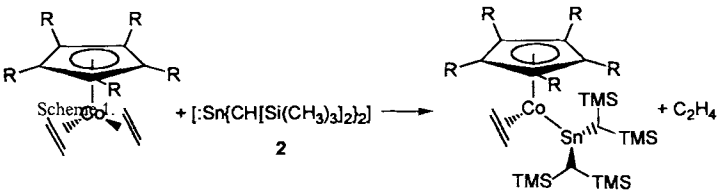
The reaction of $[(\eta^5\text{-}C_5R_5)Co(\eta^2\text{-}C_2H_4)_2]$ (R = H[6] **1a**, R = Me[7] **1b**) with $[:Sn^{II}\{CH[Si(CH_3)_3]_2\}_2]$ (**2**)[8] leads to the formation of brown and black crystals of **3a** and **3b**, respectively, in up to 60% yield (Scheme 1).



1a R = H
1b R = CH_3

3a R = H
3b R = CH_3

According to IR and NMR spectra the Co/Sn ratio is 1:1, and the ethene ligand is π-bound. The signals of the ethene protons of **3a** and **3b** appear as very broad signals in the ^{1}H NMR spectrum, which is an indication of a possible temperature dependency of the spectra due to hindered olefin rotation. Surprisingly, however, neither decreasing the measuring temperature to −80 °C nor increasing it to +80 °C resulted in a significant change in the form of the signal present at room temperature. Similar broadening of the ^{1}H NMR signals of a π-complexed ethene molecule was reported for $[(\eta^5\text{-}C_5H_5)(\eta^2\text{-}C_2H_4)Co\text{–}Sn(C_6H_4CH_2o\text{-}NMe_2)_2]$.[9]

The crystal structure analysis[10] of **3a** (Figure 1) revealed a very short Co–Sn distance (2.396(1) Å), which is significantly shorter than the sum of the covalent radii of Co and Sn (2.55 Å) and also significantly shorter than that in $[(\eta^5\text{-}C_5H_5)(\eta^2\text{-}C_2H_4)Co\text{–}Sn(C_6H_4CH_2o\text{-}NMe_2)_2]$ (2.44 Å),[9] the (apart from **3a,b**) only known Co–stannylene complex. The Co–Sn bond is also significantly shorter than other M–Sn bonds in similar complexes of the stannylene **2**,[11] which indicates possible

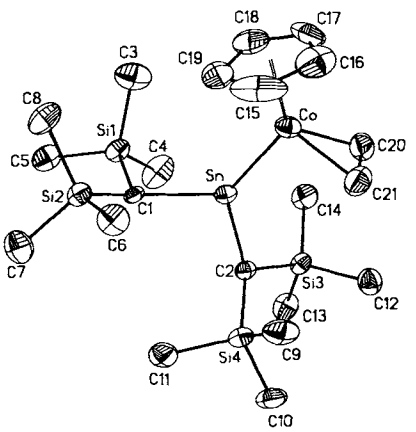


Figure 1. Crystal structure of **3a**. Selected bond lengths [Å] and angles [°]: D1–Co 1.707, Co–Sn 2.396(1), D2–Co 1.891, Sn–C1 2.206(5), Sn–C2 2.202(7), C1–Si1 1.863(6), Si2–C1 1.876(5), Si3–C2 1.871(5), Si4–C2 1.882(6); C1-Sn-C2 97.4(2), Sn-C1-Si1 112.3(3), Sn-C1-Si2 117.2(2), Sn-C2-Si3 117.1(3), Sn-C2-Si4 110.7(2), Sn-Co-D1 129.0, Sn-Co-D2 98.2; D1 and D2 are the centers of the cyclopentadienyl ring and the C=C bond in ethene, respectively.

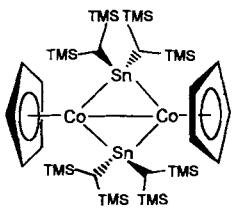
π-back bonding contributions (Co(3d) → Sn(5p) and Sn(5d)) in **3a**.[12]

A reaction—analogous to that in Scheme 1—between $[(\eta^5\text{-}C_5H_5)Co(\eta^2\text{-}C_2H_4)_2]$ and $[(\eta^5\text{-}C_5H_5)_2Sn^{II}]$ does not lead to the formation of the corresponding stannylene complex. Instead cobaltocene $[(\eta^5\text{-}C_5H_5)_2Co]$ forms as a result of cleavage of the two ethene ligands and transfer of the cyclopentadienyl ligand from the stannocene to a $(\eta^5\text{-}C_5H_5)Co$ fragment. Compound **3a** has two potential reactive sites for subsequent reactivity. Both the ethene ligand and also the $Sn^{II}\{CH[Si(CH_3)_3]_2\}_2$ group are displaced under mild conditions. Thus, under mass spectrometric conditions (EI, 70 eV, above 70 °C), ethene is eliminated from **3a**, and molecular ions appear for cobaltocene and the dinuclear complex **4**.[13] If solid **3a** is heated to 100 °C, only cobaltocene is isolated. The reaction of **3a** with excess 2-butyne leads to the elimination of ethene and stannylene, and, through cyclotrimerization of the alkyne, hexamethylbenzene, $[(\eta^5\text{-}C_5H_5)Co(\eta^6\text{-}C_6(CH_3)_6]$, and traces of cobaltocene are formed. The same reaction with **3b** affords an as yet unidentified Co/Sn complex as the major product.



4

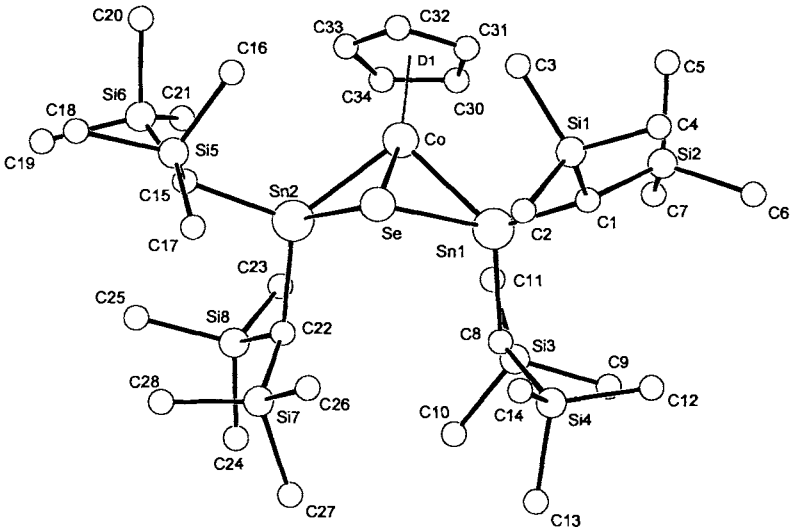


Figure 2. Crystal structure of **5**. Selected bond lengths [Å] and angles [°]: Sn1–Co 2.473(1), Sn2–Co 2.487(1), Sn1–Se 2.628(1), Sn2–Se 2.636(1), Se–Co 2.473(1), Co–D1 1.685, Sn1–Sn2 3.75; Co-Sn1-C1 122.2(2), Co-Sn2-C15 121.8(2), Se-Sn2-C22 112.7(2), Co-Sn1-C8 118.0(1), Co-Sn2-C22 129.9(2), Se-Sn1-C8 111.6(2), Sn2-Se-Sn1 90.9(1), Sn2-Co-Sn1 98.3(1), Sn2-Se-Co 58.2(1), Sn1-Se-Co 57.9(1), Co-Sn1-Se 57.9(1), Co-Sn2-Se 57.6(1), Sn1-Co-D1 130.6, Sn2-Co-D1 129.3. Selected bond lengths [Å] and angles [°] for **6** (not shown): Sn1–Co 2.4937(14), Sn2–Co 2.5140(13), Sn1–Te 2.8164(9), Sn2–Te 2.8284(9), Te–Co 2.6471(13), Co–D1 1.686, Sn1–Sn2 3.84; Co-Sn1-C1 123.2(2) Co-Sn2-C15 122.8(3), Te-Sn-C22 113.1(3), Co-Sn1-C8 127.2(3), Co-Sn2-C22 130.2(3), Te-Sn1-C8 110.8(3), Sn2-Te-Sn1 85.87(2), Sn2-Co-Sn1 100.32(4), Sn2-Te-Co 59.05(3), Sn1-Te-Co 54.21(3), Co-Sn1-Te 59.43(3), Co-Sn2-Te 59.05(3), Sn1-Co-D1 129.3, Sn2-Co-D1 128.1.

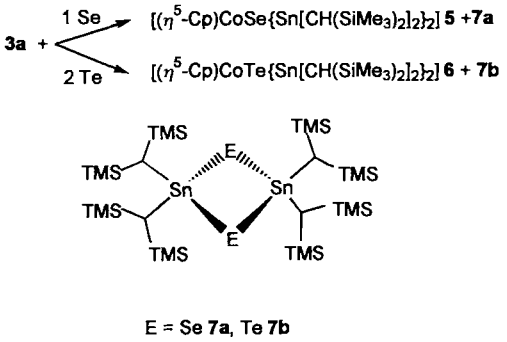
Compound **3a** undergoes additions to the Co–Sn bond, because this bond is exposed to attack due to the lack of a bridging ligand, and in addition the Sn atom is trigonally coordinated and thus coordinatively unsaturated. Compound **3a** reacts with elemental Se or Te at 20 °C, leading to loss of the ethene ligand and insertion of the chalcogen into the Co–Sn bond (Scheme 2). Additional activation [14] of the chalcogen is not



Scheme 2. Cp = C_5H_5.

necessary, which is further evidence of the high reactivity of the Co–Sn bond in these additions. This reaction leads to the ternary clusters **5** and **6**, which contain direct Sn–Se–Co and Sn–Te–Co bonds, respectively, and which are prototypes for complex compounds of this type. The binary Sn/chalcogen compounds **7a** (E = Se) and **7b** (E = Te)[15] are formed as by-products (Scheme 2).

The butterfly-like arrangement of the (Sn_2-μ_3-E-Co) core (E = Se, Te) (Figure 2)[10] is a characteristic feature of the isostructural complexes **5** and **6**. The two Sn atoms are located at the wing-tips, the chalcogen atoms bridge the two Sn atoms and the Co atom; thus, this is the first example in which these three heavy atoms are linked directly with each other. The tilt of the two triangular faces about the Co–E axis is more pronounced for **5** (E = Se) than for **6** (E = Te) and is attributed to the larger Sn1-E-Sn2 angle at the Se atom. The C-Sn-C angles of the two $[CH(SiMe_3)_2]$ groups bound to the Sn atoms in **5** and **6** deviate only marginally from the tetrahedral angle. This is due to their isoclinic arrangement, through which steric overcrowding at the Sn atoms is avoided to a great extent, so that an almost ideal tetrahedral geometry results. The μ_3-chalcogen atoms function as 4e donors and thus, the Co atoms each achieve a configuration with 18 valence electrons.

According to ^1H and ^{13}C NMR spectra of **5** and **6** in solution, the methine protons (two signals) and the protons of the trimethylsilyl groups (four signals) are not equivalent; this is attributed to the rigid inclusion of the Sn atoms in the framework of the M/M′ polyhedron. Furthermore, the change of the hybridization ($sp^2 \rightarrow sp^3$) at the Sn atoms on the transition from **2** to **5** or **6** also causes an interlocking of the $[CH(SiMe_3)_2]$ groups, because the organosilyl groups move closer together, and thus their rotational freedom is additionally limited.

Experimental Section

3a (**3b**): **1a** (**1b**) (2.8 mmol) was dissolved in ether (30 mL) and treated with solid **2** (1.23 mmol); after a short time, release of ethene was accompanied by a color change from brown to red-violet. The mixture was allowed to stir for 12 h at 20 °C (**3a**) or under reflux (**3b**). Crystallization from pentane at −30 °C gave crystalline **3a** (1.0 g, 1.7 mmol) (crystalline **3b** (0.9 g, 1.4 mmol)).

3a: IR (KBr): $\tilde{\nu}$ (cm^{-1}) = 3068 (C_2H_4, Cp), 2949, 2896 ($CH(SiMe_3)_2$), 2844 (C_2H_4), 1487 (C_2H_4), 1423, 1248 ($CH(SiMe_3)_2$), 1182 (C_2H_4), 1111 (Cp), 1011 (Cp), 843, 667 ($CH(SiMe_3)_2$); MS(70 eV, decomposition at 70 °C): *m/z*: 28 [C_2H_4], 189 [Cp_2Co], at 140 °C: *m/z*: 1124 (correct isotope pattern for $C_{38}H_{86}Si_8Sn_2Co_2$, $[Cp_2Co_2Sn_2\{CH(SiMe_3)_2\}_4]$); ^1H NMR (300 MHz, [D_6]benzene, 27 °C): δ = 0.24 (s, 36H, $SiMe_3$), 1.37 (s, ^1J(Sn,H) = 41 Hz, 2H, CH), 2.75 (br. s, $\nu_{1/2}$ = 170 Hz, 4H, C_2H_4), 4.57 (s, 5H, Cp); ^{13}C NMR (75 MHz, [D_6]benzene, 27 °C): δ = 3.97 ($SiMe_3$), 4.99 (^{29}J(Si,C) 20 Hz, CH), 23.51(C_2H_4), 80.63 (Cp).

3b: IR (KBr): $\tilde{\nu}$ (cm^{-1}) = 3050 (C_2H_4), 2947, 2901 ($CH(SiMe_3)_2$, Me_5C_5), 2854, 1483, 1168 (C_2H_4), 1456, 1379 (Me_5C_5), 1246, 1168, 1012, 842, 773 ($CH(SiMe_3)_2$); MS(70 eV): decomposition; ^1H NMR (300 MHz, [D_6]benzene, 27 °C): δ = 0.27 (s,

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3607-0740 $ 17.50+.50/0

36H, $SiMe_3$), 0.05 (s, 2H, CH), 1.68 (s, 15H, Me_5C_5), 2.46 (br. d, $\nu_{1/2}$ = 20 Hz, 2H, C_2H_4), 2.06 (br. d, $\nu_{1/2}$ = 20 Hz, 2H, C_2H_4); ^{13}C NMR (75 MHz, [D$_6$]benzene, 27 °C): δ = 4.67 ($SiMe_3$), 1.43 (CH), 11.07 (Me_5C_5), 29.85 (C_2H_4), 90.1 (Me_5C_5).

5 (**6**): A solution of **3a** in toluene [prepared from **1a** (2.8 mmol) and solid **2** (1.23 mmol)] was stirred for 12 h at 40 °C and then treated with Se metal (1 equiv) (Te metal (2 equiv)) and stirred for 2 d at 20 °C. Repeated crystallization of the solid residue from ether at −30 °C gave **7a** (0.15 g, 0.14 mmol) [**7b** (0.2 g, 0.18 mmol)], and subsequently **5** (1.1 g, 1 mmol) and **6** (1.21 g, 1.1 mmol), respectively, were obtained from ether/CH_3CN (5/1) at −30 °C.

5: ^1H NMR (300 MHz, [D$_6$]benzene, 27 °C): δ = 0.32, 0.38, 0.42, 0.44 (each: s, 18H, $SiMe_3$), 0.94 (s, ^1J(Sn,H) = 74 Hz, 2H, CH), −0.06 (s, ^1J(Sn,H) = 60 Hz, 2H, CH), 4.78 (s, 5H, Cp); $^{13}C\{^1H\}$ NMR (75 MHz, [D$_6$]benzene, 27 °C): δ = 4.78, 4.96, 5.25, 5.61 (all $SiMe_3$), 13.8, 17.5 (both CH), 75.9 (Cp); MS (70 eV): decomposition.

6: MS (70 eV, 150 C): *m/z*: 942 (6) [$M^+ - CH(SiMe_3)_2$], 783 (4) [942 − $CH(SiMe_3)_2$], 624 (28) [783 − $CH(SiMe_3)_2$], 189 (100) [Cp_2Co]; ^1H NMR (300 MHz, [D$_6$]benzene, 27 °C): δ = 0.42 (br. s, 36H, $SiMe_3$), 0.38, 0.34 (each s, 36H, each $SiMe_3$), 0.03 (s, ^1J(Sn,H) = 58 Hz, 2H, CH), 1.07 (s, ^1J(Sn,H) = 74 Hz, 2H, CH), 4.79 (s, 5H, Cp); $^{13}C\{^1H\}$ NMR (75 MHz, [D$_6$]benzene, 27 °C): δ = 4.96, 5.12, 5.33, 5.73 (each: s, 18H, $SiMe_3$), 17.25 (s, $^1J(^{29}Si,C)$ = 40 Hz, 2H, CH), 18.75 (s, $^1J(^{29}Si,C)$ = 40 Hz, 2H, CH), 75.70 (s, Cp). All compounds gave correct C,H elemental analyses.

Asymmetric Dihydroxylation with MeO–Polyethyleneglycol-Bound Ligands**

Carsten Bolm* and Arne Gerlach

The osmium-catalyzed asymmetric dihydroxylation (AD) according to Sharpless is an efficient method for the oxidation of unfunctionalized olefins.[1] After their discovery in 1988[2] the alkaloid ligands were optimized so that highly enantioselective catalyst systems are now available for almost all classes of olefins.[3] Even though recovery of the ligands is usually not a problem, there have been many attempts to heterogenize them by attachment to polymers to enable separation from the product mixture by simple filtration.[4] Reactions with these insoluble ligands lead to lower enantioselectivities and longer reaction times than catalyses in solution.[4, 5] To combine the advantages of homogeneous catalysis with the easy separation of a ligand bound to the solid phase, Han and Janda attached

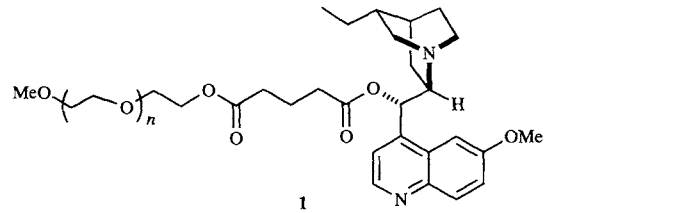
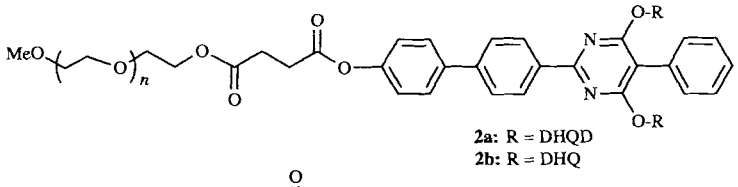
an alkaloid ligand to polyethyleneglycol methyl monoether (MeO–PEG).[6] This report caused us to present our own results in this area now.

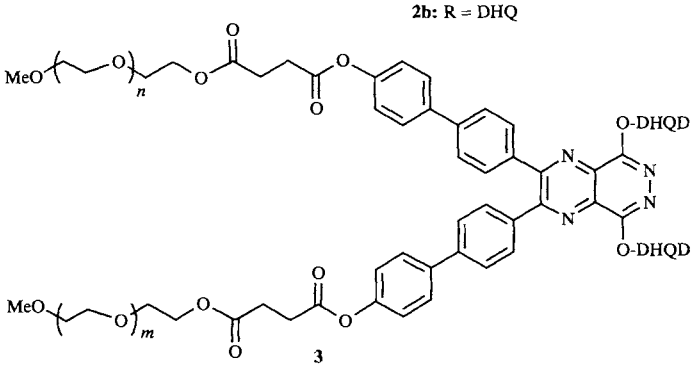
MeO–PEGs have been used for the modification of enzymes for a long time,[7,8] since increased solubility in organic solvents and often improved activity as well as selectivity are obtained. For asymmetric metal catalysis, the advantage of MeO–PEG modification is that the reaction itself is performed in the *homogeneous* phase.[6c–e] The molecularly enlarged ligand can then be precipitated quantitatively by simple addition of solvent. Important features of the catalysis, for example ligand acceleration,[9] remain unaffected. Han and Janda chose the secondary hydroxyl group of the dihydroquinidine (see ligand **1**) for attachment of MeO–PEG.[6a] This connection causes the catalytic system to be less efficient; even in the AD of stilbene only 88% *ee* is obtained.[10] According to our concept, the high symmetry of the DHQ and DHQD ligands originally introduced by Sharpless[1,11] should be preserved as far as possible. Compounds **2** and **3** were therefore synthesized and tested in the osmium-catalyzed AD.



1



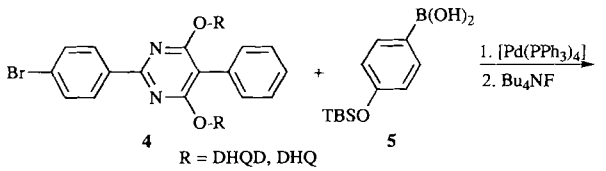
2a: R = DHQD
2b: R = DHQ



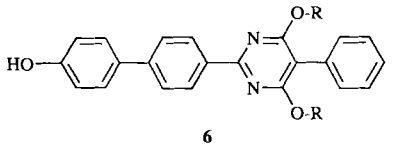
3

For the synthesis of the pyrimidine ligand **2**, aryl bromides **4**, which were obtained in high yields following standard procedures,[12] were coupled with arylboronic acid **5** under palladium catalysis. After cleavage of the silyl groups with tetrabutylammonium fluoride, **6** was esterified with MeO–PEG (**7**)[13] acylated with succinic anhydride to yield **2**. The pyridazine ligand **3** could be synthesized from dibromide **8** by an analoguous reaction sequence.[14] Structure determination and confirmation of ligand attachment was achieved by NMR spectroscopy.

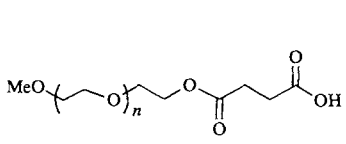
The properties of these new alkaloid ligands and their ability to transfer chirality in the AD were investigated in reactions with selected olefins (Table 1). The results can be summarized as follows: 1) The MeO–PEG-modified ligands are completely soluble in the reaction mixture. 2) The catalysis is fast, and good yields are obtained after short reaction times (max. 5 h). 3) *The enantioselectivities are very high*, and the diols can be obtained



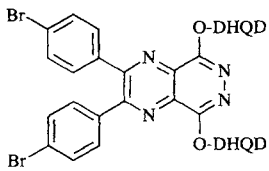
4 R = DHQD, DHQ **5**



6



7



8

with up to 99% *ee*. With $K_3[Fe(CN)_6]$ as oxidant[15] the *ee* values correspond to those obtained with the original Sharpless systems.[1,3] The MeO–PEG attachment through the "aryl spacer" therefore does not disturb the chirality transfer in the AD. 4) When the reaction is finished the ligand can be precipitated by addition of *tert*-butyl methyl ether, and the uniform product (HPLC and NMR analysis) remains in solution. More than 98% of the ligand can be recovered by simple filtration; its repeated use in the catalysis resulted in the formation of product with almost unchanged *ee* value and identical chemical yield (85–92%).[16] 5) As with the original system described by Sharpless,[1–3] the DHQ and DHQD ligands (**2a** and **2b**) yield products of opposite configuration.

Table 1. Enantioselectivities in the AD with **2** and **3** [17].

Entry	Olefin	Ligand	Yield [%]	*ee* [%] [a]	Abs. config.
1	C_6H_5, C_6H_5	**3**	91	99 (99) [b]	(*R*,*R*)
2	C_6H_5	**3**	92	98 (99)	(*R*)
3	Me, C_6H_5	**3**	89	95 (96)	(*R*)
4	C_8H_{17}	**2a**	86	87 (89)	(*R*)
		2b	88	74 (76)	(*S*)
5	$(H_3C)_3C$	**2a**	84	90 (92)	(*R*)

[a] Determined by HPLC with a chiral stationary phase [18]. The *ee* values of products that were obtained from catalyses with nonpolymer-enlarged DHQ and DHQD ligands [3b, 11] are given in parentheses. [b] Reference value from a reaction with a structurally related $(DHQD)_2PHAL$ ligand [3c] (PHAL = 1,3-phthalazinediyl).

The concept of using soluble polymer-bound ligands that can easily be recovered after the reaction is finished has proven worthwhile. With the polymer attachment presented here, very high enantioselectivities that are comparable to those obtained with the original system reported by Sharpless[1–3] could be achieved for the first time.

A Molecular Composite Constructed in Aqueous Alkaline Solution from a Double Six-Ring Silicate and α-Cyclodextrin**

Klaus Benner, Peter Klüfers,* and Jörg Schuhmacher

Silicate and aluminosilicate networks appear to be constructed by different stategies in the course of natural and technical syntheses. Thus, whereas in the production of zeolites one strives to structure the aqueous regions, in the sense of modeling the later pores, by the addition of organic additives to the aqueous precursor gels,[1] silicic acid building blocks seem to be directly inserted into the growing silicate network in the course of biogenic silica deposition.[2] One of the basic issues of research on boundary-organized biomineralization[3] and biomimetic synthesis of advanced materials concerns the nature of substrate–matrix interactions. Biopolymers are of significance as organic matrices for nucleation of biominerals in organisms, and they assemble the inorganic–organic interface through polar interactions such as ionic or hydrogen bonds.[4] For instance, polysaccharides are considered as the probable organic matrix in the deposition of amorphous silica in plants.[2] We report here on the structure of a molecular inorganic–organic composite constructed from a double six-ring silicate and α-cyclodextrin (cyclomaltohexaose, α-CD) as an oligosaccharide component. The structure of the assembly may be regarded as a model of an extended hydrogen-bonded silicate–polyol interface at an atomic level.

Triclinic crystals of a potassium dicyclohexasilicate–α-cyclodextrin adduct of the formula **1** (instead of an expected poly-

$$K_{12}Si_{12}O_{30} \cdot 2\alpha\text{-CD} \cdot 36H_2O \quad \mathbf{1}$$

olatosilicate) form from the reaction of α-cyclodextrin with tetramethoxysilane in aqueous potassium hydroxide solution. The X-ray crystal structure analysis[5] reveals a prismatic dicyclohexasilicate ion intercalated in a pair of α-cyclodextrin tori as the most salient feature of the crystal structure (Figure 1). The silicate prisms resemble the well-known "secondary buildung units" (SBUs) of the zeolite structures.[1] Furthermore, these dicyclohexasilicate ions are found as the anions in the mineral milarite and some isotypic synthetic silicates (for distances and angles see Table 1, entries 8–10).[6] Direct cation–silicate contacts are characteristic for the mostly anhydrous milarite compounds; however in **1**, the terminal, formally anionic, silicate oxygen atoms act as acceptors in isolated hydrogen bonds. The hydrogen bonding system of the wider rim of the cyclodextrin cone, which fixes the conformation of the toroidal oligosaccharide, is entirely detached in favor of the carbohydrate–silicate bonds (Table 1, entry 1). As a result, *all* of the 24 secondary hydroxy groups of the cyclodextrin cone act as donors, and *all* of the 12 formally O^- functionalities of the silicate act as acceptors (Scheme 1). The flexible oligosaccharide molecules[7] exhibit an unusual flat conical shape; however, there is no evidence in terms of the geometric parameters that the almost D_6 symmetrical assembly exhibits steric strain (Table 1, entries 2–4).[8] Besides the saccharide, water mole-

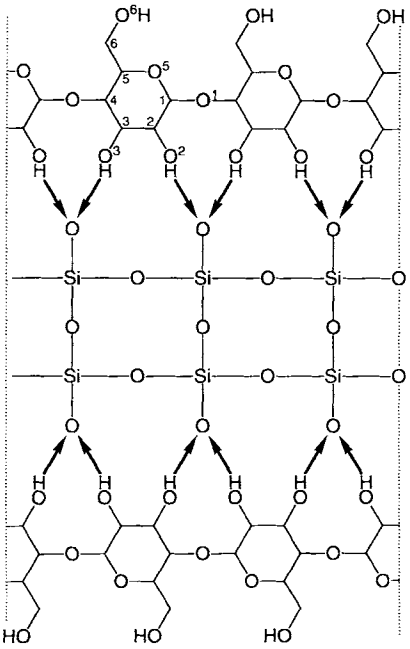
[a] K. K. Chacko, W. Saenger, *J. Am. Chem. Soc.* **1981**, *103*, 1708–1715. [b] Angle between best planes through the pyranose ring atoms (plane 1) and through the acetal oxygen atoms of a cyclodextrin torus (plane 2). [c] D. Cremer, J. A. Pople, *J. Am. Chem. Soc.* **1975**, *97*, 1354–1358; the chair conformation of the pyranose rings is only slightly distorted; all θ values are smaller than 11°. [d] The average has been calculated by using distances less than 3.1 Å because a gap occurs in the frequency distribution curve between 3.1 and 3.2 Å.



Scheme 1. Schematic representation of the aggregate **1**, which has been halved and unreeled into a plane, showing the numbering scheme of the cyclodextrin atoms, and the hydrogen bonds.

cules act as hydrogenbond donors towards the silicate-O^- acceptors (on average 1.3H_2O molecules are bound per O^- site). Thus, the dodecasilicate ion lies in the same typical environment in which a silicate has been previously found in the crystal structures of highly hydrated salts of the well-known cubic octamer $[Si_8O_{20}]^{8-}$, whose terminal oxygen atoms are acceptors of about three hydrogen bonds (see Table 1, entries 5 and 6 for distances).[9] Hence, although the prismatic dodecamer is not a significant species in aqueous alkaline silicate solutions,[10] its enrichment in the mother liquors of **1** may be considered a consequence of maximizing entropy by leaving numerous potential water donors unbound.

The charge on the silicate ion is compensated by potassium ions, which form no direct contacts with the silicate-O^- functionalities. The potassium counterions are coordinated by an average of 3.5 water molecules and 3.5 cyclodextrin O2/3 atoms. This is true for ten of the twelve potassium ions of each formula unit; the two remaining potassium ions are part of the silicate–cyclodextrin assembly, in which each ion is coordinated by a hexagonal face of a silicate prism.[11] As a result, these two potassium ions, together with an aqua ligand, project into the hydrophobic cyclodextrin cavity (Figure 1; Table 1, entry 7). The basic motif of the inorganic–organic assembly is adopted by the crystal structure since "inorganic" silicate layers alternate with "organic" cyclodextrin double layers along hexagonally packed rods. (Figure 2).

The unconstrained interlocking of the building blocks of **1** supports the concept of template-directed oligosilicate synthesis on the cyclodextrin as a matrix; thus, **1** could serve as a model for silica deposition on a polysaccharide surface. More tangibly, **1** could serve as a model of thermodynamically stable polysaccharide–silicate assemblies in silica-containing plants, in which the isolated silicate species alone would be unstable.[12]

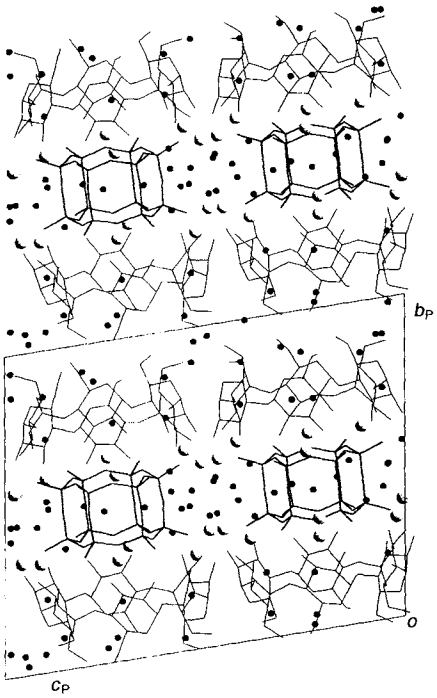

Figure 2. A projection of the unit cell of **1** along [$\bar{1}$00] showing layers of "inorganic" and "organic" building blocks. Water molecules are drawn as small black circles, the potassium ions are drawn as light grey circles. The projection of b and c onto the (100) plane is denoted b_P and c_P, respectively.

To our knowledge, **1** is the first molecular assembly in which a cyclodextrin acts as a multidentate hydrogen-bond donor. After having been also used as multidentate ligands in metal complexes recently,[13] cyclodextrins represent building blocks of high information content, which allow construction of assemblies through exact fitting of binding site patterns.[14]

Experimental Section

$Si(OMe)_4$ (1.83 g) and 3M KOH (4 mL) were added to a solution of α-cyclodextrin (1.32 g) in water (10 mL), and ethanol vapor was allowed to diffuse into the solution. Small, colorless platelets formed in the course of a few days. Crystal plates of higher quality and size were obtained by heating the solution prior to ethanol diffusion to 140 C for 1 d.

[8] Note the O3–H···O$^-$ bonds are shorter than the O2–H···O$^-$ bonds, which results from a geometric peculiarity of a cyclodextrin cone. It may be shown by simple geometric considerations that the distance of the O3 atoms to the center of the cone (and hence to the silicate double ring, which has a smaller diameter than the cyclodextrin) is shorter than in the case of O2 [13a]. In **1**, there is only a slight correction in terms of a rotation of the silicate prism towards the O2 atoms.

[11] It appears the potassium ions bind to the finished assembly and do not have a significant influence on its formation, as experiments with sodium as the cation have shown. An analogous silicate–cyclodextrin adduct is even obtained from sodium hydroxide solution; however, in the homologous sodium compound, the potential cation binding sites next to the prism bases are only partly occupied by sodium ions, while other positions remain free from cations (which in this case are unfavorably small).

Ab Initio Density Functional vs Hartree Fock Predictions for the Structure of [18]Annulene: Evidence for Bond Localization and Diminished Ring Currents in Bicycloannelated [18]Annulenes**

Kim K. Baldridge and Jay S. Siegel*

On the basis of steric arguments, Mislow predicted in 1952 that higher annulenes should not be planar and therefore should not enjoy "aromatic" stabilization (Figure 1).[1] This plausible prediction came from weighing the known high energetic costs for a molecule to form intramolecular contacts at less than van der Waals distances and extended angles against what at that

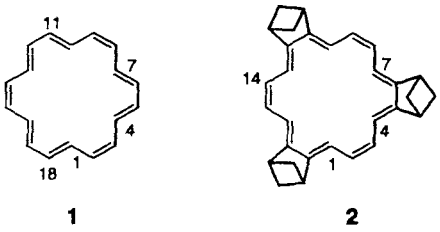
time was a more vague estimation of the aromatic stabilization energy. Indeed, only through clever subversions, such as Vogel's methano[10]- and -[14]annulenes[2] and Boekelheide and Mitchell's dimethyldihydropyrenes,[3] have we gained insight into the stable members of Hückel's $(4n + 2)$ hydrocarbons with $n = 2$ and 3. Although the highly reactive [10]- and [14]annulenes could be prepared,[4-6] it was Sondheimer's synthesis and characterization of the relatively stable [18]annulene (**1**) that provided unambiguous evidence that "aromatic" character could outweigh steric effects in simple annulenes.[7]

During the time that these novel higher annulenes were being synthesized and characterized, no ab initio computations were presented that correctly predicted their structure. Baumann and Haddon had proposed early on that dynamical electron correlation would be needed to handle the higher annulene structures, but the computational effort was not expended.[8-10] In the last few years, computations including electron correlation have been performed on the all-*cis*-[10]annulene, but comparison with experimental values is limited with this system.[11-13] Very recently, density functional (DF) methods have been shown to predict accurately the structure and energy of dimethyldihydropyrene and derivatives,[14] Kekulene,[15] and *syn*- and *anti*-bismethano[14]annulene.[16] Schulman and Disch showed that MP2 single-point analysis of the energies of symmetry-constrained Restricted Hartree–Fock (RHF) optimized geometries for **1** favor a D_{6h} structure,[17] but as of yet no correlated ab initio structure predictions exist and no reliable computational level for higher order arenes has been established. The present study and the subsequent paper[16] demonstrate the suitability of hybrid RHF/DF methods to predict the structure of larger annulenes such as **1** and we propose a bicycloannelated derivative of **1** with a bond-localized geometry.



1 **2**

When dynamical electron correlation is neglected, **1** (RHF/dzv(2d,p)) is predicted to be D_3-symmetrical and bond-localized with average double and single bond lengths of 1.339 and 1.472 Å, respectively (Table 1).[18] Thus, at this level the potential energy surface along the bond localization coordinate is predicted to be a double-welled potential. Addition of dynamical electron correlation, by application of either MP2 or DF methods, dramatically lowers the energy of the D_{6h} structure such that the potential energy surface becomes single-welled; no stationary points of D_{3h} or D_3 symmetry are found at correlated levels. The molecular geometry predicted by the correlated computations (B3PW91/dz(2df,2p)) agrees well with

Cruickshank's recently determined disorder-modeled crystal structure of **1** at 110 K.[43] Imperative is the use of correlated methods and extensive polarization functions in order to predict the molecular geometry with experimental accuracy.

Bicycloannelation induces bond localization in benzene and dimethyldihydropyrene.[14, 44] The special nature of **1**, which is on the border of the breakdown in the Hückel $(4n + 2)$ rule, makes it a natural target for further examination of the bond-localizing effect of bicycloannelations, and symmetry considerations favored the choice of 2,8,14-tris(bicyclo[2.1.1]hexeno)-[18]annulene (**2**) for investigation.

HF/6-31G(2d,p) computations on **2** predict a double-welled potential energy surface with respect to a bond localization coordinate; the energetic preference for the isomer in which the double bonds are *exo* to the bicyclic appendages is 30.4 kcal mol^{-1} (Table 2).[18] Implementation of methods

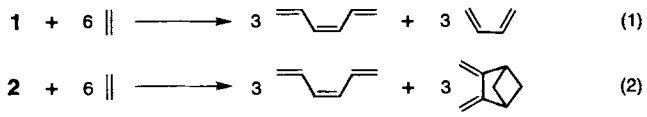
[a] See Table 1, footnote [e]. [b] See Table 1, footnote [g]. [c] Calculation was performed at the BPW91/6-311G(df,p) level [18].

that include dynamical electron correlation (B3PW91/dz(d,p)) predict a single-welled potential energy surface centered about a regularly alternate structure with double bonds *exo* to the bicycloannelations. The degree of bond localization can conveniently be measured by the difference in the average double and single bond lengths (0 pm in **1**; 6.8 pm in **2**). The preference for the *exo* double bonds and magnitude of bond localization is analogous to results found for annelated benzenes and dimethyldihydropyrenes.[14, 44, 45]

Bond localization in **2** suggests a significant loss in ring current. Thus, the large anisotropy reflected in the difference in the NMR chemical shifts of the inner and outer protons of **1** should be substantially diminished for the protons of **2**. DF GIAO computations of the NMR properties of **1** and **2** corroborate these qualitative predictions.

Focusing first on **1**, we find that the predicted NMR signal for outer protons falls within 0.4 ppm of that determined experimentally; however, the prediction for the signals of the inner protons is off by several ppm at all computational levels attempted. Sondheimer noted a strong temperature dependence of the chemical shift of the inner protons.[46] The discrepancy between experiment and theory may arise in part from temperature factors but is most likely because the ring current is overestimated at these computational levels. A redetermination of the low-temperature high-field ^{1}H NMR spectrum of **1** and a computational study of hexahydrocoronene should shed some light on this question. Nonetheless, similar computations of the NMR properties of **2** show unequivocally that it has a lower ring current than **1**; the difference in chemical shift between *exo* and *endo* protons is calculated to be reduced from 23.6 ppm for **1** to 14.8 ppm for **2** (BPW91/6-311G(df,p//BPW91/dz(d)). Thus, bicycloannelation is directly associated with bond localization and loss of ring current.

Aromatic stabilization is another factor to be assessed in bond-localized annulenes.[12] The energy of the homodesmic reaction (1) predicted by DF methods ($\Delta H = 17.95$ kcal mol^{-1} [22.9 kcal mol^{-1}[47]) agrees reasonably well with that measured experimentally (19.0 kcal mol^{-1}).[18, 31, 32] Comparison of the DF-determined energies for the homodesmic reactions (1) and (2) ($\Delta H = 0.8$ kcal mol^{-1}) shows that **2** lacks the stability of **1** based on similar fragmentation analysis.



In conclusion, the aromatic character of annulenes higher than benzene is attenuated by severe steric interactions. Bicycloannelation, as in **2**, significantly reduces the geometrical bond delocalization, ring current, and stabilization energy of **1**. These novel structural, energetic, and spectroscopic predictions should motivate the synthesis and characterization of **2**.

[18] RHF calculations were performed with the aid of analytically determined gradients and the search algorithms contained within GAMESS [19], by using the 6-31G(2d,p) [20,21] and dzv(2d,p) basis sets [22]. These basis sets include two sets of six d polarization functions on all heavy atoms, and one set of p polarization functions on hydrogen atoms. DF calculations using sufficient nonlocal potentials were performed by using the DF formalism within CADPAC [23] and G94 [24], and by using the dz(ndmf,qp) basis sets [25] where $n = 1, 2$, $m = 0, 1$, and $q = 0–2$. In addition, a variety of functionals (including BPW91 [26,27], B3PW91 [28], and B3PLYP [27,28]) were considered for geometry optimization of **1** in order to establish an appropriate level of theory before the more costly calculations involving **2** were undertaken. The results of

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3607-0747 $ 17.50+.50/0

the DF calculations were compared with those of the more traditional MP2 [29,30] technique. It was found that all DF and MP2 methods behaved essentially equivalently in this study, and that the accuracy of the results is more dependent on quality of basis set. Based on assessments of the results of **1**, it was then considered most economical to optimize the geometry of **2** at only the BPW91/dz(d) level of theory. Frequency calculations were performed where appropriate to establish the character of minima found. The quantitative measure of the delocalization stabilization was estimated by using one of a variety of possible reaction schemes for bond separation [31, 32]. We have previously found that a similar qualitative picture results over all treatments [33,34]. Additionally, NMR shielding tensors were calculated from fully optimized structures at select levels of theory, by using the Gauge-Independent Atomic Orbital (GIAO) method [35–37]. As with the geometry optimizations, several basis sets were used for NMR calculations on [18]annulene (**1**) and we found these levels to be self-consistent. Such basis sets [38,39] are necessary to describe properly the NMR properties of structures with such complex interactions [40–42].

The Bond Localization Energies in the Aromatic Bismethano[14]annulenes**

Maja Nendel, Kendall N. Houk,* L. M. Tolbert, Emanuel Vogel, Haijun Jiao, and Paul von Ragué Schleyer*

New experimental and theoretical developments have returned the concept of aromaticity to center stage.[1] Substituents that distort benzene towards "cyclohexatriene" structures have been found.[2] Arguments over the fundamental origin of bond-length equalization in aromatic compounds continue.[3] Electron-correlated ab initio methods are often employed to predict the structures and energies of delocalized aromatic systems,[4, 5] but examples have been found for which both MP2 and DFT methods give errors.[6, 7]

Two key questions are addressed in this study: How much energy is required to distort aromatic systems having equalized bond lengths to structures with alternating double and single bonds? Does bond-length localization alter the magnetic properties[1] when good overlap of the cyclic array of π orbitals is maintained? Besides answering these questions, we also report that high-level computations, usually considered to give reliable predictions, can give unbalanced descriptions of localized polyolefins and delocalized aromatic structures. When this is not recognized, erroneous interpretations and predictions can result.

Vogel's[8, 9] isomeric *syn*- (**1**) and *anti*-bismethano[14]annulenes (**2**) have strikingly different structures and magnetic properties; the nature of bonding can be summarized by the representations shown. In *syn*-**1** the C–C double bonds are nearly equal in length (X-ray data: $r = 1.37-1.42$ Å or 1.39 ± 0.03 Å),[10] whereas the 2-methoxycarbonyl derivative of *anti*-**2** has alternating single and double C–C bonds ($r = 1.34-1.50$ Å or 1.42 ± 0.08 Å) around the perimeter.[11] *syn*-**1** has a strong diamagnetic ring current (the ^{1}H NMR signals of the perimeter protons have downfield chemical shifts ($\delta = 7.4-7.9$), while the signals of the methano bridge protons are shifted upfield to $\delta = 0.9$ and -1.2).[7] No ring current is apparent from the ^{1}H NMR shifts of *anti*-**2** (perimeter protons at $\delta = 6.2$ and methano bridge protons at $\delta = 2.5$ and 1.9).[8] The energy of the "aromatic" (delocalized) form of **2** can be estimated from the

barrier to double bond isomerization, 7.1 kcal mol^{-1} from dynamic ^{1}H NMR experiments.[8]

We have investigated the delocalized and localized structures of *syn*- (**1**) and *anti*-bimethano[14]annulene (**2**) with common computational methods.[12] The four RHF/6-31G*-optimized geometries are shown in Figure 1, and the relative energies at various theoretical levels are summarized in Figure 2. To compare the different methods, the dashed line represents the average energy of the localized *syn* (**1L**) and *anti* (**2L**) structures. The geometric and magnetic parameters are given in Table 1.

Table 1. Geometrical parameters (Δr_m [a] and A [b]), and total magnetic susceptibility exaltations (Λ, in ppm cgs) of *syn*- (**1L** and **1D**) and *anti*-bismethano[14]annulenes (**2L** and **2D**) by various computational methods [c].

[a] Δr_m (maximum deviation of the mean C–C bond) in Å. [b] A (Julg parameter) is unitless. [c] The values for the delocalized structures, **1D** and **2D**, are given in parentheses. [d] No localized structures at this level.

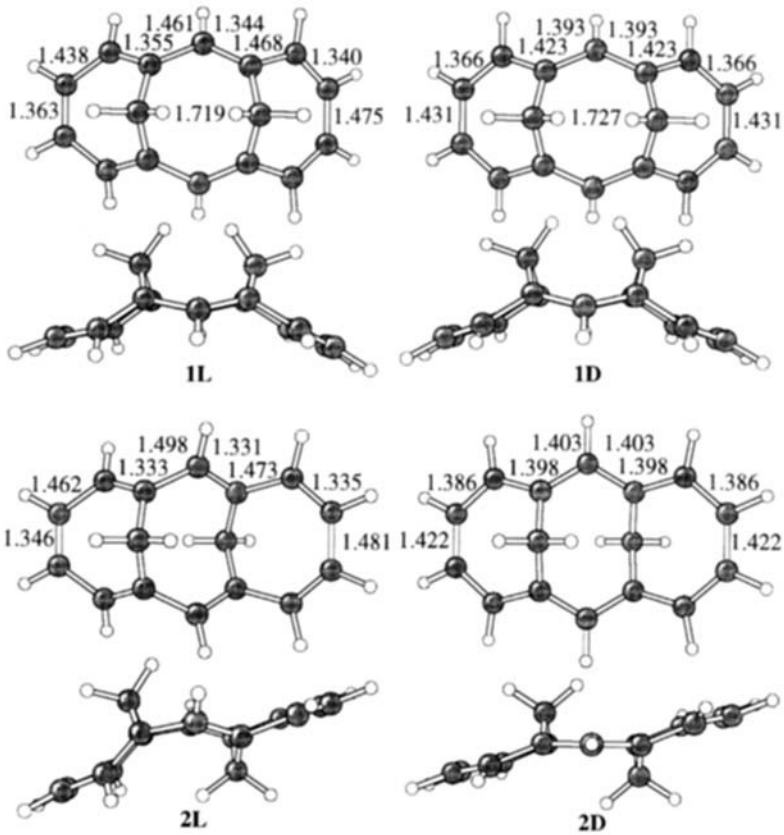

Figure 1. RHF/6-31G*-optimized geometries for localized (**1L** and **2L**) and delocalized (**1D** and **2D**) *syn*- and *anti*-bismethano[14]annulenes.

At the RHF/6-31G* level both localized structures (**1L** and **2L**) have nearly planar dimethylenecycloheptadiene moieties (right half of each structure in Figure 1), which are doubly linked to a cycloheptatriene (left half of each structure). The carbon skeletons are similar in the localized (**1L**) and delocalized (**1D**) *syn* structures. In contrast, the localized *anti* structure (**2L**) has little π orbital overlap between the central and bridgehead carbons, and the angle between the π orbitals at these carbons is 79° in **2L**, compared to only 34° in **1L**. Effective π orbital overlap in the delocalized *anti* structure (**2D**) can only be achieved when the central ring is almost planar, but this introduces considerable strain.

Both the semiempirical PM3 and the ab initio RHF/6-31G* methods favor bond-localized structures for the *syn* and *anti* isomers (Figure 2). Errors in the computed energies can be estimated based on the experimental barrier to double bond isomerization between **2L** and **2D** (7.1 kcal mol^{-1}). Due to the neglect of correlation energy (Figure 2),[13] PM3 overestimated this barrier by 25.9 and RHF/6-31G* by 19.4 kcal mol^{-1}. When these errors are subtracted from the energy of **1D**, **1D** becomes more stable than **1L**, as is found experimentally.

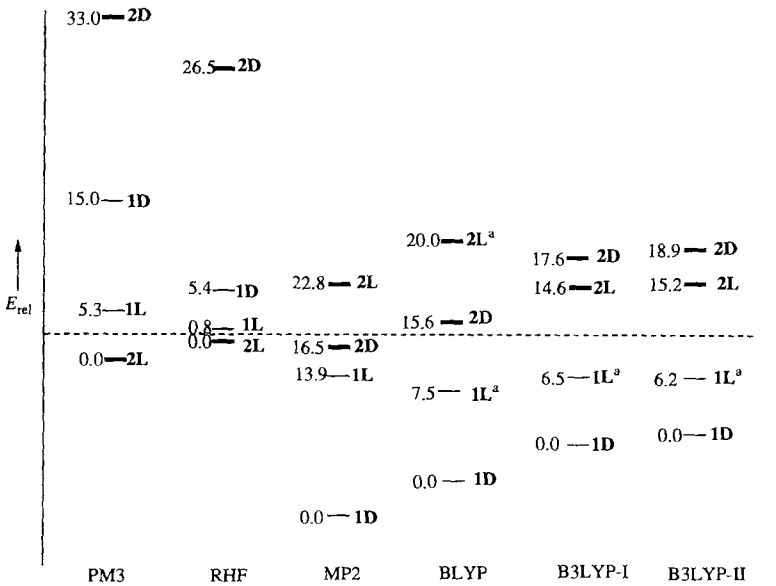

Figure 2. Summary of relative energies [kcal mol^{-1}] of localized and delocalized *syn*- (**1L** and **1D**) and *anti*-bismethano[14]annulenes (**2L** and **2D**) from calculations at the PM3, RHF/6-31G* (RHF), MP2/6-31G*//6-31G* (MP2), BLYP/6-31G* (BLYP), Becke3LYP/6-31G* (B3LYP-I), and Becke3LYP/6-311 + G**//Becke3LYP/6-31G* (B3LYP-II) levels. a: Single-point calculation on the RHF/6-31G* geometries.

MP2/6-31G*//RHF/6-31G* single-point calculations favor the delocalized structures to such an extent that both **1D** and **2D** are more stable than **1L** and **2L**. MP2 underestimates the energy difference between **2L** and **2D** by 13.4 kcal mol^{-1} (Figure 2). This considerable error indicates that MP2 overestimates the correlation energies of aromatic systems[14] and "aromatic" transition states.[15]

BLYP/6-31G* optimizations also strongly overestimate the extent of delocalization and provide two minima with delocalized structures. The *syn* structure (**1D**) is more stable than the *anti* structure (**2D**), primarily due to the distortion of the carbon framework to accommodate π overlap in the latter. BLYP/6-

31G* single-point calculations on the RHF/6-31G* geometries predict **2D** to be too stable relative to **2L** by 11.5 kcal mol^{-1}. This amounts to about half the error in the RHF calculations, albeit in the opposite direction (Figure 2).

The hybrid density functional, Becke3LYP/6-31G*, is the only method employed here that predicts the correct geometries and gives a delocalized *syn* and a localized *anti* minimum. While the barrier to double bond delocalization in **2** is underestimated by 3.4–4.1 kcal mol^{-1}, this method yields the smallest absolute error of all the methods tested. Becke3LYP performs well because exchange is computed by a mixture of Hartree–Fock and Kohn–Sham methods, each of which err in opposite directions. Therefore, although the results may not represent quantum mechanics correctly, they do yield nearly the right energy difference in this as in many other cases.[16]

The computed magnetic susceptibility exaltations (A) of the RHF/6-31G* geometries show that both **1D** and **2D** are strongly aromatic.[17] In addition, **1L** still is somewhat aromatic, possessing 40% of the magnetic susceptibility exaltation of the **1D**, but the corresponding **2L** is nonaromatic. Geometric criteria, such as Δr_m (the maximum deviation of the mean C–C bond length) and the Julg parameter A,[18] give the same conclusion (Table 1). The same results are achieved on the BLYP/6-31G* and Becke3LYP/6-31G* delocalized geometries; in other words, **2D** is more aromatic than **1D**, and **2L** is not aromatic.

Due to the similar stability orders after energy correction, we conclude that the *syn* delocalized structure (**1D**) is most likely the global minimum. The strain due to repulsion of the two inner methano bridge protons is compensated by the favorable delocalization energy. Becke3LYP single-point calculations on the RHF/6-31G* geometries of **1L** and **1D** predict **1D** to be 6.2–6.5 kcal mol^{-1} lower in energy.

Surprisingly, the aromatic stabilization energies of planar π systems are not altered drastically either by bond localization or by modest out-of-plane deformations, as long as π overlap is maintained.[19] Similarly, the ring currents (as judged by the magnetic criteria) decrease only modestly upon localization and disappear only in twisted structures (such as the *anti* isomer, **2L**) in which π overlap is eliminated.

The consequences on future theoretical studies are clear: predictions of a specific delocalized or localized structure must be made with caution; the magnitude and direction of errors expected from each type of calculation must be considered. MP2 and BLYP calculations may give significant errors. Predictions of structures of large aromatic systems, such as the fullerenes,[20] require highly correlated wavefunctions or appropriately parametrized semiempirical methods.[21]

The chemical consequences of this study are significant as well. Systems such as benzene or **1**, which can assume localized structures by a simple "breathing" distortion, do so with little energy loss (benzene: 4.3 kcal mol^{-1};[19b] **1**: 6 kcal mol^{-1}). Such relatively small energy differences can be overcome by other effects and bond alternating structures result. The partially localized cyclohexatriene structures[1] arise from the hyperconjugation interactions in the reference molecules analyzed earlier by Jorgensen.[22] While aromatic properties, including stabilization, are maximized at the delocalized geometries, the energies for such distortions in benzene or **1** are small compared to the total stabilization of the system, and little loss of aromaticity results.[19]

6-Guanidinopyranoses: Novel Carbohydrate-Based Peptidomimetics**

Hans Peter Wessel,* David Banner, Klaus Gubernator, Kurt Hilpert, Klaus Müller, and Thomas Tschopp

Dedicated to Professor Hans Paulsen on the occasion of his 75th birthday

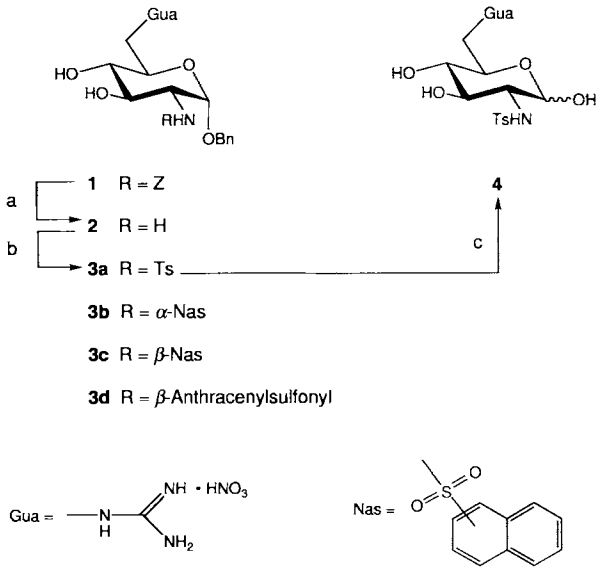
A classical approach to drug development is based on mimicking bioactive peptides that are enzyme substrates or receptor ligands. Non-peptidic structures are of particular interest. We report here on such peptidomimetics, which have been developed in a project directed at identifying thrombin inhibitors.

Thrombin is a key enzyme of the coagulation cascade. It cleaves fibrinogen to fibrin, activates the coagulation factors V and VIII, and is a main stimulator in the activation of platelets. Thrombin thus plays a central role in physiological hemostasis as well as pathological thrombosis.[1] Therefore, the direct inhibition of thrombin is an attractive paradigm for the development of a new antithrombotic agent; some thrombin inhibitors[2, 3] are already used in clinical trials.[4]

Thrombin is a serine protease with high specificity for arginine-containing peptide sequences.[5] As a result, known thrombin inhibitors contain arginine residues (for example Argatroban)[6] or guanidine (for example Ro46-6240)[7] or amidine derivatives (for example NAPAP)[8] as arginine mimetics. We have investigated 6-guanidinohexoses, which can be viewed as conformationally restricted arginine mimetics. Fitting of these structures into an enzyme model allowed the prediction that such compounds could be accommodated in the recognition pocket of thrombin.

The favored synthesis of 6-guanidinohexoses from the corresponding 6-amino derivatives with 3,5-dimethylpyrazolylformamidinium nitrate (DPFN) has been described.[9] We started from benzyl-2-benzyloxycarbonylamino-2,6-dideoxy-6-guanidinio-α-D-glucopyranoside nitrate (**1**),[9] which afforded the glucosamine derivative **2** on selective catalytic hydrogenation with palladium on charcoal (Scheme 1). The transformation of the free amino group to amides or sulfonamides was straightforward; reaction of the hydroxyl groups was prevented by the presence of water, and the pH was controlled so that a guanidinium salt was present. That is, protons served as a "protective group" for the guanidino functionality. Thus, reaction of **2** with aromatic sulfonyl chlorides led to the sulfonamides **3**.

While amide derivatives of **2** did not display any substantial biological activity, a thrombin inhibitor with micromolar activity was obtained with the tosyl derivative **3a**. The enlargement of the aromatic moiety to the α-naphthylsulfonyl derivative **3b** resulted in an inactive compound, whereas the analogous β-naphthylsulfonyl derivative **3c**[10] and the β-anthracenylsulfonyl derivative **3d** exhibited slightly increased thrombin inhibitory activity (Table 1). To judge the selectivity of thrombin inhibition, the related but less discriminating[11] serine protease trypsin was investigated (Table 1). Since, according to the enzyme model, an interaction of the anomeric center with the active site of thrombin seemed possible, the anomeric benzyl group of **3a** was removed by hydrogenolysis. However, as the resulting free pyranose **4** showed no activity, we could conclude that the anomeric center does not interact with the serine of the catalytic triad of the serine proteases under investigation.



Scheme 1. a) H_2, Pd/C, MeOH/H_2O 2/1, room temperature (RT), 4 h, quantitative; b) TsCl, THF/H_2O 2/3, NEt_3, 0 °C, 6 h, 36%; α-NasCl, H_2O/pyridine 5/3, NEt_3, RT, 5 h, 95%; β-NasCl, H_2O/pyridine 5/3, NEt_3, RT, 5 h, 79%; β-anthracenyl chloride, H_2O/pyridine 1/1, NEt_3, RT, 20 h, 78%; c) H_2, Pd/C, EtOH/H_2O 1/1, RT, 18 h, quantitative.

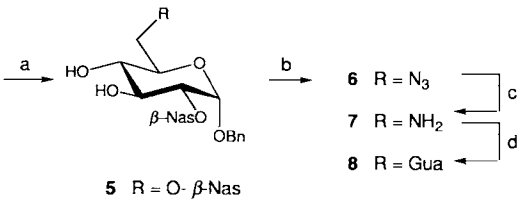
Table 1. Thrombin inhibition of some guanidino hexoses and their selectivities vs. trypsin [a].

Compound	K_i [μM]	Selectivity
1	410	–
3a	4	19
3c	1.1	109
3d	0.9	>227
8	1.4	143

[a] Selectivity = K_i(trypsin) K_i(thrombin)$^{-1}$

An analogous sulfonate was synthesized to study the influence of the sulfonamide nitrogen atom. Activation of benzyl-α-D-glucopyranoside with bis(tributyltin) oxide followed by acylation with β-naphthylsulfonyl chloride gave, as expected,[12] the bis(sulfonate) **5** as the main product. The guanidino derivative **8**[13] was prepared via azide **6** and amine **7** by the established synthetic strategy[9] (Scheme 2). This sulfonate had an activity comparable to that of the sulfonamide, but slightly higher selectivity (Table 1).

The position of **8** in the recognition pocket of thrombin was proven by an X-ray structure[14] of an inhibitor complex with



Scheme 2. a) Benzyl α-D-glucopyranoside [20, 21], $(Bu_3Sn)_2O$, toluene, reflux, 4 h; β-NasCl, 60 °C, 15 h, 34%; b) NaN_3, DMF, 55 °C, 16 h, 79%; c) PPh_3, THF/H_2O 20/1, RT, 24 h, 95%; d) DPFN, DMF, 80 °C, 24 h, 49%.

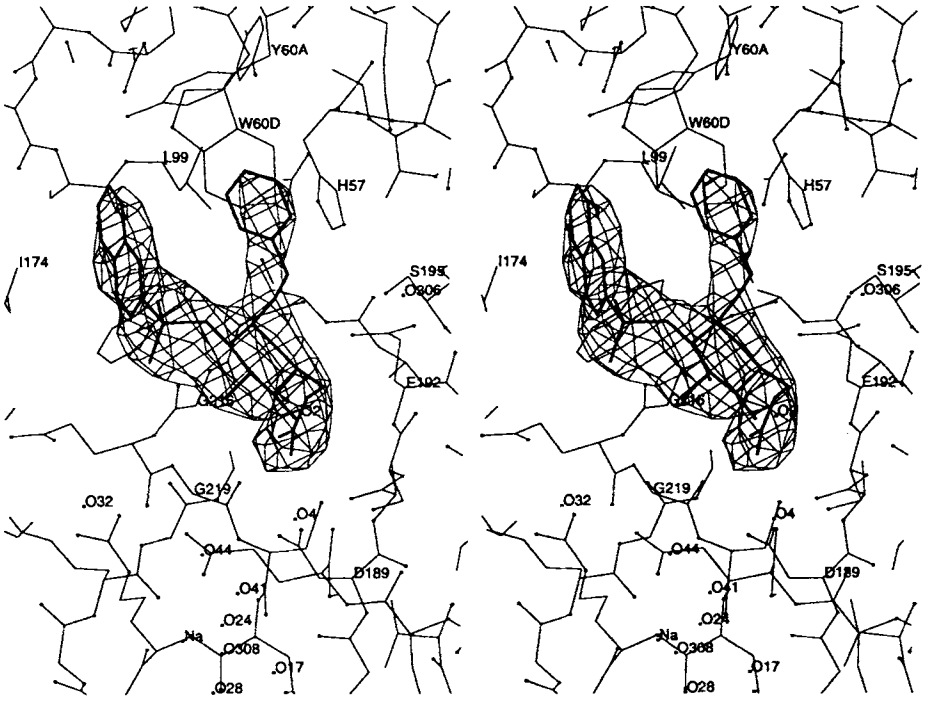

Figure 1. Steroview of the refined structure of the complex between **8** (electron density contour representation) and human thrombin (line representation). Water molecules (labeled "O") are the same as found for other inhibitors; only O 306 (right of **8**) in the oxyanion hole is new here. In contrast to most known complexes of thrombin inhibitors, there are no hydrogen bonds to glycine 216 (hidden by **8**). The sugar hydroxyl groups form only one hydrogen bond to the protein (between O3′ and -NH of glycine 219). The guanidinium group has very weak hydrogen bonds (3.4 and 3.9 Å) to the oxygen atoms of aspartic acid 89 at the bottom of the recognition pocket, but good hydrogen bonds (2.8 and 2.9 Å) to the C=O group of glycine 218 and the water molecule O2. Other possible conformations of the guanidinium group were examined, but were found to be less favorable. These nonoptimal hydrogen bonds of inhibitor **8** may explain its rather moderate activity.

thrombin. This guanidinohexose binds without direct contact to the active site serine ("inhibitor binding mode"[15]). The naphthyl residue binds in the D-pocket,[16] and the benzyl group in the P-pocket. The guanidinium moiety is found in the recognition pocket as expected (Figure 1). Thus, guanidinohexoses can indeed function as arginine mimetics. Analogous use of aminohexoses as conformationally restricted lysine mimetics might be envisaged. An advantage of this approach is that these readily accessible hexose derivatives may serve as templates,[17, 18] due to their high natural functionalization, for the introduction and variation of other functional groups.

[14] Crystals of the complex of human thrombin with **8** were prepared, and data measured to 3.3 Å resolution and processed as described [7, 16]. With initial atomic coordinates from the best available thrombin structure, the difference electron density clearly showed the inhibitor bound in the active site. The structure was refined with tight geometrical constraints to $R = 0.126$ with standard deviations of 0.011 Å for bond lengths, 1.88° for bond angles, and 1.96° for torsion angles relative to standard parameters [19].

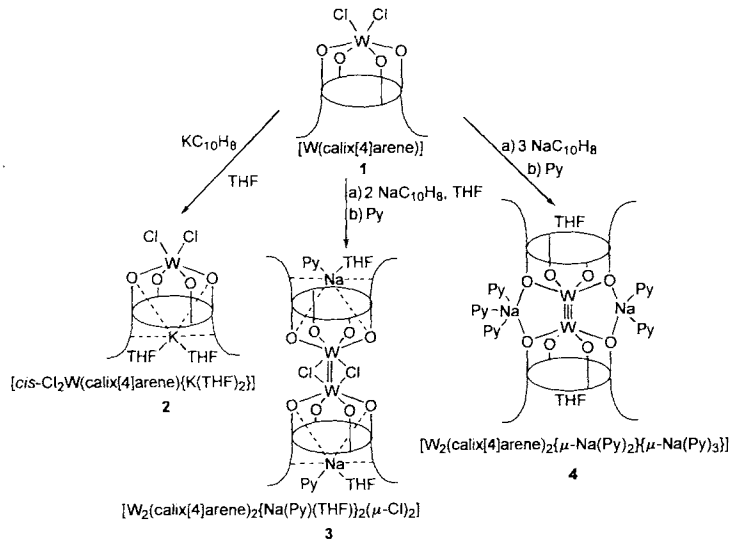
Metal–Metal Multiple Bonds Formed Across Two Tungsten-Calix[4]arenes by a Reductive Coupling Reaction**

Luca Giannini, Euro Solari, Antonio Zanotti-Gerosa, Carlo Floriani,* Angiola Chiesi-Villa, and Corrado Rizzoli

The importance of metal–metal multiple bonds has been exhaustively covered in the classic book by Cotton and Walton.[1] The chemistry of these functional groups is strongly dependent on the nature of the ligand donor atoms and the coordination geometry. This is particularly true in the chemistry of the Group 6 metal–metal bond supported by alkoxo groups.[1, 2] Here we consider the calix[4]arene tetraanion as the supporting ligand.[3, 4]

Our entry into this area[5] was through the reduction chemistry of the parent compound [*cis*-Cl_2W(calix[4]arene)] (**1**).[4b] The formation of the geometrical isomer [*trans*-Cl_2W(calix[4]arene)] by Lewis acid catalyzed isomerization of **1** must be avoided in these experiments.[6] Complex **1** undergoes controlled reduction according to Scheme 1.



Scheme 1. Py = pyridine.

The results summarized in Scheme 1 apply for the conditions detailed for **3** and **4**. We have not investigated all variables (nature of the reducing agent, solvent, stoichiometric ratio) that affect the reduction processes. Each of the three reduction pathways shown in Scheme 1 led to structurally and chemically novel compounds. When the reduction was carried out with a K:W molar ratio of 1:1, the paramagnetic tungsten(v) derivative **2** was obtained. It does not differ greatly in its structure from the parent compound **1**, except for the unusual complexation of K^+ inside the calix[4]arene cavity, whereby the alkali metal cation is partially solvated by the π-donor cavity.[7–9] Increasing the reducing agent to tungsten ratio to 2:1 and using naphthalene-sodium led to a W≡W bonded metallacalix[4]arene (**3**), X-ray quality crystals of which were obtained by recrystallization from pyridine/THF. Figure 1 shows the structure of the centrosymmetric dimer **3**.[10]

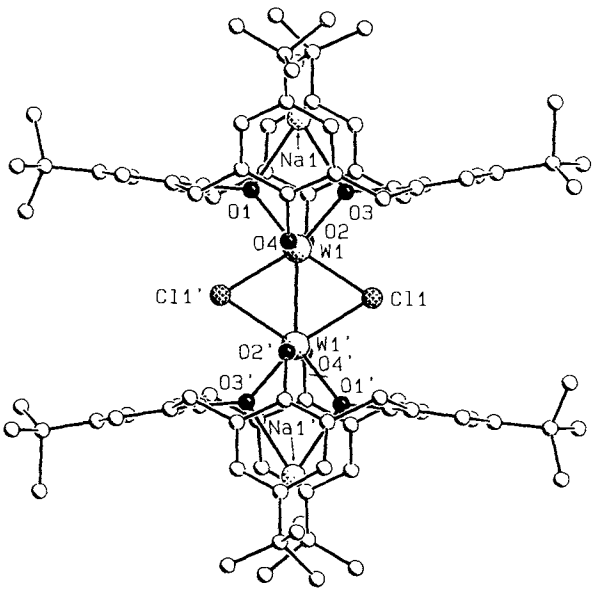


Figure 1. SCHAKAL view of complex **3**. Selected interatomic distances [Å]: W1–W1′ 2.614(1), W1–Cl1 2.430(3), W1–Cl1′ 2.433(3), W1–O1 2.004(7), W1–O2 1.976(8), W1–O3 2.010(8), W1–O4 1.985(8), Na1–O1 2.344(8), Na1–O3 2.346(11), Na1–O5 2.446(14), Na1–N1 2.432(17). Selected bond angles [°]: Cl1-W1-Cl1′ 115.0(1), Cl1-W1-O3 83.1(3), Cl1-W1-O1 161.3(2), Cl1′-W1-O1 83.7(2), Cl1′-W1-O3 162.0(2), O2-W1-O4 168.8(3), O1-W1-O3 78.2(3), W1-Cl1-W1′ 65.0(1). Disordered atoms have been omitted for clarity. Prime denotes a transformation of $-x, -y, -z$. Solvent molecules around Na have been omitted.

The sixfold coordination of the metal atom removes the planarity of the O_4 set of donor atoms and the cone conformation of the calix[4]arene, the opposite C1 ··· C6 and C15 ··· C20 rings being nearly parallel to each other [dihedral angle 16.7(4)°] and to the reference plane C7,C14,C21,C28 [dihedral angles 173.0(3) and 170.3(3)°]. The sodium cation, which is solvated by O1, O3, THF, and Py, is in addition η^3-bonded to the C22 ··· C27 arene [Na ··· C22, 3.228(14); Na ··· C26, 3.213(13); Na ··· C27, 3.094 Å].[7–11] Complex **3** can be regarded as a NaCl carrier in hydrocarbon solvents. Both **2** and **3** display a novel sequestering mode of the alkali cation by the calix[4]arene cavity.[8, 9] The structural parameters of the core of the dimer lie in the normal range, with W≡W [2.614(1) Å],[12] W–Cl [W–Cl1, 2.430(3); W–Cl1′, 2.433(3) Å] and W–O [W–O_{av}, 1.995(8) Å] bond lengths longer than those of **1** [W–Cl, 2.319(2) Å; W–O_{av}, 1.870(4) Å]. Reduction of **1** with three equivalents of naphthalenesodium, or reduction of **3** with one equivalent, gave the dimer **4** (Figure 2).[13]

The complex has *m* symmetry and, as expected for complexes with five-coordinate metal atoms, the calix[4]arene exhibits the cone conformation. The metal is displaced 0.316(1) Å from the planar O_4 core, and the W–W axis forms a dihedral angle of 4.5(2)° with the normal to the O_4 plane. The coordination environment of the W≡W unit is a tetragonal prism, in which the tungsten atoms lie in the center of two faces, and the dihedral angle between the two O_4 planes is 9.0(2)°. The structural parameters are within the normal range. The W–W distance of

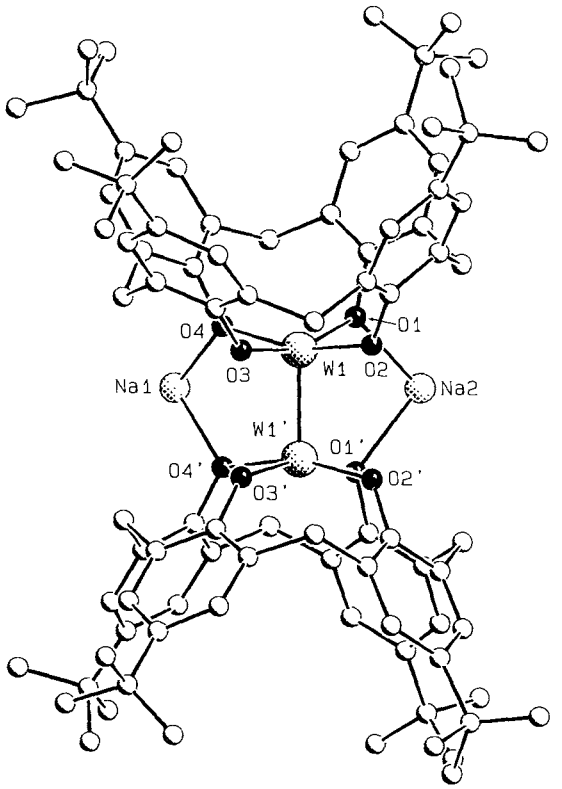

Figure 2. SCHAKAL view of complex **4**. Selected interatomic distances [Å]: W1–W1′ 2.313(1), W1–O1 2.018(5), W1–O2 1.958(5), W1–O3 1.937(5), W1–O4 2.016(5), Na1–O4 2.279(7), Na2–O1 2.356(7), Na2–N3 2.586(16), Na2–N4 2.545(15). Selected bond angles [°]: O3-W1-O4 87.5(2), O2-W1-O4 162.6(3), O2-W1-O3 88.9(2), O1-W1-O4 87.7(2), O1-W1-O3 160.6(3), O1-W1-O2 90.1(2). Disordered atoms have been omitted for clarity. Prime denotes a transformation of $x\cdot 0.5-y\cdot z$. Solvent molecules around Na have been omitted.

2.313(1) Å is consistent with a metal–metal triple bond.[14] Our current investigations are focused on a) freeing the M–M core of bridging ligands, which would render **3** and **4** accessible to reactivity studies; b) using the dimers **3** and **4** as building blocks for supramolecular aggregates;[15] and c) exploiting the complexation of alkali metal cations by metallocalix[*n*]arenes, as found in complexes **3** and **4**. In this context we will elaborate the strategy for shaping the cavity of calix[4]arene in order to bind organic and inorganic cations inside and use these compounds as alkali metal cation carriers in hydrocarbon media, the calix[4]arene cavity being a very hydrophobic environment.

Experimental Section

3: A solution of $NaC_{10}H_8$ (45 + 6.5 + 3 mL, 0.315 M, total 17.2 mmol) in THF was added dropwise to a THF (100 mL) suspension of $\mathbf{1}\cdot 3C_6H_6$ (7.95 g, 7.01 mmol) between −60 °C and room temperature to give a suspension of a yellow solid in a green solution. The mixture was heated to reflux for 2 h and then allowed to stand at room temperature for 12 h. The solid was extracted with THF (100 mL) for 2 d to give a yellow suspension. The solid was collected and dried in vacuo (2.91 g, 37.5%). Elemental analysis for $\mathbf{3}\cdot 2THF$, $C_{112}H_{152}Cl_2Na_2O_{14}W_2$ calcd (found): C 60.95 (61.04), H 6.94 (7.20). ^{1}H NMR ([D$_5$]pyridine, 323 K): $\delta = 7.22$ (s, ArH), overlapping with [D$_5$]pyridine signal, 7.03 (s, 4H, ArH); 4.93 (d, $J = 13.7$ Hz, 4H, *endo*-CH_2); 3.65 (m, 12H, THF); 3.46 (d, $J = 13.7$ Hz, 4H, *exo*-CH_2); 1.64 (m, 12H, THF); 1.29 (s, 18H, *t*Bu); 0.98 (s, 18H, *t*Bu). The solid recrystallized from py/THF gave crystals of $\mathbf{3}\cdot 1.6$ py$\cdot 0.2$ THF (a different solvated form) suitable for X-ray analysis.

4: A solution of $NaC_{10}H_8$ (50.5 mL, 0.315 M, 15.9 mmol) in THF was added dropwise to a suspension of $\mathbf{1}\cdot 3C_6H_6$ (6.00 g, 5.29 mmol) in THF (200 mL) at −30 °C. The resulting green mixture was allowed to warm to room temperature over 12 h, then heated to reflux (3 h). NaCl was filtered off to give a green solution which was concentrated in vacuo to ca. 80 mL, and finally pyridine (80 mL) was added. The resulting suspension was heated to reflux (1 h). Standing at room temperature for 6 h gave green crystals of **4**, which were collected and dried in vacuo (3.94 g, 68.8%). Drying in vacuo removed one pyridine of solvation. Elemental analysis for **4**, $C_{116}H_{140}N_4Na_2O_{10}W_2$ calcd (found): C 64.38 (64.40), H 6.52 (6.65), N 2.59 (2.70). ^{1}H NMR ([D$_3$]acetonitrile, 298 K): $\delta = 8.48$ (m, 4H, py); 7.64 (m, 2H, py); 7.23 (m, 4H, py); 6.97 (s, 8H, ArH); 4.77 (d, $J = 11.2$ Hz, 4H, *endo*-CH_2); 3.55 (m, 4H, THF); 3.05 (d, $J = 11.2$ Hz, 4H, *exo*-CH_2); 1.71 (m, 4H, THF); 1.06 (s, 36H, *t*Bu).

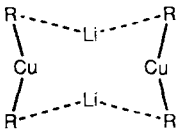
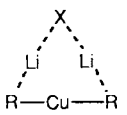
Determination of the Degree of Aggregation of Organocopper Compounds by Cryoscopy in Tetrahydrofuran**

Andreas Gerold, Johann T. B. H. Jastrzebski, Claudia M. P. Kronenburg, Norbert Krause,* and Gerard van Koten*

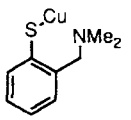
Organocopper compounds belong to a class of frequently used organometallic reagents in organic synthesis, because they are readily accessible and exhibit high reactivities and selectivities for the formation of C–C bonds. This bond formation occurs by (stoichiometric or catalytic) substitution, addition, or carbocupration reactions.[1] In contrast to the overwhelming number of preparative applications, however, little is known about the reaction mechanisms[2] or structures of the organocopper species involved.[3] Whereas monoorganocopper compounds are usually aggregates to some degree, polyorganocuprates mostly exist as discrete species in the solid state, and dimeric complexes of type **1** are frequently observed.[3]



1



2



3

For the preparative application of these reagents, information on the solution structure is highly relevant but currently scarce. Spectroscopic investigations by NMR spectroscopy have revealed the existence of equilibria between a number of different organocopper species in solution.[4] The aggregation behavior of these cuprates has only been examined for lithium dimethylcuprate (Me_2CuLi). This compound has been shown to exist as a dimer (probably also of type **1**) by ebullioscopy and vapor pressure measurements in ethereal solvents.[5] The structures of cyanocuprates of the stoichiometry $R_2Cu(CN)Li_2$ (from two equivalents of RLi and one equivalent of CuCN), which were introduced by Lipshutz fifteen years ago,[1b–d] are particularly controversial. The high reactivity of these reagents was initially explained by the assumption that the cyanide ion was bound to the Cu center as a third carbon substituent to form a "higher order" cyanocuprate ($[R_2Cu(CN)]^{2-} + 2\ Li^+$). The structures of cyanocuprates in the solid state are still unknown, and investigations by NMR spectroscopy provided contradictory conclusions about the nature of the complexes in solution.[6] It was later shown by EXAFS and XANES spectrocopy that most of the Cu atoms (more than 90%) in cuprates formed from two equivalents of MeLi or *n*BuLi and one equivalent of CuCN do not contain a coordinated cyanide ligand.[7] Ab initio calculations for $[Me_2Cu(CN)Li_2]$ have also pointed to species **2** (R = Me, X = CN) as the most stable structure, that is, one without a Cu–CN bond but instead containing a lithium-coordinated cyanide ion.[7c, 8] One possible explanation for the discrepancy between the structural and reactivity studies is that the thermodynamically most stable complex is not the kinetically most reactive one. The work detailed above only helps to underline the necessity of gathering further information about the structures of organocopper compounds in solution. To this end, the examination of the aggregation behavior of cuprate reagents in tetrahydrofuran (THF) by cryoscopy should provide some insight into this important area of organometallic chemistry. The conditions used here to examine the copper species are very similar to those used in the preparative application of the reagents. Investigations of this kind have been carried out successfully with a number of organolithium compounds[9] but not with organocopper complexes.

After the determination of the cryoscopic constant E_k of THF for the apparatus (see Experimental), the degrees of aggregation n[10] of several organolithium reagents used in this work were determined. These values are in good agreement with those found in the literature (Table 1); thus for MeLi values for n between 3.89 and 4.20 were observed (in ref. [9a] 4.37) whereas monomeric *t*BuLi gave values of 1.15–1.20 (in ref. [9b] 1.1). In a similar way, phenyllithium was shown to exist not as single species in THF but rather as a 2:1 mixture of dimer and monomer, as reported previously.[9a] These results firmly establish the validity of our experimental protocol to be used in the organocopper case.

Table 1. Cryoscopic investigation of organocopper and organolithium compounds in THF.

Substrate	c_{nom} [mmolal]	$n = c_{nom}/c_{exp}z$
$[MeLi]_n$	90.9–150.9	3.89–4.20 [9a]
$[t\text{BuLi}]_n$	78.1–151.5	1.15–1.20 [9b]
$[PhLi]_n$	27.4–88.2	1.63 [9a]
$[Me_2Cu(I)Li_2]_n$	45.5–75.5	0.95–1.03
$[MeCu(CN)Li]_n$	27.0–113.0	[a]
$[t\text{BuCu(CN)Li}]_n$	70.4	1.05
$[PhCu(CN)Li]_n$	88.2	2.00
$[Me_2Cu(CN)Li_2]_n$	35.2–72.9	1.08–1.19
$[t\text{Bu}_2\text{Cu(CN)Li}_2]_n$	46.0–75.7	0.74–0.76 [b]
$[Ph_2Cu(CN)Li_2]_n$	25.5	1.18
$[t\text{Bu}(i\text{Pr}_2\text{N})\text{Cu(CN)Li}_2]_n$	51.3	0.97 [c]
3	13.7–41.1	0.95–1.06

[a] The degree of aggregation could not be determined because some of the cuprate precipitated prior to crystallization of the solvent. [b] See text. [c] After taking into account the formation of 1 equiv $(CH_3)_3CH$ from the reaction of *t*BuLi with $i\text{Pr}_2\text{NH}$.

The Gilman cuprate $[Me_2CuLi]_n$ (+ LiI) was formed by the addition of 0.5 equivalents of CuI to a cold MeLi solution. The degree of aggregation determined by cryoscopy gave a value of $n = 0.95–1.03$ when taking into account that two molecules of MeLi are bound in the cuprate (i.e., $z = 2$[10]). This neutral species exists as a monomer in THF, and the LiI formed during its preparation is bound to this complex, which therefore has the stoichiometry $[Me_2Cu(I)Li_2]$. This finding is in agreement with the experimental observation that the chemical reactivity of Gilman cuprates depends on the presence of a lithium salt.[11] In contrast to our experiment, the salt-free cuprate was used in the earlier determination of the aggregation state of Me_2CuLi,[5] and this exists as a dimer in solution. The related Gilman cuprate $t\text{Bu}_2\text{CuLi}$ could not be examined here, because its low

thermal stability results in considerable decomposition during the preparation of this reagent. Similarly, the aggregation state of the "lower order" cyanocuprate $[MeCu(CN)Li]_n$ (prepared by the addition of one equivalent of CuCN) could not be measured because of the inherent low solubility of this complex in cold THF. For the analogous reagents $[RCu(CN)Li]_n$, however, values of $n = 1.05$ and $n = 2.00$ were determined for R = *t*Bu and Ph, respectively. This indicates that these cyanocuprates exist as discrete monomeric and dimeric species in THF solution. In accordance with previous studies[1b-d, 6] the cyanide is probably bound to these aggregates, because free LiCN would precipitate during cooling due to its known low solubility in cold THF. The formation of a precipitate was not observed with these reagents under the conditions used.

The degree of aggregation was also found to depend on the nature of the R group for the "higher order" cyanocuprates $R_2Cu(CN)Li_2$ (formed from 1.0 equiv of RLi and 0.5 equiv of CuCN). Values of $n = 1.08-1.19$ and 1.18 were measured for R = Me and Ph, respectively, indicating that these cuprates are monomers in THF. In contrast, values of n between 0.74–0.76 were determined when R = *t*Bu. The degree of aggregation of $n \approx 0.75$ for $[tBu_2Cu(CN)Li_2]_n$ ($z = 2$) corresponds to a $c_{nom}/c_{exp} \approx 1.5$ (with regard to the *t*BuLi used). This result suggests an equilibrium between a "higher order" and a "lower order" cyanocuprate in solution according to Equation (a).

$$[R_2Cu(CN)Li_2]_n \underset{}{\overset{K}{\rightleftharpoons}} [RCu(CN)Li]_o + [RLi]_p \qquad (a)$$

Both species [*t*BuCu(CN)Li] and *t*BuLi[9b] are known to be monomeric in THF (Table 1). Therefore, assuming that the cuprate $[tBu_2Cu(CN)Li_2]_n$ also exists as a monomer, a value of $c_{nom}/c_{exp} = 1.5$ is calculated with an equilibrium constant K of 0.5. Unfortunately, our attempts to show the presence of the "lower order" species [*t*BuCu(CN)Li] in a [D_8]THF solution of the "higher order" cuprate by low temperature ^{13}C NMR spectroscopy were unsuccessful. Only one cyanide resonance for $[tBu_2Cu(CN)Li_2]$ was observed in the ^{13}C NMR spectrum at $\delta \approx 160$, whereas cyanide signals at $\delta \approx 150$ are typical for [RCu(CN)Li].[6, 12] Thus, if an equilibrium according to Equation (a) does exist, a rapid exchange on the NMR time scale between two copper species must take place.[13]

Finally, the aggregation behavior of two other organocopper compounds in THF was examined. These were the amidocuprate $[tBu(iPr_2N)Cu(CN)Li_2]_n$ and the copper arenethiolate **3**. Amidocuprates obtained by the formal replacement of one carbon group of a homo- or cyanocuprate by a chiral amide ligand are particularly interesting for applications in enantioselective Michael additions.[1, 14] Therefore, as a model of these reagents, the cuprate formed from one equivalent each of *t*BuLi, iPr_2NLi, and CuCN were examined. The complex is present as a monomeric species in THF ($n = 0.97$) and there is no evidence of an equilibrium according to Equation (a). The copper arenethiolate **3** is an important catalyst for both Michael additions and S_N2' substitution reactions.[1, 2h, 15] It also exists mostly as a monomer in THF ($n = 0.95-1.06$). The free coordination sites at the copper center are probably occupied by THF molecules (Cu-S-Cu bridges are formed in the absence of this donor, and **3** exists as a trimeric aggregate in the solid state and in nonpolar solvents[3, 16]).

To summarize the results of this study, cryoscopy is an excellent method for the determination of the aggregation behavior of organocopper reagents in THF solution. The "lower order" cyanocuprates of the stoichiometry RCu(CN)Li formed from one equivalent each of RLi and CuCN have been shown to exist as discrete monomeric (R = *t*Bu) or dimeric (R = Ph) species. The latter might possess a structure of type **1** with alternating Ph and CN bridges. In a similar way, we have shown for the first time that the Gilman cuprate $[Me_2Cu(I)Li_2]_n$ is present in THF solution as a monomer with coordinated iodide (in contrast to the salt-free cuprate), and the same is true for the cyanocuprates $[R_2Cu(CN)Li_2]$ (R = Me, Ph) and the amidocuprate $[tBu(iPr_2N)Cu(CN)Li_2]$.

Cryoscopic measurements cannot be used to determine whether the ligand X = I or CN associated with the reagents of the stoichiometry $R_2Cu(X)Li_2$ is coordinated to Cu[1b-d, 6b, e] or Li.[6a, c, 7, 8] Also, this method provides information about the thermodynamically most stable complex only, which may differ from a kinetically active species that is involved in the reactions of these compounds. The solid-state structure of a neutral aggregate related to the cuprates $[R_2Cu(X)Li_2]$ was reported recently. The copper complex $[\{C_6H_4(CH_2N(Me)CH_2CH_2NMe_2)\text{-}2\}_2Cu_3Br]$ contains a Cu-Br-Cu bridge (Figure 1).[3, 16] By analogy, the organocopper compounds found in this work to be monomeric might adopt a similar structure of type **2** with a Li-X-Li bridge in the thermodynamically most stable form. This structure is therefore a reasonable alternative to the well-known dimeric structures of type **1**.

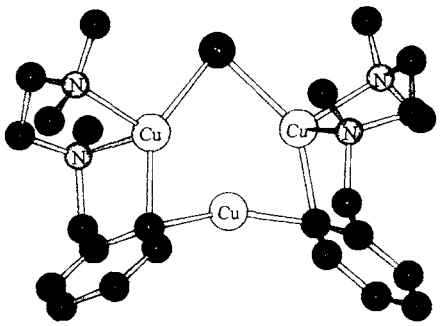

Figure 1. Solid-state structure of $[\{C_6H_4(CH_2N(Me)CH_2CH_2NMe_2)\text{-}2\}_2Cu_3Br]$ [3,16] (hydrogen atoms were omitted for clarity).

Experimental

The cryoscopic measurements were conducted under nitrogen in a double-walled Schlenk flask. The temperature was determined with a F25 precision thermometer provided with a glass-mantled Pt-100 sensor (±0.005 K), or with an S2541 thermolyzer and a metal-mantled Pt-100 sensor (±0.01 K). THF (23.7–28.3 g) was weighed into the flask and cooled by immersion into liquid nitrogen. By application of vacuum or a stream of gaseous nitrogen to the outer part of the double-walled flask, the cooling rate was controlled to about 10 K min^{-1} down to 150 K and to 1.2–1.5 K down to the freezing point. The cooling curve was recorded with a *RE-511 recorder*.

For the calibration, naphthalene was added in the form of weighed tablets, and the freezing point of the solutions thus obtained was determined. Repetition of this procedure with different amounts of naphthalene gave the following cryoscopic constants: $E_k = 5.187$ K kg mol^{-1} for the F25 precision thermometer and $E_k = 2.245$ K kg mol^{-1} for the S2541-thermolyzer (ref. [9a]: $E_k = 1.874$ K kg mol^{-1}) [17].

Solid MeLi and *t*BuLi were obtained by removal of the solvent from commercially available solution in diethyl ether or pentane, respectively. Phenyllithium was prepared according to a published procedure [9a]. The addition of the organolithium reagents as weighed tablets took place under a nitrogen atmosphere to the precooled apparatus (170 -210 K). After dissolution, the freezing point was determined (three repetitions), and care was taken to observe whether the organolithium compound remained in solution completely prior to its crystallization. The same procedure was applied to copper arenethiolate **3**.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3607-0756 $ 17.50+.50/0

The cuprates were formed by addition of weighed tablets of CuI or CuCN to the precooled (170–210 K) solutions of the organolithium reagents. After complete dissolution of the copper salt (occasionally with slight warming), the freezing point was determined as above. In the case of the amidocuprate [*t*Bu(*i*Pr$_2$N)Cu(CN)Li$_2$], one equivalent of diisopropylamine was added prior to CuCN.

[17] The dependence of the cryoscopic constants on the thermometer may be attributed to different heat conductabilities and immersion depths of the sensors used.

Total Synthesis of (−)-Epothilone B: An Extension of the Suzuki Coupling Method and Insights into Structure–Activity Relationships of the Epothilones**

Dai-Shi Su, Dongfang Meng, Peter Bertinato, Aaron Balog, Erik J. Sorensen, Samuel J. Danishefsky,* Yu-Huang Zheng, Ting-Chao Chou, Lifeng He, and Susan B. Horwitz

Recently, synthetic studies directed to epothilone A (**3**)[1, 2] culminated in its first total synthesis.[3–5] Our synthesis passed through the *Z*-desoxy compound (**4**), which underwent highly stereoselective epoxidation with 2,2-dimethyldioxirane, under carefully defined conditions, to yield the desired β-epoxide. The same myxobacterium of the genus *Sorangium* that produces **3** also produces epothilone B (**1**). The latter is significantly more potent than **3** both in antifungal screens and in cytotoxicity assays in some cell lines.[6, 7] Clearly then, there was a strong rationale for preparing epothilone B (**1**).

Our interim goal structure was desoxyepothilone B (**2**) or a suitable derivative thereof. With access to such a compound, we could investigate the regio- and stereoselectivity of the epoxidation of the C12–C13 double bond. Not the least interesting issue in the project was the synthesis of *Z*-trisubstituted olefinic precursors of **2** with high margins of stereoselection. In our synthetic route to epothilone A[3] we had employed a palladium-mediated B-alkyl Suzuki coupling[8, 9] of the *Z*-vinyl iodide **5** with borane **7** derived from hydroboration of compound **6** with 9-BBN (Scheme 1).

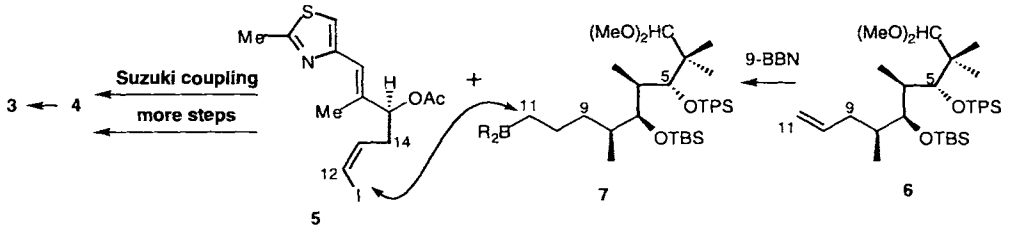

Scheme 1.

Naturally, our first instinct was to apply the same line of thinking to reach a *Z*-trisubstituted olefin en route to **2**. Here, two serious issues had to be addressed. First, it would be necessary to devise a method to prepare vinyl iodide **8**, the trisubstituted analog of **5**. If this goal could be accomplished, we would still face the challenge of conducting the required B-alkyl Suzuki coupling reaction to reach a *Z*-trisubstituted olefin. Such an intermolecular transformation, with a B-alkyl as opposed to a B-alkenyl group, and where the vinyl iodide is not partof a *β*-iodoenoate (or *β*-iodoenone), was not precedented.[10]

We first dealt with the synthesis of compound **8** (Scheme 2). Our route started with olefin **10**, which was prepared[4] by catalytic asymmetric allylation of **9**[11] followed by acetylation. Site-selective dihydroxylation of **10** followed by oxidative cleavage of the glycol generated the unstable aldehyde **11**. Remarkably, **11** reacted with phosphorane **12**[12] (preparation shown at the bottom of Scheme 2) to afford the *Z*-iodide **8** albeit in modest overall yield. Borane **7** was generated from **6** as previously described.[3] Gratifyingly, the coupling of compound **7** and iodide **8** could be conducted to produce the pure *Z*-olefin **13**.

With compound **13** in hand, we apply protocols similar to those employed in the synthesis of **4**.[3] Thus, hydrolysis of the acetal linkage led to aldehyde **14**, which was now subjected to macroaldolization (Scheme 3). The highest yield of aldol product was obtained by carrying out the reaction under conditions that produced a 1.5:1 mixture of *α*/*β* epimers at C3. Fortunately, we could convert the 3*R* isomer to the required 3*S* epimer by reduction of its derived C3 ketone (→**15**).[13] Cleavage of the C5 triphenylsilyl ether was followed sequentially by monoprotection (*tert*-butyldimethylsilyl) of the C3 hydroxyl group, oxidation at C5 (→**16**) and, finally, cleavage of the silyl protecting groups to expose the C3 and C7 hydroxyl groups (→**2**).

Z-Desoxyepothilone B (**2**) does indeed undergo very rapid and substantially regio- and stereoselective epoxidation[14] to afford epothilone B (**1**), which is identical with an authentic sample (^{1}H NMR, MS, IR , $[\alpha]_D$). Thus, the first total synthesis of (−)-epothilone B has been accomplished.

In retrospect, the total synthesis carries with it several important teachings. Certainly, the stereospecific preparation of the vinyl iodide **8** by use of the rarely employed phosphorane **12**, even with the unstable *β*-acetoxyaldehyde **11** could not have been predicted.[12] Moreover, the successful Suzuki coupling to construct the trisubstituted *Z*-double bond constitutes an important extension of the prior art.[10, 15] Finally, the highly regio- and stereoselective epoxidation of *Z*-desoxyepothilone B (**2**) with dimethyldioxirane was highly gratifying.

With epothilone B (**1**) and its *Z*-12,13-desoxy precursor (**2**) in hand through total synthesis, we were in a sound position to explore their biological activities. Also available to us from our previous studies[3, 4] were epothilone A (**3**), its *Z*-12,13-desoxy precursor **4**, and the *E* variant (**17**) of the latter. Through an alternative

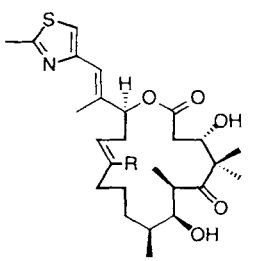
route we also gained access to the *E* compound in the B series (**18**).[16] All of these compounds manifested the ability to bind to microtubules in the absence of guanosine triphosphate (GTP), biological activity reminiscent of that of Taxol™.[17]



R = H, *trans*- desoxyepothilone A **17**
R = Me, *trans*- desoxyepothilone B **18**

They also manifest high levels of cell killing as seen in Table 1. By the cytotoxicity standard, the trisubstituted compounds **1** and **2** outperform their disubstituted counterparts **3** and **4**. The desoxy compounds **2** and **4** are comparable and, in some instances, superior to the natural products (**1** and **3**). In this regard it is interesting that though **18** is still quite active, it is significantly less potent than the corresponding *Z* systems **2** and **4**, and the disubstituted *E* system **17**.

All proposals addressed to the pharmacological modeling of the epothilones must now take notice of these interesting structural findings. Certainly they are of significant consequence in our own analog strategy program, which is well underway.

Table 1. Relative efficacy of epothilone compounds against drug-sensitive and resistant CCRF-CEM cell lines [a].

Compound	CCRF-CEM IC_{50} [μM] [b]	CCRF-CEM/VBL IC_{50} [μM] [b]	CCRF-CEM/VM_1 IC_{50} [μM] [b]
epothilone A (**3**)	0.003	0.020	0.003
desoxyepothilone A (**4**)	0.022	0.012	0.013
trans-desoxy A **17**	0.052	0.035	0.111
epothilone B (**1**)	0.0004	0.003	0.002
desoxyepothilone B (**2**)	0.009	0.017	0.014
trans-desoxy B **18**	0.090	0.262	0.094
Taxol™	0.002	3.390	0.002

[a] The cytotoxicities of test compounds were determined by the growth of human lymphoblastic leukemic cells CCRF-CEM or their sublines resistant to vinblastine and taxol (CCRF-CEM/VBL) or resistant to etoposide (CCRF-CEM/VM-1). XTT-microculture tetrazolium/formazan assays [18] were used. [b] The IC_{50} values were calculated based on five or six assays at various concentrations; a median-effect plot [19] was generated with computer software [20].

[13] The stereochemically controlled aldol condensation giving a product with the natural 3*S* configuration as previously described in the epothilone A series [3] was accomplished. However, the overall yield for reaching the 3*S* epimer is better with the protocol described here.
[14] Although precise comparisons are not available, the epoxidation of **2** appears to be more rapid and regioselective than that of **4** [3].
[15] To the best of our knowledge, this is the first successful Suzuki coupling between a B-alkyl system and an unconjugated, trisubstituted alkene.
[16] Compound **18** was prepared by a stereorandom olefin metathesis route which also led to **2**. These geometric isomers could be separated only with great difficulty. Details of the nonstereoselective route will be provided in a subsequent fuller disclosure.
[17] Experiments conducted by Dr. Susan Horwitz at the Albert Einstein College of Medicine, Bronx, NY (USA): Microtubule protein (MTP) was purified from calf brains by two cycles of temperature-dependent assembly and disassembly [21]. In control assembly experiments, MTP (1 mg mL^{-1}) was diluted in assembly buffer containing 0.1 M MES (2-(*N*-morpholino)ethanesulfonic acid), 1 mM EGTA (1,2-di(2-aminoethoxy)ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid), 0.5 mM $MgCl_2$, 1 mM GTP, and 3 M glycerol, pH 6.6. The concentration of tubulin in MTP was estimated to be about 85%. Assembly was followed spectrophotometrically at 350 nm, 35 °C for 40 min, by monitoring changes in turbidity as a measure of polymer mass [22]. Drugs were tested at a concentration of 10 μM in the absence of GTP. Microtubule formation was verified by electron microscopy. To determine the stability of microtubules assembled in the presence of GTP or drug, turbidity was monitored for 40 min after the reaction temperature was shifted to 4 °C.

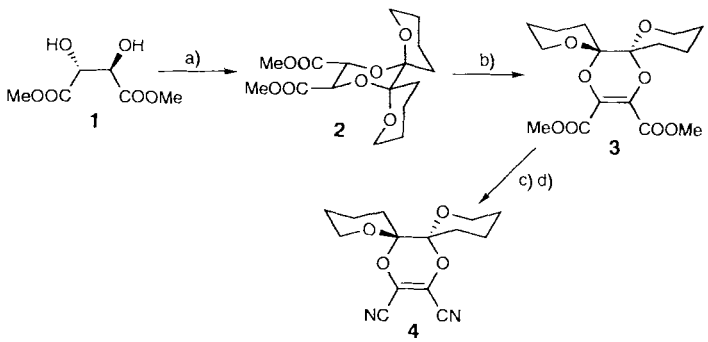
Enantiomerically Pure "Winged" Spirane Porphyrazinoctaols**

Andrew S. Cook, D. Bradley G. Williams, Andrew J. P. White, David J. Williams, Steven J. Lange, Anthony G. M. Barrett,* and Brian M. Hoffman*

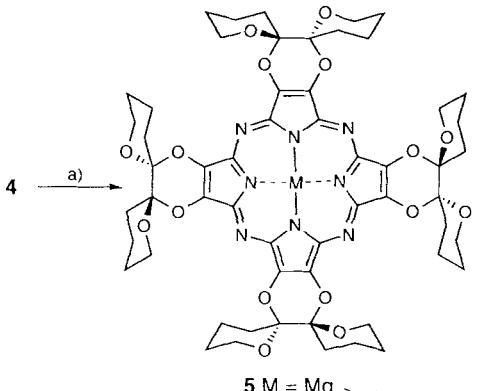
Dedicated to Professor Dieter Seebach on the occasion of his 60th birthday

Herein we report the first synthesis of porphyrazinoctaol derivatives—the enantiomerically pure, "winged" spirane porphyrazines—through the use of a simple, reliable strategy based on the Ley dispoke protection procedure.[1] We earlier described the synthesis of porphyrazinoctathiol derivatives by macrocyclization of 2,3-bis(benzylthio)maleonitrile with magnesium propoxide in propanol,[2] their transmetalation, and reductive debenzylation.[3] The octathiol thus obtained exhibited diverse coordination chemistry. Complexes were isolated with four metal cations peripherally bonded to the eight thiolate residues by either bidentate (S–S) or tridentate (S-*meso*-N–S) coordination, in addition to internal metal–ion complexation. These *star* porphyrazines readily lend themselves to the study of indirect metal–metal interactions through the porphyrazine π system and are unique in that the binding mode may be selected at will. We subsequently reported the synthesis and characterization of various porphyrazinoctamine derivatives as well as the formation of charge-transfer complexes with tetracyanoquinodimethane (TCNQ) and C_{60}.[4] This paper presents the synthesis of chiral porphyrazines **5** and **6**.[5]

Reaction of excess L-(+)-dimethyl tartrate (**1**) with 3,3′,4,4′-tetrahydro-6,6′-bi-2*H*-pyran (bis-DHP)[1,6] in diethyl ether in the presence of hydrogen chloride gave the dispiroketal **2** in a 60% yield (Scheme 1). Strong anomeric effects dominate the stereochemical outcome of the reaction under thermodynamic conditions, which gives rise to only one diastereoisomer of **2**.[1,7] The chirality inherent in the tartrate induces sterogenicity at the ketal centers and results in a product in which the methoxycarbonyl moieties are equatorial. Monoiodination, followed by base-mediated *anti*-dehydroiodination, afforded chiral alkene **3** (53%). Amide formation and dehydration proceeded smoothly to give dinitrile **4** in 77% overall yield. A solution of **4** and magnesium propoxide in propanol under reflux provided the magnesium porphyrazine **5** in 45% yield. Strong acids such as trifluoroacetic acid rapidly demetalated **5**; unfortunately these conditions also caused degradation of the macrocycle. However, reaction with glacial acetic acid resulted in clean demetalation without epimerization and production of the D_2-symmetric, enantiomerically pure porphyrazine **6** (Scheme 2).



Scheme 1. a) Bis-DHP, HCl, Et_2O, 0 °C, 16 h; b) lithium 2,2,6,6-tetramethylpiperidide, THF, −78 °C, then I_2 in THF, −78 °C ⟶ 0 °C; c) NH_3, MeOH, 20 °C, 4 d; d) $(CF_3CO)_2O$, pyridine, −30 °C ⟶ 20 °C, 3 h.



Scheme 2. a) $(PrO)_2Mg$, PrOH, 100 °C, 14 h, 45%; b) AcOH, 20 °C, 16 h, 78%.

Confirmation of structure was obtained from a single crystal X-ray determination of **6** (Figure 1).[8] The molecule has noncrystallographic D_2 symmetry; the central core is planar to within 0.08 Å. The presence of hydrogen atoms on the nitrogen centers distorts the potential D_4 symmetry of the non-hydrogen atoms: the transannular porphyrin N···N distances differ by about 0.15 Å. Spectroscopic data for **6** reflect this distortion:[9] its electronic absorption spectrum exhibits a split Q band with peaks at 632 and 554 nm in addition to a less intense peak at 427 nm and the Soret band[10] at 338 nm.

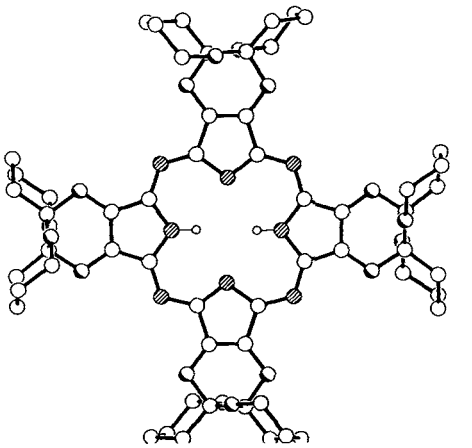


Figure 1. Crystal structure of **6**.

[**] We thank Glaxo Group Research Ltd. for the generous endowment (A.G.M.B.), the Wolfson Foundation for establishing the Wolfson Centre for Organic Chemistry in Medical Science at Imperial College, the Engineering and Physical Sciences Research Council, the National Science Foundation, NATO, the Foundation for Research and Development (South Africa), and Zeneca for generous support of our studies.

The electrochemical properties of **5** and **6** were studied by cyclic voltammetry in dichloromethane.[11] The freebase porphyrazine **6** exhibits one reversible oxidation at $E_{1/2} = +0.73$ V (vs. Fc^+/Fc, Fc = ferrocene; Figure 2). Comparison of the electrochemical properties of **6** with those of $H_2[pz(S\text{-}Et)_8]$[12] and $H_2[pz(Pr)_8]$[13] reveals that all have similar first oxidation potentials (+0.65–0.73 V vs. Fc^+/Fc). In contrast, the $H_2[pz(N\text{-}Me_2)_8]$[4] macrocycle is more easily oxidized by 1.00 V. This is consistent with the primary function of O-alkyl and S-alkyl substituents being σ donors, but of N-alkyl substituents being strong π donors. Compound **6** exhibits reversible ring reductions at $E_{1/2} = -1.22$ and −1.66 V (vs. Fc^+/Fc). Incorporation of a Mg^{II} ion in the porphyrazine core (**5**) broadens the first reduction wave and shifts it by 300 mV to a more negative potential; any second ring reduction is shifted out of the solvent potential window. The ease of reduction of the differently functionalized porphyrazines follows the order: $H_2[pz(S\text{-}Et)_8]$, −0.95 V > $H_2[pz(O\text{-alkyl})_8]$, −1.22 V > $H_2[pz(Pr)_8]$, −1.37 V > $H_2[pz(N\text{-}Me_2)_8]$, −1.61 V. These data are summarized in Table 1.

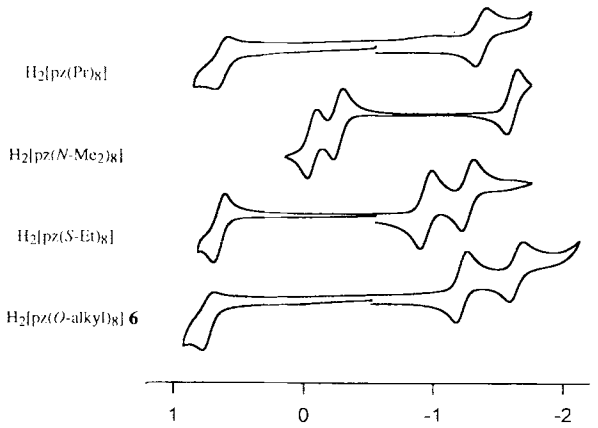

Figure 2. Cyclic voltammograms of **6** and other porphyrazines (potential vs. Fc^+/Fc).

Table 1. Electrochemical data for **6** and other porphyrazines in dichloromethane (potential vs Fc^+/Fc).

Compound	$E_{1/2}(Pz^{2+}/Pz^+)$ (ΔE_p [mV])	$\Delta E_{1/2}(Pz^+/Pz)$ (ΔE_p [mV])	$\Delta E_{1/2}(Pz/Pz^{-1})$ (ΔE_p [mV])	$\Delta E_{1/2}(Pz^{-1}/Pz^{-2})$ (ΔE_p [mV])
5	+1.01 [a]	+0.46 (115)	−1.53 (210)	–
6	+1.09 [a]	+0.73 (90)	−1.22 (100)	−1.66 (125)

[a] A coupled chemical reaction follows the electrochemical step.

We have established a rapid, reliable approach for preparing porphyrazinoctaol derivatives. The simple, high-yielding synthesis represents a convenient entry to enantiomerically pure porphyrazine systems. We are presently investigating the use of such porphyrazines in organic and coordination chemistry. Studies on deprotection and metal-ion complexation of **6** (and related compounds) will be reported in due course.

[8] Crystal data for **6**: $C_{56}H_{66}N_8O_{16}$, $M_r = 1107.2$, orthorhombic, space group $P2_12_12$, $a = 16.895(5)$, $b = 23.715(4)$, $c = 14.396(2)$ Å, $V = 5768(2)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.28$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 7.9$ cm^{-1}, $F(000) = 2344$, $T = 173$ K. A flaky, iridescent, green plate of dimensions $0.27 \times 0.27 \times 0.03$ mm was used. The 3973 independent reflections were measured on a Siemens P4/RA diffractometer with $Cu_{K\alpha}$ radiation (graphite monochromator) and ω scans. The structure was solved by direct methods. Despite collecting the data with copper radiation and a rotating anode operating at 14 kW over a period of several days at reduced temperature, the diffracted intensities were still very weak, and the number of observed data severely limited. Consequently, the 24 non-hydrogen atoms of the porphyrazine core, which are not normally subject to significant anisotropic vibration, were refined isotropically, and only the non-hydrogen atoms of the peripheral substituents were treated anisotropically. Refinement by full-matrix least squares based on F^2 gave $R_1 = 0.078$ and $wR_2 = 0.191$ for 2710 independent observed reflections [$|F_o| > 4\sigma(|F_o|)$, $2\theta \leq 110°$] and 602 parameters. The absolute chirality of the structure could not be determined crystallographically and was assigned on the basis of the known absolute stereochemistry of **1** and the expected stereochemical bias of dispoke protections [1, 7]. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100184. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK, (fax: Int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

[11] Cyclic voltammetric measurements were carried out with a Cypress Systems CS-1087 computer-controlled potentiostat. A single compartment cell was used with a platinum disk working electrode, Ag/AgCl reference electrode, and silver wire auxiliary electrode. Measurements were made in dichloromethane, freshly distilled from calcium hydride, with recrystallized tetra-*n*-butylammonium hexafluorophosphate as supporting electrolyte. Solutions containing approximately 10^{-3} M analyte (0.1 M Bu_4NPF_6) were deaerated for several minutes by purging with nitrogen. Ferrocene was added as an internal reference for all measurements, and all $E_{1/2}$ values were calculated from $(E_{pa} + E_{pc})/2$ at a scan rate of 110 mV s^{-1}.

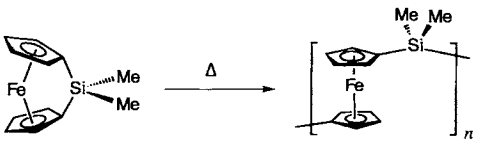
Architectural Control in the Transition-Metal-Catalyzed Ring-Opening Polymerization of Silicon-Bridged [1]Ferrocenophanes**

Paloma Gómez-Elipe, Peter M. Macdonald, and Ian Manners*

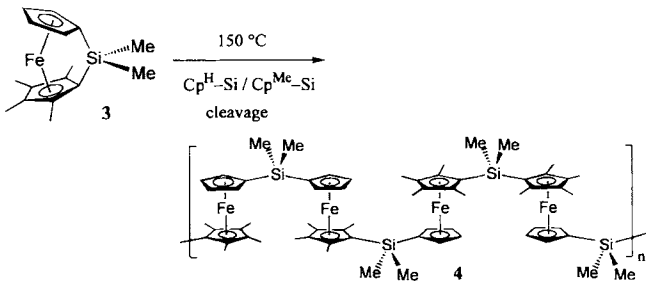
Transition-metal-based polymers are attractive with respect to their physical properties and possible applications.[1-4] The discovery[5] of a thermal ring-opening polymerization (ROP) route to poly(ferrocenylsilane)s such as **2** from strained, ring-tilted ferrocenophanes such as **1** has provided access to a range of high molecular weight examples of these materials with intriguing properties.[6-8]



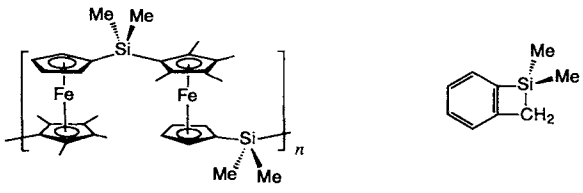
1 **2**

The ROP of silicon-bridged [1]ferrocenophanes has also been achieved with anionic initiators, and this permits access to polymers of defined chain length and architecture (e.g., block copolymers).[9,10] However, strict control of the experimental conditions is required when using this method, which is a severe practical drawback.[11] With this in mind, the recent discovery[12,13] that a variety of Rh^{I}, Pd^{0}, Pt^{0}, Pd^{II}, and Pt^{II} complexes catalyze the ROP of **1** in solution at room temperature to yield high molecular weight **2** is of particular significance.[12-16] However, apart from the convenient formation of random copolymers from **1** and other [1]ferrocenophanes[13,14] or cyclic carbosilanes,[15] the use of transition-metal-catalyzed ROP in the controlled synthesis of polyferrocenes is unexplored. Here we report that the transition-metal-catalyzed ROP of silicon-bridged [1]ferrocenophanes, which permits considerable control over the architecture of the resulting poly(ferrocenylsilane)s.

Thermal ROP of the unsymmetrical [1]ferrocenophane **3** proceeds by nonselective cleavage of the Si–Cp^{H} and Si–Cp^{Me} bonds to yield the poly(ferrocenylsilane) **4**.[17] This material is very soluble in toluene or THF and contains three different silicon environments (Cp^{H}-Si-Cp^{H}, Cp^{H}-Si-Cp^{Me}, and Cp^{Me}-Si-Cp^{Me}) but only one iron environment (Cp^{H}-Fe-Cp^{Me}).[18] Consistent with the lack of structural regioregularity, samples of polymer **4** are amorphous.

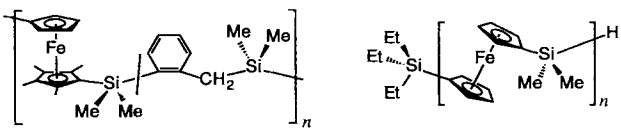


In contrast, transition-metal-catalyzed ROP of **3** (toluene, 25 °C, 12 h, 1 mol% $PtCl_2$ or $[Pt(cod)_2]$; cod = 1,5-cyclooctadiene) yielded an orange, insoluble polymer. This new polymer **5** was analytically identical to **4** but was crystalline, as indicated by the wide-angle X-ray scattering pattern (which displayed several sharp peaks) and the presence of a melt transition (T_m = 285 °C) detected by differential scanning calorimetry (DSC). Moreover, a low molecular weight (M_n < 1200) fraction of **5** was extractable with THF.[19] In contrast to **4**, ^{1}H NMR analysis of the extract showed a single $SiMe_2$ resonance, which indicated the presence of a single Cp^{H}-Si-Cp^{Me} environment.[20] These results are consistent with selective Cp^{H}–Si bond cleavage in **3** to form a regioregular poly(ferrocenylsilane) of structure **5**.[21,22] To provide further evidence for the regioselective transition-metal-catalyzed ROP of **3** we attempted to form a more soluble polymer by copolymerization of **3** with the benzosilacyclobutane **6**.



5 **6**

In the presence of $PtCl_2$ or $[Pt(cod)_2]$ (ca. 1 mol%) equimolar quantities of **3** and **6** afforded a pale orange, toluene- and THF-soluble poly(ferrocenylsilane)–poly(carbosilane) random copolymer **7**, which exhibited a monomodal molecular weight distribution [$M_n = 2.4 \times 10^4$, polydispersity index (PDI) = 2.3]. The ^{1}H and ^{29}Si NMR spectra of **7** were consistent with a random copolymer structure and showed the presence of characteristic switching groups between the poly(ferrocenylsilane) and poly(carbosilane) segments.[15,23] NMR analysis of **7** (in C_6D_6) indicated the presence of a single silicon environment (Cp^{H}-Si-Cp^{Me}) in the poly(ferrocenylsilane) segments. Thus only one $SiMe_2$ resonance was detected by ^{1}H (δ = 0.81) and ^{29}Si NMR (δ = −6.4). These chemical shifts are similar to those



7 **8**

assigned to the Cp^{H}-Si-Cp^{Me} environments in **4**.[24] In addition, the ^{29}Si NMR spectrum of **7** showed no signal around δ = −7.5 in the region characteristic of a Cp^{H}-Si-Ar environment.[15] The structure of **7** therefore provides further evidence for the regiocontrolled ROP of **3** with transition-metal catalysts.

The molecular weight of poly(ferrocenylsilane) homopolymers can be controlled in the range of M_n = 2000–45000 by adding defined amounts of Et_3SiH to the polymerization mixture of **1** and the Pt catalyst.[25] A plot of M_w and M_n as a function of the **1**:Et_3SiH molar ratio is shown in Figure 1.[26] Evidence for the presence of Et_3Si and Si–H end groups in the resulting polymers **8** was provided by ^{29}Si NMR and IR analysis. Thus, for the sample of **8** with M_n = 2100 (PDI = 1.09), ^{29}Si

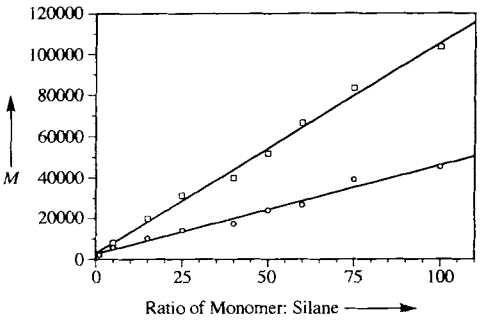

Figure 1. Plot of M_n (□) and M_w (○) versus the monomer **1**: Et_3SiH molar ratio for the synthesis of poly(ferrocenylsilane) **8**.

NMR resonances at $\delta = 2.5$ (Et_3Si-Cp), and -18.2 (Si–H) were detected (Figure 2), and an IR absorption at 2114 cm^{-1} characteristic for ν(Si–H) was observed. Based on recent mechanistic considerations for the transition-metal-catalyzed ROP of silicon-bridged [1]ferrocenophanes[27, 28] it is likely that oxidative addition of the Si–H group of the silane competes with that of the strained Si–C bond of **1** at the catalytic center, and reductive elimination reactions lead to the observed $Cp-SiEt_3$ and Si–H end groups.

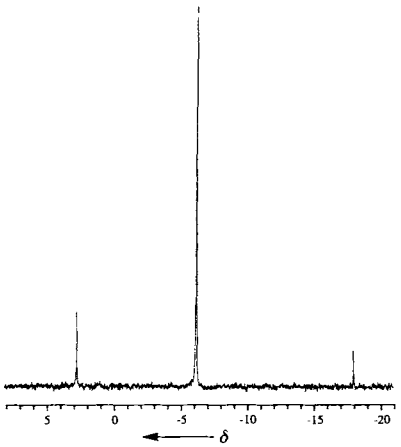

Figure 2. $^{29}Si\{^1H\}$ NMR spectrum (79.5 MHz, C_6D_6, DEPT $J = 51$ Hz) for polymer **8** with $M_w = 2300$ (PDI = 1.09).

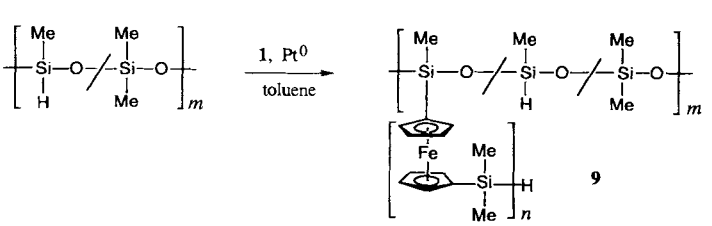
We have exploited the ability to control the end-group structure of the poly(ferrocenylsilane)s to synthesize novel graft copolymers. For example, the reaction of **1** with poly(methylhydrogensiloxane–dimethylsiloxane) copolymer as the Si–H source in a 2:1 molar ratio in the presence of [Pt(cod)$_2$] (1 mol%) yielded a poly(dimethylsiloxane)-graft-poly(ferrocenylsilane) copolymer **9** as an orange gum with a monomodal molecular weight distribution ($M_n = 8.2 \times 10^3$, PDI = 1.7).



The ^1H, ^{13}C, and ^{29}Si NMR spectra of **9** showed characteristic resonances for both polymer segments as well as for the switching and terminal groups.[29] An approximate grafting efficiency of 50% was determined by IR spectroscopy, which showed two ν(Si–H) absorptions at 2150 cm^{-1} (unreacted hydrogensiloxane) and 2114 cm^{-1} (terminal fcSi–H). The length of the ferrocenyl grafts was four repeat units on average, as determined by ^1H NMR integration of the SiMe resonances.

In summary, transition-metal-catalyzed ROP of [1]ferrocenophanes permits convenient control of the polymer regiochemistry, molecular weight, and end-group structure, as well as allowing access to novel materials such as **9**. Further exploration of the potential of this method is underway.

Experimental Section

5: A solution of monomer **3** (350 mg, 1.17 mmol) in toluene (5 mL) was stirred for 12 h in the presence of $PtCl_2$ (1 mol%) as ROP catalyst. The precipitated solid was separated by filtration and washed with THF (3 × 5 mL) until the washings were colorless, and then with methanol (2 × 5 mL). Polymer **5**, an orange powder, was then dried under vacuum. Yield: 310 mg (84%). Oligomeric **5** was obtained in ca. 10% yield from the THF mother liquors after solvent evaporation [19].

7: A mixture of **3** (40 mg, 0.13 mmol) and **6** (20 mg, 0.13 mmol) was stirred in toluene (2 mL) at room temperature in the presence of $PtCl_2$ or [Pt(cod)$_2$] (1 mol%) for 24 h until all of the monomers had been consumed. Over time the solution became more viscous. The solution was filtered and the product isolated by precipitation into methanol to give 52 mg (87%) of copolymer **7** as an orange powder [23].

8: Similar procedures were used for the various monomer/Et_3SiH molar ratios. The following is typical (1:1 ratio): A mixture of **1** (200 mg, 0.83 mmol) and Et_3SiH (132 μL, 0.83 mmol) was stirred in toluene (1.5 mL) at room temperature in the presence of [Pt(cod)$_2$] (1 mol%). Over time the solution became more viscous and after 2 h all the reactive monomer had been consumed. The solution was filtered, and the product isolated by precipitation into methanol to give 142 mg (71%) of polymer **8** as an orange powder.

GPC (THF, polystyrene standard): $M_n = 2100$, PDI = 1.09. ^1H NMR (200 MHz, C_6D_6): $\delta = 0.26$ (s, 6H, $SiMe_2H$), 0.52 (s, 42H, $SiMe$), 0.74 (q, $^3J(HH) = 7.7$ Hz, 6H, CH_3CH_2), 1.06 (t, $^3J(HH) = 7.7$ Hz, 9H, CH_3CH_2), 4.01–4.25 (m, 64H, C_5H_4), 4.68 (m, 1H, Si–*H*); $^{13}C\{^1H\}$ NMR (50.3 MHz, C_6D_6) $\delta = -0.4$ (s, fc–$SiMe_2$), 1.4 (s, $SiMe_2H$), 5.2 (s, CH_3CH_2), 8.2 (s, CH_3CH_2), 71.5–74.0 (m, C_5H_4); $^{29}Si\{^1H\}$ NMR (79.5 MHz, C_6D_6, DEPT $J = 51$ Hz): $\delta = -18.2$ (s, *Si*–H) −6.4 (s, $SiMe_2$), 2.5 (s, Et_3Si). IR (nujol, Si–H stretch): $\tilde{\nu} = 2114$ cm^{-1}.

9: A mixture of **1** (200 mg, 0.83 mmol) and poly(methylhydrogensiloxane–dimethylsiloxane) 50–55% copolymer (55 mg, 0.41 mmol) was stirred in toluene (1.5 mL) at room temperature in the presence of [Pt(cod)$_2$] (1 mol%). After 3 h all the reactive monomer had been consumed, and the solution was filtered and precipitated into methanol to give polymer **9** as an orange gum [29].

[18] The ^{1}H NMR spectrum of **4** shows three broad resonances in the $SiMe_2$ region in a 1:2:1 integration ratio. Similarly, the ^{29}Si NMR spectrum shows three sets of resonances in a 1:2:1 intensity ratio. In each case the most intense peak (the central resonance) is assigned to Cp^H-Si-Cp^{Me} environments [17].
[19] For insoluble fraction of **5**: ^{29}Si{^{1}H} CPMAS NMR (59.5 MHz) $\delta = -7.8$ (br s); ^{13}C{^{1}H} CPMAS NMR (75.3 MHz) $\delta = 2.6$ (br, SiMe); 14.4 (br s, C_5Me_4); 68.1 (s, *ipso*-Cp); 77.3 (br, Cp^H); 84.6 (br, Cp^{Me}). DSC: $T_g = 154\,^\circ$C, $T_m = 285\,^\circ$C. Anal. calcd. for $C_{16}H_{22}FeSi$: C 64.43, H 7.43; found: C 63.77, H 7.31. For soluble oligomeric fractions of **5**: GPC (THF, polystyrene standard): $M_n = 1.100$; PDI = 2.02. ^{1}H NMR (200 MHz, $CDCl_3$) $\delta = 0.59$ (s, 6H, SiMe), 1.65 (s, 6H, C_5Me_4), 1.83 (s, 6H, C_5Me_4), 3.74 (s, 2H, C_5H_4), 3.87 (s, 2H, C_5H_4).
[20] In the ^{1}H NMR spectrum of the soluble extract of **5** in $CDCl_3$ only one signal was found for the methyl substituents on silicon (at $\delta = 0.59$), whereas for the soluble polymer **4** obtained by thermal ROP three resonances (at $\delta = 0.38$, 0.59, 0.81) in a 1:2:1 ratio were detected.
[21] Attempts to distinguish between **4** and **5** by solid-state ^{13}C and ^{29}Si CPMAS NMR were unsuccessful as the resolution proved insufficient.
[22] Attempts to polymerize the permethylated [1]ferrocenophane [Fe(η^5-C_5Me_4)$_2$$SiMe_2$] by using transition metal catalysts (toluene, 25 °C, 1 mol% $PtCl_2$ or [Pt(cod)$_2$]) were unsuccessful. This supports a Cp^H–Si bond-cleavage mechanism for **3**, as does the microstructure of **7**.
[23] For **7**: GPC (THF, polystyrene standards): $M_n = 2.4 \times 10^4$, PDI = 2.3. ^{1}H NMR (200 MHz, C_6D_6) $\delta = 0.23$–0.36 (m, 6H, Ar–SiMe), 0.81 (br, 6H, fc–SiMe), 1.76–1.87 (m, 12H, C_5Me_4), 2.20–2.60 (m, 2H, CH_2), 3.80–4.10 (m, 4H, C_5H_4), 7.03–7.60 (m, 4H, Ar); ^{29}Si {^{1}H} NMR (79.5 MHz, C_6D_6) $\delta = -6.5$, -6.4 (Cp^{Me}-Si-Cp^H), -5.9 to -5.7 (m, Cp^{Me}-Si-Ar), -3.8 to -3.6 (m, CH_2-Si-Ar), -2.1 to -2.3 (m, Cp^H-Si-CH_2). DSC: T_g (1) = 66 °C, T_g (2) = 147 °C.
[24] J. K. Pudelski, I. Manners, *J. Am. Chem. Soc.* **1995**, *117*, 7265.
[25] For control of the chain length of oligo(carbosilane)s ($M_n = 500$–4800) by using in the ROP of cyclocarbosilanes in the presence of Pt^{II} catalysts at 100 °C, see W. R. Bamford, J. C. Lovie, J. A. C. Watt, *J. Chem. Soc. C* **1966**, 1137.
[26] Data were reproducible, since similar molecular weight distributions were obtained for the same ratios in different experiments. The values of M_n are higher than calculated from the ratio of **1**:Et_3SiH as **1** appears to react more rapidly at the catalytic center.

[29] For **9**: GPC (THF, polystyrene standard): $M_n = 8.2 \times 10^3$, PDI = 1.7. ^{1}H NMR (200 MHz, C_6D_6) $\delta = 0.20$–0.36 (m, 20H, OSiMe), 0.53 (s, 24H, fc-SiMe_2), 4.09–4.53 (m, 32H, C_5H_4), 4.69 (br, 1H, CpSiH), 5.10 (br, 1H, OSi–H); ^{13}C{^{1}H} NMR (100.6 MHz, C_6D_6) $\delta = -2.8$ (br, MeHSiO), -1.3 (br, *Me*SiO-fc), -0.5 (s, *Me*$_2$Sifc), 1.7 (s, Me_2SiO), 71.8–74.0 (m, C_5H_4); ^{29}Si {^{1}H} NMR (79.5 MHz, C_6D_6) $\delta = -36.9$ (br, MeHSiO), -29.1 (br, MeSiO–fc), -21.0 (Me_2SiO), -18.2 (s, fc–SiH), -6.4 (s, fc–$SiMe_2$), 11.2 (s, Me_3SiO terminal). IR(nujol, Si–H stretch): $\tilde{\nu} = 2150\ cm^{-1}$ (OSi–H); 2114 cm^{-1} (Cp-Si–H). DSC: $T_g(1) = -120\,^\circ$C, $T_g(2) = -87\,^\circ$C.

Long-Range Electrostatic Effects in Synthesis: Dipole-Controlled Nucleophilic Addition to a Naphthoquinone Acetal in Model Studies toward Diepoxin σ**

Peter Wipf* and Jae-Kyu Jung

The prediction and rationalization of the face selectivity of nucleophilic additions to carbonyl groups has served as a central paradigm for mechanistic organic chemistry. Fundamental benchmarks were set in the conception of the Cram,[1] Prelog,[2] and Cornforth[3] rules and the Felkin–Anh[4] and Cieplak[5] models.[6] A large number of related theoretical analyses have been complemented by computational studies of steric and hyperconjugative electronic effects.[7] In apparent contrast, models based on electrostatic fields increasingly stress the influence of coulombic interactions in π-facial stereoselection.[8] We have recently reported the first quantitative model for the prediction of the ratio of α- vs. β-facial 1,2-attack in reactions of dienones **1** (Figure 1).[9] The component of the molecular dipole moment parallel to the π plane, $\mu_\perp$, which can be calculated by fast semiempirical MO methods, has a straightforward linear rela-

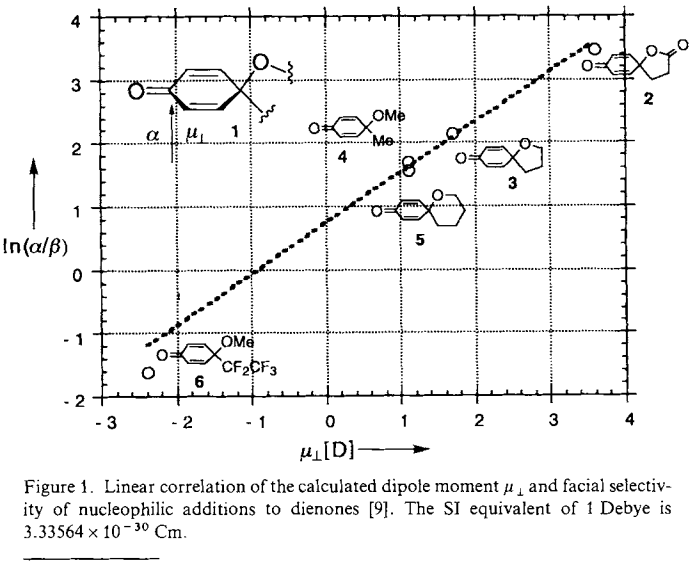

Figure 1. Linear correlation of the calculated dipole moment $\mu_\perp$ and facial selectivity of nucleophilic additions to dienones [9]. The SI equivalent of 1 Debye is 3.33564×10^{-30} Cm.

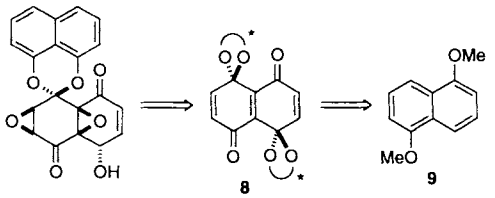
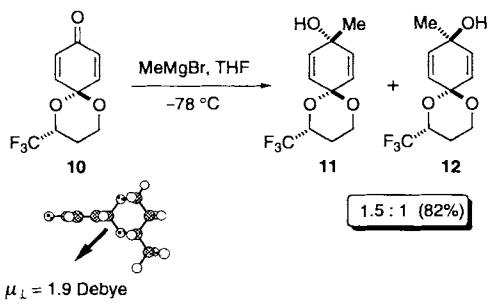
tionship with the logarithm of the experimental ratio of α and β attack of organometallic reagents. This correlation allows the quantitative prediction of experimental 1,4-diastereoselectivities. We now report on the use of this model for the development of a new class of chiral auxiliaries and their application in long-range, 1,6-stereochemical induction.

The antifungal antitumor agent diepoxin σ (**7**) has been independently isolated from several fungal cultures.[10] Its absolute configuration was determined recently by exciton-coupled circular dichroism.[11] In our retrosynthesis (Scheme 1), we envisioned the use of chiral acetals (as in **8**) to differentiate the prochiral faces of naphthalene **9** as part of an asymmetric synthesis of the natural product.

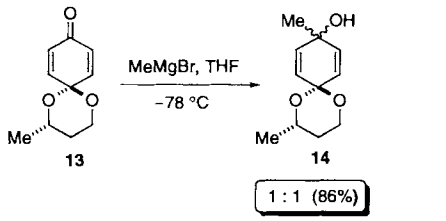


Scheme 1. Retrosynthesis of diepoxin σ (**7**).

Calculation of the molecular dipole moment of a model compound, trifluoromethyl acetal **10**, gave us a prediction of a 2:1 selectivity for the carbonyl addition of a Grignard or organolithium reagent based on the correlation shown in Figure 1. Experimentally, we observed a stereoselectivity of 1.5:1 with methylmagnesium bromide (Scheme 2). The configuration of the major isomer was confirmed by X-ray analysis of **11**.[12] A control experiment with methyl acetal **13** ($\mu_\perp \approx 0$) led to a clean 1:1 mixture of addition products **14**. Therefore, the modest but highly relevant diastereoselectivity observed for acetal **10** is due to the long-range electrostatic field caused by the presence of the remote trifluoromethyl group, and is not simply an effect of steric hindrance. Chelation effects by the distant oxygen atoms have been excluded in earlier studies.[9] The 1,6-diastereoselection with **10** is remarkable given the distance of 5.1 Å between the carbonyl group and the asymmetric carbon atom. Of further interest is the increase of diastereoselectivity when the reactions are conducted in solvents of higher dielectric constant. In a 9:1 mixture of THF and HMPA, reaction of **10** with methyl Grignard reagent gave a 2.1:1 ratio of **11** and **12**, whereas in Et_2O the selectivity dropped to 1.2:1. Since an increase in the dielectric constant of the medium leads to an increase in the induced dipole moment of the solute,[13] this solvent effect is in good qualitative agreement with an electrostatic control of the reaction. The lack of information concerning solvent effects has been cited as a possible weakness of electrostatic models.[7p] The experimental data shown in Scheme 2 will hopefully form the basis for further discussions of this important issue.



Solvent	MeMgBr	MeLi
THF/Hexane (1:2)	1.3 : 1	-
THF/PhMe (1:2)	1.4 : 1	-
Et_2O	1.2 : 1	1.3 : 1
THF	1.5 : 1	1.4 : 1
THF/HMPA (10%)	2.1 : 1	1.6 : 1



Scheme 2. 1,6-Diastereoselectivity and solvent effects in nucleophilic additions to cyclohexadienones.

In spite of the modest diastereoselectivity of nucleophilic additions to trifluoromethyl acetal **10**, this model system augured well for the use of remote electrostatic effects in the planned asymmetric synthesis of diepoxin σ. AM1 calculation of the naphthoquinone acetal **15** revealed a strong cumulative dipole moment of 3.7 D, which should result in a 12:1 selectivity in the addition reaction (Figure 2).

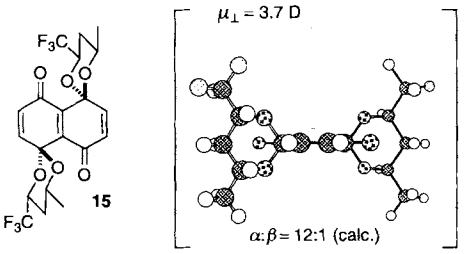


Figure 2. Model and calculated dipole moment for naphthoquinone bisacetal **15**.

The desired acetal **15** was readily prepared in seven steps. Formylation of 1,5-dimethoxynaphthalene (**9**) followed by demethylation and Mitsunobu etherification with enantiopure diol **18**[14] gave diol **19** in 55% yield (Scheme 3). After oxidative removal of the formyl groups, oxidation with hypervalent iodine[15] in trifluoroethanol resulted in a mixture of **21**, **22**, and **15**, which was converted into **15** in 32% overall yield from **20** by exposure to pyridinium *p*-tolylsulfonate (PPTs) in benzene. Only one acetal ring conformation and relative configuration is possible for **15** as a consequence of 1,3-diaxial and transannular strain. 2D NOESY spectra confirmed the ring conformers shown for **15** that were also obtained as global energy minima in molecular mechanics calculations.

As expected from the dipole calculations, 1,2-addition of methyllithium to **15** provided the desired diol **23** in 50% yield as the major isomer besides the *syn*/*anti* product **24** in 12% yield (Scheme 4). The rest of the mass balance comprised aromatized compounds; the third possible 1,2-addition product, *syn*/*syn* isomer **25**, was not detected in the HPLC analysis of the reaction mixture. After statistical correction, the ratio **23**:**24** corresponds to a facial preference of 9:1 for attack *anti* to the trifluoromethyl substituents, very close to the calculated ratio. Partial hydrolysis of the acetals with PPTs gave dienone **26** in 57% yield, and

an X-ray analysis of this compound confirmed the envisioned double attack of the nucleophile *anti* to the remote trifluoromethyl substituents (Figure 3).[12] The bisequatorial orientation of the two acetal substituents is evident in Figure 3 and, accordingly, the similarity in steric hindrance between the two faces of the naphthoquinone. Complete removal of the chiral auxiliaries to give enantiomerically pure naphthoquinol **27** was possible with toluenesulfonic acid in aqueous acetone (Scheme 4).

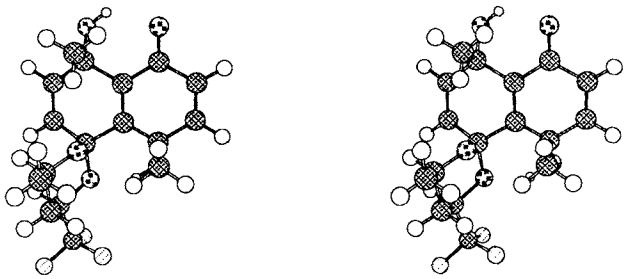

Figure 3. Stereoview of the X-ray crystal structure of monoacetal **26** [12].

In conclusion, our model studies toward the synthesis of diepoxin σ demonstrate that electrostatic effects determine the face selectivity of nucleophilic additions to carbonyls in sterically unhindered cyclohexadienones and naphthoquinones. Quantitative predictions of diastereomer ratios are possible for these closely related substrates. For the first time, the effects of solvent on electrostatic control have been investigated experimentally, and the considerable increase of the face selectivity as a function of the polarity of the organic solvent is in agreement with induced dipole moments. Based on electrostatic control that remains effective over a long distance, new chiral auxiliaries can be designed that avoid deactivating steric interactions and direct reagents by aligning the dipoles. The diastereoselectivity observed in the addition to bisacetal **15** is a remarkable demonstration of the directing power of strong dipole moments. Further applications of these principles in organic synthesis, specifically toward the total synthesis of diepoxin σ, are in progress.

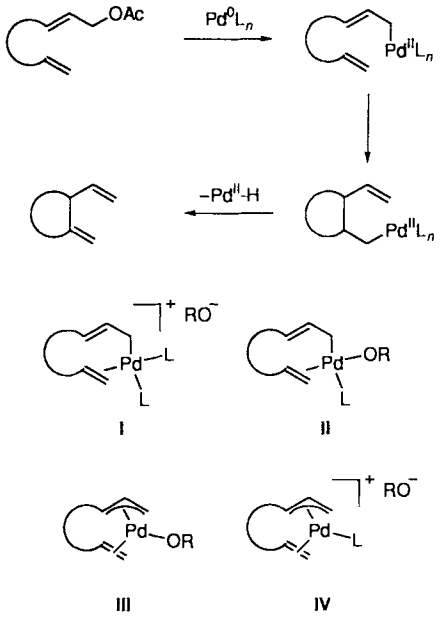

Scheme 1. Palladium–ene reaction with possible intermediates.

Cationic Intermediates in the Intramolecular Insertion of Alkenes into (η^3-Allyl)palladium(II) Complexes**

Enrique Gómez-Bengoa, Juan Manuel Cuerva, Antonio M. Echavarren,* and Gabriel Martorell

In memory of Wolfgang Oppolzer

The palladium-catalyzed intramolecular carbocyclization of allyl acetates with alkenes is a powerful method for the formation of five- and six-membered rings.[1, 2] Most of these reactions only proceed satisfactorily in polar solvents such as HOAc at 70–100 °C in the presence of a palladium(0) catalyst with PPh_3 ligation.[1–3] Oppolzer et al. have hypothesized that carbopalladation may proceed by a pericyclic-type reaction of a (η^1-allyl)palladium(II) complex (palladium–ene reaction, Scheme 1).[1, 2] Although the coordination at the metal center is undetermined in most mechanistic proposals, it seems likely that, in the presence of excess ligand, the key intermediate is coordinated with two donor phosphane ligands, for example as in **I**, which could be in equilibrium with neutral (η^1-allyl)-palladium(II) complex **II** (R = Ac). Alternatively, the insertion may proceed via (η^3-allyl)palladium(II) complexes **III** or **IV**.[4]

It would be desirable to perform the cyclization of allylic substrates bearing sensitive functionalities under milder and/or neutral reaction conditions. In addition, we have observed that the usual reaction conditions[5] are not satisfactory for the cyclization of the more highly substituted allyl substrates. We therefore decided to examine the reaction under stoichiometric conditions. An important motivation for studying the mechanism of this cyclization in more detail was the prospect of rationally developing asymmetric versions with appropriate mono- or bidentate chiral ligands. Here we report that the reaction proceeds through cationic complexes of type **IV**, in which the palladium atom is coordinated with only one phosphane ligand.

The (η^3-allyl)palladium(II) complexes were prepared from the allyl trifluoroacetates.[6, 7] Thus, **1** was treated with $[Pd_2(dba)_3]\cdot$dba (dba = dibenzylideneacetone)[8] in THF/MeCN (3/1) at 25 °C to afford **2** in quantitative yield (Scheme 2). The ^{13}C NMR spectrum of **2** showed resonances for the η^3-allyl carbon atoms at δ = 93.3, 80.6, and 75.0. The alkene group gave rise to signals at δ = 115.4 and 107.2, which is in agreement with the expected values for an η^2-coordinated olefin (Table 1).[9–11] Treatment of **2** with excess NaOAc (acetone, 25 °C) led to complex **3**, which on attempted isolation underwent reductive elimination to furnish the allylic acetate **4**.[7a, 12, 13] Trifluoracetato complexes **5** and **6** were prepared from **2** with one equivalent of 1,10-phenanthroline (phen; Et_2O, 25 °C, 10 min, 95%)[14] or 1,2-bis(diphenylphosphane)ethane (dppe; Et_2O, 25 °C, 45 min, 73%). Complex **7** was prepared in almost quantitative yield from **2** with two equivalents of PPh_3 ($CDCl_3$, 25 °C). Reaction of **2** with one equivalent of PPh_3 afforded **8**. The NMR spectra of **5**–**8** clearly showed a noncoordinated alkene.[15]

The trifluoroacetato complex **2** was very stable and failed to cyclize after being heated at reflux in [D_6]benzene, [D_6]acetone, or $CDCl_3$. In contrast, the acetato complex **3** yielded **4** and metallic palladium after being heated at 60–70 °C in [D_6]benzene or $CDCl_3$. Complexes **5**–**7**, which are likely precursors to complexes of type **I**, also failed to cyclize under the usual conditions (0.2–0.02 M solutions).[16]

Complex **8**, which was stable in solution at 25 °C for several days, underwent smooth cyclization in [D_6]benzene or $CDCl_3$ at reflux to yield **11** and **12** (1:1) in almost quantitative yield. The alkene of **8** can presumably displace the trifluoroacetate ligand to give cationic **9**, which undergoes insertion and β-hydrogen

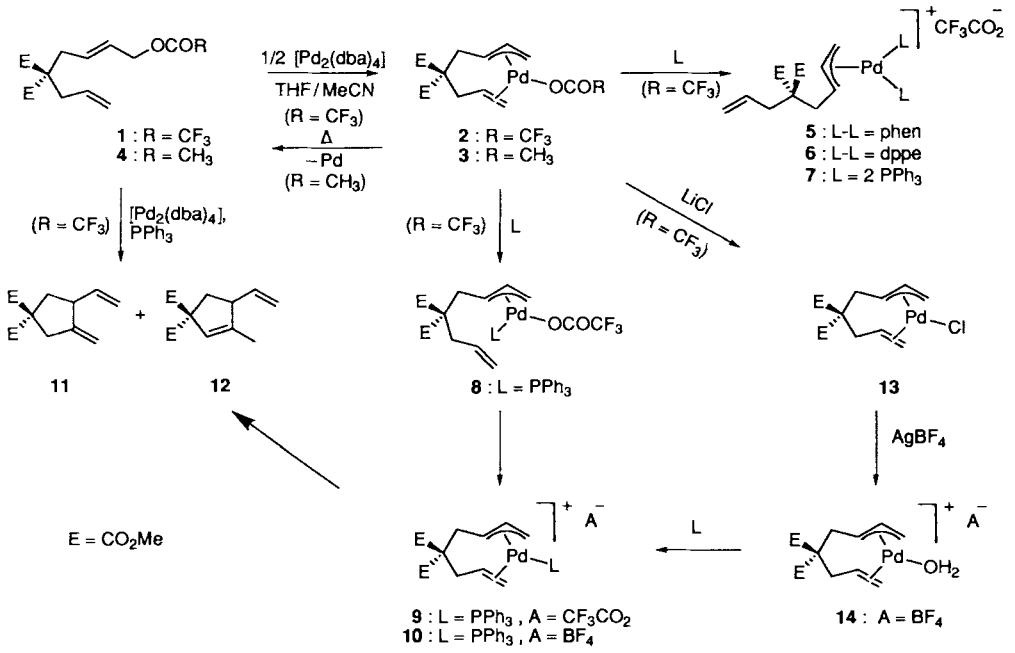

Scheme 2.

elimination to yield **11**[1] and a palladium hydride. The more stable endocyclic alkene **12** originates from the reaction of the palladium hydride with **11** followed by elimination. An increase in the cone angle of the phosphane[17] has a detrimental effect on the cyclization rate. Thus, addition of one equivalent of a bulky ligand such as PCy_3 or $P(o\text{-}MeC_6H_4)_3$ led to slower cyclizations in $CDCl_3$.[18] On the other hand, poorer donor ligands (for example $P(OMe)_3$, $P(OPh)_3$, or $AsPh_3$) led to incomplete conversions into **11** and **12**. The best results were obtained by treatment of **8** with $NaBF_4$ in CH_2Cl_2: the cyclization of **8**, presumably proceeding via **10**, at 30 °C gave pure **11** in 62% yield (24 h, 82% conversion by ^1H NMR spectroscopy).[19]

Isolation of the key cationic intermediates **9** or **10** could not be achieved from **8**, since the cyclization proceeded at a rate similar to that of ligand substitution. An alternative synthesis of **10** was realized from **13** (Table 1), which was readily prepared in quantitative yield from **2** and excess LiCl in acetone (Scheme 2). Complex **13**[20] showed no propensity to cyclize after being heated in $CDCl_3$. Treatment of **13** with $AgBF_4$ gave cationic **14**, in which the metal is coordinated with one water molecule (Table 1).[21] Addition of one equivalent of PPh_3 led quantitatively to **10**, whose structure was confirmed by NMR spectroscopy. $^1H-^{13}P$ HOESY correlation demonstrated that the palladium center is coordinated with the phosphane, alkene, and allyl group (η^3, Figure 1).[22] In contrast with **14**, which failed to undergo cyclization, a smooth reaction was observed for **10** (CH_2Cl_2, 30 °C), giving a mixture of five-membered ring carbocycles.[23]

The results summarized in Scheme 2 suggested that the cyclization of **1** could be effected under neutral conditions with a palladium catalyst containing just one equivalent of phosphane as ligand. Indeed, **1** was converted into **11** (75–79% yield, contaminated with about 5% of **12**) in the presence of 5 mol% $[Pd_2(dba)_3]\cdot dba$ and 10 mol% PPh_3 or PCy_3 in toluene at 100 °C for 24 h.[24] The inertness of complexes with bidentate ligands (for example **5** and **6**) towards insertion was also demonstrated under catalytic conditions.[25]

These results indicate that formation of intermediates of type **IV** is the key to successful cyclization. When allyl acetates are used as the starting materials under catalytic conditions, both oxidative addition and formation of cationic **IV** are unfavorable processes. In these cases, the acidic solvent probably promotes the reaction by protonation of the acetate ligand, thereby facilitating formation of **IV**. Although this study does not exclude the involvement of internal η^1-allyl species as intermediates in the catalytic cycle,[26, 27] the results are in accordance with direct insertion of the η^3-allyl group into the alkene. Our conclusions are supported by the recent, independent work of Keim et al. and Brookhart et al.,[28] which demonstrate that insertion of ethylene proceeds smoothly on cationic (η^3-allyl)palladium complexes.

We have found that cyclization of substrates such as **1** may proceed under neutral conditions. Cationic complexes, which are key intermediates in the palladium-catalyzed reactions of

[14] M. P. T. Sjögren, S. Hansson, B. Åkermark, A. Vitagliano, *Organometallics* **1994**, *13*, 1963, and references therein.

[15] The stereochemistry of **8** could not be assigned rigorously because of the appearance of broad signals for the η^3-allyl ligand, a consequence of a rapid ligand-exchange process. See also a) A. Gogoll, J. Örnebro, H. Grennberg, J.-E. Bäckvall, *J. Am. Chem. Soc.* **1994**, *116*, 3631; b) C. Breutel, P. S. Pregosin, R. Salzmann, A. Togni, *ibid.* **1994**, *116*, 4067.

[16] However, heating **7** under more diluted conditions (2×10^{-3} M in toluene, 90 °C, 16 h) led to the formation of a mixture of **11** and **12** in moderate yield. We thank one of the referees for suggesting this experiment.

[17] C. A. Tolman, *Chem. Rev.* **1977**, *77*, 313.

[18] Cyclization via the presumed cationic complexes analogous to **10** [L = PCy_3, P(*o*-$MeC_6H_4)_3$] to a mixture of **11** and **12** was observed in $CDCl_3$ after 8 h at 60 °C. Complex **1** was converted into **11** in 79% yield (toluene, 100 °C) with a catalyst prepared from [$Pd_2(dba)_3$]·dba (5 mol%) and PCy_3 (10 mol%). Similar conditions with P(*o*-$MeC_6H_4)_3$ as the ligand provided **11** in 52% yield in DME under reflux.

[19] Treatment of **2** with one equivalent of PCy_3 and $NaBF_4$ (CH_2Cl_2, 40 C) led to **11** in similar yield.

[20] The NMR data of **13** are consistent with the cyclic structure shown (Table 1). In contrast, a lower homologue of **13** prefers an open halogen-bridged dimeric structure: R. P. Hughes, T. Jack, J. Powell, *J. Organomet. Chem.* **1973**, *63*, 451.

[21] The high affinity of water for palladium in cationic complexes has been demonstrated: a) J. M. Brown, K. K. Hii, *Angew. Chem.* **1996**, *108*, 679; *Angew. Chem. Int. Ed. Engl.* **1996**, *35*, 657; b) P. J. Stang, D. H. Cao, G. T. Poulter, A. M. Arif, *Organometallics* **1995**, *14*, 1110; c) G. M. DiRenzo, P. S. White, M. Brookhart, *J. Am. Chem. Soc.* **1996**, *118*, 6225.

[22] a) A $^{1}H-^{31}P$ HOESY NMR sprectrum [22b] of **10** was acquired in the phase-sensitive mode (States-TPPI method). The spectrum was carried out at 0 °C on a Bruker AMX-300 [mixing time = 600 ms, spectral widths = 12 (F_1) and 18 (F_2)]; b) W. Bauer, P. von R. Schleyer, *Magn. Reson. Chem.* **1988**, *26*, 827; c) no changes were observed in the ^{31}P NMR spectrum of **10** between 0 and −80 °C.

[23] Three other olefin isomers were also obtained in addition to **11** and **12** (overall yield 65%).

[24] Addition of excess PPh_3 did not improved the yield. The best result was obtained in DME under reflux (9:1 mixture of **11** and **12**, 81% yield).

[25] No cyclization was observed when **4** was heated in HOAc with catalysts prepared from [$Pd_2(dba)_3$]·dba and 1,4-bis(diphenylphosphane)butane or 1,1′-bis(diphenylphosphane)ferrocene. 1,1-bis(diphenylphosphane)methane, which probably acts as a monodentate ligand, led to a 1.2:1 mixture of **11** and **12** (44% yield).

[26] Well-characterized (η^1-allyl)palladium(II) complexes react with alkenes to yield [3 + 2] cycloadducts instead of insertion derivatives: H. Kurosawa, A. Urabe, K. Miki, N. Kasai, *Organometallics* **1986**, *5*, 2002, and references therein.

[27] However, insertion of alkenes into (η^3-allyl)palladium hexafluoroacetylacetonate has been proposed to proceed through (η^1-allyl)palladium intermediates: a) R. P. Hughes, J. Powell, *J. Organomet. Chem.* **1973**, *60*, 387; b) *ibid.* **1973**, *60*, 409.

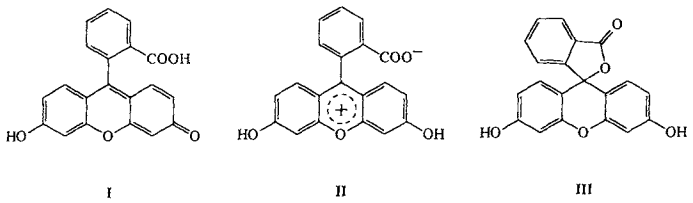
Structure Determination of a Complex Organic Solid from X-Ray Powder Diffraction Data by a Generalized Monte Carlo Method: The Crystal Structure of Red Fluorescein**

Maryjane Tremayne, Benson M. Kariuki, and Kenneth D. M. Harris*

Fluorescein has been widely used in biomolecular sciences, ophthalmology, and other scientific disciplines, since its first preparation more than a century ago.[1] There are various solid forms of fluorescein that exhibit a wide selection of properties, and differ substantially in color. Progress in understanding the properties of fluorescein in particular, and crystalline solids in general, depends on knowledge of their crystal structures; however, to our knowledge, the different forms of solid fluorescein can only be obtained as microcrystalline powders, thus prohibiting crystal structure determination by conventional single-crystal diffraction methods. IR spectroscopy[2] and solid-state ^{13}C NMR spectroscopy[3] indicate that the different forms of fluorescein can be grouped into three categories (Scheme 1): 1) red fluorescein with quinoid structure **I**, 2) yellow fluorescein with



I II III

Scheme 1.

zwitterionic structure **II**, and 3) colorless fluorescein with lactoid structure **III**. We focus here on crystal structure determination of the red form of fluorescein from powder diffraction data. It has been reported previously[2, 4] that samples of red fluorescein prepared by different methods give different powder diffraction patterns, and there has been much speculation[3] regarding the arrangement of fluorescein molecules in these different materials.

As illustrated by fluorescein, many important crystalline materials cannot be prepared as single crystals of sufficient size and quality for single-crystal X-ray diffraction studies, and for these materials it is essential that structural information can be established from powder diffraction data.[5] However, there are several intrinsic difficulties associated with solving crystal structures from powder diffraction data, originating primarily from extensive peak overlap in the powder diffractogram. This peak overlap limits the reliability of intensity information that can be extracted directly from the powder diffractogram, and, as the traditional approaches (e.g. direct methods, Patterson methods) for structure solution require accurate intensity data of this type, the success of these approaches can be severely restricted. The solution of the crystal structure for "equal-atom" organic molecular solids (that is those containing only C, H, N, or O) from X-ray powder diffraction data presents the greatest challenges, as there is substantially less data of significant intensity at high diffraction angles and, for these materials, a substantial fraction (at least 50%) of the atoms in the structure must generally be located correctly in the structure solution stage in order for subsequent structure refinement to be successful. As a consequence of these challenges, the structures of only a few previously-unknown "equal-atom" compounds have been determined from powder diffraction data.[6-11] In all but one[6] of these cases, prior knowledge of the molecular geometry was exploited by use of a *rigid* molecular fragment in the structure solution calculation. Clearly the extension to *nonrigid* molecular fragments is essential to allow the general application of this approach to all types of organic compound.

Among the techniques that can be used to solve structures from powder diffraction data, the Monte Carlo method[11-17] has been a significant recent development. Importantly, this technique does not require intensity information to be extracted directly from the powder diffraction pattern, thus circumventing the major problem associated with traditional approaches for structure solution from powder diffraction data. The crystal structure determination of red fluorescein reported here represents the first application of our Monte Carlo structure solution method for the case in which the molecule is treated as a nonrigid structural fragment; to our knowledge, it also represents the first crystal structure determination from powder diffraction data (by any technique) for an "equal-atom" organic compound containing more than 20 non-hydrogen atoms in the asymmetric unit.

The X-ray powder diffraction pattern of red fluorescein was measured[18] using synchrotron X-ray radiation, and the lattice parameters and space group were determined[20] directly from the powder diffraction pattern. The Monte Carlo structure solution calculation was then carried out using the program OCTOPUS,[22] with the complete fluorescein molecule (excluding hydrogen atoms) taken as the structural fragment. Standard bond lengths and bond angles were used to construct this structural fragment, and all C–O bond lengths were considered to be equal. The benzoic acid moiety and the hydroxyxanthenone moiety were both maintained as planar rigid bodies, and the interplanar angle (which is not known a priori) was allowed to vary in the Monte Carlo calculation by rotation around the C–C bond that connects the two moieties. In generating trial structures under the Monte Carlo algorithm, translation and rotation of the structural fragment within the unit cell was carried out simultaneously with variation of this angle. The initial values of all degrees of freedom defining the position, orientation, and intramolecular geometry of the structural fragment were arbitrary. The best structure solution (that is the one with the lowest R_{wp} value) corresponded to an R_{wp} value of 31.6%, whereas the R_{wp} value was typically about 54% for most structures sampled in the Monte Carlo calculation (corresponding to "wrong" positions of the structural fragment). A few other structures had R_{wp} values less than 39.4%, and were all close to the best structure solution; clearly there is good discrimination in the R_{wp} value between the "correct" structure solution and "wrong" positions of the structural fragment.

The best structure solution generated in the Monte Carlo calculation was then taken as the starting structural model for Rietveld refinement using the program SR15LS.[23] The positions of all atoms were refined subject to geometrical restraints,

and isotropic atomic displacement parameters were fixed at physically plausible values (and not refined). All C–O bond lengths were initially restrained to be 1.30 Å, although as the refinement progressed there was clear discrimination in these bond lengths, with some tending to become longer than 1.30 Å (assigned as C–OH) and others tending to become shorter than 1.30 Å (assigned as C=O). Furthermore, this assignment of the C–OH and C=O bonds represents a highly reasonable intermolecular hydrogen-bonding scheme, whereas other possible assignments of the C–OH and C=O bonds do not. The C–O bond lengths were subsequently restrained according to their new assignment as C–OH or C=O (that is 1.35 Å or 1.23 Å, respectively). Finally, hydrogen atoms (except those of the C–OH groups) were added to the molecule in positions consistent with standard geometries. The final Rietveld refinement (Figure 1) gave the agreement factors $R_{wp} = 13.7\%$, $R_e = 10.6\%$,

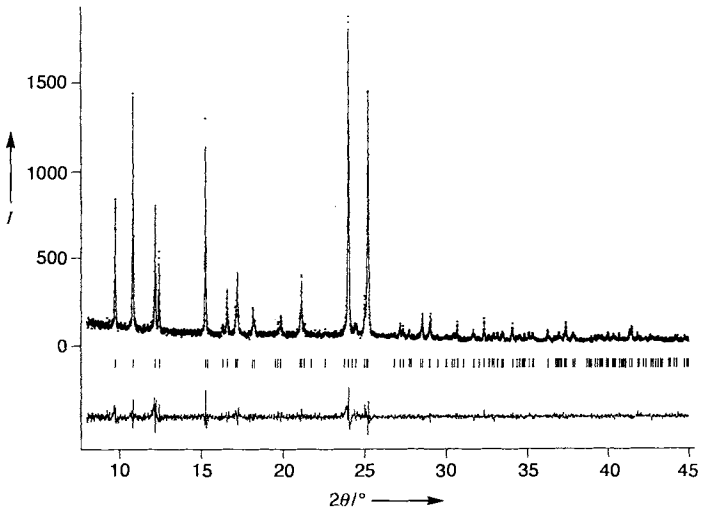

Figure 1. Experimental (dots), calculated (solid line) and difference (lower line) X-ray powder diffraction profiles for the Rietveld refinement of red fluorescein. Reflection positions are marked. The calculated powder diffraction profile is for the final refined crystal structure, details of which are given in Table 1.

$R_p = 10.7\%$, $R_B = 7.8\%$, and $\chi^2 = 1.66$ for 138 reflections, 127 refined parameters, and 99 geometrical restraints. Details of the final refined crystal structure are given in Table 1. It is interesting to note: 1) the atoms of the hydroxyxanthenone moiety in the structure solution are closer to their corresponding refined positions than those in the benzoic acid moiety, probably on account of the larger total scattering power of the hydroxyxanthenone moiety; 2) the interplanar angle between the hydroxyxanthenone and benzoic acid moieties is very similar in the structure solution (87.1°) and refined crystal structure (82.2°).

Table 1. Atomic coordinates for the non-hydrogen atoms in the final refined crystal structure of red fluorescein [$Pn2_1a$; $a = 10.4595(4)$, $b = 13.2191(4)$, $c = 10.5664(4)$ Å]. For each atom, Δ represents the distance between the position in the final refined structure and the position in the Monte Carlo structure solution.

The crystal structure (Figure 2) comprises a network of intermolecular C=O···H–O hydrogen bonds, with each fluorescein molecule involved in four hydrogen bonds of this type. The structure can be regarded to be composed of layers parallel to the ***ac*** plane (see Figure 2 top), with two such layers per unit cell along the ***b*** axis. Within each layer (see Figure 2 bottom), columns of molecules are stacked (vertical in Figure 2 bottom)

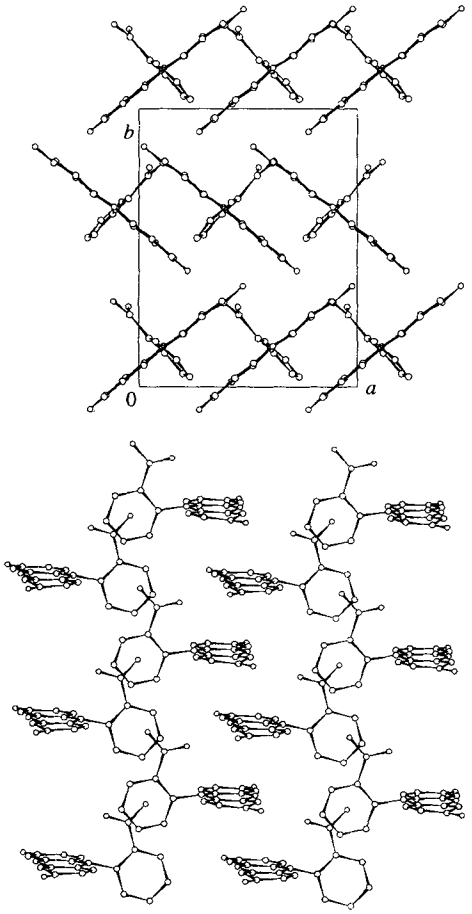

Figure 2. Top: Final refined crystal structure of red fluorescein (hydrogen atoms not shown) viewed along the crystallographic *c* axis. Bottom: One layer of the structure of red fluorescein, viewed approximately along the [2$\bar{1}$0] direction, with the *c* axis horizontal.

with their hydroxyxanthenone moieties approximately parallel to each other, although the amount of π···π overlap between adjacent hydroxyxanthenone moieties in these stacks is not substantial. Along a given stack of hydroxyxanthenone moieties, the benzoic acid moieties alternate on either side of the stack. The angle between the planes of the hydroxyxanthenone moieties in adjacent layers is about 77°. Of the four intermolecular C=O···H–O hydrogen bonds per molecule, two are formed with neighboring molecules in the same layer and the other two connect molecules in adjacent layers (with one hydrogen bond to each of the two adjacent layers).

The crystal structure of red fluorescein reported here has direct relevance to previous discussions of structural properties of this material. Powder diffraction data for samples of red fluorescein, prepared by different routes, have been reported;[4] the X-ray powder diffractogram of the sample of red fluorescein used in the present work shows the same d-spacings as the X-ray powder diffractogram for a sample crystallized from water.[4] Furthermore, the structure of red fluorescein reported here has important implications for the interpretation of the decomposition of the 1:1 complexes[24] of fluorescein with acetone and methanol.

The results reported here demonstrate that the crystal structures of relatively complex "equal-atom" organic compounds can be solved from X-ray powder diffraction data by using a nonrigid structural fragment in the Monte Carlo approach. This represents a significant advance in demonstrating the potential of the Monte Carlo method for crystal structure solution from powder diffraction data for the general case in which the molecular geometry is not known a priori. In principle, all types of structural problem can be defined in a Monte Carlo structure solution calculation by using a nonrigid structural fragment defined by a sufficient number of intramolecular degrees of freedom.

[18] A polycrystalline sample of red fluorescein (Aldrich) was used directly as received. High-resolution solid-state ^{13}C NMR spectroscopy [19] confirmed that the fluorescein molecules are in the quinoid form. For powder diffraction measurements, the sample was loaded into a capillary (1.0 mm diameter) and mounted on the high-resolution powder diffractometer at station 2.3 of the Synchrotron Radiation Source, Daresbury Laboratory. The X-ray powder diffraction data were recorded with 2θ in the range 5° to 60° in 0.01° steps, at a wavelength of 1.4000 Å. The total data collection time was 90 minutes. The data at high diffraction angle were not significant above the noise level, and only data in the range $5° < 2\theta < 45°$ were used in the structure determination calculations.
[19] A. E. Aliev, M. Tremayne, B. M. Kariuki, K. D. M. Harris, unpublished results.
[20] The X-ray powder diffraction pattern was indexed using the program TREOR [21] on the basis of the first 20 observable peaks. This gave the unit cell $a = 10.456$, $b = 13.219$, $c = 10.569$ Å, $\alpha = \beta = \gamma = 90°$ with figures of merit $M_{20} = 30$ and $F_{20} = 40$ (0.005861, 86). Systematic absences were consistent with the orthorhombic space groups *Pnma* and $Pn2_1a$. Density considerations suggest that there are four molecules per unit cell. Thus, if the space group is *Pnma*, the fluorescein molecule must either lie on a mirror plane, or two halves of the molecule must be related across a center of inversion. Neither of these situations is plausible for the quinoid form of fluorescein, and the space group was therefore assigned as $Pn2_1a$.

Carbohydrate-Substituted Triarylphosphanes—A New Class of Ligands for Two-Phase Catalysis**

Matthias Beller,* Jürgen Gregor Elmar Krauter, and Alexander Zapf

The two basic problems of homogeneous catalysis—separation and recycling of the catalyst—can be elegantly solved by using two-phase catalysis.[1] Here, the catalyst is in a hydrophilic phase in which the organic products are insoluble. In order to implement this principle, it was necessary to develop new ligands that are soluble in hydrophilic phases. Diphenylphosphinoacetic acid[2] and the TPPTS ligand (TPPTS = trisodium salt of triphenylphosphane trisulfonate),[3] which was prepared by Kuntz, served as the starting points for these developments; nowadays they are produced on the tonne-scale for the most important industrial two-phase processes—the *S*hell *H*igher *O*lefin *P*rocess (SHOP)[2] and the Ruhrchemie/Rhône-Poulenc process for the hydroformylation of propene to butyraldehyde.[4] Butadiene telomerization (Kuraray)[5] and allyl substitution (Rhône-Poulenc)[6] are two further examples of the technical application of two-phase catalysis. Newly developed methods, which are currently used on the laboratory-scale for aminations,[7] carbonylations,[8] hydrogenations,[9] and even bioorganic applications[10] serve to illustrate the topicality of two-phase catalysts in the field of homogeneous catalysis. In order to attain sufficient solubility of the ligands in polar media (particularly water), ionic groups (sulfonic and carboxylic acids, quaternary aminoalkyl/aryl groups, and phosphonium salts) are usually used as substituents in the phosphanes. In contrast, nonionic ligands, such as phosphino alcohols,[11] phosphanes with polyether substituents,[12] crown ether substituted phosphanes,[13] and diphenylphosphinoalkyl-substituted carbohydrates,[12c] are used to a lesser extent.

We present here a new class of polar, hydrophilic triarylphosphanes for two-phase catalysis; the hydrophilic character of these compounds is attributed to a sugar moiety. We have employed aryl-β-*O*-glycosides of glucose, galactose, and glucosamine.

The glycosidation of hydroxy-substituted triphenylphosphanes turned out to be extremely difficult;[14] the usual methods of homogeneous glycosidation—with Lewis acid catalysts

or with stoichiometric amounts of heavy metal activators—gave the required products in unsatisfactory yields (2–14%). Nevertheless, the new ligands were obtained in satisfactory to good yields after optimization of the reaction conditions of the two-phase glycosidation[15, 16] and subsequent cleavage of the acetyl groups (Table 1).

Table 1. Yields of **3a–c** from the two-step synthesis.

Compound	parent sugar	yield [%]
3a	glucosamine	68
3a	glucosamine	52 [a]
3b	galactose	50 [a]
3c	glucose	33

[a] Deviation from the given procedure (1 equiv **1**, 2 equiv **2**), yields relative to **1**.

Excess acetyl-protected halopyranoses **1**[17] were allowed to react with the glycoside-acceptor *p*-hydroxyphenyldiphenylphosphane **2**[18] in the two-phase system dichloromethane/sodium hydroxide solution at room temperature in the presence of the phase-transfer catalyst tetra-*n*-butylammonium hydrogen sulfate (TBAHS). Subsequent Zemplén saponification of the acetyl groups and chromatographic purification led to the product **3** (Scheme 1).

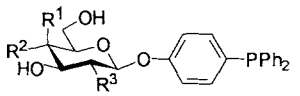
1b X = Br, R^1 = OAc, R^2 = H, R^3 = OAc
1c X = Br, R^1 = H, R^2 = OAc, R^3 = OAc



3a R^1 = H, R^2 = OH, R^3 = NHAc
3b R^1 = OH, R^2 = H, R^3 = OH
3c R^1 = H, R^2 = OH, R^3 = OH

Scheme 1. Synthesis of glycoside-triarylphosphanes **3a–c**.

The best yields were obtained with galactose and glucosamine (**3a,b**); surprisingly, glucose gave lower yields (33%). The β-linked glycosides were formed with high stereoselectivity because of the neighboring group effect of the acetyl-protecting group. The respective 2-acetoxyglucals, and in the case of glucosamine, the corresponding dihydrooxazole, were obtained as by-products; as expected the highest amount of by-product was obtained with glucose.[16]

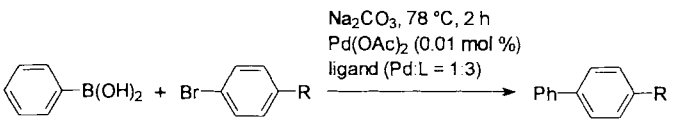
A particular property of phosphanes containing polyglycol ethers is their thermoreversible solvation,[1] that is the reversible loss of the hydrate shell as the temperature increases and thus an increase of the lipophilic character. In order to check whether this effect was occurring for the ligands presented here, the Nernst distribution coefficient α was determined for **3a** at different temperatures in the two-phase system ethanol, water/di-*n*-butyl ether (2/1/3, v/v/v)[19] (Table 2).

Table 2. Nernst distribution coefficient α for **3a** at different temperatures.

Temperature [°C]	α [a, b]
5	0.077
25	0.086
30	0.094
50	0.117

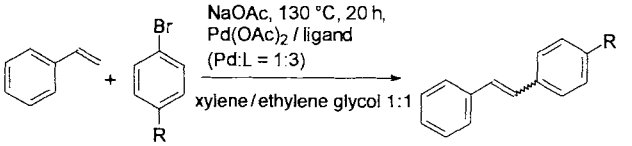
[a] Loading (mg **3a** per mg solvent) of the nonpolar phase per loading of the polar phase. [b] Standard deviation 0.001.

The concentration of **3a** in the di-*n*-butyl ether phase increased on raising the temperature, as revealed by an increase in the value of α. Measurements with TPPTS as a ligand gave no indications of a thermoreversible solvation. Therefore, the solubility of hydrophilic catalysts with **3a** as a ligand in the organic phase is greater than that of catalyst systems with TPPTS. Thus, higher catalytic activities with **3a** should be obtained for nonpolar substrates. This hypothesis was tested with the ligands **3** and TPPTS in Heck and Suzuki reactions. In the Suzuki reaction (Scheme 2) 4-bromoacetophenone and 1-bromo-4-chlorobenzene were treated with phenylboronic acid to give the substituted biphenylenes **6**. In the two-phase Heck reaction (Scheme 3) 4-bromoacetophenone and 1-bromo-4-nitrobenzene were treated with styrene to give stilbenes **9**.



4 **5** **6**

Scheme 2. Suzuki coupling in the two-phase system with TPPTS, **3a**, and **3b** (R = $COCH_3$, Cl).



7 **8** **9**

Scheme 3. Heck reaction in the two-phase system with TPPTS, **3a**, and **3b** (R = $COCH_3$, NO_2).

In all cases, better yields and higher catalyst activities were obtained for the Heck and the Suzuki reactions with **3a** and **3b** than those with TPPTS (Tables 3 and 4). Very good yields were

achieved with as little as 0.1 mol% catalyst, as demonstrated by the treatment of 1-bromo-4-nitrobenzene with styrene. The improvement attained in the results for the new carbohydrate–phosphane ligands, as compared to those for TPPTS, is attributed to the greater concentration of catalyst in the nonpolar phase. The extent of the influence of electronic effects of the substituents on the ligand is currently under investigation.

Experimental Section

Compound **2** (1 equiv) and TBAHS (0.5 equiv) were dissolved in CH_2Cl_2 (ca. 0.4 M solution) and treated with the same volume of 1 M NaOH solution. After 5 min, **1** (5 equiv) was added and after 1 h the mixture was diluted with the 8-fold amount of ethyl acetate. The organic phase was washed with 1 M NaOH solution (2×), with water (2×), and with saturated NaCl solution (2×). After the organic phase had been dried over $MgSO_4$, the solvents were evaporated, and the residue taken up in methanol and treated with a little 1 M sodium methanolate solution. After 30 min the mixture was diluted with methanol, and the solution neutralized with acidic ion exchanger (Amberlyst 15). The ion exchanger was filtered off, the solvent evaporated, and the residue purified by column chromatography (silica gel 60) ($CHCl_3$/MeOH/hexane 6/1/1, v/v/v).

Activity of $[Sm(C_5Me_5)_3]$ in Ethylene Polymerization and Synthesis of $[U(C_5Me_5)_3]$, the First Tris(pentamethylcyclopentadienyl) 5f-Element Complex**

William J. Evans,* Kevin J. Forrestal, and Joseph W. Ziller

For decades it was thought that molecules of formula $[M(C_5Me_5)_3]$ were too sterically crowded to exist. Indeed, no examples had been found despite extensive work with a variety of C_5Me_5/M combinations. However, in 1991 the first tris(pentamethylcyclopentadienyl) complex was made simply by mixing the divalent complex $[Sm(C_5Me_5)_2]$ and cyclooctatetraene [Eq. (a)].[1] An improved synthesis of $[Sm(C_5Me_5)_3]$ was subsequently developed with the Sm^{II} precursor $[Sm(C_5Me_5)_2(Et_2O)]$ and $[Pb(C_5Me_5)_2]$.[2]

$$2[Sm(C_5Me_5)_2] + C_8H_8 \longrightarrow [Sm(C_5Me_5)_3] + [(C_5Me_5)Sm(C_8H_8)] \quad (a)$$

The isolation of $[Sm(C_5Me_5)_3]$ implied that other $[M(C_5Me_5)_3]$ complexes should exist if M is of similar or greater size than Sm and if synthetic routes are available. However, to date the only successful syntheses of $[Sm(C_5Me_5)_3]$ have involved Sm^{II} precursors.[2, 3] Since Sm^{II} has rather unique reactivity,[4] these routes are not available to any other metal. This is unfortunate since the interesting chemistry already shown for $[Sm(C_5Me_5)_3]$ (for example, the synthesis of complexes of thermally stable nonclassical carbonium ions) is incentive to make other $[M(C_5Me_5)_3]$ complexes.[5] We report here that $[Sm(C_5Me_5)_3]$ initiates ethylene polymerization and that this observation suggested a new route to $[Sm(C_5Me_5)_3]$, which can be applied to uranium to make $[U(C_5Me_5)_3]$.

$[Sm(C_5Me_5)_3]$ polymerizes ethylene at 344 kPa in toluene in 1 hour to form polyethylene, whose molecular weight is too high to be studied by NMR or field desorption mass spectroscopy (FD-MS).[6] The catalysis of ethylene polymerization by this sterically crowded molecule was unexpected since it contains

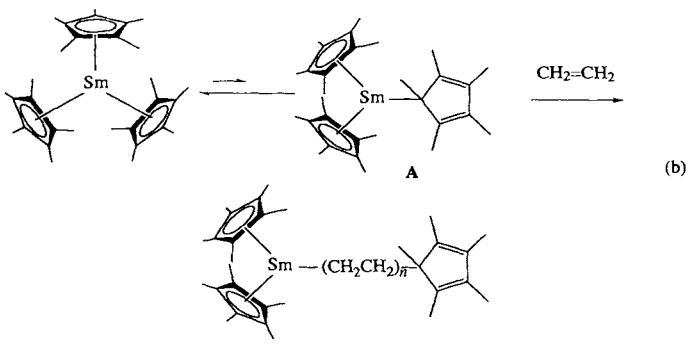
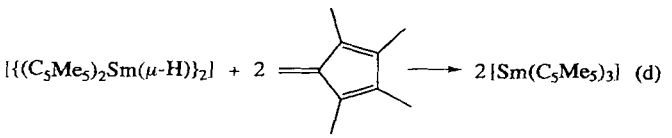
none of the usual hydride, alkyl, or Sm^{II} initiating sites.[6] The most likely route is via the η^1-C_5Me_5 intermediate **A** [Eq. (b)], but no evidence for the η^1 structure was obtained by low temperature NMR spectroscopy (− 80° C in toluene). However, reaction of $[Sm(C_5Me_5)_3]$ with H_2 formed $[\{Sm(C_5Me_5)_2(\mu\text{-}H)\}_2]$ and C_5Me_5H [Eq. (c)], which is analogous to reactions of σ-bound alkyl complexes $[Sm(C_5Me_5)_2R]$ with H_2,[7] and represents a rare example of the hydrogenolysis of a pentamethylcyclopentadienyl ligand.



(b)

$$2[Sm(C_5Me_5)_3] + 2H_2 \longrightarrow [\{(C_5Me_5)_2Sm(\mu\text{-}H)\}_2] + 2C_5Me_5H \quad (c)$$

If intermediate **A** is accessible with $[Sm(C_5Me_5)_3]$, β-hydrogen elimination could form $[\{Sm(C_5Me_5)_2(\mu\text{-}H)\}_2]$ and tetramethylfulvalene. Since this was not observed, we examined the reverse reaction and found that $[Sm(C_5Me_5)_3]$ could be obtained in greater than 90% yield from tetramethylfulvalene and $[\{Sm(C_5Me_5)_2(\mu\text{-}H)\}_2]$ [Eq. (d)].



(d)

This synthetic technique was applied to uranium to obtain the first tris(pentamethylcyclopentadienyl) complex of a 5f-element. $[U(C_5Me_5)_2H(dmpe)]$[8] reacted with tetramethylfulvalene to form $[U(C_5Me_5)_3]$ in 50% yield, which was characterized by elemental and chemical analysis, NMR and IR spectroscopy, magnetic susceptibility, and X-ray crystallography[9] (Figure 1). The 36 Hz line width of the ^1H NMR C_5Me_5 signal was consistent with values observed for other C_5Me_5-ligated U^{III} complexes.[8, 10, 11] Furthermore, reaction with D_2O exclusively formed D_2 as expected for a U^{III} complex.

$[U(C_5Me_5)_3]$ is isostructural with $[Sm(C_5Me_5)_3]$[1] and has the same crystallographic $\bar{6}$ symmetry at the uranium center, which leads to only three unique U−C bond lengths and a rigorous 120° Cn-U-Cn angle (Cn = ring centroid). The average U−C bond length (2.84(4) Å) is equivalent within experimental error to that in $[Sm(C_5Me_5)_3]$ (2.82(5) Å). The Shannon radius for U^{III} is 0.067 Å larger than that of Sm^{III}.[12] As in $[Sm(C_5Me_5)_3]$, the rings in $[U(C_5Me_5)_3]$ are oriented to minimize steric interactions. The progression U−C1 > U−C2 > U−C3 shows that each ring is tipped away from the uranium atom such that the U-Cn-C1 angle (94.1°) is larger than the idealized 90° and also larger than U-Cn-C2 (89.8°) and U-Cn-C3 (88.2°). The methyl groups are bent away from the center of the molecule, and the methyl carbon atoms lie out of the plane of the ring carbon atoms by 0.18 (C5) to 0.51 Å (C4). This methyl group displacement causes the Cn-C(ring)-C(methyl) angles to deviate from 180°; the angle containing C1 is distorted the most (Cn-C1-C4 162.5°, Cn-C2-C5 170.9°, Cn-C3-C6 167.3°).

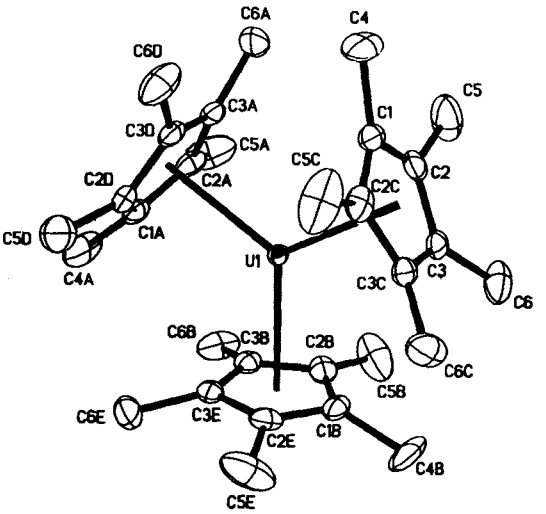


Figure 1. Molecular structure of $[U(C_5Me_5)_3]$. Thermal ellipsoids are drawn at the 50% probability level. Selected distances [Å]: U−C1 2.920(4), U−C2 2.840(3), U−C3 2.813(3), U−Cn 2.581.

