [%]) and differential thermal analysis (DTA; ΔU [μV]) of dried xerogel **3**, as well as the monitoring of the pyrolysis under Ar by mass spectrometry of the product gases N_2, CH_4, and C_2H_3N. Heating rate: 2 K min^{-1}.

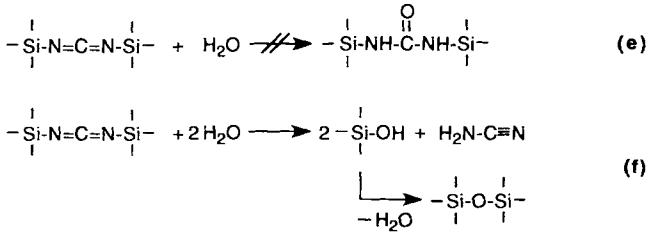
mass spectrometry were identified as predominantly methane (m/z 16) and acetonitrile or methyl isonitrile (m/z 41), and their fragments. Between 850 and 1120 °C there was a further mass loss of about 10%, which is attributed to the cleavage of nitrogen (Figure 2).

FT-IR investigations of samples annealed at different temperatures revealed that during decomposition between 500 and 600 °C the deformation vibrations $\gamma = 1270\ cm^{-1}$ of the Si-CH_3 groups were not detected after thermal treatment. After annealing of **3** above 800 °C the intensity of the carbodiimide vibrational band at 2152 cm^{-1} decreased continuously; however, it was still detectable by FT-IR spectroscopy at 1200 °C.

The thermoanalytical and spectroscopic results correlate very well with the elemental analytical data of **3**: the elemental composition of **3**, $SiC_{2.5}N_3H_3$ changes to $SiC_{1.23}N_{2.50}$ and to $SiC_{1.12}N_{1.63}$ after tempering at 700 and 1200 °C, respectively.

Xerogel **3** is very sensitive to hydrolysis on account of the carbodiimide groups. In contrast to organic diimides, **3** does not react with formation of a urea derivative, but with hydrolytic cleavage of the silyl groups [Eqs. (e) and (f), respectively].[8]



There is no indication of the presence of the carbonyl vibration of the urea derivative in the FT-IR spectra. After a short exposure of **3** to air, the IR spectrum displays a broad band at 3272 cm^{-1} (SiO-H and N-H), an intense band at 1063 cm^{-1} (Si-O-Si), and a band at 1578 cm^{-1} (H_2N-CN). The shift of the vibrational bands at 2152 cm^{-1} (carbodiimide group) to 2264 cm^{-1} (cyanamide) points to hydrolysis in accord with Equation (f).

The anhydrous sol-gel process allows the implementation of a whole series of technologically relevant production processes, which are already known from conventional sol-gel techniques. At the moment we are working on the synthesis of silicon carbonitride ceramics in the form of nanospherical powders, monolithic structural parts, fibers, and membranes as well as on the coating and infiltration of porous substrates. In addition, the transfer of this novel sol-gel process to other elements is under further investigation.

Experimental Section

All the reactions were carried out in pre-heated glass vessels in an anhydrous stream of argon. The samples for the IR (KBr) and Raman investigations were prepared and measured under inert gas. The STA measurements (Netzsch 429, mass spectrometer: Balzers QMG 420) were performed under helium with a heating rate of 2 K min^{-1}.

2: *Method a*: Cyanamide (2.5 mol, 105 g) in anhydrous THF (150 mL) was slowly added dropwise with vigorous stirring to hexamethyldisilazane (2.5 mol, 403 g). The reaction was initiated by gentle heating, which lead to the evolution of ammonia. The remaining dissolved cyanamide was subsequently added dropwise very slowly at room temperature. After the evolution of ammonia was complete, the reaction mixture was heated to reflux for about 1.5 h until no more gas was evolved under these conditions. The solid components that had formed were filtered off under inert gas, and the filtrate concentrated, followed by fractional distillation of the residue (twice) over a 30 cm Vigreux column. At 164 °C, 377 g (2.03 mol, 81% yield) **2** was obtained. – *Method b* [10]: A mixture of dicyanodiamide (42 g), hexamethyldisilazane (177 g), and ammonium sulfate (0.2 g) was heated to reflux for 8 h. Distillation (twice) over a Vigreux column at 164 °C gave 134 g (72%) **2**. The spectroscopic data correspond to those given in ref. [8,9].

$[MeSi(NCN)_{1.5}]_n$ (gel): **2** (20.0 g, 107 mmol) was treated with **1** (10.7 g, 71.6 mmol) under inert gas. After addition of pyridine (566 mg, 10.7 mmol), the mixture was heated to 90 °C. The gel point was reached after 13 h. The reaction mixture was aged at 45 °C. The gel point could be changed by varying the amount of pyridine added and/or the reaction temperature. At room temperature and with 10.7 mmol of pyridine, the reaction mixture gelled after 50 d. After completion of the aging process, excess liquid was decanted off, and the remaining liquid evaporated at 50 °C under inert gas, to produce a transparent, shaped xerogel. FT-IR (KBr): $\tilde{\nu}$ = 2965 (SiMe), 2152 (NCN), 1270 (SiMe), 748 cm^{-1} (SiN); Raman: $\tilde{\nu}$ = 2974 (SiMe), 2906 (SiMe), 1533 cm^{-1} (NCN); ^{29}Si CP/MAS-NMR (300 MHz): δ = −62.3; elemental analysis [11] (calcd for $C_{2.5}H_3N_3Si$ (103.16): C 29.11, N 40.73, O 0.00, Si 27.23): C 28.75, N 38.3, O 0.28, Si 26.9; (700 °C): C 19.0, N 44.8, O 0.26; pyrolysate (1200 °C): C 21.1, N 34.4, O 0.32.

Asymmetric Mannich Synthesis of β-Amino Acids with Two New Stereogenic Centers at the α and β Positions**

Horst Kunz,* Andreas Burgard, and Dirk Schanzenbach

Dedicated to Professor Leopold Horner on the occasion of his 85th birthday

Chiral β-amino acids are important constituents of natural products and drugs, for example peptides,[1] antibiotics,[2] and cytostatics such as taxol.[3] In addition, they can be converted into β-lactams, which are a prominent class of antibiotics themselves.[4] By virtue of this background, the asymmetric synthesis of chiral β-amino acids has been receiving increasing attention. Apart from stereoconservative strategies starting from enantiomerically pure α-amino acid derivatives,[5, 6] conjugate addition reactions of amines and amides with α,β unsaturated carboxylic acid derivatives[5, 7] and reactions of imines with ester enolate equivalents[5, 8–12] have been employed in the stereoselective synthesis of these compounds. β-Amino acids containing stereogenic centers at the α and β positions have been synthesized by a Michael addition and subsequent alkylation.[13] Alternatively, the reaction of chiral ester enolates[8, 10–12] with imines often leads directly to β-lactams.[11, 12] In some cases, amino acid thioesters[10] or *N*-aryl β-amino acid esters[8] have been isolated as intermediates.

We have found that the zinc chloride-catalyzed Mannich reaction of 2,2-disubstituted silyl ketene acetals with *N*-galactosylaldimines furnishes β-amino acid esters in high yield and diastereoselectivity.[9] A further advantage of this synthesis is that the auxiliary can be removed and recovered by simple acidolysis of the *N*-glycosidic bond. Unfortunately, this process can not be applied to prochiral monosubstituted silyl ketene acetals with comparable success. In the case of sterically less hindered silyl ketene acetals, zinc chloride catalyzes a rapid $O \rightarrow C$ *silyl shift* before the reaction with the imine can take place.

However, a general access to β-amino acids with two new stereogenic centers is provided by the reaction of *N*-galactosylimines **1** with bis(*O*-trimethylsilyl) ketene acetals[14] in the presence of zinc chloride in THF (Table 1). As a rule, yields and diastereoselectivities of these Mannich reactions between two prochiral components are high. Without exception, only two of the four possible diastereomers are formed. In most cases one of them is obtained in large ecxess.

Table 1. Asymmetric Mannich synthesis of α-branched β-amino acids.

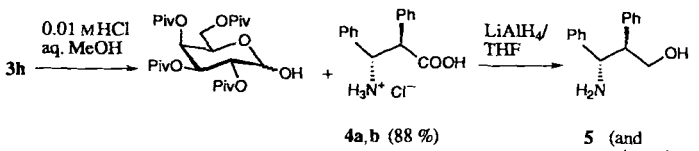
[a] 400 MHz ^{1}H NMR of crude product. Due to the betaine structure of the products, no satisfactory separation could be achieved by HPLC.

It is noteworthy that naphthaldimine **1e** and benzaldimine **1a** show low reactivity and only convert at about 0 °C. Nevertheless, the reaction of **1a** with the bis(silyl) ketene acetal **2a**, derived from propionic acid, to *give* **3a** proceeds with excellent diastereoselectivity. This also holds true for the reaction of **2a** with imines of substituted benzaldehydes. A second diastereomer was not unequivocally detected for products **3b**–**3d**. The *N*-galactosylimines **1b**–**1d** and **1f** as well as the aliphatic compound **1g** even react with the more demanding bis(silyl) ketene acetals with high diastereoselectivity. After conversion into the methyl esters with diazomethane, separation or a high degree of enrichment of the diastereomeric β-amino acid derivatives can be achieved.

In order to assign the configuration of the β-amino acids **3**, 2,3-diphenyl-β-alanine (**4**) is released from **3h** with 1 N HCl in methanol. Subsequent reduction with lithium aluminum hydride yields 3-amino-2,3-diphenylpropanol (**5**), for which all four stereoisomers have been described.[15, 16]

The ^{1}H NMR spectrum of **4** shows that the two diastereomers of **3h** (ratio 8:1, Table 1) contain enantiomers of the β-amino acid **4**. Comparison of the optical rotation value and the ^{1}H NMR spectrum of **5** with data reported in the literature[15, 16] proves that the *erythro* compounds **4a** and **4b** have been formed (Table 2) with **4a** (2*R*,3*S*) as the favored enantiomer. Provided that no epimerization occurs during reduction, this assignment of configuration should apply to all the β-amino acids **3** (Table 1).



Scheme 1. Determination of configuration of the β-amino acids **3** *by release of* **4** *from* **3h** *and subsequent reduction to* **5**; *only* **4a** *is shown.*

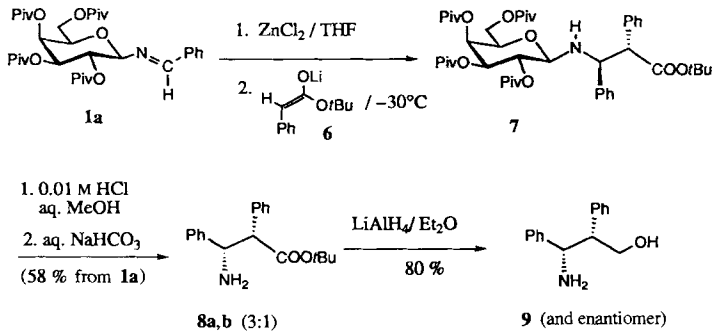
Interestingly, the reaction of the zinc chloride complex of **1a** with the lithium ester enolate **6**, derived from *tert*-butyl phenylacetate, exclusively yields *threo*-diastereomeric β-amino acid esters **7** (Scheme 2). Because partial cleavage of the *N*-glycosidic



Scheme 2. Reaction of **1a** with **6** in the presence of zinc chloride to form the *threo* diasteromeric β-amino acid esters **7**; only one enantiomer of δ is shown.

bond of **7** occurs during purification, the crude product is immediately converted into the amino acid ester **8** (overall yield 58%). The ratio of enantiomers is determined after amide formation with Mosher's acid.[17] Reduction to the amino propanol **9** and comparison of its optical rotation value and ^{1}H NMR spectrum with reported data[15,16] prove that the *threo*-enantiomers (ratio 3:1 in favor of the (2*S*,3*S*) enantiomer) have been exclusively obtained (Table 2).

Table 2. Assignment of configuration for **5** and **9** by comparison with ^{1}H NMR data [15,16] for the *erythro* and *threo* isomers (*J* in Hz).

$H_2N-\underset{H_C}{\overset{Ph}{C}}-\underset{H_X}{\overset{Ph}{C}}-\underset{H_B}{\overset{H_A}{C}}-OH$	J_{AX}	J_{BX}	J_{CX}	J_{AB}	$[\alpha]_D^{22}$ [a]	Configuration
erythro	9.3	2.7	9.0	11.3	+71.9	(2*R*,3*S*)
threo	6.0	6.0	8.0	6.0	−30.6	(2*S*,3*S*)
5 (*ee* 78%)	8.6	3.7	9.4	11.2	+55.0 (+56.0)	*erythro*
9 (*ee* ca. 50%)	6.3	6.3	7.7	6.3	−13.9 (−15.3)	*threo*

[a] $c = 3$, $CHCl_3$; calculated values in parentheses.

These results show that, remarkably, access to both series of α,β disubstituted β-amino acids diastereomers can be controlled by the choice of the C-nucleophile. Prochiral bis(silyl) ketene acetals selectively lead to *erythro* diastereomers, while only *threo* diastereomers are formed with lithium ester enolates. In the latter case, further examples and variations aimed at enhancing the asymmetric induction will be investigated. The *N*-galactosyl-β-amino acid esters **7** can be stabilized by *N*-acylation. This allows purification of these derivatives and should make enantiomers of the *threo* series accessible.

The astonishing concerted facial differentiation on both imine and bis(silyl) ketene acetal or lithium ester enolate can not yet be explained. The imine is attacked from the sterically less shielded *Si* side, thus yielding the major diastereomers **3** and **7** with (3*S*) configuration. Alternatively, when 2,3,4-tri-*O*-pivaloyl-α-D-arabinsylamine is used as the auxiliary instead of the galactosylamine, the opposite enantiomers of **4** and **8** can be synthesized by the same strategy.[18] In conclusion, all four stereoisomers of α- and β-substituted β-amino acids are stereoselectively accessible by the method described here.

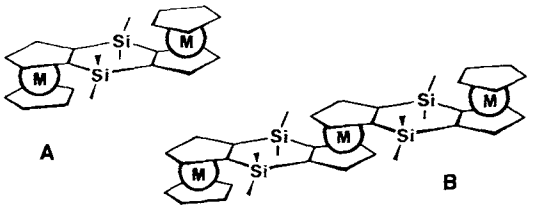
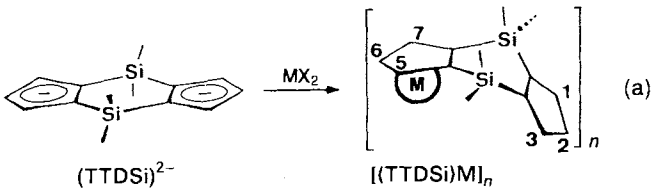
metal ions will introduce useful properties like conductivity and magnetism. In terms of studying whether next-neighbor interactions are the basis of the properties in question, investigations are best carried out with di- and trinuclear model compounds, because polymers are often less well defined. We have chosen this approach, and applied the doubly silyl-bridged biscyclopentadienyl ligand $(TTDSi)^{2-}$[3] in the metallocenes **A** and **B**.[4]



However, the shape of the polymer should also determine cooperative phenomena. Therefore, we have set out to study the polygemination[5] of $(TTDSi)^{2-}$ and metal dihalides (Scheme 1).



Scheme 1.

For M = Co and Ni, solids were obtained that are insoluble in all common organic solvents, as expected for polymeric $[(TTDSi)M]_n$.[6] In contrast, for M = Fe[7] the solid could be partly extracted with hexane. The soluble product had a molecular weight of 2200 Da, as determined by gel permeation chromatography (GPC).[8] The ^1H and ^{13}C NMR spectra[9] of the purified extract showed that only bridging ligands are present; in particular, no signals of a chain-terminating ligand were visible. The occurrence of two MeSi signals proved that, unlike the planar dianionic precursor $TTDSi^{2-}$,[3b] the ligand was bent and had methyl groups (pseudo)axial and equatorial with respect to the six-membered disila ring. In addition, two sets of signals for the bridged cyclopentadiene (Cp) rings indicated the presence of nonequivalent Cp rings. This was consistent with a cyclic oligomer $[(TTDSi)Fe]_n$, and the heaviest ion found in the mass spectrum[9] and the GPC pointed to $n = 7$.

The solvent-free orange compound proved rather thermally robust. Differential scanning calorimetry gave a curve that showed no melting point or phase transition up to 650 °C. Rather a step at 360–390 °C indicated the onset of decomposition, which was accompanied by a darkening of the sample. Block-shaped orange-red crystals were obtained from a solution in benzene by slow evaporation of the solvent. In a thermogravimetry experiment these crystals underwent a stepwise weight loss of 18% between 25 and 220 °C. This corresponds to the liberation of five to six solvate molecules per $[(C_{14}H_{18}Si_2)_7Fe_7]$ molecule, which we abbreviate as $[(TTDSi)Fe]_7$. The above-mentioned decomposition was evident from another weight loss of 35% between 360 and 580 °C.

Four of the benzene solvate molecules could be localized unequivocally in the X-ray crystal structure analysis,[10] the remaining benzene molecule showed disorder around a center of inversion. The structure of the oligomer is represented in Figure 1. It consists of seven ferrocene units linked by seven

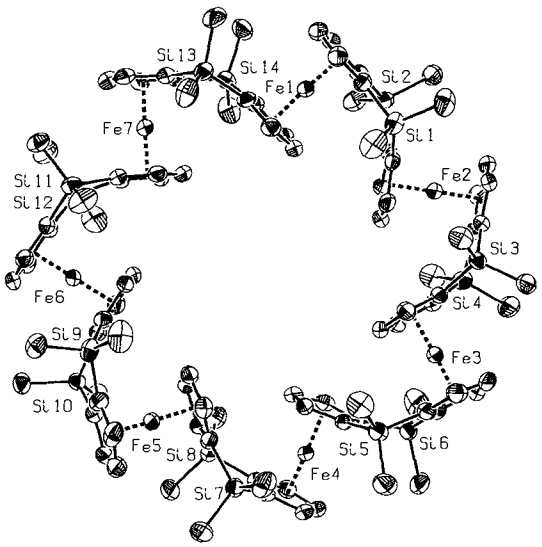


Figure 1. Crystal structure of $[(TTDSi)Fe]_7$. Distances [pm] given as mean values/range of distances: C–C 143.2/139.5(10)–146.5(8), Si–C 187.0/185.4(6)–188.8(8), Fe···Fe (next neighbor) 572.1/568.3(1)–576.4(1), Fe–Cp(center) 166.5.

pairs of Me_2Si groups in such a way that an almost regular cycle is formed. When idealized symmetry is assumed, the molecule belongs to the rare point group C_{7h}. In the crystal (space group $P\bar{1}$) the scoop wheel-like species are packed such that the orientation of the scoops alternates.

The two Cp rings of the bridging ligand alternately point slopingly in- and outside the cycle. At the periphery of the cycle "outer" Cp rings and pairs of CH_3 groups alternate, while seven $Si-CH_3$ bonds jut out of either side of the heptagonal plane. Thus, the molecule may be regarded as a wheel with a hydrocarbon tire, which provides good solubility. The "inner" Cp rings form another hydrocarbon layer, in which H2 [cf. Scheme 1] penetrates the cone of the chemical shift anisotropy above the neighboring Cp ring. This leads to a considerable shielding, which has been studied in detail with other sandwich compounds,[11] and shifts the NMR signal of H2 from $\delta = 4.30$ for the iron reference compound of type **A**[7a] to $\delta = 3.23$ for $[(TTDSi)Fe]_7$. The unique signal served as a basis for further assignments.[9] The distances given in the legend to Figure 1 do not deviate from common values. The cyclic structure allows only small deviations of the interplane angles (Figure 2) from the idealized values. Thus, the bend angle at silicon (129.2°) is close to the expected value of 128.6°, and, similarly, the average angle between the planes of every second Cp ring is 126.9°. A small bending (1.4–11.2°) exists between the Cp rings and the neighboring planes that contain two silicon atoms.

The cyclic voltammogram[12] of $[(TTDSi)Fe]_7$ (Figure 3) indicated three chemically reversible oxidations, which could be simulated with the successive transfer of three, one, and again

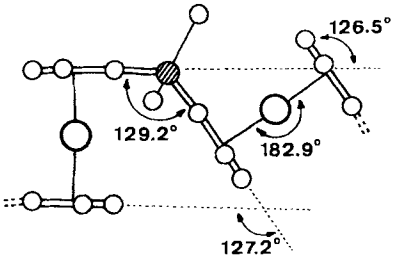

Figure 2. Bend angles of $[(TTDSi)Fe]_7$ (average values).

three electrons at $E_{1/2}$ = 5, 208, and 403 mV, respectively, relative to $E_{1/2}$ of $[Cp_2Fe]^0/[Cp_2Fe]^+$. We conclude from this that Coulomb interaction determines the stepwise oxidation. Thus, at first three charges are distributed on the cycle such that next-neighbor ferrocenium centers (see Figure 3) are avoided. Subsequently, a unique charge can be added that meets only one next-neighbor charge. The remaining three charges, which eventually make up the heptacation, meet two next-neighbor charges. Other cycles of this type with an uneven number of metal centers should show similar cyclic voltammograms. In contrast, the one-electron transfer should be missing for an even number of metal centers. Note that open chains behave in the opposite way.[13]

$[(TTDSi)Fe]_7$ may be regarded as a metallocenophane.[5, 14] Although the potential of the chemistry of metal-containing phanes[14, 15] has initiated numerous studies, there are very few well-characterized compounds in which more than three sandwich fragments are assembled in a cycle. In recent years considerable progress has been made in the synthesis of biscyclopentadienyls as components of bent-metallocene catalysts for the polymerization of olefins.[16] The suitable combination of such ligands with metal ions may allow the assembly of neutral and charged cycles of variable size.

[12] The cyclic voltammetric measurements were carried out in specially designed cells with an internal drying column filled with highly activated alumina. As working electrode a Pt electrode with a diameter of 1 mm sealed in soft glass was used. A Pt wire, wrapped around the working electrode, served as counter electrode. Cyclic voltammetry was performed with a Jaissle potentiostat IMP 88 and a PAR 175 programmer. The oxidations were measured in a mixture of CH_2Cl_2/CH_3CN (1/1). All potentials were determined relative to internal cobaltocenium-perchlorate (− 0.96 V vs. Ag/AgCl) and then related to ferrocene (0.35 V vs. Ag/AgCl).

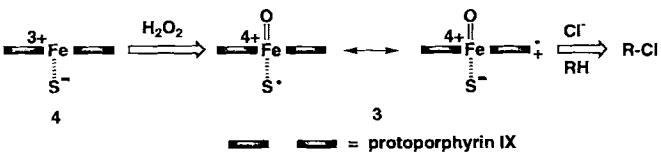
New Active-Site Analogues of Chloroperoxidase—Syntheses and Catalytic Reactions**

Hans-Achim Wagenknecht and
Wolf-Dietrich Woggon*

The heme–thiolate proteins comprise a large number of important enzymes such as cytochrome P450,[1] NO-synthase,[2] and chloroperoxidase (CPO).[3] The inherent reactivity of these enzymes is attributed to an iron protoporphyrin IX complex located at the active center. It is connected to the protein by hydrogen bridges of the two propionate side chains, hydrophobic interactions, and a thiolate ligand coordinated to the iron. The thiolate ligand is delivered by a cysteine residue in a highly conserved area of the protein and is placed at the face of the porphyrin opposite to the binding site of oxygen and the substrate. The thiolate ligand plays a crucial role in the reactivity of the heme group[4] and influences the redox potential of the iron porphyrin.[5] Furthermore, X-ray structure determinations of different forms of cytochrome $P450_{cam}$[6] and CPO[7] revealed that S^- is also hydrogen-bonded to two peptide amide groups.

CPO, first isolated from the fungus *Caldariomyces fumago*,[8] is the most versatile of the heme–thiolate proteins. It can catalyze the halogenation of activated C–H bonds as well as other reactions that are known for peroxidase, catalase, and cytochrome P450.[1] Except for a few details, the reaction mechanisms of the latter three reactions are well understood.[9] The halogenation of activated C–H bonds is catalyzed by CPO in the presence of H_2O_2 and Cl^- at pH = 3. In this way, 1,3-diketones such as monochlorodimedone (**1**) react to form 2,2-dichlorodimedone (**2**). It has been suggested[10] that the chlorination proceeds via compound **3**, which is produced by the reaction of the enzyme's resting state **4** with H_2O_2 (Scheme 1).



Scheme 1. Reaction of H_2O_2 with the resting state of **4** from CPO to yield **3**, the high-valent oxoiron(IV) intermediate of the catalytic cycle.

Furthermore, it may be that **3** reacts with Cl^- and, depending on the concentration of Cl^-, either Cl_2 or HOCl is released into solution where halogenation of the substrate RH occurs.[10]

The participation of a "free, halogenating species" is in agreement with the observation that halogenation of small, apolar substances often proceeds nonstereospecifically.[11] In contrast, however, the CPO-catalyzed addition of HOBr (KBr, H_2O_2, pH = 3.0) on a highly substituted glycal occurs stereospecifically.[12] Despite numerous investigations of the enzyme,[13] the mechanism of chlorination and identification of significant reactive intermediates remain elusive.

We report here on the design, syntheses, and catalytic reactivity of new active-site analogues of CPO as well as on their significance with regard to the native enzyme. Our main objective was to prepare a heme–thiolate enzyme model, which could

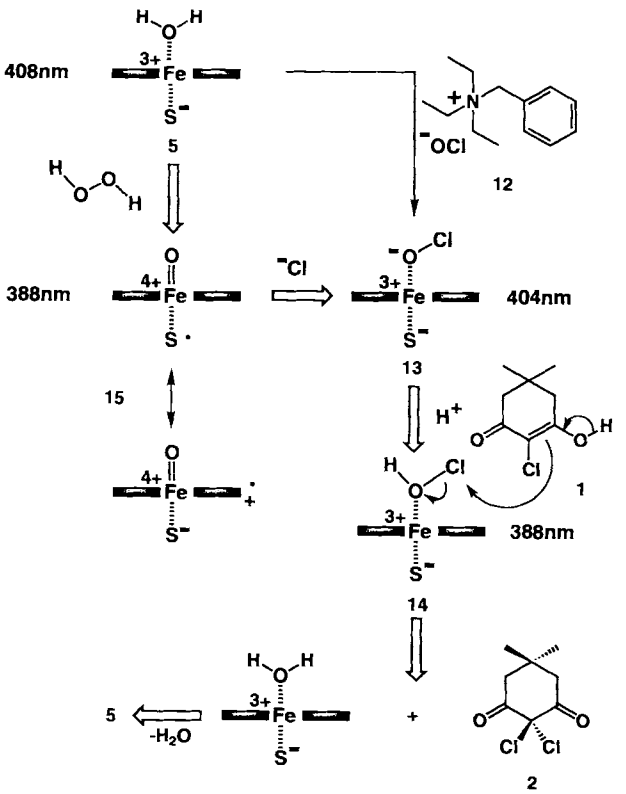
bind ^-OCl or HOCl. We further hoped that this complex would release Cl^+ in the presence of substrate.

The target compound **5** (Scheme 2) is a face-protected iron(III) diphenylporphyrin with a thiophenolate ligand as part of a bridge, which tightly spans the porphyrin plane. As a result, the S^- unit is forced into coordination with the iron center, and steric effects prevent decomplexation.[4] The substrate binding site is protected against μ-oxo dimer formation as well as porphyrin–porphyrin π stacking interactions by two pivalylamido groups,[14] which also provide H-bonding to ligands coordinated to the iron center.

The synthesis of the porphyrin chromophore was achieved by condensation of the protected aldehyde **6**[15] with the dipyrromethane **7**[16] under acid catalysis (Scheme 2).[17] The resulting mixture was treated with *o*-chloroaniline to oxidize chlorine, and zinc(II) was subsequently inserted to facilitate chromatographic purification. Cleavage of the methyl phenyl ether[18] furnished the porphyrin **8**[19] as an inseparable mixture of α,α- and α,β-atropisomers (only α,α-**8** is shown in Scheme 2), which was condensed[4] with the dimesylate **9**.[16] Subsequent removal of the protecting group at the thiophenol gave **10**,[20] and iron insertion completed the preparation of **5**.[21]

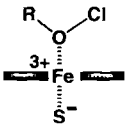
Complex **5** is a high-spin iron(III) porphyrin (g = 6.393 and 2.073) displaying a Soret band at λ_{max} = 408 nm. The corresponding water-free complex shows λ_{max} = 400 nm, which is similar to that of the resting state of CPO (λ_{max} = 399 nm). Reduction of **5** with $NaBH_4$ in THF quantitatively provided an iron(II) complex (λ_{max} = 418 nm), which displays the expected bathochromic shift to λ_{max} = 440 nm upon addition of CO (**11**).

To obtain a sufficient concentration of ^-OCl in CH_2Cl_2, the benzyltriethylammonium salt **12**[22] was prepared and allowed to react with **5** at room temperature (RT) to produce quantitatively the high-spin hypochlorite complex **13**[23] (g = 6.090 and 2.071, λ_{max} = 404 nm, Scheme 3). However, **13** shows very little chlorination activity towards monochlorodimedone **1**. Addition of AcOH provided the HOCl adduct **14**[24] (g = 6.216 and 2.057, λ_{max} = 388 nm), which catalyzed the chlorination of **1** (Table 1).



Scheme 3. Catalytic cycle of the enzyme model **5** which mimics the reaction mechanism of chloroperoxidase.

Table 1. Chlorination of **1** and **20** with catalysts **14** and **16**–**19**; TON = turnover number, n. r. = no reaction.



14: R = H
16: R = $SnCl_4$
17: R = BF_3
18: R = $ZnCl_2OEt_2$
19: R = $TiCl_4$

Catalyst	Reaction 1→2 [mol%]	TON	yield [%]	Reaction 20→21 + 22 [mol%]	TON	yield [%]
14	1.3	37	52	n. r.		
16	0.7	81	72	0.4	154	98 (**21**:**22** 4:1)
17	0.7	87	87	0.4	134	65 (**21**:**22** 13:1)
18	0.7	97	83	n. r.		
19	–	–	–	0.4	103	88 (**21**:**22** 3:1)

In order to mimic the enzymatic activity of CPO, **5** was successively treated with H_2O_2, Cl^-, and AcOH. Addition of H_2O_2 quantitatively gave a new complex whose UV/Vis spectrum (λ_{max} = 388 nm) correlates to the oxoiron(IV) porphyrin **15**.[25] This compound is an analogue of **3**, which is the reactive intermediate in the catalytic cycles of cytochrome P450 and CPO (λ_{max} = 367 nm)[26] and is capable of oxygen insertion. Subsequent addition of Cl^- yielded **13**, the same complex which was obtained from the direct reaction of **5** with ^-OCl. Protonation of **13** furnished **14**, which reacts smoothly with **1**.

These results show that **5** is a spectroscopic and chemical model of heme–thiolate proteins. It displays the reactivity of CPO, and careful experiments have identified the missing intermediates **13** and **14**[27] of the catalytic cycle of CPO. Furthermore, these results indicate that neither "free HOCl" nor Cl$^+$ are involved in the CPO-catalyzed chlorination, but rather that an iron-bound HOCl is the source of Cl^+. Enzymatic intermediates analogous to **13** and **14** have not yet been detected as they are too short-lived under the normal reaction conditions (pH < 3).

To improve the reactivity of the Cl^+-donor and the turnover of the catalytic reaction, we decided to replace the proton in **14** by Lewis acids. The adducts **16**–**19**,[28–31] prepared from **13** under anhydrous conditions (Table 2), display values for λ_{max} similar to that for **14**. This suggests that the addition of H^+ or other Lewis acids to **13** forms a very similar coordination sphere at the iron center. Thus, the structures of **16**–**19** shown in Table 1, though not rigorously proven, are plausible.

At low catalyst concentrations (0.7 mol%), the chlorination of monochlorodimedone (**1**) and anisole (**20**) was achieved with a turnover of up to 154 (Table 1). It is interesting to note that the product mixture obtained by chlorination of **20** only contained *p*-chloroanisole (**21**) and *o*-chloroanisole (**22**). There were no traces of chloromethyl phenyl ether, a product expected from the reaction of **20** with Cl$^\cdot$.[32]

An earlier study with immobilized manganese porphyrins without thiolate coordination achieved a maximum turnover of 6 for the chlorination of dimedones.[33] Evidently the design of the CPO-model (which should closely resemble the enzyme's active site) and careful modification of its reactivity considerably enhance the turnover. We anticipate that the enzyme model **5** can be further improved and become less sensitive to oxidative degredation when the free *meso* positions (C-5 and C-15 in **5**) are substituted with electron-withdrawing groups.[34]

Experimental Section

12: Benzyltriethylammonium chloride (200 mg, 0.44 mmol) was dissolved in CH_2Cl_2 (200 mL) and stirred with a concentrated solution of NaOCl in water (Sigma, 5% Cl, 3.2 mL) for 30 min. After separation, the organic layer was dried with Na_2SO_4 and directly used for the chlorination experiments.

Chlorination experiments: The substrate (**1**: 40 mg, 0.230 mmol; **20**: 40 mg, 0.370 mmol) was dissolved in CH_2Cl_2 and treated with **5** (2.0 mg, 0.0015 mmol) and AcOH (1.2 equiv) or Lewis acid ($ZnCl_2 \cdot 2OEt_2$ 0.1 equiv; $SnCl_4$ 0.1 equiv; $TiCl_4$ 0.1 equiv; $BF_3 \cdot OEt_2$ 0.02 equiv). A freshly prepared solution of **12** in CH_2Cl_2 (for **1** 6.3 mL, for **20** 9.0 mL) was added with an infusion pump over 15 min. The reaction solution was then concentrated to a volume of 1 mL. The products were purified by column chromatography (Merck silica gel 60; 2 × 20 cm; for the reaction with **1**: hexane/EtOAc/AcOH = 20/20/1; for the reaction with **20**: hexane/EtOAc = 3/1) and analyzed by ^{1}H NMR (Varian Gemini, 300 MHz, $CDCl_3$, TMS) and MS (Finnigan MAT 312; EI). All experiments were repeated in the absence of **5** under identical conditions. Monochlorodimedone (**1**) was recovered unchanged in all cases. In contrast, anisole (**20**) was chlorinated in the presence of the following Lewis acids (yields in parentheses): $SnCl_4$ (14%), $BF_3 \cdot OEt_2$ (19%), and $TiCl_4$ (37%). The values in Table 1 have been corrected for these "background reactions".

A Short-Lived Radical Dication as a Key Intermediate in the Rearrangement of a Persistent Cation: The Oxidative Cyclization of 2,2-Dimesityl-1-(4-*N*,*N*-dimethylaminophenyl)ethenol**

Michael Schmittel* and Anja Langels

In the course of our ongoing investigations on the chemistry of enol radical cations in solution[1] we have come across a rare event—the selective activation of a cationic intermediate via the corresponding radical dication. Since radical dications result from one-electron oxidation of electron-deficient cationic precursors, these highly reactive species are difficult to prepare and

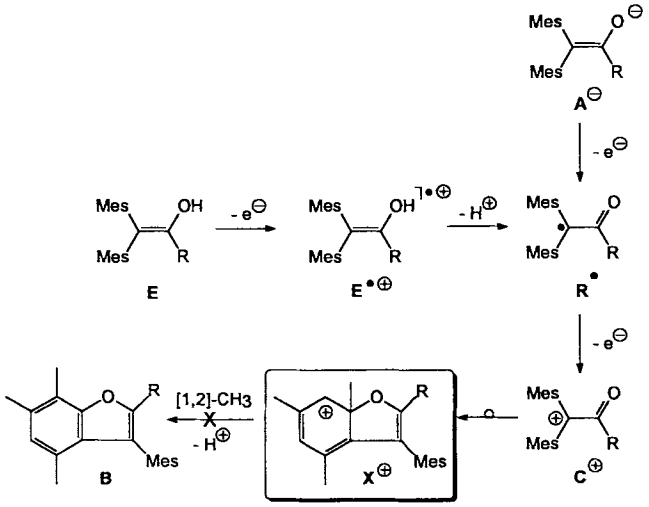
[**] Enol Radical Cations in Solution, Part 10. This research was supported by the Volkswagen-Stiftung, the Fonds der Chemischen Industrie, Degussa AG, and the Deutsche Forschungsgemeinschaft (SFB 347: "Selective Reactions of metal activated molecules"). Part 9: [4d].

almost completely unknown. Only few reports have been concerned with the reactivity[2] and characterization[3] of radical dications.

We describe here the ^{1}H NMR and cyclic voltammetric characterization of the cation $\mathbf{X}^+$ (Scheme 1), a novel cation that

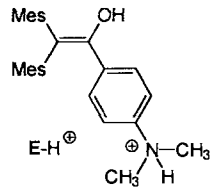


Scheme 1. Mes = mesityl, R = *p*-*N*,*N*-dimethylaminophenyl.

is persistent at room temperature ($t_{1/2} = 4.6$ min; $k = 2.5 \times 10^{-3}\ s^{-1}$). After one-electron oxidation of $\mathbf{X}^+$ to $\mathbf{X}^{\bullet 2+}$, an unprecedented rearrangement of the radical dication takes place instantaneously ($k > 1\ s^{-1}$) to furnish $\mathbf{B}^{\bullet +}$ in a clean reaction. Analogously, the same rearrangement can be triggered by means of the protonated cation $\mathbf{X}^+ - H^+$.

In line with other enol oxidations,[1,4] preparative oxidation of the novel enol $\mathbf{E}$[5] with 200 mol% tris(*p*-tolyl)aminium hexachloroantimonate ($E_{1/2} = 0.39$ V[6]) in acetonitrile afforded pure benzofuran $\mathbf{B}$ in 71% yield.[7] At first, formation of $\mathbf{B}$ seemed to be readily understandable based on our earlier mechanistic investigations, which had established an ECECC mechanism (E = electron transfer, C = chemical reaction) for all β,β-dimesityl enol oxidations[4a] as outlined in Scheme 1. However, cyclic voltammetry (CV) results and independent preparation of $\mathbf{X}^+$ provide unambiguous evidence (vide infra) that the anticipated [1,2]-methyl shift and the final deprotonation to $\mathbf{B}$ do not occur.

The cyclic voltammogramm of enol $\mathbf{E}$ exhibits three irreversible oxidation waves in acetonitrile at $E_{pa} = 0.13$, 0.76, and 1.10 V (Figure 1 left). The assignment of waves I and II is straightforward: the first oxidation wave corresponds to the oxidation of enol $\mathbf{E}$ and the second to the oxidation of the protonated enol $\mathbf{E}-H^+$. This assignment is derived from the observation that when trifluoromethanesulfonic acid ($pK_a = 2.6$ in acetonitrile[8]) was added, the height of the oxidation wave I diminished until it disappeared completely in the presence of approximately two equivalents of acid (see Figure 1 right). The current for wave II augmented accordingly. The opposite effect was seen when 4-dimethylaminopyridine (DMAP) was added as a strong base (pK_a of DMAP$-H^+ \approx 16$). In this case, wave II vanished and the current of wave I increased accordingly. Notably, wave III always showed up regardless of whether we recorded the spectrum in the presence of acid or base.



Finally, wave III could be assigned unambiguously to the oxidation of $\mathbf{X}^+$ to give the radical dication $\mathbf{X}^{\bullet 2+}$, based on the following results. Oxidation of enol $\mathbf{E}$ and enolate $\mathbf{A}^-$ using tris(*p*-bromophenyl)aminium hexafluoroantimonate ($E_{1/2} = 0.70$ V) and copper(II)triflate ($E_{1/2} = 0.67$ V), respectively, directly in an NMR tube at $-15\,^\circ$C furnished $\mathbf{X}^+$ in almost quantitative yield. $\mathbf{X}^+$ exhibited an irreversible wave in CV experiments at $E_{pa} = 1.12$ V that coincided with wave III. The structural assignment of $\mathbf{X}^+$ is straightforward. Characteristically, the ^{1}H NMR signals of the two NMe_2 groups appear as singlets ($\delta = 3.35$ and 3.43), indicating high barriers for rotation about the $C_{bf}\cdots C_{Ar}$ and $C_{Ar}\cdots N$ bonds. The double bond character of these bonds can be rationalized by the significant stabilization of the cation through the *p*-NMe_2 group.[9] Furthermore, a doublet ($J = 9.8$ Hz) for one proton at low field ($\delta = 8.27$) can be assigned to H_b. In contrast, H_b' resides in the shielding region of the mesityl ring and its signal appears together with those of H_a and H_a' at $\delta = 7.04$–7.18 (multiplet). Likewise, a new aliphatic methyl group gave rise to a singlet at $\delta = 1.64$. In agreement with these ^{1}H NMR data, a key feature in the AM1-calculated[10] minimum structure is that the mesityl group is located almost perpendicular to the *N*,*N*-dimethylaminophenyl unit (Figure 2).

Additional support for the assignment of wave III was derived from the CV investigations of the enolate $\mathbf{A}^-$. Besides a reversible oxidation wave for $\mathbf{A}^- \rightleftharpoons \mathbf{R}^{\bullet}$ at $E_{1/2} = -0.96$ V and an irreversible one for oxidation of $\mathbf{R}^{\bullet}$ at $E_{pa} = 0.09$ V, wave III also appeared and was assigned to $\mathbf{X}^+ \rightarrow \mathbf{X}^{\bullet 2+}$. Hence, enolate oxidation accounts for the independent generation of cation $\mathbf{C}^+$ according to Scheme 1; $\mathbf{C}^+$ cyclizes rapidly to $\mathbf{X}^+$.[11]

Earlier investigations[4c] indicated that the [1,2]-methyl shift in the cyclohexadienyl cation $\mathbf{X}^+$ (see Scheme 1) would consti-

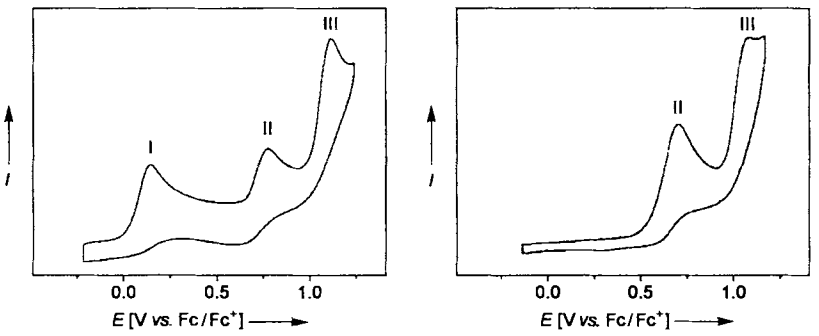


Figure 1. Cyclic voltammograms of $\mathbf{E}$ (left) and $\mathbf{E}-H^+$ (right); $v = 100$ mV s^{-1}, $c = 1$ mM in acetonitrile, working electrode = 1 mm platinum disk; counter electrode = platinum wire, reference electrode = silver wire.

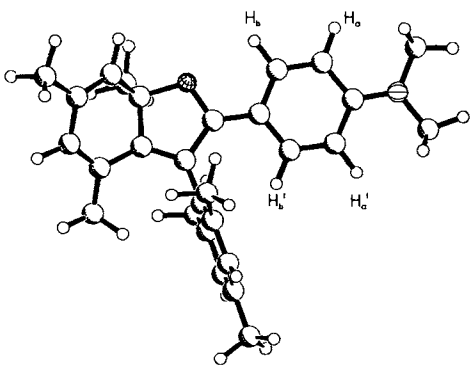

Figure 2. Structure of $\mathbf{X}^+$ calculated by AM1.

tute the slowest step in the oxidative formation of benzofuran; this step is slowed down the more electron-donating the substituent R. When R is a stabilizing *p*-NMe_2-phenyl group, $\mathbf{X}^+$ is persistent at room temperature for several minutes, as demonstrated by ^{1}H NMR investigations ($k = 2.5 \times 10^{-3}\ s^{-1}$). However, if the cation $\mathbf{X}^+$ is prepared by oxidation of the enolate, it decomposes to a plethora of unidentified products, which did not include the benzofuran **B**. Hence, the last step shown in Scheme 1 ($\mathbf{X}^+ \rightarrow \mathbf{B}$) is not operative.

Importantly, multisweep experiments revealed that benzofuran formation on the time scale of the CV experiment is immediately triggered once we increase the potential to that of wave III. For instance, when we analyzed enol **E** in a multisweep experiment ($v = 500\ mVs^{-1}$) with $E_{\lambda 1} = 0.30$ V and $E_{\lambda 2} = 0.92$ V as switching potentials, no reduction wave evolved in the region investigated (Figure 3 left, trace a). But when $E_{\lambda 2}$ was set at 1.41 V, thus increasing the potential range also to wave III (Figure 3 left, trace b), two new reduction waves at $E_{pc} = 0.69$ V[12] and at $E_{pc} = 0.25$ V emerged ($v = 200$ and $500\ mVs^{-1}$), which correspond to the reduction $\mathbf{B}^{2+} \rightarrow \mathbf{B}^{\bullet+}$ and $\mathbf{B}^{\bullet+} \rightarrow \mathbf{B}$, respectively.[13]

A similar picture was obtained from multisweep CV experiments starting with $\mathbf{E}-H^+$ generated through protonation of **E** with tetrafluoroboric acid. When the potential was varied between the switching potentials $E_{\lambda 1} = 0.30$ V and $E_{\lambda 12} = 0.95$ V, no reduction waves of any follow-up products were registered. However, when the potential range was extended to higher anodic potential ($E_{\lambda 1} = 0.30$ V and $E_{\lambda 2} = 1.30$ V as switching potentials), the reduction wave at $E_{pc} = 0.64$ V was again detected (Figure 3 right).

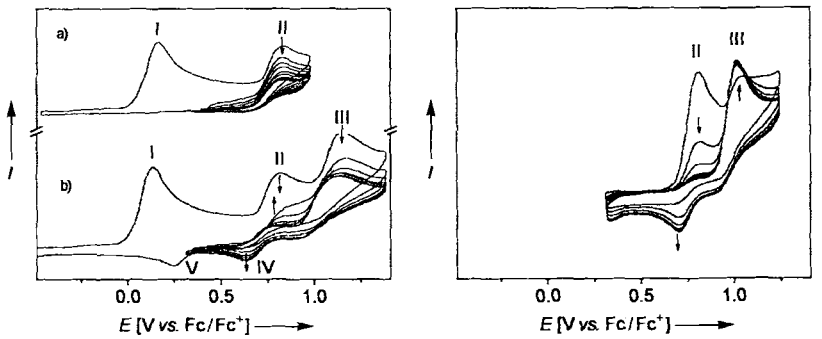

Figure 3. Multisweep cyclic voltammograms of **E** (left) and $\mathbf{E}-H^+$ (right); $v = 500\ mVs^{-1}$, $c = 1$ mM in acetonitrile, working electrode = 1 mm platinum disk; counter electrode = platinum wire, reference electrode = silver wire.

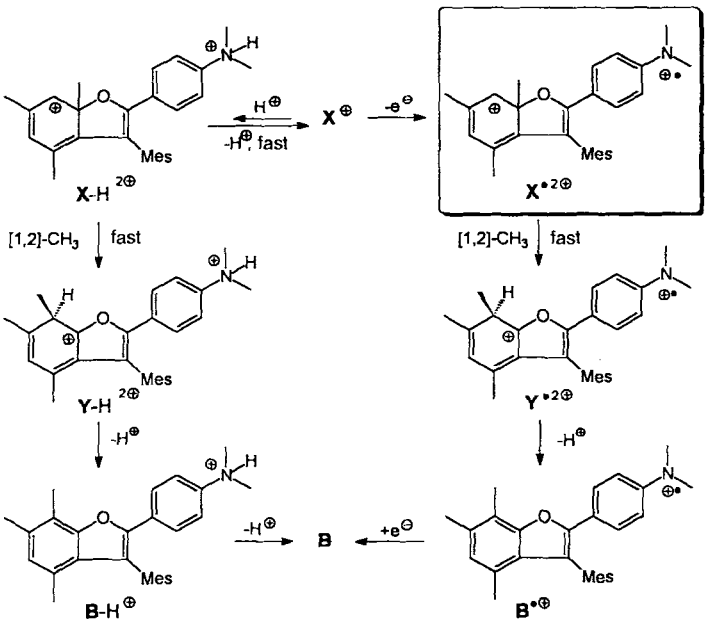
Indeed, all experimental findings are consistent when we assign the third oxidation wave to the one-electron oxidation of cation $\mathbf{X}^+$ to give radical dication $\mathbf{X}^{\bullet 2+}$. Since the electron-releasing substituent $C_6H_4NMe_2$ in $\mathbf{X}^+$ is replaced by the electron-withdrawing substituent $C_6H_4NMe_2^{\bullet+}$ in $\mathbf{X}^{\bullet 2+}$, a fast [1,2]-methyl shift with subsequent deprotonation to provide the benzofuran radical cation $\mathbf{B}^{\bullet+}$ must be taking place. At the applied anodic potential the radical cation $\mathbf{B}^{\bullet+}$ is promptly oxidized to the benzofuran dication $\mathbf{B}^{2+}$,[14] which can act as a strong oxidant and oxidize **E** or $\mathbf{E}-H^+$ in the diffusion layer. This additional one-electron oxidation step readily explains the fact that the current of the third wave stays constant in the multisweep experiment with $\mathbf{E}-H^+$, while wave II disappears almost completely.[15]

But how is benzofuran **B** formed in the oxidation of **E** with tris(*p*-tolyl)aminium hexachloroantimonate? In the course of the deprotonation of $\mathbf{E}^{\bullet+}$ to give $\mathbf{R}^{\bullet}$[16] a second enol molecule



Scheme 2.

is protonated at the nitrogen to afford $\mathbf{E}-H^+$. In this respect, the oxidation of **E** is similar to that of dimethylaminophenol[17] and of 2,6-di-*tert*-butyl-4-(4-dimethylaminophenyl)phenol.[18] In line with the mechanism depicted in Scheme 1, $\mathbf{E}-H^+$ should furnish the dication $\mathbf{X}^+-H^+$. Because $\mathbf{X}^+$ is formed quantitatively in the CV experiments from $\mathbf{E}-H^+$, the dication $\mathbf{X}^+-H^+$ must deprotonate in a rapid and exergonic reaction to yield $\mathbf{X}^+$, even in the presence of added acid (Scheme 2). Under the conditions of the chemical oxidation, however, $\mathbf{X}^+$ is persistent. Thus, in presence of protons $\mathbf{X}^+-H^+$ is regenerated from $\mathbf{X}^+$ in an endergonic equilibrium. Owing to the electron-withdrawing ability of NMe_2H^+, $\mathbf{X}^+-H^+$ rapidly rearranges to the protonated benzofuran $\mathbf{B}-H^+$. In line with this proposal, $\mathbf{X}^+$ generated from enolate oxidation afforded $\mathbf{B}-H^+$ (62%, isolated as **B**) after addition of CF_3SO_3H.

In summary, we have unequivocally established a novel, clean rearrangement of the persistent cation $\mathbf{X}^+$ either via the reactive dication radical or a protonated cation to finally yield the benzofuran **B**. Preliminary results indicate that in oxidations of other $Mes_2C{=}C(OH)R$ derivatives (with R = *p*-anisyl and 3,4-$C_6H_3(OMe)_2$) rearrangement via the radical dication can be observed as well, indicating that such intermediates may be more common than previously anticipated.

[9] In structurally related ammonium ions hindered rotation about the C–N bond was reported: U. Pindur, *Arch. Pharm.* **1980**, *313*, 301–306.

[10] M. J. S. Dewar, E. G. Zoebisch, E. F. Healy, J. J. P. Stewart, *J. Am. Chem. Soc.* **1985**, *107*, 3902–3909.

[11] Unfortunately, attempts to measure the kinetics of the cyclization of $\mathbf{C}^+$ using fast scan cyclic voltammetry failed due to rapid electrode coating. The occurrence of an irreversible wave at $v = 500\ mVs^{-1}$ for $\mathbf{R}^\bullet \rightarrow \mathbf{C}^+$ only indicates that the half-life of cation $\mathbf{C}^+$ is less than 1 s. For comparison, kinetic investigations on the cyclization of the related *p*-anisoyl-dimesitylmethyl cation provided $k = 1.4 \times 10^5\ s^{-1}$: M. Schmittel, M. Röck, unpublished results.

[12] Notably, in all multisweep experiments the current of the reduction wave at $E_{pc} = 0.69$ V increased with the number of cycles.

[13] Cyclic voltammetric investigation of pure **B** revealed two reversible waves at $E_{1/2} = 0.23$ V and at 0.72 V, the first of which was assigned to $\mathbf{B} \rightarrow \mathbf{B}^{\bullet+}$ and the latter to $\mathbf{B}^{\bullet+} \rightarrow \mathbf{B}^{2+}$.

[14] Wave III reflects two oxidation processes, namely the oxidation of $\mathbf{X}^+$ to $\mathbf{X}^{\bullet 2+}$ and of $\mathbf{B}^{\bullet+}$ to $\mathbf{B}^{2+}$, thus explaining the high peak intensity of wave III.

[15] The almost complete disappearance of wave II in the multisweep experiment starting with $\mathbf{E}\text{–}H^+$ is in full agreement with the proposed mechanism. Accordingly, the depletion of $\mathbf{E}\text{–}H^+$ in the diffusion layer is expected as a result of the redox process between $\mathbf{E}\text{–}H^+$ and $\mathbf{B}^{2+}$. In addition, the wave of $\mathbf{B}^{\bullet+} \rightleftharpoons \mathbf{B}^{2+}$ is no longer reversible in the presence of acid because the endergonic disproportionation $2\mathbf{B}^{\bullet+} \rightleftharpoons \mathbf{B}^{2+} + \mathbf{B}$ is followed by quantitative protonation of **B**.

[16] The deprotonation of $\mathbf{E}^{\bullet+}$ is a fast chemical reaction ($k > 10^4\ s^{-1}$) since even at $v = 15000\ Vs^{-1}$ no sign of reversibility was found in the CV experiment.

First Biosynthetic Studies on Trail Pheromones in Ants**

Hans Jürgen Bestmann,* Elke Übler, and Bert Hölldobler

Ants are amongst the most important animals in almost all terrestrial ecologic systems. There are about 9500 known species of ants, and their ecological success is based on the social organization of the colonies in which they live. The division of labor of the thousands of individuals living in an ant-state can only work with the aid of a communication system. Communication in the ant-state largely depends on chemical signals. When, for example, a new food source is discovered, the successful scout marks the way back to the nest with a trail pheromone. Nestmates are stimulated to follow this odor trail to the newly discovered resource, which leads finally to the well-known ant-streets. Only for a few ant species (about 20–25) is the chemical structure of these trail pheromones known.[1,2] Biosynthetic studies on trail pheromones in insects generally and ants in particular have not been reported so far.[3]

Recently we identified in the rectal bladder of several ant species of the subfamily Formicinae two classes of compounds that function as trail pheromones, namely 3,4-dihydroisocoumarins and 3,5-dimethyl-6-alkyl-tetrahydro-2*H*-pyran-2-ones (δ-lactones).[4] In addition to the biologically active components the rectal bladder often contains other derivatives of the same class of compounds, but no behavioral function could be attributed to them. Table 1 shows the species and their respective trail pheromone examined. We investigated whether the 3,4-dihydroisocoumarins and δ-lactones derive from related biosynthetic pathways.

As can be seen in Table 1, the rectal bladders of many species contain 3,4-dihydro-8-hydroxy-3-methylisocoumarin (**1**, mellein). This compound is fairly ubiquitous in nature.[5] For instance, it has been found in the species *Aspergillus* and in various insects like the Oriental fruit moth, *Grapholita molesta* Busck,[6] in the wing glands of the bumble-bee wax moth, *Aphomia sociella* L.,[7] in the gaster of *Rhytidoponera metallica*,[8] and in the mandibular gland secretion of some carpenter ant species, for example *Camponotus pennsylvanicus*, *C. herculeanus*, and *C. noveboracensis*,[9] to which we can add *C. rufipes* and *C. silvicola* according to our own investigations.[4c,g] It was therefore tempting to assume that the ants take up mellein (for example with food), methylate it during digestion at various positions on the aromatic ring and then store the methylated derivatives in the rectal bladder as trail pheromones. To test this hypothesis we synthesized (*R,S*)-[D_5]mellein (D_5-**1**) (Figure 1) by a method adapted from the literature[10] and fed the labeled compound to *C. rufipes*, *C. silvicola*, and *L. niger*,

[**] Pheromones. Part 107. This work was supported by the Deutsche Forschungsgemeinschaft. We thank Dr. Kunesch for stimulating advice. Part 106: E. Janssen, H. J. Bestmann, B. Hölldobler, F. Kern, K. Tsuji, *J. Chem. Ecol.*, in press.

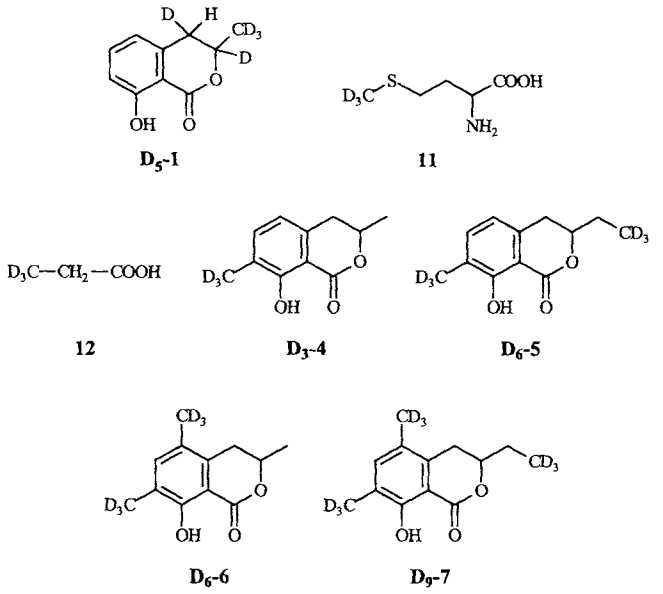

Figure 1. Deuterium-labeled precursors and labeled 3,4-dihydroisocoumarins obtained after feeding with CD_3CH_2COOH.

which all use "methylated" melleins as trail pheromone. After a feeding period of 14 days we excised the hindguts of the freshly killed worker ants and analyzed the chemical composition of the rectal bladders by gas chromatography coupled with mass spectrometry (GC–MS), using a solid-sampling injection technique.[11] Since in all cases we found large quantities of the labeled substance D_5-**1** among the other well known volatile constituents, we were certain that the labeled compound had been taken up; however, none of the trail pheromones (see Table 1) had incorporated the deuterium label.

In subsequent experiments we fed the ants [D_3]methionine (**11**), a compound known to transfer methyl groups during biosynthesis, but again no evidence was obtained to support the incorporation of labeled methyl groups into trail pheromones.

Table 1. 3,4-Dihydroisocoumarins **1**–**7** and δ-lactones **8**–**10** (++ = compound serves as trail pheromone; + = compound merely detected) found in the rectal bladder of ants of the subfamily Formicinae.

Art	1	2	3	4	5	6	7	8	9	10
C. silvicola [4c, g]	+	+	+			++	+			
C. rufipes [4c, g]	+			++	+	+				
C. inequalis [4h]						++				
C. herculeanus [4b]						+		++		++
C. ligniperdus [4f]						+		++	++	++
C. vagus [4f]								++		
C. pennsylvanicus [4f]								++	+	
C. socius [4f]								++		
C. atriceps [4d]									++	
C. floridanus [4d]	+									
L. niger [4a]						++	+			
L. fuliginosus [4e]	++									
F. rufa [4a]	++									
F. sanguinea [4a]				+	+					
F. fusca [4a]	+					+				

According to these results the modification of mellein by methylation as a possible biosynthetic pathway to the trail pheromones of *C. rufipes*, *C. silvicola*, and *L. niger* could be excluded.

Biosynthetic studies on *Aspergillus mellus*[12] and *Rhytidoponera chalybaea*[13] with labeled acetate demonstrated that mellein can arise by the polyketide pathway. To establish a de novo biosynthesis for all identified 3,4-dihydroisocoumarins listed in Table 1, and for the pheromones **4** and **6** especially, we fed *C. rufipes*, *C. silvicola* and *L. niger* with [D_3]acetate over 14 days. In all cases deuterium was weakly incorporated into the pheromones, as indicated directly by the MS data of the GC–MS analysis, which clearly revealed a molecular ion with increased mass $M^+ + X$ ($X = 1-6$). Because of the low concentration of deuterium-enriched 3,4-dihydroisocoumarins we could not determine with certainty the defined distribution of the label.

The methyl groups at the aromatic ring are unlikely to be derived from acetate. To check whether they originate from incorporation of propionate we synthesized β-[D_3]propionic acid (**12**) and fed an aqueous solution of its sodium salt to the species named above. After an incorporation time of 14 days we focused on **6** and the homologue **7** (occurrence in *C. silvicola* and *L. niger*), and on **4** and **5** (*C. rufipes*). The resulting GC-analysis exhibited new peaks in front of the expected and known signals, which were unambiguously assigned to the deuterated compounds. The molecular ion of **4** increased by three, those of **5** and **6** by six, and those of **7** by nine mass units. The fragmentation pattern definitly demonstrated the incorporation of CD_3 groups into the aromatic ring and also into the 3-ethyl group of **5** and **7**. In Table 2 the MS data of natural and labeled pheromones **4** and **6** are compared.

Table 2. MS data (EI, 70 eV) recorded from unlabeled and labeled 3,4-dihydroisocoumarins **4** and **6** after feeding with CD_3CH_2COOH.

Fragment	D_3-**4**(%)	**4**(%)	D_6-**6**(%)	**6**(%)

$M^+ - H_2O - CO$	149(9)	146(12)	166(6)	160(6)
$M^+ - H_2O - CH_3 - CO$ [a]	134(2)	131(13)	151(7)	145(15)
$M^+ - H_2O - CD_3 - CO$ [b]	131(1)	–	148(5)	–
$M^+ - CH_3CHO - CO$	123(15)	120(15)	140(9)	134(12)

[a] 3-methyl-fragmentation and for **6** and **4** in addition 7-methyl-fragmentation (*ortho*-effect) [4a]. [b] 7-CD_3-fragmentation (*ortho*-effect) [4a].

These results clearly illustrate that in ants of the subfamily Formicinae the 3,4-dihydroioscoumarin pheromones are biosynthesized from acetate as well as from propionate, presumably by a polyketide pathway as illustrated schematically in Figure 2. Thus the construction of **4** would require one acetyl-

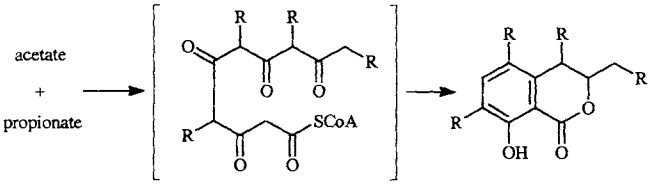

Figure 2. Model for the formation of 3,4-dihydroisocoumarins via a pentaketide precursor biosynthesized from acetate (R = H) and propionate (R = CH_3).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3604-0396 $ 15.00+.25/0

CoA, three malonyl-CoA, and one methylmalonyl-CoA unit, of **6** one acetyl-CoA, two malonyl-CoA, and two methylmalonyl-CoA units, of **5** one propionyl-CoA, three malonyl-CoA, and one methylmalonyl-CoA unit, and of **7** one propionyl-CoA, two malonyl-CoA, and two methylmalonyl-CoA units. For **6** the GC–MS analysis also showed a compound that had incorporated only one CD_3 group because one natural and one deuterated propionate molecule was used in the biosynthesis. Significant amounts of labeled compounds biosynthesized during the feeding experiment were detected by GC–MS (30–40%).

These results prompted us to investigate whether the second class of trail pheromones occurring in the rectal bladders of formicine ants, the δ-lactones, are biosynthesized in a related way by lipid metabolism. We fed labeled propionate **12** to *C. ligniperdus* and *C. herculeanus*, which both utilize lactone **8** and **10** (and for *C. ligniperdus* also **9**) as trail pheromones. Subsequently, after a feeding period of two weeks, the hindgut contents of the ants were analyzed by GC–MS. For both species the gas chromatogram showed in front of the peaks for **8** and **10** new signals assigned to the compounds with incorporated CD_3 groups. Only for **9** this was not so distinct because of its very low concentration in the rectal bladder. The molecular ion of **8** showed an increase of six, those of **9** of nine, and those of **10** of twelve mass units. The fragmentation pattern definitly pointed to the structures D_6-**8**, D_9-**9** and D_{12}-**10** (Table 3).

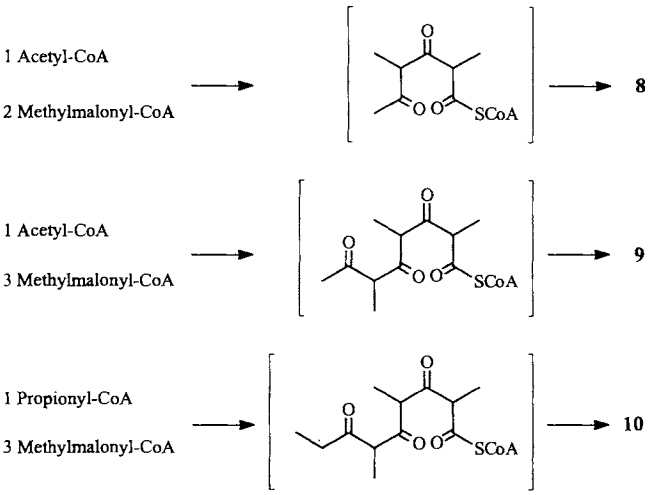

Figure 3. Model of the biosynthesis of 3,5-dimethyl-6-alkyl-tetrahydro-2*H*-pyran-2-ones (δ-lactones).

known.[7] Preliminary investigations by feeding experiments showed that the biosynthesis of the trail pheromones in the ants is not considerably impaired by antimycotics and antibiotics.

CD_3CHCO	59(100)	–	59(20)	–	59(32)	–

These results establish the incorporation of labeled acetate and particulary propionate into the biologically active δ-lactones found in the rectal bladders of formicine ants and are consistent with the biosynthetic pathway shown in Figure 3. The amount of labeled pheromones produced is considerable (up to 85%).

While the 3,4-dihydroisocoumarins are biosynthesized from pentaketide chains by the use of at least one acetyl unit and a variable number of propionyl units, the δ-lactones require three or four carboxylic acid equivalents, among which the propionyl precursor predominates. Acetate is not essential: pheromone **10** is biosynthesized by the exclusive use of propionate.

Many of these ant species are richly endowed with endosymbionts living in the gut system. Whether these micro-organisms play a role in the synthesis of the trail pheromones is not yet

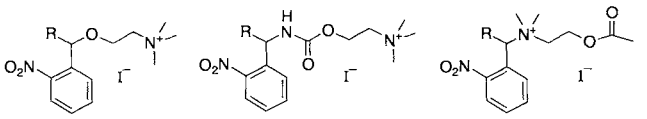
Synthesis and Characterization of Photolabile Compounds Releasing Noracetylcholine in the Microsecond Time Range**

Ling Peng, Jakob Wirz, and Maurice Goeldner*

Temporally and spatially controlled release of biologically active molecules can be achieved with suitable photolabile precursors. Such compounds are important tools for the study of fast biological processes.[1] Hydrolysis of the neurotransmitter acetylcholine (ACh) by acetylcholinesterase (AChE[2]) is a particularly fast enzymatic process, with a turnover number approaching 20000 s^{-1}.[3] Knowledge of the 3-D structure of AChE[4] and several AChE–inhibitor complexes[5] has permitted a better understanding of structure–function relationships in the cholinesterases, but has also raised cogent new questions concerning the traffic of substrate and products to and from the active site[6, 7] in view of the high turnover rate. Time-resolved crystallography would present an ideal approach for investigating this issue at the atomic level and in real time, provided that suitable probes, which ensure efficient and synchronized initiation of the dynamic process, were available.[8] Photolabile precursors to the enzymatic product choline (**1a–3a**)[9] and the AChE substrate carbamoylcholine (**1b–3b**)[10] have been recently evaluated for their interaction with AChE and their potential use in time-resolved crystallographic studies.[11]



1a: R = Me
2a: R = H
3a: R = CH_2NCS

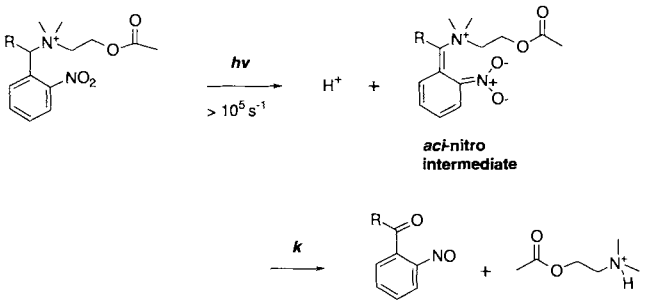
1b: R = Me
2b: R = H
3b: R = COOH

1c: R = Me
2c: R = H

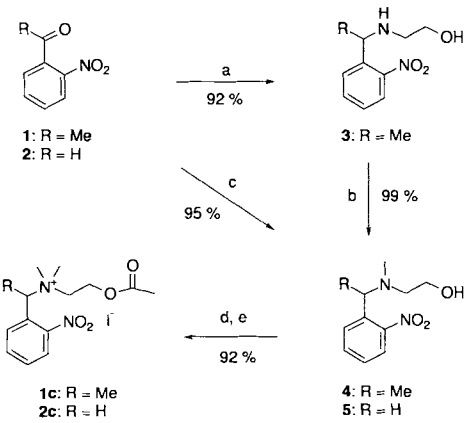
Here, we report the synthesis and characterization of a new type of photolabile probe (**1c** and **2c**) for time-resolved studies of AChE. These 2-nitrobenzyl derivatives of noracetylcholine (*N*,*N*-dimethylaminoethyl acetate) are close analogues of acetylcholine.[2] Hydrolysis of noracetylcholine by AChE follows an enzymatic reaction mechanism, which is similar to the hydrolysis of the natural substrate acetylcholine.[2, 12] Thus, hydrolysis of noracetylcholine, photogenerated from its precursor within the enzyme's active site, may closely mimic the hydrolysis of the neurotransmitter acetylcholine and serve as a paradigm for studying the catalytic mechanism of AChE under the conditions of time-resolved crystallography.

2-Nitrobenzyl groups have been used as photolabile protecting groups[13] to mask or "cage" biological molecules.[1, 14] The photochemical fragmentation reactions of 2-nitrobenzyl derivatives such as ethers, carbamates, carboxylic esters, and amines have been studied[1, 14] and parallels drawn to the analogous photochemical release of ATP from the 2-nitrobenzyl P^3-ester of ATP ("caged" ATP).[15] In this case, the decay of an "*aci*-nitro" intermediate (Scheme 1) was correlated to the formation of ATP. Compounds **1c** and **2c** are the first examples of 2-nitrobenzyl quaternary ammonium derivatives as "caged" effectors.

The syntheses of **1c** and **2c** are outlined in Scheme 2. The 2-nitrobenzyl group was introduced by reductive amination[16]



Scheme 1. Proposed mechanism for the photochemical fragmentation of 2-nitrobenzyl derivatives of noracetylcholine.



Scheme 2. Reagents and conditions: a) $HOCH_2CH_2NH_2$, $NaBH_3CN$, $ZnCl_2$, MeOH; b) CH_2O, $NaBH_3CN$, $ZnCl_2$, MeOH; c) $HOCH_2CH_2NHMe$, $NaBH_3CN$, $ZnCl_2$, MeOH; d) CH_3COCl, NEt_3, CH_2Cl_2; e) MeI, CH_3CN.

of either 2-nitroacetophenone (**1**) with ethanolamine or of 2-nitrobenzaldehyde (**2**) with *N*-methylethanolamine in the presence of sodium cyanoborohydride and zinc chloride. The tertiary amines **4** and **5** were subsequently acetylated and methylated, leading to the final products **1c** and **2c** in greater than 80% overall yields.

Photorelease of noracetylcholine from compounds **1c** was monitored by UV spectroscopy, HPLC, and an enzymatic assay (Figure 1). The observed isobestic points in the UV absorption spectra (Figure 1a) are consistent with a uniform photodecomposition process. This was confirmed by a quantitative HPLC analysis (Figure 1b) and a noracetylcholine assay (Figure 1c), which showed that the amount of starting material photolyzed matched the amount of nitroso product and noracetylcholine formed. These results also indicate a stoichiometric conversion of noracetylcholine from its precursor **1c**.

The quantum yields for compounds **1c** and **2c** (Table 1) were determined by comparing the extent of their photoconversion with that of 1-(2-nitrophenyl)ethyl carbamylcholine (Φ = 0.25).[9, 10] Dependence of the quantum yield of 2-nitrobenzyl derivatives on α-benzylic substituents has been previously documented,[1, 14] but the large difference between **1c** and **2c** is re-

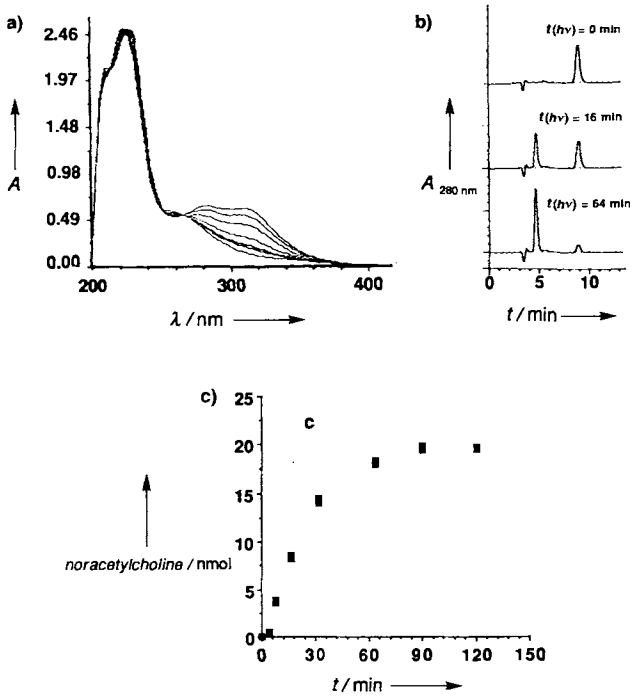

Figure 1. A solution of **1c** (0.2 mM) in 50 mM phosphate buffer at pH = 7.2 was exposed to irridiation (364.5 nm) from a Hg-Xe lamp. a) UV-spectra recorded during photolysis. The lowest trace at 230 and 300 nm and the highest trace at 260 nm correspond to the starting material **1c**. b) Aliquots (20 mL) of the irradiated sample were analyzed by HPLC. Compound **1c** had a retention time of 8.9 min. The peak at 4.7 min corresponds the photolysis by-product, 2-nitrosoacetophenone. c) The photoreleased noracetylcholine was quantified by an enzymatic assay with 100 mL aliquots of the irradiated sample.

Table 1. Spectroscopic properties, photofragmentation parameters, and inhibition constants for compounds **1c** and **2c**.

Compd.	ε[M^{-1}cm^{-1}] [a]	k [sec^{-1}] [b]	Φ [c]	K_i [μM] [d]
1c	3900 (254 nm)	2.82×10^4	0.10	0.70 ± 0.06
2c	5100 (262 nm)	2.90×10^4	<0.01	4.52 ± 0.35

markable. The low quantum yield of **2c** may limit its further application in time-resolved studies of AChE.

By the 351 nm laser flash photolysis of **1c** and **2c**, a transient absorption was detected around 400 nm (Figure 2, top), which is characteristic[1, 14, 15] of an *aci*-nitro intermediate. The transients were formed within the 20 ns duration of the laser pulse, and the subsequent decay accurately obeyed a first-order rate law (Figure 2, bottom). The decay rates (around 2.8×10^4 s^{-1}) were insensitive to pH at physiological values from 6.5 to 8.0. This observation may be explained by the mechanism proposed in Scheme 1. The release of noracetylcholine is therefore independent of pH since the benzylic nitrogen atom of the *aci*-nitro intermediate remains positively charged. Surprisingly, the substituent at the α-benzylic position does not influence the decay rate: the *aci*-nitro signals for compound **1c** and **2c** decayed at very similar rates (Table 1). Most importantly, the decay of the *aci*-nitro intermediates can be used as a kinetic measure for the release of the product.[15]

Both **1c** and **2c** showed inhibitory properties on purified *Torpedo* acetylcholinesterase. The inhibition constants are in the micromolar range (Table 1) and correspond to the values expected for aromatic molecules carrying a quaternary ammonium group. AChE remained fully stable when exposed to 351 nm laser flashes. The photolytic by-product from compound **1c**, 2-nitrosoacetophenone, had no toxic effects on the activity of acetylcholinesterase, even at 1 mM concentration (data not shown).

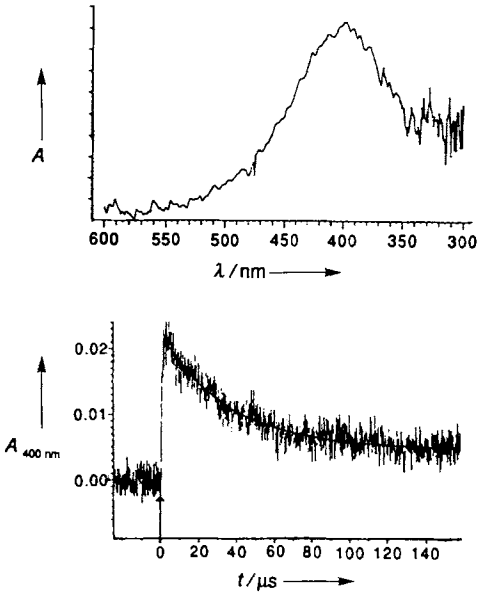

Figure 2. 351 nm laser flash photolysis of compound **1c** (1.5 mM **1c** in 0.1 M phosphate buffer, pH = 7.2, 20 °C). Top: transient absorption spectrum 1 ms after the laser pulse. Bottom: kinetic trace of the transient absorbance changes at 400 nm. The arrow indicates the begining of the laser flash.

In summary, our results demonstrate that photolysis of 2-nitrobenzyl quaternary ammonium derivatives **1c** and **2c** generates noracetylcholine over an *aci*-nitro intermediate. Probe **1c** shows excellent kinetic properties ($k = 2.82\times10^4$ s^{-1}, 20 °C) for the photolytic release of noracetylcholine and is comparable to the turnover rate of acetylcholinesterase ($k \approx 2\times10^4$ s^{-1}). Furthermore, the quantum yield for **1c** should ensure a sufficient photorelease of noracetylcholine. Thus, among all the probes synthesized up to now, compound **1c** is the most promising candidate for a time-resolved crystallographic study for investigating the molecular reaction mechanism of acetylcholinesterase.

Experimental Section

All details for the photochemical reactions, activity assay of AChE, and inhibition of ligands on AChE can be found in ref. [9].

1c: Yellow crystals, m.p. 143–145 °C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.78 (d, 3H, J = 4.5 Hz), 1.97 (s, 3H), 2.92 (s, 3H), 3.08 (s, 3H), 3.65–3.72 (m, 2H), 4.32–4.41 (m, 2H), 5.39 (q, 1H, J = 4.5 Hz), 7.59–7.64 (m, 1H), 7.71–7.76 (m, 1H), 7.84–7.88 (m, 2H); MS (FAB positive): m/z(%): 281.1 (100) [$C_{14}H_{21}N_2O_4$]; correct elemental analysis.

2c: Yellow crystals, m.p. 123–125 °C. ^{1}H NMR (300 MHz, $CDCl_3$): δ 2.17 (s, 3H), 3.37 (s, 3H), 3.38 (s, 3H), 4.30–4.35 (m, 2H), 4.65–4.72 (m, 2H), 5.60 (s, 2H), 7.74–7.93 (m, 2H), 8.13–8.18 (m, 1H), 8.34–8.39 (m, 1H); MS (FAB positive): m/z(%): 267.1 (100) [$C_{13}H_{19}N_2O_4$]; correct elemental analysis

HPLC conditions: C18 reversed phase column (250 mm × 3.9 mm), isocratic elution with a mixture of 30% acetonitrile and 70% aqueous solution of 5 mM sodium dodecylsulfate and 5 mM sodium sulfate at pH = 2.00.

Enzymatic assay for noracetylcholine: 100 mL aliquots of photolysis samples were withdrawn and added to a 900 mL solution containing one unit of acetylcholinesterase, five units of choline oxidase, four units of peroxidase, 0.74 mM 4-aminoantipyrine, 0.34 mM $CaCl_2\cdot H_2O$, and 5.3 mM phenol in 50 mM Tris buffer (pH = 7.8). After 30 min at 25 °C, the developed red dye was measured at 505 nm. The corresponding amount of noracetylcholine was deduced from a standard reference.

The Trimesitylsilylium Cation**

Joseph B. Lambert* and Yan Zhao

No tricoordinated silylium ion, R_3Si^+, has been reported to date.[1] The most widely accepted criteria for determining silylium character are the ^{29}Si chemical shift and suitable structural parameters obtained from crystallography that indicate tricoordination and planarity. The closest approaches to such a species with alkyl groups have been our work[2] with the tetrakis(pentafluorophenyl)borate anion (TPFPB) and Reed's work[3] with various carborane anions. Chemical shifts in the range of $\delta(^{29}Si) = 90-115$ and C-Si-C angles of 114–117° were observed.[2, 3] The ideal angle for tricoordination is 120° and, according to calculations for the gas phase, chemical shifts of $\delta = 350-380$ are expected for these alkyl substituents.[3] Reed et al. noted that nonspecific solvation beyond the van der Waals radius of silicon may significantly lower the chemical shift. In their opinion, the optimal species observed to date have 36–52% silylium ion character.[3]

The high electrophilicity of tricoordinate silicon is responsible for its strong kinetic drive to coordinate. Calculations by Schleyer and co-workers[4] have shown that even rare gases, such as argon, and the C–H bonds of alkanes will coordinate with a tricoordinate silicon center. In order to avoid coordination by external nucleophiles, primarily solvent and anions, it is necessary to protect silicon sterically with appropriate substituents. Frenking[5] has suggested that the bis(pyrrolidino)-(2,5-di-*tert*-butylpyrrolidino)silylium ion would provide the appropriate steric protection. We have chosen to examine the trimesitylsilylium (mesityl = 2,4,6-trimethylphenyl = Mes) cation for similar reasons. Our molecular mechanics calculations suggest that the *ortho* methyl groups are very effective in sealing the silicon atom from large nucleophiles. To determine whether the *ortho* methyl groups are capable of interacting with the silicon atom, we carried out RHF/6-31G(d) calculations on the (2,6-dimethylphenyl)dihydrosilylium ion ($2,6\text{-}Me_2C_6H_3\text{-}SiH_2^+$). The methyl C–H bond lengths and other geometrical factors are not perturbed, which indicate little interaction. Evidently, the C–H bonds are sufficiently far from the silicon center.

Thus, the trimesitylsilylium ion appears to be an optimal choice since the *ortho* methyl groups shield the silicon center from attack by large nucleophiles but are prohibited by their geometry from interacting with the silicon. Indeed, the mesityl group proved successful in the preparation of the first monomeric, tricoordinate aluminum species, trimesitylaluminum.[6] The question then devolves on finding a method for generating the corresponding silylium ion in condensed phase. The most successful approach to date has been removal of hydride from a suitable silicon hydride (R_3Si-H) by reaction with the triphenylmethylium (trityl) cation.[2, 3] More than a decade ago, we tried to apply this approach to trimesitylsilane, but the reaction failed even upon prolonged heating. Apparently the *ortho* methyl groups prohibit the approach of trityl for reaction with the Si–H bond. We now report a novel leaving group that permits the preparation and NMR spectroscopic characterization of the trimesitylsilylium cation.

The strategy involves constructing a tetracoordinate silicon center with three mesityl substituents and a fourth group possessing a reactive site outside the steric sphere of influence of the *ortho* methyl groups. This fourth group must be capable of reaction with a suitable reagent that would result in its removal and generation of a silylium cation. The allyl group fulfills these specifications. We prepared allyltrimesitylsilane by reaction of chlorotrimesitylsilane with allyllithium. The X-ray crystal structure of this material (Figure 1) shows that the double bond extends beyond the *ortho* methyl groups and should be available for reaction with electrophiles.

A C–Si bond is weakened through hyperconjugation with a positive charge on a β-carbon atom. Uhlig[7] found that treatment of allylsilanes with triflic acid resulted in removal of the allyl group as an alkene. The proton attacks the double bond, which creates a positive charge at the position β to the silicon atom. Triflate (or another nucleophile) then attacks silicon to generate a silyl triflate and an alkene. Similarly, Shade and Mayr[8] found that trityl tetrachloroborate reacts with allyltrimethylsilane to break the C–Si bond, expel the allyl group as allyltriphenylmethane, and produce chlorotrimethylsilane.

In the present case, the bulky mesityl groups should shield the silicon center from attack by large external nucleophiles, so that loss of the allyl group would produce the free silylium ion and an alkene (Scheme 1). The driving force would be provided by relief of steric strain around the original tetracoordinate silicon center. The same steric interactions then would prevent the silylium ion from reacting with the solvent, the anion accompanying the cationic electrophile, or the product alkene.

$Mes_3SiCH_2CH^+CH_2E\ TPFPB^- \longrightarrow Mes_3Si^+\ TPFPB^- + H_2C{=}CHCH_2E$

Scheme 1.

The first electrophile we allowed to react with allyltrimesitylsilane was trityl, as the TPFPB salt. After three days at 60 °C, a very weak ^{29}Si peak was observed at $\delta = 225.5$. Reaction with the much stronger electrophile triethylsilylium TPFPB (Et_3Si^+ coordinated with the solvent benzene[2]) produced a strong signal at $\delta = 225.5$, as well as several other peaks at $\delta \approx 50$. The latter peaks are in the correct region to indicate addition of triethylsilylium to the product alkene.[9] As a third candidate for the electrophile, we chose the recently prepared β-silylcarbocation diphenyl[(triethylsilyl)methyl]methylium TPFPB ($Et_3SiCH_2CPh_2^+$).[9] Indeed, reaction of this electrophile with allyltrimesitylsilane provided a product with a single ^{29}Si resonance at $\delta = 225.5$, as well as the expected resonances in the ^1H and ^{13}C spectra. These reactions were carried out at room temperature, and the resulting trimesitylsilylium ion is stable for several weeks.

To test whether solvent could coordinate with the trimesitylsilylium ion, we examined the ion's ^{29}Si resonance in mixed arene solvents. We had observed that the signal of the coordinated triethylsilylium ion was solvent-sensitive, appearing at $\delta = 92.3$ in C_6D_6 and 81.8 in $C_6D_5CD_3$.[2] In contrast, trimesitylsilylium showed signals at $\delta = 225.5$ in C_6D_6, 225.7 in $C_6D_6/C_6H_5CH_3$ (1/3), and 225.6 in $C_6D_6/p\text{-}(CD_3)_2C_6D_4$ (1/1). Thus, aromatic solvents are not able to move into the coordination sphere of the cation, presumably because of steric constraints. Stronger and smaller nucleophiles, however, can react: the resonance moves to $\delta = 37.0$ in C_6D_6/CD_3CN (1/3) and 47.1 in C_6D_6/Et_3N (1/1). These small nitrogen nucleophiles can navigate around the *ortho* methyl groups and penetrate to the silicon atom. It is also possible that electron transfer reactions occur.

To assure that the components of the trimesitylsilylium ion were intact, we allowed the mixture to react with tributyltin hydride. The weaker Sn–H bond should be cleaved in favor of the stronger Si–H bond. The exclusive product was indeed trimesitylsilane.

No calculations have been reported that predict the position of the ^{29}Si resonance of triarylsilylium ions. Olah and Field[10] estimated a range for δ of 100 to 150 for Ph_3Si^+ by comparison of isostructural carbon and silicon compounds and their respective ^{13}C and ^{29}Si chemical shifts. This method underestimated the shift for Me_3Si^+ by about $\Delta\delta = 100$; a similar underestimation would bring the value close to our observation, $\delta = 225.5$.[11]

Although there is no significant coordination with solvent, we cannot entirely exclude some interaction with the TPFPB anion. The observed chemical shift, however, strongly favors a nearly free, tricoordinate silylium ion.

[11] T. Müller (Humboldt Univerität zu Berlin) has obtained a ^{29}Si shift δ of 208.9 from GIAO calculations on a fully optimized Ph_3Si^+ ion with a phenyl twist angle of 28° (B3LYP/6-311+G**//B3LYP/6-31G*). The presence of the *ortho* methyl groups is expected to increase the twist angle and the chemical shift.

Tracking Down Chlorophyll Breakdown in Plants: Elucidation of the Constitution of a "Fluorescent" Chlorophyll Catabolite

Walter Mühlecker, Karl-Hans Ongania, Bernhard Kräutler,* Philippe Matile, and Stefan Hörtensteiner

Until very recently, the phenomenon of chlorophyll breakdown in plants was considered a major biological enigma.[1] However, newest findings[2] indicate that an unexpectedly rapid degradation of the green pigments to colorless, "nonfluorescent" linear tetrapyrroles occurs in senescent leaves.[3–7] About five years ago, the constitution of the secophytoporphyrinate *Hv*-NCC-1 (**1**) from senescent primary leaves of barley (*Hordeum vulgare* cv. Gerbel) was determined.[4] This provided

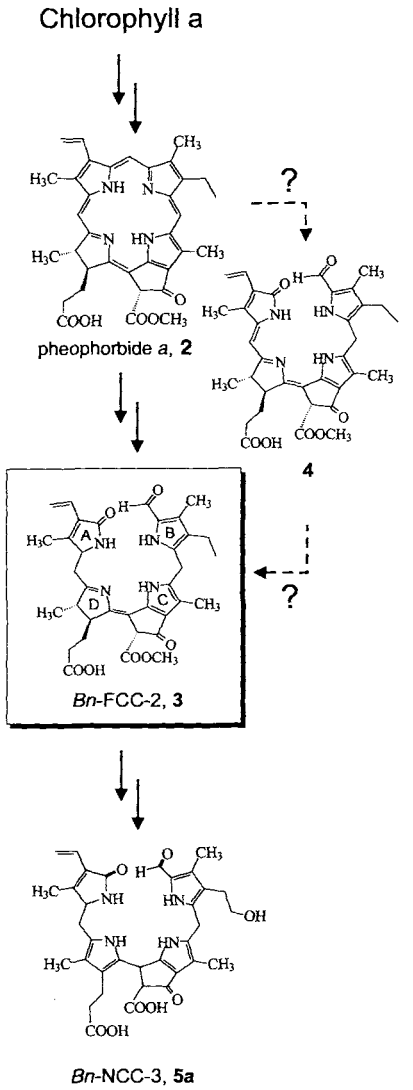

Scheme 1. Posulated breakdown pathway for chloroplyll *a*.

the first structural insight into chlorophyll degradation and contradicted all earlier expectations.[1] Meanwhile, further colorless, nonfluorescent chlorophyll catabolites have been isolated from yellowing leaves of various plants.[5-7] All of them show the same basic structure of a 4,5-seco-4,5-dioxophytoporphyrinate that was discovered in **1**. This common structural motif suggests a (constitutionally) uniform breakdown of chlorophyll in plants, in which the crucial step is an enzymatic oxidative ring opening of pheophorbide *a* (**2**).[8]

Recent HPLC studies of samples from senescent plants have provided evidence for the intermediary occurrence of trace amounts of fluorescent chlorophyll catabolites,[9] whose structure determination could provide information on "earlier" critical breakdown steps. We report here, for the first time, on the constitution of such a "fluorescent" chlorophyll catabolite, *Bn*-FCC-2 (**3**).

The catabolite **3** was produced enzymatically from pheophorbide *a* (**2**) with the help of an enzyme extract from chloroplasts of senescent cotyledons of *Brassica napus*,[8] which had been treated with glucose-6-phosphate, dihydronicotinamide adenine dinucleotide phosphate (NADPH),[9] ferredoxin, and glucose-6-phosphate dehydrogenase. After two cycles of purification by HPL chromatography, desalting, and lyophilization of the residue, a uniform sample of **3** was isolated.

The constitution of the 1-formyl-19-oxobilane **3** was deduced from its spectroscopic data.[10] The molecular formula of $C_{35}H_{40}N_4O_7$ was determined from the signal of the quasimolecular cation at $m/z = 629.301 \pm 0.004$ in the high resolution FAB/MS (calcd 629.2975). The UV/Vis spectrum of **3** shows absorbance maxima at 321 and 361 nm (Figure 1). The longwave absorption maximum at 361 nm and the photoluminescence at 450 nm are due to a conjugated π system extending over the C and D rings (Scheme 1).[11]

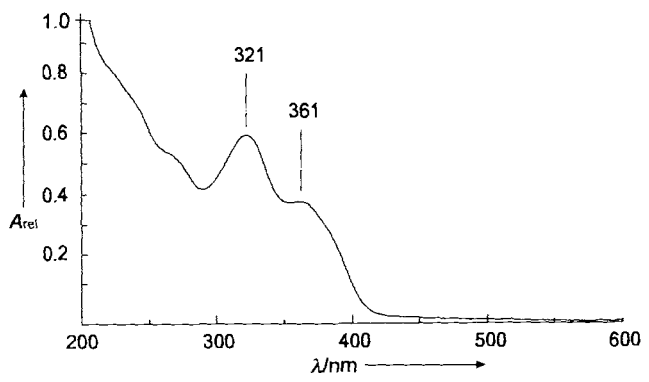

Figure 1. UV/Vis spectrum of a solution of *Bn*-FCC 2 (**3**) in water.

The signals of all 36 carbon-bound protons were detected in the 500 MHz ^{1}H NMR spectrum (H/D exchange led to gradual disappearance of the singlet for HC(13^2) at $\delta = 4.62$). These include signals for one vinyl and one ethyl group, a singlet at $\delta = 9.33$ for a formyl group, as well as four singlets for methyl groups, one of them for an ester methyl group. A fifth methyl group produced a doublet at $\delta = 1.13$. In homonuclear 2-D experiments (DQF-COSY, TOCSY),[12] six spin systems were observed for **3** (Figure 2). HMQC spectra[12] provided ^{13}C chemical shifts for proton-bearing carbons. ROESY spectra[12] enabled the positions of the substituents on the tetrapyrrolic skeleton to be determined and, consequently, the site of the oxidative ring opening.

Based on the spectroscopic data **3** can be deduced to be a 3^1,3^2-didehydro-13^2-methoxycarbonyl-4,5-seco-4,5-dioxo-1,4,5,10,17,18,20-(22H)-octahydrophytoporphyrinate.[13] This optically active 1-formyl-19-oxobilane has four stereogenic centers of uniform configuration, three of them with the same relative configuration as in pheorbide *a* (**2**). As a result, the absolute configuration of these three centers is most likely identical in **2** and **3**.

The fluorescent secophytoporphyrinate **3** exhibits the same HPLC properties[14] and UV/Vis and luminescence spectro-

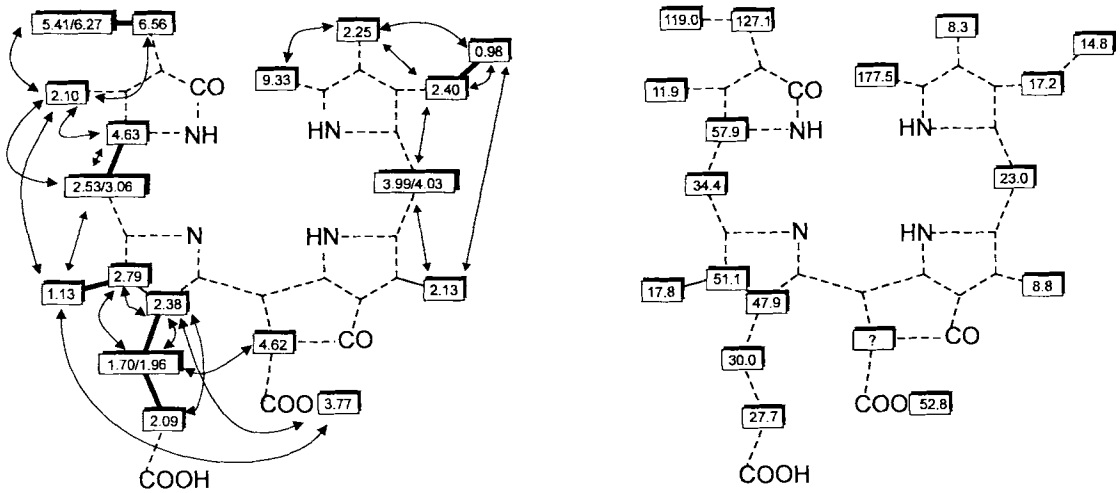

Figure 2. Left: signal assignment for the 500 MHz ^{1}H NMR spectrum of *Bn*-FCC-2 (**3**) in MeOD as well as homonuclear correlations from COSY and NOE spectra (solid lines and arrows). Right: assignment of ^{13}C signals in HMQC spectra by heteronuclear correlations with directly bonded protons.

scopic properties as authentic *Bn*-FCC-2, which is the less polar of two FCCs from senescent rape cotyledons.[9a] We therefore conclude that **3** and *Bn*-FCC-2 are identical and constitute an intermediate product in chlorophyll breakdown.

Bn-FCC-2 (**3**) can be formally derived from pheophorbide *a* by addition of one molecule of oxygen and two molecules of hydrogen. Therefore, a possible breakdown intermediate in senescent rape cotyledons could be the 4,5-seco-4,5-dioxo-4,5,10,17,18-(22H)-hexahydrophytoporphyrinate **4**, whose enzymatic reduction may lead to **3**. The subsequent breakdown of **3** to "nonfluorescent" *Bn*-NCC-3 (**5a**)[5] involves (in a yet unknown sequence) the terminal hydroxylation of the ethyl group at ring B, the tautomerization of a 4,5-seco-4,5-dioxo-1,4,5,10,17,18,20-(22*H*)-octahydrophytoporphyrinate to a 4,5-seco-4,5-dioxo-1,4,5,10,15,20-(22*H*,24*H*)-octahydrophytoporphyrinate,[15] and (most likely as the final step[16]) the hydrolysis of the ester function.

The dimethyl ester derivative of **4**, isolated from red tetrapyrrolic excretions from *Chlorella protothecoides*, has been structurally characterized by Gossauer and co-workers and identified as a derivative of a chlorophyll catabolite of this green alga.[17] Isotopic labeling studies show that only one of the two new oxygen atoms comes from molecular oxygen.[18] It remains to be determined whether in this respect chlorophyll breakdown follows the same pathway in plants as in green alga. Interestingly, catabolites of both chlorophyll *a* and chlorophyll *b* were found in *Chlorella protothecoides*,[17] whereas only derivatives of chlorophyll *a* could be detected in plants.[2-8]

The structure elucidation of the fluorescent chlorophyll catabolite *Bn*-FCC-2 (**3**) is an important step forward for the detailed description of enzymatic chlorophyll degradation in senescent rape cotyledons[2] and in plants in general. Furthermore, these experiments may lead to a closer characterization of the unique enzymatic oxygenolysis of the chlorine macrocycle in senescent plants.

Experimental Section

Chloroplast membranes from 670 g of senescent cotyledons of *Brassica napus* L cv. Arabella [8,9] were suspended in 12.5 mL of a 25 mM tris(hydroxymethyl)-aminomethane(tris)-2-(*N*-morpholino)ethane sulfonic acid buffer with 1% Triton X-100 for 30 min at 4 C. The mixture was subsequently centrifuged for 1 h at 260000 g. The supernatant (soluble membrane extract) was diluted with 60 mM NADPH (830 μL), 100 mM glucose-6-phosphate (830 μL), glucose-6-phosphate dehydrogenase (25 μL, 0.5 U μL^{-1}), ferredoxin (400 μL, 10 U μL^{-1}), and pheophorbide *a* (**2**, 2 mg). After incubation at room temperature for 1 h in the dark, MeOH (19 mL) was added. The mixture was centrifuged (10 min per 12000 g), and the supernatant diluted with 8 mL water and separated by HPLC (column: Stagroma, Wallisellen, Switzerland, Spherisorb ODS-2 5 μm, 8 × 125 mm; MeOH/100 mM potassium phosphate 55/45, pH = 7; flow rate 2.8 mL min^{-1}; UV detection at 320 nm; emission at 450 nm, excitation at 320 nm). The fractions with a retention time of approximately 10 min were collected and frozen in N_2. The combined fractions were diluted to 10 vol% methanol by addition of 100 mM potassium phosphate (pH = 7) and applied to a Waters-C18 SepPak cartridge. A yellow fraction was eluted with methanol/40 mM potasium phosphate (9/1 v/v, pH = 7), diluted with H_2O to 50 vol% methanol, and purified a second time by HPLC, as described above. The HPLC eluates were applied to a C18 cartridge and washed with H_2O (20 mL). After eluting **3** with (9/1 v/v) methanol/H_2O, it was immediately lyophilized at $T < 0$ °C, yielding approximately 0.1 mg of **3** (yellow powder).

Synthesis and Structure of the First Si-Al-NH Cage Compound from a Stable Triaminosilane and Trimethylaluminum**

Carsten Rennekamp, Alexander Gouzyr, Andreas Klemp, Herbert W. Roesky,* Christiane Brönneke, Jörg Kärcher, and Regine Herbst-Irmer

Dedicated to Professor Oskar Glemser on the occasion of his 85th birthday

Aluminosilicates serve as important catalysts in many industrial processes,[1–3] and Al–Si oxonitrides have been known as ceramic materials since the 1970s.[4] In this context it seemed a reasonable goal to construct model compounds for a nitrogen-analogous aluminosilicate chemistry from stable triaminosilanes. Compounds of this kind are hitherto unknown and should offer a new range of properties.

Conversions of stable silanetrioles of the type $RSi(OH)_3$ to inorganic cage molecules have already been frequently reported. Thus, for instance, a titanium silasesquioxane could be obtained from $RSi(OH)_3$ (R = iPr$_2$C$_6$H$_3$NSiMe$_3$) and Ti(OiPr)$_4$. This can be considered as a model compound for titanium-doped zeolites.[5] Another example is the product of the reaction of $RSi(OH)_3$ with diisobutylaluminum hydride giving a soluble zeolite precursor.[6] The reaction of $RSi(OH)_3$ (R = iPr$_2$C$_6$H$_3$NSiMe$_3$) with Me_3Al leads to a corresponding cubane.[7]

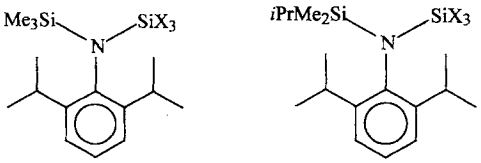
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Hoechst AG, the Witco GmbH, and by the Bundesministerium für Bildung und Forschung.

In 1993 Power et al. reported on the synthesis of the first monomeric triaminosilane, 2,4,6-$Ph_3C_6H_2Si(NH_2)_3$, by ammonolysis of the corresponding trichlorosilane.[8] In analogy, stable triaminosilanes can be synthesized from the precursors of the above-mentioned silanetrioles, the trichlorosilanes of the type $RSiCl_3$ (R = iPr$_2$C$_6$H$_3$NSiMe$_3$ (**1a**), 2,4,6-tBu$_3$C$_6$H$_2$O).[9] Our primary goal was the synthesis of Si-Al-NH cage compounds by reaction of triaminosilanes $RSi(NH_2)_3$ with simple organoaluminum compounds.



1a : X = Cl
1b : X = NH_2

2a : X = Cl
2b : X = NH_2

Me_3Al reacts with $RSi(NH_2)_3$ (R = iPr$_2$C$_6$H$_3$NSiMe$_3$) (**1b**) to give a product that is almost insoluble in all common organic solvents and thus difficult to characterize. Replacement of a methyl group in the trimethylsilyl group by an isopropyl group should lead to an increase in the solubility of this product. Thus, the trichlorosilane **2a** was prepared and converted to the triamine **2b** by ammonolysis. Single crystals of **2b** were obtained from pentane/hexane. In the asymmetric unit there are two molecules of **2b**,[13] and one pentane molecule disordered about the twofold axis (Figure 1). The bond lengths and angles of the two

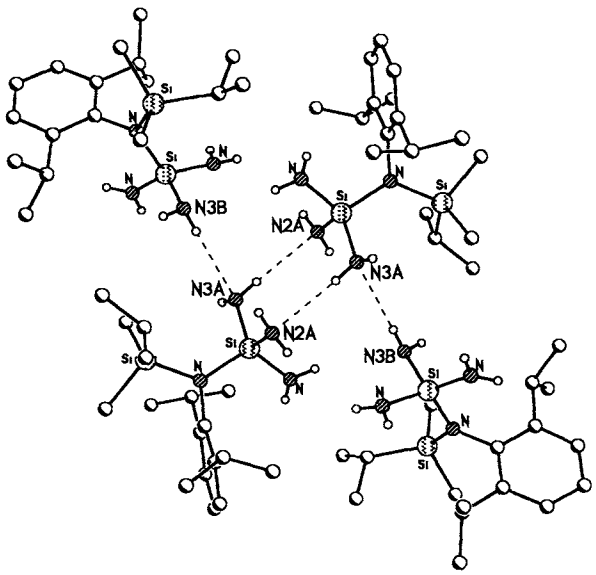


Figure 1. Crystal structure of **2b**.

independent molecules show negligible differences. These two molecules are linked to each other and to two additional symmetry-related molecules through hydrogen bonds (N3B–N3A 336.4, N3A–N2A 329.2 pm); thus, unlike in **1b**, which is dimeric, **2b** exists as a tetramer.

The reaction of **2b** with Me_3Al leads to **3** [Eq. (a)]. Single crystals suitable for X-ray structure analysis were obtained from THF/hexane. The molecular structure of **3** in the crystal shows point symmetry (Figure 2).[14] The central cage framework consists of two six-membered Al_2N_3Si rings present in the boat

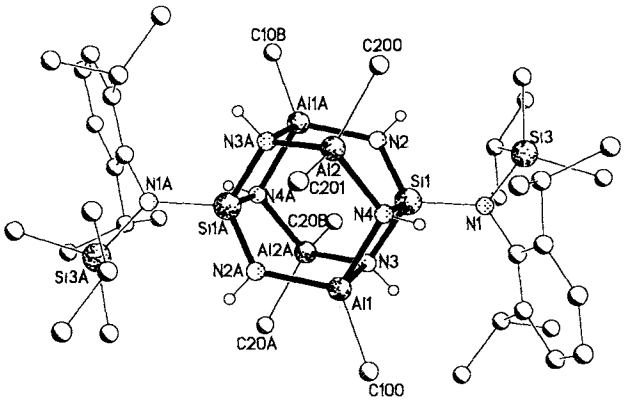

Figure 2. Crystal structure of **3**. Selected bond lengths [pm] and angles [°]: N1–Si1 172.8(1), Si1–N3 178.4(1), N4–Al2 195.0(1), Si1–N2 169.4(1), Si1–N4 179.4(1), N3–Al1 197.2(1), N4–Al1 195.0(1); N2-Si1-N1 114.2(1), N1-Si1-N3 115.4(1), N1-Si1-N4 112.8(1), N2-Si1-Al1 122.0(1), Si1-N2-Al1A 123.3(1), Si1-N4-Al2 118.9(1), Si1-N3-Al1 92.2(1), N2A-Al1-Si1 114.7(1), N2-Si1-N3 108.8(1), N3-Si1-N4 92.5(1), N1-Si1-Al1 123.7(1), N4-Al1-N3 82.5(1).

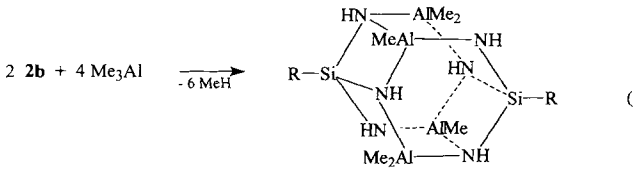
conformation, which are linked to each other through two Al–N and two Si–N bonds. The aluminum atoms are four coordinate; in each case two interactions involve dipolar bonds to the nitrogen atoms. The ^{1}H NMR spectrum of **3** shows the



(a)

R = 2,6-*i*Pr$_2$C$_6$H$_3$NSiMe$_2$*i*Pr

3

expected signals. Thus, the singlets ($\delta = -1.38, -0.85$) are assigned to the protons of the methyl groups at the aluminum atom. The corresponding signals for the ligands of **3** can be assigned correctly through integration.[11] The most intense signals in the mass spectrum (EI) appear at *m/z* 881 (100%) and 433 (38%), and were assigned to the molecular ion and half the molecular ion minus a methyl group in each case, respectively.

Although the NH group is isoelectronic to the O atom, a cubane compound analogous to that obtained in the reaction of the silanetriole with Me_3Al is not formed;[7] however, the structure of **3** is similar to that of the product from the reaction of Me_3Ga with *i*Pr$_2$C$_6$H$_3$NSiMe$_3$Si(OH)$_3$.[10]

Compound **3** is unusually thermally stable and decomposes only at 280 °C. Interestingly, even when the stoichiometry of the reactants was altered, **3** was always obtained as the product. Thus, reactions of the starting materials in a molar ratio 1:1 also gave **3**. Even, the reaction of **2b** with the dimethylaminoalane $Me_2Al(iPr_2C_6H_3NSiMe_3)$ in a molar ratio 1:1 afforded **3**, further emphasizing the preferred formation of this product.

Since **3** is a bifunctional compound, many subsequent reactions can be envisaged. We are currently interested in the metalation of the imino groups and in the substitution of the methyl groups at the aluminum atoms. Furthermore **3** could serve as a precursor for ternary ceramics and open up the possibility of many applications in the context of chemistry analogous to that established for the aluminosilicates. Thus, the planned construction of supramolecular structures with characteristic properties is conceivable with **3** and also with the abovementioned siloxanes.

Experimental Section

2a was prepared from *i*Pr$_2$C$_6$H$_3$NHSiMe$_2$*i*Pr and $SiCl_4$ analogous to the synthesis of **1a** [4]; yield 3.2 g (72%); m.p. 35 °C; ^{1}H NMR (200 MHz, C_6D_6): $\delta = 0.13$ (s, 6H, Si(CH_3)$_2$*i*Pr), 0.92 (d, ^3J(H,H) = 7.1 Hz, 6H, CH(CH_3)$_2$), 1.19 (d, ^3J(H,H) = 6.8 Hz, 6H, CH(CH_3)$_2$), 1.23 (d, ^3J(H,H) = 6.8 Hz, 6H, CH(CH_3)$_2$), 1.31 (sept., ^3J(H,H) = 7.1 Hz, 1H, C*H*(CH$_3$)$_2$), 3.60 (sept., ^3J(H.H) = 6.8 Hz, 2H, C*H*(CH$_3$)$_2$), 7.03 (m, 3H, ArH); ^{29}Si NMR (50 MHz, C_6D_6): $\delta = 16.3$ (Si(CH_3)$_2$*i*Pr), −27.0 ($SiCl_3$); IR (KBr, Nujol): $\tilde{\nu}$ = 1362, 829, 752 cm^{-1}; MS (EI): *m/z* (%): 411 (8) [M^+], 368 (100) [$M^+ - i$Pr]; correct elemental analysis [12].

2b: **2a** (1.09 g, 2.7 mmol) was dissolved at −78 °C in liquid ammonia (ca. 15 g), which had previously been dried over sodium metal. The ammonia was allowed to evaporate from the reaction mixture under stirring over 14 h. During this period the mixture was allowed to warm slowly from −55 to −30 °C. The remaining white residue was taken up in CH_2Cl_2 (15 mL), the ammonium chloride that formed was filtered off, and the solvent was removed in vacuo. Crystals suitable for X-ray structure analysis were obtained by recrystallization from hexane/pentane (5 mL). After removal of all of the volatile components, the colorless product was purified by sublimation (55 °C, 10^{-2} bar). Colorless crystals of **2b** were obtained in 70% yield (0.67 g); m.p. 62 °C; ^{1}H NMR (200 MHz, C_6D_6): $\delta = 0.99$ (s, 6H, Si(CH_3)$_2$*i*Pr), 0.45 (br. s, 6H, Si(NH_2)$_3$), 1.03 (d, ^3J(H,H) = 7.1 Hz, 6H, CH(CH_3)$_2$), 1.23 (d, ^3J(H,H) = 6.8 Hz, 6H, CH(CH_3)$_2$), 1.27 (d, ^3J(H,H) = 6.8 Hz, 6H, CH(CH_3)$_2$), 1.31 (sept., ^3J(H,H) = 7.1 Hz, 1H, C*H*(CH$_3$)$_2$), 3.65 (sept., ^3J(H,H) = 6.8 Hz, 2H, C*H*(CH$_3$)$_2$), 7.06 (s, 3H, ArH); ^{29}Si NMR (50 MHz, C_6D_6): $\delta = 7.9$ (Si(CH_3)$_2$*i*Pr), −41.8 (Si(NH_2)$_3$); IR (KBr, Nujol): $\tilde{\nu}$ = 3489, 3407, 1362, 829, 752 cm^{-1}; MS (EI): *m/z* (%): 352 (4) [M^+], 309 (100) [$M^+ - i$Pr]; correct elemental analysis [12].

3 (from **2b** and Me_3Al): Me_3Al (2.3 mL, 2M solution in heptane, 4.6 mmol) was added dropwise to a solution of **2b** (0.82 g, 2.3 mmol) in toluene (20 mL) at −70 °C. As soon as the gas evolution had ceased, the mixture was allowed to warm to room temperature and stirred for 12 h. The solvent was removed in vacuo, and the remaining yellow oil was taken up in hexane. A white solid precipitated that was filtered off. Compound **3** was obtained in 75% yield (0.77 g). Starting from **2b** and Me_3Al in the molar ratio 1:1 the yield of **3** was 0.39 g (75%).

3 (from **2b** and $Me_2Al(iPr_2C_6H_3NSiMe_3)$): A solution of $Me_2Al(iPr_2C_6H_3NSiMe_3)$ (0.70 g, 2.2 mmol) in hexane (20 mL) was added dropwise to a solution of **2b** (0.80 g, 2.2 mmol) in hexane (30 mL) at 0 °C. After the gas evolution had ceased, the reaction mixture was stirred for 12 h at room temperature, followed by 1 h at 30 °C. The solvent was concentrated under vacuum to 15 mL, and the white solid residue was filtered off; yield 0.40 g (82%); decomp 280–285 °C; ^{1}H NMR (200 MHz, [D$_8$]THF): $\delta = -1.37$ (s, 6H, $AlCH_3$), −0.83 (s, 12H, Al(CH_3)$_2$), 0.08 (s, 12H, Si(CH_3)$_2$*i*Pr), 0.89 (br. s, 6H, Si(NH)$_3$), 1.15 (d, ^3J(H,H) = 6.8 Hz, 12H, CH(CH_3)$_2$), 1.20 (d, ^3J(H,H) = 6.8 Hz, 12H, CH(CH_3)$_2$), 1.32 (d, ^3J(H,H) = 6.8 Hz, 12H, CH(CH_3)$_2$), 1.38 (sept., ^3J(H,H) = 7.1 Hz, 2H, C*H*(CH$_3$)$_2$), 3.52 (sept., ^3J(H,H) = 6.8 Hz, 4H, C*H*(CH$_3$)$_2$), 7.23 (s, 6H, ArH); IR (KBr, Nujol): $\tilde{\nu}$ = 3407, 3345, 3328, 1383, 825, 753 cm^{-1}; MS (EI): *m/z* (%): 433 (38) [(*M*/2)$^+$ − Me], 881 (100) [M^+ − Me]; correct elemental analysis [12].

[11] The ^{1}H NMR spectrum also shows a second series of signals for the ligand protons and a broad signal ($\delta = -0.85$) for the protons of the methyl groups at the aluminum atom. From this we conclude that apart from **3**, $RSi(NH)_3Al_2Me_3$ is probably also present in THF. This is also supported by temperature-dependent ^{1}H NMR measurements.

[12] Small deviations in the elemental analyses are attributed to the formation of metal carbides and metal nitrides.

[13] a) Crystallographic data of **2b**: $C_{17}H_{36}N_4Si_2 \cdot 0.25\,C_5H_{12}$, $M_r = 370.71$, space group $P2/c$, $a = 1511.1(1)$, $b = 980.8(1)$, $c = 3137.1(3)$ pm, $\beta = 96.59(1)^\circ$, $V = 4.6187(7)$ nm^3, $Z = 8$, $\rho_{calcd} = 1.066$ Mg m^{-3}, $F(000) = 1636$, $\lambda = 71.073$ pm, $\mu(Mo_{K\alpha}) = 0.162$ mm^{-1}. Data for the structure were collected on a Stoe-Siemens AED diffractometer. Intensity measurements were performed at 193 K on a rapidly cooled crystal in an oil drop [15] according to the $2\theta/\omega$ method in the range $7^\circ \le 2\theta \le 48^\circ$. The monoclinic crystal was colorless and had the dimensions $0.7 \times 0.5 \times 0.3$ mm. Of 8892 measured reflections 7243 were independent ($R_{int} = 0.0362$). The structure was solved by direct methods (SHELXS-90) [17] and refined according to the least-squares method on F^2 [16]. Hydrogen atoms, apart from those of the amino groups, were calculated in their ideal geometrical positions and refined according a riding model in which the methyl groups were able to rotate about their local axes. The hydrogen atoms of the amino groups could be localized by difference-Fourier synthesis and refined with distance restraints. The pentane molecule is disordered about the twofold axis. 218 restraints were used for the final refinement of the 558 parameters. The final difference-Fourier synthesis gave a minimum of -248 and a maximum of $+392$ e nm^{-3}. $R1 = 0.0406$ (for reflections with $I > 2\sigma(I)$) and $wR2 = 0.1045$ (all data). $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $wR2 = \{[\Sigma w(F_c^2 - F_c^2)^2]/[\Sigma w(F_c^2)^2]\}^{1/2}$. b) Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100052. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: Int. code +(1223) 336-033; e-mail deposit@chemcrys.cam.ac.uk).

[14] Crystallographic data of **3**: $C_{40}H_{84}Al_4N_8Si_4$, $M_r = 897.43$, triclinic, space group $P\bar{1}$, $a = 1042.2(3)$, $b = 1164.5(3)$, $c = 1218.6(3)$ pm, $\alpha = 94.67(1)$, $\beta = 107.16(1)$, $\gamma = 104.14(1)^\circ$, $V = 1.3514(7)$ nm^3, $Z = 1$, $\rho_{calcd} = 1.103$ Mg m^{-3}, $F(000) = 488$, $\lambda = 71.073$ pm, $T = 193$ K, $\mu(Mo_{K\alpha}) = 0.209$ mm^{-1}. Data for the structure were collected on a Stoe-Siemens-Huber diffractometer with a Siemens CCD detector. Intensity measurements were performed at 193 K on a rapidly cooled crystal with the dimensions $0.9 \times 0.7 \times 0.4$ mm in an oil drop [15] in the range $6.36^\circ \le 2\theta \le 56.56^\circ$. Of 21086 measured reflections 6569 were independent ($R_{int} = 0.0203$). A semiempirical absorption correction was carried out on all data. The structure was solved by direct methods (SHELXS-90) [17] and refined according to the full-matrix least-squares method on F^2 [16]. The positions of the hydrogen atoms of N–H bonds were refined with distance restraints and those of C–H bonds were calculated in their ideal geometrical positions and refined according to the riding model. An extinction correction was carried out. In total 277 parameters were refined. $R1(I > 2\sigma(I)) = 0.033$, $wR2 = 0.094$ (all data). The largest deviations in the final difference-Fourier synthesis are $+714$ and -439 e nm^{-3} [13b].

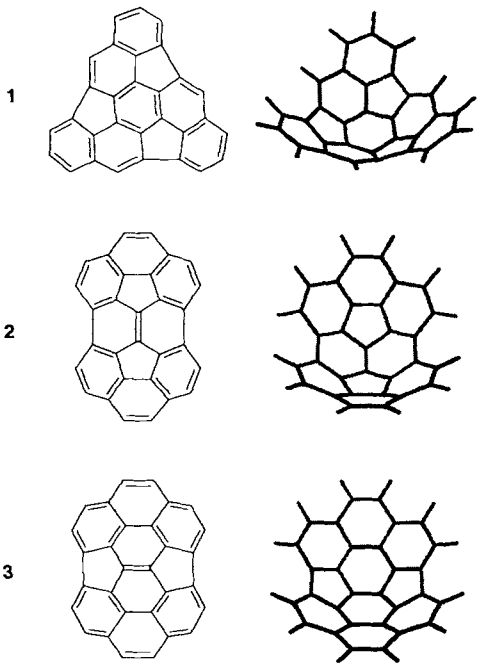
Novel Syntheses of Three $C_{30}H_{12}$ Bowl-Shaped Polycyclic Aromatic Hydrocarbons**

Stefan Hagen, Matthew S. Bratcher, Mark S. Erickson, Gerhard Zimmermann, and Lawrence T. Scott*

Bowl-shaped polycyclic aromatic hydrocarbons (PAH) are currently attracting considerable attention as the "missing links" between normal planar PAH and the tremendously strained, closed polyhedral fullerenes.[1] In our continuing efforts to define the scope and limitations of the flash vacuum pyrolysis (FVP) strategy for preparing such compounds,[2] we have developed short syntheses for the three isomeric $C_{30}H_{12}$ bowl-shaped hydrocarbons **1**, **2**, and **3**.[3]



"Buckybowls" **1** and **2** both map directly onto the surface of C_{60} and have recently been prepared by distinctly different routes in quantities sufficient for NMR characterization by Rabideau et al.[4, 5] The bowl-shaped PAH **3**, on the other hand, was unknown until now and does not map onto the ring system of any known fullerenes smaller than C_{78}.[6] Herein we describe new syntheses for all three compounds.

When looking for potential precursors to **1** that already embody the C_3 symmetry of the final target compound, one is naturally drawn to the $C_{30}H_{18}$ PAH benzo[c]naphtho[2,1-p]-chrysene (**4**, Scheme 1). This attractive compound is now conveniently available in multigram quantities by our new four-step synthesis.[7] Earlier, unsuccessful attempts to prepare **1** by FVP (1100 °C) of **4**[8] underscore the generalization that synthetic routes to strained bowl-shaped PAH based on uncatalyzed cyclodehydrogenation reactions of hydrocarbons rarely work well[9, 10] and sometimes fail completely (as in this case). On the other hand, we have previously found that aromatic hydrocarbons bearing a bromine atom at the site of each intended cyclization reaction significantly outperform the unsubstituted parent hydrocarbons as precursors for the synthesis of bowl-shaped PAH such as dibenzo[a,g]corannulene and diindeno[1,2,3,4-*defg*;1′,2′,3′,4′-mnop]chrysene.[2b] The weakly bound bromine atoms are easily lost at elevated temperatures, and this prearranged homolysis can be used to generate reactive aryl radicals specifically at the sites required for ring-closure reactions.[11] To implement this aryl radical cyclization strategy in the present case, we simply brominated hydrocarbon **4** and subjected the resulting tribromide to flash vacuum pyrolysis.

As anticipated, bromination of **4** with Br_2 (9 equiv, refluxing chlorobenzene, 1 h) results in the selective formation of 6,12,18-tribromobenzo[c]naphtho[2,1-p]chrysene (**5**, 90%).[12] We found it necessary to use a high-boiling solvent in order to keep

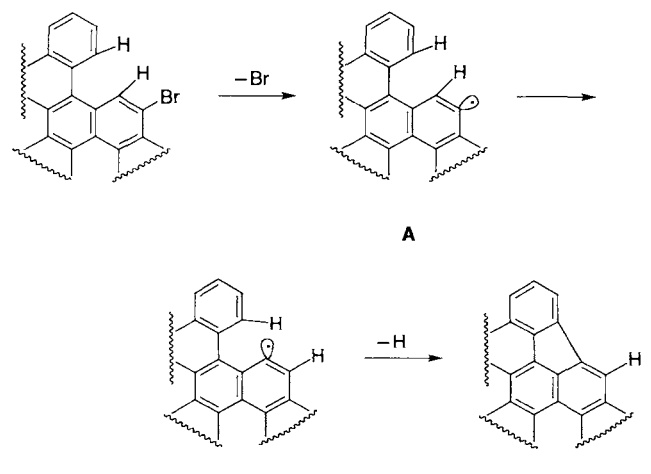
Scheme 1. Conversion of **4** [7] to the chiral $C_{30}H_{12}$ bowl **1** (FVP = flash vacuum pyrolysis).

the sparingly soluble mono- and dibrominated intermediates in solution until the reaction reached completion.

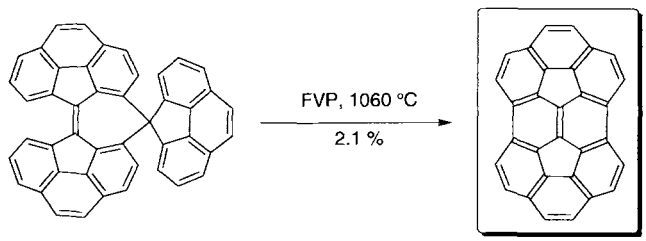
Samples of up to 1.0 g of tribromide **5** were subjected to FVP (1050 °C, 2.0 mbar, N_2 as carrier gas),[13] and the PAH **1**[5] was isolated in 7.5–9% yield by chromatography of the pyrolysate on an alumina column (hexane/toluene gradient). By this procedure, 50 mg samples of purified $C_{30}H_{12}$ (**1**) can be prepared in a single pyrolysis run from the easily available tribromide **5**.

The formation of **1** from **5** is believed to occur by a stepwise loss of the Br atoms, whereby each homolysis initially leads to an aryl radical of type **A** (Scheme 2). The sterically hindered H atom at the adjacent site then, in accordance with our plan, apparently shifts out of the fjord region by a 1,2-H migration. This yields an energetically preferred aryl radical of type **B** with a less crowded fjord region. The net results of these steps are the generation of a reactive aryl radical at the site where ring closure is desired and a reduction in the distance between the two carbon atoms destined to be joined. This new trick will undoubtedly find other applications in the synthesis of still larger fullerene fragments.



Scheme 2. Proposed pathway for cyclizations in Scheme 1. For example, **1** is formed by 1,2-H migration and loss of hydrogen from **A** in each fjord region.

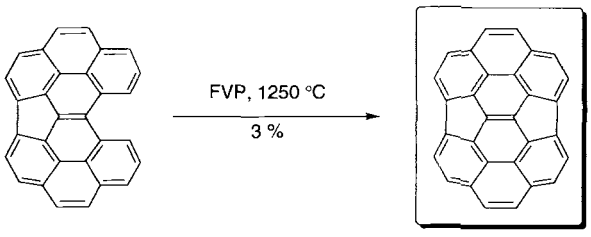
As a potential precursor to the curved PAH **2**, we examined the spiro compound **6**, a hydrocarbon that can be synthesized in just three steps from commercially available cyclopenta-[*def*]phenanthrene in moderate yield.[14] We anticipated that elevated temperatures should induce homolytic scission of an sp^3–sp^2 C–C bond and that the diradical resulting from rupture of the seven-membered ring could reclose to form a new six-membered ring, thereby preparing the way to molecule **2** (Scheme 3). Indeed, flash vacuum pyrolysis of **6** (1060 °C, 1.5 mbar, N_2 as carrier gas)[13] gives the $C_{30}H_{12}$ fullerene fragment **2**[4] in 2.1% yield after chromatographic separation on alumina (hexane/toluene gradient) and recrystallization (CH_2Cl_2/CH_3OH).



6 2

Scheme 3. *Fragmentation of* **6** *[14] to the* $C_{30}H_{12}$ *[5,5]fulvalene circulene* **2**.

Our recent success in the synthesis of a $C_{36}H_{12}$ subunit of C_{60} by threefold thermal cyclodehydrogenation of decacyclene at temperatures of 1200–1300 °C[10] inspired us to reinvestigate the pyrolysis of dibenzo[*de,hi*]fluoreno[2,1,9,8,7-mnopqr]-naphthacene (**7**). In contrast to our previous experience with FVP of **7** at temperatures up to 980 °C,[15] we have now found that FVP of **7** at 1250 °C (0.5 mbar, N_2 as carrier gas)[13] gives small amounts (3%) of a new red hydrocarbon, to which we assign structure **3** on the basis of its spectroscopic properties (Scheme 4).[16] As expected for its C_{2v} symmetry, hydrocarbon **3** has a very simple ^1H NMR spectrum,[16] showing a singlet at $\delta = 7.18$ and a pair of doublets at $\delta = 7.40$ and 7.47 ($J = 8.0$ Hz). The ^{13}C NMR and mass spectra support the assigned structure.[16]



7 3

Scheme 4. Cyclodehydrogenation of **7** [15] to the new $C_{30}H_{12}$ bowl-shaped **3**.

The results described here provide short, new routes to the previously known $C_{30}H_{12}$ fullerene fragments **1** and **2** as well as the first synthesis of the isomeric bowl-shaped PAH **3**. The approach based on homolysis of C–Br bonds to generate aryl radicals at predetermined sites (Schemes 1 and 2) proved to be

decidedly superior to less controlled homolyses (Scheme 3) or the uncatalyzed thermal cyclodehydrogenation of a PAH (Scheme 4). Semifullerene **1** is now available in sufficient quantities to permit further experimental studies.

Unusual Reaction Pathways in the Photolysis of Diazido(phosphane)nickel(II) Complexes: Nitrenes As Intermediates in the Formation of Nickel(0) Complexes**

Horst Hennig,* Katrin Hofbauer, Katrin Handke, and Rainer Stich

Dedicated to Professor Derk J. Stufkens on the occasion of his 60th birthday

The photochemical specificity of azide ligands is due to their redox behavior:[1] depending on the central ion nitrido complexes,[2] azidyl radicals,[3] or nitrene intermediates form.[4] Whereas photochemical redox reactions with participation of the central ion are well described,[1] only with azido complexes of iridium(III),[5] rhodium(III),[6] and diazidonickel(II) complexes with azamacrocycles as ligands[7] have photochemical nitrene reaction pathways been observed, and then indirectly by secondary hydrazine formation. We were able to show that the primary photoreaction due to charge transfer (CT) excitation of nickel(II) complexes of the constitution $[Ni(''P_2'')(N_3)_2]$ (P_2: mono- and diphosphane ligands; **1**–**4**) leads to the generation of nitrenes as intermediates.

The transition metal complexes $[Ni(Et_3P)_2(N_3)_2]$ (**1**), $[Ni(dppe)(N_3)_2]$ (**2**, dppe = 1,2-bis(diphenylphosphino)ethane), $[Ni(dppp)(N_3)_2]$ (**3**, dppp = 1.3-bis(diphenylphosphino)propane) and $[Ni(vpp)(N_3)_2]$ (**4**, vpp = 1.2-bis(diphenylphosphino)-ethene)[10] show photoinduced redox reactions in CH_2Cl_2 or EtOH as solvents (Figure 1). The estimated quantum yields

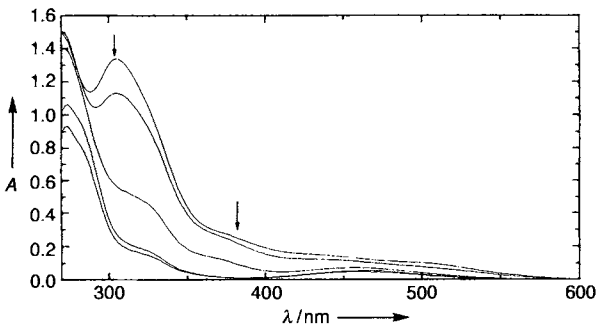

Figure 1. Course of the photolysis of **2** in CH_2Cl_2 monitored by UV/Vis spectroscopy: irradiation time (from top) 0, 10, 30, 60, 120 s; wavelength of irradiation $\lambda^{irr} = 313$ nm; A = absorption (arbitrary units).

are in the order of $\Phi^{313} \approx 0.5 \times 10^{-1}$ with insignificant variations depending on the constitution of the metal complexes used. The stationary photolysis [Eq. (a)] yields the final prod-

$$2\,[Ni(''P_2'')(N_3)_2] \xrightarrow{h\nu} [Ni^0(''P_4'')] + [Ni(N_3)_2] + 3\,N_2 \qquad (a)$$

ucts $[Ni(N_3)_2]$ (detection by means of IR spectroscopy and elemental analysis), N_2, and tetrakis(phosphane)- and bis(diphosphane)nickel(0) complexes (respectively **1c**, **2c**, **3c**, and **4c**; comparison of elemental analysis, UV/Vis, and IR and NMR spectroscopy with nickel(0) complexes[11] prepared independently; Scheme 1). Moreover, the stationary photolysis of **1**–**4**

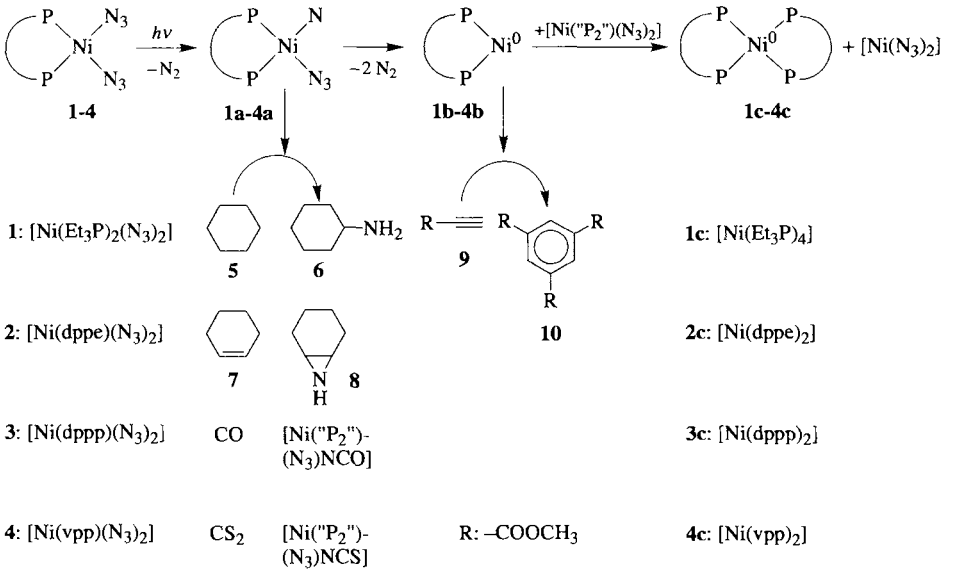

Scheme 1. Survey of the photolysis of **1**–**4** in the presence of cyclohexane (**5**), cyclohexene (**7**), CO, CS_2 as well as methyl propiolate (**9**) or in inert solvents (formation of **1c**–**4c**).

opens a novel and convenient route to the nickel(0) complexes **1c**–**4c**.[12]

The generation of nickel(I) complex fragments ([Ni^I-("P_2")(N_3)]) and azidyl radicals ($N_3^{\bullet}$) as primary products of the photolysis of **1**–**4** were definitely excluded by means of ESR and ESR spin trapping, whereas both conventional and time-resolved IR spectroscopy showed that the intensity of bands at 2062 cm^{-1} typical for coordinated N_3^- decreased. Therefore, according to Basolo,[4] the primary products generated are mononitrene complexes of the type [Ni("P_2")(N_3)(N)] (**1a**–**4a**) [Eq. (b); Scheme 1]. These species decay thermally to short-lived, coordinatively unsaturated bis(phosphane)- and mono(diphosphane)nickel(0) complexes (**1b**–**4b**) via dinitrenenickel(II) complexes [Ni("P_2")(N_2)] [Eq. (c) and (d), Scheme 1).

$$[Ni("P_2")(N_3)_2] \xrightarrow{h\nu} [Ni("P_2")(N_3)(N)] + N_2 \quad (b)$$

$$[Ni("P_2")(N_3)(N)] \longrightarrow [Ni("P_2")(N)_2] + N_2 \quad (c)$$

$$[Ni("P_2")(N)_2] \longrightarrow [Ni("P_2")] + N_2 \quad (d)$$

The direct detection of nitrene intermediates by both time-resolved UV/Vis and IR spectroscopy in particular gave no clear results, because the low photosensitivity of **1**–**4** afforded inaccurate IR detection. Merely the expectedly fast decrease in the intensity of the azide bands (decay of the IR band of **4** at 2062 cm^{-1} faster than 30 μs) was observed. However, the generation of nitrene intermediates was shown indirectly by means of suitable scavenging reactions. The formation of singlet nitrenes was presupposed, because triplet nitrenes are not detected by ESR spectroscopy.

Typical nitrene scavenging processes are reactions with cyclohexane (**5**) and cyclohexene (**7**), as well as with CO and CS_2. The insertion into aliphatic CH bonds with amine formation may be regarded as a specific nitrene reaction,[8] whereas with electron-poor olefins in particular, as well as with CO and CS_2, bimolecular cycloaddition reactions with subsequent N_2 scission may also occur.[9b] According to Beck this reaction pathway requires a coordinative interaction with the scavenging reagents that was not observed by UV/Vis spectroscopy for **1**–**4** under the photochemical conditions used.

Irradiation of **1** ($\lambda^{irr} > 320$ nm) in cyclohexane (sufficient solubility of **1** relative to that of **3** and **4**) leads to the formation of cyclohexylamine (**6**; polychromatic irradiation, 200 W Hg/Xe lamp, Ar, 50 mL glass kuvette, glass filter, irradiation adjusted to 90% photolysis of **1** monitored by UV/Vis spectroscopy, direct injection of filtered photolysis solution into GC–MS system VG 12–250, molecular ion peak and decay peaks of **6** in agreement with literature;[13] no further derivatives of **5** detectable; product yield based on **1** > 5%). To improve the solubility the photolysis of **3** and **4** in the presence of **5** required the addition of 2-methyltetrahydrofurane (2-MeTHF) or CH_2Cl_2. These solvents also led to N-insertion with formation of **6** (see Scheme 1). The use of 2-MeTHF, however, gave rise to side reactions.

The photolysis of **1**–**4** in the presence of cyclohexene (**7**) leads to N-insertion with formation of an aziridine (**8**). Under preparative conditions the photolysis of **2** with **7**, for example, yields 7-azabicyclo[4.1.0]heptane (**8**) (for instance: 8 h polychromatic irradiation of **2** (1.5 g) in CH_2Cl_2 (150 mL) and **7** (50 mL), 250 mL photoreactor, Ar, precipitation by *n*-hexane; vacuum distillation of the filtrate yields **8** (0.32 g, ≈23% based on **2**); NMR, GC, refraction value, formation of derivates of **8** in accordance with commercially available samples and literature[13, 14]).

Photolysis of **1**–**4** in the presence of CO yields isocyanato complexes [Eq. (e) and (f); Scheme 1), in agreement with findings of Beck,[9a] who observed for the reaction of **2** with CO under comparably extreme thermal conditions the formation of [Ni(dppe)$(NCO)_2$]. A nitrene intermediate was postulated for that reaction pathway.[9b]

$$[Ni("P_2")(N_3)(N)] + CO \longrightarrow [Ni("P_2")(N_3)NCO] \quad (e)$$

$$[Ni("P_2")(N)_2] + 2\,CO \longrightarrow [Ni("P_2")(NCO)_2] \quad (f)$$

Because the photolysis products [Ni("P_2")(N_3)NCO] and [Ni("P_2")$(NCO)_2$] were themselves light-sensitive, the irradiation was ended after 50% consumption of **1**–**4** (monitored by UV/Vis-spectroscopy) to avoid secondary photolysis of the isocyanato complexes. Separation of the complexes and complex mixtures obtained after precipitation by cyclohexane was not performed, because analysis by IR spectroscopy and HPLC enabled unambiguous product assignment on comparison with independently synthesized complexes of the constitution [Ni("P_2")(N_3)(NCO)] and [Ni("P_2")$(NCO)_2$]. Complex **1** reacts to form di(isocyanato)nickel(II) complexes, whereas **2**–**4** afford azidomono(isocyanato)nickel(II) complexes.

The photolysis of **1** in CS_2 suspensions leads to addition reactions yielding di(isothiocyanato)nickel(II) complexes, whereas that of **2**–**4** yield azido(isothiocyanato)nickel(II) complexes. The constitution was determined by HPLC and IR spectroscopy on comparison with independently synthesized complexes of the type [Ni("P_2")$(NCS)_2$] and [Ni("P_2")(N_3)(NCS)].[15] Because [Ni("P_2")$(NCS)_2$] and [Ni("P_2")(N_3)(NCS)] complexes are also

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3604-0409 $ 15.00+.25/0

considerably photosensitive, their analytical characterization was performed analogously to that of the isocyanato complexes.

Finally, we were able to show that without nitrene scavengers CT excitation of **1**–**4** yields coordinatively unsaturated metal complex fragments of the kind [Ni^0("P_2")] (**1b**–**4b**). These species initiate, for instance, the photoinduced catalytic cyclotrimerization of methyl propiolate (**9**) to trimethyl benzene-1.3.5.-tricarboxylate (**10**). Thus, irradiation of **2** in CH_2Cl_2 leads exclusively to the formation of **10** as shown by GC–MS[16] (see Scheme 1).

Thus the photolysis of **1**–**4** depends strongly on the substrates used and differs completely from that of the analogous complexes of the heavier d^8-metal ions Pd^{II} and Pt^{II}.[1, 3c] Moreover, the single steps according to Scheme 1 open a convenient photochemical entry to reactive intermediates. Their use in photocatalytic systems is the subject of further investigations.

Asymmetric Epoxidation of Chalcones with Chirally Modified Lithium and Magnesium *tert*-Butyl Peroxides**

Catherine L. Elston, Richard F. W. Jackson,* Simon J. F. MacDonald, and P. John Murray

The asymmetric epoxidation of alkenes is central to many of the recent developments in the stereoselective synthesis of chiral molecules. The discovery of catalytic methods for the asymmetric epoxidation of allylic alcohols,[1] and of alkenes with isolated double bonds,[2] has been the starting point for the preparation of a wide variety of valuable, enantiomerically enriched intermediates. The asymmetric epoxidation of electron-deficient alkenes, specifically chalcone derivatives, has also been studied. The most efficient process known to date employs basic hydrogen peroxide in a three-phase system in which polypeptides are used as the source of chirality.[3] Very recently, efforts to extend this method to other substrates have met with some success.[4] Other methods for the asymmetric epoxidation of unsaturated ketones exist,[5] although they appear not to have the utility of the polypeptide-based system. Enders et al.[6] recently reported the efficient stoichiometric asymmetric epoxidation of electron-deficient alkenes by using chirally modified zinc alkyl peroxides. This is the first report on the use of chirally modified metal alkyl peroxides, in which the alkyl peroxide fragment is a nucleophilic oxidant rather than an electrophilic oxidant (as is the case for the Sharpless epoxidation).[7] Herein we report our own results on the asymmetric epoxidation of chalcone derivatives by using other, chirally modified metal alkyl peroxides.

Given the stereospecific nature of the epoxidation of electron-deficient alkenes with lithium *tert*-butyl hydroperoxide,[8] (which is easily prepared by the addition of *n*-butyllithium in hexanes to a solution of *tert*-butyl hydroperoxide in toluene) we first sought to develop a stoichiometric asymmetric epoxidizing agent by the addition of chiral modifiers. We chose chalcone **1a** as the substrate in view of the precedent regarding its use.[3–5] The epoxidation of **1a** with lithium *tert*-butyl peroxide in toluene, in the absence of chiral modifiers, proceeds rapidly and in high yield (90%, 1 h). After screening a variety of ligands (tartrate diesters, *S*,*S*-1,2-diphenylethane-1,2-diol, (−)-ephedrine, (−)-*N*-methylephedrine, and simple chiral alcohols), it became clear that good yields of the enantiomerically enriched epoxide (+)-**2a** could be obtained. The best results were achieved by using (+)-diethyl tartrate (1.1 equiv) as the chiral modifier in toluene (Scheme 1); this reaction provided the chalcone epoxide (+)-**2a** after two days (71–75% yield, 62% *ee*). Reactions carried out in the presence of a chiral ligand, specifically (+)-diethyl tartrate, did not proceed at all in the absence of an additional equivalent of lithium butoxide (or other lithium

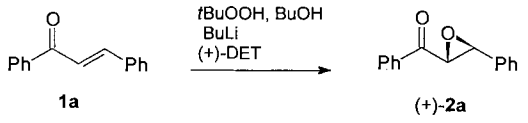


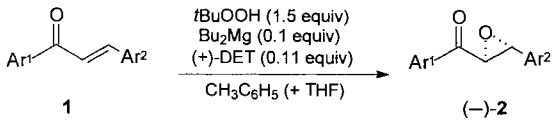
Scheme 1. Stoichiometric asymmetric epoxidation of chalcone with lithium *tert*-butyl peroxide in the presence of (+)-diethyl tartrate ((+)-DET).

alkoxide). The latter reagent could easily be included by addition of butanol (1 equiv) to the solution of *tert*-butyl hydroperoxide (1.5 equiv) in toluene prior to the addition of *n*-butyllithium (2.1 equiv). Addition of coordinating solvents such as THF suppressed the reaction substantially. Despite much effort, no better ligand was discovered, and attempts to perform the epoxidation with less than stoichiometric amounts of the reagent met with no success.

In order to develop a catalytic system, commercially available dibutylmagnesium was employed in place of *n*-butyllithium. In a preliminary experiment, it was established that epoxidation of chalcone with *tert*-butyl hydroperoxide and catalytic amounts of dibutylmagnesium (0.2 equiv, solution in heptane) in toluene gave racemic chalcone epoxide **2a** in high yield (90%). Addition of dibutylmagnesium (1 equiv) to a solution of *tert*-butyl hydroperoxide (1.5 equiv, 3.7 M in toluene) in additional toluene (10 mL on a 2 mmol scale) resulted in the formation of a gel, which dissolved upon addition of (+)-diethyl tartrate (1 equiv). Addition of chalcone to this solution led to a slow epoxidation, which after two days afforded (−)-chalcone epoxide **2a** in satisfactory yield (51%) and with improved enantiomeric purity (78% *ee*). Surprisingly, the product had the opposite absolute configuration to that obtained by using the lithium alkyl peroxide, even though the same chiral ligand had been employed. This observation indicates that there are substantial differences between the two reactions.

Reduction in the amount of dibutylmagnesium (relative to the amount of (+)-diethyl tartrate) employed resulted in an increase in the enantiomeric excess of the product (to 93% *ee* in the case of 0.2 equiv of Bu_2Mg), although there was a substantial decrease in the reaction rate and yield. Since the use of a catalytic system implies that the concentration of the catalytic intermediate is lower than in a stoichiometric reaction, we simply omitted the additional toluene, and added the chalcone **1a** as a solid. The only solvent, therefore, was that derived from the reagents dibutylmagnesium and *tert*-butyl hydroperoxide. Under these concentrated conditions, the amount of both dibutylmagnesium and (+)-diethyl tartrate may be reduced (to as little as 5 mol% and 6 mol%, respectively). Satisfactory yields (40 to 60%) and good levels of enantiomeric excess (>90% *ee*) are obtained, provided that there is a small excess of (+)-diethyl tartrate over dibutylmagnesium. The best compromise between the amount of catalyst required and yield of product was achieved by using 10 mol% dibutylmagnesium and 11 mol% (+)-diethyl tartrate.

Having developed a new catalytic asymmetric epoxidation of chalcone, we then sought to explore the generality of the process by using related unsaturated ketones **1**. A practical difficulty is that many substrates are essentially insoluble in the small amounts of toluene and heptane in which the epoxidation is conducted. Although the detrimental effect of polar solvents (specifically THF) in the asymmetric lithium *tert*-butyl peroxide epoxidations had already been established, addition of small amounts of THF allowed the substrates to dissolve, and did not compromise the enantiomeric excess (Scheme 2, Table 1).



Scheme 2. Catalytic asymmetric epoxidation of chalcone derivatives with magnesium *tert*-butyl peroxide in the presence of (+)-DET.

Table 1. Asymmetric epoxidation of chalcone derivatives **1** with *tert*-butyl hydroperoxide by using dibutylmagnesium (10 mol%) and diethyl tartrate (11 mol%) on a 10 mmol scale.

Ar^1	Ar^2	THF [mL]	Product	Yield [%]	*ee* [a]	$[\alpha]_D$ [b]	*t* [d]
Ph	Ph	-	(−)-**2a**	61	94	−229	1
Ph	Ph	-	(+)-**2a** [c]	53	89	+218	1
Ph	*p*-ClPh	2	(−)-**2b**	54	81	−195	1
Ph	*p*-MePh	2	(−)-**2c**	36	84	−210	3
p-MePh	Ph	2	(−)-**2d**	36	87	−198	1
2-naphthyl	Ph	2	(−)-**2e**	46	92	−125	1

[a] All *ee* values were determined by chiral phase HPLC (Daicel Chiralcel OD column) by using 95:5 heptane/ethanol (flow rate 1.0 mL min^{-1}). [b] Specific rotations were recorded in CH_2Cl_2 ($c = 1$). [c] (−)-Diethyl tartrate was used in place of (+)-diethyl tartrate.

The results obtained for the chalcone substrates are comparable with, or better than, those achieved by using the optimized polypeptide-based systems. At present, our working hypothesis is that the active catalyst is a magnesium bis(alkoxide) derived from (+)-diethyl tartrate. It appears that the chiral ligand binds the magnesium cation so tightly that effective catalytic asymmetric induction is possible despite the substantially reduced reactivity of the magnesium peroxide when the ligand is bound.

Since all the components used in this process are commercially available at relatively low cost, we believe that it may be of preparative value. Further development is underway, which may provide a general procedure for the catalytic asymmetric epoxidation of electron-deficient alkenes.

Experimental Section

An anhydrous solution of *tert*-butyl hydroperoxide (3.7 M in toluene [9], 4.05 mL, 15 mmol) was placed under a nitrogen atmosphere in a dry 50 mL flask with side arm (septum) and dibutylmagnesium (1 M in heptane, 1.0 mL, 1 mmol) [10] was added dropwise by syringe at room temperature. After the evolution of butane, a colorless gel was formed, which was stirred at room temperature for 1 h. (+)-Diethyl tartrate (0.19 mL, 1.1 mmol) was added in one portion and the mixture was stirred at room temperature for 1 h, resulting in a colorless solution. Chalcone **1a** (2.08 g, 10 mmol) was added as a solid in one portion (together with freshly distilled THF in the case of the less soluble substrates, as indicated in Table 1). After 24 h at room temperature (TLC sampling) the reaction was quenched with saturated aqueous NH_4Cl (10 mL), and 10% aqueous Na_2SO_3 (15 mL) and Et_2O (10 mL) were added. The aqueous layer was washed with Et_2O (3 × 10 mL), the combined organic extracts were washed with saturated aqueous NaCl, dried over $MgSO_4$, and the solvent was removed under reduced pressure. After purification by flash chromatography on silica gel (petroleum ether (40/60)/EtOAc 20:1) the α,β-epoxyketone (−)-**2a** was obtained. (+)-Diethyl tartrate can be recovered quantitatively with no observable change in enantiomeric purity from the same chromatographic column by increasing the proportion of EtOAc in the eluent.

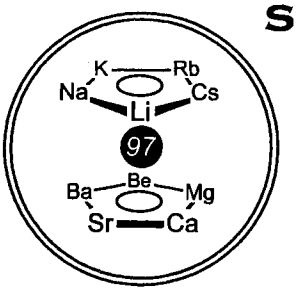
EVENTS



SECOND INTERNATIONAL CONFERENCE ON THE CHEMISTRY OF THE ALKALI AND ALKALINE EARTH METALS

ERLANGEN, GERMANY
SEPTEMBER 17 - 20, 1997

The Second International Conference on the Chemistry of the Alkali and Alkaline Earth Metals succeeds the First Conference held in Cambridge, England, in 1994. The Conference will be organized by Paul von Ragué Schleyer and Walter Bauer (both Erlangen). Two events will contribute to the scope of the Conference: the 100th birthday of Georg Wittig and the impending retirement of Paul Schleyer from Erlangen.

The Conference will consist of 26-28 plenary and invited lectures. Lecturers who have agreed so far:
F. Bickelhaupt, G. Boche, H. Bock, L. Brandsma, W. Clegg, D. Collum, Ö. Davidsson, U. Edlund, H. Günther, R. W. Hoffmann, N. J. R. van Eikema Hommes, D. Hoppe, G. Klumpp, A. Maercker, C. Marsden, H. Reich, D. Seebach, R. Snaith, D. Stalke, A. Streitwieser, P. Williard, D. Wright.

For further information please contact: Priv.-Doz. Dr. Walter Bauer, Institute of Organic Chemistry, University of Erlangen-Nuremberg, Henkestrasse 42, D-91054 Erlangen, Germany, Phone +49-9131-852987, FAX +49-9131-859132, e-mail bauer@organik.uni-erlangen.de.

The proceedings of the Conference and pre-registration facilities are available on WWW:
http://www.organik.uni-erlangen.de/research/NMR/c97.html (Germany mirror site)
http://paul.chem.uga.edu/www.wbauer/c97.html (US mirror site)

New Light on Molecular Modeling

Since the early 1980s there have been enormous developments in techniques for simulating molecular properties to gain a better understanding of macroscopic or chemical phenomena, especially with a view to "designing" new compounds for particular applications (e.g., in pharmaceuticals, vaccines, or plastics), and molecular modeling is now an important and very active area of research. However, it is unfortunate that some researchers, and especially commercial organizations offering software for this field, have raised quite unrealistic expectations by understating the complexity of these methods. This has helped to create the impression that anyone can now carry out molecular modeling by using a system as a "black box", without needing to understand the chemical, physical, and mathematical fundamentals. This eventually results in failure for many, if not the majority, of molecular modeling projects, which comes as no surprise to experts in the field. That in turn has led to a widespread feeling in some circles that knowledge has not yet advanced far enough to enable one to successfully model and design molecular properties. This is not so, but in order to appreciate that one must take the trouble to understand the principles of molecular modeling, so that one can use the methods effectively, taking into account the present state of knowledge. As can be seen from the titles of the three books reviewed below, their authors have set out to equip the reader with the necessary knowledge.

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Guidebook on Molecular Modeling in Drug Design. Edited by *N. C. Cohen*. Academic Press, San Diego, 1996. 361 pp., hardcover \$ 59.95.—ISBN 0-12-178245-X

The editor of this book is an industrial chemist, and consequently it is firmly orientated towards the applications of modeling techniques. The various aspects are treated in seven chapters, and an eighth chapter is a glossary with short explanations of terms commonly used in drug design and theoretical methods.

The first chapter, written by the editor, gives a general overview of modeling techniques used in the development of new drugs. Cohen describes the history of such techniques, and compares them with the alternative of "chemical intuition", citing some examples.

In Chapter 2 Roderick Hubbard (University of York) describes the rapid development of computer graphics hardware, which made it possible for the first time to model molecular structures. Methods of displaying molecules are also briefly discussed.

In Chapter 3 Tamara Gund (New Jersey Institute of Technology) concentrates on the methods used for modeling small molecules. Unfortunately there is some overlapping here with the subject matter of the previous two chapters. The topics covered include the concept of the pharmacophore, receptor mapping, docking, QSAR methods, molecular orbital (MO) and molecular mechanics approaches, and some illustrative examples.

Chapter 4, by Akiko Itai and colleagues (University of Tokyo), deals with the design of new lead structures. The authors discuss the different approaches that are used, depending on whether or not one knows the three-dimensional structure of the target molecule (e.g., a receptor or an enzyme). Much space is devoted to the docking and "structure construction" programs developed by the Tokyo group, but others are treated only briefly and selectively.

In Chapter 5 John Priestle and Gregory Paris (Ciba-Geigy) describe methods for obtaining three-dimensional molecular structures, some experimental results from these methods in connection with interactions of proteins, and data banks of 3D molecular structures for proteins and compounds of low molecular mass. They also discuss ways of extracting information from these sources. Lastly they explain the IUPAC nomenclature conventions for amino-acids, nucleic acids, and sugars, a topic that seems rather out of place in a book of this kind.

Chapter 6, by Peter Gund and coauthors (MSI), presents another viewpoint on computeraided searching for active agents. There is considerable overlapping with material covered in the earlier chapters.

Finally, in Chapter 7, Konrad Koehler and colleagues (Molecular Biology Research Institute, Rome) describe methods for modeling drug–receptor interactions. They also discuss interactions of proteins, force-field techniques, and docking techniques, including receptor mapping. Various "drug targets" are also discussed.

A particular strength of the book is its practically-orientated approach, with detailed descriptions of the techniques used for modeling. However, the considerable degree of overlapping between the chapters is annoying for the reader. Although each chapter has its individual strengths, since the authors emphasize different aspects of concern to the novice, the absence of a unifying plan means that the book is less useful than it could have been. It is actually a collection of articles on drug design methods seen from the different viewpoints of the individual authors. Considering all the chapters together, the coverage of the field is fairly comprehensive. This book is of interest to the reader who is already working in a related field and seeks detailed information about specific topics; however, it does not constitute a systematic textbook-style introduction for the beginner.

Fundamental Principles of Molecular Modeling. Edited by *W. Gans, A. Amann* and *J. C. A. Boeyens*. Plenum, New York, 1996. 249 pp., hardcover \$ 79.50.—ISBN 0-306-45305-3

This book contains the proceedings of an international workshop on the basic

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3604-0413 \$ 15.00+.25/0

principles of molecular modeling, held in Skukuza, in the Krüger National Park, South Africa, in August 1995. It displays both the strengths and the weaknesses usually found in books of this kind. From the negative standpoint, it is a rather arbitrary collection of articles from different topic areas, and there is no attempt at a comprehensive coverage of the subject. On the other hand, such publications often contain excellent articles that are frequently cited later. It is not possible to describe the book in just a few paragraphs, and therefore this review will concentrate on a few articles chosen from the 13 included in the book.

The introductory article by J. C. A. Boeyens contains a very brief overview of structure-fitting methods. The author puts forward the unconventional view that there is no experimental evidence to indicate that molecules in the gas phase have a clearly defined shape, expresses reservations about the usual practice based on the interpretation of X-ray diffraction data, and challenges the notion that one can compute chemical structures using quantum mechanics. Few chemists are likely to agree with these views at the present time. However, Sutcliffe of the University of York also expresses reservations about the concept of molecular structure within the quantum-mechanical context. In several further chapters by different authors the concept of three-dimensional structures is discussed very thoroughly, mainly from the standpoint of the quantum theoretician; the conclusions they reach do not agree in all cases.

There is an abrupt change of subject in the article by Frank H. Allen (Cambridge, UK), who describes the setting up of the Cambridge Crystallographic Data Bank and explains its purposes. He shows how, by comparing a large number of molecular structures, one can obtain information, such as the nature of noncovalent interactions, that would not be accessible by studying structures in isolation. The following article by Gilli et al. (Ferrara) discusses the importance of hydrogen-bonding interactions, in particular their geometry, in the context of molecular modeling.

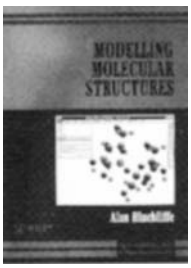
Another chapter is concerned with the determination of electrical properties from diffraction data. This is followed by a chapter in which Comba (Heidelberg) discusses the modeling of structures and spectroscopic properties of transition metal compounds, a topic that undoubtedly has enormous potential for future development. Some interesting examples of applications in this area are described. Another short chapter is devoted to theoretical predictions of crystal packing in compounds of low molecular mass.

Lastly there are chapters on the molecular structures of special compounds, accompanied in some cases by tables of crystallographic data, atomic coordinates, and bonding parameters; these chapters are likely to be read only by those with a particular interest in the compound classes treated.

To summarize, the book contains some articles that are certainly worth reading in view of the unconventional standpoints adopted by the authors, so that one can consider these and perhaps challenge them. However, for the reader who wishes to gain an understanding of the theoretical fundamentals and the background, both experimental and theoretical, to modern modeling methods, or perhaps even to apply them, only about 10% of the contents of this book is likely be of practical value. Moreover, this material is not particularly novel, and is therefore available elsewhere in the many other books published during the last 10–15 years.

Modelling Molecular Structures. By *A. Hinchliffe.* Wiley, Chichester, 1996. 256 pp., paperback £ 24.95.—ISBN 0-471-95923-5

This book is a revised and considerably extended version of the author's *Computational Quantum Chemistry,* first published in 1988. Much of it is written in a deliberately relaxed style, with bylines such as "What on Earth is Chapter 0?", and "Congratulations and welcome to the text". However, the title of the book is misleading. It is not an introduction to molecular modeling in general, as one would assume from the title, nor does it contain a survey of the methods or computer programs used. Instead it consists mainly of an exposition of the quantum-mechanical methods, accompanied by a short description of molecular mechanics methods which, being only 16 pages long, is quite inappropriate. There is also a half-page paragraph on protein docking which looks rather lost in this context.



The main part of the book is concerned with topics such as the Born–Oppenheimer approximation, LCAO methods, the hydrogen molecule, descriptions based on the molecular orbital (MO) and valence bond (VB) methods, Slater orbitals, choice of orbitals, electron correlation methods, etc.—the range of topics usually covered in books on quantum chemistry. In the discussion of ab-initio and semi-empirical methods, the former is given much more attention. The MNDO method is covered in exactly six lines with one literature reference, while the AM1 method (the most modern one mentioned in the book) is given ten lines and one reference. In contrast, an entire chapter is devoted to the "Gaussian 92" suite of programs.

In the last quarter of the book the author deals with potential energy hypersurfaces, gives a very incomplete description of optimization procedures in connection with the multiple minima problem, and discusses primary and induced properties of molecules, from electric multipole moments to magnetic susceptibilities. The last 20 pages are devoted to some applications, such as calculations of rotational barriers, coupling constants, or crystal lattice parameters, but the author fails to do adequate justice here to the applied aspects of molecular modeling.

The book is accompanied by a diskette containing a few exercises and solutions in the forms of Wordperfect, Acrobat Reader, and Postscript data files. There are also programs in Basic, which provide demonstrations of some of the most common quantum-mechanical calculations for the hydrogen and water molecules using various MO methods, such as the determination of CNDO parameters, or Hückel calculations.

The question as to which readers can benefit from this book is not easily answered. It deals with some selected topics from the development of quantum chemistry during the past 30 years, but does not treat any of these in great detail, and the fascinating applications that have been developed since the early 1970s are scarcely covered at all. Moreover, the compilations of results obtained using "Gaussian 92", some of which extend over several pages, also fail to redeem the book, as very little interpretation is offered. Many simple structural formulas are unnecessarily large, giving the impression that the main aim was to fill some pages. If a high school student were to be given the title of this book as an essay topic, and handed in this text, the comment at the end would be: "misses the main point".

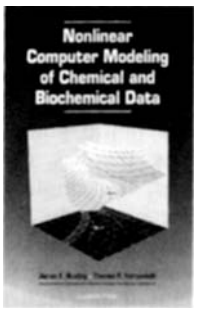
Nonlinear Computer Modeling of Chemical and Biochemical Data. By *J. F. Rusling* and *T. F. Kumosinski.* Academic Press, San Diego, 1996. 268 pp., hardcover $ 64.95.—ISBN 0-12-6044-90-2



With the increasing capabilities of modern computers, the digital storing of experimental data has become part of normal everyday practice. It is also increasingly common for the processing of the data to be carried out using commercial software. However, one is usually not so well served when nonlinear processes have to be analyzed. Tasks of this kind require not only suitable procedures for modeling complex processes but also, most importantly, nonlinear regression methods.

Up to now chemists have only been concerned marginally with these problems. It is therefore a welcome development that two authors with many years of experience in the area of chemometry have set out to explain the principles of nonlinear regression analysis in this form. The book is intended as an introduction for advanced students of chemistry as well as practicing chemists, with many examples to illustrate the wide variety of applications.

The authors begin by explaining the basic principles of linear regression analysis in a clear and didactic style, then from this groundwork they move on to nonlinear regression and describe the methods of calculation. However, since only 70 pages (out of a total of about 270 pp.) have been allowed for this first part, there is insufficient space to go into much detail. Moreover, the fragments of computer programs that are given in the margin are not enough to enable the reader with little computing experience to create programs for processing his or her own experimental data. Nevertheless, the information provided is very helpful for understanding regression calculations, and will certainly enable the reader to evaluate their usefulness.

The limitation of the theoretical treatment is counterbalanced in the second part of the book by a wealth of practical examples from the authors' own field of research. The results described and the related discussion show the reader how the raw data obtained by modern instrumental methods can be used to yield reliable information about the parameters of the systems being studied. The experimental methods in the examples range from NMR and IR spectroscopy through electrochemical analysis to chromatography and other analytical techniques. With the exception of the electrochemical investigations, the main emphasis is on applications to biochemical problems. However, most of these involve principles that one could easily adapt for use in other areas of chemistry.

In the discussions of the examples it is not always made clear that the first step in analyzing any set of data must be to develop a model for the experiment. This stage is especially laborious when the experiment is of a kind that can only be described by a digital simulation rather than by an analytical approach. If the quality of the simulation is not good enough, the regression calculation cannot yield a reliable result.

The book should encourage readers to become involved in the complex field of chemometrics. It will be useful for everyone who needs to interpret experimental data and wishes to gain a background knowledge of data-processing methods. However, the authors have not fully succeeded in their aim of enabling the reader to develop models and programs independently.

Understanding Medications. What the Label Doesn't Tell You. By *A. Burger.* American Chemical Society, Washington, DC, 1995. 206 pp., hardcover $ 39.95.—ISBN 0-8412-3210-5

Alfred Burger, one of the founders of the *Journal of Medicinal Chemistry,* and its editor for many years, has written this book for "...people who are better educated and more alert to innovations than the average men or women of any age...". His aim was "...to satisfy and stimulate the curiosity of educated lay people who, on the whole, lack the biochemical and pharmacological background for the study of medicinal agents", and he has certainly achieved that. In a fluent and readable style, while also maintaining scientific soundness and accuracy throughout, Burger leads his readers through the many different aspects of the discovery and development of various classes of drugs, some long-established and others only recently introduced, with special emphasis on the basis of their pharmacological activity. The book begins with seven introductory chapters (about 60 pp. altogether), which summarize the history of medicines from the earliest times to the present day, and aspects of modern practice, under the following headings: "Drugs: Historical Beginnings"; "Early Modern Medicines"; "Naming Drugs"; "Biomedical Research"; "Modern Drug Discovery and Development"; "Molecular Modification of Prototype Drugs"; "Drug Use and Abuse". Using this background of basic information, the author then discusses various types of drugs, classified according to their purpose and mode of action. The 12 chapters (about 120 pp. altogether) are: "Neurohormones and Drugs that Affect the Central Nervous System"; "Drugs for the Relief of Pain"; "Local Anaesthetics, Antispasmodics, and Antihistamines"; "Drugs that Act on the Blood Pressure and the Heart"; "Intestinal Tract Medications"; "Hormones and Vitamins"; "Drugs for the Treatment of Cancer"; "Drugs Affecting the Immune Response"; "Drugs for Infectious Diseases"; "Antiparasitic Drugs"; "Antiviral Drugs"; "Antiseptics and Disinfectants". The book ends with a short chapter on "Computer Assistance in Medicinal Research" and a brief look at likely future developments under the heading "What's Next".

Burger explains the relevant facts of medicinal chemistry, its successes, and its future tasks in a way that is understandable by the educated lay person with an interest in the subject. Without using an undue amount of technical language, he explains how and why the various types of medications, many of which have long been familiar, produce their effects, and describes the physiological processes that are affected and what happens when the agents are administered. The information is skillfully interwoven with interesting historical facts and anecdotes, so that the whole makes easy and enjoyable reading. It is only rarely that the reader is overburdened with specialist language, and in such cases the glossary of terms in the form of an appendix is a useful aid. Although the "educated lay person" referred to by the author does not need to have a considerable background knowledge of biochemistry or pharmacology, a good secondary school education or its equivalent is a prerequisite for being able to follow the discussions without difficulty. Anyone with this minimum background will read the book with enjoyment and sustained interest. Burger does not attempt to give answers to the question that is so often asked, with unconcealed mis-

trust, after a visit to the doctor: "should I really be taking this medication?" – a question that is increasingly put to me (and, no doubt, to other chemists) by friends or relatives. Instead he presents background information that is normally lacking for the reader who has not been closely involved with science or medicine. Thus, the book will help to remedy a gap in understanding that unfortunately exists for a large part of the educated public (especially in Germany), and which is largely responsible for the deplorably poor image of science and technology at present. Readers of *Angewandte Chemie* do not, of course, belong to that tendency. Nevertheless, I recommend them to take a look at this book by Alfred Burger, and to allow it to circulate among their friends and relatives, or even to consider it as a suitable gift. By doing so they would do their science a good service.

Ways to Successful Strategies in Drug Research and Development. By *H. H. Sedlacek, A. M. Sapienza* and *V. Eid.* VCH Verlagsgesellschaft, Weinheim, 1996. 250 pp., paperback DM 128.00.—ISBN 3-527-29415-5.
Critical Success Factors in Biomedical Research and Pharmaceutical Innovation. By *S. W. F. Omta.* Kluwer, Dordrecht, 1995. 300 pp., hardcover $ 124.50.—ISBN 0-7923-3563-5

Anyone in the pharmaceutical industry who is or has been involved in challenging discussions of research and development strategies, for example in the context of a major reorganization, will immediately recognize that the book **Ways to Successful Strategies in Drug Research and Development** has been written by authors who have been intimately involved in such exercises. However, rather than formulating recipes for successful strategies from specific personal perspectives, the authors offer a comprehensive outline of important factors, parameters, conditions for pharmaceutical R & D management, their interplay and impact on critical R & D processes, and their assessment in the context of defining overall R & D strategies. This outline is the result of actual experience with, and recent surveys of, a representative collection of pharmaceutical companies. Those who have already gone through such experiences will often have a sense of "déjà vu" on reading about the many typical scenarios which the book describes in a well structured and easily readable format, shedding its unforgiving light on both the right and the wrong decisions. For those newly confronted with these issues, it will be an eye-opener in many respects. Thus, the book can and should be recommended to both middle and upper, junior and senior management alike. While it covers the many important internal and external driving forces and factors which have to be considered in formulating a successful pharmaceutical R & D strategy, it also reserves ample space to address important cultural, sociological, and psychological issues, to discuss important ethical aspects of current and future health care systems, and to review moral obligations towards humans, animals, and the environment. In some of these regards, the book reflects the special expertise of the authors, and appears to provide a somewhat overly extensive coverage at the cost of other important aspects, such as the impacts, integration, and management of information and automation technologies, or the assessment, implementation, and management of research collaborations, joint ventures, or strategic alliances with academic or industrial groups. However, one can forgive this bias in view of the many comprehensive and clear representations of current wisdom, accompanied by expert commentaries and illustrative examples. In this way the book provides both practical toolkits and conceptual frameworks for analyzing the strengths and weaknesses of one's own organization and R & D portfolio, for formulating and evaluating different strategic options, and for assessing their potential risks and benefits.

There are essentially two ways of reading Omta's book **Critical Success Factors in Biomedical Research and Pharmaceutical Innovation**. One would be the hard sequential way of working systematically through the study methodology, the study design, theory construction, hypothesis generation, data collection, processing and analysis in order to get to the results, discussions and conclusions. Alternatively, one can start directly with the latter towards the end of the book, and leave the more technical part to a later stage in case of need or particular interest. In either case, one quickly learns that this study is confined to a survey of Dutch universities and institutes, thus presenting a relatively narrow perspective. On the industrial side it is based on a number of (mostly undisclosed) multinational companies, but appears to ignore important companies from certain geographical areas. However, the conclusions from this statistical survey, based on the usual types of cross-checked questionnaires and personal interviews, remain sufficiently vague and so full of truisms that any concerns about potential hidden biases become irrelevant. In fact, anyone concerned with research management in one way or another may be surprised to find so much sophisticated systems theory machinery being used just to reconfirm what appears to be commonsense or day-to-day experience. However, the reader interested in learning about current state-of-the-art systems analysis instruments may concentrate more on the first part of the book, which provides an overview of many techniques, methodologies, theories, concepts, and terminologies, as exemplified in the context of this specific study. Perhaps more important than this overview are the occasional discussions of potential weaknesses and pitfalls of such statistical analyses in general, and the exceptions to statistically based generalizations that the author points out in this particular study. The fact that the data collection was already completed in the early nineties may be a cause for concern. Since then the world of biomedical research, particularly that of the pharmaceutical industry, has changed dramatically. Inevitably, therefore, some conclusions of this study have already been superseded by the rapid pace of development in this area. Finally, a word of caution may be appropriate regarding the title of the book. It acts as a bait, but with little meat on the hook. The critical success factors of modern multidisciplinary biomedical research are not comprehensively addressed here, nor is the definition and measurement of pharmaceutical innovation discussed at more than a superficial level. Although certainly less attractive, a more conservative title might have been better, and would be less likely to leave readers unsatisfied.

Combinatorial Peptide and Nonpeptide Libraries. A Handbook. Edited by *G. Jung.* VCH Verlagsgesellschaft, Weinheim, 1996. 545 pp., hardcover $ 135.00.—ISBN 3-527-29380-9

In a few years, combinatorial chemistry has developed from a largely academic endeavor into a well-respected and much discussed technique within the pharmaceutical industry. The main reason for the interest in combinatorial chemistry is the possibility of speeding up the drug devel-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3604-0416 $ 15.00+.25/0

opment process, mainly by increasing the number and diversity of compounds to be tested, thereby increasing the chances of identifying a compound with the desired (biological) activity. The field started out with peptide libraries, but currently there is a clear shift to nonpeptide libraries, due to the inherent limitations of peptides as therapeutics. This book, edited by Günther Jung, is one of the first to summarize the developments in this area, with the emphasis on peptide libraries.

The first three chapters offer an overview of the possibilities for the synthesis and analysis of libraries. In the first chapter, Jung goes back to the natural origins of molecular diversity and libraries, using examples from polypeptide antibiotics and MHC (major histocompatibility complex) Classes I and II. In the final part of Chapter 1, an overview is given of the remainder of the book, and references are made to existing reviews in this field. The emphasis is, as already said, on all aspects of the design, synthesis, analysis, and testing of peptide libraries. Most of the biological applications are chosen from the MHC and T-cell epitope field.

Chapter 2 deals with the organic chemistry on the solid phase, with emphasis on nonpeptide chemistry. The content of this chapter has been published before as a review paper in *Angewandte Chemie*. An overview of existing methods for the synthesis of multiple peptides and peptide libraries is given in Chapter 3. Curiously, a discussion of the chemistry involved is not included in this chapter, nor anywhere else in this book.

In Chapter 4, the portioning-mixing (split-pool) method is treated extensively from a theoretical point of view. Chapter 5, by Houghten and coworkers, describes the use of nonsupport-bound libraries and details the methods of identifying an active peptide from a combinatorial library. In Chapter 6, Lam and Lebl give an overview of the one-bead-one-compound concept, with the emphasis on identifying beads containing an active compound by coloring. Some examples of nonpeptide libraries are discussed. Peptide and cyclopeptide libraries, synthesized using the premix method, are dealt with in Chapter 7. Mass-spectrometric analysis of these libraries by electrospray ionization is described in Chapter 8. Another analytical technique, peptide sequence analysis by Edman degradation, is the subject of Chapter 9. This method can be used both for natural and synthetic peptide mixtures. The application to libraries of MHC peptides is described. Epitope mapping or identifying and the synthesis of peptides on pins is the topic of Chapter 10 by Geysen and coworkers, again using MHC peptides as the example. In Chapter 11, Spatola and Romanovskis again treat cyclic peptides libraries, although in more detail, and synthesized in a manner different from that described in Chapter 7. The use of random peptide libraries in immunology is the topic of Chapter 12, overlapping with Chapter 7. Yet another method of synthesizing peptides libraries, the SPOT technique on membrane supports, is described in Chapter 13.

In Chapters 14 and 15 two nonpeptide libraries are described, first the peptoids library, as advocated by Chiron, and then the benzodiazepine library, in an overview by Ellman. The material presented in these two chapters has already been published several times elsewhere. The properties of PEG grafted polystyrene tentacle polymers as a solid phase for organic chemistry are dealt with in Chapter 16, followed in Chapter 17 by a general review (including price range) of polymeric supports for solid phase organic synthesis. The reverse order of these chapters would have been more logical. In Chapter 18 the mass spectrum simulation program QMass is described. It would have been more appropriate to include this material as an appendix to Chapter 8, and to add a "future prospects" chapter instead. A glossary and an index form the conclusion of this book.

As can be expected in such a rapidly expanding and multifaceted field as combinatorial chemistry, this book is already outdated to some extent. As remarked above, the current interest is in nonpeptide libraries. In this respect, the book may be a disappointment. Despite the promise of the title, all aspects of the synthesis, analysis, and biological testing of peptide libraries are discussed in great detail, but only a limited amount of space is devoted to nonpeptide libraries. This is regrettable, as the techniques used for the analysis of peptide libraries have only limited applicability to nonpeptides. There is no information on topics such as diversity analysis, virtual libraries, library size and the complexity of mixtures to be tested, and differences between random and targeted libraries. These are all "hot" topics in the literature and on the Internet at the moment, mainly discussed with respect to nonpeptide libraries, although they have relevance in the peptide field as well.

In conclusion, this book offers a good starting point for every chemist who wants to learn about combinatorial chemistry using peptide libraries. There is a wealth of practical information about the synthesis, analysis, and biological testing of peptide libraries. However, scientists interested in nonpeptide libraries will learn little that is new. It is hoped (and expected) that the next edition, which is already mentioned in the preface, will fill the gaps referred to here.

An RNA phosphodiester (left) bound to a guanidinium electrophile (bottom right) along with the 2´-OH of the ribose ring bound to a general base imidazole (right). This is one of the models currently under investigation for catalysis of RNA cleavage-transesterification.

Unifying the Current Data on the Mechanism of Cleavage–Transesterification of RNA

Denise M. Perreault and Eric V. Anslyn*

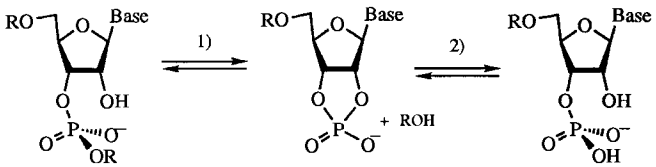
The various mechanisms by which RNA is hydrolyzed are currently under intense investigation. The first step in the hydrolysis pathway is a cleavage–transesterification in which a 2′-OH group attacks a 3′,5′-phosphodiester linkage with departure of the 5′ group. The second step involves the opening of a 2′,3′-cyclic phosphodiester. Complications in these steps arise from multiple possible pathways involving specific acid and base as well as general acid and base catalysis. In addition, controversy exists concerning the protonation states of the phosphodiesters and any intermediate phosphoranes under various experimental conditions. A summary of mechanistic studies involving general and specific acid/base catalysis of RNA hydrolysis and the hydrolysis of RNA analogs is presented herein, along with the interpretations given by the original authors. Included are theoretical calculations, kinetic studies, pK_a determinations, isotope effects, Hammett and Brønsted correlations, and model studies. Recent analyses of the mechanism of RNase A are also briefly reviewed. Two limiting mechanisms for the cleavage–transesterification step that unify the data in the literature and differ only in the role of the phosphorane and its protonation state are given at the outset. An analysis of the literature studies supporting these mechanisms is then provided.

Keywords: hydrolysis · kinetics · reaction mechanisms · RNA

1. Introduction

The mechanism of the non-enzymatic hydrolysis of RNA phosphodiesters has been investigated for many years. Recently, the investigation has been driven by the desire to produce synthetic catalysts for RNA hydrolysis.[1] A complete picture of the mechanism would facilitate the rational design of a synthetic or semisynthetic RNA hydrolyzing catalyst, which could be used in gene therapy.[2] In addition, the interpretation of an enzymatic mechanism often depends upon knowledge of the mechanism in solution, since an enzyme has evolved to stabilize the transition state in solution.[3] Therefore, two independent driving forces exist for the extensive work devoted to this topic.

The hydrolysis occurs in two stages; the first is a cleavage–transesterification reaction, the second, a hydrolysis reaction (Scheme 1). These two steps seem simple; however, each has been found to have complex pH dependencies and to be catalyzed by both general and specific acids and bases. Scheme 2 shows the possible mechanisms for the cleavage–transesterification step in greater detail. The first step in both of these mechanisms is nucleophilic attack of the ribose 2′-OH group to form a trigonal-bipyramidal phosphorane. The second step involves expulsion of the leaving group. The mechanisms must be able to account for products resulting from pseudorotation, and by extension, a phosphorane intermediate such as **1** or **2**. The details of the specific and general acid and base catalysis of these steps, as well as the structure and lifetime of the phosphorane, are not completely understood.



Scheme 1. The two steps in the hydrolysis of RNA. 1) Cleavage–transesterification and 2) hydrolysis of the cyclic phosphodiester.

Much of the research on RNA hydrolysis centers on the nature of the phosphorane intermediate. Three aspects of this intermediate are of paramount importance: the lifetime of the phosphorane, the protonation state of the phosphorane, and the dependence of these first two aspects on the leaving group. In addition, how these three aspects depend upon experimental conditions, such as the type of catalysis used and the pH, is also currently being debated. Solving these issues is critical to a thorough understanding of the RNA hydrolysis mechanism.

In this review, eight hypotheses about RNA hydrolysis are presented along with two limiting mechanisms. The concepts behind these hypotheses are not new, but are also not necessarily well-accepted. Following these hypotheses and mechanisms are

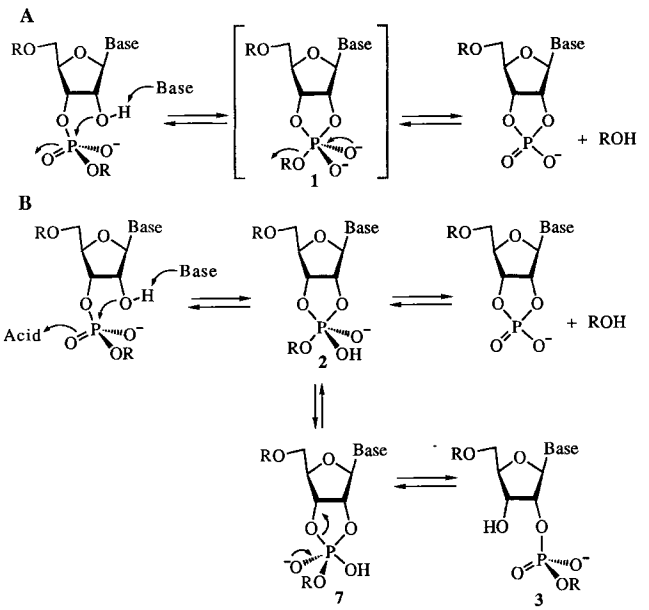


Scheme 2. Two mechanisms consistent with the vast majority of studies. A) Mechanism proceeding via either a fleeting dianionic phosphorane or a dianionic phosphorane-like transition state. B) Prior or simultaneous protonation of the phosphodiester with nucleophilic attack leads to a monoanionic/monoprotic phosphorane intermediate that can react further by cleavage or migration.

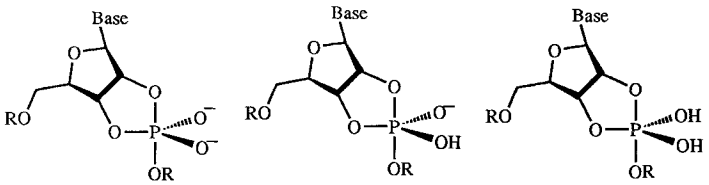
discussions of older studies as well as more recent studies relating to the RNA hydrolysis mechanism. Each section is intended to support the hypotheses and mechanisms, and in some cases, experiments that are missing from the literature are discussed. However, we realize that some studies can be interpreted differently than presented herein. The impetus for our interpretations is to support two simple mechanisms. These mechanisms are not original to this article, but have been discussed previously in various forms. The goal of this article is to present these two mechanisms under the light of a large amount of supporting data. It is left to the reader to agree or disagree with the arguments, and it is left the researcher to further probe the validity of the mechanisms.

2. Hypotheses and Mechanisms

2.1. Hypotheses

1. A dianionic phosphorane cannot be distinguished kinetically from a transition state.[4] Its lifetime is not long enough for protonation.

2. Dianionic phosphorane-like transition states involved in RNA hydrolysis are formed by both general base and specific base mechanisms.



Scheme 3. Dianionic, monoanionic/monoprotic, and neutral/diprotic phosphoranes.

3. In order for a phosphorane to be a kinetically significant intermediate along the RNA hydrolysis pathway, it must be either monoanionic and monoprotic or neutral and diprotic.

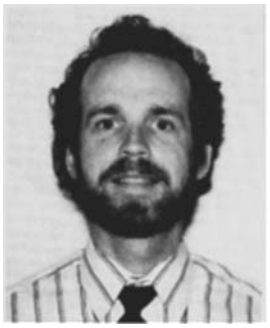
4. Monoanionic/monoprotic or neutral/diprotic phosphoranes are formed by protonation of the phosphodiester either prior to or simultaneously with nucleophilic attack.

5. Only a mechanism in which protonation occurs prior to or simultaneously with nucleophilic attack can lead to products arising from pseudorotation, such as RNA 2′,5′-phosphoesters from 3′,5′-phosphoesters by migration.

6. RNA analogs with good leaving groups are hydrolyzed via dianionic phosphorane-like transition states, except at low pHs where monoanionic/monoprotic transition states and neutral/diprotic phosphorane intermediates are possible.

7. A change in mechanism from one involving a phosphorane intermediate to one with a phosphorane-like transition state is a function of the pK_a of the leaving group, the pK_a of the phosphorane, the pH, and the presence of acids and bases.

Eric V. Anslyn, born June 9, 1960, obtained his doctorate in 1987 at the California Institute of Technology under the supervision of Prof. Robert H. Grubbs. After a year and a half of postdoctoral work at Columbia University with Prof. Ronald Breslow, he joined the faculty at The University of Texas at Austin. He was granted tenure in 1995. Using the tools of physical organic and supramolecular chemistry to study catalysis is the main focus of his research. He has been named a Presidential Young Investigator, a Sloan Foundation Fellow, and a Camille and Henry Dreyfus Teacher-Scholar.



E. V. Anslyn

D. M. Perreault

Denise M. Perreault, born February 19, 1968, received her Bachelor of Arts degree in Chemistry and French at Wellesley College, Wellesley, MA (USA), in 1990. She worked as an assistant scientist in the Exploratory Research Department at Polaroid Corporation, Cambridge, MA, for one year in the design, synthesis, and characterization of photographic reagents and their utilization in molecular assemblies. She entered The University of Texas at Austin in 1991 as a Robert A. Welch Foundation Fellow (1991–1993), completed her doctoral studies under the direction of Professor Eric V. Anslyn, and is currently a postdoctoral research associate with Prof. Laura L. Kiessling at the University of Wisconsin-Madison.

8. Mechanisms involving dianionic phosphorane-like transition states and protonated phosphorane intermediates can operate simultaneously.

2.2. Mechanisms

Two mechanisms that summarize the eight hypotheses are given in Scheme 2. In accord with Hypothesis 1 the dianionic phosphorane **1** directly expels a leaving group without a chance for protonation (Scheme 2A). Either general or specific base catalysis of this one-step displacement is possible (Hypothesis 2). The leaving group is expelled either as an anion or as an alcohol, if it is protonated by a preassociated acid. The mechanism in Scheme 2A also describes the mechanism best suited to RNA analogs with good leaving groups, except at low pH values (Hypothesis 6). In contrast, Scheme 2B shows a mechanism in which the phosphodiester is activated by a proton transfer from an acid. In this scenario, the phosphorane **2** is an intermediate (Hypothesis 3). The proton transfer occurs either prior to or simultaneously with nucleophilic attack by the 2′-OH group (Hypothesis 4). Therefore, both specific and general acid catalyses are possible. This is the mechanism that also yields migration product **3** as a result of pseudorotation (Hypothesis 5). Furthermore, in either mechanism, the 2′-hydroxyl group can attack as a neutral OH group, as a general base delivered anion, or after deprotonation to an O^- function. A third mechanism exists at low pH in which the phosphodiester linkage is protonated twice and therefore is cationic. This mechanism is not presented here, since it is not very relevant to RNA cleavage under physiological conditions, but will be covered later. The change from mechanism A to B should depend upon the pH, the availability of general acids and bases, the pK_a of the phosphorane, and the leaving group (Hypothesis 7). Thus, under certain experimental conditions both mechanisms may be operative (Hypothesis 8).

The following sections review the literature that can be used to support the hypotheses and the proposed mechanisms. Data relating to the phosphodiester stability, phosphorane pK_a values, α and β values, isotope effects, kinetics, model systems, and theoretical calculations are all examined.

3. Why Use RNA Analogs to Study RNA Hydrolysis?

The rate of hydrolysis of RNA at neutral pH and ambient temperature is quite slow, and therefore the reaction is difficult to follow experimentally. The rate is heavily dependent upon the presence of the 2′-OH group. The best evidence for this is that phosphodiesters lacking the 2′-OH group, for example in DNA, are exceptionally stable species at neutral pH. For example, the rate of hydrolysis of dimethylphosphate is $2 \times 10^{-14} s^{-1}$.[5] With a 2′-OH group or a 2′-OH analog, the corresponding transesterification reaction is faster by several orders of magnitude. For instance, the effective molarity of the 2′-OH group of RNA has been estimated at 3×10^7 M for the hydroxide-catalyzed reaction of a phenyl ester.[6] Although a 2′-OH group imparts such an acceleration, the half-life for the hydroxide-catalyzed cleavage of cytidylylcytidine is still quite long (1000 to 10000 days at 60 °C and pH 7).[7]

When the ester groups on the phosphoester are readily susceptible to nucleophilic attack on carbon, the mechanism of hydrolysis can change. The hydrolyses of dimethylphosphate and dibenzylphosphate involve the cleavage of the C–O and not the P–O bond.[7] Aryl and alkylphosphodiesters not susceptible to nucleophilic attack on carbon primarily suffer P–O bond cleavage (Scheme 2).

Phosphodiesters with leaving groups that are better than alkoxides have been studied as mimics of RNA and DNA. Still, these hydrolyses are very slow. For example, diphenylphosphate is unchanged after five hours at 100 °C and pH 10, and the bis-*p*-nitrophenyl analog has a half-life of four months at 100 °C and pH 3–4, whereas the bis-2,4-dinitrophenyl analog has a half-life of 75 minutes under the same conditions.[8] Despite these low rates, the hydronium- and hydroxide-catalyzed hydrolyses of diphenylphosphodiesters can be followed. Specific acid/base catalysis accounts for almost all the hydrolysis over the pH range from 0 to 10. Attaching a ribose ring with a 2′-OH or a 2′-OH analog further increases the rate of hydrolysis. Arylphosphoesters are the most widely used phosphodiesters for investigating mechanistic questions, because their hydrolysis rates are on a reasonable time frame and the course of the hydrolysis can be monitored by UV/Vis spectrophotometry.

Trialkyl phosphotriesters have also been studied more extensively than dialkyl phosphodiesters because of their faster rates of hydrolysis. As discussed in Sections 9 and 16, trialkyl esters typically have hydrolysis rate constants 10^5 to 10^6 times larger than those of diesters. Triesters are also about one to two orders of magnitude more reactive than phosphodiesters with aryl leaving groups.

Cyclic phosphodiesters incorporating five-membered rings are also much more reactive.[9] The original postulate concerning the high reactivities maintained that strain in the substrate is alleviated upon formation of a phosphorane-like transition state.[10] Recently, however, it has been found that the difference in the solvation of the substrate and the phosphorane can account for the rate enhancement.[11]

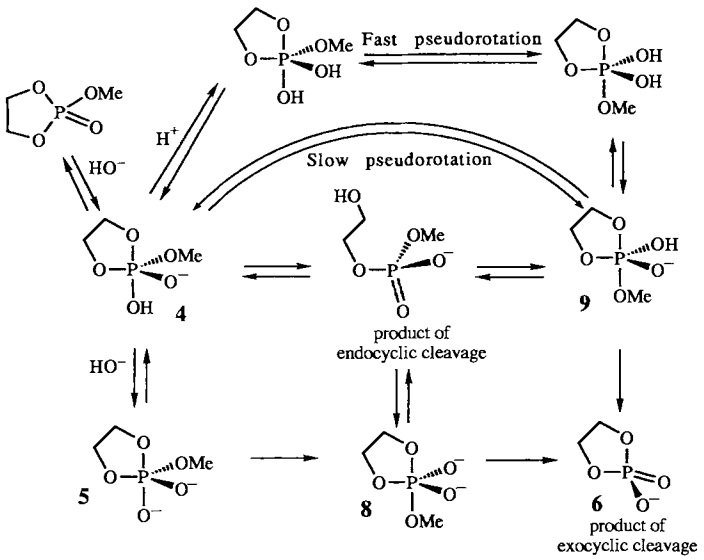
In summary, despite the enhancement imparted by the 2′-OH group, the mechanism of RNA hydrolysis is difficult to determine because of the slow reaction rate. It has been studied mostly by using more reactive analogs such as cyclic phosphates, triesters, and phosphodiesters with good leaving groups. Therefore, with the exception of studies published by the Breslow and Lönnberg groups (see Sections 13 and 14), the majority of the evidence summarized below will concern these more activated substrates.

4. Cyclic Phosphotriesters and Pseudorotation

A cyclic phosphate is the product formed in the transesterification step in the RNA cleavage pathway; hydrolysis of this cyclic phosphate is the second step. This same hydrolysis can therefore be viewed as analogous to the reverse of the RNA transesterification step, with water acting as the nucleophile instead of a 5′-OH group. Therefore, the hydrolysis of cyclic

phosphates has been used to probe possible mechanisms for RNA hydrolysis. Probably the most widely recognized studies on the mechanisms of cyclic phosphate hydrolysis are those performed by Westheimer et al. on methyl ethylene phosphate (MEP) and ethylene phosphate.[12] These studies have been reviewed and discussed several times,[13] and therefore only those points needed as background for our arguments are presented here.

Scheme 4 shows the products and proposed pathway for the hydrolysis of MEP; Figure 1 is a plot of the extent of exocyclic cleavage as a function of pH. Exocyclic cleavage is highest at lower pH, approaches zero at between pH 10 and 13,



Scheme 4. Mechanism of the hydrolysis of methyl ethylene phosphate (MEP) as first discussed by Westheimer et al.

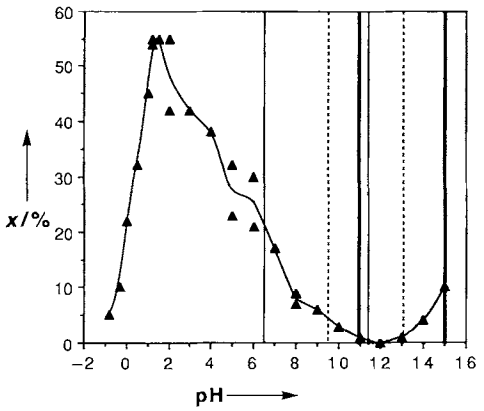


Figure 1. Plot of the proportion x of exocyclic cleavage of MEP as a function of pH (adapted from ref. [12]); pK_a values determined by Guthrie (——), by Westheimer et al. ( ), and by us (——).

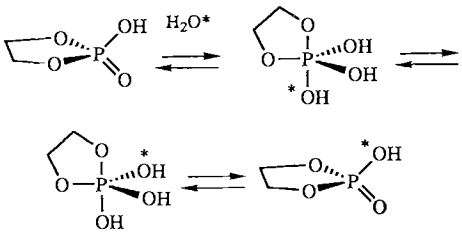
and again is evident at higher pH. Although some studies by Gorenstein et al. indicated no increased exocyclic cleavage above pH 13,[14] further work by Kluger and Thatcher verified the exocyclic cleavage.[15] The plot of the extent of exocyclic cleavage versus pH supports a mechanism in which rapid breakdown of the first formed phosphorane **4** occurs before pseudorotation between pH 9 and 13. At lower pH exocyclic cleavage results from an acid-catalyzed pseudorotation, and at higher pH there is base-catalyzed pseudorotation. The base-catalyzed pathway was postulated to involve the dianionic phosphorane intermediate **5**.

Since exocyclic cleavage can only follow pseudorotation and is faster in acid, and because the hydrolysis of the cyclic phosphate is analogous to the reverse of RNA transesterification, one would conclude that migration of an RNA phosphodiester from the 3′ to the 2′ position must also result from pseudorotation and should be faster in acid. As will be discussed in Sections 13 and 14, this migration is indeed faster in acid. In addition, phosphorane intermediates from phosphodiesters are well-precedented under acidic conditions[16] (see Section 5). In fact, even phosphomonoesters are found to have phosphorane intermediates that can undergo pseudorotation, but only when the hydrolysis reaction is performed under acidic conditions.[17] Another example is the synthesis of oligoribonucleotides: when a protecting group for the 2′ functionality is removed under acidic conditions, partial isomerization occurs.[18] Therefore, it is clear that both protonation of a phosphoester prior to or simultaneously with phosphorane formation, or protonation of a dianionic phosphorane after its formation can increase pseudorotation and as a consequence migration.

5. ^{18}O Exchange

Phosphoranes as intermediates have been explored by ^{18}O exchange between isotopically labeled water and phosphoesters. For example, oxygen exchange into ethylene phosphate accompanies the hydrolysis under acidic conditions but not under basic conditions (Scheme 5).[12, 19] Under acidic conditions the



Scheme 5. Mechanism of ^{18}O exchange between water and ethylene phosphate.

ratio of the rate of ^{18}O exchange to that of hydrolysis is approximately 0.2:1. Similar results were found for ^{18}O incorporation into glycerolphosphoric acid.[19] The 2′-OH analog of glycerol 2-monophosphate is involved in isomerization and cleavage. The substrate is rapidly rearranged to glycerol 1-monophosphate with incorporation of ^{18}O from solvent water under acidic conditions[20] but not under basic conditions.[17, 21]

Products resulting from pseudorotation and ^{18}O exchange under acidic to neutral conditions, and not under basic conditions, have been key to deciphering phosphoester hydrolysis mechanisms. These observations are most easily explained if a dianionic phosphorane is either a transition state or is conformationally locked. Protonation of the phosphorane increases its lifetime and the possibility for ^{18}O incorporation and pseudo-

rotation. Therefore, ^{18}O exchange and phosphate migration are consistent with both mechanisms A and B in Scheme 2. Under acidic to nearly neutral conditions the protonation state of the phosphorane allows for pseudorotation and reversal to starting material. Under basic conditions neither of these reactions occurs.

One question, however, remains: at what point is the phosphorane protonated? The phosphoester could be protonated prior to or simultaneously with nucleophilic attack (Scheme 2B), or a dianionic phosphorane could have a lifetime long enough for protonation, or both could be possible.

6. Theory

The first evidence we present addressing the timing of phosphorane protonation is the result of theoretical calculations. The calculations show that dianionic phosphoranes exist in potential energy wells of only a few kcal mol^{-1}, even if the phosphorane is solvated and has alkyl groups. Based upon the calculations, we draw the conclusion that a dianionic phosphorane is too short-lived for protonation under neutral conditions.

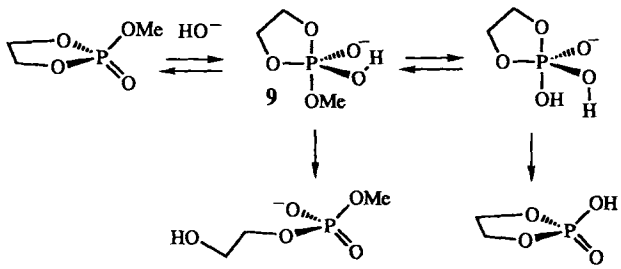
The stabilities of dianionic and monoprotic/monoanionic phosphoranes have been probed by ab initio calculations. Studies on the STO-3G level indicated that dianionic phosphoranes exist in very deep potential energy wells.[22] Higher level calculations demonstrated that the deep wells were due to the minimal basis sets and that the dianionic phosphoranes are actually kinetically insignificant or true transition states.[23] Ab initio studies by both Karplus and Taira supported the notion that dianionic phosphoranes are very unstable. In contrast, monoanionic/monoprotic phosphoranes are stable, albeit with a distorted trigonal-bipyramidal geometry.[24]

Calculations also predicted stabilization of the phosphorane by solvation. A Born-type model of charge stabilization predicted that dianionic intermediates will be stabilized more than two singly charged groups, since the Gibbs free energy of solvation is proportional to the square of the ionic charge.[24b, 25] In fact, Karplus has calculated that solvation can stabilize a dianionic phosphorane such that in solution the Gibbs free energy of activation for nucleophilic attack is reduced from the gas-phase value by about 60 kcal mol^{-1}. This solvation brought the calculated activation energy for forming a dianionic phosphorane-like transition state in range with that found experimentally.[24b, 25]

Calculations conducted by Taira et al. led them to the conclusion that the nonexistence of dianionic phosphoranes in the gas phase is due to an inability to delocalize two full negative charges. This conclusion was supported by the great instability of an all-hydrogen-substituted dianionic phosphorane;[26] replacement of the hydrogens by simple methyl or ethylene bridges was found to increase phosphorane stability.[27] Thus, dianionic phosphoranes formed from RNA phosphodiesters would be expected to delocalize charge better, and consequently exist. Solvation would also increase stability by further delocalization of charge. In fact, even the most unstable phosphorane exists as the dianionic species when solvated with six water molecules,[28] and phosphoranes with ethylene bridges were found to be stabilized when solvated with only one water molecule.[27b] Taira et al. stated that their calculations are consistent with the lack of ^{18}O exchange and the lack of phosphoryl migration under basic conditions. They concluded that these observations result from a high energy barrier to pseudorotation and are not evidence that the phosphorane is a transition state.[27] They went on to postulate that any dianionic phosphorane will exist as an intermediate as long as it is solvated.[29]

The calculations demonstrate that solvated dianionic phosphoranes are intermediates. However, the barriers to the departure of the leaving group are calculated to be only on the order of 2 kcal mol^{-1}, resulting in rate constants for expulsion near 10^{11} s^{-1} at 25 °C.[27–29] Increasing solvation is predicted to increase this barrier, but to what extent is currently unknown. Using 2 kcal mol^{-1} as the best current estimate for the barrier to leaving group departure, one can calculate that the first-order decomposition would be faster or comparable to possible diffusion-controlled second-order reactions. For example, the rate constants determined for leaving group departure are larger than the predicted rate constants for protonation (see Section 7). We cite this as the first evidence that dianionic phosphoranes have little chance for protonation at neutral pH.

Other calculations have also been performed to understand the stability of phosphoranes and the ratio of exo- and endocyclic cleavage of MEP. Lim and Tole have performed ab initio calculations for the attack of hydroxide on MEP, with results similar to those of Taira and Karplus. However, they found that the hydroxide attack is concerted with pseudorotation, giving **9** initially (Scheme 6),[24c] and that ring opening is faster than



Scheme 6. Mechanism of cleavage of MEP as postulated by Lim and Tole.

exocyclic cleavage. The differences in endo- and exocyclic cleavage were calculated to result from differences in the rotamers of the equatorial P–OH bond. The orientation of the oxygen lone pairs dictates the ratio of endo- to exocyclic cleavage through stereoelectronic effects.

In summary, theoretical calculations suggest that dianionic phosphoranes most likely exist in solution, but that their lifetimes are either barely long enough or not long enough to allow for most diffusion-controlled processes. Therefore, they cannot be distinguished kinetically from transition states (Hypothesis 1). The phosphoranes immediately expel their leaving groups, not allowing for pseudorotation or ^{18}O incorporation as proposed by Todd et al. in 1956.[30] We will support these calculations in Sections 7, 13, and 16, where experimental evidence is cited that dianionic phosphoranes with alkoxide leaving

groups are nearly transition states. In Sections 10–12 we will present experimental evidence that dianionic phosphoranes with good leaving groups are true transition states.

Let us accept for the moment that dianionic phosphoranes are not long-lived enough for protonation. Since their protonated forms are required for pseudorotation and ^{18}O incorporation, the protonation must occur on the phosphodiester prior to or simultaneously with nucleophilic attack (Hypothesis 3).

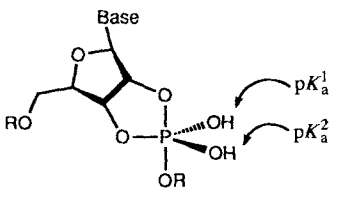
7. Dianionic Phosphoranes: Rate of Protonation

We are arguing that the ab initio calculations support the notion that the rate of decomposition of a dianionic phosphorane intermediate exceeds the rate of protonation by water or buffer. In fact in 1970 Usher offered a convincing argument for this using the mechanism of hydrolysis of MEP shown in Scheme 4.[31] He noted that the rate of breakdown of the monoanionic phosphorane **4** has to be faster than pseudorotation of **4**, which had been predicted to occur with a rate constant of about $10^8\ s^{-1}$.[32] Further, he noted that the rate of breakdown of dianionic phosphorane **5** should certainly be faster than that of **4**. Therefore, Usher was led to the conclusion that the breakdown of a dianionic phosphorane has a first-order rate constant of 10^{10} to $10^{11}\ s^{-1}$, greater than the pseudo-first-order rate constant for protonation, which he predicted to be $10^9\ s^{-1}$.[33] The Usher argument predicts that the dianionic phosphorane is indeed an intermediate, and that its fleeting existence does not allow diffusion-controlled reactions. This is the same conclusion reached by analysis of the ab initio calculations discussed in Section 6.

Since the rate of leaving group expulsion from a dianionic phosphorane is most likely faster than protonation, as first presented by Usher, a monoanionic/monoprotic phosphorane must be formed by prior or simultaneous protonation of the phosphodiester with nucleophilic attack (Hypothesis 3). We will present further experimental data in Sections 12–14 and 16 to support this claim, but first we will examine more phosphorane reactivity as a prelude to these discussions.

8. Phosphorane Reactivity and pK_a Values

The preceeding discussions have demonstrated that pseudorotation of a phosphorane in RNA hydrolysis is dependent upon its protonation state, which in turn is dependent upon the pH and the pK_a values of the phosphorane. Westheimer et al.[12] have estimated $pK_a^1 = 9$ and $pK_a^2 = 13$ for phosphoranes, by using the method of Branch and Calvin (Scheme 7).[34] Guthrie has calculated values of 6.5 and 11.3 from heats of formation.[35] Values of about 11 and 15 have been measured in our laboratory by pulse radiolysis.[36] Although different phosphoranes should have different pK_a values, the range reported seems unreasonably large; as a result this issue is not yet fully settled.



Scheme 7.