Although tris(cyclopentadienyl) 5f-element complexes have been known for years,[13] only a few containing sterically demanding η^5-cyclopentadienyl ligands have been characterized by crystallography: $[Th\{1,3\text{-}(Me_3Si)_2C_5H_3\}_3]$,[14] $[U(Me_3SiC_5H_4)_3]$,[15] and $[U(C_5Me_4H)_3]$.[16] $[U(C_5Me_5)_3]$ is the first example of a fully permethylated analog. Comparison of this structure with other C_5Me_5-ligated U^{III} complexes is limited to just three crystallographically characterized examples: $[\{U(C_5Me_5)_2(\mu\text{-}Cl)\}_3]$,[10] $[U(C_5Me_5)_2H(dmpe)]$,[8] and $[U(C_5Me_5)(C_8H_8)(4,4'\text{-}Me_2\text{-}bpy)]$.[11] The average U−C distance in $[U(C_5Me_5)_3]$ is much larger than in these compounds (2.77(1), 2.79(3), and 2.752 Å, respectively). Interestingly, the U−Cn distance to the C_5Me_5 ring (2.58 Å) is only slightly longer than that to the C_5Me_4H ring in $[U(C_5Me_4H)_3(CO)]$ (2.53 Å).[16]

The synthesis of $[U(C_5Me_5)_3]$ will allow the reactivity of $[M(C_5Me_5)_3]$ complexes of 5f and 4f elements to be compared. Preliminary studies have shown that $[U(C_5Me_5)_3]$ also initiates polymerization of ethylene to high molecular weight, but does not form the same CO reaction product as generated by $[Sm(C_5Me_5)_3]$.[5] Extension of this synthetic technique to other metals should provide further examples.

Experimental Section

$[Sm(C_5Me_5)_3]$: Addition of tetramethylfulvalene [17] (3 mg, 0.024 mmol) to $[\{Sm(C_5Me_5)_2(\mu\text{-}H)\}_2]$ [18] (10 mg, 0.012 mmol) in C_6D_6 (1 mL) in an argon glovebox caused an instantaneous color change of the solution from orange to dark brown. The product was identified by ^1H NMR spectroscopy as $[Sm(C_5Me_5)_3]$ and isolated by removal of solvent (13 mg, 95%).

$[U(C_5Me_5)_3]$: Addition of tetramethylfulvalene [17] (74.0 mg, 0.55 mmol) to $[U(C_5Me_5)_2H(dmpe)]$ [8] (240 mg, 0.37 mmol) in toluene (5 mL) in an argon glovebox caused an immediate color change of the solution from black to brown. The solvent was removed to give a brown powder, and crystallization from hot toluene afforded very dark brown crystals (118 mg, 50%). ^1H NMR (500 MHz, 25°C, C_6D_6): $\delta = -0.93$. A frequent by-product of this reaction has a ^1H NMR resonance at $\delta = 7.89$, but this material has not yet been identified. ^{13}C NMR (500 MHz, 25°C, C_6D_6): $\delta = 324.8, -86.7$. Magnetic susceptibility: $\chi_m = 4.0 \times$

Stabilization of Iron Clusters by Polyolato Ligands and Calcium Ions: An Fe_{14} Oxocluster from Aqueous Alkaline Solution

Joachim Burger and Peter Klüfers*

The oxoiron(III) core of ferritin and the iron(III) mineral ferrihydrite, $Fe_5O_3(OH)_9$, appear to adopt a similar structure.[1] This structure has still not been resolved, and even the coordination number of the iron atoms is a matter of debate.[2] Hexagonal densest packing (hdp) is assumed for the oxygen atoms, thus explaining the transformation paths into the thermodynamically stable hdp phases goethite, α-FeO(OH) (diaspore structure), and hematite, α-Fe_2O_3 (corundum structure).[3] The high activation energy of the formation of crystalline phases indicates a fundamental structural reorganization in the course of the phase transition; this is apparently the reason for the metastability of noncrystalline ferric oxides/hydroxides.[4] We report herein on an oxoiron(III) cluster, which is formed in aqueous solution, and which is stabilized by polyolato ligands and calcium ions. Hematite fragments that are considered to be characteristic for the ferrihydrite structure are combined in the sense of a microtwin; thus, the formation of a crystalline bulk phase is not possible by mere nucleus growth.

The nonchiral sugar alcohol erythritol (*meso*-butane-1,2,3,4-tetraol) and ferric nitrate in the molar ratio 3:1 form green-yellow solutions on addition of aqueous sodium hydroxide solution ($c(Fe^{III}) = 0.25$, $c(OH^-) = 2.5\ mol\,L^{-1}$). Such greenish ferrate solutions may also be prepared by using simple diols in place of the tetraol.[5] In the course of a few months, solutions containing erythritol that have been slowly enriched with calcium ions turn brown, thus indicating increasing aggregation of ferric species ("RT-solution"). Ion chromatography reveals formiate and further carboxylates due to incomplete exclusion of oxygen. However, partial oxidation is not a basic requirement for aggregation; a brown coloration can also be achieved within a few hours when the NaOH-containing solutions are heated to 55 °C.[6] Subsequent addition of calcium nitrate causes calcium hydroxide to initially precipitate, but on continued stirring, redissolution takes place ("55 °C-solution"). Light scattering experiments on the RT-solution revealed particles of a hydrodynamic radius of about 2 nm; the particle radii ranged between 1 and 10 nm. Analysis of the 55 °C-solution revealed a wider distribution of the particle radii.[7] Solely in terms of the hydrodynamic radius, the oxoiron(III) cation described in the following is a typical, but not the only ferric species, in the brown solutions.

Half a year after the preparation several brown, well-formed tetragonal crystals formed in the carboxylate-containing RT-solution. X-ray crystal structure analysis[8] reveals the formula **1**

$$[Ca_{12}(H_2O)_{24}Fe_{14}(\mu_3\text{-}O)_{12}(\mu_2\text{-}OH)_4(OH)_{12}(LH_{-3})_4(LH_{-2})_4]X_6 \cdot 8H_2O \quad \mathbf{1}$$

(L = erythritol, X = formiate and other oxidation products of erythritol;[9] μ_n refers exclusively to Fe, not to Ca).

C*, **1996**, *52*, 2972–2975.

The S_4-symmetric hexacations contain an $Fe_{14}O_{12}(OH)_{16}$ core that is surrounded by deprotonated erythritolato ligands and diaquacalcium ions (Figure 1). The calcium ions are bound

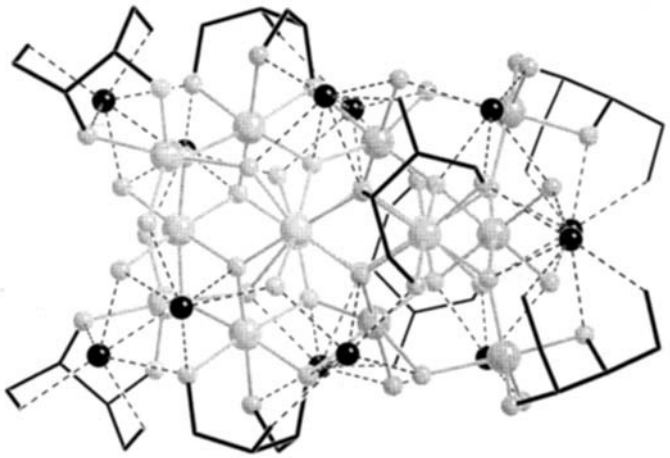

Figure 1. The $[Ca_{12}Fe_{14}O_{12}(OH)_{16}(LH_{-3})_4(LH_{-2})_4]^{6+}$ ion in **1** (two H_2O per Ca omitted); calcium ions and deprotonated erythritol ligands are highlighted. The S_4 symmetry axis runs horizontally. Distances [Å] (coding scheme for the O atoms: LH_{-3} ligand: O*n*1, LH_{-2} ligand: O*n*2, μ_3-O: O1–O3, μ_2-OH: O4, terminal OH group: O5–O7, water: O9*n*): from Ca1 to: O6 2.384(5), O1 2.448(5), O41^{i} 2.460(5), O91 2.467(6), O31 2.479(5), O21 2.480(6), O4^{ii} 2.494(5), O93 2.610(7); from Ca2 to: O11 2.345(6), O6 2.380(5), O7 2.388(6), O3 2.406(4), O98 2.453(8), O95 2.456(8), O5 2.464(6); from Ca3 to: O5 2.402(6), O32 2.414(6), O12 2.434(6), O92 2.467(6), O94 2.474(8), O11 2.501(5), O2 2.523(5), O42 2.524(6); symmetry codes: ^{i} $y, 1-x, 1-z$, ^{ii} $1-y, x, 1-z$.

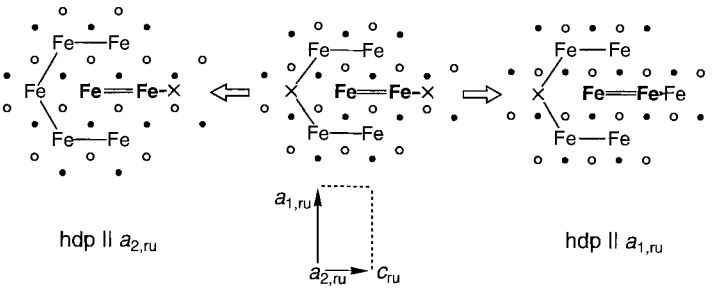
to all of the hydroxo ligands, thus preventing further condensation. Moreover, the oxocluster is also shielded by the polyolato ligands. The inner core of the oxo cluster is formed by ten iron centers, which are coordinated by μ_3-oxo, hydroxo, and LH_{-3} ligands (Figure 2). Four additional iron atoms are attached to the core through two oxo/hydroxo ligands each; these iron atoms are also coordinated to one LH_{-2} and one terminal hydroxo ligand and thus are five-coordinate with a trigonal-bipyramidal arrangement. Although, the inner Fe_{10} core appears as a compact entity, it is not a fragment of a common crystal structure type. The basic structural motif of **1** only becomes apparent after removal of the two iron atoms on the S_4 axis (in Figure 2 the two iron atoms in the middle of the cluster)—an M_8O_{32} fragment of the rutile structure (the darker portion in Figure 2), which is distorted by fitting in the central pair of iron atoms.[10] The construction principle of the entire $Fe_{10}O_{36}$ nucleus may be best derived by considering the rutile structure as a distorted variant of a hdp of oxide ions—a view that, though being common practice, should otherwise be avoided for symmetry reasons.[11] As a starting point, the projection of the Fe_8O_{32} rutile core along $[0\bar{1}0]_{rutile}$ is drawn in the middle of Scheme 1. The two equally feasible ways of altering the 11-coordinate sphere packing of the rutile oxide ions to a 12-coordinate hdp are depicted in the right and the left part of Scheme 1. On the left-hand side, the projection axis is the hexagonal stacking axis, thus a top view of the densest packed layers



Scheme 1. Relationship of the structure of the $Fe_{10}O_{36}$ core to the rutile and hematite structure. A double layer consisting of 2×13 O atoms is drawn, five O atoms above and below the double layer are omitted in each case (the corresponding symmetry-related atoms form the top and bottom edge of the drawing). Projections of hdp structures are drawn by assuming $c/a = 1.63$, the rutile core is drawn with the parameters of rutile itself. Iron(III) atoms that fit into octahedral voids of the oxygen packing are shown with their chemical symbol; non-fitting iron atoms are marked by a cross; boldface: a pair of iron atoms above and below the oxygen double layer; the S_4 axis of **1** runs horizontally.

Figure 2. The $Fe_{14}O_{48}$ core of the ion shown in Figure 1 in a projection approximately along S_4; the Fe_8O_{32} rutile core is the darker portion. Distances [Å] (Fe4 is five-coordinate, Fe2 is in a special position on the S_4 axis; coding scheme for the O atoms see Figure 1; Fe–Fe distances are listed for the edge-shared octahedra only): from Fe1 to: O2^{i} 1.976(5), O3^{i} 1.978(4), O1 1.988(4), O31^{i} 2.030(5), O41^{i} 2.067(5), O11^{i} 2.080(5), Fe3 3.0535(13); from Fe2 to O3 and O3^{iii} 2.003(4), O2 and O2^{iii} 2.006(5), O5 and O5^{iii} 2.022(5), Fe1^{i} and Fe1^{ii} 2.9289(12); from Fe3 to: O3 1.929(5), O1^{i} 1.932(5), O1 1.953(5), O6 2.056(5), O31^{i} 2.193(5), O4 2.210(5); from Fe4 to O2^{iii} 1.875(5), O7 1.947(6), O22^{iii} 1.950(6), O4 2.016(5), O32^{iii} 2.023(6). Angles [°] at the bridging oxo ligands: Fe3^{ii}-O1-Fe3 132.1(2), Fe3^{ii}-O1-Fe1 119.4(2), Fe3-O1-Fe1 101.6(2), Fe4^{iii}-O2-Fe1^{ii} 132.1(3), Fe4^{iii}-O2-Fe2 121.5(3), Fe1^{ii}-O2-Fe2 94.7(2), Fe3-O3-Fe1^{ii} 126.4(2), Fe3-O3-Fe2 126.0(2), Fe1^{ii}-O3-Fe2 94.7(2), Fe4-O4-Fe3 117.4(2); symmetry codes see Figure 1, in addition: ^{iii} $1-x, 1-y, z$.

is shown. One of the two iron atoms that was omitted in the last simplification step now fits into an octahedral void of the hdp, and together with four additional Fe atoms forms a U-shaped chain of five edge-linked FeO_6 octahedra. Fe_5 fragments of this geometry are sections of the honeycomb pattern of Fe atoms in hematite. In addition, they form a significant structural motif in the disorder model of ferrihydrite, which is based upon an hdp of oxide/hydroxide/water.[2a] The complete $Fe_{10}O_{36}$ core is built up by repeating the formal addition of a ferric ion that does not fit into the original rutile nucleus after transformation to an oxide hdp array. This second nonfitting iron atom is the right one in Scheme 1; it causes a distortion of the rutile structure according to hdp-stacking along $[100]_{rutile}$. Consequently, a hematite microtwin is formed by the interlocking of two Fe_5 fragments; this preserves the S_4 symmetry of the rutile core in the sense of a twin symmetry element.[12] In this context the left-hand side of the real structure (Figure 3) corresponds to the representation in Scheme 1 left and the right-hand side of the real structure to the representation in Scheme 1 right. Therefore, the construction of the $Fe_{10}O_{36}$ cluster provides an example of a well-structured oxoiron(III) species, which, however, is still not suitable as a nucleus for a macrocrystal. Thus, a path becomes apparent between the extremes of chaotic olation[4] to give amorphous gels and nucleation to give crystalline phases.

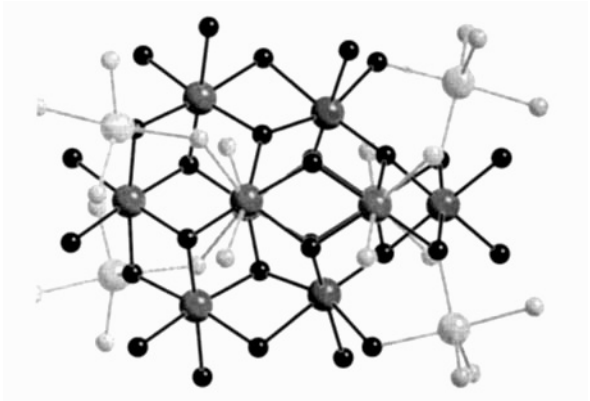


Figure 3. The micro-twinned $Fe_{14}O_{48}$ core (see text) in the same projection as in Figure 1; the idealized section of the structure drawn in Scheme 1 is darker.

For the analysis of the magnetic properties of **1**, a few of the larger (up to 1 mm) tetragonal crystals were ground, and the magnetic susceptibility was measured in the temperature range between 3 and 300 K (Figure 4).[13] The large extent of antiferromagnetic spin compensation[14] is, at first, unexpected for a three-dimensional coupling system like that in **1**. However, a qualitative relationship between spin coupling paths and cluster structure may be established to explain at least the higher temperature data. As an approximation, only the antiferromagnetic coupling through oxo-type ligands was taken into consideration, and the influence of bridging hydroxo and alkoxo ligands was neglected.[15] If the most obtuse Fe-O-Fe angles (see legend to Figure 2) are considered as being indicative of the strongest coupling, that is by applying the Goodenough–Kanamori rules,[16] the coupling scheme outlined in Figure 4 is obtained, in which each Fe_{14} cluster is divided into two Fe_7 fragments of opposite spin. Thus, the expected coupling scheme of the Fe_8 rutile core[17] is supplemented by six further Fe^{III} centers without changing.

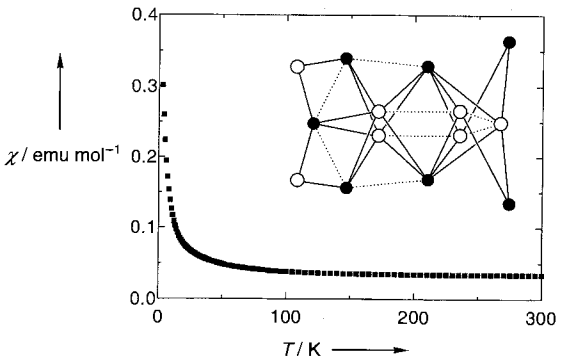

Figure 4. Temperature dependence of the maguetic susceptibility of **1**. In the insert two iron centers are linked by a solid line when the corresponding Fe-O-Fe angle is greater than 115°, and by a dotted line when the Fe-O-Fe angle is less than 105°. Two compensating spin systems are drawn in such a way that all obtusely connected iron centers are coupled antiferromagnetically. The direction of the projection corresponds approximately to that in Figure 3.

The three-dimensional[18] oxoiron(III) cluster in **1** is one of the rare examples of an oxoiron(III) cluster aggregated in aqueous solution. The largest clusters of this type (Fe_{17} and Fe_{19} species) have been described by Powell et al. and exhibit a brucite-type two-dimensional arrangement of octahedra.[19] Also the first polyolatoiron(III) cluster, which is a hexaferrate(III) with deprotonated inositol ligands, was prepared from aqueous solution.[20] As in **1** the oxo ligands in these clusters adopt the μ_3 bridging mode. As a rule, oxo bridges of higher hapticity are found in clusters that have been prepared in anhydrous or almost anhydrous media, which is in accord with the lower availability of oxo ligands in these solutions.[21] Here, typical bonding modes are μ_6 and μ_4, the latter is also the bonding mode of the oxide ions in hematite. Evidently, under the unphysiological conditions for the synthesis, structures are obtained with typical bridging modes, which may be different in a pure aqueous system.

Integrated Chemical Process: An Extremely Concise Synthesis of Vitamin A

Akihiro Orita, Yasuo Yamashita, Akiji Toh, and Junzo Otera*

Compaction of multistep chemical syntheses is strongly desired from both economical and ecological points of view. The ultimate goal is the one-pot process that has received extensive attention under names such as tandem, cascade, or domino reactions.[1] Although these reactions, once realized, are very elegant, much elaboration is necessary for preparing the precursors to the consecutive reactions. Hence, the overall process does not always gain in brevity when all steps from real starting materials are taken into account. In these reactions, the focus has been primarily on the carbon–carbon bond formation. This is quite reasonable in terms of the central role this manipulation plays in organic synthesis. In actual chemical processes, however, other steps such as functional group transformation and protection or deprotection of functional groups are equally important. Thus, it is more practical to devise one-pot processes that can accommodate chemical transformations of wider scope.

In conventional synthesis, a route to a target molecule is appropriately designed by, for example, retrosynthesis and fractioned into unit reactions. Each reaction then is optimized independently; in most cases, each step is conducted under different conditions. One-pot consecutive reactions are therefore only feasible when the reaction conditions of the successive steps are the same or similar *by chance*. Our basic idea has the opposite approach. First, reaction conditions that can be shared by all steps are chosen. Second, every step is optimized under these conditions. Consequently, all the steps can then be integrated to give a one-pot procedure.[2] Here, we exemplify the effectiveness of this "integrated chemical process" for a synthesis of vitamin A based on the double-elimination method previously disclosed.[3]

The stepwise procedure is illustrated in Scheme 1. The lithium salt of cyclogeranylsulfone **1** was treated with aldehyde **2** to give the addition product **3** (step 1). Alcohol **3** was converted to acetal **4** (step 2), and finally, exposure of **4** to *t*BuOK or MeOK furnished vitamin A (**5**) (step 3). Steps 1 and 3 were conducted under basic conditions, and step 2 under acidic conditions. We anticipated that a one-pot process would be feasible if the conditions for step 2 were made compatible with the others. This was indeed the case.

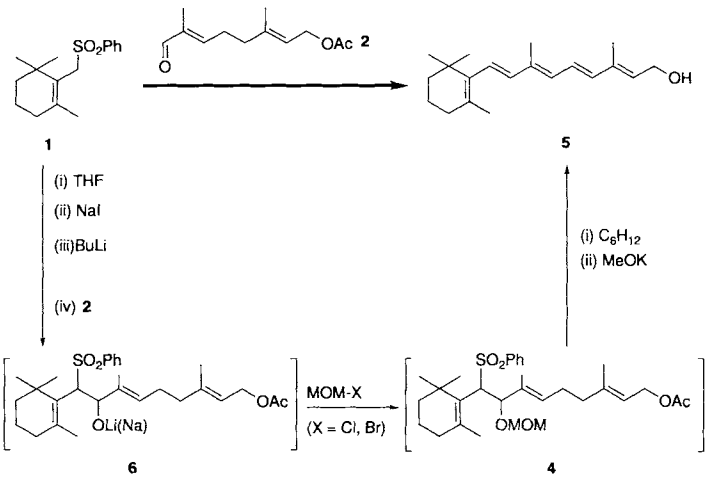
A typical one-pot procedure is depicted in Scheme 2; all steps were conducted under basic conditions. The lithium salt of **1** was treated with **2**, and the resulting addition product **6** was trapped with $MeOCH_2Br$ (MOMBr). The MOM ether **4** then underwent double elimination upon exposure to MeOK (10 equiv) to



Scheme 2. One-pot synthesis of vitamin A (**5**).

afford vitamin A. The yield of the acetate form was determined by HPLC to be about 50%. This is not too bad considering it is the total yield of the four sequential reactions (step 3 consists of elimination of first MOMOH and then $PhSO_2H$).[3c] However, polymeric materials derived from diene **7** formed as by-products. Fortunately, elimination of the terminal allylic alkoxide was suppressed by addition of NaI, which was given to the reaction mixture from the beginning since it did not influence the reaction in step 1. Moreover, addition of NaI allowed use of the more readily available MOMCl, which otherwise had failed to acetalize **6** in situ, probably by conversion of MOMCl to MOMI. Finally, addition of cyclohexane as a co-solvent in the elimination step increased the yield slightly (by ca. 3%). These modifications improved the yield to 76%, which is higher than 67% obtained by the corresponding stepwise process (step 1: 93, step 2: 92, step 3: 78%)[3c] Provided that the yield of step 3 was the same as that in the stepwise process (78%),[4] the total yield of 76% should have resulted from nearly quantitative reactions for steps 1 and 2. Apparently, material loss due to isolation and purification of the intermediates in the stepwise process is circumvented. Of further note is the isomeric purity of **1**: the high

all-*E* content characteristic of the double elimination process holds for the present case as well: all-*E*:9*Z*:[(11*Z*) + (13*Z*)] = 91:4:5.

We compared this new process with those used commercially.[5] The Hoffmann–La-Roche process involves a $C_{14} + C_6$ route, and BASF makes use of the Wittig reaction between C_{15} and C_5 building blocks. Rhône–Poulenc also employs the $C_{15} + C_5$ combination based on the Julia sulfone coupling. Our strategy is novel in that two C_{10} components are coupled. The C_{10} skeletons are one of the most common units in terpenoid derivatives and, accordingly, readily available. As a whole, our process has the twofold benefit of ready availability of the starting materials and simple operation.[6]

We have shown that the following reactions can be integrated: a) addition of carbanion to carbonyl, b) O-alkylation of the addition product, and c) successive elimination of the alkoxy and sulfinyl groups. The only modification of the stepwise process is made for the O-alkylation. This results in not only compaction of the process but increase in the total yield. Although we took up a rather simple case in this study, it has proved that even a slight modification can bring about critical improvements of the chemical process. This suggests the importance and potential of the integrated chemical process for designing a synthesis.

Experimental Section

NaI (225 mg, 1.5 mmol), cyclogeranyl sulfone **1** [3c] (362 mg, 1.3 mmol), and THF (2 mL, dried over sodium benzophenoneketyl) were placed in a flame-dried, two-necked flask. A solution of BuLi in hexane (1.6 M, 0.75 mL, 1.2 mmol) was added, and the mixture stirred at −78 °C (dry ice/MeOH) under argon for 1 h. After the addition of aldehyde **2** [3c] (211 mg, 1.0 mmol) in THF (1 mL) followed by MOMCl (0.09 mL, 1.2 mmol), the solution was stirred for 4 h at −78 °C and 1 h at room temperature. Cyclohexane (3 mL) and KOMe (701 mg, 10 mmol) were added, and the mixture stirred for 1 h at room temperature and 1 h at 40 °C. The reaction was quenched with aqueous $NaHCO_3$ solution (10 mL) and ethyl acetate (15 mL). After separation of the organic layer and extraction of the aqueous phase with ethyl acetate (2 × 15 mL), the combined organic fractions were washed with brine (20 mL), dried over $MgSO_4$, and concentrated under reduced pressure (crude, 452 mg). Hexane (5 mL), pyridine (0.5 mL), acetic anhydride (2 mL), and DMAP (48 mg, 0.4 mmol) were added to the crude product under argon, and the mixture stirred for 1 h at room temperature. Aqueous $NaHCO_3$ solution (20 mL) and ethyl acetate (15 mL) were added at 0 °C, and the organic layer separated. The aqueous phase was extracted with ethyl acetate (2 × 15 mL), and the combined organic fractions washed with brine (20 mL), dried over $MgSO_4$ and concentrated under reduced pressure (crude, 504 mg). The crude oil was analyzed by HPLC; 76% yield, 248 mg, all-*E*:9*Z*:[(11*Z*) + (13*Z*)] = 91:4:5 (column: ZORBAX SIL 4.6 mm × 25 cm; eluent: *tert*-butylmethyl ether/hexane 5/100; internal standard: 2,6-xylenol).

[6] Of course, accessibility of the key building blocks is an important factor for assessing the overall brevity of the process. A more detailed discussion will be given in a full paper.

Combinatorial Chemistry with Laser Optical Encoding

Xiao-yi Xiao,* Chanfeng Zhao, Hanan Potash, and Michael P. Nova

In the rapid development of synthetic and combinatorial chemistry,[1] solid-phase combinatorial synthesis[2] continues to be one of the most effective techniques for building diverse libraries. Advantages of solid-phase synthesis over solution chemistry include ease of intermediate isolation, use of excess reagents to drive reactions to completion, and potential use of the highly efficient pool and split[3] synthesis technique. Two elements are essential for successful solid-phase combinatorial library generation and evaluation: an efficient solid-support chemical reaction sequence and a reliable means for structural elucidation and confirmation[4] of library members. Although considerable efforts have been devoted to the development of solid-support chemistry,[2] the choice of methods for structural elucidation (spatial addressing,[5] mixture deconvolution,[6] direct microanalysis,[7] or chemical tagging[8]) is rather limited. Tagging—especially nonchemical, noninvasive tagging—is potentially the most efficient and reliable encoding method. We have recently developed a new, nonchemical, noninvasive radiofrequency encoding technology.[9] Here we report another strategy for noninvasive synthetic chemistry encoding, namely, laser optical tagging, with LOSCs (*L*aser *O*ptical *S*ynthesis *C*hips). This technology is applicable to library synthesis of all types of compounds including small molecules, peptides, and oligonucleotides in multimilligram quantities.

The LOSC technology combines the most advanced developments in laser bar code etching and identification as well as organic synthesis on novel solid supports. The initial LOSC is shown in Figure 1. It is fabricated by combining a two-dimensional 16-digit bar code for encoding and a polymeric support for chemical synthesis. The 2-D bar codes are laser-etched with a CO_2 laser on 6 × 6 segments of a chemically inert alumina ceramic plate (the actual size of each bar code is 3 × 3 mm). The surrounding synthesis support is a stable polypropylene or fluoropolymer square (10 × 10 × 2 mm), which is radiolytically

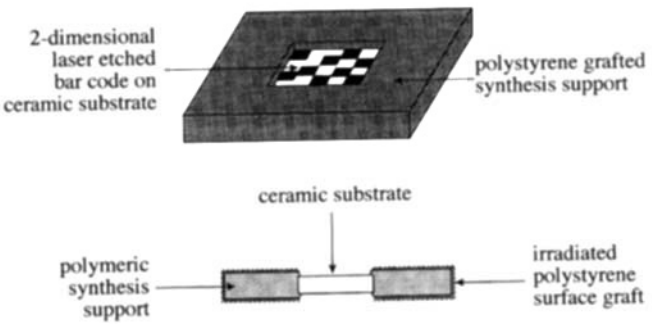

Figure 1. Illustration of the laser optical synthesis chip (LOSC), viewed from the top (top) and in cross-section (bottom). The size of the LOSC is 10 × 10 × 2 mm.

grafted with low cross-linking polystyrene.[10] Very small LOSCs can be manufactured, since the laser-etching optical resolution of an entire bar code can be extended well below a total diameter of 0.5 mm. Two-dimensional bar coding allows more data compression in a much smaller surface area than regular linear bar coding.

The LOSCs are then subjected to a modified aminomethylation[11] (or other procedures for introducing groups other than aminomethyl[12]) to functionalize the polystyrene surface graft. A loading of 5–8 μmol per chip is typically obtained, as measured by Fmoc (Fmoc = 9-fluorenylmethoxycarbonyl) analysis. The chips are now ready for use in chemical synthesis.

A "directed sorting" strategy (instead of statistical pool and split) is used with the LOSC for constructing combinatorial libraries with *zero redundancy* (that is, the number of LOSCs is equal to the number of library members). A small camera (QuickCam) that is linked to a proprietary pattern recognition and combinatorial synthesis manager software is used to scan the bar codes and register the chips with the library members. Before each reaction with n splits, the chips are scanned and sorted (split) into n groups as directed by the computer. After completion, the structure of the compound synthesized on each LOSC (if every reaction in the entire synthesis is successful) or the reaction pathway to which each LOSC has been subjected can be decoded simply by optically reading the 2-D image on the chip (Figure 2).

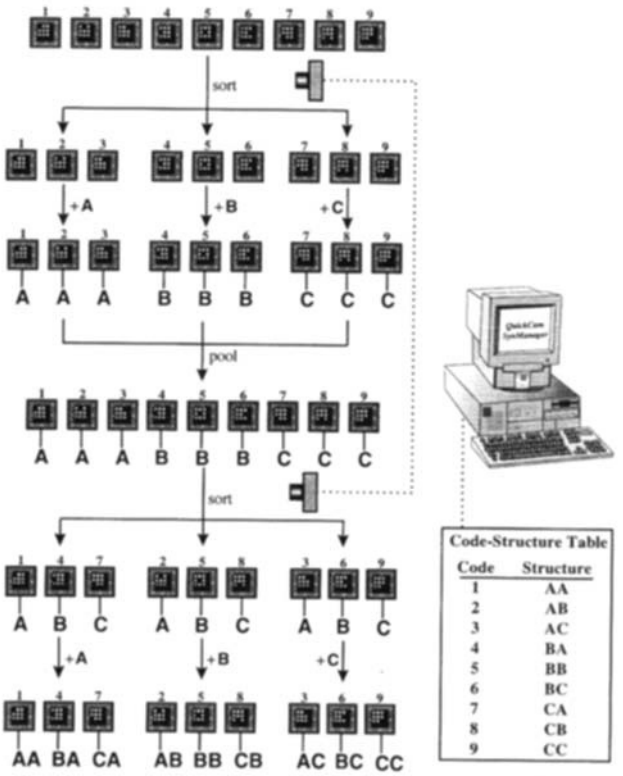

Figure 2. Schematic representation of a 3 × 3 pool and split combinatorial synthesis with the LOSCs and directed sorting. **A**, **B**, and **C** are building blocks. The numbers above each LOSC represent their 2-D bar codes (single-digit codes are used for brevity).

To demonstrate the utility of the LOSCs in chemical synthesis, a library of 27 oligonucleotides of general structure X_4-X_3-X_2-**T** was synthesized on 27 LOSCs with the directed sorting strategy. Standard oligonucleotide chemistry[13] was applied with the following modifications: CH_3CN/CH_2Cl_2 (2/3 v/v) was used for the coupling reactions, and ammonia in water/1,4-dioxane (1/1 v/v) for the cleavage. The cleaved, crude oligonucleotides were 67% to 97% pure, as determined by HPLC. Between 2 and 5 mg of pure oligonucleotide were isolated for each library member. The structures of the oligonucleotides were confirmed by MS, ^{1}H NMR spectroscopy,[14] and sequence analysis.[15]

The LOSC shown in Figure 1 can be widely varied in shape, configuration, and polymeric support. The ceramic 2-D bar codes carry at least 8 bytes of information. When etched on ceramics they are inert to the majority of organic synthesis conditions, easy and reliable to use, inexpensive, and very amenable to mass production. The low cross-linking polystyrene surface graft (and other polymer grafts) on the stable and inert base polymer provides an ideal solid support for chemical synthesis with excellent functionalizability and chemokinetics. LOSC technology can also be applied to the synthesis of other types of compounds, especially small organic molecules.[16] Potential advantages of LOSC technology over existing chemical tagging combinatorial techniques include 1) low manufacturing cost, 2) noninvasive encoding, 3) high encoding reliability and capacity, 4) total chemistry flexibility, 5) excellent chemokinetics, 6) easy and clean washing between reactions, 7) utilization of the highly efficient directed sorting strategy, 8) delivery of pure, discrete compounds in multimilligrams quantities, and 9) amenability to full automation. Integration of LOSC technology with automation will further enhance its applicability in high through-put chemical synthesis and biological screening and is now in progress.

Corrigendum

In the communication "Isolation of a Nonicosahedral Intermediate in the Isomerization of an Icosahedral Metallacarborane" by S. Dunn, G. M. Rosair, Rh. Ll. Thomas, A. S. Weller, and A. J. Welch (*Angew. Chem. Int. Ed. Engl.* **1997**, *36*, 645–647) incorrect $^{11}B\{^1H\}$NMR values were given in the *Experimental Section* for $BTMA^+$ $\mathbf{1}^-$. The correct values are as follows: $^{11}B\{^1H\}$NMR (128.4 MHz, (D_3CN): $\delta = -0.9$ (1B), -4.7 (2B), -8.1 (1B), -9.8 (2B), -10.9 (2B), -16.5 (1B).

Kompetenz in Wort und Bit

VCH biblio

Bibliographic Data Manager

VCH Software

VCH Biblio version 3.0 for Windows places at your disposal a bibliographic data manager that works the way you've always wanted.

More than just a database for organizing data manually, **VCH Biblio** also establishes vital connections to other information sources, turning data import from various popular databases (i.e. Medline, Chemical Abstracts, World Patent Index, Current Contents) into child's play.

Brief overview of the most important features

→ exceptionally flexible database
→ support for OLE 2.0
→ BASIC macro language
→ intuitive "drag and drop" operation
→ rapid searching, both indexed and full-text
→ data export in various formats
→ custom output formats
→ network compatibility
→ wide variety of data-import modules

Chemistry a Threat?

Green Chemistry. Designing Chemistry for the Environment. Edited by *P. T. Anastas* and *T. C. Williamson*. American Chemical Society, Washington, DC, 1996. 251 pp., hardcover $ 89.95.—ISBN 0-8412-3399-3

In 1983 the journal *Chemie in unserer Zeit* carried a report of an interesting experiment. Schoolchildren from eight classes in Basel, aged between 11 and 15, were asked to draw their impressions of what the word "chemistry" meant to them. The result—at a time only a few years after the Seveso accident—gave a clear message: a large majority of the children felt that "chemistry" was a threat to them and to their environment. Since then these children have grown up, and their impressions of chemistry will certainly not have changed. One of their pictures could almost be seen as a prophecy of the Bhopal catastrophe that came only a year later, and was at that time the worst accident in the history of the chemical industry. More than 2000 people died, and it is estimated that 300000 in a surrounding area of 10–20 km^2 suffered ill-effects. The disaster would not have occurred if the process for manufacturing the important insecticide carbaryl had been designed differently, so that the reactive and highly toxic intermediate methyl isocyanate, instead of being prepared separately and stored before use, would be formed only in situ and converted immediately into the end-product.

Since then there has been strong pressure from politicians to integrate environmental protection measures into process design, both in the chemical industry and beyond. That is slowly being put into practice, but it cannot be achieved overnight, nor without basic research. Therefore, in 1993 the National Science Foundation (NSF) and the Environmental Protection Agency (EPA) in the USA began a program aimed at furthering basic research on environmental aspects of synthetic methods and processes. The book reviewed here is evidently an early product of that program. It is based on the papers presented at a symposium held by the Division of Environmental Chemistry at the 208th National Meeting of the American Chemical Society in Washington, DC, on 21–25 August, 1994. The editors, P. T. Anastas and T. C. Williamson, belong to the EPA's Office of Pollution Prevention and Toxics.

In the first chapter the editors explain what is meant by "Green Chemistry" (or environmentally benign chemistry, since the literal translation would carry political overtones in Germany). They define it thus: "Simply stated, 'Green Chemistry' is the use of chemistry techniques and methodologies that reduce or eliminate the use or generation of feedstocks, products, by-products, solvents, reagents, etc., that are hazardous to human health or the environment." They see "Green Chemistry" as a new paradigm that requires every chemist to ask the question: "Is the chemistry I am doing the most benign that I can make it?"

The book contains 16 contributions that vary widely in character. Some describe interesting examples of environmentally benign chemistry in accordance with the above definition, whereas others are of a more speculative nature.

Several articles are concerned with the challenging task of reducing, and eventually eliminating, the use of phosgene as an intermediate in the chemical industry. In Chapter 2, K. Komiya and coauthors, of the Japanese chemical company Asahi, describe a new process for manufacturing polycarbonates. Bisphenol A is first prepolymerized with diphenyl carbonate in the melt. The prepolymerizate can be crystallized very easily, and polymerization then proceeds in the solid state to give the high molecular mass polycarbonate. This environmentally benign process for polycarbonate has the double advantage of eliminating the use of both phosgene and of methylene chloride as solvent. The polycarbonate produced is of better quality than that obtained with the phosgene process, and the cost of production appears to be competitive. Asahi has also developed innovative phosgene-free processes for diphenyl carbonate and for all the industrially important isocyanates.

In Chapter 4, W. D. McGhee and colleagues of Monsanto, USA, describe a method for synthesizing carbaryl without the use of phosgene and without isolation of methyl isocyanate. Isocyanates are generated from an amine and carbon dioxide using *o*-sulfobenzoic acid anhydride as an electrophilic dehydrating agent and are converted in situ to the final product. In Chapter 6, F. Rivetti, U. Romano, and D. Delledonne of EniChem, Italy, describe the synthesis of dimethyl carbonate by oxidative carbonylation of methanol using CuCl as the catalyst. Then, in Chapter 7, P. Tundo and coauthors report on the selective monomethylation of arylacetonitriles and of esters of arylacetic acids, using dimethyl carbonate as a non-toxic methylating agent.

Titanium-containing zeolites have interesting possibilities as catalysts for oxidation reactions using hydrogen peroxide. In Chapter 3, G. Petrini and coauthors (EniChem, Italy) describe a new process for the production of cyclohexanone oxime from cyclohexanone, ammonia, and hydrogen peroxide, with titanium silicalite as catalyst. This method avoids the formation of ammonium sulfate and greatly reduces the emission of SO_2, NO_x, and NH_3, which is a serious problem with the conventional process. The same catalyst has also been used for the epoxidation of olefines by hydrogen peroxide, resulting in a process that is much more environmentally acceptable than the conventional method, and is described in Chapter 5 by M. G. Clerici and P. Ingallina of Eniricerche, Italy.

In Chapter 12, M. D. Donohue, J. L. Geiger, A. A. Kiamos, and K. A. Nielsen (Johns Hopkins University and Union Carbide, USA) report in detail on the use of supercritical carbon dioxide in the spraying of paints and lacquers, which completely eliminates the problem of vapor from volatile organic solvents, and gives coatings of excellent quality. Chap-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

ter 11 is also concerned with the use of supercritical carbon dioxide as an environmentally benign solvent; the examples described here by D. A. Morgenstern and coauthors (USA) are the enantioselective catalytic hydrogenation of enamines and the copolymerization of CO_2 with epoxides.

The rest of the articles deal with more speculative topics. The environmental aspects of catalytic reactions discussed in Chapters 8–10 and of biotechnological processes in Chapters 13–15 are undoubtedly very important, as also is the education of chemists in accordance with the new principles of environmentally benign chemistry (Chapters 16–17).

This book should be in every chemistry library, and will provide many stimulating ideas for chemists involved in production, in basic research, and in teaching. Some of the articles may even come to be regarded in the future as milestones on the road to a new science of chemistry and a new chemical industry that is once more looked on favorably by society as a whole.

Multiply Bonded Main Group Metals and Metalloids. Edited by *R. West* and *F. G. A. Stone*. Academic Press, San Diego, 1996. 408 pp., paperback $ 65.00.—ISBN 0-12-744740-7

We are probably all familiar with a situation such as the following. While scanning through *Chemical Abstracts* you come across some interesting review articles that have appeared in Volume 39 of *Advances in Organometallic Chemistry*. You go eagerly to the library to find the articles, only to discover after a long and fruitless search that the order for this series has, like many others, had to be cancelled so as to achieve the savings targets that the authorities have demanded.

Is this an unfortunate isolated case? No, it is already an everyday situation in the libraries of many German universities. For this reason the initiative of Academic Press in starting to introduce a moderately priced paperback edition of this monograph is especially welcome. The book reviewed here is a paperback version of reviews covering novel types of multiple bonding for the heavier Main Group elements, a research topic that has contributed appreciably to the renaissance of molecular chemistry during the last two decades. The editors have assembled a team of recognized experts to write the individual chapters, many of whom have also made pioneering advances in their respective fields.

The book begins with a very readable survey by P. J. Brothers and P. P. Power of multiple bonding involving the heavier elements of Main Group 3, namely aluminum, gallium, indium, and thallium. The authors begin with a lucid description of homo- and heteronuclear single bonding situations for these elements; these are then compared with isolated or postulated multiple bonding situations, and plausible explanations of the bonding in the molecules are given.

The article by A. G. Brook and M. A. Brook on the chemistry of silenes, a class of compounds with a silicon–carbon double bond, occupies nearly a quarter of the book. Every facet of these still quite novel compounds is discussed thoroughly and clearly, and an extensive bibliography is provided. This overview reflects the tendency of some organic chemists to coin not only reactions, but also compounds, by attaching the names of researchers rather than functionalities. Thus, when the authors refer to the "Brook", "Wiberg", or "Jones-Auner" silenes, one wonders of whether these labels will stand the test of time. The authors' view that the heyday of silenes chemistry has now passed is probably justified, but a resurgence cannot be completely ruled out.

The articles on multiply bonded silicon–nitrogen compounds (J. Hemme and U. Klingebiel) and silicon–phosphorus and silicon–arsenic compounds (M. Driess) are much shorter, but are just as competently written as the previous one. Molecules containing these structural elements have in most cases only been isolated in pure form within the last few years, and consequently the range of their known chemistry is still rather limited compared with that of other multiply bonded systems that have been investigated more thoroughly.

Thus it is surprising to find that the article by R. Okazaki and R. West on the now well documented chemistry of the stable or nearly stable disilenes, compounds with a silicon–silicon double bond, is only slightly longer than the above. However, by means of clearly set out tables and numerous well-planned formula schemes the authors achieve the feat of presenting all the relevant information within a small space. The declared "threat" that no publications earlier than 1987 were to be referred to is, fortunately, not strictly enforced, and older papers are also mentioned where appropriate.

K. M. Baines and V. G. Gibbs took on the difficult task of reporting on homo- and heteronuclear double-bonding with germanium and tin as bonding partners. By presenting information in the form of easily readable tables and clearly drawn structural formulas and schemes, they have covered this rather heterogeneous topic in a convincing and successful way.

The penultimate article, in which A. J. Ashe and S. Al-Ahmed deal with diheteroferrocenes containing arsenic, antimony, or bismuth, is something of a disappointment, because it misses the opportunity to report on the latest developments in multiply bonded systems with these elements, for instance the arsaalkenes and arsaalkynes. Although the article is just as well written as the others in the book, it seems out of place here because of the different choice of subject matter. This is all the more surprising when one remembers that Ashe has made important research contributions in the area of multiple bonding of elements of Main Group 5, for example through elegant syntheses of phospha-, arsa-, stiba- and bismuthabenzenes.

It is difficult to understand why the excellent article by J. J. Eisch on boron–carbon multiple bonding has been relegated to the last position. With the exception of carboranes, which the author prefers to leave to the inorganic chemists, the review contains a very good account of all aspects of the topic, including acyclic boranes, cyclic and polycyclic systems, and the nonclassical methyleneboranes. The book ends with a very comprehensive keyword index.

The editors have evidently had to arrive at a compromise between an ideal treatment and one that is achievable in practice. Although most of the chapters include some mention of theoretical aspects, it would have been desirable to draw these together in a unified form. Also, in view of the inclusion of a chapter on boron–carbon multiple bonding, one has to ask why there is not one on boron–nitrogen multiple bonding.

However, considered as a whole this is a very useful book. The typesetting is clear, and the structure diagrams are well drawn and mostly in a consistent style. The literature coverage extends to the end of 1994 in most cases, and occasionally into early 1995. The fact that a few of the chapters already need to be extended to include new knowledge is an indication of the high level of research activity in this field. The monograph can be recommended for everyone with an interest in the molecular chemistry of the Main Group elements.

The Chemistry of Heterocycles. By *T. Eicher* and *S. Hauptmann.* (Series: Organic Chemistry Monographs.) Thieme, Stuttgart, 1996. 504 pp., softcover DM 84.00, hardcover DM 148.00.—ISBN 3-13-100511-4/3-13-100521-1

Despite the undeniable significance of heterocyclic chemistry in organic synthesis, biochemistry, medicine, agriculture, and industry, this rich and vital area does not always receive the attention that it deserves. During the 1980s few new textbooks on this subject became available, and the focus shifted to synthetic methodology, retrosynthetic analysis, and emerging areas such as molecular recognition. However, the central importance and significance of heterocyclic chemistry remains, and is now being increasingly recognized. Reference works such as Katritzky's *Advances in Heterocyclic Chemistry* and *The Chemistry of Heterocyclic Compounds* continue to appear on a regular basis, but these are now being joined by new series such as *Progress in Heterocyclic Chemistry* (Pergamon) and *Advances in Nitrogen Heterocycles* (JAI Press). The second edition of *Comprehensive Heterocyclic Chemistry* (Pergamon) will also be making a timely and authoritative appearance in the near future. On the textbook front, Joule, Smith, and Mills' splendid *Heterocyclic Chemistry* (Chapman and Hall) appeared as a long overdue third edition in 1994, and the third edition of Gilchrist's excellent *Heterocyclic Chemistry* is also due out in 1997. Here Eicher and Hauptmann offer an alternative textbook entitled *The Chemistry of Heterocycles.* This book originally appeared as a German edition in 1994, and is now available as an English translation.

Eicher and Hauptmann approach their topic in a very traditional way, working through the various families of heterocyclic compounds in a thorough and logical fashion. The book formally consists of nine chapters, although Chapter 1 is really just a brief introduction and Chapter 9 is simply a 3-page summary of source materials. Chapters 3 and 4 deal briefly with three- and four-membered ring systems, respectively. Small-ring systems are described at an appropriate level of detail, but they are not given an in-depth treatment. In Chapters 5 and 6, which make up more than 80% of the text, five- and six-membered ring systems are covered in much greater detail. Seven-membered ring systems have their own brief chapter, while Chapter 8 deals with "Larger Ring Heterocycles".

The individual chapters are subdivided and redivided into multiple sections. For instance, Chapter 5 starts out with 11 pages on the synthesis and properties of furans, and follows this up with shorter sections on benzo[*b*]furans, benzo[*c*]-furans, dibenzofurans, and tetrahydrofurans. The chapter continues with thiophenes, pyrroles, and their relatives, before moving on to ring systems with multiple heteroatoms. Although reduced structures are covered in a perfunctory way, the major emphasis is placed on heteroaromatic structures. Each heterocyclic system is described in up to five subsections, A–E. Initially (section A), the structure and spectroscopic properties of the heterocycles are related. A nice aspect of this format is that spectroscopic data (UV–vis, proton NMR, carbon-13 NMR, etc.) for the parent structure are provided, and this allows the reader to make useful comparisons between different heterocyclic ring systems. This is followed by a description of the chemical properties/reactions (Section B) and common synthetic methods/ring synthesis (Section C) for the heterocycle under review. A description of important derivatives, industrial applications, and occurrence in nature is given in Section D, where relevant. Finally, section E notes the uses of a given heterocyclic system as a building block or auxiliary for organic synthesis, and thereby attempts to bridge the gap to mainstream organic chemistry.

Chapter 8 describes heterocycles with 8-membered or larger ring systems, although two-thirds of this 15-page chapter deal with the porphyrins and related structures such as phthalocyanines. This area is very close to the heart of this reviewer and perhaps received more scrutiny than other readers would have given it. Although the presentation of this material was clearly laid out, I was left with the feeling that this section might well have been written in virtually the same way 25 years earlier. Few of the new developments in porphyrin chemistry are included, although, to be fair, several examples of newer "porphyrin analogs" from the work of Franck and Vogel are included at the end of this section. An expansion of the discussion of aromaticity in porphyrinoid structures might have helped to integrate this material with the rest of the textbook.

Overall, I found *The Chemistry of Heterocycles* to be an authoritative and valuable resource. Each chapter has a selection of pertinent references, and while these are by no means exhaustive they emphasize the recent literature rather than subjecting the reader to a long list of ancient citations that are readily available elsewhere. The highly segmented approach used by the authors makes *The Chemistry of Heterocycles* very easy to use as a reference book, although this does interfere somewhat with the flow of the text and thus with its readability. Nonetheless, this is an excellent and relatively inexpensive book, and it deserves a place on the bookshelf of any organic chemist with an interest in heterocyclic compounds.

The Application of Analytical Methods to the Detection of Hidden Explosives and Explosive Devices

Peter Kolla*

The detection of hidden explosives has undergone an enormous development due to an increased desire for safety and the increased terrorist attacks in the last few years. This development was made possible in particular by the rapid advances in the development of powerful analytical techniques in general. These technologies, however, must be specially adapted for the problems of explosives detection. These problems encompass, for example, the large variety of different explosives, the camouflage of explosive devices, and the complexity of the composition of suspicious objects. Frequent air-travelers have most certainly already been confronted with a so-called explosives detection apparatus. Baggage controls at airports are a very important and well-known example of the application of detection technologies. This example also serves to demonstrate the high technological requirements, such as the variability of the object to be examined and a control procedure for a sealed object that must be completed with high reliability in a short period of time. The search for explosive devices or weapons cannot, however, be limited to the recognition of an external appearance with the help of X-ray imaging. These days, explosive devices, in particular, can readily be installed and hidden in objects of daily life by the use of tiny electric and electronic elements. Therefore, in addition to the application of X-ray imaging, the use of other technologies becomes necessary. The following article describes and discusses methods and scientific limits of explosives detection under the precondition of possible use at security checkpoints.

Keywords: analytical methods · explosives · gas analysis · γ irradiation · X-rays

1. Introduction

Using technical criteria, one can roughly differentiate two approaches for the detection of explosive devices: 1) the detection of typical elements of explosive devices based on their appearance, such as wires, power supply (batteries, accumulators), parts of the release mechanism (clocks, pressure sensors), or detonators; 2) the detection of the explosive itself.

The two approaches require different technologies[1] and are based to some degree on the similar design of explosive devices. Home-made explosive devices with an unconventional design are correspondingly difficult to detect. Very exotic explosive devices will not be discussed herein. The technologies presented in this article will be discussed with respect to their applicability to the majority of explosive devices, which primarily consist of industrial components.

The detection based on morphology requires fixed, well-defined components of explosive devices. These include the power supply for the release mechanism (e.g., batteries), wires, detonator, and the triggering mechanism. In general, each of these components contains metallic parts, if the device is electrical or electronic in nature.

The simplest exclusion method is the application of conventional metal detectors. The information provided by this technique is too meager (a yes/no response) to allow further conclusions. Classical X-ray imaging[2] is much more effective in this area. In this technique one obtains a very good pictorial representation of a container's interior as a function of the X-ray absorption behavior. The quality of the image is dependent on the resolution of the instrument in question. With some experience, it is possible to recognize most everyday items from the X-ray image, and objects that could potentially represent a threat can be selectively examined. An expert can recognize an explosive device within a container containing a moderately complex mixture of items; however, the large variability in the design of explosive devices, in particular improvised ones, does not allow a reliable classification in most cases. If there are several objects within the container that contain metallic parts, or if electrical/electronic devices such as radios, computers, or cameras are present, the presence of an explosive device cannot be safely excluded. There have already been cases of explosive devices installed in these units in such a manner as to maintain the original functionality, for example as a radio.

These general considerations and, in particular, the ill-defined design of improvised, unconventional explosive devices have

[*] Dr. P. Kolla
Bundeskriminalamt
D-65173 Wiesbaden (Germany)
Fax: Int. code +(611)55-3875

lead to a concentration on detection techniques that target the energy carrier, that is, the explosive itself. The development of techniques for the detection of explosives necessitates several challenging limiting conditions for an explosives detector, which rule out the application of certain techniques. Such limiting conditions are:

- detection of the explosive within a closed container
- reliable detection of all explosives
- no false positives for materials that are, in fact, not explosives
- short cycle times
- (semi)automatic process

For some of these requirements, compromises are possible, but the ideal instrument would fulfill all conditions.

Before discussing possible technical solutions, it is necessary to consider the chemical nature of explosives, in particular with respect to the question: Which characteristic do all explosives have in common (except the inherent danger of detonation) that can be utilized for detection, and which clearly distinguishes explosives from other materials of daily life?

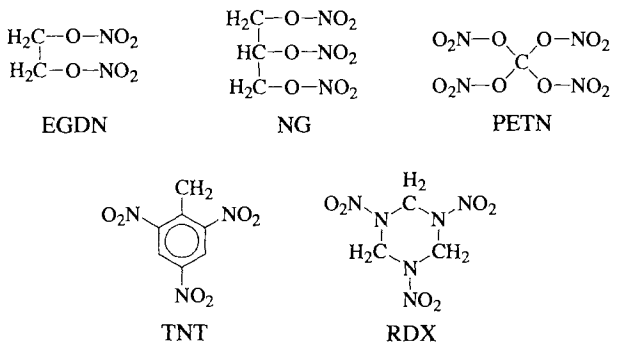
2. General Review of Explosives

Explosives are compounds that can deliver a very large amount of energy by a very fast internal chemical reaction.[3] This reaction is an oxidation and proceeds without the participation of an external reactant. Oxidant (oxygen carrier) and reductant (fuel) can either be present in two separate molecules (mixtures) or be part of the same molecule. If both reactants are present within the same molecule, the reaction proceeds fast, and the species is categorized as a high explosive. In general, mixtures of oxygen carriers (usually inorganic salts) and fuels react more slowly and have smaller detonating forces. The power of such mixtures can be significantly enhanced by the addition of high explosives.

2.1. High Explosives

The traditional high explosives are nitro compounds. The nitro group is fairly readily introduced into organic molecules, and the resulting nitro compounds are relatively stable in spite of the large number of nitro substituents required.

Scheme 1 shows some typical examples of nitro compounds that are utilized as explosives themselves or in explosives mixtures. Based on the bonding of the nitro group, nitrate esters (nitroglycerin, nitropenta), nitramines (hexogen) and aromatic nitro species (TNT) can be distinguished. In terms of detection, the nitro group itself, as well as the density of nitro groups, represent distinguishing features.



Scheme 1. Typical nitro compounds in explosives. EGDN = ethyleneglycol dinitrate, NG = nitroglycerine, PETN = pentaerythritol tetranitrate, TNT = trinitrotoluene, RDX = hexogen.

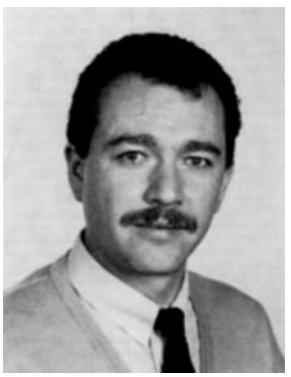
2.2. Initiating Explosives

Initiating explosives are also high explosives, but in addition they also detonate readily and are chemically different from the above-mentioned nitro explosives. The most commonly used species are lead trizinate, lead azide, mercuric fulminate, or diazodinitrophenol.[4] The heavy metal content of lead and mercury compounds can be exploited for detection purposes.

2.3. Commercial Explosives

The term commercial explosives[5] is used for species that are manufactured for civilian applications, for example, in quarries, mining, or tunnel construction. These explosives must be cheap and efficient and generally do not require high detonation veloc-

Dr. Peter Kolla, born January 17, 1960, studied chemistry from 1980 to 1985 at the Universität des Saarlandes. During the final phase of his studies, he concentrated his interests on the areas of physical chemistry and instrumental analytical chemistry. In 1986 he moved to the Max-Planck Institut für Kohlenforschung in Mülheim/Ruhr, where he joined the group of Professor Schomburg. His dissertation about ion chromatography was also supervised by Professor Engelhardt at the Universität des Saarlandes. After obtaining his Ph.D. and a brief further stay at the Max-Planck-Institut für Kohlenforschung, he moved to the Bundeskriminalamt (German Federal Police) to specialize in the area of explosives and unconventional explosive devices. Apart from his work as forensic expert in this field, he is also active as scientific adviser to the responsible agencies in the area of detection of explosives in the context of air traffic safety. Dr. Kolla is known through his publications in specialized journals, as well as through numerous talks at international meetings and workshops on forensic studies and detection of explosives.



ities. In general, they consist of nitrate salts (usually ammonium nitrate), which are mixed with fuels such as oil or other carbon compounds. When required, power-enhancing additives (e.g. explosive oils) can be added to these mixtures. The nitrate component or the power-enhancing additives can be used for detection purposes.

2.4. Home-Made Explosives

For home-made explosives, a general chemical classification is not possible. Apart from organic substances, such as individually prepared nitro compounds or peroxides (e.g., triacetone triperoxide[6]) one finds various mixtures of strong oxidants and fuels among this type of explosive. The most commonly used oxidants are nitrates, chlorates, perchlorates, and permanganates. The fuels used range from mineral oil over vegetable oils and sugar to metal powders, sulfur and phosphorus. Most mixtures are very sensitive to shock or friction and containment is generally necessary for the construction of an explosive device. Due to the large variability of these home-made devices, any detection must be based on the identification of the substance used as opposed to the identification of common characteristics.

2.5. Propellants

Propellants[7] are closely related to explosives. The primary difference lies in the reaction velocities. Propellant charges undergo a more rapid burn. The burn velocity is controlled by the particle size, the particle geometry, and chemical additives.

Like many home-made mixtures, propellant charges in tightly sealed containers can be utilized as explosives. In ammunition, propellant charges consist of nitrocellulose, which is mixed with stabilizers, phlegmatizers, and gelling agents. In multibase powders, nitroglycerin or diethyleneglycol dinitrate is added.

Solid rocket propellants consist, for example, of strong oxidants such as ammonium perchlorate and polymeric binders. The detection of propellants is possible through the nitro group in the case of nitrocellulose powder, while the other materials must be identified by their chemical nature.

3. Detection Techniques

The techniques utilized for the detection of explosives are closely related to the general methods of instrumental chemical or physical analysis. In practice, two fundamentally different approaches are chosen: 1) detection by interaction with radiation and 2) gas analysis of the components of explosives. The fundamental difference between these two techniques is that the gas-analytical methods actually collect and use molecules or parts of the explosive to be detected, while the radiation-based methods can function without material consumption. The radiation-based methods require a certain minimum quantity of explosive. The gas-analytical techniques require a minimum amount of collectable traces, independent of the actual amount of explosive present.

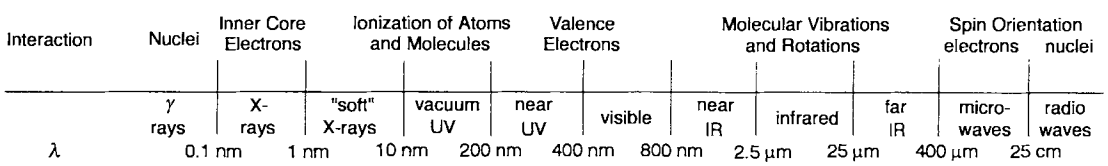
3.1. Detection of Explosives by Interaction with Radiation

These methods are commonly employed for the examination of materials, but the present problem is significantly more difficult. As a result of the limiting conditions mentioned at the outset, one does not deal with optimally prepared samples; rather it is necessary to detect the explosive in any given form from the outside of its complex container.

Upon consideration of the types of radiation that are available and their specific interaction with matter (Scheme 2), it is readily apparent that, from an analytical viewpoint, there is a dilemma: The types of radiation that, due to the wavelengths employed, can yield specific information about molecules and bonds (microwaves, infrared, visible light, or even UV radiation), cannot penetrate an object, exactly because of their specific interaction with matter. More or less energetic radiation[8] either does not yield any interaction at all or leads to electronic transitions within atoms or even nuclear reactions. Whether these types of radiation can nevertheless be employed for the detection of explosives is discussed in the following sections.

3.1.1. Detection with Radio- and Microwaves

Radio waves can interact with nuclear spin states within magnetic fields. This effect forms the basis for the much-utilized method of nuclear spin resonance (NMR).[9] The application of this technique to the detection of hidden explosives in containers requires several extensive modifications of technical specifications and in particular the choice of a suitable nucleus. Serious problems arise from the interference of everyday materials that are also present in the containers under examination, such as textiles, plastics, groceries. The conventional measurement of the chemical shift of ^1H nuclei for the characterization of organic substances is not applicable here, because of the complex mixture of signals and the interference mentioned above. The relaxation time[10] for ^1H nuclei, however, is more specific to explosive molecules in complex environments. The requirements for the sensitivity of the detection of small amounts of explosive (e.g., in suitcases) and the limited time available for measurements at the checkpoint lead to many false alarms.[11]



Scheme 2. Types of radiation and their interaction with matter.

An interesting alternative could be found in the large number of ^{14}N nuclei in explosives.[12, 13] However, though the method applied to these nuclei, nuclear quadrupole resonance (NQR), is much more specific than ^{1}H NMR, there are still problems connected with a reliable detection of explosives in varying environments.

The application of microwaves would allow the use of electron spin resonance (ESR). This technique is similar to nuclear resonance spectroscopy, but instead of the nuclear spin, the different energy states of unpaired electrons are employed for the interaction. The application of ESR to the detection of hidden explosives is very limited. Most explosives do not contain unpaired electrons; sometimes, however, a weak ESR signal can be detected that stems from unknown impurities. The best chance for detection was found for black powder, for which a rather sensitive ESR signal was found.[14]

Apart from interacting with the magnetic properties of unpaired electrons, microwaves are also scattered in the material they penetrate.[15] This effect of microwave radiation is based on the macroscopic structure of the material, and the density, in particular, has a significant influence. Microwaves of higher frequency, which could be useful for gaining information about the molecular structure, do not, in general, penetrate the container walls to the environment of the explosives.

The main disadvantage of radio and microwaves stems from the ease of shielding and camouflaging explosives against this radiation. Simple wrapping in metal foils would be sufficient. Further disadvantages include interference from everyday materials, an enormous increase in the number of false alarms due to the multitude of explosives to be detected, possible damage to electronic components or data storage devices by the strong magnetic fields necessary for NMR or ESR, and the long wavelengths of the radiation that would prohibit a reasonable spatial resolution within the examined container.

Advantages which should be noted include the possible automation of these methods, the fact that NMR or ESR yield information specific to the detected molecules, and the potential detection of liquid explosives.

3.1.2. Detection with X-Rays and γ-Rays

On the short-wavelength side of the electromagnetic spectrum, X-rays and γ-rays as forms of penetrating radiation have wavelengths between less than 10 nm and 0.001 nm.[16] These short wavelengths preclude an interaction with molecular bonds or vibrational or rotational excitation in molecules. X-rays and γ-rays penetrate nearly all materials and are therefore of particular interest for the detection of hidden explosives.[17]

In order to judge the applicability of X-rays for detection purposes, it is first necessary to consider the different interactions and analytical applications. There are three analytical applications.

3.1.2.1. Emission of X-Rays

This method is based on the fact that the X-radiation emitted from excited atoms is characteristic for the element in question and that its intensity is proportional to the number of excited atoms. The excitation of atoms can be achieved by direct electron bombardment (direct emission analysis) or irradiation with X-rays of higher frequency (X-ray fluorescence analysis). Direct electron bombardment cannot be applied to the detection of explosives, as electrons are absorbed by the container surface, making penetration of the object impossible.

The excitation by X-rays of higher frequency is penetrating, but the intensity of the resulting fluorescence radiation is smaller by a factor of 1000 than that released by electron bombardment. Apart from technical problems, such as the spectral resolution, very sensitive X-ray detectors would be required.

Organic nitro compounds, the most common high explosives, are not detectable because of the very low intensities, and the usefulness of the method is greatly reduced for elements with atomic numbers smaller than that of magnesium.

3.1.2.2. Absorption of X-Rays

The different absorption by materials, depending on elemental composition, thickness, and density, has long been used to image the hidden contents of a variety of objects. The basic equation governing the transmission of a monochromatic X-ray beam is a simple exponential function [Eq. (a), I = intensity,

$$I = I_0 \exp(\mu(gt)) \qquad \text{(a)}$$

μ = mass absorption coefficient, t = thickness of the sample, g = density].[18] The mass absorption coefficient is independent of the physical or chemical state of the material. It does depend on the wavelength (energy) of the X-ray photon and the absorbing atom. The mass absorption coefficient encompasses four physical phenomena, the sum of which determines the total attenuation: a) The photoelectric effect: this describes the absorption of a photon by an atom and the ejection of an electron (with an energy that is equal to the incident X-ray energy minus the binding energy of the electron). This effect is important for heavy elements (large atomic numbers). b) Classical scattering without a change in energy. At higher energies this effect is masked by the Compton effect. c) The Compton effect: this describes the interaction between an X-ray photon and an electron of the absorbing atom. The photon transfers part of its energy to the electron and a deflected photon of reduced energy results. The Compton effect is important for lighter elements. d) Pair formation: this describes the transformation of a high-energy photon into a positron and an electron upon the interaction with the nucleus of a heavy atom. This effect is only relevant for energies of more than 1 MeV and is discussed in Section 3.1.3.1 on methods utilizing γ-radiation.

These phenomena can be exploited in several ways for the detection of explosives. The transmission of X-rays can be measured opposite the source (Figure 1), or scattered X-rays can be detected at other locations around the object under examination.

In the usual application, the transmission of X-rays is measured in a linear field by X-ray detectors. The object under examination moves on a transport belt through the radiation. The machines used at checkpoints usually employ X-rays of energies below 150 kV, so that the first three of the above mentioned effects, namely the photoelectric effect, general scattering, and the Compton effect, contribute to the attenuation.

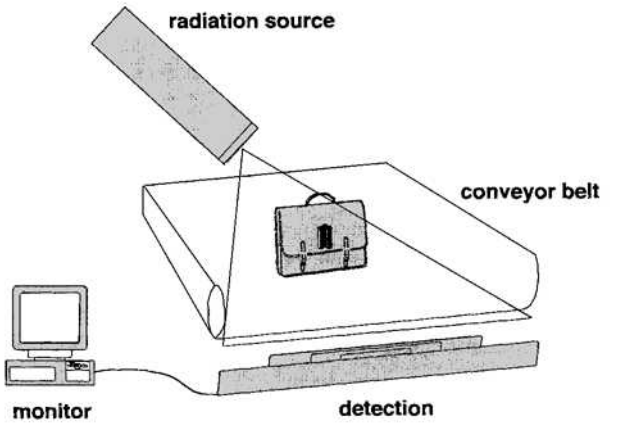


Figure 1. Schematic representation of an imaging process.

The highest information content would be achieved if each finite area segment could be examined by energy-dispersive analysis. The spectra obtained thus would allow a qualitative elemental analysis, because the photoelectric effect yields absorption edges typical for each element. The energy-dispersive analysis of such finite area segments, however, is probably technologically not feasible due to the limiting conditions imposed on the detection of explosives. In addition, most of the information collected applies to atoms of elements with higher atomic numbers; consequently this method is of less interest for organic explosives.

If a simple absorption measurement is performed, that is, without energy resolution, the problem arises that the transmission is not only determined by the mass absorption coefficient, but also by the density and thickness of the material. Thick, but only weakly absorbing materials lead to the same absorption as thin, but strongly absorbing matter. In order to eliminate this problem, the dual-energy method was introduced.[19, 20] This is fairly readily realized technically, either by the use of two types of detectors or by shielding some of the detectors with a more strongly absorbing material. The dual-energy method utilizes the fact that the photoelectric effect is strongly dependent on the atomic number. Light materials absorb only low-energy X-rays, while heavier ones absorb lower and higher energy radiation. The ratio of these transmission values at low and high energy is no longer dependent on the thickness or the density of the material in question. Hence, this ratio can be used to indicate the kind of material under examination. A high value for this quotient points to the presence of organic materials; heavy elements yield small ratios.

The Compton effect can be used more directly by setting up the detectors on the same side of the object under examination as the X-ray source. This method of detecting the Compton backscattering[21] yields information on light materials within the object, as long as they are not shielded by heavy materials.

The successful application of X-rays to the detection of hidden explosives is primarily limited to explosives that contain heavier elements. These include many initiating explosives and home-made devices with high chlorine or metal content. Organic materials can only be distinguished when clearly distinct values for the effective atomic numbers are present. Even in this case, a sufficient number of similarities between explosives and harmless materials still provide difficulties. The newest systems, which utilize the method of determining the effective atomic number to a high degree of accuracy, are capable of making distinctions even in situations where only small differences are present. In general, a direct elemental resolution is not feasible and reliable identification of explosives is not possible. Therefore, tolerant settings of the detection limits will lead to many false negatives and false positives. The main advantage of modern X-ray applications, such as the dual-energy method, Compton backscattering, or even X-ray tomography, lies in the excellent images obtained of the contents of the examined objects. Potentially dangerous objects can be identified with these methods, which can subsequently be more closely examined with more specific techniques.

3.1.2.3. Coherent X-Ray Scattering

This method, which is known from crystal structure analyses, exploits the coherent scattering of X-rays at the crystal lattice planes of solid substances. X-ray photons of a given energy are scattered at a defined angle.[22] The mathematical relationship is given by Bragg's law [Figure 2 and Eq. (b), where n = order of

$$n\lambda = 2d\sin\theta \qquad \text{(b)}$$

the scattered radiation, λ = wavelength of the X-ray photon, d = separation of crystal lattice planes, θ = scattering angle]. A

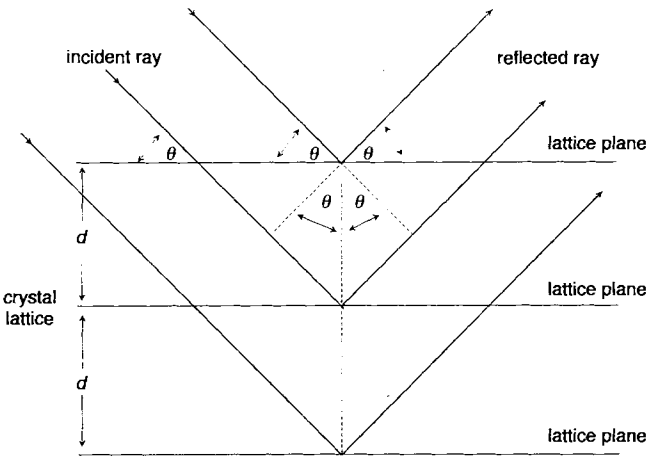

Figure 2. X-ray diffraction by crystal lattice planes.

photon of wavelength λ is scattered at an angle θ in a crystal with the lattice plane separation d. This relationship can be exploited for analyses in two ways:

1) On use of a monochromatic beam of X-rays, a limited number of scattering angles will be obtained. If a film or detector array is placed behind the sample, lines or points are recorded at specific distances from the incident beam, depending on the type of sample used (powders or single crystals, respectively).

2) On use of a polychromatic X-ray beam, specific energies can be measured at certain distances from the incident beam, which are scattered in a coherent fashion. The peaks obtained when the intensity is plotted versus the wavelength are specific for the substance in question.

The application of coherent X-ray scattering to the problem of the detection of explosives yields very interesting perspectives. With penetrating radiation, information that is specific to the substance in question, but independent of its elemental composition can be obtained.

The technical realization, however, must overcome big difficulties, such as selecting the spectra of explosives from the mixture of scattering spectra that stem from the other container contents or the requirements for an exact geometric setup. Possible solutions might be found in the spatial resolution of the object under examination into small volume segments.

3.1.3. Detection with γ-Radiation–Radiochemical Methods

γ-Rays possess the highest energy in the electromagnetic spectrum. They are created by nuclear reactions or within particle accelerators. Their application in analytical chemistry is classified under radiochemical methods. The frontier between γ-rays and high-energy X-rays is ill-defined. Usually radiation of more than 500 keV energy is classified as γ-radiation. The analytical applications can be categorized as absorption and emission analyses, as was the case for X-rays.

3.1.3.1 γ-Ray Absorption

Comparable to the absorption of X-ray photons, where photon energies are absorbed that match the corresponding electron binding energies, γ-rays of certain energies are absorbed by atomic nuclei. The absorbed energy is re-emitted in the form of fluorescence radiation, an effect that is termed resonance fluorescence.[23, 24] The measurement of this absorption yields information about the concentration of certain elements in the irradiated object. For instance, it is possible to determine the content of nitrogen, carbon, and oxygen in a sample, as they all possess different resonance absorption energies. This method has significant disadvantages due to interference from other elements (false alarms) and a low sensitivity.

3.1.3.2 Pair Formation

This method of emission analysis relies on the earlier mentioned pair formation with high-energy photons. During the interaction of a γ-photon of a specific energy with an atomic nucleus, a positron–electron pair is formed, and the photon energy is transferred to this positron–electron pair. This process occurs primarily with heavy elements and photon energies above 1.02 MeV.

The energy of 1.02 MeV corresponds to double the mass of an electron ($2mc^2$).[25, 26] When a positron and an electron encounter each other, they annihilate each other, and two γ-photons of 0.5 MeV are generated, which are emitted in opposite directions.

The lower limits for the pair formation reaction are different for different elements. The most important energy for nitrogen is 10.8 MeV. Above this energy, a (γ,n) reaction is initiated, which transforms ^{14}N into ^{13}N. ^{13}N then transforms into ^{13}C and a positron. When this positron encounters an electron, two photons of 0.5 MeV are created, which can be picked up with detectors placed opposite each other.

This technique has been studied with respect to its application to the detection of explosives.[27, 28] In addition to the enormous problems connected with handling such high energies, this method proved to be not selective enough. It is not even selective for nitrogen. Some elements other than nitrogen can yield signals during the detection of γ-photons from the positron–electron reaction.

3.1.3.3. Neutron Activation Analysis

The promising methods for the detection of explosives of the late 80s and early 90s were all based on the technique of neutron activation analysis.[29–32] Many radiochemical applications for elemental analysis are known that employ excitation by fast or thermal neutrons. The measurement of the γ-radiation that is the primary product of these reactions can be utilized for the detection of explosives. The γ-photons are formed by the capture of thermal neutrons or by inelastic scattering of fast neutrons. Only the elements nitrogen, oxygen, and carbon can be used in the case of organic high explosives. Possible reactions for these elements and the thereby emitted radiation are listed in Table 1. Based on the energy of the activating neutron and the subsequent reactions, one can differentiate two types of applications, thermal neutron activation (TNA) and fast neutron activation (FNA).

Table 1. Selected nuclear reactions initiated by neutron bombardment.

Element	Reaction	Neutron energy [MeV]	Energy of the γ-rays [MeV]
C	n,n′	>5	4.4
N	n,n′	>5	2.3
N	n,γ	[a]	10.8
O	n,n′	>6.5	6.1

[a] Thermal neutrons.

The use of activation with thermal neutrons for the detection of explosives uses the selective emission of γ-photons at an energy of 10.8 MeV. This is one of the highest observed energies for such reactions.[30] The intensity of the radiation and its spatial distribution yield strong indications for the presence of nitrogen.[33] This method therefore relies on an extraordinarily high nitrogen content of explosives. This, however, is not generally the case. On one hand, there are explosives that do not exhibit the high nitrogen content of highly explosive nitro compounds. On the other hand, there are materials of daily life that do exhibit a very high nitrogen density, such as polymers with amide or urethane structures as well as proteins. The problem of potential false alarms will be discussed in Section 4.2.

Table 2 summarizes the element densities of some selected materials with high nitrogen content. The table does not show average values for representative substances, but is meant to demonstrate possible interference during the detection of nitrogen alone. The values were calculated from the molecular weights and corrected according to the physical density in order to obtain the element density per unit volume. The bulk density was also taken into account for substances in powder form. For clarity, Table 2 is also presented in graphical form in Figure 3.

Table 2. Densities ρ of selected elements in explosives and other nitrogen-rich materials.

Material	ρ_C [g mL^{-1}]	ρ_N [g mL^{-1}]	ρ_O [g mL^{-1}]
PETN powder	0.24	0.22	0.75

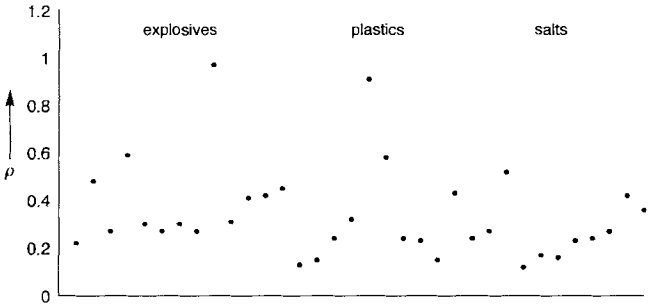

Figure 3. Nitrogen density (•) [g mL^{-1}] of explosives and other nitrogen-rich materials.

The use of fast neutrons for activation has the advantage that carbon and oxygen can be detected in addition to nitrogen. The formation of γ-photons stems from the inelastic scattering of neutrons at nuclei. An optimum application of the FNA effect for the detection of hidden explosives in closed containers is found in the pulsed activation with fast neutrons (PFNA). The pulsed neutron beam reduces the γ-ray background. The coordination of the timing of the neutron pulse and the γ-photon detection with the position of the object on a transport belt makes it possible to obtain spatial resolution. In effect, the optimum application of PFNA yields information about the C, N, and O densities and their ratios within small unit volumes ($5 \times 5 \times 5$ cm^3).[34, 35] Compared to TNA, the PFNA method has the advantage of a significantly higher information content, which increases the reliability of the detection.

In general, the application of γ-radiation-based techniques to the detection of explosives exhibits a bad ratio of benefits to the technical and financial efforts involved. The γ-absorption analysis only yields nonselective information about general element concentrations and is not suitable for organic explosives. The γ-photon-induced γ-emission analysis also yields only nonselective information, because the same photon energies are measured for different elements and the only differences between the elements lie in the activation threshold energies. The detection of nitrogen is hampered by false positive signals from, for example, copper, silver, or gold. Thermal neutron activation is very selective in terms of the nitrogen content of the sample, but this is not a specific characteristic for explosives. The activation with pulsed fast neutrons yields the highest information content with element ratios for C, N, and O, together with their spatial distribution.

A significant obstacle towards the general introduction of γ-radiation-based techniques is the generation and processing of high-energy radiation and neutrons. Substantial shielding and other protective measures would be required, which in general necessitates rebuilding the checkpoints. The required neutron sources, such as ^{252}Cf or deuterium–tritium, also present additional problems in this context.

3.2. Detection of Gaseous Components

The detection of explosives by the analysis of gaseous components is fundamentally different from the detection by interactions with radiation.[36, 37] This detection principle has also been termed explosive vapor detection (EVD), because during the infancy of this technique, the gaseous emanations only were analyzed by means of their vapor pressure. Today, particle traces on dust or microparticles of the explosive itself can be detected, depending on the sampling procedure and sample introduction into the detection system. This type of detection, whether centered on gaseous components, droplets, or particles, is dependent on the collection of material from the explosive, which then must be brought to the analyzer. Hence, the type of controls involved and the time required are very different from those found for the radiation-based detection.

The discussion of explosive vapor detection begins with the question of the chemical substances that can emanate from an explosive. In addition, these components must be specific for explosives as well. With this knowledge one can select appropriate analytical methods.

3.2.1. Components Specific to Explosives That Can Be Utilized for Explosive Vapor Detection

A critical parameter for this discussion is the vapor pressure of typical components. The vapor pressure plays an important role as detection should also be possible if no particle or droplet transfer occurred during packaging.

Such surface contaminations naturally simplify the detection with trace-analytical methods. Nearly all relevant trace-analytical techniques, however, operate on the principle of gas analysis; hence the vapor pressure of the components is relevant even in the case of surface contamination.

The only characteristic materials contained in explosives are in general just the explosive materials themselves, which usually account for 80% of the material. Even in mixed commercial explosives, the single components such as nitro compounds are seldom present in less than 5%. If, for the present discussion, we ignore primary (initiating) and home-made explosives, the low vapor pressure of inorganic salts limits the compounds that could be detected this way to the organic nitro compounds (vide supra). Table 3 lists typical organic nitro compounds and their vapor pressures.[38]

Table 3. Vapor pressures of pure explosives.

Explosive	Vapor pressure [ppt (v/v)]	Explosive	Vapor pressure [ppt (v/v)]
EGDN	100000000	TNT	9500
NG	580000	PETN	18
DNT	56000	RDX	6

As can be gleaned from their readily detectable odor, the explosive oils nitroglycerin (NG) and nitroglycol (*e*thyleneglycol *di*nitrate, EGDN) possess a significantly higher vapor pressure (ppm range) than the other species. The explosive oils are, in fact, readily identified even without complicated techniques. The detection of DNT or TNT requires better and in particular more sensitive methods. The vapor pressure of nitropenta and hexogen is so low (low ppt range) that these components are virtually undetectable even with very elaborate techniques. As the components in explosive mixtures often are present as less than 50% of the total, and binders are present as well, the vapor pressure is reduced accordingly.

The biggest obstacle for the straight explosive vapor detection, however, is the wrapping that is usually present, either as matter of course, or intended as camouflage. A rough estimate of the reduction of the equilibrium vapor pressure caused by the wrapping leads to a factor of 1000, which means the ppm range moves into the ppb realm, while the ppb range is pushed into the ppt domain. A reasonably functional system must therefore provide for a sensitivity in the low ppt range. This estimate intentionally neglects diffusion or absorption processes, as these are much too dependent on materials and time intervals to be estimated with reasonable confidence.

3.2.2. *Detection Methods*

The requirements of explosive vapor detection lead directly to gas-analytical methods. The required sensitivity and selectivity further limit the number of applicable methods. Special consideration must be given to the issue of a system's selectivity. Aside from possible trace concentrations of explosives, significant amounts of other materials are present that will gain access to the detection chamber. These everyday materials can either mimic or camouflage explosives. A selective detection system must address itself to characteristic properties of explosives, just as was the case for radiation-based methods.

3.2.2.1. *Mass Spectrometry*

The best known gas-analytical trace technique is mass spectrometry. Molecules can be identified from their typical fragmentation patterns or their molecular weight. The most common methods of mass spectrometry differ primarily, apart from the type of ionization and sample injection employed, in the dispersion technique that is utilized (magnetic field, quadrupole, time-of-flight). The analytical capabilities of all systems is very high, and a large amount of useful information can be obtained. In the area of the detection of explosives, however, laboratory applications have shown that, for certain explosives, the selectivity is not sufficient.[39] This is a problem especially with small nitrate esters, such as EGDN, NG, or PETN, as these compounds do not exhibit significant, unmistakable fragmentation patterns. Even the common combination with gas chromatography as a prior separation technique is not able to separate complex mixtures sufficiently to reliably exclude overlap with materials of daily life. In addition, the often only moderate sensitivity and the high cost limit the use of conventional mass spectrometry in the gas-analytical detection of explosives.

3.2.2.2. *Ion Mobility Spectrometry (IMS)*

Ion mobility spectrometry is comparable to time-of-flight mass spectrometry. It does, however, not operate in a high vacuum but at atmospheric pressure. At this relatively high pressure, ions are not separated according to their mass/charge ratio, but the collision cross-section has a significant effect on the time of flight. IMS systems are of particular interest for the detection of explosives because of their high sensitivity for traces of compounds with electron capture properties, such as nitro compounds. The ionization process is similar to that in an electron capture detector (ECI).[40]

The selectivity of good IMS instruments stems from the combination of the selective ionization method and the detection under selected drift conditions. Basic IMS systems with simple ionization of the surrounding air and detection of single sample peaks still give many false alarms due to overlap with everyday materials. Better IMS systems work with multiple-peak detection, which are generated by the reaction with special drift gases. This causes an explosives molecule to transform, for example, into an $(M-H)^-$ ion by proton abstraction, an $(M+Cl)^-$ ion stemming from the chlorine of the carrier gas, and nitrate ions $(M+NO_3)^-$. Thus the combination of several selective steps leads to a specific identification.

The IMS technique is definitely quite applicable to the detection of organic explosives. A particular advantage lies in the additional ability to detect explosives without nitro groups, such as home-made peroxides.

3.2.2.3. *Gas Chromatography—Electron Capture Detection*

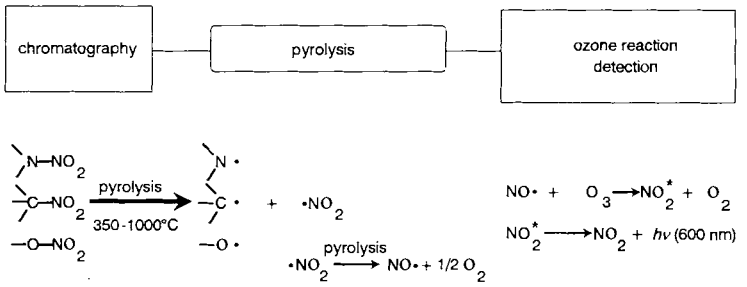
Gas chromatography with electron capture detection (GC-ECD) is a generally known method for trace analysis.[41] The electron capture detector (ECD) is very sensitive for compounds with electronegative functional groups, for example, chlorides, esters, or nitro species. The ECD consists of two electrodes, between which the gas to be analyzed flows. One electrode is coated with a radio isotope (^{63}Ni) that emits high-energy elec-

trons. These generate large numbers of secondary thermal electrons in the carrier gas, which in turn are collected at the opposite, positively charged electrode. Molecules with electron-capture properties react with the thermal electrons and thereby reduce the current, which yields a measurable electrical signal.

The gas chromatographic separation under normal laboratory conditions is too slow for the detection of explosives in practice, therefore the GC-ECD systems designed for this application operate with very short separation capillaries and high gas flows. Preprogrammed temperature profiles are either run through very rapidly or the systems work isothermally at high temperatures. The instruments can generally be built at reasonable prices, but due to the low selectivity of the ECD detector, they show a high rate of false alarms and are very sensitive to overloading by foreign substances.

3.2.2.4. Gas Chromatography–Chemiluminescence Detection

The method of gas chromatography–chemiluminescence detection is being successfully employed for the trace analysis of explosives for forensic purposes.[42] GC-chemiluminescence is very sensitive and shows a high selectivity for nitro compounds.[43] Its basic principle is the formation of nitric oxide during the pyrolysis of nitro compounds (Scheme 3). The nitric



Scheme 3. Chemiluminescence detection of nitro compounds.

oxide formed is allowed to react with ozone in a detection chamber to yield electronically excited nitrogen dioxide, which in turn emits photons at 600 nm. These photons can be detected with a photomulitiplier, and an electrical signal is generated. This type of detection allows the registration of GC peaks only of nitro or nitroso species that form nitric oxide during pyrolysis.

The requirements for the gas chromatographic separation are similar to GC-ECD. There is currently only one well-functioning, but very expensive instrument on the market that is based on this detection technology.

3.2.3. Sampling

The most important and time-consuming step during the use of "sniffing detectors" is the actual sampling process.[44–46] The traces of explosives must be collected and transported into the analytical system. A schematic diagram of sniffing detection is shown in Figure 4.

The task of collecting the maximum amount of all possible forms of traces requires a mechanically assisted sampling process. The simple collection of air samples either does not pick up many explosives or the collected amount of material is too

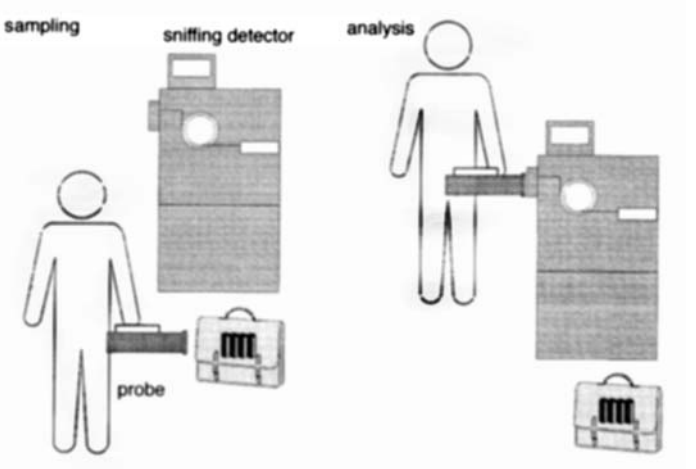


Figure 4. Schematic diagram of the process of sniffing detection.

small. Experience from forensic trace analysis of explosives has shown that these substances often tend to stick very well to surfaces. They can be picked up with cotton balls that have been soaked with solvent.[47] This type of sampling for forensic studies is primarily mechanical in nature, as the wiping involved does not lead to a dissolution of the explosives particles. The solvent enables an improved removal from the surface and better adhesion to the cotton.

A comparable, slightly modified sampling procedure is also best suited for sniffing detections. The surface can be wiped with a paper towel, which is then studied. It is obviously necessary to avoid large quantities of solvent. The paper towel can be heated and placed into an absorption chamber to transfer the sample into the analytical system, or the vapor can be directly introduced in the gas analysis system. During the transfer into the gas analytical system, it is necessary to employ specially heated air filters to retain loose dust particles, fibers, or other contamination.

The optimization of the sampling procedure is a very important aspect, as this significantly affects the sensitivity of the system. It is therefore necessary to test the entire system, sampling and gas analysis, when a suitable sniffing detector is chosen.

4. Discussion

The discussion about detection systems for explosives always centers around two basic problems: the ability to detect hidden explosives and the number of false alarms that occur. Both concerns are influenced by the time required, as well as the effort and costs incurred. As mentioned earlier, the two different approaches of radiation-based detection and explosive vapor detection can be compared only with difficulty. The radiation systems are being developed with large numbers of objects to be examined in mind, as is the case for luggage inspection at airports. The sniffing detectors require a lot of time and cannot be automated. They are well suited to the inspection of single suspicious objects. Sniffing detectors should be as transportable as possible, while radiation-based systems can be installed at fixed points. No system can completely replace the other.

4.1. Positive Identification of Explosives

The discussion about the correct identification of explosives (the failure to identify an explosive constitutes a false negative response) is only possible in connection with the chemical nature of explosives and the frequency with which the explosive in question is used. Most commercial and military explosives show a high nitrogen content, like in nitrates and nitroso species. Many initiating explosives also contain nitrogen, but not necessarily in the form of nitro groups. Initiating explosives are generally salts or salt-like and have virtually no measurable vapor pressure. In the case of home-made explosives, the variability is much higher. Nitrogen or nitro groups are only present if nitrates are employed as oxidants or if highly explosive nitro species themselves are synthesized. The danger from nitrogen-free explosives in this category cannot be neglected.

Containers with solid walls are also not always necessary for containment, like in the case of chlorate/sugar mixtures. Perchlorate/aluminum or chlorate/phosphorous mixtures can detonate without prior containment. Certain organic peroxides resemble highly explosive nitro compounds and detonate even more readily.

The positive identification of explosives can therefore not depend, like many radiation-based techniques, solely on the detection of high nitrogen densities or on a more general identification of elements present. A reliable detection is only possible with an analytical method that relies on the recognition of specific molecular characteristics. In terms of radiation-based techniques, this requirement, when combined with the required penetration of closed containers, only leaves the long wavelength methods of nuclear resonance and the short wavelength techniques based on X-ray scattering. The sniffing detectors can at least exploit specific molecular interactions in the chromatographic separation system and in sequent detectors that are specific for certain functionalities.

4.2. False Alarms

False positive alarms represent a significant problem for the real-life application of explosives detectors. As each alarm identifies an object that might harbor explosives, the corresponding measures have to be taken. These can be very time consuming and tend to block further controls, so that false alarms can significantly interrupt regular operation.

False alarms are clearly connected with the selectivity of the applied technique. As was true for the need of positive identification, a detection system based on specific molecular characteristics is therefore a priority. The degree to which the various detection techniques satisfy the demands for a low rate of false alarms has already been discussed for each method.

In summary, only the following techniques operate on the basis of specific molecular characteristics: for radiation-based methods, nuclear resonance and X-ray scattering; for sniffing methods, mass spectrometry, ion mobility spectroscopy, as well as indirectly the GC–chemiluminescence approach.

5. Conclusions

The detection of hidden explosives requires demanding technical systems. The fundamental techniques are based on experience gained from instrumental analytical chemistry. The necessity to adapt to the special problems posed by the detection of explosives severely limits the number of applicable techniques. A preselection of possible methods can be based on theoretical considerations, but the actual applicability can only be demonstrated in practical tests with complex objects. The most stringent limitations result from the requirement of rapid controls of closed containers. The best example for the high demands placed on detection systems for explosives is the luggage check at airports.

The detection systems can be classified into two groups: the detection by interaction with radiation and the chemical analysis of components emitted by the explosives (sniffing detection). Because of the essential penetrating ability, systems for radiation-based detection employ either low energy radiation such as radio waves or very high energy radiation such as X-rays or γ-rays. Inasmuch as the detection relies on element distribution (such as the nitrogen density), these methods have much too high rates of false responses (specifically, false positive alarms). A useful and selective detection of explosives is only feasible with approaches that are specific for certain molecular characteristics, such as nuclear resonance or X-ray diffraction. Modern X-ray absorption methods are very well suited for the imaging of the contents of containers, in spite of their inability to detect explosives selectively.

Useful sniffing detectors do not only detect gaseous components of explosives, but are also able, depending on their sampling and analysis procedures, to collect and analyze particles, traces of explosives on particles, or droplets. The collection of traces of explosive matter from a closed container is, however, crucial to their basic function. The capabilities of the sniffing detection can be significantly enhanced in the future if, based on an existing ICAO convention, lower-boiling additives (such as dimethyldinitrobutane) are added to plastic and sheet explosives, which are currently difficult to detect. This, however, would necessitate legal requirements in all countries that manufactures these explosives.

In the commercial sector, a large number of explosives detectors are available. Until now, however, no instrument has been able to detect reliably all possible explosives in any quantity and form without false alarms. Currently the best solution can be found in a combination of different systems, such as high resolution X-ray methods or dual-energy techniques for preselection, a further radiation-based technique for further identification, and a sniffing detector for the final control.

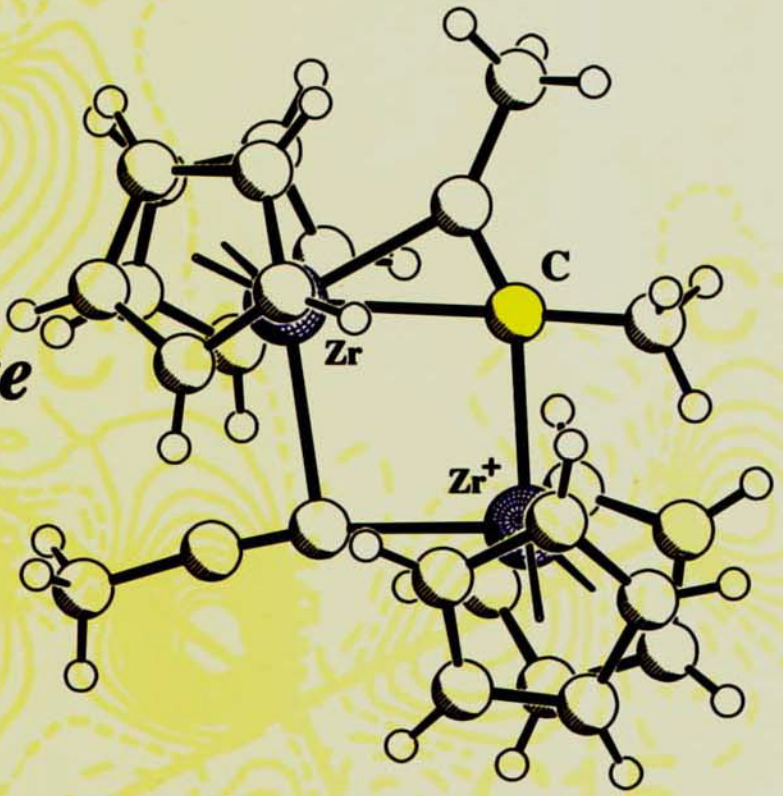
Deposition of Data from X-Ray Structure Analyses

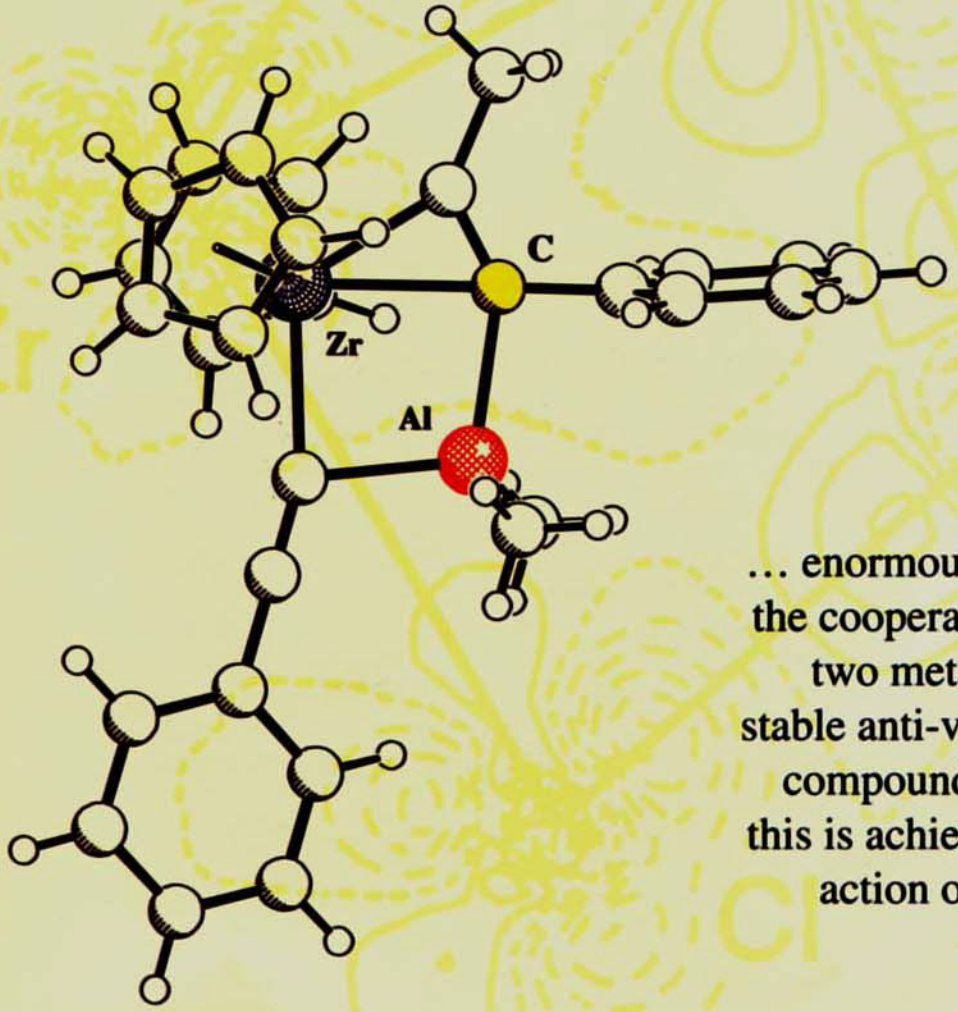
In order to make life easier for authors and referees the Cambridge Crystallographic Data Centre (CCDC) and the Fachinformationszentrum Karlsruhe (FIZ) have unified their procedures for the deposition of data from single-crystal X-ray structure analyses.

Prior to submitting your manuscripts please deposit the data for your compound(s) **electronically** at the appropriate data base, that is, at the CCDC for organic and organometallic compounds and at the FIZ for inorganic compounds. Both data bases will be pleased to provide help (see our *Notice to Authors* in the first issue of this year). In general, you will receive a depository number from the data base within two working days after electronic deposition; please include this number with the appropriate standard text (see our *Notice to Authors*) in your manuscript. This will enable the referees to retrieve the structure data quickly and efficiently if they need this information to reach their decision.

This is now the uniform procedure for manuscripts submitted to the journals *Advanced Materials, Angewandte Chemie, Chemische Berichte/Recueil, Chemistry—A European Journal,* and *Liebigs Annalen/Recueil.*

planar *tetracoordinate* carbon





… enormously stabilized by the cooperative influence of two metal centers. In the stable anti-vant't Hoff LeBel compounds depicted here, this is achieved by the interaction of the metal pairs Zr/Al or Zr/Zr^+.

Compounds Containing Planar-Tetracoordinate Carbon

Dirk Röttger and Gerhard Erker*

It is a great challenge to synthesize compounds containing planar-tetracoordinate carbon that are stable enough to be isolated, investigated, and handled under ambient conditions. There have therefore been many attempts to construct hydrocarbon frameworks that can incorporate and stabilize tetravalent carbon in this "unnatural" planar coordination geometry, for example, by steric constraints. However, success is apparently more readily achieved if the "square planar" carbon atom is stabilized electronically. Planar-tetracoordinate carbon is sp^2-hybridized and has an electron deficient σ system. The p orbital orthogonal to the bonding plane is occupied by two electrons. Therefore, σ-donor/π-acceptor substituents—that is, many metals—are in principle able to stabilize this "unnatural" geometry of tetravalent carbon. Meanwhile, well-established procedures for synthesizing very stable "anti-van't Hoff/LeBel compounds" have been devised, in which the planar-tetracoordinate carbon atom is stabilized, usually by the combined action of two directly bonded metals. In most cases, the square-planar carbon is part of a double bond system. Typical stabilizing metal combinations are Zr/Al or Zr/B, but there are also examples containing two transition metals from the right-hand side of the periodic table. Reliable estimates for the energy of stabilization of square planar carbon in such compounds are now available. Both theoretical and experimental investigations show that square planar carbon atoms that are stabilized by Zr/Zr^+ and Zr/Al in dimetallic compounds are favored by about 12 and 40 kcal mol^{-1}, respectively, over the trigonal planar alternatives. Square planar coordinated carbon is thus no longer an unusual feature in organometallic chemistry and must now be more frequently considered as an alternative structural possibility.

Keywords: anti-van't Hoff/LeBel compounds · coordination modes · organometallic chemistry · planar-tetracoordinate carbon

1. Introduction

The work of J. H. van't Hoff and J. A. LeBel marked an important milestone for the understanding of the spatial arrangement of molecules.[1] In 1874 both scientists independently recognized that a tetravalent carbon atom prefers the tetrahedral arrangement for its substituents. As a result, they paved the way for a profound understanding of the structural properties of organic molecules long before their model was confirmed, for example by X-ray structure analysis.[2]

Nature appears strict in its adherence to tetrahedral coordination of tetravalent carbon atoms.[3] It took almost a hundred years for the alternative coordination geometry, namely planar tetracoordination, to be more seriously considered as a structural possibility for carbon compounds. In 1970 R. Hoffmann et al. formulated the basic model for hypothetical planar methane.[4] The synthesis of "anti-van't Hoff/LeBel compounds"[*] was not the main focus of these considerations, but merely the potential occurrence of this coordination geometry in transition states. The results of this investigation proved to be a landmark for further theoretical and preparative studies, which continue up to this day and no longer solely emphasize generation of a "pathological" structure. Instead, more general questions arise from the central aspect of planar tetracoordination at carbon atoms. Typical examples are theoretical bonding models (Section 2), the effects of angular strain in organic molecules (Section 3), reaction mechanisms (Section 4 and 5.4), and structure–reactivity relationships. Because of the special electronic features of planar-tetracoordinate carbon, organometallic chemistry is making a significant contribution to this field. The investigation of unusual structural characteristics may also further contribute to a deeper understanding of catalytic processes and intermediates. This review gives a brief summary of the results from the last 25 years in the search for compounds that contain planar-tetracoordinate carbon.[5]

[*] The term anti-van't Hoff/LeBel compound, which is semantically comparable to anti-Bredt compound, does not in any way question the work and conclusions of van't Hoff and LeBel, but only indicates an alternative (coordination) geometry, similar to, for example, the term antiprism. Compounds with planar-tetracoordinate carbon represent an extension of the naturally occuring coordination geometries at carbon by a structural type whose significance for normal organic compounds was correctly excluded by van't Hoff and LeBel.

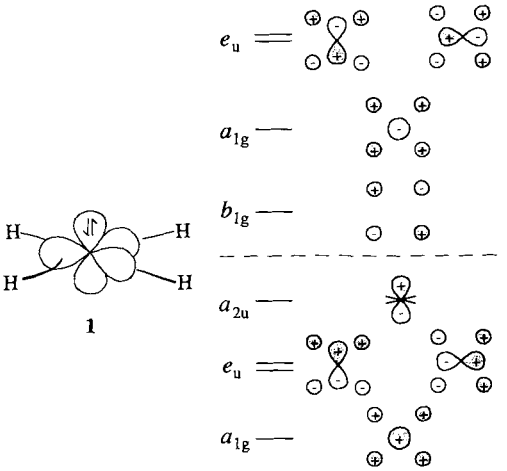
2. Planar Methane and the Theoretical Foundations

J. H. van't Hoff and J. A. LeBel developed the concept of tetrahedral coordination at carbon in its saturated compounds on the basis of phenomenological considerations. This arrangement of hydrogen atoms in methane has meanwhile become a matter of course for the organic chemist. Orbital models further illustrate the bonding features. The hybrid orbitals of the sp^3-hybridized carbon atom in methane can be described as forming bonds with the four hydrogen atoms. However, the bonding features in the planar methane molecule **1** are conceptually different (Scheme 1). Because of the orthogonality of the p orbitals, no hybridization is possible by which the four hybrid orbitals lie in a single plane. The most favorable structure is based on sp^2 hybridization of the carbon atom. In the σ-bond system, six electrons form the four bonds to the hydrogen atoms, and the p orbital, which is vertical to the bonding plane, is occupied by two electrons.[4] This model by R. Hoffmann et al. for hypothetical planar methane contains all the features of anti-van't Hoff/LeBel compounds, in particular the need to develop multicenter bonds in the σ plane.[4, 5d]



Scheme 1. MO description of the bonding features in planar methane (**1**).

It follows from the electronic features of planar methane that this molecule will probably never be stable. A variety of calculations has shown[6] that the destabilization of such a structure relative to the tetrahedral geometry (about 120 kcal mol^{-1})[6a] lies significantly higher than the energy required for C–H bond cleavage (103 kcal mol^{-1}).[7] Even stereomutation of the methane molecule via nonplanar transition states appears to be disfavored with respect to bond cleavage.[8] In view of methane derivatives, studies on the chemistry of planar-tetracoordinate carbon follow two trends. First, attempts are being made to impose a planar geometry by incorporating the carbon atom into sterically rigid systems. Compounds of this type are described in Section 3. A second synthetic strategy tries to stabilize electronically the unfavorable coordination geometry with appropriate substituents. This includes increasing electron density in the σ-bond system and reducing that in the π system. The latter can be achieved by delocalization into suitable, empty orbitals of substituents or by incorporation into a conjugated π system. Additionally, incorporation into small ring systems can direct a compound to a planar geometry since bond angles are reduced for the transition from tetrahedral to planar coordination. Incorporation into polycyclic systems, in which steric factors induce planarity, is also favorable.[4, 6, 9]

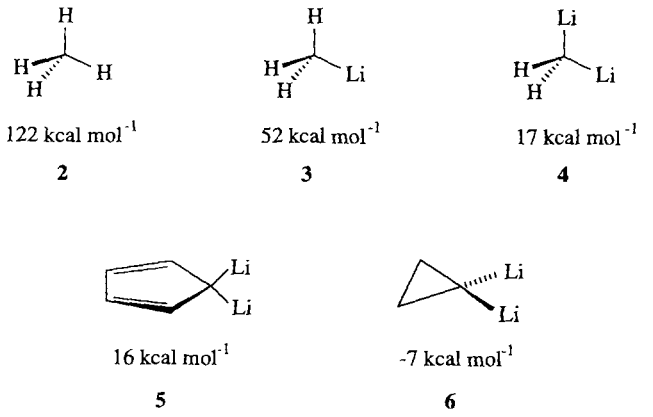
G. Erker

D. Rittger

Gerhard Erker, born in 1946 in Oberhausen, Germany, studied chemistry at the Universität Köln, Germany. He obtained his doctoral degree in 1973 in Bochum, Germany with W. R. Roth. After a postdoctoral year with M. Jones, Jr. at Princeton, USA, he finished his habilitation at the Universität Bochum in 1981. He then moved to the Max-Planck-Institut für Kohlenforschung in Mülheim an der Ruhr as a Heisenberg Fellow and to the Universität Würzburg in 1985. In 1989 he became the successor to Prof. T. Kauffmann in Münster having previously been offered a chair at the Universität Karlsruhe, Germany, and in 1994 a position at the Universität München. He was a guest professor at the Universities of Strasbourg, France (1989), Toulouse, France (1990), British Columbia in Vancouver, Canada (1992), and Fukuoka University, Japan (1995). He has received many honors, including the Krupp-Preis (1986), the Max-Planck Forschungspreis (1993), and the Otto-Bayer-Preis (1995). Since 1995 he has served as an elected referee for the Deutsche Forschungsgemeinschaft and a member of the editorial board of Chemische Berichte. Since 1996 he has also been a member of the board of the Gesellschaft Deutscher Chemiker. His main research interests are in the areas of organometallic chemistry and catalysis.

Dirk Röttger, born in 1966 in Recklinghausen, Germany, studied chemistry at Münster and there joined Prof. Erker's group in 1992. He obtained his doctoral degree in 1995 with a thesis on the synthesis of compounds containing planar-tetracoordinate carbon and the reactions of zirconocene cations. He received a Doktorandenstipendium des Fonds der Chemischen Industrie and was a member of the Graduiertenkolleg "Hochreaktive Mehrfachbindungssysteme" at Münster. He recently joined Huls AG as a research and development chemist.

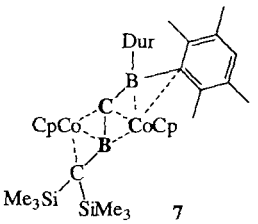
Calculations have shown that electropositive metals as substituents on carbon are suitable for reducing the energy difference between tetrahedral and planar coordination. They can delocalize the high electron density of the occupied p orbital by interaction with unoccupied metal orbitals and, at the same time, act as σ donors to increase the electron density in the electron-deficient σ-bond system. P. von R. Schleyer et al. have illustrated this effect by calculations on methane (**2**) and the lithiated derivatives **3**–**6**. The energy difference between tetrahedral and planar coordination for dilithiomethane (**4**) is reduced to 17 kcal mol^{-1}, and the planar geometry becomes the ground state for 1,1-dilithiocyclopropane (**6**, Scheme 2).[6c]



Scheme 2. Calculated energy differences between the planar and (distorted) tetrahedral coordination geometries for selected alkyllithium compounds.

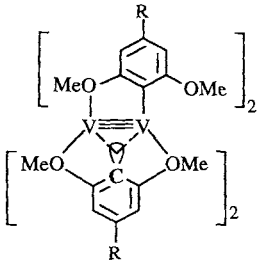
Reduction of the high electron density of the nonbonding p orbital of the carbon atom in planar methane can also be achieved by simple oxidation to the mono- or dication. Based on calculations, the methane dication, which has been experimentally observed by H. Schwarz et al. by mass spectrometry,[10] is assumed to take on a planar structure.[11]

In recent publications a distinctive approach to the electronic properties of the planar-tetracoordinate carbon atom has been undertaken in the theoretical analysis of structurally characterized anti-van't Hoff/LeBel compounds. In certain cases the σ-donor/π-acceptor interaction with the metal center has been confirmed, and delocalization of electron density from the p orbital has been attributed considerable significance. An examination of **7**, in which the planar carbon atom forms bonds to two boron and two cobalt atoms,[12] indicates an electronic situation that is very similar to the one discussed above (one of the boron atoms is also planar-tetracoordinate, see Section 6).[13]

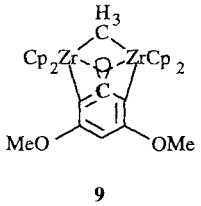


7

In contrast, the planar-tetracoordinate carbon centers in **8** and **9** are part of aromatic systems.[14, 15] The structure of the divanadium complex **8a** was published by F. A. Cotton and M. Millar in 1977,[14a] and in 1979 R. Keese recognized that this was probably the first crystallographically characterized compound with a planar-tetracoordinate carbon atom.[22f]

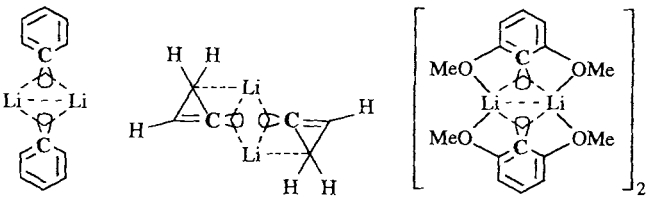


8a (R = H), **8b** (R = OMe)



9

The structurally related dizirconocene complex **9** was synthesized by S. L. Buchwald et al.[15] Planar tetracoordination of the carbon atom in this type of complex arises from formation of a σ-multicenter bond between the carbon atom of the aryl anion and the two metal centers. In addition, "anchoring groups" at the *ortho*-positions of the aromatic moieties fixate the planar configuration. This approach essentially expresses the bonding features that have been investigated in detailed calculations by M. Bénard et al.[16] for **8** and **9**.[*] P. von R. Schleyer et al. have predicted corresponding dimeric structures that contain planar-tetracoordinate carbon atoms for phenyl lithium (**10**) and cyclopropenyl lithium (**11**).[17, 18] However, in the experimentally isolated compounds, coordination of donor molecules to the metal center often prevented formation of the planar geometry.[18, 19] Planar tetracoordination could eventually be enforced in **12** by



10 **11** **12**

14

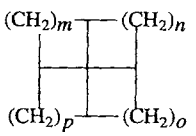
[*] In compounds whose bonding status can thus be clearly described, the orbital of the tetracoordinate carbon atom involved in the multicenter bond is specifically drawn as such in this article; dashed lines to the substituents indicate the multicenter bonding status.

intramolecular solvation,[20] and an approximation to planar geometry was thus achieved for **13** and **14**.[21]

The bonding features discussed with respect to these theoretically well-investigated examples are characteristic of metal-stabilized anti-van't Hoff/LeBel compounds; further examples are cited in Sections 5.1 and 5.2. Reference to the description of the bonding properties of planar-tetracoordinate carbon in phenyl or vinyl anions that bridge two metal centers will be made during the discussion of Group 4 metallocene complexes in Sections 5.3.2 and 5.4.

3. Planar-Tetracoordinate Carbon in Fenestranes and Other Polycyclic Ring Systems

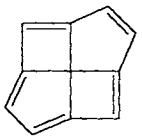
Various calculations have also been carried out on the stabilization of planar-tetracoordinate carbon in metal-free systems.



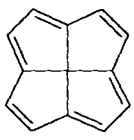
15

Strained polycyclic systems, such as fenestranes **15**, represent a promising group of molecules that are capable of stabilizing planar-tetracoordinate carbon in an organic matrix.[22] Excellent reviews of theoretical and preparative studies have been published by W. Luef and R. Keese[5e] as well as W. C. Agosta[5f]; only a brief review of this chemistry will be given here. The term fenestrane is obvious from the nature of the structure itself. The numerical prefixes *m*–*p* indicate the size of the rings (see also Scheme 3).

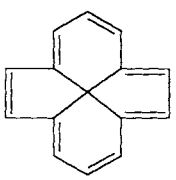
Initial considerations of the stabilization of planar-tetracoordinate carbon in fenestranes again come from R. Hoffmann et al.[4] If the central carbon atom of the fenestrane is part of an annulated, polycyclic, π system, planarity could potentially provide π stabilization of sufficient magnitude to compensate energetically for the σ destabilization. No stabilization has been calculated for **16** and **17**,[4] and precise calculations on the promising candidates **18** and **19** have also demonstrated that nonplanar structures are favored.[23]



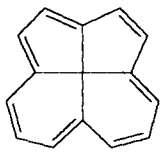
16



17

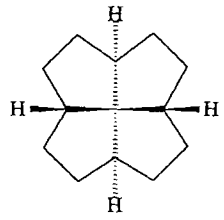


18

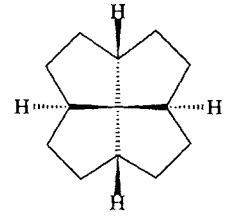


19

Meanwhile numerous calculations have been carried out on fenestranes, and reliable values for the strain energies in these systems have been obtained.[5e] These are highly dependent on whether the rings in the fenestranes are *cis*- or *trans*-fused. For a planar geometry of the central carbon atom to be achieved, the greatest possible number of *trans*-linkages of the rings is necessary. However, such systems are highly strained, energetically disfavored, and, consequently, difficult to prepare. The all-*cis*-[5.5.5.5]fenestrane **20** was synthesized by M. Luyten and R. Keese by two different methods.[24] The all-*trans*-isomer **21** has a strain energy that is 175 kcal mol^{-1} higher, according to MNDO calculations, and could not yet be prepared.[25]

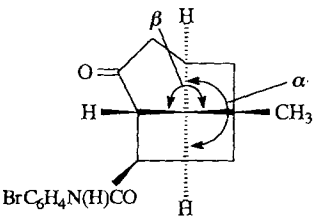


20



21

A measure of the deviation from ideal tetrahedral geometry for the central carbon atom of a fenestrane is provided by the increase in the α and β bond angles. Angle expansions determined by X-ray crystallography for fenestranes **22**–**27** are given in Scheme 3. The values for **22** are $\alpha = 128.3$ and $\beta = 129.2°$. In



[4.4.4.5] fenestrane **22**
$\alpha = 128.3°$, $\beta = 129.2°$

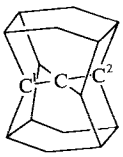
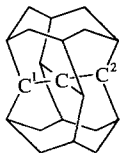
[5.5.5.7] fenestrane **27**
$\alpha = 117.9°$, $\beta = 118.9°$

Scheme 3. Examples of fenestranes; the α and β angles were determined by X-ray crystal structure analysis.

23, which contains a *trans*-fusion of two rings, the α angle is increased to 132.7°.[5e, 22t] Despite the notable distortions, these molecules are still far away from having planar-tetracoordination at the central carbon atom.



28



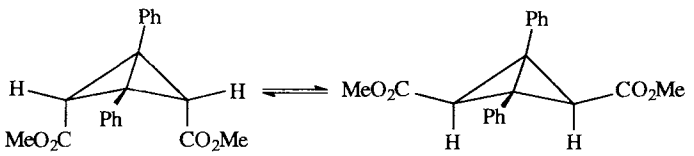
29

A new group of polycyclic hydrocarbons with potential planar-tetracoordinate carbon atoms are the alkaplanes, for which calculations reveal geometries with extensive distortions at the central carbon atom. Examples are hexaplane (**28**) and octaplane (**29**). A global minimum exhibiting a C1-C-C2 angle of 168.8°, which is not far from 180° for the planar structure, has been found for **29**.[26] The monocation of **29** is reported to have a planar-tetracoordinate carbon atom in the ground state.[26]

4. Transition States with Planar-Tetracoordinate Carbon Centers

4.1. Inversion of sp^3-Centers

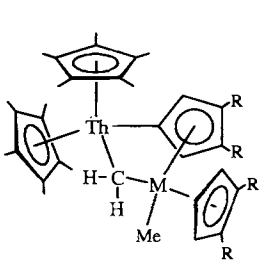
In agreement with theoretical predictions, it seems to be possible to stabilize planar-tetracoordinate carbon in ground state molecules by, for example, metal substitution. The occurrence of this structural element in transition states has been rarely investigated until now. For the bicyclic system **30**, a surprisingly small barrier for the **30-A**⇌**30-B** ring flip has been observed;[27]



30-A **30-B**

an anti-van't Hoff/LeBel structure in the transition state was considered as an explanation. However, theoretical studies on bicyclo[1.1.0]butane indicate that no planar transition state arises by ring inversion; planarity of the four-membered ring requires that the hydrogen atoms at the bridgehead atom lie out of the plane.[27]

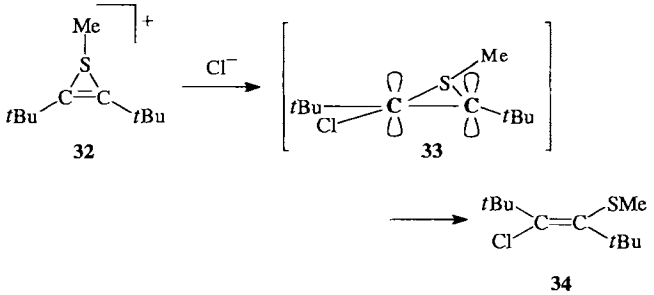
Another dynamic system that could potentially exhibit a transition state with planar-tetracoordinate carbon has been described by T. J. Marks et al.[28] The two metal centers in **31** are bridged by a methylene group, the protons of which are diastereotopic due to the C_1-symmetry of the complex. Dynamic behavior for these protons has been observed by NMR spectroscopy: separate signals are obtained at low temperatures, which coalesce with increasing temperature. At room temperature one averaged signal is observed for both protons. The resonances for the ligand framework are not affected by this dynamic feature, which suggests an interchange process for the two methylene protons. This could take place via a transition state with planar carbon tetracoordination of the methylene unit; this is supported by extended Hückel MO calculations.[28] The NMR spectroscopic investigations provided an activation energy of about 11 kcal mol^{-1} for the dynamic process. By assuming a planar transition state for compounds **31**, the energy difference between tetrahedral and planar coordination would be about 110 kcal mol^{-1} lower than that of methane, and these would be the first dimetallamethane derivatives for which this energy difference could be experimentally obtained. However, (reversible) metal–CH_2 bond cleavage cannot be totally excluded.



31a M = Hf, R = H
31b M = Zr, R = H, Me

4.2. S_N2-Vin Reactions

In addition to inversion at sp^3-carbon atoms, planar coordination geometry in transition states has been discussed with regard to S_N2-vin reactions. In this S_N2-type the sp^2-carbon atom in the σ-bonding plane is attacked on the side opposite to the leaving group,[29] and a planar-tetracoordinate geometry at the carbon atom is formed in the transition state. Inversion of the carbon atom configuration follows from this mechanism. Only a few possible examples of this *in-plane* S_N2 mechanism are currently known. Nucleophilic opening of three-membered rings such as the thiirenium cation **32**, which takes place with complete inversion at the sp^2-carbon atom, has been under discussion since 1978. The only product is isomer **34**, in which the *tert*-butyl groups are *trans* to each other; this indicates that **33** may be the intermediate. By alternative attack of the nucleophile at the π system, ring opening and formation of the *cis*-isomer would be expected.[30]



32 **33** **34**

Recent investigations of the ring opening of three-membered rings by intramolecular rearrangements also point to a S_N2-vin mechanism.[29] Furthermore, initial calculations show that nucleophilic attack in the σ plane may be preferred to that at the π system.[31]

5. Stable Anti-van't Hoff/LeBel Compounds

5.1 Dimetallic Complexes

In addition to the anti-van't Hoff/LeBel compounds **8**, **9**, and **12** already described in Section 2, a number of additional com-

plexes with planar-tetracoordinate carbon are known (the important characteristics of these complexes are summarized in Table 1). One group of compounds is formally derived from cumulenes that form coordinating bridges between two metal centers.

In 1989 M. H. Chisholm et al. characterized **35**, in which an allene group bridges two tungsten atoms.[32] Both metal atoms and the three carbon atoms of the bridging ligand lie almost perfectly in one plane. Complexes **36a**–**c** and **37**, described by F. A. Cotton et al., are analogous systems with heteroatoms in the bridging unit.[33] Comparable structures are formed in the dipalladium complexes **38** and **39** with bridging carbon disulphide or allenyl units.[34]

Planar coordination geometry at tetravalent carbon can also exist in 1,3-diyne ligands that bridge two metals. J. H. Teuben et al. were able to establish the structures of **40**, in which two carbon atoms exhibit planar-tetracoordination.[35] Further examples have been characterized (Table 2) by W. J. Evans et al. (**41**) and U. Rosenthal et al. (**42**).[36, 37] Alternatively, these compounds could be viewed as 1,4-dimetallated 1,2,3-trienes, in which the metal atoms are arranged in a *trans*-fashion. Complex **43** does not possess a completely planar framework, probably because of the unsymmetric Cp*ClTi fragments.[38] In **44** a

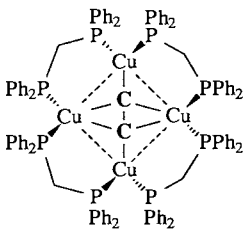
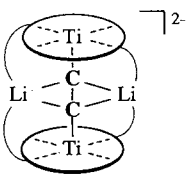
nickel complex fragment coordinates to two ring atoms of a titanacyclocumulene; this also results in a structure with a pair of planar-tetracoordinate carbon atoms.[39]

Anti-van't Hoff/LeBel structures are also observed in **45** and **46**, in which two metal centers formally coordinate side-on to a dimetallated acetylene moiety (Figure 1).[40] Both compounds contain planar $M_2M'_2C_2$ units and two planar-tetracoordinate carbon atoms.



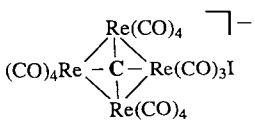
45



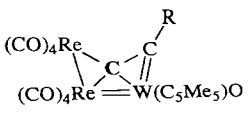
46

Figure 1. Planar-tetracoordinate carbon by coordination of metal atoms to dimetallated acetylenes. The ligands represented by rings in **46** are octaethylporphyrinogen tetraanions, which are each additionally coordinated to the lithium atoms through two of the aromatic groups.

The rhenium complex **47**, a tetrametalla[3.3.3.3]fenestrane, also exhibits an almost planar coordination geometry at the



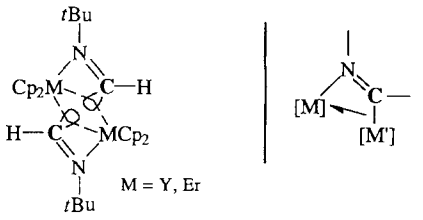
47



48

central carbon atom.[41] As deviations from the common plane in **48** are only marginal, it too can be included in the group of anti-van't Hoff/LeBel compounds. The planar structure in **48** is stabilized by three metals: one tungsten and two rhenium atoms.[42]

Complexes **49**, structurally characterized by W. J. Evans et al. in 1987, are examples of anti-van't Hoff/Le Bel compounds, in which a hydrogen atom is bound to the planar-tetracoordinate carbon center (Scheme 4).[43] In the case of the erbium complex



49

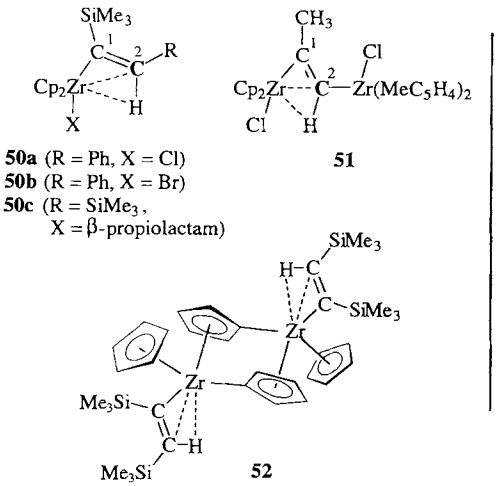
Scheme 4. Structure and schematic description of the bonding situation in **49**.

the hydrogen atom could be located by X-ray crystallography. The planar-tetracoordinate structure at the carbon atom in these complexes is again stabilized by two metals. The bonding features are most readily understood as multicentered bonds between the sp^2-carbon atom of the N-alkylformimidoyl ligand and the two metals; the planar structure is fixed by the additional metal–nitrogen bond (see Section 5.3.2).

5.2. Mononuclear Metal Complexes and Limits of Planar Tetracoordination

In contrast to the dimetallic complexes, mononuclear systems **50–52** can be regarded as examples of anti-van't Hoff/LeBel compounds, in which only one metal center stabilizes the planar geometry (the second zirconium fragment in **51** is probably not essential for stabilization of the structure).[44] The fourth in-plane bonding of the carbon atom results from the agostic interaction of the metal with the β-CH bond (Scheme 5).[45]

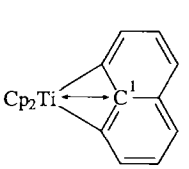
A. Berndt et al.[46a] justifiably referred to the equivalence of describing the bonding in **49** as an agostic interaction (of a metal–carbon bond with a second metal) or as a multicenter



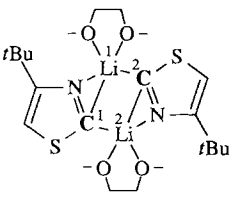
Scheme 5. Structure and schematic description of the bonding situation in **50–52**.

bond.[46b,c] Hence, complexes with agostic interactions as in **50–52** can be regarded as anti-van't Hoff/LeBel compounds.

In these complexes, as well as in **29**, the planar-tetracoordinate geometry at the carbon atom does not formally result from flattening of an alternative, distorted tetrahedral geometry, but from additional interaction of a σ bond of the sp^2-hybridized C2 with the acceptor orbital of a metal atom. The strength of the bonding interaction between C2 and the two other atoms of the multicenter bond can differ considerably. How strong the fourth bonding interaction in the σ plane must actually be to allow tetracoordination of the carbon atom to be considered must be investigated for each example on the basis of structural data and, possibly, supporting calculations. Limiting cases of planar tetracoordination are mainly found in metallacyclobutadienes, metallacyclopentadienes, and other metallacycles of small ring size, in which the distance of the metal atom to the β-carbon atom often shifts into the region of a bonding interaction.[47,48] However, in many cases it is unclear whether an electronic interaction actually arises in this way. For example, in the titanocene complex **53** the Ti–Cl distance (2.442(7) Å) is shorter than the sum of the van der Waals radii, but a bonding interaction is excluded on the basis of orbital symmetry considerations.[49] On the other hand, in the lithiated 4-*tert*-butylthiazole **54**, which was characterized by G. Boche et al.



53



54

in 1995,[50] a weak bonding interaction between the planar carbon atoms and the "second" lithium atom may be assumed; this is understandable on the basis of the overall bonding situation (C1–Li1 2.512(5), C1–Li2 2.177(5), C2–Li2 2.558(5), C2–Li1 2.175(5) Å).[50]

5.3. Dimetallic Complexes of Groups 4 and 13

In the above discussion of anti-van't Hoff/LeBel compounds, individual examples of systems with planar-tetracoordinated carbon atoms have been described. In contrast, more than 40 examples of the heterodimetallic complexes **55** are known, of which more than a quarter have been characterized by X-ray crystallography (Table 3).[5a–c,51,52]

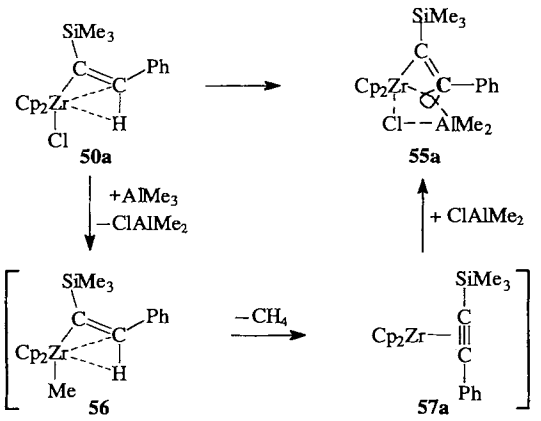
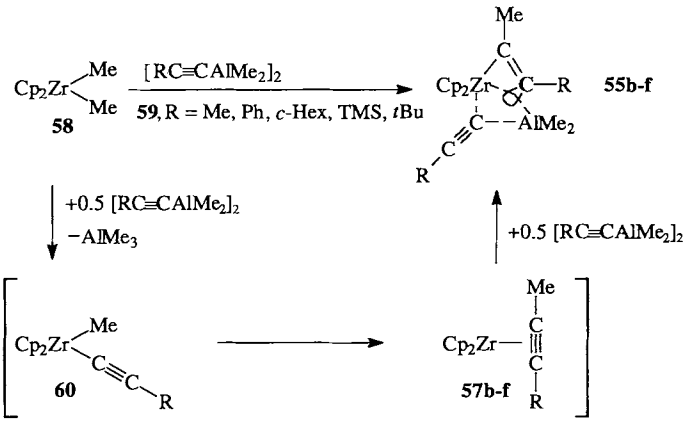
5.3.1. Synthesis

Several systematic synthetic routes to **55** have been developed, most of which presumably proceed via the (alkyne)-metallocene intermediate **57**, which is then trapped by a main group organometallic compound. The first example in this series was obtained from the reaction of **50a** with trimethylaluminium. In the first reaction step the (alkenyl)methylzirconocene **56** is most likely formed by σ metathesis, from which **57a** may be



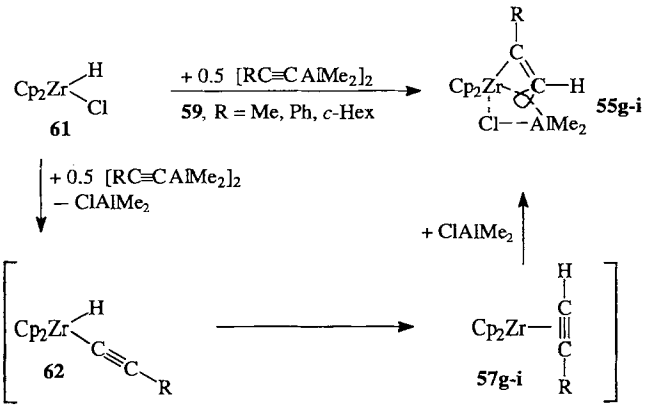
generated by elimination of methane. This is then trapped by Me_2AlCl, which is formed in the initial reaction step.[51h] In resulting **55a** the two metal centers are bridged by chloride and an alkyne unit. The bicyclic structure is formed by μ-η^1:η^2 coordination of the alkyne; the central Zr-C-C-Al-Cl unit is completely planar (maximum deviation from the plane ± 0.04 Å). The bridgehead atom C2 is planar-tetracoordinate, and the sum of the bond angles at C2 is 360.2°.[*]

Further examples of this complex type have been obtained by reaction of dimethylzirconocene (**58**) with (alkynyl)dimethylaluminium **59**. Here too a reaction pathway is assumed, in which the (alkyne)metallocene **57** is formed as an intermediate. Reductive coupling of the (alkynyl)metallocene species **60**, derived



from σ metathesis in the first step, results in **57**, which then reacts with further **59** to yield the anti-van't Hoff/LeBel compound.[51c] In addition to the μ-η^1:η^2 alkyne unit with a planar-tetracoordinate carbon atom, a μ-η^1:η^1-coordinated alkyne ligand bridges the two metal centers in **55b–f**.

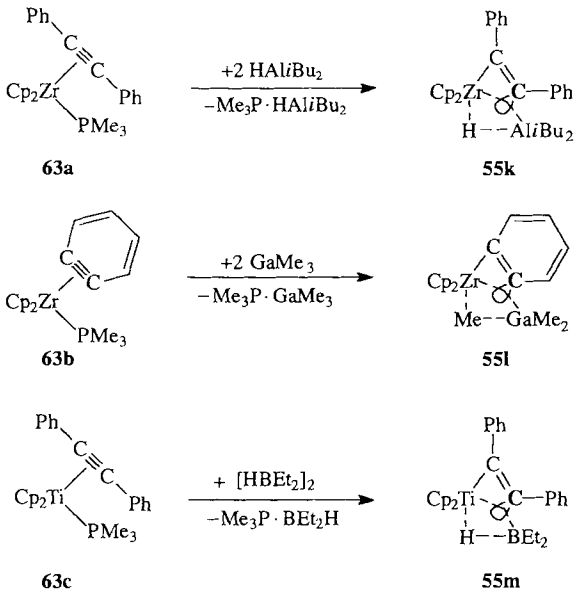
An analogous pathway is assumed for the reaction of chloro(hydrido)zirconocene (**61**) with **59** (Scheme 6).[5a–c] In the resulting complexes a hydrogen atom would be bonded as the fourth substituent at C2, as in **49**. Although no crystal structure analysis is available for these reaction products, anti-van't Hoff/LeBel structures may be assumed by analogy to **49** and the other complexes of type **55**.



Scheme 6. Synthesis of complexes of type **55** from chloro(hydrido)zirconocene **61** via the probable intermediates **62** and **57**.

[*] An sum of angles of 360° is indeed necessary, but not sufficient for characterization of a planar-tetracoordinate carbon atom. For a detailed analysis see ref. [5e].

Whether (alkyne)zirconocenes **57** actually exist as reactive intermediates in these reactions has yet to be investigated in detail. Recent studies on similar bis(zirconocene) complexes (see Section 5.4) suggest involvement of the alkylmetal compound (in this case the organoaluminium compound), for example, as an initiator in the reductive coupling step.[53] However, it is also possible to construct compounds of type **55** from donor-stabilized alkyne- or arynemetallocene complexes **63ac** (Scheme 7).



Scheme 7. Examples of the synthesis of anti-van't Hoff-LeBel compounds of type **55** from alkyne- and arynemetallocenes.

Reaction of triphenylphosphane-stabilized alkyne- or arynemetallocene complexes with two equivalents of the organoaluminium compound directly leads to heterodimetallic complexes (for example **55k**).[51b,f] Zr/Ga complexes, in which a planar-tetracoordinate carbon atom is stabilized in the same manner as in the Zr/Al complexes, have also been prepared by this route (for example, **55l**).[51e] P. Binger et al. extended this series of compounds by the use of organoboron compounds (for example, **55m**). The anti-van't Hoff/LeBel structure remains stable in these complexes also.[52] In addition to the μ-η^1:η^2 coordinated alkyne, these complexes contain a hydride, methyl, or ethyl group[52d] as the second unit bridging the metal centers.

5.3.2. *Structural and Bonding Properties*

In the heterodimetallic complexes **55** the planar-tetracoordinate carbon atom is stabilized by a Group 13 metal and a Group 4 metallocene. In all the examples that have been crystallographically investigated, the bond lengths show strong bonding of the "square planar" carbon atom to the main group metal M2. An additional interaction with the metallocene fragment [M1] leads to planar tetracoordination (Figure 2). In all cases the bond length M1–C2 is shorter than the C_{Cp}–M1 bonds, which indicates significant interaction between the orbitals of aluminium, carbon, and zirconium (Table 3). From an electron

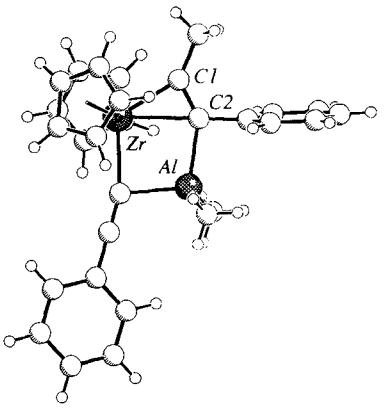


Figure 2. Crystal structure of **55c**; C2 is planar-tetracoordinate.

density investigation of **55a**, the differential density map shows a local maximum that lies inside the Zr-C2-Al triangle, that is, outside the C2–Al or C2–Zr vectors (Figure 3).[54] This observation suggests a multicenter arrangement.

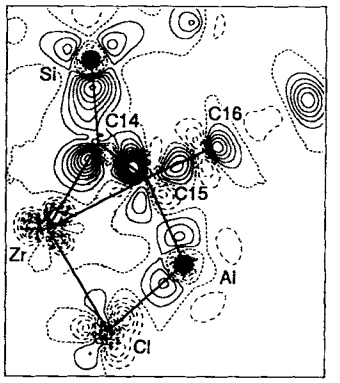

Figure 3. Electron difference density map of **55a** (a cross-section through the plane of the central ring system is shown with non-systematic numbering).

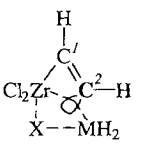
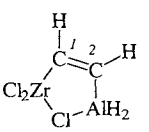
Quantum chemical analysis confirms this hypothesis. Calculations on the model systems **64a–c** show that structures with planar-tetracoordinate carbon centers are mainly stabilized by a strong Zr–C2 interaction.[55] Therefore, the anti-van't Hoff/LeBel structure is based on strong electronic interactions between C2 and the two metal atoms.



M = Al, X = H **64a**
M = Al, X = Cl **64b**
M = B, X = H **64c**

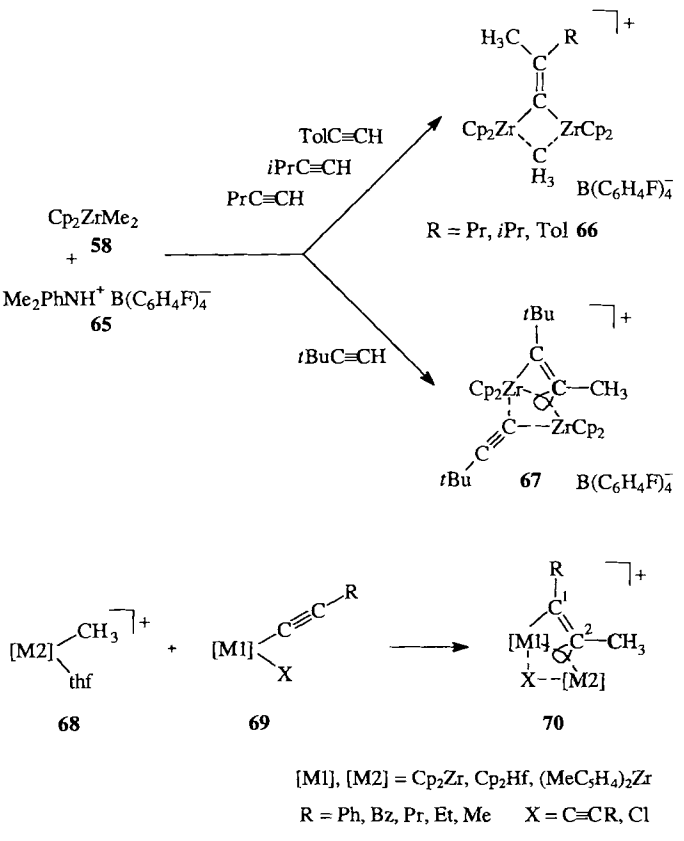


64b'

As already discussed in Section 2, the bonding situation can be as easily described as for an alkenyl anion that is σ-coordinated to two metals. Even vinyllithium forms such structures, although a planar-tetracoordinate geometry is not obtained.[56] This is enforced in **55** by the additional Zr–C1 bond. The zirconium atom is thus simultaneously a substituent on C1 and a member of the multicenter bond at C2 (for the position of the orbitals of the bent metallocene fragment, see ref. [57]). Apparently, significant π interaction of the planar-tetracoordinate carbon atom with the two metal centers does not exist; the C1–C2 bond is both structurally and spectroscopically (NMR) regarded as a "normal" double bond (see below).

Formation of the additional bond inside the five-membered ring has significant consequences for the geometry of **64**. The Zr-C1-C2 angle in the three-membered ring of the bicyclic system of about 80° deviates significantly form the ideal value of 120° for sp^2 hybridization. If the restriction that the olefinic carbon atom exhibits "normal" sp^2 hybridization is introduced into the calculation, monocyclic systems are obtained as optimized structures (for example **64b'**), which are about 40–50 kcal mol^{-1} higher in energy than the bicyclic anti-van't Hoff/LeBel structure **64**.[55]

The planar-tetracoordinate carbon atom in **55** is part of a double bond, and the C1–C2 bond lengths lie in the normal range (see Table 3). In contrast, Zr–C1 is noticeably short (average 2.16 Å) for a zirconium–carbon bond; this suggests an interaction of the olefinic π system with the metal. The ^{13}C NMR resonance for C1 is significantly shifted to low field ($\delta \approx 190-210$). However, analogous shifts have also been found for other vinyl units bound to zirconocene fragments. The signal for the planar-tetracoordinate carbon atom lies in the range of $\delta = 110-150$. Thus, the uncommom structure apparently does not result in very unusual NMR spectral data. No special correlation between the unusual structure and spectroscopic behavior has been recognized with other anti-van't Hoff/LeBel compounds (see Table 1).[5a–c, 51, 52]



5.4. Homodimetallic Group 4 Systems

Complex **67**, obtained by A. Horton et al. in 1992 while attempting an alkyne oligomerization in the presence of **58** and **65**,[58] corresponds to the heterodimetallic complexes **55** with a (formally cationic) zirconocene unit in place of the main group organometallic moiety. Unfortunately this pathway apparently does not allow the introduction of other substituents since complexes of type **66** are obtained. However, a general access to complexes of type **67** has been opened by a new synthesis.[53, 59]

5.4.1. Synthesis and Dynamic Behavior

By reaction of Jordan's methylmetallocene cation **68** with bis(alkynyl)metallocenes **69** (X = C≡CR), complexes **70** are obtained in yields of over 80% (in each case the counterion is BPh_4^-).[53, 59] Important data on several of these compounds are given in Tables 3 and 4. Figure 4 shows the structure of one of these complexes, as determined by X-ray crystallography.

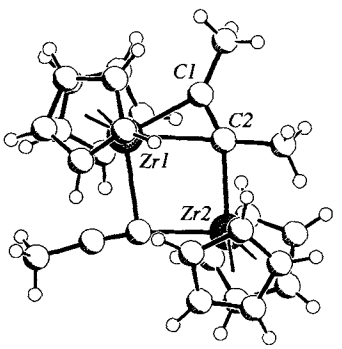


Figure 4. Crystal structure of **70a** (only the cationic part is shown); C2 is planar-tetracoordinate.

The mechanism of this reaction has been investigated with double labeling experiments. By assuming a reaction pathway that is analogous to that postulated for the heterodimetallic

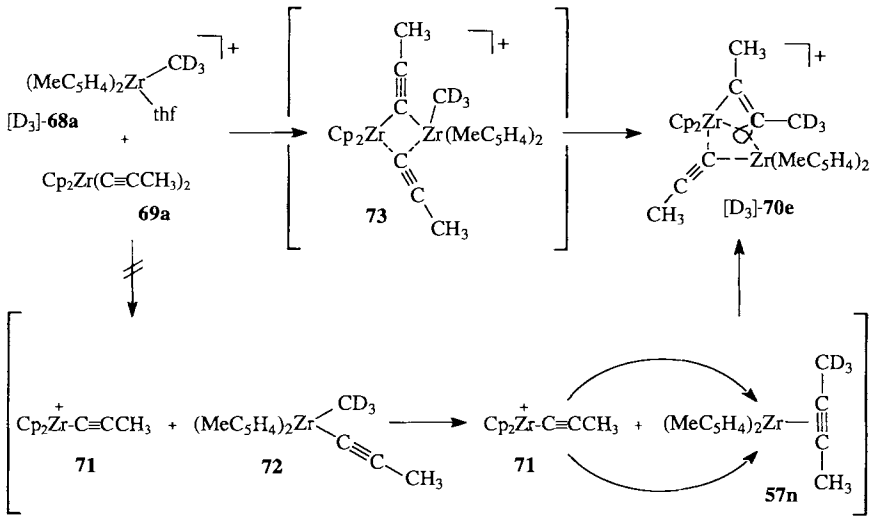
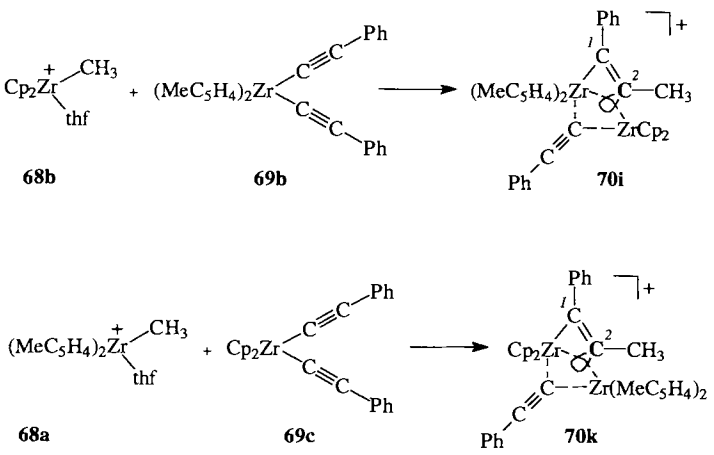
[a] At 183 K.

systems, a mixture of two isomers should be obtained from the reaction of [D_3]-**68a** with **69a** since the (alkynyl)zirconocene cation **71** can add to either side of the (alkyne)zirconocene **57n**, which is formed by reductive coupling from **72** (Scheme 8). However, only one isomer is observed, in which the methyl group from [D_3]-**68a** lies adjacent to the metallocene fragment from which it originates. This organometallic "memory effect" is also maintained by other substitution patterns, and the relative position of the substituents is controllable.

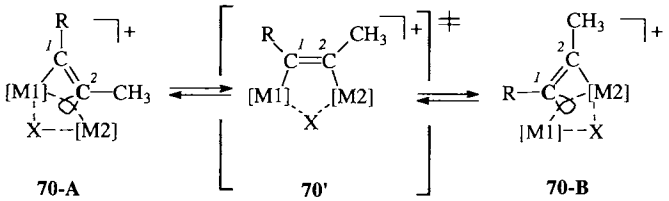


Scheme 8. Double labeling experiment for investigating the formation of **70e**.

A mechanism in which reductive coupling takes place at binuclear **73** explains the high regiospecificity of the reaction, but does not offer a complete explanation for the observed isomers. The predicted product **70i** is indeed obtained from the reaction of **68b** with **69b**. However, the product from the reaction of **68a** with **69c** is not the compound with a phenyl group at the planar-tetracoordinate carbon atom, but rather **70k**. Again the product is obtained, in which the methyl group is adjacent to the metallocene fragment from which it originates; however, the metallocene fragments are in "exchanged" positions. Opening of the bicyclic system to the five-membered ring (**70′**), which then cyclizes to the thermodynamically more favorable product (see Table 4), offers a clear explanation for this observation.

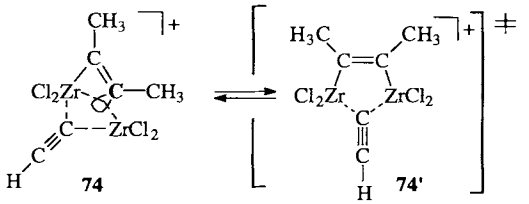


The position of the **70-A**⇌**70-B** equilibrium is dependent on both the metallocene and the substituent on the double bond



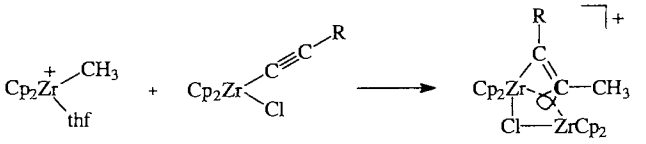
(see Table 4). Placing the methyl group at the planar-tetracoordinate carbon atom is primarily preferred. With two methyl substituents attached at the olefinic unit, the electronic properties of the metallocenes control the isomeric ratio. These can be varied by the ligand or metal. In the combination of a zirconocene fragment with a hafnocene fragment, the isomer in which the zirconocene unit is η^2 coordinated to the alkyne ligand is the sole product (**70g**). In the competition of a $(C_5H_5)_2Zr$ unit with a $(MeC_5H_4)_2Zr$ unit, the isomer with the unsubstituted cyclopentadienyl ligand in this position is over 95% populated (**70e**).

Opening of the bicyclic system to the five-membered ring has been investigated for **64** with quantum chemical methods to obtain a measure of the energetic stabilization of the planar-tetracoordinate structure (see Section 5.3.2). These homodimetallic complexes offer the possibility of determining the energy difference between the "normal" olefinic structure in the five-membered ring **70′** and the planar-tetracoordinate geometry in a simple manner. In **70a** both systems **A** and **B** are identical. If the rearrangement process were to proceed here, there would be a mutual interchanging of the methyl groups and the metallocene fragments. The thermally induced automerization of this system can be followed by ^{1}H NMR spectroscopy. At room temperature **70a** shows only one signal for the two metallocene fragments and one signal for the two methyl groups. Broadening of these signals is observed at lower temperatures, and finally the cyclopentadienyl and methyl protons each show two resonances. Simulation of the spectra allows determination of the activation barrier to the process (**70a**: $\Delta G^{\ddagger} = 11.8 \pm 0.5$ kcal mol^{-1} at 250 K).[59a] Quantum mechanical investigations on the model compound **74** show that the isomeric monocyclic five-membered ring system is a transition state and not an intermediate.[53]



ΔE (RHF) = 8.9 kcal mol^{-1}
ΔE (RMP2//RHF) = 14.2 kcal mol^{-1}

Thus, the experimentally determined activation barrier serves as a direct measure of the stabilization energy of the planar-tetracoordinate structure relative to the normal olefinic structure in the five-membered ring. The energy difference of the isomeric structures obtained from ab initio calculations on **74** agrees well with the experimentally obtained activation energy of the rearrangement. Furthermore, additional interaction between the planar carbon and the second zirconium atom is the main factor for stabilization of the anti-van't Hoff/LeBel structure.



68b **75** **70l** (R = Me), **70m** (R = Pr), **70n** (R = CH_2Ph)

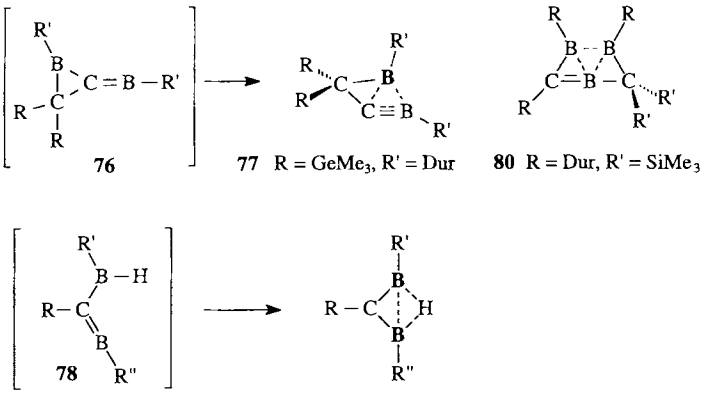
That the bridging alkynyl unit has no significant influence on the automerization process is shown in analogous measurements on chloride-bridged **70l**. The complex was obtained by reaction of the methylzirconocene cation **68b** with chloro(propynyl)zirconocene **75**. The activation energy $\Delta G^{\neq}$ (**A**$\rightleftharpoons$**B**) for the automerization reaction of **70l** is 11.3 kcal mol^{-1} (240 K) and almost identical to that of **70a**. Complexes with the chloride bridge also show no significant structural deviations; the bonding features of the planar-tetracoordinate carbon atoms correspond to those of the alkynyl bridged species.[59c]

5.4.2. *Structural and Bonding Properties*

Structurally, the cationic homodimetallic zirconium complexes **70** are closely related to the heterodimetallic Zr/Al systems (see Table 3). The Zr1–C1 bond in **70** (average 2.22 Å) is very short; the C1–C2 bond length (1.31 Å) lies in the typical range for C=C.[60] The separations between the planar-tetracoordinate carbon and the two metal centers are 2.35 (C2–Zr2) and 2.50 Å (C2–Zr1), which confirms bonding interactions to the two metals. In all of these cationic complexes there are indications of an agostic interaction between a hydrogen atom of the methyl group on C2 and the M2 center. This is also evidenced by a characteristic ^{13}C NMR signal for the methyl carbon atom C2–CH_3, whose resonance is high-field shifted and in the range of $\delta = -10$ to -25 (see Table 4). The high-field shift is not so pronounced in the ^1H NMR spectrum, and the signals are at about $\delta = 0$. In contrast, the $^1J_{CH}$ coupling constants of 130 Hz are normal. Quantum mechanical investigations on **74** predict an interaction of the methyl hydrogen atom with the metal center. However, this is of secondary importance for the stabilization of the bicyclic structure. Detailed investigations to confirm this agostic interaction in solution are currently being carried out.

6. Heteroanalogous Systems

The search for anti-van't Hoff/LeBel compounds is not restricted to systems with planar-tetracoordinate carbon, although the main emphasis of research activities has been here. Calculations on planar tetracoordination have been carried out on the heavy homologues of carbon as well as on a few other second row elements and phosphorus.[6b,c,9b,61] Quantum chemical considerations of a number of boron compounds have led to the prediction of nonclassical structures for, for example, boriranylideneboranes **77** or borylmethyleneboranes **79**.[5d,62,63]



76 **77** R = $GeMe_3$, R' = Dur **80** R = Dur, R' = $SiMe_3$

78

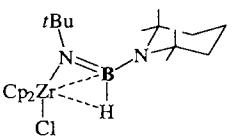
79a R = $SiMe_2$Dur, R' = Dur, R'' = $CH(SiMe_3)_2$

79b R = $C(SiMe_3)_2BEt_2$, R' = R'' = Dur

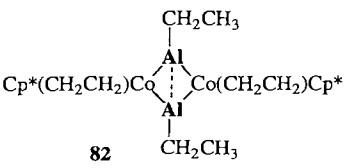
Dur = 2,3,5,6-tetramethylphenyl

In both systems, the unusual bonding features have meanwhile been experimentally confirmed. In **76**–**80**, investigated by A. Berndt et al., anti-van't Hoff/LeBel structures at the boron atom are stabilized by multicenter bonding. The planar-tetracoordinate boron center forms bonds to other boron, carbon, or hydrogen atoms. In contrast to carbon, stabilization of planar tetracoordination at boron is possible without additional neighboring metal centers.[46,63,64]

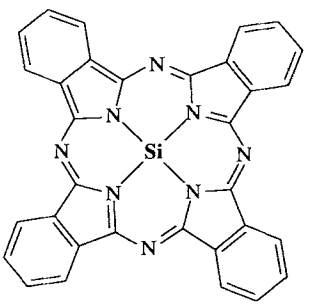
In addition, examples of planar-tetracoordinate boron atoms in metal complexes are known. The cobalt complex **7** contains a carbon and a boron atom, both of which exhibit planar tetracoordination (see Section 2); the boron is bonded to both transition metal atoms.[12] A monometal-stabilized anti-van't Hoff/LeBel structure exists in **81**, which is obtained by hydrozirconation of an iminoborane (H. Nöth et al., 1985).[65] The compound exhibits a bonding situation analogous to that in **50**–**52**. The Zr–Br distance of 2.627(2) Å is 0.18 Å longer than that expected for a single bond. The interaction between the boron and zirconium centers also explains the magnetic shielding of the boron atom $\delta = 21.5$).[65]



81



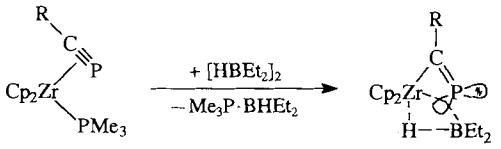
82



83

A complex of the higher homologue of boron, aluminium, that can possibly be included in the group of anti-van't Hoff/LeBel compounds is also known. The aluminium atoms in the cobalt complex **82** have a separation of 2.663(3) Å, which lies within the range of a bonding interaction.[66] The Co–Al bond lengths [2.336(1) and 2.333(1) Å] are shorter than in other Co/Al clusters.[66]

A planar-tetracoordinate silicon atom has been observed in a crystal of a phthalocyanine, in which 17% of the ligand is occupied with this semi-metal (**83**).[67] Several compounds with planar-tetracoordinate oxygen, in which the oxygen atom is coordinated to four metal centers,[68] are known. In contrast, to our knowledge no compounds of nitrogen with anti-van't Hoff/LeBel structure have yet been unambiguously characterized. P. Binger et al. obtained the phosphorus-containing Zr/B complexes **85**, which are closely related to heterodimetallic **55**.[69]

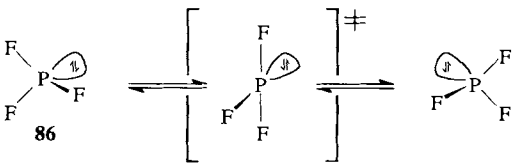


84 **85**

R = *t*Bu, Ad

Analogous to the reaction of (alkyne)metallocenes with Group 13 organometalic compounds (see Section 5.3.1), complexes **85** are synthesized from phosphane-stabilized (phosphaalkyne)metallocenes **84** and tetraethyldiborane. These complexes are formally derived from compounds of type **55** by substitution of the planar-tetracoordinate carbon with a phosphorus atom; an electron lone pair replaces the fourth substituent. An unusual situation arises in which the phosphorus atom participates in a multicenter bond with the metals yet has a free electron pair, which is not directly involved in a bond with the metals. Calculations support this simple model, but show that the orbital of the free electron pair has extensive s character (80%).[70]

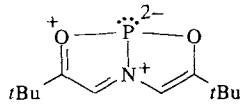
An electron lone pair as a fourth substituent on planar PR_3 presumably also arises in the transition state for the inversion of phosphorus trifluoride (**86**, Scheme 9). Inversion of NH_3 takes



Scheme 9. Possible mechanism for the inversion of PF_3 (**86**).

place via a trigonal planar structure, in which the electron lone pair is in a p orbital that is vertical to the plane of the substituents. In contrast, for PF_3 the three fluorine atoms and the free electron pair may lie in one plane; this leads to a T-shaped molecular structure in the transition state.[71]

In **87**, investigated by A. J. Arduengo et al., a hypervalent structure with ten electrons on phosphorus is formed. In this structure a free electron pair lies in the plane of the planar, bicyclic system, which results in tetracoordination similar to that in **85**.[72] However, there is no in-plane coordination in metal complexes of these compounds; distorted tetrahedral or pentacoordinated structures are formed.[73]



87

7. Summary and Prospects

Since 1970 when R. Hoffmann et al. published their fundamental papers on compounds containing planar-tetracoordinate carbon, this topic has proved to be one of continuing innovation. This area was initially the domain of theoretical chemistry, to which preparative chemistry later gained admission. The latter was and remains divided. On one hand, individual examples of stable compounds with planar-tetracoordinate carbon that did not result from a directed synthesis of anti-van't Hoff/LeBel compounds are continously being discovered. One example is the divanadium complex **8a**, which is probably the first anti-van't Hoff/LeBel compound to be examined crystallographically, but was not characterized as such for some time. On the other hand, an extremely fruitful symbiosis of theoretical and preparative chemistry has resulted, for example, in the targeted synthesis of the dimethoxyphenyl lithium dimer **12** as a compound with a planar-tetracoordinate carbon.

Following the recognition of individual representatives, simple synthetic methods have been developed for preparing hetero- and homodimetallic complexes **55** and **70**. More than a dozen complexes of this type have since been characterized by X-ray crystallography. The planar-tetracoordinate structure is stabilized by two metals that form a multicenter bond with the carbon atom. As in many other examples, the magnitude of the energetic stabilization of the planar-tetracoordinate geometry in these complexes was predicted by quantum mechanical investigations. For the first time experimentally established values for the stabilization of the planar-tetracoordinate structure have been obtained with the homodimetallic zirconium complexes **70**. The anti-van't Hoff/LeBel structure in these compounds is about 12 kcal mol^{-1} more stable than the alternative coordination state, in which the sp^2-hybridized carbon atom forms only three bonds. This experimental value correlates well with the calculated stabilization energy of planar-tetracoordinate carbon in such compounds.

Although there has not been immediate success in forming planar-tetracoordinate carbon structures with the fenestranes and other polycyclic organic compounds, recent calculations have revealed that the chances of finding anti-van't Hoff/LeBel structures here are also promising.[26] Over the last 25 years it has been demonstrated that it is possible to stabilize planar-tetracoordinate carbon with metal atoms. It can only be hoped that a continuously expanding spectrum of such compounds will also lead to an uncovering of their own chemistry, in which the unusual coordination geometry can be used as a specific functionality.[74]

We wish to acknowledge generous support of our work on this topic from the Volkswagen-Stiftung, the Deutsche Forschungsgemeinschaft, the Alfried-Krupp-von-Bohlen-und-Halbach-Stiftung, the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen, and the Fonds der Chemischen Industrie. We also thank Professor Rolf Gleiter, Professor Paul Binger, and Professor Carl Krüger and their colleagues for a very interesting and stimulating cooperation and Dr. Roland Fröhlich and his team for many crystal structure analyses. G. E. would like to thank Dr. Roland Zwettler and Dr. Markus Albrecht for their contributions to the development of this area.

Structure–Activity Relationships by NMR: A New Procedure for Drug Discovery by a Combinatorial–Rational Approach

Horst Kessler*

The search for new lead structures for drug development was always a combination of serendipity and rational design. The possibility of discovering new, biologically active structures was dramatically increased by screening pools of substances. In the rational approach medicinal chemists optimized the properties of the active compound either using personal experience only or partly utilizing molecular structure. Disillusionment followed the extreme overemphasis of rational design (which certainly was stimulated by the suggestive power of colored computer pictures of the molecules), because it was soon evident that a medicinal product with desired and distinct properties such as high activity and selectivity, metabolic stability, and bioavailability cannot be attained simply by molecular design. However, directly or indirectly, design certainly plays a significant role in developing new pharmaceutical products.

Recently eminent representatives of the pharmaceutical research field have expressed the opinion that rational design does not work. Instead they concentrate fully on the combinatorial approach. Combi-chem, the new buzzword, will certainly give new impetus to pharmaceutical research[1] but again disillusionment will soon follow, as limitations are already obvious in this new development.[1] Extreme viewpoints always have a short lifespan, and the choice will not be between combi-chem or rational design, but a combination of the techniques will be used to accelerate the development of new drugs.

In recent years our understanding of biological processes in healthy or afflicted organisms has brought the identification of ever increasing numbers of molecular structures, whose inhibiting or activating factors reveal a promising goal for pharmaceutical products. In this regard proteins in the form of enzymes, receptors, or inhibitors play a decisive role. Their biotechnological identification, expression, isotope labeling, and structural clarification allows a targeted, structure-oriented search for partners that build supramolecular complexes with the desired biological effect.

Development of substrates with optimal adaption to clefts and pockets of protein receptors is more complicated than expected. Molecular recognition is not a simple docking of given surfaces but is based on a double-induced fit, in which both molecules change their conformations for mutual optimization (Figure 1). In addition, the rational approach suffers from the fact that the free enthalpy, which determines the stability of the complex, is difficult to calculate, and that water molecules often fill gaps at the binding site in an unpredictable way or form hydrogen bonds across long distances.[2] Hence, molecular structures certainly help in improving known substrates, but, despite promising first results (for example with the program package LUDI),[2] the de novo design of new structures has still to be tested.

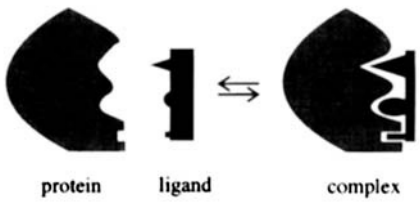

Figure 1. Mutually induced adaption of receptor and substrate during molecular recognition.

That is why one strongly prefers the thorough screening of mixtures of compounds ("libraries"). When a library contains an active compound, its structure is identified by more or less sophisticated procedures. If it is possible to synthesize a mixture of compounds with large structural diversity, this technique saves many biological tests as well as the tedious synthesis and purification of single substances with potential activity. A disadvantage of this procedure is that in large libraries only very active compounds can be identified due to the limited sensitivity of the biological test system. In addition, the problem of high structural diversity from different functional groups needs to be worked out. The use of amide or ester bonds in pharmaceutical chemistry is limited, because they restrict the applicability as drugs.[3]

Recently a pioneering study was published by the group of Fesik (Abbott Laboratories). They elegantly combined the advantages of both approaches—rational design and combinatorial chemistry—by a technique which was dubbed "SAR by NMR", that is, structure–activity relationships by NMR spectroscopy.[4] The new procedure[5] offers the advantage of combining rational drug design of certain object molecules and combi-chem with ^{15}N-enriched proteins of molecular weights up to about 30 kDa, for which assignment of the signals for

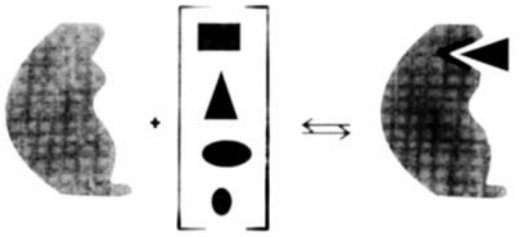
protons and nitrogen atoms of the amide groups is often not difficult. The $^{15}N-^{1}H$ pairs of folded proteins usually give well-resolved, two-dimensional HSQC[6] spectra. Addition of a substrate with sufficient affinity to the ^{15}N-enriched protein in solution yields a shift of the HSQC NMR signals for all groups next to the binding site (Figure 2).



^{15}N-labeled protein | small substance library | identification of the complexation by 2-D ^{15}N-^{1}H HSQC NMR.

Figure 2. Screening of libraries for binding ligands with NMR spectroscopy. One ligand induces a change in the chemical shift of the NH protons and nitrogen atoms as noted by 2-D $^{15}N-^{1}H$ NMR spectroscopy.

The procedure was demonstrated with ^{15}N-labeled FKBP[7] (FK506[8] binding protein), which is important for the suppression of the immune response in organ transplantation. The HSQC spectra (data acquisition over about 10 min with automated sample changing on a 500 MHz spectrometer) were run with mixtures of ten compounds each from the substance pools at Abbott Laboratories. When enough protein is available, a pool of 1000 compounds can be screened in one day. If a pool contains a binding compound, it is identified by the shift of the NH signals near the binding site, which can also be simultaneously located. From the active mixtures, one can identify the single, active compounds with a few measurements.

Fesik et al. chose two molecules with different but adjacent binding sites (Figure 3). Both compounds bound in the submillimolar range. These structures were optimized after a few trials, and the structure of the ternary complex with FKBP was determined with NMR methods. Suitable linkers for the two ligands were then modeled on the computer. Synthesis of only five different linked compounds yielded superactive molecules, all in the nanomolar range; the best compound had a K_d of 19 nmol.

The efficiency of the procedure is impressive. It is based on the fact that the advantages of structure-oriented design and screening of substance pools are combined. This is truly "combi-chem design".

Screening of substructures of complex ligands yields, for example, for two binding sites with a library of 1000 compounds each an equivalent of a conventional library with $1000 \times 1000 =$ 1 million compounds. The distinct advantage of the Fesik approach is that one needs only weak binding for single ligands. Linking such weak binders provides not only the product of binding constants of the single substances but an additional entropic contribution [Eq. (1), Figure 4].

$$\Delta G_{AB} = \Delta G_A + \Delta G_B + \Delta G_{link} \quad (1)$$

A further advantage is the possibility of directly investigating allosteric effects. Screening of libraries in the presence of the first ligand allows identification of further ligands that only bind in the presence of the first one (Figure 5).

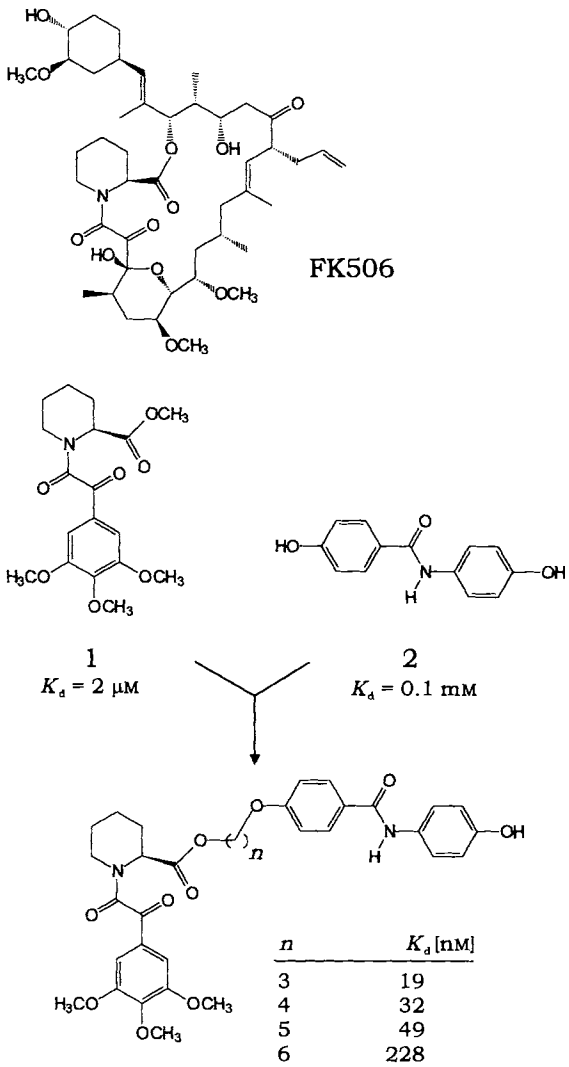


Figure 3. FK506 and two weak ligands identified with SAR by NMR and their connection. While ligand **1** is rationally derivable as a structural analog of FK506, this is not true for **2**. Only the identification of the binding site with NMR yields quick access to the connection site and therefore to high-affinity ligands.

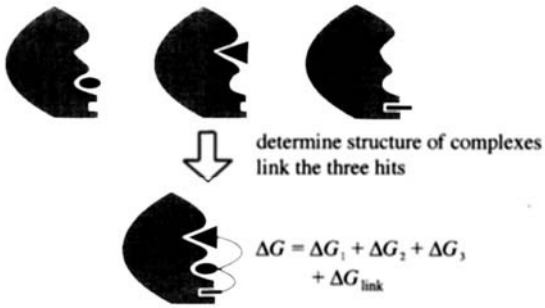

Figure 4. Connection of several ligands to different sites yields superactive substrates.

Of course this procedure has its limitations. For example, the size of the protein should not exceed the 30 kDa limit dramatically. In addition, it is important that the protein be expressed in high yields; a minimum of 200 mg ^{15}N-labeled material is needed. However, thanks to the continuous extension of our biochemical knowledge of pathological disorders on a molecu-

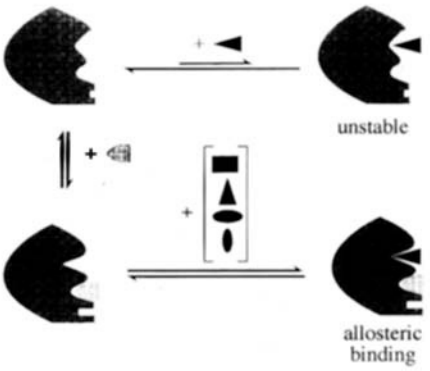

Figure 5. Screening of the allosteric effect: Binding of the triangular ligands only occurs if the second binding site is occupied. Further binding sites can be established with a 1:1 complex of protein and ligand.

lar level, there are and will be many new targets for SAR by NMR. The group of Fesik has already applied their technique to other proteins.

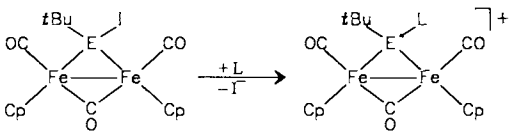
The First Triple Bond between Germanium and a Transition Metal

Ulrich Siemeling*

The chemistry of transition metal carbyne (= alkylidyne) complexes plays an important role in organometallic chemistry. Nowadays a large number of complexes are known with terminal and also with doubly and triply bridging CR ligands.[1] In contrast, the homologs of carbon are found only rarely in similar coordination modes. The longest known and comparatively most common examples of such species are complexes with triply bridging silanetriyl (silylidyne) or germanetriyl (germylidyne) units μ_3-ER (E = Si, Ge).[2]

The first complexes with base-stabilized μ_2-silanetriyl or μ_2-germanetriyl units were reported in 1991 and 1994, respectively, by Ogino, Tobita, and co-workers.[3] The cationic μ_2-silane- and -germanetriyl complexes $\mathbf{2a}^+$–$\mathbf{2c}^+$ with four-coordinate E are formed from the μ_2-E*t*BuI-bridged diiron complexes **1** by replacement of the iodine substituent with a strong Lewis base L (Scheme 1). The peak of the corresponding base-free cations occurs with high intensity in the FAB mass spectra of the complexes $\mathbf{2}^+$.



1a: E = Si
1b: E = Ge

2a$^+$: E = Si, L = NMI
2b$^+$: E = Si, L = DMAP
2c$^+$: E = Ge, L = NMI

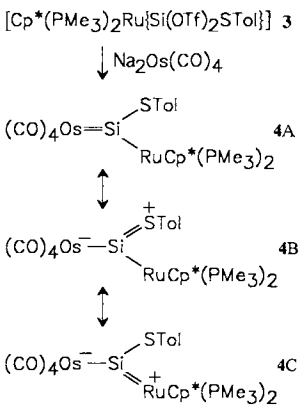
In 1993 Grumbine, Tilley, and Rheingold obtained the heterodimetallic complex **4** with a planar tricoordinate Si atom (sum of angles 360.1°) in a metathesis reaction from the ruthenium complex **3** (Cp* = C_5Me_5, Tol = *para*-tolyl, OTf = OSO_2CF_3) and $Na_2[Os(CO)_4]$.[4] The X-ray crystal structure analysis of **4** revealed that of the three meaningful resonance structures **4A**–**4C**, the zwitterionic resonance structure **4C** makes the most important contribution: The Os–Si distance is 241.9(2) pm and thus lies in the typical range for Os–Si single bonds, and the Ru–Si distance (228.6(2) pm) is significantly shorter than that expected for a single bond. Complex **4** can be described as a metal-substituted silanediyl complex and as a base-free μ_2-silanetriyl complex.



The cation $\mathbf{5}^+$, which was recently obtained by Berry and co-workers from the thermolysis of $[Cp_2W(SiMe_3)(GeMe_2OTf)]$ (Figure 1),[5] can be understood as a base-free μ_2-germanetriyl complex. Since both the chemical shift as well as the H–W coupling constant of the tungsten-bound hydride ion are normal for tungstenocene hydride, the authors ruled out a nonclassical Ge-H-W interaction. The Ge1 atom is trigonal planar

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3608-0831 $ 17.50+.50/0

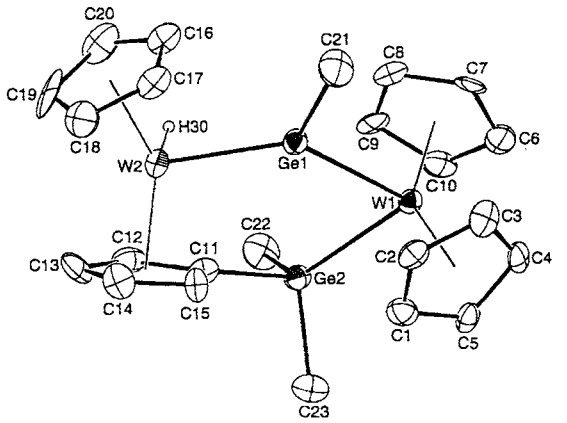


Figure 1. Crystal structure of 5^+ [5].

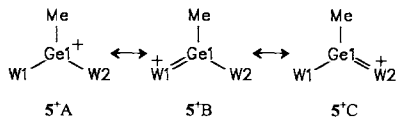
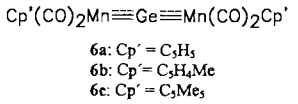
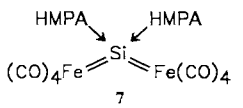
(sum of angles 360°). The structural parameters of 5^+ confirm that 5^+C is the most important of the three possible resonance structures for the description of the bonding at this Ge atom. The W1–Ge1 bond length (258.3(2) pm) is typical for a W–Ge single bond; in contrast, the W2–Ge1 distance of 248.7(2) pm is significantly shorter.



What is the situation with corresponding analogs of complexes with terminal alkylidyne ligands? Such species should contain an almost linear dicoordinate Si or Ge atom. Compounds, in which this coordination is present, have been known for germanium for many years! Nevertheless, these were not complexes with terminal germanetriyl ligands, but dimetallaheterocumulenes of the type **6** with a linear Mn-Ge-Mn unit.[6] Fenske–Hall

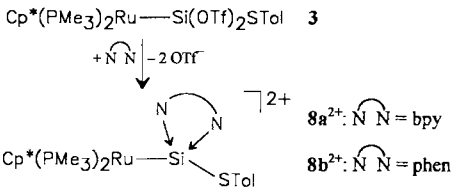




calculations as well as vibrational spectroscopy and structural evidence indicate that the Mn–Ge bonds in **6** have partial triple bond character; thus, the Mn-Ge-Mn multiple bond system contains, in a simplified view, an almost cylindrical three-center–four-electron π bond.[7]

A typical reaction of **6** is the formation of Lewis base adducts, for example **6b**·bpy (bpy = 2,2′-bipyridine).[8] A similar compound is known for silicon, the HMPA adduct **7** (HMPA = hexamethyl phosphoramide), which contains a distorted tetrahedrally coordinated Si atom.[9]

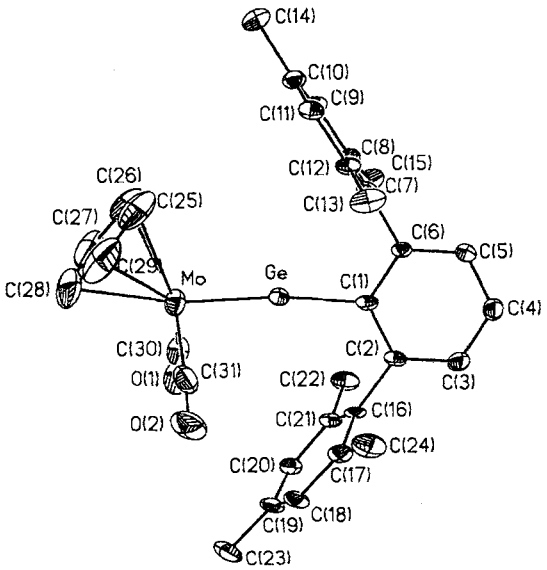
Complexes **6b**·bpy and **7** are closely related to two compounds published by Tilley and co-workers in 1992. The reaction of **3** with bpy or phen (phen = 1,10-phenanthroline) leads ed by the authors as complexes with donor-stabilized terminal silanetriyl ligands (Scheme 2);[10] the synthetic strategy—substitution of a good nucleofugic leaving group, which leaves as an anion, by a neutral Lewis base—is similar to that employed by Ogino and Tobita for the synthesis of $\mathbf{2a}^+$–$\mathbf{2c}^+$. The Ru–Si distance in complex $\mathbf{8b}^{2+}$ is 226.9(5) pm, and is thus only slightly shorter than the Ru–Si distance in the μ_2-silanetriyl complex **4** (228.6(2) pm). The S–Si distance (217.9(7) pm) is somewhat shorter than in $[Cp^*(PMe_3)_2RuSi(STol)_3]$ [222.3(1), 219.6(1) and 219.5(1) pm],[4] which infers a certain S–Si π-bonding contribution.



Scheme 2. Synthesis of the base-stabilized complexes **8**.

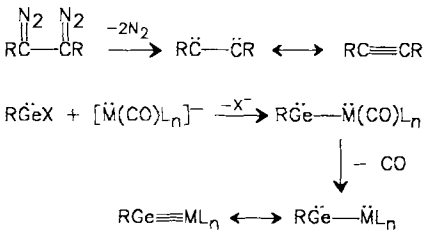
The first evidently "genuine" analog of a complex with a terminal alkylidyne ligand, in which a metal–element triple bond is present, was recently published by Simons and Power.[11] After tungsten– and molybdenum–phosphorus triple bonds had caused a stir in 1995,[12] now the molybdenum–germanium triple bond is creating a furore. This is partly because despite many years of intensive research into multiply bonded systems of the heavier elements of the fourth main group, particularly Si and Ge, a triple bond has remained elusive.[13]

The germanetriyl complex **9** (Figure 2) is formed surprisingly simply by metathesis from the in situ generated germylene 2,6-$Mes_2C_6H_3GeCl$ (Mes = 2,4,6-$Me_3C_6H_2$) and $Na[MoCp(CO)_3]$ in THF under decarbonylation at 50°C. The Mo-Ge-C unit is approximately linear (172.2(2)°). The Mo–Ge distance is



227.1(1) pm, which corresponds to a shortening of about 35 pm in comparison to a Mo–Ge single bond length and is consistent with the presence of a triple bond. An interaction of the Ge atom with the carbonyl ligands can be ruled out.

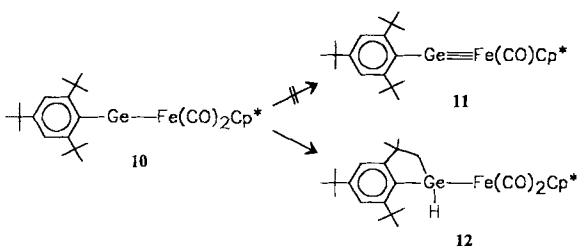
The principle behind the synthesis employed by the authors can be traced back over a hundred years to work by Curtius,[14] who produced C–C triple bonds by double N_2 elimination from 1,2-bis(diazo) compounds generated in situ by oxidation of 1,2-dihydrazones (Scheme 3). This principle has been applied very



Scheme 3. The old reaction scheme employed for the generation of a C–C triple bond by Curtius (top) can be used for the generation of a Ge–M triple bond (bottom).

successfully in phosphorus chemistry by Bertrand and co-workers particularly for the construction of compounds with a formal P–C triple bond.[15] There have also been attempts at using this approach in germanium chemistry for generating a transition metal germanium triple bond. In 1994 Jutzi and Leue observed a peak of high intensity for the radical cation of the decarbonylated species in the mass spectrum of the (supermesityl)ferriogermylene **10**; however, preparative attempts at the decarbonylation of **10** did not afford the desired germanetriyl complex **11**.[16] Instead of a decarbonylation, **10** reacts under intramolecular C–H insertion to give the germaindane derivative **12** (Scheme 4), a reaction, which proceeds similar to that of the germylene $(2,4,6\text{-}C_6H_2tBu_3)_2Ge$, which was first described by du Mont and co-workers.[17]

The choice of the organic substituent at germanium, 2,6-$Mes_2C_6H_3$, certainly plays a decisive role in the successful synthesis of complex **9** with a terminal germanetriyl ligand. It will be interesting to see in the future what reactions are still possible at the Mo–Ge triple bond despite the steric shielding by this substituent.



Scheme 4. Unsuccessful attempt at the synthesis of complex **11** with a terminal germanetriyl ligand.

Carbon Networks Based on Dehydrobenzoannulenes: Synthesis of Graphdiyne Substructures**

Michael M. Haley,* Stephen C. Brand, and Joshua J. Pak

Exploration into the formation of novel carbon allotropes continues to be an area of intense investigation.[1] To date, most synthetic research has focused on planar polymeric networks comprising *sp* and sp^2 carbon atoms.[1,2] Diederich et al. have prepared a variety of perethynylated monomers such as tetraethynylethene,[3] tetraethynylbutatriene,[4] and hexaethynyl[3]radialene.[5] Copper-mediated oxidative oligomerization of *cis* doubly deprotected tetraethynylethene derivatives produced remarkable annulenic substructures,[6] which were themselves potential precursors to additional networks. Whereas desilylation and subsequent oxidative dimerization of the perethynylated molecules should lead to the desired diacetylenic carbon allotropes, the deprotected polyynes are highly unstable and decompose even in dilute solutions at subzero temperatures; thus, oligomerization or polymerization studies of these systems have been restricted significantly.

Incorporation of a stabilizing aromatic ring into the network backbone might make preparation and isolation of larger substructures feasible. Replacement of the ethene units in a polymer with benzene moieties thus leads to the all-carbon network **1**. With a heat of formation of 18.3 kcal per g-atom C,[7] graphdiyne[8] (**1**) is the most stable carbon allotrope containing diacetylenic linkages. Graphdiyne should exhibit fascinating properties such as high, third-order nonlinear optical susceptibility, conductivity or superconductivity when doped with alkali metals, and enhanced redox activity. The latter is due to the fact that the large holes (about 2.5 Å) in the planar sheets can facilitate through-sheet transport of smaller ions and accommodate a variety of larger metal ions. In addition, graphdiyne could provide a method of dopant storage that is not available to graphite, namely intrasheet intercalation. In pursuit of graphdiyne, we report here the preparation and characterization of annulenic substructures **2** and **3**.

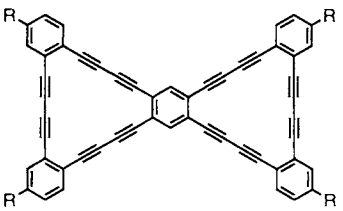
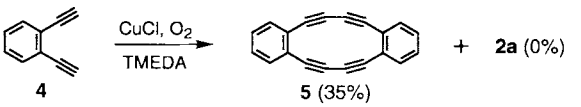
2b, R=*n*Dec



3a, R=*t*Bu
3b, R=*n*Dec

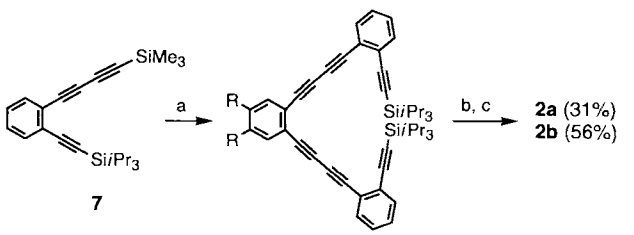
Macrocycle **2a**, the smallest subunit of **1**, has had a long and varied history. Originally claimed in 1957 to be the product of Eglinton–Glaser coupling of 1,2-diethynylbenzene (**4**, Scheme 1),[9] it was shown by chemical means[10] and by X-ray



Scheme 1. Cyclooligomerization of 1,2-diethynylbenzene.

crystallography[11] that strained dimer **5**, not trimer **2a**, was the sole product of the cyclization reaction. Recent work by Swager and co-workers has shown that, even with a different catalytic system, only **5** is produced from **4**.[12] However, it is interesting to note that inclusion of two alkyl or alkoxy groups on **4** did lead to a mixture of dimers, trimers, and tetramers that were difficult to separate.[12] Given these problems, any further attempts to prepare exclusively **2a** warranted a different synthetic route.

An intramolecular oxidative dimerization reaction was envisaged for forming **2a** (Scheme 2). The requisite hexayne **6a** was



Scheme 2. Synthesis of **2a**,**b**. a) 1,2-Diiodobenzene (for **6a**) or 4,5-didecyl-1,2-diiodobenzene (for **6b**), KOH, H_2O, $[Pd(PPh_3)_4]$, $[Pd(PPh_3)_2Cl_2]$, CuI, Et_3N, THF; b) Bu_4NF, EtOH, THF; c) $Cu(OAc)_2 \cdot H_2O$, pyridine, MeOH.

easily constructed in 71% yield from triyne **7**[13] and 1,2-diiodobenzene by an in situ deprotection/alkynylation sequence.[13] Desilylation of **6a** with Bu_4NF followed by dimerization with $Cu(OAc)_2$ in pyridine furnished **2a** as the sole product. The poor solubility of **2a** created difficulties for product manipulation and was no doubt responsible for the low yield of isolated **2a** (about 30–35%). The outcome improved on repetition of the synthesis with 4,5-didecyl-1,2-diiodobenzene[12]: macrocycle **2b** was isolated in 56% yield, which is attributable to the solubilizing effect of the twin decyl groups.

Assembly of bismacrocycle **3** was considerably more involved. From the outset, we recognized the need for including solubilizing substituents. Our initial attempt made use of four *tert*-butyl groups at the corners of the molecule (Scheme 3).

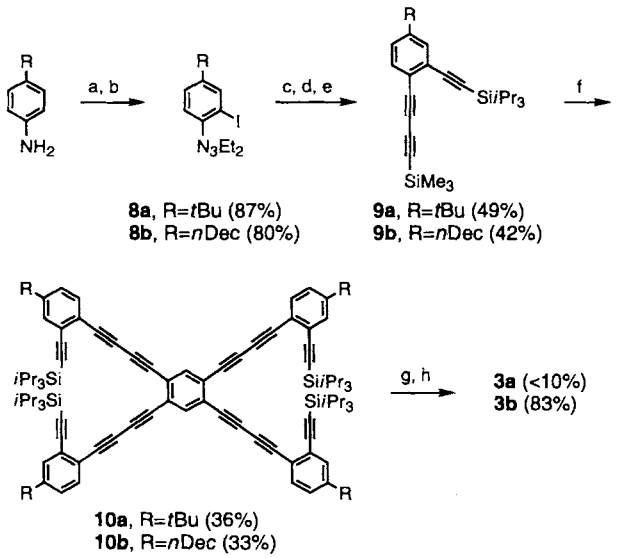

Scheme 3. Synthesis of **3a,b**. a) $(BnNEt_3)ICl_2$, CH_2Cl_2; b) 1. $NaNO_2$, HCl, H_2O, CH_3CN, THF; 2. Et_2NH, K_2CO_3, H_2O; c) *i*$Pr_3SiC{\equiv}CH$, $[Pd(PPh_3)_2Cl_2]$, CuI, Et_3N; d) MeI, 120 °C; e) $Me_3SiC{\equiv}CC{\equiv}CH$, $[Pd(PPh_3)_2Cl_2]$, CuI, Et_3N; f) 1,2,4,5-tetraiodobenzene, KOH, H_2O, $[Pd(PPh_3)_4]$, $[Pd(PPh_3)_2Cl_2]$, CuI, Et_3N, THF; g) Bu_4NF, EtOH, THF; h) $Cu(OAc)_2$, pyridine, MeOH, Et_2O.

Iodination of 4-*tert*-butylaniline with $BnEt_3N^+ICl_2^-$[14] followed by conversion of the amino group into a diethyltriazine moiety[15] gave **8a** in 87% yield. Sequential alkynylation of **8a** with triisopropylsilylacetylene, conversion of the triazene into an iodide with iodomethane at 120 °C,[15] and alkynylation with excess 1-trimethylsilylbuta-1,3-diyne[16] afforded triyne **9a** in 49% overall yield. In the presence of 1,2,4,5-tetraiodobenzene,[17] **9a** reacted by the in situ deprotection/alkynylation sequence[13] to give the tetracoupled product **10a** in 36% yield. Although modest, this yield implies an average conversion of about 90% for each of the eight transformations necessary. Subsequent removal of the four triisopropylsilyl groups was accomplished with Bu_4NF and could be readily followed by TLC. Oxidative intramolecular coupling of the free acetylenes with $Cu(OAc)_2$ led to **3a** in less than 10% yield, since isolation of purified product proved impossible due to extremely limited solubility.

In hope of improving the solubility of the final product, the synthetic sequence was repeated with 4-decylaniline to provide dodecayne **10b** (Scheme 3). Desilylation and oxidative cyclization with anhydrous $Cu(OAc)_2$[18] gave **3b**. Elution of the crude product adsorbed on silica gel with hexanes/CH_2Cl_2 (3/1) removed undesired by-products without desorbing **3b**. Treatment with boiling CH_2Cl_2 followed by carbon disulfide extracted the bismacrocycle into solution. Recrystallization from CH_2Cl_2 afforded an excellent yield of pure **3b** as a bright yellow solid, which was moderately soluble in carbon disulfide, hot dichloromethane, and hot toluene. Only limited solubility was observed in most solvents at room temperature.

All annulenic structures and intermediates were unequivocally identified and characterized spectroscopically (Table 1). Both as pure solids and in solution, the macrocycles proved remarkably robust and remained spectroscopically unchanged over a period of several weeks in air. Onset of decomposition occurred around 200 °C. DSC analysis showed this to be an extremely exothermic process that occurred over a relatively narrow 10–15 °C range. The possibility that this is a topochemical polymerization of the diacetylene moieties[19] is an intriguing prospect that we are pursuing.[20]

Table 1. Selected physical data for **2a**, **3b**, **6a**, and **8b**–**10b**.

2a: M.p. = 210 °C (decomp.); ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.68 (*AA'*, *J* = 7.9 and 1.3 Hz, 6H), 7.42 (*BB'*, *J* = 7.9, 1.3 Hz, 6H); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 132.72, 128.81, 125.29, 80.73, 77.21; UV (CH_2Cl_2): λ_{max} (ε) = 266 (13400), 280 (18900), 309 (42500), 330 (69400), 359 (19000), 369 (21100) nm; IR (CH_2Cl_2): $\tilde{\nu}$ = 3054, 2207 cm^{-1}; MS (EI, 70 eV): *m/z* (%) = 372 (M^+, 100), 371 (8), 370 (26), 368 (11), 91 (24).

It is widely accepted that annelation of arenes provides rigidity and stability to the annulenic core, but weakens the diatropicity of the macrocycle significantly.[21] Trisannelated systems, such as **2**, are believed to no longer reveal global delocalization but only local aromaticity in the benzenoid rings.[21] We believe this generalization is not valid for **2** or **3**, since the diatropic character of the [18]annulene core can be readily discerned from the ^{1}H NMR and electronic absorption spectra. Although all protons are at a remote distance from the central π system, the benzene resonances of the macrocycles show small but distinct downfield shifts ($\Delta\delta$ = 0.2–0.25) relative to their acyclic precursors. For example, the two protons on the central benzene of desilylated **10b** appear as a singlet at δ = 7.70, yet at δ = 7.94 for **3b**.[22] Diederich et al. observed a similar effect in cyclobutenodehydroannulenes **11** and **12**.[23]

The electronic absorption spectrum of **2a** (Figure 1) exhibits the characteristic pattern for this dehydroannulene core. Comparison of the assigned four diagnostic peaks with spectra reported for related annulenes **11**–**16** is presented in Table 2. It is interesting to note that the wavelengths of these peaks in tribenzo derivative **2a**, although slightly blue-shifted, agree within 3–19 nm with the corresponding peaks in the parent system **13**.[24] A bathochromic shift (about 40 nm) is observed for **3b**, which is likely due to cross-conjugation of the two 18 π electron circuits. In all cases, the trend in peak intensities (2 → 1 → 3, 4) is maintained. Based on this strong spectral correlation, we conclude that, contrary to accepted convention, the dehy-

[8] The term graphdiyne comes from the name graphyne [2], which in turn is derived from graphite. Graphyne, the monoacetylenic analogue of **1**, can be viewed as resulting from replacement of one-third of the carbon–carbon bonds in graphite by -C≡C- linkages. It follows that the diacetylenic version be called graphdiyne.

Azuliporphyrin: A Case of Borderline Porphyrinoid Aromaticity**

Timothy D. Lash* and Sun T. Chaney

The idea of replacing one or more pyrrole rings in the porphyrin macrocycle with other cyclic subunits is not new,[2, 3] but has recently been exploited in the production of novel aromatic structures that incorporate benzene (**1**), pyridine (**2**), cycloheptatriene (**3**) or indene moieties (**4**).[1, 3–5] The six-membered

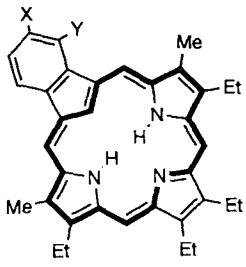
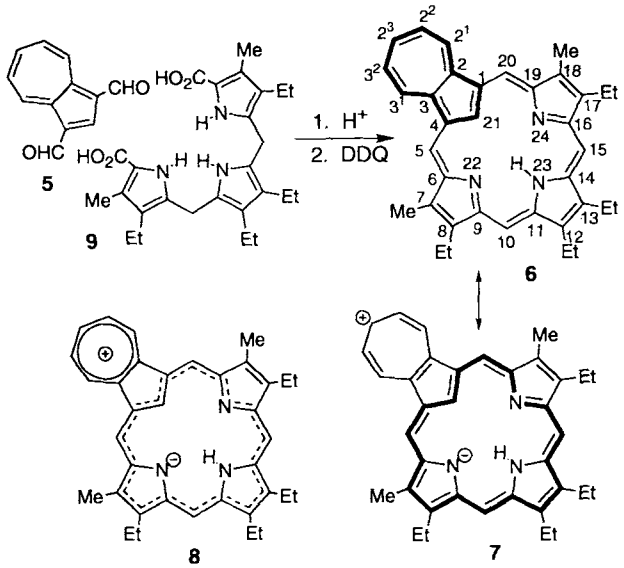
3 tropiporphyrin



4 a. X = Y = H; b. X = CHO, Y = H; c. X = H, Y = CHO

rings in **1** and **2** forfeit the aromaticity of the original arene (or azine) subunit to generate hybrid [18]annulene/porphyrinoid structures. This is aided in these examples by the formation of a carbonyl moiety from the hydroxyaromatic precursor.[3, 4] Tropiporphyrin (**3**)[1, 5] could potentially favor tropylium cation character over porphyrinoid aromaticity, but this is not significant for either the free base or the related monoprotonated species.[1] The presence of a diatropic ring current confirms macrocyclic aromaticity. On the other hand, **3** is relatively unstable, possibly due to angle strain in the unsaturated, seven-membered carbacycle.[1, 5]

We are presently investigating the full potential of this little-explored approach to bridged annulene structures. By exploiting the "3 + 1" methodology,[6] by which porphyrinoid systems are constructed from a tripyrrane and a cyclic dialdehyde, the synthesis of many additional highly conjugated macrocycles can be contemplated. The possibility of introducing an azulene subunit into a porphyrinoid system was appealing, in part due to the accessibility of the required dialdehyde **5**[7] (Scheme 1). In **6**, for which we propose the name "azuliporphyrin", the azulene



Scheme 1. Synthesis of azuliporphyrin **6**.

subunit effectively interrupts conjugative pathways within the macrocycle. However, dipolar resonance contributors (for example **7**) can be imagined, in which the seven-membered ring takes on tropylium-cation character and thereby enables the remaining macrocycle to resemble a carbaporphyrin anion (for example **8**). Hence, tropylium character would promote porphyrinoid aromaticity in **6**, whereas the two options are mutually exclusive in **3**.[1] The dipolar nature of azulene[8] also suggested that this scenario was realistic. While our work was still in the planning stages, a report on the acid-catalyzed condensation of **9** (Scheme 1) with 1,3-azulenedicarboxaldehyde (**5**) appeared.[5] However, this study did not produce the azulene-containing macrocycle **6**; instead, low yields of benzocarbaporphyrins **4a–c** were isolated. Clearly, a ring contraction had occurred during macrocycle formation, although no mechanisms were proposed to explain these observations. We have investigated the acid-catalyzed condensation of **5** and **9** under different conditions and now report the isolation of the new porphyrinoid **6**.

Tripyrrane **9**[9] was treated with trifluoroacetic acid (TFA), diluted with CH_2Cl_2, and allowed to react with **5** under a nitrogen atmosphere for 16 h (Scheme 1). The mixture was neutralized with Et_3N and oxidized with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ). Following workup and chromatography on neutral alumina, a single macrocyclic product was isolated in 28% yield. The product formed bright green solutions in CH_2Cl_2 and appeared to be quite stable.

The ^{1}H NMR spectrum of **6** in $CDCl_3$ showed a weak macrocyclic ring current. The *meso*-protons appeared as two singlets at $\delta = 8$ and 9, and the internal C–H proton gave an upfield resonance near $\delta = 1.5$. These data suggested that azuliporphyrin has borderline porphyrinoid aromaticity; dipolar canonical forms with tropylium character (for example **7**) clearly make important contributions, but do not dominate the spectroscopic properties of this molecule. The UV/Vis spectrum of **6** in CH_2Cl_2 was also consistent with this supposition. It showed a series of moderately strong absorption bands between 350 and 480 nm (Figure 1, dashed line) but lacked the very strong Soret band that is present in species with porphyrin-like aromaticity. The structure of **6** was also supported by FAB-MS.

Addition of trace amounts of TFA resulted in the formation of the corresponding dication **10**. This species displayed a far more pronounced diatropic nature in its ^{1}H NMR spectrum,

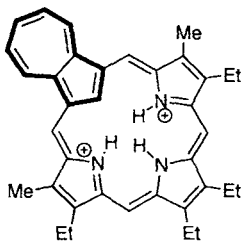
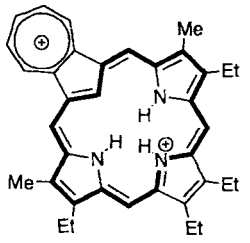
suggesting that the porphyrinoid–tropylium partnership was far more successful under these circumstances. In particular, the *meso*-protons were shifted downfield by $\Delta\delta \approx 1.4$, and the inner methine protons appeared upfield at $\delta = -2.56$. The UV/Vis spectrum of **10** showed two strong Soret bands at 364 and 460 nm and several Q bands between 580 and 800 nm (Figure 1, solid line). This was characteristic for porphyrin-like compounds and confirmed the dominant role of tropylium structure **11** in the diprotonated system. In **10** the increased emphasis on porphyrinoid aromaticity aids in delocalization of the positive charge; for the neutral species dipolar contributors such as **7** are presumably disfavored by the resulting charge separation.



10



11

The excellent yields obtained in the synthesis of porphyrinoids **1**–**3**[1, 3, 4] and **6** demonstrate that our methodology has significant advantages over other procedures. In addition, azuliporphyrin further extends the whole concept of porphyrinoid aromaticity. This new system is likely to exhibit unique chemical properties. However, **6** does not rearrange under the conditions used to prepare carbaporphyrins **4a**–**c** (HBr/CH_3CO_2H in THF/CH_2Cl_2), and the divergent results reported by Berlin et al.[5] must have arisen at an earlier stage in the condensation.

Experimental Section

6: Dicarboxylic acid **9** [9] (100 mg) was stirred with TFA (1 mL) under a nitrogen atmosphere for 10 min. CH_2Cl_2 (19 mL) was added followed immediately by **5** [7] (40.6 mg), and the mixture was stirred under nitrogen for a further 16 h. The mixture was neutralized by the dropwise addition of Et_3N, DDQ (51 mg) was added, and the resulting solution was stirred for an additional 1 h. The mixture was washed with water (200 mL) and purified by chromatography on Grade 3 basic alumina with 5% $MeOH/CHCl_3$ as eluant. A deep green fraction was collected and recrystallized from $CHCl_3$/hexanes to give **6** (32 mg; 28%) as dark blue crystals. M.p. > 300 °C; UV/Vis (1% Et_3N/CH_2Cl_2): λ_{max} ($lg_{10}\varepsilon$) = 354 (4.78), 396 (4.69), 444 (4.70), 472 (4.81), 622 (4.16), 658 nm (4.16); UV/Vis (0.5% TFA/CH_2Cl_2): λ_{max} ($lg_{10}\varepsilon$) = 364 (4.95), 460 (5.08), 592 (3.85), 638 (4.46), 678 (4.17), 734 nm (3.82); ^{1}H NMR (300 MHz, [D$_5$]pyridine): $\delta = 1.59$ (s, 1H, H21), 1.64 (2 overlapping t, 12H, 4 × CH_2CH_3), 3.11 (s, 6H, 2 × porphyrin CH_3), 3.51 (2 overlapping q, 8H, 4 × CH_2CH_3), 7.8–7.9 (m, 3H, H2^2,2^3,3^2), 8.64 (s, 2H, H10,15), 9.55 (s, 2H, H5,20), 9.73 (d, $J = 8.4$ Hz, 2H, H2^1,3^1); ^{1}H NMR (300 MHz, $TFA/CDCl_3$): $\delta = -2.56$ (s, 1H, H21), 1.65 (t, 6H), 1.73 (t, 6H, 4 × CH_2CH_3), 3.44 (s, 6H, 2 × porphyrin CH_3), 3.77–3.87 (2 overlapping q, 8H, 4 × CH_2CH_3), 8.44 (t, 1H, H2^3), 8.56 (t, 2H, H2^2,3^2), 9.42 (s, 2H, H10,15), 9.95 (d, $J = 9.9$ Hz, 2H, H2^1,3^1), 10.32 (s, 2H, H5,20); ^{13}C NMR ($TFA/CDCl_3$): $\delta = 11.52$, 16.06, 16.94, 19.60, 95.20, 110.25, 124.95, 128.13, 140.33, 141.97, 142.06, 142.19, 142.39, 144.49, 144.76, 146.18, 147.50, 154.11; HR-MS (FAB): *m/z* calcd for $C_{36}H_{37}N_3 + H$: 512.3066; found: 512.3072; elemental analysis calcd for $C_{36}H_{37}N_3 \cdot H_2O$: C 81.62, H 7.42, N 7.93; found C 81.23, H 7.36, N 7.86.

Carbaporphyrins**

Timothy D. Lash* and Michael J. Hayes

The "3 + 1" approach to porphyrinoid systems,[2] although little used until two years ago,[3] has recently been exploited in the synthesis of novel aromatic structures that combine elements of porphyrin and bridged annulene systems.[1, 4–8] In particular, tripyrranes (for example **1**) condense with various dialdehydes to give a series of remarkable, new macrocycles, many of which possess 18-π-electron delocalization pathways and exhibit powerful diamagnetic ring currents in their ^{1}H NMR spectra. We have reported the preparation of novel aromatic porphyrinoids with benzene,[4] pyridine,[5] cycloheptatriene,[6, 7] or azulene rings[1] in place of one of the pyrrole subunits. We now present the direct synthesis of indenylporphyrinoid **2**, which can be considered as a member of the newly discovered family of carbaporphyrins,[8] and comment on some flaws in earlier reports[7, 8] of these systems.

Carbaporphyrins, porphyrin analogues in which one or more of the pyrrole units have been replaced by cyclopentadienyl moieties, have been the subject of theoretical speculation for

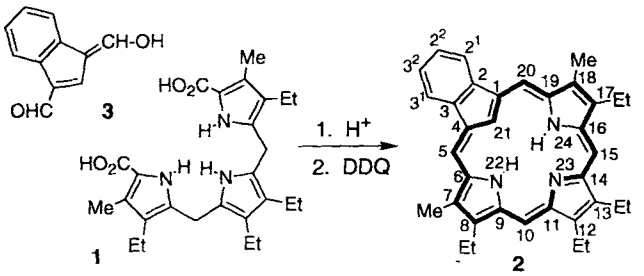
[**] Conjugated Macrocycles Related to the Porphyrins, Part 9. This work was supported by the Donors of the Petroleum Research Fund (administered by the American Chemical Society) and the U. S. National Science Foundation (grant no. CHE-9500630). Part 8: ref. [1].

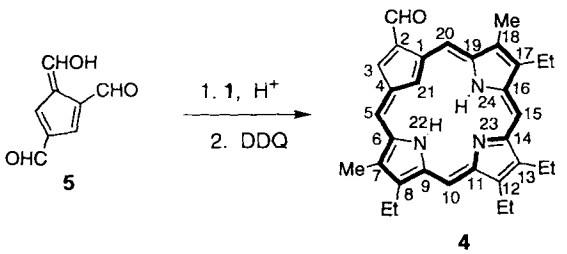
many years,[9] but the first examples of these unusual, bridged annulenes have only very recently been reported.[7, 8, 10] Berlin et al. isolated low yields of benzocarbaporphyrins (such as **2**) from the acid-catalyzed condensation of 1,3-azulenedicarboxaldehyde with **1**.[7] The mechanism of the ring-contraction step remains obscure. We speculated that **2** might be obtained more efficiently from the reaction of 1,3-indenedicarboxaldehyde **3** with **1**. Dialdehyde **3** is easily prepared by a three-step procedure[11] from commercially available indene and exists as the enol tautomer (Scheme 1). The "3+1" condensation of **3**



Scheme 1. Synthesis of benzocarbaporphyrin **2**.

with **1** in 5% TFA/CH_2Cl_2 (TFA = trifluoroacetic acid), followed by neutralization with Et_3N and dehydrogenation with one equivalent of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ), afforded **2** in 43% yield. Workup was straightforward, and the product crystallized from $CHCl_3$/MeOH as fluffy, deep copper/bronze-colored needles. This approach makes **2** easily accessible and will facilitate the detailed investigation of the chemical and spectroscopic properties of this exciting new porphyrinoid family.

While this work was nearing completion, a communication by Berlin[8] on the synthesis of formylcarbaporphyrin **4** from diformylhydroxyfulvene **5**[12] appeared (Scheme 2); the yield re-



Scheme 2. Synthesis of formylcarbaporphyrin **4**.

ported was again very low (7.6%). The author claimed that **2**, **4**, and a related methyl-substituted porphyrin exist in solution as a mixture of conformers or tautomers that fail to interconvert on the NMR timescale, even at elevated temperatures. We were somewhat skeptical about this report, as these observations were inconsistent with our results for **2** or related macrocycles such as oxybenziporphyrin.[3, 13] The ^{1}H NMR spectra for our samples of **2** in $CDCl_3$ at room temperature were in accord with the proposed structure: The internal C–H protons appeared upfield close to $\delta = -7$, and the bridging methine protons were observed as two 2H singlets near $\delta = 10$. The precise values for these resonances varied somewhat with concentration (the *meso*- and internal CH protons were shifted upfield at higher concentrations), possibly due to varying degrees of aggregation in solution. The observed ^{1}H NMR resonances were consistent with a symmetrical structure, and no additional signals could be discerned, even at 500 MHz (Figure 1A). The ^{13}C NMR spectrum also confirmed that this structure has a plane of symmetry.

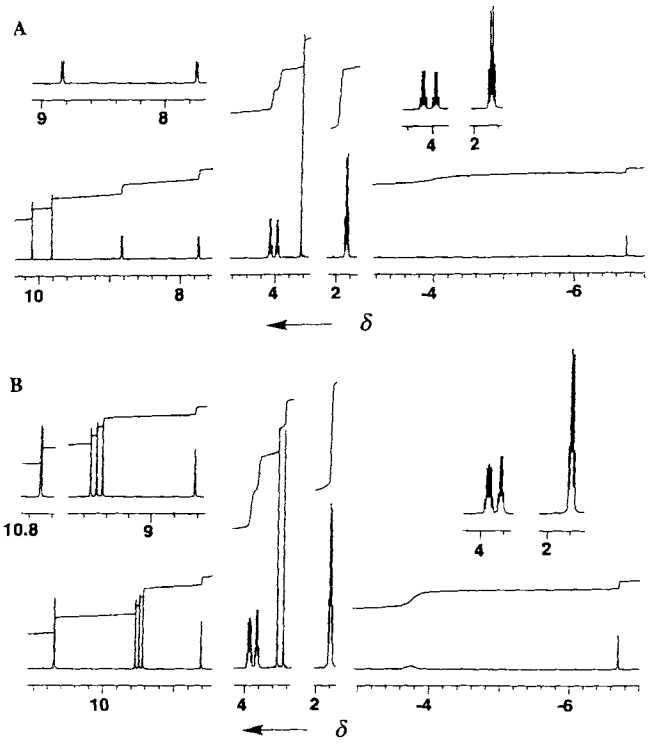


Figure. 1. A. 500 MHz ^{1}H NMR spectrum of benzocarbaporphyrin **2** in $CDCl_3$. B. 500 MHz ^{1}H NMR spectrum of formylcarbaporphyrin **4** in $CDCl_3$. Comparison of these data to Figure 1 in ref. [8] provides a telling contrast.

EI-MS at 70 eV showed the expected molecular ion at $m/z = 499$ with very little fragmentation, although a strong (17% relative abundance) doubly charged ion (M^{2+}) was observed. The UV/Vis spectrum for **2** was porphyrin-like and exhibited a strong Soret band near 420 nm. The UV/Vis absorption maxima reported by Berlin and Breitmaier for the free base[7] were in good agreement with our values, but their recorded molar extinction coefficients were less than 50% of the values determined for our samples.

Addition of trace amounts of TFA induced significant changes in the UV/Vis spectra of **2**, possibly due to the formation of the related monocation **6**. At a higher concentration of acid (>30% TFA), a new species was formed that showed an intense Soret band at 426 nm. C-protonation of **6** might lead to dications such as **7**; internal protonation in **7** would allow the system to retain macrocyclic aromaticity by altering the pathway(s) for 18 π delocalization, thus relieving some of the steric crowding in the macrocyclic cavity. Several species ap-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3608-0841 $ 17.50+.50/0

pear to be generated at intermediate acidities; this phenomenon requires further investigation.

Given the controversial nature of our findings, we decided to prepare **4** under our conditions (Scheme 2). Only modest yields (7.7%) were obtainable, but this reaction is no doubt complicated by the presence of the third aldehyde grouping. ^{1}H NMR data again only showed the presence of the expected resonances; the extra peaks noted by Berlin et al. were absent, even for spectra recorded at 500 MHz (Figure 1B). The UV/Vis spectrum[14] for the free base gave much higher molar absorptivity values than reported (the Soret band at 434 nm gave $\varepsilon = 87\,600$; $\varepsilon < 40\,000$ was reported by Berlin[8]), which is in accord with our expectations for a porphyrin analog of this type. It is also worth noting that our samples were obtained as deep purple microneedles and not as the dark green/brown solid previously isolated.[8]

Our new findings demonstrate that no unusual conformational or tautomeric processes are occurring for carbaporphyrins **2** or **4**. The anomalous spectroscopic data reported by Berlin et al.[7, 8] are most likely due to impurities arising from the less favorable reaction conditions used in their studies.[15, 16]

Experimental Procedure

2: Dicarboxylic acid **1** [17] (100 mg) was stirred with TFA (1 mL) under an atmosphere of nitrogen for 10 min. CH_2Cl_2 (19 mL) was added followed immediately by 1,3-diformylindene (38 mg), and the mixture stirred for a further 2 h. The mixture was neutralized by the dropwise addition of Et_3N, DDQ (50 mg) added, and the resulting solution stirred for an additional 1 h. The mixture was washed with water and purified by chromatography on neutral Grade 3 alumina with CH_2Cl_2 as eluant, and a dark brown fraction was collected. Repeated chromatography on a silica column with CH_2Cl_2 as eluant gave the product as a broad, brown band. Recrystallization from $CHCl_3$/MeOH afforded **2** (47 mg, 43%) as fluffy copper/bronze-colored crystals. M.p. = 270 °C (decomp.); UV/Vis (1% Et_3N/CH_2Cl_2): λ_{max} ($lg_{10}\varepsilon$) = 306 (4.32), 376 (4.62), 424 (5.21), 510 (4.25), 544 (4.17), 602 (3.70), 662 nm (3.25); UV/Vis (50% TFA/CH_2Cl_2): λ_{max} ($lg_{10}\varepsilon$) = 348 (4.60), 426 (5.15), 462 (4.47), 614 (3.85), 670 nm (4.31); ^{1}H NMR (500 MHz, $CDCl_3$): $\delta = -6.74$ (s, 1H, H21), -4.0 (v br, 2H, 2×NH), 1.85 (t, 6H), 1.87 (t, 6H, 4×CH_2CH_3), 3.64 (s, 6H, 2×porphyrin CH_3), 3.97 (q, 4H), 4.07 (q, 4H, 4×CH_2CH_3), 7.74 (m, 2H, H2^2,3^2), 8.83 (m, 2H, H2^1,3^1), 9.82 (s, 2H, H10,15), 10.10 (s, 2H, H5,20); ^{13}C NMR (75.46 MHz, $CDCl_3$): δ = 11.44, 17.40, 18.58, 19.65, 20.05, 95.50, 98.76, 109.68, 120.65, 126.64, 132.50, 133.90, 135.59, 137.83, 141.65, 144.49, 152.87; HR-MS (EI) *m/z* calcd for $C_{35}H_{37}N_3$: 499.29795; found: 499.29875; elemental analysis calcd for $C_{35}H_{37}N_3 \cdot 0.25H_2O$: calcd C 83.38, H 7.49, N 8.33; found C 83.31, H 7.29, N 8.19.

Nonenzymatic Oligomerization of Ribonucleotides on Guanosine-Rich Templates: Suppression of the Self-Pairing of Guanosine**

Markus Kurz, Karin Göbel, Christian Hartel, and Michael W. Göbel*

Dedicated to Professor Gerhard Quinkert on the occasion of his 70th birthday

The occurrence of information-carrying molecules capable of propagation and evolutionary development through self-replication, is often seen as a prerequisite for the origin of life.[1] Could RNA have played such an important role? Several results support this idea. Research carried out primarily by Orgel et al.[2a–d] has shown that the oligomerization of 2-methylimidazolides of nucleoside 5′-monophosphates on complementary oligonucleotide templates can proceed with astonishing efficiency.[2, 3] This process, which functions without the help of enzymes, is directed by Watson–Crick base-pairing and by base-stacking. Nevertheless, the occurrence of self-replication[4, 5] is blocked by serious obstacles: The most important of these is perhaps the tendency of guanosine-rich strands to tetramerize. This process renders them incapable of serving as templates for the synthesis of oligocytidine units. The second phase of the replication is thus blocked.[6] This problem can be circumvented by the modification of the nucleic acid structure;[7, 8] for RNA itself, however, the aggregation of guanosine-rich strands has only been avoided so far by the use of extremely high dilution.[2b]

Recently we reported the synthesis of an acridine dye that can be coupled to nucleic acids by standard methods and that has high chemical stability as an advantageous characteristic.[9] We have now developed a system for the investigation of template-directed synthesis of RNA oligomers, which is based on the extension of acridine-labeled primers. This method offers great flexibility in the experimental setup and allows the equally rapid and precise investigation of the kinetics through the use of high-pressure liquid chromatography (HPLC); as we could demonstrate by this technique, the aggregation of guanosine units can

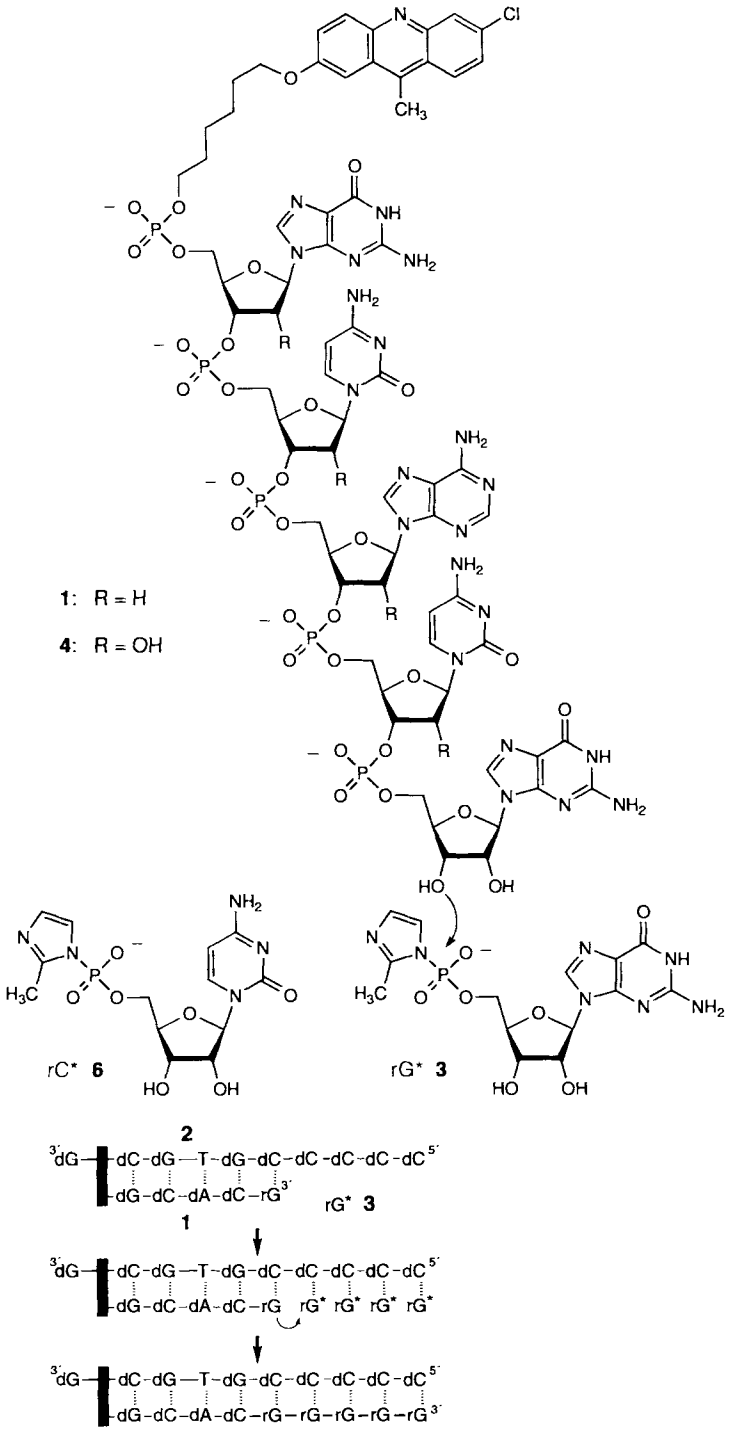
be reduced to a minimum by optimization of the reaction conditions.

Our first experiments were carried out with primer **1**, which consists of a 3′-terminal *ribo*-guanosine and deoxyribonucleotides (Scheme 1 top). Primer **1** forms a stable double helix with the DNA template **2**, whose melting point is approximately 15 K higher than that of the corresponding acridine-free double helix (Table 1). The single-stranded portion of the complex **1**·**2** serves as the template, which can associate with up to four



Scheme 1. Top: Formulas of the acridine-labeled primers **1** and **4** and the imidazolides **3** and **6**, which were used for chain extension. Bottom: Extension of the DNA primer **1** on the template **2** by four guanosine units. The black rectangle denotes the intercalator.

Table 1. Thermal stability of the oligonucleotide duplexes tested here.

Primer P	c(P) [μM]	c(**2**) [μM]	T_m [°C]	Conditons [a]
1	30	50	50.2	a
1	1.2	2	31.3	a

d(GCACG)	1.2	2	18.8	a
1	0.8	0.8	19.8	b
4	0.8	0.8	19.8	b

[a] a: 0.25 M TRIS·HCl, pH = 7.65. b: 10 mM phosphate, pH = 7.0, 70 mM NaCl; detection in each case at 260 nm.

complementary guanosine units **3** (Scheme 1 bottom). The chain extension takes place within the double-helical aggregate **1**·**2**·(**3**)$_n$. This process can be easily analyzed by reversed-phase HPLC. While retention times of the usual mono- and oligonucleotides are short, **1** is strongly retained due to its lipophilic dye component. Chain-extension products of **1** have shorter retention times with increasing polarity. Fluorescence detection leads to a further improvement in the detection limit, as shown by the typical chromatogram in Figure 1a, b. More than 50% of the primer is converted in only 5 h.[10] The rate of each extension step can be determined from the integral of the peak (Figure 1c, Table 2). It turned out that the last step is as much as 10 to 20 times slower than the two preceding steps. This effect, which has been observed previously, can be explained by the weak stacking interactions of the last incorporated mononucleotide.[2a] Surprisingly, also the first step of the extension of **1** is approximately five times slower than the second.

Experiments with the primer **4** have contributed to the understanding of this effect. Primer **4** has an identical sequence to **1**, with the exception that it consists entirely of ribonucleotides. When **4**, as a complex with the template strand **2**, is chain-extended by the guanosine unit **3**, the first and second extensions proceed with similarly high rates (Figure 2, Table 2). A comparison of the CD spectra of the primer–template duplexes **1**·**2** and **4**·**2** helps to explain the difference: Despite identical sequences, the spectra deviate from one another dramatically (Figure 3). Therefore the duplex conformations must be different. While the spectrum of **1**·**2** closely resembles that of a B-helix, the spectrum of **4**·**2** is characteristic for the A-form.[11] This makes the difference in reaction kinetics understandable: The oligomerization of RNA proceeds optimally only when the primer–template duplex corresponds to the A-form. Since **1**·**2** is formed completely from DNA components, it prefers the B-conformation. The first step is therefore slow. DNA–RNA hybrids, on the other hand, are fixed in the A-form. When the first bond is formed between ribonucleotides, the conformation type of the primer–template duplex alters, with the consequence that the further coupling steps (with the exception of the last) proceed more rapidly. The duplex **4**·**2** adopts the A-form from the beginning. It therefore displays its full reactivity even in the first step. As a consequence, the overall yield of chain-extended strands rises on changing to the RNA primer **4**, from around 85 to approximately 99% (of which 90% are fully extended). This is of major importance when problematic nucleotides are going to be incorporated.

A chain extension of the primers **1** and **4** can be achieved only when the template **2**, the activated building block **3**, and Mg^{2+} ions are present. The concentration of Na^+ is, on the contrary, insignificant: Oligomerization experiments carried out with **1**, **2**, and **3** displayed no significant difference in rate in a concentration range from 0.05 to 0.85 M (Table 3). This is important, since Na^+ induces the formation of guanosine tetrads. Self-associa-

spectra are associated with the formation of parallel quadruple strands.[12]

With the complexed primers **1** and **4**, the single-stranded portion of template **5** should induce the incorporation of the activated cytidine derivative **6** (Scheme 2). The choice of reaction conditions, that is the use of either a DNA or a RNA primer and the use of high or low alkali metal ion concentrations, has a major influence on the outcome of the experiments (Table 4). In

Table 4. Extension of the primer (P) **1** and **4** on the guanosine-rich template **5** (incorporation of the cytidine building block **6** from P + 1 up to P + 4). In each case the product distribution is given for a typical experiment.

[a] Approximately 87% after five days.

accord with earlier results,[1,2] the extension of DNA primer **1** in 1 M NaCl solution proceeds sluggishly. Lowering the Na^+ concentration to 50 mM leads to a strong rate enhancement. The reactivity of the RNA primer **4** is also reduced by certain alkali metal ions: very strongly by K^+, strongly by Na^+, and hardly at all by Li^+ (1 M in each case, Table 4). This effect correlates with the ability of these ions to induce aggregation of the guanosine-rich template **5**. When high concentrations of Na^+ and K^+ ions are avoided, the primer **4** in the system **4**·**5** does not react more slowly with cytidine than does, for example, the primer **1** in the system **1**·**2** with guanosine.

According to the results described here, the obstacle to replication, caused by self-association of guanosine is not an intrinsic property of RNA! It appears in fact to be predominantly associated with the high concentrations (more than 1 M) of Na^+ ions that have been employed. Under optimized conditions the self-aggregation of short guanosine sequences can be easily avoided even at template concentrations of 100 μM. We see, thus, much better chances for the self-replication of RNA through the use of imidazole-activated mononucleotides than has been thought possible for a long time.

Experimental Section

Oligomerization experiments: Into a 1.5-mL polyethylene tube were pipetted the following three solutions: buffer, primer **1** or **4**, template **2** or **5**. After equilibration for 15 min at room temperature, they were cooled to 10 °C. Finally, a freshly prepared solution of **3** or **6** was added, the solutions mixed, the tube sealed, and then maintained at (10 ± 0.2) °C. The final concentrations were: 30 μM primer, 100 μM template, 50 mM imidazolide, 250 mM buffer (TRIS·HCl, pH = 7.7, Na^+-free or 1 M in KCl, NaCl or LiCl; or HEPES, pH = 7.7, 1 M NaCl), 200 mM Mg^{2+}.

HPLC analysis: The reaction mixture (3 μL) was diluted with 8 M aqueous urea solution (10 μL), heated to 90 °C for 1–2 min and then, after cooling, injected onto the column. Separation conditions: Column Merck LiChrospher 100 RP-18 endcapped, 5 μm, 125 × 4 mm. Linear gradient from 5 to 36% A in B in 22 min, 1 mL min^{-1}, A: 50 mM triethylammonium acetate, H_2O, pH = 6.5/acetonitrile 40/60, B: 50 mM triethylammonium acetate, H_2O, pH = 6.5/acetonitrile 90/10. UV detection at 260 nm; fluorescence: λ_{ex} = 355, λ_{em} = 450 nm. The extinction coefficients of the products, which increase with the chain length, were corrected by the use of empirical factors when the UV peak was integrated.

Chemical Selection and Self-Assembly in a Cyclization Reaction**

Dmitry M. Rudkevich and Julius Rebek, Jr.*

Dedicated to Professor Dieter Seebach on the occasion of his 60th birthday

New chemical behaviors frequently emerge at the interface between noncovalently bound molecules, and self-assembly is one means of uncovering such phenomena.[1] For example, reversible encapsulation of small molecules can be observed in hydrogen-bonded, self-complementary dimers; the encapsulation process is governed by unusual thermodynamic parameters.[2] Here we present evidence that even the synthesis of these capsules can involve molecular recognition.

The system consists of a cyclization reaction on a template, but differs from the many such reactions of, say, crown ether or catenane chemistry[3] in that the product is a replica of the template. However, in contrast to the previously published self-replicating systems,[4] hydrogen bonds here provide the molecular recognition elements not between the reactants and the product (template), but rather with an intermediate. Moreover, a unimolecular, rather than a bimolecular reaction is the likely object of the selection process in the case at hand (Figure 1).

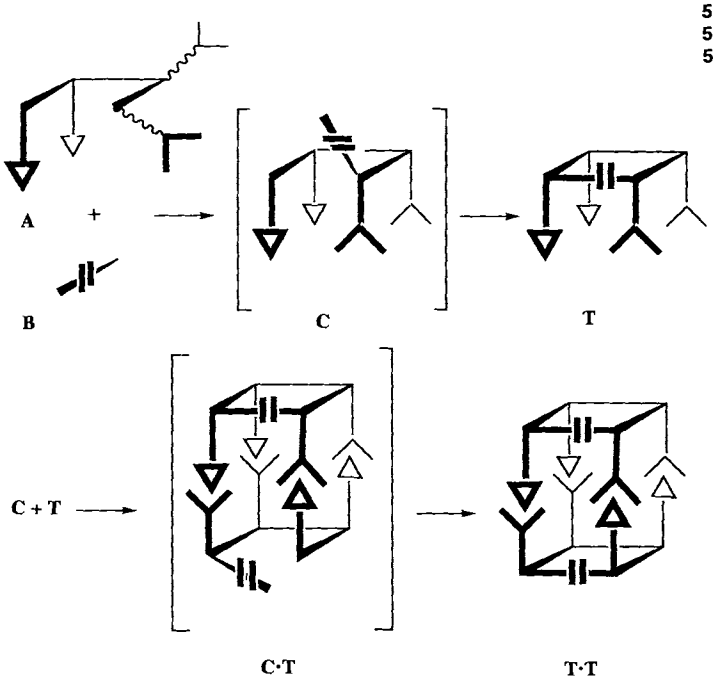

Figure 1. Schematic representation of template production.

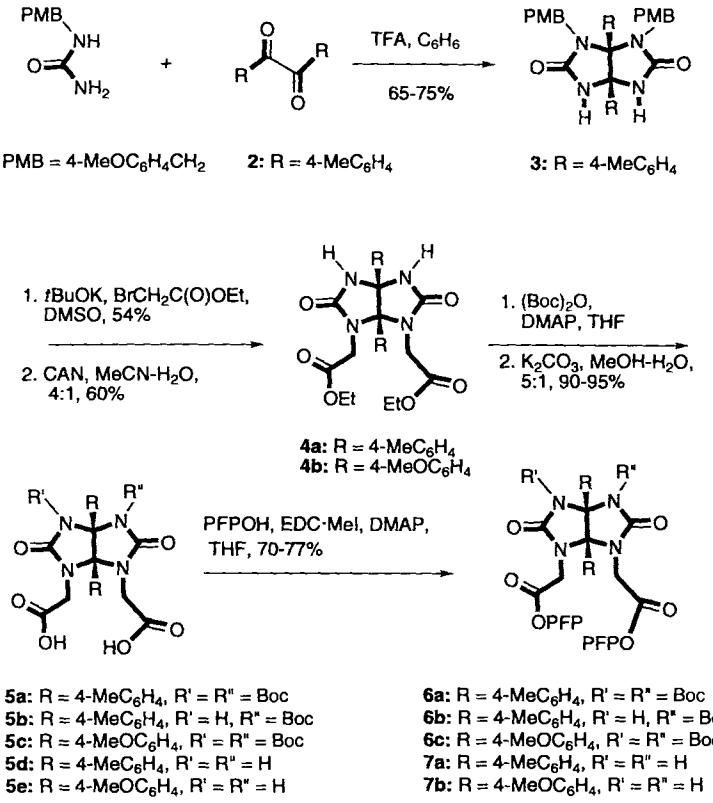
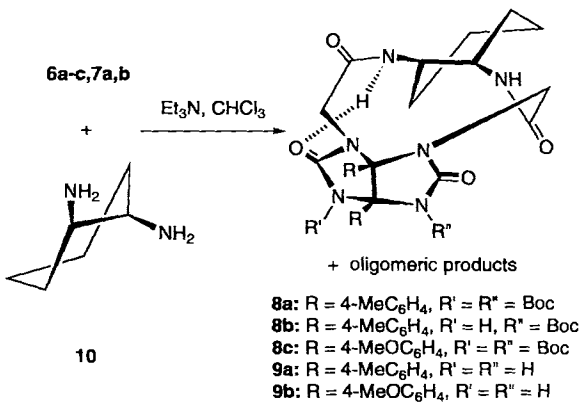
Suitable compounds were prepared by condensation of unsymmetrical *p*-methoxybenzylurea **1** with diketone **2** to give the protected glycoluril **3** in good yield (Scheme 1).[5] Compound **3** was alkylated with ethyl bromoacetate and deprotected with cerium(IV) ammonium nitrate (CAN) to give the corresponding glycoluril **4a**. Diesters **4a,b** were protected with $(Boc)_2O$ and then saponified with K_2CO_3 to give diacids **5a–c**. The *tert*-butoxycarbonyl (Boc) protecting groups were then removed with trifluoroacetic acid (TFA) in CH_2Cl_2 to afford glycolurils **5d,e**. Diacids **5a–e** were subsequently activated with 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide (EDC)·MeI and pentafluorophenol to give the pentafluorophenyl (PFP) esters **6a–c** and **7a,b**.



Scheme 1. Synthesis of **6a–c** and **7a,b**.

The cyclization of diesters **7a,b** with *trans*-1,2-diaminocyclohexane **10** was carried out under conditions of not particularly high dilution (2.0×10^{-2}–1.0×10^{-1} M) in the presence of Et_3N (5 equiv, Scheme 2). The new substances **9a,b** that result showed all of the spectroscopic features of self-assembled dimeric structures (see Scheme 3):[6] 1) The signals in ^1H NMR spectra are sharp in $CDCl_3$ or $CDCl_3$/[D_8]toluene mixtures. 2) The



Scheme 2. Cyclization of **6a–c** and **7a,b** with **10**.

Markey Charitable Trust & The NIH Shared Instrumental grant 1 S10 RR07273-01 for the ESI-MS facilities. We also acknowledge Dr. T. S. Szabo for the preliminary experiments on preparation of unsymmetrically substituted glycolurils.

chemical shifts were concentration independent, which is consistent with a high dimerization constant ($K_D > 10^5\ M^{-1}$) in these solvents. 3) The chemical shifts of the glycoluril N-H resonances were observed far downfield at $\delta = 8.12$, 7.09 for **9a** and $\delta = 8.25$, 7.15 for **9b**. In contrast, model glycolurils **3**, **4a**,**b**, **6b**, and **7a**,**b** all showed concentration-dependent chemical shifts for the glycoluril N-H resonances, which appear—even at the high concentration of 1.0×10^{-1} M—below $\delta = 6.50$. This is typical of weak, nonspecific aggregation. 4) Compound **8b**, which incorporates the eleven-membered ring but with one of the glycoluril N-H sites protected, shows no tendency toward dimerization: the remaining glycoluril N-H resonance appears below $\delta = 6.20$. 5) The positive-ion FAB-mass spectra of the compounds **9a** and **9b** (with *m*-nitrobenzyl alcohol as a matrix) show—in addition to the molecular ion peaks at 517 and 549, respectively,—quite intense (ca. 20–25%) peaks for the dimers at 1032 and 1096, respectively. The ESI-MS spectra of the compounds **9a** and **9b** in CH_2Cl_2 and $CHCl_3$ featured the corresponding dimeric structures as the most intense peaks, along with peaks for the monomeric species. Taken together, these characteristics indicate a dimeric stucture for **9a** and **9b** in $CHCl_3$ that is maintained by four intermolecular hydrogen bonds. An energy-minimized (MM2)[7] structure proposed for the dimer **9a** is shown in Figure 2; it is C_2 symmetric and resembles a partially opened capsule.[8]

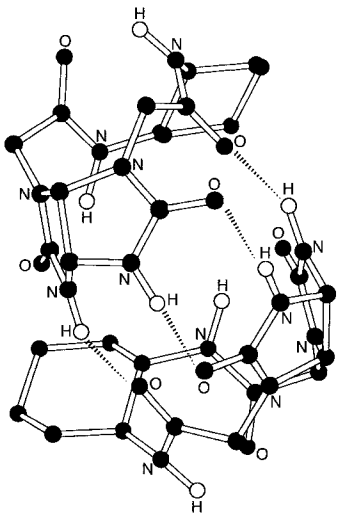

Figure 2. Energy-minimized (MM2) structure of the self-assembled dimer of **9a**. The aromatic fragments and some hydrogen atoms are omitted for clarity.

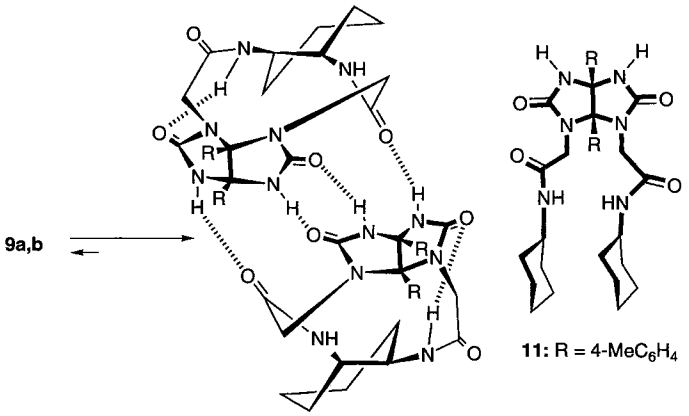
In addition, another N-H signal appeared in the ^{1}H NMR spectra of **9a**,**b** at $\delta = 7.90$ (d, $^3J(H,H) = 9$ Hz), which is attributed to an intramolecularly hydrogen-bonded amide. This arises through the conformational restrictions of the eleven-membered ring in **9a**,**b** that hold the hydrogen atom of one amide in contact with a glycoluril carbonyl oxygen atom six atoms away (Scheme 3). The same conformational restrictions also present the carbonyl of the other amide to the glycoluril N-H group of a second molecule for intermolecular hydrogen bonding. For comparison, the bis(cyclohexylamido)glycoluril **11** (Scheme 3) was prepared. The amide N-H proton signals of **11** appear at $\delta = 6.20$–6.00; this indicates that these hydrogen atoms are not involved in intramolecular hydrogen bonding.[9]

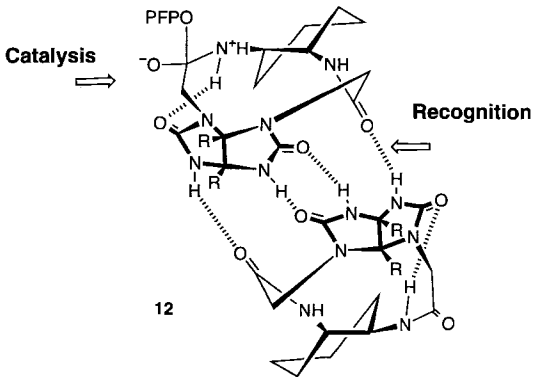
The coupling reaction with diamine **10** in $CHCl_3$ takes place within a few minutes and leads to surprisingly high yields for such a cyclizations (50–55%), even in quite concentrated solutions (5.0×10^{-2}–1.0×10^{-1} M).[10, 11] In contrast, when the glycoluril N-H protons are protected with two and one Boc-fragments (PFP esters **6a** and **6b**, respectively), a variety of products was observed in which the corresponding cyclic structures **8a** and **8b** were minor components; their yields did not exceed 15-20%, and FAB-MS or ESI-MS spectra showed the presence of the entire series of oligomeric macrocycles among the products, up to a [6 + 6] stoichiometry of **6** and **10**.[11] A direct competition experiment using a 1:1 mixture of PFP esters



Scheme 3. Dimerization of **9a**,**b**, and formula of **11**, which was synthesized for comparison.

7a and **6b** with a limited amount of **10** in chloroform (5.0×10^{-2} M) led to the ratio of **9a**:**8b** of >3:1; a significant amount of PFP ester **6b** remained unconverted. Accordingly, recognition processes play a role in the synthesis of **9a** and **9b**.

The increase in yield that accompanies the increase in hydrogen bonding available to **9a** and **9b** implies a moderate but reproducible *chemical selection*, which may be attributed to a template effect. The reaction product recognizes the intermediate by intermolecular hydrogen bonding to the initially formed amide within complex **12** (Scheme 4). This restricts



Scheme 4. Region in complex **12** in which catalysis and recognition occurs.

internal rotations and helps position the remaining amino group for the cyclization transition state. The exact details of how the reaction is channeled to products **9a**,**b** remain to be elucidated, but one possibility involves the internal glycoluril carbonyl group. This function is well-placed to offer catalysis for the breakdown of the tetrahedral intermediate leading to the cyclic product.[12]

Whether or not true autocatalysis occurs in this system must await detailed kinetic studies of the product-determining step. Earlier experiments on unnatural selection and nonenzymatic self-replication in chemical systems, including nucleotides[4, 13] and peptides,[14] have led to the suggestion that at least two reactants must be recognized by the reaction product for replication.[15] The present results, in which even unimolecular reactions can show product selection based on molecular recogni-

tion, implies that a broader range of possibilities may exist for self-replicating systems.

[8] The host–guest chemistry of the dimeric structures **9a,b**, and related *chiral* assemblies will be reported elsewhere.

[9] This intramolecular hydrogen bonding is not essential for the assembly; strong dimerization was also observed for the corresponding N_{amide}-methylated eleven-membered glycolurils.

[10] In a typical experiment, the solution of *trans*-1,2-diaminocyclohexane (1 equiv) and Et_3N (5 equiv) in dry $CHCl_3$ (5.0×10^{-2} or 1.0×10^{-1} M) was added to the corresponding pentafluorophenyl diester (1 equiv), and the homogenous mixture was stirred at 20 °C for 1 h. The reaction was quenched with 5% HCl_{aq}. The organic layer was separated, washed with water, dried over Na_2SO_4, and evaporated. In case of Boc-diprotected compounds, deprotection with TFA in CH_2Cl_2 was subsequently carried out. The crude residue was analyzed by ^{1}H NMR spectroscopy in $CDCl_3$ and [D$_6$]DMSO. The singlets for glycoluril N–H protons and for methyl protons of the aromatic fragments as well as the doublet for the methylene protons of the acetamide group were employed for integration; the estimated error is 10%. The crude mixture was then separated by preparative TLC (silica gel, ethyl acetate as an eluent). The products were analyzed by NMR spectroscopy and FAB- and ESI-MS spectrometry. All the runs were repreated at least twice.

[11] Our yields are higher than theoretically predicted for macrocyclization under kinetic control, see: A. D. Cort, G. Ercolani, A. L. Iamiceli, L. Mandolini, P. Mencarelli, *J. Am. Chem. Soc.* **1994**, *116*, 7081–7087. For the related syntheses of cyclic polyamides, although at much lower concentrations see: a) L. Cazaux, M.-C. Duriez, C. Picard, P. Tisnes, *Tetrahedron Lett.* **1989**, *30*, 1369–1372. The yield of the corresponding [1 + 1] dilactam was 20% at 1.0×10^{-2} M; b) M. Yamaguchi, H. Okubo, M. Hirama, *Chem. Commun.* **1996**, 1771–1772. The yield of the [1 + 1] dianilide was 29%, however, under high dilution conditions (2.0×10^{-3} M); c) F. J. Carver, C. A. Hunter, R. J. Shannon, *ibid.* **1994**, 1277–1280. The yield of the corresponding [1 + 1] diamides varied between 15 and 37% under high dilution conditions (less than 1.0×10^{-3} M) when the reactants were mixed over 24 h. However, when intramolecular hydrogen bonding was employed, the yields increased up to 88%.

Self-Assembly and Subsequent Self-Organization of a Semiconductor Nanocrystallite Superlattice**

Lucy Cusack, Rosalba Rizza, Alexander Gorelov, and Donald Fitzmaurice*

Dedicated to Professor David A. Brown on the occasion of his 65th birthday

The self-assembly and self-assembly of nanocrystallites and molecules to form complex nanostructures in solution is an important objective of materials chemistry and physics.[1] Its importance results from a desire to "program" the "bottom-up" assembly of nanometer-scale devices in solution. An important interim goal in this research is the self-assembly and self-organization of nanocrystallite arrays or superlattices in solution,[2–4] which is far less advanced than the self-assembly and self-organization of molecules in solution.[5] Here we describe the recognition-directed self-assembly and self-organization of a superlattice of TiO_2 nanocrystallites in solution by using an approach that offers the prospect of wide applicability.

The self-assembly of complexes containing a nanocrystallite and a molecule is known.[6, 7] In these complexes, which are referred to as heterosupermolecules, the intrinsic properties of the nanocrystallite and the molecule persist and there exists an associated heterosupramolecular function. For instance, the associated function for the heterosupermolecule TiO_2-(**I** + **II**) is light-induced electron transfer (Scheme 1).[7] To self-assemble TiO_2-(**I** + **II**), a colloidal dispersion of TiO_2 nanocrystallites is prepared in the presence of the stabilizer **I** (TiO_2-**I**).[8, 9] The viologen **II** is then added to this dispersion, and is recognized and selectively bound by TiO_2-**I** to form TiO_2-(**I** + **II**).[7]

In light of the above, it was expected that two appropriately modified nanocrystallites would recognize and selectively bind each other (Scheme 2). Specifically, TiO_2-**I** should recognize and selectively bind TiO_2-**III** (a colloidal dispersion of TiO_2 nanocrystallites prepared in the presence of the stabilizer **III**). Furthermore, under appropriate conditions, these heterosupermolecules are expected to self-organize to form a superlattice.

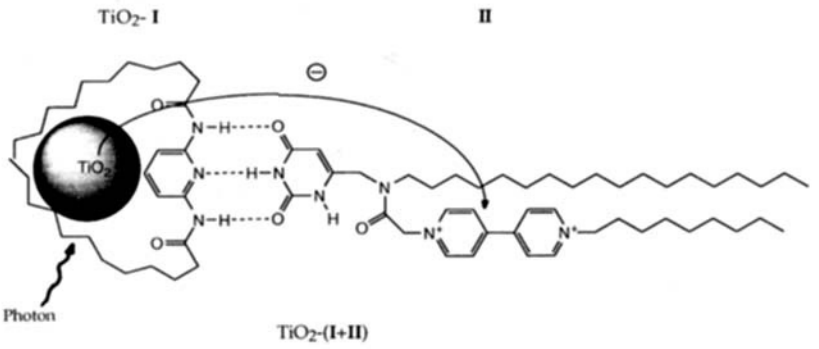
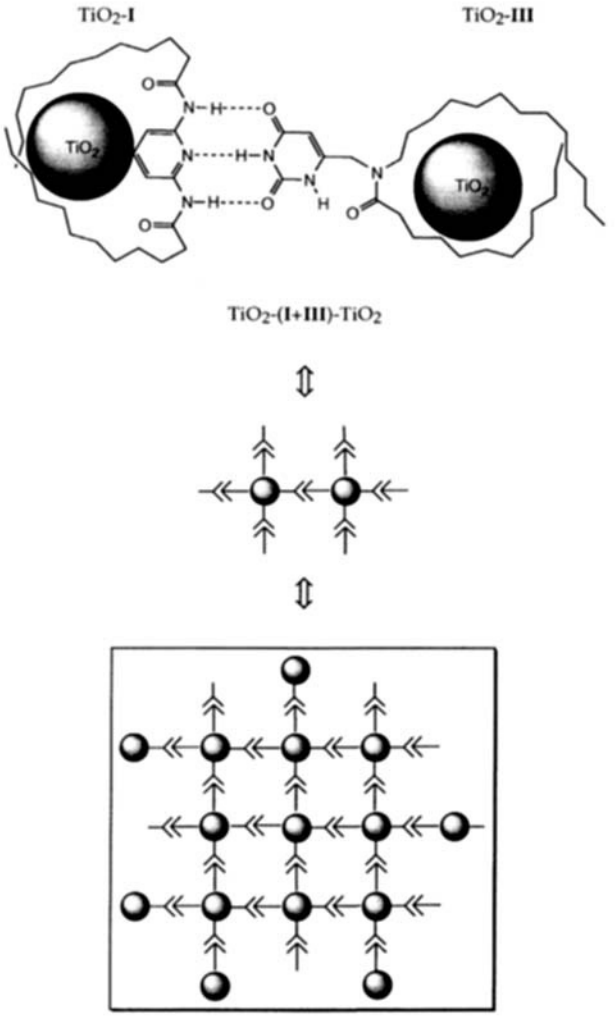


Scheme 1.



Scheme 2. Self-assembly of TiO_2-(**I** + **III**)-TiO_2 to give a superlattice (bottom).

^{1}H NMR spectra of TiO_2-**I**, TiO_2-**III**, and TiO_2-(**I** + **III**)-TiO_2[6, 9–13] (Figure 1a) reveal that upon mixing of TiO_2-**I** and TiO_2-**III** to form TiO_2-(**I** + **III**)-TiO_2, the resonance signals of the amidic protons in TiO_2-**I** ($\delta = 7.53$) and that of the imidic proton in TiO_2-**III** ($\delta = 8.02$) are shifted downfield to $\delta = 7.64$ and 8.29, respectively. Following ageing of TiO_2-(**I** + **III**)-TiO_2 for 10 days, these signals are shifted further downfield to $\delta = 8.23$ and $\delta = 9.52$, respectively.

The corresponding FT-IR spectra (Figure 1b)[6, 14–21] show that upon mixing of TiO_2-**I** and TiO_2-**III** to form TiO_2-(**I** + **III**)-TiO_2, the bands at 3424 and 3395 cm^{-1}, which are assigned to the amidic protons in TiO_2-**I** and to the imidic proton of the uracil ring in TiO_2-**III**, respectively, are reduced in intensity. A series of new bands at 3271, 3203, and 3061 cm^{-1} are assigned to the intermolecularly hydrogen-bonded amidic and imidic protons in TiO_2-**I** and TiO_2-**III**, respectively. Following ageing of TiO_2-(**I** + **III**)-TiO_2 for 10 days, the bands assigned to the amidic protons in TiO_2-**I** and the imidic proton in TiO_2-**III** are further reduced in intensity, while the newly observed bands are further increased in intensity.

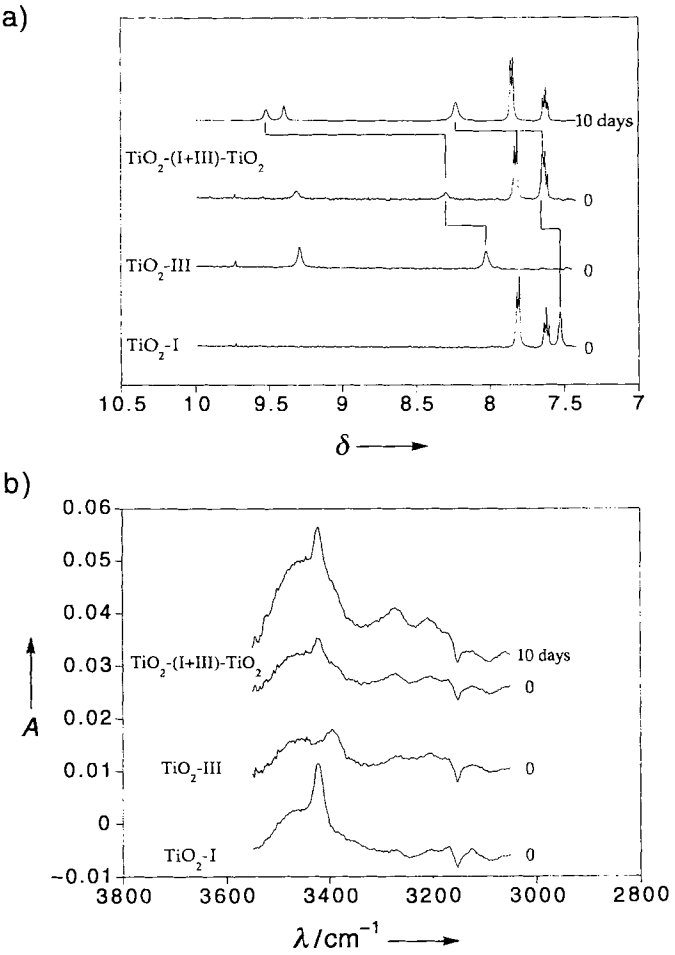


Figure 1. a) ^{1}H NMR and b) FT-IR spectra of TiO_2-**I**, TiO_2-**III** and TiO_2-(**I** + **III**)-TiO_2 (1:1 (v:v)mixture) prior to ageing and of TiO_2-(**I** + **III**)-TiO_2 following ageing for 10 days in the dark at 25 °C. No ageing of TiO_2-**I** or TiO_2-**III** was detected spectroscopically over 10 days. A = absorption in arbitrary units.

It is clear from the ^{1}H NMR and FT-IR studies that TiO_2-**I** and TiO_2-**III** self-assemble by complementary hydrogen bonding to form the heterosupermolecule TiO_2-(**I** + **III**)-TiO_2 (Scheme 2).[6, 9–21] Furthermore, the fact that the hydrogen bonds are formed on a time-scale of days and are weaker than those formed in the adduct (**I** + **III**) immediately upon mixing **I** and **III**,[6] strongly supports the assertion that **I** and **III** are mostly at the surface of a TiO_2 nanocrystallite.[22]

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3608-0849 $ 17.50+.50/0

The average diameter of the aggregates present in TiO_2-**I**, TiO_2-**III** and TiO_2-(**I** + **III**)-TiO_2 was determined by dynamic light scattering (Figure 2a). As expected, some aggregation is observed in both TiO_2-**I** and TiO_2-**III** over 10 days. Specifically, the average aggregate diameter in TiO_2-**I** increases from an initial value of less than 10 nm to 50 nm, while in TiO_2-**III** it increases from an initial value of less than 10 nm to 27 nm. In the case of TiO_2-(**I** + **III**)-TiO_2, however, the extent of aggregation over 10 days is significantly greater. Specifically, the average aggregate diameter increases from an initial value of less than 10 nm to a value of 260 nm after three days and a final value of greater than 1000 nm after 10 days. The measured correlation suggests these aggregates are loose-packed. We note also that the growth of these mesoaggregates is superlinear.

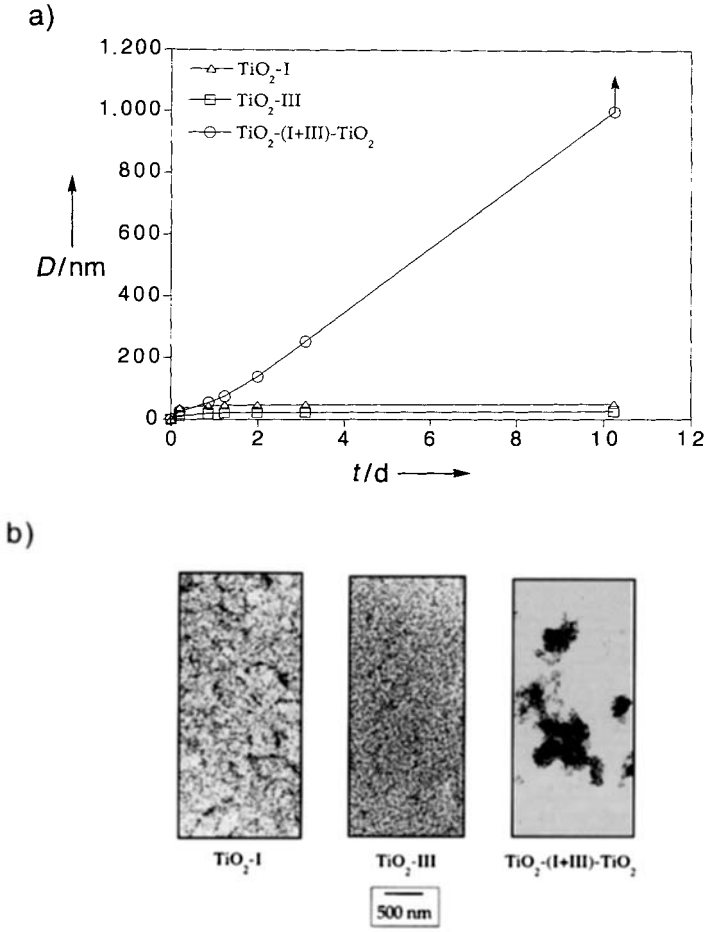

Figure 2. a) Plot of the average aggregate diameter D as a function of time in TiO_2-**I**, TiO_2-**III**, and TiO_2-(**I** + **III**)-TiO_2 (1:1 (v:v) mixture) over 10 days ageing in the dark at 25 °C. b) Low-resolution electron micrographs of samples in (a) that had been aged for 10 days.

Figure 2b shows the low-resolution electron micrographs of samples prepared from the dispersions aged for 10 days (Figure 2a). In accord with the results of the light scattering studies, limited aggregation is observed for TiO_2-**I** and TiO_2-**III**; however, significant aggregation leading to the formation of loose-packed mesoaggregates (with diameters in the range 500 nm–1500 nm) is observed for TiO_2-(**I** + **III**)-TiO_2. Indeed the above mesoaggregates are loose-packed to an extent that they appear fractal. The observed superlinear growth of these mesoaggregates is consistent the latter assertion, that is an available active surface area that increases with time.

The light scattering and electron microscopy studies described above further support the view that TiO_2-**I** and TiO_2-**III** self-assemble by complementary hydrogen bonding (Scheme 2) to form the heterosupermolecule TiO_2-(**I** + **III**)-TiO_2. However, they also clearly demonstrate that these heterosupermolecules subsequently self-organize to form mesoaggregates, which implies there is an ordering of the constituent nanocrystallites within the mesoaggregate.[2–5] That this is the case, or that a superlattice is indeed formed, is clearly seen from the medium-resolution electron micrograph of a mesoaggregate (Figure 3a). The corresponding high-resolution electron micrograph (Figure 3b) shows that the superlattice consists of nanocrystallites that are 12 ± 2 Å in diameter and organized in planes that are separated by 6 ± 2 Å. This, in turn, is consistent with an observed onset for absorption of 350 ± 10 nm and the presence of the modified stabilizers **I** and **III** at the surface of the constituent nanocrystallites of the superlattice.[22–24]

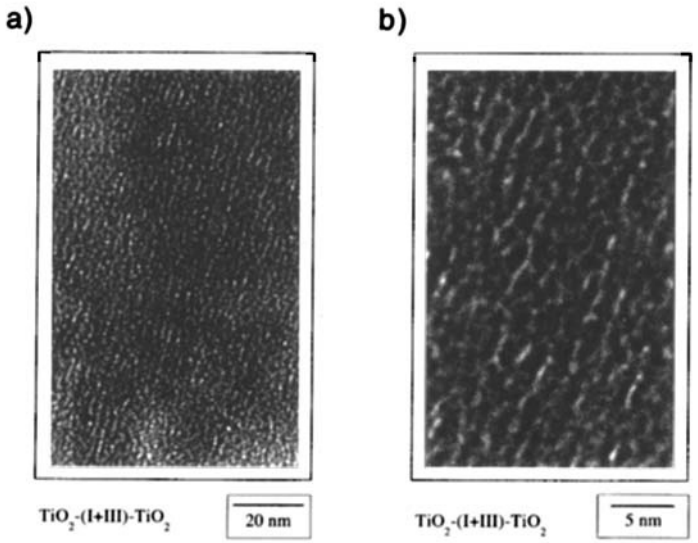

Figure 3. Transmission electron micrographs of a mesoaggregate in TiO_2-(**I** + **III**)-TiO_2 at medium (a) and high-resolution (b); the mesoaggregate had been prepared as described in Figure 2 and aged for 10 days in the dark at 25 °C.

It has been demonstrated that the methodology whose development has accompanied that of heterosupramolecular chemistry may be extended to permit the self-assembly and self-organization of semiconductor nanocrystallite superlattices.[1, 6, 7] Currently our work is directed toward extending the above methodology to the self-assembly and self-organization of a range of metal and mixed-metal semiconductors based on nanocrystallite superlattices. Closely related reports have recenty appeared by Murray et al., Mirkin et al., and Alivisatos et al.[2–4] Finally, our future work will be directed toward the self-assembly and self-organization in solution of complex heterosupramolecular structures that possess diverse function.

Experimental Section

^{1}H NMR spectra were recorded at 25 °C with a Varian 500 FT spectrometer. FT-IR spectra were recorded at 25 °C with a Mattson Galaxy 3000 FT spectrometer (variable temperature cell, CaF_2 windows, 0.20 mm path-length). The samples studied contained TiO_2 (anatase) nanocrystallites (4×10^{-7} mol dm^{-3}, average diameter 12 ± 2 Å, λ_{onset} 350 ± 10 nm) prepared in the presence of **I** or **III** (4×10^{-4} mol dm^{-3}) in $CDCl_3$. Under these conditions more than four fifths of **I** and **III** are at the surface of a nanocrystallite [6]. The average aggregate diameter was determined by dynamic light scattering by using a Malvern System 4700c submicron particle analyser. The dynamic range of this instrument and the concentration of nanocrystallites present allowed aggregates possessing average diameters between 10 nm and about

1000 nm to be analyzed. Transmission electron micrographs were recorded by using a JEOL 2000 FX Temscan (80 K eV) for samples deposited on carbon-coated copper grids. The usual precautions were taken to minimize changes in the morphology of the aggregates to be studied during sample preparation. The samples studied contained TiO_2 (anatase) nanocrystallites (4×10^{-7} mol dm^{-3}, average diameter 12 ± 2 Å, λ_{onset} 350 ± 10 nm) prepared in the presence of **I** or **III** (1×10^{-5} mol dm^{-3}) in $CDCl_3$. Under these conditions more than nine tenths of **I** and **III** are at the surface of a nanocrystallite [6].

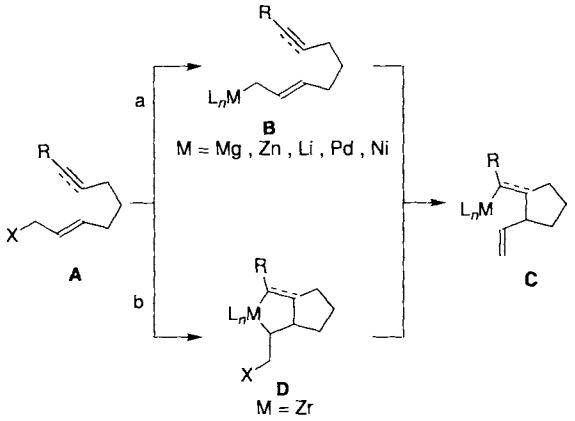
Titanium(II)-Mediated Intramolecular Cyclizations of 2,7- and 2,8-Bis-Unsaturated Carbonates and Acetates: A New and Efficient Synthesis of Cycloalkanes

Yuuki Takayama, Yuan Gao, and Fumie Sato*

Intramolecular metallo-ene reactions (e. g. **A** → **B** → **C**, path a in Scheme 1) provide a highly efficient methodology for preparation of polysubstituted cycloalkanes and corresponding natural products.[1] The conversion of **A** to **C** can also be achieved by a metallabicyclization reaction to give the intermediate **D** and subsequent elimination of X (path b in Scheme 1). However, in spite of the high potential of the latter reaction, examples reported to date have been limited to applications based



Scheme 1. Possible reaction paths of the annulation reaction of **A** to **C** mediated by metal complexes.

on Negishi's zirconocene equivalent. Thus, the reaction of $[Cp_2ZrBu_2]$ with 2,7- and 2,8-bis-unsaturated ethers[2] afforded organozirconium compounds of type **C**. However, the lower reactivity of organozirconium compounds toward electrophiles in comparison with that of organometallic compounds prepared by lithium-, magnesium-, and zinc-ene reactions somewhat diminishes the value of the reaction.[3] Herein we report the titanium(II)-mediated intramolecular cyclization of **A** to **C** via **D**, and show that, owing to the high reactivity of the resulting organotitanium compound,[4] the reaction, which closely resembles the above-mentioned metallo-ene reaction, provides a highly efficient method for synthesizing cycloalkanes.

Recently we reported that $[(\eta^2\text{-}CH3CH{=}CH_2)Ti(O\mathit{i}Pr)_2]$ (**1**), formed in situ by the reaction of $[Ti(O\mathit{i}Pr)_4]$ with two equivalents of *i*PrMgX (X = Cl, Br), can be used as a versatile Ti^{II} equivalent in numerous applicaitons in organic synthesis.[5] For instance, **1** reacts with alkynes to give alkynyltitanium complexes **2**,[5a] and with allylic compounds (allyl-X) such as halides, acetates, and carbonates to give allyltitanium compounds **3** by an oxidative addition[5b] (Scheme 2). We also found that complex **1** mediates the cyclization of 1,6- or 1,7-dienes, -enynes, and -diynes.[5c] These findings prompted us to investigate the feasibility of the conversion of **A** to **C** ($ML_n = Ti(O\mathit{i}Pr)_2$) by the reaction with **1** via **B** and/or **D**.

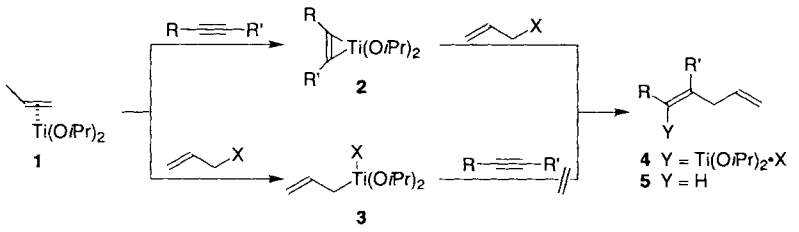

Scheme 2. Syntheses of **2** and **3** from **1** as well as their reactions with allyl halides or alkynes.

First, we investigated the viability of the postulated methodology by carrying out an intermolecular reaction. We found that the reaction of the 4-octyne titanium complex **2** (R = R′ = *n*Pr) with allyl bromide afforded, after hydrolysis, the corresponding coupling product **5** (R = R′ = *n*Pr) in 60% yield.[6, 7] In contrast, the reaction of the allyltitanium compound **3** (X = Br) with 4-octyne did not afford any **5** (R = R′ = *n*Pr) (Scheme 2). We also found that treatment of a mixture of an allyl-X and alkyne with **1** afforded the corresponding product **5** in excellent yield (Table 1, entries 1 and 2); this result strongly indicated the selective formation of the alkynyltitanium complex **2** in the presence of allyl-X and the subsequent reaction with allyl-X to afford the organotitanium compound **4**. These findings strongly suggested the possibility of the conversion of **A** to **C** by the reaction with **1** along path b in Scheme 1. Moreover, the successful trapping of **4** with an aldehyde (Table 1, entry 3) indicated that the reaction might become synthetically equivalent and/or supplementary to lithium-, magnesium-, and zinc-ene reactions.

The intramolecular variant of this reaction proceeded readily with a variety of allylic or propargylic carbonates or acetates having an extra carbon–carbon multiple bond at the appropriate position. Thus, 2,7-dienyl acetate **6**, 2,7-enynyl carbonates **7**, **8**, and **9**, and 2,7-diynyl acetate **11** provided, after hydrolysis, the corresponding cyclopentanes **13**, **14**, **18**, **19** and **24** in excellent yields (Table 1, entries 4, 5, 9, 10, and 15, respectively). Similarly, starting with 2,8-enynyl carbonate **10**, the cyclohexane product **23** was obtained in 82% yield (entry 14). In contrast, 1,7-enyn-3-yl carbonate **25** did not afford the five-membered cyclized product **14** but provided the cyclohexane **26**[9] as a result of a titanabicyclization.[5c] This is consistent with our assumption that the cyclization pre-

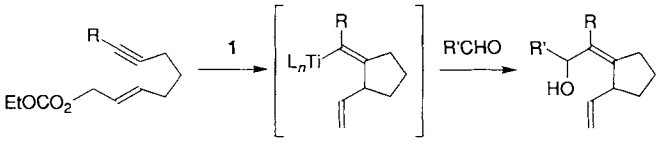
sented here proceeds along path b, and not along path a (Scheme 1).

The alkenyltitanium intermediate of type **C** (Scheme 1, $ML_n = Ti(OiPr)_2$) can be trapped by iodine in excellent yield (Table 1, entry 7). This intermediate reacted with an aldehyde to give the adduct in high yield (entries 8, 11–13), thus allowing the extension of the side chain after the cyclization by an one-pot procedure (Scheme 3).



Scheme 3. Trapping with an aldehyde of the intermediate obtained from **1** and the 2,7-enynyl carbonate **7**.

The sequence of cyclization followed by trapping with an aldehyde has been widely utilized in the case of lithium- and magnesium-ene reactions for synthesis of polysubstituted cycloalkanes and corresponding natural products.[1a] The present reaction, which can be regarded as synthetically equivalent, at least in part, to these intramolecular metallo-ene reactions, should also find wide applicability in organic synthesis. Moreover, several functionalities that are labile under the reaction conditions for the magnesium- and lithium-ene reactions are not attacked by the titanium compounds (see Table 1, entries 12 and 13). Thus, the present reaction could offer an even wider range of possibilities, which we are currently investigating.

Experimental Section

Typical procedure (synthesis of **20**, Table 1, entry 11): To a solution of **9** (0.082 g, 0.308 mmol) and $[Ti(OiPr)_4]$ (0.113 mL, 0.385 mmol) in ether (3.0 mL) was added *i*PrMgCl (0.65 mL, 1.13 M in ether, 0.739 mmol) at −50 °C, and the reaction mixture was subsequently allowed to warm to room temperature. After the reaction mixture had been stirred for 1 h, propanal (0.033 mL, 0.462 mmol) was added, and the mixture was stirred for a further hour. Aqueous workup (1 N HCl) and column chromatography (silica gel, hexane/AcOEt 30/1) provided **20** (0.054 g, 74% yield) as a 58:42 mixture of diastereoisomers. ^1H NMR (300 MHz, $CDCl_3$): major diastereoisomer: $\delta = 0.74-0.89$ (m, 6H), 1.17–1.64 (m, 12H), 1.65–1.79 (m, 1H), 1.82–2.08 (m, 2H), 2.11–2.34 (m, 2H), 3.26–3.36 (m, 1H), 4.27–4.36 (m, 1H), 4.89–4.96 (m, 1H), 5.80 (ddd, $J = 17.0$, 10.2, 6.82 Hz, 1H); minor diastereoisomer: $\delta = 0.74-0.89$ (m, 6H), 1.17–1.64 (m, 12H), 1.65–1.79 (m, 1H), 1.82–2.08 (m, 2H), 2.11–2.34 (m, 2H), 3.26–3.36 (m, 1H), 4.27–4.36 (m, 1H), 4.78–4.85 (m, 1H), 5.61–5.73 (m, 1H); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 10.49$, 10.88, 14.09, 22.50, 23.41, 23.47, 27.66, 28.23, 28.69, 28.83, 29.52, 29.57, 30.09, 30.26, 32.77, 33.64, 45.15, 45.60, 74.36, 74.41, 112.74, 113.00, 134.90, 135.20, 141.45, 141.61, 142.35, 142.60.

Reduction of Dicarbapentaboranes(5) to 1,2-Diborata-4-boracyclopentadienes: Antiaromatic Compounds with 4π-Electron Systems**

Markus Unverzagt, Heinz-Jürgen Winkler, Michael Brock, Matthias Hofmann, Paul von Ragué Schleyer, Werner Massa, and Armin Berndt*

Dedicated to Professor Gerhard E. Herberich on the occasion of his 60th birthday

The tetragonal pyramidal constitutions **2**–**4** have been assigned to the reduction products of *closo*-dicarbapentaboranes(5) **1**.[1, 2] Such structural changes are expected to accompany the transition from *closo* to *nido* compounds with $2n+2$ and $2n+4$ skeletal electrons, respectively.[3]

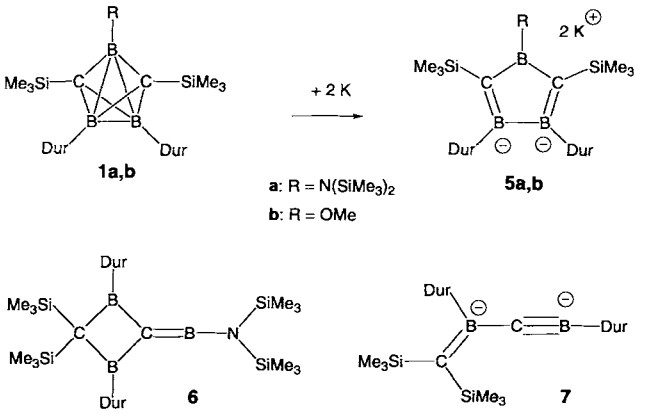
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

We now show that reduction of **1a,b** leads to five-membered rings, the 1,2-diborata-4-boracyclopentadienes **5a,b**. Ab initio computations reveal that the unsubstituted parent five-membered ring **5u** is also lower in energy than all tetragonal-pyramid isomers. Nonetheless, **5u** is a 4π-electron antiaromatic compound.



The dicarbapentaborane(5) **1a** is formed by thermolysis of the aminomethylenborane **6** (Dur = duryl, i.e, 2,3,5,6-tetramethylphenyl), while **1b** is obtained by treating **1a** with methanol in the presence of hydrochloric acid. Borane **6** is available from the borataalkyne **7**[4] and bis(trimethylsilyl)aminodifluoroborane. Reduction of **1a,b** with potassium in diethyl ether gives 1,2-diborata-4-boracyclopenta-dienes **5a,b**. Oxidation of the latter with hexachloroethane, iodine, or air leads to re-formation of **1a,b**.[5]

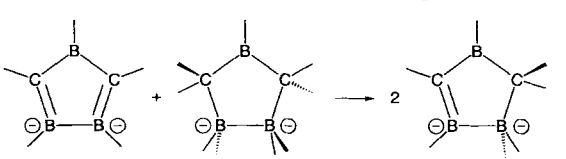
The constitutions of **1a,b** and **5a** were confirmed by X-ray analyses. The similarity of the NMR data (Table 1) of **5a** and **5b** verifies the constitution of the latter. Figure 1 shows the structure of **5a** in the crystal obtained from toluene.[6]

The five-membered ring of **5a** bears duryl substituents on the adjacent boron atoms, and trimethylsilyl groups on the carbon atoms. One potassium ion is coordinated to a toluene molecule and the five-membered ring, and the other to a toluene molecule and the two duryl substituents. The Si3-N1-Si4 plane of the bis(trimethylsilyl)amino substituent at B3 is twisted by 85° relative to the C1-B3-C2 plane. The B1–C1 [150.7(5) pm] and B2–C2 [149.0(5) pm] bonds are considerably shorter than B3–C1 and B3–C2 [155.6(5) and 157.7(4) pm]. The five-membered ring is folded by 25° along the C–C axis.

We performed MP2/6-31+G* computations on the parent compounds to clarify the geometric and energetic relationships without the influence of substituents. The planar five-membered ring **5u** with C_{2v} symmetry is an energy minimum that lies 2.2, 14.2, 27.1, and 9.7 kcal mol^{-1} below the tetragonal pyramids **2u–4u** and the dianion **8** with a *closo* structure, respectively.[7]

In the presence of a η^5-coordinating Li^+ counterion, the C_2B_3 ring is folded considerably: by 44.1° in **5u**-Li and by 40.1° in **5u**-Li_2. In solution **5a** is likely to be a free, solvated dianion with a planar five-membered ring. This is indicated by the ^{11}B NMR chemical shifts of δ = 48 and 63 calculated for **5u** with GIAO-MP2/tzpdz,[8] which match the measured value of 62 ppm much better than those calculated for **5u**-Li and **5u**-Li_2 (see Figure 2).

With four cyclically conjugated π-electrons, **5u** is antiaromatic. The bond lengths alternate considerably[10, 11] (computed for **5u**: B2–C3: 150.4 pm, C3–B4: 155.6 pm);[12] energetic and magnetic criteria are also characteristic of antiaromaticity.[13] An antiaromatic destabilization[10] of 30.3 kcal mol^{-1} is estimated for **5u** by Equation (a), which balances strain effects as far as possible. In addition, **5u** shows a paramagnetically in-



(a)

Table 1. Some physical properties of **1a,b**, **5a,b**, and **6**.

1a: colorless solid, m.p. >380 °C, yield 69%. ^{1}H NMR (500 MHz, $CDCl_3$, −40 °C): δ = −0.02 (s, 18H, $SiMe_3$), 0.17 (s, 18H, $SiMe_3$), 1.91, 2.12, 2.19, 2.28 (each s, each 6H, *o*- and *m*-CH_3), 6.96 (s, 2H, *p*-H); ^{13}C NMR (125 MHz, $CDCl_3$, −40 °C): δ = −0.6 (q, 6C, $SiMe_3$), 4.3 [q, 6C, $N(SiMe_3)$], 20.3, 21.0, 22.9 (each q, total of 8C, *o*- and *m*-CH_3), 117.5 (s, 2C, CB_3), 131.2 (d, 2C, *p*-C), 133.2, 133.5, 135.7, 135.9 (each s, each 2C, *o*- and *m*-C), 133.8 (s, 2C, *i*-C). ^{11}B NMR (96 MHz, toluene, 90 °C): δ = 22, 29 (ratio 1:2).

1b: colorless solid, m.p. 144 °C (no decomp.), yield 100%. ^{1}H NMR (500 MHz, $CDCl_3$, −40 °C): δ = −0.02 (s, 18H, $SiMe_3$), 2.06, 2.21, 2.25, 2.28 (each s, each 6H, *o*- and *m*-CH_3), 3.86 (s, 3H, OCH_3), 6.99 (s, 2H, *p*-H); ^{13}C NMR (125 MHz, $CDCl_3$, −40 °C): δ = −0.3 (q, 6C, $SiMe_3$), 19.4, 20.0, 20.3, 21.7 (each q, total of 8C, *o*- and *m*-CH_3), 108.4 (s, 2C, CB_3), 130.9 (d, 2C, *p*-C), 132.8, 133.0, 134.7, 134.9 (each s, each 2C, *o*- and *m*-C); ^{11}B NMR (96 MHz, $CDCl_3$, 90 °C): δ = 19, 32 (ratio 1:2).

5a: red solid, m.p. 160–170 °C at 0.0025 Torr (decomp), yield: 98%. ^{1}H NMR (500 MHz, [D_8]THF, 0 °C): δ = −0.37, 0.29 (each s, each 18H, $SiMe_3$), 1.11 (t, total of 12H, Et_2O), 2.02, 2.18 (each s, each 12H, *o*- and *m*-CH_3), 3.37 (q, total of 8H, Et_2O), 6.41 (s, 2H, *p*-H); ^{13}C NMR (125 MHz, [D_8]THF, 0 °C): δ = 5.9, 6.1 (each q, each 6C, $SiMe_3$), 15.7 (q, total of 4C, Et_2O), 20.2, 21.4 (each q, each 4C, *o*- and *m*-CH_3), 66.2 (t, total of 4C, Et_2O), 111.3 (s, 2C, CB_2), 125.0 (d, 2C, *p*-H), 131.9, 132.1 (each s, each 4C, *o*- and *m*-C), 169.0 (s, 2C, *i*-C); ^{11}B NMR (96 MHz, toluene, 25 °C): δ = 62.

5b: red solid, m.p. >251 °C (decomp), yield: 99%. ^{1}H NMR (500 MHz, [D_8]THF, −20 °C): δ = −0.28 (each s, each 18H, $SiMe_3$), 2.04, 2.22 (s, 12H, 3 *o*- and *m*-CH_3), 3.88(s, 3H, OMe), 6.36 (s, 2H, *p*-H); ^{13}C NMR (125 MHz, [D_8]THF, −20 °C): δ = 5.3 (q, 6C, $SiMe_3$), 20.6, 21.2 (each q, each 4C, *o*- and *m*-CH_3), 98.9 (br s, 2C, CB_2), 124.9 (d, 2C, *p*-C), 131.7 (s, *o*- and *m*-C), 168.5 (br s, 2C, *i*-C); ^{11}B NMR (96 MHz, Et_2O, 25 °C): δ = 59.

6: pale yellow solid, m.p. 68 °C, yield: 98%. ^{1}H NMR (300 MHz, $CDCl_3$, −40 °C): δ = 0.18, 0.21 (each s, each 18H, $SiMe_3$), 2.28, 2.44 (each s, each 12H, *o*- and *m*-CH_3), 6.95 (s, 2H, *p*-H); ^{13}C NMR (125 MHz, $CDCl_3$, −40 °C): δ = 1.8 [6C, $N(SiMe_3)_2$], 4.6 (6C, $SiMe_3$), 20.1, 21.5 (each 4C, *o*- and *m*-CH_3), 51.0 (br 2C, BCB), 98.6 (br, 1C, sp^2 CB), 129.9 (2C, *p*-C), 132.5, 134.0 (each s, each 4C, *o*- and *m*-CH_3), 146.5 (br, 2C, *i*-C); ^{11}B NMR (96 MHz, toluene, 90 °C): δ = 61, 51 (ratio 2:1).

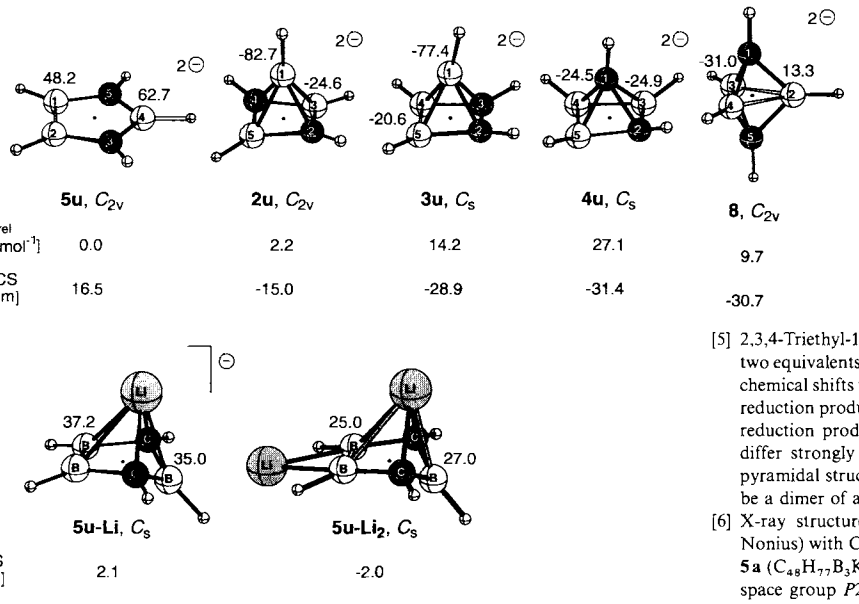

Figure 2. Computed relative energies (E_{rel}) and nucleus independent chemical shifts (NICS, at the positions marked by dots) as well as ^{11}B chemical shifts (δ) for various $C_2B_3H_5^{2-}$ minima.

creased susceptibility: the value Λ is -9.4 ppm cgs [calculated with IGLO/II for Equation (a)].[14]

Such paramagnetic ring currents, which are characteristic of antiaromatic compounds, cause upfield shifts outside rings and downfield shifts inside rings. We have suggested recently nucleus-independent chemical shifts (NICS) as a criterion for (anti)aromaticity. NICS is based on magnetic shieldings, which have long been calculated by simple methods,[15] and now can be computed with modern ab initio technique.[16] To conform with the usual experimental convention, NICS is the negative value of the shielding evaluated, for example, at the center of a ring. Aromaticity is characterized by negative NICS values, antiaromaticity by positive NICS, and nonaromatic compounds by values close to zero. With a NICS value of 16.5 ppm (GIAO-SCF/6-31+G*//MP2(fc)/6-31+G*), **5u** is clearly antiaromatic. Loss of planarity and consequently of cyclic conjugation in **5u**-Li and **5u**-Li$_2$ eliminates the antiaromaticity. This is shown by the NICS values of 2.1 and -2.0 ppm for **5u**-Li and **5u**-Li$_2$, respectively.

In accordance with empirical rules,[3b] the carbon atoms prefer nonadjacent low-coordinate sites in the *nido* structure (tetragonal pyramid). However, more negative NICS values (computed in the center of the open face; see Figure 2) are found in order of decreasing stability (**2u** > **3u** > **4u**). Hence, the larger electron delocalization is associated with the less stable isomers. As has already been demonstrated for bis(heterobicycle)s, the stability of isomers does not necessarily parallel the degree of aromaticity when other factors are important.[17]

The two-electron reduction of dicarbapentaboranes(5) does not lead to tetragonal pyramids, but to five-membered rings. The unsubstituted five-membered ring has been characterized as antiaromatic on the basis of geometric, energetic, and magnetic criteria.

[5] 2,3,4-Triethyl-1,5-dimethyldicarbapentaborane(5) can also be reduced with two equivalents of cesium and reoxidized by iodine [2b]. Unfortunately, no ^{11}B chemical shifts were reported for the reduction product. Oxidation of the other reduction products gave C_4B_6 clusters (i.e., dimers). The ^{11}B NMR data of the reduction product of pentaethyldicarbapentaborane, $\delta = -14.2$ and -37.1, differ strongly from the values computed for **2u**–**4u** and **8**. Therefore, a pyramidal structure can definitively be ruled out. The reduction product may be a dimer of a radical anion of pentaethyldicarbapentaborane.

[6] X-ray structure analysis with a four-circle diffractometer (CAD4, Enraf-Nonius) with $Cu_{K\alpha}$ radiation ($\lambda = 154.178$ pm) at $-60\,^{\circ}C$: colorless crystals of **5a** ($C_{48}H_{77}B_3K_2NSi_4$), crystal dimensions $0.5 \times 0.3 \times 0.2$ mm, orthorhombic, space group $P2_12_12_1$, $Z = 4$, $a = 1295.0(1)$, $b = 1767.9(1)$, $c = 2372.2(1)$ pm, $V_{EZ} = 5430.8(6) \times 10^{-30}$ m^3, $\rho_{calcd} = 1.09$ g cm^{-3}; total of 20119 reflections collected in ω scan mode for $2\theta = 136^{\circ}$; LP correction and semiempirical absorption correction (Ψ scans, $\mu = 26.0$ cm^{-1}, $T_{min,max} = 0.52, 0.66$); all 9908 independent reflections used in subsequent calculations. The structure was solved by direct methods and refined with full matrix against the F^2 data. All hydrogen atoms could be localized. They were considered in the calculation riding on their bonding partners in groups with common isotropic temperature factors. The methyl group of one toluene molecule was disordered over two alternative orientations. Anisotropic temperature factors were used for all heavy atoms, $wR_2 = 0.1275$ and $R = 0.0492$ for 7785 reflections with $F_o > 4\sigma(F_o)$. The maximum residual electron density was 0.33 e Å^{-3}. A Flack Parameter $x = 0.00(1)$ proves that the correct enantiomer has been refined. The crystallographic data (without structure factors) were deposited as "supplementary publication no. CCDC-179-165 at the Cambridge Crystallographic Data Center. Enantiomeric Resolution of Chiral Metallobis(porphyrin)s: Studies on Rotatability of Electronically Coupled Porphyrin Ligands**

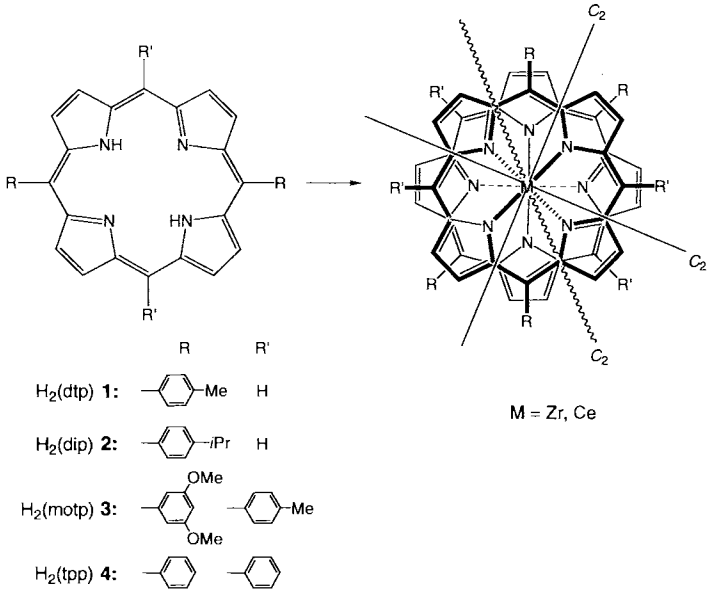
Kentaro Tashiro, Katsuaki Konishi, and Takuzo Aida*

Complexes with a metal atom sandwiched by two porphyrin ligands have caught special attention due to the unique absorption, emission,[1] and redox[2] properties associated with the strong $\pi-\pi$ interaction between the two facing porphyrin ligands. Therefore, it is of interest to investigate the rotatability of the porphyrin ligands in double-decker complexes. So far, zirconium and cerium complexes have been extensively studied with variable-temperature NMR. It was concluded that their porphyrin ligands hardly rotate on the NMR time scale even at 110 °C.[3] Here we report the first enantiomeric resolution of chiral zirconium and cerium sandwiches complexes of D_2 symmetry. Their racemization profiles demonstrate that the porphyrin ligands are *rotatable*, depending on the central metal atom, steric bulk, and acidity of the medium.

Double-decker complexes of zirconium and cerium bis(porphyrinate)s have a square antiprismatic coordination geometry in the solid state.[4] Therefore, sandwich complexes synthesized from D_{2h}-symmetric porphyrin-free bases (**1**,[5,6] **2**,[5] and **3**[5c]) should be chiral (symmetry group D_2, Scheme 1), and their enantiomers may be separable if relative rotation of the porphyrin ligands is prohibited. We synthesized several chiral double-decker complexes such as $[Zr(dtp)_2]$, $[Zr(dip)_2]$, $[Ce(dtp)_2]$, and $[Ce(motp)_2]$ as well as heteroleptic [Zr(dtp)(dip)] and [Ce(motp)(tpp)] (Scheme 1). We also succeeded in resolving $[Zr(dtp)_2]$, $[Zr(dip)_2]$, and $[Ce(motp)_2]$: High-performance liquid chromatography (HPLC) of *rac*-$[Zr(dtp)_2]$ or $[Zr(dip)_2]$ on cellulose tris(3,5-dimethylphenyl)carbamate as chiral stationary phase and hexane/EtOH (98/2) as eluent produced two bands with comparable areas. The fractions corresponding to these two bands were optically active and provided perfect mirror-image circular dichroism (CD) spectra of each other (Figure 1 A). In sharp contrast, $[Ce(dtp)_2]$ showed no sign of optical resolution in HPLC under similar conditions, although the enantiomers of the sterically more crowded tetraaryl analogue $[Ce(motp)_2]$ were successfully separated (Figure 1 B).



Scheme 1. The free porphyrine bases **1**–**3** should provide D_2-symmetric metal bis(porphyrinate)s by the reaction with metal ions.

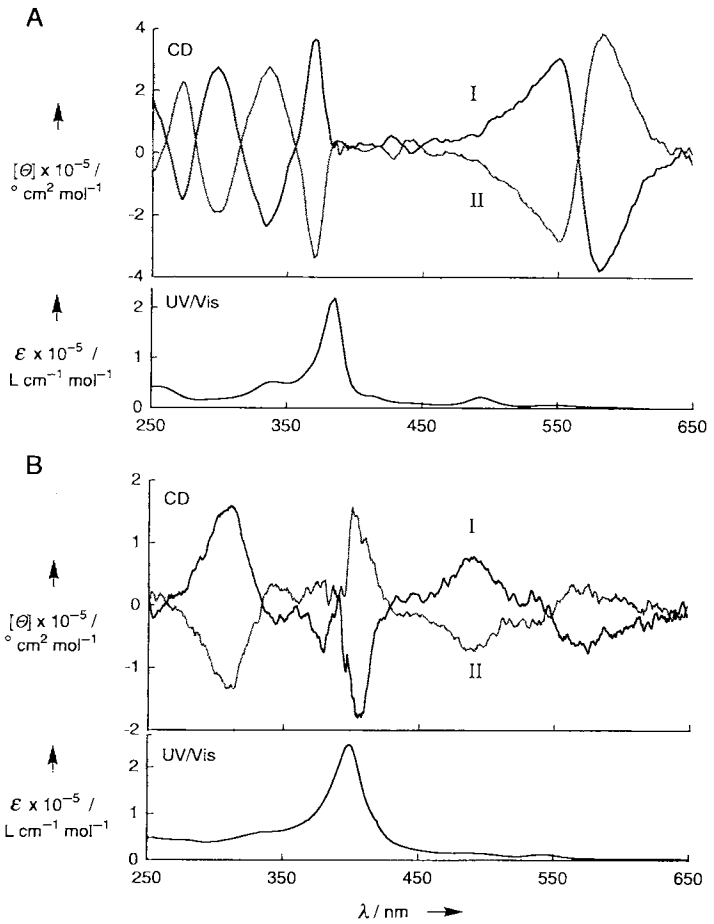


Figure 1. CD and UV/Vis spectra of A) $[Zr(dtp)_2]$ in hexane/EtOH (98/2 v/v) and B) $[Ce(motp)_2]$ in THF at 25 °C. **I** and **II** represent the metal bis(porphyrinate) fractions obtained by HPLC.

In agreement with previous reports,[3] the chiral zirconium double-decker complexes $[Zr(dtp)_2]$ and $[Zr(dip)_2]$ were quite stable against thermal racemization. For example, the CD bands of $[Zr(dtp)_2]$ did not decrease in intensity even upon heating in toluene at reflux for 2 h. On the other hand, $[Ce(motp)_2]$ slowly racemized even at 10 °C in benzene; the half-life of the optical activity was 7.5 h. Upon elevation of the temperature to 35 and 50 °C, the half-lives shortened to 45 and 10 min, respectively. From the thermal racemization profile of $[Ce(motp)_2]$, the first-order racemization rate constants were evaluated to be 1.1×10^{-5}, 1.2×10^{-4}, and $4.9\times10^{-4}\,s^{-1}$ at 10, 35, and 50 °C, respectively, and the thermal parameters $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta G^{\ddagger}_{286}$, were calculated to be 16.5 kcal mol^{-1}, -22.8 cal K^{-1} mol^{-1}, and 23.0 kcal mol^{-1}, respectively. The racemization of $[Ce(motp)_2]$ is considered a result of *intramolecular* ligand rotation in a nondissociative fashion, since ligand

[**] We thank Dr. N. Morisaki and Mr. J. Tsuchiya for HRMS and EPR measurements, respectively.

scrambling to give heteroleptic [Ce(motp)(tpp)] was not observed for an equimolar mixture of [Ce(motp)$_2$] and [Ce(tpp)$_2$] in benzene for 3 days.[7].

Due to the staggered configuration of the porphyrin ligands, the chiral double-decker complexes should have two nonequivalent β-pyrrole units. The ^{1}H NMR spectrum of [Zr(dtp)$_2$] at $-60\,^\circ$C in [D$_8$]toluene showed two sets of paired doublets for the β-pyrrolic protons (Figure 2A). Upon elevation of the temperature to 110 °C each set showed a spectral change profile similar to that of the free base **1** (Figure 2C),[8] but did not coalesce with its counterpart. Similarly, no coalescence was observed for thermally rotatable [Ce(motp)$_2$], indicating that ligand rotation is much slower than the NMR time scale. In contrast, [Ce(dtp)$_2$], which is difficult to optically resolve, showed clear coalescence of the β-pyrrolic proton signals at about 13 °C (Figure 2B) as a result of rapid ligand rotation; the exchange rate constant for the two pyrrole units was calculated to be 80 s^{-1}[9] ($\Delta G^{\ddagger}_{286} = 14.2$ kcal mol^{-1}). This value corresponds to the rotation rate of 20 Hz[10] and is 5×10^6 times higher than that of the sterically more crowded tetraaryl analogue [Ce(motp)$_2$] at the same temperature.

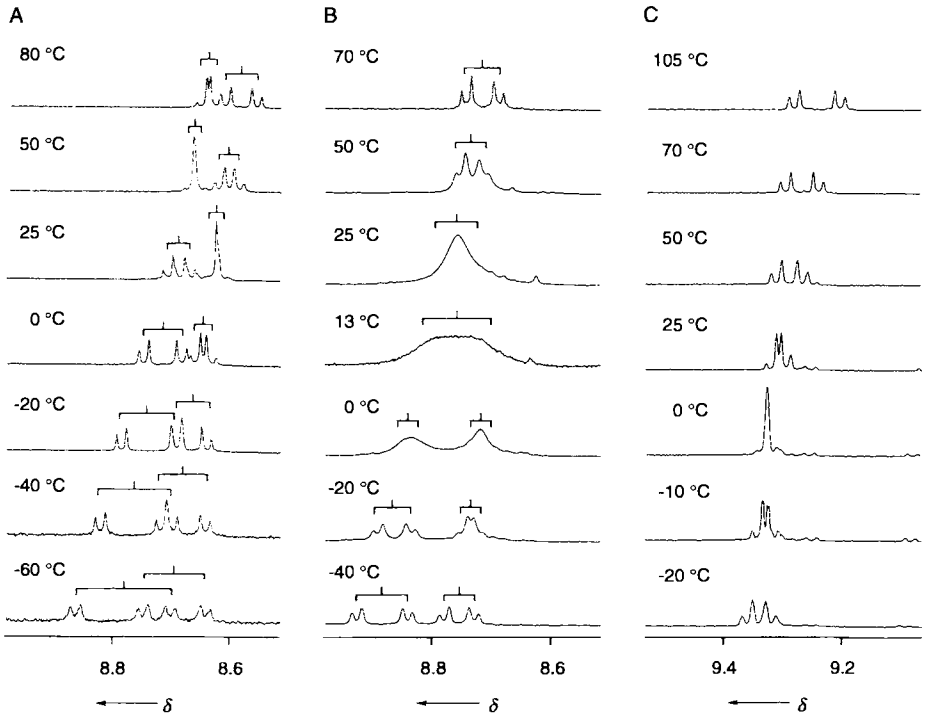

Figure 2. ^{1}H NMR spectral profiles (β-pyrrole proton regions) of A) [Zr(dtp)$_2$], B) [Ce(dtp)$_2$], and C) **1** in [D$_8$]toluene at various temperatures.

As described above, the antiprismatic coordination geometry of zirconium bis(porphyrinate)s is thermally stable. However, in a protonic acid such as $(CF_3)_2CHOH$ as solvent, the optical activity of [Zr(dtp)$_2$] completely disappeared within only 3 min, even at room temperature. The racemization of [Zr(dtp)$_2$] also occurred in HCl/dioxane, TsOH/THF (TsOH = toluenesulfonic acid), CF_3CO_2H, and CH_3CO_2H/benzene, but not in PhOH and MeOH. Addition of a base such as Et_3N resulted in complete inhibition of the racemization. Upon mixing optically active [Zr(dtp)$_2$] and [Zr(dip)$_2$] (1:1; each 3×10^{-6} M) in a solution of TsOH in THF (9.0×10^{-4} M), both racemized without formation of the ligand-scrambled product [Zr(dtp)(dip)].[11] Again, this indicates that the acid-induced racemization is a consequence of intramolecular porphyrin ligand rotation. The racemization rate of [Zr(dtp)$_2$] (6×10^{-6} M) in THF containing TsOH (3×10^{-5} to 9×10^{-4} M) was dependent on the protonic acid concentration and first-order in TsOH concentration; the rate constant was 1.9 M^{-1}s^{-1}.[12, 13]

In conclusion from the optical activity of metal bis(porphyrinate)s of D_2-symmetry, we have demonstrated clearly that the porphyrin ligands in double-decker complexes can rotate about each other, depending on the central metal atom and the steric bulk. The large porphyrin-to-porphyrin distance in cerium complexes appears to allows easier ligand rotation than in the zirconium complexes.[14] Finally, the H$^+$-responsive rotation of the porphyrin ligands indicates a new potential of double-decker complexes as a molecular lock, for which a protonic acid is the key.

Experimental Section

1 [5, 6], **2** [5], and **3** [5c] were prepared from the corresponding aldehydes and dipyrrylmethane or pyrrole. Porphyrin **3** was isolated as the third fraction from six regioisomers by flash column chromatography on silica gel with CH_2Cl_2 as eluent. **2**: ^{1}H NMR (270 MHz, $CDCl_3$, 25 °C, $CHCl_3$): $\delta = 10.33$ (s, 2H; *meso*), 9.41 (d, $^3J = 4.71$ Hz, 4H; β-pyrrole), 9.15 (d, $^3J = 4.71$ Hz, 4H; β-pyrrole), 8.22 (d, $^3J = 8.13$ Hz, 4H; *o*-H in C_6H_4iPr), 7.69 (d, $^3J = 8.13$ Hz, 4H; *m*-H in C_6H_4iPr), 3.32 (sept., $^3J = 6.84$ Hz, 2H; CHMe$_2$), 1.60 (d, $^3J = 6.84$ Hz, 12H; CH_3). **3**: ^{1}H NMR (270 MHz, $CDCl_3$, 25 °C, $CHCl_3$): $\delta = 8.95$ (d, $^3J = 4.70$ Hz, 4H, β-pyrrole), 8.88 (d, $^3J = 4.71$ Hz, 4H; β-pyrrole), 8.12 (d, $^3J = 7.91$ Hz, 4H; *o*-H in C_6H_4Me), 7.58 (d, $^3J = 7.91$ Hz, 4H; *m*-H in C_6H_4Me), 7.43 (d, $^4J = 2.35$ Hz, 4H; *o*-H in C_6H_3(OMe)$_2$), 6.92 (t, $^4J = 2.35$ Hz, 2H; *p*-H in C_6H_3(OMe)$_2$), 3.98 (s, 12H; OCH_3), 2.74 (s, 6H; $C_6H_4CH_3$); (HR)-MS (FAB) calcd for $C_{50}H_{42}N_4O_4$: 762.3206 [M^+], found: 762.3208.

Zirconium bis(porphyrinate)s: A mixture of **1** (1.73 g, 3.6 mmol) and $(Me_3Si)_2NLi$ (2 equiv) in THF (190 mL, distilled) was heated at reflux for 3.5 h [15], and the aresulting lithium salt allowed to react with [Cp_2ZrCl_2] (1.06 g, 3.6 mmol) in 1,2,4-trichlorobenzene (360 mL, distilled) at reflux for 5 h [16]. Column chromatography of the reaction mixture on silica gel with hexane/$CHCl_3$ (3/2) as eluent allowed isolation of [Zr(dtp)$_2$] as the first fraction (120 mg, 6.2%). Likewise, [Zr(dip)$_2$] was obtained from **2** (83 mg, 0.15 mmol) and isolated as the first fraction by flash column chromatography on silica gel with hexane/$CHCl_3$ (1/1) as eluent. [Zr(dtp)(dip)] was isolated as the second fraction (hexane/$CHCl_3$ 1/1) from the reaction of lithiated **1** and **2** (each 0.20 mmol) with [Cp_2ZrCl_2]. [Zr(dtp)$_2$]. ^{1}H NMR (270 MHz, [D$_8$]toluene, 25 °C, $PhCD_2H$): $\delta = 10.21$ (br. s, 4H; *o-endo*-H in C_6H_4Me), 9.26 (s, 4H; *meso*), 8.71 (d, $^3J = 4.29$ Hz, 4H; β-pyrrole), 8.67 (d, $^3J = 4.29$ Hz, 4H; β-pyrrole), 8.62 (s, 8H; β-pyrrole), 8.15 (br. s, 4H; *m-endo*-H in C_6H_4Me), 6.47 (br. s, 4H; *o-exo*-H in C_6H_4Me), 2.76 (s, 12H; $C_6H_4CH_3$), the signal due to *m-exo*-H in C_6H_4Me overlapped with the solvent signal; UV/Vis (THF): λ_{max} (ε) = 342 (75900), 385.5 (302000), 494.5 (31600), 545.5 (10200), 704 nm (1410); HR-MS (FAB) calcd for $C_{68}H_{48}N_8Zr$: 1066.3049 [M^+], found: 1066.3092.

[Zr(dip)$_2$]: ^{1}H NMR (270 MHz, $CDCl_3$, 25 °C, $CHCl_3$): $\delta = 9.82$ (br. d, 4H; *o-endo*-H in C_6H_4iPr), 9.27 (s, 4H; *meso*), 8.68 (br. s, 8H; β-pyrrole), 8.37 (br. s, 8H; β-pyrrole), 8.15 (br. d, 4H; *m-endo*-H in C_6H_4iPr), 7.10 (br. d, 4H; *m-exo*-H in C_6H_4iPr), 6.21 (br. d, 4H; *o-exo*-H in C_6H_4iPr), 3.32 (sept., $^3J = 6.84$ Hz, 4H; CHMe$_2$), 1.63 (d, $^3J = 6.84$ Hz, 24H; CH_3); UV/Vis (THF): λ_{max} = 344, 386.5, 495, 545.5, 704.5 nm; HR-MS (FAB) calcd for $C_{76}H_{64}N_8Zr$: 1178.4301 [M^+], found: 1178.4272.

[Zr(dtp)(dip)]: ^{1}H NMR (270 MHz, C_6D_6, 25 °C, C_6H_6): $\delta = 10.31$ (br. s, 4H; *o-endo*-H in C_6H_4iPr and C_6H_4Me), 9.34 (s, 4H; *meso*), 8.84–8.66 (m, 16H; β-pyrrole), 8.31 (br. s, 2H; *m-endo*), 8.17 (br. s, 2H; *m-endo*), 6.56, 6.54 (br. s, 4H; *o-exo*-H in C_6H_4iPr and C_6H_4Me), 3.37 (sept., $^3J = 6.84$ Hz, 2H; CHMe), 2.77 (s, 6H; $C_6H_4CH_3$), 1.75 (d, $^3J = 6.84$ Hz, 12H; $CH(CH_3)_2$), the signals due to *m-exo*-H in C_6H_4iPr and C_6H_4Me overlapped with the solvent signal; UV/Vis (THF): λ_{max} = 342.5, 386.5, 495, 547, 704.5 nm; HR-MS (FAB) calcd for $C_{72}H_{56}N_8Zr$: 1122.3675 [M^+], found: 1122.3648.

[Ce(dtp)$_2$]: **1** (66 mg, 0.135 mmol) was allowed to react with [Ce(acac)$_3$ · (H$_2$O)$_n$] (262 mg) in 1,2,4-trichlorobenzene at reflux (12 mL) for 3 h [17]. Column chromatography of the reaction mixture on alumina with hexane/$CHCl_3$ (2/1) as eluent allowed the isolation of [Ce(dtp)$_2$] as the first fraction (4 mg, 5%). ^{1}H NMR (270 MHz, [D$_8$]toluene, −40 °C, PhCD$_2$H): δ = 10.19 (d, ^3J = 7.81 Hz, 4H; *o-endo*-H in C$_6$H$_4$Me), 9.19 (s, 4H; *meso*), 8.93 (d, ^3J = 4.40 Hz, 4H; β-pyrrole), 8.85 (d, ^3J = 4.40 Hz, 4H; β-pyrrole), 8.78 (d, ^3J = 4.40 Hz, 4H; β-pyrrole), 8.74 (d, ^3J = 4.40 Hz, 4H; β-pyrrole), 8.20 (d, ^3J = 7.81 Hz, 4H; *m-endo*-H in C$_6$H$_4$Me), 7.15 (d, ^3J = 7.81 Hz, 4H; *m-exo*-H in C$_6$H$_4$Me), 6.64 (d, ^3J = 7.81 Hz, 4H; *o-exo* H in C$_6$H$_4$Me), 2.80 (s, 12H; CH$_3$); UV/Vis (CH$_2$Cl$_2$): λ_{max} (ε) = 384 (148000), 482 (11500), 530.5 nm (7940); HR-MS (FAB) calcd for $C_{68}H_{48}CeN_8$: 1116.3056 [M^+], found: 1116.3085.

[Ce(motp)$_2$] and [Ce(motp)(tpp)]: **3** (50 mg, 0.065 mmol) was allowed to react with [Ce(acac)$_3$ · (H$_2$O)$_n$] (126 mg) in 1,2,4-trichlorobenzene (5 mL) at reflux for 14 h. Flash column chromatography of the reaction mixture on silica gel with $CHCl_3$ as eluent allowed the isolation of [Ce(motp)$_2$] as the second fraction (5 mg, 9.3%). Likewise, [Ce(motp)(tpp)] was obtained from a mixture of **3** (65 mg, 0.083 mmol) and **4** (25 mg, 0.042 mmol) and isolated as the third fraction by silica gel column chromatography with $CHCl_3$ as eluent: [Ce(motp)$_2$]: ^{1}H NMR (270 MHz, [D$_8$]toluene, 25 °C, PhCD$_2$H): δ = 9.96 (br.s, 4H; *o-endo*-H in C$_6$H$_4$Me), 9.47 (s, 4H; *o-endo*-H in C$_6$H$_3$(OMe)$_2$), 8.91 (d, ^3J = 4.64 Hz, 4H; β-pyrrole), 8.77 (d, 4H; β-pyrrole), 8.76 (d, 4H; β-pyrrole), 8.63 (d, ^3J = 4.39 Hz, 4H; β-pyrrole), 7.89 (br.s, 4H; *m-endo*-H in C$_6$H$_4$Me), 6.66 (br.s, 4H; *o-exo*-H in C$_6$H$_4$Me), 6.12 (s, 4H; *o-exo*-H in C$_6$H$_3$(OMe)$_2$), 4.40 (s, 12H; *endo*-OCH$_3$), 3.26 (s, 12H; *exo*-OCH$_3$), 2.67 (s, 12H; C$_6$H$_4$C*H*$_3$), the signals due to *m-exo*-H in C$_6$H$_4$Me and *p*-H in C$_6$H$_3$(OMe)$_2$ overlapped with the solvent signal; UV/Vis (benzene): λ_{max} (ε) = 401.5 (257000), 482.5 (15800), 543.5 (12000), 635.5 nm (3240); HR-MS (FAB) calcd for $C_{100}H_{81}CeN_8O_8$: 1661.5232 [M^+ + H], found: 1661.5286.

[Ce(motp)(tpp)]: ^{1}H NMR (270 MHz, $CDCl_3$, 25 °C, $CHCl_3$): δ = 9.66 (br.s, 4H; *o-endo*-H in Ph), 9.44 (br.s, 2H; *o-endo*-H in C$_6$H$_4$Me), 8.92 (s, 2H; *o-endo*-H in C$_6$H$_3$(OMe)$_2$), 8.40 (d, ^3J = 4.39 Hz, 4H; β-pyrrole in motp), 8.34 (s, 4H; β-pyrrole in tpp), 8.29 (*d*, ^3J = 4.39 Hz, 4H; β-pyrrole in motp), 8.22 (br.s, 4H; β-pyrrole in tpp), 8.16 (br.s, 4H; *m-endo*-H in Ph), 7.92 (br.s, 2H; *m-endo*-H in C$_6$H$_4$Me), 7.71 (t, 4H; *p*-H in Ph), 7.08 (br.s, 2H; *m-exo*-H in C$_6$H$_4$Me), 6.87 (t, ^4J = 2.20 Hz, 2H; *p*-H in C$_6$H$_3$(OMe)$_2$), 6.40 (br.s, 4H; *o-exo*-H in Ph), 6.30 (br.s, 2H; *o-exo*-H in C$_6$H$_4$Me), 4.43 (s, 6H; *endo*-OCH$_3$), 3.52 (s, 6H; *exo*-OCH$_3$), 2.72 (s, 6H; C$_6$H$_4$C*H*$_3$), the signal due to *m-exo*-H in C$_6$H$_3$(OMe)$_2$ overlapped with the solvent signal; UV/Vis (CH_2Cl_2): λ_{max} = 398, 487, 542, 628.5 nm; HR-MS (FAB) calcd for $C_{94}H_{69}CeN_8O_4$: 1513.4496 [M^+ + H], found: 1513.4581.

Optical resolution of [Zr(dtp)$_2$], [Zr(dip)$_2$], and [Ce(motp)$_2$] was carried out on a 0.46/25 cm HPLC column packed with silica gel coated with cellulose tris(3,5-dimethylphenylcarbamate) as chiral stational phase. A solution (40 μL) of the racemate in CCl_4 was loaded on a JASCO Type TWINCLE equipped with a JASCO Type 875-UV variable wavelength detector at a flow rate of 1.0 mL min^{-1} at room temperature. Retention times of the enantiomers (eluent): 6.7 and 8.8 min (hexane/EtOH 98/2) for [Zr(dtp)$_2$], 5.6 and 8.6 min (hexane/EtOH 98/2) for [Zr(dip)$_2$], and 11.0 and 13.6 min (hexane/EtOH 92/8) for [Ce(motp)$_2$].

Racemization of the double-decker complexes was followed by the change in intensity of the CD bands. Protonic acid induced racemization was carried out in the presence of hydroquinone (4.5×10^{-2} M) to prevent oxidation of the complexes [18], and the CD spectra were taken after addition of Et$_3$N.

[18] The zirconium double-decker complexes, as observed by UV/Vis and EPR, were subject to oxidation in the presence of protonic acids, to form the corresponding cation radicals (g = 2.0026, a^N = 0.5 G). No racemization took place without TsOH in the presence of hydroquinone.

Dynamic Kinetic Protonation of Racemic Allenylmetal Species for the Asymmetric Synthesis of Allenic Esters

Koichi Mikami* and Akihiro Yoshida

van't Hoff predicted the existence of chiral allenyl species in 1875.[1] Since then, much attention has been paid to the asymmetric synthesis of allenic acids and esters in particular because they constitute an important class of natural products and synthetic intermediates.[2] The first optically active allenes synthesized, (+)- and (−)-1,3-diphenyl-1,3-di(1-naphthyl)allene, were obtained, though in quite a low enantiomer excess (*ee*), by asymmetric dehydration of 1,3-diphenyl-1,3-di(1-naphthyl)-prop-2-en-1-ol with (+)- and (−)-camphor-10-sulfonic acid, respectively.[3] Subsequent asymmetric syntheses of allenes were mainly based on chirality transfer from a chiral center to the allene axis and optical resolution. Optical resolution of allenic acids was reported through crystallization of the salts of natural alkaloids such as brucine, which has a yield of 50% at best.[4] Chirality transfer reactions of propargylic alcohol derivatives by chlorination with thionyl chloride,[5] substitution reactions of organocuprates,[6] and sigmatropic rearrangements[7, 8] leading to allene derivatives generally give a high degree of chirality

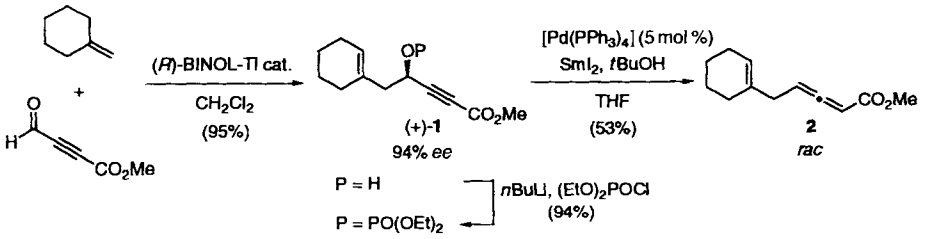
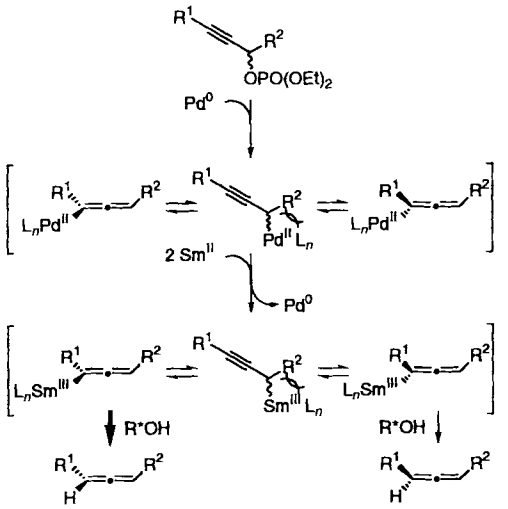


Scheme 1. Pd^0-catalyzed reduction of **1** with SmI_2 in the presence of 1.1 equiv. *t*BuOH.

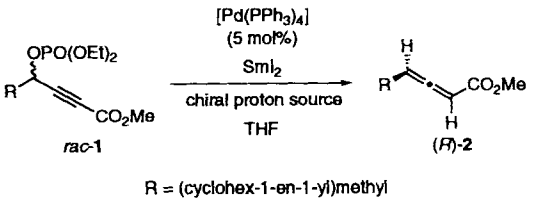
transmission. We describe here the asymmetric synthesis of allenic esters by enantiomer selective protonation of racemic allenylmetal compounds[9] by deracemization without chirality transfer or "destruction" of the allenyl enantiomer. This dynamic kinetic resolution[10] by asymmetric protonation,[11] in other words dynamic kinetic protonation, is a powerful strategy for the asymmetric synthesis of allenic compounds from racemic allenylmetal species.

σ-Allenyl- and σ-propargylpalladium(II) complexes[12] are mainly used in reactions with nucleophiles such as alkylmagnesium and -zinc reagents, hydrides, carbon monoxide, and malonates.[13] Recently, Inanaga and we reported[15] on the umpolung[14] of allenyl-/propargylpalladium(II) complexes to give nucleophilic species by reduction with samarium(II) iodide.[16] This strategy was used to effect the highly regioselective reaction of secondary propargylic phosphates with proton sources or ketones to provide allenes rather than acetylenes. Here we report the results of the dynamic kinetic protonation and deracemization of racemic allenylsamarium(III) intermediates with Pd^0/SmI_2 and a chiral proton source.

For the asymmetric synthesis of α-allenic esters, the chirality transfer reaction was first attempted with an optically active propargylic phosphate in the presence of Pd^0/SmI_2 and an achiral alcohol. For this purpose the chiral propargylic phosphate **1** was prepared from a conjugated ynal[17] by asymmetric carbonyl–ene reaction catalyzed by a binaphthol-derived chiral titanium complex[18] followed by phosphorylation (Scheme 1). The Pd^0-catalyzed reduction of **1** with SmI_2 in the presence of 1.1 equivalents of the achiral *tert*-butyl alcohol as a proton source was attempted. The allenic product **2** was obtained without any contaminating acetylenic product and surprisingly in racemic form since rapid racemization occurred before protonation. This result suggests the possibility of the dynamic kinetic protonation of allenylsamarium(III) species using chiral proton sources even when racemic phosphates serve as starting compounds (Scheme 2).



Scheme 2. Dynamic kinetic protonation with Pd^0, SmI_2, and a chiral proton source.



Scheme 3. Protonation of racemic **1** with a chiral proton source.

Table 1. Pd^0/SmI_2-mediated reduction and protonation of *rac*-**1** to give (*R*)-**2**.

Entry	Chiral proton source	Yield [%]	*ee* [%] [a]
1		52	41
2		70 [b]	24 [c]
3		71	67 [c]
4		86	13
5		71	86
6		68	≥95

[a] Detemined by LIS NMR (LIS = *l*anthanide-*i*nduced *s*hift) analysis using $[Eu(hfc)_3]$ [18]. [b] Methyl 5-(cyclohex-1-en-1-yl)pent-2-ynoate was also obtained in 7% yield. [c] (*S*)-**2** was obtained.

The dynamic kinetic protonation of the racemic propargylic phosphate **1** was examined with various chiral proton sources (Scheme 3, Table 1). The reactions with (*R,R*)-(+)-hydrobenzoin (entry 5, Table 1) and (*R*)-(−)-pantolactone[19] (entry 6, Table 1) provided allenic ester **2** regioselectively with high enantiomeric purity and reasonably high yield (>50%). The absolute configuration of **2** was deduced by application of the Lowe–Brewster rule[4] to be (*R*) because the compound is levorotatory at the sodium D line. The result thus obtained is the first example of the asymmetric synthesis of allene derivatives by selective protonation of one enantiomer without destruction of the other. The selective protonation by the (*R,R*)-diol to provide the (*R*)-(−)-allenic ester is in agreement with the proposed transition state model (Scheme 4), in which steric repulsion between the alkyl groups in the allenylsamarium(III) species and in the chiral proton source plays a key role.

In summary, we have disclosed the asymmetric synthesis of allenic esters by dynamic kinetic protonation of racemic al-

lenylmetal species without the involvement of chirality transfer or destruction of the allenyl enantiomer. This should become a powerful strategy for the asymmetric synthesis of allenic compounds from racemic allenyl-/propargylmetal species.

Experimental Section

To a solution of the phosphate (0.5 mmol), $[Pd(PPh_3)_4]$ (29 mg, 0.025 mmol, 5 mol%), and the chiral alcohol (0.55 mmol) in anhydrous THF (2.5 mL) was added a 0.1 M solution of samarium(II) iodide in THF (10 mL, 1.0 mmol) at room temperature under an argon atmosphere. After stirring for 10 min, the reaction mixture was quenched with saturated NH_4Cl. Standard workup followed by silica gel chromatography afforded the allenic ester **2**.

Hexameric Aggregates in Crystalline (Pentamethylcyclopentadienyl)gallium(I) at 200 K**

Dagmar Loos, Elke Baum, Achim Ecker, Hansgeorg Schnöckel,* and Anthony J. Downs

Dedicated to Professor Hans Bürger on the occasion of his 60th birthday

Univalent derivatives of Group 13 metals with organic ligands have attracted considerable attention by virtue of their synthetic potential and the teasing problems of aggregation and structure that they pose.[1] The first such gallium compounds—[GaCp][2] (Cp = C_5H_5) and $[Ga_4\{C(SiMe_3)_3\}_4]$[3]— were not synthesized and authenticated until 1992. The pentamethylcyclopendadienyl ligand (Cp*), known for its stabilizing ability, yields more or less robust derivatives [MCp*] (M = Al,[4] Ga,[5] In,[6] or Tl[7]), which all vaporize as monomers with MC_{10} skeletons of C_{5v} symmetry (M = Al,[8] Ga,[9] In,[6] or Tl[10]). In the solid state the aluminum compound is a tetramer based on a central Al_4 tetrahedron with comparatively short Al–Al edges.[4] The indium compound is made up of "hexamers" incorporating near-octahedral In_6 units with long In–In edges,[6] whereas the thallium compound forms polymeric zig-zag chains with even longer Tl···Tl distances.[7] Here we describe the crystal structure of the missing link, namely [GaCp*].

We succeeded in growing a single crystal, not from a solution, but by cooling a molten sample of the pure, freshly condensed material[11] in a rigorously preconditioned, Pyrex-glass capillary at about +4 °C. Under these conditions, the oil affords colorless crystals that belong to the trigonal space group $R\bar{3}$ with 18 GaCp* units in the hexagonal "triple cell";[12] solid [GaCp*] is thus isomorphous with [InCp*].[6] The structure of this gallium compound at 200 K consists of discrete hexameric aggregates composed of a Ga_6 core enclosed by a shell of Cp* ligands (Figure 1). The Ga_6 unit is not strictly octahedral but compressed along a C_3 axis to give two distinct Ga_3 units; the Ga···Ga distances within and between these units are 417.3(3) and 407.3(2) pm, respectively (indicating a larger distortion than in $[In_6Cp^*_6]$,[6] d(In···In) = 396.3(1) and 394.2(1) pm). The individual GaCp* units of the hexamer show η^5-coordination of the Cp* ligands; Ga–C distances range from 238.0(9) to 242.1(9) pm (average 240.0 pm), which gives a Ga–centroid distance of 208.1 pm. The corresponding dimensions for the monomer, as determined by electron diffraction of the vapor at 60 °C, are d(Ga–C) = 240.5(4) and d(Ga–centroid) = 208.1(5) pm.[9] As in the case of solid [InCp*],[6] the Ga–centroid vectors do not point towards the center of the hexameric cluster but are tilted significantly towards the faces of the cluster (S_3 symmetry). By contrast, the Al–centroid vectors of the tetramer $[Al_4Cp^*_4]$ point towards the center of the Al_4 tetrahedron.[4]

The orientation of the Cp* ligands with respect to the M_6 core of $[M_6Cp^*_6]$ (M = Ga or In) is consistent with a second-order

[**] This work was supported in Germany by the Deutsche Forschungsgemeinschaft (postdoctoral grant to D. L.) and the Fonds der Chemischen Industrie, and in the UK by the EPSRC. It was described in part at the XVIIth International Conference on Organometallic Chemistry, Brisbane, July 1996.

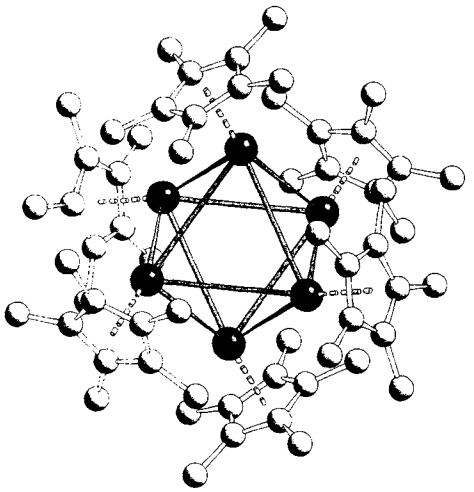

Figure 1. Crystal structure of hexameric (pentamethylcyclpentadienyl)gallium(I): Ga (dark); $d(M\cdots M) = 407.3/417.2$ pm; d(Ga–ring) = 208.1 pm.

Jahn–Teller effect, which enhances the metal···metal overlap population.[13] This implies a stereochemical role for the electrons formally occupying the *ns* valence orbital of the metal. However, the M···M distances close to 400 pm (cf. 245–307 and 325 pm in Ga and In metal, respectively[14]) attest to weak metal···metal interactions, whose of significance for the structure is questionable. For the reasons given below we propose that the structures of these compounds are enforced primarily by van der Waals fitting of the organic envelope, and $M^I\cdots M^I$ interactions have little, if any, influence on the equilibrium geometry.

1) Taking into account differences in temperature, the unit cells of solid [GaCp*] and [InCp*] have very similar volumes, despite the fact that the metal–ring distance is, as expected, 22.1 pm (11%) longer in the indium compound (Table 1).

2) Most telling is the finding that the corresponding metal···metal distances in solid [GaCp*] are 13 and 21 pm *longer* than those in [InCp*].[6]

3) That the monomeric GaCp* molecules interact only weakly with one another is signaled by its comparative volatility,[9] the spectroscopic properties of solutions at low temperature,[11] and the finding that the dimensions of the GaCp* units in the hexameric aggregates do not differ significantly from those of the gaseous molecule.[9, 15]

Two further examples of isomorphous cyclopentadienyl derivatives of univalent Group 13 metals are worth mentioning, namely [InCp^B] and [TlCp^B] [Cp^B = $C_5(CH_2Ph)_5$]. Both solids show dimeric aggregates with identical, very long $M^I\cdots M^I$ distances (363 pm).[16] More structures and elaborate quantum chemical calculations are needed for a better understanding of the behavior of these and related derivatives. However, the results presented here lend considerable weight to the notion that oligomerization is not enforced by metal···metal interactions but by the packing requirements of the ligands in the umbrella-like[13] MCp* units.

Experimental Section

[GaCp*] was prepared as described [5]. Separation from solvent and Cp*H was achieved by fractional condensation in a preconditioned all-glass apparatus ($\leq 10^{-4}$ torr) [17]: the [GaCp*] fraction is less volatile than the other components and was trapped at −30 °C. The purity of the product was checked by NMR [5] and vibrational spectroscopy.

ration of metal flakes. Raman and NMR spectra of solutions between −40 and 20 °C indicate an equilibrium of two distinct species, probably $[GaCp^*]_n \rightleftarrows n[GaCp^*]$, as both series of spectra can be interpreted for the presence of hexameric and monomeric species. The Raman spectra show low-lying a_1 modes for $(GaCp^*)_6$ at 158 cm^{-1} (Ga_6) and 130 cm^{-1} (Cp^*_6). A ring-tilt mode mixes with the out-of-plane mode of five CH_3 ligands of the Cp* ring at 331 cm^{-1}; GaCp* monomer modes appear at 318 cm^{-1} and 180 cm^{-1} (shoulder). The two normal modes for the Ga–Cp* stretch and out-of-plane vibrations are strongly mixed. The ^1H NMR spectrum at −50 °C shows a single, broad signal at $\delta = 1.738$, which sharpens and shifts to high field upon raising the temperature to 10 °C ($\delta = 1.672$); it can be attributed to a hexamer. An additional signal for a monomer species is observed first as a shoulder ($\delta = 1.803$, −30 °C) and then as a sharp signal ($\delta = 1.741$, 10 °C). From both spectroscopic studies the formation of a tetrameric cluster instead of a hexameric one cannot be ruled out.

A Synthetic Receptor Selective for Citrate**

Axel Metzger, Vincent M. Lynch, and Eric V. Anslyn*

Selective binding of ions in highly competitive media, such as water, has intrigued supramolecular chemists for many years.[1] The binding of biologically active anions, for example phosphates or carboxylates, has been one focus of interest for investigations that aim to mimic enzymes or transport proteins.[2] These investigations are typically focused upon binding strength and selectivity. The first can be regulated by the choice of functional groups or solvent systems. The second can be achieved by introducing elements complementary to the shape and binding motifs of the substrate.[3] The field of molecular recognition is becoming sophisticated enough that both binding strength and selectivity can be tuned for many classes of guests.[4] However, strong and selective binding of hydrophilic guests in high dielectric media is still quite elusive.

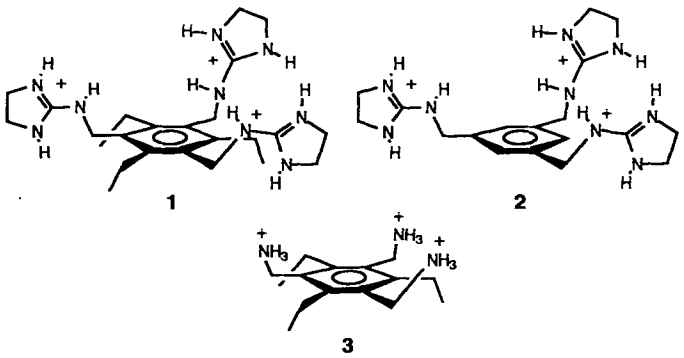
To study the recognition of hydrophilic guests we chose to target citrate, which is of commercial interest because of its abundance in citrus fruits and common beverages.[5] Citric acid, a tricarboxylic acid, is hydrophilic and highly charged near neutral pH. These characteristics offer the possibility of studying the effect of design principles, such as preorganization, hydrogen bonding, and charge pairing, to achieve selective and strong binding of anions in water.

Each of these design principles is a well-accepted molecular recognition paradigm. However, either the precedent was performed under different conditions, or conflicting results have been found. For example, although the benefits of preorganization are well documented,[3] the studies have mostly been conducted in low dielectric media or on hydrophobic interactions in water. Contradictory results are found for the binding of hydrogen-bonding groups to phosphates and carboxylates in water. For instance, ammonium ions are more effective for charge pairing than guanidinium ions because of the higher localization of charge,[6] yet nature prefers to use arginine rather than lysine to bind these anions, possibly due to an increase in the number of potential hydrogen bonds.[7] It is also generally found that the higher the charge on the host or guest, the larger the binding constant.[6] Each one of these three molecular recognition principles needed to be probed to state confidently that receptors selective for the recognition of anions, such as citrate, could be found in water.

Combining the molecular recognition paradigms discussed above led to the design of a preorganized receptor (**1**) complementary to both the charge distribution and hydrogen bonding sites of citrate. The guanidinium group embedded in an aminodihydroimidazolium group has already proved to be an efficient binding motif for carboxylic acids, and gives binding constants of 10^1–10^4 M^{-1} for host–guest complexes in highly competitive solvents such as DMSO or methanol.[8] Preorganization was achieved by incorporating these recognition groups into the 1,3,5-triethyl-2,4,6-trimethylbenzene motif. Alternating steric bulk around the benzene spacer has been found to be preferred by approximately 3.5 kcal mol^{-1} in similar systems.[9] To test if the preorganization was advantageous, we studied **2**, a compound lacking the ethyl groups. To test the difference between guanidinium and ammonium groups, compound **3** was also analyzed. The counterion for all compounds **1**, **2**, and **3** was chloride.



1 **2** **3**

Receptor **1** was synthesized by the reaction of **3** with (*S*)-2-(methylsulfanyl)dihydroimidazole.[10] Although a synthesis of **3** was documented,[11] it involved hydrogenation of 1,3,5-tricyano-2,4,6-triethylbenzene, a step which proved difficult to perform on a scale greater than 1 g. Therefore, the route shown in Scheme 1 was developed. Initially bromomethylation of

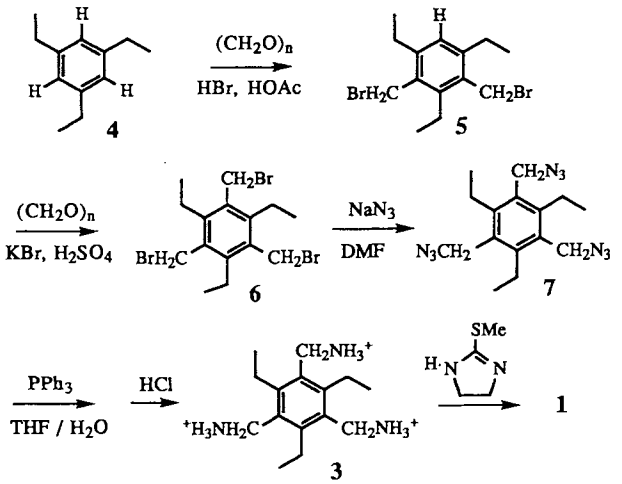

Scheme 1. Synthesis of **3**, the crucial precursor for the synthesis of **1**.

1,3,5-triethylbenzene (**4**) yielded **6** in greater than 53% yield over two steps.[12] The brominated products were then converted into the azides. Finally, reduction of the azides with triphenylphosphane in THF/water gave the triamine **3**. Compound **2** was synthesized from (*S*)-2-(methylsulfanyl)dihydroimidazole and 1,3,5-tris(aminomethyl)benzene.[13]

The complexation of several anionic guests by **1** was studied by ^{1}H NMR spectroscopy. Binding constants were obtained by ^{1}H NMR titration techniques,[14] followed by computer fitting of the experimental isotherm with the typical 1:1 binding algorithm.[15] To explore the effect of buffer on complexation strength, binding constants were determined with added phosphate and HEPES buffers (Table 1). As expected, a phosphate

Table 1. Binding constants of the complex **1**/citrate (99–127 mM/10–14 mM) in various solvent systems and with two different buffers (0.1 M at pH 7.4). Citrate signals were followed [a].

Buffer	Solvent system	Binding constant [M^{-1}][b]
phosphate	D_2O	1.2×10^2
phosphate	D_2O/CD_3CN (4/1)	41
phosphate	D_2O/CD_3CN (3/2)	24
HEPES	D_2O	2.0×10^2
HEPES	D_2O/CD_3CN (4/1)	1.8×10^2
HEPES	D_2O/CD_3CN (3/2)	2.1×10^2
HEPES	D_2O/CD_3CN (2/3)	2.1×10^2

[a] HEPES = 2-[4-(2-hydroxyethyl)-1-piperazinyl]ethanesulfonic acid. [b] The error is ±15%.

buffer inhibited citrate binding due to the relatively high concentration (10-fold excess) of the buffer compared to citrate. Even buffers containing sulfonate groups, known for their weak interaction with guanidinium groups, decreased the binding of host **1** to citrate, but with less impact. The binding constants remained unchanged, within the experimental error, when HEPES buffer was used, and the ratio of organic solvent was increased. However, addition of organic solvents to solutions buffered with phosphate actually decreased the binding constant for citrate. This is likely due to increased competition from the buffer as the dielectric constant of the media is lowered. In low dielectric media there is a tendency to form nonselective binding with the anion in greatest excess (the buffer). This effect demonstrates that the selectivity of receptor **1** for citrate is best in high dielectric media.

Citrate and tricarballate (1,2,3-propanetricarboxylate, a citrate analogue lacking the OH) yield binding constants near 7×10^3 M^{-1} in pure water (Table 2 and Figure 1). These guests

Table 2. Binding constants of the receptors **1**–**3** with several guests in D_2O. All solutions were adjusted to pH 7.4 prior to use.

Host	Guest	Binding constant [M^{-1}][c]
1[a]	citrate	6.9×10^3
1[b]	tricarballate	7.3×10^3
1[b]	succinate	2.1×10^2
1[b]	glutarate	2.2×10^2
1[b]	acetate	<10
1[b]	ATP^{4-}	1.2×10^3
1[b]	3'-Up	2.1×10^2
1[b]	cyclo-2,3-Up	<10
3[a]	citrate	3.0×10^3
2[a]	citrate	2.4×10^3

[a] Guest signals (1.1 mM) were followed. [b] Signals of receptor **1** (1.8–3.0 mM) were followed. [c] The error is ±15%.

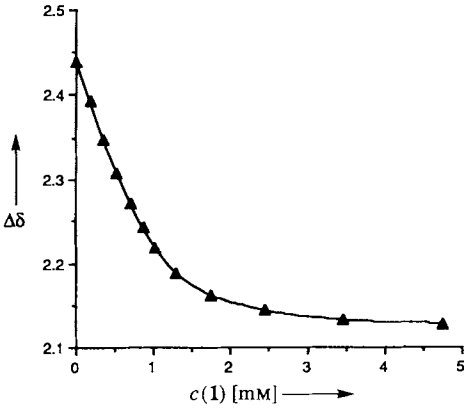

Figure 1. Isotherm of the binding of citrate with receptor **1**. The points are data from an ^{1}H NMR titration in D_2O. The change in citrate signals (11 mM) were followed on addition of receptor **1** (18 mM).

give the largest binding constants obtained in these studies. Even greater charge as found with ATP^{-4} did not result in stronger complexation, indicating the complementarity between receptor **1** and citrate. Smaller binding constants for succinate and glutarate were found (both near 2×10^2 M^{-1}). Acetate showed very weak binding (estimated to be <10 M^{-1}), but the binding isotherm indicated equilibria beyond simple one to one association. Receptor **1** also proved to be capable of binding citrate in a crude extract of orange juice[16] at pH 7.4, remarkably with a binding constant of 4.6×10^3 M^{-1}. The influence of other carboxylates in orange juice (e.g. malate, ascorbate, and succinate)[5], ionic strength, and other compounds such as organic/inorganic phosphates as well as sugars is small. These results emphasize the selectivity of **1**.

To verify that guanidinium groups are important in the carboxylate recognition, we examined the binding of **3** with citrate. The binding constant in pure water was found to be 3.0×10^3 M^{-1}, less than half the binding constant of **1**. Since ammonium cations in other hosts are typically better receptors for carboxylates in water,[6] we conclude that when extensive hydrogen bonding, and not just charge pairing is involved in the host/guest complex, guanidinium groups are better receptors for carboxylates. Further, we verified the advantages to binding imparted by the preorganization of **1**. The analog **2**, which lacks steric preorganization, yields a binding constant of only

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3608-0863 $ 17.50+.50/0

$2.4 \times 10^3\ M^{-1}$ with citrate. Therefore, host **1** is indeed quite complementary to citrate, and possesses good selectivity for citrate-like structures.

An X-ray crystal structure of receptor **1** and tricarballate confirmed the presence of hydrogen bonds and ion pairs in the host guest complex.[17] However, two different complexes were found in the unit cell (Figure 2). All carboxylates in both structures, with the exception of one, make contact with the guanidinium groups. The exception is the carboxylate shown pointing up in structure B. This carboxylate forms hydrogen bonds with two methanol molecules, which in turn participate in hydrogen bonding to guanidinium ions in a type A structure. Interestingly, the A structure has one ethyl group oriented on the same face of the benzene ring as the guanidinium groups. This is not likely to be the thermodynamically favored conformation in solution.[9] Close examination of the crystal packing reveals the reason for this unexpected conformation. The guanidinium residues next to this ethyl group make very short hydrogen bonds (2.54 Å) to carboxylates of an adjacent type B structure. This orients a guanidinium group of an adjacent B structure very close to the ethyl group, forcing it to rotate into the conformation found. Irrespective of this one ethyl group, the crystal structure confirms that the guanidinium units are on the same side of the spacer when binding tricarballate, and that a large number of hydrogen bonds and ion pairs between the host and guest are formed.

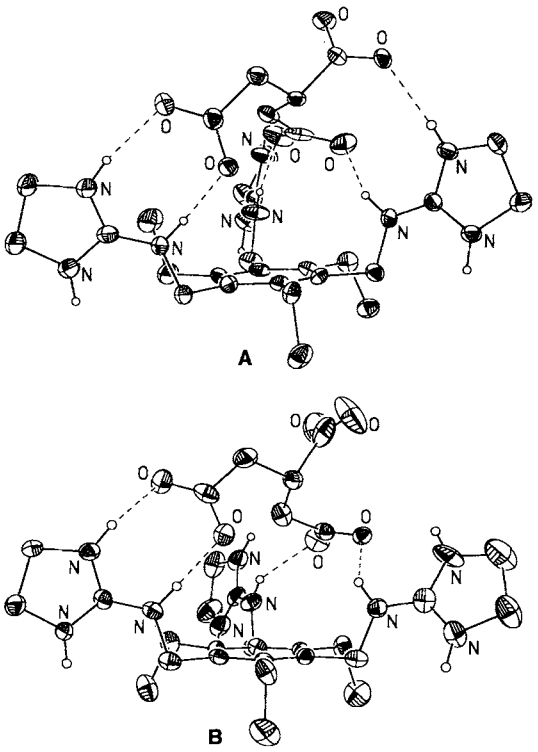

Figure 2. X-ray structure of the complex of receptor **1** with tricarballate. One unit cell contains two different host/guest complexes **A** and **B**.

In summary, we have developed a receptor that is selective for citrate in the presence of other common carboxylic acids. The study confirms that preorganization is important, that guanidinium ions can be more effective than ammonium ions, and that increased charges do not alone determine the binding strength and selectivity of salts in aqueous media. Finally, the study demonstrates that rational design can lead to quite strong and selective receptors for highly hydrophilic guests in aqueous media.

Experimental Section

1: Receptor **3** (766 mg, 2.14 mmol) and (*S*)-2-(methylsulfanyl)dihydroimidazole (893 mg, 7.69 mmol) were mixed thoroughly and transferred to a glass pressure tube. The stirred mixture was heated to 95 °C. After 10 min both compounds had melted, and a layer of methyl sulfide had formed. After 3 days the mixture was allowed to cool to room temperature, and the tube was opened cautiously under the fume hood (stench!). The methyl sulfide was blown off by a stream of air, and the residue was dissolved in 5% acetic acid in water (200 mL) and lyophilized. The residue was dissolved in water, and the product was adsorbed on a cation exchange column (Sephadex CM C-25, 3 × 25 cm) and eluted with a salt gradient from 0.1 M–1 M NH_4Ac (pH 6.8). The product fractions were collected and lyophilized repeatedly until the weight was constant; yield 63%. The acetate was converted into the chloride by anion exchange (Amberlite IRA-400). M.p. 162 °C (decomp.); ^1H NMR (250 MHz, CD_3OD): $\delta = 4.46$ (s, 6H; CH_2), 3.78 (s, 12H, CH_2), 2.73 (q, 6H, CH_2), 1.22 (t, 9H, CH_3); 13C NMR (62 MHz, CD_3OD): $\delta = 160.8$; 146.4, 131.3, 44.19, 42.2, 24.2, 16.5; MS (CI, free base): m/z (%): 454 (100) $[M+1]^+$; HRMS (free base): calcd for $[M+H]^+$ 454.3407, found: 454.3399.

[16] Minute Maid orange juice (150 mL) was filtered through Celite and lyophilized. The residue was stirred with absolute ethanol (200 mL) for 3 h at room temperature. After filtration and evaporation of the solvent, NMR analysis confirmed that no detectable amounts of citrate were extracted. This procedure was necessary to reduce the complexity of the ^{1}H NMR spectra for the following binding study. The residue was dissolved in water (100 mL), the pH adjusted to 8.0, and the solution lyophilized. Part of the very hygroscopic residue (0.987 g) was dissolved in D_2O (5 mL), and the pH was adjusted to 7.4 with DCl and NaOD solutions. On applying a NMR titration method with standard solutions of THF and acetonitrile in D_2O and subsequent integration, the citrate concentration of this solution was determined to be 14 mM. This solution was used for the binding study.
[17] Crystal X-ray data of the colorless crystals of $[(\mathbf{1})(C_6H_5O_6)^{3-}]_2 \cdot H_2O$: monoclinic, space group $P2_1/c$, $a = 11.214(2)$, $b = 25.812(4)$, $c = 25.193(4)$ Å, $\beta = 93.274(4)$°, $V = 7280(2)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.28$ g cm^{-3}. Data were collected on a Siemens P4 diffractometer at -90 °C on use of graphite monochromatized $Mo_{K\alpha}$ radiation. The structure was solved by direct methods and refined by full-matrix least squares on F^2 with anisotropic displacement parameters for the non-hydrogen atoms. The hydrogen atoms on carbon and nitrogen were calculated in idealized positions. No hydrogen atoms on the methanol or water oxygen atoms were included in the refinement model. Final $R_w(F^2) = 0.172$ for 12228 unique reflections. Conventional $R(F) = 0.110$ for 4523 reflections with $F_o > 4(\sigma(F_o))$. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100017. β-Cyclodextrin-Modified Diphosphanes as Ligands for Supramolecular Rhodium Catalysts

Manfred T. Reetz* and Siegfried R. Waldvogel

Dedicated to Professor Walter Siebert on the occasion of his 60th birthday

The combination of molecular recognition,[1] phase transfer catalysis,[2] and transition metal catalysis,[3] performed by one and the same catalyst, could lead to an interesting form of supramolecular catalysis,[1, 4, 5] in, for instance, hydrogenation and C–C bond forming reactions. The use of a catalytically active host compound capable of efficient molecular recognition should result in unusual substrate selectivities, which cannot be achieved in traditional transition metal catalyzed reactions.[6] Furthermore, in a two-phase system, such a catalyst could function as a mediator or carrier for the transfer of the starting material and the product between the different phases, thus leading to enhanced catalytic activity. We report here on rhodium complexes with β-cyclodextrin (β-CD)-modified diphosphanes as ligands. These function as supramolecular catalysts that lead to exceptionally high substrate selectivities when used in hydrogenations of olefins. Furthermore, they are extremely active and selective when employed in the hydroformylation of olefins in a two-phase system.

The amine **3** was prepared starting from mono(*O*-6-tosyl)-6-deoxy-β-cyclodextrin (**1**),[7] which is available in 100 g quantities by tosylation of β-CD in water.[8] Phosphanomethylation of **3** with $Ph_2P(CH_2OH)_2Cl$ led to the diphosphane **4** (Scheme 1).[9]

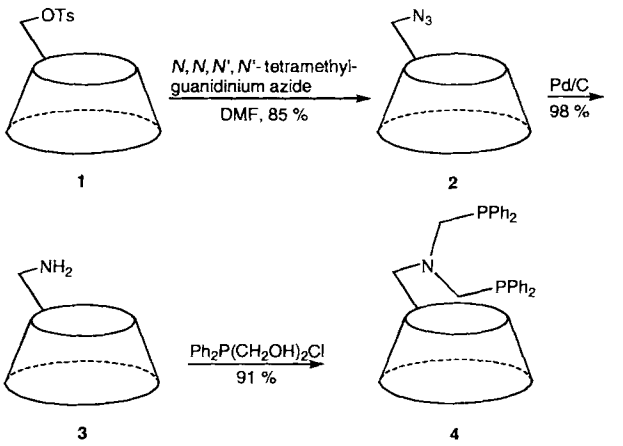
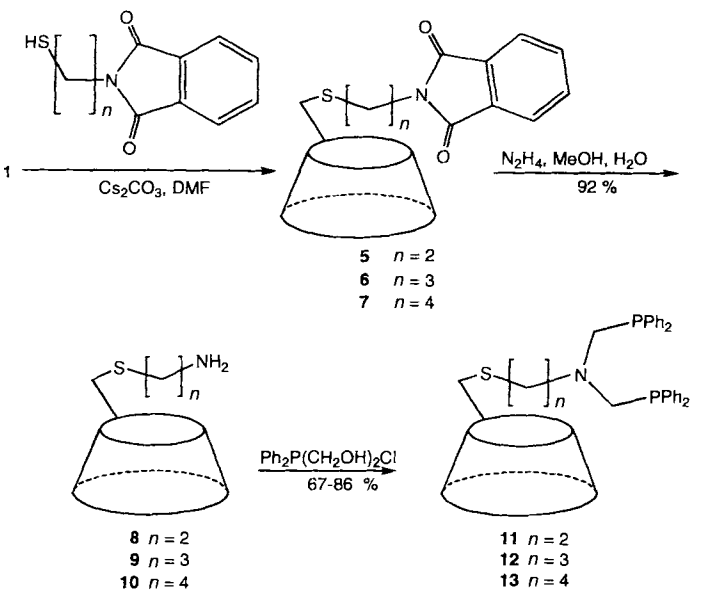
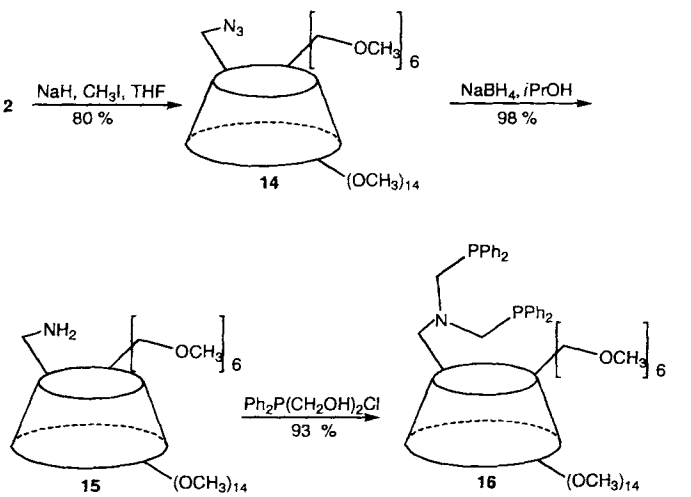


Scheme 1. Synthesis of diphosphane **4** from tosylated β-CD.

The β-CD-modified diphosphanes **11**–**13** (Scheme 2) and **16** (Scheme 3) could also be prepared in a straightforward manner.[8] The rhodium complexes of the ligands as well as of the



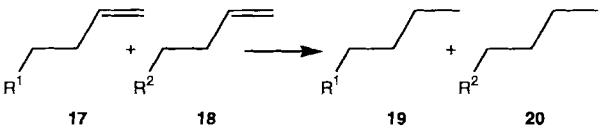
Scheme 2. Synthesis of the β-CD-modified diphosphanes **11**–**13**.



Scheme 3. Synthesis of the β-CD-modified diphosphane **16**.

β-CD-free parent compound $PhN(CH_2PPh_2)_2$[10] were prepared by reaction with bis(1,5-cyclooctadienyl)rhodium tetrafluoroborate $[Rh(cod)_2]BF_4$, and characterized by spectroscopy. All complexes were of very high purity. For instance, the ^{31}P NMR spectrum of the **11**/$[Rh(cod)]BF_4$ complex shows only one absorption at $\delta = +7.14$ (d,J(P,Rh) = 143 Hz).

To establish whether these β-CD-modified rhodium catalysts function as supramolecular catalysts, the alkenes **17** and **18**, which possess similar substitution patterns at the double bonds, were subjected to competition experiments (Scheme 4). In these experiments, 1:1 mixtures of the two olefins were hydrogenated up to 10% conversion in a solvent at room temperature in the presence of a catalyst. The ratio of the products **19** and **20**, as determined by gas chromatography, was used as a measure of the substrate selectivity.



17 **18** **19** **20**

(R = Ph) (R = n-C_6H_{13})

Scheme 4. Competitive hydrogenation of alkenes **17** and **18**.

No substrate selectivity was achieved in the control experiment with the β-CD-free catalyst $PhN(CH_2PPh_2)_2$/$[Rh(cod)]BF_4$ (product ratio 50:50). In contrast, the use of the β-CD-modified rhodium catalyst led to a substantial substrate selectivity: the phenyl-substituted alkene **17** was preferentially converted to form alkane **19**. The length of the spacer between the β-CD and the diphosphane group plays a crucial role in these reactions (Table 1). We postulate that a recognition step precedes the hydrogenation and furthermore that the phenyl group of **17** preferentially enters the hydrophobic cavity of the β-CD framework.[11]

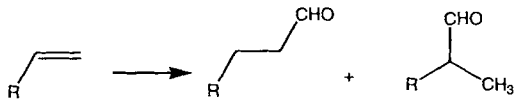
Table 1. Substrate selectivity in the hydrogenation (1 atm H_2) of **17**/**18** in DMF at 22 °C.

Catalyst [a]	**19**/**20**
$[PhN(CH_2PPh_2)_2Rh(cod)]BF_4$	50/50
4/$[Rh(cod)]BF_4$	68/32
11/$[Rh(cod)]BF_4$	74/26
12/$[Rh(cod)]BF_4$	71/29
13/$[Rh(cod)]BF_4$	66/34
4/$[Rh(cod)]BF_4$ [b]	82/18
11/$[Rh(cod)]BF_4$ [b]	81/19
16/$[Rh(cod)]BF_4$ [b]	87/13

[a] 0.5 mol% catalyst. [b] Two-phase system; aqueous phase contains 30% DMF.

Since the rhodium complexes are highly water-soluble, several of the competition experiments were also performed in the two-phase system water/substrate pair. The $[Rh(cod)]BF_4$ complexes of **4**, **11**, and **16** revealed significantly enhanced activity (factor 3–6) and afforded selectivities of 82, 81, and 87%, respectively, in favor of the reaction of **17**. This observation supports the postulated interplay of molecular recognition, phase transfer catalysis, and rhodium catalysis. Indeed the substrate selectivity decreases drastically when working in the presence of *p*-xylene, which competes for the space in the β-CD cavity; for instance, for the catalyst **11**/$[Rh(cod)]BF_4$ the selectivity dropped from 81/19 to 57/43.

Since the hydroformylation of olefins[3] in the two-phase system H_2O/olefin continues to be a challenge,[12, 13] it appeared attractive to test the rhodium complexes of the β-CD-modified ligands **4** and **11**–**13** in this reaction as well. In all cases, unexpectedly high catalyst activities were observed. For instance, in the hydroformylation of 1-octene (**21**) in the two-phase system H_2O (30% DMF)/olefin with 0.03 mol% of the catalyst **11**/$[Rh(cod)]BF_4$ at 80 °C and 100 bar, quantitative conversion was achieved within 18 h (76% regioselectivity in favor of the *n*-product **22**; Scheme 5). For a turnover number (TON) of 3172,



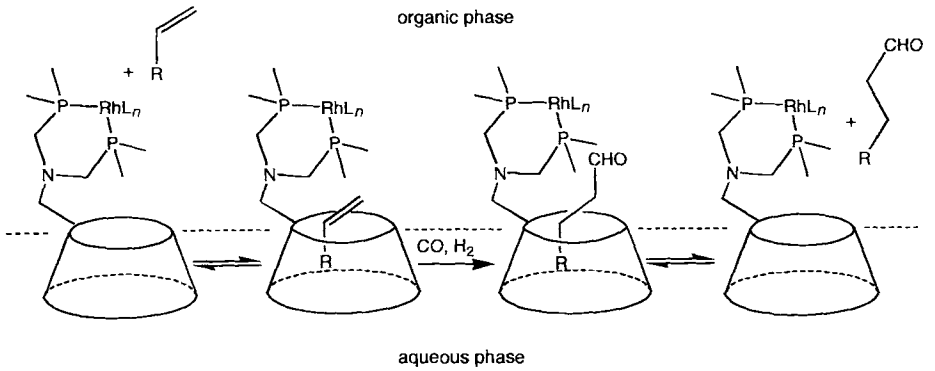
21 (R = n-C_6H_{13}) **22** **23**

Scheme 5. Hydroformylation of 1-octene (**21**).

the chemoselectivity was >99%, that is, no undesired hydrogenation or isomerization products could be detected by gas chromatography in the crude product. Similar activities and selectivities were also obtained in the two-phase system H_2O/olefin without DMF in the aqueous phase; however, the addition of DMF offers certain advantages in the preparation of the catalyst.[8, 14] In a control experiment with the likewise water-soluble rhodium catalyst based on $P(C_6H_4SO_3Na)_3$,[12] only <1% conversion was obtained under the same reaction conditions. Only at higher temperatures (120 °C) was approximately 4% of **22** and **23** observed after 18 h. Based on these results, our catalytic system is >150 times more active at 80 °C than the traditional system at 120 °C. In fact, the reaction with **11**/$[Rh(cod)]BF_4$ can also be cleanly performed at 60 °C (95% conversion after 18 h, *n*-selectivity 76%, <1% isomerization products). Even at decreased pressures (10 bar at 60 °C), the results are still acceptable (69% conversion after 18 h, *n*-selectivity 74%, 9.5% isomerization products). Moreover, relatively unreactive olefins such as (*E*)-3-hexene can be cleanly hydroformylated in the two-phase system (0.03 mol% **11**/$[Rh(cod)]BF_4$, 60 °C, 100 bar H_2/CO 1/1, 70 h, TON 3008, 90% 2-ethylpentanal and 4% 2-methylhexanal). In the commonly used two-phase system Rh/p-$(C_6H_4SO_3Na)_3$,[12] olefins of this type cannot be converted even in the presence of phase-transfer catalysts.[13]

The rhodium complexes of the other β-CD-modified diphosphanes are also highly active and selective catalysts for the hydroformylation of **21** in the two-phase system (0.03 mol% catalyst, 60 °C, 100 bar H_2/CO 1/1, 18 h, conversion and chemoselectivity >99%): **4** (TON 3179, **22**/**23** 75/25), **12** (TON 3170, **22**/**23** 69/31), **13** (TON 3170, **22**/**23** 67/33). Although the direct comparison of one-phase and two-phase systems is difficult, it appears that the catalytic activity reported here is similar to that of homogeneous rhodium–phosphite systems in organic solvents, which are known to constitute the highest catalytic activities.[3] The importance of the cyclodextrin substituent in our system is demonstrated, inter alia, by the unexpectedly high regioselectivity. For instance, the change from $[PhN(CH_2PPh_2)_2Rh(cod)]BF_4$ in a one-phase system to the β-CD-modified catalyst **11**/$[Rh(cod)]BF_4$ results in an increase in the isomer ratio **22**/**23** from 62/38 to 76/24. A possible explanation for this enhanced selectivity is the participation of the host–guest complex, which plays an important role in the phase-transfer catalysis (Scheme 6). If the water-soluble catalyst is in the region of the phase boundary, the olefin molecules can

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3608-0866 $ 17.50+.50/0



Scheme 6. Mode of action of the host-guest complexes in phase-transfer and Rh catalysis.

easily enter the hydrophobic cavity of the β-cyclodextrin. Since the catalytically active metal center is fixed nearby in space, a rapid entropy-favored reaction takes place. It remains unclear how the β-CD-modified catalyst is oriented relative to the phase boundary. Surface tension measurements provided data for obtaining information about the surface activity: distilled water: 73.6 $N m^{-1}$; H_2O/DMF 3/1: 55.6 $N m^{-1}$; 1.2×10^{-3} M sodium dodecyl sulfate in H_2O/DMF 3/1: 53.4 $N m^{-1}$; 1.2×10^{-3} M **11** in H_2O/DMF 3/1: 53.3 $N m^{-1}$; 1.2×10^{-3} M **11**/[Rh^I(cod)]BF_4 in H_2O/DMF 3/1: 43.6 $N m^{-1}$. Thus, the addition of DMF decreases the surface tension considerably. Further addition of the conventional surfactant sodium dodecyl sulfate showed only a minor effect. Addition of the rhodium complex **11**/[Rh(cod)]BF_4, however, causes a further significant decrease in the surface tension. Thus, β-CD-modified phosphanes are amphiphilic ligands that are capable of stabilizing catalytically active rhodium as well as acting as a carrier between the two nonmiscible phases. In the presence of toluene, which also enters the β-CD cavity,[11] the regioselectivity is reduced to 65/35. These and other results[8] clearly show that participation of phosphane-free Rh(CO)*n* species is highly unlikely.

Although only very small amounts of the rhodium catalyst were used in the hydroformylations, it appeared appropriate to perform experiments oriented towards studying the stability and recovery of the catalyst. Thus, the phases were separated after completion of the reaction and the organic phase was washed once with water. In a standard reaction with approximately 10 mL of the olefin and 0.03 mol% of the rhodium catalyst, typically 6–90 ppm rhodium were detected by atomic absorption spectroscopy in the organic phase, depending on the olefin and the catalyst ligand. Additional washings led to further reductions in the rhodium concentration. Reuse of the aqueous phase in the hydroformylation yielded a remaining catalytic activity of approximately 50%. These data do not meet the rigid specifications required by an industrial process, they are, however, very promising. Studies are currently underway targeted towards the optimization of the catalysts based on β-CD-derivatives and on other amphiphilic compounds for the combined use in both transition metal catalysis and phase transfer catalysis.

[12] The industrial-scale hydroformylation of propene in a two-phase system with water-soluble phosphanes of the type $P(C_6H_4SO_3Na)_3$ as rhodium ligands (Ruhrchemie AG) cannot be easily extended to homologous olefins such as 1-octene, [13] since these show low solubilities in water: a) B. Cornils, E. G. Kuntz, *J. Organomet. Chem.* **1995**, *502*, 177; b) G. Papadogianakis, R. A. Sheldon, *New J. Chem.* **1996**, *20*, 175.

[13] Monflier et al. recently modified the Ruhrchemie AG [12] procedure by using *O*-alkylated β-CD additives (10–14 fold excess) to enhance the solubility; thus, substrates such as 1-octene or 1-decene can be converted, but not nonreactive internal olefins such as 3-hexene: a) E. Monflier, G. Fremy, Y. Castanet, A. Mortreux, *Angew. Chem.* **1995**, *107*, 2450; *Angew. Chem. Int. Ed. Engl.* **1995**, *34*, 2269; b) E. Monflier, S. Tilloy, G. Fremy, Y. Castanet, A. Mortreux, *Tetrahedron Lett.* **1995**, *36*, 9481; c) J. R. Anderson, E. M. Campi, W. R. Jackson, *Catal. Lett.* **1991**, *9*, 55.

[14] Typical procedure: Cyclodextrin diphosphane (2.4×10^{-5} mol) and [$Rh(cod)_2$]BF_4 (2×10^{-5} mol) were dissolved in DMF (5 mL). H_2O (15 mL) and 1-octene (10 mL) were added, and the hydroformylation was carried out in a steel autoclave (200 mL), equipped with a teflon sleeve and a magnetic stirrer, at a temperature of 60 °C under a synthesis gas atmosphere (CO/H_2 1/1; 100 bar). After completion of the reaction (Table 1), the mixture was poured into a separating funnel, the aqueous catalyst solution removed and washed with H_2O (10 mL) to remove residual DMF. The organic phase was then dried over $MgSO_4$ and filtered.

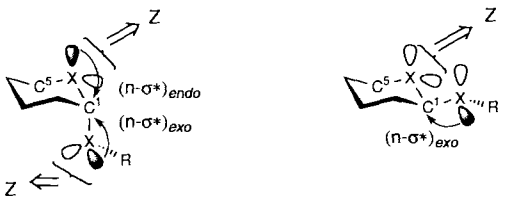
Relative Nucleophilicity of the Two Sulfur Atoms in 1,5-Dithioglucopyranoside**

Hideya Yuasa, Yujiro Kamata, and Hironobu Hashimoto*

The anomeric effect has been extensively studied in the four decades since its discovery,[1] especially in connection with understanding the structure and the reactivity of biologically important oligosaccharides.[2] The term anomeric effect refers to the tendency of a glycosidic bond of a pyranose to assume the axial rather than the equatorial orientation despite unfavorable steric interactions. Though several rationales for this effect have been proposed, for example destabilizing dipole–dipole[3] or 4e orbital interactions[4] in the equatorial glycoside, the most widely accepted explanation is the stabilizing interaction (delocalization) between the nonbonding n orbital of the ring oxygen (O5) and the antibonding σ* orbital of the glycosidic bond (C1–O1) in the axial glycoside (Scheme 1).[5] This n–σ* hypothesis is

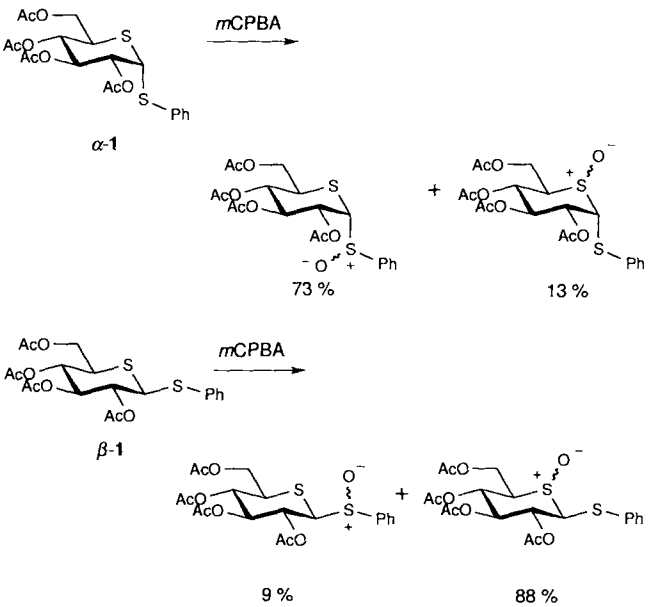


Scheme 1. The n–σ* hypothesis to explain the anomeric effect and the proposed site of the electrophilic attack in glycopyranosides.

particularly successful in explaining the shortening of the C1–O5 bond in anomers with an axial glycosidic bond. Furthermore, the difference in reactivities of the anomeric glycosides has been frequently attributed to the n–σ* interaction.[2a, 6] However, there are some criticisms of this hypothesis.[4, 7] For example, it is not consistent with the relative nucleophilicities of O1 and O5 estimated from experiments.

In the anomer with the axial glycosidic bond, two n–σ* interactions are actually assumed: the $(n-\sigma^*)_{endo}$ interaction described above and the $(n-\sigma^*)_{exo}$ interaction between the lone pair orbital of the glycosidic oxygen (O1) and the antibonding orbital of the C1–O5 bond (Scheme 1). In contrast, the anomer with the equatorial glycosidic bond can accommodate only one such interaction, $(n-\sigma^*)_{exo}$. Therefore, the n–σ* hypothesis leads to the following postulates:[2a] 1) the nucleophilicity of both O1 and O5 should be attenuated in the axial anomer because the lone pair electrons of each oxygen atom are equally perturbed by both the $(n-\sigma^*)_{exo}$ and $(n-\sigma^*)_{endo}$ interactions, and 2) O5 of the equatorial anomer should be more nucleophilic than O1 since only the latter is involved in such an interaction ($(n-\sigma^*)_{exo}$), which provides O5 with electrons on the one hand and deprives O1 of electrons on the other. These postulates have been supported by ab initio calculations of dimethoxymethane.[9] In apparent contradiction to what is expected from the n–σ* hypothesis, experiments indicate that O1 of both anomers is more nucleophilic than O5, and that O1 of the equatorial anomer is much more nucleophilic than that of the axial anomer.[4] However, the reactions used to probe the O1 nucleophilicities of α- and β-glycosides, for example ozonolysis of glycopyranosides and O-methylation of glycopyranoses, are too complex to be informative, thus weakening the criticism. In this context, it is desirable to reexamine the relative nucleophilicities and their origin. Determination of the relative nucleophilicity would require observations of the protonation site, but this is difficult owing to its fast equilibration.[10] On the assumption that dithioacetals would exhibit a stronger anomeric effect than acetals[2d, 11] and that the nucleophilicity of sulfur atom could be probed by measuring the rate of electrophilic oxidation, we decided to examine the oxidation of 1,5-dithioglucopyranosides and 5-thioglucopyranosides to investigate whether a relationship exists between the relative nucleophilicities and the n–σ* interaction.