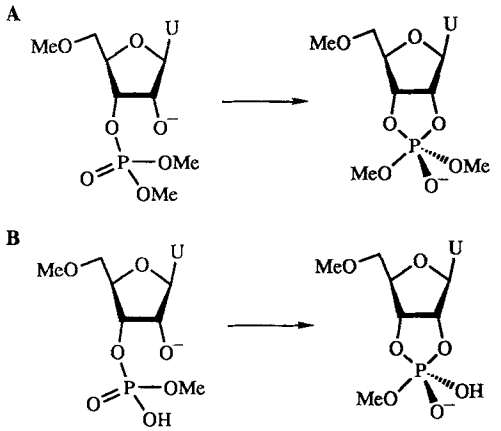
Even though the pK_a values for phosphoranes are not yet well-established, we will analyze the dependence of the exocyclic cleavage on pH (Figure 1). If the pK_a values of the phosphoranes derived from MEP influence the ratio of endo- to exocyclic cleavage, one would expect change in this ratio at pH values near the pK_a values, and little change at intermediate values. Several lines are drawn in Figure 1 indicating the pK_a values determined for diprotic/neutral phosphoranes by Guthrie, Westheimer et al., and by our group. The pK_a^1 value determined by Guthrie (6.5) falls in a region of rapid change in the profile. At pH < 6.5 the phosphorane is completely protonated and the chance for pseudorotation is at its highest, leading to increased exocyclic cleavage. At pH > 6.5 the anionic form of the phosphorane dominates and pseudorotation is slower, yielding less exocyclic cleavage. As the pH approaches pK_a^2 (11.3), no exocyclic cleavage is observed. The switch to increased exocyclic cleavage at pH > pK_a^2, however, is difficult to explain. Westheimer's values bracket the region of little exocyclic cleavage. At pH values below the first pK_a (9) and above the second pK_a (13), exocyclic cleavage increases. This agrees with the original interpretation of the data (Section 3). We determined a pK_a^1 value of about 11, which falls in the pH range where no exocyclic cleavage occurs. Below this value protonation would increase the rate of pseudorotation, and as a result the proportion of exocyclic cleavage. At pH values approaching the estimated pK_a^2 value of nearly 15, such as pH 13–14, the ratio of exo- to endocyclic cleavage should again start to change due to partial deprotonation of the apical OH group, resulting in dianion **5**, which would rapidly pseudorotate and expel either the exocyclic or endocyclic leaving group. The fact that base-catalyzed exocyclic cleavage occurs at pH $\approx$ 15 is most consistent with our value for pK_a^2 of 15.

In summary, it is clear that the exact pK_a values of phosphoranes should be investigated further. Knowing them will allow better interpretation of cleavage and isomerization data for phosphodiesters and RNA.

9. Analogy to Phosphotriesters

The mechanism of hydrolysis of a phosphotriester should be a good analogy to that of a protonated phosphodiester, assuming that an alkyl group and a proton influence phosphoester reactivity similarly. Phosphotriesters are hydrolyzed about 10^5 to 10^6 times faster than phosphodiesters under similar conditions (see Section 16). Therefore, protonation of a phosphodiester to give a neutral compound is thought to impart a similar rate enhancement to hydrolysis.[37] With this analogy in mind, Lönnberg has studied the acidic, neutral, and basic hydrolyses of phosphotriesters.[38] Phosphate migration and hydrolysis proceed at similar rates near pH 2, while the rate of hydrolysis is faster at lower pH. Migration becomes faster between pH 3 and 4. Keeping with the analogy, Lönnberg compared these data to those of phosphodiesters. The pH-independent hydrolysis and isomerization of a phosphodiester can proceed by two kinetically equivalent mechanisms. One involves the attack of an un-ionized sugar hydroxyl group on the monoanionic phosphodiester, while the second involves the attack of the ionized hydroxyl group on a neutral diester. Lönnberg has suggested

that in the case of the phosphotriesters the attacking nucleophile is the anion of the 2′-OH group even under relatively acidic conditions (pH 3, Scheme 8 A). Therefore, Lönnberg postulates that the pH-independent hydrolysis mechanism for the diester hydrolysis proceeds by attack of the ionized hydroxyl group on the protonated phosphodiester (Scheme 8 B). This is essentially the mechanism given in mechanism B in Scheme 2, but with prior deprotonation of the 2′-OH group.



Scheme 8. Analogy between phosphotriesters (A) and -diesters (B) put forth by Lönnberg et al.

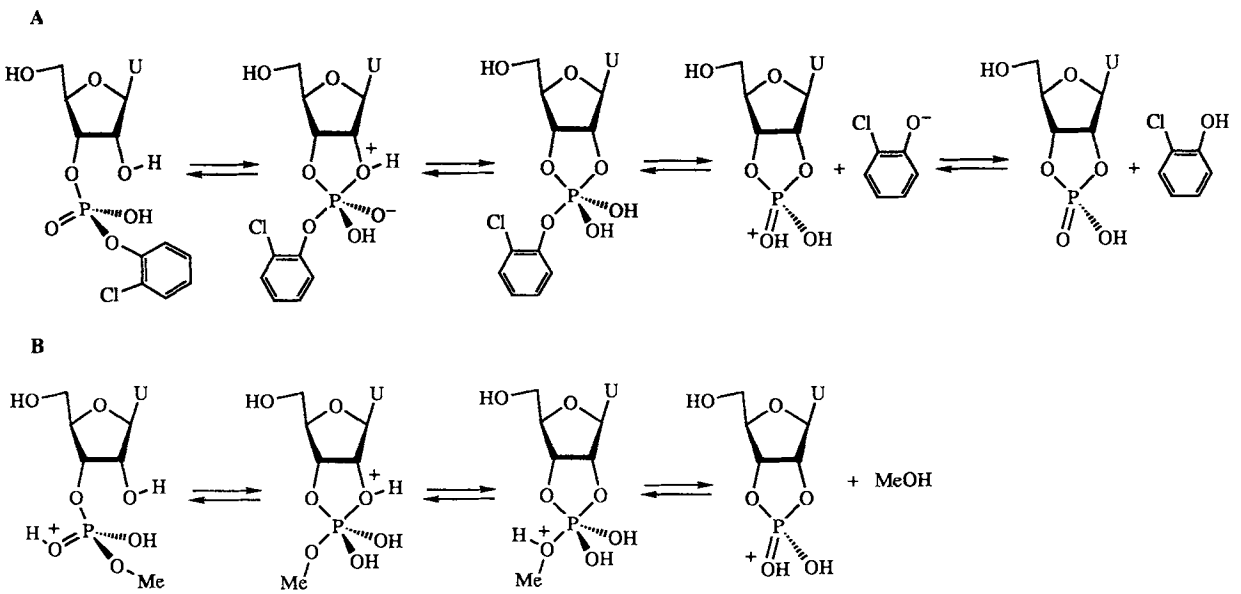
Lönnberg has also examined the hydrolysis and migration of phosphotriesters catalyzed by general acids and bases.[38b] When formic acid buffers were used, both the isomerization and hydrolysis were found to be kinetically dependent upon the basic and not the acidic component of the buffer. This is in contrast to a phosphodiester. As will be discussed in Section 14, isomerization of phosphodiesters is also buffer-catalyzed, but it is the acidic component of the buffer upon which the rate is dependent. Therefore, one can conclude that the alkyl group of a triester takes the place of the required proton in the diester.

In summary, similarities in the kinetics of the hydrolysis of phosphodiesters and -triesters led Lönnberg to postulate that RNA diesters are hydrolyzed at nearly neutral pH via intermediates with neutral and protonated phosphates and ionized 2′-OH groups. Furthermore, the difference in the kinetics of migration of phosphodiesters and -triesters catalyzed by general acids and bases supports prior protonation of phosphodiesters rendering them triester-like. Further examples of this will be presented in Sections 14–16.

10. RNA Analogs with Good Leaving Groups

As a means of deciphering RNA hydrolysis mechanisms, extensive research has been performed with phosphodiesters containing good leaving groups. In one example, Lönnberg studied the hydrolysis of uridine 3′-(2-chlorophenyl)phosphate (Scheme 9) and determined that its hydrolysis is faster than migration of the phospho linkage over the entire pH range.[39] The migration was detected only at pH values below 2. Migration requires the shifting of an electron-withdrawing group into an equatorial position during pseudorotation and is thus slower than hydrolysis.

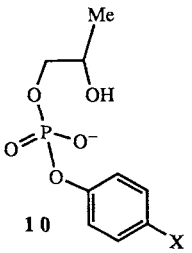
The Lönnberg studies revealed an interesting aspect about the pH dependence of the reactivity of the 2-chlorophenyl ester compared to that of the methyl ester, as well as the change in mechanism on going from an activated phosphoester to a non-activated phosphoester (Scheme 9 A·B).[39,40] At pH values below the phosphate pK_a, the methyl ester exhibits a second-order dependence on hydronium ion concentration, indicating attack of the 2′-OH group on the cationic, diprotonated phosphate linkage. The phosphorane could then expel a neutral alcohol. In contrast, the 2-chlorophenyl ester exhibits a first-order dependence on hydronium ion concentration, supporting the attack of the 2′-OH group on a neutral/monoprotonated phosphodiester,



Scheme 9. The protonation state required for nucleophilic attack of the 2′-OH is different for activated (A) and unactivated phosphodiesters (B).

which would expel a phenoxide leaving group. The electron-withdrawing ester group facilitates the nucleophilic attack and therefore changes the protonation state of the phosphoester required before nucleophilic attack. The phosphodiester with the poorer leaving group requires a higher protonation state for facile nucleophilic attack.

Not only is the kinetic order of specific acid catalysis different with activated and unactivated phosphodiesters, but it is also different with buffer catalysis. For example, as will be described in Section 14, buffer-catalyzed RNA hydrolysis can involve both the acidic and basic components of the buffer. However, with reactive substrates such as **10** (X = NO_2), the catalysis is solely dependent upon the basic component of the buffer.[41] The different requirements for phosphodiester protonation states as a function of leaving group ability are key to understanding the change in mechanisms of hydrolysis of phosphodiesters with or without good leaving groups (Hypothesis 7).

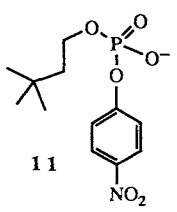


10

In summary, the study of phosphodiesters with good leaving groups may not give valid conclusions for RNA phosphodiesters. This is because leaving group ability can affect the kinetic order for protonation of a phosphodiester. In fact, not only is the kinetic order for protonation changed, but the stability of the resulting phosphorane intermediate is dramatically altered. As the next two sections will show, dianionic phosphoranes as well as monoanionic phosphoranes with good leaving groups are true transition states.

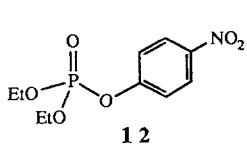
11. Isotope Effects

Isotope effects are excellent probes for determining the extent of bond breakage and formation in transition states, and therefore can be used to analyze the formation and decomposition of phosphoranes. Using ^{15}N isotope effects, Hengge and Cleland measured the degree of bond breaking in the transition state from *p*-nitrophenyl phosphodiester **11**.[42] In support of the hypothesis that phosphodiesters with good leaving groups such as *p*-nitrophenolate are hydrolyzed by direct displacement with no phosphorane intermediate, the isotope effects indicated 57% bond cleavage at the leaving group in the transition state under alkaline conditions and 25–32% cleavage under acidic conditions. The large extent of bond breakage makes it evident that phosphoranes formed in these reactions are transition states. The minimal cleavage at the leaving group found under acidic conditions supports the hypothesis that protonated phosphorane transition states do not have as much bond breakage at the leaving group (Hypothesis 6) as the dianionic species.

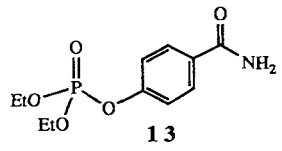


11

Similarly, Cleland and Raushel have studied ^{18}O isotope effects in the alkaline hydrolysis of *p*-nitrophenyl and *p*-carbamoylphenyl phosphotriesters **12** and **13**, respectively, to measure the extent of leaving group departure in the transition state.[43] A phosphorane derived from a phosphotriester will be



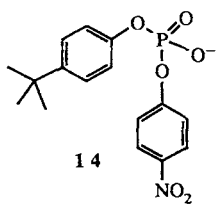
12



13

monoanionic and predictably more stable than the dianionic phosphorane formed in the alkaline hydrolysis of a phosphodiester. The magnitude of the ^{18}O isotope effect on the phosphotriesters indicates changes in bond order at the leaving group that support a phosphorane-like transition state and not a phosphorane intermediate. Therefore, in direct analogy to the phosphotriester-derived phosphorane with a good leaving group, a monoprotic/monoanionic phosphorane derived from a phosphodiester with a good leaving group would also be a transition state. Clearly a dianionic phosphorane with a good leaving group would be a transition state.

Heavy atom isotope effects have also been used to analyze the hydrolyses of *p*-nitrophenyl phosphodiesters **11** and **14** catalyzed by imidazole-derivatized β-cyclodextrins and the enzyme phosphodiesterase I.[44] The isotope effects on the imidazolyl-β-cyclodextrin-catalyzed reaction indicate significant bond cleavage at the leaving group in the transition state, with no phosphorane intermediate. In contrast, a large inverse ^{18}O isotope effect was measured on the enzyme-catalyzed cleavage, suggesting protonation of the nonbridging oxygen in the phosphorane-like transition state. Therefore, phosphorane-like intermediates or transition states can be protonated at enzyme active sites as a means of electrophilic activation (see Section 17).

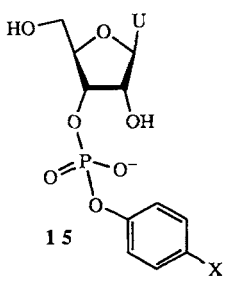


14

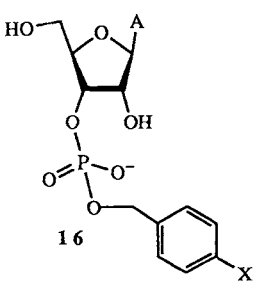
In summary, isotope effects support the hypothesis that a phosphorane is a transition state in the hydrolysis of a phosphodiester or -triester possessing a good leaving group (Hypothesis 6).

12. β_{lg} Values

In addition to isotope effects, Brønsted and Hammett correlations are useful in deciphering the extents of bond cleavage and formation in transition states. Several β_{lg} values (lg = leaving group) have been determined for phosphoryl transfer reactions.[45] The most pertinent values for the hydrolysis of RNA are those determined for the aryl esters **15** studied by Williams[46] and the benzyl esters **16** studied by Inoue.[47] Williams was able to measure the charges on oxygen atoms in



15



16

the transition state for the cyclization of aryl esters of **15**. He found first-order kinetics for this imidazole-catalyzed phosphoryl transfer with no evidence of imidazolium involvement. β_{lg} values of -0.59 and -0.54 were determined for imidazole and hydroxide, respectively, which are very close to the β_{lg} value of -0.56 for the hydrolysis of phosphodiester **10** found by Usher.[48]

The Williams data were interpreted as support for a phosphorane-like transition state with no intermediate, in which the dianion favors a concerted displacement mechanism (Hypothesis 6). The similar β_{lg} values for hydroxide- and imidazole-catalyzed phosphoryl transfers indicate similar transition states. Thus, with these phosphodiesters, catalysis by imidazole does not proceed via protonated transition states. However, in imidazole catalysis, the largest pK_a value for the leaving group in the phosphodiesters was 9.38, approximately 5.4 units away from the pK_a value of the leaving group in RNA.[49] Thus, none of the phosphodiesters was as deactivated as RNA itself. In order to compare these data to that of less activated substrates such as RNA, Williams extrapolated his β_{lg} plot for the hydroxide-catalyzed reaction to predict rate constants for substrates with benzyl alcohol leaving groups. These leaving groups were chosen since they had been studied by Inoue[47] and would also be expected to better mimic the poorer leaving groups in RNA due to their higher pK_a values. Williams found that the rate constants for hydrolysis predicted from his extrapolated graph and those determined by Inoue agree within an order of magnitude. Thus, under strongly alkaline conditions, phosphodiesters with poor leaving groups as well as those with good leaving groups are hydrolyzed by means of a direct displacement mechanism with no phosphorane intermediate. Williams also examined the Leffler index for the reaction and found even more charge on the benzyl leaving group than on an aryl leaving group in the transition state, as would be expected for a Hammond effect on a concerted direct displacement mechanism.[46] This is some of the best evidence that dianionic phosphoranes are nearly transition states in water, even when they have poor leaving groups (Hypothesis 1).

No rates for the imidazole-catalyzed cleavage of the benzyl esters **16** have been determined, and consequently one cannot extrapolate Williams' β_{lg} plot for imidazole catalysis to see if the data for benzyl leaving groups would lie close to the line. In the case of imidazole catalysis, it is well-precedented that phosphorane intermediates are formed from phosphodiesters with poor leaving groups because migration is observed (see Section 14). Since our premise is that a phosphorane can only be an intermediate and lead to migration if it is supplied with a proton, we would not expect the data for benzyl or RNA esters to correspond to the Brønsted plot of phenyl esters undergoing imidazole catalysis. However, if both mechanisms in Scheme 2 are operating simultaneously in buffer-catalyzed RNA hydrolysis (see Section 14), then the rate of cleavage may be very close to the value from Williams' β_{lg} plot. Unfortunately, these predictions have not been tested.

In summary, Brønsted correlations relating leaving group abilities to hydrolysis rates indicate that phosphodiesters with good leaving groups are hydrolyzed via phosphorane-like transition states with no intermediates. These data have been compared to those for phosphodiesters with poor leaving groups undergoing alkaline hydrolysis. They compare favorably, thus supporting dianionic phosphorane-like transition states for RNA phosphodiesters undergoing base-catalyzed hydrolysis (Hypothesis 2). Since dianionic phosphoranes are akin to transition states, we cite this as further evidence that the lifetimes of dianionic phosphoranes are not long enough for protonation (Hypothesis 1).

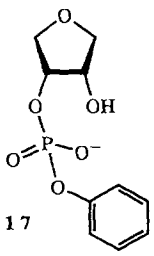
13. Specific Acid/Base Catalysis

The kinetics for acidic, neutral, and alkaline cleavage and migration of dinucleotide monophosphates have been studied in detail,[30,50] most recently by Lönnberg,[40] who has shown that alkyl esters of 2'- and 3'-AMP undergo three competitive reactions in acid: loss of the alkyl group to yield a 2'- or 3'-AMP, depurination, and isomerization. Hydrolysis to produce adenosine was negligible. The isomerization reaction is first-order with respect to hydronium ion at pH < 1, is second-order between pH 1 and 2, and becomes pH independent at pH 3–8. The rate versus pH profiles for isomerization of these phosphodiesters are essentially identical to those found for 2'- and 3'-ribonucleotides. The only difference is that isomerization of the monoesters becomes first-order in hydronium ion above pH 7, suggesting that protonation of the phosphomonoester catalyzes isomerization.[51] The proton on the phosphomonoester thus plays the role of an alkyl group in a phosphodiester.

Lönnberg also demonstrated a similarity between the rate versus pH profiles for phosphate migration and phosphodiester hydrolysis at pH < 2 and presents these data to support a common pentacoordinated intermediate. Under strongly acidic conditions the mechanism would involve protonation of the phosphoryl oxygen of a neutral phosphodiester followed by nucleophilic attack of the adjacent 2'-OH group. At pH ≈ 7 the rate of isomerization would be independent of hydronium or hydroxide ions. As one possible mechanism, Lönnberg proposed an ionized 2'-OH attacking a protonated phosphodiester, thereby forming a monoanionic/monoprotic phosphorane (Scheme 8 B); this is essentially the mechanism given in Scheme 2 B.

This mechanism involves a monoprotic/monoanionic phosphorane and relies on either general base delivery of the 2'-OH group or full ionization of the 2'-OH group. In the past it has been assumed that full ionization of the 2'-OH group occurs prior to nucleophilic attack; therefore a kinetic analysis of the rate of hydrolysis of model compound **17** at pH values close to the pK_a of 2'-OH revealed a kinetic pK_a value of 13.9.[7] The fact that a kinetic pK_a value could be determined supports Lönnberg's premise of prior ionization.

In summary, the kinetics of specific acid/base catalysis of RNA phosphodiesters imply the presence of a monoanionic/monoprotic phosphorane under neutral conditions, which is formed by nucleophilic attack of the ionized 2'-OH on the protonated phosphodiester. These results further support the validity of Mechanism B.

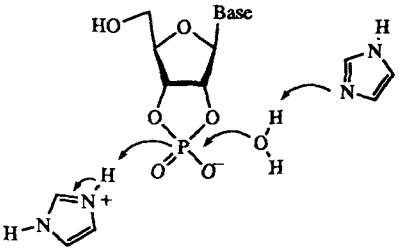


17

14. General Acid/Base Catalysis

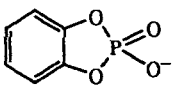
Usher was one of the first investigators to analyze the general base (morpholine) catalyzed cleavage of RNA analog **17**.[52] The catalysis was believed to involve either delivery of the 2'-OH group to the phosphodiester by the nitrogenous base or a preequilibrium with full deprotonation of the 2'-OH group. The data demonstrated general base formation of a monoanionic/monoprotic intermediate. The reaction of the intermediate either back to starting material or forward to product was found to be catalyzed unequally by the acid and base components of the buffer. Usher proposed that after formation of an intermediate having a 2'-O^- group, acid catalyzes both the formation and breakdown of the phosphorane. This is a variation on the mechanism in Scheme 2 B. He concluded that the reaction changed from general acid to general base catalyzed when the ratio of morpholine to morpholinium was decreased.

In another study of general-species-catalyzed cleavage of an RNA analog, Eftink studied imidazole buffer catalyzed ring opening of cyclic phosphodiesters. At pH values (6.5, 7.0, 7.4) at which the imidazole buffer exists in both acid and base forms, the ring openings of cUMP and cCMP were found to be second-order in total buffer concentration, as shown by the upward curvature of the plots of the first-order rate constants versus buffer concentration.[53] This implies that imidazolium and imidazole are involved in the hydrolytic opening of the cyclic phosphate (Scheme 10). Eftink postulated that imidazole–



Scheme 10. Eftink's picture of the bifunctional hydrolysis of an RNA cyclic phosphodiester.

imidazolium dimers exist at high buffer concentration, and that each component of the buffer catalyzes a different part of the reaction. Similarly, Haake has described imidazole buffer catalyzed opening of phosphodiester **18**.[54a] He also found that imidazolium is a significant catalyst.

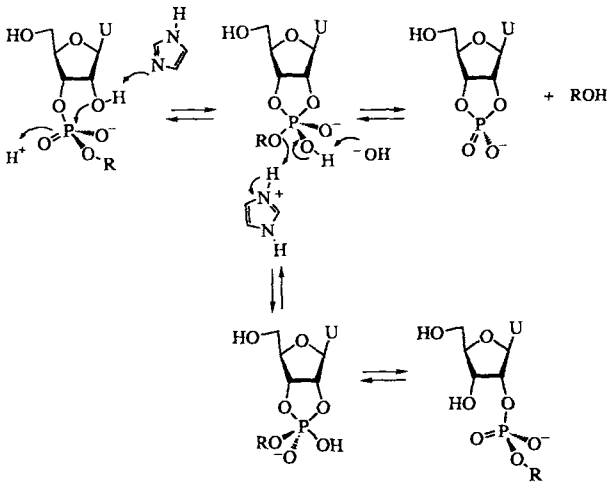


18

The most extensive and controversial studies of buffer-catalyzed hydrolysis of RNA were performed by Breslow et al. They studied the imidazole buffer catalyzed cleavage of polyuridylic acid (poly-U),[55] of 3',5'- and 2',5'-uridylyluridine (UpU),[56] and of 3',5'-adenylyladenosine (ApA).[57] In addition, the morpholine buffer catalyzed cleavage of 3',5'-UpU was also examined.[58] Each cleavage reaction was first-order in buffer, with imidazole yielding bell-shaped rate versus pH profiles. Breslow originally interpreted the bell curve as an indication that both buffer components are involved in catalyzing the cleavage reaction. Since the reaction is first-order in buffer, the buffer components must act sequentially, not simultaneously. One component of the buffer catalyzes the formation of a phosphorane; the other catalyzes the breakdown of this intermediate. As the ratio of the two components of the buffer changes, the rate-determining step changes to the one involving the component that is in the lowest concentration. As discussed toward the end of this section, this original interpretation has been modified in view of new results concerning medium effects.

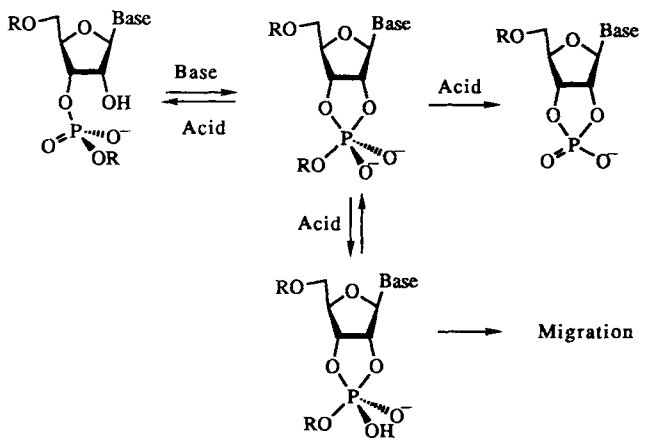
In the original interpretation, the bell-shaped plot of cleavage rate versus pH and a first-order dependence upon buffer for UpU and poly-U did not distinguish which buffer component is involved in formation of the intermediate and which catalyzes breakdown of the intermediate. However, by following the isomerization reaction (3',5' → 2',5') of the phosphodiester linkages in UpU and ApA, Breslow discovered how to make such a distinction. The isomerization was first-order in imidazole buffer for the 3',5' and 2',5' compounds, but only the imidazolium component was required.[56] When the ratio of imidazolium to imidazole was low, the isomerization of UpU was slightly retarded at higher buffer concentrations, an effect for which the term "negative catalysis" was coined.[57] The trend was the same in the imidazolium-catalyzed isomerization of ApA when a fixed concentration of imidazole and a varying concentration of imidazolium buffer were used.[57] Morpholine buffer catalyzed isomerization of UpU showed this effect to an even greater extent.[58] This supports the hypothesis that a common intermediate forms both the cleavage and migration products in a ratio that depends upon the basic component of the buffer. These data were interpreted to mean that the acidic component of the buffer is involved in the first step of the cleavage reaction. Since the substrate is predominantly in the anionic form at neutral pH, a proton and the basic form of the buffer are required in this first step. Therefore the reaction appears to be catalyzed by the general acid imidazolium (Scheme 11). The results and interpretation of the imidazole- and morpholine-catalyzed reactions of RNA have been reviewed recently.[59]

The premise of the Breslow papers has been strongly criticized by several researchers. The first criticism was put forth by Menger,[60] who found fault with some of the experimental de-

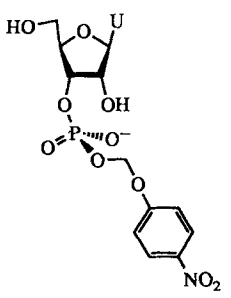


Scheme 11. Breslow's mechanism for the buffer-catalyzed cleavage of RNA.

tails of the UpU and ApA studies and attributed the negative catalysis to faulty analysis of the data. Breslow later showed that this criticism was unfounded.[58] The second criticism was put forth by Haim,[61] who argued that Breslow's kinetic model did not reproduce the reported rate constants.[62] In addition, he proposed that the existence of a common intermediate in the isomerization and cleavage reactions was inconsistent with the kinetic measurements. Breslow later showed that his data were consistent with a common intermediate by using Haim's own analysis.[58] In a criticism similar to that of Haim, Perrin suggested that the data for morpholine-catalyzed hydrolysis of UpU are best described by classic general base catalysis.[63] He noted that both the rate of cleavage and the ratio of cleavage to isomerization rates are linearly dependent upon buffer concentration, while the intercepts of these plots increase with increasing basic component of the buffer, as is true for general base catalysis. He proposed a mechanism that involves general base formation of a dianionic phosphorane intermediate, followed by general acid catalyzed protonation of leaving groups to yield either starting material or product (Scheme 12). The isomerization pathway branches from the dianionic phosphorane; a nonbridging oxygen is protonated to allow for pseudorotation. The extent of phosphorane protonation controls the amount of pseudorotation. At pH values where the acid component of the buffer is high, more isomerization is observed. Thus, the Perrin mechanism accounts for the drop in isomerization seen with increasing basic component of the buffer. Although Perrin agrees with Breslow that the data support a common intermediate in the cleavage and isomerization reactions, his proposed mechanism is inconsistent with a bell-shaped rate versus pH profile. Perrin suggested that this curve could result from an effect of the medium, and as discussed below, such an effect has been found by both Kirby and Breslow.



Scheme 12. Perrin's mechanism for the buffer-catalyzed cleavage of RNA.



19

Kirby was the first to show that medium effects are important in the RNA hydrolysis mechanism. He found that the bell-shaped rate versus pH profiles described for poly-U and UpU may be due to a medium effect.[64] Kirby studied the imidazole buffer catalyzed cleavage of the RNA analog **19**. He found a bell-shaped rate versus pH profile like that found by Breslow and co-workers with RNA, but the curve did not fit the kinetic equations developed in the Breslow group. Instead, the rate constant increased linearly with increasing fractions of imidazole until the apex of the bell and then dropped off. Data were also collected for the background rate (hydroxide-catalyzed cleavage) by extrapolating the second-order buffer plots to zero buffer concentration. He found that the background reaction was the dominant pathway when the imidazole buffer consisted of 80 to 90% of the free base. He further discovered that the rate of the hydroxide-catalyzed reaction was significantly depressed by the addition of imidazole. Therefore, Equation (a) describes the observed

$$v = k_{cat}[\mathrm{Im}] + k_o[\mathrm{OH}] - k_{corr}k_o[\mathrm{OH}][\mathrm{Im}] \quad (a)$$

served reaction rate v, in which the third term represents the depression of the hydroxide-catalyzed rate by imidazole buffer. Kirby corrected for this observed rate depression at high pH and high imidazole buffer concentration by adding the $k_{corr}k_o[\mathrm{OH}][\mathrm{Im}]$ term to the observed rate constants, and the resulting curve was a straight line. Kirby used this as evidence that the bell-shaped rate versus pH profile found by Breslow and co-workers was the result of a medium effect; otherwise the reaction is best described by general base catalysis.

Kirby's analysis of medium effects is insightful.[64,54b] However, it may not be completely relevant to the hydrolysis of UpU and poly-U since the leaving group can have an effect on the kinetic order for protonation (see Section 10); the more reactive phosphodiester possibly may require less protonation. The demonstrated reactivity of **19** is several hundredfold higher than that of UpU at the same pH. Kirby estimates that the pK_a of the leaving group is about 11, whereas that of UpU is estimated at 14.8.[49] These pK_a values differ by roughly 4 units. It may be expected that a phosphorane derived from **19** is much closer to a transition state than an intermediate due to the better leaving group. Therefore, owing to its higher reactivity **19** may require no protonation, and a bell-shaped pH-rate profile would not be expected. Since the isomerization of **19** was not investigated, it is difficult to know if a phosphorane intermediate is involved. If the rate versus pH profile for the migration of **19** is similar to that of RNA, then it is likely that the medium effect found by Kirby is relevant to RNA. If migration does not occur, it is likely that the phosphorane derived from **19** is closer to a transition state than an intermediate. It follows that the mechanism is closer to that in Scheme 2A, whereas that of RNA may better resemble that in Scheme 2B. Irrespective of the exact correlation between **19** and RNA, Breslow has indeed found that medium effects are important for the hydrolysis and migration reactions of RNA.

Breslow has studied the effects of the medium on the buffer-catalyzed cleavage–transesterification and isomerization of RNA. The bell-shaped rate versus pH profiles for the cleavage reaction are due to the lack of control of the ionic strength of the medium. The cleavage reaction is predominantly catalyzed by the general base component of the buffer, but only when basic buffers such as morpholine are used. In the case of imidazole buffers, there are two dominant pathways for cleavage: one which involves general base catalysis, and one which involves general acid catalysis followed by general base catalysis as was

originally postulated. With acidic buffers such as acetate/acetic acid, the acid-catalyzed pathway for cleavage dominates. With all buffers, however, the isomerization reaction is acid-catalyzed and shows negative catalysis with the basic component of the buffer. Therefore, two mechanisms for buffer-catalyzed cleavage can occur simultaneously (Hypothesis 8), but there is only one mechanism for isomerization. The isomerization mechanism involves prior or simultaneous protonation of the phosphodiester with nucleophilic attack (Hypotheses 3–5).

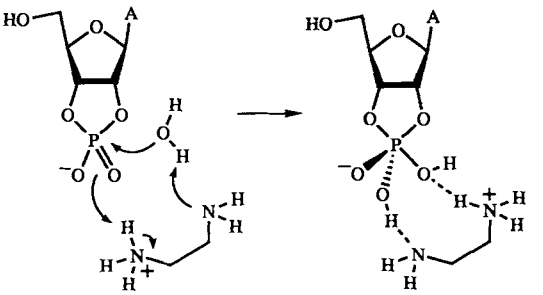
Since the bell-shaped rate profile for the cleavage of RNA has been found to be due to a medium effect, the Perrin interpretation is reasonable. However, one of the premises given at the beginning of this review is that the lifetime of a dianionic intermediate is too short to allow for protonation. Perrin postulates that the dianionic phosphorane exists long enough to be protonated and that the protonation state of the phosphorane determines the amount of isomerization product observed. His mechanism also requires protonation of a leaving group for formation of either starting material or product. We have discussed the current literature data that support the notion that a dianionic phosphorane is akin to a transition state and that a pathway involving such an intermediate cannot lead to migration.

Breslow's conclusion that a mechanism analogous to that in Scheme 2 B is operative in the buffer-catalyzed cleavage–transesterification and migration of RNA is similar to many other researchers' conclusions that have been presented to this point. First, Usher found imidazolium catalysis with **17**. Second, Eftink has found imidazolium-catalyzed hydrolysis of cyclic phosphates simultaneous with imidazole delivery of water. Finally, Lönnberg has concluded that RNA phosphodiesters are hydrolyzed via protonated neutral phosphates and 2′-O^- groups. Therefore, one may expect a similar mechanism in buffer catalysis except that the buffer functions like a general base to ionize the 2′-OH group.

In summary, a significant amount of research has been devoted to understanding buffer-catalyzed RNA cleavage–transesterification and isomerization. Although it currently appears that the first step of cleavage–transesterification can be both base- and acid-catalyzed (Scheme 2 A and B, respectively), and that the first step in isomerization is always acid-catalyzed (Scheme 2 B), much more research is required to understand the details of the relative energies of these two pathways.

15. Oligomeric Amines as Catalysts

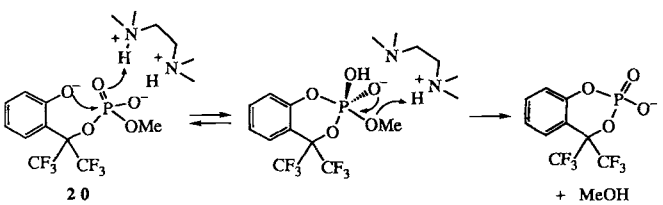
If both the acid and base components of a buffer can play roles in RNA cleavage and migration, one would expect that linking the acid and base together would result in cooperativity. Such cooperativity has been seen with oligomeric amines. Eftink found that histamine significantly enhanced the rate of ring opening of RNA cyclic phosphodiesters, supporting bifunctional general acid/general base catalysis.[53] Similarly, Komiyama has determined that simple diamines hydrolyze RNA.[65] Ethylenediamine, triethylenetetramine, and pentaethylenehexamine were all effective, yet ethylamine gave little, if any, catalysis. In addition, Komiyama has demonstrated hydrolysis of adenosine 2′,3′-cyclic phosphate by diamines at pHs where they exist as monocations.[66] The hydrolysis rate of this phosphodiester reaches a maximum when three carbons separate the amino groups. Komiyama postulates that catalysis arises from delivery of water by a general base to the phosphodiester and simultaneously with electrophilic activation by the ammonium group (Scheme 13), which is reminiscent of the Eftink proposal (Scheme 10). In addition, Barbier and Brack have shown that basic polypeptides accelerate the hydrolysis of RNA.[67] Defined copolymers of arginine and lysine with hydrophobic amino acids gave significantly increased rates.



Scheme 13. Bifunctional general acid/general base catalysis of hydrolysis with diamine catalysts.

In all of these systems a second amine functionality was required for activity. This observation supports a cooperative general acid/general base mechanism. A proton is transferred to the phosphoryl group simultaneously with delivery of the nucleophile by the general base. Komiyama has shown evidence for such a mechanism with the substrate bis(2,4-dinitrophenyl)-phosphate.[68] The efficient cleavage of this substrate is catalyzed by the monocations of *N*,*N*,*N*′,*N*′-tetramethylalkanediyldiamines. Since these types of substrates react as nucleophiles and not as general bases,[69] Komiyama assumed a similar nucleophilic mechanism and interpreted a deuterium isotope effect of 1.6 to mean that the reaction involves general acid catalysis. In support of this hypothesis, no isotope effect was found when the neutral forms of the diamines were used as catalysts.

Kirby has probed cooperativity in the breakdown of the phosphorane. The second step in the hydrolysis mechanism for phosphodiester **20** is rate-determining (Scheme 14).[70] The nucleophilic attack is part of a fast preequilibrium. The effective molarity (EM) of the nucleophile was measured at greater than 10^{10} M. This high EM results in extremely efficient intramolecular nucleophilic attack, and loss of the alkoxy group occurs with

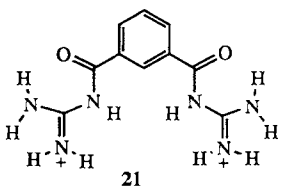


Scheme 14. Kirby's proposal for the catalyzed departure of the leaving group from phosphoranes.

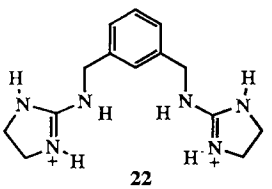
all protonated and anionic forms of the substrate. Loss of the leaving group is strongly general acid catalyzed, with an α value of -0.33. Cationic diacids such as $Me_2NH^+(CH_2)_nNH^+Me_2$ ($n = 2-4$, 6) demonstrate significantly enhanced catalysis, whereas the behavior of the monocations of these diamines is similar to that of monoamines. The mechanism is postulated to be one of electrostatic stabilization of the anionic phosphorane. However, the mechanism likely involves hydrogen bonding or proton transfer, since tetramethylethylenediammonium was not as effective a catalyst.

The electrostatic stabilization by an ammonium group could involve proton transfer. One would predict that amines should act as general acids toward a phosphorane based upon any of the phosphorane pK_a values put forth by Guthrie, Westheimer et al., and our group. The pK_a^2 values are all higher than the pK_a values of ammonium groups. Therefore, if the conjugate acids of phosphorane-like transition states also have high pK_a values, the amines are supplying protons to the phosphoranes in analogy to Scheme 2B.

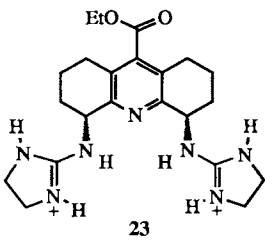
Amino and ammonium groups are not the only nitrogen-based functional groups that cleave phosphodiesters. Our group,[71] Hamilton et al.,[72] and Göbel et al.,[73] have demonstrated that guanidinium groups can also be effective phosphoryl transfer catalysts for RNA and RNA analogs. With lutidine as a general base in acetonitrile, compound **21** enhances the cleavage of **10** (X = NO_2) by approximately 1000-fold, whereas **22** enhances the ring opening of **18** by about 2000-fold in DMF, and **23** catalyzes the cleavage of RNA in conjunction with



21



22



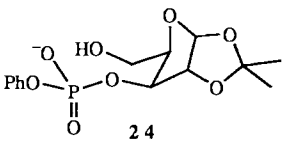
23

imidazole in water with an enhancement of 20-fold. It has not yet been shown if the guanidinium groups act solely as electrostatic catalysts or as general acids. However, the phosphorane pK_a values we measured would predict that the guanidinium moieties are general acids. This is currently being investigated.[74]

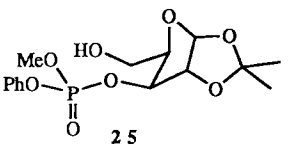
In summary, cooperativity can be achieved between general acids and bases in the cleavage of phosphodiesters, as would be expected from the mechanism in Scheme 2B. Based upon the phosphorane pK_a values given in the literature, we conclude that the interaction between phosphoranes and ammonium groups is one of proton transfer, and not solely electrostatic.

16. Model Studies

Kirby has stated, "there is no doubt that protonation of the exceedingly unreactive phosphate diester anion will increase its reactivity toward nucleophilic attack, but it is not a simple matter to quantify the rate factor involved".[75] In an attempt to quantify this enhancement Kirby was able to measure that protonation of the phosphodiester oxygen of dianion **20** leads to a 5.5×10^5-fold enhancement, and that imidazolium as a general acid leads to a 8.1×10^4-fold enhancement.[76] Cyclization and expulsion of the aryl leaving groups in **24** and **25** were general

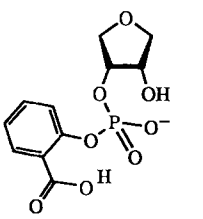


24



25

base catalyzed, and with very basic general bases, hydroxide-catalyzed reactions were faster than general base reactions. A rate enhancement for the reaction of **25** over that of **24** of 4.6×10^5 was determined. A similar enhancement (2.7×10^5) can be estimated for trimethyl-, as compared to dimethylphosphates, by extrapolation of literature values.[75,77]

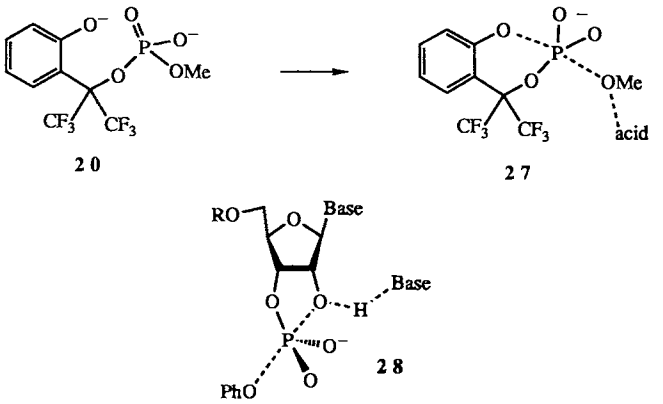


26

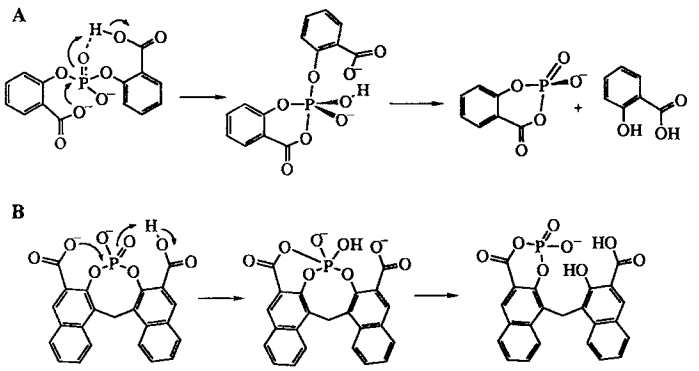
Kirby further studied protonation of phosphoranes occurring simultaneously with nucleophilic attack by examining phosphodiester **26**. This phosphodiester has a leaving group and an internal general acid.[78] The rate versus pH profile for **26** shows a "step" near pH 4, indicating that the spontaneous hydrolysis of **26** is faster when the carboxylic acid is protonated. With formate and acetate buffers the reaction follows general acid catalysis, giving an α value of -0.38. However, polyamine buffers gave both general acid and general base catalysis. One possibility is that the intramolecular general acid plays a role similar to the acid in Scheme 2B.

Kirby has also analyzed the stability of dianionic phosphoranes.[76] He concluded that the lifetime of a dianionic phosphorane is too short for diffusional equilibration (Hypothesis 1). In the spontaneous hydrolysis reaction of the dianion **20**, a β_{lg} value of -1.13 was determined, suggesting that substantial negative charge develops on the departing alkoxide in the transition state. This charge cannot be stabilized by proton transfer from water since methanol and water have similar pK_a values, and the Jencks libido rule[79] would predict little driving force for general acid catalysis by solvent. In addition to a substantial extent of leaving group departure, bond formation to the nucleophile was well advanced in the transition state. The β_{lg} value was found to be larger than the β value of the nucleophile, indicating that the increase in negative charge density on the leaving group was larger than the decrease in negative charge density on the nucleophile.[76] As a result, little negative charge could develop on the PO_2 group of the phosphorane, demon-

strating that a dianionic phosphorane intermediate was not involved. Kirby thus proposed a transition state complex such as **27**. The reverse of this reaction could be viewed as the cleavage of an RNA analog with a good leaving group; a transition state resembling **28** would be predicted (Hypothesis 6).



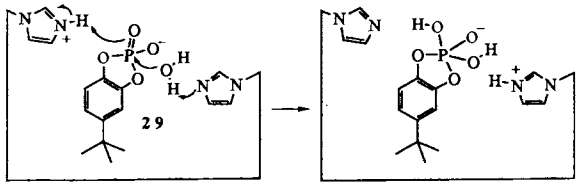
Model systems have also been used in the analysis of bifunctional acid/base and bifunctional acid/nucleophile catalyses. Bell-shaped rate versus pH profiles were found for intramolecular phosphoryl transfers.[80] Scheme 15 shows two examples



Scheme 15. A), B) Two examples of bifunctional intramolecular phosphoryl transfers catalyzed by a general acid.

that involve simultaneous nucleophilic and general acid catalyses of a phosphoryl transfer. We postulate that the role of the general acid is to transfer a proton to the nonbridging phosphoester oxygen simultaneously with nucleophilic attack. Blaskó et al., the authors of the original studies, discuss this, yet they also point out that the acid could transfer a proton to the leaving group. However, the leaving group in both of these examples is an aryl group, and as discussed in Sections 10–12, the resulting phosphorane is more akin to a transition state in which a phenoxide bond breaks. Thus, one would expect proton transfer to the phosphorane-like transition state due to the high pK_a values of phosphoranes. Certainly, if in these model compounds a hydrogen bond is formed between the nonbridging phosphoryl oxygen and the carboxylic acid prior to nucleophilic attack, a significant amount of proton transfer to the phosphorane is expected, since both pK_a values of a phosphorane are greater than that of a carboxylic acid. Therefore we interpret the bell-shaped curves to reflect a mechanism similar to that in Scheme 2B.

Breslow has also studied bifunctional acid/base catalysis. In a series of papers,[81] he examined bisimidazolyl-β-cyclodextrin-catalyzed cleavage of **29** (Scheme 16). A bell-shaped rate versus



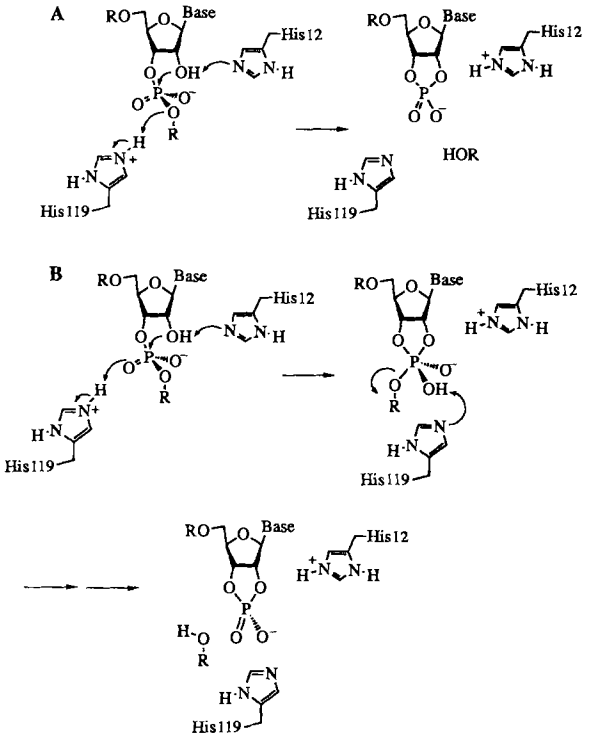
Scheme 16. Bis-imidazolyl β-cyclodextrin-catalyzed hydrolysis of a cyclic phosphodiester.

pH profile was obtained, indicating that both the acidic and basic forms of imidazole are required. The data were originally interpreted to support general base catalyzed delivery of water, followed by general acid catalyzed protonation of the leaving group. However, studies with different regioisomers of the bisimidazolyl-β-cyclodextrin catalysts supported general acid protonation of the nonbridging oxygens. If the substrate were bound by a hydrogen bond between the negatively charged phosphodiester and the imidazolium group, proton transfer would be in accord with the relative pK_a values of phosphoranes and the imidazolium ion. In fact, proton transfer to the phosphorane-like transition state was confirmed by a proton inventory study. Two protons were found to be necessary, suggesting general base catalyzed delivery of water simultaneously with general acid catalyzed protonation of a nonbridging phosphoryl oxygen.

In summary, several model studies using RNA analogs and cyclic phosphodiesters have indicated that dianionic phosphoranes are akin to transition states. These species have been found to be stabilized by proton transfer simultaneously with their formation, thus supporting a mechanism similar to that given in Scheme 2B.

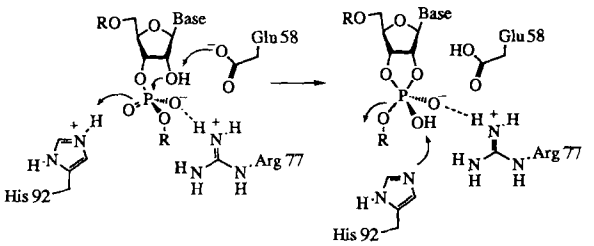
17. Analogous Mechanisms for RNase A

The mechanism of RNA hydrolysis catalyzed by ribonuclease A (RNase A) has been discussed in terms of the two mechanisms shown in Scheme 2. The classical mechanism (Scheme 17A) is analogous to that in Scheme 2A, and the mechanism proceeding via a triester-like species (the Breslow mechanism, Scheme 17B) is analogous to that in Scheme 2B. In the classical mechanism, an imidazole group (His12) delivers the 2′-OH group as a nucleophile, and either in a second step or simultaneously with nucleophilic attack, an imidazolium group protonates the leaving group. In the triester mechanism, the imidazolium group (His119) protonates the phosphorane, and then removes a proton and places it on the leaving group. In this "push–pull" mechanism an imidazolium proton moves toward the phosphorane to lower the barrier to nucleophilic attack, and then is removed from the phosphorane to lower the barrier to leaving group departure.



Scheme 17. Mechanisms of RNA hydrolysis catalyzed by RNase A. A) Classical mechanism, B) triester mechanism.

Usher was one of the first individuals to suggest that an imidazolium group at the active site of RNase A may activate the phosphate toward nucleophilic attack by converting it to a triester-like species.[48] He noted that a triester could represent a protonated diester. In 1975 a similar mechanism was proposed by Satoh and Inoue for RNase T1 (Scheme 18).[82] Two acids



Scheme 18. A possible mechanism for RNA hydrolysis catalyzed by RNase T1.

(imidazolium and guanidinium ions) complex the phosphate to stabilize the developing negative charge as the nucleophile attacks. One of these acids then shifts within the active site to protonate the leaving group. These two proposals resemble the mechanism given in Scheme 2B.

Whether an imidazolium ion can protonate a phosphorane-like transition state and render it triester-like can be determined on the basis of relative pK_a values. All the estimated and measured pK_a^2 values for phosphoranes are higher than the pK_a of the imidazolium ion. So, if an RNA substrate is bound at the active site of RNase A with a hydrogen bond between the phosphate and the imidazolium prior to nucleophilic attack, one would expect proton transfer to the transition state. Titration experiments with enzyme–substrate complexes have supported this proposed prior contact between the imidazolium and a nonbridging oxygen.[83] An ammonium group on lysine, however, is often believed to assume this role of ion pairing or proton transfer to the transition state.[84] As discussed in Section 13, based upon the relative pK_a values, an ammonium ion can also be expected to transfer a proton to a phosphorane. However, it is not yet clear whether the histidine or the lysine residue serves as the general acid that stabilizes the phosphoryl transfer transition state.

Although the mechanism for buffer catalysis proposed by Breslow has come under scrutiny, the triester mechanism is still a viable alternative for the enzyme RNase A. In a molecular dynamics simulation of the active site of RNase A Karplus has found that His119 is positioned to protonate the phosphate, not necessarily the leaving group.[85] In crystal structure analyses of ribonuclease A this imidazolium group has been found in many different positions;[86] therefore the two mechanistic alternatives cannot be distinguished. Clearly there is a great need for clever experiments that will distinguish between the alternatives.

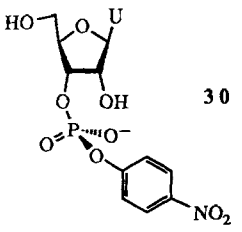
Herschlag has attempted to distinguish the two pathways for RNase A.[87] He points out several pieces of data obtained with sulfur analogs of the phosphodiesters that are not consistent with a triester-like mechanism. For example, the thio-effects (defined as the ratio of the rate constants of the hydrolysis of a phosphodiester to those of the corresponding phosphodiesterthioates) on the hydroxide-catalyzed cleavage of RNA dimers range from 1.3 to 6. The thio-effects on triesters, however, are much larger, in the range of 10 to 160. Therefore, Herschlag would not predict a large thio-effect for the classical mechanism but would predict a large effect for the triester RNase A mechanism. The thio-effects on the ring opening of both the (R_P) and (S_P) thio-isomers of cUMP catalyzed by RNase A are small, in the range of 5. The thio-effects on k_{cat} and k_{cat}/K_M are also quite small for RNase T2. Herschlag uses these values to argue against a triester mechanism for phosphodiester ring opening catalyzed by RNase A and RNase T2. It should be noted that a mechanism involving simultaneous proton transfer and nucleophilic attack certainly would depress any expected thio-effect. To what extent thio-effects would be depressed is not known, although Herschlag predicts only a small amount.

In contrast to the small thio-effect with cUMP, that on the (S_P) thio-isomer of UpA with RNase A is between 70 and 100. Clearly this supports a triester mechanism. Yet, Herschlag argues against this mechanistic alternative since the (R_P) thio-effect of 2–4 is consistent with the classical mechanism. Both (R_P) and (S_P) isomers should have large thio-effects in the triester mechanism due to the fact that the substitution of a sulfur for a nonbridging oxygen lowers the pK_a values of both the S and O. Although the prediction that a thio-effect should be observed for both isomers in solution is sound, extending this prediction to an asymmetric active site in an enzyme may be difficult. The local microenvironments of an enzyme active site can dramatically influence pK_a values. Therefore it is possible that the asymmetry of the active site could affect the pK_a values of non-bridging P–O and P–S groups quite differently, such that the thio-effect is manifested in only one isomer.

Herschlag's analysis is intriguing not only with respect to the enzymatic mechanism, but also with respect to the mechanism

for buffer-catalyzed RNA cleavage in solution. The thio-effects for both UpU and UpA are 1.3 under highly basic conditions. If the hypothesis that RNA cleavage under basic conditions involves a phosphorane-like transition state, and under neutral conditions involves a protonated phosphorane, then a thio-effect similar to that of a triester should be observed in the imidazole-catalyzed reaction. Furthermore, if both mechanisms in Scheme 2 are operating simultaneously, and the one in 2B accounts for the migration while that in 2A accounts for the majority of cleavage, then the thio-effect should be large for migration and not for cleavage.

Raines has investigated the triester mechanism by using site-directed mutagenesis at the active site of RNase A.[88] Converting the general base histidine to an alanine slowed the catalytic cleavage of RNA, as well as that of an RNA analog **30**, which has a good leaving group. Converting the general acid histidine to an alanine similarly slowed the catalysis of RNA cleavage, but in contrast did not affect the rate for **30**. Raines interpreted that the role of the general acid is to protonate the leaving group and not a nonbridging oxygen. This interpretation was based upon the fact that *p*-nitrophenolate does not need to be protonated for departure; thus eliminating the general acid would not be expected to affect the catalysis. This is a clever experiment to probe possible protonation of a nonbridging oxygen. However, as was discussed in Section 10, phosphodiesters with good leaving groups may require different kinetic orders for protonation. It is possible that an RNA substrate requires protonation to render it triester-like, but that highly activated substrates such as **30** do not. Further experiments will help to delineate the difference in the kinetic order in acid required by **30** and RNA substrates.



30

Raines has also studied the role of lysine as a potential general acid for ion pairing or proton transfer to a phosphorane transition state at the active site of RNase A.[89] He combined site-directed mutagenesis with semisynthesis to create a series of mutants having different amine hydrogen-bonding patterns and pK_a values at the lysine position in the active site. The more acidic the side chain in the mutant, the higher the catalytic activity found. This supports the concept that lysine acts as a general acid/electrostatic catalyst during the catalysis.

Recently, calculational methods have been applied to probe the mechanism of hydrolysis with RNase A[90] and RNase T1.[91] Although substantially different methods were employed, remarkably similar results were obtained. For example, Lim and Tole found that at the active site of RNase A, proton transfer to the phosphorane intermediates was crucial to lowering the barrier to nucleophilic attack.[24a] However, unlike the Breslow proposal, the imidazole from His12 is responsible for both the deprotonation of the 2′-OH and the protonation of the phosphorane, whereas His119 ion pairs with the phosphodiester and protonates the leaving group. A monoanionic/monoprotic phosphorane is the key intermediate. Proton transfers from the active site residues to the phosphorane intermediate were also found by Wladkowski. In his study[90] both a histidine imidazolium group and the lysine ammonium group transfer a proton, resulting in a neutral/diprotic phosphorane intermediate. Similarly, in the case of RNase T1,[91] Saenger proposed that the general acid His92 was in position to transfer a proton to the phosphorane intermediate and not to protonate the leaving group. All of these theoretical studies find that the active site residues mediate proton transfers to and from the nonbridging oxygens of the phosphorane so as to minimize charge buildup on the phosphorane.

In summary, there is significant evidence that protonation of a phosphodiester prior to or simultaneously with nucleophilic attack is a viable mechanism for enzyme-catalyzed reactions. There is also considerable evidence for a direct displacement reaction. Different kinetic studies and various crystal structures have been used to support either mechanism. Whereas calculational studies are found to support the former, thio-effects and site-directed mutagenesis support the latter.

Four pieces of theoretical and experimental data support Hypothesis 1, "Dianionic phosphoranes do not exist long enough for protonation." The data supporting this come from both specific and general acid/base catalysis (Hypothesis 2) and theoretical calculations. First, analysis of the hydrolysis of methyl ethylene phosphate led Usher to conclude that the lifetime of a dianionic phosphorane is not long enough for protonation. Second, according to ab initio calculations dianionic phosphoranes are in very shallow potential energy wells even when solvated, but monoanionic/monoprotic phosphoranes have much longer lifetimes. Third, β_{lg} plots were extended to include phosphodiesters with poor leaving groups, and these plots indicated that even these phosphodiesters were hydrolyzed via dianionic phosphorane-like transition states with no intervening dianionic phosphorane intermediates. Finally, model studies using a substrate having a nucleophile of high effective molarity indicated that dianionic phosphoranes do not have lifetimes sufficiently long to allow for diffusional equilibration. Since dianionic phosphoranes do not exist long enough for protonation, a phosphorane intermediate must be protonated in order to exist (Hypothesis 3). Therefore a protonated phosphorane must arise by either prior or simultaneous phosphodiester protonation with nucleophilic attack (Hypothesis 4). Only such a mechanism can lead to migration (Hypothesis 5).

Several experimental observations support protonation of the phosphodiester as a viable mechanism for RNA cleavage–transesterification. One is the analogy to a phosphotriester which indicates a 10^5- to 10^6-fold rate enhancement for nucleophilic attack imparted by protonation. Another is the kinetics of specific acid/base catalysis for RNA, which have been interpreted to support nucleophilic attack by an ionized 2′-OH group on a protonated neutral phosphodiester under neutral pH conditions, leading to a monoprotic/monoanionic phosphorane. It has also been found that both imidazolium and imidazole groups act simultaneously in the catalyses of the hydrolysis of cyclic phosphodiesters and that the imidazolium group supplies a proton to the phosphoester. Furthermore, although much of the data related to imidazole buffer catalyzed cleavage–transesterification of RNA is still under investigation,

the kinetic dependence of migration upon imidazolium is indicative of protonation of the phosphodiester. Prior or simultaneous protonation of a phosphodiester with nucleophilic attack is also supported by the observation of cooperativity between amines in polyamine-catalyzed hydrolysis. Isotope effects on such reactions support proton transfer to the developing phosphorane intermediate. In addition, the estimated and measured pK_a values for phosphoranes all predict the transfer of a proton from the amine to the phosphorane. Moreover, proton transfer to phosphodiesters simultaneously with nucleophilic attack has been observed with substrates possessing intramolecular general acid residues and with cyclic phosphodiesters bound in bisimidazolyl-β-cyclodextrin complexes. Finally, RNA phosphodiesters with good leaving groups have been shown not to require protonation, whereas phosphodiesters with poorer leaving groups can require, under certain conditions, a higher protonation state for facile nucleophilic attack. Although it is clear that a mechanism such as that in Schceme 2 A is operative for transesterification–cleavage, the information just summarized presents a compelling case that a mechanism like that in Scheme 2 B is also operative.

We conclude that two limiting mechanisms that differ in the protonation state of the phosphorane intermediate can be used to explain the current mechanistic data relating to RNA cleavage–transesterification. Catalysis by both of these mechanisms is possible, but subtle differences in the design of catalysts should be considered. The first mechanism involves a dianionic phosphorane that is akin to a transition state and expels a leaving group without the possibility of protonation. This mechanism is operative for general and specific base catalysis of RNA hydrolysis, as well as for hydrolysis of RNA analogs with good leaving groups (Hypothesis 6). This mechanism can be catalyzed by the coordination of Lewis-acidic metals to the phosphodiester and by protonation or metalation of the leaving group. The second mechanism involves a prior or simultaneous protonation of the phosphodiester with nucleophilic attack to form a monoprotic/monoanionic phosphorane. The latter mechanism can lead to migration, whereas the first cannot. This mechanism can be catalyzed by coordination of the phosphodiester to a Brønsted acid such as an ammonium, imidazolium, carboxylic acid, or guanidinium group. The change between these two mechanisms depends upon the leaving group ability, the pH, and the availability of general acids and bases (Hypothesis 7). Under certain experimental conditions, it is reasonable that both of these mechanisms can operate simultaneously, thereby giving different kinetic orders in acid and base for cleavage and migration (Hypothesis 8). Taken together, these two mechanisms and eight hypotheses present a comprehensive picture of this important biological transformation and yield two different strategies for designing synthetic RNA hydrolysis catalysts.

Research funds have been awarded to E. V. A. for the study of RNA hydrolysis mechanisms and for developing RNA hydrolysis catalysts by the Searle Foundation (Chicago Community Trust), the National Institutes of Health, the National Science Foundation, the Dreyfus Foundation, the Sloan Foundation, and the Welch Foundation. We thank Ronald Breslow for communication of unpublished work concerning medium effects on the buffer-catalyzed cleavage/transesterification and migration of RNA.[92] *We also thank the following individuals for helpful suggestions: Daniel Herschlag, Anthony J. Kirby, Harri Lönnberg, Ronald T. Raines, and Kazunari Taira.*

Octopolar reconstruction of an NiO(111) film on an Ni(111) surface is clearly evident from electron diffraction and electron energy loss spectroscopy (dark ellipses: superstructure reflections; light grey shaded circles: main structure reflections), and is modeled as shown on the left.

Adsorption of Gases on Complex Solid Surfaces

Hans-Joachim Freund*

Dedicated to Professor Gerhard Ertl on the occasion of his 60th birthday

During the last thirty years the research field of surface science with its various disciplines has progressively played a more and more important role in the field of catalysis. The main focus of attention for a long time was research on metal surfaces, on which, in time, the whole spectrum of developed surface analytical methods was applied. This led to a better understanding of the mechanisms of catalytic reactions, such as the synthesis of ammonia and the oxidation of CO, especially through the work of Gerhard Ertl.[1, 2] In contrast to clean metal surfaces, surfaces of real catalysts are complex entities, the structures of which can have a strong influence on the processes occurring on the surface. Thus, it seems logical to employ the typical structural characteristics and the morphology of the catalytic surface as guidelines in the investigation of complex model systems. In this review the preparation, and structural and electronic characterization of such model systems will be discussed. Clean surfaces of catalytically active oxides, as well as model systems for dispersed transition metal/support catalysts will be characterized in terms of their morphology and electronic structure as well as their adsorption and reaction capabilities.

Keywords: adsorption · heterogeneous catalysis · surface analysis · surface chemistry

1. Introduction

Surfaces of solid materials are interesting research objects.[3] Nowadays, a detailed knowledge of the correlation between geometric and electronic structure and their effects on chemical reactivity is already available for certain classes of materials such as metals and elemental semiconductors.[4] In contrast, corresponding information for many, very simple compound systems such as oxides, carbides, and nitrides is still very rudimentary.[5, 6] This is even more surprising, since a great number of compound systems show technically relevant reactivities on surfaces, and oxides are suitable support materials for dispersed metal catalysts. In such cases, there are distinct interactions between metal and oxide such that the complex structural and electronic processes on the interface between metal and support determine the chemical reactivity. Presumably these are the reasons for the recently increased activity in this area.[5–15] In their book *Surface Science of Oxide Surfaces* Henrich and Cox impressively summarized the data known up to the beginning of the 1990s on the clean substrate.[6] It is clear that for experiments on oxide surfaces, a typical example of a compound surface, the preparation of the sample plays a significant role: from the thermodynamic point of view, a well-defined oxygen pressure in the gas phase determines the oxide stoichiometry.[16] This does not exist under ultrahigh vacuum (UHV) conditions necessary for surface experiments. The stoichiometry of the material under these conditions is, thus, sometimes determined only by a kinetic hindrance, and therefore the method of sample preparation is of significant importance. The methods of preparation of the surface give rise to essentially two categories of experiments on compound surfaces: 1. Experiments on surfaces on single crystals;[5] 2. experiments on epitaxially grown thin films.[7]

Whereas, in research on thin films one must always consider whether the electronic structure of the substrate corresponds to that of the single crystal, this problem naturally does not occur for samples of the first catergory. However, experimental difficulties associated with the execution and interpretation of electronic spectroscopic measurements can occur (charging etc.) when dealing with an electrical insulator as a single crystal. Also rapid heating and cooling of the surface of the sample can be a problem in such cases. In thin film studies these problems are limited by the thickness of the film, from which it is possible to determine if the electronic structure of the film is comparable to that of a single crystal. Furthermore, different crystallographic orientations in the form of thinly covered surfaces can be successfully prepared. This can be a distinct advantage over the use of single crystals when considering experiments on polar surfaces of ionic solids. This question will be dealt with in more detail in Section 3.1.

The comprehensive study of compound surfaces would certainly benefit from a combination of both strategies. It appears highly likely that in the future experiments will provide similarly detailed information about compound surfaces as is known about metal surfaces.[3] With the increasing knowledge about compound surfaces, such as oxides, it becomes more tempting to go a step further in terms of the complexity of the system and move towards modeling dispersed metal catalysts.[19] Hereby we could possibility benefit from the combination of the above-mentioned research directions and to a certain extent form a bridge to application. In this area the experience gained with metal surfaces and compound surfaces can be combined. To fulfill the modeling of dispersed model catalysts metals would be introduced onto the appropriate compound surfaces (e.g. oxide surfaces).[20] Some examples will be discussed in this review, though not only in terms of the structure and morphology of these systems but also in terms of their electronic structure, their adsorption properties, and their chemical reactivity.

Thus, in light of these considerations we include a section on clean oxide surfaces followed by one about dispersed metal systems on oxide supports; however, first of all in the next section we introduce the terms applied and list the techniques utilized.

2. Terms and Techniques

If one splits a regular lattice along one of the crystallographic directions, two sublattices are formed that both have regular surfaces as boundaries. With elementary solids these surfaces are identical; however, this is not necessarily the case for compounds. The resulting surfaces are termed volume-terminated. The surface atoms are located at a different coordination environment than the atoms in the bulk. This leads to a change of the interatomic distances and manifests itself, for example, through the relaxation of the interlayer distances or in a reconstruction; that is, a full lateral and vertical (buckling) restructuring of the atoms in the surface and in the regions near to the surface.

The structures are frequently characterized by electron diffraction (low energy electron diffraction (LEED)) or by imaging procedures (scanning tunneling microscopy (STM), atomic force microscopy (AFM)), and the surface lattice is characterized in terms of lattice vectors in units of length and with respect to the orientation of the bulk lattice vectors.[21, 22] Figure 1 (for an extensive discussion see Section 3.1) shows situations in which both the lateral order of the atoms and the interlayer distances have changed. The lattice vectors of the surface unit cell are twice as long as those in the bulk and are oriented in exactly the same way. This is referred to as a $p(2\times2)$ structure (p = primitive, (2×2) = double length in both directions of the surface). Correspondingly, $(\sqrt{3}\times\sqrt{3})R30^\circ$ denotes a structure with crystal vectors, which are $\sqrt{3}$ times longer than that of the

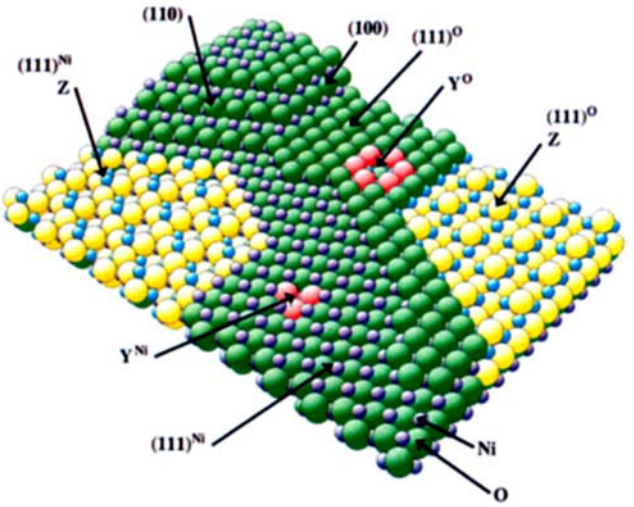

Figure 1. Possible defects in a predominantly (111)-orientated NiO surface. The ideal (111) surfaces could occur as oxygen- or nickel-terminated. Furthermore, facets could exist with (110) or (100) orientation next to point defects Y and octopolar reconstructed regions Z. The reconstructed surface can be both nickel- and oxygen-terminated.

Hans-Joachim Freund, born in 1951, studied physics and chemistry at the Universität Köln as a fellow of the Studienstiftung des Deutschen Volkes and received his doctorate in 1978 under the supervision of G. Hohlneicher, for a thesis on quantum chemical calculations and spectroscopic studies on transition metal carbonyl compounds in comparison with CO adsorbates. Between 1979 and 1981 he worked in the group of E. W. Plummer in the Physics Department at the University of Pennsylvania on synchrotron studies of the electronic structure of adsorbates. After his return to Köln he recieved a venia legendi in chemical physics in 1983, and in the same year accepted a position as associate professor at the Institut für Physikalische und Theoretische Chemie der Universität Erlangen-Nürnberg. There he worked on CO_2 and N_2 activation. In 1987 he accepted a position as full professor for physical chemistry at the Ruhr-Universität Bochum, where he founded and until 1995 headed a DFG research group on model catalysts. After not following further offers for chairs in physical chemistry at other universities, he accepted a position as scientific member and director at the Fritz-Haber Institut der Max-Planck-Gesellschaft in Berlin, where he now heads the Department of Chemical Physics. In 1995 he received the Gottfried Wilhelm Leibniz Award of the Deutsche Forschungsgemeinschaft, and since 1996 he is an ordinary member of the Chemical Sciences Section of the Academia Europaea. He is a member of several scientific societies and has published more than 200 scientific papers.

bulk and which are both rotated by 30° anticlockwise with respect to the bulk lattice vectors (R30°).

In order to determine the interatomic distances and atom coordination experimentally, in the electron diffraction experiment a definite geometry is chosen, and the wavelength of the scattered electrons is varied simply through a change in the acceleration voltage V. The number of diffracted electrons in a certain reflection, that is the current I, is then determined as a function of V. Thereby I/V curves are obtained, which are fitted through model calculations for structure determination.[22] The system is stabilized by surface reconstructions and adopts the corresponding minimal surface energy.[23]

Surface defects and inhomogeneities play a special role in the stability of the surface. Defects can be characterized with respect to their structure and distribution by analysis of the reflection profiles in electron diffraction patterns. In order to eliminate the influence of the surroundings such that clean surfaces can be investigated, the surfaces are prepared under ultrahigh vacuum conditions of between 10^{-8} and 10^{-9} Pa, under which only a comparitively small number of collisions per centimeter squared of surface is expected in about an hour. If a "clean" surface is placed in a gas atmosphere, the surface atoms in regular sites and defects are capable of bonding through their unfilled valencies to atoms or molecules from the gas phase, and thus stabilize the surface.

The surface structures adopted after gas adsorption clearly are generally different from those of the clean surfaces. The lattice vectors are characterized as discussed above. Evidently, the structures formed depend on the amount of gas adsorbed. Since the actual amount of gas bound is determined by the sticking probability, frequently no absolute surface coverage is given, but only the gas dosage. The unit of the dosage is the Langmuir (L) and corresponds to a supply of a gas at 10^{-4} Pa for 1 s. This unit became established because at this dosage it was possible to obtain full coverage with a sticking probability of 1 on a surface of 1 cm^2 in 1 s.

Even though absolute coverages are not usually indicated, they can be determined experimentally.[24] A typical procedure is based on thermal desorption spectroscopy (TDS), in which the flow of the desorbed particles from the surface is determined with a quadrupole mass spectrometer, while the temperature of the sample is continually increased. Kinetic parameters such as the activation energy for the desorption and the desorption rate and order can be determined from the form and temperature range of the observed desorption structures. Thermodynamic data are accessible by analyzing the adsorption isotherms. Calorimetric measurements are likewise possible.

Scheme 1. Surface-sensitive spectroscopic procedures.

The spectroscopic properties are established by a number of surface-sensitive procedures. Scheme 1 contains acronyms and procedures, which are frequently applied. The methods have been disccused in detail in the literature.[4, 21–24] A final comment: the reason for the use of electron spectroscopic procedures is based on the strong interaction between electrons and the condensed state. This limits the escape depth of the electrons from the solid and causes the high surface sensitivity of the procedures.

3. Experiments on Clean Oxide Surfaces

3.1. Structural Principles and Energetics

Systems that crystallize in a simple lattice type are particularly well suited to introducing structural principles and energetics of compound systems.[6] These systems include binary oxides that exhibit a rock salt lattice, that is NiO,[23] CoO,[24] FeO.[25] Figure 1 shows a schematic representation of the NiO surface[25] with differently oriented facets. The corresponding surface energies are given in Table 1. The following discussion will show that the greatly differing energies, which will be considered in detail, fundamentally determine the reaction behavior.

Table 1. Surface energies in the NiO system.

Surface	E_{OF} [$J m^{-2}$]
NiO(100)	1.74 [29]
NiO(110)	3.98 [29]
NiO(111)	∞ [29]
NiO(111) missing row	8.18 [30]
NiO(111) octopolar	4.28 [30]
NiO(111) hydroxylated	not known, but possibly $< E_{OF}$(110) [32]

Starting from the nonpolar (100) surface, the surface potential will be discussed with the aid of the stacking sequence along the normal of the surface[26] as shown in Figure 2. Thereby we will start with the extreme case of full ionic bonding; that is the covalent share of the bonding and of the hybridization will be initially neglected. On a nonpolar surface there are equal numbers of cations and anions available. This is not only valid for the surface but also for every layer along the {001} direction. This results in a disappearing dipole moment μ perpendicular to the surface, regardless of the number of stacked layers. The potential has its final value directly on the surface and drops exponentially in vacuum.

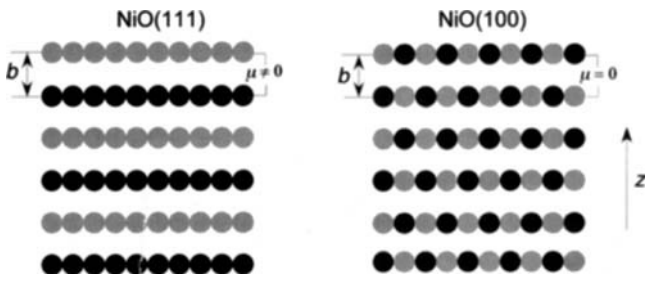

Figure 2. Charge distribution in polar (left) and nonpolar (right) oxide surfaces. Section perpendicular to surface. b = interatomic distance.

In contrast, a completely different situation exists on polar surfaces. Every layer is occupied with only one sort of ion, and consequently, because of the stoichiometry, a transition to the next layer results in a change in the type of ion and charge. Thus, there is a dipole moment perpendicular to the surface that increases linearly with the number of layers N and diverges with N tending to infinity. In the simplest case of a completely ionic bond the potential V at the surface can be described with Equation (a).[27] The potential disappears only very slowly into the vacuum with clear expansion of the surface (S: size of the surface unit cell).

$$V = \frac{2\pi}{S}[Nb(2\sigma - 1) + b(1 - \sigma)] \qquad \text{(a)}$$

Such a situation leads to unstable surfaces, which as a rule cannot be produced to a high standard through cleavage of a single crystal. The corresponding attempts led to strongly faceted surfaces, in which the facet faces again consist of the stable, nonpolar layers with the characteristic coordination of the ions. A coordination like that of the polar surface is found only at the corners and tips of the faceted areas.[5, 28, 29]

Concepts of how such an unstable situation can be stabilized can be derived from Equation (a): Since σ represents the charge on the surface relative to a reference layer in the center of the crystal, it shows clearly that the surface charge reduces to half its value ($\sigma = 1/2$) through the disappearance of the linear divergence terms in N. This layer charge reduction can be achieved in several ways:

a) by the loss of ions from the first layer of the surface[30]
b) by a reconstruction of the surface affecting several layers[28, 29]
c) by a terracing with long-range periodicity
d) by providing the surface with an adsorbed layer with only half the charge.[31]

Figure 3 shows schematically how these charge reductions alter the surface structure. In Figure 3a half of all ions in rows in the first layer have been arbitrarily removed. Since on a hexagonal surface there are three equivalent directions, a domain structure can be expected with an electron diffraction pattern corresponding to a p(2 × 2) structure. Figure 3b shows a reconstruction extending over several layers, which has already been discussed very early on by Lacman[28] as a possible stabilization of the polar rock salt surface. Recently Wolf[29] showed theoretically that this is in fact the most stable reconstruction (see also Table 1).[32] This kind of surface reconstruction is described as an octopolar reconstruction because it can be identified by octopolar cube units in the surface. This reconstruction can also be regarded as a faceting with (100) microfacets. A more detailed examination allows us to recognize the concept of charge reduction.[6] Concentrating on the first layer, three-quarters of the cations are missing, which corresponds to a charge reduction of 75%, which is correspondingly 50% more than the condition required for stability (i.e. 50% charge reduction). In contrast, in the second, negatively charged layer, only a quarter of the corresponding counterions are missing, thus 50% less than the requirements for stability. The third layer is already complete. In summary, the first and second layers give an overall charge reduction of 50%. This reduction would lead to a hexagonal structure likewise with a p(2 × 2) electron diffraction pattern.

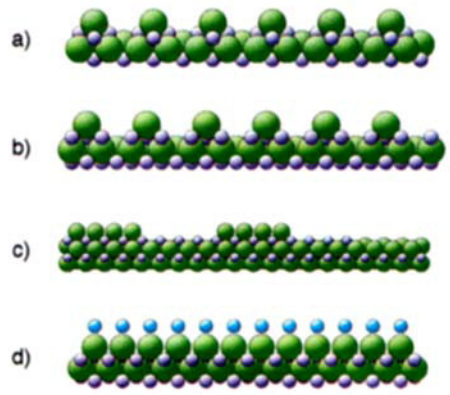

Figure 3. Possibilities for stabilizing polar surfaces: a) Charge reduction by removal of half of the O^{2-} ions. b) octopolar reconstruction. c) domain formation. d) adsorption.

Figure 3c depicts a terracing, which involves the first to third layers and leads on average to a halving of the charge on the surface. However, one must not forget that above every single terrace the surface potential diverges, and only on average is the condition for stability fulfilled. Thus, it is assumed that if such a situation occurs, the size of the terraces must be very limited. The diffraction pattern relative to that obtained in the reconstruction case would not be changed to a first approximation. Figure 3d shows the adsorbate termination of the polar surface. In exact terms, this could be imagined as a layer of OH^- ions, which would have only half the charge of a pure O^{2-} ion layer. The formation would occur either through the adsorption of protons on an oxygen-terminated layer or through adsorption of OH^- ions on a nickel-terminated layer.[31] The electron diffraction pattern would not be differentiated from the nonreconstructed layer with respect to the symmetry. However, the changed electron diffraction cross sections would be revealed experimentally from the current–voltage curves.

Nonpolar and polar surfaces can be prepared experimentally in different ways.[7–17] The techniques have been described often and thus shall not be discussed in detail here. In summary there are three techniques: In the first, the single crystal is cleaved in situ under UHV conditions and investigated.[5] In the second method the single crystal is cut under non-UHV conditions and then under UHV conditions cleaned and prepared through sputtering, and finally heated in an oxygen atmosphere.[5, 12–16] The third method involves the production of thin films through epitaxial growth.[7] The advantages and disadvantages of the different kinds of sample were indicated in the introduction.

3.2. Adsorption and Reactivity: Nonpolar Surfaces

Nonpolar surfaces show, when perfectly prepared, increasingly low adsorption enthalpies. In conjunction with this the surface loses chemical reactivity. In all documented experiments the perfect terraces are very similar to a bulk-terminated surface. LEED experiments[33–38] and increasingly also He diffraction studies[39, 40] show only small relaxations and a slight "buckling" of the first layer with outward relaxation of the large

anions. The effects are all within the range of a few percent of the interlayer distances and will not be described in detail here. In the ideal case of perfect terraces, molecules such as NO and CO are relatively weakly bound to the nonpolar surface. CO/MgO(100) has an adsorption energy of 0.2 eV and represents a physisorbed system.[41-43] CO/NiO(100)[44] and NO/NiO[22] display adsorption energies of 0.3 and 0.5 eV, respectively, somewhat stronger interactions, which one would describe as strong physisorption or very weak chemisorption. In spite of the relatively weak bond, the molecules are aligned on the surface.[40] On the NiO(100) surface CO is oriented perpendicular to the plane of the surface such that the carbon atom is coordinated to Ni. In contrast, the axis of a NO molecule is tilted at 45° to the surface normal.[23] As with CO, the coordination is to Ni, though the bond takes place through the nitrogen atom.

A series of theoretical studies has been carried out on the bonding of CO to MgO and NiO.[23, 45-50] The calculations all give binding energies that are far too small in relation to those obtained experimentally. However, agreement exists since the bond is based fundamentally on electrostatic effects: the ionic surface interacts with the multipole moments of the molecule. Covalent bonding components were not found in the given examples. In particular, it appears that the tried-and-tested Blyholder model[51] for transition metals cannot be used for the analysis of the bond between CO and a transition metal oxide surface. There are many reasons for this,[45-51] among which the most important is that the open d shell in NiO cannot hybridize with the energetically high-lying s orbital of Ni^{2+} and thus loses the flexibility of the "preparation" of suitable bonding orbitals that is possible on the surface of a metal. The open d shell is thus strongly spatially localized such that in addition to the hindrance from the bulky oxygen atoms, a molecule cannot be bound through a σ-donor–π-acceptor interaction. Figure 4 provides a detailed comparison of the classical Blyholder bonding mechanism with that of the effective bonding mechanism of the examined oxide surfaces.

In the first case a metal band exists with considerable dispersion. In this metal band structure, the s- and d-metal atom orbitals are hybridized because their energies lie in approximately the same energy region. Unfilled metal bands interact with the filled 5σ orbital of the CO molecule and contribute to the formation of a σ-donor bond. Occupied bands can form a π-acceptor bond with the unoccupied 2π orbital of the CO molecule.

In the second case the metal atoms or ions are separated by the oxygen neighbors, such that the development of a band structure for the resultant strongly localized d states can be neglected to a first approximation. The typical ligand field splitting of a square pyramid with a triplet ground state is observed. Naturally, the oxygen orbitals develop a band structure whose energetic position is schematically shown (O 2p). Calculations show that the unoccupied s orbitals of the Ni ions are very strongly destabilized. Thus, only an exceptionally weak 5σ-d donor bond or none at all can be formed, particularly since the relevant d_z orbital of the Ni^{2+} is singly occupied. For a π-acceptor back bond, the CO molecule must move very close to the d orbitals; on a (100) surface this is prevented by the Pauli repulsion between the 5σ and 1π electrons and the electrons of the oxygen atoms. The situation with MgO is even more apparent, since Mg^{2+} has formally no valence electrons.

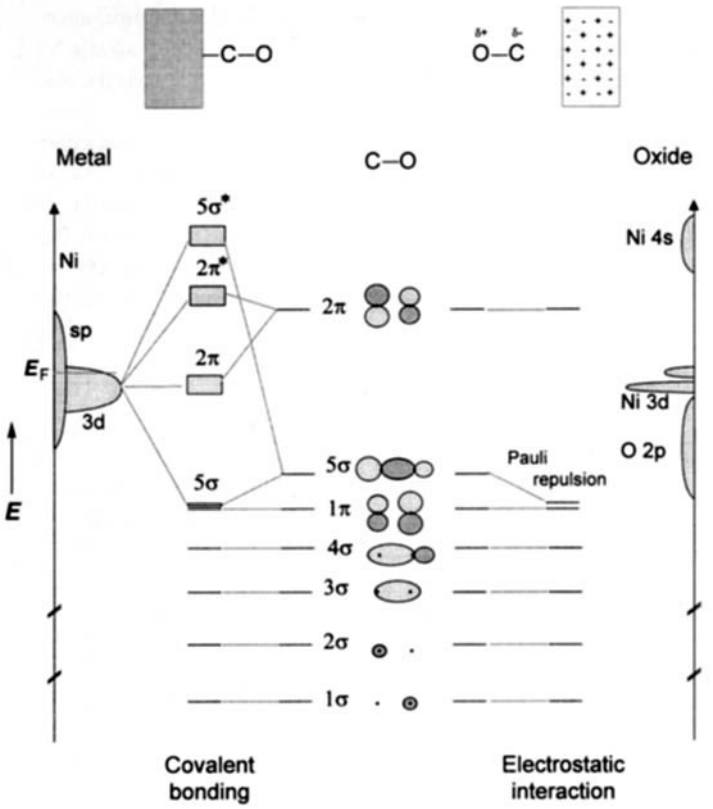

Figure 4. Schematic representation of the bonding of CO on transition metal surfaces (left) and oxide surfaces (right).

The changes in vibrational frequencies for CO and NO relative to those in the gas phase can also be understood in the context of an electronically dominated interaction. Here, three effects play a role. The first is the wall effect,[48] which takes into account that in a CO bond stretch, the carbon atom vibrates against a more-or-less rigid wall. This shifts the vibrational frequency to higher values. The second effect is dipole–dipole couplings: A chemical interaction which represents the third effect would lead to a lowering of the vibrational frequency provided that through this interaction the antibonding 2π orbital of the CO molecule is populated. A shift of this kind occurs for adsorbed NO.

For CO on MgO(100),[41-43] NiO(100),[44] and CoO(100),[47] the CO stretching frequencies are near or even slightly above that of the gas phase value. This is consistent with the above-mentioned electronic considerations. However, for NO there is a great deal of support that it not only electrostatically interacts with NiO(100) and CoO(100), since the NO stretching frequency is between 9 and 13 meV lower than that in the gas phase, which at the moment can only be explained succinctly through chemical interactions.[23, 52]

Calculations by Staemmler et al. support this statement.[23] These calculations use the "cluster approximation" in which the molecule interacts with a relatively small part of the NiO surface that is described fully and correctly by ab initio methods. This cluster is then embedded in a half-infinite arrangement of point charges, in order to simulate the docking to the bulk crystal. Figure 5 shows an extremely simplified MO diagram. Two extreme cases—perpendicular and tilted NO—are compared.[23] In contrast to CO the 2π orbital is occupied, and lies energetical-

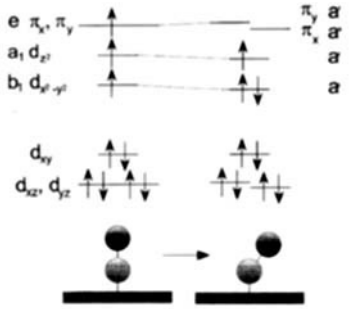

Figure 5. Schematic representation of the bonding of NO adsorbed on NiO(100) with perpendicular (left) and angled geometry (C_s symmetry, right) from the single-electron picture.

ly at a clearly lower energy, thus nearer to the Ni d orbitals. Nevertheless, this orbital cannot interact in the perpendicular NO direction with the d orbitals for symmetry reasons. However, if the opposing symmetry is overcome by tilting the molecule, the 2π orbital can interact, forming a bonding and antibonding combination and with the corresponding occupation lead to a stabilization of the bond. Detailed calculations reveal that the configuration after NO adsorption shown in Figure 5 right is one of many possibilites. However, configuration calculations show that the angled configuration is the most stable. Evidently, one must be clear that the bonding on the oxide support layer, if it exists, can only be compared in the extreme case with the bonding in NO complexes. At any rate the calculated charge transfer between the systems on adsorption is very small.

3.3. Adsorption and Reactivity: Polar Surfaces

Polar surfaces are more reactive, even if their structure is well developed.[10, 11, 31, 53–57] Their preparation by epitaxy is just as possible as that of nonpolar surfaces. Reasons for the high reactivity are quite evident.[45–51] In general, the fundamentally higher surface potential is the source of the increased reactivity and strong molecule–substrate bond. In addition, local effects such as the changed coordination of the metal ions in the surface, which limits their ease of reachability for the molecules in the gas phase, and the large influence of local field strengths have to be taken into account. The local situation faced on a polar surface evidently also occurs in defects on nonpolar surfaces. For instance the oxygen site on a (100) surface: The microfacets in this case are (111) oriented. Needless to say the opposite situation is observed on the tip of a (100)-oriented crystal. Pacchioni and Bagus[45] have shown with help from SCF calculations the following trend: the interaction energy on such defects increases relative to that on (100) terraces even if the estimated absolute value is viewed with a certain amount of sceptisism due to difficulties that arise in the estimation of adsorption energies. Analogous conditions should be expected also for polar surfaces. However, in addition in this case there is the above-mentioned global surface potential, which can induce distinctive reconstructions of the surface. We would like to demonstrate this with two examples.

First let us consider the NiO(111) surface. It can be produced either as a relatively thick film (≥ 50 Å) on the Ni(111) surface by oxidation,[31] or as a relatively thin film (≤ 10 Å) on a Au(111) surface by oxidation of vapor-deposited Ni.[58] Films grown on Ni show a well-developed p(1 × 1) LEED diagram, regardless of their actual thickness. Analysis by vibrational spectroscopy, in this case electron energy loss spectroscopy (EELS), shows that OH groups are located on the surface.[31] This means that the surface has stabilized itself during the growth by uisng the impurities present in the gas, and thus created a situation like that shown in Figure 3d: the first layer is saturated with OH groups and in this way reduces its surface charge by a factor of 2, which is a necessity for stabilization. Removal of the OH layer by heating, leads to the intermediate formation in the ideal case of an OH-free NiO(111) surface, which is not electrostatically stable and thus reconstructs.[59] The above-mentioned octopolar reconstruction is observed (see Figure 3b). If water is added to the reconstructed surface with the p(2 × 2) LEED pattern, the final state leads again to a p(1 × 1) LEED pattern. We observed this event with a SPA-LEED apparatus[59] and with a focused μ-LEED system.[60] A thin film on Au(111) shows that this is not a reversible phenonomen.[62] Furthermore, in this case the film forms in the reconstructed form and cannot be forced into the p(1 × 1) structure through the use of H_2O.

Figures 6 and 7 show the appropriate experimental data. LEED and structural data for the relatively thick NiO film on Ni are shown in Figure 6,[9] and the atomically resolved structure of the thin Ni film as an STM picture in Figure 7.[58]

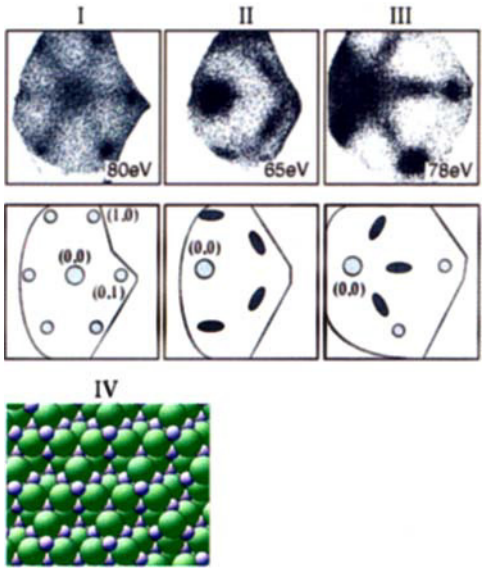

Figure 6. LEED pictures of the NiO(111)/Ni(111) system and their schematic representations (dark ellipses: superstructure reflections, light grey shaded circles: main structure reflections). I: Unreconstructed surface; II and III: p(2 × 2) reconstructed surface; IV: Model of the octopolar reconstructed NiO(111) surface.

It is assumed that the lacking influence from adsorbed H_2O on the very thin film is attributed to the lack of a distinctive surface potential divergence, which could drive the process. This is observed during the reconstruction with the formation of (100) facets, which are arranged at an angle of 70° to the global (111) direction, and also confirmed by adsorption experiments.[52] If CO is adsorbed on an octopolar reconstructed surface, a global tilting angle of the CO axis is observed, which is consistent with that of the facets, if, as in the case of adsorption on NiO(100), a perpendicular ordering of the axis is assumed for CO.

This together with the surface reconstruction that accompanies the adsorption of H_2O could have significance in real catalytic events, as Helmut Papp and co-workers have recently

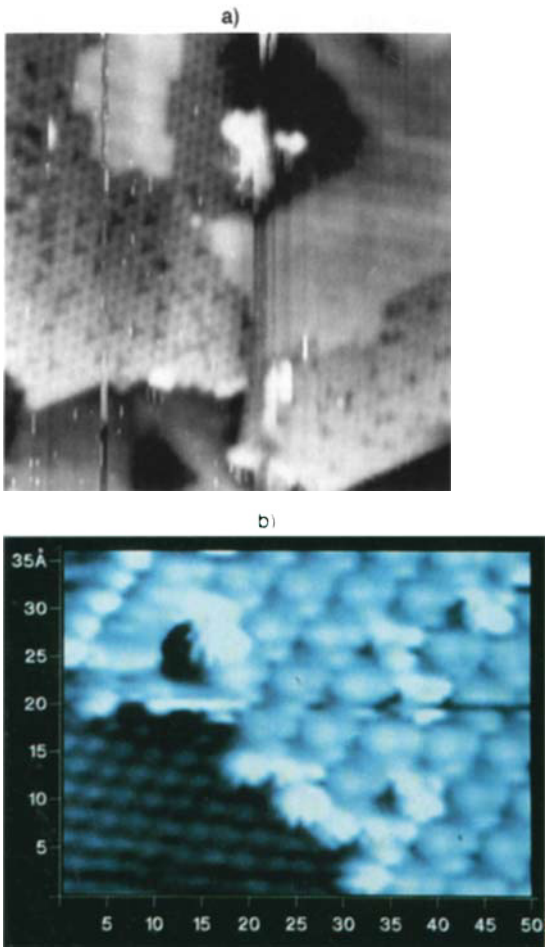

Figure 7. a) STM diagram of the p(2 × 2) reconstructed NiO surface, epitaxically grown on Au(111) (constant current topography (CCT), 250 Å × 250 Å, −5 V, 0.5 nA). b) Sample as in a) (CCT, 35 Å × 35 Å, −0.3 V, 0.5 nA).

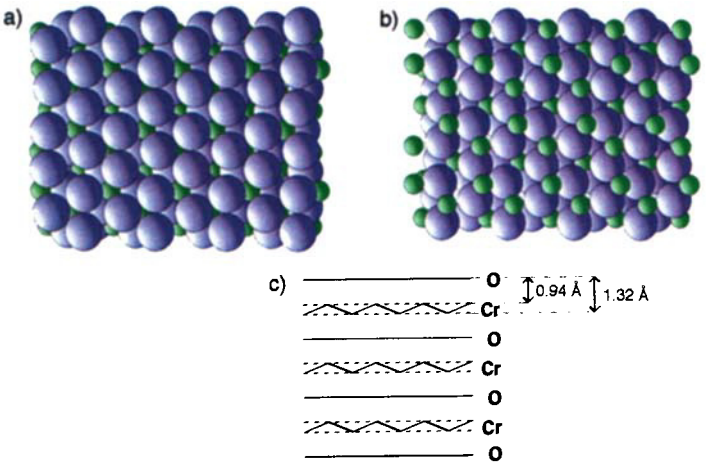

Figure 8. Different terminations of a Cr_2O_3 surface: a) by a complete layer of oxygen ions, b) by a complete layer of chromium ions. c) Schematic representation of the layer sequence.

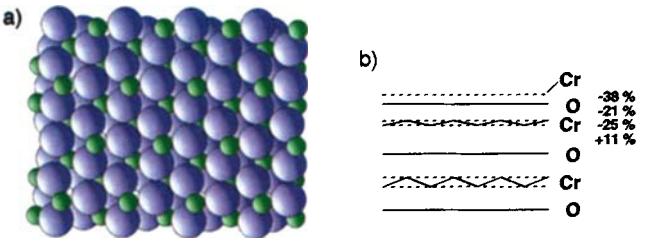

Figure 9. a) View of the reconstructed, depolarized Cr_2O_3(0001) surface. b) Schematic representation of the relaxation in the interlayer distance after surface reconstruction.

shown:[61] through topotactical decomposition of $Ni(OH)_2$, NiO powder can be produced whose crystallites show predominantly the (111) orientation. The activity of this powder was tested with the DeNOx reaction, that is the decomposition of NO with NH_3 to give N_2 and water. The activity was shown to only start at a temperature above 400 K. At this temperature the last thrust of water loss takes place, and the OH groups bound to the initially well-defined NiO(111) film begin to separate off as water. Thus the next logical step is to combine both processes, which leads to the conclusion that the water-free but reconstructed surface has sufficient energy to drive the DeNOx reaction, whereas this is not the case for the OH-covered surface.

As a second example we chose the Cr_2O_3(0001) surface, a polar surface of the corrundum type.[5] Schematic representations of the of possible structures of the terminated bulk are given in Figure 8.[62–64] These are unstable for the same reason as the corresponding structures with the rock salt structure. A reconstruction that resembles that shown in Figure 3a occurs on the Cr_2O_3(0001) surface. We know from ion-scattering spectroscopic measurements[65] and from LEED I/V analysis[66, 67] that only half of the expected chromium ions lie on the surface after bulk termination. From the honeycomb structure only a hexagonal arrangement of Cr ions remains (Figure 9a), which, however, still gives the same LEED scattering pattern as the full layer. This pattern is, however, only observed at low temperatures (90 K).[64] On increasing the temperature a sharp scattering pattern of a $(\sqrt{3} \times \sqrt{3})R30^\circ$ structure develops at 150 K, which at higher temperatures becomes diffuse.[64] The relaxation of the interlayer distances at 90 K is very pronounced and reaches deep into the solid.[67] This leads to the conclusion, as Figure 9b shows, that the surface chromium ions are nearly embedded in the oxygen layer. There are some indications for strong relaxations from theoretical approximations on Al_2O_3,[68, 69] which is isostructural to Cr_2O_3. The relaxations amount to 50% of the interlayer distances. Furthermore, the observed structural changes with increasing temperature point to dynamic processes. The temperature-dependent EEL spectra indicate that the ions could either undergo site changes or magnetic scattering in the antiferromagnetic material or small local surface distortions could occur;[64] however, very little is known about the exact mechanism.

Further indications of dynamic processes on films are obtained from adsorption experiments with oxygen.[57, 70, 71] If a clean Cr_2O_3(0001) surface is dosed with molecular oxygen, this will be adsorbed molecularly at 90 K. IR spectra (Figure 10) contain an absorption band at about 1000 cm^{-1}, which by exchange of $^{16}O_2$ for $^{18}O_2$ gives, in accord with the isotope effect, a small shift in frequencies.[71] The band is relatively wide, and experiments concerning the O_2 coverage, point to the presence of many different adsorbed O_2 species.[72] If the temperature is

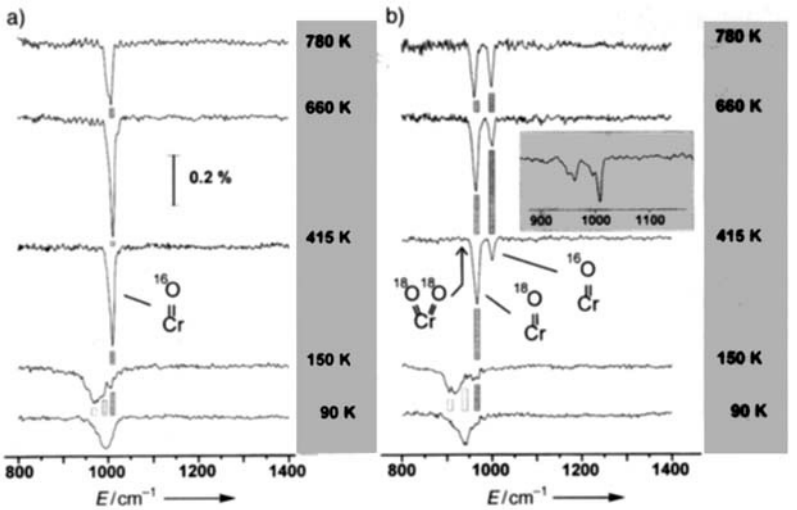

Figure 10. IR spectra of a $Cr_2{}^{16}O_3(0001)$ surface after dosing with 6L $^{16}O_2$ (a) and 6L $^{16}O_2$ (b), respectively, at 90 K, and subsequent heating to the given temperatures. The insert in (b) shows the spectrum of another preparation.

increased to 415 K, oxygen dissociates and chromyl groups are formed. The IR spectrum now contains a sharp, slightly asymmetric band. If the dissociation is monitored with isotope-labeled $^{18}O_2$, in addition to the Cr~^{18}O band shifted by the isotope effect, the Cr~^{16}O band is also present. Whereas the molecular O_2 adsorption occurs with no exchange with the oxygen in the lattice, O_2 dissociation and the formation of the chromyl groups leads to an exchange with lattice oxygen.

These observations allow a few conclusions to be drawn about the bonding state of the oxygen on the surface: firstly O_2 is known not to be IR active in the gas phase. Evidently, the adsorption leads to a noticeable change in the electronic structure of the molecule. Photoemission experiments[73] reveal that these changes possibly arise from a very small charge transfer from the surface to the molecule. Thus, this cannot be considered as a fully formed O_2^- species even though the shift of the vibrational frequency from 1555 cm^{-1}[74] to 1010 cm^{-1} would be consistent with this.

The observation of the O_2 vibration in the adsorbed state also allows conclusions to be made about the bonding geometry: If the molecule lays flat on the surface, the induced dipole can be screened from the electrons in the underlying layer, provided that the polarizability is sufficiently large.[75] This leads to an overlap of two opposing dipoles and thus to a disappearing transition dipole moment. In contrast, if in the other extreme case where the molecule is perpendicular to the surface, the overlap leads to a strengthening of the induced dipole moment. For the system considered here, we conclude that the adsorbed O_2 molecule does not lie flat on the $Cr_2O_3(0001)$ surface but end-on bound to a chromium ion. As already mentioned, after the O_2 dissociation a chromyl species develops. The IR absorption of the Cr–O double bond lies in the same frequency range as that of the modified O_2 bond. This is also evident from a comparison with the IR spectrum of CrO_2Cl_2.[76] The two relatively heavy Cl atoms represent to a good approximation the "surface" onto which the chromyl groups are bound. The vibrational stretches of the chromyl groups occur at 990 and 1000 cm^{-1} for the symmetric and antisymmetric combination, respectively, of the two Cr=O vibrations.

We had initially expected that two chromyl bonds per chromium ion form on the surface, since the Cr=O band was always asymmetric and in many cases clearly split. This splitting could be attributed to the corresponding symmetric and antisymmetric combinations. However, there could also be two different chemical species with single Cr=O bonds on the surface next to each other. Isotope labeling experiments[70, 72] clearly indicate that only single Cr=O bonds form on the surface, and thus there must be two different species. If this is compared to the situations after dissociation from $^{16}O_2$ and from $^{18}O_2$ on a $Cr_2(^{16}O)_3(0001)$ surface, the expected band for the two Cr=^{18}O bonds is never found in one molecule. This result agrees remarkably well with the findings for polycrystallized Cr_2O_3.[77–79] Interestingly, chromyl groups form on the surface not only through adsorption of O_2 from the gas phase, but also by repeated heating of the clean surface. Isotope labeling experiments show that these groups form by oxygen diffusion through the film.[72]

The above-mentioned experiments indicate that the chromium ions on the surface are the active adsorption sites. This becomes even more apparent if, after coverage with oxygen, attempts are made to adsorb a further compound such as ethene or CO.[70, 73] Thermal desorption studies show that after saturated coverage with O_2 the adsorption of further particles is strongly reduced.

In contrast, if ethene or CO is supplied to a clean, that is not oxygen-covered, $Cr_2O_3(0001)$ surface, a bond is formed to the support.[70, 73] Figure 11 shows the results from an IR spectro-

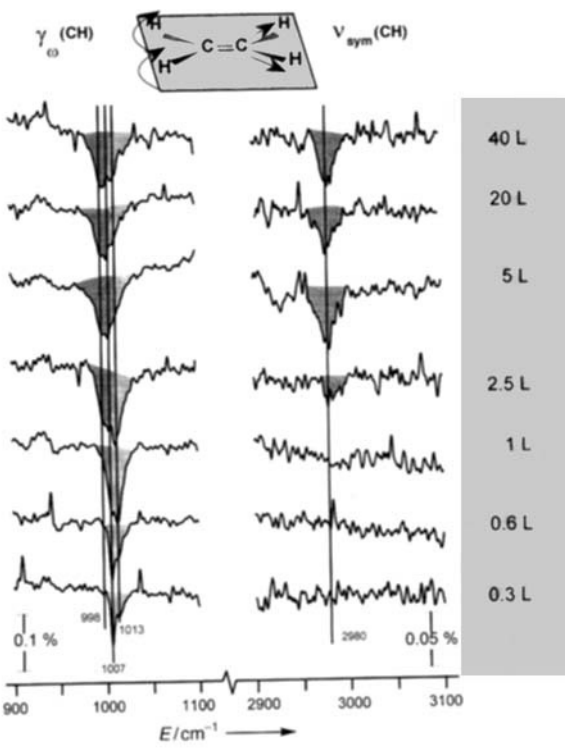

Figure 11. IR spectra of a $Cr_2{}^{16}O_3(0001)$ surface after dosing with different amounts of C_2H_4 at a surface temperature of 90 K.

scopic study of the coverage with C_2H_4 at 90 K. The frequency regions of the CH bending vibration γ_o(CH) and the symmetric CH stretching vibration ν_{sym}(CH) are shown. Even for small coverages the bending vibration begins to shift in frequency with a dose of 1 L. A measureable vibrational signal occurs from about this amount of coverage. As for the case of the oxygen adsorption discussed, the absence of the stretching vibrational signal points to an ethene molecule oriented parallel to the surface, possibly bound to a chromium ion. The photoemission measurements provide evidence of a small charge transfer from the molecule to the surface. At a large dosage the population takes on a physisorbed state, which shows, through the occurrence of both IR bands, that there appears to be no detectable, preferred orientation relative to the surface.

When these experiments are carried out under ultrahigh vacuum conditions, chemi- and physisorption are fully reversible, which means that with a temperature increase the ethene desorbs completely. In contrast, if the adsorption is performed at about 1 bar and about 400 K, a reaction on the surface takes place that we have interpreted as a polymerization of ethene,[73] which is in complete agreement with data from the Zecchina group.[80] After the polymerization, adsorbed OH groups are formed. Such a finding is not completely surprising, since chromium oxide is part of the well-known Phillips catalyst for the synthesis of polyethylene.[81, 82] In addition, similar experiments have already been carried out on polycrystalline samples.[80] Based on the results described here, more can now be said about a possible mechanism for this technically important reaction: C_2H_4 is adsorbed side-on on to a Cr^{3+} ion through a small charge transfer, resulting in changes in the electronic states of the Cr^{3+} ion, as we could show by EEL spectroscopic analysis of the surface excitations of the chromium ions.[73]

Hitherto, there were no experimental results on thin film systems that indicated the direct formation of Cr^{2+} on the surface as a consequence of ethene adsorption. Rather, the more accurate picture is one in which an interaction between ethene and a coordinatively unsaturated chromium ion is the active center for ethene polymerization.[80–82] This result corresponds to the classical bonding theory of a π-bonded ethene molecule.

In contrast, CO bonds in a nonclassical way on a Cr_2O_3(0001) support layer. Angle-resolved photoelectron spectra[66] support a case in which the CO molecule lies flat on the surface, and the lone pairs of electrons on carbon (5σ) and on oxygen (4σ) are involved in the bond. This is further supported by the shifting of the ionization energies of the appropriate states.[66, 83] The behavior of CO/NiO(100),[48] in which the interaction exists only through the carbon atom, deviates considerably from that of CO/Cr_2O_3(0001).[83] In contrast, it seems that NO on Cr_2O_3(0001) is bound in a tilted manner in a similar way as on NiO(100).[23] How can the CO/Cr_2O_3(0001) interaction be modeled? We know now that in contrast to previous assumptions the Cr_2O_3 surface is very strongly relaxed. This means that the chromium ions are not as exposed on the surface as was previously thought.[84] It is, thus, not likely that the CO molecule can simultaneously form bridging interactions with two chromium ions. On the contrary, it is more likely that CO, similar to ethene, is bound through a single Cr ion (Figure 12). Thereby, a π bond is formed, which leads to a shift of the 1π ionization energy to a higher value. Only one component of the 1π orbital is influenced by this shift because of the high symmetry of the adsorbate site. However, since CO adopts a position at an angle to the surface plane, hybridization effects must be taken into consideration, so that a clear separation into two components is not possible. The 5σ and 4σ orbitals of CO in this arrangement contribute very little to a chemically bonding interaction, but experience the pronounced Pauli repulsion of the closed-shell oxygen ions, and are therefore shifted to higher binding energies. This shift resembles the pure electrostatic shift of the 5σ orbital in the CO/NiO(100) system (see Figure 4).[44] As a result of the changed adsorption geometry, in this case both σ orbitals are influenced.

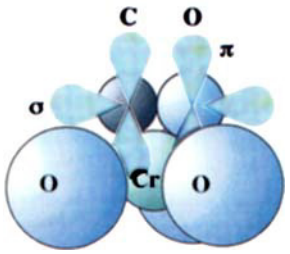

Figure 12. Schematic representation of the interaction of CO (with its p_π and p_σ orbitals) with a Cr ion on the reconstructed Cr_2O_3(0001) surface.

The bonding of CO on the support layer comprises two opposing contributions: the stabilization by the π orbital and the destabilization by the repulsive σ interactions with the substrate (see Figure 12). The attempt to derive a charge transfer between the CO molecule and the surface in the photoelectron spectrum was not successful.[84] CO produces the only adsorbate system up to now on Cr_2O_3(0001) for which an ordered structure has been found. The LEED picture has $(\sqrt{3}\times\sqrt{3})R30°$ symmetry and could be confused with the pattern of the phase transition of the substrate. However, the I/V behavior differs clearly for the superstructure reflections of the two structures.[85] Furthermore, the CO superstructure is also detected at low temperatures at which the phase transition is not active. Whether the interaction of the CO molecules with the Cr ions on the surface stabilizes or influences the phase transition is still not clear. The adsorption of a number of other different compounds leads, however, to the disappearance of the phase transition.

4. Experiments on Metal-Deposited Modified Oxide Surfaces

The binary systems discussed in Section 3.3 can be modifed by the introduction of additional chemical components. We concentrate here on the modifications achieved by deposition and growth of ultrathin metal films. The systems created in this way[87–117] can be considered as model systems for disperse metal catalysts. Thus, their study has a certain practical relevance.

Typical metal support systems are those in which the metal is a transition metal, and the support is, for example, composed of SiO_2, Al_2O_3, or MgO. The methods discussed in Section 3.3 can be employed to produce well-ordered layers of MgO[41–43, 118–120] and Al_2O_3.[121–129] The preparation of ordered SiO_2 layers still gives difficulties.[130] We have focused our attention until now on the support system Al_2O_3, and thus in the following, initially the structure and properties of the support,[121, 126] as well as the possibilities of its chemical modification by functionalization[131] will be considered, and thereafter the growth, morphology, adsorption, and reaction behavior of the metal films deposited.[131–142]

4.1. Structure of a Support

A well-ordered, thin Al_2O_3 film can be generated on a (110) surface of a NiAl alloy single-crystal by oxidation and tempering at 900 K.[121, 126] The choice of this system has several advantages. If one tried to produce an Al_2O_3 film on an Al substrate, a film would be produced that covers the whole surface, and thus to order this film, the temperature would need to be raised to such an extent that the substrate would melt. In contrast, NiAl has a high melting point of 1638 °C. Al_2O_3 is produced on the surface by oxidation; the freed Ni dissolves in the NiAl bulk through heating because the thermodynamically most stable phase in the NiAl system is the nickel-rich Ni_3Al. The dissolution of nickel in the bulk can be monitored, for example, by ESR spectroscopy.[143] The thickness of the film was determined to be 4–5 Å from angle-dependent X-ray photoelectron spectroscopy[144] and from Auger spectroscopy.[145] The stoichiometry of the film corresponds within the limits of experimental error to that of Al_2O_3.[121] Photoelectron spectroscopy and EEL spectroscopy were used to show that the film contained no metallic Ni and no NiO.[121] The film is chemically unreactive, and CO adsorbs on it only at low temperatures (< 80 K),[123, 124] whereas CO binds to the NiAl substrate up to significantly higher temperatures.[146] Thermal desorption studies confirm the film formed covers the whole surface of the alloy. Figure 13 shows a scanning tunneling microscope (STM) image[132] of the growing Al_2O_3 film. The STM image shows two terraces of the NiAl substrate, and above this an extended domain of the Al_2O_3 film, characterized by the striped pattern in the direction of the twist of the domain. The Al_2O_3 film is remarkable in the way it spreads itself over the steps of the substrate like a "carpet", a phenomenon that is known, for example, for the growth of alkali metal halide films on elemental semiconductors.[147]

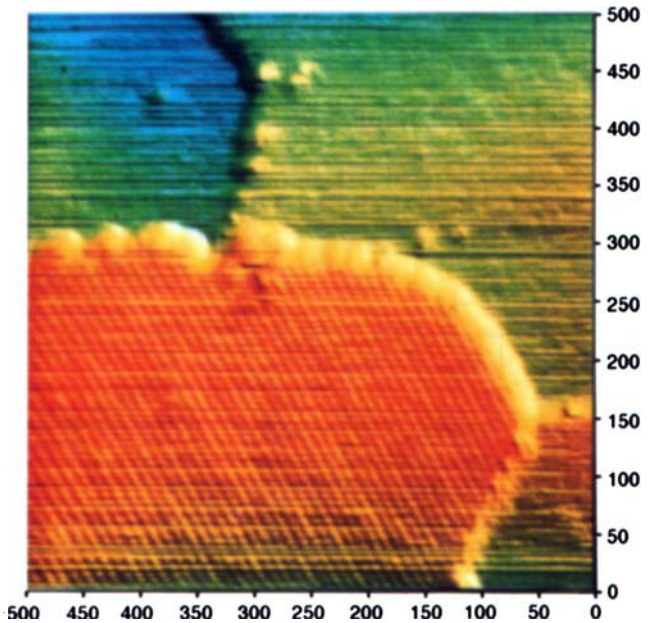

Figure 13. STM diagram (CCT, 500 Å × 500 Å, +4 V, 2 nA) of a partly oxidized NiAl(110) surface. The Al_2O_3 film can be identified by the characteristic striped pattern (bottom left). A step of the NiAl substrate can be seen above [132].

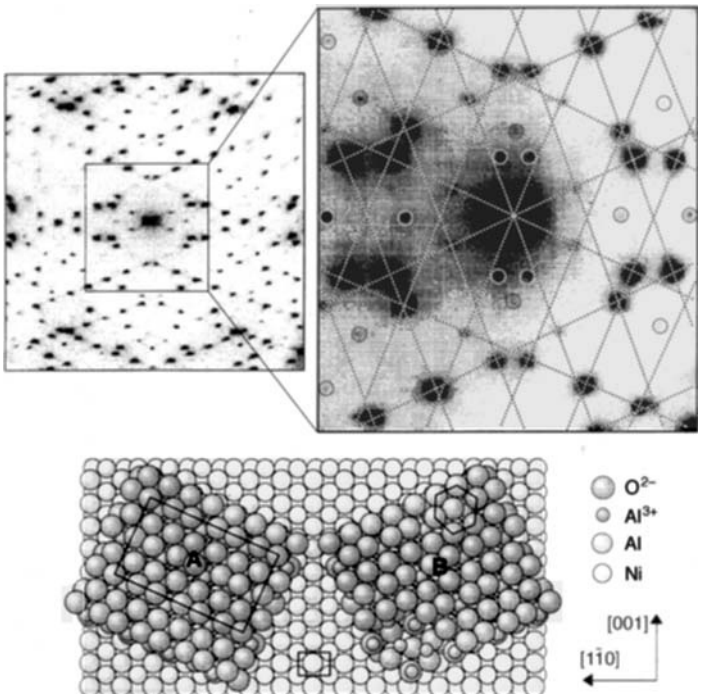

Figure 14. Top: Global LEED picture (85 eV) of the Al_2O_3/NiAl(110) system as well as the enlarged representation of a region around the (0,0) reflection. The reflections that appear in addition to those of the oxide (marked grid) are attributed to double scattering on the substrate and oxide structure (incommensurably grown along [001]). Bottom: Schematic structural model derived from γ-Al_2O_3. The size of the unit cell of the oxide superstructure determined from the diffraction pattern is marked.

Figure 14 shows the electron scattering pattern of the film together with a schematic structural model.[121] The LEED picture, as indicated, still shows the reflections of the substrate. Superimposed onto the substrate spots are the reflections derived from a superposition of two domain LEED patterns, as indicated in the diagram. The double diffraction reflections through scattering on the Al_2O_3 film and substrate exist but are of a weak intensity (see Figure 14).[122] The two domain directions A and B are at an angle of 24° to each other. This twist is forced by the arrangement of the large, nearly square unit cells on the (110) NiAl surface. The arrangement of the Al_2O_3 layer in the (110) direction is substrate-related and commensurable, in the perpendicular direction, however, incommensurable.

Figure 15 shows an STM image of the domain interface,[126] which has no atomic resolution, rather the protrusions show a global variation of the electronic structure about the marked

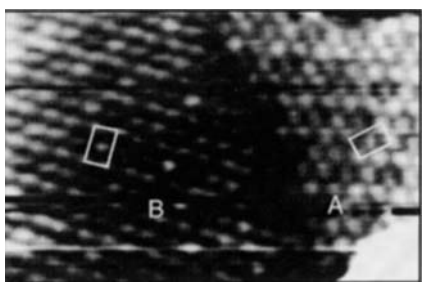

Figure 15. STM image of the Al_2O_3/NiAl(110) system (CCT, 210 Å × 130 Å, −2 V, 0.5 nA). The unit cells of the differently oriented domains A and B are marked (cf. Figure 14).

unit cells. The STM image was recorded under conditions at which electrons from the oxide layer tunnel to the tip of the scanning tunneling microscope. Since the occupied density of states of the oxide begins at about 4 eV below the Fermi energy of the alloy substrate, high tunneling voltages are required. Therefore, the distance between the tip and the substrate is relatively large, and the lateral resolution is limited. If small tunneling voltages are used, the electrons tunnel mainly from the substrate through the film to the tip. This can be used to reproduce the atomic structure of the NiAl layer immediately beneath the Al_2O_3 film.

Figure 16a shows an image of the hidden layer in the NiAl substrate, directly bordering the oxide with atomic resolution, which was recorded under the above tunneling conditions.[126]

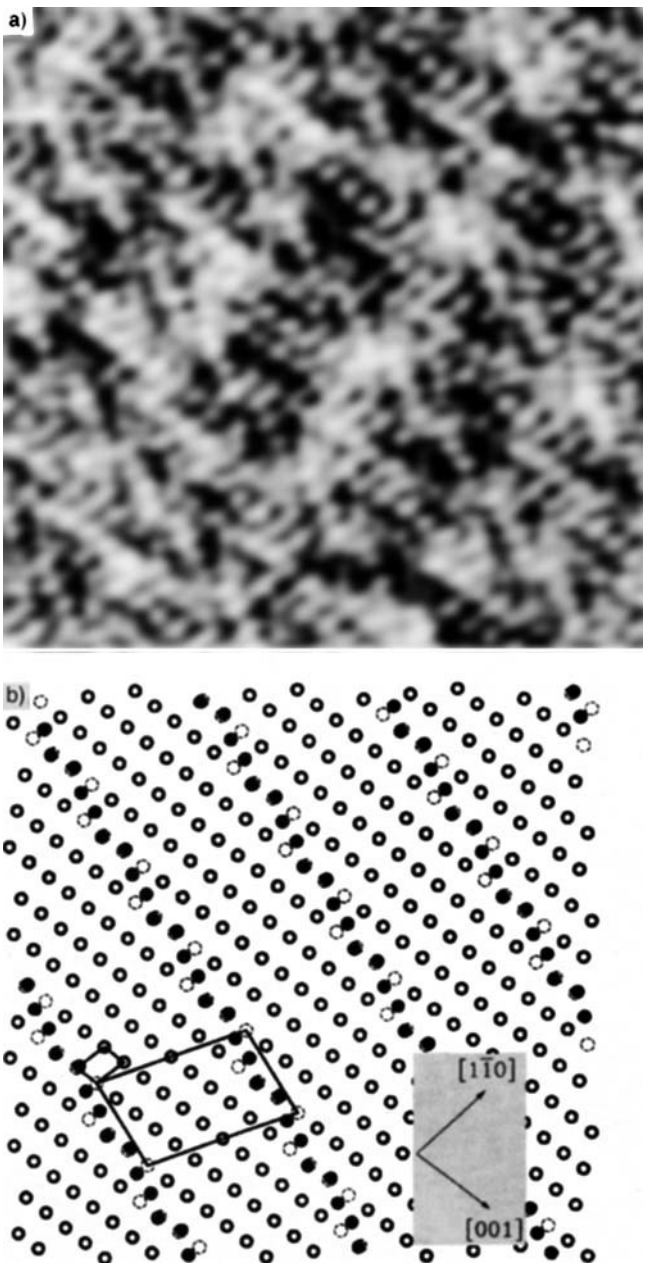

Figure 16. a) STM image of the Al_2O_3/NiAl(110) system (CCT, 90 Å × 90 Å, −1 V, 1.5 nA); b) schematic representation of the atomic structure of the NiAl(110) layer beneath the oxide layer (derived from (a)).

Together with the schematic representation in Figure 16b it is clear that through a regular displacement of every fourth atom the incommensurability of the Al_2O_3 unit cell is compensated in this direction. The existence of this interface also clarifes why the double scattering reflections in the LEED image were so weakly pronounced.

The thickness of the Al_2O_3 film is comparable with two Al–O double layers, as shown schematically in Figure 17. The Al_2O_3 film is oxygen-terminated, as we know from ion-scattering spectroscopic experiments.[133–135] Both the intensity distribution in the electron scattering pattern and the measurements of the Al_2O_3 band structure by angle-resolved photoelectron spectroscopy hint at the formation of hexagonal oxygen layers.[121]

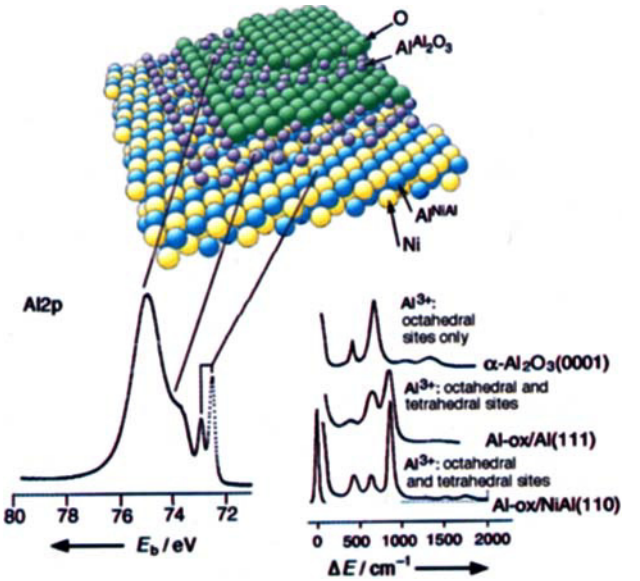

Figure 17. Top: Schematic buildup of the Al_2O_3/NiAl(100) system. Bottom: High-resolution photoelectron spectrum (left, $h\nu = 150$ eV, perpendicular emission) and HREEL spectrum (right). Substrate, interface, and oxide components are clearly separated in the photoelectron spectrum (E_b = binding energy). The HREEL spectrum of the Al_2O_3 film on NiAl(110) is compared to those of Al(ox)/Al and α-Al_2O_3 (ΔE = energy loss).

Additional evidence for the formation of the layer is obtained from photoelectron spectra in the region of the Al-2p core electrons.[121] The photoelectron spectroscopic signals of individual layers in the film are assigned in Figure 17: The sharp doublet arises without doubt from the alloy support layer; the weak shoulder at about 74 eV must stem from the interlayer region, since it returns strongly in terms of its relative intensity when the spectrum is recorded at grazing electron emission, that is, lower escape depths of the electrons;[144] the most intensive signal in the photoelectron spectrum stems from the fully oxygen-coordinated Al ions. The nature of the coordination environment (octahedral or tetrahedral) of the Al ions is hard to decipher from this information alone. Similar information is provided in Figure 17 (bottom right) from the phonon spectrum of the film,[121] which was recorded by using electron loss spectroscopy. Comparison with the spectra of α- and γ-Al_2O_3 leads to the conclusion that the coordination corresponds more to that of γ-Al_2O_3 than that of α-Al_2O_3. This means that tetrahedrally and octahedrally surrounded Al ions are present.

We have thus achieved an extensive characterization of the film and established that we are dealing with a well-ordered Al_2O_3 film, which is free of hydroxy groups and which fully covers the surface. Evidently, this film cannot correspond in every way to a bulk single crystal, since in the direction perpendicular to the surface the thickness of a unit cell of γ- or α-Al_2O_3 is not achieved. Nevertheless, it appears that in many ways the properties of this film are those typical for γ-Al_2O_3, and the layer thickness has only a limited influence on the observed properties.

The film prepared in this way can now be directly covered with metal, but it can also be chemically modified prior to the introduction of the metal.[131] Thus, it has been possible to study the influence of functional groups on the Al_2O_3 surface on the growth and reactivity of thin metal films: Of special significance in this context are hydroxy groups on the Al_2O_3 surfaces, and in the following the ways in which chemically modified films can be prepared will be discussed briefly.[131, 148–153]

The basic concept is the following: Metallic aluminum is absorbed on to the ordered Al_2O_3 film and then the layer thickness can be increased by oxidation with either pure oxygen, or by oxidation with H_2O a somewhat thicker hydroxylated aluminum oxide layer is achieved. This process can be monitored by photoelectron spectroscopy (Figure 18).[154] The bottom

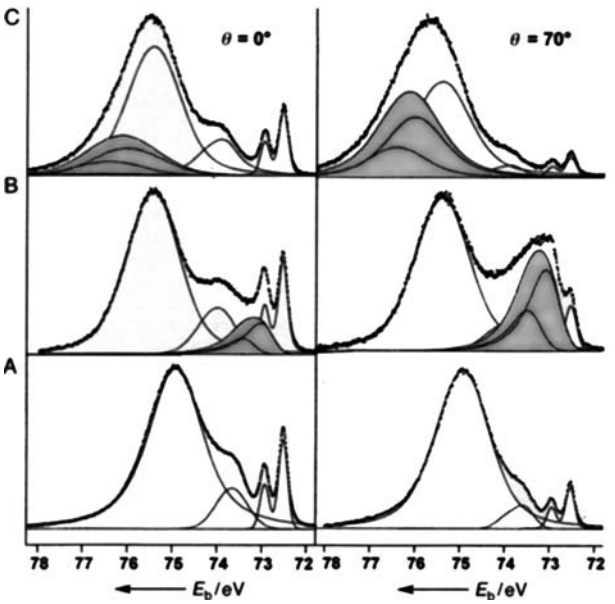

Figure 18. Al 2p photoemission spectra of the chemically modified Al_2O_3/NiAl(110) surface ($h\nu = 150$ eV grazing (70°) and perpendicular emission (0°)). A: Clean Al_2O_3 film; B: After deposition of 1 Å Al at 300 K; C: After H_2O exposition at 90 K and subsequent warming to 300 K.

spectra (A) are those of the clean Al_2O_3 film, on the left hand side by perpendicular electron emission, and on the right hand side by grazing electron emission. Deposition of a part of a monolayer of metallic aluminum leads to the spectra B. From the production and the comparison with different spectra recorded at different angles of emission, it can be seen straight away that Al lies on the surface of the Al_2O_3 layer. Notably, in addition to the appearance of new bands, the whole spectrum is shifted to a smaller energy range. This is attributed to the fact that depending on the charge polarization in the interfacial layers, potential differences occur through the insulator layer. These differences can also be discussed in terms of band bending,[131] and lead to these shifts. Hydroxylation with water leads to a conversion of the metallic aluminum to the ionic form and to the top spectrum in the series (C). At the same time, the O 1s spectrum indicates the formation of a shoulder, which is typical for the presence of hydroxy groups. It is not surprising that through this process the order of the surface is changed, though it is by no means fully lost. The concentration of functional groups can be controlled by varying the dosage of aluminum. Evidently, it is conceivable that the formed OH groups can be used to further functionalize the surface.

4.2. Morphology of Metal Deposits

Metals can be deposited on clean and on chemically modified surfaces. Figure 19 shows two STM images of metal deposits on a clean Al_2O_3 surface—after deposition of 1/3 of a monolayer of silver,[132] and after about the same amount of Pt was deposited on the same substrate.[135] The substrate was at room temperature. Owing to the relatively high mobility of Ag, large particles form that deposit on the pronounced step defects of the surface (Figure 19b). In contrast, the mobility of Pt is reduced to such an extent that the platinum particles nucleate on the terraces. The competition between the interaction between metal and oxide and the thermal energy clearly decides on these processes. The adsorption energy E_{ads} is described by the classical Young

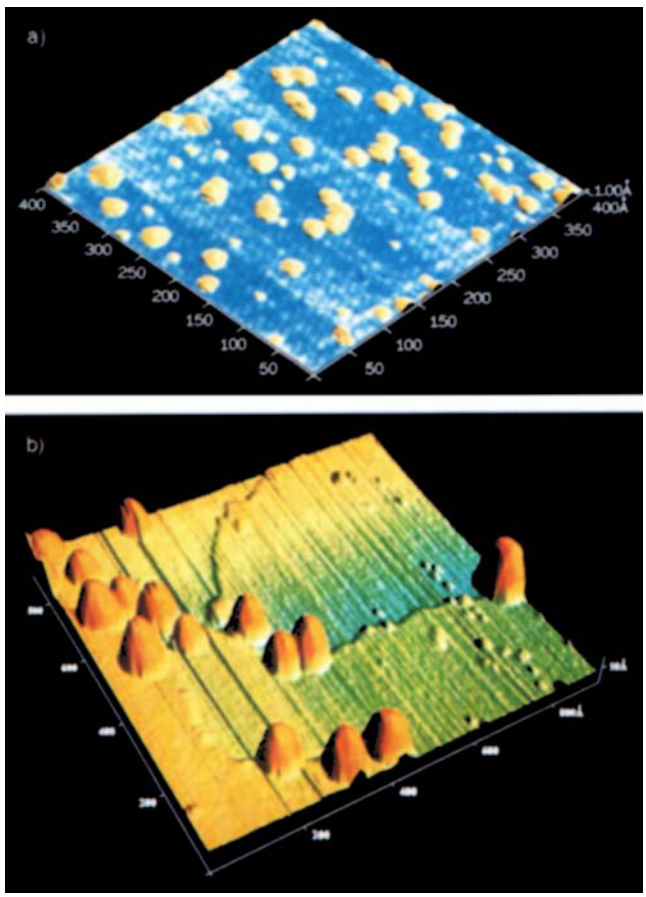

Figure 19. STM images of the Al_2O_3/NiAl(110) system after metal deposition: a) Pt growth at 300 K (CCT, 400 Å × 400 Å, −4 V, 0.8 nA), b) Ag growth at 300 K (CCT, 900 Å × 900 Å, −0.6 V, 0.5 nA).

approximation [Eq. (b)],[155–157] for which approximate values are known for the first two interaction energies, but the oxide/metal term is usually not known.

$$E_{ads} = E_{oxide/gas} + E_{metal/gas} - E_{oxide/metal} \quad (b)$$

Whether the metal particles move at a given temperature depends on E_{ads}. If $E_{ads} < 0$, full coverage is attained, that means a layer growth of the Frank–van der Merwe type. If $E_{ads} > 0$, three-dimensional islands are formed (Volmer–Weber growth mode).[157] If a layer-by-layer growth is replaced at a known layer thickness by a three-dimensional growth, it is referred to as a Stranski–Krastanov mode. Naturally, the detailed defect structure of the substrate and the introduced particles play an important role for these processes, since the defects of the oxide layer are nucleation centers for the deposited particles, as is apparent from Figure 19.

However, it's not just a case of the existence of defects per se but also their nature. Palladium, for example, has a growth behavior that is influenced by the existence of domain interfaces, as well as by the steps in the substrate and point defects in the oxide layer.[137] This is illustrated in Figure 20a, in which Pd was deposited at 90 K. The Pd particles partly decorate the domain interfaces, as can be seen in the figures. In addition, there are particles on the terraces. If the same amount of Pd is separated off at room temperature, the mobility is increased and clearly larger aggregates form. Some of the aggregates in Figure 20b adopt the form of small crystals. That these crystals are limited by planes with a (111) orientation is apparent from the electron scattering diagrams, such as that shown in Figure 20c.[137] The oxide reflections are two diffuse, but clearly definable, hexagonal (111) superstructure reflections rotated 12° towards each other. The double reflections stem from the growth of the particles on both the Al_2O_3 domains.

Figure 21 shows by using the (0,0) reflection as an example, the shoulders of the reflection, which, after deposition of Pd at two temperatures, become clearly defined at logarithmic intensity. From the form and the energy dependency of the shoulder in the LEED reflection profiles, that is the dependency on the energy of the scattered electrons, a well-documented analysis[158, 159] provides information about the average island size, island distance, island density, and number of atoms per island (see Figure 22). At 300 K the size of the islands reaches a plateau (Figure 22A, I). At this point an equilibrium between nucleation, diffusion, and growth is reached. Only if there is more than 12–15 Å of material deposited does the average island size grow further, through coalescence processes, that is the fusing together of the islands. The islands then have a regular form with well-developed facets that are crystallographically well-oriented. This is also borne out in the energy dependency (Figure 21 left). Clear in-phase and out-of-phase relationships between

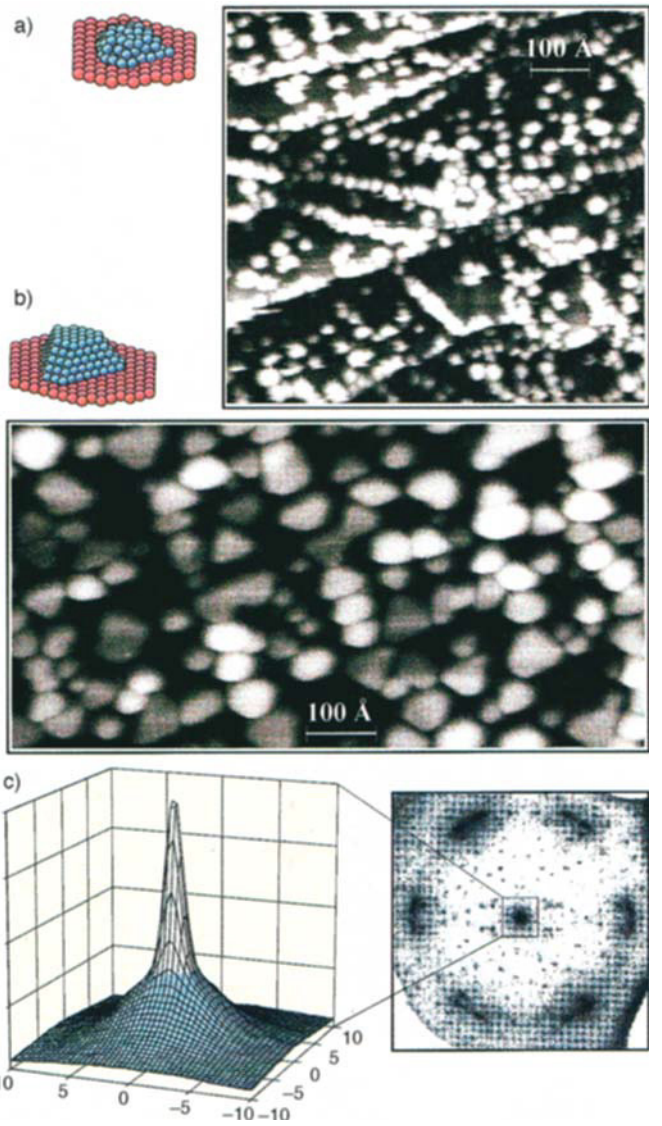

Figure 20. Pd growth on Al_2O_3/NiAl(110): a) STM image for growth at 90 K (CCT, 1.6 V, 2.2 nA). b) STM image for growth at 300 K (CCT, +0.4 V, 0.5 nA). c) LEED image after deposition of 20 Å Pd at 300 K (right, overview, 85 eV) as well as the intensity profile of a region around the (0,0) reflection (left $k_{\parallel}$ in $\%G_{1\bar{1}0}$ is plotted on the axes; $k_{\perp}$ is the wave vector with respect to the distance of the NiAl(110) reflections in the [1$\bar{1}$0] direction; 50 eV).

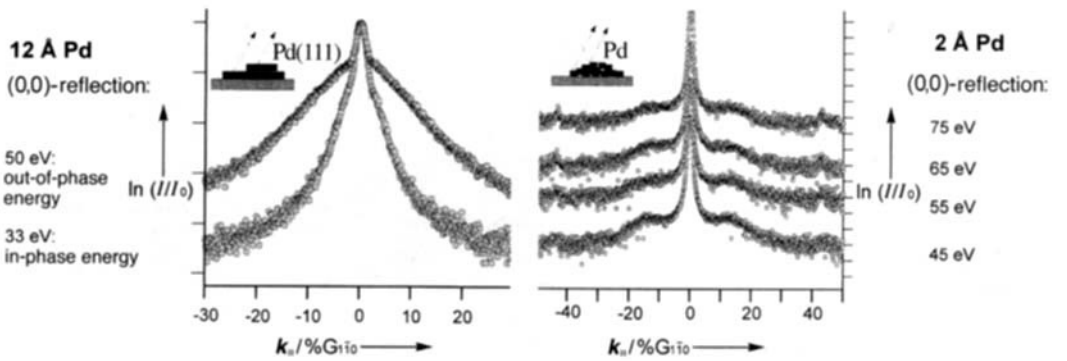

Figure 21. Intensity profile of the LEED (0,0) reflection after Pd deposition on Al_2O_3/NiAl(110) at different temperatures and electron energies. Left: Growth at 300 K, right: Growth at 90 K.

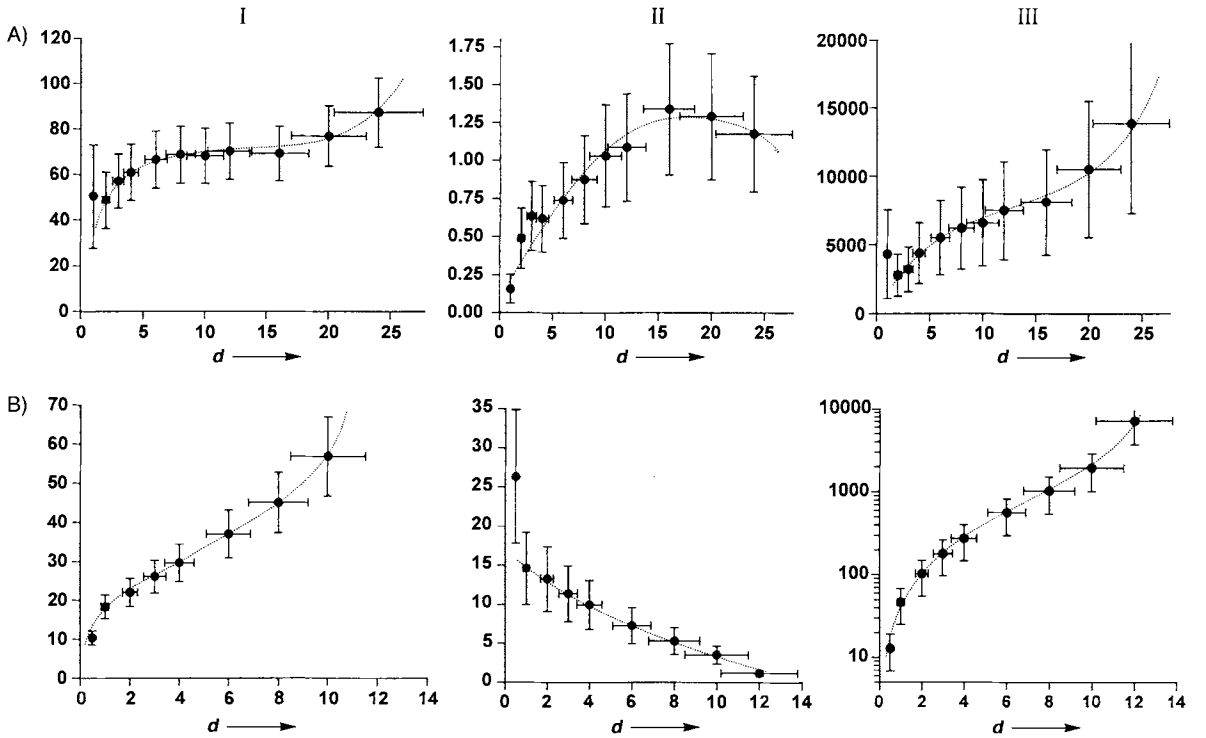

Figure 22. Variations in several of the quantities characteristic for the growth behavior for the deposition of Pd on Al_2O_3/NiAl(110), derived from LEED reflection profile analysis. A) Growth at 300 K, B) growth at 90 K; I: Average island size in Å, II: Island density in 10^{12} cm^{-2}, III: Average number of atoms per island; *d* nominal film thickness in Å.

the rays scattered on different terraces of the growing metal particles are again apparent in the reflection profiles. This is not the case for deposition at 90 K (Figure 21 right). A pronounced shoulder is still observed for the (0,0) reflection, but an energy dependency such as that at 300 K is not observed. Also the island growth shows clear differences relative to that seen at 300 K. Particularly characteristic is that no drop to a plateau is observed (Figure 22 B, I). This is possibly linked to the impaired diffusion during the deposition at 90 K. Nucleation centers are among others the domain interfaces on the Al_2O_3 layer, but pronounced nucleation also occurs on the terraces.

Figure 22 II and III provide a comparison of the derived island densities from the results discussed above and the number of atoms per island, respectively. As mentioned above indications are that at 300 K in the range up to a layer thickness of 10 Å the density of island sites increases strongly (II). Evidently, a considerable number of the islands is not produced at the start of the growth process by heterogeneous nucleation at strongly favored centers, but instead only in the latter stages either by homogeneous nucleation or nucleation at weakly favored adsorption sites. Also the number of atoms per island (III) shows the discussed growth phases; notably, even at low metal coverages large aggregates of more than a 1000 atoms can be formed. At 90 K the situation is clearly different. The rapid increase of island size originates from the fact that the very high island density of 10^{13} cm^{-2} is achieved even by small coverages. Coalescence processes that begin early on allow the island density to steadily fall. This growth behavior has as a consequence that the number of atoms per island varies as a function of the amount of metal deposited over a large region. Under these conditions both the smallest particles with the least number of atoms as well as the very large aggregates are accessible.

For Pd many different metal deposits could be studied in this detailed manner. Rhodium shows a growth behavior similar to that of Pd.[131] A special feature for Rh is the strong nucleation tendency along one certain defect structure, particularly that of the antiphase domains of the oxide film.[131] We will not consider this aspect in any more detail here.

Figure 23 summarizes the growth behavior of the different metals on the Al_2O_3 film studied up to now and comparisons are made by using examples of the reflection profiles at 90 and 300 K. A characteristic of the growth of Ag at 300 K is the formation of larger aggregates, which leads to an extremely small outer shoulder that is hardly separable from the central

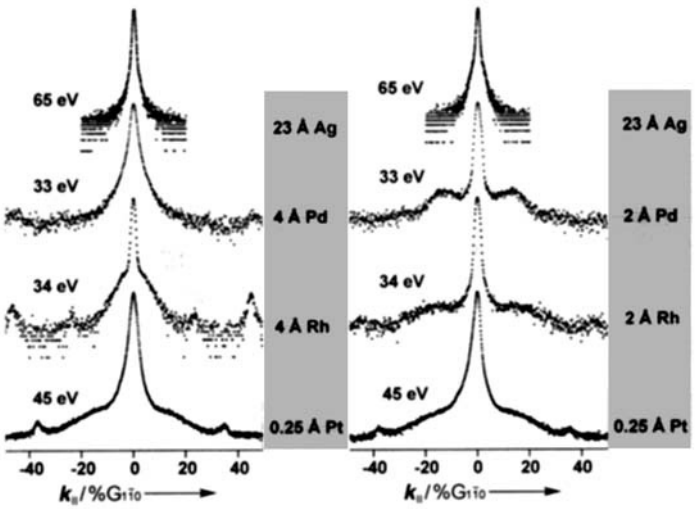

Figure 23. Comparison of the characteristic intensity profiles of the (0,0) reflection for Ag, Pd, Rh, and Pt growth on Al_2O_3/NiAl(110) at growth temperatures of 90 (right) and 300 K (left). The intensity is plotted logarithmically.

reflection. The large diffusion length of Ag leads to larger aggregates even at 90 K. This behavior corresponds to that of Ag on massive Al_2O_3 single-crystal surfaces.[160] The opposite extreme case with a well-pronounced shoulder is represented by the Pt/Al_2O_3 system. At both 90 and 300 K, small two-dimensional islands form due to the strong interaction. These offer possibilities to study substrate-induced changes of the properties of metal films.[9, 132, 133] Pd and Rh are categorized somewhere between the two extreme cases; Rh interacts somewhat stronger with the substrate than Pd. Thus, in terms of the strength of their interaction derived from the growth behavior with the oxide, the metals are arranged as follows: $Pt > Rh \geq Pd > Ag$. This sequence is consistent with the formation enthalpies of the corresponding oxides.[161] ($\Delta H_f^{\ominus}$(AgO): $-12.1\ kJ\,mol^{-1}$, $\Delta H_f^{\ominus}$(PdO): $-85.4\ kJ\,mol^{-1}$, $\Delta H_f^{\ominus}$(RhO): $-90.1\ kJ\,mol^{-1}$, $\Delta H^{\ominus}_f(PtO_2)$: $-172.0\ kJ\,mol^{-1}$. This comparison, however, can only be interpreted as a hint towards considerations of the stability.

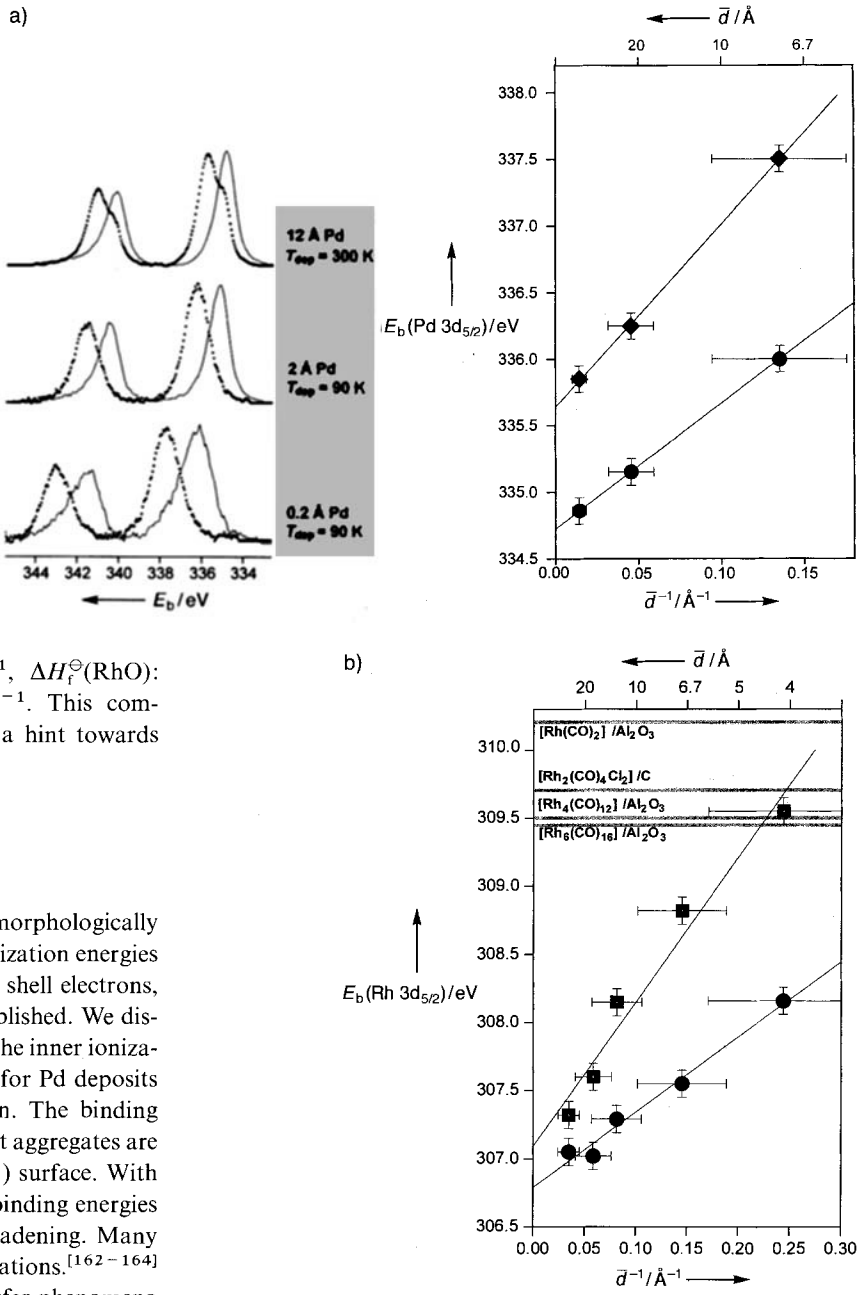

Figure 24. a) Left: Pd 3d photoelectron spectra ($h\nu$ = 420 eV) for different Pd deposits on Al_2O_3/NiAl(110), in each case before (solid line) and after saturation with CO at 90 K (dotted line; 20 L CO). Right: Plot of the binding energy of the Pd surface components as a function of the average particle size $\bar{d}$ for the CO-free (●) and the CO-saturated systems (•). b) Plot of the binding energy of the surface components as a function of the particle size for CO-free (●) and CO-saturated Rh deposits (■). For comparison, the results for carbonyl compound deposits are given [179]. The best fits in (a), right, and in (b) are based on the Coulomb energy of the final state.

4.3. Electronic Structure and Adsorption

Photoelectron spectra can be recorded of the morphologically characterized systems.[138–140] Both for the ionization energies of valence electrons and also for those of inner shell electrons, the dependency on the particle size can be established. We discuss for the clean, adsorbate-free particles only the inner ionizations. Figure 24a summarizes some 3d spectra for Pd deposits that were recorded with synchrotron radiation. The binding energy and the line width observed for the largest aggregates are practically the same as that of the solid Pd(111) surface. With decreasing particle size, a clear shift to higher binding energies is observed together with a significant line broadening. Many effects could contribute to both of these observations.[162–164] Generally, it can be said that both charge transfer phenomena such as initial-state effects and also influences, which only arise in the ionized state of the system, could play a role. The discussion of line widths is especially difficult.[162, 163, 165–168] One can at the moment only speculate that the nonequivalence of the different metal atoms within the differently sized aggregates and the interaction of some of the metal atoms with the substrate combined with the final state effects are responsible for the spread.

In contrast, the interpretation of binding energy shifts, which are graphically summarized on the right of Figure 24a for Pd aggregates and in Figure 24b for Rh aggregates, is somewhat clearer:[164, 169] Specific metal–support interactions,[166] in the sense that charge is transferred from the metal to the support, can be discussed by using initial state effects. The discussion of final state effects is here also urgently necessary, since the screening of the positive charge formed by ionization leads to clear binding energy shifts. Whilst for a bulk crystal a fully delocalized positive charge results, the charge delocalization is limited for a metal aggregate not centrally bound to the substrate. Therefore, a charge distribution builds up on the particle, whose size depends on the average radius of the particle according to Equation (c),[164, 169] and the binding energy shifts to

$$E_c \propto R^{-1} \qquad (c)$$

higher binding energies as the radii become smaller. There are numerous experimental results[162–169] that are in accord with Equation (c) and with the explanation of the binding energy

shift described in Figure 24b. The shifts are generally attributed to final state effects. With a pronounced influence of charge transfer in a nonionized system, one would expect a strong influence on the bonding energy of the substrate, which, however, in our case is only 10% of the total effect. Possible reasons why pronounced charge transfer effects were observed with Pd[170-172] and Ni deposits on Al_2O_3 layers, which were on Al substrates, are different interactions on the metal/oxide interface, which are dependent on the defect density and stoichiometry of the film.

Binding energy shifts and line shapes change considerably if carbon monoxide is adsorbed onto the metal deposits. The study of the CO adsorption is worthwhile, because extensive comparative material of CO adsorption on metal single crystals is available.[83, 173-175] The Pd 3d spectra with and without CO coverage for desposits at 90 K and 300 K are compared in Figure 24. If the available spectra are considered after CO saturated coverage at 90 K, the highest Pd coverage (corresponds to a mean island size of 70 Å) again shows clear parallels to the Pd(111) surface.[176-178] The Pd 3d signal of the clean surface shows a bulk and a surface component, which are shifted towards one another by about -0.3 eV[176] and which could not be resolved. CO adsorption leads to a shift of the surface component by about 1.1 eV to a higher binding energy; thus, both sections (see shoulder in spectrum) could be well separated. The bulk portion amounts to 40% in this case, decreases to 13% with 2 Å Pd (average island size of 22 Å), and can no longer be distinguished with 0.2 Å Pd (average island size 7.5 Å). The CO-induced binding energy shift grows with decreasing island size to about 1.5 eV. Experiments on single crystals show that the binding energy shifts depend on the number of coordinated CO molecules.[177, 178] Further analysis of the data[131] leads us to suspect that for smaller aggregates the number of coordinated CO molecules per surface Pd atom increases from one to two. The coordination numbers of transition metal carbonyls were never achieved.[131] Nevertheless, for cases in which the metal ionization in carbonyl compounds can be compared with those from the deposited particles,[179] the observed ionization energies of the carbonyl compounds are in agreement with those of the smallest aggregate. Figure 24b shows the comparison for Rh ionization. The binding energies obtained for the smallest aggregates are in agreement with the determined island sizes in the range of bi- to hexanuclear rhodium carbonyls.[179] The well-known $Rh(CO)_2$ species on an Al_2O_3 surface has an even higher binding energy of 310.2 eV.[179] However, the limited comparability of the substrate used must be taken into consideration in these comparisons.

Further indications of the electronic structure of the systems can be derived from the valence and the C 1s ionizations of the adsorbed CO and also from thermal desorption spectroscopy (TDS). The TD spectra of several Pd deposits are given in Figure 25.[140] For large Pd coverages, the desorption spectrum obtained closely resembles the spectrum of an adsorbate on a single crystal.[180] The relatively sharp, slightly intensive desorption maximum at 240 K stems from a hydrogen impurity.[131] As the size of the deposited particles decreases, a desorption maximum occurs between 250 and 300 K. The comparability of the system prepared at 90 K with the films produced at higher growth temperatures may be impaired by the limited thermal

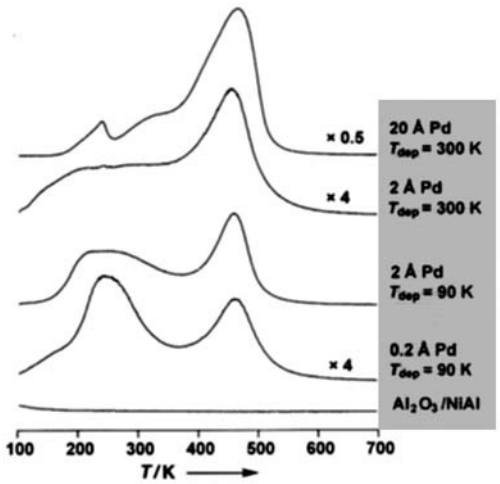

Figure 25. TD spectra of CO ($m/z = 28$) for the $CO/Pd/Al_2O_3/NiAl(110)$ system (adsorption temperature 90 K, adsorbate quantity 20 L, heating rate about 1.5 $K s^{-1}$). The sequence of the TD spectra corresponds to increasing particle size from bottom to top. The deposited amounts are given in the form of effective layer thickness.

stability of the system. Thus, it is conceivable that the observed desorption between 200 and 300 K arises from a thermally limited structural reorganization of the metal aggregate alone as a result of the low growth temperature. A corresponding experiment based on warming the CO-saturated systems to 300 K and subsequent saturation with CO at 90 K, provides, however, a virtually identical desorption spectrum.[131] The low-temperature desorption in the range between 200 and 300 K is thus an inherent property of very small Pd aggregates.

The changes caused by CO adsorption in the region of the valence electron ionization are conveyed in Figure 26.[140] Firstly, the 4σ and $5\sigma/1\pi$ emissions of the chemisorbed CO are evident in the regions around 11 and 8 eV binding energy, respectively. The significantly higher intensity for the 90 K deposit compared to that of the film prepared at room temperature is easy to understand when the growth behavior is considered in terms of a clearly larger surface area in the first case.[131] The interaction of the valence states of the metal with those of the

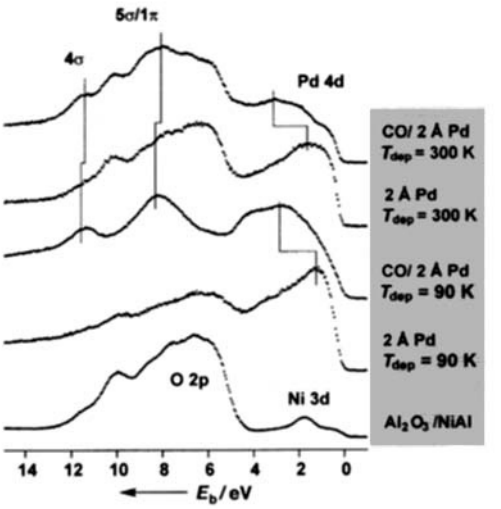

Figure 26. Comparison of the photoemission spectra of the valence electron ionizations of Pd deposits on $Al_2O_3/NiAl(110)$ before and after saturation with CO; $h\nu = 42$ eV.

adsorbate leads to considerable changes in the region of Pd 4d emission. Here again, the considerable difference in size of the aggregate clearly shows the dependence on the conditions of preparation: owing to the low proportion of bulk atoms at small coverages, CO saturation for the 90 K deposit leads to even larger changes in the region of the Fermi level.

The C 1s spectra in Figure 27 are typical for molecularly bound CO and are therefore comparable to the spectra of transition metal carbonyls[181-183] and the C 1s spectrum of CO

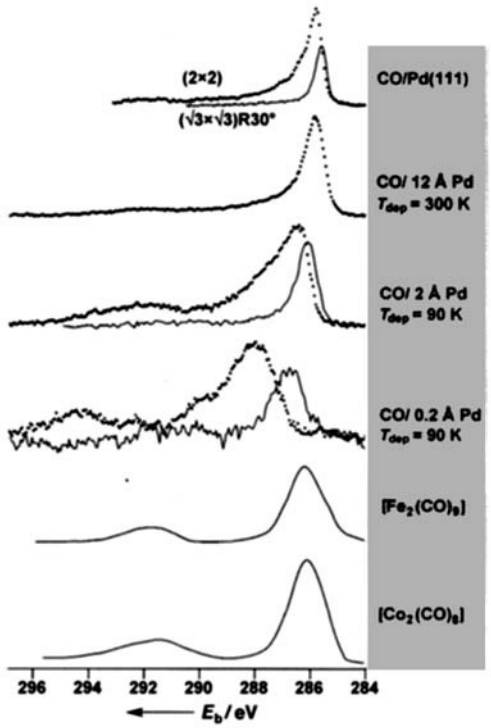

Figure 27. C 1s photoelectron spectra ($h\nu$ = 380 eV) of CO/Pd/Al_2O_3/NiAl(110) after CO saturation at 90 K (dotted line) as well as after a short warming to 300 K (solid line). For comparison, the C 1s spectra of two ordered CO superstructures on Pd(111) (top) as well as of two transition metal carbonyls (bottom) are given.

adsorbed on Pd (111).[184] The weakly defined fine structure in the latter spectrum is attributed to CO molecules on different adsorption sites. The C 1s spectrum for 12 Å Pd is, apart from insignificant broadening, identical to the spectrum of the single-crystal adsorbate. The transition to smaller aggregates reveals a significant shift to higher binding energies, an increase in the line width, and an increase in the intensity of "shake-up" satellites.[182, 185-191] After the removal of some of the CO by warming to 300 K for a short period, a shift to lower binding energies as well as a decrease in line width, asymmetry, and shake-up intensity is observed (solid lines).

Shake-up satellites are a much-discussed and well-understood consequence of the fact that ionization is a complex multiparticle process, which despite the emission of a single electron leads to the simultaneous excitation of many ion states.[182, 185-191] How intensive these different ion states appear in the spectrum of an adsorbate depends on, for example, how strong the bond is between CO and metal.[181, 182, 191] A detailed theoretical analysis shows that the charge transfer satellites adopt relatively large intensities for a weak chemisorption coupling between CO and metal.[181, 182, 191] Thus, in agreement with the results from TDS experiments, the changes of the satellite intensities confirm the occurrence of an important change that appears with decreasing particle size: while the strength of the chemisorption bond for small aggregates depends sensitively on the coverage, this is not so evident for large particles or single-crystal surfaces. The lack of well-ordered crystal surfaces for small aggregates leads inevitably to the situation that a distribution of different geometries can occur, which contribute decisively to the observed line broadening. Additional effects can also contribute to the line width,[189, 192-194] but these shall not be discussed here.

The observed binding energy shift must, as when dealing with the Pd ionizations, be attributed to screening processes in the final state of the ionization.[163] This is verified by the X-ray absorption experiments[131] compiled in Figure 28. The result-

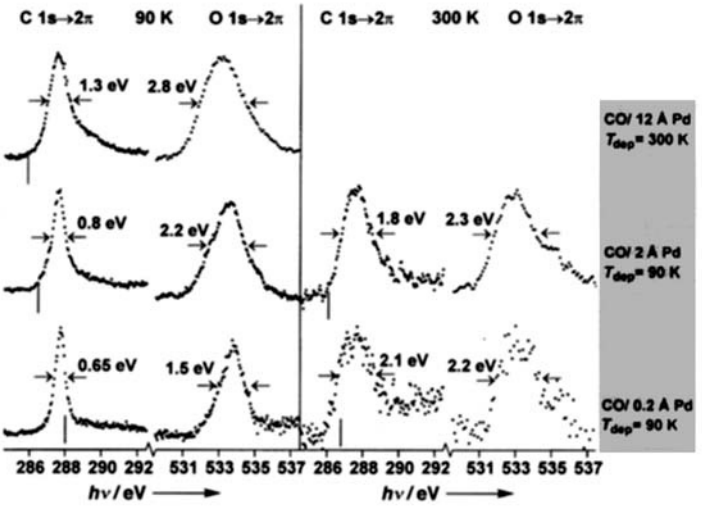

Figure 28. X-ray absorption spectra of C 1s and O 1s → 2π* resonances for CO/Pd/Al_2O_3/NiAl(110). Left: After CO saturation at 90 K. Right: After short warming to 300 K. The vertical marks show the position of the photoemission signals on a binding energy scale.

ing spectra show the excitation of a C 1s or an O 1s electron into the unfilled 2π orbital of the CO molecule.[195-199] Since the excited electron in the 2π orbital remains in the molecule, it is responsible for a large part of the core hole screening. Thus, whereas the screening and the associated shift in binding energy for the C 1s ionization is strongly dependent on the particle size, a much smaller influence on the signal is expected from the particle size itself with X-ray absorption. However, the strength of the bonding interaction between CO and metal should influence the signal in the following way: the synergic σ-donor–π-acceptor bonding mechanism leads to an interaction between unfilled CO π orbitals (see Figure 4) and filled Pd 4d orbitals. Since the 4d orbitals form a band, the interaction with the 2π orbitals of the CO molecule leads to a 2π state density distribution, whose width apart from the Pd 4d band width depends on the strength of the CO metal interaction. As systematic experiments on single-crystal adsorbates have shown, the lifetime of the excitation, vibrational excitations, and intermolecular interactions clearly play minimal roles.[199] Two effects dominate: the width of the resonance increases for systems with the same

geometry with increasing chemisorption energy, and it also increases with increasing coordination of the CO molecule; that is in the transition from atop to bridging to hollow site. These concepts can be used to interpret the resonance positions and widths in Figure 28.

While the ionization energy, indicated by the vertical markings in the C 1s → 2π spectrum, shifts to larger values as a function of the decreasing particle size, the C 1s → 2π resonance remains more or less at the same energy. At the same time with larger aggregates, it beomes broader, as expected for increasing chemisorption energy. The same is valid for the O 1s → 2π resonance in the case of the deposition at 90 K. After the sample is heated to 300 K, the resonance is broader, which is consistent with the discusssion conducted above—a clear indication of the strength of the bond! All experimental findings point to a strong chemisorption bond in the region of *small* CO coverage for the Pd/Al_2O_3 system *for all* island sizes. For small Pd aggregates the strength of this bond, however, decreases considerably for increasing coverage, and lies finally for the smallest Pd aggregate and CO-saturated coverage only in the region of weakly chemisorbed systems.

The comparison with Rh deposits is interesting. Thermal desorption and X-ray absorption spectroscopy of Rh/Al_2O_3 point to very modest changes of the CO-adsorption properties depending on the aggregate size. Thus, only the smallest islands exhibit a slightly different desorption behavior. A possible explanation for the different behavior of Pd/Al_2O_3 and Rh/Al_2O_3 could lie in the differences between the saturated-CO adsorption geometry of the smaller aggregates. It is known that on the relevant adsorption sites, Rh tends to an overall higher coordination through the adsorbate (formation of dicarbonyl species).[179] This is also in agreement with the results of experiments not considered here in detail,[200–203] according to which a reconstruction of the Rh islands—detectable by corresponding LEED profile measurements—takes place after CO exposure at 300 K, This, in turn, leads to an increased adsorption capacity after CO exposure at 90 K.[131]

4.4. Particle-Size-Dependent Reactivity

In contrast to the Pd deposits, the Rh deposits undergo a further reaction channel on warming,[104, 204–207] namely CO dissociation, which we will mention briefly in the following. This channel is active between 300 and 400 K, as shown in the spectra in Figure 29a. The signal that verifies the appearance of atomic carbon occurs at 284 eV on warming. At the same time CO desorbs from the surface. After complete removal atomic carbon remains, and the 2π-CO resonance is no longer detectable in the X-ray absorption spectra.

The model systems offer the possibility of studying the dissociation as a function of particle size.[205–207] Figure 29b shows a corresponding series of C 1s photoelectron spectra for Rh films deposited at 90 K that have an average layer thickness of between 0.6 and 12 Å and, thus, island sizes of between 5 and 30 Å. In each case the C 1s signals after CO saturation (40 L) at 90 K are compared with those obtained after a short warming to 400 or 600 K. If the relationship between the molecular C 1s emission immediately after the adsorption and the atomic C 1s signal after full CO desorption is considered for small and large aggregates, the latter signal is characterized by a considerably small relative intensity. Also a further quantitative analysis[131] leads to the conclusion (Figure 29b) that the smallest aggregate actually shows a low dissociation activity.[205–207] A geometric effect could play a role: the products of the dissociation process, atomic carbon and oxygen, prefer highly coordinated adsorption sites. Calculations[208] estimate that these sites have to be sufficiently apart from each other. A reaction path of this kind,

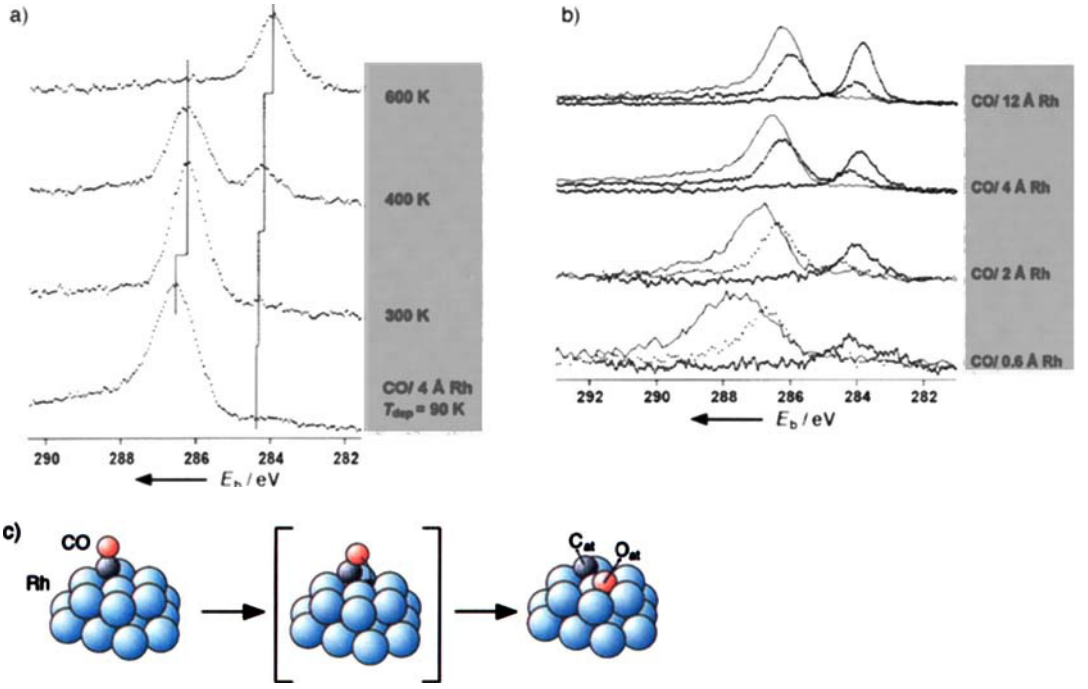

Figure 29. a) Series of C 1s photoelectron spectra ($h\nu$ = 380 eV) and C 1s → 2π* X-ray absorption spectra of $Rh/Al_2O_3/NiAl(110)$ after CO saturation at 90 K and short warming to the given temperatures. b) Comparison of the normalized C 1s photoelectron spectra ($h\nu$ = 380 eV) as a function of the thickness of the Rh layer after CO saturation at 90 K (solid line) as well as after warming to 400 K (dotted line) and 600 K. c) Schematic representation of the CO dissociation process.

as shown schematically in Figure 29c, implies that the Rh aggregates must have a considerable minimal size in order to permit efficient dissociation. In addition, electronic effects also play what may even be a dominant role.

We have arrived at a point in the discussion at which the reactivity could be linked with the particle morphology. In order to understand the effects that occur in catalyst preparation, attempts should next be made to influence[200–203] the morphology chemically and thereby control the chemical reactivity.

4.5. Influence of the Support Modification on the Morphology

In the context of the observations made in Section 4.1 about the modification of the aluminum oxide film by hydroxylation,[184–153] the effects the chemical modification has on the particle morphology will now be discussed briefly. This was investigated as part of a study, which included LEED, TDS, and photoelectron spectroscopic experiments.[131] Evidently, the interaction of Rh with the hydroxylated surface changed relative to that with the OH-free surface.[200–203] The Al 2p and O 1s photoelectron spectra, in particular, experienced changes through Rh deposition.[131] These changes are attributed to the occurrence of specific interactions between the deposited metal and the hydroxylated regions of the surface. In this way the formation of a highly dispersed Rh film results from the different interaction with the modified film at 300 K, which with regard to its growth behavior seems to be comparable with the metal films prepared on the unchanged oxide film at 90 K. This statement concerns merely the morphology; however, self-evidently a change in the Rh–substrate bond is expected. That this is in fact so becomes clear after CO exposure at 300 K. Unlike for the nonmodified substrate, in the case of the modified aluminum oxide film there is no reconstruction of the Rh islands under these conditions, which is evident from an enhancement of the CO adsorption ability.[131] This is consistent with a strong metal–substrate interaction. Finally, if the dissociation reactivity in the modified systems is considered, the activity is reduced to about half, which is consistent with the formation of smaller Rh aggregates on the modified film. In summary, the investigation of model systems allows the study of typical questions that arise with catalyst preparations, and, in particular, allows the changes that occur to be monitored directly by spectroscopy. The investigations are readily linked to the well-documented research on CO-induced Rh redispersion on Al_2O_3[200–203] and other substrates.[209–211] These investigations[200–203, 209–211] revealed that with sufficiently high CO partial pressures it is possible to reduce the metallic substrate under the formation of a dicarbonylrhodium species. This points to the fact that also in the real model systems carbonyl formation takes place with involvement of the hydroxyl groups of the Al_2O_3 surface.

4.6. Metal Deposition in Adsorbate Atmospheres

If the adsorbate is not applied separately but instead is present in the gas phase during the deposition, thus as a surfactant, it can intervene directly in the growth process.[212–215] An example is the deposition of Pd aggregates in a CO atmosphere.[136] Figure 30 shows the TD spectra after deposition of different amounts of Pd. The dominant feature in all of the spectra is a very sharp signal at 200 K. This is typical for the

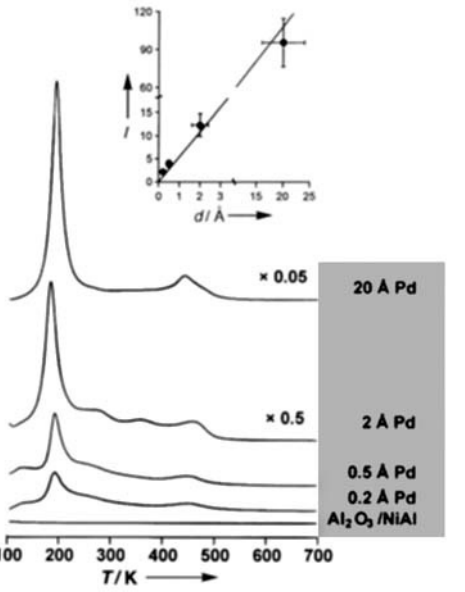

Figure 30. TD spectra of CO ($m/z = 28$) for different Pd coverages on Al_2O_3/NiAl(110), deposited in a CO atmosphere (2×10^{-6} mbar) at 90 K (heating rate about 1.5 K s^{-1}). The insert shows the integral intensity I of the desorption signals as a function of the nominal Pd layer thickness d.

decomposition of a compound formed on the surface. The weak signals at higher temperatures (up to 500 K) are attributed to the desorption of intermediates, which form in the course of the decomposition. The intensity of the signal of the bond decomposition is directly proportional to the nominal layer thickness d, as shown in the insert in Figure 30. That this compound is a transition metal carbonyl is also confirmed by the valence photoelectron spectra and spectra of the inner electrons.[83, 181, 182]

Figure 31a shows photoelectron spectra of the valence electrons that were obtained after stepwise Pd deposition in a CO atmosphere. Through the application of difference spectra, the substrate emission could be eliminated (Figure 31b). It is now clear that, apart from a binding energy shift, the valence electron spectra are almost unchanged over the whole coverage range. At 20 Å Pd the spectra are dominated by the $1\pi/5\sigma$ emissions at 8.8 eV and the 4σ emissions at 11.9 eV,[83, 216] and, the ligand field splitting of the Pd 4d orbitals[181, 217] at 4.1 and 3.3 eV is clearly apparent. With sinking coverages the signals shift by about 1 eV to lower binding energies. A remarkable observation concerns the region of the Fermi energy ($E_b = 0$). Even with high coverages the state density remains minute in this region. Therefore, in agreement with the proposed formation of a metal carbonyl species, the presence of large metal aggregates can be excluded even at large coverages.

Schematically the growth of this metal carbonyl species can be conceived as shown in Figure 31c. This model of the formation of branched, low-dimensional structures accounts for a variety of observations from LEED, XPS, and TDS experiments. The formation of this species is thoroughly unexpected,

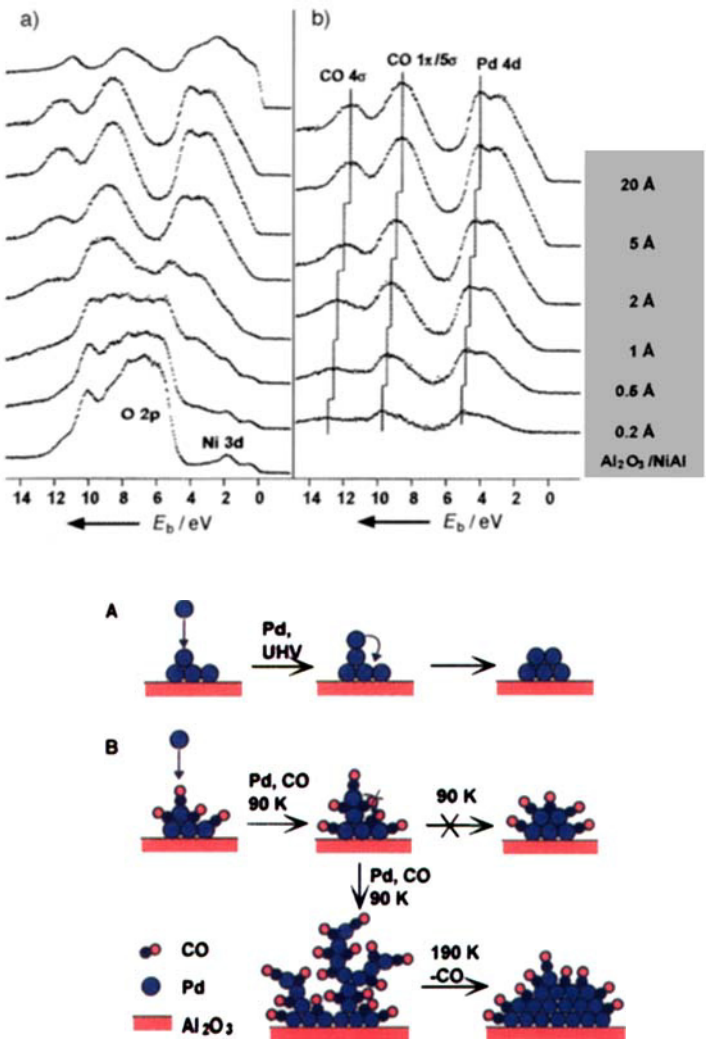

Figure 31. a) Valence electron–photoelectron spectra ($h\nu$ = 42 eV) after successive Pd deposits on Al_2O_3/NiAl(110) at 90 K in a CO atmosphere (2×10^{-6} mbar). The spectrum (top) for 20 Å Pd deposited under UHV conditions at 300 K and the ensuing CO saturation is given for comparison. b) Photoelectron difference spectra after subtraction of the oxide- and substrate-induced emissions. c) Schematic representation of a possible growth model for Pd deposition in a CO atmosphere.

since binary palladium carbonyls are generally very unstable.[217–224] Unlike for the Pt/TiO_2 system,[89] in which the CO-induced changes were discussed fundamentally on a thermodynamic basis, kinetic controlling mechanisms must be present here.

5. Synopsis

Today compound surfaces, such as those discussed here, can be prepared with different crystallographic orientations. The dependence of the chemical reactivity of the surface on the orientation can be clearly proven. This is substantiated by the presented comparison of nonpolar and polar surfaces of NiO and Cr_2O_3. The reactivity-accompanying restructuring for polar surfaces can be studied by electron diffraction and adsorption experiments. The adsorption behavior of small molecules on oxide surfaces has been investigated with a multitude of surface analytical techniques, and the adsorption sites as well as the adsorption geometry determined. Besides simple adsorption behavior, reactions that have a certain technical importance could also be investigated on single-crystal substrates, for example the DeNOx reaction and ethene polymerization. These reactions proceed on clean oxide surfaces. Furthermore, there is a range of reactions that are also of technical interest and that proceed on disperse metal systems on an oxide support. Such systems could, for example, be simulated on thin well-ordered Al_2O_3 layers by deposition of metals. The morphology and structure of the metal deposits can be studied by STM and LEED, and the adsorption of molecules on these complex systems by TDS and photoelectron spectroscopy. Here reactivity studies have provided clear indications about the particle-size-dependent reaction behavior, for example, for the CO dissociation on Rh.

Processes, which play a role in catalyst preparation and reaction, such as adsorbate-induced restructuring or increased influence of the metal dispersion by support modification, could be studied with the model systems. The models are also used to study metal deposition under ambient conditions. All in all the study on model compound surfaces should provide a number of interesting insights into the fundamental principles of catalytic reactions.

A large number of co-workers obtained the results that are reported here. At the same time I have profited greatly through the collaboration and discussion with colleagues. I would like to mention several people in alphabetical order: B. Adam, Priv.-Doz. Dr. K. Al-Shamery, Prof. P. Andresen (Bielefeld), Dr. M. Bäumer, Dr. B. Bartos, Dr. B. Baumeister, Dr. I. Beauport, Dr. M. Beckendorf, M. Bender, Dr. D. Cappus, Dr. B. Dillmann, Dr. D. Ehrlich, Dr. C. Fischer, M. Frank, Dr. H. Geisler, Dr. H. Hamann, Dr. M. Hassel, Dr. I. Hemmerich, T. Hill, Dr. K. Homann, Dr. G. Illing, Dr. R. Jaeger, Dr. U. Katter, M. KLimenkov, Dr. J. Klinkmann, Dr. G. Klivenyi, T. Klüner, Priv.-Doz. Dr. H. Kuhlenbeck, Dr. J. Libuda, Dr. M. Menges, Dr. T. Mull, Prof. H. Neddermeyer (Halle), E. Neuhaus, Prof. M. Neumann (Osnabrück), Dr. G. Odörfer, Dr. T. Porwol, Dr. T. Risse, Dr. F. Rohr, Dr. A. Sandell, N. Sauerwald, H. Schlienz, O. Seiferth, Prof. V. Staemmler, S. Stempel, Dr. C. Ventrice, Dr. J. Wambach, M. Wilde, Dr. F. Winkelmann, K. Wirth, Dr. S. Wohlrab, Dr. C. Xu, Dr. I. Yakovkin (Kiev). I am also very grateful to a number of research development agencies for the support of our work: Deutsche Forschungsgemeinschaft, Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen, Bundesministerium für Forschung und Technologie, European Union, German–Israeli Foundation and Fonds der Chemischen Industrie. At the same time I give my thanks to the Studienstiftung des Deutschen Volkes, which made available the grants for a number of my co-workers. Last but not least, I would like to thank the technical employees of Physikalische Chemie I of the Ruhr-Universität Bochum for their excellent support during the last nine years: H. Böhm, G. Humme, H. Messing, T. Michels, H. Rayess, C. Risse, U. Uhde, and T. Wasmuth.

CVD OF NONMETALS

Rees, W.S. (ed.)

CVD of Nonmetals

1996. XVII, 424 pages with 149 figures and 46 tables. Hardcover.
DM 238.00.
ISBN 3-527-29295-0
(VCH Weinheim)

Written by leading experts in the field, this handbook offers an up-to-date, critical survey of this burgeoning field of research. Technological issues as well as new scientific results are discussed and the viability of the method, both technically and economically, is compared with other deposition techniques available.

From the contents:
Rees: Introduction. Marks/Schulz: Superconductors. Lackey: Structural Materials. Gerfin/Dahmen: Conducting Materials. Tompa: Semiconducting Materials. Barron: Insulating Materials. Kräuter/Rees: Other Materials.

Titanosilicates: Recent Developments in Synthesis and Use as Oxidation Catalysts**

Ramaswamy Murugavel and Herbert W. Roesky*

Dedicated to Professor Karl-Heinz Büchel on the occasion of his 65th birthday

Catalytic oxidation processes play an important role in the industrial production of fine chemicals and several other commodities. Liquid-phase epoxidation of olefins is known to proceed in the presence of hydroperoxides as oxidants over catalytic systems that contain titanium. For example, the catalytic conversion of propylene to propylene oxide over Ti/SiO_2 in the presence of alkyl hydroperoxides is an industrially important epoxidation process that accounts for an annual production of more than one million tons of propylene oxide worldwide.

The earlier industrial processes for the oxidation of hydrocarbons depended on the use of several homogeneous catalysts (such as Mo and W complexes) and metal ions supported on silica surfaces (Ti/SiO_2).[1] However, the hydrophilicity of silica supports limits the use of simple and cheap oxidizing agents such as aqueous H_2O_2 as the oxygen source in these reactions. Hence many of these catalytic conversions are being carried out with highly concentrated H_2O_2 (which makes the processes hazardous!) or more expensive organic hydroperoxides. Phase-transfer catalysts are not very useful for this purpose since the lower alkenes normally lead to water-soluble epoxides. Other disadvantages of such systems include low yields of the desired products due to side reactions, and formation of environmentally unfriendly side products. In contrast, the use of H_2O_2 as oxidant results in the formation of water as the side product.

Zeolite-based metal oxide systems are effective catalysts for many selective oxidation reactions. In particular, titanium-containing zeolites (isomorphous substitution of Si^{4+} by Ti^{4+} ions in the zeolite framework) have given rise to a number of interesting catalysts over the last few years. The multitude of titanium-doped silicates published to date can be conveniently classified into several groups on the basis of their similarities in structure to synthetic aluminosilicate zeolites.

The discovery of the Ti-substituted molecular sieve silicalite (TS-1),[2] a catalyst for selective oxidation reactions with hydrogen peroxide, in 1983 at Enichem, Italy, opened up active research in the area of titanosilicates. TS-1 is a ZSM-5 type molecular sieve with MFI topology. This microporous crystalline titanosilicate was subsequently shown to catalyze the oxidation of unsaturated hydrocarbons with aqueous H_2O_2 (for example the epoxidation of alkenes), oxidation of alcohols to ketones, hydroxylation of aromatic hydrocarbons, and the conversion of amines into oximes.[3] The discovery of TS-1 is interesting since water is detrimental to conventional Ti-based catalysts. Thus organic peroxides have to be used as oxygen sources and these give rise to toxic side products. The hydrophobic nature of this silicalite favors diffusion of nonpolar substrates to the active site. The hydrophobic micropores (6 Å in diameter) of the catalyst are assumed to exclude water from its internal voids and thus protect the active site from deactivation. The titanium atoms in TS-1 are tetrahedrally coordinated to four oxygen atoms in the framework, and it is generally considered that the hydroperoxides are accommodated in the Ti coordination sphere in the first step of the catalytic conversion.[1]

TS-1 has been synthesized by three methods. While the first procedure employs silicon and titanium alkoxides as the source of Si and Ti, the second method involves an additional step for the formation of peroxytitanates by the reaction of aqueous H_2O_2 with a second aqueous solution containing hydrolyzed titanium alkoxide. The third method uses coprecipitated amorphous TiO_2-SiO_2 in an aqueous solution of tetrapropylammonium hydroxide. The synthesis is carried out in the absence of alkali metal cations under nitrogen. Precautions are necessary to avoid precipitation of TiO_2 as a separate phase, which often acts as a catalyst poison in the subsequent oxidation reactions.

Although the discovery of TS-1 is a milestone in heterogeneous catalysis, the smaller pore size of the zeolite-type framework restricts its use, even for small molecules such as simple alkenes. Conformationally rigid as well as larger substrates also can not approach the catalytically active sites. Thus new materials with larger pore size have always been sought.

Titanium silicalite-2 (TS-2), of similar titanium–silica composition to TS-1, synthesized by Ratnasamy et al., also shows similar catalytic behavior.[4] The pore size in TS-2 is of the same order as TS-1. TS-2 is a ZSM-11 type molecular sieve and has the topology of MEL zeolite. The methods employed for the preparation of TS-2 are similar to those for TS-1. However, when a TiO_2-SiO_2 coprecipitate is employed, tetrabutylammonium hydroxide is used as the structure-directing agent for the MEL structure (instead of the tetrapropylammonium hydroxide used for TS-1). Another titanosilicate, Ti-ZSM-48 with the

ZSM-48 topology, is prepared by employing a TiO_2–SiO_2 coprecipitate and 1,8-octanediamine as structure-directing agent.[5]

Another interesting development in titanosilicates is the synthesis of Ti-doped zeolite β (Ti-β).[6] This is a high-silica zeolite (little or no aluminum) with a three-dimensional pore system containing twelve-membered ring apertures. The pore size is of the order of 7×7 Å. Unlike TS-1 and TS-2, Ti-β shows high reactivity in aprotic solvents such as acetonitrile. The Ti-β zeolite framework is hydrophilic, and the large pore size makes this material suitable for branched and cyclic alkenes. Also, higher selectivity and catalytic activity are observed with organic hydroperoxide oxidants. Normally Ti-β has a Si/Al ratio of more than a few hundred. In the case of aluminum-containing Ti-Al-β zeolite,[7] the Brönsted acid sites (Al centers that catalyze the ring opening of the epoxides) react with the epoxides, and side products such as diols, aldehydes, and ketones are also formed. The use of a basic solvent reduces these side reactions by poisoning the acidic centers.

Ti-β is synthesized by mixing TiO_2, SiO_2, tetraethylammonium hydroxide, and hydrogen peroxide, followed by heating. These compounds have a very low aluminum content ($<0.01\%$). Aluminum-containing Ti-β (Ti-Al-β) is synthesized from a mixture of tetraethyl orthotitanate, tetraethylammonium bromide, and silica, to which aqueous aluminum nitrate is added as the Al source.

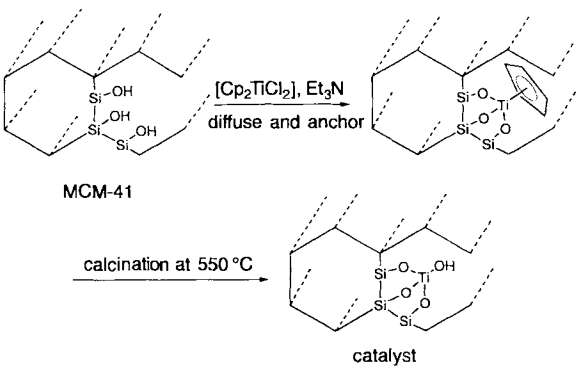
The need for catalysts with larger pore size and different coordination environments of the catalytically active Ti centers recently led to the discovery of ETS-10 (Engelhard Corporation Titanosilicate) and of ETS-4 by Kuznicki.[8] In ETS-10 the octahedral Ti^{4+} ions are linked to the tetrahedral Si^{4+} ions through corner sharing of O^{2-} ions. The negative charge of these framework structures is compensated by Na^+/K^+ counterions. ETS-10 is a large-pore hydrophilic molecular sieve (the pore system contains a twelve-membered ring in a highly disorded structure) with TiO_6 octahedra that are not exposed at the surface of the large channels.[8d, e] ETS-10 is also used as large-pore molecular sieve for adsorption and ion exchange. In contrast, ETS-4 is a small-pore molecular sieve whose structure matches that of the mineral Zorite.

The synthesis of ETS-10[8a–c] was carried out initially by using sodium silicate, sodium hydroxide, potassium fluoride, $TiCl_3$, NaCl, and an ETS-4 seed. However, the use of $TiCl_3$ as titanium source gives rise to an ETS-4 impurity. The use of a cheaper titanium source such as $TiCl_4$ by Sivasanker et al. resulted in thermally stable ETS-10 free of ETS-4.[9a] Very recently, a new method that employs a TiO_2/anatase/rutile mixture (P25, Degussa, 76–24%) as the titanium source has been reported by Liu and Thomas.[9b] Here, TiO_2 is polydispersed in water to which NaOH, KF, and colloidal silica are added. Vigorous mixing and heating yields ETS-10. ETS-4 is prepared by a similar method that uses NaF instead of KF.

One of the latest contributions to the preparation of mesoporous titanosilicates stems from the synthesis of mesoporous siliceous materials (M41S) by Beck and co-workers.[10] Following their original preparation, several Ti-substituted M41S materials have been reported recently. Depending on the basic geometry of the pore arrangement, they are classified into three groups, namely, Ti-HMS (hexagonally ordered mesoporous silica), MCM-41 (hexagonal), and MCM-48 (cubic).[11] The pore size in these materials varies from 16 to 100 Å. Due to their mesoporosity and the easy access to the catalytically active sites, this class of compounds has an advantage in selective oxidation of large alkenes. These catalysts have already shown good catalytic activity in the oxidation of large molecules such as norbornene in the presence of bulky oxidants (*tert*-butyl hydroperoxide). Such reactions were not possible with first generation TS-1 catalysts due to the small pore size.

The M41S class of catalysts are prepared by hydrogel impregnation of the precipitates with organic compounds. Ti-HMS is synthesized by acid hydrolysis of tetraisopropyl orthotitanate and tetraethyl orthosilicate with dodecylamine as template, followed by heat treatment Ti-MCM-41 is synthesized by a similar procedure, with a quaternary ammonium bromide as the structure-templating agent.

In all the above cases, either Ti alkoxides are treated with silicon compounds, or TiO_2 is mixed with silica. The zeolite-type compound is then prepared directly. Thomas et al. have recently reported a new method of introducing Ti centers into a zeolite-type framework.[12] They have shown that the large channels of MCM-41 are big enough to intercalate and graft titanium-based organometallic compounds into the pores. The material is prepared by diffusing a solution of $[Cp_2TiCl_2]$ in chloroform into the mesopores, followed by treatment with Et_3N to activate the Si–OH groups of the silica walls to form Si–O–Ti linkages (Scheme 1). The final catalyst is obtained on removal of the



Scheme 1. Strategy used by Thomas et al. for grafting Ti centers into MCM-41 materials.

cyclopentadienyl groups by calcination at 550 °C. Spectroscopic studies have shown that before calcination, the Ti atoms are bound to a Cp group and to three oxygen atoms which are attached to silicon atoms of the zeolite framework. After calcination the Cp site is occupied by an OH group. Epoxidation of cyclohexene with this catalyst in the presence of tetrabutylperoxyhydroxide exhibits 50% olefin conversion with 95% selectivity for epoxide formation. Although this catalyst is rapidly deactivated, it can be regenerated by calcination at 550 °C without any detectable structural degradation or loss of catalytic activity.

Continuing their search for new titanosilicates, Thomas et al., along with a Chinese research group, have recently synthesized a novel layered titanosilicate of composition $Na_4Ti_2Si_8O_{22} \cdot 4H_2O$.[13] This compound, named JDF-L1 (Jilin Davy Faraday

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3605-0478 $ 15.00+.25/0

Layered Solid Number 1) after its discoverers, contains five-coordinate titanium atoms in a unique noncentrosymmetric tetragonal layered structure. This is the first synthetic zeolite-type material with pentacoordinate titanium. The structure of JDF-L1, determined by X-ray absorption spectroscopy and powder X-ray diffraction, reveals that each titanosilicate layer is made up of small cage-type units, each of which contains eight tetrahedral SiO_4 units and one square-pyramidal TiO_5 polyhedron. Two of these layers are separated by a layer of water molecules sandwiched between two layers of Na^+ ions. The interlayer distance of 10.7 Å can almost be tripled (to 29.7 Å) by replacing the layer of Na^+ ions by amines such as monoprotonated nonylamine.

JDF-L1 is prepared by mixing tetrabutylorthotitanate, aqueous ammonia, aqueous hydrogen peroxide, tetrabutylammonium bromide, and fumed silica. The mixture is stirred for several hours and then heated for 10 d under pressure. After filtration, washing with distilled water, and drying, a microcrystalline powder is obtained which is known as "JDF-L1 in as prepared state". In this state JDF-L1 is inactive as a catalyst for alkene epoxidation. However, treatment with dilute hydrochloric acid and aqueous hydrogen peroxide gives a material that converts phenol and 1-naphthol to the corresponding quinones (hydrogen peroxide is used as oxidant, and acetone as solvent). JDF-L1 is not only unique in terms of its structure; its discovery also opens up new avenues in the synthesis of stable layered structures with a variety of metal/nonmetal ion combinations having potential applications in catalysis and materials science.

Considering the enormous impact of porous titanosilicates in important industrial oxidation processes, it is surprising that until now the mechanisms of these reactions are not fully understood, even though nearly all solid-state analytical methods have been applied to this problem. One reason for this is surely that the active Ti centers are present only in low concentration. Therefore, apart from the interest in preparing new titanosilicates for heterogeneous catalysis, there also have been efforts to prepare soluble homogeneous models for these compounds in order to understand their complex structural chemistry and the nature of the catalytically active sites. One such attempt involves the use of stable organosilanetriols and various titanium-containing organometallic precursors as building blocks. With this strategy it has been possible to prepare a series of molecular titanosilicates with cage structures containing Ti centers in the formal oxidation state of IV with tetrahedral (TiO_4), trigonal bipyramidal (TiO_5), and octahedral (TiO_6) coordination environments.[14] These molecules can be viewed as single-phase titanosilicates having a high titanium content. Recently the crystal structure of a titanium-rich titanosilicate $[Cs_3HTi_4O_4(SiO_4)_3 \cdot 4H_2O]$, synthesized under hydrothermal conditions, was also reported.[15] The structure of this compound resembles that of the mineral pharmacosiderite.

In conclusion, the last few years have seen tremendous interest in the synthesis of new homogeneous and heterogeneous titanosilicates and their use as oxidation catalysts for diverse substrates. In 1996 alone, more than 200 original papers reporting on various aspects of titanosilicate chemistry have appeared. Everybody working in this area is hopeful that one day it will be possible to synthesize catalysts that can oxidize many hydrocarbons with cheap oxidants such as air or oxygen.

As a concluding note, it should be mentioned that recently Yoshida and co-workers have made further progress in the search for suitable catalysts for epoxidation of olefins.[16] They have demonstrated that the photooxidation of propylene to propylene oxide by molecular oxygen proceeds over silica and Mg oxide loaded silica (1 % MgO) with good activity and selectivity. Such recent developments indicate that the day of the ultimate catalytic system is not too far away.

In Vitro Selected Receptors Rationalized: The First 3D Structures of RNA Aptamer/Substrate Complexes**

Martin Egli*

The development of new drugs is nowadays often preceded by the determination of the three-dimensional structure of the receptor targeted. If the specific receptor is a protein, knowledge of the geometrical features of its binding site and the distribution of the chemical groups docking the ligand can provide valuable input for a host of approaches, including computational methods, organic synthesis, and combinatorial chemistry, all aimed at identifying the optimal inhibitor. Such structure-based design contributed to the development of HIV protease inhibitors, which promise dramatic improvement in the treatment of AIDS. Although this approach is far from becoming routine, the opposite strategy, namely tailoring a receptor for a chemically and structurally well-characterized molecule, is an even more formidable challenge. Particularly in an aqueous environment, mastering the many small contributions from hydrogen bonds and hydrophobic interactions is very difficult. With the advent of in vitro selection, advanced by tools such as polymerase chain reaction (PCR) and reverse transcription, it has become possible to isolate ribonucleic acid receptors with a desired property, ranging from the specific recognition of a chosen substrate to the ability to catalyze a particular chemical reaction.[1-3]

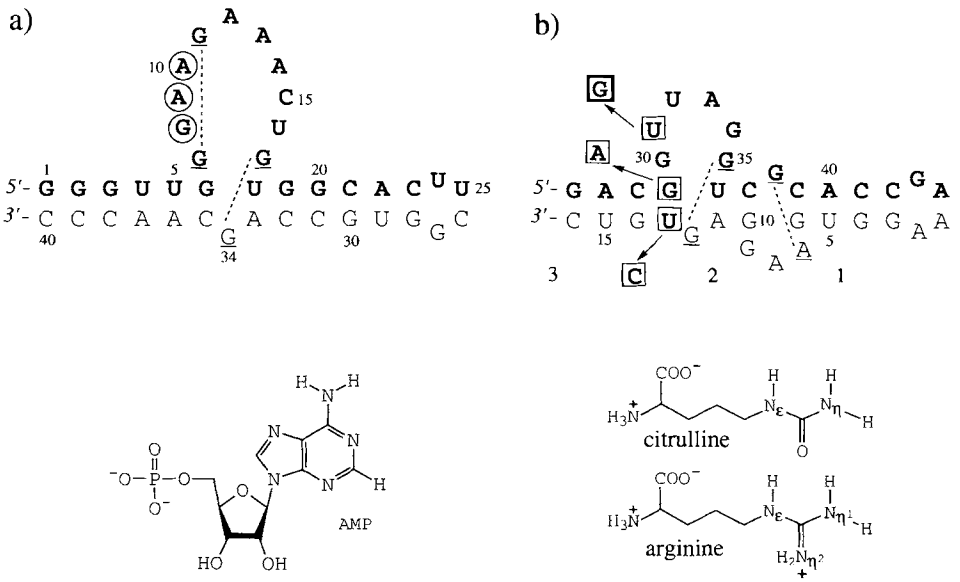

Figure 1. Base sequence, numbering, and proposed secondary structure (now essentially confirmed by solution NMR experiments) for the RNA aptamer of ATP (a) and of arginine and citrulline (b). Bases of one strand are in bold to facilitate tracing of the folded chain depicted in Figures 2 and 3. Dashed lines indicate the formation of noncanonical homopurine base pairs in G·G and G·A (these bases are underlined) in the 3D structures. In the ATP aptamer (a) the circled nucleotides form a GNRA tetraloop motif together with the AMP substrate. In (b) the three variant nucleotides that are critical for arginine and citrulline specificity, respectively, are boxed, and the numbers 1–3 under the receptor mark the stem regions.

Starting from randomized pools with roughly 10^{10} to 10^{15} molecules, RNA and DNA species have been recovered that recognize simple dye molecules, biologically important cofactors, amino acids, and antibiotics.[4] The list of selected catalytically active nucleic acid molecules includes RNA with polynucleotide kinase activity,[5] a self-alkylating ribozyme,[6] RNAs and DNAs with ligase activity,[7-9] and both RNAs and DNAs that undergo metal ion mediated autolytic cleavage.[10-12] Selected and optimized RNA species that are able to bind small organic molecules with dissociation constants in the mM to nM range, so-called RNA aptamers, are quite compact, with lengths of around 40 nucleotides, and their deduced secondary structures display some common features, notably asymmetric internal loops (see Figure 1). Although chemical methods are very effective in determining which portions of the RNA binder are essential for substrate recognition, they are not suited for establishing the details of the chain folding and the binding site geometry. Recently, four NMR studies of RNA–substrate complexes in solution have opened the door to a 3D view of RNA's aptameric repertoire. Three of these studies were conducted on binders of the biologically important cofactors adenosine triphosphate (ATP) (Figure 1a, two independent studies[13,14]) and flavin mononucleotide (FMN),[15] which were previously selected in the research groups led by Jack Szostak,[16] and Michael Famulok,[17] respectively. The fourth study concerns RNA aptamers for the amino acids citrulline and arginine,[18] which were selected earlier on by the latter researchers (Figure 1b).[19]

The solution NMR structure of the complex between the ATP aptamer and the adenosine monophosphate (AMP) substrate reveals that the RNA molecule assumes an L shape (Figure 2). The internal loop folds into two tightly packed hairpin loops, each capped by a noncanonical G·G base pair; one of these guanine residues is the bulged G34 (Figure 1a). The binding

[**] I am grateful to Dr. Michael Famulok and Prof. Dinshaw Patel for sending me the coordinates of the aptamer complexes of arginine/citrulline and ATP, respectively.

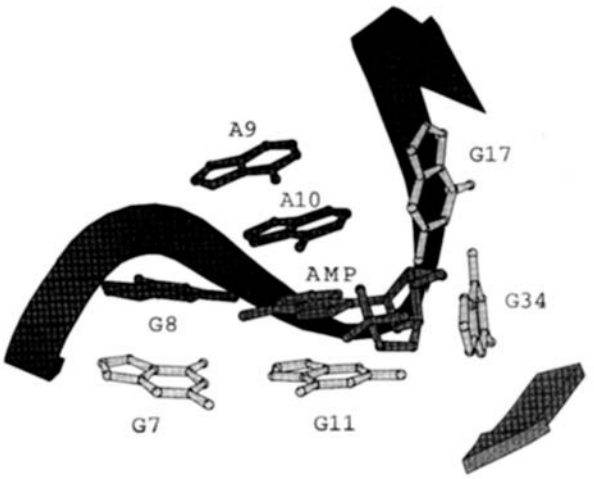

Figure 2. Sketch of the substrate binding site of the ATP aptamer with the bound AMP molecule (center). The RNA backbones are drawn as ribbons: residues G6 to U18 are dark gray, and A33 to C35 are light gray. The folding of the large portion of the asymmetric loop into two adjacent hairpins is clearly visible. The substrate binding site is located at their junction, and the AMP is part of a stable G8-A9-A10-A(MP) loop motif (bases are dark gray). The G·G base pairs capping each hairpin and enclosing the substrate are light gray.