We have demonstrated that electrophilic oxidation of phenyl α- and β-1,5-dithioglucopyranosides **1** is regioselective: the α-glycoside is oxidized mainly at the glycosidic sulfur (S1) while the β-glycoside is oxidized mainly at the ring sulfur (S5) (Scheme 2).[12] This regioselectivity indicates that S1 is more nucleophilic than S5 in the α-anomer (axial), and that S5 is more nucleophilic than S1 in the β-anomer (equatorial). However, we have not yet determined whether this relative nucleophilicity originates from the n–σ* interactions.



Scheme 2. Oxidation of phenyl α- and β-1,5-dithioglucopyranosides α- and β-**1** with *meta*-chloro peroxybenzoic acid (*m*CPBA).

To evaluate the influence of the aglycon structure on the nucleophilicity of S5, pseudo-first-order rate constants (k_{obs}) were measured for the oxidation of 4-substituted phenyl α- and β-5-thioglucopyranosides α- and β-**2**-X with a large excess of peracetic acid (Scheme 3, Table 1).[13] The rates for the β-glycosides were five to seven times greater than those for the corresponding α-glycosides, which is consistent with what would be expected from the n–σ* hypothesis. Hammett analyses were performed for the k_{obs} values obtained with σ_p as a substituent constant[14] (Figure 1). The reaction constant ρ and correlation coefficient r were −0.414 and 0.990, respectively, for the α-glycosides and −0.277 and 0.981, respectively, for the β-glycosides. The reac-

Scheme 3. Oxidation of aryl α- and β-5-thioglucopyranosides α- and β-**2**-X with peracetic acid.

Table 1. Pseudo-first-order rate constants (k_{obs}) for the oxidation of α- and β-**2**-X [a].

X	k_{obs}(α-**2**-X) [10^4 s^{-1}]	k_{obs}(β-**2**-X) [10^4 s^{-1}]
OMe	7.03±0.06	35.7±0.4
H	5.56±0.07	29.4±0.4
F	4.85±0.03	29.5±0.2
Cl	4.20±0.05	27.1±0.4
CF_3	3.50±0.04	23.2±0.2
NO_2	2.46±0.05	17.3±0.2

[a] Each glycoside was oxidized with 20 equiv peracetic acid at 30 °C in EtOH, and consumption of the substrate was monitored by HPLC.

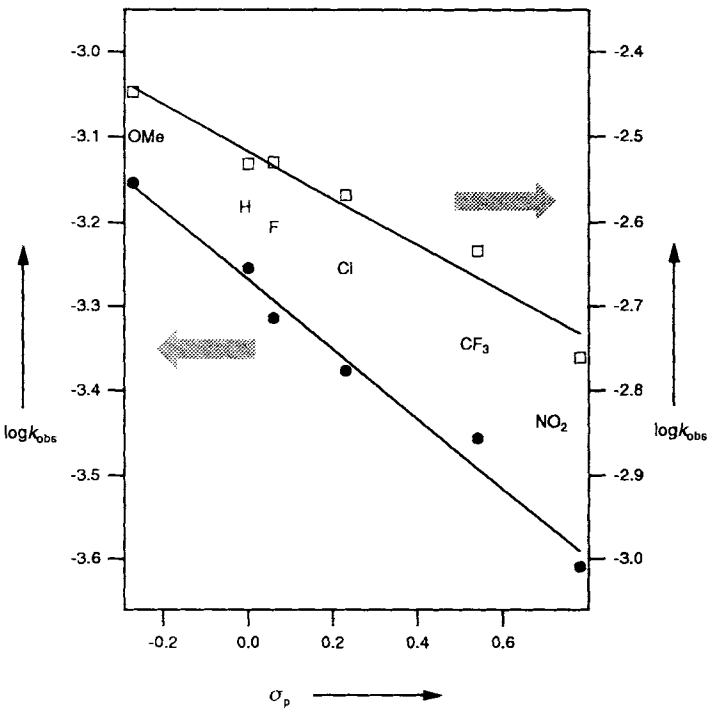

Figure 1. Hammett plot for the oxidation of aryl 5-thioglucopyranosides α-(●) and β-**2**-X (□).

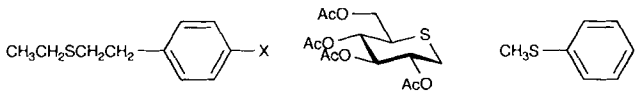
tion rates were thus found to correlate with the electronic properties of the substituents X. The negative values of ρ indicate that the oxidation is certainly electrophilic and hence the value of k_{obs} reflects the nucleophilicity of the ring sulfur atom. That the nucleophilicity of the α-glycosides is roughly 1.5 times more sensitive than that of the β-glycosides to the electronic properties of the glycosidic substituent, based on comparison of ρ, supports the presence of an additional electron pathway in the α-glycosides—the $(n-\sigma^*)_{endo}$ interaction. In other words, the electron-withdrawing inductive effect should lower the energy of the antibonding orbital of the glycosidic bond (σ^*_{CO}) and thereby the energy of the lone pair orbital (n_S) through the $(n-\sigma^*)_{endo}$ interaction, which, in turn, decreases the nucleophilicity. The other two hypotheses proposed for the anomeric effect, dipole–dipole[3] and 4e orbital[4] interactions, assume that the Üdestabilizing interactions between the ring heteroatom and the anomeric substituents are stronger in the β-glycosides than in the α-glycosides, and thereby fail to account for the reduced sensitivity of the β-glycosides to the electronic properties of the substituents. Therefore the lower nucleophilicity of S5 in the α-glycosides relative to that in the β-glycosides is most probably due to the $(n-\sigma^*)_{endo}$ interaction.

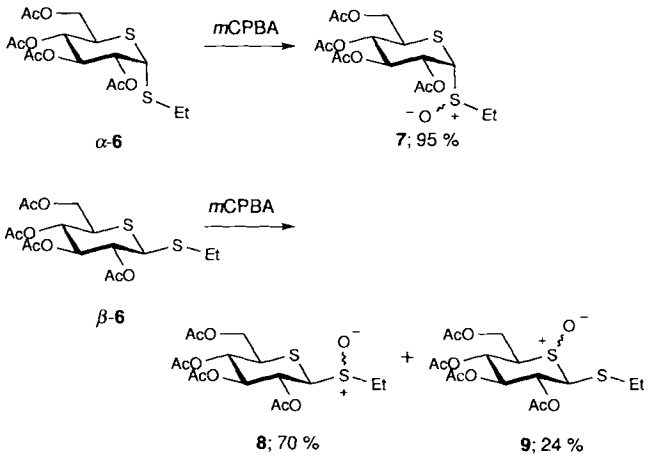
The rather small magnitude of ρ for the β-glycosides may be merely due to an ordinary inductive effect. To examine whether the $(n-\sigma^*)_{exo}$ interaction affects the nucleophilicity of S5, the oxidation rates of 4-substituted ethyl phenethyl sulfides **3**-X were investigated under the same reaction conditions as those employed for the oxidation of the 5-thioglucopyranosides. In **3**-X the sulfur atom and the benzene ring are separated by two



3-X (X = OMe, Cl, H) **4** **5**

atoms, as is the case in the 5-thioglucopyranosides, even though the former lacks an oxygen atom. The rates of **3**-OMe and **3**-Cl relative to that of **3**-H are 1.00 and 0.95, respectively. Since the corresponding rates for the β-glycosides β-**2**-OMe and β-**2**-Cl relative to that of β-**2**-H are 1.21 and 0.92, respectively, only the electron-releasing methoxy group appears to have a special effect in enhancing the nucleophilicity of the β-glycoside. This is in accord with the proposed $(n-\sigma^*)_{exo}$ interaction, which provides the ring heteroatom with electrons.

Although these results are consistent with the n–σ* hypothesis, which accounts for the difference in the regioselectivities of the oxidation of aryl 1,5-dithioglucopyranosides (Scheme 2), the S1 selectivity for the α-glycoside α-**1** is still difficult to explain. A possible explanation is that the inherent nucleophilicity of S5, which we assume is not involved in n–σ* interactions, is lower than that of S1. This was demonstrated by a competition experiment for model compounds that do not have n–σ* interactions. 1-Deoxyper-*O*-acetyl-5-thioglucopyranoside (**4**), the S5 model compound, is approximately 20 times less nucleophilic than thioanisole (**5**), the S1 model compound. The difference in the inherent nucleophilicities of S5 and S1 is probably due to steric and/or electronic effects: the attenuation of the nucleophilicity of S5 caused by either the sterically defined ring skeleton or the electron-withdrawing oxygen atoms attached to the ring is larger than the reduction of the nucleophilicity of S1 due to the phenyl group. In practice, when the phenyl group of compound **1** was replaced with a less electron-withdrawing and presumably less bulky ethyl group, the nucleophilicity of S1 was further increased for both anomers (Scheme 4). That is, oxidation of ethyl 1,5-dithio-α-glucopyranoside α-**6** with mCPBA gave only the *exo*-sulfoxide **7**, and that of β-**6** gave mainly the *exo*-sulfoxide **8** together with a small amount of the *endo*-sulfoxide **9**. Interestingly, this result is consistent with the acid-catalyzed solvolyses of normal alkyl glycopyranosides. That is, while the α-glycosides are protonated exclusively at O1 allowing only the *exo*-cyclic cleavage, the β-glycosides are protonated at both O1 and O5 allowing both *exo*- and *endo*-cleavage.[15, 16] In conclusion, the relative nucleophilicities of glycopyranosides



Scheme 4. Oxidation of ethyl α- and β-1,5-dithioglucopyranosides α- and β-**6** with *m*CPBA.

that we have deduced experimentally are somewhat different from those proposed based on complex reactions and on the n–σ* hypothesis alone. Our results can be explained by a combination of the n–σ* interaction and the inherently reduced nucleophilicity of the ring heteroatoms, and thus the criticism of the n–σ* hypothesis is weakened.

[16] The consistency may be fortuitous, because not only the protonation equilibrium but also the C–O cleavage step is critical for the apparent rate in the acid-catalyzed acetal hydrolysis.

Pyranosyl-RNA Also Forms Hairpin Structures**

Ronald Micura, Martin Bolli, Norbert Windhab, and Albert Eschenmoser*

Dedicated to Professor Gerhard Quinkert on the occasion of his 70th birthday

One of the consequences of the discovery of the ribozymes[2, 3] was a development in our views on the meaning of the terms genotype and phenotype. On a molecular level these terms no longer necessarily imply that a genotype and a phenotype are embodied in different families of molecular structure in which members of one family encode the synthesis of members of the other. Instead, genotype and phenotype may be aspects of one and the same family of molecules in the sense that the former display the constitutional diversity and the latter the conformational diversity of that family.[4] In this case, the intrinsic dependence of conformation on constitution replaces the encoding of the phenotype synthesis by the genotype. How this conceptual development facilitates the design of etiological models of biogenesis is exemplified by the idea of an "RNA world".[5]

In the chemical etiology of nucleic acid structure,[6] potential nucleic acid alternatives are systematically compared to RNA with respect to chemical properties that are fundamental to RNA's biological function. Alternatives are nucleic acid analogues that from a chemical point of view could have been, but were not, chosen by nature as molecular genetic systems. In order to function as a genetic oligonucleotide system, the chemical properties that are to be considered in such a study include, in order of ascending requirements, the capacity to store combinatorial structural information by base pairing, the ability to self-replicate, the encoding of conformational diversity by a sequence diversity, and finally the potential for sequence-specific (and thus potentially "inheritable") catalytic properties that can act as (phenotypic) selection factors in replication.[7]

Investigations on pyranosyl-RNA ("p-RNA") have shown that this RNA alternative exhibits not only stronger but also more selective base pairing than RNA.[8–11] These surprising characteristics of the pyranosyl isomer of natural RNA appear to be a consequence of the pronounced inclination between the (approximated) backbone and base pair axes in the structure of p-RNA duplexes, as well as of the conformational rigidity of the p-RNA pyranosyl ring relative to that of the furanosyl ring—and therefore a result of the smaller number of freely rotating bonds in the backbone (Figure 1). In the light of this difference in strand flexibility, it is not self-evident that a constitutional diversity in p-RNA can give rise to a corresponding conformational diversity, as is the case for RNA, where it is essential both

We further thank Dr. Uwe Pieles (Ciba-Geigy AG, Basel) for recording the MALDI-TOF spectra. Parts 5 and 20: ref. [1].

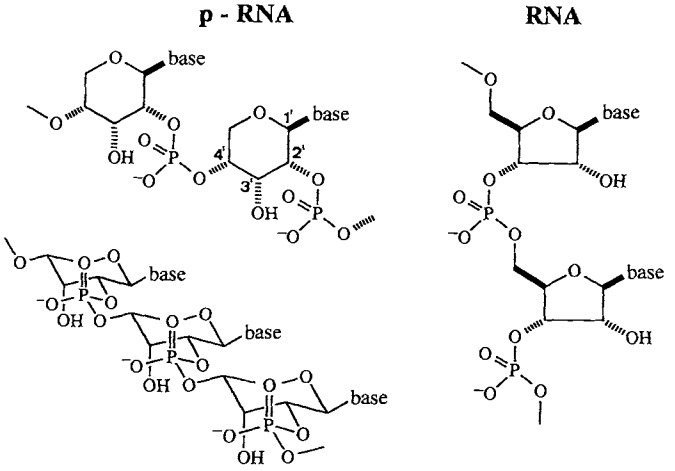

Figure 1. Constitution of p-RNA and RNA, and (idealized) pairing conformation of p-RNA [8].

for RNA's biological function and for the etiological concept of an RNA-world. On the other hand, qualitative conformational analysis of the repeating unit of a p-RNA single strand shows that the ensemble of least strained (idealized) conformations contains, beside the repetitive pairing conformation, not less than eight nonrepetitive conformations that, in idealized models, can mediate conformational diversity within sequence domains that are not involved in base pairing.[8, 12]

Key prerequisite for a conformational diversity in oligonucleotide pairing systems is the ability to form hairpin structures. We report here that p-RNA forms such structures as easily as RNA and consequently—like RNA—has the potential for phenotypic properties.[13]

Prompted by preliminary experiments in which we observed that the melting temperature of the p-RNA-oligonucleotide of the base sequence pr(GCGCTTTTTGCGC) seems to lie just above the observation window, we synthesized the base sequences listed in Table 1 and investigated their pairing characteristics. For the preparation of p-RNA oligonucleotides we used the methods of synthesis, purification, and characterization described earlier.[8-9, 14] The molecular masses of all sequences made were verified by MALDI-TOF mass spectrometry.[15] Under the conditions used, the melting temperatures determined by UV spectroscopy and, in some cases, by circular dichroism (CD)[16] are—with the exception of the sequence pr(GCGTTCGC)—independent of the oligonucleotide concentration (Table 1, Figures 2 and 3). From this and corresponding thermodynamic data (Table 1) we conclude that under the conditions used all the sequences (with the exception of that mentioned above) have a hairpin structure at room temperature.[17] Normally, melting points of duplex-forming p-RNA oligonucleotides of similar length differ by approximately 10 K when the concentration is changed from about 5 to about 100 μM. The hyperchromicities observed for the hairpin sequences in Table 1 corresponds to differences expected for the base pairs that form hairpin stems: for the sequences with (A–T) base pairs it is consistently higher than for those with (G–C) base pairs,[8, 9] and—in accordance with the presence of non-pairing bases—generally lower than that in corresponding sequences that form fully paired duplexes.

In the case of the sequence pr(GCGTTCGC), both the dependence of the melting temperature on the concentration and the thermodynamic data of the melting process indicate that this octamer favors duplex formation over hairpin formation. This is hardly surprising, since the loop sequence of the corresponding hairpin would contain only two bases. Under standard conditions, already the nonamer pr(GCGTTTCGC) exists as a hairpin (Figure 3); at higher oligonucleotide concentrations, however, it shows distinct signs of competitive duplex formation (Figure 2b). The decamer pr(GCGTTTTCGC) clearly exhibits the behavior of a hairpin structure with a stability similar to the one of an RNA hairpin.[17]

We used hairpin-forming base sequences of the type described above to illustrate one of the selectivity phenomena that p-RNA is expected to show as a consequence of the dominance of INTERstrand stacking.[8-11] These effects can all be traced back to the especially pronounced inclination between (approximated) backbone and pair axes, which is considered to be characteristic for p-RNA duplexes. They include the strong preference for antiparallel (as opposed to parallel) strand orientation,[18, 19] the regio- and chiroselectivity of the template-controlled ligation of short oligonucleotide 2',3'-cyclophosphates,[1, 9] the chiroselectivity of the self-directing oligomerization of tetramer-2',3'-cyclophosphates,[20] and the generally higher duplex stability of (4' → 2')(pyrimidine–purine) motives than that of the isomeric (4' → 2')(purine–pyrimidine) motives.[8, 9, 1, 21] Whether dangling bases[22] (bases without pairing partner at strand ends) will enhance the stability of p-RNA pairing complexes as they do in the DNA and RNA series[22] can be predicted by considering the relationship between axes inclination and interstrand base stacking on the basis of the postulate that it is primarily INTERstrand and not INTRAstrand base

Table 1. Thermodynamic data of the hairpin and duplex formation as well as MS data and melting points T_m of selected pyranosyl-RNA sequences.

stacking that actively contributes to duplex stability in conjunction with base pairing. According to the structure of p-RNA duplexes[8] confirmed by NMR analysis and molecular dynamics modeling,[10] the positioning of the base pairs is such that interstrand stacking operates between a base n of strand A (paired with base m of strand B) and the base $(m+1)$ of strand B (and not the base $(m-1)$ of strand B; Figure 4), whereas there is hardly any opportunity for INTRAstrand stacking.[10] Dangling bases, therefore, are expected to enhance the stability of pairing complexes when located at the 2′-end of a p-RNA strand (Figure 4).

The experimental data shown in Scheme 1 confirm the expectation, and furthermore, provides a qualitative measure of

the relative contribution to stability by purine–purine interstrand stacking and pyrimidine–purine stacking. Both the structural parameter that defines the inclination between the (approximated) backbone and base pair axes and the resulting differentiation between inter- and intrastrand base stacking are relevant not only with regard to the properties of pyranosyl-RNA, but, when properly applied to the natural pairing systems, also with respect to certain differences in the properties of RNA and DNA.[19]

Composite Solids Constructed From One-Dimensional Coordination Polymer Matrices and Molybdenum Oxide Subunits: Polyoxomolybdate Clusters within $[\{Cu(4,4'\text{-bpy})\}_4Mo_8O_{26}]$ and $[\{Ni(H_2O)_2(4,4'\text{-bpy})_2\}_2Mo_8O_{26}]$ and One-Dimensional Oxide Chains in $[\{Cu(4,4'\text{-bpy})\}_4Mo_{15}O_{47}]\cdot 8H_2O$**

Douglas Hagrman, Chloe Zubieta, David J. Rose, Jon Zubieta,* and Robert C. Haushalter*

The significant interest in crystal engineering of composite organic/inorganic solid-state materials reflects their diverse properties, with applications to catalysis, sorption, clathration, electrical conductivity, magnetism, and photochemistry.[1–6] One approach has exploited appropriate metal centers that are linked through suitable polydentate ligands for the self-assembly of extended networks.[5–7] Polyfunctional rod-like ligands such as 4,4'-bipyridine are effective tethers for construction of extended solids with diverse topologies.[8–13] Another approach relies on linking molecular cluster subunits from the vast family of chemically robust polyoxoanions, either through direct condensation to form oxo-bridged arrays of clusters[14] or through transition metal coordination compounds acting as inorganic bridging ligands.[15] The diversity of topologies adopted by metal–4,4'-bpy (bpy = bipyridyl) solids and the variability in the channel dimensions associated with these structures suggested that metal oxide clusters or low-dimensional subunits could be incorporated into the void space in the $\{M(4,4'\text{-bpy})_x\}^{n+}$ scaffolding. This in effect combines the two strategies for molecular design of solids and provides a route to composite organic/inorganic materials. This expectation has been realized in the isolation and characterization of **1** and **2**, which were constructed from $[Mo_8O_{26}]^{4-}$ clusters incorporated within the scaffolding afforded by $\{Cu(4,4'\text{-bpy})\}_n^{n+}$ and $\{Ni(H_2O)_2(4,4'\text{-bpy})_2\}_n^{2n+}$ subunits, respectively. In addition, $\mathbf{3}\cdot 8H_2O$, which exhibits infinite one-dimensional $\{Mo_{15}O_{47}\}_n^{4n-}$ chains within a matrix of $[Cu(4,4'\text{-bpy})]^+$ subunits, was also isolated and characterized.

$[\{Cu(4,4'\text{-bpy})\}_4Mo_8O_{26}]$ **1**

$[\{Ni(H_2O)_2(4,4'\text{-bpy})_2\}_2Mo_8O_{26}]$ **2**

$[\{Cu(4,4'\text{-bpy})\}_4Mo_{15}O_{47}]\cdot 8H_2O$ $\mathbf{3}\cdot 8H_2O$

Compound **1** was synthesized as blue blocks in 46% yield by the hydrothermal reaction of $CuSO_4\cdot 5H_2O$, MoO_3, 4,4'-bipyridine, and water in the molar ratio 1:2.2:2:1930 at 200 °C for 96 h. The infrared spectrum of **1** exhibited intense bands at 890 and 920 cm^{-1}, attributed to ν(Mo=O), and features at 1610, 1390, 1360, and 1340 cm^{-1} characteristic of 4,4'-bipyridine.

The structure of **1**[16] is constructed from two subunits, δ-$[Mo_8O_{26}]^{4-}$ clusters and $[Cu(4,4'\text{-bpy})]^+$ linear chains. The anionic unit consists of a $\{Mo_6O_6\}$ ring that is capped on opposite poles by tripodal $\{MoO_4\}$ tetrahedra. The central ring of this cluster is made up of two pairs of edge-sharing octahedra bridged by two $\{MoO_4\}$ tetrahedra, each adopting a bipodal, corner-sharing motif. The α, β, and γ isomers of $[Mo_8O_{26}]^{4-}$ have been isolated in a number of salts,[17] and the δ form has been reported as the $(\alpha-\delta)$ or $(\beta-\delta)$ "intermediate" structure in $[(RhCp^*)_2(\mu_2\text{-}SCH_3)_3]_4[Mo_8O_{26}]\cdot 2CH_3CN$.[18] The cation component $[Cu(4,4'\text{-bpy})]^+$ provides the scaffolding as chains of digonally coordinated CuI centers. The relative orientation of the chains is unusual and results in cavities within the scaffolding that accommodate the $[Mo_8O_{26}]^{4-}$ units. There are two distinct chain environments forming a right angle or virtual square network. The chains associated with the Cu1 site form pairs of parallel, face-to-face rods that run parallel to the crystallographic *a* axis. Propagation of this motif in the *ab* plane results in a bilayer of parallel $\{Cu(4,4'\text{-bpy})\}_n^{n+}$ strands. The parallel orientation of the aromatic rings within the chains allows a close approach of the paired chains within the bilayer. In contrast, the chains associated with the Cu2 site exhibit a 44.3° twist between the rings of the bipyridyl units, which precludes close approach of a neighboring strand. The Cu2 chains are at right angles to the Cu1 bilayers, run parallel to the crystallographic *b* axis, and propagate as parallel strands in the *ab* plane.

The $[Mo_8O_{26}]^{4-}$ clusters occupy cavities defined by two adjacent pairs of Cu1 chains and one Cu2 strand from each of two adjacent layers. The terminal oxo group of one tripodal Mo site exhibits weak long-range interactions of 2.555(5) and 2.691(4) Å with the Cu1 sites, while oxo groups of tetrahedral and octahedral ring Mo sites display essentially non-bonding interactions with the Cu2 sites. This long-range connectivity provides a virtual layer structure, in which the Cu1 bilayers and $[Mo_8O_{26}]^{4-}$ subunits are sandwiched between the layers of parallel $\{Cu(2)(4,4'\text{-bpy})\}_n^{n+}$ strands (Figure 1). Adjacent layers are slotted together since alternate Cu2 strands interact with $[Mo_8O_{26}]^{4-}$ clusters of an adjacent layer.

Modification of the coordination polymer scaffolding in these materials can be readily accomplished by introducing a d-block cation with coordination requirements different from those of Cu^I, such as Ni^{II} for which octahedral geometry is most common. The reaction of $NiCl_2\cdot 6H_2O$ with MoO_3 and 4,4'-bipyridine yielded **2** as light blue plates in about 60% yield.

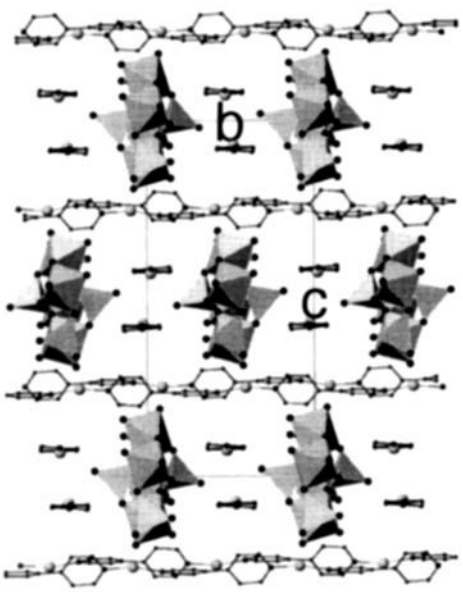

Figure 1. The virtual layer structure of **1** as viewed perpendicular to the *bc* plane. The $[Mo_8O_{26}]^{4-}$ subunits exhibit only weak interactions with the Cu coordination polymers.

The structure of **2**[19] is constructed from novel ε-$[Mo_8O_{26}]^{4-}$ clusters and $\{Ni(H_2O)_2(4,4'\text{-bpy})_2\}_n^{2n+}$ 1-D zig-zag chains. The molybdate cluster adopts an unprecedented structure consisting of six $\{MoO_5\}$ square pyramids and two $\{MoO_6\}$ octahedra linked by edge-sharing interactions into an ellipsoidal cluster, whose major axis is defined by the vector joining the octahedral sites. The geometry adopted by this ε-$[Mo_8O_{26}]^{4-}$ subunit reflects the steric constraints imposed by the polymer scaffolding of the $[Ni(H_2O)_2(4,4'\text{-bpy})]_n^{2n+}$ motif. The cationic component forms zig-zag chains of *fac*-$\{NiO_3N_3\}$ octahedra linked through bridging, bidentate 4,4'-bpy groups. Each Ni^{II} site of the chain is coordinated to nitrogen donors from three 4,4'-bpy ligands, two aqua ligands, and a terminal oxo group from the molybdate cluster subunit. Since the 4,4'-bpy groups occupy *cis* positions on the Ni^{II} sites, the $\{Ni(H_2O)_2(4,4'\text{-bpy})_2\}_n^{2n+}$ chain has a fold of about 90° at each Ni atom. It is noteworthy that the third bpy unit of each Ni center adopts monodentate coordination. The pendant bpy groups of adjacent $\{Ni(H_2O)_2(4,4'\text{-bpy})_2\}_n^{2n+}$ chains project into the interchain region to form π-stacked pairs, which define the boundaries of the interchain cavity.

The polymeric scaffolding of **2** is connected to the polyoxoanion clusters by covalent bonding of the terminal oxo group of one Mo center to the Ni^{II} site. This produces a 3-D covalent framework with "chains" of $[Mo_8O_{26}]^{4-}$ groups incorporated within the polymeric $\{Ni(H_2O)_2(4,4'\text{-bpy})_2\}_n^{2n+}$ backbone. The anionic subunits are confined within a rectangular channel defined by neighboring $\{Ni(H_2O)_2(4,4'\text{-bpy})_2\}_n^{2n+}$ strands and the pendant 4,4'-bpy groups that project from these strands (Figure 2). The ellipsoidal structure adopted by the $[Mo_8O_{26}]^{4-}$ moiety in **2** conforms to the shape constraints thus imposed.

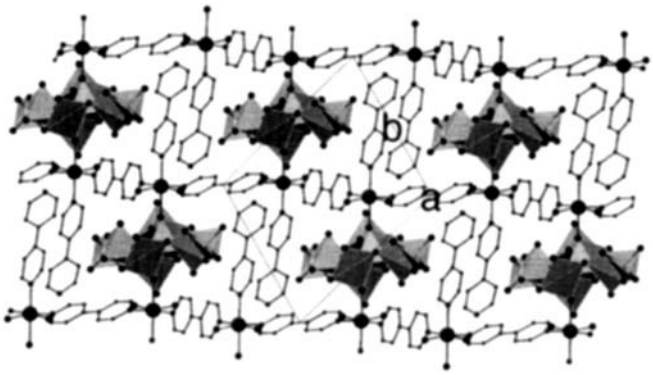

Figure 2. Crystal structure of **2**. Connectivity of the cluster subunits to the polymeric cationic chains results in a 2-D framework of molybdenum oxide clusters incorporated in a coordination polymer scaffolding.

Compound **3** was prepared as brown blocks in 10% yield (the stoichiometry of the starting materials was identical to that for **1**) again by heating at 200 °C, but only for 24 h. Heating time is crucial to the synthesis of **3** as longer times yield mixtures of **1** and **3** or **1** exclusively. The infrared spectrum of $\mathbf{3}\cdot 8H_2O$ is characterized by intense bands at 885 and 930 cm^{-1}, attributed to $\nu(Mo{=}O)$, and bands at 1605, 1385, 1365, and 1330 cm^{-1} for the 4,4'-bipyridine group.

The structure of $\mathbf{3}\cdot 8H_2O$[20] is constructed from $\{Mo_{15}O_{47}\}_n^{4n-}$ chains parallel to the crystallographic *a* axis and $\{Cu(4,4'\text{-bpy})\}_n^{n+}$ rods parallel to the *b* axis. There are two dis-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3608-0874 $ 17.50+.50/0

tinct Mo environments. The Mo1 sites form chains of *trans*, corner-sharing octahedra and have two terminal, one doubly bridging, and three triply bridging oxo groups. Two Mo1 chains are linked by a double chain of Mo2 centers, which is constructed from *cis*-planar, edge-sharing octahedra. Each Mo2 site has a single terminal, one doubly bridging, and four triply bridging oxo groups. The terminal oxo group of each Mo1 site is directed toward a Cu^{I} site of the $\{Cu(4,4'\text{-bpy})\}_n^{n+}$ rods that extend at right angles to the $\{Mo_{15}O_{47}\}_n^{4n-}$ chains. The result is an inorganic virtual layer of parallel molybdenum oxide chains that is sandwiched between organic/inorganic composite layers; water molecules of crystallization occupy the interstrand region (Figure 3).

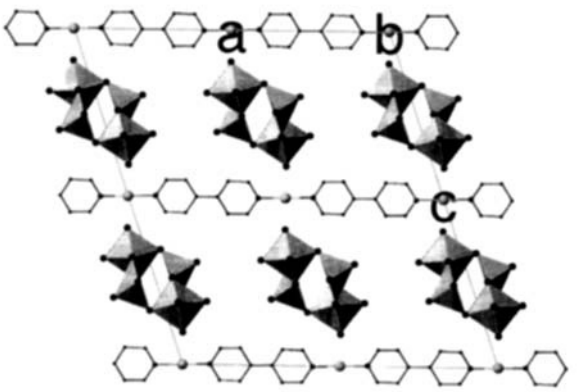

Figure 3. Inorganic virtual layers of parallel $\{Mo_{15}O_{47}\}_n^{4n-}$ chains as viewed parallel to the *c* axis. $\{Cu(4,4'\text{-bpy})\}_n^{n+}$ rods occupy the interlayer region.

A noteworthy feature of the structure of $\mathbf{3}\cdot 8H_2O$ is the polyhedral connectivity within the $\{Mo_{15}O_{47}\}_n^{4n-}$ chains, which is distinct from that reported for the 1-D molybdenum oxides $K_2Mo_3O_{10}$,[21] $(NH_4)_2Mo_3O_{10}$,[22] $(H_3NCH_2CH_2NH_3)Mo_3O_{10}$,[23] $(H_3N(CH_2)_6NH_3)Mo_3O_{10}$,[24] and $Na(NH_4)Mo_3O_{10}$.[24] Furthermore, refinement of the population parameters of the sites occupied by one molybdenyl unit confirms partial occupancy of about 0.875. This is consistent with the formulation of $\{Mo_{15}O_{47}\}_n^{4n-}$ for the chain, which fulfills the charge requirements of the $[Cu(4,4'\text{-bpy})]^{1+}$ scaffolding, rather than the putative $\{Mo_{16}O_{48}\}$ for the chain without defects. While charge considerations and structure refinement demonstrate that one of every eight Mo2 sites is vacant, the absence of reflections associated with a superstructure suggests that the vacancies are not ordered, but randomly dispersed along the chain.

The title compounds **1** and **2** demonstrate that members of the vast family of polyoxoanion clusters may be employed as structural motifs in designing solid-state materials. Since the structural variability of the cationic scaffolding extends to 1-D, 2-D, and 3-D coordination polymers with tunable void volumes, a variety of polyanion clusters and even low dimensional metal oxides may serve as anionic components. This versatility has been realized in the isolation of $\mathbf{3}\cdot 8H_2O$, which contains molybdenum oxide chains separated by $[Cu(4,4'\text{-bpy})]_n^{n+}$ strands. It would appear that this synthetic approach provides a method for structural modification of metal oxide solids and, consequently, tuning of electronic, magnetic, and optical properties of the oxide phases. However, the architecture of the coordination polymer scaffolding cannot be predicted, and it is not clear whether the cluster or the polymer serves as the reaction template. One approach to resolving this question may be to employ preformed clusters at lower temperatures. Alternatively, 2-D or 3-D polymer frameworks may allow some control of the packing of the organometallic components, which is absent in 1-D chains. We are currently exploring such alternative synthetic designs.

Experimental Section

The syntheses were performed in 23 mL Teflon-lined stainless steel vessels filled to 30–50% capacity.

1: A mixture of $CuSO_4\cdot 5H_2O$ (0.0418 g), MoO_3 (0.051 g), 4,4′-bipyridine (0.050 g), and H_2O (10 mL) in the molar ratio 1:2.2:2:3470 was heated at 200 °C for 96 h to give orange-brown blocks of **1** (0.08 g) and an unidentified black powder. Compound **1** is diamagnetic over the temperature range 50–300 K, which is consistent with the Cu^{I} oxidation state.

2: A mixture of $NiCl_2\cdot 6H_2O$ (0.040 g), MoO_3 (0.122 g), 4,4′-bipyridine (0.053 g), and H_2O (10 mL) in the molar ratio 1:5:2:3270 was heated at 160 °C for 72 h to give light blue crystals of **2** (0.10 g). Compound **2** exhibits a room-temperature magnetism μ_{eff} of 3.17 μ_B, which is consistent with the Ni^{II} oxidation state.

$\mathbf{3}\cdot 8H_2O$: A mixture of $CuSO_4\cdot 5H_2O$ (0.042 g), MoO_3 (0.051 g), 4,4′-bipyridine (0.050 g), and H_2O (10 mL) in the molar ratio 1:2.2:2:3470 was heated at 200 °C for 24 h to give brown blocks of $\mathbf{3}\cdot 8H_2O$ in about 10% yield. Compound **3** is diamagnetic over the 50–300 K temperature range.

An FT–Raman Study of the Template–Framework Interaction in $AlPO_4$-Based Molecular Sieves

Sunil Ashtekar, Patrick J. Barrie,* Mark Hargreaves, and Lynn F. Gladden*

The role played by the organic template in the synthesis of zeolite and $AlPO_4$-based molecular sieves is a poorly understood but frequently discussed topic.[1] $AlPO_4$-based molecular sieves are formed from the hydrothermal treatment of reactive gels containing an organic base; the organic base is typically an amine or quaternary ammonium complex. Incorporation of silicon into the framework leads to SAPO molecular sieves, and incorporation of a metal (Me; for example Zn, Mn, Mg, Co) leads to MeAPO species.[2] Some structures may be formed with many different templates, while others require very specific templating species to be present.[3] The commercial importance of molecular sieves means that there is an increasing need to understand more about the template–framework interactions that affect their synthesis.

Recently a number of computational studies have attempted to provide insight into the template–framework interaction.[4] There are, however, problems in choosing appropriate force fields and modeling the Coulombic interactions that exist between the framework and the template. Single-crystal X-ray diffraction and ^{13}C solid-state NMR studies on the template structure and position are frequently hampered by considerable disorder in the template location, particularly for SAPO materials.[5] In this communication we show that FT–Raman spectroscopy is an effective probe of the organic template and so has the potential to examine template–framework interactions. Since the development of near-infrared Fourier transform methods, Raman spectroscopy has undergone a renaissance with much improved signal-to-noise ratios.[6] The different selection rules from conventional infrared spectroscopy results in only weak scattering from the molecular sieve framework, and so the organic template may readily be studied.

[**] We thank BNFL for provision of the Raman spectrometer.

In this study FT–Raman spectra have been obtained of morpholine within SAPO-34 and MeAPO-34 (Me = Zn, Mn, or Mg) and of cyclohexylamine within SAPO-44 and MeAPO-44 species. Both the 34 and 44 structure types are based on the framework of the zeolite chabazite, and they are selective catalysts for the formation of olefins from methanol.[7] The synthesis and characterization of the samples investigated has been reported in detail, and the Brønsted acid sites in the calcined samples have been assessed quantitatively by temperature-programmed desorption of ammonia.[8] Spectral assignments reported in this communication were aided by Raman measurements on liquid morpholine, cyclohexylamine, piperidine, and tetrahydropyran in both neutral and protonated forms.

Figure 1 shows the N–H and C–H stretching region of the Raman spectrum of morpholine, protonated morpholine, as-prepared SAPO-34, and three MeAPO-34 samples. In neutral

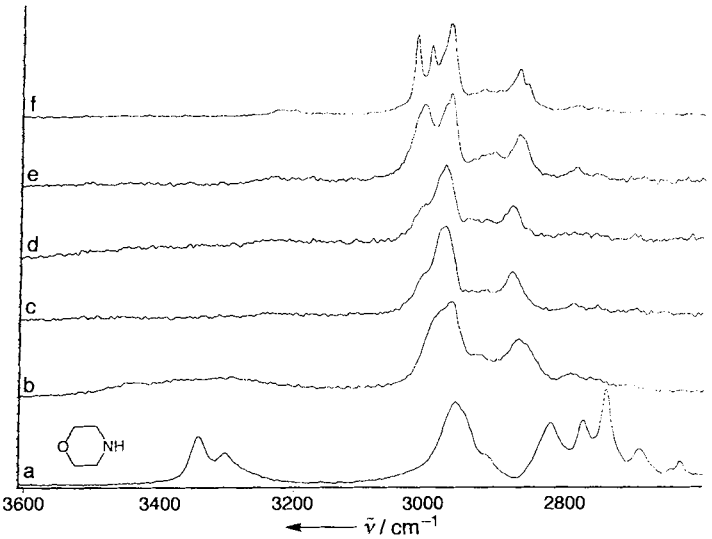

Figure 1. FT–Raman spectra of morpholine (a) and protonated morpholine (b), as well as of morpholine in SAPO-34 (c), MgAPO-34 (d), MnAPO-34 (e), and ZnAPO-34 (f) in the region 2500–3600 cm^{-1}. The analysis of the chemical composition of the samples determined by ICP/AES yielded the following relative amounts of framework elements: Si 0.164, Al 0.480, P 0.354 in SAPO-34; Mg 0.16, Al 0.35, P 0.49 in MgAPO-34; Mn 0.13, Al 0.42, P 0.45 in MnAPO-34; Zn 0.21, Al 0.28, P 0.51 in ZnAPO-34. The spectra were obtained on a Nicolet Magna-IR 750 spectrometer equipped with a Raman module and an InGaAs detector. The samples were exposed to a laser power of 300–500 mW at an excitation wavelength of 1064 nm (Nd:YAG laser). Two hundred scans were co-added. The spectral resolution was 4 cm^{-1}. An FT–Raman spectrum of CoAPO-34 was not informative due to the strong cobalt d–d absorption band in the near-infrared region.

morpholine two N–H stretching bands are clearly observed at 3342 and 3302 cm^{-1}. The six-membered ring of morpholine will be in the chair conformation, and the higher frequency band is assigned to the conformation with the nitrogen atom's lone pair in the axial position, while the lower frequency band has this lone pair in the equatorial position.[9] The CH_2 stretching region normally occurs at 2850–3000 cm^{-1}, and the band at 2962 cm^{-1} and the shoulder at 2922 cm^{-1} in liquid morpholine can be attributed to antisymmetric stretching of $CH_2(O)$ and $CH_2(N)$ groups. The region 2700–2830 cm^{-1}, known as the Bohlmann region, contains principally overtone and combination bands enhanced by Fermi resonance.[10] These have considerable intensity for morpholine and depend mainly on the presence of a lone pair on the heteroatom adjacent to the CH_2 group.[9, 11, 12]

Addition of dilute hydrochloric acid to morpholine protonates the amine group, resulting in loss of the simple N–H stretch. In general, NH_2^+ vibrations give rise to weak Raman bands below 3000 cm^{-1}, which tend to be masked by the more intense CH_2 asymmetric vibrations. Protonation of the amine group also removes the intense Bohlmann bands in the region 2700–2830 cm^{-1}, as there is no longer any lone pair on the nitrogen atom. Thus the main spectral features of protonated morpholine are antisymmetric CH_2 vibrations (overlapping bands at 2983 and 2970 cm^{-1}) and symmetric CH_2 vibrations (2871 cm^{-1}); the latter are possibly affected to some extent by the lone pair on the oxygen atom.

The spectra of as-prepared SAPO-34 and MgAPO-34 are similar to that of protonated morpholine but the signals are slightly shifted to higher wavenumber: the major bands are now at 3012/2981 cm^{-1} and 2882 cm^{-1}. This shift is probably a reflection of the confined space around the organic molecule. The spectrum thus confirms that the organic template is in the protonated form, which is to be expected given that the samples were prepared under mildly acidic pH conditions.[8]

In the case of MnAPO-34 the CH_2 antisymmetric stretch is now split into two resolved bands, at 3014 and 2975 cm^{-1}, while in ZnAPO-34 three bands are observed at 3026, 3004, and 2977 cm^{-1} (Figure 1). This provides clear evidence the template structure or location in MnAPO-34 and ZnAPO-34 is different from that in SAPO-34, and thus that there are different template–framework interactions within them. The most likely interactions are hydrogen bonding between any Brønsted OH acid groups in the framework and the oxygen atom of the morpholine, and between the NH_2^+ hydrogens and oxygen atoms in the framework. Such hydrogen bonding interactions are expected to cause some changes in vibrational frequency. Maximizing these favorable interactions with the framework may also cause the morpholine molecule to adopt different conformations within the pore space (e.g., chair and boat conformations), and this could cause the peak splittings that are observed here.

A similar series of spectra were obtained of SAPO-44 and MeAPO-44 species with cyclohexylamine as templating agent. The neutral template as a pure liquid shows two NH_2 bands, due to symmetric and antisymmetric stretches, and strong bands in the Bohlmann region as well as the expected CH_2 vibrations. Protonation of cyclohexylamine results in a simpler FT–Raman spectrum with three strong bands at 2949 (asymmetric CH_2 stretch), 2908 (CH stretch) and 2863 cm^{-1} (symmetric CH_2 stretch).[12, 13] The spectra of SAPO-44, MgAPO-44, MnAPO-44, and ZnAPO-44 are virtually identical to this spectrum of protonated cyclohexylamine, but with a small shift (2–8 cm^{-1}) to higher wavenumbers for all three main bands. In contrast to the situation for morpholine within MeAPO-34 species, no additional peaks are observed in the cyclohexylamine/MeAPO-44 system. This is indicative of less interaction between the template and the framework, and probably reflects the fact that cyclohexylamine does not contain any oxygen atom to which hydrogen bonding might occur.

Figure 2 shows the FT–Raman spectra in the low frequency region for morpholine and the various element-substituted 34 framework structures. In conventional IR spectroscopy this region is dominated by the tetrahedral stretching motions of the framework, and little information on the template can normally be gleaned. By contrast, the FT–Raman spectra are dominated by the organic template. For pure liquid morpholine, fundamental bands such as methylene scissor (1460 and 1444 cm^{-1}), wag (1305 cm^{-1}), twist (1202 cm^{-1}), and rocking motions are observed in this region, together with the symmetric CNC stretch (910 cm^{-1}) and a ring-breathing motion (834 cm^{-1}).[12]

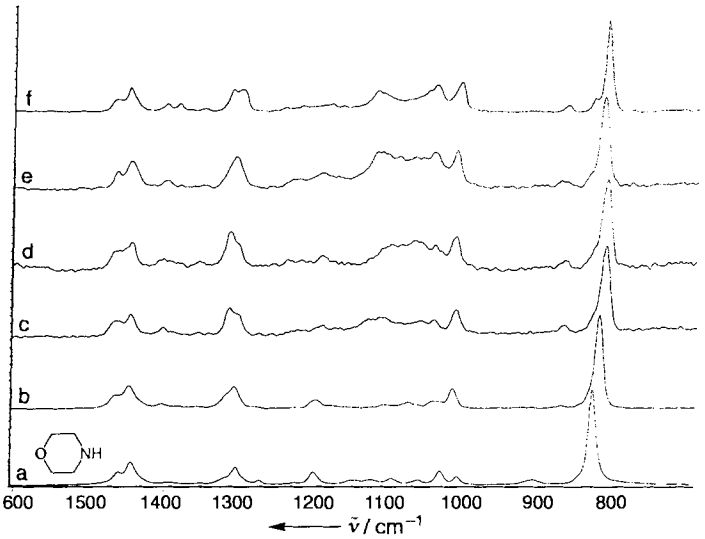

Figure 2. FT–Raman spectra of morpholine (a) and protonated morpholine (b), as well as morpholine in SAPO-34 (c), MgAPO-34 (d), MnAPO-34 (e), and ZnAPO-34 (f) in the region 600–1600 cm^{-1}.

Upon protonation, most of the methylene bands shift by about 4 cm^{-1} to higher frequency; there is now a symmetric CN^+C band at 876 cm^{-1}, and the ring-breathing motion occurs at lower frequency (825 cm^{-1}). The spectra of SAPO-34 and MeAPO-34 species show small changes in frequency and relative intensity relative to that of the signals of pure protonated morpholine, with some additional peaks that are again indicative of interactions between template and framework.

In conclusion, FT–Raman spectroscopy allows a vibrational spectrum of the organic template occluded in molecular sieves to be obtained with little interference from the framework. Small increases in vibrational frequency are observed that probably relate to the confined space around the organic template. In the case of morpholine within MeAPO-34 species, significant peak splittings occur, indicating a strong template–framework interaction and a possible change in conformation of the organic molecule. Although Raman spectroscopy has not revealed precise information about the nature of template–framework interactions, it does show that differences exist between the samples studied. The unexpected behavior observed for the morpholine/$AlPO_4$-34 system is an interesting result that warrants further investigation by other techniques.

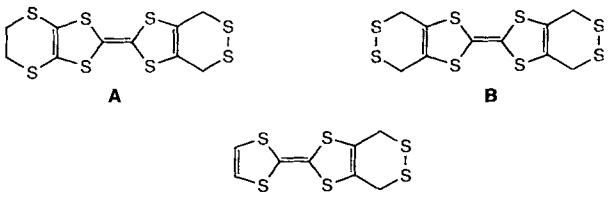
Studies of the First S-Position Isomer of Bis(ethylenedithio)tetrathiafulvalene**

Piétrick Hudhomme,* Philippe Blanchard,* Marc Sallé, Soazig Le Moustarder, Amédée Riou, Michel Jubault, Alain Gorgues, and Guy Duguay

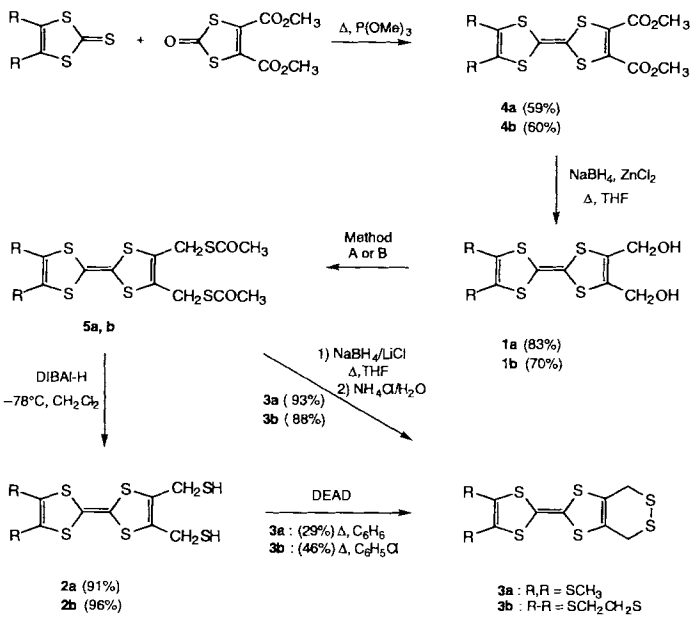
Over the last two decades chemical modifications of the tetrathiafulvalene (TTF) framework[1] have been developed to favor enhanced dimensionality in the related charge-transfer salts.[2] One of the most promising strategies consists of introducing additional sulfur atoms at the periphery of the TTF skeleton. In particular, the famous bis(ethylenedithio)-TTF (BEDT-TTF) is known to form superconducting salts with the highest T_c yet observed for that series;[3, 4] all of them exhibit two-dimensional (2-D) character (for example β and κ phases). The prominent role of the outer sulfur atoms has also been recognized in highly conducting or superconducting salts of TTF derivatives.[5–7]

We therefore focused our attention on the peripheral S-position isomers of BEDT-TTF and (ethylenedithio)-TTF (EDT-TTF) **A**, **B**, and **C** as new synthetic targets. Our general synthetic strategy for these is based on 1) conversion of the appropriate vicinal bis(hydroxymethyl)-TTF **1**[8] into its corresponding, new bis(sulfanylmethyl)-TTF **2** and 2) disulfide bridge formation by selective, intramolecular, oxidative ring closure.



A **B** **C**

We present here a straightforward access to new **3a** and **3b** by the steps shown in Scheme 1 and report on their π-donor ability. The latter is demonstrated by preliminary electrooxidation experiments with generation of the radical cation salts **3a**·PF_6 and **3a**·ClO_4, whose X-ray structures are presented together with that of neutral **3a**.



Scheme 1. **a**: R, R = SCH_3; **b**: R-R = SCH_2CH_2S. Synthesis of the disulfide TTFs **3** from bis(hydroxymethyl)-TTFs **1**. Method A: DEAD/PPh_3, CH_3COSH, THF, **5a**: 58%. Method B: $Me_2NCH(OEt)_2$, CH_3COSH, Δ, CH_2Cl_2. **5a**: 59%, **5b**: 60%.

The starting materials **1a** and **1b** were prepared by our standard procedure.[8c] Cross-coupling (with $P(OMe)_3$) of two 2-thioxo-1,3-dithiole or 2-oxo-1,3-dithiole moieties afforded the unsymmetrical 2,3-dimethoxycarbonyl derivatives **4a** and **4b**. Reduction of the ester functionalities gave **1a** and **1b** in 83 and 70% yield, respectively. Although the obvious reaction sequence starting from **1** (tosylation or bromination followed by nucleophilic displacement with sodium hydrosulfide) failed,[9] the Mitsunobu reaction[10] could be used. Thus, a one-pot conversion into **5a** was achieved by treatment of **1a** with the diethyl azodicarboxylate/triphenylphosphane (DEAD/PPh_3) complex and subsequent in situ displacement of the resulting leaving group with thiolacetic acid, as described by Volante.[11] However, in the case of compound **1b** this procedure was not convenient due to the well-known sensitivity of the ethylenedithio bridge with respect to bases.[12] The hydroxy group was therefore activated with *N*,*N*-dimethylformamide dialkylacetal.[13] By treatment of **1b** with excess thiolacetic acid and *N*,*N*-dimethylformamide diethylacetal, the corresponding bis(thiolester) **5b** was formed in 60% yield. Compound **5a** was obtained from **1a** in 58% yield by the same route.[14] The dithiols **2a** and **2b** were then generated by reduction and isolated in 91 and 96% yields, respectively, as orange/red, crystalline powders after purification on florisil and recrystallization.[15] Oxidative conversion of the dithiols into the disulfides[16] was first attempted for **2a** with iodine in acetone/ethanol: a dark green charge-transfer complex formed rapidly as a result of the π-do-

[**] Financial support was provided by the CNRS, the Ministère de l'Enseignement Supérieur et de la Recherche (MESR; research studentship for P. B.), and the Ville d'Angers (grant for S. L. M.). We thank Dr. S. Jobic, Institut des Matériaux de Nantes, for extended Hückel calculations.

nating ability of the TTF framework. This slowly converted into the neutral disulfide **3a**, which was isolated (55%) as red, shiny crystals after chromatography on SiO_2. This procedure gave poor reproducibility in the case of **3b**, but, as expected, DEAD[17] promoted the required oxidation of **2a** to **3a** (29%) and of **2b** to **3b** (46%), the first peripheral S-position isomer of BEDT-TTF.[18] Furthermore, direct conversion of **5** to **3** could readily be achieved in a one-pot reaction by heating with $NaBH_4$ in the presence of LiCl in THF at reflux[19] and subsequent treatment with an aqueous ammonium chloride solution and air oxidation (**3a**: 93%, **3b**: 88%).

Single crystals of neutral **3a** were obtained by recrystallization from CH_2Cl_2/petroleum ether, and its molecular structure was determined by X-ray diffraction. As shown in Figure 1, the central TTF framework of **3a** is essentially planar, and both $S-CH_3$ bonds clearly deviate to the same side of the molecular plane (42 and 75°). As in the case of BEDT-TTF,[3a] the outer six-membered ring is highly distorted around the S–S bridge and adopts a half-chair conformation.

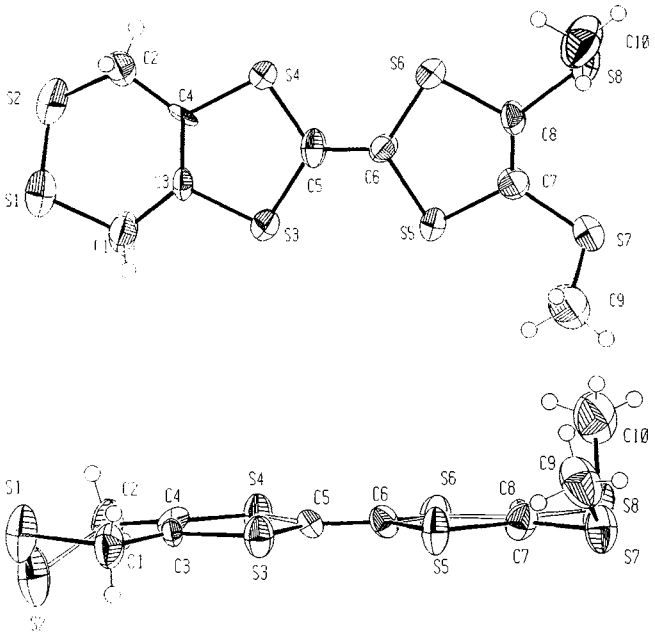

Figure 1. Two views of the crystal structure of **3a**. The TTF framework is essentially planar; the two $S-CH_3$ bonds deviate from this plane.

Calculation of the orbital coefficients of the HOMO of **3a** was carried out by the extended Hückel method. As expected, the HOMO is extended over the TTF framework and the sulfur atoms of the methylsulfanyl groups, while the outer sulfur atoms of the disulfide bridge have a poor contribution (Figure 2).

The cyclic voltammograms of these new π donors (D) exhibit two reversible, one-electron oxidation peaks at E_{pa1} and E_{pa2} (Table 1). This indicates good stability of the corresponding radical cation D^{+} and dication D^{++} and is consistent with two reversible steps: $D \rightleftharpoons D^{+} \rightleftharpoons D^{++}$. The redox potentials of **3b** are very similar to those of BEDT-TTF.

Shiny, black, needle-like single crystals of **3a**·PF_6 and **3a**·ClO_4 were grown on a platinum wire anode by oxidation of the donor **3a** in solutions of Bu_4NPF_6 or Bu_4NClO_4 (0.1 M in chlorobenzene) at constant, low-current density (0.5 $\mu A\,cm^{-2}$).

Both salts crystallize in the $P2_1/c$ space group and are isostructural; they each contain one independent donor molecule in the unit cell. As shown in Figure 3, the donor moiety of

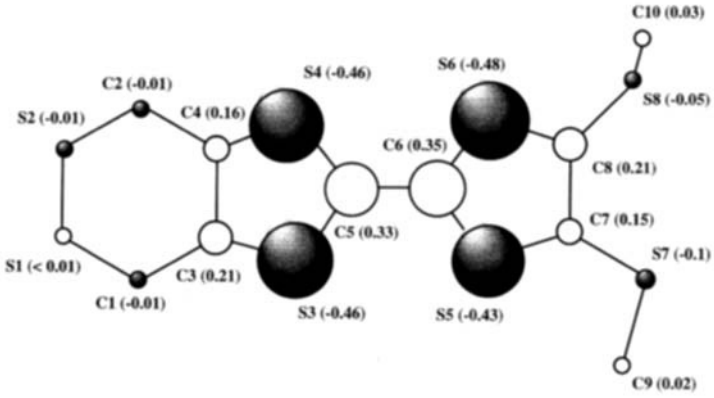

Table 1. Oxidation potentials E_{pa1} and E_{pa2} of disulfide TTFs **3a,b** and several other compounds for comparison as determined by cyclic voltammetry. Conditions: standard calomel electrode, Pt electrode, 20 °C, nitrogen atmosphere, Bu_4NPF_6 (0.1 M in CH_2Cl_2), scan rate 0.1 Vs^{-1}, [compound] = 10^{-3} M.

Compound	E_{pa1} [V]	E_{pa2} [V]	ΔE_p [V]
BEDT-TTF	0.51	0.92	0.41
3a	0.51	0.91	0.40
3b	0.49	0.93	0.44
2a [20]	0.49	0.90	0.41
2b [20]	0.48	0.90	0.42
5a	0.50	0.89	0.39
5b	0.48	0.91	0.43

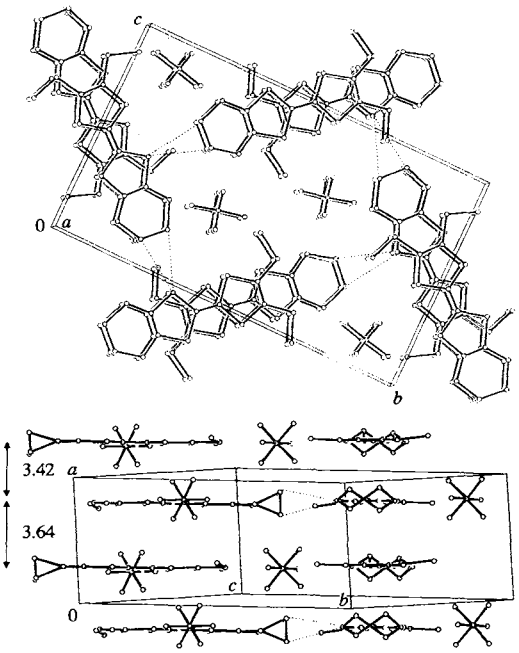

Figure 3. Two views of the stacking mode of **3a**·PF_6. Top: Projection onto the *bc* plane; outer sulfur atoms are engaged in S···S interstack contacts. Bottom: View perpendicular to the stacking axis *a*; donor molecules are stacked in a head-to-tail manner.

3a·PF_6 is almost planar except for the terminal disulfide bridge. These sulfur atoms are found together in two positions with an occupation ratio of 57:43 and are associated with two highly distorted half-chair conformations of the external disulfide

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3608-0879 $ 17.50+.50/0

heterocycle [d(S1a–S2a) = 2.015(8) and d(S1b–S2b) = 2.05(1) Å]. In contrast to the neutral molecule, the two external S–CH_3 bonds in **3a**·PF_6 extend roughly in the molecular plane with dihedral angles of 8.15 and 3.95° for C9-S7-C7-S5 and C10-S8-C8-S6, respectively. This marked conformational difference between the neutral and the oxidized states has been observed in other cation radical salts of MeS-substituted TTF derivatives[21] and results in a compact packing mode of the crystallographic network of the **3a**·PF_6 salt. As expected, the C5–C6 bond length of the donor moiety increases in **3a**·PF_6 [d(C5–C6) = 1.368(13) Å] relative to **3a** [d(C5–C6) = 1.347(15) Å].[22]

Donor molecules are stacked along the a axis in a head-to-tail manner, which gives rise to dimer units in the column (intra- and interdimer distances of 3.42 and 3.64 Å respectively). There are several S···S contacts shorter than the sum of the van der Waals radii (3.70 Å) in the stack inside a dimer [d(S6–S'5) = d(S5–S'6) = 3.51, d(S3–S'8) = d(S8–S'3) = 3.51, d(S4–S'7) = d(S7–S'4) = 3.55 Å). A main feature of **3a**·PF_6 is the occurrence of the perpendicular donor array in the bc plane; because of their low orbital coefficients in the HOMO of **3a**, S1 and S2 are not expected to participate significantly in electron delocalization.[23] Nevertheless, both are clearly engaged in S···S interstack contacts as shown by short intermolecular distances within the bc plane (d(S1a–S3) = 3.59, d(S2a–S3) = 3.56, d(S1b–S3) = 3.63, d(S2b–S3) = 3.60 Å). Thus, the terminal disulfide bridge of **3a** seems to play a role in the association mode of the network.

Although no mixed-valence salts have yet been obtained from **3b**, efforts will be made to synthesize them as well as to apply the present synthetic methodology for **B** and **C**. Noteworthy is the straightforward access of unprecedented sulfanylmethyl TTFs. The latter are also promising π donors due to their redox active TTF framework and their SH groups, which are prone to incorporation in hydrogen bond networks[2, 24] and are potent precursors to dithiolato complexes.[25]

Experimental Section

All new compounds present satisfactory analytical and spectroscopic data. X-ray structures were determined with an Enraf–Nonius MACH3 four-circle diffractometer.

3a: M.p. = 173–174 °C. ^{1}H NMR ($CDCl_3$): δ = 2.42 (s, 6H, SCH_3), 3.48 (s, 4H, CH_2SSCH_2). MS: m/z (%) = 386 (16, [$M^{\cdot+}$]), 324 (29), 322 (100), 307 (29), 274 (16), 172 (21). Elemental analyses calcd for $C_{10}H_{10}S_8$ (386.671): C 31.06, H 2.61, S 66.33; found: C 31.16, H 2.52, S 65.85.

Crystal data for **3a**: $C_{10}H_{10}S_8$, M_r = 386.67, red plates, 1 × 0.04 × 0.03 mm, monoclinic, $P2_1/c$, a = 5.096(5), b = 11.726(4), c = 25.804(7) Å, β = 94.88(5)°, V = 1536(2) Å^3, Z = 4, ρ_{calcd} = 1.665(1) g cm^{-3}, λ($Mo_{K\alpha}$) = 0.71073 Å, 5140 reflections ($2<\theta<30°$) were collected at 298 K, 861 with $I>3\sigma(I)$ were in the refinements, 163 refined parameters, R = 0.058, Rw = 0.059.

Crystal data for **3a**·PF_6: $C_{10}H_{10}S_8PF_6$, M_r = 531.67, black needles, 1 × 0.07 × 0.03 mm, monoclinic, $P2_1/c$, a = 7.088(9), b = 21.260(7), c = 12.763(4) Å, β = 87.64(6)°, V = 1922(3) Å^3, Z = 4, ρ_{calcd} = 1.838(1) g cm^{-3}, λ($Mo_{K\alpha}$) = 0.71073 Å, 6278 reflections ($2<\theta<30°$) were collected at 298 K, 1208 with $I>3\sigma(I)$ used in the refinements, 244 refined parameters, R = 0.056, Rw = 0.057. According to the two-probe technique, the conductivity of **3a**·PF_6 was lower than 10^{-5} S cm^{-1} at room temperature.

Crystal data for **3a**·ClO_4: $C_{10}H_{10}S_8ClO_4$, M_r = 486.15, black needles, 0.6 × 0.06 × 0.04 mm, monoclinic, $P2_1/c$, a = 7.039(5), b = 20.927(7), c = 12.551(4) Å, β = 92.93(5)°, V = 1846(2) Å^3, Z = 4, ρ_{calcd} = 1.749(1) g cm^{-3}, λ($Mo_{K\alpha}$) = 0.71073 Å, 3627 reflections ($2<\theta<25°$) were collected at 298 K, 688 with $I>3\sigma(I)$ used in the refinements, 168 refined parameters, R = 0.062, Rw = 0.064. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100062. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: Int. code +(1223) 336-033; e-mail: deposit@chemcrys.cam.ac.uk).

3b: M.p. = 236–238 °C (chlorobenzene). ^{1}H NMR (CS_2 + $CDCl_3$): δ = 3.27 (s, 4H, SCH_2CH_2S), 3.45 (s, 4H, CH_2SSCH_2). MS: m/z (%) = 384 (15, [$M^{\cdot+}$]), 322 (32), 320 (100), 294 (17), 292 (64), 216 (15), 172 (47). Elemental analysis calcd for $C_{10}H_8S_8$ (384.655): C 31.22, H 2.10, S 66.68; found: C 30.50, H 2.15, S 67.32.

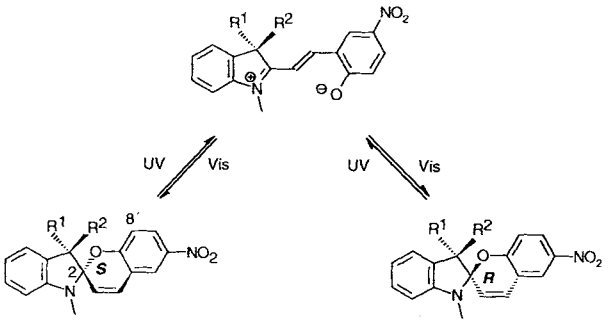
A Spiroindolinopyran with Switchable Optical Activity**

Lutz Eggers and Volker Buss*

Spiropyrans are photo- and thermochromic compounds of considerable technical interest. The physical basis for their use as optical filters, recording material, or in display devices[1] is the equilibrium between the colorless "closed" spiro and the colored "open" merocyanine form. Besides by thermal equilibration, interconversion between the two is effected by irradiation with UV and visible light, which shifts the equilibrium towards the open and closed form, respectively (Scheme 1).



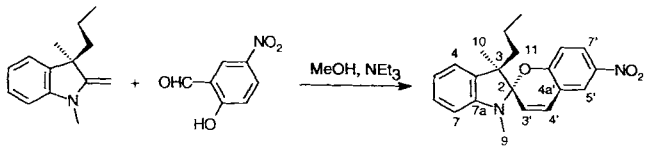
1 $R^1 = R^2 = CH_3$
2 $R^1 = CH_3$; $R^2 = C_3H_7$

Scheme 1.

All spiropyrans are chiral, since the spiro carbon atom C2 acts as a stereogenic center; if no other chiral source is present, the equilibrium between the two enantiomers (Scheme 1) is always 1:1. Separation of the enantiomers is only feasible in the dark and at temperatures low enough to prevent equilibration via the achiral merocyanine; at ambient temperatures any optical activity will rapidly decay. Miyashita[2] attempted to retain optical activity with a derivative of **1** by introducing a chiral substituent at C8'. The resulting diastereomers were seperated by fractional crystallization and showed an optical purity of 84:16. However, in solution the derivative epimerizes, and the optical activity resulting from the spiropyran moiety is lost.

The reason for the failure to conserve the optical activity can only be the distance between the two stereogenic sites, which is too large for sufficient chiral recognition. A better result may be expected by converting C3 (the α-position) into an asymmetric center. Gruda et al.[3,4] have studied compounds of this kind by synthesizing spiropyrans with two different substituents at C3 and found diastereomeric ratios between the two pairs of enantiomers varying between 2.5:1 and 1.3:1, depending on the substituents and solvent. Since no separation of enantiomers or diastereomers was attempted at any stage of the synthesis the question of optical activity connected with these compounds was never addressed. Here we report the successful synthesis of **2**, the first spiropyran with permanent optical activity.

Spiroindolinopyrans are conveniently prepared by condensation of a 2-methyleneindoline (Fischer base) with an *ortho*-hydroxybenzaldehyde.[1] One possible route to **2** is the reaction of the chiral Fischer base **3** with 2-hydroxy-5-nitrobenzaldehyde **4** (Scheme 2). The synthesis of **3** was reported recently.[5] Reaction with **4** in boiling methanol yields **2** as a tarry, reddish oil. Whereas achiral spiroindolinopyrans crystallize easily, all attempts to crystallize **2** failed—possibly already an indication of its chiral nature. Purification was achieved instead by column chromatography on silica gel.



3 **4** **2**

Scheme 2.

The existence of two diastereomers was confirmed by NMR spectroscopy. Whereas some unresolved signals remain in the ^1H NMR spectrum, all those that could be resolved appear in pairs with an intensity ratio of 1:1.6. This ratio, which is a measure of the chiral discrimination due to the C3 substituents, is in accordance with former results of Gruda et al.[4] A detailed ^1H NMR analysis of the parent 1,3,3-trimethylspiropyran **1**[6] was the basis for the assignment of both diastereomers of **2**. With the aid of CH-COSY and COLOC spectra a complete assignment of the ^{13}C NMR peaks (and of all resolved proton signals) was possible. NOE (NOE = nuclear Overhauser effect) difference experiments at 303 K were performed with the methylene signals of the propyl group of the two diastereoisomers: When the methylene protons H11* at $\delta = 1.51$ are irradiated (the asterix denotes the excess diastereomer), an NOE is observed at $\delta = 6.03$ (doublet) with the H3'* proton of the double bond. No NOE around $\delta = 6$ is detected when the H11 methylene signal at $\delta = 1.85$ is enhanced. These results prove unambiguously that in solution at 303 K the major isomer has oxygen on the less crowded (methyl) side of the spiropyran, a conclusion that Gruda et al.[4] tentatively arrived at on the basis of (unpublished) NOE experiments. A dynamic ^1H NMR exper-

iment revealed no change of the diastereomeric ratio at temperatures as low as 193 K.

While the relative orientation between the indolyl and the pyranyl part of the molecule can be elucidated by NMR spectroscopy, this method cannot exclude the possibility that the configuration at C3 is not maintained. The observation of permanent optical activity in **2** would be tantamount to confirmation of the integrity of the stereogenic center C3. This is indeed the case, as is revealed by a study of its chiroptical properties.

The UV/Vis spectra of **2** after irradiation with UV light (254 nm) and with visible light (>530 nm) are shown in Figure 1; these spectra reflect the photochromism of **2** and are practically identical to those of the parent compound **1**.

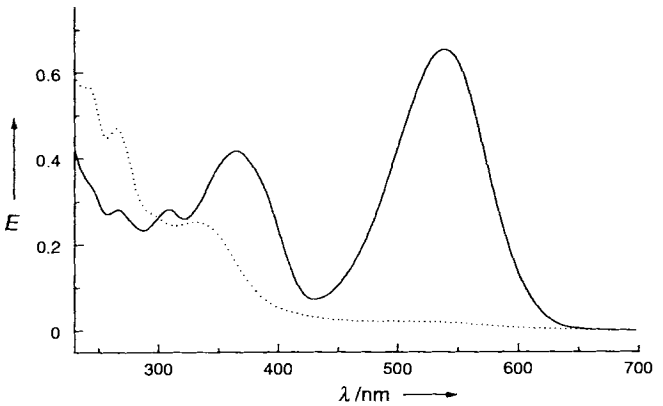

Figure 1. UV/Vis spectra of **2** [$c = 3.4 \times 10^{-5}$ mol L^{-1}, $d = 1$ cm] in ethanol/methanol (4/1) at 24 °C; (—) after irradiation with UV light, (····) after irradiation with visible light.

The CD (circular dichroism) spectra taken under these conditions are shown in Figure 2. At room temperature the spiro form is characterized by a negative absorption band around 250 nm, with a shoulder at 260 nm. After irridiation with UV light this absorption is reduced to about half of its prior intensity, because the equilibrium has been shifted towards the open form. The absence of any CD above 400 nm, the region of the strong merocyanine UV absorption, is not surprising: in the open form with its practically planar chromophore[1] the only remaining stereogenic center C3 is insufficient to induce observable CD in the cyanine band of **2**, as we have shown in comparable systems.[7] However, the asymmetric induction by C3 becomes apparent when, upon irradiation with visible light, the ring is closed again and the asymmetric center C2 is reestablished, since under these conditions the CD spectrum of the spiro form is completely restored. The reversibility of the photochromic equilibrium observed by CD proves that the configuration of the stereogenic center at C3 (R[8]) is stable; with this information the configuration of the predominant diastereomer can be deduced from the NOE experiments to be (2*S*,3*R*); the minor diastereoisomer is the (2*R*,3*R*) configuration.

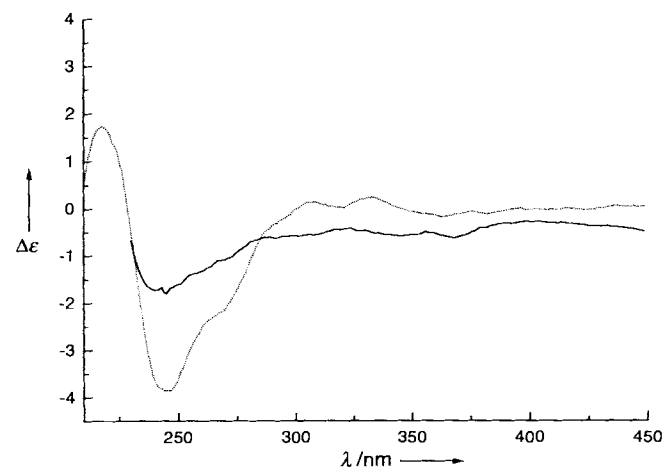

Figure 2. CD spectra of **2** [$c = 7.6 \times 10^{-4}$ mol L^{-1}, $d = 0.1$ cm] in ethanol/methanol (4/1) at 24 °C; (—) after irradiation with UV light, (····) after irradiation with visible light.

Some peculiar observations are made when samples are irradiated at different temperatures (Figure 3). When the closed form (spectrum ①) is cooled to −150 °C in the dark (spectral series ②), the shoulder at 260 nm becomes gradually more positive, while the intensity of the negative 245 nm band remains unaffected. These spectral changes do not reflect a change in diastereomeric composition, which is constant according to the dynamic ^{1}H NMR experiment, at least down to −80 °C. Also incompatible with an equilibrium shift is the constant spectral intensity of the 245 nm band. We therefore attribute the observed change in the 260 nm region to an independent dynamic process, for example freezing of the nitro group rotation or of the *N*-methyl group inversion.

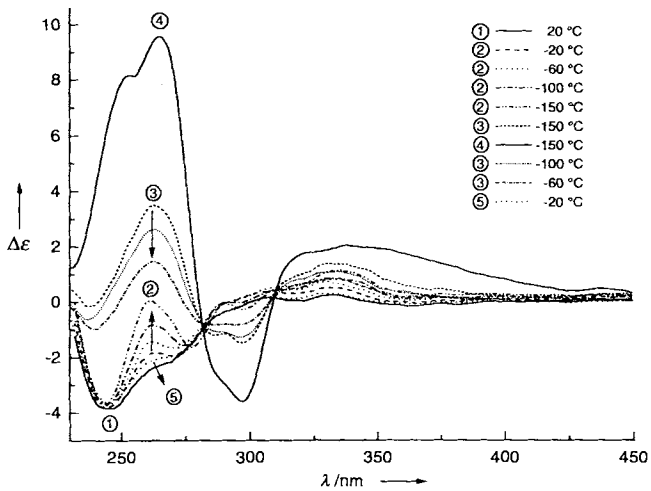

Figure 3. Temperature-dependent CD spectra of **2** [$c = 7.6 \times 10^{-4}$ mol L^{-1}, $d = 0.1$ cm] in ethanol/methanol (4/1); for irradiation conditions see text.

When this solution is irradiated at −150 °C with UV light, the negative 245 nm band disappears and a broad positive absorption with maximum at 260 nm appears instead (spectrum ③). The intensity of this band depends both on the temperature and the duration of the irradiation. Maximum positive absorbance, $\Delta\varepsilon_{max}$(250 nm) = 8, is obtained when the sample is continuosly irradiated with UV light at −150 °C (spectrum ④). At intermediate temperatures, the maximum positive absorbance is smaller ($\Delta\varepsilon_{max}$ = 7 and 2 at −100 and −50 °C, respectively). In these instances, irradiation with visible light has to follow UV irradiation in order to convert the merocyanine formed under these conditions into the closed form. At very low temperatures this is not necessary, because the spiro form is inherently more stable and the merocyanine concentration becomes very small. Regardless of the final shape of the spectrum, the original spectrum is slowly restored upon warming the sample in the dark (spectra ⑤ and ①).

The process that is manifest in the changes from spectra ② to ③ or ④ involves an equilibrium between two species, a fact that

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3608-0882 $ 17.50+.50/0

is clearly revealed by the existence of two isosbestic points. These two species are most probably the two diastereomeric spiropyrans, which equilibrate via the photochemically produced open merocyanine. Theoretical considerations support this conclusion. According to CNDO/S-calculations, the (2*S*,3*R*) isomer is characterized by two excited states, at 285 and 253 nm, with rotatory strengths of -15 and -29×10^{-40} cgs units, respectively. The corresponding values for the (2*R*,3*R*) isomer are 7 and 33×10^{-40} cgs, that is, the chiroptical properties are pseudo-enantiomeric, as expected. The positive amplitude of the 250 nm band is then a measure of the diastereomeric excess of (2*R*,3*R*) over (2*S*,3*R*). In spectra ① and ② (23% *de* of (2*S*,3*R*)-**2** over (2*R*,3*R*)-**2** determined experimentally), this band is negative.

Optically active spiropyrans might have useful applications as chiroptical switches.[9] Since the merocyanine form, which can be stabilized in a polymer matrix,[1] exhibits different chiroptical properties from the spiro form, information regarding the state of the compound ("open" or "closed") can be obtained by nondestructively reading the corresponding data, that is, the optical rotation or ellipticity. Also, because of their chirality optically active spiropyrans might be useful as photochemically switchable chiral dopants, for example, in liquid crystal displays.[10]

A second switch is based on the temperature-dependent inversion of the diastereomeric composition[11] ("diastereomeric switch"). Writing would be achieved by irradiating the "frozen" room-temperature equilibrium of **2** with UV light; for reading any chiroptical property (for example, optical rotation outside the absorption region of the two diastereomers) could be used. The information is photochemically permanent (not reversible with visible light) but could be erased simply by heating. Presently limited to temperatures below $-40\,^{\circ}C$, suitable molecular variation might allow exploitation of the diastereomeric equilibrium at technically more practical temperatures.

Experimental Section

2: Benzaldehyde **4** (290 mg, 1.7 mmol) was dissolved in dried methanol (6 mL) and triethylamine (0.7 mL) under nitrogen. A solution of **3** (370 mg, 1.7 mmol) [5] in dried methanol (6 mL) was prepared. This solution was added in one portion to **4** and heated for 4 h at reflux. After cooling to room temperature the solvent was removed, and column chromatography was performed twice with the residue (silica gel 60; (ethyl acetate)/ethanol 6/1; $R_f = 0.45$). Yield: 260 mg (44%). ^{1}H NMR (500 MHz, [D$_6$]acetone, * = 2*S*,3*R*-spiropyran): $\delta = 0.72$ (t, 3H; H-13), 0.79 (t, 3H; H-13*), 1.20–1.22 (m, 2H; H-12*), 1.23 (s, 3H; H-10), 1.26 (s, 3H; H-10*), 1.48–1.53 (m, 4H; H-12, H-11*), 1.83–1.87 (m, 2H; H-11), 2.66 (s, 3H; H-9), 2.75 (s, 3H; H-9*), 6.03–6.07 (t, $^3J = 3.1$ Hz, 2H; H-3′, H-3′*), 6.57 (dd, $^3J = 8.1$, $^4J = 1.0$ Hz, 1H; H-7), 6.61 (d, $^3J = 7.8$ Hz, 1H; H-7*), 6.80–6.84 (m, 3H; H-5, H-5*, H-8′*), 6.87 (dd, $^3J = 9.0$, $^4J = 0.5$ Hz, 1H; H-8′), 7.07–7.08 (ddd, 1H; H-6*), 7.13–7.21 (m, 5H; H-4, H-4*, H-4′, H-4′*, H-6), 8.03 (dd, $^3J = 9.0$, $^4J = 2.8$ Hz, 1H; H-7′*), 8.06 (dd, $^3J = 9.0$, $^4J = 2.8$ Hz, 1H; H-7′), 8.12 (d, $^4J = 2.8$ Hz, 1H; H-5′*), 8.15 (d, $^4J = 2.8$ Hz, 1H; H-5′). ^{13}C NMR (*S*,*R* form, [D$_6$]acetone): $\delta = 14.2$ (C-13), 17.5 (C-10), 17.7 (C-12), 28.6 (C-9), 39.3 (C-11), 56.3 (C-3), 107.4 (C-7), 107.7 (C-2), 115.6 (C-8′), 119.4 (C-5), 119.6 (C-4a′), 122.1 (C-3), 123.0 (C-5′), 123.4 (C-6), 125.9 (C-7′), 128.1 (C-4), 128.8 (C-4′), 134.2 (C-3a), 141.4 (C-6′), 149.0 (C-7a), 160.3 (C-8a′); (*R*,*R* form, [D$_6$]acetone): $\delta = 14.8$ (C-13), 17.9 (C-12), 22.9 (C-10), 27.7 (C-9), 37.1 (C-11), 54.2 (C-3), 105.5 (C-2), 107.3 (C-7), 115.6 (C-8′), 119.3 (C-4a′), 119.9 (C-5), 122.0 (C-6), 122.7 (C-3), 123.1 (C-5′), 125.9 (C-7′), 127.5 (C-4′), 128.0 (C-4), 137.1 (C-3a), 141.4 (C-6′), 147.7 (C-7a), 159.6 (C-8a′). MS (EI, 70 eV): *m*/*z* (%): 350 (24) [M$^+$], 308 (44), 200 (42), 158 (100). CD spectra were recorded on an AVIV CD spectrometer 62A DS. Samples of **2** were irradiated at 4 W with a 254 nm filter and 150 W with a >530 nm filter.

The Redox Potential of Selenocystine in Unconstrained Cyclic Peptides**

Dörthe Besse, Frank Siedler, Tammo Diercks, Horst Kessler, and Luis Moroder*

Selenocysteine (Sec) can be viewed as the 21st amino acid in terms of ribosome-mediated protein synthesis.[1, 2] It is present in numerous prokaryotic and eukaryotic proteins, and nature uses the UGA termination codon to specify the insertion of this selenoamino acid rather than a posttranslational modification mechanism. Most of the selenoproteins identified so far are redox enzymes, in which the low pK_a value of the selenol function (5.73 for Sec vs. 8.53 for Cys) confers unique biochemical properties. However, the redox potential of selenocysteine itself as well as of selenocysteine-containing peptides and proteins has not yet been determined. In the present study we measured the apparent redox potential of selenocystine in peptidic structures using the strongly reducing dithiol dithiotreitol (DTT) as reference redox system.

Previous studies on aliphatic and aromatic selenols have clearly shown that the strong acidity and the resulting high nucleophilicity of selenols is responsible for the observed catalytic activity of selenols in thiol–disulfide interchange reactions with strongly reducing dithiols.[3] This redox activity requires regeneration of the catalytic selenol from the diselenide, at least to some extent. In fact, diselenides were found to be reduced by strongly reducing dithiols like DTT in aqueous solution at pH 7.6,[4] whereas monothiols cannot reduce diselenides to any significant extent.[3] This was fully confirmed even in the case of a selenocystine-containing peptide dimer, which was only partially reduced with a 10^3-fold excess of glutathione at pH 7.6.[5] This partial reduction by glutathione is apparently sufficient to maintain in living cells a concentration of selenocysteine suitable for its bioincorporation into selenoproteins. In fact, with

selenocystine in the growth medium the (Sec^{32},Sec^{35}) analog of thioredoxin, a thiol-protein oxidoreductase, was efficiently expressed recently in cysteine-auxotrophic *E. coli*.[2] The redox properties of this thioredoxin mutant differ significantly from those of the parent cysteine-protein. It could be reduced quantitatively only with $NaBH_4$ or a very large excess of DTT, whereas in the case of the mixed (Sec^{32},Cys^{35})- and (Cys^{32},Sec^{35})-thioredoxin, partial reduction was already obtained with β-sulfanylethanol. These results led Müller et al.[2] to postulate for the Sec,Sec-thioredoxin a redox potential between that of thioredoxin (-270 mV)[6] and DTT (-323 mV).[7]

In previous studies using glutathione as reference redox buffer we have determined the redox potentials of the active-site octapeptide fragments of thiol-protein oxidoreductases containing the characteristic Cys-Xaa-Yaa-Cys sequence motif.[8] A comparison of the 3D structures of the oxidized fragments with those of the active sites in the parent proteins clearly revealed that the disulfide-bridged cyclic structure of the active site in glutaredoxin is the least affected by the three-dimensional fold of the enzyme; it is essentially dictated by the local conformational preferences of the disulfide loop.[9, 10] As therefore anticipated, the redox potential of glutaredoxin and that of the related active site-fragment grx-(10–17) were found to be very similar and only slightly less reducing than those of disulfide dimers, such as glutathione.[8] In view of these results the Cys,Cys-octapeptide of glutaredoxin was chosen to determine the redox potential of selenocystine in an unconstrained, diselenide-bridged, linear peptide.

The Arg16 residue of grx-(10–17) was replaced by Lys to facilitate the synthesis of the Sec-peptides [Sec^{11},Sec^{14}]- and [Sec^{11},Cys^{14}]-grx-(10–17) (Scheme 1); the methoxybenzyl group was used for protection of the selenol function, andSe–stacking that activeSe and Se–S bridging was carried out with the DMSO/TFA procedure.[10, 11] The ^{77}Se NMR spectrum (DMSO, 300 K) of the [Sec^{11},Sec^{14},Lys^{16}]-grx-(10–17) fragment in the oxidized form shows a strong signal at $\delta = 266.6$, whereas in presence of a large excess (10^3-fold) of DTT two signals of almost identical intensity were detected at $\delta = -176.2$ and -190.6, respectively. With this NMR spectrum the quantitative reduction of the diselenide bridge with DTT was confirmed as well as the absence of mixed Se–S species derived from the reducing sulfanyl, in full agreement with the results reported for alkanediselenides.[3]

Scheme 1. Primary structures of the active-site fragment grx-(10–17) of glutaredoxin and of the selenocysteine analogs [Sec^{11},Cys^{14}, Lys^{16}]-grx-(10–17) and [Sec^{11},Sec^{14},Lys^{16}]-grx-(10–17).

Attempts to determine the redox potentials of the Sec-peptides with DTT as reference redox system by quantification of the single species at equilibrium with HPLC (as reported previously for the grx-(10–17) fragment[8]) failed because of partial irreversible adsorption of the reduced Sec-peptides on the reversed phase matrix. Similarly, quantification of the oxidized and reduced species with NMR spectroscopy in analogy to the method reported by Houk and Whitesides[12] could not be performed, because the low natural abundance of ^{77}Se required long measurement times over which the redox systems could not be maintained at equilibrium. The fluorescence of the Tyr residue was found to be unaffected by the reductive diselenide ring opening, but the CD spectra of the reduced and oxidized grx-(10–17) peptides differed significantly. Thus, the dichroic intensities at 230 nm were used to monitor the concentrations of the reduced and oxidized species, and the resulting plots of the amount of oxidized species X_{ox} against equivalents of DTT (Figure 1) revealed that DTT/peptide molar ratios of 0.5, 1.15, and 44 were required at pH 7.0 and 20 °C for 50% reduction of the [Cys^{11},Cys^{14}]-, [Sec^{11},Cys^{14}]- and [Sec^{11},Sec^{14}]-octapeptide, respectively. These results confirm the high stability of the diselenide bridge toward interchange reactions with thiols, whereas the mixed Se–S bridge appears to be significantly less stable in

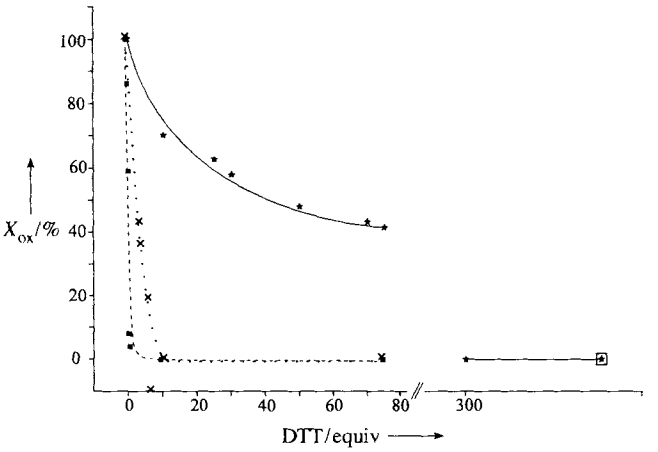

Figure 1. Reduction of [Cys^{11},Cys^{14}]- (■), [Sec^{11},Cys^{14},Lys^{16}]- (×) and [Sec^{11},Sec^{14}, Lys^{16}]-grx-(10–17) (*) in the oxidized cyclic form with DTT in 0.1 M phosphate buffer (pH 7.0) at 20 °C as monitored by CD at 230nm; □: upon quantitative reduction with $NaBH_4$.

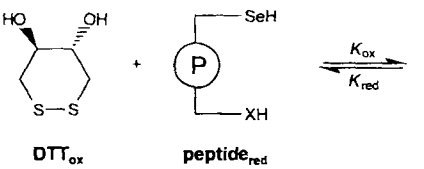
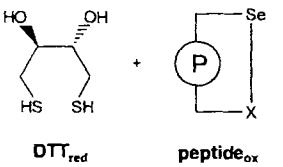
reducing media. Since the CD spectra recorded for the different DTT concentrations remained constant over at least 30 minutes, conditions of equilibrium were established in this system, thus enabling the determination of K_{ox} values [Eqs. (1) and (2), Table 1]. These were then converted into the redox potentials



(1)



$$K_{ox} = \frac{[peptide_{ox}][DTT_{red}]}{[peptide_{red}][DTT_{ox}]} \quad (2)$$

Table 1. Equilibrium constants of oxidation (K_{ox}) of the Cys,Cys-, Sec,Sec- and Sec,Cys-peptides by thiols [Eqs. (1) and (2)] [a].

Peptide	Reducing agent	K_{ox} pH 7.0	pH 8.5
grx-[10–17]	glutathione	0.142 M	
[Sec^{11},Sec^{14},Lys^{16}]-grx-[10–17]	DTT	85	6.5
[Sec^{11},Cys^{14},Lys^{16}]-grx-[10–17]	DTT	1.3	
[Sec^{11},Cys^{14},Lys^{16}]-grx-[10–17]	$HSCH_2CH_2OH$	15700 M	

[a] The peptides in the oxidized form were equilibrated at 20 °C in 0.1 M phosphate buffer (pH 7.0 and 8.5) with glutathione [8], DTT, and β-sulfanylethanol as reductants.

according to the Nernst equation (3) ($E_0 = -323$ mV at pH 7.0

$$E = E_{0(\text{reductand})} - 0.03 \lg K_{ox} \quad (3)$$

and -366 mV at pH 8.1 for DDT[7]). Because of the relatively facile reduction of the mixed Se–S bridge in the [Sec[11],Cys[14]]-octapeptide with DTT and thus possibly nonideal conditions of equilibrium, reduction of this peptide was also performed with β-sulfanylethanol ($E_0 = -207$ mV at pH 7.0[7]). The redox potentials of the [Sec[11],Cys[14]]-octapeptide extracted from the two experiments ($E = -326$ mV against DDT and -332 mV against β-sulfanylethanol at pH 7.0) compare well within the limits of error of the measurements. The differences of the redox potentials of the Sec- and Cys-peptides referred to glutathione (as the main redox system of the living cells[13]) are reported in Figure 2.

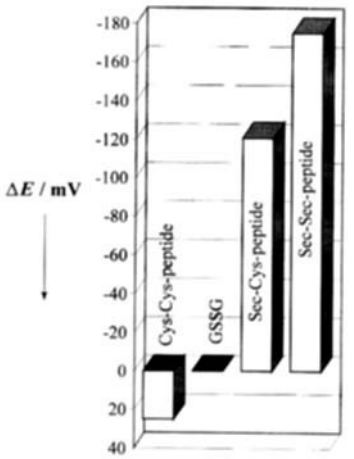

Figure 2. The redox potentials of [Cys[11],Cys[14]]-, [Sec[11],Cys[14],Lys[16]]- and [Sec[11],Sec[14],Lys[16]]-grx-(10–17) at pH 7.0 and 20 °C referred to that of glutathione (GSSG). The redox potential of [Cys[11],Cys[14]]-grx-(10–17) of -180 mV was calculated from the K_{ox} value determined previously with glutathione as redox buffer [8] with the value of $E_0 = -205$ mV for glutathione determined by Szajewski and Whitesides [7].

The redox potential ($E = -381$ mV at pH 7.0 and -389 mV at pH 8.5 and 20 °C) of the selenocystine peptide [Sec[11],Sec[14],Lys[16]]-grx-(10–17) proved to be remarkably lower than that of DTT ($E = -323$ mV) in contrast to previous speculations,[2] but in good agreement with that of selenocystamine ($E = 349$ mV; calculated from the K_{ox} value of 7.14 M^{-1} determined with DTT as reductant[3]). Conversely, the redox properties of the mixed Sec,Cys-peptide are very similar to those of DTT ($E = -326$ mV vs -323 mV for DTT) and thus significantly more reducing than glutathione (-205 mV[7]). Since the K_{ox} of the Sec,Sec-peptide is remarkably higher than that of the mixed Sec,Cys-peptide (Table 1), formation of mixed Se–S bridges is apparently very disfavored relative to the formation of an Se–Se bridge. This observation could open an interesting new approach for the design of productive intermediates in the oxidative folding pathway of synthetic peptides and recombinant proteins, since Se–Se bridging should occur independently of the presence of additional cysteine residues. Moreover, alkaneselenols are known to enhance the rates of thiol/disulfide interchange reactions;[3, 14] thus, such a built-in chemical device in protein sequences could facilitate the oxidative refolding process by mimicking the action of protein disulfide isomerase.

Absolute Configuration of Bromochlorofluoromethane from Experimental and Ab Initio Theoretical Vibrational Raman Optical Activity**

Jeanne Costante, Lutz Hecht, Prasad L. Polavarapu,* André Collet,* and Laurence D. Barron*

Bromochlorofluoromethane **1** is one of the simplest examples of the Le Bel and van't Hoff asymmetric carbon atom, and since its first synthesis by Swarts a century ago[1] a number of attempts have been made to separate its enantiomers and measure their optical rotation. These efforts culminated in 1985 with the first analytical resolution[2] of a weakly enantiomerically enriched sample obtained by Wilen et al.,[3] which enabled a maximum specific rotation (i.e., the rotation for the pure enantiomer) of $[\alpha]_D^{25} = \pm 1.6$ (neat, $\rho = 1.91$ kg dm^{-3}) to be estimated.[4] Since then the absolute configuration of **1** has been the subject of speculation. The simple empirical rule of Brewster,[5] based on atom polarizabilities, predicts the (*S*)-(+) configuration for **1**, assuming the polarizability order H > F.[6] The same prediction has been made by Applequist, who used an atom–dipole interaction model;[7] in this model, however, the polarizability order is inverted (F > H). In view of its simple structure, bromochlorofluoromethane has long been considered an ideal sample for vibrational optical activity studies, and semiempirical methods have been used to calculate both its vibra-

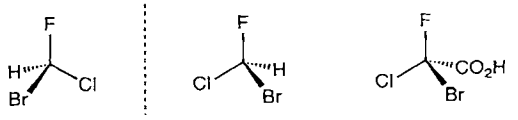
tional circular dichroism (VCD)[8, 9] and Raman optical activity (ROA)[9-11] spectra, but no experimental support for these calculations could be provided due to lack of sufficiently resolved samples. Suitable samples have recently become available, and we report here the experimental ROA spectrum of the (−) enantiomer of **1** in conjunction with an ab initio computation, which has allowed us to confirm that the absolute configuration of **1** is indeed (*S*)-(+) or (*R*)-(−).

This study was made possible by recent work of Doyle and Vogl,[12] who reported that partially resolved strychnine salts of bromochlorofluoroacetic acid **2** undergo smooth decarboxylation at 120 °C in ethylene glycol to give resolved **1** with remarkable conservation of optical activity. The sample of (−)-**1** used



(*S*)-(+)-**1** (*R*)-(−)-**1** (*R*)-(−)-**2**

for the ROA measurements was obtained by decarboxylation of a partially resolved strychnine salt of (*R*)-(−)-**2** (51% *de*; see Experimental Section). Its optical rotation was $[\alpha]_D^{25} = -0.64 \pm 0.03$ ($c = 6.5$ in cyclohexane), and its enantiomeric excess was estimated at (36 ± 2)% by ^{1}H NMR in the presence of (+)-cryptophane C as a chiral host shift reagent[2] (Figure 1). On this basis, the extrapolated maximum specific rotation of **1** in cyclohexane is $[\alpha]_D^{25} = \pm(1.78 \pm 0.18)$, which reasonably matches the previous value of ±1.6 mentioned above for the neat liquid.

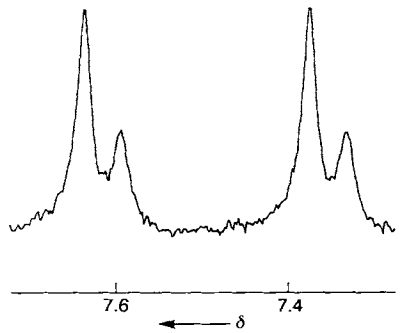


Figure 1. The ^{1}H NMR spectrum ($J_{H,F} = 52$ Hz) of the sample of (−)-**1** used in the ROA experiments in the presence of (+)-cryptophane C. The largest doublet (downfield shifted) corresponds to (−)-**1**, the smallest to (+)-**1**.

ROA measures vibrational optical activity by means of a small difference in the intensity of Raman scattering from chiral molecules in right and left circularly polarized incident visible laser light.[13-16] Although first observed over 20 years ago,[17] applications were originally limited by the low sensitivity and long acquisition times of the ROA instruments. However, thanks to new developments in instrumentation,[18] ROA can now be measured rapidly and routinely on a wide range of samples. Another important development is the introduction of ab initio methods that can compute the sign and magnitude of the ROA intensity for all normal vibration modes of a small chiral molecule.[19, 20] A gauge-invariant ab initio approach, which is expected to give improved predictions, has also been developed.[21]

The depolarized Raman and ROA spectra of neat liquid (−)-**1** measured in right-angle scattering over the spectral range 130–3130 cm^{-1}, together with the corresponding ab initio computed spectra for the CHF^{35}Cl^{79}Br isotopomer of the (*R*)-enantiomer, are shown in Figure 2. The origin of the fine structure in

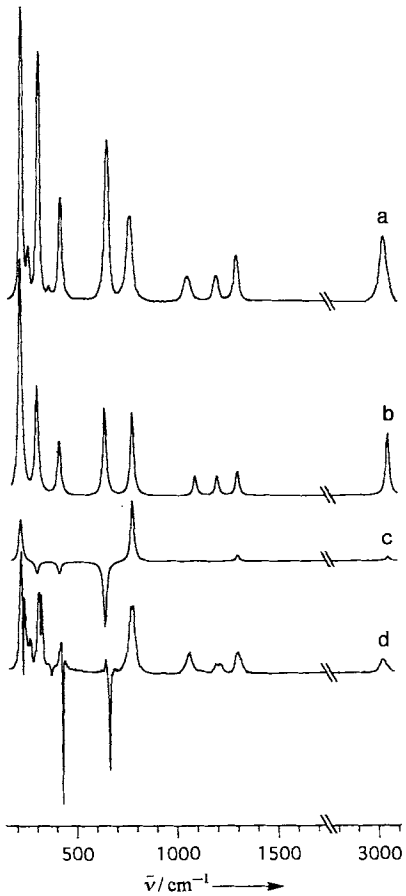

Figure 2. The experimental depolarized Raman (a; plot of $I_z^R + I_z^L$) and ROA (d; plot of $I_z^R - I_z^L$) spectra of (−)-bromochlorofluoromethane together with the spectra calculated ab initio for the (*R*)-enantiomer (b, c).

the first four ROA bands (spectrum d) is unclear: it does not appear to be due to experimental artefacts or direct isotope effects (e.g., negligible differences were found in the computed ROA spectrum of the four isotopomers) and will not be discussed further here. The spectral range shown covers all $3N - 6 = 9$ fundamental bands, the relevant experimental and calculated data of which are listed in Table 1. The experimental

band positions agree well with earlier liquid-phase Raman data,[22, 23] but differ significantly from those in the gas-phase IR spectrum.[24] The computation predicts the correct sign for seven of the nine fundamental ROA bands (or seven out of eight if we disregard the theoretical band at 1266 cm^{-1} whose magnitude is so close to zero that the formal negative sign is meaningless). Thus we can say with a reasonable degree of confidence that the absolute configuration of the enantiomer in excess is (*R*)-(−). Interestingly, the early calculations based on the atom–dipole interaction[10] and bond polarizability[11] models predict six and seven correct signs, respectively.

Our confidence in this assignment of absolute configuration is reinforced by an ab initio computation of the specific rotation. This is based on the Rosenfeld equation for the optical rotation angle, which depends on the trace of the electric dipole/magnetic dipole optical activity tensor[13] and is obtained automatically as part of the ROA computation. Our calculated value for $[\alpha]_D^{25}$ of the (*R*)-enantiomer is −8.0, which has the correct sign and is within the same order of magnitude as the experimental values. The details of ab initio specific rotation calculations are given elsewhere.[25]

This study has provided an assignment of the absolute configuration of bromochlorofluoromethane as (*S*)-(+) or (*R*)-(−) by both measurement and ab initio calculation of the ROA and optical rotation. Since the decarboxylation of the salt *R*-(−)-**2** yields *R*-(−)-**1**, this reaction must proceed with retention of configuration. This conclusion is consistent with a recent observation by Schurig et al.[26] that decarboxylation of (*R*)-(+)-1-methoxytetrafluoropropionic acid gives (−)-1,2,2,2-tetrafluoroethyl methyl ether with retention of configuration.

Experimental Section

(−)-**1**: Racemic bromochlorofluoracetic acid **2** was resolved by fractional crystallization of its diastereomeric strychnine salts as described elsewhere [27]. A fraction (9.49 g, 17.9 mmol) of the more soluble salt having $[\alpha]_D^{25} = -123$ ($c = 1.2$ in $CHCl_3$), containing (−)-**2** in ca. 51% *ee*, was decarboxylated by heating at 120 °C in ethylene glycol (11 mL) for 30 min. **1** was collected into two cold traps (−78 °C) and then distilled under vacuum; yield 1.34 g (51%) of colorless liquid. ^1H NMR [200 MHz, $CDCl_3$, $\delta(CHCl_3) = 7.24$]: $\delta = 7.59$ (d, $J_{H,F} = 52$ Hz); ^{19}F NMR [188 MHz, $CDCl_3$, $\delta(CFCl_3) = 0$]: $\delta = -82.1$ (d, $J_{H,F} = 52$ Hz). This sample yielded the following $[\alpha]^{25}$ values: $[\alpha]_D^{25} = -0.64$, $[\alpha]_{578}^{25} = -0.66$, $[\alpha]_{546}^{25} = -0.77$, $[\alpha]_{436}^{25} = -1.16$, $[\alpha]_{365}^{25} = -1.32$ ($c = 6.5$ in cyclohexane; error ±5%). The enantiomeric excess was estimated by simulating the ^1H NMR spectrum obtained in the presence of (+)-cryptophane C as a chiral host shift reagent [2] (Figure 1) by assuming Lorentzian peaks with a band width of 4.3 and 5.3 Hz for the largest and smallest doublet, respectively.

ROA experiments: The depolarized Raman and ROA spectra were measured with the latest version of the Glasgow right-angle scattering instrument [18,28]. It features a single grating *f*/4.1 spectrograph equipped with a multichannel detector in the form of a CCD camera and a holographic notch filter to suppress the Rayleigh line. The ROA is measured by synchronizing the spectral acquisition with an electro-optic modulator that switches the polarization of the incident laser beam between right and left circular polarization at a suitable rate. The spectra are displayed in raw analogue-to-digital converter (ADC) units in the form of a circular intensity sum $I_z^R + I_z^L$ for the parent Raman spectrum and a circular intensity difference $I_z^R - I_z^L$ for the ROA spectrum, where I_z^R and I_z^L are the Raman scattered intensities in right and left circularly polarized incident light, and the subscript z denotes the linear polarization state selected by an analyzer in the scattered radiation oriented parallel to the scattering plane. Experimental conditions: sample volume ca. 50 μL in a custom quartz microfluorescence cell, laser wavelength 514.5 nm, laser power at the sample 500 mW, spectral bandpass at 500 nm (FWHH) 2.4 cm^{-1}, acquisition time 3 h.

Ab initio calculations were performed as described previously [19,20]. They depend on the calculation of an optimized geometry for the molecule and the associated normal vibrational coordinates, together with a calculation of the particular polarizability and optical activity tensor invariants which contribute to the Raman and ROA intensities and the derivatives of these tensor invariants with respect to the normal vibrational coordinates. Structural optimizations were performed by using the CADPAC program [29] with the DZP basis set (as provided in the TURBOMOLE program library [30]) and electron correlation by the MP2 method.[31] The contraction scheme used in this basis set is as follows: H[4s1p/2s1p], C[8s4p1d/4s2p1d], F[8s4p1d/4s2p1d], Cl[11s7p1d/6s4p1d], Br[14s11p6d/8s6p3d]. The optimized MP2/DZP energy is −3170.7774042 Hartree. The vibrational frequencies, normal modes and derivatives of the electric dipole–electric dipole polarizability tensor $\alpha_{\alpha\beta}$ were obtained with the DZP basis set and electron correlation incorporated via the MP2 method. The derivatives of the electric dipole/magnetic dipole and electric dipole/electric quadrupole optical activity tensors $G'_{\alpha\beta}$ and $A_{\alpha\beta\gamma}$, respectively, were obtained with the same basis set but without electron correlation.

The First Transition Metal Complex of a Silaborane**

Lars Wesemann,* Yves Ramjoie, Beate Ganter, and Bernd Wrackmeyer

Dedicated to Professor Gerhard E. Herberich on the occasion of his 60th birthday

Complexes of the dicarbollide anion $[C_2B_9H_{11}]^{2-}$, which can be derived from 1,2-dicarba-*closo*-dodecaborane(12) (1,2-$C_2B_{10}H_{12}$, "*ortho*-carborane"), are known for almost every transition metal.[1] This fascinating class of compounds developed by Hawthorne et al., showed that the carborane ligand is comparable both electronically and sterically to the Cp^{*-} ligand.[2] Ever since the disilaborane 1,2-dimethyl-1,2-disila-*closo*-dodecaborane(12) became available,[3] a major attractive aspect of its chemistry has concerned similarities and/or differences to the behavior of the corresponding carborane. For instance, 7-methyl-7-sila-*nido*-undecaborate(1 −) (**1**) is accessible by nucleophilic degradation of the disilaborane,[4] whereas in the case of the corresponding reaction of 1,2-$C_2B_{10}H_{12}$, both carbon atoms remain part of the cluster skeleton (Figure 1). Reactions

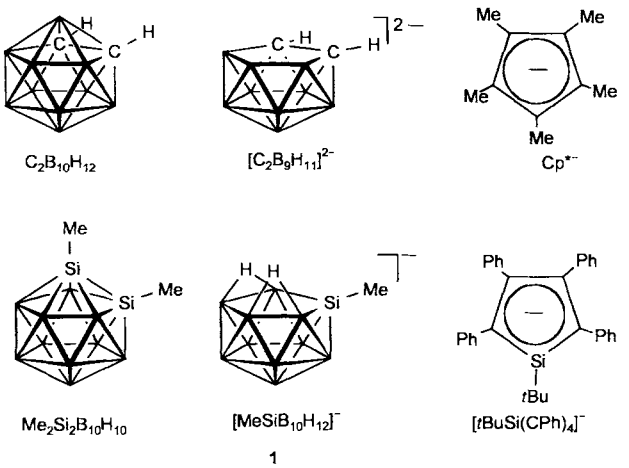

Figure 1. Carboranes, silaboranes, and the related cyclopentadienide and silacyclopentadienide ligands.

of **1** with electrophiles such as $SnCl_2$ led to new heteroboranes or -borates.[5] Bearing in mind the current research activities in the field of the silacyclopentadienide ion with respect to the question of its aromaticity[6] and its coordination chemistry,[7] as well as with respect to the analogy between $[C_2B_9H_{11}]^{2-}$ and Cp^{*-}, transition metal complexes containing the silaborate ligand **1** are of considerable interest.

Here we describe the first synthesis of a silaborane transition metal complex. Following the procedure employed by Hawthorne et al. to produce the ferrocene analogue $[(C_2B_9H_{11})_2Fe]^{2-}$,[8] two equivalents of the deprotonated ligand $[MeSiB_{10}H_{10}]^{3-}$, which is available from $[Me_3NH]$-**1** [Eq. (a)], were treated with $FeBr_2 \cdot DME$.

$$[Me_3NH][MeSiB_{10}H_{12}] + 3\,K[HBEt_3] \longrightarrow K_3[MeSiB_{10}H_{10}] + Me_3N + 3\,H_2 + 3\,BEt_3 \quad (a)$$

However, we failed to isolate any defined product from the reaction of the completely deprotonated ligand $[MeSiB_{10}H_{10}]^{3-}$ with $FeBr_2 \cdot DME$. By using less than three equivalents of $K[HBEt_3]$ (see [Eq. (a)]), the reaction with $FeBr_2 \cdot DME$ gave a red violet solution at −78 °C, which turned dark green at room temperature. A green solid was isolated, dissolved in water, and after addition of $[nBu_4N]Br$ a green precipitate was formed that could be recrystallized from water/acetone at 4 °C and identified as the tetrabutylammonium salt of the anionic dinuclear silaborate iron complex **2**. The yield could be improved to 63% by employing the stoichiometries shown in Equations (b) and (c). The formation of the cluster dianion

$$3\,[Me_3NH][MeSiB_{10}H_{12}] + 7\,K[HBEt_3] \longrightarrow 3\,Me_3N + 7\,BEt_3 + 7\,H_2 + 2\,K_2[MeSiB_{10}H_{11}] + K_3[MeSiB_{10}H_{10}] \quad (b)$$

$$2\,K_2[MeSiB_{10}H_{11}] + K_3[MeSiB_{10}H_{10}] + 2\,FeBr_2 \longrightarrow K_2[\{HFe(MeSiB_{10}H_{10})\}_2] + K[MeSiB_{10}H_{10}] + 4\,KBr \quad (c)$$

K_2-**2**

requires a reduction equivalent, which is evidently the *nido*-trianion $[MeSiB_{10}H_{10}]^{3-}$ [Eq. (c)]. However, so far it has not been possible to isolate or identify the presumable oxidation product, the *closo*-silaborate cluster $[MeSiB_{10}H_{10}]^-$. Interestingly, the carborane homologue $[CB_{10}H_{10}]^{3-}$ can be oxidized by iodine to give the eleven-vertex *closo*-cluster $[CB_{10}H_{10}]^-$.[9]

The molecular structure of the dianion **2** is shown in Figure 2.[10] All hydrogen atoms were located in the final difference Fourier analysis and refined isotropically. The Fe–B bond lengths (2.206(2)–2.082(2) Å) are in the expected range (see

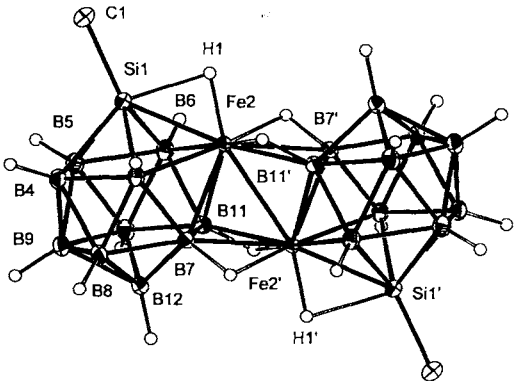

Figure 2. Structure of the anion **2** in the crystal (PLATON representation [19], ellipsoids at 30% probability level). Selected distances [Å] (standard deviations in parantheses): Fe2–Fe2' 2.423(1), Fe2–Si1 2.209(1), Fe2–B3 2.208(2), Fe2–B6 2.206(2), Fe2–B7' 2.168(2), Fe2–B7 2.082(2), Fe2–B11' 2.169(2), Fe2–B11 2.075(2), Si1–C1 1.852(2), Si1–B3 2.079(2), Si1–B4 2.060(3), Si1–B5 2.069(2), Si1–B6 2.084(2), B3–B4 1.836(3), B3–B7 1.770(3), B3–B8 1.782(3), B4–B5 1.856(3), B4–B8 1.766(3), B4–B9 1.764(3), B5–B6 1.838(3), B5–B9 1.769(4), B5–B10 1.772(3), B6–B10 1.791(3), B6–B11 1.769(3), B7–B8 1.778(3), B7–B11 1.751(3), B7–B12 1.783(3), B8–B9 1.779(3), B8–B12 1.768(3), B9–B10 1.790(3), B9–B12 1.755(3), B10–B11 1.781(3), B10–B12 1.777(3), B11–B12 1.790(3), Fe2–H1 1.46(2), Si1–H1 1.86(2).

[**] This work was supported by the Deutsche Forschungsgemeinschaft (DFG-Schwerpunktprogramm "Polyeder").

$[(CO)_3Fe(C_2B_9H_{11})]$: Fe–B 2.173(9)–2.160(9) Å),[13] whereas the Fe–Si bond length (2.209(1) Å) is somewhat shorter than those in silyl-substituted iron complexes (2.252(3)–2.488(6) Å).[14] It appears that each Fe–Si bond is bridged unsymmetrically by a hydrogen atom. The Si–H (1.86(2) Å) and Fe–H bond lengths (1.46(2) Å) indicate that the ironhydride character dominates. However, work by Schubert et al. indicates that a significant bonding interaction has to be taken into account.[15] The short distance[16] between the two iron atoms (2.423(1) Å) points toward an Fe–Fe single bond. This is also supported by electron counting, which gives each iron atom an 18-electron configuration. Investigations on the electronic structure of **2** are currently in progress.

All NMR spectroscopic evidence (see Figure 3 for some selected data) indicates that the principal features of the solid-state structure of the dianion **2** are retained in solution. The $^{11}B\{^1H\}$ NMR spectrum shows six signals in an intensity ratio of 2:1:1:2:2:2, which is consistent with a C_{2h}-symmetric structure, and the connectivities within the B_{10} frameworks follow clearly from the 2D COSY $^{11}B\{^1H\}/^{11}B\{^1H\}$ experiment. The ^1H NMR signal of the Fe–Si bridging protons ($\delta = -2.03$) is accompanied by ^{29}Si satellites. The $^1J(^{29}Si,^1H)$ coupling constant of 29.2 Hz is indicative of weak but still significant[13] Si–H interactions. The ^1H(MeSi) NMR signal is split into a doublet ($^3J(^1H,^1H) = 0.9$ Hz), and selective $^1H\{^1H\}$ double resonance experiments confirmed that this coupling arises from the presence of the hydrogen atom in the Fe-H-Si bridge. Finally, the linkage between the two cluster fragments in **2** is unambigously evident from the ^1H NMR signals of the four B-H-Fe bridging hydrogen atoms ($\delta = -14.02$), from the cross peak with the $^{11}B(7,11)$ signals in the 2D HMQC $^1H\{^{11}B\}/^{11}B\{^1H\}$ NMR spectrum, and from the reduced magnitude of the coupling constants $^1J(^{11}B,^1H) = 73$ Hz (a value of $^1J(^{11}B,^1H) = 134$ Hz is typical of a "free" BH group).

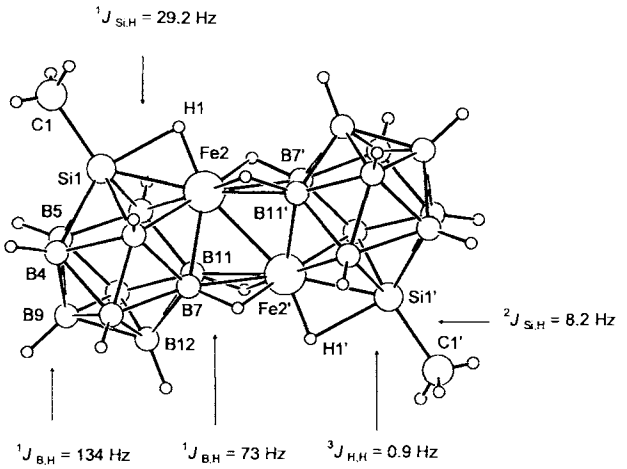

Figure 3. Selected coupling constants and $^{11}B\{^1H\}$ NMR data of **2**: −20.0 *B*8/10, −14.2 *B*4/5, −12.0 *B*3/6, −5.3 *B*12, 4.1 *B*9, 10.0 *B*7/11.

In complexes with heteroboranes[17] and boranes,[18] sandwich-type coordination modes are very common. Thus, the homologue of the silaborate ligand, the carba-*nido*-undecaborate(1 −) $[CB_{10}H_{13}]^-$, reacts after deprotonation with $FeCl_2$ to give the sandwich complex.[17b] In the analogous reaction with the silaborate, no sandwich complexes have been observed so far, but there are surprising and novel alternatives, such as the anionic dinuclear cluster **2**.

Experimental Section

$[nBu_4N]_2$-**2**: $[Me_3NH]$-**1** (250 mg, 1.13 mmol) in THF (50 mL) was treated with $K[HBEt_3]$·THF (2.64 mL of a 1 M solution) at −78 °C. Gas started to evolve immediately and the cooling bath was removed. After 0.5 h a white solid separated and all volatiles were removed under vacuum. The solid was suspended in THF (50 mL) and cooled to −78 °C. Then $FeBr_2$·DME (230 mg, 0.76 mmol) was added, and the color of the suspension changed immediately to red violet. After the mixture had been stirred for 1 h at room temperature, the color changed to green, and after stirring for a further 2 h all volatiles were removed *in vacuo*. The resulting dark green solid was dissolved in water, filtered, and treated with $[nBu_4N]Br$ (1.5 g, 4.5 mmol). A green solid precipitated, which was filtered off and washed with water to give $[nBu_4N]_2[\{HFe(MeSiB_{10}H_{10})\}_2]$ (0.219 g, 63.0%) [20]. Single crystals suitable for X-ray crystal structure analysis were obtained from a mixture of acetone and water at 4 °C. NMR spectra were recorded in $[D_6]$acetone at 25 °C; ^1H NMR (500 MHz, TMS): $\delta = -14.02$ (s, 4H, B*H*Fe), −2.03 (br, 2H, Fe*H*Si), 1.07 (s, *H*3/6), 1.19 (d, $^3J(H,H) = 0.9$ Hz, 6H, $SiCH_3$), 1.37 (s, 4H, *H*8/10), 1.79 (s, 4H, *H*4/5), 2.05 (s, 2H, *H*12), 3.09 (s, 2H, *H*9); ^{11}B NMR (160 MHz, $Et_2O{\cdot}BF_3$): $\delta = -20.0$ (d, $^1J = 134$ Hz, 4B, *B*8/10), −14.2 (d, $^1J = 134$ Hz, 4B, *B*4/5), −12.0 (d, $^1J = 73$ Hz, 4B, *B*3/6), −5.3 (d, $^1J = 134$ Hz, 2B, *B*12), 4.1 (d, $^1J = 134$ Hz, 2B, *B*9), 10.0 (d, $^1J = 134$ Hz, 4B, *B*7/11); $^{13}C\{^1H\}$ NMR (125 MHz, TMS): $\delta = 13.8$, 20.3, 24.4, 59.7 (s, $NCH_2CH_2CH_2CH_3$), −0.5 (s, $SiCH_3$); ^{29}Si NMR (100 MHz, TMS): $\delta = 10.8$.

Helical, Polymeric Chains in Crystalline Gallaborane $[GaBH_6]_n$ at 110 K**

Anthony J. Downs,* Simon Parsons, Colin R. Pulham, and Philip F. Souter

Our knowledge of gallium hydrides has long been restricted by the weakness of Ga–H relative to H–H and other bonds to gallium.[1–3] However, through the stratagem of matrix isolation and the development of appropriate high-vacuum techniques, with rigorous exclusion of volatile impurities and temperature control,[2] it has been possible to prepare and characterize a number of binary and ternary gallium hydrides.[4–7]

Such compounds are noteworthy for several reasons. From a practical standpoint, they may be suitable as precursors to the metal itself as well as various derivatives.[2, 3] The course of decomposition often varies markedly according to whether the compound is in the vapor or condensed phase, a feature which may well reflect the influence of aggregation and the structural changes accompanying the more to higher molecular concentrations. It is therefore important to seek structural patterns for these hitherto elusive compounds not just in the gas phase, but also in the condensed phases.

Gallaborane $[GaBH_6]_n$ (**1**) is typical in many ways of this class of compound.[6] It is the most volatile derivative of gallium to be authenticated so far. The solid has a melting point of about 228 K and a vapor pressure at 195 K in the order of 1 torr; decomposition to the metal occurs above 238 K. Although the predominant vapor species is the diborane-like $H_2Ga(\mu\text{-}H)_2BH_2$,[6] aggregation of these molecules undoubtedly occurs in the condensed phases. Solutions in toluene or methylcyclohexane exhibit NMR spectra that imply an equilibrium between species of different nuclearity, and IR and Raman spectra of annealed solid films at 77 K suggest the embodiment of either oligomers or polymers with terminal GaH_2 and BH_2 units.[8] Here we report the structure of a single crystal of **1** at 110 K.

Crystals of **1** were obtained adventitiously during attempts to grow single crystals of the bis(tetrahydroborate) $[HGa(BH_4)_2]$ (**2**).[9] With a melting point near 200 K, **2** is also thermally labile and apparently subject to aggregation in the condensed phases. Controlled freezing of the melt yielded a colorless single crystal, which was identified as a mono(tetrahydroborate), that is, gallaborane **1** and not the expected **2**. On synthesis, **2** is invariably accompanied by small amounts of the less stable, more volatile **1**, from which it is not easily freed by fractional condensation in vacuo. In addition, decomposition of **2** probably proceeds initially with the elimination of BH_3 (as B_2H_6) and the formation of **1**. This process is facilitated by a base that is able to coordinate the BH_3 fragment[9] and may thus be subject to autocatalysis at high concentrations of **2**.

The crystal structure of **1** consists of helical chains made up of alternating pseudotetrahedral GaH_4 and BH_4 units (Figures 1 and 2).[10] In forming a helical polymer, **1** emulates

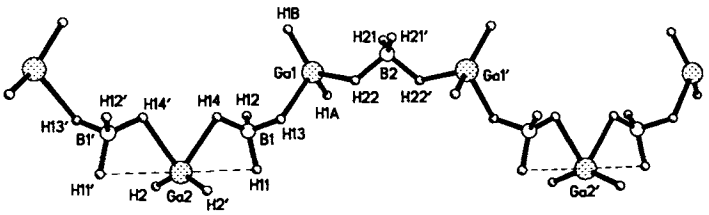

Figure 1. Helical, polymeric structure of crystalline gallaborane $[H_2GaBH_4]_n$ (**1**) at 110 K as determined by X-ray diffraction; primed atoms are symmetry-related to nonprimed atoms.

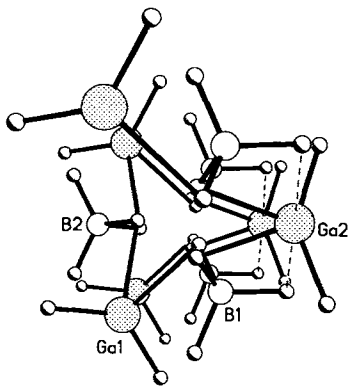

Figure 2. Structure of **1** at 110 K as viewed along the helical axis.

$[Be(BH_4)_2]$,[11] $[Me_2AlBH_4]$,[12] and $[MeZnBH_4]$.[13] These analogues are all disposed about screw axes, whereas **1** repeats along a glide plane. The BH_4 unit based on B1 forms primary interactions through H13 to Ga1 [2.04(7) Å] and H14 to Ga2 [1.86(7) Å] and a weaker, secondary contact through H11 to Ga2 [2.41(6) Å]. The BH_4 unit based on B2, which, like Ga2, lies on a twofold axis, is highly unusual in that it links two adjacent metal centers through single hydrogen bridges (through H22 and H22', Ga1–H22 1.87(7) Å). This is unprecedented in the series of tetrahydroborate derivatives referred to above; the

only other molecular compound known to display a similar mode of coordination is $[(C_5Me_5Ir)_2H_3(BH_4)]$,[14] which features an Ir–Ir bond bridged on one side by the BH_4 group.

Table 1 collates some of the salient dimensions of crystalline **1** with corresponding parameters of the gaseous molecule and some other tetrahydroborates. X-ray diffraction, unlike electron diffraction, measures distances between centers of maximum electron density, and comparisons of parameters (especially those with H atoms) can therefore be complicated. It is clear, though, that crystallization and attendant polymerization cause an increase in the Ga–B distance from 2.179(2)[8] to an average of 2.47(1) Å and in the difference between the bond lengths Ga–H_t and Ga–H_b (from 0.24 to 0.52 Å; t = terminal, b = bridging). In contrast to $[Be(BH_4)_2]$,[11] $[Me_2AlBH_4]$,[12] and $[MeZnBH_4]$[13]—in which the metal centers are 5- or 6-coordinated in the solid state—the Ga atom in **1** retains its characteristic fourfold primary coordination in the solid, albeit in a modified form. However, the coordination geometry is very far from tetrahedral with H_t-Ga-H_t = 133(3) and 145(3)° and H_b-Ga-H_b = 72(3) and 76(3)° at Ga1 and Ga2, respectively: by contrast the BH_4 groups do not deviate significantly from tetrahedral geometry. In keeping with the vibrational spectra of the solid, these properties imply a significant degree of ionic character in the sense of $[H_2Ga]^+[BH_4]^-$.[8]

Several factors, such as electronic properties and size of the metal atom as well as the nature and number of other substituents, are likely to determine the way hydride molecules like $GaBH_6$ aggregate and the structures they adopt in the condensed phases. More crystal structures need to be characterized, including those of the related compounds $[HGa(BH_4)_2]$[9] and $[GaH_3]_n$,[2, 3, 5] to develop a fuller picture of the patterns and principles that are at work.

Table 1. Comparison of selected dimensions of crystalline and gaseous gallaborane **1** with those of related crystalline tetrahydroborates [a].

Parameter [b]	Crystalline $[GaBH_6]_n$ (110 K)	Gaseous $GaBH_6$ [8] [c]	Crystalline $[Be(BH_4)_2]$ [11]	Crystalline $[Me_2AlBH_4]$ (150 K) [12]	Crystalline $[MeZnBH_4]$ (150 K) [13]

[a] Average values are given for the crystalline solids, where appropriate. [b] M = Ga, Be, Al, or Zn; t = terminal; b = bridging. [c] Determined by electron diffraction. For technical reasons connected with the reactivity and thermal instability of the compound, it has been impossible as yet to make satisfactory measurements on the vapor at more than one camera distance. [d] Parameters could not all be refined independently.

Experimental Section

The preparation of **2** from $GaCl_3$ and $LiBH_4$ followed the procedure described previously [9]. Purification was effected by fractional condensation at pressures below 10^{-4} torr, and the identity of the product was checked by its vibrational and ^1H and ^{11}B NMR spectra [9]. A single crystal was grown by careful cooling of the sample, which was held in a preconditioned, Pyrex glass capillary mounted on the diffractometer [10]. A stable solid/liquid phase boundary was established at about 213 K, and crystal growth effected by slow cooling to 190 K at approximately 90 K h^{-1}.

[8] This is indicated, for example, by the pairs of bands appearing at 2530/2450 and 2009/1989 cm^{-1} in the IR spectrum of the solid. The fact that the $\nu(B-H_t)$ and $\nu(B-H_b)$ fundamentals are separated by only about 200 cm^{-1} argues for the presence of relatively ionic BH_4 moieties.

[10] X-ray structure analysis: Stoe Stadi 4 four-circle diffractometer equipped with an Oxford Cryosystems L. T. device [15]; $Mo_{K\alpha}$ radiation, $T = 110$ K, $a = 10.036(3)$, $b = 8.932(3)$, $c = 11.294(4)$ Å, $\beta = 100.57(2)°$, $V = 995.2(6)$ Å^3, space group $I2/a$, $Z = 12$, $\rho_{calcd} = 1.733$ g cm^{-3}, $F(000) = 504$, crystal size $0.39 \times 0.19 \times 0.19$ mm, ω-2θ mode, ω half-width $(1.32 + 0.35\tan\theta)°$, $2.93 \le \theta \le 24.99°$, $\mu(Mo_{K\alpha}) = 7.970$ mm^{-1}, 1015 measured reflections ($-14 \le h \le 0$; $0 \le k \le 12$; $-15 \le l \le 15$) of which 864 were independent ($R_{int.} = 0.0216$); 744 reflections with $|F| > 4\sigma(|F|)$ were considered observed. Following corrections for Lp effects and absorption (ψ scan, $T_{min} = 0.457$, $T_{max} = 0.740$) the structure was solved by Patterson methods for the Ga positions, and the B and H atoms were located in subsequent ΔF maps. The structure was refined by full-matrix least squares against F^2. The positions of H atoms bound to B centers were refined freely, and those of H atoms bound to Ga centers made subject to H–Ga similarity restraints. $R_1 = 0.0344$, $wR_2 = 0.0990$ (all data) for 60 parameters, maximum/minimum electron density for the final ΔF synthesis: $+0.604/-0.604$ e Å^{-3}. Calculations with SHELXTL, version 5 (G. M. Sheldrick, Siemens Analytical X-ray Inc., Madison, Wisconsin, **1995**). Even with the relatively low precision of the H-atom parameters, the H atoms showed up very clearly in the electron density maps. Since the presence of boron (at least ^{11}B) effectively precludes useful neutron diffraction measurements, our results probably represent the best structural data available for a simple compound of this type. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the depository number CSD-406271.

Filling the Gap in Surfactant Science

Vesicles. By *M. Rosoff.* (Series: Surfactant Science, Vol. 62. Series editor: *J. Schick.*) Marcel Dekker, New York, 1996. 752 pp., hardcover $ 195.00.—ISBN 8247-9603-9

The *Surfactant Science* series, to which this volume belongs, is a detailed encyclopedia on surface-active agents. Recent volumes in the series have covered amphoteric and nonionic surfactants, foams, dispersions, and emulsions. The latest volume, by M. Rosoff, contains an up-to-date survey of the various associated forms of phospholipids, with particular emphasis on unilamellar and multilamellar vesicles. In addition to these aggregates the volume also deals with liquid-crystalline structures and films at interfaces. In the last few years this field of research has undergone a great renaissance due to the stimulus of new theoretical ideas and rapid progress in experimental techniques. Another cause of these rapid developments is the interest generated by technological advances in areas such as the encapsulation of drugs, new methods of diagnosis for various conditions, and the controlled release of pharmacologically active substances. These modern applications of surfactant science have also resulted in an increased demand for texts dealing with the fundamental principles. This new book fills that gap, and covers the basic principles of vesicle formation. The chapters have been written by 25 recognized experts with many years of experience in this area. As a consequence of the large number of authors there is a considerable amount of repetition. However, this has some advantages, since it means that each chapter is self-contained, so that readers who are only interested in one special topic or aspect can concentrate on the relevant chapters.

The main aspects covered in this book are the physicochemical properties of vesicles, new methods for analyzing their structures, and a detailed consideration of the various transport mechanisms. As well as matters of a fundamental nature, technological applications in the pharmaceutical and medical fields are also described. Like many others of a similar kind, this textbook is partly based on lecture courses, and the continual exchange of views with students has enabled the authors to present the complicated subject matter in an attractive way and with considerable didactic skill.

The contents are arranged under four main subject areas, each divided into a number of chapters. A brief introduction to the basic principles of vesicle formation is followed by a discussion of the thermodynamic and kinetic properties of the aggregates. The aspects treated are mainly well-illustrated by appropriate figures of excellent visual quality. After explaining the most important aggregation phenomena, the authors turn to the behavior at interfaces. Surface tension, adsorption, and the molecular structure of lipid films are all discussed in detail. The following chapters are concerned with different types of syntheses of vesicles and with the physical properties of these aggregates. These include, for example, mechanical properties such as the bending modulus of membranes and the compression modulus. In describing the numerous measurement methods used, the authors also include the essential principles of modern techniques such as micropipetting and fluorescence measurements. In addition to normal vesicles, inverse systems formed in hydrophobic solvents are also treated in detail. The storage of active agents in lipid membranes is very important in pharmacology, and a separate chapter is therefore devoted to this topic. The fifth article is concerned with the many different types of interactions with surface-active agents, and also considers different forms of aggregation of surfactant molecules. This is followed by a section on the characteristic fluctuation phenomena exhibited by vesicles, with a short introduction to the various hydrodynamic models. The next chapter describes the use of light scattering techniques to determine the sizes of vesicles. These methods can be used to determine not only the vesicle dimensions but also the size distribution, and flow-induced phase changes are also discussed. A particularly interesting technique discussed is the labeling of vesicles with fluorescent probes. Another important topic is the mechanical properties of lipid membranes, and the measurement of these by the micropipette method is described in detail. This is followed by a discussion of the properties of liposomes for pharmaceutical applications, including the microencapsulation of drugs and the various transport mechanisms involved. The last chapters are concerned with relevant technological developments in areas such as the diagnosis of diseases, applications in immunology, and the controlled release of drugs.

The chapters provide up-to-date introductions to many interesting topics, and are written in such a way that even the reader without previous knowledge can quickly absorb the essential information. The articles are of a high scientific standard and include interesting examples from many different areas of surfactant chemistry. The authors have succeeded in explaining complex subjects in clear and easily understandable language. Thus the book is enjoyable to read, and the user will make rapid progress in learning about the field.

In view of the good choice of highly topical subject matter, the book will be of interest to a wide readership, not only among pure scientists. It will be useful to technicians, medical scientists, pharmaceutical chemists, and environmental scientists as a source of detailed information on modern methods. The articles will provide many new ideas, and the book can therefore be recommended unreservedly.

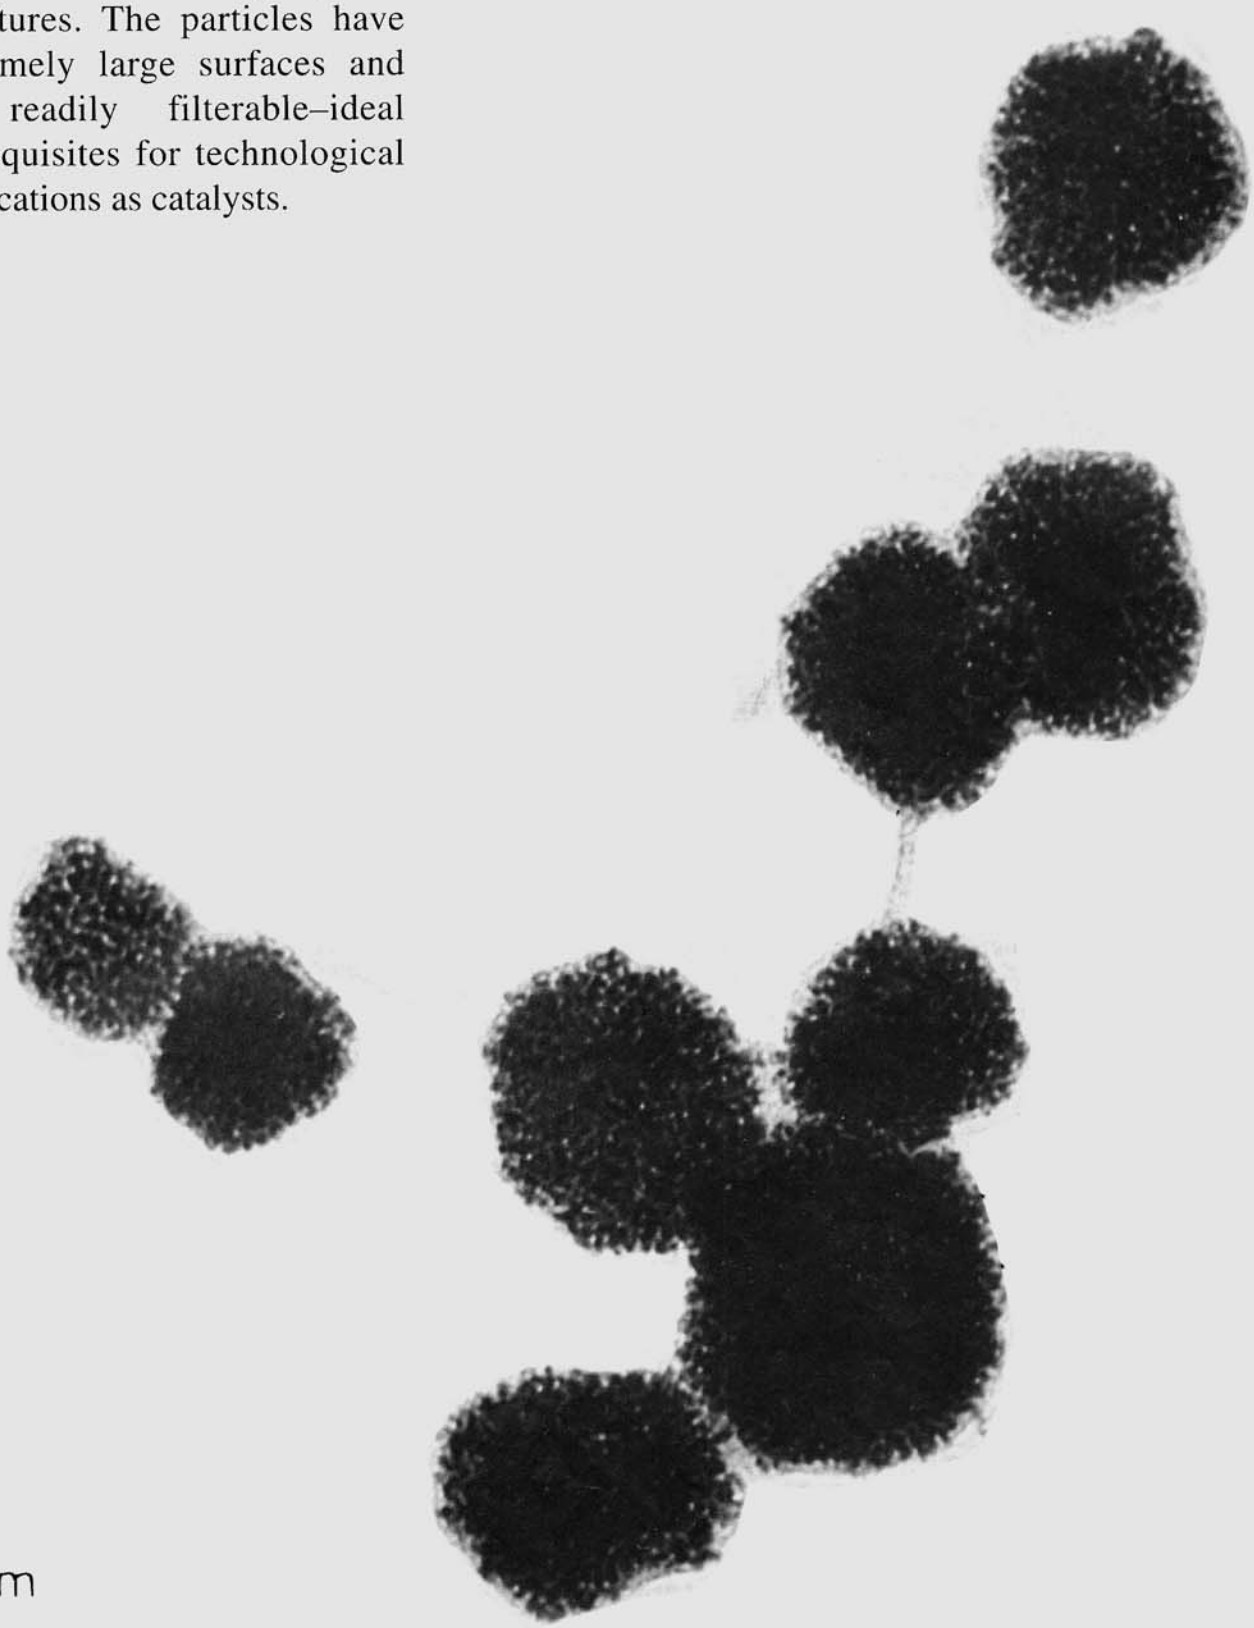
This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Collodial palladium particles with nanometer-scale spongelike structures. The particles have extremely large surfaces and are readily filterable–ideal prerequisites for technological applications as catalysts.



Superstructures of Functional Colloids: Chemistry on the Nanometer Scale

Markus Antonietti* and Christine Göltner

Chemistry is classically concerned with the connection of atoms and molecules into new functional units. The rules of connection are yet to be extended to the generation and connection of larger objects, whose dimensions are measured in nanometers. However, linking objects of this size through molecules approaching each other randomly is inefficient, instead the principle of self-assembly is decisive, in which lyotropic structure formation or amphiphilic interaction play a significant role. As a result of the nature of the energetic driving forces, the objects generated in this way are often well-defined aggregate structures or highly symmetric volume phases. In contrast to "molecular chemistry", the linking of larger objects also disregards the inherent borders of classical fields of chemistry: for example, the nanoscale association of inorganic colloids with polymers affords hybrid materials that combine the physical properties of both partners. In such a way, catalytic, optical, and electronic features of inorganic colloids might be combined with the mechanical characteristics of polymers such as film formation, elasticity, and melt processibility.

Keywords: colloids · materials science · nanostructures

1. Introduction

During the last few years, researchers from many different scientific fields have put forward the idea that the controlled construction of structures with increasing complexity needs not necessarily be carried out with the help of atoms and molecules as building blocks, but that it can also be based on significantly larger entities. J.-M Lehn and others introduced the concept of supramolecular chemistry;[1] A. J. Bard, who rather focused on properties and performance of materials, developed the idea of "integrated chemical systems",[2] an analogy to the integrated circuits of microelectronics. A comparison of these definitions makes it quite clear that they all rely on one common idea: the formation of chemical systems with novel properties and novel combinations of properties by utilizing preformed building blocks and by their connection into ordered nanostructures. The dimensions of the resulting chemical systems (and sometimes also that of the building blocks) are 1–2 orders of magnitude above those of classical low molecular weight compounds; accordingly, this branch of science has become known as "nanochemistry" or "chemical nanotechnology".

Naturally, a colloid chemist tends to recognize the great concepts and building blocks of the colloid chemistry of the early 20th century in this approach: in fact many structural features of supramolecular chemistry are closely related to classical micellization and aggregation, and the rules of stability and solubility of heterophase systems follow those applied to classical colloids. In 1915 Wolfgang Ostwald paraphrased this regime between 1 and 500 nm, which bridges the gap between atoms and molecules on the one hand and solid-state science on the other, "Die Welt der vernachlässigten Dimensionen" ("the world of neglected dimensions"[3]). In modern terminology, we refer to these dimensions as "mesoscopic".

This categorization, however, does not do justice to the interdisciplinary character of this trend in science: similar structural concepts were also developed in biochemistry, inorganic chemistry, polymer science, and supramolecular chemistry. As the building blocks constituting the larger objects are not necessarily molecules in a literal sense, the terms "nanochemistry" or "modular chemistry" seem appropriate.

A characteristic feature of the approach described in this review is the prefabrication of subunits or components, which subsequently aggregate, either spontaneously or under special conditions, into larger structures. In the ideal case, the build-up of complex matter is performed by using a hierarchical construction principle and structural integration on various levels. The resulting materials can exhibit synergistic properties or combinations of properties, which go beyond those of single components. Hence, the features are not only born by the single molecules on the level of single molecules, but are also based on the build-up of the material on different levels.

2. Concepts

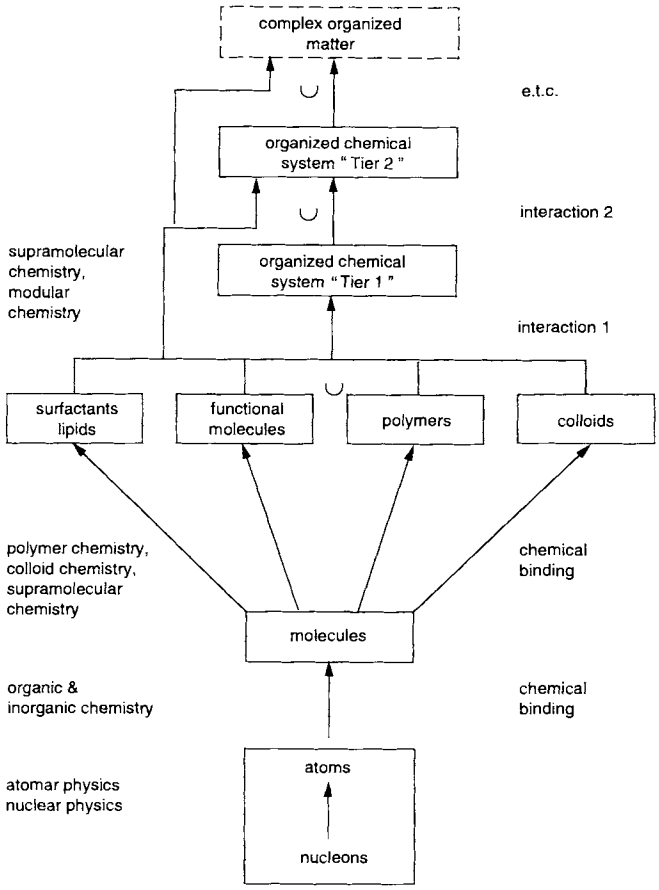
As the concepts of "nanochemistry" have been put forward from diverse points of view and have emerged from several fields of science, the aim of this review can only be to screen the various concepts, to put them in context with one another, and to establish a uniform terminology, at least within the scope of the work presented here. This should then allow the recognition of the common features of these new concepts and, based on these, to develop new research strategies.

Again, it was Jean-Marie Lehn who drew our attention to the meaning, but also to the danger of too strict a conceptualization and definition by quoting Roland Barthes.[4] Furthermore, "shaping of the language of a new field must avoid becoming a burden".[1] The following paragraph should be viewed bearing this in mind.

The concept according to which chemical systems of increasing complexity and performance were produced by nature is outlined in Scheme 1. After the integration steps from nucleons to atoms (nuclear chemistry) and from atoms to molecules (cosmo- and geochemistry, molecular chemistry), Lehn and Bard define a level, on which suitably functionalized molecules are connected to form more complex molecules or noncovalently linked supermolecules, molecular hybrids, as well as "systems". This first hierarchical level (Tier 1) of nanochemistry can be followed by a series of further steps of higher complexity, which can include further components or whole systems.

In the following we shall refer to the units that constitute the molecular hybrid or chemical system as *components* or as chemical *modules*. A component or a chemical module is therefore defined as a subunit made up by atoms or larger constituents, which is well characterized with respect to molecular weight, shape, architecture, and functionality. Here, functionality can be chemical, that is based on a certain number and arrangement of substituents, or physical, that is based on the anisotropy of shape or particular electronic or magnetic properties. Chemical modules or components represent, figuratively speaking, the elements of the nanochemical Periodic Table and replace the molecule as the object of chemical consideration.

The idea of components has already been described by Lehn, who further distinguished between functional, structural, and ancillary components as constituents of a chemical system.[1] The task of the structural components within a system is obvious: they form the scaffolding, to which the functional components can be attached. The responsibility of the ancillary component can be manifold: they modify, break down the construction or make it flexible, support the functionality as a



Scheme 1. Concept of the hierarchical construction of matter, as occurs in nature. Self-assembly is driven by various competing interactions, which—from step to step—cause the resulting systems to exhibit increasing complexity and performance. A research field has recently been established above the level of classical molecular chemistry, polymer, and colloid science, which is focused on the organization of such components into larger systems.

Markus Antonietti completed his habilitation in physical chemistry at the Universität Mainz. Subsequently he moved to the Universität Marburg, where his interests focused on polymer chemistry. Since 1993 he has carried out his research at the Max-Planck-Institut für Kolloid- und Grenzflächenforschung in Teltow, Germany.

Christine Göltner studied chemistry at the Universität Göttingen and completed her diploma there with work on dye chemistry. She received her doctorate at the Universität Mainz for work on thermotropic, discotic liquid crystals, and subsequently developed new mesoporous silicate glasses by templating lyotropic surfactant phases at the University Southampton, England. At the Max-Planck-Institut für Kolloid- und Grenzflächenforschung, Teltow, Germany, she heads the research group on "mesoporous materials".

C. Göltner

cofactor, or stabilize the whole system. Examples for all three types of component are given below.

One remarkable peculiarity of the nanochemical approach lies in the connection of the components: the connection cannot occur without a series of rules, since the chemistry of large molecular units is too complex. Experience has shown that the binding based on the random mutual approach of molecules, as is applied in molecular chemistry (mix and reflux), only affords negligible yields. The control required for the binding process makes self-assembly, prior to connection, an important prerequisite, that is an approach of the components under specified environmental conditions into a well-defined structure has to be arranged. This self-assembly is based on a suitable interaction between the modules, which, on the one hand, is sufficiently weak to allow the exploration of the potential energy surface of mutual approach, and on the other hand, must provide sufficient strength to stabilize the desired structure as a molecular entity. The alternative structure, which results from instantaneous and strong binding, is that of a statistical aggregate, which is described by dynamic percolation theory.[5] The theoretical grounds of self-assembly are currently subject of discussion.[6]

These demands with respect to energy make reversible, directed, and short-range interactions particularly suitable for the defined construction of superstructures, and in supramolecular chemistry the most important interactions are hydrogen bonding and metal complexation.[1] For larger objects, such as colloidal aggregates or proteins, the binding of the components can no longer be performed by a single group, which is why "fit" interaction and amphiphilic interaction play an important role in generating ordered equilibrium structures. Fit interaction is the precise fitting of the interacting surfaces with respect to geometry, electron density, and polarizability, as demonstrated in an enzyme–receptor/substrate complex. The control of the fit interaction is extraordinarily demanding, and chemists have only just begun to understand it from approaches like molecular evolutionary biology[7] or "molecular imprinting".[8] At the same time, this interaction is very specific for a pair of interacting components; the disadvantage is that it is not possible to generalize it.

In this article we therefore focus on the preorganization of components through amphiphilic interaction, which is a superposition of van der Waals and polar interaction, in which differences in polarity and cohesion energy density are built up on the level of components in a controlled manner. These differences are then compensated by the formation of domains in the resulting chemical system. Known examples from the field of colloid chemistry are the formation of micelles or lyotropic liquid crystal phases by surfactants in suitable solvents (mainly water), as surfactants consist of a polar as well as an apolar part of the molecule (amphiphilicity).[9] As most of the systems described in this article do not contain any solvent, we prefer not use the term "lyotropic" for ordered solid structures based on amphiphilic interactions.

When chemical systems shall be created with the help of more than one level of complexity, the different levels must not obstruct one another. Therefore, each step within a construction cascade has to make use of a different type of interaction. Thus, the whole supramolecular structure with all its integration levels and their different interactions is coded in the primary components.

The chromatin structure, which is constructed by a cell to store genetic information, serves as an instructive example: four different histones (small spherical proteins) aggregate into dimers (fit interaction), and through their hydrophobic domains (amphiphilic character of the dimers) they form octamers. These octamers can bind sections of the acidic DNA to their surface base functions (acid–base interactions, hydrogen bonds). This leads to a kind of pearls-on-a-string structure, which is coiled into a helix with five complexes per pitch (minimization of interfacial energy)[10, 11] (Figure 1). The special function of the chromatin superstructure is evident: it allows the storage of the highest information density and at the same time provides excellent data security and good readability.

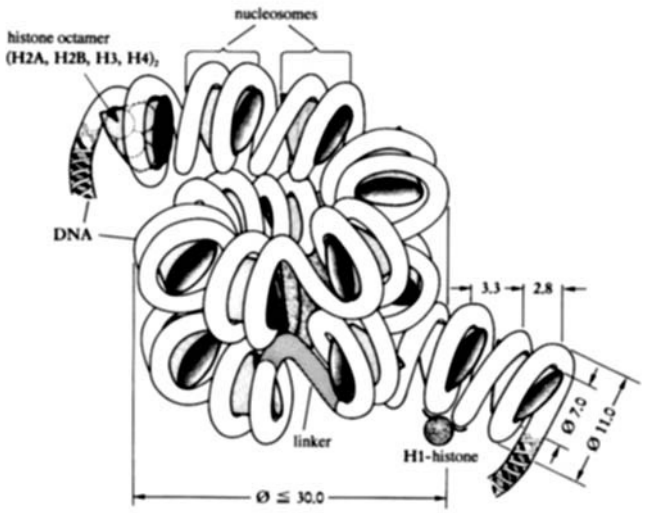

Figure 1. The superstructure of chromatin (adapted from ref. [11]) as an example for a chemical system with a coded structural hierarchy.

At this stage two further deductions should be mentioned that are typical of a nanochemical approach and that have a great influence on the work with such systems. Scanning the necessarily relatively flat potential energy surfaces results in a thermodynamic equilibrium of high complexity, but at the same time involves a distinct kinetic lability. Lehn pointed out that the inherent energetic structure of such a chemical system allows it to tolerate errors and to heal defects. The interesting, however often forgotten, inversion of this principle is the fact that the presence of thermal energy is always accompanied by a Boltzmann probability of introducing defects. A uniform, faultless modular system is therefore a contradiction in terms. If a certain property that is sensitive to defects (e.g. electrical conductivity in one dimension or permeation in two dimensions) is to be programmed into such a system, a defect-tolerant construction outline is mandatory.

It is interesting from a point of view of application that the products of nanochemistry are novel materials with new, useful properties, but that there is not necessarily a need for new starting materials: new applications and properties rather are a result of tailoring matter on a nanometer scale and subsequently arranging the components by means of chemical interactions. One can say that the components are "trained" to undergo molecu-

lar "team formation", and complex tasks are solved by "compartmental sharing of functions". Such a concept has many advantages with respect to environmental protection, manufacturing costs, and certification procedures: new properties need not be coded on the molecular level, which is usually expensive, but in the ideal case they arise from a combination of inexpensive and environmentally harmless components. This "soft chemistry" (soft because of the softness of the interactions) is a welcome supplement to the classical "hard chemistry"; the latter usually employs increasingly complicated synthesis procedures affording increasingly complex molecules, which are accompanied by a vast amount of financial effort, manpower, and unclear consequences.

Heteromodular compounds, such as nanohybrids made from metal, ceramics, and plastics, show an especially high potential for further development. The materials properties of hybrids of this kind would extend the limits of classical materials, and would particularly benefit from molecular team formation, as the chemically very different "specialized" single modules would introduce a great variety of physical properties into the resulting system.

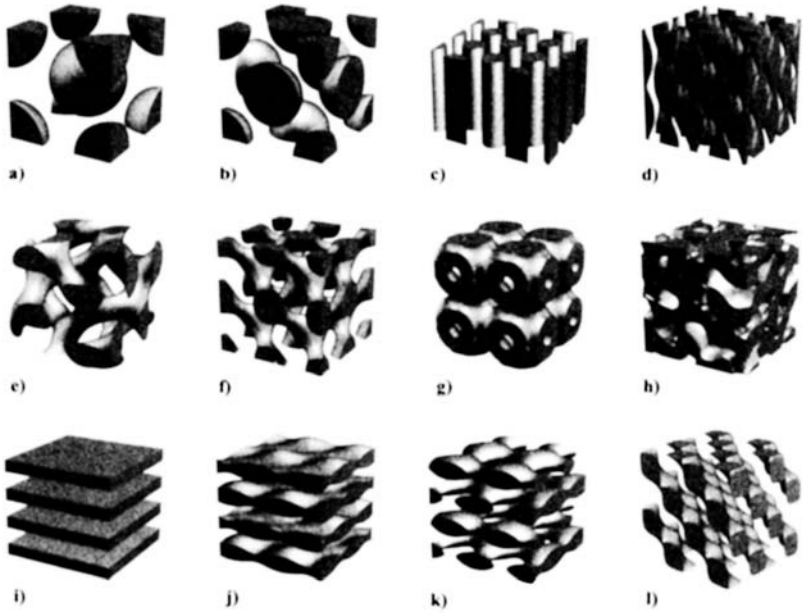

Figure 2. Typical mesophase structures of lyotropic liquid crystal phases or segregating block copolymers [14]: a) body-centered cubic (bcc) packing of disperse spheres; b) face-centered cubic (fcc) packing of disperse spheres; c) hexagonal structure; d) undulated cylinders with tetragonal packing; e) gyroid phase; f) bicontinuous double-diamond structure; g) *Im3m* phase; h) L_3 phase (spongelike structure); i) planar lamellar structure; j) undulated lamellae with tetragonal symmetry; k) tetragonally perforated lamellae; l) hexgonally perforated lamellae with rhombohedral symmetry.

3. Chemical Realization

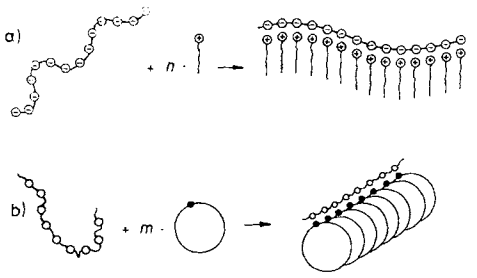
In order to demonstrate the successful realization of the concepts presented in Section 2, we have selected four examples that emphasize different aspects of this wide branch of research. The choice of examples is not to be understood as a judgment, but rather as a consequence of our activity in these areas, which allows a widely up-to-date description of the concepts.

3.1. Polyelectrolyte-Surfactant Complexes as Self-Organizing Building Blocks—Does Nature Know How To Play Molecular Origami?

The self-assembly of surfactants (soaps) into micelles is probably one of the best known and most utilized phenomena. For an introduction into the chemistry and physics of surfactants the authors recommend textbooks[9, 12] and review articles.[13] It is also commonly known that the aggregation of surfactants into micelles is the basis of a variety of technological processes, such as the washing process and phase-transfer catalysis. In contrast, the beauty and complexity of lyotropic liquid crystal phases, which are formed in high-concentration surfactant solutions, is mainly the domain of the specialist. As a result of the underlying energetic rules, these phases show highly symmetric architectures, some representatives of which are depicted in Figure 2. Despite their beauty it has not been possible to utilize these architectures because of their fragility: dynamic exchange processes cause these structures to rapidly interconvert as a result of environmental parameters. Their consistency is best described as oil- or margarinelike, which allows their application by virtue of their function (e.g. shampoos), but not by virtue of their structure.

In order to exploit the surfactant phase structures in all their various morphologies, these aggregates have to be nanochemically stabilized by a second component, without compromising their ability to form structures. The function of the second component in this "team" is the introduction of mechanical stability and the improvement of handling. During the past few years it has been shown that this is possible by complexing a charged polymer (polyelectrolyte) with oppositely charged surfactants. The formation of polyelectrolyte–surfactant complexes (PESurfs) follows a very simple process of self-assembly: PESurfs are "synthesized" by adding an aqueous solution of the polyelectrolyte to an aqueous solution of the surfactant. The opposite charges on the surfactant molecules and the polymer backbone cause an attractive Coulomb interaction, which—increased by the additional hydrophobic interaction of the alkyl chains—initiates a cooperative aggregation process, reminiscent of a zipper. As a result, the PESurf becomes increasingly less water-soluble and precipitates, usually in a strict 1:1 stochiometry. This mechanism of formation is illustrated schematically in Scheme 2.

This mostly perfect fulfillment of stochiometry (with respect to charge) has been known for a long time,[15–17] and accordingly allows the quantitative determination of surfactant (or polyelectrolyte) contents, for example, in wastewater. The significance of these easily accessible PESurfs as structure materials, however, is new, and has only become evident as a result of investigating their solid-state structures. Flexible films of high homogeneity, good optical quality, and very often high mechanical stability can be cast from these complexes.



Scheme 2. Schematic representation of polyelectrolyte–surfactant complex formation: In a zipper mechanism, the polyelectrolyte thread is complexed highly cooperatively in a 1:1 stochiometry as a result of Coulomb attraction and hydrophobic interaction (a). Towards the end of the reaction the complex precipitates from solution. This mechanism is not restricted to surfactants, but also allows the line-up of other molecular geometries arising from other interactions (b).

As the complexes still possess the structural features of the surfactant (a line-up of matching charges on the one hand and the incompatible, waxlike alkyl chains on the other), a microphase separation occurs in the solid state. As a result of the surfactant geometry, the formation of microphases is limited at approximately twice the length of the surfactant molecule, and formation of an ordered structure is observed. The phase structures formed by such systems can be extraordinarily manifold and are often highly symmetric (see Figure 2); the particular morphology depends on a delicate balance of the relative volumes of alkyl and ionic phase, the absolute interface energy (determined by the number of surfactant molecules per unit volume), the spontaneous curvature of the interface as well as many other factors, which are associated with the geometries of the surfactant and the polyelectrolyte component. The characteristic length of the sequence of microphases (better: nanophases) depends on the nature of the surfactant and on the symmetry, but usually lies between 2 and 8 nm.

A very instructive example for ordering effects in solid PESurfs is the complex made from polyacrylic acid and dodecyl trimethylammonium counterions (PAA-C_{12}). This complex is a rubbery, highly deformable, self-reinforcing material, which is strongly birefringent in the aligned state.[18] The small-angle X-ray diffractogram (Figure 3) illustrates the high degree of order on a nanometer scale.

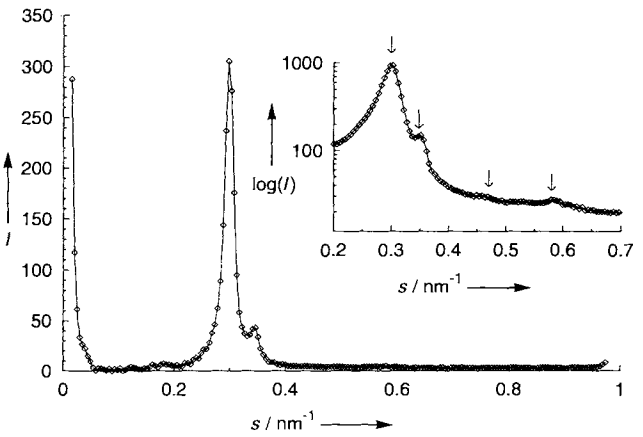


Figure 3. Small-angle X-ray diffractogram of the complex consisting of polyacrylic acid and a cationic C_{12} surfactant (PAA-C_{12}). The scattering vector s is defined as $s = 2\sin\theta\lambda^{-1}$. For the purpose of clarity the inset shows the logarithmic plot of the data.

Although completely amorphous on a nanometer scale (as revealed by wide-angle X-ray diffractograms, which are not depicted here), a series of very narrow scattering peaks is observed in the small-angle region, which can be indexed according to a face-centered cubic (fcc) lattice. The optical and mechanical behavior, however, contradicts the expectations held for such a morphology and rather suggests a cylindrical arrangement of the microphase-separated complex. For that reason, the structure model shown in Figure 4 was proposed. As a result of the relative volumes of the ionic and the alkyl chain domains in a cylindrical phase structure, the problem arises that the system has to accommodate an excess of surfactant head groups and the associated interface (demanded by the surfactant geometry). This excess is distributed over undulations within the cylinders, which are coupled with each other and therefore adopt a cubic lattice. The existence of such undulations has been theoretically described by de Gennes,[19] and because of their origin, namely the conflict between two energy contributions that cannot be optimized at the same time, has been called the "frustration effect". Similar periodic density fluctuations perpendicular to the principle symmetry elements have been observed for lyotropic surfactant phases, although not to this extreme extent.[20]

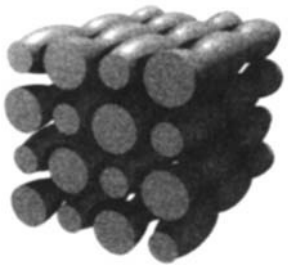

Figure 4. Model of the phase structure of PAA-C_{12}.

It should be pointed out that the polyelectrolyte chains also have to put up with strict geometric rules in the microphase. It can be calculated that the nanocylinder in such a phase offers space for approximately four polyelectrolyte chains. Following the microphase geometry, these chains have to adopt a stretched conformation. This "molecular spinning" is reflected by the tendonlike, self-reinforcing mechanical behavior of the overall structure (note that tendons, following a similar structural principle, consist of single collagen strands forming nanofibrils).

In the context of the above-mentioned definitions, PESurfs are a typical example for the nanochemical approach and for the resulting chemical systems: a highly symmetric, ordered structure is generated on a nanometer scale by self-assembly, and the particular properties introduced by the two incompatible components are preserved. The surfactant introduces the possibility of self-assembly and structure formation, while the polymer chain provides mechanical robustness, processibility, and handling for the resulting hybrid material. The mechanical properties of this system are strictly synergetic, as the polymer properties of the polyelectrolytes are enhanced by avoiding their statistical conformation, which is achieved purely by self-assembly (molecular stretching).

Besides cylindrical phase morphologies cubic and lamellar structures have been reported. The lamellar complexes allow precise adjustment of the microphase structure by subtle changes of the chemistry. The homologous series of complexes obtained from polystyrene sulfonic acid (PSS) with different alkyltrimethyl counterions (C_{12}–C_{22}) is an instructive example. Here, the extent of undulation that is superimposed on the prin-

ciple symmetry can be fine-tuned by varying the chain length of the surfactant.[21, 22]

As a consequence of the steric demands of the polyelectrolyte chain, all these complexes are lamellar. An extension of the surfactant alkyl chain, however, changes the "characteristic ratio" of the amphiphile, and thus also the spontaneous curvature of the interface. The curvature of the two-dimensional interface is a result of energy minimization. PSS-C_{14} forms a planar lamellar phase (Figure 5a), the structure of PSS-C_{16} shows irregular undulations on the lamellae, PSS-C_{18} exhibits a morphology in which periodic undulations adopt an fcc lattice, which is superimposed onto the lamellar phase (we call this kind of morphology a "mattress phase"; Figure 5b). The structure of PSS-C_{20} is characterized by a periodic piercing of the ionic layers by alkyl domains (in this case the structure is only metastable; Figure 5c).

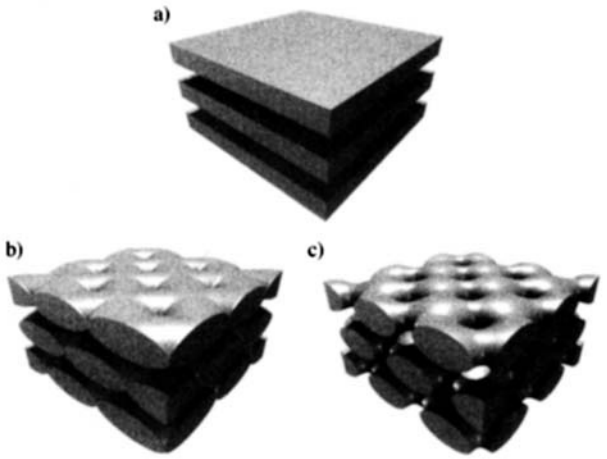

Figure 5. Lamellar phase modifications of polyelectrolyte–surfactant complexes: a) planar lamellar phase; b) "mattress phase" (undulated lamellae); c) perforated lamellar phase.

One variation on the theme of PESurfs, which was adopted from nature is the complexation of polyelectrolytes with lipids instead of surfactants. The central feature of the nanostructure of materials obtained by this procedure is bilayers that are stabilized by the polyelectrolyte chains. This structure is reminiscent of the cell membrane with the difference of being a volume material. Approximately 200000 stabilized bilayers are stacked on top of each other per millimeter of material. First experiments in this direction were presented by Kunitake et al.[23, 24] and Okahata et al.,[25, 26] who complexed model lipids both with synthetic and also with natural polyelectrolytes. The resulting materials are soluble in organic solvents, and the films cast from these complexes show the stack-of-bilayer morphology that is typical of lipids. This result suggests that the presence of the polyelectrolyte hardly affects the phase morphology. The characteristic phase transition of such membranes, which is attributed to the melting of the chains, is slightly shifted towards higher temperatures; this shift indicates a restricted mobility of the alkyl chains and an efficient coordination of the lipid to the polyelectrolyte. This is another example of how the complexation of lipids can make their aggregation structures more stable.

As it is of general interest to produce biomimetic membrane materials at low cost, the complex made from soybean lecithin (a natural mixture, extracted in large quantities from soybeans, which contains a variety of partly anionic head groups and alkyl chains) and cationic polyelectrolytes is of considerable importance. This material exhibits some extraordinary physical properties.[27] Unlike most synthetic model compounds of the PESurf family, this complex is rubberlike and highly malleable. The stacks of membranes can be readily aligned by simple stretching. These orientation processes can be monitored impressively by polarized light optical microscopy (Figures 6a–c):The as-made membrane film appears white when viewed be-

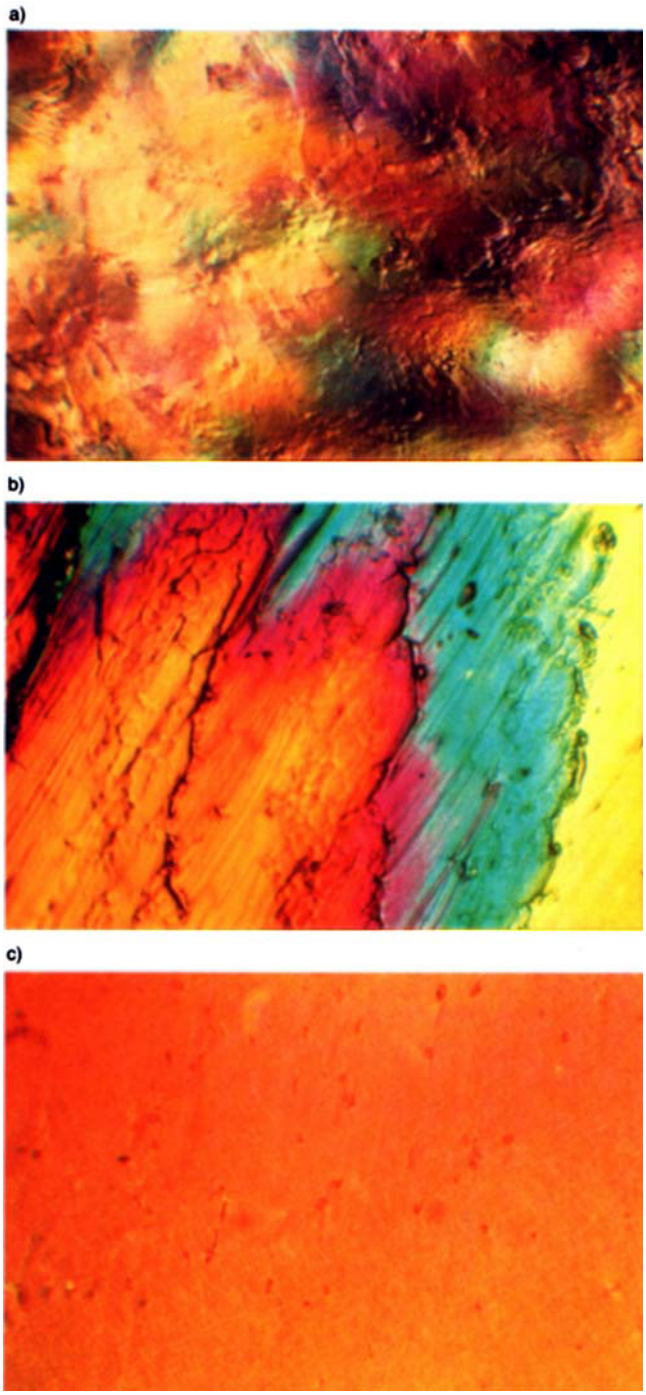

Figure 6. Polarized light optical micrographs of plastic polyelectrolyte–surfactant complexes at different degrees of stretching: a) untreated material; b) beginning mesoscopic orientation under slight stretching (30–100%); c) perfect orientation at complete stretching (300%). The slight color shift is a result of uneven thickness of the film.

tween crossed polarizers, as it contains only small domains with little long-range order. In the partially aligned state, the anisotropic monodomains grow beyond the length scale of the wavelength of visible light, thus the film shows all colors of the rainbow. After completing the alignment the film shows a uniform color when viewed between crossed polarizers, as the membranes adopt an alignment parallel to the stretching direction and perpendicular to the film surface.

The perfection of alignment can also be quantified by X-ray diffraction. In view of their rubber elasticity and their membrane features, these complexes were named "plastic membranes". The reason for the unusual physical properties of the soybean lipid complex lies in a particular phase morphology, which interestingly is only observed for the natural lipid mixture. This morphology is also lamellar, but here the stacks of bilayers undulate with extreme amplitudes. A computer-generated picture of this superundulated phase structure is depicted in Figure 7a.

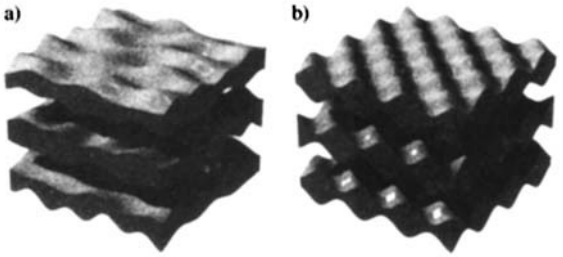

Figure 7. Phase structures in natural membrane lipid complexes: the "superundulated" phase (a) is very flexible and elastic, whereas the "egg carton" phase is brittle and highly ordered (b).

Quantitative evaluation of the small-angle X-ray scattering data reveals that the actual interface per projected plane area (A/A_0) has a value of 1.38. Typical values caused by thermal excitation of lamellar phases are significantly lower and in the order of $A/A_0 = 1.1-1.2$.[28] This excess "roughness" is of utmost importance for the materials properties of this complex, and has been postulated by Helfrich et al. to account for some of the physical membrane properties of naturally occurring bilayer membranes, which cannot be explained by a planar bilayer structure.[29-31] The phase morphology found for the soybean lecithin complex seems to be evolutionarily flexibility and nonstickiness, since the additional interface area supports the deformable character. Here, the reseachrer working in the field of nanochemistry, whose aim it is to optimize materials properties by utilizing supramolecular architecture can only admire nature and learn.

As the undulations on the bilayers provide a large amount of excess interface area, it is interesting to gain a deeper insight into how sensitive the system is to compositional changes in the natural lipid mixture. This can be achieved for the soybean lecithin by artificially increasing the amount of the lipid fraction with inositol phosphatidyl choline head groups in the natural lipid mixture. In fact the resulting complex shows behavior significantly different to that of the material discussed above;[32] for instance, it is extremely brittle, very much in contrast to the plastic membrane. At the same time the stacks of bilayers are packed in a highly ordered fashion, as revealed by small-angle X-ray diffraction. These effects are explained by the occurrence of a new order phenomenon, which was theoretically predicted by Helfrich and Götz:[33] the undulations, which occurred statistically before, are now packed into a periodic arrangement, and the structure proposed for this material resembles that of an egg carton (Figure 7b). Here, the lamellae show periodic undulations that render the high rigidity that is also observed macroscopically. It is well known that corrugated iron or cardboard as well as palm leaves (which all rely on the same architectural principle) are far more difficult to bend than the pure materials they are made of, because they are reinforced by a periodic arrangement of undulations.

As the natural mixture of head groups in soybean lecithin is the product of an evolutionary process, the similarity of the flexible superundulated phase to the extremely rigid egg-carton phase (note that there is no classical planar structure observed between the two) cannot possibly happen by chance: evidently, Mother Nature knows how to play "molecular Origami".

To the modern scientist, these naturally occurring folding tricks are an inspiration with respect to the possible application of such materials. Within the nanochemical approach, these "structural components" can even serve as a matrix for chemical functional components, which are mixed into the material as a "cosurfactant". Some functionality already arises from the architecture of such complexes. Okahata et al. demonstrated that the permeability of polyelectrolyte–lipid complexes can be modified by applying weak electric fields,[25, 34] which opens a route towards mechanically stable, electrically switchable artificial membranes, or release systems for pharmacological application. Ishikawa and Kunitake employed such complexes as matrices for functional molecules in order to study controlled membrane processes.[24]

More recent work involved the investigation of the mechanical and dielectric behavior of PESurfs and polyelectrolyte–lipid complexes.[35, 36] For example, the complex between polyacrylic acid and didodecyldimethylammonium conterions at room temperature shows a high elasticity and storage modulus of $G' \approx 200$ MPa, which is an unusually high value for an elastomer. The mechanical properties are reminiscent of those of reinforced rubber (such as certain polyurethanes or carbon-black-reinforced polyisoprenes). The superundulated lecithin complex shows even better elastic yields; however, the storage modulus at room temperature is decreased.[35] Both observations underline the vast possibilities for materials science that are rendered by the nanochemical approach.

The extraordinarily high order of PESurfs and polyelectrolyte–lipid complexes also allows applications that at first sight do not seem to be related to any structure formation. For example, complexation of polyelectrolytes with perfluorinated surfactants affords materials, the surface of which are "sealed" by an almost perfect packing of trifluoromethyl groups. As a result, such compounds show an extremely low interfacial energy with respect to air,[37] which almost reaches the theoretically calculable minimum value for solids. They undercut even the technologically widely applied poly(tetrafluoroethylene) (PTFE) by about 40%. Such a surface repels all other materials and is not even wetted by silicon oil, which is a widespread wetting agent.[37]

Other complexes of this type, in which the ionic phase is designed to show a high ion mobility, can reach specific electric conductivities in the order of $\sigma > 10^{-5}$ S cm^{-1}, and at the same time maintain their flexibility and transparency.[36] Furthermore, first tests on the applicability of such materials as highly selective membranes for gas separation, which utilizes the differences in solubility of different gases as well the multilayer architecture on the nanometer scale, showed promising results. The permeability and pressure resistance of these compounds is simultaneously optimized by sharing these functions between the two components: oxygen can be separated from nitrogen and carbon dioxide from fuel gases.[38]

The "synthesis" of PESurfs and polyelectrolyte–lipid complexes by simply mixing components and relying on their tendency to self-assemble opens access to a variety of nanostructured materials, and is comparable to playing with a "LEGO" set: flexible films or colloidal egg cartons are materials, whose properties result from a superstructure controlled directly by mixing. Furthermore, this family of compounds demonstrates instructively the synergistic hybridization of the single component's physical properties in a material, which is a central feature of the nanochemical approach. This was shown by many aspects, all of which are based on the combination of the advantageous properties of surfactant phases (order, low interfacial energy) with those of polymers (stability, elasticity processibility).

3.2. Polymerization in Heterophases, Lyotropic Phases, and Microemulsions: Design and Utilization of Large Surfaces

Whereas the structural effects caused by amphiphilic self-assembly were described in Section 3.1, here the emphasis is on the internal interface associated with such structural patterns and with its chemical functionalization. In order to understand the importance of internal and external interface areas of colloidal systems it should be mentioned that the distribution of a material as nanoparticles with a radius of 5 nm generates no less than 600 m^2 per cm^3 material, which are then readily available to the chemist.

In the case of inorganic materials such small spheres can be stabilized by precipitation at low concentrations and high charge densities;[39, 40] a wider variety of synthetic possibilities is realized by introducing structural components based on polymers. This can be achieved by applying modern methods of heterophase polymerization, which are simple, inexpensive, and technologically interesting. As most standard polymers are relatively apolar, the high gradient of polarity between the polymer particle and the dispersion medium water can be exploited in a nanochemical approach by utilizing amphiphilic association as a principle for structural lay-out. Surfactants play an important part in the various methods of heterophase polymerization, as they are mandatory as auxiliary stabilizers of the reaction mixture during particle formation. However, the surfactants are not employed as structural components, and they can even be removed from particular systems after polymerization.

Among the different ways of conducting heterophase polymerization processes, the polymerization in microemulsions is especially interesting for those who want to synthesize functionalized nanosystems, as this method affords the smallest possible particles. A microemulsion is a thermodynamically stable mixture consisting of water, an organic substance (e. g. an oil), and a suitable surfactant; this mixture is macroscopically homogeneous, because its phase separation occurs on a nanometer scale. For microphase polymerization, one or both phases contain a polymerizable monomer that is supposed to polymerize without disrupting the microphase structure.

3.2.1. Synthesis of Small, Functional Spheres

Simple, globular microemulsions consist of small oil droplets (between 5 and 50 nm in diameter), which are stabilized by a dense surfactant layer. Polymerization in microemulsions utilizes these droplets as casting molds by solidifying their cores. In the ideal case the polymerization copies the initial microphase structure, that is a large quantity of very similar, small particles is generated in one step. Because of the particle size and the translucent appearance, such dispersions are also called "microlatices".

The size of the microlatices extends slightly above the dimension of the parental microemulsion, which is caused by a secondary process; however, the size still is directly controlled by the amount of surfactant present in such polymerization reactions.[41, 42] The synthetic potential of this polymerization technique was significantly increased by turning away from standard surfactants and employing more specialized stabilizers, such as surfactants containing copper ions.[43, 44] Another interesting approach involves making the surfactant counterions contribute to the structure formation of the microemulsion ("organically modified surfactants"[45]). Meanwhile, polymeric nanoparticles with radii down to 5 nm and a narrow size distribution are accessible. It should be noted that the polymeric cores of the smallest microlatices have molecular weights around 10^5 g mol^{-1}, which justifies treating them as molecular objects.

A synthetic route that uses organically modified surfactants can be understood as the first step in a nanochemical structure cascade, since the geometric shape of the surfactant molecule, its function, or even more complex surfactant topologies can be adjusted by a simple secondary interaction, and utilized to control the construction of further structure.[45] A beautiful example is represented by the "cocogems" (counterion-coupled gemini surfactants), in which two ionic surfactant molecules (the twin) are associated to a bifunctional organic counterion, for example tartrate, through Coulomb interactions. These surfactants show a significantly improved performance compared with standard amphiphiles.

The dependence of the particle size of microlatices on the amount of surfactant present is illustrated in Figure 8 a. It shows that the size of these nanospheres can be well-adjusted between 5 and 50 nm by simply changing the composition of the polymerization mixture. Figure 8 b shows a typical molecular weight distribution of the crosslinked polymer cores, as determined by field-flux fractionation (with multiangle light scattering detection[46]), a thermal chromatographic method commonly applied in the analysis of nanosized objects. As typical for colloid and polymer science, these components are not uniform, but show a narrow distribution of size and molecular weight.

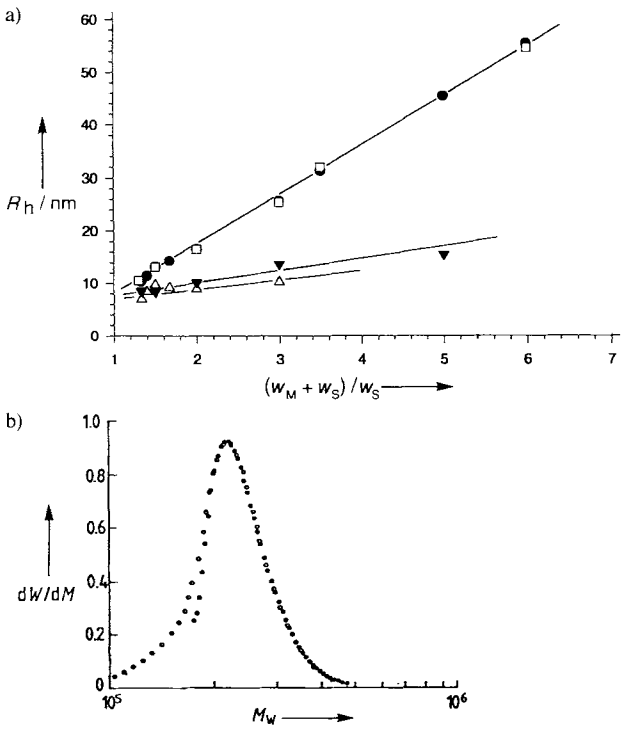

Figure 8. a) Polymer particle size of emulsion polymerization as a function of the reciprocal weight fraction of the surfactant: classical cationic surfactants (□, ●), copper-containing surfactants (△), "cocogems" (▼). The decrease of the particle size by using a compartmented system is significant. b) Molecular weight distribution determined by thermal field-flux fluctuation with absolute molecular weight determination.

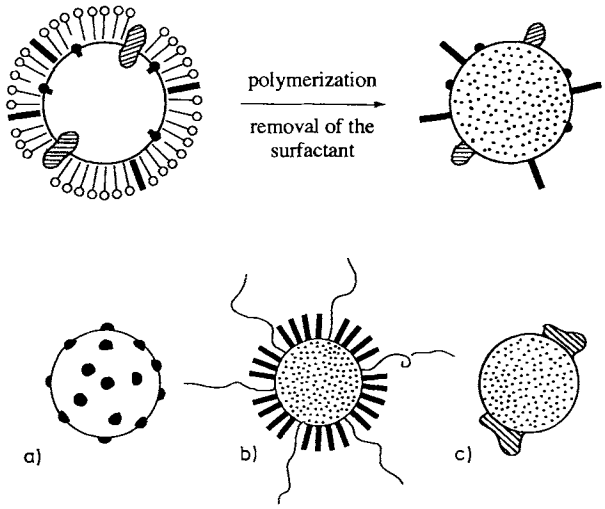
Besides the control of the size and shape of the building blocks, the chemist has to consider a functional layout of the very large particle surface mentioned above. In the case of polymerization in microemulsion, this is performed by simply casting other molecules or components into the particle.[47, 48] As a result of the high polarity gradient, all amphiphilic compounds or those, whose polarity lies between that of water and that of the oil, are enriched and included in the interface of the microemulsion (similar proteins within a cell membrane). Almost all interesting compounds with function match this profile. Microemulsions, however, do not always tolerate the introduction of large amounts of functional components, and the overall system is often destabilized and disrupted. Interestingly, this addition can also have an opposite, synergistic effect, and the latex particle size is decreased again as a consequence of adding a functional cocomponent. Therefore, the art of formulating such polymerizable microemulsions lies in choosing a surfactant system that is well suited to the desired product function.[48]

Thus, microlatices with densely hydroxylated, carboxylated, or aminated surfaces were prepared,[47] but also more specialized functionalities such as complexing bipyridyl units were introduced.[49] Also, mixed surface patterns were achieved. Functional microlatices can be dispersed in water and can be regarded as "white activated carbon", the extremely large surface of which is modified for a desired function. This feature is a considerable advantage with respect to chromatography and catalysis. The specific surface areas of such microlatices are extremely large: in a one-pot reaction in a one-liter flask we cover—figuratively speaking—the area of a medium-sized city square nanometer by square nanometer with a specific pattern by applying the principles of self-assembly.

The compounds cast into the surface of microlatices can contain very simple functional moieties, but they can also be big building blocks such as macromolecules or even colloids with very specific properties. This approach, which is borrowed from molecular cell biology, can be called "modular functionalization". For example short block copolymers of the type polystyrene-*block*-poly(4)vinylpyridine were added to a microemulsion (Scheme 3): here, the hydrophobic block acts as an



Scheme 3. Top: The principle of surface functionalization of microlatices: droplets in a microemulsion cause amphiphilic components or molecules to assemble in the interface, where they are entrapped by polymerization. Removing the surfactant results in the generation of particles with high specific surface area and sometimes high degree of functionalization. Bottom: Schematic representation of such particles: a) simply functionalized colloids as multivalent reagents; b) microgels equipped with polymeric, selectively metal-binding "receptors"; the additional longer polymer tentacles serve as stabilizers of the colloid in the loaded state; c) protein-functionalized microlatices.

anchor by sticking in the glassy polymer core.[47] The external poly(4)vinylpyridine "tentacles" can complex metal ions, that is they act as molecular receptors. These functional microlatices can be applied to the separation of transition metals such as mercury or platinum from aqueous solutions. As ubiquitous ions such as sodium, potassium, or calcium are not affected by this separation procedure, not only waste-water can be purified with such systems, but also more delicate fluids, such as cellular liquids and wine. Such a metal-binding latex particle has an average molecular weight of $2 \times 10^7\ g\,mol^{-1}$, typically carries about 1000 receptors on its surface, and can bind transition metal ions in amounts up to 16% of its own weight.[47, 48] This "intelligent ion exchange resin" can distinguish between "bad" ions (transition and heavy metals) and "good" ions (alkaline and alkaline earth metals) and therefore leaves the chemical appearance of the solution to be purified unaffected.

The use of biogenic functional groups, such as surface-active enzymes or lectins, is especially interesting (see Scheme 3). As many surfactants denature or at least deactivate enzymes, microemulsion recipes based on naturally occurring lipids and suitable cosurfactants had to be developed at first.[49] Such systems readily incorporate proteins, sometimes even generating a

synergistic effect. These proteins are then cast into the surface of the microlatex, and some of them still show their biological activity.[50] An especially promising example is the lectin Con A, a tetrameric protein with a molecular weight of 102000 g mol^{-1}, which can be bound to the surface of a microlatex without losing its specific binding activity for glucose. The Con A-modified latex particles can be attached to all sorts of biological surfaces. C.-M. Lehr et al. showed by confocal laser microscopy that such latex particles (Figure 9), despite their large size of a few

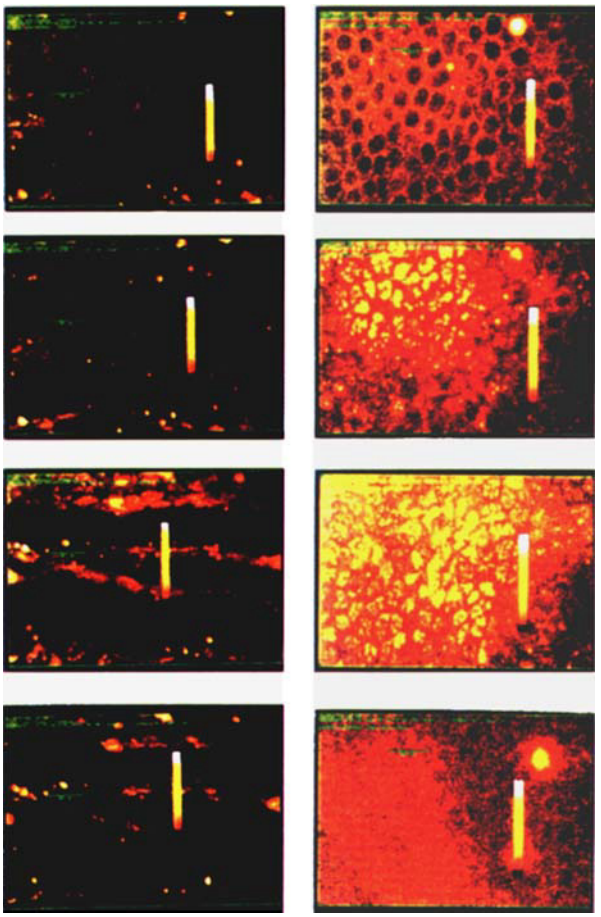


Figure 9. Transport of Con A-functionalized microparticles through epithelium cells; this process was made visible by fluorescence markers and confocal laser scanning microscopy. The fluorescence of the control group (particles without Con A, left column) can only be observed in the holes of the cell culture, while the protein-carrying particles (right column) have been transported approximately 18 μm deep into the cell material after 1 h (layer depth of the pictures from top: 9.1, 13.6, 18.1, 31.8 μm).

nanometers, can penetrate a culture of intestinal epithelium cells quite rapidly. This penetration occurs by active transport,[51] the modified latex, so to speak, is a "fare dodger" on the biological public transport system, the microtubuli.

This active transport through the cell material replaces diffusive or passive transport, which both work for small drug molecules only. By surmounting the size limit, a way is shown how even larger or very sensitive drugs, such as encapsulated proteins or other colloidal drug carriers, could be applied through the nose, the lung, or the intestine. Although the system Con A/polystyrene is just a model, it is likely that other protein-modified particles, which are generated by amphiphilic self-assembly, can act similarly to deliver even more sensitive drugs.

3.2.2. *Polymerization To Generate Three-Dimensional Structures*

Reactions in lyotropic phases or microemulsions are not restricted to particulate structures; first experiments indicate that it is also possible to generate three-dimensionally extended, organized structures. Here, attempts are made to construct lamellar, hexagonal, and bicontinuous cubic phases from polymerizable starting materials by a one-step reaction in order to achieve functionalized polymer rods, sheets, or spongelike structures.[52, 53] However, the growing polymer chain has a considerable thermodynamic influence on its template, which complicates the situation:[54] the entropy loss of the polymer chain within its confined environment usually causes a loss of order on the nanometer scale. As a consequence, this approach affords products with novel morphologies, which, however, are not directly affected by the template. This effect is clearly illustrated in the polarization optical micrographs of a hexagonally structured lyotropic polymerization mixture (Figure 10), which exhibits characteristic structural elements on a micrometer scale. This micrograph is considerably different to the scanning electron micrographs (Figures 11a–c) of a polymer gel generated from that very same mixture.[55]

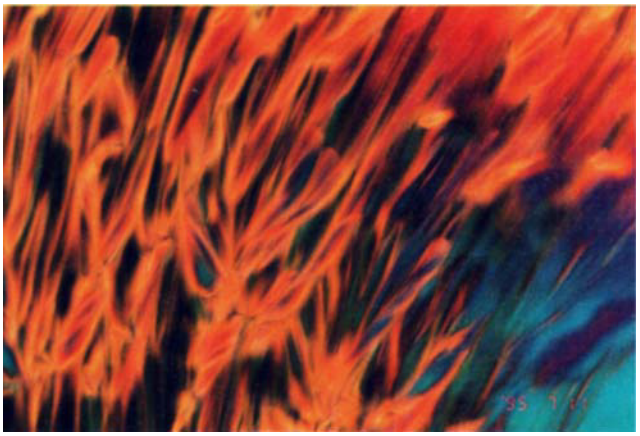

Figure 10. Polarized light optical micrographs of the spontaneous orientation of a polymerizable, hexagonal microemulsion.

The polymerization products are no longer nanoporous, but they show characteristic structural elements on a micrometer scale. Although not a 1:1 copy of the original template, the pore size of this polymer gel is very interesting, as it is within the optimum range of the pore diameter required for protein and DNA separation. The combination of uniform pore diameter and mechanical stability is unique for separation gels, therefore such materials have a great potential despite the nanostructuring using lyotropic phases failing, and in the meantime such polymer gels are discussed as separation media for gel electrophoresis.

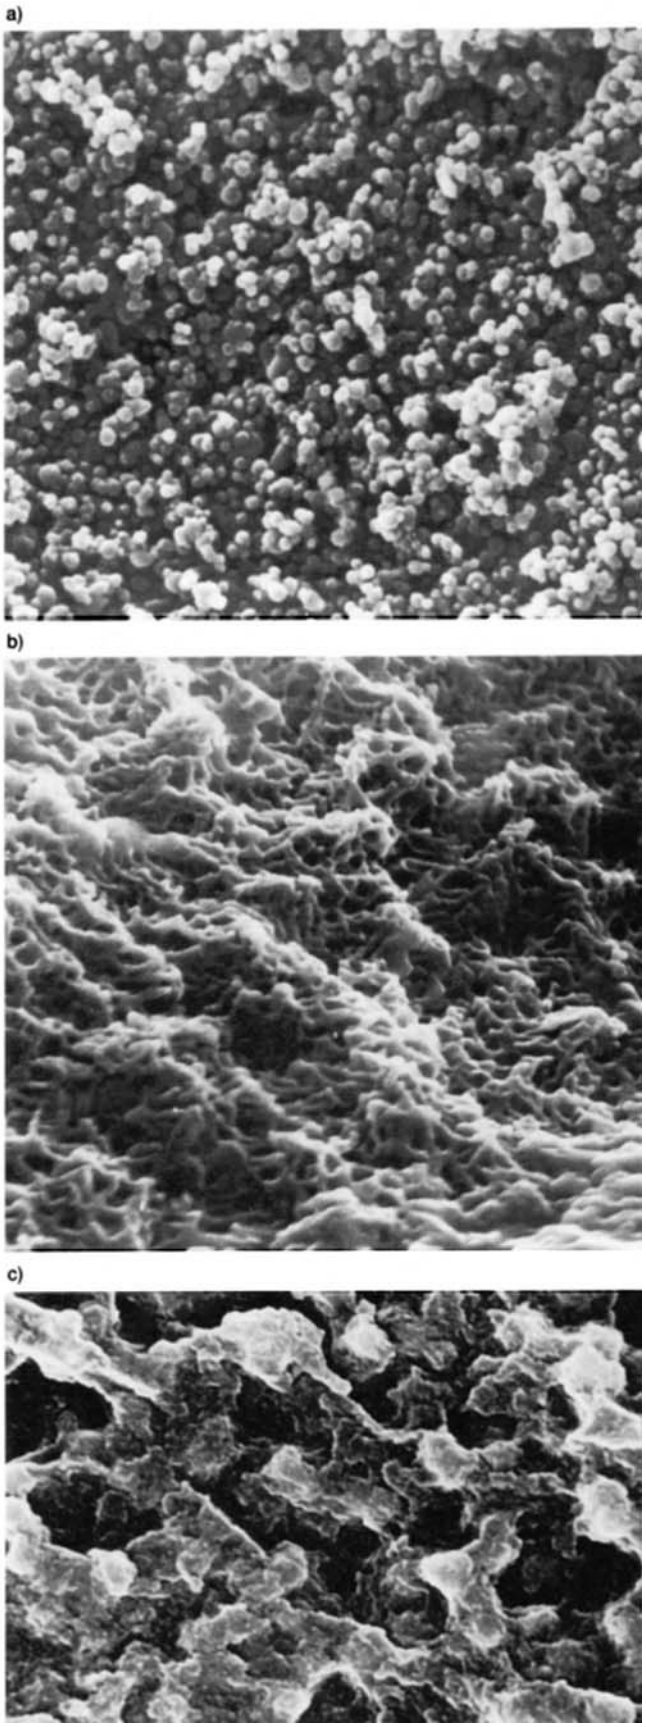

Figure 11. Scanning electron micrographs (from ref. [55]) of different mesoporous polymer gels obtained from polymerization in bicontinuous microemulsions: a) Spherical morphology; b) cavity morphology; c) platelet morphology.

3.2.3. Lyotropically Organized Inorganic Compounds: Mesoporous Ceramics and Particles with Internal Structure

Microemulsions and lyotropic surfactant phases can also be used to produce metal colloids and oxide nanoparticles. Here, the surfactant does not just act as a stabilizer, but it also contributes significantly to the generation of a nanostructure. Pileni and co-workers[56, 57] showed that it is possible to control the structure of metal colloids in micellar solutions and lyotropic phases of ternary and quaternary amphiphile systems. Both the size and the shape of the particles can be accurately adjusted. Similar routes have been pursued by other research groups.[58–60]

Effects similar to those observed for polymerization in lamellar and bicontinuous microemulsions have been found for inorganic polyreactions. Thus, highly defined, spongelike inorganic networks were produced by coprecipitation of calcium and magnesium ions as carbonates from a bicontinuous microemulsion;[61] however, the characteristic length of the structures is found to be at least one order of magnitude above that of the parental microemulsion.

Once again with respect to the generation of ordered and layered inorganic compounds nature has a technological lead over man: a mollusk, for example, uses surface-active proteins to produce something as beautiful as mother of the pearl and something as hard as its shell, both from something as simple as calcium carbonate.[62–64] Also the superior mechanical properties of a tooth are attributed to the mesoscopic design of matter using certain polymeric molecules as auxiliary agents for its construction.

It is noteworthy that all these processes, which generate bioceramics with a diversity of physical features, occur at room temperature. The order of amphiphilic systems that results from self-assembly is here preserved in a solid material, which is non-self-assembling in its own right. Figuratively speaking: a structured system is used as a casting mold (template) for the generation of a nanostructured material, which is the supramolecular analog to the lost-wax casting technique.

For example, in the presence of ionic surfactants, silicates self-assemble into ordered aggregates, in which the microphase separation between hydrophobic and hydrophilic domains causes the generation of a regular, nanostructured system.[65–67] Following classical zeolite synthesis, in which a low molecular weight amine acts as a structure-directing agent, a mesoporous solid with a narrow pore size distribution and a large specific surface area is obtained. As the reaction mixtures are complex and heterophasic, materials are formed with small domain size and a low degree of long-range order. Furthermore, phase changes can be observed during the phase formation, which makes it difficult to predict the structure of the product.[68, 69]

A significantly improved variant of utilizing a self-assembled system as a template for nanostructure design was developed by Attard et al. Here, the polycondensation of an inorganic monomer (e.g. silicic acid) is carried out in a bulk lyotropic liquid crystal phase.[70, 71] Hydrophilic silicic acid is dissolved into the aqueous domains of the liquid crystal, where it is stabilized by hydrogen bonding between water and the surfactant head groups. As a result, the polycondensation is confined to these domains of the ordered phase. In order to monitor this

templating process, a variety of analytical methods were applied, such as X-ray diffraction, NMR spectroscopy,[71] and electron microscopy; however, the simplest method of proving that the structure of the liquid crystal phase is maintained during the reaction is again polarized light optical microscopy (Figure 12). Figure 12a shows a texture typical of a hexagonal lyotropic mesophase observed for a siliceous liquid crystalline mixture. The polycondensation of the same preparation (Figure 12b) was achieved by heating to 90 °C for a short period of time. The cracks shown in the resulting solid (Figure 12b) are

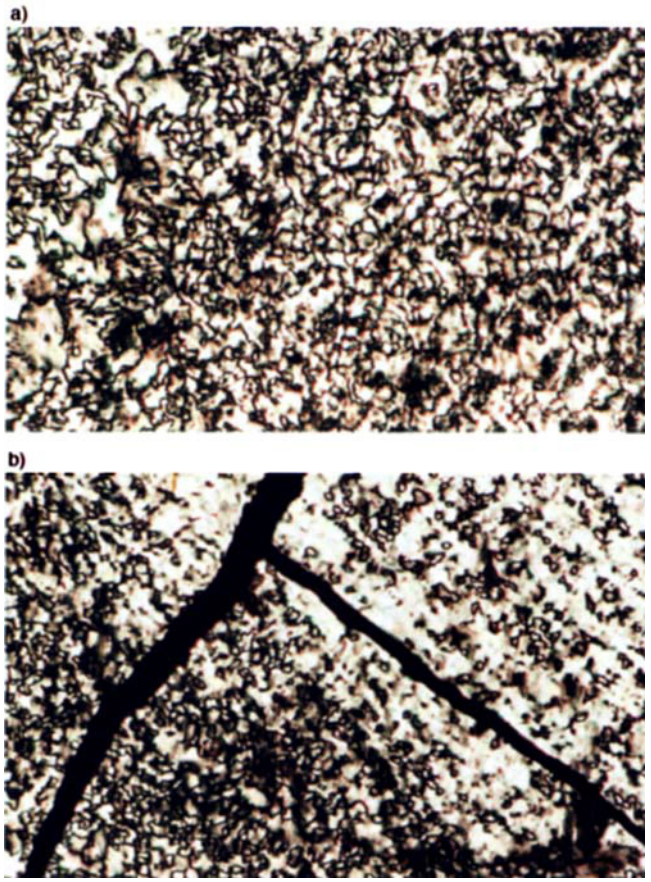

Figure 12. Polarized light optical micrographs of a siliceous hexagonal mesophase a) before polycondensation and b) after polycondensation. The mesoscopic structure remains unaltered, as is visible from the textures; the differences in density are compensated by cracks in the brittle material.

due to shrinkage, which is a consequence of polycondensation. At the same time it is evident that the optical textures remain unchanged (no phase separation is observed), which is the direct proof of the liquid crystal phase acting as an immediate template. After removing the template by either solvent extraction or calcination, the nanostructure of the parental lyotropic mesophase is preserved in the mesoporous silicate, where it is mechanically stable and can be studied by transmission electron microscopy (TEM, Figure 13a–c).

The simplicity of this route suggests that as long as certain requirements of a nanochemical approach are fulfilled, many aggregation structures can be used as templates for nanostructure preparation. In fact it is possible to employ amphiphilic block copolymers in the same way for generating inorganic

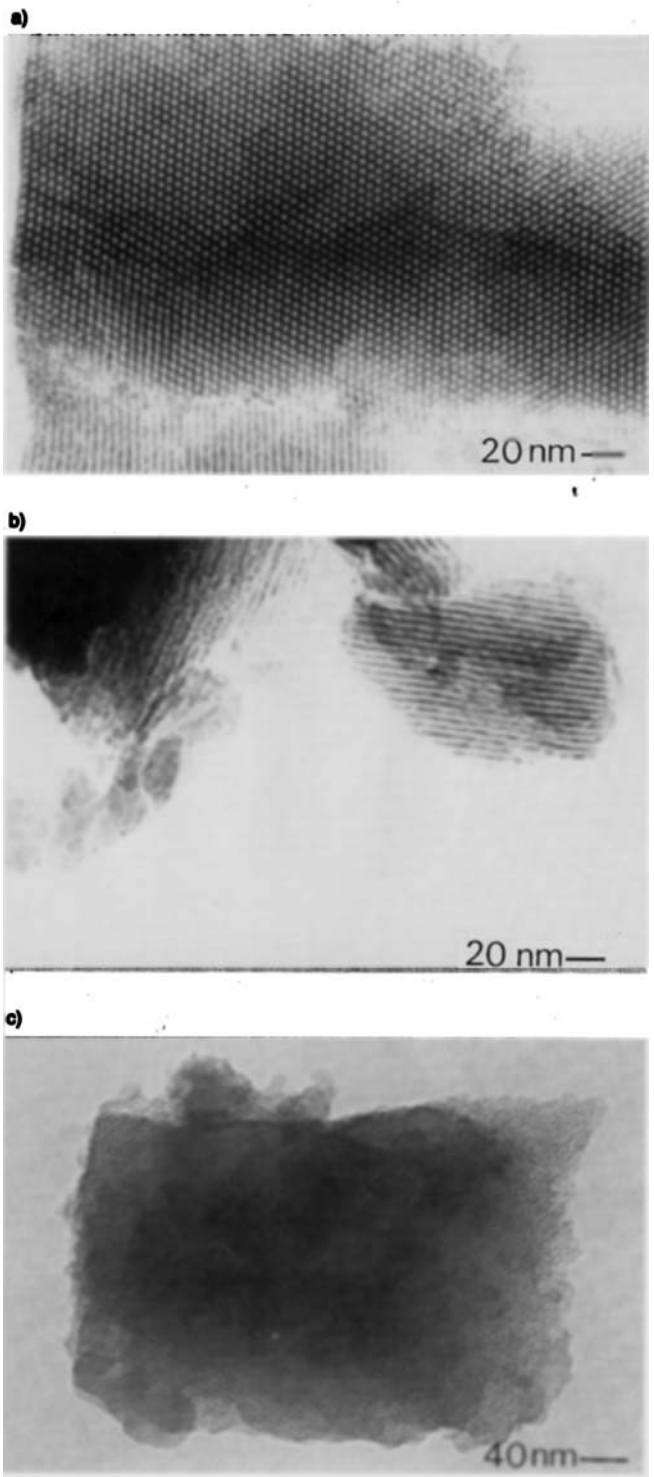

Figure 13. TEM images of mesoporous silicas: a) hexagonal morphology; b) lamellar morphology; c) cubic morphology.

nanostructures.[72] The only requirement for the template is its ability to form stable preorganized aggregation structures in the presence of solvent mixtures. This procedure affords mesoporous ceramic oxides whose characteristic lengths lie in the range between 5 and 30 nm; thus the pore size, the wall thickness, and the stability of the resulting material are improved.

This kind of chemistry is not restricted to the generation of silicates: in principle the wide field of sol–gel chemistry for the

production of functionalized silicates or other mesoporous metal oxides is available for generating inorganic nanostructures. One example is the incorporation of Brønsted acidic aluminum ions into a mesoporous silica network.[73]

3.2.4. Iron Oxide Organelles

In order to nanochemically design inorganic materials, nature hardly ever makes use of an "exo-template" (a molecular casting mold), but usually prefers "endo-templates". Here, specialized proteins (or in the simpler case polymer templates) bind crystallization seeds or primary particles of inorganic colloids during precipitation processes. This procedure allows the specific size and shape of the hybrid material to be controlled. Furthermore, the adsorbed polymer can lower the nucleation barrier of a specific morphology and thus lead to the generation of a new crystal modification. These processes have been described in detail for biomineralization, where proteins determine the controlled growth of inorganic crystals.[74–76] Biomineralization is based on the ordering molecular interaction between a supramolecular aggregate and one or more inorganic components. These principles can be reproduced by the chemist. For instance, it is possible to conduct "crystal design" on Langmuir–Blodgett monolayers of amphiphiles. Here, different amphiphiles induce different shapes or morphologies of crystals. Polymers, polymer gels, peptides, or microemulsions can likewise be employed to control the crystal morphology.[77] Heteronucleation offers possibilities to influence the features of a precipitation product. Depending on the template and processing conditions, size, shape, and structure of crystals, as well as the overall morphology of the mesoscopic superstructure can be designed.

One of our most recent discoveries concerns the preparation of iron oxide colloids by precipitation in the presence of polysaccharides containing sulfonic acids, which illustrates the aspect of controlling structure on a nanometer scale.[78] A TEM image of one of the morphologies found in such a material is shown in Figure 14. The particles obtained evidently show a very uniform size and shape; more importantly, these colloids are characterized by a noticeable internal structure, in which polymer and iron oxide layers alternate on a length scale of 10 nm. The overall scheme for the structure buildup is reminiscent of that of cell components such as mitochondria, and thus opens room for speculation about the extent to which such processes contributed to evolutionary processes. The presence of similarly structured systems in meteorites is not a piece of evidence supporting the existence of extraterrestrial life forms, but only of the wide appearance of templated growth processes!

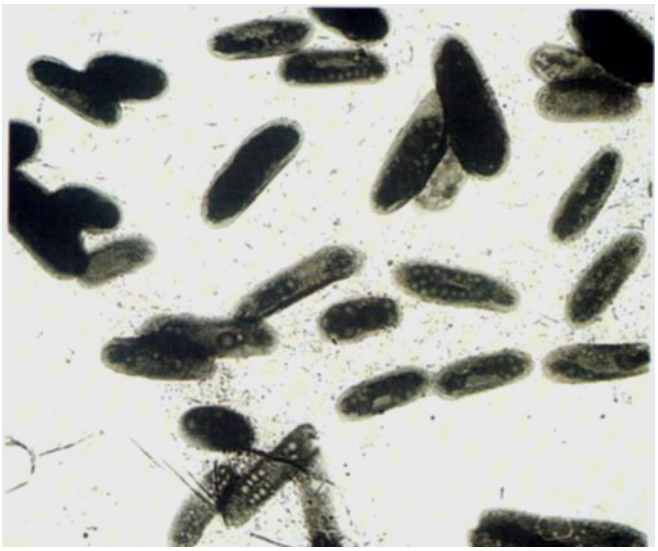

Figure 14. TEM image of iron oxide, precipitated in the presence of polysaccharide templates.

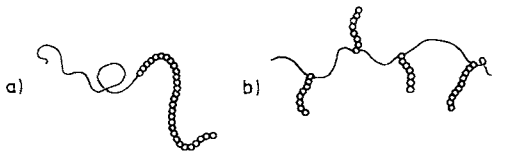
3.3. Amphiphilic Block and Graft Polymers: The Concept of Connectors or Molecular "Glues" against Incompatibility

3.3.1. Synthesis and Micellization

Sections 3.1 and 3.2 were mainly concerned with the controlled construction of nanostructures by self-assembly and the chemical design of their interfaces, while this section focuses on the developments of possible joints and connectors for nanochemistry. Obviously, a desired combination of physical properties through association of two components can often not be fulfilled because the two components are incompatible or not miscible. In the sense of a mesoscopic molecular toolbox, there is a demand for a connecting component, which assembles the two components together and allows them to function as a hybrid system. Thus, connectors are typical ancillary components. This "molecular glue", which attaches the two other (functional or structural) components to each other, can be provided by modern polymer science in the form of amphiphilic block and graft polymers (ABCs; Scheme 4).



Scheme 4. Schematic illustration of the molecular architecture of a block copolymer (a) and a graft copolymer (b). The parts of the molecules have different polarity for amphiphilic systems.

ABCs, like no other molecular species, allow the use of the term "amphiphilicity" in its literal meaning as "the liking of both sides". An amphiphile is a molecule that exhibits hydrophilic and hydrophobic characteristics and therefore can stabilize oil/water interfaces (the classical field of detergents). The "philicity" of ABCs, however, can be adjusted in such a way that any interface between incompatible substances, with their different cohesion energies and their different interface energies, can be stabilized.

The stabilization of the interface between completely different substances is not only academically intriguing, but also most interesting from a technological point of view: any transition from glass and polymer to metal, or even the realization of a mesoscopic mixture of the three components is technologically of utmost importance. A further example that can be regarded as a key technology is the control of the interface to low-cohesion energy media, such as air or carbon dioxide. This is an

important field with respect to the production of nonstick surfaces, nanoporous insulation foams, and the development of solvent-free processing techniques. A third class of interfaces of high technological importance is that between polymers and ceramic oxides.

Thus, for the ABCs, the polymer chemistry workshop allows a much greater variation of the molecular properties than possible for low molecular weight surfactants. The chemical structure of these polymers can be controlled by the choice of the repeat unit, by possible copolymerization with (maybe differently) functionalized comonomers, and by the length and shape of the individual building blocks. Besides making the polymeric stabilizers by classical polymerization processes, in which certain requirements (such as functionality and the accessibility of corresponding monomers or their polymerizability) often cannot be achieved simultaneously, a modular approach for the synthesis of the ABCs proved successful. This approach, which again can be regarded as the first step of the supramolecular construction ladder, allows the decoupling of the control of length, statistics, and architecture of the chain from the chemical function and the distribution of polarity.[79-81] This task is fulfilled on the basis of a commercially available block copolymer, polystyrene-*block*-polybutadiene. This polymer is converted into a reactive intermediate to which the particular functional components are eventually attached. These components were chosen to solve various tasks mentioned above, such as the stabilization of the interface between polymers and metal salts and metals,[79] air and other media of low cohesion energy density,[80] and ceramic materials.[81]

As a result of the pronounced chemical differences between both parts of the molecule, almost all ABCs form micelles in several solvents. The controlled construction of such micelles can be illustrated by means of electron microscopy. Figure 15 shows the TEM image of spherical micelles formed by a polystyrene-*block*-poly(4)vinylpyridine block copolymer. Evidently, owing to thermodynamic control, all micelles have approximately the same size; the polydispersity of these molecular hybrids is so low and their stability so high that the micelles pack into lattices without losing their individual identity by rearrangement.

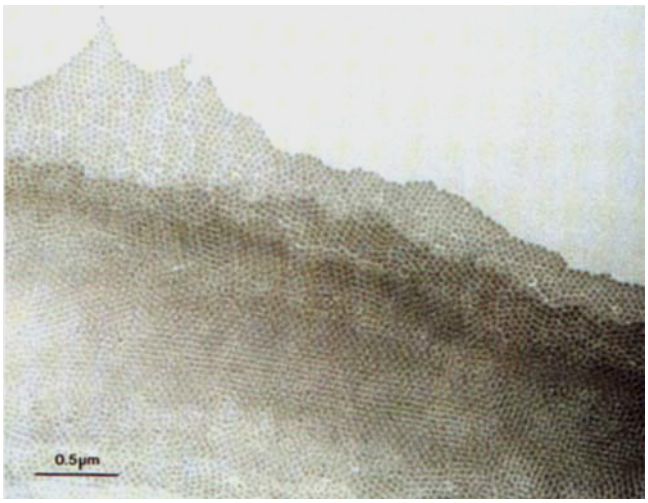


Figure 15. Electron micrograph of spherical polystyrene-*block*-poly(4)vinylpyridine micelles. The preparation was sputtered with Pt/C at an angle of 45° in order to evoke a quasi-three-dimensional image. The grey scaling arises because the picture shows up to three micellar monolayers. The top, third layer, shows an almost perfect packing of the individual micelles.

The control of the micellar parameters, such as shape, size, and polydispersity, is the basis for their application as nanoreactors or templates. It has been shown during the past few years that the aggregate properties can be controlled almost perfectly by carefully adjusting the length of the solvatophile and the core-forming block as well as the interfacial energy between micellar core and solvent. For systems with high interfacial energy, a simple relationship has been established between the aggregation number of the micelles and the block length.[82,83] Surprisingly, this description is valid for chemically very distinct systems and architectures, such as ionic and nonionic block copolymers and graft copolymers.[83] While the organized aggregation is already coded in the primary structure of the block copolymer, the handling and controlled construction of micelles as simple organized superstructures lies in our hands.

3.3.2. *Use of ABCs at Interfaces and as Exo-Templates*

There are various ways of employing block copolymers as interfacial stabilizers. For the first group of applications, block copolymer micelles organize along a surface, which attracts the core-forming polymer block. Reorganization of the whole system lowers its energy. This corresponds to the example of exo-templating mentioned in Section 3.2.3. This procedure can be utilized to stabilize precipitation processes, which is important with respect to the colloidal formulation of drugs or the preparation of ceramic nanoparticles. The structure of the supramolecular hybrid is not directly determined by the micellar character any more, nor by the micellar structure, but by the chemistry of each ABC molecule alone.

Block copolymers with an ultra-low interfacial energy are useful examples for illustrating this application. These polymers are composed of one molecular part consisting of a common polymer block, and a second one with perfluorinated side groups.[80,84] Thus, this sequence exhibits high differences in terms of the hydrophobicity, which causes microphase separation even in the solid state (Figure 16). The ordering phenomena

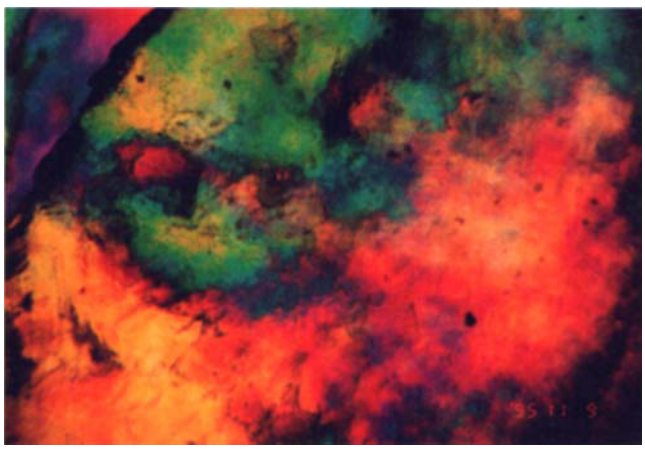

Figure 16. Polarized light optical micrograph illustrating the spontaneous orientation of a partially fluorinated block copolymer (undulated hexagonal mesophase).

responsible for the optical appearance of this material are also manifested in the X-ray diffractograms, and a series of mesophase structures similar to those described in Figure 2 has been identified.[80]

Like the corresponding fluorinated PESurfs, these systems show an extremely low interfacial energy that arises from the high local order on the nanometer scale. The value for the interfacial energy is again close to the theoretical minimum for solids, which causes these materials to efficiently suppress cohesion and friction. This effect is even maintained upon blending these block copolymers with standard polymers. In contrast to the technologically widely used poly(tetrafluoroethylene) (PTFE), these fluorinated block copolymers are soluble in common solvents, show a good melt processibility, and have a smooth surface. The extremely low cohesion energy density of the fluorinated block causes such polymers with an appropriate block ratio to form micelles in supercritical carbon dioxide. This suggests an application of these materials as stabilizers for the production of dry particles by precipitation during the dilatation of critical gases.[85]

3.3.3. *Utilization of ABCs as Endo-Templates: The Concept of Molecular Reactors*

An alternative application of amphiphilic block copolymers is the exploitation of their stable micelles as "molecular reaction flasks"; in such micelles, chemical and physical reactions can be confined to the fluid micellar cores, the size of which are measured on a nanometer scale.[86–89] This possibility is especially relevant with respect to reactions that afford solids, such as reductions or precipitations of oxides and sulfides, as the size of the product is limited by the mesoscopic reaction flask.

Thus, the block copolymer micelles are initially loaded with the reactants, for example metal salts. This usually does not affect the structural parameters of micelles with high interfacial energy. In contrast, the formation of micelles by weakly aggregating block copolymers can even be induced by the incorporation of ionic species.[90] In both cases the metal salt needs not be dissolved in the pure solvent: usually the dispersing effect of the polymers is strong enough to incorporate the salt crystals by simple stirring. The driving force of the salt solvation by ABCs can arise from acid–base interactions; other possibilities are based on the complexation of the ions by the core-forming part of the polymer or highly dipolar zwitterions attached to the polymer. The latter systems can even "dissolve" sodium chloride in toluene. The solvation in incompatible media nicely illustrates the "generalization of amphiphilicity". By utilizing this stabilization potential, ABCs cannot only be employed for nanostructure design, but they can also efficiently assist in reactions in which species are reacted in different phases (a kind of phase-transfer catalysis).

In the context of our own work we have studied block copolymers of the type polystyrene-*block*-poly(4)vinylpyridine, which stabilize a whole range of semiconductor and metal colloids.[79, 88, 89, 91] Following a modular approach, such metal-binding block copolymers can be synthesized with a variety of binding sites by polymer-analogous reaction: the variation of binding sites and types of ligands allows the stabilization of a whole range of metal ions, from hard, highly charged metal ions (e.g. Co^{3+}, Fe^{3+}) to soft, polarizable metal ions (e.g. Pd^{2+}, Pd^0). Furthermore, the electronic properties and the reactivity of the resulting metal–polymer hybrids can be finely adjusted by an appropriate choice of ligands.

The conversion of the loaded micelles, for example by reduction or by oxidic or sulfidic precipitation, affords the chemical system, which consists of the metal or semiconductor component (functional component) and the block copolymer (structural and ancillary component). Various ordered colloidal morphologies can be achieved by particular reaction conditions and the kind of interaction between the polymer and the inorganic colloid. Three especially intriguing morphologies are illustrated in Figure 17a–c.

A homogeneous reaction under slow nucleation conditions affords a material, in which each nanoreactor contains one particle only: we named this the "cherry morphology" (Figure 17a). When the reaction is conducted homogeneously with rapid nucleation, each micellar core contains many small particles, whose number per micelle depends on the supersaturation ratio. In this case we obtained very stable particles, but their size cannot be adjusted by the micellar shape. Figure 17b shows this "raspberry morphology", which is obtained, for example, from the reduction of gold, palladium, and ruthenium with the very efficient reagent superhydride ($LiBEt_3H$).

These morphologies cannot only be imaged with a transmission electron microscope, but can also be distinguished by their differing catalytic, electronic, magnetic, and optical properties, and often they can be judged simply by their color.

The cherry morphology allows the optical, electronic, and magnetic properties of the system to be tuned by varying the size of the micellar reactor and accordingly the size of the metal or semiconductor colloid. The adjustment of the electronic properties (plasmon resonance for metals, band gap for semiconductors) is based on the quantum-size effect,[92, 93] and is of utmost importance with respect to some modern applications of colloids, such as electro- and photoluminescence, as well as the photolysis of water.[94]

With regard to the magnetism of colloids, it is known that some compounds allow a fine adjustment of the magnetic properties by varying the particle size: very small iron or cobalt clusters show paramagnetic, medium-size colloids superparamagnetic, and larger particles ferromagnetic response. The microreactor concept with ABCs shows great promise for controlling the magnetism of particles, as was recently demonstrated by preparing a series of differently sized cobalt colloids by controlled reduction in block copolymer micelles.[95] Especially the superparamagnetic cobalt hybrids with their high spin density are of interest for application as magnetofluids and magnetic plastic parts.

The raspberry morphology is the more promising candidate with respect to catalysis, as it shows an extremely high metal surface of a very stable colloid. Recent studies on polystyrene-*block*-poly(4)vinylpyridine-stabilized palladium as a hydrogenation catalyst revealed that some of these systems show the same reactivity as industrially applied heterogeneous catalysts,[89, 96] and an increased lifetime and selectivity. The reasons for the increased lifetime and selectivity are readily apparent: these palladium colloids are sterically stabilized and deactivated by complexation. The increased reactivity is some-

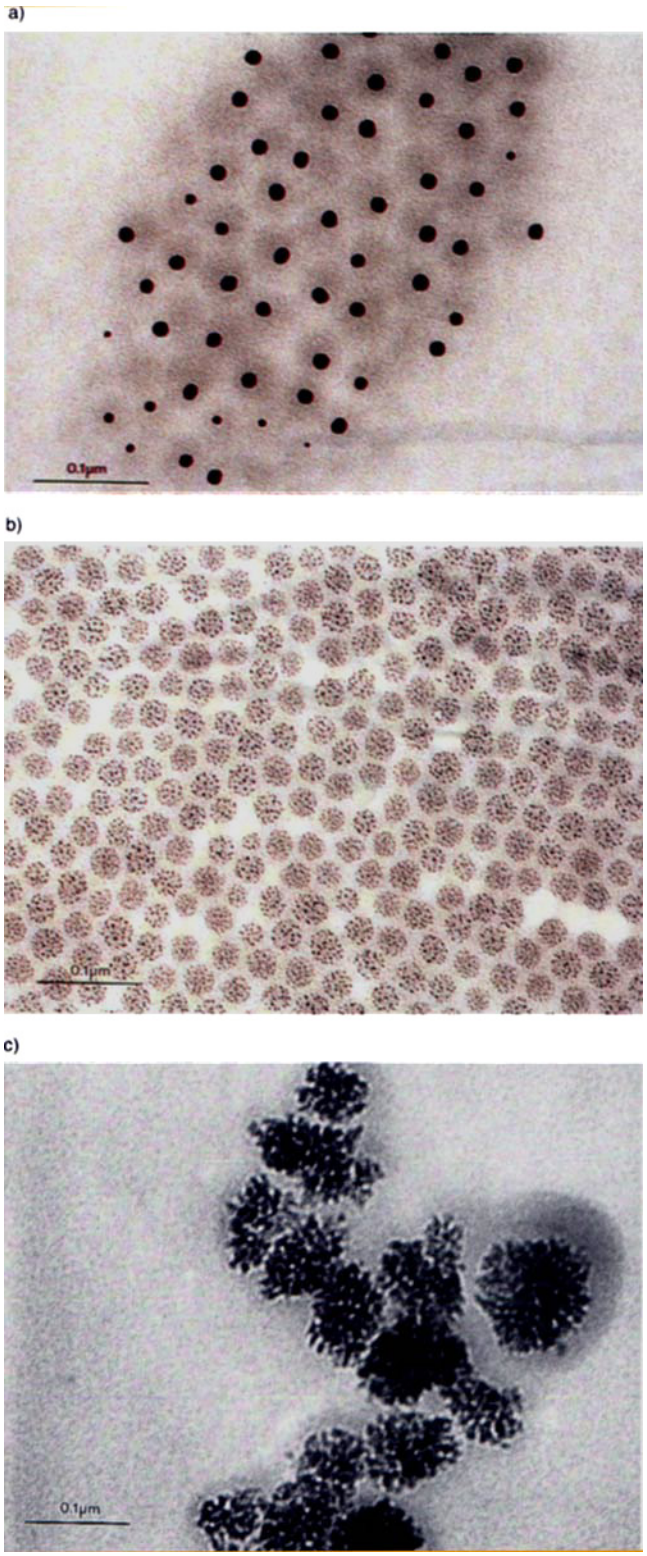

Figure 17. TEM images of different morphologies of block copolymer stabilized colloidal particles: a) "cherry" morphology; b) "raspberry" morphology; c) "cauliflower" morphology.

what surprising: it can only be speculated that the steric hinderance is compensated by the enhanced surface area and that the concentration of catalytically active sites is high. This seems to be a general tendency for colloidal catalysts, as superior activities, longer lifetimes and higher selectivities have been found experimentally also for surfactant-stabilized hydrogenation catalysts.[97–99]

Novel studies on the palladium-catalyzed C–C linkage (Heck reaction) using block copolymer- or surfactant-stabilized colloids confirm the results obtained from the hydrogenation experiments.[100, 101] Here, the polymer–metal colloid hybrids exhibit a slightly decreased activity, but superior lifetimes (turnover number $>50{,}000$).[101]

The scope of the microreactor concept, however, goes further: as it is possible to fuse all metal ions within a micelle into one particle, bimetallic systems of variable constitution are accessible. In contrast to standard preparations, in which each metallic component often forms separate particles, the metals entrapped in a microreactor have to fuse into one particle and are therefore electronically coupled, resulting in interesting possibilities with respect to electrochemical potentials and catalytic activity. The reactivities of palladium colloids, for instance, were increased significantly by incorporating 30% gold (which is catalytically inactive in the pure form).[95]

These chemical systems, consisting of amphiphilic polymers and colloidal particles, also offer the possibility of finely adjusting the catalyst solubility according to demand: these solution properties are provided by the polymer component and are inherited by the final hybrid material. When the catalytic reaction is carried out above the θ-temperature of the solvatophilic block (its thermodynamic solubility limit), a quasi-homogenous reaction is achieved; after cooling the reaction mixture below the θ-temperature, however, the catalyst precipitates quantitatively, and the product can be separated from the catalyst. This precipitate can be reintroduced into the reaction without further purification by simple heating. The resulting hybrid material consisting of colloidal particles and polymeric micelles proves to be extremely stable: like a pure polymer, it can be precipitated and redissolved, be cast into films and applied in chemical reactions without altering its colloidal features such as particle size and size distribution.

Besides cherry and raspberry morphology there are a number of other hybrid architectures, which rely on the fact that the primary colloids formed are not sufficiently stabilized by the block copolymer coating. One morphology of a zinc colloid entrapped in block copolymer micelles is shown in Figure 17c. The primary particles that result from precipitation can in fact not be completely immobilized by the polymeric stabilizer, but they aggregate into stable cauliflowerlike superstructures with a narrow size distribution. This structural feature turned out to be rather typical for oxidic ceramic and semiconductor colloids. Interestingly, this aggregation leaves the optical and electronic properties of the small primary particles, such as band gap, exciton frequency, and resonator strength, unaffected. A typical UV/Vis spectrum of such a zinc colloid is shown in Figure 18.[102]

The potential use of this colloid arises from its optical properties: the zinc oxide particles are efficient UV adsorbers, which are absolutely transparent in the visible region. Such simple, harmless colloids can be applied in transparent wrappers or in cosmetic formulations. Here they replace commonly employed low molecular weight UV absorbers, which are known to show many disadvantages.

In our opinion the preparation and utilization of stable functional colloids in block copolymer micelles is an illustrative ex-

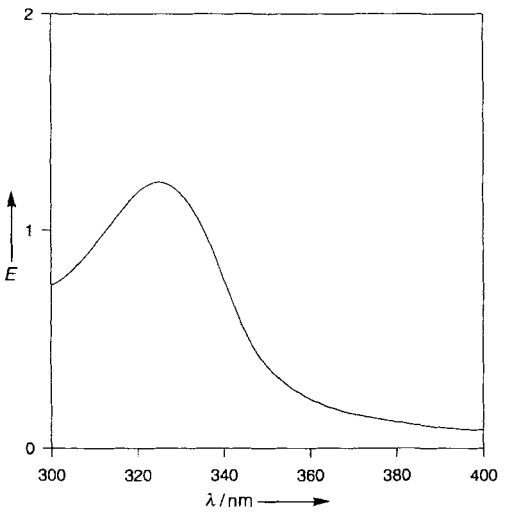

Figure 18. UV/Vis spectrum of block copolymer stabilized ZnO colloids. The UV adsorption edge corresponds to the distance between valence and conduction band in this wide-bandgap semiconductor, and can be adjusted by the particle size. E = extinction.

ample for the design of chemical systems, which underlines the wide potential of a nanochemical approach: the controlled assembly of incompatible materials on a nanometer scale by the utilization of specific interactions combines polymeric features (stability, elasticity, film-forming properties) with those of colloidal particles (optical, electrical, and magnetic properties).

4. Conclusion and Outlook

Today's chemist is in the position to preorganize and connect suitably functionalized building blocks, often polymers or colloids, by employing amphiphilic molecules. Materials with a structural hierarchy and order on a nanometer scale are generated, which obtain their properties or combinations of properties through the appropriate arrangement and "teamwork" of functional components. The potential applications arising from this transition from molecules to chemical systems are well described by the corresponding step in electronics, which involved the transition from the single component to the integrated circuit.[2]

The properties or combinations of properties resulting from the superstructure of chemical systems are not restricted to particular materials properties, but include, for example, sensoric and electrooptical effects as well as transport phenomena. Functionalized polymer dispersions capable of permeating cell membranes or conducting selective ion exchange are the first indicators of such effects. Some examples of the current research trend of developing novel compounds that act as nanochemical components were given in Section 2, but in reality the chances and possibilities of a nanochemical approach are less restricted than this selection, and go beyond polymeric, colloidal, and mesoporous hybrid materials.

Besides the development of more chemically orientated methods for the generation of new components that are capable of self-assembly, research needs to focus on the development of methods to arrange these components on a supramolecular level or which allow them to self-assemble: the lyotropic or amphiphilic self-organization presented here is just one of several ways of achieving these aims.

The materials resulting from this nanochemical approach are not just beautiful and academically intriguing; there are numerous applications in almost all areas of day-to-day life, from high-tech applications to the demand for solvent-free coatings, harmless functional components, smooth drug formulation, or efficient waste-water purification.

The chemical generation of structures on a nanometer scale and the exploration and utilization of their surfaces is top of the priority list of most development commissions that gathered to evaluate the possibilities of science and technology in the 21st century. For example, the Amundsen Report by the American Science Foundation, in which suggestions about coordinated future activities are made to the American research institutions, includes options for nanochemistry in four of the seven "key technologies". Apart from the expected spin-off projects of such enterprises, there is the final aim of the controlled construction of artificial materials—analogous to the construction of biogenic materials—over several integration levels and structural hierarchies, in order to obtain more efficient and more intelligent chemical functional systems and materials. We would like to summarize this sentiment by quoting J.-M. Lehn: "The development of advanced materials may take full advantage of the control provided by information-dependent supramolecular processes for the production of large scale architectures in a sort of molecular and supramolecular *tectonics* leading to a *nanotechnology* and *nanomaterials* of organic or inorganic nature".[1] Thus, not only from a purely aesthetic point of view are we eagerly awaiting this development.

The authors would like to thank Michael Breulmann, Helmut Cölfen, Stephan Förster, Jürgen Hartmann, Susanne Henke, Hans-Peter Hentze, Sascha Oestreich, and Annette Pape for their direct help with the manuscript or for providing the scientific material. Special thanks are owed to Christian Burger for the computer graphics, George S. Attard and Mark Edgar for the collaboration on the field of mesoporous ceramic oxides, and Claus-M. Lehr for the collaboration concerning the drug delivery systems. The constant support from the Max-Planck-Gesellschaft is also gratefully acknowledged.

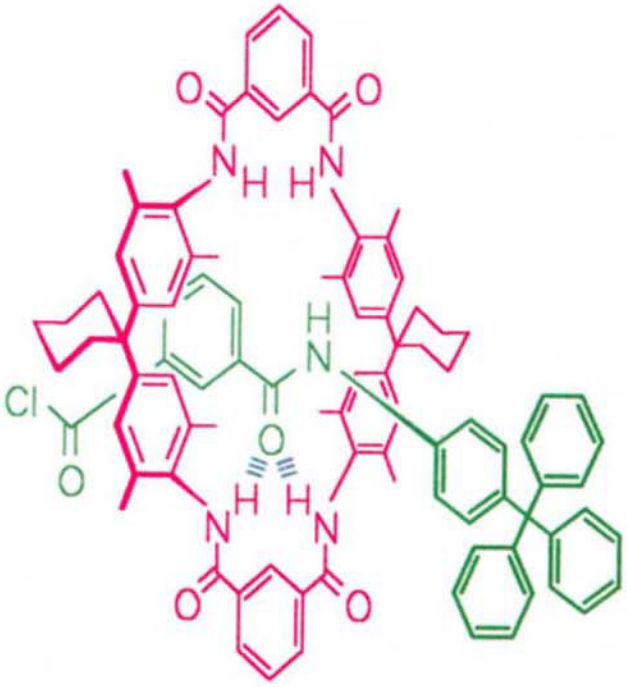
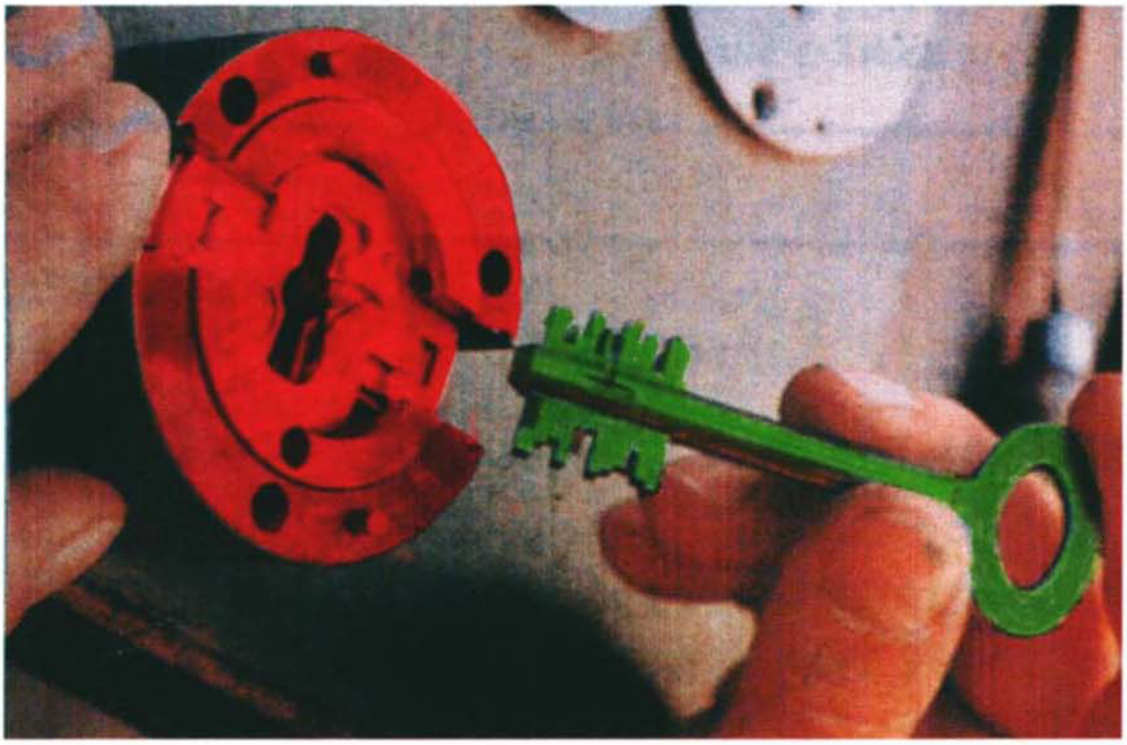
How does one thread a stringlike molecule through the eye of a large ring?



One uses the lock-and-key interaction (molecular recognition) between the string and the ring; in this case through hydrogen bonding between amide groups (supramolecular template effect).



A New Synthetic Strategy towards Molecules with Mechanical Bonds: Nonionic Template Synthesis of Amide-Linked Catenanes and Rotaxanes

Ralf Jäger und Fritz Vögtle*

After Sauvage et al. and Stoddart et al. had developed the now commonly used and well-established catenane and rotaxane synthesis utilizing phenanthroline/Cu^+ and bipyridinium/crown units, a new way to synthesize mechanical bonds was discovered in 1992—the synthesis of amide-linked catenanes and rotaxanes around a neutral template. The formation of the template, which leads to the host–guest bond, does not proceed by covalent or ionic interaction, but by weak supramolecular interactions, such as hydrogen bonding, π-stacking, π-donor–π-acceptor interaction, and steric complementarity. The simple synthetic units (arene dicarboxylic acid dichlorides and diamines) can be varied in an astonishing number of ways, few steps are required to obtain the target molecules, and the yields of these syntheses approach those of ordinary organic syntheses. After the preparation of [2]catenanes, it took only a few years to prepare [2]-, [3]-, and bis[2]-rotaxanes of the amide type. The introduction of sulfonamide groups enabled alkylation of the sulfonamide nitrogen atom, and this made chemical reactions with catenanes and rotaxanes feasible. Intra- and intermolecular connections of catenanes and rotaxanes were then possible, and a molecule with the topology of a "pretzel" has recently been prepared. This allowed new insights into the molecular recognition processes of neutral guest and host substances, as well as further understanding of these processes in template synthesis, isomerism in catenanes, and the regioselectivity of the formation of catenane isomers. Competitive binding studies of guest molecules in the cavity of concave receptors with more than one binding site can be performed. These studies might result in higher synthetic yields of molecules with mechanical bonds and lead to further progress in the development of supramolecular nanostructures and molecular switches.

Keywords: catenanes · macrocycles · mechanical bonds · rotaxanes · template synthesis

1. Introduction

The significance of mechanically connected molecules has increased due to the recent discovery of networks with thousands of natural DNA-catenanes (Figure 1).[1] Some proteins are also known to form molecular knots.[2] Rotaxanes are of particular interest with respect to the flagellum motor of bacteria, which rotates with a speed of 60 rotations per second. In the case of *E. coli* four rings on the rotating flagellum form a rotaxane-like basal body.[3]

Although the first molecules with "mechanical bonding"[4] were already reported in the 1960s, they were regarded as exotic compounds that could only be obtained in low yields and by a difficult multistep synthetic pathway. Only the pioneering work of Sauvage et al.[5] (coordination complex **I**, Figure 2) and Stoddart et al.[6] (charge-transfer complex **II**, Figure 2) in the 1980s, who used ionic template effects[7] for their directed syntheses, enabled these compounds to be made on a preparative scale. In 1992, independently of each other, Hunter and Vögtle et al.,[10, 12] synthesized amide-linked catenanes for the first time. Their syntheses involved a *neutral* template of type **III** (Figure 2).

Figure 2. Overview comparing the intermolecular interactions used for template synthesis of molecules with mechanical bonds: ionic coordination complex **I**, ionic donor–acceptor complex **II**, and neutral complex **III** with hydrogen bonds and $\pi-\pi$ interactions (further possibility: cyclodextrin complexes with hydrophobic interactions).

2. Amide-Linked Catenanes

In 1991 Hunter prepared a host compound for the complexation of *p*-benzoquinone (**1**) in order to utilize it as a potential model for the investigation of fundamental processes in photosynthesis.[8] The host molecule (tetralactam macrocycle **7**) was designed to interact with the guest by hydrogen bonding and $\pi-\pi$ interactions.[9] The association constant with **1** was determined to be $10^3\,\text{M}^{-1}$ in $CHCl_3$.

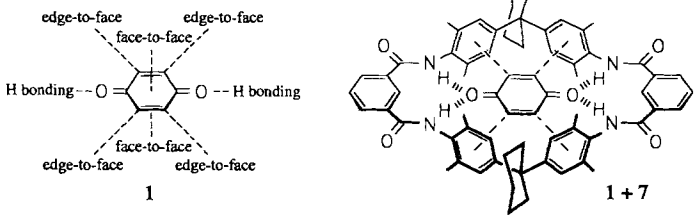

Figure 3. Host–guest interaction when *p*-benzoquinone (**1**) is complexed by macrocycle **7**.

Because of the relatively low yields (10%) resulting from the direct synthesis from **4** and **5** (Figure 4), Hunter modified the synthetic strategy and increased the yield of **7** to 51% through a stepwise preparation.[10] Furthermore, he obtained two other products: the tetrameric macrocycle **8** and its catenane isomer **9**, whose structure was elucidated by two-dimensional NMR spectroscopy and mass spectroscopy. Since the macrocycle **7** was designed to interact with **1** by hydrogen bonding and $\pi-\pi$ interactions, it was speculated that the template mechanism[7] of the catenane synthesis was driven by the same forces.

Temperature-dependent NMR studies revealed that the free rotation of the macrocycle in catenane **9** through the center of the other ("circumrotation"[6]) is blocked by the bulky cyclohexylidene groups. This prevents the inner and outer isophthaloyl units from exchanging their positions (Figure 5). Only a swinging movement of 90° over the isophthaloyl units is possible, for which, however, a high energy barrier (73 kJ mol^{-1}) must be overcome. Information about the resulting ground state of the catenane was obtained from the signal splitting in NMR spectra on addition of chiral shift reagents.

We started to synthesize basket-shaped host molecules (like **14**) in 1983 to create cyclodextrin-like molecules with a conelike cavity.[11] The bottom of the basket should provide the possibility of attractive interactions (hydrogen bonding, electrical attraction) for potential guest molecules. The lipophilic diamine **4**, which is easily obtainable, was used amongst several other possibilities, and reaction with **10** gave the desired macrocycle **12**.

Fritz Vögtle, born in 1939 in Ehingen an der Donau, studied chemistry in Freiburg and chemistry as well as medicine in Heidelberg. There he received his Ph.D. for research with H. A. Staab on the valence isomerization of double Schiff bases. After his habilitation on steric interactions inside cyclic compounds, he became professor in Würzburg (1969–1975). He then accepted a position as full professor and director of the Institut für Organische Chemie und Biochemie in Bonn. Awards obtained include a literature prize for his book Supramolekulare Chemie (translated into English, Japanese, and Chinese) and the Israeli Lise-Meitner–Alexander-von-Humboldt Prize. He is co-editor of the book Dendritic Molecules and of the 11 volume Comprehensive Supramolecular Chemistry. His main research topics are supramolecular chemistry, dendrimers, concave molecules, supramolecular photochemistry, structure–chiroptic relationships of planar chiral and helical molecules, and—of course—catenanes and rotaxanes.

F. Vögtle

R. Jäger

Ralf Jäger was born in 1969 in Siegburg and studied chemistry at the University of Bonn from 1989 to 1995. During his Diplomarbeit he synthesized amide-linked [2]rotaxanes in Fritz Vögtle's research group. His PhD research in the same group involves the synthesis of amide and sulfonamide [n]rotaxanes, [2]catenanes, and molecules with new topologies. In 1995 he worked for six weeks with Professor Kari Rissanen at the University of Jyväskylä in Finland studying supramolecular chemistry. Since 1995 he has had a scholarship of the Graduiertenkolleg Spektroskopie isolierter und kondensierter Moleküle at the University of Bonn.

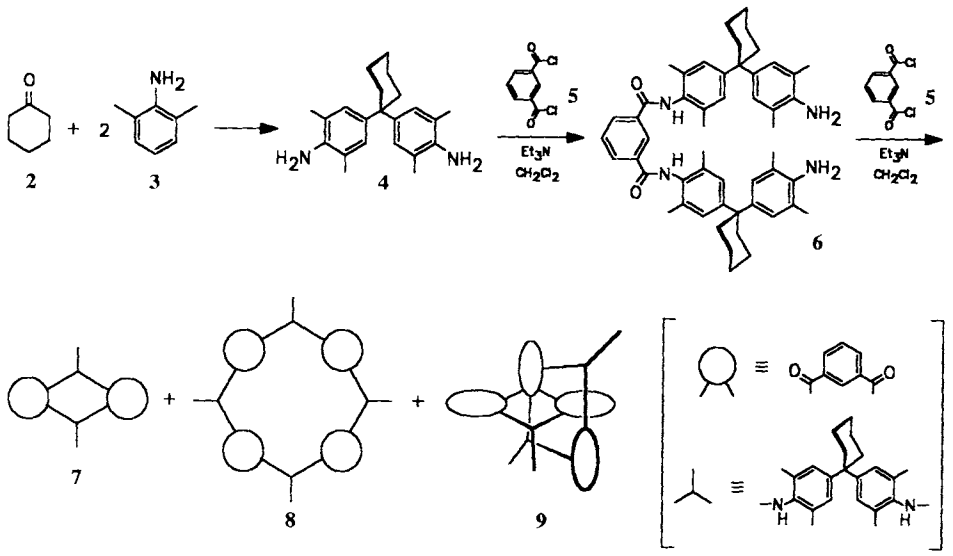

Figure 4. Two step synthesis of [2]catenane **9** according to Hunter.

stituted macrocycle **19** (see Figure 9), the corresponding dimethoxy-substituted tetrameric macrocycle (cf. tetrasubstituted tetrameric macrocycle **12** in Figure 6), and the dimethoxy catenane isomers **16** and **17** (Figure 7). To obtain the third dimethoxy-substituted catenane isomer **18**, the substitution patterns of the starting materials were reversed (route **B**), that is, 5-methoxyisophthaloyl chloride **10** was treated with the unsubstituted diamine **6**.

The selective formation of the catenane isomers, which depends upon the synthetic pathway, now allows conclusions to be drawn about the formation mechanism.

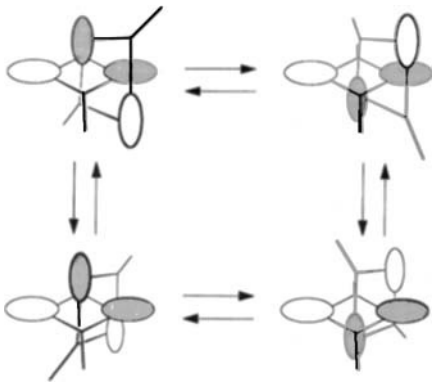

Figure 5. Dynamic behavior of catenane **9**: because circumrotation is restricted by the bulky cyclohexylidene groups, the inner (grey) isophthaloyl units are not able to exchange their positions with the outer ones.

The four methoxy functional groups of **12** are ideal for binding to the basket bottom. Apart from the expected macrocycles (**11**, **12**), we obtained the catenane **13** with four methoxy groups (Figure 6).[12]

Because conformational movements of the catenane are limited (see Figure 5), mono- and disubstituted catenanes can exist as stable conformational isomers, whose selective synthesis can provide information about the mechanism of formation.[13] We prepared the disubstituted isomeric [2]catenanes **16**–**18** using different synthetic routes. In the case of **16** and **17** we followed route **A**, in which the methoxy-substituted diamine **15** was treated with isophthaloyl chloride **5**. The products of this reaction were a methoxy-sub-

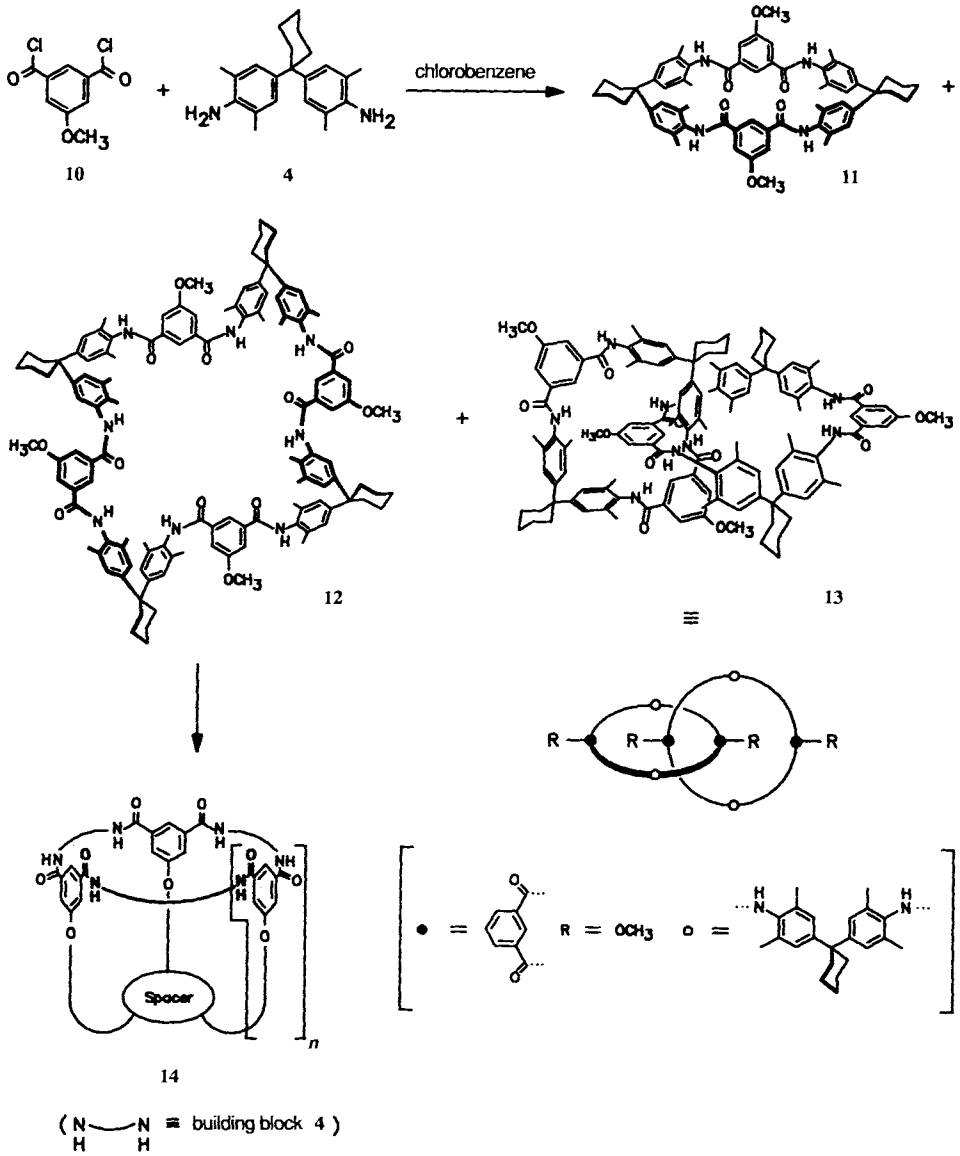

Figure 6. One-step synthesis of the tetramethoxy-substituted catenane **13** according to Vögtle et al., from **4** and **10** (synthetic strategy for basket-shaped molecules of type **14**).

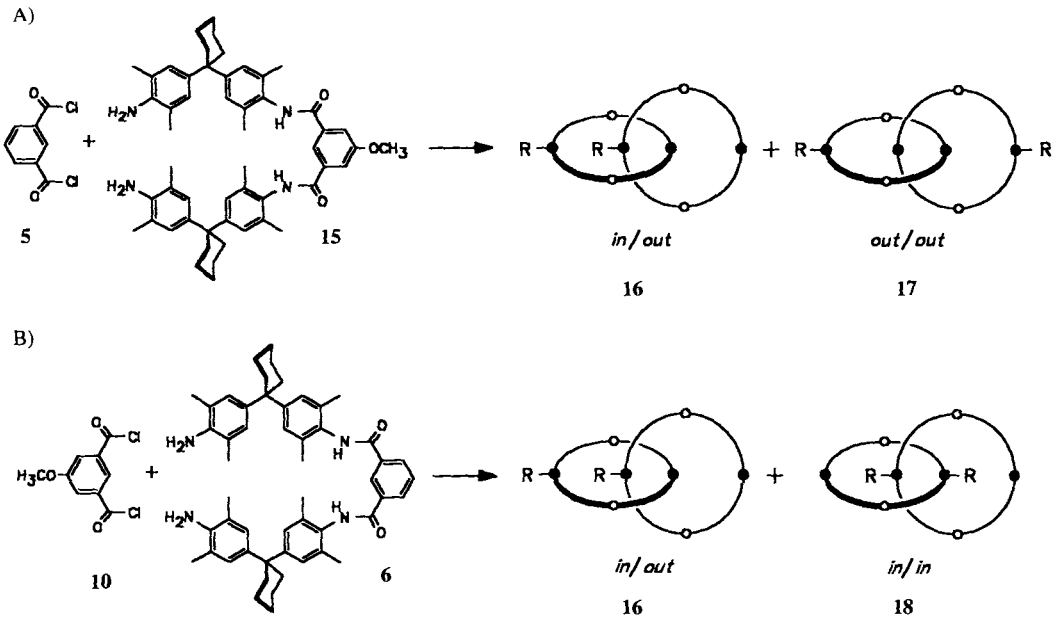

Figure 7. Route A leads to different dimethoxy-substituted catenanes (**16**, **17**) than route B (**16**, **18**).

We suspect that a supramolecular template (nonionic, cf. **I**–**IV**) is formed by orthogonal inclusion of the isophthaloyl chlorides (**5**, **10**) or the monoamides formed by reaction of **5** with **15** or **10** with **6** into an intermediate host macrocycle.[13c] As a result of the different substitutions of the isophthaloyl units of the macrocycle, two orientations of the guest within the host are possible. The subsequent reactions that form the catenane result in the formation of two of the three theoretically possible isomers (Figure 8).

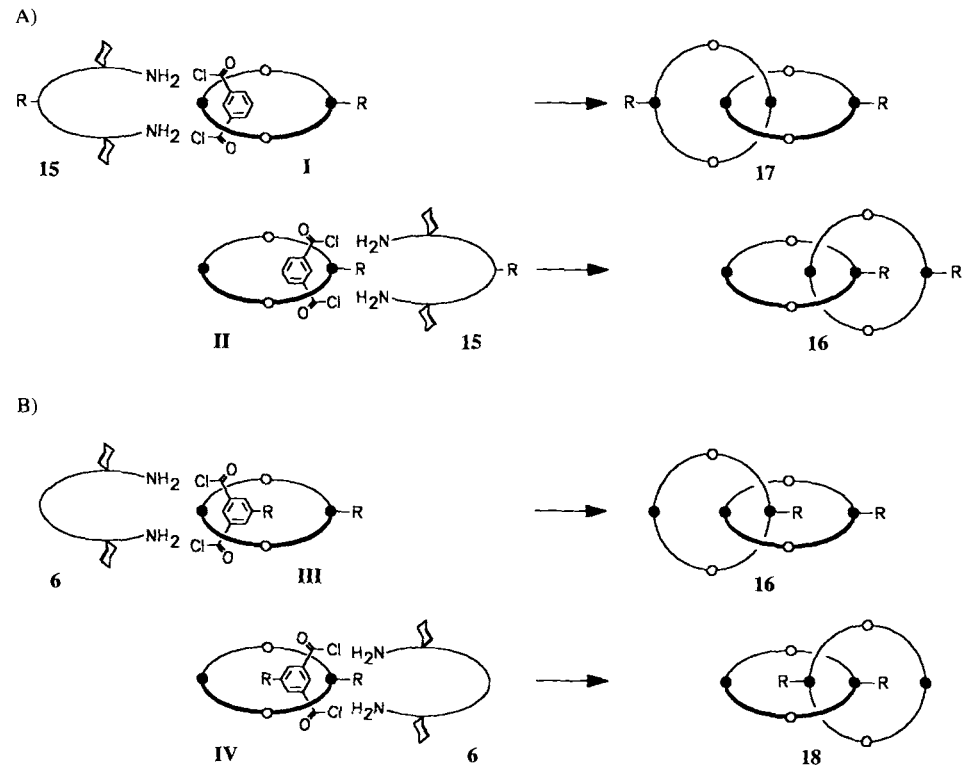

Figure 8. The proposed template and orthogonalization mechanism (cf. **I**–**IV**) proceeding via an intermediate macrocycle, which provides an explanation for the formation of different catenane isomers from routes A and B.

To verify whether the catenane formation can proceed via a macrocycle (as concave template), the macrocycle **19** was used as starting material for the catenane synthesis. The formation of catenane **20**, which could only be formed by reaction of the three units **19**, **5**, and **6** seems to be in agreement with the proposed mechanism. Alternative mechanisms, in particular the intertwining of two open chain units (e.g. **6**) are not relevant. Furthermore, compound **20** is the first amide-linked catenane that consists of two different macrocycles. This has the advantage that **20** can be identified without doubt in the mass spectrum of the crude product, because a tetrameric macrocycle corresponding to the catenane **20** (with the same molecular weight) cannot be formed. The same synthetic strategy enabled the isophthaloyl unit to be replaced with a terephthaloyl unit in an amide-linked catenane for the first time (**22**, Figure 9).[14]

By exchanging one isophthaloyl unit for a pyridine moiety Hunter et al. synthesized a tetrameric host cycle **25**, which has a "folded" conformation that enables binding to two *p*-benzoquinone molecules **1**.[15] The unusual structure of **25** is stabilized by electrostatic interactions of the amide protons with the nitrogen atom of pyridine. The *cis* orientation of the pyridine-2,6-dicarbonyl and the *trans* orientation of the isophthaloyl oxygen atoms result in a "folding" of the macrocycle. This unusual conformation led to the first amide-linked "tetramer–dimer catenane" **26** and traces of the corresponding [3]catenane. However, the formation of the "dimer–dimer catenane" was, surprisingly, not observed (Figure 10).[16]

An X-ray single crystal structure analysis of an *in/out*-[17] and *out/out*-furanocatenane[18] (**30** and **31**, respectively) was the final proof for the existence of stable catenane isomers. The reaction of the diamine **6** with 2,5-furanedicarboxylic dichloride **27** yielded only the macrocycle **28** (Figure 11).

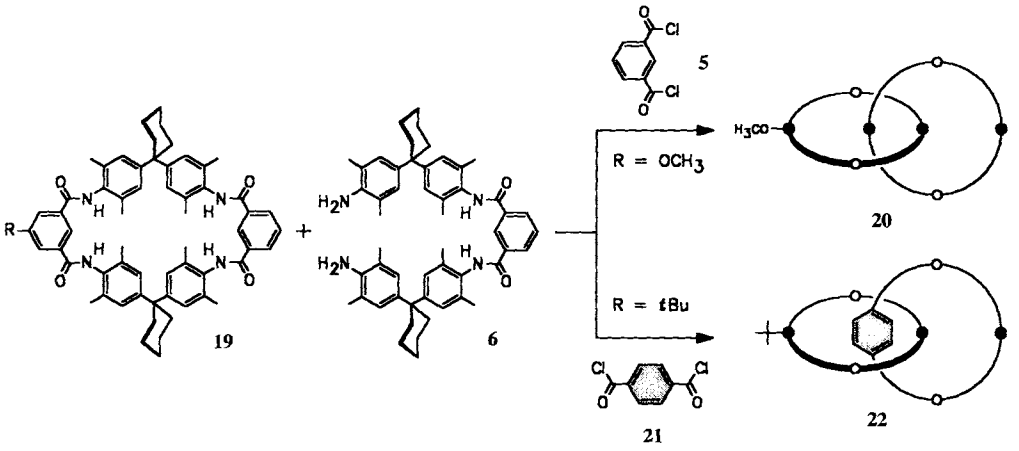

Figure 9. Catenane synthesis using a previously isolated macrocycle **19** leads to catenanes with two different macrocycles.

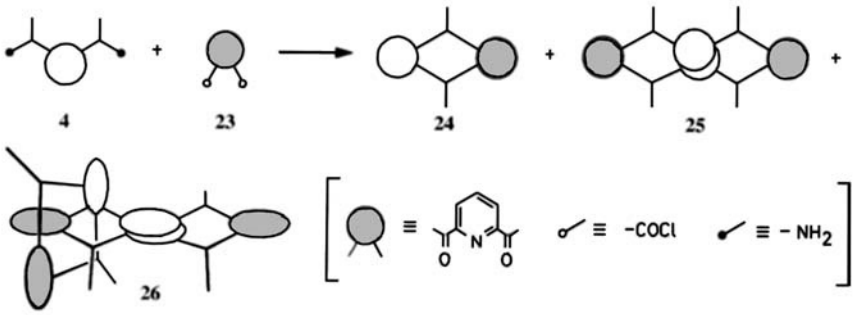

Figure 10. Synthesis of the "folded" tetramer **25** and the "dimer–tetramer catenane" **26**.

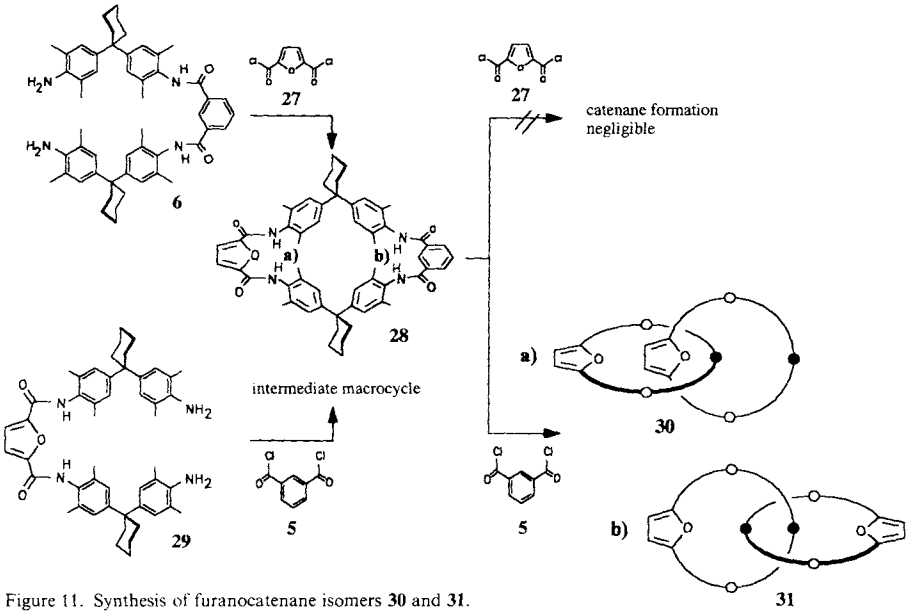

Figure 11. Synthesis of furanocatenane isomers **30** and **31**.

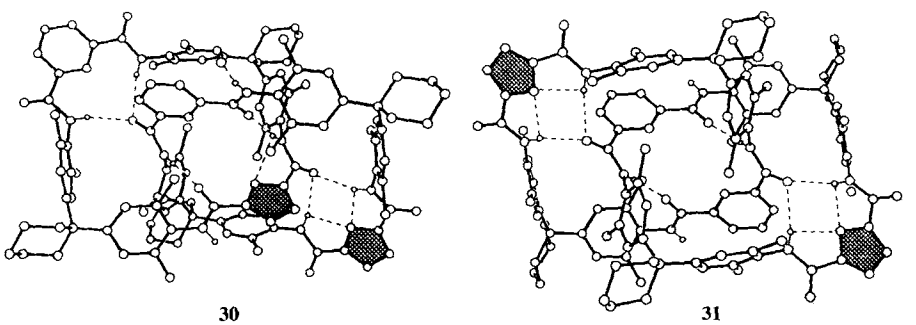

Figure 12. X-ray crystallographic analysis of the furanocatenane isomers **30** and **31**.

The "reverse" reaction of the components **29** and **5** led not only to the macrocycle **28** but also to the catenane isomers **30** and **31**, whose formation is in agreement with the mechanism proposed above. Although both reactions produce the macrocycle **28**, only the presence of **5** in the cavity of the macrocycle leads to a selective formation of the corresponding catenanes **30** and **31**.

Probably the easiest catenane synthesis so far was carried out by Leigh et al. in 1995.[19] Their target was to synthesize a macrocyclic host for carbon dioxide, and they treated the commercially available materials isophthaloyl chloride (**5**) and 1,4-bis(aminomethyl)benzene at high dilution (Figure 13). Unexpectedly the amide-linked [2]catenane **32** precipitated readily from the reaction mixture in 20% yield and could be separated from other cyclic and acyclic products without column chromatography. The catenane structure was elucidated with NMR spectroscopy, FAB mass spectrometry, and X-ray crystallography.

In contrast to the catenanes prepared by Hunter et al. and Vögtle et al., the macrocyclic rings of **32** can undergo free circumrotation depending on the substituent R, because they lack the cyclohexylidene moiety in the diamine part. The synthesis of these conformationally mobile amide-linked catenanes is conducive to a large number of variations of the acid chloride and diamine units.[20]

In 1996 the same research group reported the synthesis of catenanes, which depending upon their environment display translational isom-

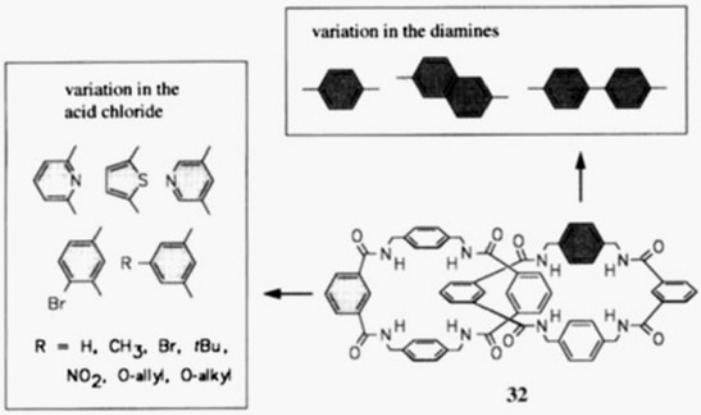

Figure 13. Synthesis of catenanes with unrestricted circumrotation according to Leigh et al

erism.[21] After the diol **33** was converted into **34**, which is soluble in halogenated solvents, the reaction with aliphatic dicarboxylic dichlorides afforded different catenanes **35** with lipophilic units (Figure 14).

In polar solvents the lipophilic decanedioyl chain is located in the interior of the molecule thus allowing the polar groups of the catenane to form hydrogen bonds with the solvent (**II**). Nonpolar solvents reverse this preferred conformation and **I** is formed (Figure 15). These studies indicate that hydrogen bonds are significant for amide-linked catenanes. Assuming that the mechanism of the formation of benzylamide catenanes also proceeds by inclusion of the acid chloride into the cavity of the intermediate host macrocycle, $\pi-\pi$ interactions would not necessarily be needed for their synthesis.

3. Amide-Linked Oligo-[2]catenanes

In 1995 Müllen et al. prepared the first oligo-[2]catenanes of the amide type in cooperation with us. They consist of open-chain oligomers of bifunctional catenanes which are connected by rigid segments (cf. **39**).[22] They were synthesized by coupling the *in/out* catenane isomer **38** with appropriate comonomers under Suzuki conditions,[23] which resulted in the formation of oligomers with a degree of polymerization n of between 1 and 5.

4. Topological Chiral Sulfonamide Catenanes

To change the process of molecular recognition in the first formed host cycle, we introduced sulfonamide groups into amide-linked catenanes in 1995.[24] In analogy to the threading mechanism described above, the intermediate macrocycle **41** should result, in which the included acid chloride or monoamide has two possible orientations. From the two possible isomers (*in/out* and *out/out*) only the *in/out* isomer **42** was formed regioselectively (Figure 17).

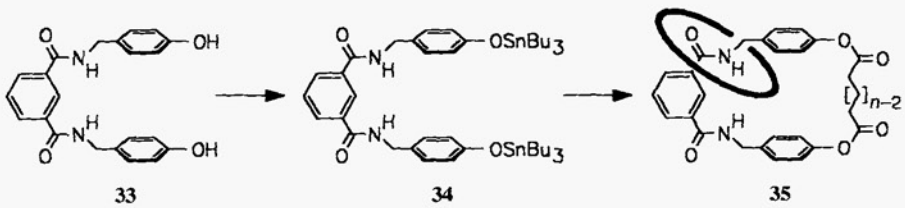

Figure 14. Synthesis of the amphiphilic benzylamide-[2]catenane according to Leigh et al.

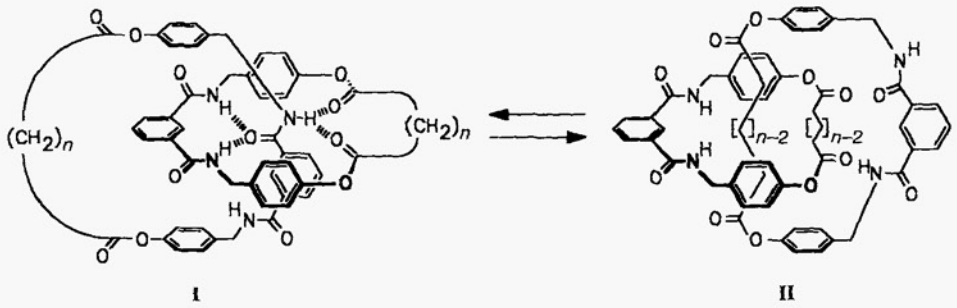

Figure 15. Translational isomers of [2]catenane **35**.

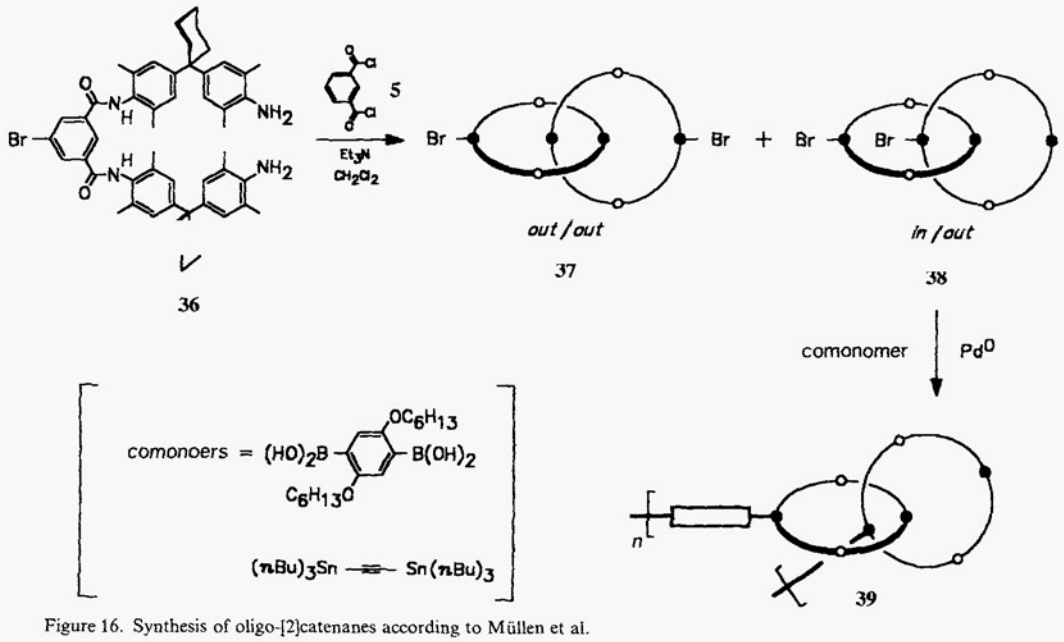

Figure 16. Synthesis of oligo-[2]catenanes according to Müllen et al.

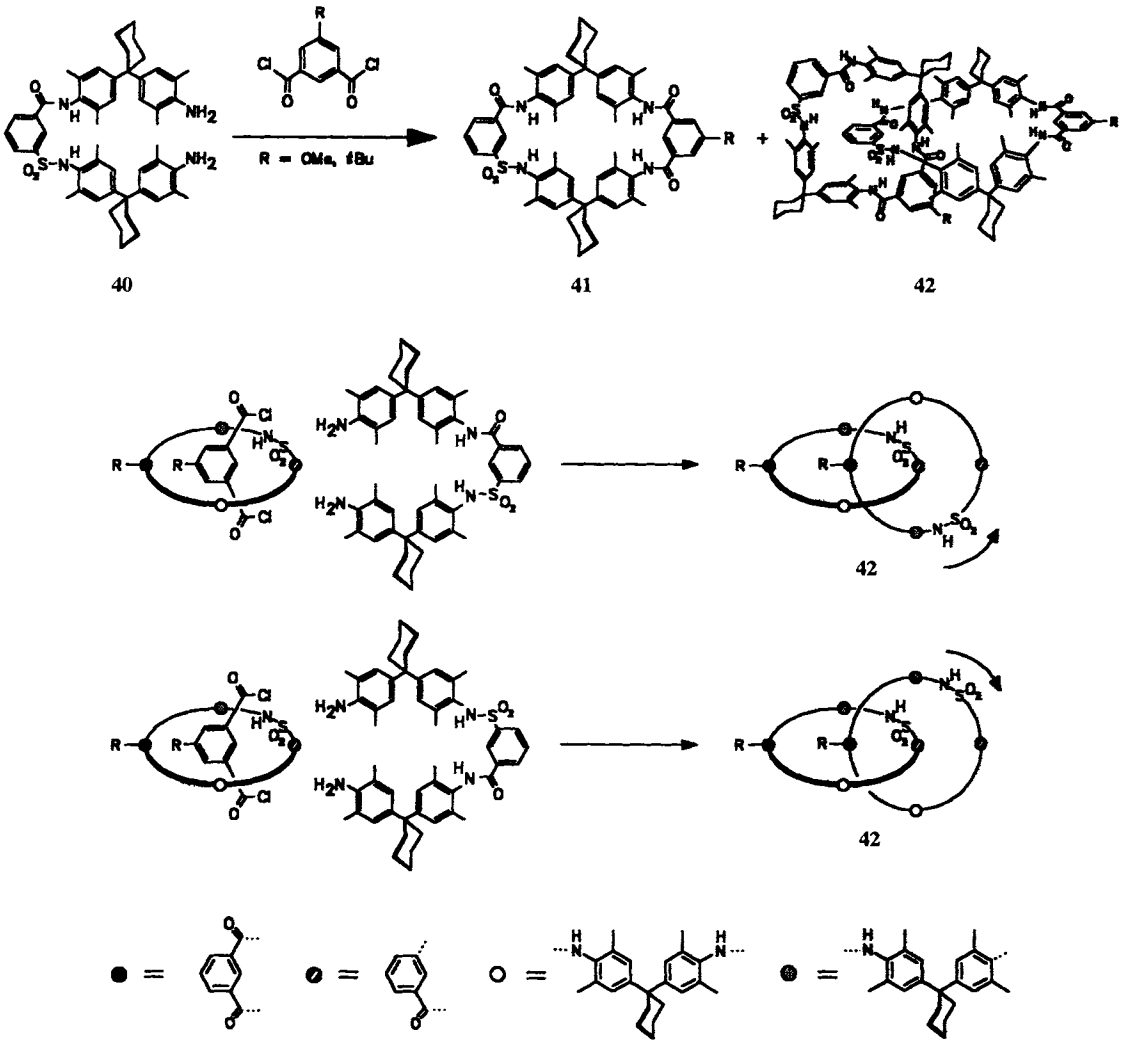

Figure 17. Synthesis of topological chiral sulfonamide catenanes according to Vögtle et al.

Two enantiomers of **42** are possible depending upon the orientation of the sulfonamide group. This rare form of topological isomerism[25] can be observed in this particular case, which results from the different sequence of amide functions.[45]

5. The First "Pretzel"-Shaped Molecules—Via Intermediate Catenanes

The higher acidity of sulfonamide protons relative to amide protons allows the (chemo)selective deprotonation of the former in the presence of the latter with mild bases. The introduction of sulfonamide functional groups into amide-linked catenanes of type **42** makes the directed substitution with suitable iodine compounds (like **43**) possible. The reaction of these catenanes **42** with a bifunctional alkylation agent, whose length was related to the distance between the two SO_2NH groups, allowed us to prepare molecules with the topology of a pretzel (**44**). This was achieved by intramolecular cyclization (Figure 18).[26]

An attempt to attach salt to the polar sites of the molecule by the addition of potassium hexafluorophosphate did not result in the anticipated NMR shifts of the signals. This might have been due to the short open chain crown ether in **44**. Side products of the "pretzel-synthesis" were identified as a dimeric crown-ether catenane **45**, a disubstituted catenane **46**, and catenane **47** (Figure 19).

We succeeded recently with aliphatic diamines **48** to synthesize the amide-linked [2]catenane **51**, whose circumrotation is

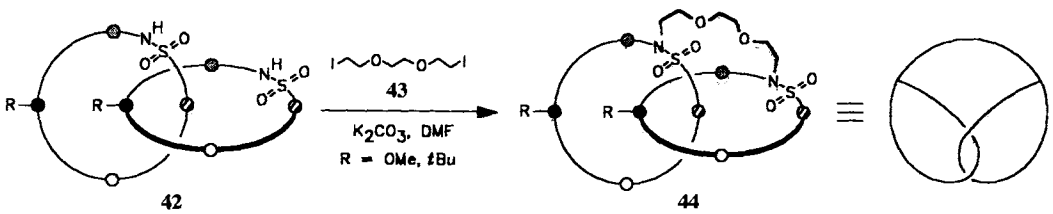

Figure 18. Synthesis of the first compound with the shape of a pretzel (**44**) via intermediate catenanes according to Vögtle et al. DMF = dimethylformamide.

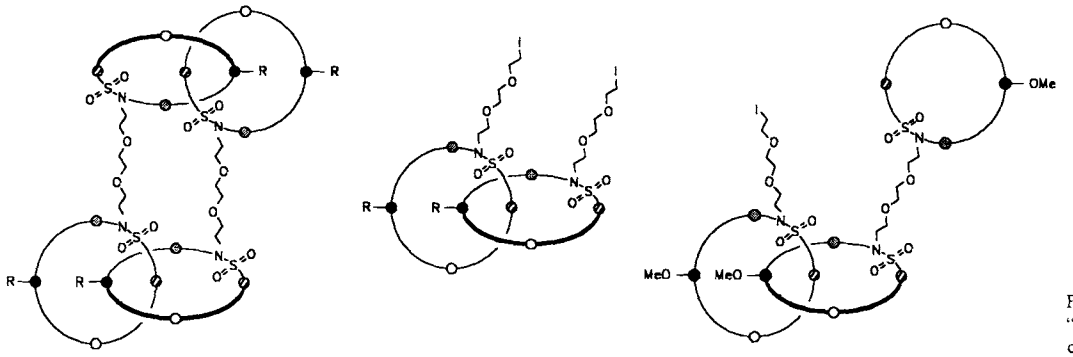

45 46 47

Figure 19. Side products from the "pretzel-synthesis": (crown ether)-catenane dimer **45**, disubstituted catenane **46**, and catenane **47**.

not significantly hindered. The substitution of the sulfonamide protons with bulky 2,2'-bipyridine units (cf. **53**) resulted in the subsequent restriction of the circumrotation of *one* of the macrocycles in the catenane (Figure 20).[27]

6. Amide-Linked [2]Rotaxanes

On the basis of our proposed mechanism for catenane formation, we synthesized the first amide-linked [2]rotaxanes (**58a–g**) in 1995.[28] The synthesis, which proceeds with a neutral template, is surprisingly easy: the middle part of the "axle" **54** (guest) is added to the "wheel" **50**, which acts as a concave template. The reaction with (4-aminophenyl)triphenylmethane (**55**), which acts as blocking group, results in a mechanical bond between "wheel" and "axle" and the [2]rotaxane **58a** (Figure 21).

The exchange of the *meta*- with a *para*-phenylene unit and with five-membered heteroarenes led to the synthesis of other [2]rotaxanes with different middle parts within the axle (Figure 21).[29] To our surprise even the sulfonyl chlorides **54e–g**[30] were included in the "hospitable" macrocycle **50**, which enabled the synthesis of the first [2]rotaxanes with sulfonamide units in yields as high as 41%. Temperature-dependent NMR studies (−80 to 20 °C) revealed that no rotaxane isomers were present, which could theoretically form from the different substituted isophthaloyl units of **50**.

Our next target was the synthesis of [2]rotaxanes with nonequivalent blocking groups. The new blocking groups

Figure 20. Synthesis of the amide-linked [2]catenanes **51** and **53** from the aliphatic diamine **48** and (bottom) the resulting inability of one of the macrocycles in catenane **53** to circumrotate freely (elicited by substitution of the sulfonamide protons).

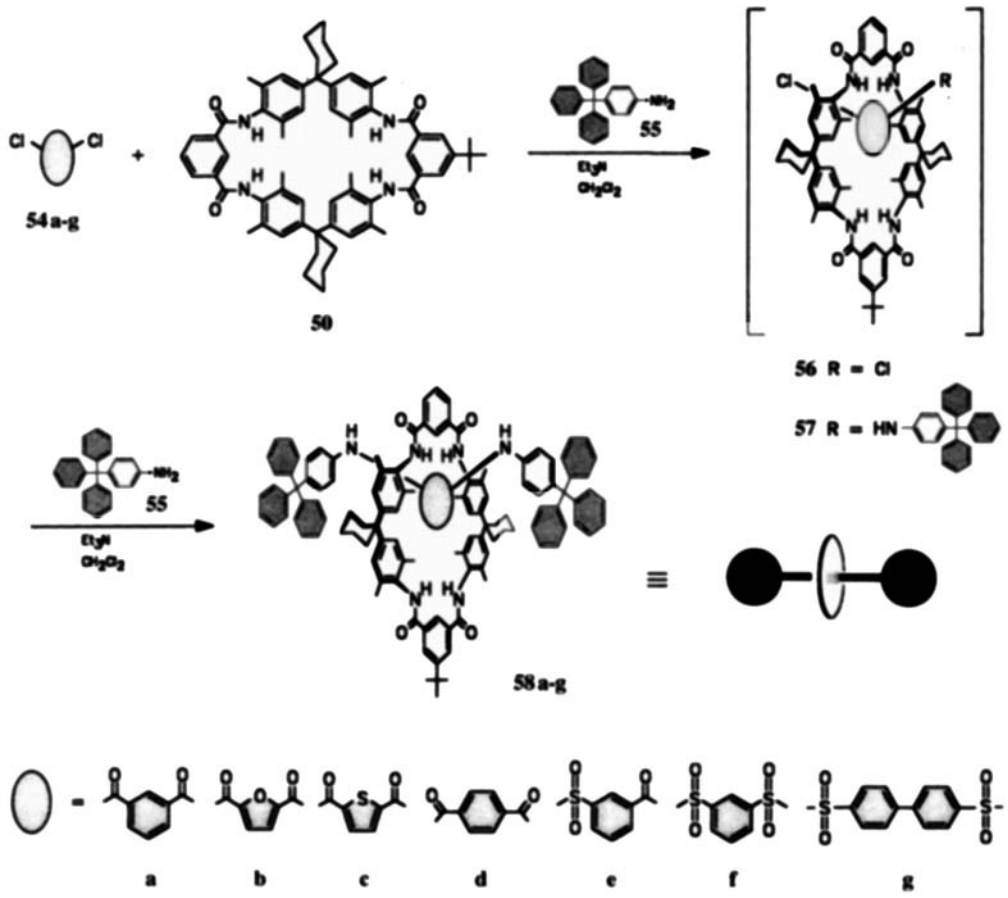

Figure 21. Synthesis of the first amide-linked [2]rotaxanes **58a–g** according to Vögtle et al.

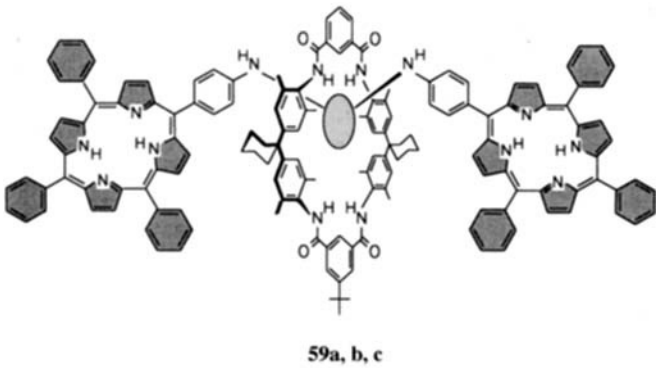

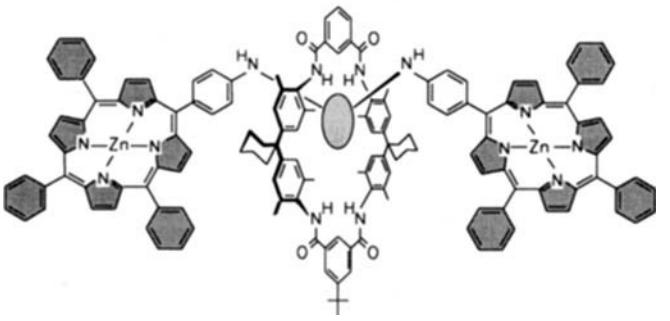

Figure 22. Amide-linked rotaxanes **59a,b,e** with porphyrin blocking groups and the Zn complex **60b**.

should provide additional supramolecular functions, and because of their steric and other properties, porphyrins were regarded to be ideal for this purpose. Following the established synthetic strategy we prepared the rotaxane **59** and its Zn complex **60** (Figure 22).[31]

We finally obtained the unsymmetrical amide-linked rotaxane **61** with two different blocking groups in a one-pot reaction with the two blocking groups (Figure 23).[31]

7. Amide-Linked [3]Rotaxanes

The macrocycle **50** also served as host compound for the synthesis of the first amide-linked [3]rotaxane.[32, 33] The first attempt with a longer axle, however, only resulted in the synthesis of the corresponding [2]rotaxane **63a** ($n = 1$). The formation of the corresponding [3]rotaxane is probably suppressed due to the repulsive steric interactions of the bulky macrocycle **50** (cf. Figure 25). If, however, the axle is extended even further, the formation of the [3]rotaxane **62** (Figure 24) and [2]rotaxane **63b** ($n = 2$) is observed.

The two isophthaloyl units in the axle of the [2]rotaxanes **63a** and **63b** are chemically equivalent in the ^{1}H NMR spectrum at room temperature. This leads to the conclusion that the wheel can translate freely along the axle (Figure 25). Even at temperatures as low as $-60\,^{\circ}C$ the equivalence is not disturbed: the rotation around the axle and the movement along the axle can thus not be significantly influenced.

8. Chemistry of the Rotaxanes

When sulfonamide groups were introduced into the wheel and the axle of amide-linked rotaxanes, the mechanically bonded molecules could be used as starting material for preparative reactions (cf. Section 5).

8.1. Intramolecular Bridging

To test whether the macrocycle (wheel) could sterically interfere with a substituent on the axle of a rotaxane, a methyl group, which is sterically not very demanding, was chosen. The reaction of the rotaxane **58e**, which carries a sulfonamide group on

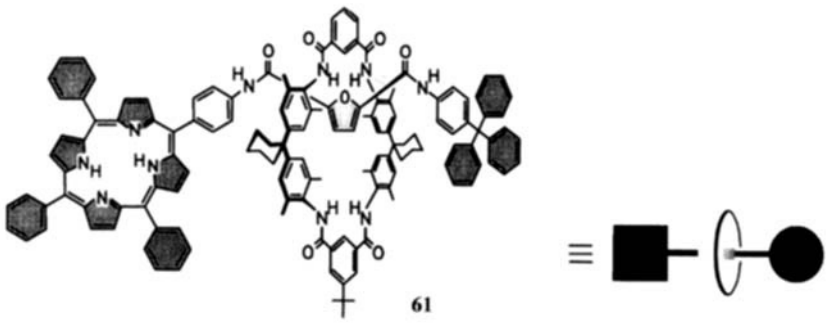

Figure 23. Unsymmetrically blocked rotaxanes.

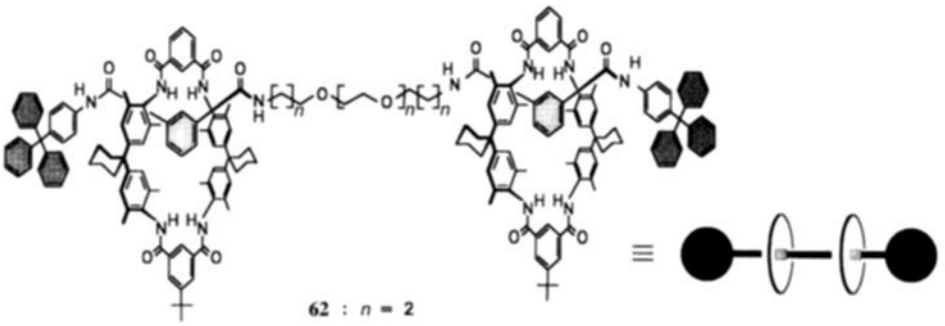

Figure 24. The first amide-linked [3]rotaxane **62** according to Vögtle et al.

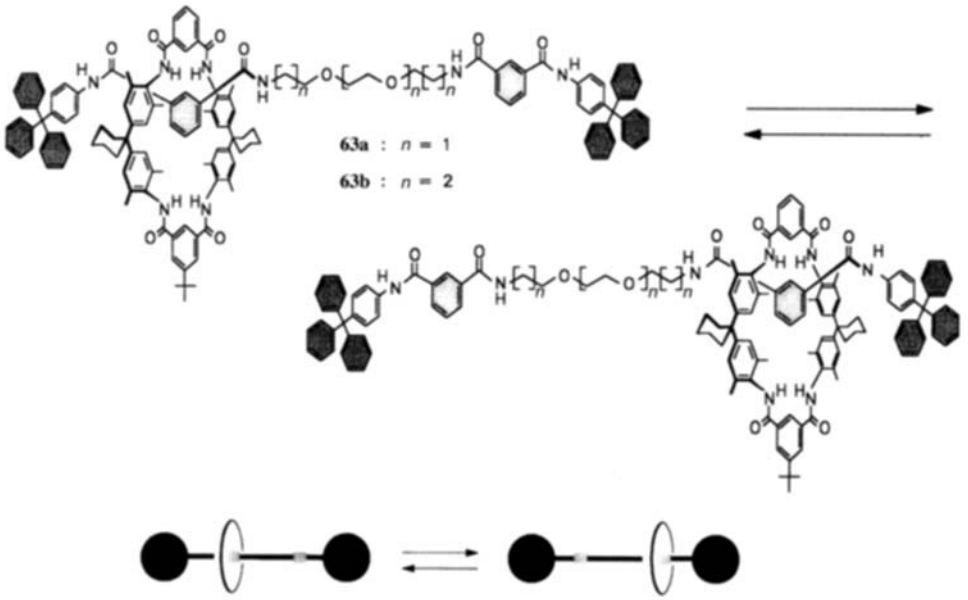

Figure 25. Dynamic stereochemistry of the [2]rotaxanes **63**.

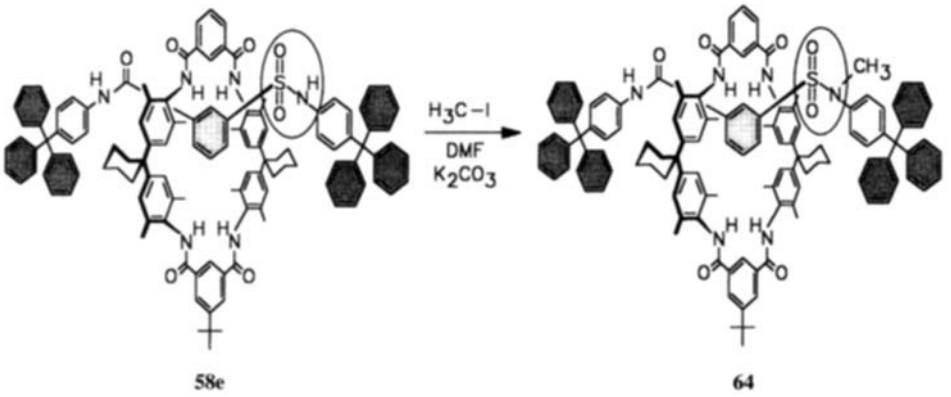

Figure 26. Substitution of the sulfonamide proton with a methyl group in the presence of C(O)–NH groups.

its axle, with iodomethane in the presence of a mild base resulted in the desired methylated product **64** without any problems (Figure 26).[34]

This result encouraged us to synthesize a rotaxane with a sulfonamide unit on the axle and a second sulfonamide unit on the wheel (**65**). The subsequent *intra*molecular bridging reaction between wheel and axle of **65** to give **66** (Figure 27) was achieved by using the appropriate alkylation agent **43**.[34] Rotaxane **66** can be regarded as a "[1]rotaxane" since the two mechanically connected molecules of a [2]rotaxane are connected by an additional covalent bond. In the classical understanding of bonds, this is *one* molecule. The axle and wheel of this "tethered" rotaxane **66** can no longer move freely as in a "free" [2]rotaxane.

The [2]rotaxane **65** and the [1]rotaxane **66** are, to our knowledge, the first examples of cycloenantiomers,[4] which consist of axle and wheel that are not themselves chiral. In this case the image and its mirror image are created by different sequences of the three amide groups and the sulfonamide group on the wheel in a rotaxane with an unsymmetrical axle. This unsymmetry results from the amide and the sulfonamide groups on the axle of **65** and **66**. If the order of the atoms within the wheel is examined, in one enantiomer the sulfonamide nitrogen atom is passed before the sulfonamide sulfur, whereas in the other enantiomer the order of the atoms is reversed (Figure 28).[45]

8.2. Intermolecular Bridging

These results lead to the conclusion that an *inter*molecular bridge between macrocycles and rotaxanes should be feasible. The reaction of the monosulfonamide macrocycle **41** with the bifunctional alkylation agent **43**, which was used successfully before for

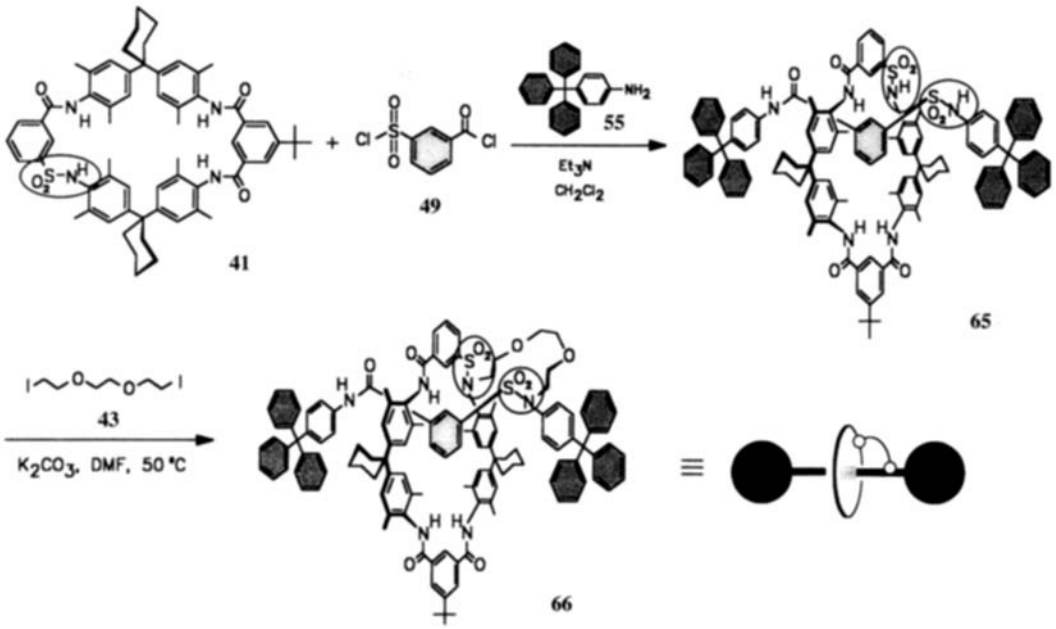

Figure 27. Intramolecular covalent bridge between wheel and axle of a [2]rotaxane **65** leading to a "[1]rotaxane" **66**.

the intramolecular connection, resulted in the preparation of the bis(macrocycle) **67** (Figure 29).[34]

The same strategy was used for the synthesis of a bis[2]-rotaxane. The connection of two wheels of two [2]rotaxanes, which only carry one sulfonamide group on their wheel, resulted

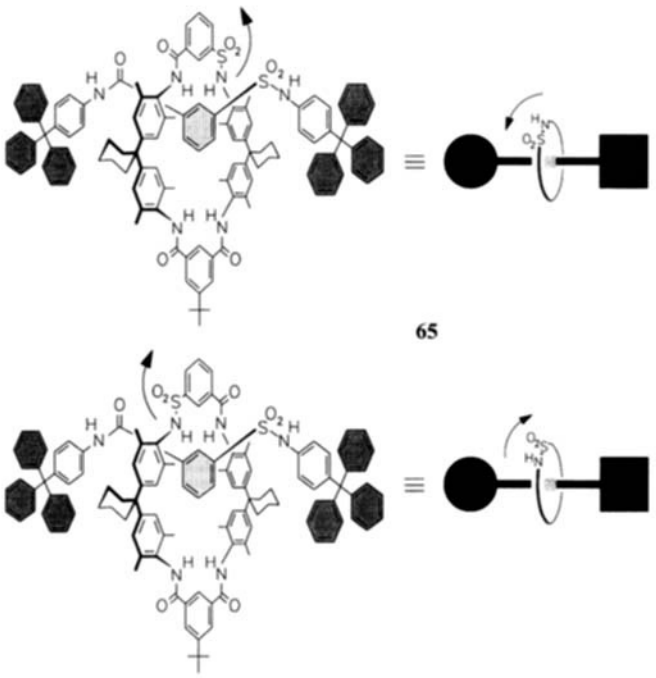

Figure 28. Cycloenantiomers of rotaxane **65**.

in the desired product **70** (Figure 30) with 76% yield.[34] The astoundingly stable, isolable side product, the iodine-substituted rotaxane **69**, is a suitable starting material for the synthesis of higher rotaxane assemblies.

9. Amide-Linked [2]Rotaxanes by "Slipping"

We recently discovered a very simple method for preparing amide-linked rotaxanes (**73**, **74**), namely, heating the axle **72** and wheel (**41**, **71**) in the absence of a solvent (Figure 31).[35] This synthesis most probably proceeds by a "slipping" process[36] and allows, in the case of **73**, the preparation of rotaxanes that decompose to give their units (axle and wheel) if they are left to stand at room temperature in solution. In contrast, rotaxane **74** is stable. Conclusions about the steric demands of the blocking groups and their complementary wheel cavities may be drawn from these results and may in the future allow the design of rotaxanes tailored to display special slipping and rethreading effects.

10. Summary and Outlook

Amide-linked catenanes and rotaxanes, which are thought to be formed through simple hydrogen bonds and $\pi-\pi$ interactions, present a vast potential of structural and functional design possibilities to create new molecules and supramolecules with mechanical bonds. The nonionic host–guest system offers the opportunity for detailed studies of the molecular recognition processes between neutral molecules as precursors for new template syntheses. This system should be far more versatile than the charged donor–acceptor or coordination complexes, whose units could lead to undesired coulomb interactions and solubility problems. The variations of the simple acid chloride and diamine units presented in this review prove that the system is astonishingly insensitive towards structural changes. It should therefore be possible to prepare a large number of new, tailored amide-linked catenanes and rotaxanes.

The directed introduction of sulfonamide groups into amide-linked catenanes and rotaxanes and the subsequent substitution of the sulfonamide protons allows these molecules to be used as

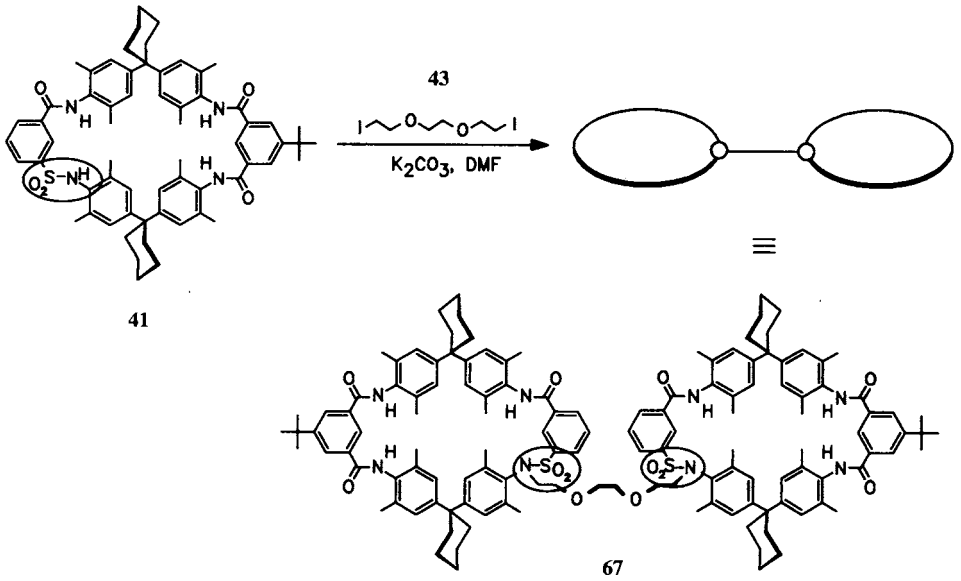

Figure 29. Intermolecular connection of monosulfonamide groups of macrocycle **41** leading to a bis(macrocycle) **67**.

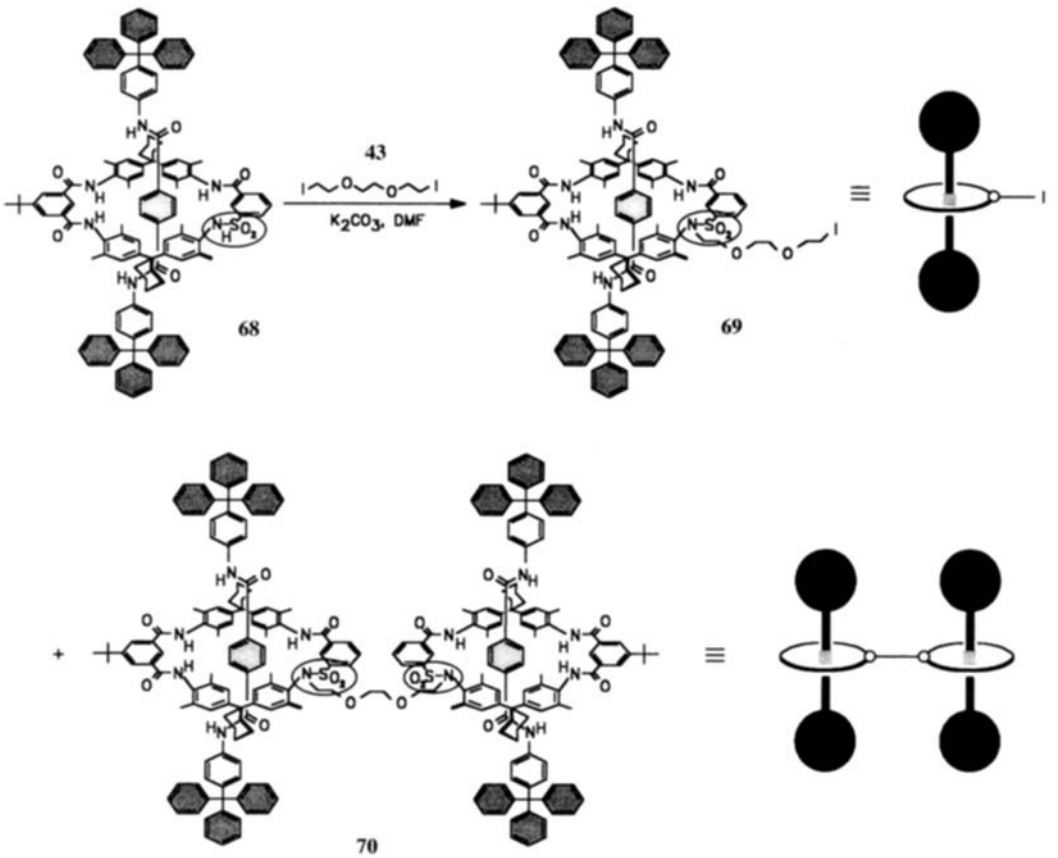

Figure 30. Synthesis of bis[2]rotaxane **70** by intermolecular coupling of the monosulfonamide macrocycle of [2]rotaxane **68** according to Vögtle et al.

starting material for further reactions. This functionalization can be introduced without difficult substitution on the mechanically bonded molecule and opens vistas of preparative chemistry with catenanes and rotaxanes that can lead to new shapes and topologies, which were so far only difficult or impossible to obtain (e.g. pretzel **44**).

Applications of mechanical bonds in molecular switches,[37] electron transfer reactions,[38] sensor units and in polymers[39] are currently under intense investigation. The mixing of units of the amide strategy with those of the phenanthroline-,[5,40] bipyridinium-,[6] cyclodextrin-[41] and palladium/aza-arene strategies[42] should result in the development of further structural and functional types of supramolecules.

The investigation of the influences of the possible hydrogen bonds upon the mechanism of templating of amide-linked catenanes and rotaxanes is very important. Because the electronegativity of sulfur is lower than that of oxygen, a thioamide macrocycle[43] **75** should have weaker hydrogen bonds with the guest.

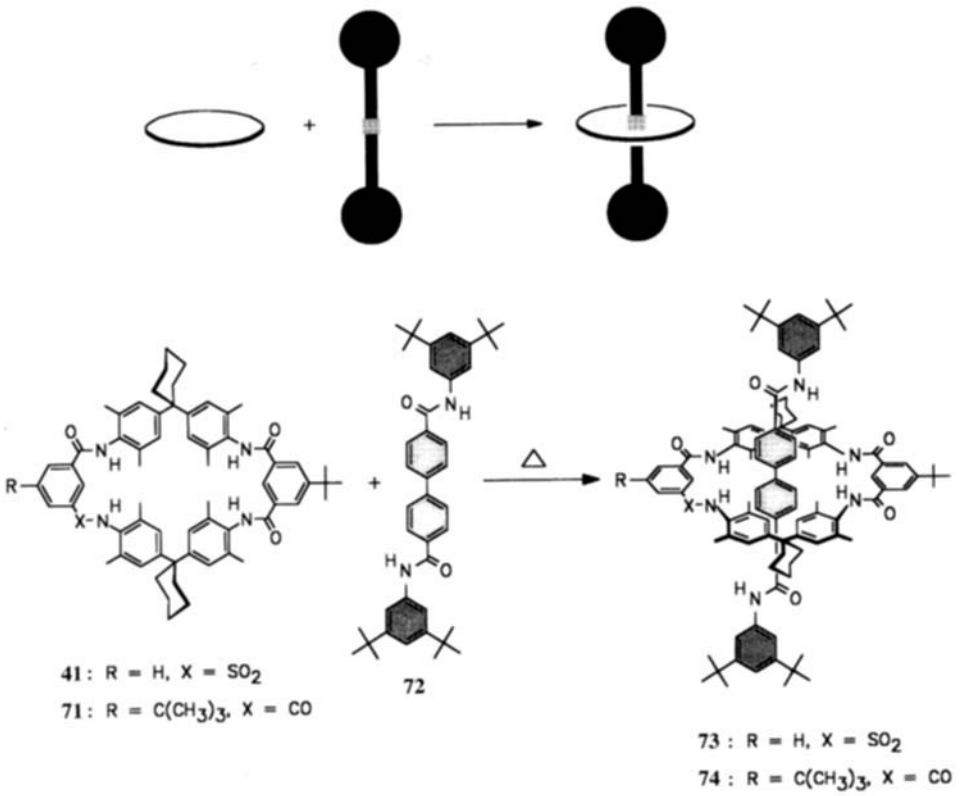

Figure 31. Synthesis of rotaxane **73** (and **74**) by reaction of the tailormade complementary units wheel **41** (or **71**) and axle **72** in the absence of solvent.

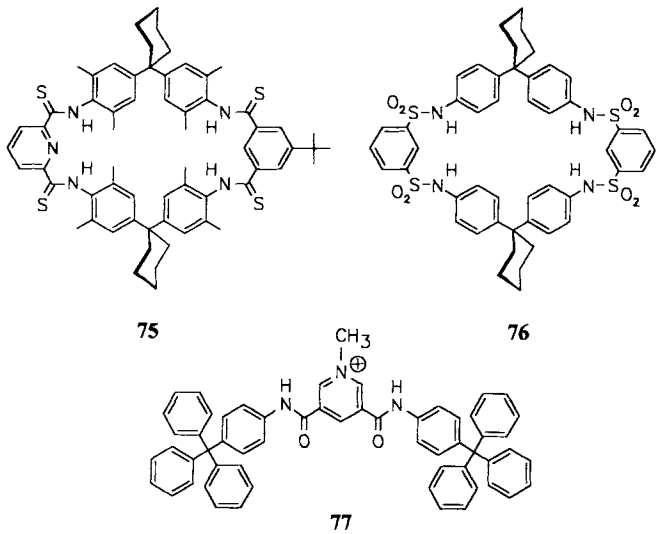

Figure 32. Thioamide macrocycle **75** and tetrasulfonamide macrocycle **76** as potential concave templates for the threading of suitable axle units, and the ionic axle **77**.

Substitution of the sulfonamide protons of the tetrasulfonamide macrocycle[24] **76** with, for instance, methyl groups should result in the suppression of attractive hydrogen-bond interactions.

If charges are desired in a particular part of the molecule, for example for the study of electron transfer processes, they can be specifically introduced into the compounds. The methylation of pyridine nitrogen atoms (cf. methylated axle **77**[44]) introduces electrical charge into amide-linked rotaxanes and catenanes.

The growing experience with molecular recognition processes and the further improvement of already sophisticated analytical techniques should lead to a further increase in preparation of both coincidentally found and deliberately designed molecules with mechanical bonds in the next few years.[46] It will become possible to synthesize molecules that move with a (light-powered) apparatus similar to the flagellum motor mentioned in the introduction. Furthermore, molecules acting as molecular machines and computers are also anticipated.

Fritz Vögtle would like to thank his coworkers Friedrich Ahuis, Sven Baumann, Stefan Braschohs, Thomas Dünnwald, Mirko Händel, Christiane Heim, Ralf Jäger, Stephan Meier, Stephan Ottens-Hildebrandt, and Thomas Schmidt for their enthusiasm, skill, and patience, and for fruitful discussions, which led to many new ideas. For financial support we would like to thank the Deutsche Forschungsgemeinschaft (DFG, Vo 145/47-1). We also thank Dipl.-Chem. Norbert Kamp, University of York, for the translation of this paper.

Deposition of Data from X-Ray Structure Analyses

In order to make life easier for authors and referees the Cambridge Crystallographic Data Centre (CCDC) and the Fachinformationszentrum Karlsruhe (FIZ) have unified their procedures for the deposition of data from single-crystal X-ray structure analyses.

Prior to submitting your manuscripts please deposit the data for your compound(s) **electronically** at the appropriate data base, that is, at the CCDC for organic and organometallic compounds and at the FIZ for inorganic compounds. Both data bases will be pleased to provide help (see our *Notice to Authors* in the first issue of this year). In general, you will receive a depository number from the data base within two working days after electronic deposition; please include this number with the appropriate standard text (see our *Notice to Authors*) in your manuscript. This will enable the referees to retrieve the structure data quickly and efficiently if they need this information to reach their decision.

This is now the uniform procedure for manuscripts submitted to the journals *Advanced Materials, Angewandte Chemie, Chemische Berichte/Recueil, Chemistry—A European Journal*, and *Liebigs Annalen/Recueil*.

Amorphous Plastics Pave the Way to Widespread Holographic Applications

Klaus Meerholz*

When two coherent light beams overlap, one containing information about an arbitrary image or object ("object beam") and the other being a plane wave ("reference beam"), a characteristic interference pattern evolves. By overlapping these beams in an appropriate medium, the material's absorption and/or index of refraction are altered nonuniformly as a result of the nonuniform illumination. A holographic "grating" (hologram) is formed that can diffract light. This hologram contains intensity and phase information about the object. The information stored in the material can then be read out by a plane-wave incident from the original direction of the reference beam. The virtual image of the object evolves as a diffracted signal in the original direction of the object.

Photorefractivity, first reported in 1966 as a detrimental effect in lithium niobate $LiNbO_3$, is now considered one of the most promising mechanisms for producing holograms.[1] Interest is mainly driven by the variety of applications that use holography, such as high-density data storage and optical correlation. In holographic storage, "data pages" consisting of 256 kbits, for example, in form of white and black squares representing the 0's and 1's are stored in the appropriate recording medium. Extremely high storage densities can be achieved by "multiplexing" several holograms in the same volume of the material, for example, by using different tilt angles for storing each single hologram or by varying the wavelength of the light used in the writing process. By optical correlation, two images superimposed on the light beams generating the hologram can be compared optically (in the Fourier plane), since the hologram only develops in locations where the two images are identical or at least similar. The comparison of entire gray-scale images (corresponding to several megabytes of data) requires the same amount of time as the comparison of just two bits alone. Depending on the material and the optical components used for detection, one correlation takes between several tens of milliseconds and seconds. Thus, both areas of application profit from the highly parallel nature of optical processing schemes, and are preferable over electronic processing, if large amounts of data are involved requiring long computing times.

The formation of a holographic grating in a photorefractive (PR) medium involves several steps (Figure 1): In brief, following the nonuniform illumination of the material, charge carriers are generated inside the material and redistributed such that the spatial positions of the centers of positive and negative charges are different. The field emerging from this space-charge separation then modulates the refractive index of the material. Thus, in order to be photorefractive a material has to combine photosensitivity and photoconductivity, and possess a field-dependent refractive index, most commonly through the electrooptic (Pockels) effect. Uniform illumination smears out the charge distribution and erases the hologram, that is the materials are suitable for dynamic (i.e. reversible) and real-time holography.

A unique property of the PR effect is the nonlocal nature of the index grating, that is the light and refractive index pattern are out of phase (see Figure 1). This gives rise to asymmetric

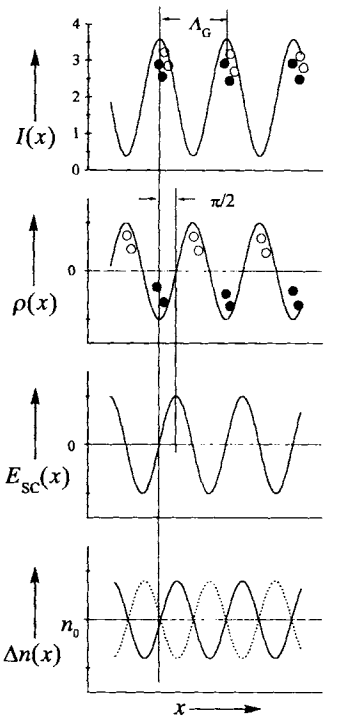

Figure 1. Illustration of the photorefractive effect. Two coherent light beams are overlapped inside a holographic medium, producing a sinusoidal light intensity pattern $I(x)$. In the regions where the light intensity is high, charge carriers are generated through absorption of photons; the filled (hollow) circles represent negatively (positively) charged carriers. By contrast, where the light intensity is low, only few or no charge carriers are formed. Typically, one type of carrier is much more mobile than the other. The mobile carrier type (in this case the positive) can migrate away from the regions of high light intensity either by diffusion due to the concentration gradients following the nonuniform excitation or under the influence of an externally applied electric field. The charge transport process is limited by energy traps present in the material. As long as there is enough local light intensity, the carriers can be reactivated by light and drift/diffuse further away from the location where they were originally generated. Over time, transport of the carriers leads to the separation of the centers of positive and negative charge $\rho(x)$ and, gradually, to the build-up of an internal electric field, the "space-charge field" $E_{sc}(x)$. Note, that the space-charge field is $\pi/2$-phase shifted with respect to the space-charge distribution $\rho(x)$ due to the Poisson relation, which predicts maximum field strength between the centers of positive and negative charge. The space-charge field finally modulates the refractive index of the material $n(x)$. The full (dashed) line in the bottom figure symbolizes the electric field-induced increase (decrease) of the bulk refractive index. Since the space-charge field is phase-shifted, the resulting index grating is also shifted with respect to the light intensity pattern. The overall phase shift ϕ depends on the relative contributions of drift and diffusion processes. For pure diffusion or drift (the case considered here), a value of $\phi = \pi/2$ is expected, whereas for all mixed cases $0 < \phi < \pi/2$.

energy transfer ("two-beam coupling"), in which one of the writing beams gains energy at the expense of the other. This property that can be exploited for all-optical image amplification.

Until recently, all PR materials were inorganic crystals.[1] Despite the proof-of-principle demonstration of a number of the above-mentioned applications, none of them has been commercialized on a large scale. One reason for this is the tremendous progress that has been achieved in semiconductor and integrated circuit technologies, making electronic computing fast, powerful, and rather inexpensive, while optical schemes require costly high-precision optics. Another reason is the difficulty in reproducibly growing crystals with sufficiently high PR performance. Recently, due to the progress made in the fields of CCD (charge-coupled device) and SLM (spatial light modulators) technologies, holographic processing using PR crystals has experienced a renaissance because of the highly parallel nature of optical processing. Nevertheless, the relatively high cost for a high-quality crystal prevents their use in widespread applications.

The search for better PR materials has continued over the years, and in addition to many new inorganic crystalline materials,[1] photorefractivity was discovered in semiconductors,[2] organic molecular crystals,[3] and polymers.[4] Orientational effects enabled even the use of materials without or with very little apparent optical nonlinearity such as liquid crystals[5] and amorphous glasses.[6] In particular, the discovery of photorefractivity in polymers in 1991[4a] triggered a great deal of research effort towards improving the performance of these new materials.[4b,c] One inherent advantage of organic noncrystalline materials is that unlike in inorganic crystals, the individual properties (photosensitivity, photoconductivity, and nonlinear optical properties) necessary to obtain a PR material can be optimized more or less independently from each other by varying the different functionalities. The new field profited much from the earlier developments in the fields of organic photoconductors for xerography and organic nonlinear optical materials developed for fast electrooptic (EO) light modulators.

Typically, photoconductivity is provided by redox-active molecules that are easily oxidized (reduced). The hole (electron) transport proceeds by hopping between spatially separated redox sites that undergo a series of oxidation or reduction steps (trapping/detrapping). The transporting species are radical cations (or radical anions, respectively). Photosensitivity in the visible region can be achieved by adding an electron acceptor (or electron donor, respectively), for example fullerenes or pigments such as squaryllium dyes. The third "ingredient", nonlinear optical moieties, consist of a π-electron "bridge" endcapped with substituents of disparate electron affinities (electron donors and acceptors, respectively) to induce the asymmetry required for second-order optical nonlinearity, such as the EO effect. The delocalization of the π electrons along the molecular axis leads to an increased electron density at the acceptor site at the expense of electron density at the donor group, resulting in a permanent dipole moment μ. In order to obtain materials with macroscopic second-order nonlinear properties, the chromophores are aligned by applying an electric field E. The latter also serves to enhance the charge generation efficiency and at the same time is the driving force for carrier transport since charge diffusion is very inefficient in amorphous organic materials. Thus, typical organic PR devices consist of two glass slides coated with transparent electrodes (for example indium tin oxide, ITO) for the application of the electric field (Figure 2). The organic material is sandwiched between these glass slides, and the thickness is adjusted by appropriate spacers (100–200 μm).

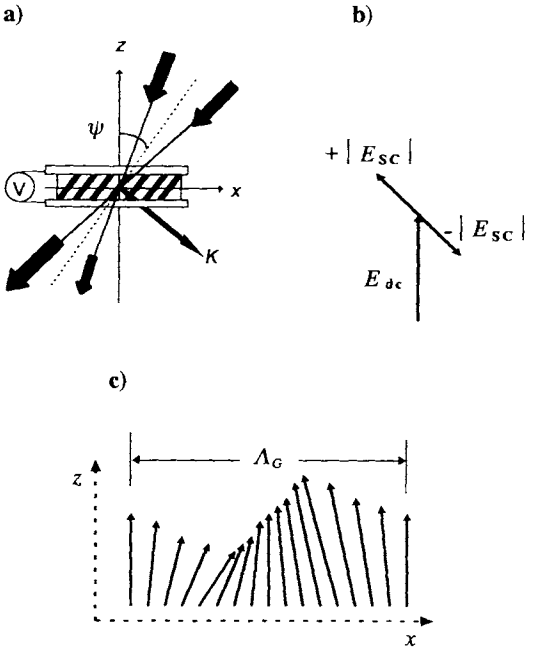

Figure 2. Illustration of the "orientational enhancement mechanism" [8]: a) Typical tilted geometry (tilt angle ψ) used for recording holograms in organic PR materials. The tilt of the device with respect to the bisector of the beams is necessary, because the electric field that is applied for the drift of the charge carriers, would be perpendicular to the holographic grating vector for the untilted geometry; the varying size of the arrows symbolizing the light beams after passing through the device indicates the energy transfer due to "two-beam coupling". b) Vector diagram illustrating the relative directions of the uniform external field E_{dc} and the nonuniform internal space-charge field $E_{sc}(x)$. c) Spatial variation of the total field $E_{tot}(x)$ for one grating period Λ_G.

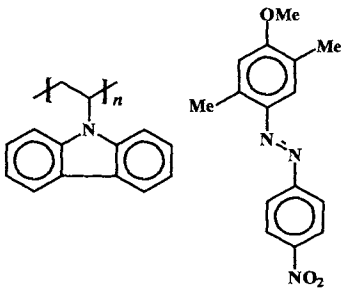
The first PR polymer to be developed was a nonlinear-optical (NLO) polymer doped with a low molecular weight photoconductor.[4a] Its performance, however, was initially limited: Diffraction efficiencies for the readout of a hologram in the order of 2×10^{-5} at $E \approx 12\ V\,\mu m^{-1}$ were reported. The "inverse" situation, that is a photoconducting polymer doped with NLO chromophores, turned out to yield superior photorefractive properties. In particular, composites based on poly(*N*-vinylcarbazole) (PVK, **1**), well-known from xerography, showed excellent properties.[4b,c] A first milestone towards practical application of the new materials was achieved two years ago, when researchers developed a PVK-based PR composite with near-100% diffraction efficiency for the readout of a hologram as well as extremely high net gain ($\Gamma > 200\ cm^{-1}$).[7] This material thus exceeded the performance of the inorganic counterparts ($\Gamma \approx 40-50\ cm^{-1}$ in $BaTiO_4$). The highly soluble azo dye



1 **2**

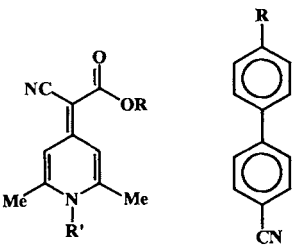
 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3609-0946 $ 17.50+.50/0

2,5-dimethyl-(4-nitrophenyl)azoanisole (2,5-DMNPAA, **2**) was used as the NLO molecule. The index modulation at $\lambda =$ 675 nm was as large as $\Delta n \approx 1 \times 10^{-3}$ (6.4×10^{-3}) at electric fields of $E = 40$ (90) V μm^{-1}. The improvement over earlier PR materials was achieved by better optical quality and uniformity, allowing the use of higher electric fields.

The most important feature of this and related composites, however, was that their glass-transition temperature T_g was close to room temperature, which permits in-situ alignment of the chromophores within the viscous polymer matrix. This was achieved by adding the plasticizer *N*-ethylcarbazole, which strictly lowers the T_g without reducing the photoconductivity. The local electric field responsible for poling the system is the superposition of the externally applied electric field E_{dc} and the PR space-charge field E_{SC} (Figure 2b). It thus varies periodically in amplitude *and* direction, leading to spatial variations of the direction and the degree of the local orientation of the chromophore (Figure 2c). As a result, the linear polarization of the material (birefringence) is modulated with the period of the space-charge field. In addition, the refractive index is further modulated by the space-charge field through the EO effect like in traditional PR crystals. In conclusion, the PR effect in such materials with low T_g is much stronger than that in a hypothetical PR polymer, where the (identical) chromophores would all be oriented in the same direction (like in permanently poled polymers). This phenomenon was first discussed by Moerner et al. and is referred to as the "orientational enhancement mechanism".[8] Most of the recently developed high-performance PR composites (see for example the one reported in reference [7]) owe at least 60% of the accessible refractive index modulation amplitude to the orientational effects. The figure-of-merit for photorefractivity in such materials with low T_g values is $[(A^*\Delta\alpha\mu^2)/kT + \beta\mu]/M$, where $\Delta\alpha = \alpha_{\parallel} - \alpha_{\perp}$ is the difference of the linear polarizability parallel and perpendicular to the molecular axis of the nonlinear chromophore, β is its first hyperpolarizability, μ is its dipole moment, and M is the molecular weight of the chromophore; A^* is a factor that accounts for the different degeneracy factors of the two contributions.

A new class of materials, reported most recently by Lundquist et al.[9] now takes full advantage of the birefringence contribution by using a type of chromophore without apparent second-order nonlinearity ($\beta \approx 0$), but with an "optimized" term $\Delta\alpha\mu^2$ in the PR figure-of-merit for organic materials with low T_g. Furthermore, the chromophores of the alkyl-2-(*N*-alkyl-2,6-dimethyl-4*H*-pyridone-4-ylidene)-2-cyanoacetate family **3** used are glass-forming with T_g values near room temperature, opening a favorable alternative route to monolithic PR materials. This route is much easier to follow than the complicated synthesis of fully functionalized polymers, in which the functional moieties required for photorefractivity are attached to or incorporated covalently into the polymer backbone.[10] In monolithic materials, the phase separation problem often observed in highly doped composites (typical amounts of the chromophore are up to 40-50% wt) can be completely avoided. One of these organic glasses shows very large index modulation amplitudes: $\Delta n \approx 1.5 \times 10^{-3}$ (10^{-2}) at $E = 40$ (90) V μm^{-1}. This is about 1.5 times higher than the best value previously reported for organic polymers.[7] The proof for the PR nature of the gratings was provided by a large net gain coefficient of $\Gamma_{net} \approx 65$ cm^{-1} at $E = 40$ V μm^{-1}. However, these materials show very slow response times compared to most of the other PR polymers reported to date. A significant increase in the hologram growth rates can be achieved by doping the chromophore with a small amount of polymer, such as polymethylmethacrylate (PMMA), but nevertheless the response times remain slow ($\tau = 83$ s at $E = 40$ V μm^{-1}).

Photorefractivity has also been observed in liquid crystals, such as the biphenyl derivatives 4-cyano-4′-pentylbiphenyl (5CB, **4a**, R = C_5H_{11}) and 4-cyano-4′-octyloxybiphenyl (8OCB, **4b**, R = OC_8H_{17}).[5] Like in the glassy materials, the PR effect is here almost purely based on orientational birefringence. The operating voltage required is much lower (2-3 V) than for PR composites or glasses (several thousand of volts; note, however, that the overall power consumption is low). Nevertheless, Δn can reach values beyond 10^{-2}, most probably due to cooperative reorientation of the liquid crystalline phase. Unfortunately, good PR performance is only observed for large grating spacings Λ_G (several hundreds of μm), but much less so for smaller spacings. The response times can be as fast as 40 ms for $\Lambda_G = 2$ μm.[5b]



3 **4**

Due to the tremendous progress achieved recently, organic noncrystalline PR materials have been seriously considered as an alternative to the long-known inorganic crystals as erasable holographic storage media. An important aspect in the design of a well-performing PR device is the choice of the right material for a particular application. As a general rule, organic PR materials with fast response times (fastest reported 40 ms in liquid crystals,[5b] 100 ms in polymers [7]) exhibit rather short storage times (minutes to hours), whereas materials showing long storage times (weeks to months) possess a very slow response (several minutes[9]). This is due to the fact that in the materials investigated so far low dark conductivity (required to keep the charges in the places where they were originally stored) resulted in low photoconductivity and vice versa. This clearly shows that there is not one single amorphous organic PR material that is suitable for real-time *and* storage applications.

For real-time applications, for example optical correlation or interferometry, only one hologram is stored in the material at a time, which is why the signal-to-noise ratio is not as crucial because the entire dynamic range (Δn) of a material can be used. In this case, fast response times are preferable to achieve high processing rates. PR composites with low glass-transition temperatures near room temperature and good photoconductivity seem to be the most suitable materials, offering large diffraction efficiencies, reasonably fast response times (100 ms), and high spatial resolution (grating period $\Lambda_G \approx 1$ μm; see Figure 1). The use of such high-performance PR polymers in a optical pattern recognition system for security verification has been demonstrated recently.[11] Liquid crystals are an alternative class of materials for real-time applications, in particular because of their low operating voltage. However, liquid crystal devices driven by a direct current voltage suffer from electrochemically induced damage. Therefore, the PR composites are still preferable.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3609-0947 $ 17.50+.50/0

To achieve high storage densities, a large number of holograms has to be stored in the same volume of the PR material. Thus, the dynamic range has to be shared between the different holograms, making the need for good signal-to-noise ratio much greater. As a result, optical clarity, uniformity, and scattering become very crucial. Furthermore, the dark conductivity must be low in order to keep the charge carriers in the locations in which they were generated during hologram recording. The glass-forming chromophores **3**[5, 9] seem ideal materials for such applications due to their large dynamic range and their excellent optical quality (low scattering). Multiplexing of ten holograms has been demonstrated in a material showing "non-destructive readout".[12] In both cases, slow response times were anticipated, preventing direct use of such materials in actual storage devices at this time. Materials with low dark and high photoconductivity would be the materials of choice.

In conclusion, amorphous organic PR materials are emerging as attractive materials for optical devices and processing systems. The materials are easy to process compared to time-consuming crystal growth. Very compact devices as well as large area ones can be fabricated with excellent reproducibility. Organic materials offer wide flexibility for varying the chemical functions that can be incorporated in the material. Only organic noncrystalline PR materials with high rotational mobility of the chromophores enable orientational effects, a strong advantage for obtaining good photorefractivity. Recent materials have optimized the $\Delta\alpha$ values, but even better performance can be expected for materials with chromophores with large dipole moments. However, the compatibility with unpolar organic matrices may be the limiting factor here.

In contrast to more traditional holographic recording media, such as silver halide films or thermoplastic polymers, PR materials do not require additional processing steps to develop or erase a hologram. This is a great advantage. The proof-of-principle for the use of noncrystalline organic PR materials in optical correlation and storage devices has been demonstrated.[9, 11, 12] The wavelengths at which devices are typically operated (600–800 nm) are compatible with commercial low-power laser diodes. The sensitivity at these wavelengths is very high and, most importantly, can easily be adjusted by the external electric field. The compatibility with laser diodes is instrumental for widespread applications in order to keep the overall manufacturing cost low and also to miniaturize the devices. The latter issue became even more favorable due to recent developments of high-precision plastic optical elements such as lenses and beam splitters, as well as waveguide integrated optics.

Quo vadis? Although the stability problem particularly related to highly doped composites has been overcome, little is known about the long-term performance of the materials under continuous operation at this point. This information is crucial before steps towards commercialization can be taken. The next issues to be addressed are faster response times, a reduction of the voltages necessary to achieve good photoreactivity, and the extension of the range at which good photoreactivity can be achieved to wavelengths of technical interest, such as those used in telecommunications (1300 and 1500 nm). A very promising area will be the holographic investigation of biological samples (tissue) with a transparency window around 800 nm.

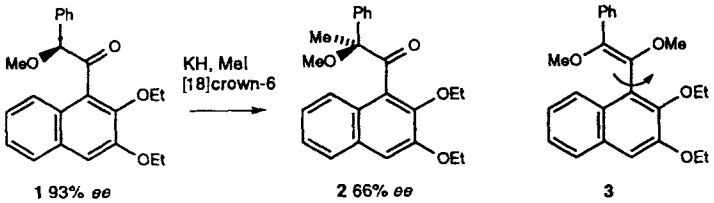
Non-Biaryl Atropisomers: New Classes of Chiral Reagents, Auxiliaries, and Ligands?

Jonathan Clayden*

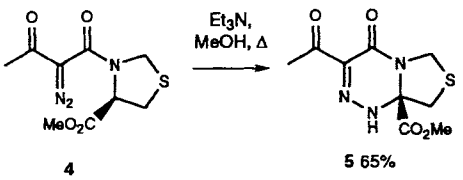
While many chemists are familiar with the problems posed by abnormally large barriers to rotation about single bonds when it comes to interpreting NMR spectra, few have sought to make use of these barriers as tools for stereoselective synthesis. A renewal of interest in this prospect followed the remarkable observation by Fuji et al.[1] of stereospecific alkylation of ketone **1**. The configuration of the starting material **1** was retained in the product **2** despite the intermediacy of an apparently achiral enolate (Scheme 1).[1]



Scheme 1. Chiral memory in an alkylation.

The conveyor of "chiral memory" in the reaction turned out to be restricted rotation in the enolate intermediate, and Fuji et al. were able to show that the enol ether **3**, formed as a by-product in the reaction, was chiral because of restriction to rotation about the arrowed bond, and could be recovered enantiomerically enriched. The enantiomeric excess *ee* of **3** decayed with a half-life of about 1 h at ambient temperature, and the enantiomers of **3** are atropisomers.[2]

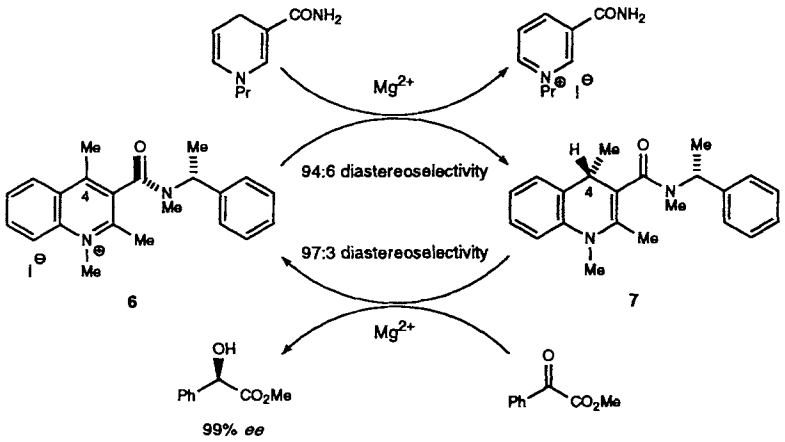
A similar phenomenon was observed by Stoodley and co-workers in the stereospecific cyclization of **4** to give a single isomer of **5**.[3] Again, the most likely explanation was an intermediate with a barrier to racemization sufficiently high to prevent it interconverting with its enantiomer on the timescale of the reaction (Scheme 2).



Scheme 2. Chiral memory in a cyclization.

Reactions like these, in which stereoselectivity is the consequence of steric hindrance to bond rotation, are most well known among biaryl derivatives, and binaphthyl derivatives have provided chemists with a valuable range of chiral ligands.[4-6] But the biaryl derivatives are only a small subset of axially chiral compounds containing two trigonal centers linked by a rotationally restricted single bond. Many others are known, some with much greater barriers to rotation than Fuji's enol ether.[7] Yet until quite recently there were no reports of reactions in which non-biaryl atropisomers were the source, conveyor, or product of asymmetric induction.

An early attempt to exploit the atropisomerism inherent in aromatic amides[8] drew inspiration from the suggestion that the orientation of the C=O bond in nicotinamide was fundamental to the stereoselectivity of hydride transfer to or from NADH.[9] Ohno and co-workers managed to separate a quinolinamide from its atropisomeric diastereoisomer and showed that the face-selectivity of hydride transfer to its methiodide salt **6** was stereoselective (Scheme 3).[10] When the diastereomer of **6** with the opposite configuration about the C–CO bond was used as the starting material, the diastereoselectivity was inverted, so the configuration of **7** must be controlled by the axial chirality of **6**. Similar experiments on enantiomeric atropisomers of dihydropyridines have confirmed this.[11]



Scheme 3. Asymmetric induction using axial chirality and stereoselective regeneration of atropisomerism.

The dihydroquinoline **7** formed from **6** turned out to be an enantioselective reducing agent, since it transformed methyl benzoylformate to methyl-(*S*)-mandelate with 99% *ee*. This reaction is not controlled by axial chirality because with an sp^3-hybridized C4 atom there is free rotation about the C–C=O bond of **7**. Yet the re-oxidized quinolinium salt **6** returned by these reactions recovers its axial chirality with almost complete stereospecificity, making this reaction the first example of an asymmetric synthesis of a non-biaryl atropisomer. The com-

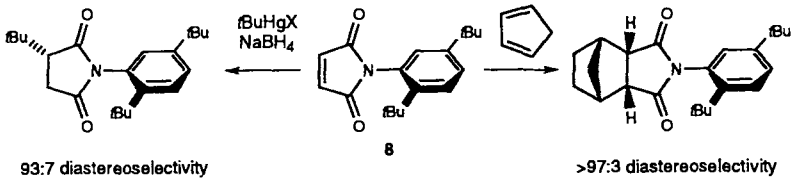
pound is also unique in being what we could term a "chiral shuttle", in which chirality is transferred from the C–CO bond to the chiral center at C4 and vice versa; the source of asymmetric induction is destroyed each time.

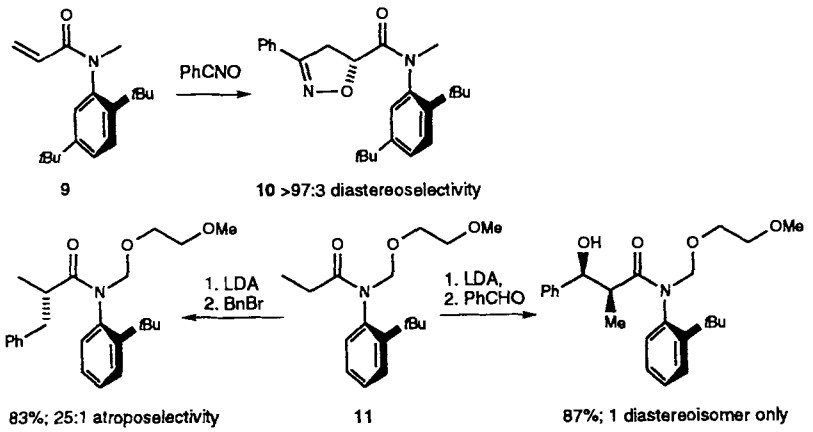
There are as yet no reports of successful translation of axial chirality of non-biaryl derivatives directly into chiral centers in other molecules. However, some recent publications indicate the potential of non-biaryl atropisomers, and in particular atropisomeric amides, for intramolecular asymmetric induction.

Curran et al.[12] showed in 1994 that maleimides bearing *ortho*-substituted aryl groups could react diastereoselectively, favoring a single atropisomer of the product. Curran termed these reactions "atroposelective". Racemic maleimide **8** underwent radical reactions and cycloadditions from the face unshielded by the *tert*-butyl group (Scheme 4).



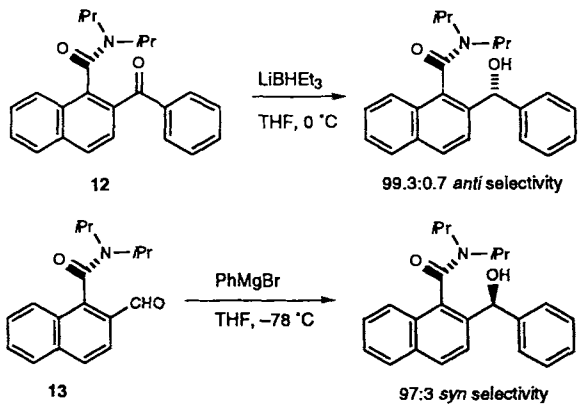
Scheme 4. Atroposelective attack on a maleimide.

Acyclic compounds will also react atroposelectively: amide **9** gave the isoxazoline **10** with >97:3 diastereoselectivity,[12] and only one diastereoisomer was obtained from the alkylations of or aldol reactions of **11**[13] (Scheme 5). Reactions such as this suggest the use of atropisomeric amides as a new class of chiral auxiliary, provided methods can be found to remove the auxiliary with retention of its axial configuration.



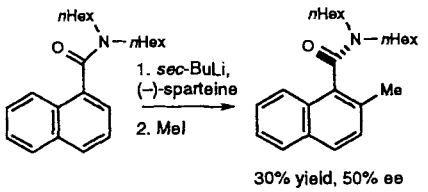
Scheme 5. The potential for atropisomeric amides as chiral auxiliaries. LDA = lithium diisopropylamide.

More recently, we have shown that atroposelective additions to carbonyl groups are possible[14] by using amides with restricted rotation about the C–CO bond. Reduction of ketonaphthamides such as **12** with bulky reducing agents gives very high selectivities for attack *anti* to the bulky *N,N*-dialkyl group (Scheme 6). Interestingly, reaction of the aldehyde **13** with phenylmagnesium bromide generates the other diastereoisomer atroposelectively.



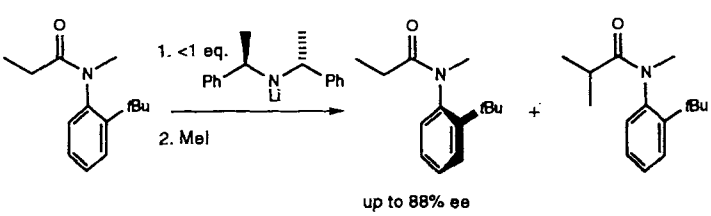
Scheme 6. Complementary atroposelective additions to carbonyl groups.

Efficient methods for making non-biaryl atropisomers enantioselectively could allow them to be used as chiral auxiliaries or as chiral ligands. In 1996 two enantioselective routes to atropisomeric amides were published—one an *ortho*-lithiation (Scheme 7)[15] and one a kinetic resolution (Scheme 8).[13]



Scheme 7. Enantioselective *ortho*-lithiation.

These reactions, and other successful resolutions (both classical[16,17] and on chiral stationary phase[8,18,19]) of atropisomeric aromatic amides mean that non-biaryl atropisomers are available enantiomerically enriched. The electronic properties of the carbonyl oxygen atom on the one hand and the steric bulk of the dialkylamino group on the other make these amides good candidates as asymmetric ligands; for example, coordination between magnesium and the amide carbonyl group is probably crucial for the stereoselective additions reported by Ohno et al. [10,20], by Vekemans et al.,[11] and by ourselves.[14] Maybe we will shortly see non-biaryl atropisomeric



Scheme 8. Kinetic resolution of atropisomeric amides.

Towards Radiation-Sensitive Quasi-Biological Display**

Franciscus M. H. de Groot, Giovanni Gottarelli,* Stefano Masiero, Gloria Proni, Gian Piero Spada, and Nicoletta Dolci

Liquid crystals are anisotropic fluids that are characterized by some degree of order. These features are the basis of their response to weak, external perturbations and, hence, of their use in many display systems.

In water DNA[1] and homoguanylic oligonucleotides[2] give rise to columnar, cholesteric liquid crystals; in the latter the columns are formed by an extensive self-assembly process. The cholesteric pitch can be directly measured with an optical microscope from the spacing between the retardation lines that appear in the fingerprint texture.[3] The distance between two lines is half the pitch. It is therefore easy to evaluate the effect of perturbations such as temperature change and added ions or dyes[4] on the cholesteric structure by directly observing the variation in this distance.

We were interested in exploring whether the pitch of these "biological" cholesterics was sensitive to ionizing radiation. In fact, the cholesterics are composed of molecules that, in living organisms, are believed to be the most sensitive and endangered targets of ionizing radiation. Furthermore, the cholesteric structure of DNA seems to be relevant in the chromosomes of some primitive algae and even in sperm nuclei from many species.[5]

The first experiments were carried out with cholesterics of DNA with an average length of 100 ± 20 base pairs. The samples were subjected to γ radiation with doses varying from 5 to 200 kGy. The pitch before irradiation was 2.96 ± 0.12 μm, and no significant change was observed up to a dose of 20 kGy. After irradiation with doses in the range of 30 to 100 kGy, a small decrease of the pitch was observed (about 8%). The solution became isotropic after a dose of 200 kGy.

These results were disappointing, and we thought that the cholesteric phase formed by 2′-deoxyguanylyl-(3′ → 5′)-2′-deoxyguanosine [d(GpG)] might be more sensitive to γ radiation than DNA for two simple reasons: Firstly, damage to one guanine unit of the dimer should severely affect the self-assembly process, which eventually leads to the cholesteric phase and, secondly, of the four bases guanine is the most sensitive to radiation-induced oxidative stress.[6] Furthermore, d(GpG)·Na gives a cholesteric phase at low concentration,[7] and its pitch is considerably longer than that of DNA and allows more accurate measurements. The effect of γ radiation on the pitch is displayed in Figure 1, and Figure 2 shows the fingerprint textures of an untreated sample and one after a dose of 20 kGy. There is a linear dependence of the inverse pitch (twist) on the applied dose of between 0 and 20 kGy. Appreciable variations start at 4 kGy, and the twist increases approximately 330% on irradiation with 20 kGy. For higher doses a transition to the isotropic phase was observed. We have also measured the optical density of the samples at 252 nm (λ_{max} for guanine absorption), and a small, linear decrease was found. An 8% decrease in concentration occurs upon increasing the dose from 4 to 60 kGy, indicating the breakdown of the guanine chromophore. The shortening of the pitch is definitely not related to the decrease in concentration of d(GpG), which should instead lead to longer pitches,[7] but rather to the formation of products with a higher twisting power. For example, the twisting power of 2′-deoxyguanosine 5′-monophosphate [5′(pG)], which is one of the possible degradation products, is about twice that of d(GpG), whereas the handedness is the same.[7, 8] Although it is a possible pathway, cleavage of the phosphodiester group to give guanosine

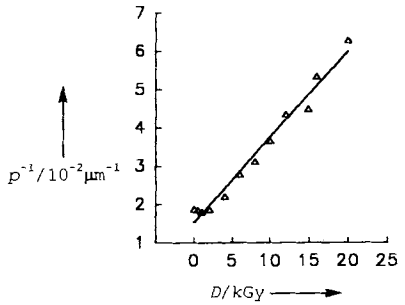

Figure 1. The inverse pitch P^{-1} of the d(GpG) cholesteric phase as a function of the absorbed dose. The average error of the pitch measurements is 9%.

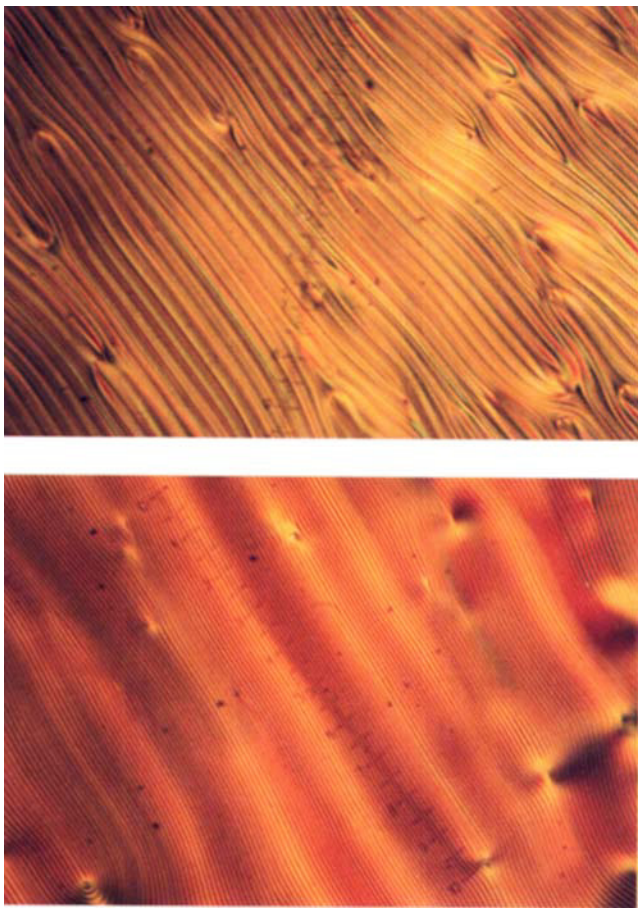

Figure 2. Fingerprint textures of the d(GpG)·Na cholesterics (original magnification 100×). Top: A nonirradiated reference sample. Bottom: A sample after a dose of 20 kGy.

monomers is probably not the main degradation process.[9] Other degradation products are instead obtained through OH radical attack on the heterocyclic base moiety.[10] These experiments point out a sensitivity that is lower than that of classical, chemical reference methods (Fricke).[11] Unfortunately, doses that are sufficient for the direct reading of our display are much higher than those that produce a biological response in living organisms.

However, the sensitivity of the method could be improved by, for example, addition of sensitizers,[12] use of different oligonucleotides, and experiments with liquid crystals formed in the presence of additives such as polyamines or basic polypeptides, which do not inhibit the formation of the cholesteric phase and might better simulate a cellular situation.[13] An alkaline medium also favors cleavage of the sugar-phosphate backbone once the base has been damaged.[12] Considering that the pitch before irradiation is about 58 μm, the cell can be miniaturized to approximately 300 μm, a length that is sufficient for reading five fingerprint lines.

To our knowledge, the effect of ionizing radiation on liquid crystals of DNA and guanosine analogs had not yet been studied, and there is no information available on the dependence of the cholesteric pitch on radiation. All published data in this field deal with the change of thermodynamic and dielectric properties after irradiation of cholesterics made of cholesterol derivatives.[14]

Experimental Section

Calf thymus DNA (Sigma) was sonicated as described in ref. [4]. The DNA samples (32 wt% in water) were prepared by sealing a drop of solution between two cover slides with the commercially available SureSeal system (thickness 0.2 mm) as a spacer. For each dose two samples were exposed, and the blank pitch was determined with 12 samples. The dimer d(GpG)·Na was synthesized and purified following a previously described procedure [7]. Samples of the d(GpG) cholesteric phase (4.8 wt% in water) were prepared, sealed in flat glass microslides (Vitro Dynamics, thickness 0.3 mm), and exposed to γ radiation (^{60}Co source, dose rate: 38 Gy min^{-1}) for different times corresponding to doses between 1 and 20 kGy (three slides were used for each irradiation time, and the experiment was doubled; the blank pitch was determined over 18 different slides). The microslides were kept in a magnetic field (0.8 T) for 4 h to form and align the fingerprint lines [3b]. A Zeiss microscope (Standard 16) was used for determining the pitch.

Monitoring In Situ Growth and Dissolution of Molecular Crystals: Towards Determination of the Growth Units**

David Gidalevitz, Robert Feidenhans'l,* Sophie Matlis, Detlef-M. Smilgies, Morten J. Christensen, and Leslie Leiserowitz*

Molecular crystal growth in solution takes place at the crystal–fluid interface. The local structure at this boundary plays a primary role in determining the composition, growth, and habit of the crystal. Until recently experimental in situ studies of crystal growth made use mainly of optical methods, which provided information not only on the micron level[1] but also on monomolecular steps.[2, 3] With the advent of atomic force microscopy (AFM)[4] it became possible to monitor the crystal–liquid interface on the subnanometer scale.[5–8]

Over the last decade grazing incidence X-ray diffraction (GID) has proven to be a powerful tool for obtaining information on surfaces at the atomic and molecular levels.[9, 10] The technique was developed for studies of metal and semiconductor surfaces under ultrahigh vacuum[10] but, due to the penetrating power of X-rays, can also be used for interfaces such as Langmuir layers on water[11, 12] or electrolyte systems.[13, 14] In this study we applied GID to probe the surfaces of organic, molecular crystals and their growth and dissolution interfaces.

As model systems we chose crystals of β-alanine ($^+H_3NCH_2CH_2CO_2^-$) and α-glycine ($^+H_3NCH_2CO_2^-$). Both are composed of zwitterionic molecules that are interlinked through strong N–H···O hydrogen bonds to form centrosymmetric bilayers (Figure 1). We thus anticipated that the surface layers would be sufficiently smooth and well-ordered to detect a GID signal. We addressed principal questions of crystal

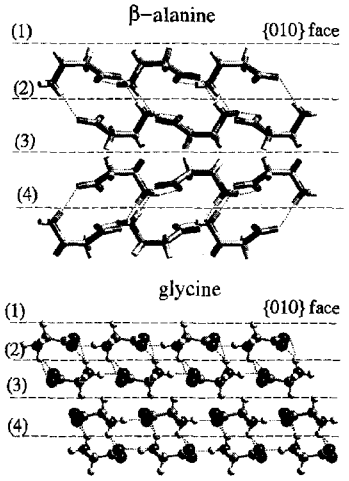

Figure 1. Packing arrangement of β-alanine (top) and α-glycine crystals (bottom) viewed along the c and a^* axes, respectively. The adjacent layers 1 and 2 as well as 3 and 4 are related to each other by a center of inversion and are bound though strong hydrogen bonds; layers 1 and 3 as well as 2 and 4 are related by a twofold screw axis that is parallel to b.

growth, namely, the molecular arrangement of the growing crystal surface and the structure of the building units that dock onto them from solution. It is possible to glean information on the number of molecules making up the building units by comparison of the theoretical growth under vacuum and the experimental morphology.[15–18] However, for crystal grown from solution it is generally difficult to assess the contribution of solvent in determining the morphology. On comparison of the "theoretical" morphology of α-glycine and that obtained by sublimation, Berkovitch-Yellin proposed that the glycine molecules form cyclic dimers in the gas phase.[19] The absence of large {010} faces for α-glycine obtained from aqueous solution was interpreted in terms of docking of cyclic dimers.[20] Myerson et al.[21–23] employed Gouy interferometry measurements of diffusion coefficients and evaluation of concentration gradients in a column of supersaturated glycine solution to obtain an average size of the glycine cluster of about 1.8 molecules. These results are in agreement with the characterization of the α-glycine growth interface from AFM and phase-measurement interferometric microscopy by Carter et al.[24] They obtained a lower limit of 1 nm for the step size on the (010) glycine face during growth from a saturated aqueous solution, which is close to the thickness of the hydrogen-bonded bilayer. However, the assignment of the (010) glycine surface structure is ambiguous when only AFM measurements are considered, since the possible surface layer structures 1 and 2, or 3 and 4 (Figure 1, bottom) cannot be distinguished.

We show here that GID and AFM may be combined to advantage to determine the structure with near atomic resolution of the crystal–fluid interface of β-alanine and α-glycine during growth and dissolution. This method provides information on the crystal growth units.

β-Alanine, which crystallizes in the orthorhombic space group $Pbca$ ($a = 9.9$, $b = 13.8$, $c = 6.1$ Å, $Z = 8$),[25, 26] was grown from an aqueous solution to about $8 \times 10 \times 6$ mm^3; it exposes two dominant {010} faces and eight {111} side faces. The crystal is composed of hydrogen-bonded bilayers that are juxtaposed along the b axis by van der Waals C–H···H–C contacts (Figure 1, top). The crystal can be cleaved parallel to the plane of the bilayer. In principle, the cleaved face may contain the equivalent layers 1 or 3 (in which CH_2 groups are exposed), layers 2 or 4 (in which CO_2^- and NH_3^+ groups are exposed), or a combination of these two.

The surface of a freshly cleaved (010) face of β-alanine was extremely smooth. Indeed, AFM measurements[27] on such a surface yielded molecular resolution with unit-cell dimensions $a = 9.2 \pm 0.9$, $c = 6.1 \pm 0.5$ Å (Figure 2a), which are close to the bulk values. In situ dissolution of a freshly cleaved (010) surface of β-alanine in 1-hexanol (Figure 2c)[28] and 1-pentanol was monitored by AFM at room temperature.

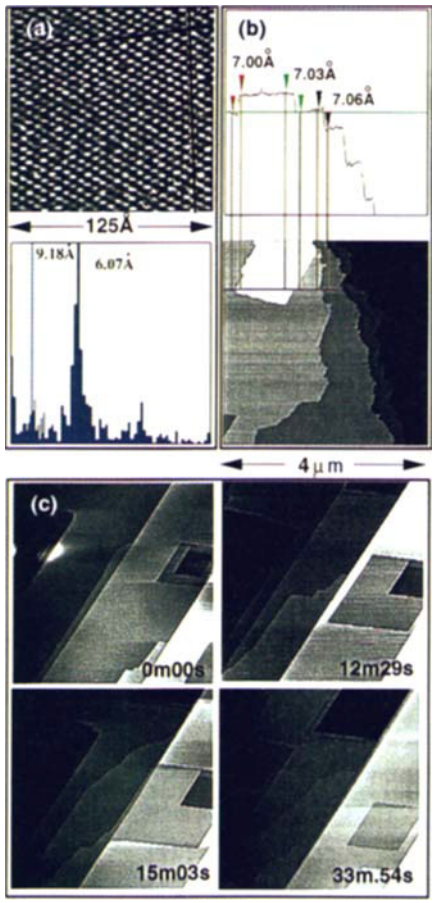

Figure 2. AFM images of the {010} face of β-alanine. a) Molecular resolution on the freshly cleaved surface (top) and the results of a Fourier transformation along the lines shown (bottom). The lattice periods of 9.18 Å and 6.07 Å are very similar to the a and c unit-cell axes of β-alanine obtained from X-ray diffraction measurements. b) Height profile of a β-alanine crystal surface during dissolution in 1-hexanol. c) Snapshots following dissolution of a freshly cleaved {010} face in 1-hexanol. The time elapsed after addition to the solution is given in the bottom right corners.

α-Glycine crystallizes in the monoclinic space group $P2_1/n$ ($a = 5.1$, $b = 11.8$, $c = 5.5$ Å, $\beta = 112°$, $Z = 4$).[29] Crystals grown from a pure, aqueous solution exhibit bipyramidal morphology expressing {110}, {011}, and {010} faces. As in the case of β-alanine, α-glycine can be easily cleaved parallel to the hydrogen-bonded bilayer to yield {010} faces with two possible surface terminations. A freshly cleaved (010) face of glycine was molecularly smooth (Figure 3b). Dissolution of a freshly cleaved (010) face of glycine in 1-propanol (Figure 3c) and growth in a saturated solution in ethanol/water (3/1, Figure 4), was monitored by AFM at room temperature.

A series of snapshots of the same region of the surface was taken during these AFM measurements. Both dissolution and growth proceeded as step flow with an average minimal step height of 7 ± 0.5 Å for β-alanine (Figure 2b) and 5.7 ± 0.5 Å for α-glycine (Figure 3c). We may conclude from the β-alanine and α-glycine crystal structures that this corresponds to two molecular layers.

A cell was constructed to measure synchrotron X-rays scattering from the crystal–solution interface (Figure 5). The measurements were performed at the BW2 and W1 wiggler beamlines at the Hamburg Synchrotron Radiation Laboratory (HASYLAB, Germany).[30] The sharp termination of a crystal at its surface gives rise to rods of diffuse scattering in the direction of the surface normal; they pass through the bulk Bragg

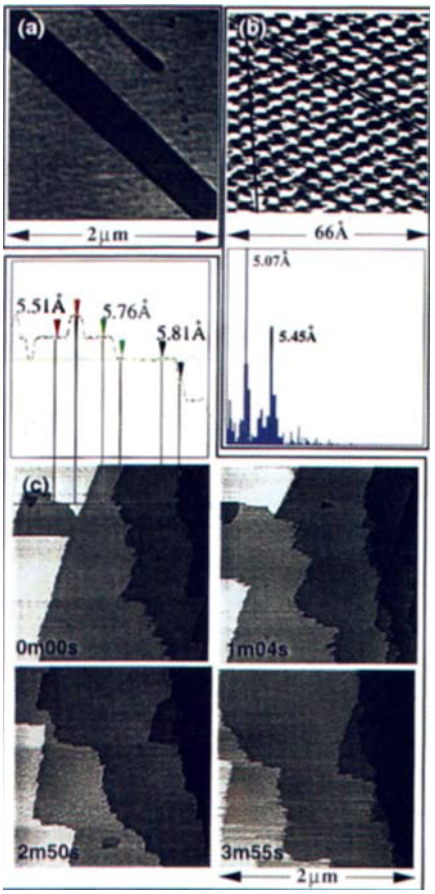

Figure 3. AFM images of the {010} face of α-glycine. a) Freshly cleaved surface on a micron scale. b) Molecular resolution on the freshly cleaved surface (top) and the results of a Fourier transformation along the lines shown (bottom). The lattice periods of 5.07 Å and 5.45 Å are very similar to the *a* and *c* unit-cell dimensions of α-glycine obtained from X-ray diffraction measurements. c) Snapshots following dissolution of the freshly cleaved {010} face of α-glycine in 1-propanol. The height profile for the top, left picture is indicated.

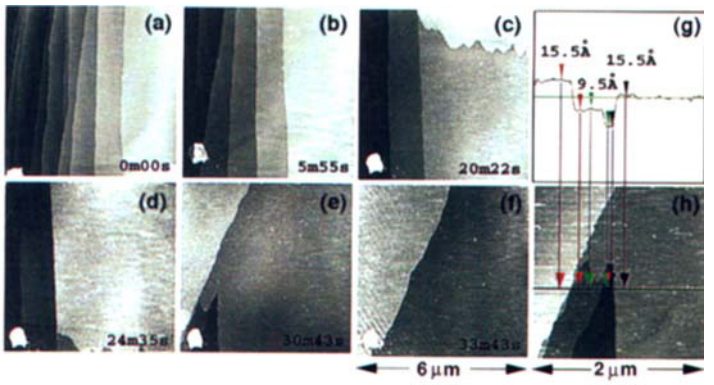

Fignre 4. AFM snapshots of the same region on the {010} face of α-glycine during its growth from a saturated solution of ethanol/water (3/1), and the molecular resolution (g) of one such surface (h). Snapshot (h) lies between (d) and (e).

reflections. These rods are called crystal truncation rods (CTR),[31] and their shape between the Bragg points contains information about the molecular structure at the surface, such as changes in interlayers distances, atomic rearrangements, and surface roughness.[10] In particular, these rods are sensitive to the changes in surface termination during growth.

Cleaved (010) crystal surfaces of β-alanine and α-glycine were prepared in the same way as for the AFM measurements. Each specimen crystal was glued to the top surface of a copper block in the cell and aligned so that the exposed {010} surface was parallel to the block surface. For crystal growth or dissolution experiments a drop of solution was spread onto the cleaved surface. A stretched, polypropylene film was then tightly pressed onto the solution to keep the liquid layer as thin as possible and to prevent its evaporation. Pure ethanol was used for dissolution of the β-alanine (010) face, and a saturated solution in ethanol/water (3/1) for growth of the glycine (010) surface.

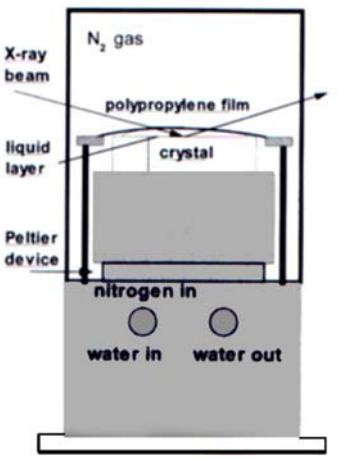

Figure 5. Schematic view of the cell containing the specimen crystal, which is placed on a copper block in contact with a Peltier thermoelectric device to control crystal temperature. The crystal surface is exposed to a thin, fluid layer that is then covered with a polypropylene film (6 μm). N_2 gas is pumped through the cell to prevent water precipitation at low temperatures.

X-ray structure factor calculations[9] yielding CTRs from molecularly smooth {010} glycine and β-alanine faces in which the surface atoms were placed at the terminated bulk positions reveal dramatic differences depending on surface termination (Figure 1). Therefore, GID measurements are a sensitive tool for probing surface composition during in situ crystal growth or dissolution.

Measurements of the (0*k*4) CTR were made on a dry, freshly cleaved {010} face of β-alanine at 0 °C (Figure 6a). The data points (open squares) lie close to the calculated curve (solid line) for a crystal terminated at layers 1 and 3 (Figure 1, top). The calculated CTR curve (dashed, red line) for a crystal terminated at layers 2 and 4 is very different. This proves that the cleavage occurs between the hydrogen-bonded bilayers. Measurements for all samples were performed in high-symmetry directions along the surface to search for higher order reconstructions of the surface, but none were found.

Dissolution of the same {010} face of β-alanine was monitored by repeating the GID measurements after spreading a drop of pure ethanol on the surface. From the results of our AFM measurements of glycine and β-alanine dissolution in different solvents, we estimated that the crystal lost approximately 1000 molecular layers during the experiment. The measured CTR profile (Figure 6a; filled, red rhombs) again corresponded to a β-alanine surface with exposed layers 1 or 3.[32] The width of rocking curves along the CTR did not change as a function of time, which means that the crystal preserved its quality.

The (0*k*1) CTR of a pure, cleaved (010) face of α-glycine was measured at room temperature (Figure 6b). The CTR profile (open squares) coincided with the model curve (solid line) for a crystal terminated at layers 1 or 3 (Figure 1, bottom). Again, the calculated curve (dashed, red line) for a crystal terminated at layers 2 or 4 is very different. A drop of a saturated solution in ethanol/water was spread on the surface, and the diffraction measurements were repeated (Figure 6b). From the information on growth rate derived from independent AFM measurements, we estimate that the {010} face grew by approximately 100–200 molecular layers during the two hours of X-ray data collection. Once again the observed data (filled, red rhombs) are very similar to that measured on the dry, cleaved crystal (open squares). A minor decrease in the width of the

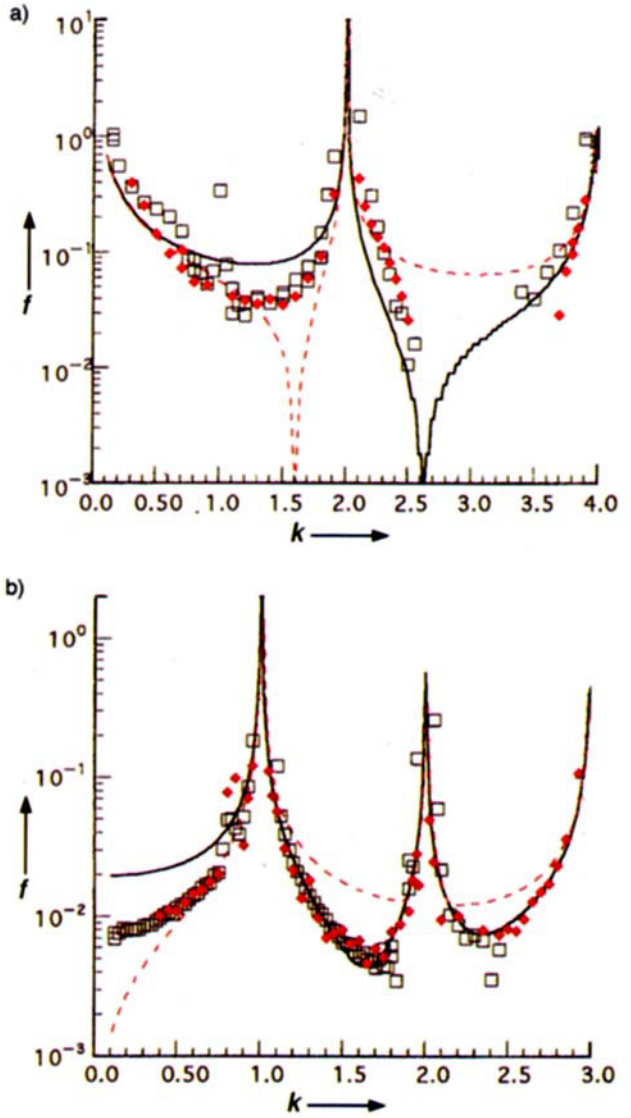

Figure 6. a) The (0*k*4) CTRs from a β-alanine {010} surface during dissolution in pure ethanol. b) The (0*k*1) CTRs from an α-glycine {010} surface during growth from a saturated solution of ethanol/water (3/1). Open squares: data points measured on the pure dry {010} cleaved surface; filled, red rhombs: data points measured in situ during the dissolution of β-alanine and growth of α-glycine; solid line: calculated model for the crystal terminated at layers 1 and 3 (Figure 1); dashed, red line: calculated model for the crystal terminated at layers 2 and 4 (see Figure 1). *k* is the (continuous) Miller index along the CTR; *f* is the structure factor.

rocking scans of the CTR was observed after growth, indicating that the surface quality was marginally improved during growth. This is consistent with AFM observations (Figure 4) that clearly showed improved smoothness of the glycine crystal surface during growth.