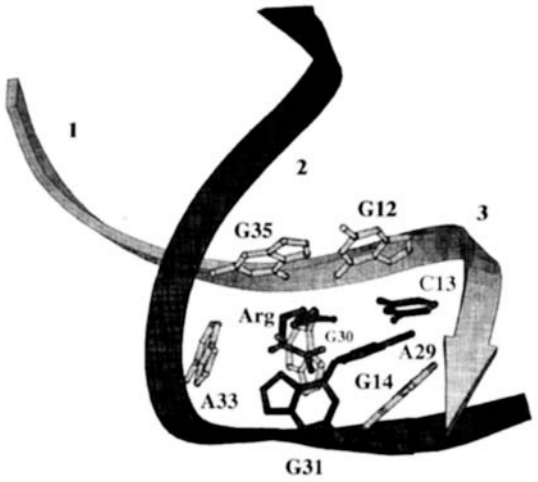

Figure 3. Sketch of the substrate binding site of the arginine aptamer with the bound arginine molecule (center). The RNA backbones are drawn as ribbons: residues A27 to A40 are dark gray, and U5 to U15 are light gray. The large segment of the asymmetric internal loop, visible on the left in the foreground, faces the minor groove formed by stems 2 and 3. The three variant residues 13, 29, and 31 are dark gray, and other residues defining the binding pocket, including the G·G base pair that caps the internal loop, are light gray.

pocket for the substrate, which is located virtually at the junction between the two hairpin loops, is formed by residue A10 from above and residues G7 and G11 from below. The latter two bases form an asymmetic homopurine pair; G7 faces the Hoogsteen edge of G11 with its Watson–Crick edge. The walls of the binding pocket are provided by residues G8, A12 (not shown in Figure 2), and G17. The first residue is paired with the adenine base of the substrate through two hydrogen bonds (to N1 and N6 of AMP); the exocyclic amino groups of A12 and G17 each form a hydrogen bond with N3 of AMP. While A12 is stacked onto G34, G17 and G34 form a Hoogsteen-type pair with G34 adopting a *syn* conformation. In addition to these specific hydrogen bonding contacts to the base portion of the substrate, several stacking interactions contribute to the stabilization of the AMP molecule in the binding pocket. The most remarkable feature of this aptamer complex is that the RNA ties the substrate into a thermodynamically stable GNRA loop motif (N = any base, R = purine), which includes G8, A9, A10, and the adenine residue of AMP (Figures 1a and 2). The RNA has found an ingenious way here to stabilize the substrate by letting it take care of the formation of at least part of its own binding site.

Selection of the L-arginine binder was achieved with an RNA pool predisposed for L-citrulline, and the RNA molecule acquired arginine specificity by mutation at three nucleotide positions. One of these sites was located in the longer portion of the internal loop (U31 to G31) and the others capped that loop at the adjacent stem 3 (G29·U13 to A29·C13, Figure 1b). In both complexes, the Watson–Crick and Hoogsteen edges of bases from residues of this loop region face the virtually continuous minor groove formed by the coaxially stacked stems 2 and 3 (Figures 1b and 3) and thus generate a pocket for the substrate. Nucleotides G9 (not shown in Figure 3), G12, and G35 form the roof of the cavity, G14 and G(U)31 insert themselves underneath, and C(U)13 and A33 provide the walls, while G30 seals off the back.

Two of the variant residues in the aptamers, C(U)13 and G(U)31, are in direct contact with the guanidino and urea portions of the arginine and citrulline substrates, respectively. However, the orientations of these substrate moieties relative to the minor groove (stems 2 and 3) are quite different. The guanidino group of arginine is practically coplanar with the base plane of residue C13 in stem 3, but the urea part of citrulline is rotated by roughly 90° and is thus nearly perpendicular to the base plane of residue U13. Nucleotide 13 is directly involved in the specific recognition of the substrate, and the O2 and N3 atoms of C13 in the arginine aptamer form hydrogen bonds with the protons at N_ε and $N_{\eta 1}$, respectively. In the citrulline complex, the altered arrangement of hydrogen bond donors and acceptors in the substrate is now matched by U13, which forms contacts to N_ε through its O2 atom and to the carbonyl oxygen through its N3 atom. Nucleotide 13 in turn is held in place by a hydrogen bond to the covariant nucleotide 29. Although the substrate moieties are rotated relative to one another in the binding pockets of the two complexes, the base planes of residues G31 and U31 have similar orientations within the pocket. Thus, the different frameworks of guanine and uracil allow an optimal overlap between the lone pair orbitals of their carbonyl oxygens and the π^* orbitals of the guanidino and urea groups, respectively, providing similar stabilizing contributions in the two aptamer complexes. These structures have clearly revealed how RNA can complex small-molecule ligands with high stability. They have also provided insight into the structural origins of recognition by directly linking variant positions to substrate-specific hydrogen bonding interactions and stereoelectronic effects.

The structures of the ATP and amino acid aptamers demonstrate two radically different ways of how RNA uses one of its common secondary structure elements, an asymmetric internal loop, to acquire a specific function, namely recognizing a small, charged organic molecule by means of hydrophilic and hydrophobic interactions. Both internal loops are rich in purines, many of which were conserved among the molecules isolated

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3605-0481 $ 15.00+.25/0

after several rounds of selection. The loop of the ATP aptamer is longer than that of the arginine aptamer, allowing this binder to adopt more complex folds. Nevertheless, the actual double hairpin fold displayed by the ATP aptamer is unexpected, and it would have been clearly impossible to predict the formation of the prominent hairpin motif by the GAA segment together with the substrate.

The structure of the flavin mononucleotide (FMN) binder reveals yet another way of accommodating a substrate: adoption of a noncanonical duplex by an internal loop region.[15, 17] There, formation of a stretch of noncanonical purine–purine base pairs widens the major groove but leaves stacking intact and generates an intercalation site for the FMN chromophore. The aromatic isoalloxazine system is flanked by a base triple and a G·G base pair, resulting in extensive stacking interactions between substrate and RNA. Additional stability is provided by the formation of two hydrogen bonds between the uracyl-like edge of the intercalated isoalloxazine ring with the Hoogsteen edge of an adenosine residue. Thus, functionally important homopurine base pairs, particularly between guanines, are found in all three RNA aptamer complexes. A common feature of the ATP and arginine/citrulline binders is the recruitment of the bulged guanine residue facing the large portion of the loop. A G·G pair forms, sealing the loop and extending base stacking beyond regular Watson–Crick paired stem regions.

Perhaps not surprisingly, the regions in the substrates that surround the site used to immobilize them on the column during selection are not contacted by the RNA. Thus, the N7 and C8 atoms of the AMP molecule are facing the solvent and the α-amino groups of arginine and citrulline are only loosely bound. It is noteworthy that there is no contact between the RNA aptamer and the phosphate group of AMP. One could argue that the actual interaction mode may depend on the concentration of metal cations in the selection experiments and that the phosphate groups in the folded RNA backbone may not tolerate the accomodation of the substrate phosphate in a binding cleft. However, the stacking of a phosphate group on an adjacent base in the stable U-turn motif in tRNA and c hammerhead ribozyme demonstrates convincingly that RN can deal with such a situation as well. Moreover, closely s aced phosphate groups are tolerated in alternative nucleic acid tructures when compensated for by a variety of stabilizing con ributions.[20] Another notable feature of the arginine aptamer complex is the absence of an interaction between the guar dino group of the substrate and a phosphate. This is quite dif.erent from the situation in protein–DNA complexes, where such interactions occur frequently and help to orient a variety of sequence-recognizing protein folding motifs with respect to the DNA major and minor grooves. The simultaneous contacting of the guanidino system by several bases in the RNA aptamer complex is also strikingly different from the more common, sequence-specific, 1:1 interaction between arginine and the Hoogsteen side of guanine in protein–DNA complexes. This demonstrates a fundamental difference between protein–DNA and protein–RNA interactions. Rather than merely probing for sequence, proteins may recognize RNA through a certain three-dimensional structural motif or folding pattern.

What, then, have we learned from these structures? Seemingly similar RNA secondary structure motifs may generate divergent tertiary and quarternary structures. The backbones in internal loops can wind around a stem in a continuous manner, be sequestered into subdomains, or be zippered up by means of noncanonical base pairs into a stem structure. Just as the clover leaf diagram for tRNA only faintly resembles the actual 3D shape of the molecule, loops may confer different degrees of kinking and result in a range of topologies. However, certain motifs are recurring, despite the small number of available 3D structures of RNA, for example the GNRA loop and a variety of homopurine base pairs at functionally important sites. As might have been expected, RNA and proteins both reach into the same toolbox to master substrate binding and recognition. The formation of the GAAA loop is only possible when the substrate is docked and is thus an induced fit mechanism. Another similarity is the use of the same structural motif; with perhaps a small variation, in an entirely different functional context. Still, the 3D conformational versatility of RNA remains largely unexplored. The door has just been opened a crack; now let's push it wide open!

Polyoxomolybdate giant wheels are linked by Mo-O-Mo bonds in the crystal to form parallel chains, which are illustrated here in a simplified form by the rods. A polyhedral representation of one complete ring is shown, and for the other rings only the 14 molybdenum atoms on the equator of the units are given. More about this unusual system is reported by A. Müller et al. on the following pages.

An Unusual Polyoxomolybdate: Giant Wheels Linked to Chains**

Achim Müller,* Erich Krickemeyer, Hartmut Bögge, Marc Schmidtmann, Frank Peters, Carsten Menke, and Jochen Meyer

Dedicated to Professor Gottfried Huttner on the occasion of his 60th birthday

Complex systems in biology are built up in a stepwise manner through a sequence of programmed chemical processes. The chemist is in a position to connect elementary building blocks and their derivatives in different ways, enabling him to synthesize a large variety of important and remarkable substances. Of particular interest in this context are the simple anionic species of the type EO_n^{m-} (E = elements of the p and d block in high oxidation states), which also play an important role beyond the domain of the chemist and his laboratory,[1-5] for example in the geosphere (silicates) and biosphere (diatoms). We have employed the above-mentioned reaction types and previously succeeded in isolating compounds with discrete structures that themselves have a molecular size and mass of the order of proteins.[3] We have now succeeded in taking the next step on a promising pathway: the linking of such giant particles.

The blue, mixed-valence (type III according to Robin and Day) diamagnetic compound **1**[6,7] was isolated by a stepwise reduction of a hydrochloric acid solution containing poly-

$$Na_{15}\{Mo_{144}O_{409}(OH)_{28}(H_2O)_{56}\}\cdot ca.250\,H_2O \quad \mathbf{1}$$

molybdate ions in the presence of sodium ions. The preparation yields well-formed, triclinic crystals of **1**, as well as a fraction of poorly crystalline material (for further discussion of this problem see ref. [3 b]). The compound was characterized by spectroscopic methods (Vis/NIR, IR, Raman, and ESR spectroscopy), elemental analyses (also of single crystals), and manganometric redox titration as well as by X-ray crystallography.[6] (For details of error limits see below and ref. [7]).

The rather intricate single-crystal X-ray structure analysis[6] revealed that the characteristic structural features of **1** are chains of linked rings (Figure 1), which resemble, apart from defects in **1**, the recently published compound **2** (Figure 2). Thus, the

$$(NH_4)_{25\pm5}[Mo_{154}(NO)_{14}O_{420}(OH)_{28}(H_2O)_{70}]\cdot ca.350\,H_2O \quad \mathbf{2}$$

triclinic unit cell of **1** contains two crystallographically different ring-shaped $\{Mo_{144}O_{409}(OH)_{28}(H_2O)_{56}\}$ building units, which occupy two inversion centers. The structural similarities that they possess are discussed as follows: Two neighboring rings are formally linked (at (H_2O) Mo=O positions of **2**) by four Mo-O-Mo groups through a type of condensation process (cf. Figure 2). The similarity of the ring-shaped building units in **1** and **2** is particularly significant above all with respect to the presence of 14 $\{Mo_8\}$ basic fragments in each case, which also appear in numerous related giant clusters.[3-5] In addition, the OH groups and the reduced Mo centers are at the same position in

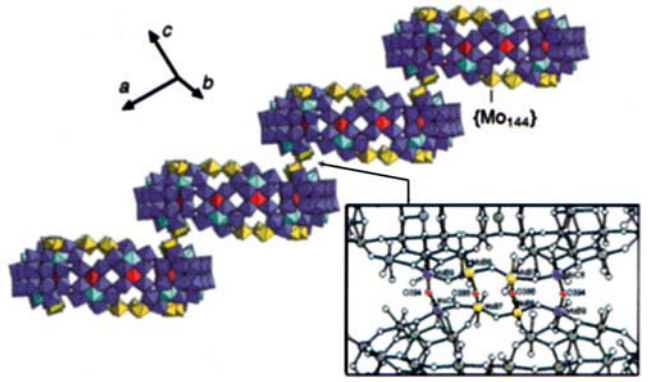

Figure 1. Polyhedral representation of a selected chain in **1** and ball-and-stick representation of the linking types (the linking centers are identical with the crystallographic inversion centers). Color coding of the polyhedra: Mo octahedra: blue; pentagonal bipyramids in the centers of the $\{Mo_8\}$ units: turquoise; $\{Mo_2\}^{2+}$ groups linking the $\{Mo_8\}$ units: yellow; $\{Mo_1\}$-type linking units: red.

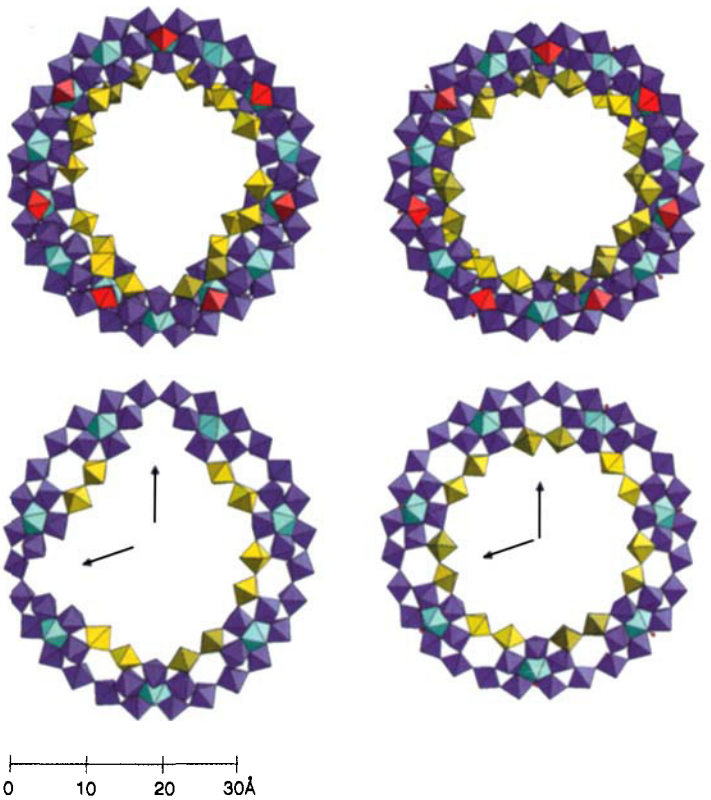

Figure 2. Comparison of the rings in **1** (left) and **2** (right). Top: Complete rings; bottom: View of only the upper half of each ring to clarify the positions of the missing $\{Mo_2\}$ units in **1**. These missing $\{Mo_2\}$ groups in **1** lie at the positions indicated by arrows and correspond to the hatched yellow polyhedra in **2**. The relevant Mo positions in **1** that are involved in bridges possess a $(H_2O)Mo{=}O$ function in **2**. The hatched position in **1** is occupied up to about 50% with an $\{Mo_2\}$ group (color coding as in Figure 1).

both compounds **1** and **2**.[3a] In **2** the $\{Mo_8\}$ units above and below the equator of the ring are each connected through seven (in total 14) $\{(H_2O)O_2Mo{-}O{-}MoO_2(H_2O)\}^{2+}$ units ($\equiv\{Mo_2\}^{2+}$), which are positioned at the upper and lower edges of the central cavity resulting in an approximate D_{7d} symmetry.[3] As shown in the bottom of Figure 2 (marked by arrows), a total of five of these connecting units are missing at certain positions in **1**. This correlates with the observation that the rings in **1** are somewhat compressed at these

[**] We wish to thank Prof. Dr. G. M. Sheldrick (Universität Göttingen, Germany) for allowing us to use the unpublished program SHELXS-96.

positions and thereby possess an ellipsoidal appearance. Formally, the following structure or construction principle emerges for the rings in **2** and **1**, respectively: 14 $\{Mo_8\}$ units are linked through 14 $\{Mo_1\}$ and $14-x$ $\{Mo_2\}$ groups ($\{Mo_{154}\}$ ($\{Mo_{144}\}$ in **1**) $\equiv$ [14 $\{Mo_8\}$ +14 $\{Mo_1\}$] +14 $\{Mo_2\}$ (partially occupied in **1**)). This corresponds to the formula $\{Mo^{VI}_2O_5(H_2O)_2\}_{14-x}\{Mo_9O_{26}(OH)_2(H_2O)_3\}_{14}$ ($x = 5\pm1$ for **1**). The $\{Mo_1\}$ units refer to the Mo centers that link the $\{Mo_8\}$ fragments in the equatorial plane (see Figure 2 and ref. [3a]).

An essential difference between the preparation of **2** and **1**, is that elemental iron was used instead of $NH_2OH\cdot HCl$ as the reducing agent in **1**. Since under the chosen reaction conditions (low pH values), species exist with the above-mentioned $\{Mo_8\}$ fragments,[3, 4] which possess a pentagonal bipyramid of the type $Mo(NO)O_6$ (or MoO_7) in their center, the replacement of $\{ONMo\}^{3+}$ fragments of **2** by $\{OMo\}^{4+}$ in **1** leads to a lower negative charge on the intermediate products in solution (cf. refs. [3–5]). Current knowledge suggests that a lower charge density not only facilitates a further condensation, but also leads to a lower nucleophilicity and consequently to a lower occupation of the $\{Mo_2\}$ positions. This is evidently essential for the formation of **1**. Therefore, it is basically possible to control the relevant connectivity (and consequently the cluster size) through changes in pH value and reduction state (or charge density). An increase in the H^+ ion concentration favors condensation, whereas an increasing charge density has the opposite effect. This assertion is valid for the relevant range of H^+ and Mo^V/Mo^{VI} concentrations. The final product at high H^+ concentration, when no reducing agent is present, is $MoO_3\cdot 2H_2O$, which shows certain structural similarities to **1** and **2**, that is, coordinated and noncoordinated H_2O molecules.[9] In this context it is interesting to note that a "molybdenum blue" solution contains species that correspond to hydrated and protonated molecular (polynuclear) molybdenum trioxide with the approximate composition $(MoO_3)_m(H_2O)_nH_p$ and in particular with basic ring-shaped structures (see ref. [4]). The structural differences between the rings in **1** and **2** are so insignificant that they are only marginally reflected in their IR (i.e. by a characteristic band at about 750 cm^{-1}) and Vis/NIR spectra. In the case of the IR spectrum, this is a consequence of the weakly coupled vibrations located mainly in units that are terminated by heavy Mo atoms.[4]

These investigations substantiate our view expressed in the introduction that one can anticipate further important results in the area of polyanion and polycation chemistry with respect to aspects of structural chemistry and materials research (cf. zeolite research[10]). Here, in **1**, for example, chains exist that are built up from electron storage units! This reaffirms that a type of organization principle[1b] is operating that is based on the high formation tendency of $\{Mo_8\}$ fragments and their ability to link together in different ways.[3,4]

It is especially remarkable that oxide phases with the previously mentioned structural variety are found not only at the molecular level but also in macroscopic forms. This is shown quite impressively by the "artistic" structures that are formed from ten thousand different types of diatoms which have eukaryontic cells. In the diatoms, the connection of XO_4 units occurs under dissipative conditions, that means under entropy export in an open system.[11, 12] Now the central question arises, whether it is possible, under dissipative conditions, to create similar macroscopic metastable structures formed from other EO_n basic units (dissipative self-organization leading to a stationary nonequilibrium state[13]). In any case, it can be presumed that with a knowledge of the intrinsic features of the investigated reaction system, coupled with the relevant choice of special reaction conditions, a huge variety of novel molecular structures with high complexity and multifunctionality[14] can be created, based on conservative processes in the area of polyoxoanion chemistry.

Experimental Section

1: A solution of $Na_2MoO_4\cdot 2H_2O$ (p.a.) (50 g, 206.7 mmol) in H_2O (450 mL) in a 500 mL Erlenmeyer flask was adjusted with stirring to a pH value of about 0.8 with 32% hydrochloric acid (p.a.). After addition of iron powder (500 mg, 9 mmol) (Merck; 150 μm) the mixture was left to stand at 20 °C (hydrogen evolution) in a flask covered with a watch glass. After 24 h, a further 500 mg of iron powder was added to the deep-blue reaction mixture which was allowed to stand without further disturbance (to improve the formation of crystals). After 5 to 6 weeks of **1** was separated with a glass frit under an argon atmosphere, and dried in an argon atmosphere over calcium chloride. Yield: 10.5 g (27.4% based on Mo). Compound **1** also forms in a shorter time at a higher temperature but precipitates without a significant crystalline fraction. Characterization of **1**: IR (KBr disk, under argon, some characteristic bands): $\tilde{\nu}$ [cm^{-1}] = 1614 (m, $\delta(H_2O)$), ca. 995 (sh), 972 (m), 911 (w–m) (ν(Mo=O)), ca. 810 (sh), 746 (s), 713 (m), 633 (s), 557 (s). Vis/NIR (degassed H_2O; adjusted to pH 1.5 with HCl, the structure of **1** in solution is unknown, but the number of Mo^V centers is the same as in the solid **1**, see [7]): λ[nm] (ε_M[10^5 L mol^{-1} cm^{-1}]) = 745 (1.7, intervalence charge transfer (IVCT)), 1060 (1.4, IVCT) (bands in degassed methanol: 745 and 1045 nm); for additional control solid-state Vis/NIR spectrum (KBr pellet in transmission): ≈750 and ≈1080. The ε value, which is dependent on the numbers of Mo^V centers, can be interpreted in solution upon chain cleavage.

[6] **1**: space group $P\bar{1}$; $a = 2540.9(7)$, $b = 3415.3(8)$, $c = 4510.2(14)$ pm, $\alpha = 91.28(2)$, $\beta = 92.14(2)$, $\gamma = 100.59(2)^\circ$, $V = 38429(18)\times 10^6$ pm^3 ($\mu = 23.9$ cm^{-1}); $Z = 2$; solution with direct methods, $R = 0.124$ for 39487 independent reflections ($F_o > 4\sigma(F_o)$); Siemens R3m/V diffractometer $Mo_{K\alpha}$ radiation, graphite monochromator. Because of the long time required for data collection, the deep blue crystals of **1** were mounted in oil when removed from the mother liquor, and the measurement was conducted at −70 °C. The measurements of other individual crystals gave the same results. The data set was measured to a 2θ value of 39°. The structure was solved by using the program SHELXS-96, and refined with the program SHELXL-93. A comparison of the structures of **1** and **2** showed that at the corresponding positions where electronically shielded reduced Mo centers (which means MoNO groups) occur in **2** [3, 5], M=O groups with Mo^{VI} centers are incorporated into **1**. In addition, the distribution of the other reduced Mo centers as well as H_2O and OH ligands is practically identical in **1** and **2**. Furthermore, a symmetric O=Mo–O–Mo-(H_2O)↔(H_2O)Mo–O–Mo=O disorder is found at the linking positions in the rings in **1**. Our interpretation of this disorder is chemically motivated, as the observed distribution of the electron density could in principle be crystallo-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3605-0485 $ 15.00+.25/0

graphically interpreted by the existence of HO–Mo–O–Mo–OH units. Our elucidation is supported by the fact that we could explain the previously mentioned disorder in related structures that show an analogous type of linking. In addition, the comparable O=Mo–H_2O-/H_2O–Mo=O disorder is found in numerous other (also mononuclear) compounds. Furthermore, all molybdenum atoms with two (*trans* positioned) or three non-bridging oxygen ligands (52 in total) possess a coordinated H_2O ligand. The sodium atoms are disordered to the extent that it was not possible to determine all of their positions. Therefore, several sodium analyses were carried out. The detection of a somewhat higher Na value than expected from the given formula for **1** correlated with the discovery of chloride in the elemental analysis (about 0.4% Cl corresponding to about 0.4% Na excess). The presence of about 1000 atoms in the asymmetric unit of **1** could indicate that we are dealing here with one of the most complicated inorganic structures. The figures were prepared with the program DIAMOND ("Diamond, Informationssystem für Kristallstrukturen" by Dr. K. Brandenburg, Universität Bonn, Germany). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-406337.

[7] Due to the size of the system, the complexity of the structure, the quality of the measurement and the crystals, and the disorder in the system, it is reasonable to expect that the given formula has an error limit. The number of oxygen (409) and molybdenum (144) atoms, have—in agreement with the disorder—error limits of ± 5 and ± 2, respectively. The related value for the anion charge is 15 ± 3 (see also ref. [6]). The results of the manganometric titration and the extinction coefficient of the IVCT band at higher energy of the type $Mo^{V} \rightarrow Mo^{VI}$ show in **1** as in **2** (without consideration of the electronically inert MoNO groups) that 33 ± 3 molybdenum centers are according to the present study (formally) reduced. These are distributed as in **2** (cf. ref. [3]), and thus only the $\{Mo_1\}$ and $\{Mo_8\}$ groups are involved in the related electron delocalization [8]. The number of delocalized electrons (in the 4d pseudo band) is 33 ± 3, also practically in agreement with the given charge of the anion of **2**, at the lower limit of error (20− [3a], which corresponds to the more realistic value).

[8] The mixed-valence compound **1** features a small phase range with respect to the stoichiometry, a phenomenon which is certainly more common in metal chalcogenide solid-state structures than is frequently assumed (". .progress is still blocked by a slavish devotion to the cult of the molecule and a naive faith in the general applicability of Dalton's laws of chemical combination.": N. N. Greenwood, *Ionic Crystals, Lattice Defects, and Nonstoichiometry*, Butterworths, London, **1968**, p. 5). This type of compound, however, is found especially frequently in mixed-valence transition metal chalcogenides, which, precisely because of this feature, also exhibit important physical features like superconductivity (*Mixed Valency Systems: Applications in Chemistry, Physics and Biology*, (Ed.: K. Prassides), Kluwer, Dordrecht, **1991**). Interestingly, the anion of **1** shows the composition of the hydrogen–molybdenum bronzes H_xMoO_3 (see A. F. Wells, ref. [1a], pp. 617–618) that demonstrate conductor as well as storage properties of electrons and protons (for general aspects see also *Low-Dimensional Electronic Properties of Molybdenum Bronzes and Oxides*, (Ed.: C. Schlenker), Kluwer, Dordrecht, **1989**).

Unprecedented Layered Structure of a Fulleride: Synthesis, Structure, and Magnetic Properties of a Potassium-Containing Salt with a C_{60}^{2-} Counterion**

Thomas F. Fässler,* Annette Spiekermann, Michael E. Spahr, and Reinhard Nesper

Dedicated to Professor Hans Georg von Schnering on the occasion of his 66th birthday

Since the discovery of superconductivity[1] and ferromagnetism[2] in alkali metal (A) fullerides of the type A_3C_{60},[3,4] there has been considerable interest in the magnetic and structural properties of compounds containing C_{60}^{2-} anions ($n = 1$–6). Although many intercalation compounds have been synthesized, they are frequently polycrystalline powders with anions in a statistical orientational disorder.[3,5–7]

Knowledge of the molecular structure of C_{60} anions and their mutual interaction is especially important for understanding the physical properties of these intercalation compounds.[8,9] Symmetry-lowering vibrations and intermolecular interactions of the fulleride molecules have been discussed within the framework of an electron–phonon mechanism of superconductivity.[10–12] The threefold degeneracy of the LUMO in MO models of C_{60} allows degenerate ground states for the anions[14] leading to lower symmetries for these molecules.[15] Although C_{60}^{-} and C_{60}^{3-} display the expected paramagnetic properties,[16] the nature of the ground state in C_{60}^{2-} is controversial.[3,17,18]

We recently reported the high-yield syntheses and structures of [K([2.2.2]crypt)] salts[19] of the paramagnetic trianions of the heavier carbon homologues E_9^{3-} (E = Ge, Sn, Pb).[20] An attempt to synthesize and crystallize the trianion of C_{60} resulted in the isolation of $[K([2.2.2]crypt)]_2C_{60}$ (**1**) as transparent, red, rhombic crystals [Eq. (a)]. To our knowledge, only one other

$$C_{60} \xrightarrow[\text{toluene/[2.2.2]crypt}]{\text{DMF / K}} [K([2.2.2]crypt)]_2C_{60} \qquad \text{(a)}$$

crystal structure determination of a compound with ordered dianions, $(PPN)_2^{+}C_{60}^{2-}$, has been reported.[18] However, the fullerene molecules in this compound are completly separated by the cations. Here we report the structure and the magnetic properties of a novel alkali metal fulleride salt containing alternating layers of ordered C_{60}^{2-} anions and $[K([2.2.2]crypt)]^{+}$ cations.

The results of a single crystal structure determination of **1** at room temperature were consistent with the space group $C2/c$.[21] However, only one [K([2.2.2]crypt)] moiety could be localized in the asymmetric unit of the unit cell. An investigation of the crystals at lower temperatures showed an increase in intensity for many weak reflections. Using the data collected at 113 K, we were able to identify fragments of a fullerene molecule in the difference Fourier map in addition to the [K([2.2.2]crypt)] unit. Further refinement with a localized model for C_{60} was possible in the acentric space group Cc. Two [K([2.2.2]crypt)] units were observed for each C_{60} molecule (Figure 1a). The coordination

[**] This work was supported by the ETH Zürich. We are grateful to H.-J. Muhr, Dr. M. Wörle, and Prof. L. Venanzi for valuable discussions.

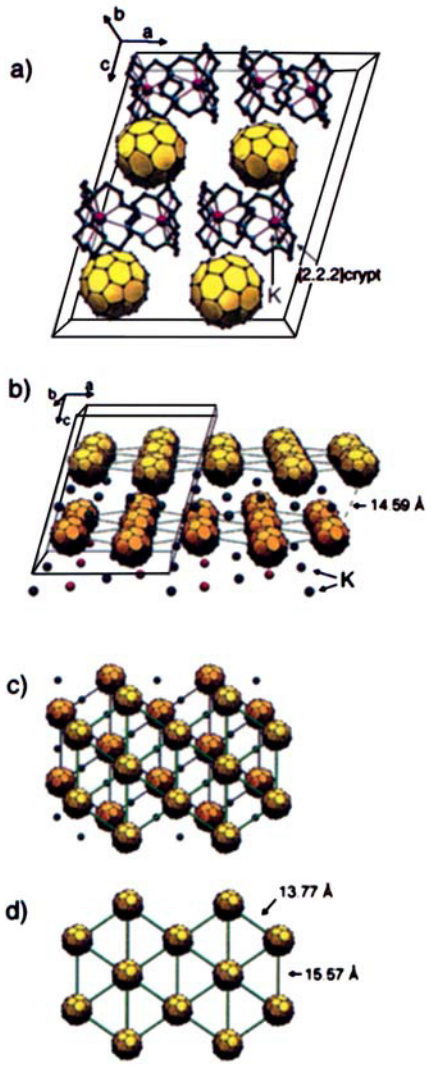

Figure 1. a) Structure of crystalline **1**·4toluene. Unit cell as viewed along the *b* axis. The ordered fullerene molecules are seperated by layers of $[K([2.2.2]crypt)]^+$ cations; solvent molecules (not shown) are also ordered. b)–d) Layered arrangement of the fulleride ions. Only the potassium atoms of the [K([2.2.2]crypt)] units are shown. The C_{60} anions form a distorted, hexagonal close packing; b) view along the *b* axis; c) view orthogonal to the *ab* plane; d) one distorted hexagonal layer.

sphere of the potassium atoms consists of the two nitrogen and six oxygen atoms of the cryptand molecule at distances typical for potassium cations.[20] This allows a charge assignment of -2 to the fullerene molecule. Additionally, each formula unit of **1** contains four ordered toluene molecules. Although the C_{60} anions are ordered, the sixty crystallographically independent carbon atoms possess larger displacement parameters than the other atoms.

The refinement was constrained so that there are two unique C–C bond lengths as is the case for an ideal C_{60} molecule; those are at 6:6 and 5:6 ring junctures. The resulting distances of 1.39(1) and 1.45(1) Å are identical within the standard deviation (3σ-limit). However, the trend of shorter 6:6 bonds is followed; these bonds are longer than those in the neutral C_{60} molecule (average values for 6:6 and 5:6 distances, respectively, in C_{60} 1.355(9) and 1.449(3) Å,[22] in $[Ni(C_5Me_5)_2]^+C_{60}^-\cdot CS_2$ 1.389(3) and 1.449(3) Å,[23] and in $(PPN)_2^+C_{60}^{2-}$ 1.399(2) and 1.449(3) Å[18]).

The fulleride ions form distorted hexagonal layers, which are parallel to the *ab* plane and separated by the [K([2.2.2]crypt)] cations (Figure 1b–1d). The distances between the centers of gravity of the fulleride ions are 13.77 (4×) and 15.66 Å (2×) within an anion layer and 14.59 Å (2×) between the layers (four longer distances of 15.48 and 17.46 Å). The coordination number 12 results from the distorted, hexagonal close packing of the fulleride ions. Short intermolecular C···H contacts with the hydrogen atoms of the toluene and cryptand molecules (four contacts in the range of 2.59–2.70 Å) could be responsible for the high degree of orientation of the C_{60} molecules.

EPR investigations of powders of **1** at room temperature show an isotropic signal with a *g*-value of 2.01.[24] Susceptibility measurements[25] display a temperature-dependent paramagnetism, which cannot be described as Curie–Weiss behavior (Figure 2). The effective magnetic moment increases rapidly

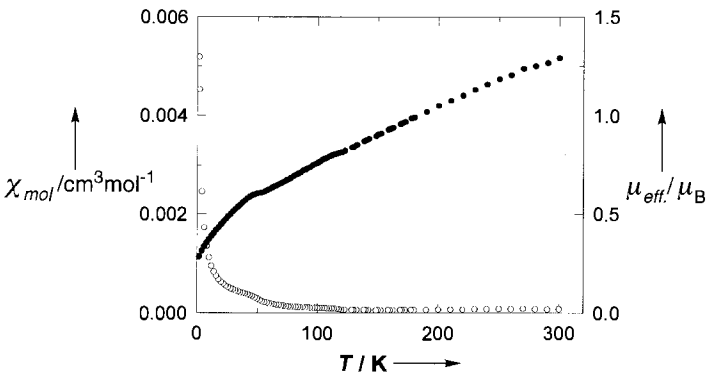

Figure 2. Temperature dependence of the magnetic susceptibility χ_{mol} (○) [25] and the effective magnetic moment μ_{eff} (●).

with temperature and reaches a value of 1.29 μ_B at 300 K. This is below the expected value of 2.83 μ_B calculated for an isolated spin-triplet ($S = 1$), but in the range found for other dianionic fulleride salts.[28] The decrease in the effective magnetic moment with decreasing temperature could be caused either by strong antiferromagnetic coupling or an increase in spin-singlet states ($S = 0$). The relatively large distances (>13.77 Å) between the centers of the C_{60}^{2-} ions in the crystal should give rise only to very weak antiferromagnetic interactions. In contrast, a singlet ground state and an energetically very low lying triplet state have been discussed for the dianion.[3, 14, 17c]

The spin system in **1** is more dilute than in other compounds; the shortest distances between the centers of the fulleride ions are approximately 1 Å longer than in related compounds.[16, 18] As intermolecular interactions between the buckminsterfullerides in an anion layer can be excluded, further spectroscopic investigations on dianions of C_{60} in the solid state are possible.

Experimental Section

1: Potassium (10.8 mg, 0.28 mmol) and C_{60} (50.0 mg, 0.07 mmol) were added to freshly destilled dimethylformamide (DMF, 3 mL) in a Schlenk tube under an argon atmosphere. The mixture was stirred for 20 hours. [2.2.2]Crypt (104.6 mg, 0.28 mmol) was added to the intense deep-red solution, and the resulting mixture layered with toluene (1 mL). Crystalline product formed after several days at −20 °C. After decanting the solvent, the product was washed with toluene and dried under vacuum. Yield: 50 mg (38%); elemental analysis for **1**·3DMF ($C_{105}H_{93}K_2N_7O_{12}$): calcd C 71.21, H 5.25, N 5.53, K 4.42; found C 70.70, H 5.11, N 4.97, K 4.29.

[21] Structure determination of **1**·4toluene: a crystal plate of dimensions $0.30 \times 0.20 \times 0.08$ mm^3 was inserted into a glass capillary after decantation of the solvent. Lattice parameters at 293 K: $a = 23.84(2)$, $b = 15.36(1)$, $c = 28.90(2)$ pm, $\beta = 112.00(6)^\circ$; $V = 9814.9 \times 10^6$ pm^3; at 113 K: $a = 22.696(4)$, $b = 15.580(2)$, $c = 27.523(4)$ pm, $\beta = 106.20(2)^\circ$; $V = 9346.0 \times 10^6$ pm^3, space group Cc (monoclinic), $Z = 4$. $\rho_{calcd} = 1.365$ g·cm^{-3}. Data collection: STOE IPDS, $Mo_{K\alpha}$ radiation, $2\theta_{max} = 48.28^\circ$ (Image plate distance 80 mm), $T = 113$ K, of 26093 reflections 12086 were independent ($R_{int} = 16.3\%$). $R_1 = 10.9\%$ for 962 parameters and 5228 reflections with $I > 3\sigma(I)$, $wR = 28.3\%$ (based on F^2). Structure solution (direct methods) and refinement (based on F^2) were carried out with SHELXS-86 and SHELXL-93 programs, respectively (G. M. Sheldrick, Universität Göttingen). By applying direct methods, a [K([2.2.2]crypt)] unit could be localized in the space group $C2/c$ for both the room-temperature and low-temperature data. The maxima of difference electron density are situated on a sphere and reveal portions of five- and six-membered ring structures. Several models were considered for the refinement of the fullerene molecule. Application of a model with complete orientational disorder of the fullerene molecules using a hollow sphere with the integral electron density of 60 carbon atoms (Bessel function) did not lead to a significant improvement. The difference density maxima could be fitted, and the structure further refined with a localized model in space group Cc. A transformation of the coordinates to $C2/c$ showed that the twofold rotation axis of the fullerene molecule is tilted with respect to the crystallographic rotation axis. A refinement with a corresponding 50:50 split model led to a poor fit with the data and lower resolution of the electron density. Although the space group $C2/c$ cannot be excluded by the current data, the refinement was completed in Cc in two blocks with a total of 460 coupled parameters (the displacement parameter of neighboring carbon atoms of the fullerene molecule were constrained by means of the DELU (SHELXL93) command). Maximum and minimum residual electron density: 0.9 and -0.7 e Å^{-3}. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication no. CCDC-100-074. Copies can be obtained free of charge on application to The Director, CCDC, 12 Union Road, GB-Cambridge CB21EZ (Fax: Int. code +(1223)336-033, e-mail: deposit@chemcrys.cam.ac.uk).

[24] EPR spectra were recorded on a Varian E-12 EPR spectrometer.
[25] Magnetic susceptibility measurements were carried out with a SQUID magnetometer (MPMS 5, Quantum Design) at a magnetic field of 1000 G. An aluminum crucible in a suprasil tube (diameter = 5 mm) was used as a sample holder, and its signal experimentally corrected. For the determination of the paramagnetic molar susceptibility, the diamagnetic contribution for the two [K([2.2.2]crypt)] moieties and three DMF molecules ($\chi_{mol}^{dia} = -624.6 \times 10^{-6}$ cm^3 mol^{-1} [26]) were substracted from the total molar susceptibility. The contributions of C_{60} to the total susceptibility can be ignored as the diamagnetic and paramagnetic components cancel out [3, 27]. Measurements (30 mg samples from different reactions) on analytically pure powders of **1**·3DMF gave identical temperature dependencies. Minor contributions from molecular oxygen, which also appear in pure C_{60} [27], cannot be excluded. Further investigations on the magnetic properties and the appearance of a shoulder at about 50 K (Figure 2) are yet to be carried out.

Double Helical Octaphenylene**

Andrzej Rajca,* Andrej Safronov, Suchada Rajca, and Richard Shoemaker

Chiral π-conjugated molecules and polymers attract continuing interest as synthetic challenges and organic materials with interesting electronic properties.[1–4] Our strategy in design of such materials centers on a double helical π-conjugated system that combines chirality with molecular entanglement and very high barriers for racemization. Such molecules or polymers may facilitate better three-dimensional interactions and chirooptical properties. In addition, there is the intriguing question about the effect on electrical conductivity, especially in the presence of external magnetic fields.[2–4]

The approach to the double helix is inspired by the achiral carbon allotrope, "three-dimensional graphite", proposed by Riley et al.[5] This structure may be conceived as composed of double helical polymers, in which two polyphenylene helices are intertwined or tetra-*o*-phenylene units sequentially annelated. The beauty of this double helix, the important materials properties associated with polyphenylenes, such as electrical conductivity and electroluminescence, and the very high barriers for racemization of tetra-*o*-phenylenes provide impetus for synthesis of fragments of this double helix such as *t*Bu-substituted octaphenylene **1** (Figure 1).[6–8]

Double helices are typically assembled from single strands by metal ion complexation, hydrogen bonding, etc.[9, 10] An alter-

[**] This research was supported by the National Science Foundation (DMR-9204826 and CHE-9510096). We thank Dr. R. Cerny of the Nebraska Center for Mass Spectrometry for the mass spectral determinations. We thank Dr. Charles R. Ross, II for the help with the X-ray crystallography and graphics.

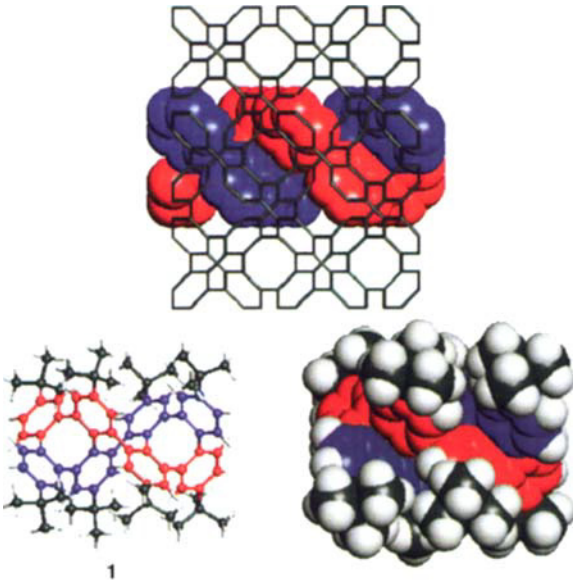

Figure 1. Top: Space-filling model for a double helical polyphenylene molecule, derived from a three-dimensional carbon net; bottom left: Double helical octaphenylene **1**; bottom right: Space-filling model for **1**. The two helices are colored red and blue; *t*Bu groups are shown in grey/black.

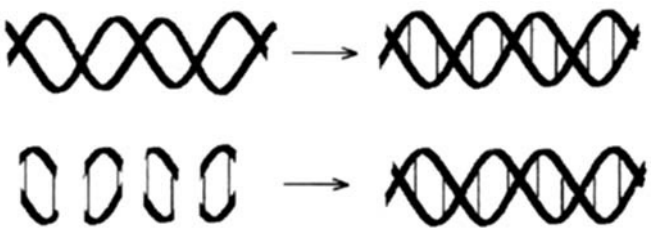
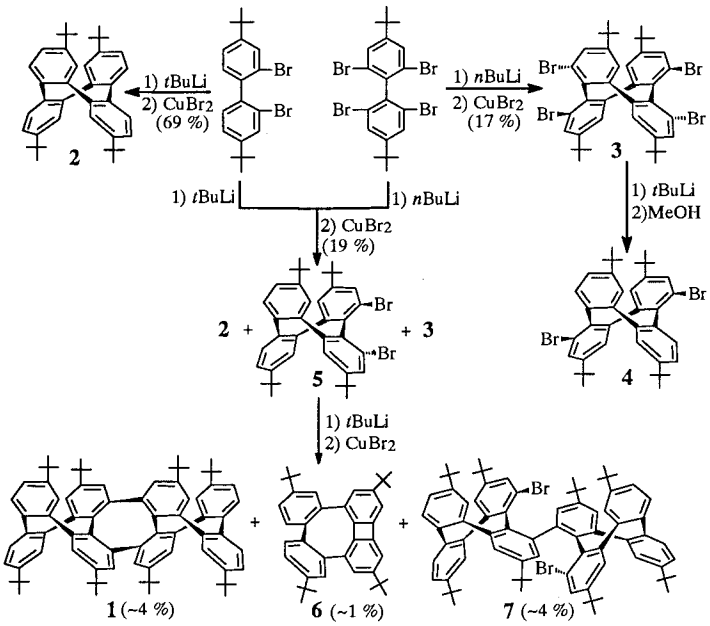
native route to a double helix is based on sequential connection of doubly helical fragments; this may be advantagous in reducing the number of degrees of freedom when kinetically controlled, irreversible reactions of organic synthesis are employed (Scheme 1). We report here on the synthesis of octaphenylene **1**, the first example of a double helical π-conjugated hydrocarbon, by sequential annelation of two tetra-*o*-phenylene fragments.



Scheme 1. Formation of a double helix by stepwise linkage of double helical fragments.

Following the double Li/Br exchange on 2,2′-dibromo-4,4′-di-*tert*-butylbiphenyl and 2,2′,6,6′-tetrabromo-4,4′-di-*tert*-butylbiphenyl, the resultant dilithiobiphenyls are oxidized with $CuBr_2$ to give **2** and **3**, respectively (Scheme 2, Table 1).[11–14] When tetraphenylene **3** is subjected to Li/Br exchange, and reaction mixture is quenched with MeOH, the 4,13-dibromo-substituted tetraphenylene **4** is obtined as the major product; the arene protons of **4** show no NOE effect (<1%). Moreover, the desired 4,5-dibromo-2,7,10,15-tetra-*tert*-butyl(tetra-*o*-phenylene) **5** is not detected in the reaction mixture. Similarly, attempts to selectively dimetalate **2** failed. Apparently, the stablizing effect of the ion triplet, which is invoked for planar 2,2′-dilithiobiphenyl and other analogous dilithium compounds, does not apply to these nonplanar, rigid derivatives of biphenyl.[15–17]

When a 1:1 mixture of 2,2′-dilithio-4,4′-di-*tert*-butylbiphenyl and 2,2′- dilithio-4,4′-di-*tert*-butyl-6,6′-dibromobiphenyl is treated with $CuBr_2$, **5** can be separated from the symmetrical coupling products **2** and **3** (Scheme 2, Table 1). The structure of



Scheme 2. Synthesis of octaphenylene **1**. Except for the reaction step leading to tetraphenylene **4**, which was carried out in THF, the aryldilithium compounds were generated by adding 2.5 M *n*BuLi in hexane (1+ equiv) or 1.7 M *t*BuLi in pentane (2+ equiv) to the bromoaryl compound in ether at −78 °C. After 2 h at −78 °C, dry $CuBr_2$ (3 equiv) was added. The reaction mixture was allowed to warm to room temperature over 12 h and then usual aqueous workup was performed.

5 is confirmed by the presence of an NOE (12%) between H8 and H9 (and the other symmetry-related pair). After dilithiation of **5** and subsequent oxidation with $CuBr_2$, **1**, **6**, and **7** could be isolated. The structure of the double helical octaphenylene **1** is confirmed by mass spectrometry (HR-MS) and NMR spectroscopy.[18] In the mass spectrum (EI), the most intense cluster (relative intensity 100%) in the range m/z 100–1350 corresponds to M^+; the M^+, $[M+1]^+$, $[M+2]^+$, $[M+3]^+$ peaks have masses within less than 2 ppm of the calculated values and possess adequate relative intensities for $C_{80}H_{92}$. The spectrum shows only three other clusters with relative intensities greater than 10%, which are identified as follows: $[M-CH_3]^+$ (29%), $[M]^{2+}$ (15%), $[M-2CH_3]^{2+}$ (50%). The ^{1}H NMR spectrum ($CDCl_3$) contains two resonances for *t*Bu groups (36/36) and a set of five resonance signals (4/4/4/4/4) for the arene protons; ^{13}C DEPT/NMR spectra corroborate the spectral assignment. In the arene region of the ^{1}H NMR spectrum, a 2D-COSY correlation indicates that the three most downfield resonances (dd, d, d, J = 8, 2 Hz) and the two most upfield resonances (d, d, J = 2 Hz) correspond to protons at the outer and inner benzene rings, respectively.

The NOE studies were carried out for **1** in CD_2Cl_2. The ^{1}H NMR spectra in $CDCl_3$ and CD_2Cl_2 are similar, except for differences in chemical shifts. The 2D-ROESY experiment (Figure 2) gives two negative-phase cross peaks, between protons H3 and H5 and H3 and H4 (integrated ratio of 5/1).[19] In the 1D NOE experiment, the H3,H5 and H3,H4 proton–proton contacts give an NOE of 10% and no NOE (<2%), respectively. The H3,H5 contact (r = 3.0 Å)[20] is similar to the H8,H9 contact in **5**, and the H3,H4 contact (r = 3.8 Å)[20] is characteristic of the double helix of **1**.

UV/Vis spectra (cyclohexane) for **1** (λ_{max} = 219, 253 (sh), 288 (sh) nm) and **2** (λ_{max} = 219, 242 (sh), 278 (sh) nm) possess similar spectral envelopes.[21, 22] These spectra can be compared to the longest wavelength absorptions for oligo-*p*-phenylenes(247, 279, and 294 nm for biphenyl, terphenyl, and quaterphenyl, re-

NOE (500 MHz, $CDCl_3$, 7.30): $\delta = 7.07$ (12%), 7.01 (<1%); $^{13}C\{^1H\}$ NMR/DEPT (125 MHz, $CDCl_3$): $\delta = 152.0$ (q), 150.0 (q), 143.4 (q), 141.5 (q), 138.3 (q), 137.4 (q), 129.0 (CH), 128.1 (CH), 125.1 (CH), 124.6 (CH), 124.14 (CH), 124.07 (q), 34.7 (q), 34.5 (q), 31.4 (CH_3), 31.2 (CH_3).

6: yellow powder, m. p. 125–130 °C, yield 1%; HR EIMS: *m/z* (ion type, relative intensity in % for *m/z* 50–550, deviation for the formula): 526.36026 ($[M]^+$, 10%, 0.6 ppm for $^{12}C_{40}H_{46}$), 511.33570 ($[M-CH_3]^+$, 3%, −1.5 ppm for $^{12}C_{39}{}^1H_{43}$); ^{1}H NMR (500 MHz, $CDCl_3$): $\delta = 7.32$ (d, $J = 2$, 2H), 7.25 (dd, $J_1 = 2$, $J_2 = 8$, 2H), 7.16 (d, $J \sim 1$, 2H), 6.83 (d, $J = 8$, 2H), 6.66 (d, $J \approx 1$, 2H), 1.34 (s, 18H), 1.30 (s, 18H).

7: white powder, m.p. 135–141 °C, yield 4%; LR EIMS: *m/z* (relative intensity in % for *m/z* 500–1350): 1210.5 (45), 1211.5 (40), 1212.5 (100), 1213.5 (80), 1214.5 (75), 1215.5 (45), 1216.5 (15); calcd for $C_{80}H_{92}Br_2$: 1210.6 (43), 1211.6 (38), 1212.6 (100), 1213.6 (80), 1214.6 (75), 1215.6 (46), 1216.6 (18); ^{1}H NMR (500 MHz, $CDCl_3$, ^{1}H-^{1}H COSY cross peak in the region of the arene protons): $\delta = 7.31$ (d, $J = 2$, 2H, 7.14), 7.29 (d, $J = 2$, 2H, 7.18), 7.245 (d, $J = 2$, 2H, 6.94), 7.18 (dd, $J_1 = 2$, $J_2 = 8$, 2H, 7.29, 7.08), 7.14 (dd, $J_1 = 2$, $J_2 = 8$, 2H, 7.31, 6.97), 7.08 (d, $J = 8$, 2H, 7.18), 7.05 (d, $J = 2$, 2H, 6.79), 6.97 (d, $J = 8$, 2H, 7.14), 6.94 (d, $J = 2$, 2H, 7.245), 6.79 (d, $J = 2$, 2H, 7.05), 1.27 (s, 18H), 1.141 (s, 18H), 1.135 (s, 18H), 0.92 (s, 18H); $^{13}C\{^1H\}$NMR/DEPT (125 MHz, $CDCl_3$): $\delta = 150.5$ (q), 149.5 (q), 149.3 (q), 148.1 (q), 145.2 (q), 143.4 (q), 143.3 (q), 142.3 (q), 139.6 (q), 139.3 (q), 138.0 (q), 135.9 (q), 135.7 (q), 128.5, 126.7, 126.3, 126.0, 125.6, 124.2, 124.0, 123.7, 123.0, 122.6, 122.4 (q), 34.5 (q), 34.4 (q), 34.3 (q), 34.2 (q), 31.33 (overlapped two peaks), 31.27, 31.08.

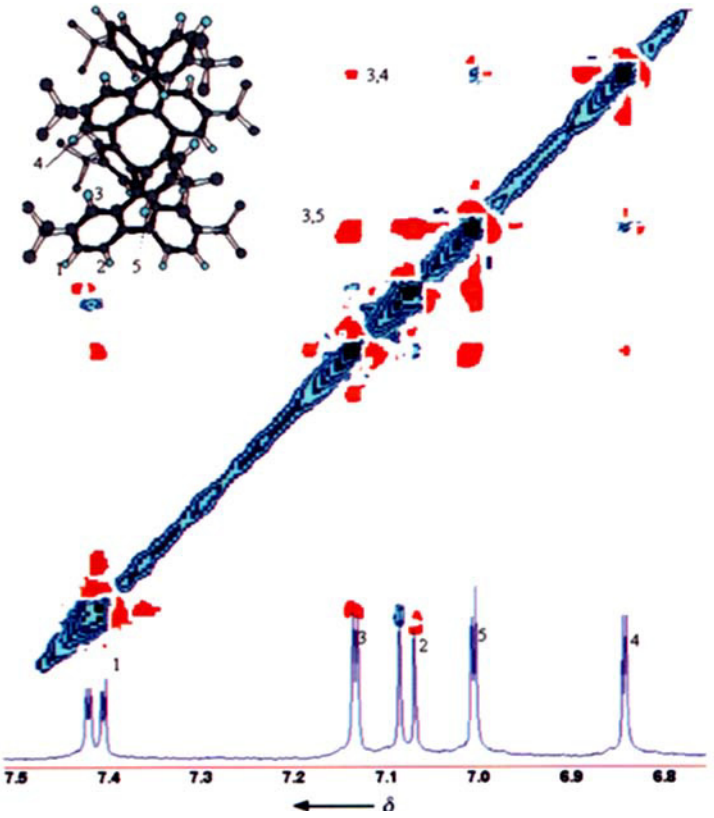

Figure 2. 2D-ROESY (500 MHz) spectrum for **1** in CD_2Cl_2. The ROESY cross peaks are orange/red and labeled "3,5" and "3,4"; the orange/red cross peaks adjacent to the diagonal are phase artefacts. The blue/purple cross peaks are due to residual Hartmann–Hahn effects.

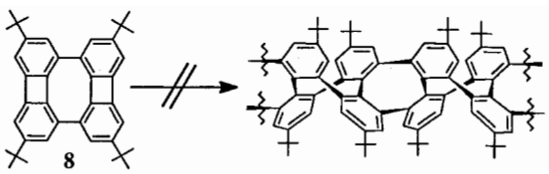
spectively).[22] The bathochromic shift, which is attributed to the extension of conjugation from **2** to **1**, is relatively small compared to that of oligo-*p*-phenylenes. Thus, the π-conjugation in **1**, which accommodates the helical twist and *meta*, *ortho* connectivities between the benzene rings, is decreased but not diminished compared to that of oligo-*p*-phenylenes.

The yields of symmetrical tetraphenylenes (with two C–C bonds formed) isolated decrease sharply in the order **2** (69%), **3** (17%), **1** (4%), whereas the amounts of the side products in which only one C–C bond is formed, such as the dimer derived from 2,2′,6,6′-tetrabromo-4,4′-di-*tert*-butylbiphenyl and tetraphenylene dimer **7**, increase. Notwithstanding the details of the mechanism, the formation of tetraphenylene formally requires two homochiral 2,2′-dimetal biphenyl fragments; therefore, in a racemic mixture, whenever heterochiral fragments combine (one C–C bond formed) and the barrier for configuration inversion is high, competing reactions take over.

The synthesis of higher homologoues of **1** and, in particular, the corresponding double helical polymer poses a synthetic challenge in which the formation of the tetra-*o*-phenylene ring in high yield and the use of homochiral building blocks (and/or high enantioselectivity) are prerequisites. The recently prepared biphenylene dimer **8** partially satisfies these requirements;[11]



however, the reaction of **8** under conditions typical for the conversion of biphenylene to tetra-*o*-phenylene[23] yields neither **1** nor its higher homologues as products.[24]

The development of efficient enantioselective methodologies for the construction of tetra-*o*-phenylenes and less sterically constrained biphenylene dimers is in progress in our laboratory.

Monitoring the Progress of Solid-Phase Oligosaccharide Synthesis by High-Resolution Magic Angle Spinning NMR: Observations of Enhanced Selectivity for β-Glycoside Formation from α-1,2-Anhydrosugar Donors in Solid-Phase Couplings**

Peter H. Seeberger,* Xenia Beebe, George D. Sukenick, Susan Pochapsky, and Samuel J. Danishefsky

The vital roles played by oligosaccharides in cell–cell signaling and adhesion have led to greatly increased interest and appreciation of this class of compounds. It is now recognized that these complex biomolecules, in the form of glycoprotein and glycolipid conjugates, carry detailed structural information, which serves to mediate a variety of biological events including inflammation,[1] immunological response,[2] and metastasis.[3] Furthermore, cell-surface carbohydrates act as biological markers for various tumors.[4]

Of the three major classes of biooligomers, polysaccharides have proven to be the most difficult to synthesize. The synthesis of structurally defined oligopeptides[5] and oligonucleotides[6] has greatly benefited from assembly on polymer supports. In most cases the preparation of peptides and oligonucleotides can be carried out on automated synthesizers, which allow rapid formation of the target compounds. To simplify the very labor-intensive solution-phase synthesis of carbohydrates, considerable efforts have been directed toward developing strategies and sequences for solid-phase synthesis.[7] Recent advances have demonstrated that methodologies useful for glycosidation in solution can be applicable on a polymer support. Indeed, large, biologically important oligosaccharides have been prepared by solid-phase methods.[8]

Glycals have proven to be effective building blocks for the synthesis of increasingly complex oligosaccharides.[9] The approach is applicable to the synthesis of both glycopeptides and oligosaccharides on the solid support.[10] While significant progress has been made, a generally applicable method for the rapid assembly of oligosaccharides and glycopeptides by automated solid-phase synthesis strategies has not yet been developed.

A major limitation is the difficulty in characterizing the reaction products or intermediates as they evolve during the course of the synthesis. Currently, it is necessary to cleave these products from the resin to investigate them by classical spectroscopic methods (for example solution NMR and mass spectrometry). This is time-consuming, expensive, and wasteful for multistep syntheses. Full characterization of the products while they are *still bound to the resin* would hold many advantages.

In recent years there have been numerous reports on the use of NMR for characterizing compounds bound to solvent-swollen resins. Among the measurements described are ^{13}C, ^{1}H, ^{19}F, ^{2}H, and ^{31}P determinations.[11] The quality of the spectra obtained greatly depends on the type of resin used. Not surprisingly, ^{1}H NMR resonances are generally broad when the experiments are conducted in traditional high-resolution probes, which makes characterization by NMR spectroscopy difficult.

Recourse to magic angle spinning (MAS) combined with a high-resolution probe has, in some instances, resulted in high-quality ^{1}H and ^{13}C NMR spectra of small resin-bound compounds.[12] We report here the use of high-resolution MAS NMR (HR-MAS) for characterizing a trisaccharide glycal bound to a Merrifield resin. This compound, which is the product of a multistep synthesis, is one of the largest moieties analyzed by HR-MAS to date.

The trisaccharide 2-*O*-acetyl-3,4-carbonyl-D-galactopyranose(1→6)-*β*-D-2-*O*-acetyl-3,4-carbonyl-galactopyranose-(1→6)-*β*-D-3,4-dibenzyl-glucal was assembled by the glycal solid-support synthesis strategy previously reported.[10] Polystyrene polymer crosslinked with 1% divinylbenzene was used as the polymeric support due to its high loading capacity and stability towards a broad range of conditions. This type of resin gives significantly broader lines in the ^{1}H and ^{13}C NMR spectra than resins with longer tethers, for example, the increasingly popular, but more expensive, TentaGel resins, which have a lower loading capacity.

Polymeric support-bound trisaccharide **3** was assembled in five steps (Scheme 1) and examined by ^{1}H, ^{13}C, and $^{1}H-^{13}C$ HMQC NMR. Spin-echo techniques[13] were used to reduce the signal of the polystyrene backbone observed in the ^{1}H NMR spectrum (Figure 1a). Although the lines in the obtained spectrum are broadened (relative to those for the resin-cleaved sample), several indications of a successful coupling reaction can be readily identified. The resonance at $\delta \approx 6.4$ is characteristic of the glucal C1 proton. This signal, in conjunction with four doublets at $\delta = 4.83$, 4.69, 4.64, and 4.55 for two methylene units of the benzyl protecting groups, this signal strongly suggests that glucal had indeed been successfully incorporated. Acetylation of the C2 hydroxyl group of the coupled product is indicated by a methyl signal at $\delta \approx 2.10$. The resonances in the range of $\delta = 0.8-1.2$ are assignable to the protons of the isopropyl group attached to the silyl linker, through which the first galactose is connected to the polystyrene support. The broad signals in the region of $\delta = 1.3$ to 1.9 originate from the polymer and may also contain impurities. A two-hour ^{13}C experiment (Figure 1b) confirmed the presence of two acetyl-type carbonyl groups ($\delta =$ 169.3 and 169.1) as well as two carbonate carbonyls ($\delta = 154.3$ and 153.6). Furthermore, a two-hour $^{1}H-^{13}C$ HMQC experiment provided confirmation of the proposed structure (Figure 2). All signals are clearly distinguishable, and several diagnostic signals could be assigned based on their chemical shifts. The two anomeric carbon atoms and the C2/H2 of the glycal can be identified in the range of $\delta = 90-100$. Although not all of the ring protons and carbons could be rigorously assigned, the total number of signals confirms the presence of a trisaccharide. Correct assignment of every signal, which is not required for the general utility of HR-MAS monitoring of synthetic progress, would be possible by performing TOCSY and COSY experiments on the support-bound material. More important is that detailed information about the success of the chemical transformations on the solid support can be obtained from a few relatively short NMR experiments. To collect data of comparable quality, it would have been necessary to cleave the reaction product from the support and then characterize it.

The spectra show that HR-MAS can be used for monitoring the solid-phase synthesis of oligosaccharides in a very sensitive fashion. Parenthetically, the measurements tend to confirm our earlier claim that solid-support coupling reactions—using properly protected 1,2-anhydro sugars (at least in this series)—are highly stereoselective, even more so than the solution-based couplings.[15] The original claim was based on the finding that no α-linked products could be found upon cleavage from the polymer and subsequent purification. Of course, arguments of this sort are subject to uncertainties as to whether other stereoisomers might have been inadvertently overlooked during the removal and purification sequence. The argument becomes more persuasive as one examines the "crude reaction mixture" bound to the solid phase. While the data we obtained cannot exclude adventitious overlapping of signals from small amounts of isomeric α-products, it certainly indicates a high degree of control of each coupling event conducted on the solid phase. We attribute this excellent β-stereoselectivity in this and related solid-state experiments[9, 10] to the relative diminution of effective solvation upon complexation of the oxirane by the zinc chloride promoter. Solvation forces can lend the anomeric oxiranyl donor oxonium-like qualities. A donor species, which is far advanced in the direction of a free oxonium ion, is likely to be responsible for the formation of small but significant amounts of α-glycosides from the solution-based α-epoxide donor.

In summary, the development of novel methodologies for the assembly of oligosaccharides on the solid support will undoubtedly benefit from this discerning "on-resin" analytical method. Chemists will be able to determine whether coupling has occurred and quickly estimate the specificity of the coupling step. Complete assignments can be made after the product is cleaved from the solid support and deprotected.

Experimental Section

All spectra were obtained on a Bruker DRX 500 spectrometer, operating at 500.13 MHz (^{1}H) and 125.76 MHz (^{13}C), equipped with a 4 mm Bruker CCA HR-MAS probe. Trisaccharide **3** (20 mg at 0.54 mmol g^{-1} loading, 10.8 μmol) was loaded into a ceramic rotor, suspended in 30 μL $CDCl_3$, and spun at the magic angle at 3.5 KHz. ^{1}H NMR spectra were obtained with a Carr-Purcell-Meiboom-Gill pulse sequence [13]; 128 transients (1.64 s acquisition time, 0.5 s relaxation delay) were accumulated. The $^{13}C\{^{1}H\}$ spectrum was obtained in 2 h 10 min (3000 transients, 0.6 s acquisition time, 2 s relaxation delay). The phase-sensitive (TPPI) $^{1}H-^{13}C$ HMQC spectrum was obtained in 2 h (16 scans per 256 increments, 0.17 s acquisition time, 1.3 s relaxation delay) with a BIRD sequence to minimize resin signals [14]. Total time for ^{1}H, ^{13}C, and HMQC NMR experiments was 4 h 15 min.

Novel Carbocyclic Ring Closure of Hex-5-enopyranosides

Sanjoy Kumar Das, Jean-Maurice Mallet, and Pierre Sinaÿ*

Carbohydrates have been used as starting materials for the synthesis of an extensive range of enantiomerically pure noncarbohydrate natural products and related substances.[1] The intramolecular ring closure of carbohydrates to form carbocyclic compounds is an attractive transformation, which offers direct access to highly functionalized cyclohexane derivatives. In this

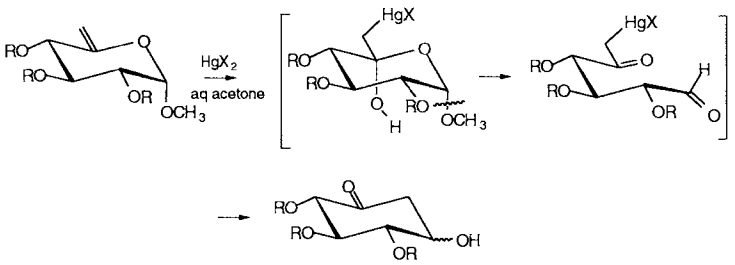
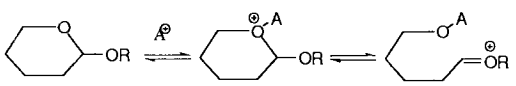
ring-closure reaction a carbanionic center (C6) usually attacks the electrophilic carbonyl center (C1). An early example is the Grosheintz–Fischer synthesis[2] of deoxy nitroinositols from 6-deoxy-6-nitrohexoses.

In 1979 Ferrier reported the convenient conversion of an easily available hex-5-enopyranoside into a highly functionalized cyclohexane derivative in the presence of mercury(II) chloride.[3] Hydroxymercuration of the vinyl ether moiety of a hex-5-enopyranoside gives an unstable hemiacetal, which loses methanol to generate a critical dicarbonyl intermediate (Scheme 1). This species then undergoes an aldol-like intramolecular cyclization to form a substituted cyclohexane. Mechanistic and stereochemical studies[4] as well as modified reaction conditions[5] have been published. Highly functionalized cyclohexane derivatives are of major significance for several groups of natural products. This remarkable rearrangement—the Ferrier-II reaction[6]—has provided a practical route to a large variety of bioactive substances such as aminocyclitols, pseudosugars, and inositols.[7] A basic feature of the Ferrier-II reaction is the loss of alcohol, for example methanol (Scheme 1), and generation of an electrophilic aldehyde, which is necessary for the aldol reaction.

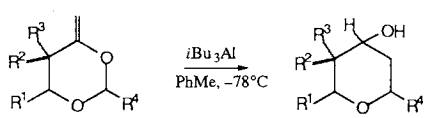


Scheme 1. Proposed mechanism for the Ferrier-II reaction [7].

We now report an alternative, direct conversion of hex-5-enopyranosides into highly functionalized cyclohexane derivatives without cleavage of the glycosidic bond. The discovery of this novel carbohydrate rearrangement is a result of a logical deduction from two independent facts: 1) Acyclic products of the selective cleavage of the ring carbon–oxygen bond of glycopyranosides have occasionally been observed[8] upon treatment with suitable electrophilic species (Scheme 2). 2) Hex-5-enopyranosides are vinyl acetals with a vinyl ether subunit as part of an acetal moiety. Among the various reactions known for vinyl acetals,[9] the triisobutylaluminum-assisted reductive rearrangement provides an elegant entry to substituted cyclobutanes,[10] cyclopropanes,[11] tetrahydrofurans,[12] and tetrahydropyrans[13] (Scheme 3).

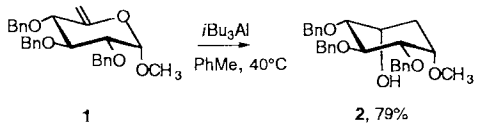


Scheme 2. *Endo* activation in glycoside cleavage.



Scheme 3. Stereocontrolled Petasis synthesis [13] of substituted tetrahydropyrans from substituted vinyl acetals.

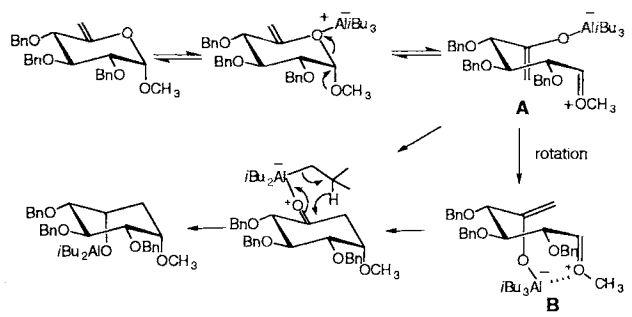
As predicted, the reaction of the known carbohydrate vinyl acetal **1**[14] with four equivalents of triisobutylaluminum (TIBAl) at 40 °C resulted in the transposition of an oxygen atom on the ring with the exocyclic carbon atom (Scheme 4).



Scheme 4. Typical example of the novel carbohydrate transposition.

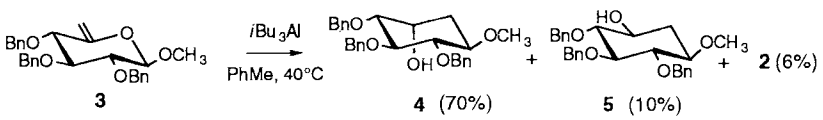
The only isolated product of the reaction (79%) was the secondary alcohol **2**, which was formed by the subsequent stereoselective reduction of the carbonyl group by TIBAl. Starting material (20%) was also recovered.

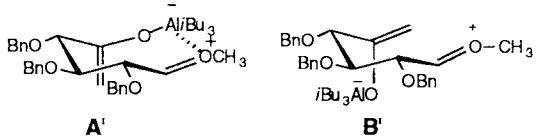
Although a detailed mechanism for the formation of **2** is still a matter of speculation (Scheme 5), the reaction is presumably initiated[13] by the coordination of the aluminum atom of TIBAl with the endocyclic enolic oxygen atom. This *endo* activation is followed by a ring opening step with the generation of the zwitterionic aluminum enolate intermediate **A**. Assuming that **A** retains its geometry on the time scale of the reaction, it may then undergo direct cyclization through a twist form,[15] thus keeping the anomeric stereochemical "memory". Alternatively, a rotation would give the intermediate **B**, which could then undergo cyclization through a chair-like six-membered ring. In this case, the electrostatic attraction between the positively charged oxygen and the negatively charged aluminum unit would hold the enolate in proximity to the C–O π bond (tight ion pair), which nicely explains the observed stereochemical outcome. In both cases the intramolecular aldol condensation goes through the favored[16] 6-*exo*-trig process. The final reduction of the keto group with TIBAl leads exclusively to the alcohol **2** by intramolecular hydrogen delivery from the less hindered β side.



Scheme 5. Probable mechanism of the transposition. Bn = benzyl.

Reaction of the vinyl acetal **3** under the same reaction conditions provided the three secondary alcohols **4** in 70%, **5** in 10%, and **2** in 6% yield (Scheme 6, physical and spectroscopic data





Scheme 6. Application of the transposition to a β-glucoside.

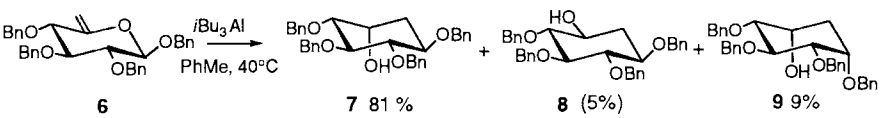
[a] All compounds gave correct elemental analyses.

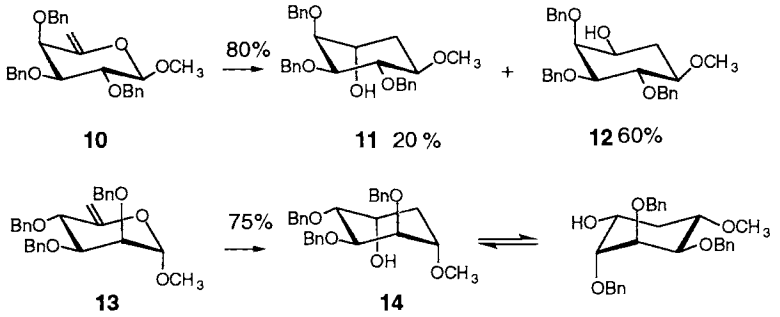
are given in Table 1). Interestingly, **4** and **5** (that is, 80% of the products) retain the stereochemical information of the anomeric center. Again, this reaction may proceed through the ion pair **A′** or the intermediate **B′**. Therefore, a distinctive feature of this entry to highly functionalized cyclohexanes is the retention of the anomeric stereochemical information in the starting glucoside. This is in sharp contrast to the Ferrier-II reaction, where the reaction inherently requires an *exo* cleavage to eject the aglycon.

In the same manner, the benzyl glucoside **6** was converted into the alcohol **7** (83%); isomers **8** (5%) and **9** (9%) were also isolated as minor products. Compound **7** has recently been prepared in racemic form from *myo*-inositol (Scheme 7).[17]



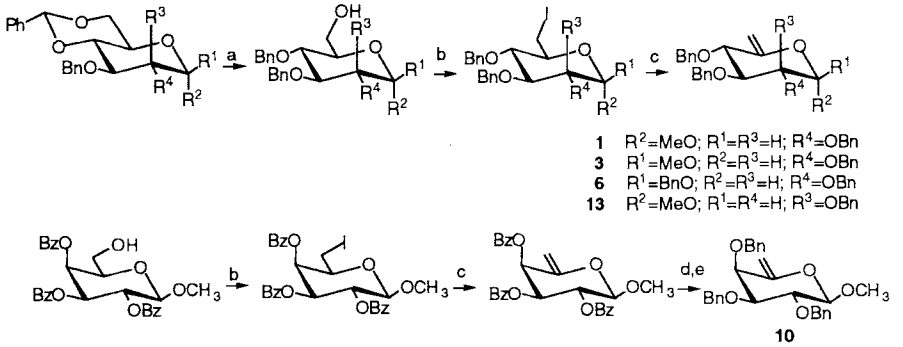
Scheme 7. An expedient synthesis of an optically active protected monodeoxygenated derivative of *myo*-inositol.

Finally, the same conditions were applied to vinyl acetals **10** and **13** (Scheme 8), which are derived from methyl β-D-galactopyranoside and methyl α-D-mannopyranoside, respectively (Scheme 9). In the case of **10**, the axially oriented benzyloxy group at C4 probably hinders reduction from the β side; compound **12** is the major product (60%).



Scheme 8. Application of the transposition to a β-galactoside and an α-mannoside.

In conclusion, we have developed a novel, stereoselective access to substituted cyclohexane derivatives, starting from hex-5-enopyranosides. A distinctive feature of the reaction is the retention of the anomeric stereochemical information. An extension to disaccharides and oligosaccharides is therefore attractive. It would also provide an expedient and stereoselective entry to pseudo disaccharides and oligosaccharides,[18] which are compounds of potential biological interest.[19]



Scheme 9. Preparation of the hex-5-enopyranosides: a) $LiAlH_4$, $AlCl_3$, CH_2Cl_2, ether, 30 °C (80%); b) I_2, Ph_3P, imidazole, toluene, 70 °C (80%); c) DBU, THF, reflux (75%); d) MeONa, MeOH, RT; e) BnBr, NaH, DMF, RT (80%); Bz = benzoyl, DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene.

Experimental Section

A 1 M solution of triisobutylaluminum in toluene (1.8 mL, 1.8 mmol) was added to **1** (200 mg, 0.45 mmol) in freshly distilled, dry toluene (15 ml) at 0 °C. The reaction mixture was then stirred at 40 °C for 6 h. After completion of the reaction, excess triisobutylaluminum was quenched with ice-cold water. The reaction mixture was filtered, and the organic phase separated. The water layer was extracted twice with ethyl acetate. The combined organic fractions were dried ($MgSO_4$) and concentrated, and the residue subjected to flash chromatography (eluent: cyclohexane/ethyl acetate 2/1) to give **2** as a syrup(158 mg, 79%).

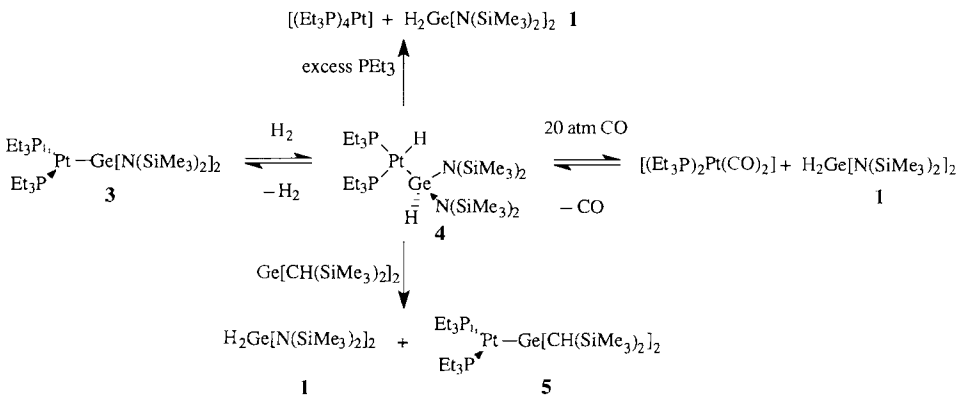
Transition Metal Germylene Complexes as Hydrogenation Catalysts: The Synthesis of a Rare Bis(amino)germane**

Kyle E. Litz, John E. Bender IV, Jeff W. Kampf, and Mark M. Banaszak Holl*

Molecules in which germanium is bound to both hydrogen and nitrogen are surprisingly rare.[1] Of the known examples, namely, H_3GeN_3,[2] H_3GeNCS,[3] H_3GeNCO,[3] $(H_3Ge)_3N$,[4] $F_3CN{=}GeH_2$,[5] $H_3GeN{=}C{=}NGeH_3$,[6] and $Ph_2(H)GeNR_2$,[7] the first three complexes contain pseudohalogen ligands and thus resemble the well-established halogermanes. The fourth example, $(H_3Ge)_3N$, is widely known to exhibit delocalized π bonding and enhanced Ge–N bond strength, whereas $Ph_2(H)GeNR_2$ is unstable and readily disproportionates to Ph_2GeH_2 and $Ph_2Ge(NR_2)_2$. Other than $(H_3Ge)_3N$, we are not aware of any aminogermanes of stoichiometry $HGe(NR_2)_3$, $H_2Ge(NR_2)_2$, or H_3GeNR_2 previously reported. In fact, amino groups are commonly employed as leaving groups when germanes are formed by hydrogenation reactions, which makes the easily accessible complexes of general stoichiometry $Cl_xGe(NR_2)_y$ unsuitable as precursors to aminogermanes.[8] Standard approaches for making aminogermanes, which involve reagents such as $LiAlH_4$ and $NaBH_4$, typically result in amine formation. Recently, we have synthesized $H_2Ge[N(SiMe_3)_2]_2$ (**1**) and $H_2Ge[CH(SiMe_3)_2]_2$ (**2**) by both stoichiometric and catalytic routes using well-defined, three-coordinate, Group 10 metal germylene complexes of general stoichiometry $[(R_3P)_2MGeR'_2]$.[9] The three-coordinate catalysts are similar to compounds previously reported by Lappert and co-workers.[10] In addition, we have found that Ni^0 complexes such as $[Ni(cod)_2]$ (cod = 1,5-cyclooctadiene) can serve as catalyst precursors, even in the absence of phosphane.

The initially discovered routes to **1** and **2** made use of **3** and **4**, as summarized in Scheme 1:[11] Treatment of a benzene



Scheme 1. Synthetic route to **1**.

solution of **4** with 20 atm CO at ambient temperature in a stainless steel bomb generates aminogermane **1** and $[(Et_3P)_2Pt(CO)_2]$.[12] Upon removing the carbon monoxide **4** is regenerated. Treating a benzene solution of **4** with $Ge[CH(SiMe_3)_2]_2$ also gives **1**, along with the new platinum-germylene complex $[(Et_3P)_2PtGe\{CH(SiMe_3)_2\}_2]$ (**5**)[13]. $H_2Ge[N(SiMe_3)_2]_2$ (**1**) exhibits singlets at $\delta = 5.69$ and 0.27 in the ^1H NMR spectrum with an integrated ratio of 1:18, assigned to the GeH and Me fragments respectively. A single peak is observed at $\delta = 4.51$ in the ^{13}C NMR spectrum. Elemental and mass spectrometric analyses, including the isotope distribution observed for the parent ion at m/z 396, are also consistent with the structure of **1**. The platinum-based chemistry provides multiple stoichiometric routes to the novel bis(amino)germane product, but none of the routes are practical. To achieve a more useful synthesis of the bis(amino)germane, and as part of our broader study of catalytic hydrogenation chemistry with metal germylene complexes, we pursued the synthesis of nickel analogues of **3** and **4**.

The three-coordinate nickel complexes were obtained by adopting the general method of Fahey and Mahan.[14] Two equivalents of PR_3 (R = Et or Ph) and one equivalent of germylene GeQ_2 [Q = $CH(SiMe_3)_2$ or $N(SiMe_3)_2$] were added sequentially to a solution of $[Ni(cod)_2]$[15] to generate **6** (Q = $CH(SiMe_3)_2$; **6a**: R = Ph, **6b**: R = Et) or **7** (Q = $N(SiMe_3)_2$; **7a**: R = Ph, **7b**: R = Et) quantitatively [Eq. (1)].

$$[Ni(cod)_2] + 2\,PR_3 + GeQ_2 \xrightarrow{C_6H_6} \underset{\mathbf{6,7}}{[(R_3P)_2NiGeQ_2]} + 2\,cod \qquad (1)$$

The X-ray crystal structure of **7a** is shown in Figure 1.[16] The Ni–Ge bond length of 2.206(1) Å is 0.16 Å shorter than the sum of the covalent radii, a fact that may be attributed to the three-coordinate ligand sphere of both metals. By way of comparison, the Pt–Ge bond length of **3** is 0.22 Å shorter than the sum of the covalent radii.[11] The bond lengths and angles of the phosphane and germylene ligands are unexceptional and compare well with previously determined structures.[10, 11]

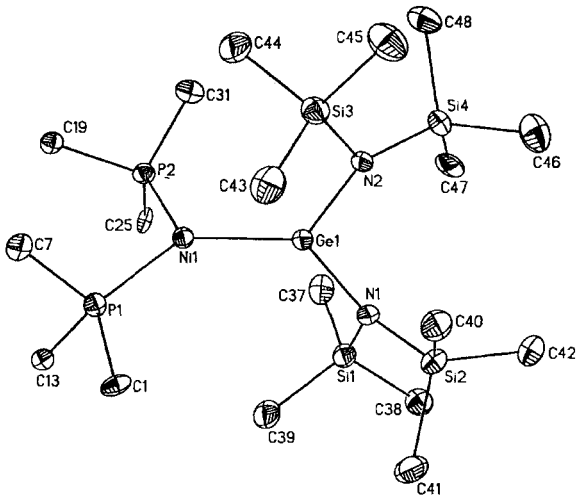

Figure 1. X-ray crystal structure of **7a**. Only the *ipso* C atoms of the phenyl rings are shown. Selected bond lengths [Å] and angles [°]: Ni–P(1) 2.157(1), Ni–P(2) 2.164 (1), Ge–N(1) 1.867(2), Ge–N(2) 1.885(3), P(1)-Ni-P(2) 113.81(4), P(1)-Ni-Ge 125.04(3), P(2)-Ni-Ge 121.13(3), Ni-Ge-N(1) 127.44(8), Ni-Ge-N(2) 127.49(8), N(1)-Ge-N(2) 105.0(1).

The reaction of **6** or **7** with one equivalent of H_2 leads to the rapid formation of **2** or **1**, respectively, possibly via an intermediate of the nickel analogue of hydride complex **4**. The weaker Ni–Ge bond changes the thermodynamic balance and allows reductive elimination to form **1** or **2**.[17] The rapid elimination of germane products suggested that these reactions might provide a useful catalytic synthesis of the germanes from the corresponding germylenes [Eq. (2)].

$$H_2 + GeQ_2 \xrightarrow[25\,^\circ C,\ C_6H_6]{2\ Mol\text{-}\%\ [(R_3P)_2NiGeQ_2]} \underset{\mathbf{1,2}}{H_2GeQ_2} \qquad (2)$$

A solution of 0.57 g $Ge[N(SiMe_3)_2]_2$ in benzene was treated with **7b** (2 mol%) and 1 atm H_2. After 72 h all volatiles were removed, and pure **1** was obtained by sublimation from the residue (64% yield). An analagous procedure gave similar results for **2**, but attempts to hydrogenate $Ge(OAr)_2$ (Ar = 2,6-tBu$_2$-4-MeC_6H_2) resulted in catalytic formation of HOAr. Germane **1** was also obtained in 95% yield by treating a solution of $Ge[N(SiMe_3)_2]_2$ (10.0 g) in pentane (10 mL) with $[Ni(cod)_2]$ (1.5 mol%) and H_2 (27 atm) for 1 h. It is likely that different catalytic species are active in this case as excess germylene does not displace the phosphane groups from complexes **3**, **6**, or **7**, and the $[Ni(cod)_2]$-catalyzed reaction procedes at a faster rate under the same conditions than those catalyzed by **6** or **7**. It is also interesting to note that H_2GePh_2 can serve as a source of hydrogen for the catalytic hydrogenations.

In summary, a novel reaction utilizing a transition metal germylene complex as catalyst has been used to synthesize a rare bis(amino)germane complex. The mild conditions employed avoid the typical problems of Ge–N bond scission and formation of amines. We are continuing to explore the use of the transition metal germylene complexes in catalytic hydrogenations and the applications of the bis(amino)germane, which due to the presence of the amino leaving groups provides a convenient GeH_2 synthon.

Experimental Section

All procedures were performed under exclusion of air and with dry, deoxygenated solvents [18]. ^1H (300 MHz) and ^{13}C NMR (90.6 MHz) spectra were recorded in C_6D_6, and shifts are relative to the $\delta = 7.15$ (C_6H_6 impurity) and 128.0 ($^{13}C_6D_6$), respectively. ^{195}Pt and ^{31}P shifts are relative to K_2PtCl_4 in D_2O and 85% H_3PO_4 in D_2O. Germylenes were prepared according to the method of Lappert and coworkers [15]. $[Ni(cod)_2]$ was purchased from Strem Chemicals, Danbury, MA, USA.

1: A solution containing $Ge[N(SiMe_3)_2]_2$ (0.57 g) and 2 mol% **7b** in benzene, generated in situ, was stirred under H_2 (1 atm) for 72 h; conversion into bis(amino)germane (**1**), as monitored by ^1H NMR spectroscopy, was quantitative. After removal of all volatiles in vacuum, pure **1** was obtained in 64% yield by sublimation onto a 0 °C cold finger from the reaction mixture at 32 °C and 10^{-3} torr. IR(Nujol): $\tilde{\nu} = 2095$ and 2067 cm^{-1} (GeH_2); MS (70 eV, EI): m/z (%): 396 (4.3) [M^+]; density (22 °C) 1.024 $g\,mL^{-1}$; elemental analysis for $C_{12}H_{38}N_2GeSi_4$: found C 35.74, H 9.24, N 6.91; calcd. C 6.5, H 9.68, N 7.08.

An analagous procedure with catalyst **6b** was employed to synthesize **2** in 68% yield. Data for **2**: ^1H NMR: $\delta = 0.18$ (CH_3), −0.42 (t, CH, ^3J(H,H) = 3.6 Hz), 4.23 (t, GeH, ^3J(H,H) = 3.6 Hz); $^{13}C\{^1H\}$ NMR: $\delta = 1.98$ (CH_3), 0.63 (*C*H); IR(Nujol): $\tilde{\nu} = 2024\ cm^{-1}$ (GeH_2); MS (70 eV, EI): m/z (%): 379 (28) [$M^+ - CH_3$]; elemental analysis calcd. for $C_{14}H_{40}GeSi_4$: C 42.7; H, 10.2; found: C 41.4, H 9.5.

7b: To a 12 mL solution containing $[Ni(cod)_2]$ (0.5 g) in benzene, two equivalents of PEt_3 (0.55 mL) and one equivalent of germylene $(Ge[N(SiMe_3)_2]_2$ were added sequentially, to generate **7b** in quantitative yield. The solution was filtered, volatiles removed, and the resulting solid recrystallized from cold pentane to give 0.87 g dark red microcrystals (66% yield). ^1H NMR: $\delta = 1.39$ (q, 12H, CH_2CH_3), 1.02 (m, 18H, CH_2CH_3), 0.53 (s, 36H, $SiCH_3$); $^{13}C\{^1H\}$ NMR: $\delta = 20.60$ (t, CH_2CH_3), 8.98 (m, CH_2CH_3), 6.10 (s, $SiCH_3$); $^{31}P\{^1H\}$ NMR: $\delta = 15.40$; elemental analysis for $C_{24}H_{66}N_2GeNiP_2Si_4$: found C 41.52, H 9.39, N 3.92; calcd. C 41.88, H 9.67, N 4.07.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3605-0497 $ 15.00+.25/0

6a, **6b**, and **7a** were synthesized analogously to **7b**. Spectroscopic data: **6b**: ^{1}H NMR: $\delta = 1.42$ (m, 12H, CH_2CH_3), 1.01 (m, 18H, CH_2CH_3), 0.92 (m, 2H, CH), 0.46 (s, 36H, $SiCH_3$); $^{13}C\{^1H\}$ NMR: $\delta = 35.74$ (t, CH), 20.60 (t, CH_2CH_3), 8.81 (m, CH_2CH_3), 4.30 (s, $SiCH_3$). $^{31}P\{^1H\}$ NMR: $\delta = 15.03$. Elemental analysis for $C_{24}H_{66}N_2GeNiP_2Si_4$: found C 45.4, H 9.7; calcd. C 45.5, H 10.0. **7a**: ^{1}H NMR: $\delta = 7.41$ (m, 10H, C_6H_5), 7.00 (m, 20H, C_6H_5), 0.50 (s, 36H, $SiCH_3$). $^{13}C\{^1H\}$ NMR: $\delta = 6.37$ (s, CH_3), 128.06, 128.08, 134.04, 137.01 (C_6H_5), $^{31}P\{^1H\}$ NMR: $\delta = 38.3$. **6a**: ^{1}H NMR: $\delta = 7.41$ (m, 10H, C_6H_5), 6.96 (m, 20H, C_6H_5), 0.41 (s, 36H, $SiCH_3$); $^{13}C\{^1H\}$ NMR: $\delta = 136.9$, 134.0, 128.8, 128.3 (C_6H_5), 39.04 (m, CH), 0.41 (s, $SiCH_3$); $^{31}P\{^1H\}$ NMR: $\delta = 36.6$.

CDA: Calcium-Dependent Peptide Antibiotics from *Streptomyces coelicolor* A3(2) Containing Unusual Residues**

Christoph Kempter, Dietmar Kaiser, Sabine Haag, Graeme Nicholson, Volker Gnau, Tilmann Walk, Karl Heinz Gierling, Heinrich Decker, Hans Zähner, Günther Jung, and Jörg W. Metzger*

Dedicated to Professor Ernst Bayer on the occasion of his 70th birthday

In 1983 Hopwood et al.[1] isolated a substance from *Streptomyces coelicolor* A3(2) that inhibits the growth of gram-positive bacteria in the presence of Ca^{2+} ions. Because of this activity it was named CDA (*c*alcium-*d*ependent *a*ntibiotic). In planar lipid bilayers, CDA forms channels that in the presence of calcium ions selectively transport singly charged cations.[1]

Depending on the culture medium used, either two or four very similar antibiotic main components were detected by HPLC-ESI-MS (ESI = electrospray ionization). Fermentation with yeast extract as a nitrogen source provided CDA1 and CDA2 (relative monoisotopic molecular masses M_r of 1562 and 1576, respectively), whereas the use of soy peptone and meat extract as the nitrogen source gave CDA3a, CDA3b, CDA4a, and CDA4b ($M_r = 1480$, 1482, 1494, and 1496, respectively). After optimization of the production, preparative HPLC yielded 10–50 mg L^{-1} of the active crude fraction. Repeated chromatography afforded CDA1 (8 mg) and CDA2 (16 mg) in high purity, as well as CDA3a/b (total ca. 4 mg) and CDA4a/b (total ca. 8 mg) with a purity of up to 80%.

After hydrolysis of the peptide (6 N HCl, 24 h) and derivatization to *N*-trifluoroacetyl-*n*-propyl esters, the amino acids L-Asx (3.04), Gly (0.79), L-Ser (1.00), and L-Thr (0.99) were found by capillary GC-MS on Chirasil-Val with enantiomer labeling.[2] Hydrolysis under oxygen-free conditions and addition of thioglycolic acid also yielded a 1:1 ratio of L- and D-Trp. In addition, the hydrolysate contained the unusual amino acids D-4-hydroxyphenylglycine and D-3-hydroxyaspartic acid (2*R*:3*S*), which were identified by comparison with reference compounds. The GC-MS of a third unusual amino acid showed similarities to that of glutamic acid, but the masses of all main fragment ions were 14 mass units higher. The TOCSY[3] and HSQC[4]

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 323) and the Fonds der Chemischen Industrie. We thank Prof. Dr. D. A. Hopwood (John Innes Centre, Genetics Department, Norwich, UK) for providing us with the strain *Streptomyces coelicolor* A3(2) 2377. Parts of this work have already been presented at the 8th Irseer Naturstofftagung of the DECHEMA (February 21–23, 1996) in Kloster Irsee and at the 29th Jahrestagung der Arbeitsgemeinschaft Massenspektrometrie der Deutschen Physikalischen Gesellschaft, the Gesellschaft Deutscher Chemiker and the Bunsengesellschaft für Physikalische Chemie (AGMS 1996, May 28–31, 1996) in Bremen.

NMR spectra indicated the presence of 3-methylglutamic acid. D,L-3-Methylglutamic acid can be synthesized by a Michael addition of acetylaminomalonic acid diethyl ester to crotonic acid nitrile, followed by acidic hydrolysis and decarboxylation. Comparison of the GC-MS spectrum of the unknown amino acid with that of synthetic D,L-3-methylglutamic acid led to its unequivocal identification as 3-methylglutamic acid. The four isomeric *N*-trifluoroacetyl-*n*-propyl esters of synthetic, racemic D,L-3-methylglutamic acid showed only two peaks of equal intensity in the gas chromatogram (separation on L-Chirasil-Val). These correspond to the two pairs of diastereomers (experience shows that enantiomers are always separated on Chirasil-Val). 3-Methylglutamic acid in CDA2 had the same retention time as the second peak in the chromatogram of the synthetic product. Since D-amino acids are generally eluted first, CDA2 probably contains L-3-methylglutamic acid or the corresponding amide.

CDA2 gave no reaction with ninhydrin and could not be sequenced directly by Edman degradation; this suggests the presence of a N-terminal block on the peptide. HMBC[5] NMR spectroscopy identified 2,3-epoxyhexanoyl as the blocking group at the N-terminus. The $^1H-^{13}C$ HSQC spectrum, which was recorded without decoupling during acquisition, provided $^1J(C,H)$ coupling constants of 172 and 179 Hz for the C-2 and C-3 atoms, respectively, of the 2,3-epoxyhexanoyl moiety. These values are characteristic for oxirane rings[6]. To identify 2,3-dihydroxyhexanoic acid in the hydrolysate of CDA2, a reference compound was synthesized from hex-2-enoic acid and performic acid with subsequent hydrolysis of the intermediate oxirane.

Signals for all the amino acids found in the hydrolysate, except those of D-3-hydroxyasparagine/aspartic acid, were observed in the amide region of the TOCSY NMR spectrum. The chemical shift values of the amino acid and 2,3-epoxyhexanoyl residues were assigned with TOCSY and HSQC NMR spectra (Table 1). The signals for the two protons at the C_α and C_β atoms of D-3-hydroxyasparagine/aspartic acid could be assigned unequivocally in the aliphatic region. The ESI-MS product ion spectrum of CDA2 with a $[M+H]^+$ ion at $m/z = 1577$ showed a main fragment ion whose mass was 98 u lower than that of the precursor ion. Such a fragmentation is typical of phosphorylated peptides. Accordingly, the product ion spectrum of CDA2 after sevenfold methylation with diazomethane ($m/z = 1675$; methylation of one phenolic, four carboxy, and the phospho group) contained a main fragment ion at $m/z = 1549$, which can be explained by β-elimination of the phosphoric acid dimethyl ester (-126 u). The position of the phosphorylation site was determined by a one dimensional $^1H-^{31}P$ HMBC NMR experiment. The spectrum showed a proton shift at $\delta = 4.62$, which is caused by the coupling of the phosphorus atom to the proton on the C_β atom of the D-3-hydroxyasparagine/aspartic acid residue.

Since many of the correlations (NH–CO and $C_\alpha H$–CO) necessary for sequencing could not be observed in the HMBC spectrum, a NOESY[7] spectrum (Figure 1) was used for sequence determination by NMR. An NOE contact between the amide proton of the serine residue at position 1 ($\delta(^1H) = 7.94$) and the proton at the C-2 atom of the 2,3-epoxyhexanoyl group ($\delta(^1H) = 3.33$) indicated that this residue forms the N-terminus of the peptide antibiotic. The amino acid sequence of CDA2 could be determined almost completely from sequential contacts in the NOESY spectrum.

A considerable part of the sequence determined by NMR were confirmed by Edman degradation. Because of the N-terminal block, CDA2 was cleaved with 3-bromo-2-(*o*-nitrophenylsulfenyl)skatole (BNPS-skatole)[8] prior to Edman sequencing. The cleavage occurs selectively after tryptophan residues. As there were no phenylthiohydantoin (PTH) derivatives of the unusual amino acids in CDA2 available for conventional Edman sequencing, a gas-phase sequencer was coupled to an ESI mass spectrometer to identify them. After changing the HPLC eluent of the sequencer from a phosphate buffer to an ammonium acetate buffer (1 mM, pH = 4.3), which is compatible with electrospray MS, the molecular masses of the eluting PTH amino acids were determined on-line. The partial sequence Asp-Asp-hydroxyphenylglycyl-Asp-Gly-Xxx-methylglutamic acid was obtained. The sixth cycle (Xxx, Figure 2) yielded a PTH

Table 1. ^1H and ^{13}C chemical shifts of the peptide antibiotic CDA2 ([D$_6$]DMSO, $c = 16$ mg mL^{-1}, 305 K); Eph = 2,3-epoxyhexanoyl, Hpg = 4-hydroxyphenylglycin, PHAsn = 3-phosphohydroxyasparagine, 3MeGlu = 3-methylglutamic acid [a].

^{11}Trp	8.51	52.5	4.55	26.0	3.09; 3.20	(108.7), (123.4/7.15), (NH: 11.1), (135.6), 126.8), (118/7.54), (112.5/6.95), (120.5/7.03), (110.8/7.30)

[a] Since most of the ^{13}C chemical shifts for the carbonyl carbon atoms could not be assigned from the HMBC spectrum, no CO shifts are given. The ^{13}C shift of the C-1 atom in the phenyl ring of Hpg could not be assigned either.

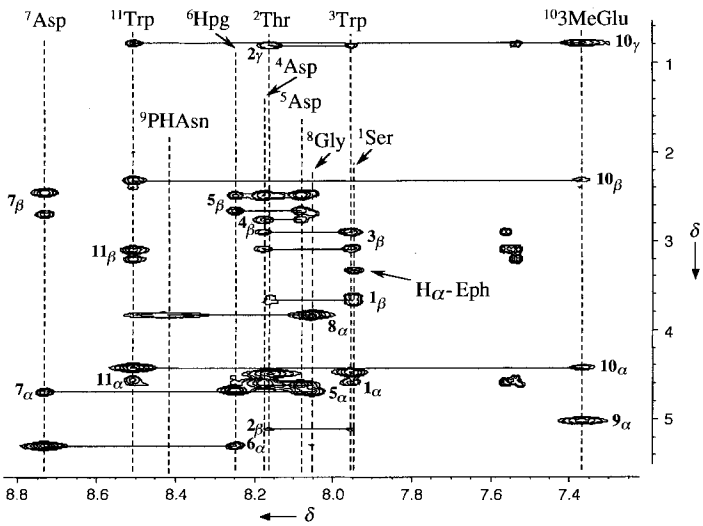

Figure 1. Amide region of the NOESY spectrum of CDA2 (Eph = 2,3-epoxyhexanoyl) that allows almost complete sequencing of the peptide.

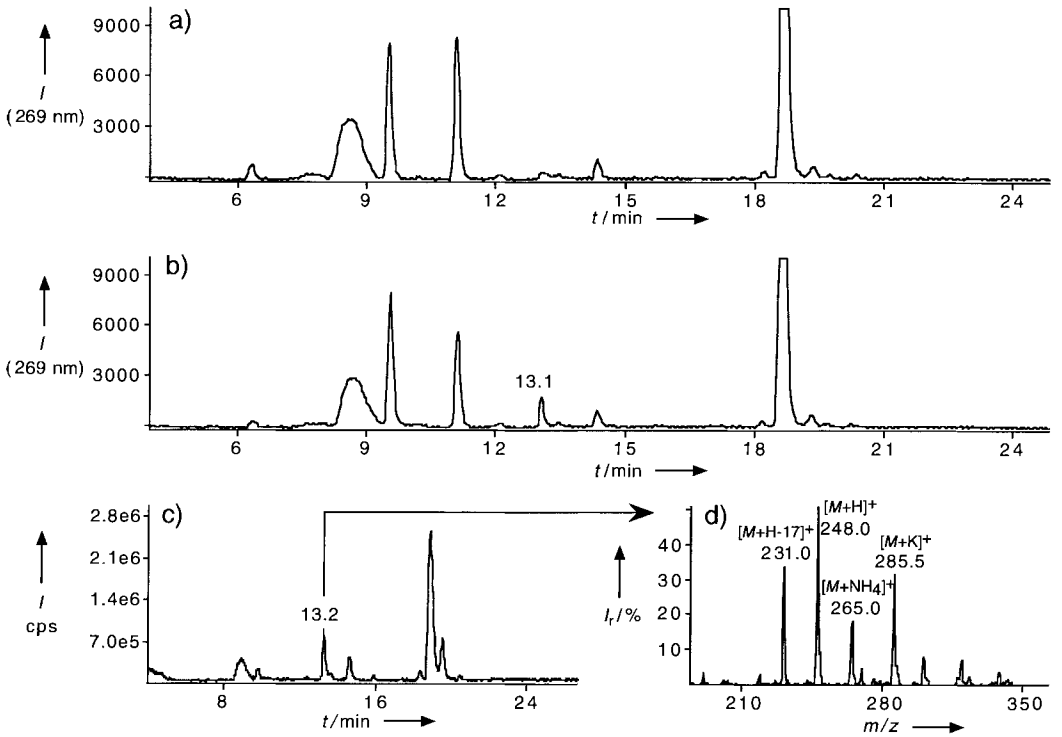

Figure 2. Edman degradation of partially hydrolyzed CDA2, which has been cleaved with BNPS-skatole, with on-line coupling of a gas-phase sequencer to a ESI-mass spectrometer; a) UV chromatogram of the fifth cycle, b) UV chromatogram of the sixth cycle, c) MS chromatogram of the sixth cycle, d) mass spectrum corresponding to the peak at 13.2 min. For the PTH derivative $M_r = 247$ ($m/z = 248$, $[M + H]^+$; $m/z = 265$, $[M + NH_4]^+$; $m/z = 286$, $[M + K]^+$), which corresponds to the amino acid 2,3-didehydroasparagine obtained by β-elimination of phosphoric acid from 3-phosphohydroxyasparagine. The fragment ion at $m/z = 231$ is formed in the transport region of the ESI source by elimination of NH_3 from the amide.

derivative with a relative molecular mass of 247 ($m/z = 248$, $[M + H]^+$; $m/z = 265$, $[M + NH_4]^+$). This corresponds to the PTH derivative of the unsaturated amino acid 2,3-didehydroasparagine, which may have been formed by β-elimination of phosphoric acid from D-3-phosphohydroxyasparagine under the conditions for Edman sequencing. To our knowledge O-phosphorylated hydroxyasparagine has not yet been found in a natural compound .

The sum of the masses of the eleven identified amino acid residues and 2,3-epoxyhexanoyl residue is 1594, in contrast to the value of 1576 experimentally found for native CDA2. The difference of 18 u suggests that a cyclization reaction has taken place (formation of a lactone ring). Since the HMBC and NOESY spectra show no clear contacts, the position of the bridge was located with derivatization reactions. To determine which of the carboxy groups participates in lactone formation, all free carboxy groups of CDA2 were amidated with 2-propylamine and HOBT/TBTU (1/1, HOBT = *N*-hydroxybenzotriazole, TBTU = 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium tetrafluoroborate). The product was subsequently treated with NaOH (1 N, 30 min, ambient temperature) to allow ring opening and thereby more pronounced fragmentation in the MS; product ion spectra of derivatized CDA with an intact lactone bridge generally contained only little sequence information. Formation of the product with $M_r = 1661$ can be explained as amidation of the four carboxy amino acid residues with 2-propylamine ($+ 4 \times 41$), partial hydrolysis ($+ 2 \times 18$ u) corresponding to the opening of one oxirane and one lactone ring, dephosphorylation of the 3-phosphohydroxyasparagine residue ($- 98$ u), and elimination of water (-18 u). The elimination of water is presumably due to nitrile formation of 2,3-didehydroasparagine under these conditions. The product ion spectrum of the amidated CDA2 derivative (Figure 3) shows all C-terminal Y″-frag-

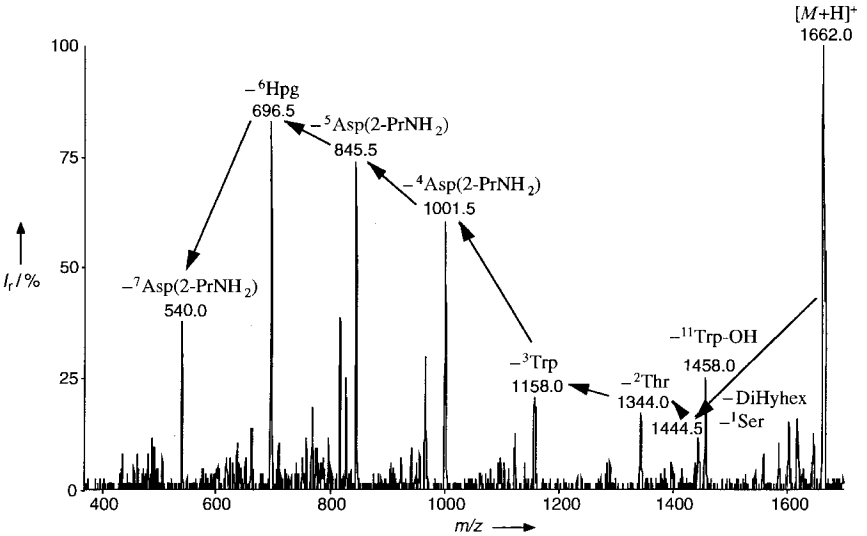

Figure 3. Product ion spectrum of CDA2 that has been fourfold amidated with 2-propylamine with opened oxirane and lactone rings (Hpg = 4-hydroxyphenylglycyl, DiHyHex = 2,3-dihydroxyhexyl); elimination of water at the 3-phosphohydroxyasparagine residue during basic partial hydrolysis leads to $M_r = 1661$.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3605-0500 $ 15.00+.25/0 Angew. Chem. Int. Ed. Engl. 1997, 36, No. 5

ment ions[9] (bond cleavage between CO and NH) up to the glycine residue at position 8. In addition, an N-terminal fragment ion at $m/z = 1458$ results from cleavage of the unmodified C-terminal tryptophan residue. According to these results, all aspartic acid residues and the 3-methylglutamic acid were converted into 2-propylamides by this reaction. The lactone bridge therefore involves the C-terminal tryptophan.

To identify the hydroxy group involved in the lactone bridge, all free hydroxyamino acids were oxidized with chromic acid[10] (10 h, RT), which leaves ester groups intact. After oxidation only small amounts of serine were found in the hydrolysate, whereas the content of threonine was not changed. Hence the lactone bridge in CDA2 involves the C-terminal tryptophan residue and the threonine residue in position 2.

To determine the configuration of the two tryptophan residues in CDA2, partially hydrolyzed CDA2 with opened oxirane and lactone rings was cleaved enzymatically with endoproteinase Asp-N. The N-terminal fragment that was obtained by cleavage after position 7 contained D-Trp, whereas L-Trp was found in the C-terminal fragment. From these results we conclude that CDA2 has the structure shown in Figure 4.

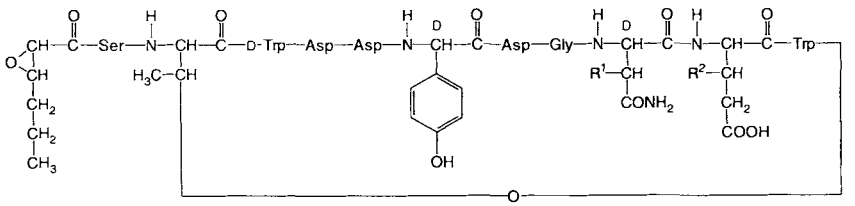

Figure 4. Structures of the CDA components CDA1, CDA2, CDA3b, and CDA4b; residues with D-configuration at the C_α atom are marked, all others have L-configuration (CDA1: $R^1 = OPO_3H_2$, $R^2 = H$; CDA2: $R^1 = OPO_3H_2$, $R^2 = CH_3$; CDA3b: $R^1 = OH$, $R^2 = H$; CDA4b: $R^1 = OH$, $R^2 = CH_3$).

The hydrolysates of the components CDA1 ($M_r = 1562$) and CDA3a and CDA3b ($M_r = 1480$ and 1482) contain L-glutamic acid instead of L-3-methylglutamic acid, thereby explaining the mass difference of 14 u between CDA1/CDA2 and CDA3a/CDA4a as well as CDA3b/CDA4b. Edman degradation with on-line UV- and MS-detection of a CDA1 sample cleaved with BNPS-skatole confirmed the replacement of 3-methylglutamic acid in position ten by glutamic acid; the rest of the sequence is identical. No mass loss of 98 u is seen in the product ion spectrum of the $[M + H]^+$ ions of CDA3a/b and CDA4a/b, indicating that these compounds are not phosphorylated. The mass difference of 80 u between CDA3b and CDA1 or CDA4b and CDA2 can be explained as replacement of D-3-phosphohydroxyasparagine by D-3-hydroxyasparagine. Edman sequencing with UV- and MS-detection of CDA4a/b cleaved with BNPS-skatole yielded a PTH derivative with a mass of 265 in the sixth degradation cycle. This corresponds to the PTH derivative of 3-hydroxyasparagine. The structures of the components CDA3a and CDA4a, which exhibit a mass difference of 2 relative to the corresponding CDA3b and CDA4b, could not yet be elucidated due to insufficient substance.

It is striking that the channel-forming peptides of the CDA group contain numerous acidic and aromatic residues. There is possibly an interaction between the acidic groups and the Ca^{2+} ions. After aggregation of several CDA molecules, aromatic residues may be involved in selective ion transport. At the moment conformational studies in the presence of Ca^{2+} are being carried out with circular dichroism and NMR spectroscopy to elucidate these questions.

Experimental Section

Streptomyces coelicolor strain A3(2) 2377 was used for the production of CDA [11]. Production media: medium 1: mannitol 20 g L^{-1}, soy peptone 10 g L^{-1}, meat extract 10 g L^{-1}, histidine 250 mg L^{-1}, uracil 100 mg L^{-1}, pH = 7.4; medium 2: mannitol 20 g L^{-1}, yeast extract 20 g L^{-1}, histidine 250 mg L^{-1}, uracil 100 mg L^{-1}, pH = 7.4.

ESI- and MS-MS spectra were recorded on the triple-quadrupole mass spectrometer API *III* (Sciex, Thornhill, Canada) equipped with a nebulizer-assisted electrospray source. NMR experiments were performed on a AMX-600 spectrometer (Bruker, Karlsruhe, Germany) with an inverse $^1H,^{13}C,^{15}N$-triple resonance probe at 305 K. ^{31}P NMR spectra were recorded on a DRX-250 spectrometer (Bruker, Karlsruhe, Germany).

A protein sequencer 476A (ABI, Weiterstadt, Germany) was used. GC and GC-MS investigations were performed on a gas chromatograph Sichromat 1 (Siemens) with an N-selective detector, Spektraphysics 4290 Integrator, and a mass spectrometer MAT 112S (Finnigan, Bremen, Germany) with AMD Intectra data system employing glass or fused silica capillaries (20 m × 0.3 mm or 0.25 mm, L-Chirasil-Val, $d_f = 0.13$ µm).

RP-18 HPLC: Semi-preparative separations (Nucleosil C18, 5 µm, 250 × 8 mm, Grom, Herrenberg, Germany) were performed with a Waters HPLC system (Waters, Eschborn, Germany) equipped with a photodiode array detector 990. Trifluoroacetic acid (0.1%, eluent A) and acetonitrile with 0.1% trifluoroacetic acid (eluent B) were used as mobile phases. For the HPLC-MS coupling, a HPLC-system (Applied Biosystems ABI 140A, Weiterstadt, Germany) as described in ref. [12] was used.

Chemical modification reactions (subsequent purification with RP-18 HPLC): 1) Partial hydrolysis with NaOH: CDA2 (0.1 mg) was treated with NaOH in H_2O (1 N, 0.5 mL) for 30 min at room temperature. 2) Enzymatic cleavage with endoproteinase Asp-N: partially hydrolyzed CDA2 (ca. 50 µg) was incubated with endoproteinase Asp-N (2 µg; "sequencing grade", Boehringer, Mannheim, Germany) in sodium phosphate buffer (100 µL; pH = 8) for 24 h at 36 °C. 3) BNPS-skatole cleavage: CDA2 (0.1 mg) was treated in 70% acetic acid for 30 min with a solution of 3-bromo-2-(*o*-nitrophenylsulfenyl)skatole (Sigma, St. Louis) in acetic acid (0.5 mL; 6 mM). 4) Amidation with 2-propylamine: CDA2 (0.2 mg), TBTU (2.5 mg), HOBT (1.16 mg) and 2-propylamine (1 µL) were dissolved in a mixture of *N,N*-dimethylformamide (20 µL) and acetonitrile (0.5 mL). The reaction products were purified after 4 h at room temperature.

"Grignard-Analogous" Rhodium Phosphane Complexes**

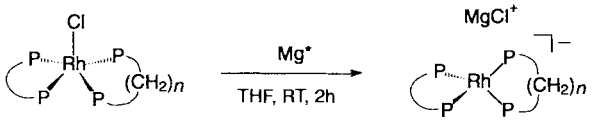
Borislav Bogdanović,* Walter Leitner,* Christian Six, Ursula Wilczok, and Klaus Wittmann

Dedicated to Professor J. Halpern

The chemistry of mononuclear rhodium complexes bearing phosphane ligands is dominated by compounds with the transition metal center in the +I or +III oxidation state.[1] Although $[(Me_3P)_4Co]^-$ has been well studied,[2] corresponding rhodium compounds have so far been restricted to cases where highly π-acidic ligands are present, for example $K[(F_3P)_4Rh]$,[3] $Na[(Ph_3P)_2(CO)_2Rh]$,[4] and Li[(triphos)(CO)Rh] (triphos = {2-[(diphenylphosphano)methyl]-2-methylpropane-1,3-diyl}bis-(diphenylphosphane)).[5] In sharp contrast, the reduction of $[(Me_3P)_4RhCl]$ with Na/Hg leads to the formation of the heterobimetallic cluster $[(Me_3P)_{12}Hg_6Rh_4]$.[6]

Here we report the synthesis, spectroscopic properties, and reactivity of bimetallic complexes of the form $[(P_2)_2Rh][MgCl]$ (**1a** and **1b**, P_2 is the bidentate chelating phosphane ligand $Ph_2P(CH_2)_nPPh_2$ termed **2a** when $n = 2$ and **2b** when $n = 3$), which contain rhodium in the formal oxidation state -1. They are the first examples of a new class of highly nucleophilic transition metal compounds that can be referred to as "Grignard-analogous" rhodium phosphane complexes.[7, 8]

A THF slurry of the yellow chloro complex $[(\mathbf{2a})_2RhCl]$[9] (**3a**) reacts smoothly with an excess of specially activated magnesium (Mg*)[10] at room temperature to give a dark red solution of **1a** (Scheme 1). Within 2 h **3a** disappears completely, and



$n = 2$: **3a** **1a**
$n = 3$: **3b** **1b**

Scheme 1. Synthesis of Grignard-analogous rhodium phosphane complexes $[(P_2)_2Rh][MgCl]$ (**1a–b**) from the corresponding chloro complexes **3a,b** and active magnesium (Mg*). The chelating phosphane ligands are schematically displayed: methylene groups are shown for only one ligand, and the phenyl substituents at the phosphorous atom have been omitted. RT = room temperature.

exactly one equivalent of Mg* is consumed; no further reaction occurs under these conditions. Monitoring of the reaction by $^{31}P\{^1H\}$ NMR spectroscopy (81.01 MHz, room temperature)[11] indicates the clean formation of **1a**, which is characterized by a doublet of slightly broadened lines centered at $\delta = 62.0$ ($J(Rh,P) = 197$ Hz).[12] Although no directly related data can be found in the literature, identical trends have been observed for $[(\mathbf{2a})_2RhX]$ (X = Cl, H, MgCl) and [(triphos)-(CO)RhX] (X = Cl, H, Li).[5, 13] This strongly supports the assignment as **1a** (Table 1).

Table 1. $^{31}P\{^1H\}$ NMR spectroscopic data for $[(\mathbf{2a})_2RhX]$ (X = Cl, **3a**; X = H, **4a**; X = MgCl, **1a**) and [(triphos)(CO)RhX] (X = Cl, H, Li) [a].

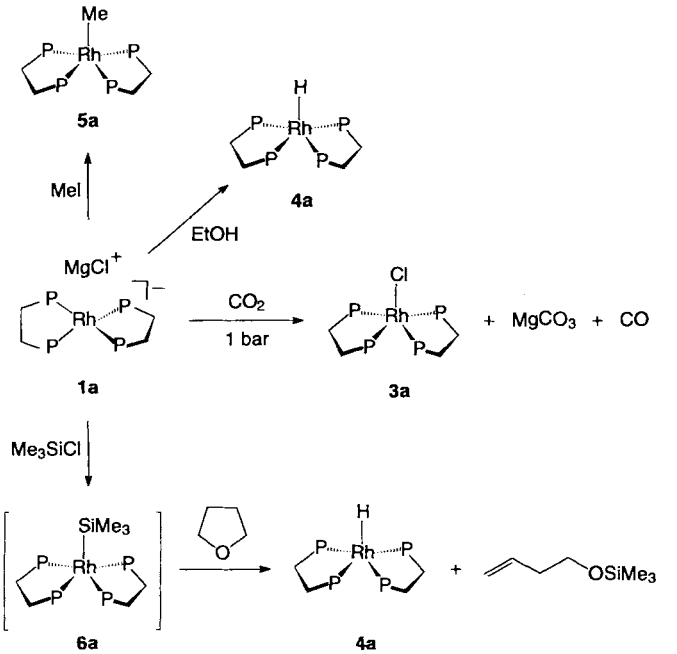
	X = Cl	X = H	X = M
$[(\mathbf{2a})_2RhX]$	**3a** $\delta = 58.2$, d $J = 133$ Hz	**4a** $\delta = 56.7$, d $J = 143$ Hz	**1a**, M = MgCl $\delta = 62$, d, br $J = 197$ Hz
[(triphos)(CO)RhX]	[b] $\delta = 3.0$, d $J = 107$ Hz	[c] $\delta = 16$, d $J = 116$ Hz	[b], M = Li $\delta = 21.4$, d $J = 155$ Hz

[a] All values in $[D]_8THF$; [b] ref. [5]; [c] ref. [13].

After filtration, a THF solvate of **1a** can be precipitated from the reaction mixture with pentane. The IR spectrum of this extremely air- and moisture-sensitive, dark red, microcrystalline solid (m.p. = 110–113 °C)[14] reveals the absence of the characteristic bands for the Rh–Cl and Rh–H units in **3a** (353 cm^{-1}) and **4a** (1897 cm^{-1}) and exhibits a new band for the Mg–Cl vibration at 321 cm^{-1}.

The reaction of **3b** with Mg* proceeds in an identical manner to give **1b**, which exhibits ^{31}P NMR data similar to that of **1a** ($\delta \approx 24.8$, very broad doublet, $J \approx 170$ Hz, 121.06 MHz, RT). Preliminary experimental results show that the NMR spectra of **1a** and **1b** are highly dependent on field strength, temperature, and concentration. This suggests an intermolecular dynamic exchange process in solution. The high conductivity of **1a** and **1b** at room temperature[15] strongly supports their formulation under these conditions as solvent-separated ion pairs with tetrahedral coordination at the d^{10} transition metal center in the $[(P_2)_2Rh]^-$ core,[2] which may be in equilibrium with a pentacoordinated covalent bimetallic species.[16] Nevertheless, other possible processes such as Schlenk-type equilibria cannot be ruled out.

The Grignard-analogous reactivity of **1a** (Scheme 2) and **1b** clearly reflects the high nucleophilicity of the rhodium



Scheme 2. Reactivity of the Grignard-analogous rhodium complex **1a** towards various electrophiles and carbon dioxide. All reactions were carried out in THF or $[D]_8THF$ at room temperature. P = PPh_2.

centers and gives further unambiguous evidence for their formulation as $[(P_2)_2Rh][MgCl]$. Careful protonolysis with stoichiometric amounts of EtOH gives the hydride complexes **4a** and **4b** in quantitative yields. Methylation of **1a** with methyl iodide leads to the rhodium complex **5a**, which can be readily separated from the magnesium salts and isolated in 76% yield.[17, 18]

In principle, the reaction of Grignard-analogous phosphane complexes with R_3SiX should offer an interesting approach to bimetallic phosphane complexes with nonbridging Rh–Si units. This class of compounds has attracted considerable interest in recent years.[19, 20] However, the reaction of **1a** and Me_3SiCl at room temperature leads to quantitative formation of the hydride **4a**. GC analysis of the volatile components reveals the presence of the trimethylsilyl ether of 1-butenol. This suggests the intermediate formation of $[(\mathbf{2a})_2RhSiMe_3]$ (**6a**), which undergoes a ring-opening reaction with solvent THF. The thermal instability of complexes $[(R_3P)_nRhSiR_3]$ ($n = 3,4$) is well documented,[19] but Aizenberg and Milstein have very recently reported complexes of type $[(Me_3P)_4RhSiR_3]$. These species have a limited, but definite lifetime in THF at room temperature.[20c]

Complexes **1a** and **1b** should also be suitable for activation of CO_2[21] since they contain both a highly electron-rich and an electron-deficient metal center. A similar methodology has been introduced by Floriani and co-workers.[21, 22] Replacement of the argon atmosphere over a THF solution of **1a** with CO_2 results in the immediate formation of a yellow precipitate, which consists of an approximately 1:1 mixture of **3a** and $MgCO_3$. The supernatant also contains small amounts of **3a**; this is therefore the only phosphorus-containing product. Labeling experiments with $^{13}CO_2$ and GC/MS analysis of the gaseous products revealed the concomitant formation of ^{13}CO. Thus, the overall process is the conversion of two molecules of CO_2 to CO and CO_3^{2-}. This reaction has been frequently observed for transition metal complexes that attack carbon dioxide at the Lewis acidic carbon center.[21a, c] In the present case, the highly nucleophilic rhodium center provides the two electrons required for this process.

As the starting material (**3a**) for the formation of **1a** is regenerated in this reaction, the possibility of a catalytic cycle based on this process was tested. Unfortunately, conversion of **3a** to **1a** with excess Mg* under one atmosphere CO_2 was not very effective; only three catalytic turnovers were obtained after 24 h. Nevertheless, this reaction provides the first example of a homogeneously catalyzed reduction of CO_2 to CO at a transition metal center, whereby the two reduction equivalents are provided by a main group metal and not a by photo- or electrochemical process.[21b] To the best of our knowledge, this is the first example of a nonelectrochemical catalytic process based on the interconversion of rhodium(−I) and rhodium(I) centers, which are coordinated only to phosphane ligands.

In conclusion, transition metal phosphane complexes such as **3** react with Mg* to give well-defined molecular compounds **1** with highly nucleophilic, mononuclear rhodium centers in formally negative oxidation states. The phosphorus ligands at the central metal atom provide a straightforward, diagnostic tool for studying the structure and reactivity of these species in solution. Based on their composition and chemical behavior, compounds of type **1** can be referred to as Grignard-analogous transition metal phosphane complexes. Their use as versatile reagents for organometallic transformations, including the synthesis of other heterobimetallic complexes and catalytic processes, offers a broad range of potential applications.

Experimental Section

All manipulations were carried out under an argon atmosphere in flame-dried glassware with standard Schlenk techniques. THF and $[D]_8THF$ were distilled from [Mg·anthracene·3 thf] prior to use. NMR spectra were recorded in sealed tubes or in tubes equipped with J. Young valves.

$[(\mathbf{2a})_2Rh][MgCl]$ (**1a**): Mg* (0.65 g, 24.8 mmol) was added to a slurry of **3a** (2.41 g, 2.59 mmol) in THF (80 mL), and the mixture stirred at room temperature. After 2 h the solution was filtered and evaporated to dryness. The residue was then redissolved in THF (10 mL). Subsequent addition of pentane (5/1 v:v) yielded **1a**·xTHF (2.73 g) as a dark red, microcrystalline solid. Analytical data are summarized in Table 1 and in the text. Complex **1b** was synthesized by the same procedure on a smaller scale (**3b**: 0.57 g).

[7] The term "inorganic Grignard reagents" is often restricted to bimetallic complexes $[L_nMMgCl]$, for which X-ray diffraction studies suggest a direct M–Mg bond. For example see a) H. Felkin, G. Swierczewski, *Tetrahedron* **1975**, *31*, 2735; b) H. Felkin, P. J. Knowles, B. Meunier, *J. Organomet. Chem.* **1978**, *146*, 151; c) S. G. Davies, M. L. H. Green, *J. Chem. Soc. Dalton Trans.* **1978**, 1510; d) K. Jonas, G. Koepe, C. Krüger, *Angew. Chem.* **1986**, *98*, 901; *Angew. Chem. Int. Ed. Engl.* **1986**, *25*, 923. However, many bimetallic transition metal/magnesium complexes containing carbonyl ligands exhibit bridging M(μ-CO)Mg units rather than direct M–Mg interactions; examples: e) G. B. Vicker, *Inorg. Chem.* **1975**, *14*, 2087; f) S. W. Ulmer, P. M. Skarstad, J. M. Burlitch, R. E. Hughes, *J. Am. Chem. Soc.* **1973**, *95*, 4469; g) J. L. Detrich, R. Konečný, W. M. Vetter, D. Doren, A. L. Rheingold, K. H. Theopold, *ibid.* **1996**, *118*, 1703. Therefore, we prefer the wider use of inorganic Grignard reagents which implies analogy to organic Grignard reagents in terms of composition, synthesis, and reactivity.
[8] For ligand-free inorganic Grignard reagents, see a) L. E. Aleandri, B. Bogdanović, P. Bons, C. Dürr, A. Gaidies, T. Hartwig, S. Huckett, M. Lagarden, U. Wilczok, R. A. Brand, *Chem. [10] a) E. Bartmann, B. Bogdanović, N. Janke, S. Liao, K. Schlichte, B. Spliethoff, J. Treber, U. Westeppe, U. Wilczok, *Chem. Ber.* **1990**, *123*, 1517; b) commercial Mg powder (250 mesh) reacts under ultrasonic irradiation, but the reaction is sluggish and accompanied by considerable amounts of side products.
[11] For the application of $[(\mathbf{2a}-\mathbf{b})_2Rh]^+$ as easily detectable probes in NMR spectroscopic investigations of the catalytic hydrogenation of CO_2, see T. Burgemeister, F. Kastner, W. Leitner, *Angew. Chem.* **1993**, *105*, 781; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 739.
[12] The corresponding signal accounts for about 90% of the total intensity in the ^{31}P spectrum; the only other detectable product is the hydride **4a** [9]. As THF has been excluded as the hydride source by labeling experiments, this side product is most likely formed by the reaction of **1a** or **3a** with inevitable traces of moisture or MgH_2 (in Mg*), respectively. Furthermore, it has been independently checked that **4a** is inert towards Mg*.
[13] J. Ott, L. M. Venanzi, C. A. Ghilardi, S. Midollini, A. Orlandini, *J. Organomet. Chem.* **1985**, *291*, 89.
[14] The extreme sensitivity of the material has hampered all attempts to detect the anion $[(\mathbf{2a})_2Rh]^-$ by ESI-MS. This, together with the tendency of the compounds to retain varying amounts of THF, has also prevented us from obtaining satisfactory elemental analyses. However, analytically determined elemental ratios of Mg:Rh:Cl:P = 1:1:1:4 are acceptable for both **1a** and **1b**.
[15] **1a**: 3.40×10^{-4} S (THF, $c = 0.06$ mol L^{-1}, RT); **1b**: 5.42×10^{-4} S (THF, $c = 0.04$ mol L^{-1}, RT).
[16] As the quality of the crystals did not allow X-ray diffraction studies, we tried to obtain evidence for a Rh–Mg interaction in the solid state with EXAFS investigations. Unfortunately, due to the small contribution of a Mg back scatterer to the $\chi(k)k^3$ function, no conclusions about its presence or absence at or below 3.5 Å was possible (FEFF calculations).

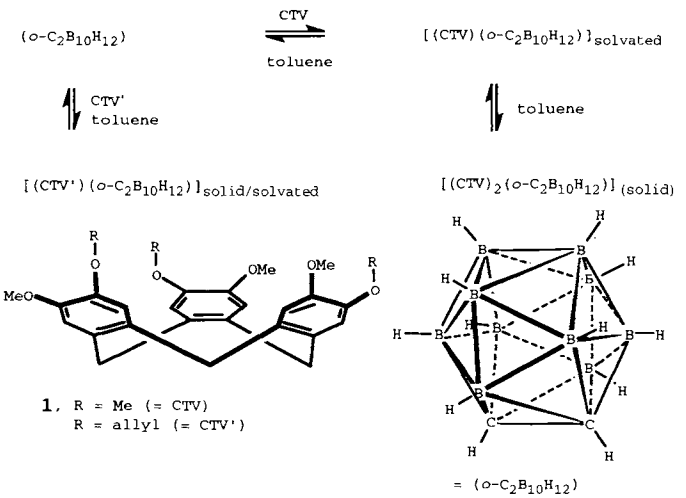

Scheme 1.

Supramolecular Complexation of 1,2-Dicarbadodecaborane(12)**

Rodney J. Blanch,* Mark Williams, Gary D. Fallon, Michael G. Gardiner, Rana Kaddour, and Colin L. Raston*

Although the carboranes *o*-, *m*-, and *p*-$C_2B_{10}H_{12}$ [1,2-, 1,7-, and 1,12-dicarbadodecaborane(12)] have been known for over thirty years, their potential for building macromolecules and forming supramolecular assemblies has only recently been explored.[1–4] These studies include linkage of the cages through the carbon centers by organic groups[1, 2] or metal centers[3] and inclusion complexation of *o*-$C_2B_{10}H_{12}$ in α-, β-, or γ-cyclodextrin as 2:1 and 1:1 complexes in aqueous media.[4] The formation of the 2:1 complexes possibly involves complete encapsulation of the carborane by two host molecules. In the case of the 1:1 complexes, polymeric structures in which both sides of each cyclodextrin make contact with a carborane may prevail. The different dipole moments of the three carboranes may be a useful property to exploit for purification of the carboranes. Conventional chromatographic techniques make the separation of the *p*- and *m*-isomers difficult.[5]

The inclusion chemistry of carboranes has been very limited so far. This is surprising given the nexus between these clusters and the buckminsterfullerene C_{60}, for which there have been several studies.[6, 7] The carboranes and C_{60} are all remarkably thermally stable, icosahedral clusters with similar diameters of about 8 and 10.0 Å, respectively. However, it is noteworthy that only the *p*-isomer is nonpolarized in the ground state, like C_{60}.

Here we report complexation of the *ortho*-carboranes by the rigid, bowl-shaped cyclotriveratrylene (CTV)[8, 9] and its symmetrically tris(allyl)-substituted analogue (CTV') in nonaqueous media (Scheme 1).[10] Both species form complexes with C_{60}.[6] Despite the use of equimolar amounts of the two starting materials, CTV forms a 2:1 adduct with *o*-$C_2B_{10}H_{12}$ in the solid state. While the 2:1 ratio can indicate that two host molecules encapsulate the cluster, the X-ray structure revealed that only one of the ligands binds to the cluster. The other one seems to act as a space filler (see below). The IR spectrum shows a significant shift of 13.5 cm^{-1} to lower energy of for the ν_{C-H} band of the carborane and a shift of 15.3 cm^{-1} to higher energy for the ν_{B-H} band. This is consistent with the involvement of the C–H bonds in nonclassical hydrogen bonding. Dispersal of the extra charge on the carbon atoms results in a strengthening of the B–H bonds. CTV' also complexes to *o*-$C_2B_{10}H_{12}$, and the product shows similar IR shifts (12.5 cm^{-1}, ν_{C-H}; 3.2 cm^{-1}, ν_{B-H}). However, the crystals obtained were unsuitable for crystallographic studies.

^{1}H NMR solution spectra of the 2:1 complex show that a rapid exchange process occurs between complexed and uncomplexed carborane. Single peaks observed for the *o*-carborane C–H groups are significantly shifted upfield. The ^{1}H NMR spectra of complexed and uncomplexed CTV are essentially the same. Variation of the molar fraction of carborane relative to CTV shows a nonlinear relationship with the chemical shift of the carborane C–H protons (from $\delta = 3.53$ to 3.36 for ratios of *o*-carborane to CTV of 5:1 to 1:5). This implies that the complexation is not a simple 1:1 supramolecule formation. Indeed, the inability to fit the NMR data to this simple model indicates that *o*-carborane can bind in both an *endo* and *exo* fashion to the cavity of the CTV.

In the solid state[11] the 2:1 complex consists of *o*-$C_2B_{10}H_{12}$ in a host–guest contact with one of the CTV molecules (Figure 1). The other CTV forms a zigzag π-stacked column in which the intermolecular CTV contacts are at the van der Waals limit (Figure 2). The asymmetric unit is made up of one host–guest species and one CTV of the column, which is built up by a screw axis along the *b* axis such that π stacking is only effective for a part of two of the aromatic rings of each CTV. The structure represents the first authentic host–guest complex of a main group cluster other than C_{60}.[6] The lengths of the covalent bonds in the CTV molecules[9] and the carborane[13] are in the expected range.

The cavity of CTV is shallow relative to the diameter of the carborane, and association of the two units is best described as a perching complex.[14] Diffraction data were collected at −100 °C: this facilitated the refinement of the hydrogen

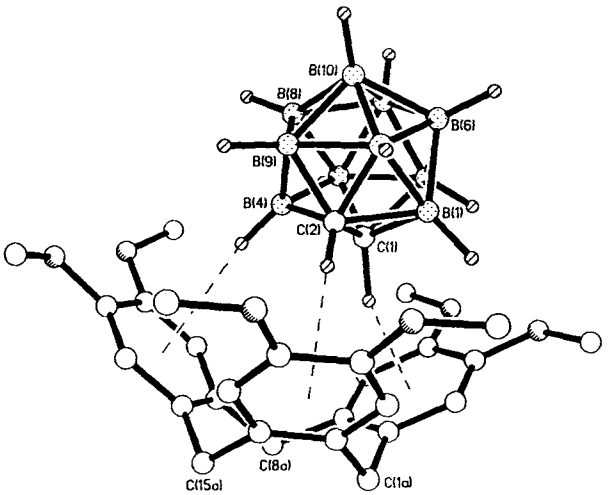

Figure 1. Projection of the host–guest structure with nearest contacts shown as dashed lines; distances from the centroid of the aromatic rings to the H atoms on C(1), C(2), and B(4) are 2.184, 2.556, and 2.765 Å, respectively (corresponding distances from C(1), C(2), and B(4) to the centroids, 3.299, 3.503, 3.701 Å, respectively).

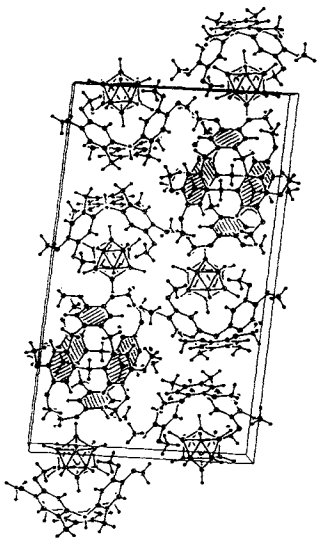

Figure 2. Crystal packing diagram of $[(CTV)_2(o\text{-}C_2B_{10}H_{12})]$ as viewed along the *b* axis.

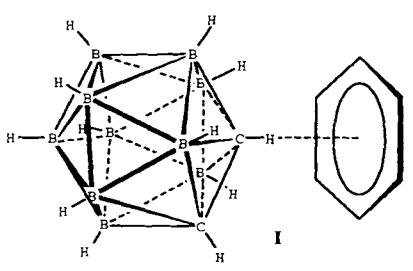
atoms of the cluster and allows some meaningful discussion on the nature of the host–guest complex. Close inspection of the nonbonded distances shows that three hydrogens of a triangular face of the icosahedron are directed towards the aromatic rings of the CTV, albeit unsymmetrically (Figure 1). The origin of this is most likely the energetically favored nonclassical hydrogen bonds between each of the two acidic hydrogen atoms on cluster carbon atoms and two aromatic rings of the CTV. Furthermore, this allows repulsion between the hydrogen atom on a cluster boron atom and the third aromatic ring of the CTV.

Thus, alignment of the carborane in the CTV cavity is consistent with the acidic nature of the protons attached to the carbon centers of the carborane. This is supported by theoretical studies, which give the protons on carbon a residual charge of +0.299; the hydrogen atoms on boron show charges of 0.068 to 0.091.[15] A single C–H π interaction between benzene and the carborane lowers the total energy by 2.72 kcal mol^{-1} (CH $\cdots$ benzene ring centroid = 2.694 Å, structure **I**). This compares well with values calculated for interactions between hydrogen atoms on carbon centers of chloroform and benzene (3.94 kcal mol^{-1}).[17] Furthermore, such nonclassical hydrogen bonding has precedence in dichloromethane[18] and water[19] inclusion complexes of calix[4]arenes.



I

Our findings establish that nonclassical hydrogen bonds aid the formation of host–guest nanostructures between carboranes and host molecules containing aromatic rings. This has potential for assembling complex structures.

Experimental Section

$[(CTV)_2(o\text{-}C_2B_{10}H_{12})]$: $o\text{-}C_2B_{10}H_{12}$ (0.032 g, 0.22 mmol) was added to a solution of CTV (0.1 g, 0.22 mmol) in toluene ($\approx$10 mL). The solvent was then allowed to evaporate slowly. After one week crystals had formed, which were collected (60 mg, 52% yield) and investigated by IR and NMR spectroscopy. The X-ray crystal structure was also determined.

$[(CTV')(o\text{-}C_2B_{10}H_{12})]$: This 1:1 complex was synthesized in an analogous manner. However, no crystals of X-ray quality were recovered.

[15] Calculations were carried out at the 6-31G* level with Gaussian 92 [16]; $o\text{-}C_2B_{10}H_{12}$ and benzene were fully optimized in the point groups C_{2v} and D_{6h}, respectively, which were constrained. The benzene was constrained so that its centroid was along a C–H vector of the carborane; the benzene plane was perpendicular to the same C–H vector. Additionally, the C–C vector of two *para*-carbon atoms of benzene was arbitrarily aligned with the projection of the C–C vector of the carborane onto the benzene plane.

Acyclic Diyne Metathesis (ADIMET), an Efficient Route to Poly(phenylene)ethynylenes (PPEs) and Nonconjugated Polyalkynylenes of High Molecular Weight**

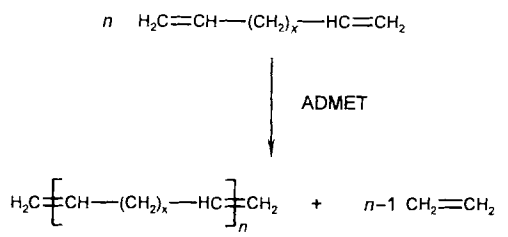
Karin Weiss,* Armin Michel, Eva-Maria Auth, Uwe H. F. Bunz, Timo Mangel, and Klaus Müllen

Dedicated to Professor Max Herberhold on the occasion of his 60th birthday

Conjugated polymers such as poly(*p*-phenylene)vinylenes (PPV)[1] and poly(*p*-phenylene)s[2] have been studied intensively because of their optical and electronic properties. These polymers can be used as antielectrostatic coatings, solar cells, light emitting diodes,[3] and "molecular wires". The dehydrogenated analogues of PPV, the poly(phenylene)ethynylenes (PPEs), are a class of polymers that received far less attention in the past;[4] however, nowadays because of their valuable optical,[5] electronic,[6] and coating properties[7] they are intensively used for different applications. The synthetic route to PPEs and their oligomeric model compounds was based on the palladium-catalyzed polycondensation of aromatic dihalides (especially diiodides) with diynes.[8] However, this reaction is encumbered with the typical problems of palladium-catalyzed reactions, such as dehalogenation, the appearance of diyne units in the polymer, and in some cases, the difficult separation of the phosphorus- and palladium-containing catalyst residues.

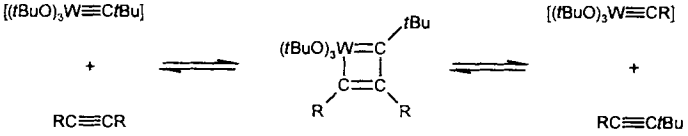
Acyclic metathesis of dienes has been known since 1973.[9] However, the reaction delivers only low molecular weight products when classic metathesis catalysts are employed. Wagener et al.[10] were able to produce polymers of high molecular weight when the reactions were carried out under vacuum, and the volatile metathesis products such as ethene or 2-butene were removed from the reaction mixture. Tungsten or molybdenum carbene complexes of the Schrock type were used as catalysts, and were added to the reaction mixtures in several portions. This type of reaction is referred to as an ADMET reaction (*A*cyclic *D*iene *Met*athesis) (Scheme 1).[10]

The stoichiometric and catalytic metathesis of monoalkynes with tungsten carbyne complexes has been studied in detail by Schrock et al. (Scheme 2).[11] They also reported the stoichiometric metathesis of a conjugated diyne,[12] and the reaction of 2,10-dodecadiyne with the carbyne complex [(*t*BuO)$_3$W≡C*t*Bu].



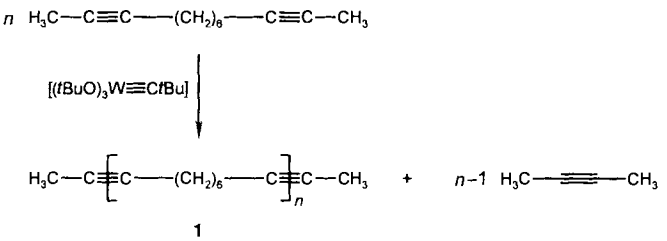
Scheme 1.

This condensation resulted in an insoluble polymer, which was not further analyzed.[13] The reactions of 4,4-disubstituted 1,6-heptadiynes with carbene–Mo^{VI} complexes yield cyclic polymers.[14]



Scheme 2.

We have developed a reaction with diynes and [(*t*BuO)$_3$W≡C*t*Bu] as catalyst, which is analogous to the ADMET condensation of dienes. However, a disubstituted alkyne is required in this case, because carbyne tungsten complexes prefer to polymerize 1-alkynes.[15] Practical considerations lead to the conclusion that under suitable conditions (vacuum) bispropynyl compounds and bisbutynyl compounds should be able to undergo a condensation analogous to the ADMET reaction by elimination of the volatile components 2-butyne and 3-hexyne, respectively. The *A*cyclic *D*iyne *Met*athesis (ADIMET reaction) of 2,10-dodecadiyne with [(*t*BuO)$_3$W≡C*t*Bu] as catalyst produced an insoluble polyoctynylene **1** through elimination of 2-butyne (25–60 °C, 0.01 hPa, 24 h) (Scheme 3).



Scheme 3.

3,9-dodecadiyne reacted under the same conditions (with elimination of hexyne) to form a soluble polyhexynylene **2** (Scheme 4).

Furthermore, we have been able to synthesize soluble polyoctynylenes **1**, which can be characterized by NMR spec-

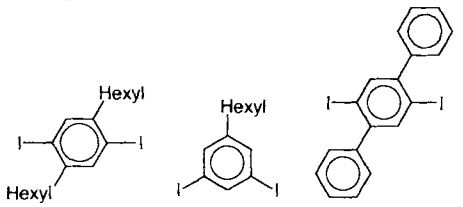
[a] Starting period of ADIMET reaction. [b] Further catalyst addition after 5 h. [c] Further catalyst addition after 24 h and 48 h. [d] Chloroform-soluble part.

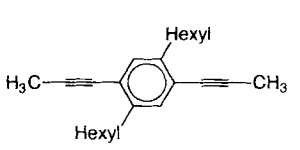
troscopy, by shortening the reaction times of the reaction of 2,10-dodecadiyne with $[(t\mathrm{BuO})_3\mathrm{W}{\equiv}\mathrm{C}t\mathrm{Bu}]$ and by carrying out the reaction at normal pressure (Table 1). ^{13}C and ^1H NMR investigations of the nonconjugated soluble polyalkynylenes **1** and **2** show the expected absorptions in the -C≡C- region, but no absorptions in the olefinic region, as expected for cross-linked products.

Following the successful preparation of nonconjugated polyalkynylenes, we set about the synthesis of PPEs by metathesis condensation. The bispropynylbenzene derivatives were prepared by the palladium-catalyzed reaction of the diiodobenzene derviatives **3**–**5** with propyne according to the Heck–Cassar–Sonogashira method.[8]

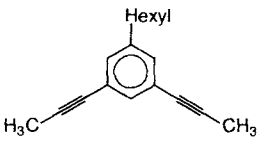


3 **4** **5**

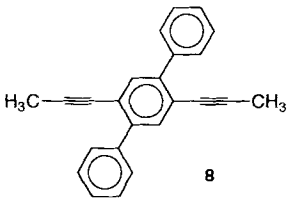
The bispropynylbenzene derivatives **6**–**8** were separated by chromatography in high yields (99%, 97%, 98%) as pale yellow solids (**6** and **8**) or as a pale yellow oil (**7**).



6



7

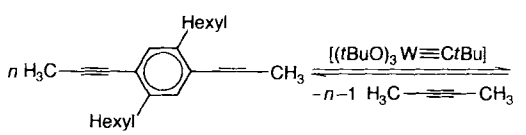


8

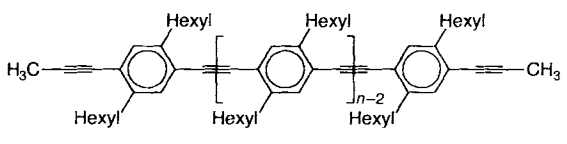
These conjugated bispropynylbenzene derivatives were then subjected to ADIMET reactions. For instance, a concentrated solution of **6** in 1,2,4-trichlorobenzene was treated with $[(t\mathrm{BuO})_3\mathrm{W}{\equiv}\mathrm{C}t\mathrm{Bu}]$ (2 mol%), and the reaction mixture held at 80 °C and 12 hPa for 24 h. An additional small portion of catalyst and further solvent was added when the reaction mixture became viscous. After 72 h the polymerization was stopped by adding methanol, and a bright yellow polymer **9a** precipitated out of methanol in 68% yield, which was analyzed by gel permeation chromatography (GPC) and NMR spectroscopy. The molecular weight M_n of the soluble part (50 wt% in $CHCl_3$) was determined by GPC to be 40000 with a polydispersity $M_w/M_n = 2.1$ (Table 2).

In order to minimize the amount of the less soluble polymer **9**, **6** was polymerized in trichlorobenzene under identical conditions, but the reaction was now stopped after 24 h. The resulting product **9b** was now completely soluble and was studied by NMR spectroscopy and GPC. The polymer **9b** had a molecular weight M_n of 4100 and a polydispersity of 2.3 (determined by GPC). The ^{13}C NMR spectrum of **9b** showed no additional signals in the region of sp^2-hybridized C atoms, which indicates that cross-linking of **9** may be excluded. This interpretation is also supported by the monomodal molecular weight distribution.

The NMR and mass spectra of **9** confirm the presence of propynyl end groups, which can then be used for further reactions. The optical and spectroscopic properties of **9** are identical with those of the polymer **9** that we synthesized by the Heck–Cassar–Sonogashira method (Scheme 5).[5]

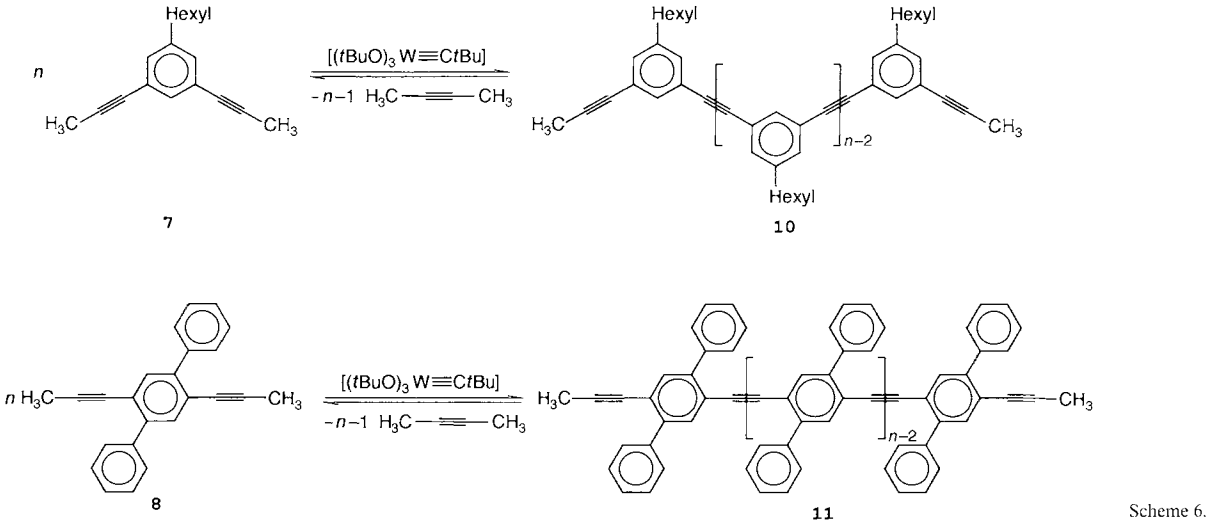


6



9

Scheme 5.



Scheme 6.

The polymerization of **7** and **8** can also be achieved in trichlorobenzene under the same conditions to form ocher and light beige solids **10** and **11**, respectively (Scheme 6). The molecular weights M_n of **10** and **11** were determined to be 2800 and 1000 amu.

The considerably lower molecular weight of **11** is attributed to the significantly reduced solubility of this material in organic solvents (48% in $CHCl_3$). The phenyl subtituents do not enhance the solubility of the polymer chain. The molecular weights of the resulting polymers are dependent on reaction time, temperature, pressure, and solubility (Table 2). The ADIMET reaction of **6** gave as expected the polymer **9** with the highest molecular weight. The two hexyl substituents of **6** enhance the solubility of the polymer in organic solvents.

In summary, we have demonstrated that PPEs can be prepared not only by Heck–Cassar–Sonogashira coupling,[8] but also by a completely different process, namely the ADIMET condensation, to give pure polymer products with high molecular weights in some cases. Further studies are in progress on the control of the molecular weights of the PPEs during the course of the ADIMET condensation and on the end capping reactions of PPEs with two equal or different functional groups.

Experimental Section

The catalyst $[(tBuO)_3W{\equiv}CtBu]$ was prepared according to the method applied by Schrock et al. [16]. The syntheses of the diiodides **3** and **4** were reported in ref. [4], that of **5** in ref. [17].

Syntheses of polyoctynylenes **1** and polyhexynylenes **2**: Diyne (2.11 mmol) was added under argon to $[(tBuO)_3W{\equiv}CtBu]$ (10 mg, 0.021 mmol) in a Schlenk tube, connected through a cooling trap to a high vacuum (HV) pump, or left at normal pressure. The reactions were either carried out under isothermal conditions or the temperature was raised over one hour to the final temperature (Table 1). The reactions were stopped by addition of methanol, and the oligomeric products, which were soluble in methanol, were then separated from the insoluble brown polymers.

1: ^{1}H NMR (250 MHz, $CDCl_3$): $\delta = 2.05$ ($C{\equiv}C\text{-}CH_2$), 1.7 ($C{\equiv}C\text{-}CH_3$), 1.4 ($\text{-}CH_2\text{-}$); ^{13}C NMR (63 MHz, $CDCl_3$): $\delta = 80.1$ ($CH_2\text{-}C{\equiv}C\text{-}CH_2$), 79.1 ($CH_3\text{-}C{\equiv}C\text{-}CH_2$), 75.3 ($CH_3\text{-}C{\equiv}C\text{-}CH_2$), 28.6, 18.6 ($\text{-}CH_2\text{-}$), 3.3 ($CH_3\text{-}C{\equiv}C$)

2: ^{1}H NMR (250 MHz, $CDCl_3$): $\delta = 2.12$ ($C{\equiv}C\text{-}CH_2$), 1.54 ($C{\equiv}C\text{-}CH_2\text{-}CH_3$), 1.1 ($\text{-}CH_2\text{-}$); ^{13}C NMR (63 MHz, $CDCl_3$): $\delta = 81.6$ ($CH_2\text{-}C{\equiv}C\text{-}CH_2$), 28.2, 18.3 ($\text{-}CH_2\text{-}$)

6, **7**, and **8**: Piperidine (75 mL) was added to **3** (4.98 g, 10 mmol), $[Pd(PPh_3)_2Cl_2]$ (351 mg, 0.5 mmol), and CuI (190 mg, 1 mmol) in a 100 mL three-necked flask fitted with a gas distribution tube, septum, argon balloon, and a condensor (acetone/dry ice cooling). Propyne was slowly fed into the solution over a period of 2–3 h. The solvent was removed and the residue was dissolved in petroleum ether and filtered through silica gel. Evaporation of the solvent gave 3.20 g (99%) **6** as a pale yellow solid. Analogous syntheses gave **7** in 97% (pale yellow oil) and **8** (pale yellow solid) in 98% yield.

6: M.p. 43 °C; ^{1}H NMR (200 MHz; $CDCl_3$): $\delta = 7.15$ (s, 2H; H-3, H-6), 2.64 (t, $J = 7.7$ Hz, 4H; α-CH_2), 2.06 (s, 6H; CH_3), 1.65–1.52 (m, 4H; β-CH_2), 1.38–1.23 (m, 12H; CH_2), 0.88 (t, $J = 6.5$ Hz, 6H; CH_3); ^{13}C NMR (50 MHz; $CDCl_3$): $\delta = 141.8$ (C-2, C-5), 132.2 (C-3, C-6), 12.6 (C-1, C-4), 89.6 (-C≡C-), 78.6 (-C≡C-), 33.8, 31.7, 30.4, 29.1, 22.6, 14.1, 4.4 ($C{\equiv}C\text{-}CH_3$); IR (KBr): $\tilde{\nu}$/cm^{-1}: 2959, 2949, 2926, 2889, 2867, 2847, 2228, 1491, 1465, 1454, 1427, 1394, 1378, 1367, 1338, 1259, 991, 908, 873, 729; MS (FD): m/z (%): 322.3 (100) [M^+]

7: ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 7.24$ (s, 1H; H-2), 7.11 (s, 2H; H-4, H-6), 2.50 (t, $J = 7.5$ Hz, 2H; α-CH_2), 2.01 (s, 6H; $\text{-}CH_3$), 1.65–1.45 (m, 2H; β-CH_2), 1.35–1.20 (m, 6H, CH_2), 0.88 (t, $J = 6.6$ Hz, 3H; CH_3); ^{13}C NMR (50 MHz, $CDCl_3$): $\delta = 142.9$ (C-5), 131.8 (C-2), 130.8 (C-4, C-6), 123.9 (C-1, C-3), 85.6 (-C≡C-), 79.4 (-C≡C-), 35.5, 31.7, 31.1, 28.9, 22.6, 14.0, 4.2 ($C{\equiv}C\text{-}CH_3$); IR (KBr): $\tilde{\nu}$/cm^{-1}: 3043, 2956, 2927, 2867, 2856, 2248, 1590, 1465, 1456, 1442, 1376, 882, 869, 694; MS (FD): m/z (%): 238.2 (100) [M^+]

8: M.p. 176 °C; ^{1}H NMR (200 MHz; $CDCl_3$): $\delta = 7.67$–7.59 (m, 4H; H′-2, H′-6), 7.53 (s, 2H; H-3, H-6), 7.48–7.31 (m, 6H; H′-3, H′-4, H′-5), 1.94 (s, 6H, CH_3); ^{13}C NMR (50 MHz; $CDCl_3$): $\delta = 142.0$ (*tert* C of the outer ring), 127.9 (*tert* C of the outer ring), 127.4 (*tert* C of the outer ring), 121.8 (C-1, C-4), 90.1 (-C≡C-), 79.0 (-C≡C-), 4.5 ($C{\equiv}C\text{-}CH_3$); IR (KBr): $\tilde{\nu}$/cm^{-1}: 3061, 3039, 3026, 2955, 2922, 2914, 2870, 2851, 2232, 1600, 1508, 1480, 1445, 1432, 1384, 1372, 1178, 1074, 1028, 979, 917, 904, 767, 720, 697, 684; MS (FD): m/z (%): 306.1 (100) [M^+]

9: **6** (338 mg, 1.05 mmol) was dissolved in 1,2,4-trichlorobenzene (7 mL) at 80 °C and then treated with the catalyst $[(tBuO)_3W{\equiv}CtBu]$ (10 mg, 0.021 mmol). The reaction mixture was stirred for 30 min at normal pressure and then for 72 h at a pressure of 12 hPa. After 24 h and 48 h a small amount of catalyst (2 mg) was added. The reaction was stopped by addition of methanol (20 mL). The polymer was filtered off, washed several times with methanol, and dried to yield **9** (230 mg, 68%) as a bright yellow solid.

9a: ^{1}H NMR (250 MHz, $CDCl_3$): $\delta = 7.36$ (Ph-H), 2.81 (Ph-CH_2), 2.08 ($C{\equiv}C\text{-}CH_3$), 1.70–1.53 (CH_2), 1.33–1.23 (CH_2), 0.87 ($CH_2\text{-}CH_3$); ^{13}C NMR (63 MHz, $CDCl_3$): $\delta = 141.9$ (Ph), 132.4 (Ph), 122.8 (Ph), 93.1 (Ph-C≡*C*-Ph), 34.2, 31.8, 30.7, 29.3, 22.6 (CH_2), 14.1 ($CH_2\text{-}CH_3$); IR (KBr): $\tilde{\nu}$/cm^{-1}: 3020, 2954, 2922, 2853, 2196, 1773, 1502, 1457, 1376, 1259, 1185, 1113, 968, 892, 812, 722, 667

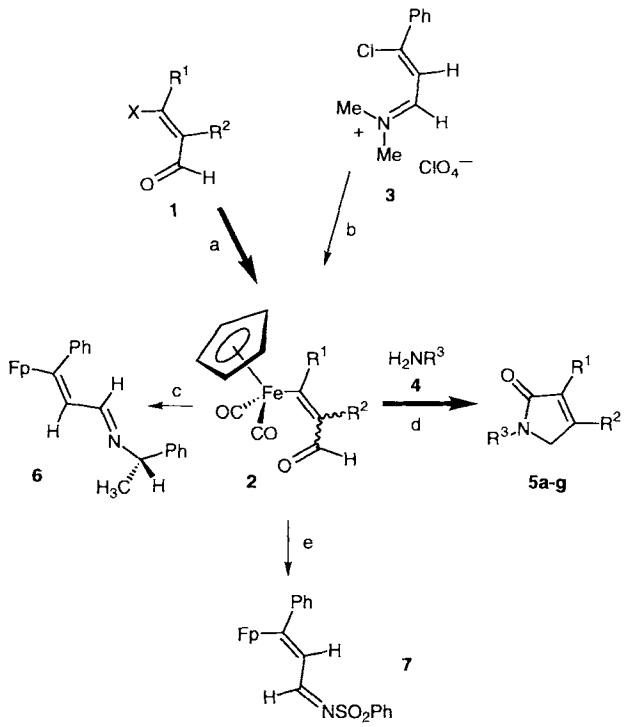
α,β-Unsaturated γ-Lactams from $TiCl_4$-Mediated Transformations of Vinylogous Iron Formyl Complexes**

Karola Rück-Braun*

Domino processes and other reactions that proceed by C–C bond formation in the coordination sphere of a transition metal are of particular interest in organic synthesis.[1] This also holds true for reactions in which carbonyl ligands are inserted from the metal fragment furnishing organic compounds.[2, 3] Very significant is that the electronic surrounding of the metal, in addition to steric factors, directs the reactivity of the attached functional groups, thereby opening various possibilities for specifically influencing the reaction pathways.

Vinylogous iron acyl complexes have been scarcely applied in organic synthesis.[4] Due to the spatial proximity of the aldehyde moiety and the metal fragment in *cis*-configurated iron formyl complexes **2**, chelation interactions are facilitated,[3c, 5] and a specific reactivity pattern is expected. In this paper, the synthesis of **2** from β-bromo or β-chloro vinyl aldehydes **1** (Scheme 1, pathway a) and the reactions of *cis*-configurated **2** with donor-substituted primary amines **4** (H_2NR^3) to yield 2,5-dihydro-1*H*-pyrrol-2-ones **5** (α,β-unsaturated γ-lactams; Scheme 1, pathway d) are described.

The iron formyl compounds **2** were formed by the reaction of ferrates $[Cp(CO)_2FeM]$ (FpM; M = Na, K)[6] with β-bromo or β-chloro vinyl aldehydes of type **1** or with the iminium salt **3** (Scheme 1). These aldehydes and iminium salts are available



Scheme 1. Fp = $Cp(CO)_2Fe$; X = Br, Cl. a) FpNa, −78 °C, THF, 1 h; b) FpK, −78 °C, THF, 1 h, 59% [(*Z*)-**2a**:(*E*)-**2a** = 10:90]; c) solution of (*E*)-**2a** in CH_2Cl_2, addition of **4a** (1 equiv) and NEt_3 (2.33 equiv) at 0 °C, addition of $TiCl_4$ (0.6 equiv, 1 M in CH_2Cl_2) after 30 min, room temperature (IR monitoring). 57% **6**; d) amine **4** (1.05 equiv), Et_3N (2.3 equiv), 0 °C, 30 min, afterwards addition of $TiCl_4$ (1 equiv, 1 M in CH_2Cl_2), room temperature until IR spectrum reveals complete turnover (18–24 h), aqueous workup and subsequent chromatography; e) reaction conditions: analogous to c), (*Z*)-**2a** was allowed to react with H_2NSO_2Ph (1 equiv), 94% **7**.

from α-methylene ketones and Vilsmeier–Haack reagents, according to the procedure of Arnold and Zemlicka.[7] Aldehyde (*Z*)-**1a** (X = Cl, R^1 = Ph, R^2 = H) and FpNa react under kinetic control to form the *cis*-configurated complex (*Z*)-**2a** [81%, (*Z*)-**2a**:(*E*)-**2a** = 83:17 (R^1 = Ph, R^2 = H); Scheme 1], whereas **3**[8] and FpK preferentially deliver the *trans*-configurated complex (*E*)-**2a** (59%, (*Z*)-**2a**:(*E*)-**2a** = 10:90; Scheme 1, pathway b) by a thermodynamically controlled addition–elimination process. The crude product first obtained as an iminium salt is hydrolyzed with 15% NaOH in $CHCl_3/H_2O$. The isomers can be separated by chromatography on silica gel, and the configuration determined by NOE measurements.

Analogous to the procedure by Weingarten et al.[9] for the synthesis of imines, (*E*)-**2a** reacts with (*S*)-phenylethylamine **4a** in the presence of NEt_3 and $TiCl_4$ to give the aldimine **6** in 57% yield after aqueous workup (Scheme 1, pathway c). However, treatment of a solution of (*Z*)-**2a** (1.0 mmol), (*S*)-phenylethylamine (**4a**, 1.05 mmol), and NEt_3 (2.3 mmol) in CH_2Cl_2 at

0 °C with $TiCl_4$ (1.0 mmol, 1 M solution in CH_2Cl_2), followed by stirring at room temperature under an argon atmosphere yields pyrrolinone **5a** (Scheme 1, Table 1).[10] Apparently, this product is formed in the coordination sphere of the iron center by attack of the primary amine **4** on the formyl functionality, carbonylation as well as intra- or intermolecular hydrogen transfer, and ring closure. IR spectroscopic monitoring of the reaction shows complete turnover within 18–24 hours, as indicated by the increase in intensity of the C=O band for **5a** at 1680 cm^{-1} as well as the decrease in intensity and disappearance of the C≡O bands for (*Z*)-**2a** and the corresponding aldimine intermediate at about 2028 and 1978 cm^{-1}, respectively. The subsequent aqueous workup, therefore, has no influence on the course of the cascade. ^1H NMR spectra of the crude product only display signals for **5a**. Moreover, no formation of **5a** is observed in the absence of $TiCl_4$ (IR monitoring). Preliminary studies on the reaction of (*Z*)-**2a** with **4a** in the presence of one equivalent of $TiCl_4$ revealed that no **5a** is afforded, even in the absence of a tertiary amine such as NEt_3 or *N*-methylmorpholine. Likewise, lactam formation does not occur if a multifold excess of a primary amine is used instead of a tertiary amine. In conclusion, both the Lewis acid and the tertiary amine determine the course of the reaction cascade.[10]

A variety of primary amines **4** react with (*Z*)-**2a** under standard conditions in the presence of $TiCl_4$ and NEt_3 to deliver exclusively 2,5-dihydro-2*H*-pyrrol-2-ones **5** (Table 1, entries 1–4). Product **5d** was obtained in 44% yield from an amino acid hydrochloride after addition of 3.3 equivalents of NEt_3 (Table 1, entry 4). In the case of acceptor-substituted amines of weaker basicity, such as benzylamine, aniline, or even benzenesulfonamide, solely the formation of the corresponding imines, but no lactams, was observed by IR spectroscopy and thin layer chromatography. Compound **7** was isolated in 94% yield after aqueous workup (Scheme 1, pathway e).

Table 1. Synthesis of vinylogous iron formyl complexes **2** and $TiCl_4$-mediated transformation to 2,5-dihydro-2*H*-pyrrol-2-ones **5** according to Scheme 1.

Entry	2	R^1	R^2	Yield [%] [a, f]	5	R^3	Yield [%] [d, f]
1	(*Z*)-**a**	Ph	H	81 [b, c]	**a**	(*S*)-$CH(CH_3)Ph$	61
2	(*Z*)-**a**	Ph	H		**b**	*t*Bu	80
3	(*Z*)-**a**	Ph	H		**c**	C_6H_{11}	56
4	(*Z*)-**a**	Ph	H		**d**	(*R*)-$CH[CH(CH_3)_2]CO_2Me$	44 [e]
5	**b**			41	**e**	(S)-$CH(CH_3)Ph$	31 [e]
6	**c**			81	**f**	(*S*)-$CH(CH_3)Ph$	63
7	**d**	$-(CH_2)_4-$		52 [b]	**g**	(*S*)-$CH(CH_3)Ph$	55

[a] According to Scheme 1, pathway a, the vinylogous iron formyl complexes were obtained from the corresponding β-bromo vinyl aldehyde or [b] the β-chloro vinyl aldehyde and FpNa. [c] (*Z*)-**2a**:(*E*)-**2a** = 83:17, separation of isomers by flash chromatography. [d] Yield of isolated product after flash chromatography on florisil or [e] silica gel. [f] Yields are not optimized.

To define the scope of the outlined reaction protocol, conversions of the cyclic formyl derivatives **2b–2d** with **4a** were examined (Table 1, entries 5–7). Compounds **2b–2d** are accessible from cyclic β-halogen vinyl aldehydes and FpNa at −78 °C (Scheme 1, pathway a; Table 1) and are isolated as yellow-brown amorphous powders or crystals after chromatography on silica gel (41–81%).[11] Under standard conditions employing $TiCl_4$ and NEt_3, the reactions proceed smoothly to yield the dihydropyrrolones **5e–5g**[11].

In the case of *cis*-configurated **2**, reaction with donor-substituted primary amines **4** in the presence of $TiCl_4$ and NEt_3 should also proceed first via a hemiaminal or aldimine intermediate.[9] As reactive species that activate the carbonyl group, a complex consisting of the primary amine, the tertiary amine, and $TiCl_4$ can be considered.[9c] Apparently, chelating interactions between the titanium species formed, the metal fragment, and the nitrogen functionality of the imine or hemiaminal intermediate dominate the subsequent course of reaction. However, the exact sequence of the individual steps is as yet unknown.

In the case of 18 electron metal carbonyl complexes, carbonylation reactions[3] can be induced by single electron oxidation,[12] and the reaction rate dramatically increases upon addition of Lewis acids.[13] Complexes of metal carbonyl with Lewis acids have been isolated, and the structure elucidated by X-ray analysis.[13a] Due to the electron deficiency at the metal centers, these compounds and intermediates display increased reactivity towards nucleophiles.[2]

In the current case, CO insertion into the alkenyl–metal bond could be catalyzed by titanium. In a subsequent reaction step, intramolecular nucleophilic attack by the donor-substituted nitrogen residue on the iron acyl moiety should facilitate ring closure to form the lactam. On the other hand, titanium-mediated nucleophilic attack by the amine or imine nitrogen on one of the carbonyl ligands is also likely. This would lead to a carbamoyl complex as the reactive intermediate.[2, 14] Both carbonylation pathways should certainly be favored by donor substituents at the nitrogen atom.

The most surprising aspect of the reaction sequence is the formal reduction of the imine moiety. As the reaction cascade proceeds rapidly, no information about possible inter- or intramolecular hydrogen transfer or hydride intermediates could be obtained so far. The hydrogen atom could stem from the condensation reaction or the tertiary amine[15] and is possibly transferred by an iron hydride species[16] to the aldimine carbon.

Elucidation of the reaction mechanism and application of this novel reaction in natural product synthesis are the aims of further investigations. In light of the results presented, *cis*-configurated vinylogous iron acyl complexes may be useful tools for the synthesis of various γ-lactams, including biologically active 5-substituted 2,5-dihydro-2*H*-pyrrol-2-ones such as microcolin A.[17]

[10] Compound (*Z*)-**2a** does react with **4a** in the presence of $MgSO_4$ in diethyl ether to yield the aldimine. IR spectroscopic monitoring of the reaction reveals that **5a** forms, but nonreproducibly as a by-product in low yield (0–15%). The addition of $TiCl_4$ and Et_3N to crude aldimine in CH_2Cl_2 gives **5a**, but turnover and yield proved to be low (0–30%) and nonreproduciable relative to the one-pot procedure described here.
[11] Satisfactory spectroscopic data and mass spectra or elemental analyses were obtained for all new compounds. Supramolecular Assemblies Containing Nucleic Bases and Magnesium(II) Hexahydrate Ions**

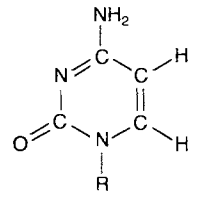
Morten Andreas Geday, Giovanni De Munno,* Marcella Medaglia, Jane Anastassopoulou, and Theophilos Theophanides

The interaction of metal ions with nucleic acids has been a subject of study for many years.[1] Much effort has been devoted, in particular, to the determination of the coordinating site of the nucleic acids and the explanation of the stabilization (Ca^{II}, Mg^{II}, Mn^{II}) or destabilization (Cu^{II}, Cd^{II}, Pt^{II}, Hg^{II}) induced on DNA by metal ions.[1] The large number of studies on metal–nucleobase complexes in solution[2] contrasts with the lack of studies of these complexes in the solid-state. With regard to cytosine (cyt) and its derivatives such as 1-methylcytosine (1-Mecyt), only nine solid-state structures of compounds with transition metals of the first row, such as Cu^{II}[3], Co^{II}[4], Ni^{II},[5] and Mn^{II}[6], are known to date. Among these, the Ni^{II} and Mn^{II} compounds are particularly interesting, because they are the only ones in which the base is coordinated to the metal ion only through its oxygen atom. Conversely, copper and cobalt are coordinated to the nitrogen atom N(3); the bond to the O(2) atom is only weak.



R = H (cyt), CH_3 (1-Mecyt)

As part of a systematic study of the unusual coordination modes of cytosine and its derivatives towards transition metal and main-group metal ions,[7] we have prepared compounds **1**–**3**.

$[Mg(H_2O)_6(1\text{-Mecyt})_6](ClO_4)_2\cdot(H_2O)$ **1**

$[Mg(1\text{-Mecyt})_2(H_2O)_4](ClO_4)_2\cdot 2(1\text{-Mecyt})$ **2**

$[Mg(cyt)_2(H_2O)_4](ClO_4)_2\cdot 2(cyt)\cdot 2(H_2O)$ **3**

We characterized **1**–**3** by elemental and X-ray structure analyses. As far as we are aware, they are the first isolated cytosine-containing magnesium(II) complexes.

Compound **1** constists of $[Mg(H_2O)_6]^{2+}$ ions, uncoordinated ClO_4^- ions, 1-Mecyt molecules, and water molecules of crystallization. Each magnesium atom in $[Mg(H_2O)_6]^{2+}$ is coordinated to six water molecules in an octahedral environment (Figure 1). The Mg–O distances are in the range 2.027–2.086(4) Å, and are shorter than those found in another previously reported hexaaquamagnesium(II) species.[8] Every $[Mg(H_2O)_6]^{2+}$ ion is linked through ten hydrogen bonds to six 1-Mecyt molecules to form the supramolecular assembly $[Mg(H_2O)_6(1\text{-Mecyt})_6]^{2+}$.[9] Four 1-Mecyt molecules form bridges between the water molecules of the best equatorial plane of the octahedron, through O(3), O(5), O(3a), and O(5a). The last two 1-Mecyt molecules, instead, are linked to the two axial water molecules through single hydrogen bonds, in which only the N(3) nitrogen atom is

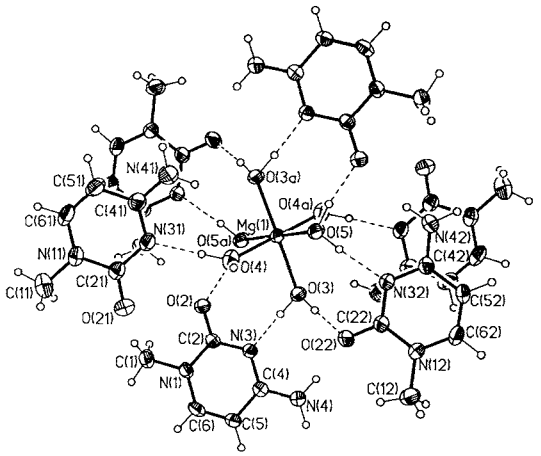

Figure 1. Crystal structure and atomic labeling of the $[Mg(H_2O)_6(1\text{-Mecyt})_6]^{2+}$ ion in **1**. Selected distances [Å] with standard deviations in parentheses: Mg(1)–O(3) 2.074(3), Mg(1)–O(4) 2.081(3), Mg(1)–O(5) 2.027(3).

involved. Bond lengths and angles in the 1-Mecyt ligand are in agreement with reported values.

Compounds **2** and **3** comprise $[MgL_2(H_2O)_4]^{2+}$ ions (L = 1-Mecyt (**2**) and cyt (**3**)), uncoordinated ClO_4^- ions, and crystallization nucleobase molecules. Water molecules of crystallization are also present in **3** (Figures 2 and 3). Both compounds contain the same octahedral coordination sphere at Mg^{II}, comprising four aqua and two additional ligands (cyt or 1-Mecyt) *trans*-coordinated through oxygen atoms. The main difference lies in the arrangements of the crystallization nucleobase molecules. In compound **2** these molecules are connected to the magnesium coordination sphere through hydrogen bonds with coordinated methylcytosine molecules, whereas in compound **3** they form base pairs with the coordinated cytosine molecules, without any link with Mg^{II} ion. In both compounds the octahedral geometry around Mg^{II} is slightly elongated; the best equatorial plane is defined by the atoms O(2), O(2a), O(3), O(3a). The Mg(1)–O(2) and Mg(1)–O(3) distances average 2.061(4) (**2**) and 2.056(4) (**3**) Å and are in the range found in **1** for Mg–O, while the Mg(1)–O(4) distances are slightly longer (2.107(3) (**2**) and 2.113(2) (**3**) Å). Four hydrogen bonds, which involve aqua ligands and nitrogen atoms N(3), N(3a) (**2**) or N(1), N(1a) (**3**), respectively, contribute to the stabilization of the compounds. In **3** two water molecules of crystallization and two perchlorate ions are linked to each other and to the $[Mg(cyt)_2(H_2O)_4]^{2+}$ ion and the base pairs in such a way that two rings form. The bond lengths and angles in the cyt and 1-Mecyt ligands are in agreement with known values.

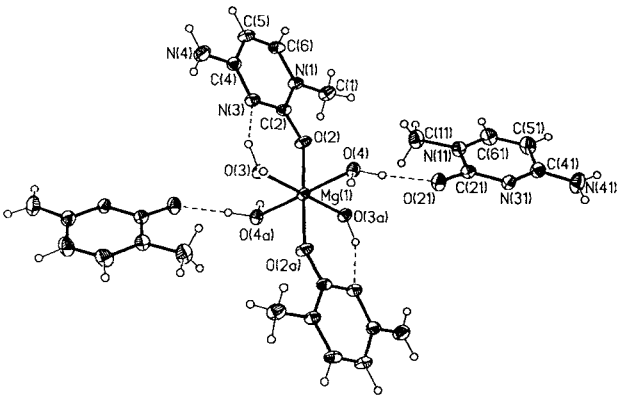

Figure 2. Crystal structure and atomic labeling of the $[Mg(1\text{-Mecyt})_2(H_2O)_4]\cdot 2\text{-}(1\text{-Mecyt})$ ion in **2**. Selected distances [Å] with standard deviations in parentheses: Mg(1)–O(2) 2.040(1), Mg(1)–O(3) 2.059(2), Mg(1)–O(4) 2.113(2).

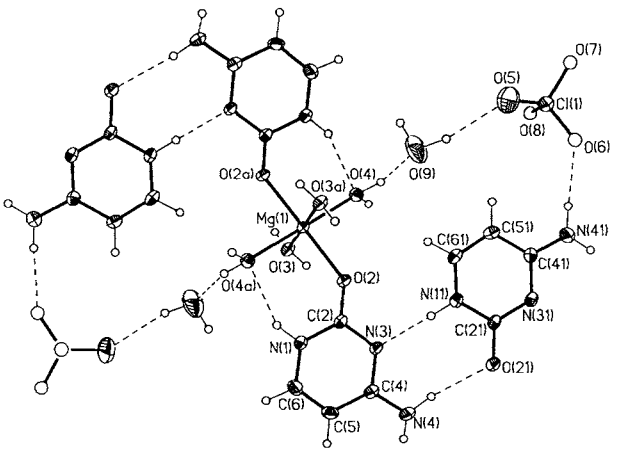

Figure 3. Crystal structure and atomic labeling of **3**. Selected distances [Å] with standard deviations in parentheses: Mg(1)–O(2) 2.070(4), Mg(1)–O(3) 2.053(4), Mg(1)–O(4) 2.108(3).

Since complexes **1** and **2** are obtained from the same solution, it is reasonable to assume that they coexist in solution. This could give useful information on the reactivity of 1-Mecyt towards the magnesium ion, because **1** could be seen as a precursor of **2**. Indeed, compound **2** may be obtained from compound **1** through the mechanism illustrated in Figure 4: two of the four bridged methylcytosine molecules are pushed out of the supramolecular assembly with the two *trans*-coordinated water molecules, which are hydrogen bonded to their O(2) atoms. In this way enough room is made to allow the direct coordination to the Mg^{II} ion of the two bases, which in **1** were linked to the water molecules through their N(3) atoms and are left with their O(2) atoms available for the coordination to the metal (Figure 4).

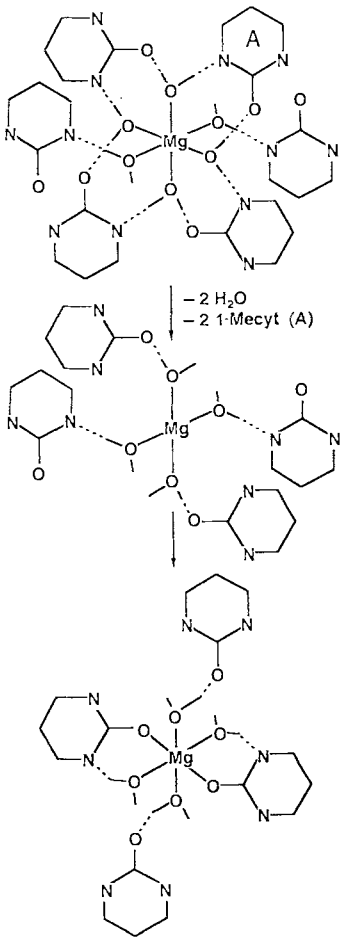

Figure 4. Schematic representation of the reaction leading from **1** to **2**.

A comparison of compounds **2** and **3** shows that both contain two ligands that are directly bound to the Mg^{II} ion through their O(2) oxygen atoms. However, in compound **2** it is the lone pair of electrons on the oxygen atom near N(3) that participates in the Mg–O(2) bonding, whereas in **3** it is the lone pair of electrons that is near the N(1) atom. This difference is most probably attributed to the formation of base pairs in compound **3**. The base pairing might also account for the different way in which the coordi-

nation process proceeds in the cytosine complex for which no hexaaqua complex could be isolated. The coordination of cytosine or its derivatives solely through O(2) was found, until now, only in Ni^{II} and Mn^{II} complexes.[5, 6] Finally, our structural data show that Mg^{II} ions form Mg–O covalent bonds similar to those of Mn^{II} or Ni^{II} ions, and this could mimic the behavior of the transition metals. In conclusion, these studies show that the complex formation between Mg^{II} and 1-Mecyt in aqueous solutions passes through a precursor supramolecular assembly that contains hexaaquamagnesium ions, which is linked to the ligands through hydrogen bonds.[10] To check the affinity of Mg^{II} and transition metal ions, we tested the reactivity of 1-Mecyt towards Mn^{II} and Co^{II} ions. In the case of Mn^{II} only one complex similar to **1** was found, while for Co^{II}, besides the hexaaqua complex, also a compound with methylcytosine coordinated to the cation through its nitrogen atoms was observed. This validates the hypothesis that **1** is really a precursor. Further studies are required to establish whether this behavior also occurs for other metal–nucleobase systems.

Experimental Section

1–3: Compounds **1** and **2** were obtained, as a mixture of parallelepiped and polyhedral crystals, respectively, by slow evaporation at room temperature of aqueous solutions containing equimolar amounts of magnesium perchlorate hexahydrate and 1-Mecyt. Compound **3** was obtained in the same way, as needles together with platelike crystals of cyt, from a solution of magnesium perchlorate hexahydrate and cyt. Perchlorate was chosen because it forms very stable salts or complexes and is relatively inert. The yields were 15% and 70% for **1** and **2**, respectively, and 75% for **3**. All the compounds provided correct elemental analyses (C, H, N).

Crystal structure analyses of **1–3**: Siemens R3m/V automatic diffractometer, $Mo_{K\alpha}$, $\lambda = 0.71073$ Å, graphite monochromator, 295 K. Data collection, solution, and refinement: ω-2θ scan (**1**, **3**), ω scan (**2**), direct methods with subsequent Fourier recycling, SHELXTL PLUS [11]. The perchlorate group of **3** is disordered. This disorder has been treated by assuming a population factor 0.7 for three oxygen atoms. **1**: $C_{30}H_{56}Cl_2MgN_{18}O_{21}$, monoclinic, space group $P2_1/n$, $a = 7.592(2)$, $b = 32.017(7)$, $c = 10.427(3)$ Å, $\beta = 104.30(2)°$, $V = 2456.0(11)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.474$ g cm^{-3}, $3 < 2\theta < 52°$, crystal dimensions $0.64 \times 0.36 \times 0.40$ mm^3, 4848 unique reflections and 2863 assumed as observed with $I > 3\sigma(I)$. Refinement of 346 parameters with anisotropic thermal parameters for non-hydrogen atoms gave $R = 0.054$, $Rw = 0.063$, and $S = 1.77$. **2**: $C_{20}H_{36}Cl_2MgN_{12}O_{16}$, triclinic, space group $P\bar{1}$, $a = 7.386(2)$, $b = 8.938(2)$, $c = 14.331(3)$ Å, $\alpha = 108.09(2)$, $\beta = 101.15(2)$, $\gamma = 92.32(2)°$, $V = 877.2(4)$ Å^3, $Z = 1$, $\rho_{calcd} = 1.506$ g cm^{-3}, $3 < 2\theta < 54°$, crystal dimensions $0.42 \times 0.39 \times 0.25$ mm^3, 3866 unique reflections and 2916 assumed as observed with $I > 3\sigma(I)$. Refinement of 229 parameters for non-hydrogen atoms (except the oxygen atoms of disordered perchlorate group) gave $R = 0.046$, $Rw = 0.056$, and $S = 1.79$. **3**: $C_{16}H_{32}Cl_2MgN_{12}O_8$, triclinic, space group $P\bar{1}$, $a = 6.776(5)$, $b = 9.981(4)$, $c = 12.896(5)$ Å, $\alpha = 71.86(3)$, $\beta = 87.40(5)$, $\gamma = 71.86(5)°$, $V = 786.3(7)$ Å^3, $Z = 1$, $\rho_{calcd} = 1.638$ g cm^{-3}, $3 < 2\gamma < 54°$, crystal dimensions $0.60 \times 0.15 \times 0.05$ mm^3, 3456 unique reflections and 2005 assumed as observed with $I > 3\sigma(I)$. Refinement of 221 parameters with anisotropic thermal parameters for non-hydrogen atoms gave $R = 0.063$, $Rw = 0.071$, and $S = 1.88$. Hf_2NiP: The Planned Modification of an Intermetallic Phase by (Formal) Substitution of Nickel by Phosphorus**

Holger Kleinke and Hugo F. Franzen*

In the last few decades the metal-rich pnictides and chalcogenides of the early transition elements have attracted wide interest.[1,2] Expanding these systems by adding a late transition metal atom has led to the synthesis of new high-temperature materials with new structural types that are stabilized by strong early–late transition metal bonds and correspond to the Lewis acid/base concept. Examples are $Nb_9Ni_{2-x}S_{3+x}$,[3] $Ta_9M'_2S_6$ (M' = Fe, Co, Ni),[4] $Ta_{11}M'_2Se_8$ (M' = Fe, Co, Ni),[5] Ta_8NiSe_8,[6] $Hf_8M'Te_6$ (M' = Mn, Fe),[7] $Hf_5M'Te_3$ (M' = Fe, Co),[8] $Hf_5Co_{1+x}P_{3-x}$,[9] and $Zr_9M'_2P_4$ (M' = Co, Ni),[10] and all of their structural types contain extended regions of the early transition element with interstitial late transition elements, located in one-, two-, or three-capped trigonal prisms. The chalcogen atoms usually sheathe either channels or layers, whereas the P atoms of both phosphides, $Zr_9M'_2P_4$ and $Hf_5Co_{1+x}P_{3-x}$, are situated in trigonal prismatic arrangements comparable to those of the late transition metal. Only the structure of $Zr_9M'_2P_4$ consists in part of bcc fragments, which is a common feature among binary sulfides, selenides, and phosphides. One striking feature is that in two cases, $Nb_9Ni_{2-x}S_{3+x}$ and $Hf_5Co_{1+x}P_{3-x}$, the nonmetal and late transition metal atoms are statistically disordered on one atomic position. Although Zr and Hf are very similar, which is also true of Nb and Ta, for none of these compounds has the analogue containing the corresponding metal from the other period been synthesized so far.

The striking structural motif of six-membered Hf channels with the Hf_5CoP_3 structure, filled with infinite zigzag Co–P chains, is closely related to that observed in the structure of HfNi (CrB type), which contains an infinite zigzag Ni–Ni chain (Figure 1).[11] In contrast, HfCo crystallizes in the CsCl structural type.[11] It was anticipated that formal substitution of every other Ni atom in the Ni–Ni chain by phosphorus would lead to $HfNi_{0.5}P_{0.5} \equiv Hf_2NiP$, forming a new superstructure of the CrB structural type.

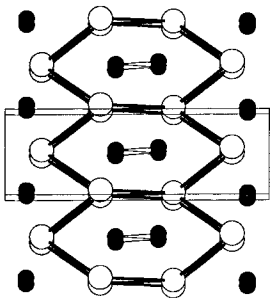

Figure 1. Structure of HfNi in a projection along [001]. Vertical: a axis. Small, black circles: Ni; large, white circles: Hf.

Therefore, we arc-melted a pressed mixture of 1.25 mmol HfP, 1.25 mmol Hf, and 1.25 mmol Ni (ratio Hf/Ni/P = 2/1/1). Annealing this sample in a welded Ta tube at 1400 °C for one week gave homogeneous Hf_2NiP, as shown by the powder diffraction pattern.

The alternation of Ni and P in the structure of Hf_2NiP[12] is associated with a lower (monoclinic) symmetry. The unit cell is a $2c$ superstructure of the primitive cell of HfNi. Figure 2 emphasizes the condensed Hf channels, which surround the Ni–P chain in such a way that each Ni and each P atom is located in a trigonal Hf_6 prism, in which the rectangular faces are capped by one Hf and two P or two Ni atoms (Figure 3).

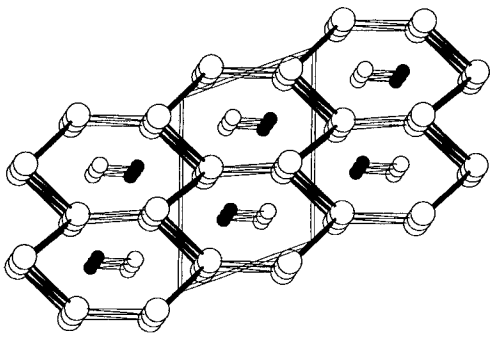

Figure 2. Structure of Hf_2NiP in a projection along [010]. Vertical: c axis. Small, black circles: Ni; medium, white circles: P; large, white circles: Hf.

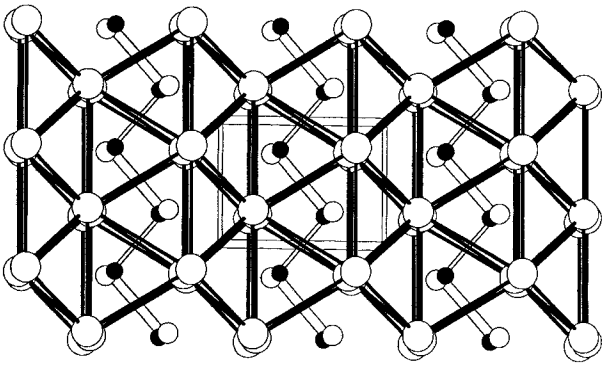

Figure 3. Structure of Hf_2NiP in a projection along [001]. Vertical: b axis. Small, black circles: Ni; medium, white circles: P; large, white circles: Hf.

As in the structures of $Zr_9Ni_2P_4$ and $Hf_5Co_{1+x}P_{3-x}$, the Hf–P bonds are slightly longer ($\bar{d}_{Hf-P} = 2.733$ Å) than the Hf–M′ bonds ($\bar{d}_{Hf-Ni} = 2.704$ Å), although the unit cell volume of HfNi is slightly larger than that of Hf_2NiP (129.7 Å^3 vs. 129.05(8) Å^3). The corresponding distances within similar coordination spheres are $\bar{d}_{Zr-Ni} = 2.732$ Å and $\bar{d}_{Zr-P} = 2.759$ Å for $Zr_9Ni_2P_4$, and $\bar{d}_{Hf-Co} = 2.677$ Å and $\bar{d}_{Hf-P} = 2.691$ Å for $Hf_5Co_{1+x}P_{3-x}$. In order to compare the lattice constants of Hf_2NiP and HfNi, we transformed the unit cell of HfNi to the setting of Hf_2NiP (transformation matrix: 0.5,0.5,0/0,0,1/$\bar{2}$,0,0). The resulting lattice constants of the transformed cell of HfNi are $a = 5.152$ Å, $b = 4.117$ Å, $c = 6.436$ Å, $\beta = 108.2°$, and therefore $d_{001} = 6.114$ Å. The a axes and d_{001} of Hf_2NiP are longer (by ca. 1.4% and 5%, respectively), whereas the b axis is about 11% shorter.

Accordingly, a significant difference occurs between the Ni–Ni and Ni–P chains of HfNi and Hf_2NiP running parallel to [010]: the Ni–P distances of 2.337(7) Å are much shorter than the Ni–Ni distances of 2.607 Å, and the bond angles vary from 103.1° (Ni-P-Ni) to 104.3° (Ni-Ni-Ni). (The atomic positions for HfNi were taken from refinements of the isostructural ZrNi, with $d_{Ni-Ni} = 2.616$ Å.[11]) Although these M′–P bonds are longer than those observed in $Hf_5Co_{1+x}P_{3-x}$ ($d_{Co-P} = 2.32(2)$ Å, whereby $r_{Co} > r_{Ni}$) and $HfNi_xP$ ($d_{Ni-P} = 2.1578(7)$ Å)[15] in which Co, Ni, and P are also located in trigonal Hf_6 prisms, bonding character is assumed, as shown by the bond order of $n = 0.73$, calculated with Pauling's equation: $d(n) = d(1) - 0.6 \lg n$ (d = bond length, $r_{Ni} = 1.154$ Å, $r_P = 1.10$ Å).[16] The formation of strong bonding Ni–P interactions is most likely the main driving force for this deformation. On the other hand, the Ni–Ni contacts in HfNi have only weak bonding character. Probably as a consequence of the structure deformation, the mean Hf–Ni distance of 2.687 Å in HfNi is significantly smaller than in Hf_2NiP ($d_{Hf-Ni} = 2.704$ Å).

The substitution of Ni by P leads to the occurrence of two crystallographically different Hf atoms in the structure of Hf_2NiP: one is coordinated by three Ni and four P atoms, and the other by four Ni and three P atoms, with similar Hf environments for both types of Hf atom. The shortest Hf–Hf distances in Hf_2NiP of about 3.2 Å (corresponding distances in HfNi about 3.4 Å) occur within puckered Hf layers parallel to (011), as emphasized with bold lines in Figure 2, which are interconnected parallel to [110] by longer Hf–Hf bonds of about 3.4 Å (HfNi: 3.4 Å). Hf–Hf distances of 3.4 Å are still to be considered as bonding (Pauling bond order of 0.14, calculated with $r_{Hf} = 1.442$ Å).[16] The Hf–Hf interactions along the b and c axes, which complete the trigonal prisms surrounding the interstitial atoms, are significantly different from those in HfNi (parallel to c axis of Hf_2NiP: alternating 3.473(5) Å and 3.719(5) Å vs. 4.117 Å in HfNi; b axis: 3.6567(8) Å vs. 3.218 Å). Altogether, the sums of the Hf–Hf (Pauling) bond orders (PBOs) do not significantly differ from Hf_2NiP (mean total $PBO_{Hf-Hf} = 1.43$ per Hf atom) to HfNi (total $PBO_{Hf-Hf} = 1.40$ per Hf atom).

Delocalized electrons within the three-dimensional framework of Hf atoms should lead to metallic behavior. To explore this expectation and our considerations of the bonding character of the different interactions further, we calculated the band structure of Hf_2NiP, using the Extended Hückel approximation.[17] The Hf and Ni parameters were obtained by solid-state charge iteration on Hf_7P_4[18] and $Zr_9Ni_2P_4$,[10] respectively, and the P parameters were taken from standard sources.[19] Figure 4 shows the calculated DOS (density of states) curve and the Hf and Ni contributions for the total DOS for Hf_2NiP, highlighting the Fermi levels for the different valence electron counts of Hf_2NiP (46 e^-), and (theoretical) "Hf_2CoP" (44 e^-) and "Hf_2FeP" (42 e^-).

As expected, because of the nonsaturated character of Hf_2NiP, a significant density of states occurs at the Fermi level of −9.2 eV, which consists mainly of the Hf 5d states. The 3d states of Ni are located in a small region around −11 eV, which is well below the Fermi level. This leads to the assumption that the d states are completely filled, and thus, since the s states are not significantly filled, to a formal oxidation state of Ni^0. Since the 3p block of P is found between −13 eV and −15.5 eV, a formal oxidation state of −III can be assumed for the P atoms, and therefore Hf can be formally regarded as $Hf^{1.5+}$. This leads

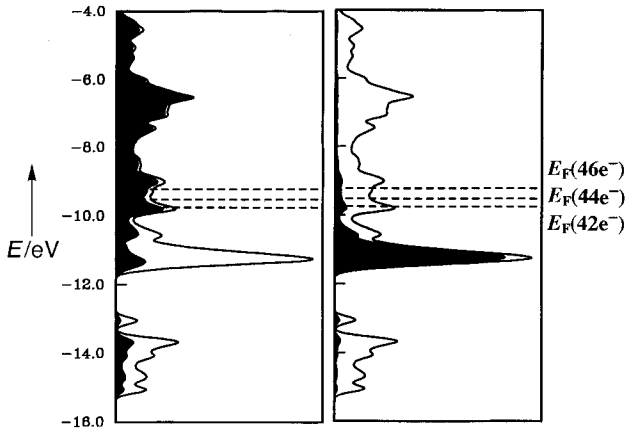

Figure 4. Density of states of Hf_2NiP. Left: Hf contributions; right: Ni contributions emphasized.

to the formal ionic formula $(Hf^{1.5+})_2Ni^0P^{3-}$ and indicates that 2.5 *d* electrons per Hf atom remain for the formation of metal–metal bonds. The mixing of Hf and Ni states with the *p* block of P, however, indicates covalent interactions with the *p* orbitals of P. Thus, the discussion of oxidation states is a formal one and is not meant to imply ionic interactions.

The crystal orbital overlap populations (COOP curve, see Figure 5) do indeed show the bonding character of the Hf–Hf and Hf–Ni interactions, which are the only interactions with

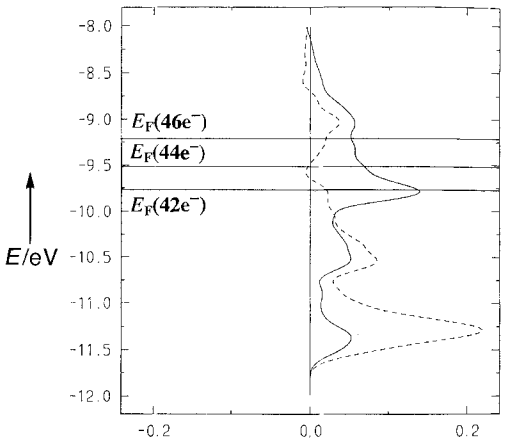

Figure 5. COOP curve of Hf_2NiP. Solid line Hf–Hf, dashed line Hf–Ni interactions. The left half of the diagram covers the antibonding, the right half the bonding interactions.

significant overlap populations at the Fermi level. Decreasing the valence electron concentration, which corresponds to a substitution of Ni by Co or Fe, would result in loss of bonding Hf–Hf and Hf–M′ interactions (M′ = Fe, Co, Ni). From this point of view, the possibility of the formation of isostructural "Hf_2CoP" and "Hf_2FeP" is unlikely but not impossible.

The sum of the overlap populations for the Hf–Hf bonds per Hf atom decreases from HfNi (0.99) to Hf_2NiP (0.83); this indicates that fewer electrons are available in Hf_2NiP for Hf–Hf bonding. This is in accordance with the higher oxidation state of the P atom. The mean Mullikan overlap population (MOP) for the Hf–Ni bonds in Hf_2NiP (0.10) is only slightly smaller than that for the HfNi structure (0.12). Both values can be directly compared to the Zr–Ni interactions in $Zr_9Ni_2P_4$ (MOP = 0.13). In all of these cases, strong bonding interactions between the early and the late transition metals are confirmed by our calculations, in accordance with the Lewis acid/base concept. Of course, the metal–nonmetal interactions also have strong bonding character, with averaged Mullikan overlap populations for the Hf–P bonds of 0.23 and for the Ni–P bonds of 0.14.

The expectation of metallic behavior of Hf_2NiP, in accordance with the calculations of the electronic structure, were confirmed by the experimentally determined weak Pauli paramagnetism, which is temperature independent between 6 and 300 K.

For a more detailed consideration of the differences between HfNi and Hf_2NiP, we calculated the band structures for the isolated Ni–Ni chain of HfNi and for the Ni–P chain of Hf_2NiP. As can be seen in Figure 6, the DOS of the Ni–P chain

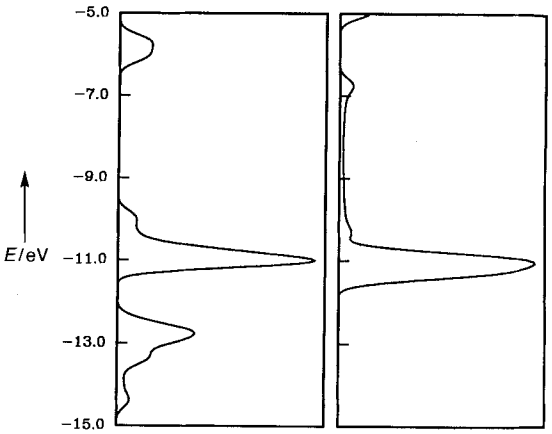

Figure 6. DOS curves of the Ni–P chain in Hf_2NiP (left) and of the Ni–Ni chain in HfNi (right).

contains a band gap of about 3 eV in the region of the Fermi level of Hf_2NiP (−9.2 eV). Therefore, the Ni–P chain does not contribute to the metallic character of Hf_2NiP; in contrast the Ni–Ni chain does contribute to the metallic properties of HfNi, since it does not have a band gap in the region of the Fermi level of HfNi (−9.34 eV). The energy window shown between −15 and −5 eV consists in the case of the Ni–P chain of three well-separated parts: the *p* block of P is found below −12 eV, the *d* states of Ni around −11 eV and the *s* states of Ni at approximately −6 eV, well above the Fermi level. Thus, the orbitals of the Ni–P chain are filled with exactly 18 electrons below the large band gap, which corresponds to the above-mentioned electron count, in which Ni is formally regarded as Ni^0, and P as P^{3-}. The states of the isolated Ni–Ni chain can be filled with approximately 21.5 electrons up to the Fermi level of −9.34 eV, which indicates a negative charge of the Ni–Ni chain. As a consequence, the *s* orbitals of Ni are assumed to be partially filled only in the case of HfNi, since they are spread over the range of −11.5 to −6.5 eV.

In summary, the formation of Hf_2NiP clearly shows that new structures are predictable in some cases, and that in general small late transition metal atoms in intermetallic phases can be substituted by nonmetal atoms such as phosphorus. In this particular case, a negatively charged Ni–Ni chain with metallic character was replaced by a more negatively charged Ni–P chain that does not contribute to the metallic properties. Further attempts to modify other refractory intermetallic phases, for example ZrNi, which is isostructural with HfNi, by substitution of the late transition metal by P or S are currently in progress.

[12] Crystal structure analysis of Hf_2NiP: lattice constants for the ideal monoclinic cell (space group $P2_1/m$) were obtained from Guinier powder patterns under vacuum, with Si as an internal standard: $a = 5.2259(9)$ Å, $b = 3.6567(8)$ Å, $c = 7.192(1)$ Å, $\beta = 110.12(1)°$, $V = 129.05(8)$ Å^3 (12 reflections, $Cu_{K\alpha} = 1.5406$ Å). An automatic four-circle diffractometer with a rotating anode was used for the data collection (AFC6R, Rigaku, 23 °C, $Mo_{K\alpha}$). Experimental details of data collection: $Z = 2$, $\rho = 11.49$ g cm^{-3}, $\mu = 870.7$ cm^{-1}, $2\theta_{max} = 70°$, min./max. transmission: 0.75–1.26. Refinements and absorption correction (Ψ scan, followed by DIFABS [13]) were carried out with the TEXSAN program package [14]. Final residuals are $R(F^2) = 0.065$, $R_w(F^2) = 0.070$, GOF = 1.08 with 184 independent observed reflections ($I > 3\sigma(I)$) and 23 refined parameters. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository uumber CSD-405616.

Assembly of Mesoporous Molecular Sieves Containing Wormhole Motifs by a Nonionic Surfactant Pathway: Control of Pore Size by Synthesis Temperature**

Eric Prouzet and Thomas J. Pinnavaia*

The Mobil M41S family of mesoporous molecular sieves[1,2] has expanded greatly the range of materials available for heterogeneous catalysis[3–6] and supramolecular assembly.[7,8] These mesostructures are formed through structure-directing interactions between surfactant micelles and inorganic precursors. Assembly can occur by electrostatic charge-matsching mechanisms[1,9–13] or by electrically neutral pathways that depend on hydrogen bonding[14–18] or complexation[19,20] at the organic/inorganic interface. Whereas M41S structures characteristically exhibit long-range hexagonal or cubic symmetry, less ordered structures with wormhole motifs have been obtained recently through the N^0I^0 assembly of nonionic polyethylene oxide (PEO) based surfactants (N^0) and neutral inorganic precursors (I^0).[17,21] These wormhole structures, which have been denoted MSU-X, lack regular channel packing order. Nevertheless, they exhibit uniform channel diameters over a range comparable to M41S materials and offer attractive advantages for processing, owing in part to the low cost and biodcgradability of N^0 surfactants.

Here we report an unprecedented property of N^0 surfactants for mesostructure assembly, namely, the ability to control pore size rationally simply by regulating the synthesis temperature in the presence of a single surfactant. Previous approaches to mediating the pore sizes of mesostructures have depended on the use of surfactants of different chain lengths, organic cosurfactants,[1] and post-synthesis hydrothermal treatments[22,23] for modifying pore structure. However, only the N^0I^0 pathway is capable of tailoring pore size by choice of the assembly temperature. For instance, the average pore diameter of MSU-X silicas can be altered by as much as 2.4 nm simply by controlling the assembly temperature over a relatively narrow range (25–65 °C).

Our approach to the pore-size-selective N^0I^0 assembly of MSU-X silicas utilizes a homogeneous reaction medium. This "solution" method differs from the gel-based procedure developed earlier for N^0I^0 assembly.[17] The inorganic alkoxide precursor is added to an aqueous N^0 suspension, and then the mixture is allowed to age at room temperature to obtain a homogeneous solution. Mesostructure assembly is initiated in a second step by the addition of fluoride ion, which catalyzes alkoxide hydrolysis[24] and mesostructure cross-linking. This second step is the key to facilitating mesostructure formation from solution and to varying the pore size through the synthesis temperature.

N^0I^0 assembly of MSU-X silicas from solution has been accomplished by using several commercial PEO surfactants, including the Tergitol 15-S-*n* series of the type $C_{11-15}H_{23-31}O(CH_2CH_2O)_nH$ with $7 < n < 20$ (Union Carbide, Danbury, Connecticut), Triton X-100 $(CH_3)_3CCH_2C(CH_3)_2C_6H_4(CH_2CH_2O)_{10}H$ (Union Carbide), and Igepal RC-760 $CH_3(CH_2)_{11}C_6H_4(CH_2CH_2O)_{18}H$ (Rhône-Poulenc, Cranbury, New Jersey). Because the mesostructures obtained with the Tergitol family of surfactants are representative of the pore size properties generally observed for solution N^0I^0 assembly, only these derivatives will be considered in detail.

X-ray patterns of calcined MSU-1 silicas prepared from Tergitol 15-S-12 at 35 °C and at different NaF/TEOS molar ratios are displayed in Figure 1. To facilitate comparison, the diffraction peaks have been separated from the background scattering by fitting the background to the exponential $Ae^{(-B/2q)+C}$. The background-corrected peaks are shown in the insert in Figure 1. Fluorine not only improves the scattering intensity, but also increases the basal spacing from about 4.2 to about 4.7 nm; this indicates the probable presence of fluorine in the as-synthesized structure. Magic angle spinning (MAS) ^{29}Si NMR spectra of MSU-1 silicas prepared at molar NaF/TEOS ratios up to 10% all exhibited Q^3 and Q^4 signals with relative intensity ratios close to 0.4. Although some of the silicon centers in the as-synthesized materials are bonded to fluorine, all fluorine is removed upon calcination at 600 °C, as shown by ^{19}F NMR spectroscopy.

Figure 2 shows the XRD patterns for MSU-1 silicas assembled from Tergitol 15-S-12 at two temperatures. The *d* spac-

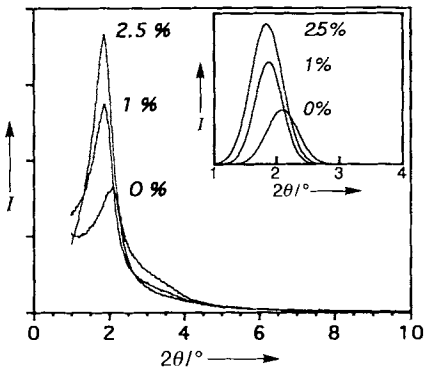

Figure 1. Powder XRD patterns of calcined MSU-1 silicas prepared by N^0I^0 assembly at 35 °C in the presence of Tergitol 15-S-12 as the structure director with molar NaF/TEOS ratios of 0, 1.0, and 2.5%. Patterns were obtained with a Rigaku Rotaflex diffractometer equipped with a rotating anode and $Cu_{K\alpha}$ radiation ($\lambda = 0.15418$ nm). Insert: diffraction peaks obtained by subtracting background scattering (see text). I = relative intensity.

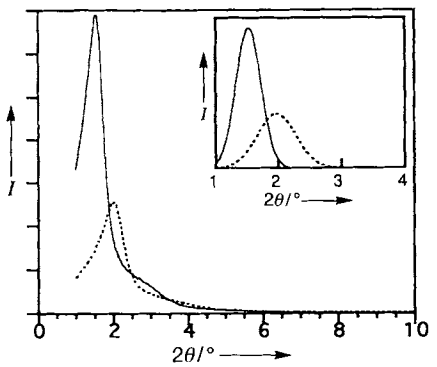

Figure 2. Powder XRD patterns of calcined MSU-1 silicas prepared at 25 °C (dotted line) or 65 °C (continuous line) in the presence of Tergitol 15-S-12 at an NaF/TEOS molar ratio of 2.5%. Insert: diffraction peaks corrected for background scattering.

ing increases from 4.5 to 5.8 nm upon increasing the synthesis temperature from 25 to 65 °C. A similar 1.0–2.0 nm increase in basal spacing with increasing synthesis temperature up to the cloud point temperature of the surfactant is observed for all N^0 structure directors. Concomitant with the increase in basal spacings is an increase in the pore size of the reaction products. Figure 3 illustrates the N_2 adsorption/desorption isotherms for the materials with the smallest and largest pore sizes obtained with Tergitol 15-S-12 as the structure director. For the product with the smallest pores, which was assembled at 25 °C, the isotherm shows a linear region from $P/P_0 = 0.1$ to 0.3 indicative of supermicroporosity.[25] In contrast, the sample with the largest pores, which was prepared at 65 °C, exhibits an adsorption step near $P/P_0 = 0.5$ typical of mesoporosity. The desorption hysteresis observed for the 65 °C sample, as well as for related mesoporous products prepared at temperatures between 25 and 65 °C, may indicate necking of the channel structure.

Although MSU-X silicas have wormhole motifs and are devoid of hexagonal, cubic, or any other regular long-range order, the observed d spacings nevertheless should be related to the channel correlation length. If we assume that the d spacing is a direct measure of the average distance between channel centers, the average wall thickness can be deduced by subtracting the pore size from the d spacing. Table 1 summarizes this and other structural parameters for MSU-1 silicas assembled from two different Tergitol 15-S-n surfactants at temperatures in the range 25–65 °C. Clearly, increasing the synthesis temperature over

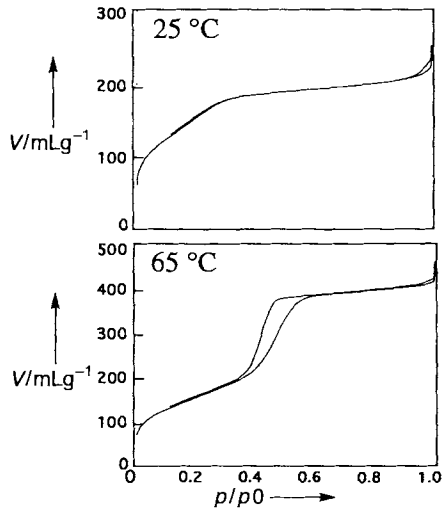

Figure 3. Nitrogen adsorption and desorption isotherms for calcined (600 °C) MSU-X silicas assembled at 25 °C (top) or 65 °C (bottom) in the presence of Tergitol 15-S-12 at an NaF/TEOS molar ratio of 2.5%. The volume of N_2 sorbed is expressed at standard temperature and pressure; P/P_0 is the partial pressure of N_2 in equilibrium with the sample at −196 °C. Before analysis the samples were evacuated at 150 °C and 10^{-6} torr for 16 h.

Table 1. Structural parameters and BET surface areas for MSU-1 silica prepared from two different C11–15 $(EO)_n$ (n = 9, 12) surfactants at temperatures in the range 25–65 °C.

Synthesis temperature [°C]	d-spacing [nm]	Pore diameter [nm]	Wall thickness [m]	BET surface area [$m^2\,g^{-1}$]
Surfactant: Tergitol 15-S-9				
25	4.3	2.0	2.3	850

assembled at 25 °C from homogeneous fluoride solutions of Tergitol 15-S-9 and 15-S-12 (2.0 and 2.1 nm, respectively) are smaller than those obtained from more concentrated, fluoride-free gels of the same surfactants (2.5 and 3.1 nm).[17]

The unprecedented temperature dependence of MSU-X pore structures may be explained in terms of the amphiphilic character of the PEO-based structure directors. These surfactants promote framework assembly through hydrogen bond formation between the hydrophilic $(EO)_n$ segments and the silanol groups of the neutral inorganic precursor. The hydrogen bonding interactions are expected to decrease as the assembly temperature approaches the cloud point of the surfactant. At the cloud point all amphiphilic character is lost, surfactant phase segregation occurs, and no mesostructure is formed. Conformational changes (e.g., coil to rod) in the $(EO)_n$ segment with increasing temperature up to the cloud point will cause both the hydrophilicity and the overall size of the EO head group to decrease. Consequently, the curvature of the micelle will decrease, and the size of the hydrophobic core, which determines the framework pore size, will increase with increasing temperature. This model is supported further by the decrease in the wall thickness and the increase in basal spacing with increasing assembly temperature (see Table 1).

As the assembly temperature of an MSU-X silica approaches the cloud point of the surfactant, the intensity of the reflections in the diffraction pattern weaken and they broaden, signifying a loss of channel structure and a reduction in the fidelity of the pore diameter. For example, N^0I^0 assembly with Tergitol 15-S-7 at ambient temperature does not form a highly mesostructured silica, because the cloud point of this surfactant is very low (CP $\approx$ 37 °C). For Tergitol 15-S-9 (CP $\approx$ 60 °C), there is progressive loss of channel structure as the synthesis temperature is increased above room temperature. A similar behavior is observed for mesostructures prepared above 50 °C from Triton X-100 (CP $\approx$ 65 °C). Mesostructures assembled from Tergitol 15-S-12 (CP $\approx$ 85 °C), 15-S-15 (CP > 100 °C) or Igepal RC-760 (CP > 100 °C) exhibit XRD intensities and line widths that change little with increasing synthesis temperature until the CP is approached. Thus, these high-CP surfactants are best suited for controlling the pore sizes of MSU-X mesostructures by judicious choice of synthesis temperature.

Experimental Section

The preparation of a MSU-1 silica with Tergitol 15-S-12 as structure director illustrates a typical pore-size-specific N^0I^0 synthesis. To a sonicated 0.02 M solution of the surfactant in water at room temperature was added sufficient tetraethyl orthosilicate (TEOS) to obtain a molar TEOS/Tergitol ratio of 8.0. Sonication was continued for a short period to obtain a milky suspension. The mixture was allowed to age without agitation for 12 h to give a clear, colorless solution. At this stage no mesostructure formation had occurred. A 0.24 M solution of sodium fluoride was then added dropwise with stirring to the TEOS/surfactant solution to obtain a molar NaF/TEOS ratio of 0.025. The solution was placed in a shaking bath (shaking speed, 40 rpm) at 25 to 65 °C for 48 h. A white precipitate formed progressively. After 48 h the precipitate was separated from the solution by centrifugation, dried in air at 70 °C and then at 200 °C for 6 h with a heating rate of 5 °C min^{-1}. Finally, the product was calcined at 600 °C for 6 h to remove the surfactant.

For comparison purposes a mesostructured silica was assembled from Tergitol 15-S-12 by the same solution procedure described above, except that NaF was omitted from the reaction mixture and the reaction time at 35 °C was increased to 125 h.

XRD patterns were obtained with a Rigaku Rotaflex diffractometer equipped with a rotating anode and $Cu_{K\alpha}$ radiation (λ = 0.15418 nm). N_2 isotherms were obtained on a Coulter Omnisorp 360CX Sorptometer operated under continuous adsorption conditions.

Asymmetric Heck Reactions via Neutral Intermediates: Enhanced Enantioselectivity with Halide Additives Gives Mechanistic Insights**

Larry E. Overman* and Daniel J. Poon

Since the first reports in 1989,[1] catalytic asymmetric Heck reactions have emerged as powerful transformations for controlling absolute stereochemistry in the formation of C–C bonds.[2] Intramolecular asymmetric Heck reactions have received particular attention and have served as a cornerstone of asymmetric total syntheses of natural products.[3] The vast majority of asymmetric Heck reactions reported to date are of triflates or halides in the presence of silver or thallium salts and enantiopure chiral bis(phosphane)palladium catalysts.[2, 4] Counter to the prevailing dogma at the time,[5] we revealed in

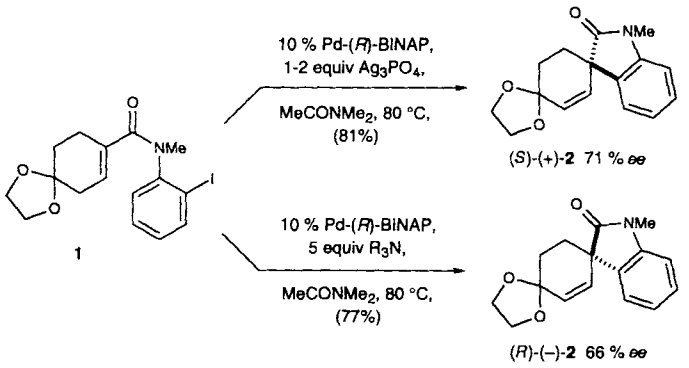
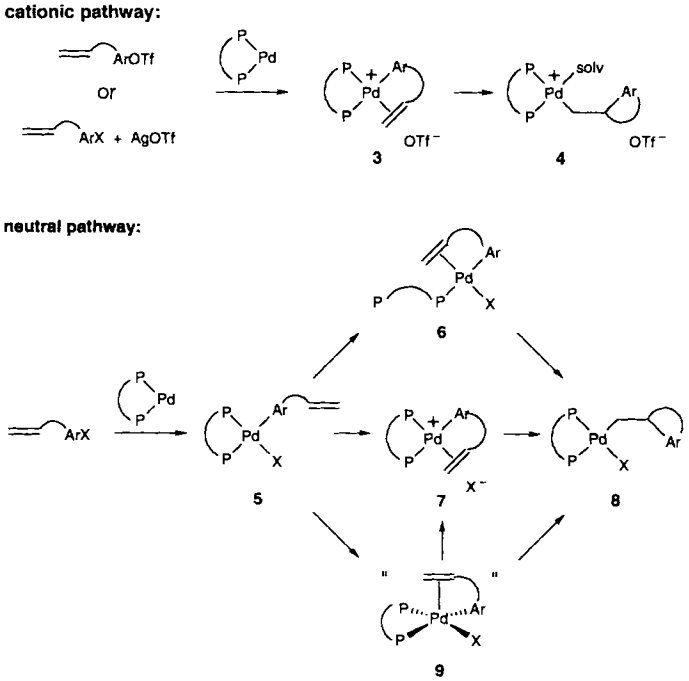
Hollis for their insightful discussion and S. Pitram for assistance in preparing **16**.

1992 that a halide scavenger was not obligatory for realizing high enantioselection in bis(phosphane)palladium-catalyzed asymmetric Heck insertions of halide substrates.[6] We demonstrated that the sense of enantioselection could be opposite in Heck cyclizations of aryl iodides conducted in the presence or absence of silver salts (**1** → **2**),[6] and that some substrates give higher enantioselectivities without silver ions.[3b]



It is widely accepted that the insertion step in bis(phosphane)palladium-catalyzed asymmetric Heck reactions of triflates or halides in the presence of silver or thallium salts involves cationic Pd(II) intermediates (Scheme 1, **3** → **4**).[7] The pathway of related Heck insertions of halide substrates conducted in the absence of halide scavengers is less clear. Three possibilities for the insertion step of this neutral pathway (that is, via the neutral intermediate **5**) are illustrated in Scheme 1: insertion from a four-coordinate intermediate generated by phosphane dissociation (**5** → **6** → **8**),[5, 6, 8] insertion from a four-coordinate intermediate generated by halide dissociation (**5** → **7** → **8**),[9] or insertion from a five-coordinate intermediate (**5** → **9** → **8**).[6, 10–12] In this communication we report a) that halide additives can increase enantioselection in Heck cyclizations of triflates by diverting the insertion to the neutral pathway, and b) that the neutral pathway does not proceed by phosphane dissociation.



Scheme 1. Cationic and neutral pathways for intramolecular Heck reactions.

We recently investigated asymmetric Heck cyclizations of (*Z*)-butenanilide triflate **10** and iodide **11** with Pd-(*R*)-BINAP (generated in situ from 5% $[Pd_2(dba)_3]\cdot CHCl_3$ and 12% (*R*)-BINAP) to form (*R*)-oxindole **12** under identical reaction conditions.[13] Enantiomeric purity was determined by converting **12** into oxindole alcohol **13**, which was analyzed by HPLC.[14] As we had reported earlier,[3b] enantioselection in the cyclization of iodide **11** is higher in the absence of a silver salt (Table 1, entries 9, 13). Identical low enantioselection (43% *ee*) is observed in the cyclization of triflate **10** or iodide **11** in the presence of AgOTf (compare entries 1 and 13 in Table 1), observations that are consistent with a common stereochemistry-determining step for both cyclizations. The beneficial effect of halide salts on intramolecular Heck insertions of triflate **10** was striking. Cyclization of **10** in the presence of one equivalent of tetrabutylammonium iodide, bromide, or chloride affords **13** in 90–93% *ee*, within experimental uncertainty of the *ee* observed in the cyclization of iodide **11** (Table 1, entries 2–4 and 9). Nearly identical results are obtained when the cyclization of **10** is conducted in the presence of one equivalent of the hydrohalide salts of 1,2,2,6,6-pentamethylpiperidine (PMP) (Table 1, entries 6–8). That this enhancement is due to the halide and not a general salt effect was signaled by the negligible influence of added tetrabutylammonium triflate (Table 1, entry 5). Not surprisingly,

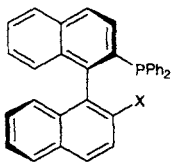
added halide salts had little effect on cyclizations of iodide **11** (Table 1, entries 10–12). The results summarized in Table 1 demonstrate that added halide can divert cyclization of triflate substrates to the neutral pathway,[15] which in the case of a (*Z*)-butenanilide occurs with much higher stereoinduction.

To examine the possibility of phosphane dissociation in the neutral asymmetric Heck pathway, we studied the cyclization of iodide **11** in the presence of the monophosphane (*R*)-BINAP analogs **14**–**16**. The ligands **14** and **15** were prepared as described by Hayashi et al.,[16] while monophosphane **16**, which is a close model of monocoordinated BINAP, was synthesized from (*R*)-ester **17**.[17, 18] Cyclizations of **11** in the presence of 5% of $[Pd_2(dba)_3]\cdot CHCl_3$ and 11% of the monophosphanes **14**, **15**, or **16** (4 equiv PMP, 0.1 M in $MeCONMe_2$, 100 °C) provided (*S*)-oxindole alcohol **13** with low *ee* (**14** 27% *ee*, **15** 23% *ee*, **16** 19% *ee*). Two observations suggest that a (phosphane)-palladium species is the active catalyst under these conditions: 1) Heck cyclizations of **11** in the presence of ligands **14**–**16** take place within minutes at room temperature; in marked contrast, cyclizations of **11** under analogous conditions with $[Pd_2(dba)_3]\cdot CHCl_3$ require 60–80 min at 55 °C, while cyclizations with (*R*)-BINAP take 20–60 min at 100 °C to go to completion. 2) Nearly identical results are obtained when the ratio of monophosphane **14** to Pd is increased through 1.6:1 (21% *ee*) and 2.1:1 (21% *ee*) to 2.9:1 (24% *ee*). The observation that cyclization of iodide **11** in the presence of Pd-(*R*)-**16** proceeds with low enantioselection to deliver the opposite oxindole enantiomer to that produced with Pd-(*R*)-BINAP provides strong evidence that both phosphanes of BINAP are coordinated to Pd during the enantioselective step, ruling out the sequence **5** → **6** → **8** of Scheme 1.



14 X = OTBDMS
15 X = O*i*-Pr
16 X = $CHPh_2$
17 X = CO_2Me
(*R*)-BINAP X = PPh_2

What then can we say about the mechanism of the neutral pathway? Certainly, insertion from a pentacoordinate intermediate can not be ruled out. However, both the general theoretical treatment by Thorn and Hoffmann[12] and Samsel and Norton's kinetic investigation[19] indicate that insertions from five-coordinate intermediates have much higher barriers than those from four-coordinate square-planar complexes. Thus, we favor **7** → **8** for the insertion step of the neutral pathway. However, to be consistent with our observations, the influence of a chiral bis(phosphane) ligand on the formation or insertion of intermediate **7** would have to be distinctly different from its influence on the nearly identical intermediate **3** of the cationic pathway. Since Jutand and Mosleh have demonstrated through conductivity studies that *trans*-$[ArPd(PPh_3)_2OTf]$ is fully dissociated in *N*,*N*-dimethylformamide,[15a] the different nature of the counterion in **3** and **7** is likely not sufficient to rationalize the disparate stereoinduction seen in cationic and neutral asymmetric Heck reactions.[6, 20] We suggest an alternative explanation in which the enantioselective step of the neutral pathway occurs during formation of cationic four-coordinate intermediate **7** by associative displacement of X (**5** → **9** → **7**).[21–24] The key feature is that this step would be influenced quite differently by a chiral bis(phosphane) ligand than an enantioselective step involving in-plane coordination of the alkene (for example, dissociative alkene coordination to generate **3** from a triflate precursor or conversion of **3** → **4**).

In summary, these studies demonstrate for the first time that a) enantioselection in asymmetric Heck insertions of triflates can be enhanced dramatically by the addition of halide salts,[25] and b) both the chiral bis(phosphane) and the halide can be coordinated to palladium during the enantioselective step of asymmetric Heck reactions that achieve high stereoinduction. Further investigations will be required to establish the scope of these observations, particularly with regard to variations of the substrate and solvent. Nonetheless, the finding that under some reaction conditions the enantioselective step of asymmetric Heck reactions involves a five-coordinate intermediate broadens the vista for the design of asymmetric ligands for this and related reactions.

[13] Representative experimental procedure for Heck cyclizations reported in Table 1: A base-washed, flame-dried 10 mL Schlenk flask was charged with $[Pd_2(dba)_3]\cdot CHCl_3$ (8.1 mg, 0.008 mmol) and (*R*)-BINAP (11.2 mg, 0.018 mmol) and purged with Ar. Dry *N*,*N*-dimethylacetamide (DMAC, 0.8 mL) was added, and the resulting purple-brown suspension was stirred for 2 h to give a bright orange solution. A solution of triflate **10** (75 mg, 0.16 mmol), PMP (120 μL, 0.66 mmol), $nBu_4NCl\cdot H_2O$ (53 mg, 0.18 mmol), and dry DMAC (0.8 mL) was added, the suspension stirred until homogeneous (about 15 min), and the resulting red-orange solution degassed (three freeze-pump-thaw cycles) and then heated at 100 °C for 23 h. After cooling to 23 °C, the reaction mixture was partitioned between saturated aqueous $NaHCO_3$ solution and EtOAc, and the combined organic layers were dried (Na_2SO_4), filtered, and concentrated. The resulting dark brown residue was partially purified by chromatography on silica gel (4/1 hexanes/EtOAc) to give a 20:1 mixture of (*E*)- and (*Z*)-eneoxysilanes **12** (contaminated with some dba) as a yellow oil. This mixture was hydrolyzed at 23 °C in 1/1 THF/(3 N HCl), and the resulting crude product was purified on silica gel (4/1 to 2/1 hexanes/EtOAc) to give 21 mg (65%) of the corresponding aldehyde. This intermediate was reduced with $NaBH_4$ and EtOH at 23 °C to afford 17 mg (52% overall for three steps) of (*R*)-**13** [3b] as a colorless oil: 93% *ee*, Chiralcel AS column, 9/1 hexane/2-propanol, 1.0 mL min^{-1}).
[14] A Diacel Chiralpak AS or OB-H column was employed; precision in measuring *ee* is ±2%.
[15] The formation of *trans*-$[ArPdX(PPh_3)_2]$ from the reaction of aryl triflates with palladium catalysts in the presence of added chloride has been described and shown to proceed without formation of a cationic triflate intermediate by initial oxidative addition of ArOTf to $[PdCl(PPh_3)_2]^-$: a) A. Jutand, A. Mosleh, *Organometallics*, **1995**, *14*, 1810; b) ref. [10a].

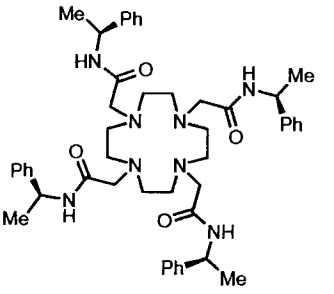
[21] Ligand substitution would involve multistep rearrangement of an initially formed, square-pyramidal complex **9** to a square-pyramidal isomer having X in apical position, the latter being the immediate precursor of **7**;[22] for brevity these intermediates are not shown in Scheme 1.
[22] Substitution reactions of 16e square-planar complexes are typically associative: R. J. Cross, *Adv. Inorg. Chem.* **1989**, *34*, 219.
[23] Palladium(II) halide complexes of general formula [RPdCl(N–N′)(η^2-alkene)] are well known and have been crystallographically characterized: V. G. Albano, C. Castellari, M. E. Cucciolito, A. Panuzi, A. Vitalgliano, *Organometallics*, **1990**, *9*, 1269.
[24] This step could be either the formation of a pentacoordinate intermediate from **5** or the evolution of a pentacoordinate intermediate to **7**. The first irreversible enantiodifferentiating step would determine asymmetric induction: C. R. Landis, J. Halpern, *J. Am. Chem. Soc.* **1987**, *109*, 425.
[25] There are scattered reports of various effects of halide additives on Heck reactions of triflates: a) modified regioselection: C. M. Andersson, A. Hallberg, *J. Org. Chem.* **1988**, *53*, 2112; b) modified yield: W. Cabri, I. Candiani, S. DeBernardinis, F. Francalanci, S. Penco, R. Santi, *ibid.* **1991**, *56*, 5796; c) decreased enantioselection: C. Sonesson, M. Larhed, C. Nyqvist, A. Hallberg, *ibid.* **1996**, *61*, 4756, and ref. [4]; d) Shibasaki [2] has reported that addition of sodium halides to an asymmetric Heck cyclization/η^3-allylpalladium carbanion trapping reaction resulted in moderate increases in enantioselectivity that were ascribed to complexation with the sodium enolate.

Structural Rigidity and Luminescence of Chiral Lanthanide Tetraamide Complexes Based on 1,4,7,10-Tetraazacyclododecane**

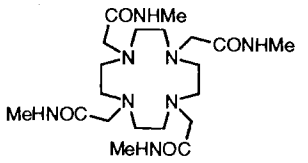
Rachel S. Dickins, Judith A. K. Howard, Christian W. Lehmann, Janet Moloney, David Parker,* and Robert D. Peacock

N-Substituted octadentate ligands derived from 1,4,7,10-tetraazacyclododecane form kinetically robust square-antiprismatic complexes in aqueous solution with metal ions that prefer a coordination number of eight, such as calcium, the lanthanides,[1, 2] and lead.[3, 4] When the N substituents contain amide groups, the neutral ligand forms tripositive complexes capable of binding further to one water molecule.[1, 2] Such complexes (e.g. of La) have been considered as artificial nucleases and may also function as NMR shift reagents for anions in aqueous media.

We now report the structural characterization and chiroptical properties of selected lanthanide complexes of the chiral tetraamide ligand **1** and compare their behavior to that of complexes of the achiral analogue **2**.[5] Chiral europium and terbium complexes are of particular interest since they may function as emissive chiral probes in biological media and are particularly amenable to analysis by circularly polarized luminescence spectroscopy.[6] In order to be useful as a probe that may interrogate interactions with other chiral molecules or macromolecules, a single enantiomer of the complex is desirable that is conformationally rigid on the time scale of the metal-based emission lifetime; that is, of the order of milliseconds.



1



2

Chiral anionic complexes incorporating propionate or benzylphosphinate pendant groups have been described previously that are conformationally rigid on the NMR time scale.[7] The Eu and Tb carboxylate complexes exist as a diastereoisomeric mixture in solution and are only weakly emissive (and lack a suitable organic chromophore). The chiral phosphinate complexes exist as a diastereoisomeric mixture in solution in which one diastereoisomer predominates, and whilst these diastereoisomers have yet to be resolved they may be studied as chiral probes following circularly polarized excitation.

Reaction of (*S*)- or (*R*)-*N*-2-chloroethanoyl-2-phenylethylamine with 1,4,7,10-tetraazacyclododecane (DMF, K_2CO_3, 60 °C) afforded the tetraamide ligands (*S*)-**1** or (*R*)-**1** (m.p. 151–152 °C, $[\alpha]_D^{20} = +241.7$ ($c = 0.12$ in methanol) for (*R*) enantiomer). Reaction of **1** with lanthanide trifluoromethanesulfonates (Ln = Pr, Eu, Tb, Dy, Yb) in CH_3CN afforded cationic complexes, which were crystallized from acetonitrile as their triflate or trifluoroacetate complexes. The enantiomeric terbium complexes showed equal and opposite rotations, for example for $[Tb\cdot(R)\text{-}\mathbf{1}]^{3+}$, $[\alpha]_D^{20} = +104.2$ ($c = 2.21$ in methanol); $[Tb\cdot(S)\text{-}\mathbf{1}]^{3+}$, $[\alpha]_D^{20} = -104.2$ ($c = 0.14$ in methanol). The CD spectra of the enantiomeric terbium complexes are mirror images of each other, but show no evidence for exciton coupling between the aryl chromophores above 200 nm. Crystal structures[8] of the enantiomeric $[Eu\cdot\mathbf{1}]^{3+}$ complexes (the *S* complex as its trifluoromethanesulfonate salt, the *R* complex as a trifluoroacetate) reveal that the chirality of the remote amide stereocenter determines the handedness of the arrangement of the N substituents as well as the conformation of the twelve-membered tetraaza macrocycle (Figure 1). The complex contains one metal-bound water molecule, and the Eu–O distances (Eu–O = 2.435(4) Å) are very similar to those previously reported for nine-coordinate europium-aqua complexes.[2, 9] The mean Eu–O and Eu–N distances are 2.39 and 2.67 Å, respectively, while the isostructural dysprosium complex of (*S*)-**1** (as its triflate salt) has slightly shorter bond lengths (mean Dy–O = 2.34 Å, Dy–N = 2.64 Å) in accord with the smaller ionic radius of Dy^{3+}.

The hydrogen atoms of the lanthanide-bound water molecule engage in hydrogen-bonding interactions with the oxygen atoms of the proximate counterions (Figure 2). This stabilizing interaction in the solid-state lattice may help to explain, at least in part, the extraordinarily slow rate of water exchange for the

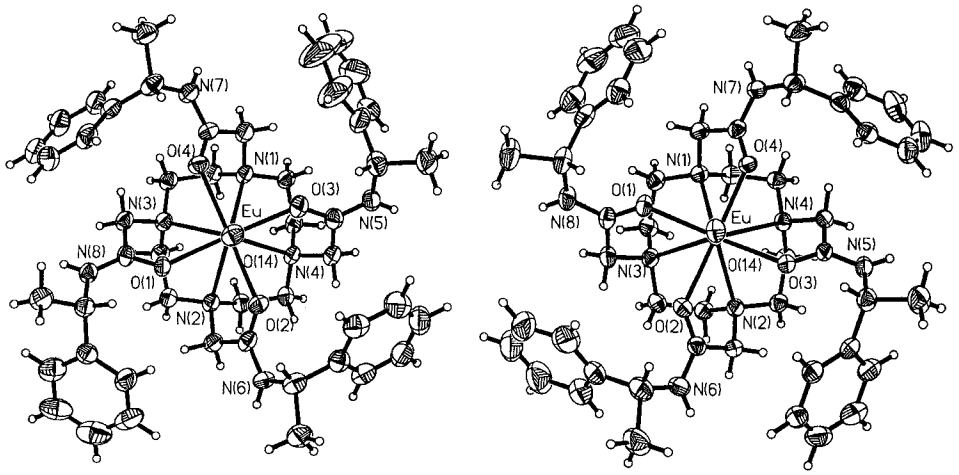

Figure 1. Structures of the enantiomeric complexes [Eu·(*S*)-**1**]$^{3+}$ (left) and [Eu·(*R*)-**1**]$^{3+}$; view down the C_4 axis.

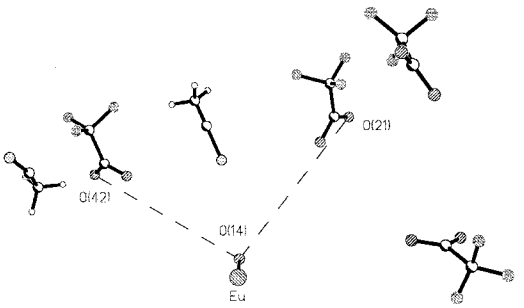

Figure 2. Arrangement of the bound water molecule and the trifluoroacetate and acetonitrile solvent molecules in the crystal lattice of [Eu·(*R*)-**1**](CF$_3$CO$_2$)$_3$; the dashed lines indicate the hydrogen bonding between the Eu-bound oxygen and the counterion oxygen atoms (O···O distances are 2.831(5) and 2.832(5) Å).

related [Gd·**2**]$^{3+}$ complex (as its triflate or trifluoroacetate salt) in the pH range 4 to 12. A value for the water exchange lifetime of 22 μs (298 K, pH 7) has been determined,[5] which is sufficiently large that the observed relaxivity of the gadolinium complex is small (2.7 dm^3 mmol^{-1} s^{-1}; 20 MHz, 298 K).

Solution NMR studies in CD_3OD confirm the presence of a single C_4-symmetric complex for [Eu·**1**]$^{3+}$ that does not show any evidence for exchange broadening in the range 193–320 K (400 MHz). As with [Eu·**2**]$^{3+}$, no change in the shifted spectral pattern was observed over the pH range 1 to 11, although with [Eu·**2**]$^{3+}$ in D_2O, exchange broadening does occur ($T_c \approx 295$ K, 200 MHz) presumably through interconversion of the major

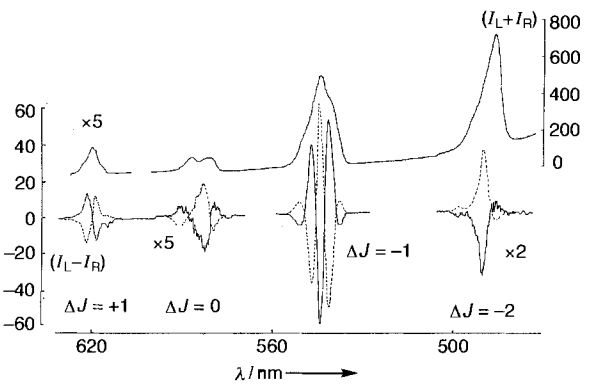

Figure 3. Total luminescence ($I_L + I_R$) and circularly polarized luminescence spectra ($I_L - I_R$) of [Tb·(*S*)-**1**]$^{3+}$ (solid line) and [Tb·(*R*)-**1**]$^{3+}$ (dashed line), [293 K, MeCN, 2×10^{-3} mol dm^{-3}].

(>90%) square antiprismatic diastereoisomer and the minor inverted square antiprismatic species,[12] in a manner akin to that established for [Eu·dota]$^-$ (dota = 1,4,7,10-tetraazacyclododecanetetraacetate), which involves a concerted rotation of the N substituents about the rigid quadrangular macrocyclic ring.[13] In aqueous solution the [Tb·**1**]$^{3+}$ complex is highly luminescent ($\tau_{H_2O} = 1.74$ ms, $\tau_{D_2O} = 3.45$ ms ($\lambda_{exc} = 254$ nm); $q = 1.19$, $\varphi = 0.25$), and the Tb-based emission may be detected either following direct laser excitation at 380 nm or sensitized excitation by the proximate aryl chromophore ($\lambda_{exc} = 254$ nm). The corresponding [Tb·**2**]$^{3+}$ complex behaves very similarly ($\tau_{H_2O} = 1.67$ ms, $\tau_{D_2O} = 3.29$ ms ($\lambda_{exc} = 254$ nm), $q = 1.24$). Direct laser excitation of the terbium ion in [Tb·**1**]$^{3+}$ with linearly polarized light gave rise to a striking circularly polarized emission spectrum (Figure 3), which showed high emission disymmetry factors g_{em} ($g_{em} = \Delta I/0.5 I_{tot}$) for the allowed transitions associated with a change in magnetic dipole, at 545 nm ($\Delta J = -1$, $g_{em} = -0.25$) and 620 nm ($\Delta J = +1$, $g_{em} = +0.29$).

With due consideration to the triplet energy of the chiral organic chromophore and the nature of the bound lanthanide (e.g. Tb or Eu),[12] the substituents around the stereogenic center at carbon may be systematically varied (e.g. Ph vs naphthyl or MeO-Ph; Me vs CO_2R). This may allow a rigorous study of both intra- and intermolecular energy transfer by circular dichroism (CD) and circularly polarized luminescence spectroscopy, based on the well-defined model chiral lanthanide complexes of **1** reported herein.

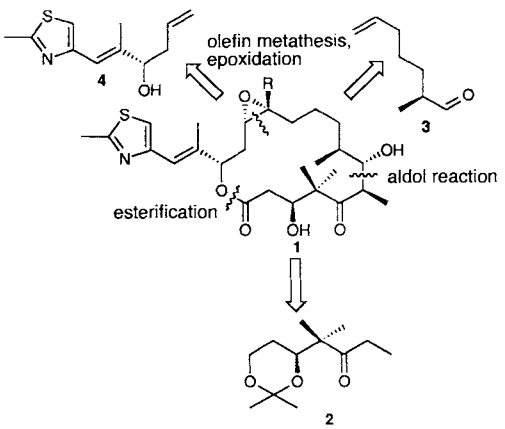
Total Synthesis of (−)-Epothilone A**

Dieter Schinzer,* Anja Limberg, Armin Bauer, Oliver M. Böhm, and Martin Cordes

Epothilones represent a new class of microtubule-stabilizing natural compounds with taxol-like effects. Especially their cytotoxic activity against drug-resistant tumor cell lines is of enormous importance in view of potential applications to cancer therapy.[1–3]

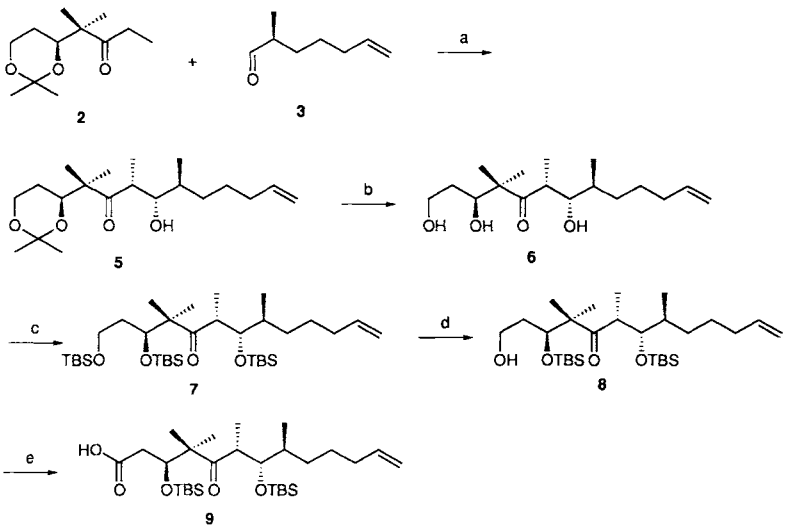
Epothilones (A (**1**): R = H, B: R = Me) were isolated by Höfle et al. from myxobacteria and can be produced on a large scale by fermentation.[1] Due to their very interesting biological properties, the chemical synthesis of epothilones is of greatest importance. Recently several synthesis strategies were published,[4–8] and Danishefsky et al.[9] and Nicolaou et al.[10] have now disclosed the total synthesis of **1**.[***] Here we report a total synthesis of **1** based on our previously described strategy.[5] Epothilone **1** is obtained by a convergent strategy from **2**, **3**, and **4**.[5] Fragments **2** and **3** can be coupled by a stereoselective aldol reaction (Scheme 1). Esterification with subunit **4** provides the



Scheme 1. Retrosynthetic analysis.

almost completely functionalized fragment **17**, which yields deoxyepothilone A (**19**) after cyclization by ring-closing metathesis. Final epoxidation provides **1**.

The key step in our approach is the stereoselective aldol reaction of **2** and **3**, which is obtained by asymmetric synthesis from commercially available hept-6-enoic acid.[5] The desired compound **5**, the only diastereomer with four correctly placed stereogenic centers, is obtained in 70% yield under kinetic control in the presence of LDA. Both reactants are in optically pure form; the preferred Cram-selectivity of the aldehyde **3** is overruled by double stereodifferentiation (Scheme 2).[11]



Scheme 2. a) LDA, THF, −78°C, 70%; b) pyridinium *p*-toluenesulfonate (PPTS), MeOH, RT, 36 h, 88%; c) 12 equiv tBuMe$_2$SiOTf (Tf = trifluoromethanesulfonate), 6 equiv 2,6-lutidine, CH_2Cl_2, −78 °C, 96%; d) 0.2 equiv CSA, MeOH, CH_2Cl_2, 0°C, 5 h, 82%; e) 11 equiv PDC, DMF, RT, 36 h, 79%.

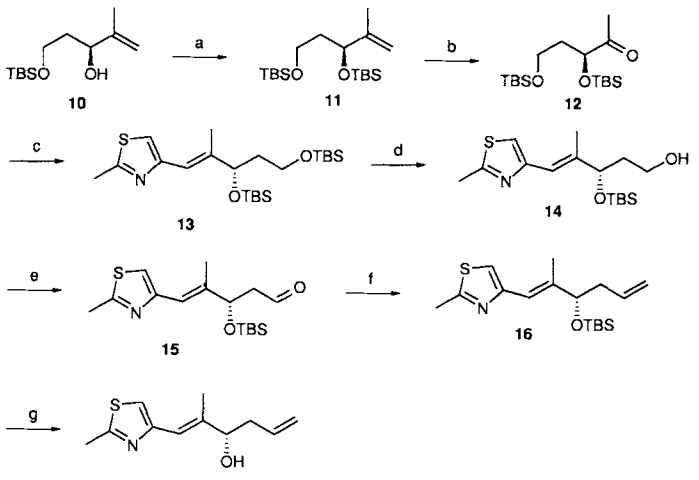
[***] Editorial note: see also the contribution from Nicolaou et al. in this issue (pp. 525–527).

Cleavage of the acetonide **5** proceeds smoothly in the presence of PPTS to give the triol **6**. Subsequent triple silylation with TBSOTf and lutidine provides the desired **7**. To make the oxidation to acid **9** possible, the primary silyl group has to be cleaved selectively. This can be achieved in the presence of CSA to generate **8**. Final oxidation with PDC provides fragment **9**, which contains the C1–C12 subunit of **1**. Our previously reported synthesis of the thiazole subunit **4** could be considerably improved.[5]

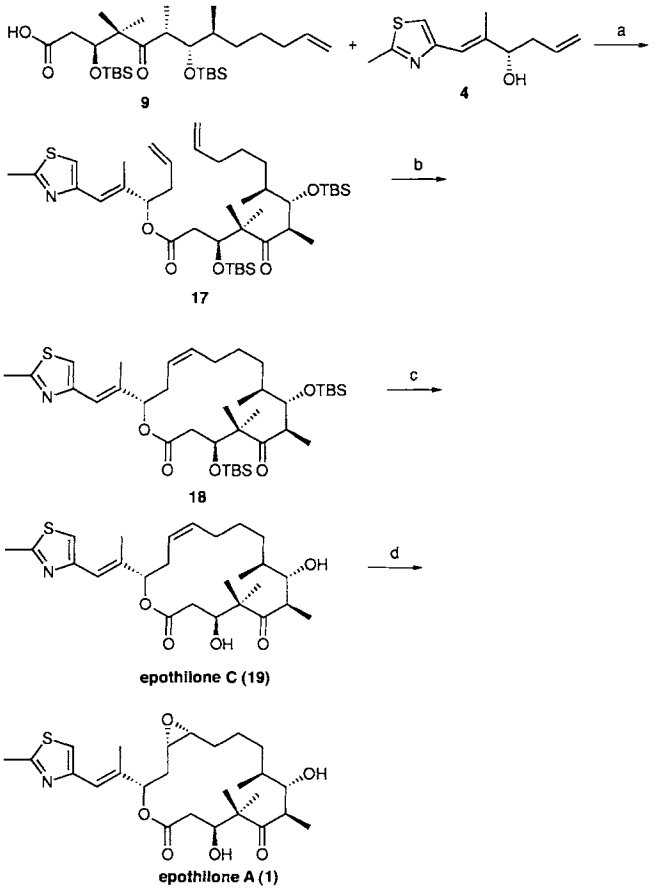
(*S*)-alcohol **10** (obtained by Sharpless resolution)[5] was silylated with TBSCl, transformed to the methyl ketone **12** by ozonolysis, and converted into the trisubstituted olefin **13** by a stereoselective Horner–Wadsworth–Emmons reaction (Scheme 3). Selective desilylation with HF in acetonitrile provides **14**. This takes place only in the presence of a few splinters of glass; the reaction is apparently catalyzed by H_2SiF_6. Dess–Martin oxidation followed by Wittig olefination generates **16**, which is desilylated with TBAF in THF to fragment **4**.



Scheme 3. a) TBSCl, imidazole, DMF, RT, 10 h, 98%; b) O_3, PPh_3, CH_2Cl_2, −78°C, 70%; c) 1.5 equiv diethyl 2-methylthiazole-4-yl methanephosphonate, *n*BuLi, THF, −78°C → RT, 75%; d) HF, MeCN, a few splinters of glass, 0°C, 87%; e) Dess–Martin periodinane, CH_2Cl_2, RT, 1 h, 78%; f) 1.85 equiv $PPh_3MeBr/NaNH_2$, THF, RT, 20 min, 83%; g) 2.5 equiv TBAF, 4 Å molecular sieves, THF, −78°C → RT, 99%.

Esterification of the subunits **9** and **4** in the presence of DCC and 4-DMAP provides stereochemically homogeneous **17** (Scheme 4). Ring-closing metathesis[12] with $[RuCHPh]Cl_2 \cdot (PCy_3)_2$ in CH_2Cl_2 produces **18** as a mixture of diastereomers ($Z:E = 1:1$) in 94% yield. The final steps of the total synthesis are desilylation with HF in acetonitrile/ether to provide **19**[13] and regio- and stereoselective epoxidation with dimethyl dioxirane to yield **1**.[14]

Our highly convergent synthesis of **1** can be easily extended to analogs that are very important in view of their biological activity. Only one type of protecting group (TBS), which is attached or removed in selective reactions, is employed. The stereoselectivity of the aldol reaction is remarkable and represents another impressive example of the diastereofacial selectivity inherent to the chiral enolate. Although ring-closing metathesis leading to **18** is achieved in 94% yield of isolated product, a 1:1 mixture of the *Z*- and *E*-isomers is obtained. This ratio could be improved by variation of reaction conditions and/or protecting groups. Studies toward the synthesis of the biologically more active epothilone B, which should be accesssible by the same route, are under investigation.



Scheme 4. a) 1.3 equiv dicyclohexyl carbodiimide (DCC), 0.2 equiv 4-dimethylamino pyridine (4-DMAP), CH_2Cl_2, RT, 12 h, 80%; b) $[RuCHPh]Cl_2 \cdot (PCy_3)_2$, CH_2Cl_2, RT, 12 h, 94% ($Z:E = 1:1$); c) HF, MeCN, Et_2O, RT, 12 h; 65%, d) dimethyl dioxirane, CH_2Cl_2, −35°C, 2 h, 48%.

Total Synthesis of Epothilone A: The Macrolactonization Approach**

K. C. Nicolaou,* Francisco Sarabia, Sacha Ninkovic, and Zhen Yang

Dedicated to Professor Stephen Hanessian on the occasion of his 60th birthday

The novel molecular structures of the epothilones, for example epothilone A (**1**, Figure 1), coupled with their antifungal[1, 2] and antitumor activities[1–4] and microtubule binding properties[4] promise an exciting new chapter in chemistry, biology, and medicine. Particularly intriguing is the ability of these compounds to displace taxol from its binding site on microtubules,[4] towards which epothilones exhibit much higher affinity than taxol.[5] An indication of the intense interest in this field is the flurry of activity[6] directed toward their total synthesis within the relatively short time since their structural elucidation.[2] While our first total synthesis[6f] of **1** enjoys the benefits of the olefin metathesis reaction, the one we wish to report here relies on a macrolactonization process for constructing the main ring skeleton. In addition, the reported synthesis is highly convergent and flexible and therefore allows entry into a large library of epothilones, including epothilone B and all of the 2^6 stereoisomers of **1**.

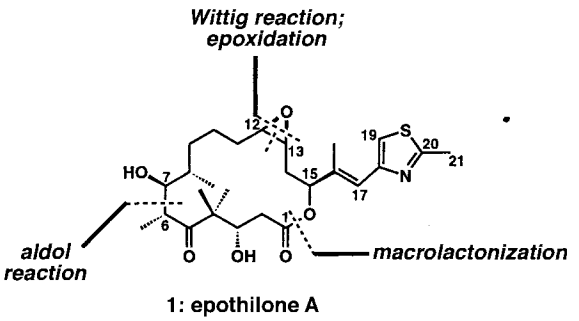

Figure 1. Structure and retrosynthetic analysis of epothilone A (**1**).

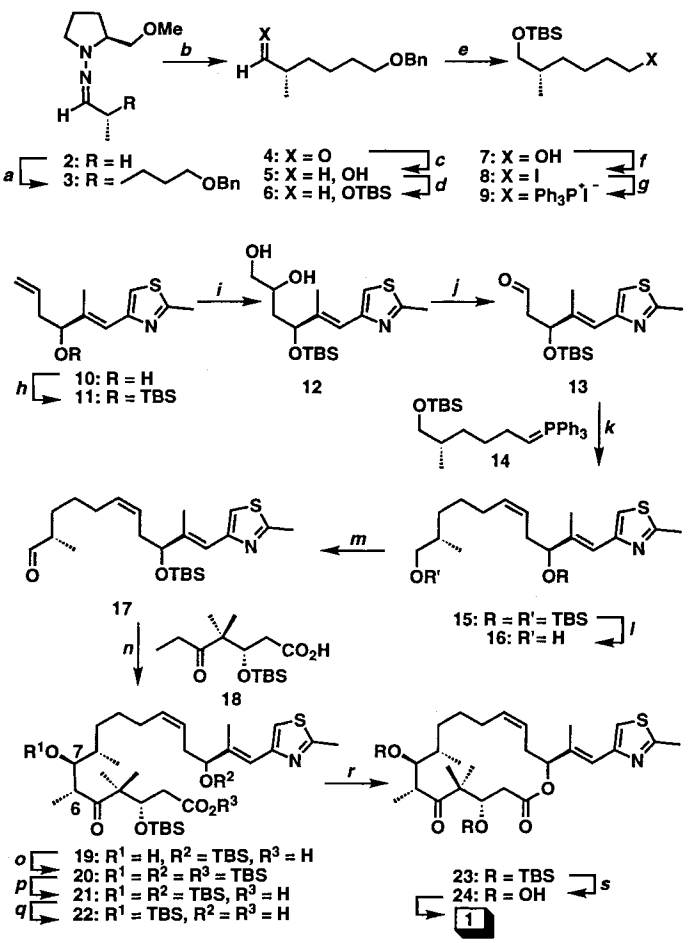
By the macrolactonization approach to **1** (Figure 1), three fragments (C1–C6, C7–C12, and C13–C21), each containing a stereogenic center, are to be constructed stereoselectively by asymmetric synthesis procedures, united, and elaborated to the final target. A Wittig and an aldol reaction will be used for the coupling of these fragments, whereas the C(O)–O bond formation is reserved for the macrocycle forming process, in the form of a macrolactonization. It is important to note that this strategy allows for the preparation of all the possible stereoisomers of **1**, since the configuration of each stereocenter can easily be reversed.

The execution of this rather simple strategy proceeded smoothly for **1** (Scheme 1). The SAMP derivative **2**, obtained by reaction of SAMP[7] with propionaldehyde, was alkylated with 4-iodo-1-benzyloxybutane in the presence of LDA in THF at $-100\,^{\circ}C$ according to the method of Enders et al.[7] to produce **3** in 92% yield and greater than 98% *ee*.[8] Ozonolysis of **3** followed by treatment with $NaBH_4$ furnished alcohol **5**, via aldehyde **4**, in 77% overall yield. Protection of the hydroxyl group in **5** as a *tert*-butyldimethylsilyl (TBS) ether, followed by standard elaboration of the other end of the molecule (hydrogenolysis of benzyl ether, iodonation, and phosphonium salt formation) yielded the desired fragment **9** in 79.5% overall yield (from **5**).



Scheme 1. Total synthesis of epothilone A (**1**): a) 1.1 equiv LDA, THF, 0 °C, 8 h; then 1.5 equiv 4-iodo-1-benzyloxybutane in THF at −100 to 0 °C, 6 h, 92%; b) O_3, CH_2Cl_2, −78 °C, 77%; c) 3.0 equiv $NaBH_4$, MeOH, 0 °C, 15 min, 98%; d) 1.5 equiv TBSCl, 2.0 equiv Et_3N, CH_2Cl_2, 0 to 25 °C, 12 h, 95%; e) H_2, $Pd(OH)_2$ cat, THF, 15 min, 40 psi, 25 °C, 95%; f) 1.5 equiv I_2, 3.0 equiv imidazole, 1.5 equiv Ph_3P, Et_2O/CH_3CN (3:1), 0 °C, 0.5 h, 91%; g) Ph_3P, neat, 100 °C, 2 h, 92%; h) 1.5 equiv TBSCl, 2.0 equiv imidazole, THF, 0 to 25 °C, 1 h, 99%; i) 1 mol% OsO_4, 1.1 equiv NMO, 25 °C, 14 h, 95%; j) 1.1 equiv $Pb(OAc)_4$, EtOAc, 0 °C, 10 min, 99%; k) 1.2 equiv **9**, 1.2 equiv NaHMDS, THF, 0 °C, 0.25 h, then addition 1.0 equiv aldehyde **13** at 0 °C, 15 min, 69% (*Z*:*E* ≈ 9:1); l) 1.0 equiv CSA in portions over 1 h, CH_2Cl_2/MeOH (1:1), 0 °C, then 25 °C, 0.5 h, 86%; m) 2.0 equiv SO_3·pyridine, 10.0 equiv DMSO, 5.0 equiv Et_3N, CH_2Cl_2, 25 °C, 0.5 h, 82%; n) 3.0 equiv LDA, THF, 0 °C, 0.25 h, then 1.2 equiv **18** in THF at −78 to −40 °C, 0.5 h, then 1.0 equiv **17** in THF at −78 °C, high yield of **19** and its 6*S*,7*R*-diasteromer (ca. 1:1 ratio); o) 3.0 equiv TBSOTf, 5.0 equiv 2,6-lutidine, CH_2Cl_2, 0 °C, 2 h; p) 2.0 equiv K_2CO_3, MeOH, 25 °C, 15 min, 31% of **21** and 30% of its 6*S*,7*R*-diasteromer from **17**; q) 6.0 equiv TBAF, THF, 25 °C , 8 h, 79%; r) 5 equiv 2,4,6-trichlorobenzoylchloride, 6.0 equiv Et_3N, THF, 25 °C, 15 min, then addition to a solution of 10.0 equiv 4-DMAP in toluene (0.002 M based on **22**), 25 °C, 0.5 h, 90%; s) 20% CF_3COOH (v/v) in CH_2Cl_2, 0 °C, 1 h, 92%. LDA = lithium diisopropylamide; 4-DMAP = 4-dimethylaminopyridine; TBS = *tert*-butyldimethylsilyl; NaHMDS = sodium bis(trimethylsilyl)amide; DMSO = dimethylsulfoxide; Tf = triflate; NMO = *N*-methylmorpholine *N*-oxide.

[**] This work was financially supported by The Skaggs Institute of Chemical Biology and the National Institutes of Health (USA). F. S. thanks the Fundacion Ramon Areces for a postdoctoral fellowship.

The second requisite fragment, thiazoline aldehyde **13**, was rapidly constructed from the thiazoline derivative **10**[6f] by silylation (TBSCl, imidazole, 99%), selective 1,2-dihydroxylation[9] (OsO_4, NMO, 95%), and $Pb(OAc)_4$ cleavage (99%). Generation of the phosphorane **14** from the phosphonium salt **9** with sodium bis(trimethylsilyl)amide (NaHMDS), followed by addition of aldehyde **13**, led predominently to the (*Z*)-olefin **15** in 69% yield ($Z:E \approx 9:1$). The primary TBS group was selectively removed from **15** with camphorsulfonic acid (CSA) in MeOH to give alcohol **16** (86% yield), which was oxidized to the corresponding aldehyde (**17**) by the action of SO_3·pyridine (82% yield). Condensation of the dilithio derivative of **18**[6f] (2.6 equiv of LDA, THF, −78 to −40 °C) with aldehyde **17** proceeded at −78 °C to afford a mixture of diastereomers (**19** + 6*S*,7*R*-diastereomer; ca. 1:1 to 1:2 ratio depending on precise conditions) in good yield. This mixture was carried through the sequence until compound **21**, at which stage it was separated into its components by silica gel chromatography. Thus, the aldol products (**19** + diastereomer) were fully silylated with TBSOTf/2,6-lutidine. The resulting mixture of *tetra*-TBS derivatives (compound **20** + diastereomer) was briefly exposed to K_2CO_3 in MeOH to afford, after preparative thin layer chromatography, pure carboxylic acid **21** (31% overall yield) and its 6*S*,7*R*-diastereomer (30% overall yield from **17**; **21**: $R_f = 0.61$, 6*S*,7*R*-diastereomer: $R_f = 0.70$, silica gel, 5% MeOH in CH_2Cl_2, for spectroscopic details of **21**, see Table 1). The indicated stereochemical assignment for the slower moving isomer **21** was based on its successful conversion to macrolactone **24**[6f] and **1**.

At this stage, it was necessary to deprotect the C15 hydroxyl group selectively for the intended macrolactonization reaction. This task was successfully accomplished with tetra-*n*-butylammonium fluoride (TBAF) in THF at 25 °C, leading to the desired hydroxy acid **22** in 78% yield (Table 1). Steric hindrance at the sites of the other TBS groups was presumed to be responsible for this selectivity. The key ring closure of **22** was smoothly effected under Yamaguchi conditions[10] (2,4,6-trichlorobenzoyl chloride, Et_3N, 4-DMAP, THF/toluene, 25 °C), furnishing the 16-membered ring lactone **23** in 90% yield (Table 1). Finally, exposure of **23** to CF_3COOH (20% by volume) in CH_2Cl_2 at 0 °C led to the targeted olefinic diol **24** (92% yield). The latter compound was then converted into **1** by exposure to *m*CPBA as already described.[6f]

This expedient route to epothilone A (**1**) may easily be extended to epothilone B and a variety of analogs of these naturally occurring compounds for biological investigations. Indeed, the molecular design, chemical synthesis, and biological screening of such analogs should be among the next priorities in this field.[11]

Table 1. Selected physical properties of compounds **21**–**23**.

21: $R_f = 0.61$ [silica gel, methanol:dichloromethane (5%)]; $[\alpha]_D^{22} = -8.8$ ($c = 0.8$ in chloroform); IR (film): $\tilde{\nu} = 2931, 2856, 1712, 1466, 1254, 1083, 836\ cm^{-1}$; ^1H NMR (600 MHz, $CDCl_3$): $\delta = 6.94$ (s, 1H, −C=CHS−), 6.61 (s, 1H, −C=CH−C=), 5.44–5.41 (m, 2H, −CH=C*H*−CH_2−, −C*H*=CH−CH_2−), 4.40 (dd, 1H, $J_1 = 3.2$ Hz, $J_2 = 6.5$ Hz, −$(CH_3)_2$C−C*H*−), 4.11 (dd, 1H, $J_1 = 5.9$ Hz, $J_2 = 6.5$ Hz, −C*H*(OSi$(CH_3)_2$*t*Bu)−), 3.75 (dd, 1H, $J_1 = 3.0$ Hz, $J_2 = 6.5$ Hz, TBSO−C*H*−CH(Me)), 3.12 (dq, 1H, $J_1 = 7.0$ Hz, $J_2 = 6.5$ Hz, −C(O)C*H*(CH_3)−), 2.69 (s, 3H, −S−C(CH_3)=N−), 2.48 (dd, 1H, $J_1 = 3.2$ Hz, $J_2 = 16.0$ Hz, −C*H*$_2$−COOH), 2.35 (dd, 1H, $J_1 = 6.7$ Hz, $J_2 = 16.0$ Hz, −C*H*$_2$−COOH), 2.31–2.28 (m, 2H, −C*H*$_2$CH=CH), 2.10–2.00 (m, 2H, −C*H*$_2$−CH=CH), 1.95 (s, 3H, −C(C*H*$_3$)=CH−C=), 1.42–1.30 (m, 5H), 1.18 (s, 3H, −C(C*H*$_3$)$_2$), 1.10 (s, 3H, −C(C*H*$_3$)$_2$), 1.06 (d, 3H, $J = 7.0$ Hz, −C(O)−CH(C*H*$_3$)−), 0.90–0.85 (m, 30H, −C(O)−CH(C*H*$_3$)−, 3× −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$), 0.12 (s, 3H, −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$), 0.09 (s, 3H, −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$), 0.07 (s, 3H, −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$), 0.05 (s, 3H, −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$), 0.04 (s, 3H, −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$), 0.03 (s, 3H, −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$); ^{13}C NMR (600 MHz, $CDCl_3$): $\delta = 218.2, 176.1, 164.9, 152.7, 142.8, 131.4, 126.0, 118.5, 114.7, 78.7, 73.3, 53.7, 44.7, 40.0, 39.0, 34.7, 30.8, 28.0, 27.8, 26.2, 26.0, 25.8, 23.6, 19.0, 18.8, 18.5, 18.2, 17.2, 15.8, 13.8, −3.8, −3.9, −4.2, −4.6, −4.7, −4.9$; HRMS: calcd for $C_{44}H_{83}NO_6SSi_3$ ($M + Cs^+$) 970.4303, found 970.4318.

22: $R_f = 0.40$ [silica gel, methanol:dichloromethane (5%)]; $[\alpha]_D^{22} = -19.2$ ($c = 0.1$ in chloroform); IR (film): $\tilde{\nu} = 3358$ (br, OH), 2932, 2857, 1701, 1466, 1254, 1088, 988, 835 cm^{-1}; ^1H NMR (600 MHz, $CDCl_3$): $\delta = 6.95$ (s, 1H, −C=CHS−), 6.61 (s, 1H, −C=CH−C=), 5.58–5.54 (m, 1H, −CH=C*H*−CH_2−), 5.43–5.39 (m, 1H, −C*H*=CH−CH_2−), 4.39 (dd, 1H, $J_1 = 3.9$ Hz, $J_2 = 6.7$ Hz, −$(CH_3)_2$-C−C*H*−), 4.18 (dd, 1H, $J_1 = 5.0$ Hz, $J_2 = 7.5$ Hz, −C*H*(OH)−), 3.78 (dd, 1H, $J_1 = 3.0$ Hz, $J_2 = 6.9$ Hz, −SiO−C*H*−CH(Me)), 3.11 (dq, 1H, $J_1 = 6.9$ Hz, $J_2 = 6.7$ Hz, −C(O)−C*H*(CH_3)−), 2.70 (s, 3H, −S−C(CH_3)=N−), 2.43 (dd, 1H, $J_1 = 3.9$ Hz, $J_2 = 16.2$ Hz, −C*H*$_2$−COOH), 2.40–2.35 (m, 2H, −C*H*$_2$−CH=), 2.35 (dd, 1H, $J_1 = 6.7$ Hz, $J_2 = 16.2$ Hz, −C*H*$_2$−COOH), 2.15–2.10 (m, 1H, −C*H*$_2$−CH=), 2.00 (s, 3H, −C(C*H*$_3$)=CH−C=), 1.99–1.95 (m, 1H, −C*H*$_2$−CH=), 1.48–1.30 (m, 5H), 1.18 (s, 3H, −C(C*H*$_3$)$_2$−), 1.08 (s, 3H, −C(C*H*$_3$)$_2$), 1.05 (d, 3H, $J = 6.7$ Hz, −C(O)−CH(C*H*$_3$)−), 0.89–0.84 (m, 21H, −C(O)−CH(C*H*$_3$)−, −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$), 0.09 (s, 3H, −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$), 0.05 (s, 3H, −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$), 0.04 (s, 3H, −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$), 0.03 (s, 3H, −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$); ^{13}C NMR (600 MHz, $CDCl_3$): $\delta = 218.9, 175.4, 166.3, 152.8, 134.4, 125.7, 119.5, 115.9, 74.4, 74.3, 54.7, 45.5, 40.9, 40.0, 34.3, 31.9, 30.6, 28.9, 28.8, 27.0, 26.9, 24.4, 22.0, 21.4, 20.0, 19.6, 19.3, 19.1, 17.9, 17.1, 15.5, 8.6, −2.9, −3.1, −3.3, −3.8$; HRMS: calcd for $C_{38}H_{69}NO_6SSi_2$ ($M + Cs^+$) 856.3439, found 856.3459.

23: $R_f = 0.37$ [silica gel, hexane:ether (2:1)]; $[\alpha]_D^{22} = -22.9$ ($c = 0.3$ in chloroform); IR (film): $\tilde{\nu} = 2926, 2854, 1734, 1693, 1463, 1381, 1252, 1099, 829\ cm^{-1}$; ^1H NMR (500 MHz, $CDCl_3$): $\delta = 6.98$ (s, 1H, −C=CHS−), 6.58 (s, 1H, −C=CH−C=), 5.53 (m, 1H, −CH=C*H*−CH_2−), 5.43–5.34 (m, 1H, −C*H*=CH−CH_2), 5.00 (d, 1H, $J = 6.0$ Hz, −O−CH), 4.03 (d, 1H, $J = 10.0$ Hz, −C*H*(OH)−), 3.89 (d, 1H, $J = 9.0$ Hz, −C*H*(OH)), 3.04–2.98 (m, 1H, −C(O)−CH−), 2.85 (d, 1H, $J = 15.0$ Hz, OOC−C*H*$_2$−), 2.72 (s, 3H, −S−C(CH_3)=N−), 2.66 (dd, 1H, $J_1 = 15.0$ Hz, $J_2 = 10.0$ Hz, OOC−C*H*$_2$−), 2.42–2.31 (m, 2H), 2.11 (s, 3H, −C(C*H*$_3$)=), 1.92–1.83 (m, 1H), 1.66–1.38 (m, 4H), 1.20 (s, 3H, −C(C*H*$_3$)$_2$−), 1.16 (s, 3H, −C(C*H*$_3$)$_2$, 1.09 (d, 3H, $J = 7.0$ Hz, −C(O)−CH(C*H*$_3$)−), 0.95 (d, 3H, $J = 7.0$ Hz, −CH(C*H*$_3$)−), 0.94 (s, 9H, −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$), 0.85 (s, 9H, −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$), 0.12 (s, 3H, −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$), 0.10 (s, 3H, −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$), 0.08 (s, 3H, −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$), −0.10 (s, 3H, −SiC(C*H*$_3$)$_3$(C*H*$_3$)$_2$). ^{13}C NMR (600 MHz, C_6D_6): $\delta = 215.0, 171.3, 135.1, 122.7, 79.5, 76.4, 53.3, 48.0, 38.8, 31.7, 29.7, 29.2, 28.4, 26.4, 26.2, 26.1, 25.0, 24.2, 19.1, 18.7, 18.6, 17.7, 15.3, −3.1, −3.2, −3.7, −5.8$; HRMS: calcd for $C_{38}H_{67}NO_5SSi_2$ ($M + H^+$) 706.4357, found 706.4382.

Surface Analysis with STM and AFM NEW

Experimental and Theoretical Aspects of Image Analysis

1996. X, 300 pages with 230 figures and 5 tables. Hardcover. DM 198.00/$ 125.00/£ 80.00.
ISBN 3-527-29313-2 (VCH Weinheim)

Scanning tunneling microscopy (STM) and atomic force microscopy (AFM) are powerful tools for surface examination. In the past, many STM and AFM studies led to erroneous conclusions due to a lack of proper theoretical considerations and of an understanding of how image patterns are affected by measurement conditions. For this book, two world experts, one on theoretical analysis and the other on experimental characterization, have joined forces to bring together essential components of STM and AFM studies: The practical aspects of STM, the image simulation by surface electron density plot calculations, and the qualitative evaluation of tip-force induced surface corrugations.

Practical examples are taken from:
• inorganic layered materials • organic conductors • organic adsorbates at liquid-solid interfaces • self-assembled amphiphiles • polymers

This book will be an invaluable reference work for researchers active in STM and AFM as well as for newcomers to the field.

DiNardo, John

Nanoscale Characterization of Surfaces and Interfaces

1994. X, 163 pages with 150 figures and 2 tables. Hardcover.
DM 138.00/$ 100.00/£ 56.00.
ISBN 3-527-29247-0 (VCH Weinheim)

Derived from the highly acclaimed series Materials Science and Technology, this book provides in-depth coverage of STM, AFM, and related non-contact nanoscale probes along with detailed applications. Many high-quality images demonstrate the power of these methods in the investigation of surfaces and the processes which occur on them.

Buckyball Chronicles

Science of Fullerenes and Carbon Nanotubes. By *J. S. Dresselhaus, G. Dresselhaus* and *P. C. Eklund.* Academic Press, San Diego, 1996. 965 pp., hardcover £ 95.00.—ISBN 0-12-221820-5

Research on fullerenes and the many different aspects that have developed continues to generate much excitement, even though the gold-rush fever of the first few years has subsided. A large body of knowledge has already been accumulated through the intensive research carried out, and the time is now ripe to review the subject. In the book *Science of Fullerenes and Carbon Nanotubes*, three well recognized experts in the area of carbon-based materials have devoted over 900 pages to that endeavor. The whole field of fullerenes research is treated in 20 chapters, beginning with an interesting historical introduction, from which even the specialist will gain a somewhat broader perspective.

Chapter 2 considers the place of the fullerenes within the overall context of carbon-based materials. Here the authors are able to draw on their broad experience of the field, resulting in an excellent chapter which will be very useful to anyone who has hitherto regarded the fullerenes as merely a class of compounds suitable for synthetic work or studies in chemical physics. This clear and accurate overview will also make stimulating reading for materials scientists.

Chapter 3, on the structure of the fullerenes, describes the basic structures of C_{60}, C_{70}, and the higher fullerenes, then discusses the physical properties of C_{60} and C_{70}. Surprisingly, however, neither the excellent *Atlas of Fullerenes* by Fowler and Manoupoulos, nor the results of calculations on fullerenes published by Scuseria and coworkers, is cited in this or the following chapter.

Chapter 4 deals with the closely related subject of symmetry aspects of fullerene molecules. The vibrational modes of C_{60} and C_{70} are discussed, but the higher fullerenes are given too little attention here. There is a useful discussion of symmetry in isotope distributions, although the main emphasis is on syntheses of ^{13}C-enriched fullerenes, with ^{13}C in natural abundance being mentioned only incidentally.

After these two theoretically-oriented chapters, Chapter 5 moves on to the preparative aspects of fullerenes research, covering synthesis, extraction, and purification, then the mechanism of formation of fullerenes is discussed in more detail in Chapter 6. The first part of Chapter 5 deals with the synthetic routes to fullerenes. However, the discussion of the carbon-arc methods does not include all the variations that have been investigated, and one is also surprised to find that the preparation of fullerenes in flames is not mentioned at all. The description of the extraction of fullerenes is too brief, and consequently the reader will not gain an appreciation of the most effective methods and solvents. The section on purification has some even more serious shortcomings. The treatment of HPLC, the most important separation method, contains far too little detail regarding the many possible combinations of column packing materials and solvents, a serious omission for readers whose interest lies in the preparation of fullerenes. This chapter also contains a final section on the synthesis of endohedral fullerenes, including the characterization of some of these structures by mass spectrometry and ESR spectroscopy. Although this description cites the most important publications up to mid-1994, it is again obvious that much new knowledge and many new structures have been added in the last two years. Chapter 6, on the formation of fullerene molecules, discusses the growth model and the stability of fullerenes in general, and the molecular dynamics of fullerenes from the experimental and (more briefly) theoretical standpoints.

Chapter 7 is devoted to the crystal structure of the fullerenes, also including polymeric fullerenes. This otherwise quite comprehensive chapter fails to mention polymerization in doped materials, a topic that has provided some of the most important publications on fullerene polymers. This omission is only remedied later in Chapter 10.

Chapter 8 contains a classification of doped fullerenes and a survey of these fullerites. The division into exohedral and endohedral doping is probably accepted by most fullerene investigators, but the use of the term "substitutional doping" to describe the preparation of heterofullerenes is unusual. The classification of C_{60}–TDAE complexes and metal–fullerene multilayers as exohedral fullerene structures is sensible, but it is quite incomprehensible that epoxides and clathrates should also be treated under this heading.

The growth of single crystals and epitaxial layers is treated separately in Chapter 9. It would have been better to include this in Chapter 7 or Chapter 8.

In Chapter 10 the authors have tried to cover the chemistry and electrochemistry of fullerenes in just 30 pages. Despite a concisely written text, this has some shortcomings, in addition to having omitted to review several important publications on the chemistry. Stereochemical aspects are not touched on, and the photochemistry does not get the separate section that it deserved.

The discussion of the vibrational modes of the fullerenes in Chapter 11, a good review of the published work up to 1994, is one of the book's strong points.

Chapter 12 is concerned with the electronic structure of the fullerenes. The emphasis is firmly on the theoretical aspects; here one would have liked more coverage of experimental studies.

Following logically from the above, Chapter 13 deals with the optical properties, covering not only doped and empty fullerenes but also the higher species and fullerene–polymer composites. In the treatment of thermal and transport properties (Chapter 14) the main emphasis, as expected, is on the electrical conductivity of doped fullerenes. Nevertheless, an appropriate amount of space is also given to

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

thermal properties in this well-balanced chapter.

A separate chapter (Ch. 15) is devoted to superconductivity in fullerenes, with a good survey of the state of knowledge and outstanding problems in this area of research, covering work up to 1994. The application of magnetic resonance methods to fullerenes is also treated in a separate chapter (Ch. 16), in accordance with the importance of these techniques. However, for NMR spectroscopy especially I would have liked to see more on its capabilities for studying isomers. In the chapter as a whole one is again made aware that in most respects only the state of progress up to 1994 is presented. Chapter 17, on surface science studies, is mainly concerned with the use of spectroscopic methods to study the electronic structure of fullerenes, as discussed earlier in Chapter 12. Less space is devoted to the very important investigations of the structures of surfaces and interfaces involving fullerenes.

Although the magnetic properties of fullerenes are treated in a separate chapter (Ch. 18), this is only a brief one. That is no criticism of the authors, but merely illustrates that this topic has had insufficient attention by the research community. The chapter includes an excellent account of a study of ferromagnetism in a purely organic fullerene complex, thus highlighting an interesting facet of the magnetic properties of fullerenes.

Chapter 19 is a long one on nanotubes; it is a good balanced presentation of this specialist topic, justifying its mention in the title of the book. Here the authors' experience in this area is seen to good advantage.

Chapter 20, the last, is concerned with the applications of fullerenes. Here the authors had a difficult task, in view of the considerable amount of speculation and extravagant predictions that followed the start of intensive research on fullerenes. A sober appraisal must lead to the conclusion that the great breakthrough in applications has failed to materialize. However, this in no way detracts from the value of fullerenes research as part of the general advancement of scientific knowledge. The task of investigating the properties of fullerenes with a view to possible applications remains to be continued, even though a quick payoff now seems unlikely. In reviewing potential applications the authors indicate a wide variety of possible directions, although here and there a more critical appraisal of the literature would have been appropriate.

To sum up, the authors deserve credit for having completed an enormous task. They have not entirely succeeded in the ambitious aim of writing a true monograph on the "science of fullerenes", and perhaps also the publishers would have been rather uneasy about the prospect of producing a work of 2000 pages. Thus we have here a book in which the main emphasis is on the physics of fullerenes and nanotubes. In these fast-moving times it is certainly hard on a book when the literature coverage ends two years before the date of publication, by which time some material will have been superseded and new topics of interest will have emerged.

A particularly good feature of this book is the comprehensive index, enabling one to work efficiently with it; that is not always provided in scientific books nowadays. The work affords an important means of access to the literature on fullerenes, and it should be available to every group working in the field. It is to be hoped that the book will reach a wide readership. That will give the authors the opportunity to prepare a second edition, so that in the course of revising the work they can achieve their goal of producing a monograph on the science of fullerenes.

Comprehensive Supramolecular Chemistry. Volumes 1–11. Edited by *J. L. Atwood, J. E. D. Davies, D. D. MacNicol, F. Vögtle,* and *J.-M. Lehn.* Pergamon/Elsevier, Oxford, 1996. 8500 pp., hardcover $ 4320.00.— ISBN 0-08-042713-8 (Vol. 1); 0-08-042714-6 (Vol. 2); 0-08-042715-4 (Vol. 3); 0-08-042716-2 (Vol. 4); 0-08-042717-0 (Vol. 5); 0-08-042718-9 (Vol. 6); 0-08-042719-7 (Vol. 7); 0-08-042720-0 (Vol. 8); 0-08-042721-9 (Vol. 9); 0-08-042722-7 (Vol. 10); 0-08-042723-5 (Vol. 11)

Comprehensive Supramolecular Chemistry is the first all-embracing survey of this field. The objectives of supramolecular chemistry are to describe the interactions between molecules and to discover how they can be used in a controlled way. It aims to find answers to these problems by a multidisciplinary approach. This is reflected in the very wide range of topics treated in the 11-volume work, encompassing aspects as diverse as molecular recognition in organic molecules, bioinorganic chemistry, solid state chemistry, and the technology of sensors and drug delivery systems.

Volume 1, edited by G. W. Gokel, is entitled "Molecular Recognition: Receptors for Cationic Guests", and is concerned with the complexation of metal ions by organic molecules, a subject that has been studied very thoroughly. First the properties and methods of synthesis of the various host molecules are described. These are arranged according to structural types, ranging from podands through crown ethers, lariat ethers, cryptands, and spherands to cation-binding natural products. The second part of this volume deals with the structures of the complexes and the complexation mechanisms. Special aspects such as the binding of organic cations, the activation of anions by complexation with cations, cationic sensors, and complexes of organometallic compounds are also covered.

Volume 2, "Molecular Recognition: Receptors for Molecular Guests" (ed.: F. Vögtle), is also concerned with host molecules that bind selectively, but here the guests are neutral molecules. A brief account of the development of the subject is followed by a description of the most important methods for synthesizing macrocyclic receptors and the principles of their bonding. The next chapter deals in detail with the chemistry and bonding properties of calixarenes, cyclophanes, cryptophanes, and carcerands. The volume ends with a discussion of hydrogen-bonding receptors, and the simultaneous binding of a cation and a neutral molecule, or of a cation and an anion.

Volume three, "Cyclodextrins" (eds.: J. Szejtli and T. Osa), is devoted solely to these compounds. Up to 1995 more than 12 000 papers were published on the chemistry and applications of cyclodextrins, and the authors have attempted to summarize the most important results. As well as the synthesis and derivatization of cyclodextrins, the volume contains much information about applications in pharmacology and biotechnology.

In Volume 4, "Supramolecular Reactivity and Transport: Bioorganic Systems" (ed.: Y. Murakami), we move on from smaller molecules to the supramolecular aspects of bioorganic chemistry. Topics given special emphasis include catalytic antibodies, DNA-binding substances, protein mimetics, and enzyme models.

Volume 5 is the bioinorganic partner to the previous volume, with the title "Supramolecular Reactivity and Transport: Bioinorganic Systems" (ed.: K. S. Suslick). The topics covered include enzyme models based on porphyrins, the structure and function of metalloproteins, and the chemistry of coordination polymers.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3605-0530 $ 15.00+.25/0

Volumes 6 and 7 deal with supramolecular aspects of solid state chemistry. Volume 6 is devoted to crystal engineering and Volume 7 to the formation of two- and three-dimensional networks.

A very important aspect of research in supramolecular chemistry is the characterization of the structures formed. Stoichiometric measurements, structure determinations, and measurements of bond strengths are essential to gain more information about the nature of molecular interactions. Supramolecular structures can involve a very wide variety of substances, and consequently the methods used to characterize them are many and varied. Volume 8, "Physical Methods in Supramolecular Chemistry" (eds.: J. E. D. Davies and J. A. Ripmeester), contains a survey of the many different physical methods for the characterization of molecular aggregates. Some of the most important of these are X-ray crystallography, calorimetry, potentiometry, spectroscopic techniques, and mass spectrometry.

The phenomena of self-organization and self-assembly are of central importance in supramolecular chemistry. Volume 9, "Templating, Self-assembly, and Self-organisation" (eds.: J.-P. Sauvage and M. W. Hosseini), summarizes the main research results in this area. After describing the template effect in the synthesis of macrocycles and the principles involved in the formation of catenanes, rotaxanes, and helices, the discussion moves on to the fascinating subject of the nanometer-scale architecture of artificial membranes, vesicles, and ducts. The many clear figures illustrate what can be achieved by programmed self-organization based on non-covalent interactions (synkinetics).

Volume 10, entitled "Supramolecular Technology" (ed.: D. N. Reinhoudt), describes applications of supramolecular systems, which extend into such widely different areas as the simple transport of salts, liquid crystal devices, and isotope separation.

The editors have succeeded well in organizing the very heterogeneous subject of supramolecular chemistry, which involves many different disciplines and types of substances, into a valuable work of reference. Each volume is a self-contained treatment of its branch of the subject. This has been achieved at the cost of some unavoidable repetition, but by using the combined index in Volume 11 the reader can quickly locate information on specific aspects of a substance or technique. The numerous figures and clearly set out schemes invite one to browse through the volumes and read whatever catches one's interest, while the comprehensive and up-to-date lists of references give quick and easy access to the original literature. Even though the rapid pace of development in some areas must inevitably soon make parts of the work outdated, the availability of this first detailed survey of the results from many different fields is of great benefit to supramolecular chemistry. It can therefore be recommended unreservedly as a reference source for all chemistry departments whose research or teaching interests involve aspects of supramolecular chemistry.

The Crystal as a Supramolecular Entity. Edited by *G. R. Desiraju*. Wiley, Chichester, 1996. 314 pp., hardcover £ 90.00.—ISBN 0-471-95015-7

This book is the second volume of the series *Perspectives in Supramolecular Chemistry*, and it covers a broad range of topics focused around crystalline molecular systems. It includes six contributions in all, touching on the organic, inorganic, and biomolecular fields. Such a broad scope was the intention of the editor, in an effort to reflect the enormous diversity of the subject. Before discussing the individual contributions in detail, here are a few general comments. First, for a subject so rich in captivating images and molecular graphics, I found the quality of the diagrams and the author's selection of figures to be extremely disappointing. Even the eight color plates were unstimulating and of no scientific value. Several of the black and white images in my copy did not reproduce well. Many of the figures were too large for the amount of information they contained. Others were almost meaningless views of packing diagrams. Only one chapter used stereodiagrams and these were helpful, but the quality of their reproduction was poor. The index was of little value and the table of contents did not include subheadings of chapters, an unfortunate oversight since two of the chapters are rather long.

The first chapter, by Dunitz, is a thought-provoking, critical examination of the field, and points out important flaws that have crept into the literature (e.g., the inappropriate use of quadrupole and dipole models to account for molecular packing in crystals; the incorrectness of spherically symmetric atomic force fields; the inaccurate use of the term "clathrate compound" as synonymous with "inclusion compound"). There are useful thoughts on polymorphism and the importance of entropy in solids, phase transitions, self-recognition and crystal symmetry, intermolecular interactions, and force-field calculations of crystal packing. The chapter is well-written and is a nice way to open the book.

The second chapter, by Desiraju and Sharma, focuses on the comparison between crystal engineering and molecular recognition. Although it is written in a rather ornate style, there are useful insights to be extracted. The premise of the chapter is that "Crystal engineering and molecular recognition are twin facets of supramolecular chemistry that depend on multiple matching of functionalities which may have varying strengths, directionalities, and distance-dependent properties." The chapter reviews basic intermolecular interactions with a focus on those that are directionally reliable. Use of the Cambridge Structural Database to deduce important patterns of intermolecular interactions is emphasized. A table is provided which contrasts molecular recognition and crystal engineering. Overall I did not find this chapter as interesting or useful as Desiraju's 1995 review article (*Angew. Chem.* **1995**, *107*, 2541; *Angew. Chem. Int. Ed. Engl.* **1995**, *34*, 2311), even though there was considerable overlap.

Chapter 3 is titled "Molecular Shape as a Design Criterion in Crystal Engineering" and it is an interesting review of work by Whitesell and coworkers on designing noncentrosymmetric crystalline phases. It begins with a nice introduction that outlines the problem and important concepts, but then shifts to specific examples. Although the ideas are interesting, it is not clear that such a specialized chapter will capture wide appeal. Nonetheless, it does provided a nice example that illustrates how concepts are developed and tested in the field of crysal engineering. Moreover, it is a good example of goal-oriented research.

The fourth chapter, by Fagan and Ward, describes the use of molecular skeletons as electrostatic templates. Using examples from the authors own work, this chapter illustrates the role that organometallic chemistry can play in creating solids with interesting electronic properties such as conductivity, ferromagnetism, and nonlinear optics. While electrostatic effects are often considered as non-directional, Fagan and Ward show how molecular architectures can be designed that break away from these limitations. As such, this chapter nicely illustrates the interplay of molecular architecture and crystal engineering.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3605-0531 $ 15.00+.25/0

The fifth and longest chapter in the book is titled "Supramolecular Inorganic Chemistry." In spite of this exciting title, I found this to be the low point of the book. It was difficult to read, and filled with verbose and lengthy discussions on terminology and semantics. I found the concepts that were introduced, such as "domains of molecules," to be of no value. The illustrations were dreadful and the organization was hard to follow. Several sections had little to do with crystalline systems. It is unfortunate that this chapter consumes one-third of the entire book.

Chapter 6 was an interesting and informative description of the (beta-alpha)8 barrel protein architecture. The author worked from the basics to build a wonderful picture of the marvels of protein self-assembly and self-organization. Even though the subject did not fit perfectly into the main theme of crystals as supramolecular entities, there are many valuable lessons to be learned from these biomolecular systems that could be applied to more traditional molecular solid state chemistry. The chapter was well written and easy to understand, even for a non-specialist in this area.

On the whole, the book is consistent with the philosophy of the "Perspectives" series concentrating on goal-oriented supramolecular chemistry. Although I would not call this a treasure-trove of crystalline supramolecular chemistry, there are a few contributions which may be worthwhile to those with an interest in the field.

Energetics of Organic Free Radicals. (Series: Search, Vol. 4). Edited by *J. A. M. Simões, A. Greenberg* and *J. F. Liebman*. Chapman and Hall, London, 1996. 301 pp., hardcover £ 39.95.—ISBN 0-7514-0378-4

I have often wished, while working with an interesting textbook or monograph, that it had been available to me some years earlier, for example in my time as a final year degree student or during postgraduate study. In that way I might have gained a deeper insight into some of the topics studied, especially if, for example, the concepts of thermochemistry and the reactive properties of free radicals had been explained so clearly as they are in this fourth volume of the *Search* series. In this book the editors have set out to provide a broadly based introduction to the structures, energetics, and reactivities of free radicals, by including multidisciplinary contributions from a number of recognized experts.

Free radical reactions occur much more commonly in the biosphere and atmosphere around us than one might at first suppose in view of the short-lived nature of these intermediates. Cheves Walling, author of the article "Free Radical Reactions", has several decades of experience in this field of research. He begins with the basic principles of free radical chemistry, and explains the meanings of the various thermochemical quantities involved. The concept of an elementary reaction is then defined, with appropriate examples, and on this basis some important reaction mechanisms are identified. This approach enables the reader to gain a sound understanding of energy barriers and the factors that contribute to them, and of the rate constants for some important processes. Since reactions involving free radicals mostly take place under neutral conditions, the thermochemistry of the educts, intermediates, and products is of great importance for predicting the behavior of processes with applications in synthesis. The various methods for determining standard enthalpies of formation, for example from kinetic measurements, from calculations based on thermodynamic cyclic processes, or even directly from mass-spectrometric data, are described here in two articles, by Wing Tsang and by John C. Traeger and Barbara M. Kompe. But how does one obtain meaningful values for heats of formation in systems for which it is difficult to set up precise experiments, such as those involving ethynyl, vinyl or chloroxyl radicals? In fact, for many such systems theoretical methods have been developed to such an extent that, after first carefully evaluating the available methods and choosing the one best suited to the problem, it is possible to calculate the required thermodynamic quantities with reasonable accuracy. In some cases this gives very good results indeed, as exemplified in the article "Theoretical Studies of the Energetics of Radicals", by Joseph S. Francisco and John A. Montomery, Jr. One method for the direct measurement of reaction enthalpies in solution is photoacoustic calorimetry, described in the article by Joshua L. Goodman, with examples of applications to photochemical reactions and to the reactions of 1,2- or 1,3-biradicals. The data thus obtained can be used to estimate the behavior of allowed or forbidden processes. By applying such considerations to free radical 1,2-rearrangements, which are common in the chemistry of carbocations, it has been shown that there is a high energy barrier to such processes if a paramagnetic intermediate is involved. However, in the article "Resonance and 1,2-Rearrangement Enthalpies in Radicals: From Alkyl Radicals to Alkylcobalamins", Arthur Greenberg and Joel F. Liebman describe how the latter reactions can be carried out remarkably easily with the help of the coenzyme B_{12}. Against this background one can well understand why the editors have included in this book on free radicals the article "A Short and Illustrated Guide to Metal-Alkyl Bonding Energetics", by J. A. Martinho Somões and M. E. Minas Da Piedade. This article and the last one, which deals with a topic that will undoubtedly remain very important in the future: "Solvent Effects of Neutral Free Radicals", by James M. Tanko and N. Kamrudin Suleman, are the two most impressive in the book.

The book is intended mainly for advanced and postgraduate students whose particular interests include organic and physical chemistry. It offers a thoroughly up-to-date treatment of the methods, with many references to the relevant literature. The introductory sections on basic concepts are seldom longer than necessary, while adequate space is devoted to describing the methods and critically evaluating the extensive (and sometimes contradictory) literature data on the thermodynamics of free radical reactions. Such an evaluation is an important aid for anyone involved in mechanistic studies or synthetic work using free radicals. The tables of thermochemical data and the descriptions of the methods used to determine them will enable the reader to quickly gain an appreciation of the factors affecting the quality of such data.

The Chemistry of Free Radical Polymerization. By *G. Moad* and *D. H. Solomon*. Pergamon/Elsevier, Oxford, 1995. 408 pp., hardcover £ 75.00. – ISBN 0-08-42078-8

Interest in free radical polymerization has increased greatly in the last few years. This is due mainly to a combination of two factors. Firstly, the conventional theories do not give a completely satisfactory description of free radical polymerization; in particular, they do not enable one to predict the dependence of the polymer-

ization rate and the polymer microstructure on the reaction conditions, the proportion of monomer converted, and the molecular mass distribution. Secondly, new techniques can now yield detailed information about the polymer microstructure and the kinetics and mechanisms of polymerization, leading to a more thorough and practically useful knowledge of the relationships between mechanism, structure, and properties. This now makes it possible to obtain homopolymers and block copolymers with a narrow range of molecular variation by the free radical polymerization route.

These recent developments were the main reason that motivated the authors to write this book. In it they review and evaluate the most recent published work, and take a fresh look at some older literature, occasionally reinterpreting it when necessary. The main purpose is to arrive at a better understanding of free radical polymerization, and to clarify the relationship between reaction conditions and the structure and properties of the resulting material, so that one can produce polymers with predictable and reproducible properties. This does not, of course, mean throwing out all our previous knowledge about free radical polymerization or standing it on its head, and therefore the structure of the book essentially follows the conventional sequence: initiation, then growth, then chain termination.

The first chapter is an introduction, in which the authors begin by explaining the reasons for the technological success of free radical polymerization. The most important relationships governing the process were discovered as early as the 1940s and 1950s, but studies of the role of defect structures in determining the properties of the polymers are more recent. This latter topic recurs constantly through all the chapters, with particular emphasis on the mechanisms that cause such defects and on techniques for studying them.

The following chapter is devoted to free radical reactions, and begins by considering how radicals react with carbon–carbon double bonds. The authors explain concisely and clearly how these reactions are affected by steric and polar factors and by the conditions under which they occur, such as the temperature and the solvent, and they discuss the theory of these effects. A separate section explains the importance of the transfer of hydrogen atoms from the substrate to the radicals, and describes the steric, polar, and stereoelectronic factors that control this transfer. The role of the competition between addition and transfer processes is described, and it is shown that this competition can be controlled by altering the nucleophilicity of the radicals. This chapter also discusses radical–radical reactions and the factors that control the competition between recombination and disproportionation. The chapter contains a comprehensive bibliography, including both recent publications and references to important earlier work.

Chapter 3 (about 100 pp.) is concerned with initiation, and includes critical appraisals of both recent and earlier studies. It is shown how the initiation stage affects not only the kinetics of the reaction but also the properties of the polymer obtained. Particular attention is given to methods for characterizing the end-groups and polymer defects caused during initiation. First the various types of possible reactions are described with examples; these include reactions with the monomer, with solvents, with oxygen, with radicals, and with impurities, and also fragmentation reactions. The types of compounds that can be used for generating free radicals are described in detail. This chapter contains much interesting information about the many facets of free radical chemistry. The chemistry involved in the initiation of a polymerization reaction is remarkably complex and absorbing, and can certainly not be reduced to a straightforward and rather uninteresting process in which a radical is formed and simply adds on to a carbon–carbon double bond. The authors thoroughly and conscientiously summarize the various methods that have been or can be used for analyzing the products and thereby investigating the different reaction pathways. The text is backed up by 480 literature references. This excellent chapter is a mine of information for polymer chemists and organic chemists. However, in a future edition of the book, which I hope will appear in due course, the authors should devote more space to the numerous studies on asymmetrical azo compounds that have been reported by our group and by that of Rüchardt.

Chapter 4, dealing with growth reactions, is much more interesting than even the specialist in the field might at first expect to find. The many different reactions that the growing radicals can undergo are described very competently. The question of tacticity is discussed concisely but in an understandable way; the authors explain why this is not such an important problem in the case of free radical polymerization. Considerable space is devoted to the analysis of defect structures, such as head-to-head linkages. The general principles are reinforced by practical examples and by well-planned tables and diagrams. The section on the polymerization of cyclic monomers with vinyl substituents is especially well worth reading. Some space is also devoted to the polymerization of double-ring compounds such as spiro-orthocarbonates. However, the comment on page 182 concerning the volume expansion of monomers of this type during polymerization is not supported by the latest knowledge.

Chapter 5 is concerned with chain termination. One's first reaction on finding 70 pages devoted to a reaction that textbooks often dismiss in only a few lines is that the authors have overdone this. However, that impression changes as one reads this very important chapter. Every kind of event that can end the growth of an active chain is covered here, for example a reaction between two polymeric radicals, termination of the chain by addition of a primary radical, chain transfer reactions, and inhibition processes. After discussing these in a general way, the authors describe in detail how they relate to several actual polymers. It is especially pleasing that the discussions are reinforced by descriptions of experiments. To enable the reader to study growth reactions in more depth, nearly 300 relevant literature references are given at the end of this chapter.

Chapter 6, on copolymerization, is much shorter than the previous ones, but is nevertheless a lucid treatment, covering all the most important aspects of the terminal model, the penultimate unit model, and the monomer complexes model. It is pleasing to find that methods for preparing block copolymers and graft copolymers are also included, although the treatment of these is too brief.

Chapter 7, on controlled polymerizations, is excellent. The authors describe methods for the control of microstructure, functionality, stereochemistry, molecular size, and molecular mass distribution. The most recent published work is reviewed and expertly evaluated. They even include several recent publications on the possibility of "living free radical polymerization".

I can unhesitatingly recommend this highly informative and comprehensive account of the present state of knowledge on free radical polymerization. Scientists in universities and industry will find it extremely useful. It should also be of considerable help to advanced degree and postgraduate students who include polymer chemistry in their interests. I value the book as an important addition to my personal library.

Polypropylene Handbook. Polymerization, Characterization, Properties, Processing, Applications. Edited by *E. P. Moore, Jr.* Hanser-Gardner, Cincinnati, 1996. 419 pp., hardcover $ 136.00. – ISBN 1-56990-208-9

Polypropylene (PP) is one of the most widely used polymers, ranking alongside polyethylene, polystyrene, and polyvinylchloride. World production of the polymer is currently about 19 million tonnes, having increased twelve-fold since 1970, and the annual growth rate is forecast to continue at 6–8% in the near future. PP is already used in several thousand different applications in everyday life and in technology, and new ones are still being added. Work on further improving production methods is also going on apace; an example of this is the development of metallocene catalysts, a topic which has also reawakened interest in polyolefines-related research in universities. However, most of the innovative work in a field such as PP is, as one would expect, carried out in industrial research laboratories. It was therefore appropriate that the publishing house Hanser should choose a team of authors from industry to write this monograph. Of the 20 authors, 18 are from Montell Polyolefins, the world's largest producer of PP and also the main licensor for PP production technology.

The range of topics covered here is broader than in previous monographs on PP and other polyolefins. Scientific, technological, and economic aspects are all treated, with a broad division of the subject into two parts.

Part 1 has the overall title "Polypropylene: The Material". A brief historical introduction is followed by chapters on catalysts and polymerization mechanisms, the structure and morphology of PP, additives, compounded PP products, and physical properties. Two of the contributions are particularly worth mentioning. In the chapter on catalysts E. Albizzati and colleagues give a very precise and comprehensive account of the six successive generations of catalysts that have been developed for propylene polymerization, including their mechanisms. Results from industrial research especially are well described and astutely analyzed. The 527 references include 140 patents. The chapter on the structure and morphology of PP, by R. A. Phillips and M. D. Wolkowicz, is concise, rigorous, and easily understandable; it is certainly the best treatment of the subject that has been written up to now. The illustrations too are excellent; they include a series of photographs showing with remarkable clarity the microstructure of various elastomer-modified PP blends. A noticeable characteristic of both these chapters, as also of the others in Part 1, is that the authors have been concerned throughout to explain the observed facts or to discuss them in a wider context, whereas earlier treatments have often been content to merely present them without further comment.

Part 2, entitled "Polypropylene: The Business", begins with a wide-ranging introductory chapter surveying all the commercial aspects of PP (trends in production figures and available capacity, processes used, the producers themselves, sources of monomer, economics of production, range of products, patent rights, environmental aspects, and recycling). The comprehensive information in the form of numerical data and tables gives some interesting insights. Thus, in 1994 there were 117 PP producers worldwide, including 43 in Asia excluding Japan; by 1998 this region will have 27% of the world's production capacity, having overtaken both North America (23%) and Western Europe (24%). The rest of the chapters in Part 2 cover specific aspects in detail: production processes, downstream processing methods, applications (end-products), and government regulations and legislation affecting certain types of PP products, such as specifications for food industry applications. The chapter by E. P. Moore on downstream processing methods for PP is especially comprehensive and clearly written. The contribution by C. G. Oertel on applications contains much fairly mundane information but also some amusing items: for example, we discover that there are now even banknotes made of PP (in Australia), and learn why carpeting in airports is made of PP rather than nylon (PP is not attacked by battery acid that may leak from electric trolleys). However, some of the photographs in this chapter are very poorly reproduced, a fault of production which the publishers will need to rectify as soon as possible.

On comparing all the chapters it is seen that there is a certain amount of overlapping. For example, the different generations of catalysts and their relative importance in technological and product development are discussed in detail three times, in Chapters 2, 7, and 8. There is also some duplication in the descriptions of the many different variants and types of polypropylene and their structures and properties. This is undoubtedly one of the disadvantages of having so many authors, but other comparable monographs fare no better in this respect. The book is indispensable for everyone who seeks an up-to-date survey of any aspect of polypropylene. It contains a wealth of detailed information and expert in-depth analysis, and a comprehensive bibliography for further reading.

Walter Spaleck
Hoechst AG
Frankfurt am Main (Germany)

The Chemistry of Paper. (Series: RSC Paperbacks.) By *J. C. Roberts*. Royal Society of Chemistry, London, 1996. 190 pp., paperback £ 15.95.—ISBN 0-85404-518-X

This book by J. C. Roberts is intended for students and others who wish to learn more about paper manufacture. Its affordable price has been made possible by avoiding color printing. That is unfortunate in one sense, as the more complicated explanations could have been presented much more impressively if color had been used. In fact the chemistry of colloids, wood constituents, process chemicals, and dispersions, with which the book is concerned, is actually quite complex. The treatment is divided into ten chapters, which lead the reader carefully through the various aspects. It can be said at the outset that the author presents the whole subject in a well-integrated way, although some topics are treated too briefly.

In Chapter 1, "An Introduction to Paper", the author begins by summarizing, on the first page, the present state of the art in high-speed paper handling machinery. However, the rate of 60 $km\,h^{-1}$ given here as the upper limit is not up-to-date, since there are now some newsprint paper machines that achieve 90 $km\,h^{-1}$ (or 1500 $m\,min^{-1}$, in the units normally used in the paper industry). Among the figures that illustrate the text, the micrographs of fibers and paper structure are especially effective (e.g., on pages 2, 7, 13, 14, 66, 72, 81, 85, 86, 119, and 142). Figure 5.2 is particularly good. However, a few of the others are not as clear and informative as one would have liked, for example on page 36 (structural assignment not given), page 42 (the carbanion structure shown is confusing), page 55 (the dihedral angle is not defined), page 56 (badly printed), page 116 (Fig. 7.6) and page 133 (no scale divisions on the axis), and page 146 (the structure of amylopectin is much more complex, and an oxygen atom at the 4-position is missing).

After these ten pages of introduction the reader has still not yet seen any part of a paper machine, nor been given much information about them. It is not until

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3605-0534 $ 15.00+.25/0

page 87 that we find the first diagram of an important component, namely a part of the fourdrinier, then the next one is on page 112. By including a photograph of a modern paper machine at the beginning of the book, the author could have conveyed to every reader something of the fascination of such a marvel of technology.

In Chapter 2, "The Material of Paper", the reader learns about the morphology of paper, and about fibers and how they are formed in different types of plants. The discussion of softwood fibers on page 16 fails to explain the nature of the lumen and the distribution of the lignin in the cell walls. A few sentences about lignin appear later in the chapter (p. 24), but then it is treated in detail in the following chapter. The explanation of the structure of the fibers, from the plant cells to the glucose molecules (p. 19), is excellent. Here, as also elsewhere in the book, a topic is started and then interrupted, to be taken up again in the next or the next but one chapter. A complete and uninterrupted treatment of the topic would, in my opinion, be easier to understand than a fragmented one appearing at several different places in the book, even though the author takes considerable care to include appropriate cross-references.

Chapter 3, as already mentioned, treats the chemistry of lignin in great detail. Occasionally, however, the discussion strays from the area defined by the book's title.

On page 50, where the bleaching of chromophores in wood-pulp is under discussion, the work of Prof. Krause (Darmstadt) was not mentioned.

Networks formed from cellulose fibers are then described. Structural data for native cellulose are given, although its structure is not yet completely understood. The penetration of liquids into paper (pp. 66ff.) would have formed a good introduction to the subject of sizing, but unfortunately the latter is treated at two different places in the book (pp. 124ff. and 142ff.). In the treatment of sizing there is no mention of polymeric sizing agents (dispersions and solutions). It is well known that polymer dispersions are used both in the wet end and in the size press. Then we come to the central topic, the actual paper manufacturing process. On page 69 the author promises that the chemical aspects will be thoroughly covered, but it soon turns out that the emphasis is on the physical chemistry and physics. Next the author moves on to the colloid chemistry of fiber surfaces. The explanation of freeness on page 97 is too brief, and a more detailed treatment would be preferable.

On page 98 the author mentions that polyelectrolyte titration can also be used for determining the fiber charge. That is not such a straightforward matter as suggested here, because the stoichiometry is not necessarily 1:1. From page 100 onward the chemicals used in the paper manufacturing process are described in detail. Unfortunately, however, there are frequent errors in the structural formulas, for example on pages 100 and 104 ("complete protonation nitrogen atoms"), page 114 (cationic polyacrylamides: two errors in the same formula), page 123 (an entirely novel formula!), and at the bottom of page 136. There is no mention at all of brighteners and dyes, which are used in large quantities in paper manufacture.

Figures 6.10 and 6.11 are not from the publication by E. J. Goethals (Pergamon Press, Oxford, 1980) to which they are attributed here; instead both these and Figure 6.15 are from D. Horn and J. Melzer, *Trans. 6th Fundamental Research Symp.*, BPBIF, Oxford (**1978**). The explanation of the mechanisms of retention (pp. 113ff.) is not very successful, either in the text or in the figure. Figure 7.6 is difficult to understand, while Figure 7.7 is oversimplified, and gives no indication of the actual relationship between the diameters (in μm for fibers but in nm for polymer chains!).

Starches are discussed briefly as early as page 119, but their structure is not discussed in detail until page 144.

In the discussion of coating machines the author should have also mentioned film presses, which can now achieve rates up to 1700 m min^{-1}. The whole subject of paper coating is treated too briefly. Styrene–acrylate binders are not mentioned at all. Recycling of fiber feedstocks is treated briefly, which is appropriate in view of the importance of recycled paper as a feedstock. The last chapter contains a good and detailed discussion of the environmental aspects of paper manufacture, a very important topic. For the first time we have a detailed description of test methods (measurements of TOD, COD, and BOD). It is stated on page 171 that "dioxins" are extremely toxic, but six lines later we read that the toxicity varies according to the structure, and that out of 210 isomers only 15 are toxic. In Figure 10.4 the correct name is polychloro*dibenzo*dioxin, not "dibenzyl". Then, in Table 10.6 (p. 173), it is not stated which aquatic organisms were used to test the toxicity of LC50.

In the bibliography it would have been useful to classify the references. However, the index is very good. I can recommend the book, subject to some reservations.

$[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]^+$ and analogons unsaturated chiral complexes (see element symbols along the fingertips) can form two diastereomeric adducts with prochiral alkenes, aldehydes, and ketones. The ratio of these diastereomers is a measure of the chiral recognition, symbolized by the hands, of the reaction partners. The rhenium complex mentioned is depicted above the hands (Re: light gray, P: yellow, N: light blue, O: dark blue, Ph, Cp: dark gray). The selectivity of alkene complexation can be analyzed (and predicted) by considering the sizes of the substituents a–d on the alkene and correlating them with the steric conditions in the chiral complexes, which can be represented with three-dimensional bar graphs.

Chiral Recognition in π Complexes of Alkenes, Aldehydes, and Ketones with Transition Metal Lewis Acids; Development of a General Model for Enantioface Binding Selectivities

J. A. Gladysz* and Brian J. Boone

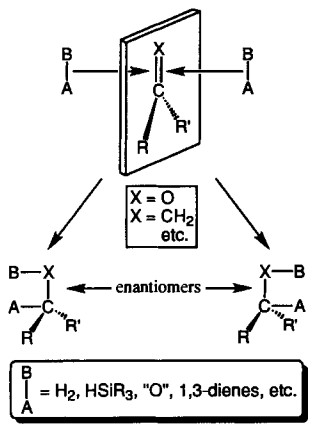
Prochiral alkenes, aldehydes, and ketones constitute the most frequently used starting materials for enantioselective organic syntheses. Protocols often involve chiral binding agents or Lewis acids that can give two diastereomeric adducts, the ratios of which are measures of chiral recognition. With π adducts, the diastereomers differ in the enantioface of the C=C or O=C group bound to the Lewis acid. This review provides the first comprehensive analysis of such equilibria and related binding phenomena with chiral transition metal Lewis acids. An extensive body of data from the authors' laboratory for complexes of the pyramidal rhenium fragment $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]^+$ (**I**) affords particular insight. Literature data for other complexes are also summarized. A general model for chiral recognition based upon the relative steric properties of four quadrants is presented. This enables binding selectivities to be individually and rationally optimized for different classes of ligands. Electronic effects are also identified and correlated with specific structural properties. Relationships between binding equilibria, reactivity, and product configurations are discussed.

Keywords: alkene complexes · carbonyl complexes · chiral recognition · stereoselective syntheses · transition metal Lewis acids

1. Introduction

Methodologies for enantioselective syntheses of chiral organic compounds from achiral precursors are developing hypertrophically.[1] Among the many classes of prochiral starting materials, alkenes, aldehydes, and ketones are the most common. As illustrated in Scheme 1, these undergo a variety of 1,2-addition reactions that give chiral, but normally racemic, products. Enantioselective versions of many such additions have been crafted and continue to be actively sought. Despite the considerable mechanistic diversity of these reactions, some common attributes are apparent. For example, many protocols feature a chiral binding agent or Lewis acid[2] that can give two diastereomeric adducts. These adducts in turn evolve to products via two (or more) diastereomeric series of transition states. Often, the Lewis acid activates the substrate towards attack of an external agent, which fixes a product stereocenter. The dominant configuration or degree of "enantioselection" is determined by rate differences. Either the familiar Curtin–Hammett or Winstein–Holness limits may apply.[3] In the latter case, there can be a direct link between binding selectivity and product selectivity.

Regardless of the exact origin of enantioselection, "chiral recognition" is in some context required. For the purposes of this review, chiral recognition will be defined as the selective formation of one of two possible diastereomeric adducts from two chiral or prochiral species.[4] Of course, there is an important distinction between kinetic and thermodynamic selectivities. The latter will be implied unless stated otherwise. Also, competing transition states are often easily analyzed from the standpoint of chiral recognition.



Scheme 1. Enantioselective syntheses from achiral alkenes, aldehydes, and ketones.

This review provides a detailed and comprehensive analysis of chiral recognition in η^2 π complexes of prochiral alkenes, aldehydes, and ketones with chiral transition metal Lewis acids. Surprisingly, this subject has only received fragmentary treatment in the literature previously. It should be emphasized in passing that such phenomena can also play key roles in reactions that do not give chiral or nonracemic products. For example, in the polymerization of propene by chiral metallocene catalysts, the tacticity of the polypropylene depends upon the

enantioface of the propene C=C bond that inserts into the metal–carbon bond of the growing polymer.[5]

This review begins with a discussion of the general properties of transition metal Lewis acids and alkene, aldehyde, and ketone π complexes. Adducts of the chiral rhenium Lewis acid $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]^+$ (**I**) are then analyzed in detail. This extensive body of data has been acquired in the authors' laboratory over the last decade and affords numerous new insights. Next, a general model for chiral recognition in π complexes is presented. This is based upon the relative steric properties of four quadrants and enables binding selectivities to be individually and rationally optimized for different classes of ligands. In the fourth part of this review, literature data for π complexes of other chiral transition metal Lewis acids are summarized. Finally, relationships between binding equilibria, reactivity, and product configurations are discussed.

2. Transition Metal Lewis Acids

Transition metal Lewis acids are ubiquitous and can be subdivided into various classes. Sixteen-valence-electron complexes are probably the most common. Some are isolable, whereas others are easily generated by the dissociation of weakly bound ligands from coordinatively saturated, eighteen-valence-electron precursors. There are obvious parallels to six-valence-electron species such as trivalent boron Lewis acids and carbocations. However, unlike boron Lewis acids, transition metal Lewis acids with other valence electron counts can also be generated or isolated.

A transition metal Lewis acid need not exist as a discrete entity. For example, a metal fragment might move from Lewis base to Lewis base strictly through associative mechanisms. Nonetheless, organic substrates may be activated, and relative binding strengths can be quantified, as with Lewis acids that can exist in unassociated forms.

Chiral transition metal Lewis acids can be divided into two classes: 1) those in which the Lewis base binding sites are stereocenters,[6] often described as "chiral-at-metal", and 2) those that have ligand-based stereocenters such as in chiral phosphane ligands. The former have no counterparts among common main-group-element Lewis acids. For example, BF_3 and $AlCl_3$ have trigonal-planar binding sites and can be rendered chiral only with chiral substituents.

One distinguishing feature of transition metal Lewis acids deserves emphasis. Namely, except in the case of d^0 species such as Ti^{IV} or Ta^V, occupied d orbitals are present. These are normally the highest energy orbitals and capable of backbonding to acceptor orbitals on Lewis bases. Thus, most transition metal Lewis acids are more accurately viewed as amphoteres. As a consequence, the relative binding affinities of various Lewis bases can differ markedly from those of archetype Lewis acids such as H^+, Li^+, and BF_3.[7] In these cases, donor orbitals are either absent or are very low in energy.

It should also be noted that backbonding can be an important determinant of ligand conformation. Such interactions are almost always of π symmetry, resulting in a purely electronic component to the barrier for rotation about the metal–ligand axis. A familiar illustration is the Dewar–Chatt–Duncanson model for bonding in alkene complexes. Further, in an asymmetric environment, all d orbital degeneracies are removed. Thus, for the types of π complexes in this review, it will generally be assumed that only one electronic conformational energy minimum need be considered (derived from the d orbital HOMO). Backbonding has other types of structural consequences, several of which are examined in this article.

Finally, the unique electronic properties of transition metal Lewis acids also allow the binding and/or activation of many small molecules such as H_2 and CO. Thus, transformations that would not be possible with main-group-element Lewis acids can be effected (hydrogenation, hydroformylation, etc.).

B. J. Boone

John A. Gladysz is a native of the Kalamazoo area in Michigan (USA). He obtained a B. S. degree from the University of Michigan (1971) and a Ph.D. degree from Stanford University (1974) for research conducted with E. E. van Tamelen. He subsequently moved to the University of California, Los Angeles as an Assistant Professor. In 1982 he accepted an appointment at the University of Utah, where he is now Professor of Chemistry. He is a fellow of the Alfred P. Sloan Foundation (1980–1984) and a Camille and Henry Dreyfus Teacher-Scholar (1980–1985). He received an Arthur C. Cope Scholar Award in 1988, the University of Utah Distinguished Research Award in 1992, the ACS Award in Organometallic Chemistry in 1994, and a Research Award for Senior Scientists from the Alexander von Humboldt Foundation in 1995. Since 1984 he has been Associate Editor of Chemical Reviews. He has authored over 225 publications and his research spans a wide range of topics in the general area of synthetic and mechanistic organometallic chemistry.

Brian J. Boone was born in 1968 in Botwood, Newfoundland (Canada). He obtained a B. Sc. (Honors) degree from the Memorial University of Newfoundland (1990) and twice received the National Science and Engineering Research Council Award for Undergraduate Studies. He is currently a graduate student at the University of Utah, where he was awarded a Henry Eyring Research Fellowship.

3. Classes of Alkene, Aldehyde, and Ketone π Complexes

3.1. Alkene Complexes

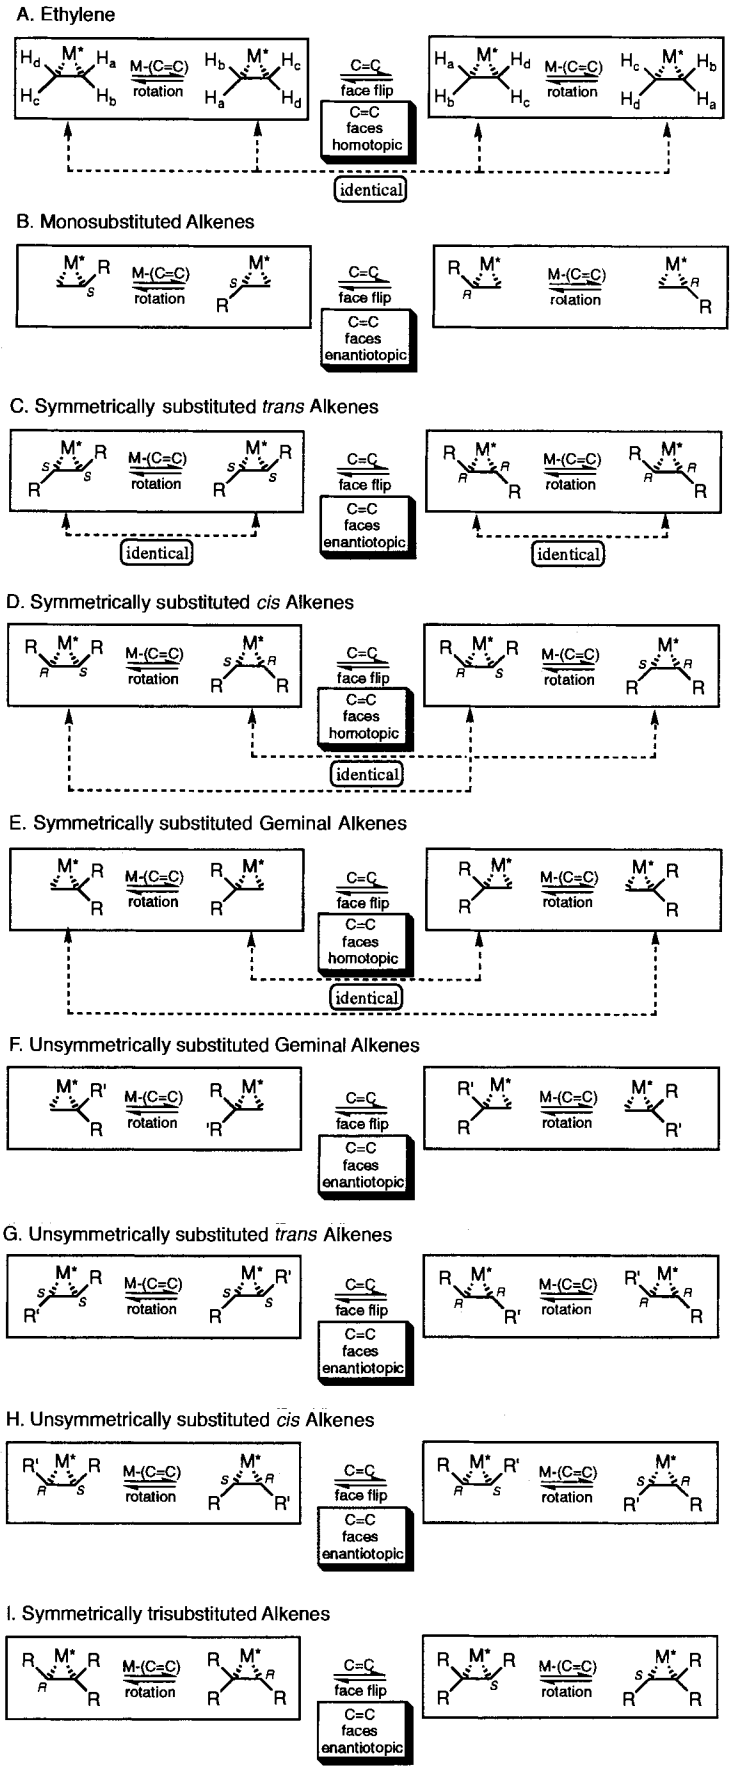
Consider a chiral transition metal Lewis acid of fixed absolute configuration, and simple achiral alkenes with all possible substitution patterns; Scheme 2 depicts the principal binding modes. As analyzed in this section, these include both configurational and conformational diastereomers. To help convey structural and conceptual similarities to three-membered-ring organic compounds, metallacyclopropane resonance forms are utilized. Many instructive relationships are apparent, and therefore each class of alkene ligand is individually discussed.

A) Ethylene: ethylene is not prochiral.[8] The π faces of the C=C bond are homotopic or identical, and the C=C termini bear identical substituents. Consequently, adducts with chiral transition metal Lewis acids can only exist as a single isomer. Nonetheless, the four vinylic protons and two carbon atoms of the double bond become inequivalent. Thus, four =CH ^{1}H NMR signals and two $=CH_2$ ^{13}C NMR signals will be observed in the slow-exchange limit. This renders ethylene a useful probe ligand for the determination of dynamic properties, as will be described later.

B) Monosubstituted alkenes: such alkenes are prochiral. The C=C faces are enantiotopic,[8] and the C=C termini bear different substituents. Thus, four isomeric complexes are possible. First, two *configurational diastereomers* can exist, which differ in the C=C enantioface bound to the metal and can interconvert by a "face flip".[9] The =CHR carbons are stereocenters, and their configurations can be designated by the *R*/*S* conventions analogous to those used for three-membered-ring organic compounds.[10, 11] Second, for each configurational diastereomer, two *conformational diastereomers* or M–(C=C) rotamers can exist. These differ by a 180° rotation in the C=C π nodal plane and can be distinguished with terms such as *sc*/*ac* or *sp*/*ap*.[12]

C) Symmetrically substituted *trans* alkenes: such alkenes are prochiral. The C=C faces are enantiotopic and thus, as with monosubstituted alkenes, two configurational diastereomers are possible. However, the C=C termini bear identical substituents, which are exchanged by a 180° rotation about the M–(C=C) axis. Hence, each diastereomer has only one M–(C=C) rotamer. Importantly, in these complexes the *trans* alkene ligands have two =CHR stereocenters. The configurations are fixed relative to each other, as a single inversion would give a *cis* alkene ligand. A reciprocal situation exists with *cis* alkene ligands.

D) Symmetrically substituted *cis* alkenes: such alkenes are not prochiral. The C=C faces are homotopic or identical, and the C=C termini bear identical substituents. Nonetheless, two isomeric complexes are possible. These can be viewed as configurational diastereomers that can interconvert by a C=C face flip, or conformational diastereomers that can interconvert by a 180° rotation about the M–(C=C) axis. Regardless, such isomers can lead to enantiomeric organic products. For example, consider the 1,2-addition of an achiral species A–B from the side opposite to the metal, and in a regiospecific fashion (that is A always adds to *C*=C and B to C=*C*). One isomer will give one



Scheme 2. Classification of complexes formed from chiral transition metal Lewis acids and achiral alkenes [8].

product enantiomer, and the other the opposite enantiomer. Nonracemic mixtures would be expected.[13]

E) Symmetrically substituted geminal alkenes: such alkenes are not prochiral. Although the C=C faces are homotopic or identical, the C=C termini bear different substituents. Hence, two M–(C=C) rotamers are possible. However, in this case (as well as for ethylene), 1,2-addition of an achiral species cannot give a chiral organic product.

F) Unsymmetrically substituted geminal alkenes: such alkenes are prochiral. The C=C faces are enantiotopic, and the C=C termini bear different substituents. Thus, both configurational diastereomers and M–(C=C) rotamers are possible, in analogy to monosubstituted alkenes.

G) Unsymmetrically substituted *trans* alkenes: such alkenes are prochiral and give isomers that are analogous to those analyzed in F) but having two =CHR stereocenters.

H) Unsymmetrically substituted *cis* alkenes: such alkenes are prochiral and give isomers analogous to those analyzed in G).

I) Trisubstituted alkenes: all trisubstituted alkenes are prochiral, regardless of substitution pattern. When the three substituents are identical, the isomers are analogous to those analyzed in B). Otherwise (except when the geminal substituents are identical), there will be two =C stereocenters, as in G) and H).

J) Tetrasubstituted alkenes: the preceding examples can be extended to tetrasubstituted alkenes in which all four substituents are identical (see A)), three substituents are identical (see B)), both pairs of *trans*, *cis*, or geminal substituents are identical (see C), D), and E)), and one pair of geminal, *trans*, or *cis* substituents is identical (see F), G), and H)). Tetrasubstituted alkenes with four different substituents would be analogous to trisubstituted alkenes with three different substituents.

3.2. Aldehyde and Ketone Complexes

The preceding analysis is easily applied to π complexes of achiral aldehydes and ketones. Formaldehyde and symmetrically substituted ketones will give isomeric complexes analogous to those of symmetrically substituted geminal alkenes (E). Other aldehydes will give isomeric complexes analogous to those of monosubstituted alkenes (B), and other ketones will give isomeric complexes analogous to those of unsymmetrically substituted geminal alkenes (F).

3.3. Related Classes of Complexes

Two extensions of Scheme 2 deserve emphasis:

1) Consider adducts of *achiral* transition metal Lewis acids and prochiral alkenes (B), C), F)–I)), aldehydes, and ketones. Carbon stereocenters will be generated, resulting in *chiral* complexes. The enantiomers will normally form in equal amounts. If the achiral transition metal Lewis acid is also prochiral, then metal stereocenters will be concurrently generated. The metal/carbon configurational diastereomers will normally form in unequal amounts.

2) Most chiral alkenes have *diastereotopic*[8] C=C faces (exceptions would include chiral alkenes with C_2 symmetry). Consider as an example a monosubstituted alkene with one allylic stereocenter. In any type of π complex, a second carbon stereocenter will be generated. Thus, *achiral* (nonprochiral) transition metal Lewis acids will give either two or four configurational isomers, depending upon whether the alkene is enantiomerically pure or racemic (two diastereomers, or two diastereomers and their enantiomers). Similarly, *chiral* transition metal Lewis acids will give up to eight configurational isomers. In both cases, the diastereomers will normally form in unequal amounts.

Chiral alkenes will be treated only in passing in this review. However, the development of chiral transition metal Lewis acids that will selectively bind or promote the reaction of one enantiomer of a racemic chiral alkene is of obvious importance. The bonding models developed here provide a basis for rational approaches.

4. Alkene Complexes; General Bonding Considerations

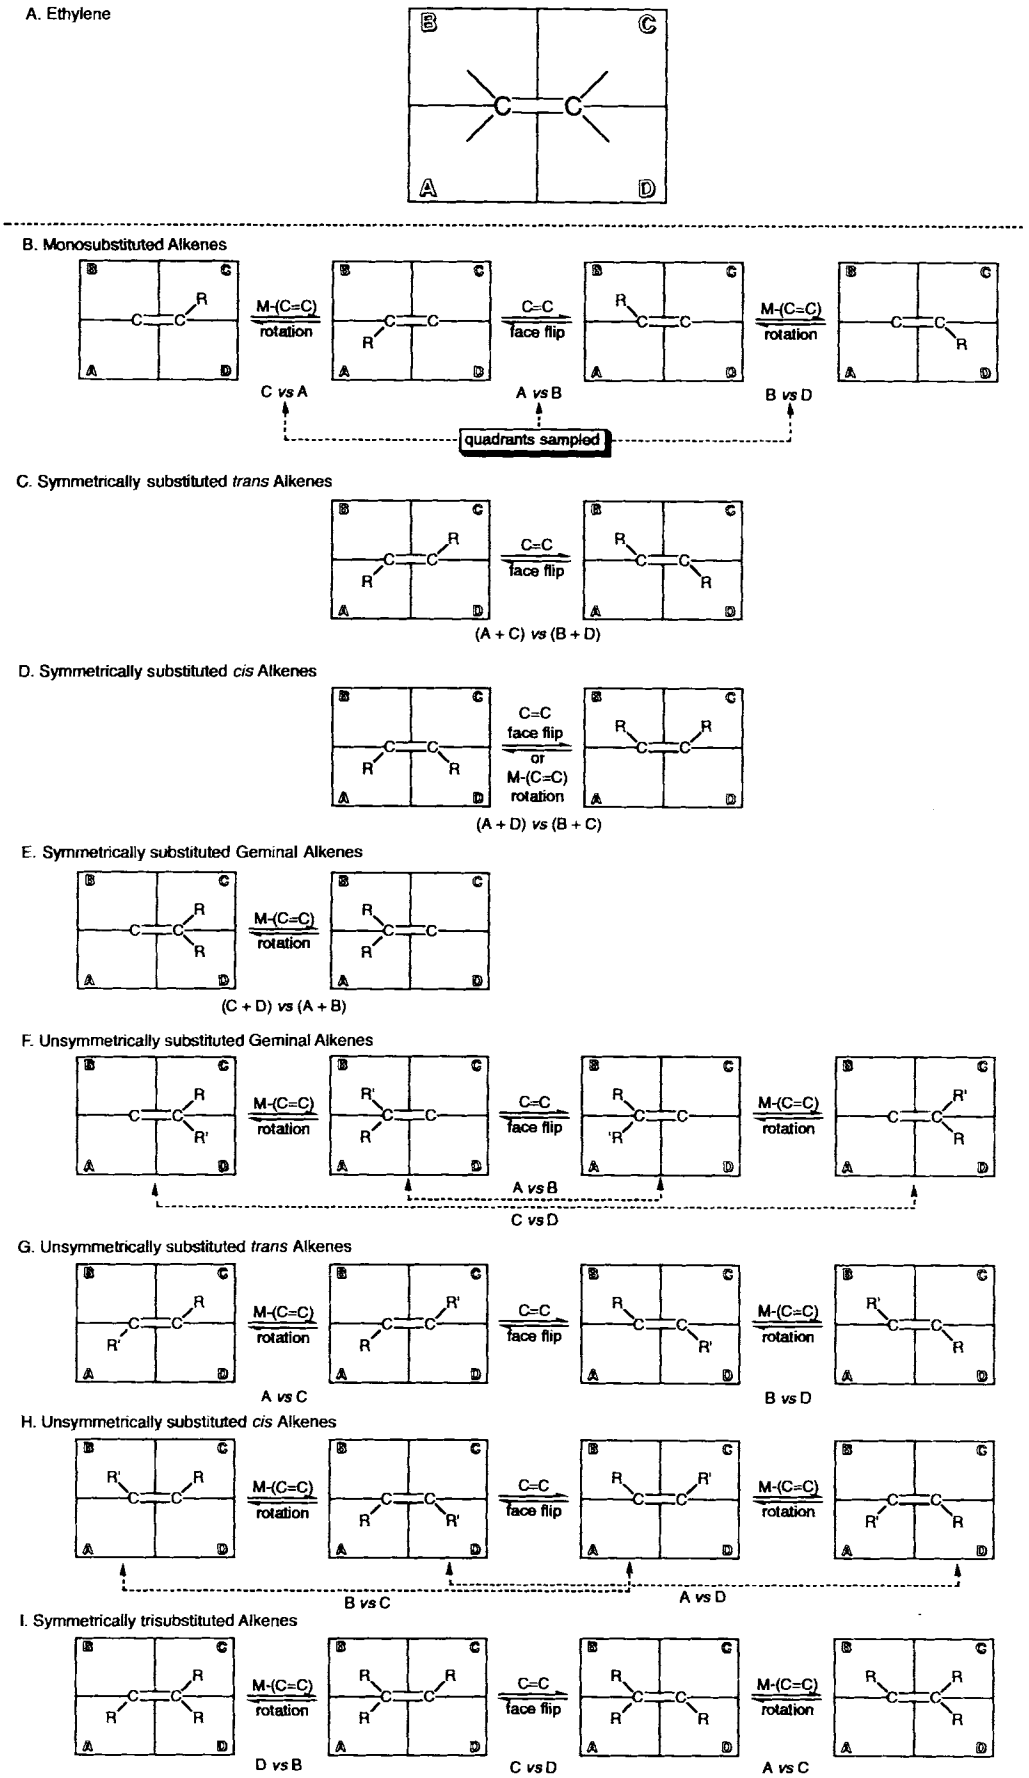
Many books and reviews have been devoted to transition metal alkene complexes.[14] Their structural and electronic properties have been analyzed in detail. These include several subtle features, and aspects of this extensive earlier literature will be introduced as needed.

Chiral receptors for alkenes have sometimes been analyzed in terms of the steric properties of "quadrants" corresponding to each vinylic position.[15, 16] A quadrant lettering system (A–D) that will be used throughout this review is given at the top of Scheme 3. Such diagrams and extensions introduced in Sections 22–24 allow control elements in chiral recognition to be easily conceptualized.

Considerable effort has gone into the quantification of steric properties of organometallic fragments and ligands.[17] Steric properties of organic groups are often probed by measurements of various types of diastereomeric equilibria. One familiar example would be the "A values" associated with axial substituents in cyclohexanes.[18] However, with alkene complexes of chiral metal fragments, it was apparently not recognized that measurements of binding equilibria can provide a semiquantitative map of the relative steric environments of the quadrants.

For example, consider the configurational diastereomers of the complex of a symmetrically substituted *trans* alkene (C in Scheme 3). The equilibrium constant will reflect the relative steric environments of quadrants (A + C) and (B + D). Similarly, the equilibrium constant for the M–(C=C) rotamers of the complex of an unsymmetrically substituted *trans* alkene (G in Scheme 3) will reflect the relative steric environments of quadrants A and C (for one configurational diastereomer), and of B and D (for the other configurational diastereomer).

In principle, such equilibria might be established by keeping the configurations of the alkene carbons constant and inverting the chiral transition metal Lewis acid. This pathway would give the enantiomers of the products depicted in many of the schemes in this review. However, conclusions regarding the relative steric environments of the quadrants would not be affected. Such mechanisms are highly improbable for most Lewis acids with ligand-based chirality. For example, any carbon stereocenters in chiral phosphane ligands would have to undergo inversion. Re-



Scheme 3. Relationships between alkene binding equilibria and the relative steric environments of the quadrants of the Lewis acid receptors.

gardless, if nonracemic adducts are available, the epimerizing stereocenter is usually easy to identify. Accordingly, the chiral-at-metal complexes studied in the authors' laboratory and described in subsequent sections of this review have been shown to equilibrate with retention of configuration at the metal and inversion at carbon.

Any analysis of the relative steric environments of quadrants carries several potential sources of nonideality. Most importantly, chiral receptors are not necessarily structurally invariant. Some have many degrees of freedom and might offer a different rictus to different types of alkenes. Alternatively, consider a chiral metal fragment with two orthogonal d orbitals that are close in energy, both of which can backbond with an alkene C=C π* acceptor orbital. Some alkene ligands may, for steric or other reasons, adopt M–(C=C) conformations orthogonal to others.

Also, alkene ligands have a surprisingly large number of degrees of freedom. First, the C=C linkage can be "rocked" around either of the two axes separating the four quadrants in Scheme 3, as well as the axis perpendicular to the plane of the paper. These correspond to the roll, pitch, and yaw axes in aircraft navigation—an appropriate metaphor in view of the similarities between a docking maneuver and Lewis acid/base complexation.

Alkene ligands can furthermore undergo "slippage",[19] the primary manifestation of which is

the lengthening of one metal–carbon bond relative to the other. These bond elongations are particularly favored by strongly carbocation-stabilizing substituents on the C=C unit, such as nitrogen or oxygen donors. A slippage parameter can be defined that has two intuitively logical limiting values: 1) 0% when the perpendicular from the metal to the C=C bond intersects the bond at the bond midpoint, as in an equilateral triangle, and 2) 100% when the perpendicular from the metal to the C=C bond intersects the bond at a carbon atom.[20]

As expected from the Dewar–Chatt–Duncanson model and backbonding, the ligating carbons in alkene complexes rehybridize, adopting considerable sp^3 character. Thus, substituents move out of the π nodal plane of the free ligand and away from the metal fragment. This attenuates steric interactions between substituents and the metal fragment. There are several ways to quantify this feature.[21] In this review "bend-back angles" will be employed. These are computed by first defining a plane that contains the C=C linkage but is perpendicular to the metallacyclopropane plane. The angle of the carbon–substituent bond with this plane is then the bend-back angle. Bend-back angles involving hydrogen atom positions determined by X-ray crystallography are not usually reliable.

5. The Chiral Rhenium Lewis Acid I

The chiral, pyramidal,[22] d^6 sixteen-valence-electron rhenium fragment $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]^+$ (**I**) has, in various synthetic and mechanistic contexts, captivated the attention of the senior author for almost two decades.[23] Mass spectra show that it can exist as a discrete species, but as described in Section 6 it is probably rarely generated in solution.[24] Yet it can pass from one organic molecule or Lewis base to another, or between functional groups in a single molecule, always with retention of configuration at rhenium.[22] Some structural features of **I** and its adducts **II** and **III** with generic Lewis bases are given in Figure 1.

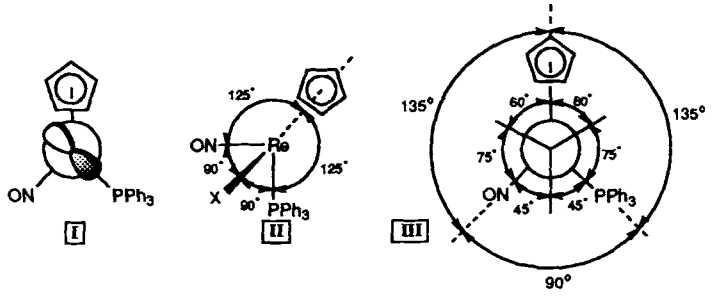


Figure 1. Key steric and electronic features of the chiral rhenium Lewis acid $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]^+$ (**I**) and its Lewis base adducts **II** and **III**.

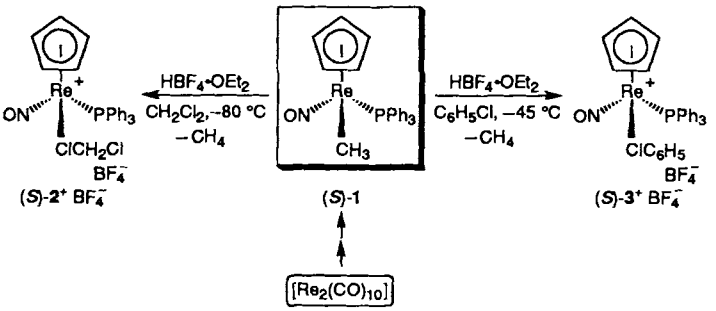
Several steric properties of **I** deserve emphasis. First, the PPh_3, cyclopentadienyl, and nitrosyl spectator ligands differ greatly in size (large, medium, and small, respectively). Second, the coordination geometry at rhenium is formally octahedral; the cyclopentadienyl ligand occupies three coordination sites. Thus, the idealized ON-Re-P bond angle is 90°, and angles from the cyclopentadienyl centroid to the other three ligands are 125°. Third, from the perspective of a Lewis base, the angularly compressed interstice between the NO and PPh_3 ligands is the most congested; that between the two smallest ligands, NO and C_5H_5, is the least congested;[25] that between the two largest ligands, PPh_3 and C_5H_5, is actually intermediate. These conclusions follow from numerous studies of conformational and diastereomeric equilibria.[26, 27]

The electronic properties of **I** and/or its Lewis base adducts have been studied both theoretically[22, 28] and experimentally.[29] These data establish that **I** is a strong π donor, with the d orbital HOMO shown in Figure 1. When unsaturated ligands bind to **I**, they commonly adopt conformations that allow high degrees of overlap of their acceptor orbitals with this d orbital, even when this is sterically unfavorable.[30] The high HOMO energy is derived from the poor π-accepting capabilities of the PPh_3 ligand.[28a] The two orthogonal d orbitals that can overlap with the nitrosyl ligand acceptor orbitals are much lower in energy.

6. Functional Equivalents of the Rhenium Lewis Acid I

Adducts of **I** and an extremely broad spectrum of organic Lewis bases have been isolated. Preparations begin with commercial $[Re_2(CO)_{10}]$, which is converted to the chiral methyl complex $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(CH_3)]$ (*rac*-**1**) in four steps and 57% overall yield.[31] Resolution is easily effected en route in two steps and 76% yield.[31a] As shown in Scheme 4, **1** is then



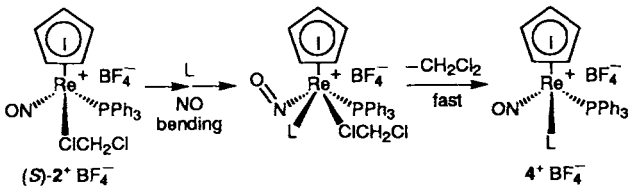
Scheme 4. Generation of functional equivalents of the chiral Lewis acid $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]^+$ (**I**).

transformed to the substitution-labile dichloromethane complex $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(ClCH_2Cl)]^+ BF_4^-$ ($\mathbf{2}^+ BF_4^-$)[32] or a related chlorobenzene complex ($\mathbf{3}^+ BF_4^-$).[33] These react with a variety of neutral and anionic Lewis bases to give adducts of **I** with overall retention of configuration at rhenium.

The chlorohydrocarbon complexes $\mathbf{2}^+ BF_4^-$ and $\mathbf{3}^+ BF_4^-$ have fascinating properties, many of which have been studied and described in detail. Both the formation and substitution reactions of $\mathbf{2}^+ BF_4^-$ occur with retention at rhenium.[32, 34] Above −20 °C, enantiomerically pure $\mathbf{2}^+ BF_4^-$ decomposes to an enantiomerically pure bridging chloride complex. Consequently, it is impossible to measure a racemization rate, since thermal decomposition occurs more rapidly. The chlorobenzene complex $\mathbf{3}^+ BF_4^-$ is a mixture of linkage and constitutional isomers.[33] Although the relative populations of isomers vary as samples are warmed from −45 °C to 100 °C, all are converted to

Lewis base adducts. Thus, the mixtures of isomers of $\mathbf{3}^+ BF_4^-$ that undergo substitution will be different with strongly nucleophilic and weakly nucleophilic Lewis bases. In any event, adducts form with overall retention at rhenium regardless of reaction temperature.

Kinetic binding selectivities are a reflection of the mechanism of adduct formation. Accordingly, the mechanisms of the reactions of $\mathbf{2}^+ BF_4^-$ and the indenyl (η^5-C_9H_7) analog with cyclohexanone have been investigated in detail.[34] In both cases, the corresponding σ ketone complexes form. Rate measurements show that these substitutions are *associative*. The data also indicate that slippage of the cyclopentadienyl ligand does not occur prior to or during the rate-determining step. Although there is not a compelling choice among the remaining mechanistic possibilities, one plausible pathway is shown in Scheme 5.



Scheme 5. One possible mechanism for dichloromethane substitution in $\mathbf{2}^+ BF_4^-$.

7. Complexes of I with Alkenes; General Bonding Considerations

From the frontier orbital properties noted in Section 5, alkene complexes of **I** should adopt the idealized Re–(C=C) conformation shown in **II** (Figure 2). The labels used for the substituent positions in **II** (a–d) are maintained throughout the review. It was anticipated that positions a and b, which are *anti* to the bulky PPh_3 ligand, would be less congested than positions c and d, which are *syn*. It was further anticipated that position b, in which steric interactions with the cyclopentadienyl ligand should be possible, would be more congested than position a, which is proximal to the small nitrosyl ligand. Finally, it was thought that position d, which projects into the small interstice between the PPh_3 and nitrosyl ligands, would be more congested than position c. Note that in principle, the PPh_3 ligand contributes equally to congestion in positions c and d.

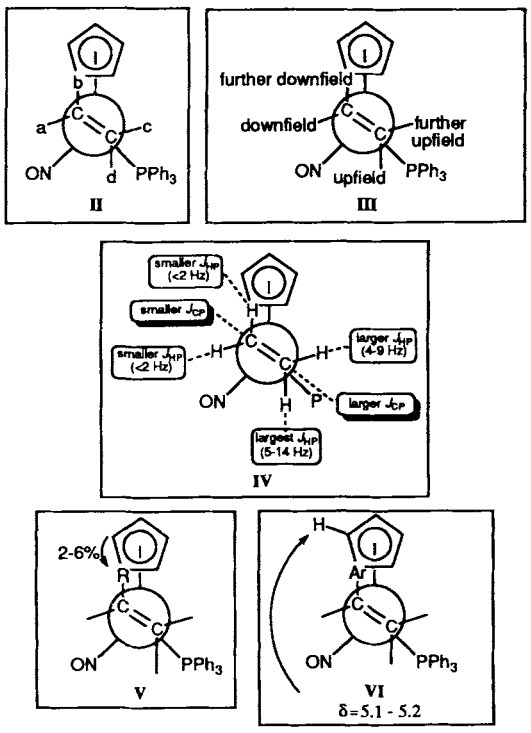


Figure 2. Key properties of alkene complexes of **I**. **II**) Idealized Re–(C=C) conformation; **III**) trends in ^1H and ^{13}C NMR chemical shifts for vinylic or allylic groups; **IV**) trends in NMR coupling constants; **V**) ^1H NOE enhancements, R = H, CH_2R'; **VI**) the effect of an aryl group in position b on the ^1H NMR signal of the cyclopentadienyl ligand.

Ten crystal structures of alkene complexes of **I** have been executed. These closely approximate the idealized structure **II**, and key features are summarized in Figure 3. In **II**, the angle formed by the rhenacyclopropane plane and the Re–P bond is 0°. The values in the crystal structures range from 2 to 23.5°, with an average of 16°. In all cases the rhenacyclopropane plane is rotated slightly counterclockwise from its position in **II**. Thus, there is a modest degree of freedom (ca. 20°) about the Re–(C=C) axis. The counterclockwise deviation might serve to relieve steric interactions involving position d. Other geometric measures of this feature are possible (for example the angle formed by the rhenacyclopropane plane and the plane defined by the cyclopentadienyl centroid, rhenium, and the C=C midpoint), and give comparable values and trends.

The bend-back angles involving the non-hydrogen C=C substituents range from 13 to 28°, with an average of 20.3° (Figure 3). There do not appear to be any significant trends. Slippage values are generally small.[20] Other features of these crystal structures are analyzed in Section 18. Structures of these complexes in solution have commonly been assigned from NMR data. Some key trends are summarized in Figure 2.

The ethylene complex of **I** has been isolated.[35] The two C=C ^{13}C NMR signals coalesce at 96.2 °C ($CDCl_2CDCl_2$). Alkene ligands normally dissociate from **I** only at much higher temperatures. Hence, a 180° rotation about the Re–(C=C) axis is required to render the NMR signals equivalent. A barrier of 16.4 kcal mol^{-1} ($\Delta G^{\neq}$, 369 K) can be calculated. Also, a [D_2]ethylene complex with the CD_2 label in positions c and d can be generated by a $[Re{=}CD_2]^+/CH_2N_2$ coupling reaction at −95 °C.[36] The CH_2/CD_2 termini rapidly scramble above −40 °C, consistent with the barrier determined by ^{13}C NMR spectroscopy. No equilibrium deuterium isotope effect was detected.

8. Complexes of I with Monosubstituted Alkenes (R = Alkyl, Aryl, Silyl)

8.1. Kinetic Binding Selectivities

In typical experiments, the dichloromethane complex $\mathbf{2}^+ BF_4^-$ and five to ten equivalents of simple monosubstituted alkenes were combined at −80 °C (Scheme 6).[35, 37] Workup at room temperature gave the corresponding alkene complexes $\mathbf{5a–c,e–h}^+ BF_4^-$ in 63–99% yields as mixtures of configurational diastereomers. The diastereomer ratios of both crude and purified products were assayed. These ranged from 63:37

(*RS,SR*/*RR,SS*)[38] to 75:25, except for the bulkier *tert*-butylethylene complex **5g**$^+$ BF_4^-, which gave a higher value (84:16). The chlorobenzene complex **3**$^+$ BF_4^- afforded alkene complexes with comparable diastereomer ratios, except for **5g**$^+$ BF_4^-, which gave an even higher value (96:4). Throughout this review, isomer ratios are normalized to 100, and error limits on each integer are ± 2 (e.g. 63:37 $\equiv$ (63$\pm$2):(37$\pm$2)) or less.[39]

8.2. Thermodynamic Binding Selectivities

Configurational diastereomers of **5**$^+$ BF_4^- equilibrate over the course of 6–24 h in chlorohydrocarbon solvents at 95–100 °C. Scheme 7 gives data for all of the compounds in Scheme 6 (C_6D_5Cl; ca. 0.01 M, 100 °C), a 1,4-pentadiene complex prepared subsequently (**5d**$^+$ BF_4^-; kinetic selectivity not measured),[40] and other compounds described in Sections 15 and 16. With **5a**–**h**$^+$ BF_4^-, the equilibrium ratios range from 90:10 to >99:1 (*RS,SR*/*RR,SS*). Similar values are obtained in $CHCl_2CHCl_2$, from syntheses conducted directly at 95–100 °C and from thermolyses of diastereomerically pure complexes. In all cases, mass balance is excellent. Rate measurements give $\Delta H^{\neq}$ and $\Delta S^{\neq}$ values of 29 kcal mol^{-1} and 2 cal mol^{-1} K^{-1} for the isomerization of the less stable styrene complex (*RR,SS*)-**5e**$^+$ BF_4^- (CD_2ClCD_2Cl; $\Delta G^{\neq}$(369 K) 28 kcal mol^{-1}).[41]

8.3. Interpretation

The kinetic binding selectivities for **5a**–**c**,**e**–**h**$^+$ BF_4^- in Scheme 6 are lower than the thermodynamic binding selectivi-

Scheme 7. Complexes of **I** with monosubstituted alkenes; thermodynamic binding selectivities. The PF_6^- salts of **5n**$^+$ and **5o**$^+$ were equilibrated.

ties in Scheme 7. The rhenium and carbon stereocenters should be much closer together in the complexes than in the progenitor transition states. Consequently, the differences in energy between the diastereomeric transition states ($\Delta\Delta G^{\ddagger}$) should be less than those between the diastereomeric complexes (ΔG), giving lower kinetic binding selectivities. Other alkene complexes of **I** exhibit analogous trends, and kinetic isomer ratios are not further tabulated in this review. The fascinating mechanism by which the equilibrations in Scheme 7 occur has been studied in detail.[41] In brief, alkene ligands with *cis* and *trans* deuterium labels do not undergo scrambling. This establishes that the entire C=C enantioface is exchanged, not just that of the CHR terminus. Surprisingly, equilibration occurs without alkene dissociation, and an intermediate "σ bond complex" of **I** and a vinylic hydrogen has been implicated.

The high *RS,SR*/*RR,SS* equilibrium ratios follow logically from the steric environments of positions a–d. As shown in Scheme 6, both diastereomers would be expected to favor Re–(C=C) rotamers in which the larger CHR termini are *anti* to the bulky PPh_3 ligands (*RS,SR*: **VII** ≫ **IX**; *RR,SS*: **VIII** ≫ **X**). To date, no evidence has been found for a second rotamer of any diastereomer of **5a**–**h**$^+$ BF_4^- in low-temperature NMR studies. However, Re–(C=C) rotamers are easily detected for complexes of **I** with disubstituted alkenes as described below. Hence, the *RS,SR*/*RR,SS* equilibrium ratios will very closely match the **VII**/**VIII** ratios (Scheme 7) and can be viewed as measures of the relative steric environments of positions a and b.[42]

Several trends are evident in the *RS,SR*/*RR,SS* equilibrium ratios for **5a**–**h**$^+$ BF_4^-. For example, sp^3-hybridized substituents on the C=C unit that are unbranched at the allylic carbon (**5a**–**d**$^+$ BF_4^-) give binding selectivities of 96:4–98:2. With sp^3-hybridized substituents that are branched at the allylic carbon, or trimethylsilyl (**5f**–**h**$^+$ BF_4^-), binding selectivities increase to >99:1. However, with a sp^2-hybridized phenyl substituent (**5e**$^+$ BF_4^-), the binding selectivity decreases to 90:10. For convenience, this and similar phenomena below will be termed "small phenyl" effects.

Several rationales have been considered for the lower selectivity with **5e**$^+$ BF_4^-. For example, a phenyl substituent might enhance slippage relative to an alkyl substituent, increasing the distance between the rhenium and CHR stereocenters. This should diminish chiral recognition. The crystal structures of both diastereomers of **5e**$^+$ BF_4^- have been determined, as well as of two analogs with alkyl substituents ((*RR,SS*)-**5c**$^+$ PF_6^-, (*RS,SR*)-**5f**$^+$ BF_4^-; see Figure 3). However, the error limits on the bond lengths are too large for any conclusion. Regardless, data below show that other factors must contribute.

In this context, phenyl groups exhibit smaller effective steric sizes than methyl groups in many types of equilibria.[43] Also, there is increasing evidence for attractive interactions between sp^2 carbon–hydrogen bonds and π electron clouds of unsaturated functional groups.[44] This would uniquely stabilize the higher energy diastereomer (*RR,SS*)-**5e**$^+$ BF_4^- and is furthermore consistent with the ^{1}H NMR shielding effect in **VI** (Figure 2). Indeed, Brunner has previously proposed that the hydrogen atoms of the cyclopentadienyl ligand can attractively interact with the π electron clouds of phenyl rings.[44a] He is also, to our knowledge, the first to invoke this type of phenomenon as a factor in a diastereomeric equilibrium. This intriguing "small phenyl" effect will be further analyzed as other equilibria are presented in subsequent sections (10–12, 15, 19, and 20).

9. Complexes of I with Symmetrically Substituted *cis* Alkenes

9.1. Binding Data

Complexes of **I** with *cis*-2-butene, *cis*-3-hexene, *cis*-stilbene, and *cis*-1,2-dichloroethylene (**6a–d**$^+$ BF_4^-) can be prepared by procedures analogous to those in Scheme 6.[45] As summarized in Scheme 8, NMR spectra recorded at sufficiently low temperatures show two diastereomers (*RSR,SRS*/*RRS,SSR* or **XI**/**XII**).[38b] Equilibrium ratios are lowest for *cis*-1,2-dichloroethylene complex **6d**$^+$ BF_4^- (59:41), highest for *cis*-stilbene complex **6c**$^+$ BF_4^- (93:7), and intermediate for **6a,b**$^+$ BF_4^-. With **6a**$^+$ BF_4^-, a significant solvent effect is observed.

	Ratio	$\Delta G^{\ddagger}$ [kcal/mol]	T_{coal} [K]

d, *n*+4 = 8	85:15

Scheme 8. Complexes of **I** with symmetrically substituted *cis* alkenes; thermodynamic binding selectivities [45, 46].

Complexes of **I** with cyclopentene, cyclohexene, cycloheptene, and cyclooctene (**7a–d**$^+$ BF_4^-) have also been prepared.[46] As summarized in Scheme 8, these give comparable mixtures of diastereomers.[47] 2D NMR spectra show that the diastereomers interconvert by Re–(C=C) rotations as opposed to C=C "face flips".[45] The former exchanges the substituents of the C=C unit in positions a and c, and b and d, whereas the latter exchanges substituents in positions a and b, and c and d.

9.2. Interpretation

The binding equilibria for the *cis*-2-butene and *cis*-3-hexene complexes **6a,b**$^+$ BF_4^- in Scheme 8 (**XI**/**XII**) reflect the relative steric congestion in positions (a + d) vs (b + c) (cf. D in Scheme 3). As analyzed in the preceding section, binding equilibria for complexes with monosubstituted alkenes **5a,b**$^+$ BF_4^-, which have comparably sized sp^3-hybridized substituents on the C=C unit, reflect the relative steric congestion in position a vs b. Thus, if position d were to be more congested than position c, binding selectivities for **6a,b**$^+$ BF_4^- should be lower than those for **5a,b**$^+$ BF_4^-. Accordingly, **6a,b**$^+$ BF_4^- give lower isomer ratios than **5a,b**$^+$ BF_4^- (84:16–85:15 in $CDCl_3$ at ≤ -62 °C vs 96:4–97:3 in C_6D_5Cl at 100 °C). Hence, the CHR termini of *cis* alkenes are mismatched with respect to the binding properties of the chiral receptor **I**.

The data in Scheme 8 also require that there be a larger difference in steric congestion for positions a and b than for positions c and d. Otherwise, the stability order of the isomers (**XI** > **XII**) would be reversed. Thus, for both **5a,b**$^+$ BF_4^- and **6a,b**$^+$ BF_4^- the dominant diastereomer is controlled by the difference in congestion in positions a and b. However, for **6a,b**$^+$ BF_4^-, the dominant diastereomer is destabilized with respect to the minor diastereomer because position d is more congested than position c. This leads to the corollary that complexes of **I** with *trans* alkenes should show higher binding selectivities than **5a,b**$^+$ BF_4^-, which is tested below. Curiously, the *cis*-stilbene complex **6c**$^+$ BF_4^- gives a higher binding selectivity than the styrene complex **5e**$^+$ BF_4^- (93:7 vs 90:10). However, the difference is very slight, and additional anomalous trends involving phenyl substituents are described in Sections 10–12, and 15.

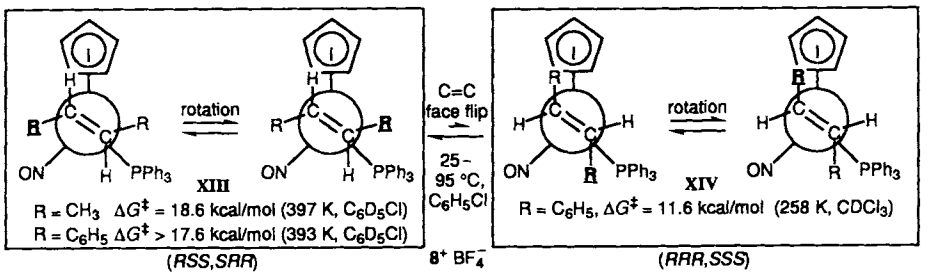
The barriers to Re–(C=C) rotation given in Scheme 8 are also easily rationalized. For **6a–c**$^+$ BF_4^-, there is a slight increase with the size of the CHR substituent (CH_3/CH_2CH_3/C_6H_5 11.0–11.1/12.6–12.8/13.2 kcal mol^{-1}), subject to the ambiguities with phenyl groups noted above. However, the *cis*-1,2-dichloroethylene complex **6d**$^+$ BF_4^- gives a much higher barrier (>17.5 kcal mol^{-1}). Accordingly, vinylic chloride substituents enhance the π acidities of alkenes, and π backbonding diminishes along the reaction coordinate. Thus, the ground state will be stabilized more than the transition state, raising the barrier to rotation. The small size of the chloride substituents in **6d**$^+$ BF_4^- accounts for the lower binding selectivity.

The data for **6a**$^+$ BF_4^- in Scheme 8 show that the solvent can appreciably affect conformational equilibria that exchange positions of the substituents on the C=C unit. It would logically follow that there could be solvent effects upon configurational equilibria that exchange positions of C=C substituents. However, none have been found to date. One factor may be the limited range of solvents suitable at the equilibration temperatures required (e.g. 95–100 °C for Scheme 7). For example, a significant amount of alkene ligand displacement occurs in acetonitrile. Alkene complexes of **I** are usually insoluble in hydrocarbons and ethers. Hence, only a few halohydrocarbons have been employed as solvents.

10. Complexes of I with Symmetrically Substituted *trans* Alkenes

10.1. Binding Data

Complexes of **I** with *trans*-2-butene, *trans*-3-hexene, and *trans*-stilbene (**8a–c**$^+$ BF_4^-) can be prepared by procedures analogous to those described above.[45] However, these complexes form at much slower rates than the corresponding *cis*



a, R = CH_3	99:01
b, R = CH_2CH_3	>99:1
c, R = C_6H_5	98:02

Scheme 9. Complexes of **I** with symmetrically substituted *trans* alkenes; thermodynamic binding selectivities [45].

alkene complexes **6a**–**c**$^+$ BF_4^-, indicating decreased alkene nucleophilicity. Mixtures of two configurational diastereomers are obtained (89:11–76:24). Importantly, as summarized in Scheme 9, **8a**–**c**$^+$ BF_4^- exhibit thermodynamic binding selectivities (*RSS,SRR*/*RRR,SSS* or **XIII**/**XIV** >99:1–98:2) much higher than those of **6a**–**c**$^+$ BF_4^-. In each series of diastereomers, Re–(C=C) rotational barriers can be determined by NMR spectroscopy.

10.2. Interpretation

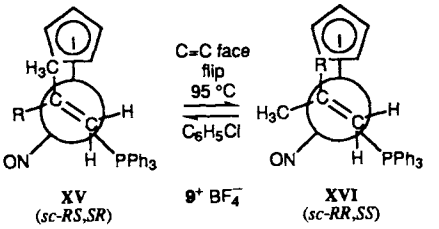
The binding equilibria for **8a**–**c**$^+$ BF_4^- in Scheme 9 (**XIII**/**XIV**) reflect the relative steric congestion in positions (a + c) vs (b + d) (cf. C in Scheme 3). In accord with the prediction in the previous section, the isomer ratios are greater than those of related complexes with monosubstituted alkenes **5a,b,e**$^+$ BF_4^-. Thus, the steric congestion in position d must be greater than that in position c, and the CHR termini of *trans* alkenes are matched with respect to the binding properties of the chiral receptor **I**.

The barriers to Re–(C=C) rotation in the more stable *RSS,SRR* diastereomers (**XIII**; >17.6 kcal mol^{-1}) are much higher than those of the corresponding complexes with *cis* alkenes (Scheme 8; 11.1–13.2 kcal mol^{-1}). Importantly, exchange of the CHR termini in **XIII** requires passage of a CHR moiety over the bulky PPh_3 ligand. In contrast, the isomeric *cis* alkene complexes **XI** and **XII** can interconvert without passage of a CHR moiety over the PPh_3 ligand. However, the barrier to Re–(C=C) rotation in the less stable *RRR,SSS* diastereomer of *trans*-stilbene complex **8c**$^+$ BF_4^- (**XIV**) is much lower (11.6 kcal mol^{-1}). Since the phenyl substituents in this compound occupy the most congested positions on each C=C terminus, strain in the ground state likely lowers the barrier to rotation. Accordingly, (*RRR,SSS*)-**8c**$^+$ BF_4^- slowly isomerizes to (*RSS,SRR*)-**8c**$^+$ BF_4^- at room temperature—much faster than the isomerizations of complexes of monosubstituted alkenes in Scheme 7.

11. Complexes of I with Geminally Disubstituted Alkenes

11.1. Binding Data

Data for three complexes of **I** with geminally disubstituted alkenes (**9a**–**c**$^+$ BF_4^-) are summarized in Scheme 10.[48] In each case, one substituent on the C=C unit is a methyl group. Although in principle Re–(C=C) rotamers are possible, equilibria should be even more biased than with the complexes of monosubstituted alkenes **5**$^+$ BF_4^-. Hence, only the more stable rotamer (*sc*) of each configurational diastereomer is depicted (*RS,SR*: **XV**; *RR,SS*: **XVI**).



a, R = CH_2CH_3	68:32
b, R = $CH_2CH_2CH_3$	68:32
c, R = C_6H_5	36:64

Scheme 10. Complexes of **I** with unsymmetrically substituted geminal alkenes; thermodynamic binding selectivities [48]. The higher energy *ac* Re–(C=C) rotamers are not depicted.

11.2. Interpretation

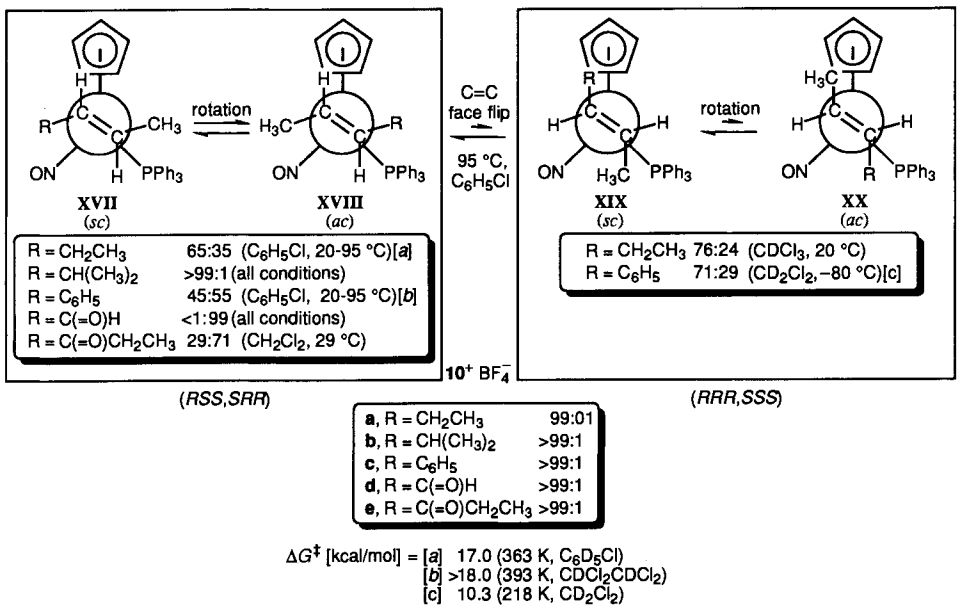
The **XV**/**XVI** equilibrium ratios can be viewed as direct measures of the relative steric environments of positions a and b. In contrast to the similar situation with **5**$^+$ BF_4^-, a non-hydrogen substituent must occupy position b. As would be expected, the data for the 2-methyl-1-butene and 2-methyl-1-pentene complexes **9a,b**$^+$ BF_4^- show that methyl groups partition into position b in preference to ethyl or propyl groups. However, the differences in sizes are not sufficiently large to give high binding selectivities. As the bulk of the non-methyl substituent increases (for example to *tert*-butyl), binding selectivities are certain to increase.

In contrast to the situation with the propene and styrene complexes **5a,e**$^+$ BF_4^-, the α-methylstyrene complex **9c**$^+$ BF_4^- allows an internal as opposed to external comparison of the relative sizes of methyl and phenyl substituents. Importantly, any slippage induced by the carbocation-stabilizing phenyl group should be equal in both diastereomers. Interestingly, **9c**$^+$ BF_4^- gives a binding selectivity opposite to that of **9a,b**$^+$ BF_4^-, with the methyl group preferentially in position a. Hence, either a phenyl group exhibits a smaller effective size than a methyl group in positions a and b, or there is a special attractive interaction in position b.

12. Complexes of I with Unsymmetrically Substituted *trans* Alkenes

12.1. Binding Data

Data for three complexes of **I** with methyl/alkyl- and methyl/phenyl-substituted *trans* alkenes (**10a**–**c**$^+$ BF_4^-) are given in Scheme 11.[48] As found for complexes **8**$^+$ BF_4^- with symmetri-



Scheme 11. Complexes of **I** with unsymmetrically substituted *trans* alkenes; thermodynamic binding selectivities [48, 50].

cal *trans* alkenes (Scheme 9), one configurational diastereomer is much more stable than the other (*RSS,SRR*/*RRR,SSS* ≥ 99:1). However, each configurational diastereomer can now give two Re–(C=C) rotamers (**XVII**/**XVIII**; **XIX**/**XX**). These interconvert with barriers comparable to those of the corresponding isomers of **8**$^+$ BF_4^-. The other complexes in Scheme 11 are analyzed below.

12.2. Interpretation

For the more stable *RSS,SRR* diastereomers of **10a**–**c**$^+$ BF_4^-, the rotameric equilibria (**XVII**/**XVIII**) reflect the relative steric congestion in positions a and c (cf. G in Scheme 3). In the *trans*-2-pentene and *trans*-4-methyl-2-pentene complexes **10a,b**$^+$ BF_4^-, the methyl group preferentially occupies position a. Selectivities are modest with **10a**$^+$ BF_4^- (65:35, CH_3 vs CH_2CH_3), but high with **10b**$^+$ BF_4^- (>99:1, CH_3 vs $CH(CH_3)_2$). The first ratio is very close to the binding selectivity observed for the geminally disubstituted alkene complex **9a**$^+$ BF_4^- (68:32), in which methyl and ethyl groups are partitioned between positions a and b. Thus, the steric environments of positions b and c appear to be comparable.

The β-methylstyrene complex **10c**$^+$ BF_4^- gives a reversed selectivity, with a slight preference for the methyl group in position a and the phenyl group in position c. Thus, either a phenyl group exhibits a smaller effective size than a methyl group in positions a and c, or there is a special attractive interaction in position c, for example between the phenyl rings of the PPh_3 ligand and the phenyl ring of the alkene.

For the less stable *RRR,SSS* diastereomers, the rotameric equilibria (**XIX**/**XX**) reflect the relative steric congestion in positions b and d. In the two complexes of which sufficient samples could be obtained (**10a,c**$^+$ BF_4^-), there are moderate preferences for methyl groups in the more congested position d. In the case of **10c**$^+$ BF_4^-, the phenyl group no longer exhibits a smaller effective size than the methyl group. This suggests that a special attractive interaction may be associated with position b.

13. Complexes of I with Unsymmetrically Substituted *cis* Alkenes

13.1. Binding Data

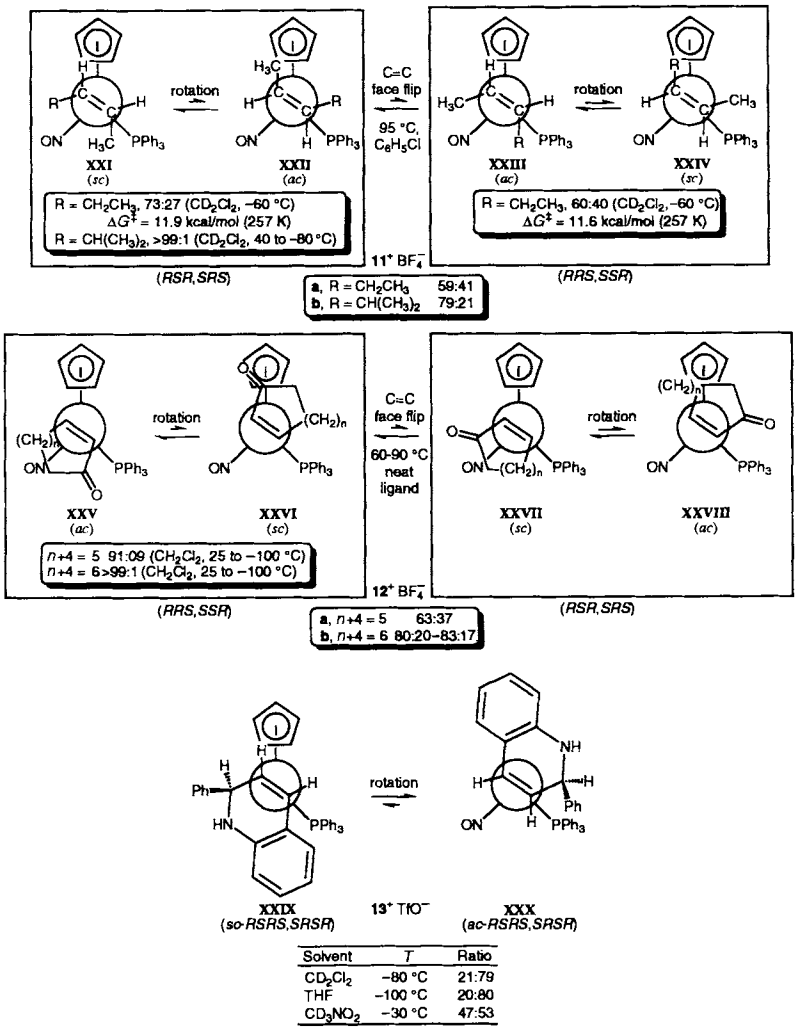
Data for two methyl/alkyl-substituted complexes of **I** with *cis* alkenes (**11a,b**$^+$ BF_4^-) are given in at the top of Scheme 12.[48] One configurational diastereomer is slightly more stable than the other (*RSR,SRS*/*RRS,SSR* 59:41–79:21). Two Re–(C=C) rotamers are observed for each configurational diastereomer of the *cis*-2-pentene complex **11a**$^+$ BF_4^- (**XXI**/**XXII**; **XXIII**/**XXIV**). These interconvert with barriers comparable to those of the *cis*-2-butene and *cis*-3-hexene complexes **6a,b**$^+$ BF_4^-. The other classes of complexes in Scheme 12 (**12**$^+$ BF_4^-, **13**$^+$ BF_4^-) are treated in Section 17.2.

13.2. Interpretation

These binding equilibria are complicated to analyze. Consider first the more stable *RSR,SRS* diastereomer of the *cis*-2-pentene complex **11a**$^+$ BF_4^-. In the major rotamer (**XXI**), the larger ethyl and smaller methyl groups are matched into the less congested position a and more congested position d, respectively. In the minor rotamer (**XXII**), the larger ethyl group is mismatched into the slightly more congested position c. Thus, the **XXI**/**XXII** equilibrium ratio (73:27) is slightly greater than the **XI**/**XII** ratio for the *cis*-2-butene complex **6a**$^+$ BF_4^- (70:30), when measured in the same solvent.

Conversely, in the major rotamer of the less stable *RRS,SSR* diastereomer of **11a**$^+$ BF_4^- (**XXIII**), the larger ethyl and smaller methyl groups are mismatched into the more congested position d and less congested position a, respectively. In the minor rotamer (**XXIV**), the ethyl group is matched into the slightly less congested position b. Thus, the **XXIII**/**XXIV** equilibrium ratio (60:40) is less than the **XI**/**XII** ratio for **6a**$^+$ BF_4^-.

Rotamers of the configurational diastereomers of the *cis*-4-methyl-2-pentene complex **11b**$^+$ BF_4^- cannot be detected by low-temperature NMR spectroscopy. However, with the more stable diastereomer, this is certainly because the **XXI**/**XXII** equilibrium ratio is much higher than that of **11a**$^+$ BF_4^-, as would be expected from the greater difference in size between the isopropyl and methyl substituents. Thus, a >99:1 mixture is indicated in Scheme 12. We speculate that with the less stable diastereomer, rotamer **XXIV** may dominate. This should occur when the non-methyl substituent becomes sufficiently large.



Scheme 12. Complexes of **I** with unsymmetrically substituted *cis* alkenes; thermodynamic binding selectivities [48, 50, 53].

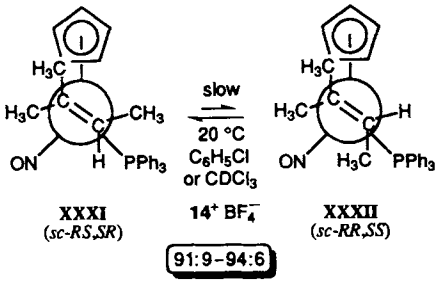
Additional generalizations about binding selectivities in this class of compounds are difficult to make. As the non-methyl substituent on the C=C unit becomes larger, **XXI** should become increasingly favored relative to the other three isomers **XXII**–**XXIV**. However, with two very large substituents ($R_L > R_{L'}$), an isomer analogous to **XXIV** might be the most stable. This would avoid occupancy of the most congested position d. Receptors that give more clear-cut predictions for binding selectivities of unsymmetrically substituted *cis* alkenes are illustrated below.

A **XXI**/**XXII**/**XXIII**/**XXIV** equilibrium ratio can be calculated for the *cis*-2-pentene complex **11a**$^+$ BF_4^- from the data in Scheme 12 (43:16:25:16). However, this is formulated from measurements at markedly different temperatures and must be analyzed with caution. For example, the **XXI**/**XXIII** ratio, 45:25 or 63:37 (normalized), should reflect the partitioning of methyl and ethyl groups between positions a and d. The **XXII**/**XXIV** ratio, 16:16 or 50:50, would be an analogous measure for positions b and c. However, Schemes 10 and 11 give equilibrium constants that directly reflect the partitioning of methyl and ethyl groups between positions a/b, a/c, and b/d. Careful analysis of these suggest that the **XXI**/**XXIII** ratio calculated from Scheme 12 is too small. Minor internal inconsistencies are not unexpected in view of the many caveats discussed above and below.

14. Complexes of I with Trisubstituted Alkenes

14.1. Binding Data

Complexes of **I** with trisubstituted alkenes having only alkyl or aryl substituents on the C=C unit are much less stable. Parallel trends are found for alkene complexes of other metal fragments.[14a] Consequently, only the 2-methyl-2-butene complex **14**$^+$ BF_4^- shown in Scheme 13 has been studied.[48] To avoid decomposition, equilibrations were conducted over extended periods at room temperature or below. Thermodynamic binding selectivities (*RS,SR*/*RR,SS*) were bracketed as 91:6–94:9.



Scheme 13. Complexes of **I** with trisubstituted alkenes; thermodynamic binding selectivities [48]. The higher energy *ac* Re–(C=C) rotamers are not depicted.

14.2. Interpretation

It is assumed that **XXXI** and **XXXII** (Scheme 13) constitute the dominant Re–(C=C) rotamers of each configurational diastereomer. Hence, the *RS,SR*/*RR,SS* equilibrium ratio reflects the relative steric environments of positions c and d, and shows the latter to be much more congested. The slightly greater equilibrium ratio for the propene complex **5a**$^+$ BF_4^- (96:4, Scheme 7) indicates that the difference in congestion between positions c and d is less than that between positions a and b, in accord with other data above.

These data further indicate that high binding selectivities can be expected for complexes of **I** with trisubstituted alkenes whenever the size of the geminal substituent that is *trans* to the CH*R* group is greater than or equal to that of the other geminal substituent. This allows the larger groups on each C=C terminus to occupy positions a and c.

15. Complexes of I with 1,3-Dienes

15.1. Binding Data

Unsymmetrically substituted 1,3-dienes are bifunctional Lewis bases. Both *trans*-piperylene and isoprene complexes of **I**

have been prepared (**5i,j**$^+$ BF_4^-, Scheme 7).[49] Consistent with literature precedent,[14a] the monosubstituted C=C unit show much higher thermodynamic binding affinities than the disubstituted C=C units (>99:1 and 97:3). As summarized in Scheme 7, the monosubstituted C=C units give enantioface binding selectivities (*RS,SR*/*RR,SS*) of 90:10 and 98:2, respectively. These ligands, and others with X=C–C=X moieties below, can also exist as s-*cis*/s-*trans* isomers. Such equilibria play important roles in many enantioselective syntheses, and it is frequently possible to assign the dominant isomer from spectroscopic data. These data, which are outside the theme of this review, are given in the original papers cited.[49]

15.2. Interpretation

The *trans*-piperylene and styrene complexes **5i**$^+$ BF_4^- and **5e**$^+$ BF_4^- give identical binding selectivities (*RS,SR*/*RR,SS* 90:10). In each case, the substituent on the C=C unit is sp^2-hybridized. Alkene complexes **5a–d**$^+$ BF_4^-, which have sp^3-hybridized substituents, give higher selectivities. Thus, sp^2-hybridized substituents may have intrinsically smaller effective steric sizes. Alternatively, attractive cyclopentadienyl C–H$\cdots\pi$ interactions[44] may be operative in the *RR,SS* diastereomers of **5e,i**$^+$ BF_4^-.

As shown in Figure 3, in crystalline (*RS,SR*)-**5i**$^+$ BF_4^- the Re–CH_2 bond is shorter than the Re–CHR bond (2.16(1) vs 2.23(1) Å). The resulting slippage value (16.4%) is the largest to date for a complex of **I** with a monosubstituted alkene. As analyzed above, this could also contribute to the reduced binding selectivity. However, both rhenium–carbon bonds appear to be shorter than those of the other alkene complexes in Figure 3. This should enhance binding selectivity, contrary to the trend observed. The contracted bonds may arise from the enhanced π basicity and π acidity of 1,3-dienes, as predicted from simple Hückel π MO theory.

When the unbranched 1-propenyl substituent on the C=C unit in **5i**$^+$ BF_4^- is replaced by the α-branched 2-propenyl substituent in isoprene complex **5j**$^+$ BF_4^-, the binding selectivity increases to 98:2 (Scheme 7). However, this ratio is still less than that of isopropylethylene complex **5f**$^+$ BF_4^- (>99:1), which has an α-branched but sp^3-hybridized substituent on the C=C unit.

16. Other Complexes of I with Monosubstituted Alkenes (R = C(=O)X)

16.1. Binding Data

Unsaturated carbonyl compounds such as enals and enones constitute heterobifunctional Lewis bases. Interestingly, the carbonyl moieties are much more nucleophilic towards the dichloromethane complex **2**$^+$ BF_4^- in all cases studied to date.[50] Thus, O=C adducts of **I** are the exclusive kinetic products. However, isomerizations to C=C adducts occur at higher temperatures. For all ligands except cycloalkenones, only C=C adducts remain at equilibrium. Thus, kinetic and thermodynamic binding selectivities are completely divergent. Although the bases for these phenomena are beyond the scope of this review,[51] the stability trend is even more pronounced in transition metal Lewis acids that are stronger π donors.[51b] Regardless, as summarized previously in Scheme 7, binding selectivities have been measured for five complexes of monosubstituted alkenes having C(=O)X substituents (**5k–o**$^+$ X^-).[36, 50]

16.2. Interpretation

The three α,β-unsaturated ketone complexes **5l,m**$^+$ BF_4^- and **5n**$^+$ PF_6^- give binding selectivities of 94:6–96:4 (*RS,SR*/*RR,SS*).[36, 50] Consistent with other trends noted above, these ratios appear to be slightly lower than those of alkene complexes with comparably sized sp^3-hybridized substituents on the C=C unit. The α,β-unsaturated ester complex **5o**$^+$ PF_6^- gives the lowest binding selectivity in this series (93:7).

Curiously, (*RS,SR*)-**5o**$^+$ PF_6^- is the only complex of **I** with a monosubstituted alkene for which Re–(C=C) rotamers have been detected.[36] As expected, the equilibrium ratio is high (**VII**/**IX** 93:7; Scheme 6). In view of the small effective size of the ethoxycarbonyl substituent on the C=C unit, this ratio is likely much higher for other complexes (*RS,SR*)-**5**$^+$ X^-. Surprisingly, the NMR signals do not coalesce in spectra recorded up to 160 °C ($CHCl_2CHCl_2$). This bounds the $\Delta G^{\ddagger}$ value for Re–(C=C) rotation as $\geq$21.4 kcal mol^{-1} (433 K). Since both isomers give diagnostic J_{HP} and J_{CP} coupling constants for the =*CH* ^{1}H and ^{13}C NMR signals (see **IV**, Figure 2), assignments are unequivocal. The high barrier is provisionally attributed to the electron-withdrawing nature of the ethoxycarbonyl group—similar to the effect of the chlorine substituents in the *cis*-1,2-dichloroethylene complex **6d**$^+$ BF_4^- (Scheme 8). The normalized equilibrium ratio for the three observable isomers (**VII**/**VIII**/**IX** 86:7:7; Scheme 6) indicates that the steric congestion in positions b and c is comparable.

Interestingly, the acrolein complex **5k**$^+$ BF_4^- has the smallest substituent on the C=C unit in this series of compounds, but shows the highest binding selectivity (>99:1).[50, 52] Although a simple explanation is not apparent, an electronic effect is certainly implicated. Also, **5k–o**$^+$ X^- can give s-*cis*/s-*trans* isomers about the O=C–C=C linkages. Perhaps these equilibria, which will depend upon the C(=O)X group, can affect the *RS,SR*/*RR,SS* ratios.

17. Other Complexes of I with Alkenes Having Unsaturated Substituents

17.1. Complexes with *trans* Disubstituted Alkenes

Data for two complexes with *trans* methyl and C(=O)X (X = H, CH_2CH_3) substituents, **10d,e**$^+$ BF_4^-, are given in Scheme 11.[50] As observed for the other complexes of *trans* alkenes, one configurational diastereomer is much more stable than the other (*RSS,SRR*/*RRR,SSS* $\geq$99:1). The rotameric equilibria (**XVII**/**XVIII**) show that the C(=O)H moiety in crotonaldehyde complex **10d**$^+$ BF_4^- has a much smaller effective steric size than a methyl group, and the $C(=O)CH_2CH_3$ moiety in **10e**$^+$ BF_4^- has a slightly smaller size than a methyl group. Interestingly, the latter compound crystallizes as the less stable Re–(C=C) rotamer (Figure 3).

17.2. Complexes with *cis* Disubstituted Alkenes

Data for cycloalkenone complexes **12a,b**$^+$ BF_4^- are given in Scheme 12 (middle).[50] Two configurational diastereomers are observed but equilibrium ratios are modest (*RRS,SSR*/*RSR,SRS* 63:37–83:17), paralleling those of complexes **11a,b**$^+$ BF_4^- with unsymmetrically substituted *cis* alkenes. In the more stable configurational diastereomers, Re–(C=C) rotamers that direct the smaller carbonyl substituent *syn* to the PPh_3 ligand are more stable.

In connection with another project, a C=C adduct of **I** and a 1,2-dihydroquinoline ligand, (*RSRS,SRSR*)-**13**$^+$ TfO^- (Scheme 12, bottom), was prepared and crystallographically characterized (Figure 3).[53] With this compound, the relative stability of the two Re–(C=C) rotamers was opposite to those of other *cis* alkene complexes (**XXX** > **XXXI**). Also, the equilibrium ratio in CD_3NO_2 differed considerably from those in CD_2Cl_2 or THF. Apparently, the two large substituents on the C=C unit are most readily accommodated in positions b and c which have intermediate steric congestion. Furthermore, there is the possibility of an attractive cyclopentadienyl C–H···π interaction[44] involving the aryl substituent on the C=C unit in **XXX**.

17.3. Complexes with Allenes

Several allene complexes of **I** have been prepared.[54] With the simplest prochiral allene, $H_2C{=}C{=}CHCH_3$, very high binding selectivity for one diastereoface of the unsubstituted $H_2C{=}C$ moiety is observed. These somewhat more complicated equilibria can be analyzed by extensions of the bonding models outlined above.[54]

18. A Second Look at the Steric Properties of Lewis Acid I

The preceding binding data for alkene complexes of **I** provide a detailed map of the relative steric environments of positions a–d. However, an interlude to reassess key assumptions or approximations is instructive. First, the crystallographic response of **I** to various types of alkene ligands will be scrutinized.

Figure 4 shows the structures of the cations of the diastereomeric styrene complexes (*RS,SR*)-**5e**$^+$ BF_4^- and (*RR,SS*)-**5e**$^+$ BF_4^- (Figure 3 and **VII**, **VIII** in Scheme 7).[55] The eleven-atom (η^5-C_5H_5)**Re**(**NO**)(**P**Ph_3)(**C=C**) units in each are virtually superimposable. Thus, the only significant difference is the position of the phenyl substituent on the C=C unit. The bend-back and Re-CH-C_6H_5 bond angles in (*RR,SS*)-**5e**$^+$ BF_4^- are slightly greater than those in (*RS,SR*)-**5e**$^+$ BF_4^- (19.4° vs 15.4°; 120.1(5)° vs 116.8(6)°), suggestive of net repulsive steric interactions between the phenyl group and the cyclopentadienyl ligand in the former. However, when the structure is viewed on a stereoscopic viewing screen with atomic radii set at van der Waals radii, the phenyl/cyclopentadienyl spatial overlap is small. Accordingly, the ΔG value, 1.64 kcal mol^{-1} as calculated from the 90:10 equilibrium ratio at 100 °C, is modest.

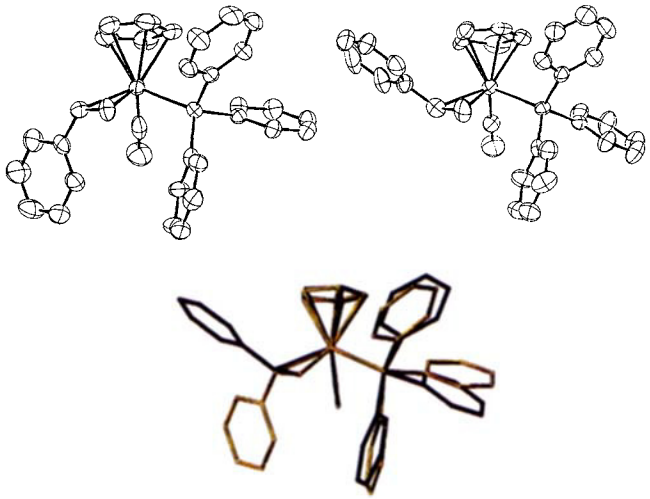


Figure 4. Structures of the cations of styrene complexes (*RS,SR*)-**5e**$^+$ BF_4^- (top left) and (*RR,SS*)-**5e**$^+$ BF_4^- (top right), and a superposition of the two (bottom).

Figure 5 shows the structures of the cations of the *cis*-2-butene complex (*RSR,SRS*)-**6a**$^+$ BF_4^- and the *trans*-2-butene complex (*RSS,SRR*)-**8a**$^+$ BF_4^- (Figure 3 and **XI**, **XIII** in Schemes 8 and 9).[45] In principle, these differ only in the position of a methyl substituent on the C=C unit. However, in contrast to the example in Figure 4, this involves the more congested positions c and d. Accordingly, the structure of the fragment **I** varies slightly more than in Figure 4. In particular, the conformation of the PPh_3 ligand appears to respond to the methyl group in position c, with the closest phenyl ring rotating away in a clockwise direction. There is a reciprocal response of a phenyl ring (pointing down in Figure 4) to a methyl group in position d. Interestingly, the cyclopentadienyl ligands adopt

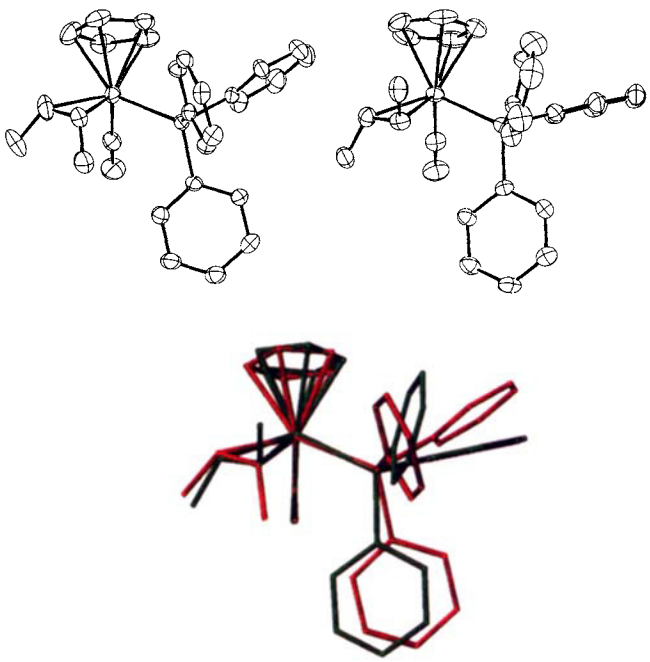

Figure 5. Structures of the cations of *cis*-2-butene complex (*RSR,SRS*)-**6a**$^+$ BF_4^- (top left) and *trans*-2-butene complex (*RSS,SRR*)-**8a**$^+$ BF_4^- (top right), and a superposition of the two (bottom).

orthogonal conformations (Figure 5, bottom) that differ by approximately 36° (360°/10) rotations about the rhenium–cyclopentadienyl centroid axis.

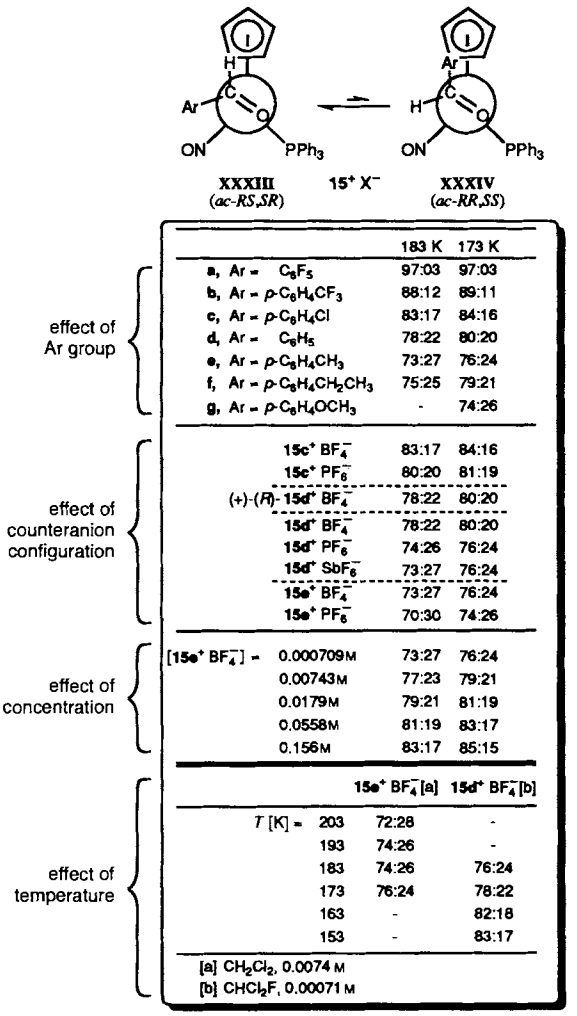
Importantly, PPh_3 ligands have "propeller" chirality.[56] This additional stereogenic element generates another set of diastereomers. Such diastereomers normally interconvert very rapidly in solution, and equilibrium ratios are likely comparable for structurally similar types of ligands. However, only one type of PPh_3 rotor will commonly crystallize. The structures in Figure 4 have identical propeller chirality, and the structures in Figure 5 have identical propeller chirality. However, the helical senses are opposite. The allylbenzene and piperylene complexes (*RR,SS*)-**5c**$^+$ PF_6^- and (*RS,SR*)-**5i**$^+$ BF_4^- also crystallize with propeller chiralities like that in Figure 4, whereas the other alkene complexes in Figure 3 crystallize with chiralities like that in Figure 5. There is not an obvious relationship between alkene type and PPh_3 chirality. Fortunately, this degree of freedom does not appear to be able to invert the relative steric congestion of any pair of positions (a–d). However, it remains a source of nonideality, and may be a factor in some of the trends involving phenyl or other unsaturated substituents on the C=C unit in positions c and d.

19. Complexes of I with Aromatic Aldehydes; Electronic Effects

Aldehydes and monosubstituted alkenes differ only at one X=C terminus (X = O vs X = H_2C) and are approximately isosteric. Accordingly, the complexes of **I** with aromatic aldehydes $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(\eta^2\text{-}O{=}CHAr)]^+ BF_4^-$ (**15**$^+$ BF_4^-)[57] give configurational diastereomers and Re–(X=C) rotamers analogous to those of the complexes with monosubstituted alkenes **5**$^+$ BF_4^- (Scheme 6). In brief, equilibrium constants are similar. However, diastereomers of **15**$^+$ BF_4^- rapidly interconvert below room temperature. The isomerization mechanism involves intermediate σ complexes—a type of energy minimum not available to alkene complexes **5**$^+$ BF_4^-.[58] With *p*-methoxybenzaldehyde, the σ isomer is actually more stable at room temperature.

Under standard conditions (0.00071 M, CH_2Cl_2, 173 or 183 K), complexes **15a–g**$^+$ BF_4^- give the binding selectivities (*RS,SR*/*RR,SS* or **XXXIII**/**XXXIV**) summarized in Scheme 14.[59] Multiple determinations have been made, and the small standard deviations are listed elsewhere.[59] A profound electronic effect is obvious. Electron-withdrawing aryl substituents, which enhance π acidity, give higher selectivities (up to 97:3). In contrast, electron-donating aryl substituents, which diminish π acidity and enhance σ basicity, give diminished selectivities (as low as 73:27). Hammett plots are linear, with ρ values of 0.60 (183 K) and 0.46 (173 K).

We thought, perhaps optimistically, that these electronic trends might reduce to a simple, one-parameter, structural explanation. Specifically, the distances between the rhenium and carbon stereocenters might decrease in adducts of the more π-acidic aldehydes.[60] This would enhance destabilizing steric interactions between the cyclopentadienyl ligands and aryl groups in the *RR,SS* diastereomers (**XXXIV**), giving higher *RS,SR*/*RR,SS* ratios and chiral recognition as observed. The

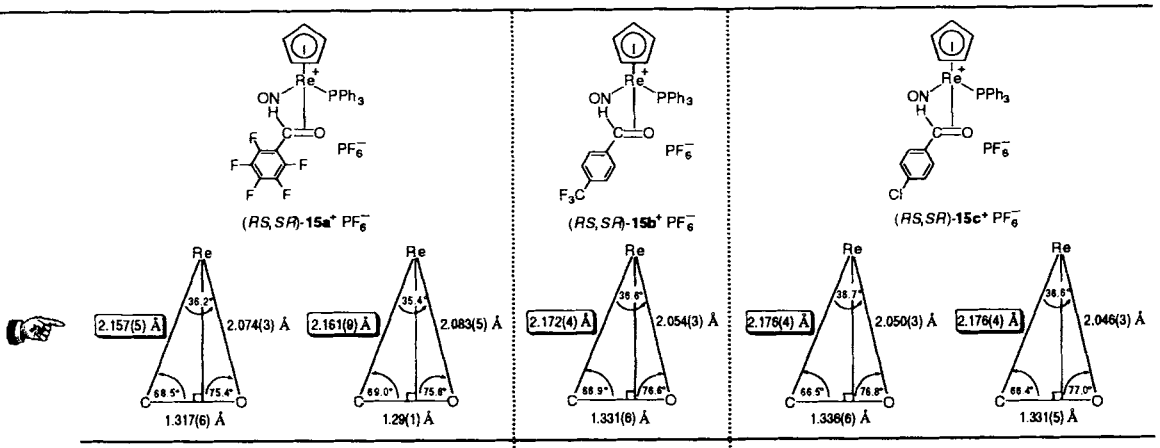


Scheme 14. Complexes of **I** with aromatic aldehydes; thermodynamic binding selectivities [59].

rhenium–carbon bonds would not necessarily be equal in the two diastereomers. However, they would undergo parallel changes as substituents are varied. With the diastereomeric styrene complexes **5e**$^+$ BF_4^- (Figures 3 and 4), the Re–CHC_6H_5 bond lengths differ only slightly (2.258(9) vs 2.284(7) Å).

Accordingly, the crystal structures of five complexes were determined at room and/or low temperature (Figure 6). Each compound crystallized as the more stable *RS,SR* diastereomer. The rhenium–carbon bond lengths are plotted vs the *RS,SR*/*RR,SS* ratios in Figure 7. Importantly, as the rhenium–carbon bonds contract from 2.199(6)–2.184(5) Å ((*RS,SR*)-**15f**$^+$ PF_6^-) to 2.161(9)–2.157(5) Å ((*RS,SR*)-**15a**$^+$ PF_6^-), the binding selectivities increase monotonically from 75:25–79:21 (**15f**$^+$ BF_4^-, 183 or 173 K) to 97:3 (**15a**$^+$ BF_4^-). Figure 7 can be viewed as a "crystallographic map" of a chiral recognition event. By the commonly employed criterion of three times the estimated standard deviation, the bond lengths in adjacent pairs of compounds in Figure 7 are not significantly different. However, there is a statistically rigorous overall correlation with the *RS,SR*/*RR,SS* ratios (χ^2 test).[59]

The crystal structures recorded at room temperature are overlaid in Figure 8. Although some variations are evident, the posi-



T [°C]	-80	16	16	-125	16

Figure 6. Key structural parameters of complexes of **I** with aromatic aldehydes [59].

tions of the ten-atom (η^5-C_5H_5)**Re**(**NO**)(**P**Ph_3)(O=**C**) segments are virtually superimposable. Figure 6 shows that the bend-back angles (20.5–17.4°) and O=C-C=C torsion angles (165 to 177° and −14 to −3°) are also similar, indicating comparable aryl group conformations. In all cases, the rhenium–oxygen bonds (2.083(5)–2.046(3) Å) are shorter than the rhenium–carbon bonds (2.199(6)–2.157(5) Å). This reflects the greater affinity of the more electronegative oxygen for the electropositive rhenium, and the greater ability of carbon to support a partial positive charge. Although the slippage values (20–33%) are larger than for complexes of **I** with monosubstituted alkenes (1–16%; Figure 3), it should be noted that the rhenium–carbon distances generally remain *shorter*.

Figure 8 also shows that complexes (*RS*,*SR*)-**15a–d**,**f**$^+$ X^- crystallize with two types of PPh_3 ligand conformations with opposite propeller chiralities. Curiously, the propeller chiralities of the *p*-trifluoromethylbenzaldehyde and *p*-chlorobenzaldehyde complexes (*RS*,*SR*)-**15b**,**c**$^+$ PF_6^- differ from all other complexes of **I** with aldehydes, thioaldehydes, and selenoaldehydes that have been structurally characterized to date

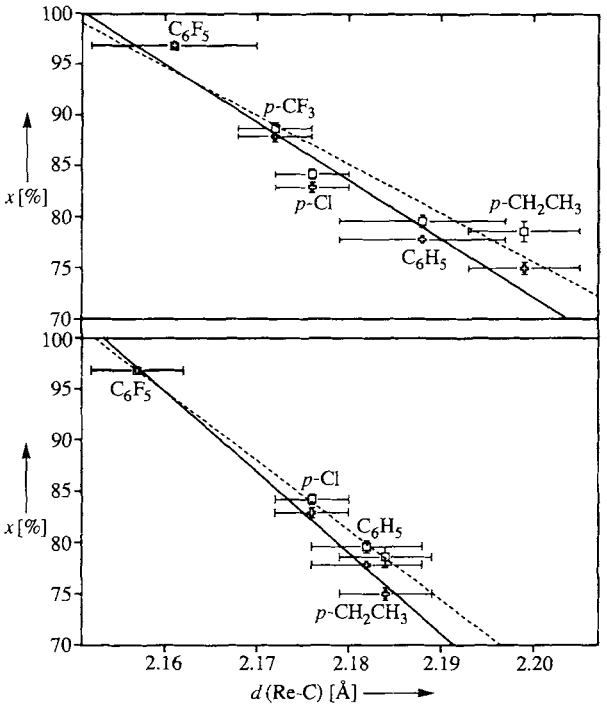

Figure 7. A "crystallographic map" of chiral recognition in complexes **15a–d,f**$^+$ X$^-$. The y axis gives the proportion of the *RS,SR* diastereomer in mol%. The bond lengths plotted along the x axis are obtained from crystal structure analyses conducted at 16 °C (top plot) and at low temperature (bottom plot). ⌬ (——): data recorded in solution at 183 K, □(– – –): data recorded in solution at 173 K. Error bars correspond to one standard deviation.

Figure 8. A superposition of the structures of the cations of the aromatic aldehyde complexes shown in Figure 6.

(see Sections 20 and 21). However, we presume that the equilibrium ratios of propeller diastereomers are similar for all compounds in solution. We speculate that the different propeller chiralities may disrupt monotonic trends in some of the geometric parameters in Figure 6. For example, the oxygen–carbon and rhenium–oxygen bond lengths and the angles of the rhenium-oxygen-carbon planes with the rhenium–phosphorus bonds might have been expected to correlate with the aldehyde ligand π acidity. However, these features involve the aldehyde oxygen, which is proximal to the PPh_3 ligand and perhaps slightly affected by the propeller chirality. Other possible contributing factors have been discussed.[59b]

Since the configurational diastereomers of aromatic aldehyde complexes **15**$^+$ X$^-$ could be more easily equilibrated than those of alkene complexes **5**$^+$ X$^-$, effects of other variables were examined. As exemplified in Scheme 14, binding selectivities increase somewhat at lower temperatures, as would be intuitively expected. Selectivities also vary slightly with the counter anion ($BF_4^- > PF_6^- > SbF_6^-$). This shows that chiral recognition can be influenced by species formally exogenous to the Lewis acid/Lewis base pair. However, there are no close contacts of the anions and cations in the crystal structures. Significant counter anion effects have been observed with adducts of chiral ammonium salts and chiral crown ethers.[61]

Unexpectedly, binding selectivities are markedly concentration dependent (Scheme 14). One rationale would involve the formation of aggregates in more concentrated solutions. However, racemic and enantiomerically pure samples of benzaldehyde complex **15d**$^+$ BF_4^-, which should aggregate differently, give identical diastereomer ratios. Also, the polarity of a medium becomes increasingly affected by the solute at higher concentrations. Unfortunately, diastereomer ratios can only be measured in a small number of solvents, all of which are chlorinated, due to a combination of freezing point limitations, insolubility (ethers, hydrocarbons), and reactivity (isopropanol). All of these parameters are deserving of further study and interpretation, particularly in view of the desirability of accurately comparing binding data from different types of transition metal Lewis acids.

Surprisingly, electronic effects in chiral recognition have not been investigated very extensively.[61] Furthermore, several fascinating electronic effects in transition metal mediated enantioselective syntheses have recently been reported.[62] In most cases, the mechanistic bases for the observed trends are poorly understood. The preceding data provide what we believe to be the first electronic effects involving a common step in metal-catalyzed enantioselective reactions (π complexation) that can be easily and intuitively interpreted.[60] These findings lead to the important general prediction that chiral recognition should be enhanced when either the π acidity of the ligand or the π basicity of the metal fragment is increased. To our knowledge, this represents a new approach to the optimization of chiral receptors, which are most commonly designed and then modified based upon steric principles.

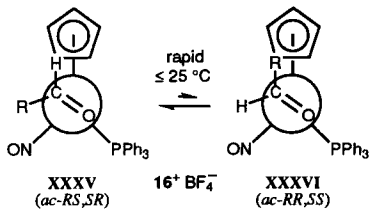
20. Complexes of I with Aliphatic Aldehydes

Binding selectivities for complexes of **I** with aliphatic aldehydes, **16**$^+$ BF_4^-),[63] are particularly difficult to determine.

$[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(\eta^2\text{-}O{=}CHR)]^+ BF_4^-$ **16**$^+$ BF_4^-

Measurements are complicated by the low temperatures required for decoalescence of NMR signals and the very small quantities of the less stable *RR,SS* diastereomers present at equilibrium. Data acquired to date are summarized in Scheme 15.[59b] These establish the expected steric effect upon binding selectivities, with *RS,SR*/*RR,SS* (**XXXV**/**XXXVI**) ratios increasing from 99.0:1.0 for acetaldehyde complex **16a**$^+$ BF_4^- (unsubstituted α carbon) to 99.8:0.2–99.5:0.5 for propionaldehyde and butyraldehyde complexes **16b,c**$^+$ BF_4^- (unbranched α carbons), to >99.9:0.1 for isobutyraldehyde and pivalaldehyde complexes **16d,e**$^+$ BF_4^- (branched α carbons). However, propionaldehyde appears to give a higher diastereomer ratio than butyraldehyde.