GID experiments on dissolution of the (010) face of β-alanine and growth of the (010) face of α-glycine, which showed that the surface termination of the crystals did not change during X-ray data collection, are consistent with the AFM measurements (Figures 2–4). Moreover, the termination was the same as after cleavage of the crystals. In other words, within the time frame of the dissolution and growth experiments, the crystal {010} surfaces did not show surface truncations different from the layers 1 or 3, in which CH_2 groups are exposed. Otherwise the observed data points would not all lie on a line consistent with the model CTR curve for layers 1 and 3, but somewhere between this curve and that for layers 2 and 4.

The results described here are compatible with a model in which molecules of β-alanine and glycine effectively dock or leave the crystal surface as cyclic, hydrogen-bonded dimers. It is possible that this is preferred over docking as monomers, since the former is less solvated. This growth model is in agreement with previous arguments and experiments and also suggests that precipitation of the α- and γ-polymorphs of glycine may depend, to some extent, on the behavior of glycine in solution. Thus, crystallization of the α-form from an aqueous solution would be favored by the presence of cyclic dimers, whereas the γ-form,[33] which does not contain cyclic dimers, crystallizes from acid or base solutions that disrupt cyclic-dimer formation of glycine.

[27] Conventional AFM imaging was performed with a Nanoscope III instrument (Digital Instruments). The sample was scanned in the contact mode with a commercial Si_3N_4 tip attached to a cantilever with a spring constant of 0.38 $N\,m^{-1}$. Images were acquired at room temperature (in air and in solution) in a fluid cell with a capacity of 0.1 cm^3 (zero flow rate). Large-scale images were taken under minimum force as allowed by feed-back sensitivity ($\approx$10 nN in air and $\approx$1 nN in solution).
[28] AFM measurements were performed during dissolution of the {010} faces of β-alanine (1-pentanol and 1-hexanol) and α-glycine (ethanol, 1-propanol, 1-butanol, and 1-pentanol). Since the results were very similar for these solvents we present here dissolution of β-alanine in 1-hexanol and growth of α-glycine in 1-propanol.

Surface X-ray Scattering Study of Stereospecific Adsorption of Additives onto the Surface of a Molecular Crystal Grown from Solution**

David Gidalevitz, Robert Feidenhans'l, and Leslie Leiserowitz*

Nucleation, growth, and habit of solution-grown molecular crystals are strongly affected by the nature of the solvent[1–3] and the presence of molecular additives.[4–6] This is primarily a result of the interaction between the "foreign" molecules and the crystal faces. The effect of such interactions on the structure of the crystal was deduced from knowledge of the crystal structure and macroscopic properties such as morphology and symmetry of the resulting crystal,[6] but it has not been possible to observe the surface-bound "foreign" molecules directly.[7]

Recently various experimental methods have been introduced for examining the surfaces of three-dimensional molecular crystals at the subnanometer scale and thereby probing the structures of foreign molecules adsorbed on such surfaces. For example, atomic force microscopy was used to characterize the structure of an organic diacid on a layered clay surface.[9] X-ray diffraction is a very powerful technique for studying surfaces and interfaces on the atomic and molecular level[10, 11] and does not require handling of the samples under vacuum. So far the technique has mainly been applied to surfaces of metals and semiconductors, but it has recently also been used for characterizing mineral surfaces.[12] One restriction when applying the diffraction techniques for the study of adsorbed foreign molecules is that the surface has to be very smooth, and the adsorbing molecules have to be ordered with respect to the host crystal.

α-Glycine, which crystallizes in the monoclinic space group $P2_1/n$,[13] was chosen as a model substrate system. The structure is composed of bilayers parallel to the *ac* plane (Figure 1, top) in which the molecules are interlinked through strong hydrogen bonds. Bipyramidal crystals are obtained from an aqueous solution of pure glycine. Experiments have shown[4–6] that enantiomerically pure α-amino acid additives are enantioselectively adsorbed onto the {010} faces[14] of glycine and affect their growth and morphology. Additives of (*R*)-α-amino acid inhibit growth along the $+b$ direction, and the resulting pyramidal crystal has a large (010) face; (*S*)-α-amino acids inhibit growth along the $-b$ direction to yield enantiomorphous pyramids with $(0\bar{1}0)$ bases. This observation was explained as follows: An (*R*) additive can substitute a glycine molecule only at sites 1 or 3 of the (010) face (Figure 1, top) causing growth inhibition along $+b$, and, by symmetry, (*S*) additives can occupy sites 2 and 4 on the $(0\bar{1}0)$ face inhibiting growth along $-b$.

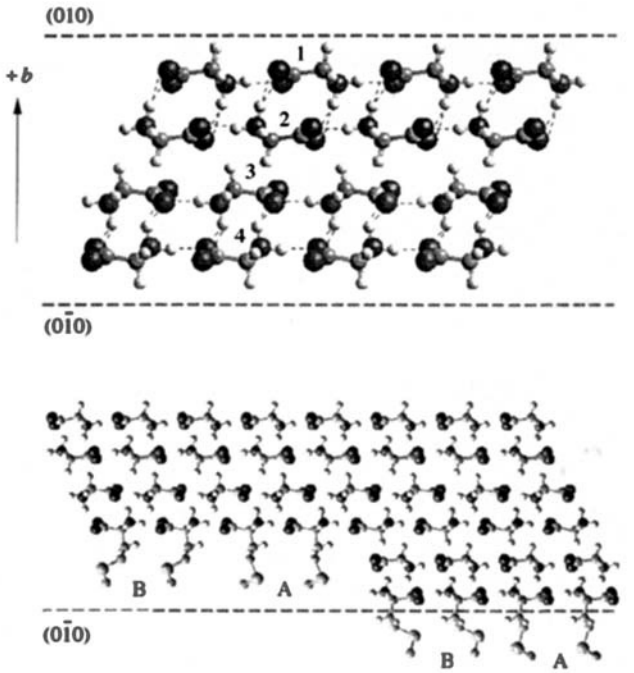

Figure 1. Top: packing arrangement of the α-glycine crystals viewed along a^*. The symmetry-related layers 1–4 as well as the (010) and $(0\bar{1}0)$ faces are indicated. The N–H···O hydrogen bonds within and between layers are shown as dashed lines. Layers 1 and 2 as well as 3 and 4 are interlinked by three-center hydrogen bonds (N–H···O,O). The top bilayer shows one type of hydrogen bond, the bottom bilayer the other. Bottom: proposed packing arrangement of the $(0\bar{1}0)$ glycine surface regrown in the presence of (*S*)-methionine (9 wt%). The ordered (*S*)-methionine molecules are bound through a pseudo center of inversion to glycine. The conformers A and B each form separate domains on the $(0\bar{1}0)$ glycine surface.

To facilitate detection of layer of adsorbed α-amino acid additive by surface X-ray diffraction and to distinguish between adsorption of a chiral-resolved additive on the opposite (010) and $(0\bar{1}0)$ faces, (*S*)-methionine ($CH_3SCH_2CH_2CH(NH_3^+)$-CO_2^-) was used as an additive. It should inhibit growth only at the $(0\bar{1}0)$ face, and the sulfur atoms enhance the contrast in the X-ray images.

A crystal of α-glycine was grown to approximately $8 \times 10 \times 6$ mm^3, dried, and cleaved along the central *ac* plane to yield two halves with large (010) and $(0\bar{1}0)$ faces. The two halves, each about 3 mm thick, were placed in a vessel with their cleaved faces exposed to the same saturated, aqueous, solution of glycine with (*S*)-methionine (9 wt%) as additive. The two crystals were grown further for approximately four hours, removed, and dried with filter paper. They now revealed distinct differences. The half with the large $(0\bar{1}0)$ face maintained its original thickness, whereas the other had grown by about 3 mm at the exposed (010) face.

Grazing incidence X-ray scattering experiments (GID) were performed on a six-circle, surface X-ray diffractometer on the wiggler BW2 beamline at the Hamburg Synchrotron Radiation Laboratory (HASYLAB) of the German Electron Synchrotron (DESY).[15] The measurements were aimed at determining the distribution and structure of the methionine molecules at the (010) and (0$\bar{1}$0) faces.

Termination of a single crystal surface induces diffuse rods of scattering in addition to the Bragg peaks.[16] These are called crystal truncation rods (CTR), are perpendicular to the surface, and run through the Bragg reflections. Two different types of CTRs were measured: specular and nonspecular. To give a contribution to the specular CTR, the surface layers have only to be ordered parallel to the surface; no in-plane crystalline order is required. In contrast the nonspecular CTRs have an in-plane component of the momentum transfer. The shape of the rods are dependent on the termination of the surface and the registry of the adsorbed molecules with respect to the underlying bulk crystal.[10]

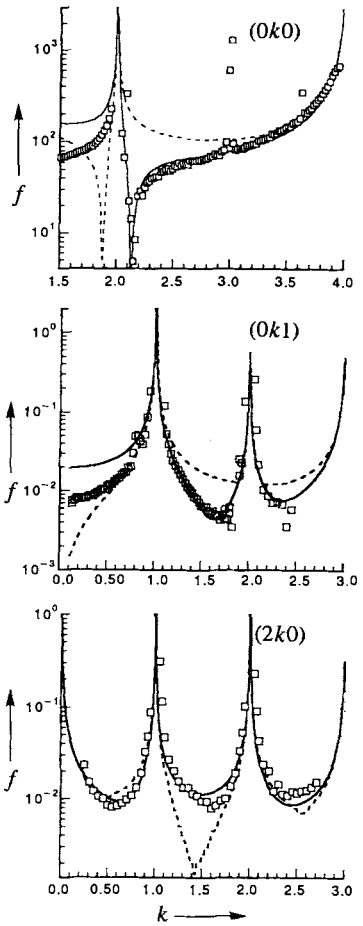

Figure 2. Measured (squares) and calculated (0k0), (0k1), and (2k0) CTRs (solid and dashed lines) of the pure, cleaved (010) α-glycine surface. Solid lines correspond to a surface terminated by CH groups (layers 1 and 3 in Figure 1), dashed lines to a surface composed of exposed CO_2^- and NH_3^+ groups (layers 2 and 4). The solid lines clearly give the better fit to the observed data. The Bragg peak at $k = 3$, which corresponds to a symmetry-forbidden (030) reflection, probably arises from multiple diffraction. k is the (continuous) Miller index along the CTR; f is the structure factor.

The specular (0k0) and nonspecular (0k1) and (2k0) CTRs (Figure 2) were measured at room temperature on the (010) face of the freshly cleaved glycine crystal and the (010) and (0$\bar{1}$0) faces of two glycine crystals that had been regrown in a saturated glycine solution with (*S*)-methionine as additive (Figure 3). The structures of the pure (010) and (0$\bar{1}$0) cleaved faces of α-glycine are related by point mirror symmetry and, therefore, must yield identical surface X-ray diffraction patterns. A cleaved {010} surface of α-glycine can in principle be composed of molecular layers with C–H bonds (for example layer 1 in Figure 1, top), carboxylate and amino groups (for example layer 2 in Figure 1, top), or a combination of the two exposed at the surface. The first possibility is preferred since energy considerations clearly favor cleavage across an interface in which van der Waals contacts would be broken rather than N–H···O hydrogen bonds.

This model was verified by X-ray structure factor calculations (Figure 2). The analysis showed that a reasonable fit to the CTRs is obtained only if the pure glycine (010) face, and the (0$\bar{1}$0) face of the other half by virtue of symmetry is composed of the molecular layer with exposed C–H groups. Introduction of surface roughness in the model structure made the agreement between the observed and calculated specular rods worse. This result was in keeping with the molecularly flat nature of the freshly cleaved {010} faces of α-glycine over micrometer distances determined from atomic force microscopy measurements.[17] This flatness persisted even during growth of α-glycine from solutions of glycine in water/ethanol.

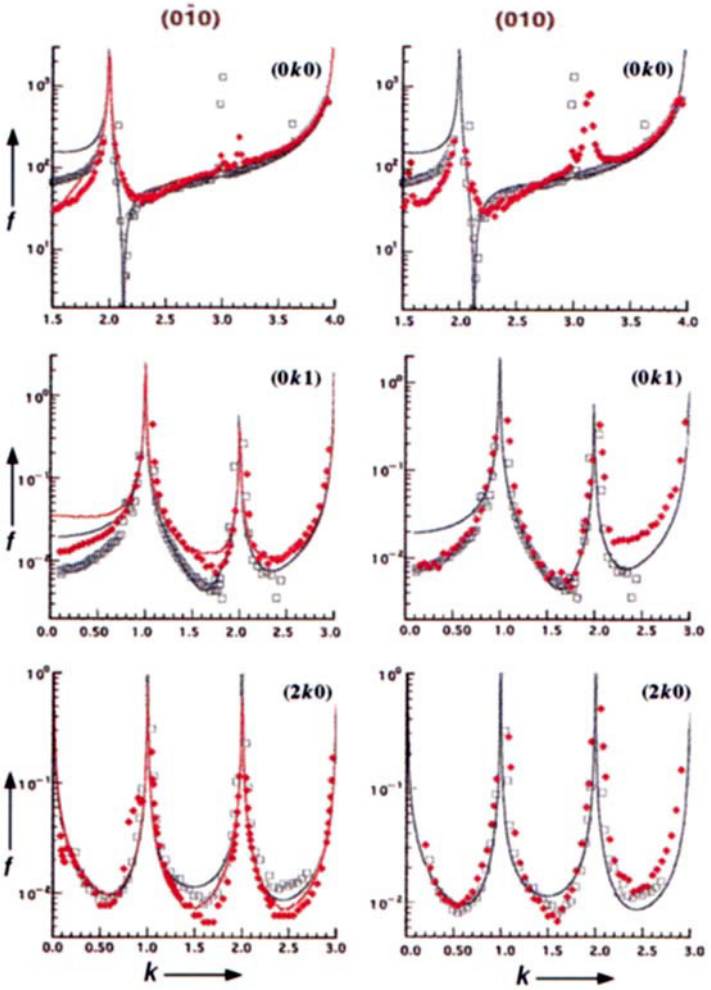

Figure 3. The (0k0), (0k1), and (2k0) CTRs of the (0$\bar{1}$0) (left) and (010) faces (right) of a α-glycine crystal after growth in an aqueous solution containing (*S*)-methionine as additive. Squares measured data, solid line calculated curve for the pure, cleaved surface (see Figure 2); red rhombs measured data, red line calculated curve for the surface regrown in the presence of (*S*)-methionine (9 wt%).

The specular (0k0) CTRs from (010) and (0$\bar{1}$0) surfaces that had been exposed to the solution (red rhombs of Figure 3, top) are significantly different from those obtained from the pure, cleaved {010} surface (squares of Figure 3, top and Figure 2, top), but there are similarities. The deep dip in the (0k0) CTR at $k = 2.13$ for the cleaved surface is due to a cancellation effect in the structure factor of the bulk unit cell and, hence, is a strong signature of well-ordered surface layers. Any deviation means that the surface is terminated differently or covered with foreign molecules that are scattering coherently at a certain height with respect to the bulk glycine crystal. These results show that the (010) and (0$\bar{1}$0) surfaces that have been exposed to glycine solutions with methionine contain adsorbed material with similar electron density profiles that are perpendicular to the crystal surfaces.[18]

The distinct differences between the intensity patterns of nonspecular $(0k1)$ and $(2k0)$ CTRs obtained from the $(0\bar{1}0)$ affected face and the pure $\{010\}$ face (red rhombs and open squares of Figure 3, middle left and bottom left) indicate that the adsorbed molecules on the $(0\bar{1}0)$ face are also ordered in the surface plane. The experiments were repeated a number of times and, apart from a few data points in the $(0k1)$ CTR at $k>2$, always reproduced these differences. However, there is little or no difference between the measured nonspecular CTR patterns obtained from the pure and affected (010) faces (Figure 3, middle right and bottom right). We therefore deduce that the adsorbed material on the (010) face is in a disordered arrangement so that the top layer is ordered normal to the surface (on the $(0\bar{1}0)$ face) but disordered parallel to the surface. The other possibility is that the adsorbed material is ordered in a lattice that is incommensurate with that of α-glycine. Unfortunately, at the time of the experiment, such a possibility was not realized and not looked for (see below).

We could not perform an ab initio structure determination with the present data, but did test if possible models are in accordance with the data. We obtained reasonable agreement with the measured specular CTR from the $(0\bar{1}0)$ face regrown in the presence of (*S*)-methionine by assuming the following model: The (*S*)-methionine molecules are bound to the underlying glycine layer through N–H ··· O hydrogen bonds over a pseudo center of inversion (Figure 1, bottom) forming a bilayer akin to that observed in bulk glycine. The best agreement (Figure 3, top left, red line) yielded a molecular layer of (*S*)-methionine and glycine with a relative molecular occupancy of 0.8:0.2.[19] Furthermore, the analysis suggested that the (*S*)-methionine molecules adopt two molecular conformations [20] (see A and B, Figure 1, bottom)

We may safely assume molecular flatness of the (010) and $(0\bar{1}0)$ α-glycine faces after growth in the presence of (*S*)-methionine in light of the match between the observed $(0k0)$ CTRs within the range $2.3 \leq k \leq 3.9$ before and after growth (see squares and red rhombs of Figure 3, top). Moreover, introduction of surface roughness in the model structure made the fit between the calculated and observed specular CTRs worse.

The $(0k1)$ and $(2k0)$ CTRs on the $(0\bar{1}0)$ glycine face grown further in the presence of (*S*)-methionine (Figure 3, middle and bottom left) were fitted with the same structural model as the $(0k0)$ CTR, but the relative occupancy of methionine to glycine in the surface layer was found to be 0.5:0.5.[23] This yields the calculated curves shown red. Scattering along off-specular CTRs requires atomic ordering along the surface plane. We therefore explain the significant difference between the ratios 0.5:0.5 and 0.8:0.2 as less ordering of the $CH_2CH_2SCH_3$ moieties of the methionine molecules parallel to the surface plane. The glycine crystal structure (Figure 1, top) embodies twofold screw symmetry along the *b* axis. Therefore, the (*S*)-methionine molecules can be bound on glycine layers 2 and 4, which are related by the twofold screw axis and separated along this axis by *b*/2 (Figure 1, bottom).

As mentioned earlier the $(0k0)$ specular CTRs from the $(0\bar{1}0)$ and (010) surfaces exposed to a glycine solution with (*S*)-methionine are very similar; therefore, the electron density profile perpendicular to these two faces must also be alike. We may explain the $(0k0)$ specular CTR from the (010) surface if we assume that the (*S*)-methionine/glycine bilayer formed at the $(0\bar{1}0)$ face (Figure 1, bottom) can be fitted onto the (010) face. Intermolecular contacts between the surface bilayer and the underlying crystal at the (010) face may be achieved by pseudo-twofold screw symmetry about the diagonal axis $(a+c)$ to yield an imperfect lattice match (Figure 4A) and, thus, an incommensurate interbilayer arrangement (Figure 4B)[24].

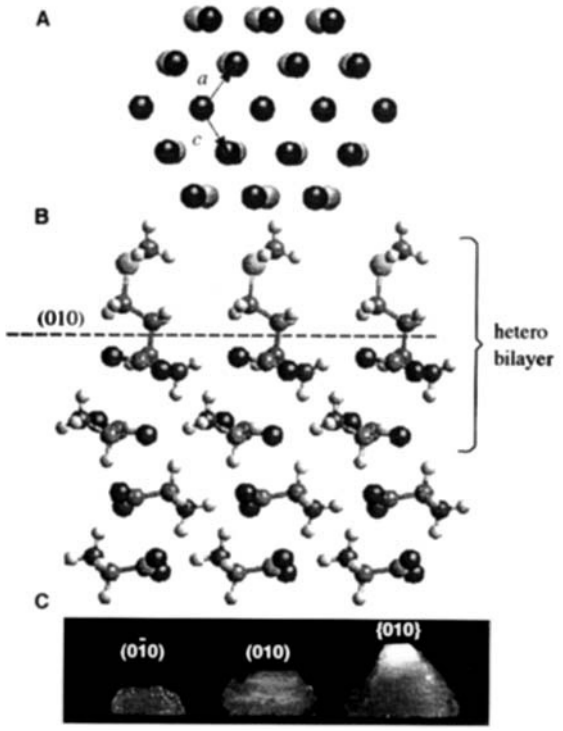

Figure 4. A) Superposition of the *ac* lattice of α-glycine upon itself after rotation by 180° about the $(a+c)$ axis. B) Proposed packing arrangement of the glycine/methionine bilayer at the (010) face. This bilayer is related to the underlying glycine bilayer by pseudo-twofold rotation about the $(a+c)$ axis. C) Photograph of cleaved crystals of glycine whose {010} cleavage faces were exposed to different supersaturated solutions of glycine. Before the growth experiment all three glycine plates were approximately the same size. Two plates exposing $(0\bar{1}0)$ (left) and (010) faces (center) were regrown in a supersaturated solution of glycine with (*S*)-methionine (9 wt%). The third glycine plate (right) was regrown in a supersaturated solution of pure glycine. Growth of the crystal with the $(0\bar{1}0)$ face exposed to a solution of glycine with (*S*)-methionine (left) was almost completely inhibited. Growth of the crystal that exposed the (010) face to a solution of glycine with (*S*)-methionine was also inhibited but to a lesser extent. Crystal growth in a pure solution of glycine was uninhibited.

We explain the stability of the (*S*)-methionine/glycine heterobilayer on both the (010) and $(0\bar{1}0)$ faces of α-glycine, which has the very high relative concentration of 0.8 (*S*)-methionine molecules, in terms of stronger interactions between methionine than betweeen glycine molecules. The model structure of the heterobilayer bound to the (010) face of glycine indicates that the (*S*)-methionine layer should, in principle, inhibit interlayer growth. We therefore performed experiments in which cleaved crystals of glycine were grown under identical conditions in supersaturated, aqueous solutions of pure glycine and glycine with (*S*)-methionine (9 wt%) as additive. Figure 4C shows that fastest growth along the *b* axis occurs for the cleaved crystals in pure glycine solution, whereas growth in a solution of glycine plus (*S*)-methionine is distinctly slower on the cleaved (010) plate and almost completely inhibited (along $-b$) for the $(0\bar{1}0)$ face.[27]

The formation of an (*S*)-methionine/glycine heterobilayer on the (010) face of α-glycine (Figure 4B), the crystal twinning of α-glycine upon growth in the presence of (S)-leucine,[24] and the evidence in favor of the cyclic, hydrogen-bonded dimer of glycine as the growth unit on the $\{010\}$ face[17] can be more easily understood by making the following assumption: The α-amino acid solute molecules tend to aggregate into cyclic, hydrogen-bonded dimers in solution and dock onto the growing crystal surface as dimers.

We have demonstrated here that the surface of a molecular crystal is sufficiently smooth that its surface structure can be elucidated by GID. We have also provided strong evidence in favor of an ordered adsorption layer of foreign molecules.

[7] For "tailor-made" additives the stereospecific adsorption onto particular crystal faces was also established by methods that showed that the additives occupied crystallographically appropriate sites within the crystal. This was only possible by stereospecific adsorption at molecular sites on the growing crystal faces. These methods included optical birefringence [8], second harmonic generation, solid state-photochemistry, and X-ray and neutron diffraction of the bulk crystals [5·6].

[14] The symbol {*hkl*} represents all symmetry-related faces, whereas (*hkl*) refers only to faces pertaining to *h*, *k*, and *l*. Therefore {010} represents the faces (010) and $(0\bar{1}0)$.
[15] An X-ray wavelength of 1.31 Å was used. For the nonspecular CTR measurements the surface was vertical and aligned with a laser such that the surface normal was parallel with the ω axis of the diffractometer, which ensures a constant angle of incidence throughout the experiments. The angle of incidence was set at 0.2°. The CTR scans were measured by a rocking scan around the surface normal at each momentum transfer in the direction perpendicular to the surface in order to measure the integrated intensity. For the specular reflection the sample was remounted with the surface nearly horizontal in order to keep a vertical scattering plane. The scan along the specular rod was performed along the ridge of scattering. The background was measured along a slightly off-specular direction by off-setting the ω angle to lower the radiation damage, which is much more severe in the specular than the nonspecular case due to the larger intersection of the crystal with the beam. The intensities were corrected for Lorentzian and polarization factors and variations in active area in order to achieve a structure factor intensity for both specular and nonspecular CTRs.

[18] The peak at $k = 3.15$ in the CTRs for the (010) and $(0\bar{1}0)$ surfaces (red rhombs of Figure 3, top) corresponds to the (004) reflection of (*S*)-methionine. The platelike crystals of methionine were deposited onto both the (010) and $(0\bar{1}0)$ faces of α-glycine but were not attached stereospecifically. In a separate experiment on growth of α-glycine in the presence of (*S*)-methionine under similar experimental conditions, we observed very small ($\approx$0.1 mm) methionine plates randomly distributed on both the glycine surface and the bottom of the vessel. These plates could be easily removed and, therefore, were not structurally attached to glycine. These methionine crystallites do not contribute to the nonspecular diffraction patterns.
[19] When the relative occupancies were varied by more than 0.1 from the best value, the fit became significantly worse.
[20] To find possible conformations of the (*S*)-methionine molecules bound to the $(0\bar{1}0)$ glycine surface, energy minimization calculations were performed [21]. The calculated energy of a layer of (*S*)-methionine molecules, bound through a pseudo center of inversion to the underlying glycine layer, as a function of $CH-CH_2-CH_2-S$ and $CH_2-CH_2-S-CH_3$ torsion angles yielded six possible methionine conformations. We tested all of them in different combinations with varying occupancies for X-ray structure factors calculations. The best fit to the observed data was obtained for the molecular conformations A (*trans–gauche*) and B (*gauche–gauche*), which are similar to those in the three-dimensional crystal structures of (*S*)- and (*R,S*)-methionine [22], with occupancies of 0.5 and 0.3, respectively.
[21] Lattice energy and all molecular packing arrangements were calculated with Cerius², a molecular modeling software package for materials research, BIOSYM/Molecular Simulations, Cambridge, UK.
[22] K. Torii, Y. Iitaka, *Acta Crystallogr. B* **1973**, *29*, 2799.
[23] The A:*B* occupancy ratio for methionine was kept at 0.5:0.3 [20]. Furthermore, the two conformers appear to pack in separate domains. Models with A and B within the same crystal domain (coherent addition) yielded poorer agreement to the observed data than the model in which they pack in separate domains (incoherent addition).
[24] Pseudo-twofold symmetry interlinking the hydrogen-bonded bilayers in an incommensurate arrangement has also been invoked to explain packing disorder in racemic valine [25] and the formation of twinned crystals of α-glycine grown in the presence of (*S*)-leucine [26], when the glycine concentration was greater than 8 mg mL^{-1}. In the latter system the two bilayers lie in the central plane of the crystal and are each composed of heterodimers of glycine and (*S*)-leucine in an arrangement similar to that of the glycine/(*S*)-methionine heterobilayer (Figure 4B).

[27] GID results on the (010) face do not contradict the experimental observations of stereospecific inhibition of the {010} faces of glycine with enantiomerically pure α-amino acids as additives. Our experiments were performed with cleaved crystals of glycine and concentrations of α-amino acid additive as high as 9 wt%.

Design of Antisense (Complementary) Peptides as Selective Inhibitors of Cytokine Interleukin-1**

Joseph W. Davids, Ali El-Bakri, Jonathan Heal, Gary Christie, Gareth W. Roberts, John G. Raynes, and Andrew D. Miller*

Double-helical DNA comprises two complementary oligonucleotide chains. Traditionally, one of these chains, the sense strand, defines the genetic code, whilst the complementary chain, the antisense strand, provides the means of propagating that code. However, the relationship between sense and antisense strands of DNA now appears to be more complex. In 1984 Blalock and Smith observed that antisense strand DNA was able to code for peptides, known as antisense peptides, which are the hydropathic complement of those sense peptides coded for in the normal way by sense strand DNA.[1] Subsequently, evidence has been accumulating to suggest that antisense and corresponding sense peptides may interact specifically, with important biological consequences.[2] The physical basis for these

[**] Antisense Peptide Chemistry, Part 1. This work was supported by the Mental Health Foundation and the Medical Research Council. We thank Immunex for providing the soluble human IL-1 receptor type II, and Professor D. Boraschi for sending us the BhrD2 antibody.

interactions is not yet completely understood although it appears to be closely related to the mutual hydropathic complementarity shown between an antisense peptide and its corresponding sense peptide.[3–5] Here we report a direct application of this specific interaction between antisense and sense peptide in the design of inhibitors of the well-known, biologically important cytokines interleukin-1α (IL-1α) and interleukin-1β (IL-1β). The approach that we describe could be generalized for the design of inhibitors of other protein or peptide effectors, given certain limitations.

IL-1α and IL-1β are isoforms of the potent cytokine interleukin-1 (IL-1). They perform central mediatory roles in immunity, hematopoiesis, and inflammation with consequences for rheumatoid arthritis and septic shock,[6] as well as neurodegenerative diseases such as Alzheimer's disease.[7] IL-1α and IL-1β have almost identical tertiary structures[8–10] and act through the same cell surface receptors (IL-1 RI, IL-1 RII and accessory chain) eliciting similar responses with few exceptions.[11, 12] IL-1 activity is controlled within biological systems by mechanisms that involve a third member of the IL-1 family, namely the interleukin-1 receptor antagonist (IL-1ra),[13–15] which binds competitively to IL-1 cell surface receptors without eliciting a comparable biological response.[16] Recent attempts to inhibit IL-1 effects include the use of recombinant IL-1ra as well as soluble receptor antagonists and pyridinylimidazole inhibitors.[17, 18]

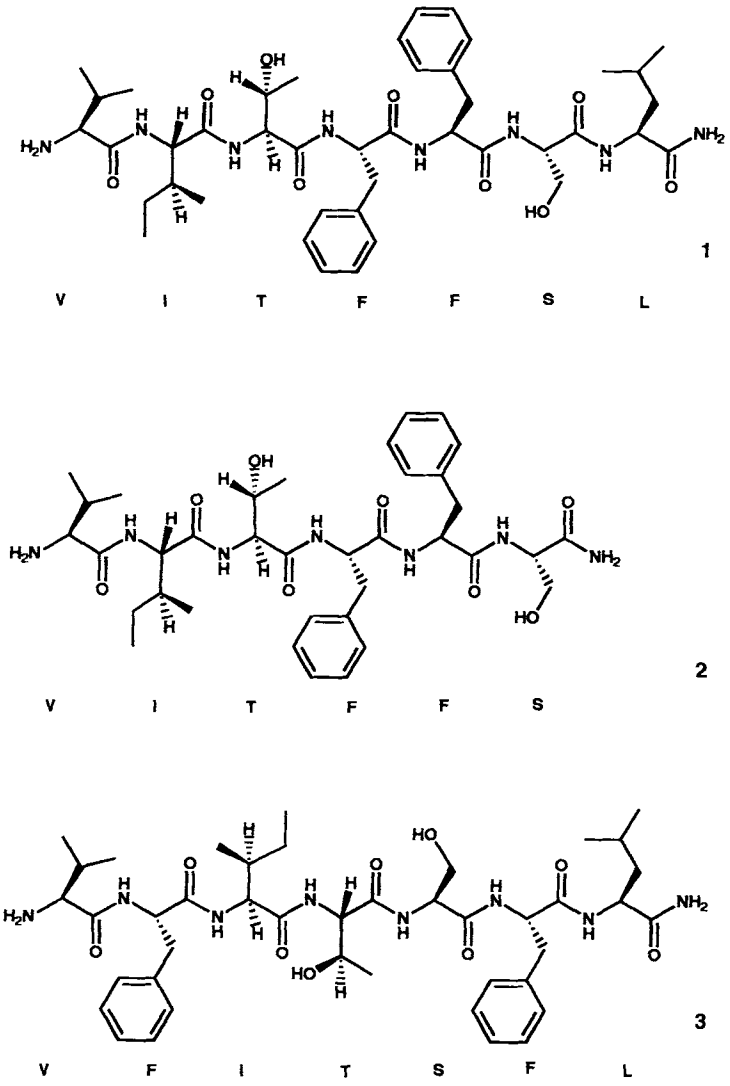
The first stage in the design of inhibitors of IL-1α and IL-1β was to identify a suitable target region from amongst the overlapping functional regions of these IL-1 isoforms, against which antisense peptides could be designed to act. Therefore, the X-ray crystal structures of IL-1β, IL-1α, and IL-1ra[9, 10, 14] were reviewed in conjunction with the results of recent mutational studies performed on all three proteins.[19] When the IL-1β and IL-1ra structures were superimposed (Figure 1a), it was observed that IL-1β possesses a β-bulge structure proximal to the known receptor binding amino acid residues, which is absent in the antagonist IL-1ra. IL-1α has a similar β-bulge in the same location (overlay not shown). In fact, the IL-1β and IL-1α β-bulge structures appeared to represent the only significant difference between the three-dimensional structures of these two IL-1 isoforms and the three-dimensional structure of IL-1ra. This absence of secondary structure was also mirrored at the primary amino acid sequence level, where IL-1ra was found to have no equivalent stretch of amino acids to the β-bulge regions of IL-1β (residues 48–54 [mature protein sequence]) or IL-1α (residues 60–66 [mature protein sequence]) (Figure 1b). These structural differences suggested that the β-bulge regions of IL-1β and IL-1α might be promising targets for antisense peptide inhibitors. This suggestion was supported by the observation that these same β-bulge regions may have important roles in receptor stimulation.[20] Furthermore, Boraschi and co-workers had reported that a peptide, corresponding in sequence to the β-bulge region of IL-1β, exhibited some biological activities similar to those of IL-1.[21] The β-bulge of IL-1β is more pronounced than that of IL-1α (Figure 1a), therefore we anticipated that β-bulge-directed inhibitors might be more effective against IL-1β than IL-1α. As a result, antisense peptides were designed to primarily target the β-bulge region of IL-1β, which was re-christened the Boraschi-loop.

Antisense peptides to the Boraschi-loop were designed with reference to the DNA sequence of IL-1β.[22] Having identified the DNA sequence coding for the loop, the antisense DNA sequence was deduced and the code translated in the 5′→3′ direction beginning with the N-terminal amino acid residue (Figure 1c). Two antisense peptides were then synthesized on

Figure 1. a) Overlay of the α-carbon backbone traces derived from the X-ray crystal structure coordinates of IL-1β (red) and IL-1ra (yellow). The β-bulge structure of IL-1β is clearly visible as is the absence of an equivalent β-bulge in IL-1ra. The key amino acid residues of the β-bulge of IL-1β (known as the Boraschi-loop) have been labeled. b) Alignment of the gene-derived amino acid sequences of IL-1α, IL-1β, and IL-1ra showing corresponding β-bulge amino acid sequences in IL-1α and IL-1β (sequences in italics) as well as the lack of equivalent sequence in IL-1ra. c) Design of the antisense peptides. The DNA sequence coding for the β-bulge of IL-1β (Boraschi-loop) is shown in alignment with the antisense DNA sequence. The amino acid sequences of antisense peptides were deduced from the antisense DNA sequence by translating the code in the 5′→3′ direction. d) Comparison of the Kyte–Doolittle hydropathic profiles x of the Boraschi-loop sequence *N*-QGEESND-*C* (■), of the antisense peptide **1** (sequence *N*-VITFFSL-*C*, □), and of the control peptide **3** (sequence *N*-VFITSFL-*C*, ●). The amino acid residues (AA) were abbreviated as follows: V: valine; I: isoleucine; T: threonine; F: phenylalanine; S: serine; L: leucine; Q: glutamine; G: glycine; E: glutamic acid; N: asparagine; D: aspartic acid.

the basis of this translated antisense code. The first antisense peptide **1** was synthesized with the sequence *N*-VITFFSL-*C*, which is complementary to the Boraschi-loop segment *N*-QGEESND-*C* (IL-1β residues 48–54) (Figures 1a and 1b). The second antisense peptide **2** was synthesized with the sequence

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3609-0963 $ 17.50+.50/0



N-VITFFS-*C*, which is complementary to Boraschi-loop segment *N*-GEESND-*C* (IL-1β residues 49–54). Both peptides were prepared as C-terminal amide derivatives. The Kyte–Doolittle hydropathic profile of antisense peptide **1** plotted (Figure 1 d) with the profile of the Boraschi-loop segment, *N*-QGEESND-*C*, illustrates the mutual complementarity of their hydropathic profiles. The hydropathic profile of **1** was also found to be reasonably complementary to the profile of the IL-1α β-bulge sequence, *N*-KSSKDDA-*C* (residues 60–66) (Figure 1 b), leading us to believe that antisense peptides **1** and **2** may also target IL-1α, even though these peptides had not been primarily designed to do this. Given the apparent importance of hydropathic complementarity in antisense/sense peptide interactions,[3–5] a third peptide **3** was synthesized with the reordered sequence *N*-VFITSFL-*C*. The hydropathic profile of this peptide (Figure 1 d) is completely different to that of the parent antisense peptide **1** and more closely ressembles the profile of the Boraschi-loop segment *N*-QGEESND-*C*. As a result, peptide **3** was not expected to interact with either IL-1β or IL-1α and was therefore expected instead to provide a first control in the following studies.

The interaction of antisense peptide **1** with IL-1α, IL-1β, and several control proteins was then investigated by means of the recently established technique of surface plasmon resonance (SPR) biosensor spectroscopy.[2,3] Both IL-1α and IL-1β were immobilized on SPR cuvettes and treated with increasing concentrations of **1**. In both cases, a significant binding interaction was observed (Figure 2). Analysis of the affinity profiles revealed that dissociation constants (K_d) (Table 1) for the interaction with both cytokines were comparable to those measured for the interaction of other sense and antisense peptides.[3] By contrast, antisense peptide **1** was not found to interact significantly above background with either immobilized IL-1ra, which lacks the crucial β-bulge sequence (Figure 1), nor any other immobilized protein tested. Other immobilized proteins tested included interleukin-4, interleukin-5, interleukin-8, lysozyme, and glycoprotein CD59. Therefore, it appeared that peptide **1** was interacting specifically with the IL-1 isoforms IL-1α and IL-1β. This conclusion was further strengthened by the behavior of the reordered control peptide **3**, which failed to interact significantly with either IL-1α or IL-1β (Table 1). Peptide **3** also failed to interact significantly above background with any of the other proteins as well, including IL-1ra.

Having demonstrated what appeared to be a specific interaction between antisense peptide **1** and the IL-1 isoforms IL-1α

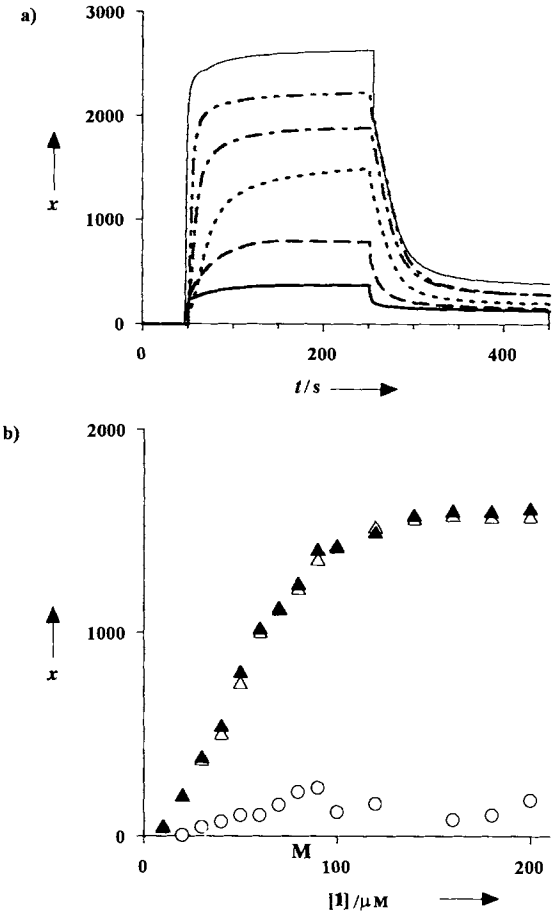


Figure 2. a) Surface plasmon resonance (SPR) affinity profiles (x = response change in arc sec) obtained from the interaction of antisense peptide **1** with immobilized IL-1β. The peptide concentrations were 20 μM (——), 40 μM (- - -), 70 μM (· · ·), 90 μM (- · -), 100 μM (- · · -), and 200 μM (–), whilst IL-1β was immobilized at a surface concentration of 22 μg mL^{-1}. b) Maximum affinity profile response changes x (in arc sec) (after background correction) are plotted as a function of the concentration of the antisense peptide **1** so as to demonstrate binding saturation. Results shown are those obtained with immobilized IL-1β (surface concentration 22 μg mL^{-1}) in the absence (▲) and in the presence (○) of the Boraschi-loop peptide *N*-QGEESND-*C* (equimolar with antisense peptide **1**), and those obtained with immobilized IL-1α (△) (surface concentration 15 μg mL^{-1}).

Table 1. Summary of binding data determined from sets of SPR affinity profiles. The data was obtained by analyzing (using IAsys software) a set of saturation affinity profiles generated from the interaction of each of the listed peptides with immobilized IL-1α and IL-1β. Errors are approximately $\pm 50\%$ of quoted value. Amino acid residue abbreviations are as described in the legend to Figure 1. Additional abbreviations are: R arginine; P proline.

Peptide		k_{ass} [$M^{-1}s^{-1}$]	$10^4 \times k_{diss}$ [s^{-1}]	K_d [μM]

[a] Too weak to be determined.

and IL-1β, we tested both **1** and the shorter antisense peptide **2** as IL-1 inhibitors in a hepatoma cell line assay system,[24] using comparable buffer conditions to those applied during the SPR biosensor spectroscopic measurements. In this assay system, either IL-1β or IL-1α independently stimulate cellular synthesis of the proteins serum amyloid A (SAA) and haptoglobin.[25] Therefore, inhibition of either IL-1 isoform would reduce the levels of both proteins synthesized. In the event, both **1** and **2** inhibited IL-1β- and IL-1α-stimulated synthesis of SAA and haptoglobin in a dose-dependent manner (Figure 3a; Table 2).

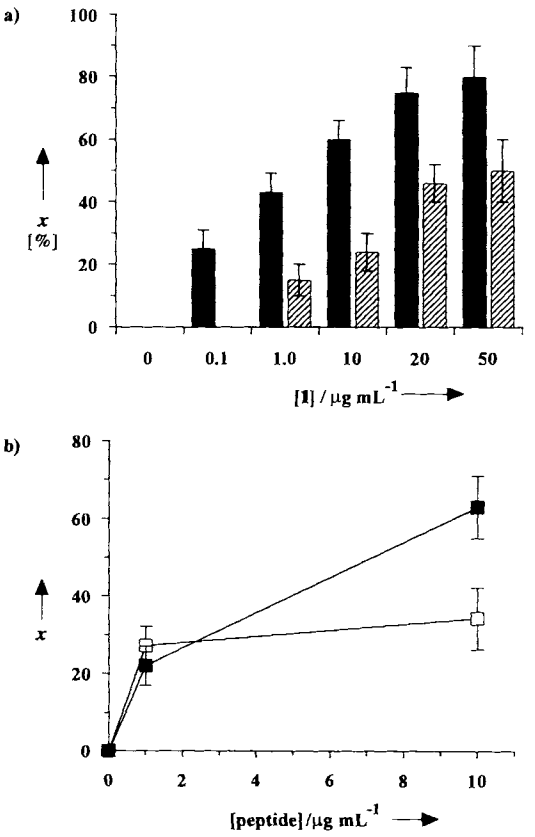

Figure 3. a) Dose-dependent percentage inhibition x of IL-1β-stimulated synthesis of serum amyloid A (SAA) (black bars) and haptoglobin (hatched bars) by antisense peptide **1**. b) Percentage inhibition x of IL-1β interaction with soluble human IL-1 type II receptor (sIL-1 RII) by antisense peptides **1** (■) and **2** (□).

Table 2. Summary of optimal inhibition data obtained with the HuH7 hepatoma cell line assay system. The peptides and proteins listed below were tested as inhibitors of both IL-1α- and IL-1β-stimulated synthesis of serum amyloid A (SAA) and haptoglobin in HuH7 cells. Inhibition is expressed as a percentage of controls performed in the absence of putative inhibitor. ND: not determined.

Peptide	SAA inhibition [%] IL-1α [a]	SAA inhibition [%] IL-1β [a]	Haptoglobin inhibition [%] IL-1α [a]	Haptoglobin inhibition [%] IL-1β [a]
1 [b]	75	78	ND	66
2 [b]	55	65	ND	57
3 [c]	<10	<10	<10	<10

[a] 1 $ng mL^{-1}$. [b] 20 $\mu g mL^{-1}$. [c] 10 $\mu g mL^{-1}$. [d] 10 $\mu g mL^{-1}$ [24].

The levels of inhibition approach or even exceed those observed when either the natural inhibitor IL-1ra or soluble human IL-1 type II receptor (sIL-1 RII) were used as inhibitors in the same assay system (Table 2). The data shows (Figure 3a; Table 2) that SAA protein synthesis was inhibited more readily than that of haptoglobin, which is consistent with previous observations made using IL-1ra.[24] The reordered control peptide **3** failed to inhibit either IL-1β or IL-1α within the experimental limits (<10% inhibition) of the biological assay (Table 2).

In the light of the SPR binding data (Table 1), it was proposed that antisense peptides **1** and **2** may be acting as IL-1 inhibitors by binding to IL-1β or IL-1α and sterically blocking the interaction with the IL-1 receptor. To test this hypothesis, a series of receptor binding assays were performed to determine if the antisense peptides would be able to inhibit the interaction between the soluble IL-1 receptor protein sIL-1 RII and immobilized IL-1β. In the event, both **1** and **2** did indeed inhibit the interaction of sIL-1 RII and immobilized IL-1β in a dose-dependent manner (Figure 3b), peptide **1** by at least 63% compared to control binding in the absence of peptide. Therefore, it seems reasonable to suggest that the antisense peptides were indeed acting as inhibitors by binding to the IL-1 isoforms and sterically opposing receptor interaction.

Finally, three further antisense peptide variants were synthesized for further control studies in addition to those performed with the reordered control peptide **3**. The first, *N*-LSFFTIV-*C*, has the same sequence and hydropathic profile as peptide **1** but in reverse. The second, *N*-LLSLLRV-*C*, has a similar hydropathic profile to antisense peptide **1** but with a significantly different amino acid sequence. The third, *N*-LLSLLPV-*C*, also has a similar hydropathic profile to **1** but its amino acid sequence was deduced by translating the antisense DNA code sequence in the 3′ → 5′ direction, as opposed to the customary 5′ → 3′ direction (Figure 1c). All three new control peptides were found to interact with IL-1α and IL-1β (Table 1) but the binding affinities of these peptides were observed to be between 20- and 60-fold lower than those affinities observed with antisense peptide **1**. This appears to be largely a result of their faster dissociation rates k_{diss} (Table 1). Given these weaker interactions, it was considered unlikely that any of these three peptides would be inhibitors of IL-1-induced protein synthesis. Therefore, it came as no surprise that all three new control peptides failed to be effective inhibitors within the experimental limits (<10% inhibition) of the biological assay (Table 2).

Taken together, the results of all the experiments described above support the view that antisense peptides **1** and **2** are acting as specific inhibitors of IL-1-stimulated protein synthesis by a

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3609-0965 $ 17.50+.50/0

mechanism of action involving direct association with the cytokine, thereby blocking receptor binding. Therefore, both peptides could be described as "mini receptor" inhibitors. We cannot be completely sure that **1** and **2** are binding to IL-1α and IL-1β through their respective β-bulge structures. However, several pieces of evidence do suggest that they probably are. First, antisense peptide **1** was unable to interact with IL-1ra, which is without a β-bulge structure (Figure 1). Second, the interaction of **1** with IL-1β was severely reduced in the presence of a Boraschi-loop peptide with the sequence *N*-QGEESND-*C* (Figure 2b). This is presumably because this loop peptide is competing directly with the equivalent Boraschi-loop sequence in IL-1β to bind with antisense peptide **1**. Finally, antisense peptides **1** and **2** were both found to be weak inhibitors of the association between IL-1β and the low-affinity antibody BhrD2 (results not shown), which is specific to IL-1β amino acid residues 45–87, a region of IL-1β that incorporates the Boraschi-loop sequence (Figure 1b).

In conclusion, purpose-designed antisense peptides have proven to be effective "mini receptor" inhibitors of IL-1-induced protein synthesis in a human hepatoma cell line. We believe that purpose-designed antisense peptides could represent a new, versatile type of small molecule inhibitor of protein effectors, provided that they are targeted against appropriately identified receptor binding or effector loops in a protein effector under consideration.

Experimental Section

The X-ray crystal structure coordinates of IL-1α [10], IL-1β [9], and IL-1ra [14] were obtained from the Brookhaven Protein Data Bank. All the peptides described, unless otherwise stated, were synthesized according to standard procedures on an ABI 431A solid-phase peptide synthesizer using *N*-terminal Fmoc-protected amino acids (Bachem Ltd.) and a Rink Amide MBHA solid-phase resin (Novabiochem). Following deprotection and cleavage from the resin, peptides were desalted by gel filtration (P2 Biogel; column: diameter 2 cm, length 30 cm) eluting with 0.1% aqueous trifluoroacetic acid (TFA). Final purification was effected by reversed-phase HPLC (Pep RPC HR10/10 attached to Pharmacia FPLC system) eluting with a linear gradient of acetonitrile in 0.1% aqueous TFA. Peptides were stored, following freeze drying, at $-20\,^{\circ}C$ under anhydrous conditions. The identity of all peptides was confirmed, before use, by positive-ion FAB-MS and quantitative amino acid analysis; purity was judged to be >95% by reversed-phase HPLC.

Surface plasmon resonance (SPR) biosensor spectroscopy [23], was performed on an IAsys instrument (Affinity sensors) in which proteins (including IL-1α and IL-1β) were immobilized over 30 min in 10 mM acetate buffer, pH 4.75, onto a carboxymethylated dextran (CMD) coated cuvette surface at 37 °C by means of the standard *N*-hydroxysuccinimide/1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (NHS/EDC) coupling procedure. Aliquots of peptide stock solutions (200 μM peptide in phosphate buffered saline (PBS) Tween-20 (0.05%, v/v), pH 7.4, containing DMSO (1%, v/v)) were then diluted in PBS Tween-20 (0.05%, v/v), pH 7.4, to give peptide solutions ranging in concentration from 20 to 200 μM. The cuvette was then treated at 37 °C in PBS Tween-20 (0.05%, v/v), pH 7.4 (assay buffer), with each peptide solution in turn and the affinity profile recorded. Typically, an "association" time of 200–250 s was used followed by assay buffer "dissociation" washes. Between runs, the cuvette surface was regenerated free of bound peptide by a 1–2 min acid wash (50 mM HCl) followed by assay buffer washes. Affinity profile data were then analyzed (using IAsys software) to give association, k_{ass}, and dissociation, k_{diss}, rates from which dissociation constants K_d were evaluated.

IL-1β and IL-1α inhibition assays were performed by using a previously described HuH7 hepatoma cell line inhibitor assay system [24]. Putative inhibitor peptides were predissolved in DMSO (10 mg mL^{-1}) and diluted to the desired concentrations in the wells of 24-well plates that contained confluent HuH7 human hepatoma cells under the stimulation of IL-1β or IL-1α (1 ng mL^{-1}). Specific concentrations of serum amyloid A and haptoglobin were measured after 48 h by enzyme-linked immunosorbent assay (ELISA), as described previously [24]. Cell viability was monitored throughout by assays of albumin synthesis.

Receptor binding assays were performed by prior immobilization of IL-1β (10 μg mL^{-1}) on Immulon II plates, for 16 h at 4 °C in PBS buffer, pH 7.4. Plates were blocked with PBS Tween-20 (0.05%, v/v), pH 7.4, containing bovine serum albumin (BSA) (1%, w/v), and then soluble human IL-1 type II receptor (sIL-1 RII) (Immunex Corporation) (4 ng mL^{-1}) was added in the presence of peptides at the indicated concentrations. The extent of receptor binding to immobilized IL-1β after 2 h at 4 °C was evaluated by ELISA using rabbit polyclonal anti-sIL-1 RII antibody (Immunex Corporation) and an anti-rabbit IgG Horse Radish Peroxidase (HRP) conjugate (Jackson Laboratories). The HRP substrate used was 3,3′,5,5′-tetramethylbenzidine (TMB).

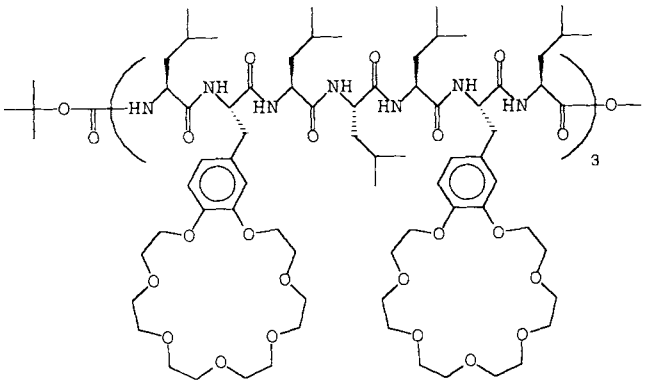
A Synthetic Transmembrane Channel Active in Lipid Bilayers**

Jean-Christophe Meillon and Normand Voyer*

In the last decade numerous studies[1] have focused on the synthesis of artificial devices designed to mimic natural ion channel protein. Only few of them clearly showed single-channel activity.[2] Recently, we reported[3] that the 21 amino acid peptide **1** bearing six [21]crown-7 moieties displayed ion transport ability similar to that of gramicidin A in a vesicle experiment. The crown rings are proposed to align to form a transmembrane channel. Furthermore, because the peptide contains 15 L-leucine residues it is both sufficiently hydrophobic to be incorporated in lipid bilayers[4] and favors α-helical conformation.[5] In this form the crown ether rings in **1** are almost perfectly aligned (Figure 1). Herein we present the results of studies on the conformation of **1** and its incorporation in planar lipid bilayers, confirming that the hexacrown peptide **1** possesses the features of a functional ion channel.



1

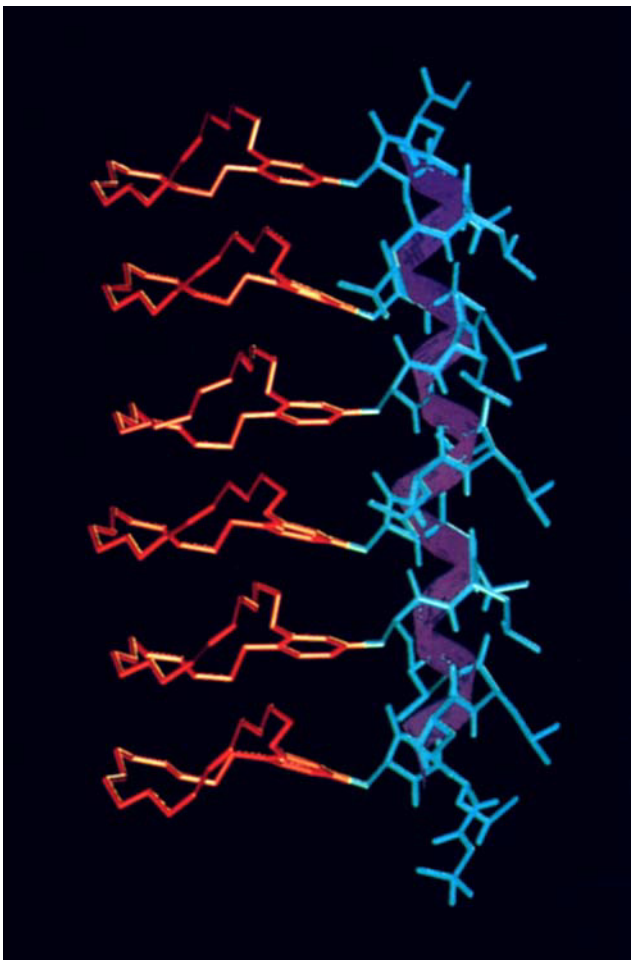


Figure 1. Structure of peptide **1** in its most stable conformation after minimization (SYBIL). The crown ether rings are in red, and the peptidic framework in blue. The violet ribbon emphasizes the helical conformation of the backbone.

We used circular dichroism spectropolarimetry (CD) for conformational studies of peptide **1** in solution. Measurements were performed in different solvents with a peptide concentration of 1 mg mL^{-1} and in egg yolk lecithin vesicles with a lipid-to-peptide ratio of 80:1. In the latter case the lipids and the peptide were codissolved in chloroform. The mixture was dried under a stream of helium to give a film and then further dried under vacuum. The films were hydrated with a 0.01 M HCl solution then sonicated until a clear solution was obtained.[6] In all of the media examined, protic as well as hydrophobic, **1** displayed CD spectra (Figure 2a) that indicated a preference for the predicted α-helical conformation, in which the crown ether units form a functional channel. This conclusion is corroborated by IR spectroscopy. In both chloroform and hydrated diphytanoyl phosphatidyl choline (DPPC) solutions, peptide **1** shows an absorption at 1656 cm^{-1} characteristic of the amide I band of α-helical structures.[7] Moreover, the CD spectra of **1** remained un-

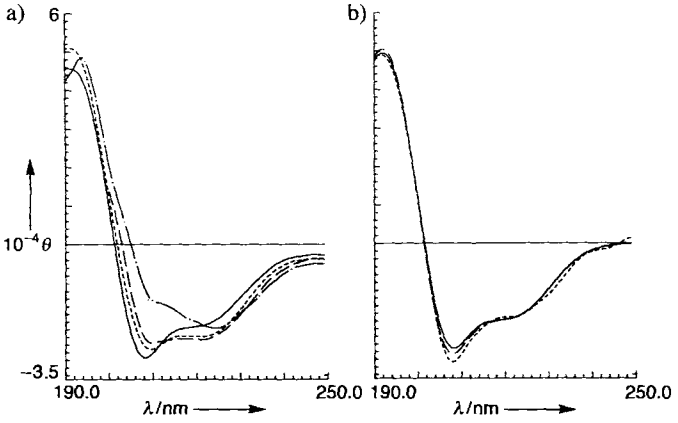

Figure 2. a) CD spectra of peptide **1** in 2,2,2-trifluoroethanol (TFE) (solid line), methanol (dotted line), 1,2-dichloroethane (dashed line), and egg yolk lecithin vesicles (dotted and dashed line) at 25 °C. The peptide concentration is 2.3×10^{-4} M in all cases and the lipid/peptide ratio is 80:1 in the vesicles. b) CD spectra of **1** at 25 °C in TFE at different concentrations: 2.3×10^{-4} M (solid line), 2.3×10^{-5} M (dashed line), and 2.3×10^{-6} M (dotted line). Values of θ are reported in mean residue molar ellipticity [deg cm^2 dmol^{-1}].

changed at three different concentrations in trifluoroethanol (Figure 2b). Although aggregated forms cannot be ruled out, these results suggest that **1** exists as a monomer in media of low polarity within the range of concentrations used for conductivity recordings.[8]

To demonstrate the ion channel activity of peptide **1**, we carried out single-channel measurements[9] using a modified patch clamp technique.[10] A 0.1 mM solution of **1** in methanol was used in two distinct types of experiments. In a first assay 2 μL of the solution was introduced in a 2-mL cell containing an unbuffered 1 M KCl solution (pH 5.8); the bilayer was constructed on a pipet tip from either uncharged glycerol monooleate (GMO) or zwitterionic DPPC (5 mg mL^{-1} in hexadecane or decane, respectively). In a second assay 2 μL of the peptide solution was mixed with 100 μL of the lipid sample, methanol was removed under vacuum, and the bilayer was prepared by using the lipid/peptide mixture. In both experiments a transmembrane potential was applied, then the data were acquired and analyzed.

The conductance recordings shown in Figure 3 are characteristic of ion channel activity. Typical transitions ("steps") between closed and open states are evident throughout the experiment; the discrete conductances depend on the number of channels in the open state.[9] In the DPPC bilayer the channel has a current level of 3.5 ± 0.2 pA with lifetimes for the open states of around 1 s.[11] However, in the GMO bilayer both the current level (1.0 ± 0.1 pA) and the lifetimes for the open states (less than 200 ms) are different. In the first set of assays peptide **1** was incorporated with difficulty when added to the bulk KCl solution. This might be due to its high tendency to form aggregates on contact with water. As soon as the methanolic solution of **1** was added to the cell, a white precipitate formed which delayed the observation of active channels. In the second set of assays the stability of the bilayer was frequently perturbed and characteristic channel recordings were not obtained. This could be due to the preferential adsorbance of the peptide at the surface of the membrane through electrostatic interactions between the crown ether units and the polar head groups of the lipids. As soon as a peptide molecule is incorporated in the bilayer parallel to the lipids chains, channel activity can be observed. This behavior has been described by DeGrado et al. with related peptidic systems.[2c] Furthermore, the lack of polar head groups on **1** could partly explain its tendency to remain at the surface of the bilayer.

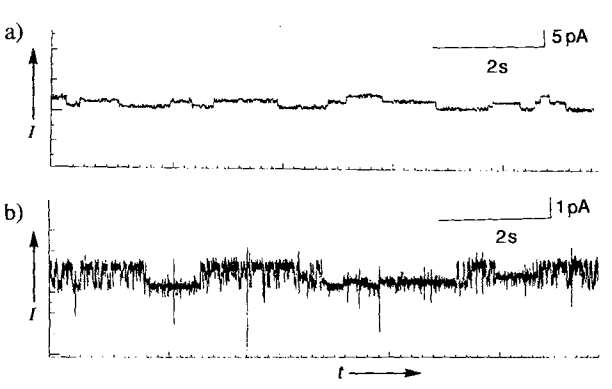

Figure 3. Single-channel conductance recordings of peptide **1** in 1 M KCl (at +100 mV, filtered at 200 Hz) a) in a DPPC bilayer (current level 3.5 ± 0.2 pA, average lifetimes of open states >1 s), b) in a GMO bilayer (current level 1.0 ± 0.1 pA, average lifetimes of open states <200 ms).

In conclusion, we have described a functional artificial ion channel operating most probably in a well-characterized monomeric form. The results reported illustrate well the utility of peptidic scaffolds for the construction of molecular devices[12] and could have important implications for the development of ion-sensitive field effect transistors (ISFETs)[13] and molecular wires.[14] Peptide **1** displays typical single-channel features dependent on the structure of the lipid bilayer. The difficulty in incorporating **1** to give functional channels could be solved easily owing to the simplicity and the versatility of our synthetic strategy.[15] We are currently working in this direction and are also synthesizing analogs of **1** to study its structure/activity relationship and to probe its active form in detail.

Crystal Engineering of Melamine–Imide Complexes; Tuning the Stoichiometry by Steric Hindrance of the Imide Carbonyl Groups**

Ronald F. M. Lange, Felix H. Beijer, Rint P. Sijbesma, Rob W. W. Hooft, Huub Kooijman, Anthony L. Spek, Jan Kroon, and E. W. Meijer*

The proposed infinite, two-dimensional lattice, formed by complexation of melamine with cyanuric acid through triple hydrogen bonds,[1] has been a unique inspiration to supramolecular chemists.[2] Various model studies have been performed to mimic this triple hydrogen bond formation.[3–9] Whitesides et al. reported the formation of a well-defined complex of six melamine and six cyanuric acid derivatives, linked together by 36 hydrogen bonds.[3] Using substituted melamines and barbituric acid derivatives, they were also able to prepare molecular tapes, crinkled tapes, and rosettes.[4] A variation of the linear tape was described by Lehn et al.[5] Furthermore, helical[6] and tube-like[7] nanostructures are formed by complexation of dialkyl-substituted melamines with a diimide, whereas Rebek et al. reported on a trisimide which could act as a molecular "tool chuck" for melamine.[8] Until now, only two crystalline complexes containing melamine have been reported in literature.[9]

Here, we present the formation of supramolecular 1:1, 1:2, and 1:3 complexes of melamine with imides. We show that the availability for hydrogen bonding of the carbonyl groups in the imide is strongly influenced by subtle differences in its molecular structure. The result that the stoichiometry of the supramolecular complexes can be tuned represents a distinct step forward towards crystal engineering.[10]

Cocrystallization of melamine with succinimide from water or DMSO in a molar ratio between 1:10 and 1:1 resulted in the formation of a supramolecular 1:1 complex of melamine and succinimide. When a molar excess of melamine was used, crystals of pure melamine were formed together with crystals of the 1:1 complex. X-ray analysis[11] of the complex revealed a 1:1 sheetlike structure (Figure 1). In both molecules, every donor and acceptor site available for hydrogen bonding is used. Surprisingly, when glutarimide was crystallized with melamine from water or DMSO in melamine:imide ratios between 1:10 and 1:2, a 1:2 complex of melamine and glutarimide was obtained. X-ray analysis[12] showed a 1:2-herringbone structure (Figure 2). In this complex, one of the four carbonyl acceptor sites of the imide is not involved in hydrogen bonding. Therefore, by masking two of the four carbonyl acceptor sites of an imide, it should be possible to obtain a 1:3 cocrystal with melamine. To verify this hypothesis, we co-crystallized melamine with a variety of imides (adipimide, 2,3-diphenylmaleimide, phthalimide, diphenylimide, and 1,8-naphthalimide) in various ratios of DMSO, DMF, ethanol, or NMP as solvent. However, crystallization did not result in single crystals of the desired 1:3 melamine–imide complex. This is possibly due to the large solubility difference between the imides and melamine.[13]

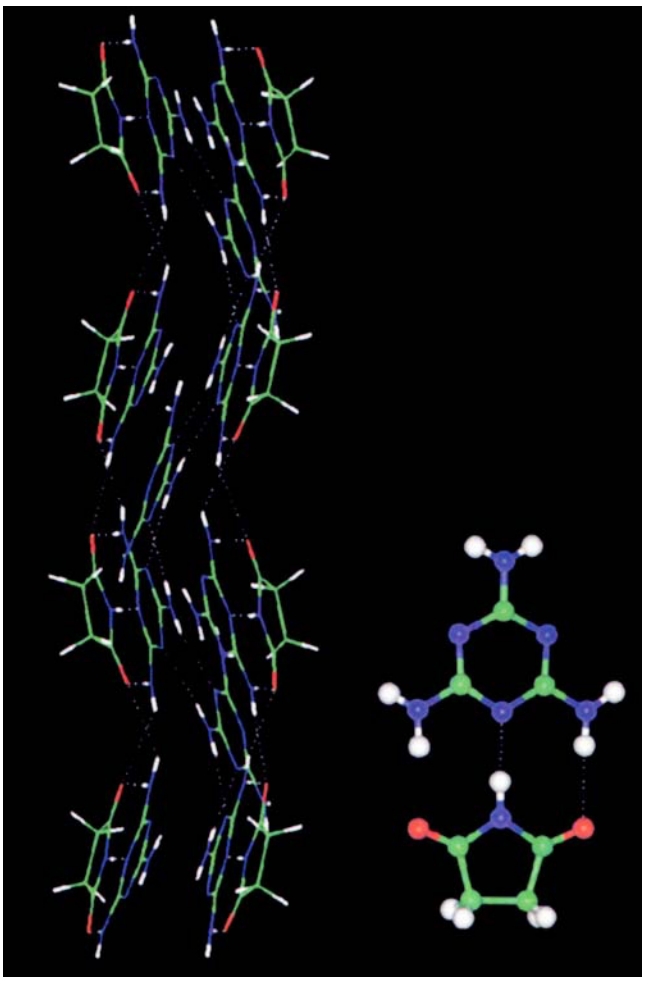

Figure 1. X-ray crystal structure of the 1:1 complex between melamine and succinimide (PLUTON plot).

However, cocrystallization of melamine with the water-soluble 1-*N*-propylthymine from water or 96% ethanol in initial

molar ratios between 1:2 and 1:5 resulted indeed in the crystallization of the desired 1:3 melamine–imide complex. X-ray analysis[14] showed a 1:3 C_3-symmetrical structure with disordered propyl groups and small quantities of disordered solvent in infinite channels perpendicular to the plane of molecules (Figure 3).

The crystal structures of the complexes show that all hydrogen-bond lengths and angles agree well with values in other melamine complexes[4, 5, 9] and support the triple hydrogen-bond motif. In the 1:1 melamine–succinimide crystal structure the molecules are paired through three anti-parallel hydrogen bonds (Figure 1).[15a] Two independent pairs are present in the unit cell, and a two-layer zigzag sheet is formed. Intermolecular hydrogen bonds within the two-layer zigzag sheet connect the different pairs parallel to the *a*,*c* plane (Figure 1). No hydrogen bonding occurs between different two-layer zigzag sheets along the *b* axis. Detailed analysis of this complex crystal structure reveals that each succinimide molecule uses all four H-bond acceptor sites and its H-bond donor site, while melamine uses three H-bond acceptor and all its six H-bond donor sites. This results in a 1:1 complex with seven donors and seven acceptors per pair.

In the 1:2 melamine–glutarimide crystal structure, each melamine molecule is connected to two glutarimide molecules by three anti-parallel hydrogen bonds.[15b] These units, located on a crystallographic twofold rotation axis, are connected in a one dimensional hydrogen-bonded chain, forming an α-network in which the arrangement of the molecules resembles a herringbone structure. No specific interactions between the α-networks are detected. All molecules in the complex leave one of their H-bond acceptor sites unused. Assuming that one of the four imide carbonyl acceptor sites is not available due to steric hindrance, it is obvious that a 1:2 stoichiometry gives an optimal balance of donor and acceptor sites.

In the 1:3 melamine–(1-*N*-propylthymine) crystal structure four molecules are connected by nine H-bonds to form a planar C_3-symmetrical structure.[15c] Here, two carbonyl acceptor sites are not used, because they are masked by the methyl and the N-propyl group. This 1:3 arrangement of molecules around melamine resembles the hydrogen-bonding motif of the cyanuric acid–melamine lattice.

These results show that it is possible to influence the ratio of the components of the complex of melamine with succinimide (1:1), glutarimide (1:2), and 1-*N*-propylthymine (1:3). The availability of the imide carbonyl acceptor sites affords a handle to tune the supramolecular crystal structure with melamine. Because of the hydrophobic interactions, water seems to be the best medium from which the different crystals can be grown. The 1:3 melamine–imide structure is consistent with the arrangement of cyanuric acid around melamine in the 1:1 com-

plex of melamine and cyanuric acid.[11] It also supports the 1:3 complexation of melamine with an alternating copolymer of maleimide and styrene, in which the polymer backbone is presumed to mask two carbonyl acceptor sites of the maleimide.[16] The present results suggest that uncovering assembly rules that govern the crystallization of a restricted group of related complexes is a useful approach to the design of crystalline solids.[10, 13] Further research to extend these new insights into the formation of supramolecular lattices is in progress.

Experimental Section

Typical procedure for the cocrystallization of melamine and succinimide: melamine (99.1 mg, 0.79 mmol) and succinimide (78.7 mg, 0.79 mmol) were dissolved in water (5 mL) under reflux and slowly cooled to ambient temperature. After filtration 136.9 mg (0.61 mmol, yield 77%) of the 1:1 melamine–succinimide cocrystals were obtained. The 1:2 melamine–glutarimide and the 1:3 melamine–(1-*N*-propylthymine) complexes were obtained in a similar manner.

[11] Crystal data for 1:1 melamine-succinimide: $C_3N_6H_6 \cdot C_4H_5NO_2$, $M_r = 225.21\ g\,mol^{-1}$, colorless, block-shaped crystal ($0.25 \times 0.62 \times 0.75$ mm), monoclinic, space group $P2_1/c$ (no. 14), $a = 10.1648(8)$, $b = 14.0935(6)$, $c = 14.5361(5)$ Å, $\beta = 106.253(5)°$, $V = 1999.2(2)$ Å^3, $Z = 8$, $\rho_{calcd} = 1.4964(1)$ g cm^{-3}, $F(000) = 944$, $\mu(Cu_{K\alpha}) = 9.4\ cm^{-1}$. Of 5187 reflections measured, 4126 were independent; $R_{int} = 0.050$, ($3.1° < \theta < 75.0°$, $\omega/2\theta$ scan, $T = 295$ K, $Cu_{K\alpha}$ radiation, Ni filter, $\lambda = 1.54184$ Å) on an Enraf-Nonius CAD4-F diffractometer in a sealed tube. Data were corrected for Lp effects, extinction, and for a linear instability of 2% in three reference reflections during 59 h of X-ray exposure time; no absorption correction applied. The structure was solved by automated direct methods (SHELXS86). Refinement on F was carried out by full-matrix least-squares techniques (SHELX76); final R value 0.043, $wR = 0.056$, $w = 1/\sigma^2(F)$, for 3836 data with $I > 2.5\sigma(I)$ and 357 parameters. Hydrogen atoms were located on a difference Fourier map and subsequently included in the refinement. All non-hydrogen atoms were refined with anisotropic thermal parameters; the hydrogen atoms were refined with one overall isotropic thermal parameter. A final difference Fourier showed no residual density outside -0.09 and $0.09\ e\,Å^{-3}$.

[12] Crystal data for 1:2 melamine–glutarimide: $C_3H_6N_6 \cdot 2C_5H_7NO_2$, $M_r = 352.36\ g\,mol^{-1}$, colorless, block-shaped crystal ($0.25 \times 0.25 \times 0.50$ mm), monoclinic, space group $C2/c$ (no. 15), $a = 14.5430(3)$, $b = 8.5816(3)$, $c = 13.2400(4)$ Å, $\beta = 97.697(3)°$, $V = 1637.49(8)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.4292(1)\ g\,cm^{-3}$, $F(000) = 744$, $\mu(Cu_{K\alpha}) = 8.8\ cm^{-1}$. Data collection and reduction was performed as described in ref. [11]. Of 3041 reflections measured, 1699 were independent; $R_{int} = 0.011$, ($3.4° < \theta < 75.0°$). The structure was solved by automated direct methods (SIR92). Refinement on F^2 was carried out by full-matrix least-squares techniques(SHELXL-93); no observance criterion was applied during refinement. Hydrogen atoms were located on a difference Fourier map and subsequently included in the refinement. All non-hydrogen atoms were refined with anisotropic thermal parameters; hydrogen atoms were refined with individual isotropic thermal parameters. Refinement converged at $wR_2 = 0.095$, $1/[\sigma^2(F^2) + (0.0412P)^2 + 0.57P]$, $P = (\mathrm{Max}(0,F_o^2) + 2F_c^2)/3$, $R_1 = 0.033$ (for 1598 reflections with $I > 2\sigma(I)$), $S = 1.11$, for 156 parameters. A final difference Fourier showed no residual density outside -0.15 and $0.22\ e\,Å^{-3}$.

[13] C. B Aakeröy, K. R. Seddon, *Chem. Soc. Rev.* **1993**, 397.

[14] Crystal data for 1:3 melamine–(1-*N*-propylthymine): $C_3H_6N_6 \cdot 3C_8H_{12}N_2O_2$, $M_r = 1261.41\ g\,mol^{-1}$, colorless, block-shaped crystal ($0.1 \times 0.2 \times 0.5$ mm), hexagonal, space group $P6_3/m$ (no. 176), $a = 17.212(2)$, $c = 6.3697(5)$ Å, $V = 1634.2(3)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.282\ g\,cm^{-3}$, $F(000) = 672$, $\mu(Mo_{K\alpha}) = 1.0\ cm^{-1}$. All data, where relevant, are given without disordered solvent contribution (*vide infra*). Of 4825 reflections measured, 1366 were independent; $R_{int} = 0.14$, ($1.37° < \theta < 27.5°$, ω scan, $T = 100$ K, $Mo_{K\alpha}$ radiation, graphite monochromator, $\lambda = 0.71073$ Å) on an Enraf-Nonius CAD4 Turbo diffractometer on rotating anode. Data were corrected for Lp effects and for a linear decay of 4% of three reference reflections during 59 h of X-ray exposure time; no absorption correction was applied. The structure was solved by automated direct methods (SHELX86). Refinement on F^2 was carried out by full-matrix least-squares techniques (SHELXL-93); no observance criterion was applied during refinement. The *N*-propyl moiety is disordered over four positions, two of which are generated by space-group symmetry. The occupancy ratio of the two unique conformations was included as a parameter in the refinement. The unit cell contains a channel parallel to the c axis and passing through the origin, filled with disordered solvent (probably water). This density was modeled by introducing two partially occupied oxygen sites in the channel. Hydrogen atoms were located on a difference Fourier map and subsequently included in the refinement. All non-hydrogen atoms were refined with anisotropic thermal parameters except for the carbon atoms in the disordered *N*-propyl moiety. Hydrogen atoms were refined with a fixed isotropic thermal parameter related to the value of the equivalent isotropic displacement parameter of their carrier atoms by a factor of 1.5 for the methyl, disordered methylene, and amine hydrogen atoms, and by a factor of 1.2 for the other hydrogen atoms. Refinement converged at $wR_2 = 0.179$, $w = 1/[\sigma^2(F^2) + (0.0483P)^2 + 1.81P]$, $R_1 = 0.065$ (for 690 reflections with $I > 2\sigma(I)$), $S = 1.07$ for 113 parameters. A final difference Fourier showed no residual density outside -0.26 and $0.28\ e\,Å^{-3}$. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100114. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code + (1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

[15] a) The NH···O hydrogen bonds are of comparable length (3.125(2), 3.048(2), 3.120(2), and 3.150(2) Å), while the NH···N hydrogen bond is shorter (2.812(2) and 2.814(2) Å). The hydrogen bonds connecting the pairs range from 2.913(2) to 3.054(2) Å. b) The length of triple anti-parallel hydrogen bonds is the same within 0.063 Å (2.941(1), 2.961(1), and 3.005(1) Å), while the other hydrogen bond is somewhat longer (3.095(1) Å. c) The three triple anti-parallel hydrogen bonds range from 2.881(6) Å (NH···N distance) to 2.867(5) and 2.881(1) Å (NH···O distance).

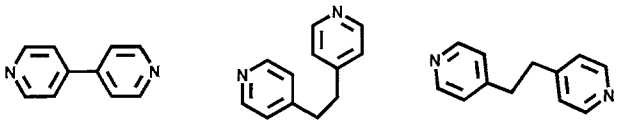
Supramolecular Isomerism in Coordination Polymers: Conformational Freedom of Ligands in $[Co(NO_3)_2(1,2\text{-bis}(4\text{-pyridyl})ethane)_{1.5}]_n$**

Tracy L. Hennigar, Donald C. MacQuarrie, Pierre Losier, Robin D. Rogers, and Michael J. Zaworotko*

That the architecture of coordination polymers can be reasonably well predicted rests upon the simple premise that the coordination geometry of metals can be propagated with rigid bridging ligands ("spacers"). It is therefore unsurprising that a wide range of one-,[1] two-,[2] and three-dimensional[3] infinite frameworks have already been generated with simple, linear spacers such as 4,4′-bipyridine (**1**). However, that the issue of isomerism and its manifestation upon structure and bulk properties has not yet been addressed is perhaps surprising. Exploitation of spacers with conformational freedom, which are expected to engender supramolecular isomerism in the coordination polymer because of conformational isomerism,[4] has until recently remained largely unexplored.[5] Here we report the dramatic effect on network morphology that conformational freedom in a ligand can impart to a coordination polymer. 1,2-Bis(4-pyridyl)ethane (**2**) can adopt *gauche* (angular) or *anti* (linear, see **1**) conformations, and $[Co(NO_3)_2(\mathbf{2})_{1.5}]_n$ (**3**) can exist in at least three different supramolecular isomers, two of which, to our knowledge, represent novel motifs for a coordination polymer.[6]



1 *gauche*-**2** *anti*-**2**

The architecture of the coordination polymers obtained from complexation of $Co(NO_3)_2$ with **1** is limited by metal:ligand stoichiometry and thus far includes simple chains (1:1),[1,7] ladders (1:1.5),[2a,8] and grids (1:2).[2b-d,7] The latter two motifs can be regarded as polymeric forms of "molecular boxes"[9] and possess square, hydrophobic cavities (effective area about 8×8 Å), which enclathrate up to four guest organic molecules.[8] We anticipated that the extended spacer **2** would generate analogues with enhanced cavity size. However, reaction of $Co(NO_3)_2 \cdot 6H_2O$ with **2** in solutions of MeOH/MeCN, MeOH/MeCN/ferrocene, and MeOH/$CHCl_3$ afforded three isomeric forms of $[Co(NO_3)_2(\mathbf{2})_{1.5}]_n$ (**3a**–**c**, respectively).

Complexes **3a**–**c** have identical molecular formulas and asymmetric units; however, the conformational freedom of **2** manifests itself by sustaining three entirely different network structures. X-ray structural analyses[10] revealed statistically identical heptacoordinate environments at the Co^{II} centers (Figure 1). The three pyridyl moieties form a "T-shaped" or meridional arrangement at the metal atom; the remaining coordination sites are occupied by two bidentate, nitrate anions.[11] Isomer **3a** is isostructural with its Cd analogue, $[Cd_2(gauche\text{-}\mathbf{2})_2(anti\text{-}\mathbf{2})(NO_3)_4]_n$,[6] and contains two *gauche* spacers that link Co^{II} centers to afford empty, square boxes (7×7 Å), which are linked at the metal edges by an *anti* spacer to form linear chains.

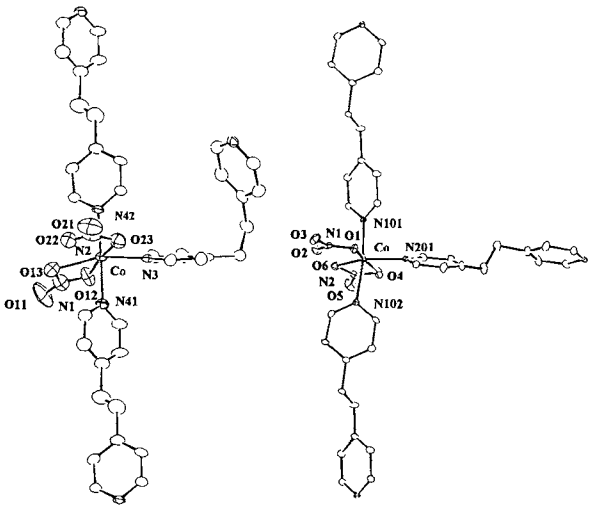


Figure 1. ORTEP views of "T-shaped" environments at the metal centers of **3a** and **3b**. Bond lengths [Å] are comparable: N–Co 2.122–2.171, O–Co 2.157–2.239 and 2.251–2.477 Å.

If the crystallization is conducted in the presence of ferrocene, a second supramolecular isomer **3b** is obtained, presumably by a template effect.[12] Complex **3b** contains two *anti* spacers for every *gauche* spacer. The resulting motif can be called a molecular bilayer sustained by coordinate covalent bonds (Figure 2).

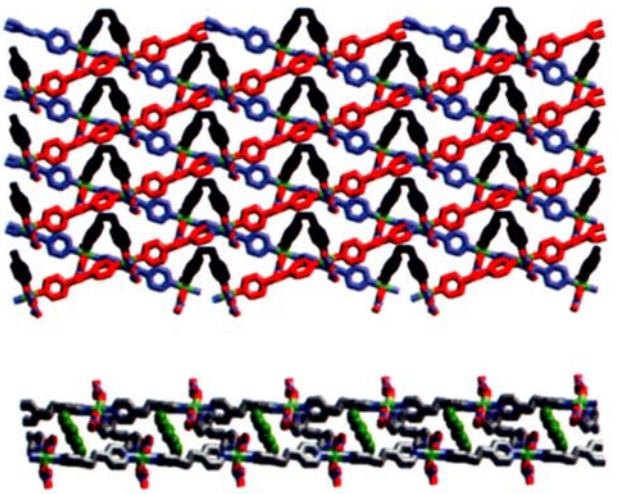

Figure 2. a) Overhead view of the molecular bilayer in **3b** showing cross-hatched chains of *anti*-**2** spacers (red and blue) pillared by *gauche*-**2** spacers (black). This bilayer is parallel to the crystallographic *ab* plane. b) Illustration of a single molecular bilayer of **3b** and the channels of solvent (green, space-filling representation) that run through the structure.

The faces of the bilayer comprise linear chains formed by two *anti* ligands that bridge Co^{II} moieties (Figure 2, top). The faces are cross-hatched and "pillared" at every metal center by a *gauche* spacer (Figure 2, bottom). The resulting bilayers contain channels filled with MeCN (*b* axis) and stack along *c* through hydrogen bonds between the terminal nitrate groups and the bridging ligands of adjacent bilayers (C(H)···O 3.4–3.6 Å). To our knowledge, such a bilayer is unique, and, from its struc-

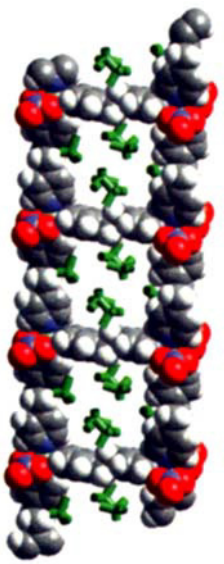

Figure 3. Space-filling view of the open-framework ladder motif in **3c** showing the six $CHCl_3$ molecules (green) within each square cavity.

ture, we anticipate that it will be able to expand if the *gauche* spacer converts to its *anti* conformation.

Complex **3c** is an open-framework molecular ladder in which all spacer ligands adopt *anti* conformations (Figure 3). A related structure was obtained when $Co(NO_3)_2$ was allowed to react with **1**,[8] but **3c** contains much larger square cavities (effective area about 10×10 Å) that enclathrate six $CHCl_3$ molecules. The solvent molecules are held by weak C(H)···Cl hydrogen bonds (3.5–3.9 Å). In the crystal lattice, the ladders extend along *b* and are arranged as books in a bookshelf along *c*. Within this plane (*ab* plane) adjacent ladders are offset by half the length of the *b* axis, and the superposition of these sheets creates large, square channels running along *a* that are filled with $CHCl_3$ molecules.

We consider two aspects of this study to be of broad relevance to the subject of crystal engineering and coordination polymers: 1) Supramolecular isomerism in coordination polymers can influence crystal structure and therefore bulk properties more significantly than typically seen in molecular polymorphs[13] and 2) the crystallization medium (that is, solvent(s) and/or template) can influence nucleation and the architecture of coordination polymers. Finally, the all-*gauche* conformation of a discrete molecule of **3** has not yet been observed; however, such a cage-like, macrocyclic complex would be of interest in the study of self-assembly and guest–host molecular recognition.[14]

Experimental Section

In a typical reaction, $Co(NO_3)_2 \cdot 6H_2O$ (0.07 g, 0.25 mmol) was dissolved in dry MeOH (≈ 5 mL) and added to a solution of **2** (0.14 g, 0.75 mmol) in the appropriate solvent (≈ 35 mL; 0.50 g of ferrocene was added for **3b**). In all cases red crystals formed within a day (yields: **3a** 0.08 g, 0.17 mmol, 72%; **3b** 0.06 g, 0.12 mmol, 50%; **3c** 0.14 g, 0.17 mmol, 74%). Crystals of **3b** and, in particular, **3c** appear to lose solvent molecules readily and decompose within minutes in the absence of solvent.

Synthesis of Boryl Metal Complexes with Additional Agostic Stabilization by Hydroboration of Fischer Carbyne Complexes**

Hubert Wadepohl,* Ulrich Arnold, and Hans Pritzkow

Dedicated to Professor Walter Siebert on the occasion of his 60th birthday

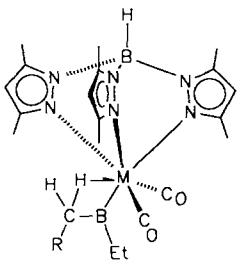
After a long hiatus,[1, 2] interest in boryl transition metal complexes has recently revived.[3–7] This is principally due to their importance as intermediates in hydroborations catalyzed by metal complexes.[8] It has been suggested that boryl groups are capable of forming element–metal multiple bonds. A π backbonding contribution to the transition metal–boron bond had been proposed in earlier works[9], but was not considered to be of particular importance.[2–7] Virtually all boryl metal complexes that have been structurally characterized have heterosubstituents (OR, NR_2) with π-donor properties attached to the boron atom. Therefore possible M → B back bonding is masked by the dominating π interaction between the boron and the heteroatom. Weak M-B-π bonding contributions were discussed for the only metal complexes known to us containing diorganoboryl ligands, **1**[4a] and **2**[5a], but these did not result in a shortened bond.

fac-[$(PMe_3)_3(H)_2$Ir(borabicyclo[3.3.1]nonyl)] **1**

[$Cp(CO)_2$Fe(BPh_2)] **2**

Our investigations into the hydroboration of metal–carbon multiple bonds [10] have now resulted in the synthesis of the first low-valent metal complexes containing dialkylboryl ligands. The Fischer carbyne complexes **3** and **4** [tpb′ = tris(3,5-dimethylpyrazol-1-yl)hydroborate] react readily at room temperature (R = Me) or 60 °C (R = *p*-tolyl) with the hydroborating agent "Et_2BH".[11] IR and NMR spectra of the products **5** and **6**, which were isolated in yields of 65–85% (Table 1), indicate the presence of (tpb′)$(CO)_2$M fragments (two ν_{CO} bands, two sets of ^{1}H and ^{13}C NMR signals for the three pyrazolyl rings with an intensity ratio 2:1). In addition to the signal for the tpb′ ligands, the ^{11}B NMR spectra reveal a low-field signal ($\delta \approx 77$) that lies in the region for resonances attributed to triorganoboranes.[12]

[(tpb′)$(CO)_2$M≡CR] **3**, M = Mo, R = *p*-Tolyl; **4a**, M = W, R = Me; **4b**, M = W, R = *p*-Tolyl



5, M = Mo, R = *p*-Tolyl

^{1}H NMR (200 MHz, in C_6D_6, δ[*J*(H,H)/Hz]): **5** (in C_6D_6): 1.54[8] (t, 3H, CH_2CH_3), 1.99 (s, 6H, tpb′-CH_3), 2.05 (s, 3H, tpb′-CH_3), 2.07 (s, 3H, tpb′-CH_3), 2.11 (s, 6H, tpb′-CH_3), 2.33[8] (q, 2H, CH_2CH_3), 2.41 (s, 2H, CH_2-*p*-tolyl), 2.71 (s, 3H, Me-4), 5.41 (s, 1H, tpb′-CH), 5.48 (s, 2H, tpb′-CH), 6.87[8]/7.11[8](AA′BB′ system, 4H, C_6H_4). **6a**: 1.03[7] (q, 2H, CH_2CH_3), 1.28[8] (t, 3H, CH_2CH_3), 1.44[7] (t, 3H, CH_2CH_3), 1.92[8] (q, 2H, CH_2CH_3), 2.27 (s, 6H, tpb′-CH_3), 2.34 (s, 3H, tpb′-CH_3), 2.40 (s, 6H, tpb′-CH_3), 2.50 (s, 3H, tpb′-CH_3), 5.87 (s, 1H, tpb′-CH), 5.93 (s, 2H, tpb′-CH). **6b**: 1.27[8] (t, 3H, CH_2CH_3), 1.97 (s, 6H, tpb′-CH_3), 2.00[8] (q, 2H, CH_2CH_3), 2.32 (s, 3H, Me-4), 2.36 (s, 3H, tpb′-CH_3), 2.42 (s, 6H, tpb′-CH_3), 2.56 (s, 3H, tpb′-CH_3), 2.65 (s, 2H, CH_2-*p*-tolyl), 5.89 (s, 2H, tpb′-CH), 5.90 (s, 1H, tpb′-CH), 7.05[8]/7.11[8] (AA′BB′ system, 4H, C_6H_4).

^{13}C{^{1}H} NMR (in CD_2Cl_2, δ): **5**: −11.0 (br, BCH_2-*p*-tolyl), 9.2 (CH_2CH_3), 12.6, 13.1, 14.4, 14.9 (tpb′-CH_3), 20.1 (br, BCH_2CH_3), 20.7 (Me-4), 106.8, 107.2 (tpb′-CH), 128.9, 130.6 (CH[C_6H_4]), 135.5, 136.3, 145.4, 145.5, 152.0, 153.6 (C[C_6H_4, tpb′-CCH_3]), 221.8 (CO). **6a**: −30.2 (br, BCH_2CH_3), 9.4 (CH_2CH_3), 12.7, 13.2, 15.2, 15.6 (tpb′-CH_3), 15.9 (CH_2CH_3), 19.0 (br, BCH_2CH_3), 107.4 (tpb′-CH), 145.2, 145.6, 152.6, 154.3 (tpb′-CCH_3), 216.7 (CO). **6b**: −14.8 (br, BCH_2-*p*-tolyl), 9.4 (CH_2CH_3), 12.5, 13.0, 14.5, 15.2 (tpb′-CH_3), 19.3 (br, BCH_2CH_3), 20.6 (Me-4), 106.7, 106.9 (tpb′-CH), 128.5, 130.2 (CH[C_6H_4]), 135.2, 136.3, 145.0, 145.3, 152.0, 153.5 (C[C_6H_4, tpb′-CCH_3]), 216.4 (CO).

^{11}B{^{1}H} NMR (in CD_2Cl_2, δ): **5**: −9.3 (tpb′-BH), 76 (br, MoB). **6a**: −9.3 (tpb′-BH), 77 (br, WB). **6b**: −9.3 (tpb′-BH), 78 (br, WB)

IR($\tilde{\nu}$(CO) in cm^{-1}, in toluene): **5**: 1908, 1830; **6a**: 1893, 1814; **6b**: 1896, 1817

X-ray crystal structure analysis[13, 14] shows that **6b** contains an ethyl(*p*-tolylmethyl)boryl ligand which, in addition to the M–B bond, has an agostic interaction between the tungsten atom and the methylene group attached to the benzene ring (Figure 1). IR and NMR spectra indicate that the same basic structure also exists for **5** and **6a**. The W–B bond length of 2.07(1) Å in **6b** is the shortest of all known W–B bonds;[16] comparable boryl complexes with hetero-substituted boryl ligands have considerably longer W–B bond lengths ([Cp_2W(H)(BCat)] 2.190(7) Å,[5c] [Cp_2W(BCat)$_2$] 2.19(1) and 2.23(1) Å[5d] (BCat = catecholboryl); [$Cp(CO)_3$W{B(NMe_2)-B(NMe_2)Cl}] 2.370(8) Å[17]). The relatively short W1–C2 distance (2.45(1) Å) and the acute W1-B1-C2 angle [81.9(7)°] are characteristic of a β agostic interaction.

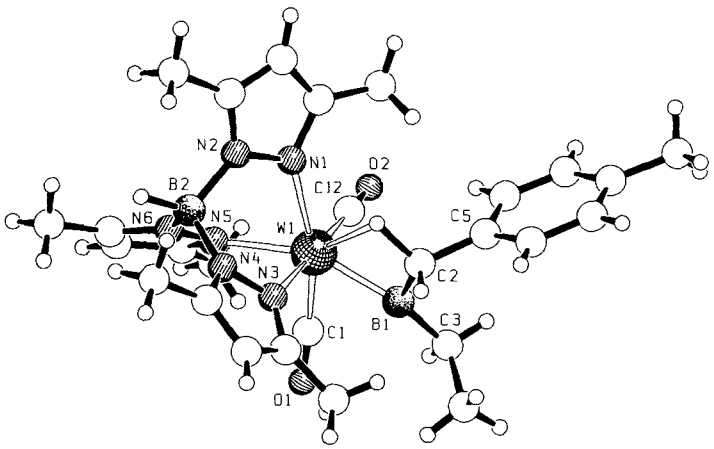

Figure 1. Molecular structure of **6b** in the crystal. Selected bond lengths [Å] and angles [°]: W1–N1 2.240(9), W1–N3 2.251(9), W1–N5 2.185(8), W1–C1 1.90(1), W1–C12 1.96(1), C1–O1 1.21(1), C12–O2 1.16(1), B1–C2 1.64(2), B1–C3 1.58(2), C2–C5 1.51(1); C2-B1-C3 121(1), C2-B1-W1 81.9(7), C3-B1-W1 157.0(9), W1-C1-O1 176.1(8), W1-C12-O2 178.1(9).

[**] This work was supported by the Sonderforschungsbereich 247 der Universität Heidelberg and the Fonds der chemischen Industrie. H. W. thanks the Deutsche Forschungsgemeinschaft for a Heisenberg Stipendium.

Although the ^{1}H NMR signals of the agostic methylene groups are not anomalously shifted (singlets at $\delta = 2.41$ (**5**), 2.65 (**6b**), and a quartet at $\delta = 1.03$ (**6a**)), the same groups do show unusual high-field shifts in the ^{13}C NMR spectra ($\delta = -11$ (**5**), -30.2 (**6a**), -14.8 (**6b**)). The spectra are not noticeably temperature dependent between room temperature and 210 K. This implies a low barrier to interchange of the agostic and terminal hydrogen atoms of the methylene groups.[18] The two ethyl groups in **6a** do not change places.

The boryl complexes **5** and **6** are closely related to the cationic carbene complexes **7**[20]. The complexes can be interconverted

$[(tpb')(CO)_2W{=}C(Ph)(CH_2R)]^+$ **7a**, R = H, **7b**, R = Me

according to [Eq. (1)] by isolobal and isoelectronic exchange of the boryl ligand R_2B with the cationic carbene ligand R_2C^+.

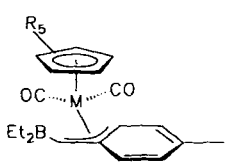
$$L_nM{=}C \longleftrightarrow L_nM{-}C \longleftrightarrow L_nM{-}B \longleftrightarrow L_nM{=}B \qquad (1)$$

The structures of **6b** and **7a** are very similar. The short W–C distance in **7a** (1.94(2) Å, 94% of $\Sigma r_{cov.}$, the sum of the covalent radii[21]) is consistent with a strong metal–carbon π bond.[22] The W–B bond length in **6b** is only 95% of $\Sigma r_{cov.}$. In contrast, the M–B distances in **1** and **2** correspond to almost exactly the sum of the covalent radii (98 and 99%, respectively). Furthermore, all boryl metal complexes $[L_nMBR_2]$ known up to now have ^{11}B NMR signals that are shifted to low-field with respect to the signal of the corresponding free borane $B(alkyl)R_2$, whereas in **5** and **6** high-field shifts ($\Delta\delta \approx 10$) are observed. From these results we deduce that there is significant W–B multiple-bond character in **5** and **6**. The low CO stretching frequencies show, however, that the metal atom is affected by the high electron density[23] from the tpb' ligand, which is principally delocalized over the carbonyl ligands.

Without wishing to imply a mechanism, the formation of **5** and **6** can be viewed as an addition of "$EtBH_2$" to the M–C triple bond, by which the carbyne carbon atom is reduced to a methylene group and the borylene :BEt is inserted into the M–C bond. Triethylborane was detected in the reaction solution, which supports the idea that active ethylborane is probably formed by dismutation of "$EtBH_2$" [Eq. (2)].[24]

$$(Et_2BH)_2 \longrightarrow BEt_3 + \text{"}EtBH_2\text{"} \qquad (2)$$

The Fischer carbyne complexes $[L(CO)_2MCR]$ (M = Mo, W) react with "Et_2BH" to yield very different products depending on L and R. For instance, cyclopentadienyl derivatives ($L = C_5H_5$, C_5Me_5) are hydroborated at the carbyne carbon atom when R is an aryl group.[10] The latter group plays an important role in stabilizing the products **8** and **9** through partial coordination to the metal. In contrast, $[(C_5Me_5)(CO)_2WCMe]$ is reduced to the boron-free ethylene(hydrido) complex **10**[25] probably via the coordinatively unsaturated intermediate **11**.[25, 26] The



8, M = Mo, R = Me
9, M = W, R = H, Me

$[(C_5Me_5)(CO)_2W(C_2H_4)(H)]$ **10** $[(C_5Me_5)(CO)_2W(C_2H_5)]$ **11**

substrates $[(tpb)(CO)_2MC(p\text{-tolyl})]$ with the unsubstituted hydrotris(pyrazolylborate) ligand (tpb) decompose in the presence of "Et_2BH" at 0 °C. Therefore, it can be seen that in the hydroboration reaction carbyne–metal complexes behave very differently to their isolobal organic analogues, the alkynes.

Experimental Section

Typical synthesis procedure: Tetraethyldiborane (310 mg, 4.43 mmol hydride)[28] was added to **4b** (530 mg, 0.83 mmol)[27] in toluene (20 mL). The mixture was heated to 60 °C for 15 min (color change to yellow). After cooling, the solution was concentrated under vacuum and allowed to crystallize at −20 °C. The microcrystalline precipitate was dissolved in a small volume of toluene and chromatographed on a silica column with toluene at −45 °C. The solvent was removed from the eluate under reduced pressure, the residue washed several times with pentane, and then dried under vacuum. Yield 380 mg (67%) of pale yellow powder. Correct C,H,N analysis.

[11] H. I. Schlesinger, L. Horvitz, A. B. Burg, *J. Am. Chem. Soc.* **1936**, *58*, 407. As is the case for all noncyclic organodiborane-6 compounds $B_2H_nR_{6-n}$, tetraethyldiborane-6 is an equilibrium mixture of diboranes differing in their number of alkyl substituents, since the exchange of alkyl groups between the boron atoms is catalyzed by the BH functional groups: R. Köster, G. Bruno, P. Binger, *Justus Liebigs Ann. Chem.* **1961**, *644*, 1.
[12] "Nuclear Magnetic Resonance Spectroscopy of Boron Compounds": H. Nöth, B. Wrackmeyer, *NMR Basic Princ. Prog.* **1978**, *14*, Chap. 4.
[13] The extremely air-sensitive single crystals that are obtained by slow cooling of the reaction mixture contain one (disordered) toluene molecule and half a molecule of tetraethylborane-6 per assymmetric unit [d(B–C) = 1.58(2), 1.62(2) Å; d(B–B) = 1.82(4) Å, C-B-C angle 120(1)°].
[14] Crystallographic data for **6b**·0.5$(Et_2BH)_2$·toluene: triclinic, $P\bar{1}$, a = 10.153(7), b = 11.039(8), c = 18.546(14) Å, α = 98.39(5), β = 96.66(5), γ = 102.29(5)°, V = 1986(3) Å^3, Z = 2. Data collection: Stoe Siemens four-circle diffractometer (203 K, $Mo_{K\alpha}$ radiation, graphite monochromator), ω-scan, $3 \le 2\theta \le 48°$, $-11 \le h \le 11$, $-12 \le k \le 12$, $0 \le l \le 20$, μ = 2.94 mm^{-1}, 6006 measured, 6002 independent reflections. Structure solution: direct methods[15a]; Refinement: least-squares against F^2 (full matrix). All non-H atoms anisotropic, H atoms of the BH and the BHB groups as well as the methylene unit of the benzyl group were localized by difference Fourier synthesis, all other H atoms in calculated positions[15b]. One disordered molecule of toluene per asymmetric unit was refined isotropically with a rigid, idealized benzene ring in two positions (occupation factors 0.6/0.4). A relatively close intramolecular contact exists between B1 and C1 (2.06(2) Å). R = 0.057 (4461 reflections with $F_o \ge 4\sigma(F_o)$), $wR2$ = 0.131 (relative to F^2, all reflections), $w = [\sigma^2(F_o^2) + (0.0526P)^2 + 1.70P]^{-1}$, $P = [\max(F_o^2) + 2F_c^2)/3$, GooF = 1.025. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre

[18] The proton-decoupled ^{13}C NMR spectrum of **6b** contains a triplet with $J(C,H) = 115$ Hz due to the methylene group of the benzyl ligand. Therefore **6b** does not differ substantially from normal alkylboranes in that respect, although a reduction in the C–H coupling constant would be expected for an agostic methylene group. Due to the fast exchange between the two methylene protons however, the value obtained is an average of the ^{13}C–^{1}H coupling constants of the terminal and agostic protons. The relatively large value can be explained by the usual increase in $^{1}J(C,H(terminal))$ when $^{1}J(C,H(agostic))$ becomes smaller[19]; this has been experimentally verified for the carbene complexes **7**[20]. The obvious comparison with the signal of the methylene group of the nonagostic ethyl group in **6** is not possible due to overlap with the methyl signals.

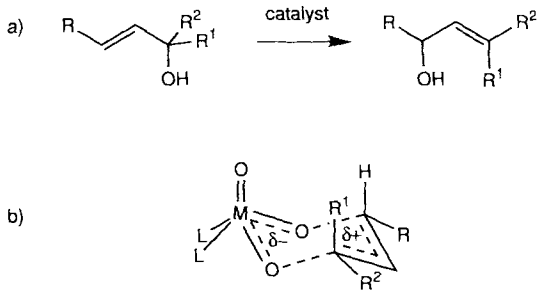
Mechanistic Insights into the Very Efficient [ReO_3OSiR_3]-Catalyzed Isomerization of Allyl Alcohols

Stéphane Bellemin-Laponnaz, Hervé Gisie, Jean Pierre Le Ny, and John A. Osborn*

Dedicated to the late Geoffrey Wilkinson, mentor, inspirer, and friend

The isomerization of allyl alcohols by the 1,3 transposition of an hydroxy group (Scheme 1 a) is catalyzed by certain high oxidation state transition metal oxo complexes, and has been carried out industrially by using [$VO(OR)_3$] or [$WO(OR)_4$] catalysts at high temperatures (ca. 130–200 °C) for the production of terpenic alcohols.[1] Recently Mo and V catalysts have been reported[2, 3] that are active at 25 °C. However, we find that in the case of the MoO_2X_2 complexes (X = Cl, O*t*Bu), slow reduction of the Mo^{VI} center by the alcohol takes place,[3] thereby causing a loss of catalytic activity with time. Based on these observations we have developed dioxomolybdenum(VI) catalysts that under appropriate conditions oxidize allyl and benzyl alcohols selectively to aldehydes.[4]

The proposed mechanism of the isomerization process, however, is still largely dependent on the original insight of Charbardes et al.,[1] and involves a cyclic transition state (Scheme 1 b), akin to that of a Claisen type rearrangement, incorporating a metal oxo unit. Further, we have proposed[3] that



Scheme 1. Catalytic isomerization of allyl alcohols (a) and the proposed cyclic transition state (b).

the efficiency of the [$MoO_2(OR)_2$] catalysts results, in part, from the second oxo group serving as a spectator ligand,[5] helping to stabilize negative charge developed on the metal in the transition state, thereby lowering the activation barrier for the rearrangement. We reasoned that a further increase in the number of oxo ligands around the metal may lead to an even greater stabilization of the charge and thus a more active catalyst system. We present here some catalytic studies on the trioxorhenium complexes [$ReO_3(OSiR_3)$] **1** (R = Me[6]) and **2** (R = Ph[7]), which we found are by far the most efficient catalysts yet known for this isomerization reaction, and thereby have allowed us to obtain further details on the mechanism. Additionally these complexes are considerably more stable towards reduction, giving long-lived catalysts.

For example, using 2.2×10^{-2} M of the rhenium catalyst **1** in acetonitrile at 25 °C, 50 equivalents of hex-1-en-3-ol are isomerized at an initial rate (v_i) of 8 turnovers per min (graphically determined by extrapolation to initial time); the equilibrium[8] with *trans*-hex-2-en-1-ol is reached in less than 10 minutes. This rate is over 10^2 times higher than that observed for the previously described dioxomolybdenum(VI) catalyzed systems under similar conditions which require about 24 h to reach this equilibrium. Even at 0 °C v_i with **1** is 2.5 turnovers per min. The analogous triphenylsiloxy derivative **2** is found to be even more active ($v_i > 10$ turnovers per min at 0 °C; equilibrium is reached in about 5 min). In contrast to the molybdenum catalysts, no degradation of these rhenium systems is observed over 50 h. Further, using **1** and 2-methylbut-3-en-2-ol as substrate, equilibrium with 3-methylbut-2-en-1-ol is obtained in 2 min at 22 °C but, in contrast to the molybdenum catalysts, no concomitant diallyl ether formation is observed.[9] Only after leaving the products in contact with the catalyst over a further two hours are such ethers detectable.

The greater catalytic activity of **2** in comparison to that of **1** results from inhibition caused by the formation of water when **1** is used. ^{1}H NMR studies show that, as expected, the allyl alcohol substrate displaces the R_3SiOH from **1** and **2** but unlike triphenylsilanol, trimethylsilanol condenses rapidly to form hexamethyldisiloxane and water. Indeed, addition of small quantities of water was found to inhibit the catalytic process,

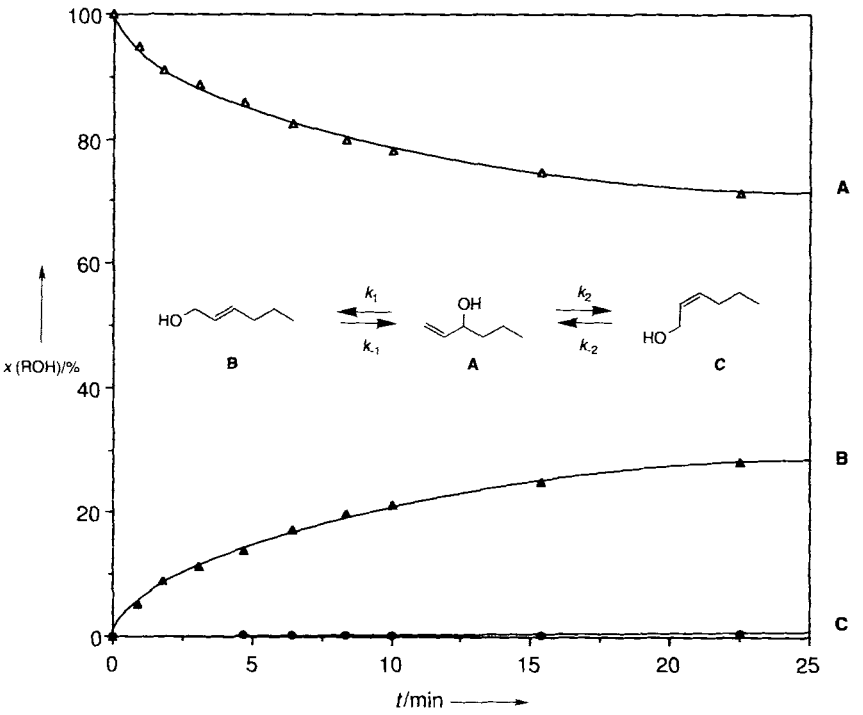

Figure 1. Conversion of **A** into **B** and **C** in CH_2Cl_2 at 6 °C (proportion x [%] of the alcohol in the course of the reaction determined by gas chomatography). Catalyst: **2**,[2] = 4.4×10^{-3} mol L^{-1}, 100 equiv of substrate.

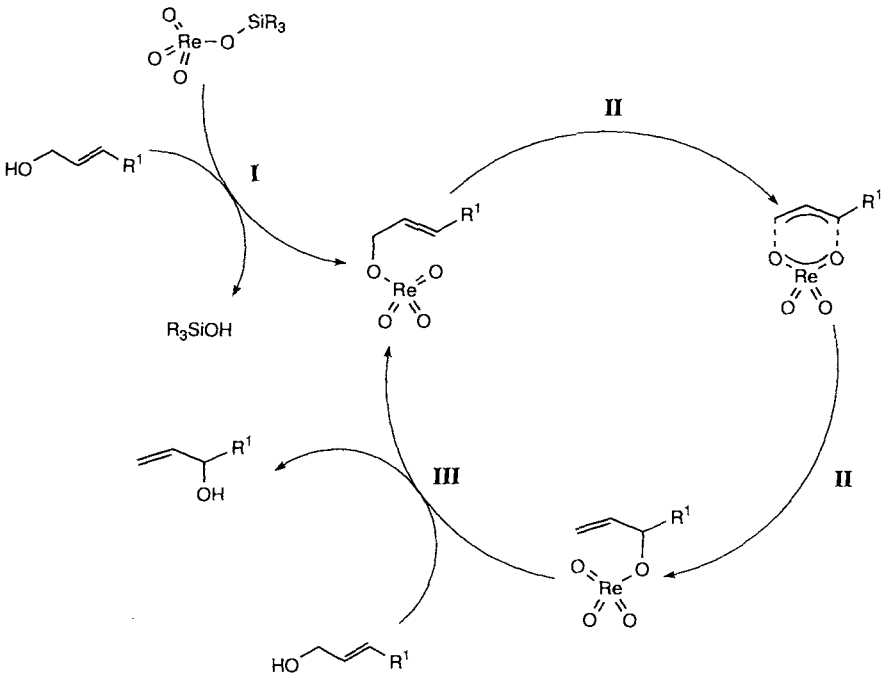
presumably the water competes with the alcohol substrate for a metal binding site leading to the formation of perrhenic acid. The $(Bu_4N)[ReO_4]$/*p*-TsOH combination also catalyzes such isomerizations, but activities were found to be at least an order of magnitude inferior to those reported here and moreover, extensive dehydration of secondary and tertiary alcohols was found to occur.[10]

Kinetic studies were carried out with **2** using each of the three hexenols separately as substrates, and the conversion of a given hexenol into the other two isomers was monitored by gas chromatography (see Figure 1). The most striking observations are 1) the extremely low rate of formation of the *cis*-hex-2-en-1-ol (**C**) ($v_i = 0.07$ turnovers per min) compared with that of the *trans*-hex-2-en-1-ol (**B**) ($v_i = 9.00$ turnovers per min) in the catalyzed isomerization of hex-1-en-3-ol (**A**), and 2) the extremely slow conversion of the *cis* isomer into the other isomers ($v_i = 0.16$ turnovers per min). We have measured the initial rate of isomerization at different concentrations of **2** and the substrate as well as at different temperatures and in several solvents. The kinetic dependence measured at 0 °C in CH_2Cl_2 was found to be given by Equation (a) for all experiments. Consequently, in the presence of an excess of substrate, the kinetic data are consistent with the rearrangement of the allyl moiety in the complex being the rate-determining step (Scheme 2, step II) and not the alcohol exchange step (Scheme 2, steps III and I).

$$v_i = -\,\mathrm{d[substrate]/dt} = k[\mathrm{cat.}]^1[\mathrm{substrate}]^0 \qquad \text{(a)}$$

Thermodynamic activation data were obtained from studies of the initial rates as a function of temperature (between 0 °C and +30 °C). Hence for the formation of **B** from **A**, $\Delta H_1^{\ddagger} = 13.3 \pm 0.3$ kcal mol^{-1} and $\Delta S_1^{\ddagger} = -14.8 \pm 1.0$ e.u., and for the reverse reaction $\Delta H_{-1}^{\ddagger} = 12.4 \pm 0.6$ kcal mol^{-1} and $\Delta S_{-1}^{\ddagger} = -18.3 \pm 2.2$ e.u. The largely negative activation entropy $\Delta S^{\ddagger}$ and the value of $\Delta H^{\ddagger}$ are in agreement with the intervention of a cyclic transition state with some charge separation, that is with a partially positively charged allyl group migrating intramolecularly across a partially negatively charged perrhenate moiety. However, for the slow formation of **C** from **A**, and its reverse reaction, rather higher activation enthalpies ($\Delta H_2^{\ddagger} = 20.9 \pm 0.4$ and $\Delta H_{-2}^{\ddagger} = 24.9 \pm 0.7$ kcal mol^{-1}) and positive activation entropy values ($\Delta S_2^{\ddagger} = 3.1 \pm 1.5$ e.u. and $\Delta S_{-2}^{\ddagger} = 19.3 \pm 2.2$ e.u.) are found. The higher enthalpy values would appear to indicate a greater charge difference and/or separation (distance effect) in the transition state involving the *cis*-hexenol rearrangement; indeed, when more polar solvents are used for the hex-1-en-3-ol rearrangement, the increase in rate of formation of *cis*-hexenol is notably relatively greater than that of *trans*-hexenol. The unexpected positive entropy of activation for the *cis*-hexenol case may result from a quasi-ionic pair transition state, in which the highly positively charged allyl group is well separated from the perrhenate moiety. The reason for this increase in charge separation is unclear. On supposing a cyclohexane-like transition state (Scheme 1), a *trans*-axial interaction between an oxo ligand and the propyl substituent on the migrating allyl group, which will be greater for the *cis* isomer, may



Scheme 2. Proposed mechanism of the $[ReO_3(OSiR_3)]$-catalyzed isomerization of allyl alcohols.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3609-0977 $ 17.50+.50/0

enforce an increase in the charge separation. However, whether an oxo ligand is sufficiently voluminous to have this steric effect is debatable, and calculations are currently underway to resolve this question.[11] Although the greater thermodynamic stability of the *trans* alcohol with respect to that of the *cis* isomer (ca. 1.5 kcal mol^{-1}) could lead to a relative lowering of the transition state free energy (invoking the Hammond postulate), it would be insufficient to account for these effects. Interestingly, in the thermal gas phase rearrangements of allyl esters,[12] in which a similar mechanism involving an allyl migration process is postulated, the *cis* product was also found to be formed at a considerably lower rate than the *trans* isomer.

Overall these results are in good agreement with the model proposed by Charbardes et al., which, however, must be modulated by some rather subtle effects in the charge distribution in the cyclic transition state and its effects on selectivity. It appears that the type of bond formed between the allyl fragment and the perrhenium fragment in the transition state may vary greatly from ionic–covalent to nearly totally ionic.[13] Finally, given the very high activity of these rhenium catalysts under mild conditions, urther modification of the ligand environment, for example by replacing oxo ligands with imido groups, would appear to offer the prospect of both greater catalyst control and selectivity in rearrangements of this type.

$[H_3N(CH_2)_2NH_3]^{2+}_{0.5}[Sn_4P_3O_{12}]^-$: An Open-Framework Tin(II) Phosphate**

Srinivasan Natarajan, Martin P. Attfield, and Anthony K. Cheetham*

The ever-growing family of microporous aluminophosphates, first reported in 1982 by Flanigen et al.,[1] continues to stimulate interest in the synthesis of other phosphate compounds with open-framework structures. More recent examples include the aluminophosphate DAF-1 (two 12-ring channel system),[2] the gallophosphate cloverite (20-membered ring opening),[3] and a number of zinc[4] and indium phosphates.[5, 6] In addition, the rich chemistry of molybdenum and vanadium has been exploited in the synthesis of a variety of similar materials with interesting architectures.[7–10] It is now clear that judicious choice of reaction conditions (such as gel composition, structure-directing agent, and temperature) is necessary for synthesizing new compounds with open-framework structures. We are currently studying the tin/phosphorus system.

Small concentrations of tin can be substituted into the framework of aluminosilicates.[11–14] These materials find use as adsorbents,[11] ionic conductors,[12] and catalysts.[13] A large number of dense tin phosphates are known to exist,[15–21] of which most contain Sn^{IV},[15–17] and only a few Sn^{II}.[18–21] However, we are not aware of any open-framework structures based on tin phosphate. The challenge of synthesizing such a compound with tin in the oxidation state II is all the more interesting because of the lone pair on Sn^{II}. Sn^{II} compounds often adopt layered structures in which the lone pairs are perpendicular to the plane of the layers. Three-dimensional, open-framework structures would be promising materials as catalyts with Sn^{II} as a redox center or a host for base-catalyzed chemical reactions. In addition, open-framework structures offer higher stability and accessibility to guest molelcules than layered materials, which often require post-synthetic treatment such as pillaring to enhance these properties. Here, we report the synthesis and structure of *en*-SnPO-1, the first compound with an open-framework structure based on tin phosphate.

Colorless *en*-SnPO-1 crystallizes in the orthorhombic space group *Pnaa* (see Experimental Section). The structure is based on a network of strictly alternating pyramidal SnO_3 and tetrahedral PO_4 moieties, in which all the vertices are shared; the framework has the formula $[Sn_4P_3O_{12}]^-$. Charge neutrality is achieved by incorporation of the organic template ethylenediamine (en) in its diprotonated form: there are 0.5 $[H_2en]^{2+}$ ions per framework formula unit.

The asymmetric unit of *en*-SnPO-1 contains 21 non-hydrogen atoms (Figure 1a). The framework is constructed from cages containing four eight-membered rings that are linked to form four sides of a cube. The other two faces of the cube consist of a six-membered ring and two edge-sharing, four-membered rings (Figure 1b). The protonated en molecules sit inside these cages on a twofold rotation axis along *c*. The cages are stacked to form an eight-ring channel, in which alternating cages are rotated by 90° (Figure 1c). Four of these channels are connected to each other to define a second channel with squashed twenty-

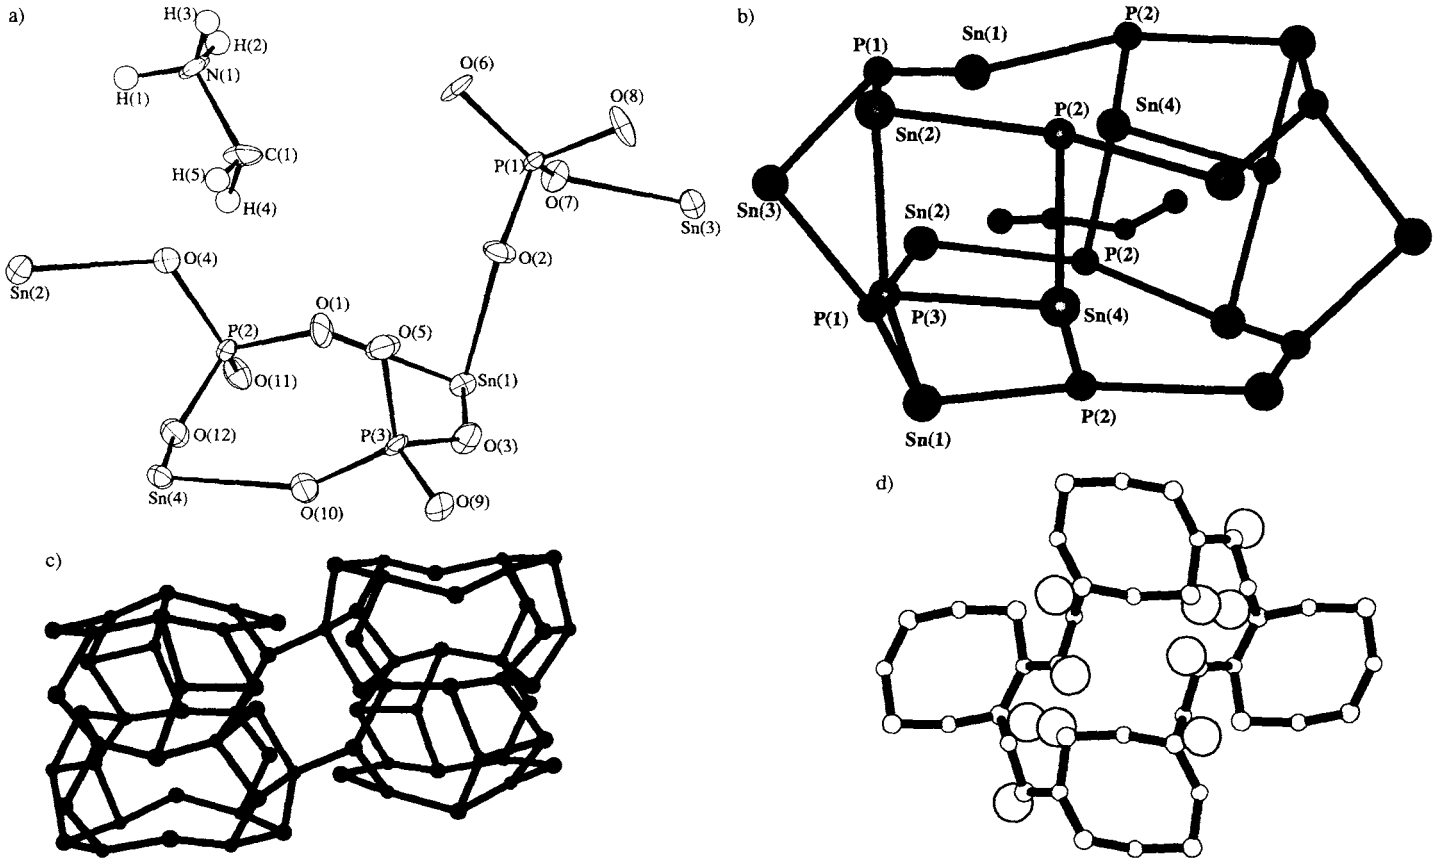

Figure 1. a) Asymmetric unit of *en*-SnPO-1. b) Basic building unit showing the eight-, six-, and four-membered rings; for clarity only the Sn and P atoms are shown. c) The eight-ring channels and the connectivity between them (large sphere = Sn, small sphere = P). d) The squashed twenty-membered ring (large sphere = Sn^{II} lone pair). The eight-membered rings on the left and right lie in one plane and those on the top and bottom in another.

membered rings (Figure 1d). These rings are stacked at right angles to each other, which makes passage through this channel difficult. The central overlapping space of the twenty-membered channel gives it the appearence of an eight-membered channel projecting along the *a* axis (Figure 2). The eight-ring channels also run parallel to the *a* axis and are between 8.5 and 4.8 Å wide (longest and shortest atom–atom contact distances, not including van der Waals radii).

All the Sn atoms are coordinated with three oxygen atoms and occupy the vertex of a trigonal pyramid; the unobserved lone pair presumably occupies the fourth vertex of the tetrahedron. Thus, as the template molecule occupies the eight-membered channel, the lone pair effectively fills up the void in the squashed twenty-membered channel rendering it inaccessible to guest molecules.

All the Sn–O bond lengths are in the range from 2.077 to 2.206 Å (av. 2.12 Å), and the O-Sn-O bond angles are between 78.73 and 94.05° (av. 87.12°), which is typical of tricoordinate Sn^{II}. These values are in excellent agreement with those for other tin phosphates.[18–21] The P–O distances are between 1.515 to 1.546 Å (av. 1.530 Å), and the O-P-O bond angles are in the range of 106.86 to 112.44° (av. 109.5°). These values are comparable to those in many alumino- and gallophosphates.[1, 2, 22, 23]

Thermogravimetric analysis (TGA) of *en*-SnPO-1 was carried out in the presence of oxygen from room temperature to 700 °C. Only one weight loss was observed in the region of 390–450 °C, which corresponds to about 5% of the total mass of the sample and can be directly correlated to decomposition of the occluded en (calculated 4.2%). The powder X-ray diffraction pattern of

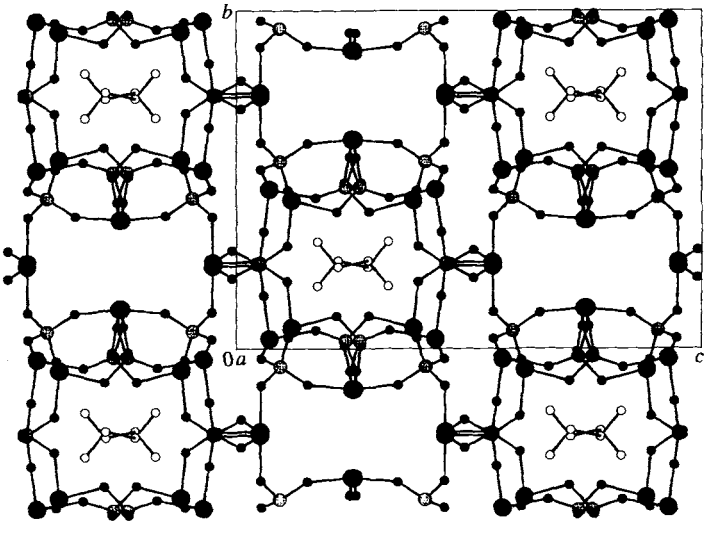

Figure 2. Structure of *en*-SnPO-1 as viewed down the *a* axis. Two of the H_2en^{2+} ions residing inside the eight-ring channels are shown (hydrogen atoms omitted). The squashed twenty-ring channels are unoccupied aside from the Sn^{II} lone pairs.

the decomposed sample indicates a poorly crystalline phase, for which all of the lines correspond to those for the crystalline phase $Sn_2P_2O_7$ (JCPDS: 35–28); it seems likely that an amorphous phase with a Sn:P ratio greater than 4:3 is also present.

The synthesis of a tin phosphate with an open-framework structure has been accomplished. Our efforts to remove the

organic molecule by thermal methods and render the material microporous have not been successful, and we are now pursuing softer chemical techniques (such as Soxhlate extraction). Preliminary results indicate that related structures are formed under hydrothermal conditions with other structure-directing agents.

Experimental Section

The title compound was synthesized from a tin phosphate gel containing en as a structure-directing agent. Tin(II) oxalate (Aldrich), phosphoric acid (85 wt%, Aldrich), en (Aldrich), and water in a ratio of 1.0:1.0:1.0:55 were mixed and stirred until homogeneous. The mixture was sealed in a PTFE-lined, stainless-steel autoclave (Parr, USA) and heated at 160 °C for 2 days under autogeneous pressure. The resulting product, containing predominantly colorless single crystals, was filtered and washed thoroughly with deionized water. A suitable, needle-like single crystal ($0.025 \times 0.025 \times 0.15$ mm) was selected under a polarizing microscope. The crystal structure determination was performed on an Enraf-Nonius CAD4-MACH four-circle diffractometer equipped with a Rigaku rotating anode ($Cu_{K\alpha}$ radiation, $\lambda = 1.5418$ Å). The unit-cell constants were determined from 25 well-centered reflections within $43.0 \leq 2\theta \leq 60.8°$. Crystal data for *en*-SnPO-1: orthorhombic, space group *Pnaa* (no. 56 non-standard setting), $a = 9.7876(7)$, $b = 15.0686(10)$, $c = 20.8523(19)$ Å, $V = 3078.18(1)$ Å^3, $Z = 8$, $M_r = 790.73(1)$ and $\rho_{calcd} = 3.412(1)$. Data were collected at 25 °C with ω-2θ scans and scan width $\Delta\omega = (1.0 + 0.15\tan\theta)°$ extending 25% on each side for background measurement. A total of 3799 reflections were collected at $1 \leq 2\theta \leq 144°$ and merged to give 2819 unique data ($R_{merg} = 3.75$), of which 2304 with $I > 3\sigma(I)$ were considered to be observed. The structure was solved by direct methods with SHELXS-86 [24] and difference Fourier syntheses. Final $R = 3.98$, $R_w = 4.56$, and $S = 1.4$ were obtained for 211 parameters. Absorption correction was carried out with the DIFABS calculation routine. DIFABS minimum and maximum correction: 0.78 and 1.83. Hydrogen atoms on the amine groups were placed geometrically and held in the riding mode. Final Fourier map minimum and maximum: -1.39 and $1.70\ e\text{Å}^{-3}$. Full-matrix, least-squares structure refinement against $|F|$ was carried out with the CRYSTALS [25] program package. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum, Karlsruhe, D-76344, Eggenstein-Leopoldshagen (Germany), on quoting the depository number CSD-405960.

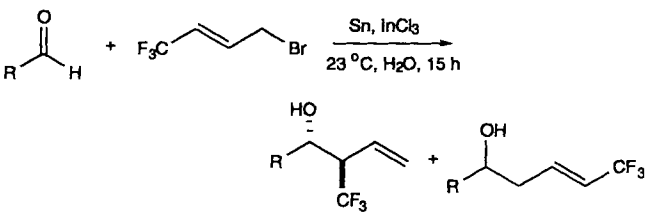
A Highly Stereoselective Synthesis of β-Trifluoromethylated Homoallylic Alcohols in Water**

Teck-Peng Loh* and Xu-Ran Li

Growing interest in trifluoromethylated organic compounds in fields such as medicine, pharmaceuticals, and fluoropolymers has led to a new focus on discovering a facile method for introducing trifluoromethyl groups into useful intermediates or desired substrates.[1] The trifluoromethyl group—with its strong electronegativity, stability, and lipophilicity—often induces considerable changes in chemical, physical, and physiological properties upon the transformed molecule. However, synthetic methods for introducing this group into a special site of organic compounds suffered from low reactivity and selectivity.[2] Consequently, the synthesis of intermediates carrying a trifluoromethyl group is an attractive approach. In connection with our interest in developing a practical method for trifluoromethylation in aqueous solution, we found that β-trifluoromethylated homoallylic alcohols can be easily synthesized by allylation in water. The novel reagent 1,1,1-trifluoro-4-bromobut-2-ene reacted with various aldehydes in the presence of tin and $InCl_3$ to form trifluoromethylated allylated products in high yields and excellent regio- and diastereoselectivities (Scheme 1).



Scheme 1. Synthesis of β-trifluoromethylated homoallylic alcohols in water.

1,1,1-Trifluoro-4-bromobut-2-ene was prepared by reduction of commercially available 4,4,4-trifluorocrotonate (Scheme 2) and bromination of the resulting alcohol with PBr_3. The

product was purified by fractional distillation of the ether extract. The allylation reactions of aldehydes and this trifluoromethylated allylic bromide were performed under optimized conditions,[3] and reactions proceeded very smoothly at room temperature. The results are shown in Table 1.

We discovered that, unlike in our previous work,[3a] $InCl_3$ is essential for tin-mediated allylation (entries 1 and 2). High yields of the coupling products were obtained in all cases, and several characteristic features were observed. 1) This reaction used in this reaction directly (entries 3 and 7). 3) The γ-coupled product was the major one for the described conditions, and the regioselectivity was dependent on the type of aldehyde used. 4) The diastereoselectivity of the reaction was excellent. The *anti* products were the major isomers in most allylation reactions. 5) The *syn* product formed only when 2-pyridinecarboxaldehyde and glyoxylic acid were used.

Table 1. Allylation reaction of aldehydes with 1,1,1-trifluoro-4-bromobut-2-ene [a].

3b J_{H1-H2} = 1.43 Hz

Scheme 3. Determination of the configuration of **1** by chemical manipulation to the corresponding acetonide **3**.

The configuration of the allylation product was confirmed by chemical manipulation to the corresponding acetonide **3** (Scheme 3). Compound **1** was ozonolyzed and then directly reduced to diol **2**,[4] which was allowed to react with 2,2-dimethoxypropane in the presence of a catalytic amount of *p*-TsOH to furnish **3**. The *anti* and *syn* stereochemistry of **1a** and **1b**, respectively, was deduced from the ^1H NMR coupling constant of the axial proton adjacent to both the hydroxy and trifluoromethyl group in **3a** and **3b**.

No allylation occurred in the absence of $InCl_3$, indicating its significance in the transmetalation process.[3a] Interestingly, some α-coupling adduct was produced along with the γ product. Based on the transmetalation mechanism, the α product would form when reactive aldehyde attacked the allyl indium species **4** (Scheme 4). The strong preference for reaction of the *anti* adduct can be explained by the six-membered transition state. The trifluoromethyl group is in an equatorial position and appears to be sterically very bulky. This is consistent with the findings of Corey et al. as well as Kitazume and Yamazaki et al.[5] In contrast, the high *syn* selectivity observed with 2-pyridinecarboxaldehyde and glyoxylic acid indicates that the 2-pyridinyl and COOH groups prefer the axial position. This is probably due to the five-membered ring chelation with indium shown in Scheme 4.

This study provides a highly stereoselective method for synthesizing β-trifluoromethylated homoallylic alcohols, which may be readily transformed into biologically active compounds. Further investigations are in progress for applying this methodology to the synthesis of optically pure trifluoromethyl compounds.

Experimental Section

General procedure for the synthesis of β-trifluoromethylated homoallylic alcohols: The aldehyde (1 mmol) was added to a mixture of tin powder (1.5 mmol), $InCl_3$ (1.5 mmol), and 1,1,1-trifluoro-4-bromobut-2-ene (1.5 mmol) in H_2O (5 mL). The resulting suspension was stirred at room temperature for 15 h. After usual workup, the product was purified by chromatography on silica gel.

1-(3-Pyridinyl)-2-trifluoromethylbut-3-en-1-ol (colorless oil): ^1H NMR ($CDCl_3$): δ(major product) = 2.90–2.94 (m, 1H), 5.07 (d, 1H, J = 17.24 Hz), 5.24(d, 1H, J = 3.23 Hz), 5.37 (d, 1H, J = 10.38 Hz), 5.89–5.96(m, 1H), 7.28 (m, 1H), 7.70 (m, 1H), 8.45 (m, 2H); δ(minor product) = 5.45 (m, 1H); ^{13}C NMR ($CDCl_3$): δ = 148.79, 147.56, 137.22 134.48, 127.02, 126.29, 124.78, 124.26, 123.31, 68.80; ^{19}F NMR ($CDCl_3$): δ = 8.05 (d, CF_3, J = 7.32 Hz); EI-HRMS calcd for $C_{10}H_{10}F_3NO$: 217.07144, found: 217.07261.

$(CuI)_3Cu_2TeS_3$: Layers of Cu_2TeS_3 in Copper(I) Iodide**

Arno Pfitzner* and Stefan Zimmerer

The reactivity of copper(I) halides toward the chalcogens S, Se, and Te is completely different from that of the corresponding silver and gold halides. Thus, up to now for copper halides only compounds containing *neutral* chalcogen fragments, such as screwlike $^1_\infty[Te^0]$ and $^1_\infty[Se^0]$ chains or six-membered Se rings, are known. They can be described as adducts of copper(I) halides and neutral polymeric or oligomeric chalcogen ligands. Typical compositions are CuClTe, $CuClSe_2$, and $CuISe_3$.[1-3] With the exception of AgITe,[4] which also contains neutral Te chains, the corresponding compounds of silver and gold have to be described as mixed chalcogenide halides, that is the chalcogen atoms are *negatively* charged in these compounds. Examples are known containing either divalent anions (Ag_5Te_2Cl[5]) or dianions ($AuTe_2Cl$[6]). In systematic investigations on new adducts of copper halides with neutral polymeric ligands, we recently synthesized ordered mixed-chalcogen chains $^1_\infty[SeTe^0]$ in CuXSeTe (X = Cl, Br, I)[7] and $^1_\infty[STe^0]$ in CuXSTe (X = Cl, Br).[8] In $CuISe_{1.5}Te_{1.5}$ we obtained the hitherto unknown six-membered Se_3Te_3 rings.[9] Compounds of copper(I) halides with phosphorus contain either neutral polymers, for example $^1_\infty[P^0_{12}]$ in $(CuI)_3P_{12}$[10] and $^1_\infty[P^0_{14}]$ in $(CuI)_2P_{14}$,[11] or polyanions, for example $^1_\infty[P^{1-}_{15}]$ in $Cu_3P_{15}I_2$[12] or $^1_\infty[P^{2-}_{20}]$ in $Cu_{12}P_{20}Br_{10}$.[13] Evidently, the copper halide matrix is very flexible and adapts to numerous different ligands.

In an attempt to synthesize the "missing" compound CuISTe, we obtained the first example of a complex chalcogenide ion in the copper(I) halide matrix. Here we report on the synthesis, crystal structure, and spectroscopic investigations of $(CuI)_3Cu_2TeS_3$. This compound crystallizes as large black shiny hexagonal plates and its crystal structure was determined by single-crystal X-ray diffraction.[14] It contains layers of the complex thioanion $[TeS_3]^{2-}$ embedded between layers of iodide ions (Figure 1 left). Thiotellurate(IV) ions have been observed in a limited number of solids, such as $RbCuTeS_3$,[15] $BaTeS_3$,[16] and $(NH_4)_2TeS_3$,[17] and are rarely observed in minerals.[18] In $(CuI)_3Cu_2TeS_3$ all $[TeS_3]^{2-}$ units within one layer are oriented parallel, that is the central tellurium atoms are directed towards one layer of iodide ions and the corresponding sulfur atoms towards another iodide layer. As a consequence the tellurium atoms in the title compound have no additional sulfur atoms as next nearest neighbors but can be regarded as isolated in the copper halide matrix. Nevertheless, no drastic effect on the interatomic distances compared to those in the above-mentioned solids is observed for the $[TeS_3]^{2-}$ group in $(CuI)_3Cu_2TeS_3$ (Figure 2). With an average value of $\bar{d}$(Te–S) = 2.374 Å they fit well with the published data and are about 0.11 Å smaller than the $\bar{d}$(Te–S) distance of 2.48 Å in *neutral* $^1_\infty[STe^0]$ chains.[8] By contrast the average S-Te-S bond angle is 96.35° and is thus about 5° smaller than those in the other examples for thiotellurate(IV) ions and in the *neutral* $^1_\infty[STe^0]$ chains. FT-IR spectroscopy reveals two vibrational frequencies for the $[TeS_3]^{2-}$ group, a strong band at 330 cm^{-1} and a weak one at 374 cm^{-1}. Since the

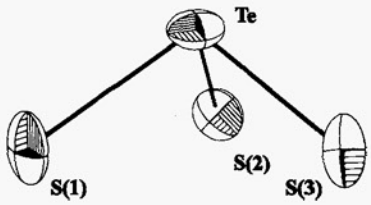

Figure 2. Structure of the thiotellurate(IV) ion in $(CuI)_3Cu_2TeS_3$. Bond lengths [Å] and angles [°]: d(Te–S(1)) 2.376(3), d(Te–S(2)) 2.366(3), d(Te–S(3)) 2.381(3); S(1)-Te-S(2) 97.26(11), S(1)-Te-S(3) 94.82(10), S(2)-Te-S(3) 96.81(11). The ellipsoids are drawn at a probability level of 90%.

amount of spectroscopic data for the $[TeS_3]^{2-}$ group is limited,[15] it is not possible to draw conclusions with regard to a change of bonding properties within this complex anion. The geometry of the $[TeS_3]^{2-}$ ion fits perfectly to that of the iodide layers (Figure 1 right). Therefore, this reduction of the angle might be explained by packing effects.

As already mentioned, the crystal structure of $(CuI)_3Cu_2TeS_3$ is composed of layers of iodide and $[TeS_3]^{2-}$ ions. From a topological point of view the sheets of iodide can be described as edge-sharing iodoiodate(–1) octahedra, and a composition of $[II_{6/3}]^{3-} = [II_2]^{3-}$ results. Thus, the iodide layers can be regarded as analogous to those in CdI_2. The central iodine atoms I(1) and I(2) are coordinated by iodine I(3) and I(4), respectively, with distances d(I–I) > 4.2 Å. Due to the mutual orientation of the thiotellurate(IV) and the iodide sheets the height of the iodide layers around I(1) and I(2) differs significantly. Since layer 1 (around I(1)) is only surrounded by S^{2-} ions—copper atoms are neglected here—it seems to be compressed to a resulting height of 1.63 Å. Electrostatic interactions between Te^{4+} and I^- lead to a height of 2.78 Å for layer 2 (around I(2)). Nevertheless, no direct contacts between tellurium and iodine occur (d(Te–I) > 3.7 Å).

Copper atoms are distributed over a large number of voids in the arrangement of iodine and sulfur atoms. Thus, polyhedra such as $[CuS_2I]$, $[CuSI_2]$, $[CuS_2I_2]$, and $[CuSI_3]$ result. Coordination of copper exclusively by iodide or sulfide ions is not observed. The distances range from $2.118 \leq d(Cu–S) \leq 2.31$ Å and $2.453 \leq d(Cu–I) \leq 3.10$ Å. Six tetrahedral and five trigonal voids are occupied by copper. Nevertheless, summation of the occupation factors shows some preference for the trigonal coordination. Only one copper position is fully occupied, yielding a $[CuS_2I]$ triangle. Full occupation of all three-coordinate copper positions would result in the correct composition $(CuI)_3Cu_2TeS_3$. Taking only these positions into consideration, a network of six-membered rings consisting either of Cu and S or of Cu, Te, S, and I results (Figure 3 left). Within the unit cell three blocks separated by I(2) are stacked along [001]. Since these blocks are rotated by 120°, a relatively large c axis of 38.832 Å is observed. Coordination of copper is different around the two iodide layers (see Figure 1 left). Thus, for layer

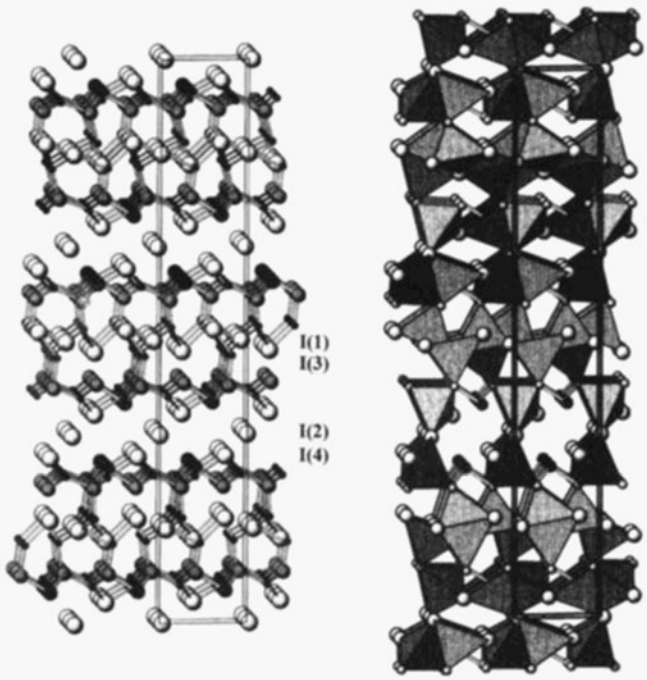

Figure 3. Crystal structure of $(CuI)_3Cu_2TeS_3$ showing only three-coordinate copper atoms (left), building blocks are separated by I(2) atoms, and the framework of tetrahedrally coordinated copper ions (right), view along [010]. The channels in the structure are clearly evident. Cu: small dark spheres, Te: large dark spheres, S: dark grey spheres, and I: light grey spheres.

1 two iodine atoms (I(1) and I(3)) and one sulfur atom form the threefold coordination sphere, whereas for layer 2 copper is surrounded by two sulfur and only one iodine atom (I(4)). The central I(2) of layer 2 does not bond to three-coordinate copper. This fact and the well known flexibility of copper with respect to its trigonal or tetrahedral environment[20] can be regarded as the reason for the pronounced disorder of the copper atoms. Thus, several tetrahedral voids are partly occupied (Figure 3 right). The composition of these tetrahedra and their linkage is different for the two iodine layers. Around layer 1 they consist of one S, one I(1), and two I(3) atoms. These tetrahedra are linked through a common face to form trigonal bipyramids, in which copper partially occupies two positions. The bipyramids are linked through common corners. Around layer 2 the tetrahedral voids are built up by two S and two I atoms (I(2), I(4)). These tetrahedra share common edges (I(2), S(2)) and common corners. Temperature-dependent structure analyses and thermoanalytical investigations are in progress to check whether the disorder of copper in the title compound is dynamic in nature.

A fourfold, almost planar coordination by copper with distances $d(\mathrm{I(2)-Cu}) \approx 2.76$ Å is found for I(2). This results in channels in the crystal structure of $(CuI)_3Cu_2TeS_3$, in which one expects the lone pairs of the Te^{4+} ions to be situated (Figure 3 right).

Due to the strong two-dimensional character of $(CuI)_3Cu_2TeS_3$ this compound can be regarded as a composite material of the hitherto unknown Cu_2TeS_3 and CuI. Only one compound of similar composition, namely $Cu_{17.6}Te_8S_{26}$[21] $\approx 8 \times Cu_2TeS_3$, is known; however, it has a completely different structure that is closely related to that of the tetrahedrite type.[22]

We have some experimental evidence for the existence of similar compounds $(CuI)_nCu_mM^{(6-m)+}S_3$, with M for example As, Sb. Given that these colored materials also crystallize in acentric space groups interesting physical properties are to be expected.

Experimental Section

Pure $(CuI)_3Cu_2TeS_3$ was prepared by reaction of stoichiometric amounts of CuI, Cu, Te, and S (CuI:Cu:Te:S = 3:2:1:3) in evacuated quartz ampoules. After a period of 7 d at a temperature of 400 °C, black shiny hexagonal platelets with edges of up to 3 mm were obtained. The samples were characterized by powder X-ray diffraction and FT-IR spectroscopy. In addition to the characteristic vibrations of the $[TeS_3]^{2-}$ ion at 330 (s) and 374 (w) cm^{-1} a very broad band was observed around 125 cm^{-1}, which is probably to be assigned to Cu–I vibrations. From selected crystals the composition was determined by semiquantitative EDX analyses (EDX = energy dispersive X-ray analysis): Cu:I:Te:S = 0.40:0.23:0.09:0.28 (calc: 0.417:0.250:0.083:0.250).

Intermediates in the Intermolecular, Asymmetric Heck Arylation of Dihydrofurans**

King Kuok (Mimi) Hii, Timothy D. W. Claridge, and John M. Brown*

We recently reported the observation of a reactive alkylpalladium intermediate in the arylation of methyl acrylate with aryl triflates and its relationship to earlier and later species in the catalytic cycle.[1] This encouraged us to turn our attention to the intermolecular, asymmetric Heck reaction in the hope of gaining insight into the mechanism and origin of stereoselectivity.[2]

The most impressive examples in this class remain the arylation of dihydrofuran catalyzed by Pd–BINAP complexes discovered by Hayashi, Ozawa, and co-workers[3] and a series of closely related reactions. A consistent feature of this work, noted earlier by Larock et al.,[4] is the requirement for double-bond isomerization to release Pd and regenerate the catalyst. For phenylation of 2,3-dihydrofuran (**1**), this can lead to the 2,5-dihydrofuran **2** or to the doubly isomerized 2,3-dihydrofuran **3**. Characteristic of Hayashi's asymmetric synthesis is that the

[**] We thank the EPSRC for postdoctoral support for K. K. H. and Johnson–Matthey for the loan of palladium salts. Dr. H. Doucet kindly helped with assays of enantiomeric purity.

product ratio and *ee* values depend on a subtle interplay of catalyst precursor, solvent, and base, in which the predominant product **3** gains in enantiomeric enrichment at the expense of the singly isomerized product **2** as the yield of the latter increases.[5] With diphenylphosphinoaryloxazoline ligands,[6] high *ee* values are obtained but arylated 2,5-dihydrofuran is the predominant product.

Following the protocols of earlier work[1] the aryl triflate **4a**, derived from (*S*)-BINAP ($\delta_P = 14.6$, 34.6; $J(P,P) = 35$ Hz; Scheme 1) was allowed to react with 2,3-dihydrofuran in THF at -70 to $-40\,^{\circ}C$. The reaction was followed by ^{31}P NMR spectroscopy (Figure 1). A single, new species **5a** was cleanly formed ($\delta_P = 22.5$, 37.0; $J(P,P) = 31$ Hz), which was stable in this temperature range but slowly decomposed at $-30\,^{\circ}C$ to form **6a** ($\delta_P = 22.4$, 38.7; $J(P,P) = 34$ Hz) and **6a′** ($\delta_P = 19.4$, 37.8; $J(P,P) = 27$ Hz), each associated with two low-field protons in the ^1H NMR spectrum, in comparable amounts with concomitant release of (*S*)-2-phenyl-2,3-dihydrofuran (**3**, 91 %*ee*). With the aid of electrospray mass spectrometry **5a** was identified as the formal product of Pd–Ph addition to the dihydrofuran (*m/z* 876), and **6a** and **6a′** as the products of addition of Pd–H to the dihydrofuran (*m/z* 800).

The structure of the first intermediate **5a** was determined by one- and two-dimensional NMR techniques and corroborated by a parallel reaction between **4a** and [2-D]**1**.[7] At $-35\,^{\circ}C$ the ^1H NMR displays six different, highly coupled, multiplet signals, each integrating for one proton. Connectivities between these protons and the carbon skeleton were established by TOCSY as well as phase-sensitive DQFCOSY and HMQC. Remarkably, the Pd atom has migrated from its original position at C3 by a double dyotropic shift, which must occur intramolecularly since there is no exchange with excess **1**. A complete assignment is as follows. Two low-field proton signals are observed. The ABX multiplet centered at $\delta = 5.5$ is assigned to H5 since it is absent in the sample generated from [2-D]**1**; the resonance at $\delta = 5.3$ is due to H2. The ^{13}C chemical shift of C2 is at very low field for a carbon atom that is σ-bonded to a metal center and implies significant oxonium ion character, as in **7**. The lack of large coupling of H2 to either proton on C3 is consistent with a φ-axial C–Pd bond, whereas H5 is clearly axial on the basis of the 12 Hz coupling to one H4 proton. Through-space interactions were studied with 1-D gradient ROESY (GROESY, which is effective since the gradients cleanly remove signals due to solvents and excess 2,3-dihydrofuran).[8] Given the ease with which complex **5a** is formed and the implications for the relative stability of the possible alkylpalladium species, there is a surprising paucity of crystallographic models for potentially anomeric C–M bonds in cyclic ethers.[9] However, in

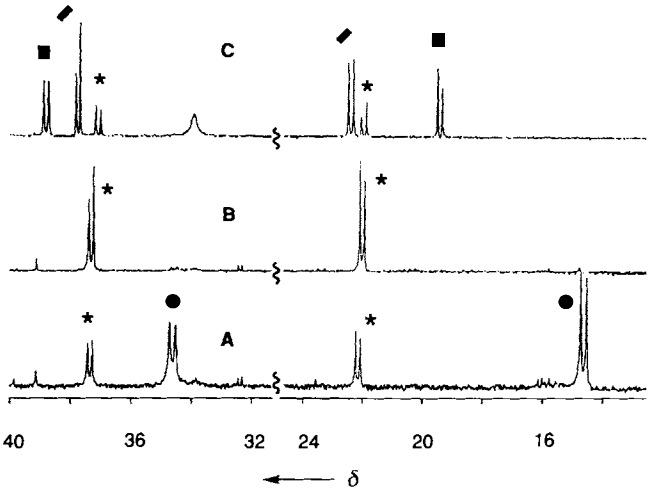

Figure 1. ^{31}P NMR spectra of the reaction sequence between **4a** and **1**; complex **4a** ●, complex **5a** *, complex **6a** ■, complex **6a′** ◢. A) Partial conversion of **4a** to **5a** at $-50\,^{\circ}C$; B) after complete formation of **5a** at $-40\,^{\circ}C$; C) nearly complete decomposition of **5a** at $-30\,^{\circ}C$ to form **6a** and **6a′**; a peak due to an impurity is at about $\delta = 34$. The downfield phosphorus atom is P_a.

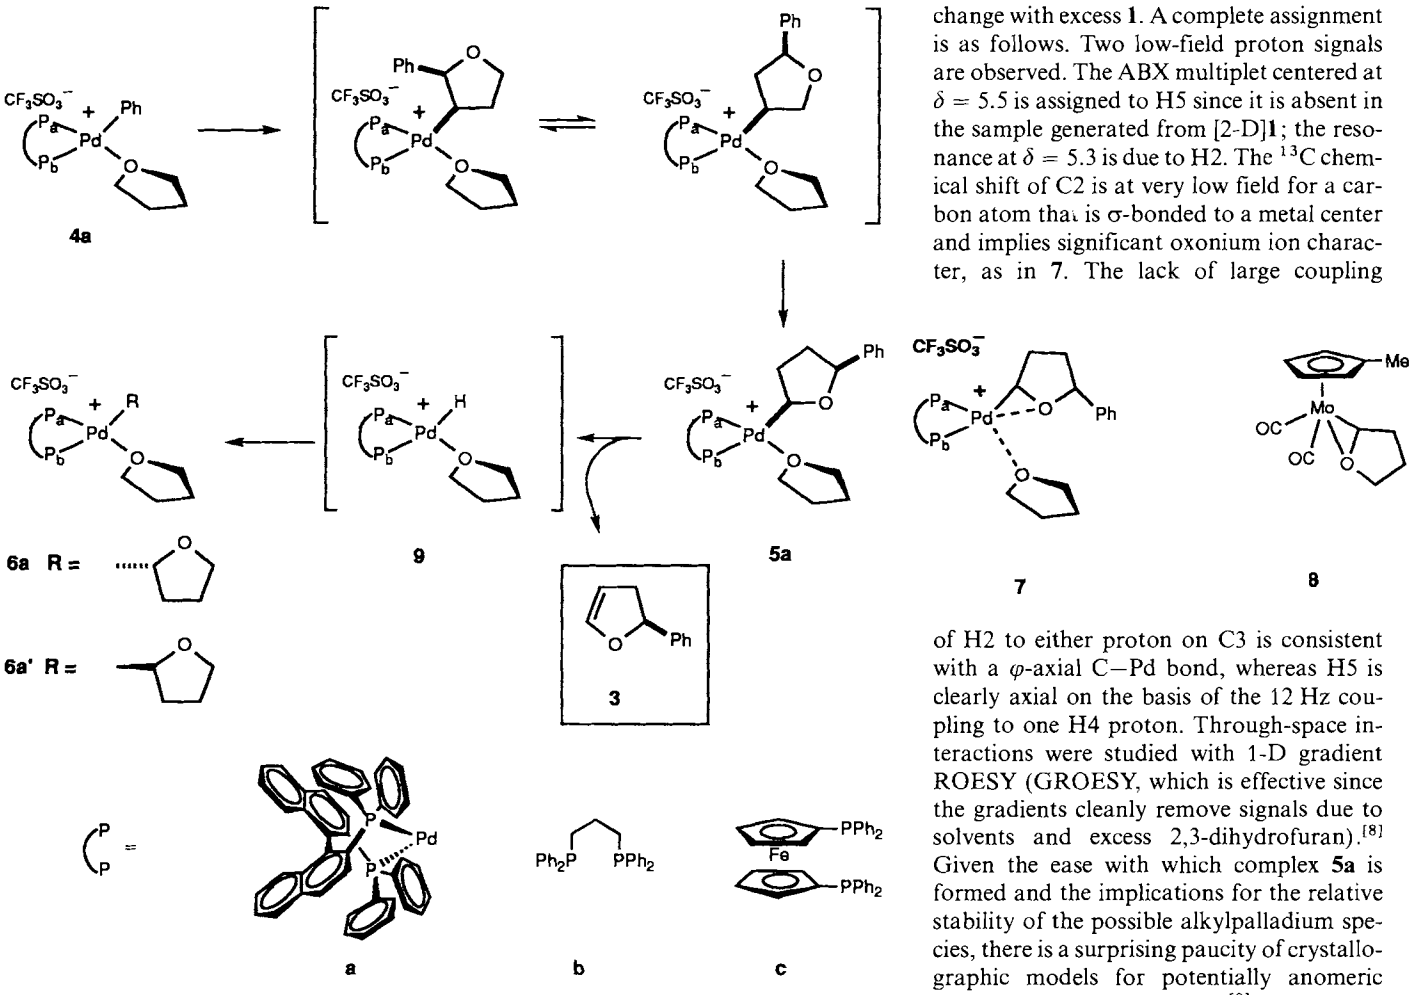

Scheme 1. Sequence of intermediates for the (*S*)-BINAP complex **4a** (similar for **b** and **c**).

8 the oxygen atom occupies a vacant coordination site to give a metallaoxacyclopropane structure. This cannot be ruled out in the present case, and the 8 Hz five-bond coupling between P_a and H2 strengthens the case for σ contact between the palladium and oxygen centers. Taking the evidence in sum provides a unique structure and conformation (Figure 2). An O1–C2 half-chair conformation for the five-membered ring is supported by the three contiguous ax–ax ^3J(H,H) couplings and the observed NOE between H3 (ax) and H5.

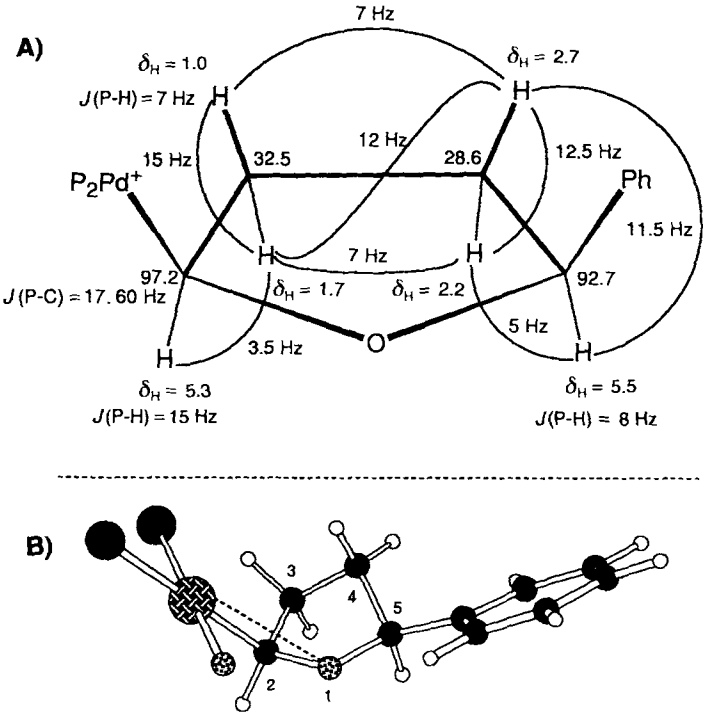

Figure 2. A) ^{13}C and ^1H NMR chemical shifts as well as J(H,H), J(H,P), and J(C,P) for **5a** in [D_8]THF at −40 °C. The experimental spectrum was matched against δ and J values simulated with gNMR [11]. B) Chem-3D model in a minimized conformation based on the NMR data.

The formation of two isomers of **6a** in comparable amounts concurrent with the disappearance of **5a** indicates decomposition to **3** and the Pd–H complex **9**. Further addition of **1** (Scheme 1) occurs with regiochemistry opposite to that of Pd–Ph addition of the first step. As before, it was possible to assign some of the NMR signals of the two diastereomers,[10] thereby demonstrating the structural similarity between **5** and **6**. When [2-D]**1** is employed, the H2 signal is absent in both **6a** and **6a′**, which demonstrates that the Pd–H addition is not stereospecific, and migration of palladium between C2 and C5 does not occur.

Similar observations were made when the triflates **4b** and **4c**, derived from 1,3-bis(diphenylphosphino)propane (dppp) and 1,1′-bis(diphenylphosphino)ferrocene (dppf), respectively, were employed, but without the potential complexity of diastereoisomerism in the alkyl intermediates. The palladium complex **5b** was found to be less thermally stable. At −60 °C β-H elimination occurred at a rate comparable to that of alkyl formation to give the turnover products **3** and **6b**. The dppf complex **5c** is stable up to −40 °C and was characterized by NMR spectroscopy. Its ^1H NMR spectrum is similar to that of the BINAP analogue **5a**, but the corresponding complex **6c** exhibits interesting dynamic NMR behavior. Unlike all related complexes, the two ^{31}P nuclei exchanged above −50 °C, and the signal for H2 broadened from the A component of an AMX system at the low-temperature limit towards the A component of an AMX_2 system; the AX coupling was halved. This is most simply explained by the process shown in Scheme 2 ($k_1 \approx 40\ s^{-1}$ at −40 °C),[11] since it formally requires that the alkyl group exchanges intramolecularly between adjacent sites on the square plane. There is evidence for stereochemical lability in square-planar hydrides of d^8 metals.[12]

What is the relationship of these intermediates to the catalytic asymmetric Heck reaction? The observed regiochemistry in catalysis depends on the base employed; the maximum *ee* and, concomitantly, the lowest ratio of **3** to **2** is associated with 1,8-bis-(dimethylamino)naphthalene.[5] When the NMR experiment was repeated in the presence of a twentyfold excess of this base, formation of **5** proceeded as before, but **6a** and **6a′** were not observed. Therefore, the base competes successfully for Pd–H under these conditions. A catalytic reaction (5 mol% Pd, $Me_2NC_{10}H_6NMe_2$, THF, 40 °C, 140 h) with **4a**, prepared in situ led only to doubly isomerized **3** in 78% *ee*, but using $Pd(OAc)_2$ and (*S*)-BINAP under otherwise identical conditions gave (*S*)-**3** (86% *ee*) as well as (*R*)-**2** (55% *ee*).[13] Careful examination of the initial ^1H NMR spectrum of **5a** indicates that trace amounts (<5%) of other transient species are observed below −40 °C concurrent with or immediately subsequent to formation of **5a**. We speculate that they arise from the less favored (*S,R*)-diastereomer of the initial Pd–Ph addition product. The observed *ee* of **3** (91%) under stoichiometric conditions at −40 °C reflects the enantioselectivity of the alkene addition step and correlates reasonably with the value (78%) obtained with **4a** as catalyst.

The strong driving force towards an α-oxoalkyl palladium intermediate points to the possibility of a second route for catalysis under Hayashi–Ozawa conditions, which favors the opposite enantiomer and is less disposed to double isomerization.[14] We note the precedent for two competing catalytic pathways with opposite enantioselectivity in earlier asymmetric Heck chemistry[15] and consider that a parallel study of the singly isomerizing P–N palladium catalysts[6, 16] will be enlightening.

Experimental Section

Enantiomeric excesses were determined by gas chromatography, with a 25 m, CHIRAL-DEX-bonded silica column. Electrospray MS was performed by Dr. H. E. K. Matimba and Dr. R. T. Aplin. All NMR spectra were recorded on a Bruker AMX 500 spectrometer (^{1}H: 500 MHz) with an inverse gradient probe at low temperatures; the heteronuclear experiments (^{31}P: 202 MHz, ^{13}C: 125 MHz) were carried out with a broad-band probe. TOCSY was performed with the MLEV-17 spin lock (8.3 kHz) with a mixing time of 70 ms (bracketed by 2.5 ms "trim pulses"). Signals for a modified 1-D gradient ROESY (GROESY) were selected by 25 ms Gaussian 180° pulses with application of a continuous-wave spin lock (2.6 kHz), a relaxation delay, and mixing times of 4 s and 300 ms. The gradients used were 14: -6: -20% of the maximum gradient strength (about 45 G cm^{-1}).

Typical procedure for preparing samples for in situ NMR experiments: Silver triflate (0.006 g, 0.02 mmol) was added to a vigorously stirred solution of [(*S*)-(BINAP)Pd(Ph)(I)] [17] (0.020 g, 0.02 mmol) in [D$_8$]THF (0.5 mL) at -78 °C. Stirring was continued for 10 min, during which time a white precipitate formed. The suspension was centrifuged cold, and the pale colored liquid rapidly decanted over a cannula into a 5 mm NMR tube containing 2,3-dihydrofuran (10 µL, 0.13 mmol, excess) at -78 °C. The tube was transferred to the pre-cooled probe, and spectra measured as described.

Zirconocene-Benzyne-Mediated Intramolecular Coupling of Bis(alkynyl)phosphane: A Way to Mono- and Tricyclic 1,2-Dihydrophosphetes**

Laurence Dupuis, Nadine Pirio, Philippe Meunier,* Alain Igau, Bruno Donnadieu, and Jean-Pierre Majoral*

In recent years, much attention has been paid to the chemistry of zirconocene complexes,[1] which show versatile behavior in a number of coupling and insertion reactions. The zirconocene synthon [Cp$_2$Zr] has, for example, promoted intramolecular coupling of alkynyl groups with formation of cyclic derivatives,[2] coupling of diynes with generation of zirconacyclic cumulenes,[3] and cleavage of the central C-C single bond of butadiynes.[3, 4] Insertion of acetylenic systems into zirconocene-benzyne has also been described,[5] but to our knowledge, there is no example of a reaction of dialkynes with zirconocene-aryne complexes.

Here we report a novel, intramolecular coupling reaction of a dialkynylphosphane (tBuP(C≡C-Ph)$_2$) and zirconocene-benzyne, which provides unusual 1,2-dihydrophosphete-zirconium complexes. One of these complexes is a useful reagent for the synthesis of a stilbene tricyclic system and a 1,2-dihydrophosphete bearing an exocyclic carbon-carbon double bond.

Addition of bis(alkynyl)phosphane **2** to one equivalent of the transient benzyne complex [Cp$_2$Zr(η^2-C$_6$H$_4$)] (**1a**), generated in situ by thermolysis of a solution of [Cp$_2$ZrPh$_2$] in toluene at 80 °C over 24 h, resulted in the unexpected zirconacycle **3a** in 65% yield ($\delta(^{31}P) = 59.9$, Scheme 1). Complex **3a** was fully characterized by usual methods, but identification based only on spectroscopic data was uncertain (Table 1). The molecular

Table 1. Selected spectroscopic data for **3a**, **3b**, **4**, and **5** (correct mass spectra or/and elemental analyses were obtained) [a].

3a: $^{31}P\{^1H\}$ NMR (82 MHz, $CDCl_3$): $\delta = 59.9$; ^1H NMR (200 MHz, $CDCl_3$): $\delta = 0.74$ (d, 9H, $^3J(H,P) = 11.3$ Hz, *t*BuP), 6.26 (d, 5H, $^5J(H,P) = 0.6$ Hz, Cp), 6.56 (d, 5H, $^5J(H,P) = 0.6$ Hz, Cp); $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$): $\delta = 28.2$ (d, $^2J(C,P) = 12.0$ Hz, CCH_3), 33.2 (d, $^1J(C,P) = 29.8$ Hz, CCH_3), 112.6 (s, Cp), 112.7 (s, Cp), 140.0 (d, $J(C,P) = 13.9$ Hz), 140.9 (d, $J(C,P) = 6.7$ Hz), 142.2 (d, $J(C,P) = 10.1$ Hz), 143.1 (d, $J(C,P) = 6.2$ Hz), 150.1 (d, $J(C,P) = 6.2$ Hz), 163.9 (d, $J(C,P) = 2.4$ Hz), 184.5 (s, ZrC), 214.4 (d, $J(C,P) = 4.3$ Hz, ZrC).

3b: $^{31}P\{^1H\}$ NMR (82 MHz, C_6D_6): $\delta = 61.6$; ^1H NMR (200 MHz, C_6D_6): $\delta = 0.93$ (d, 9H, $^3J(H,P) = 10.8$ Hz, *t*BuP), 1.02 (s, 9H, *t*BuCp), 1.13 (s, 9H, *t*BuCp), 5.74, 5.79, 5.87, 5.95, 6.21, 6.28, 6.41 (7 pseudo-q, 7 × 1H, *t*BuCp), the eighth pseudo-quadruplet is masked by multiplets due to aromatic protons; $^{13}C\{^1H\}$ NMR (50 MHz, $CDCl_3$): $\delta = 28.5$ (d, $^2J(C,P) = 12.0$ Hz, $PCCH_3$), 30.9 (s, $CpCCH_3$), 31.6 (s, $CpCCH_3$), 33.3 (s, $CpCCH_3$), 33.6 (d, $^1J(C,P) = 31.4$ Hz, $PCCH_3$), 33.9 (s, $CpCCH_3$), 103.4, 105.3, 106.1, 110.6, 111.2, 111.3, 114.0, 118.6 (8s, *t*BuCp), 140.9 (d, $J(C,P) = 13.8$ Hz), 141.2 (s), 142.0 (d, $J(C,P) = 4.6$ Hz), 142.7 (d, $J(C,P) = 10.2$ Hz), 143.5 (d, $J(C,P) = 5.5$ Hz), 145.7 (s), 150.5 (s), 164.1 (s), 184.8 (s, ZrC), 214.2 (d, $J(C,P) = 4.3$ Hz, ZrC).

4: $^{31}P\{^1H\}$ NMR (82 MHz, C_6D_6): $\delta = 39.8$; ^1H NMR (200 MHz, C_6D_6): $\delta = 0.92$ (d, 9H, $^3J(H,P) = 11.7$ Hz, *t*BuP), 1.40 (d, 1H, $^2J(H,P) = 15.1$ Hz, =CH); $^{13}C\{^1H\}$ NMR (50 MHz, C_6D_6): $\delta = 27.8$ (d, $^2J(C,P) = 12.3$ Hz, $PCCH_3$), 32.4 (d, $^1J(C,P) = 27.0$ Hz, $PCCH_3$), 135.5 (s), 136.3 (d, $J(C,P) = 10.2$ Hz), 136.6 (d, $^2J(C,P) = 10.2$ Hz, PCCH), 138.1 (d, $J(C,P) = 6.5$ Hz), 140.9 (d, $J(C,P) = 5.5$ Hz), 142.3 (s), 154.6 (d, $J(C,P) = 5.5$ Hz).

5: $^{31}P\{^1H\}$ NMR (82 MHz, $CDCl_3$): $\delta = 73.7$; ^1H NMR (200 MHz, C_6D_6): $\delta = 0.77$ (d, 9H, $^3J(H,P) = 11.7$ Hz, *t*BuP); $^{13}C\{^1H\}$ NMR (50 MHz, $CDCl_3$): $\delta = 27.6$ (d, $^2J(C,P) = 12.3$ Hz, $PCCH_3$), 33.5 (d, $^1J(C,P) = 27.0$ Hz, $PCCH_3$), 134.1 (s), 135.1 (d, $J(C,P) = 2.3$ Hz), 137.1 (d, $J(C,P) = 8.1$ Hz), 137.3 (d, $J(C,P) = 5.0$ Hz), 137.4 (d, $J(C,P) = 11.6$ Hz), 140.1 (s), 140.2 (d, $J(C,P) = 3.5$ Hz), 140.7 (s), 147.0 (d, $J(C,P) = 6.9$ Hz), 163.3 (d, $J(C,P) = 5.8$ Hz).

[a] All NMR spectra were recorded at 25 °C on a Bruker AC 80, AC 200, or Bruker WM 250 instrument. ^{31}P: external 85% H_3PO_4 ($\delta = 0$), ^1H and ^{13}C: external $(CH_3)_4Si$ ($\delta = 0$).

structure of **3a** was established by X-ray crystallography (Figure 1).[6] In this tricyclic molecule zirconium is included in a six-membered ring, and phosphorus in a four-membered ring.

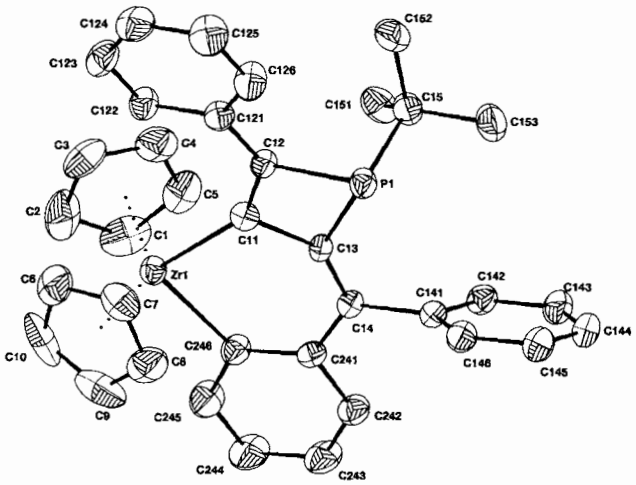

Figure 1. X-ray crystal structure of **3a** (thermal ellipsoids at 50% probability). Selected bond lengths [Å] and angles [°]: Zr1–Cp1 2.218(6), Zr1–Cp2 2.208(6), Zr1–C246 2.289(9), C246–C241 1.40(1), C241–C14 1.49(1), C14–13 1.36(1), C13–C11 1.53(1), Zr1–C11 2.229(8), C11–C12 1.37(1), P1–C12 1.835(8), P1–C13 1.844(8); Cp1-Zr1-Cp2 136.1(2), C246-Zr1-C11 91.7(3), Zr1-C11-C13 115.3(5), Zr1-C11-C12 148.0(6), C12-C11-C13 96.7(7), C11-C13-P1 92.7(5), C11-C12-P1 98.7(5), C13-P1-C12 72.3(3). Cp1 and Cp2 are the gravity centers of the cyclopentadienyl rings.

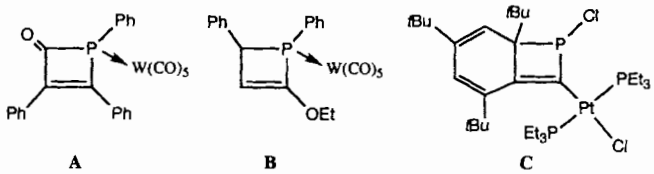
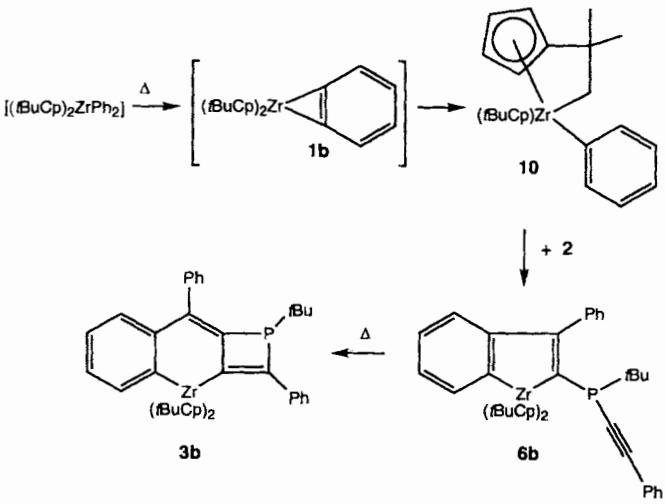
All the atoms of the three cycles lie in the same plane. The Cp1-Zr1-Cp2 (136.1(2)°) and C246-Zr1-C11 (91.7(3)°) angles are typical of a bent metallocene.[7] The bond length between the sp^2 ring carbon and phosphorus atoms (1.844(8) Å) is as expected for a C–P single bond (1.85 Å). This is in marked contrast to the values for dihydrophosphetes **A**,[8] **B**,[9] and **C**,[10] for which a very weak P–C bond was detected (1.93(1), 1.902(5), and 1.911(6) Å, respectively).



Treatment of **3a** with HCl conveniently provided phosphete **4** (Scheme 1), a polyunsaturated cyclic phosphane,[11] by cleavage of the two Zr–C bonds. The exchange reaction of **3a** with $PhSbCl_2$ led to the corresponding tricyclic **5** (Scheme 1). The transformation was diastereospecific, as indicated by the singlet in the ^{31}P NMR spectrum of the crude product. Reaction of the more hindered $[(tBuCp)_2Zr(\eta^2\text{-}C_6H_4)]$ (**1b**) and **2** in toluene at 90 °C for 20 h led to the zirconacycle **3b** in 87% yield (Scheme 2). Its ^{31}P NMR signal ($\delta = 61.6$, Table 1) was similar



Scheme 2. Evidence for presence of **6b** in the synthesis of **3b**.

to that of **3a**. We and others have demonstrated[12] that the cyclometalated complex **10**, resulting from C–H bond activation of the methyl substituent of a *tert*-butyl group, often reacts at lower temperatures than zirconocene–benzyne. This prompted us to treat **2** with a freshly prepared solution of **10** in toluene at room temperature: the 2-(alkynyl)phosphinozirconaindene **6b** was obtained in near quantitative yield after stirring for 21 h (Scheme 2). The ^{31}P chemical shift ($\delta = -16.6$) was in the expected range, and the IR spectrum shows a band at 2172 cm^{-1} clearly indicating the presence of a P–C≡C group. Thermolysis of **6b** for 24 h at 80 °C in benzene gave **3b**.

Therefore, the first step of the reaction of **1b** (or **10**) and **2** is insertion of one of the alkynyl groups of **2** into a Zr–C bond of **1b** to form **6b**. Such an intermediate can be also detected when **2** is treated with **1a** at 80 °C for only 4 h. The ^{31}P NMR spectrum of the crude product showed a major peak at $\delta = -25.5$, compatible with the structure of **6a**, in addition to minor peaks at $\delta = 59.9$ (**3a**) and -38.9 (**2**). Further investigations are in progress to elucidate the mechanism for the formation of **3a,b** and to extend this methodology to other mono-, di-, or tricyclic systems.

Experimental Section

3a: A solution of $[Cp_2ZrPh_2]$ (1.195 g, 3.184 mmol) and **2** (0.923 g, 3.184 mmol) in toluene (35 mL) was heated to 80 °C for 24 h. After removal of the solvent in vacuo, the solid was washed with pentane and then recrystallized from toluene/pentane to afford **3a** as orange crystals (1.210 g, 2.058 mmol, 65%).

3b: A solution of $[(t\text{BuCp})_2ZrPh_2]$ (0.241 g, 0.494 mmol) and **2** (0.143 g, 0.494 mmol) in toluene (10 mL) was heated to 90 °C for 20 h, and the solvent then removed in vacuo. The solid was washed with pentane to afford **3b** as an orange powder (0.301 g, 0.430 mmol, 87%).

4: A solution of toluene (20 mL) saturated with HCl was added dropwise to a solution of **3a** (0.826 g, 1.431 mmol) in toluene (20 mL) and stirred for 1.5 h at room temperature. The volatile components were then removed in vacuo, and the resulting brown oil was extracted with pentane (20 mL) and filtered. The crude product was purified by column chromatography (SiO_2, pentane/ether 99/1) to afford **4** as a yellow oil (0.247 g, 0.693 mmol, 47%).

5: $PhSbCl_2$ (0.303 g, 1.112 mmol) in toluene (10 mL) was added dropwise to a solution of **3a** (0.660 g, 1.112 mmol) in toluene (15 mL) cooled to −30 °C. The reaction mixture was left to warm slowly to room temperature and then stirred for 12 h. After removal of the solvent in vacuo, the residue was purified by column chromatography (SiO_2, pentane) to afford **5** as a yellow powder (0.175 g, 0.309 mmol, 28%).

IR Spectroscopic Evidence for the Absence of Structural Hydroxyl Groups in Cloverite**

Frédéric Thibault-Starzyk, André Janin, and Jean-Claude Lavalley*

Cloverite is an unusually large-pore molecular sieve with supercages with a body diagonal of 29 Å.[1] The potential unique catalytic activity of this gallophosphate is linked to its eventual acidity, which remains controversial. The X-ray structure of cloverite suggests the presence of a great number of GaOH and POH groups (192 per unit cell); their existence and associated acidity have been the subject of contradictory reports published recently.[2–5] We report here on the analysis of the IR spectra of cloverite. This technique is the most appropriate for the accurate description of acidic hydroxyl groups. The important spectral bands in the IR spectrum of the as-synthesized cloverite are attributed to the quinuclidinium template: their intensity decreases on progressive activation of the material. Upon activation, almost no new bands for hydroxyl groups appear, and the number of hydroxyl groups detected is estimated by adsorption of pyridine and carbon monoxide to be only 3–4% of the expected amount. Carbon monoxide indicates a medium to low acidity of these hydroxyl groups. We therefore suggest that the few hydroxyl groups detected on the activated sample are due to defects in the material.

A very strong and broad band at 3160 cm^{-1} in the IR spectrum of the as-synthesized cloverite was previously attributed to hydroxyl groups[3] (Figure 1). The intensity of this band decreases upon heating under ozone, and completely vanishes after the sample had been maintained at 573 K for 2 h. Activation is also possible under oxygen; however, the activation under ozone takes place efficiently at a temperature 100 K lower than that required for oxygen activation, thus reducing the risk of

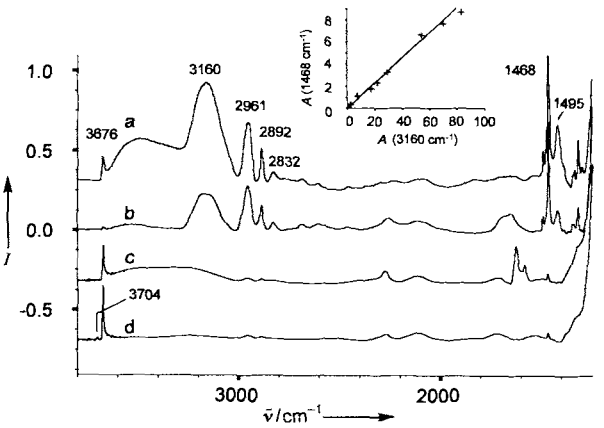

Figure 1. Activation of cloverite. Cloverite was synthesized as previously published [1]. The IR spectra were recorded on a Nicolet Magna 750 with an optical resolution of 4 cm^{-1} and a graphical resolution of 2 cm^{-1} (one level of zero filling for the Fourier transform calculation). The solid was pressed to a self-supporting wafer (23 mg, 2 cm^2). Heating rate 1 K min^{-1}. Spectra obtained after a) evacuation at 10^{-5} Torr for 1 h at 373 K, b) evacuation at 10^{-5} Torr for 3 h at 473 K, c) after successive cycles of ozone introduction (1 Torr) and evacuation at 473 K, and d) evacuation at 10^{-5} Torr for 1 h at 573 K. I = Absorbance. Insert: Area A of the band at 1468 cm^{-1} versus that of the band at 3160 cm^{-1} in various spectra recorded during calcination.

damaging the temperature-sensitive structure. There is a clear relationship between the intensity of the band at 3160 cm^{-1} and that of a sharp band at 1468 cm^{-1}: they decrease at the same rate (Figure 1 insert). The sharp band at 1468 cm^{-1} is characteristic of quinuclidinium ions,[6] and we suggest that the strong band at 3160 cm^{-1} is not attributed to hydroxyl groups but to the template, which is also expected in large quantities (192 molecules per unit cell). We observed the same strong band in the region 3000–3150 cm^{-1} in the spectra of quinuclidinium fluoride (Figure 2). Exchange with D_2O shifts the band to approximately 2400 cm^{-1}, thus indicating that it is due to an exchangeable proton. We assign this band to the ν(NH) vibration of the quinuclidinium ion with fluoride as a counterion.

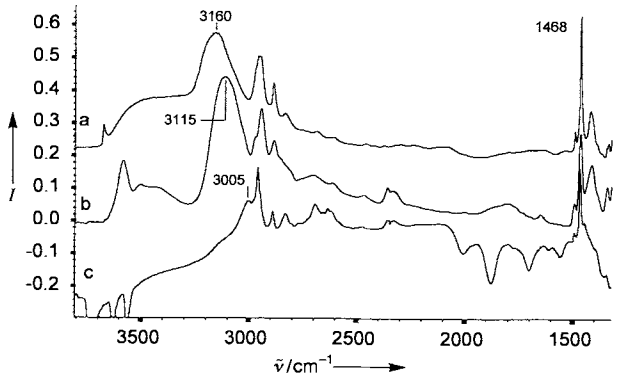

Figure 2. Comparison of the IR spectra of a) cloverite evacuated at 373 K, b) quinuclidinium fluoride prepared by reaction of quinuclidine on HF, supported on a silicon disk, and c) quinuclidinium fluoride adsorbed on H-Y zeolite (Si/Al = 40) (the spectrum of the activated Y zeolite has been subtracted). I = Absorbance.