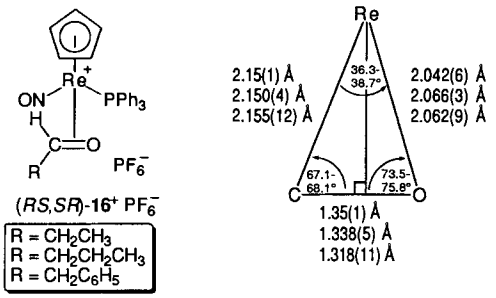
Regardless, aliphatic aldehydes bind much more selectively to **I** than aromatic aldehydes. As summarized in Figure 9, the crystal structures of the acetaldehyde, propionaldehyde, and



a,	R = CH_3 [59]	99.0:1.0
b,	R = CH_2CH_3 [59]	99.8:0.2
c,	R = $CH_2CH_2CH_3$ [59]	99.5:0.5
d,	R = $CH(CH_3)_2$ [59]	>99.9:0.1
e,	R = $C(CH_3)_3$ [59]	>99.9:0.1
g,	R = $CH{=}CH_2$ [50]	>99:1
h,	R = C(=O)H [64]	95:05

Scheme 15. Complexes of **I** with aliphatic and other aldehydes; thermodynamic binding selectivities.

phenylacetaldehyde complexes (*RS,SR*)-**16b,c,f**$^+$ PF_6^- have been determined.[63] These exhibit a very high degree of homology, as illustrated by the tabulated data and overlaid structures. The PPh_3 ligand conformations are close to those of the aromatic aldehyde complexes (*RS,SR*)-**15a,d,f**$^+$ X^- in Figure 6. The distances between the rhenium and carbon stereocenters range from 2.15(1) to 2.155(12) Å. Importantly, these constitute three independent determinations and allow an "average" rhenium–carbon bond length of 2.15 Å, which is statistically shorter than that in the aromatic aldehyde complexes, to be confidently assigned. When this value is extrapolated on the "crystallographic map" in Figure 7, >99:1 *RS,SR*/*RR,SS* equilibrium mixtures are predicted.



slippage	24% / 20% / 23%
O=C bond	1.35(1) Å / 1.338(5) Å / 1.318(11) Å
angle, Re-O=C plane with Re-P bond	17.0° / 20.5° / 22.8°
C-R bend-back angle	19.2° / 19.3° / 19.0°
O=C-C-R torsion angle	76.8(16)° / 77.2(6)° / 94.5°

Figure 9. Summary of crystallographic data for complexes of **I** with aliphatic aldehydes. [63]

Although the preceding correlation gives a good agreement with experiment, there are several hints that it is fortuitous. For example, the crystal structures of the alkene complexes in Figure 3 do not show any obvious bond length trends. The styrene and piperylene complexes (*RS,SR*)-**5e**$^+$ BF_4^-, (*RR,SS*)-**5e**$^+$ BF_4^-, and (*RS,SR*)-**5i**$^+$ BF_4^-, which give lower binding selectivities in solution, do not exhibit longer rhenium–carbon bonds than isopropylethylene and allylbenzene complexes (*RS,SR*)-**5f**$^+$ BF_4^- and (*RR,SS*)-**5c**$^+$ PF_6^-, which give higher binding selectivities. Other ligands for which rhenium–carbon bond lengths do not correlate with binding selectivities are noted in Section 21. Therefore, we attribute the lower binding selectivities with aromatic aldehydes to a "small phenyl" effect, derived from slight stabilizing interactions between the aryl substituent and the cyclopentadienyl ligand in the *RR,SS* diastereomers and/or steric properties (see Sections 8, 11, 15).

21. Other Complexes of I with Aldehydes or Ketones

Additional types of aldehyde complexes of **I** have been studied. First, an O=C adduct of acrolein, **16g**$^+$ BF_4^-, has been isolated (Scheme 15).[50] This is a linkage isomer of (and precursor to) the C=C adduct **5k**$^+$ BF_4^- in Scheme 7. By analogy to complexes of **I** with monosubstituted alkenes having sp^2-hybridized vinyl substituents on the C=C unit (**5i,j**$^+$ BF_4^-, Scheme 7) the binding selectivity of **16g**$^+$ BF_4^- would be expected to be lower than that of the propionaldehyde complex **16b**$^+$ BF_4^-. However, careful NMR analyses under a variety of conditions show no evidence for a second isomer. Thus, we presume that **16g**$^+$ BF_4^- exists as a >99:1 *RS,SR*/*RR,SS* equilibrium mixture. The linkage isomer **5k**$^+$ BF_4^- also exhibits an anomalously high binding selectivity. Hence, some selectivity-enhancing factor is apparently associated with acrolein (presumably electronic) that is applicable to both O=C and C=C binding modes.

A glyoxal complex of **I**, **16h**$^+$ BF_4^-, has also been prepared (Scheme 15).[64] In solution, **16h**$^+$ BF_4^- always occurs as a 95:5 mixture of *RS,SR*/*RR,SS* diastereomers. This is presumed to be an equilibrium value. However, the NMR signals do not coalesce at 100 °C (CD_3CN). This bounds the $\Delta G^{\neq}$ value for isomerization as $\geq$20.0 kcal mol^{-1} (373 K). The high barrier is likely due to the superior π acidity of glyoxal. Isomerization barriers for aromatic aldehyde complexes **15**$^+$ BF_4^- exhibit a pronounced electronic effect, with values increasing from 8.5–8.6 kcal mol^{-1} for the *p*-methoxybenzaldehyde complex **15g**$^+$ BF_4^- to >16.6 kcal mol^{-1} for the pentafluorobenzaldehyde complex **15a**$^+$ BF_4^-.[58, 59]

Diastereomerically pure (*RS,SR*)-**16h**$^+$ BF_4^- can be crystallized. The crystal structure shows a rhenium–carbon bond slightly shorter than those of the other aldehyde complexes in Figures 6, 7, and 9 (Re–CHR 2.129(5) Å, Re–O 2.056(3) Å). This would be expected to enhance the binding selectivity—contrary to the data. As discussed for similar cases (see Sections 16, 17), a smaller effective steric size of the sp^2-hybridized C(=O)H substituent, or attractive interactions involving the cyclopentadienyl ligand in the *RR,SS* diastereomer, can be invoked. However, the approximately isosteric acrolein complex **16g**$^+$ BF_4^- behaves differently.

Formaldehyde, thioformaldehyde, and selenoformaldehyde complexes of **I** have also been synthesized and their crystal structures determined.[65] The Re–(X=C) conformations are analogous to those in the aldehyde complexes above. The rhenium–heteroatom bond lengths progressively increase, as would be expected from size and diminishing electronegativity (Re–CH_2 2.108(18), 2.199(8), 2.173(6) Å; Re–X 2.036(11), 2.381(2),

2.522(1) Å). Recently, Schenk has isolated thiobenzaldehyde, *p*-chlorothiobenzaldehyde, and *p*-methoxythiobenzaldehyde complexes of **I**.[66] Low-temperature NMR spectra show only one set of resonances, and a crystal structure of the thiobenzaldehyde complex establishes relative rhenium/carbon configurations identical to those in the more stable complexes (*RS*,*SR*)-**15**$^+$X$^-$ (Re–CHC_6H_5 2.207(9) Å, Re–S 2.376(3) Å). However, two isomers of the analogous thioacetaldehyde complex can be detected at −60 °C (96:4). This suggests that isomers of the thiobenzaldehyde complexes might be observed at still lower temperatures.[66]

A π complex of **I** and a symmetrical ketone, 1,3-difluoroacetone, has been isolated and crystallographically characterized (Re–$C(CF_3)_2$ 2.17(1) Å; Re–O 2.044(6) Å).[67] However, due to steric and electronic factors analyzed elsewhere, nearly all ketones give σ as opposed to π adducts of **I**. Regardless, based upon the data in Scheme 10 for complexes with unsymmetrically substituted geminal alkenes (**9**$^+$ BF_4^-), modest binding selectivities would be expected, except when the carbonyl substituents differ markedly in size. Early transition metal Lewis acids and fragments that are stronger π donors than **I** show a much greater preference for π ketone complexes.[51b, 68]

22. General Analysis of Chiral π-Type Receptors for Alkenes, Aldehydes, and Ketones

The approach detailed above provides a paradigm for mapping the steric properties of chiral receptors for η^2 π ligands. It would be of obvious interest to compile similar binding data for other chiral transition metal Lewis acids and compare selectivities for various types of ligands. Some relevant equilibria have been reported and are summarized below. However, it is of equal or greater importance to generalize the key concepts embodied in the preceding analysis. In particular, we seek predictive and testable models for binding selectivities with other classes of chiral receptors.

Thus, we turn from the rhenium Lewis acid **I** and the accompanying positions a–d, to the generic Lewis acid in Scheme 3 with the attendant quadrants A–D. Importantly, only six types of chiral receptors are possible for η^2 π ligands, as classified by the relative steric environments of the four quadrants. These are illustrated in **A**–**F** in Figure 10. A lower bar indicates a less congested quadrant, and a higher bar indicates a more congested quadrant. A simple integral step function is utilized for the relative heights (1–4), giving a sum of ten arbitrary units. In molecular mechanics parlance,[17b] the heights of the bars height can be viewed as "steric energy". To facilitate comparisons, quadrant A is defined as the least congested. The bars in the other quadrants then differ in the pattern of ascent. Enantiomeric receptors exist but are not depicted.

Although the analysis in Figure 10 is simple, we are unaware of any previous comprehensive treatments that encompass all six cases. Many refinements can be envisioned. For example, the relative steric environments of the quadrants certainly do not have to correspond to integral step functions. However, even at this primitive level, a number of testable predictions are easily generated. For instance, receptors **C** and **D**, in which the two least congested quadrants are *trans*, should give higher binding

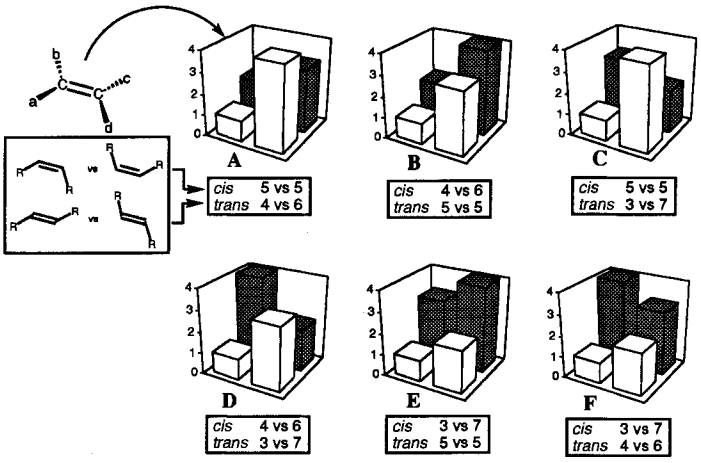


Figure 10. Types of chiral receptors for alkenes, classified by the relative steric properties of each quadrant; the values in the boxes are relative energies of the isomers.

constants with *trans*-2-butene than *cis*-2-butene—contrary to the generalization in most textbooks.[14a]

Consider receptors for symmetrically substituted *trans* alkenes, which will give two configurational diastereomers but degenerate Re–(C=C) rotamers (Schemes 2C and 3C). Binding selectivities should decrease in the order **C**,**D** > **A**,**F** > **B**,**E**. In the most selective set of receptors (**C**, **D**), the two least congested quadrants are *trans* (sum of bar heights = 3), favoring one diastereomer. The two most congested quadrants are also *trans* (sum of bar heights = 7), disfavoring the other (energy difference of four units). In the least selective receptors (**B**, **E**), the least and most congested quadrants are *trans* (sum of bar heights = 5), and the sterically intermediate quadrants are *trans* (sum of bar heights = 5). Thus, binding either enantioface results in comparable steric interactions.

Receptors for symmetrically substituted *cis* alkenes can be analyzed in the same way, and binding selectivities should decrease in the order **E**,**F** > **B**,**D** > **A**,**C**. In the most selective set of receptors (**E**, **F**), the two least congested quadrants are *cis* (sum of bar heights = 3) and the most congested quadrants are *cis* (sum of bar heights = 7). In the least selective receptors (**A**, **C**), the least and most congested quadrants are *cis* (sum of bar heights = 5), and the sterically intermediate quadrants are *cis* (sum of bar heights = 5).

Unsymmetrically substituted alkenes require slightly more involved analyses. With monosubstituted alkenes, the most stable of the four possible configurational diastereomers and Re–(C=C) rotamers will always be that with the CHR substituent in the least congested quadrant A. Thus, some degree of binding selectivity is always expected. To optimize enantioface binding selectivity, the key energy difference to maximize is that between the more stable Re–(C=C) rotamer of one configurational diastereomer and the more stable rotamer of the other. Here, receptor **D** provides a particularly favorable architecture. In one diastereomer, the substituent can occupy either of the two least congested quadrants (A or C; bar heights = 1, 2). In the other, the substituent can occupy either of the two most congested quadrants (D or B; bar heights = 3, 4). Thus, there will be a energy difference of two units (1 vs 3, quadrants A vs D).

An identical result is obtained with receptor **C**, in which the steric environments of quadrants D and B are reversed. At first

glance, receptor **D** might seem to be superior, as the least and most congested quadrants (A, D) have a geminal relationship. However, this only serves to maximize the energy difference between the more stable Re–(C=C) rotamer of the more stable configurational diastereomer and the corresponding rotamer of the least stable diastereomer. Similar analyses of the other receptors give energy differences of only one unit. However, binding selectivities can still be high, as with **I** (see also Section 23). Parallel conclusions are easily reached for aldehyde ligand receptors.

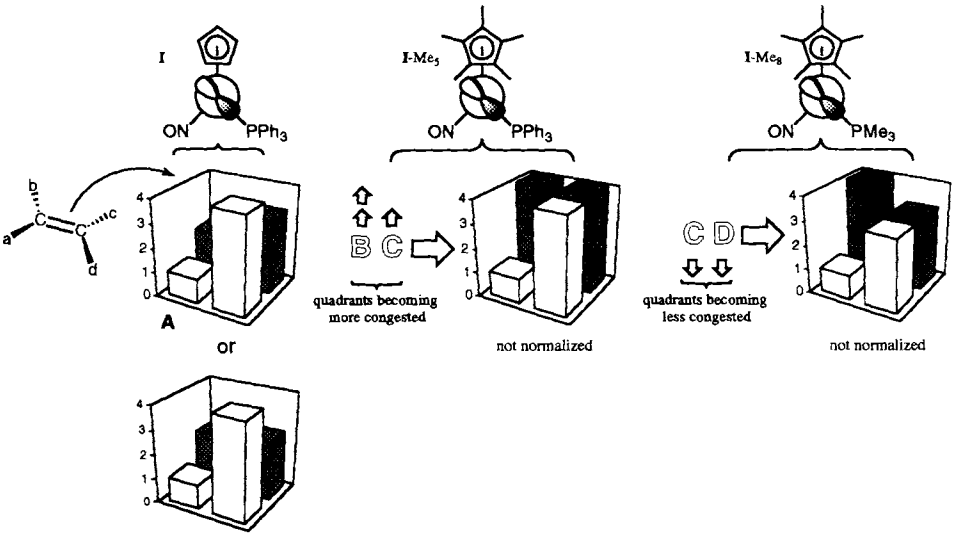

Figure 11. Some modifications of the rhenium Lewis acid **I**: steric consequences.

With unsymmetrically disubstituted alkenes, the relative size of the substituents (R_L, R_S) must be considered. As R_L becomes infinitely large relative to R_S, the binding situation asymptotically approaches that analyzed for monosubstituted alkenes. Although quantitative treatments of intermediate cases are complex,[69] many interesting qualitative observations are possible. For example, consider *cis* alkenes and receptors **C**, **D**, and **F**. In one configurational diastereomer, the R_L and R_S groups can partition into the less congested and more congested quadrants in both Re–(C=C) rotamers. However, in the other configurational diastereomer, there will be mismatches in both rotamers. Thus, receptor **C** will always give enantioface binding selectivities superior to those of its counterpart **A**. Similarly, **D** will be superior to **B**, and **F** will be superior to **E**. With geminally disubstituted alkenes, a similar situation exists for receptors **A**, **C**, and **D**, and counterparts **B**, **E**, and **F**.

Although many other relationships and predictions can be derived from Figure 10, the preceding are representative. The application to rhenium Lewis acid **I** and derivatives thereof are examined next.

23. Experimental Evolution of the Receptor Model; Modification of Lewis Acid I

23.1. General Features of Lewis Acid I

The binding selectivities given above clearly show that the chiral rhenium Lewis acid **I** belongs to receptor type **A**. However, some data suggest that the steric environments of positions b and c are likely quite close, as illustrated in the modified quadrant diagram in Figure 11. Furthermore, as elaborated in Section 24.4, such diagrams can give misleading impressions of sterically homogeneous environments within each quadrant. For reference, space-filling representations of **I**, taken from the crystal structure of propionaldehyde complex (*RS,SR*)-**16b**$^+$ PF_6^- (Figure 9), are given in Figure 12.

Of the receptors in Figure 10, **A** clearly represents a good choice for giving appreciable binding selectivities with a broad range of alkenes. For example, **I** binds monosubstituted alkenes with high enantioface binding selectivities (minimum 90:10) and

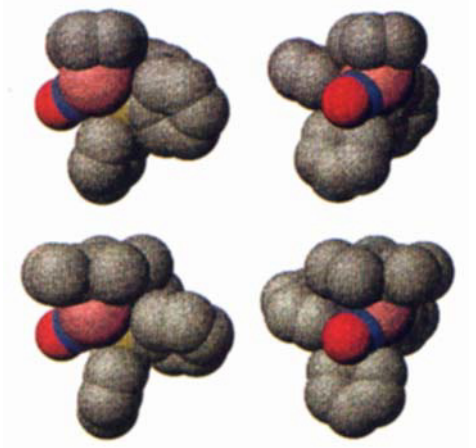

Figure 12. Space-filling models of **I** (top) and **I**-Me_5 (bottom) with atoms at van der Waals radii, taken from the crystal structures of propionaldehyde complexes (*RS,SR*)-**16b**$^+$ PF_6^- and (*RS,SR*)-**16b**-Me_5^+ PF_6^-, respectively.

trans alkenes with even higher enantioface binding selectivities (minimum 98:2). Many types of trisubstituted alkenes should also be bound with high selectivities. However, *cis* and unsymmetrically substituted geminal alkenes generally give lower binding selectivities.

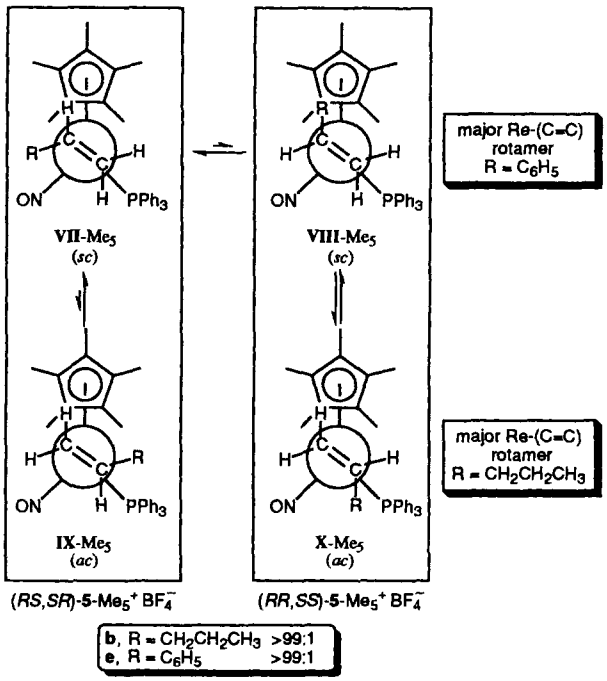
With **I**, a "small phenyl" effect is observed in equilibria that involve position b. Although steric interactions of the cyclopentadienyl ligand and groups in position b are unfavorable, there is apparently an ameliorating interaction involving cyclopentadienyl C–H bonds and the π electron clouds of aryl and other unsaturated substituents.[44] This phenomenon also seems to be manifested to varying degrees in positions c and d, presumably involving phenyl C–H bonds of the conformationally flexible PPh_3 ligand.

23.2. Modifications of I

The preceding analysis suggests several structural modifications of **I** that may give improved binding selectivities for certain types of alkenes. In particular, the cyclopentadienyl ligand

could be replaced by the bulkier and more electron-releasing[70] pentamethylcyclopentadienyl ligand. Electronically, the resulting Lewis acid **I**-Me_5 would be a somewhat weaker acceptor and stronger donor, but with frontier orbitals analogous to those of **I**. However, quadrant B would now be much more congested, and quadrant C would be slightly more congested (Figure 11).

Although it would be difficult to predict the relative steric congestion in quadrants B–D in advance, it is immediately obvious that binding selectivities for monosubstituted alkenes and unsymmetrically substituted geminal alkenes should be enhanced. Data for the 1-pentene and styrene complexes of **I**-Me_5, **5b**,**e**-Me_5^+ BF_4^-, are given in Scheme 16.[71] As anticipated, the *RS*,*SR*/*RR*,*SS* equilibrium ratios are much higher (>99:1).[72] Also, low-temperature NMR spectra of π aldehyde complexes of **I**-Me_5 show only one diastereomer.[73]



Scheme 16. Complexes of **I**-Me_5 with monosubstituted alkenes; thermodynamic binding selectivities [71].

As would be expected, the propionaldehyde adduct crystallizes as the *RS*,*SR* diastereomer.[73] The orientation of the propionaldehyde ligand is close to that in the cyclopentadienyl analog, except for an roughly 120° clockwise change in conformation about the $=CH-CH_2$ bond. Space-filling representations of the **I**-Me_5 moiety in this structure are given at bottom of Figure 12 and allow the greater bulk of the pentamethylcyclopentadienyl ligand to be easily visualized. There appears to be a slight secondary effect upon the phosphorus–carbon conformations in the PPh_3 ligand.

The less stable *RR*,*SS* diastereomers of **5b**,**e**-Me_5^+ BF_4^- exhibit some unique characteristics. Low-temperature NMR spectra do not show distinct Re–(C=C) rotamers. However, ^{13}C NMR spectra of the 1-pentene complex (*RR*,*SS*)-**5b**-Me_5^+ BF_4^- indicate that the rotamer with the CHR terminus *syn* to the PPh_3 ligand (*ac*) is dominant—in contrast to the corresponding adducts of **I** (Scheme 6). However, with the styrene complex (*RR*,*SS*)-**5e**-Me_5^+ BF_4^-, the opposite rotamer (*sc*) appears to be dominant. Thus, to some extent a "small phenyl" effect seemingly operates in position b of the Lewis acid **I**-Me_5, where cyclopentadienyl C–H···π interactions are not possible. Regardless, the steric environment in quadrant B has become comparable to that in quadrant D.

Modifications of **I**-Me_5 can in turn be considered. For example, the substitution of PPh_3 by PMe_3, which has a smaller cone angle, would give "**I**-Me_8" (Figure 11). This Lewis acid would be less congested in quadrants C and D. In the event that quadrant D is in turn less congested than C, the two most spacious quadrants are *cis* (A, D), but maintain an appreciable steric difference. This receptor, which is a variant of **F** in Figure 10, should be particularly favorable for the selective binding of unsymmetrically substituted *cis* alkenes such as *cis*-2-pentene. If quadrant C is less congested than D (variant of receptor **D**), high selectivities are also possible. When quadrants C and D are sterically comparable, monosubstituted, *trans*, and *cis* alkenes with identical CHR substituents should give nearly identical binding selectivities.

Some adducts of **I**-Me_5 are not as configurationally stable as those of **I**.[71] However, the trifluorinated pentamethylcyclopentadienyl ligand, $C_5Me_4CF_3$, is now readily available.[74] This ligand has an inductive effect similar to that of the cyclopentadienyl ligand, which may enhance configurational stability. However, the steric bulk is identical with that of pentamethylcyclopentadienyl. Thus, the Lewis acid $[(\eta^5\text{-}C_5Me_4CF_3)Re(NO)(PPh_3)]^+$ should give alkene binding selectivities comparable to those of **I**-Me_5 and possibly greater configurational stability. The electronic properties could be optimized by increasing or decreasing the number of fluorines.

24. Further Refinements in the Receptor Model

24.1. Receptors with C_2 Symmetry

Chiral reagents and catalysts with C_2 symmetry are frequently employed in enantioselective syntheses. This popular design element minimizes the number of possible competing diastereomeric transition states, facilitating analyses. With C_2 receptors, the two pairs of *trans* quadrants (A and C, B and D) will have identical steric environments. As a result, M–(X=C) rotamers become degenerate. This greatly reduces the number of possible isomeric alkene complexes in Scheme 2. In fact, isomers are no longer possible with symmetrically substituted *cis* or geminal alkenes.

Two possible steric profiles are illustrated in **G** and **G'** in Figure 13. These are distinguished by the difference in congestion between the pairs of *trans* quadrants (sum of bar heights 2 vs 8, or 4 vs 6). It is apparent that as the difference becomes greater, enantioface binding selectivities for monosubstituted alkenes, unsymmetrically substituted geminal and *cis* alkenes, and all types of *trans* alkenes, will increase.

24.2. Binding Thermodynamics

In Figure 10, the sum of the heights of the four bars is normalized to ten arbitrary units of steric energy. However, other re-

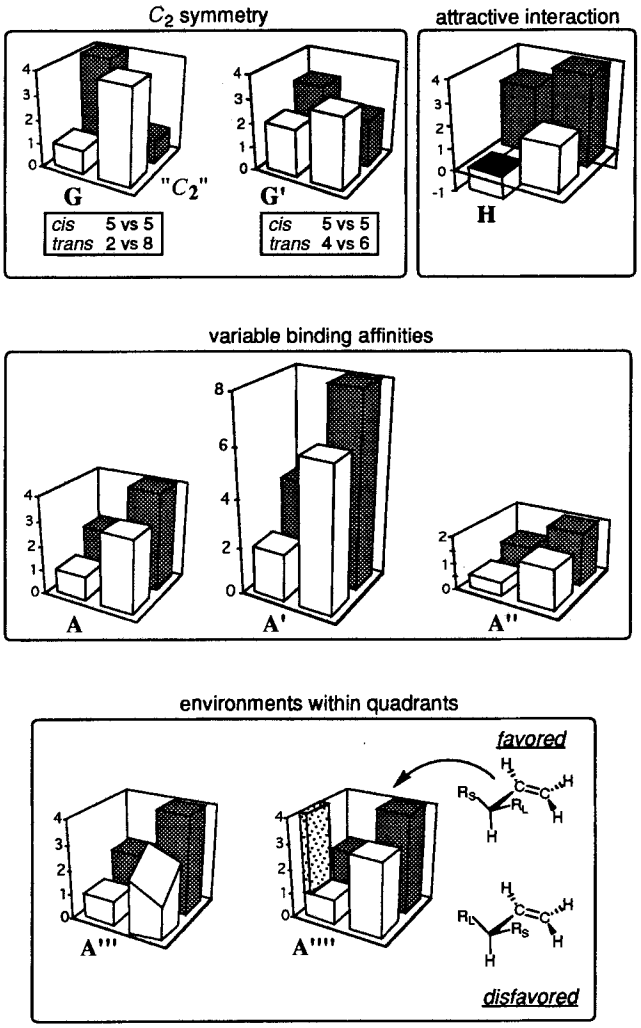


Figure 13. Extensions and refinements of the receptor model in Figure 10.

ceptors might give intrinsically weaker or stronger binding. Higher bars could represent receptors with poorer thermodynamically weaker binding strengths. For example, the bars in **A'** in Figure 13 are normalized to twenty arbitrary units, which could indicate a binding energy half of that of **A** with respect to a calibrating ligand. Conversely, the bars in **A''** in Figure 13 are normalized to five arbitrary units, indicating a binding energy twice that of **A**.

24.3. Attractive Interactions

Figure 10 was formulated in the context of simple repulsive steric interactions. However, some receptors may be capable of special attractive interactions with certain types of X=C substituents. These numerous possibilities would include hydrogen bonding, dipole–dipole, and charge transfer interactions. The "small phenyl" effect with **I** is likely due, at least in part, to attractive interactions involving the cyclopentadienyl ligand. However, in this example unfavorable steric interactions are only ameliorated. In extreme cases, the situation illustrated in receptor **H** (Figure 13) might be realized. Here, a strongly attractive interaction is indicated by a negative energy. However, this feature can also be arbitrarily introduced in all receptors by slightly raising the energetic "floor". Conversely, special repulsive interactions that do not have a steric origin (for instance dipole–dipole) may sometimes need to be considered.

24.4. Environments within Quadrants, and Chiral Ligands

For most chiral transition metal Lewis acids, the steric congestion in each quadrant will diminish with increasing distance from the X=C binding site. This is illustrated in quadrant D of receptor **A'''** (Figure 13). However, in some specialized situations, the reverse may occur, as depicted by the "steric wall" in quadrant A of **A'''**. Similarly, "pockets" commonly surround enzyme receptors, allowing substrates of only a limited size range to be bound. These might be encountered, for example, in metal complexes with dendrimer-type ligands,[75a] or macrocyclic ligands containing "picket fences".[75b]

Although the previous two examples are adequate for some purposes, a more general approach would be to subdivide each quadrant into subquadrants. This would allow chiral environments within quadrants to be represented. In this context, the binding equilibria described above generally involve prochiral ligands. However, if receptors are to be designed to selectively bind one enantiomer of a chiral ligand, such additional levels of analysis are required. For example, consider a monosubstituted alkene with an allylic stereocenter ($H_2C{=}CHCHR_SR_L$) as discussed in Section 3.3. Assume that the lowest energy conformation about the =CH–C bond always has the allylic hydrogen pointing "down", as illustrated in Figure 13. A receptor such as **A'''** would then selectively bind the enantiomer in which R_S, not R_L, abuts the "steric wall".

In unpublished studies, several complexes of the chiral rhenium Lewis acid **I** and chiral monosubstituted alkenes and aldehydes of the type $X{=}CHCHR_SR_L$ have been prepared. The rhenium precursors were enantiomerically pure, whereas the ligands were racemic. However, in no case was a significant preference (>67:33) for binding one enantiomer observed. Actually, this is to be expected from the data in Scheme 6. Kinetic binding selectivities are almost always modest, and coordinated ligands exchange with free ligands only at very high temperatures, if at all. In order to attain equilibrium with respect to the CHR_SR_L stereocenter, exchange with a pool of racemic ligand would be required.

Finally, it should be noted that receptors that would selectively bind one enantiomer of certain special classes of chiral alkenes are easily visualized. For example, any receptor that can discriminate between the enantiofaces of *trans*-2-butene should be able to discriminate between the enantiomers of *trans*-cyclooctene. Similarly, any receptor that can discriminate between the enantiofaces of unsymmetrically substituted *cis* alkenes should be able to discriminate between the enantiomers of helically chiral *cis* alkenes.[76]

24.5. Alternative Constructs

Some of the chiral receptors in Figure 10 have been previously analyzed in alternative but equivalent ways. For example,

Marks et al. have prepared a family of chiral bis(cyclopentadienyl) lanthanide catalysts for the enantioselective hydrogenation and hydroamination of alkenes.[77] As represented in Figure 14, the larger cyclopentadienyl ligand is pentasubstituted, and the smaller is disubstituted, with one group chiral. These likely contain alkene binding sites analogous to that of receptor **A**. Marks et al. have analyzed the enantioselectivities in terms of "lateral" and "transverse" shape discrimination, as defined in Figure 14.

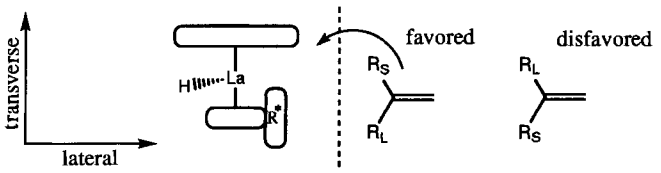

Figure 14. An alternative analysis of receptors [77].

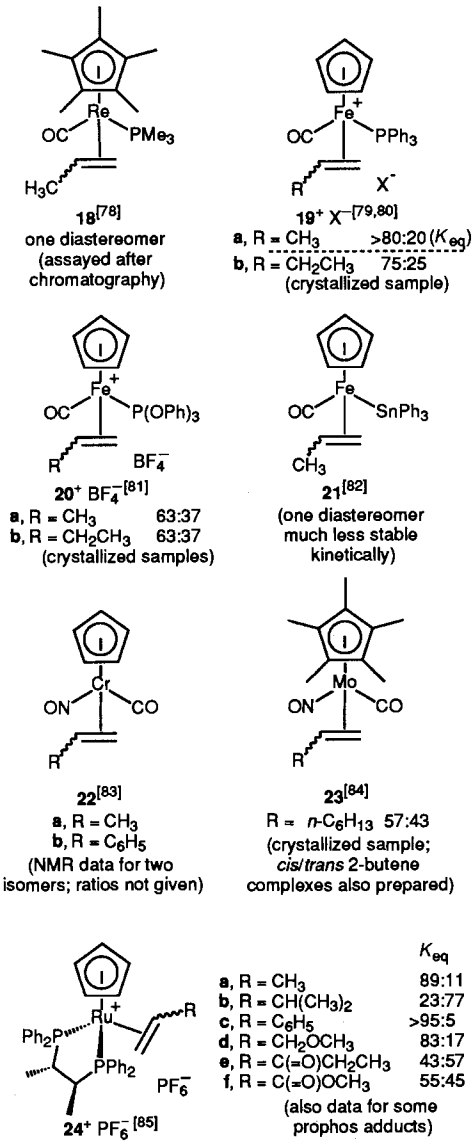
25. Chiral Recognition in Other Alkene, Aldehyde, and Ketone Complexes

A variety of other complexes of chiral transition metal Lewis acids and prochiral η^2 π ligands have been prepared. However, there is no practical, systematic way to search the literature for all examples. Furthermore, in many cases binding equilibria have only been partially characterized. Often, diastereomer ratios are reported after workup and without configurational assignments. All data that the authors have been able to locate over several years are summarized in Schemes 17A–F. Ratios that unambiguously constitute equilibrium values are designated K_{eq}.

25.1. Alkene Complexes of Other d^6 [(η^5-C_5R_5)M(L)(L')] Lewis Acids

These are the most closely related to alkene complexes of **I**, and will be considered in the order grouped in Scheme 17A. First, the propene complex of the neutral rhenium Lewis acid [(η^5-C_5Me_5)Re(CO)(PMe_3)] (**18**) has been isolated in diastereomerically pure form in 36% yield following chromatography.[78] Of course, this does not in itself establish a high thermodynamic binding selectivity for one propene enantioface. However, this Lewis acid is isoelectronic and isosteric with the nitrosyl-substituted cation **I**-Me_8 (Figure 11), and a very high binding selectivity is most probable. Although the relative configurations of the rhenium and carbon stereocenters in **18** were not determined, they are very likely analogous to those of (*RS*,*SR*)-**5**-Me_n^+ X^- (n = 0, 5; Schemes 7 and 16).

The cationic iron propene complex **19a**$^+$ X^- can be viewed as isoelectronic with the rhenium propene complex **5a**$^+$ BF_4^-. The frontier orbitals and steric properties of the iron fragment should be similar to those of **I**. Furthermore, metal–ligand bonds in this first-row metal complex will be 6–9% shorter, which should enhance chiral recognition. The configurational diastereomers of **19a**$^+$ TfO^- interconvert below room temperature, and the equilibrium ratio can be bound as >80:20.[79] The



Scheme 17A. Alkene complexes of other d^6 [(η^6-C_5H_5)M(L)(L')] chiral transition metal Lewis acids with prochiral alkenes and aldehydes. K_{eq} = equilibrium constant.

analogous 1-butene complex **19b**$^+$ BF_4^- has been isolated as a 75:25 mixture of diastereomers.[80] Some data are also available for the related iron complexes **20**$^+$ BF_4^- and **21**.[81, 82] A closer investigation of these compounds may establish high thermodynamic binding selectivities. However, in no case have the relative configurations of the iron and carbon stereocenters yet been established.

The neutral chromium and molybdenum alkene complexes **22**[83] and **23**[84] have been synthesized. Since nitrosyl ligands are stronger π acceptors than carbonyl ligands, both metal fragments will have d orbital HOMOs similar to that of **I**.[28a] However, due to the identical sizes of the nitrosyl and carbonyl ligands (and the absence of a bulky phosphane ligand), the steric properties of the four quadrants should not be as differentiated. Based upon the limited data available, monosubstituted alkenes appear to give low binding selectivities. Nonetheless, highly diastereoselective syntheses involving nucleophilic additions to cationic π allyl precursors have been reported.[84b]

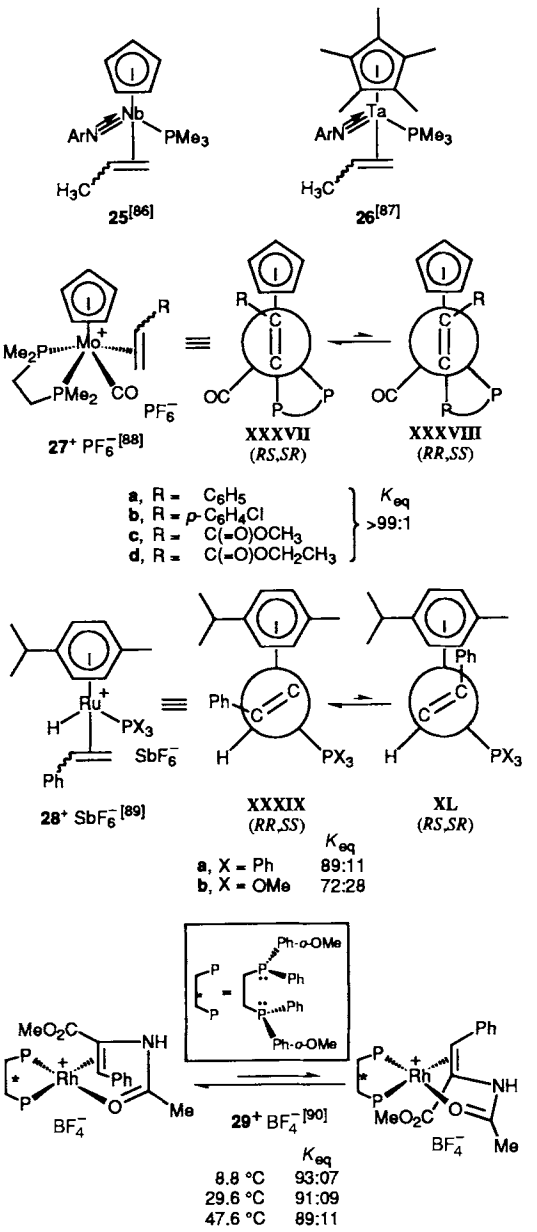
A series of cationic chiraphos ruthenium alkene complexes, $\mathbf{24}^+ PF_6^-$, and prophos analogs with one less methyl group, have been reported.[85] In contrast to the preceding examples, complexes $\mathbf{24}^+ PF_6^-$ have ligand-based chirality. The diastereomers interconvert rapidly in solution, and relative configurations have been assigned by NMR. Styrene exhibits a slightly higher enantioface binding selectivity than propene (>95:5 vs 89:11), in contrast to the situation with **I**. Curiously, isopropylethylene gives an opposite binding selectivity (23:37). This might reflect some nonideal behavior of the ruthenium receptor such as changes in the chiraphos ligand or Ru–(C=C) conformations. With regard to the latter, the energies of the two highest occupied d orbitals are likely more closely spaced than with the other Lewis acids in Scheme 17A. Alternatively, the phenyl groups of the chiraphos ligand may create some type of pocket or "steric wall" that for one diastereomer readily admits the substituents on the C=C units of propene and styrene, but not that of isopropylethylene. Crystallographic data that would help address these possibilities are not yet available.

25.2. Alkene Complexes of Other Non-Platinum Chiral Lewis Acids

These are grouped in Scheme 17B. The only adducts of early transition metal chiral Lewis acids that appear to have been isolated to date are the four-coordinate niobium and tantalum propene complexes **25** and **26**[86,87] and the zirconium(II) complexes **47** (Scheme 17F). Electronically, these differ considerably from alkene complexes of **I** or **I**-Me_8 (e.g. d^2 vs d^6). However, the types of spectator ligands **25** and **26** can be viewed as similar; the nitrosyl ligand is replaced by a larger NAr moiety. In solution, all four possible configurational diastereomers and M–(C=C) rotamers can be detected. Binding selectivities are modest. With **25**, the diastereomer ratio can be bound as 60:40–80:20 (74:26 and 58:42 rotamer ratios).[86] Nonetheless, only one isomer crystallizes. The relative configurations of the metal and carbon stereocenters and the M–(C=C) conformation are identical to those in **VII** (Scheme 6), the most stable isomer for monosubstituted alkene complexes of **I** (angle of niobium-carbon-carbon plane with Nb–P bond, 7.1°).

Several complexes of five-coordinate, cationic molybdenum with monosubstituted alkenes, $\mathbf{27}^+ PF_6^-$, and analogs with the "pom-pom" ligand $(MeO)_2PCH_2CH_2P(OMe)_2$ have been prepared.[88] These have metal-centered chirality, and the configurational diastereomers equilibrate in solution at room temperature. In all cases, binding selectivities are very high (>99:1). Several crystal structures have been determined, and the relative configurations and Mo–(C=C) conformations depicted in **XXXVII** (more stable) and **XXXVIII** (less stable) established. With these fragments, it would seem particularly worthwhile to map the relative steric properties of the quadrants through additional binding studies. The available data indicate that the two least congested quadrants have a geminal relationship (both *syn* to the cyclopentadienyl ligand), and the receptor is likely of type **B** (Figure 10).

Recently, the cationic arene ruthenium styrene complexes $\mathbf{28}^+ SbF_6^-$ were isolated.[89] Although the metal fragment lacks a cyclopentadienyl ligand, there are some similarities with the



Scheme 17B. Alkene complexes of other chiral non-platinum Lewis acids.

Lewis acids in Section 25.1. In solution, the configurational diastereomers rapidly equilibrate below room temperature. Depending upon the phosphorus donor ligand, styrene enantioface binding selectivities can be as high as 89:11. A crystal structure and extensive NMR analyses establish the configurations and Ru–(C=C) conformations shown in **XXXIX** (more stable) and **XL** (less stable). Only very small quantities of the alternative Ru–(C=C) rotamers are present. Hence, the two least congested quadrants of this receptor have a *cis* relationship.

Square-planar adducts of chiral rhodium Lewis acids and chelating trisubstituted alkenes, such as $\mathbf{29}^+ BF_4^-$,[90] are intermediates in a large family of highly enantioselective catalytic hydrogenation reactions. These have ligand-based chirality. Binding selectivities are high and depend slightly upon temperature. Selectivities are even higher with complexes having other chelating diphosphanes. However, as emphasized in other sections of this review, the least stable isomers are more reactive.[90]

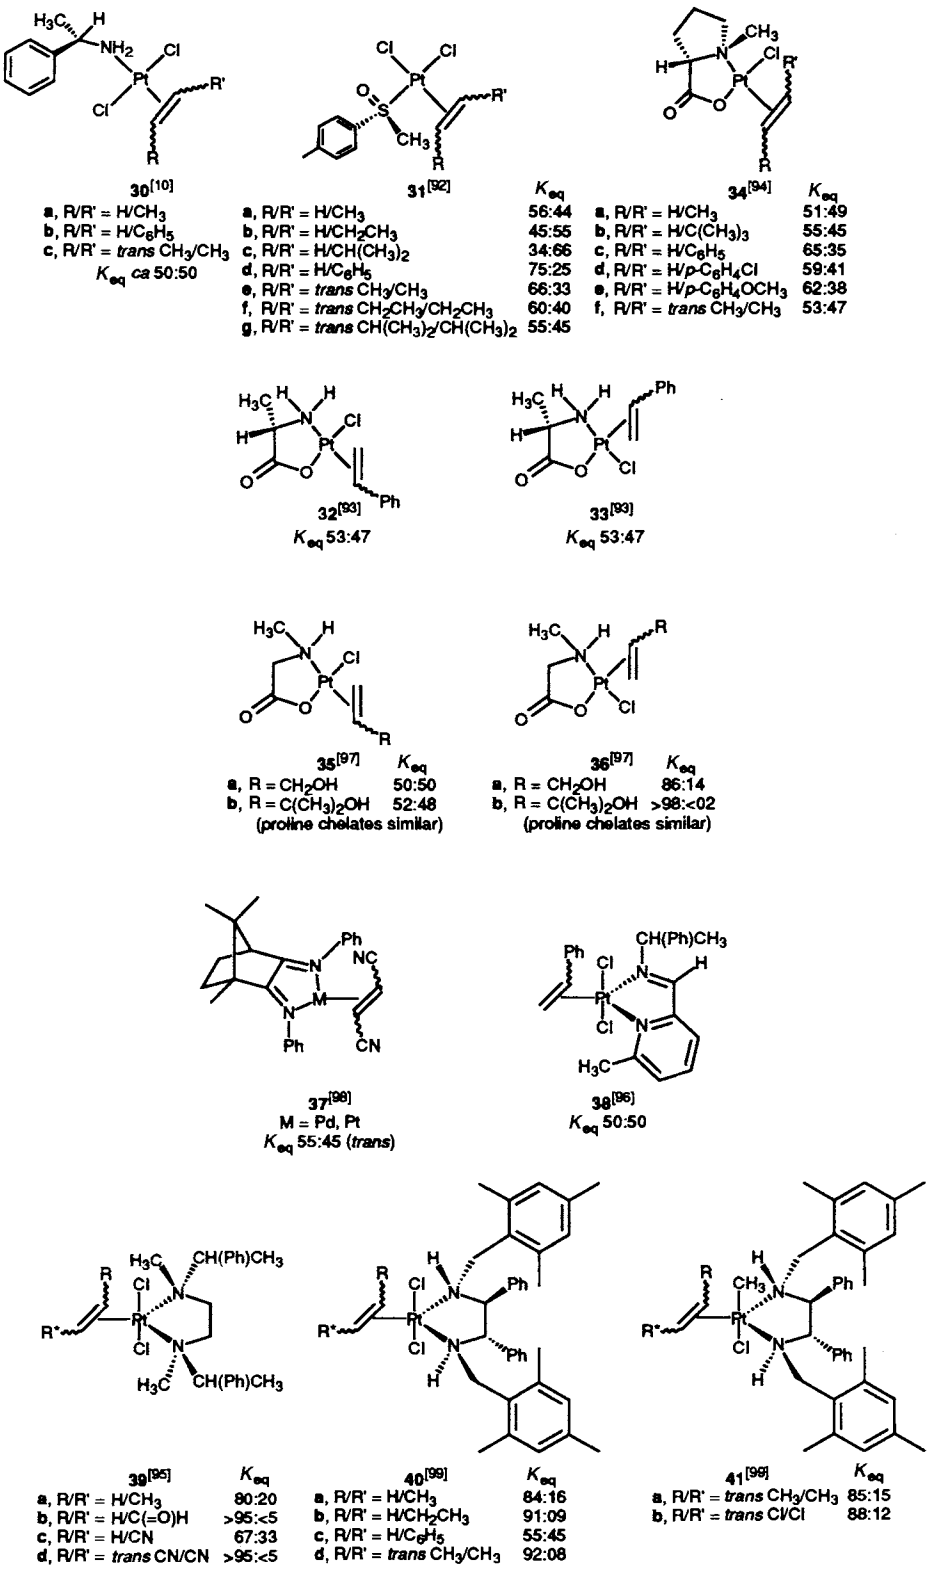
25.3. Alkene Complexes of Chiral Platinum Lewis Acids

Equilibrium data are available for alkene complexes of several types of chiral d^8 platinum(II) Lewis acids, as summarized in Scheme 17C.[10, 91–99] All of these have ligand-based chirality, and in most cases configurations have been assigned. Note that the configurations of any stereogenic nitrogen donor atoms, which would rapidly invert in the free ligands, become fixed upon coordination. In the absence of special features (discussed below), four-coordinate square-planar adducts uniformly give poor alkene enantioface binding selectivities. However, with five-coordinate trigonal-bipyramidal adducts, binding selectivities can be much higher.

In the square-planar complexes **30**,[10] the alkene is *trans* to a chiral primary amine. The stereocenter is one atom removed from platinum, and alkene enantioface binding selectivities are very low. With **31**,[92] the alkene is *cis* to a sulfoxide ligand stereocenter, and binding selectivities are slightly higher. Trends seem to parallel those noted with $\mathbf{24}^+ PF_6^-$: styrene gives a higher binding selectivity than propene (75:25 vs 56:44), and isopropylethylene exhibits an opposite binding selectivity (34:66). With the chelating *N*-methylproline derivatives **34**,[94] the alkene is *trans* to a *tertiary* nitrogen stereocenter. Binding selectivities remain low. Adducts of styrene, *p*-chlorostyrene, and *p*-methoxystyrene have been characterized. Curiously, electron-withdrawing and electron-donating *para* substituents both slightly lower binding selectivities (59:41 and 62:38 vs 65:35).

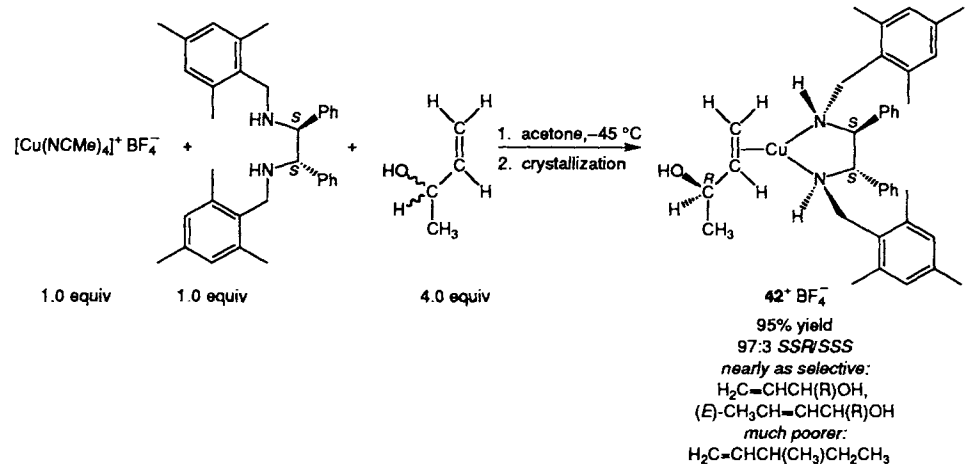
In contrast to **34**, the chelating nitrogen in the alanine derivatives **32** and **33**[93] is not a stereocenter. Styrene enantioface binding selectivities become even lower (53:47). With the sarcosine derivatives **35** and **36**,[97] nitrogen stereocenters—now secondary—are restored. The alkene and nitrogen are *cis* in the latter, and allylic alcohols now give high binding selectivities (>98:2–86:14). When the allylic alcohol and nitrogen are *trans* as in **35**, binding selectivities plummet (52:48–50:50). This suggests some type of special attractive interaction involving one quadrant of the metal fragment in **36** (see **H** in Figure 13). Indeed, the crystal structure of **36b** shows a close contact of the NH proton and the alcohol oxygen.[100] Since sarcosine lacks a carbon stereocenter, **35** and **36** cannot be directly obtained in nonracemic form. However, proline analogs of **36** give only slightly diminished binding selectivities.

The trigonal-bipyramidal complexes **40**[99] feature a C_2-symmetric receptor with a chiral secondary diamine. The configurations of the nitrogen stereocenters are controlled by carbon



Scheme 17C. Alkene complexes of chiral platinum Lewis acids.

stereocenters in the chelate backbone. Propene, 1-butene, and *trans*-2-butene give high enantioface binding selectivities. As would be expected from the quadrant diagrams for C_2-symmetric receptors (**G**, **G'** in Figure 13), the equilibrium constant for *trans*-2-butene (which must bind in a matched or mismatched manner with respect to *both* $CHCH_3$ termini) is greater than that of propene (92:8 vs 84:16). Curiously, styrene gives a much lower selectivity (55:45). Related complexes in which a methyl ligand has replaced one axial chlorine (**41**) have been characterized.[99] The binding selectivity for *trans*-2-butene is slightly lower (85:15).



Scheme 17D. Reactions of a chiral copper Lewis acid and racemic chiral alkenes [103].

Complexes **39** feature a C_2-symmetric receptor with two tertiary amino groups.[95] Chirality is now derived from carbon stereocenters on the N-alkyl groups and not stereocenters in the chelate backbone. Propene shows a slightly lower binding selectivity than with **40** (80:20 vs 84:16). Fumaronitrile, with two *trans* CN groups, gives a higher diastereomer ratio than acrylonitrile (>95:5 vs 67:33). In all of these C_2-symmetric systems, the more stable diastereomers are believed to have the CHR substituents *trans* to the bulkier nitrogen substituents (*cis* to NH or NCH_3). Complex **38**[96] can be regarded as an sp^2 nitrogen donor analog of **39**, but with only one chiral N-alkyl group. While it is not surprising that the binding selectivity is low, it would be interesting to study a C_2-symmetric variant. The three-coordinate complex **37**[98] also contains a chelate ligand with two sp^2 nitrogen donors, but the carbon stereocenters are further removed from the binding site. Accordingly, fumaronitrile gives a much lower enantioface binding selectivity (55:45) than in **39**.

25.4. Complexes of Chiral Alkenes

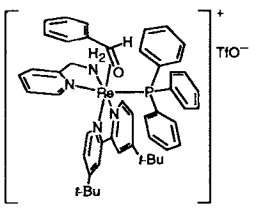
Although chiral alkenes are outside the focus of this review, several points deserve attention in passing. First, chiral platinum Lewis acids have played a historically important role in the resolution of racemic chiral alkenes, such as *trans*-cyclooctene.[101, 102] However, they have been used to complex both enantiomers. The diastereomers were then physically separated and the enantiomerically pure alkenes then detached. Hence, thermodynamic binding selectivities were not factors. Approaches to designing receptors that can selectively bind one enantiomer of a chiral alkene are discussed in Section 24.3.

Towards this end, a chiral d^{10} copper(I) Lewis acid has recently been reported that can efficiently discriminate between the enantiomers of chiral secondary allylic alcohols.[103] As illustrated in Scheme 17D, equimolar quantities of $[Cu(NCMe)_4]^+ BF_4^-$ and the same C_2-symmetric chelating diamine utilized in **40** (Scheme 17C) are combined. Then an excess of racemic 3-buten-2-ol is added. Crystallization gives the alkene complex **42**$^+$ BF_4^- in 95% yield and 97% diastereomeric purity. Although additional tests would be desirable, this almost certainly reflects a high thermodynamic binding selectivity rather than any type of kinetic effect. Structural data are not yet available, but with the *SS* diamine the *R* alcohol is preferentially bound. Chiral alkenes without allylic OH-substituted stereocenters give much lower binding selectivities, suggesting that a special attractive interaction involving the hydroxyl group plays a key role.[100]

A further conceptual step would entail the selective reaction or "kinetic resolution" of one enantiomer of a chiral alkene. Of course, such processes do not have to involve a metal alkene complex. However, only this category is considered here. A relatively early example would be the (binap)ruthenium(II)-catalyzed hydrogenation of chiral secondary allylic alcohols.[104] Enantiomers typically exhibit 11- to 75-fold rate differences. However, this versatile catalyst system remains difficult to interpret. More recently, a chiral zirconium catalyst has been found to effect highly selective carbomagnesations of the C=C moieties of chiral 2-alkyl dihydropyrans.[105] The enantiomers normally react at much different rates. A related chiral titanium catalyst effects highly selective hydrogenations of the N=C moieties of one enantiomer of substituted dihydropyrroles.[106] In both systems, there is excellent evidence and precedent for the structures of the intermediate Lewis acids and X=C adducts. These lead to convincing rationales for the observed selectivities. Related complexes and transformations are highlighted in Section 26 on reactivity.

25.5. Aldehyde and Ketone Complexes of Other Chiral Transition Metal Lewis Acids

To our knowledge, binding selectivities have been reported for only one other π adduct of an aldehyde and a chiral transition metal Lewis acid, the rhenium benzaldehyde complex **43**$^+$ TfO^- (Scheme 17E).[107] Careful NMR measurements indicate a >97:3 mixture of configurational diastereomers. The relative configurations and Re–(O=C) conformation depicted in Scheme 17E are likely. This receptor, which has relatively few degrees of freedom, is well suited for binding studies, steric analyses of quadrants, and structural modifications and/or optimization, in analogy to the studies on **I**. It seems probable that



43⁺ TfO⁻[107]
K_{eq} >97:3

Scheme 17E. Benzaldehyde complex of a chiral rhenium Lewis acid.

the least and most congested quadrants have a *trans* relationship.

We are not presently aware of any π complexes of prochiral ketones and chiral transition metal Lewis acids.[68] However, a chiral titanium catalyst depicted in Scheme 19 probably gives high binding selectivities with aryl ketones.

25.6. Addendum

Additional complexes of chiral transition metal Lewis acids and prochiral alkenes that have come to our attention since this review was accepted for publication are summarized in Scheme 17F. These include three examples of d^6 $[(\eta^5\text{-}C_5R_5)\text{-}M(L)](L'$ Lewis acids (**44**⁺ BAr_4^-, **45**⁺ BAr_4^-, **46**⁺ X^-).[127, 128] The zirconium complexes **47** are especially noteworthy.[129] These can be crystallized at low temperature, and NMR spectra show only one isomer. Given the variety of highly enantioselective transformations catalyzed by closedly related Lewis acids (cf. Scheme 19), high binding selectivities with many types of alkenes can be anticipiated.

The C_2-symmetric copper Lewis acid in **52**⁺ PF_6^- gives very high binding selectivities with a variety of aromatic alkenes.[134] The crystal structure of the styrene complex **52a**⁺ PF_6^- shows that the phenyl substituent occupies a cleft where it is roughly coplanar to one mesityl group and perpendicular with the other. This is consistent with attractive interactions discussed in Sections 8, 11, 15, and 20, and such tandem effects have great promise as general design elements in chiral recognition. This interpretation is further supported by the much lower binding selectivity of vinylcyclohexane (**55g**⁺ PF_6^-) and aromatic alkenes with *ortho* substituents that disrupt the edge–face interaction (**55d,e**⁺ PF_6^-). The binding selectivities are too high for electronic effects analogous to those in Scheme 14 to be measured.

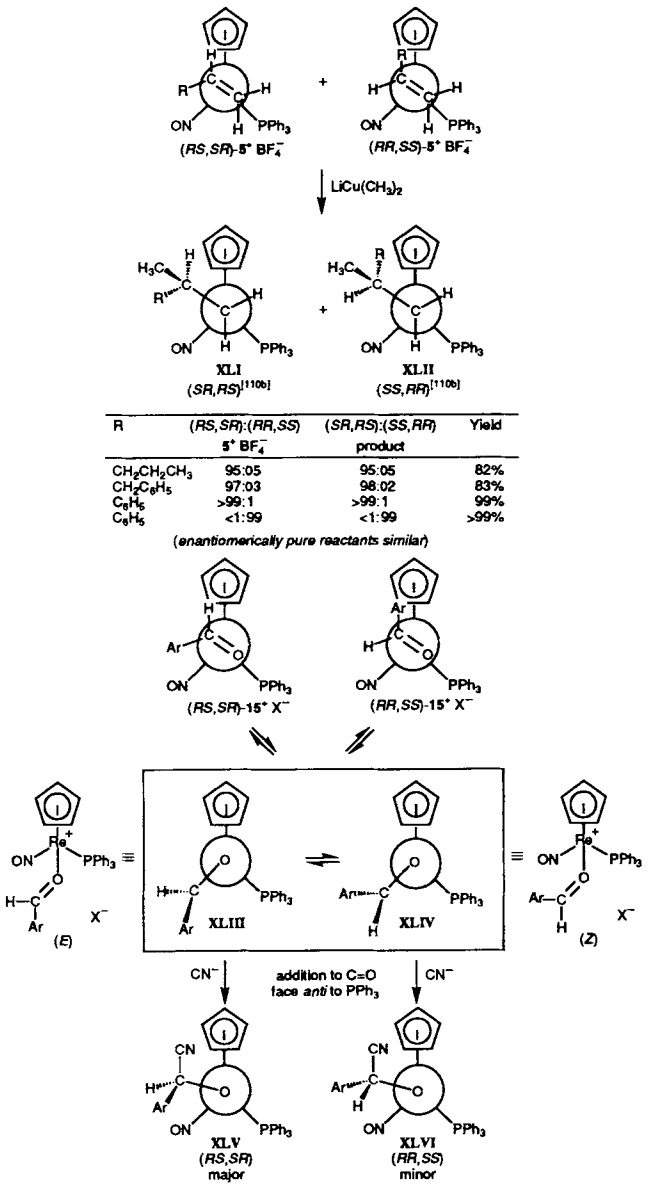
26. Binding, Reactivity, and Product Selectivity

Does the extensive body of binding data analyzed above lead to any insight regarding reactivity or optimization of product selectivity? Indeed, for many Rh^I-catalyzed enantioselective hydrogenations, the less stable configurational diastereomer of the intermediate alkene complex (see **29**⁺ BF_4^-, Scheme 17B) is known to be more reactive.[90, 108] However, transition state properties are commonly correlated to and interpreted in the context of reactant and product properties. Thus, for a given transformation, the enantioselectivities obtained with various types of alkenes could be compared to the enantioface binding selectivities of different chiral metal receptors (**I**, **I**-Me_5, **I**-Me_8, etc.). A correlation could be used as evidence for the steric environment of the transition state.

Consider first the more easily visualized realm of stoichiometric transformations and an attack of an external reagent upon the π ligand that fixes a product stereocenter. When the equilibration of configurational diastereomers is slow relative to the rate of the attack, diastereomer ratios will directly translate into product enantiomer ratios.[109] Enantioselectivities will be high 1) when kinetic binding selectivities are high, or 2) when thermodynamic binding selectivities are high and equilibration can be effected prior to reagent addition. Interestingly, the potential importance of high kinetic binding selectivities in enantioselective transformations does not appear to be widely appreciated. In this case, the activating Lewis acid, ligand, and attacking agent can be combined in a simple sequential operation, whereas with case 2 an intervening step is required (for example Scheme 7 for alkene complexes of **I**).

When the equilibration of configurational diastereomers is rapid relative to the rate of attack, the Curtin–Hammett limit will apply,[3] and product enantioselectivities will be determined by the differences in energies of the competing transition states. In some cases, there will be a correlation with binding selectivities, and in other cases (such as the Rh^I-catalyzed hydrogenations) none.

In these contexts, the additions of nucleophiles to complexes of **I** with monosubstituted alkenes and aldehydes are instructive. As shown in Scheme 18, the former are attacked at the substituted carbons and on the C=C faces opposite the rhenium to give neutral alkyl complexes with C_β stereocenters (**XLI**, **XLII**).[110] The enantiomer and diastereomer ratios of the products are identical with those of the reactants. Thus, additions are enantiospecific, diastereospecific, and regiospecific.[8] In contrast, similar additions to aldehyde complexes give alkoxide complexes (**XLV**, **XLVI**) in which the diastereomer ratios do not match those of the reactants.[63a, 73, 111, 112] Rate studies and other



R	(RS,SR):(RR,SS) $5^+ BF_4^-$	(SR,RS):(SS,RR) product	Yield
$CH_2CH_2CH_3$	95:05	95:05	82%

C_6H_5	>99:1	>99:1	99%
C_6H_5	<1:99	<1:99	>99%

(*enantiomerically pure reactants similar*)

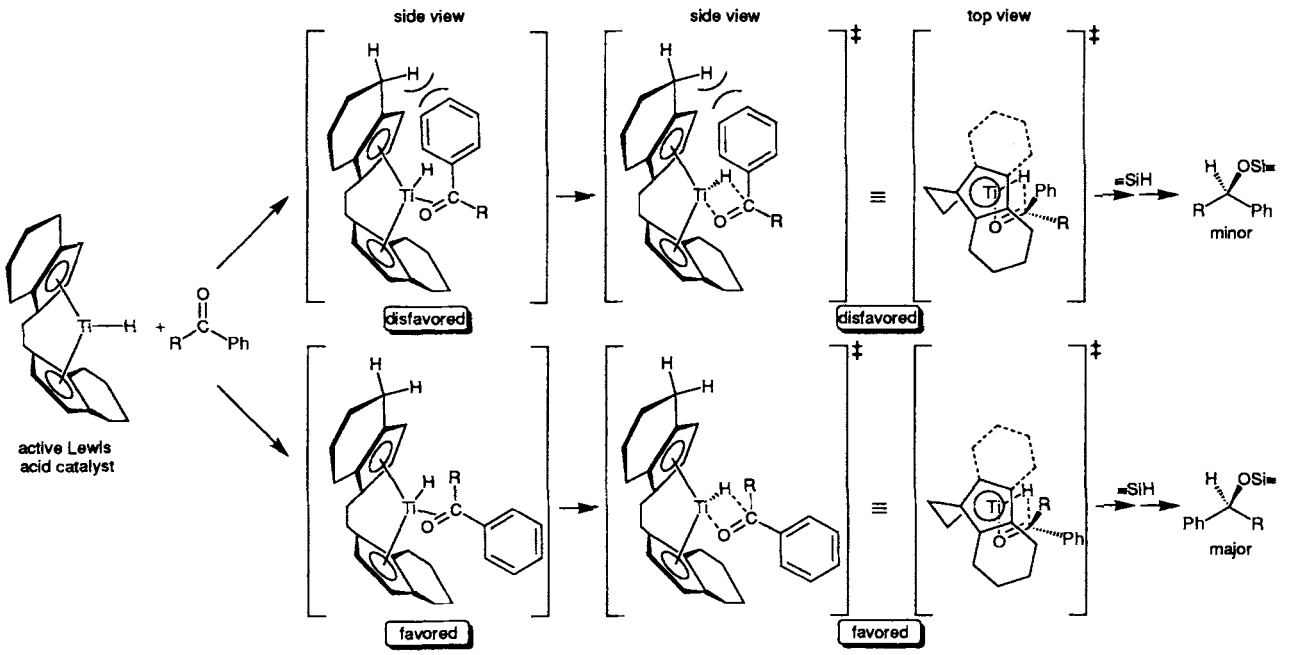
Scheme 18. Relationship between binding and reactivity for nucleophilic additions to alkene and aldehyde complexes of **I** [110–112].

data show that the aldehyde ligands first undergo π to σ isomerization (**XLIII**, **XLIV**).[112] Furthermore, two regimes can be identified: one at higher nucleophile concentrations in which isomerization is rate determining ("saturation kinetics"), and another at lower nucleophile concentrations in which addition is rate determining. Interestingly, in the former limit it still remains possible for the diastereomer ratio of the π complexes to correlate (by a "torquoselective"[113] isomerization to an *E* or *Z* σ complex) with the diastereomer ratio of the alkoxide complexes.

Consider next the rapidly growing body of enantioselective reactions catalyzed by chiral metallocenes.[5, 13a, 77, 105, 106, 114–117] One example is the asymmetric hydrogenation of alkenes by the lanthanide catalysts shown in Figure 14.[77] Another is the asymmetric hydrosilylation of aryl ketones by the titanium catalyst shown in Scheme 19.[114] These reactions commonly involve a π complex of the substrate. A subsequent migration of a hydride or alkyl moiety from the catalyst then fixes a product stereocenter. Suppose that for the more stable configurational diastereomer of the π complex, the receptor favors the M–(X=C) rotamer with the reactive terminus *syn* to the migrating group. In this case, it would be difficult to imagine a situation in which the most stable isomer were not the most reactive. In Scheme 19 the alternative Ti–(O=C) rotamers would certainly be less stable, and therefore correlations of enantioface binding selectivities, reactivities, and product configurations would be expected.[118]

Binding data for complexes of chiral bent metallocene Lewis acids and prochiral alkenes, aldehydes, and ketones are currently extremely scarce.[119, 129] Equilibrium measurements would be of direct use in optimizing this growing area of catalytic chemistry, which now also includes enantioselective imine hydrogenations,[104, 113] alkene carbomagnesations[13a, 105] and carboaluminations,[116] and diene cyclopolymerizations.[5a, c] As an illustration of an attractive system for study, niobocene alkene hydride complexes of the formula $[(\eta^5\text{-}C_5R_5)_2Nb(H_2C{=}CHR)(H)]$ have been carefully characterized.[120] It should be possible to prepare similar alkene complexes of chiral niobocene Lewis acids that would be close structural models for the key titanium and zirconium intermediates in the preceding transformations. Regardless, we suggest at this time that the titanium Lewis acid in Scheme 19 probably belongs to receptor type **F** (Figure 10, mirror image), with a *cis* relationship between a prohibitively congested quadrant and the next most congested quadrant.

Of course, π complexes of chiral transition metal Lewis acids and alkenes, aldehydes, and ketones play key roles in a variety of other catalytic enantioselective reactions. However, from available data it is only possible to speculate on transformations in which binding selectivities will correlate with product configurations. One recently reported possibility would be the palladium-catalyzed alkylation of alkenes containing two allylic geminal alkoxycarbonyl groups.[121] The key intermediates might be modeled by alkene complexes of chiral bis(phosphane) platinum(0) Lewis acids. Chiral palladium(II) catalysts that combine monosubstituted and disubstituted alkenes and CO to give alternating copolymers of high enantiomeric purities have also been described.[13b, 122] These mechanistically well-defined systems are particularly suited for additional study.



Scheme 19. Probable relationship between binding selectivity and enantioselectivity obtained with titanium Lewis acid that catalyzes ketone hydrosilylation [114]. The angle between the cyclopentadienyl planes is exaggerated for clarity.

Other obvious areas for inquiry would include metal-catalyzed enantioselective cyclopropanations[123] and epoxidations[124, 125] of alkenes. However, in many of these reactions metal alkene complexes are not intermediates. In cases in which the first new bond formed fixes all product stereocenters, correlations with the binding selectivities of a specific chiral receptor might nonetheless be expected. This could, as noted above, be used as a probe of the steric properties of the reactive site. However, in some cases product stereocenters are fixed in subsequent steps.[124] Here, no meaningful correlations would be expected.

27. Conclusion

All stereoisomers that can result when achiral alkenes, aldehydes, and ketones bind in an η^2 π manner to chiral transition metal Lewis acids have been identified (Scheme 2). Further analyses show that there are only six types of chiral metal receptors, as classified by the relative steric properties of four quadrants. The corresponding quadrant diagrams in Figure 10 allow many types of binding selectivities to be easily predicted or rationalized. They also provide starting points for more refined bonding models of broader utility or improved quantitative capability (Figure 13).

In particular, these constructs enable ready identification of receptors that will be superior for binding one enantioface of a prochiral alkene, aldehyde, or ketone. Alternatively, rational ways to modify receptors to achieve improved binding selectivities become apparent. Receptors for which the steric properties are unknown may be "mapped" by measurements of various binding equilibria, as exemplified for the chiral rhenium Lewis acid **I**. Although **I** has not been structurally optimized, a literature survey (Figure 17) shows that it presently offers the highest binding selectivities for the broadest spectrum of alkenes. Other metal fragments certainly hold promise, and even higher selectivities should eventually be realized.

Electronic effects can also be incorporated into these bonding models. In appropriate situations, they can be pronounced. In the case of complexes of **I** with aromatic aldehydes, a clear-cut underlying structural basis has been established. Finally, many of these concepts can be extended to transition states. In some cases a correlation between binding selectivities and product configurations can be expected, but in other cases not.

This review points the way to less empirical and more quantitative approaches to chiral recognition, which is required in some context in all enantioselective syntheses. An important future direction will be to extend this analysis to σ complexes, which are responsible for enantioselection in many types of chiral Lewis acid promoted transformations. Here, *E*/*Z* and rotameric equilibria about the σ bond will play much the same roles as the configurational diastereomers and M–(X=C) rotamers discussed above. Complementary types of steric and electronic[126] effects will be operative.

We thank the U. S. National Institutes of Health for support of this research, Dr. T.-S Peng for assistance with an early version of the manuscript, and the Alexander von Humboldt Foundation for a Senior Scientist Research Award that enabled the completion of this review at the Fachbereich Chemie der Philipps-Universität in Marburg, Germany.

[15] Quadrant diagrams frequently appeared in the early literature on enantioselective hydrogenations and hydroformylations of alkenes with chiral Rh^I catalysts [16a,b]. The authors have sought to identify the earliest use of a quadrant diagram for the analysis of any reaction leading from a prochiral alkene to a chiral product. Since such a search cannot be conducted systematically, examples from readers are welcome. More recently, some highly stylized version of quadrant diagrams have evolved [16c].

[22] Molecular orbital analyses predict that diamagnetic d^6, sixteen-valence-electron [(η^5-C_5H_5)M(L)(L')] species should have pyramidal, not planar, ground states: P. Hofmann, *Angew. Chem.* **1977**, *89*, 551; *Angew. Chem. Int. Ed. Engl.* **1977**, *16*, 536; see also P. Hamon, L. Toupet, J.-R. Hamon, C. Lapinte, *Organometallics* **1996**, *15*, 10.

[23] To our knowledge, the first adducts of **I** were reported in 1979: W. Tam, W. K. Wong, J. A. Gladysz, *J. Am. Chem. Soc.* **1979**, *101*, 1589.

[24] Third-row transition metal sixteen-valence-electron species appear to be much less stable relative to their eighteen-valence-electron counterparts than first- or second-row sixteen-valence-electron species: C. P. Casey, T. L. Underiner, P. C. Vosejpka, J. A. Gavney, Jr., P. Kiprof, *J. Am. Chem. Soc.* **1992**, *114*, 10826, and references therein.

[25] The vector that connects rhenium and the cyclopentadienyl centroids in **I**–**III** actually extends behind the plane of the paper. In contrast, the rhenium–nitrogen and rhenium–phosphorus bonds are in the plane of the paper. Although this somewhat diminishes the steric effect of the cyclopentadienyl ligand, crystal structures of Lewis base adducts of the types **II** and **III** always show one or two X-Re-(Cp(carbon)) angles of less than 90°. Thus, the cyclopentadienyl ligand extends into the plane of the paper.

[38] a) The configuration at rhenium is specified first [11] and followed by those of the =CHR stereocenters [10]. In complexes with two =CHR stereocenters, the configuration of the carbon with the higher Cahn–Ingold–Prelog priority (e.g. $=CHCHCH_3$ > $=CHCH_3$) is given first. If the priorities are equal, the configuration of the =CHR group *anti* to the PPH_3 ligand is given first. b) The configuration of a given carbon is not affected by a 180° rotation about the Re–(C=C) axis. However, when the preceding convention is applied to the complexes in Scheme 8 with symmetrical *cis* alkenes, there is an apparent inversion. c) In many schemes only one enantiomer of a racemate is depicted. These always correspond to the first enantiomer specified in the diastereomer designation (for example the *RS* enantiomer for the *RS,SR* diastereomer).

[39] a) In many cases replicate determinations have been conducted and standard deviations are much less. b) Unless noted otherwise, detection limits are 1%. Hence a ratio of > 99:1 implies that the second isomer cannot be detected. In such cases, either an authentic sample enriched in the second isomer is available, or two isomers of a closely related compound can be detected easily under similar conditions.

[42] No significant counter anion effects have been detected to date for the equilibria in Scheme 7. For example, $\mathbf{5e}^+ PF_6^-$ and $\mathbf{5h}^+ PF_6^-$ give *RS,SR*/*RR,SS* ratios of 92:8 and > 99:1, respectively [36]. Similar data are available for π aldehyde complexes of **I**.

[51] a) Since these reactions proceed by associative substitution (Scheme 5) [34], we speculate that less congested σ (as opposed to π) O=C adducts are generated first. The greater nucleophilicity of the O=C group would then be explained by the smaller size (no substituents on oxygen), the higher energy oxygen-based nonbonding HOMO, and the greater bond dipole. Nonconjugated analogs such as 5-hexen-2-one behave similarly: E. J. Fairfax, M. Sc. Thesis, University of Utah, **1993**. b) For similar results involving the achiral

osmium Lewis acis $[Os(NH_3)_5]^{2+}$, see W. D. Harman, W. P. Schaefer, H. Taube, *J. Am. Chem. Soc.* **1990**, *112*, 2682.

[69] One of the simpler approaches can be illustrated with *cis*-2-pentene. The methyl and ethyl substituents are assigned (arbitrary) values. These act as multipliers for the bar heights of the occupied quadrants. The sum is taken as the steric energy. With methyl = 1 and ethyl = 2, receptor **A** gives energies of 6, 7, 8, and 9 units for the four possible isomers.

[72] Interestingly, the kinetic binding selectivities obtained for alkenes with $\mathbf{I}\text{-}Me_5$ are not higher than those with the less congested analog **I**. In fact, in the case of the 1-pentene complex $\mathbf{5}\text{-}Me_5^+ PF_6^-$, the less stable *RR,SS* diastereomer forms faster [71].

[76] These generalizations are not necessarily limited to chiral *trans* or *cis* alkenes with C_2 symmetry. Consider, for example, a racemic *trans* cycloalkene with a remote geminal dimethyl group in the backbone. Each configurational diastereomer would now have two M–(C=C) rotamers. However, both rotamers of one diastereomer would likely be more stable than both rotamers of the other. Alternatively, a C_2-symmetric chiral receptor could be employed, in which case each diastereomer would again have only one M–(C=C) rotamer.

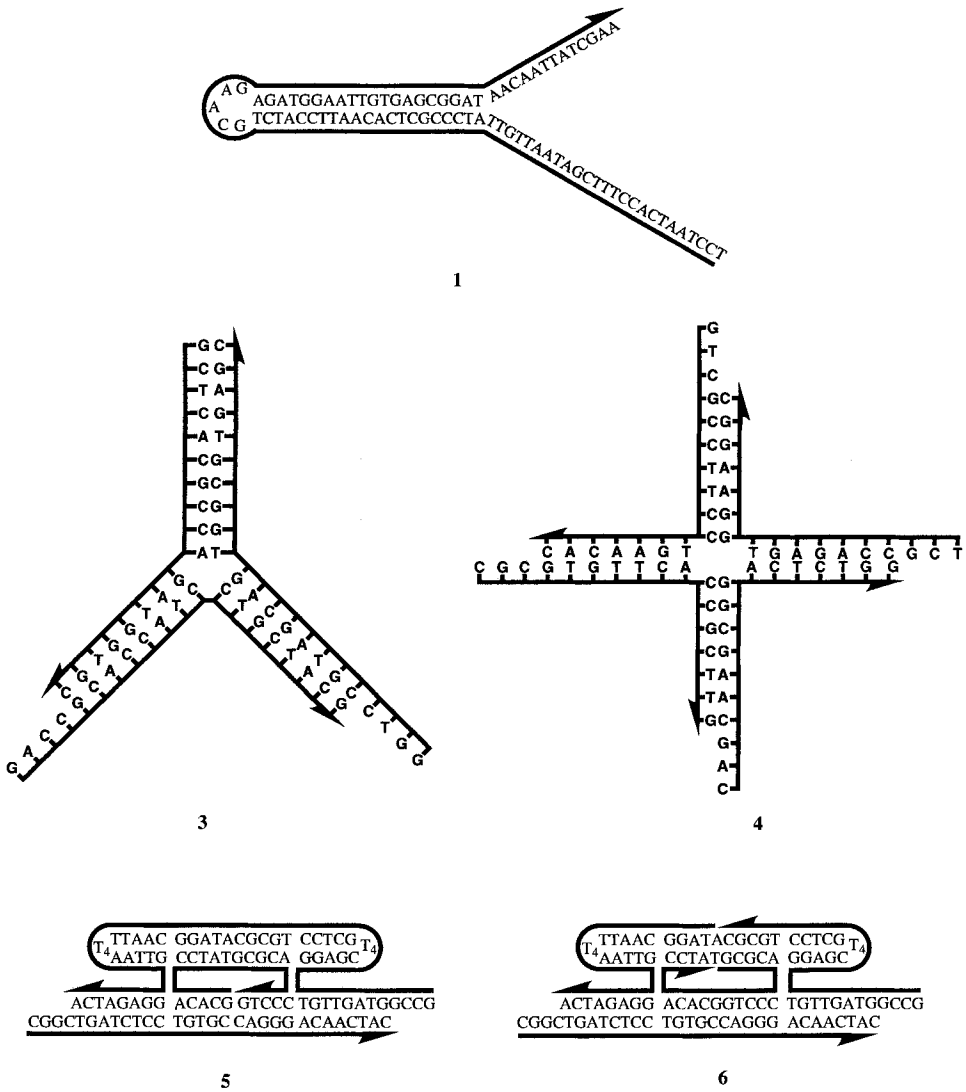
DNA as a Material for Nanotechnology

Christof M. Niemeyer*

Nanotechnology is the new term describing recent research devoted to the generation of nanometer-scaled structural and functional elements. Because further reduction of the currently available microsystems by "engineering down" (for example by photolithographic methods) is uneconomical, new "engineering-up" strategies are being explored for the assembly of small molecular building blocks to form larger devices, preferably by self-assembly.[1] Biological macromolecules such as proteins and nucleic acids may be used as components for the construction of nanostructured systems. DNA seems particularly suitable. This molecule, a unique information carrier, not only occurs in a large variety of structures[2] but also displays comparably high physicochemical stability and mechanical rigidity.[3]

As an example, DNA might be used in the construction of chips to attain circuit sizes below 100 nm. A concept formulated by Di Mauro and Hollenberg[4] is based on the construction of DNA networks on suitable solid supports using oligonucleotides such as **1** (Scheme 1) as initiation points for enzymatic DNA synthesis or hybridization. These networks may then be used as scaffolds for the deposition of conducting materials such as gallium arsenide or indium phosphite by chemical vapor deposition (CVD) procedures. Shadowing techniques currently used for the preparation of DNA for electron microscopy studies should allow the preparation of basic microelectronic elements. The calculable advantage of DNA technology is based on the precision of DNA biosynthesis and hybridization in the process of matrix generation. The accuracy of photolithographic techniques may therefore be improved by about two orders of magnitude. Furthermore, since the DNA double helix is only 2 nm in diameter, the lower size limit of the structures should be substantially reducible.



Scheme 1. Synthetic DNA motifs for the construction of DNA frameworks: oligonucleotide **1** with a hairpin loop motif used as an initiation point for enzymatic DNA synthesis [4]; three- [12a] (**3**) and four-arm (**4**) DNA junction [5]; DNA double-crossover molecules (**5**, **6**) [12e]. The 3′-ends of the oligonucleotide compounds are indicated with arrowheads.

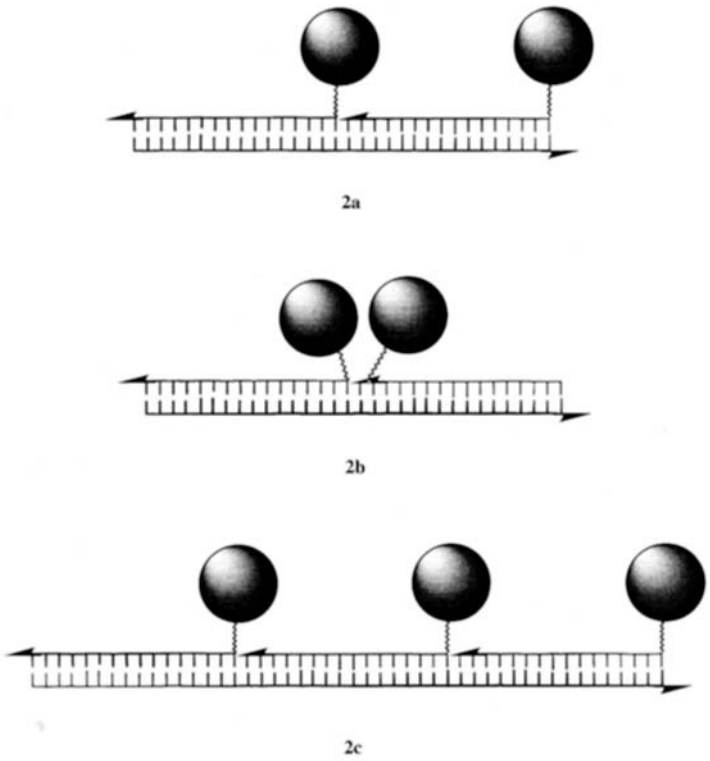
The concept of using DNA as a framework for the precise spatial arrangement of molecular devices[5, 6] has recently been applied to the assembly of supramolecular aggregates from DNA-derivatized gold colloids.[7, 8] Such defined arrangements of nanocrystalline metal clusters (quantum dots) are being investigated for new material properties and may have actual applications in the field of laser technology.[9] The sort of application could rely on, for example, superlattices or quantum dot molecules, in which crystallites of different materials are spatially assembled in predetermined arrangements. Recent strategies have been based on self-assembly and synthetic chemical methods.[10]

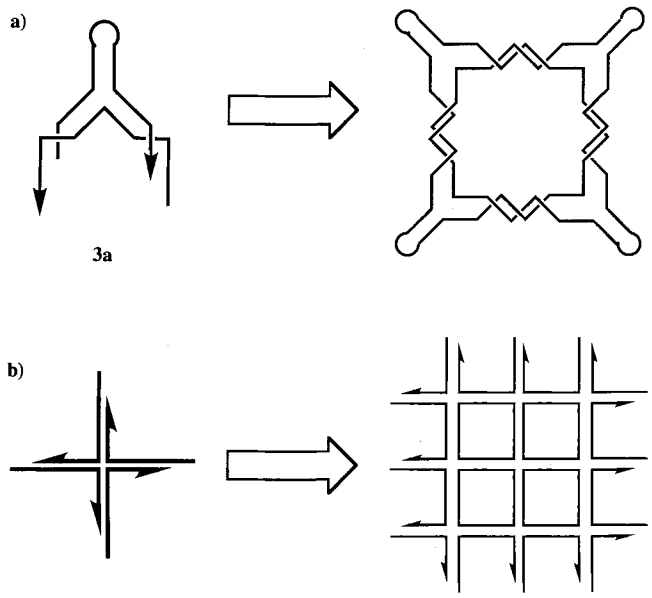
In separate reactions, Mirkin et al.[7] coupled two noncomplementary oligonucleotides with 13-nm gold particles by means of thiol adsorption. A DNA duplex molecule containing a double-stranded region and two cohesive single-stranded ends complementary to the gold-bound DNA was used as a linker. The addition of the duplex to a mixture of both clusters led to aggregation and slow precipitation of a DNA colloid material. The reversibility of this process was demonstrated by the temperature-dependent changes in the UV/Vis spectrum. Since the clusters contained multiple DNA molecules, the aggregates developed were well-ordered and three-dimensionally linked as judged by transmission electron microscopy (TEM). Images of single-layer, two-dimensional aggregates revealed close-packed assemblies of the colloids with uniform particle separations of about 6 nm.

Alivisatos et al.[8] synthesized defined monoadducts from commercially available 1.4-nm gold clusters containing a single reactive maleimido group. By coupling with thiolated 18-mer oligonucleotides, the nanocrystals were supplied with an individual "codon" sequence. Upon addition of a single-stranded DNA template molecule containing complementary codons in any given order, nanocrystal molecules self-assemble (Scheme 2). Following this concept, which had previously been used to position enzymes and antibodies along nucleic acids,[11] purified DNA cluster conjugates were assembled to generate the head-to-head and head-to-tail homodimeric target molecules **2a** and **2b**, respectively. TEM characterization of the aggregates revealed that approximately 70% of the complexes have the dimeric structure expected. The center-to-center distances observed in the two isomers are about 3–10 nm (**2a**) and 2–6 nm (**2b**), consistent with model calculations. Also the trimeric molecules (**2c**) show the structures expected, as judged from TEM images.

DNA hybridization opens up a new, simple strategy for synthesis: Many different devices are connected to a defined codon and subsequently ordered on a suitable template strand. The utilization of appropriate nucleic acid scaffolds should even enable construction of complex supramolecular structures by means of a modular construction kit. The last 15 years Seeman and co-workers [5, 6] have been engaged in the rational construction of DNA frameworks. They use branched DNA molecules containing three, four, and more double helical arms (termed "DNA junctions", see **3**, **4**, and Scheme 3). These modules are similar in structure to the replicational junction and the Holliday junctions of genetic recombination.[2] They can be prepared easily by briefly heating stoichiometric mixtures of the oligonucleotide components and then stepwise cooling. The synthesis



Scheme 2. Assembly of nanocrystal molecules using DNA hybridization. Conjugates of gold particles and oligonucleotide codons self-assemble to form supramolecular assemblies on addition of a template strand. The use of 3′- or 5′-derivatized oligonucleotides leads to formation of head-to-head (**2a**) and head-to-tail (**2b**) homodimers, respectively. A template containing the complementary sequence in triplicate causes the formation of the trimer **2c**. The wavy lines represent the spacer chains between DNA and the gold particle [8].



Scheme 3. Construction of geometric objects and periodic frameworks from DNA. a) Synthesis of a macrocyclic molecule from bivalent three-arm DNA junctions (**3a**) having two cohesive ends [13a]. b) Construction of two-dimensional DNA lattices from tetravalent modules. Linear double helical regions are represented by parallel lines [5].

of periodic matter from DNA[12] was initially attempted with three-arm junctions.[12a] Connection of the cohesive ends of **3** using DNA ligase yielded a mixture of linear and cyclic

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3606-0586 $ 17.50+.50/0

oligomers starting with the trimer. Since double helical arms 5–7 nm in length behave like rigid rods, the proportion of cyclized products can lead to conclusions about the variation of the valence angle between the ligation arms of the molecules. Subsequent experiments with four-,[12b] five-, and six-arm junctions[12c] confirmed the high flexibility of the modules. Thus, these "simple" motifs are not suitable for the assembly of large repetitive constructs.

Recently, the ligation of double-crossover motifs has been reported.[12e] This class of molecules contains two junctions connected by two double helical DNA arms and is differentiated by the relative orientation of their helix axes as well as the number of double helical half-turns between the two crossovers. Polymerization of model compound **5** (a "DAE molecule"), in which the second domain is closed with dT_4 loops, leads almost exclusively to the production of linear oligomers. This observation can be explained by the reduced flexibility of the ligation arms and was not found for control compound **6**. Here, the nicked backbone of the second helical domain permits higher flexibility. Due to the rigidity of the DAE molecules, comparably long oligomers containing up to 17 monomers are formed during ligation. In contrast, in the case of the more flexible junctions (e.g. **3**) oligomers beyond heptamers were hardly formed. The utilization of structurally related DAE motifs containing an additional ligation arm should allow the construction of periodic lattices from DNA.[12e]

Geometric objects[13] can be constructed from modules whose valence arms are supplied with individual cohesive ends. For example, the synthesis of a DNA molecule containing four vertices[14] proceeds readily from three-arm junctions (**3a** in Scheme 3) in approximately 15% yield.[13a] A more complex object containing eight vertices,[13b] however, can be constructed in only 1% yield. This covalently closed, cubelike[14] construct has edges of about 7 nm in length. Each of the six faces is a cyclized oligonucleotide connected by two turns of a double helix with the four neighboring strands. The development of a solid-support methodology[13c] allows one to synthesize complete segments of DNA objects on Teflon surfaces. This method not only leads to a remarkable increase in product yields, but should also be amenable to automation. Its power has been demonstrated by the synthesis of a polyhedron containing 24 vertices, which proceeded in 1% yield. The resulting "truncated octahedron" is a complex [14]catenane with a molecular weight of about 790 kDa and contains six square and eight hexagonal faces.

The utilization of DNA in biotechnological applications for electrical, optical, catalytic, and numeric[15] devices may have additional advantages: DNA can be processed in aqueous media and is suitable for convenient (e.g. biological) decomposition. In addition, the reversibility of the Watson–Crick base pairing is supplemented by the possibility of fixating the structures with selective crosslinking.[16] Furthermore, the prospect of high economic profits in nanotechnology[9b] justify the current financial expenditure. In any case the rapid development of synthetic DNA derivatives[17] and DNA ligands,[18] improved techniques of microscopy and manipulation,[19] and the recently reported electron transfer in DNA[20] promise further exciting developments in DNA technology.

Integrin Antagonists and Other Low Molecular Weight Compounds as Inhibitors of Angiogenesis: New Drugs in Cancer Therapy**

Athanassios Giannis* and Frank Rübsam

Angiogenesis (neovascularization), the process by which new blood capillaries are formed from an already existing blood vessel, is of fundamental importance for a number of physiological and pathological events including embryogenesis, wound healing, chronic inflammation, and malignant processes.[1] Due to the observation that an adequate blood supply is necessary for tumor growth, Folkman postulated in the early 1970s that inhibitors of angiogenesis are of potential use in cancer therapy.[2] Subsequent investigations revealed that not only tumor growth but also tumor metastasis depends on angiogenesis.[3] In recent years many endogenous regulators of angiogenesis have been isolated and identified. The most important positive regulators include growth factors like basic fibroblast growth factor (bFGF), vascular endothelial growth factor (VEGF), and tumor necrosis factor α (TNF-α). An additional component controlling the progress of neovascularization at several stages is a protein derived from endothelial cells, SPARC (secreted protein, acidic, cysteine-rich). Its proteolytic degradation generates fragments containing the sequence Gly-His-Lys, which stimulate angiogenesis both in vitro and in vivo.[4] The negative regulators include thrombospondin 1, angiostatin, platelet factor 4, and interferon α. The complex process of angiogenesis proceeds in the following stages (Figure 1): a) activation of endothelial cells (EC) and pericytes by the growth factors, b) degradation of the basal lamina of the bloodvessel by the action of proteases (collagenases, plasminogen activator), c) migration (and proliferation) of EC and pericytes towards the angiogenic stimulus, d) formation of a new capillary vessel lumen, e) appearance of pericytes around the forming vessel, f) development of a new basal lamina, and g) anastomosis of the proximal ends of two forming vessels enabling blood flow.

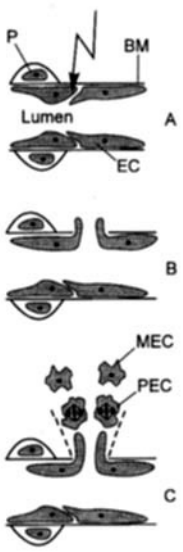

Figure 1. Schematic representation of angiogenesis. An angiogenic stimulator (A) triggers the secretion of proteases (collagenases and plasminogen activator) by endothelial cells, leading to degredation of the basal lamina of the blood vessel (B). The endothelial cells proliferate and migrate within the extracellular matrix in the direction of the angiogenic stimulator (C). The migration within the extracellular matrix is enabled by the continous secretion of proteases. For further details see text. P: pericyte, EC: endothelial cell, BM: basal lamina, PEC: proliferating endothelial cell, MEC: migrating endothelial cell.

In the last few years considerable progress has been made in tracing the biochemical events of angiogenesis. The mechanism of endothelial cell migration within the extracellular matrix has been investigated extensively. The adhesion of endothelial cells to the extracellular matrix was shown to be mediated by the interaction of a membrane-bound integrin $\alpha_v\beta_3$ (vitronectin receptor) with the tripeptide sequence RGD (Arg-Gly-Asp).[5] The binding of the ligand, which occurs in a multivalent form, leads to integrin clustering[6] (Figure 2). This in turn initiates

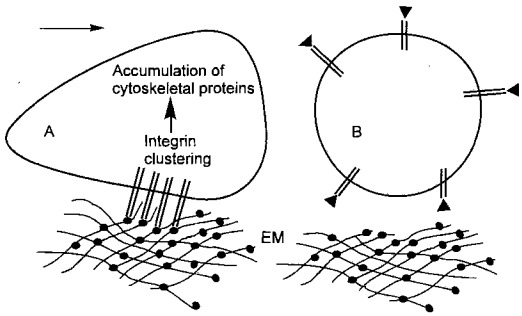

Figure 2. $\alpha_v\beta_3$ Integrins and angiogenesis. The action of different growth factors stimulates the expression of integrin $\alpha_v\beta_3$ on endothelial cells. During the subsequent migration of endothelial cells in the direction of the angiogenic stimulator (arrow), integrin $\alpha_v\beta_3$ binds to RGD sequences present in multivalent form on the extracellular matrix (EM). As a consequence, integrin receptors aggregate on the cell membrane (A) and proteins of the cytoskeleton such as talin, paxilin, α-actinin, tensin, vinculin, and F-actin accumulate. This in turn results in maintenance of the migration process, serves as a signal for the survival of endothelial cells, and finally leads to the formation of a new blood vessel. Prevention of integrin aggregation by soluble monovalent RGD analogues (B) leads to programmed cell death (apoptosis) of the migrating endothelial cells and therefore prevents vessel formation.

an intracellular signal cascade that supports both migration of endothelial cells and protection of the cells from programmed cell death (apoptosis). In contrast, interaction of $\alpha_v\beta_3$ integrins with soluble monovalent RGD ligands or their analogues causes death of migrating endothelial cells and therefore prevents neovascularization.

The RGD sequence is a partial structure of proteins belonging to the extracellular matrix such as vitronectin, fibronectin, osteopontin, thrombospondin, and the von Willebrandt factor. It also occurs in the blood protein fibrinogen, which decisively contributes to blood coagulation. The RGD group serves as a ligand not only for the $\alpha_v\beta_3$ integrin, but also for other integrins, for example $\alpha_5\beta_1$, $\alpha_v\beta_1$, $\alpha_v\beta_5$, and $\alpha_v\beta_6$, as well as for the platelet integrin $\alpha_{IIb}\beta_3$ (fibrinogen receptor). The specificity of the RGD–integrin interaction is generated by a combination of variations in the RGD conformation in different proteins and contributions of sequences near the RGD moiety.[7] Structure–

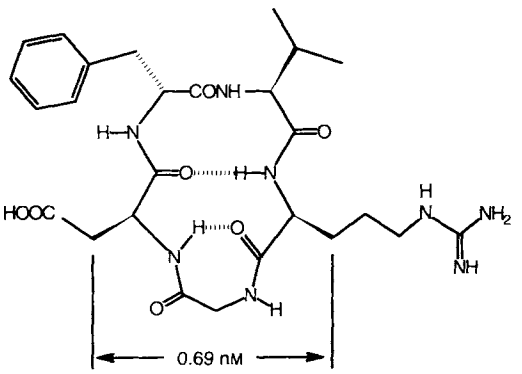
activity relationships have shown that within linear RGD-containing peptides the exchange of glycine for alanine or aspartate for glutamate prevents recognition and binding of the resulting peptides by the integrins.[8]

Until now the search for RGD analogues was dominated by the demand for potent, selective and orally available $\alpha_{IIb}\beta_3$ antagonists. These efforts culminated in the synthesis of nonpeptidic RGD analogues, which are currently in clinical trials as anticoagulants.[9] They constitute the first clinically valuable antiintegrins and provide important contributions to the treatment of thromboembolic diseases. These results together with further insights into the importance of angiogenesis for tumor growth and metastasis prompted several groups in the pharmaceutical industry and in academia to search intensively for antagonists of the endothelial cell integrin $\alpha_v\beta_3$ in order to block angiogenesis. Inhibitors of angiogenesis are not only of interest as anticancer drugs but also for the treatment of disorders in which neovascularization plays a critical role. These conditions include diabetic retinopathy (leads to blindness) and arthritis (leads to destruction of the joints).

A severe problem in the design of $\alpha_v\beta_3$ antagonists is their selectivity. A suitable antagonist should have a high affinity to the vitronectin receptor as well as favorable pharmacokinetic properties. In the long term it is desirable to develop potent, selective, and orally available nonpeptidic ligands. The oral availability is of particular importance since angiogenesis should be blocked for a longer period of time. A decisive contribution to the understanding of the RGD–$\alpha_v\beta_3$ interaction and therefore to the development of such drugs was provided by the group of H. Kessler at the Technische Universität München. Already in 1991 these researchers incorporated the RGD sequence into different cyclopeptides and investigated their affinity and selectivity towards different integrins.[10] The cyclopentapeptide *cyclo*(Arg-Gly-Asp-*D*-Phe-Val) (c(RGDfV)) **1** turned out to be a selective $\alpha_v\beta_3$ ligand.



1

The IC_{50} value for the binding of **1** to both soluble and immobilized $\alpha_v\beta_3$ integrin is 50 nM.[11] Therefore its affinity to this integrin is comparable to the affinity of the endogenous ligand vitronectin (IC_{50} = 25 nM). In compound **1** the RGD sequence forms a γ-turn with glycine in the central position. NMR spectroscopic investigations in solution indicate that a parallel arrangement of the side chains of arginine and aspartate results. As expected, the D-amino acid occupies the $i+1$ position of a βII′-turn. The distance between the β carbon atoms of the Asp and Arg side chains within peptide **1** was determined by NMR spectroscopy to be 0.69 nm, which is considerably shorter than the distance thought to be optimal for recognition by the fibrinogen receptor (0.75–0.85 nm). These findings were confirmed by Bach et al.[12]

Recently, Kessler et al. synthesized all possible stereoisomers of peptide **1** and of its retro-sequence (32 peptides).[13] An important result of the subsequent biochemical and NMR spectroscopic investigations was that the retro-inverso compound c(vFdGr) shows a drastically reduced affinity towards the $\alpha_v\beta_3$ integrin, since its conformation is different from that of peptide **1**. More importantly, another peptide, c(VfdGr), shows nearly no affinity to the vitronectin receptor although the orientation of its side chains is identical to that of **1**. This means that not only the side chains but also the peptide backbone contribute to receptor binding by the formation of at least one hydrogen bond. In the same study a sterically demanding group in position 4 (D-Phe) was shown to be necessary for the biological activity of cyclopeptide **1**. In contrast to this, the L-valine residue can be replaced by any other amino acid.

Brooks et al. proved that peptide **1** is suitable as a blocker of angiogenesis.[5] The authors implanted human tumor tissue (melanoma) on the chorioallantoic membrane (CAM) of 10-day-old chick embryos. Implantation is accompanied by angiogenesis caused by the tumor. Integrin $\alpha_v\beta_3$ is expressed on endothelial cells and tumorous tissue is supplied with blood vessels. After 24 hours a single dose of peptide **1** (300 mg per 100 mL) was administered intravenously. Two days later neovascularization of the tumor tissue was observed to be interrupted. The control peptide *cyclo*(Arg-Ala-Asp-D-Phe-Val) had no effect on the growth of new blood vessels. Comparable results were achieved with monoclonal antibodies against $\alpha_v\beta_3$ integrin. In this case also a regression of different tumors implanted on CAM was observed. The treatment had no influence on already existing vessels of CAM. These studies showed for the first time that $\alpha_v\beta_3$ antagonists are potentially beneficial in the therapy of malignant diseases and other disorders characterized by excessive angiogenesis.

In general, antiangiogenic therapy is well tolerated, exhibits low toxicity, and does not lead to resistance phenomena. In studies on antiangiogenic therapy platelet factor 4 as well as the fungal metabolite fumagillin (**2**) (Scheme 1) and its synthetic derivative AGM-1470 (or TNP-470) **3** were used; the latter is the most potent low molecular weight inhibitor of angiogenesis (IC_{50} = 10 pg per mL).[15] The angioinhibitoric action of AGM-1470 depends in part on the inhibition of cyclin-dependent kinases in endothelial cells.[16]

An additional angiogenesis blocking agent is the well-known drug thalidomide (**4**), which was removed from the market in the 1960s because of its teratogenic action. When applied orally (200 mg per kg) it inhibits bFGF-induced corneal neovascularization in rabbits.[17] Recently published data reveal that thalidomide downregulates the expression of βintegrins.[18] This might explain both the angioinhibitoric and the teratogenic action of thalidomide.

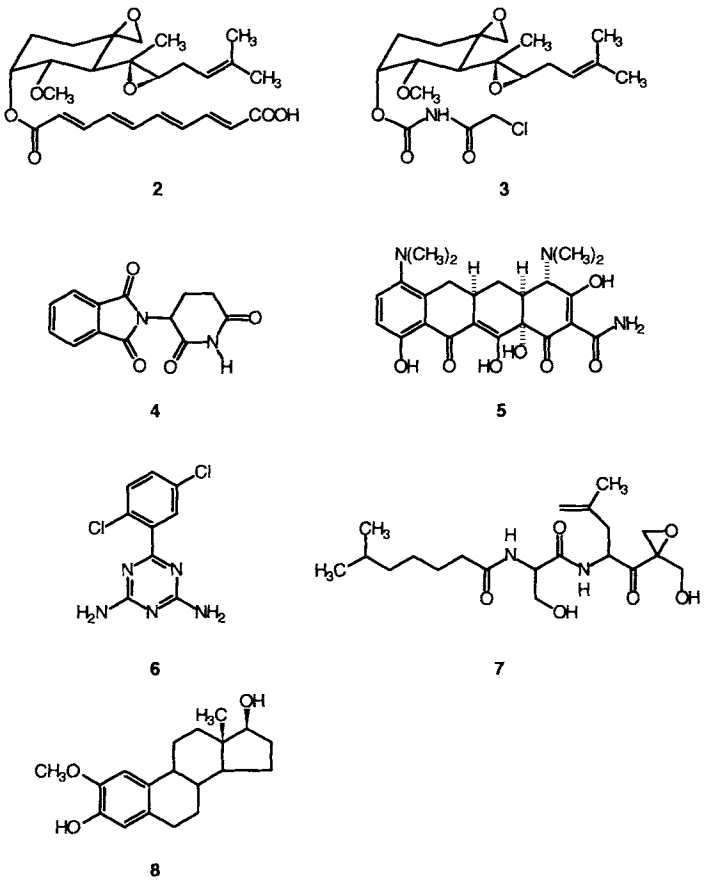

Scheme 1. Low molecular weight inhibitors of angiogenesis.

Currently several angioinhibitoric drugs are in clinical or preclinical trials.[1b] In addition to AGM-1470 and thalidomide, orally active protease inhibitors (inhibitors of basal lamina degradation) are also used. This group of compounds includes the well-known antibiotic minocyclin (**5**), an inhibitor of collagenase.[19] The antiulcus drug irsogladin (**6**) suppresses the degradation of the basal lamina by inhibition of plasminogen activator biosynthesis.[20] Another drug worth mentioning is the fungal metabolite eponemycin (**7**), which was discovered in a screening study. This natural product inhibits the proliferation and migration of endothelial cells ($IC_{50} = 77$ nM and 740 nM, respectively), thereby inhibiting neovascularization.[21] The estradiol metabolite 2-methoxyestradiol (**8**), which does not display glucocorticoid activity, is the most recently discovered compound of endogenous origin with angioinhibitoric action ($IC_{50} = 130$ nM).[22] Its mechanism of action is not known.

In summary, the investigation of the molecular aspects of angiogenesis has led to a deeper understanding of many pathological processes. Folkman's assumption that angiogenesis inhibitors are of potential use in cancer therapy initiated a search for such compounds. It proved to be a valuable concept and led to alternative forms of treatment for malignant diseases. Preclinical trials showed that inhibitors of angiogenesis per se are not sufficient for cancer therapy, but they enhance the effect of traditional chemotherapy. After traditional therapy they can force metastases that may still be present into a microscopically dormant state.[1b] The fact that angiogenic therapy is generally well-tolerated makes it probable that inhibitors of neovascularization will find broad use in the treatment of other diseases accompanied by excessive angiogenesis, for example rheumatism, arthritis, and diabetic retinopathy. Most of the currently employed drugs were discovered by screening, but the structure–activity relationships introduced by Kessler et al. constitute a valuable basis for the rational development of low molecular weight $\alpha_v\beta_3$ antagonists. Future work in this area will certainly refer to the general principles in the design of peptidomimetics[23] and to the experience in the design of $\alpha_{IIb}\beta_3$ antagonists.

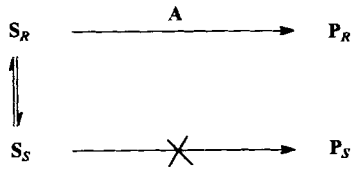
Deracemization by Enantiodifferentiating Inversion in 1,3-Diols

Anthony P. Davis*

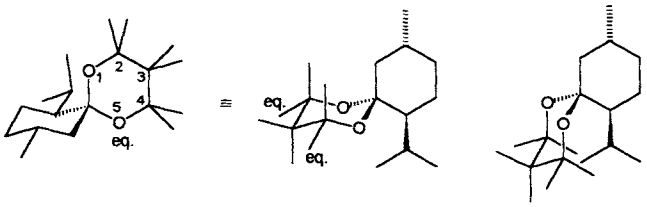
The conversion of achiral molecules into enantiomerically pure chiral compounds[1] is generally accomplished by one of two methods. On the one hand, a chiral reagent, catalyst, or auxiliary may be applied to effect an enantioselective synthesis, in which asymmetric induction desymmetrizes the starting material to give molecules that are chiral in predominantly one sense. On the other, the use of simple achiral reagents gives a racemic mixture of chiral molecules, which may then be resolved by interaction with a chiral agent. While the first of these methods may lead to, in principle, 100% conversion of an achiral starting compound into enantiomerically pure product, the second is limited to 50% conversion in most cases. Only certain circumstances allow "dynamic resolution", wherein equilibration of the starting enantiomers permits the enantiodifferentiating reagent, catalyst, or complexing agent to deliver the enantiomerically pure product in quantitative yield of (Scheme 1).[2]



Scheme 1. Dynamic resolution of an equilibrating mixture of enantiomers. S_R and S_S represent substrate enantiomers, A represents the resolving agent (reagent, catalyst, or complexer), and P_R represents the enantiomerically pure product.

An alternative and quite distinct approach to the synthesis of enantiomerically pure compounds has been demonstrated in particular by Harada, Oku, and co-workers during the past few years.[3] Like dynamic resolution it employs racemic mixtures as starting compounds, yet can give 100% conversion to the desired product. However, unlike the foregoing method it does not rely on equilibration of the starting enantiomers. Rather, the enantiomers are differentiated by a chiral agent and are taken through reaction sequences that result in convergence on a single enantiomerically pure product.

The methodology developed by the Japanese group is based on the chemistry of menthone-derived spiroketals **1**.[3a] The [6,6]bicyclic framework of this system sets up interactions and dispositions that rigorously control the stereochemistry of many of its reactions. The major source of stereochemical bias is the isopropyl group, which determines the conformation of the menthone-derived ring (see **1a**) and also fixes that of the 1,3-dioxane ring (see **1b**) by prohibiting conformation **2**. Important consequences are that a) substituents at positions 2 and 4 of the dioxane must take just one of the two possible orientations (marked eq. in **1b**) to avoid 1,3-diaxial interactions with a menthone ring carbon, and b) the dioxane oxygens occupy very different steric environments; the equatorial oxygen (see **1a**) is far more accessible to an approaching electrophile.



1a **1b** **2**

The well-defined preferences of **1** offer various opportunities for the development of stereoselective methodology, not least the desymmetrization of *meso*-1,3-diols (Scheme 2).[4] Ketalization of trimethylsilyl ethers **3** with *l*-menthone (**4**) under thermodynamic control leads exclusively to dioxanes **5**, in which both R groups are equatorial. When compounds **5** are treated with silyl enol ether **6** and $TiCl_4$ at low temperature, the less hindered equatorial ketal oxygen is attacked preferentially by the Lewis acid. The resulting oxonium ion is quenched selectively from the equatorial direction[5] to give "monoprotected diol" **7** as a single stereoisomer. Derivatization of the free hydroxyl group followed by base-induced removal of the chiral auxiliary can result in the alternative protection pattern shown in **8**. Notably, this sequence can be carried out even on *meso*-1,3-diols contam-

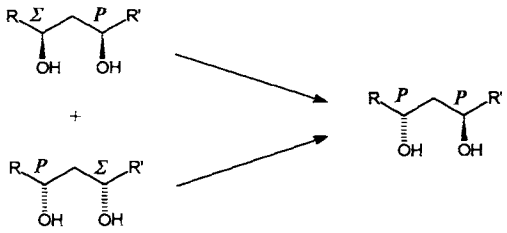
9

inated by the *d,l*-diastereomer. The latter can only form "eq.-ax." acetals such as **9** in the initial step and therefore do not react.

This procedure is elegant and useful, but conventional in that, like most enantioselective syntheses, an achiral starting material is desymmetrized by a chiral reagent. However, the methodology has been extended in a remarkable and unusual direction through the application of similar chemistry to racemic starting materials (Scheme 3).[6, 3b] To allow a generalized discussion of this and subsequent procedures, it is helpful to introduce special stereochemical descriptors for use with 1,3-diols and their derivatives. *P* and Σ asymmetric centers are defined as equivalent to *R* and *S* centers with the proviso that the central carbon of the 1,3-dioxygenated system is assigned higher priority than all external substituents (Figure 1).[7] Turning to Scheme 3, when trimethylsilyl ethers **10** are derivatized with *l*-menthone, diaxial interactions can be avoided only if Σ-**10** reacts to give **11**, while *P*-**10** reacts to give **12**. Accordingly, **11** and **12** are the only stereoisomers detectable.[6] Now if this mixture is treated with **6**/$TiCl_4$, the course of reaction is again dictated by the conformation of the bicyclic system. Only the equatorial C–O bonds are cleaved, so that **11** leads to **13** and **12** leads to **14**.[3b] The diol enantiomers have been differentiated, such that the secondary hydroxyl groups in the Σ and *P* isomers are exposed and protected, respectively. A Mitsunobu reaction inverts the exposed center in **13** and results in a "stereoneutral" displacement in **14**. On base-induced deprotection, the products (now regioisomers) converge on *R*-diol **15**, which is formed in ≥95% enantiomeric excess.

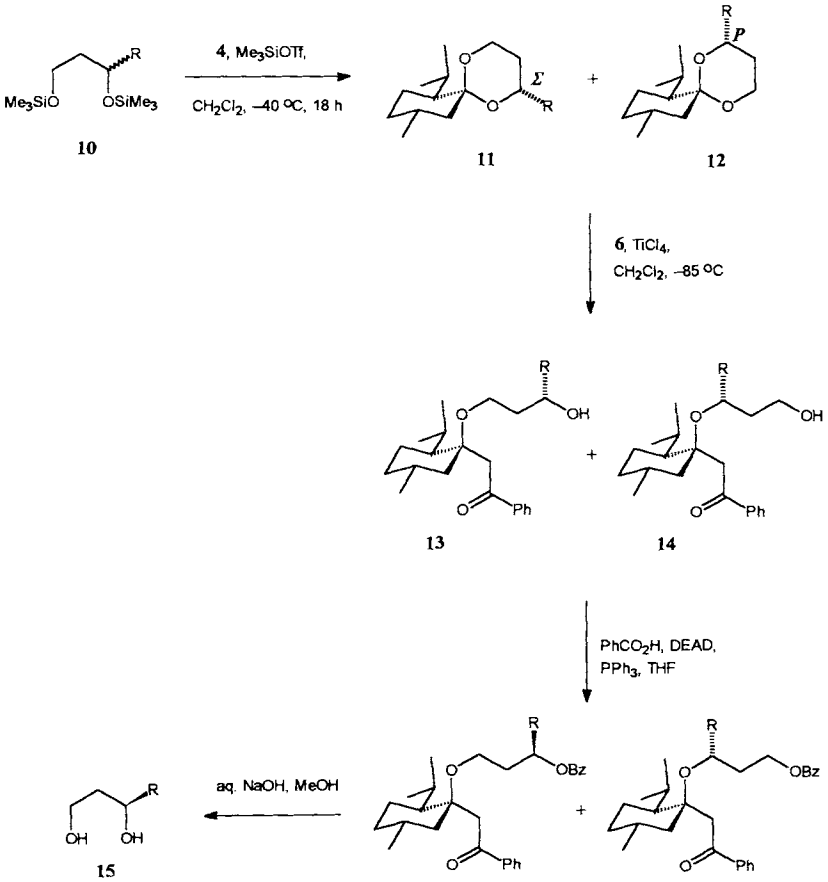
Figure 1. Σ and *P* centers in 1,3-dioxygenated molecules. External substituent R takes lower priority than the central carbon atom C2.

The essential basis of this method is that the equatorial oxygen in an *l*-menthone derivative must be attached to a Σ center while the axial oxygen must be connected to a *P* center. As the equatorial C–O is cleaved in the second step, the Σ center is selectively exposed and converted to *P*, resulting in deracemization. This analysis encourages consideration of racemates **16**, in which both Σ and *P* centers are present. If the Σ centers in both enantiomers could be converted to *P*, deracemization would again be possible (Scheme 4).



16

Scheme 4.



Scheme 3. α-Monosubstituted chiral 1,3-diols prepared from racemic mixtures. DEAD = diethyl azodicarboxylate.

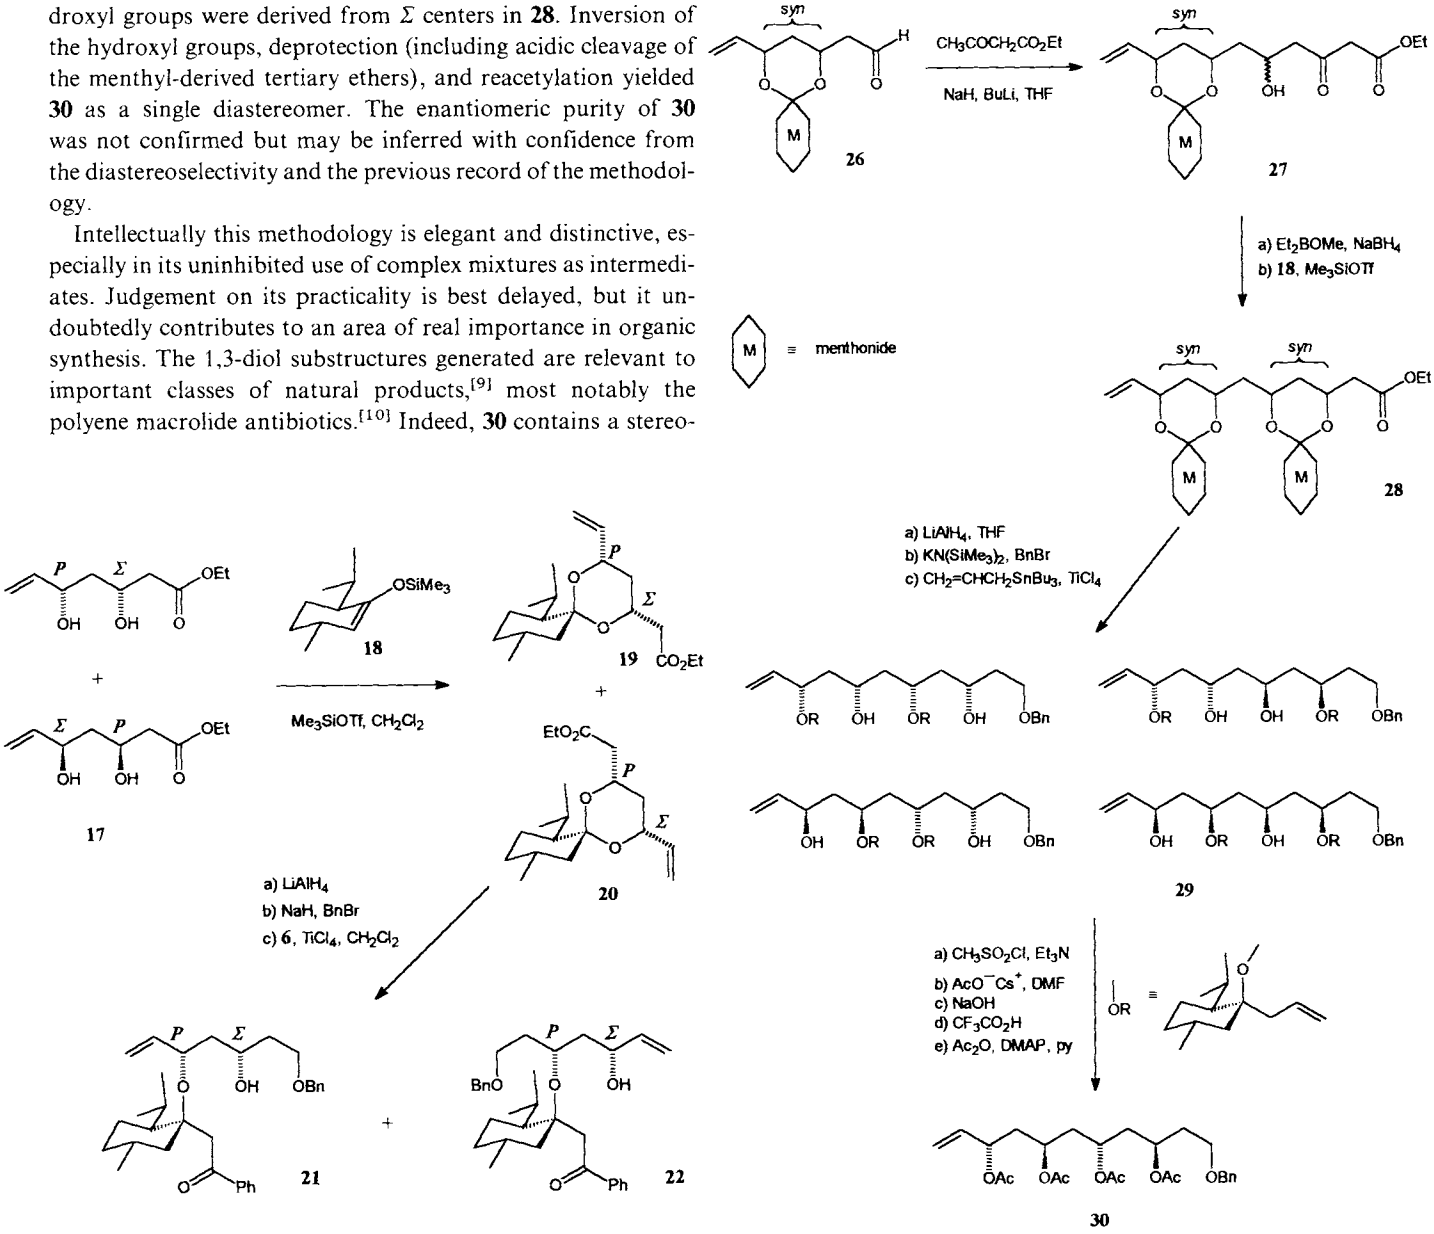
In a recent tour de force, Harada, Oku, and co-workers show that this process can indeed be effected.[3c] In an initial demonstration (Scheme 5), diol enantiomers **17** were converted directly to menthonides **19** and **20** by treatment with silyl enol ether **18** and Me_3SiOTf. After conversion of the esters to benzyloxy groups, the Σ centers were revealed by reaction with **6**/$TiCl_4$ to give **21** and **22**. Mitsunobu inversion of this mixture gave **23** and **24**, which on deprotection gave enantiopure diol **25** (>95% *ee*).

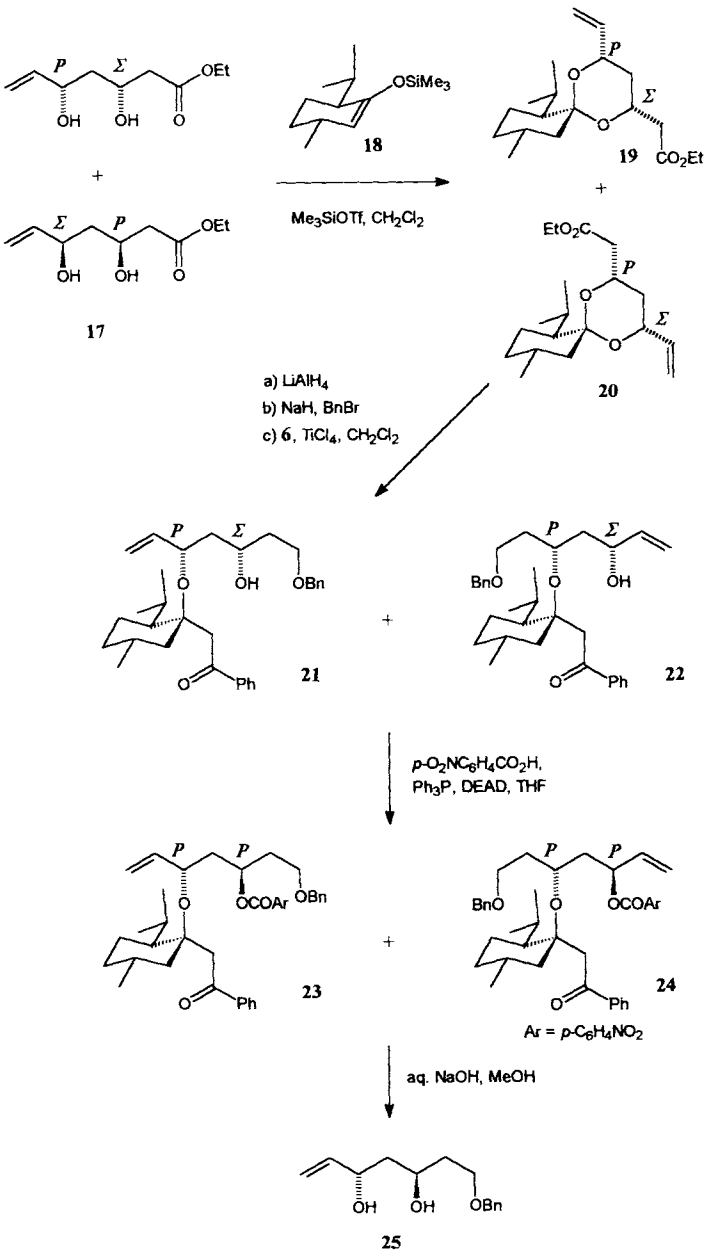
The scope of the strategy was then extended in spectacular fashion (Scheme 6). The mixture of **19** and **20** was transformed into the corresponding aldehydes **26** through reduction/oxidation of the ester groups. Treatment with the dianion derived from ethyl acetoacetate then led to hydroxyketones **27**. Chelation-controlled, *syn*-selective reduction[8] of this mixture followed by menthonide formation gave **28** as four diastereomers, each containing two Σ and two *P* centers. After ester reduction and O-benzylation, the stage was set for Σ-selective unmasking, inversion, and convergence. The usual conditions employing **6** were unsuccessful, but the combination of $TiCl_4$ with allyltributylstannane produced the desired effect. Equatorial-selective ring-opening yielded the mixture of compounds **29**, in which all the hy-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3606-0592 $ 17.50+.50/0 Angew. Chem. Int. Ed. Engl. 1997, 36, No. 6

droxyl groups were derived from Σ centers in **28**. Inversion of the hydroxyl groups, deprotection (including acidic cleavage of the menthyl-derived tertiary ethers), and reacetylation yielded **30** as a single diastereomer. The enantiomeric purity of **30** was not confirmed but may be inferred with confidence from the diastereoselectivity and the previous record of the methodology.

Intellectually this methodology is elegant and distinctive, especially in its uninhibited use of complex mixtures as intermediates. Judgement on its practicality is best delayed, but it undoubtedly contributes to an area of real importance in organic synthesis. The 1,3-diol substructures generated are relevant to important classes of natural products,[9] most notably the polyene macrolide antibiotics.[10] Indeed, **30** contains a stereochemical pattern present in several such targets, including rotaxicin and mycoticin A and B. From another perspective, the work further demonstrates the value of organosilicon- and organotin-based nucleophiles in organic synthesis.[11] Owing to their comparatively low reactivity, catalysis is often required, which provides a dimension of control that may be exploited to various stereochemical ends.[12] The application in this case is delightfully oblique (C–C bond formation is not usually employed to elaborate a protecting group in a synthetic intermediate) and nicely illustrates the versatility of these widely used reagents.





Scheme 5. Conversion of **17**, which contain both *P* and Σ centers, into **23** and **24**, which each contain two *P* centers. Subsequent deprotection yields the enantiomerically pure diol **25**.

Deposition of Data from X-Ray Structure Analyses

In order to make life easier for authors and referees the Cambridge Crystallographic Data Centre (CCDC) and the Fachinformationszentrum Karlsruhe (FIZ) have unified their procedures for the deposition of data from single-crystal X-ray structure analyses.

Prior to submitting your manuscripts please deposit the data for your compound(s) **electronically** at the appropriate data base, that is, at the CCDC for organic and organometallic compounds and at the FIZ for inorganic compounds. Both data bases will be pleased to provide help (see our *Notice to Authors* in the first issue of this year). In general, you will receive a depository number from the data base within two working days after electronic deposition; please include this number with the appropriate standard text (see our *Notice to Authors*) in your manuscript. This will enable the referees to retrieve the structure data quickly and efficiently if they need this information to reach their decision.

This is now the uniform procedure for manuscripts submitted to the journals *Angewandte Chemie, Chemische Berichte/Recueil, Chemistry—A European Journal*, and *Liebigs Annalen/Recueil.*

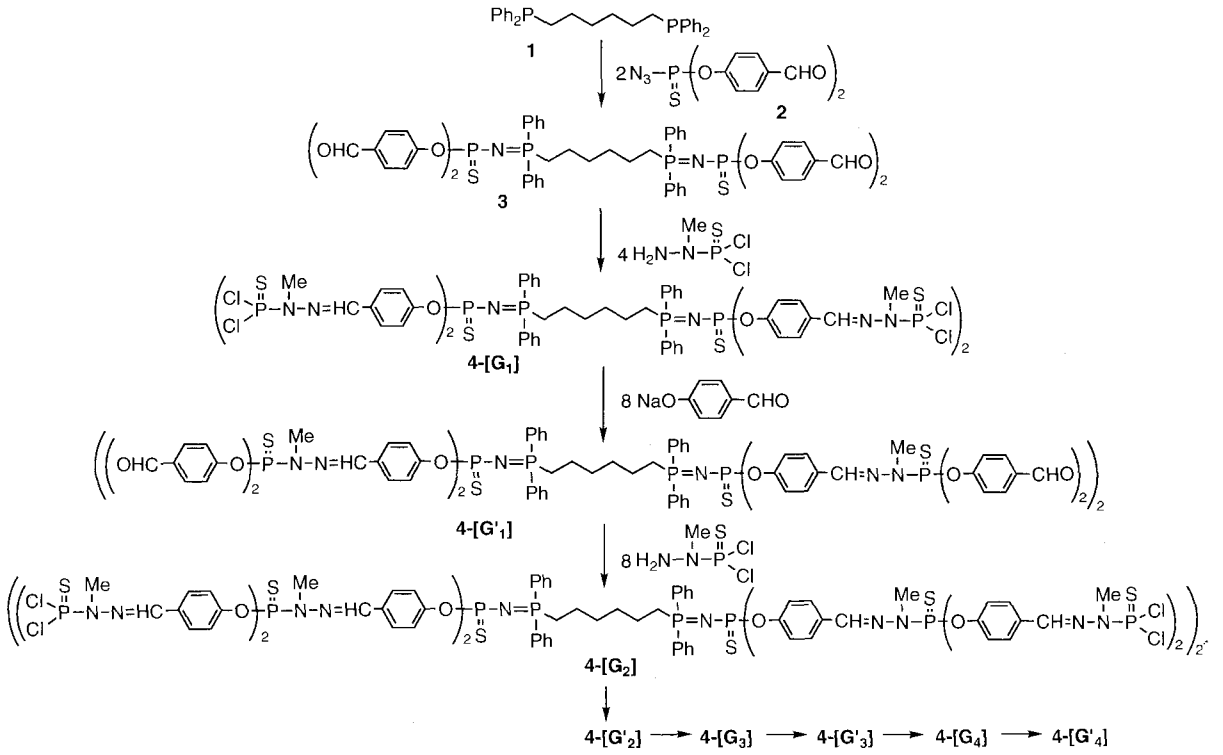
Chemoselective Polyalkylations of Phosphorus-Containing Dendrimers**

Christophe Larré, Anne-Marie Caminade,* and Jean-Pierre Majoral*

The introduction of phosphorus atoms into the backbone of dendrimers is of great interest for several reasons. The presence of phosphorus groups allows the construction of the dendrimers to be accurately monitored (by ^{31}P NMR spectroscopy) up to the highest generations reported so far for such macromolecules (generation 12).[1] In addition the reactivity of the terminal $P(X)Cl_2$ groups (X = S, O) provides the possibility of preparing a number of multifunctionalized (di-, tri-, or tetrafunctionalized) dendrimers.[2] Furthermore, the surface of the dendrimers can be covered with a variety of metals;[1a, 3] the terminal phosphane groups function as ligands. In this way, the size of these macromolecules can be visualized by electron microscopy.[1a]

duction of charges in different layers of the macromolecule: at the core, at the core and at the surface, within the cascade structure (core and internal generations), or even within the cascade structure and at the surface. Up to 322 charges can be chemoselectively incorporated in the skeleton; the resulting macromolecules remain fairly soluble in several solvents. This methodology allows charges to be created, where and when required, in different parts of the dendrimer skeleton. Remarkably, even the core of a sixth generation dendrimer (theoretical molecular weight 98430) is accessible.

By using a spacer such as the diphosphane $Ph_2P(CH_2)_6PPh_2$ (**1**) as in this present work or other polyphosphanes, a new core for the construction of dendrimers can be prepared. Treatment of **1** with the azide **2** leads to the formation of the tetraaldehyde **3**, which possesses two $(Ph)_2P{=}N{-}P(S){<}$ fragments (Scheme 1). Starting from **3** as the core and by employing a known strategy,[5a] first generation (**4-[G$_1$]**, **4-[G′$_1$]**), second generation (**4-[G$_2$]**, **4-[G′$_2$]**), third generation (**4-[G$_3$]**, **4-[G′$_3$]**),



Scheme 1. Synthesis of dendrimers **4-[G$_1$]**–**4-[G′$_4$]**.

Up to now only phosphorus-containing dendrimers having charges within the cascade structure (at each generation) and elaborated to the third generation[4] as well as a number of neutral phosphorus dendrimers have been reported;[5–8] the ionic dendrimers are insoluble from the third generation upwards (40 phosphonium centers).

We report here a strategy for the synthesis of phosphorus-containing dendrimers with generations of differing constitution.[9] This strategy allows for the first time the selective introand fourth generation dendrimers (**4-[G$_4$]**, **4-[G′$_4$]**) can be prepared in high yield (Scheme 1). The $O{-}C_6H_4CH{=}N{-}N(CH_3){-}P(S)$- fragment functions as the linker between each generation in all these new dendrimers.

The introduction of a new repeat unit at the surface of **4-[G′$_4$]** is outlined in Scheme 2. The reaction of methylhydrazine with the 64 terminal aldehyde groups of **4-[G′$_4$]** leads to the formation of **4-[G″$_4$]**, which undergoes further reaction with the phosphane Ph_2PCH_2OH (10% excess) to give **4-[G‴$_4$]**, a compound with 64 terminal phosphane groups. The last step of the construction of this new surface layer consists of the reaction of **4-[G‴$_4$]** with the azide **2** (64 equiv). This results in the formation of high yields of **5-[G′$_5$]**, a fifth generation dendrimer with 128 terminal aldehyde groups and a $\text{-}O\text{-}C_6H_4CH{=}N{-}N(CH_3){-}CH_2P(Ph)_2{=}N{-}P(S)(O{-}C_6H_4CHO)_2$ unit at the surface (Scheme 2).

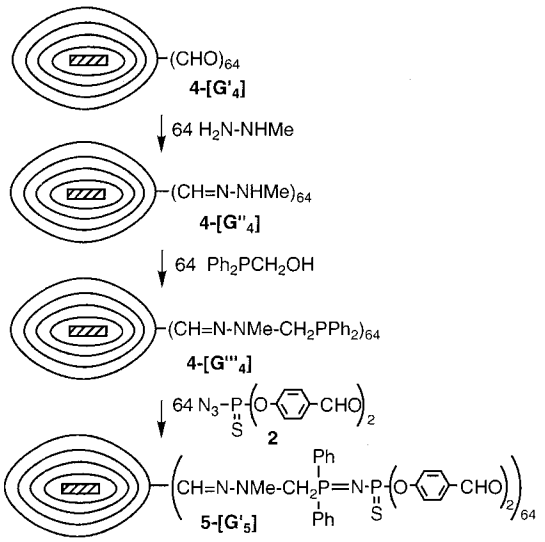
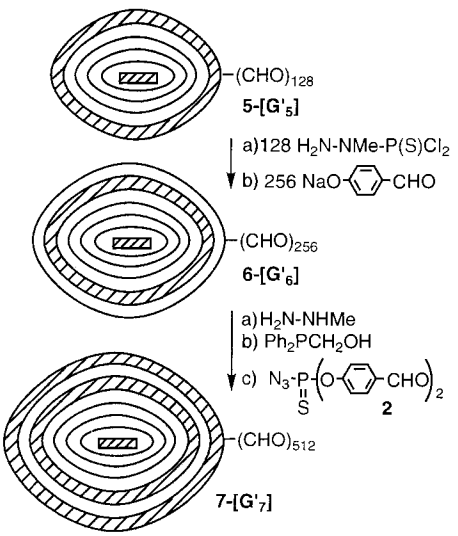


Scheme 2. Synthesis of dendrimers **4-[G"$_4$]**, **4-[G'"$_4$]**, and **5-[G'$_5$]**.

The application of the strategies in Schemes 1 and 2 to **5-[G'$_5$]** leads to the formation of dendrimer **6-[G'$_6$]** (sixth generation, 256 terminal aldehyde groups) and its subsequent conversion to **7-[G'$_7$]** (seventh generation, 512 terminal aldehyde groups) (Scheme 3).

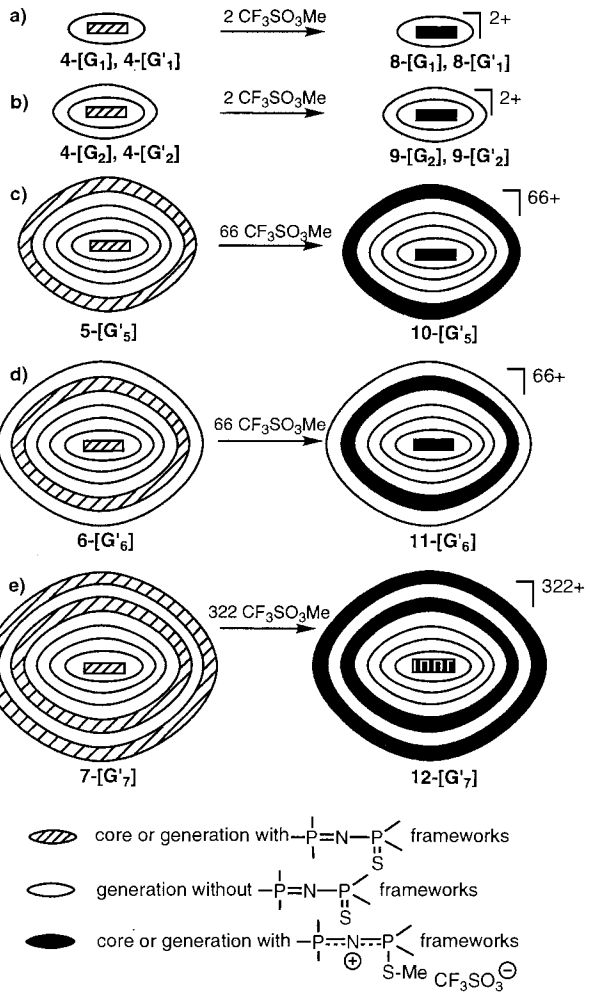


Scheme 3. Synthesis of dendrimers **6-[G'$_6$]** and **7-[G'$_7$]**.

Representations of dendrimers **4-[G$_1$]**–**4-[G'$_1$]**, **4-[G$_2$]**–**4-[G'$_2$]**, **5-[G'$_5$]**, **6-[G'$_6$]**, and **7-[G'$_7$]** are given in Scheme 4. The respective polycationic dendrimers were readily prepared by selective alkylation of the thiophosphoryl groups of the -(Ph)$_2$-P=N–P(S)- units.[10] Thus, addition of two equivalents of methyl trifluoromethanesulfonate to **4-[G$_1$]** or **4-[G'$_1$]** leads to the dicationic compounds **8-[G$_1$]** or **8-[G'$_1$]**, respectively, which possess a core of type **A**. The surface is neutral and carries

$[>(MeS)P{=}N{=}P(Ph)_2\text{-}(CH_2)_6\text{-}(Ph)_2P{=}N{=}P(SMe)<]^{2+}$ **A**

either terminal P(S)Cl$_2$ groups (**8-[G$_1$]**) or P(S)(O-C$_6$H$_4$CHO)$_2$ groups (**8-[G'$_1$]**) (Scheme 4a). The reactions can be easily monitored by ^{31}P $\{^1$H$\}$ NMR spectroscopy, since the two doublets attributed to the -(Ph)$_2$P=N–P(=S)- neutral fragments are replaced by two doublets for the $[\text{-}(Ph)_2P{=}N{=}P(SMe)<]^+$ cationic moieties (**4-[G$_1$]**: $\delta = 20.1$ (d, $^2J_{P,P} = 35$ Hz, P(Ph)$_2$) and 51.9 (d, $^2J_{P,P} = 35$ Hz, P$_0$=S); **8-[G$_1$]**: $\delta = 28.6$ (d, $^2J_{P,P} = 17.3$ Hz, P(SMe)) and 33.0 (d, $^2J_{P,P} = 17.3$ Hz, P(Ph)$_2$); **4-[G'$_1$]**: $\delta = 20.6$ (d, $^2J_{P,P} = 36$ Hz, P(Ph)$_2$) and 53.2 (d, $^2J_{P,P} = 36$ Hz, P$_0$=S); **8-[G'$_1$]**: $\delta = 28.8$ (d, $^2J_{P,P} = 18$ Hz, P(SMe)) and 32.9 (d, $^2J_{P,P} = 18$ Hz, P(Ph)$_2$)). ^{31}P NMR spectra recorded without proton decoupling clearly indicate that the external P=S bonds are not alkylated.



Scheme 4. Polyalkylations of dendrimers **4-[G$_1$]**, **4-[G'$_1$]**, **4-[G$_2$]**, **4-[G'$_2$]**, **5-[G'$_5$]**, **6-[G'$_6$]**, and **7-[G'$_1$]**.

Similar dialkylations can be achieved starting from second generation dendrimers such as **4-[G$_2$]** (eight terminal P(S)Cl$_2$ groups) and **4-[G'$_2$]** (16 terminal O-C$_6$H$_4$CHO groups) by reaction with two equivalents of CF$_3$SO$_3$Me, giving **9-[G$_2$]** and **9-[G'$_2$]**, respectively (Scheme 4b).[11]

More interestingly, treatment of the dendrimer **5-[G'$_5$]** (fifth generation, 128 terminal O-C$_6$H$_4$CHO groups, two internal, and 64 external -(Ph)$_2$P=N-P(S)- groups) with CF$_3$SO$_3$Me (66 equiv; Scheme 4c) gives **10-[G'$_5$]** (Figure 1). Alkylation takes place as expected at the periphery, which is now covered by 64 $[\text{-}(Ph)_2P{=}N{=}P(SMe)<]^+$ fragments, but also at the core (two $[\text{-}(Ph)_2P{=}N{=}P(SMe)<]^+$ fragments). ^{31}P NMR spectra (proton decoupling or not, selective irradiations) show that the core (two d at $\delta = 20.4$ and 51.2, $^2J_{P,P} = 34.0$ Hz for **5-[G'$_5$]**; two d at $\delta = 25.1$ and 33.4, $^2J_{P,P} = 18.5$ Hz for **10-[G'$_5$]**) as well as the periphery of the dendritic system (two d at $\delta = 14.2$ and 52.1, $^2J_{P,P} = 31$ Hz for the upper >P=N–P(S)< moieties

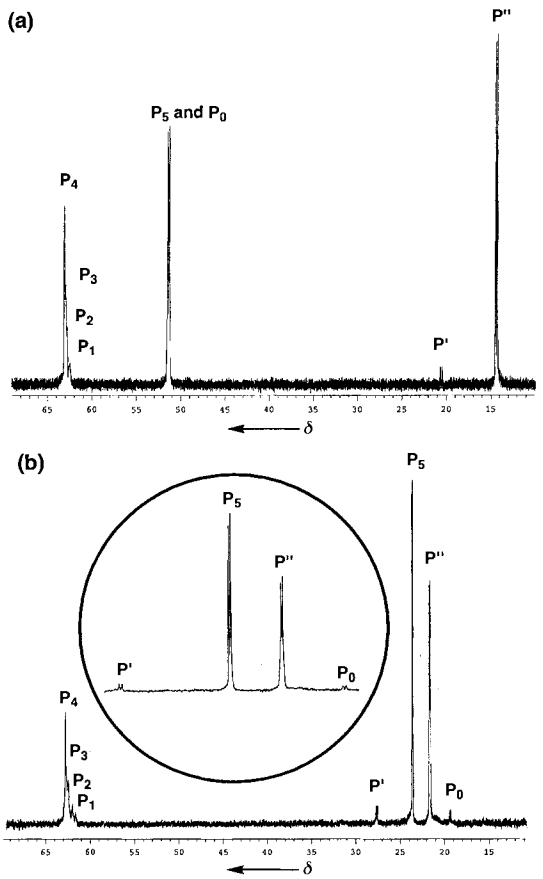


Figure 1. ^{31}P NMR spectra of **5-[G′$_5$]** (a) and **10-[G′$_5$]** (b). (See Scheme 5 for the numbering of phosphorus atoms).

of **5-[G′$_5$]**; 2 d at $\delta = 27.4$ and 29.3, $^2J_{P,P} = 17.5$ Hz for the upper moieties of **10-[G′$_5$]**)[11] is alkylated (Scheme 4c). As mentioned previously for first and second generation dendrimers, no alkylation of the other internal P=S groups occurs.

Remarkably, alkylation of the core of the dendrimer **6-[G′$_6$]** (sixth generation: two -$(Ph)_2P$=N−P(S)< linkages at the core, 64 for the fifth generation, and an upper generation incorporating 256 terminal O-C_6H_4CHO groups) can be clearly performed as demonstrated by ^{31}P NMR spectroscopy[12] (Scheme 4d). This bisalkylation of the core is accompanied, of course, by alkylation of the 64 -$(Ph)_2P$=N−P(S)< fragments of the fifth generation, giving rise to the polycationic macromolecule **11-[G′$_6$]**, which, therefore, incorporates charges at the core as well as within the cascade structure, and has a neutral surface. Here again no alkylation of the other P=S bonds takes place. This demonstrates for the first time that the core of this sixth generation dendrimer is available for certain reactions.

We have also studied the alkylation of the seventh generation dendrimer, **7-[G′$_7$]** (322 -$(Ph)_2P$=N−P(S)< fragments: two at the core, 64 for the fifth generation, 256 at the surface). Addition of CF_3SO_3Me (322 equiv) to **7-[G′$_7$]** gave the dendrimer **12-[G′$_7$]** (Scheme 4e). ^{31}P NMR experiments clearly indicate that alkylations of fifth and seventh generation dendrimers take place,[11] but do not unfortunately provide evidence as to whether the core is alkylated because signals due to central $[-(Ph)_2P{=}N{=}P(SMe)-]^+$ fragments cannot be detected. Further studies on the 24 dendrimers reported here and others are currently in progress.

[10] The selective alkylation of the thiophosphoryl group of the -$(Ph)_2P$=N−P(S)< fragments can be easily explained when the the polarity of these units is taken into account: -$(Ph)_2{}^+P$−N=$P(S^-)$<. If a large excess of methyl trifluoromethanesulfonate is used, alkylation of HC=N−$N(CH_3)$P(S) can occur under more drastic conditions but the resulting products quickly decomposed.

Stability and Conformational Switching in a Mini-Cyclic Oligonucleotide Conjugate**

Mathias K. Herrlein and Robert L. Letsinger*

The thermal stability of oligonucleotide duplexes in dilute aqueous solution can be increased by capping the termini with covalent linkers. Stilbenedicarboxamide bridges have proved particularly effective.[1] To test the limits of such stabilization, we have synthesized the small cyclic oligonucleotide conjugate **2**, which contains the four common nucleotides and two stilbenedicarboxamide bridges. With the capacity to form only two base pairs, **2** represents a minimal nucleotide construct that could make a "mini DNA duplex" by base stacking. We show here that **2** indeed adopts a remarkably stable conformation in neutral solution at room temperature that "melts out" on heating and switches in alkaline solution to a novel conformation that bring the stilbene groups in juxtaposition.

The method for preparing the cyclic conjugate (Scheme 1) is based on a facile ligation that has been observed for oligonucleotide-3'-phosphorothioates and 5'-*O*-tosyloligonucleotides brought into close proximity by hybridization.[2] The precursor **1** was synthesized by procedures reported for related conjugates with Expedite reagents (Millipore Corp., for introducing dA, dG, and dC units) and phosphoramidite derivatives of 5'-*O*-tosylthymidine and a protected stilbenedicarboxamide conjugate for introducing dT and the bridging unit, respectively.[2] On standing for 28 hours at 22 °C in 1 M aqueous NaCl at pH = 7, **1** converted smoothly into a new compound that eluted faster than **1** on reversed-phase high-pressure liquid chromatography (RP-HPLC, Figure 1). Ion-exchange chromatography (pH = 12) of the isolated product confirmed that it was homogeneous (single peak eluting at 23.7 min). We assign a cyclic structure (see **2**) to this product on the basis of the mode of formation and its chromatographic, thermal, spectral, and photochemical properties.

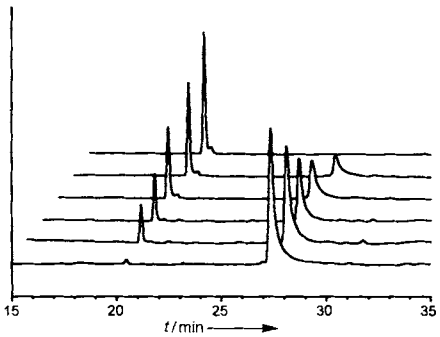

Figure 1. RP-HPLC profiles (monitored at 260 nm) for the reaction of **1** (ca. 1.3 μM) in 1 mL of aqueous buffer (pH = 7.2, 30 mM phosphate, 1 M NaCl) at 22 °C for (front to back) < 1 min, 3 h, 6 h, 12 h, 18 h, and 28 h. Compounds **1** and **2** elute at 27.3 and 20.4 min, respectively.

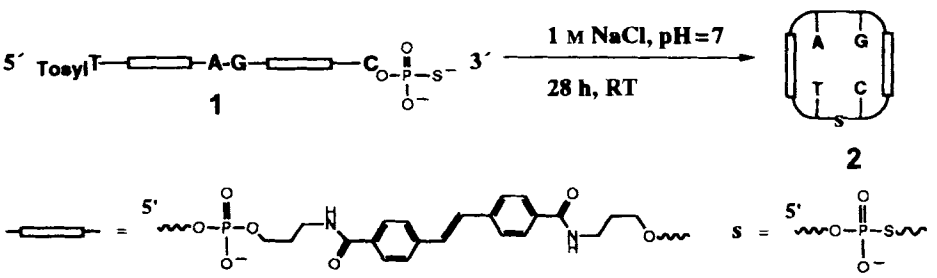
The increased mobility on RP-HPLC is consistent with loss of the tosyl group and with the pattern exhibited for closure of larger oligonucleotide rings by which a tosylate is displaced by a phosphorothioate.[2] In principle, tosylate displacement might proceed by either direct unimolecular cyclization of **1** to give **2** or a bimolecular reaction leading to linear or cyclic polymers. The latter possibility can be excluded in this case, however, since bimolecular reactions of oligonucleotide tosylate derivatives in the micromolar concentration range are far too slow to account for the reaction of compound **1**.[3] Unimolecular cyclization can be favored by the rigidity of the stilbenedicarboxamide linkers and possibly by formation of a transient intermediate that is stabilized by base pairing.

A striking feature of **2** is the high thermal stability of a base-stacked conformation. The slope of a melting curve observed at 260 nm for an aqueous solution of **2** (0.1 M NaCl, 30 mM phosphate, pH = 7) was still increasing at 90 °C (estimated $T_m > 80$ °C). In 50% ethanol, a solvent that destabilizes hybridization, a more complete melting curve was observed ($T_m \approx 66$ °C, Figure 2). The enhancement in stability may be attributed to the stilbenedicarboxamide bridges, which restrict fraying at the termini and place the nucleotides in positions that favor interaction. For comparison, T_m for the highly stabilized mini-hairpin structure, formed by folding of dGCGGAAAGC in 0.1 M aqueous NaCl, is 76.5 °C.[4] In this case base stacking in the dGGAAA loop as well as in the two terminal dGC base pairs apparently contributes to the stability.



Scheme 1. Cyclization of a small oligonucleotide conjugate.

[**] This research was supported by the National Institute of General Medical Sciences (GM10265).

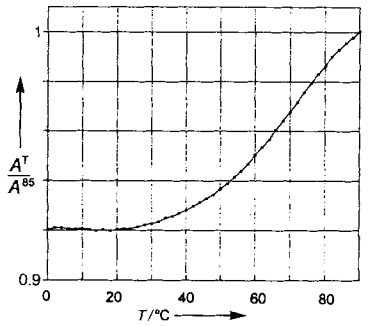

Figure 2. Melting curve for **2** (measured at 260 nm, ca. 0.5 Abs_{260} units) in 1 mL of a buffer (50% ethanol, 0.1 M NaCl, 10 mM Tris/HCl; pH = 7). A^T = absorbance at a given temperature; A^{85} = absorbance at 85 °C.

Stilbenedicarboxamide bridges can serve as useful reporter groups for hybridization of oligonucleotides.[5] An oligonucleotide bearing a single stilbenedicarboxamide group exhibits a fluorescence band with a maximum at about 380 nm, but when two stilbenedicarboxamide groups are aligned in proximity to one another by hybridization of adjoined oligonucleotides, the fluorescence shifts to an excimer band with $\lambda_{max} \approx 450$ nm.[5] Subsequent addition of alkali dissociates the duplex; the stilbenedicarboxamide groups are thereby separated, and the fluorescence shifts back to that characteristic for the single fluorophore. The pattern for **2** is reversed. It exhibited fluorescence characteristic of nonaligned fluorophores under conditions for hybridization (pH = 7) and a band in the region for the excimer in the presence of NaOH (Figure 3).[6]

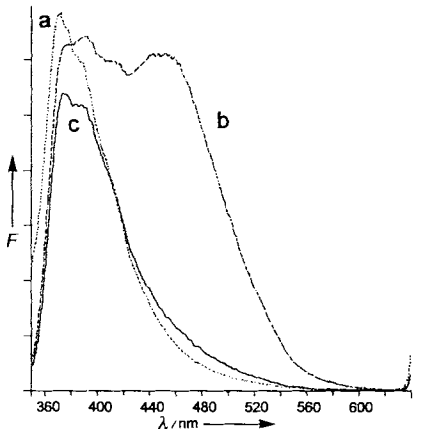

Figure 3. Fluorescence spectra of **2** (0.04 Abs_{340} units): a) in 2.5 mL water; b) after addition of 100 μL of 1 M NaOH; c) after addition of 1.5 mL of ethanol to solution formed in b).

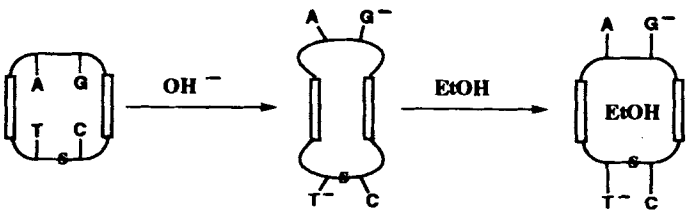
We conclude that interaction of the two stilbenedicarboxamide groups in the small cyclic conjugate is screened by the intervening base groups in neutral solution and that the compound undergoes a conformational change in alkaline solution that brings the fluorophores into close proximity. An attractive model for this transfer is depicted in Scheme 2: deprotonation of either thymine or guanine causes the bases to twist out, thereby permitting the stilbenedicarboxamide groups to approach each other. Interestingly, addition of alcohol, which destabilizes the interaction of organic chromophores in aqueous solution, then caused the excimer band to revert to that for the stilbenedicarboxamide group (Figure 3). This shift most likely reflects insertion of ethanol molecules between the two stilbene moieties.



Scheme 2. Conformational switching in a cyclic oligonucleotide stilbenedicarboxamide conjugate containing two pairs of nucleotides.

The model is further supported by the photochemical behavior of the cyclic conjugate. Stilbenedicarboxamide groups that are aligned by hybridization of pendant oligonucleotides readily photodimerize on irradiation in water.[5] This reaction is considerably faster than the *trans–cis* isomerization observed on irradiation of single-stranded conjugates under the same conditions.[1] The UV spectra in Figure 4 show that the cyclic product

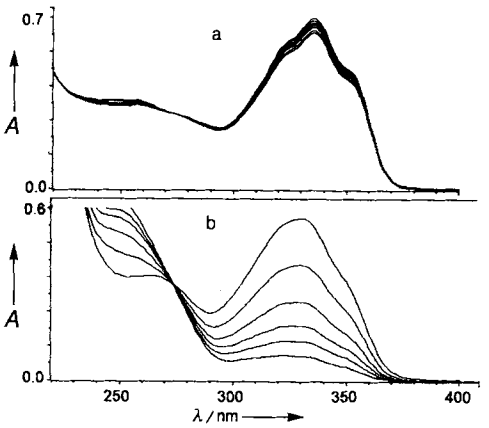


Figure 4. a) Ultraviolet spectra after irradiation of a solution of **2** in 1 mL of water for (top to bottom) 0.5 min, 1 min, 1.5 min, 2 min, 3 min, 4 min, and 5 min. b) Ultraviolet spectra after irradiation of a solution of **2** in 900 μL of water and 100 μL of 1 M NaOH for (top to bottom spectra) 0.5 min, 1 min, 1.5 min, 2 min, 3 min, and 4 min.

is relatively stable to irradiation (>300 nm) in solution at pH = 7. This is in accord with the view that the chromophores are separated by the nucleotide base pairs. In contrast, irradiation of **2**, after addition of sodium hydroxide, led to a rapid decrease in absorbance between 300 and 370 nm, as expected for photodimerization of stilbenedicarboxamide groups in close proximity.

Experimental Section

The oligonucleotides were synthesized on a Millipore Expedite 8905 DNA synthesizer. Reversed-phase chromatography was carried out on a Hewlett Packard ODS Hypersil column (4.6 × 200 mm) with 0.03 M $Et_3NH^+OAc^-$ at pH = 7.0 with a 1% min^{-1} gradient of CH_3CN and aqueous 0.03 M $Et_3NH^+OAc^-$ (95/5); flow rate = 1.0 mL min^{-1}. Ion-exchange chromatography was carried out on a Dionex Nucleo Pak NA 100 column in 10 mM aqueous NaOH with a 2.0% min^{-1} gradient of 1.0 M NaCl in 10 mM NaOH; flow rate = 1.5 mL min^{-1}. Melting curves were recorded on a Perkin Elmer Lambda 2 UV/VIS spectrophotometer, and absorbance changes at 260 nm followed while ramping the temperature at the rate of 1 °C min^{-1}. Fluorescence spectra were run at 20 °C on a Perkin Elmer LS 50B spectrofluorimeter, and irradiation carried out with a Rayonet reactor with two 350 nm lamps.

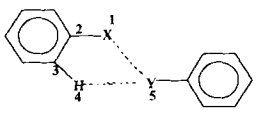
[6] This result is consistent with the cyclic structure **2** and inconsistent with a cyclic dimer, in which two stilbene units would be aligned in the base-stacked conformation and therefore exhibit excimer fluorescence.

Chains, Ladders, and Two-Dimensional Sheets with Halogen···Halogen and Halogen···Hydrogen Interactions

Oshrit Navon, Joel Bernstein,* and Vladimir Khodorkovsky

Intermolecular interactions have been traditionally classified by the nature of their energetic relationship: hydrogen-bonding, van der Waals interactions, charge-transfer forces, and others.[1] Many of these, in turn, are based on models best defined by a particular atom···atom potential. With the advent of supramolecular chemistry, there has been an increasing focus on recognizing the *structural patterns* of interactions as driving forces to a particular aggregation state.[2] As any crystal structure represents a balance of forces, these structural patterns may be composed of one kind of intermolecular interaction, if a single interaction dominates the formation of patterns (for example hydrogen bonds), or may arise from a combination of different types of interactions.[1, 3] The term recently proposed for describing structural patterns is supramolecular synthon.[3]

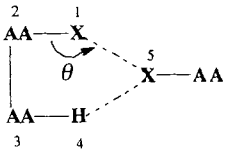
The recognition of structural patterns and their use in understanding intermolecular interactions and subsequently designing desired structures has been particularly relevant for hydrogen bonds.[2] This is a natural consequence of their being among the strongest and most highly directional of the intermolecular forces. Considerably less attention has been paid to the structural patterns exhibited by other interactions. In the course of investigating the relationship between molecular conformation and crystal forces,[4] we recently noted a recurring pattern of intermolecular interactions **I**, which include both halogen···halogen and C–H···halogen contacts.



I, X, Y = Cl, Br

A number of crystallographically isostructural compounds with similar substitution all contained this pattern, which was accompanied by a nonminimal energy molecular conformation. Other closely related compounds did not exhibit the pattern and adopted a minimal energy conformation in the crystal structure. Recognition of the pattern and its apparent role in stabilizing an otherwise unfavorable molecular conformation prompted us to characterize the nature and extent of this interaction. The results indicate that this pattern is not uncommon and can be used for designing supramolecular arrays.

Characterization of the pattern is based on a survey of the Cambridge Structural Database (CSD, April 1996),[5] which was carried out by searching for and analyzing structures containing the five-membered intermolecular ring pattern **I** and Cl or Br substituents on the aromatic group. The search was subsequently expanded to find other structures in which the two intermolecular halogen···halogen and H···halogen interactions are still present, but aromatic substitution was no longer a restriction (see structure **II**). X···X and X···H distances were defined by van der Waals radii (Br = 1.85, Cl = 1.75, H = 1.2 Å) with a tolerance of 0.2 Å. Table 1 contains data for which the C–H bond length was normalized to 1.089 Å.[6] This search led to 411 hits, indicating the widespread nature of this intermolecular pattern. Of these hits, 157 do not contain a metal atom.



II, X = Cl, Br
AA = C, N, P, B

Table 1. Results of the CSD search for structures of form **II**.

Group	Hits	X···X [Å]	X···H [Å]	θ [°]
Br···Br	10	3.40–3.70	2.90–3.90	82.41–123.1
Cl···Cl	37	3.30–3.50	2.80–4.00	78.20–133.5
Br···Cl	2	3.40–3.60	3.20–3.50	91.80–111.7
AA = metal, nonmetal	411	3.10–3.70	2.30–4.00	38.5–133.4
AA = C, N, P, B	157	3.20–3.70	2.70–4.00	70.0–126.2

Examination of the metal-free compounds found in the search showed that this intermolecular ring motif virtually always results in one of three recurring infinite crystal packing patterns (Table 2): 1) a single-stranded chain with one five-membered ring per molecule (**III**, Scheme 1a), 2) a "ladder" with two patterns per molecule (**IV**, Scheme 1b), and 3) a two-dimensional pattern with more than two rings per molecule (**V**; Scheme 1c).

Table 2. Frequency of pattern types for the 157 compounds with AA = C, N, P, B.

Pattern type	Hits	No. of cmpds with X–X =		
		Cl···Cl	Br···Br	Cl···Br
Chain	90	23	5	1
Ladder	27	8	1	–
Layer	10	5	2	–
Other	30	1	2	1

For most hits AA is a carbon atom, as was expected from the frequency of structure types studied and compiled in the CSD. Of the 157 hits for nonmetallic AA, 152 were with C, three with N (one hit included also P), and two with B.

Despite the preponderance of structural evidence for the intermolecular interaction **I**, the question still remains whether

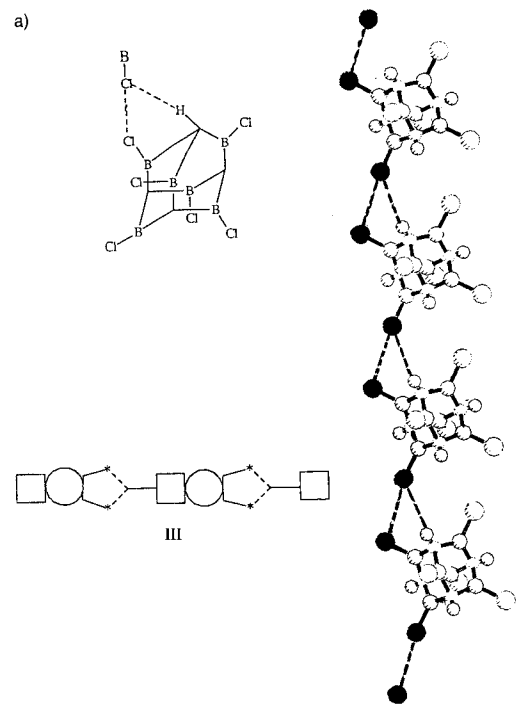

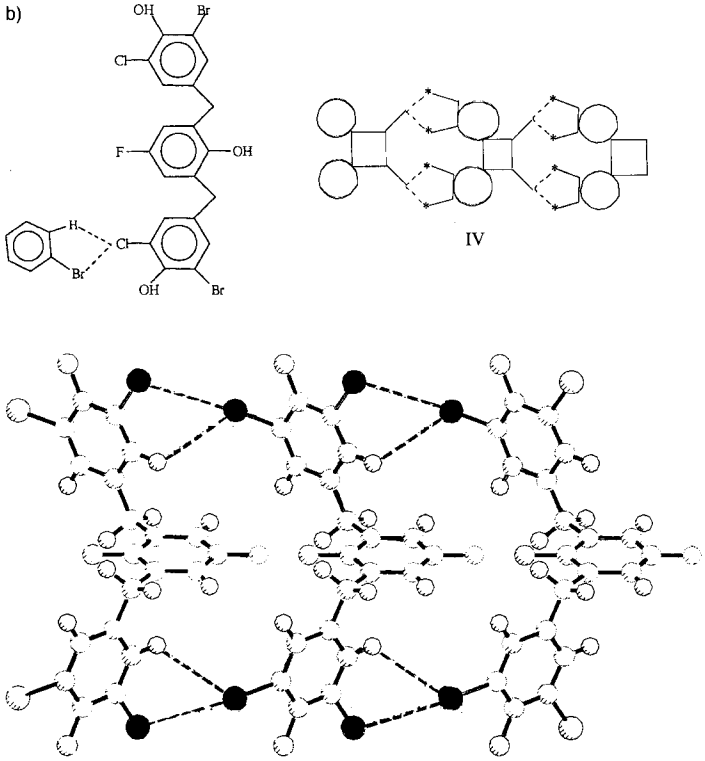

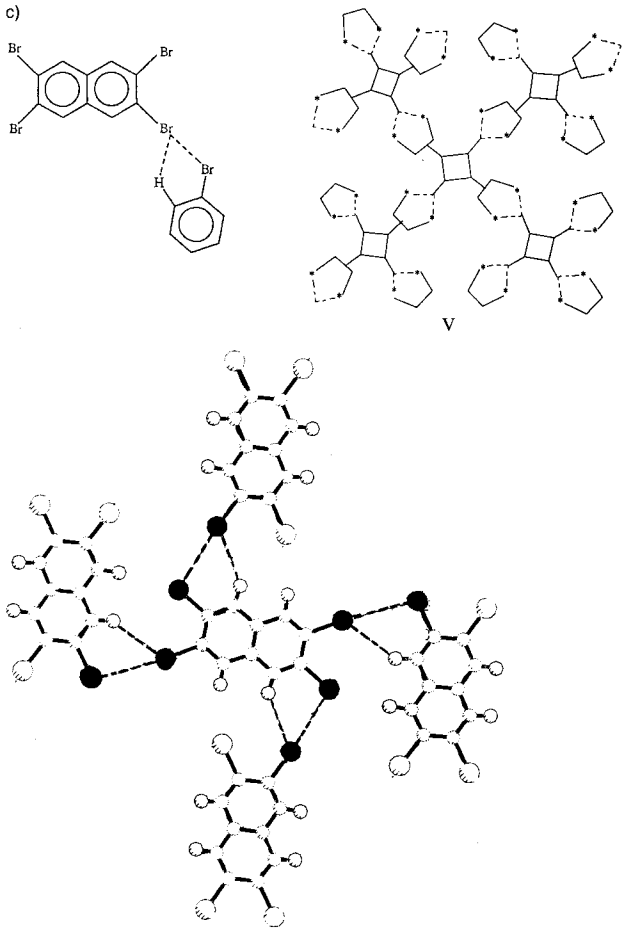

Scheme 1. Examples of the three types of crystal networks resulting from the pattern **I**. Each indicates schematically the chemical structural formula for the pattern at the molecular level, an idealized representation of the network, and its manifestation in the crystal structure. Halogen atoms are represented as solid spheres. a) The chain network for VAKFES CSD reference code. b) The ladder network for BCFPLB. c) The two-dimensional network for BRNPHL.

such an interaction is energetically stabilizing. We therefore investigated the energetics of this pattern with a number of molecular orbital computational techniques at various levels of sophistication. The test structure was a pair of benzene rings with one halogen atom arranged as in **I**, and the reference energy was computed for the two molecules at infinite separation. Calculations were performed on the four possible pairing combinations for X, Y = Cl, Br in **I** (Table 3). Furthermore, ab initio calculations[7] were carried out for *N*-(*p*-chlorobenzylideneaniline/*m*-chloroaniline), one of the isostructural structures also containing this pattern, in the different basis sets presented above (Table 4).

Table 3. Computed AM1 stabilization energy upon formation of **I**.

X···Y in **I**	E_s [kcal mol^{-1}]	X–Y in **I**	E_s [kcal mol^{-1}]
Cl···Cl	0.12	Cl···Br	0.86
Br···Br	1.94	Br···Cl	0.18

Table 4. Stabilization energies (E_s) for *N*-(*p*-chlorobenzylidene)-*m*-chloroaniline as determined by ab initio calculations.

Basis set	E_s [kcal mol^{-1}]	Basis set	E_s [kcal mol^{-1}]
STO-2G	0.90	STO-3G*	0.10
STO-3G	0.10	3-21G	0.16

These results clearly indicate a stabilizing interaction for this pattern irrespective of X or the basis set. The energetics thus support the qualitative observation, based on the recurring structural pattern, that the intermolecular atomic arrangement **I** is indeed a motif for molecular recognition and the generation of crystal structures.

The First Crystalline Solids in the Ternary Si-C-N System**

Ralf Riedel,* Axel Greiner, Gerhard Miehe, Wolfgang Dressler, Hartmut Fuess, Joachim Bill, and Fritz Aldinger

Dedicated to Professor Ekkehard Fluck on the occasion of his 66th birthday

Advanced non-oxide ceramics and ceramic composites with compositions in the ternary Si-C-N system (Figure 1) are of high technical relevance. Carbon, in the form of graphite and diamond, is industrially used as electrode and abrasive material. The binary compounds silicon carbide (SiC) and silicon nitride (Si_3N_4) have received much attention in the past two decades with respect to their application as cutting tools or structural materials in engine components.[1] The existence of the carbonitride C_3N_4 with a β-Si_3N_4 structure has been postulated since 1989 and is still controversial.[2]

Recently polycrystalline Si_3N_4/SiC composites with superplastic behavior[3] and enhanced mechanical properties[4] or ultra-high oxidation resistance[5] relative to monolithic Si_3N_4 and SiC counterparts have been reported. Composite ceramic materials comprising polycrystalline Si_3N_4 and SiC are presently produced by 1) sintering of Si_3N_4/SiC powder mixtures, 2) chemical vapor deposition with hexamethyldisilazane as the reaction gas,[4] or 3) thermally induced conversion of polyorganosilazanes under Ar, N_2, or NH_3/N_2 atmospheres at 1000–1100 °C.[6, 7] Procedures 2 and 3 provide intermediate amorphous solids in the ternary Si-C-N system of general composition $Si_{3x+y}C_{1-x}N_{4x}$ with $0 \le x \le 1$ and $0 \le y \le 1$. Subsequent in situ crystallization of the amorphous phase results in the formation of α,β-Si_3N_4 and α,β-SiC polymorphs with nanosized SiC particulates.[4, 6] Kawamura has found a β-SiC with interstitial nitrogen atoms that prevent 3C–SiC transformation to hexagonal α-SiC.[8a] However, crystalline ternary solids with a covalently bonded Si-C-N network structure have not yet been reported.[8b] These are of basic fundamental and technical interest for further development of single source Si_3N_4/SiC precursors with well-defined structural features and adjusted compositions.

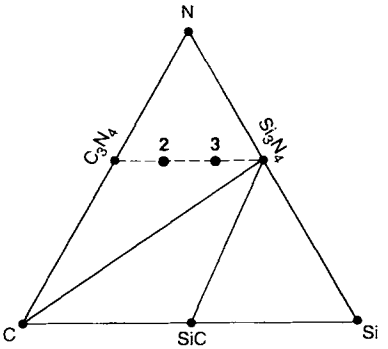

Figure 1. Isothermal section of the ternary Si-C-N phase diagram valid below 1440 °C and 0.1 MPa N_2 pressure [30]. Solid lines: Si_3N_4/C and Si_3N_4/SiC tie lines, dashed line: hypothetical Si_3N_4/C_3N_4 tie line.

In the course of our work on the synthesis of alternative Si_3N_4/SiC precursor materials, we recently developed a novel class of organosilicon polymers, denoted as polyorganosilylcarbodiimides, that are synthesized by the reaction of dichloroorganosilanes with cyanamide or bis(trimethylsilyl)carbodiimide [**1**, Eq. (a) and (b)].[9, 10] The polyorganosilylcarbodiimides can be thermally decomposed at 1100 °C under Ar to form amorphous Si-C-N solids in 30–64 wt% yield.

$$MeRSiCl_2 + H_2N{-}CN + 2n\ Py \longrightarrow [{-}MeRSi{-}N{=}C{=}N{-}]_n + 2n\ Py \cdot HCl \quad (a)$$

Py = pyridine; R = H, Me, $CH{=}CH_2$

$$n\ Me_2SiCl_2 + n\ Me_3Si{-}N{=}C{=}N{-}SiMe_3 \xrightarrow{Py} \underset{\mathbf{1}}{} [{-}Me_2Si{-}N{=}C{=}N{-}]_n + 2n\ Me_3SiCl \quad (b)$$

The reaction of $SiCl_4$ with **1** at temperatures between 25 and 100 °C directly provides silicon dicarbodiimide SiC_2N_4 (**2**) with a polymeric inorganic network structure [Eq. (c)]. This reaction is catalyzed by pyridine and provides **2** in quantitative yields as a colorless, X-ray-amorphous powder with residual trimethylsilyl end groups, as analyzed by FT-IR and ^{29}Si MAS-NMR spectroscopy. Subsequent calcination in vacuum at

$$n\ SiCl_4 + 2n\ Me_3Si{-}N{=}C{=}N{-}SiMe_3 \xrightarrow{Py,\ T = 100\,^\circ C} \underset{\mathbf{1}}{} [Si(N{=}C{=}N)_2]_n + 4n\ Me_3SiCl \quad (c)$$

350 °C completes the polycondensation reaction [Eq. (c)] and reduces the trimethylsilyl groups by evolution of Me_3-Si–N=C=N–$SiMe_3$. Elemental analysis of the moisture-sensitive product annealed at 600 °C gives the stoichiometry SiC_2N_4 and supports the formation of **2** according to Equation (c). In situ high-temperature X-ray powder diffraction studies reveal that initial crystallization of the amorphous material begins above 400 °C to give polycrystalline silicon dicarbodiimide (**2a**). Once **2a** has formed at 400 °C, it undergoes a reversible phase transition at 150 °C with minor hysteresis. The X-ray powder diffractogram of the room temperature phase, for which the crystal structure has not yet been determined, displays very broad lines. If this broadening is attributed to particle size effects, a mean diameter of 10–20 nm can be estimated. The high-temperature phase **2a** is cubic; the structure was derived from powder diffraction data.[11] It displays the topology of an *anti*-cuprite structure (Figure 2a), which can be considered as two

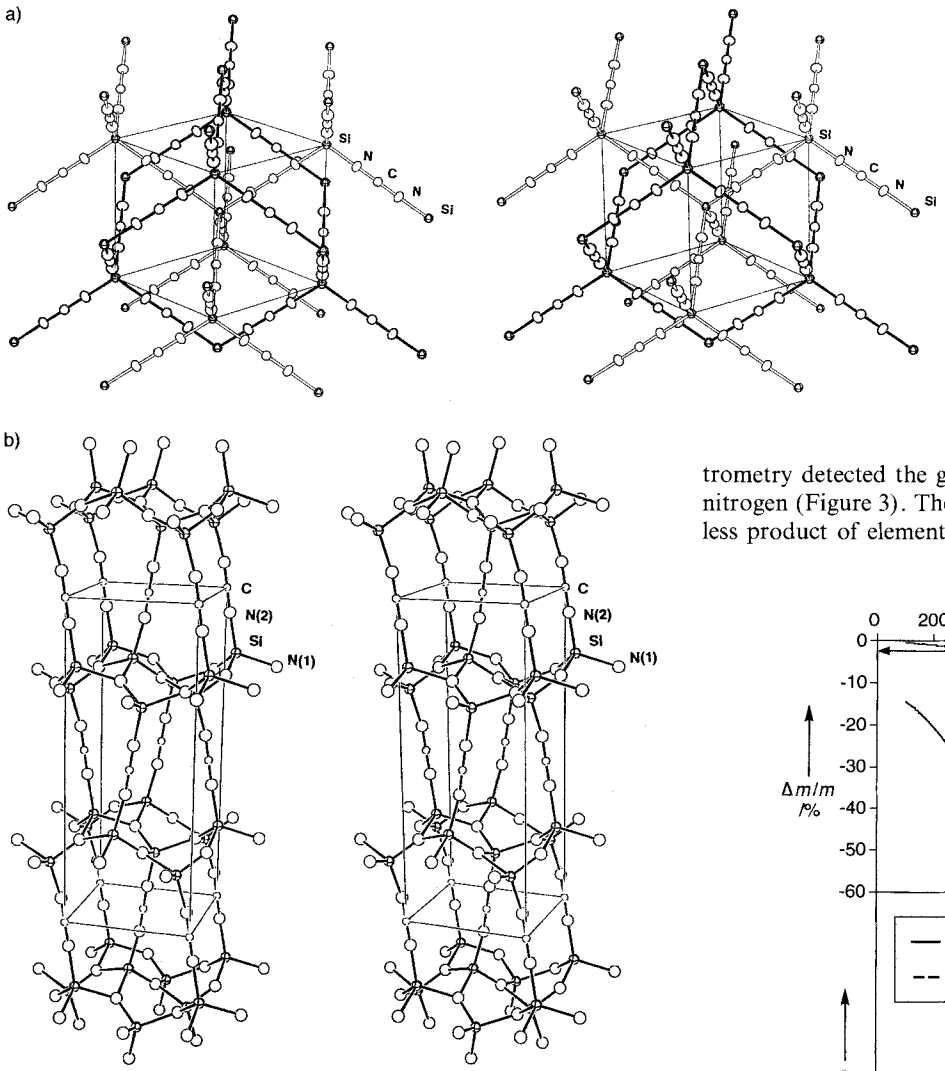

Figure 2. a) Stereoview of the crystal structure of **2a**. The *anti*-cuprite type structure is shown as two interpenetrating β-cristobalite structures, light and bold, origin at Si (0.25, 0.25, 0.25); probability ellipsoids at 1.2%. b) Stereoview of the crystal structure of **3**.

interpenetrating networks[12] of the high cristobalite (SiO_2) type. The X-ray powder diffractogram shows sharp lines and an extreme decrease in intensity with decreasing d-value. Rietveld refinement[13] of the only free positional parameter (x(N)) and of individual temperature factors for the three independent atoms leads to rms amplitudes of about 50 pm for *all* atoms. This indicates considerable static (rather than dynamic) disorder. The average structure with symmetry enforced Si-N-C bond angles of 180° has very short calculated interatomic distances (Si–N 158 pm, C–N 110 pm). Since all sites are of the type x,x,x (but the real Si-N-C angles are certainly not 180°) these distances may be considered as the projections of the true distances onto the space diagonal of the unit cell. The comparatively narrow line profiles show that long-range order is preserved.

The ^{29}Si MAS-NMR spectrum (59.6 MHz, 25 °C, TMS) of **2a** reveals a single peak at $\delta = -103$. This extraordinarily high-field shift for silicon coordinated to four nitrogen atoms is explained by the pseudo-chalcogenic character; that is, by the group electronegativity of the carbodiimide unit, which is similar to that of oxygen.[14] Accordingly, the ^{29}Si NMR chemical shift of **2a** is on the order of that for SiO_2 ($\delta = -110$), in contrast to $\delta = -48.7$ for β-Si_3N_4.[15] The presence of carbodiimide units in **2** and **2a** is proven by the ^{13}C MAS-NMR signal (100.55 MHz, 25 °C, TMS) at $\delta = 120$[10] and the characteristic vibrational absorption band in the FT-IR spectrum (KBr) at $\tilde{\nu} = 2174\ cm^{-1}$ (N=C=N).[16]

The silicon dicarbodiimide **2a** is thermally stable under argon up to 900 °C. At higher temperatures SiC_2N_4 reveals a weight loss of about 40 wt%, as analyzed by thermal gravimetric analysis (TGA, Figure 3). Simultaneous mass spectrometry detected the gaseous products cyanogen (C_2N_2) and nitrogen (Figure 3). The decomposition reaction gives a colorless product of elemental composition Si_2CN_4, as determined

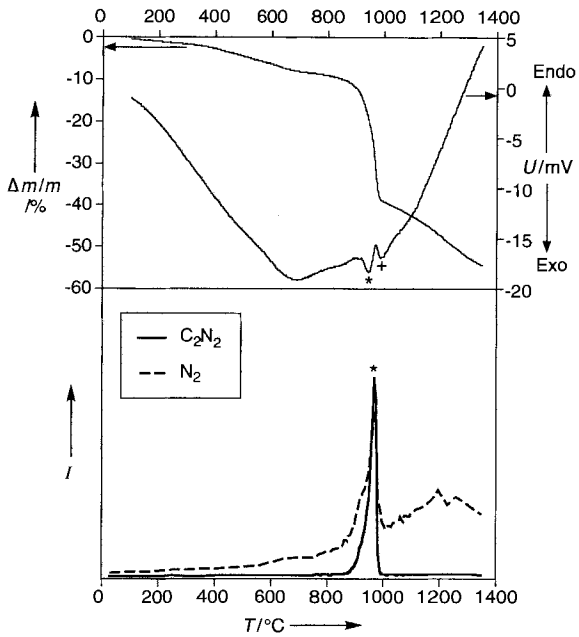

Figure 3. Simultaneous TGA-MS anaysis of amorphous **2**. Heating rate: 2 K min^{-1} in a stream of helium. * = Exothermal DTA peak corresponding to the decomposition of **2**, accompanied by the formation and evolution of C_2N_2 and N_2. + = Exothermal DTA peak related to the crystallization of **3**.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3606-0604 $ 17.50+.50/0

by bulk analysis. Taking into account the TGA/MS and the analytical results, the formal reaction Equation (d) can be derived.

$$\underset{\mathbf{2a}}{4\ SiC_2N_4} \xrightarrow{T = 920\text{–}1000\,^\circ C} \underset{\mathbf{3}}{2\ Si_2CN_4} + 3\ C_2N_2 + N_2 \qquad (d)$$

In contrast to **2** and **2a**, compound **3** is relatively stable in air. In the differential thermal analysis (DTA), two exothermal peaks at 945 and 990 °C can be assigned to decomposition of the SiC_2N_4 phase and crystallization of Si_2CN_4, respectively (Figure 3). FT-IR and ^{13}C MAS-NMR studies are unequivocal evidence for the presence of carbodiimide units in **3** [FT-IR (KBr): $\tilde{\nu} = 2170\ cm^{-1}$ (N=C=N); ^{13}C MAS-NMR (100.55 MHz, 25 °C, TMS): $\delta = 116$]. Broadening of the X-ray powder diffraction lines of **3** indicates the formation of nanocrystals, which is confirmed by transmission electron microscopy (TEM, Figure 4). Nanocrystalline Si_2CN_4 has a plate-like shape with a thickness of 4 to 10 nm and a lateral extension of 20 to 70 nm.

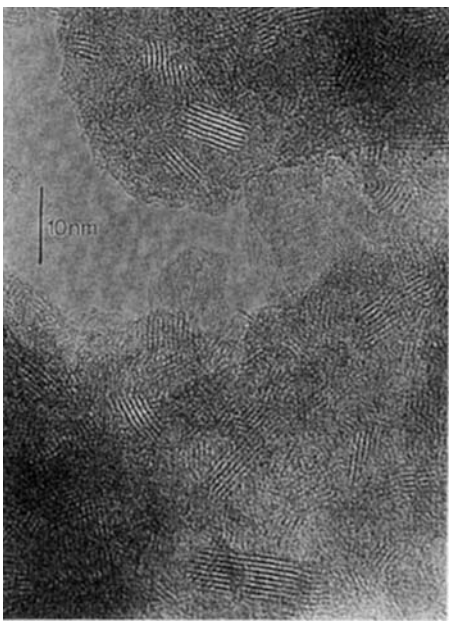

Figure 4. HRTEM micrograph of nanocrystalline **3**.

The X-ray powder diffractogram displays broad lines of different shape and half-width; the *hkl*-dependence of the latter is in good agreement with the finding from TEM work (Figure 4). The crystal structure of **3**[17] was determined with X-ray powder diffraction data and HRTEM (HR = high resolution). The latter reveals a concentration of scattering density in planes about 0.7 nm away from each other. The diffraction symbol is *mmmAba*. While in space group *Abam* no reasonable structure can be realized that corresponds to the findings from both FT-IR spectroscopy and HRTEM, there is a unique possibility in *Aba*2.

The appearance of the X-ray powder diffraction lines hampers a conventional Rietveld refinement. The refinement procedure, however, is numerically stable and preserves the topology of the initial model.[17] The parameters given in ref. [17] are to be seen as merely a description of the topology. Calculated interatomic distances (Si–N 151–189 pm) and angles (103.5–117.2° within the SiN_4 tetrahedron) are severely falsified since the origin of the complex line shape is not part of the refined model.

Compound **3** consists of layers of condensed SiN_4 tetrahedra. The apical N atoms belong to carbodiimide groups that link the layers along the *b* axis (Figure 2b, interlayer distance 0.679 nm). If the N=C=N connections between the layers are broken and newly arranged by shifting each second layer by the vector [0.5, 0, 0.5], the topology of the structure of **3** transforms to that of silicon oxynitride Si_2N_2O,[18] in which oxygen plays the part of the carbodiimide group. Moreover, the structural similarity of **3** with silicon oxynitride is documented in the ^{29}Si MAS-NMR spectrum with a single peak at $\delta = -67$ (Si_2N_2O: $\delta = -64$).

The crystal structures of **2a** and **3** differ significantly from those of the α- and β-Si_3N_4 polymorphs and cannot be considered as being formed by successive substitution of silicon in Si_3N_4 by carbon atoms. In contrast to the ternary carbon(IV) nitrides $M^I_2CN_2$ (M^I = Li,[19] Na,[20] K,[21] Tl,[21] Ag,[22] In,[23] NaIn[23]) and $M^{II}CN_2$ (M^{II} = Mg,[24] Ca,[25] Sr,[24] Ba,[24] Zn,[19] Pb[23]) with the linear cyanamide anion CN_2^{2-},[23, 24] **2a** and **3** are novel carbon nitrides with isomeric NCN groups covalently bonded to silicon. The title compounds are compositionally located on a hypothetical tie line between Si_3N_4 and C_3N_4 in the ternary Si-C-N phase diagram (Figure 1). Future work should be directed at evaluating possible reaction conditions (temperature and N_2 pressure) that allow SiC_2N_4 and/or Si_2CN_4 to partition to C_3N_4 and Si_3N_4.

In accordance with thermodynamic considerations represented in Figure 1, annealing Si_2CN_4 above 1000 °C results in continuous loss of nitrogen (Figure 3). This high-temperature decomposition of **3** gives an amorphous Si-C-N material that crystallizes at temperatures above 1500 °C to form a polycrystalline α-Si_3N_4/α-SiC composite powder in 74 wt% yield (calculated: 70 wt%).

In summary, the aforementioned findings encourage us to search for novel, crystalline ternary Si-C-N solid phases and the carbon nitride C_3N_4. Moreover, the carbodiimide groups found in **2** and **3** can be further utilized for hydrosilylation and hydroboration reactions to provide new Si-C-N or Si-B-C-N compositions.[9, 26, 27]

Experimental Section

All experiments were performed under pure and dried argon or nitrogen [28]; synthesis of **1** according to ref. [29].

2: $SiCl_4$ (21 mL, 0.183 mol) was mixed with dried toluene (25 mL) and added dropwise at room temperature to a stirred mixture of **1** (85 mL, 0.375 mol), toluene (25 mL), and pyridine (8.2 mL, 0.1 mol). The reaction was completed by heating at reflux for 1 h. After distillation of the solvent and formed $(CH_3)_3SiCl$, the resulting white powder was calcined under vacuum at 350 °C to remove residual trimethylsilyl end groups. Afterwards, colorless silicon dicarbodiimide **2** was isolated (18.8 g, 0.174 mol, 95.1% yield). Annealed samples were prepared by heating the material in a quartz tube under argon to the desired temperature with 4 h isothermal hold. Elemental analysis of **2** calcined at 350 °C [wt%] (calcd for $(CH_3)_3$-Si–N=C=N–[Si(N=C=N)$_2$]$_n$–Si$(CH_3)_3$, $n = 4$): Si 27.8 (27.23), N 41.8 (40.73), C 29.9 (29.11), O 0.5 (0.0), H not determined. (2.93). Elemental analysis of **2a** annealed at 600 °C [wt%] (calcd for SiC_2N_4): Si 28.8 (25.97), N 47.7 (51.81), C 20.3 (22.21), O 0.52 (0.0)

3: SiC_2N_4 was heated under argon to 970 °C to yield nanocrystalline Si_2CN_4 (56.5%, calcd: 57.4%). Crystallization experiments at temperatures above 1000 °C were conducted in boron nitride crucibles in a graphite furnace under nitrogen. *Elemental analysis of* **3** *annealed at 1050 °C [wt%] (calcd for* Si_2CN_4*)*: Si 46.3 (45.22), N not determined (45.11), C 9.9 (9.67)

[16] The linear carbodiimide group of $D_{\infty h}$ symmetry allows exclusively the asymmetric stretching and deformation vibration in the IR spectrum; the symmetric vibration band is no longer forbidden for the cyanamide group of lower symmetry (C_{2v}). Therefore, the absence of the symmetric stretching mode in SiC_2N_4 and Si_2CN_4 is strong evidence for the existence of the carbodiimide rather than cyanamide structure (see also ref. [24]).

To Couple or Not To Couple: The Dilemma of Acetylide Carbons in $[(\eta^5\text{-}C_5H_5)_2M(\mu\text{-}CCR)_2M(\eta^5\text{-}C_5H_5)_2]$ Complexes (M = Ti, Zr)— A Theoretical Study for R = H, F**

Eluvathingal D. Jemmis* and Kalathingal T. Giju

C–C coupling reactions mediated by transition metal complexes form a major area of chemical research. Several sophisticated synthetic steps are brought about by multinuclear transition metal organometallics.[1] We focus our attention here on C–C coupling reactions with diamagnetic homodinuclear Ti and Zr complexes. More than 25 years ago Teuben and de Liefde Meijer suggested structures **1a** or **2a** (Scheme 1) for

their dimer of bis(η^5-cyclopentadienyl)phenylethynyl titanium.[2] An X-ray structure analysis of the related $[(\eta^5\text{-}C_5H_4CH_3)_2Ti(\mu\text{-}PhC_4Ph)Ti(\eta^5\text{-}C_5H_4CH_3)_2]$ by Sekutowski and Stucky in 1976 showed it to have the C–C coupled geometry **3b**; a result that, along with spectral data, demonstrated that Teuben's compound also has a similar structure (**3a**).[3] It was also shown that **3b** can be obtained from PhC≡C–C≡CPh. In 1989 Hawthorne and co-workers discovered that trimethylsilyl-substituted acetylene led to the Ti complex **2c**; the C–C coupled product **3c** was not formed.[4] Three years later Rosenthal and co-workers showed that reactions with $(CH_3)_3Si\text{-}C{\equiv}C\text{-}C{\equiv}CSi(CH_3)_3$ gave the bis(acetylide) structure **2c** instead of **3c**.[5] All of these results indicate the delicate, thermodynamic balance that exists between **2** and **3** for M = Ti. This were further demonstrated by Royo and co-workers with a

bridged bis(cyclopentadienyl) ligand.[6] They could isolate the paramagnetic dimer **1**, which, depending on solvent and temperature, isomerizes to the diamagnetic structures **2** and **3**. The C–C coupling and cleaving reactions mediated by Ti naturally led to interest in analogous reactions with Zr. Early X-ray crystallography investigations from Erker and co-workers showed that the dinuclear Zr complex with bridging alkynyl ligands has the structure **2f**.[7a] Detailed studies displayed that the structure is fluxional, but in no case was the Zr complex with the C–C coupled product **3f** isolated.[7c] Changing the ligands to the bridged cyclopentadienyls also did not yield a complex of structure **3**; only **2e** was obtained.[6] Attempts by Metler and Nöth with trimethylsilylacetylides as starting ligands did not proceed beyond **2g**.[8] An early extended-Hückel MO study suggested closed shell species corresponding to **2** and **3**, but could not explain the absence of C–C coupling in the Zr complexes.[9]

Is this contrasting behavior of Ti and Zr a direct consequence of a variation in thermodynamic stability of the resulting structures **3**? Is there a substantial difference in the activation energies for the formation of these two products? These are important questions in view of the continuing interest in C–C bond-forming reactions[10]. We present here ab initio MO and density functional studies, which suggest substituents that would force the reaction in Equation (a) to the product side.

Realistic model complexes were chosen for **2** and **3**. Thus the singlet C_{2h} complexes **4**–**7**, in which cyclopentadienyl derivatives were replaced by C_5H_5 (Cp), and the acetylide substituent R by hydrogen, were fully optimized at the Hartree-Fock (HF) level. The effective core potentials of Hay and Wadt[11] along with the valence basis sets, available in Gaussian94[12] package as LANL2DZ, were used for all atoms. The effect of electron correlation was estimated by calculating the energy at the B3LYP/LANL2DZ level[13] with the HF geometry. The total and relative energies are given in Table 1, and important geometric parameters in Table 2.

Complexes of the kind **4**, **5**, and **6** are experimentally known, while examples of type **7** have not yet been prepared. This agrees with the fact that the relative energies for **4** and **5** are similar while **6** is calculated to be 13.5 kcal mol^{-1} lower in energy than **7**. Changes in the substituents and ligands in Ti complexes **4** and **5** can tilt the equilibrium one way or the other. Experimentally, substituting the phenyl group on the alkyne by $Si(CH_3)_3$ led to the preferential formation of the bis(acetylide) structure **2c** instead of the C–C coupled product **3b**.[4] Formation of the C–C cleaved product from $(CH_3)_3SiC{\equiv}C{-}C{\equiv}CSi(CH_3)_3$ dramatically demonstrates the ability of the dinuclear template to reduce the high activation barrier usually associated with rupture of a C–C bond.[5] There is a reversal of the relative stabilities with Zr. As mentioned above, **6** is 13.5 kcal mol^{-1} lower in energy than **7**; no Zr complex of type **3** has been observed so far.

Table 1. Total energies (E_{tot}) [Hartree], zero point energies (ZPE), and relative energies (E_{rel}) [kcal mol^{-1}] at HF/LANL2DZ, B3LYP/LANL2DZ//HF/LANL2DZ (**4**–**9**) and B3LYP/LANL2DZ (**10**–**13**, **TS1**, and **TS2**) levels. The number of imaginary frequencies and the lowest vibrational frequency [cm^{-1}] are given in parentheses.

[a] Unscaled ZPE corrections are included for **10**–**13**, **TS1**, and **TS2**.

Formal oxidation states +3 can be assigned to the metal in **2** and +4 to the metal in **3**. This would lead to a 17e complex with additional metal–metal interactions that are mediated through the bridging ligands in **2**. Structure **3** has two 16e metal centers. The reaction may be described as an unusual oxidative coupling (change from +3 to +4 oxidation state with concomitant C–C coupling). It is tempting to conclude that Ti, a first-row transition metal, can accommodate both 16 and 18 electron counts, but Zr may not be able to do so.[14] However, this need not be true, because the substituents may also change the thermodynamic stabilities substantially.

Table 2. Important geometric parameters for **4**–**9** (bond lengths [Å] and bond angles [°]). The numbering is the same as in Equation (a). The experimental values of related complexes are given in parentheses.

[a] Experimental data from [a] ref. [4], [b] ref. [3], and [c] ref. [7c].

The preference for the bis(acetylide) structure **2** shown by Ti complexes with R = $Si(CH_3)_3$ suggests a complementary strategy for stabilizing the C–C coupled structures **3** for Zr. They might be accesible with electron-withdrawing substituents such as fluoride. This has the added advantage that fluoride tends to bind to an sp^2-hybridized carbon atom rather than to an sp-hybridized carbon [Eq. (b)].[15] Accordingly, structures **8** and **9**

$$HC{\equiv}CF + H_2C{=}CH_2 \longrightarrow HC{\equiv}CH + H_2C{=}CHF \qquad \Delta H_r = 17\ \text{kcal mol}^{-1} \qquad \text{(b)}$$

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3606-0607 $ 17.50+.50/0

[see Eq. (a)] were studied. The change in the thermodynamic stability in going from R = H to R = F (**6**/**7** → **8**/**9**) was as expected. While **7** (R = H) is 13.5 kcal mol^{-1} *less* stable than **6**, complex **9** (R = F) is 17.6 kcal mol^{-1} *more* stable than **8**. These trends will be of use in designing appropriate ligands so that even the Zr complexes with C–C coupled products can be obtained. The relative energies at the B3LYP/LANL2DZ level show that electron correlation does not affect the trend of isomerization.

An explanation for the difference in reactivity between the Ti and Zr complexes was sought from the molecular orbitals.[9] The Walsh diagrams for the process **2** → **3** were essentially the same for the two metals. The difference in the ionic radii between Ti and Zr suggests another explanation. The larger size of Zr leads to longer Zr–acetylene distances, which in turn results in a longer C3–C4 bond (3.081 Å) in **6**. In the isostructural Ti complex **4** the corresponding bond length is 2.714 Å, which is further along the path to C–C bond formation. We found that fluoride substitution also helps in reducing the C3–C4 distance; it was calculated to be 2.898 Å in **8**.

Due to the enormous sizes of **4**–**9**, locating the corresponding transition states and calculating the vibrational frequency are beyond our computing facilities. However, we have carried out DFT calculations at the B3LYP/LANL2DZ level on the simplified models **10**–**13** (C_{2h}). The relative energies (Table 1) indicate similar trends between the Ti and Zr complexes. Comparison of two sets of structures, **4**–**7** and **10**–**13**, reveals that replacement of Cp by H has a larger effect on the model Ti complexes than on the Zr complexes. The transition structures for conversion of **10** to **11** (**TS1**) and **12** to **13** (**TS2**) have been characterized fully with one imaginary frequency each. The relative energies of the transition structures indicate that C–C coupling is considerably more favorable for Ti (**10**) than for Zr (**12**). We expect similar trends for **4** and **6**.

In conclusion, the unusual C–C coupling observed in dimeric bis(η^5-cyclopentadienyl)phenylethynyltitanium complexes and lacking in the corresponding zirconium complexes is a consequence of thermodynamic energy differences. Highly electron-withdrawing substituents on the ethynyl bridging group might help in making structure **7** more competitive to **6**. Model studies indicate that Ti is preferred over Zr for the C–C coupled product **3** when R = H. When R = F, the C–C coupled structure is more favorable for Zr complexes than the uncoupled structure.

Synthesis and Resolution of the Configurationally Stable Tris(tetrachlorobenzenediolato)phosphate(v) Ion**

Jérôme Lacour,* Catherine Ginglinger, Chantal Grivet, and Gérald Bernardinelli

In memory of Wolfgang Oppolzer

The octahedral geometry of pentavalent hexacoordinated phosphorus allows the formation of chiral phosphate anions by complexation with three identical, symmetrical, bidentate ligands.[1] Enantiopure anions of D_3 symmetry could be used in several fields of chemistry that involve chiral or prostereogenic cationic species. Resolution of enantiomeric cations, determination of their enantiomeric purity, or asymmetric synthesis of cationic species are several applications. However, known optically pure or enriched phosphate(v) ions with a hexacoordinated phosphorus center[2] cannot easily be used since they lack either configurational[2g–k] or chemical stability with respect to acids and oxidants.[2a–e] We thus decided to synthesize and resolve the enantiomers of a readily available, configurationally stable anion with a hexacoordinated phosphorus atom.

Although the tris(benzenediolato)phosphate(v) anion (**1**) is easy to prepare as an ammonium salt from catechol, PCl_5, and an amine, it is unfortunately configurationally labile.[2j, k] Enantioenriched **1**,[3] which is synthesized stereoselectively with brucin as the amine, undergoes fast epimerization in solution. Mechanistic studies by Koenig and Klaebe[2i–k] showed that racemization of **1** was acid-catalyzed and followed a rate law

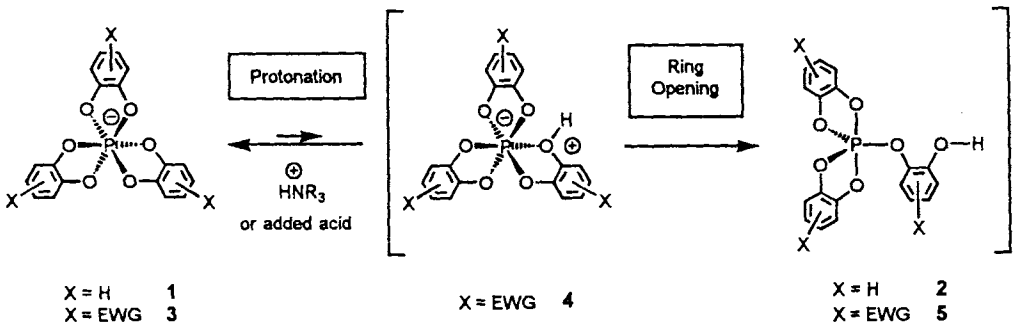
that is first-order in substrate. An irregular, intramolecular one-ended dissociation mechanism was proposed to explain the results.[2h, j] Ring opening of **1** to the trigonal bipyramidal spirophosphorane intermediate **2**, followed by pseudo-rotation of the substituents about the phosphorus atom and random recyclization, result in the observed loss of chirality. Determination of the kinetic parameters ($\Delta H^{\neq} = 20.3$ kcal mol^{-1}, $\Delta S^{\neq} = -4.1$ kcal mol^{-1} K^{-1}) led the authors to suggest pseudo-rotation as the rate-determining step.

However, it appeared to us that the observed acid catalysis would influence the ring opening to the phosphorane more (Scheme 1, **1** → **2**) than the pseudo-rotation step. Protonation[4] of an oxygen atom of a catecholate ring in **1** by the added acid (or the ammonium counterion) forms a better leaving group. This promotes the opening to the phosphorane **2** that is required for the epimerization.[5]

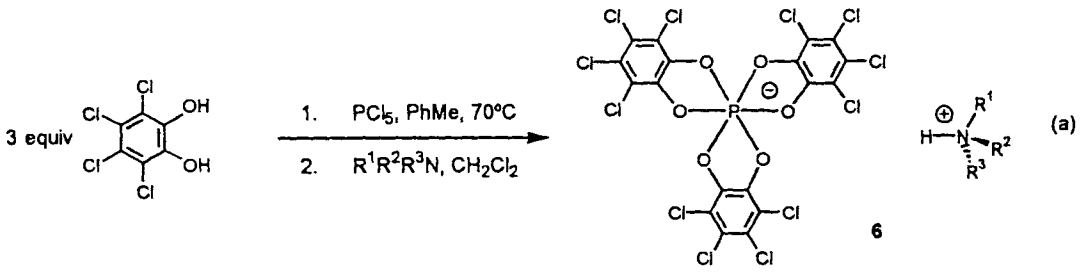


Scheme 1. Hypothetical acid-promoted ring opening. Anions **1** and **3** are arbitrarily represented with *M* absolute configuration. EWG = electron-withdrawing group.

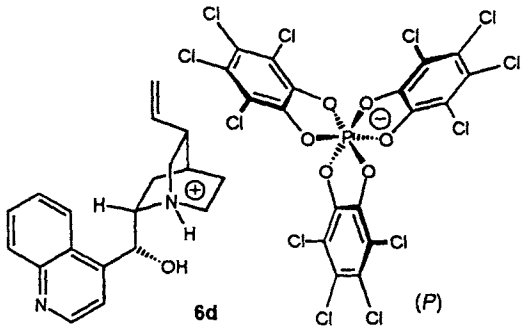
If the ring opening is associated with prior protonation of an oxygen atom of the catecholate rings, decreasing the basicity of the oxygen atoms in **3** would avoid protonation (**3** → **4**). This would stop the opening to the phosphorane (**4** → **5**) and hence avert the epimerization. Consequently, configurationally stable phosphate(v) ions with hexacoordinated phosphorus atoms (**3**) should result from the use of catechols substituted with electron-withdrawing groups.

To test this hypothesis, we prepared the tris(tetrachlorobenzenediolato)phosphate(v) anion (TRISPHAT, **6**: ammonium TRISPHAT salt) from electron-poor, readily available tetrachlorocatechol.[6, 7] Increased hindrance around the phosphorus atom, resulting from substitution of the hydrogen by chlorine atoms, was considered to be beneficial for further applications of the anions.

Tetrachlorocatechol easily forms phosphate(v) ions with a hexacoordinated phosphorus center [Eq. (a)]. Treatment of PCl_5 with three equivalents of tetrachlorocatechol in hot toluene followed by addition of an amine affords the ammonium phosphate salts **6a**–**e** in good yields (benzylammonium salt **6a** (74 %), morpholinium salt **6b** (89 %), tributylammonium



(**6c**, 72 %), and cinchonidinium salts **6d**,**e** (50–70 %)).[8] ^{31}P NMR spectra of **6a**–**e** show a single signal in the region from $\delta = -79$ to -82, which is characteristic of phosphate anions



with unsaturated, cyclic substituents.[9] With cinchonidine[10] mixtures of the diastereomeric salts cinchonidinium-(*P*)-TRISPHAT (**6d**) and cinchonidinium-(*M*)-TRISPHAT (**6e**) are obtained with varying diastereoselectivity ($[\alpha]_D^{20} = +30$ to -40, $c =$ 0.1 in EtOH).[11] No change of the specific optical rotation of the mixtures **6d**,**e** in organic solvents was observed in solution, which was a first indication of the configurational stability of **6**.