The cloverite structure remains intact after calcination under ozone or oxygen: vibrational bands characteristic of the framework of cloverite at about 1100, 650, and 490 cm^{-1} in the spectra of the silicon disk supported material remain unaffected. This shows that the cloverite structure is maintained under the conditions used in the IR cell, when water is carefully excluded.[7] Two weak bands appear in the OH region upon activation under ozone or oxygen (Figure 1). They were already present in the spectrum of some of the as-synthesized samples we had. The assignment of the band at 3704 cm^{-1} has not been clearly proven yet, and some authors suggest it could be attributed to GaOH groups.[5] We have shown[6] that the second band at 3676 cm^{-1} is due to free POH groups, as revealed by the clear relationship between the intensity of this band and the intensity of a band at 944 cm^{-1}. During the elimination of the template, no sign of any other hydroxyl group was detected. After complete elimination of the quinuclidinium template, the acidity of the free OH groups can be estimated by adsorption of basic probe molecules such as carbon monoxide. Under CO (500 Pa) and at low temperature (Figure 3), only the band at 3676 cm^{-1} is consumed, whereas that at 3704 cm^{-1} remains almost unaffected. A perturbed ν(OH) band appears at 3495 cm^{-1} together with a ν(CO) band at 2169 cm^{-1}. The latter is always accompanied by another band at 2142 cm^{-1} due to physisorbed CO species. This clearly indicates that the Brønsted acidity of the activated material is only related to the hydroxyl groups characterized by the band at 3676 cm^{-1}, that is the POH groups. In comparison with the $\Delta\nu$(OH) shift obtained from CO adsorption on silica[8] and on zeolites,[9] the strength of the Brønsted acid sites on cloverite can be considered as medium.

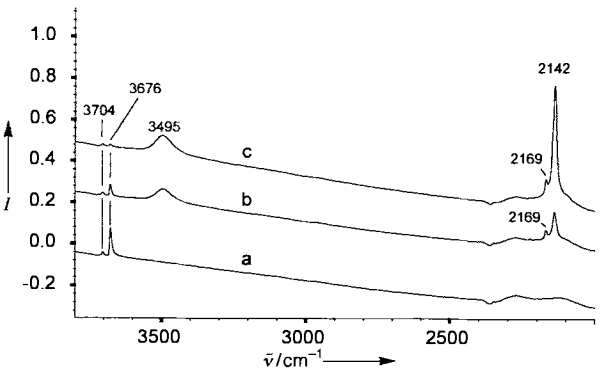

Figure 3. Adsorption of carbon monoxide on cloverite. IR spectra of a) cloverite activated under O_2 (100 Torr) at 673 K, b) after introduction of CO (0.05 Torr) at equilibrium at 100 K, and c) after introduction of CO (0.25 Torr) at equilibrium at 100 K. I = Absorbance.

The number of perturbed CO molecules (that is the number of POH groups) can be estimated, after deconvolution of the ν(CO) bands, by using a molar extinction coefficient of 2.7 cm μmol^{-1}, which is generally accepted for this type of band in this frequency range on metal oxides,[10] and has also been measured in the case of OH groups in amorphous aluminosilicates.[11] This number is quite low: 24.7 μmol per gram of the starting cloverite. This means that the number of the corresponding POH groups does not exceed 3.5% of the amount expected from structural considerations.

Assuming[12] that $\varepsilon_{pyH^+} = 1.8$ cm μmol^{-1}, the number of pyridinium species obtained from pyridine adsorption at room temperature on cloverite activated at 725 K is 26.7 μmol per gram, that is 3.5 pyridinium ions per unit cell (Figure 4). This value corresponds to that obtained from CO adsorption.

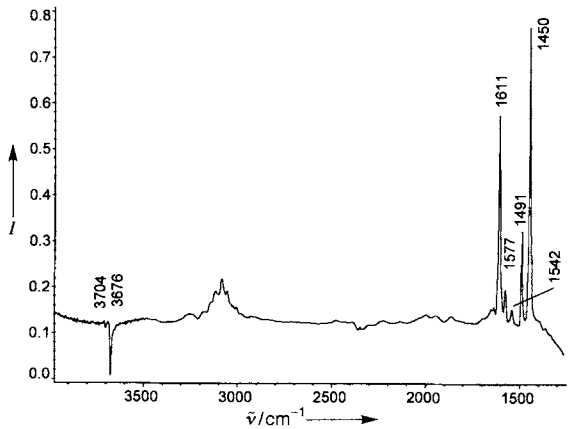

Figure 4. Difference spectrum after adsorption of pyridine (1 Torr) and evacuation (10^{-4} Torr, 300 K) on activated cloverite. The band at 1542 cm^{-1} is used for quantitative measurement of the Brønsted acid hydroxyl groups, and the band at 1611 cm^{-1} indicates the Lewis acidic sites. I = Absorbance.

Figure 5 shows a comparison of the OH regions of the IR spectra of the same mass of cloverite and zeolite Y. Even if the Beer–Lambert law must be considered critically for adsorbates on solids, the OH bands in the two solids without any basic probes are not on the same order of magnitude. This shows the dramatic difference between the expected number and the observed number of hydroxyl groups in cloverite.

A large number of Lewis acidic sites was also detected by adsorption of pyridine. Such sites were not detected on the as-synthesized sample.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3609-0990 $ 17.50+.50/0 Angew. Chem. Int. Ed. Engl. 1997, 36, No. 9

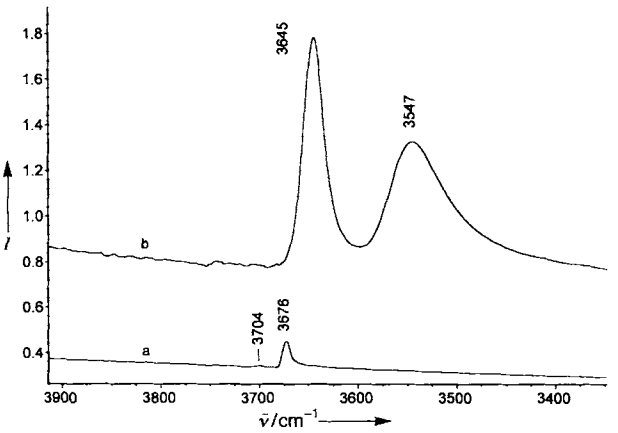

Figure 5. Comparison of the OH regions of the IR spectra of activated cloverite (a) and Y zeolite (b, Linde LZY62, Si/Al = 2.4). The spectra were normalized to 10 mg solid, and based on the structures of the solids the ratio between the area of OH bands in cloverite and Y zeolite should be at least approximately 1:3; however, the observed value is only 1:40. I = Absorbance.

In conclusion, this study reveals that the postulated terminal OH groups in the framework of cloverite are not detectable by IR spectroscopy. Free OH groups, in particular those due to POH groups that vibrate at 3676 cm^{-1}, are observed before and after activation of cloverite at 573 K under ozone. Their number increases upon activation but remains quite low, about 3.5 % of the expected number, indicating that they correspond to defect sites. This study does not cast doubt on the results of the X-ray structure analysis, but rather on whether the terminal oxygen atoms in the structure really belong to hydroxyl groups.

Hydrothermal Synthesis of Microporous Transition Metal Squarates: Preparation and Structure of $[Co_3(\mu_3\text{-}OH)_2(C_4O_4)_2]\cdot 3H_2O$**

Siegfried O. H. Gutschke, Michel Molinier, Annie K. Powell, and Paul T. Wood*

Many microporous main group oxides have been prepared by hydrothermal synthesis[1] but it has long been a goal to produce lacunary materials with modulated catalytic activity by constructing frameworks with d-block metals in close proximity to the voids. Haushalter et al. have shown how this can be achieved for vanadium and molybdenum phosphates.[2] The usefulness of superheated fluids for preparing extended frameworks based on metal–ligand interactions has recently been demonstrated both by ourselves[3] and others,[4] and we now wish to report the extension of this technique to the preparation of a cobalt squarate with a microporous structure. The cobalt–squaric acid system has been extensively investigated under ambient conditions[5] and gives compounds based on the framework found in **1** in most cases; analogous structures are also formed by the corresponding compounds of manganese, iron, nickel, and zinc. We report herein on compound **2**, which has a structure unlike those previously observed.

$[Co(C_4O_4)(H_2O)_2]$ **1** $\{[Co_3(\mu_3\text{-}OH)_2(C_4O_4)_2]\cdot 3H_2O\}_n$ **2**

The hydrothermal reaction of $CoCl_2\cdot x H_2O$ with squaric acid and KOH in the ratio 2:3:8 in water at 200 °C produces well-formed dark maroon crystals of **2**. Small quantities (< 5%) of pink crystals that we tentatively assign as the known compound[5a] **1** are also sometimes produced. The structure[6] of **2** is based on a backbone of $Co_3(OH)_2$ strips that run parallel to the crystallographic c axis. The strips are formed from μ_3-OH bridged equilateral triangles of cobalt atoms, which share alternating edges and vertices with the hydroxide groups lying above and below alternate triangles (Figure 1). There are two different

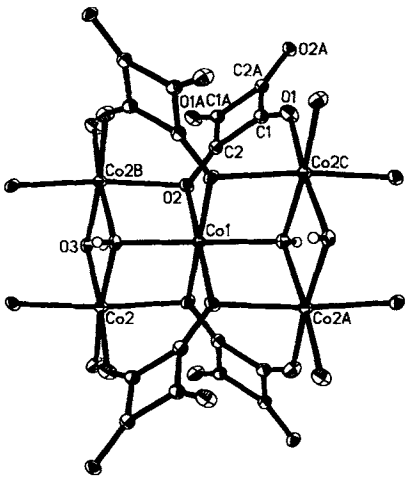

Figure 1. ORTEP view of part of the cobalt chain in **2** showing the bridging of squarate ligands.

cobalt environments, both of which have octahedral geometry. The cobalt center Co1, which lies at the shared vertex, is coordinated to two bridging hydroxide groups (Co1–O3 2.017(3) Å) and to four oxygen atoms from squarate ligands (Co1–O2 2.118(2) Å), which bridge the two unshared edges of each triangle. The cobalt center Co2 and its symmetry equivalent Co2B form the shared edge of two triangles and are bonded to two bridging (Co2–O2 2.171(2) Å) and two terminal (Co2–O1 2.049(2) Å) squarate oxygen atoms and to two hydroxide groups (Co2–O3 2.060(2) Å). The triangles formed by the cobalt atoms are close to equilateral; the Co1–Co2 distance is 3.160(1) Å and the Co2–Co2B distance 3.102(1) Å.

The squarate ligands lie about an inversion center, have C–C distances of 1.460(4) and 1.461(4) Å, and bridge a total of six cobalt atoms in two adjacent chains. The metal–ligand interactions result in infinite channels parallel to the *c* axis, with cobalt hydroxide chains along the edges and squarate anions forming the faces (Figure 2). The channels have lozenge-shaped cross-

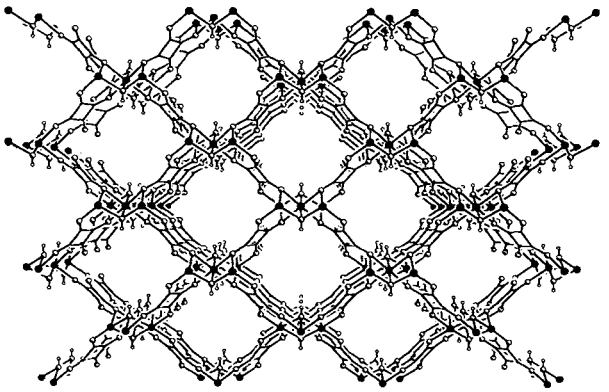

Figure 2. Packing diagram of **2** parallel to [001]. The cobalt centers are drawn as solid spheres.

sections; the distances of approximately 9.3 and 12.9 Å between opposite vertices correspond to the lengths of the *a* and *b* axes, respectively. Allowing for the van der Waals' radii of the atoms this leaves approximately 7.5 Å of free space between opposite vertices. The bridging hydroxide group points directly into the void and is hydrogen-bonded to one of the water molecules (O3–O4 2.847(7) Å), whilst the second water molecule has only a weak interaction with the framework (O5–O2 3.162(15) Å). The cobalt hydroxide strips are based on the $Mg(OH)_2$ (brucite) structure, the same as for $Co(OH)_2$,[7] with a portion of the μ_3-bridging hydroxide groups replaced by oxygen atoms from the squarate ligands. Thus, the structure can be viewed as $Co(OH)_2$ which has been modified by inclusion of squarate anions. Modification of mineral structures by organic templates has peviously been observed by us for polyhomometallic Fe^{3+} and Al^{3+} hydroxo(oxo) clusters.[8]

Thermal gravimetric analysis performed under an inert atmosphere shows that the compound loses 9% of its mass smoothly between 100 and 300 °C, corresponding to loss of the included water. No further changes occur until 405 °C where there is a sharp loss of a further 41% of the original mass corresponding to decomposition to one of the oxides of cobalt. Single crystals of **2** have been dehydrated but readily reabsorb most of the water to regenerate a variant of the original structure that contains slightly less water. Hence the totally dehydrated form must retain the same framework topology, and we are currently investigating its ability to absorb small molecules.

$[Cu_3(OH)_2(C_4O_4)_2]\cdot 4H_2O$ has a similar open framework structure with even larger channels, whereas Mn^{II} and Zn^{II} form $[M_2(OH)_2(C_4O_4)]$, which contains a different morphology of brucite-like strip that allows tighter stacking of squarate anions and consequently less free space within the lattice.[9]

In conclusion, we have shown that hydrothermal synthesis is a powerful technique for preparing new coordination solids containing transition metals. The use of templates to modify recognized mineral forms to produce materials tailored for specific functions is common in Nature in the form of biomineralization. The parallels between this process and our approach are clear and indicate that this methodology is a promising route for engineering tailored materials.

Experimental Section

Hydrated cobalt(II) chloride (0.250 g, 1.93 mmol), squaric acid ($H_2C_4O_4$) (0.329 g, 2.88 mmol), and KOH (0.433 g, 7.72 mmol) were placed along with water (7 mL) in a 23 mL-Teflon-lined autoclave and heated at 200 °C for 112 h. The autoclave was allowed to cool to room temperature over 4 h. The product was filtered and washed with water to give the product as well-formed dark maroon crystals. Yield 0.15 g, 48% based on Co. Elemental analysis: Calcd. for $C_8H_8O_{13}Co_3$: C 19.65,; H 1.65; found: C 19.91, H 1.27%.

Small Gold Clusters with Carborane Ligands: Synthesis and Structural Characterization of the Novel Compound $[Au_4\{(PPh_2)_2C_2B_9H_{10}\}_2(AsPh_3)_2]$**

Olga Crespo, M. Concepción Gimeno, Peter G. Jones, Antonio Laguna,* and M. Dolores Villacampa

The chemistry of homo- or heteropolynuclear gold clusters is still attracting a great deal of interest, and many examples with different nuclearities are known.[1-5] However, small clusters are poorly represented; the only tetrahedral clusters described thus far are $[Au_4I_2(PPh_3)_4]$[6] and $[Au_4(SnCl_3)_2(PPh_3)_4]$,[7] in which the two iodine or $SnCl_3$ groups, respectively, bridge two opposite edges of a tetrahedron of gold atoms, and the recently reported[8,9] clusters $[Au_4L_4](BF_4)_2$ (L = P*t*Bu$_3$, P(mesityl)$_3$), which show approximate tetrahedral symmetry. All these clusters were minor products (yields 5–15%), with the exception of $[Au_4\{P(mesityl)_3\}_n](BF_4)_2$, which was obtained in high yield. The interest in this chemistry is not only focused on the new complexes but also on understanding their formation, and thereby being in a position to develop convenient and reproducible syntheses of a desired product. Here we report the high-yield synthesis of the tetranuclear gold cluster, $[Au_4\{(PPh_2)_2C_2B_9H_{10}\}_2(AsPh_3)_2]$ by a novel and unexpected reaction. This complex is the first example of a gold cluster stabilized by arsane ligands. We are currently studying reactions involving partial degradation of the carborane cage in the diphosphane [1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$] to afford the anionic *nido*-ligand [7,8-$(PPh_2)_2$-7,8-$C_2B_9H_{10}]^-$. Thus, treatment of $[AuCl(PR_3)]$ with the diphosphane in refluxing ethanol led to complexes of the type $[Au\{(PPh_2)_2C_2B_9H_{10}\}(PR_3)]$.[10] Here we describe reactions starting from $[AuCl(AsPh_3)]$, in which the more labile ligand plays a decisive role in directing the reactivity.

The reaction of $(PPh_2)_2C_2B_{10}H_{10}$ with $[AuCl(AsPh_3)]$ in the molar ratio 1:1 gives a mixture of two very different complexes; the $^{31}P\{^1H\}$ NMR spectrum of each complex shows the presence of an AA'BB' system, but the chemical shifts differ considerably ($\Delta\delta$ about 40). One complex was identified as the four-coordinate derivative $[Au\{(PPh_2)_2C_2B_9H_{10}\}\{(PPh_2)_2C_2B_{10}H_{10}\}]$ (**1**), which contains one partially degraded carborane moiety. This result was confirmed by carrying out the reaction in a 2:1 molar ratio in refluxing ethanol, which afforded **1** in high yield. We have also synthesized **1** by reacting $[AuCl\{(PPh_2)_2C_2B_{10}H_{10}\}]$ with the diphosphane under the same conditions. In the first step in this reaction the diphosphane is coordinated to the gold atom, then electron density is transferred from the metal to the cage. Thus, one of the apical boron atoms is susceptible to nucleophilic attack, which leads to partial opening of the cage. In this case ethanol is a suitable nucleophile. It is noteworthy that tetrahedral $[Au(L\text{-}L)_2]$ compounds are usually cationic; complex **1** is novel in that it is neutral, because the decapping of the carborane cage provides an anionic phosphane ligand. The positive-ion FAB mass spectrum shows the molecular peak at m/z 1212 (100%).

The structure of complex **1** was confirmed by an X-ray structure analysis (Figure 1).[11] The gold center is chelated by the two diphosphane ligands, and thus shows a distorted tetrahedral geometry. The distortions mainly arise from the small bite

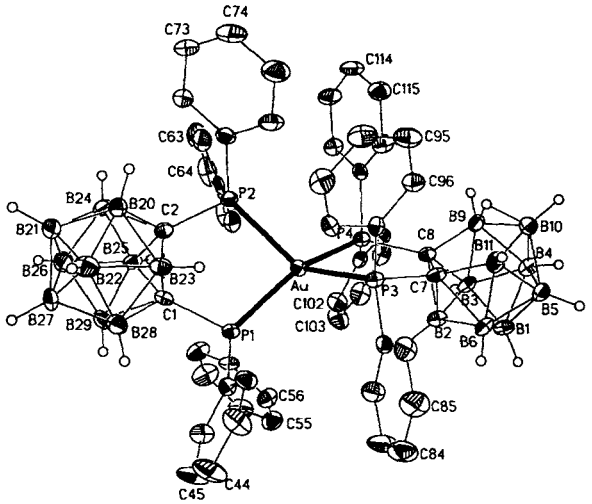

Figure 1. The structure of complex **1** showing the atom-numbering scheme. Hydrogen atoms were omitted for clarity; radii are arbitrary.

angles of the diphosphanes (P1-Au-P2 89.25(4)°, P3-Au-P4 86.05(5)°), which are slightly narrower than in the complex $[Au\{(PPh_2)_2C_2B_{10}H_{10}\}\{(SPPh_2)_2CH_2\}]ClO_4$ (89.72(6)°).[12] The dihedral angle between the two planes defined by Au,P1,P2 and Au,P3,P4 is 70.3°. The five-membered chelate rings display an envelope conformation; the gold atom lies 0.57 and 0.43 Å out of the plane of the other four atoms. The Au–P distances are dissimilar: two are short (Au–P1 2.3688(13) Å and Au–P3 2.3945(11) Å) and two are long (Au–P2 2.4874(11) Å and Au–P4 2.4397(14) Å); these values lie at the extremes of the range observed in other tetrahedral gold(I) derivatives, for example $[Au(PMePh_2)_4]PF_6$ (2.449(1) Å),[13] $[Au(dppe)_2]^+$ (2.389(3)–2.416(3) Å),[14,15] dppe = 1,2-bis(diphenylphosphanyl)ethane. The extra hydrogen atom in the pentagonal C_2B_3 open face is strongly bonded to the central boron atom (B10–H12 1.08 Å), but is semibridging to B9 (B9–H12 1.35 Å). We have observed a similar arrangement of H atoms in other complexes of the open-face carborane ligand;[10] however, the position of H atoms may not be reliable in the presence of heavy atoms such as gold.

Based on the overall stoichiometry, it seemed clear that the other derivative (**2**) should contain more gold than diphosphane. Therefore we treated $(PPh_2)_2C_2B_{10}H_{10}$ with $[AuCl(AsPh_3)]$ in the molar ratio 1:2 in refluxing ethanol, and obtained the pure second product as an orange solid in 90% yield. The positive-ion FAB mass spectrum shows the highest peak at $m/z = 2404$ (45%), which is attributed to $[Au_4\{(PPh_2)_2C_2B_9H_{10}\}_2(AsPh_3)_2]$ (**2**); the experimentally determined isotopic distribution is in accord with the calculated distribution. The elemental analysis data are also consistent with this formulae.

The structure of complex **2** was determined by an X-ray crystal structure analysis (Figure 2).[11] It consists of a tetrahedral gold core in which two of the gold atoms (Au1 and Au2) are

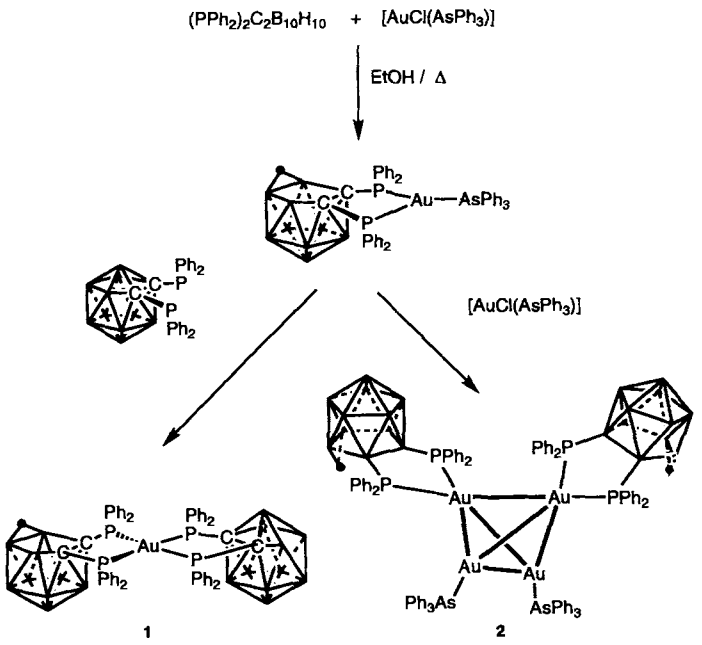

Scheme 1. Synthesis of **1** and **2**.

chelated by the anionic diphosphane, and each of the other two (Au3 and Au4) are bonded to one arsane ligand. The Au–Au distances can be classified into three groups: long (Au3–Au4 2.9148(8) Å), medium (Au2–Au4 2.8371(8) and Au1–Au3 2.8062(7) Å), and short (Au1–Au4 2.6036(7), Au2–Au3 2.6167(8), and Au1–Au2 2.6751(8) Å). These values are more extreme than those reported for other tetrahedral gold clusters such as $[Au_4I_2(PPh_3)_4]$ (2.659(1)–2.828(1) Å),[6] $[Au_4(\mu\text{-}SnCl_3)_2(PPh_3)_4]$ (2.6341(5)–2.8128(5) Å),[7] $[Au_4\{P(mesityl)_3\}_4]^{2+}$ (2.7337(9) Å), and $[Au_4(PtBu_3)_4]^{2+}$ (2.7031(9)–2.7302(7) Å);[8,9] two of them are the shortest found in these type of clusters. The Au–P bond lengths (2.342(2)–2.373(2) Å) are as expected slightly longer than those in gold clusters with monodentate phosphanes. The coordination geometry at Au1 and Au2 is distorted trigonal bipyramidal; the phosphorus atoms of the diphosphane occupy one equatorial and one axial position. The distortions mainly arise from the restraints of the tetrahedral cluster geometry. The angles P1-Au1-P2 and P3-Au2-P4 (89.10(8) and 86.51(9)°, respectively,) are close to ideal values, and the angles P4-Au2-Au3 (172.93(6)°) and P2-Au1-Au4 (169.47(6)°) approach linearity.

We propose a pathway that would explain the formation of complexes **1** and/or **2** depending on the stoichiometric ratio of the reactants (Scheme 1). The first step would be the formation of the intermediate complex $[Au\{(PPh_2)_2C_2B_9H_{10}\}(AsPh_3)]$ (similar complexes have been obtained starting from $[AuCl(PR_3)]$[10]). This intermediate should be very reactive towards the coordination of free diphosphane, leading to displacement of the arsane ligand, and formation of the four-coordinate complex **1**; alternatively the intermediate could react further with $[AuCl(AsPh_3)]$ to give the cluster compound **2**.

Another possibility is that **2** could react with the diphosphane to give complex **1** and metallic gold; however, we have carried out this reaction and recovered only the starting materials. Thus it seems that the intermediate complex $[Au\{(PPh_2)_2C_2B_9H_{10}\}(AsPh_3)]$ plays an important role in the quest for a general route to this type of gold clusters. Our efforts are now focused on the preparation of this or a similar complex and on subsequent reactions with other gold derivatives, which should allow the controlled synthesis of clusters with four or more gold atoms.

Experimental Section

1: $[AuCl(AsPh_3)]$ (0.1 mmol, 0.053 g) was added to a solution of $(PPh_2)_2C_2B_{10}H_{10}$ (0.2 mmol, 0.104 g) in ethanol (30 mL). The mixture was heated to reflux for 30 min and the resulting yellow solid was filtered off and dried in vacuo. Yield 75%. Elemental analysis (%): Found: C 51.55, H 4.65; calcd. for $C_{52}H_{60}AuB_{19}P_4$: C 51.55, H, 5.0. IR: $\tilde{\nu}$(B–H) = 2552 cm^{-1}; $\Lambda_M = 5\,\Omega^{-1}\,cm^2\,mol^{-1}$; $^{31}P\{^1H\}$ NMR (121 MHz, H_3PO_4): AA′BB′ system (not well resolved) $\delta(A) = \delta(A') = 42.5$, $\delta(B) = \delta(B') = 38.3$. ^1H NMR (300 MHz): $\delta = -2$ (br, BH), 7.3–7.6 (m, 40H, Ph); ^{11}B NMR: −0.8 (br, 2B), −5.2 (br, 4B), −8.5 (br, 5B), −13.5 (br, 6B), −28.7 (br, 1B), −34.0 (br, 1B); mass spectrum (FAB^+): *m/z*: 1212 ($[M]^+$, 100%).

2: $[AuCl(AsPh_3)]$ (0.2 mmol, 0.106 g) was added to a solution of $(PPh_2)_2C_2B_{10}H_{10}$ (0.1 mmol, 0.052 g) in ethanol (30 mL). The mixture was heated to reflux for 15 min and the resulting orange solid was filtered off and dried in vacuo. Yield 92%. Elemental analysis (%): Found: C 43.45, H 3.30; calcd. for $C_{88}H_{90}As_2Au_4B_{18}P_4$: C 43.95, H 3.75. IR: $\tilde{\nu}$ = (B–H) 2532 cm^{-1}. $\Lambda_M = 2\,\Omega^{-1}\,cm^2\,mol^{-1}$; $^{31}P\{^1H\}$ NMR (121 MHz, H_3PO_4): AA′ BB′ system (not well resolved) $\delta(A) = \delta(A') = 95.1$, $\delta(B) = \delta(B') = 89.3$, $J(A,A') = 180$ Hz, $J(A,B') = J(A',B) = 0$, $J(A,B) = 70$ Hz; ^1H NMR (300 MHz): $\delta = -2$ (br, BH), 7.3–7.6 (m, 70H, Ph); ^{11}B NMR −9.2 (br, 4B), −16.3 (br, 6B), −18.1 (br, 4B), −29.0 (br, 2B), −34.5 (br, 2B); mass spectrum (FAB +): *m/z*: 2404 ($[M]^+$, 42%).

[11] X-ray structural data data for compounds **1** and **2**. **1**: $C_{52}H_{60}AuB_{19}P_4$, $M_r = 1211.24$, monoclinic, space group $P2_1/c$, $a = 17.678(4)$, $b = 19.021(4)$, $c = 17.070(7)$ Å, $\beta = 94.55(3)°$, $V = 5722(3)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.406$ Mg m^{-3}, $\mu(Mo_{K\alpha}) = 2.72$ mm^{-1}, $F(000) = 2424$, Siemens AED-2 diffractometer, $\lambda(Mo_{K\alpha}) = 0.71073$ Å, $T = -100\,°C$. A yellow tablet $0.45 \times 0.38 \times 0.26$ mm was used to collect 6448 reflections with intensities to $2\theta_{max}$ 45°, of which 6276 were unique ($R_{int} = 0.009$). Scan type: ω/θ. Because of instrumental difficulties no ψ scans could be measured, and a ΔF absorption correction was therefore

applied with the program SHELXA, with transmissions 0.71–0.82. The structure was solved by direct methods and subjected to full-matrix least-squares refinement on F^2 (SHELXL-93), non-H atoms except B refined anisotropically, phenyl and closed-face carborane H atoms included with a riding model, open-face carborane H atoms located from difference syntheses and refined with B–H distance restraints. Restraints were also applied to the temperature factors of the light atoms and ring planarity. Refinement proceeded to $wR(F^2) = 0.055$ for 6269 reflections, 713 parameters and 588 restraints, conventional $R(F) = 0.023$, $S(F^2) = 1.09$, max. $\Delta\rho = 0.33\ e\,Å^{-3}$. **2**·$CH_2Cl_2$, $C_{89}H_{92}As_2Au_4B_{18}Cl_2P_4$, $M_r = 2488.69$, triclinic, space group $P\bar{1}$, $a = 14.368(3)$, $b = 16.094(3)$, $c = 20.145(3)$ Å, $\alpha = 88.22(2)$, $\beta = 87.04(2)$, $\gamma = 83.60(2)°$, $V = 4622(2)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.788\ Mg\,m^{-3}$, $\mu = 7.2\ mm^{-1}$, $F(000) = 2384$, $T = -100\,°C$. Data were collected from two crystals (Siemens P4 diffractometer): 1) tablet, $0.25 \times 0.2 \times 0.1$ mm, 10154 reflections to $2\theta 50°$, transmissions by ψ scan correction 0.498–0.933; 2) platelet, $0.55 \times 0.1 \times 0.03$ mm, 12387 reflections to $2\theta 45°$, transmissions 0.779–0.988. The datasets were merged with appropriate scaling to give 13513 unique reflections, $R_{int} = 0.064$. The structure was solved by direct methods, with other data as for complex **1**. Refinement proceeded to $wR(F^2) = 0.068$ for 13513 reflections, 570 parameters and 218 restraints, conventional $R(F) = 0.0387$, $S(F^2) = 0.834$, max. $\Delta\rho = 1.4\ e\,Å^{-3}$. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100011. Asymmetric Synthesis of α-Methyl α-Amino Acids by Diastereoselective Alkylation of Optically Active 6-Isopropyl-3-methyl-2,3-dihydro-6*H*-1,4-oxazin-2-ones**

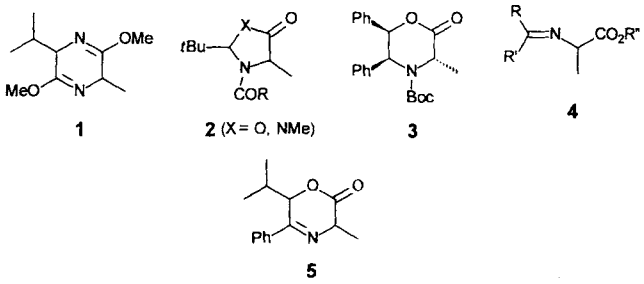
Rafael Chinchilla, Larry R. Falvello, Nuria Galindo, and Carmen Nájera*

Dedicated to Professor Dieter Seebach on the occasion of his 60th birthday

The present, high interest in the synthesis of nonproteinogenic amino acids is based on their remarkable pharmacological and conformational properties, both as free amino acids and as components of biologically active peptides. α-Methyl α-amino acids (AMAA) are important members in the family of modified amino acids. Some representative examples are a) naturally occurring α-aminoisobutyric acid (Aib) and (*R*)-2-amino-2-methylbutyric acid (D-Iva), which are constituents of peptaibols (microbial peptide antibiotics that form transmembrane ion channels),[1] b) (*S*)-α-methyl-DOPA (Aldomet), which is an inhibitor of DOPA decarboxylase (an important commercial antihypertensive);[2] c) (*S*)-α-methyltyrosine, which (as a substitute of tyrosine 4 in angiotensin II) results in a peptide that is resistant to chymotryptic degradation,[3] and d) (*R*)-α-methylaspartic acid,[4] (*R*)- or (*S*)-2-methylglutamic acids,[4b] as well as (*R*)- and (*S*)-α-methylserine,[5] which can be used to stabilize β-turn and α-helical conformations in short peptides.

The most direct synthetic approach to enantiomerically pure AMAAs is α-alkylation of chiral alanine anion equivalents;[6] the most noticeable are cyclic derivatives such as Schöllkopf's bis(lactim) ether **1**, Seebach's oxazolidinones and imidazolidinones **2**, and Williams' diphenyloxazinones **3**. High diastereoselectivities have been achieved by enolization with strong bases (such as *n*BuLi, LDA, and LHMDS) at low temperature followed by reaction with electrophiles. An easily enolizable, chiral alanine derivative is desirable for preparing optically active AMAAs under simple and mild reaction conditions. Due to the high acidity of their α-hydrogen atoms, imines derived from amino acid esters **4** are unique substrates for alkylation with solid–liquid phase-transfer catalysis (PTC)[7] and Pd-catalyzed allylation under neutral conditions[8] at room temperature.[9] Chiral imino esters[10] (up to 55% *ee*), cinchona-derived, quaternary ammonium salts[11] (up to 66% *ee*), and a sultam-derived glycine imine synthon[12] (up to 99.5% *de*) have been used in the asymmetric synthesis of amino acids under PTC alkylation conditions.



1 **2** (X = O, NMe) **3** **4**

5

Searching for iminic alanine derivatives, we focused our attention on 2,3-dihydro-6*H*-1,4-oxazin-2-ones **5**[13] for the following reasons: a) These compounds are cyclic imines of an alanine ester derived from an aromatic ketone; the phenyl group should favor easy formation of a highly stabilized enolate. b) They have a stereogenic center at the 6-position, which can be used to transfer its chirality to the 3-position for alkylation of the planar enolate. c) They can be easily hydrolyzed (this last step is very difficult for α,α-dialkylated α-amino acid derivatives).[14] d) They can be easily prepared enantiomerically pure using alanine as the source of chirality. Here we describe the diastereoselective alkylation of **5** under very mild conditions and their hydrolysis to the corresponding AMAAs.

Chiral oxazinones **5** were obtained by the reaction of α-bromoisovalerophenone with the potassium salt of *N*-Boc-L-alanine in DMF (Scheme 1).[15] Esters **6** were formed in a diastereomeric ratio of approximately 1:1, separated by flash chromatography, and isolated in 31% yield each. The Boc group of (*S*,*R*)-**6** was deprotected with HCl(g) in EtOAc, and treatment of the resulting hydrochloride with the base Et_3N in the presence of molecular sieves provided **5** in 70% yield. These compounds were obtained as a mixture of *cis*–*trans* diastereomers in a ratio of about 1:20 due to facile epimerization of the stereogenic C-3 center. Since C-3 will be part of the planar enolate after deprotonation, its configurational stability is irrelevant for the diastereoselectivity of the alkylation. Re-

crystallization afforded pure *trans* diastereomer (3*S*,6*R*)-**5**, whose relative configuration was determined by NOE experiments and X-ray structure analysis (Figure 1). Molecular me-

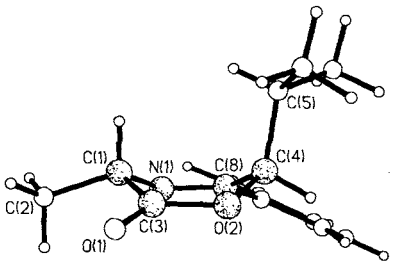

Figure 1. Crystal structure of (3*S*,6*R*)-**5** [18].

chanics calculations[16] corroborated that these 3,6-substituted oxazinones **5** prefer a quasi-boat conformation with the isopropyl group in an axial position. A similar orientation of the isopropyl group, which allows effective blocking of one of the faces and preferred anti-attack at the 3-position by electrophiles (1,4-induction), was predicted for the corresponding enolate.

When (*S*,*S*)-**6** was transformed into **5**, a mixture of *cis*–*trans* diastereomers in a ratio of about 1:2.5 was obtained. Surprisingly, the specific rotation of the *trans* derivative was considerably lower than that of the corresponding enantiomer (3*S*,6*R*)-**5**, which shows that epimerization at C-6 also occurred. This prevented the use of the enolate of oxazinones (6*S*)-**5** as enantiomeric counterparts of enolates from (6*R*)-**5**. As an alternative synthetic route (*S*,*R*)-**6** could be prepared by DCC-mediated (DCC = dicyclohexylcarbodiimide) esterification of (*R*)-α-hydroxyisovalerophenone[17] and *N*-Boc-L-alanine; this would avoid chromatographic separation.

The reaction of (6*R*)-**5** with different electrophiles (such as activated alkyl halides, paraformaldehyde, and methyl acrylate) in the presence of K_2CO_3 (3 equiv) and tetra-*n*-butylammonium bromide (TBAB, 0.1 equiv) in CH_3CN at room temperature provided the oxazinones **7** generally in good yields and diastereoselectivities (Table 1). The relative configuration of these heterocycles was confirmed by NOE experiments [(3*S*,6*R*)-**7a**] and X-ray diffraction analysis[18] [(3*S*,6*R*)-**7b**, Figure 2].

employed, attack on the (η^3-allyl)palladium complexes took place preferentially (entries 3–6) or exclusively (entry 7) at the less substituted position. The configuration of the double bond in the allylic group R is (*E*) for **7i–l**.

The alkylation conditions were also varied: The lithium enolate of (3*S*,6*R*)-**5** reacted with allyl acetate under Pd-catalyzed substitution at −60 °C to give the corresponding substituted allyl derivative **7a** in 45% yield and a diastereomer ratio of 96:4. Moreover, low-temperature alkylations with LDA as base were also performed with (3*S*,6*R*)-**5** for synthesizing **7a** and **7c**, but no improvements were achieved in yield or diastereoselectivity.

Representative alkylated oxazinones **7** were hydrolyzed with 6N aqueous HCl at 150 °C (pressure tube), and the obtained hydrochlorides transformed into the corresponding optically active (*S*)-AMAAs **8** by treatment with propylene oxide in ethanol (Table 3). The *ee* values for these amino acids correlated well with the corresponding *de* values for (3*S*,6*R*)-**7**.

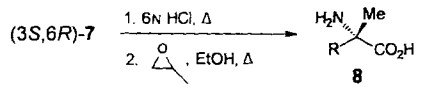

Table 3. Synthesis of α-methyl α-amino acids **8** by hydrolysis of oxazinones (3*S*,6*R*)-**7**.

[a] Yield of isolated product. [b] Determined by comparing [α] values. [c] See ref. [19]. [d] (*R*) enantiomer, see ref. [20]. [e] See ref. [21]. [f] Measured at 436 nm in 6N HCl, see ref. [20]. [g] ≥97% *ee*.

A second, milder cleavage method that is ideal for isolating acid-sensitive amino acids was used in the case of the allyl derivative **7a**, which was obtained by PTC alkylation (Table 1). The imine group was hydrolyzed with 2N HCl in THF at room temperature for 1 h, and the ester group with LiOH (3 equiv) in THF/H_2O also at room temperature for 6 h. Subsequent Dowex chromatography gave (*S*)-α-allylalanine in 57% yield and 93% *ee*.[22]

We have found a practical and experimentally simple method for the synthesis of optically active (*S*)-AMAAs by alkylation or allylation of substituted 2,3-dihydro-6*H*-1,4-oxazinon-2-ones under solid–liquid PTC and Pd catalysis, respectively, followed by final hydrolysis. The method features simple preparation of starting materials from commercially available compounds and very mild reaction conditions. These heterocycles are promising chiral templates for the asymmetric synthesis of other types of α-amino acids.

Experimental Section

PTC alkylation of (6*S*)-**5**: A heterogeneous mixture of (6*S*)-**5** (231 mg, 1 mmol), TBAB (33 mg, 0.1 mmol), finely ground, technical-grade K_2CO_3 (400 mg, 3 mmol), and the corresponding electrophile (1.5 mmol) in CH_3CN (3 mL) was stirred at room temperature until the starting material had been totally consumed (GC, see Table 1). The mixture was filtered through a pad of silica gel, the solvent removed by 15 Torr, and the residue purified by flash chromatography on silica gel to afford **7**.

Pd-catalyzed allylation of (6*S*)-**5**: A solution of $[Pd(PPh_3)_4]$ (29 mg, 0.025 mmol) and dppe (28 mg, 0.07 mmol) in dry THF (0.5 mL) was added to a solution of (6*S*)-**5** (116 mg, 0.5 mmol) and the corresponding allylic carbonate (0.5 mmol) in dry THF (1 mL) and stirred at room temperature until the reaction was completed (see Table 2). The solvent was removed by 15 Torr, and the residue purified by flash chromatography on silica gel to afford **7**.

Dioxygen Binding at Ambient Temperature: Formation of a Novel Peroxodicopper(II) Complex with an Azole Macrocyclic Ligand**

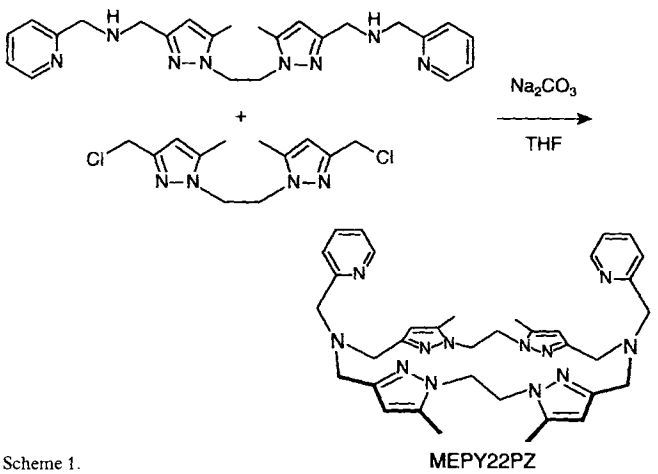
Johan E. Bol, Willem L. Driessen,* Raymond Y. N. Ho, Bas Maase, Lawrence Que, Jr.,* and Jan Reedijk*

The activation of molecular dioxygen by transition metals has fascinated chemists for decades.[1] In particular copper–peroxo complexes play a central role in biochemical O_2 processing, but synthetic, room-temperature stable Cu-O_2-Cu adducts are scarce. Dinuclear copper proteins such as hemocyanin or tyrosinase are of vital importance in biochemical O_2 processing and use O_2 as an environmentally favorable oxidant in, for example, the selective oxidation of aromatic substrates.[2] Consequently, the search for biomimetic copper complexes that bind O_2 under mild conditions (room temperature, protic solvent, normal O_2 pressure) has continued to attract considerable interest.

Synthetic peroxodicopper(II) species containing rigid tripodal N_3 or N_4 nitrogen-donor ligands (L) have only been characterized in recent years;[3] two have been crystallized.[3a, b] These complexes are stable in solution only at low temperatures and in aprotic solvents. In these studies, the mononuclear $[Cu^IL]^+$ fragments need to assemble in solution to form peroxodicopper(II) complexes when exposed to O_2; this only occurs at temperatures low enough to prevent rapid decomposition in solution. One exception, recently reported by Krebs et al.,[4] is an unusual tetranuclear Cu^{II} complex in CH_3OH at room temperature, in which a peroxo dianion is coordinated in a rare μ_4-$(\eta^1)_4$ fashion. Macrocyclic, dinucleating ligands have been used to bind two copper ions in a preorganized fashion, but these macrocycles[5] normally contain hard, aliphatic nitrogen donors, and so far no clear evidence for the formation of Cu^{II}_2–peroxo intermediates in such systems has been found.

We have integrated the above-mentioned approaches for the synthesis of a novel macrocyclic ligand, MEPY22PZ, with four azole and two pyridine donors preorganized in a double tripodal N_4 donor set, which is separated by ethylene spacers (Scheme 1).[6] The first results are highly encouraging. The peroxodicopper(II) complex presented here can be regarded as an important step towards functional biomimetic compounds that are capable of activating O_2 *at room temperature in protic media.*

The 22-membered ligand MEPY22PZ was obtained by a rational ligand design based on X-ray structures of oxyhemocyanin by Magnus et al.[7] The detailed synthetic pathway for the present and related ligands is described elsewhere.[8] The basic idea was to connect covalently all azole donor groups attached to the copper ions, so that no assembly of mononuclear copper species would be required in solution. A model ligand for dinuclear copper proteins should bind two copper ions, leaving an available coordination site on each Cu^I ion for O_2 binding. This has been accomplished by arranging two pyridine and four pyrazole groups in two rigid, tripodal N_4 donor sets that are connected by two semirigid alkyl spacers. From computer modeling, an ethylene spacer in the basal plane and a methylene spacer for the pendent pyridine arms were expected to provide an unstrained environment for the binding of O_2 inside the macrocyclic cavity.[9] In the case of MEPY22PZ pyrazole donors instead of imidazoles were chosen for their synthetic accessibility, and because pyrazoles mimic imidazoles both electronically and structurally.[10] The pyrazoles in MEPY22PZ are selectively functionalized at the N1 and C3 positions;[8] the aminomethylene group at the C3 position is much more stable than the corresponding N1-functionalized pyrazoles.[11]



Scheme 1.

The MEPY22PZ ligand reacts with two equivalents of $[Cu^I(CH_3CN)_4]X$ salts[12] in solution to yield dinuclear Cu^I complexes of general composition $[Cu_2(MEPY22PZ)]X_2$ (**1**: $X = ClO_4^-$ or PF_6^-), as characterized by NMR titrations (300 MHz, $[D_3]CH_3CN$). The observed ^1H and ^{13}C NMR downfield shifts of the azole groups indicate that all nitrogen donors in MEPY22PZ are coordinated to the Cu^I ions.[13] Bubbling dry O_2 through a pale yellow solution of **1** in CH_3CN at 21 °C oxygenates the complex and results in an immediate color change to intense purple. The corresponding UV/Vis spectrum (Figure 1) shows strong absorptions at λ_{max} (ε [$M^{-1}cm^{-1}$/Cu_2]) = 525 nm (4010), 625 nm (2290), and a weak shoulder at

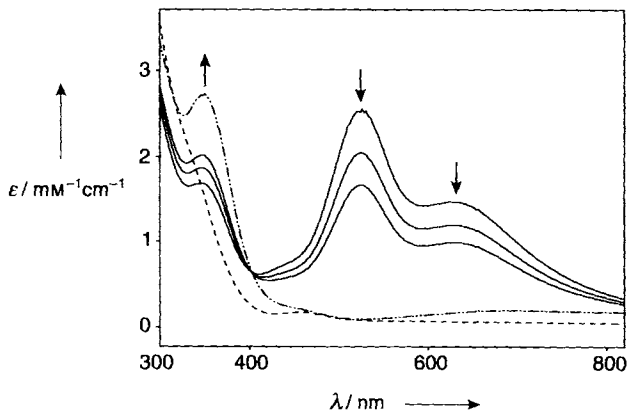


Figure 1. Electronic spectra of the dinuclear Cu^I complex **1** (– – –) and **2** (——) after oxygenation with O_2 in CH_3CN at 21 °C. The final spectrum (–·–·–) corresponds to a pale green dicopper(II)–MEPY22PZ decomposition product.

Zuberbühler (Universität Basel, Switzerland) for fruitful discussions.

438 nm (710). The UV/Vis spectrum of the purple complex **2** is characteristic for the formation of a *trans*-μ-1,2-peroxodicopper(II) compound and very similar to that of $[\{Cu(tmpa)\}_2(\mu\text{-}O_2)](PF_6)_2$ ($-80\,^{\circ}C$, CH_2Cl_2; tmpa = tris(2-pyridylmethyl)-amine), originally reported by Karlin and co-workers.[14] Concentrating a solution of **2** at $-20\,^{\circ}C$ provides **2** as a dark purple powder.[15] Its ligand-field powder spectrum (diffuse reflectance) at room temperature shows strong Cu^{II}–peroxo charge transfer (CT) absorptions at 522 nm and 654 nm, which are similar to the main UV/Vis ligand-to-metal CT bands for **2** in solution. Therefore, the formation of a dinuclear copper–dioxygen adduct with a trigonal bipyramidal geometry around each Cu^{II} ion and formula $[Cu_2(MEPY22PZ)(\mu\text{-}O_2)]X_2$ (**2**: $X = ClO_4^-$ or PF_6^-) is evident. The strong absorptions at 525 and 625 nm are assigned to $O_2^-(\pi_\sigma^*) \rightarrow Cu^{II}$ (d_{z^2}) and $O_2^-(\pi_v^* \rightarrow Cu^{II}$ (d_{z^2}) CT transitions in accordance with SCF-Xα-SW calculations by Solomon et al.[16]

Resonance Raman spectra of **2** in CH_3CN ($-40\,^{\circ}C$) were recorded to determine the binding mode of the bridging peroxo anion (Figure 2). Oxygenation of **1** with $^{16}O_2$ yields an intense

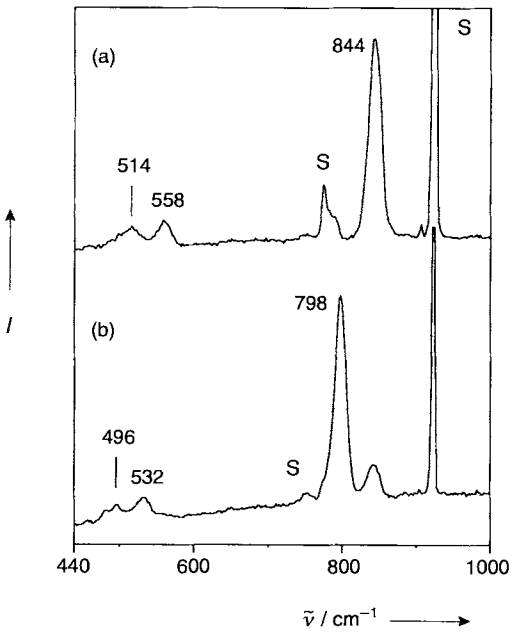

Figure 2. Resonance Raman spectra (514.5 nm excitation line) of **2**, obtained by oxygenation of **1** with a) $^{16}O_2$ and b) $^{18}O_2$ in dry CH_3CN at $-40\,^{\circ}C$.

Raman peak at 844 cm^{-1}, which is assigned to an intra-peroxide ν(O–O) stretch. The observed value for **2** is 12 cm^{-1} higher than that reported for $[\{Cu(tmpa)_2\}(O_2)]^{2+}$.[14, 16] Upon using $^{18}O_2$ the ν(O–O) stretch of **2** shifts to 798 cm^{-1}. In addition, a smaller peak at 558 cm^{-1}, observed when $^{16}O_2$ is used, shifts to 532 cm^{-1} in the case of $^{18}O_2$. This peak is assigned to a ν(Cu–O) stretch.[14, 16] The resonance Raman vibrations for **2**, including the $^{16}O_2/^{18}O_2$ isotope shifts, are in full agreement with the values reported for $[\{Cu(tmpa)_2\}(O_2)]^{2+}$ and strongly support end-on *trans*-μ-1,2-peroxo bridging.

To ascertain that **2** is indeed an intramolecular O_2 adduct, as opposed to intermolecular $\{Cu_2(L)O_2\}_n$ oligomers,[9] an electrospray ionization (ESI) mass spectrum of **2** was recorded at $-40\,^{\circ}C$ in CH_3OH (Figure 3). It shows prominent ion clusters at $m/z = 401$ and 947. These masses and their isotope patterns are consistent for a dication $[Cu_2(MEPY22PZ)(O_2)]^{2+}$ (separated by 0.5 Da) and a monocation $\{[Cu_2(MEPY22PZ)(O_2)](PF_6)\}^+$ (separated by one mass unit). The observed ion peaks clearly indicate a Cu:O_2 ratio of 2:1 and prove that O_2 is bound in an intramolecular fashion in **2**.

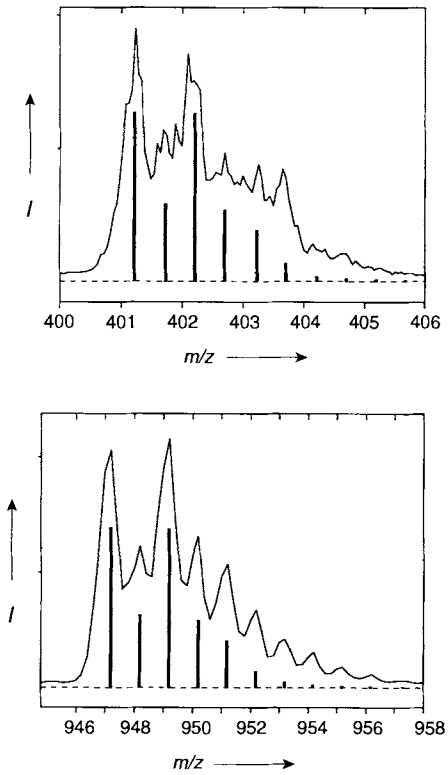

Figure 3. Positive ion ESI-MS data for **2**; $m/z = 401$ and +947 ($[Cu_2(MEPY22PZ)(O_2)]^{2+}$ (top) and $\{[Cu_2(MEPY22PZ)(O_2)](PF_6)\}^+$ (bottom), respectively); the calculated isotope patterns are represented by bars.

Upon formation the purple complex **2** slowly decomposes at room temperature, as evidenced by the fading of the purple color. A pale green solution remains after about 30 min. The decomposition reaction follows (pseudo) first-order kinetics with $t_{1/2} = 200$ s in dry CH_3CN. Remarkably, **2** can also be generated under similar conditions (21 °C) in CH_3OH without explicit drying of the solvent. In fact, the purple color is observed for several minutes when up to 20% H_2O is added to a solution of **2** in CH_3OH. Kinetic studies in CH_3OH (21 °C) give $t_{1/2} = 250$ s, indicating that the peroxo complex is equally stable in a protic solvent.

As expected, the same purple Cu^{II}–peroxo complex **2** can also be formed from the corresponding dicopper(II) complex[12] in CH_3OH by adding one equivalent of aqueous H_2O_2 in the presence of two equivalents of base.[3b] An immediate color change to intense purple is observed, and the UV/Vis spectrum is similar that of **2** in CH_3CN: λ_{max} (ε [$M^{-1}cm^{-1}/Cu_2$]) = 516 nm (4450), shoulder at 625 nm (1825). A frozen, purple solution (MeOH/EtOH 9/1; 77 K) of **2**—from either Cu^I and O_2 or Cu^{II}, H_2O_2, and base—is EPR silent. Complex **2** is also EPR silent in the solid state (77 K); this is suggestive of antiferromagnetically coupled Cu^{II} ions.[3b] The "peroxide-shunt" reaction of a Cu^{II} complex with H_2O_2 and base is analogous to the observations described by Kitajima et al.[3a]

All obtained data support the conclusion that the dicopper(I) complexes $[Cu_2(MEPY22PZ)]X_2$ bind one equivalent of molecular O_2 at room temperature intramolecularly between two copper ions as an O_2^{2-} anion in an end-on *trans*-μ-1,2-peroxo fashion inside the 22-membered macrocyclic cavity. Molecular

mechanics calculations also suggest that an intramolecular Cu_2^{II}–μ-peroxo structure for **2** is feasible.[17] The enhanced inertness of **2** is likely to result from the protective nature of the MEPY22PZ ligand, which slows down the decomposition reaction and allows its study in protic solvent. Although the mode of O_2 binding in **2** is different from that in the native protein hemocyanin (*trans*-μ-1,2-peroxo instead of μ-η^2-η^2), **2** is the first example of a dinuclear copper complex capable of binding molecular O_2 at room temperature in a protic solvent. The macrocyclic ligand probably lowers the reaction entropy for O_2 binding and allows formation of a dinuclear Cu^{II}–peroxo complex at room temperature.[9, 19]

Experimental Section

Caution: Complexes with organic ligands and perchlorate anions are potentially explosive!

MEPY22PZ: Under a dry N_2 atmosphere, dry Na_2CO_3 (3.7 g, 26.6 mmol), 1,2-di[3-(2-pyridin-2-ylmethylamino)-5-methyl-1-pyrazolyl]ethane (5.52 g, 12.8 mmol), and 1,2-di[3-chloromethyl-5-methyl-1-pyrazolyl)ethane (1 equiv) were suspended in dry THF (1.7 L) with dry MeCN (300 mL). The reaction mixture was heated to reflux for 10 d, during which time it gradually turned light brown. A solution of saturated NaCl (600 mL) was added followed by HCl (1 M, 50 mL) until pH $\leq$ 1. The aqueous layer was separated, washed with Et_2O, made alkaline with concentrated ammonia, and extracted with CH_2Cl_2. The organic layer was dried with Na_2SO_4. Evaporation of the solvent yielded a dark, red-brown solid ($\approx$4.5 g). Column chromatographic purification on silica gel with CH_2Cl_2/MeOH (85/15) as eluent gave a pale, yellow solid ($R_f \approx 0.6$), which was recrystallized from MeOH/Et_2O. Yield: 1.28 g (1.99 mmol; 16%). ^{1}H NMR ($CDCl_3$): δ = 8.41 (d, J = 5.6 Hz, 2H, Py-H6), 7.85 (dd, J = 7.7 Hz, 2H, Py-H4), 7.38 (d, J = 7.7 Hz, 2H, Py-H3), 7.46 (m, 2H, Py-H5), 5.92 (s, 4H, Pz-H4), 4.41 (s, 8H, Pz-αCH$_2$), 3.56 (s, 4H, Py-CH$_2$), 3.36 (s, 8H, Pz-CH$_2$N), 2.15 (s, 12H, Pz-CH$_3$); ^{13}C NMR ($CDCl_3$): δ = 159.2 (Py-**C**2), 149.6 (Py-C6), 149.3 (Pz-C3), 145.3 (Py-C4), 138.5 (Pz-C5), 125.2 (Py-C5), 123.7 (Py-C3), 107.5 (Pz-C4), 60.1 (Py-αCH$_2$), 50.7 (Pz-CH$_2$N), 47.7 (Pz-αCH$_2$), 10.8 (Pz-CH$_3$); ESI-MS (positive ion): m/z = 645 [M^+ + H and parent peak, calcd: 644.82], 667 [M + Na$^+$], 683 [M + K$^+$], 323 [M + 2H]$^{2+}$; IR (KBr, cm^{-1}) $\tilde{\nu}$ = 1588 (s), 1568 (s) (both C=N (Py), 1545 (vs) (C=N (Pz), 1474 (s), 1437 (s), 1398 (s), 1320 (s), 792 (s), 763(s). The product contains 0.5 equiv H_2O (^{1}H NMR ($CDCl_3$): δ = 1.7). Elemental analysis calcd for $C_{36}H_{44}N_{12}\cdot 0.5\,H_2O$: C 66.13, H 6.94, N 25.71; found: C 66.09, H 6.84, N 25.57.

1: 0.68 mL of a 51.5 mM solution of [Cu^I(CH$_3$CN)$_4$](ClO$_4$) (34.1 μmol) was added to a solution of MEPY22PZ (11.0 mg, 17.06 μmol) in dry CH_3CN (15 mL), and the bright, yellow solution stirred for 15 min. ^{1}H NMR (300 MHz, [D$_3$]CH$_3$CN): δ = 8.51 (d, J = 4.6 Hz, 2H, Py-H6), 7.93 (dd, J = 7.5 Hz, 2H, Py-H4), 7.42 (d, J = 7.5 Hz, 2H, Py-H3), 7.48 (m, 2H, Py-H5), 5.94 (s, 4H, Pz-H4), 4.45 (s, 8H, Pz-αCH$_2$), 3.86 (s, 4H, Py-CH$_2$), 3.63 (s, 8H, Pz-CH$_2$N), 2.18 (s, 12H, Pz-CH$_3$); ^{13}C NMR ($CDCl_3$): 159.7 (Py-C2), 150.5 (Py-C6), 150.2 (Pz-C3), 146.5 (Py-C4), 138.8 (Pz-C5), 124.6 (Py-C5), 125.2 (Py-C3), 106.2 (Pz-C4), 61.4 (br., Py-αCH$_2$), 54.3 (Pz-CH$_2$N), 48.9 (Pz-αCH$_2$), 11.3 (Pz-CH$_3$). Dry O_2 was bubbled through a 1 mM solution of **1** in CH_3CN (or CH_3OH) for 30 s at room temperature to generate **2**.

Electrospray ionization mass spectra of **2** at room temperature were acquired as described [18]. Spectral data were collected with a PE Sciex API III triple quadrupole mass spectrometer (Sciex, Thornhill, ON, Canada). Aliquots from a solution of **2** in CH_3OH (1 mM) at $-40\,^\circ$C were injected by a Harvard Apparatus Model 22 syringe infusion pump (South Natick, MA) through a fused silica capillary line (internal diameter 76 μm, flow rate 15 mL min^{-1}). Mass spectra were acquired with a step size of 0.2 Da (5–10 ms dwell per step). Without cooling the syringes, peaks of the peroxo product **2** were visible at room temperature as long as the purple color persisted.

Soluble Molecular Titanosilicates**

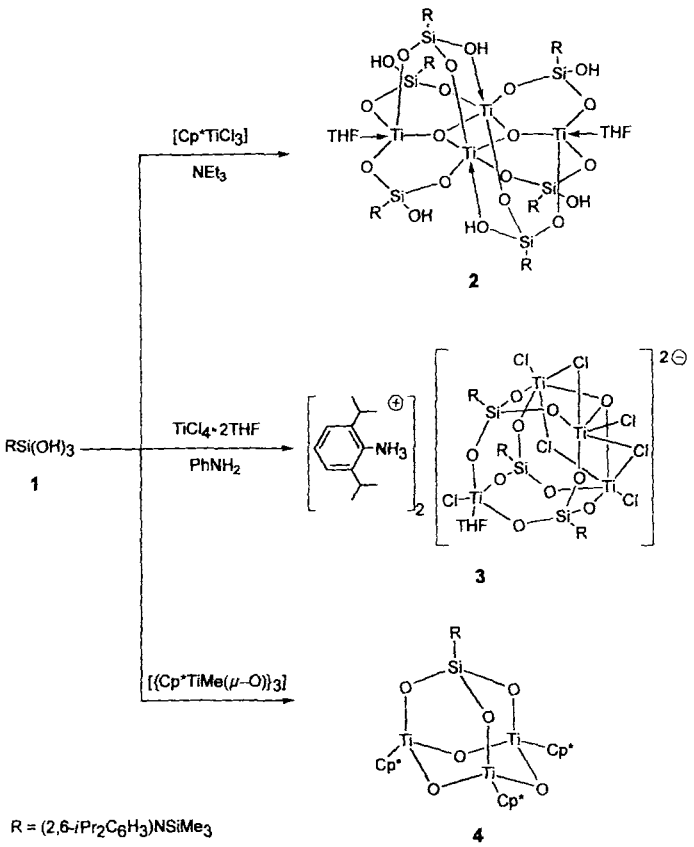
Dedicated to Professor Robert Wolf

The discovery of Titanium Silicalite-1 (TS-1)[1] in 1983 opened up active research on the synthesis of heterogeneous catalysts containing titanium atoms (in formal oxidation state +4) for oxidation and epoxidation reactions involving many organic molecules, of which the conversion of propylene to propylene oxide is an industrially important process.[2] Since then many research groups have contributed to this idea and in the ensuing years several titanosilicates, such as TS-2, MCM-41, aluminum-free Ti-β-zeolite, ETS-4, and ETS-10, showing varying catalytic activity and size- and shape-selectivity were reported.[3] It has been identified that, unlike in TS-1, in which Ti centers are coordinated to four oxygen atoms, ETS-4 and ETS-10 contain six-coordinate Ti atoms. In an important breakthrough reported recently, Thomas et al. have described the synthesis of a new titanosilicate (JDF-L1) that can intercalate large organic molecules.[4, 5] An interesting feature of this material is the presence of five-coordinate Ti atoms in the layered structure, a rare example among naturally occurring and synthetic zeolites. On the other hand, owing to the microporosity of many synthetic zeolites, there have been many successful attempts to support Ti centers on SiO_2 for the oxidation reactions of bigger substrates. However, the activity of these catalysts seems to suffer from the hydrophilic nature of the support and the decomposition of the oxidant (H_2O_2) over TiO_2 particles formed during the synthesis.[6]

In spite of the structural diversity and varying degrees of catalytic activity and selectivity shown by these insoluble titanosilicates and Ti/SiO_2 systems, there has been very little effort to successfully model these compounds and eventually realize smaller soluble analogues of these rather complex materials. We have been concentrating on the use of soluble silanetriols $RSi(OH)_3$ for the preparation of three-dimensional metallasiloxanes, which would model many synthetic zeolites.[7] In this direction, we synthesized a range of Al-, Ga-, In-, and Ti-containing siloxanes with cubic $M_4O_{12}Si_4$ frameworks, and indicated the relevance of our studies in understanding the structures of many synthetic zeolites. We report herein on the reactions of a silanetriol with a series of Ti-containing precursors, which leads to titanosilicates that show interesting structural properties.

The reactions of (arylamino)silanetriol **1**[8] with $[Cp^*TiCl_3]$, $TiCl_4 \cdot 2THF$, and $[\{Cp^*TiMe(\mu\text{-}O)\}_3]$ lead to titanosiloxane cages **2**, **3**, and **4**, respectively (Scheme 1; $Cp^* = C_5Me_5$). The new titanosiloxanes have been fully characterized by elemental analysis, mass spectrometry, IR and NMR spectroscopy, and single-crystal X-ray diffraction studies.[9]

The reaction between **1** and $[Cp^*TiCl_3]$ in the presence of NEt_3 as HCl acceptor affords the cage compound $[(RSi(OH)O_2)_6Ti_4(\mu_3\text{-}O)_2]$ (**2**), which is free of Cp* and Cl ligands. Compound **2** contains four Ti centers, which are surrounded by six $RSi(OH)O_2$ silanolate ligands, two μ_3-O atoms, and two coordinated THF molecules (Figure 1). The central unit of the molecule is made up of a planar four-membered Ti_2O_2 ring. Each of the four sides of this ring also forms part of a six-membered Ti_2SiO_3 ring. If the central Ti_2O_2 ring and the four surrounding Ti_2SiO_3 rings are considered to be approximately



Scheme 1. Synthesis of soluble molecular titanosilicates **2**–**4**.

coplanar, on either side of this plane there is a $RSi(OH)O_2$ moiety, which acts as a ligand linking three Ti atoms. The Si–O bond (1.663 Å) between Si(5) and the oxygen atom O(22), to which a hydrogen atom is attached, is longer than the other two Si–O distances around Si(5) (av 1.626 Å).

There are two distinct types of Ti centers in **2**. The two peripheral Ti centers are five-coordinate with a distorted TiO_5 trigonal-bipyramidal coordination sphere. The two central Ti centers have a TiO_6 octahedral arrangement around them. Although it has been recently shown that JDF-L1[5] contains pentacoordinate Ti centers with a square-pyramidal geometry, it should be noted that five-coordinate Ti centers have rarely been observed in titanosilicates. On the other hand, a TiO_6 octahedral arrangement around titanium atoms is observed in the case of the rutile modification of TiO_2[10] and in the ETS family of synthetic titanosilicates. Moreover, **2** can be considered as a soluble molecular silicate in which formal TiO_2 fragments are trapped inside.

The reaction of **1** with $TiCl_4 \cdot 2THF$ leads to the ionic cage compound $(2,6\text{-}i\text{Pr}_2C_6H_3NH_3)_2[(RSiO_3)_3Ti_4Cl_7(\mu_3\text{-}O)] \cdot C_6H_5NH_3Cl \cdot THF$ (**3**) (Figure 2). The polyhedron defined by

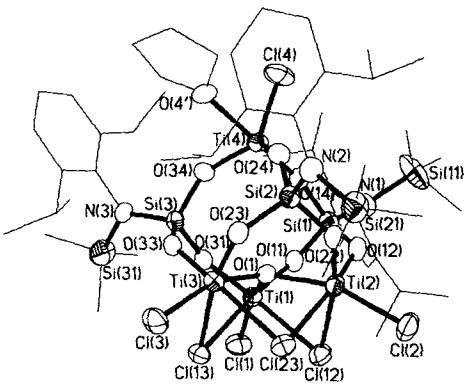

Figure 2. Core structure of **3**. Selected average bond lengths [pm]: Ti–μ_2-O 179.7, Ti–μ_3-O 197.1, Ti–Cl 230.1, Ti–μ_2-Cl 261.3, Si–O 163.2.

the four Ti atoms and the three SiO_3 units in **3** can been described as an open-cube. The main difference between **3** and the previously reported neutral cubic titanosiloxanes[11] is the absence of the fourth SiO_3 unit of the cubic polyhedron. The open space around the eighth corner of the cubic polyhedron in **3** is occupied by a μ_3-O dianion, which lies 38 pm above the Ti_3 plane. Each of the four Ti atoms in **3** bears a terminal Cl atom. Furthermore, the three Ti centers occupying the open corners of the cube are also symmetrically bridged by three Cl atoms. As a result, the whole titanosiloxane cage bears a -2 charge. Two 2,6-diisopropylanilinium ions compensate the charge in the crystal. Also the whole molecule cocrystallizes with a molecule of $PhNH_3Cl$, which shows interactions with the cations in **3**. While Ti(4) is pentacoordinated (TiO_4Cl) with a trigonal-bipyramidal geometry, the other three Ti atoms are in an octahedral (TiO_3Cl_3) coordination sphere.

The reaction between the cyclic organometallic complex $[\{Cp^*TiMe(\mu\text{-}O)\}_3]$[12] and a stoichiometric quantity of **1** yields the titanosiloxane **4**. Compound **4** has an adamantane structure resulting from a Ti_3SiO_6 structural unit (Figure 3). The geometry of the cage in **4** resembles the core structure of the *all*-Ti adamantanoid molecule $[Cp^*_4Ti_4O_6]$.[13] Compound **4** is a rare example of an adamantanoid structure with two different metal atoms (Ti and Si) in the bridgehead positions.

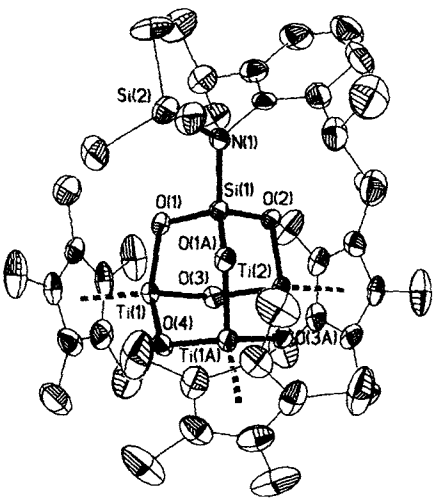

Figure 3. Molecular structure of **4**. Selected bond lengths [pm] and angles [°]: Ti(1)–O(1) 186.0(3), Ti(1)–O(3) 183.4(3), Ti(1)–O(4) 184.3(2), Ti(2)–O(2) 186.6(4), Ti(2)–O(3) 183.6(3), Si(1)–O(1) 163.3(3), Si(1)–O(2) 163.0(4); O(3)-Ti(1)-O(4) 102.0(2), O(3)-Ti(1)-O(1) 100.3(1), O(4)-Ti(1)-O(1) 100.7(2), O(3)-Ti(2)-O(3A) 101.5(2), O(3)-Ti(2)-O(2) 100.0(1), Si(1)-O(1)-Ti(1) 121.2(2), Si(1)-O(2)-Ti(2) 121.0(2), Ti(1)-O(3)-Ti(2) 122.7(1), Ti(1)-O(4)-Ti(1A) 121.1(2).

In summary, we have highlighted here the use of silanetriol **1** in synthesizing a variety of titanosiloxane cages through HCl or CH_4 elimination reactions. The compounds **2**–**4** described herein possess several interesting structural features that have relevance to the structures of titanosilicates. Furthermore, the structure of compound **2** demonstrates how quasi-inorganic structural units such as TiO_2 can effectively be trapped in soluble metallasilicate frameworks.

Experimental Section

2: To a solution of **1** (1.64 g, 5 mmol) and NEt_3 (1.45 g, 15 mmol) in THF (30 mL), $[Cp^*TiCl_3]$ (1.52 g, 5 mmol) in THF (50 mL) was added dropwise, and the reaction mixture was heated under reflux for 2 d during which the color of the reaction mixture changed from red to red-brown. After removal of the solvent in vacuo the residue was extracted six times with hot *n*-hexane. From the concentrated extract, 0.4 g of pale yellow crystals of **2** suitable for X-ray crystal structure analysis were obtained after one week. M.p. 283 °C (decomp); ^{1}H NMR (200 MHz, $CDCl_3$, TMS): $\delta = 0.11, 0.14$ (s, 54 H, $Si(CH_3)_3$), 1.28 (m, 72 H, $CH(CH_3)_2$), 1.32 (m, 4 H, THF), 3.43 (m, 4 H, THF), 3.71 (m, 12 H, $CH(CH_3)_2$), 7.10 (m, 18H, H_{arom}), 10.30 (s, 6 H, OH); IR (KBr, Nujol): $\tilde{\nu} = 3640, 3623, 1250, 1185, 1106, 1044, 1018, 970, 939, 897\ cm^{-1}$; elemental analysis $C_{104}H_{192}N_6O_{22}Si_{12}Ti_4$: calcd. C 51.9, H 8.0, N 3.5; found C 50.3, H 8.2, N 3.6.

3: A suspension of $TiCl_4 \cdot 2THF$ (2.0 g, 6 mmol) in Et_2O (50 mL) was added at room temperature over 20 min to a solution of **1** (1.97 g, 6 mmol) and aniline (1.64 g, 18 mmol) in Et_2O (35 mL) and stirred for 12 h. The reaction mixture was concentrated to about 60 mL and filtered. The pale yellow residue obtained after the removal of the solvent was washed with *n*-hexane and dried in vacuo to obtain 1.5 g of **3** as a microcrystalline powder. M.p. 195 °C (decomp); ^{1}H NMR ([D_8]THF, 200 MHz, TMS): $\delta = 0.08$–0.41 (s, many singlets, 27 H, $Si(CH_3)_3$), 1.29 (d, 60 H, $CH(CH_3)_2$), 3.65 (sept, 10 H, $CH(CH_3)_2$), 7.28 (m, 15 H, H_{arom}), 10.49 (s, 6H, NH_3); IR (KBr, Nujol): $\tilde{\nu} = 3090, 1578, 1489, 1461, 1377, 1260, 1098, 1028, 931, 847, 799\ cm^{-1}$; elemental analysis: $C_{79}H_{134}Cl_8N_6O_{11}Si_6Ti_4$, calcd. C 47.7, H 6.7, Cl 14.3, Si 8.4; found C 46.5, H 6.7, Cl 14.0, Si 8.3.

4: A solution of **1** (0.33 g, 1 mmol) in toluene (30 mL) was added at room temperature to a solution of $[Cp^*TiMe(\mu\text{-}O)]_3$[13] (0.64 g, 1 mmol) in toluene (30 mL). The reaction mixture was heated under reflux for 3 h and concentrated to half of its volume in vacuo and cooled at -20 °C to yield 0.78 g (85%) of **4** as an orange microcrystalline solid. M.p. >200 °C; ^{1}H NMR (250 MHz, $CDCl_3$, TMS): $\delta = 0.08$ (s, 9H, $Si(CH_3)_3$), 1.18 (d, 12 H, $CH(CH_3)_2$), 1.92 (s, 15H, $C_5(CH_3)_5$), 3.52 (sept, 2 H, $CH(CH_3)_2$), 7.10 (m, 3 H, H_{arom}); IR (KBr, Nujol): $\tilde{\nu} = 1261, 1181, 1099, 1021, 870, 801, 703, 571\ cm^{-1}$; MS ((EI): *m/z*: 922 [$M^+$]; elemental analysis: $C_{45}H_{71}NO_6Si_2Ti_3$: calcd. C 58.6, H 7.7, N 1.5, Si 6.1, Ti 15.6; found C 57.8, H 7.5, N 1.4, Si 5.9, Ti 15.2.

Cation-Cyclization Selectivity: Variable Structures of Protonated Cyclopropanes and Selectivity Control by Catalytic Antibodies**

Jeehiun K. Lee and Kendall N. Houk*

Cation cyclizations provide nature with selective routes to complex steroids and terpenes.[1] Biomimetic analogs are useful synthetic pathways to steroids.[2] Many different products such as alkenes and alcohol stereoisomers as well as partially cyclized materials may be formed in solution, whereas enzyme-catalyzed processes are in general highly selective. Several antibodies have been found that catalyze cyclizations leading selectively to cyclopropanes, alcohols, or alkenes, depending on the substituents.[3–5]

Ab initio calculations reported here on the protonated cyclopropane intermediates formed in these reactions show how the substituents perturb the geometry of the protonated cyclopropane. The calculated variations in nonclassical ion structure, combined with recent studies of the 1-methylcyclohexyl ion,[6] provide a map of geometrical variations induced by substitution in cyclohexyl cations. The stereochemistry of deprotonation of a protonated cyclopropane to form the cyclopropane product has also been determined for the first time. Force-field modeling of the binding of these intermediates in an antibody complementarity site adapted from the cation-binding region of the antibody McPC603 suggests a novel way in which the binding orientation can influence the reaction selectivity. Our finding is relevant to a recent report on synthetic analogs of this same antibody.[7] We have discovered that amplification of a slight, inherent propensity for reaction can occur in the binding sites of antibodies. This amplification of selectivity may explain why antibody catalysts give high yields of a single product even when the background reaction produces low selectivity. The catalysis of reactions that are disfavored or minor in the absence of catalyst is one of the major promises of antibody catalysis.[8, 9]

Antibody IgG TM1-87D7, elicited against hapten **1**, catalyzes a series of selective reactions with **2a–c**, including cyclopropanation (**4–6**, Scheme 1).[3] All reactions are believed to proceed through **3**, a protonated cyclopropane belonging to a class of species that is experimentally and theoretically well-established[10–15] and includes the famous nonclassical norbornyl cation.[16, 17] Increasingly accurate quantum mechanical methods have led to the capability to predict reliably the structures and energies of these important intermediates.[13, 15]

Calculations were conducted at the MP2/6-311G* level to pinpoint the most stable structures for **3a–c**;[18] the $CPhMe_2$ group was replaced by H. At lower levels (RHF 3-21G and 6-31G*) the nonclassical structure cannot be found for any of the cations, and the cyclohexyl cation is the most stable structure. However, when electron correlation is included (MP2), protonated cyclopropane geometries with varying degrees of bridging are found for these three species. Structure **3c′** (Scheme 2) has the least amount of bridging, but considerable hyperconjugative stabilization results from interaction of the

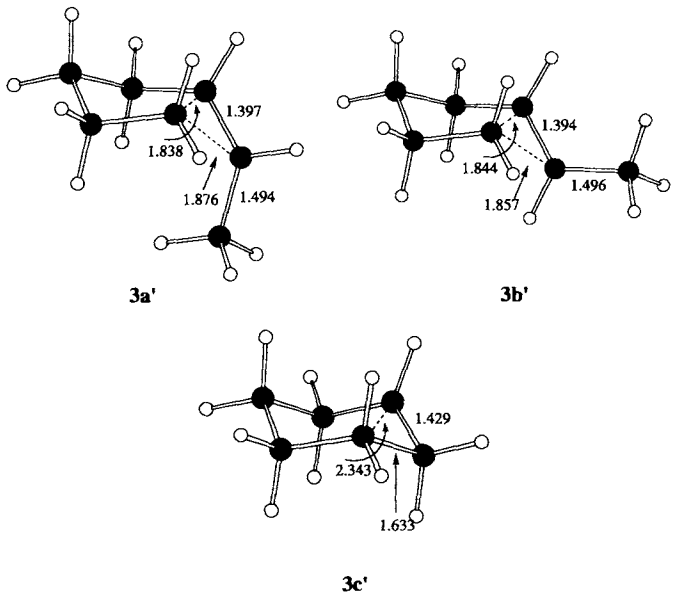


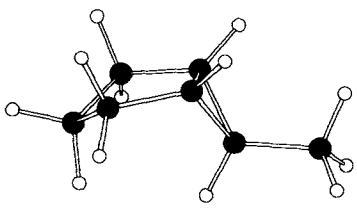
Scheme 2. Calculated structures (MP2/6-311G*) of three protonated cyclopropanes.

C2–C3 and C5–C6 bonds with the unoccupied equatorial *p* orbital. The isomeric axial cation with C–H hyperconjugation is 4.9 kcal mol^{-1} higher in energy.

Both **3a'** and **3b'** are closer to fully bridged, protonated cyclopropane. *Trans* **3b'** has the corner-protonated cyclopropane structure and is a nonclassical cation, like the norbornyl cation. It is useful to visualize this species as a *trans*-alkene that is bridged symmetrically by an alkyl cation. Reaction with nucleophiles at either "alkene" carbon or deprotonation of the bridging alkyl group are likely fates of such a species. In *cis*-substituted **3a** the C1–C6 bond is longer than the C2–C6 bond (1.88 and 1.84 Å, respectively), which indicates a perturbation towards a more classical structure (**3a'**). The *cis*-methyl group makes **3a'** 1.6 kcal mol^{-1} less stable than **3b'**. Extensive, unsuccessful attempts to locate other structures for **3a–c** show that **3a'–c'** are the only stable species in the gas phase. Solvation studies on the norbornyl cation indicate that the nonclassical structure is not perturbed by solvent,[17] and it is thus quite likely that these structures are also maintained in solution.

Therefore, variation in substitution causes differences in the structures of **3a'–c'**, which may lead to altered reactivity. However, no cyclized products are experimentally observed in solution from the reactions of **2a–c**, and so the degree of selectivity in the absence of antibody is unknown.[3]

Formation of the fused-ring cyclopropane from **3a** or **3b** might occur by base-induced removal of either the equatorial or axial proton on C6. Calculations at the MP2/6-311G* level on deprotonation of either proton by water indicate that equatorial deprotonation is preferred at all distances. This not only establishes the stereochemistry of deprotonation, but also provides an additional reason why deprotonation is more facile for **3b** than for **3a**, which has a *cis*-methyl group partially blocking the access of a base to the equatorial hydrogen atom. Another interesting aspect of cyclopropane formation is that the fused-ring product has a boat and not a chair conformation (**7**, Scheme 3).[19]



7

Scheme 3. Calculated structure (MP2/6-311G*) of bicycle 7.

Despite the intrinsic differences in geometry among **3a–c**, the high selectivities observed in the antibody-catalyzed reactions are still astounding. The antibody clearly plays a role in amplifying the intrinsic selectivities. To model the manner by which an antibody might do this, we examined the active site of McPC603, an antibody that is specific for phosphorylcholine (PC).[20–22] The active site residues elicted by the ammonium group of PC are charged (aspartate and glutamate) as well as aromatic (tyrosine and tryptophan).[22, 23] The Asp97L, Tyr33H, and Trp107H residues in the X-ray crystal structure of McPC603 form a possible binding site for **1** and **3a–c**. It has recently been shown that a synthetic analog with these features could also bind PC analogs.[7] Hapten **1** was docked with the cation near the aspartate, and the remaining steric repulsions were minimized. Forcefield minimizations yielded the overall geometry shown in Figure 1 (**1''**).[24] The ammonium cation is nestled in the binding

cavity; the nitrogen atom is located at 3.7 and 3.8 Å from the aspartate carboxylate oxygen atoms.

The binding of **3a–c** was modeled by docking the cationic site near the carboxylate group (≈2 Å), which is placed to stabilize the forming cation as the sulfonate group leaves. The carboxylate may act as a base to deprotonate the cation or as a general base to deprotonate water as it attacks. The results for **3a–c** are shown in Figure 1 (**3a″–3c″**). In each case the cation moiety is near the carboxylate of Asp 97, whereas Trp 107H and Tyr 33H form a hydrophobic, cation-stabilizing binding pocket for the remainder of the substrate. This arrangement can enhance the charge at the cation site of the highly polarizable, protonated cyclopropane. by orienting the position of maximum positive charge near the carboxylate group. However, each substrate is bound in a slightly different manner depending on its structure. The antibody may enhance and amplify predisposed selectivity by differential binding of the substrates. For example, **3b″** binds in such a manner that water capture at C1 or C2 is not favored; the best pathway available is deprotonation to yield the fused ring product. In contrast, **3a″** cannot be readily deprotonated to a fused-ring structure, since C1, and not C6, is near the carboxylate group. The aspartate carboxylate presumably plays a role in deprotonation, either to actually deprotonate or as a general base. The structure of **3c″** is predisposed to form cyclohexanol; its mode of binding also discourages any alternate pathway.

In conclusion, substituents cause significant perturbations in the structures of protonated cyclopropanes causing a tendency to follow different reaction pathways. Antibodies that bind and stabilize these perturbed cations are likely to amplify the inherent biases of structure, resulting in high selectivity.

Noncovalent Synthesis of Nanostructures: Combining Coordination Chemistry and Hydrogen Bonding**

Wilhelm T. S. Huck, Ron Hulst, Peter Timmerman, Frank C. J. M. van Veggel,* and David N. Reinhoudt*

For the synthesis of nanosized particles with structures defined at the molecular level, conventional methods of multistep covalent synthesis have reached their limitations. Consequently, noncovalent synthetic methodologies that equal the precision of covalent synthesis but proceed by simple assembly of building blocks are needed. Such methods should be self-correcting under conditions of thermodynamic equilibrium. Zimmerman et al.[1] have exploited hydrogen bonding in the self-assembly of dendrimers centered around a hydrogen-bonded, hexameric nucleus, and we have described a divergent assembly route to dendrimers using coordination chemistry.[2, 3] Hitherto, the combination of two different types of compatible, noncovalent interactions for the assembly of finite nanostructures has not been employed.[4] Here we describe the combined use of hydrogen bonding and coordination chemistry in the assembly of nanosized metallodendrimers with molecular weights of up to 28 kDa. The combination of three metallodendrimer wedges, constructed by coordination chemistry, into a hydrogen-bonded rosette[5, 6] allows fast and controlled assembly of nanostructures by both divergent[7] and convergent[8] strategies.

Dendrons DG_0[9, 10] to DG_3 (Scheme 1), which contain one barbituric acid residue capable of hydrogen bonding, were synthesized on a 50 mg scale by controlled assembly of appropriate building blocks. DG_1 was assembled from DG_0 by activating the Pd center with $AgBF_4$. This gives an intermediate, cationic solvento complex, to which the bis(Pd–Cl) building block BB-Cl[3] coordinates (through its cyano moiety). The higher generation dendrons DG_2 and DG_3 were assembled in a one-pot procedure by repeating these activation and addition steps.

The activation by $AgBF_4$ and the assembly of the building blocks are fast and quantitative reactions; purification is not necessary, and precipitated AgCl is easily removed by filtration. DG_1–DG_3 were characterized by ^{1}H NMR spectroscopy, ES-MS (ES = electrospray), and elemental analysis (Table 1).[11] In

Table 1. Selected physical data for DG_0–DG_3.

DG_0: M.p. 143–144 °C; ^{1}H NMR (250 MHz, $CDCl_3$, 25 °C, TMS): δ = 8.40 (s, 2H, NH), 7.81–7.75 (m, 4H, Ar_5H), 7.42–7.23 (m, 6H, Ar_5H), 6.83 (s, 2H, $Ar_{Pd}H$), 4.53 (br. s, 4H, CH_2S), 3.40 (s, 2H, $C(O)CH_2$), 1.92–1.88 (m, 2H, CH_2), 1.6 (br. s, 2H, H_2O), 1.31–1.25 (m, 4H, CH_2), 0.87 (t, 3H, CH_3); ^{13}C NMR ($CDCl_3$): δ = 171.7, 150.4, 147.6, 132.0, 131.5, 130.3, 129.8, 115.2, 53.0, 51.6, 40.1, 38.8, 26.1, 22.4, 13.6; FAB-MS (*m*-nitrobenzyl alcohol, NBA): m/z = 669.2 ($[M - Cl]^+$), calcd 667.9; elemental analysis calcd for $C_{30}H_{29}O_5S_2N_2PdCl \cdot H_2O$: C 49.94, H 4.33, N 3.88; found: C 50.34, H 4.28, N 3.76.

DG_1: M.p. 146–147 °C; ^{1}H NMR (250 MHz, CD_3NO_2, 25 °C, TMS): δ = 8.77 (s, 2H, NH), 7.79–7.73 (m, 12H, Ar_5H), 7.50 (s, 2H, ArH), 7.38–7.30 (m, 19H, Ar_5H, ArH), 6.68 (s, 6H, $Ar_{Pd}H$), 5.06 (s, 4H, CH_2O), 4.6 (br. s, 12H, CH_2S), 3.94 (s, 2H, CH_2CN), 3.39 (s, 2H, $C(O)CH_2$), 1.96–1.93 (m, 2H, CH_2), 1.35–1.31 (m, 4H, CH_2), 0.90 (t, 3H, CH_3); ES-MS: m/z = 1765.0 ($[M - BF_4]^+$), calcd 1766.4; elemental analysis calcd for $C_{80}H_{70}O_7S_6N_3Pd_3Cl_2BF_4 \cdot 2H_2O$: C 50.82, H 3.94, N 2.22, S 10.17, Cl 3.76; found: C 50.61, H 3.92, N 2.40, S 9.64, Cl 4.06.

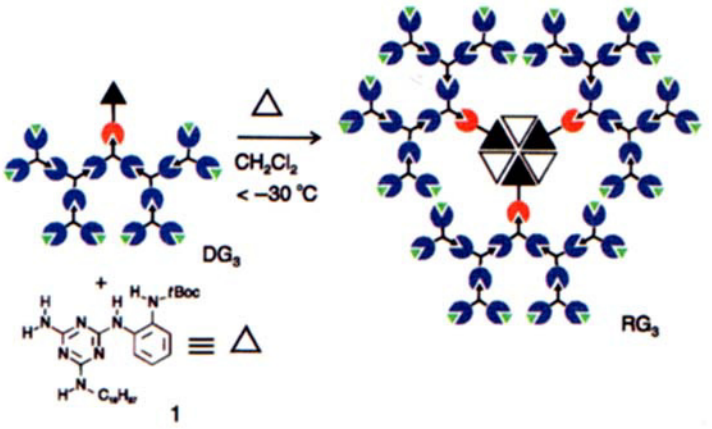
DG_2: M.p. 149–150 °C; ^{1}H NMR (250 MHz, CD_3NO_2, 25 °C, TMS): δ = 8.54 (s, 2H, NH), 7.69–7.64 (m, 28H, Ar_5H), 7.39 (s, 6H, ArH), 7.33–7.28 (m, 45H, Ar_5H, ArH), 6.67 (s, 14H, $Ar_{Pd}H$), 4.98 (s, 12H, CH_2O), 4.5 (br. s, 28H, CH_2S), 3.81 (s, 6H, CH_2CN), 3.27 (s, 2H, $C(O)CH_2$), 1.95–1.91 (m, 2H, CH_2), 1.35–1.32 (m, 4H, CH_2), 0.80 (t, 3H, CH_3); ES-MS: m/z = 3986.0 ($[M - 2BF_4]^+$), calcd 3983.2; elemental analysis calcd for $C_{180}H_{152}O_{11}S_{14}N_5Pd_7Cl_4B_3F_{12}$: C 52.01, H 3.69, N 1.68, S 10.80, Cl 3.41; found: C 52.24, H 3.84, N 1.66, S 10.63, Cl 3.32.

DG_3: M.p. 157–158 °C; ^{1}H NMR (250 MHz, CD_3NO_2, 25 °C, TMS): δ = 8.56 (s, 2H, NH), 7.70–7.66 (m, 60H, Ar_5H), 7.39 (s, 14H, ArH), 7.31–7.25 (m, 97H, Ar_5H, ArH), 6.65 (s, 30H, $Ar_{Pd}H$), 4.97 (s, 28H, CH_2O), 4.5 (br. s, 60H, CH_2S), 3.79 (s, 14H, CH_2CN), 3.28 (s, 2H, $C(O)CH_2$), 1.92–1.89 (m, 2H, CH_2), 1.35–1.31 (m, 4H, CH_2), 1.07 (t, 3H, CH_3); ES-MS: m/z = 8625.9 ($[M - BF_4 - Cl]^+$), calcd: 8632.7; elemental analysis calcd for $C_{380}H_{316}O_{19}S_{30}N_6Pd_{15}Cl_8B_7F_{28}$: C 52.09, H 3.64, N 1.44, S 10.98, Cl 3.24; found: C 52.41, H 3.74, N 1.42, S 10.77, Cl 2.85.

all cases coordination of the cyano groups to the Pd centers was confirmed by FT-IR (the band for the C≡N stretch shifts from 2250 to 2290 cm^{-1} upon coordination).[12] ES-MS spectra of solutions in CH_3NO_2 clearly show formation of the dendrons with the masses 1765.3 Da (DG_1, 1766.7 calcd for $[M - BF_4]^+$), 3986.0 Da (DG_2, 3983.2 calcd for $[M - 2BF_4]^+$), and 8625.9 Da (DG_3, 8632.7 calcd for $[M - BF_4 - Cl]^+$).

The rosettes were subsequently constructed by addition of *N*-octadecanyl-*N'*-(2-*N*-*t*Boc-amino)phenylmelamine (**1**) to DG_1–DG_3; the assembly with DG_3 is depicted in Scheme 2. The barbituric acid groups bind to the melamine through six hydrogen bonds in a cyclic [3 + 3] fashion to form the hexameric rosette. Whereas DG_1–DG_3 are only soluble in CH_3NO_2, the assemblies readily dissolve in CH_2Cl_2 after addition of **1**. This increased solubility is a common feature of rosettes.[13]

The structural assignment of RG_1–RG_3 in solution (concentrations > 4mM) is based on low temperature ^{1}H NMR (400 MHz) experiments in CD_2Cl_2. The characteristic signals for the rosette structure[14] are present in the range of −60 °C to −30 °C Figure 1); they disappear at temperatures above −20 °C. Whitesides et al.[15] have shown that monorosettes are not kinetically stable on the NMR timescale. The



Scheme 2. Rosette formation of DG_3 with melamine **1**.

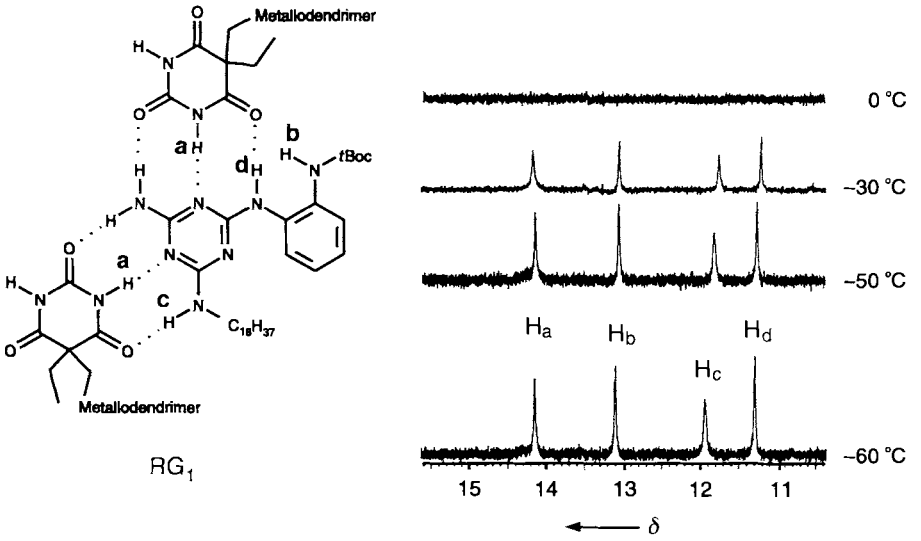


Figure 1. Low-temperature ^{1}H NMR spectra (400 MHz) of RG_1 in CD_2Cl_2.

characteristic signal at $\delta = 14.15$ corresponds to the hydrogen-bonded imido protons of the barbituric acid residues (H_a). Based on 2-D NOESY and TOCSY experiments, the two signals at $\delta = 11.50$ (H_d) and 12.01 (H_c) can be assigned to the melamine NH protons. The 2-D NOESY spectrum shows strong NOE cross signals of H_a with H_c and H_d (NH–$C_{18}H_{37}$ and NH–phenyl) of the melamine residue. The extremely downfield-shifted signal for the NH–*t*Boc proton (H_b) at $\delta = 13.10$ does not show a NOE cross peak with H_a. Long range COSY and TOCSY experiments give further evidence that H_b, H_c, and H_d are connected to the same fragment. The distances between the imido protons H_a and the secondary amine protons H_c and H_d were determined with the NOE initial rate approximation[16] and are in agreement with a rosette structure (Table 2).[6, 17] The gradual increase of these distances upon increasing size of the assemblies may be an indication of increasing steric interactions between the dendrons in the rosettes.

Table 2. Interatomic distances in RG_1–RG_3 as determined by 2-D NOESY experiments.

Rosette	H_a–H_c [Å]	H_a–H_d [Å]
RG_1	2.5 ± 0.1	2.8 ± 0.1
RG_2	2.6 ± 0.2	3.1 ± 0.2
RG_3	2.8 ± 0.4	3.4 ± 0.4

Rosette formation was further confirmed by build-up curves measured for the NOE interactions between the methylene bridge protons as well as other isolated resonances. This enabled us to determine the rotation correlation times τ_c.[18] Assuming isotropic tumbling and exclusive dipole–dipole relaxation—that is, no internal motion—the cross relaxation rates $\tau_{1,2}$ were determined, and the corresponding τ_c values calculated.[19] As expected, the τ_c values increase with increasing size of the rosette dendrimers (Table 3).[19]

Table 3. Rotation correlation times τ_c and molecular weights.

Rosette	$\tau_c \times 10^{-9}$ [s]	M_{calcd} [Da]
RG_1	1.32	7266
RG_2	2.75	14177
RG_3	3.55	27972

These are the first nanosized assemblies held together by two different types of noncovalent, compatible interactions: coordinative and hydrogen bonds. From a synthetic point of view it is important that the two types of interactions are "orthogonal", that is, mutually compatible. This is a prerequisite for a generally applicable methodology.

Novel Clusters of Transition Metals and Main Group Oxides in the Alkylamine/Oxovanadium/Borate System

Job T. Rijssenbeek, David J. Rose, Robert C. Haushalter,* and Jon Zubieta*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 66th birthday

Hydrothermal synthesis is an area of rapidly increasing importance for the synthesis of new and structurally complex, hybrid, organic–inorganic, solid-state compounds. Utilizing the ability of polar organic molecules to direct the crystallization of inorganic frameworks by incorporation in a geometrically specific manner through multipoint hydrogen bonding, we have been able to prepare several new classes of materials. Presynthesized organic molecules were used to imprint structural information onto inorganic oxide lattices, and microporous solids with the largest cavities and lowest framework densities known,[1] lamellar transition metal oxides or phosphates with organic cations[2] or coordination compounds[3] between the layers, polyoxometalates linked by coordination compounds into 2-D and 3-D solids,[4] materials with interlaced 1-D organic and inorganic chains,[5] and organically templated transition metal halides[6] have all been made. Even polyoxometalate metal species,[7] including the unusual $[H_{16}(VO_2)_{16}(CH_3PO_3)_8]^{8-}$,[8] have been synthesized by hydrothermal synthesis. We report here the use of this technique for the synthesis of **1** and **2** (en = ethylenediamine), which represent a novel type of clusters of transition metals and main group oxides in the organic cation/vanadium/borate system and possess unprecedented structures. Although a large number of borate mineral structures are known,[9] and substantial progress has been made in classifying and understanding their structures, synthetically prepared and structurally characterized examples are rare.[10, 11]

$(enH)(enH_2)_4[(VO)_{12}B_{17}O_{38}(OH)_8]\cdot H_2O$ **1**

$(enH_2)_5[(VO)_{12}O_6\{B_3O_6(OH)\}_6]\cdot H_2O$ **2**

The general procedure for preparing **1** and **2**, as well as other vanadium borate clusters,[12] consists of concentrated hydrothermal treatment of a vanadium oxide source (V_2O_3 or V_2O_5) with B_2O_3 or H_3BO_3 and amine at 170 °C in water. Large, structurally complicated, highly crystalline clusters spontaneously form in good yield from these simple starting materials and synthetic conditions.

The structure of the $V_{12}B_{17}$ cluster in **1**[13] contains several highly interesting features, the most extraordinary of which may be the contorted vanadium oxide ring (Figure 1a). The ring can be described as two semicircles of five *trans*, edge-sharing VO_5 square pyramids that partially interpenetrate—like the seams on a tennis ball. The four ends of the semicircles connect through two additional VO_5 units to form a continuous V_{12} ring of unprecedented connectivity (Figure 1b). All 12 terminal vanadyl (V=O) groups radiate away from the cluster surface. The clefts formed by the ring are occupied by two novel B_8 and B_9 polyborate chains (Figure 1c). The $B_8O_{17}(OH)_4$ chain is composed of two linked $B_3O_6(OH)$ FBBs (fundamental building blocks)[7] that are capped on each end by a tetrahedral $BO_3(OH)$ group. The second chain, $B_9O_{18}(OH)_4(enH)$, retains the approximate shape of the first. However, the OH groups on the terminal boron atoms have been replaced by a pendant, planar $BO(OH)_2$ triangle on one end and an enH^+ molecule on the other to give a tetrahedral BO_3N coordination environment (Figure 1a). The interior cavity of the cluster is occupied by poorly defined electron density, probably due to an occluded H_2O molecule. The intercluster space is filled by enH_2^{2+} and water molecules.

The $V_{12}B_{18}$ cluster in **2**[14] consists of a puckered $B_{18}O_{36}(OH)_6$ ring sandwiched between two triangles of six alternating *cis* and *trans*, edge-sharing vanadium atoms. Each vertex of this novel triangular metal–oxo moiety contains a *cis*, edge-sharing VO_5 square pyramid, whereas the midpoint of each edge is occupied by a *trans*, edge-sharing VO_5 polyhedron (Figure 2a–c). Again, all the vanadyl groups radiate away from the cluster surface. The B_{18} ring (Figure 2d,e) is composed of six $B_3O_6(OH)^{4-}$ FBBs and exists in a cyclohexane-like chair conformation with a B_3 unit at each of the six vertices. The two V_6 triangles are coordinated to each face of the B_{18} ring through six "axial" B-O-V bonds and three B_2-(μ_3-O)-V bonds. On average, ten of the twelve vanadium atoms per cluster are V^{IV}, and two are V^V; this accounts for the dark red color of the crystals. The V oxidation states were determined by considering the other known charges present in the unit cell and confirmed by valence bond calculations,[15] which show a valence of about +4.22 for each V atom. This value is close to the +4.17 expected for a V^{IV}:V^V ratio of 5:1, and it appears that each vanadium site has an equal possibility of containing a V^{5+} ion.

Consistent with the fact that borate minerals are often found in dry lakebeds,[16] the borate starting material remains in solution if too much water is present during the synthesis of these oxovanadium borates, and single crystals of layered vanadium oxides[2] are formed. We have observed, in this and other hydrothermal metal oxide systems, that the presence of a small amount of dissolved borate (from B_2O_3 or H_3BO_3) greatly enhances the dissolution of the starting materials and very favorably affects the subsequent crystallization of the metal oxide.

Thus, the mineralizing effect of the boron oxides could lead to larger, more perfect single crystals of such compounds.

The facile, high-yield preparation of these structurally and compositionally unprecedented vanadium borate clusters again points out that hydrothermal synthesis is a particularly useful, and increasingly important, method for preparing new compounds. The two examples discussed here and others[12] show that novel, unpredicted transition metal oxo clusters and main group polyanions can be easily accessed within this vanadium/borate system. The ease with which the borates attack and solubilize relatively unreactive transition metal oxides at low temperatures, combined with the large phase space associated with the highly specific, structure-directing nature of the organic cation, portends a very rich chemistry of structurally complex, kinetically metastable compounds.

Experimental Section

Syntheses were conducted in acid-digestion bombs lined with polytetrafluorethylene (23 mL) and filled to about 8% at room temperature. The borate was added first followed by the vanadium source, water, and the amine. The reaction conditions typically resulted in a pH value of 8–9.

1: A mixture of B_2O_3 (0.278 g), V_2O_3 (0.075 g), H_2O (1 mL), and en (0.061 g) in a molar ratio of 8:1:111:2 was heated at 170 °C for 72 h to give a nearly pure phase of orange crystals. The product was thoroughly cleaned by repeated cycles of immersion in an ultrasonic bath and washing with water. Yield: 0.1316 g.

2: A mixture of H_3BO_3 (0.500 g), V_2O_5 (0.182 g), H_2O (1 mL), and en (0.061 g) in a molar ratio of 8:1:55:1 was heated at 170 °C for 190 h to give a mixture of very dark red and pale orange crystals (about 20:1 by visual inspection). The product was cleaned by repeated cycles of immersion in an ultrasonic bath and washing with water. Yield: 0.329 g.

Super Oil-Repellent Surfaces**

Kaoru Tsujii,* Takamasa Yamamoto, Tomohiro Onda, and Satoshi Shibuichi

Surfaces that repel both water and liquid oils completely are very useful in daily life and in industry. Although surfaces with outstanding water-repellent properties have been developed and intensively studied recently,[1-3] surfaces with excellent oil-repellent properties, however, have not yet been reported in spite of their crucial importance. Wettability of a solid surface with a liquid is enhanced by the surface roughness,[4] in particular by the presence of fractal structures. When the contact angle between a liquid and a flat solid surface is larger than 90°, the surface repels the liquid completely if the surface rough enough.

For a fractal rough structure the relationship between the contact angle of the flat surface θ and that of the rough surface θ_f is expressed by the Equation (a).[2, 3, 5] In Equation (a),

$$\cos\theta_f = (L/l)^{D-2}\cos\theta \qquad (a)$$

$(L/l)^{D-2}$ is the surface area magnification factor, L and l are the upper and lower limits of the fractal behavior of the surface, and D the fractal dimension. This idea has been realized recently for super water-repellent surfaces having the contact angle of 174°, on using fractal surfaces.[2, 3] We have applied the same concept in this work to the completely novel, super oil-repellent surfaces. The greatest difficulty in obtaining the super oil-repellent surface is to make a flat surface that has a contact angle greater than 90° for oils. Here the surface tension of the solid needed to achieve this condition is estimated. The contact angle θ on the flat surface is determined by Young's equation [Eq. (b),

$$\cos\theta = (\sigma_S - \sigma_{SL})/\gamma_L \qquad (b)$$

where γ_S, γ_L, and γ_{SL} are the surface tensions of the solid, the liquid, and the solid/liquid interfacial tension, respectively]. When the contact angle is 90°, γ_S must be equal to γ_{SL}. The interfacial tension γ_{SL} can be approximated by Equation (c)

$$\gamma_{SL} = \gamma_S + \gamma_L - 2\sqrt{\gamma_S\gamma_L} \qquad (c)$$

when the interaction force between the two materials is same kind.[6] Combining Equations (b) and (c), we obtain $\gamma_S = \gamma_L/4$ as condition for $\theta = 90°$.

Typical surface tensions of oils are 20–30 mN m^{-1}, and the value of γ_S must be on the order of several mN m^{-1}. Such a small surface tension for a solid can probably be provided only by the trifluoromethyl group.[7] Accordingly, our strategy for making super oil-repellent surfaces was to obtain a surface of enough roughness and then to cover the rough surface with trifluoromethyl groups by treating it with fluorinated compounds.

Figure 1 shows a scanning electron microscopic photograph of the anodically oxidized rough surface of aluminum plate. This surface was analyzed by the box counting method[2, 3] and found to be a fractal (dimension 2.16). This untreated surface is superwettable towards liquids, but can be converted into a super

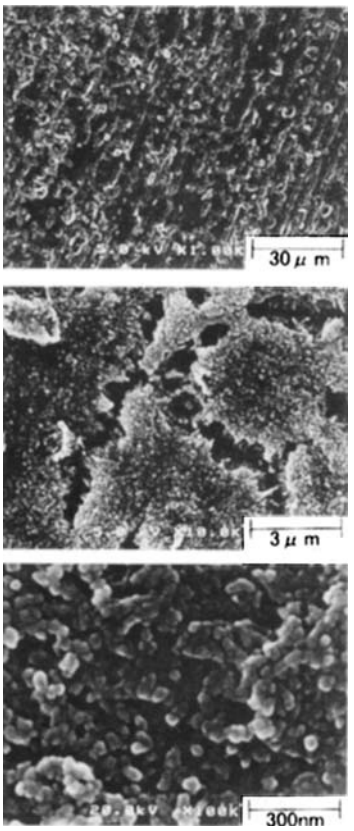

Figure 1. Scanning electron microscopic images with three different magnifications of an anodically oxidized aluminum plate surface.

oil- (and also water-) repellent surface by immersing the plate in an ethanolic solution of fluorinated monoalkylphosphates (n-$CF_3(CF_2)_mCH_2CH_2OP(=O)(OH)_2$, $m = 7$ and 9; abbreviated as F_{m+1}-MAP). An droplet of rapeseed oil on the treated, anodically oxidized aluminum surface remains beautifully spherical with a very high contact angle of 150° (Figure 2). So high a

contact angle for the oil droplet on any kind of solid surface has never been reported before. The oil droplet rolls around even if the surface is tilted only slightly, without attaching to the surface. Figure 3 shows the contact angles plotted against surface tension of various kinds of oils put on the anodically oxidized aluminum surface treated with F_8-MAP (Figure 3a) and F_{10}-

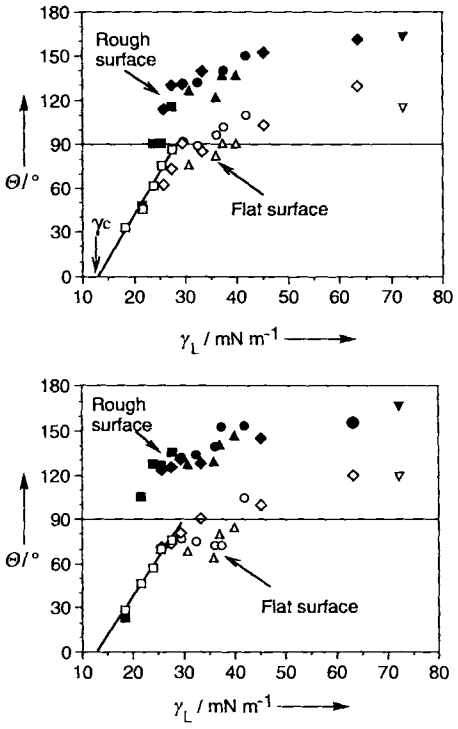

Figure 3. The contact angles θ of various kinds of oil (■/□ alkane, ♦/◇ alcohols and polyols, ●/○ esters, ▲/△ arenes, ▼/▽ water) on the super oil-repellent (filled symbols) and flat (open symbols) aluminum surfaces plotted against the surface tension γ_L of the oils. Both surfaces of rough (super oil-repellent) and flat structure are treated with F_8-MAP (top graph) and F_{10}-MAP (bottom graph).

MAP (Figure 3b). Oil-repellent surfaces with a contact angle greater than 120° have been achieved for oils with a surface tension of approximately 23.8 mN m^{-1} (decane). As expected the contact angles of some of the oils on the rough surface is much greater than those on the flat surface. Some of the liquids, however, exhibit an apparently curious behavior: the contact angles on the rough surface are more than 100° although they are less than 90° on the flat surface. These results are not strange, however, because the two surfaces are different chemical species. The rough surface is aluminum oxide, and the flat one should be essentially metallic aluminum. The adsorbed structure of F_8-MAP and F_{10}-MAP molecules must vary on the oxidized and the metallic aluminum surfaces, and the arrangement of trifluoromethyl groups at the top of the surface might also differ.

A hydrophobizing agent is essential to obtain the super oil-repellent surfaces mentioned above. We tried to apply other reagents such as fluorinated fatty acids, fatty alcohols, or a silane coupling agent with the similar carbon chain lengths as the fluorinated MAP, but they did not work well. The result of the silane coupling agent is shown in Figure 4 as an example. These results indicate that the ability of the trifluoromethyl groups to arrange compactly depends sensitively upon the chemical structure of the surface treatment agent. To evaluate the packing of trifluoromethyl groups at the surfaces, the critical surface tension (γ_C) values were estimated from Figures 3 and 4. They are 12–13 mN m^{-1} for the flat surfaces treated with F_8-MAP and F_{10}-MAP, and 17–18 mN m^{-1} for the rough surface treated with the silane coupling agent. These values are between those of Teflon (18.5 mN m^{-1}) and the trifluoromethyl group (about 6 mN m^{-1}). Our oil-repellent surfaces are still far ideal. The concept of combining the high fractal dimension of the metal surface and the compact packing of trifluoromethyl groups on it has been shown by this work to be a valid guiding principle.

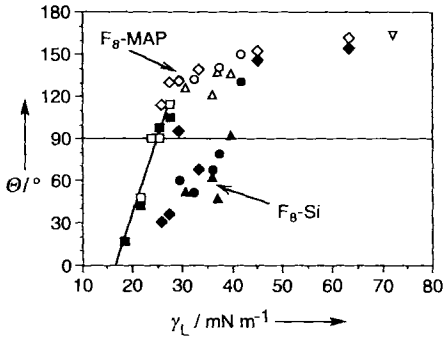

Figure 4. Effect of the hydrophobizing reagent on the oil repellency of the anodically oxidized aluminum surface. The contact angles θ on the surfaces treated with F_8-MAP (open symbols) and silane coupling agent (filled symbols) were plotted against the surface tension γ_S of the oils. Symbols as in Figure 3.

Experimental Section

The rough aluminum surfaces were prepared by anodic oxidization as follows: Two aluminum plates (10 cm × 5 cm × 1 mm) were washed with chloroform and then used as the two electrodes 5 cm apart in 1 N aqueous solutions of sulfuric acid (direct current, current density 10 mA cm^{-2}, 3 hours). The fractal dimension of the aluminum oxide surface roughened as above was determined by a box counting method. An anodically oxidized aluminum plate was embedded in an epoxy resin and cut by a microtome with a diamond knife to obtain a smooth cross-section. The cross-section was examined by a field emission scanning electron microscope (FE-SEM; Hitachi, S-4000) at several magnifications (×150, ×1500, ×6000, and ×30000), and the rough structure of the surface was traced. The box counting method was applied to the traced curves, and the fractal dimension of the cross-section was determined. The fractal dimension of the surface was calculated by adding 1 to the above cross-sectional dimension. The anodically oxidized aluminum surface was hydrophobized by treatment with the fluorinated monoalkylphosphates F_8-MAP and F_{10}-MAP. An anodically oxidized aluminum plate was washed with pure water and then immersed in a solution of F_8-MAP or F_{10}-MAP in ethanol (2.0 wt%) for 1 week at room temperature. The surface was treated with silane coupling agent as follows: Under a dry N_2 atmosphere the oxidized aluminum plate was put into solutions of silane coupling agent (1 mL 1H,1H,2H,2H-perfluorodecyl-trichlorosilane, 300 g hexadecane, 30 g chloroform, 30 g carbon tetrachloride) at 20 °C for 12 hours. The solvent was carefully dried prior to use. The treated plate was washed well with chloroform and dried, and then washed again with distilled water. To measure the contact angles (optical contact angle meter from the company Kyowa Interface Science, type CA-A) an oil droplet (1–3 mm diameter) was dropped carefully onto the solid surface from the distance of 5 cm, and then given gentle vibration by tapping the sample stand to obtain the equilibrium contact angle.

6_1 Helices from Tetrahedral Ribbons $^1_\infty[BP_2O_8^{3-}]$: Isostructural Borophosphates $M^IM^{II}(H_2O)_2[BP_2O_8]\cdot H_2O$ (M^I = Na, K; M^{II} = Mg, Mn, Fe, Co, Ni, Zn) and Their Dehydration to Microporous Phases $M^IM^{II}(H_2O)[BP_2O_8]$**

Rüdiger Kniep,* Horst Günter Will, Insan Boy, and Caroline Röhr

Dedicated to Professor Hans Georg von Schnering

In our search for new compounds with microporous structures we deal with borophosphates.[1] Most of the compounds already known contain anionic partial structures in which phosphorus and boron are tetrahedrally surrounded by oxygen.[1, 2] However, there are already several examples in which boron also shows trigonal-planar coordination.[3] At present the maximum extension of the anionic partial structures is mainly restricted to infinite, chain-like aggregates with bridging or branching. Recently the borophosphate $CoB_2P_3O_{12}(OH)\cdot C_2H_{10}N_2$ was described as an open-framework structure formed from corner-sharing BO_4 and PO_4 tetrahedra as well as CoO_6 octahedra.[9] The analogy to the framework structures of the AlPOs discussed in that paper needs to be qualified, since linkage of the BO_4 and PO_4 tetrahedra only leads to two-dimensional aggregation. Nonetheless, it was the first borophosphate with an anionic partial structure of infinite two-dimensional extension. A further borophosphate, $Co_5BP_3O_{14}$,[10] contains planar BO_3 groups[3] that are linked to PO_4 tetrahedra to form dimeric $[BPO_6]^{4-}$ units.

The new group of isotypic title compounds (Table 1) again contains only infinite one-dimensionally linked, anionic partial structures. In this case condensation of PO_4 and BO_4 tetrahedra through common vertices leads to tetrahedral ribbons $^1_\infty[BP_2O_8^{3-}]$, which are arranged around 6_1 screw axes to form helices (Figure 1). The spiral ribbons are built up from four-rings of tetrahedra in which the BO_4 and PO_4 groups alternate. Each BO_4 tetrahedron also belongs to the adjacent four-ring of tetrahedra along the ribbon, in such a way that all vertices of the BO_4 groups participate in bridging functions with PO_4 tetrahedra. The phosphate groups occupy the borders of the ribbons with two terminal oxygen atoms. Bond lengths and angles within the tetrahedral helices are similar to known values for borophosphates.[7]

Table 1. Refined lattice constants of the isotypes $M^IM^{II}(H_2O)_2[BP_2O_8]\cdot H_2O$ (hexagonal, space group $P6_122$). Standard deviations are given in parentheses. We have not yet succeeded in preparing an isostructural Cu^{II} compound. In the system Na_2O-CuO-B_2O_3-P_2O_5-H_2O we obtained the intermediate phase $Na_4Cu_3[B_2P_4O_{17}H_2]\cdot 2HPO_4$ [6].

[a] Single crystal data [4]. [b] X-ray powder data [5].

The helical structure is remarkable in that space groups with 6_1 screw axes are very rare and had not previously been observed for tetrahedral structures (Figure 1). The remaining organization of the crystal structure is also fascinating. The free loop of the borophosphate helix is occupied by alkali metal ions, which are fixed along the tetrahedral helix by an irregular arrangement of six oxygen atoms from adjacent phosphate groups.[7] A double helix $^1_\infty\{(M^I[BP_2O_8])^{2-}\}$ results, the central channel of which is filled by a helix made up of water molecules: $^1_\infty\{(M^I[BP_2O_8]H_2O)^{2-}\}$. The water molecules form hydrogen bonds with each other along the spiral (O_{H_2O}—O_{H_2O} 292 pm, O_{H_2O}-O_{H_2O}-O_{H_2O} 156°) as well as to two oxygen atoms from borate tetrahedra on the inner wall of the double helix (O_{H_2O}—O_B 292 pm, O_{H_2O}-O_{H_2O}-O_B 88°).

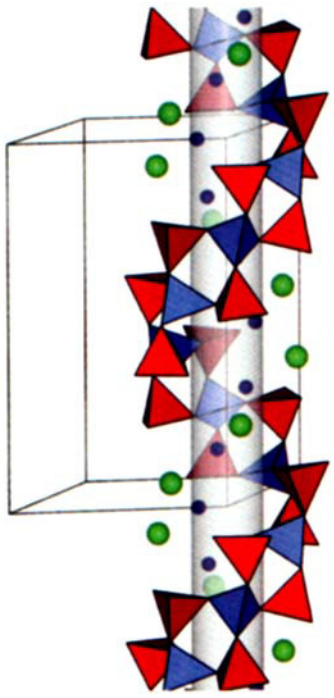

Figure 1. Tetrahedral helices $^1_\infty[BP_2O_8^{3-}]$ in the crystal structure of $M^IM^{II}(H_2O)_2[BP_2O_8]\cdot H_2O$ (BO_4 tetrahedra blue, PO_4 tetrahedra red). M^I ions (green spheres) complete a double helix, and the central channel of the double helix is filled by a spiral chain of H_2O molecules (blue spheres).

A section of the crystal structure as viewed along the hexagonal c axis is shown in Figure 2. Starting at the corners of the cell (6_1 screw axes), the structure unfolds in radial shells (values for the NaMn compound): central O_{H_2O} helix (diameter 244 pm), B helix (diameter 500 pm), M^I helix (diameter 644 pm; ≈P helix), "followed" by "interactive" shells (water of coordination and M^{II} centers of coordination octahedra), which effect the linkage of the double helices $^1_\infty\{(M^I[BP_2O_8]H_2O)^{2-}\}$ filled with water. The linkage principle, shown in Figure 3, is the formation of coordination octahedra $M^{II}(O_P)_4(H_2O)_2$ by four O_P functions

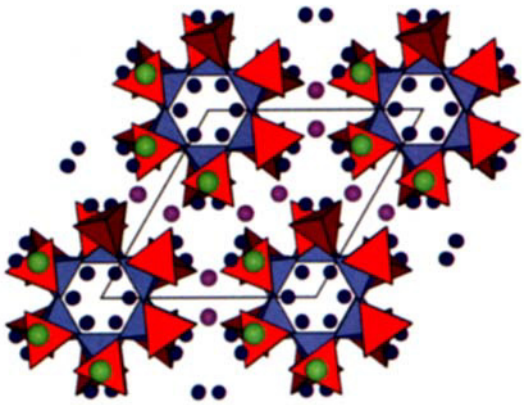

Figure 2. Section from the crystal structure of $M^IM^{II}(H_2O)_2[BP_2O_8]\cdot H_2O$ as viewed along the hexagonal c axis (BO_4 tetrahedra blue, PO_4 tetrahedra red, M^I green spheres, H_2O blue spheres, M^{II} violet spheres).

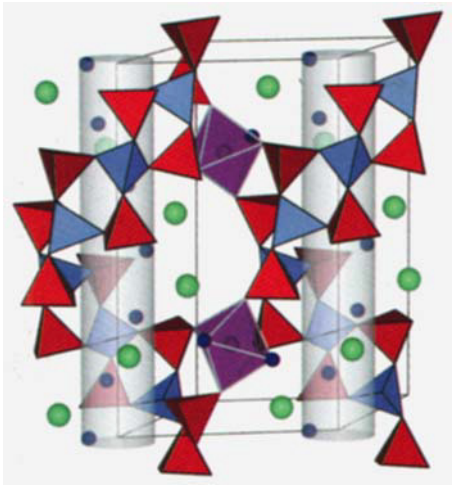

Figure 3. Linkage of the borophosphate helices in the crystal structure of $M^{I}M^{II}(H_2O)_2[BP_2O_8]\cdot H_2O$ through coordination octahedra $M^{II}(O_P)_4(H_2O)_2$ (BO_4 tetrahedra blue, PO_4 tetrahedra red, M^{I} green spheres, H_2O blue spheres, M^{II} coordination octahedra violet).

from two adjacent borophosphate helices and two H_2O ligands (*cis*-positions). The arrangement of the *cis*-oriented H_2O molecules on the M^{II} centers leads to additional channels formed exclusively from H_2O, which also run parallel to the hexagonal *c* axis (Figure 2).

The synthesis of the title compounds $M^{I}M^{II}(H_2O)_2[BP_2O_8]\cdot H_2O$ (Table 1) can be successfully carried out under mild hydrothermal conditions (about 150 °C, degree of filling 25–30%) in aqueous HCl solutions made from mixtures of hydrogen phosphates, borates, and sometimes even chlorides within approximately two weeks.[8] Single crystals (hexagonal bipyramids) can be grown under these conditions to a size of up to 0.5 mm.

Thermal dehydration of the new borophosphates (Netzsch TG/DTA, heating rate 1 K min^{-1}, open system in air) is a two-stage process. In the first step, two moles of H_2O per formula unit are released (temperature ranges, for example: NaMn 80–238 °C, NaFe 80–210 °C, NaZn 80–160 °C). Temperature-dependent X-ray powder studies (capillary method) show a diffraction pattern that hardly changes to the end of this first stage (example: NaMn). The morphology of the crystal also remains intact. Rehydration at room temperature is quantitative ($+2H_2O$). The X-ray powder pattern of the rehydrated product is identical to that of the starting product, and renewed thermal decomposition ($-2H_2O$) shows no differences to that of the "first" thermal dehydration (example: NaZn). These experimental findings are consistent with the following description and interpretation, even though further investigation (for example on single crystals) is necessary. The first stage of the dehydration ($-2H_2O$) of $M^{I}M^{II}(H_2O)_2[BP_2O_8]\cdot H_2O$ leading to $M^{I}M^{II}(H_2O)[BP_2O_8]$ is reversible in the sense of a topochemical reaction with preservation of crystal morphology. The water of crystallization (spiral structure within the channels of the M^{I}-borophosphate double helices) and one mole of coordination water (at the M^{II} centers) are released in a collective process. The M^{II} centers are then only pentacoordinate. The crystalline dehydration products $M^{I}M^{II}(H_2O)[BP_2O_8]$ can be described as microporous borophosphates with channel structures ("hollow" tubes formed from the M^{I}-borophosphate double helices). The thermal stability of the microporous phases varies between 180 °C (NaZn) and 305 °C (NaMn). At higher temperatures release of the last mole of coordination water (second stage of the dehydration) leads to X-ray amorphous products.[11]

Explosive Topics for Specialist and Novice

Catalytic RNA. (Series: Nucleic Acids and Molecular Biology. Vol. 10.) Edited by *F. Eckstein* and *D. M. J. Lilley*. Springer, Berlin, 1996. 417 pp., hardcover DM 248.00.—ISBN 3-540-60795-1

There can scarcely be any other area of science that has undergone such an explosive phase of development in recent years as the chemistry and biochemistry of ribonucleic acids. Up to the beginning of the 1980s the only biopolymers regarded as having catalytic properties were proteins. However, the first published reports of catalytic RNAs stimulated numerous investigations, which have subsequently led to the identification of catalytic RNA motifs in various organisms, and to the development of combinatorial strategies for the evolution of artificial catalysts. The development of this branch of research has extended the study of biochemical catalysis to a hitherto unexplored system, provoked speculations about the origins of life in a prebiotic "RNA world", and introduced the possibility of some important practical applications.

In *Catalytic RNA*, published as Volume 10 of the series *Nucleic Acids and Molecular Biology*, over 50 recognized experts have contributed to a comprehensive survey of the current state of research. The first three chapters are concerned with the system that served as the historical starting point for this field of research, the self-splicing group I introns. First there is an excellent and instructive account of the structure and mode of action of these ribozymes. The reader is given a sound and understandable introduction to the subject, including considerations of substrate recognition, different catalytic strategies, and a comparative analysis of mechanisms. This is followed by a discussion of the dynamics of group I ribozymes, which have been investigated by fluorescence spectroscopy, and a lucid summary of structural data and models for describing the interactions with different substrates.

Next there come five articles on separate topics: on the interactions of aminoglycoside antibiotics with different RNAs, on the group II introns, which have a wide variety of catalytic functions, on the ribonuclease P formed from RNA and protein subunits, on the hairpin ribozyme, and on circular RNAs.

The largest part of the book is devoted to the system that is at present the most thoroughly understood: the hammerhead ribozyme. The crystal structure of this ribozyme is discussed in detail and compared with the structure determination in solution. Several articles are devoted to mechanistic studies by means of chemical modification. In addition to fundamental studies of structure and mechanism in this system, considerable work has been carried out on the use of such molecules for the control of gene expression. Different strategies for introducing ribozymes into cells and organisms are described, as also are approaches for using ribozymes to inhibit HIV replication. Ribozymes and antisense RNA in fungi are discussed. The volume ends with two articles on in vitro selection of artificial ribozymes, comparing the two different procedures used: direct selection and selection against transition state analogs. These recent studies are especially interesting to chemists, as they offer the possibility of developing tailored catalysts.

The editors have succeeded in putting together an excellent and well-integrated work. Most of the chapters are thorough and detailed review articles of an excellent didactic standard, and can usefully be read by newcomers to the field as well as by specialists. The figures are of high quality, some in color, and are a valuable aid to the reader's understanding. The high standard of the work is also maintained in the well chosen and up-to-date literature references. The long section on the hammerhead ribozyme contains some unavoidable repetition and overlapping of subject matter; however, this has the advantage that these chapters are self-contained and can be read independently.

A work such as this, reviewing progress in a rapidly advancing field, is inevitably a snapshot of the situation, and in the short time since the publication deadline some further new and interesting facets have appeared. The volume can be thoroughly recommended, both as an introduction and for a more detailed study to gain a thorough understanding of the subject. Every biochemistry library should have a copy. I strongly recommend not only bioorganic chemists but also others working in interdisciplinary areas between chemistry and the biosciences to read this book.

Crop Protection Agents from Nature. Natural Products and Analogues. Edited by *L. G. Copping*. Royal Society, London, 1996. 501 pp., hardcover £ 129.50.—ISBN 0-85404-414-0

Plant protection is essential. That cannot be denied by any serious person with a responsible attitude towards ensuring that agricultural products are available in the required amounts and quality for feeding a population of 5 billion. During the past 50 years we have all become accustomed to the very good and reliable supply of food that has been made possible by modern high-yielding agriculture. However, it is now no longer generally appreciated that the increase in efficiency, which is quite amazing from a historical standpoint, has largely been achieved through the use of chemical crop protection agents. Instead, public attitudes are now focussed not on the benefits but almost exclusively on the risks. The demand for limiting the use of plant protection chemicals has led to a large number of regulatory controls, prohibitions, and restrictions on innovation. The problem of protecting plant crops against other organisms (fungi, insects, weeds, etc.) still remains, and therefore research on new

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

products continues despite the restrictions, while on the other hand there is a search for effective alternatives to the conventional methods.

The balance between those processes that destroy life and those that protect it has become incorporated into nature as a working principle. This is one of the areas in which alternative principles of plant protection are being sought, by some people in a spirit almost akin to a religious crusade, and by others with a cool, rational purposefulness.

In this book L. G. Copping has brought together 14 experienced specialists (or research groups) to report on this subject, drawn from universities (28%), public research institutes (32%), and industry (22% from manufacturers of conventional pesticides and 16% from biotechnology businesses). Two-thirds of the contributors are from the USA and Great Britain. The end result is an excellent book which analyzes the complex scientific and practical problems with a refreshing Anglo-American pragmatism, and proposes solutions. The theme of using the methods of nature, which is so often presented as part of a revolutionary new movement, is instead treated here in a factual and unpretentious way, with a wealth of historical background, empiricism, and appraisal of successes and failures, and distinguishing between what is possible and what is unattainable.

Thus, in considering ways of protecting plants by the use of natural products, synthetic variants of these, or antagonistic organisms, the book does not aim to give answers to the question "good or bad?", but instead examines whether they are suitable or unsuitable.

In his introduction Copping presents some interesting statistics about the importance of natural products, and about information from nature that is relevant to research on substances with pharmacological or plant protection activity. Of the 25 most important pharmaceutical products, about half are natural products or variants thereof. Pyrethroids and carbamates, which are synthetic variants of lead structures derived from nature, are very important as insecticides. If one also includes relationships that became apparent only after the discovery of active agents, then even the organophosphates are seen to have their forerunners in nature, and the same is true of the newly developed chloronicotinyls. Thus, it is well worth seeking clues from nature.

The chapter by Lange and Lopez describes 32 microbial active agents that already have important applications in plant protection or have potential in that area. The authors also discuss the mechanisms of their activity, thus providing important information for research on new active agents. Regrettably, however, there are no data about levels of activity, nor even qualitative comparisons.

The following chapter, by Yamaguchi, is more informative in that respect, giving details of 11 microbial active agents, mostly Japanese discoveries, that are currently in use in Japan. The use of such expensive but very interesting substances is only possible because of the unusual situation in Japanese agriculture, which is generously subsidized. This excellent chapter would have been even more useful if the author had included a critical discussion of the economic aspects. Nevertheless, the descriptions of the individual active agents are packed with valuable information, including their mechanisms, and should be read by all researchers in the field. Unfortunately the structures are very complex and therefore cannot be seriously considered as a starting point for synthetic analogs.

On the other hand, all chemists interested in synthesizing variants based on lead structures will enjoy reading the chapter by Sauter, Ammermann, and Roehl, in which they describe the work that led from the natural fungicide strobilurin to the new synthetic variants developed for practical use. Woven within their account of the discovery, biological evaluation studies, and synthetic work, the reader will find a great wealth of information on structure and activity. The chapter is an instructive example for anyone involved in research on active agents.

Duke, Abbas, Amasoga, and Tanaka contribute a more factually orientated chapter on 24 microbial phytotoxins, including their structures and modes of action. However, they do not give enough information about levels of activity, activity spectra, and their potential for practical use.

This is followed by an extensive review (by Dixon) of biologically active substances from algae including 175 structural formulas, mostly quite complicated, and over 600 literature references. This is very interesting so far as it goes, but contains little information relating directly to plant protection. However, the reader is given an excellent insight into the world of algae and their biology, classification, lifestyle, and metabolic products, aspects that are of interest from a medical standpoint.

The chapter entitled "Pesticides from Nature" consists of three short contributions of varying quality by different authors. Altogether 73 structures are given, mostly of well-known types (although that of azadirachtin is incorrect). Here again, however, the other important aspect, the biological activity (level of activity, comparisons, activity spectrum), is hardly covered at all.

The chapter by Benner on plant protecting substances derived from higher plants (with 26 structures) reviews practical applications of such agents, and includes some important critical comments about the worthwhileness of evaluating natural products with weak activity, an important issue in all areas of natural products research.

The three most successful lines of research starting from natural lead structures up to now have been those based on the strobilurins (the most recent example, still an active topic), the earlier juvenoids, and the pyrethroids, now regarded as virtually worked out. Elliott, the doyen of research in this area, has contributed a 50-page chapter which is a tour de force of the high standard expected from this author. It is in effect a mini-textbook on the optimization of active agents derived from lead structures, with a wealth of historical background and detailed analysis of structure–activity relationships for the synthetic variants evaluated. Every chemistry student about to take a final degree examination should read this beforehand. Regrettably, this kind of science has not yet become an essential part of all university chemistry courses.

Parr contributes a very good chapter in which he considers whether plants have genuine natural protection mechanisms of their own, and summarizes current knowledge bearing on this central question. The conclusion is that in the vast majority of cases they do, by means of repellent substances, elicitors, plant hormones, warning substances such as salicylic acid, and their immune systems, and indeed one can see this just by looking out from one's window. The biochemical chains of activity are explained in detail. This makes interesting reading for the chemist involved in research on active agents, and raises the question of how this knowledge can be translated into a practical form for use by the farmer.

Toxins produced by animals to catch insects hold a special fascination for chemists working in the area of insecticides. Blagborough and Moya discuss research based on such toxins as lead structures, and give 80 structural formulas; unfortunately, however, they do not include the required information about the effects of the compounds on insects. The pharmacology of insects differs in some respects from that of other animals, and

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3609-1016 $ 17.50+.50/0

therefore some information about the mechanisms of activity would have been useful for the reader. Thus, the collection of structures given here is of little use to the chemist working on active agents, and does not offer lead structures for the synthetic chemist.

The main facts about one natural product of considerable practical importance can be found in the 20-page chapter by Adams, Liu, MacIntosh, and Starnes, who present a very good survey of a class of insecticides: the crystal protein toxins derived from *Bacillus thuringiensis*. Their toxicity to insects is, in molar terms, about 300 times greater than that of pyrethroids! The authors give a concise and informative account of the history, analysis, and classification of the toxins and the different species of bacteria, their activities, practical applications, the underlying molecular biology, and the mode of action. The present situation with regard to their practical usefulness and potential is critically evaluated.

In an equally good chapter Leiry and Fuxa discuss the difficulties encountered in developing practical applications of natural and genetically modified baculoviruses as insect pathogens. They devote special attention to the problems of obtaining registration to allow the use of such methods of plant protection.

A topic that is even further removed from plant protection based on chemicals is the use of antagonistic microorganisms to protect against fungal diseases. Pusey gives a concise, critical, and readable account of the most important potential uses and the practical problems.

The use of microorganisms to combat weeds is another strategy that is still far from being developed to a stage suitable for use by the farmer. Drawing on knowledge from many years of work in this area, Greaves gives a detailed explanation of the principles and of strategies that have already been tried or can be envisaged, and summarizes results from experiments over a period of 20 years. He critically evaluates the prospects for this speculative and risky area of research, and emphasizes the need to concentrate expensive research effort on weeds of greatest practical importance. The closer one gets to success with proposed solutions of this kind, the more one is concerned about the problem of obtaining registration for these "biological weapons" against weeds.

In the last chapter Plimmer discusses the complications involved in getting registration for alternative methods of plant protection. These 20 pages should be compulsory reading for everyone who is concerned with the legislation governing the use of plant protection systems. Furthermore, critics of plant protection measures should read this chapter to learn about the safety requirements that are imposed by the authorities, and must have been satisfied by any modern plant protection agent.

To summarize, Copping's book contains a wealth of valuable information for chemists, biologists, agronomists, and specialists employed by public bodies, as well as non-scientists interested in environmental matters. At a time when some of the expectations with regard to using the natural world are unrealistic (as in the background to the International Convention on Biodiversity), this book is a factual resource to help one evaluate research aimed at learning from nature for the purpose of plant protection.

Klaus Naumann
Leverkusen (Germany)

Golf Balls, Boomerangs and Asteroids—The Impact of Missiles on Society. By *B. H. Kaye*. VCH Verlagsgesellschaft, Weinheim, 1996. 418 pp., hardcover DM 168.00/softcover DM 78.00.—ISBN 3-527-29332-1/3-527-29323-X

In this book Brian Kaye has undertaken the challenging task of introducing liberal science students to a variety of physical problems, using an interesting approach which is based on the concept of missiles. His notion of missiles ranges from sports tools such as golf balls and boomerangs up to ballistic missiles and asteroids. Finally he also treats human beings as missiles, when they are involved in car accidents or boxing matches. This spans a wide range of physical problems that are covered in the book, from thermodynamics, mechanics, astrophysics, and optics, up to some aspects of modern particle physics such as the detection of solar neutrinos. Thus, the reader obtains a broad overview of physics.

Aiming at students without a science background, the author manages to present this wide variety of topics in a down-to-earth fashion using a well-structured approach. Each section starts with a historical introduction describing the evolution of the individual area of science and the achievements of the scientists involved. He uses "word webs" to explain the Latin or Greek origins of the related terminology and to provide links to words used in other areas of technology. This avoids the risk of the inexperienced reader being confused simply by the words. The author's writing style and a selection of very graphic examples (such as the physics of baseball and tennis, and the fight between David and Goliath, which was decided by the use of a missile, namely the stone slung by David) result in an entertaining and interesting excursion into the world of physics. Using numerous diagrams and viewgraphs instead of equations, the author is able to explain complicated matters in a way easily accessible to the inexperienced reader. Unfortunately, he relies heavily on examples taken from weapons technology, which he describes with evident fascination.

Many questions that will interest others as well as first-year students are answered in this book: why do golf balls have dimples?—how are hailstorms produced? Newspaper articles and accounts from witnesses of the manifestations of physical phenomena enliven the graphic style of his explanations. Especially impressive (and shocking) are reports describing the impact of meteors, and a first-hand account of the effects of a laser beam hitting a human eye and leading to its irreversible destruction.

The book, which is intended as the second in a triad constituting a course for liberal science majors, is not only interesting for students who want to get a first idea of physics. It also constitutes an ample reservoir for university teachers and provides examples, explanations, and suggestions for pepping up introductory physics courses. A lot of interesting ideas and experiments can be used to raise interest in physics, in particular in audiences that include students with different specializations. As a treatment of physics at an introductory level, the book has its limitations for the scientific reader. It is, however, a good choice for people without a physics background who are interested in the historical aspects.

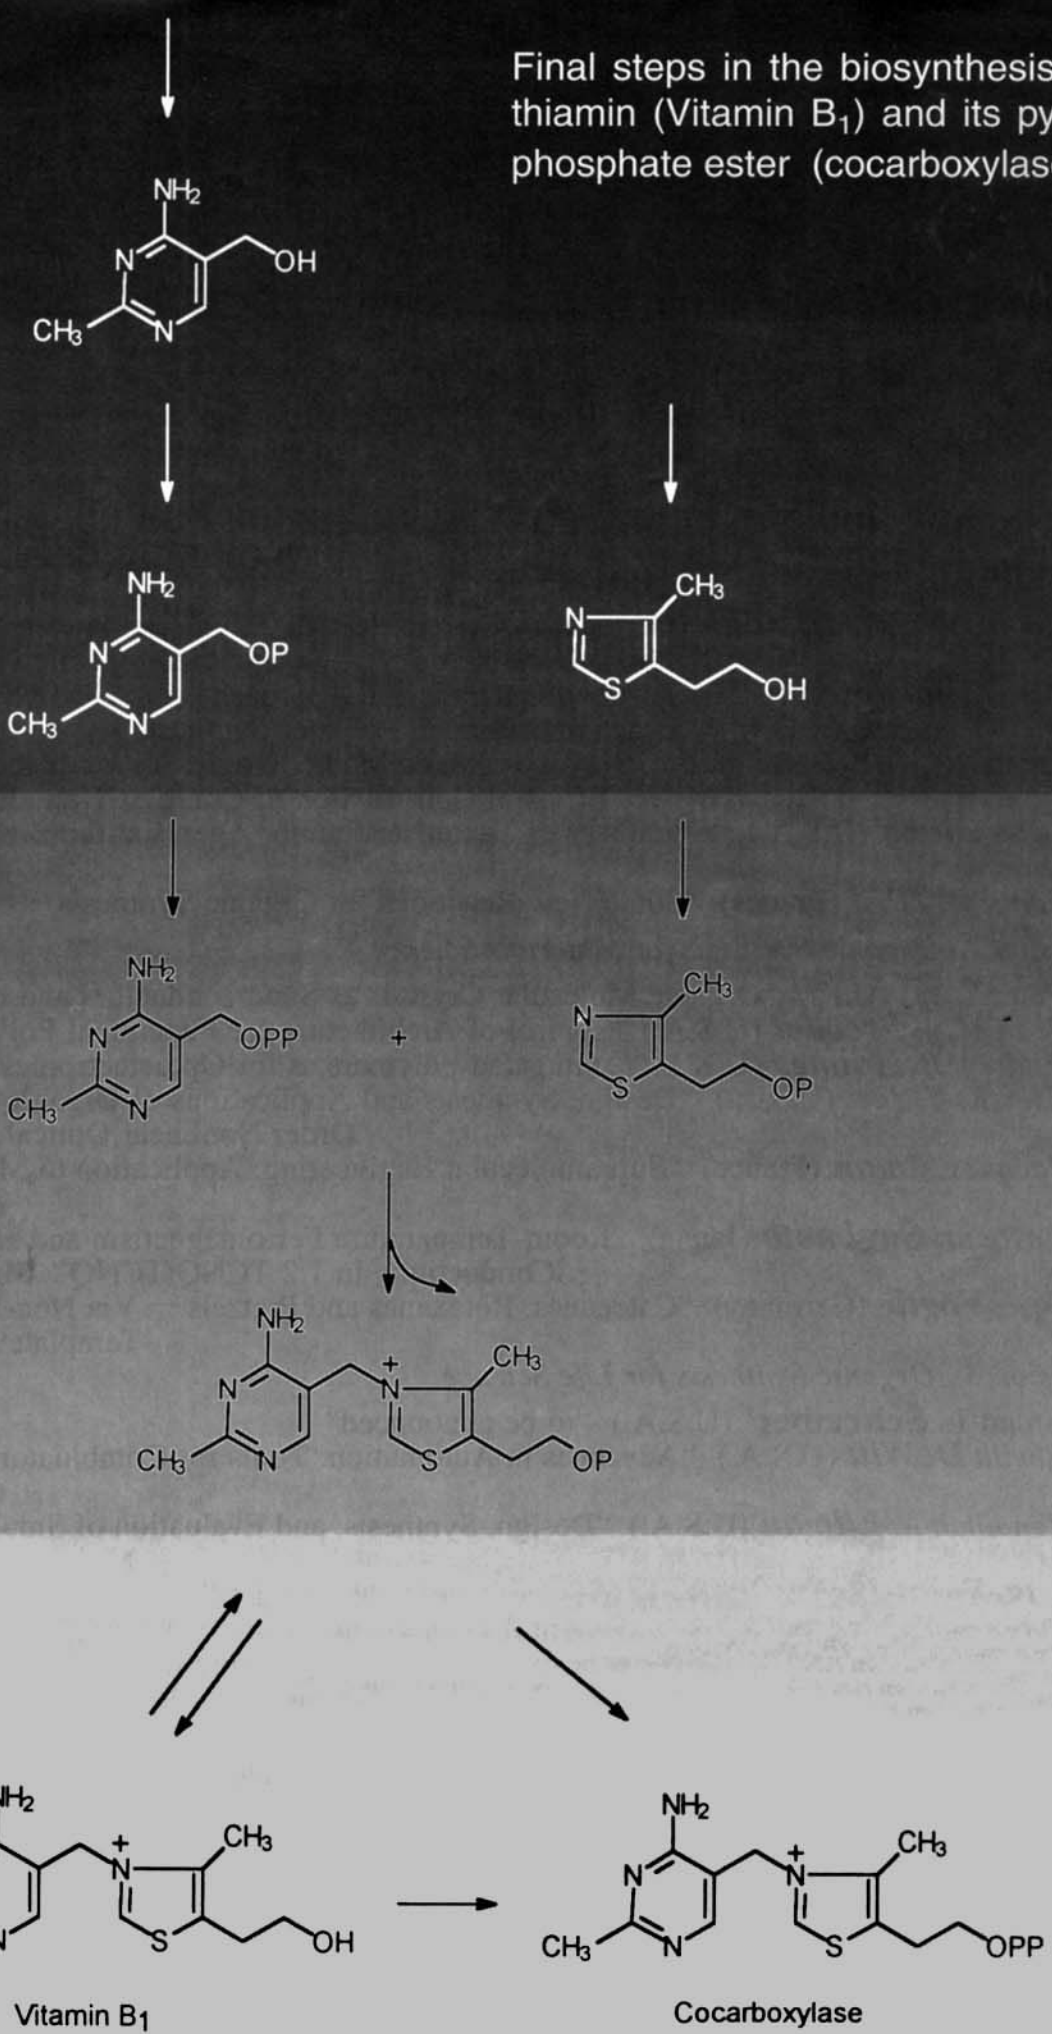
Final steps in the biosynthesis of thiamin (Vitamin B_1) and its pyrophosphate ester (cocarboxylase).



Vitamin B_1

Cocarboxylase

Biosynthesis of Vitamin B_1 (Thiamin): An Instance of Biochemical Diversity

Ian D. Spenser* and Robert L. White

The elucidation of the biosynthetic pathway to thiamin (Vitamin B_1) and its pyrophosphate ester, the important coenzyme "cocarboxylase", has challenged researchers for many years and continues to do so. The problem of the origin of thiamin can be separated into three parts: the independent pathways to the pyrimidine moiety 4-amino-5-hydroxymethyl-2-methylpyrimidine and to the thiazole moiety 5-(2-hydroxyethyl)-4-methylthiazole, and the route from these subunits to the vitamin. The steps in the latter process were fully established some twenty years ago, and it was shown that the route in aerobic bacteria and yeast differs to some extent from that in enteric bacteria. The pathways to the subunits, on the other hand, are still not clarified. Significant differences exist in the routes whereby each of the two subunits, the pyrimidine moiety and the thiazole moiety, originate in bacteria and yeast. One difficulty that delayed progress was that the incorporation patterns of labeled precursors, which were observed by different research groups in different microorganisms, could not be reconciled on the basis of a single pathway to each of the two subunits. It is now accepted that in each case different pathways exist in enteric bacteria and yeast, and that the biosynthesis of Vitamin B_1 represents an instance of biochemical diversity. A second factor that added to the difficulties is the minute amount of thiamin synthesized in microbiological cultures (about 15 μg per L culture). This limited the investigations until very recently either to the use of radioactive tracers or to the use of stable isotopes in conjunction with mass spectrometric analysis. It is widely recognized that both methods are associated with pitfalls in the interpretation of results. High-field ^{13}C NMR, the most powerful modern method available for the determination of incorporation patterns, has only very recently been successfully employed in investigations of thiamin biosynthesis. As a result of the conceptual and experimental problems, even the primary precursors of each of the two relatively simple heterocyclic subunits of thiamin are still not completely established. A search for committed intermediates, the study of the enzymes, and identification of the genes that are involved are the matter of current research.

Keywords: biosynthesis · enzymes · NMR spectroscopy · vitamins

1. Introduction

Vitamin B_1 (**6**), the nutritional factor that prevents and reverses the symptoms of beri-beri, was first isolated from rice bran in 1926 by B. C. P. Jansen and W. F. Donath.[1, 2a] Its structure was elucidated in 1936 by R. R. Williams, and its synthesis reported soon thereafter.[1, 2b, 3] The biochemical function of the compound was recognized in 1937,[4] when the corresponding pyrophosphate (**8**) was identified as cocarboxylase, the coenzyme of pyruvate decarboxylase (EC 4.1.1.1), pyruvate dehydrogenase (EC 1.2.4.1), transketolase (EC 2.2.1.1), and several other enzymes.

Thiamin (**6**)[5] is readily available. The annual world production of synthetic Vitamin B_1 (thiamin) exceeds 4000 metric tons, and its wholesale price is 30–35 US dollars per kg (1993 figures).[6] The recommended daily intake is approximately 1.5 mg,[7] and to prevent the recurrence of deficiency diseases, in the Western world the synthetic compound is routinely added to bread.

It is therefore most surprising that knowledge of the biosynthesis of thiamin (that is, of the steps whereby it is generated from primary precursors within the organisms that produce it) and of the biochemical mechanism, the enzymology, and the genetics of these steps is still fragmentary. The current state of knowledge of the biosynthesis of thiamin and cocarboxylase is summarized in the present review.

Biosynthesis of thiamin occurs in most microorganisms and higher plants. A convergent pathway (Scheme 1) generates thiamin monophosphate (**7**) from the phosphorylated forms of two independently synthesized subunits, 4-amino-5-hydroxymethyl-2-methylpyrimidine (**1**, the "pyrimidine unit") and 5-(2-hydroxyethyl)-4-methylthiazole (**4**, the "thiazole unit"). In enteric

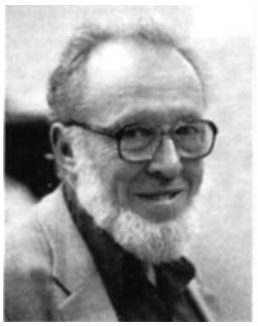
bacteria, the active coenzyme thiamin pyrophosphate (**8**, cocarboxylase) is formed from **7** by phosphorylation. However, in yeast and aerobic bacteria, **7** is hydrolyzed to thiamin (**6**), and a pyrophosphate group is added in one step to yield **8**. Most of the enzymes controlling the coupling and phosphorylation processes have been partially purified, and almost all the genes responsible for the production of these enzymes have been located in *Escherichia coli* and in yeast. New insights concerning the enzymology and the genetics that have been gained since the publication of earlier reviews[8] will be described, and adequate documentation is provided to summarize the current state of knowledge of the final stages of thiamin biosynthesis.

Precursor–product relationships for the heterocyclic subunits of thiamin have only been established with certainty in the past 15 years. Other than (5-aminoimidazole)ribotide (AIR, **9**), no committed intermediate has yet been recognized, and the enzymology leading to the two subunits is entirely unknown. Recent investigations have provided initial genetic information for these pathways.[9] Whether the biosynthetic pathways to the heterocyclic subunits produce the free pyrimidine (**1**) and free thiazole (**4**) units or their phosphate esters (**2** and **5**, respectively) is not yet established.

Thiamin biosynthesis is a remarkable example of biochemical diversity: not only is there diversity in the final stages of coenzyme biosynthesis, but two entirely different pathways are established for both the pyrimidine and thiazole units, one in enteric bacteria and the other in yeast. The information available indicates that aerobic bacteria utilize the yeast pathway for



I. D. Spenser

R. L. White

Ian Spenser studied Chemistry at the University of Birmingham, and at King's College, University of London, England, where he completed his Ph.D. in Biochemistry in 1952 under the direction of William Robson and his D. Sc. in 1969. From 1952 until 1957 he was a lecturer in the Department of Biochemistry of the Medical College of St. Bartholomew's Hospital, University of London. In 1953–1954, as postdoctoral fellows in Leo Marion's laboratory at the National Research Council of Canada Laboratories in Ottawa, he and the late Eddie Leete, who became a life long friend, carried out the first radioactive tracer experiments to test biogenetic hypotheses of the origin of natural products. In 1957 he joined the Department of Chemistry of McMaster University, Hamilton, Canada, as Assistant Professor and now holds the rank of Professor Emeritus. At McMaster he continued his tracer studies of alkaloid biosynthesis. In the late 1960s he turned his attention to the biosynthesis of two B vitamins, pyridoxine and thiamin, work that is continuing today. He was Visiting Professor at the Technical University of Denmark (with A. Kjaer, 1977), at the University of Tokyo (with U. Sankawa, 1983), and at the Universities of Karlsruhe (with J. Rétey and H. Musso, 1981) and Bonn (with E. Leistner, 1989), and "Akademischer Gast" at the ETH, Zürich (with D. Arigoni, 1971, 1989). Among his honors are the Fellowship of the Royal Society of Canada (1980), a NATO Senior Scientist Award (1982) and the John Labatt Ltd. Award of the Chemical Institute of Canada (1983).

Robert L. White was born in Halifax, Nova Scotia, on the day that Watson and Crick's paper on the structure of DNA was published in Nature. He studied at Dalhousie University and McMaster University, where he received his Ph.D. on thiamin biosynthesis under the direction of Ian D. Spenser in 1979. As a postdoctoral fellow, he worked on penicillin biosynthesis with Sir Edward Abraham and Professor Jack Baldwin at the University of Oxford, and on enzyme inhibitors at Syntex, Inc. He is an Associate Professor of Chemistry at Dalhousie University, engaged in research on the biosynthesis of natural products, particularly nonprotein amino acids and antibiotics. In 1994, he became a Fellow of the Chemical Institute of Canada.

thiazole biosynthesis and that plants use the route defined in enteric bacteria to form the thiazole unit.

The work that led to the recognition of the primary precursors will be briefly summarized, and the biogenetic anatomy of the pyrimidine and thiazole units of thiamin, in prokaryotes and in eukaryotes, will be compared and contrasted. The reader is referred to the original literature for details of the methods that were used to establish the sites of incorporation of the labeled substrates employed to trace the origin of the pyrimidine and thiazole units. Only those contributions that gave conclusive results will be included. Earlier reviews provide detailed summaries of the biosynthetic process in eukaryotes[10] and prokaryotes[10, 11] as it stood in 1984/85. In this review we intend to stress the advances that have been made during the past ten years, to compare and contrast the diverse pathways, and to direct attention to the problems that remain to be solved. In particular, we shall deal with current investigations of the biosynthesis of the pyrimidine and thiazole units.

1.1. Methodology

Published investigation of the biosynthetic incorporation of labeled substrates into thiamin have so far been limited to the use of radioactive tracers or of stable isotopes in conjunction with mass spectrometric analysis. High-field ^{13}C NMR, the most powerful modern method available for the determination of incorporation patterns, has only very recently been successfully employed in investigations of thiamin biosynthesis.[12, 13]

The radioactive tracer method demands not only the isolation of thiamin and its separation from other ionic water-soluble compounds such as amino acids, a procedure whose difficulty explains the persistent contamination of the desired product by radioactive impurities, but also the preparation and purification of derivatives by chemical manipulation on a minute scale. The lack of rigorous purification of the compounds whose radioactivity was being determined has sometimes led to erroneous conclusions. This was probably the origin of results that appeared to indicate, wrongly, that methionine was implicated in the biosynthesis of the thiazole unit of thiamin. In most cases published reports of radioactive tracer experiments do not include a description of the methods of purification and degradation that were employed.

Moreover, it is important, for reasons of internal control, to account for the sites of the total radioactivity within thiamin as a whole and not merely within one or other of the two subunits: only when this was done did it become evident that glycine was incorporated into the pyrimidine unit in enteric bacteria but not in yeast, whereas it entered the thiazole unit in yeast but not in enterobacteria. This finding served as conclusive evidence for the existence of different pathways in prokaryotes and eukaryotes.

Although the mass spectrometric method requires gas chromatographic separation of the compounds whose fragmentation pattern is being recorded, none of the reports employing this analysis include primary data on the efficiency of the gas chromatographic separation of impurities from the investigated compound. Thus, it is often not possible to assess the purity of the materials whose radioactivity or fragmentation pattern serves as the basis of biosynthetic inferences.

In our most recent studies[12, 13] we have succeeded in detecting, by means of high-field nuclear magnetic resonance spectroscopy (NMR), the incorporation of substrates labeled with the stable isotopes ^{13}C or ^{2}H as the isotopic markers. In particular, the application as substrates of samples that are fully ^{13}C-enriched at contiguous carbon atoms ("bond-labeled" samples) has led to significant progress, since by use of such samples it is possible to observe the transfer of intact multicarbon units from precursor into biosynthetic product. Substrates bond-labeled with fully enriched ^{2}H attached to fully enriched ^{13}C may be employed similarly. Application of ^{14}C-labeled samples provided a method for the detection of the transfer of individual carbon atoms but not of multicarbon units.

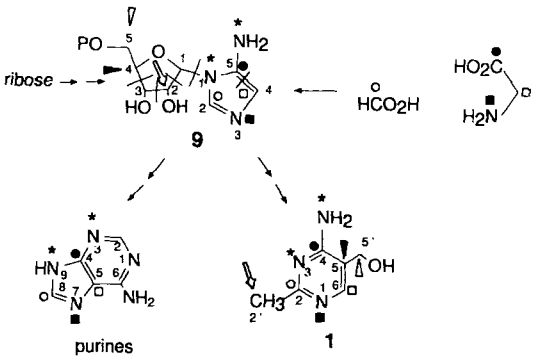
Even though the sensitivity of detection of ^{13}C by NMR is approximately three orders of magnitude lower than that of ^{14}C by liquid scintillation counting,[14] application of ^{13}C labeled and particularly ^{13}C bond-labeled substrates is currently the method of choice in biosynthetic studies that focus on investigations of precursor–product relationships. A significant advantage of the method lies in the fact that ^{13}C NMR not only detects the site of labeling, but at the same time confirms the identity of the labeled sample and determines its degree of chemical purity. Thus, an obligatory component of biosynthetic investigations employing radioactive tracers,[15] namely the chemical manipulation of very small samples (which was required to prepare chemical derivatives of the radioactive products in order to determine radiochemical purity and to execute sequences of controlled chemical degradation in order to determine the precise sites of labelling), is minimized with the use of ^{13}C labeled substrates.

Tracer studies with ^{13}C isotopes can only be successful if signal assignments within the ^{13}C NMR spectrum of the product are reliable and if the level of ^{13}C enrichment within the product is adequate for detection by high-field NMR spectroscopy. Low levels of ^{13}C enrichment at single sites in a product are much more difficult to detect with certainty than enrichment from bond-labeled samples, since in the former instance signal enhancement must be determined by comparison with the intensity of a natural abundance signal, whereas in the latter instance enrichment by intact incorporation of a pair of contiguous ^{13}C enriched carbon atoms is indicated by the presence of new satellite peaks that are absent in the spectrum of a natural abundance sample. Furthermore, the presence of such satellite peaks resulting from incorporation of $^{13}C-^{13}C$ contiguously labeled (that is, bond-labeled) substrates in the signals of the ^{13}C NMR spectrum of a biosynthetic product provides direct evidence for the transfer from substrate to biosynthetic product of an intact multicarbon unit.

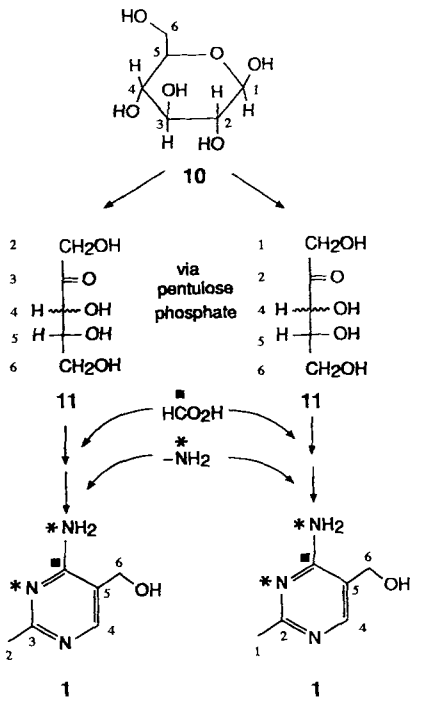
A serious operational difficulty with the method stems from the fact that very few specialized ^{13}C-labeled (and particularly ^{13}C bond-labeled compounds) other than the most common substrates are commercially available, and even these are quite expensive. For specialized investigations the required labeled substrates must be synthesized in house from labeled chemicals that are available.

2. Biosynthesis of the Pyrimidine Unit

Chemically distinct routes for the biosynthesis of the pyrimidine moiety of thiamin are strongly supported by the results of isotopic experiments carried out in several different organisms, particularly yeast (*Candida utilis* and *Saccharomyces cerevisiae*) and enteric bacteria (*E. coli* and *Salmonella typhimurium*). Formate is involved in both the yeast and the enteric bacteria routes, but enters different positions of the pyrimidine ring in the two pathways (C4 and C2, respectively). Glycine and ribose are the precursors of the other carbon atoms in prokaryotes, and in particular, in *E. coli* and *S. typhimurium* (Scheme 2). In eukaryotes, glycine is not utilized in the formation of the pyrimidine unit, and glucose (presumably via pentulose phosphate) supplies all other carbon atoms (Scheme 3). There is evidence



Scheme 2. The biosynthesis of the pyrimidine unit (**1**) of thiamin in facultative anaerobic bacteria. Precursor–product relationships show the intermediacy of **9**, a purine precursor (N* stems from the amide N atom of glutamine; for the steps on route from **9** to **1** see Scheme 4; the atoms indicated by wedges, circles, or squares were labeled in several experiments).



Scheme 3. The biosynthesis of the pyrimidine unit (**1**) in eukaryotes (major pathway) and precursor–product relationships. Numbers on carbon atoms refer to the carbon atoms of glucose (**10**). N* stems from the amide N atom of glutamine.

concerning the identity of some of the intermediates between the early precursors and the final product, but committed intermediates have not been identified, and the mechanism whereby the building blocks are joined to form the final structure is almost entirely unknown.

2.1. Formate and Glycine as Precursors

Formate was the first precursor of the pyrimidine unit to be identified by isotopic tracer experiments.[16] Chemical degradation of labeled thiamin derived from [^{14}C]formic acid showed that in *E. coli* B[17] and other prokaryotes[18,19] label from [^{14}C]formate entered C2 of the pyrimidine unit and no other site (Scheme 2). On the other hand, in *S. cerevisiae*[20,21] and other eukaryotes[19] label entered C4 of the pyrimidine unit and no other site (Scheme 3). In a single reported instance label entered both C2 and C4 of the pyrimidine unit: about 75% of label was located at C4 and 25% at C2.[22]

In enterobacteria three atoms of the pyrimidine ring are supplied by glycine. High incorporations of radioactivity from [1-^{14}C]- and [2-^{14}C]glycine were observed in a glycine-requiring mutant of *S. typhimurium* LT2,[23] and it was subsequently shown by chemical degradation that radioactivity from the carboxyl (C1) and methylene (C2) groups of glycine entered C4[18] and C6,[24] respectively, of the pyrimidine unit (Scheme 2). Analogous results were obtained from mass spectrometric analysis of thiamin isolated from *E. coli* B incubated separately with [1-^{13}C]-, [2-^{13}C]-, and [^{15}N]glycine.[25] Whether glycine is incorporated as an intact unit into C6, C4, and N1 of the pyrimidine remains to be shown.

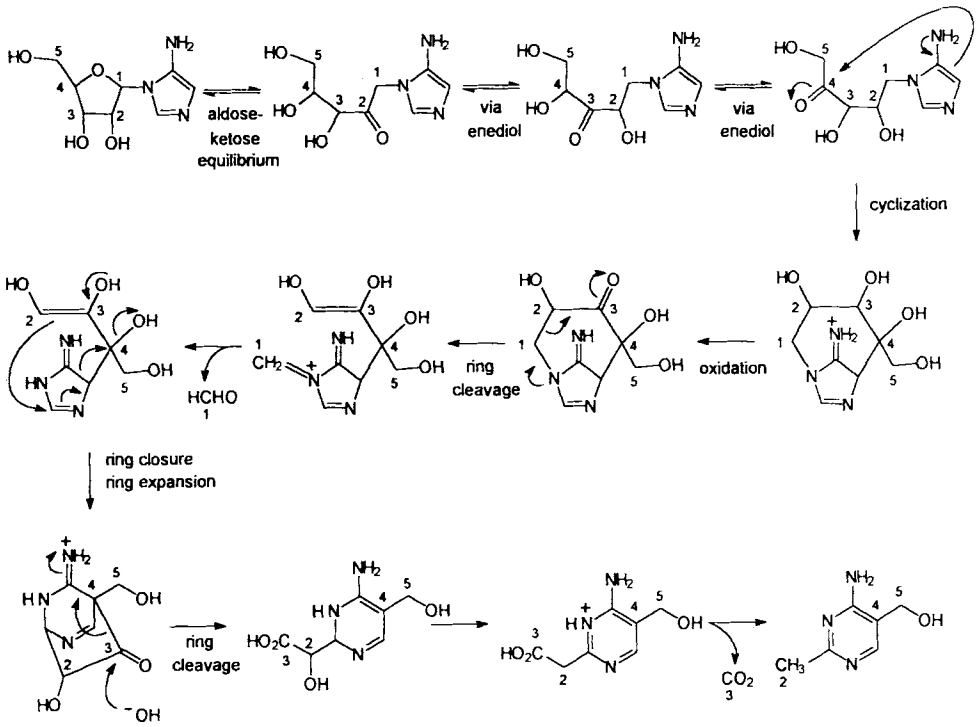
In eukaryotes, or more particularly in *S. cerevisiae*, label from [2-^{14}C]glycine[26] and from [^{15}N]glycine[27] entered the thiazole unit (see Scheme 6) but not the pyrimidine unit of thiamin. In other studies label from [1-^{14}C]glycine,[28] from [^{15}N]glycine,[29] or from [^{15}N,2-^{13}C]glycine[12] was not incorporated into the pyrimidine unit.

2.2. (5-Aminoimidazolyl)ribotide, an Advanced Precursor in Enteric Bacteria

Formate and glycine have been known for many years as precursors of the purine ring system.[30] (5-Aminoimidazolyl)ribonucleotide (AIR, **9**) serves as an intermediate (Scheme 2). C2 of the ring system of **9** originates from formate, while the C_2N unit (N3,C4,C5) originates from the intact NCC chain of glycine. The remaining nitrogen atoms (N1 and NH_2) originate from the amide nitrogen of glutamine (Scheme 2). In *E. coli* the three nitrogen atoms of the pyrimidine unit are of corresponding origin: N1 is derived from glycine[25] and the other two nitrogen atoms are supplied by glutamine.[29] That **9** satisfied the requirements of an *S. typhimurium* LT2 mutant blocked in both the purine and the thiamin pyrimidine pathways led Newell and Tucker[31] to suggest that **9** is a key intermediate also in the biosynthesis of the pyrimidine moiety of thiamin. The incorporation of a labeled sample of **9**, prepared biosynthetically from [1-^{14}C]glycine, into the pyrimidine moiety without dilution of the specific activity,[31] and the incorporation of label

from [3-^{15}N]- and from [$^{15}NH_2$]-(5-aminoimidazolyl)riboside into N1 and NH_2, respectively, of the pyrimidine unit,[32] fully support this hypothesis (Scheme 2).

The CH_3 group (C2′) and the C_2 unit (C5,C5′) of the pyrimidine moiety are not derived from the aminoimidazole nucleus of (5-aminoimidazolyl)riboside or -ribotide. The ribose unit of (5-aminoimidazole)ribotide was suggested as the precursor of C5,C5′ of the pyrimidine unit when it was observed that C5′ was labeled from [6-^{14}C]glucose in *E. coli* B (IFO 13168).[33] Incorporation of an intact C_2 unit derived from D-[1,2,3,4,5,6-$^{13}C_6$]glucose into the C5,C5′ unit of the pyrimidine in *E. coli* B mutant WG2 was recently confirmed by ^{13}C NMR spectroscopy.[12] That (5-aminoimidazole)ribotide serves as the precursor of all the carbon atoms of the pyrimidine unit was demonstrated in Newell and Tucker's *S. typhimurium* strain thi 10/T by David and his collaborators. The pyrimidine unit labeled with ^{13}C was formed from [U-^{13}C]-(5-aminoimidazolyl)riboside in the presence of glucose, but no labeling of the pyrimidine unit was observed when [U-^{13}C]glucose and unlabeled (5-aminoimidazolyl)riboside were used.[34] In a separate experiment, label from (5-aminoimidazolyl)[U-^{14}C]riboside was located mainly at C2′ and at C5,C5′, the three carbon atoms not derived from the 5-aminoimidazole ring. Experiments employing radioactive samples of (5-aminoimidazolyl)riboside[35] as well as of (5-aminoimidazolyl)[2-^{13}C]riboside[32] demonstrated that C2′ of the pyrimidine unit was derived from C2 of the ribose moiety of (5-aminoimidazolyl)riboside. The intramolecular nature of this transformation was deduced by analyzing the simultaneous incorporation of [^{13}C]ribose- and [^{15}N]imidazole-labeled samples of (5-aminoimidazolyl)riboside.[32]



Scheme 4. A chemically rational, hypothetical mechanism for the intramolecular conversion, in prokaryotes, of (5-aminoimidazolyl)riboside into the pyrimidine unit of thiamin.

Thus, in prokaryotes, (5-aminoimidazole)ribotide (**9**) is an intermediate in the biosynthesis not only of the nucleic acid purines but also of the pyrimidine unit of thiamin. To account for the results of the isotopic experiments described above (summarized in Scheme 2), conversion of (5-aminoimidazolyl)-riboside (or (5-aminoimidazolyl)ribotide) to the pyrimidine unit (or the corresponding 5′-phosphate ester) requires the cleavage of five bonds of the precursor (imidazole C4–C5; ribose C1–C2, C2–C3, C3–C4; and imidazole N1–ribose C1) with the expulsion of two carbon atoms (C1 and C3) of the ribose unit and the creation of three new bonds (imidazole C2–ribose C2, yielding pyrimidine C2,C2′; imidazole C4–ribose C4, yielding pyrimidine C6–C5; and imidazole C5–ribose C4, yielding pyrimidine C4–C5). The accumulated evidence suggests that this must take place intramolecularly. A hypothetical, chemically rational mechanism for such a process is shown in Scheme 4.

2.3. Glucose as a Precursor in Yeast

In yeast the carbon atoms of the pyrimidine nucleus of thiamin are derived from formate and glucose. While (5-aminoimidazolyl)ribotide is a precursor of nucleic acid purines in *S. cerevisiae*, and presumably in other eukaryotes,[30] it is not an intermediate of thiamin biosynthesis in this yeast. The mode of incorporation of carbohydrate precursors further distinguishes the biosynthetic pathway to the pyrimidine unit in yeast from that in enterobacteria. In *C. utilis* label from [1-^{14}C]-, [2-^{14}C]-, and [6-^{14}C]glucose (**10**) entered the pyrimidine unit, but efforts to locate the sites of activity led to ambiguous results.[36] In *S. cerevisiae* ATCC 24903 the distribution of label within the pyrimidine nucleus (from [1-^{14}C]-, [2-^{14}C]-, [6-^{14}C]-, and [6-^{14}C,6-^{3}H]glucose and from [1-^{14}C]fructose) was fully accounted for by complete chemical degradation.[22] A complex pattern of distribution was observed, which was interpreted in terms of the simultaneous occurrence of two different independent pathways, one major, the other minor. In the major pathway formate enters C4 of the pyrimidine, and the five carbon atoms C2′, C2, C6, C5, and C5′ of the pyrimidine originate from glucose, presumably via C1 to C5, respectively, of a pentulose (**11**; see Scheme 3). In the minor pathway, not depicted in Scheme 3, formate enters C2, and the glucose-derived carbon atoms C1,C2 of a pentulose supply C5,C4 of the pyrimidine. The origin of C2′, C5′, and C6 is still unknown. It should be noted that this duality of routes has so far not been observed in any other strain of *S. cerevisiae*, or indeed in any other eukaryote.

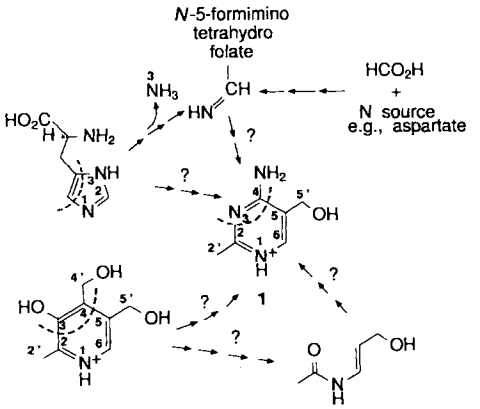
A recent ^{13}C NMR study on the incorporation of label from D-[1,2,3,4,5,6-$^{13}C_6$]glucose into thiamin in *S. cerevisiae* ATCC 7752 (= IFO 1234) provides evidence of the incorporation of an intact C_2 unit derived from glucose into the C_2 unit C2′, C2 and

of an intact C_3 unit into the C_3 unit C6, C5, C5′ of the pyrimidine unit of thiamin,[12] confirming the mode of entry of glucose by the major pathway demonstrated earlier by the tracer work with ^{14}C. No indication for the existence in this strain of yeast of the minor pathway was detected.

2.4. Advanced Pyrimidine Precursors in Yeast

An early report of the isolation, from *S. cerevisiae*, of a late intermediate in the evolution of the pyrimidine unit[37] has remained unresolved. The compound was reported to show ultraviolet absorption with a maximum at 259 nm, and to yield a ^1H NMR spectrum showing three signals: $\delta = 2.0$ (s, 3H, possibly CH_3CO), 6.2 (d, 2H, possibly vinylic $CH_2CH=$), and 8.5 (t, 3H, ?). Without further information a structure cannot be proposed on this basis, and the substance will have to be reisolated before useful inferences can be drawn.

Recent results appear to implicate histidine[38] and pyridoxine[39, 40] as the progenitors of the pyrimidine moiety of thiamin in *S. cerevisiae* IFO 1234 (Scheme 5). Radioactivity from L-[2-^{14}C]histidine enters an unspecified site (assumed to be C4) within the pyrimidine unit with little change in specific activity.



Scheme 5. Reported incorporation pattern of fragments of pyridoxol and of L-histidine into the pyrimidine unit of thiamin in yeast.

The label from [1,3-$^{15}N_2$]histidine entered N3 and the NH_2 group of the pyrimidine unit. Since N1 of histidine is derived from the amino group of aspartic acid and since label from [^{15}N]aspartic acid entered N3 of the pyrimidine, it was inferred that N1 of histidine generates N3 of the pyrimidine and that N3 of histidine, which in turn is derived from the amide nitrogen atom of glutamine, becomes the NH_2 group of the product. It should be noted, however, that both N3 and the NH_2 group of the pyrimidine are derivable from the amide nitrogen atom of glutamine.[29] ^{15}N from DL-[α-amino-^{15}N]histidine did not enter the pyrimidine, nor did the other carbon atoms of histidine play a part in the biosynthetic process.[41] These results were interpreted as showing that an intact N1,C2,N3, fragment of histidine, derived by cleavage of the imidazole ring, supplies the intact NCN unit N3, C4, NH_2 of the pyrimidine. Both the intact incorporation of the histidine fragment or an early amination step in the pyrimidine pathway are consistent with the reported nonincorporation of a deuterated sample of 4-hydroxy-5-hydroxymethyl-2-methylpyrimidine in *S. cerevisiae*.[42]

Incorporation of the intact NCN fragment of the imidazole ring of histidine has not been tested by direct experiment, however, and another interpretation of the results is plausible: The catabolism of histidine via urocanic acid and imidazolonepropionic acid is a general metabolic process that has been extensively studied in bacteria (but has apparently not yet been investigated in yeast). This process eventually leads to the transfer to folic acid of the N1,C2 unit of the imidazole nucleus of histidine, that is, of the aspartate-derived nitrogen atom and the formate-derived carbon atom, to yield *N*-5-formiminotetrahydrofolate[43] and then N-5-formyltetrahydrofolate, two of the classical donors of formate units.[44] In our view, it is likely that C2 and possibly also N1 of the histidine nucleus enters the thiamin pyrimidine by this indirect route.

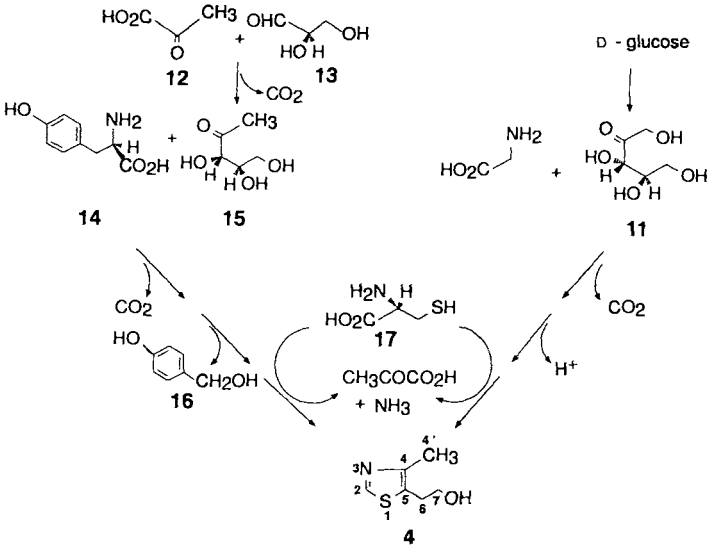
The remaining C_2NC_3 fragment of the pyrimidine (C2′,C2,N1,C6,C5,C5′) is inferred to be derived directly from the corresponding C_2NC_3 unit of pyridoxol,[40] on the basis both of the results of competition experiments with $^{15}NH_4^+Cl^-$ in the presence of various unlabeled substrates including pyridoxol,[39] and of incorporation experiments with ^{13}C- and ^2H-labeled samples of pyridoxol.[40] The biosynthesis of pyridoxol in yeast is entirely unexplored and for obvious reasons cannot be assumed to follow the same route that is now emerging for pyridoxol biosynthesis in *E. coli*.[45] What is known about the latter route, however, is not compatible with a direct entry of a pyridoxol fragment into the pyrimidine, since the established mode of incorporation of several labeled substrates (e.g., pyruvate and glycine) into pyridoxol in *E. coli*, on the one hand,[45] and into the pyrimidine unit in yeast, on the other (see above), are not reconcilable.

Judgement on the inferences concerning the incorporation of an intact pyridoxol fragment into the pyrimidine unit will have to be reserved until something is known about pyridoxol biosynthesis and catabolism in eukaryotes. Pyridoxine catabolism has been studied in a number of soil bacteria that are capable of utilizing the vitamin as sole carbon and nitrogen source.[46–48] A reaction sequence that occurs in these organisms, of a type that may be of relevance to the present findings, is the oxidation of both the C4′ and C5′ hydroxymethyl groups of pyridoxol, followed by loss of the carboxyl group at C4. 3-Hydroxy-2-methylpyridine-5-carboxylic acid,[46, 47] the compound so generated, then undergoes enzyme-catalyzed oxidative cleavage of the C2–C3 bond of the pyridine nucleus, to yield 4-N-acetylamino-3-carboxybut-3-enoic acid ($CH_3CONHCH=C(CO_2H)CH_2CO_2H$ = α-*N*-acetylaminomethylenesuccinic acid[46]), which is then degraded further.[48] An analogous reaction sequence in which the C5′ hydroxymethyl group does not undergo oxidation but is preserved prior to ring cleavage would generate an intermediate that might account for the biogenetic relationship between pyridoxol and the pyrimidine unit of thiamin which appears to be indicated by the tracer results.

3. Biosynthesis of the Thiazole Unit

Isotopic feeding experiments performed to identify the primary precursors have firmly established that distinct routes are used by enteric bacteria and yeast for the biosynthesis of the

thiazole unit. In *E. coli* and *S. typhimurium*, tyrosine and a deoxypentulose provide the nitrogen and carbon atoms of the thiazole moiety, whereas glycine and a pentulose are the precursors in yeast (Scheme 6). Other available evidence indicates that



Scheme 6. The biosynthesis of the thiazole unit (**4**) in facultative anaerobic prokaryotes (*E. coli* and other enterobacteria, as well as higher plants, left) and in eukaryotes (aerobic bacteria, yeasts; right). Precursor–product relationships are shown. For the steps between **14** + **15** and **4**, see Scheme 7 and for those between **11** and **4**, Scheme 8.

green plants utilize the same pathway as enterobacteria, whereas the yeast pathway is employed by aerobic bacteria (*Bacillus subtilis* and *Pseudomonas putida*). The source of the sulfur atom is not certain, but is assumed to be cysteine. Chemically rational hypotheses are available to account for the formation of the thiazole unit from these substrates (see Schemes 7 and 8), but intermediates of the pathway have not been identified.

3.1. The Source of the Sulfur Atom

Incorporation efficiencies and competition experiments have been employed to probe this unsolved problem, but definitive conclusions will be possible only on the basis of results of future enzymological and genetic experiments. Cysteine is generally regarded as the precursor of the sulfur atom in enterobacteria. Label from [^{35}S]cysteine or [^{35}S]methionine is incorporated with equal efficiency in *E. coli* ATCC 9637,[49] but higher incorporations of cysteine in *E. coli* IFO 13168[50, 51] have been reported. Cysteine more effectively dilutes the incorporation of label from [^{35}S]sulfate in *E. coli* mutant 70-17[52] and from [^{34}S]thiocysteine in *E. coli* K-12 hpbλ^-.[53] However, in *S. typhimurium* ATCC 23592 methionine dilutes the incorporation of cysteine.[54]

Radioactivity from L-[^{35}S]cystine and L-[^{35}S]methionine is incorporated into thiamin by *S. cerevisiae*. Evidence on the relative efficiency of incorporation from the two substrates is conflicting.[50, 51] In *S. cerevisiae* NCYC 1062, L-methionine was more effective than L-cysteine in diluting the incorporation of ^{35}S from [^{35}S]sulfate, but many other sulfur containing substances, including Na_2S, were also effective in lowering ^{35}S incorporations.[55]

3.2. Glycine and Tyrosine as Precursors

In yeast and aerobic bacteria a CN fragment, derived from glycine by decarboxylation, serves as the precursor of the C2,N fragment of the thiazole moiety. The label from [^{15}N]glycine was incorporated into the thiazole unit by *B. subtilis* and *P. putida*,[56] and in *S. cerevisiae*[27, 56] and several other eukaryotes.[56] The only carbon atom labeled by [α-^{14}C]glycine in *B. subtilis* ATCC 6633 is C2 of the thiazole moiety.[57] Incorporation of label from [α-^{14}C]glycine into C2 of the thiazole unit was demonstrated by chemical degradation also in several strains of *S. cerevisiae* [26, 27, 58, 59] The carboxyl group of glycine was not incorporated into thiamin.[27, 59] Intact incorporation of the ^{15}N–^{13}C unit of [^{15}N,2-^{13}C]glycine into the N3,C2 fragment of the thiazole unit was recently demonstrated.[12]

By contrast, label from [α-^{14}C]glycine is not incorporated into the thiazole unit by *S. typhimurium*,[60] and [^{15}N]glycine is not incorporated into the thiazole unit by either *E. coli* or *Enterobacter aerogenes*.[56] However, the nitrogen and the α-carbon of another amino acid, tyrosine, provide the C2,N fragment of the thiazole unit. [^{15}N]Tyrosine supplies the nitrogen atom of the thiazole moiety in *E. coli*[56, 61] and *E. aerogenes*,[56] and label from [α-^{14}C]tyrosine (**14**) is incorporated into C2 of the thiazole in *E. coli*[62] and *S. typhimurium*.[60] This label entered in the presence of unlabeled glycine and methionine, making their participation in the biosynthetic construction of the unit unlikely. Incorporation of radioactivity from [α-^{14}C]tyrosine into thiamin has also been reported in spinach leaf chloroplasts, but the position of the label was not established.[63] In *E. coli* only C2 of the thiazole unit is labeled by [U-^{14}C]tyrosine,[62] which indicates that the α carbon atom of tyrosine is the only one that is incorporated into the thiazole unit. The intact incorporation of the α-C,N unit of tyrosine is likely, but not as yet demonstrated by experiment. Deuterium from [3′,5′-^{2}H$_2$]tyrosine is incorporated into *p*-hydroxybenzyl alcohol (**16**) in *E. coli* B, and the correlation observed between *p*-hydroxybenzyl alcohol and thiamin synthesis suggests that the phenolic alcohol is formed during thiamin biosynthesis.[64]

No incorporation of label from [^{15}N]tyrosine into thiamin was observed in *B. subtilis* or in *P. putida*,[56] nor was label from [α-^{14}C]tyrosine incorporated into thiamin in *S. cerevisiae*.[26] The mutually exclusive incorporation results of glycine and tyrosine support the existence of different routes for thiazole biosynthesis: one in aerobic bacteria and yeast, and another in enterobacteria and plants (Scheme 6).