TRISPHAT was prepared in an optically pure form so that its configurational stability could be investigated further. Efficient resolution of **6** by crystallization of mixtures of **6d**,**e** in EtOAc/acetone (3/1) afforded, after filtration, pure **6d** as a solid with one molecule of EtOAc in 48–52 % yield ($[\alpha]_D^{20} = -375$, $c = 0.111$ in EtOH). The near perfect octahedral structure and absolute *P* configuration of the TRISPHAT anion in **6d** were unambiguously confirmed by X-ray structure analysis (Figure 1).[12] The largest deviation from octahedral angles at the phosphorus atom is 2.9°. The chelate rings are essentially planar, and the maximum mean plane deviation of the phosphorus atom is 0.25 Å. The chelate rings are oriented at 53, 57, and 56° with respect to the pseudo-threefold axis of the cation. The average P–O bond length is 1.714 Å,[18] but two bonds (P–O(1) and P–O(3)) are markedly longer than the others. Closer inspection suggests that, for P–O(3), this is due to hydrogen bonding with the ammonium cation. The relative positions of the anions and cations in the molecular packingare fixed by hydrogen-bonding interactions involving the hydrogen atom of the ammonium (N(2a)···O(3) = 3.06(1) Å, H(02a)···O(3) = 2.27(9) Å, N(2a)–H(02a)···O(3) = 154°) and

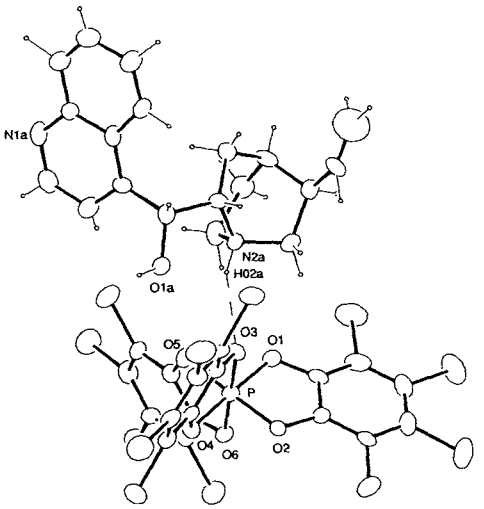

Figure 1. Perspective view of the crystal structure of **6d** showing the hydrogen bond between the anionic and cationic moieties. Ellipsoids are represented at 40% probability level, and one molecule of EtOAc has been omitted. Selected bond lengths [Å]: P–O(1) 1.726(6), P–O(2) 1.715(6), P–O(3) 1.725(6), P–O(4) 1.705(6), P–O(5) 1.711(6), P–O(6) 1.700(6).

stacking interactions between one chelate ring and the aromatic part of the cation (mean interplane distance = 3.59 Å).

In contrast to Munoz's results with phosphates derived from pyrocatechol,[2j, k] solutions of **6d** showed no variation of the specific optical rotation with time at room temperature. This demonstrates the intrinsic chemical and configurational stability of **6**.

We are currently in the process of further investigating the configurational stability of TRISPHAT salts. Applications of enantiopure TRISPHAT as a chiral reagent are being pursued.

Experimental Section

6a–e: Tetrachlorocatechol (5.21 g, 21.0 mmol, 3.0 equiv) was added in portions over 30 min to a solution of PCl_5 (1.46 g, 7.0 mmol, 1.0 equiv) in toluene (17 mL) at 50 °C. The evolved HCl gas was trapped with a concentrated solution of NaOH. After being stirred for 12 h at 70 °C, the reaction was cooled to room temperature and concentrated in vacuo. The resulting gray powder was suspended in CH_2Cl_2 (45 mL) and hexane (5 mL). Addition of a solution of amine (1.0 equiv) in CH_2Cl_2 (25 mL) led to precipitation of a white solid. The mixture was stirred for 12 h to ensure maximum precipitation and then filtered over a Büchner funnel. The solid was washed with cold hexane and dried under reduced pressure at 50 °C to afford **6a–e**.

Resolution procedure: Crude **6d,e** (202.2 mg, 0.19 mmol, $[\alpha]_D^{20} = +30$, $c = 0.14$ in EtOH) was suspended in EtOAc (3 mL). Acetone (≈1 mL) was added at room temperature to ensure complete dissolution. Slow evaporation of acetone over 3–5 days afforded pure **6d**·EtOAc (105.4 mg, 0.099 mmol, $[\alpha]_D^{20} = -375$, $c = 0.111$ in EtOH, m. p. = 245–260 °C (decomp.)) as colorless plates. Filtration and concentration of the mother liquor in vacuo yielded mostly **6e** (94.6 mg, 0.089 mmol, $[\alpha]_D^{20} = +230$, $c = 0.206$ in EtOH) as a white solid. If the specific optical rotation of the isolated **6d** was lower than the expected value ($-306 < [\alpha]_D^{20} < -370$), a second recrystallization under the same conditions increased the value to −375.

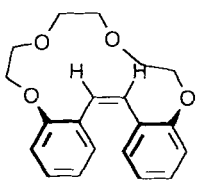
Oligo(ethylenoxy)oxy-Bridged Stilbenes as Ligands for σ- and π-Coordinated Ag^+ and Na^+ Ions

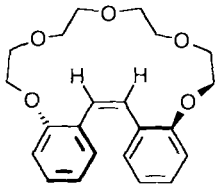
Thomas Futterer, Andreas Merz,* and Johann Lex*

Although the formation of silver(I) complexes of crown ethers in solution has been widely confirmed by association constants,[1] X-ray crystal structures of such complexes are rare.[2] This is different when two or more oxygen atoms are replaced by nitrogen[3] or sulfur atoms, [4] which then make the main enthalpic contribution to complexation.[5] Covalently bound fluorine has also proven a better donor than oxygen.[3d] Apart from the aforementioned σ donors, aromatic[6] and olefinic π-electron systems[7] are suitable ligands for Ag^+ complexes, which are usually rather labile and which crystallize in diverse, sometimes bridged stuctures. Kinetically stable complexes, which are being discussed as reagents in the radiation therapy of cancer,[4a] are generally obtained with ligands that contain multiple binding sites in a suitable geometry, such as cyclophanes,[8] calixarenes,[9] and cryptands.[3d]

Since the (*Z*)-stilbene crown ether **2**[10] has already proven to be a ligand for well-crystallizing alkali metal complexes, we became interested in the behavior of **1** and **2** towards Ag^+ salts, particularly because for related macrocycles with *para*, *para'*-oligo(ethylenoxy)oxy-linked di- and tetraarylethenes an interaction between Ag^+ ions and the arene units has been detected by ^1H and ^{13}C NMR spectroscopy.[12]



1

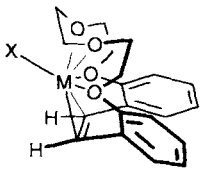


2

3 = **1** · $AgNO_3$

4 = **2** · $AgNO_3$

5 = **1** · $NaClO_4$



M^+X^- = $AgNO_3$ (**3**), $NaClO_4$ (**5**)

Generally it seems that the coordination of silver with aromatic substituted alkenes preferably occurs through the arene unit.[13] The crystal structures of the (*E*)- and (*Z*)-stilbenes[14] are unknown, but, for instance, the related acenaphthylene adds the silver ions at the 4,5 and 6,7 positions and *not* at the 1,2 positions.[13a] According to semiempirical calculations (ZINDO-1),[15] the Ag^+ ion coordinates to (*Z*)-stilbene symmetrically between the two phenyl rings, which are rotated completely perpendicular with respect to the plane of the double bond; the shortest distances (2.46 Å) are formed to the two *para*-C atoms. A similar structure is calculated for 1,2-diphenylethane; however, an intramolecularly bridged structure with an *anti*-arrangement of the phenyl groups is observed in the crystal.[6d]

The silver nitrate complexes **3** and **4** have now been obtained from **1** and **2**, respectively. Their crystal structures are shown in Figure 1 together with that of **1**.[16] In light of the above-mentioned preference of the silver ion for arene binding sites, it is surprising that in both complexes the silver ion coordinates at the central double bond and at oxygen atoms of the crown ether and the nitrate anion, without any bonding to the arene units. Complexes **3** and **4** are, to the best of our knowledge, the first silver complexes that exhibit simultaneous coordination at "hard" ether oxygen atoms and a "soft" π-bond, and are the first stilbene silver complexes.

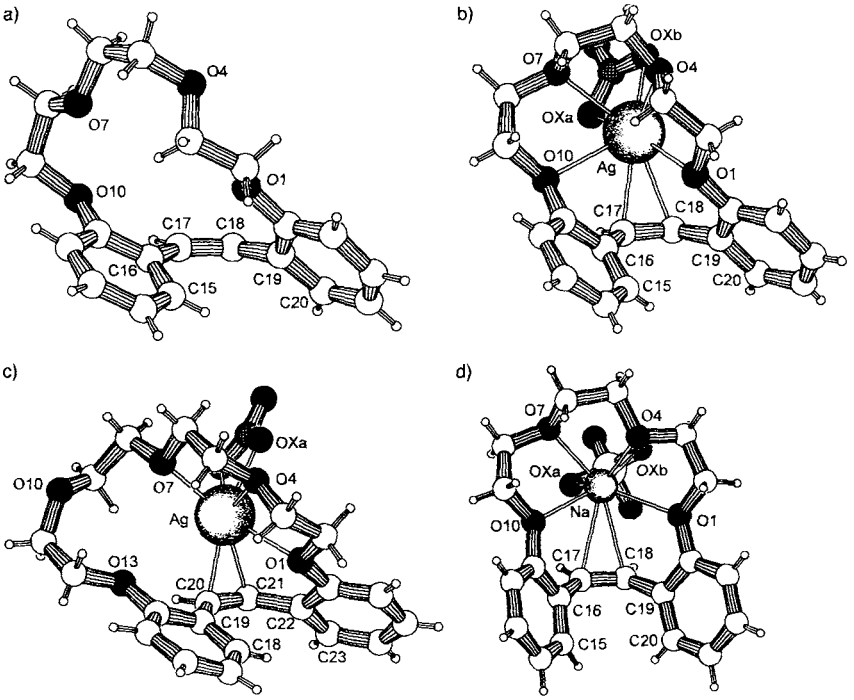


Figure 1. PLUTON representation of the structures of a) **1**, b) **3**, c) **4**, and d) **5a** in the crystal.

A closer look at the crystal structures reveals a close similarity between the conformations of the ligand **1** in the free and complexed state. In **1** the ethylenedioxy bridges have a $g^-g^+g^-$ sequence. Thus, for complexation only the central unit has to be twisted into the g^- conformation, and therefore the conformation at the double bond is not changed significantly.

Similarities are also apparent between **3** and **4**. While in **3** the Ag–O10 distance is significantly greater than the other Ag–O distances, in **4** only three oxygens, O1, O4, and O7 participate in the coordination (Table 1). The structures of **1**, **2**,[9] **3**, and **4** are very similar in terms of the sequence of atoms O1 to O7, and

with the exception of **2** they are asymmetric. Thus, no major restructuring of the ligand conformation is necessary to accommodate the Ag^+ ion as guest. The asymmetric coordination sphere of the silver ion in **3** and **4** consists of a flat tetragonal or trigonal pyramid, respectively, with the Ag^+ ion above the ring oxygen atoms; it is supplemented by the double bond and the nitrate ion, resulting in coordination numbers of 5 and 6, respectively.

The geometry at the stilbene unit can be described as follows (Table 1): a) the alkene bond lengths are considerably longer in **3** and **4** than in **1** and **2**. b) The geometry of the double bonds is not planar: in **1** and **2** they are *twisted* along the bond axis by about 4°, in the complexes they are *folded* in a rooflike manner with the silver ion above the "ridge". In **4** the dihedral angle between the two C–H bonds is approximately 0°; in **3** the angles at the double bond are more distorted. c) The two phenylene groups are rotated in the same direction with respect to the plane of the double bond in all four structures. The phenylene groups at C17(20) have larger torsional angles (46–51°) than those at C18(21). d) The C17(20)-Ag-C18(21) and H17(20)-C17(20)-C18(21) planes in **3** and **4** are exactly perpendicular to each other, and the silver ion is displaced by 18% (**3**) and 12.5% (**4**) of the bond length from the center of the double bond towards C18(21). The geometry of the silver coordination at the stilbene double bonds of **3** and **4** is in very good agreement with structural data of silver complexes with exclusively olefin ligands.[3, 4d, 7] The same is true for the Ag–O distances to the ether oxygen atoms[2] and the nitrate ion,[7] which acts as a bidentate ligand.

Complexes **3** and **4** represent a new type of crown ether complex that differs substantially from the symmetric alkali metal complexes of **2**.[11] For a comparison with **3** we have also carried out an X-ray structure analysis of **5**, the sodium perchlorate complex derived from **1**. The unit cell of **5** contains the enantiomer pairs of the two diastereomeric C_1-symmetric conformers **5a** (see Figure 1) and **5b**, which differ significantly only in terms of the conformation of the central ethylenedioxy unit (O4–O7). This asymmetry arises because a C_s-symmetric array as observed for **2**·$NaClO_4$[11] would require an unfavorable eclipsed conformation of the O4–O7 sequence. Because of the rooflike *anti* arrangement of the two phenylene groups, **5** is related to its next higher homologue.[11] However, the two phenylene groups are arranged at such a steep angle to the double bond that the oxygen coordination sphere is constricted in such a way that the cation no longer fits into the cavity, and instead a coordination pyramid is formed like that by crown ethers that are too small for a cation.[17] Thus, the sodium ion inevitably comes in close proximity to the stilbene double bond, whose π-electron density is directed towards the cation. The coordination sphere of the Na^+ ion is completed by the ClO_4 ion in a similar way to that in **3** and **4**.

The short Na–C17 and Na–C18 distances of about 2.8 Å suggest a bonding interaction between the sodium ion and the double bond. Recently cation-π-interactions, particularly with quaternary ammonium salts, have been discussed as very weak bonds in biological systems.[18] In several cyclophane- or calixarene-like compounds interactions of this kind have been considered likely to occur on the basis of MS and NMR investigations,[19] for example the π-interaction of Cs^+ and Rb^+ in the cavity of [1.1.1.1]paracyclophane.[19b] Therefore, a coordinative bond between a sodium cation and a π-bond appears to have been realized for the first time in **5**, which is induced and supported by the oligo(ethylenoxy)oxy bridge; thus **5** can also be regarded as a complex structurally related to **3** and **4**.

The ^1H NMR spectra of **3**–**5** in CD_3NO_2 at 25 °C (Table 2), like those of the free ligands **1** and **2**,[11] show symmetrical AA′BB′ spin systems for the ethylenedioxy protons as well as

Table 2. Selected 250 MHz ^1H NMR chemical shifts and multiplicities of **1**–**5** in CD_3NO_2. The numbers in parentheses refer to the atom numbering schemes for **2** and **4**.

singlets for alkene protons and only a single set of signals for the arene protons, which corresponds to a conformationally averaged C_{2v} symmetry. Thus the dissociation equilibrium of the complexes is fast relative to the NMR time scale. A signal broadening of the protons H3/8 in the spectrum of **3** indicates a slight diastereotopy of these CH_2 groups. The low-field shifts of the signals in the spectra of the complexes compared to those of the free ligands ($\Delta\delta$(H2) = 0.16 (**2**, **4**) and 0.11 (**5**); $\Delta\delta(H_{olefin})$ = 0.42 (**3**), 0.31 (**4**), and 0.14 (**5**)) demonstrate, however, that the dynamic equilibrium is predominated by the complexes.[20] Among the alkali metal complexes of **2** the strongest low-field shift ($\Delta\delta$ = 0.11) was observed for H20/21 of the potassium complex, while the value for the sodium complex was only $\Delta\delta$ = 0.02.[11]

Experimental Section

The crystals of the complexes were obtained by dissolving equimolar amounts of the ligands [10] (ca. 0.3 M) and the corresponding salts in dry CH_3CN (**3**, **4**) or THF (**5**) at room temperature, and subsequent cooling to 4 °C (m.p. see ref. [16]). FAB-MS: *m/z*: 433/435 (**3**), 477/479 (**4**), 369 (**5**), each with 100% intensity.

Metal-Induced Self-Assembly of Cavitand-Based Cage Molecules**

Paola Jacopozzi and Enrico Dalcanale*

In memory of Gerhard Mann

Polymacrocyclic cage molecules constitute a very interesting class of organic compounds with peculiar host–guest properties.[1] The confined space within carcerands and hemicarcerands, for example, can be regarded as a new phase of matter for which reactivity,[2] stereoisomerism,[3] and photochemical and photophysical[4] properties of the guest molecules are different from those in the bulk phases.

So far, cage molecules have been constructed mainly by formation of covalent bonds;[5] more recently, self-assembly through noncovalent interactions such as hydrogen bonding has proved to be a viable alternative.[6] Metal-induced self-assembly—widely used for generating helicates, grids, boxes, and other multicomponent inorganic architectures[7]—has rarely been employed for the formation of molecular-sized cages. One remarkable exception is the trinuclear Pd^{II} cage from Fujita et al; the cationic complex assembles in high yield only in the presence of a specific guest molecule.[8]

Here we report the quantitative self-assembly of stable, large organopalladium and organoplatinum cage molecules of struc-

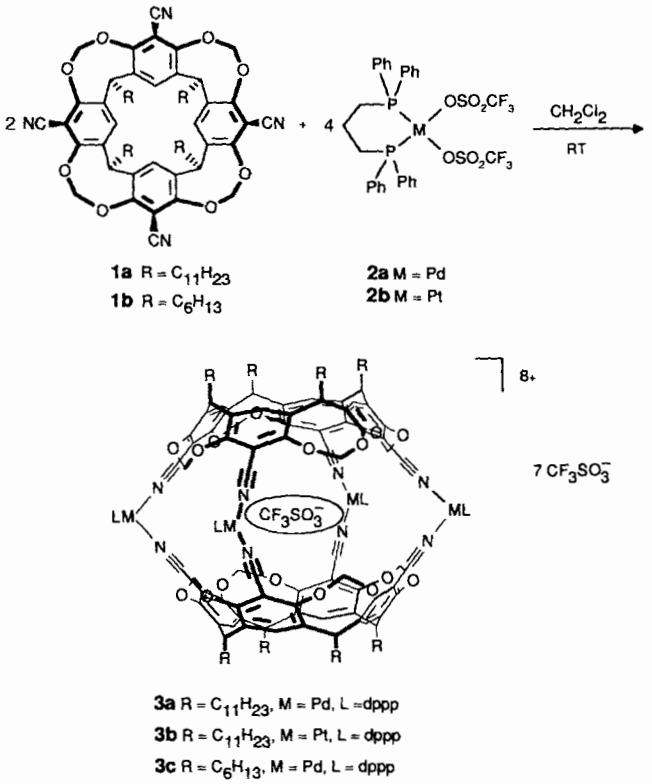
[**] We thank Dr. F. Corana (Bracco S. P. A.) for mass spectroscopic analyses and acknowledge the Centro Interfacoltà di Misure of the Università di Parma for instrumental facilities. This work was supported by MURST.

ture **3**, which are composed of two tetracyanocavitand derivatives connected through four Pd^{II} or Pt^{II} square-planar complexes. Preorganization of the cavitand is essential for achieving this extremely efficient self-assembly. We therefore synthesized a rigid, methylene-bridged cavitand with appropriate donor atoms in the desired spatial orientation. Cages **3a–c** were assembled by simply mixing **1** with **2** in a 1:2 molar ratio at room temperature in solvents such as CH_2Cl_2, $CHCl_3$, or acetone (Scheme 1). In all cases, the cage formed immediately as the



Scheme 1. Self-assembly of Pd and Pt cage molecules. L = 1,3-bis(diphenylphosphino)propane (dppp).

only product; there was no detectable presence of oligomeric material. When the reaction was carried out with a 1:1 molar ratio of **1** and **2**, a mixture of the cage and the free cavitand **1** was obtained (Figure 1). Furthermore, if an excess of the metal complex precursor was present, the reaction led only to the desired cage plus unchanged **2**. The metal-induced self-assembly process was also monitored by FT-IR spectroscopy: the nitrile stretching band of the cage is shifted to a higher wavenumber than that of the free cavitand.

Characterization of the cages followed from NMR (^1H, ^{13}C, ^{31}P, ^{19}F) and FT-IR spectroscopy, ESI-MS, and vapor-phase osmometry (VPO, Table 1). The extremely simple ^1H and ^{31}P NMR spectra indicated that the molecules are highly symmetric (D_{4h}). ESI-MS showed prominent $[M - 2CF_3SO_3^-]^{2+}$ peaks for all three cages; $[M - 3CF_3SO_3^-]^{3+}$ ions were also observed. The molecular ions could not be detected since their molecular weights exceed the limit of the instrument. VPO of **3a** in dichloromethane gave an effective molecular weight of 5830 ± 800 Da, which is consistent with the calculated value of 5775 Da.

Cages **3a–c** are stable both in the solid state and in solution. A tetrachloroethane solution of **3a** was kept overnight at 100 °C and then the cage was recovered unchanged. Furthermore, no

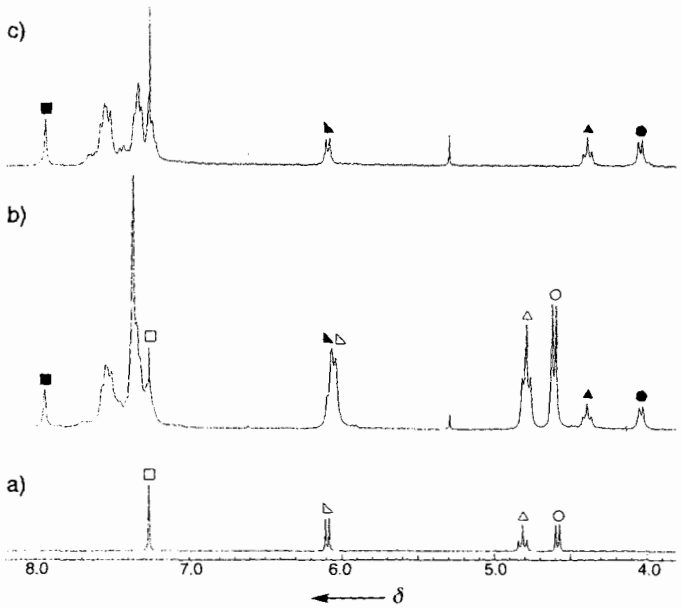


Figure 1. Monitoring of the metal-induced self-assembly of **3a** by ^1H NMR spectroscopy (300 MHz, $CDCl_3$, 25 °C). a) Free cavitand **1a**; b) **1a** (excess) + **2a**; c) **1a** + **2a** in a 1:2 molar ratio. Empty and solid symbols refer to the cavitand signals of free **1a** and cage **3a**, respectively. Upon formation of the cage, upfield shifts were observed for the inner methylene bridge and the methyne protons; aromatic protons were shifted downfield.

Table 1. Physical and spectroscopic data for **3a–c**.

3a: ^1H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta = 7.94$ (s, 8H, ArH), 7.60–7.21 (m, 80H, C_6H_5), 6.07 (d, $J = 7.3$ Hz, 8H, OCH_2O, outer), 4.38 (t, $J = 8.2$ Hz, 8H, CH), 4.03 (d, $J = 7.3$ Hz, 8H, OCH_2O, inner), 2.95 (s, br, 16H, $Ph_2PCH_2CH_2CH_2PPh_2$), 2.55 (s, br, 8H, $Ph_2PCH_2CH_2CH_2PPh_2$), overlapping with 2.43 (m, 16H, $CHCH_2(CH_2)_9CH_3$), 1.48 (s, br, 16H, $CHCH_2CH_2(CH_2)_8CH_3$), 1.34–1.20 (m, 128H, $CH_3(CH_2)_8$), 0.81 (t, $J = 6.8$ Hz, 24H, CH_3); ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): $\delta = 156.4$, 138.9, 133.3, 132.7, 132.3, 131.2, 129.8, 124.9 (Ar), 124.0 (ArCN), 121.2 (CF_3, $J = 319$ Hz), 116.9 (Ar), 99.0 (OCH_2O), 36.6 (CH), 31.8, 30.2, 29.7, 29.6, 29.5, 29.3, 28.7, 28.4, 28.1 (CH_2), 22.6, 18.6 ($P(CH_2)_3P$), 14.0 (CH_3); ^{31}P NMR (81 MHz, $CDCl_3$, 25 °C): $\delta = 10.1$ (s, br); ^{19}F NMR (188.3 MHz, $CDCl_3$, 25 °C): $\delta = -78.2$ (21F, $CF_3SO_3^-$, external), −81.5 (3F, $CF_3SO_3^-$, internal); IR (KBr): $\tilde{\nu} = 2288$ cm^{-1} (C≡N); ESI-MS: *m/z*: 2738 $[M - 2CF_3SO_3^-]^{2+}$, 1775 $[M - 3CF_3SO_3^-]^{3+}$; VPO (CH_2Cl_2): 5830 ± 800 Da ($C_{276}H_{320}N_8O_{40}F_{24}P_8Pd_4S_8$).

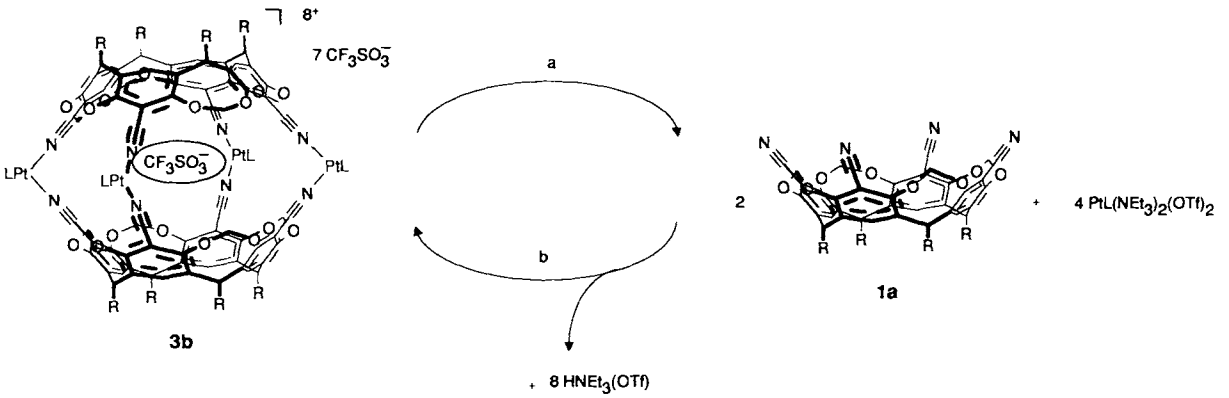

Scheme 2. Control of the self-assembly of the Pt cage. a) 8 equiv NEt_3; b) 8 equiv CF_3SO_3H. L = dppp.

variation was observed in the ^1H NMR spectra of **3a** and **3b** in $C_2D_2Cl_4$ between 25 and 110 °C.

The possibility of the presence of medium components trapped inside the cage during the self-assembly process was also investigated. No evidence for inclusion of solvent molecules was found by either ^1H NMR or ESI-MS. Interestingly, there were two signals in the ^{19}F NMR spectra of **3a–c** at $\delta = -81$ and -75 in a 1:7 integral ratio; this indicates encapsulation of one of the eight triflate counterions inside the cage. Examination of the CPK models confirmed that the equatorial portals of the cage are not large enough for the bulky triflate anion to escape.

Control of the self-assembly process was achieved through metal–ligand exchange (Scheme 2). Addition of eight equivalents of a competing ligand such as triethylamine to preformed **3b** led to complete and clean disassembly of the cage into its cavitand component and $[Pt(dppp)(NEt_3)_2(OTf)_2]$. Subsequent addition of eight equivalents of triflic acid restored the original Pt complex **2b**, which immediately reassembled the cage quantitatively.

These results prove that metal-induced self-assembly is a simple and convenient route for generating stable, molecular-sized cages in quantitative yields directly from a preorganized set of precursors. We are currently investigating the extension of this method for the formation of other cage molecules from different sets of molecular components.

Experimental Section

Tetracyano ligands **1a,b** were prepared by a known procedure [9] from the corresponding tetrabromo cavitands [10]. General procedure for **3a–c**: $[M(dppp)(OTf)_2]$ (**2**) [11] (0.048 mmol) was added to a solution of **1** (0.024 mmol) in 10 mL of CH_2Cl_2, and the resulting solution stirred at room temperature for a few minutes. Removal of the solvent under vacuum yielded **3a–c** in quantitative yields. **3a**: M = Pd, R = $C_{11}H_{23}$, green powder, m.p. = 187 °C (decomp.); **3b**: M = Pt, R = $C_{11}H_{23}$, white powder, m.p. = 250 °C (decomp); **3c**: M = Pd, R = C_6H_{13}, green powder, m.p. = 180 °C (decomp).

The molecular weight of **3a** was determined by VPO at 35 °C in HPLC-grade dichloromethane at concentrations of 2, 4, and 8 mM; three to four measurements were taken at each concentration. The calibration curve was generated with a long-chain, dodecasubstituted cavitand (M_r = 3237 Da) as the standard compound.

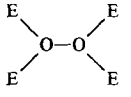
A μ_4-Peroxo Complex of Antimony: Synthesis and Structure of $(o\text{-Tol}_2SbO)_4(O_2)_2$**

Hans Joachim Breunig,* Tamara Krüger, and Enno Lork

Peroxides of main group elements usually contain the dioxygen group as a bridging unit (μ-O_2) in the arrangement E-O-O-E.[1] The quadruply bridging arrangement has been observed only twice in transition metal complexes.[2, 3] We report here on the synthesis and the structure of **1** (*o*-Tol = *o*-tolyl), the first main



(μ_4-O_2)

group element peroxide with μ_4-O_2 coordination. The known organoantimony peroxides have been described as μ-O_2-compounds.[4-7]

The synthesis of **1** is performed according to Equation (a) by complete oxidation of tetra-*o*-tolyldistibane in air and subsequent reaction with hydrogen peroxide. The intermediate $(o\text{-Tol}_2Sb)_4O_6$ was detected by mass spectrometry and elemental analysis. The novel peroxide **1** is a colorless solid that is stable

$$2\,R_2SbSbR_2 \xrightarrow{+3O_2} (R_2Sb)_4O_6 \xrightarrow[-2H_2O_2]{+2H_2O_2} (R_2SbO)_4(O_2)_2 \qquad (a)$$

R = *o*-Tol **1**

at ambient temperature and very soluble in organic solvents. In contrast the related phosphorus compound $Ph_2P(O)OO(O)PPh_2$ decomposes above $-80\,^{\circ}C$.[8] Mass spectra of **1** obtained by different ionization techniques (DCI, EI) show the molecular ion as the ion of highest mass.

After crystallization of **1** from toluene, its crystal structure was determined by X-ray structure analysis[9] on a single crystal of composition **1**·0.5 toluene. The unit cell contains two independent molecules of **1** and one toluene molecule. The structure of one of the molecules of **1** is depicted in Figure 1. The antimony atoms and the oxygen atoms form a closed cage that consists of an $(SbO)_4$ heterocycle and two O_2 bridges. The $(SbO)_4$ unit can be approximately described as a folded square whose edges consist of almost linear O-Sb-O groups. The folding occurs along the axes that join two opposite oxygen atoms. Consequently, four antimony atoms approximate to a square, which is capped above and below the plane by mutually perpendicular μ_4-O_2 groups. The outside of the compact antimony oxygen cage is protected by *o*-tolyl groups. Therefore, there are no close intermolecular contacts with other cage molecules or with toluene molecules. The high solubility and the relatively high stability of **1** may be explained by the coordinative saturation of the atoms in the cage and their shielding by the *o*-tolyl groups. The mean O-O bond lengths of the peroxide bridges are 147 pm. Similar values have been found for the H_2O_2 molecule[11] and for organoantimony alkyl peroxides.[5] The mean Sb-O distance in the $(SbO)_4$ ring of 196 pm lies in the normal range for Sb-O single bond lengths.[10] However the bond lengths between the antimony and oxygen atoms of the peroxo groups are considerably longer (226 pm). They exceed the Sb-O bond lengths of antimony alkyl peroxides by 15-20 pm.[5] Comparable distances sometimes occur in bonds between antimony atoms and triply bridging oxygen atoms.[7]

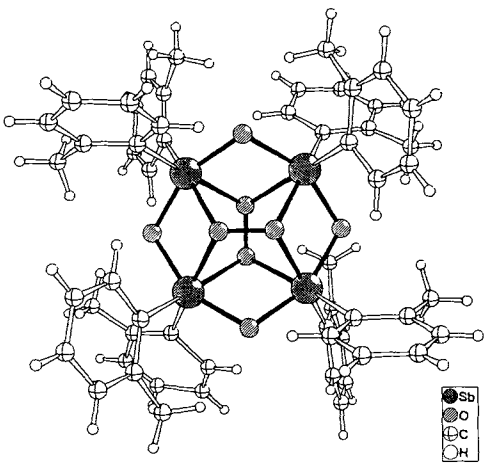

Figure 1. Structure of one of the independent molecules of **1** in the crystal. Selected mean bond lengths [pm] and angles [°]: O-O 147.8, Sb-O(Sb) 195.4, Sb-O(O) 222.5; O-Sb-O 153.3, Sb-O-O 113.5, O-Sb-O 74.2, Sb-O-Sb 93.7.

Presumably the structure of **1** is maintained in solution. Accordingly, the ^1H NMR spectrum in benzene shows that all the *o*-tolyl groups are equivalent. The Raman spectrum shows a signal of medium intensity at 798.6 cm^{-1} and several weak lines in the region of the O-O valence vibration of peroxides.[2, 11]

Comparing the molecular structure of **1** with the known transition metal complexes with quadruply bridging O_2 ligands reveals only a few common features in the case of $[Fe_6O_2(O_2)(O_2CPh)_{12}(OH_2)_2]$,[2] since the peroxo group in this iron complex is coordinated by metal atoms in a planar arrangement. However, the similarities with the anion of $K_4[Mo_4O_{12}(O_2)_2]$[3] are astonishing. The structure of this inorganic molybdenum compound can formally be derived from **1** by replacing the antimony atoms with molybdenum atoms, and the *o*-tolyl groups with oxygen atoms. This structural relation between an organoantimony peroxide and a peroxy molybdate is surprising but not completely unexpected. A similar relationship exists between $(Ph_2Sb)_4O_6$[7] and the anion $[(Ph_2Sb)_2(MoO_2)_2O_6]^{2-}$,[12] and can be attributed to the similar radii of the six-coordinate ions Mo^{6+} (73 pm) and Sb^{5+} (74 pm).

For the elucidation of the geometry of **1** a comparison with the P_4O_6 structure is also useful, because the replacement of two bridging oxygen atoms by peroxo groups leads to cages with analogous connectivity. However, consideration of the three-dimensional structures reveals important differences: while the phosphorus atoms in P_4O_6 form a tetrahedron, the antimony atoms of **1** are arranged as a square.

Experimental Section

$(o\text{-Tol}_2Sb)_4O_6$: A stream of air was passed through a yellow solution of tetra-(*o*-tolyl)distibane [13] (3.01 g, 4.97 mmol) in diethyl ether (150 mL) for 2 h. The solution became colorless and $(o\text{-Tol}_2Sb)_4O_6$ (3.01 g, 92.1%) formed as a white powder insoluble in hydrocarbons. MS (DCI positive, NH_3): *m/z* (%): 1313 (16) $[M^+ + H]$, 320 (100) $[(C_7H_7)_2SbH^+]$.

1: H_2O_2 (75 mL of a 30% aqueous solution) was added slowly to a suspension of $(o\text{-Tol}_2Sb)_4O_6$ (0.94 g, 0.70 mmol) in diethyl ether (100 mL) with stirring. After 4 h a white solid was obtained, washed with water and diethyl ether, and dried under reduced pressure. The yield was 0.90 g (76.8%). ^1H NMR (360 MHz, $CDCl_3$, 25 °C): δ = 2.47 (s, 3H; CH_3), 6.72-6.78, 6.90-6.92, 6.98-7.02, 7.90-7.95 (m, 4H; C_6H_4); MS (DCI pos., NH_3): *m/z* (%): 1345 (100) $[M^+]$.

A Samarium-Mediated, Highly Stereoselective Reaction of 1,1-Dihaloalkanes with Aldehydes: Generation of a Chiral α-Iodoethyl Building Block from Achiral 1,1-Diiodoethane**

Seijiro Matsubara, Masahito Yoshioka, and Kiitiro Utimoto*

The reaction of α-heteroatom-substituted alkylmetal reagents with carbonyl compounds is established as a method to prepare β-substituted alkanols.[1] α-Halogen-substituted reagents have been extensively studied, since their reaction with carbonyl compounds yields β-halohydrins of high synthetic potential.[2] Synthesis of stereochemically defined halohydrins needs both stereoselective generation of α-haloalkylmetals and diastereoselective reaction with carbonyl compounds. Many reports on these transformations have focused on the use of lithium or magnesium as key metals. Diastereoselective formation of α-haloalkyllithium or -magnesium reagents from the corresponding geminal dihaloalkane and organometallic compounds provided a functionalized building block for reaction with carbonyl compounds.[2, 3] While these diastereoselective syntheses of α-haloalkylmetals have been well investigated, enantiotopic transformation of 1,1-diiodoalkanes into optically active α-haloalkylmetals is still undeveloped and a challenging problem. Because of the high reducing power of samarium diiodide, we selected samarium as a key metal. Although SmI_2 is reported to produce an iodomethylsamarium reagent from diiodomethane,[4, 5] homologous diiodides have not been applied. 1,1-Diiodoalkanes are expected to produce the corresponding 1-iodoalkylsamarium reagents, which should react with aldehydes in a diastereoselective manner.[6] Here we wish to describe a stereoselective generation of α-iodoalkylsamarium reagents from 1,1-diiodoalkanes and their diastereoselective reaction with aldehydes. This reaction was extended to generate chiral 1-iodoethyl building blocks from 1,1-diiodoethane when chiral 2-substituted aldehydes were used as substrate.

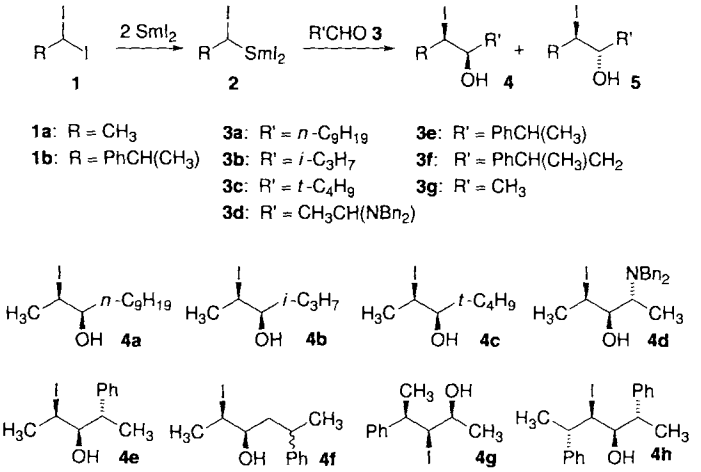
[a] A mixture of aldehyde (1.0 mmol) and geminal diiodide (2.0 mmol) was treated with SmI_2 in THF (4.0 mmol) at 25 °C for 0.5 h. [b] Yields of isolated products. [c] Racemate was used. [d] Given is the ratio between the major product **4** and all other possible diastereomers. [e] No diastereofacial selectivity was observed.

SmI_2 gives α-iodoethylsamarium (**2a**),[8] which reacts with decanal (**3a**) to afford 2-iodo-3-dodecanol (**4a**) with excellent diastereoselectivity (Scheme 1).



Scheme 1.

Achiral, α-mono- or α,α-disubstituted aldehydes also produced the corresponding iodohydrins in a highly diastereoselective manner (entries 2 and 3). Reaction of **2a** with racemic aldehydes containing a stereogenic center at the α-position (**3d** and **3e**; entries 4,5) gave the corresponding iodohydrins **4d,e** diastereoselectively (>98% *de* with respect to the α-stereogenic center and hydroxy-substituted carbon atom, and >94% *de* with respect to the hydroxy- and iodo-substituted carbon atoms).[10] The reaction of **2a** with β-substituted aldehyde **3f** afforded the halohydrin **4f**; the stereoselectivity with respect to the iodo- and hydroxy-substituted C-atom was extremely high (>98% *de*), but no diastereoselectivity was observed with respect to the β-substituted and the hydroxy-substituted C-atom. The diastereochemically defined building block iodohydrin (**4g**, entry 7)) can be generated from the β-substituted iodide **1b** in the reaction with acetaldehyde (**3g**).[11, 12] The SmI_2-mediated reaction of α-substituted aldehyde **3e** with β-substituted diiodide **1b** proceeded diastereoselectively to give halohydrin **4h**, which possesses four adjacent stereogenic centers.

When the reaction was carried out with optically active aldehydes (*ent*-**3d,e**), the adduct was obtained both diastereo- and enantioselectively. The yield and selectivity were not affected by the changing the ratio of the reagents (Table 2). This result rules out the possibility of kinetic resolution of the racemic α-haloalkylmetal species and implies that the prochiral 1,1-diiodoalkane was almost quantitatively converted into the optically pure α-halometal compound.[13]

Table 2. Reaction of (*S*)-**3e** [a] with **1a**.

1a [mmol]	(*S*)-**3e** [mmol]	SmI_2 [mmol]	Yield (*ent*-**4e**) [%] [b,c]	Ratio [d]
2.0	1.0	4.0	86	95.5:4.5
1.0	1.0	2.0	85	95:5
0.5	1.0	1.0	91	95:5

[a] >98% *ee*. [b] >98% *ee*. [c] Yields of isolated products. [d] Given is the ratio of the major diastereomer *ent*-**4e** to all other possible diastereomers (three diastereomers).

Although no evidence of α-haloalkylsamarium formation has been obtained, a reactive α-iodoethyl species is undoubtedly generated in an optically active form. In conclusion, the reaction of 1,1-diiodoalkanes with samarium(II) diiodide in the presence of chiral aldehydes produces α-haloalkyl building block in an enantioselective or diastereoselective manner.[13] The further applications and limitations of the method are now under investigation.

Experimental Section

A mixture of aldehyde (0.5 mmol) and 1,1-diiodoalkane (1.0 mmol) in THF (2 mL) was added dropwise to a THF solution of SmI_2 (0.1 M, 2.0 mmol) under Ar atmosphere. After the obtained mixture had been stirred for 30–60 min, 1 M hydrochloric acid (5 mL) was added. THF was removed by rotary evaporator. The resulting mixture was extracted with ether, and the combined organic layers subsequently washed with saturated $NaHSO_3$, saturated $NaHCO_3$, and brine. The obtained solution was dried over anhydrous Na_2SO_4 and concentrated. The diastereomer ratio was determined by ^1H NMR spectroscopy of the crude product. Purification by column chromatography (silica gel) gave the corresponding iodohydrin as a mixture of diastereomers.

[8] With the exception of iodomethylation, iodoalkylation of carbonyl compounds with SmI_2 and geminal dihaloalkanes has not been reported [5]. The structure of the intermediate is not clear but assumed to be α-iodoethylsamarium diiodide.

[9] The diastereoselectivity was determined ^1H NMR analysis of the crude product and stereospecific conversion of iodohydrin into the corresponding epoxide by a treatment with NaH in THF/hexamethyl phosphoric triamide.

[10] The relative configuration between the α-stereogenic and hydroxy-substituted centers was determined after removal of iodo group by Et_3B and Bu_3SnH.

[11] Although the yield of the iodohydrin increased on use of excess diiodide and SmI_2, the diastereoselectivity was unchanged. The results of the yields and diastereoselectivities under various pentanal/**1b**/SmI_2 ratios were as follows: 1.0/1.0/2.0 mmol: 31% (99:1); 1.0/2.0/4.0 mmol: 47% (99:1); 1.0/3.0/6.0 mmol: 62% (99:1). If excess reagent was used, 1-iodo-2-phenylpropane and 2,5-diphenyl-3-hexene were observed as by-products. The reduction of diastereotopic iodide may not proceed selectively, and the unfavored intermediate might decompose into these by-products.

[12] Treatment of aldehyde with 1,1-dibromoethane and SmI_2 did not afford halohydrin. Instead, a reduction of aldehyde to form alcohol was detected. Addition of a catalytic amount of a Co(II) compound allowed the addition to proceed. The catalyzed reaction gave *syn*-iodohydrin selectively: M. Yoshioka, M. Horiuchi, S. Matsubara, K. Utimoto, *unpublished results*.

[13] The results described in this communication show that a 1,1-diiodoalkane can be used as a precursor of a chiral α-iodoalkyl building block. Since no evidence for the formation of a chiral α-iodoalkylsamarium species has been obtained, the reaction can be explained either by enantioselective formation of an α-iodoalkylsamarium species by the reduction of the diiodide with a chiral SmI_2–aldehyde complex or by the preferred reaction of one enantiomer of the α-iodoalkylsamarium species and facile racemization of the other. Mechanistic studies are underway.

Solid-Phase Synthesis of a Tumor-Associated Sialyl-T_N Antigen Glycopeptide with a Partial Sequence of the "Tandem Repeat" of the MUC-1 Mucin**

Beate Liebe and Horst Kunz*

Dedicated to Professor Hans Paulsen on the occasion of his 75th birthday

The development of vaccines against tumor-associated antigens is of particular interest. Incomplete glycan side chains of mucins, for instance T_N-(GalNAcα-*O*-Ser/Thr) and T-antigen (Galβ1-3GalNAcα-*O*-Ser/Thr), have been reported to be tumor-associated cell surface structures.[1, 2] The T_N structure and its sialylation product, the sialyl-T_N antigen (NeuAcα2-6GalNAcα-*O*-Ser/Thr),[3, 4] are considered more tumor-selective than the T-antigen.[5] However, the peptide chain also influences the carbohydrate antigens, as was shown for immunodifferentiation of asialoglycophorins with a monoclonal anti-

body that was induced with a synthetic T-antigen glycopeptide.[6, 7] The immunological importance of the peptide chain was proven for the polymorphic epithelial mucin MUC-1.[8] It contains a domain that consists of tandem repeats of 20 amino acid residues. Most glycosylation sites are located in this domain. The glycans in the tumor-associated MUC-1 are formed incompletely.[9] for example, as T_N or sialyl-T_N antigens. The preferred glycosylation site of these tandem repeats was recently identified;[10] it is at the threonine of the undecapeptide sequence **1**.

Ala-Pro-Pro-Ala-His-Gly-Val-Thr*-Ser-Ala-Pro **1**

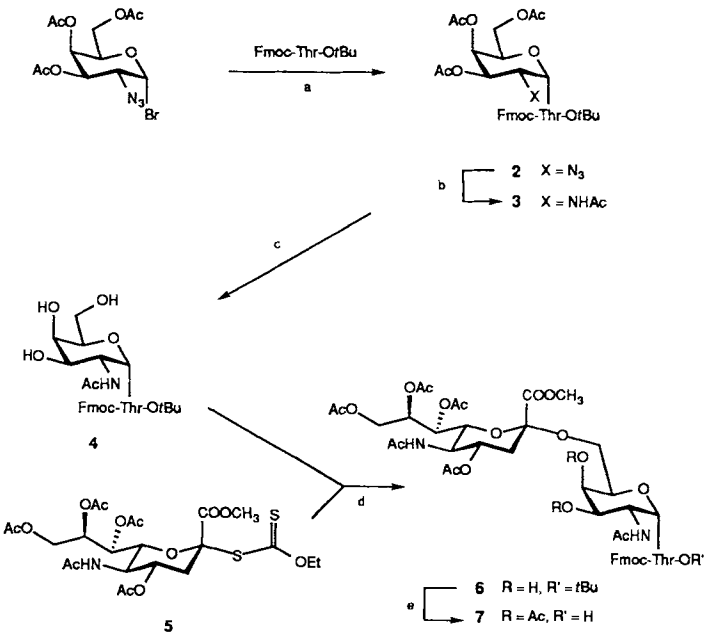
The synthesis of glycopeptide **1**, which carries a sialyl-T_N saccharide at this threonine, is of interest for interdisciplinary investigations. The solid-phase synthesis of this compound was carried out with the combination of an allylic anchor (HYCRON) with a polar spacer.[11] At the same time, the problem of protecting the carboxy function of sialic acid, which must be differentiated from the peptide functionalities, was solved.

Sialyl-T_N serine conjugates have been synthesized by Ogawa et al.[12] by coupling of the disaccharide with *N*-benzyloxycarbonyl(Z)-serine benzyl ester. After hydrogenolysis of the benzylic groups, the NeuNAc methyl ester of the no longer CH-acidic conjugate could be subjected to alkaline hydrolysis. Because these building blocks are not useful for syntheses of glycopeptides, Ogawa et al.[13] later employed the benzyl ester of *N*-acetylneuraminic acid, which is not easy to synthesize. A thioether group is temporarily required in the 3 position of the neuraminic acid donor to achieve stereoselective glycosylation, a process that requires additional, rather difficult synthetic steps on the complex conjugate.

We have therefore developed an alternative strategy by which the simple acetyl-protected methyl ester of neuraminic acid is regioselectively coupled to the Z-[*O*-(2-acetamidogalactosyl)]-threonine ester, which is unprotected in the glycan portion, to furnish the sialyl-T_N structure.[14] However, a prerequisite for synthesis of sialyl-T_N glycopeptides by this principle is that the NeuNAc methyl ester can be removed from the glycopeptide without epimerization of amino acid or β-elimination of the glycan side chain.

Furthermore, solid-phase syntheses require a Fmoc-protected sialyl-T_N threonine (or serine) building block (Fmoc = fluorenylmethoxycarbonyl). The selective removal of the *O*-acetyl groups from the base-sensitive *O*-glycosyl threonine ester is much more difficult than for the Z-protected analogue. To solve this problem, Kihlberg et al. recently pursued a multistep methodology via *O*-silyl-protected galactosamine derivatives.[15]

To test the short strategy of regioselective sialylation of the Fmoc-protected T_N building block, Fmoc threonine was selectively converted into its *tert*-butyl ester (77%) by treatment with dicyclohexyl carbodiimide (DCC) and *tert*-butyl alcohol in the presence of CuCl.[16] The obtained ester was glycosylated with 3,4,6-tri-*O*-acetyl-2-azido-2-desoxy-α-D-galactopyranosyl bromide[17] to yield the α-glycosylated Fmoc threonine ester **2**. After conversion of the 2-azido into the 2-acetamido group (to give **3**), the *O*-acetyl groups were selectively removed by dropwise addition of sodium methanolate (1% in methanol) to a solution of **3** in methanol at a pH lower than 8.5 (pH paper). The galactosamine threonine ester **4** was obtained in 77% yield, and the base-sensitive Fmoc group was not affected (Scheme 1).



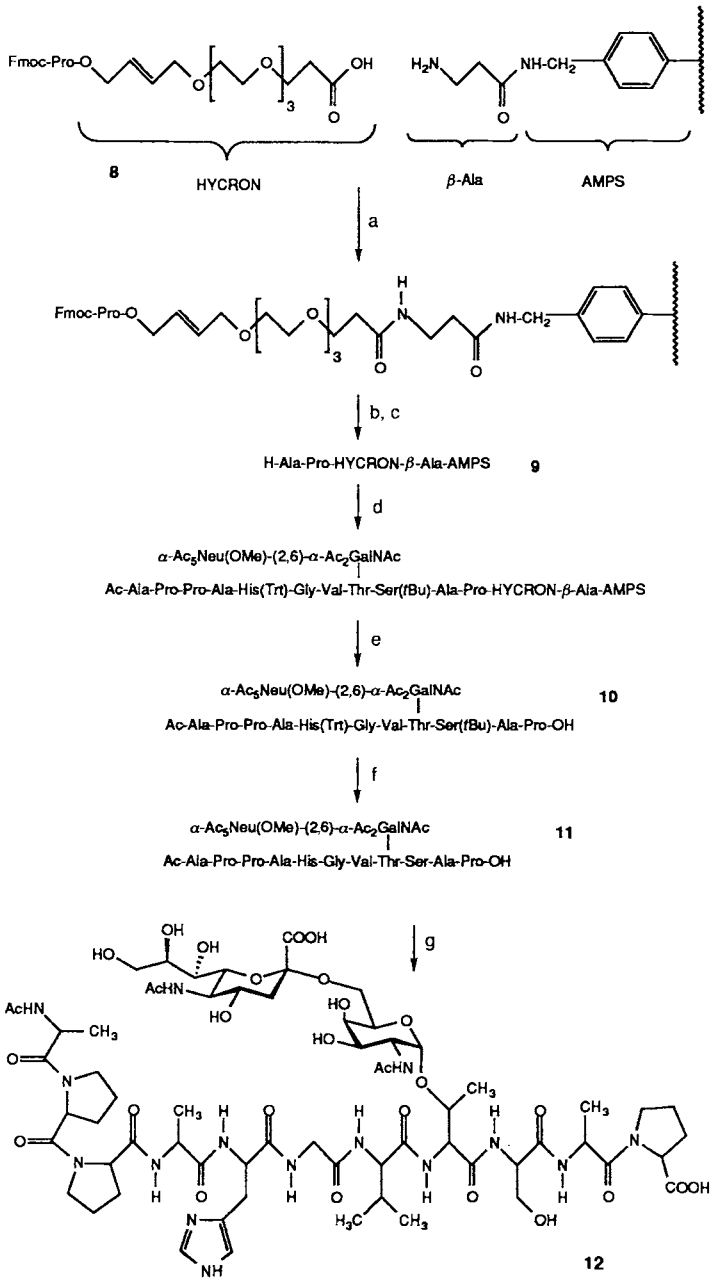
Scheme 1. a) $AgClO_4/Ag_2CO_3$ (1/11), CH_2Cl_2/toluene (10/9), 47%; b) CH_3COSH, 84%; c) CH_3OH, $NaOCH_3$, pH < 8.5, 77%; d) CH_3SBr, AgOTf, CH_3CN, CH_2Cl_2, −62 °C, 32% after preparative RP-HPLC, 8% of the β-anomer; e) 1. Ac_2O, pyridine, 88%, 2. TFA/anisole (13/1), quantitative.

The regioselective sialylation of **4** was achieved with sialyl-xanthogenate (**5**)[18] and activation with methylsulfenyl triflate[19] in acetonitrile/dichloromethane. Besides the desired α-6-*O*-linked sialyl-T_N building block **6** and its β-anomer (α/β 4/1), only the glycal of sialic acid was formed. Flash chromatography and preparative RP-HPLC yielded **6** on a gram scale. After acetylation of the 3,4-positions and acidolysis of the *tert*-butyl ester, the Fmoc-sialyl-T_N threonine component **7** was isolated. The OH groups in the carbohydrate portion of **7** are exclusively protected with *O*-acetyl groups, which ensure sufficient stability against acids. Due to these properties, **7** can immediately be used in solid-phase synthesis.

For the synthesis of the glycoundecapeptide **12**, the HYCRON conjugate **8** (containing Fmoc proline, the allylic anchor, and the triethyleneglycol spacer[11]) was coupled to β-alanyl(aminomethyl)polystyrene. Amino acid analysis[20] provided a loading of 0.43 mmol proline per gram. Following a typical solid-phase synthesis protocol, the Fmoc group was removed with DMF/morpholine (1/1), and the coupling reactions were carried out with a fourfold excess of *N*-protected amino acid, *O*-(1*H*-benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate (TBTU),[21] 1-hydroxybenzotriazole (HOBt), and *N*-methylmorpholine (NMM) in DMF. Unchanged amino groups were acetylated in each cycle. The reaction time was extended from 4.5 to 15 h for the coupling of the sialyl-T_N unit **7**; 19 h were required for the 9th and 10th couplings. The first coupling to give the polymer-linked dipeptide was performed with Boc-alanine. Due to the stability of the allylic anchor against acids as well as bases, the Boc group could be removed with trifluoroacetic acid (TFA/CH_2Cl_2 1/1). The hydrotrifluoroacetate was deprotonated with diisopropylethylamine prior to the second coupling. This change from the Fmoc to the

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3606-0619 $ 17.50+.50/0

Boc strategy prevented diketopiperazine formation. The subsequent steps were carried out with Fmoc-protected building blocks (Scheme 2).



Scheme 2. a) DIC, HOBt, CH_2Cl_2; b) 1. morpholine/DMF (1/1), 50 min, 2. Boc-Ala-OH, TBTU, HOBt, NMM, DMF; c) 1. TFA/CH_2Cl_2 (1/1), 2. CH_2Cl_2/iPr_2NEt (10/1); d) see text; e) cat. $(Ph_3P)_4Pd$, morpholine, DMF/DMSO (1/1); f) TFA, anisole, EtSMe; g) NaOH in CH_3OH. AMPS = (aminomethyl)polystyrol. HYCRON = allylic anchor.

The Fmoc group was exchanged for an acetyl group after the 10th coupling. The selectively carboxy-deblocked sialyl-T_N undecapeptide **10** was detached from the resin by palladium(0)-catalyzed cleavage of the allylic anchor.[11, 22] Amino acid analysis of the resin provided a yield of 98% for the detachment reaction. The acid-labile side-chain protecting groups were removed with TFA. The glycopeptide **11**, still protected at the glycan portion, was isolated by preparative RP-HPLC in an overall yield of 42%, based on the polymer-linked C-terminal amino acid. Compound **11** had a purity of greater than 98% according to analytical HPLC (Table 1).

Table 1. Spectroscopic and analytical data for **1** and **11**.

11: ^{1}H NMR (400 MHz, D_2O): δ = 5.06 (dd, J(2,3) = 11.2 Hz, 1H, H-3), 5.01 (d, J(1,2) = 3.5 Hz, 1H, H-1), 4.79 (ddd, 1H, H-4'), 4.53 (d, 1H, T^α), 4.45 (q, 1H, A^α), 2.67 (dd, J(3'e,3'a) = 12.9, J(3'e,4') = 4.4 Hz, 1H, H-3'e), 1.28–1.20 (m, 12H, A^β, T^γ), 0.86 (t, 6H, V^γ); ^{13}C NMR (100.6 MHz, D_2O): δ = 99.3 (C-1), 98.9 (C-2'), 77.9 (T^β), 71.9 (C-6'), 69.6, 69.5 (C-3, C-4'), 68.7 (C-5), 68.4, 68.2, 67.7 (C-4, C-7', C-8'), 63.4 (C-6), 62.4 (C-9'), 61.6 (S^β), 57.3 (T^α), 55.4 (S^α), 53.7 (P^α), 47.8, 47.7 (P^δ), 42.6 (G^α), 36.8 (C-3'), 30.5 (V^β), 18.6, 18.4, 18.0 (T^γ, V^γ), 16.6, 15.6 (A^β); MS (FAB): m/z (%) = 1807.3 (44) [M + H$^+$].

As expected, the hydrolysis of the NeuNAc methyl ester was difficult. It demanded more basic conditions than for the hydrolysis of *O*-acetyl groups. To avoid β-elimination of the carbohydrate from **11**, the hydrolysis was studied systematically with increasing concentrations of NaOH (1 M aqueous solution) in methanol. The *O*-acetyl groups were cleaved at pH = 10–11. To hydrolyze the methyl ester of the *N*-acetylneuraminic acid portion, the obtained product was stirred with 5 mM aqueous NaOH (10 equivalents, pH = 11.5) for 3 h. Complete hydrolysis of the methyl ester occurred, and β-elimination of the carbohydrate could hardly be detected. The deblocked sialyl-T_N antigen sequence **12** of the tandem repeat of MUC-1 was obtained in an overall yield of 76% over these two steps.

For the first time, the biologically interesting sialyl-T_N antigen glycopeptides have been synthesized on a preparative scale by solid-phase synthesis and structurally characterized by ^{1}H and ^{13}C NMR spectroscopy. Even the stable methyl ester can be used for protecting the *N*-acetylneuraminic acid. It can be selectively removed at pH-values of 11–11.5 without undesired β-elimination. This procedure is of general applicability for the syntheses of *O*-6-sialyl-glycopeptides.

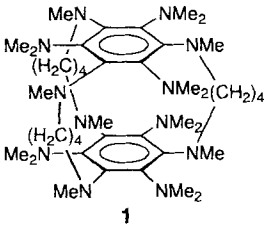
Synthesis and Structure of a Dimeric Peralkylated Hexaaminobenzene: Hexakis(dimethylamino)hexamethylhexaaza[6$_3$](1,3,5)cyclophane**

J. Jens Wolff,* Andreas Zietsch, Hermann Irngartinger, and Thomas Oeser

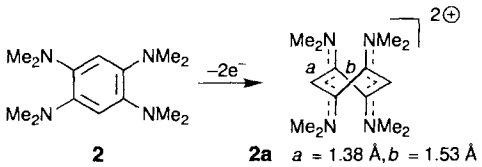
Dedicated to Professor Dr. Rolf Gleiter on the occasion of his 60th birthday

The experimental verification of theories on the kinetics of electron transfer (ET)[1] requires the synthesis of compounds with known and well-defined structures. To this end, molecules that consist of two identical subunits symmetrically connected by a rigid spacer are especially well-suited. Both the neutral molecule and its oxidized or reduced form must be stable. Most organic compounds that fulfill these conditions,[2] however, show such rapid ET for the intermolecular case already that its exact measurement for the intramolecular case is cumbersome and fraught with difficulties. In addition, theoretical predictions may not be equally valid for slow and fast ET processes. To reduce the rate constant, the inner reorganization energy[3] of the ET process has to be increased; this reorganization energy is a measure of the energetic difference between the structures of the neutral molecule and its oxidized (or reduced) form. In this context, Nelsen et al. have synthesized and studied bis(hydrazines).[4]

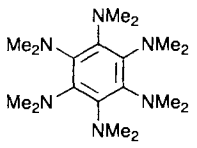
We reasoned that the oxidation of hexaaminobenzene derivatives should also have a high inner reorganization energy: investigations by several groups[5] have shown that the π-system of benzenes substituted at least in 1-, 2-, 4-, and 5-positions with amino groups as in **2**–**4** reorganizes to a trimethinecyanine cation and a trimethinecyanine radical on loss of one electron, and to a bis(trimethinecyanine) such as **2a** on loss of two electrons. Not only is a drastic change in bond lengths associated with these oxidations, the rings also become quite nonplanar and adopt twist conformations. These effects lead to a high kinetic barrier towards intermolecular electron transfer.[6] To peruse this intrinsic high barrier in an intramolecular process we synthesized dimeric hexaaminobenzene derivatives that are linked together through three spacers, for example methylene chains. The distance between the two arenes should be easily adjustable. Here we report on the synthesis and the structure of **1**, a representative of this class of compounds.



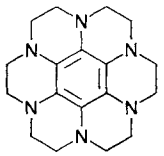
1



2 **2a** a = 1.38 Å, b = 1.53 Å

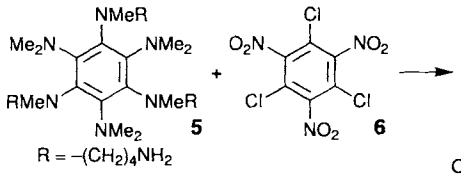


3



4

None of the standard cyclophane syntheses[7] are suitable for the construction of the sterically encumbered **1**. We reasoned, however, that the cyclization of a hexaaminobenzene derivative of type **5** with trinitrotrichlorobenzene (**6**) in a nucleophilic aromatic substitution reaction should be possible. First, we found that **6** and the model compound hexakis(dimethylamino)benzene (**3**) form a weak charge transfer (CT) complex.[8] Preorganization of reactants **5** and **6** is therefore possible. Moreover, the ring in amino-substituted trinitrobenzenes deviates strongly from planarity,[9] and cyclization is thus facilitated. Furthermore, we had found that the second and especially the third substitution of the chloro groups in **6** with monoalkylamines by the S_NAr mechanism are favored with respect to the first substitution even though the electron density formally increases with each substitution: the repulsive interactions of the chlorine atoms force the nitro groups to rotate strongly out of the plane of the ring. In contrast, after substitution of **6** with monoalkylamines the nitro groups form intramolecular hydrogen



5 R = $-(CH_2)_4NH_2$ **6**

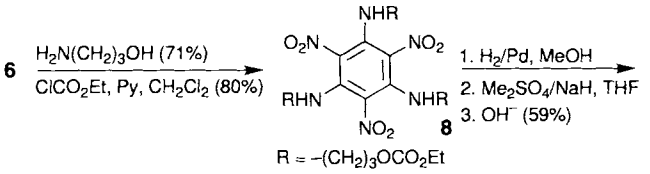
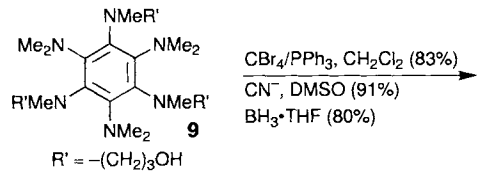
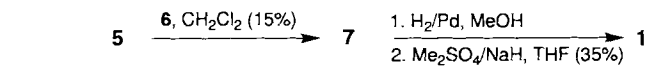
bonds with the NH groups and are nearly coplanar with the ring. The formation of a Meisenheimer complex is favored through increased conjugation.[10]

We synthesized the substituted hexaaminobenzene **5** by the following sequence. Compound **6** was transformed into the tricarbonate **8** by threefold nucleophilic aromatic substitution with aminopropanol and protection of the triol under standard conditions. Reduction of the nitro groups and peralkylation, followed by removal of the carbonate protecting groups gave triol **9**. After **9** had been transformed into the corresponding tribromide, the amino alcohol chains were lengthened by a Kolbe sequence; subsequent reduction with diborane then gave **5**. The reaction of **5** with **6**—not under special high-dilution conditions—led to the isolation of pure **7** in 15% yield. Compound **7** was then transformed into **1** in two steps.







We have performed a structural analysis of **1** (Figure 1), because the precise knowledge of geometrical parameters is a prerequisite for investigations on electron transfer. In addition, to the best of our knowledge, no structural analysis of a [6$_3$]metacyclophane has been published.[11] The two six-membered rings are nearly planar; their least-squares planes are nearly parallel and form an angle of 0.18(4)° at a distance of 5.740(4) Å. This geometry is a consequence of the steric requirements of the three chains in 1-, 3-, and 5-positions, which adopt a close to extended conformation.[12] A reduction in the distance between the rings and hence a diminution of the sizeable intramolecular cavity is energetically favorable only if the two six-membered rings are rotated with respect to each other.[13] Accordingly, the six-membered rings are only slightly displaced but rotated by 12°, quite in contrast to the structures of [6.6]paracyclophanes of comparable ring size,[11b,c] in which the rings lie parallel but are displaced with respect to each other. The distance between the rings is therefore markedly smaller in those paracyclophanes.

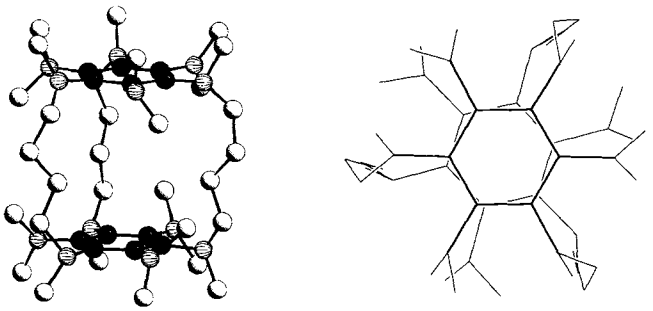


Figure 1. Side view (left) and top view (right) of **1** in the crystal.

The average endocyclic C–C and exocyclic C–N bond lengths in **1** are comparable to those in **3**;[5b] however, the C–N bond lengths in **1** are a little shorter (C–C: 1.404(4), 1.406(4) Å vs. 1.402(2) Å; C–N: 1.422(3), 1.431(3) Å vs. 1.440(2) Å).

Preliminary cyclovoltammetric measurements indicate that **1** undergoes chemically reversible oxidation up to the tetracation with separate peaks for the oxidation of the two rings.[14] Despite the large interring distance in the neutral molecule, pronounced interaction of the π-systems is evident at least in the oxidized form.

Experimental Section

All new compounds gave correct data for C, H, N, Br in combustion analyses.

7: A solution of **5** (1.23 g, 2.42 mmol) and ethyldiisopropylamine (970 mg, 7.50 mmol) in 100 mL of anhydrous CH_2Cl_2 and a solution of **6** [15] (791 mg, 2.50 mmol) in 100 mL of anhydrous CH_2Cl_2 were added simultaneously under argon within 2 h to 700 mL of stirred CH_2Cl_2. The reaction mixture was stirred for 16 h at room temperature then filtered. The filtrate was concentrated to a volume of ca. 25 mL and filtered over 100 g neutral aluminum oxide, (activity III; CH_2Cl_2/ethyl acetate 2/1). Subsequent chromatography (100 g neutral aluminum oxide, activity III) gave **7** as a yellow microcrystalline powder (decomp >220 °C) which was used in the next step. For microanalysis, **7** was recrystallized from mesitylene. ^{1}H NMR (300 MHz, $CDCl_3$; all signals broadened): δ = 0.97, 1.66, 1.73 (together 12H), 2.44 (s, 3H), 2.60 (s, 18H), 2.70 (s, 6H), 2.98 (s, 6H), 3.81 (s, 6H), 9.42 (s, 1H), 11.25 (s, 2H). Due to poor solubility and excessive broadening ^{13}C NMR data could not be obtained. Elemental analysis for $C_{33}H_{54}N_{12}O_6$ (714.9): calcd. C 55.45, H 7.61, N 23.51; found C 55.75, H 7.76, N 23.30. Further dilution in the cyclization reaction had no significant influence on the yields.

1: Catalytic reduction (10% Pd/C, MeOH) of **7** at ambient pressure and 50 °C for ca. 24 h and subsequent methylation (dimethylsulfate, NaH, THF in analogy to ref. [16]) under argon provided **1**. The product was isolated by continuous extraction with diethyl ether and crystallized from toluene in 35% overall yield (decomp >240 °C). ^{1}H NMR (300 MHz, [D$_2$]tetrachloroethane, 343 K): δ = 1.32 (br, 12H), 2.69 (br, 36H), 2.78 (br, 18H), 3.06 (br, 12H). ^{13}C NMR (75.5 MHz, [D$_2$]tetrachloroethane, 343 K): δ = 27.76, 43.79, 44.31, 56.49; signals for aromatic carbon atoms were not detectable due to poor solubility. Elemental analysis for $C_{42}H_{78}N_{12}$ (751.2): calcd. C 67.16, H 10.47, N 22.38; found C 67.26, H 10.31, N 22.44.

Structural analysis of **1**: Colorless six-sided plates (cut piece 0.50 × 0.50 × 0.25 mm) from toluene under argon. $C_{42}H_{78}N_{12}$ (751.2); triclinic, $P\bar{1}$, a = 10.433(1), b = 10.441(1), c = 23.631(5) Å; α = 84.06(2), β = 78.43(1), γ = 60.13(1)°, Z = 2; V = 2186.9(6) Å^3; ρ_{calcd} = 1.14 g cm^{-3}; μ = 0.07 mm^{-1}. F(000) = 828; Enraf-Nonius CAD4 diffractometer, $Mo_{K\alpha}$ radiation, graphite monochromator, ω–2θ scans. 2.3° ≤ θ ≤ 28.0°; 10771 reflections, 10519 independent and 6213 observed reflections [$(I > 2\sigma(I)$]. Solution by direct methods (SHELXS-86 [17]), full-matrix least-squares refinement versus F^2 (SHELXL-93 [18]): heavy atoms anisotropic, H atoms at calculated positions. 701 parameters refined. R = 0.097 (R_w = 0.295), S = 1.07, largest and smallest residual electron density peaks: 0.52 and −0.40 e Å^{-3}, respectively. The methyl and methylene groups are disordered. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the depository number CSD-406008.

$[(CF_3)_2Hg(\mu\text{-}F)_2Hg(CF_3)_2]^{2-}$: Synthesis, Structure, and Reactivity**

Detlef Viets, Enno Lork, Paul G. Watson, and Rüdiger Mews*

Dedicated to Professor Oskar Glemser on the occasion of his 85th birthday

In the past few years mercura-heterocycles have been successfully used as host molecules for halide ions X^- (X = Cl, Br, I).[1, 2] Previously, the 2:1 adduct of 1,2-phenylenedimercury dichloride and tetraphenylphosphonium chloride, the first anionic organomercury derivative, was structurally characterized.[3] Mononuclear organomercury compounds, R^1HgR^2 also show acceptor properties, which are particularly pronounced for perfluoroalkyl derivatives; Emeléus and Lagowski used conductivity measurements to show that bis(trifluoromethyl)-mercury, the first perfluorinated organometallic compound,[4] undergoes addition of halide ions (X = Cl, Br, I) in aqueous solution to form $[(CF_3)_2HgX]^-$ and $[(CF_3)_2HgX_2]^{2-}$.[5] Korpar-Čolig et al. were able to isolate the crystalline salts $Ph_4A^+[(CF_3)_2HgX]^-$ (A = P, As; X = Cl, Br, I) under similar conditions by using larger organic cations. The X-ray crystal structures indicated halide-bridged dimers in the solid-state, for example, $[(CF_3)_2Hg(\mu\text{-}Cl)_2Hg(CF_3)_2]^{2-}$.[6] All attempts to synthesize the corresponding fluoro complexes have been unsuccessful to date.

By reacting $(CF_3)_2Hg$ with TAS fluoride $(Me_2N)_3S^+Me_3SiF_2^-$ [TAS = $(Me_2N)_3S^+$],[7] we have been able to synthesise the first anionic fluoromercury complex [Eq. (1)].

$$\underset{\mathbf{1}}{2\ Hg(CF_3)_2} + 2\ (Me_2N)_3S^+(Me_3Si)F_2^- \xrightarrow[-40\,^\circ C]{CH_3CN} [(Me_2N)_3S^+]_2\ \underset{\mathbf{2}}{[(CF_3)_2Hg(\mu\text{-}F)_2Hg(CF_3)_2]^{2-}} + 2Me_3SiF \quad (1)$$

Compound **2** was isolated as a colorless solid at −40 °C by precipitation from an acetonitrile solution with diethyl ether. The ^{19}F NMR spectrum showed the expected two resonances at $\delta = -35.3$ (s, CF_3) and −83.6 (s, br, HgF); Hg–F coupling ($^2J = 1324$ Hz) appeared only for the CF_3. However, from the available data it is not possible to conclude whether the complex is monomeric or dimeric in solution.

The X-ray crystal structure analysis[8] (Figure 1) indicates dimeric units in the solid state.[9] The anion of **2** is isostructural with that of the analogous chloro derivative.[6] The central four-membered Hg_2F_2 ring (Hg–F 239.5(7) and 241.8(7) pm, F-Hg-F 82.4(2)°) is formed by interaction of the lone pairs of electrons of the bridging fluoride ions with the empty p orbitals of the Hg centers. The original, linear C-Hg-C bond of the starting material $Hg(CF_3)_2$[10, 11] is significantly deformed in the anion, although with a bond angle of 162.1(5)°, sp character still dominates.

The distance between Hg and the fluoride bridges is similar to the Hg–F distance in the predominately ionic HgF_2 (Hg–F 240 pm, CN 8).[12] The Hg–C distances of 208.6(14) in the solid state and 210.5(13) pm in the gas phase do not differ considerably from those of the starting material **1** (210.9(16)[10] and

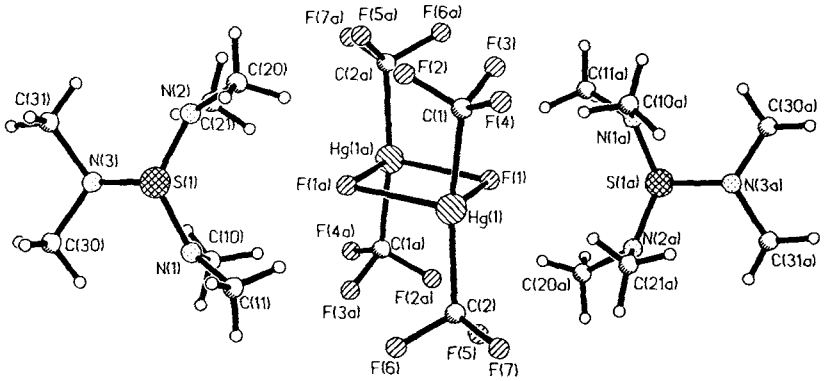

Figure 1. Structure of $[(Me_2N)_3S^+]_2[(CF_3)_2\,Hg(\mu\text{-}F)_2Hg(CF_3)_2]^{2-}$.

210.1(5),[11] respectively). The corresponding distances in the chloro derivative of **2** are 206.7(22) and 204.2(22) pm.

Astonishingly, fluoride ion addition leads to an unusual labilization of the Hg–C bond. Formation of CF_3H was observed on warming a solution of **2** in CH_3CN to 0 °C. We therefore conclude that **2** can be employed as a trifluoromethanide equivalent. The parent compound **1** cannot be used for nucleophilic transfer of CF_3 groups due to the very strong Hg–C bond, but it does have interesting applications as a source of CF_3 radicals and of difluorocarbene.[13] We treated **2** with NSF_3 and were able to isolate NSF_2CF_3 (**3**), which has been inaccessible to date [Eq. (2)].

$$\mathbf{2} + 2\,NSF_3 \xrightarrow[-30 \longrightarrow 0\,^\circ C]{CH_3CN} 2\,NSF_2(CF_3) + 2\{TAS(CF_3)HgF_2\} \qquad (2)$$

Compound **3** was characterized by mass spectrometry and ^{19}F NMR spectroscopy. The ^{19}F NMR spectroscopic data are consistent with those of the reported *S*-perfluoroalkyl thiazyldifluorides (Table 1). The ^{14}N nucleus in **3** couples to the sulfur-bonded fluorine nucleus ($^2J(N,F) = 9.6$ Hz) like in NSF_3[14] and the isoelectronic $NS(O)F_2^-$ ion.[15]

Table 1 ^{19}F NMR Spectroscopic data of NSF_3 and its perfluoroalkyl derivatives (J in Hz); n.o. = not observed.

The activation of the Hg–C bond by fluoride resembles that of the Si–C and Sn–C bonds in Me_3SiCF_3[16] and Me_3SnCF_3, respectively.[17] Both systems have found wide-ranging applications as nucleophilic trifluoromethylating agents. Owing to the ready accessibility of **1**,[18] the reaction pathway reported here may be an interesting preparative alternative.

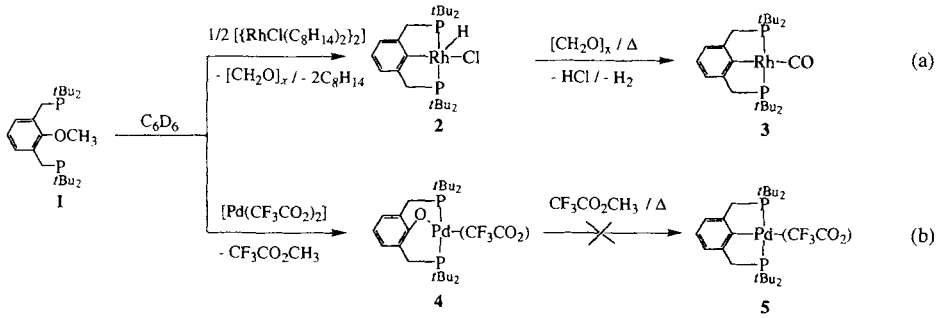
Selective Activation of Alkyl- and Aryl-Oxygen Single Bonds in Solution with Transition Metal Complexes**

Milko E. van der Boom, Shyh-Yeon Liou, Yehoshoa Ben-David, Arkadi Vigalok, and David Milstein*

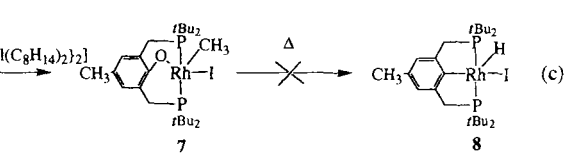
Activation of C–O single bonds by metal complexes has been proposed as a key step in the hydrodeoxygenation of crude oil and may lead to the design of novel catalytic reactions.[1] As yet few clear examples with unstrained bonds have been reported.[2, 3, 4a]

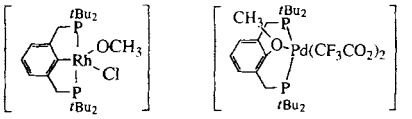
We present here the first metal insertion into the strong aryl–O bond of an aryl ether under mild conditions in solution. This reaction occurs directly, with no intermediacy of C–H activation or insertion into an adjacent weaker Me–O bond. Furthermore, it is possible to direct the C–O activation process to either an aryl–O or alkyl–O bond by choice of the metal complex. Insertion of metal complexes into aryl–N[4a] and aryl–C[4b–e] bonds was reported recently.

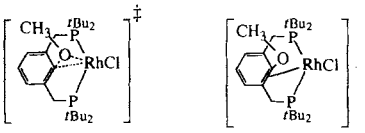
To probe the possibility of activating C–O bonds, we prepared the aromatic ether **1**, which can direct the metal to the vicinity of these bonds.[5] Reaction of $[\{RhCl(C_8H_{14})_2\}_2]$ (C_8H_{14} = cyclooctene) with two equivalents of **1** in C_6D_6 at 85 °C (3 h in a sealed tube) quantitatively affords the known rhodium complex **2** [Eq. (a)],[6] which was characterized by various NMR techniques and was identical to an authentic sample. No other complexes were found. The reaction proceeds even at room temperature (20% conversion of **1** into **2** after 24 h). Heating the product solution at 140 °C or performing the reaction at this temperature leads to formation of complex **3**,[6] presumably by decarbonylation of the initially formed formaldehyde, which, however, was not directly detected. In support of this, heating **2** with ten equivalents of paraformaldehyde results in decarbonylation and quantitative formation of **3**.



To evaluate whether activation of the weaker CH_3–O bond (bond dissociation energies: $Ph-OCH_3 = 91$, $PhO-CH_3 = 80$ kcal mol^{-1})[7] is an intermediate step in the observed Ar–O bond activation process or perhaps a reversible parallel process, we prepared complex **7**. This is the iodide analog of the expected product of Rh^I insertion into ArO–CH_3 [Eq. (c)]. Deprotonation of the new aromatic phosphane alcohol **6** with KH in THF,[5] followed by reaction with $[\{RhCl(C_8H_{14})_2\}_2]$ (0.5 equiv) and oxidative addition of $^{13}CH_3I$ (1 equiv) in C_6D_6, leads to quantitative formation of **7**, which was fully characterized by various NMR techniques and FD-MS.[8] Complex **7** is stable under conditions in which **1** readily undergoes Ar–O cleavage with $[\{RhCl(C_8H_{14})_2\}_2]$ (85 °C, 1.5 h). This constitutes strong evidence that the sp^2–sp^3 C–O activation by Rh^I is a direct process. Cleavage of ArO–CH_3 is neither involved on the reaction coordinate nor in a side equilibrium. Thus, Ar–O activation in **1** by Rh^I is kinetically prefered over activation of the CH_3–O bond. The presumably formed (unobserved) Rh–OCH_3 intermediate **A** undergoes β-H elimination to afford **2** and formaldehyde.[9]







Interestingly, it is possible to direct the activation process towards the CH_3–O bond by choice of the metal complex. Thus, reaction of $[Pd(O_2CCF_3)_2]$ with a stoichiometric amount of **1** in C_6D_6 (85 °C for 3 h) results in exclusive activation of the sp^3–sp^3 C–O bond and quantitative formation of the phenoxy palladium complex **4** (40% conversion of **1** into **4** at room temperature after 24 h) [Eq. (b)]. This complex, which was fully characterized by ^1H, $^1H\{^{31}P\}$, $^{31}P\{^1H\}$ NMR spectroscopy, and FD-MS,[10] exhibits similar spectroscopic features to two analogous benzylic and phenoxy palladium complexes.[11] $CF_3CO_2CH_3$ was also formed, as detected by ^1H NMR upon addition of an authentic sample. The expected product of Ar–O cleavage (**5**) was not observed,[12] nor was it formed upon treatment of **4** with a tenfold excess of $CF_3CO_2CH_3$ at 85 °C. Thus, in striking contrast to the reactivity of Rh^I, CH_3–O activation is kinetically (and perhaps thermodynamically) preferred over Ar–O activation for Pd^{II}. Metal insertion into ArO–CH_3 has also been observed by Shaw, Tolman, and Dunbar.[3]

Aromatic ethers, such as anisole are known to react with HI or HBr at elevated temperatures to give an alkyl halide and an aromatic alcohol [Eq. (d)].[13] Lewis acids such as $AlCl_3$ or BF_3 are also effective.

$$ArO-CH_3 + HX \longrightarrow ArOH + CH_3X \qquad (d)$$

The reaction proceeds by protonation of (or Lewis acid binding to) the oxygen atom followed by nucleophilic attack by the anion on the alkyl group. This results in exclusive cleavage of the sp^3-sp^3 C–O bond. It is likely that the electrophilic Pd^{II} center reacts as a Lewis acid via an intermediate such as **B**.

The reaction of the Rh^I complex appears to be unique. Direct insertion into the strong Ar–O bond by the electron-rich Rh^I center may proceed over a concerted transition state **C** or an η^2-arene complex **D**, followed by 1,2-migration of the methoxy group. Further studies are underway to clarify the mechanism and scope of this unprecedented transformation.

In conclusion, rhodium insertion proceeds directly only into the strong aryl–oxygen single bond of an aromatic ether under mild conditions in solution. Although the two metal complexes studied each contain a d^8 metal center, the nucleophilic Rh^I complex activates the Ar–O bond, whereas the more electrophilic Pd^{II} cleaves the CH_3–O bond.

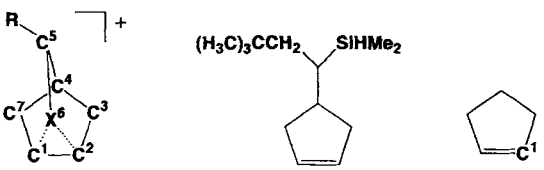
The 2-Silanorbornyl Cation: An Internally Stabilized Silyl Cation**

Hans-Uwe Steinberger, Thomas Müller, Norbert Auner,* Christoph Maerker, and Paul von Ragué Schleyer*

Dedicated to Professor Günter Szeimies on the occasion of his 60th birthday

We report evidence for the preparation of the theoretically predicted silicon analog (**1**)[1] of the nonclassical 2-norbornyl cation **2**.[2] The intramolecularly π-stabilized silyl ion **3**, prepared by a hydride transfer reaction[3] by the π route[4] from **4**[5] at room temperature, shows no coordination to a counterion or solvent (Scheme 1).[6, 7]



1 X= SiH_2, R= H; **2** X= CH_2, R= H; **3** X= $SiMe_2$, R= $CH_2C(CH_3)_3$; **5** X= $SiMe_2$, R= H; **6** X= $SiMe_2$, R= Me

4 **11**

Scheme 1.

The single peak at $\delta = 87.7$ in the ^{29}Si NMR spectrum of **3** in toluene (INEPT, no kinetic line broadening down to $-20\,^\circ C$)[8] is in the range of arene–silyl cation complexes (see for example, experimental[9, 10] or computed[7] structures). However, the deshielding of C^1 and C^2 in **3** ($\delta = 153.74$ with $^1J(C,H) = 174$ Hz) and $\delta = 150.52$ with $^1J(C,H) = 174$ Hz, respectively) relative to the corresponding signals in the starting silane **4** ($\delta = 130.57$ with $^1J(C,H) = 156$ Hz and $\delta = 130.41$ with $^1J(C,H) = 156$ Hz, respectively) provides evidence for intramolecular π-complexation of the positively charged silicon.[11]

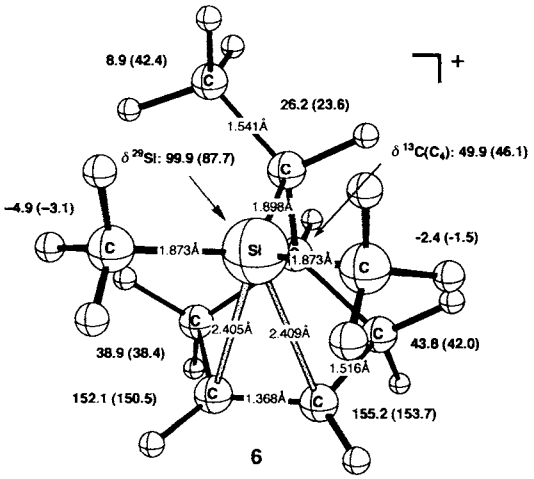

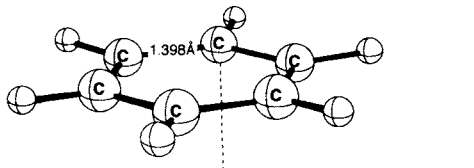

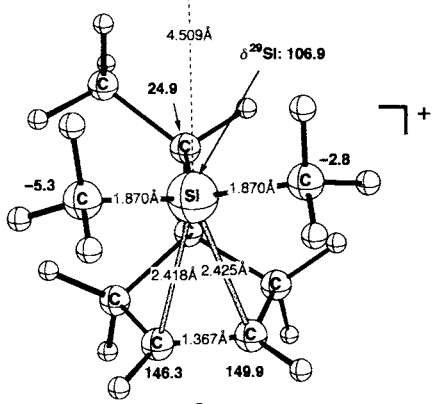

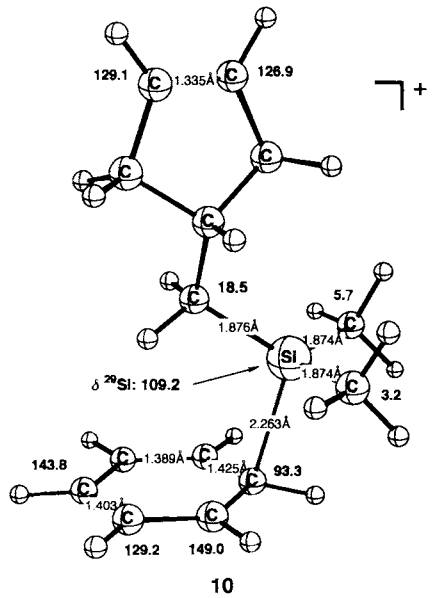

Figure 1. B3LYP/6-31G* optimized geometries of **6**, **8**, and **10**. Bond lengths in Å, computed ^{13}C and ^{29}Si NMR chemical shifts (**6**: IGLO-DFPT/BIII; **8**,**10**: IGLO-DFPT/BII) are given in bold face, experimental chemical shifts (of **3**) in parentheses.

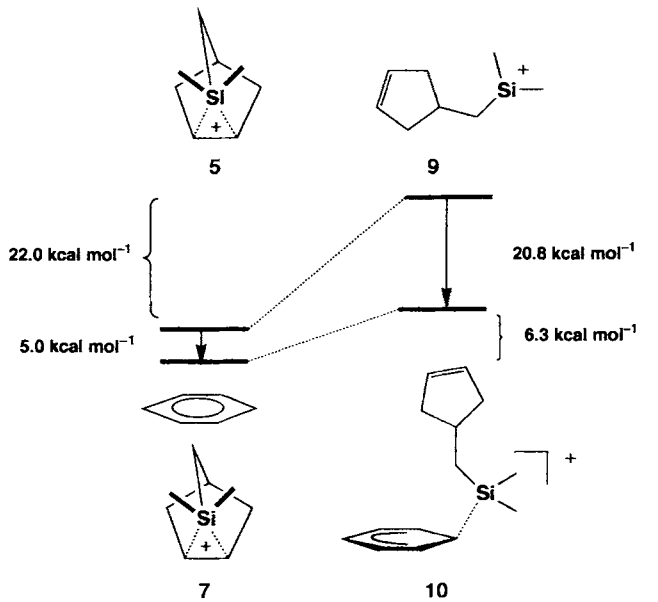
Ab initio calculations[12] on model compounds and their benzene complexes (**5**–**10**), optimized at the density functional B3LYP/6-31G*[13, 14] level, support the experimental findings. Cations **5** (C_s) and **6** (C_1) are local minima, and even the C^1–Si^6 and C^2–Si^6 bonds are of almost equal length in unsymmetrical **6** (Figure 1).

The NLMO/NPA[15] bond orders of Si–Me (0.58) and Si–C^5 (0.56) in **6** are significantly lower than 1.0 due to the polar contribution to bonding between silicon and all directly bound carbon atoms. The long Si–C^1 and Si–C^2 bonds (bond orders of 0.28) have more ionic character. The silicon center bears a large positive charge (approximately +1.9 in **6**) but this is counterbalanced to some extent by the negatively charged methyl groups (net charge on each is about −0.39). The positive charge on the C=C bond is rather small (+ 0.06 per CH). The total bond angle sums (Σ°) of 351 to 353° indicate only small deviations from planarity at silicon in **5** and **6**. The "open" isomer **9**, a local minimum that is 22.0 kcal mol^{-1} higher in energy than **5**, has an essentially planar silicon environment ($\Sigma^\circ = 360^\circ$).

Benzene coordination to cations **5** and **6** (computed for **7** and **8**) has minor structural consequences for the cation subunits. For instance, the C^1–Si^6 and C^2–Si^6 bond lengths are increased by only 0.1 Å. The benzene complexation energies of 5.0 kcal mol^{-1} for both **5** and **6** are quite small. Compound **10**, the benzene complex of the "open" form **9**, has a much larger benzene complexation energy (20.8 kcal mol^{-1}, Scheme 2). Consequently, **10** is only 6.3 kcal mol^{-1} less stable than **7** (all data at B3LYP/6-31G* + 0.89·ZPE(SCF/6-31G*); Table 1). As **10** is also disfavored entropically, it is probably not present experimentally.

The best evidence for a "closed" silanorbornyl cation is provided by the agreement between experimental and computed NMR chemical shifts[16a] and spin–spin coupling constants[16b] (Table 2). In particular, the deshielding of C^1/C^2 relative to **4** and the $\delta(^{13}C)$ value of the methyl groups at silicon are reproduced well. In contrast, the methyl groups in **9** or **10** are more deshielded than in **4**, and the olefinic $\delta(^{13}C)$ values are like those of cyclopentene **11** ($\delta = 130$). A closed silanorbornyl cation is supported further by ^1J(C,H) spin–spin coupling constants. The experimental $^1J(C^1,H)$ value of 174 Hz for **3** is between those for **11** (161.6 Hz)[17] and the secondary 2-norbornyl



Scheme 2.

[a] Ref. [17]. [b] $\delta(^{13}C)$ and $\delta(^{29}Si)$ vs. $\sigma(^{13}C(TMS)) = 179.3$ and $\sigma(^{29}Si(TMS)) = 345.3$. All data at IGLO-DFPT/BIII//B3LYP/6-31G* employ the Perdew–Wang exchange correlation functional [19]. [c] Coupling constants ^1J(H,C) (perturbation on H) computed at IGLO-DFPT/BIII//B3LYP/6-31G* employ the Perdew exchange correlation functional [20]; high grid resolution of Radial = 64 used. [d] $\delta(^{13}C)$ and $\delta(^{29}Si)$ vs. $\sigma(^{13}C(TMS)) = 184.3$ and $\sigma(^{29}Si(TMS)) = 364.4$. All data at IGLO-DFPT/BII//B3LYP/6-31G* employ the Perdew–Wang exchange correlation functional [19]. [e] Ref. [4f].

cation **2** (187.7 Hz).[4f] Although the theoretical ^1J(C,H) values are not highly accurate at the IGLO-DFPT/BIII[16,18] level employed, the experimental trend of ^1J(C,H) (**2**) > ^1J(C,H) (**3**) > ^1J(C,H) (**11**) is reproduced nicely (Table 2).[19,20]

In summary, there is strong evidence for the preparation of the first intramolecularly π-stabilized silanorbornyl cation **3**[21] in solution that is not coordinated to solvent or a counterion.[22] Species **3** also can be regarded as a nearly symmetrically bridged β-silyl carbocation with siliconium ion character.[23]

Experimental Section

3: Trityltetrakis(pentafluorophenyl)borate (2.46 g, 2.62 mmol) was placed in an evacuated, flame-dried 10 mm NMR tube under argon. After [D$_8$]toluene (2.5 mL) and **4** (551 mg, 2.62 mmol) had been added, the resulting mixture was stirred vigorously, and two layers formed. The top layer was removed, and the lower layer, consisting of **3** and triphenylmethane, was examined by NMR spectroscopy.

^{1}H NMR (300.133 MHz, [D$_8$]toluene, 25 °C, $\delta(H_3CC_6H_5) = 7.16$): $\delta = 0.29$ (s, 3H, H_3CSi), 0.36 (s, 3H, H_3CSi), 0.79 (s, 9H, $C(CH_3)_3$), 0.83–1.26 (m, 2H, $CH_2C(CH_3)_3$), 1.72–2.12 (m, 4H, 2CH_2, cyclopentene), 2.33 (s, br, 1H, CH, cyclopentene), 6.28 (d, J(H,H) = 5 Hz, 1H, =CH, cyclopentene), 6.35 (d, J(H,H) = 5 Hz, 1H, =CH, cyclopentene); ^{13}C NMR (75.403 MHz, [D$_8$]toluene, 25 °C, $\delta(D_3CC_6D_5) = 20.42$): $\delta = -3.07$ (H_3CSi, ^1J(C,H) = 126 Hz), −1.50 (H_3CSi, ^1J(C,H) = 126 Hz), 23.64 (CHSi, ^1J(C,H) = 129 Hz), 28.87 ($C(CH_3)_3$), ^1J(C,H) = 126 Hz), 29.66 ($C(CH_3)_3$), 38.44, 42.02 (2CH_2, cyclopentene), ^1J(C,H) = 136 Hz), 42.39 ($CH_2C(CH_3)_3$, ^1J(C,H) = 126 Hz), 46.11 (^1J(C,H) = 150 Hz, CH, cyclopentene), 150.52 (^1J(C,H) = 174 Hz, =CH, cyclopentene), 153.74 (^1J(C,H) = 174 Hz, =CH, cyclopentene); ^{19}F NMR (282.2 MHz, [D$_8$]toluene, δ(ext. $CFCl_3$) = 0): $\delta = -133.1$ (*ortho*), −163.0 (*meta*), −167.2 (*para*); ^{29}Si NMR (59.25 MHz, [D$_8$]toluene, 25 °C, δ(ext. TMS) = 0): $\delta = 87.7$; ([D$_6$]benzene, 25 °C, δ(ext. TMS) = 0) $\delta = 87.3$

[11] Compound **3** is quite persistent at 25 °C in toluene. The decomposition of **3** in [D$_8$]toluene was followed by ^{29}Si NMR; the solution of **3** in toluene was stable in the absence of air and moisture for three weeks. After this time, a new species with $\delta(^{29}Si) = 67.5$ was detected. After eight weeks the ^{29}Si NMR signal of **3** had vanished completely, and only the peak at $\delta(^{29}Si) = 67.5$ was present.

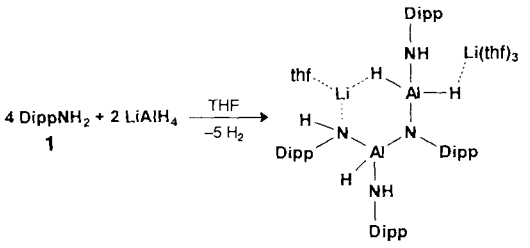
The Reaction of Primary and Secondary Amines with $LiAlH_4$ and $Na(AlHEt_3)$**

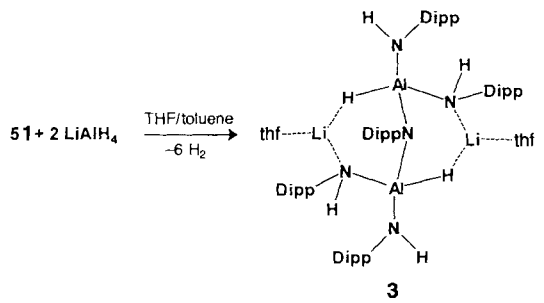
Mavis L. Montero, Helge Wessel, Herbert W. Roesky,* Markus Teichert, and Isabel Usón

Dedicated to Professor Rafael Usón on the occasion of his 70th birthday

In 1988 Nöth et al. reported on the reaction of secondary aliphatic amines with $LiAlH_4$.[1] Subsequently, in 1992 Stalke et al. isolated the intermediates $[(Me_3Si)_2NAlH_3Li(Et_2O)_2]_2$ and $[\{(Me_3Si)_2N\}_2AlH_2Li(Et_2O)_2]$.[2] Analogous studies with primary aromatic amines and with sodium organoaluminum hydrides have so far not been reported. Reactions with $LiAlH_4$ have been employed intensively for almost fifty years.[3, 4] However, over the last decade organoaluminum hydrides have also been utilized increasingly as reducing agents because they are safe and easy to handle.[5]

With the goal of isolating an intermediate in the reaction of $LiAlH_4$ with a primary amine, we added 2,6-diisopropylaniline ($DippNH_2$, **1**) in molar ratios of 1:2 and 2:5 to a solution of $LiAlH_4$ in THF. Elimination of hydrogen afforded compounds **2** and **3**, respectively.





The central structural element of **2**[6] is a six-membered Al_2HLiN_2 ring in which one of the N atoms belongs to a deprotonated, μ_2-bridged 2,6-diisopropylaniline molecule (Figure 1). The aluminum atom Al(1) binds to a terminal DippNH ligand and two hydrogen atoms (H(1) and H(2)) that are each coordinated to a lithium atom. Two DippNH ligands and a terminal hydrogen atom (H(3)) complete the coordination sphere of Al(2). In addition, one THF molecule is bound to Li(1) and three THF molecules to Li(2). Al(1) resides in a strongly distorted tetrahedral environment (bond angles 102.1–119.4°), for Al(2) this distortion is less pronounced (bond angles 102.6–116.7°).

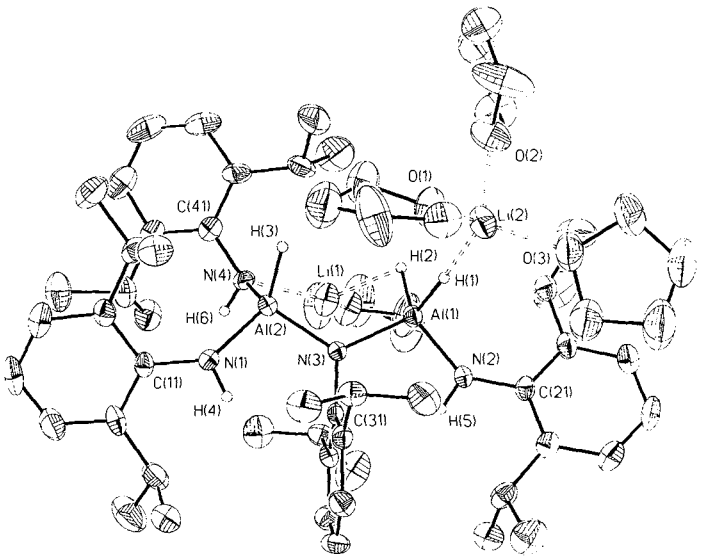


Figure 1. Molecular structure of **2** in the crystal. Selected distances [pm] and angles [°]: Al(1)–H(2) 159(3), Al(1)–H(1) 167(3), Al(1)–N(2) 185.1(3), Al(1)–N(3) 185.5(3), Al(2)–H(3) 156(3), Al(2)–N(1) 185.0(4), Al(2)–N(3) 187.6(3), Al(2)–N(4) 193.5(3), Li(1)–H(2) 200(3), Li(1)–N(4) 204.7(8), Li(2)–H(1) 183(3); Al(1)–N(3)–Al(2) 121.7(2), N(3)–Al(1)–H(2) 102.1(12), N(4)–Li(1)–H(2) 125.5(10).

The central unit in **3** comprises the basic structure of compound **2**, only that the reaction with an additional equivalent of diisopropylaniline and concurrent hydrogen elimination has led to the μ_2 nitrogen bridge between Al(2) and Li(2). This gives rise to a second six-membered Al_2HLiN_2 ring. The molecule lies on a twofold crystallographic axis and fulfils the point group C_2. Al(1) is tetrahedrally coordinated with bond angles of 105.7–117.0° (Figure 2). The six-membered Al_2HLiN_2 ring in **2** and the two six-membered Al_2HLiN_2 rings in **3** each exhibit a con-

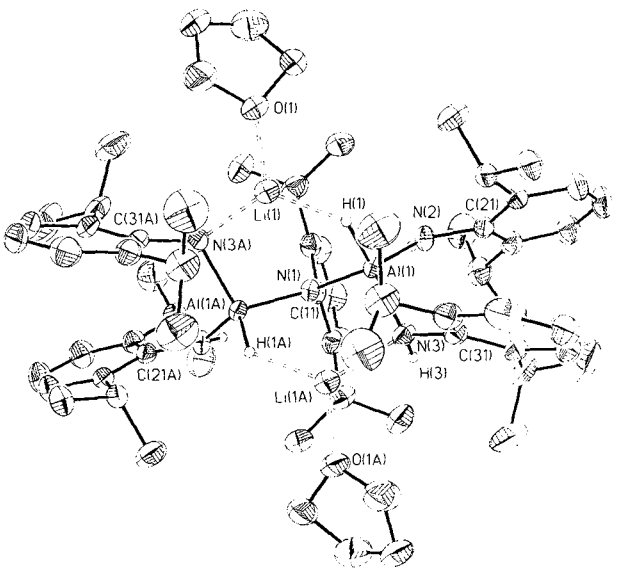

Figure 2. Molecular structure of **3** in the crystal. Selected distances [pm] and angles [°]: Al(1)–H(1) 160(2), Al(1)–N(1) 184.2(2), Al(1)–N(2) 182.8(2), Al(1)–N(3) 191.3(2), Li(1)–H(1) 188(2), Li(1)–N(3A) 202.2(4), Li(1A)–H(1A) 183(3); Al(1)–N(1)–Al(1A) 122.6(1), N(1)–Al(1)–H(1) 106.1(8), N(3A)–Li(1)–H(1) 124.1(7).

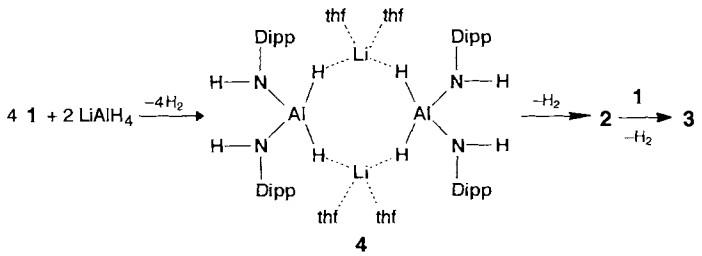
formation that can be described with a twist-boat contribution of 70%.[7]

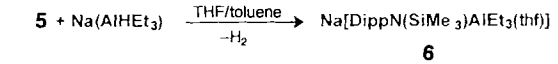
The Al(2)-H(3) and Al(1)-H(2) bond lengths in **2** (156 and 159 pm, respectively) and the Al(1)-H(1) bond length in **3** (160 pm) are in good agreement with other Al-H bond lengths determined by X-ray crystallography ($[(Me_3Si)_2NAlH_3Li\cdot(Et_2O)_2]_2$ 158 and 161 pm,[2] $[Li\{NtBuCH(tBu)CH_2NtBu\}\cdot AlH_2]_4$ 155-157 pm[8a]). The Al(1)-H(1) bond (167 pm) is slightly elongated and, therefore, more closely resembles Al-H bond lengths in aluminum amides containing bridging hydrogen atoms ($[\{2,2,6,6\text{-}Me_4C_5H_6N\}_2Al(\mu_2\text{-}H)]_2$ 167 and 168 pm,[9] $[Me_2Al(\mu_2\text{-}H)]_2$ 168 pm[10]). Li-H distances in both complexes lie between 183 and 200 pm and approach those reported for $LiAlH_4$ (four H at a distance of 188-200 pm and one H at a distance of 216 pm from the Li center).[11] The strong cation-anion interaction in **2** is evident from the presence of a contact ion pair. The counterion contact of the lithium cation is expected to result in a destabilizing localization of the negative charge in the anion; this influence is evident from the fact that the Al(1)-H(1) bond is 11 pm longer than the Al(2)-H(3) bond. Compound **2** is thermally labile, and reaction with additional amine **1** affords the stable aluminum amide **3**. A possible pathway for the reaction of $DippNH_2$ (**1**) with $LiAlH_4$ is depicted in Scheme 1.



Scheme 1. Possible pathway for the reaction of **1** with lithium aluminum hydride.

The initially formed, very reactive intermediate **4** seems to be stable only at low temperatures and could not be isolated. Related dimeric compounds with an eight-membered $Al_2H_4Li_2$ ring are known and have been characterized by X-ray structure analysis.[1, 8] The thermally labile compound **2** is formed by elimination of hydrogen from **4**. Treatment of **2** with one equivalent of **1** in boiling toluene yields **3** under hydrogen elimination.

The reaction of $Na(AlHEt_3)$ with the secondary amine 2,6-diisopropyl-*N*-trimethylsilylaniline ($DippNH(SiMe_3)$) **5** affords the sodium aluminum amide **6** under hydrogen elimination.



Compound **6**·toluene comprises an anionic framework with $DippN(SiMe_3)^-$ as the central unit (Figure 3). The sodium cation present to balance the charges is coordinated asymmetrically in a η^4 fashion to the aromatic ring. The distances between Na(1) and the carbon atoms of this ring vary between 279.9 and 310.2 pm. The distance to the oxygen atom of the coordinated THF molecule is 227.0 pm. These distances are consistent with those in similar compounds, in which multihapto-coordinated sodium cations are present.[12] Interactions between the sodium cation and carbon atoms of the methylene groups are also evident in **6**; more specifically, the Na(1A)-C(3) interaction gives rise to a chainlike association of the monomeric units. A section of this polymeric unit is shown in Figure 3.

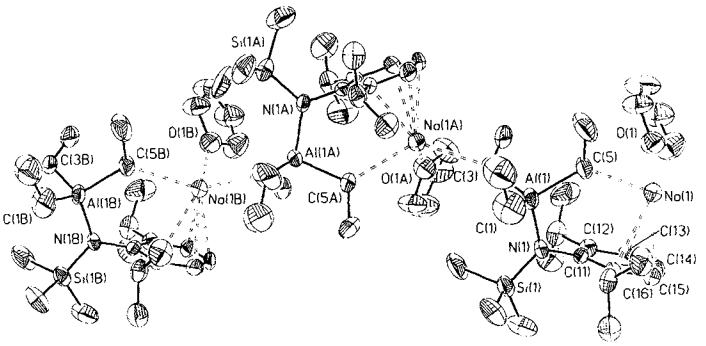


Figure 3. Molecular structure of **6** in the crystal. Selected distances [pm] and angles [°]: Na(1)-C(13) 292.8(6), Na(1)-C(14) 279.9(6), Na(1)-C(15) 287.1(6), Na(1)-C(16) 310.2(5), Na(1A)-C(3) 282.5(7), Na(1)-C(5) 282.8(6), Na(1)-O(1) 227.0(5), Al(1)-C(1) 204.5(8), Al(1)-C(3) 204.8(7), Al(1)-C(5) 202.2(6), Al(1)-N(1) 191.8(4); C(3A)-Na(1)-C(5) 118.4(2), C(3)-Al(1)-C(5) 107.6(3).

The coordination environment of Al(1) in **6** is a slightly distorted tetrahedron with bond angles of 106.3-112.0°. As a consequence of the fourfold coordination of Al, the Al-C distances are longer than those for monomeric $AlMe_3$[13] (on average by 8.1 pm) determined by electron diffraction. The Al(1)-N(1) bond length of 191.8 pm lies between that of a covalent single bond ($tBu_2AlNMes_2$ 182.3 pm[14]) and a purely coordinative bond ($Me_3Al\cdot NMe_3$ 210 pm[15]).

The sterically demanding amines $DippNH_2$ (**1**) and $DippNH(SiMe_3)$ (**5**) facilitate the stabilization of compounds **2**, **3**, and **6**, respectively. Compounds **2** and **3** are the first aluminum amides derived from a primary amine, whereas **6** is the first monomeric sodium aluminum amide. The isolation of these compounds does not necessarily imply that they are intermediates in the reductions of, for example, nitriles or aromatic nitroso and nitro compounds with $LiAlH_4$ or sodium organoaluminum hydrides, but the chemistry is suggestive of the fact.

Experimental Section

2: Compound **1** (1.42 g, 8 mmol) was added dropwise to a solution of $LiAlH_4$ (0.15 g, 4 mmol) in THF at 0 °C and stirred. The mixture was allowed to warm to room temperature and stirred for a further 12 h. After removal of the volatile components under vacuum the residue was recrystallized from *n*-hexane (30 mL) to afford **2** (1.5 g, 80%). M.p. 151 °C (decomp); ^{1}H NMR (250 MHz, C_6D_6, TMS): δ = 0.29 (s, 3H; AlH), 1.15 (m, 16H; THF), 1.27-1.56 (m, 48H; $CH(CH_3)_2$), 3.05 (s, 3H; NH), 3.20 (m, 6H; $CH(CH_3)_2$), 3.40 (m, 16H; THF), 3.85 (m, 2H; $CH(CH_3)_2$), 6.80-7.15 (m, 12H; H_{arom}); IR (KBr, Nujol): $\tilde{\nu}$ = 3360, 1786, 1622, 1591, 1262, 1044, 806, 586 cm^{-1}; EI-MS: *m*/*z* (%): 202 (20, $C_{12}H_{17}NAl$), 162 (100, $C_{12}H_{18}$); elemental analysis $C_{48}H_{74}Al_2Li_2N_4\cdot 4C_4H_8O$: calcd: C 72.22, H 9.97, Al 5.08, N 5.26; found: C 72.0, H 9.7, Al 4.8, N 5.3.

3: **1** (2.33 g, 13.15 mmol) was added dropwise to a solution of $LiAlH_4$ (0.20 g, 5.26 mmol) in THF (40 mL) at 0 °C and stirred. The mixture was allowed to warm to room temperature and stirred for a further 2 h. After volatile components were removed under vacuum, toluene (40 mL) was added. Then the solution was heated under reflux for 3 h. Upon cooling the solution, a white, microcrystalline solid precipitated. Quantitative precipitation was achieved at -20 °C. Yield: 2.30 g (80%). M.p. 189 °C (decomp); ^{1}H NMR (250 MHz, C_6D_6, TMS): δ = -0.03 (s, 2H; AlH), 1.03 (m, 8H; THF), 1.14 (d, ^3J(H,H) = 6.8 Hz, 12H; $CH(CH_3)_2$), 1.22 (d, 48H, ^3J(H,H) = 6.8 Hz; $CH(CH_3)_2$), 3.00 (s, 4H; NH), 3.14 (m, 8H; THF), 3.24 (m, 8H; $CH(CH_3)_2$), 4.50 (m, 2H; $CH(CH_3)_2$), 6.98-7.16 (m, 15H; H_{arom}); IR (KBr, Nujol): $\tilde{\nu}$ = 3340, 1591, 1363, 1260, 1038, 840, 753, 664 cm^{-1}; EI-MS: *m*/*z* (%): 203 (14, $C_{12}H_{18}NAl$), 162 (100, $C_{12}H_{18}$); elemental analysis $C_{60}H_{91}Al_2Li_2N_5\cdot 2C_4H_8O$: calcd: C 74.66, H 9.79, Al 4.94, N 6.40; found: C 73.8, H 9.6, Al 4.7, N 6.3.

6: Compound **5** (1.10 g, 4.10 mmol) was dissolved in toluene (50 mL) and $Na(AlHEt_3)$ (2 mL, 4.00 mmol of a 2 M solution in toluene/THF (20/1)) was dropwise added over 15 min at room temperature. The reaction mixture was stirred for a further 36 h, and then heated under reflux for 1 h. Hydrogen and methane which evolved in the course of the reaction were are allowed to escape through a mercury

The *R* values are $R1 = \sum||F_o| - |F_c||/\sum|F_o| = 0.0645$ ($I > 2\sigma(I)$) and $wR2 = [\sum w(F_o^2 - F_c^2)^2/\sum wF_o^4]^{1/2} = 0.1550$ (all data); min./max. residual electron density: $-263/348$ e nm^{-3}. **3**·toluene: $C_{68}H_{107}Al_2Li_2N_5O_2 \cdot C_7H_8$, $M_r = 1094.42 + 92.14$, monoclinic, space group $C2/c$, $a = 2527.2(11)$, $b = 1301.4(8)$, $c = 2289.4(9)$ pm, $\beta = 106.21(3)^{\circ}$, $V = 7.230(6)$ nm^3, $Z = 4$, $\rho_{calcd} = 1.090$ Mg m^{-3}, $F(000) = 2592$, $\lambda = 71.073$ pm, $T = 153$ K, $\mu Mo_{K\alpha} = 0.086$ mm^{-1}. Crystal dimensions: $0.8 \times 0.8 \times 0.7$ mm^3, $6^{\circ} \le 2\theta \le 50^{\circ}$; 7256 measured reflections of which 6369 were independent and included in the structure refinement (472 parameters, 197 restraints). The *R* values are $R1 = 0.0527$ ($I > 2\sigma(I)$) and $wR2 = 0.1457$ (all data); min./max. residual electron density: $-255/234$ e nm^{-3}. **6**: $C_{25}H_{49}AlNNaOSi$, $M_r = 457.71$, orthorhombic, space group $Pca21$, $a = 1848.8(6)$, $b = 998.6(3)$, $c = 1601.2(4)$ pm, $V = 2.9562(15)$ nm^3, $Z = 4$, $\rho_{calcd} = 1.028$ Mg m^{-3}, $F(000) = 1008$, $\lambda = 71.073$ pm, $T = 153$ K, $\mu Mo_{K\alpha} = 0.139$ mm^{-1}. Crystal dimensions: $0.4 \times 0.3 \times 0.3$ mm^3, $4^{\circ} \le 2\theta \le 44^{\circ}$; 20604 measured reflections of which 3350 were independent and included in the structure refinement (324 parameters, 187 restraints). The *R* values are $R1 = 0.0629$ ($I > 2\sigma(I)$) and $wR2 = 0.1377$ (all data); min./max. residual electron density: $-227/356$ e nm^{-3}. Crystallographic data for **2** and **6** were collected with a Stoe-Siemens–Huber diffractometer with Siemens CCD area detector, while crystallographic data for **3** were collected with a Stoe-Siemens-AED diffractometer. Intensities were collected with φ and ω scans. Data integration was performed with the program SAINT. All measurements were carried out on cooled crystals in oil drops [16]; for data collection on **3** the learnt-profile method [17] was applied. The structure was solved by direct methods (SHELXS-90/96) [18]. Refinement on F^2 was accomplished by the least-squares method [19]. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms bound to aluminum and nitrogen atoms in **2** and **3** were found by difference–Fourier synthesis. Hydrogen atoms bound to aluminum and nitrogen atoms in **2** were refined by setting the displacement parameters to 120% of the equivalent isotropic U_{ij} value of the respective nitrogen and aluminum atoms. N-bound hydrogen atoms were refined by employing a 1,2 distance restraint, whereas the positions of Al-bound hydrogen atoms in **3** were refined without restraints. All remaining hydrogen atoms were refined by assuming geometrically ideal positions. A THF molecule in **2** exhibits a twist disorder at C(83). The occupancy factors refined to 0.60 and 0.40. The coordinated THF molecules in **3** and **6** show disorder of the carbon atoms (85:15 and 50:50, respectively). A methyl group in **6** (C(4)) is disordered (59:41). All disorders were resolved by distance and ADP restraints and refined anisotropically. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-158. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: Int. code +(1223) 336-033; e-mail deposit@chemcrys.cam.ac.uk).

Polyphenylene Dendrimers: From Three-Dimensional to Two-Dimensional Structures**

Frank Morgenroth, Erik Reuther, and Klaus Müllen*

By making use of weak intermolecular forces and suitable reaction conditions, chemists have attempted to produce supramolecular structures from molecules of different shapes and sizes.[1] In addition to stiff rodlike and spherical molecules, disk-shaped molecules have attracted particular attention. This latter group includes polycyclic aromatic hydrocarbons (PAHs), which are characterized by their typical crystal packings and their stacking in discotic mesophases.[2–4] We have recently developed routes to extended PAHs which enable the systematic alteration of the shape and size of the disks.[5] The key step is the flattening of branched polyphenylene precursors to planar structures by means of cyclodehydrogenation. Here we describe the use of 3,4-bis[4-(triisopropylsilylethynyl)-phenyl]-2,5-diphenylcyclopentadienone (**3c** in Scheme 1) as a building block that can be used for the rapid construction of complex, highly branched polyphenylene structures and dendrimers by Diels–Alder cycloaddition.

Our synthetic strategy is based on the fact that Diels–Alder reactions of tetraphenylcyclopentadienone (**3a**) with di- (mono-)phenylacetylenes yield hexa- (penta-)phenylbenzenes.[6] The diethynyl derivative **3d** contains one diene as well as two dienophile functions. However, participation of the triple bonds in cycloaddi-

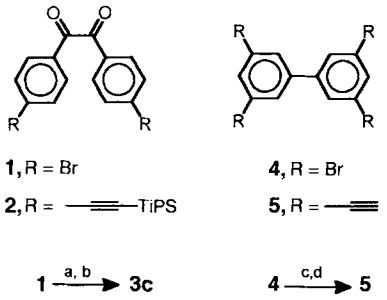
[**] We thank Dr. J. Räder and Dipl.-Chem K. Martin for recording the MALDI-TOF and LD-TOF mass spectra, and Dr. M. Wagner and Dipl.-Chem C. Kübel for the NMR spectra. F. M. thanks the Fonds der Chemischen Industrie for a Kekulé stipend. This work was supported by the Volkswagenstiftung and the Bundesministerium für Bildung und Forschung.

tion can be prevented by protecting them with triisopropylsilyl (TiPS) substituents (compound **3c**). After the Diels–Alder addition of **3c** with a suitable phenylacetylene derivative, the TiPS groups can be removed and the diethynyl functions activated for further Diels–Alder cycloadditions.

Ultimately, we intend to flatten the polyphenylene precursors prepared by this method through intramolecular cyclodehydrogenation to obtain planar PAHs. In this way three-dimensional hydrocarbon structures would be converted into two-dimensional analogues. We therefore chose tetraethynylbiphenyl **5** as the nucleus for the synthesis of a dendrimer and diethynylhexaphenylbenzene **6** as the nucleus for the generation of dendrimer sections (dendrons). Both of the starting compounds may be reduced to the topology of a 3,3′-disubstituted biphenyl.



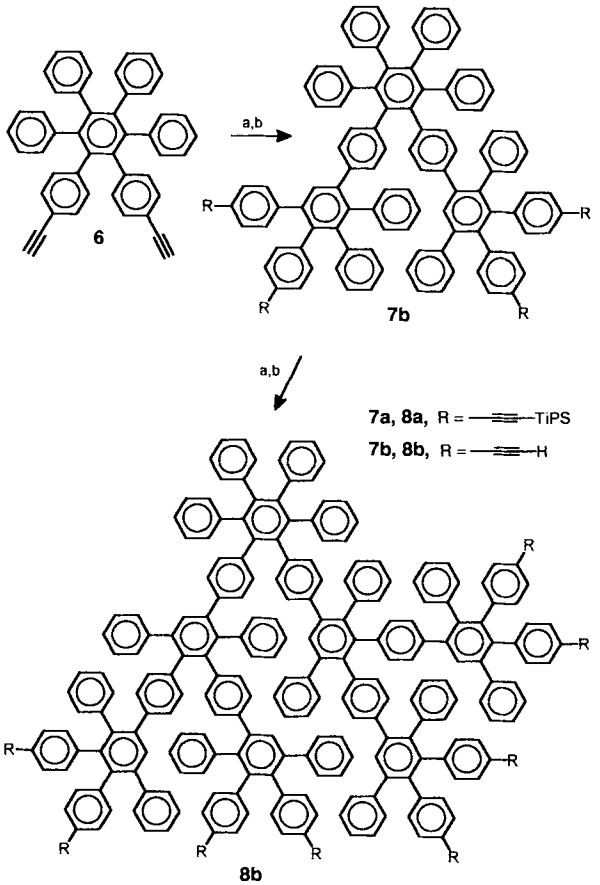
Scheme 2. a) TiPSA, $[Pd(PPh_3)_2Cl_2]$, CuI, PPh_3, Et_3N/toluene 2/1, 90 °C, 4 h (86%); b) 1,3-diphenylacetone, EtOH, KOH, reflux, 15 min (21%); c) TMSA, $[Pd(PPh_3)_2Cl_2]$, CuI, PPh_3, Et_3N/toluene 2/1, 80 °C, 4 h (61%); d) Bu_4NF, THF, room temperature (RT), 2 h (98%).

For the synthesis of **3c** we started with 4,4′-dibromobenzil (**1**), which was coupled with triisopropylsilylacetylene (TiPSA) by the method of Sonogashira et al.[7] to give benzil **2** in 86% yield (Scheme 2). Compound **2** was condensed with 1,3-diphenylacetone in the presence of potassium hydroxide to afford **3c**.[8] Attempts to couple TiPSA directly with **3b**[8] always led to hydrogenation of a double bond in the cyclopentadienone.

Several paths are available for the preparation of the acetylenic unit **6**; the simplest is [2+4]cycloaddition of cyclopentadienone **3c** with diphenylacetylene and subsequent removal of the TiPS groups with tetrabutylammonium fluoride.[9] Tetraethynylbiphenyl **5** was prepared by means of the Sonogashira coupling of the known tetrabromobiphenyl **4**[10] with trimethylsilylacetylene (TMSA) and subsequent removal of the trimethylsilyl groups (Scheme 2, 61% yield).

The synthesis of dendrons from **3c** is shown in Scheme 3. The addition of **3c** to **6** provided **7a**, which was converted to **7b**. Analogously, the related dienophile **3b** led to the corresponding bromo-substituted dendron. The bromo substituents serve as "handles" for further functionalization. Compound **7** is a first-generation (G_1) dendron constructed exclusively by the coupling of benzene rings. The C_{146} dendrimer unit **7a** contains 17 benzene rings and has a molecular mass of 2017 g mol^{-1}. The addition of **3c** to **7b** yields compound **8a**, a second-generation dendron. This step increases the number of benzenoid units to 37. Despite its large molecular mass of 4261 g mol^{-1}, the C_{310} building block **8a** is readily soluble in organic solvents such as tetrahydrofuran, chloroform, and dichloromethane, and can be characterized by NMR spectroscopy (Table 1). The high solubility is retained even after the protecting groups have been removed (**8b**).

In the synthesis of **8a** the reaction conditions for the [2+4]cycloaddition proved to be critical. Simply heating a mixture of the two components in diphenyl ether led to a mixture of di-, tri-, and tetracycloaddition products. However, when a solution of **7b** in methylnaphthalene was added under argon to two equivalents of **3c** at 180–200 °C in diphenyl ether, the TiPS-protected dendron **8a** was the sole product. Unreacted **3c** could



Scheme 3. a) **3c**, diphenyl ether/α-methylnaphthalene 1/1, 180–200 °C, 4 h (>85%); b) Bu_4NF, THF, RT, 5 h (>97%).

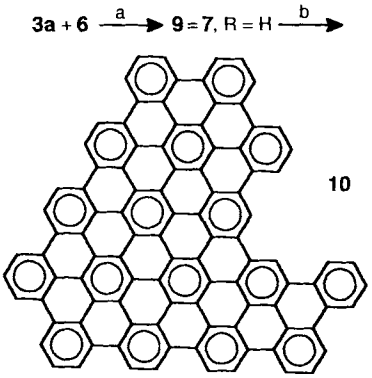


Scheme 4. a) Diphenyl ether/α-methylnaphthalene 1/1, 250 °C, 12 h (89%); b) $CuCl_2$, $AlCl_3$, CS_2, RT, 100 h (15%).

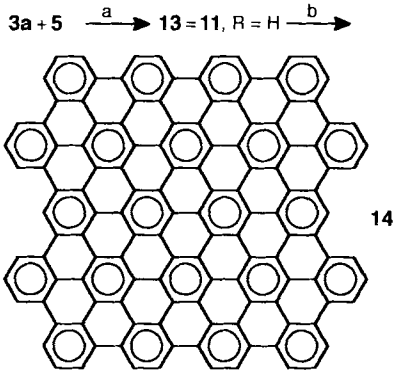
be separated subsequently by column chromatography or, more simply, by precipitation from an acetone solution on addition of methanol.

Compound **9**, which can be prepared from commercially available **3a** and **6** (Scheme 4), is an important model system for studying the flattening of dendrons. Cyclodehydrogenation of **9** under Kovacic conditions[11] afforded the planar hydrocarbon **10** (15% yield) together with partially cyclodehydrogenated compounds. Compound **10** was identified by mass spectrometry since its M^+ peak is 38 (2×19 hydrogen atoms) mass units less than that of **9** (Table 1).

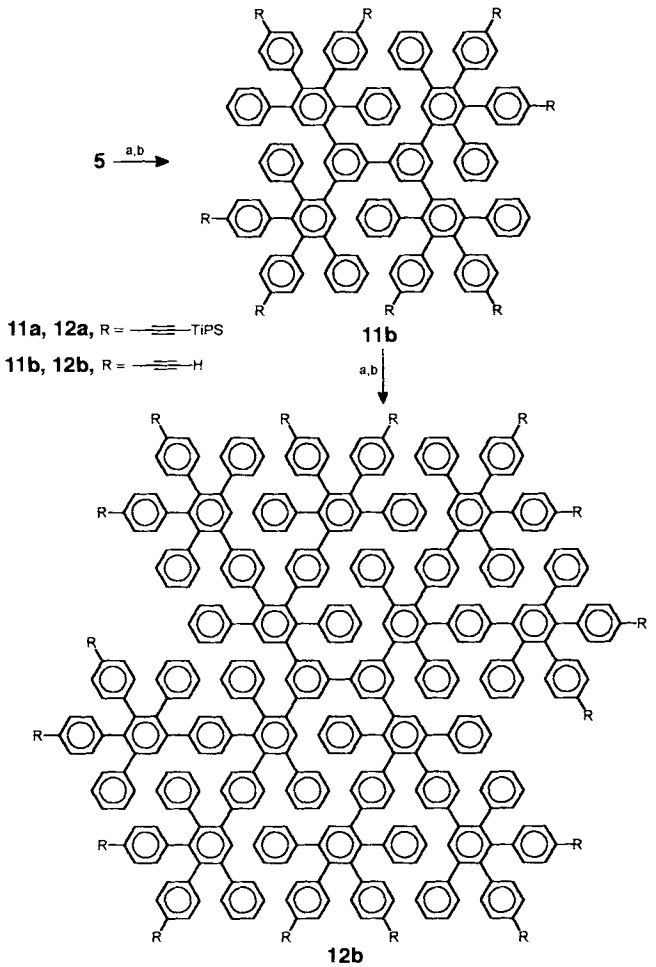
The Diels–Alder reaction of nucleus **5** with **3c** yielded the first-generation dendrimer **11a** with 22 benzenoid rings, which was deprotected to give **11b**. Reaction of the latter with **3c** yielded the second-generation analogue **12a** (Scheme 5). Thus, in two steps we selectively converted the C_{220} building block **11a** with a molecular mass of 3119 g mol^{-1} to a C_{548} unit **12a** with a molecular mass of 7606 g mol^{-1}—2.4 times that of **11a**.

In spite of their high molecular masses both **11a,b** and **12a,b** are readily soluble in organic solvents and could be characterized by both mass spectrometry and NMR spectroscopy (Table 1). In the syntheses of **11a** and **12a** it again proved necessary to add the dienophile in portionwise to an excess of the diene.

For the synthesis of planar, extended PAHs it was logical to employ the reaction of tetraethynylbiphenyl **5** with tetraphenylcyclopentadienone (**3a**) to form the polyphenyl precursor **13** (Scheme 6). Under cyclodehydrogenation conditions **13** formed



Scheme 6. a) Diphenyl ether/α-methylnaphthalene 1/1, 250 °C, 2 h (91%); b) $CuCl_2$, $AlCl_3$, $C_2H_2Cl_4$, 100 °C, 9 h (83%).



Scheme 5. a) **3c**, Diphenyl ether/α-methylnaphthalene 1/1, 180–200 °C, 4 h (>85%); b) Bu_4NF, THF, RT, 5 h (>98%).

28 new bonds to yield **14**, the planarized version of **11**, in 83% yield as a first-generation dendrimer unit. As in the case of **10** the spectroscopic characterization of **14** was difficult because of its extremely low solubility in all standard solvents. It was characterized by mass spectrometry based on its M^+ peak, which is 56 mass units (2×28 hydrogen atoms) less than that of **13** (Table 1).

Polyphenylene dendrimers formed by the direct C–C coupling[12–16] of 1,2-diphenyl-substituted arene units are available by means of the path described here. In each case the appropriate G_1 polyphenylenes **9** and **13** can be fused to form the discoidal polycyclic arenes **10** and **14**. At present we are investigating how the increasing degree of branching in the polyphenylenes leading to higher generation dendrimers affects their conformational mobility and the possibility of flattening them to form extended PAHs.

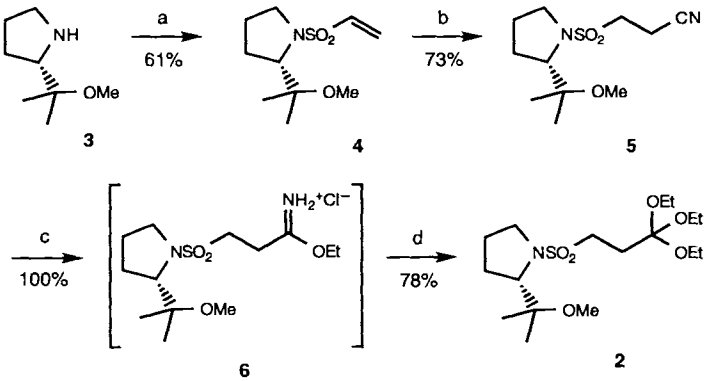
an equally simple asymmetric version of this cyclopentannulation with chiral sulfonamide orthoester **2** as 1,3 dipole reagent.

Compound **2** (pale yellow oil; $[\alpha]_D^{20} = -6.7$, $c = 1.6$ in chloroform) was readily prepared as depicted in Scheme 1 from the enantiomerically pure pyrrolidine **3** described by Enders et al.[5]



Scheme 1. Synthesis of enantiomerically pure **2**. a) $ClSO_2CH_2CH_2Cl$ (1 equiv), Et_3N (2 equiv) in CH_2Cl_2, 0 °C, 1 h. b) KCN (2 equiv), NH_4Cl (1.5 equiv) in water, **4** in DMF, 20 °C, 14 h. c) 1. **5** and EtOH (1.5 equiv) in CH_2Cl_2 at −60 °C, saturation with HCl(g). 2. 21 h at 5 °C, evaporation until a colorless solid remains. d) 1. Crude **6** in $EtOH/CH_2Cl_2$ (1/3), 20 °C, 60 h. 2. Filtration. 3. Treatment of the residue with 2 N NaOH(aq), 20 °C, until disappearance of ester carbonyl band at $\tilde{\nu} = 1740\ cm^{-1}$

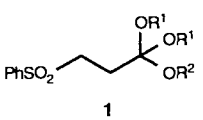
Asymmetric Cyclopentannulation of Cyclic Enones with a Chiral 1,3-Dipole Equivalent**

Catherine Huart and Léon Ghosez*

In memory of Jean-François Cordier

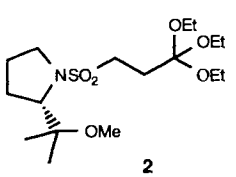
Interest in the stereocontrolled synthesis of five-membered carbocycles continues to generate many exciting strategies.[1] Among these, condensations of C_3 reagents with olefins bearing a chiral substituent have received much attention.[2] Reports on asymmetric cyclopentannulations with an olefinic substrate and a chiral C_3 reagent are less common.[3]

We have already described a very efficient method for cyclopentannulation of cyclic enones with readily available **1**.[4] The simplicity of this procedure and its generality could make it as useful as the much used Robinson annulation. We now report



1

$R^1 = R^2 =$ Me, Et
$R^1 = -CH_2CH_2-$, $R^2 =$ Et



2

The cyclopentannulation sequence and subsequent transformation of the cyclocondensation products **9** into bicyclic cyclopentenones **11** are shown in Scheme 2. Sulfonamide **2** was deprotonated with *n*BuLi to give carbanion **7**, which underwent a kinetic 1,4-addition reaction with cyclic enones in the presence of hexamethyl phosphoramide (HMPA). The resulting enolates were quenched with TMSCl (TMS = trimethylsilyl) to give a crude organic extract, which mainly contained silylenol ethers **8** as shown by ^{1}H and ^{13}C NMR spectroscopy. Without further purification, the extract was allowed to react with TMSOTf (Tf = F_3CSO_2) in the cyclization step.[6] The cyclized products **9a** and **9d** were obtained as oils (77 and ≈60%, respectively; **9d** was contaminated by some ester), and **9b** and **9c** as colorless, crystalline solids (63 and 67%, respectively). Compounds **9a–c** gave correct elemental analyses. The ^{1}H NMR spectra of **9a** and **9c** confirmed the expected *cis*-fusion of the newly formed cyclopentane ring (^3J(H,H) = 7.3–10.5 Hz for the protons of the ring fusion), but did not allow an accurate determination of the facial selectivity of the reaction. However, in the case of **9c**, we were able to show that the mixture mainly consisted of two diastereoisomers that differ by the configuration of the carbon atom bearing the sulfonamide group (*exo*:*endo* = 9:1).

The structure and absolute configuration of **9b** was further confirmed by an X-ray diffraction analysis.[7] The absolute configurations of **9a**, **9c**, and **9d** were assigned accordingly on the basis that all reactions are expected to proceed with the same facial selectivity.

Ketones **9** were transformed into bicyclic cyclopentenones **11** in a sequence of three reactions; none of the intermediates required purification (Scheme 2, Tables 1 and 2). The first step was the stereoselective reduction of cup-shaped **9**, which occurred, as expected, from the convex face. The enantiomeric excesses of **11a–d** were determined by HPLC. Mosher's esters of crude **11a** and **11b** were prepared and analyzed by ^{1}H NMR spectroscopy. Both gave consistent results.

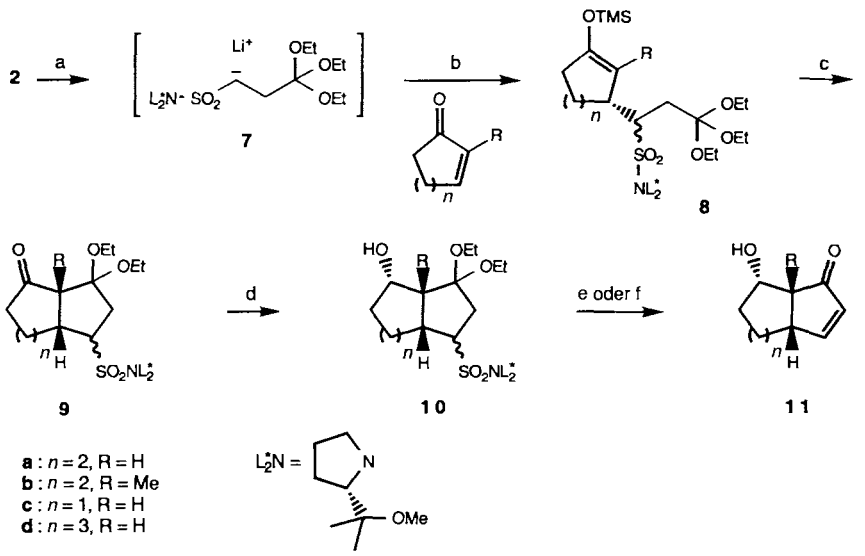

Scheme 2. Cyclopentannulation of cyclic enones and transformation of the products into bicyclic cyclopentenones **11**. a) Addition of *n*BuLi (2.44 M in hexane, 1.05 equiv) to **2** in THF and HMPA (8 equiv), −78 C, 30 min. b) 1. Addition of enone (1 equiv) at −78 °C, 45 min. 2. Addition of Et_3N (3.5 equiv) and TMSCl (4 equiv), 30 min, −78 °C → 20 °C. 3. Concentration, addition of Et_2O, workup with saturated NaCl(aq). c) Crude **8**, TMSOTf (0.1 equiv) in CH_2Cl_2, −78 °C (− 50 °C for **8c**), 45 min. d) Diisobutyl aluminum hydride (1 M in toluene, 2 equiv) in CH_2Cl_2, − 50 °C, 30–60 min. e) 1. Crude **10a**, **10c**, or **10d** in acetone/water, pyridinium tosylate (0.3 equiv), 0 °C → 20 °C, 75–90 min. 2. Flash chromatography on silica gel, Et_2O/petroleum ether (1/1). f) 1. Crude **10b** in acetone/HCl(aq) 1 N, 0 °C, 30 min, 20 °C, 10 min, work-up, then Et_3N (10 equiv) in CH_2Cl_2, 20 °C, 13 h. 2. Flash chromatography on silica gel, Et_2O/petroleum ether (1/1).

In summary, we have described the facile preparation of the new chiral reagent **2**, which can be used efficiently for cyclopentannulation of cyclic enones. The method, which is conceptually similar to the Robinson annulation, converts a prochiral cyclic enone into a bicyclic cyclopentenone of high enantiomeric purity. The stereodetermining step is the Michael addition of carbanion **7** to the cyclic enone. The available data do not allow the formulation of a reliable transition state model that takes into account the necessary presence of HMPA. Current and future endeavors are aimed at a better understanding of the facial selection in the Michael addition and development of a catalytic method for cyclopentannulation of enones.

Table 1. Annulation of cyclic enones to bicyclic cyclopentenones **11** (Scheme 2).

Solvolysis of $[B(C_6H_5)_4]^-$ in Methanol To Give the Chiral Coordination Polymer $Cd(tcm)[B(OMe)_4] \cdot x\,MeOH$, $x \approx 1.6$**

Stuart R. Batten, Bernard F. Hoskins, and Richard Robson*

Coordination polymers with organocyanide ligands constitute an area of active research because of their interesting structural features and potentially useful magnetic and electrical properties.[1] One of the simplest of these ligands is the tricyanomethanide ion $[C(CN)_3]^-$ (tcm), which can act as a trigonal 3-connecting unit. With a range of divalent metal cations, tcm gives an isostructural series of "binary" solids of composition $[M(tcm)_2]$ ($M^{2+} = Cr^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+}$), in which two independent networks with the rutile topology interpenetrate.[2] The structure of Ag(tcm) is unique and consists of two-dimensional hexagonal grid networks, which are corrugated so that two independent nets interpenetrate and give a composite interwoven 2D sheet.[3] We report here a new type of 3D network with tcm that contains solvent-filled channels. Channel-containing solids have been and continue to be intensively investigated because of their actual and potential applications, for example, as heterogeneous catalysts, and molecular sieves.

When solutions of $Cd(NO_3)_2 \cdot 4H_2O$ (55 mg, 0.18 mmol) in MeOH (5 mL), K(tcm) (23 mg, 0.18 mmol) in MeOH (5 mL), and $Na[B(C_6H_5)_4]$ (122 mg, 0.36 mmol) in MeOH (10 mL) were combined, approximately 90% of the potassium was precipitated as insoluble $K[B(C_6H_5)_4]$ (59 mg, 0.16 mmol), which was filtered off. Upon standing for four weeks, the filtrate gave large, brilliant, and beautifully formed colorless, octahedral crystals (27 mg), which were shown by X-ray crystallography to contain $[B(OMe)_4]^-$. The methanolysis of $[B(C_6H_5)_4]^-$ to $[B(OMe)_4]^-$ was unexpected. The tetraphenylborate was expected to act as a large, "inert", non-coordinating counter ion, a role it has played countless times. Although it has been known for some time that tetraphenylborate can undergo B–C bond fission under strongly acidic and/or forcing conditions, only very recently have two examples been reported of dephenylation under the mild conditions typically used to obtain complex cationic species as crystalline, tetraphenylborate salts.[4, 5] In one case two phenyl units were substituted by phenolates,[4] and in the other, three phenyl rings were cleaved off by hydrolysis to yield $[(C_6H_5)B(OH)O]^-$, which appeared as a bridging ligand in the resulting copper complex.[5] In contrast, all four phenyl rings have been detached in the example described here. It may be no coincidence that the borate product ends up associated with metal centers in all three solvolytic reactions.

Since the crystals degenerated by solvent loss upon exposure to the atmosphere, one was selected and sealed with a small amount of mother liquor in a Lindemann glass tube for X-ray crystallographic analysis.[6] The structure consists of a three-dimensional coordination polymer of composition $Cd(tcm)[B(OMe)_4] \cdot$ ca. 1.6 MeOH in which the cadmium centers are all equivalent and seven-coordinate. The metal coordination environment is shown in Figure 1. Each cadmium atom is bonded to

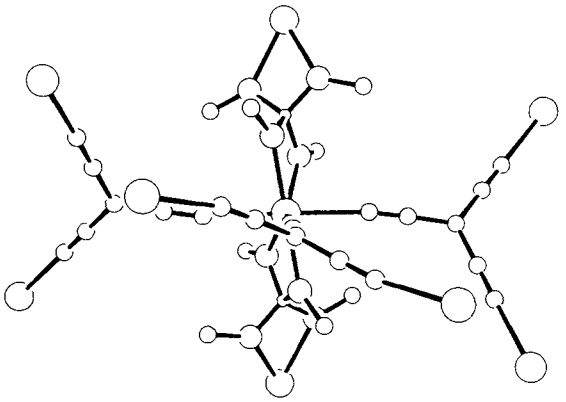

Figure 1. The cadmium coordination environment in the structure of $Cd(tcm)[B(OMe)_4] \cdot$ ca. 1.6 MeOH. Circles in order of decreasing radius represent Cd, O, C/N, and B.

three tcm units in a T-shaped arrangement (Cd–N 2.400(7) and 2.396(6) Å) and to two chelating $[B(OMe)_4]^-$ ligands (Cd–O 2.356(4) and 2.301(5) Å). The small bite angle of the chelating $[B(OMe)_4]^-$ ligands (O-Cd-O 56.4(2)°) no doubt aids in achieving the high coordination number for the cadmium atom. The tcm ligands, all of which are equivalent, coordinate to three cadmium centers. The $[B(OMe)_4]^-$ ligands, also all equivalent, bridge two cadmium atoms and chelate each metal in a bidentate fashion. The recently reported linear coordination polymer $Cd_2(bpe)_3(NO_3)_4$ (bpe = 1,2-bis(4-pyridyl)ethane) has a very similar cadmium coordination geometry with two bidentate chelating nitrate ligands (which also have small bite angles) and three bridging monodentate bpe ligands in a T-shaped arrangement.[7] The only other structurally characterized example we know of, in which tetraalkoxyborates derived from monohydroxylic alcohols coordinate to a transition metal, a Group 12 metal, or a lanthanide is $La[B(OMe)_4](NO_3)_2(CH_3OH)_2$. Here the tetramethoxyborate anion chelates and bridges in an almost identical fashion to give a 1D polymer rather than the 3D polymer we observe.[8] It is interesting to note that in this case also, the appearance of $[B(OMe)_4]^-$ was accidental and resulted from methanolysis of $[H_3B(CN)]^-$.

The essence of the topology or connectivity of the 3D net is that only two types of nodes are present, the central tcm carbon (C_c) constituting a 3-connecting node and the cadmium a 5-connecting node. Every C_c node is connected to three cadmium nodes and every cadmium node is connected to three C_c nodes as well as to two other cadmium nodes through borate bridges.

The five connections radiating from the cadmium node (that is, the three Cd···C_c vectors and the two Cd···Cd vectors) adopt an arrangement very close to trigonal bipyramidal with two tcm units occupying axial positions (Figure 1). Conversely, each tcm unit provides an axial connection to two cadmium atoms and an equatorial connection to the third.

An outstanding feature of the extended network is the presence of sixfold helices consisting of borate-bridged cadmium centers (Figure 2). The helical axes are aligned parallel to the

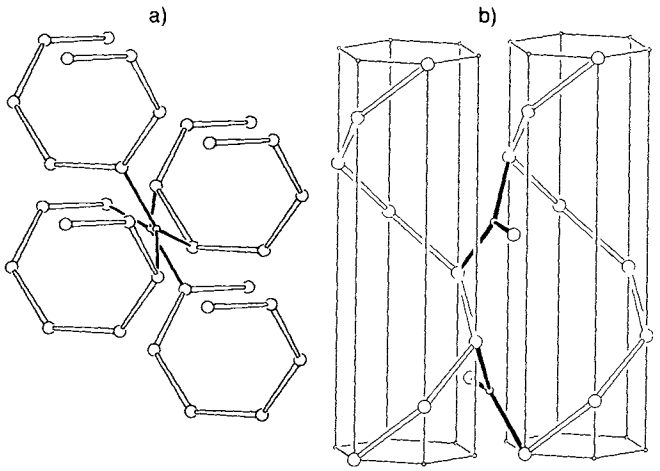

Figure 2. Representation of the connectivity. Large and small circles represent Cd and C_c nodes, respectively. "Open" connections represent Cd···Cd linkages through borate bridges, and black connections represent Cd···Cd links. a) Four of the $[Cd\{B(OMe)_4\}]_n$ helices viewed slightly displaced from the helical axis; b) two helices whose axes lie in the plane of the page and run from top to bottom.

hexagonal crystal axis, and all helices are of the right-handed screw type. The structure as a whole is therefore chiral (space group $P6_122$). The parallel helices are cemented together by tcm "glue" in the spaces between them. For simplicity Figure 2 focuses on just two tcm gluing units, but every helical column has an arrangement of these units on all six sides.

The cadmium–borate helices together with the tcm glue between them define channels, which can be clearly seen in the representation of the network in Figure 3.[9] We estimate that

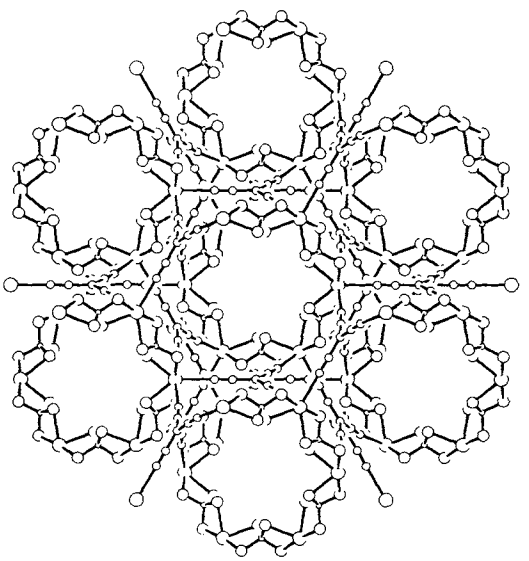

Figure 3. The network viewed directly along the helical channels. Circles in order of decreasing size represent Cd, O, C/N, and B.

the Cd(tcm) $[B(OMe)_4]$ framework occupies approximately 80% of the volume of the crystal. To the best of our knowledge this represents a new type of (3,5)-connected topology. As shown in Figure 4, the methanol of solvation is located within

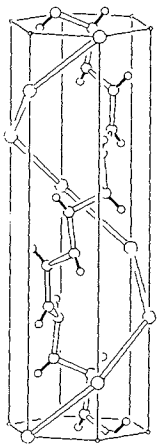

Figure 4. The helical hydrogen-bonded methanol chain inside the Cd–borate helical channels. Circles in order of decreasing radius represent Cd, O, and C. O···O distances are 2.71(1) and 2.67(2) Å. The "long" diagonal across the hexagonal cross-section of the hexagonal prism is 9.34 Å.

the hexagonal channels, forming a hydrogen-bonded helix with the same right-handedness as the enclosing Cd-borate helix. Both helices require the same distance along their common axis for one complete turn. There would be twice as many methanol molecules per turn as Cd centers if the methanol sites were completely occupied; however, they are only 80% occupied.

[6] Crystal data: $Cd(C(CN)_3)[B(OMe)_4]\cdot 1.6CH_3OH$, $M = 388.73$, hexagonal, space group $P6_122$ (no. 178), $a = 11.477(3)$, $c = 22.85(4)$ Å, $V = 2576.1$ Å^3, $Z = 6$, $\rho_{calcd} = 1.51$ g cm^{-3}, $\rho_{exp} = 1.59(1)$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 12.64$ cm^{-1}, $F(000) = 1211.99$. Intensity data were measured at 295(1) K ($Mo_{K\alpha}$ radiation, graphite crystal monochromator) with an Enraf-Nonius CAD-4F diffractometer employing the $\omega/2\theta$ scan method; absorption corrections were applied. The structure was solved with the SHELXS-86 and SHELX-76 programs. Anisotropic thermal parameters were applied to all non-hydrogen atoms except the two solvent methanol atoms. Their isotropic thermal parameters were fixed at 0.15, and their site occupation factors were allowed to refine to a final value of 0.8158 at convergence. $R = 0.0398$ and $R_w = 0.0395$ for the 1497 observed reflections $[I \geq 3\sigma(I)]$. To determine the absolute configuration, a refinement was carried out in SHELXL-93. A value of -0.03 (± 0.12) was obtained for the Flack parameter, which indicated that the correct configuration had been obtained. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-160. News from an Old Ligand: The Triple-Decker Ion Triple, Tris([18]Crown-6)-disodium Bis(tetraphenylcyclopentadienide)**

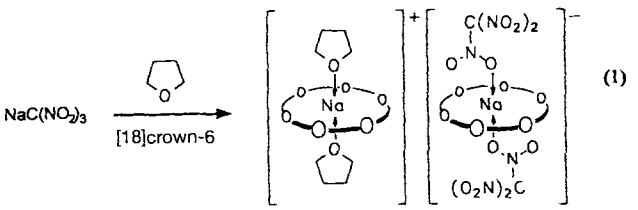
Hans Bock,* Tim Hauck, Christian Näther, and Zdenek Havlas

Dedicated to Professor Utz-Hellmuth Felcht on the occasion of his 50th birthday

The discovery of the crown ethers[1a, b] and cryptands,[1c] which selectively complex alkali metal cations, has stimulated a wealth of investigations into other host molecules with modified cavities, their changes on metal cation insertion, and self-organization phenomena both for selected model compounds and bioreceptors.[1d-f]

An informative aspect from the extensive information on metal cation complexation by polyether derivatives[1d-g] concerns the crown ethers [15]crown-5 (15-K-5) and [18]crown-6 (18-K-6) and their encapsulation of Na^+ ions:[1d] their cavity diameters (which are dependent on the conformation of the crown) of 170 to 220 pm and 260 to 320 pm, respectively, equal or exceed the Na^+ ion diameter of 190 pm. The complex association constants $\lg K_{ass} = 3.5$ (15-K-5) and 4.2 (18-K-6) in methanol at 25 °C, however, differ from each other and also from the values for the better fitting K^+ ion (diameter 226 pm, $\lg K_{ass} = 4.7$ for 15-K-5 and 6.0 for 18-K-6) by only 0.7 to 1.8 orders of magnitude.[1d] Surprisingly, therefore, a search in the Cambridge Structural Database for $[Na(18\text{-K-}6)]^+$ only yields 24 entries, of which the solvent-separated contact ion quadruple with (18-K-6)-solvated Na^+ centers both as complex cation as well as complex anion is represented.[2, 3] This contact ion quadruple crystallizes from a THF solution of sodium trinitromethanide on addition of (18-K-6) [Eq. (1)].[2]



(1)

Each Na^+ ion is eightfold (!) coordinated by oxygen centers in hexagonal bipyramids of which six sites stem from the (18-K-6) ligands.[2] The equatorial $Na\cdots O$ contacts are of comparable lengths (271 and 282 pm), whereas the axial ones of 236 pm in the cation and of 243 pm in the triple anion are shorter. Based on the structural coordinates, MNDO enthalpies of formation of -824 and $-1254\ kJ\,mol^{-1}$ are calculated for the cation and anion, respectively.[2]

Much to our surprise, independent investigations of the effects of ethers on the crystallization of the sodium tetraphenylcyclopentadienide ion[4] showed that from an aprotic *n*-hexane solution with (18-K-6) added, a solvent-separated contact ion triple containing a triple-decker dication $[(18\text{-K-}6)Na(18\text{-K-}6)Na(18\text{-K-}6)]^{2+}$ and two tetraphenylcyclopentadienide ions[5] crystallized (Figure 1).

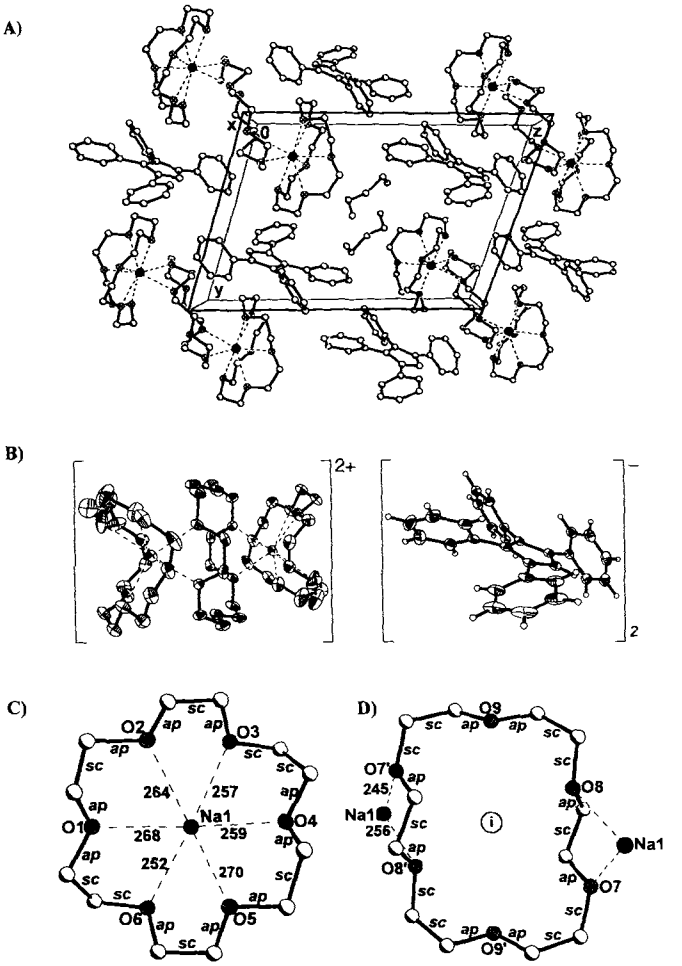


Figure 1. Crystal structure of the solvent-separated contact ion triple bis(tetraphenylcyclopentadienide) tris([18]crown-6)disodium·*n*-hexane at 150 K: A) Unit cell (triclinic $P\bar{1}$, $Z = 1$) along the *a* axis; B) triple-decker dication (side view) and tetraphenylcyclopentadienide ion (30% thermal ellipsoids) as well as C) outer and D) central ([18]crown-6) ligands viewed from the top with labeled bond torsions and $Na^+\cdots O$ contact distances [*ap* : antiperiplanar ($\omega \approx 65°$); cf. text].

In the triple-decker dication (Figure 1B), each symmetry-equivalent sodium cation is coordinated in an η^6 fashion to one of the outer ligands and in an η^2 fashion to the cation-bridging inner [18]crown-6 ligand. The contact distances $Na^+\cdots O$ to the sixfold solvating crown ether lie between 252 and 270 pm (Figure 1C); the Na^+ ion is located 72 pm outside an idealized plane through the six O centers (Figure 1B), from which these deviate between 9 and 90 pm. These outer crown ether ligands can be characterized as being "round" if viewed onto their periphery, despite their convex hemispherical distortion, whereas a structure determination characterizes the noncomplexed macrocyclic polyether,[6] like the central (18-K-6) ligand (Figure 1D), as being "rectangular". The different 18-member macrocyclic ring structures are best denoted by the antiperiplanar (*ap*, $\omega \approx 180°$) or synclinal (*sc*, $\omega \approx 65°$) bond arrangements in the six ($-O-CH_2-CH_2-O-$) subunits of the [18]crown-6: In D_{3d} symmetry of complex salts,[7] all subunits are equivalent and adopt a (*ap*, *sc*, *ap*) conformation. The "stretching" of the noncomplexed

macrocycle, the structure of which, like that of the central ligand, contains a center of inversion (Figure 1D) and therefore only three pairs of equivalent ($-O-CH_2-CH_2-O-$) subunits, is characterized by the sequence (*ap*, *ap*, *ap*, *ap*) in each long side.[6] The outer crown ether ligands of the triple cation (Figure 1C) contain four ($-O-CH_2-CH_2-O-$) subunits in an (*ap*, *sc*, *ap*) and two in an (*ap*, *sc*, *sc*) arrangement, which together result in a rather "round" periphery. An approximate D_{3d} symmetry of the [18]crown-6 macrocycle containing comparably long $Na^+ \cdots O$ contact distances are observed especially on (double facial) coordination of additional ligands to the metal cation solvated by the crown ether [see Eq. (1)].[2, 3] In the contact ion quadruple presented here, the eightfold coordination of each Na^+ ion is achieved by two additional contacts to the bridging [18]crown-6 polyether, which exhibits shorter distances of 245 and 256 pm than the 262 pm average to the outer crown ligands of the triple-decker dication. Its six O centers deviate less than 4 pm from an idealized plane and its "rectangularly stretched periphery" is due to conformational (*ap*, *sc*, *ap*) sequences between the Na^+-coordinating O centers O7 and O8 in the pair of equivalent ($-O-CH_2-CH_2-O-$) subunits (Figure 1B and D). The different deviations of the outer and the central ([18]crown-6) ligands in the tripledecker dication of idealized D_{3d} symmetry are therefore due to their Na^+ complexation: The eightfold O-solvated Na^+ ions each coordinate in an η^6 fashion to all oxygen ring centers or in an only η^2 fashion to adjacent oxygen ring sites.

Moreover, the crystallization of the rather unusual disodium triple-decker dication is remarkable, because sandwich structures of crown ether complexes of alkali metal cations are usually only detected if these are too large for an optimum macrocycle solvation: for instance, Na^+ and [12]crown-4 form a 1:2 complex.[8] Alkali metal countercations that are too small often yield dinuclear complexes, coordinate additional ligands,[1d] or deform the crown ether macrocycle considerably.[7a, 9] The contact ion quadruple presented here has been prepared by sodium metal mirror reduction in *n*-hexane, and the [18]crown-6 added is therefore the only O-coordinating ligand. The phenyl-shielded anions (the tetraphenylcyclopentadienide ions) favor the sandwich complexation of the sodium ion, and all unused oxygen coordination sites in the bridging polyether favor the formation of the thermodynamically advantageous triple-decker dication, for which, based on the structural coordinates, an MNDO enthalpy of formation of $-1623\ kJ\,mol^{-1}$ (!) is calculated.[1g, 10]

The triple-decker dication $[(18\text{-K-}6)Na(18\text{-K-}6)Na(18\text{-K-}6)]^{2+}$ in its solvent-separated ion triple with two tetraphenylcyclopentadienide ions opens novel aspects: despite numerous known "douple sandwich complexes" containing two metal cations between three molecular(ion) "slices" of even different ring size,[11] the cation encapsulation with incompatibly sized polyether rings or macrocycles with heteroatom centers might stimulate the exploration of an experimental field of, for example, complex salts with alkali metal cations that could have highly surprising structures. These, in turn, might provide essential information[12, 13] on solvation effects with small energy differences in solvent-shared or solvent-separated contact ion multiples[12] or on metal cation coordination over long distances.[13]

[5] Preparation and crystallization: In a carefully dried Schlenck trap, a metal mirror is generated from sodium (100 mg, 4.3 mmol) at 10^{-5} mbar and a solution (10 mL) of tetraphenylcyclopentadiene (280 mg, 1 mmol) as well as a surplus of [18]crown-6 in *n*-hexane dried over Na/K alloy under argon. After 3 days, the sodium metal mirror has vanished, and on covering the reaction mixture with *n*-hexane, air- and moisture-sensitive yellow crystals grow. Crystal structure determination: $2\ (C_{29}H_{21})\cdot Na_2(C_{12}H_{24}O_6)_3\cdot C_6H_{14}$, light yellow blocks ($M_r = 1750.2$), $a = 1062.1(1)$, $b = 1359.1(1)$, $c = 1857.2(2)$ pm, $\alpha = 105.07(1)$, $\beta = 94.73\ (1)$, $\gamma = 110.68\ (1)^\circ$, $V = 2376.5 \times 10^6\ pm^3$ (150 K), $\rho_{calcd} = 1.223\ g\,cm^{-3}$, triclinic, $P\bar{1}$ (no. 2), $Z = 1$, Siemens P4 diffractometer, $Mo_{K\alpha}$ radiation, $m = 0.09\ mm^{-1}$, 7624 measured reflections within $3^\circ \le 2\omega \le 48^\circ$, of which all 7193 independent reflections are used for refinement ($R_{int} = 0.0390$). Structure solution by direct methods (SHELXS-86), structure refinement vs. F^2 (SHELXL-93), 559 parameters, $\omega = 1/[\sigma^2(F_o^2) + (0.0876P)^2 + 2.37P]$, R for 5478 $F_o > 4\sigma(F_o) = 0.0653$, $wR2$ (for all 7193 data) = 0.1832, GOOF = 0.915, residual electron density 0.57/ $-0.38\ e\,Å^3$. All C, O, and Na positions are anisotropically refined, all hydrogen centers are geometrically ideally positioned and refined with individual isotropic displacement parameters according to the riding model. One O and one C center of the [18]crown-6 ligand as well as two centers of the *n*-hexane molecule are each disordered across two positions and have been refined using a split model. Contact distances [pm]: Na(1)–O(7) 244.5(2), Na(1)–O(6) 251.7(2), Na(1)–O(8) 255.9(2), Na(1)–O(3) 257.1(2), Na(1)–O(4) 258.9(2), Na(1)–O(2) 264.0(11), Na(1)–O(1) 267.5(3), Na(1)–O(5) 269.5(2). Further details of the crystal structure determination may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-406-118.

[6] a) J. D. Dunitz, P. Seiler, *Acta Crystallogr. Sect. B* **1974**, *30*, 2739; b) E. Maverick, P. Seiler, W. B. Schweizer, J. D. Dunitz, *ibid.* **1980**, *36*, 615. The noncomplexed [18]crown-6 exhibits an approximately rectangularly stretched periphery around a center of inversion. The ($-O-CH_2-CH_2-O-$) subunit configurations show six antiperiplanar ($\omega \approx 180^\circ$) and three synclinal ($\omega \approx 16^\circ$) arrangements in the following sequence: O1 (*sc*, *sc*, *ap*) O4 (*ap*, *sc*, *ap*) O7 (*ap*, *ap*, *ap*). The stretch can be denoted by the fourfold conformational sequences (*ap*, *ap*, *ap*, *ap*) on both slides.

[7] Selected examples: a) J. D. Dunitz, M. Dobler, P. Seiler, R. P. Phizackerley, *Acta Crystallogr. Sect. B* **1974**, *30*, 2733; b) M. Dobler, R. P. Phizackerley, *ibid.* **1974**, *30*, 2746; c) M. Dobler, R. P. Phizackerley, *ibid.* **1974**, *30*, 2748. For conformation specification the [18]crown-6 in the cesium rhodanide complex (c) is used, the "round" periphery of which exhibits approximate D_{3d} symmetry. All six equivalent ($-O-CH_2-CH_2-O-$) subunits exhibit identical configurations O (*ap*, *sc*, *ap*) and, therefore, of the altogether 18 arrangements 12 are antiperiplanar ($\omega = 180^\circ$) and only six synclinal ($\omega = 65^\circ$).

$N(CH_3)_4 \cdot ZnH_3(PO_4)_2$: A Large-Pore Zincophosphate Built Up from a 12-Ring Architecture with a Remarkably Low Tetrahedral-Framework-Atom Density**

William T. A. Harrison* and Lakshitha Hannooman

Work on the synthesis and characterization of new microporous materials continues apace, revealing an ever-increasing variety of framework compositions and topologies.[1, 2] Herein we report the synthesis and X-ray single-crystal structure of $N(CH_3)_4 \cdot ZnH_3(PO_4)_2$, a novel large-pore zincophosphate built up from a an unprecedented 12-ring topology. A synthetic route to small crystals of $N(CH_3)_4 \cdot ZnH_3(PO_4)_2$ and physical data on the same phase were reported earlier.[3]

$N(CH_3)_4 \cdot ZnH_3(PO_4)_2$ consists of a three-dimensional anionic Zn/P/O/H network that encloses a two-dimensional network of 12-ring channels, which are occupied by tetramethylammonium (TMA) ions. The zinc atom (site symmetry ..2) forms Zn–O–P bonds to four distinct phosphorus atom neighbors (d_{av}(Zn–O) = 1.932(4) Å) (Figure 1, Tables 1 and 2). The phosphorus atoms each bond to four distinct oxygen atom species; two bonds are formed to Zn through O(1) and O(2), and two terminal P–O links are formed to O(3) and O(4) (d_{av}(P–O) = 1.533 (4) Å). The extraframework TMA ion (N site symmetry ..2) shows extensive disorder of its carbon atoms, although the nitrogen species is well ordered. A TLS (*T*ranslation, *L*ibration, *S*crew libration) thermal motion analysis[4] indicated that the displacements of the carbon atoms of the TMA species were essentially exclusively librational, and corrected N–C bond lengths of $\approx$1.5 Å resulted.

Table 1. Positional and thermal parameters for the atoms in $N(CH_3)_4 \cdot ZnH_3(PO_4)_2$.

[a] U_{eq} [Å^2] = $[U_1U_2U_3]^{1/3}$.

The connectivity of the ZnO_4 and $(H_2)PO_4$ units in $N(CH_3)_4 \cdot ZnH_3(PO_4)_2$ results in a strict alternation of zinc- and phosphorus-centered tetrahedra. No Zn–O–Zn or P–O–P bonds are present, despite the Zn:P framework ratio of 1:2. The smallest identifiable loop configuration formed by these fused tetrahedral units is a 12-ring, that is 12 tetrahedral centers, or 24 atoms in total (6 Zn, 6 P, and 12 O; Figures 1 and 2). Each 12-ring is associated with a TMA guest ion. There are no H-bonding interactions between the TMA and the framework, since the positive charge on the N atom is shielded by its four

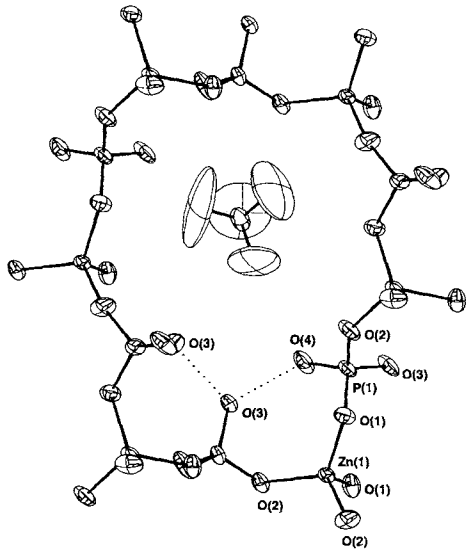

Figure 1. Crystal structure of the 12-ring building unit in $N(CH_3)_4 \cdot ZnH_3(PO_4)_2$ showing the atom labeling scheme (50% thermal ellipsoids). Possible intraframework hydrogen-bonding linkages are indicated by dotted lines.

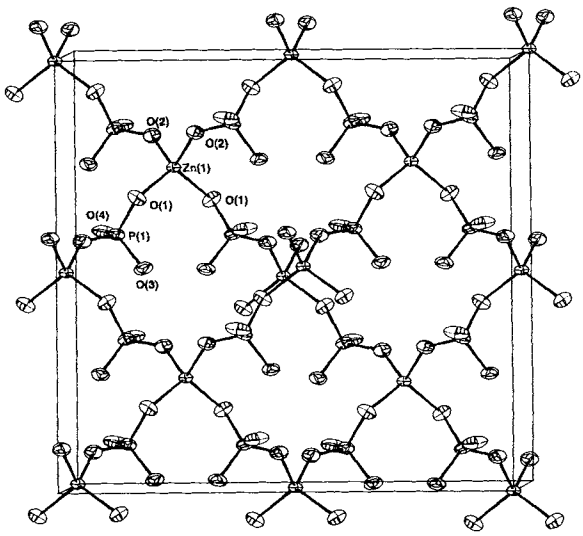

Figure 2. View approximately down [010] of the zincophosphate framework of $N(CH_3)_4 \cdot ZnH_3(PO_4)_2$ showing the 12-ring topology. The TMA ions are omitted for clarity.

methyl substituents. The framework 12-ring is constricted at one end, resulting in a pear-shaped cavity (Figure 1). Its maximum dimensions, measured from O atom to O atom, are approximately 7.1 × 8.8 Å. Charge-balancing considerations require the presence of three framework protons. These could not be located in the crystal structure determination and they may be distributed over both the terminal P–O oxygen atoms [O(3) and O(4)] with a statistical occupancy of 75%: This situation could also be represented by the "ordered" formula of $N(CH_3)_4 \cdot Zn(HPO_4)(H_2PO_4)$. Two intraframework hydrogen bonds are possible in the pear-shaped 12-ring; the short nonbonded O–O contacts are 2.41 and 2.61 Å. Overall, a two-dimensional channel system of squashed 12-ring channels propagating in the [101] and [10$\bar{1}$] directions, and more regular 12-ring channels propagating in the [110] and [1$\bar{1}$0] directions results (Figures 3 and 4).

The framework density (FD: number of tetrahedral atoms per 1000 Å^3)[5] of $N(CH_3)_4 \cdot ZnH_3(PO_4)_2$ is 10.1. This, as far as we are aware, is the lowest FD value observed so far for any

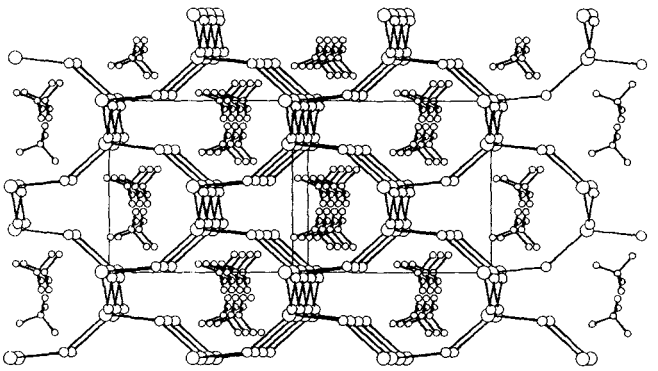

Figure 3. View approximately down [101] of the squashed 12-ring channels in $N(CH_3)_4 \cdot ZnH_3(PO_4)_2$. For clarity, the Zn/P/O framework is represented in "skeletal" form, showing Zn to P connectivity only.

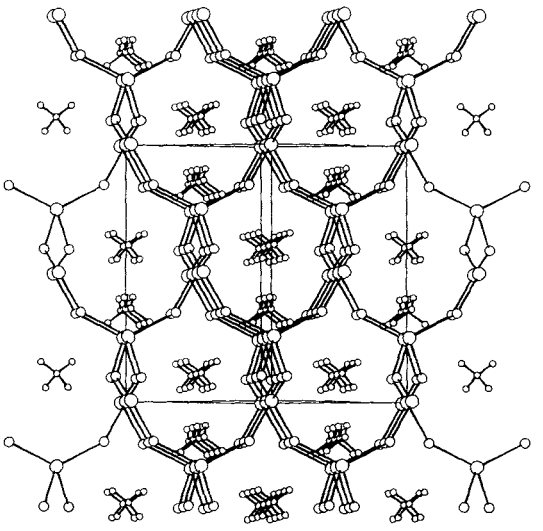

Figure 4. View approximately down [110] of the more regular 12-ring channels in $N(CH_3)_4 \cdot ZnH_3(PO_4)_2$. For clarity, the Zn/P/O framework is represented in "skeletal" form, showing Zn to P connectivity only.

open-framework material built up from tetrahedral building units, although in this case the framework is "interrupted"; that is, not all the tetrahedrally coordinated atoms make four bonding connections. The interrupted tetrahedral gallofluorophosphate framework of cloverite[6] has a FD value of 11.1, whereas $Cs_3[V_5O_9(PO_4)_2] \cdot xH_2O$, which contains a remarkable, diamondlike three-dimensional array of 32-ring spheroidal cavities[2] has a FD value of about 9.3 (square pyramidally surrounded V atoms, tetrahedrally surrounded P atoms).

A number of other zincophosphates templated by organic cations have been reported previously.[3, 7] These are mostly characterized by structurally important hydrogen bonding interactions between the guest cation and the anionic zincophosphate framework. $N(CH_3)_4 \cdot ZnH_3(PO_4)_2$ is distinct from these materials in its lack of any framework-template hydrogen bonds, although framework–framework hydrogen bonds are presumably present, as noted above. The TMA ion has found wide applicability as a template in aluminosilicate[8] and aluminophosphate[9] syntheses, although the resulting frameworks are quite different to the phase described here.

Experimental Section

Synthesis: $N(CH_3)_4 \cdot ZnH_3(PO_4)_2$ was prepared at ambient conditions from the reaction of 85% phosphoric acid (4.8 g), 25% tetramethylammonium hydroxide solution (11.66 g), and 50% rubidium hydroxide solution (2.46 g). This mixture was shaken together in a plastic bottle until homogeneous. Then zinc nitrate (5.32 g) was added, which resulted in the formation of a white gel. The bottle was shaken again and a white precipitate formed. After the initial white powder was filtered off, well-faceted plates of a rubidium zinc phosphate phase crystallized over a few minutes. A second filtration of these crystals resulted in a clear solution. After the mixture had been left to stand for two days, a mixture of numerous rods and a few large translucent lumps of $N(CH_3)_4 \cdot ZnH_3(PO_4)_2$ formed. A crystal of $N(CH_3)_4 \cdot ZnH_3(PO_4)_2$ suitable for structure determination by single-crystal X-ray methods was cut from a larger lump. We have not yet managed to obtain good quality single crystals of $N(CH_3)_4 \cdot ZnH_3(PO_4)_2$ by a more direct synthetic route.

Structure determination: A weakly diffracting crystal of $N(CH_3)_4 \cdot ZnH_3(PO_4)_2$ (dimensions $\approx 0.3 \times 0.3 \times 0.4$ mm) was selected for data collection on a Siemens P4 automated diffractometer (graphite-monochromated $Mo_{K\alpha}$ radiation, $\lambda = 0.71073$ Å, $T = 298$ K): cell parameters from 36 centered reflections ($11° < 2\theta < 30°$), 1322 reflections scanned: $2° < 2\theta < 60°$, $-1 \le h \le 22$, $-1 \le k \le 13$, $-1 \le l \le 21$. 812 reflections considered observed [$I > 3\sigma(I)$] after data reduction (Lorentz and polarization corrections; absorption corrected for on the basis of ψ scans; min./max. equivalent transmission factors = 0.465, 0.555) and merging ($R_{int} = 0.030$). Space group determined unambiguously from systematic absences, structure solved by direct methods using SHELXS86 [10], refined by full-matrix least squares using CRYSTALS [11], and illustrated by using CAMERON [12]. Anisotropic thermal factors for all atoms and a Larson-type secondary extinction correction refined. No protons could be located from final difference maps (min./max. $\Delta\rho = -1.1, +0.9$ e Å^{-3}). Final residuals: $R(F) = 0.043$, $R_w(F) = 0.049$ [$w_i = 1/\sigma_i^2(F)$]. Crystal data: $N(CH_3)_4 \cdot ZnH_3(PO_4)_2$, $M_r = 332.49$, orthorhombic, space group *Fdd*2 (no. 43), $a = 15.972(3)$, $b = 9.863(2)$, $c = 15.156(3)$ Å, $V = 2388(1)$ Å^3, $Z = 8$, $\rho_{calcd} = 1.85$ g cm^{-3}. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the depository number CSD-406078.

Metal-Ion-Templated Polymers: Synthesis and Structure of *N*-(4-Vinylbenzyl)-1,4,7-Triazacyclononanezinc(II) Complexes, Their Copolymerization with Divinylbenzene, and Metal-Ion Selectivity Studies of the Demetalated Resins—Evidence for a Sandwich Complex in the Polymer Matrix**

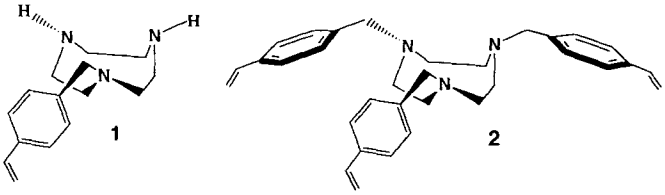
Hong Chen, Marilyn M. Olmstead, Robert L. Albright, Jozsef Devenyi, and Richard H. Fish*

The innovative studies of Wulff, Mosbach, and Shea, among others,[1] introduced and further developed the concept of templated polymers, which initially involves a host–guest relationship between a vinyl monomer host and a bound guest acting as a template. This host–guest complex is then polymerized with a cross-linking agent, which then provides spatially regulated sites in the polymer matrix and, it is hoped, further allows continual recognition of the removable guest (the template) in subsequent reintroduction experiments. One of the types of guest templates utilized in this elegant approach to highly selective polymers of defined architecture was metal ions.[2] However, metal-ion-imprinted polymers have received much less attention than polymers imprinted with organic compounds; the following aspects, for example, need to be addressed: 1) the unequivocal structures of the complexes between the vinyl monomer as ligand and the metal ion; 2) polymerization parameters such as the effect of the metal ion, ligand structure, and the nature of the cross-linking agent; 3) the structure of the imprinted metal-ion site in the polymer; and 4) whether subsequent selectivity is a consequence of the metal-ion recognition process or the thermodynamic stability of the (polymeric ligand)–(metal ion) complex.

Recently we have been developing an environmental inorganic chemistry program that focused on polymer-pendant ligands that were designed from biomimetic or specific heteroatom concepts for selective metal ion complexation.[3] These studies were successful in providing modified 6% cross-linked divinylbenzene–polystyrene beads with anchored ligands that were selective in removing a variety of metal ions from aqueous solution. However, one important goal of our program was to develop polymers that were highly selective to certain divalent metal ions (such as Cu^{2+}) in the presence of trivalent metal ions (for example Fe^{3+}, a ubiquitous metal ion found in many aqueous environmental solutions).

In this communication, we report on our initial results in the new, exciting field of metal-ion-templated polymers. We define a novel system highly selective to Cu^{2+} ions in the presence of Fe^{3+}, Co^{2+}, Ni^{2+}, Zn^{2+}, and Mn^{2+} ions, which contains the well-known 1,4,7-triazacyclononane (TACN) ligand.[4]

The synthesis of the 4-vinylbenzyl-substituted TACN ligands **1** and **2** was readily accomplished in high yields by treating 1 or 3 moles of 4-vinylbenzyl chloride with TACN, and their structures were assigned on the basis of ^{1}H NMR spectroscopy, FAB-MS, and elemental analysis (see Experimental Section). The Zn^{2+} complexes **3** and **4** from **1** and **2**, respectively, were



3 = [**1**-Zn](NO$_3$)$_2$ **4** = [**2**-Zn](NO$_3$)$_2$

prepared by reaction with $Zn(NO_3)_2$ in methanol; the unequivocal structure of complex **4** was determined by single crystal X-ray analysis (Figure 1). What is pertinent about the structure

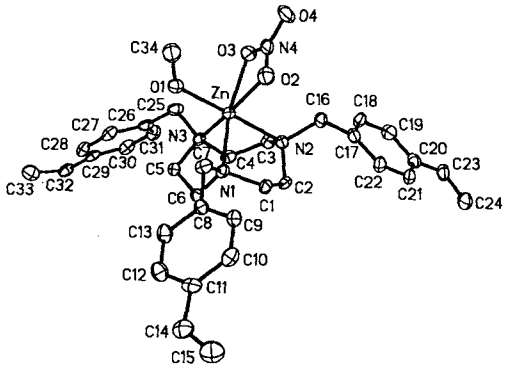


Figure 1. Structure of **4** (the uncoordinated NO_3^- counterion was omitted). Selected bond lengths [Å] and angles [°]: Zn–N1 2.128(4), Zn–N2 2.227(4), Zn–N3 2.094(4), Zn–O1 2.109(4), Zn–O2 2.150(4), Zn–O3 2.193(4), O2–N4 1.268(6), O3–N4 1.269(6), O4–N4 1.232(6); N1-Zn-N2 82.8(2), N1-Zn-N3 86.9(2), N2-Zn-N3 84.4(2).

of complex **4** is the distorted octahedral configuration around the Zn^{2+} center and the coordination of nitrate and methanol groups that apparently prevents the formation of a possible 2:1 TACN:Zn^{2+} sandwich complex.[5] In addition, we assign to complex **3** a similar structure to **4**, based on the analytical and spectroscopic data obtained for each complex; in solution, the FAB-MS for **3** and **4** also provide evidence for their 1:1 Zn:TACN structures.

The copolymerization of Zn^{2+} complexes **3** and **4** with the cross-linking agent DVB (80% divinylbenzene) on use of AIBN as initiator provided highly cross-linked, macroporous polymers **5** and **6** with a ratio of **1**:DVB or **2**:DVB of approximately 1:2.5–1:3.0 and a TACN content of 1.33 and 1.15 mmol g^{-1}, respectively. More importantly, the ratio of TACN:Zn^{2+} in both polymers **5** and **6** was 2:1—clear evidence that free Zn^{2+} ions were extruded during the polymerization process (loss of Zn^{2+}: in **5** 43%; in **6** 50%) possibly to provide a TACN–Zn^{2+} sandwich complex in the polymer matrix (Scheme 1). It is also important to note that preparation of the corresponding Cu^{2+} complexes of **1** and **2** and subsequent attempts to polymerize the resulting Cu^{2+} monomers under similar conditions to those described for **3** and **4** were not successful, due presumably to electron transfer from the developing carbon radical to the Cu^{2+} ion, which quenched or terminated the propagation step of the free radical chain reaction.[2a] Moreover, attempts to prepare an untemplated polymer with **1** and divinylbenzene un-

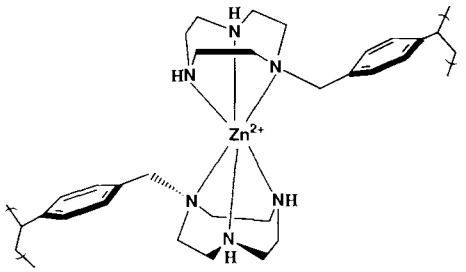
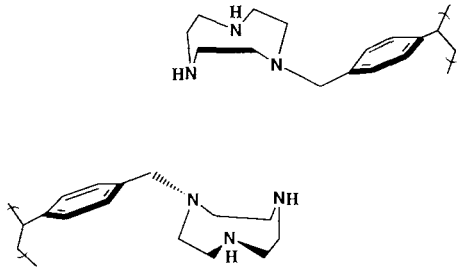


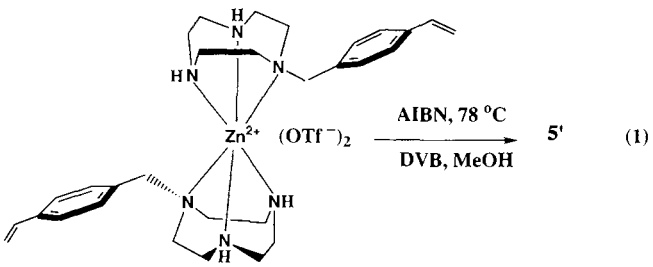
Scheme 1. The Zn^{2+} sandwich complex, whose formation is postulated in the synthesis of the polymer **5**.



Scheme 2. Postulated arrangement of the TACN ligands in the demetalated polymers **8** and **8′**.

der similar conditions to those described for **3** in order to compare its metal-ion selectivity with that of polymer **5**, were unfortunately unsuccessful, since no polymeric material formed. This latter result confirms the unique role of the metal-ion template in the kinetics of the polymerization process.[2a]

To provide further evidence for the formation of a templated, polymeric sandwich complex during polymerization reactions of **3** and **4**, we synthesized the monomeric sandwich complex **7** (see Experimental Section), which we characterized by ^1H NMR spectroscopy, mass spectrometry, and elemental analysis. Subsequent formation of polymer **5′** (TACN content 1.33 mmol g^{-1}) from **7** with DVB under similar polymerization conditions to those described for **3** and **4** clearly showed minor loss of Zn^{2+} metal ions (<15%) and the expected 2:1 ratio of TACN:Zn^{2+} in the polymer matrix (Eq. 1). This result further



7 **5′** (1)

substantiates the formation of the 2:1 TACN:Zn^{2+} sandwich complexes in the polymer matrices of **5** and **6**, possibly on thermodynamic grounds, and represents, to our knowledge, the first confirmation of the formation of sandwich complexes during the polymerization process in the synthesis of metal-ion-templated polymers.[2]

The Zn^{2+}-templated polymers **5**, **5′**, and **6**, were treated with 6N HCl at ambient temperature, which provided the facile and total removal (>99%) of the Zn^{2+} template ions. Selectivity studies were carried out with the these Zn^{2+}-demetalized polymers, designated as **8**, **8′**, and **9**, respectively, to answer the question whether the more important parameter for the introduction was templating or the thermodynamic stability in the ensuing reintroduction of various metal ions into the spatially regulated sandwich arrangement of TACN ligands (Scheme 2).

We therefore performed competition experiments with the original Zn^{2+} ion template and the divalent metal ions, Cu^{2+}, Co^{2+}, Ni^{2+}, and Mn^{2+} using polymers **8**, **8′**, and **9** at pH 4.5. Table 1 shows the results: the thermodynamic stability of the newly formed [M("TACN")$_2$]$^{2+}$ complexes appears to dominate over imprinting; that is, the Cu^{2+}/Zn^{2+} selectivity ratio for

Table 1. Selectivities of polymers **8**, **8′**, and **9** for Zn^{2+}, Cu^{2+}, Co^{2+}, Ni^{2+}, and Mn^{2+} ions at pH 4.5, and Cu^{2+} and Fe^{3+} at pH 2.0. The values reported represent concentration as wt% and in parentheses as μmol per g of resin of metal ion on the resin after reaction [a], as well as the relative selectivity with respect to the selected pair of ions.

	Polymer **8**	Polymer **8′**	Polymer **9**
Cu^{2+}	7.5 (1180)	4.4 (690)	0.77 (121)
Ni^{2+}	0.05 (8.5)	0.03 (5)	0.002 (0.34)
Co^{2+}	1.0 (150)	0.78 (130)	0.002 (0.34)
Mn^{2+}	0.05 (9.0)	0.018 (3)	0.002 (0.36)
Zn^{2+}	0.05 (7.5)	0.04 (6)	0.02 (3)
Cu^{2+}:Zn^{2+}	157:1	115:1	7:1
Ni^{2+}	0.3 (51)	0.64 (108)	0.01 (1.7)
Co^{2+}	0.7 (120)	0.66 (114)	0.005 (0.85)

Fe^{3+}	<0.01 (<1.8)	0.006 (1.0)	0.01 (1.8)
Cu^{2+}:Fe^{3+}	>44:1	240:1	3:1

[a] For the first two series of ions, 6 mg of resin was suspended with stirring in a 10 mL solution (pH 4.5) of a mixture of Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+} ions (0.04 M each) for 18 h at ambient temperature. The resin was then washed (H_2O, MeOH), dried (ambient and under vacuum), and analyzed for metal ion concentration by X-ray fluorescence. For the third series, 6 mg of resin was suspended with stirring in a 8 mL solution (pH 2.0) of a mixture of Fe^{3+} and Cu^{2+} ions (0.02 M each) for 18 h at ambient temperature. Workup and evaluation was as for the first two series.

8 is approximately 157:1, for **8′** 115:1, and for **9** 7:1. The overall order of metal-ion selectivity for all three polymers (**8**, **8′**, and partly for **9**) is $Mn^{2+} \leq Ni^{2+} \leq Zn^{2+} < Co^{2+} < < < Cu^{2+}$, which somewhat, but not exactly, follows the Irving–Williams order of stability.[6] It is interesting to note that if at pH 4.5 the Zn^{2+} ion competes with Co^{2+}, Ni^{2+}, and Mn^{2+}, *in the absence* of Cu^{2+}, for sites in polymers **8** and **8′**, the overall order is: $Mn^{2+} < Ni^{2+} < Co^{2+} < < < Zn^{2+}$ (Table 1); in this case, if the Irving–Williams order is also of significance for metal-ion-templated polymers, imprinting appears more important than stability.[6] More importantly, the stability constants for the formation of the [M("TACN")$_2$]$^{n+}$ complexes decrease in the order $Co^{2+} > Ni^{2+} > Zn^{2+}$ and further support the dominance of the imprinting effect of Zn^{2+} in the absence of Cu^{2-}.[4]

We also studied the competition between Cu^{2+} and Fe^{3+} at pH 2.0, in order to test the possible selectivity of a divalent over a trivalent metal ion. From data in Table 1, the Cu^{2+}:Fe^{3+} ion selectivity is calculated to be greater than 44:1 and 240:1 and the ratio of the equilibrium selectivity coefficients ($K_{Cu^{2+}}/K_{Fe^{3+}}$) to be 3×10^5 and 7×10^5 for polymers **8** and **8′**, respectively, whereas polymer **9** had a low selectivity ratio of 3:1 ($K_{Cu^{2+}}/K_{Fe^{3+}} = 1.5$). These exciting results demonstrate a surprisingly high selectivity for a divalent over a trivalent metal ion and might imply that one factor in imprinted metal-ion selectivity is

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3606-0643 $ 17.50+.50/0

the ionic radius of the original metal-ion template (Zn^{2+}, 0.69 Å; Cu^{2+}, 0.72 Å; and Fe^{3+}, 0.53 Å); this order of selectivity ($Cu^{2+} > > > Fe^{3+}$) is diametrically opposite to that found for the bond strengths of known $[M(TACN)_2]^{n+}$ ($n = 2 \cdot 3$) complexes as studied by X-ray crystallographic and infrared techniques ($Fe^{2+} > Co^{2+} > Fe^{3+} > Cr^{3+} > > Ni^{2+} > Cu^{2+} > Zn^{2+}$); however, more examples have to be studied before this ionic radius concept can be proven unequivocally.[7] What is also apparent from the results in Table 1 is that even though polymer **8** and **8′** were prepared from different Zn^{2+} monomer precursors (**3** and **7**), they provide very similar metal-ion selectivity orders and metal-ion capacities upon reintroduction of various metal ions. The reason, we believe, is that both **8** and **8′** have very similar, spatially regulated sites in the polymer that are readily able to form stable, metal-ion sandwich complexes, while polymer **9** appears to form a more highly cross-linked, hydrophobic polymer site, with dramatically reduced selectivities and capacities for all metal ions studied (see Table 1).

Our significant new findings in the area of metal-ion-templated polymers can be summarized as follows: 1) we synthesized imprinted polymeric metal-ion sandwich complexes; 2) we could show that thermodynamic stability is a controlling factor for the high selectivity for Cu^{2+} ions in the presence of Zn^{2+}, Ni^{2+}, Co^{2+}, and Mn^{2+} ions reintroduced to the Zn^{2+}-demetalized polymer sites; 3) we found evidence that metal-ion-imprinting is possibly an important parameter for selectivity on reintroduction of divalent metal ions in the absence of Cu^{2+} ions (Zn^{2+}, Mn^{2+}, Ni^{2+}, and Co^{2+}); and 4) we tentativley postulate that Zn^{2+}-imprinting (the ionic radius of Zn^{2+} and Cu^{2+} being comparable) accounts for the selectivity for Cu^{2+} over Fe^{3+} ions, because the Fe^{3+} ion is usually an ion that can readily compete for any polymer-pendant ligand site due to its favorable charge-to-radius ratio. Future studies will focus on the scope of the metal-ion-templated polymer field with other macrocycles that are hoped to provide high metal-ion selectivities. A continuation of our mono-*N*-(4-vinylbenzyl) TACN studies with Ag^{+}, Hg^{2+}, Cd^{2+}, and Pb^{2+} ions as templates and subsequent investigations of the templated polymers should refine the understanding of the importance of templating and thermodynamic parameters.

Experimental Section

1: To a stirred solution of TACN (0.50 g, 3.87 mmol) in ethanol (12 mL) was added a solution of LiOH (20 mg, 0.84 mmol) in water (5 mL) in one portion. The resulting cloudy solution was stirred at 50 °C for 2 h and then cooled to ambient temperature. A solution of 4-vinylbenzyl chloride (118 mg, 0.774 mmol) in ethanol (1.0 mL) was added dropwise, and the final reaction mixture was stirred at reflux for 3 h before being stripped in vacuo. The residue was triturated with water (20 mL) and extracted with CH_2Cl_2 (25 mL × 3). The combined organic layer was dried over Na_2SO_4 and stripped in vacuo to give the **1** in about 85% yield (^{1}H NMR analysis shows **1** to be >90% pure). FAB-MS (*m*-nitrobenzyl alcohol): *m/z* (%): $[M+H]^+$ 246 (100%). ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta = 7.32$ (m, 4H, aromatic H), 6.70 (dd, 1H, vinyl H_a), 5.72 (d, 1H, vinyl H_{b1}), 5.21 (d, 1H, vinyl H_{b2}), 3.69 (s, 2H, benzyl CH_2), 2.71 (m, 12H, TACN CH_2), and 2.43 (s, 2H, NH). Elemental analysis calcd for $C_{15}H_{23}N_3 \cdot 2H_2O \cdot 0.25CH_2Cl_2$: C 60.5, H 9.10, N 13.9; found: C 61.2, H 8.84, N 14.1.

2: To a stirred solution of TACN (5.0 g, 38.7 mmol) in anhydrous toluene (88 mL) in a glovebox was added powdered KOH (6.53 g, 116 mmol) slowly, and the resulting suspension was treated with 4-vinylbenzyl chloride (17.7 g, 116 mmol, dropwise). The reaction mixture was heated to 80 °C and stirred at this temperature for 8 h. After it had cooled to room temperature, it was treated with an additional portion of powdered KOH (1.1 g) and stirred for another 10 h. The final reaction mixture was filtered, and the filtrate was stripped in vacuo to give **2** in quantitative yield. FAB-MS (*m*-nitrobenzyl alcohol): *m/z* (%): $[M+H]^+$ 478 (100%). ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta = 7.31$ (m, 4H, aromatic H), 6.69 (dd, 1H, vinyl H_a), 5.74 (d, 1H, vinyl H_{b1}), 5.24 (d, 1H, vinyl H_{b2}), 3.64 (s, 2H, benzyl CH_2), and 2.88 (s, 4H, TACN CH_2). Elemental analysis calcd for $C_{33}H_{39}N_3 \cdot 2H_2O$: C 77.2, H 8.38, N 8.19; found: C 77.6, H 8.09, N 7.99.

3: To a solution of **1** (0.14 g, 0.57 mmol) in MeOH (20 mL) was added a solution of $Zn(NO_3)_2 \cdot 6H_2O$ (0.16 g, 0.54 mmol) in MeOH (5 mL) in one portion, and the reaction mixture was stirred at ambient temperature for 48 h and then filtered. The volume of the filtrate was reduced to 6.8 mL to give a solution (ca. 0.085 M) of **3** (this solution was used for the polymerization reactions). The solid **3** was obtained when enough diethyl ether vapor was diffused into this solution. FAB-MS (*m*-nitrobenzyl alcohol): *m/z* (%): $[M - NO_3^-]^+$ 371 (70%). ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C) $\delta = 7.33$ (m, 4H, aromatic Hs), 6.70 (dd, 1H, vinyl H_a), 5.77 (d, 1H, vinyl H_{b1}), 5.28 (d, 1H, vinyl H_{b2}), 4.07 (s, 2H, benzyl CH_2), and 3.22, 2.56 (m, 12H, TACN CH_2). Elemental analysis calcd for $C_{15}H_{23}N_5O_6Zn \cdot CH_3OH$: C 41.2, H 5.8, N 15.0, Zn 14.0; found: C 40.1, H 6.1, N 15.4, Zn 13.6.

4: To a vigorously stirred suspension of **2** (0.528 g, 1.11 mmol) in MeOH (50 mL) was added a solution of $Zn(NO_3)_2 \cdot 6H_2O$ (0.297 g, 1.00 mmol) in MeOH (5 mL) in one portion, and the reaction mixture was stirred at ambient temperature for 48 h and then filtered. The volume of filtrate was reduced to 15 mL to give a saturated solution (ca. 0.066 M) of **4** (this solution was used for the polymerization reactions). Upon standing, **4** crystallized as off-white needles (80% yield). FAB-MS (*m*-nitrobenzyl alcohol): *m/z* (%): $[M - NO_3^-]^+$ 603 (3.8%), $[M - NO_3^- - HNO_3]^+$ 540 (7.4%). ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta = 7.32$ (m, 4H, aromatic H), 6.69 (dd, 1H, vinyl H_a), 5.76 (d, 1H, vinyl H_{b1}), 5.29 (d, 1H, vinyl H_{b2}), 4.21 (s, 2H, benzyl CH_2), and 3.17, 2.40 (m, 4H, TACN CH_2). Elemental analysis calcd for $C_{33}H_{39}N_5O_6Zn \cdot 4CH_3OH$: C 55.9, H 6.9, N 8.8, Zn 8.2; found: C 55.3, H 5.9, N 8.7, Zn ca. 9.

7: To a solution of **1** (0.18 g, 0.74 mmol) in MeOH (30 mL) was added a solution of $Zn(OTf)_2$ (0.13 g, 0.37 mmol) in MeOH (10 mL) in one portion, and the reaction mixture was stirred at ambient temperature for 48 h, and then filtered. The volume of filtrate was reduced to 11.0 mL to give a solution (ca. 0.034 M) of **7** (this solution was used for the polymerization reactions). The solid sample of **7** was obtained when the volatiles were removed in vacuo. Electrospray ionization/MS (methanol): *m/z* (%): $[M - OTf]^+$ 703 (8%). ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta = 7.29$ (m, 4H, aromatic H), 6.70 (dd, 1H, vinyl H_a), 5.77 (d, 1H, vinyl H_{b1}), 5.29 (d, 1H, vinyl H_{b2}), 4.07 (s, 2H, benzyl CH_2), and 3.69–2.39 (m, 12H, TACN CH_2). Elemental analysis calcd for $C_{32}H_{46}F_6N_6O_6S_2Zn \cdot 6H_2O$: C 39.9, H 6.0, N 8.7, Zn 6.8; found: C 40.0, H 5.4, N 8.8, Zn 6.8.

Typical polymerization procedure with monomer **3**: A solution of monomer **3** (0.085 M), cross-linking agent DVB (0.066 M), and initiator AIBN (0.006 M), in MeOH (4 mL) was placed in a 12 mL vial and purged with argon gas for 7 min, after which the vial was capped, heated to 78 °C over a 1 h period, and kept at this temperature overnight. The resulting bulk polymer powder (**5**) was collected on a 0.45 m nylon membrane, washed with hot methanol, dried for analysis, demetalated with 6N HCl to provide **8**, which was used for the metal ion selectivity studies (see Table 1). Elemental analysis for **5**: C, 61.0; H, 7.22; N, 8.85; Zn, 5.7 (1.33 mmol TACN per gram of resin).

Isolation of a Nonicosahedral Intermediate in the Isomerization of an Icosahedral Metallacarborane**

Shirley Dunn, Georgina M. Rosair, Rhodri Ll. Thomas, Andrew S. Weller, and Alan J. Welch*

The mechanism by which the icosahedral carboranes, their C-substituted derivatives, and their heteroatom analogues rearrange has been the subject of speculation since the 1,2- to 1,7-isomerization of *closo*-$C_2B_{10}H_{12}$ was reported more than 30 years ago.[1] A number of possible mechanisms have been proposed[2] on the basis of both experimental observations (product distributions) and theoretical calculations. As far as we are aware, however, the high temperatures generally required for these isomerizations have so far precluded isolation of any intermediate species; the identification of such intermediates is clearly important for judging the relative merits of the various mechanistic proposals.

We have recently shown that targeting molecules that are severely overcrowded can dramatically lower isomerization temperatures in icosahedral metallacarboranes.[3] We now report the unexpected first isolation and characterization of an intermediate in an icosahedral-to-icosahedral rearrangement. This intermediate, which is closed but not icosahedral in shape, has previously only been identified theoretically.[2f]

Reaction of Na_2[7-Ph-7,8-*nido*-$C_2B_9H_{10}$] and [$(CH_3CN)_2$-$MoBr(\eta^3$-$C_3H_5)(CO)_2$] in THF at 0 °C affords the metallacarborane $\mathbf{1}^-$ as a benzyltrimethylammonium ($BTMA^+$) salt in good yield. The anion $\mathbf{1}^-$ exhibits two bands in the carbonyl region of the IR spectrum at 1924 and 1833 cm^{-1} (CH_2Cl_2). Crystallographic analysis[4] confirms that $\mathbf{1}^-$ has the expected icosahedral structure with a 3,1,2-MoC_2 heteroatom arrangement (Figure 1).

[**] Steric Effects in Heteroboranes: Part 16. This work was supported by a grant from the Engineering and Physical Sciences Research Council. We thank Heriot-Watt University for support of G. M. R. and Rh. Ll. T. and the Callery Chemical Company for a generous gift of decaborane. Part 15: Rh. Ll. Thomas, A. J. Welch, *J. Chem. Soc. Dalton Trans.* **1997**, in press.

An analogous product is not obtained from the diphenyl carborane anion. Rather, treatment of Na_2[7,8-Ph_2-7,8-*nido*-$C_2B_9H_9$] with the same metal substrate under the same conditions yields $\mathbf{2}^-$, which shows IR stretching bands at significantly higher frequencies (1954 and 1893 cm^{-1}). A crystallographic study[5] of the $BTMA^+$ salt of $\mathbf{2}^-$ reveals a nonicosahedral *closo* geometry with two 4-connected cluster vertices (occupied by carbon atoms) and two 6-connected vertices (one occupied by Mo, Figure 2). There is only one Mo–C (cluster) connectivity, and it is significant that the two cage carbon atoms are substantially separated.

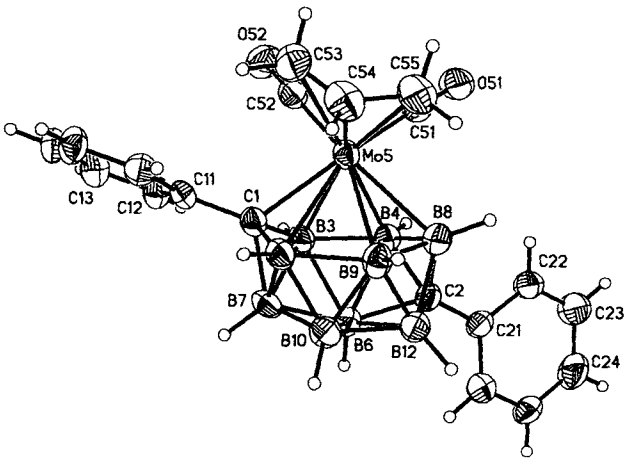

Figure 2. Perspective view of $\mathbf{2}^-$. Selected bond lengths [Å] and angles [°]: C1–C11 1.495(10), C2–C21 1.478(10), Mo5–C1 2.260(7), Mo5–C51 1.950(8), Mo5–C52 1.986(9), Mo5–C53 2.395(9), Mo5–C54 2.248(9), Mo5–C55 2.338(9), C51–O51 1.155(9), C52–O52 1.150(9); C51-Mo5-C52 79.4(3).

The ^{1}H NMR spectrum of $\mathbf{2}^-$ in CD_3CN slowly changes at room temperature (over days). This suggests that $\mathbf{2}^-$ is a kinetic rather than a thermodynamic product, and identifies it as a potential intermediate in a carbon atom isomerization process. This is confirmed by the quantitative conversion of $\mathbf{2}^-$ to $\mathbf{3}^-$ upon heating in THF at reflux (30 min); the product $Et_4N^+\mathbf{3}^-$ shows carbonyl IR bands (1920 and 1831 cm^{-1}) that are very similar to those of $BTMA^+\mathbf{1}^-$. A single crystal X-ray

[1,9-Ph_2-3,3-$(CO)_2$-3-(η^3-C_3H_5)-3,1,9-*closo*-$MoC_2B_9H_9$]$^-$ $\mathbf{3}^-$

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3606-0645 $ 17.50+.50/0

diffraction study[6] of $Et_4N^+\mathbf{3}^-$ (Figure 3) shows that this anion also has an icosahedral geometry, but this time with a 3,1,9-MoC_2 arrangement.

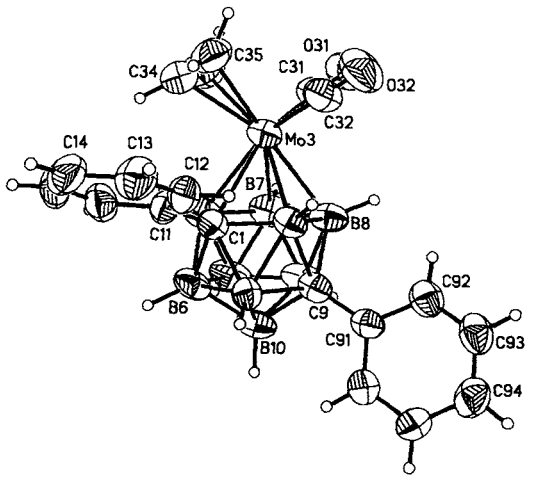

Figure 3. Perspective view of $\mathbf{3}^-$. Selected bond lengths [Å] and angles [°]: C1–C11 1.508(14), C9–C91 1.483(14), Mo3–C1 2.459(8), Mo3–C31 1.948(13), Mo3–C32 1.957(14), Mo3–C33 2.36(2), Mo3–C34 2.252(14), Mo3–C35 2.36(2), C31–O31 1.148(14), C32–O32 1.14(2); C31-Mo3-C32 79.6(5).

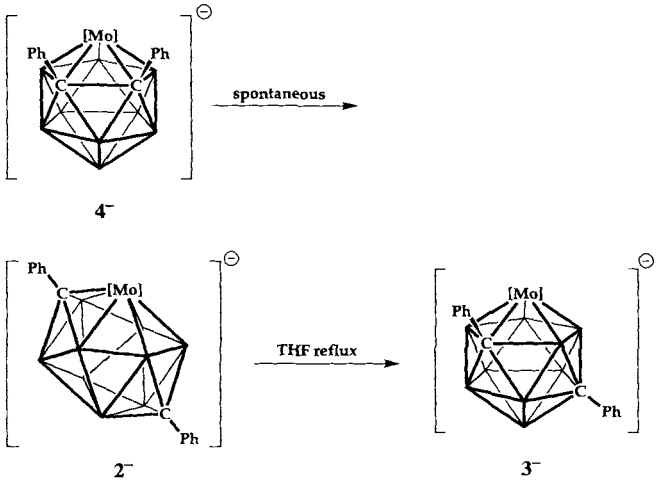
Collectively, these results are entirely consistent with the spontaneous conversion of the nonisolable metallacarborane $\mathbf{4}^-$ into nonicosahedral $\mathbf{2}^-$ to relieve steric crowding (Scheme 1).

$[1,2\text{-}Ph_2\text{-}3\text{-}(\eta^3\text{-}C_3H_5)\text{-}3,3\text{-}(CO)_2\text{-}3,1,2\text{-}closo\text{-}MoC_2B_9H_9]^-$ $\mathbf{4}^-$

Gentle thermolysis of $\mathbf{2}^-$ then affords the icosahedral $\mathbf{3}^-$, which is related to $\mathbf{4}^-$ in exactly the same way that 1,7-*closo*-$C_2B_{10}H_{12}$ is related to 1,2-*closo*-$C_2B_{10}H_{12}$.



Scheme 1. Proposed isomerization of the sterically overcrowded icosahedral anion $\mathbf{4}^-$ into $\mathbf{3}^-$ via the nonicosahedral intermediate $\mathbf{2}^-$.

Thus $\mathbf{2}^-$ is an intermediate in an icosahedral-to-icosahedral rearrangement. The nonicosahedral structure of $\mathbf{2}^-$ is experimentally unprecedented, but the analogous carborane (with $\{Mo(\eta^3\text{-}C_3H_5)(CO)_2\}^-$ replaced by $\{BH\}$) of C_2 symmetry has been identified by Wales[2f] as a stable intermediate in the 1,2- to 1,7-$C_2B_{10}H_{12}$ isomerization and a viable synthetic target. It is possible that $\mathbf{2}^-$ is isolable, hence realizing this prediction, by virtue of stabilization of the metal center in a highly-connected cluster vertex.

Experimental Section

$BTMA^+\mathbf{1}^-$: $Na_2[7\text{-}Ph\text{-}7,8\text{-}nido\text{-}C_2B_9H_{10}]$ (0.6 mmol) in THF (30 mL) was added to a stirred solution of $[(CH_3CN)_2MoBr(\eta^3\text{-}C_3H_5)(CO)_2]$ (0.6 mmol) in THF (20 mL) at 0 °C. After removal of solvent in vacuo, the resulting brown oil was dissolved in dichloromethane (30 mL). BTMACl (0.6 mmol) was added, and NaBr that was formed in situ removed by filtration. Purification by column chromatography (silica, 200–400 mesh, water-cooled) with dichloromethane eluent followed by recrystallization from dichloromethane/(diethyl ether) afforded $BTMA^+\mathbf{1}^-$ as a yellow solid (42% yield). IR (CH_2Cl_2): $\tilde{\nu}$ = 1924, 1833 cm^{-1} (CO); ^1H NMR (200 MHz, CD_3CN): δ = 7.7–7.5 (m, 5H, $BTMA^+$), 7.2–6.9 (m, 5H, phenyl), 4.4 (s, 2H, $BTMA^+$), 3.35 (m, 1H, $allyl_{center}$), 3.0 (s, 9H, $BTMA^+$), 2.7 (dd, 1H, $allyl_{syn}$), 1.45 (dd, 1H, $allyl_{syn}$), 1.1 (d, 1H, $allyl_{anti}$), 0.7 (d, 1H, $allyl_{anti}$); $^{11}B\{^1H\}$ NMR (128.4 MHz, CD_3CN): δ = −6.4 (1B), −7.9 (1B), −10.4 (1B), −14.3 (1B), −15.8 (2B), −19.1 (1B), −29.9 (1B), −33.1 (1B).

$BTMA^+\mathbf{2}^-$: Prepared analogously to $BTMA^+$ $\mathbf{1}^-$ from $Na_2[7,8\text{-}Ph_2\text{-}7,8\text{-}nido\text{-}C_2B_9H_9]$ (1.0 mmol), $[(CH_3CN)_2MoBr(\eta^3\text{-}C_3H_5)(CO)_2]$ (1.1 mmol), and BTMACl (0.9 mmol) to afford $BTMA^+$ $\mathbf{2}^-$ as a yellow solid (54% yield). IR (CH_2Cl_2): $\tilde{\nu}$ = 1954, 1893 cm^{-1} (CO); ^1H NMR (200 MHz, CD_3CN) δ = 7.9 (m, 2H, phenyl), 7.45–7.75 (m, 5H, $BTMA^+$), 7.1–7.35 (m, 8H, phenyl), 4.1 (s, 2H, $BTMA^+$), 3.75 (m, 1H, $allyl_{center}$), 2.8 (s, 9H, $BTMA^+$), 2.15 (dd, 1H, $allyl_{syn}$), 2.05 (dd, 1H, $allyl_{syn}$), 1.4 (d, 1H, $allyl_{anti}$), 0.95 (d, 1H, $allyl_{anti}$); $^{11}B\{^1H\}$ NMR (128.4 MHz, CD_3CN): δ = 16.2 (1B), 5.9 (1B), 3.8 (1B), −0.5 (1B), −4.5 (1B), −6.5 (1B), −11.7 (1B), −22.6 (1B), −23.8 (1B).

$A^+\mathbf{3}^-$ (A^+ = $BTMA^+$, Et_4N^+, Ph_4P^+, $(Ph_3P{=})_2N^+$) Method 1: $BTMA^+\mathbf{2}^-$ (0.5 mmol) was heated at reflux in THF (30 mL). Purification by column chromatography (silica, 200–400 mesh, water-cooled) with dichloromethane eluent afforded $BTMA^+\mathbf{3}^-$ as a yellow solid after trituration with pentane. Method 2: anion $\mathbf{2}^-$ was prepared by allowing equimolar solutions of $Na_2[7,8\text{-}Ph_2\text{-}7,8\text{-}nido\text{-}C_2B_9H_9]$ and $[MoBr(CH_3CN)_2(\eta^3\text{-}C_3H_5)(CO)_2]$ in THF to react. Subsequent heating at reflux in THF formed $\mathbf{3}^-$. The solvent was removed in vacuo, and the residual brown oil dissolved in dichloromethane (30 mL). Addition of a salt of the counterion (1 molequiv), filtration, and purification by column chromatography (silica, 200–400 mesh, water-cooled) with dichloromethane as eluent afforded $A^+\mathbf{3}^-$ as yellow oils. Trituration with pentane provided the products as yellow solids in quantitative yields. Data for $BTMA^+$ $\mathbf{3}^-$: IR (CH_2Cl_2): $\tilde{\nu}$ = 1920, 1831 cm^{-1} (CO); ^1H NMR (200 MHz, CD_3CN): δ = 7.45–7.65 (m, 7H, $BTMA^+$ (5H), phenyl (2H)), 7.25 (m, 5H, phenyl), 6.9 (m, 3H, phenyl), 4.4 (s, 2H, $BTMA^+$), 3.0 (m, 10H, $BTMA^+$ (9H), $allyl_{center}$ (1H)), 2.6 (dd, 1H, $allyl_{syn}$), 1.8 (dd, 1H, $allyl_{syn}$), 1.2 (d, 1H, $allyl_{anti}$), 1.05 (d, 1H, $allyl_{anti}$); $^{11}B\{^1H\}$ NMR (128.4 MHz, CD_3CN): δ = −1.9 (2B), −4.5 (2B), −6.7 (1B), −9.5 (1B), −10.4 (1B), −11.6 (2B).

The Phenylacetyl Group—The First Amino Protecting Group That Can Be Removed Enzymatically from Oligonucleotides in Solution and on a Solid Support**

Herbert Waldmann* and Armin Reidel

A central problem in the chemical synthesis of oligodeoxynucleotides on solid supports is the protection and deprotection of the amino groups of the different nucleobases.[1] Even under the strongly basic conditions required for the removal of the established blocking groups deprotection may remain incomplete,[2] and unwanted side reactions like the formation of 2,6-diaminopurines from 6-O-alkylated guanine moieties may occur.[3] In addition, new protecting groups are needed, for example, for the construction of complex and sensitive nucleopeptides,[4] nonradioactive DNA probes,[5] and aminoacyl-modified tRNAs[6] and for the preparation of matrix-bound deprotected DNA fragments.[7a] Therefore, the development of new methods for the selective protection and deprotection of the amino functions of nucleobases under alternative and mild conditions in solution and on solid supports is of particular interest in natural product synthesis.[1, 7]

Enzymatic protecting group techniques[8] have proven their efficiency (completely selective removal under mild conditions, for example pH 7, room temperature) in particular, in the construction of sensitive multifunctional acid- and base-labile peptide conjugates like lipo-,[9] glyco-,[10, 11] and phosphopeptides,[11, 12] and might also open up viable alternatives to established classical chemical methods for solution- and solid-phase oligonucleotide chemistry. Furthermore, in the light of the intense recent interest in combinatorial chemistry,[13] the successful implementation of enzymatic transformations on solid supports[14] is of general relevance. The introduction of biocatalysts for this challenging task would greatly expand the toolbox of methods available for combinatorial synthesis. We now report that the enzyme-labile phenylacetyl (PhAc) group[15] can be removed from oligonucleotides with the enzyme penicillin G acylase under very mild conditions (pH 7, room temperature) both in solution and on a solid support.

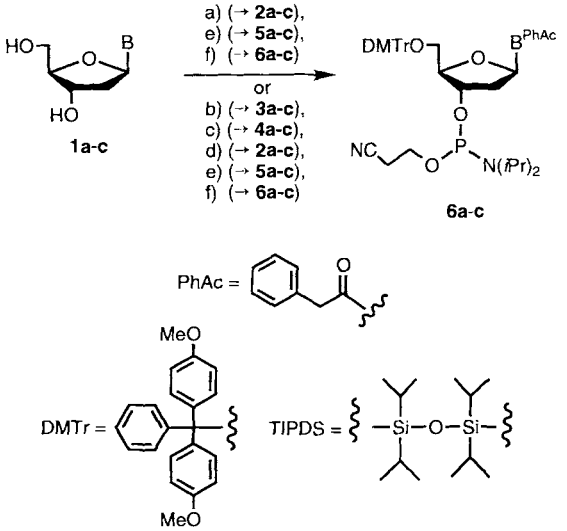
The synthesis of the selectively protected phosphoramidite building blocks **6**, which are needed for the solid-phase synthesis of the PhAc-protected oligonucleotides, is detailed in Scheme 1. The unprotected 2′-deoxynucleosides **1** were N-acylated directly by means of the "transient protection" method:[16] simultaneous O- and N-silylation was followed by treatment of the



Scheme 1. Synthesis of the PhAc-protected nucleoside phosphoramidites **6**. a) Trimethylsilyl chloride (TMSCl, 5 equiv), pyridine, room temperature, 30 min; $PhCH_2C(O)Cl$ (1.5 equiv), *N*-hydroxybenzotriazole (HOBt, 1.5 equiv), CH_3CN/pyridine 2:1, 0 °C → room temperature; yields: **2a**: 71%, **2b**: 51%; **2c**: 63%; b) 1,1,3,3-tetraisopropyldisiloxane-1,3-diyl chloride (TIPDSCl, 1.1 equiv), pyridine, room temperature; yields: **3a**; 96%, **3b**: 95%, **3c**: 97%; c) $(PhAc)_2O$ (4 equiv), pyridine, 120 °C, 30 min; yields: **4a**: 87%, **4b**: 77%, **4c**: 85%; d) $(nBu)_4NF$, (5 equiv), THF, room temperature, 1 h; yields: **2a**: 60%, **2b**: 88%; **2c**: 86%; e) 4,4′-dimethoxytriphenylmethyl chloride (DMTrCl, 1.4 equiv), 4-dimethylaminopyridine (DMAP, cat.), pyridine, room temperature, 3–5 h; yields: **5a**: 83%, **5b**: 82%, **5c**: 81%; f) $NC(CH_2)_2OP(Cl)N(iPr)_2$ (2 equiv), $(iPr)_2NEt$ (3 equiv), THF, room temperature, 20 min; yields: **6a**: 90%, **6b**: 80%, **6c**: 55%. B = adenine (**a**), guanine (**b**), cytosine (**c**).

silylated nucleosides with phenylacetyl chloride and *N*-hydroxybenzotriazole (HOBt) to deliver the desired N-PhAc nucleosides **2** in yields of 51–71%. Alternatively, the OH groups of **1a–c** were simultaneously masked with the 1,1,3,3-tetraisopropyldisiloxane-1,3-diyl (TIPDS) group.[17] The resulting TIPDS ethers **3** (obtained in 95–97% yield) were then N-acylated with phenylacetic anhydride to give the amides **4**, which were subsequently desilylated to deliver the desired N-protected nucleosides **2** in overall yields of 52–73%. After the primary OH groups of **2a–c** had been masked as DMTr ethers by alkylation with DMTrCl in the presence of DMAP, the secondary OH groups were treated with chloro(β-cyanoethoxy)-*N*,*N*-diisopropylaminophosphane to provide the desired phosphoramidites **6**. The crude products were precipitated with cold hexane and used without further purification for solid-phase synthesis of the PhAc-masked oligonucleotides **7–11** (Table 1).[18]

Table 1. Yields of oligonucleotides **7–11** produced by solid-phase synthesis [a].

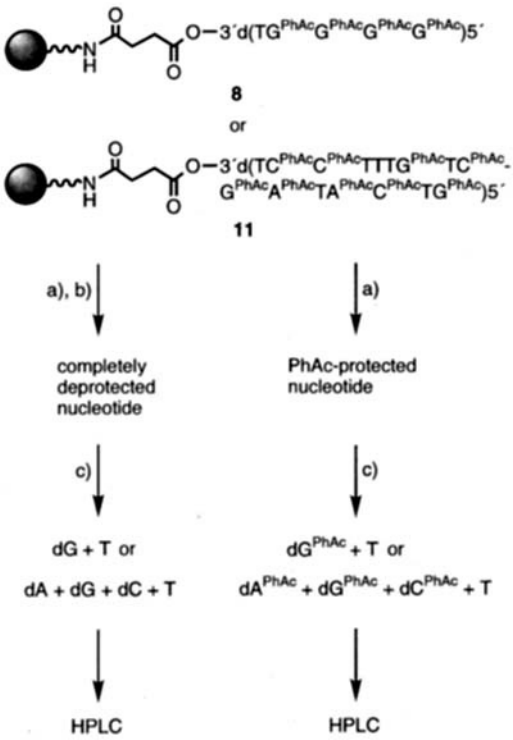
To determine whether the PhAc group can be cleaved enzymatically from oligonucleotides under mild conditions pentanucleotide **8** was removed from the solid support and simultaneously deprotected at the internucleotide linkage by treatment with concentrated ammonia for 45 min at room temperature. The PhAc-protected sample obtained was then incubated with penicillin G acylase at pH 7 for 2 h at room temperature (Scheme 2). The deprotected oligonucleotide was next digested



Scheme 2. Penicillin G acylase mediated removal of the PhAc group from the oligonucleotides **8** and **11** in solution. a) Conc. NH_3 (**8**: room temperature, 45 min; **11**: 10 °C, 10 min); b) penicillin G acylase, pH 7, room temperature, 2 h; c) phosphodiesterase from *Crotalus duriscus*, alkaline phosphatase from *E. coli*, tris(hydroxymethyl)aminomethane (TRIS) buffer, $MgCl_2$, 37 °C, 12 h; the spheres represent the CPG beads.

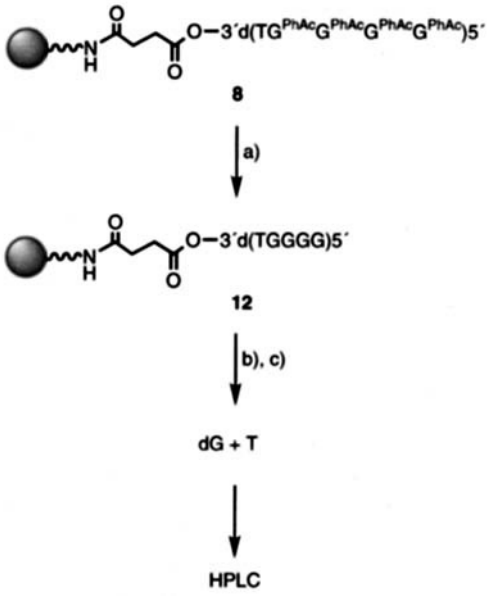
by successive treatment with phosphodiesterase from *Crotalus duriscus* and alkaline phosphatase from *E. coli*, and the resulting nucleoside mixture was analyzed by HPLC (Spherisorb ODSII RP18 column, 250 × 4 mm, 5 μm; methanol/water 30:70 v/v, flow rate 0.6 mL min^{-1}; detection at 260 nm). Parallel to these experiments a sample of **8** was subjected to the same procedure but the nucleobases were not deprotected with penicillin G acylase.[19]

When **8** was treated with penicillin acylase, only deoxyguanidine (retention time $R_t = 4.75$ min) and thymidine ($R_t = 5.01$ min) but no PhAc-protected nucleoside could be detected by chromatography. In contrast, when **8** was not enzymatically deprotected, phenylacetylated deoxyguanidine ($R_t = 56.07$ min) and thymidine were found. This result demonstrates that penicillin acylase removed the four PhAc protecting groups present in **8** quantitatively.

To determine if penicillin G acylase is also capable of removing all PhAc groups from larger nucleotides, the hexadecanucleotide **11** was cleaved from controlled pore glass (CPG) beads by treatment with ammonia at room temperature for 10 min and then subjected to the enzyme-mediated deprotection reaction. The outcome of the biocatalyzed transformation was analyzed as detailed above by enzymatic digestion and HPLC analysis; the results were compared to those obtained for a reference sample from which the PhAc groups had not been cleaved with penicillin acylase. After treatment of **11** with the acylase only the completely deprotected deoxynucleosides dA, dG, dC, and T could be detected, whereas in the control experiment the PhAc-masked nucleosides were obtained. Thus, the biocatalyst removed all nine amino protecting groups in the hexadecanucleotide **11**. For **7**, **9**, and **10** the results were analogous.

These results demonstrate that the phenylacetyl group can be applied advantageously in the construction and for the deprotection of oligonucleotides under mild conditions. Its enzymatic removal offers a viable alternative to classical deprotection by heating with concentrated ammonia for several hours.

Finally, in addition to the enzymatic unmasking of oligonucleotides in solution we investigated whether penicillin G acylase is capable of removing the amino protecting groups from a polymer-bound oligonucleotide. To this end, CPG beads with bound **8** were treated with the enzyme first to give the immobilized but deprotected pentanucleotide **12** (Scheme 3). After the



Scheme 3. Penicillin G acylase mediated removal of the PhAc group from the oligonucleotide **8** on solid support. a) Penicillin G acylase, pH 7, room temperature, 72 h; b) conc. NH_3, room temperature, 45 min; c) phosphodiesterase from *Crotalus duriscus*, alkaline phosphatase from *E. coli*, TRIS buffer, $MgCl_2$, 37 °C, 12 h; the spheres represent the CPG beads.

beads had been washed, the oligonucleotide was released from the solid support by treatment with ammonia and analyzed as described previously by enzymatic digestion and HPLC. In analogy to the enzymatic deprotection of **8** in solution, only deblocked deoxyguanosine and thymidine had formed. Thus, penicillin acylase is a biocatalyst that performs well not only in solution but also on suitable solid supports.

Penicillin G acylase is a very robust, readily available enzyme with a broad substrate tolerance. It accepts, for instance, esters and amides of various chiral alcohols and amines, α- and β-amino acids, aminophosphonic acids, and β-lactams.[20] Thus our results are not only relevant to oligonucleotide synthesis in particular but to solid-phase chemistry in general. Our findings

might open a new and advantageous route to the development of enzymatic transformations for solid-phase and combinatorial chemistry.

[18] Oligonucleotides were synthesized by established protocols with a DNA synthesizer (Applied Biosystems, model 394) on controlled pore glass (CPG) beads prederivatized with a DMTr-protected thymidine, which was linked to the solid support by a succinyl linker (see Scheme 2). The phosphoramidites were employed as 0.08 M solutions in CH_3CN; coupling was carried out in the presence of tetrazole (10 min); 3% trichloroacetic acid in CH_2Cl_2 (75 min) was used for detritylation; 3% iodine in water/pyridine/THF (2/20/75) (10 min) was employed to oxidize the phosphites to the phosphates. Average yields of coupling were determined by measuring the absorption of the DMTr cation at 498 nm released upon deprotection of the corresponding 5′-OH group.
[19] This method of analysis was developed since the oligonucleotides that still carry the PhAc-protected nucleobases cannot be analyzed unambiguously by established sequencing techniques.

A Tetrakis(imido) Phosphate Anion Isoelectronic with PO_4^{3-}

Paul R. Raithby, Christopher A. Russell,* Alexander Steiner, and Dominic S. Wright

The oxoanions of phosphorus are very numerous and exhibit great structural diversity. It is perhaps surprising then that very few analogous anions with imido groups in place of oxygen have been unequivocally identified. Recent interest in this area has been focused on cyclic PN "multianions". Lithiation of hexakis(cyclohexylamino)cyclotriphosphazene, for example, gives a complex containing $[\{NP(NCy)_2\}_3]^{6-}$.[1] In addition, recent studies on Group 16 elements have shown that the $[E(NtBu)_3]^{2-}$ dianions (E = S, Te), which are isoelectronic with the sulfite ion SO_3^{2-}, can be prepared.[2, 3] With this in mind, we wondered whether small imido phosphorus anions that are analogous to the simple oxoanions could be synthesized.

We report here the synthesis and structure of **1** (R = naphthyl, $C_{10}H_7$), which contains a $[P(NR)_4]^{3-}$ trianion that is isoelectronic with PO_4^{3-}. Complex **1** is the product of the reaction of P_2I_4 with 1-aminonaphthalene in THF/NEt_3 followed by lithiation with *n*BuLi (see Experimental Section).

$[Li(thf)_4][(thf)_2Li(\mu\text{-}NR)_2P(\mu\text{-}NR)_2Li(thf)_2]$ **1**

A low-temperature X-ray crystallographic study of **1** shows an ion-separated complex containing $[Li(thf)_4]^+$ and $[(thf)_2Li(\mu\text{-}NR)_2P(\mu\text{-}NR)_2Li(thf)_2]^-$, both of D_2 symmetry.[4] The N atoms of the anion are in a distorted tetrahedral geometry about the central P atom, and both Li cations bridge two of the N centers (Figure 1). Each Li atom has a distorted tetrahedral geometry, in which the coordination sphere is completed by two

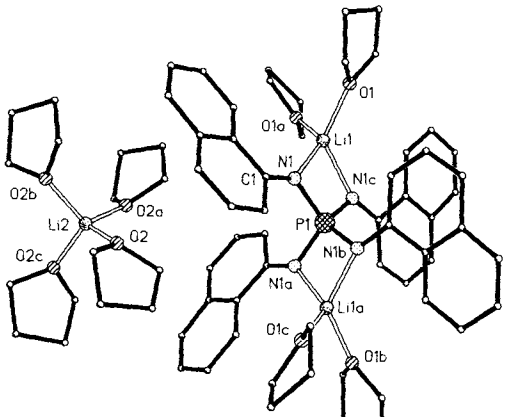

Figure 1. The crystal structure of **1**. Hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: P1–N1 1.645(4), N1–C1 1.369(6), N1–Li1 1.995(10), Li1–O1 1.99(2); N1a-P1-N1b 97.3(3), N1c-P1-N1b 113.1(3), N1c-P1-N1a 118.7(3), C1-N1-P1 123.8(3), N1-Li1-N1a 76.5(5).

THF ligands. Similar coordination of an aminoiminophosphoranate ligand to a metal center is observed in $[\{Ph_2P(Me_3SiN)_2\}Li(thf)_2]$.[5] The P–N distances in **1** (1.645(4) Å) are considerably shorter than expected for a formal single bond (cf. 1.77 Å)[6] and at the upper limit for a formal P=N (cf. 1.56–1.62 Å).[6] Studies on related PN_4 anions and cations by Schnick et al. demonstrate that the observed bond lengths can be rationalized in terms of the formal bond order and the ionic contribution to the bond. Thus, in PN_4^{7-}, which was identified from solid-state studies of alkali metal phosphorus nitrides, the very long bond (1.71 Å) has been attributed to electrostatic repulsion between the highly negatively charged N centers,[7] whereas the very short bond (1.60 Å) in the $[P(NH_2)_4]^+$ cation results from a high ionic contribution to the bond energy.[8] Evidently the bonding situation in **1** lies somewhere between these two extremes. The bond angles around the central phosphorus atom show large distortions from perfect tetrahedral geometry, presumably reflecting the strong binding of the N centers by the bridging Li atoms. Similar coordination of the related imido analogue of the metaphosphate ion PO_3^- is observed in $[(ArN)P(\mu_2\text{–}NR)_2Li(dme)]$[9] and $[(OC)_4Re(\mu_2\text{–}NR)_2P(\mu_2\text{–}NR)_2P(\mu_2\text{–}NR)_2Re(CO)_4]$.[10]

The mechanism by which **1** is formed is somewhat unclear. We have so far been unable to identify the intermediate prior to metalation with *n*BuLi. Previous reports have highlighted that the related reactions of phosphorus halides with amines are unpredictable.[11] Studies on the reactivity of P_2I_4 are somewhat scarce, but nonetheless show a high degree of complexity. For example, reactions of P_2I_4 with alcohols, amines, and Grignard reagents lead to cleavage of the P–P bond and formation of complex polymeric materials,[12] and even reactions between secondary amines and P_2I_4 are reported not to generate the simple tetrakis(dialkylamino)diphosphane.[13] We postulate that the most likely precusor to **1** is $[P(N(H)naphth)_4I]$, which forms **1** readily by deprotonation.

We are continuing to investigate the reactions leading to the preparation of **1**. In addition, we believe that the ready formation of **1** offers new opportunities in coordination chemistry as well as the possibility of higher imidophosphate homologues of general formula $[P_n(NR)_{3n+1}]^{(n+2)-}$ or cyclic imidophosphates of general formula $[P_n(NR)_{3n}]^{n-}$[14] and new isopolyanion lattices of transition metals by incorporation of imidophosphates.[15]

Experimental Section

1: NEt_3 (4 mL, 28.7 mmol) was added to a stirred solution of P_2I_4 (0.57 g, 1 mmol) and 1-aminonaphthalene (0.572 g, 4 mmol) in 10 mL of THF. A light orange solid was observed to form in the orange solution. After stirring for 16 h the reaction was filtered (porosity 3 sinter with celite) to give an orange solution. To this was added *n*BuLi (2.66 mL, 1.5 M, 4 mmol), which caused the solution to turn a lighter orange color. Removal of solvent in vacuo (to ca. 8 mL) resulted in the precipitation of an yellow solid that redissolved upon heating. Storage for 8 h at 20 °C provided yellow, rectangular blocks of **1**: 0.35 g (29.3% yield based on 1-aminonaphthalene); m.p. = 83–86°C (decomp. to a black solid); IR (Nujol): $\tilde{\nu}$ = 3022 (aromatic C–H), 1090 (P–N) cm^{-1}; ^1H NMR (25 °C, 250 MHz, [D$_8$]THF): δ = 7.8–6.6 (many muptiplets, 28H, naphthyl), 3.60 (m, 28H, THF), 1.73 (m, 28H, THF); calcd elemental analysis: C 72.5, H 7.7, N 4.7, P 2.6; found: C 72.2, H 8.0, N 5.2, P 2.6.

[4] Crystal data for **1**: $C_{72}H_{92}N_4Li_3P$, M = 596.6, orthorhombic, space group *Pban*, a = 14.557(3), b = 17.451(3), c = 14.532(3) Å, V = 3691.6(12) Å^3, Z = 2, ρ_{calcd} = 1.074 Mg m^{-3}, λ = 0.71073 Å, T = 193 K, $\mu(Mo_{K\alpha})$ = 0.089 mm^{-1}. Data were collected on a Siemens-Stoe AED with an oil-coated rapidly cooled crystal[16] of dimensions 0.5 × 0.2 × 0.2 mm in an oil drop by the $2\theta/\omega$ method ($8° < 2\theta < 45°$). Of a total of 2991 collected reflections, 2378 were independent. The structure was solved by direct methods[17] and refined by full matrix least-squares against F^2 [18] to final values of $R1$ = 0.093 ($F > 4\sigma(F)$) and $wR2$ = 0.346 (all data); largest peak and hole in the final difference map were 1.020 and −0.235e Å^{-3}. Non-hydrogen atoms were refined anisotropically, and hydrogen positions fixed geometrically. Both crystallographically independent THF molecules were disordered in two positions (occupation factors for the main components: 56.5 and 51.5%, respectively). Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-161. Copies of the data can be obtained free of charge on application to the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: Int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

Setting the Record Straight

Lise Meitner: A Life in Physics. (Series: California Studies in the History of Science, Volume 13. Series editor: *J. L. Heilbron.*) By *R. L. Sime.* University of California Press, Berkeley/Los Angeles/London, 1996. xiii, 526 pp., harcover $ 34.95.—ISBN 0-520-08906-5

Despite her significant contributions to nuclear physics and her crucial role in a scientific discovery that changed forever the world in which we live, the later years of Lise Meitner's life were marred by the disloyalty and perhaps even betrayal by her colleague of more than three decades, Otto Hahn. Furthermore, she suffered from what Ruth Lewin Sime, the author of this first (and likely to become regarded as definitive) book-length biography of the relatively neglected Austrian physicist, characterizes as "a persistent double exclusion" of the work of women scientists—both from the historical record and from the scientific record. As an avowed feminist, Dr. Sime maintains that "women have always done science, and ... the accomplishments of women, like men, have ranged from minor to extraordinary". From her childhood Sime, who has written and narrated *A Gift from Heaven*, a BBC-TV program on Meitner that was named one of the best science programs of 1992 by the Royal Society, has considered Meitner her scientific hero. Her book, long in the making, is a labor of love as well as of meticulous scholarship.

Drawing on the published literature (with references as late as 1994), interviews, Meitner's personal papers (preserved in the Churchill Archives Centre, Cambridge), correspondence, and unpublished material from German, Dutch, Danish, Swedish, and U.S. collections, Sime tells the dramatic personal and professional story of an extraordinary woman, nominated unsuccessfully several times for the Nobel Prizes for Chemistry and Physics, against a rich background of scientific, social, cultural, and political events that provide insight into and understanding of her work, her life, and the exceptionally difficult period in which she lived. In addition to a lengthy study of Hahn, she also includes character sketches of Boltzmann, Planck, von Laue, Bohr, Haber, Strassmann, Fermi, Debye, Heisenberg, and numerous other 20th-century scientific luminaries.

Like Sime, Meitner was a member of a liberal, middle-class Jewish family. Born on November 7, 1878 in Vienna, she was only the second woman to receive a doctorate in science from the University of Vienna, where she was inspired by Ludwig Boltzmann, who, unlike most professors of the time, accepted women students as a matter of course. An excellent role model for today's aspiring female scientists, who still face similar challenges (Einstein called her "our Madame Curie"), she was one of the first woman scientists to be taken seriously. Because in her native Austria she could only be a teacher rather than a research physicist, which she considered her true calling (the headstone on her grave bears the inscription: "a physicist who never lost her humanity"), in September 1907 the painfully shy young woman moved to the Universität Berlin to study with Max Planck, whom she admired with near-reverence.

Meitner was unable to find a place to work (the Chemical Institute was completely off-limits to women; Emil Fischer was afraid that they would set fire to their hair!), so when she met Otto Hahn (1879–1968), a chemist four months her junior who needed a physicist to help him with his radiochemical studies, the two young scientists, each of whom saw in the other something that he or she lacked, immediately made plans to work together. Their complementary skills resulted in an extremely fruitful collaboration; they studied every known beta-emitting radioactive source, identified several new activities, and used radioactive recoil as a powerful separation technique for discovering more.

However, after working for almost five years with Hahn, publishing twenty articles, and establishing her scientific reputation independently of him, Meitner still had no official position, no salary, and no prospects. She supplemented her parents' small allowance by translating scientific articles from English into German and by writing popular scientific articles. In 1912 she joined the newly established Kaiser-Wilhelm-Institut für Chemie in Berlin-Dahlem as an unpaid "guest," and Planck appointed her his Assistent—the first woman Assistent in Prussia—her first paid position. In 1913 she was made an Associate (Mitglied) of the institute, the same rank as Hahn's, but at a considerably lower salary, and the radioactivity section was made officially theirs—the Laboratorium Hahn–Meitner.

The two began an intriguing project, the search for the immediate precursor ("mother substance") of actinium. When World War I broke out, Hahn entered military service, working under Fritz Haber on chemical warfare, while Meitner volunteered as an X-ray nurse-technician with the Austrian army. Returning to Dahlem in October 1916, she continued to work on the project alone, keeping Hahn informed of her progress by letters. In January 1917 she was appointed head of her own physics section, the Laboratorium Meitner, with the title of Professor (the first for a woman in Germany, certainly in Prussia) and a salary equivalent to Hahn's.

By March 1918, after a five-year search, they had succeeded in discovering the elusive mother substance of actinium, which they named protactinium. Although Meitner had run the laboratory and had performed almost all the work, she listed Hahn as the senior author of their paper in *Physikalische Zeitschrift*, as she had done with every article published during this time. Twenty years later, when the situation was reversed—when she was absent from the laboratory while he carried out the experimental work—he failed to acknowledge her contribution to the discovery of nuclear fission.

By 1920 Meitner and Hahn were pursuing their separate careers, but they remained close colleagues and good friends

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

(after fifteen years they finally began using the familiar "Du" in their conversations). She had become a recognized leader in the new field of nuclear physics, and Hahn later stated that it was her reputation, more than his own, that contributed to the growing international fame of their institute.

In 1922 she received her venia legendi and became the first woman Privatdozentin in Prussia, the second in Germany. In 1926 she became "nichtbeamtete außerordentliche Professorin," making her the first woman physics professor in Germany.

In 1934, after Enrico Fermi's attempt in that year to synthesize transuranium elements by bombarding uranium with neutrons, Meitner and Hahn resumed their collaboration. In 1938 Meitner was forced to flee Germany because the Anschluss of Austria deprived her of the protection of her foreign nationality (although she had converted to Evangelical Protestantism in 1908, she was still considered "nichtarisch"—non-Aryan). After Dirk Coster, the Dutch chemist who had codiscovered hafnium, helped her enter Holland, without a passport, she emigrated to Sweden, where she never felt at home (her talents went unappreciated by Manne Siegbahn, who never considered her a member of his institute in Stockholm, where she worked). Nevertheless, Hahn's and Meitner's attempts to isolate elements beyond uranium, carried out with Fritz Strassmann, continued by correspondence (Meitner wrote to Hahn almost daily).

In December 1938, after Hahn wrote to Meitner that neutron bombardment of uranium had yielded the much lighter element barium, Meitner and her favorite nephew, Otto Robert Frisch, explained this unexpected result by postulating that the uranium nucleus had split by a process that they called "nuclear fission." Meitner was not included in the authorship of the now classic article by Hahn and Strassmann in *Naturwissenschaften* of January 6, 1939, and when Hahn accepted the 1944 Nobel Prize for Chemistry in Stockholm in December 1946, he still did not give her adequate credit for her part in their three-decade-long collaboration.

The same racial policies that had driven Meitner from Germany had made it impossible for her to be part of their publication and dangerous for Hahn to acknowledge their continuing collaboration. However, even after the fall of the Third Reich and for the rest of his life, Hahn insisted that the obviously interdisciplinary discovery relied on chemistry alone and that Meitner and physics had nothing to do with it except to prevent it from occurring sooner (actually, it was Meitner who had proposed the experiment that showed their supposed radium to be barium). Yet Strassmann always considered her "the intellectual leader of our team" and maintained that her "thought processes were present even when she was not, kept alive by the criticisms, questions and suggestions in her letters."

Except for a few brief statements, Meitner did not campaign on her own behalf and did not write an autobiography or authorize a biography. Preferring to remember the good times, she remained friends with Hahn until his death on July 28, 1968. She died in Cambridge, England, still an exile (she had declined Strassmann's request that she return to her former position), on October 27, 1968, a few days before her ninetieth birthday.

The distortion of reality and suppression of memory are recurrent themes in any study of Nazi Germany and its aftermath, and Sime devotes considerable space to a detailed chronology of the discovery and the unrecognized dishonesty, uncritical acceptance, and deliberate perpetuation of Hahn's version of events. For 35 years the Deutsches Museum displayed the fission apparatus as part of "Arbeitstisch von Otto Hahn" with no mention of Meitner until 1990, when input from women's groups and historians of science, including Sime, caused the error to be corrected. In 1991 the museum added to its Hall of Honor (Ehrensaal) a bust of Meitner, the first woman to be so honored. With the recent proposal of the Society for Heavy Ion Research (GSI) in Darmstadt that element 109 be named "meitnerium," the reassessment of Meitner's contributions by a new generation of scientists and historians, foreseen and encouraged by Sime in her engrossing, poignant, and balanced biography, seems well on the way to fulfillment.

Deciphering the Chemical Code. By *N. D. Epiotis*. VCH Verlagsgesellschaft, Weinheim, 1996. 933 pp., hardcover $ 89.95.—ISBN 1-56081-946-4

In 43 chapters and more than 900 pages Nicolaos Epiotis has set out in this book to present an entirely new general approach to understanding the chemical bond. It is in effect a continuation of two volumes on "Unified Valence Bond Theory" that were written over ten years earlier by the same author [*Lecture Notes in Chemistry*, Vol. 29 (**1982**); Vol. 34 (**1983**), Springer, Berlin]. The author starts out from the contentious premise that there have been no significant advances in the fundamental understanding of chemical bonding during the last few decades, since the work of Lewis, Pauling, and Hückel. That situation is about to be changed, according to the author, through the presentation here of "... the first post-Pauling theory of chemical bonding, in the essentials rather than in baroque details." After the tone has been set thus, it comes as no surprise to the reader when the entire edifice of the generally accepted qualitative understanding of chemical bonding is dismantled, leaving no stone resting on another. Covalent and ionic bonding, the concept of aromaticity, the Woodward–Hoffmann rules, resonance, hyperconjugation, isolobal analogies, and much more besides, are disqualified as being unhelpful notions which distract attention from the true nature of bonding. The author's rejection of conventional ideas is usually expressed in forceful language. This can actually be quite entertaining at times, as the following examples will illustrate. Thus we read: "... there seems no end to the monographs purporting to interpret chemistry through the concept of 'orbital interactions.' The idea is too simple to be resisted. But it has no connection with reality." At another point we find: "Unfortunately, the investigators use MO theory, and this turns simple problems to obscure riddles." What, then, is to be put in place of the conventional methods for the analysis of chemical bonding? The central tenet of the new viewpoint is that the one key element in all the different bonding situations is the repulsive electron–electron interaction. According to Epiotis, it is exactly this repulsion that is ignored or not sufficiently taken into account by bonding theories based on molecular orbital arguments, such as the Hückel approximation or the independent particle model. As a way around this difficulty the author chooses non-orthogonal valence bond theory (VB), which then serves as the foundation for the Epiotis model of bonding. According to the author the VB theory not only correctly takes into account the multideterminant character of the molecular wave-functions, but also allows one to form a visual picture of the different types of bonding, which can be understood easily even by those with little knowledge of the subject ("... we can rationalize old

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3606-0652 $ 17.50+.50/0

controversial trends and we can predict new chemistry in a fraction of a page").

The first part of the book is an introduction in which the required toolkit, namely the non-orthogonal VB theory, is briefly explained. The three different types of bonding that emerge from the analysis of the interactions in covalent and ionic VB structures are then defined, and are called the T, I, and E types. Of these the T bond corresponds most nearly to the conventional covalent bond, but in addition to the "perfect-pairing" VB structure it also takes into account the repulsion caused by the interaction between the electrons. If, on the other hand, the bonding is dominated by VB structures in which delocalization with charge transfer is combined with dispersion and induction, the bond is of the I type, which has no equivalent in conventional theory. Lastly, where the interactions are purely electrostatic (again in combination with dispersion and induction), we have an E bond.

This introductory part is followed by a second part (over 800 pages) in which the author sets out to illustrate the usefulness of this new theory of bonding. The many examples described here encompass an enormous range of topics, providing ample justification for the book's subtitle "Bonding Across the Periodic Table". Starting with an analysis of bonding in diatomic systems, the author goes on to consider typical problems in organic, organometallic, and inorganic chemistry, followed by discussions of the electrical, magnetic, and materials properties associated with various molecules. The discussion then moves on to biochemical problems and to the design of new superconductors with high transition temperatures, finally culminating in some considerations regarding cold nuclear fusion. Each example is interpreted in great detail from the standpoint of the theory of T, I, and E bonding. In the course of this the author does not tire of repeating over and over again his message about the inadequacy of conventional interpretations based on a one-electron picture.

So what is one to make of this theoretical model which aims to "decipher the chemical code"? Does it live up to the claim in the preface that the ideas of Lewis, Pauling, and Hückel would be left behind and replaced by a new and rigorous picture of chemical bonding that is consistent with the underlying physics? Of course the reader must be allowed to form his or her own conclusions. My personal impression is rather ambivalent, for the following reasons. The Epiotis model undoubtedly yields some original, and sometimes surprising, answers to many of the questions regarding structure and energetics that are touched on here. Furthermore, the criticisms expressed here against treating complex bonding situations by the naive and uncritical application of greatly simplified models, such as the HMO picture, are largely justified. However, one is annoyed by the author's tendency to present this theoretical approach as being entirely new and unique, and the only hope of salvation. In fact, some of the considerations based on VB theory, for example those used in defining the I-type bond, are by no means new. (Here I have in mind studies such as those by Shaik, Hiberty, and co-workers, although these authors did not find it necessary to introduce an entirely new terminology along with their results.) Also, many of the supposedly unsolved problems discussed in the book have already been answered by a full interpretation, which in many cases is very close to that offered here; however, these facts are scarcely ever mentioned by Epiotis. Instead the reader is confronted by a bewildering number of new expressions (a few examples: bicratic transition state, phantom bonding, frustrated molecules, systolic group). These are often a hindrance to following the discussions, despite the glossary provided. Often the author causes further unnecessary difficulties for the reader through his wish to present his views as new and revolutionary, rather than as a development from earlier ideas. This is reflected in the bulkiness of the book, in the introduction of so many new definitions that one can scarcely take them all in, and in the frequent digressions that occur in many of the chapters. The many printing errors and the poor quality of the figures, which are often difficult to understand, add to the problems.

Do the changes proposed by Epiotis have a chance of being adopted? Are we likely in the future to abandon covalent, metallic, and ionic bonding and instead talk of T, I, and E bonds, and to replace the Lewis-type structural formulas by T formulas and "arrow trains"? That seems scarcely possible. The model is too complex and it requires too drastic a departure from our familiar concepts. Moreover, the present situation with conventional theories is not so hopeless as Epiotis would have us believe. Nevertheless, many of the ideas put forward in the book are important, useful, and original. They may well serve to make us take a fresh look at the familiar well-trodden paths in the interpretation of bonding, and may draw attention to the fact that reducing the wave-function to a single-determinant representation and essentially neglecting the electron repulsion may often be a dangerous over simplification.

Lastly, we come to the question of who should buy this book. I cannot agree with the claim on the dustcover that it is "required reading for anyone who is seriously interested in understanding the nature of the chemical bond". However, it certainly offers entertaining reading for those who have the time and perseverance to work through it, and who enjoy encountering new and unconventional ideas.

Physical Inorganic Chemistry. A Coordination Chemistry Approach. By *S. F. A. Kettle*. Spektrum, Heidelberg, 1996. 490 pp., paperback £ 25.00.—ISBN 0-7167-4514-3

It is the objective of this book to bridge the gap between inorganic and physical chemistry by treating physical chemistry topics that are of relevance to inorganic chemistry. This treatment is focussed on coordination chemistry and embraces such topics as bonding theories, spectroscopy, magnetochemistry, thermodynamics, reaction kinetics, bioinorganic chemistry, solid state chemistry, and cluster chemistry. Furthermore, it is a largely non-mathematical text which bridges the gap between low-level treatments currently available and those at the specialist, research level.

The author introduces the topic in the first five chapters (covering almost 100 pages) in which he focusses on typical ligands and complexes, nomenclature, geometrical structure and isomerization of coordination compounds, preparation of coordination compounds, and their stability. This is the type of material usually found in standard coordination chemistry textbooks. In the following chapters, three are devoted to an impressive treatment of bonding theory for transition metal complexes. This includes molecular orbital theory (Chapter 6), crystal field theory (Chapter 7), and ligand field theory (Chapter 10). Electronic spectra and magnetic properties of coordination compounds are treated in Chapters 8, 9, and 11. The presentation of the theories and the spectroscopic and magnetic properties is very systematic and easy to follow, and is highly suitable for students of inorganic chemistry.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3606-0653 $ 17.50+.50/0

These chapters are followed by a presentation of other methods of studying coordination compounds (Chapter 12), including IR, Raman, NMR, NQR, EPR, photoelectron spectroscopy, cyclovoltammetry, and X-ray diffraction. Chapters 13 and 14 cover the thermodynamics and reaction kinetics of coordination compounds, respectively. The last three chapters are devoted to bonding in cluster compounds, some aspects of bioinorganic chemistry, and an introduction to solid state theory. Here again the treatment of bonding in clusters and in the solid state is presented in a clear and convincing manner. In addition, the author supplies 14 appendixes that cover such topics as: the conformation of chelate rings, the VSEPR model, an introduction to group theory, the Russell–Saunders coupling scheme, ligand σ group orbitals of an octahedral complex, Tanabe–Sugano diagrams, group theoretical aspects of band intensities, magnetic susceptibility, high temperature superconductors, and bonding between a transition metal atom and a C_nR_n ring.

In general, as mentioned above, the presentation of the chapters dealing with bonding theory and its direct application (spectral and magnetic properties) is entirely suitable for students of inorganic chemistry. However, the title of the book is much more general, since in focussing on physical inorganic chemistry it includes other aspects in addition to bonding and related properties. There are many more physical chemistry topics addressed in the other chapters that are difficult to understand from a coordination chemistry point of view. Unfortunately, the treatment of topics not related to bonding, such as other methods of studying coordination compounds (Chapter 12), reaction kinetics of coordination compounds (Chapter 14), and some aspects of bioinorganic chemistry (Chapter 16), is not satisfactory. There are so many important physical aspects that needed to be covered in these chapters, but the treatment is too superficial and does not meet the standard set by the other, bonding related, chapters. Bonding is certainly important in coordination chemistry, but reactivity is just as important and should be treated equally thoroughly.

The technical quality of the presentation is excellent, the figures are very clear, and at the end of each chapter there are suggestions for further reading, as well as a series of exercise problems. The author has filled the gap between physical and inorganic chemistry in an impressive way, and the book is highly recommended to all students working in coordination chemistry.

Introduction to Molecular Dynamics and Chemical Kinetics. By *G. D. Billing* and *K. V. Mikkelsen*. Wiley, Chichester, 1996. 104 pp., hardcover £ 40.00.—ISBN 0-471-12739-6

This book is described on the back of the dustcover as "the most complete introduction available to molecular dynamics and the calculation of rate of reaction". In their preface the authors explain where they start out from and what they aim to achieve. Whereas most standard works on physical chemistry merely sketch the basic ideas of reactive scattering and the theory of the transition state, their approach was to begin by explaining these concepts more precisely, and use this as a basis for what follows. According to the authors, the distinctive feature of this book is that it also develops the concepts of molecular dynamics and reactions in solution. With this approach, one should then be able to consider reactions in the gas phase, on surfaces, and in solution in relation to each other.

In fact there is as yet no suitable textbook to *explain* and *guide* the student through the important concepts of the dynamics of elastic, inelastic, and reactive collisions, classical molecular dynamics, the theory of the transition state, and stochastic effects in solution. There are a number of excellent introductions to these individual subjects, but before the student goes into any one of these in detail it is certainly desirable to have a clear overall understanding of the many different aspects of reaction dynamics. To cover all that in a single semester is a very ambitious program (this introductory treatment is based on the authors' course of lectures for third-year physical chemistry students), and one has to concentrate on certain essential aims. Thus, the basic concepts and purpose of each area studied must be presented concisely, and the essential foundation knowledge must be conveyed clearly and accurately, without unnecessary formal ballast. The special attraction and value of a good survey is that it should give the student an appreciation of the relative importance of the various topics, their interrelationships, and their common features.

With these expectations in mind, we open the book and find that it consists of 16 chapters. First some important concepts of reactive scattering are introduced: interaction potentials, relative motion, and the collisional approach. Next there are several chapters on the theory of the activated complex: partition functions, transition state theory, unimolecular reactions. The authors then return to the question of time-dependence, with chapters on classical dynamics and nonadiabatic transitions. The above topics are covered in 59 pages. There is then a slightly longer section (63 pp.) on surfaces and reactions in solution (with the main emphasis on the latter): surface kinetics, chemical reactions in solution, solvent effects, models for reactions in solution, Kramers' theory, and electron transfer. In addition each chapter contains a brief, but adequate and mostly well-chosen, list of references, and a number of exercises. There is an appendix containing integrals and functions, an explanation of the Laplacian transformation, basic aspects of the statistical mechanics of systems in equilibrium, and notes on dielectric polarization and solvation. Lastly there are some hints for solving the exercise problems. The whole book is in the style of brief lecture notes. Set up like stepping stones for exploring the various topics, and some of the essential steps are treated in the form of exercises.

Unfortunately, one is seldom aware of the internal structure, and this can lead to confusion in view of the abbreviated style of presentation. An example of this is seen in the chapter on the relative motion of two colliding particles. Here the introductory section defines the total *momentum* and the relative *velocity*, and expresses the velocity vectors of the two particles in these terms. Introduction to kinetic energy then leads to a term that later turns out to be the kinetic energy of the center of mass. Only then do the authors introduce the relative positional vector and the positional vector for the mass center. From the introductory discussion of the translational momentum of a particle, by involving the total and relative momenta and differentiating with respect to time, the authors then obtain the force as a function of distance (mentioned here for the first time, with the implicit assumption that no external fields are present), and hence the equation of motion for the relative positional vector. Next the kinetic energy for the relative motion is introduced, expressed in terms of the time-variation of distance and angle. Then the authors present us with a new form by introducing, without expla-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3606-0654 $ 17.50+.50/0

nation, an initial condition for this energy, with an impact parameter. This contains an expression represented by the symbol L, which is the contribution of the orbital angular momentum. The authors then derive an expression for an effective potential.

This procedure is confusing. Here the most natural order should instead be as follows: First, the potential and kinetic energies are written as functions of the laboratory coordinates and velocities. A transformation to the center of mass separates its kinetic energy. Next comes a transformation to the relative position and its velocity; both are then expressed in polar coordinates and angular velocity. Formation of the (conjugated) orbital angular momentum L gives an expression of the angular velocity by L. At this point one changes to a Hamiltonian description with regard to the orbital angular movement. Conservation of L allows its description by the initial conditions; finally an effective potential is obtained.

As a second example let us consider the sequence of steps in developing expressions for the effect on a chemical reaction of the fluctuating forces caused by the solvent. First the diffusion coefficient D_i is introduced by the expression for the current density for the molecular species i, $J_i = -C_i D_i \operatorname{grad} \mu_i / RT$. This is then used to derive Fick's first law. There then follows a section on diffusion as a random walk, without mentioning that here the transition probability is shared in equal parts with the nearest neighbors. However, the identification of the diffusion coefficient has to wait until Fick's second law is treated in the next section. In another section Brownian motion is treated in a formal way, which makes it difficult to understand. Later, much space is devoted to the diffusion (of position and velocity) in a potential, even including a derivation of the Klein–Kramers equation for a Brownian oscillator. Both these topics are actually treated in a more easily understandable way in the first five pages of Kramers' original paper (*Physica* **1940**, 7). Moreover, the authors have failed to include the extension to the case of high frictional coefficients (the Smoluchowski equation), which would have led on naturally to Fick's second law.

The figures do not always help the reader's understanding. In the chapter on classical dynamics, coordinate systems for describing the motion of B–C relative to A are shown. One coordinate system has A as its origin, and the figure shows the mass centre of B–C and the relative position vector. But there is also a second coordinate system with its origin at the mass center of B–C, and a special notation is used to describe positions in this system. However, in this context the second system is completely unnecessary! Another figure in this chapter purports to show how the coordinates transform when the reference frame is moved from the mass center of B–C to that of A–C. The relative positions of A, B, and C should be the same in the two coordinate systems, but the figure shows two different configurations! A figure in the chapter on chemical reactions in solution intends to visualize a "Brownian particle". This consists of a dumb-bell within a frame, and it is surrounded by concentric rings whose significance is never established. These are just a few of the many figures that convey nothing, are likely to mislead, or are simply incorrect.

The overall impression is as though, in some strange way, the book has been written in a succession of forward leaps alternating with backward steps, and it also contains many small errors. Consequently, reading through it is unnecessarily hard work. It therefore seems rather unlikely to help kindle students' enthusiasm for microscopic reaction dynamics and chemical kinetics.

Directory of Solvents. Edited by *B. P. Whim* and *P. G. Johnson*. Blackie/Chapman and Hall, London, 1996. 612 pp., hardcover £ 149.00.—ISBN 0-7514-0245-1

If one needs to choose a suitable solvent for a particular chemical reaction or technological process from the vast range nowadays available, on the basis of objective criteria, the task of extracting the necessary chemical, physical, toxicological, and other data from the literature can often be very laborious. The handbook reviewed here should prove to be a valuable aid in such cases, especially when organic solvents are to be used in technological processes.

Part 1 of the book, entitled "Solvents", treats the more general aspects. The eight chapters (the work of nine authors altogether) discuss the criteria for making a correct choice of solvent and using it most effectively. In a short introductory chapter ("Introduction to Solvents") P. Davison explains the classification of solvents, describes how they are manufactured, and discusses the quantities consumed, their environmental acceptability, and their toxicity to humans. Chapter 2, "Solvent Action and Measurement", by W. C. Aten, is mainly concerned with intermolecular solvent–solvent interactions, the Hildebrand and Hanson solubility parameters, and the solvation power, volatility, and viscosity of solvents. The next chapter, also by Aten, is entitled "Choosing a Solvent: Practical Advice", and relates particularly to the choice of solvents or solvent mixtures for manufacturing solvent-borne and water-based paints. In Chapter 4, "Solvent Flammability and Reactivity Hazards", R. L. Rogers explains the numerical properties such as flashpoint and explosible limits that determine the flammability of a solvent, an aspect of particular importance when dealing with large quantities, and describes the procedures that are demanded by legal regulations. In Chapter 5, "Protection of Health", A. M. Moses describes the various health hazards that can arise in handling solvents, and the precautions for minimizing them. Aspects that receive special attention include the toxicities of particular solvents or groups of solvents, the correct preparation of safety data sheets, measures of inhalation toxicity (e.g., MAK and TRK values), and the legislation governing these matters in the European Union, the UK and the USA. Chapter 6, by I. D. Dobson, A. S. McCormick, and D. A. King, is entitled "Solvents in the Environment". The authors describe the damaging effects of solvents on the earth's atmosphere, such as the destruction of ozone in the stratosphere by CFCs, and the toxic effects on aquatic and terrestrial environments, which are still insufficiently studied. In Chapter 7, "Solvent Transport, Storage, Recovery and Disposal", G. P. Howe explains the classification of solvents and the international regulations governing their transportation, storage, recovery, and disposal, and describes the most important methods that have been developed for the last two of these. In the last chapter of this part, under the title "Major Solvent Applications Overview", J. R. Kelsey summarizes the most important technological applications of organic solvents. In Europe in 1994 the manufacturing areas that consumed the largest quantities of solvents (leaving aside their use as chemical intermediates) were, in descending order of bulk: paints of all kinds, pharmaceuticals and agrochemicals, printing inks and adhesives of all kinds, cleaning fluids, and household products.

Part 2 of the handbook ("Solvent Data") occupies the greater proportion,

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997* *0570-0833/97/3606-0655 $ 17.50+.50/0*

about 70% of the whole, and contains data on over 350 organic solvents. These are arranged according to compound classes, listing (in SI units) the properties that are important in relation to their technological use. The data have come mainly from the manufacturers and suppliers of the solvents. In addition to the usual physical properties the compilation lists up to 37 further properties for each solvent. Among many others these include the solubility in water, the solubility of water in the solvent concerned, the solubility parameters, surface tension, heat of combustion, and TLV and MAK values. There are also seven "key parameter tables", in which all the solvents are again listed, but here in increasing order with regard to the different properties, namely boiling point, melting point, evaporation rate, vapor pressure, flashpoint, solubility parameter, and auto-ignition temperature. To complete the book there are separate lists giving the chemical names and trade names of the solvents, addresses of manufacturers and suppliers, and lastly a subject index. Surprisingly, there is no reference anywhere in the book to empirical solvent polarity parameters, of which a great number have been published, and which are easily accessible on the basis of linear free energy relationships. This is an unfortunate omission, since these parameters can be extremely useful for quantitatively predicting the effects of solvents on reaction rates and equilibria, and on the spectroscopic properties of dissolved substances. The use of empirical solvent polarity parameters for the correlation analysis of solvent-dependent rate constants and equilibrium constants should at least have been mentioned.

To sum up, this handbook is a very useful, reliable, comprehensive, and up-to-date collection of data on organic solvents, which are essential for chemists in industry and universities whenever there is a need to choose the best solvent for a specific purpose from the large number that are available commercially. It should be in every library. Furthermore, anyone who frequently has to deal with solvents would benefit from having it beside the workbench or desk.

der Universität Marburg (Germany)

Chemistry of the Environment. By *T. C. Spiro* and *W. M. Stigliani*. Prentice Hall, Upper Saddle River, NJ, 1996. 356 pp., hardcover $ 59.33. – ISBN 0-02415261-7

Our overall reaction to this book is very positive. The authors state that the book is about environmental issues and the chemistry behind them; it aims to deepen knowledge of chemistry and of the environment and to show the power of chemistry as a tool to help us comprehend the changing world around us. To this end, the authors have provided a concise, comprehensive, and readable text on basic environmental chemistry. They have successfully covered the most important environmental topics and their chemical basis in the 347 pages of text.

The book is, basically, an outgrowth of the authors' earlier two books, *Environmental Issues in Chemical Perspective* (1980) and *Environmental Science in Perspective* (1980), but the text has been completely rewritten, and the contents and figures have been modified to reflect new information. The literature is well documented up to 1995 with a reference from 1996. The visual presentation has also been improved markedly. The cover is much more attractive. The text format is presented in such a way as to make the text more easily read and understood by students. Many of the diagrams and figures look much more professional.

Like the earlier two books, the text is organized in four main parts: Energy, Atmosphere, Hydrosphere, and Biosphere. Part I (Energy) is well written. It presents a survey of various energy resources, and considers the production, consumption, advantages, and disadvantages of each form of fossil energy (petroleum, natural gas, and coal) and of nuclear energy (fission and fusion). With the predicted exhaustion of clean fossil fuels, alternative energy sources will be needed. Environmental considerations limit the suitability of high-sulfur coal or nuclear fission as the successors to petroleum and natural gas. Solar energy is clearly a favorite choice of the authors as a future energy source. Some other alternative energy sources, such as biomass, water, wind, tides, geothermal, and ocean thermal gradients are also discussed. The last section of Part I deals with energy efficiency, fuel cells, and energy conservation. Part II (Atmosphere) is the strongest part of the book. It contains a discussion of the earth's radiation balance, atmospheric chemistry, and air pollution. Topics include solar radiation, scattering by clouds and aerosol particles, molecular absorption, the greenhouse effect, climate change, free radical formation, ozone depletion, and photochemical smog. The authors discuss a number of important air pollutants, such as greenhouse gases, CFCs, CO, SO_2, NO_x, volatile organics, ozone, particulate matter, and lead, and their control. Part III (Hydrosphere) deals with water resources, acidification caused by acid rain and acid mine drainage, water hardness and soil neutralization, detergents, redox chemistry, eutrophication, water pollution, and water treatment. Part IV (Biosphere) is the most interesting topic. It concerns the relationship between chemicals and living things. The nitrogen cycle, agricultural pollution, nutrition, insecticides, herbicides, insect control, bioaccumulation, mutagenesis, carcinogenesis, hormonal effects, and the toxicity of organic pollutants (dioxins and PCBs) and heavy metals (Hg, Cd, and Pb) are covered in this part. Each part of the text ends with a summary, a set of interesting exercises, and a list of suggested reading material.

The book is designed to be used in either a one- or two-term undergraduate environmental chemistry course. It seems much more suited to the former. Instructors who teach environmental chemistry in two terms rather than one would complain that the book is a little too brief on most topics. Although the authors have assumed only a background in general chemistry, some organic chemistry is included. In the opinion of these reviewers, students who have had a one-term course in organic chemistry would be in a much better position to make maximum use of the book, particularly with respect to the discussion of nutrition and pesticides in Part 4. The book certainly lacks a detailed discussion of the principles of photochemistry and a discussion of some of the proposed mechanisms of photochemical smog formation. It is not possible to treat some of the more important aspects of atmospheric chemistry without a basic understanding of photochemistry.

In summary, this book provides an excellent picture of current environmental chemistry. It can be highly recommended as a one-term textbook for advanced undergraduates, and as a general reference source for professionals who are concerned with our environment.

Electrochemical Processes for Clean Technology. By *K. Scott*. Royal Society, London, 1995. 307 pp., hardcover £ 59.90.—ISBN 0-85404-506-0

The author of this book is an internationally recognized expert in electrochemical engineering. The first part of the book (about one-third) is a concise, well written, and highly informative survey of the overall field from the author's particular viewpoint. The remainder of the book consists of three roughly equal sections devoted to currently important environmental aspects of electrochemical technology. Two of these are concerned with electrochemical separation from industrial product streams and effluents, firstly of heavy metals in trace concentrations, and secondly of other organic and inorganic species. The third area is the environmental aspects of organic and inorganic electrosynthetic processes. The broad theme of the discussions is already evident from the book's title. More particularly, however, the author's emphasis is clearly towards the strategy of after-treatment, a purpose for which the intrinsically costly electrochemical technology is almost too sophisticated. The approach of integrating environmental protection measures into the process at the outset, which has greater potential for the future, is first mentioned only as a side-issue in the third of these sections. Many other relevant areas are not treated at all. These include, for example, electrochemical surface technology (electrochemical surface coating using water-dispersible binders, as an alternative to spraying or dipping processes that use solvent-borne coatings), rechargeable batteries (Zn/MnO_2, zinc/air, or metal-free systems based on graphite, coal, or cheap conducting polymers, as alternatives to conventional lead or cadmium batteries), and fuel cells (giving thermodynamic efficiencies of 50–70%, compared with 10–25% for conventional forms of energy conversion). These important topics are essential to an appreciation of the full potential of electrochemical technology, and should perhaps be covered in the future.

However, subject to the above reservations, the book can be recommended. It is relatively inexpensive, and can therefore be considered for addition to one's personal library. For readers interested in environmental technology generally, the book will serve as a reliable guide to the three areas covered in the second part.

Finally, some comments on matters of detail, which, despite criticisms here and there, do not significantly affect the above favorable verdict. On page 11 and elsewhere the author rightly draws attention to a serious problem with the electrolysis of aqueous effluents, the possibility that organochlorine compounds may be formed, as there will nearly always be enough chloride ions present for this to occur. In Figure 1 (p. 16) the ordinate scale should be labeled "ln j_{lim}". The stable ions in the lower part of Table 2 (p. 27) are, of course, (quaternary) ammonium ions. In Figure 11 (p. 81) the cell shown on the right is described as a bipolar electrolyzer, whereas it is in fact monopolar. On pages 233–234 the importance of heterogeneous redox catalysis is correctly pointed out, but the two examples chosen are rather unsuitable. In Equation (10) on page 233 it seems only at a second glance that the symbol $\langle\rangle$ is supposed to represent a benzene ring. In the discussion of the mechanism of the electrohydrodimerization of acrylonitrile to adiponitrile on pages 236–237, the protonation of the primary radical ion is *not* a very rapid reaction; also, in Equation (17) the negative charge on the carbanion is missing, and there is no mention of the possibility that (anionic) oligomers may be formed if the protonation of the *dimeric* anion is too slow. The "Cd removal" in this process is not mentioned. In Equation (41) on page 243 the product, 2-hydroxytetrahydrofuran, can be obtained much more easily (and cheaply) from tetrahydrofuran in dilute sulfuric acid, by selective anodic oxidation on platinum with a high current density. In describing the nowadays very important electrochemical syntheses of H_2O_2, peroxydisulfate, and ozone, on pages 268–271 and 273–276, it would have been useful to mention the monographs by A. Schmidt and A. T. Kuhn. Lastly, one of the very attractive aspects of electrochemical technology is the possibility that dangerous and highly toxic chemicals may be generated on site; the example of arsine on pages 286–287 is a good illustration of this.

The diverse chemistry of the xanthates encompasses mainly radical processes. For instance, irradiation with visible light generates radicals that can be trapped with alkenes or can provide other radicals through elimination reactions. In contrast, *S*-propargyl xanthates react to form betains that have novel structures. More on xanthates is presented on the following pages.

On the Trail of Xanthates: Some New Chemistry from an Old Functional Group

Samir Z. Zard

Dedicated Professor Sir Derek Barton

The use of free radical reactions in organic synthesis has witnessed an extraordinary development in recent years. When properly conceived, radical processes often exhibit many of the properties desired by synthetic organic chemists, such as flexibility, mildness, and selectivity. Unfortunately, the number of synthetically useful radical-generating systems is still limited, and most applications have relied on tin hydride chemistry. Secondary *O*-alkyl-*S*-methyl xanthates, for example, react with tributyltin hydride to give the corresponding alkane (the Barton–McCombie reaction). It was, however, found that the isomeric *O*-methyl-*S*-alkyl xanthates undergo cleavage of the weaker carbon–sulfur bond and that a chain reaction can be sustained without tin or other heavy metals. A variety of synthetically interesting free radicals can thus be produced and captured, the last propagating step being a reversible transfer of the xanthate group. *S*-Propargyl xanthates represent a special class. Their radical chemistry can be easily overshadowed by hitherto unknown but equally interesting nonradical behavior. Upon heating, a thermal [3,3] sigmatropic rearrangement occurs to give the allenyl isomer, which is in equilibrium with a novel betaine structure. This species is at the heart of a number of new transformations, including formal [3+2] cycloadditions, formation of esters with inversion in the case of secondary alcohols, conversion into 1,3-dithiol-2-ones, generation of cisoid dienes, carbon–carbon bond formation through reaction with acid chlorides etc. This account provides a brief description of this original radical and nonradical chemistry of xanthates, an old family of compounds that still harbors many mysteries.

Keywords: alkynes · C–C coupling · cycloadditions · radicals · xanthates

1. Introduction

Xanthates, now classed under the more systematic but less evocative name of dithiocarbonates (or carbonodithioates), have been known for almost two centuries. Xanthate salts for example were reported as early as 1822 by Zeise;[1] yet, in comparison with other functional groups, their chemistry has remained largely unexplored. A chemist's first encounter with xanthates is usually through the Chugaev elimination[2] and perhaps as intermediates in the manufacture of viscose from cellulose.[3] Later, budding organic chemists eventually come across the more recent Barton–McCombie reaction[4] for deoxygenating secondary alcohols. Unlike the widely known but little used Chugaev elimination, the Barton–McCombie radical deoxygenation has had a major impact in organic synthesis, especially for the modification of carbohydrates, and as a convenient source of radicals from alcohols in general.[5] A chance observation made in the course of a mechanistic study of this important reaction started our exploration in this area. Our peregrinations were hardly planned from the outset; we simply went where the chemistry took us. The main purpose of this review article is to relate our findings in a brief, candid manner.

2. Radical Reactions of Xanthates

2.1 The Story of a Discovery

The Barton–McCombie reaction was conceived on the basis of the mechanistic reasoning shown in Scheme 1.[4] The well-known affinity of tin for sulfur was used to advantage by treating stannyl radicals with the thiocarbonyl group of a xanthate such as **1**, with the expectation that the intermediate adduct **2** would undergo a preferential β-scission of the carbon–oxygen bond to give radical R$^{\bullet}$. Hydrogen abstraction from tributyltin hydride provides the desired alkane and a tributylstannyl radical to propagate the chain. The logical co-product **3** is unstable with respect to elimination of carbon oxysulfide. In practice the process works best with xanthates derived from secondary alcohols. Deoxygenation of primary alcohols usually requires higher reaction temperatures and yields are not always satisfactory,

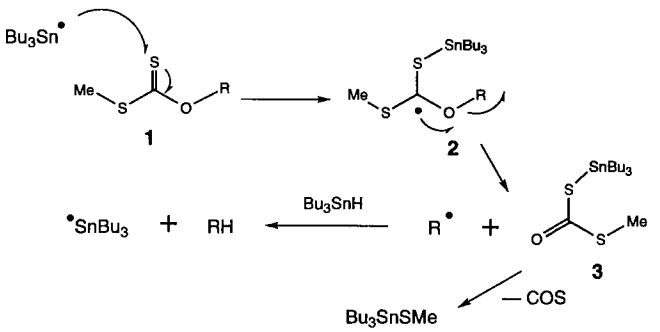
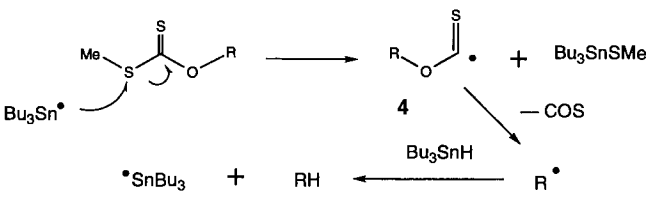


Scheme 1. The original Barton–McCombie mechanism.

whereas xanthates of tertiary alcohols are especially prone to Chugaev elimination and are thus difficult to handle in general.[4]

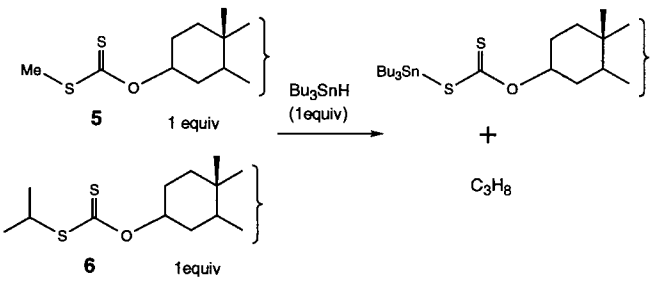
Almost a decade later, the mechanistic picture put forward by Barton and McCombie was questioned by Beckwith and Barker,[6] who observed an ESR signal corresponding to the hitherto unknown alkoxythiocarbonyl radical **4** when a xanthate was irradiated in the presence of hexabutyldistannane. Although these conditions are not those normally applied in the deoxygenation, this finding raised the possibility of an alternative route (Scheme 2) whereby the stannyl radical, in fact, reacts



Scheme 2. The Beckwith–Barker mechanism.

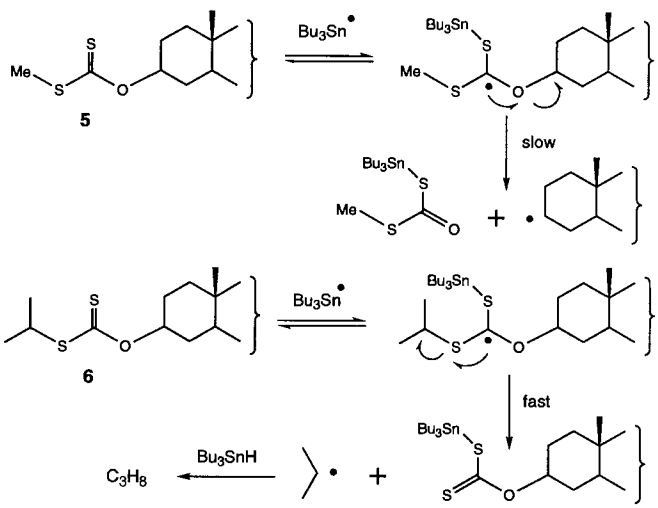
with the sulfide sulfur atom. The alkoxythiocarbonyl radical **4** created by this S_H2 process was assumed to extrude carbon oxysulfide by analogy with its oxygen counterpart, which was known to lose carbon dioxide.

The paper of Beckwith and Barker triggered a more systematic study in the Barton group, and the results strongly supported a slightly modified version of original mechanism.[7] Reaction on the thiocarbonyl group rather than on the sulfide sulfur atom was further confirmed by an elegant trapping experiment by Bachi and Bosch.[8] In retrospect, one of the key experiments in the Barton study[7] was to allow an equimolar mixture of *S*-methyl and *S*-2-propyl xanthates derived from cholestanol (**5** and **6**) to compete for one equivalent of stannane (Scheme 3): If attack occurs on the sulfide sulfur atom, steric hindrance should slow the reaction of the isopropyl derivative. If the thiocarbonyl group was the reacting center, little difference in the rates would be observed. Unexpectedly, the outcome of the actual experiment was neither of these two possibilities. As it turned out, the isopropyl analogue **6** reacted much faster than the methyl derivative **5**, which was recovered largely unchanged. And the product was not cholestane, as would be anticipated from a Barton–McCombie reaction, but propane!



Scheme 3. The key competition experiment.

Two conclusions, summarized in Scheme 4, could be drawn from this experiment : a) the addition of the tin radical on the



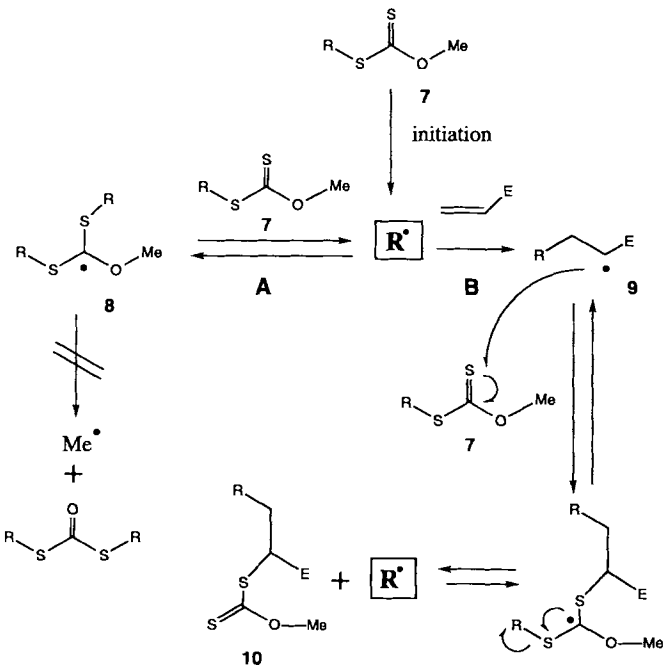
Scheme 4. Mechanistic rationale for the competition experiment.

Samir Z. Zard was born in 1955 in Ife, Nigeria. His training as a chemist started at the American University of Beirut, then at Imperial College, London, and finally at the Université Paris-Sud, France, where he received his doctorate under the supervision of Professor Sir Derek Barton. In 1981 he began working at the Centre National de la Recherche Scientifique (C.N.R.S.), but at the same time remained member of the group of Professor Barton at the Institut de Chimie des Substances Naturelles in Gif-sur-Yvette. When Professor Barton moved to the Texas A&M University in far distant College Station, Zard took up an additional part-time post as lecturer at the Ecole Polytechnique in Palaiseau—only 6 km from Gif. His main research interests concern the study and development of new reactions and processes.

thiocarbonyl group is fast and *reversible*, and b) the rate-determining step is β-scission of the carbon–oxygen or the carbon–sulfur bond, the latter being the preferred mode (at least kinetically) when radicals of similar stability are produced (in this case, both the isopropyl and 3-cholestanyl radicals are secondary). Such a reversible addition is not limited to stannyl radicals: a similar reversible addition of carbon radicals on the thiocarbonyl group of thiohydroxamate esters had to be invoked a little later in connection with the Barton decarboxylation reaction.[9]

2.2. A New Radical-Generating System

Considering these facts, we pursued the possibility of using the relatively easy rupture of a carbon–sulfur bond in xanthates in a much more general radical-chain process. The manifold of mechanisms underlying our work is set out in Scheme 5. It basically represents the behavior of a xanthate such as **7** that cannot



Scheme 5. General manifold of reactions for the generation and capture of radicals from xanthates.

undergo cleavage of the carbon–oxygen bond in the Barton–McCombie mode. Following a chemical or photochemical initiation step, a radical R$^\bullet$ thus generated has the choice of either reacting with the starting xanthate (path **A**) or with a given trap, say an olefin, placed in the medium (path **B**). The former possibility leads to an adduct **8** for which β-scission of the carbon–oxygen is very unfavorable since it would produce a methyl radical, which is thermodynamically less stable than R$^\bullet$. Rupture of either of the carbon–sulfur bonds, on the other hand, leads back to R$^\bullet$ and the starting xanthate **7**. The same will apply if the methyl group on the oxygen is replaced by another group, as long as the stability of its corresponding radical is comparable to, but preferably lower than that of R$^\bullet$ (in most applications a primary substituent is sufficient).

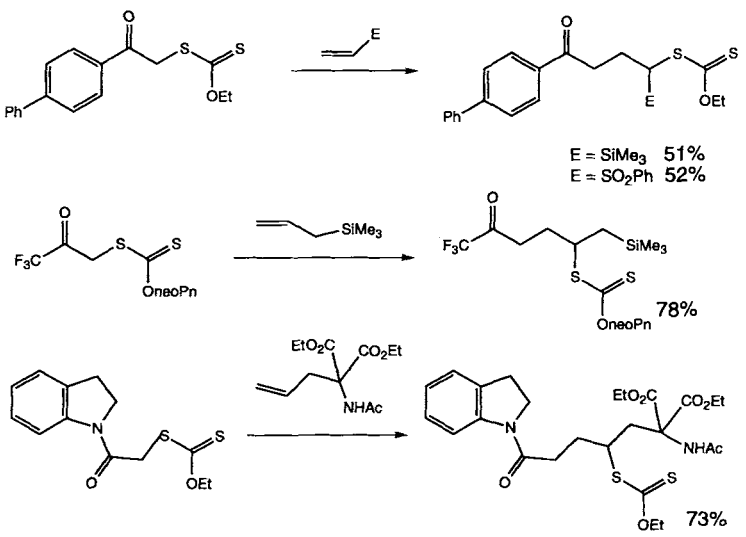
In other words, the reaction of radical R$^\bullet$ with xanthate **7** is degenerate. This path does not consume R$^\bullet$ and therefore is not in competition with the olefinic trap (that is, paths **A** and **B** effectively do not compete). This point is at the heart of the whole system. Because R$^\bullet$ is not irreversibly quenched by its precursor, its effective lifetime in the medium becomes longer, allowing it to be captured by unreactive traps that cannot normally be employed with other radical-generating systems (e.g., tin or mercury hydrides). This property, also shared by the so-called atom-transfer or Kharasch reactions (e.g., bromine or iodine atom transfer),[10] opens many synthetic possibilities for constructing frameworks hitherto accessible only with difficulty or not at all. Thus, capture of R$^\bullet$ leads to an adduct radical **9**, which in turn can react with the starting xanthate **7** to provide, after two reversible steps, another xanthate **10**; in the process a new carbon–carbon bond and a new carbon–sulfur bond have been created.

In fact, and to our delight, xanthates turned out to be a convenient source of a variety of radicals that can be handled according to the general Scheme 5—and a source not only of radicals, as will become apparent later.

At this stage several comments on the radical aspect can be made in anticipation of the results that will be shortly described. No heavy or toxic metals are involved in such a process, and the starting materials are cheap and readily available (for example, *O*-ethyl-*S*-alkyl xanthates can be made by nucleophilic displacement of an alkyl halide, tosylate, methylsulfonate etc. with potassium *O*-ethyl xanthate, which in turn is made by mixing potassium hydroxide and carbon disulfide in ethanol).[3]

Furthermore, the end product is also a xanthate and can be employed as a starting point for another radical sequence or modified further by using the immensely rich chemistry of sulfur. However, looked at from a different angle, this fact at the same time constitutes a limitation, since the reversibility of the xanthate group transfer means that the last two propagating steps (**9**$\rightleftharpoons$**10**) represent an equilibrium that is normally easier to bias in the forward direction if R$^\bullet$ is more stable than the adduct radical **9**. This point has to be kept constantly in mind when designing a synthetic sequence.

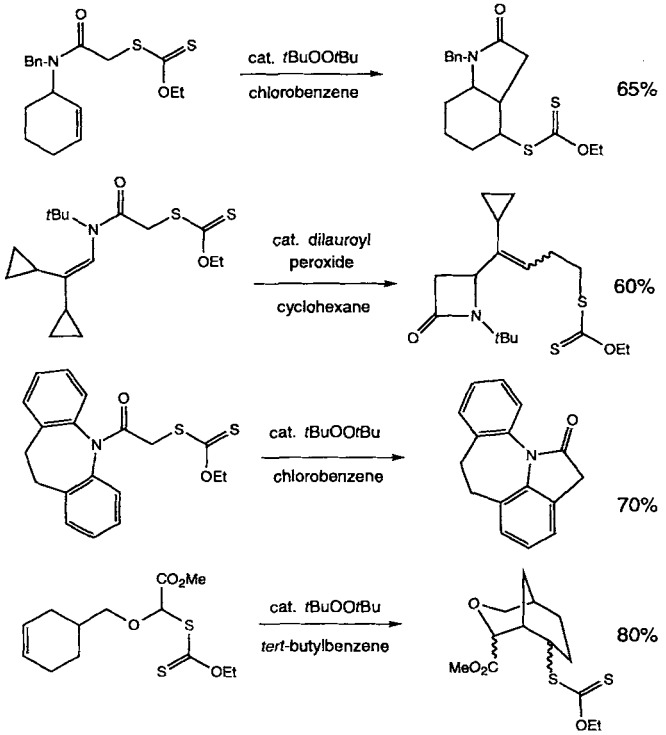
The feasibility of this new system for generating and capturing radicals was easily demonstrated with a variety of combinations of xanthates and inter- and intramolecular olefinic traps.[11] The experimental procedure is usually exceedingly simple: mere heating of the xanthate and trap in an inert solvent (benzene, cyclohexane, dichloroethane, toluene, chlorobenzene, etc.) under an inert atmosphere and in the presence of a catalytic amount of an appropriate initiator (dibenzoyl or dilauroyl peroxide, di-*tert*-butyl peroxide etc., depending on the reaction temperature, which is usually the boiling point of the solvent; azobisobutyrylnitrile (AIBN) is not generally suitable since it gives rise to isobutyryl radicals that are too stable to trigger the process).[12] A selection of examples illustrating the intermolecular case is pictured in Scheme 6. The array of functionality that can be obtained is quite amazing and has interesting synthetic implications. For instance, the derivative arising from addition to phenyl vinyl sulfone can act as a precursor of a thioaldehyde upon hydrolytic cleavage of the xanthate group,[13] whereas the chemistry of compounds formed from reaction with allyl- and vinyltrimethylsilane remains to be explored. Most of the olefinic



Scheme 6. Examples of intermolecular radical additions with xanthate transfer. (The reactions were run in cyclohexane with dilauroyl peroxide as initiator; neoPn = neopentyl.)

traps shown are not "activated" and therefore cannot normally be used with many other radical methods such as those based on tin. Another practical advantage, of some importance when operating on a large scale, is that the reactions can be run in a fairly concentrated medium, typically 0.5 M (and sometimes even without solvent), which is between tenfold and more than a hundredfold more concentrated than the medium for most other radical processes. Last (but not least), some radicals, such as the trifluoroacetonyl radical as in the second example (Scheme 6), are not readily available by other methods.

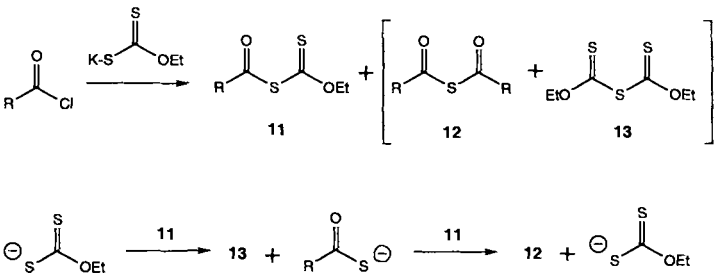
The intramolecular variant is even easier to perform and rings of various sizes and substitution patterns can be obtained (Scheme 7).[12, 14, 15] It is noteworthy that β-lactams (in the example given, cyclization is followed by opening of one cyclopropane ring) and indolones[14] (by cyclization onto an aromatic ring, which takes place slowly if at all) can be produced. For the last example, taken from a recent application of the reaction by the group of Speckamp and Hiemstra in Amsterdam,[15] none of the usual radical methods was successful in accomplishing the desired cyclization.



Scheme 7. Examples of radical cyclizations with xanthate transfer.

2.3. A Study in Yellow

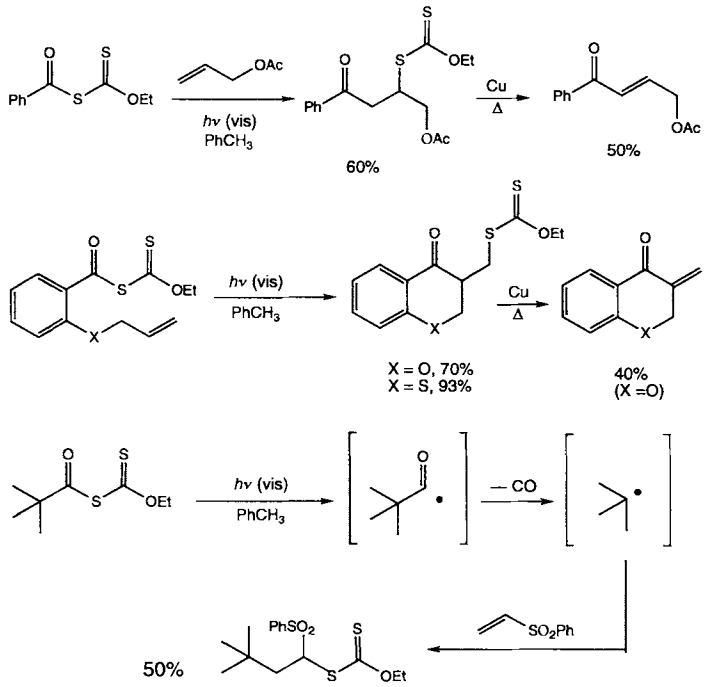
As mentioned above, radicals of various types can be generated with the appropriate xanthates. Thus acyl radicals can be made from *S*-acyl xanthates, such as *O*-ethyl derivative **11** (Scheme 8). These substances are yellow in color (the word xanthate comes from the Greek *xanthos* meaning yellow, since the xanthate salts made in the early days were yellow)[16] and have been known for almost a century.[17] In fact, their sensitivity to visible light



Scheme 8. Formation of an *S*-acyl xanthate and its decomposition by an ionic chain mechanism.

(leading to acyl radicals) was established by Barton, George, and Tomoeda[18] nearly thirty years before our own study, but at the time a radical recombination mechanism was invoked instead of a chain process (Scheme 5, with R replaced by RCO). The preparation of *S*-acyl xanthates is, in principle, quite simple and merely involves treating an acid chloride with a xanthate salt such as potassium ethyl xanthate. However, there was a hidden twist: like the chemists before us, we found that the results were not very reproducible.[17, 18] Variable amounts of the thioanhydride **12** and *O*,*O*-diethyl xanthic anhydride **13** were formed in addition to the desired *S*-acyl xanthate **11**. The explanation is that the *S*-acyl xanthate can decompose completely by an ionic chain mechanism under the influence of a small amount of the xanthate salt (Scheme 8). Indeed, addition of a small quantity of potassium ethyl xanthate to a pure sample of *S*-benzoyl *O*-ethyl xanthate caused its complete conversion into thiobenzoic anhydride (**12**, R = Ph) and *O*,*O*-diethylxanthic anhydride **13**.[19] We therefore modified the experimental procedure so as to avoid an excess of the xanthate salt at any given time (the salt is added to a slight excess of the acid chloride in the dark).

Acyl radicals can be generated by irradiating the corresponding *S*-acyl xanthate[10] with visible light (or by the usual chemical initiation) and captured in an inter- or intramolecular fashion by using appropriate olefinic traps (Scheme 9). The

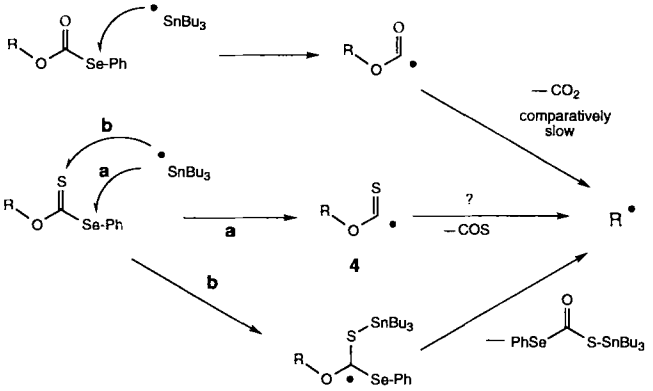


Scheme 9. Examples of radical reactions with *S*-acyl xanthates involving radical capture and xanthate transfer in the final step. Cu = copper powder, vis = visible light.

xanthate function in the adduct is in the β-position with respect to the carbonyl group and may be easily eliminated with base or by heating with copper powder (the xanthate group may also be reductively removed with tributylstannane). In the case of tertiary (or benzylic) derivatives, loss of carbon monoxide occurs from the acyl radical, and it is the tertiary (or benzylic) radical that is finally trapped, as shown by the last example in Scheme 9.

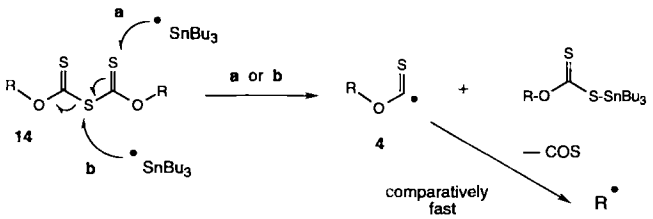
One of the key assumptions in the Beckwith–Barker mechanism (Scheme 2) for the Barton–McCombie deoxygenation concerns the ability of an alkoxythiocarbonyl radical, ROC$^{\bullet}$=S (**4**), to extrude carbon oxysulfide. Loss of carbon dioxide from the oxygen analogue ROC$^{\bullet}$=O was known to be comparatively slow (k at 25 °C is of the order of 10^5 s^{-1} for R = *tert*-butyl and much lower when R is secondary or primary),[20] and it was not clear at the outset what effect the sulfur would have on the rate of fragmentation. The main problem in answering this question was how to generate an alkoxythiocarbonyl radical cleanly and unambiguously in order to study its behavior. For example, a selenocarbonate precursor can be quite suitable for creating an alkoxycarbonyl radical,[21] but the corresponding selenothiocarbonate would not constitute an unambiguous source of an alkoxythiocarbonyl radical, because the thiocarbonyl group is at least as reactive, and probably more so, than the selenide group (Scheme 10).

A simple solution to this problem turned up in the guise of a xanthic anhydride, also a long-known member of the xanthate family.[22] Our first encounter with such a compound was with the *O*,*O*-diethyl derivative **13**, which appeared as an undesirable side product in the preparation of *S*-acyl xanthates (Scheme 8). The reaction of xanthic anhydride **14** with stannyl radicals can take place by two possible pathways: a) attack at the thiono sulfur atom or b) at the sulfide sulfur. But, because of the sym-



Scheme 10. Comparison of the conventional preparation of alkoxythiocarbonyl with two possible reaction paths and the route alkoxycarbonyl radicals.

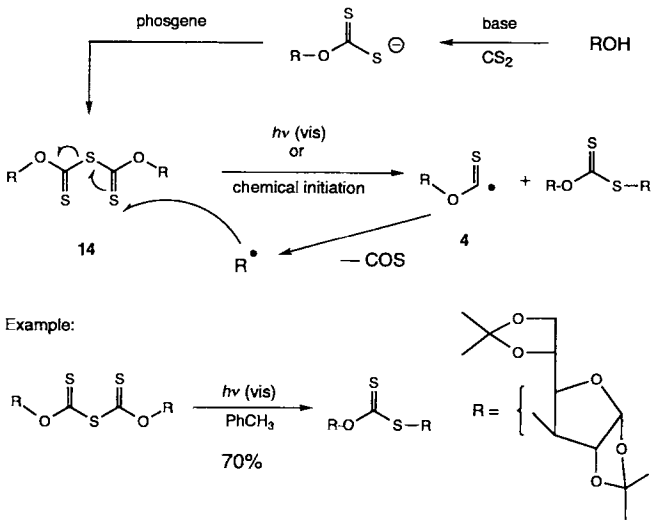
metry inherent in the structure of the xanthic anhydride, both processes lead to an identical outcome, namely an alkoxythiocarbonyl radical and a tin xanthate (Scheme 11); it does not therefore matter which sulfur atom the tin radicals attack. Using this approach, we could show that in the case of the cholestanyl derivative extrusion of carbon oxysulfide proceeds readily.[23] The assumption of Beckwith and Barker[6] was thus justified, even though their mechanistic picture for the Barton–McCombie deoxygenation is not correct.



Scheme 11. Unambiguous generation of alkoxythiocarbonyl radicals from xanthic anhydrides.

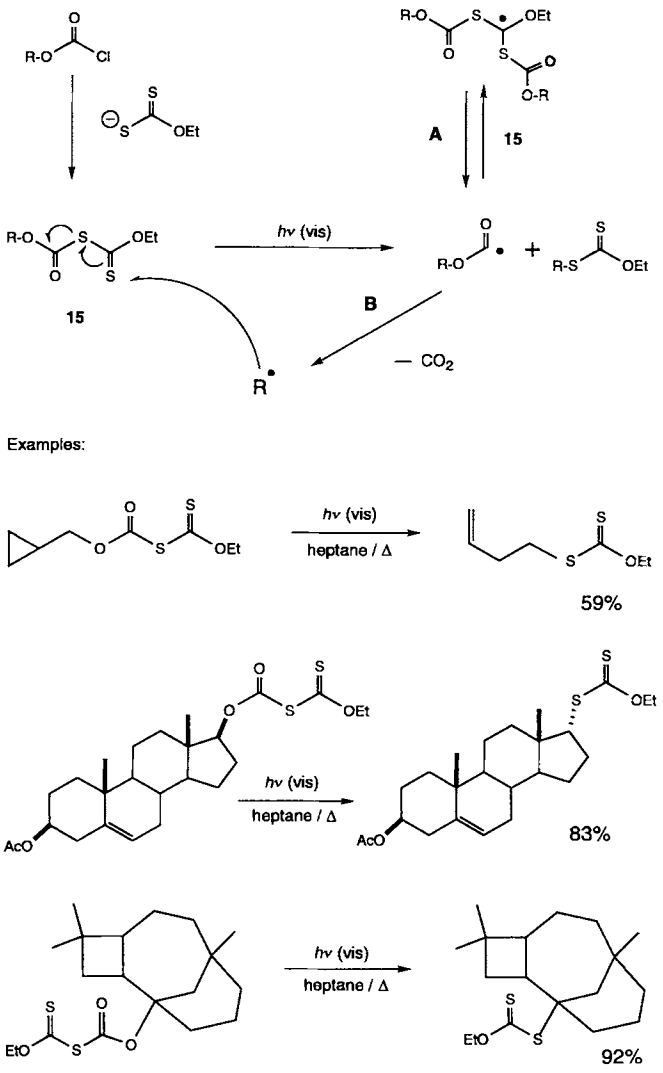
But over and beyond revealing the propensity of alkoxythiocarbonyl radicals to expel carbon oxysulfide (competition experiments indicated this to be at least an order of magnitude faster than loss of carbon dioxide from alkoxycarbonyl radicals), xanthic anhydrides **14** have an interesting chemistry of their own. In the absence of stannane, they undergo a clean radical chain transformation into a symmetrically substituted xanthate upon irradiation with visible light (like *S*-acyl xanthates, these substances are yellow) or on heating in the presence of a chemical initiator (Scheme 12). Since such anhydrides are easily made from alcohols via the xanthate salt, the process constitutes a method for generating radicals from primary or secondary alcohols (xanthic anhydrides derived from tertiary alcohols are generally not stable with respect to a Chugaev-type elimination) and a way to replace homolytically a carbon–oxygen bond with a carbon–sulfur bond, as exemplified by the conversion of the xanthic anhydride derived from glucose (Scheme 12).[23]

But this same symmetry which allowed us to answer a mechanistic question introduced a limitation from the synthetic view point. Only half of the R–O bonds in the xanthic anhydride are

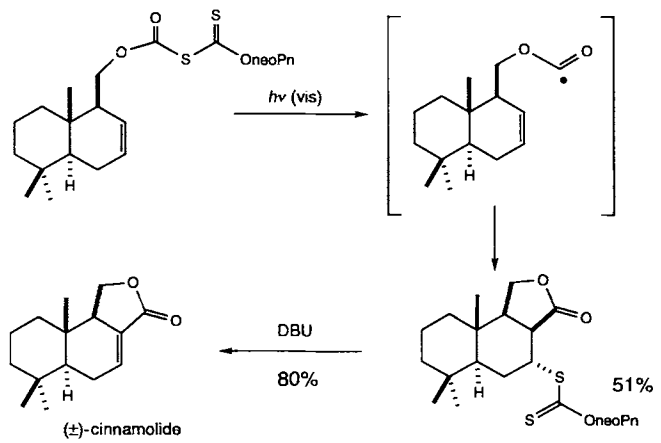


Scheme 12. Radical chain reactions of xanthic anhydrides.

exchanged for R–S bonds. Attempts to use unsymmetrical xanthic anhydrides R–O–CS–S–CS–OR′, where the OR′ unit is derived from a cheap alcohol, resulted only in frustration. The two thiocarbonyl groups had more or less the same reactivity and no selectivity could be achieved. The way out of this difficulty was in fact quite simple. All we had to do was to replace the thiocarbonyl bound directly to the OR group of the unsymmetrical xanthic anhydride with the much less radicophilic carbonyl group. This gives what may be called an *S*-alkoxycarbonyl xanthate, R–O–CO–S–CS–OR′, such as **15**. The simplest members of this family have been known for a long time,[24] but again almost nothing about their radical chemistry had been reported. By analogy with the previous xanthates, irradiation with visible light of these (also yellow) substances should lead to alkoxycarbonyl radicals. This concept is outlined in Scheme 13. We chose R′ = Et as example for clarity and also because essentially all the derivatives we examined were prepared by reaction of a chloroformate with potassium ethyl xanthate.[25] As stated above, alkoxycarbonyl radicals were known to extrude carbon dioxide relatively slowly, especially in the case of primary and secondary derivatives. However, unlike earlier methods (for example by the reaction of a selenocarbonate with tributyltin hydride;[21] see scheme 10), our system cannot react as intended unless the alkoxycarbonyl radical loses carbon dioxide (Scheme 13, path B) or is trapped in some other way, since its reaction with its xanthate precursor **15** is reversible and degenerate (path A). Thus, in the absence of a trap, the *S*-alkoxycarbonyl xanthate is converted by a chain reaction into an ordinary xanthate, in which the R–O bond has been replaced by an R–S bond. The applicability of this process to tertiary, secondary, and even primary derivatives is demonstrated by the examples in Scheme 13. Alteratively, the initial alkoxycarbonyl radical may be captured by a suitably located, internal double bond in what constitutes a simple approach to lactones. The cyclization step must of course be faster than loss of carbon dioxide. One application of this variation (Scheme 14) represents the final steps in a synthesis of cinnamolide; base-induced β-elimination of the xanthate group introduces the required unsaturation.[26]



Scheme 13. Radical chain reactions of *S*-alkoxycarbonyl xanthates.

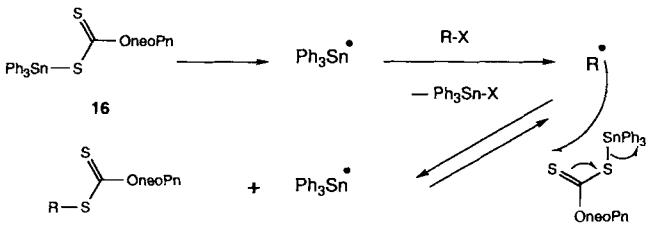


Scheme 14. Capture of an alkoxycarbonyl radical by an internal double bond as exemplified in the synthesis of cinnamolide.

2.4. A Brief Return to Tin Chemistry

In addition to the various carbon-centered radicals available through the appropriate xanthate precursors, we found that even stannyl radicals can be generated in a similar fashion by

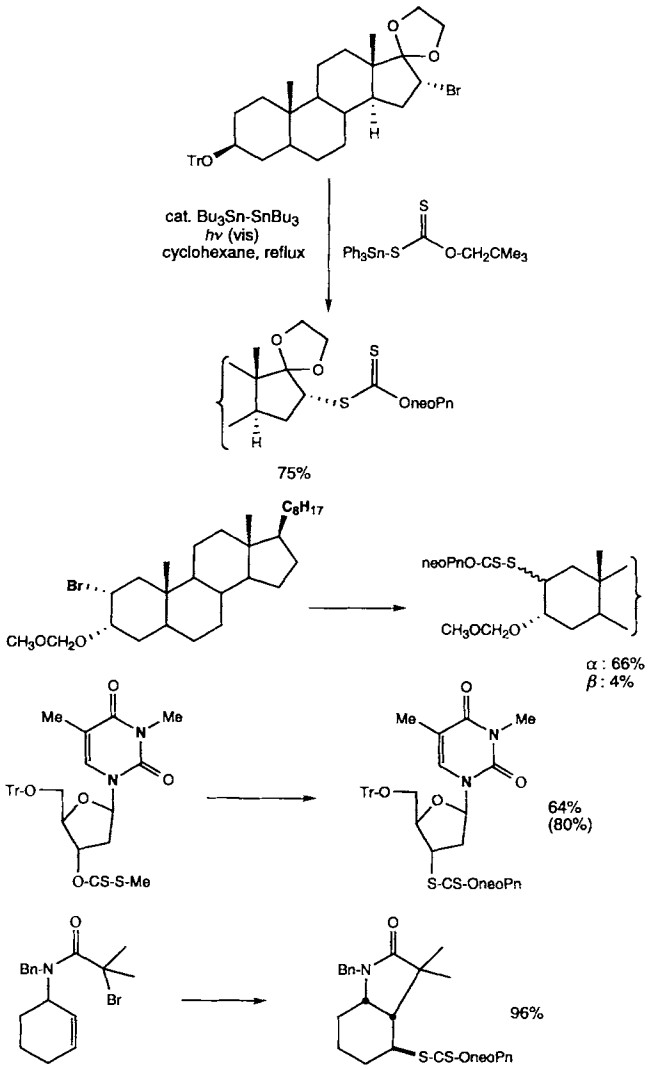
using a stannyl xanthate reagent.[27] This variation allowed us to combine the highly useful reactivity of tin radicals with the advantages that accrue from the introduction of a xanthate group and the reversibility of its transfer. After some experimentation, we selected *O*-neopentyl-*S*-triphenylstannyl xanthate **16** as the reagent of choice. This nicely crystalline compound is easily made and stored. In its simplest form, the process allows the replacement of an X group with a xanthate (Scheme 15), where X represents a group that can be abstracted by tin radicals (bromide, iodide, another xanthate etc.). The process is best triggered by addition of a few mol percent of hexabutylditin and irradiation with visible light.



Scheme 15. Generation of triphenylstannyl radicals from *S*-triphenylstannyl xanthate (**16**).

The first two examples[28] displayed in Scheme 16 illustrate the transformation of even hindered bromides into the corresponding xanthates. Not only would a traditional nucleophilic substitution be difficult to perform in these cases, but since radicals are involved, the reaction can also take place with inversion or retention depending on the steric environment in the substrate. The third example represents a modification of the Barton–McCombie reaction where, instead of the usual reduction, the C–O bond in the xanthate group of the substrate is exchanged for a C–S bond in a new xanthate derived from the reagent.[27] This is yet another homolytic route for modifying alcohols that may be compared to those presented in Schemes 12 and 14.

As with traditional tin chemistry, a cyclization step can be incorporated, so that a C–C bond is formed in addition to the xanthate transfer, as illustrated by the last example in Scheme 16.[28] Thus one obtains products of xanthate transfer without actually starting with a xanthate as we have done so far; it is perhaps worth pointing out that in these instances the corresponding initial xanthates would have been quite difficult to prepare, whereas access to the starting halides is fairly trivial.

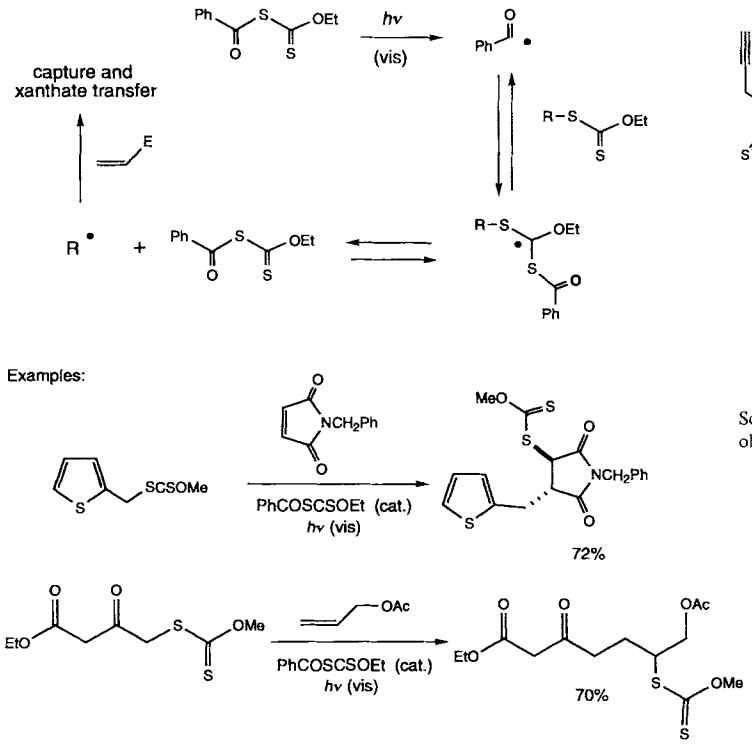


Scheme 16. Examples of transformations with *S*-triphenylstannyl xanthate (yield in parenthesis is based on recovered starting material; identical conditions for all reactions; Tr = triphenylmethyl).

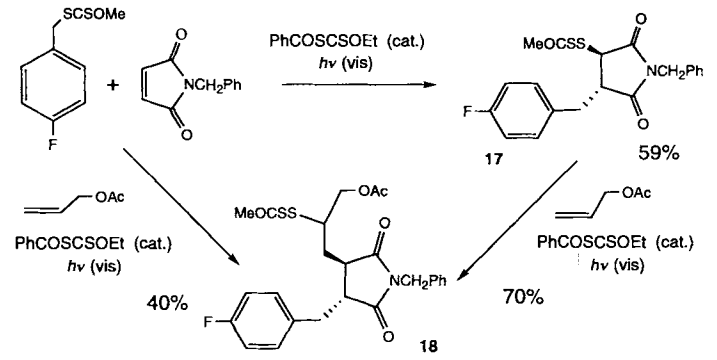
3. The Case of *S*-Propargyl Xanthates

3.1. Catching Visible Light

Ordinary alkyl xanthates are not normally sensitive to visible light, in contrast to the yellow *S*-acyl xanthates. However, we found that if a small amount of *S*-benzoyl xanthate is added to the reaction mixture, xanthate transfer from alkyl xanthates can indeed be effected with visible light, a process which otherwise would have required UV irradiation (or initiation by a peroxide). The principle of this contrivance is exposed in Scheme 17, along with a couple of examples;[10, 29] the *S*-benzoyl xanthate is regenerated in the process and is indeed catalytic. This could also be applied to a multiple radical addition sequence with two olefinic traps of different polarities, as shown in Scheme 18. A *p*-fluorobenzyl radical is produced from the corresponding xanthate and captured with *N*-benzyl maleimide to give adduct **17**, itself a xanthate and thus a starting point for another addition to allyl acetate to finally yield **18**.[29] Since all the xanthate transfer steps are reversible, it is not actually necessary to isolate intermediate **17**. All the ingredients can be mixed and irradiated with visible light to give the end product **18** (a multicomponent reaction in the now popular jargon of combinatorial chemistry!). The reaction stops at **18** (thus avoiding polymerization) because it is more difficult to form an unstabilized secondary radical from **18** than it is to generate either a benzyl radical from the benzyl xanthate or a carbonyl-stabilized radical from the first adduct **17**.



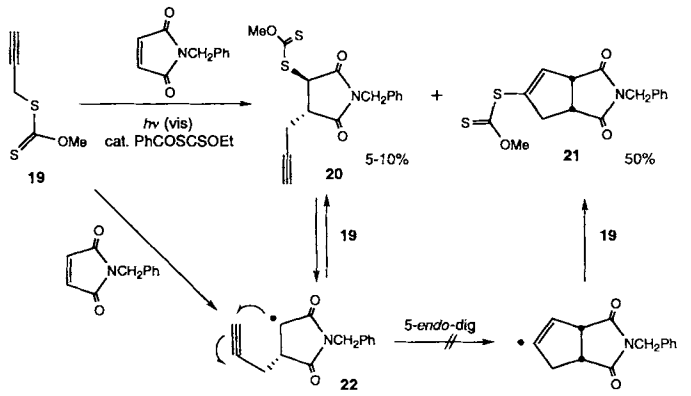
Scheme 17. Use of *S*-benzoyl xanthate in catalytic amounts to generate radicals from *S*-alkyl xanthates with visible light.



Scheme 18. Multiple addition of a xanthate to two olefinic traps of different polarities.

3.2. Serendipity Yet Again

Because the addition of the benzoyl radical to a xanthate group is reversible, the radicals that can be generated by the above "trick" must be of comparable or greater stability than the benzoyl radical itself. The procedure is hence best suited for producing resonance-stabilized radicals (benzyl, allyl, or those located next to a carbonyl group, etc.). With these limitations in mind, we set out to apply this approach to create propargylic radicals. These stabilized radicals had hardly been studied in the past and, as far as we could tell, had never been employed in synthesis. In the event, and under the same experimental conditions, the simplest *S*-propargyl xanthate **19** did produce the expected adduct **20** from *N*-benzyl maleimide but only in a dismal yield (Scheme 19). To our utter surprise, the major product turned out to be cyclopentene **21**, in yields of up to 50%.[30]



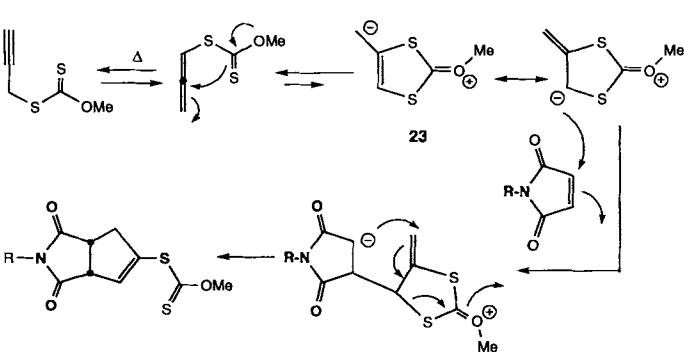
Scheme 19. Unexpected reaction of an *S*-propargyl xanthate with an electrophilic olefin.

The simplest and most natural explanation for the serendipitous formation of **21** in the context of our work seemed to be a hitherto unprecedented 5-*endo*-digonal cyclization of the intermediate radical **22** (Scheme 19). This rationale was quite satisfying in that it seemed to demonstrate in a spectacular way the long life of radicals generated by the xanthate method, allowing them to indulge in the difficult acrobatics required for a 5-*endo*-digonal cyclization. Alas, in the event our wishful speculations were not borne out by experiment, and we had to suffer what Thomas Huxley described succintly a century ago as "the tragedy of science—the slaying of a beautiful hypothesis by an ugly fact".

To adduce evidence for such a pathway, we attempted to generate radical **22** from the "normal" product **20** to show that it can indeed cyclize. But try as we might, we could not convert xanthate **20** into its cyclopentene isomer **21**. Our hypothesis that cyclopentene **21** is the result of a 5-*endo*-digonal radical cyclization was finally completely shattered when, among other experiments, we found that neither light nor an *S*-benzoyl xanthate were really necessary for the reaction to occur. Mere heating of the propargyl xanthate and the electrophilic olefin in toluene or chlorobenzene gave the observed cyclopentene derivative **21**. Under these conditions, of course, the minor radical adduct **20** is not formed.

3.3. A New Betaine Rears Its Head

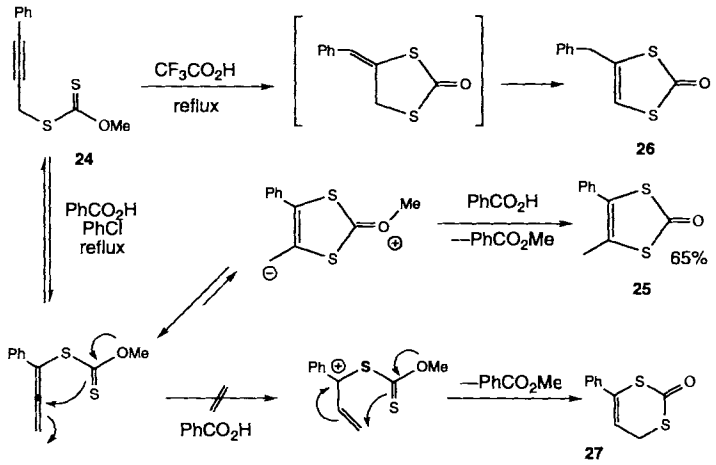
Eventually, another mechanistic hypothesis presented itself (Scheme 20). A thermal sigmatropic rearrangement of the



Scheme 20. Mechanism for the formal [3+2] cycloaddition process.

S-propargyl xanthate affords an *S*-allenyl isomer, itself in equilibrium with a betaine **23** of a novel type. The negatively charged end of this species appears to be sufficiently nucleophilic to promote a Michael type addition to an electron-poor olefin followed by cyclization.[30] Evidence for a stepwise rather than a concerted mechanism will be presented in Section 3.4.

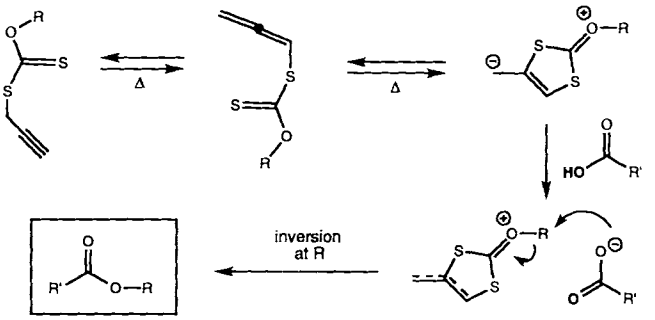
Unfortunately, from a synthetic perspective this approach to cyclopentenes was limited to highly reactive olefins. But the proposed mechanism raised intriguing questions about the existence and reactivity of such a betaine intermediate, to which we then turned our attention. One approach involved capturing the betaine with the simplest of electrophiles, the proton. It seemed to us that if the *S*-propargyl xanthate was heated in the presence of a sufficiently weak proton source (perhaps a carboxylic acid) that was incapable of reacting either with the starting propargyl xanthate or with the allenyl xanthate but could protonate the more basic betaine, then a simple examination of the end products would provide evidence for such a species. Indeed, when xanthate **24** was heated in toluene in the presence of benzoic acid, a good yield of 1,3-dithiol-2-one **25** was produced along with methyl benzoate (Scheme 21).[31] The CH_2 group



Scheme 21. Capture of the betaine of type **23** with a weak acid.

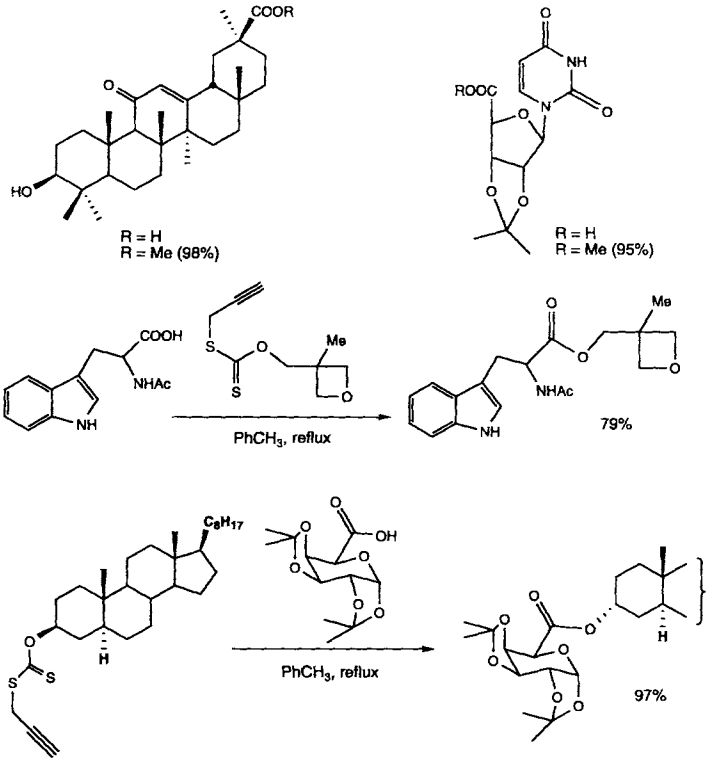
that initially carried the xanthate group in the substrate **24** was converted into a methyl group in the product **25**. Direct protonation of the starting propargylic xanthate (which can be achieved by the much stronger trifluoroacetic acid)[32] would have given the isomeric 1,3-dithiol-2-one **26**, whereas reaction at the allene level should have led to a six-membered ring derivative (**27**). Neither of these two possible compounds was formed to any significant extent, so the product obtained can only be the result of protonation of the betaine as shown. It may be mentioned in this context that another synthesis of 1,3-dithiol-2-ones by a radical process based on bis(xanthate)s has recently been devised by Y. Gareau.[33]

The transformation just described was initially designed as a probe for the existence of the betaine, but as a method for making esters (methyl benzoate in the example just discussed) the whole process acquires a completely different dimension. Upon protonation the heterocyclic unit, in fact, becomes a leaving group, and the desired nucleophile (the carboxylate) is the counteranion. It is thus ideally placed for performing a substitution to give an ester with inversion of configuration (Scheme 22).[34]



Scheme 22. Mechanism of ester formation from an *S*-propargyl xanthate. The carboxylic acid may in fact be replaced by any acid H–X of comparable acidity to give a compound R–X, again with inversion at R.

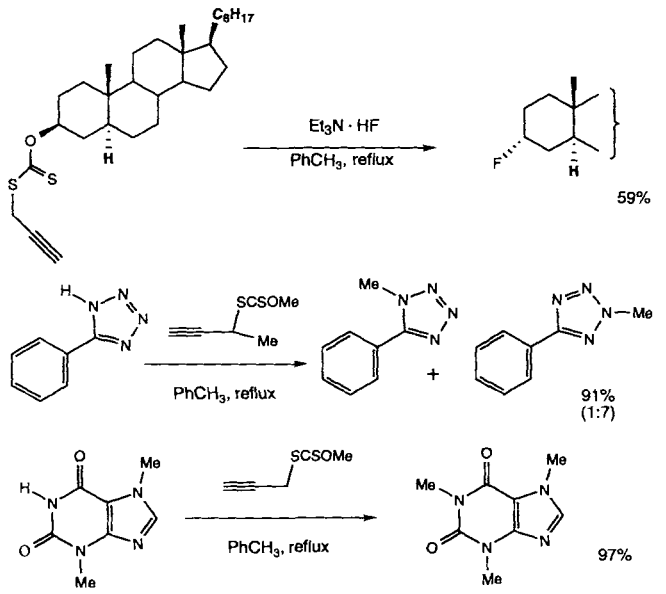
In practice, this turns out to be a highly effective and simple method for making esters by mere heating of a carboxylic acid with the appropriate *S*-propargyl xanthate. The examples displayed in Scheme 23 show the formation of various esters, some of which are quite complex. Moreover, the process is tolerant of many of the functional groups commonly encountered in natural products. The last example involves inversion of the 3-position in cholestanol as well as providing a protected galacturonate ester. We thus have in hand a reasonably efficient, cheap, and convenient method for the inversion of secondary alcohols



Scheme 23. Ester formation on use of *S*-propargyl xanthates (methyl esters were obtained by heating the carboxylic acid with *O*-methyl-*S*-propargyl xanthate or with *O*-methyl-*S*-(1-methyl-2-propynyl) xanthate in refluxing toluene or chlorobenzene.

that complements the popular Mitsunobu reaction,[35] a process that necessitates the use of a hazardous and expensive azodicarboxylate ester in conjunction with a phosphane, usually triphenylphosphane. Both of these reagents are undesirable for large scale work.

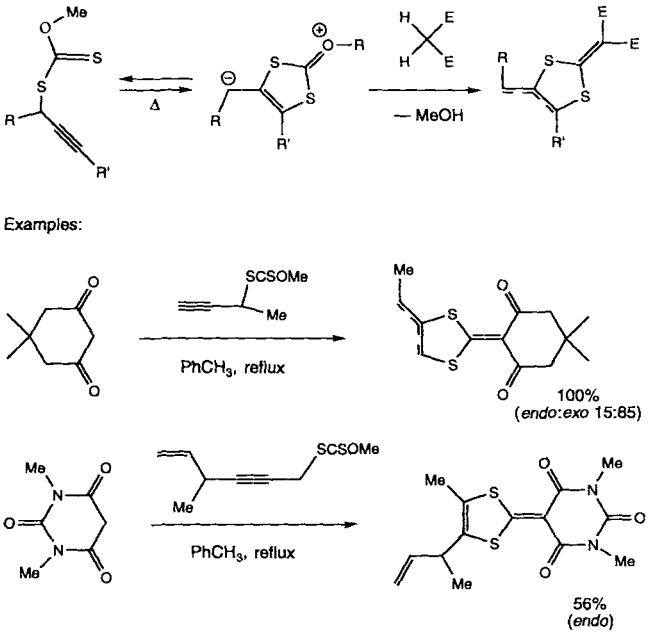
The reaction is, however, not limited to ester formation, since the protonation step may, in principle, be effected by any weak proton donor. Halides can therefore be prepared if the corresponding strong haloacid is incorporated in a "subdued" form such as an ammonium or pyridinium salt. For instance, heating *O*-β-cholestanyl-*S*-propargyl xanthate with triethylammonium hydrogenfluoride gives 3α-fluorocholestane in 59% yield, the remainder being 2-cholestene (Scheme 24).[34] Incidentally, and



Scheme 24. Preparation of halides (e.g. fluorides) and alkylation of nitrogen heterocycles containing an acidic hydrogen.

simultaneously with our work, the group of W. B. Motherwell found that fluorides could also be made from *S*-methyl xanthates by oxidation with 4-methyl(difluoroiodo)benzene.[36] Nitrogen heterocycles containing sufficiently acidic protons can be alkylated in the same way by a propargylic xanthate as illustrated by the last two examples in Scheme 24 involving the methylation of 5-phenyltetrazole and the nearly quantitative conversion of theobromine into caffeine upon heating with *O*-methyl-*S*-propargyl xanthate.[34, 37]

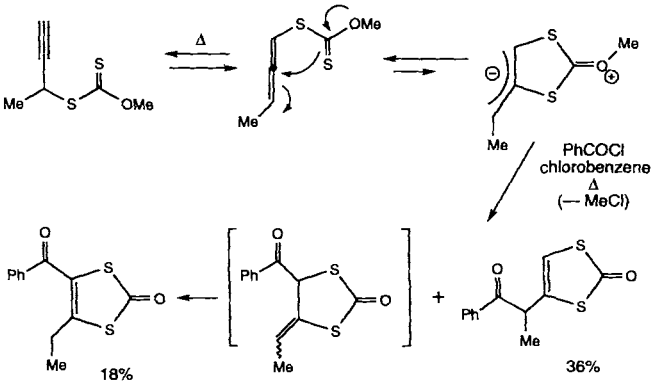
We observed another interesting transformation when we attempted to protonate the betaine with a carbon acid of the active methylene type. Under the same conditions, a condensation reaction took place to give an alkylidene dithiole through attack on the ring carbon and loss of an alcohol molecule (Scheme 25). Symmetrical carbon acids were used to avoid structural complications from geometrical isomers. Yields were quite variable and depended strongly on the nature of the xanthate and active methylene component.[38]



Scheme 25. Reaction of *S*-propargyl xanthates with active methylene compounds.

3.4. More Nonradical Chemistry from *S*-Propargyl Xanthates

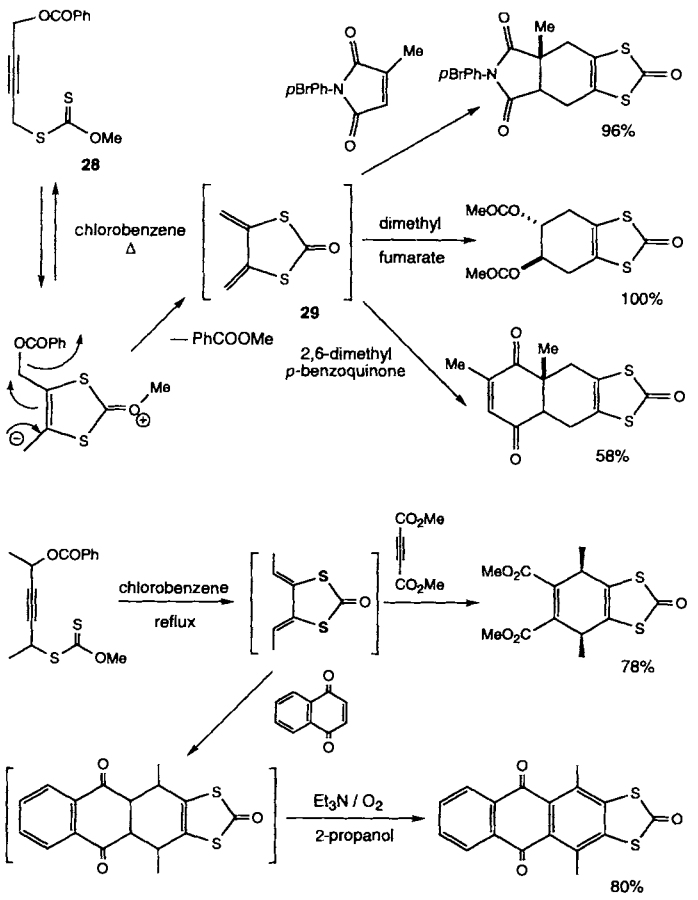
The intermediate betaine is sufficiently nucleophilic to be captured by an acid chloride. This creates a new carbon–carbon bond in a very simple manner and leads to ketones of unusual structures (Scheme 26).[39] Aliphatic or aromatic acid chlorides may be used but it is important, at least on a small scale, to add an acid scavenger such as α-pinene to remove any adventitious hydrogen chloride, which otherwise would prematurely protonate the betaine.



Scheme 26. Reaction of *S*-propargyl xanthates with acid chlorides.

But perhaps the most interesting variation in this nonradical chemistry of *S*-propargyl xanthates is to have a leaving group within the xanthate itself. Starting from an alkynediol such as 2-butyne-1,4-diol, it is very easy to prepare propargyl derivative **28** containing a xanthate and a benzoyloxy group on either side of the triple bond. The betaine produced from such a compound can expel a benzoate and collapse into the highly reactive, rigid-

ly cisoid, and at the time novel diene **29** (and methyl benzoate as the co-product).[40] This diene (and its more substituted congeners) can be intercepted by Diels–Alder cycloaddition with a variety of dienophiles including acetylenes and quinones, as shown by the examples in Scheme 27. The adducts may be aro-

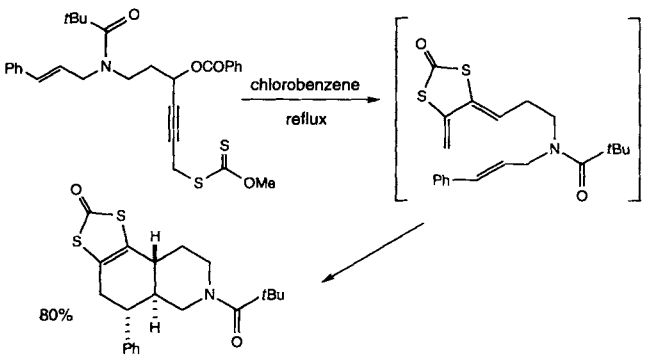


Scheme 27. Formation of dienes from *S*-propargyl xanthates.

matized through oxidation, sometimes simply by heating under air in 2-propanol containing triethylamine. Highly substituted aromatic derivatives with two sulfur atoms (in protected form) in an *ortho* disposition are thus made readily accessible. Such compounds are usually difficult to construct by conventional methods.

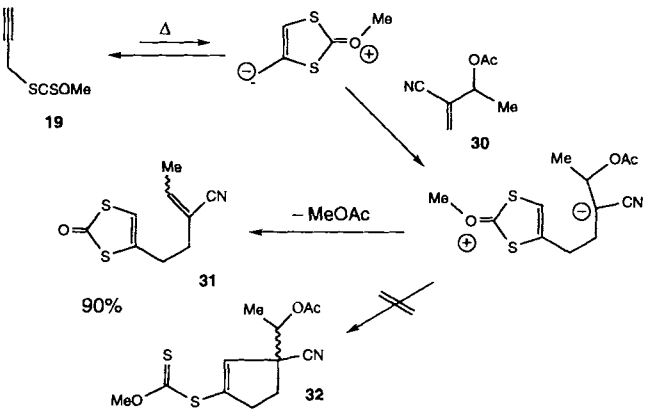
An intramolecular variant of this reaction, in which only one diastereomer is produced, is illustrated in Scheme 28.[41] In a sense, the propargylic xanthate can be viewed as a loaded spring that, upon heating, reveals a reactive diene, ready to pounce on the nearest olefinic trap. It is worth underlining the simplicity with which the precursor is assembled and the complexity of the resulting product, thanks to the powerful Diels–Alder cycloaddition step.

It may be recalled (Schemes 19 and 20) that heating an *S*-propargyl xanthate with an electrophilic olefin gives rise to a cyclopentene derivative. If a leaving group is now incorporated into the olefin, the course of the reaction is completely modified. For instance, heating propargylic xanthate **19** with unsaturated nitrile **30**, a compound easily accessible by the Baylis–Hillman



Scheme 28. Formation and intramolecular capture of a diene.

reaction,[42] gives an open chain product **31** (Scheme 29). The Michael addition is therefore followed by elimination of the acetate group and not by cyclization to give cyclopentene derivative **32** (cf. Scheme 19).[43] This observation provides compelling evidence against concertedness during the formation of the cyclopentene ring and exposes yet another aspect of the reactivity of the intermediate betaine.

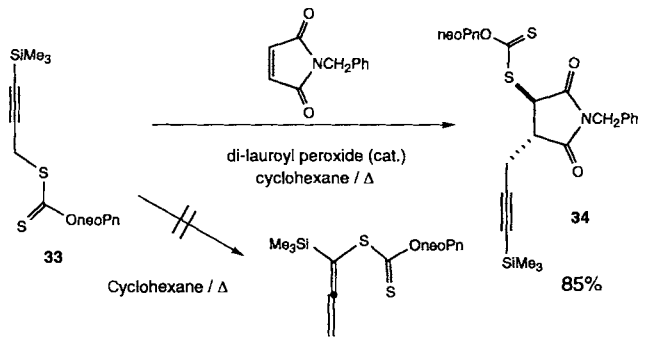


Scheme 29. Addition–elimination at a betaine derived from an *S*-propargyl xanthate.

4. Back to Radicals

But what about propargyl radicals? While trying to generate these species we unwittingly stumbled across this unusual, non-radical chemistry of propargylic xanthates. The manifold of radical reactions was in fact overshadowed by the thermal sigmatropic rearrangement leading to the allene and then to the betaine. However, during our study (and in hindsight not surprisingly), we noticed that the sigmatropic rearrangement was significantly slower, and even quite sluggish, at or below 80 °C, when the alkyne terminus bore substituents. In the light of these considerations, it seemed reasonable that with substituted propargylic xanthates and under appropriate reaction conditions, namely initiation at around 80 °C, the formation and trapping of propargyl radicals could perhaps overtake the rearrangement to the isomeric allene. Indeed, heating the trimethylsilyl derivative in the presence of *N*-benzyl maleimide and a small amount of dilauroyl peroxide under reflux in cyclohexane gave a high yield of the "normal" radical adduct **34**

(Scheme 30).[44] For comparison, in Scheme 19 with the same trap, the unsubstituted analogue **19** afforded mainly cyclopentene derivative **22** and only little of the radical addition product **20**. Work in progress indicates that even a methyl group is sufficient to allow useful radical chemistry, and that the intramolecular variant of this process is also quite effective. As far as we can tell, the addition of propargyl radicals has never been accomplished previously with such efficiency.



Scheme 30. Generation and capture of propargyl radicals.

Our xanthate-based method appears to be well-suited to accommodate the inherent sluggishness of these species. The very existence of the degenerate background reaction between the radical produced and its xanthate precursor (path **A** in Scheme 5, Section 2.2) provides the radical with a longer lifetime to survive a relatively slow trapping step caused by the unreactive nature of either the radical or the trap. All these observations open the way to many synthetic opportunities, for it is now possible by a judicious choice of substrates and experimental parameters to exploit both the radical and nonradical aspects of the chemistry of propargyl xanthates.

5. Summary and Outlook

The trail of xanthates has taken us forward; but it would be foolish to assume that this old functional group has relinquished all its secrets. Too many questions still remain to be answered, even if what we have learned so far allows us to conjecture on some future developments.

For instance, what other useful radicals will become accessible through xanthates? Phosphorus-centered radicals look quite appealing, for the recent explosive popularity in the application of radical-based methods in synthesis does not seem to have caught up with these species. We also have a keen interest in nitrogen radicals, especially iminyls, and xanthates could prove useful in this area too. More fundamentally, the kinetics of the xanthate transfer need to be determined in order to gain a greater mastery of the system. In principle, the xanthate functionality can be replaced by other related groups. Preliminary studies thus seem to indicate that trithiocarbonates are equally capable of sustaining the same type of radical chain reactions, but further work is necessary to ascertain whether they offer any special advantages.

The nonradical chemistry of *S*-propargyl xanthates also offers many opportunities for speculation. What other electrophiles are capable of reacting with the betaine? How important is aromaticity in stabilizing this species? To what extent can its reactivity be enhanced? How would extra conjugation affect its behavior? And so on and so forth. Our efforts so far have been of an exploratory nature, but since most of the new reactions form carbon–carbon bonds, new synthetic strategies can now be conceived and perhaps implemented. Some work directed towards such an aim is currently under way.

I wish to record my gratitude and appreciation to my collaborators, whose names appear in the references. The work described in this review is largely a testimony to their enthusiasm, skill, and diligence. I am also indebted to the CNRS, Ecole Polytechnique, the Royal Society, Rhône-Poulenc Chimie, and Roussel-Uclaf for generous financial and material support. It is an amusing twist of fate that potassium ethyl xanthate was one of the first organic compounds I prepared as a teenager in a small room next to the kitchen, to my mother's utter disgust. It is perhaps only fair that I should also thank her and the rest of my family for putting up with such smelly activity for a good many years.

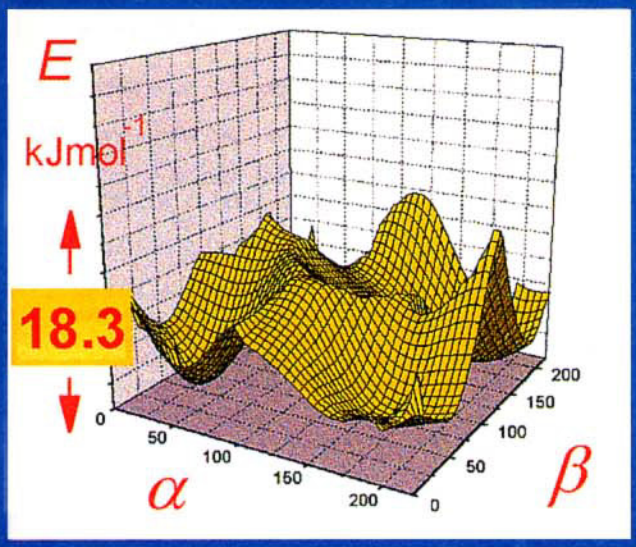
Deposition of Data from X-Ray Structure Analyses

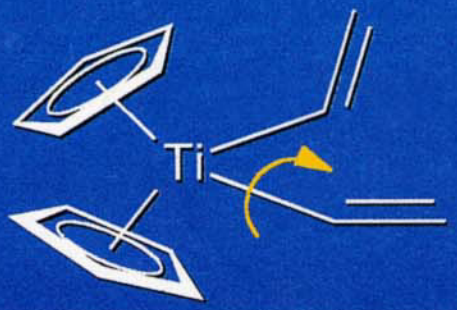
In order to make life easier for authors and referees the Cambridge Crystallographic Data Centre (CCDC) and the Fachinformationszentrum Karlsruhe (FIZ) have unified their procedures for the deposition of data from single-crystal X-ray structure analyses.

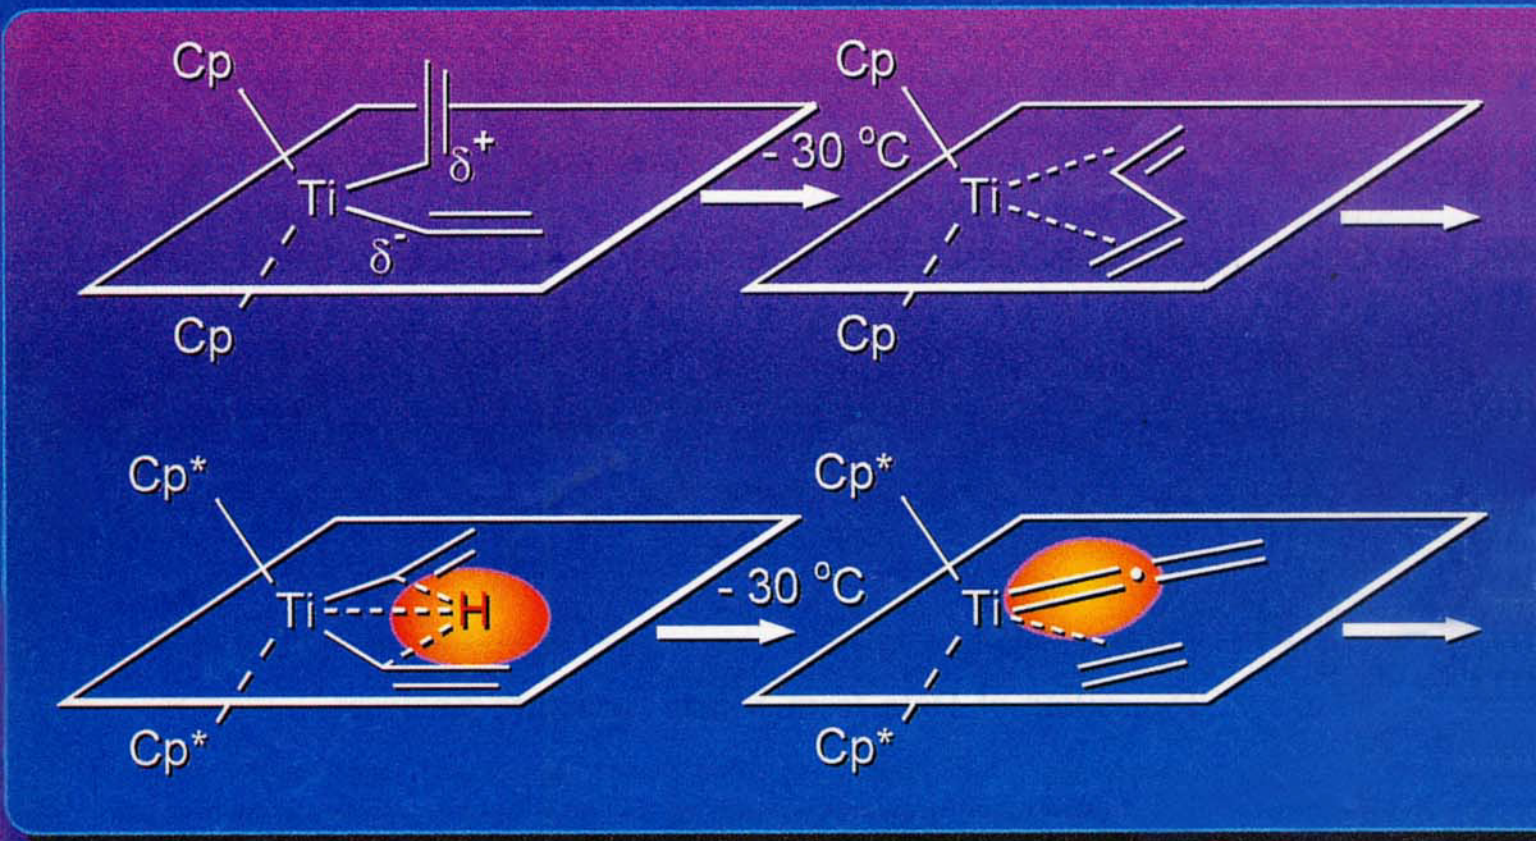
Prior to submitting your manuscripts please deposit the data for your compound(s) **electronically** at the appropriate data base, that is, at the CCDC for organic and organometallic compounds and at the FIZ for inorganic compounds. Both data bases will be pleased to provide help (see our *Notice to Authors* in the first issue of this year). In general, you will receive a depository number from the data base within two working days after electronic deposition; please include this number with the appropriate standard text (see our *Notice to Authors*) in your manuscript. This will enable the referees to retrieve the structure data quickly and efficiently if they need this information to reach their decision.

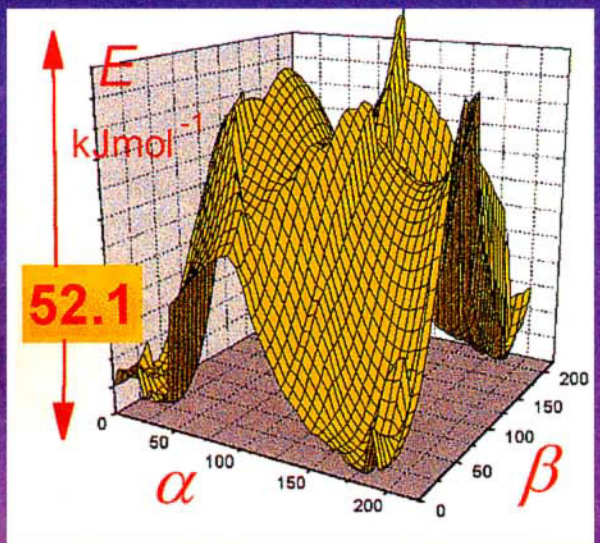
This is now the uniform procedure for manuscripts submitted to the journals *Angewandte Chemie, Chemische Berichte/Recueil, Chemistry—A European Journal*, and *Liebigs Annalen/Recueil*.

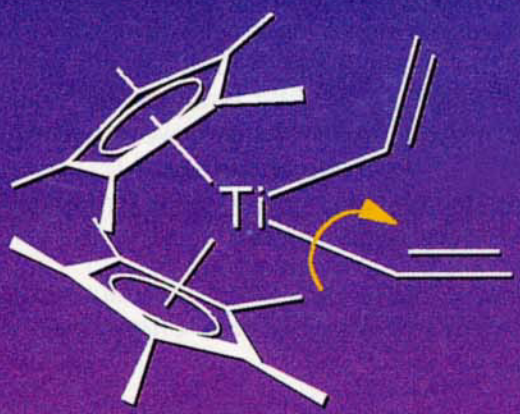


Rotation barriers about M–C σ-bonds determine the reaction behavior of 1-alkenyl transition metal complexes









Results from MMX force field calculations

Carbenoid Complexes of Electron-Deficient Transition Metals—Syntheses of and with Short-Lived Building Blocks

Rüdiger Beckhaus*

Dedicated to Professor Karl-Heinz Thiele

The relation of thermodynamic stability and kinetic lability of σ-organometallic compounds of transition metals, together with an improved understanding of the subtle interactions between central metal, ligands, and substrates, has increased the chemist's ability to plan organometallic syntheses. This article presents new results on intermediary and isolable synthetic building blocks incorporating metal–ligand multiple bonds of electron-deficient transition metals; the main emphasis will be placed on compounds with titanium–carbon double bonds. This particular class of compounds is mainly generated by H-transfer reactions starting from readily accessible alkyl and alkenyl derivatives. The preparative use of $[L_2Ti(CHR_2)R']$ derivatives as sources for $[L_2Ti{=}CR_2]$ intermediates will be discussed, as well as the nature of these intermediates. Application of the same approach to vinyltitanium compounds $[L_2Ti(CH{=}CH_2)R]$ opens up an access to a short-lived metallaallene derivative $[L_2Ti{=}C{=}CH_2]$ of an electron-deficient transition metal. The reactivity of these synthetic building blocks is mainly characterized by the nucleophilic properties of the α-C atoms as well as by the spatial orientation of the π-bonding planes. Numerous cycloaddition products with unsaturated substrates could be isolated and characterized for the first time by using $[L_2Ti{=}C{=}CH_2]$ intermediates. Hence it is possible to compare the properties of a multitude of metallacyclic ring systems with those obtained from "Tebbe–Grubbs chemistry", and in this context, the dependence of the properties of metallacyclic four-membered rings on the substitution pattern is discussed. This class of compounds includes the metallaoxetanes, which have been obtained for the first time by the cycloaddition of the $[Cp_2^*Ti{=}C{=}CH_2]$ intermediate with cumulenes and metal carbonyls. The differing cycloreversion behavior of these metallaoxetanes enables the differentiation of species exhibiting classical and nonclassical reactivity. The number and position of the exocyclic double bonds are the determining factors of the reactivity of the formed metallacycles. The discussion of the products obtained from titanium methylene and vinylidene building blocks is an up-to-date report on the formation and applications of carbene complexes and carbene intermediates of group 4 metals.

Keywords: carbene complexes · cycloadditions · metallacycles · titanium · vinylidene complexes

1. Introduction

Organometallic chemistry has shown to be a principal source of innovations in the search for new synthetic principles, new procedures for stoichiometric or catalytic reactions, or reaction pathways that simultaneously guarantee high selectivity and high reactivity. While the "formative years" of organometallic chemistry (1955–1975[1]) were characterized by the search for stable, isolable compounds, as well as for useful ligands and structural types,[2–9] today's research is concerned with the multitude of reactions and applications in this field. Initially it was considered essential to avoid thermal transformations of organometallic compounds, which had been given the negative label *decomposition pathways*. Symptomatic for this conception is the inclusion of decomposition reactions only as an aside at the end of relevant review articles.[8, 9] Today, however, such reactions are increasingly employed for preparative applications.

Transition organometallic chemistry is so exciting today—every new issue of our favorite journal brings news, from Novosibirsk or Mülheim or College Station, of a dozen new structures, twice as many reactions. Not only can we make molecules, and often see their structures, but we begin to understand the intricate, beautiful patterns in which they move, what is easy and what is difficult for them to do.

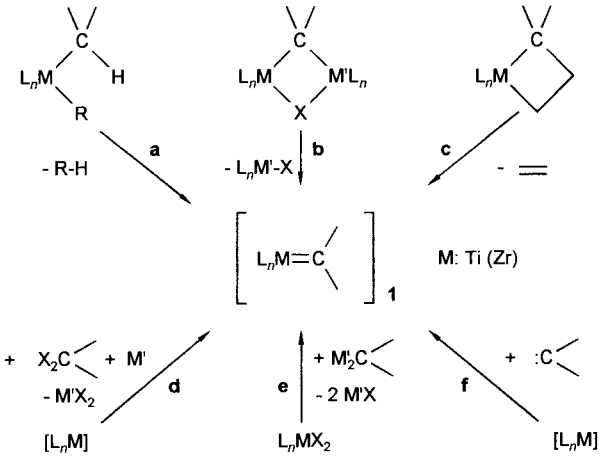
science are used, for example, for coating surfaces or preparing novel species or alloys—will not be covered here.[11–18] This article focuses on recent research on alkyl and alkenyl derivatives of electron-deficient transition metals, in particular with respect to their carbenoid properties. Particular attention is paid to isolable complexes with metal–carbon multiple bonds as well as to novel reaction products of short-lived carbene complexes of titanium group metals, with the aim of extending our knowledge of this area.[19–27]

The term *carbenoid* will be used in the sense originally formulated by Köbrich, based on work on α-halogen-substituted organolithium compounds.[28–33] Hence, the group of carbenoid compounds of transition metals will be understood to include those species with reactivities characterized by the primary formation of a carbene complex, whether they be isolable species or short-lived intermediates. The variety of reactions available for the formation of carbene complexes of electron-deficient transition metals indicates a high synthetic potential (Scheme 1). Preparative applications of carbene complexes generated by path a, as opposed to those obtained by path b, are frequently connected—when used in stoichiometric and catalytic reactions—with higher yields and selectivities, more choice of reaction media and substituents on the carbene ligand as well as more tolerant functional groups.



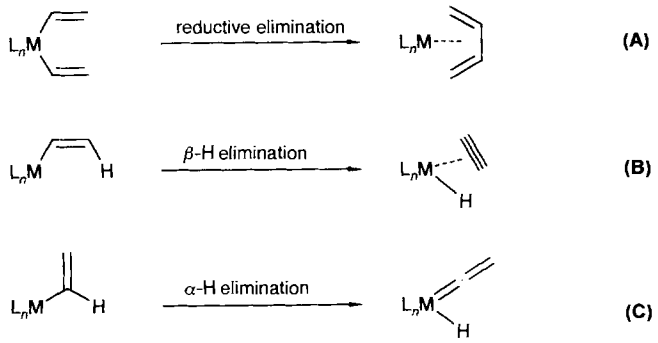
Scheme 1. Possible synthetic pathways a–f for complexes **1** with M–C double bonds.

Even though α-H eliminations have been well-established since the discovery of Schrock carbenes,[34, 35] this method (a) for the generation of **1**[36–53] has only recently been successfully applied to electron-deficient transition metal complexes. This is in contrast to the extensive use of dimetallic species,[54–60] of which, for example, the Tebbe reagent ($L_nM'X = Me_2AlCl$; path b)[24, 61–69] has assumed a prominent role in organic chemistry. Metallacyclobutanes derived from the Tebbe reagent—which have been extensively rescarched by Grubbs' group[70–72]—have also enhanced our knowledge about carbenoid transition metal compounds (path c). In addition, reagents are employed that exhibit active species that can only be derived by examining thc reaction products, such as the Takai reagent (path d).[21, 73–75] The reaction with geminal dinuclear complexes (path e) leads to the formation of intermediates with Ti–C double bonds.[76, 77] New pathways have also been obtained from the direct complexation of stable carbene ligands (path f).[78, 79] The carbene complexes of electron-deficient transition metals will be discussed according to the pathways of formation.

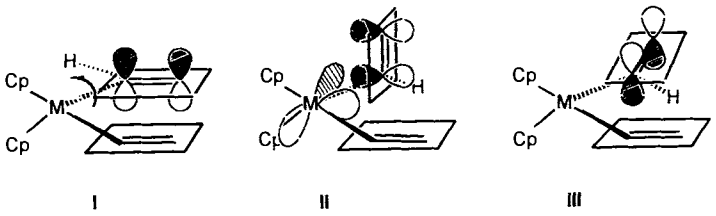
2. Reactivity of Alkyl and Alkenyl Derivatives of Titanium Group Metals

Since the discovery of stable homoleptic and heteroleptic alkyl compounds of the titanium group metals, their preferred decomposition reactions by H transfer have also been established.[80–86] For compounds incorporating no β-H-carrying ligands, α-hydride eliminations predominate.[87, 88] The thermal reaction behavior of σ-organometallic compounds is demonstrated particularly well by the chemistry of 1-alkenyl species of electron-deficient transition metals, in particular by σ-vinyl compounds. No other class of compounds allows the realization of all typical degradation pathways of M–C σ-bonds,[89] provided that the metal and ligand are well chosen.[90] For example, the divinyl compounds of unsubstituted zirconocene and hafnocene, as well as the $[(CpR)_2Zr(CH{=}CH_2)_2]$ derivatives (R = Me, Et, *i*Pr, $PhCH_2$)[91–93] form diene complexes by reductive elimination (Scheme 2A).[94–96] In contrast, substituted 1-alkenylzirconium compounds,[97] permethylated

Rüdiger Beckhaus was born in 1955 in Boizenburg/Elbe. He studied chemistry at the Technische Hochschule Leuna-Merseburg, obtaining his Diplom in 1980 with a study on organocopper compounds and his doctorate in 1984 for work on low-valent titanium and zirconium complexes under the supervision Prof. Dr. K.-H. Thiele. His habilitation thesis "The Chemistry of Vinyl Compounds of Electron-Deficient Transition Metals", submitted in 1991, laid the foundation for his current work on carbenoid compounds of the titanium group metals. These studies were extended during a period of research at the Technische Universität München as an Alexander-von-Humboldt fellow (Prof. Dr. P. Hofman, 1990/91). During 1991/92 he served as substitute C3 professor at the Rheinisch-Westfälischen Technischen Hochschule (RWTH) Aachen and in 1994, he spent time working with Prof. Dr. R. H. Grubbs at the California Institute of Technology. The author is a Heisenberg fellow of the Deutsche Forschungsgemeinschaft and since 1992 has been a Privatdozent at the Institut für Anorganische Chemie der RWTH Aachen. His main area of research covers the coordination chemistry and catalytic aspects of the organometallic chemistry of electron-deficient transition metals.



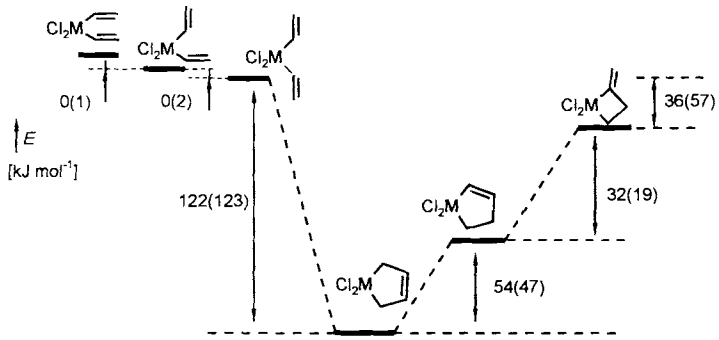
Scheme 2. Reactions of 1-alkenyl metal compounds.



C–H lateral C–H central

Scheme 4. Rotamers of 1-alkenyl groups on pseudooctahedral $[Cp_2M]$ fragments. M = Ti, Zr, Hf.

$[Cp^*_2Zr(CH{=}CH_2)_2]$ complexes ($Cp^* = C_5Me_5$),[98–100] and sterically bulky substituted $[Cp^{\#}_2Zr(CH{=}CH_2)_2]$ derivatives ($Cp^{\#}$ = tBuC$_5$H$_4$, tBu$_2$C$_5$H$_3$, iPr$_3$C$_5$H$_2$[91,92]) react by primary β-H elimination (Scheme 2B) to yield metallacyclopentenes. Probably the most interesting reaction in this chemistry is the transformation of $[Cp^*_2Ti(CH{=}CH_2)_2]$ to methylenetitanacyclobutane $[Cp^*_2TiC(=CH_2)CH_2CH_2]$,[101] which proceeds quantitatively in situ even below room temperature and is characterized by the appearance of a vinylidene intermediate (Scheme 2C). This reaction is one of the few in which an α-H elimination is preferred over a β-H elimination.[102–104] These reactions always proceed with high selectivity. Thermodynamic considerations suggest that the reductive elimination of vinyl groups should be preferred, as is shown, for example, by ab initio calculations (Scheme 3).[105] Kinetic factors are able,



Scheme 3. Results of ab initio calculations for $[Cl_2M(CH{=}CH_2)_2]$ transformation products M = Ti, Zr, values for titanium compounds given in parentheses (pseudo potential basis set according to Stevens, Basch, and Krauss).

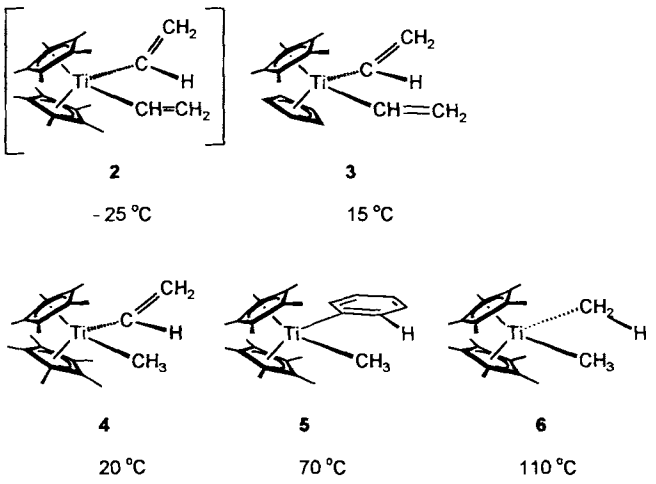
however, to force the reaction to go in different directions, especially when the metal center is not readily reduced, when hydrocarbon ligands with acidic hydrogen atoms are employed, or when only limited rotation of the 1-alkenyl groups is possible. The latter factor in particular provides insight into the reactivity of M–C σ-bonds of electron-deficient transition metals. A detailed analysis is required to understand why the divinyl species $[Cp_2Zr(CH{=}CH_2)_2]$ (Cp = C_5H_5) reacts quantitatively in situ to yield the diene complex $[Cp_2Zr(\eta^4\text{-}C_4H_6)]$, while substitutions on the alkenyl or the cyclopentadienyl moiety lead to β-H elimination products.[97] For the comparable phenylzirconium derivatives $[Cp_2ZrPh_2]$ (Ph = C_6H_5), thermal conditions lead to aryne products (β-H elimination),[106–109] while photochemical conditions yield diphenyl, the product of reductive elimination.[110] Why is it that the question of whether an alkenyl group can freely rotate determines the nature of the reaction products?

The preferred rotamers of 1-alkenyl groups on pseudooctahedral $[Cp_2M]$ complexes enable the central metal to reduce its electron deficiency through p_π–d_π interactions with the vinyl group. The rigid orientation of the frontier orbitals in the mirror plane of the bent metallocene fragment,[111] however, only allows effective interactions for the rotamer **II** (Scheme 4). The properties of rotamers **I** (*C–H lateral*) and **III** (*C–H central*) will be discussed in Section 3.1. The orientation of the C–H bond under consideration is similar to that of acyl groups in $[Cp_2Zr]$ complexes.[112] The coordination of the rotated alkenyl group in **II** to a second transition metal center allows the expected shortening of the M–C bond to be observed.[113] In divinyl compounds, an interaction of type **II** results in an asymmetric charge distribution between the α-C atoms,[105] forming nucleophilic and electrophilic α-C atoms, which favors the spontaneous thermal reductive elimination. When these rotations are hindered by substituents, the central metal interacts with neighboring C–H bonds instead of the described d_π–p_π interactions.

For the comparable phenyl compounds $[L_2TiPh_2]$, it is possible to demonstrate experimentally a restriction in the rotation around the Ti–C σ-bond upon increasing the degree of substitution on the Cp ligands.[114] The reduced coordination angle of permethylated bent metallocene fragments $[Cp^*_2M]$ as compared to nonmethylated derivatives $[Cp_2M]$ is responsible for this effect (e.g., $[Cp_2Zr]$: 95°; $[Cp^*_2Zr]$: 55°).[115] In the chemistry of vinylzirconium compounds, this reduction in the coordination angle results in the transition from the quantitative formation of diene complexes by reductive elimination to the primary β-H elimination by a preferred interaction of the β-vinyl C–H bond and the metallocene fragment,[116,117] leading to the formation of metallacyclopentenes.[90,98]

In contrast to the zirconium compounds, α-H transfers predominate in the case of titanium complexes. The minimum temperatures at which α-H transfer occurs increase with decreasing steric bulk (see **2** and **3**), while H eliminations from phenyl[118] or alkyl[87] derivatives require higher temperatures (Scheme 5). The rather mild conditions required for α-H eliminations from 1-alkenyltitanium compounds make it possible to demonstrate the chemistry of the titanaallene $[Cp^*_2Ti{=}C{=}CH_2]$ formed; it resembles that of a titanacarbene "*cumulogous*" to the $[L_nTi{=}CR_2]$ intermediates.[119]

As excellent examples for the stabilization of reactive molecules by complexation,[120] metallaallenes $[L_2M{=}C{=}CR_2]$ are very important in the organometallic chemistry of electron-rich



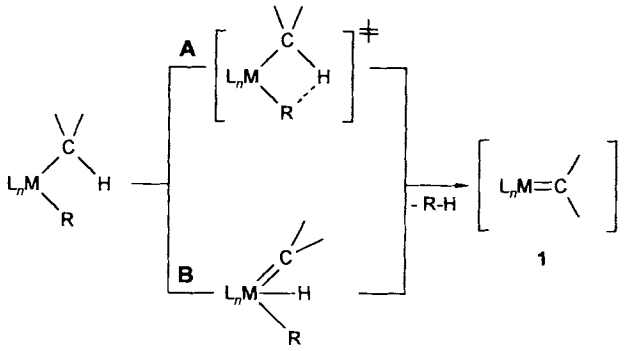
Scheme 5. Onset temperatures of H eliminations of selected titanocene complexes.

transition metals.[23, 121–123] In contrast, isolable vinylidene complexes of the titanium group metals are thus far unknown, even though their existence is demonstrated by various trapping reactions,[90, 98, 101, 118, 124–131] as well as catalytic[132] and preparative applications.[131–136] Comparable α-H transfers with participation of vinyl groups, as in the case of the formation of $[Cp_2^*Ti{=}C{=}CH_2]$, have been shown to occur only in a few cases, for example in the formation of $[Cp_2^*Ta(=C=CH_2)(H)]$[104] and $[CpIr(=C=CH_2)(H)_2]$.[137] In addition to the syntheses of vinylidene species from vinyl compounds, the transformation of allyl derivatives of tantalum[138] and the deoxygenation of ketene complexes of niobium with isonitriles[139] have been reported.

3. Isolable and Intermediary Carbene Complexes of Electron-Deficient Transition Metals

3.1. Hydrogen Eliminations and the Generation of $[L_2M{=}CR_2]$ Complexes (Scheme 1, Path a)

α-H eliminations proceed especially readily when there is significant steric crowding and where it is possible to transfer an α-hydrogen atom to a carbanionic acceptor ligand. The reaction is intramolecular, and first-order reaction kinetics are observed for organometallic complexes of the titanium group metals that show C–H bond breaking in the rate-determining step with either a cyclic reaction path (Scheme 6, path A) or a hydride intermediate (Scheme 6, path B).



Scheme 6. The course of α-H eliminations.

The activation enthalpy and entropy are characteristic of a σ-bond metathesis, which is identified by negative values for $\Delta S^{\neq}$, that is, by a high degree of order in the rate-determining step.[87, 88, 140] A comparison of activation enthalpies (Table 1) shows that, as expected, α-H abstractions occur more readily for neopentyl species[141] than for methyl derivatives.[87] The values for the activation entropies indicate a higher degree of order, corresponding to a lower mobility, for neopentyl, aryl, and vinyl derivatives than for methyl or benzyl compounds. The strong isotope effects $k_{H/D}$, in addition to the negative $\Delta S^{\neq}$ values are in agreement with a cyclic transition state (Scheme 6, path A).[87, 88, 118, 142–145] In contrast to this, hydride intermediates (Scheme 6, path B) show $k_{H/D}$ values of close to 1.[146] The half-life for the thermolysis of $[Cp_2Ti(CH_2CMe_3)_2]$ at 20 °C is between 20 and 56 minutes. The $[Cp_2Ti{=}CHCMe_3]$ that forms can be trapped with phosphanes or used in further reactions, such as intermolecular C–H activations.[141] The steric overloading favorable for α-H eliminations can be achieved by organic moieties (e.g., neopentyl groups) or by bulky ligands. In addition to permethylated cyclopentadienyl groups or those with bulky substituents,[91] substituted alkoxides[143, 147] or amides[148] fulfill this criterion.

The high selectivity of the methane elimination from the vinyltitanium compound $[Cp_2^*Ti(CH{=}CH_2)CH_3]$ (**4**) is of particular value in the generation of the vinylidene intermediate **8**.[118] The spontaneous intramolecular H transfer between the two vinyl groups in $[Cp_2^*Ti(CH{=}CH_2)_2]$ (**2**) had been discovered earlier,[98] but is proceeds under conditions that prevent the isolation of **2**. The resulting vinylidene–ethylene complex **7** reacts quantitatively to yield methylenetitanacyclobutane **9** (Scheme 7).[90, 101, 119, 129, 149]

The cyclic transition state necessary for the generation of **8** from **4** (Scheme 6, path A) can only form if the vinyl group is present as rotamer **III** (*C–H central*). Nuclear Overhauser ef-

Table 1. Selected kinetic parameters of H eliminations.

Starting material	Leaving group	Intermediate or product	$\Delta H^{\neq}$ [kJ mol^{-1}]	$\Delta S^{\neq}$ [J mol^{-1}K^{-1}]	$k_{H/D}$	Ref.

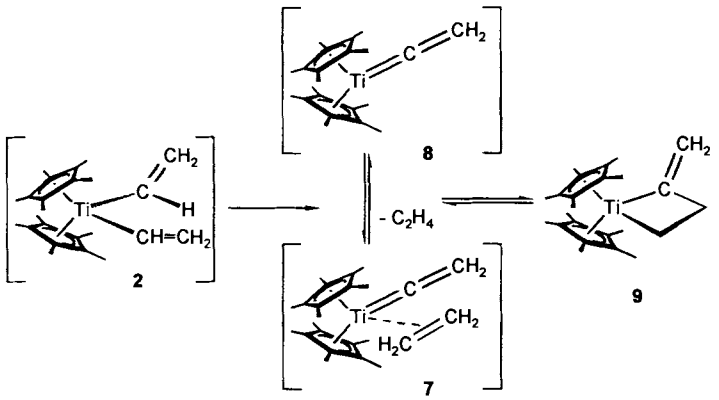


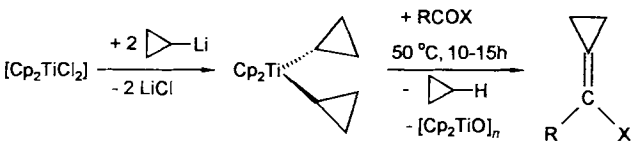
Scheme 7. Synthesis of methylenetitanacyclobutane **9** by a rearrangement of **2**.

fects (NOE) measurements, however, show the orientation of the vinyl group in **4** to be exclusively that of rotamer **I** (*C–H lateral*).[150] The *C–H lateral* conformation also predominates in crystal structures of similar complexes.[124, 126, 127] A rotation of the vinyl group (**I** → **III**) in **4** results in the immediate elimination of methane. Hence the rotation of the vinyl group around the M–C σ-bond contributes significantly to the activation energy of the reaction **4** → **8**.[151]

α-H transfer reactions are usually preceded by agostic interactions.[152, 153] A reliable method for their detection is the IPD method (IPD = isotopic perturbation of degeneracy).[154, 155] The temperature dependence of the measured values for Δ_1 and Δ_2 allows the strength of the agostic interaction to be determined. The reason for this effect can be found in the tendency of the lighter nucleus (H) to favor the agostic position M←H–C rather than the alternative interaction M←D–C. Electron-deficient complexes of transition metals often show altered alkyl group structures when C–H–M interactions occur. This is particularly true for octahedral d^0 complexes, but less so for tetrahedral d^0 complexes.[156] Studies on substituent effects have shown that π donors weaken agostic interactions, while π acceptors enhance them, especially when the ligand and the C–H bond are arranged *trans*.

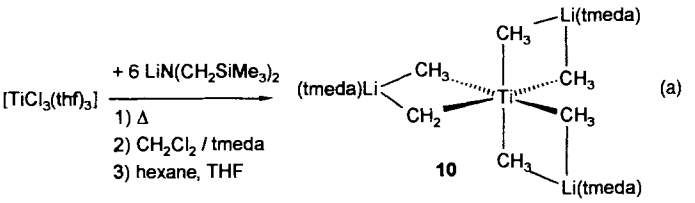
Selective α-H eliminations can also be used to generate substituted alkenylating reagents [L_nTi=CHR] (R = C_6H_5,[37] *t*Bu,[157] $SiMe_3$[38, 41]). For instance, during the thermolysis of [$Cp_2Ti(CH_2C_6H_5)_2$],[85, 158] more toluene (α-H elimination product) is formed than dibenzyl (reductive elimination product; toluene:dibenzyl = 9.4:1).[37] As the reaction of bicyclopropyltitanocene shows,[39] even β-H-containing compounds of strained ring systems can be used for "alkylidenecyclopropanation" in carbonyl olefination reactions (Scheme 8).

Apart from the above-mentioned α-H eliminations, complex reactions that form carbenoid compounds of the titanium group metals are also observed. For example, the reaction of



Scheme 8. Alkylidenecyclopropanations via Ti=C intermediates.

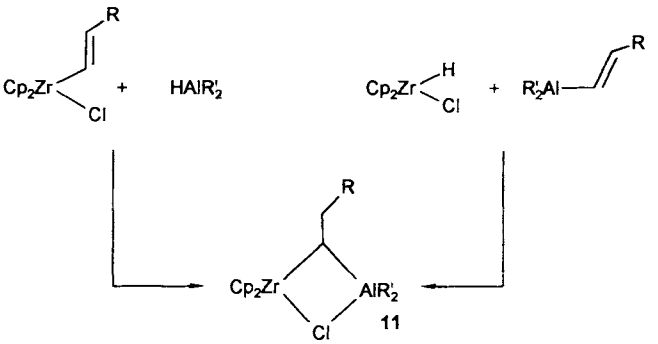
[$TiCl_3(thf)_3$] with [$(Me_3Si)_2NLi$] yields [$\{(Me_3Si)_2N\}_3Ti$] as well as the colorless, diamagnetic compound **10**[159] [Eq. (a); tmeda = *N,N,N′N′*-tetramethylethylenediamine]. NMR spectroscopic studies show that the methyl and methylene groups in **10** exchange rapidly. In the crystal, a monomeric [Ti(μ-CH_3)$_5$(μ-CH_2)] unit is present in which the titanium center is in a regular octahedral environment composed of carbon atoms. The Ti–C distances are unusually long (2.615(4) Å; see Table 2) and lie outside the range of bonding interactions. The comparably short Ti–H distances (2.229 Å) indicate that the carbon atoms are bound through hydrogen bonds to the titanium atom; however, there is no direct way of proving the existence of a methylene bridge.



(a)

3.2. Hydrocarbon-Bridged Dimetallic Complexes as Carbenoid Reagents (Scheme 1, Path b)

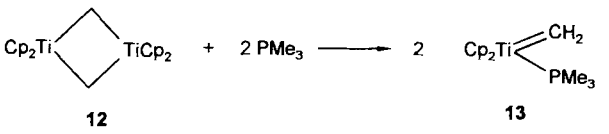
Whereas the Tebbe reagent has already been discussed in other articles as an effective and useful methylenating agent,[24, 61–63, 66, 68, 69, 160] homologous metal compounds or substituted alkenylating agents are not accessible directly by path b. One method of preparation for alkylidene-bridged Zr–Al complexes is based on the reaction of alkenezirconium or aluminum compounds with the corresponding metal hydride (Scheme 9).[161] An X-ray structure analysis of **11** revealed a



Scheme 9. Preparation of μ-alkylidene zirconium–aluminum compounds **11**.

remarkably short Zr–C distance (2.158(2) Å), clearly indicating pronounced alkylidene character in this compound. Furthermore, the Zr–Cl bond is significantly longer. The Zr=C species were generated by cleavage of $ClAl(iBu)_2$ with hexamethylphosphoric acid triamide.[162]

The dititanacyclobutane (bismethylene complex) **12** reacts rapidly and quantitatively with PMe_3 to yield **13**.[57] The carbene complex cannot be stabilized by PEt_3, PBu_3, or PPh_3.

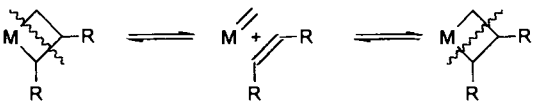


12 13

The cleavage of bis-μ-methylene complexes fails, however, for other metal combinations, such as Ti–Zr, Zr–Zr, or Ti–Si.[57, 163–166]

3.3. Cycloreversions of Metallacyclobutanes (Scheme 1, Path c)

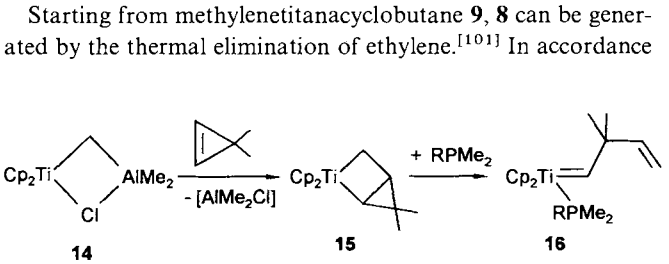
The use of titanacyclobutanes as the starting material has the advantage over the Tebbe reagent that additional Lewis acidic components such as [$Me_2AlCl \cdot L$] are not separated after the reaction. For the synthesis of titanacyclobutanes, procedures can be employed that were developed by Grubbs, using the Tebbe reagent,[58, 66, 70, 131, 135, 167–177] by Bickelhaupt,[54, 178–181] preferably using 1,3-di-Grignard species, or by Stryker,[182] employing allyl complexes. Titanacyclobutanes can also be used to generate substituted[170] or cumulogous [$Cp_2Ti{=}CR_2$] species. There is a problem, however, namely that singly substituted titanacyclobutanes such as α,β-dimethyltitanacyclobutane react preferably under elimination of butene[71] instead of propene. Hence, "productive" cleavage reactions are required (Scheme 10).



Scheme 10. "Productive" and "unproductive" cleavage of metallacyclobutanes.

A "productive" cleavage occurs when highly strained cyclic olefins like 3,3-dimethylcyclopropenes are used in conjunction with Tebbe's reagent. The resulting titanacycle is capable of transferring α-substituted carbenes in carbonyl olefinations. The reactive titanium carbene can be stabilized with PMe_3 or PMe_2Ph.[170] The reaction of the cycloaddition product with cyclopropene can be explained by the strain energy of the cyclopropene. The "nonproductive" cleavage would require the formation of the strained cycloolefin cyclopropene.

Starting from methylenetitanacyclobutane **9**, **8** can be generated by the thermal elimination of ethylene.[101] In accordance



14 15 16

with this, the electron-impact induced fragmentation of **9** in the mass spectrometer shows the stepwise release of ethylene and one C_2H_2 fragment, leading to the formation of **8** and [Cp_2^*Ti]. Theoretical considerations led to the conclusion that the interconversion of **9** and the corresponding vinylidene–ethylene intermediate **7** must be thermally allowed and that d-AO participation at the titanium center enables the conversion to take place. The model geometries that were employed showed **7** to be 40.2 kJ mol^{-1} lower in energy than its cyclic isomer **9**. This is in contrast to the generalized valence bond (GVB) calculations for the equilibrium [$Cl_2Ti{=}CH_2(H_2C{=}CH_2)$]/[$Cl_2\overline{TiCH_2CH_2CH_2}$],[183] which indicated that the methylidene–ethene complex is 46.0 kJ mol^{-1} less stable than the metallacycle. GVB calculations for [Cl_2Ti] as metal fragment show no back bonding at all from titanium (formally d^2) to the olefin ligand, while model calculations for **7** indicate very different strengths of back bonding to the vinylidene and ethene units.[101] In agreement with the differing π-acceptor properties of the vinylidene and ethene ligands, **7** contains a $C{=}CH_2$ moiety that is strongly bound to the Ti, and a significantly weaker bound C_2H_4 ligand. The alternative cycloreversion of **9** to a methylidene complex [$Cp_2^*Ti{=}CH_2$] and allene is not only kinetically (unfavorable overlap populations), but also thermodynamically less favorable. Calculations for the systems [$Cp_2Ti{=}C{=}CH_2$ (minimum geometry) + free C_2H_4] and [$Cp_2Ti{=}CH_2$ (minimum geometry) + free allene] show a favorable energy balance of 79.5 kJ mol^{-1} for the products of the ring cleavage **9** → **8**.[101] The experimental findings for **9** show that thermal decomposition with release of ethylene does not begin until about 130 °C and reactions that trap the [$Cp_2^*Ti{=}C{=}CH_2$] formed are only possible in solution at relatively high temperatures (60–100 °C), in contrast to Grubbs' findings for [Cp_2Ti]-titanacyclobutanes. This suggests a high activation barrier, which, according to model calculations, stems from the cycloreversion step.

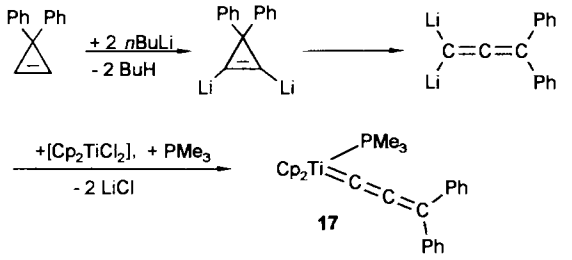
3.4. Special Carbenoid Reagents (Scheme 1, Path d)

The Takai reagent has proven to be an effective methylenating agent in preparative applications. In addition, it can be generated from commercially available components. Mixtures of CH_2I_2, zinc, and a titanium compound ($Ti(OiPr)_4$, $Ti(NEt_2)_4$, or $TiCl_4$) yield a reagent that can transform aldehydes, ketones,[184] enolizable ketones,[185] esters,[186] and other carbonyl compounds[187] into the corresponding olefins. Carbene intermediates [$X_2Ti{=}CHR$] have also been assumed for this reaction, even though it has not been possible to isolate them or identify them spectroscopically.[74] Impurities in the form of other metals, for example, traces of lead in the zinc used, often activate carbonyl olefinations[75] or deactivate cyclopropanations.[188]

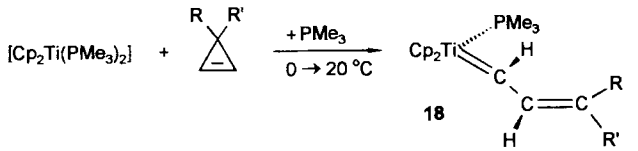
3.5. Geminal Dimetallic Compounds as Sources for Carbenoid Reagents (Scheme 1, Path e)

Analogous to the many applications of salt metathesis reactions to the generation of simple organometallic compounds, for example reactions of transition metal halides with Grignard or lithium compounds, geminal dimetallic species M'_2CR_2 can be used to prepare carbene complexes. Butyllithium reacts under mild conditions with diphenylcyclopropene to yield a 1,1'-

dilithio-3,3-diphenylallene derivative, which can react with $[Cp_2TiCl_2]$ in the presence of PMe_3 to yield the first titanabutatriene derivative **17**.[77]



The reaction of cyclopropenes with low-valent metal complex fragments leads to vinylcarbene complexes, a procedure that is employed to obtain the corresponding derivatives of the platinum metals.[189,190] The fundamental studies were done by Binger et al., who synthesized **18** in 72% yield.[191]

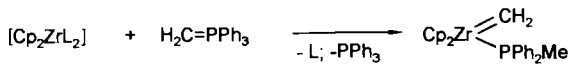


a, R = R' = Ph
b, R = Me, R' = Ph

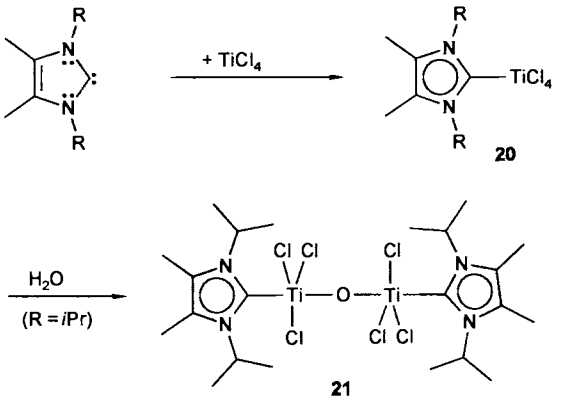
The dilithioalkylsulfone $[Li_2C(SO_2Ph)SiMe_3]$ reacts with $[(RO)_2TiCl_2]$ to yield an intermediate Ti=C derivative of unknown structure, which can be used as carbonyl olefination reagent.[76]

3.6 Carbene Transfer Reactions (Scheme 1, Path f)

One of the earliest examples of electron-deficient transition metal chemistry is the reaction of the zirconium(II) compound $[Cp_2ZrL_2]$ (L = PPh_2Me) with CH_2PPh_3 to yield the first methylenezirconium complex **19** observed in solution, which, however, decomposes within an hour.[192]



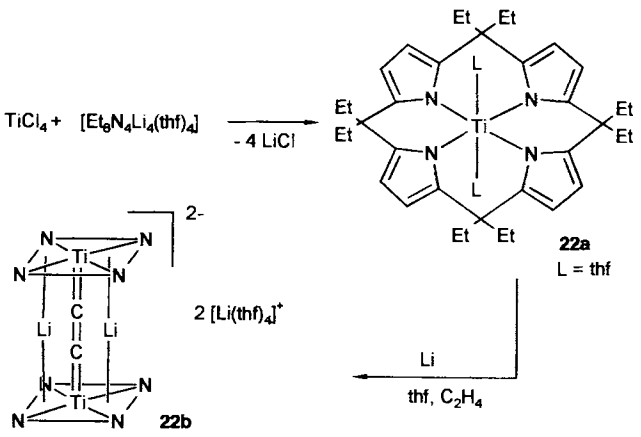
Progress has been made in this area through the use of the stable "Arduengo-carbene ligands".[78,193-198] For instance, the reaction with $TiCl_4$ allowed the isolation and characterization of the corresponding complexes **20**.[199] An X-ray crystal structure analysis of the product of a subsequent reaction (**21**) showed the expected long Ti–C bond (2.194(7); 2.202(7) Å). Owing to the lack of back bonding from the Ti^{IV} center, this bond length is in the upper range of known Ti–C σ-bonds.[200]



The ^{13}C chemical shifts of the carbene-C atoms were observed at δ = 185–186. The missing back bonding Ti → C leads to the assumption that the reactivity of these species is different from classical Ti=C systems.

3.7. Special Paths to Complexes with Ti–C Double Bonds

During the search for linear chains of carbon atoms between metal centers, Floriani et al. discovered that the one-pot synthesis of complex **22**, which contains a C_2 bridge, could be achieved



starting from ethylene.[201] This bridge is in a square-planar environment composed of two titanium and two lithium cations and is stabilized by two *meso*-octaethylporphyrinogen tetraanions ($Et_8N_4^{4-}$). The metallacumulene forms red crystals and is paramagnetic (μ_{eff} = 1.80 μ_B per titanium center at 290 K). The main structural characteristic is the Ti-C-C-Ti frame, which is linear within error limits. The Ti–C distances (1.809(9) and 1.757(7) Å) are significantly shorter than those in other $[L_2Ti=C]$ derivatives (see Table 2).[157,202]

The bistitanacumulene $[Cp_2Ti(PMe_3)=C=C=Ti(PMe_3)Cp_2]$ **23** is also characterized by a linear [Ti=C=C=Ti] chain, and is obtained by the reaction of $[Cp_2Ti(PMe_3)_2]$ with methylenecyclopropane.[202]

3.8. Spectroscopic and Structural Data of Isolated [L_nM=CR_2] Complexes

The M–C bonds of the few structurally characterized [L_nM=CR_2] complexes of titanium group metals are shortened to different extents depending on the ligand system.[157, 201–203] Earlier attempts to utilize α-H eliminations in the synthesis of, for example, isolable zirconium complexes with M=C bonds failed.[204] By employing a doubly functionalized Cp ligand and dibenzylmagnesium, it proved possible to isolate and characterize the zirconium carbene complex **24** (85%).[203] The ^{1}H resonance signal at δ = 8.1 (C*H*Ph) and the ^{13}C resonance signal of the carbene-C atom (δ = 229.4) can be considered characteristic. The low CH coupling constant of 86.8 Hz indicates an agostic interaction. The crystal structure of **24** shows a Zr–C distance of 2.024(4) Å, and the agostic interaction is evident from the corresponding values for the Zr–H distance (2.07(4) Å) and the Zr-C-C and Zr-C-H angles (169.2(3)° and 79.8(23)°, respectively; see Table 2). No rotation of the benzylidene ligand was observed. Treatment with acetone resulted in carbonyl olefination. Dineopentyltitanium compounds [L_2Ti(CH_2CMe_3)$_2$] with large phosphinoalkoxide ligands L_2 act as sources of the corresponding alkylidene complexes.[205] For example, the carbene complex **25** (R = Ph) is formed at temperatures as low as 5 °C (^{1}H NMR: δ = 12.4; ^{13}C NMR: δ = 287.3; see Table 2). The phenyl residue is metalated in solution. A metalation reaction of this kind can be avoided for R = CH_3 by creating a chelate ligand that is as rigid as possible (Z–Z = 1,2-phenylene), and dark green crystals of the titanium carbene complex **26** are obtained.[157] The Ti=C bond length (1.911(3) Å) is significantly shorter than that in the bisneopentyl starting material (2.120(4) Å; see Table 2). The Ti=C–C angle of 158.7(2)° and the Ti=C–H angle of 85(3)°, in combination with a Ti–H distance of 2.05(5) Å, indicate an α-agostic interaction in **26**, which is typical for d^0 alkylidenes. Comparison with [CpV=CHCMe$_3$(dmpe)] (dmpe = $Me_2PCH_2CH_2PMe_2$) shows a rotation of the alkylidene by 90° relative to the plane of the Cp ligand, as well as an increase of the V-C-C angle to 173.3(3)° and a decrease of the V-C-H angle to 65(3)°.[206, 207]

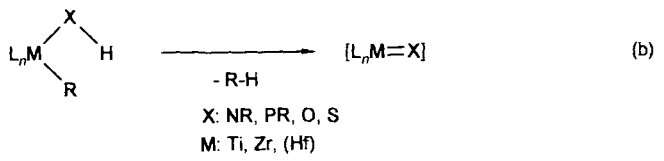
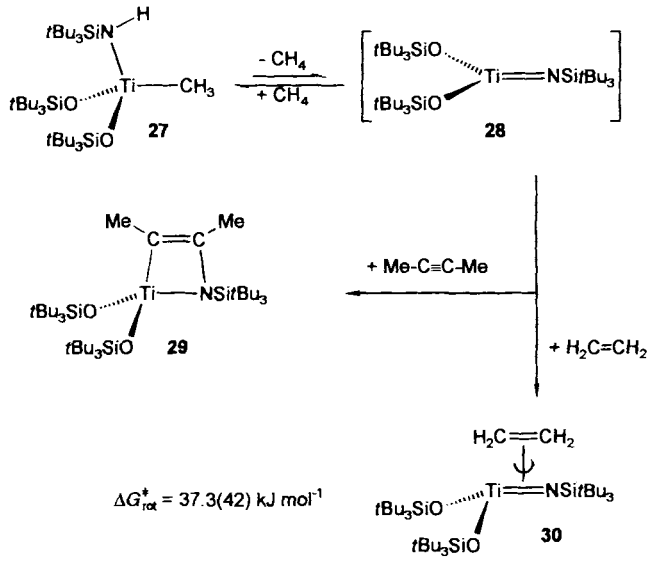
3.9. Applications of Hydrogen Eliminations to the Generation of Complexes with [L_nM=X] Moieties

α-H transfers can be used to generate multiple bonds between not only transition metals and carbon, but also between metals and other heteroatoms [Eq. (b)]. In this way, synthetic



(b)

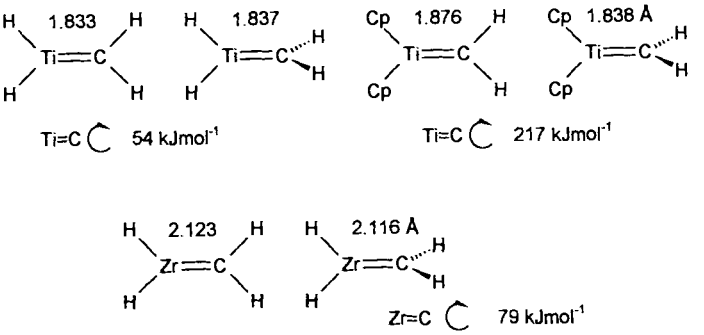
building blocks incorporating Ti=Si,[208] Ti=N,[209] Zr=N,[209, 211, 212] Zr=P,[213, 214] Zr=O,[215, 216] and Zr=S[215] bonds can be obtained. The large interest in these fragments of electron-deficient transition metal complexes,[26] in particular the imido–metal derivatives,[217, 218] stems from the possible applications in 1,2-addition reactions ($[Cp_2Zr{=}NR]$;[211, 219–222] $[(tBu_3SiNH)_2Zr{=}NSitBu_3]$;[223] $[(tBu_3SiNH)XTi{=}NSitBu_3]$;[210] $[(tBu_3SiNH)M(=NSitBu_3)_2]$, M = Ta,[224] V[225, 226]). For example, intermolecular C–H activation of alkanes[223, 224, 226] and arenes is found,[211, 219–226] reactions that are of practical and theoretical interest.[227] Studies of [2+2] cycloadditions[211, 219–222, 225, 228] have resulted in catalytic applications, such as the aminations of alkynes.[221] It was even possible to observe H–H activation with hydrogen (3 atm, 60 °C) in which $[(tBu_3SiO)_2(tBu_3SiNH)TiH]$ was formed as product (NMR: δ(Ti–H) = 8.62; IR: ν(Ti–H/D) = 1645/1185 cm^{-1}).[229] Cycloadditions of the intermediate **28** and alkynes yield azatitanacyclobutenes such as **29** (Scheme 11). The azatitanacyclobutane **30**, formed by the addition of ethylene, is characterized by its dynamic behavior; at room temperature, only one CH_2 signal of the ethylene molecule is observed.[209]



Scheme 11. Cycloadditions with $[(tBu_3SiO)_2Ti{=}NSitBu_3]$ intermediates **28**.

4. The Nature of Ti–C Double Bonds

As expected from the M–C bond order, $[L_nTi{=}C]$ derivatives exhibit higher bond energies than $[L_nTi{-}C]$ complexes.[230] The reaction of methane with Ti^+ ions in a tandem mass spectrometer allows the derivation of the corresponding dissociation energies ($D^0(Ti^+{-}H) = 226.9 \pm 10.5$, $D^0(Ti^+{-}CH_3) = 240.7 \pm 11.7$, $D^0(Ti^+{-}CH_2) = 391.0 \pm 14.6$, $D^0(Ti^+{-}CH) = 507 \pm 17$ kJ mol^{-1}). The ratios of these values to each other (1.0:1.06:1.72:2.23) correspond to those expected for a titanium single, double, and triple bond, respectively. These relations therefore also correspond to the increase in bond energy between a hydrogen molecule (H–H), alkanes ($H{-}CH_3$), olefins ($H_2C{=}CH_2$), and acetylenes ($HC{\equiv}CH$) (1.0:1.01:1.65:2.21).[230] The bond energy in Ti=C complexes increases with the rotational barrier.[231, 232] STO-3G calculations on titana- or zirconaethylenes indicate a preference of the H atoms for the coplanar orientation by 54 and 79 kJ mol^{-1}, respectively, over the distorted conformer (Scheme 12).[233] The

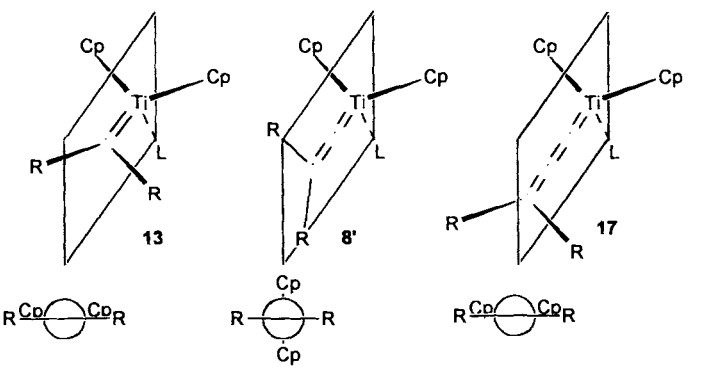


Scheme 12. Bond lengths and rotational barriers in $[H_2M{=}CH_2]$ and $[Cp_2M{=}CH_2]$ complexes (M = Ti, Zr) determined by ab initio calculations.

changes in bond lengths are not significant. For $[Cp_2Ti{=}CH_2]$, a considerably higher rotational barrier of 217 kJ mol^{-1} is calculated, which is comparable with the barrier of the *cis–trans* isomerization in olefins (271.7 kJ mol^{-1}).[234] The unexpected elongation of the Ti=C bond in coplanar $[Cp_2Ti{=}CH_2]$ compared to that in the twisted rotamer is ascribed to steric interactions.

In the cumulogous compound **8**, the character of the metal fragment MO b_2 determines that in the structure **8′** only the $C{=}CH_2$ rotamer shown allows a Ti–C_α π-bond ("back bonding"). In accordance with this, model calculations on **8′** yield a rotational barrier of 134 kJ mol^{-1}.[101] For asymmetrically substituted vinylidenetitanium compounds it is possible to show a potential rotation around the Ti=C bond in solution.[131] For the titanaallenylidene **17**, no structural dynamics are observed, and NMR data indicate that all C atoms of the cumulene lie in a mirror plane of the molecule (Scheme 13).[77]

Detailed ab initio calculations by Cundari and Gordon show that the contributions of nucleophilic and neutral resonance



Scheme 13. Geometries of titanocenemethylene, -vinylidene, and -allenylidene complexes.

structures to the description of Ti=C bonds are dominant (Table 3).[231, 235, 236] The substituent effects established correlate, for example, with solvent effects in ring-opening polymerizations of norbornenes.[41] The contributions of nucleophilic resonance structures increase with the introduction of donor substituents at the carbene-C atom, while the contributions of neutral resonance structures decrease.

Table 3. Resonance contributions to the description of titanium alkylidene complexes [235, 236].

model compound	Resonance contributions [%] nucleophilic $Ti^{+}=C^{-}$	neutral Ti=C	electrophilic $Ti^{-}=C^{+}$
$[Cl_2Ti=CH_2]$	42	51	7
$[H_2Ti=C(H)Me]$	46	48	6
$[H_2Ti=CH_2]$	48	46	5
$[H_2Ti=CCl_2]$	50	45	5
$[H_2Ti=C(Cl)SiH_3]$	52	43	4

As **8** represents the reactive species of **9** and **4**, it is therefore of the most interest and its geometry and electronic structure will be more closely examined. Figure 1 shows the bonding in **8′**

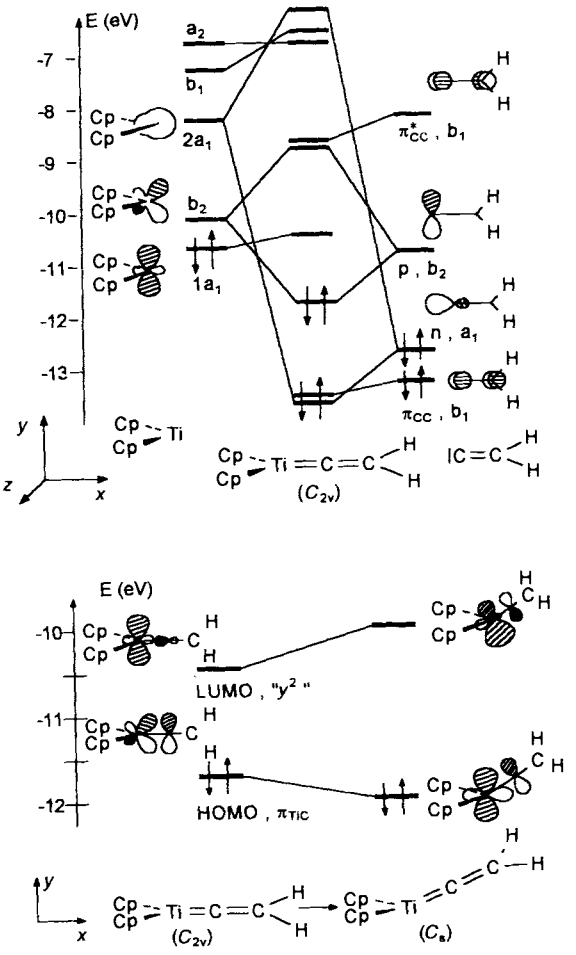


Figure 1. Top: Correlation diagram for a $[Cp_2Ti]$ fragment (C_{2v}) and vinylidene (C_{2v}) for "trigonal planar" $[Cp_2Ti=C=CH_2]$ (C_{2v}) (only relevant valence MOs are shown). Bottom: Decrease in energy for C_s-symmetrical **8**.

(Cp instead of Cp*) for C_{2v} symmetry, for which a $C=CH_2$ moiety is at the center of symmetry, using a correlation diagram between the known valence MOs of a Cp_2Ti fragment[111] and a vinylidene unit. The underlying structure with a centralized vinylidene group, however, is not the minimum geometry of **8′**. The removal of the linear $C=CH_2$ unit from the central position (with a trigonal-planar coordination at the Ti center) by 35° stabilizes the molecule by 27.2 kJ mol^{-1}. The resulting structure is shown on the right side of Figure 1. Favorable electronic conditions for the extremely strong π-acceptor ligand vinylidene explain the greater extent of the relaxation effect to the C_s geometry for **8′** (pyramidal for Ti). The electronic structure of **8′**, however, clearly indicates a singlet ground state. The two frontier orbitals help to clarify how $[Cp_2Ti=C=CH_2]$ binds by the interaction with the π and π* orbitals of ethene, or an electronically similar ligand species. The LUMO of $[Cp_2Ti=C=CH_2]$ is ideally oriented in the direction of the "open" coordination site between the two Cp rings, and its occupation by electron density from overlap with a ligand donor orbital (such as the π orbital of C_2H_4) also populates the p-AO of the C_α atom of the vinylidene unit. The HOMO of $[Cp_2Ti=C=CH_2]$ is suitable for back bonding into a ligand-acceptor MO of appropriate symmetry (such as the π* orbital of C_2H_4). Neither interaction is particularly strong, as the interaction of the vinylidene ligand with the Cp_2Ti fragment leads to a relatively high LUMO energy and a relatively low energy for the HOMO of **8′**.[101]

5. The Coordination Chemistry of Reactions with Carbenoid Metal Compounds of Electron-Deficient Transition Metals

Kinetic studies and numerous trapping experiments have shown that the thermally generated $[L_2Ti=CH_2]$ and $[L_2Ti=C=CH_2]$ species represent real intermediates.[126, 131, 142] In the following discussion, the reactions leading to their formation will only be mentioned where necessary.

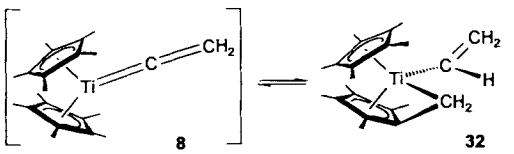
5.1. Reactions with Electrophiles

In view of the nucleophilic properties of the α-C atoms in $[L_nTi=C]$ derivatives, rapid reactions with electrophiles are expected. Reactions of the thermally generated **8** do indeed selectively yield 1-alkenyltitanium compounds. The use of CH_3OD in reactions of **9** or **4** yields products that are exclusively deuterated in the α-vinyl position.[126] This is an indication that initially cycloreversion (from **9**) or α-H transfer (from **4**) take place before electrophilic addition reactions can occur. If **9** is allowed to react with a stoichiometric amount of water, the monomeric vinyltitanium hydroxide $[Cp^*_2Ti(OH)CH=CH_2]$ **31** is obtained in 86% yield as a yellow, microcrystalline product. The selective protonation of the vinylidene species **8** can also be transferred to C–H acidic compounds.[124] This suggests that the mechanisms of reactions of sterically shielded metal alkyl compounds with electrophiles should be reconsidered,[237] as they do not necessarily have to proceed according to an acid–base mechanism as in the case of homoleptic metal alkyl compounds.[238–240]

5.2. C–H Activation Reactions on [L_nTi=C] Fragments

In order to coordinatively saturate the [L_nTi=C] derivatives, intramolecular C–H activation reactions occur in many cases. For example, **8** spontaneously reacts to yield the dark green vinylfulvene derivative **32**. This behavior is similar to the cyclometalations of other [L_nM=C] derivatives with related ligands (Ti,[87, 157, 205] Hf,[88] Nb,[241] Ta[143]).

The signal of the methyne hydrogen atom of the vinyl group in **32** is shifted to higher field (δ = 5.11)[128] than in other vinyl compounds.[126] The simultaneous broadening observed corresponds to an equilibrium between **32** and **8**.

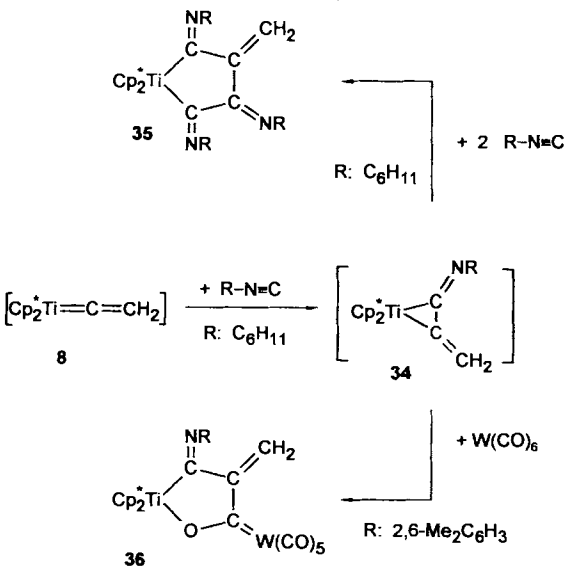


Starting from [Cp_2Ti=CH(CMe_3)], C–H bonds of benzene or *p*-xylene can undergo intramolecular activation and [Cp_2Ti(CH_2CMe_3)R'] complexes are formed.[141] This behavior is comparable to that of d^0 metal imides(Zr,[219, 223] Ti,[210, 229] V,[226] Ta[224]). Overall, this reaction type corresponds to the reverse of the original formation reaction by α-H elimination. For **8** it is possible to show that an intermolecular C-H activation of acetylene takes place, leading to the formation of [Cp_2^*Ti($CH{=}CH_2$)(C=CR)] complexes **33**.[124]

5.3. [2+1] Additions

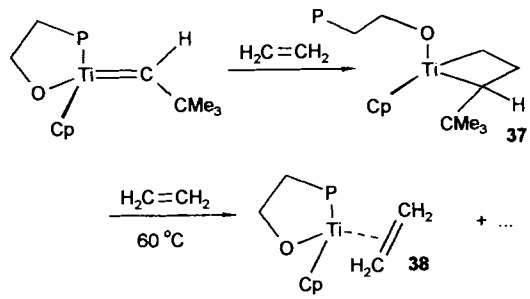
Reactions of metal–carbon multiple-bond systems with isocyanides present a potential synthetic method for the generation of keteneimines.[242] This reaction, however, has thus far been unknown for compounds of the elements of group 4. Reactions of **8** with cyclohexylisocyanide primarily yield the metallaheteroradialene **34**, which spontaneously reacts with further isocyanide to give **35**,[243] or with metal carbonyls to yield **36**.[244]

The coupling of a carbene ligand with carbon monoxide can be demonstrated for isolable carbene complexes with bulky, chelating phosphanealkoxides and a Cp ligand. Ketene complexes are formed in this reaction.[157]



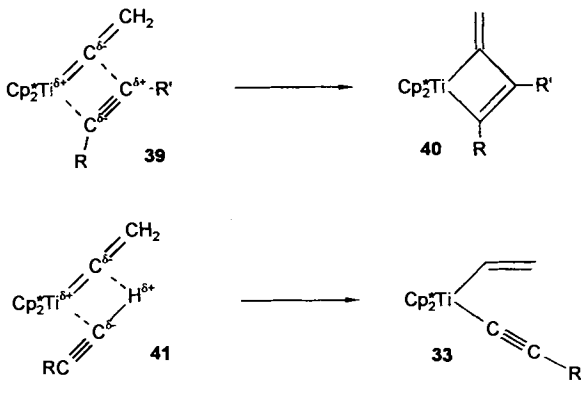
5.4. Cycloadditions with Olefins and Acetylenes

Reactions of [L_nTi=C] fragments with olefins lead, in symmetry-allowed reactions, to metallacyclobutanes, which are generally able to undergo further metathesis steps. The behavior of the metallacyclobutane complex **37** is somewhat different. The ^{31}P resonance signal (δ = – 63.6) indicates that the P atom is not coordinated. If **37** is heated, no cycloreversion to the carbene complex takes place, but in the presence of excess ethylene the formation of a crimson colored ethylene complex **38** is observed as well as the release of propene, 3,3-dimethyl-1-butene, and 4,4-dimethyl-1-pentene as products of β-H and reductive eliminations.[157]

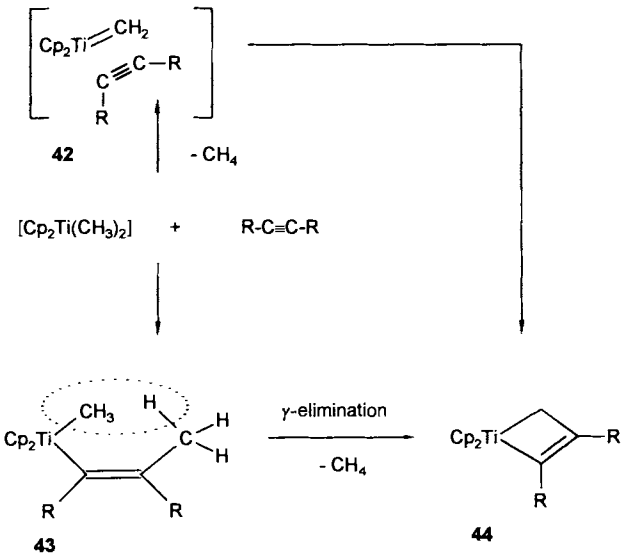


Metallacyclobutenes are found to be the products of [2+2] cycloadditions of metal carbenes with alkynes,[67, 245–248] as well as of the ring-opening of cyclopropenes.[249] The reactivity of vinylidene compounds of type **8** with alkynes is particularly important with respect to the mechanisms of polymerizations.[132, 250] Studies of the behavior of thermally generated **8** towards a number of alkynes have shown that the regiochemistry of the metallacyclobutene ring formation **39** → **40** is kinetically controlled and proceeds according to the polarity of the alkyne employed.[124, 251]

If acidic (terminal) alkynes (**41**) are used, a competing reaction occurs, namely the formation of vinylacetylides **33**. The use



of unsubstituted acetylene (HC≡CH), however, leads exclusively to the metallacycle **40**, a thermally stable compound. Competing reactions of acetylenes and olefins in cycloadditions with **8** yield exclusively the metallacyclobutene derivatives. Ab initio calculations for the systems $[Cl_2Ti{=}C{=}CH_2 + H_2C{=}CH_2]$ and $[Cl_2Ti{=}C{=}CH_2 + HC{\equiv}CH]$ indicate a preference of 101.5 kJ mol^{-1} for the metallacyclobutene ring.[105] Kinetic studies have shown that the primary alkyne insertion into a Ti–CH_3 bond with subsequent γ-elimination from **43** to give **44** could be an alternative to the direct [2+2] cycloaddition of the [Ti=C] species to the alkyne (**42**).[40]



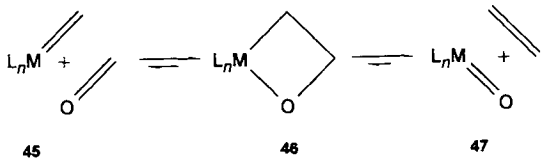
The reactivity of titanacyclobutenes is characterized by their principal ability to undergo cycloreversions **A** or electrocyclic ring-opening reactions **B** (Scheme 14). Depending on the substi-

Scheme 14. Reactions of titanacyclobutenes.

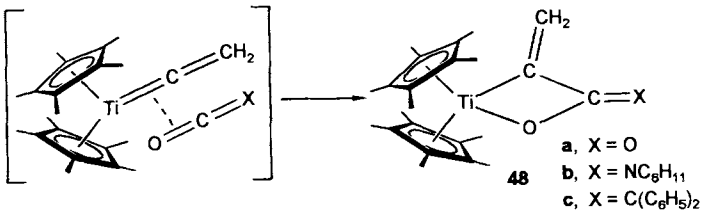
tution pattern, reaction path A or B is taken. Alkynes with particularly bulky ligands ($SiMe_3$) can be replaced by less sterically demanding ones.[67] This behavior is also observed for titanacyclobutenes generated from **8**.[124] The electrocyclic ring-opening B has so far only been demonstrated indirectly by using the products (polyacetylene) formed in the reaction.[124, 132, 252] The orthogonal orientation of the p orbitals in the metallacyclobutene ring with respect to the acceptor orbitals in the main plane of the Cp_2Ti fragment requires a direct interaction for the ring-opening B, which can only be realized in the case of metallacyclobutenes with fewer substituents.[111] This situation changes fundamentally in the case of heterocyclobutenes, for which subsequent products of electrocyclic ring-openings are found.[125] This behavior corresponds to that of tantalacyclobutenes, which can be isolated in the form of vinylcarbene complexes by the reaction with pyridine.[246, 253, 254] Kinetic studies on insertion reactions of titanacyclobutenes rule out the possibility of a primary ring-opening.[255]

5.5. Synthesis and Reactivity of Metallaoxetanes

Metallaoxetanes **46** are discussed as essential intermediates in the reactions of carbenoid metal compounds with carbonyl derivatives (**45** → **46**).[61, 62, 168, 256, 257] In addition, metallaoxetanes can be considered to be intermediates in the oxidation of olefins[258–260] as well in the formation and deoxygenation of epoxides.[261–263] Despite some progress towards experimental proof for metallaoxetanes in the case of Cr, Mo, W,[264, 265] or Ta compounds,[266, 267] the synthesis of titanaoxetanes remains a challenge. Theoretical calculations suggest that, as intermediates in carbonyl olefinations (**46** → **47**), these species should contain a planar ring structure.



The reactions of the vinylidene intermediate **8** with ketenes or carbon dioxide indicate the possibility for a synthesis of novel titanaoxetanes **48** with considerable thermal stability ($T_{decomp} > 150$ °C).[128, 129] The X-ray crystal structure analyses of **48b** (Figure 2) and **48c** confirm the presence of planar, mono-



meric metallaoxetane rings. These cycloaddition products represent the first structurally characterized titanaoxetanes with a planar ring geometry. The Ti–O (1.983(2) Å) and Ti–C bond lengths (2.121(3) Å) in **48b** are in the expected range (the values for **48c** are 1.966(3) and 2.119(6), respectively).

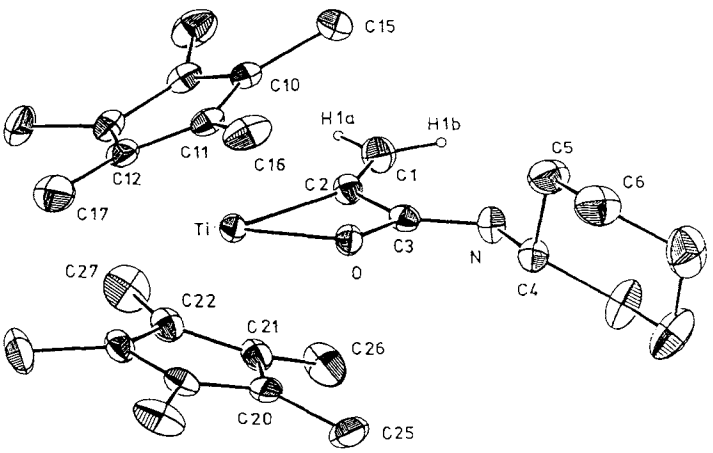


Figure 2. Crystal structure of **48b**.

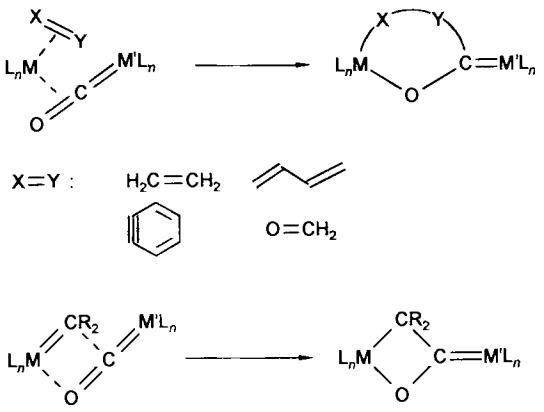
Considering that the driving force of carbonyl olefinations stems from the formation of a titanium oxide fragment,[256, 268, 269] the fact that the planar oxetanes **48** can be isolated[128, 129, 270] must be attributed to the reduced electrophilicity of the transition metal center due to the strongly basic Cp* ligands.[271, 272] This assumption is supported by the observation that titanaoxetanes similar to **48**, but with unsubstituted Cp ligands, have never been detected, even by spectroscopic means.[135] If the energy of the CO bond to be cleaved is increased by the use of metal carbonyls instead of heterocumulenes, it becomes possible to generate nonoxophilic oxetanes from **8**. Depending on the resulting reaction pattern, these metallaoxetanes can be classified as "classical" (**46** → **47**) or "nonclassical" (**46** → **45**). Mass spectrometry shows the formation of $[Cp^*_2Ti{=}O]$ fragments for the metallaoxetanes **48**, so that their classification as "classical" oxetanes is justified. As well as the effect of the Cp* ligands, the position of the exocyclic double bond in the metallacyclic ring is also essential for the high stability of the metallaoxetanes **48**. If the double bond is in the β position, such as in cycloaddition products of $[Cp^*_2Ti{=}O]$ with allene, rapid ring-opening occurs in solution, with the subsequent formation of fulvene enolates.[273]

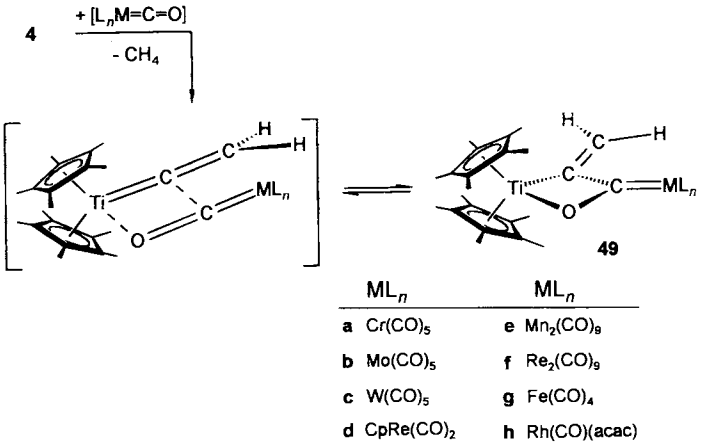
5.6. Synthesis of Heterodinuclear Carbene Complexes with a Titanaoxetane Substructure

The "nonclassical" metallaoxetanes can be obtained by the use of metal carbonyls as heterocumulene units in reactions with **8**.[274] In contrast to metal-mediated cycloadditions of metal carbonyls with arynes,[275–277] dienes,[278–285] olefins,[286] and heteroolefins[287] at metallocene fragments of group 4 metals,[288, 289] the corresponding reactions of Schrock carbene fragments with metal carbonyls are little known thus far (Scheme 15). In a few cases, corresponding intermediates have

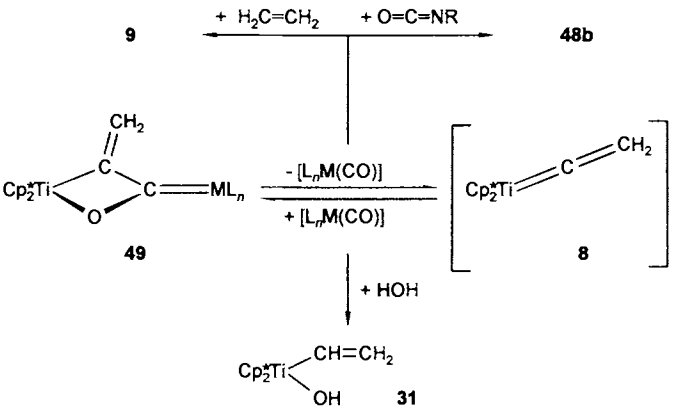


Scheme 15. Top: Metal-mediated cycloadditions to metal carbonyls; bottom: [2 + 2] cycloadditions of $[L_nM{=}CR_2]$ to metal carbonyls. M = Ti, Zr; M' = Cr, Mo, W, Mn, Re, Fe, Rh....

either been observed spectroscopically[290] or their existence has been postulated based on subsequent products.[291] For example, the reaction of **4** permits the isolation of the reaction products **49** (acac = acetylacetone) in the form of intensely colored crystals.[274]



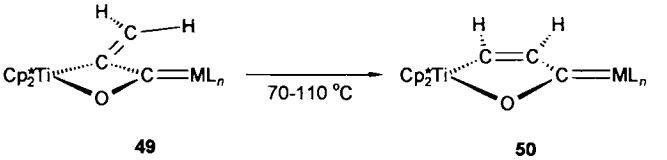
The spectroscopic data for **49** clearly indicate the titanaoxetane substructure. In the solid state, these "nonclassical" oxetanes **49** are stable up to temperatures of about 130 °C. Solutions, however, show a much higher reactivity, which is quite in contrast to the "classical" oxetanes **48**. For example, the rapid release of the heterocumulene occurs even at low temperatures, especially when potential π-acceptor ligands (ethylene, isocyanates) or even traces of moisture or oxygen are present (Scheme 16).[274] This means that the Fischer carbene com-



Scheme 16. Reactions of Fischer carbene complexes **49** with titanaoxetane substructures.

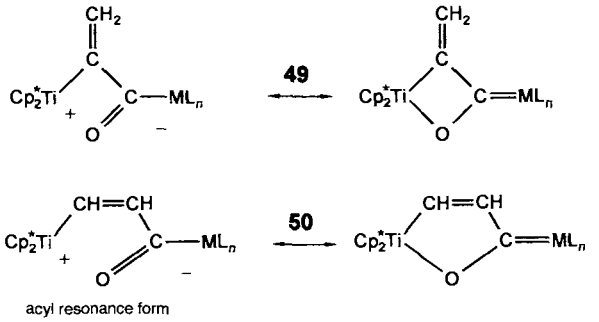
plexes **49** with a titanaoxetane substructure represent another effective source for the Schrock carbene fragment **8**. Inasmuch as complexes comparable to **49** are known at all, other decomposition reactions dominate, which exclusively proceed with the formation of metal–oxygen bonds (M = Ti;[290] M = Ta[291, 292]). This is in accordance with the expectations for metallaoxetanes.[260]

The nonclassical reaction behavior observed for heterodinuclear Fischer carbenes **49** with a titanaoxetane substructure



leads to an unusual destabilization of the titanium vinylidene moiety, which can undergo a rapid vinylidene–acetylene rearrangement.[128, 244, 274] Complex **49** isomerizes quantitatively to **50** without the appearance of any detectable intermediate products.[274]

In contrast to classical Fischer carbene syntheses with dinuclear metal carbonyls (e.g., $[Mn_2(CO)_{10}]$, $[Re_2(CO)_{10}]$),[293–298] an exclusively axial arrangement of the carbene ligands is observed in **49e** and **49f**, which remains in place even during the isomerization to give **50**. This preferred axial substitution can be taken as proof for the formation of **49** as a result of a [2+2] cycloaddition.[299] The location of the carbonyl bands in the IR spectra of **49** and **50** indicates a stronger acyl character for the four-membered rings **49** than for the five-membered species **50** (Scheme 17).[244, 274]



Scheme 17. Mesomeric structures of Fischer carbene complexes with titanacyclic substructures.

The formation of different acyl resonance structures is also suggested by the molecular structures of **50a** (Figure 3) and **50i** (L_nM = [Cp′Mn(CO)$_2$] (Cp′ = C_5H_4Me));[128, 274] **50a** exhibits a relatively long Ti–O bond (2.013(2) Å) as well as a short C(3)–O(1) distance of 1.286(3) Å. These characteristics are less

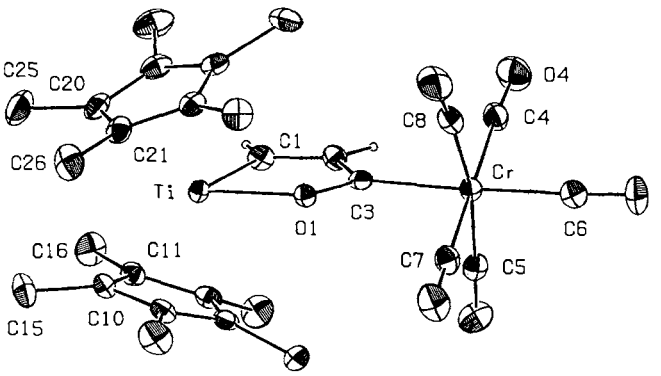


Figure 3. Crystal structure of **50a**.

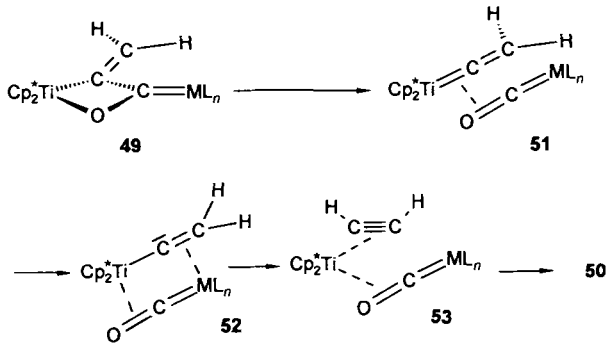
apparent in the Ti/Mn compound **50i**. Ti–O and C–O distances of 1.83 and 1.43 Å, respectively, can be considered characteristic for homonuclear titanaoxacyclopentenes, as shown in the cycloaddition product of $[Cp_2Ti(RC{\equiv}CR')]$ with acetone.[300, 301] In contrast to these complexes, a planar titanaoxacyclopentene ring, which results from the conjugated arrangement of the C=C and M=C bonds, is found to be structural characteristic. Hence the binuclear Fischer carbene complexes **50** can also be considered as 1,3-substituted η^1-vinylcarbenes.

The electron delocalization connected with this metalladiene structure is reflected in the alternating bond lengths.

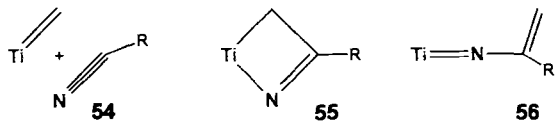
The rearrangement **49** → **50** is only found for the dimetallic compounds. The classical metallaoxetanes **48** do not exhibit such a ring expansion reaction. Apparently, the second transition metal destabilizes the Ti=C=CH$_2$ unit by interaction with the C=C bond (**52**). This implies a removal of the Ti=C double bond and must lead to a spontaneous vinylidene–acetylene rearrangement (**53**), as the orbital arrangement in **8** only allows



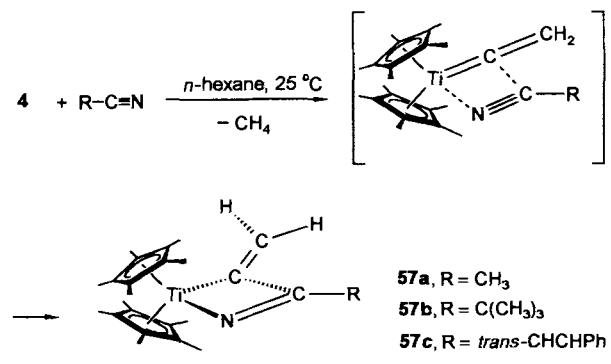
one rotamer. Hence the isomerization **49** → **50** can be considered as one of the few examples, in which a metal-coordinated vinylidene fragment undergoes a reaction that is also typical for a [:C=CH$_2$] particle in the gas phase.[120]

5.7. Synthesis and Reactivity of Heterometallacyclobutenes

Cycloadditions of nitriles with Ti=C bond systems ought to lead to the formation of azatitanacyclobutenes (**55**). The electrophilicity of the titanium center, however, also influences the reaction behavior of the primary reaction product in this case,[44, 48, 50] leading mainly to subsequent products stemming from intermediary vinylimido derivatives (**56**).[47, 48] In contrast, the corresponding heterotitanacyclobutenes can be prepared starting from **8**.[125]



The reaction with acetonitrile, pivalic acid nitrile, or cinnamic acid nitrile at room temperature leads to the near quantitative formation of the products **57a–c**. In the case of compound **57b**,



a single-crystal X-ray structure analysis was able to confirm the structures determined in solution by NMR spectroscopy (Figure 4).

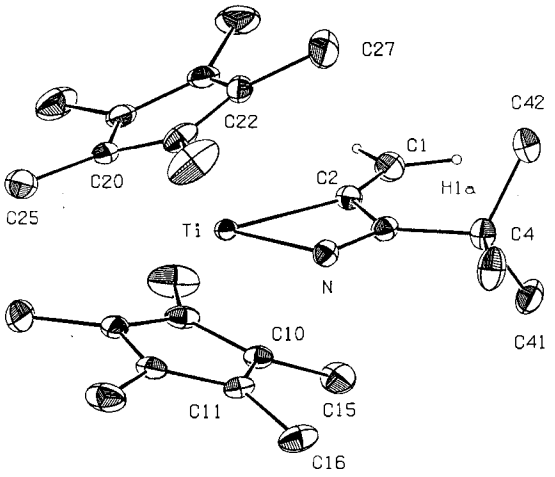


Figure 4. Molecular structure of **57b** in the solid state.

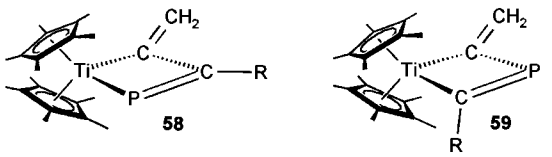
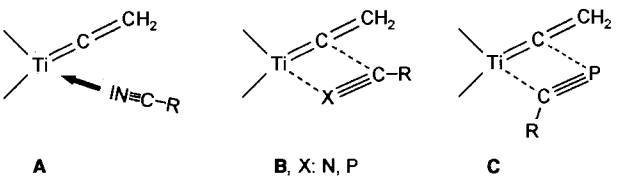
In an analogous reaction, the use of 2-*tert*-butyl-1-phosphaacetylene enables the synthesis of the heterometallacyclobutenes **58** and **59**. Compound **58** is the sterically favored isomer, while the formation of **59** is kinetically favored.

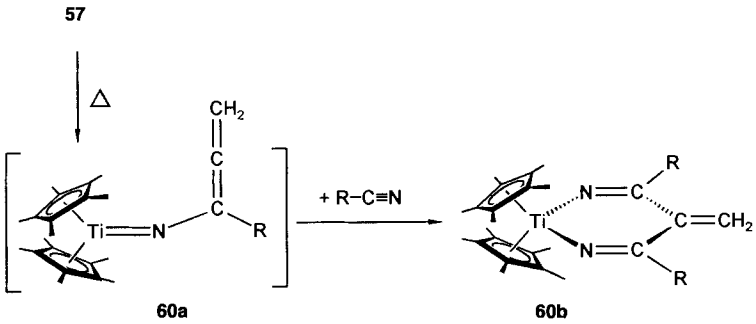


The different regioselectivities in reactions with nitriles and phosphaalkynes arises from the frontier orbital constellations of the reactants. While in nitrile complexes, *end-on* coordination dominates,[302–306] phosphaalkyne ligands prefer a *side-on* geometry, [307–310] as they posses a HOMO with π-character due to the larger π-*n* splitting. After the primary coordination of the nitrile (**A**), the cycloaddition occurs from the suprafacial orientation **B** (Scheme 18).

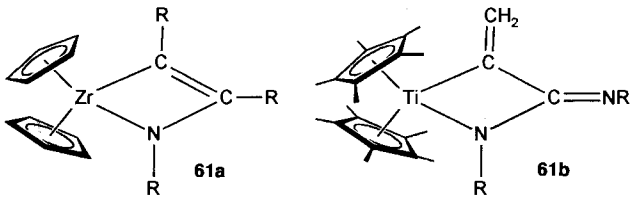


Scheme 18. *Side-on* (**A**) and *end-on* coordination modes (**B**, **C**).

The structural data found for **57b** and **58** show in each case a planar heterotitanacyclobutene. The alternating bond lengths in the sequence C1-C2-C3-X (see Figure 4 for assignments) are comparable to a conjugated π-bonding system, similar to that found in free butadiene. The Ti–X and C–X distances (X = N, P) and the small angles (Ti-X-C) indicate an sp^2-hybridized X atom with a noncoordinated lone pair of electrons.[48, 311–314] Doxsee et al. observed that the reactivity **55** → **56**[47, 48, 50] for products stemming from $[Cp_2Ti{=}CH_2]$ can be viewed as a consequence of the participation of the lone pair of electrons on the nitrogen atom in the bond to the titanocene center. This in turn results in an increase of the Ti-N-C angle and an opening of the azatitanacyclobutene ring (→ **56**).[315, 316] Only in the presence of excess nitrile and preferably at higher temperature, does the insertion of a further nitrile molecule into **57** occur, leading to **60b**.



The vinylimido species that is formed in the course of the reaction of $[Cp_2Ti{=}CH_2]$ with nitriles by an electrocyclic ring-opening of **57** can be trapped by reaction with further substrates such as ketones, nitriles, or phosphanes.[48] The azazirconacyclobutenes **61a**, which are comparable to **55**, can be formed from imido complexes and alkynes.[211, 317] They are characterized by the ability to undergo cycloreversion reactions instead of the above-mentioned electrocyclic ring-openings.[211] This behavior is similar to that of the azatitanacyclobutane **61b**[318] and must be attributed to the altered hybridization of the nitrogen atom in the ring.



5.8. Structural Data for Small Titanacycles

The numerous four-membered metallacyclic compounds that can be prepared from **8** allow a comparative discussion of their molecular structures (Table 4). All α-methylenetitanacycles are characterized by a planar four-membered ring. The bond angles indicate a stretching of the four-membered ring, which is reflected in the relatively short distances *c* (2.47 (**9**)–2.80 Å (**58**)). Particularly in **9**, this leads to an extreme high-field shift of the corresponding signals in the NMR spectrum.

The planarity of the four-membered rings is lost if the exocyclic methylene group is localized in the β instead of the α position (**63**, **64**). The automerization equilibria corresponding

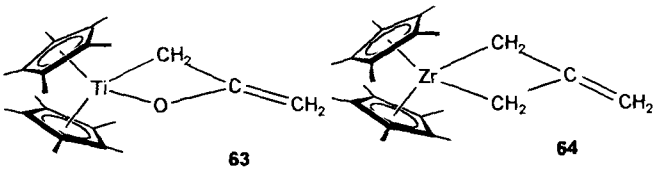
to the ring foldings (22.5° **63**; 33.0(9)° **64**) cannot be frozen out in NMR spectra for either **63**[273] or **64**.[319] Neither compound undergoes cycloreversions.

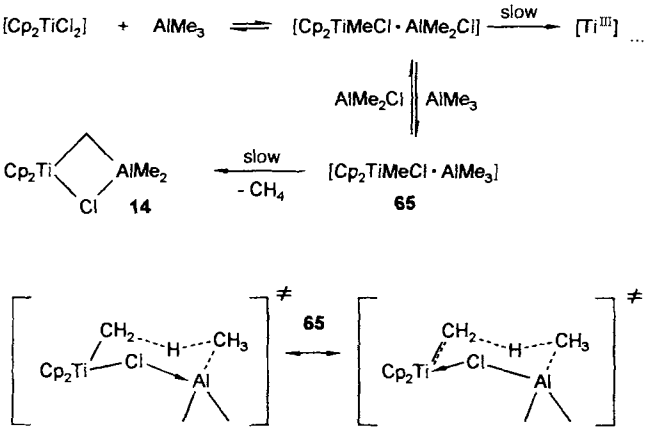


63 **64**

The Ti–C distances *a* and *b* in **9** are different (2.068(6) and and 2.137(7) Å, respectively), in agreement with the different hybridizations of the carbon atoms. The equal C–C bond lengths (*f*, *e*) (1.520(10) and 1.521(10) Å, respectively) rule out a partially ring-opened structure (→**7**). In the metallacyclobutene **40a**, inner C–C bond, which can be conjugated, shortens significantly. Bulky substituents facilitate cycloreversions, which is reflected in the longer distances *e* and *b* in **40b**. The exocyclic α-methylene groups exhibit characteristic bond lengths of 1.318(8) Å for **48c** and 1.377(4) Å for **40a**. The increase of the angle γ in **9** to 152.4° is noteworthy. The distances *b* to the heteroatoms (O, S, P) are in the expected range, while for **57b**, a slightly shortened Ti–N bond is found, which is in accordance with the observed reactivity in electrocyclic ring-openings, as well as a lengthening of the M–C bond (*a* = 2.134 Å).

5.9. The Structure of Dimetallic Compounds

The Tebbe, Grubbs, and Petasis reagents are well-established reagents in organic synthesis. Let us first look at the Tebbe reagent, the most important source of a titanium methylene compound. Ab initio calculations (STO-3G) on $[H_2Ti{=}CH_2]$/$[ClAlH_2]$ show that for the Tebbe reagent a strong bonding of the Lewis acid $[ClAlMe_2]$ must be assumed, in contrast to the much-discussed weak association.[65] The presence of a strong bond is also shown in the course of the reactions of the Tebbe reagent as compared to the Petasis or Grubbs variants.[24] Kinetic studies on the formation of **14** by the reaction of $[Me_3Al]$ with $[Cp_2TiCl_2]$ and its derivatives[64, 320] show an isotope effect $k_{H/D}$ of 2.9 and a large negative entropy value, which is in agreement with a cyclic transition state **65**. The polarization of the Ti–Cl bond by the aluminum center increases the basicity of the Al–CH_3 bond, which in turn increases the acidity of an α-H atom of the Ti-CH_3 group. This rules out the primary formation of a $[Cp_2Ti{=}CH_2]$ species with subsequent complexation by $[ClAlMe_2]$ during the course of the formation of the Tebbe reagent.



Other compounds that are particularly interesting from a coordination chemistry viewpoint are also accessible from $[L_nTi{=}CR_2]$ and suitable metal fragments. Depending on the nature of the interacting metal fragments, a variety of structures can be obtained, which exhibit symmetric or asymmetric bridges **66**–**68**. A distinct carbenoid character is revealed by the reduced

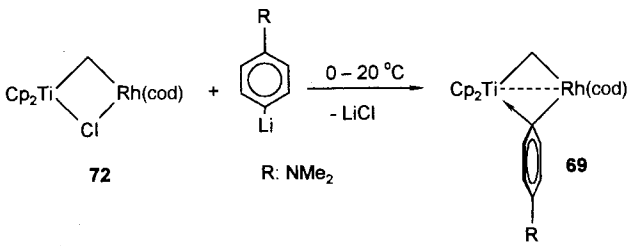
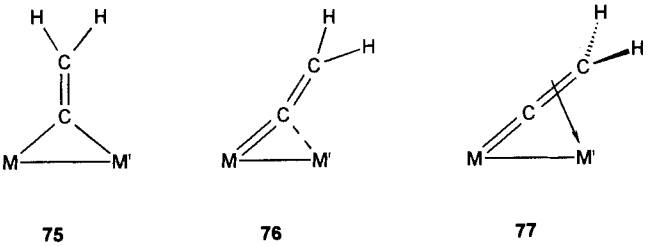
[a] Two symmetry-independent molecules.

Ti–C distances and a notably low-field shift of the μ-CH_2 signal.[56, 58, 64, 321–325] Table 5 summarizes selected examples. A participation of the mesomeric structure **68** is discussed in particular for the Ti–Pt compounds **70** and **71**. For example, in contrast to dititanacyclobutane **12**, the silatitanacyclobutane **74** shows no carbenoid activity.[165, 166]

The μ-methylene complexes **70** and **72** do not only act as more or less activated [Ti=CH_2] equivalents, but can undergo a variety of different subsequent reactions. For example, by varying the bridging ligand novel structural types can be obtained such as those with μ-phenyl or μ-methyl groups and thus providing information about the nature of these ligands. Compound **69**, the first example of a dinuclear phenyl species that is asymmetrically bridged by the *ipso*-C atom of the phenyl group,[321] can be synthesized by the reaction of **72** with phenyllithium derivatives (cod = 1,5-cyclooctadiene).



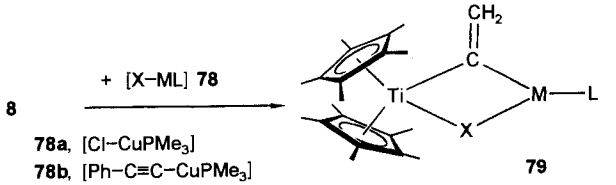
The syntheses of complexes of the types **75**–**77** are of interest in the understanding of the ring expansion reactions **49** → **50** and the related possibilities of the formation of μ-vinylidene compounds as well as in the study of this bridging ligand. The majority of known μ-vinylidene complexes belong to the structural type **75**.[136, 326–342] Some homo-[343–347] and heterodinuclear[348] μ-vinylidene complexes indicate the possibility of *side-on* bridges (**77**). A *semi*-bridge (**76**), which is characteristic for CO-[349–353] or CS-bridged[354] heterodinuclear complexes with *early–late* metal combinations[354] has been reported for comparable vinylidene complexes (Scheme 19) in just one case.[348]



75 **76** **77**

Scheme 19. Dimetallaethylene (**75**) as well as *semi*- and *side-on*-bridged structures (**76** and **77**, respectively) of dinuclear μ-vinylidene complexes.

When **8** reacts with complexes of group 11 metals (**78a**–**d**), the μ-vinylidene complexes **79** can be isolated.[355] In the com-



plexes **79a–79d**, the signal of the α-vinylidene carbon atom is shifted to very low field ($\delta = 300–330$; Table 6). This is in accordance with a *semi*-bridging structure **76** (M = Ti, M′ = Cu, Au). The possibility of a *side-on* bridge (**77**) can be ruled out due to the orientation of the π-bonding planes in **8**. The bridge type **76** is formed preferentially when **8** reacts with strongly basic transition metal complexes such as **78a–78d** that can form Cu → Ti or Au → Ti bonds.[356]

Table 6. Selected NMR data of heterodinuclear μ-vinylidene complexes **79**.

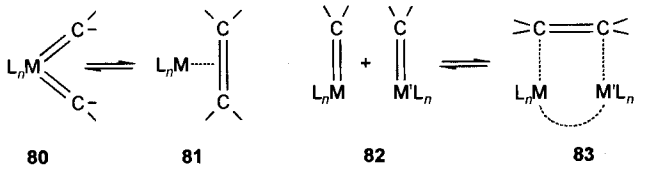
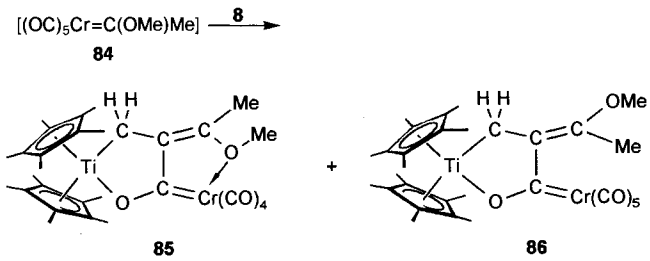
Of experimental and theoretical[357–359] interest is the olefination of carbene ligands by intramolecular coupling **80** → **81**[360–369] as well as the possible cleavage of the C–C double bond **81** → **80**[287, 370–378] in the coordination sphere of transition metals. Proof for an intermolecular, heterodinuclear C–C coupling reaction **82** → **83** has only recently been obtained.[379]



80 **81** **82** **83**

When **84** is allowed to react with **8**, an unusual coupling reaction of the Fischer carbene complex **84** and **8** takes place, forming the novel heterodinuclear complex compounds **85** and **86** by a metal-mediated linking of a vinylidene, a carbene, and a carbonyl carbon atom.[379] Cycloaddition products, which are



typical for metal carbonyls,[274] are not observed. The NMR signals of the carbene carbon atoms in **85** and **86** are in the expected range (δ = 336.7 and 328.0, respectively). The single-crystal X-ray structure analysis of **85** shows that the formation of the chelate structures by a coordination of the OCH_3 group leads to a distortion of the octahedral environment of the chromium center (Figure 5). The bicyclic system is nearly planar.

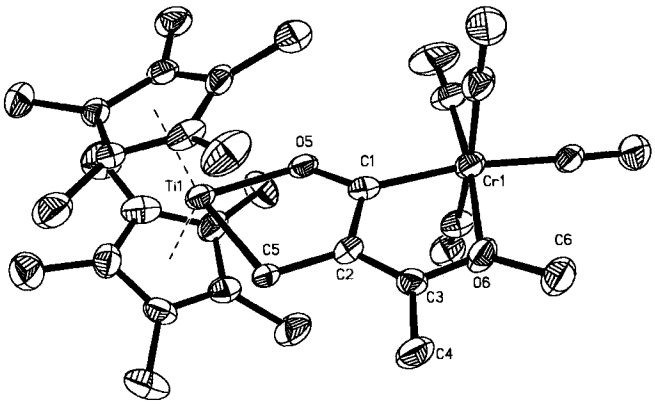


Figure 5. Crystal structure of **85**.

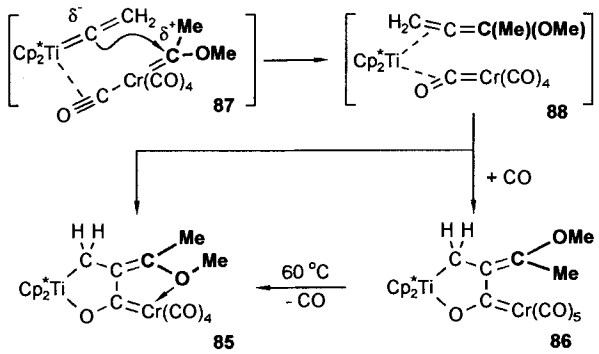
The synthesis of the reaction products **85** and **86** is in accordance with a carbene–carbene coupling with the intermediate formation of the allene complex **88**. Its formation can be explained by the primary interaction—already indicated for **87**—between the nucleophilic and electrophilic carbene-carbon



atoms, supported by the CO coordination to the oxophilic titanium center. A titanium-mediated cycloaddition of the resulting allene molecule with the remaining $Cr(CO)_5$ fragment forms the product **85** directly, and **86** is formed after a rapid addition of CO. This reaction is the first instance of an intermolecular coupling reaction of inversely polarized carbene ligands and is a further example of a reaction that leads to the metal-mediated linking of several C atoms stemming from different substrates.[380–385]

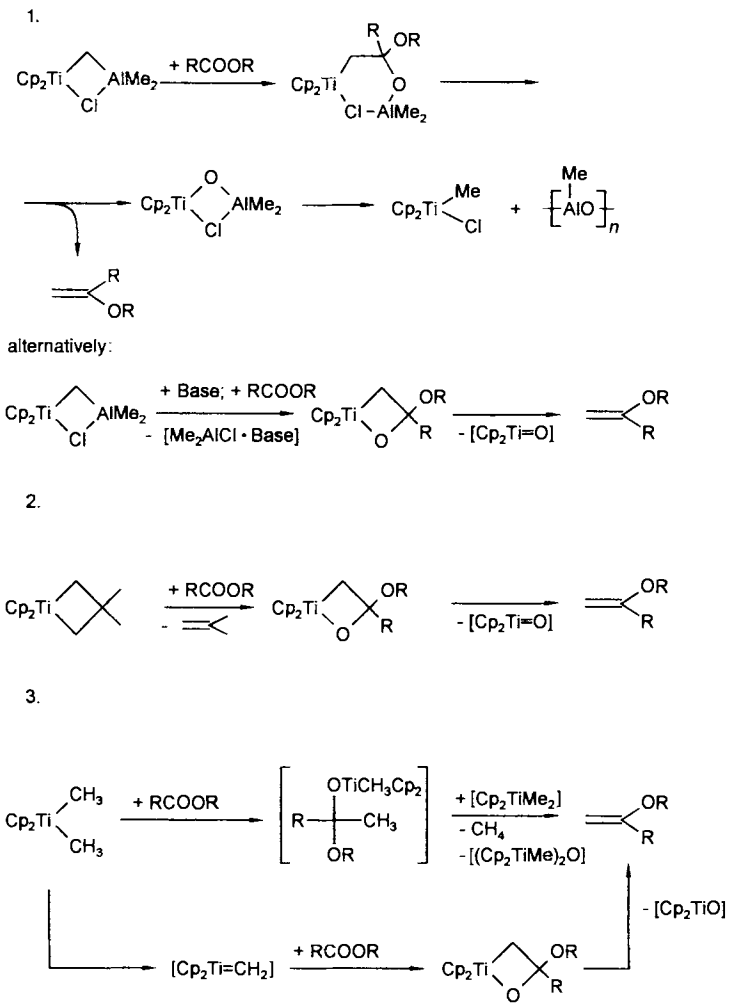
6. Stoichiometric and Catalytic Reactions of Carbenoid Metal Compounds of Electron-Deficient Transition Metals

The most important applications of carbenoid complexes of electron-deficient transition metals lie in the areas of organic synthesis and catalytic reactions, such as carbonyl olefination,[22, 59, 63, 74] the generation of cyclopropane derivatives by the oxidation of metallacyclobutanes[386, 387] or cyclopropanation,[188] the preparation of heterocyclic four-membered ring compounds,[388, 389] and the ring-opening polymerization[20, 24, 25, 72, 390–394] to obtain special polymers, such as

"living"[171, 395] or "conducting"[396] polymers. In the following sections, selected examples are presented to document the principles of the applications of Ti=C derivatives.

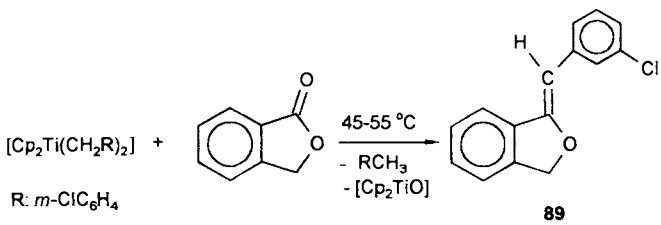
6.1. Carbonyl Olefinations with Tebbe, Grubbs, and Petasis Reagents

Many carbonyl compounds, such as esters, ketones, and amides, can be methylenated with various titanium-based reagents. The most important of these are, in particular, the Tebbe reagent, the Grubbs reagent, and the Petasis reagent. The application of the Tebbe reagent in particular has found broad interest in organic chemistry, owing to its early discovery.[22, 24, 61–63, 397] The use of $[Cp_2TiMe_2]$ is particularly advantageous, as this compound is not pyrophoric, is stable towards air and water, and no Lewis acidic aluminum by-components have to be separated later, which enables its use in olefinations of silyl esters, anhydrides, carbonates, and acylsilanes.[42, 398] A number of different, sometimes contradicting, mechanisms[24] have been proposed for the reactions that occur, which will be discussed by using the carbonyl olefination of esters as an example (Scheme 20). In the absence of an additional base, the reaction between the Tebbe reagent and the ester is first-order with respect to the titanium reagent employed. The strongly negative activation entropy observed is in agreement with a six-membered intermediate. In the presence of bases (pyridine), the reaction proceeds more rapidly and shows zero-order kinetics with respect to the ester and first-order kinetics with respect to the titanium reagent. The use of titanacyclobutanes (Grubbs reagents) in carbonyl olefinations is characterized by the primary formation of a metallaoxetane, which spontaneously decomposes to give the desired olefin and a Ti=O compound.[24] Based on the observed H/D exchange, Petasis and Bzowej favored a methyl addition mechanism;[36] however, they reported deuterium scrambling in reactions of esters with cyclopropyltitanocenes.[39]



Scheme 20. Mechanisms of carbonyl olefinations 1. with the Tebbe reagent, 2. with Grubbs reagents, 3. with the Petasis reagent.

Detailed kinetic studies show that the olefination of esters with $[Cp_2TiMe_2]$ proceeds via the titanium carbene $[Cp_2Ti{=}CH_2]$.[142] This is proved by: 1) the absence of H/D exchange or ^{13}C scrambling when labeled esters or titanium compounds are employed; 2) the finding of zero-order kinetics with respect to the ester, and first-order kinetics with respect to the titanium compound; 3) the reaction of ethyl acetate or dodecyl acetate with $[Cp_2Ti(CD_3)_2]$ yielding a $k_{H/D}$ effect of 9–10; 4) esters with different electronic and steric environments exhibiting comparable reactivities. The stoichiometry required for the Petasis reagent (1:2, substrate to Ti) can be explained by the necessity of reactions which trap the Ti=O fragment formed. The products were obtained in better yields with the Tebbe reagent than with the Wittig reagent. This is especially significant when sterically hindered ketones are to be olefinated. The Tebbe reagent can also be used in less basic media, which precludes racemizations of substrates with enolizable, chiral centers.[61] The above-mentioned formation of enol ethers by the methylenation of esters and lactones[63, 66] cannot be performed with phosphorus ylides.[160] For the generation of special vinylsilanes, there are effective reagents in the form of $[Cp_2Ti(CH_2SiMe_3)_2]$ and $[CpTi(CH_2SiMe_3)_3]$.[38] The introduction of a benzylidene residue can be successfully performed by using $[Cp_2Ti(CH_2C_6H_5)_2]$.[37] Substitutents at the *m*-position of the phenyl ring (Cl or F) increases the yield. For example, in this way aryl-substituted enol ethers **89**, which also find use as bioactive prostaglandin analogs, can be formed quantitatively.

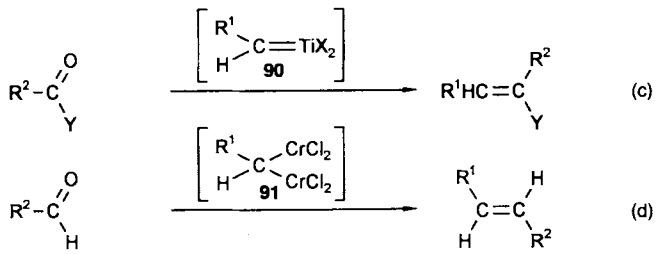


89

6.2. Carbonyl Olefinations with Other Reagents

There are derivatives related to the Tebbe reagent, in which one of the metal components has been replaced, for example aluminum by zinc ($[Cp_2TiCH_2 \cdot ZnX_2 \cdot (thf)_x]$).[59] This reagent can also be used in carbonyl olefinations.[399] When $[Cp_2ZrCl_2]$ in THF is treated with dibromomethane and zinc, a reagent is obtained that rapidly transforms aldehydes and ketones into the

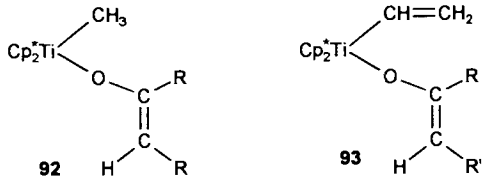
corresponding olefins.[400] Olefinations with zirconium carbenes can proceed under steric control as long as Schiff bases are used as carbonyl analogs.[401] However, reactions of 1-alkenylzirconium or 1-alkenylaluminum compounds with aluminum or zirconium hydrides, respectively, generate only low yields (20%)[402] of the substituted μ-alkylidene complexes **11** (see Scheme 9), which are potentially useful in carbonyl olefinations. The Takai reagent **90**, which is prepared from 1,1-dibromoalkanes and a mixture of $TiCl_4$ and Zn, can also be utilized in carbonyl olefinations [Eq. (c)].[74, 403] Esters are preferentially transformed into *Z*-enol esters, while silyl esters and amides are transformed into silyl enolates and enamines. Organochromium compounds (**91**), formed from 1,1-dihaloalkanes and $[CrCl_2]$ exhibit high chemoselectivity towards aldehydes, leading to (*E*)-alkenes [Eq. (d)].[74] Reagents with the composition $CH_2I_2/Zn/Ti(OiPr)_4$ or $CH_2I_2/Zn/Me_3Al$ are effective methylenating agents for aldehydes. The selective methylenation of ketones can be achieved by the addition of $Ti(NEt_2)_4$.[184]



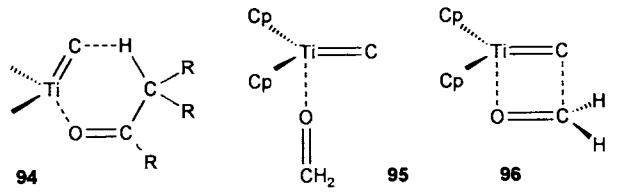
Reactions of *S*-alkylthioesters with the Takai reagent in THF at 25 °C selectively yield the corresponding (*Z*)-alkenyl sulfides (which are important as disguised carbonyl compounds) in excellent yields, and ketenedithioacetals as well as enamines are also accessible.[187] Other metal-containing carbonyl olefination reagents can be obtained by the reaction of the metal chlorides $MoCl_5$, $(EtO)_3MoCl_2$, $[MoOCl_3(thf)_2]$, $(EtO)MoOCl_2$, $MoOCl_4$, MoO_2Cl_2, $[WOCl_3(thf)_2]$, and $WOCl_4$ (but not WCl_6, or Mo^{II} or Mo^{III} compounds) with MeLi (1:2) in THF.[404] The NMR data indicate the formation of μ-methylene complexes.[405] Molybdenum carbene complexes, which are readily prepared in situ, have proven to be suitable reagents for carbonyl olefinations[406, 407] as they exhibit excellent chemoselectivity as well as low sensitivity towards hydroxyl groups.[408] Depending on the olefin employed, yields of up to 93% in carbonyl olefination reactions are possible,[407, 409] although the course of the reaction is strongly influenced by external conditions (rate of addition, solvent). Tungsten carbene complexes also undergo analogous reactions with the formation of carbonyl olefination products.[410] This method is suitable for the preparation of di-, tri-, and tetrasubstituted olefins, as well as for enol ethers and enamines. The reactivity decreases with different substrates in the order aldehyde > ketone > formate > ester > amide.

6.3. Ene Reactions

Reactions of Ti=C intermediates with carbonyl species can lead to carbonyl olefinations, as discussed in Section 6.1. Enolizable ketones, on the other hand, can react in a 1,5-sigmatropic intramolecular H shift to yield titanium enolates,[257, 411, 412] a reaction that is particularly noteworthy with respect to stereoselective C–C linkages.[413–419] The majority of studies carried out to date have used NMR spectroscopy to characterize such substrates, and only recently have studies of the solid-state structures been performed.[127, 129, 420, 421] When $[Cp_2^*TiMe_2]$ (**6**), $[Cp_2^*Ti(Me)(CH{=}CH_2)]$ (**4**), or $[Cp_2^*TiC(=CH_2)CH_2CH_2]$ (**9**) reacts with enolizable ketones, the titanocene enolates **92**[411] and **93**[127] are exclusively obtained. The formation of



products exhibiting Δ^1- and *E*-configurations is always preferred for both **92** and **93**. The observed high regio- and stereoselectivity results from the geometric conditions at the $[Cp_2^*Ti{=}C]$ intermediate **94**, which apparently only permit selected deprotonations of the acidic ketones. Theoretical studies show that for $[Cp_2Ti{=}CH_2]$ fragments, the *end-on* coordination **95** is 0.96 eV more favorable than the *side-on* mode **26**.[256] This in turn apparently leads to the observed preference for the enolate formation over the formation of oxetanes.



The single-crystal X-ray structure analysis of complex **93a** (R = C_6H_{11}; R′ = H, Figure 6) shows that the enolate group is solely coordinated by the oxygen atom. The short titanocene–oxygen distance of 1.859(2) Å is noteworthy, particularly in combination with the distinctly increased Ti-O-C(4) angle of

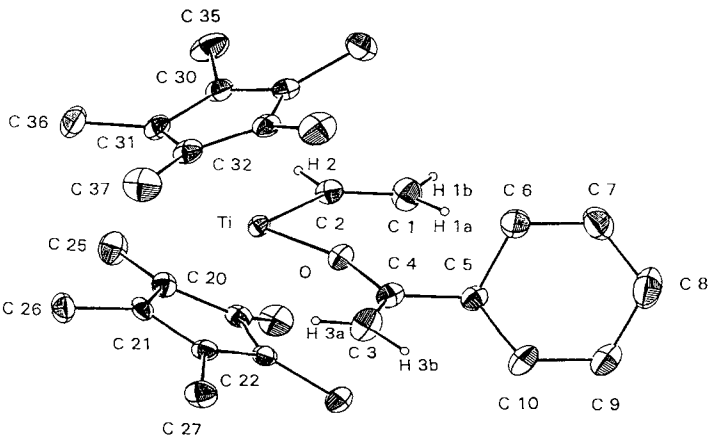


Figure 6. Molecular structure of **93a**.

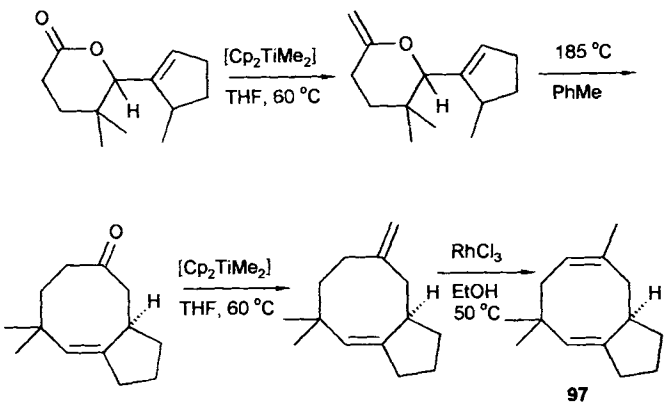
165.9(2)°. This indicates that the oxygen atom is nearly sp-hybridized, which can be explained by a strong $d_\pi - p_\pi$ interaction with partial double bond character along the Ti–O bond.[422–425] The structural data for **93a** clearly show that the enolates **93**, which are so readily accessible by the ene-reaction, exhibit a distinct alkoxide character. This reduces the nucleophilic properties of the methylene group and the oxygen atom in the enolate group, so that typical reactions with electrophiles,[426,427] such as methyl iodide or benzaldehye, do not occur.[411] This is also the case for **92**.

6.4. Complex Reactions

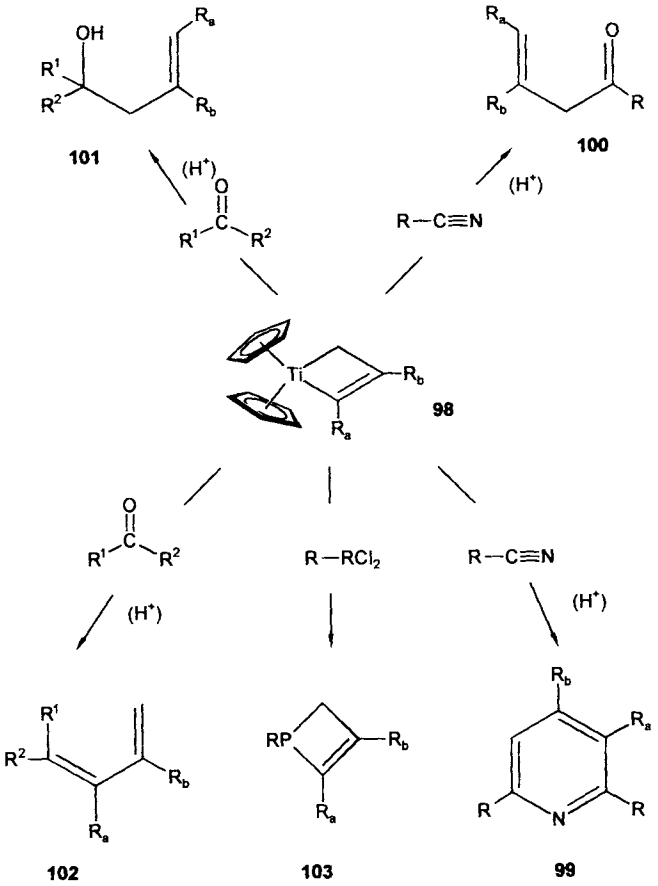
By the appropriate arrangement of various synthetic steps and by using carbenoid complexes of electron-deficient transition metals, it is possible to achieve useful syntheses. For example, vinyl-substituted lactones can undergo a titanium-mediated carbonyl olefination which, followed by a Claisen rearrangement, leads to ring expansion. In this way it is possible to obtain the cyclooctanoid natural product (±)-precapnelladiene (**97**) (Scheme 21), an unusual sesquiterpene that has been shown to exist in soft corals.[428]



Scheme 21. Synthesis of the natural product (+)-precapnelladiene **97** by titanium-mediated carbonyl olefination and subsequent Claisen rearrangement.

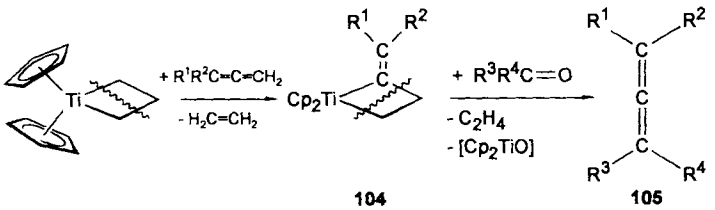
Disubstituted titanacyclobutenes **98** ($R_a = R_b = CH_3$, CH_2CH_3) react with two equivalents of nitrile under mild conditions to yield diazacyclooctatetraenes, a result of nitrile insertion into the titanium–alkyl bond as well as into the titanium–alkenyl bond. Subsequent hydrochlorination of these products yields the tetrasubstituted pyridines **99** (Scheme 22).[46] Steric bulk leads to the exclusive formation of monoinsertion products. Insertions into the metal–vinyl bond are favored over those into the metal–alkyl bond, when metallacyclobutenes with small substituents (methyl) are used. Diphenyltitanacyclobutenes, however, react with nitriles or ketones to yield solely products of monoinsertion into the titanium–alkyl bond, which can be worked up to yield the unsaturated products **100** and **101**, respectively.[46,429] Reactions of **98** with ketones can be used to generate dienes **102**[49] or, after the reaction with $RPCl_2$, the phosphacyclobutenes **103**.[45,388]

The reaction of $CFCl_3$ with a low-valent titanium compound generated from $TiCl_4$ and $[LiAlH_4]$ allows the preparation of a chlorofluorocarbene at 0 °C, which reacts with olefins to give



Scheme 22. Organic syntheses employing titanacyclobutenes.

1-chloro-1-fluorocyclopropane in good yields. Studies of the ratio of *syn*/*anti* products show that free carbenes rather than carbenoid species are involved.[430] Reactions of $[Cp_2Ti{=}CH_2]$ precursors with allenes yield the methylenetitanacyclobutanes **104**,[131] which can undergo spontaneous carbonyl olefination reactions to form the higher substituted allenes **105**.[135] This

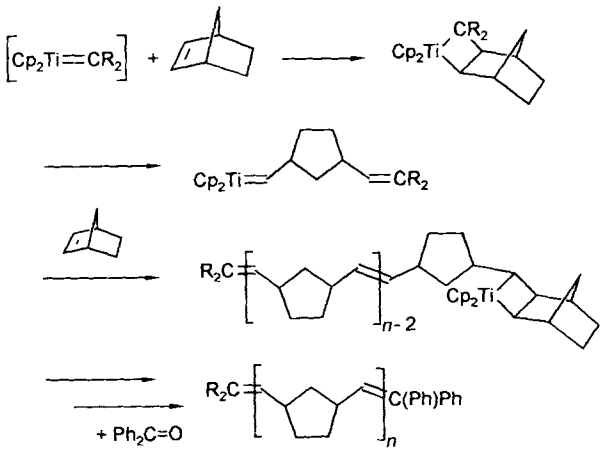


behavior stems from the intermediate appearance of a vinylidene fragment $[Cp_2Ti{=}C{=}CR_2]$. A titanaoxetane, which could also be present in these reactions, could not be observed spectroscopically.[134]

6.5. Catalytic Reactions

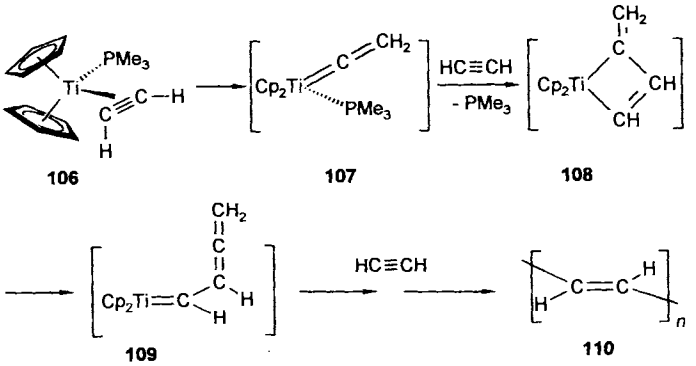
Catalytic applications of precursors for $[Cp_2Ti{=}CR_2]$ intermediates in the context of ring-opening metathesis polymerizations (ROMP) have already been summarized and discussed in various articles.[390–394,431,432] New studies show the effective use of $[Cp_2TiMe_2]$, $[CpTiMe_3]$, $[CpTiClMe_2]$, and $[Cp_2Ti(CH_2SiMe_3)_2]$ as carbenoid reagents.[41] The important

advantages in these cases are similar to those already discussed for stoichiometric reactions, namely the easier preparation and handling of the corresponding titanaalkyl compounds as compared to the Tebbe or Grubbs reagents. For example, the ring-opening polymerization of norbornene can be carried out at high temperatures in the presence of these reagents (Scheme 22). When THF is used as solvent, the reaction does not take place, even though carbonyl olefinations proceed more rapidly in THF than in toluene or hexane.[36] This effect is attributed to the nucleophilicity of the carbene-C atom. Other studies[433] show a slower rate of chain growth for THF or pyridine as solvents. In general, however, THF has only a small effect when [$CpTiMe_3$] and [$CpTiMe_2Cl$] are employed. In the case of [$Cp_2Ti(CH_2SiMe_3)_2$], THF nearly completely inhibits the ring-opening polymerization. The different ROMP activities correspond to the electronic structure of the [$Ti{=}CR_2$] derivatives according to studies by Cundari and Gordon.[231, 235, 236] These indicate, for example, that [$Cp_2Ti{=}C(H)SiMe_3$] is a particularly effective metathesis initiator. Furthermore, when electron-withdrawing substituents are present on the carbene-C atom, an increased activity can be expected, which is demonstrated by results obtained with [$Cp_2Ti(CH_2Ph)_2$] complexes.[37] While unsubstituted [$Cp_2Ti(CH_2Ph)_2$] is suitable for carbonyl olefinations, it is unable to initiate ROMP reactions.



Scheme 23. The course of the ring-opening polymerization of norbornenes.

Vinylidene derivatives of electron-deficient transition metals will be discussed as intermediates in catalytic reactions. Alt et al., for example, have suggested a vinylidene intermediate (**107**)



in the formation of *trans*-polyacetylene **110** from the acetylene-complex **106** and excess acetylene.[132] This proposed mechanism is supported by the observation that it is possible, starting from methylenetitanacyclobutene **40** (Cp* instead of Cp), to achieve the polymerization of acetylene to pure *trans*-polyacetylene.[124] The transformation of a metal-coordinated acetylene to a vinylidene ligand (**106** → **107**) has so far not been experimentally verified in an electron-deficient transition metal complex.

7. Summary and Outlook

Transformations of alkyl- and alkenyltitanium complexes under mild thermal conditions have significantly improved the access to short-lived carbene complexes of electron-deficient transition metals. Such transformations have made the isolation and characterization of compounds with Ti–C and Zr–C double bonds possible. This has widened the spectrum of preparative and catalytic applications of precursors for [$L_2Ti{=}CH_2$] intermediates considerably. Convenient syntheses of the titanaallene complex [$Cp^*_2Ti{=}C{=}CH_2$] **8**, mainly by H transfers starting from titanium vinyl species, form the basis for the study of a multitude of four-membered titanacyclic compounds. For example, it was possible to isolate and structurally characterize unusually stable complexes by the [2 + 2] cycloaddition of the Ti–C double bond in **8** to various multiple bond systems. The resulting titanaoxetanes show variable reaction behavior, which depends on the carbonyl species employed and which allows a classification into "classical" and "nonclassical" compounds. The high stability of the [2 + 2] cycloaddition products obtained from **8** can also be attributed to the reduced electrophilicity of the transition metal centers due to the Cp* ligands. The planarity of these metallacyclobutanes, -butenes, and four-membered heterocyclic species is favored by the sequence of sp^2-hybridized ring atoms. The observed ring expansions for dinuclear Fischer carbene complexes with titanaoxetane substructures—which are formed by the cycloaddition of **8** and metal carbonyls—can be attributed to a vinylidene–acetylene rearrangement that is unusual in metallaallenes. The future syntheses of classes of compounds, which have thus far been accessible only with difficulty, are becoming conceivable. A particularly stimulating area for future work should be the application of **8** to the synthesis of radialenes or molecules with radialene substructures.[434, 435] The possibilities of obtaining novel complex geometries by using carbenoid complexes of electron-deficient transition metals have certainly not yet been fully explored. The discovery of unusual reaction patterns, such as the carbene–carbene coupling reaction discussed herein, is a reminder of the continuing challenge for organometallic chemists and synthetic chemists, alike, to bring novel ideas into a field of preparative chemistry that is developing rapidly.[436]

I wish to express my particular thanks to my very active coworkers, Dr. Jürgen Oster, Dr. Javier Sang, Dipl. Chem. Isabelle Strauß, Dipl.-Chem. Jürgen Heinrichs, and Dipl.-Chem. Martin Wagner, for the large number of results obtained, as well as to the temporary members of the research group which are mentioned in the references. I am indebted to all my colleagues for constructive discussions and suggestions, in particular to Dr. Uwe Böhme

(Universität Bergakademie Freiberg) for ab initio calculations. I thank my family for their understanding and support of my scientific endeavors. I especially wish to thank the Institut für Anorganische Chemie der RWTH Aachen, where I was a guest and have carried out research for the last five years, the Arbeitskreis Kristallstrukturanalyse (RWTH Aachen), and in particular to Dr. Trixie Wagner for the numerous structure determinations. I want to gratefully acknowledge that my research was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. The Bayer AG Leverkusen and the Degussa AG are also acknowledged for their generous financial support.

[436] Note added in proof (February 24, 1997): After submission of this contribution several important publications have appeared on the formation of intermediates with Ti–C multiple bonds: The thermolyses of [Cp*TiMe$_3$] yields a methylidincubane, from which the formation of intermediates, exhibiting a Ti–C triple bond is deduced (R. Andres, P. Gomez-Sal, E. de Jesus, A. Martin, M. Mena, C. Yelamos, *Angew. Chem.* **1997**, *109*, 72–74; *Angew. Chem. Int. Ed. Engl.* **1997**, *36*, 115–117). Reaction of [Cp$^*_2$Ti(η^2-C$_2$H$_4$)] with diazoalkane leads to a titanium carbene complex that can be trapped in suitable reactions (J. L. Polse, R. A. Andersen, R. G. Bergman, *J. Am. Chem. Soc.* **1996**, *118*, 8737–8738).

Epothilones: Promising Natural Products with Taxol-Like Activity

Ludger Wessjohann*

A new group of macrocyclic natural products, the epothilones **1**, has enabled research into structure–activity relationships in the stabilization of microtubules to be conducted faster and more efficiently. This could lead to an antitumor agent with antimitotic activity that is more effective than taxol. The epothilones were first isolated from myxobacteria of the genus *sorangium* by two groups at the Gesellschaft für biotechnologische Forschung (GBF): Höfle et al., who were also responsible for the structure elucidation,[1, 2] and Reichenbach et al. As these bacteria can be cultivated in large amounts, several grams of epothilones can be obtained in a single batch. The relative configuration of the seven stereogenic centers of epothilone B (**1b**) was determined by X-ray structure analysis, the absolute configuration by chemical degradation of C13–C16 to hydroxysuccinic acid.

Specific antimycotic and cytotoxic activity (2 ng mL^{-1}) was established early on.[1] The fundamental breakthrough came with the results of Bollag et al., who were the first to recognize the microtubule-stabilizing activity of epothilones.[3] This property is shared by only two other natural products, discodermolide and paclitaxel, the latter being commercially available under the name of "taxol" or "taxotere". These pharmaceutical preparations are the most important results in the development of antitumor agents in the past decade.[4] After more than 20 years and tests on over 140000 (!) synthetic substances and extracts from natural products[3, 5] an activity similar to that of taxol was found—again in a natural product. In some assays epothilone B is twice as active as epothilone A.[1a, d] The epothilones can even displace taxol from the binding site and act faster. More importantly, they are between 1000 and 5000 times more active against multiply resistant cell lines.[1d, 3, 5–7] Their mode of action is also similar to that of taxol. However, the binding sites are probably not identical, but instead overlap. The markedly different spatial structure of the epothilones, despite allowing a certain flexibility, could not be made congruent with that of taxol. Another important advantage of epothilones over taxol is their significantly better solubility. A substantial risk of the taxol therapy derives from problems of application, since the necessary solubilizers can lead to powerful, sometimes life-endangering side effects.

The constitution of the epothilones suggests that they are derived from the polyketide metabolism like similarly built macrolides. The synthesis apparently commences with *N*-acetylcysteine, which becomes part of the aromatic thiazole. The compounds show three structural deviations from simple polyketide macrocycles: apart from the thiazole ring, it is mainly the oxirane ring and the C4 dimethyl group that disturb the usual role of methyl and hydroxyl branches ("triads").[8] Under basic conditions the dimethyl group promotes retro-aldol cleavage at the keto group.[9] Retrosynthetic analysis leads to three fragments containing these functional groups (Scheme 1): an aromatic unit, an aldol fragment in the "southern half" of the ring, and an alkyl epoxide in the "northern half". This pattern is essentially followed by the published syntheses.[6, 10–16]

The first total synthesis of epothilone A (**1a**) was achieved by Danishefsky's group from the Sloan Kettering Institute for Cancer Research,[10a] who also recently completed the first synthesis of epothilone B.[6] Shortly afterwards, Nicolaou et al.[11a, 12] and Schinzer et al.[13a] presented their approaches to epothilone A. Their work, together with some partial sequences by the groups of Mulzer,[14] Kalesse,[15] and Wessjohann[16] are described herein. In order to limit the discussion to the essential synthesis of the 16-membered macrocycle, it may

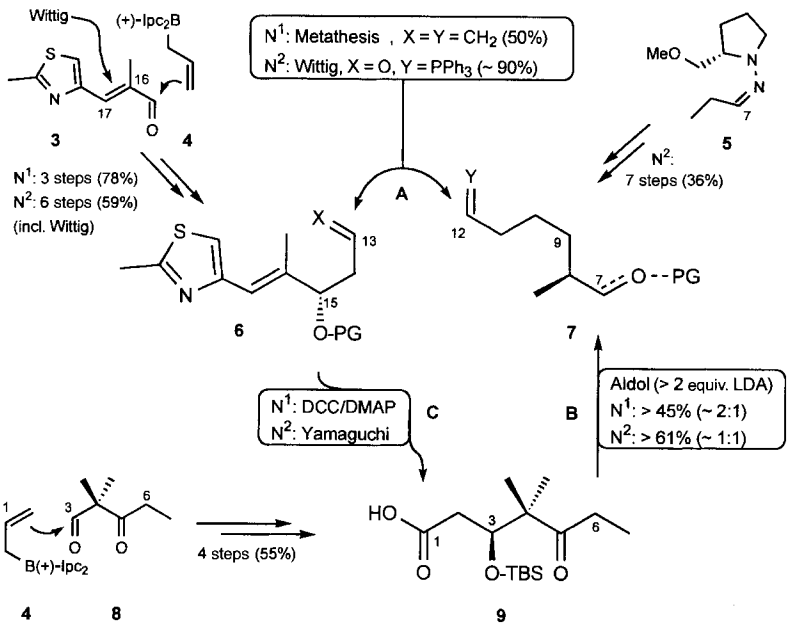
be noted ahead that the epoxidation is the last step in all cases (Scheme 1). Another feature common to all syntheses is the introduction of the thiazole group by a Wittig reaction at C16.

Nicolaou et al. presented two similar, highly convergent syntheses (N^1 and N^2, Scheme 2), in which the basic units **6**, **7**, and **9** are combined.[11a, 12] The main differences between the two



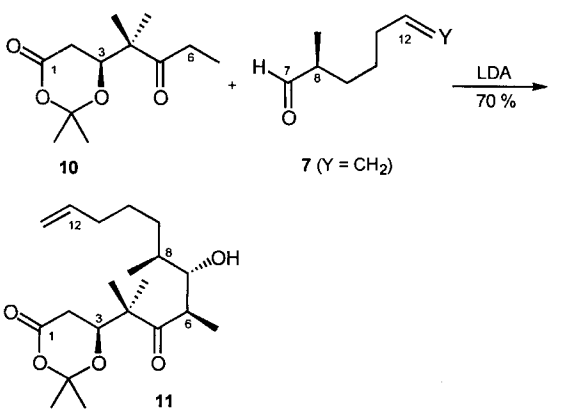
Scheme 2. Key steps of the total syntheses of **1a** by Nicolaou et al. N^1: **B** → **C** → **A**, >9 + 4 + 3 steps, overall yield: ≤6% **1a**; N^2: **A** → **B** → **C**, >17 + 6 + 4 steps, overall yield: ≤2% **1a**; DCC = dicyclohexylcarbodiimide, DMAP = 4-(*N*,*N*-dimethylamino)pyridine, Ipc = isopinocampheyl, LDA = lithium diisopropyl amide, PG = protecting group, for example TBS = $SiMe_2tBu$; Yamaguchi esterification: 2,4,6-trichlorobenzoyl chloride, NEt_3, then DMAP.

syntheses are the sequence and the method of coupling **A**. The key step of N^1 is the ring-closing metathesis $\mathbf{A^1}$ of a bisalkene, which is obtained by the aldol reaction of the aldehyde **7** (Y = CH_2, $\mathbf{B^1}$) with the dianion of **9**, followed by esterification with **6** (X = CH_2, $\mathbf{C^1}$). The metathesis $\mathbf{A^1}$ is achieved by the dilution principle in surprisingly high yields (50% of the *Z*- and 35% of the *E*-isomer) by using the Grubbs catalyst $[RuCl_2(=CHPh)(PCy_3)_2]$ (15 mol%).[11a] In a similar routine by Schinzer et al., an almost identical precursor was obtained in 94% yield (*E*:*Z* approx. 1:1).[13a] The enormous improvements in the field of metathesis, such as the development of defined, stable catalysts and the high tolerance of functional groups, have allowed this to become a standard method in olefin synthesis.[17] Despite this success, it appears that it is not always advisable to follow the latest trends. For example, Danishefsky et al. were unable to achieve ring-closing metathesis of a fully functionalized precursor with the same catalyst. Model compounds led to varying results.[10b] Evidently, at least with epothilone precursors, the success of the ring-closing metathesis is strongly dependent on the substituents and the protecting groups employed.

Accordingly, in the second, later route (Scheme 2; N^2) Nicolaou et al. employ a Wittig reaction of **6** (X = O) with **7** (Y = PPh_3, $\mathbf{A^2}$).[12] After an aldol reaction with **9** (see $\mathbf{B^2}$) the ring is closed by macrolactonization according to the approved Yamaguchi method ($\mathbf{C^2}$). This more classic approach to combine the building blocks is more effective than metathesis; however, a drawback—at least of Nicolaou's approach—is the less effective access to the precursors.

Since the method applied by Schinzer et al. and the partial sequences published so far resemble the approach adopted by Nicolaou et al. they are now treated in parallel. The building block **6** requires stereoselective introduction of the hydroxy group at C15, which was achieved very effectively by Nicolaou et al. using allyl isopinocampheylborane $Ipc_2B(allyl)$.[11a] The selective conversion of diene **6** (X = CH_2 → O) was achieved by Sharpless dihydroxylation, diol cleavage, and oxidation. In contrast, Schinzer et al. first synthesize the aldehyde **6** (X = O, seven steps, 14%), which is then converted to the corresponding alkene (X = CH_2) in a Wittig reaction.[13a] In building block **7** the configuration at C8 is adjusted by utilizing the reliable Enders and Evans auxiliaries. In the N^2 route, Nicolaou et al. alkylate the SAMP hydrazone **5**;[12] Schinzer et al. methylate a (6-heptenoyl)oxazolidinone diastereoselectively and very effectively.[13b]

The synthesis of **9** and **10** and their aldol coupling **B** is of particular interest (Schemes 2 and 3). Two aldol reactions or carbonyl additions are possible for the synthesis of the C3 stereocenter. The C3 → C4 bond, in particular, should be sensitive to basic reaction conditions and could, like in epothilone itself, be prone to the reverse reaction. Similar solutions to this problem are offered by Mulzer et al.[14] and Nicolaou et al.:[11a] the addition of $Ipc_2B(allyl)$ (**4**) to a C3 aldehyde, followed by oxidative decomposition of the allyl group to give the carboxylic acid (four steps). Whereas Nicolaou et al. employ **8** as electrophile, Mulzer et al. use a C3–C9 unit obtained in excellent yield, putting first the **B**-type aldol reaction (Scheme 2). The route taken by Schinzer et al.[13b] goes in the opposite direction; they use Ipc_2B(3,3-dimethyl allyl) to close the C4 → C3 bond (Scheme 1). However, the double bond must not only be subsequently oxidized but the additional carbon atoms must be supplied to the compound to yield **10** (Scheme 3). The apparent possibility of directly producing building blocks of the type **9** and **10** in an



Scheme 3. Highly stereoselective C6–C7 aldol reaction (c.f. Scheme 2, **B**) in the total synthesis by Schinzer et al.

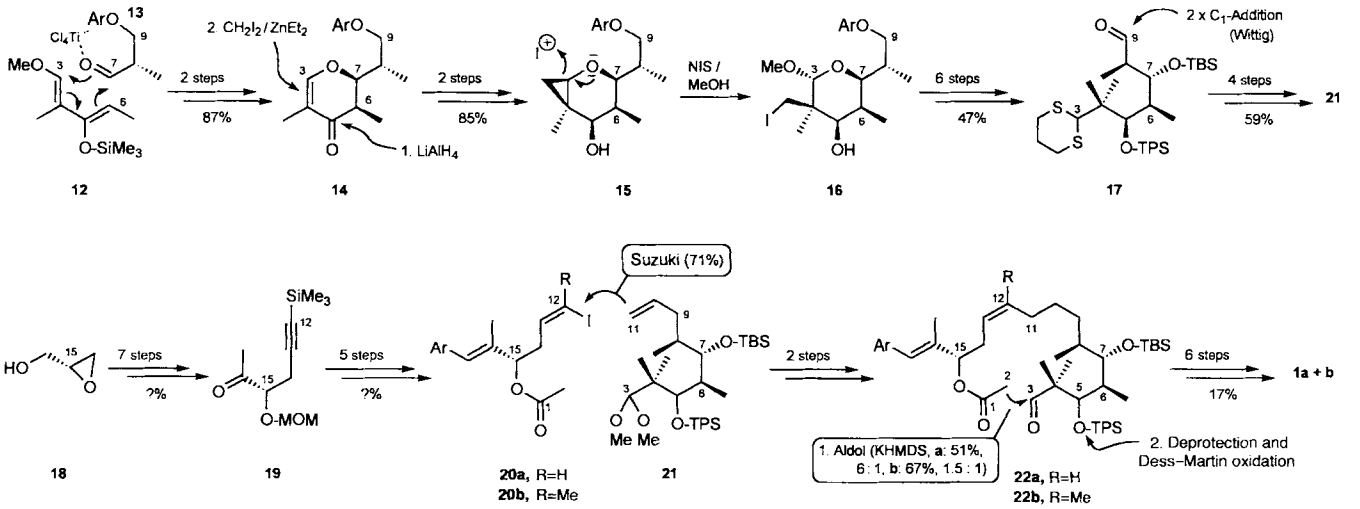
aldol reaction was accomplished by Wessjohann et al.[16] in a one-pot process by applying the chromium Reformatsky method to suitable 2-bromoacetyl derivatives, using Evans' auxiliary. In contrast to other aldol procedures, this bears no risk of a retroaldol reaction. Both the C2 → C3 and the C4 → C3 aldol reactions were successful (see W^1 and W^2, Scheme 1). The diastereoselectivities for chromium-complexed enolates of α-unsubstituted acetyl oxazolidinones are higher than with other species: *de* with Cr: 84–99, with B, Li, Ti: 4–74%.

The C6 → C7 aldol reaction (Scheme 2, **B**, and Scheme 3) should yield only one of the four possible isomers stereoselectively. All authors obtained only the desired *syn* diastereomers when *Z*-lithium enolates were employed; however, in the reaction of **7** with the dianion of **9** the diastereomers form in approximately equal amounts (Scheme 2, **B**).[11a, 12] Mulzer et al. achieve a ratio of 4:1 by using an achiral enolate and a chiral C7-C9-O-Ar building block (see **13** with Ar = 4-methoxybenzyl), although C8 offers the only possibility of control.[14] Kalesse et al. employ the almost identical C7-C9-O-Ar aldehyde **13** (Ar = benzyl),[15] while Schinzer et al. use the aldehyde **7** (Y = CH_2, Scheme 3),[13a] with which they obtained solely the desired diastereomer. This important improvement is probably due to a "matched case" influence of the chiral enolates and is an important strength of the approach adopted by Schinzer et al.

The syntheses developed by Danishefsky et al. (Scheme 4) are substantially different from the other approaches.[6, 10a, b] Whilst the synthesis of **20a**—the stereocenter C15 stems from *R*-glycidol—is effected under standard conditions, the ring closure and the synthesis of the second main precursor **21** are unusual. The diastereomer problem of the C6 → C7-aldol reaction is avoided by a chelate-controlled cycloaddition of **13** to the diene **12**. There is, however, a price to pay for this advantage: functionalization of C9 in the intermediate **14** is difficult to effect (see also ref. [14, 15]), and a methyl group is missing at C4. The latter problem is elegantly, but not exactly practically, solved by using a Simmons–Smith cyclopropanation, followed by oxidative ring-opening with electrophilic iodine (see **15**). Interestingly, the three-membered ring is preferentially opened solvolytically at the inner bond.[10b] Dehalogenation and refunctionalizing ring-opening afford the semiprotected dialdehyde **17**. The chain extension from C9 in **17** to C11 in **21** could only be effected through two consecutive Wittig reactions (with $MeOCH{=}PPh_3$ and CH_2PPh_3). This creates the necessary prerequisites for a C11 → C12 Suzuki coupling, which is an alternative to the described (unsuccessful) metathesis: The alkene **21** activated with 9-borabicyclo[3.1.1]nonane (9-BBN) is coupled to the *Z*-vinyl iodide **20a** in 71% yield under palladium catalysis. The stereoselective macroaldolization of the liberated C3-aldehyde **22** is remarkable, and affords up to 70% *de* of the correct diastereomer (51% yield). The oxidation of the ether-protected C5-hydroxy group takes place after some protecting group transformations with the Dess–Martin reagent. The concluding epoxidation with dimethyldioxirane (45%) proceeds surprisingly diastereoselectively for a macrocycle (20:1 at −50 °C)[10a] and was improved by Schinzer et al. (48% at −35 °C).[13a] When *m*-chloroperbenzoic acid is used, the epoxidation is less selective, however, a higher overall yield (55% at 0 °C) of the correct isomer is obtained.[11a]

Epothilone B (**1b**)[6] is for the most part synthesized according to the above approach. However, it contains a methyl group at C12 (Scheme 4), which is obtained by reaction of the unusual Wittig reagent $Ph_3P{=}C(I)CH_3$ with a C11 aldehyde (yield 43%). The subsequent Suzuki coupling that leads to **22b** is more effective than that for epothilone A (77% yield), as is the final epoxidation with dimethyl dioxirane (70%), which affords the desired diastereomer in excellent excess of 14:1 despite the *E*-methyl group. In this paper by Danishefsky et al., in vitro studies of the activities of derivatives are discussed for the first time.[6] It is not surprising that the natural products, especially epothilone B, show the highest activity. The nonepoxidized precursors, the deoxyepothilones **2**, are only slightly, their *trans* isomers significantly less active.

The first, more extraordinary epothilone synthesis by Danishefsky et al. is lengthier and less convergent than those by Schinzer et al. and Nicolaou et al. To date none of the syntheses can compete with the fermentation, but they offer many possi-



Scheme 4. First total syntheses of **1a** and **b** by Danishefsky et al., >22 +13 steps, overall yield: ≤2% **1a**, KHMDS = potassium hexamethyldisilazide, MOM = methoxymethyl, NIS = *N*-iodosuccinimide, TPS = triphenylsilyl, Ar = benzyl, Suzuki coupling see text.

bilities of derivatization and variation. The course of the in vivo tests will be pivotal for the further development of the epothilones and their derivatives. If the tests are positive, the advantages discussed in the beginning could lead to a replacement of the already established taxoids not only from the receptors. Apart from their immediate medicinal applications, the epothilones offer the possibility to comprehensively study the effect of tubulin stabilization with respect to structure–activity relationships for the first time, as derivatives will be available faster and at a more reasonable price than with taxol. It remains to be seen for both epothilone and taxol whether the optimization carried out by nature can significantly be surpassed, since so far no new or even only considerably better substances with these effects have been obtained. Notwithstanding this challenge to synthetically based drug screening, the discovery of the epothilones is already an extremely important advance in the fields of tumor and mitosis research.

Gas-Phase Complexes: Possible Prereactive Gateways for Reactions of Halogens with NH_3, H_2O, and H_2S

Hans Bürger*

Two molecules that collide in the gas phase in the absence of a surface have to overcome an activation barrier before they can react with each other. This requires that either one (or both) of the partners or a prereactive precursor is activated photochemically into excited electronic states, thermally into higher vibrational or rotational levels, or by an increase of translational energy (for example by collisions). The formation of weakly bound complexes with a potential minimum that precedes the activation barrier may occur by prereactive interactions between the partners. These mark a certain point along the reaction pathway and may also determine the structures of the final reaction products. Such interactions are characterized by a separation of the partners that is shorter than the van der Waals contact, but longer than an electron pair bond or an ionic bond. Although these prereactive complexes (PRCs) are related to the better-known van der Waals complexes (VDWCs) such as ArCO and ArHF, which are formed from a noble gas atom and a suitable partner, they are distinctly different. While the VDWCs fall apart reversibly into their constituents [Eq. (1a)], the PRCs may undergo a vigorous reaction to form different products [Eq. (1b)].

$$\mathrm{Ar + HF} \xrightarrow{(a)} \underset{\text{(VDWC)}}{\mathrm{Ar \cdots HF}} \xrightarrow{(b)} \mathrm{Ar + HF} \qquad (1a)$$

$$\mathrm{H_2O + F_2} \underset{(b)}{\overset{(a)}{\rightleftharpoons}} \underset{\text{(PRC)}}{\mathrm{H_2O \cdots F_2}} \xrightarrow{(c)} \mathrm{HOF + HF} \qquad (1b)$$

The "bonds" between the constituents of the VDWCs and PRCs are very weak, and are easily stretched. This is evident from the very small stretching force constant k (0.036 N cm^{-1} in

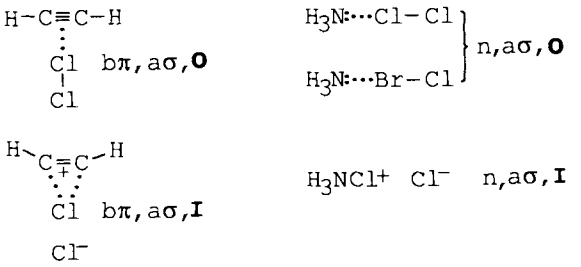
$H_2O\cdots F_2$ and generally below $0.3\,N\,cm^{-1}$ in PRCs formed from NH_3, H_2O, and H_2S with halogens) and hence orders of magnitude smaller than in molecules (Cl_2 $3.2\,N\,cm^{-1}$, N_2 $22.4\,N\,cm^{-1}$). Furthermore, both the VDWCs and PRCs undergo significant lengthening of the weak contact (shown by a dotted line) upon rotational excitation. This results in rather large values for the centrifugal distortion constants D, which are inversely correlated with k and may be considered as a measure for the strength of the interaction between the constituents.

What do such PRCs look like, and which parameters are useful for their description? According to Mulliken und Person,[1] strongly bound inner complexes (**I**) and weakly bound outer complexes (**O**) can be distinguished from one another. Significant structural changes of the constituents and substantial charge transfer occur upon formation of inner complexes, while the structures are hardly affected in outer complexes. Likewise, halogens X_2 and interhalogens XY (X, Y = F, Cl, Br) act as σ-acceptors (aσ) towards π-bonded systems (bπ) (for example ethyne) or towards lone pairs (n) of NH_3, H_2O, or H_2S. Accordingly, complexes of the type shown in Scheme 1, of which only the outer complexes **O** belong to the PRCs, may be formed.



Scheme 1. Types of complexes.

Recently, in particular A. C. Legon and co-workers have developed methods for interrupting the usually vigorous reactions of hydrogen compounds with halogens at the stage of the PRCs, which were then studied by Fourier-transform microwave (FTMW) spectroscopy. An account of these studies has been given elsewhere.[2] Here, methods for generating and studying such PRCs will first be briefly reported, and complexes of NH_3, H_2O, and H_2S with F_2, ClF, Cl_2, BrCl, and Br_2 will then be described. This discussion should clarify to what extent FTMW spectra can answer the following questions:

- What is the composition of the PRCs, how are the constituents arranged with respect to each other, and which of the halogen atoms in the interhalogens acts as an acceptor?
- What is the distance between the centers of donor n and acceptor a, and how strong is the interaction of n with a?
- To what extent will charge be transferred within the acceptor molecules, that is, how close to complete electron transfer (as is realized in the inner complexes **I**) are the PRCs?

PRCs can only be prepared [Eq. (1)] and detected provided their thermal energy is sufficiently low to prevent fragmentation into their constituents and, thereby, to inhibit advancement along the reaction coordinate. They exist only in a very shallow well of the potential that precedes the activation barrier and is accessible by rapid and efficient cooling. This is achieved by expanding a noble gas, such as Ar, from a pressurized container (for example 3 bar) through a pulsed nozzle into a vessel that is held at a pressure of about 5×10^{-5} mbar. The molecules in the supersonic jet have a very narrow velocity distribution in the direction of propagation, which corresponds to a translational temperature as low as 1 K (Joule–Thomson effect). The noble gas (Ar) contains an admixture of about 1% of the halogen. Immediately downstream from the pulsed nozzle the Ar–halogen mixture meets a stream of the reaction partner NH_3, H_2O, or H_2S, which is introduced into the vacuum chamber by a concentric capillary with an inner diameter of 0.3 mm, as in the oxyhydrogen torch. The PRCs that are formed in the expanding jet are cooled by collision with noble gas atoms, which comprise more than 98% of the mixture. This PRC jet is not in thermal equilibrium since the translational, rotational, and vibrational temperatures are about 1 K, 10 K, and 100 K, respectively. Under these conditions three-body collisions of noble gas, base, and halogen occur only very close to the nozzle; thereafter the PRCs propagate almost collisionless.

An FTMW spectrometer integrated into the vacuum chamber provides data on the geometry, structure, and charge distribution of the PRCs. A microwave pulse of precisely known frequency (between 1 and 40 GHz) is applied in a resonator to the cold PRC/noble gas molecular beam. This induces a polarization of the PRC molecules. After the pulse has been cut off, the PRC emits microwave radiation that corresponds to a transition between two rotational levels. This molecular emission is detected, amplified, and Fourier transformed to obtain a line in the rotational spectrum of the PRC. Such molecule-specific microwave frequencies provide ample and specific data on its carrier:

- The distribution of lines is related to the symmetry of the complex and indicates, for example, whether the complex possesses a threefold symmetry axis (symmetric top) or whether effects of nuclear spin statistics due to symmetry-related nuclei are present.
- The moments of inertia with regard to the principal axes, which depend on the coordinates of the atoms, can be determined from the transition frequencies. Since the number of atoms in PRCs usually exceeds the number of moments of inertia that can be determined, isotopic data (H/D, $^{16}O/^{18}O$, $^{14}N/^{15}N$, $^{35}Cl/^{37}Cl$, $^{79}Br/^{81}Br$) are of particular value. Chlorine and bromine are advantageous since they both are composed of two fairly abundant isotopes.
- Due to the weakness of the complex bond, centrifugal distortion becomes increasingly important. The distortion constant D may be obtained from the increase in the moments of inertia I upon excitation to higher rotational states.
- FTMW data are very accurate, and a resolution up to $1:10^7$ may be achieved. This enables the observation of characteristic quadrupole hyperfine structure, provided the PRC contains nuclei such as ^{14}N, $^{35/37}Cl$, and $^{79/81}Br$, which have an electric quadrupole moment owing to their $I\geq1$ nuclear spin. The charge transfer may be determined by a comparison of the nuclear quadrupole coupling constant χ in the PRC with that of the free halogen or interhalogen:

$Cl^1–Cl^2$, $\chi(Cl^1)=\chi(Cl^2)=-111.79$ MHz

$H_3N\cdots\overset{\delta+}{Cl^1}–\overset{\delta-}{Cl^2}$, $\chi(Cl^2)-\chi(Cl^1)=13.99$ MHz (^{35}Cl)

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3607-0719 $ 17.50+.50/0

This difference in χ upon complexation corresponds to a charge transfer $Cl^1 \rightarrow Cl^2$ of 0.064 e.[3] In general, it has been observed that the extent of charge transfer within the halogen correlates to the stretching force constant k for the weak base $\cdots$ acceptor interaction.[3]

Not only the differences in χ for the individual halogen atoms, but also the absolute and average values are of importance since they are a measure of the deviation of the B $\cdots$ X–Y group from its linear equilibrium geometry (Figure 1a), owing to zero point effects.[3] Thus it becomes apparent that complexes with ClF, Cl_2, BrCl, and Br_2 provide more information than those with F_2 due to isotopic and nuclear quadrupole effects.

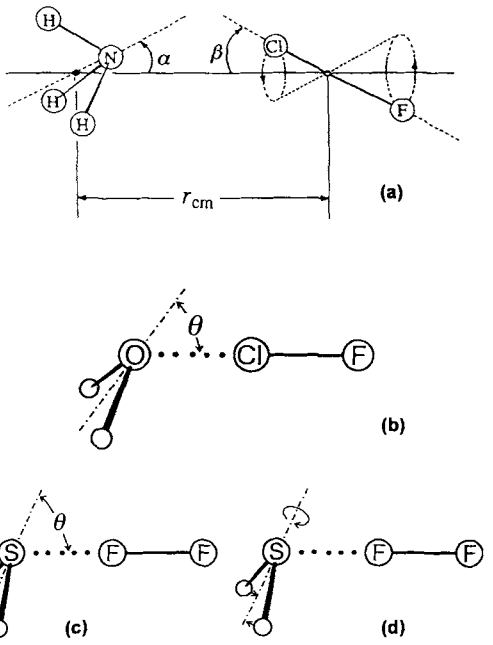


Figure 1. a) Schematic representation of the PRC $NH_3 \cdots ClF$ with definition of the angles α and β; r_{cm} is the distance of the centers of mass of NH_3 and ClF (ref. [7]). b) Model of the complex $H_2O \cdots ClF$ (ref. [13]). c) Model of the complex $H_2S \cdots F_2$ (ref. [14]). d) Illustration of the internal rotation of H_2S about its C_2 axis in the PRC $H_2S \cdots F_2$ (ref. [14]).

The uncontrolled reactions of halogens with NH_3, H_2O, and H_2S in the gas phase proceed vigorously in the case of F_2 and ClF; the reactivity of the halogens decreases significantly in going from F_2 to Br_2. The substantial heat of formation for HX is the driving force of these reactions. Likewise, NH_3, H_2O, and H_2S react with undiluted F_2 at room temperature with self-ignition; the first steps are shown in Equations (2).

$$2NH_3 + 3F_2 \longrightarrow N_2 + 6HF \quad (2a)$$

$$H_2O + F_2 \longrightarrow 1/2O_2 + 2HF \quad (2b)$$

$$H_2S + F_2 \longrightarrow 1/8S_8 + 2HF \quad (2c)$$

However, allowing F_2 to react with H_2O at $-40\,°$[4] or photolyzing an F_2/H_2O mixture at 14–20 K in an Ar or N_2 matrix[5] does not afford O_2 and HF [Eq. (2b)] but rather HOF and HF [Eq. (3)].

$$H_2O + F_2 \longrightarrow HOF + HF \quad (3)$$

Similarly, the reactions of NH_3, H_2O, and H_2S with the other halogens proceed fairly vigourously and yield N_2, O_2, and S_8, respectively, although different pathways apply upon dilution of the halogens with an inert gas or under controlled conditions, such as in the presence of a catalyst [Eqs. (4) and (5)].

$$NH_3 + 3F_2 \xrightarrow{Cu} NF_3 + 3HF \quad (4)$$

$$2NH_3 + Cl_2 \xrightarrow{N_2} NH_2Cl + NH_4Cl \quad (5)$$

The reactions of NH_3 with halogens or interhalogens in a molecular beam yield outer complexes **O** of the type n, aσ (Figure 1a). In the case of ClF or BrCl, the more electropositive halogen atom is always attached to the base. Since the N $\cdots$ X–Y backbone is linear at equilibrium, the PRCs are symmetric tops; the structural parameters of both B and X–Y are almost unchanged in the PRCs.

Complexes of NH_3 and its isotopomers with F_2,[6] ClF,[7] Cl_2,[3] BrCl,[8] and Br_2[9] have been characterized; selected structural and physical parameters are presented in Table 1. The five examples of NH_3 complexes allow a discussion of the bonding. From the distances r(N $\cdots$ X) and k, it can be deduced that the N $\cdots$ X–Y bond strength increases in the following order of X–Y: $F_2 < Cl_2 < Br_2 < BrCl < ClF$.[7] This is as expected if the B $\cdots$ X–Y interactions are mostly electrostatic.[6] ClF and BrCl possess permanent electric dipole moments ($\mu_{ClF} > \mu_{BrCl}$), while the homonuclear species F_2, Cl_2, and Br_2 show both increasing electric quadrupole moments and mean polarizabilities in the given order. If charge transfer B $\rightarrow$ X–Y were pronounced, a weakening of the B $\cdots$ X bond in the order $BrCl > Br_2 > ClF > Cl_2 > F_2$ would be expected.[6] Cl_2 and HCl resemble each other, as do BrCl and HBr, with regard to the

strength of the B···X–Y and B···H–X bond in different n and bπ bases (Scheme 1); the BX distances are highly correlated.[2, 10, 11]

Analogous PRCs of H_2O and the halogens F_2[12] and ClF[13] have recently been obtained. Their structures (Figure 1b) were deduced from the observed characteristic *a*-type transition pattern. Nuclear spin statistic effects show that the complexes are either planar at equilibrium (C_{2v}) or have a very low inversion barrier for a pyramidal equilibrium structure (C_s). This justifies the assumption that $\theta = 0°$. From the weakness of the O···X–Y bond, it may be concluded that the H_2O and X–Y units of the complexes will have the same structures as the free constituents. Some important molecular parameters are listed in Table 2.

Table 2. Complexes of H_2O and H_2S with halogens.

Complex	r(B···X) [Å]	r(X-Y) [Å] [a]	θ [°] [b]	k [N cm^{-1}]	δ_e(X-Y) [c]	Ref.

[a] Parameters adopted from the free X–Y halogen molecules. [b] Angle of the X–Y vector with the H_2O and H_2S planes. [c] Charge transfer X → Y upon complex formation. [d] Assumed.

According to their FTMW spectra, the complexes of H_2S with F_2,[14] ClF,[15] Cl_2,[16] and BrCl[17] have pyramidal structures (Table 2). The order of the bond strengths $F_2 < Cl_2 < BrCl < ClF$ is the same as for the corresponding NH_3 complexes. The $H_2S···F_2$ complex is, however, remarkable. While the S···F bond is very weak (its length corresponds to the sum of the van der Waals radii), the angle between the H_2S plane and the S···F–F vector is significantly larger than for the other complexes (Figure 1c). Furthermore, an excited state is observed in addition to the vibrational ground state.[14] This suggests that, in this particular case, a low-energy internal rotation about the local C_2 axis of the H_2S part occurs. This would favor a secondary interaction of an H atom with fluorine (Figure 1d).[14] All in all, the electrostatic model can be applied to NH_3, H_2O, and H_2S. Both the base molecules and the (inter)halogens undergo only insignificant structural changes and charge transfer. The strength of interaction increases for a given halogen in the order $H_2S < H_2O \ll NH_3$. It is about twice as strong for NH_3 than for H_2S. An analogous order has been established in complexes formed by hydrogen halides.[10]

There is no doubt that the halogen complexes are outer complexes **O** as defined by Mulliken and Person.[1] The PRCs represent the step of partner capture by electrostatic forces that occurs at an early stage of an exergonic reaction. The PRCs are labile due to the weakness of the base–halogen interactions; thus this bond can easily break. Their existence is limited to collision-free conditions at low rotational and very low translational temperatures that are far from thermal equilibrium. Whether they are precursors for transition states of subsequent reactions is still an open question.

Cross-Linked Enzyme Crystals (CLECs): Efficient and Stable Biocatalysts for Preparative Organic Chemistry

Thomas Zelinski and Herbert Waldmann*

Dedicated to Professor Maria-Regina Kula on the occasion of her 60th birthday

The advantages that enzymatic catalysis offers for regio- and stereoselective synthesis are well-established. Thus, the approximately 3000 known enzymes efficiently catalyze a broad variety of reactions under mild conditions and often with high selectivity.[1] Although the number of available enzymes is steadily increasing, their application in organic synthesis is often hampered by their instability upon storage and under reaction conditions. To overcome these problems a variety of methods to stabilize enzymes have been developed.[1] Recently, this repertoire was extended by a new, alternative technique, the development of exceptionally stable cross-linked enzyme crystals (CLECs).[2] The finding that enzymes retain their catalytic activity in crystalline form was early proof for the assumption that the conformation of proteins in solution and in the crystal are comparable.[3] Such enzyme crystals may be stabilized by cross-linking with bifunctional reagents such as glutaraldehyde without a change in their X-ray reflections.[4] This fixing leads to CLECs that retain their catalytic activity and display additional properties typical for enzymes immobilized in a conventional manner.

To generate CLECs the parameters for the crystallization must be adjusted such that microcrystals are formed (crystals with edges less 100 μm in length). Subsequent cross-linking delivers protein crystals that are no longer water-soluble, mechanically stable, and thus easy to handle. In contrast to enzymes immobilized by classical techniques, CLECs also display high catalytic activity at higher temperatures and in organic solvents. This is because the fixing of the proteins in the crystal lattice and the additional cross-linking efficiently prevents the denaturation of the enzymes through unfolding, dissociation, or aggregation.[2] In addition, CLECs are very stable towards degradation by proteases, since the protein–protein interactions necessary for this process are hindered and since the access of the proteases to the crystal lattice is limited. The crystallized enzyme preparations display long, solvent-filled channels, which in the case of thermolysin, for example, have a diameter of roughly 25 Å.[5] Since the CLECs are macroporous, small molecules with a molecular weight up to 3000 Da can penetrate into the crystal. When microcrystals are used to catalyze chemical reactions, diffusion of the substrates is thus not the rate-limiting step.[6]

The interest in CLECs increased when thermolysin-CLECs were introduced; these exhibit high protease activity under extreme conditions, for example at increased temperatures, in 1:1 mixtures of water and organic solvents, and in nearly anhydrous organic solvents, suggesting that the stabilized biocatalyst might be suitable in numerous syntheses. The synthesis of the aspartame precursor **1** was catalyzed by the thermolysin-CLEC in pure ethyl acetate at 55 °C. Compound **1** was obtained in high yields and without deactivation of the enzyme in 19 repetitive reaction cycles (Scheme 1).[5] Chiral alkylamide

derivatives of amino acids and peptides were prepared by means of subtilisin-CLECs. A variety of acyl donors **2** were coupled with nucleophiles **3** to give di- and tripeptide amides **4** at 40 °C in acetonitrile (Scheme 2).[7] Since subtilisin

catalyzes the reaction with high stereoselectivity, the racemic substrates **2a** and **3** were converted to (*S*,*S*)-**4a** with high diastereoselectivity. 3-Methyl-3-pentanol was used as the solvent since the acyl donors **2** used as methyl, ethyl, and benzyl esters were not transesterified by the enzyme in this alcohol.

CLECs of the C–C bond forming enzyme fructose-1,6-diphosphate aldolase from rabbit muscle, which were developed by Sobolov et al., are much more stable than the lyophilized enzyme preparations typically used.[8] After five days in buffered solutions or one hour in mixtures of water and organic solvents the homogeneously soluble enzyme retains less than 50% of its original activity. In contrast, under these conditions the aldolase-CLEC shows more than 90% activity. The synthetic potential of the aldolase-CLEC was demonstrated on the poorly water-soluble, nonnatural substrates **5** (Scheme 3). The enzyme-catalyzed reactions with dihydroxyacetone phosphate in 20% dioxane gave results comparable to those obtained with the natural substrate D-glyceraldehyde-3-phosphate (GA3P). The rates of the reactions of aldehydes **5** in the presence of the CLECs are 68 to 116% of that of GA3P. These rates are roughly 10 to 100 times greater than the rates of the respec-

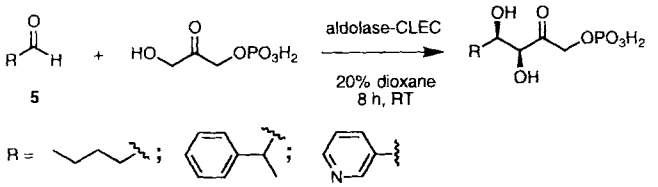
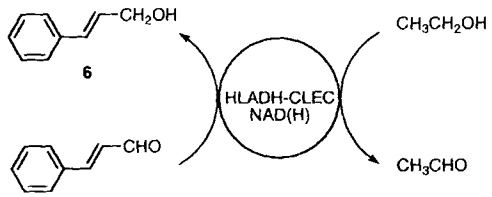


Scheme 3. Stereoselective, enzymatic C–C bond formation with aldolase-CLECs.

tive transformations in the presence of the lyophilized enzyme. Therefore, aldolase-CLECs may be suitable for increasing the reaction rates of inefficient transformations.

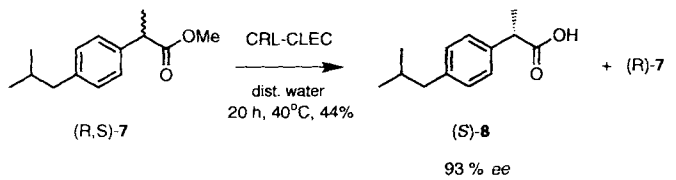
Horse liver alcohol dehydrogenase (HLADH) and rabbit muscle lactate dehydrogenase (LDH), both of which are cofactor-dependent enzymes, were used in organic syntheses as stable CLECs. Crystallization and cross-linking of HLADH was carried out in the presence of the cofactor NADH. HLADH was incorporated into the crystal lattice as a holoenzyme. The cofactor was bound so tightly to the crystal that it was not released from HLADH-CLECs even after extensive washing with buffer. (*E*)-Cinnamyl alcohol (**6**) was synthesized from the corresponding aldehyde in the presence of dimethoxyethane and ethanol as cosolvents, whereby ethanol also served as the second substrate for cofactor regeneration (Scheme 4).[9] The immobilization of



Scheme 4. Chemoselective reduction of cinnamyl aldehyde with HLADH-CLEC.

HLADH as CLECs increased its stability such that in the presence of 40% organic cosolvent its activity was the same as that in pure aqueous solution. The use of LDH-CLECs for the enantioselective synthesis of lactate solved a major problem in electroenzymatic cofactor regeneration. The complete deactivation observed for homogeneously soluble LDH in an electrolytic cell did not occur with LDH-CLECs. After an initial 10% decrease in activity, the LDH-CLECs retained constant activity over 25 days. In addition the optimal pH range of LDH was extended by the immobilization, increasing the range of applications of the enzyme.[10]

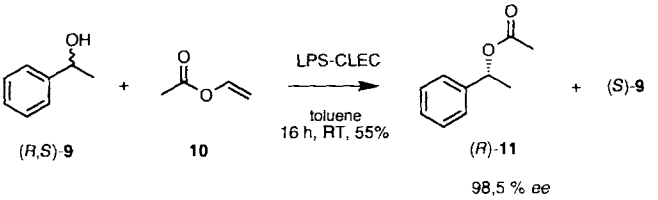
The capacity of *Candida rugosa* lipase (CRL)-CLECs was demonstrated in kinetic resolutions of the esters of arylpropionic acids (Scheme 5).[11] (*R,S*)-Ibuprofen methyl ester **7** was



Scheme 5. Enantioselective ester hydrolysis with CLECs from *Candida rugosa* lipase.

hydrolyzed in the presence of CRL-CLECs to give (*S*)-ibuprofen with an enantioselectivity of 93%—three times higher than that recorded with the crude enzyme preparations. This was attributed to the high purity of enzyme crystals (>98%) and the removal of contaminating hydrolases of opposite stereospecificity upon crystallization. The CLECs displayed a high degree of thermostability and cosolvent tolerance. Thus, CRL activity was completely retained even after incubation for ten days in 50% THF.

The reaction rates of lipase- and protease-CLEC catalyzed transesterifications in organic solvents (Scheme 6) are several



Scheme 6. Kinetic resolution by LPS-CLEC catalyzed transesterfication.

orders of magnitude lower than those recorded for the same transformations with homogeneously soluble enzymes in aqueous solutions. For subtilisin-CLECs this was explained by a shift of the optimum pH upon crystallization, the unfavorable desolvation energy of the substrates, and the low water-mediated flexibility of the proteins in the crystal lattice.[6] When denaturing solvents such as DMSO and formamide were added to the organic reaction medium, the transesterification activity of sublilisin CLEC increased by up to 100-fold, a finding that supports the flexibility theory.[12] By addition of an organic buffer system that protonates the catalytic triad of the protein in an optimal manner the activity of the sublilisin-CLECs could also be improved by two orders of magnitude.[13] Drying CLECs in the presence of detergents led to preparations that showed high activity in nearly anhydrous organic solvents. For instance, CLECs of the lipase from *Pseudomonas cepacia* (LPS) were applied advantageously for the enzymatic resolution of racemic 1-phenylethanol (**9**) by esterification with vinyl acetate (**10**). After 16 h and 50% conversion in pure toluene acetate **11** was obtained with 98.5% *ee* (Scheme 6).[14] The substrate:enzyme ratio was 4700:1; that is, even under these unusual conditions the enzymatic catalysis was fairly efficient. In the resolution of (+,−)-menthol the use of detergent-treated CRL-CLECs instead of purified and lyophilized CRL resulted in higher enantioselectivity and an increase of activity by five orders of magnitude.[15] The activation of the biocatalyst by the detergents indicated by these results has not been explained conclusively. Possible factors include the enhanced flexibility of the enzyme, the improved transport of the substrate from the solvent to the active site owing to the tightly bound water in the crystal, and the regulation of the optimal water activity.

The newly developed CLECs are highly selective and active biocatalysts with exceptional stability in aqueous and organic solvents. One example of the high expectations in this area: Ciba-Geigy and Altus Biologics Inc., the manufacturer of CLECs, have announced the development of new additives for laundry

detergents based on CLEC technology. Since CLECs are easy to handle, they promise to be valuable catalysts in organic synthesis, in particular for the synthesis of larger amounts of a given compound. Today only a small fraction of the known biocatalysts have been analyzed by X-ray structure determination. In fact many enzymes have been crystallized, but the quality of the crystals was often not sufficient for X-ray analysis. However, the know-how gained in performing these crystallizations might now be used advantageously to develop a variety of new CLECs, which may serve as efficient biocatalysts for organic synthesis.

Set price: DM 1197.00
ISBN 3-527-29444-9

Comprehensive in coverage, written and edited by leading experts in the field, this Handbook is a definitive, up-to-date reference work. The Volumes *Methods I* and *Methods II* detail the physico-chemical basis and capabilities of the various microscopy techniques used in materials science. The Volume *Applications* illustrates the results obtained by all available methods for the main classes of materials, showing which technique can be successfully applied to a given material in order to obtain the desired information.

With the *Handbook of Microscopy*, scientists and engineers involved in materials characterization will be in a position to answer two key questions: "How does a given technique work?", and "Which technique is suitable for characterizing a given material?"

A "Smart" Magnetic Resonance Imaging Agent That Reports on Specific Enzymatic Activity

Rex A. Moats, Scott E. Fraser, and Thomas J. Meade*

Modern optical microscopy techniques combined with fluorescent indicator compounds have revolutionized studies of biological structure, function, and development by allowing the physiology of intact cells and tissues to be assayed.[1] For example, fluorescent dyes are often injected into cells of transparent embryos in order to follow the fate of their lineal descendants. Fluorescent dyes that change their intensity or wavelength upon binding Ca^{2+} have afforded insights into cell physiology. Further, fluorogenic substrate dyes can be used to follow the activation of a specific gene by fusing the β-galactosidase gene with the gene of interest's regulatory domain. However, optical techniques, ranging from video-microscopy to laser scanning confocal microscopy, work best in the outermost 100 μm of biological tissue because of light scattering and uncorrected optical aberrations.[2]

Magnetic resonance imaging (MRI) of biological structures offers an alternative to light microscopy that can circumvent these limitations, and recent analyses demonstrate the feasibility of true three-dimensional MR imaging at cellular resolution (about 10 μm).[3] In order to exploit the power of MRI for biological studies, contrast agents that are analogous to fluorescent indicator dyes used in light microscopy must be developed. Here, we describe the first member of an innovative new class of enzymatically responsive or "smart" MRI contrast agents that has been designed to report on the metabolic state of cells and organs and transmit this information in the form of an acquired MRI image.

MRI typically imposes one or more magnetic field gradients upon a specimen while exciting nuclear spins with RF pulses. After collection of data with a variety of field gradients, computational processing yields a one-, two-, or three-dimensional image of the specimen. The image is based upon the NMR signal from the protons of water in a given volume element. Ultimately, the signal intensity arising from any volume element (voxel) of the 3D image is a function of the water concentration and relaxation times (T_1 and T_2). Local variations in these three parameters provide the vivid contrast seen in in vivo images obtained by MRI. MRI contrast agents can enhance the intrinsic differences in the T_1 (spin–lattice) and T_2 (spin–spin) relaxation rates. T_1 agents accelerate the T_1 relaxation rate, increasing the signal from nearby water protons and making the voxel appear "brighter" in the resulting image. This decrease in T_1 is mediated, in part, by the direct interaction of water molecules with the unpaired electrons of a paramagnetic metal ion.[4, 5]

The lanthanide ion Gd^{3+} is by far the most frequently chosen metal atom for MRI contrast agents, because it has a very high magnetic moment ($\mu^2 = 63\ \mu_B^2$), and a symmetric electronic ground state S^8. The Gd^{3+} aqua ion is quite toxic and must be bound to a chelating ligand in order to reduce toxicity. Typically, eight of the nine available Gd^{3+} coordination sites are occupied by the chelating ligand, leaving one site available for inner sphere coordination of a water molecule.[6] When the number of coordinated water molecules (q) is equal to 1, half the measured relaxivity of the agent is derived from second coordination sphere water molecules. The remaining 50% comes from water molecules that are directly bound to the Gd^{3+} ion, but are rapidly exchanging.

The inner sphere mechanism for T_1 relaxation phenomena suggested a means to create a contrast agent with two distinct relaxivities, weak and strong. By blocking the one remaining open coordination site, water protons would be excluded from the inner sphere and the effect of the Gd^{3+} ion on the T_1 would be diminished.[7, 8] This can be accomplished by strategically modifying the chelate ligand with a coordinating group that sterically blocks the remaining inner sphere site. For the agent described here, this blocking group is designed to be cleaved by an enzyme. The T_1 of nearby water molecules can therefore be increased by the removal of the blocking group.

The first of this new family of MRI contrast agents, (4,7,10-tri(acetic acid)-1-(2-β-galactopyranosylethoxy)-1,4,7,10-tetraazacyclododecane)gadolinium (EGad), positions a galactopyranose residue at the ninth coordination site of the Gd^{3+} ion (Figure 1).[9] Exposure of EGad to the common marker enzyme

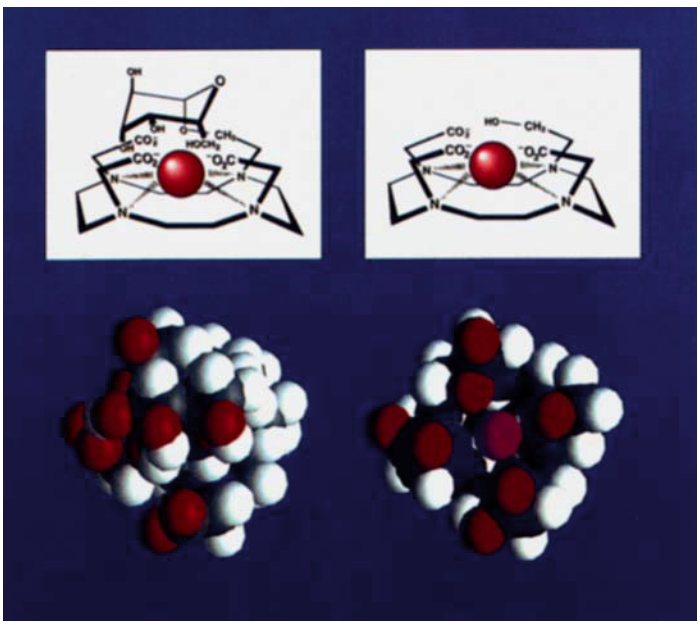

Figure 1. The MRI contrast agent with distinct weak and strong relaxivity states. Top: Structure diagram representing the attachment of the galactopyranose ring to the tetraazamacrocycle (left) and with the galactopyranose unit removed (right). Bottom: Molecular modeling illustrations of the complex with (left) and without (right) the galactopyranose side arm (the Gd^{3+} ion is depicted in magenta).

β-galactosidase (β-gal) removes the galactopyranose from the chelator and causes an irreversible transition from a weak to a strong relaxivity state. X-ray crystallographic analysis, mass spectrometry, and NMR spectroscopy confirmed the configuration and structure of the intermediates and the final product.

The ability of β-gal to remove the galactopyranose blocking group from EGad was examined by HPLC (Figure 2) by using the distinct retention times of EGad and Gad (EGad without the galactopyranose residue). When EGad was incubated with native β-gal, a peak with an elution time of 15 minutes appeared that corresponds to Gad. However, no change in the chromatogram could be detected after exposure to heat-inactivated

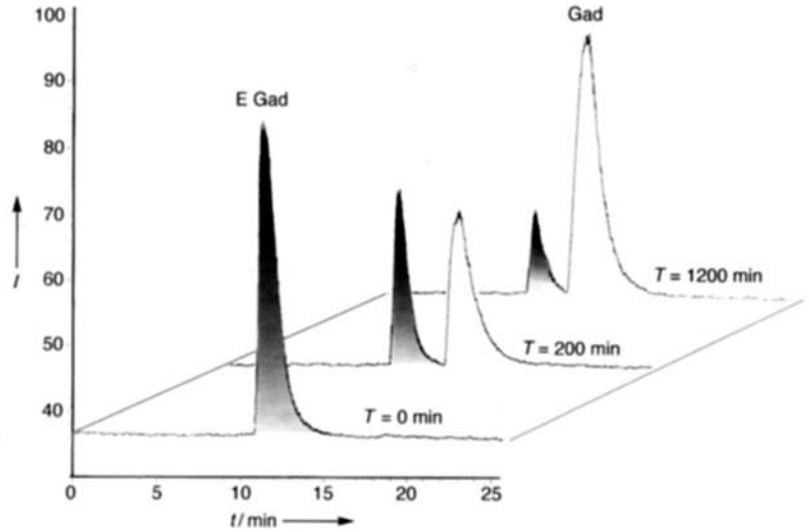

Figure 2. HPLC traces of the time dependent cleavage of the galactopyranose residue from the EGad complex by the enzyme β-gal. The Gd complex (2 mM) was incubated with β-gal (10 μM) at pH 7.3 and 37 °C in 25 mM phosphate buffer. The concentrations used approximate those required to generate MR image enhancement in vivo.

β-gal or α-galactosidase (used as negative control experiments). Thus, the HPLC experiments confirm the enzymatic processing of EGad by the appropriate, active enzyme.

An assessment of the ability of the galactopyranose residue to modulate the water exchange rate of EGad, we measured the fluorescence spectra of the terbium derivative (EGad–Tb) in water/deuterium oxide mixtures (λ_{em} 545 nm).[8, 10, 11] The fluorescence of the terbium complex is quenched by H_2O, but not by D_2O because the excited state of the terbium is strongly coupled to the OH oscillator but not the OD oscillator. Therefore, the lifetime of the fluorescence signal is longer in D_2O than in H_2O. This value was used to determine the number of water molecules (q) that are in fast exchange with the complex.[12] The q values for the terbium complexes of EGad and Gad were determined to be 0.7 and 1.2, respectively, which confirmed a significant change (about 40%) in the number of inner sphere water molecules.

The effect of the enzymatic cleavage of the galactopyranose residue from EGad on the T_1 of the complex, predicted to decrease by the spectrofluorimetry experiments, was assessed with NMR spectroscopy (Figure 3).[13] A 20% decrease in the measured T_1 values of a solution of the agent in the presence of β-galactosidase (Figure 3) is consistent with the change in measured hydration number q obtained from fluorescence measurements. Two different concentrations of β-gal resulted in identical and significant decreases in the solution T_1. Control reactions in which EGad was combined with heat-inactivated enzyme showed no decrease; in fact, the T_1 appeared to increase slightly. These results indicate that the decrease in T_1 of EGad is due to the enzymatic cleavage of the complex.

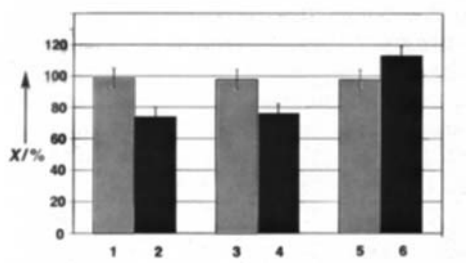

Figure 3. Change in T_1 observed upon β-gal-catalyzed cleavage of the galactopyranose residue (n = 3). The first column of each set (columns 1, 3, and 5) represent T_1 of the EGad and β-gal immediately after mixing. The second column of each set represents T_1 of the solution after incubation in the presence of β-galactosidase. Each column is reported as a ratio (X) to a control containing EGad only (that is, T_1(sample)/T_1(EGad without β-gal)). Columns 1 and 2: 2.0 mM Gd complex + 1.7 μM β-gal. Columns 3 and 4: 2.0 mM Gd + 5.1 μM β-gal. Columns 5 and 6: 2 mM Gd complex + 5.1 μM heat-inactivated β-gal.

MR images were obtained with a standard inversion–recovery sequence; the change in T_1 generated by enzymatic conversion of EGad to Gad could be visualized in an MR image (Figure 4). EGad was placed in 1.5 mm capillary tubes in the presence and absence of β-galactosidase. The images displayed in Figure 4 reveal that the T_1-mediated contrast of EGad was altered by the action of β-gal, yielding the expected image enhancement.

The successful synthesis and testing of EGad demonstrates the feasibility of using responsive MRI contrast agents to enhance images of physiological states of cells or organs deliberately. The distinct weak and strong relaxivity states of this agent offers the promise of direct, three-dimensional visualization of gene expression by MRI. Given the widespread use of β-gal as a marker enzyme in studies on mice, this new class of agent offers the immediate promise of following gene expression patterns in normal and genetically perturbed animal models.

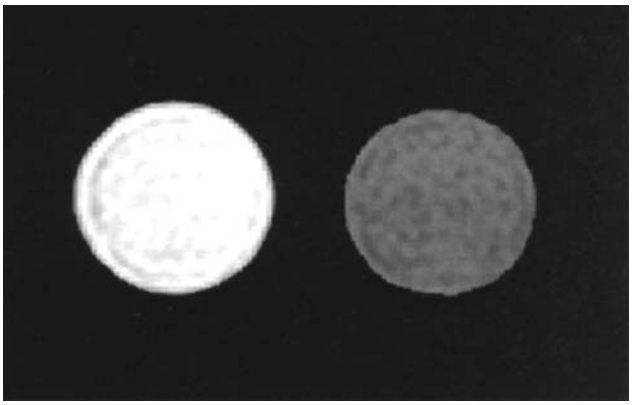

Figure 4. MRI contrast enhancement as a result of enzymatic cleavage of EGad. Images (256 × 256 × 3) of a solution of EGad in the presence (left) and absence (right) of the enzyme β-gal (2.0 mM Gd complex and 5.1 μM β-gal) were obtained horizontally through a 1.5 mm capillary tubes on a modified Bruker AMX spectrometer with a standard inversion–recovery imaging sequence and are displayed as raw data. The inversion delay was set to the average of the T_1 values (0.280 sec) and the interscan delay is 0.2 sec.

Although the issue of delivery of MRI agents to specific cell types by means other than microinjection is still under investigation,[14] the agent described here represents the first step in the evolution of a new class of image enhancement substances, and it is currently being tested in vivo. Extensions of this family of MRI contrast agents to other physiological or neuronal activation processes will permit biological issues presently inaccessible by light microscopy techniques to be investigated by MR imaging.

Experimental Section

Synthesis of 2,3,4,6-tetraacetyl-1-(2-bromoethoxy)-β-galactose: 2-Bromoethan-1-ol was treated with 2,3,4,6-tetraacetyl-1-α-bromogalactose to produce a mixture of

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3607-0727 $ 17.50+.50/0

α and β anomers (10/90) of 2,3,4,6-aceto-1(2-bromoethoxy)-β-galactose in 68% yield (8.3 g). The purified β anomer could be obtained by flash chromatography. Stereochemical assignments were made by an X-ray crystal structure of the β anomer.

2,3,4,6-tetraacetyl-1-(2-bromoethoxy)-β-galactose was treated with cyclene to produce the monosubstituted product. The acetate protecting groups were cleaved, and the three carboxylic acid substituents were added by reaction with bromoacetic acid at pH 10.5. The product 4,7,10-tri(acetic acid)-1-(2-β-galactopyranosylethoxy)-1,4,7,10-tetraazacyclododecane was isolated by anion exchange fast performance liquid chromatography (FPLC, detection at 218 nm) in 37% overall yield. Gd^{3+} or Tb^{3+} ions were incorporated into complexes, and these (EGad-Gd and EGad-Tb) were purified by repeated collections on a reverse phase HPLC analytic C_{18} column with water/acetonitrile (0–10% gradient) as the eluent (fluorescence detection $\lambda_{ex} = 274$ nm and $\lambda_{em} = 315$ nm) in 70% yield. The high resolution mass spectrum of the isolated solid provided a parent molecular ion $(M+Na)^+$, which exhibited the correct exact mass and the predicted isotope ratios.

X-ray data for $C_{16}H_{23}O_{10}Br$: CAD-4 diffractometer; monoclinic, colorless plates, space group $P2_1$ (no. 4); a total of 5603 reflections measured, 2981 used for refinement.

Fluorescence experiments [5,6] with EGad: The decay rate (inversely proportional to the lifetime) of the emission peak at $\lambda_{em} = 545$ nm ($\lambda_{ex} = 460$ nm) was measured with a Hitachi f-4500 fluorescence spectrophotometer (2 s delay, 64 scans) in H_2O, 50/50 H_2O/D_2O, and D_2O. An exponential curve fit (DeltaGraph 3, Delta Point Inc., Monterey, CA) was used to determine the decay rates. The slope of the decay rates versus D_2O concentration was compared to the literature value of a slope of $0.239/q$ to obtain q.

In three identical inversion-recovery (IR-NMR) high resolution experiments (Bruker AMX 500, 26 °C) EGad(2 mM) was incubated with two different concentrations of β-gal (1.7 μM and 5.1 μM) heat-inactivated β-gal (10 min at 80 °; 5.1 μM), and EGad alone (2 mM) in phosphate buffer (25 mM, pH 7.3) at 37 °C. Minimal enzyme concentrations were used to reduce potential interactions between the contrast agent and the enzyme. The solutions in a 40 μL round-bottomed NMR tube insert (Wilmad glass) were placed into a 5 mm NMR tube containing CD_3Cl. T_1 measurements were made immediately following mixing and after complete cleavage of the galactopyranose (>95% after incubation for 7 days). The data was processed with the program Felix (BIOSYM/Molecular Simulations, San Diego, CA), and the peak heights were fitted to an exponentially rising curve in order to obtain T_1 (regression: $R > 0.999$).

Glycylglycine Rotaxanes— The Hydrogen Bond Directed Assembly of Synthetic Peptide Rotaxanes

David A. Leigh,* Aden Murphy, John P. Smart, and Alexandra M. Z. Slawin

Although DNA displays a range of hydrogen bond assembled, topologically distinct architectures,[1–4] only recently have knotted,[5–7] catenated,[5, 6, 8, 9] and rotaxanated[5, 6, 10–12] substructures been identified in polypeptides and proteins. Unnatural DNA knots and catenanes of tremendous complexity can be synthesized[13–15] and are seen as promising forerunners to new types of drug delivery systems, nanoscale mechanical devices, and even "biochips".[16, 17] Here we report that glycylglycine derivatives can be used as templates for the formation of benzylic amide macrocycles through a five-molecule, hydrogen bond directed "clipping" strategy to give peptido[2]rotaxanes in yields as high as 62%. The four intercomponent hydrogen bonds responsible for rotaxanation "live on" in nonpolar solvents such as chloroform and, in the case of pyridine-2,6-dicarbamidobenzyl macrocycles, in the solid state and in polar solvents such as dimethylsulfoxide and dimethylsulfoxide–water mixtures. In the latter, the macrocycle forms an impenetrable molecular sheath over part of the peptide backbone making it inaccessible to external reagents as small as D_2O.

Benzylic amide [2]catenanes such as **1** are a structurally diverse family of catenanes most conveniently prepared by the eight-molecule condensation of aromatic 1,3-dicarboxylic acid dichlorides and benzylic diamines in nonpolar solvents.[18, 19] If the reactions are carried out in the presence of a suitably stoppered benzylic 1,3-diamide "thread" such as **2** [2]rotaxanes such as **3** are also formed.[20] In both cases the mechanism for the formation of the topologically complex products appears to be primarily the directed assembly of the macrocycle around two transoid amide bonds (**4**, Scheme 1).[21] Divergent hydrogen bonding sites in a similar spatial arrangement occur in adjacent amino acid residues in peptide chains, and therefore it seemed possible that these could also carry the correct structural information (**5** and **6**) to template the cyclization of benzylic amide macrocycles to give rotaxanes (Scheme 2).

To test this hypothesis the simplest dipeptide, glycylglycine, was incorporated into a suitable thread. The commercially available glycylglycine ethyl ester was N-acylated with diphenylacetyl chloride (Et_3N, THF, 90%) and then transesterified[22] at the carboxylate terminus with 2,2-diphenylethanol ($(Bu_2SnCl)_2O$, toluene, Δ, 90%). Equimolar quantities of isophthaloyl dichloride and *p*-xylylene diamine were slowly added to a solution of the dipeptide thread in anhydrous $CHCl_3$ (Scheme 2a). After five equivalents had been added, the thread was no longer consumed. Filtration and washing with acid and base left only three components in solution. These were separated by flash chromatography and identified in order of elution as the peptido[2]rotaxane **8** (62% yield), the unrotaxanated thread **7**, and [2]catenane **1**.

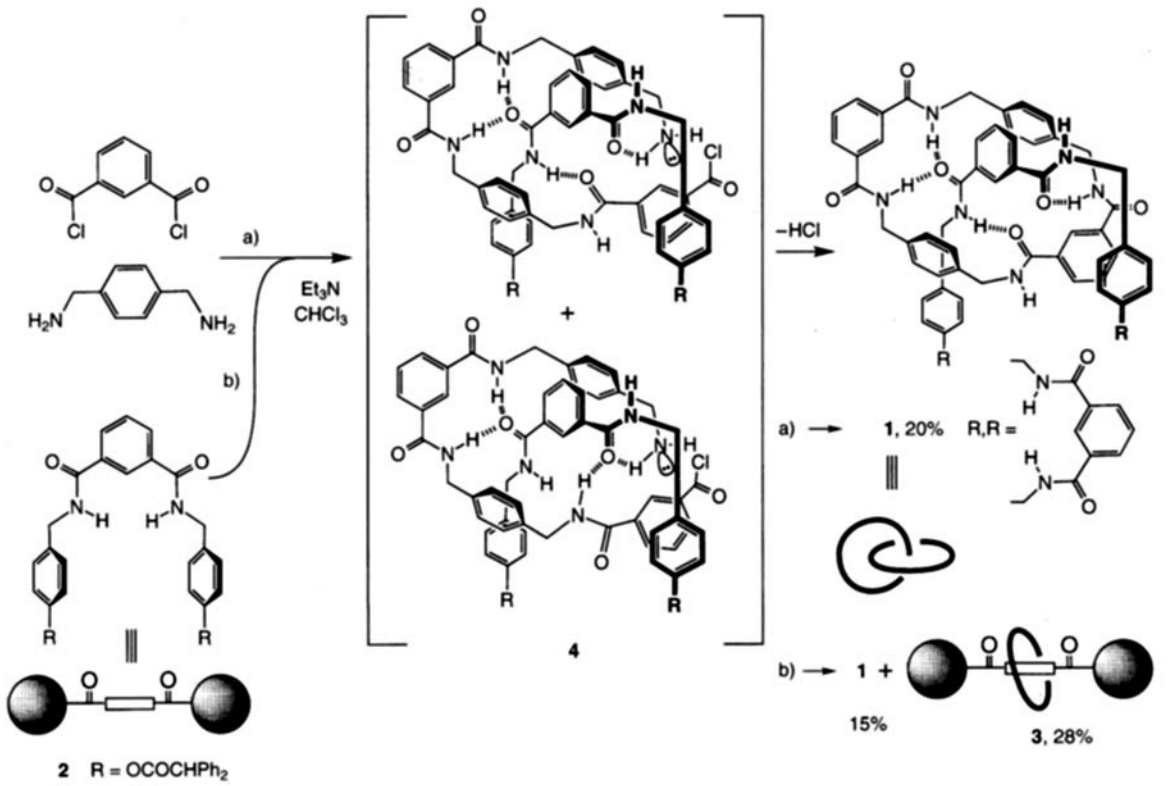
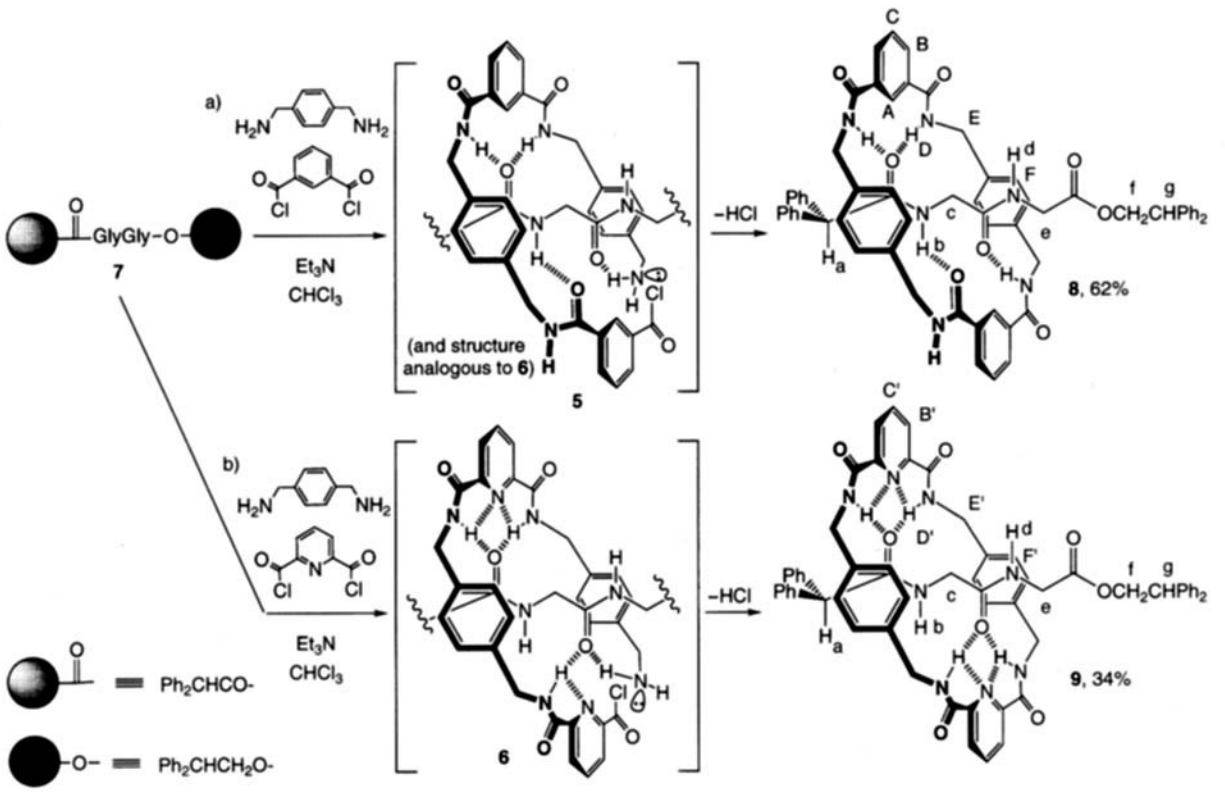


Scheme 1. a) The principle mechanism of formation of benzylic amide catenanes; b) the "clipping" strategy to benzylic amide rotaxanes. Vögtle et al. have described the synthesis of amide rotaxanes by a route in which threading is achieved by complexation of an amide group (produced in situ) in the cavity of the macrocycle [35].



Scheme 2. The synthesis of peptidorotaxanes **8** and **9** by five-molecule, hydrogen bond directed assembly. Rotaxane **9** forms via intermediate **6**, in which four hydrogen bonds form with the carbonyl groups of the dipeptide thread. Rotaxane **8** forms by two mechanisms: via an intermediate analogous to **6**, in which all four hydrogen bonds from the cyclization precursor are exclusively to the carbonyl groups of the thread, and an intermediate such as **5**, in which the cyclization precursor forms three hydrogen bonds to the two carbonyls of the dipeptide thread and a fourth hydrogen bond to an amide hydrogen atom in the thread.

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997* *0570-0833/97/3607-0729 $ 17.50+.50/0*

The ^{1}H NMR spectra of **7** and **8** in $CDCl_3$ are shown in Figure 1 a and b. With the exception of the signals of the phenyl stoppers and amide proton H_b, all the resonances for the protons in the peptide thread are shifted to significantly higher field

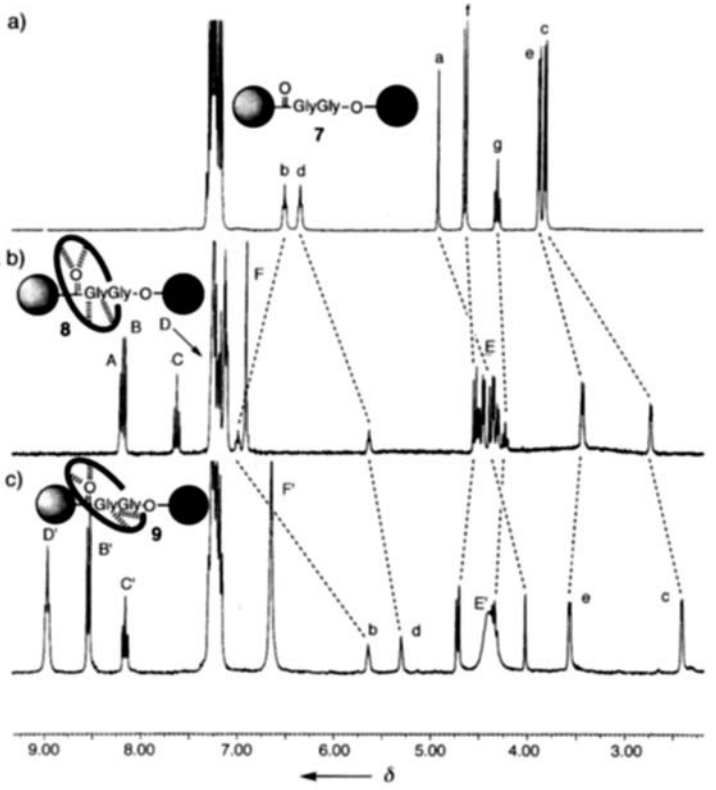


Figure 1. ^{1}H NMR spectra (300 MHz, $CDCl_3$) of a) glycylglycine thread **7**, b) peptido[2]rotaxane **8** (with the isophthaloyl macrocycle), and c) peptido[2]rotaxane **9** (with the pyridyl macrocycle).

in the rotaxane because of the shielding effects of the aromatic rings of the macrocyclic sheath. The greater shielding of the protons near the N-terminal glycine residue (particularly H_c compared to H_e) and the 0.5 ppm *downfield* shift of H_b (which indicates that the deshielding effect of intramolecular hydrogen bonding is larger than the shielding of the proton by the macrocyclic ring) is consistent with the predominant structure of **8** in $CDCl_3$ being that shown in Scheme 2. This type of hydrogen bonding motif, in which the macrocycle binds to both sides of a single amide residue, is a familiar feature in the X-ray crystal structures of benzylic amide catenanes.[18, 23] The macrocycle bridges the two amide carbonyl groups rather than one amide and the ester group, even though the hydrogen bonding sites are the same distance apart, because the ester carbonyl is a poor hydrogen bond acceptor.[24] Pirouetting of the macrocycle around the dipeptide thread is rapid on the NMR timescale at room temperature, giving rise to the simple spectrum observed for the macrocyclic component. Low-temperature NMR studies in $C_2D_2Cl_4$ give an energy barrier of 13.4 kcal mol^{-1} for the spinning process at 298 K, which corresponds to a rotation frequency of 820 s^{-1}.

In [D_6]DMSO, a hydrogen bond accepting solvent, the hydrogen bonding networks between the rotaxane components are broken and the macrocycle moves freely up and down the peptide chain. Under these circumstances the two glycine methylene groups (H_c and H_e), which are coincident in the ^{1}H NMR spectra of both the thread and the rotaxane (Figure 2 a and b), and peptide amide protons (H_b and H_d) are shielded equally by the macrocycle. A beautifully diagnostic feature of the rotaxane in both solvents is that the benzylic protons of the macrocycle (H_E) appear as an ABX system because the two sides of the macrocycle experience different environments; one faces the N-terminus of the peptide, the other the C-terminus.

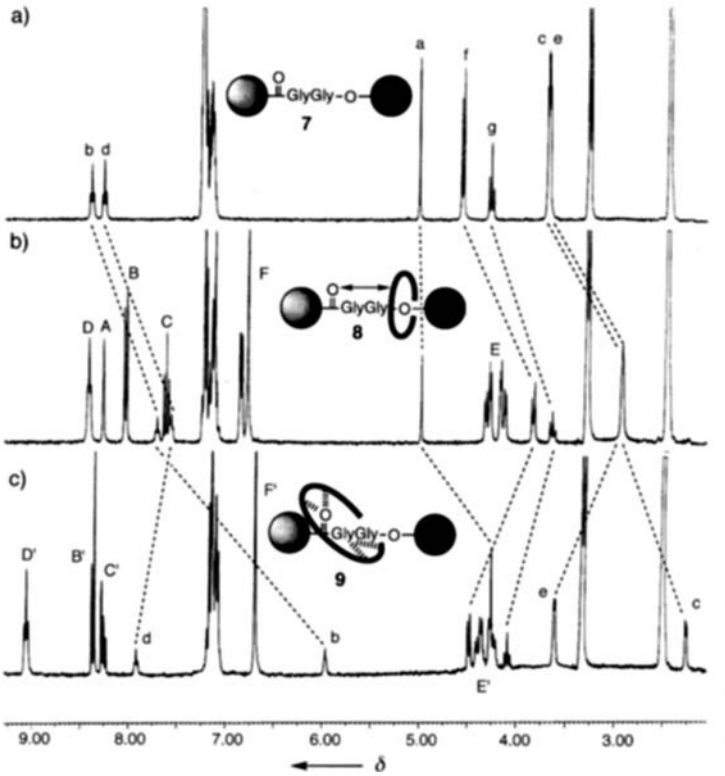

Figure 2. ^{1}H NMR spectra (300 MHz, [D_6]DMSO) of a) glycylglycine thread **7**, b) peptido[2]rotaxane **8** (with the isophthaloyl macrocycle), and c) peptido[2]rotaxane **9** (with the pyridyl macrocycle).

As in the synthesis of the original benzylic amide catenanes,[19] replacing isophthaloyl chloride with pyridyl-2,6-dicarboxylic acid dichloride (Scheme 2 b) leads to interlocked structures with differing hydrogen bonding motifs and dynamic properties. The ^{1}H NMR spectrum of the pyridyl rotaxane **9** in $CDCl_3$ is shown in Figure 1 c. The shifts in the signals of the peptide thread in this rotaxane follow the same basic trends as those of the isophthaloyl-derived system **8**, but the macrocyclic proton resonances are broader because of the slower pirouetting of the pyridyl macrocycle (100 s^{-1} at 298 K as opposed to 820 s^{-1} for **8**). Furthermore both signals for the amide protons of the thread (H_b and H_d) are now shielded, suggesting that in **9**, unlike **8**, neither of these protons act as hydrogen bond donors. Both observations are consistent with the established[19, 25] strong preference of pyridine-2,6-dicarbamido units to adopt a cisoid conformation, giving rise to the hydrogen bond network for **9** depicted in Scheme 2.

Unlike the isophthaloyl rotaxane **8**, the hydrogen bonding network in **9** is maintained even in hydrogen bond accepting solvents such as [D_6]DMSO (^{1}H NMR spectrum in Figure 2 c)! In contrast to **8**, the chemical shifts of the protons near the C-terminus (H_e, H_f, and H_g) of **9** are very similar to those of the analogous protons in the uncomplexed thread **7** (Figure 2 a), whereas H_a and H_c are shielded by 0.7 and 1.5 ppm,

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3607-0730 $ 17.50+.50/0 Angew. Chem. Int. Ed. Engl. 1997, 36, No. 7

respectively. The 2.5 ppm shielding of H_b occurs because it is encapsulated by the macrocycle and inaccessible to the hydrogen bond accepting solvent. Addition of D_2O to the sample has no effect upon the structure adopted by the rotaxane, and only a single glycine amide proton, H_d, undergoes deuterium exchange. Remarkably neither H_b nor the macrocycle amide protons $H_{D'}$, which are buried inside the rotaxane structure, are exchanged by the rapid rotation of the pyridyl macrocycle, which requires momentary breaking of all four intercomponent hydrogen bonds.[26] This shielding of the peptide backbone from external reagents augurs well for the use of rotaxanation to protect higher peptides from chemical and enzymatic degradation.

Single crystals of **9** suitable for investigation by X-ray crystallography[37] were obtained by slow evaporation of a solution of the peptidorotaxane in ethanol. The hydrogen bonding motifs and relative positions of the rotaxane components determined for the solid state (Figure 3) are identical to those established for

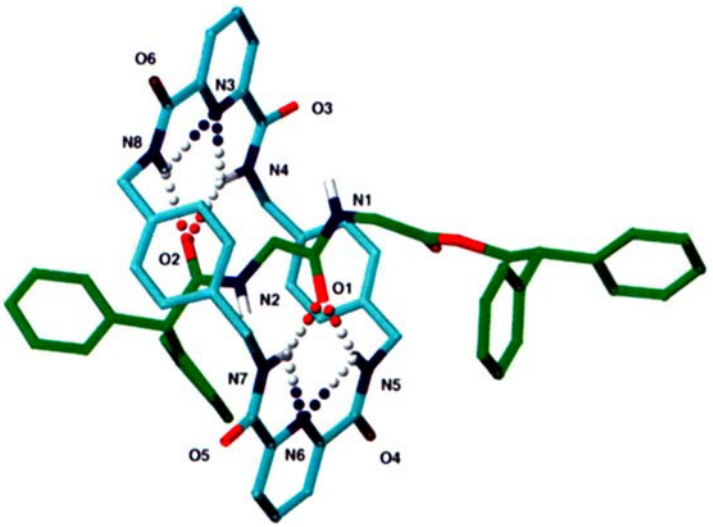

Figure 3. Solid-state structure of the peptido[2]rotaxane **9** as determined by X-ray crystallography. For clarity the carbon atoms of the macrocycle are blue and the carbon atoms of the peptide thread are green; oxygen atoms are red, nitrogen atoms purple, and hydrogen atoms white. Two water molecules of crystallization, which do not form hydrogen bonds with the rotaxane, are not shown. Lengths of intramolecular hydrogen bonds (in Å): N3–HN4 2.313, N3–HN8 2.282, N6–HN5 2.284, N6–HN7 2.248, O2–HN4 2.229, O2–HN8 2.306, O1–HN5 2.090, O1–HN7 1.923; lengths of intermolecular hydrogen bond (in Å): O5–HN1′ = 2.71.

9 in solution. The macrocycle adopts a chairlike conformation that completely encapsulates the N-terminal glycine residue. As anticipated, bifurcated hydrogen bonds occur in the macrocycle from each pyridyl nitrogen atom to the adjacent 1,3-diamide protons and from each of these to the amide carbonyl groups of the peptide thread. It is interesting to note that the hydrogen bonds are orthogonal to the lone pairs of the peptide amide carbonyl group, a motif previously seen in other hydrogen bond assembled catenanes.[18, 23, 27, 28] This illustrates the "soft" acceptor directionality[29–31] of the NH···O=C hydrogen bonding in these systems. Although no intercomponent π-stacking interactions are apparent in the rotaxane X-ray structure (nor are they possible in the assembly mechanism which appears to be solely a hydrogen bond driven process), C–H···π-arene hydrogen bonds are evident between the acidic N-terminal glycine methylene protons (H_c) of the thread and the xylylene rings of the macrocycle.

The yields of the peptide rotaxanes (62 and 34%) are significantly higher than those obtained with the benzylic 1,3-diamide thread **2** (28 and 0% when isophthaloyl dichloride and 2,6-pyridinedicarbonylchloride, respectively, are used). This reflects the excellent complementarity of the hydrogen bonding sites in the dipeptide template and the folded macrocycle precursors (**5** and **6**, Scheme 2). The subsequent tying up of the amide groups in intramolecular hydrogen bonds produces dramatic changes in the way in which the individual rotaxane components interact with their local environments—both peptidorotaxanes are more than 20000 times more soluble in chloroform than the free macrocycles. Physical properties and stabilities are also affected: the melting and decomposition point of the glycylglycine thread **7** is 148 °C, whereas the still-solid pyridyl rotaxane **9** decomposes at 230 °C.

The use of peptide-based drugs is currently complicated by their in vivo susceptibility to degradation and often poor membrane-permeability. If the hydrogen bond directed syntheses described here can be extrapolated to more complex peptides, then temporary housing within a rotaxane superstructure could simultaneously provide protection from hostile environments (in a manner similar to that suggested for the use of dendrimers as drug delivery systems[32]), improved stability, and engineered lipophilicity/solubility characteristics.

Experimental Section

General method for the preparation of peptide [2]rotaxanes: Dipeptide thread **7** (500 mg, 0.988 mmol) and triethylamine (1.60 g, 15.8 mmol) were dissolved in anhydrous chloroform and stirred vigorously whilst solutions of the amine (7.91 mmol) in anhydrous chloroform (40 mL, stabilized with amylenes rather than ethanol [18]) and the acid chloride (7.91 mmol) in anhydrous chloroform (40 mL) were added to the reaction mixture over 4 h by using motor-driven syringe pumps. The reaction mixture was filtered, washed successively with 1 M HCl (3 × 100 mL) and 5% sodium bicarbonate (3 × 100 mL) and concentrated to dryness under reduced pressure. The resulting solid was subjected to column chromatography (silica gel, $CHCl_3$/EtOAc) to yield, in order of elution, the peptido[2]rotaxane (**8** or **9**), unconsumed **7**, and [2]catenane.

Selected physical and spectroscopic data **8**: Yield 635 mg (62%); m.p. 219 °C; ^{13}C NMR (75 MHz, [D$_6$]DMSO): δ = 38.90, 41.25, 43.11, 48.91, 56.10, 65.88, 125.80, 126.50, 126.64, 127.41, 128.12, 128.36, 128.42, 128.60, 130.19, 134.31, 136.93, 139.95, 140.87, 165.68, 168.76, 169.35, 170.25, 171.39; FAB-MS (*m*NBA matrix): *m/z*: 1040 [(rotaxane + H)$^+$], 533 [(macrocycle + H)$^+$]; Anal. calcd. for $C_{64}H_{58}O_8N_6$: C 74.0, H 5.6, N 8.1, O 12.3; found: C 73.9, H 5.7, N 7.8, O 12.1.

Selected physical and spectroscopic data for **9**: Yield 350 mg (34%); m.p. 230 °C (decomp); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 41.17, 42.16, 42.59, 49.72, 58.55, 68.16, 125.60, 127.20, 127.46, 127.70, 127.97, 128.37, 128.45, 128.76, 129.03, 137.99, 139.01, 140.22, 149.35, 163.66, 169.02, 169.38, 171.32; FAB-MS (*m*NBA matrix): *m/z*: 1042 [(rotaxane + H)$^+$], 535 [(macrocycle + H)$^+$]; Anal. calcd. for $C_{62}H_{56}O_8N_8$: C 71.5, H 5.4, N 10.8, O 12.3; found: C 71.8, H 5.65, N 10.4, O 12.0. It is interesting to note that with both rotaxanes fragmentation in the mass spectrometer occurs across the macrocycle (to leave a charged species) and not the thread despite its weak ester linkage. The macrocyclic sheath protects the peptide from degradation even under the conditions of fast atom bombardment mass spectrometry.

[21] The principle mechanism for catenane formation proposed by Vögtle et al. [36] for the Hunter–Vögtle catenanes (binding of an acid chloride within the cavity of an amide macrocycle) does not account for the formation of benzylic amide catenanes. The binding constants of benzylic amide macrocycles with acid chlorides ($<10\ M^{-1}$) are at least two orders of magnitude too small to account for catenane formation.

[26] The markedly different behavior of the isophthaloyl and 2,6-pyridyl rotaxanes in polar solvents is not a consequence of the stronger hydrogen bonding interactions in the pyridyl rotaxane, but rather a result of the different hydrogen bonding geometries possible with the isophthaloyl unit that are not accessible with the pyridyl system [19, 25].

A Convergent Synthesis of a Carbohydrate-Containing Dendrimer**

Peter R. Ashton, Sue E. Boyd, Christopher L. Brown, Narayanaswamy Jayaraman, and J. Fraser Stoddart*

Amongst the distinctive features of dendrimers are their monodispersities, high molecular weights, and nanoscopic dimensions. With the rapidly growing interest in the synthesis of dendrimers, we have witnessed the use of an increasingly diverse range of building blocks for their construction.[1] The emergence[2] of neoglycoconjugates in glycobiology as a powerful means for studying carbohydrate–protein interactions offers new opportunities for the identification of different classes of neoglycosystems.[3] In this respect, carbohydrate-containing dendrimers, with their very precise and predetermined structural features for each of the carbohydrate units, are an important vehicle for the development of new and more efficient neoglycoconjugates. For example, it could be anticipated, with good reason, that such carbohydrate-containing dendrimers might elicit different biological responses from those exhibited by carbohydrate clusters located on oligomeric or polymeric backbones.[4]

We recently described[5] a highly convergent synthesis of carbohydrate-containing dendrimers with complete structural homogeneity. Here we report the preparation of even larger dendritic carbohydrate derivatives employing two different, yet closely related strategies. We encountered for the first time the problem of incomplete dendrimer formation as a result of limited core reactivity. The dendrimers[6] possess 24 and 36 peripheral D-glucopyranosidic units on a structure containing two different branching points, excluding those emanating from the core itself.

A schematic representation of the two strategies adopted in the synthesis of two closely related "36-mers" by the convergent approach is shown in Scheme 1a. In strategy 1, it was anticipated that the reaction of six equivalents of a dendritic (6-mer) wedge, containing six monosaccharide residues and a focal-reactive functionality, with one equivalent of a hexafunctional core compound (6-acid core) would afford 36-mer-A by a so-called 6×6 reaction sequence. In strategy 2, the reaction between three equivalents of a dendritic (12-mer) wedge, with 12 monosaccharide residues on its periphery, and one equivalent of a trifunctional core compound (3-acid core) was expected also to result in a 36-mer, namely 36-mer-B, by a 12×3 reaction sequence. The structural components of the dendrimers were derived from 1) the amino-protected tris(hydroxymethyl)-aminomethane (TRIS) as the glycosyl acceptor, 2) a suitably protected 3,3′-glycinamido dipropionic acid for further branching, and 3) either the 3,3′-iminodipropionic acid extended hypercore synthon or a glycine extended core synthon, both based on 1,3,5-tricarbonyl benzene, as the ultimate core component of the dendrimers.

First we synthesized the higher generation dendrimer by amide bond coupling to the hexaacid hypercore **2**[7] with the 6-mer wedge amine **1**[5] in the presence of 1,3-dicyclohexylcarbodiimide (DCC) and 1-hydroxybenzotriazole (HOBT) as cou-

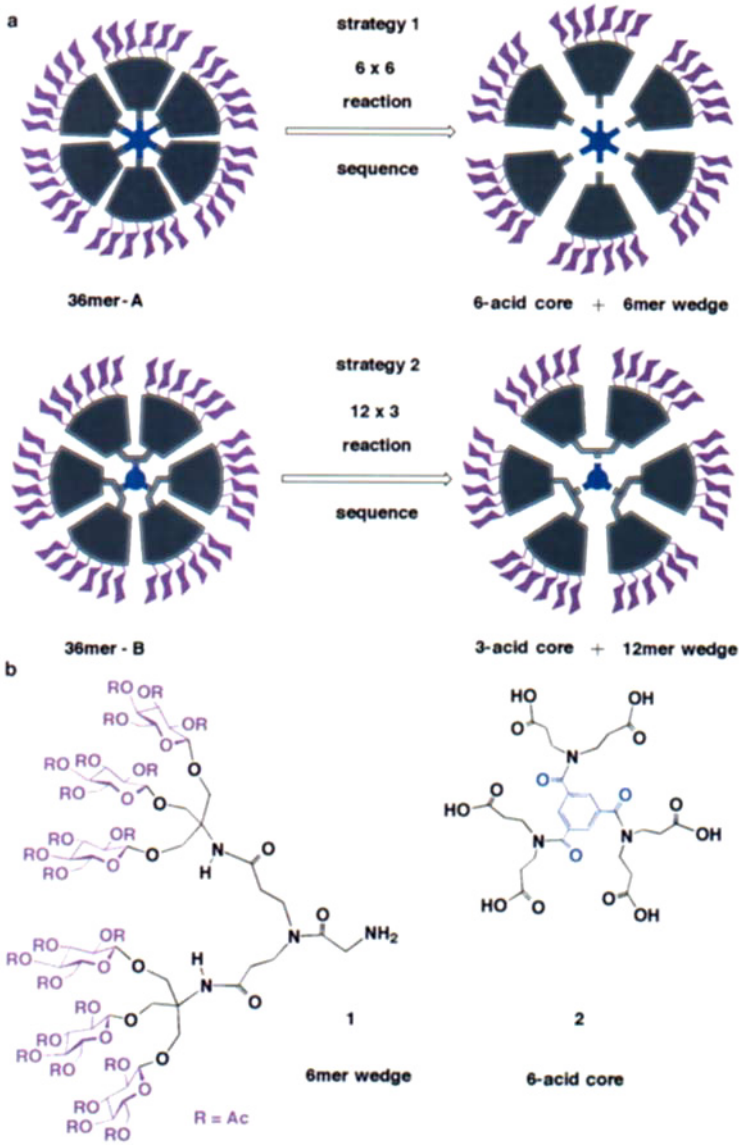
[**] Synthetic Carbohydrate Dendrimers, Part 2. This research is supported by the Engineering and Physical Sciences Research Council and the Biotechnology and Biological Sciences Research Council. Part 1: ref. [5].



Scheme 1. a) Schematic representation of the two retrosynthetic pathways adopted for the synthesis of 36-mers A and B. b) The wedge and core structural components used in the synthesis of 36-mer A by strategy 1. The components for stragety 2 for the synthesis of 36-mer B are shown in Scheme 2.

pling reagents (Scheme 1b). The crude product[8] was subjected to gel permeation chromatography (GPC).[9] The matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrum[10] of the major fraction, isolated in 52% yield, revealed that the new compound was only a tetrasubstituted 24-mer [$M_r = 10184$ Da (calcd), 10139 Da (found)] and not the expected hexasubstituted 36-mer. Both the ^{1}H (389 K)[11] and ^{13}C NMR (room temperature) spectra contain resonances[12] for all the required saccharide and nonsaccharide protons and carbon atoms. The carboxylic acid protons at the core of the 24-mer appear as a slightly broad peak at $\delta = 12.2$ in the ^{1}H NMR spectrum (room temperature).[13] Further attempts to functionalize the free carboxylic acids at the core of the 24-mer with **1** yielded the pentasubstituted 30-mer, as indicated by MALDI-TOF mass spectrometry. Also, the activation of the carboxylic acid groups on the core was changed by replacing DCC/HOBT with pentafluorophenyl ester functions. However, the mass spectrum once again indicated only the formation of dendritic products up to a pentasubstituted 30-mer. From these experiments and others, we were obliged to infer that steric hinderance around the core, arising from progressive occupation of the space within the dendrimer during its growth, is probably inhibiting complete substitution at the core.

The alternative strategy 2 in Scheme 1a for making a closely-related dendrimer was therefore pursued. The 12-mer wedge **5** was synthesized from the tetraacid **3**[14] by amide bond formation with the amine wedge **4**[5] and subsequent hydrogenolysis (Scheme 2, see page 734). A second amide bond formation between **5** and the tricarboxylic acid **6**,[5] under DCC/HOBT conditions, afforded a crude product, which was subjected to GPC. A major fraction (53% yield) and a few minor fractions with higher retention times were isolated. A comparison of the retention time of the major fraction with those of dendritic wedges and dendrimers synthesized previously indicated the expected molecular mass range for the 36-mer **7** (calcd $M_r = 14965$ Da). ^{1}H (389 K) and ^{13}C NMR (room temperature) spectra reflected the highly symmetrical structure of **7**. Its MALDI-TOF mass spectrum showed a peak at $m/z = 13857$ Da, which corresponds to the loss of one trisglucosylated amide fragment ($M_r = 1109$) from **7**. The most abundant peak in the high molecular weight region had a mass of 12825 Da, corresponding to fragmentation of two trisglucosylated amide units. De-O-acetylation of the glucoside protecting groups was performed by Zemplén's procedure, yielding the completely deprotected 36-mer **8**. The GPC trace for this compound was sharp and symmetrical and eluted faster than the previously synthesized lower generation dendrimers.[15]

To gain insight into the nature of the three-dimensional structures of **7**, molecular visualization with the Macromodel program[16] was carried out. A computer-generated CPK space-filling representation of the O-acetylated 36-mer **7** is shown in Figure 1. The average radius, measured from the plane of the benzene ring, was calculated to be about 22 Å; the average molecular volume is around 13890 Å^3.

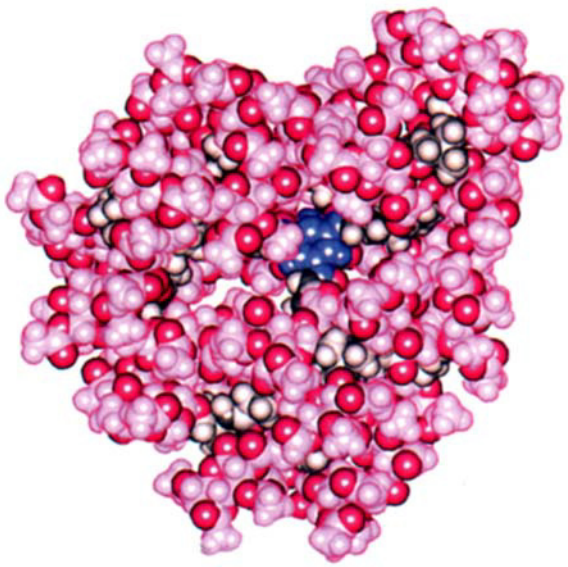


Figure 1. Computer-generated CPK space-filling representation of **7**.

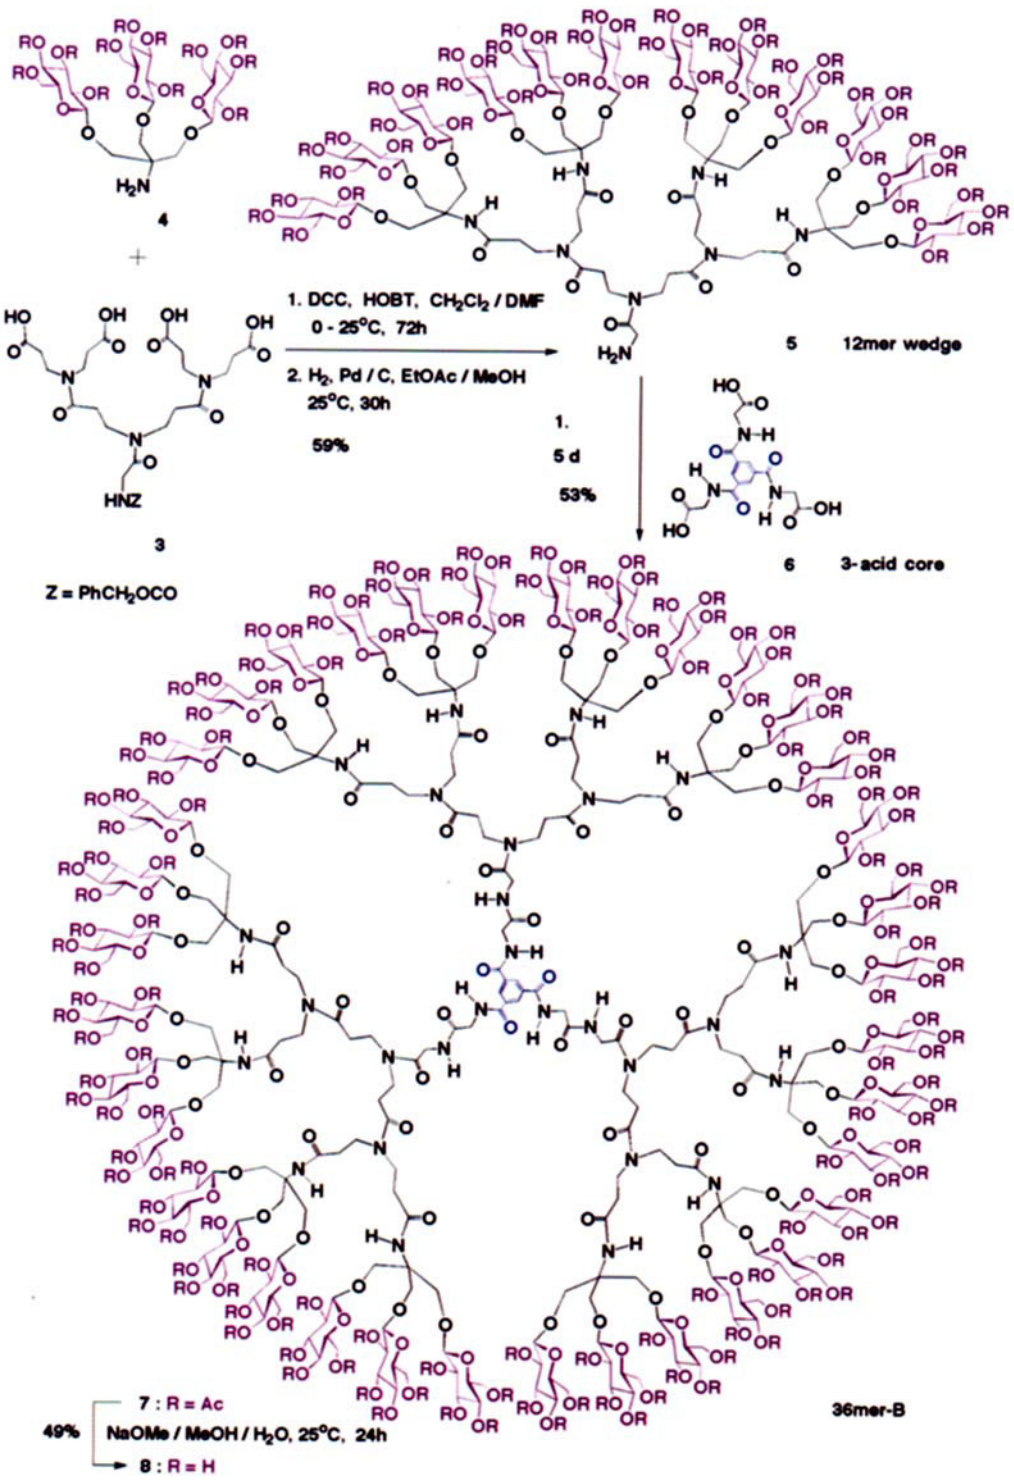
 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3607-0733 $ 17.50+.50/0



Scheme 2. Synthesis of **8** by the 12 × 3 reaction sequence shown in Scheme 1a.

We have described here two closely related strategies for the introduction of monosaccharide residues into higher generation dendrimers. Steric hinderance and filling of the interstitial space around the core component of these dendrimers are at least two factors that are believed to limit completion of the reactions at the core by the convergent growth approach. The dendrimers, as well as other compounds obtained during their synthesis, permit a facile entry into the preparation of numerous different dendritic neoglycoconjugates.

Experimental Section

5: A solution of **4** [5] (0.79 g, 0.71 mmol) in CH_2Cl_2 (15 mL) was added dropwise to a stirred solution of **3** [14] (0.10 g, 0.16 mmol), DCC (0.15 g, 0.71 mmol), and HOBT (0.096 g, 0.71 mmol) in CH_2Cl_2/DMF (1/1, 15 mL) at 0°C under an N_2 blanket. After the reaction mixture had been stirred at room temperature for 48 h, it was filtered, and the solvents were removed by evaporation. The resulting residue was dissolved in EtOAc, washed successively with 5% aqueous HCl solution (20 mL), saturated aqueous $NaHCO_3$ solution (50 mL), and H_2O (10 mL), and dried. The solution in EtOAc was concentrated under vacuum to afford a crude product, which was purified by column chromatography (SiO_2, PhMe/EtOAc 8/2) to obtain the *N*-benzyloxycarbonyl-protected derivative of **5** (0.51 g, 65%) as a semi-solid powder. A solution of this derivative (0.50 g, 0.10 mmol) in EtOAc/MeOH (1/1, 15 mL) was hydrogenolyzed over 10% Pd/C in an H_2-filled balloon for 36 h. The reaction mixture was filtered over celite, the solvents were evaporated off, and the residue was dried to obtain **5** (0.44 g, 90%) as a white, foamy powder. $[\alpha]_D^{23} = -17.6°$ ($c = 1.05$, $CHCl_3$); MALDI-TOF-MS: 4914 $[M + K]^+$; ^1H NMR (300 MHz, CD_3COCD_3) [17]: $\delta = 1.92$, 1.96, 2.01, 2.02 (4 × s, 144H), 2.52 (br., 12H), 3.65 (br., 12H), 3.73 (d, 12H), 3.94 (m, 12H), 4.13 (br., 26H), 4.28 (br., 12H), 4.67 (br. d,12H), 4.88 (br. t, 12H), 5.01 (br. t, 12H), 5.24 (br. t, 12H), 6.71 (br., 4H); ^{13}C NMR (75.5 MHz, CD_3COCD_3): $\delta = 20.5-21.2$, 28.6–30.9, 60.1, 62.7, 67.8, 69.1, 72.2, 72.3, 73.2, 101.8, 154.0, 169.9–170.9; elemental analysis calcd for $C_{204}H_{284}N_8O_{127}$ (4878.20): C 50.18, H 5.86, N 2.30; found: C 50.09, H 5.87, N 2.47.

7: A solution of **5** (400 mg, 0.082 mmol) in CH_2Cl_2 (5 mL) was added dropwise to a stirred solution of **6** [5] (9.1 mg, 0.024 mmol), DCC (17 mg, 0.082 mmol), and HOBT (11 mg, 0.082 mmol) in CH_2Cl_2/DMF (1/1, 15 mL) at 0°C under an N_2 blanket, and the reaction mixture stirred at room temperature for 5 days, filtered, and worked up as described for **5**. This crude product was purified by GPC to provide **7** (190 mg, 53%). $[\alpha]_D^{23} = -19.0°$ ($c = 1.06$, $CHCl_3$); MALDI-TOF-MS: 13857 $[M - C_{46}H_{64}O_{30}N]^+$; ^1H NMR (400 MHz, 389 K, CD_3SOCD_3): $\delta = 1.94$, 1.98, 2.02, 2.03 (4 × s, ≈432H,), 2.37 (br., 24H), 2.63 (br., 12H), 3.47 (br., 12H), 3.55 (br., 24H), 3.72 (d, $J = 10.4$ Hz, 36H,), 3.92 (br., 36H), 3.98 (d, $J = 10.4$ Hz, 36H), 4.10 (dd, 36H), 4.12 (s, 12H), 4.20 (dd, $J = 5.1$ and 12.3 Hz, 36H), 4.65 (d, $J = 7.8$ Hz, 36H), 4.80 (t, $J = 7.8$ and 9.4 Hz, 36H), 4.92 (t, $J = 9.4$ Hz, 36H), 5.19 (t, $J = 9.4$ Hz, 36H), 6.65 (br., 12H), 7.47, (br., 6H), 8.49 (s, 3H); ^{13}C NMR (100.6 MHz, 304 K, CD_3SOCD_3): $\delta = 19.6$, 19.7, 19.8, 39.0–42.0, 60.0, 62.7, 68.6, 69.2, 71.8, 72.1, 73.1, 101.4, 129.2, 140.3, 152.6, 169.0–172.0; elemental analysis calcd for $C_{627}H_{861}N_{27}O_{387}$ (14961.69): C 50.29, H 5.79, N 2.53; found: C 50.60, H 5.63, N 2.60.

8: Deacetylation of **7** (100 mg, 0.007 mmol) in MeOH/H_2O (1/1, 10 mL) was performed with a 1 M methanolic NaOMe solution (0.04 mL) for 24 h followed by neutralization of the solution with Amberlite IR-120 (H^+ form) and evaporation of the solvents. Purification by GPC afforded **8** (30 mg, 49%). $[\alpha]_D^{23} = -20.0°$

[6] Because of the difficulties in naming these mixed generation dendrimers by the notation recommended for uniform dendrimers (G. R. Newkome, G. R. Baker, J. K. Young, J. G. Traynham, *J. Polym. Sci. Part A: Polym. Chem.* **1993**, *31*, 641–651), we denote them simply as "*n*-mers" to indicate the presence of *n* peripheral monosaccharide units.

[7] The hexamethyl ester of **2**, obtained as a colorless oil by the reaction of 3,3′-iminobis(methyl propionate) [5] with benzenetricarbonyl chloride in CH_2Cl_2 in the presence of Et_3N, was hydrolyzed with aqueous 2M NaOH and MeOH to afford **2** (72%) as a foamy solid.

[8] A solution of **1** [5] (300 mg, 0.125 mmol) in CH_2Cl_2 (5 mL) was added dropwise to a stirred solution of **2** (9 mg, 0.014 mmol), DCC (23 mg, 0.112 mmol), and HOBT (15 mg, 0.112 mmol) in CH_2Cl_2/DMF (1/1, 10 mL) at 0°C under an N_2 atmosphere. The reaction mixture was stirred at room temperature for 5 days, filtered, and worked up as described for **5** (see *Experimental Section*).

[9] GPC of the fully protected dendrimers was performed on Phenogel (500 and 1000 Å, Phenomenex, Cheshire, UK) semi-preparative columns (300 × 7.80 mm) attached to a Gilson 714 high-performance liquid chromatography system fitted with a UV-detector. Detection was carried out at 260 nm, and GPC grade THF (Fisons) was used for the elutions. The fully deprotected dendrimers were purified on a Fractogel (25–40 μm, Merck) column (100 × 0.25 cm) fitted with a differential refractometer (Waters) with deionized and degassed H_2O as eluant.

[10] MALDI-TOF mass spectra were obtained with either 2,5-dihydroxy benzoic acid (gentistic acid) or *trans*-3-indoleacrylic acid and an average of 50 laser shots per sample.

[11] In line with our previous experience, ref [5], ^{1}H NMR spectra were recorded at high temperatures to reduce their complexity by ensuring that torsion around the tertiary amide bonds was fast on the ^{1}H NMR timescale.

[12] In addition to the expected signals, there are quite a few resonances that could not be assigned in both the ^{1}H NMR and ^{13}C NMR spectra. At present these peaks are presumed to arise from an impurity.

[13] To gain insight into the nature of substitution around the core, the 24-mer was allowed to react with Gly–O*t*Bu to obtain the corresponding Gly–O*t*Bu extended amide after purification by GPC. The ^{1}H NMR spectrum of the Gly–O*t*Bu extended amide, recorded in CD_3SOCD_3 at 389 K, revealed the presence of four resonances (major $\delta = 1.424$ and 1.418, minor $\delta = 1.412$ and 1.405) arising from the *tert*-butyl groups. This observation not only suggests that there are constitutional isomers as a result of disposition of the wedge around the core in the 24-mer, but also that the *tert*-butyl groups in the 24-mer residue are in two different environments. This is perhaps due to increased restriction of rotation about the tertiary amide bonds at its highly hindered core.

[14] The tetracarboxylic acid wedge **3** was obtained by coupling one equivalent of *N*-[N^a-(benzyloxycarbonyl)glycinamido]-3,3′-bis(propionic acid) [5] with two equivalents of the amine 3,3′-iminobis(methyl)propionate) followed by hydrolysis of the methyl ester functions.

[15] The MALDI-TOF mass spectroscopic analysis of the fully deprotected dendrimers **8** and the 24-mer requires Ag^+ ion assisted laser desorption: Z. Xu, M. Kahr, K. L. Walker, C. L. Wilkins, J. S. Moore, *J. Am. Chem. Soc.* **1994**, *116*, 4537–4550. Although peaks were observed in the molecular ion regions for the free saccharide-containing dendrimers named above, the spectra were complex, presumably due to the use of silver salts.

[16] Molecular simulations were carried out as described previously [5], with the exception that the molecular volume calculations were performed with Biosym's Insight and Discover software (Biosym Technologies, San Diego, CA) on a Silicon graphics Indy workstation.

[17] Since the system is in slow exchange at room temperature, average values are only quoted for the ^{1}H NMR chemical shifts.

Supramolecular Weaving**

Peter R. Ashton, Andrew N. Collins, Matthew C. T. Fyfe, Stephan Menzer, J. Fraser Stoddart,* and David J. Williams

The logical design of organized, organic, solid-state superstructures—namely, crystal engineering[1]—continues to be a formidable challenge, even though the number of identifiable design elements that can be exploited for noncovalent synthesis (supramolecular synthons)[1b] is expanding rapidly. Due to its high selectivity and directionality, the hydrogen bond[2] has become one of the most widely used implements in the crystal engineer's toolbox; it has permitted the noncovalent synthesis of a comprehensive range of solid-state systems, traversing the whole superstructural kingdom from oligomeric supramolecular macrocycles[3] and cages[4] to polymeric supramolecular arrays.[5] Nevertheless, only recently have scientists utilized the potential of the hydrogen bond for the rational synthesis of interwoven systems,[6] involving noncovalent association of pseudorotaxanes—supramolecular complexes in which a thread-like molecule or ion is encircled by a macrocyclic species *without* the presence of a mechanical bond—in the solid state.

We reasoned that by combining two recognition motifs that employ hydrogen bonding as their principal noncovalent "adhesive", namely, the carboxyl dimer[3c, 7] supramolecular synthon (**A** in Scheme 1) and the self-assembly[8] of [3]pseudorotaxanes by double threading[9] of two secondary dialkylammonium strands through the cavity of the ditopic macrocyclic polyether bis-*p*-phenylene[34]crown-10 (BPP34C10), we could synthesize

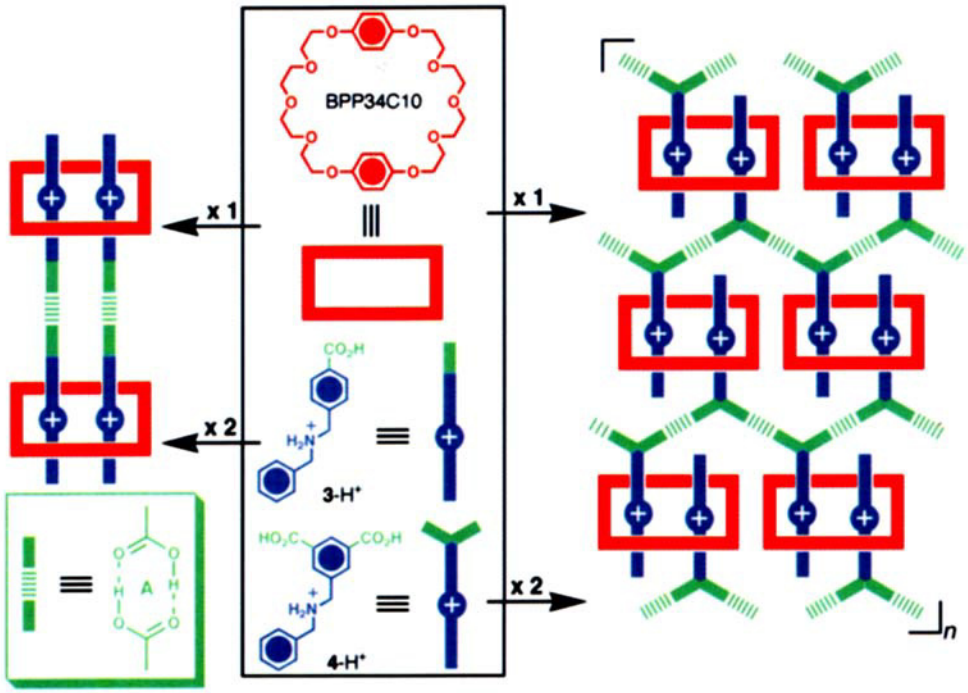

Scheme 1. Schematic representation of the supramolecular synthesis of a doubly encircled, six-component organic supermolecule and an interwoven supramolecular cross-linked polymer. The building blocks are BPP34C10 (red) and carboxyl (green) containing secondary dialkylammonium cations (blue) that utilize the carboxyl dimer supramolecular synthon. **A** and the double threading of pairs of ammonium cations through the crown ethers' cavities.

noncovalently a whole new range of encircled and interwoven superstructures. The construction of these self-assembled superstructures would be tantamount to supramolecular weaving, that is, [3]pseudorotaxanes with pendant carboxyl groups for noncovalent association could interlace with one another using the carboxyl dimer to generate novel multiply encircled supermolecules and interwoven supramolecular arrays.

Here we describe 1) the synthesis of the carboxyl-substituted ammonium salts **3**-H·PF_6 and **4**-H·PF_6, 2) the noncovalent dimerization of the [BPP34C10·(**3**-H)$_2$]$^{2+}$ [3]pseudorotaxane in the solid state to form a doubly encircled, six-component organic supermolecule (Scheme 1), and 3) the noncovalent synthesis of an interwoven supramolecular cross-linked polymer in the solid state by the noncovalent polymerization of [BPP34C10·(**4**-H)$_2$]$^{2+}$ (Scheme 1). The ammonium salts **3**-H·PF_6 and **4**-H·PF_6, which possess the requisite carboxyl groups for noncovalent association, were prepared in reasonable yields from the aminoesters **1**[9d] and **2**[10] by boiling with concentrated

hydrochloric acid, to effect hydrolysis with concomitant protonation, followed by counterion exchange from chloride to hexafluorophosphate.

The X-ray crystallographic analysis[13, 14] of the 1:2 complex[15] formed between BPP34C10 and **3**-H$^+$ reveals that both of the cations are threaded codirectionally through the center of the macrocycle (Figure 1). This arrangement is stabilized by a total of six [N$^+$–H···O] hydrogen bonds between the NH_2^+ centers and three oxygen atoms from each polyether linkage (N···O 2.86–3.18 Å). Secondary stabilization is conferred upon the [3]pseudorotaxane superstructure by an edge-to-face [C–H···π] contact between one of the methylene hydrogen atoms of the 4-carboxybenzyl group and one of the hydroquinone rings of BPP34C10 (the associated [H···π] distance and [C–H···π] angle are 2.88 Å and 143°). The centroid–centroid separation between the benzoic acid rings of distinct **3**-H$^+$ cations is about 4.6 Å, the rings being inclined by 28°, thus ruling out any significant aryl–aryl stacking interactions. Both of the independent cations have conventional "gull wing" conformations, in which each of their aromatic rings is oriented approximately orthogonally with respect to their associated planar all-*anti* $CCH_2NH_2^+CH_2C$ backbones. Furthermore, a fluorine atom from one of the PF_6^- anions is directed into the cleft between the two dialkylammonium cations and lies about 2.5 Å away from one cation's benzylic hydrogen atoms.[16] An approach of about 2.5 Å was also discovered between one of this anion's equatorial fluorine atoms and one of the hydroquinone ring's hydrogen atoms. We hypothesize that this PF_6^- anion assists the macrocyclic polyether by helping to enforce the codirectionality of the [3]pseudorotaxane's two carboxyl groups. This leads to the noncovalent association of pairs of C_i symmetrically related [3]pseudorotaxane-like complexes and the generation of doubly encircled, six-component organic supermolecules that are linked by the carboxyl dimer supramolecular synthon through pairs of strong [O–H···O] hydrogen bonds (O···O 2.61 and 2.68 Å, Figure 1). In many respects, this structure is similar to the 2:2 complex formed between α,α′-bis(benzylammonium)-*p*-xylene bis(hexafluorophosphate) and BPP34C10,[9a–c] an observation that is not surprising since the carboxyl dimer may be consid-

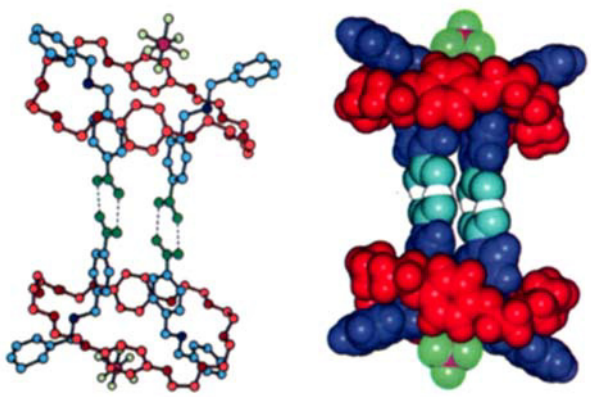

Figure 1. View of the [{BPP34C10·(**3**-H)$_2$}$^{2+}$]$_2$ supermolecule; left: ball-and-stick representation, right: space-filling representation; red: BPP34C10, green: carboxyl groups of **3**-H$^+$ (remainder in blue). For clarity, only the PF_6^- counterion associated with the benzylic methylene groups is shown.

ered to behave[1b] as a surrogate for a *p*-disubstituted benzene ring.

In contrast with the solid-state structure of $[BPP34C10\cdot(\mathbf{3}\text{-}H)_2]^{2+}$ (vide supra), the X-ray crystal structure[13, 14] of the 1:2 complex[15] formed between the BPP34C10 macrocycle and the $\mathbf{4}\text{-}H^+$ secondary dialkylammonium strand reveals that the cations are threaded centrosymmetrically with respect to each 5,other, that is, in an *antiparallel* orientation (Figure 2). Once again, stabilization of the [3]pseudorotaxane superstructure is achieved by $[N^+\text{–}H\cdots O]$ hydrogen bonds ($N\cdots O$ 2.87 and 2.88 Å) between the NH_2^+ centers and pairs of oxygen atoms in each of the macrocycle's polyether arcs. Furthermore, the cations also maintain a gull wing conformation with a planar all-*anti* $CCH_2NH_2^+CH_2C$ backbone, though the isophthalate ring is noticeably skewed from an orthogonal relationship. Noncovalent association utilizing the carboxyl dimer supramolecular synthon occurs between the pairs of carboxyl groups of each cation and their nonequivalent counterparts in symmetry-related complexes. The $[O\text{–}H\cdots O]$ hydrogen bonds are strong, and the $O\cdots O$ distances range from 2.57 to 2.69 Å. In this case, the effect of combining multiple carboxyl dimer and double threading motifs is the creation of a novel type of supramolecular polymer,[17] specifically, an interwoven supramolecular cross-linked polymer (Figure 3). Cross-linking of isophthalic acid tapes[18] is induced by the macrocyclic polyether, since it directs two isophthalic acid units from separate $\mathbf{4}\text{-}H^+$ cations in opposing directions, that is, the tapes are interlinked by the [3]pseudorotaxane unit to form two-dimensional pseudopolyrotaxane[19] sheets. The sheets are fairly thick (about 12.5 Å) since the planes of the $[O\text{–}H\cdots O]$ hydrogen bonds are approximately orthogonal to the planes of BPP34C10. Included benzene solvent molecules and disordered PF_6^- counterions are located in the interstices between the polymeric layers. Neither of these species play any significant role in determining the pseudopolyrotaxane sheet superstructure.

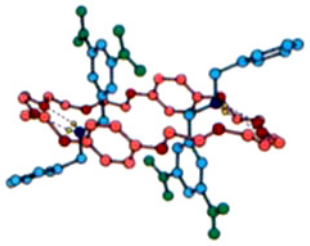

Figure 2. Ball-and-stick representation of the $[BPP34C10\cdot(\mathbf{4}\text{-}H)_2]^{2+}$ pseudorotaxane; red: BPP34C10, green: carboxyl groups of $\mathbf{4}\text{-}H^+$ (remainder in blue).

The solid-state superstructures discussed here illustrate two powerful concepts which can be utilized for the logical synthesis of interwoven systems in the crystalline phase. Firstly, the ditopic crown ether BPP34C10, possibly with assistance from attendant anions, may be used as a scaffold that orients functional groups—in this case, carboxyl groups—in space to form multiply encircled supermolecules and interwoven supramolecular arrays, that is, the macroring enforces supramolecular preorganization of the benzoic or isophthalic acid units for noncovalent association. Indeed, the $[\{BPP34C10\cdot(\mathbf{3}\text{-}H)_2\}^{2+}]_2$ and $[\{BPP34C10\cdot(\mathbf{4}\text{-}H)_2\}^{2+}]_n$ superstructures have analogies in the covalent kingdom, where molecular preorganization[20] dictates the spatial orientation of benzoate or isophthalate subunits leading to a particular superstructure. Molecular dicarboxylic acids with codirectionally oriented carboxyl groups located within the same covalent skeleton[21], like the supramolecular dicarboxylic acid $[BPP34C10\cdot(\mathbf{3}\text{-}H)_2]^{2+}$, form dimeric supermolecules in the solid state. Similarly, molecular bisisophthalic acids, in which two isophthalic acid moieties are located at the extremities of a covalent framework, have crystal structures that exhibit,[7a, 22] like the corresponding supramolecular bisisophthalic acid $[BPP34C10\cdot(\mathbf{4}\text{-}H)_2]^{2+}$, the formation of supramolecular cross-linked polymers.

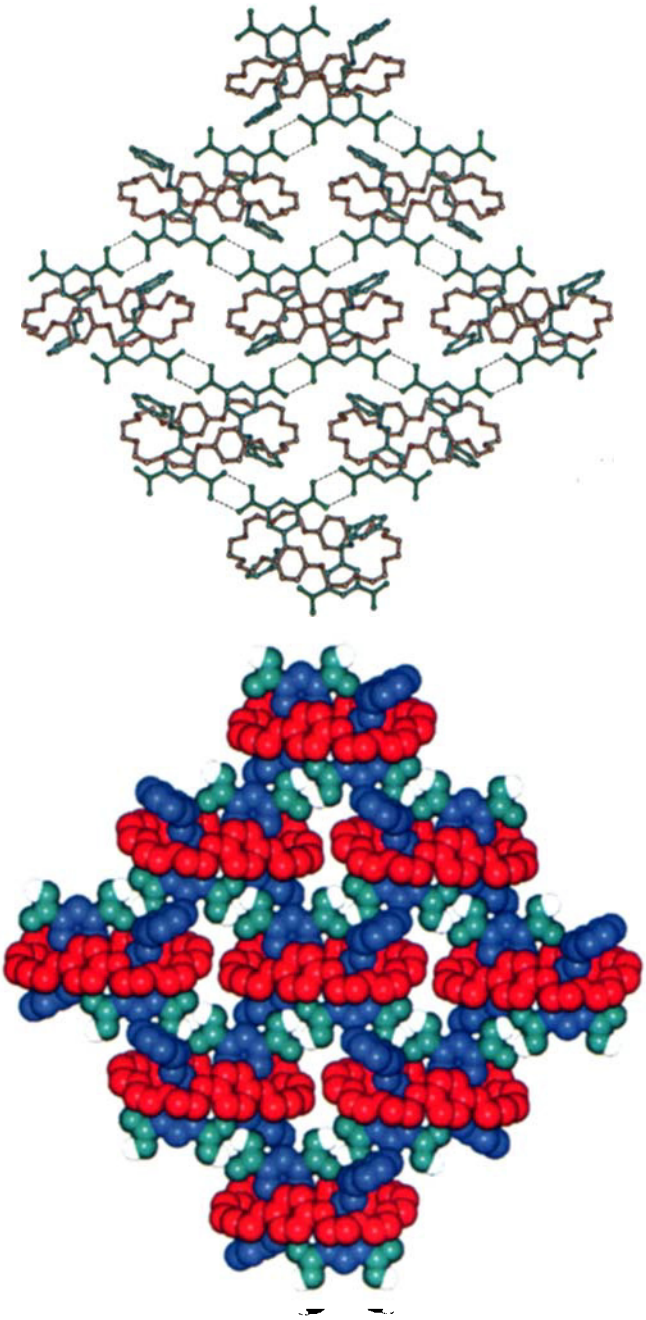

Figure 3. View of the interwoven supramolecular cross-linked polymer generated by the noncovalent polymerization of $[BPP34C10\cdot(\mathbf{4}\text{-}H)_2]^{2+}$; top: ball-and-stick representation, bottom: space-filling representation; red: BPP34C10, green: carboxyl groups of $\mathbf{4}\text{-}H^+$ (remainder in blue).

Secondly, the system described here illustrates the concurrent operation of two distinct hydrogen-bonding algorithms—namely, the self-recognition of the secondary dialkylammonium ions' carboxyl groups and the interaction of these cation's NH_2^+ centers with the polyether linkages of BPP34C10—for generating novel supramolecular aggregates and arrays. As both of these algorithms operate independently of one another, there is no crossover between the hydrogen-bonding motifs, that is, noncovalent association is observed only between the carboxyl groups of the dialkylammonium cations as well as between the cations'

NH_2^+ centers and the crown ethers' polyether arcs. Research is currently underway to test whether the paradigms presented here can be utilized in other supramolecular systems, in which the ditopic crown ether BPP34C10 could be used as a scaffold to direct other functional groups in space, thereby permitting the solid-state synthesis of novel multiply encircled and interwoven supramolecular architectures utilizing combinations of different recognition motifs.[23]

Experimental Section

3-H·PF_6: Aminoester **1** (1.03 g, 4.0 mmol) was boiled with 12 N HCl (40 mL) for 19 h. Upon cooling, the residual white solid was collected and washed with EtOH (25 mL), $CHCl_3$ (25 mL), and Et_2O (25 mL). The solid was taken up in boiling H_2O (300 mL) and treated with a solution of NH_4PF_6 (0.86 g, 5.3 mmol) in H_2O (8 mL). The cooled solution was extracted with $MeNO_2$ (3 × 200 mL). The combined $MeNO_2$ fractions were washed with H_2O (200 mL) and dried under reduced pressure to give **3**-H·PF_6 as a white solid (0.97 g, 62%): m.p. = 176–179 °C; ^{1}H NMR (300 MHz, CD_3CN, 20 °C): δ = 4.25 (s, 2H), 4.29 (s, 2H), 7.46 (s, 5H), 7.57 (d, J = 8 Hz, 2H), 8.06 (d, J = 8 Hz, 2H); ^{13}C NMR (75.5 MHz, CD_3CN, 20 °C): δ = 51.9, 52.8, 128.9, 130.2, 130.9, 131.25, 131.28, 131.32, 132.0, 136.6, 168.5. Elemental analysis calcd for $C_{15}H_{16}F_6NO_2P$: C 46.52, H 4.16, N 3.62; found: C 46.41, H 4.16, N 3.53; MS (LSI): m/z = 242 $[M - PF_6]^+$.

4-H·PF_6: This salt was obtained as a white solid in 61% yield from the aminodiester **2** by an procedure analogous to the one described above: m.p. = 194–195 °C (decomp.); ^{1}H NMR (300 MHz, CD_3CN, 20 °C): δ = 4.25 (s, 2H), 4.38 (s, 2H), 7.46 (s, 5H), 8.35 (s, 2H), 8.58 (s, 1H); ^{13}C NMR (75.5 MHz, CD_3CN, 20 °C): δ = 51.4, 52.5, 130.0, 130.5, 130.7, 131.0, 131.8, 132.2, 132.4, 136.7, 166.3. Elemental analysis calcdfor $C_{16}H_{16}F_6NO_4P$: C 44.56, H 3.74, N 3.25; found: C 44.49, H 3.95, N 3.17; MS (LSI): m/z = 286 $[M - PF_6]^+$.

[10] Amine **2** could be prepared in three steps from diethyl 5-bromomethylisophthalate [11]. Oxidation of this bromide with bis(tetrabutylammonium) dichromate [12] afforded diethyl 5-formylisophthalate, which was condensed with benzylamine to provide (3,5-dicarboethoxybenzylidene)benzylamine. Subsequent reduction with $NaBH_4$ gave the aminodiester **2** in 71% overall yield.

[13] Single crystals of [BPP34C10·(**3**-H)$_2$][PF_6]$_2$ that were suitable for X-ray crystallographic analysis were obtained when a solution of BPP34C10 and **3**-H·PF_6 (1:2) in $(ClCH_2)_2$/$MeNO_2$ was layered with iPr_2O. X-ray quality single crystals of [BPP34C10·(**4**-H)$_2$][PF_6]$_2$ were acquired by slow evaporation of a solution of BPP34C10 and **4**-H·PF_6 (1:2) in Me_2CO/PhH at 20 °C.

[14] Crystal data for [BPP34C10·(**3**-H)$_2$][PF_6]$_2$: $C_{58}H_{72}N_2O_{14}\cdot 2PF_6\cdot 1.5MeOH\cdot 2H_2O$, M_r = 1395.21, triclinic, space group $P\bar{1}$, a = 10.619(1), b = 17.292(1), c = 22.109(2) Å, α = 79.64(1), β = 79.54(1), γ = 76.94(1)°, V = 3848.2(4) Å^3, Z = 2, ρ_{calcd} = 1.204 g cm^{-3}, μ = 1.289 mm^{-1}, $F(000)$ = 1462. Of 7886 independent reflections collected on a Siemens P4/PC RA diffractometer (graphite-monochromated $Cu_{K\alpha}$ radiation, ω scans, $2\theta < 110°$) 3168 reflections had $|F_0| > 4\sigma(|F_0|)$ and were considered to be observed. The data were corrected for Lorentz and polarization effects, but not for absorption. The structure was solved by direct methods. Due to the severe shortage of observed data, all aromatic rings and PF_6^- counterions were refined as rigid bodies. Only the latter and the polyether chains were refined anisotropically, the remainder of the structure remained isotropic. Hydrogen atoms on the [3]pseudorotaxane complex were assigned idealized positions with U(H) = 1.2 U_{eq}(C), while those of the MeOH and H_2O solvent molecules could not be located. Full-matrix least-squares refinement on F^2 gave R_1 = 0.1567 and wR_2 = 0.4087 for 795 refined parameters. Crystal data for [BPP34C10·(**4**-H)$_2$][PF_6]$_2$: $C_{60}H_{68}N_2O_{18}\cdot 2PF_6\cdot C_6H_6$, M_r = 1473.21, monoclinic, space group $P2_1/c$, a = 12.513(1), b = 16.555(1), c = 18.592(1) Å, β = 96.10(1)°, V = 3829.7(5) Å^3, Z = 2 (the [3]pseudorotaxane supermolecule has C_i symmetry), ρ_{calcd} = 1.278 g cm^{-3}, μ = 1.334 mm^{-1}, $F(000)$ = 1532. Of 5661 independent reflections collected on a Siemens P4/RA diffractometer (graphite-monochromated $Cu_{K\alpha}$ radiation, ω scans, $2\theta < 120°$), 3507 reflections had $|F_0| > 4\sigma(|F_0|)$ and were considered to be observed. The data were corrected for Lorentz and polarization effects, but not for absorption. The structure was solved by direct methods, and all non-hydrogen atoms, with the exception of the partial occupancy C_6H_6 molecules, were refined anisotropically using full-matrix least squares based on F^2. Disorder was observed in the PF_6^- anions, part of the crown ether macrocycle, and the terminal N-benzyl group. In each case, this was resolved by refining two half-occupied orientations. Hydrogen atoms were assigned idealized positions with U(H) = 1.2 U_{eq}(C) and allowed to ride on their parent atoms. R_1 = 0.1101 and wR_2 = 0.3232 for 607 refined parameters. Computations for both of the structures were carried out on a SGI station with the SHELXTL package, version 5.03. The crystallographic data (excluding structure factors) for both of the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100088 Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: Int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

[15] Formation of pseudorotaxane-like inclusion complexes between BPP34C10 and the secondary dialkylammonium cations was indicated in solution and "gas" phases from ^{1}H NMR and liquid secondary ion mass spectroscopies (LSIMS, obtained from a VG Zabspec mass spectrometer equipped with a cesium ion source and utilizing a *m*-nitrobenzyl alcohol matrix), respectively. The ^{1}H NMR spectrum (300 MHz, CD_2Cl_2/MeCN 2/1, 20 °C) of a solution of BPP34C10 and **3**-H·PF_6 (1:2) shows reasonable ($\Delta\delta \geq 0.05$) chemical shift changes of $\Delta\delta$ = −0.10, −0.15, −0.08, and −0.06 for the signals of the *o*-carboxy, *m*-carboxy, connected 4-carboxybenzyl, and benzylic protons, respectively, on the **3**-H$^+$ cation; a $\Delta\delta$ of −0.08 was observed for the resonance corresponding to the γ/δ-protons on the BPP34C10 macroring. Reasonable changes in the δ value ($\geq$ 0.05) were also seen in the ^{1}H NMR spectrum (300 MHz, CD_2Cl_2/MeCN 2/1, 20 °C) of a 1:2 mixture of BPP34C10 and **4**-H·PF_6. Relatively large shifts were uncovered for the proton resonances associated with the isophthalic acid portion of the secondary dialkylammonium cation: $\Delta\delta$ values of −0.09 and −0.20 were observed for the resonances of the proton at the 4-position and the equivalent protons at the 2,6-positions of this subunit, while the neighboring 3,5-dicarboxybenzyl protons were also

shifted to higher field by −0.10. The resonances for the hydroquinone ring protons and the α-protons of the macrocyclic polyether are at $\Delta\delta = -0.11$ and −0.05, respectively. The LSIMS of a 1:2 solution of BPP34C10 and **3**-H·PF_6 displayed a peak at $m/z = 1165$, which corresponds to a [BPP34C10·(**3**-H)$_2$][PF_6] ion. Similarly, the LSIMS of a solution containing BPP34C10 and **4**-H·PF_6 (1:2) exhibited a peak at $m/z = 1254$, which can be attributed to [BPP34C10·(**4**-H)$_2$][PF_6]$_2$ with loss of one counterion.

[16] Following this discovery, we reexamined the crystal structure [9b,9c] of the 2:2 complex formed between α,α′-bis(benzylammonium)-*p*-xylene bis(hexafluorophosphate) and BPP34C10. There we found that one of the principal F–P–F axes of a PF_6^- anion was directed into the complex's central cleft between two NH_2^+ cationic centers. The contact distances from the hydrogen atoms of the 2:2 complex to either of these "axial" fluorine atoms are all greater than 2.8 Å. Nevertheless, a contact of about 2.5 Å was identified between one of the complex's benzylic hydrogen atoms and one of the "equatorial" fluorine atoms of PF_6^-.

[23] While this article was in press, we became aware of the research of Whang and Kim (D. Whang, K. Kim, *J. Am. Chem. Soc.* **1997**, *119*, 451–452), who have combined hydrogen bonding and dative bonding interactions to generate interwoven supramolecular arrays.

The Reactivity of the Unbridged Co–Sn Bond in $[(\eta^5\text{-}C_5H_5)(\eta^2\text{-}C_2H_4)Co\text{–}Sn\{CH[Si(CH_3)_3]_2\}_2]$—The First Organometallic Complexes with direct Co–Sn–Chalcogen Bonding (Chalcogen = Se, Te)**

Jörg J. Schneider,* Jörg Hagen, Dieter Bläser, Roland Boese, and Carl Krüger

Dedicated to Professor Günter Schmid on the occasion of his 60th birthday

Unbridged metal–metal bonds offer ideal prerequisites for the linkage of novel metal–element bonds by insertion or addition reactions. Metal–metal bonds in heterodimetallic complexes are particularly promising, since these bonds can be strongly polarized by the appropriate combination of metals and thus exhibit a high reactivity.[1] Our interest in this area has focused on heterodinuclear organometallic complexes containing a reactive M–M′ bond (M = transition metal; M′ = metal from group 12, 13, or 14), particularly those with an unbridged M–Sn bond. These can form low molecular weight complexes with direct Sn–chalcogen–M bonds either by insertion or addition. It is our aim to use such compounds as precursors for the deposition of ternary magnetically doped group 14/16 semiconductors, which show very promising potential for magnetooptical applications.[2] To date examples are known for the deposition of binary metal chalcogenide films such as M′/E[3] (M = Fe, Mn; E = S, Se, Te), M/E[4] ((M′ = metals from group 12, 13, or 14), and M″/E[5] (M″ = Eu, Sm, Yb) from precursor complexes of the appropriate composition.