3.3. Carbohydrate Precursors in Enteric Bacteria

The initial evidence for the origin of the C_5 chain of the thiazole unit comes from incorporation studies in *E. coli* B with samples of glucose, glycerol, and pyruvic acid, labeled with stable isotopes.[65] The multiple incorporation of deuterium from [1-^{2}H]glucose and the incorporation of label from [U-

$^{13}C_6$]glucose indicated that a C_3 unit (giving rise to C5–C7) combines with a C_2 unit (giving rise to C4′,C4). The thiazole carbons derived from the C_3 unit were also labeled by [6,6′-$^2H_2$]glucose and [5,6,6′-$^2H_3$]glucose,[65] and the incorporation of (*R*)-[(*RS*)-1-^{2}H]glycerol and of (*R*)-[(*RS*)-1-^{2}H,1-^{18}O]-glycerol provides support for the three-carbon precursor.[66] That the C_2 unit is derived from pyruvate is supported by the intact incorporation of the CD_3 group of [3-$^2H_3$]pyruvate,[65] and the incorporation of label from [U-^{14}C]alanine and [3-^{14}C]- and [2-^{14}C]pyruvate[51] in *E. coli*. However, [U-^{14}C]alanine was not incorporated in *S. typhimurium* ATCC 23592.[60]

Very recently conclusive evidence for the derivation of the five-carbon unit from two smaller fragments derived from glucose became available: The incorporation into the thiazole unit of thiamin in *E. coli* B, mutant WG2, of two intact multicarbon units derived from D-[1,2,3,4,5,6-$^{13}C_6$]glucose (a C_2 unit, entering C4′,C4, and a C_3 unit, entering C5–C7) was demonstrated by ^{13}C NMR.[12]

The C_5 compound that is derived by combination of the C_2 and the C_3 fragment and serves as the direct precursor of the five-carbon chain of the thiazole unit has been identified in *E. coli* as 1-deoxy-D-xylulose (**15**).[67, 68] Intact incorporation of [1-$^2H_3$,5-$^2H_1$]-1-deoxy-D-xylulose (1-deoxy-D-*threo*-pentulose) was indicated by the presence of deuterium at C4′ and C7 of the thiazole unit.[67] No incorporation of the corresponding D-*erythro* isomer was observed.[68]

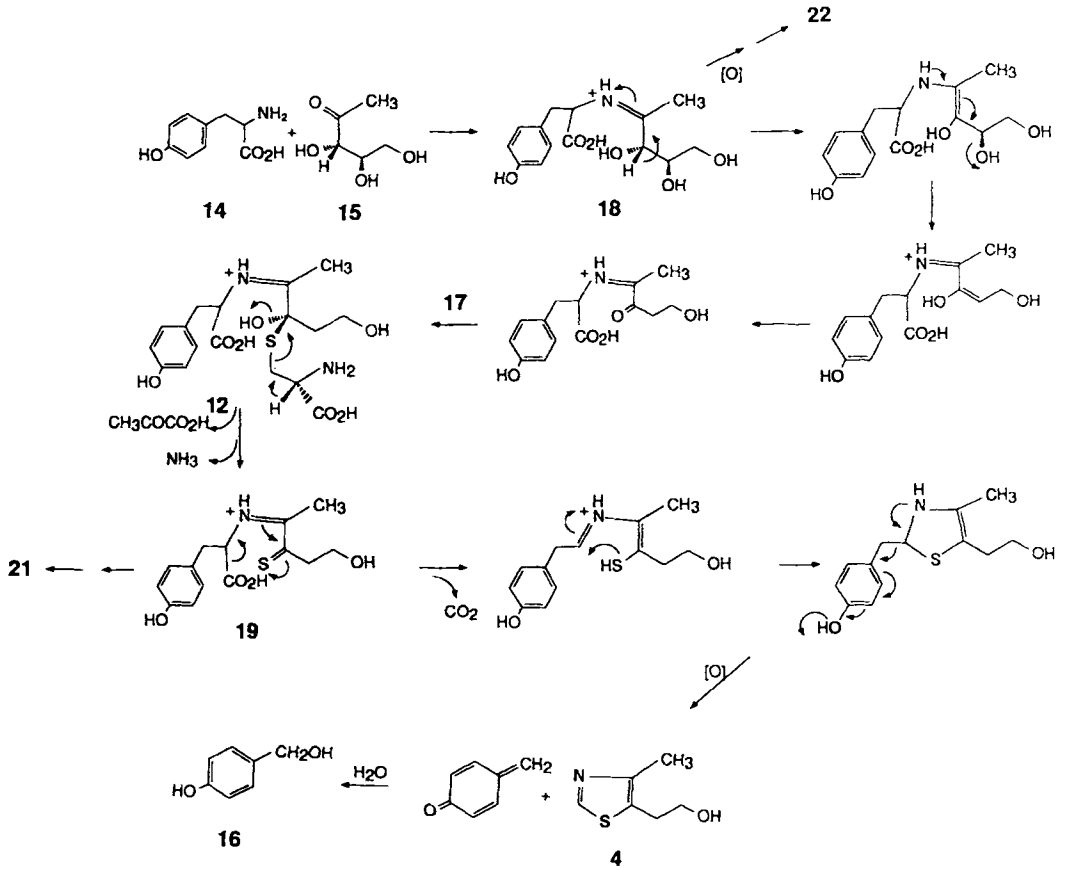
Very recently conclusive evidence was obtained in support of the intact incorporation of 1-deoxy-D-xylulose into the thiazole moiety of thiamin: it was shown by ^{13}C NMR spectroscopy that the intact ^{13}C–^{13}C bond of a sample of [2,3-$^{13}C_2$]-1-deoxy-D-xylulose[69] entered the C_2 unit C4,C5 of the thiazole moiety of thiamin in *E. coli* B mutant WG2.[13] Related investigations have demonstrated that this pentulose is also an advanced precursor of pyridoxine, another B vitamin.[13, 45]

1-Deoxy-D-xylulose has been isolated from cultures of *Streptomyces hygroscopicus* UC-5601[70] and from partially purified cell-free extracts of several bacterial species that had been incubated with pyruvate (**12**), D-glyceraldehyde (**13**), and thiamin pyrophosphate.[71] The formation of 1-deoxy-D-xylulose was detected by paper chromatography in cell-free extracts of several other bacteria, but significantly smaller amounts formed in yeast and fungal extracts.[71] Pyruvate dehydrogenase (EC 1.2.4.1) purified from *B. subtilis* IFO 13719 and *E. coli* was subsequently shown to catalyze the condensation of pyruvate with D-glyceraldehyde.[72]

The pyruvate dehydrogenase-catalyzed formation of the thiazole precursor 1-deoxy-D-xylulose implicates thiamin pyrophosphate as a required coenzyme in the thiazole pathway of thiamin biosynthesis. Although this is remarkable, it is not unique; both pyridoxine[73] and biotin[74] are also implicated in their own biosynthesis.

Thus in enteric bacteria, the thiazole unit is formed from tyrosine (**14**), 1-deoxy-D-xylulose (**15**) (or 1-deoxy-D-xylulose 5-phosphate), and a sulfur donor (e.g., cysteine (**17**)). Initial Schiff base (**18**) formation followed by a series of tautomerization, decarboxylation, elimination, and addition reactions generates the thiazole unit and *p*-hydroxybenzyl alcohol[64] (Scheme 7). With 1-deoxy-D-xylulose as a precursor, an oxidative step is required. This can be accommodated by oxidative cleavage of tyrosine, as shown in Scheme 7, or by oxidation at C3 of the deoxyxylulose unit and a subsequent reductive fragmentation of tyrosine analogous to the deprotonation step in the glycine pathway (Scheme 8). An investigation of *p*-hydroxybenzyl derivatives of thiamin and the thiazole moiety indicated that in *E. coli* mutants cleavage of the *p*-hydroxylbenzyl unit is associated with thiazole formation and not with later biosynthetic steps.[75]

Minor modifications of this reaction sequence (Schemes 9 and 10) are required to account for the formation of two *E. coli*



Scheme 7. A hypothetical mechanism for the biosynthesis of the thiazole unit in facultative anaerobic prokaryotes, from L-tyrosine (**14**) and 1-deoxy-D-xylulose (**15**); for the steps between **18** and **22**, see Scheme 10 and for those between **19** and **21**, Scheme 9.

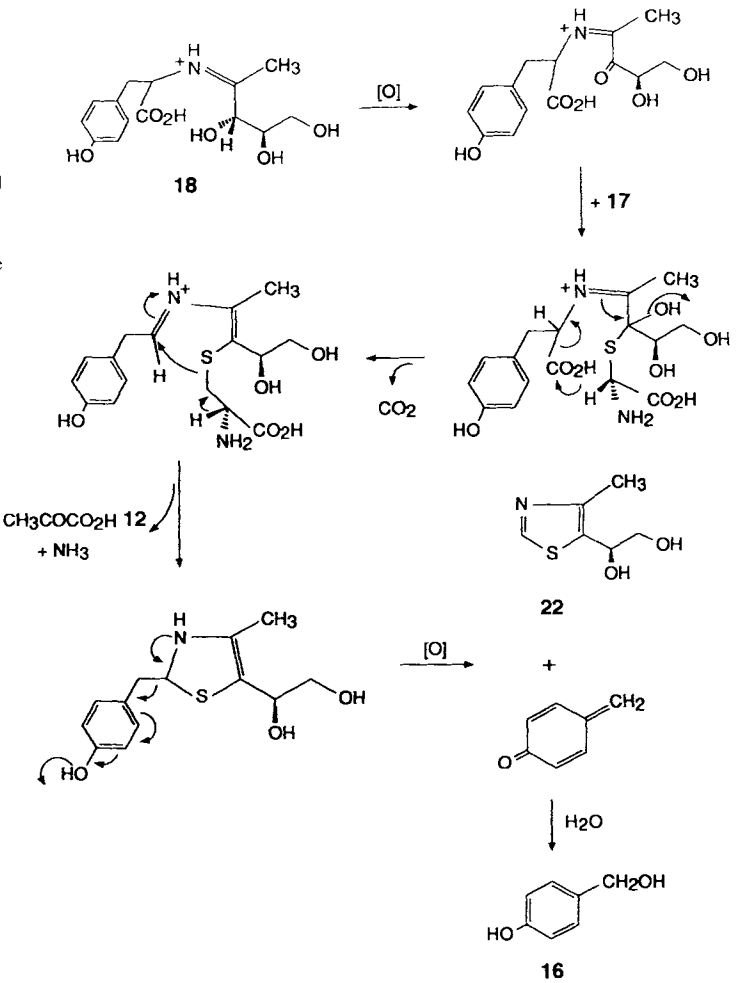
metabolites, 5-(2-hydroxyethyl)-4-methylthiazole-2-carboxylic acid (**21**)[76] and 5-(1,2-dihydroxyethyl)-4-methylthiazole (**22**),[77] that are structurally related to the thiazole unit. Label from [carboxyl-^{14}C]tyrosine is incorporated into **21**. These compounds are probably by-products rather than intermediates of thiamin biosynthesis.

3.4. Carbohydrate Precursors in Yeast

The five-carbon chain of the thiazole unit in *S. cerevisiae* ATCC 24903[78, 79] also originates from carbohydrate sources. Labeling data suggest, however, that it is not formed by combination of a C_3 with a C_2 unit via 1-deoxy-D-xylulose but is generated from an intact pentulose. The evidence, in *S. cerevisiae*, is of necessity indirect, since yeast does not grow on a medium of pentoses, and incorporation of labeled pentoses can thus not be tested directly. The indirect evidence is strong, however. Not only was label from [3-^{14}C]pyruvate,[51, 79] [U-^{14}C]alanine,[51] and [U-^{14}C]-lactate[79] not incorporated, but the labeling pattern from [1-^{14}C]-, [2-^{14}C]-, and [6-^{14}C]glucose, as well as from [1-^{14}C]fructose and [1-^{14}C]glycerol, determined by chemical degradation, indicated that the five-carbon unit of the thiazole moiety is formed by way of both the oxidative and the nonoxidative branch of the pentose phosphate pathway.[79] A similar pattern of incorporation was obtained when [1-^{14}C]-, [2-^{14}C]-, and [6-^{14}C]glucose were administered to *C. utilis*.[51, 80] Furthermore, an experiment with [6-^{14}C,6-^{3}H]glucose[78, 79] in *S. cerevisiae* indicated intact incorporation of the double label into C7 of the hydroxyethyl side chain, but incorporation of ^{14}C label only into the methyl group (C4'). These results are not consistent with the intermediacy of 1-deoxy-D-xylulose. They are consistent with the intermediacy of either D-xylulose or D-ribulose (or their 5-phosphates). Thus, the probable first step on the route to the thiazole in yeast is the formation of a Schiff base (**20**) of glycine with a D-pentulose or a D-pentulose 5-phosphate (Scheme 8).



Scheme 10. Derivation of dihydroxyethylthiazole (**22**) as a by-product of the thiazole pathway in facultative anaerobic prokaryotes.

A sequence of reactions, analogous to that leading to the product from tyrosine/deoxyxylulose (Scheme 7), generates the thiazole unit, but an oxidative step is not required, because a pentulose precursor rather than a deoxypentulose is involved in the process.

In confirmation of the inferences based on the tracer work with radioactive isotopes, the incorporation into the thiazole unit of thiamin in *S. cerevisiae* ATCC 7752 (= IFO 1234) of an intact C_5 unit derived from D-[1,2,3,4,5,6-$^{13}C_6$]glucose, entering the C_5 chain, C4′,C4–C7, was demonstrated by ^{13}C NMR.[12]

4. Coupling of the Two Subunits and Phosphorylation of Thiamin

Identification of the various phosphorylated derivatives that are intermediates of the biosynthesis of the vitamin (**6**) and of its pyrophosphate ester, cocarboxylase (**8**), and the isolation and enrichment of the enzymes catalyzing the various steps of the process in *E. coli* and *S. cerevisiae*, was accomplished by 1975.[8, 10, 11] These final steps of cocarboxylase biosynthesis are presented in Scheme 11. Relevant literature on the coupling of the subunits and the phosphorylation steps leading to **8** is summarized in Table 1, and only the more recent contributions are described below.

Table 1. Literature summary of the biosynthesis of thiamin pyrophosphate (**8**): enzymes of the phosphorylation steps and of the coupling steps of the two subunits.

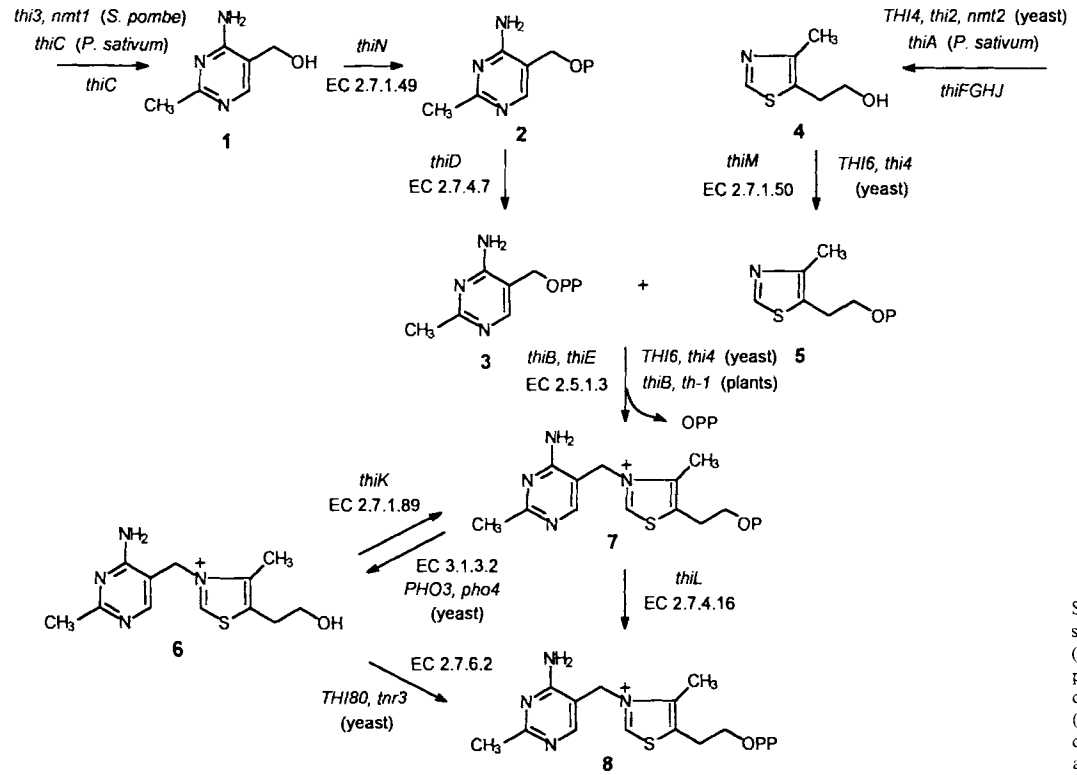
4.1. Enzymes

Enzyme activities for the phosphorylation and coupling of the heterocyclic subunits and for the phosphorylation of thiamin and thiamin monophosphate were detected in crude extracts prepared from mutants of *E. coli*, and the hydroxymethylpyrimidine kinase (EC 2.7.1.49) was purified 3300-fold.[88] Thiamin phosphate pyrophosphorylase (EC 2.5.1.3) was purified from recombinant *E. coli*,[75] and an enzyme preparation possessing both hydroxyethylthiazole kinase (EC 2.7.1.50) and thiamin phosphate pyrophosphorylase activity (EC 2.5.1.3) was isolated from *S. cerevisiae*.[85] This bifunctional protein is an octamer of 60 kDa subunits and appears to have separate catalytic sites for the two activities. Thiamin phosphate pyrophosphorylase and thiamin phosphate phosphatase from the plant *Arabidopsis thaliana* were separated and partially purified by gel filtra-



Scheme 11. Summary of the final stages of the biosynthesis of thiamin (Vitamin B_1, **6**) and its pyrophosphate ester (cocarboxylase, **8**), including the enzymes and genes (*E. coli* genes unless otherwise indicated) that are implicated in individual steps.

tion.[87] A glycosylated acid phosphatase (EC 3.1.3.2) has been purified approximately tenfold from *S. cerevisiae*[99] and from a transformed strain of *S. pombe*.[101,103] These enzymes were shown to act as thiamin phosphate phosphatases.[100,102] Each deglycosylated enzyme retained acid phosphatase activity and had a molecular mass of 56 kDa by SDS-gel electrophoresis.

5. Genetics of the Biosynthesis of Thiamin

Genetic studies of the pathways to the two subunits of thiamin are at a preliminary stage. Neither genes nor the corresponding gene products have been unambiguously assigned to specific steps in the pathways. By contrast, the genes encoding the coupling enzyme and the kinases involved in the final steps of thiamin pyrophosphate biosynthesis have been identified in *E. coli* and the eukaryotes *S. cerevisiae* and *S. pombe*. The genetic information collected for these organisms is summarized in Table 2.

5.1. Genetics of the Route to the Pyrimidine Unit

Single genes in the pathway to the pyrimidine unit of thiamin have been described in several organisms and characterized to different extents. The *E. coli* gene, *thiC*, was sequenced and shown to complement pyrimidine-requiring mutants.[9] In the eukaryote *S. pombe*, *thi3* mutants required the pyrimidine unit for growth,[102] and the *thi3* gene is allelic to the thiamin-repressible gene *nmt1*, which has been cloned and sequenced.[106] Homologues of *nmt1* have been found in *Aspergillus parasiticus* and *S. cerevisiae*.[105] The amino acid sequences of the three eukaryotic gene products are more than 60% identical, and each contains a cysteine cluster within a predicted membrane-spanning domain. Four genes *tnr1*, *tnr2*, *tnr3*, and *thi1* regulate *thi3*,[129] and the promoter of *nmt1* is regulated by *ntf1*$^+$, a gene identical with *thi1* that encodes a protein homologous to transcriptional factors containing the characteristic Cys_6 zinc finger.[128] For the higher plant *Pisum sativum*, a gene in the pyrimidine pathway, *thiC*, has been mapped to chromosome 3,[130] and an *alt* mutant is normalized by supplying the pyrimidine unit.[131]

In addition to the diversity of pyrimidine pathways described in Section 2, recent genetic studies have indicated that a route to (5-aminoimidazole)ribotide distinct from the purine pathway for nucleic acids permits *S. typhimurium* mutants blocked in (5-aminoimidazole)ribotide formation to grow without the addition of exogenous thiamin.[132] The alternative route is expressed when the bacterium is cultured anaerobically[133a] or aerobically on certain carbon sources.[133b] A gene from this pathway has been cloned and sequenced, and sequence analysis indicates that the gene product contains an NAD/FAD binding pocket.[134] More recently a second gene has been identified and assigned to an alternative pathway for the conversion of (5-aminoimidazolyl)ribotide into the pyrimidine unit.[135]

5.2. Genetics of the Route to the Thiazole Unit

Thiazole genes have been located in a cluster of tightly linked thiamin genes on both the *E. coli*[9] and *S. typhimurium*[136] chromosomes at 90 min. Transcription of the *S. typhimurium* cluster is regulated by thiamin, and the *E. coli* cluster (Table 2) has been cloned and sequenced. The *thiF*, *thiG*, and *thiH* mutants did not respond to 1-deoxy-D-xylulose; these genes are therefore required for synthesis of the thiazole unit from this precursor. The measured molecular masses for the polypeptides expressed from *thiF* and *thiG* were considerably smaller than

those predicted from the DNA sequences.[9] The predicted sequence of the *thiF* polypeptide was homologous with MoeB, the protein thought to be involved in sulfur insertion in the biosynthesis of molybdopterin. The genetic evidence indicates that at least four enzyme-catalyzed steps are required for thiazole biosynthesis in enteric bacteria, but the nature of the individual steps remains to be determined.

Single genes for the thiazole pathway (Table 2) have been identified in several eukaryotes. A thiazole gene in *P. sativum*, *thiA*, has been mapped on chromosome 2,[130] and the sequences of the genes *thi1* (*Zea mays*),[137] *thi2* or *nmt2* (*S. pombe*),[111] and *THI4* or *MOL1* (*S. cerevisiae*)[108] are homologous to that of the *Fusarium* gene *sti35*, which encodes a stress-inducible protein.[138] A putative dinucleotide binding site is present in each deduced amino acid sequence, suggesting that an NAD or FAD enzyme is employed in the thiazole pathway.[137] Expression of *thi2* is repressed by either thiamin or the thiazole unit and controlled by four regulatory genes, *tnr1*, *tnr2*, *tnr3*, and *thi1*,[110, 129] and the allelic *nmt2* gene is coordinately regulated with *nmt1*.[111]

5.3. Genetics of the Coupling Process

The genes encoding the coupling enzyme and the five kinases involved in the final steps of thiamin pyrophosphate biosynthesis are located in four regions of the *E. coli* chromosome (Table 2). The *thiE* gene was initially assigned to the thiazole pathway,[9] but subsequently shown to code for an enzyme that couples the phosphorylated subunits.[75] It has been sequenced[9] and overexpressed in *E. coli* BL21 (DE3).[75] The overexpressed polypeptide catalyzes the coupling of the heterocyclic subunits (**3** and **5**), but a thiazole unit with an attached *p*-hydroxylbenzyl group is not a substrate; the cleavage of this fragment of the tyrosine precursor (Scheme 7) thus occurs prior to the subunit coupling step. An *E. coli* transformant carrying the *thiK* (thiamin kinase) and *thiL* (thiamin monophosphate kinase) genes had elevated levels of thiamin phosphates.[139] Less genetic information is available for other bacteria, but a *B. subtilis* operon containing thiamin genes has been sequenced,[140] and genes that complement *E. coli thi* mutants are located on a megaplasmid in *Rhizobium meliloti*.[141]

Unlike in *E. coli*, where individual genes and enzymes have been characterized for the phosphorylation and subunit coupling steps, the eukaryotic genes *THI6* (*S. cerevisiae*)[115] and *thi4* (*S. pombe*)[102, 107, 116] encode bifunctional enzymes possessing thiazole kinase and thiamin phosphate pyrophosphorylase activities. The molecular mass calculated for the *THI6* gene product matches that measured for the purified enzyme,[85] and regions of the amino acid sequence are homologous to those predicted for the *E. coli thiE* and *thiF* gene products.[115] The *S. pombe* gene *thi4* is repressed by thiamin and, to some extent, by the thiazole unit.[107]

The genes coding for a thiamin-repressible acid phosphatase (EC 3.1.3.2), *PHO3* (*S. cerevisiae*)[101, 119] and *pho4* (*S. pombe*),[101, 103, 122] have been sequenced and show a similarity of only 27%.[103] However, each has a much higher homology with their corresponding phosphate-repressible acid phosphatase genes, *PHO5*[119] and *pho1*.[142] For each yeast, the gene sequences indicate that the phosphate- and thiamin-repressible acid phosphatases have cleavable amino acid signal sequences and identical numbers of potential glycosylation sites.[103, 119]

Gene disruption experiments demonstrated that the thiamin pyrophosphokinase (EC 2.7.6.2) genes *THI80* (*S. cerevisiae*)[123] and *trn3* (*S. pombe*)[116] are essential for growth. Reduced levels of thiamin pyrophosphokinase activity were detected in *thi80*[143] and *trn3*[116] mutants, and the carboxyl-terminal, amino acid sequence of the *trn3* polypeptide is 31% identical[116] with the shorter polypeptide encoded by *THI80*.[123]

Thiamin biosynthesis in yeast is controlled by several regulatory genes. Two positive regulatory genes *THI2*(*PHO6*)[124, 125] and *THI3*[126] in *S. cerevisiae* are required to express both the thiamin-repressible acid phosphatase and the enzymes required for phosphorylation and coupling of the pyrimidine and thiazole units.[125, 126] In *S. pombe*, three negative regulatory genes (*tnr1*, *tnr2*, and *tnr3*) and a positive regulatory gene (*thi1*)[107, 129] control *pho4* and *thi4* together with *thi3* (pyrimidine pathway) and *thi2* (thiazole pathway). The *tnr3* gene product, thiamin pyrophosphokinase, has both a catalytic and a regulatory role.[116] The sequence of the positive regulator *thi1* shows homology with *S. cerevisiae* transcription factors that contain a Cys_6 zinc-finger domain.[127]

In higher plants, the *th-1* mutant of *A. thaliana* is deficient in thiamin phosphate pyrophosphorylase,[87] and the *P. sativum* gene, *thiB*, has been mapped to chromosome 6.[130] Since *thiB* mutants responded only to supplements of intact thiamin, the *thiB* gene product is associated with subunit coupling or a later step of the pathway.

6. Summary and Outlook

Investigations in plants and several species of microorganisms have uncovered biochemically diverse routes for the biosynthesis of thiamin.

Most of the enzymes and genes associated with the phosphorylation and coupling steps (Scheme 11) have been identified. Thiamin pyrophosphate is formed directly from thiamin monophosphate in enteric bacteria and from thiamin in yeast and aerobic bacteria. Phosphorylation of the thiazole unit and coupling of the subunits is catalyzed by a single enzyme in yeast, whereas distinct enzymes for each step are employed in enteric bacteria. At present very little mechanistic information is available for these enzyme-catalyzed reactions.

In yeast and enteric bacteria, different primary precursors for each heterocyclic subunit have been identified by isotopic tracer experiments. Although the exact pyrimidine precursors have not been established in yeast, the evidence strongly supports two distinct pathways: one in yeast and the other in enteric bacteria. Less information is available concerning the identity of the primary precursors of the two subunits in aerobic bacteria and in higher plants.

The pathway to each subunit is likely to proceed through several enzyme-catalyzed steps, but no committed intermediates have yet been identified nor have pathway specific enzymes been detected. Moreover, only a few genes have been located. Be-

cause only minute amounts of thiamin are formed in microorganisms, it is likely that further progress in this area will be obtained only by studying the overexpressed gene products.

In our view, a combination of genetic, enzymological, and chemical (isotopic and synthetic) approaches is needed to establish the intermediates and the mechanistic details of the biosynthetic pathways to the pyrimidine and thiazole units. It is our hope that this review of the current state of knowledge will encourage researchers to employ combinations of these methods to solve the difficult problem of thiamin biosynthesis.

Research grants from the National Institute of General Medical Sciences, U. S. Public Health Service (GM 50778 to I. D. S.) and from the Natural Sciences and Engineering Research Council of Canada (to R. L. W.) are gratefully acknowledged.

Hydroformulation – a prime example of industrial application of developments from university research labs (photo: Ruhrchemie, Oberhausen, Germany).

Organometallic Homogeneous Catalysis—Quo vadis?**

Wolfgang A. Herrmann* and Boy Cornils*

In memory of Sir Geoffroy Wilkinson, a true pioneer of organometallic chemistry and catalysis

Homogeneous catalysis is the success story of organometallic chemistry. Otto Roelen's initial discovery of hydroformylation in 1938 not only entailed large-capacity production plants but was later followed by systematic research into the catalytic chemistry of the ever-growing class of organometallic compounds. Further developments in industrial chemistry towards clean, low-temperature, low-pressure, and economic processes—in feedstock or in the fine chemicals and polymer area—clearly depend on improved catalysts. Molecularly defined, tailor-made structures are the safest prerequisites for chemical selectivity; hence, organometallic compounds with their overwhelming variety of compositions and structures offer the most promising approach. Wilkinson's catalysts $[HRh(CO)\{P(C_6H_5)_3\}_3]$ and $[ClRh\{P(C_6H_5)_3\}_3]$ are outstanding examples. On the other hand, process technology has to be considered also (for example catalyst–product separation and heat-exchange problems). The following review attempts to critically assess the future trends and present demands in the applied area of organometallic catalysis—a "gentle art" that is far from being a mature field.

Keywords: homogeneous catalysis · industrial chemistry · organometallic chemistry · polymers · reagents

The discovery of truly new reactions is likely to be limited to the realm of transition-metal organic chemistry, which will almost certainly provide us with additional "miracle reagents" in the years to come.
Dieter Seebach[62b]

1. Introduction

The impact of homogeneous catalysis on industrial process technology has grown in the past 35 years to the same extent that organometallic chemistry has developed as a science. New knowledge regarding structure and reactivity of organometallic compounds has created new catalytic processes in industry or has reestablished old catalytic features under improved conditions. Important examples include the replacement of cobalt by rhodium in a number of industrially otherwise unfeasible processes (for example methanol carbonylation and hydroformylation), which at that time (1964–1976) caused much scepticism about the recycling of the precious noble metal. Ironically, it is nowadays often the price of a more or less sophisticated ligand that dictates the economics of a new process, whereas the metals themselves (even rhodium, palladium, or platinum) are irrelevant in this respect.

Homogeneous catalysis and organometallic chemistry have stimulated and supported each other since the early days of hydroformylation (1938), olefin polymerization (1953), and acetaldehyde synthesis (1959)—to name just the "battleships" of organometallic catalysis.[1] While it is certainly true that many epochal discoveries came along by serendipity[2] (a typical case is Karl Ziegler's "Metallorganische Mischkatalysatoren")[3] the majority of homogeneous catalytic applications has resulted from patient step-by-step development of industrial laboratory and plant-site research alongside the scientific growth of organometallic chemistry.[4–6] Nevertheless, heterogeneous catalysis strongly dominates the industrial scene, with a good estimate being about 85% of all known catalytic processes (including mineral oil processing).[7]

2. Why Organometallic Catalysis?

The strengths and weaknesses of homogeneous and heterogeneous catalysis are summarized in Table 1. The "two cultures" still have their difficulties with each other, especially in the pro-

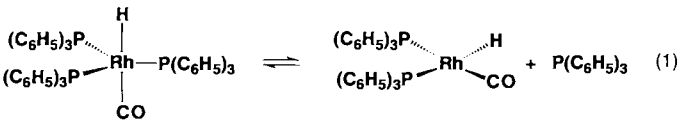
Table 1. Advantages and disadvantages of homogeneous and heterogeneous catalysis.

	Homogeneous catalysis	Heterogeneous catalysis
Activity (relative to metal content)	high	variable
Selectivity	high	variable
Reaction conditions	mild	harsh
Service life of catalyst	variable	long
Sensitivity toward catalyst poisons	low	high
Diffusion problems	none	may be important
Catalyst recycling	expensive	not necessary
Variability of steric and electronic properties of catalysts	possible	not possible
mechanistic understanding	plausible under random conditions	more or less impossible (except for model systems)

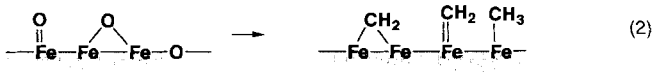
cess engineering scene. The unbeatable advantage of organometallic catalysts is their clear, normally well-defined molecular structure combined with structural variability. Tailor-made catalysts are therefore in principle possible. Disadvantages are difficulties in catalyst–product separation and their low thermal lability (<200 °C) compared to classical, heterogeneous, supported catalysts.

Despite the fact that heterogeneous catalysis has advantages in application (not without good reason do the major mineral oil processing methods use heterogeneous catalysis), homogeneous catalysis presents the far better mechanistic understanding of its microscopic processes ("catalytic cycles") and the possibility of influencing steric and electronic properties of these molecularly defined catalysts. It is often possible to optimize homogeneous catalysts step-by-step for a particular problem. This is undoubtedly the striking advantage over heterogeneous catalysis, which is said to be an alchemist's "black art",[8] even though this statement was vehemently disputed.[9]

The two "philosophies" are exemplified by two prototypal, catalytic processes: hydroformylation [Eq. (1)] and the Fischer–Tropsch reaction [Eq. (2)], which represent catalytic carbon



1 2



3 4

monoxide chemistry. In the first case, the molecular structure of the homogeneous d^8-Rh^I catalyst **1** is precisely known to be trigonal-bipyramidal.[6] The dissociation equilibrium **1** ⇄ **2** is well understood. In contrast, Fischer–Tropsch chemistry requires heterogeneous catalysts of structures similar to **3** and **4**, whose surface structures are not precisely known. As a result, no clear molecular mechanism can be provided.[10]

Organometallic surface science[11] begins to bridge the classical "antipodes". By using well-defined, molecular starting compounds (such as metal alkyls) and allowing them to react in a defined way with surface species (such as ≡SiOH groups), molecularly dispersed but immobile catalysts in a more or less well-defined chemical environment can be produced. An example is the alkylzirconium(IV) surface species **5**, which efficiently hydrogenates olefins [Eq. (3)].[11b] The molecular model

Boy Cornils, born 1938, received his Ph.D. with the organofluorine chemist G. Schiemann in Hannover (Germany). As a research chemist at Ruhrchemie AG in Oberhausen (Germany) he pioneered the industrial application of two-phase hydroformation with water-soluble organometallic catalysts in 1984. At Hoechst AG in Frankfurt (Germany) he was responsible for both research and operative business of organic chemicals. He has authored over 200 original publications and reviews in the field of applied chemistry and holds approximately 80 patents on a broad spectrum of applied organic chemistry and catalysis.

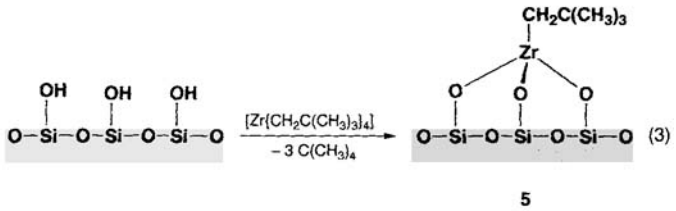
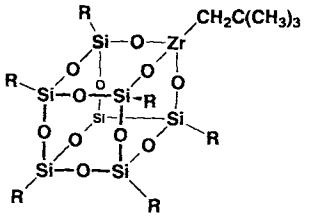
W. A. Herrmann

Wolfgang A. Herrmann, born 1948, received his organometallic academic education with E. O. Fischer (Munich, Germany), H. Brunner (Regensburg, Germany), and P. S. Skell (Pennsylvania, USA) before becoming a professor at Regensburg (1979) and Frankfurt (1982). In 1985 he was appointed the chair professor of inorganic chemistry at the Technische Universität München as the successor to E. O. Fischer. His research focuses on homogenous catalysis with a strong emphasis on synthesis, spectroscopy, and structures. He has authored about 450 scientific publications, 38 patents, and a number of review articles. He holds honorary doctoral degrees and has received numerous scientific awards. In 1996 he became president of the Technische Universität München.



5



6, R = *c*-C_5H_{11}

compound **6**, derived from a "silsesquioxane" (R = neopentyl), is related to it.[11d]

Bearing these facts in mind, it is not surprising that a compromise between heterogeneous and homogeneous catalysts has been attempted by immobilizing homogeneous catalysts. However, most experiments with supported (anchored) catalysts failed due to notorious leaching problems. Heinemann's question: "Homogeneous and heterogeneous catalysis—common frontier or common territory?" remains unanswered.[12]

2.1. Hydroformylation

Table 2 exemplifies to what extent homogeneous catalysts are tailor-made and how variable and adaptable they are. For the hydroformylation process a variety of different solutions in terms of reaction conditions and product separation technologies are available to meet any list of requirements (specifications) of a modern "oxo process". The technology and the homogeneous catalyst may be adapted to a mutual target, whereas with heterogeneous catalysis the choice of the catalyst determines the reaction conditions to a large extent (and usually the technical solution, too).

An early example of the variability of organometallic homogeneous catalysis is the synthesis of vitamin A, which was developed by Pommer et al. at BASF AG in the late 1950s. A plant producing 600 tons per year has been operational since 1971.[13] Although the key synthetic feature is a Wittig-type coupling reaction between vinyl-β-ionone (C_{15}) and γ-formylcrotyl acetate (C_5), there is an early hydroformylation step: 1-vinylethylene diacetate is hydroformylated under high-pressure conditions to yield the branched aldehyde with regioselectivities of up to 80%. This intermediate is then transferred into the α,β-unsaturated derivative that couples with the C_{15}-ylide building block to form the C_{20} vitamin A (Scheme 1).[13] An alternative Hoffmann-La Roche procedure also includes a hydroformylation step.[14] These two processes share most of the vitamin A world capacity of approximately 3000 tons per year.

2.2. Carbonylation of Methanol

Another important, commercially essential example for proving the variability of homogeneous catalysis is the synthesis of acetic acid by carbonylation of methanol. Here too a breakthrough was achieved by employing milder reaction conditions; increased yield and selectivity result from switching from cobalt (in the old BASF process) to rhodium catalysts (Monsanto). This landmark change introduced rhodium to the chemical industry as a catalyst metal. The effect is seen in Figure 1, which compares the required metal concentrations, pressures, and temperatures of the methanol carbonylation as well as the selectivities obtained.

Parallel to this change of catalyst in methanol carbonylation, the feedstock for the manufacture of acetic acid changed at several plant sites from ethylene to methanol (Scheme 2). This development began to reduce steadily the capacities of acetaldehyde that had been made before by ethylene oxidation (Wacker–Hoechst process) and converted to acetic acid. Moreover,

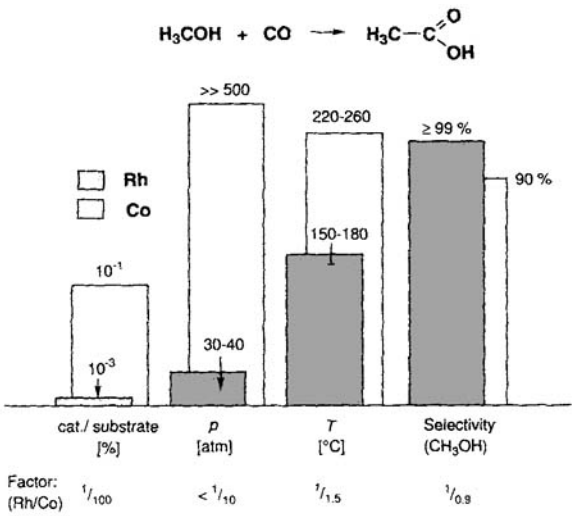

Figure 1. The breakthrough of rhodium over cobalt catalysts in the homogeneous carbonylation of methanol.

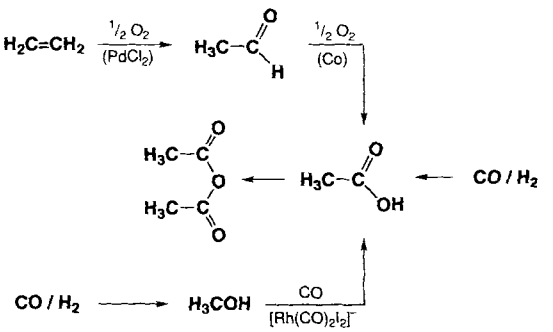

Scheme 2. Survey of feasible catalytic processes for the production of acetic acid.

the second-generation Monsanto process is now being followed by the third generation of highly efficient carbonylation processes, which enables acetic anhydride as well as acetic acid to be produced (Scheme 2, Tennessee–Eastman and BP processes). The most advanced process (Hoechst AG) has not yet been implemented industrially due to neglects of an undecisive management. It should be mentioned that the Tennessee–Eastman technology is geared (although not necessarily) to coal as a raw material and to the synthesis gas made from it by coal gasification (Scheme 2). Most recently, BP announced an iridium-catalyzed process of methanol carbonylation ("Cativa technology") for a number of old and new sites.[15]

2.3. Acrylic Acid

The steady competition between homogeneous and heterogeneous catalysis is seen in the synthesis of acrylic acid. In the early days this chemical was accessible, for example, by addition of HCN to ethylene oxide on heterogeneous catalysts. It was then almost solely made by homogeneously catalyzed carbonylation of acetylene (Ni-catalyzed). Presently, the main process is the heterogeneously catalyzed oxidation of propylene. It remains to be seen whether homogeneous catalysis will experience a renaissance in the sense of alternating "life cycles" (Figure 2): the "Union Oil process" (oxycarbonylation of ethylene with Pd/Cu catalyst systems) may hold promise of reaching the industrial stage.

2.4. Catalyst Separation and Ligand Modification

The history of homogeneous catalysis is also the success story of process technology. This becomes particularly clear with regard to catalyst separation and recycling. Catalyst recycling is free from problems in the case of heterogeneous processes but usually expensive with homogeneous processes. In other words, the catalyst metal in heterogeneous catalyses either remains in the solid bed of the reactor after reaction or can be recovered readily from a catalyst suspension by filtration or centrifugation with subsequent recycling. In the case of homogeneous catalysis it was not until strategies and techniques for catalyst–product separation were successfully developed that catalysis with organometallic complexes "took off". Metal coordination catalysts are predominantly composed of transition metals, particularly precious metals, whose high and often speculatively influenced price (Table 3) makes separation and reuse an urgent necessity.

In addition, ligand modification around the catalytic transition metal is of paramount importance. This is typically demonstrated by the development of hydroformylation (Table 2). The first processes employing $[HCo(CO)_4]$ as catalyst (O. Roelen) were followed by those with ligand-modified cobalt carbonyls (Shell process with alkylphosphanes, 1966 onwards); the latter were succeeded by Union Carbide's LPO process with Rh–triphenylphosphane. The Ruhrchemie–Rhône-Poulenc oxo

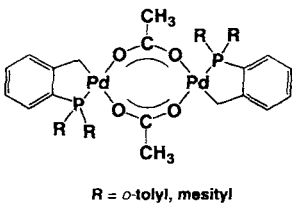
process with rhodium catalysts and water-soluble phosphanes landmarked yet another improvement (Table 2, column 5). All process variants were linked with increased selectivity and yield (LPO vs. the "classical" processes), more specific product distribution (Shell process), milder reaction conditions, facile catalyst–product separation, and simplified process technology (new Ruhrchemie–Rhône-Poulenc process since 1988).

3. Trends and Developments

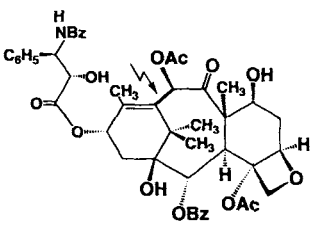
3.1. Mechanistic Knowledge—The Key to Catalyst Design

The declared goal of "going catalytic" with metal-containing reagents will depend on the fundament of mechanistic studies, including thermodynamic considerations. This is not a new insight but should always be kept in mind.[6, 16, 17] Carefully determined conversion–time diagrams, in situ spectroscopic studies, and, if possible, kinetic time laws belong to the fundamentals of catalysis research and are prerequisites for a mechanistic understanding. It is frequently seen that certain discoveries are not taken up quickly enough in an interdisciplinary effort. The versatile Heck reaction, for example, has long remained an organic chemistry domain where it has synthetic benefits; it was only recently that new, efficient catalysts—phosphapalladacycles **7**—were found in the course of accurate mechanistic studies.[18a] The new structural principle also mediates other C–C and N–C coupling reactions.[18b] It is certainly no accident that the latest synthesis of the antitumor reagent paclitaxel **8** ("taxol")



R = *o*-tolyl, mesityl

7



8

depends on an intramolecular, palladium-catalyzed Heck coupling.[18c, d] Palladacycles also catalyze amination and cross-coupling reactions.[19]

Homogeneous catalysis faces a number of obviously trivial but still unresolved problems that depend primarily on mechanistic insight. For example,[20] why do some metal oxides catalyze olefin expoxidation (V_2O_5, MoO_3, CH_3ReO_3), whereas others catalyze olefin hydroxylation (OsO_4)? What are the stereoelectronic prerequisites for this fundamentally different reactivity? If these differences become known, how can a "tunable catalyst" be synthesized?

Unfortunately, only few reliable thermodynamic data of catalytically relevant bonding situations are available; this area of physical organometallic chemistry should therefore receive greater emphasis, and theoretical approaches should be better integrated in mechanistic studies. Quantum chemical calculations—most notably density functionality theory (DFT), which takes care of relativistic effects of the (heavier) metals—should quickly become established in homogeneous catalysis research.[21] Furthermore, molecular modeling (MM) has reached a predictive state, at least for comparison of series of similar catalysts (for example the ligand periphery of a given metal).[22] Spectroscopic techniques begin to support theoretical approaches.[23] There are cases in which older mechanistic schemes or kinetic data are surpassed by new and more detailed proposals due to improved theoretical methodology.[24, 25] It remains to be seen whether this improvement entails a new catalyst and process design or even new techniques.

3.2. Catalyst Performance

An ideal situation is reached when the catalytic intermediates and at least the rate-determining step(s) are established. In addition, only the overall catalyst performance finally decides over industrial feasibility: what is the stability of the catalyst under which process conditions, and how can the catalyst lifetime be improved? From our experience, continuous micro(laboratory) plants are of pivotal importance for prognosticating the performance of a new catalyst. In situ spectroscopy (mainly IR and NMR techniques, for example *para*-hydrogen labeling)[26] are to be applied here for detecting structural features of the catalytic species involved. Chemical model reactions with the (pre)catalyst outside the reactor and in the absence of either one component or the real reaction conditions will always give only part of the truth with regard to the catalytic reaction. Mass- and energy-transport features are worth considering at the beginning of a catalytic project.

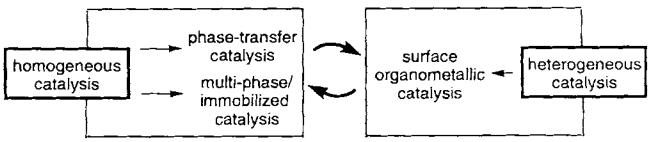
Catalyst performance is a permanent theme in industry. For example, the catalytic activity of oxo catalysts (hydroformylation) has improved in the past 50 years by a factor of 10000 by changing from diadic and triadic process technology to continous plant operation, replacing cobalt by rhodium, tailoring the ligand sphere (phosphanes), and switching the application phase from a monophasic to a biphasic process. At the same time, an improvement of selectivity has been achieved in addition to easy catalyst–product separation. A similar development seems to occur in the Monsanto acetic acid process.[27]

Homogeneous catalysts as typical captive-use catalysts normally imply a high degree of specific, in-house expertise, for which reason not many details are known in the "open" literature. They are often generated in situ, and the knowledge (again secret) is licensed, so, to some extent, any industry-independent catalysis research faces the danger of duplicating known science.

3.3. Immobilization

The strengths of organometallic catalysts—activity, chemo-, regio-, and stereoselectivity—result from a simple concept: specific ligands keep the catalytic metal in a low-nuclearity, normally monoatomic state of molecularly defined stereochemistry. At the same time these metal complexes undergo dissociation equilibria, thus promoting the reactivity of the metal center by making appropriate coordination sites available. Although solubility in common organic solvents is an additional advantage for site availability, it constitutes a severe methodological drawback for catalyst recycling.

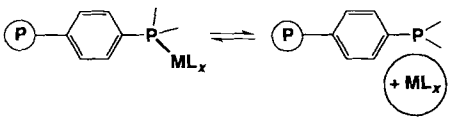
The royal road (Königsweg) to surpassing the problem is liquid–liquid two-phase catalysis. Here, the catalyst retains its beneficial molecularity but nevertheless becomes immobilized (by forming a second liquid phase as a "liquid carrier", Scheme 3). Another approach to facilitate catalyst–product separation



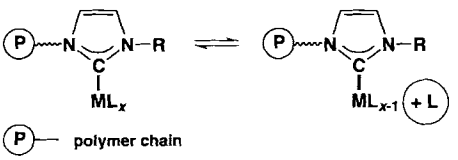
Scheme 3. Phase-transfer and immobilized catalysis at the border between homogeneous and heterogeneous catalysis.

has long been attachment of the catalyst to a polymeric, organic (for example polystyrene) or inorganic (for example polysiloxanes) resin.[28] However, a catalyst of industrial (economic) importance is unknown: catalyst "leaching" remains the central problem. Potent catalysts such as osmium tetraoxide (for stereoselective *cis*-hydroxylation of olefins) will not see an industrial plant before a satisfactory immobilization technique is available to avoid product contamination by the toxic catalyst.

Leaching normally results from the dissociation of the metal from one of the anchored ligands [Eq. (4)], thus liberating the (active) molecular catalyst. Leaching can also originate from structural changes with concomitant weakening of certain bonds during the catalytic cycle, during which the coordination sphere of a metal undergoes continuous changes. For this reason, the specific bonding type between catalyst and support is crucial. The disadvantage of leaching has hitherto only been discussed with regard to the metal centers of catalyst.



(4)

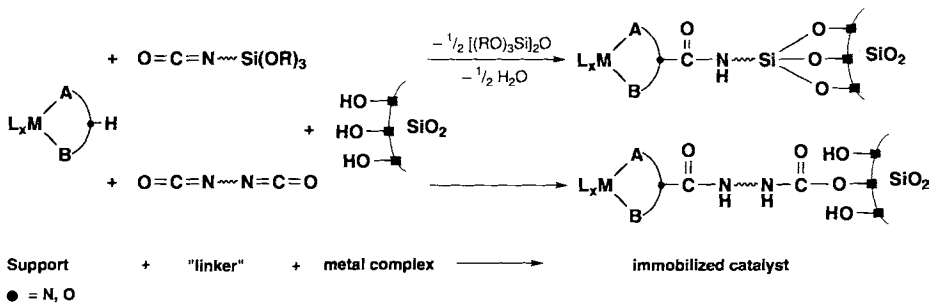


(5)

However, bleeding losses can also occur for expensive ligands, expecially those necessary in stereoselective catalysis. Every possible class of catalysis-supporting ligands should further be considered for immobilization. In this context, *N*-heterocyclic carbenes promise a successful approach to the problem [Eq. (5)]: they effect catalytic C–C-coupling reactions but, unlike phosphanes, do not dissociate from the metal centers.[29] Inorganic backbones are preferred over organic polymers as catalyst carriers because of their much higher thermal and mechanical stability. However, they may participate in metal bonding[11d] and influence the catalytic elementary steps. Diffusion problems related to the polymers surrounding the catalyst must also be considered.

An elegant way to immobilize catalysts is to fixate their ligands through isocyanates onto (acidic) surfaces (Scheme 4). This "modular technique" was recently established by Pugin et al. at CIBA-Geigy AG.[30] Success will depend on the stability of the interlinking amide structures under catalysis conditions and, once again, on the stability of the M–A and M–B metal–ligand bonds.

As far as well-defined anchoring of organometallic catalysts is concerned, the use of zeolites and polyoxometalates as active support materials has been a little-explored field. The landmark discovery of the titanium effect in the ENICHEM TS-1 catalyst shows how dramatically a transition metal in an ordered environment (for example silicalite) can influence catalytic performance.[31] An ostensibly promising concept is surface organometallic chemistry: molecular catalyst precursors are allowed to react with surface groups of (normally inorganic) supports, for example the silanol groups of silica, to attach an organometallic compound specifically at the surface and form quasi-molecular

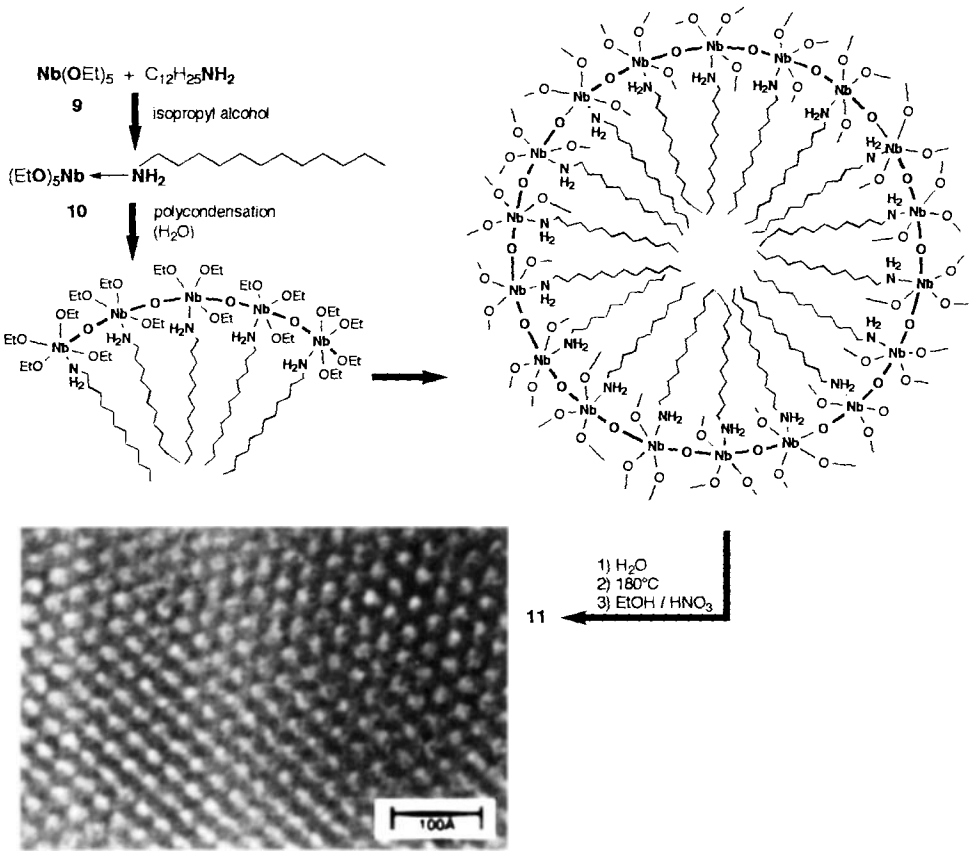


Scheme 4. "Modular technique" of Ciba-Geigy AG for catalyst immobilization [30].

domains.[32] The Zr-catalyzed degradation of CC-polymers (for example polypropylene) to oligomeric fragments and monomers opens wide horizons to this technique.[33]

This area also includes the introduction of additional catalytic sites in zeolites by organometallic precursors. Adjusting the Brønsted–Lewis acidity and directly fixating active transition metal centers inside zeolite cages and channels seem possible, but the size and structures of these precursors will be crucial. The molecular modification is all the more important as many catalytic processes will remain heterogeneous in nature, especially when the shape selectivity of sodalites, zeolites, pentasils, and others is exploited. A striking example is the recent synthesis of the wide-pore zeolite UTD-1 (channel diameter 80 nm) with $[\{\eta^5\text{-}C_5(CH_3)_5\}_2Co]PF_6$ as the structure-directing ingredient.[34]

It has long been overlooked that materials and catalysis research depend on one another, especially when the molecular and bulk concepts of homogeneous and heterogeneous catalysis, respectively, begin to overlap. Here, tailor-made catalytic supports is an ostensibly rich yet little-explored field. Mesoporous metal oxides are of particular charm due to their large, open surfaces, high hydrothermal and thermal stability, and relatively well-defined pore sizes (20–100 Å).[35] Mobil Oil researchers showed in 1992 that porous materials can be made with tensides (lyotropic phases). A typical synthesis is sketched in Scheme 5:[36] the molecular niobium(v) ethoxide precursor



Scheme 5. Synthesis of mesoporous niobium(VI) oxide **11** (specific surface: 434 $m^2 g^{-1}$); picture from ref. [36].

(**9**) is treated with a long-chain $(C_{12})_n$ alkylamine to form the "composite tenside" $(EtO)_5Nb \leftarrow NH_2C_{12}H_{25}$ (**10**) with an inorganic head group. This intermediate adopts a hexagonal arrangement. Water is added to induce hydrolysis and polycondensation. After hydrothermal treatment (100–180 °C) the hole-forming tensides are removed by oxidation with HNO_3/EtOH. The resulting mesoporous niobium(v) oxide **11** can be thought of as a support for organometallic catalysts. This synthesis could similarly be conducted in the presence of a catalyst (for example $[(cod)_2Rh_2(OEt)_2]$, cod = 1,5-cyclooctadiene) since the reaction conditions are rather mild. Therefore, the molecular design of mesoporous metal oxides warrants applications in organometallic catalysis. There are several other advantages in addition to shape-selective catalytic reactions (such as implementation of redox-active metal centers). For example, zeolite-encapsulated rhodium(I) complexes yield a dramatically increased regioselectivity in the hydroformylation of 1-hexene.[37]

"Heterogeneous modifications" of homogeneous catalysts comprise the supramolecular concepts of sol-gel entrapment,[38] templates[38,40] and host–guest interactions,[39,42–44] as well as the "ship-in-the-bottle" principle in zeolite catalysis.[45] New handbooks[46a] and monographs[46b] in this area are available.

In view of the growing industrial success, it is sufficient to say that two-phase catalysis (liquid–liquid) has not yet reached its culmination point. Novel (water-soluble) ligands pose a challenge to the synthetic chemist.[47] New reaction media will be required, too, but it is questionable whether the recently announced perfluorinated hydrocarbons indicate a certain breakthrough in this direction,[48] not least because of toxicity reasons. These studies have shown, however, that temperature-dependent miscibility of different reactants and solvents can be exploited as a simple means of verifying the "single-phase catalysis/two-phase separation" concept without additional solubilizers.

3.4. Colloidal Organometallic Catalysts

Metal colloids—links between homogeneous and heterogeneous catalysts[49,50]—represent an underestimated group of catalysts, in spite of the fact that their prestage organometallic clusters enjoyed strong scientific interest.[51] Although oligo- and multinuclear metal aggregates are subject to degradation (denucleation) under a number of catalytic conditions (for example high-pressure carbonylation) or undergo conglomeration to yield the bulk metal (by temperature effects and depletion of stabilizing ligands), there is convincing evidence that colloidal systems are engaged even in catalysis that is normally considered "homogeneous".[49,52] A good example is the long-known hydrosilylation, for which low-valent, colloidal platinum seems to work best.[52c] Little is known as to how conventional ligands and other ingredients stabilize metal colloids in a given "homogeneous" process. Such knowledge would set the scene for the directed application of ligands for colloidal metal ensembles. Both the theory of colloids (formation, nucleation kinetics, structure, stability) and their catalytic performance must clearly form a center of gravity in future research.

Recently Bönnemann et al. generated nanometal colloids from metal halides by reduction with (surfactant) hydridoboranates (for example $[N(octyl)_4][HB(C_2H_5)_3]$).[52a,b] Applied on supports, the resulting catalysts show much higher activity than the presently used (heterogeneous) catalysts. According to Baiker et al. chiral chinconidin-stabilized platinum colloids

effect the hydrogenation of ketones to alcohols with conversions of 50–100% and 69–85% *ee*, depending on particle size.[52d, e] Chiral protective shells may induce stereoselective reactions at metal colloid catalysts and, at the same time, act as inhibitors of catalyst poisoning.

3.5. Multicomponent and Multifunctional Catalysis

Bimetallic multicomponent and multifunctional catalysis is a common feature in heterogeneous catalytic processes.[53, 54] There is hardly a reaction that just employs a "pure metal" catalyst. Usually, doping additives exhibit electronic or steric effects (for example Ag–Re/Cs in the Shell oxirane process, a heterogeneous catalysis), and, for many conversions, intermetallic phases have been developed. It would once again be attractive to implement this concept on the molecular level into homogeneous catalysis. To become catalytic, numerous reactions require activation of at least two substrates by different metals. On the other hand, a single-site (molecular) catalysis could take advantage of a second, nearby metal (for example, as an electronic reservoir) to be activated again. This is not an easy synthetic problem, since the coordination chemistry of the metals to be coupled is normally very different from each other (for example Pd–Cu in the Wacker–Hoechst oxidation). Furthermore, molecular sites of Lewis and Brønsted acidity—like those so crucial for surface-type catalysts (SiOH, Al^{3+})—could be combined with a catalytic metal site. This implies high-risk research from both the synthetic and the catalytic–mechanistic side but is of great methodological importance to future "refinement" of homogeneous catalysts. The current literature does not clearly enough discriminate multicomponent from multifunctional catalyst systems: multicomponent catalysts contain two or several metals that enforce the catalytic effect upon a given reaction by a "cooperative effect". Examples are known, among others, for hydroformylation.[55] Multifunctional catalysts effect different reactions (for example simultaneous or subsequent oligomerization combined with hydroformylation).

3.6. Catalysis under Supercritical Conditions

No emphasis has so far been given to homogeneous catalysis in supercritical fluids, albeit the technique is now well-established in the extraction technology (for example for coffee, tea, hops, and natural flavors). As part of homogeneous catalyst processes,[56, 57] supercritical conditions can dramatically change the solubility profile of solvents and the reactivity of certain chemicals. For example, the rhodium-catalyzed hydrogenation of CO_2 (in the presence of amines) to formic acid is greatly facilitated under supercritical conditions,[58] which are easily achieved for CO_2 (31 °C, 74 atm). Hydrocarbon activation (for example propane) could also show progress under supercritical conditions. Although the behavior of supercritical fluids is generally hard to predict, the effects normally happen at once when the critical parameters are reached. This is a typical field in which molecular chemists have to collaborate with chemical engineers and physicochemists.

3.7. Catalyst Reactivation: Process and Reactor Technology

Only a small minority of organometallic reactions has overcome the hurdle to becoming catalytic reality in industry. Catalyst reactivation under process conditions is a relatively rare case. The famous Wacker–Hoechst ethylene oxidation became an industrial process only because the problem of palladium reactivation ($Pd^0 \rightarrow Pd^{II}$) could be solved. Academic research has paid relatively little attention to this pivotal aspect of catalysis. However, a number of useful, metal-mediated reactions result in thermodynamically stable bonding situations that are difficult to reactivate. Examples from the early transition metals[59] are the McMurry reaction (Ti), for the extrusion of oxygen from ketones to form C–C-coupled products and stable metal oxides, and the Kagan coupling reaction (Sm). Only coreactants of similar oxophilicity (and price!) suffice to establish catalytic cycles. In difficult cases, electrochemical procedures should receive more attention, because expensive chemicals could thus be avoided. Without going into details here, it is the basic, often inorganic chemistry of a catalytic metal and its redox and coordination chemistry that warrant detailed study for catalytic applicability.

At present several pilot-plant processes are of specific potential: vinylacetate from synthesis gas, precursors of polymers-like polycarbonate and polyurethanes by reductive or oxidative carbonylation, methylmethacrylates and adipic acid by alternative routes, and polypropylene and cycloolefin copolymers (COC's) using metallocenes. New ways have been opened in all these cases. The last-named example emphasizes in a nearly classical way the principle of tailor making novel, optimized homogenoeus catalysts. However, it took ten years of worldwide competitive research until the first products from metallocene catalysts appeared on the market (Section 4.5).

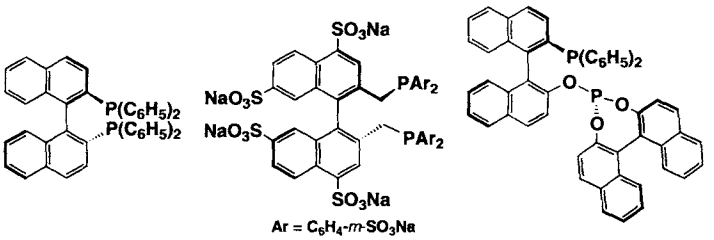
4. New Applications

4.1. Stereoselective Catalysis

Homogeneous catalysis of tomorrow will have its greatest strength in stereoselective synthesis. For 1994 total sales for the world chiral-drug market were estimated to be 45.2 billion US dollars, which corresponds to an increase of 27% in a single year! An annual growth of about 9% has been predicted for the near future (only including drugs that have already been approved by drug authorities worldwide).[60] The leading anti-inflammatory drug (*S*)-(+)-ibuprofene alone is expected to have a sales potential of one billion US dollars per year as an over-the-counter drug. It is remarkable that only 11% of chiral pharmaceuticals introduced before 1983 were produced in the single stereoisomeric form; this fraction increased to 26% for synthetic drugs introduced from 1983–1987, and there are conservative estimates that at the end of this century 80% of all chiral pharmaceuticals will be produced optically pure.[61] The same development is occurring in the agrochemical sector.[129]

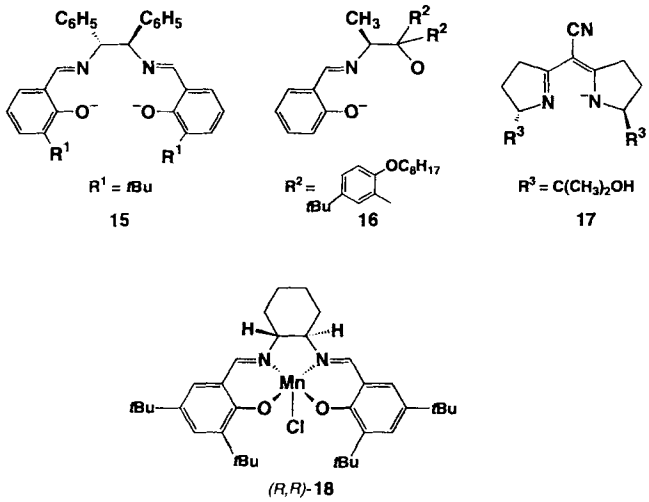
These data alone imply an enormous challenge to stereoselective synthesis. At the same time, organic synthesis of tomorrow will be governed by the "chiral selection principle".[62] Optically stable ligands (beyond phosphanes) will continue to be targets

for the synthetic organic and organometallic chemist.[63] Once again, immobilized and surface-anchored catalysts are at high demand, not only for toxicity reasons. Chiral modification of (metal) surfaces seems to effect stereoselectivity[64] and is again an area of hitherto little emphasis. It looks as if bidentate ligands of axial chirality (atropisomers) will dominate future development, at least in the area of the ubiquitous organophosphanes. The prototypal BINAP (**12**)[65a] is being succeeded by a number of related systems, of which enantiopure BINAS (**13**)[65b] and BINAPHOS (**14**)[65c-f] are successful in enantioselective hydroformylation.



(–)-BINAP **12** (–)-BINAS **13** (*R,S*)-BINAPHOS **14**

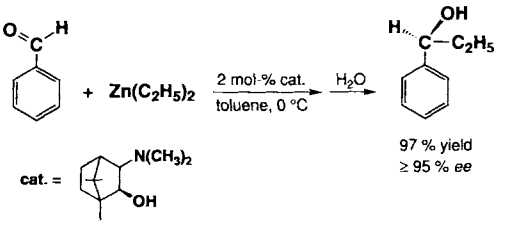
The synthesis of (chiral) N/O-oligodentate ligands such as **15**–**17** also merits future attention. Ingenious ideas are required because these ligands become more and more sophisticated.[66] Logically, N and O ligands are more resistant to oxidation than phosphanes; this is one of the reasons why tetradentate salicylaldimine derivatives like **18** prove so successful in stereoselective epoxidation.[67, 68] High optical inductions are also seen for Cu^{II}- or Co^{II}-attached semicorrine and Schiff-base ligands in olefin cyclopropanation reactions with diazoalkanes.[69] This work has opened new access to insecticides (permethrine) and drugs (Cilastatin, Sumitomo). Rigid ligands in an equatorial arrangement around the metal are particularly efficient in chirality transfer.



15 **16** **17**

(*R,R*)-**18**

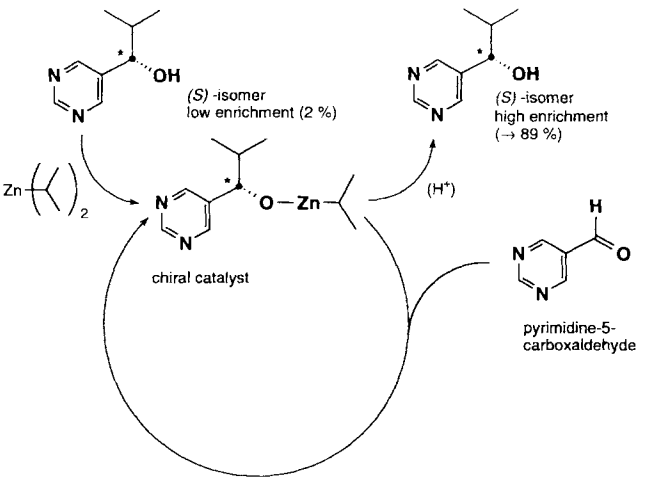
Ligands from the "chiral pool" have previously been underrepresented in both coordination chemistry and stereoselective catalysis (for example sugars, cyclodextrines, and amino and nucleic acids). Furthermore, only little is known about organometallic chemistry in biological systems such as cells.[70] Of particular charm is the phenomenon of "chirality amplification", in which a chiral ligand of low optical purity yields products of high enantioselectivity. For example, an alcohol forms with 95% *ee* from the achiral substrates benzaldehyde and diethylzinc when some [(–)-3-exo(dimethylamino)borneol] ((–)-DAIB) of only 15% optical purity is present [Eq. (6)].[69a, b]



(6)

This is a case where chiral and achiral metal complexes compete with each other (>600/1 by rate). Asymmetric autocatalysis is certainly an attractive yet largely unexplored field.[71] Two-phase processes for stereoselective syntheses are under investigation,[72] and phase-transfer catalysis is to be mentioned in this context.

A recent, convincing case of chiral amplification opens a wide horizon to stereoselective catalysis:[69c] when a 5-pyrimidyl alcohol with a small (2%) enantiomeric excess is treated with diisopropylzinc and pyrimide-5-carboxaldehyde, it undergoes an autocatalytic reaction to generate more alcohol. The chiral catalyst is formed from the initial alcohol. The *ee* of the (*S*)-isomer was successively increased in the series 2 → 10 → 57 → 81 → 89%. Amplification factors of up to about 1700 were recorded with the catalytic system shown in Scheme 6.[69c] This is the first case in which the enantiomeric excess of the product is greater than that of the chiral catalyst.[73]



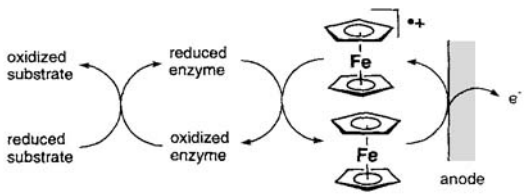
Scheme 6. Chiral amplification in the reduction of a pyrimidine-5-carbaldehyde with diisopropyl zinc to yield a chiral 5-pyrimidyl alcohol [69c].

4.2. Organometallic Electrocatalysis

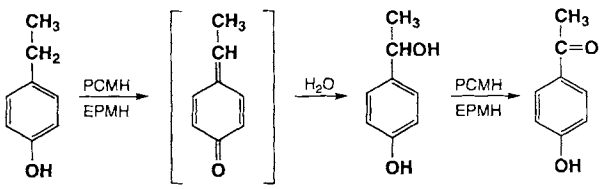
For a long time electrocatalysis was not a topic in organometallic chemistry albeit numerous known processes depend on redox reactions (for example Wacker-type catalysis, oxidative olefin carbonylation, and metal activation of carbon dioxide). However, a number of catalytic problems will resist being solved unless an electrochemical step is included.[74] To this end, the knowledge of electron-transfer and radical processes has to be

improved.[75] In numerous metal-mediated reactions, workup and reactivation of the used metal (compound) appears possible only by means of the electric current—what is not neccesarily the worst solution. Radical-type catalysis should be given emphasis; two areas are the activation of halohydrocarbons[76] and the gas-phase metal chemistry of hydrocarbons in general. Sophisticated mass spectroscopic methodology can be exploited to learn more about the elementary steps of organometallic catalysis.[77]

Electroenzymatic processes in enzyme membrane reactors may be considered as bridges towards biocatalytic reaction systems; the ferricinium cation acts as a clean, one-electron oxidant (Scheme 7). For example, 4-ethylphenol can be oxidized to 4-hydroxyacetophenone by the redox catalyst ferrocene (Scheme 8).[78]



Scheme 7. The ferricinium cation as a clean, one-electron oxidant in electroenzymatic processes.



Scheme 8. Ferrocene as a redox catalyst for enzymatic oxidation of 4-ethylphenol to 4-hydroxyacetophenone [78]. PCMH = paraquinone monooxygenase, EPMH = ethylphenol monooxygenase.

Enzyme-analogous biocatalytic and antibody processes are under intense investigation and are common territory of modern chemistry and biology.[41, 79] Comprehensive reviews are now available on this topic.[80]

4.3. New Chemical Feedstocks for Homogeneous Catalysis

To a large extent organometallic catalysis has been based on feedstock chemicals such as alkynes, alkenes and dienes, carbon monoxide, and hydrogen. The meanwhile classical mechanistic principles—σ or π complexation, oxidative addition, insertion/migration, and reductive elimination—sufficiently explain the majority of reactions making up catalytic cycles. Unfortunately, only reluctant reactivity has been seen for alternative, particularly cheap feedstock chemicals. Methane, ethane, propane, and carbon dioxide are specifically mentioned because of their general availability. C_{1-3} building blocks suffer since their known metal chemistry is not really catalytic as yet.[81–83] Nevertheless, possible advantages are clear:

- Methane is an abundant natural resource chemical and could partially substitute both olefins (refinery ethylene and propylene) and carbon monoxide.
- Propane is the most prominent refinery gas (av 60%), followed by butane (about 30%); therefore its functionalization is a topic in heterogeneous catalysis research.
- Carbon dioxide could at least be used in the synthesis of carboxylic compounds and certain heterocycles and may even partially substitute the more expensive carbon monoxide (for example, for the synthesis of formic acid). However, for reductive processes a CO_2-based feedstock is expected to be more expensive since an extra equivalent of a reductant (for example H_2) is required to carry off the oxygen.

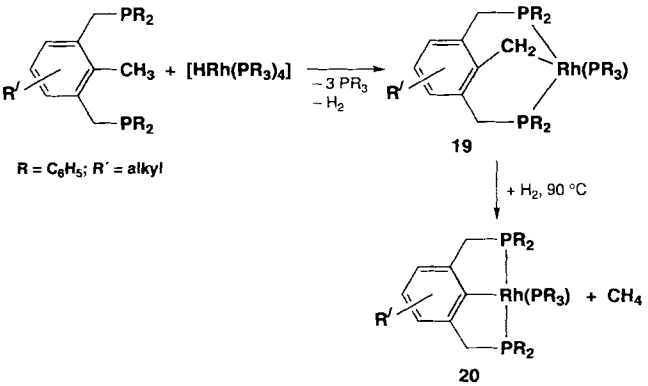
Selective and catalytic C–C and C–H bond cleavage of (unreactive, saturated) hydrocarbons such as ethane and methane is still considered the "holy grail" of catalytic chemistry. Catalytic activation of such molecules under mild (for example non-photolytic) conditions would revolutionize catalysis. This capability would contrast the classical, high-temperature reforming processes of the petrochemical industry, which constitute the largest-scale industrial catalyses. Although no solution to the problem is available as yet, a number of recent approaches regarding C–H, C–C, and C–F bonds are promising.[84–86]

4.3.1. Carbon–Hydrogen Bonds

Methane undergoes an oxidative addition reaction with the iridium complex $[(\eta^5\text{-}C_5Me_5)IrH(PMe_3)]\cdot CH_2Cl_2$ at +10 °C to give $[(\eta^5\text{-}C_5Me_5)Ir(H)_2(PMe_3)CH_3]$.[84a] This reaction matches the earlier finding that the easily dissociated carbonyl complex $[(\eta^5\text{-}C_5H_5)Ir(CO)_2]$ affords the hydrido–methyl derivative $[(\eta^5\text{-}C_5H_5)Ir(CO)H(CH_3)]$ under photochemical conditions.[84c] The reader is further reminded of Watson's elegant work on $^{13}CH_3\text{–}^{12}CH_3$ exchange in the "metal acidic" lutetium(III) complex $[(\eta^5\text{-}C_5Me_5)_2Lu(CH_3)]$ with methane.[84b]

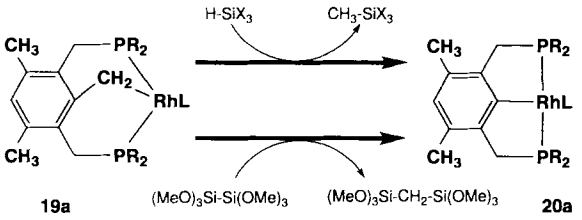
4.3.2. Carbon–Carbon Bonds

Milstein et al. demonstrated that a methyl group is C–H activated before it eliminates as methane by hydrogenolysis from the intermediate **19** (Scheme 9).[84c] The prior C–H bond activation occurs readily and is, as expected, much more rapid than the subsequent C–C cleavage. Formation of the new rhodium–phenyl bond in **20** and the special, chelating P,C,P-coordination are the driving forces. Nevertheless, cleavage of the relatively unreactive bond between sp^2- and sp^3-hybridized carbon atoms was achieved by the detour of C–H activation. More difficult is the cleavage of purely aliphatic C–C bonds, because their sp^3 orbitals (directed along the bond axis) are inaccessible to metals and therefore much less reactive.



Scheme 9. C–H activation with a hydridorhodium(I) phosphane complex [84c].

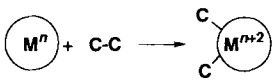
An interesting alternative is the transfer of a C–H-activated methyl group (after consecutive C–C bond cleavage) as a methylene unit to other substrates. For example, an insertion reaction with the strained rhodacycle **19a** yields **20a**, at least in a stoichiometric way [Eq. (7)].[84d, e]



19a **20a** (7)

L = $P(C_6H_5)_3$
R = C_6H_5
X = C_2H_5O, C_6H_5

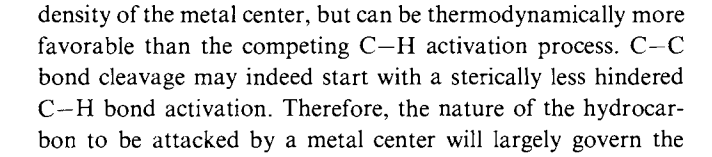
Cleavage of strong C–C bonds by transition metal insertion under mild conditions depends thermodynamically on an auxiliary chemical reaction coupled to the cleavage process (for example hydrogenation). Milstein's work shows that an oxidative addition process [Eq. (8)] is highly dependent on the electron



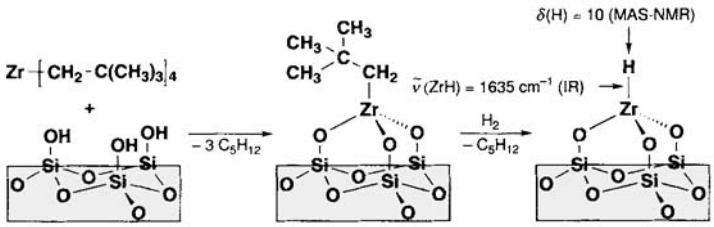
(8)

density of the metal center, but can be thermodynamically more favorable than the competing C–H activation process. C–C bond cleavage may indeed start with a sterically less hindered C–H bond activation. Therefore, the nature of the hydrocarbon to be attacked by a metal center will largely govern the chemistry.

A challenging example of a paraffinic C–C bond metathesis is the recently discovered conversion of ethane into methane and propane under mild conditions using a surface-attached but molecularly defined, electron-deficient catalyst. This unprecedented hydrocarbon "dismutation" once again starts with C–H bond activation and involves conventional alkyl–metal intermediates [Eq. (9)].[84i] This result compares with the hydridozirconium-catalyzed hydrogenolysis of simple alkanes at 25 °C on the same type of catalyst, which is generated from tetrakis(neopentyl)zirconium and partially dehydroxylated silica (Degussa Aerosil, Scheme 10). The final products are methane and



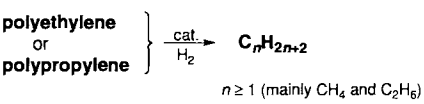
(9)



Scheme 10. Synthesis of a surface-anchored hydridozirconium species [84i].

ethane, which are not cleaved by the catalyst under a hydrogen atmosphere.[84b]

This principle can be applied to the exhaustive degradation of polyethylene and polypropylene to low molecular-weight oligomers, ethane, and methane when the zirconium catalyst in Scheme 10 is administered [Eq. (10)].[33, 84j] It will be interesting

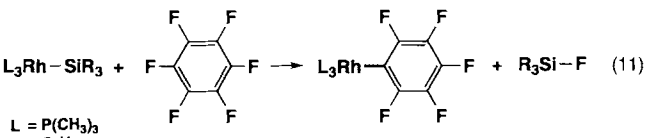


(10)

to see how polymer wastes containing chlorinated polymers (for example PVC) behave against this highly electron-deficient catalyst. In any case, Basset's results are the only "puristic" catalytic cleavages of saturated hydrocarbons so far. The catalytic degradation of polymers as a possible new feedstock basis of organic chemicals seems worthy of increased efforts [33, 84i–l]. Also the low activities of higher olefins (for example "raffinate-2") in the hydroformylation process must be a near-future goal.

4.3.3 Carbon—Fluorine Bonds

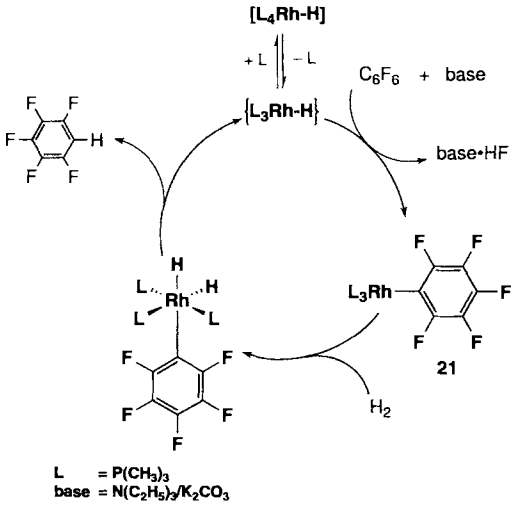
A challenge remains for the metal-induced cleavage of the strongest bond that carbon can form, the C–F bond.[84f] The functionalization of polyfluorinated organic compounds—important building blocks of chemical, pharmaceutical, and advanced materials industry—would promise a diverse market for such a process. The first success in this area is based on the stoichiometric reaction shown in Equation (11), the thermodynamics of which clearly rely on the strength of the silicon–fluorine bond. The perfluorophenyl–rhodium bond in **21** also favors this kind of C–F bond activation.[84g]



L = $P(CH_3)_3$
R = C_6H_5

21 (11)

The related rhodium—phosphane complex allows catalytic hydrogenolysis of hexafluorobenzene: when this fluorocarbon is used as a solvent, it eliminates fluorine upon heating with the catalyst $(PMe_3)_4RhH$ in the presence of a base (such as NEt_3 or NEt_3/K_2CO_3) and hydrogen; the released hydrogen fluoride is captured by the base. The proposed catalytic cycle for the hydrogenolysis involves cleavage of C–F bonds, which is induced by electron-rich hydridorhodium(I)–phosphane complexes (Scheme 11). This implies that other complexes that can serve as a good source of such species are also likely to be active. The synthetic potential of carbon—fluorine activation is enormous, provided that efficient catalysts can be found. So far turnover numbers (TON) of up to only 114 have been recorded.[84h] Although heterogeneously catalyzed hydrogenolysis of carbon—fluorine bonds is known, it requires very high temperatures and is nonselective, once again showing the future potential of homogeneous organometallic catalysis.



Scheme 11. C–F bond cleavage with hydridorhodium(I) phosphane complexes [84g].

4.4. New Reactions and Improved Catalysts

Almost every new synthetic procedure in organic chemistry proceeds through a metal-mediated step. However, many of these reagents suffer are only stoichiometric, and a "true catalysis chemist" would not include them in his area of research. One typical example is the cobalt-mediated Pauson–Khand reaction, which provides cyclopentenones as useful synthetic building blocks from cheap precursors. Metals that were previously unheard of in organic synthesis now effect synthetic steps in good yields and perfect selectivities: for example, Nb^{III} N–C couples aldehydes with imines or alkynes,[87] and SmI_2 is a selective one-electron reductant that C–C couples keto compounds.[88, 89] It is a challenge to surround these metals with ligand spheres that really make their individual reactions catalytic (that is, much less than 1 mol% catalyst). The titanium-mediated McMurry reaction for synthesizing olefins from keto compounds needs further improvement in terms of catalytic applications.[90] Divalent chromium catalysts have been used for C–C coupling (Nozaki–Hiyama–Kishi reaction) by Fürstner et al.[91]

Great potential is seen in the relatively little-explored organic chemistry of the rare-earth metals, for which a tuning of reactivity seems best possible because of the gradual change of properties ("lanthanide contraction").[59] Normally, tuning in organometallic catalysis is acheived through the ligands; in the lanthanoid series the metal properties (size, Lewis acidity) come to the fore. Immobilized catalysts that are soluble in superacids may have a future in lanthanoid chemistry, including their "smaller brothers" scandium and yttrium. Lanthanide-catalyzed Tishchenko reactions of mono- and dialdehydes were recently reported.[92] Toxicity and price reasons must push all these marvellous reagents towards their catalytic applicability and then, one step further, to their perfect separation from the product(s). "Miracle reagents" (Seebach) must become "miracle catalysts" to successfully enter the industrial scene. As a result, any newly discovered reagent should have a proper ligand outfit to (re)enter a catalytic cycle. Tremendous efforts in the coordination and organometallic chemistry of these ligands, in terms of synthesis and structure, are to be made.

Oxygen, water, and ammonia are highly preferred reagents of applied homogeneous catalysis because they are cheap. Oxidative processes make up the majority of all homogeneous catalytic processes, if metal-mediated gas-phase oxidations (for example terephthalic acid) are included.[93] A specific chance of homogeneous catalysis can be seen in the known fact that oxidation processes are limited in their selectivities (about 85%) when they operate on the basis of heterogeneous catalysts. Nevertheless, selective activation of elemental oxygen is difficult to achieve, and, in a number of cases, coupled processes (like the combination of a secondary alcohol and oxygen) are required.[94] Ironically, the Wacker-type reactions—prototypes of organometallic oxidations—exploit the catalyst metal to oxidize the ethylene, whereas oxygen reactivates the palladium center ($Pd^0 \rightarrow Pd^{2+}$). Not a single oxygen reaction with organometallics as activators is close to any application. Here is an ostensibly rich field for high-oxidation state organometallic chemistry.[20]

Hydrogen peroxide is a more reactive substitute for oxygen and has a broad and relatively well-investigated metal coordination chemistry.[94a] While it normally does not meet the tight economic requirements for the oxidative production of industrial bulk chemicals, the priority list oxygen, hydrogen peroxide, *tert*-butyl peroxide, and other oxidants (in falling order) is generally accepted.[93] For environmental reasons stoichiometric oxidants like "chromic acid" will soon be fully outdated from technical-scale applications, even if higher-price chemicals like vitamin K_3 and others are considered.[93] Catalytic syntheses are often the only reasonable alternative. Methyltrioxorhenium(VII) is an effective catalyst for a number of oxidations, particularly by hydrogen peroxide.[20, 95] It is questionable, even for stereoselective oxidations, whether oxidants yielding appreciable amounts of salt (for example NaOCl) will access and survive large-scale applications. It is therefore of forcing demand that the old topic of oxygen activation enters the high-priority list of future research in both coordination and organometallic chemistry and catalysis. The apparently primitive question of oxygen transfer from peroxometal intermediates to olefins is not undisputed in terms of the mechanism.

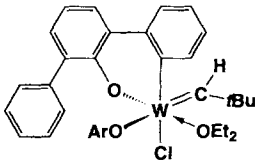
Water is an ideal, environmentally sound reagent with exciting prospects, but numerous questions are still open. Is the addition of water to olefins in the *anti*-Markownikoff mode possible? Primary alcohols would thus be available cheaply [Eq. (12)]. What is the appropriate catalyst for adding ammonia across a double bond [Eq. (13), see also hydroamination[96a]] to

$$R\text{-}CH{=}CH_2 + H_2O \xrightarrow{cat.} R\text{-}CH_2\text{-}CH_2OH \quad (12)$$

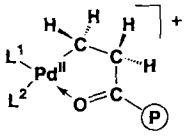
$$R\text{-}CH{=}CH_2 + NH_3 \xrightarrow{cat.} R\text{-}CH_2\text{-}CH_2NH_2 \quad (13)$$

yield organic amines as starting materials for a number of fine chemicals? Driessen-Hölscher et al. used the concept of biphasic catalysis [Pd^{II}–TPPTS; TPPTS = $P(C_6H_4\text{-}m\text{-}SO_3Na)_3$] for hydroamination to achieve improved selectivities.[96b]

On the other hand, several well-established reactions are missing certain speciality applications. For example, what would be an efficient catalyst for the hydroformylation of (per)fluoroalkenes, the products of which are of broad use as pharmaceuticals?[97] Based upon a recent development employing the special tungsten–carbene catalysts **22** for the metathesis of C–C-



22, Ar = 



23, (P) = polymer chain

unsaturated thioethers that poison any previously known catalyst, how can functionalized olefins enter industrial applications?[98] Is the directive ethylene–carbon monoxide coupling of E. Drent et al. [Eq. (14)][99a-c] and the structural principle of

$$R\text{-}Y + CO + 2\,H_2 \longrightarrow R\text{-}CH_2\text{-}Y + H_2O \qquad (14)$$

Y = OH, CO_2H

the intermediate **23** of general use (for example, to obtain functionalized olefins such as fluoroolefins or to use isonitriles in place of carbon monoxide)? What are the structural prerequisites for multiple carbonylation reactions?

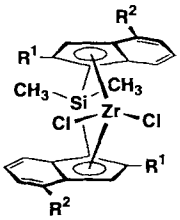
The attractive homologation reaction, a formal methylene insertion, has received little attention as yet.[100] This synthetic principle looks promising for homologous compounds, of which only one certain derivative is easily available. Novel C–C coupling reactions are about to enter metal complex catalysis, for example asymmetric aldolizations (Mukaiyama),[101,102] Diels–Alder reactions,[103] and indium- or zinc-mediated alkylations.[104]

The motif of molecular recognition should gain increased attention in catalyst design. For example, specific structural interactions of higher olefins (such as 1-decene) with chemically modified β-cyclodextrins allow efficient hydroformylation in a two-phase aqueous system, even though the olefin is completely insoluble in water. At the same time, olefin isomerization at the rhodium catalyst is suppressed.[103]

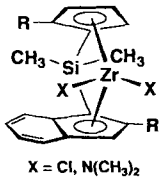
4.5. Organometallic Catalysts for Polymers: "Advanced Plastics"

Organometallic catalysts have actively accompanied many progresses in macromolecular chemistry in the past decades. Examples are the olefin metathesis (CdF Norsorex, Hüls Vestenamer, Hercules DCP), special ring-opening metathesis, and CO–C_2H_4 copolymerizations. Two-phase catalysis has also been employed.[105]

Recently, new C–C-coupling products such as COC materials (cycloolefin copolymers) with special properties including high transparency and hardness became available through structurally and precisely tailored organometallic catalysts. Novel polyketones with their high melting points (>220 °C) have already been mentioned.[99] Ziegler–Natta catalysis long remained the only organometallic catalysis in macromolecular chemistry. The area was revolutionized by the discovery that zirconocene derivatives **24**—with stereorigid, C_2-symmetrical structures—catalyze the strictly isotactic polymerization of propene.[106] It was an interdisciplinary effort that wrote this success story: Sinn and Kaminsky observed the methylalumoxane effect,[107] Brintzinger et al. designed and made the chiral zirconocene complexes,[108] and Kaminsky discovered the polymerization characteristics related to these structures.[108,109] At the same time, a strong industrial interest has pushed ahead worldwide development in numerous laboratories since 1984. New perspectives came along with new structures of type **25**–**27**, which originated from a chemistry that was neither popular nor

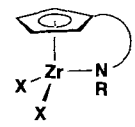


24



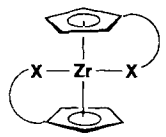
X = Cl, $N(CH_3)_2$

25



X = $N(CH_3)_2$

26

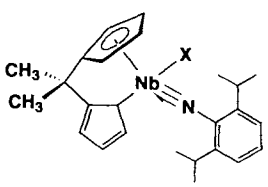


M = Ti, Zr, Hf
X = O, NR

27

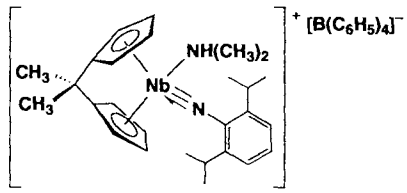
attractive before. At present special copolymers are the first-priority goals in this area of catalysis. The first polymers based on metallocene-type catalysts have just now appeared on the market: Hostacen (Hoechst AG), Exact (Exxon), and Affinity (Dow). Even sophisticated metallocenes can now be made in 10–40 kg batches.

In spite of all the recent success in the metallocene area, the purely synthetic part of the game has narrowed down to zirconium and hafnium. Little is known on *ansa*-metallocenes of related metals such as niobium and tantalum, and a loss of "synthetic culture" is seen. The imido complex **28**, its solvated cation **29**, and the rare-earth *ansa*-indenyl amides **30** are among the few examples.[110] *ansa*-Lanthanoidocenes such as the novel lanthanum complex **30** are now easily available by the amide route.[110c,f] This synthetic approach normally suppresses the otherwise dominating redox chemistry. Moreover salen-type complexes of lanthanoides are also available now.[110f]

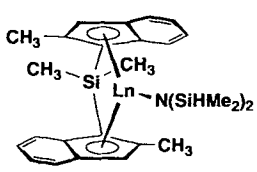


X = Cl, $N(CH_3)_2$

28



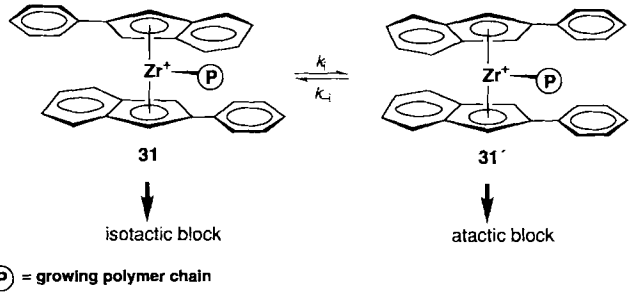
29



Ln = Y, La

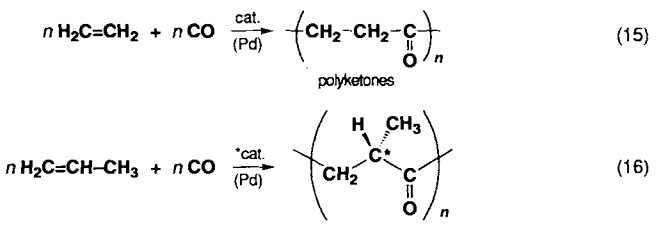
30

Of particular "intelligence" are Waymouth's unbridged zirconocenes **31**, which are "switchable" from isotactic to atactic block polymerization due to their specific conformations **31** and **31′**. Oscillation between chiral and achiral coordination ge-



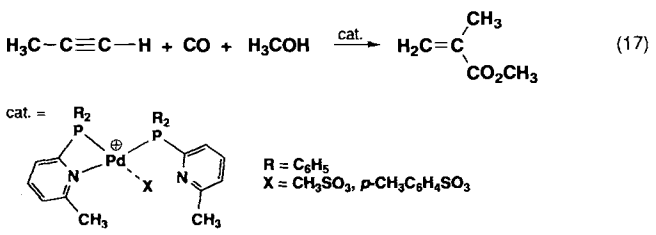
ometries is the molecular basis for making novel thermoplastic elastomeric polypropylene; the isotacticity depends on the temperature and propylene pressure (isotactic product content 6–28%).[111] This is an excellent example of how an almost forgotten "gray-hair" type of organometallics fertilizes an applied area of technology.

Based on the Shell development [Eq. (15)], a highly enantioselective, alternating copolymerization of propene or styrene and carbon monoxide with a chiral phosphane–phosphite (BINAPHOS, **14**) palladium catalyst was achieved [Eq. (16)].[99]



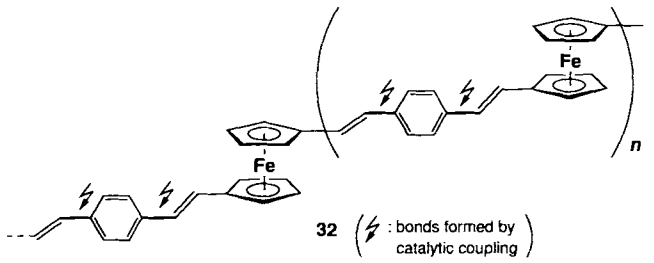
The optically active polymer has a molecular weight of about 10^5 and $M_w/M_n = 1.6$ when the cationic catalyst $[CH_3Pd\{(R,S)\text{-BINAPHOS}\}(N{\equiv}CCH_3)]^+$ was applied.[99] A new generation of polymers, for example Shell's Carilon, was developed within the short time span of a few years from the discovery of the perfect CO–olefin alternating principle.

Systematic mechanistic work in this area has also yielded a highly efficient carbonylation of propyne to methyl methacrylate (TON $= 4 \times 10^4$) in the presence of palladium(II) catalysts.[99c] The selectivity of reaction shown in Equation (17) is

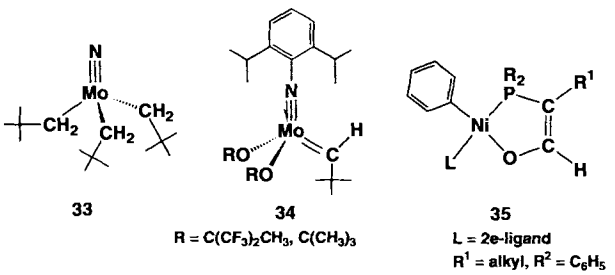


greater than 99.9% when certain 2-pyridyl phosphanes are used as catalyst ligands in addition to proton sources that exhibit only weakly coordinating anions.

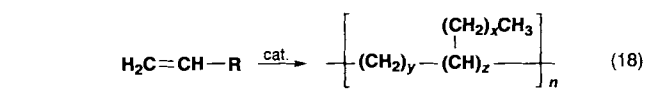
Polycoupling reactions with redox-sensitive precursor compounds to give polymers such as **32** exemplify organometallic building blocks in polymer synthesis.[112] Another field is the application of molecular catalysis to polymers; a prominent example is the "poly-Heck" coupling.[113]

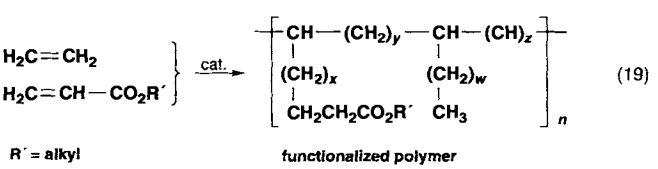


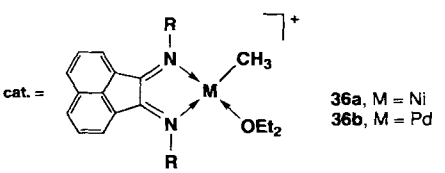
The coupling of alkynes, an old field of polymer chemistry, is on a new track due to the defined nitridometal–alkyl **33**, metal—carbene **34**, and metal–ylide catalysts **35**.[114–116] Often simple metal halides (for example $NbCl_5$) of unspecified active catalyst structures were employed before. In the case of imido(carbene) complex **34** the stereochemistry of poly(2,3-trifluoromethyl)norbornadiene can be switched from 100% *trans* ($R^2 = t$Bu) to 100% *cis* ($R^2 = C(CF_3)_2CH_3$).[115a] First chiral derivatives of **34** effect highly diastereoselective ring-closure metathesis.[115b]



A new branch of organometallic polymer chemistry arises from cationic nickel(II)- and palladium(II) complexes of N,N-chelate(diimine) ligands (**36**). According to Brookhart et al. both the homo- [Eq. (18)] and copolymerization [Eq. (19)] of

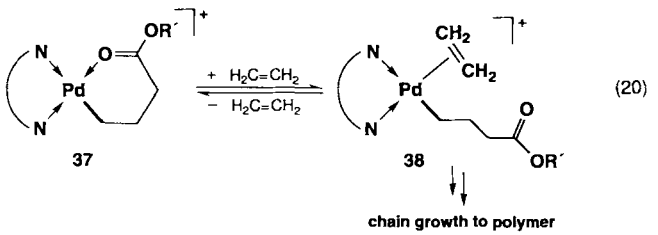






α-olefins proceed with activities that compare, in the case of nickel, with those commonly seen with metallocene catalysts. For the first time, simple variation of pressure, temperature, and ligand substituents yields an ethylene homopolymer whose structure varies from a highly branched, completely amorphous solid to a linear, semicrystalline, high-density material (degree of branching 1 to 300 branches per 1000 carbon atoms). As an alternative to **24**, the catalyst system diimine/$NiBr_2$/methylalumoxane is equally suited for the polymerization of ethylene and higher α-olefins.[117]

The special achievement of the new catalysts comes from their ability to include functionalized vinyl monomers, which normally terminate polymerization at the oxophilic, early transition-metal catalysts. On the other hand, late transition metals, especially nickel, often dimerize or oligomerize olefins due to the preference for β-hydride elimination. For this reason, ethylene–acrylate and ethylene–vinyl acetate copolymers are exclusively manufactured by radical-type processes, which often require high-pressure conditions. Palladium complexes of type **36** allow the formation of high molecular weight, random copolymers; the acrylate co-monomer is equally distributed over all molecular weights of the monomodal distribution. The branching is about 100 branches per 1000 carbon atoms; the ester groups are predomantly located at the ends of branches [Eq. (19)]. The slightly modified catalyst **37** adds the olefins in a reversible manner, whereas the intermediate **38** allows for the chain growth [for example, the consecutive insertion of the ethylene into the Pd–C alkyl bond, Eq. (20)].[118] The work of Brookhart et al. clearly opens a new possibility of organometallic catalysis in macromolecular chemistry. DuPont has filed patents in this area and expects commercialization.[119] Earlier work on this topic by Ostoja–Starzewski (Bayer AG) has to be kept in mind.[120] Novel developments include water-soluble catalysts (for example, for ring-opening metathesis)[121] and cyclic titanium(IV) amides for the living polymerization of α-olefins.[122]



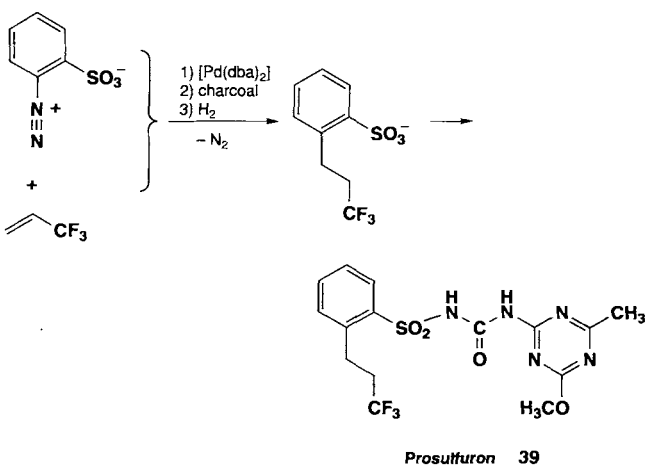
(20)

5. Homogeneous and Heterogeneous Catalysis—Common Territory

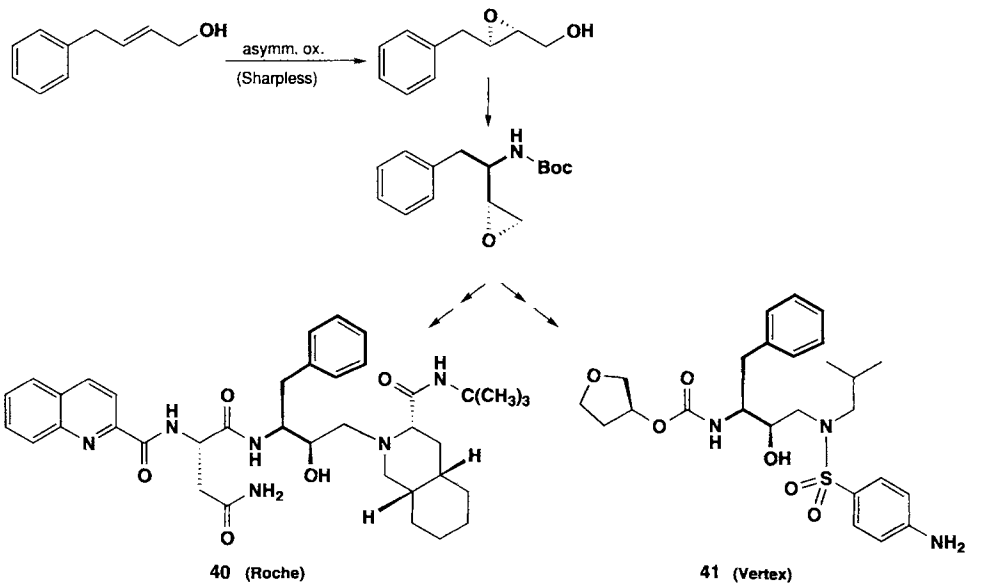
Many questions raised in this article will certainly remain open for quite some time. However, there has never been such a strong emphasis on organometallic chemistry on catalytic applications than now. More than ever, collaborations between the disciplines will prove crucial for success—the problems left are, as ever, the more difficult ones. However, a much improved methodology is available these days, and theoretical methods have become particularly strong. At the same time, large-scale, sophisticated organometallic preparations (for example metallocenes) are becoming standard in industry. It is now clear to many workers in the field that the philosophy of the "roaring sixties"—to make compound after compound for its own sake and fun—applies only for rare segments these days. It is all the more important to intensify the collaboration of homogeneous catalysis with coordination and organometallic chemistry. Moreover, theoretical chemistry and chemical engineering must be integrated in current research, not least for the sake of an early assessment of the feasibility of uniting certain reagents, reactivity, mechanisms, and processes in industry.

We note that the much talked-about gap within heterogeneous catalysis—namely, to perform structural investigations under realistic conditions and to derive reliable conclusions for the working catalyst—will remain a central problem. To put it the other way around: homogeneous catalysis has its greatest potential in step-by-step improvements, which are based on the possibility of examining (and understanding!) the molecular details of mechanism(s) under true catalytic conditions. In contrast, heterogeneous catalysis is still in the status of empirism. Unlike in heterogeneous catalysis, an encyclopedic collection of catalysts and their efficiency ("expert systems")[123] is not required to choose a homogeneous catalyst for a special purpose. In cases of direct comparison heterogeneous catalysts are frequently still cheaper than their homogeneous counterparts, mainly because of their often times very high activity and catalyst productivity.[131] A critical assessment of catalyst immobilization was given by Blaser and Pugin.[132]

It is generally observed that chemical companies include homogeneous catalysis in their research and production. For example, Ciba-Geigy just commercialized their first organometallic homogeneous catalytic process (100 tons per year), the synthesis of the agrochemical herbicide prosulfuron **39** by the $[Pd(dba)_2]$-catalyzed Matsuda reaction of 3,3,3-trifluoropropene with an aryldiazonium salt (Scheme 12).[124] The process starts with aniline-2-sulfonic acid without isolation of the diazonium intermediate. The majority of the Japanese L-menthol production depends on an organometallic (Rh) asymmetric key step.[125] The asymmetric Sharpless epoxidation has become standard in various pharmaceuticals syntheses and is part of extensive licensing policies.[126] For example, the industrial



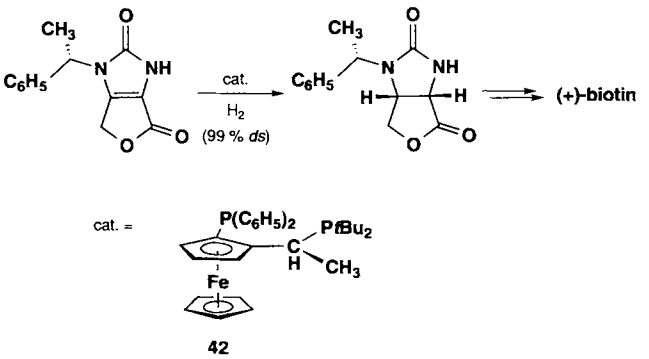
Scheme 12. $[Ph(dba)_2]$-catalyzed synthesis of the agrochemical prosulfuron (**39**, Ciby-Geigy AG) [124].



Scheme 13. Sharpless epoxidation as the first step in the industrial production of protease inhibitors **40** and **41** [126].

production of protease inhibitors such as **40** and **41** depends on a titanium-catalyzed first step (Scheme 13).[126]

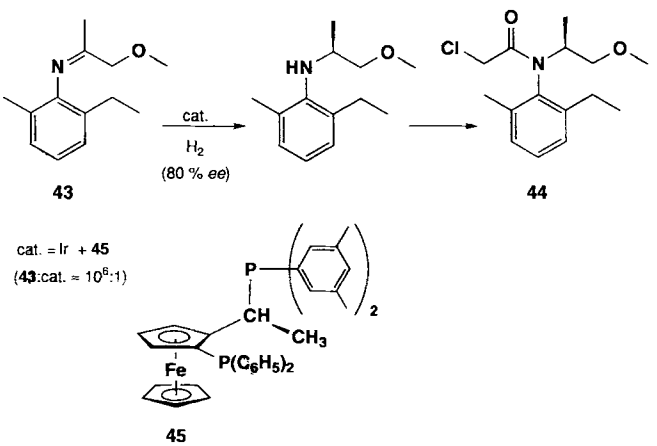
Chiral ferrocenyl phosphanes such as **42** are used in a rhodium-catalyzed hydrogenation step of a new (+)-biotin synthesis.[127] It is said that Lonza commercializes this process (Scheme 14).[128]



Scheme 14. Chiral ferrocenyl phosphanes as ligands in the rhodium-catalyzed hydrogenation as one step of a new (+)biotine synthesis [127].

Ciba-Geigy AG (now Novartis) last year announced a new synthesis of the herbicide (*S*)-metolachlor (**44**, known under the trade name DUAL) based on enantiomeric hydrogenation of the imine precursor **43** with the chiral ferrocenylphosphane **45** (Scheme 15).[129] This will be the first commercial process employing a catalyst ligand derived from ferrocene. The process implies an imine hydrogenation at iridium with a turnover number of 10^6 and a turnover frequency greater than 200000 h^{-1}! The full-scale production of more than 10000 tons per year of **44** started operation in 1996.

Hoechst AG is about to commercialize the two-phase catalysis of a Suzuki coupling[130a] with metal complexes of the water-soluble ligand TPPTS.[130b] This latter class of compounds has been investigated in terms of synthesis and analytical characterization.[130b,c] Palladacycles **7**[18a] are being tested on a pilot-plant scale for the Heck coupling of ethylene with halogenated arenes;[130d] they are easily and nearly quantitatively accessible



Scheme 15. Synthesis of the herbicide (*S*)-metolachlor (**44**, Ciba-Geigy AG) by enantioselective hydrogenation of imine **43** with chiral ferrocenyl phosphane **45** [129].

from palladium(II) acetate, and their thermal stability is unusually high.[130e]

Organometallic chemistry has grown to so central an interdisciplinary science that its opportunities to serve in catalysis is a daily, exciting challenge. Let us hope that homogeneous and heterogeneous catalysis, as a modified, less apodictic version of C. P. Snow's "two cultures"[133] approach unification.

This work was generously supported by the Fonds der Chemischen Industrie. We are indebted to Ms. Gisela Gerstberger for preparing a flawless manuscript and to Mr. Martin Geisberger for drawing the formulae and schemes. Mr. Robert Eckl is acknowledged for bringing most recent literature to our attention.

Received September 9, 1996 [A 189 IE]

[1] To be historically correct, there were earlier examples of metal-mediated homogeneous catalysis. For example, the Hg^{2+}-catalyzed hydration of acetylene to acetaldehyde became an industrial process in 1912. An intermediate π-acetylene complex activates the substrate. The "lead chamber process" for making sulfuric acid (NO_x catalysis) is even older but does not involve metals or metal complexes as catalysts.

[2] The word *serendipity* was coined by Horace Walpole in a letter to Sir Horace Mann in 1754 and is based on the fairy tale about the adventures of "The Three Princes of Serendip" (or Serendib, an ancient name for Ceylon, now known as Sri Lanka): R. M. Roberts, *Serendipity—Accidental Discoveries in Science*, Wiley, New York **1989**. This term is now being used for fortunate, totally unexpected discoveries - discoveries by accident and sagacity.

[3] Organometallic mixed catalysts for ethylene polymerization were discovered (by serendipity) when contaminated autoclaves were used to carry out an "Aufbaureaktion" of $Al(C_2H_5)_3$ with ethylene.

[4] The first comprehensive monograph, *Die Chemie der Metallorganischen Verbindungen* by E. Krause and A. von Grosse [5a], comes to mind. It appeared in 1937 just before hydroformylation was discovered. In the 900-page book only little is reported on the present-day champions of homogeneous catalysis (for example three pages and six references for Pt), and there is no mention at all of Co, Rh, or Pd. What a contrast when the monumental work *Comprehensive Organometallic Chemistry* (nine volumes, 8750 printed pages) appeared 45 years later; the second edition comprising 14 volumes is already in print! A total of about 24000 organometallic compounds has been registered by the *Chemical Abstract Service* up to now. The *Journal of Organometallic Chemistry* was chartered in 1963 and, in the meantime, has seen 500 volumes with a total of 20000 papers on 194000 journal pages! Two more key journals, the *Journal of Molecular Catalysis* (1975) and *Organometallics* (1982), broadly cover catalytic applications of organometallic compounds. Early monographs and reviews have recognized this interdependence.

Protein Synthesis by Chemical Ligation of Unprotected Peptides in Aqueous Solution

Michael A. Walker*

Proteins are essential to organic chemistry, biochemistry, and medicinal chemistry. For example, enzymes are utilized as synthetic catalysts for enantiomeric resolution and to construct challenging targets such as carbohydrates. Mutant proteins provide information that allows researchers to better understand function and structure. Medicinal chemists use proteins as targets for drug assay and as therapeutic agents. Obtaining usable quantities of protein is a basic requirement to all these areas of research.

Currently, recombinant technology plays a large role in protein synthesis. This method is applicable to linear peptides incorporating proteinogenic amino acids, however, recent advances have allowed the use of noncoded amino acids. A limitation to organic chemists attempting to synthesize proteins in this manner is the lack of expertise in molecular biology. The alternative is to synthesize proteins chemically on a solid support. However, large proteins (with more than 50 residues) are difficult to synthesize by this method due to solubility problems and the accumulation of deletion/epimerization impurities.

Chemical coupling of intermediate-sized protein fragments has been introduced to overcome these limitations. Three approaches have emerged. Fragment coupling of side-chain protected peptides on solid support,[1] enzyme-catalyzed coupling of peptide fragments,[2] and chemical ligation of unprotected peptide fragments in aqueous solution (also referred to as orthogonal ligation, native chemical ligation, or dovetailing). The latter method offers advantages over traditional coupling procedures by not requiring carboxyl-group activation or side-chain protection; this results in high chemoselectivity and increased solubility. In theory, it is applicable to a wider range of substrates than enzymatic methods.

Most chemical ligation techniques are similar to conventional protein cross-linking and conjugation methods, however, the proteins produced are homogenous rather than mixtures. "Orthogonal reactions"[3] such as hydrazone, thioester, disulfide, or thioether bond formation are used to join peptide segments. Examples include the synthesis of Degrado's four-helix bundle,[4] G-CSF and deleted G-CSF analogs,[5] an artificial protein,[6] HIV-1 protease, platelet GPIIb-IIa, and β-sheet model proteins.[7] However, these proteins are unlike natural proteins since they incorporate an unnatural functionality at the ligation site as an artifact of the coupling procedure.

Newer chemical ligation methods produce "native" amide bond coupled sites in a two-step reaction. Two fragments are first joined—head to tail—by a fast, chemoselective reaction such as thioester, disulfide, or thiazolidine formation, which places the reacting amine and carboxyl group in close proximity. This is followed by amide bond formation driven by a high "effective molarity" due to the intramolecular nature of the reaction. Side-chain protection and carboxyl-group activation are not required. This is akin to the pioneering work of Wieland et al.[8] and Brenner et al.[9] and is similar to the side chain capture method of peptide ligation by Kemp et al.[10] and to "conformation-directed recombination" of activated peptide fragments.[11] The ease and versatility of these procedures are evident in the following examples.

[Ala^{33}]IL8 (**4**), a protein with 72 amino acids, was synthesized by Kent et al. (Scheme 1).[12] The peptide segment **1** (prepared as its benzyl thioester) and the cysteine-terminating segment **2** were prepared by solid-phase synthesis. Ligation was conducted in an aqueous buffer (pH 7.6, phosphate, 6M guanidine hydrochloride) in the presence of benzyl mercaptan to prevent disulfide formation. The initial reaction of **1** with **2** gave thioester **3**, which was not isolated but spontaneously rearranged by S → N acyl group migration to deliver **4**. Remarkably, the internal cysteine thiol groups did not interfere with the coupling. The native disulfide bonds were formed on exposure to air.

Tam et al. used a similar method to synthesize model peptides of up to 54 residues.[13] The reaction was optimized with respect to pH, and additives such as R_3P (2 equiv), and R'SH (10 equiv) were employed to prevent (or revert) yield-lowering side reactions such as disulfide formation and errant acylation of internal thiols.

Peptide thioesters can also be formed by reversing the direction of nucleophilic attack. At pH 5.0 the thioacid of peptide **5** reacts with β-bromoalanine-containing peptide **6** to form thioester **7**, which is set up to undergo S → N acyl group migration (Scheme 2a). Tam et al. used this procedure to synthesize a sperm-activating peptide (12 residues) in 85% yield. Disulfide formation can also be used to tether the peptide fragments (Scheme 2b).[14] The S → N acyl group transfer reaction of **9** occurs through a transition state with a six-membered ring, which is in contrast to the above reactions that go through

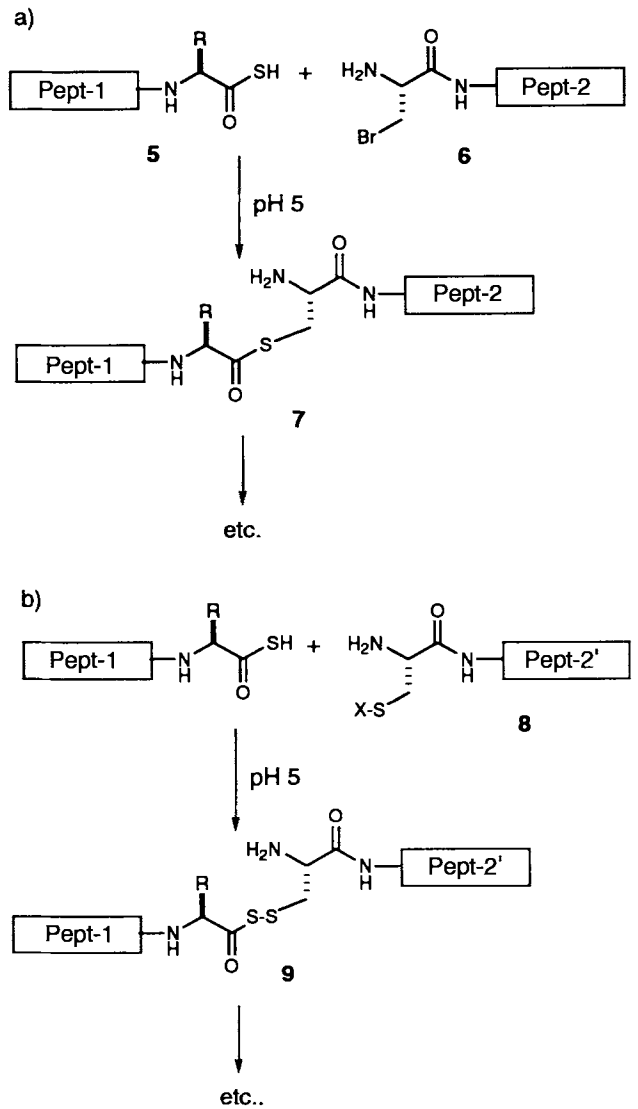
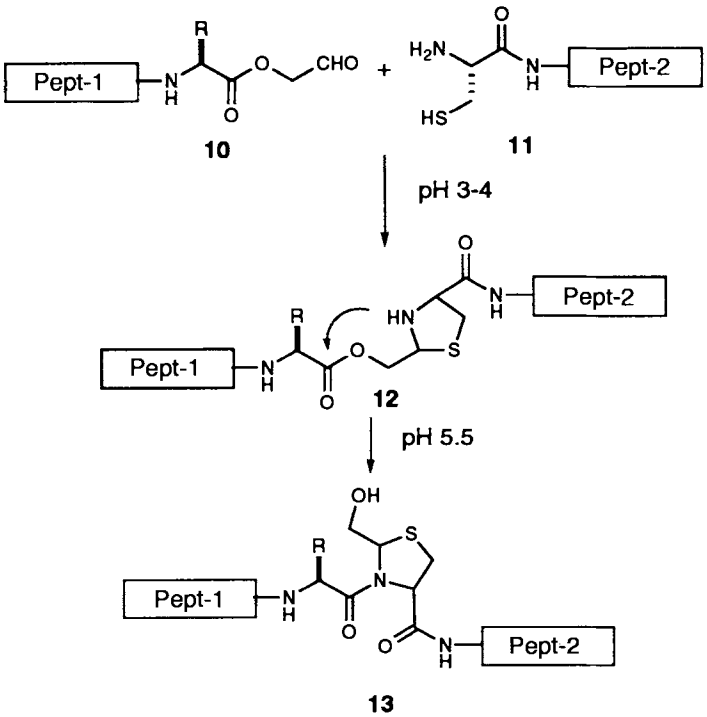


Scheme 2. Reversal of the direction of nucleophilic attack to form a) thioesters and b) carboxydisulfanes.

transition states with five-membered rings. Reduction of the hydrodisulfide side chain is required after coupling.

Remarkably, Tam et al. have demonstrated that thiazolidine formation can also be used as the side-chain capture step (Scheme 3).[15] However, a pseudoproline residue is formed at the ligation site after acyl migration. This adds some versatility, since one can consider AA-Pro as a ligation site instead of AA-Cys.

The latent N-terminal half (**10**) is synthesized as the thioester on a solid support. This is followed by Ag^+-mediated transesterification to introduce a C-terminal glycoaldehyde ester. At pH 3–4 thiazolidine ring formation is irreversible, and **12** is selectively formed over other potential aldehyde–amine condensation products. Heterocycle formation was monitored by HPLC and found to be essentially complete after less than 5 h, even under dilute conditions (0.05–0.2 mM in substrate). Raising the pH to 5.5 allowed O → N acyl group migration ($t_{1/2} \approx 20$ h). Three HIV-1 protease analogs were synthesized in this manner: [SPro^{39}, Abu^{67,95}]-HIV-1PR, [Ala^{38}, SPro^{39}, Abu^{67,95}]-HIV-1PR, and [Leu-NHCH$_2$-Thz$^{38-39}$, Abu^{67,95}]-HIV-1PR. The latter was formed from a glycinal amide that does not undergo acyl transfer after the initial thiazolidine ring forming reaction. A 50-residue epidermal growth factor was similarly synthesized.



Scheme 3. Thiazolidine side chain capture followed by acyl migration.

Chemical ligation has been successfully applied to synthesize natural and unnatural proteins of up to 10–20 kDa. Unlike recombinant methods, these techniques can be easily mastered by synthetic chemists. However, protein structural information is required in the selection of the ligation site. Improved methods should allow researchers to synthesize proteins of larger than 100–200 residues.

The nonenzymatic nature of the synthesis allows one to easily construct mutant proteins containing noncoded amino acids (for example, an all D-amino acid enzyme). The modular nature of the ligation allows one to insert or delete large structural motifs as well. Structures with no natural counter parts such as protein dendrimers are also easily prepared.

Applications of chemical ligation will allow researchers to improve stability and binding selectivity by optimizing protein structure. Furthermore, combinatorial chemistry methods could be applied at the amino-acid or at the peptide-fragment level to speed up the process.

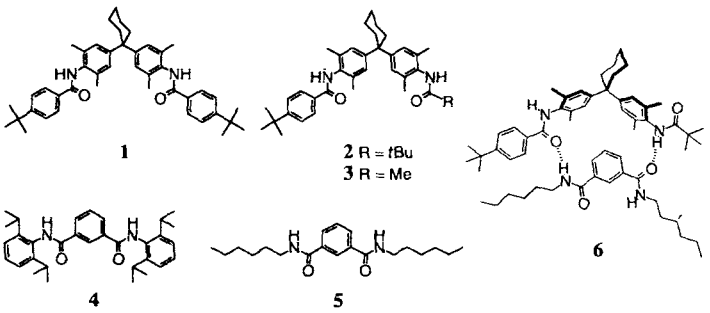
Requirements for Quantifications of Weak Intermolecular Interactions from Equilibrium Studies with Supramolecular Complexes

Comment by Hans-Jörg Schneider*

Hunter et al.[1] have recently described equilibrium constants between some ligands, in which two hydrogen bonds between amides were kept constant, while side chains contained either phenyl or alkyl groups. Based on the analysis of a—somewhat misleadingly so-called—thermodynamic cycle they derived then an increment for the phenyl–phenyl or π-π interaction of 1.4 ± 0.8 kJ mol^{-1}. Several assumptions made in this paper are questionable (see below), and the conclusions neglect to a considerable extent the available literature. Equilibrium measurements between "simple" ligands with only one binding site have for decades provided a large body of data for noncovalent interactions.[2] The different interaction scales obtained this way—neither of which are cited—are based on thousands of measurements. They do have drawbacks, mainly because of often ill-defined entitities and underlying structures. We have shown in numerous publications[3] that supramolecular complexes indeed offer a promising way to derive a large number of noncovalent free-energy binding increments, as one can design multibinding site ligands of the type used by Hunter et al.[1] with well-ordered structures. As shown before,[4] variation of one or of several interactions in synthetic host–guest complexes while keeping another constant allows one to investigate different contributions, particularly those which are weaker. In contrast to the work by Hunter et al.[1] our analyses were based on *numerous* different complexes. The observation of constant increments in complexes with an increasing number of interactions also shows to which degree different entropy contributions[5] blur the interpretation. The molecules **1**–**5**[1] are certainly not "rigid" as claimed: each ligand contains several rotatable benzylic bonds, which may well lead to loss of freedom upon complexation. One also should state clearly that the given π-π increment[1] would represent the value above any alkyl–alkyl interaction.

More disturbingly, the authors did not compare their value for the amide hydrogen bond (from complex **D** (shown here as **6**) for example $5.7/2 \approx 2.8$ kJ mol^{-1} per bond) with those from many related studies.[6] We have derived an average value of 5 ± 1 kJ mol per bond from numerous data in chloroform solution.[6d] This is actually larger (around 7 kJ mol^{-1})[6e] if—like in



systems similar to **6**[1]—no repulsive secondary interactions weaken the primary hydrogen bond. One reason for the discrepancy of the data reported by Hunter et al.[1] to literature values[6] could be that the optimal hydrogen bond conformation can only be reached at the expense of—enthalpic and/or entropic—unfavorable interactions, for example with the alkyl side chains. Similar reasons might be responsible for the striking discrepancy[1] for the CMe_3-π interactions to the results of Wilcox et al.[7] As standard method to control such possible misfit and/or strain variations one should apply molecular mechanics calculations.

The major lesson learned from analyses of experimentally derived noncovalent interactions is that one must combine the advantage of well-designed supramolecular complexes with the traditional methods of linear free-energy relationhips (LFER). There is good reason for available data bases of, for example, donor/acceptor increments containing up to 10000 measurements[2b] that allow the construction of statistically meaningful general scales of increments.[2] If for the study of conventional bond-making and bond-breaking a Hammett correlation based on less than ten different chemical systems is not really acceptable, this should be even more so for the analysis of noncovalent interactions, which are not only generally weak but much less well defined. Careful evaluation of the literature provides a rich source of data on noncovalent forces between different functionalities, as well as strategies on how to make the best use of them.

Reference [11] describes a new method that we have developed for quantifying noncovalent interaction energies in a synthetic supramolecular system. The viability of the approach was demonstrated by measuring a weak aromatic interaction, and while the value obtained is not in itself particularly significant, the success of the methodology opens the way for the kind of systematic structure–activity studies that have not been possible before. With the exception of studies on simple functional group interactions like hydrogen bonding, the data on small molecule interactions are of limited utility, because the orientation of the interacting groups (often not known) changes from one complex to the next. Supramolecular systems can overcome this problem, but the thermodynamic analysis is complicated by the many different interactions which are present. The advantage of the zipper system is that *both* interacting groups can be modified easily without disturbing the central recognition motif. This allows us to use the double mutant cycles that have proved so powerful for studying functional group interactions in proteins. This approach not only factors out contributions from the other interactions that are present but also removes many potential sources of error such as restriction of rotation of the cyclohexyl–anilide bonds in **1**, **2**, and **3**. The utility of quantitative studies of weak intermolecular interactions is limited by the choice of the experimental system used, and we do not claim that the zippers are ideal in any absolute sense. There are limitations: we assume that the alkyl groups do not interact; the binding constants are small; entropy–enthalpy compensation is not accounted for in the analysis. However, the zippers do offer significant advantages over other systems in the literature.

The experimental binding constant for complex **D** (shown here as **6**) appears not to agree with the literature values for the magnitude of a hydrogen bond, but this is exactly what one should expect. The observed free energy of complexation is the sum of an enthalpic contribution, in this case from hydrogen bonds and aromatic interactions, and an entropic contribution due to loss of translational and rotational degrees of freedom on formation of the complex. We have not yet measured the magnitude of the entropy changes in this system, but it is clear that the free energy of complexation is not equal to the total enthalpy of hydrogen bonding. It will be substantially lower due to the large entropy change. There is no discrepancy here.

This paper reports our first attempt to measure a noncovalent interaction using this approach. We have not yet made many measurements, but in the systems we are currently studying, we are finding consistent results and useful structure–activity relationships. This work will be reported in due course and will answer the criticism about the number and range of interactions examined.

A Novel Strategy towards the Total Synthesis of Cyclopeptide Alkaloids

Comment by Ulrich Schmidt*

In a contribution to this journal[1] J. Zhu et al. reported on a new ring-closure method for the construction of cyclopeptide alkaloids by way of an intramolecular S_NAr reaction. Their statement that "the main difficulty is the construction of the obviously strained macrocycles" must, however, be contradicted since the 13-, 14-, and 15-membered *p*- and *m*-ansa compounds (*para*- and *meta*-cyclophanes) are not strained; in fact merely the 14-membered *p*-ansa compounds are rigid. Furthermore, the statement "until now, only macrolactamization has been fruitful; this strategy culminated in the total syntheses of three natural products by means of an efficient activating method developed by Schmidt et al." is not correctly referenced; for completion the total syntheses of zizyphin A[2] (13-membered) and mucronin B[3] (15-membered) reported 15 and 13 years, respectively, earlier should be added. Thus, with the synthesis of the 14-membered compound frangulanin, we had achieved the first synthesis of one representative of each of the three classes.

The authors evaluate their syntheses of the 14-membered model compounds: "The easy formation of the 14-membered macrocycles is rather spectacular considering the obvious strain in this ring system and the fact that only very few methods are available." Before accepting these "rather spectacular" results, however, the reader should compare the yields of this "new synthetic strategy" with those of the lactamization. The ring-closure steps in the synthesis of zizyphin A, mucronin B and frangulanin by lactamization were achieved in yields of 85, 80, and 44%, respectively. In contrast, for the new ring-closure by way of formation of an aryl ether a yield of 70% is stated. However, after the auxiliary group (NO_2) has been removed by reduction, diazotization, and reduction, the effective yield diminishes to 38%.

The major difficulties in the synthesis of this group of natural products have been ignored: the hydroxy group in the benzyl position or the aminostyrene double bond in the ring are absent. Furthermore, the ring bears a dialkylamino group (ring closure can only be achieved in the presence of this substituent) and not a primary amino group as is required for subsequent attachement of the side chain.

Reply by Jieping Zhu*

I agree with Professor Schmidt[1] that only the 14-membered cyclopeptides are strained, and as a consequence are the most challenging synthetic targets of this family of natural products. For this reason, we selected 14-membered *para*-cyclophane as a test case for the development of our synthetic strategy.[2] Accordingly, Schmidt's work on the total synthesis of 13-[3] and 15-membered[4] cyclopeptides were not cited in our paper. However, we do feel that the term „rigid" used by Schmidt is less appropriate than „strained" to describe a high-energy cyclic form.

To the best of our knowledge, the synthetic strategy we realized[2] has never been addressed before, therefore the adjective „novel" does seem appropriate to define our synthetic strategy. However, as readers may find, we have never pretended that this strategy was the best one and in no way are we trying to understate the significant contributions made by Schmidt et al. and other research groups. Perhaps the employment of a less spectacular adjective should have been used to describe the cyclization results. However, it was pleasing to find mild conditions to effect the unprecedented macrocyclization. To elucidate further, at the inception of this work, we had a serious concern about the stability of cyclic compound **1**, namely decomposition to the acyclic compound **2**. This could conceivably occur by a facile

β-elimination due to: 1) release of ring strain; 2) the fact that *ortho*-nitro-substituted phenol is a good leaving group. We have, however, been able to avoid this complication by a judicious choice of amine protecting group.

Most of the synthetic strategies towards the preparation of cyclopeptide alkaloids have started from the dihydro derivatives, except for example Lawton's approach.[5] „*These derivatives present similar synthetic problems as reduction of the vinylic double bond does not relieve ring strain to an appreciable extent*" as written in Joullié's excellent review.[5] Thus, we are applying this methodology to the total synthesis of natural cyclopeptide alkaloids and the results will be published in due course.

Deposition of Data from X-Ray Structure Analyses

In order to make life easier for authors and referees the Cambridge Crystallographic Data Centre (CCDC) and the Fachinformationszentrum Karlsruhe (FIZ) have unified their procedures for the deposition of data from single-crystal X-ray structure analyses.

Prior to submitting your manuscripts please deposit the data for your compound(s) **electronically** at the appropriate data base, that is, at the CCDC for organic and organometallic compounds and at the FIZ for inorganic compounds. Both data bases will be pleased to provide help (see our *Notice to Authors* in the first issue of this year). In general, you will receive a depository number from the data base within two working days after electronic deposition; please include this number with the appropriate standard text (see our *Notice to Authors*) in your manuscript. This will enable the referees to retrieve the structure data quickly and efficiently if they need this information to reach their decision.

This is now the uniform procedure for manuscripts submitted to the journals *Advanced Materials, Angewandte Chemie, Chemische Berichte/Recueil, Chemistry—A European Journal,* and *Liebigs Annalen/Recueil.*

Self-Assembly of Submicrometer Rings of Particles from Solutions of Nanoparticles**

Pamela C. Ohara, James R. Heath,* and William M. Gelbart*

There has been much recent theoretical and experimental interest in ordered, nontemplated arrays of monodisperse nanocrystals of semiconductors,[1-4] metals,[5,6] and metal oxides.[7] Attention is being focused on questions that pertain to both the formation of nanocrystal superlattices and their physical properties. With respect to superlattice formation, key issues involve the relevant interparticle forces as well as the relationship between the individual particles and the final superlattice crystallographic structures.[8-10] In addition, the possibility of cooperative (interparticle) electronic phenomena, as reflected in linear and nonlinear optical response[11] and electron transport,[12] has also attracted attention. In general, most experimental work has been directed at extended two- or three-dimensional close-packed structures.

In this communication, we present the first experimental report on a novel type of two-dimensional, submonolayer array of organically passivated metal nanoparticles and provide an annular theoretical explanation of its formation. Each array consists of a ring of close-packed nanoparticles and is formed upon the pinning to the substrate of the perimeter (the contact line between fluid and substrate) of a growing hole which has nucleated in sufficiently thin films of dilute solutions of the particles.

Figure 1 (left) is a transmission electron micrograph of a typical ringlike structure which self-assembles when a drop (3.5 μL) of a dilute (about 10^{14} particles per mL) solution of metal nanoparticles in hexane is placed on an amorphous carbon substrate (3.0 mm diameter) and allowed to evaporate; the area fraction of particles on the substrate is on the order of 1–10%. The ring consists of 2.5 nm core silver nanoparticles coated with a layer of covalently bound dodecanethiol, which makes them soluble and easily manipulated in organic solvents,[10] and the ring diameter is 0.9 μm, orders of magnitude smaller than the 3D rings reported elsewhere.[13,14] The concentration of particles inside the ring is smaller than the concentration of particles outside. This is consistent with our conjecture that these rings are due to holes opening up in the liquid film and pushing particles out into their rims. To the right is a higher resolution image showing the structural detail of the ring perimeter. The particles are ordered and close-packed within the ring. This structure is controlled by interparticle interactions, which are strong enough to drive crystallization but sufficiently weak to allow annealing (also discussed in earlier work[5]).

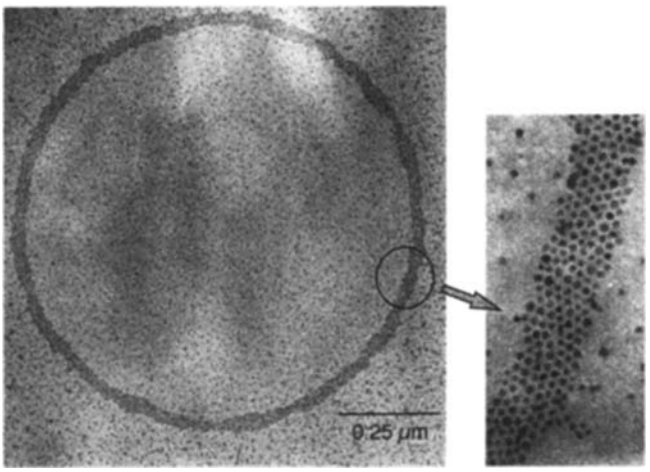

Figure 1. The left TEM micrograph shows a 0.9 μm diameter ringlike superlattice structure on a carbon substrate that self-assembled from a dilute solution of organically functionalized Ag nanocrystals (25 Å) in hexane. Most of the geometrical dimensions of such rings, including ring diameter, annulus width, and surface coverage can be controlled and may be understood within the context of the theory described in the text. To the right is a higher resolution TEM micrograph of a portion of a ring, showing the nanocrystal packing detail.

Figure 2 is a micrograph of a typical view of rings that can be observed on the substrate. This picture demonstrates that: 1) the rings are structures regularly formed in the system, 2) they are roughly the same size, and 3) although defects can be seen on this micrograph, their scale is smaller than that of the rings—in fact, most rings are perfect.

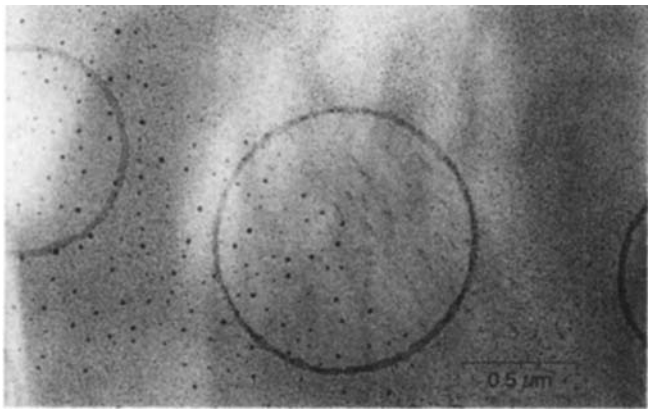

Figure 2. Low-resolution TEM micrograph showing complete and partial views of four separate rings. Both the particles themselves and each ring are similar in size and order to those shown in Figure 1.

Motivation for this research stems from our observations that when the solvent of organic solutions containing dispersed metal nanoparticles on a solid carbon substrate (a TEM grid) is evaporated, the resulting submonolayer structures involve either compact, ordered domains of particles or ringlike structures, depending on the average size and polydispersity of the sample. The formation of rings correlate with the presence of nearly monodisperse, large particles, whereas compact, size-segregated domains are associated with polydispersity or a greater number of small particles (and hence, fewer large particles). The compact, size-segregated domains were earlier postulated to be annealed, equilibrium structures:[5] size-dependent dispersional attractions between particles, being only slightly larger than thermal energies in these systems, were argued to drive reversible crystallization of the particles. We account for the formation of ringlike structures again with size-dependent interactions—but here between the particle and substrate, rather than with other particles.

The observation of rings formed in evaporating drops and films of colloidal suspensions is not new. The ubiquity of this

phenomenon is perhaps best illustrated by the ringlike signatures associated with food, mud, and coffee stains encountered on solid surfaces in everyday life. These structures correspond to macroscopic rings of macroscopic particles (e.g., tomato bits, soil grains, and coffee grounds, respectively), appearing upon evaporation of solvent (water) from a drop of the host colloidal solution. The formation of macroscopic rings of *meso*scopic particles ("polyballs"—monodisperse plastic spheres with diameters of hundreds of nanometers) is currently being investigated under ingeniously controlled laboratory conditions as models for this basic phenomenon.[13, 14] In all these cases, however, the macroscopic rings originate from single, sessile, nonwetting, drops placed on a substrate. Because flow towards the stationary rim is required to compensate for evaporation losses in maintaining an equilibrium shape of the liquid–vapor interface, particles are drawn by solvent fluxes to the edges of the pinned drop and produce a thick ring. Our present situation is fundamentally different, resulting in the spontaneous formation of *many mesoscopic* rings of meso(nano)particles arising from a single macroscopic film of solution.

We emphasize several key differences in the case of our nanorings. First, we are concerned with a solvent that completely wets the solid substrate, and which accordingly evaporates as a thin planar film (rather than as a sessile, nonwetting drop). Second, our rings result from the pinning of the contact lines of nucleating *holes* in the thin liquid film. And third, pinning is not automatic; it depends on the strength of particle–substrate interactions and hence is a function of particle size—in particular we shall argue that the advance of the growing hole rims in the solvent film is stopped when the radial force outward is no longer sufficient to overcome the frictional effects of the particles which have collected in the rim. While a great deal of work has been done on hole nucleation in *dewetting* films below a critical thickness,[15] only Elbaum and Lipson appear to have investigated the corresponding problem for *wetting* layers.[16] Their efforts, however, focus on hole nucleation in approximately 50–500 nm films involving *wet* holes, whereas our problem involves thinner films (a few nanometers thick) and *dry* holes. Our films also contain suspended colloidal particles; their effect on the inherent instabilities of these thin evaporating films must be explicitly accounted for.

We formulate a theoretical scenario for ring formation, which is schematically described in Figure 3. The drop of nanoparticle solution completely wets the amorphous carbon substrate as a thin film. It evaporates because the system is open and the equilibrium vapor pressure p^o of solvent greatly exceeds the actual pressure p above the film. Because of this condition ($p \ll p^0$), the film would need to thin, by evaporation, to unphysically small dimensions in order for the liquid to be in equilibrium with its vapor; equilibrium is reached only when all of the liquid has evaporated. Before reaching this point, the liquid evaporates steadily as a thin film until it becomes unstable with respect to the nucleation and growth of holes.

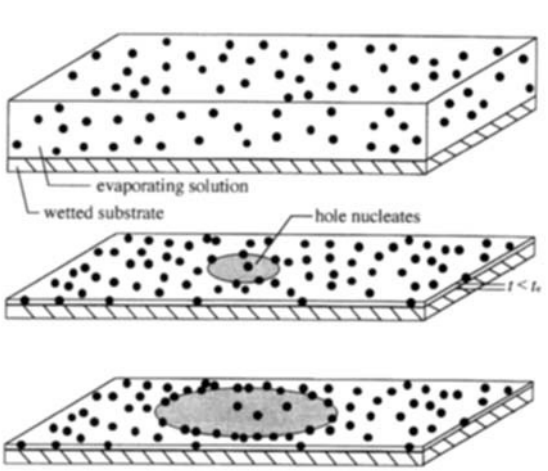

Figure 3. Illustrations sketching the process by which the evaporating solution wets the solid substrate (top) and thins to a thickness $t_{hole} < t_e$, at which a hole nucleates (middle). The hole opens, pushing most particles out along its advancing rim (bottom), which becomes a ring.

The formation of holes in an evaporating thin film is analogous to ordinary bubble nucleation in a bulk superheated liquid,[17] with the difference that holes in thin films are "open" to the vapor above the film. In addition, hole nucleation can also occur in *nonvolatile* wetting fluids, where the film becomes unstable at thicknesses t below a critical value t_{hole};[18] holes open in order to restore the film to its equilibrium thickness $t_e = (3A_H/S)^{1/2}$ (see below for definition of symbols). More explicitly, a wetting film never tends to thin too much because of the disjoining pressure contribution to the free energy per unit area, which has the form A_H/t^2 where $A_H\,(= A_{sl} - A_{ll} > 0)$ is the relevant Hamaker constant.[18] At the same time, it tends to avoid forming holes or otherwise dewetting the substrate because of the positive spreading coefficient, $S = \gamma_{sv} - (\gamma_{sl} + \gamma)$, where γ is the liquid–vapor interfacial tension and γ_{sv} (γ_{sl}) the corresponding value for the solid–vapor (solid–liquid) interface. The equilibrium thickness t_e reflects a compromise between these competing tendencies of the thinning, wetting film.[18]

Although holes can develop in our thin film because of evaporation driving forces, which act independently of the single-phase, nonvolatile solvent forces, we shall treat only the latter phenomenon, assuming that evaporation is much slower than fluid motion. We postulate not only that the film thins uniformly as solvent evaporates, but also that this proceeds slowly enough for the stability against hole nucleation to be governed by the local equilibrium physics of an effectively *nonvolatile* wetting fluid.

Let ΔA_{hole} denote the free energy associated with forming a hole of radius R in the nonvolatile thin film of thickness t. It is then straightforward to show that this quantity can be written approximately as Equation (1). Accordingly, fluctuations cor-

$$\Delta A_{hole} = [\gamma t]2\pi R + \{S - 3A_H/t^2\}\pi R^2 \qquad (1)$$

responding to small holes will grow when the maximum in ΔA_{hole} vs. R [Eq. (1)] is brought down to around $k_B T$. This happens when the film thickness t approaches t_{hole}, slightly smaller than the "pancake" dimension t_e. Below this thickness the thin film becomes unstable against the nucleation and growth of holes in its drive to achieve the optimum thickness t_e.

As holes open up and grow (see Figure 3), solvent and particles are "pushed out" toward the bulk film of solution. The force acting on the rim of a hole of radius R, neglecting hydrodynamic effects, can be represented as $2\pi RS[t_e^2/t_{hole}^2 - 1]$.[19] Because of the barrier against dewetting of the particles by the solvent, most particles in the path of an advancing hole are pushed out into its rim. It is then straightforward to develop a geometric picture of the increase in line particle density—number per unit length of rim—as the hole grows in size. Let ϕ be the area fraction of the surface covered by particles (each of radius r) in the uniform wetting layer, before the nucleation of any holes. A hole of radius R opens. Since this hole has circumference $2\pi R$, and the circular area of substrate (πR^2) contains $\pi R^2\phi/\pi r^2$ particles, it follows that the average outward force exerted *per particle* along the rim is $2\pi r^2 S[(t_2^e/t_{hole}^2) - 1]/R\phi$. This

force—arising from the drive to lower the thin film free energy by thickening—is sufficient to continue dragging along particles only up to a certain point, when the contact line of the hole becomes pinned due to particle–substrate interactions.

In determining the effect of the particles on the film, we note that capillary forces[20] between particles—arising from the deformation of the liquid surface due to the presence of particles—are weak because the film thickness is small enough for disjoining pressure to dominate over hydrostatic pressure (gravity). For nanometer thicknesses, the effective capillary length λ, or decay length of the capillary forces, is short-ranged—on the order of angstroms. More explicitly, instead of the usual $\lambda = (\gamma/\Delta\rho g)^{1/2}$ ($\Delta\rho$ = density of liquid–density of air, g = acceleration due to gravity) we have $\lambda = (\gamma t^4/A_H)^{1/2}$.[20] This expression implies that λ is several Ångstroms for $\gamma \approx 50$ dynes cm^{-1}, $A_H \approx k_B T$, and t the in nanometer range. Finally, since the effective spreading coefficient for the liquid on the particle is approximately an order of magnitude smaller than the spreading coefficient of the liquid on the solid substrate, the liquid prefers to spread on the solid substrate, rather than "riding up" the particle. It follows that the particle has little effect on the liquid, and consequently capillary forces are effectively negligible.

Consider particles, previously immersed in the wetting thin film, which are in the rim of an advancing hole. Because of downward dispersional attractions between particles and the substrate, they can move along with the expanding rim only if the force opening the hole is strong enough to overcome the static friction arising from particle–substrate and particle–particle interactions. Taking into account the former effect, we let $F_{z,\,disp}$[21] denote the downward dispersional force attracting an individual particle to the substrate, and let K (of order unity) be the associated friction coefficient. The lateral force opposing motion of each particle is the product of these quantities. The thickening force per particle was shown above to be inversely proportional to hole size R, which decreases as the rim advances. It follows that the rim will be pinned when the hole radius reaches a value R_{pin} determined by the balance between the lateral friction and outward thickening forces [Eq. (2)]:

$$F_{z,\,disp} K \approx 2\pi r^2 S[(t_e/t_{hole})^2 - 1]/\phi R_{pin} \qquad (2)$$

Since $F_{z,\,disp}$ depends only on the size r of the individual particles for a given solution of nanocrystals—that is, for a specific particle size r, solvent, and substrate (and hence for a fixed set of values for S, t_e, and t_{hole})—the ring size R_{pin} from Equation (2) is expected to vary inversely with concentration ϕ. Furthermore, for a given ϕ, all ring sizes should be the same (even though their associated holes began to grow at different times), if the particle size distribution is sufficiently narrow (see Figure 2).

It was also observed that when the concentration of particles is too small—such that the center–center ring separation becomes smaller than the ring diameter—both rings and compact structures are observed, consistent with the idea that holes percolate and crowd particles into the interstices, where they then form compact structures. Other physical properties, such as annulus width and surface coverage of rings, can also be controlled, and we are currently trying to quantify such control, through both experiment and theory.

Light-Directed Assembly of Nanoparticles**

Tobias Vossmeyer, Erica DeIonno, and James R. Heath*

A major challenge associated with the application of semiconductor and metal nanocrystals is the development of methods for placing them into chemically and structurally complex environments.[1] In particular, applications of nanocrystals in devices often require precise spatial positioning of the particles onto a substrate. Recent approaches have utilized shadow-mask evaporation or lithographic/etching technologies to prepare a pattern of two different materials. Particles are then selectively grown or attached to one of the two materials. One example is the selective heteroepitaxial growth of germanium dots on silicon microsurfaces patterned through an SiO_2 overlayer.[2]

A second example involves the selective attachment of particles, through bifunctional organic ligands, onto a gold electrode pattern on silicon.[3] Bifunctional ligands have found general use in binding particles to substrates.[4] Other than by physically removing these ligands from selected portions of the substrate by laser or electron-beam ablation, this chemistry is not spatially selective. However, in 1991 Fodor and coworkers described how photolabile protecting groups attached to glass substrates can be used for light-directed, combinatorial solid-phase peptide synthesis.[5] In this communication we describe an extension of this technique that allows the light-directed assembly of gold nanoparticles onto glass and silicon substrates. The initial assembly process, while spatially selective, is not particularly efficient. However, the attached particles themselves then serve as a chemically selective "substrate" for subsequent attachment of bifunctional ligands. We show that this selectivity can be utilized to amplify the initial photochemically defined pattern to produce arbitrarily thick, patterned films of particles.

To prepare the light-sensitive substrates, we first treated cleaned silicon or glass slides with 3-aminopropyldimethylethoxysilane. The choice of the *mono*alkoxysilane is critical for avoiding silane polymerization and for maintaining a smooth substrate surface. The amino groups were then treated with the carboxylic acid group of nitroveratryloxycarbonylglycine (NVOC-GLY) to give an NVOC-terminated sample surface (Figure 1). NVOC is a photoremovable protecting group for primary amino groups that is used in solid-phase peptide synthesis.[5-7] A pattern was defined photochemically by exposing the substrate to UV/Vis radiation ($\lambda > 340$ nm) through a microchip mask. This removed NVOC groups from the areas exposed to light and yielded a pattern of free and protected amino groups. This pattern could be monitored by fluorescence microscopy after treating the free amino groups with ATTO-TAG, a specific fluorescent marker for primary amino groups.

In order to bind gold nanocrystals to the free amino groups of the pattern, we prepared a solution of 12-aminododecane-capped gold particles (2.6 nm diameter Au cores) in toluene.[8] These particles have been shown to be kinetically, rather than thermodynamically, stabilized. They readily undergo ligand exchange with the surface-bound amino groups, and thus, a selective binding of the particles onto the patterned substrate surface is achieved. This kind of two-phase ligand exchange is further favored, because it is coupled with a precipitation of the particles onto the sample surface. After the patterned substrates had been kept overnight in the gold particle solution, binding of particles to the substrate was sometimes observable by eye, but not always. To amplify particle binding, we treated the surface-bound gold crystals with 1,8-octanedithiol to yield free, surface-bound thiol groups on areas where gold particles had already been attached to the surface. Following dithiol treatment, the slides were dipped again into the particle solution to bind more gold nanocrystals onto previously bound particles. This dithiol amplification could be repeated several times. In this way, the micropattern contrast was easily enhanced until it was readily visible by eye or through an optical microscope. An optical micrograph of an amplified pattern recorded with a CCD camera is shown in Figure 2a. The micromask structure is clear, indicating the successful light-directed assembly of gold particles.

Micropatterns prepared on silicon wafers were imaged with a scanning electron microscope (SEM). Such images are shown in Figures 2b and 2c. Figure 2c reveals that the technique is not completely selective to the light-exposed surface, as there are some Au nanocrystal grains assembled on the unexposed regions of the surface. The micropattern was also imaged with an atomic force microscope (AFM) operating in contact mode. These images confirmed that the assembly technique is not 100% spatially selective but provided no new information.

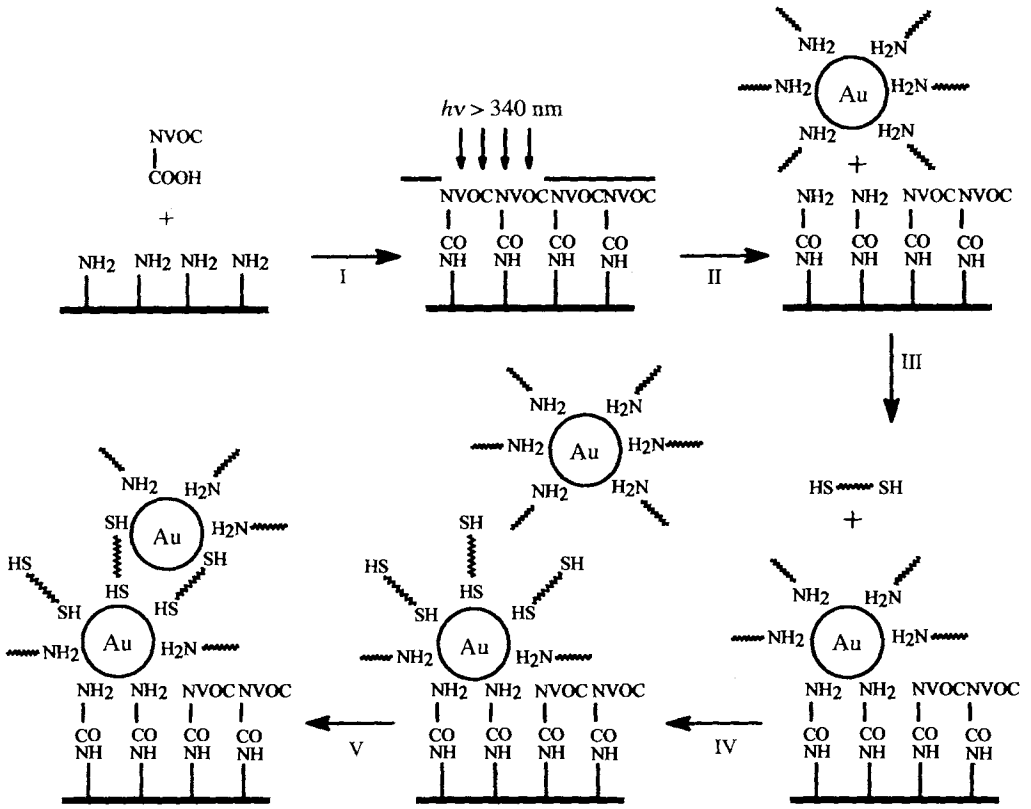

Figure 1. Reaction scheme for the light-directed assembly of Au nanoparticles onto glass and silicon substrates. An amino-functionalized substrate was first treated with NVOC-GLY (**I**) to give a photosensitive surface. Upon irradiation through a microchip mask (**II**) a pattern of free and protected amino groups was obtained and treated with a solution of amine-stabilized Au nanoparticles (**III**). The Au-particles assembled by ligand exchange on the areas with exposed free amino groups. To amplify selective particle binding, dithiols were coupled onto the surface-bound Au particles (**IV**). Renewed dipping of the sample into a solution of Au particles (**V**) led to crosslinking between dissolved and previously bound particles (**VI**).

The spatial selectivity of the assembly process was quantified by preparing macroscopic patterns on glass slides that could be probed by UV/Vis absorption spectroscopy. In Figure 3 we compare three absorption spectra. Spectrum **a** is that of a particle solution in toluene. Spectra **b** and **c** were taken from the same glass slide, and correspond to areas that were exposed to light (**b**) or kept in the dark (**c**) prior to binding gold nanoparticles. To amplify

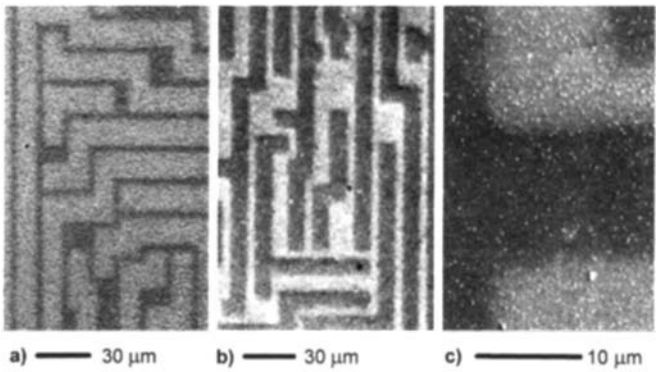

Figure 2. a) Optical microscope image of Au nanoparticles assembled on a glass substrate. The particles assemble preferentially on areas which have been exposed to light through a microchip mask. These areas appear as the darker parts of the image. To obtain a good contrast, the dithiol amplification procedure described in the text was carried out four times. b) SEM image of Au nanoparticles assembled on a silicon substrate. In this image, the lighter parts represent the areas on which the gold particles assembled. The resolution of light-directed particle binding is at least 3 μm. Dithiol amplification was carried out three times. c) SEM image at higher magnification. The image reveals some nonselective binding.

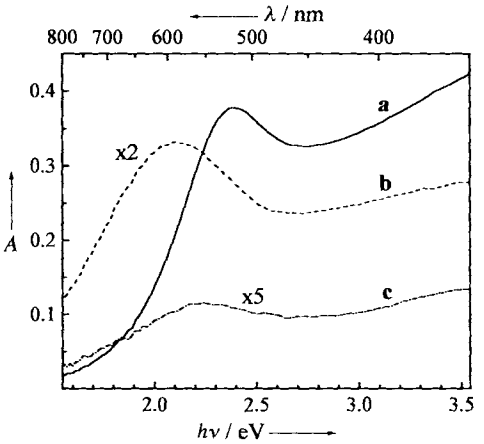

Figure 3. UV/Vis absorption spectra of Au nanoparticles. Spectrum **a** was taken of a solution of Au particles in toluene. Spectra **b** and **c** were taken of a macroscopically assembled pattern of the particles on a glass substrate to determine the degree of nonselective particle binding. Dithiol amplification was carried out three times. The plasmon absorption around 2.1 eV in spectrum **b**, taken on an area of the pattern that has been exposed to light prior to particle binding, is about seven times stronger than that of spectrum **c**, taken on an area that was kept in the dark. This result implies about 15% nonselective particle binding. For more details, see text; A = absorbance.

the macroscopic pattern, the dithiol treatment was carried out three times. The plasmon band around 2.1 eV and 2.4 eV is the optical signature of the gold particles and is detected in all three samples. In spectrum **b** the maximum absorption strength of the plasmon band is about seven times that of spectrum **c**, suggesting a ratio of about 15% unspecific binding. The shift and energy broadening of the plasmon band for the substrate-bound particles is probably due to differences in the dielectric environment and particle–particle interactions. In fact, the band shown in spectrum **b** is shifted towards lower energies than the band in spectrum **c**, suggesting stronger particle–particle interactions in the thicker film.

The method described here for the light-directed assembly of nanoparticles is a general approach that should make the preparation of complex nano/micro structures possible. Since the surface-bound amino group can be derivatized to give a thiol terminus, the light-directed assembly of CdS-, CdSe-, and other semiconductor or metal particles should be feasible. Thus, by stepwise deprotecting and derivatizing the surface groups, it should be feasible to build up structures consisting of different kinds of nanoparticles. It will be an interesting challenge to investigate the electronic, optical, and catalytic properties of such structures. It will also be a very interesting experiment to decrease the dimensions of the prepared patterns down to the submicron scale by using optical nearfield and solid imersion lens techniques.

Experimental Section

Preparation of photosensitive glass and silicon substrates: microscope cover slides and pieces of silicon wafers were cleaned as described in ref. [9] and stored under deionized water (18.2 MΩ cm) until needed. To treat the substrates with 3-aminopropyldimethylethoxysilane we used the experimental setup described by Haller [10]. The dried substrates were put into a 3.0 mM solution of the silane in dry toluene and heated at reflux under argon overnight. Following standard procedures for solid-phase peptide synthesis [11], NVOC–GLY (which was prepared as described in ref. [7]) was coupled to the surface amino groups. For this reaction diisopropylcarbodiimide (DIC) was used to activate the free NVOC–GLY carboxy group. The photosensitive substrates were stored under argon at −18 °C and used for the lithographic experiments within one week. All preparations with the light-sensitive NVOC group were carried out in the dark.

Photolytical deprotection of surface bound NVOC–glycine: The photosensitive substrates were covered with a microchip or macroscopic mask and irradiated with a 1000 W tungsten halogen lamp for about 40 min. To avoid sample damage by UV irradiation with short wavelengths, a 340 nm longpass filter was used. The success of removing the NVOC groups could be tested by treating the prepared free amino groups with ATTO–TAG (Molecular Probes) [12]. The slide was imaged with a Reichert-Jung MET fluorescence microscope equipped with a RCA silicon intensified camera.

Preparation of gold nanoparticles and coupling to surface amino groups: gold nanocrystals stabilized with dodecylamine molecules (2.6 nm metal-core diameter) were prepared according to reaction Scheme 1 described in reference [8]. In order to treat the lithographically patterned substrates, we dissolved these particles in toluene (concentration corresponded to an optical density of 0.5 for a 0.5 cm pathlength at 550 nm). The substrates were kept in this solution overnight under ambient conditions. To amplify particle binding the slides were washed with toluene and acetone and then immersed into a solution of 100 μL (0.5 mmol) 1,8-octanedithiol in 5 mL acetone for 1 h. After washing the substrates with toluene, they were treated again with a fresh particle solution overnight. This amplification process could be repeated several times. To investigate the ratio of nonspecific binding, UV/Vis spectra of a macroscopic pattern on a glass slide were taken with a Hewlett Packard 8451 A Diode Array Spectrophotometer.

Sample immaging of selectively bound gold particles: SEM images were taken with a Cambridge 360 scanning electron microscope operated at 15 kV. The optical microscope images were taken with a remodeled Reichert-Jung Polyvar Infrapol microscope in reflection mode, equipped with a CCD camera.

The $[Cu_2(O_2CMe)_4(H_2O)_2]/(py)_2CO$ System as the Source of an Unusual Heptanuclear Complex and a Novel Dodecanuclear "Flywheel" Cluster

Vasilis Tangoulis, Catherine P. Raptopoulou, Sofia Paschalidou, Evangelos G. Bakalbassis,* Spyros P. Perlepes,* and Aris Terzis*

Polynuclear transition metal complexes exhibit a fascinating variety of unusual symmetries and structural patterns.[1] The synthetic techniques that provide access to these complexes,[2] the biological relevance of some of these compounds,[3] and the magnetic properties associated with a large number of interacting paramagnetic centers in a single cluster[4] add to their interest.

Reactions between $[Cu_2(O_2CMe)_4(H_2O)_2]$ and $(py)_2CO$ (di-2-pyridyl ketone) have proved to be a rich source of interesting polynuclear copper(II) complexes. For example, in water the system $[Cu_2(O_2CMe)_4(H_2O)_2]/(py)_2CO/ClO_4^-$ yields the aceta-to-bridged, dicubane complex **1**,[5] whereas in MeOH **2** is obtained,[6] in which the four Cu^{II} atoms are coplanar with an ideal

$[Cu_8\{(py)_2C(OH)O\}_8(MeCO_2)_4](ClO_4)_4\cdot 9H_2O$ **1**

$[Cu_4\{(py)_2C(OMe)O)\}_4(MeO)_2](ClO_4)_2$ **2**

rhombic arrangement. Suspecting that we had merely scratched the surface of this chemistry, we decided to investigate the products obtained from the $[Cu_2(O_2CMe)_4(H_2O)_2]/(py)_2CO$ reaction system in the absence of ClO_4^-. Here we report on the copper(II) complexes **3** and **4**, which have unusual structural features, and describe the magnetic properties of **3**, which was obtained in pure form.

$[Cu_7\{(py)_2CO_2\}_3(MeCO_2)_6(OH)_2]\cdot H_2O\cdot 0.5\,MeCN$ **3**

$[Cu_{12}\{(py)_2CO_2\}_6(MeCO_2)_{12}]\cdot MeCN$ **4**

Treatment of $[Cu_2(O_2CMe)_4(H_2O)_2]$ with one equivalent of $(py)_2CO$ in hot MeCN afforded a deep blue solution. Layering of this solution with Et_2O/*n*-hexane (1/1) gave a mixture of well-formed green cubes, violet-blue prisms, and sky blue needles. The difference in color and shape of the crystals allowed manual separation of the three materials. The green and violet-blue crystals proved to be complexes **3** and **4**, respectively, as shown by single-crystal X-ray crystallography; the sky blue needles, which analyzed as $[Cu(O_2CMe)\{(py)_2C(OH)O\}]\cdot$ MeCN, have yet to be obtained in X-ray quality. With the identities of **3** and **4** established, we sought preparative routes to pure materials by slightly modifying the molar ratio of $[Cu_2(O_2CMe)_4(H_2O)_2]$ and $(py)_2CO$. This has so far been successful only for **3**, by employing low concentrations of the reactants.

Compounds **3** and **4** are the first metal complexes to contain doubly deprotonated ions of the hydrated *gem*-diol form of $(py)_2CO$ as ligands. This is a consequence of the high $MeCO_2^-$ to $(py)_2C(OH)_2$ ratio (4:1, 4.7:1) used in the reactions.

Figure 1 shows the molecular structure of the neutral heptanuclear complex **3**,[7] which has one μ_3:η^1:η^2:η^2:η^1-bridging

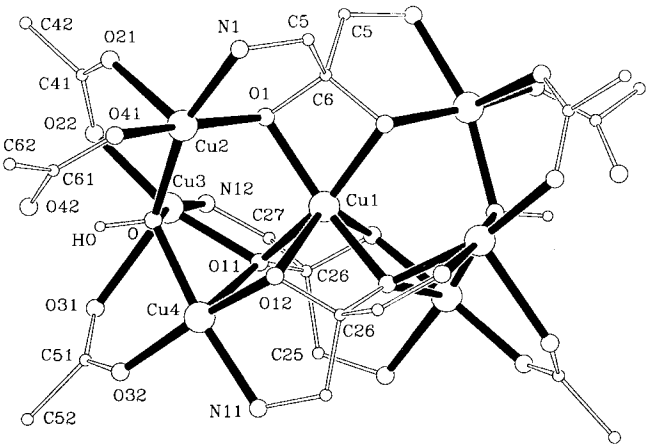

Figure 1. Central structural unit of **3**. Most carbon atoms of the pyridine rings have been omitted for clarity. A twofold axis runs through Cu1 and C6. Distances [Å]: Cu–Cu 3.04–6.44, Cu–O 1.91–2.30, Cu–N 1.99–2.01.

$(py)_2CO_2^{2-}$ dianion (**A**), two μ_4:η^1:η^2:η^3:η^1-bridging $(py)_2CO_2^{2-}$ dianions (**B**), four *syn,syn*-μ_2:η^1:η^1-$MeCO_2^-$ groups, two

monodentate $MeCO_2^-$ ions, and two μ_3-OH^- ions as ligands. A twofold crystallographic axis passes through Cu1 and C6. The four Cu^{II} centers Cu1–Cu4 occupy the corners of a distorted tetrahedron, and as a result of the twofold axis, the seven metal ions form two tetrahedra sharing a common apex at Cu1. The

peripheral metal centers have square-pyramidal geometries ($CuNO_4$ chromophores), while the coordination polyhedron of Cu1 is intermediate between a trigonal prism and a trigonal antiprism (CuO_6 chromophore). To the best of our knowledge, only two other heptanuclear Cu^{II} complexes are known.[8]

The molecule of **4**[7] (Figure 2) is located on a crystallographic center of symmetry. Inspired by its remarkable structure and considering the closest Cu–Cu distances, we refer to this compound as a molecular "flywheel" (**C**). From a different point of view, the inner six Cu^{II} centers (Cu1–Cu3 and their centrosymmetric equivalents) form a chair-shaped cluster that lies within a cluster consisting of the outer metal atoms (Cu4–Cu6 and their centrosymmetric equivalents), which also has a chair conformation. All $(py)_2CO_2^{2-}$ ligands have the μ_4:η^1:η^2:η^2:η^1 ligation mode (**D**) and bridge one outer Cu^{II} center and three Cu^{II} centers of the inner chair. Six *syn,syn*-μ_2:η^1:η^1-$MeCO_2^-$ ions bridge Cu^{II} centers belonging to different chairs, while a monodentate acetate group completes the square-planar NO_3 coordination environment at each outer metal atom. The inner copper atoms are essentially square pyramidal ($CuNO_4$ chromophores). Complex **4** is the second structurally characterized example of a discrete dodecanuclear Cu^{II} aggregate; the other example[9] is $[Cu_{12}L_2(OH)_6](NO_3)_6 \cdot 10H_2O$, where H_6L is a 30-membered, 3:3 macrocyclic ligand derived from the template condensation of 2,6-diformyl-4-methylphenol with 1,3-diamino-2-hydroxypropane. However, two large mixed Ln^{III}–Cu^{II} species (Ln = lanthanide) that contain Cu_{12} structural subunits are known[10]. As far as we can ascertain, the arrangement of the Cu^{II} atoms in **4** is unique for any metal.

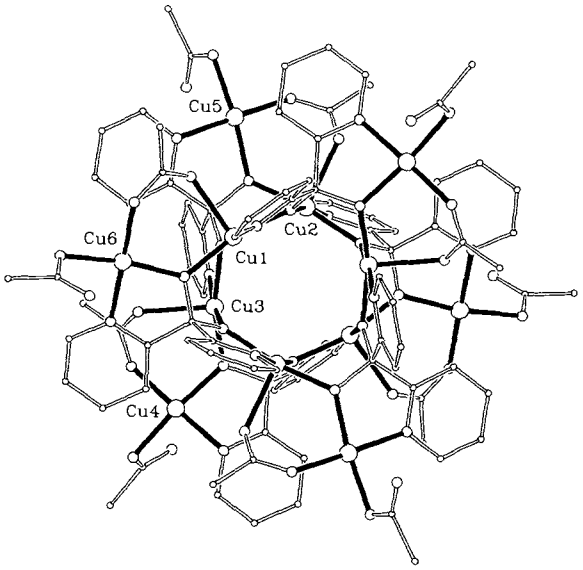

Figure 2. Central structural unit of **4**. For clarity, only the Cu^{II} atoms are labeled; the complex has a center of symmetry. Distances [Å]: Cu–Cu 3.34–11.23, Cu–O 1.93–2.27, Cu–N 1.98–2.04.

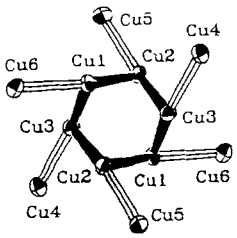
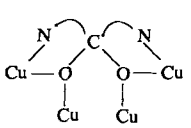


C



D

The small quantity of crystals of complex **4** precludes its magnetic characterization. For **3**, variable-temperature magnetic susceptibility measurements (300–4 K, applied field strength 0.1 T) reveal an overall antiferromagnetic coupling: the X_mT value decreases from 2.36 $cm^3 mol^{-1} K$ at room temperature to 0.435 $cm^3 mol^{-1} K$ at 4 K (X_M is the molar magnetic susceptibility per heptamer). Magnetization measurements at 3 K in the field range 0–5 T indicate that the ground state is $S = 1/2$. A thorough magnetic study and EPR measurements of **3** are in progress.

In summary, $[Cu_2(O_2CMe)_4(H_2O)_2]/(py)_2CO$ chemistry continues to be a source of polynuclear complexes with novel structural types and interesting properties.

Experimental Section

Solid $[Cu_2(O_2CMe)_4(H_2O)_2]$ (0.24 g, 0.60 mmol) was dissolved with stirring in a solution of $(py)_2CO$ (0.11 g, 0.60 mmol) in hot MeCN (28 mL). The resulting deep blue solution was layered with a 1:1 mixture of Et_2O and *n*-hexane (35 mL). Slow mixing yielded a mixture of green cubes of **3**, violet-blue prismatic crystals of **4**, and sky blue needles of an as-yet unidentified product. The three products were readily separated manually. Employing 0.60 mmol of $[Cu_2(O_2CMe)_4(H_2O)_2]$, 0.51 mmol of $(py)_2CO$, 150 mL of MeCN and 160 mL of Et_2O/*n*-hexane (1/1), gave only green cubes of **3** (yield ca. 15%). The two complexes gave satisfactory elemental analyses (C,H,N). UV/vis (DMF, λ_{max} [nm]): **3**: 338, 359, 375, 720. **4**: 345, 365, 580, 640.

Kinetically Stabilized [4]Paracyclophane—The 1,4-Bis-(dicyanomethylene)-2-ene Derivative: ^{1}H NMR Measurement and Assessment of Its Diatropicity**

Masahiro Okuyama and Takashi Tsuji*

[4]Paracyclophanes are the most strained of known paracyclophanes, but their extreme thermal instability has thwarted the exploration of their physical and chemical properties.[1-4] They are persistent only under matrix isolation at low temperature and are rapidly consumed in fluid solution even below −130 °C.[3, 4] Steric strain in [4]paracyclophanes is, however, mainly localized on the bridgehead carbon atoms, and their extreme lability also arises from the high propensity for undergoing addition at the bridgeheads. This tendency suggests that the system may be kinetically stabilized, to some extent at least, by introducing sterically demanding substituents that specifically shield the bridgehead carbon atoms from access by other reagents. We report here that the skeleton of [4]paracyclophane is kinetically stabilized successfully in **1** (Figure 1) to permit the observation of ^{1}H NMR spectrum and the evaluation of its diatropicity.

The preparation of **8**, the precursor of **1**, was carried out as outlined in Scheme 1. The addition of singlet oxygen to **2**[5] afforded *endo*-peroxide **3** as stable, colorless crystals. When treated with Et_3N, **3** was smoothly transformed into **4**, and subsequent selective hydrogenation of the enone moiety of **4** with Bu_3SnH and $[Pd(PPh_3)_4]$[6] followed by pyridinium chlorochromate (PCC) oxidation provided dione **6**. The β-ala-

nine-catalyzed condensation of malononitrile[7] to **6** furnished **7**, which was readily converted into **8** upon treatment with pyridinium bromide perbromide.

The UV/Vis spectrum (Figure 2) of **8** in a glassy mixture of isopentane–ether at 77 K exhibits a strong absorption band with a fine structure in the region of 300–390 nm. Irradiation of

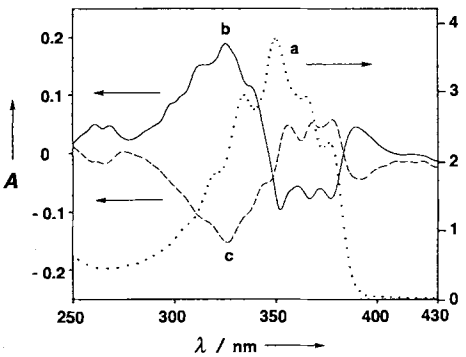

Figure 2. UV/Vis absorption spectra measured in ether–isopentane (1:1) at 77 K. a) **8** (λ_{max}(log ε) = 346 nm (5.15)); b) difference spectrum obtained by subtracting the above spectrum from that recorded after irradiation with light of wavelength 365 nm; c) difference spectrum between the spectra before and after further irradiation (>400 nm).

the mixture (λ = 365 nm) led to the development of a broad absorption band between 270 and 420 nm at the expense of the above characteristic band. The process was reversed by irradiating the resulting mixture with light of wavelength >400 nm, with which only the newly generated species was excited, and **8** was almost quantitatively regenerated as demonstrated by the accompanying spectral change. Ready photoisomerization to a Dewar benzene derivative is a feature common to [4]paracyclophanes,[3, 4] and the above observation strongly suggested that the species generated from **8** was **1**.

The generated intermediate was, however, remarkably stable for [4]paracyclophane and remained intact for more than 1 h in isopentane–ether at −50 °C, thus permitting the measurement of an ^{1}H NMR spectrum (Figure 3). The ^{1}H NMR spectrum of

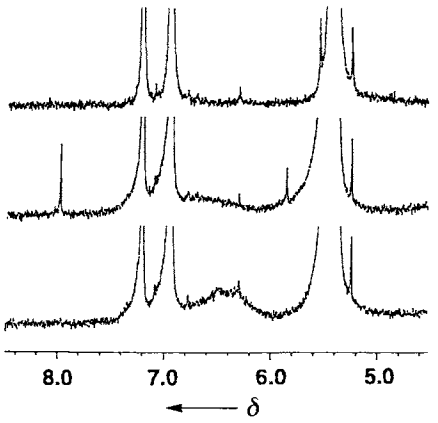

Figure 3. Changes in the ^{1}H NMR spectrum (400 MHz) observed upon irradiation of **8** in CD_2Cl_2 at −90 °C. Top: Before irradiation. Signals at $\delta = 6.93$ and 7.20 are due to H^b and H^a of **8**, respectively, and an intense peak at $\delta = 5.40$ is due to residual protons in the deuterated solvent. Middle: Spectrum after irradiation at 365 nm. Bottom: After further irradiation at >400 nm.

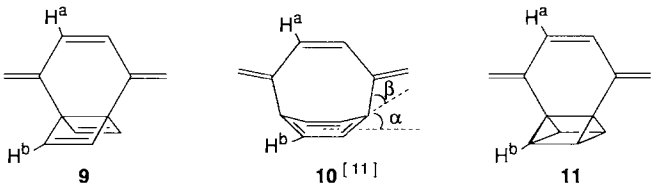
8 (in CD_2Cl_2) exhibits a pair of singlets at $\delta = 6.93$ and 7.20 in a ratio of 2:1. Irradiation of **8** with 365 nm light at −90 °C led to the development of a pair of weak singlet signals with an intensity ratio of about 1:2 at $\delta = 5.85$ and 7.97, respectively;[8] the signal of H^a has thus been shifted upfield by $\Delta\delta = 1.35$ and that of H^b downfield by $\Delta\delta = 1.04$ upon the transformation of **8** into the product. When the resulting mixture was irradiated with light of wavelength longer than 400 nm, the latter pair of signals disappeared to restore the original two line spectrum; these shifts correspond closely with the changes in the UV/Vis spectra. If the species generated from **8** is indeed **1**, the observed chemical shift changes imply the induction of a substantial aromatic ring current in its bent benzene ring moiety. The extremely simple ^{1}H NMR spectrum with such low signal intensity, however, suggested the possibility that the observed signals were due to an unknown side product. Therefore, recourse to computational analysis was made to confirm the structural assignment.

Geometrical optimization and calculations of proton chemical shifts were carried out for truncated systems **9**–**11**, since



9 **10**[11] **11**

computations for **1** and **8** to reasonable accuracy were impractical.[9] The results are summarized in Table 1. Calculated chemical shifts (GIAO[9]/6-31 + G*//B3LYP/6 − 31G*) are not in particularly good agreement with the experimental values owing to the omission of the substituents, but the results are quite instructive. Thus, H^a is predicted to be upfield shifted by $\Delta\delta = 1.34$ and H^b downfield shifted by $\Delta\delta = 1.58$ upon the isomerization of **9** to **10**, in good agreement with the experimental observation. The corresponding prismane derivative is apparently incompatible with the observed signals. Because it is expected that the effects of the cyano groups on the chemical shifts are largely compensated in those chemical shift changes, the calculation results provide a strong support for the structure **1**, and suggest that relatively strong diatropicity is sustained in the aromatic ring moiety of **1** despite its extreme bending.[11, 12]

Table 1. Calculated ^{1}H chemical shifts for **9**–**11** [a].

Compound	$\delta(H^a)$	$\Delta\delta(H^a)$ [b]	$\delta(H^b)$	$\Delta\delta(H^b)$ [b]
9	6.30	–	6.82	–
10	4.82	−1.48	8.38	1.56
11	6.51	0.21	2.72	−4.10

[a] GIAO [10]/6-31 + G*//B3LYP/6-31G*. [b] Shifts of the ^{1}H NMR signals relative to those of **9**; positive values denote downfield shifts.

Schleyer and his co-workers recently proposed two probes as effective aromaticity/antiaromaticity criteria: the diamagnetic susceptibility exaltation (Λ)[13] and the nucleus-independent chemical shift (NICS).[14] According to those definitions, significantly exalted (negative) Λ and large negative NICS denote aromaticity, whereas positive Λ and NICS indicate antiaromaticity. NICS calculated at the center[15] of the C_6 ring moiety of **10** (GIAO/6-31 + G*//B3LYP/6-31G*) is −9.0 as compared with −9.7 for planar benzene, and Λ computed for a bent benzene whose geometry was constrained to that present in **10** is −11.6 ppm cgs (CSGT[16]/6-311 + G**) as compared with −15.1 ppm cgs reported for planar benzene.[17, 18] The relatively large negative Λ and NICS values, coupled with the calculated small degree of bond alteration in the C_6 ring in **10** (0.022 and 0.018 Å at the MP2/6-31G* and B3LYP/6-31G* levels, respectively), suggest that **10** and, accordingly, **1** retain relatively good electron delocalization in their bent benzene rings.[19]

[11] According to the theoretical calculations (B3LYP/6-31G*), **10** is C_{2v} symmetric, and the deformation angles α and β, which give a measure of the degree to which the benzene ring is bent, are 28.6° and 43.0°, respectively.
[12] The UV/Vis absorption spectrum of **1** is similar in shape to that of [4]paracyclophane-1,3-diene for which a similar degree of deformation in the benzene ring has been predicted by theory[4]. No particular absorption suggesting electronic interactions between the electron-deficient side chain and the bent benzene ring in **1** was detected. The kinetic stabilization of **1** seems to be rationalized on the steric grounds, though the contribution of electronic effects exerted by the cyano groups is not rigorously ruled out.

One-Dimensional Semiconducting Chains of the Quaternary Zintl Anion in $(Et_4N)_4[Au(Ag_{1-x}Au_x)_2Sn_2Te_9]$**

Sandeep S. Dhingra, Dong-Kyun Seo, Glen R. Kowach, Reinhard K. Kremer, Julie L. Shreeve-Keyer, Robert C. Haushalter,* and Myung-Hwan Whangbo*

Dedicated to Hans Georg von Schnering on the occasion of his 65th birthday

Several chemical approaches have been developed over the last two decades for preparing one-dimensional conducting materials such as platinum chain compounds, the salts of organic donor molecules, and transition metal chalcogenides.[1] We recently initiated a study designed to determine the possibility of introducing unpaired electrons into closed-shell, low-dimensional Zintl-phase materials, by suitable structural modifications or elemental substitutions, hence increasing their electrical conductivity. In several cases the structures achieve a closed-shell electronic configuration by undergoing site specific elemental substitutions (for example $K_9GeIn_9Sb_{22}$)[2] or forming exceedingly complex structures (for example $K_8In_8Ge_5As_{17}$ or $K_5In_5Ge_5As_{14}$).[3] Likewise, several binary and ternary 1-D Zintl anions such as $InGeTe_4^-$, $HgSnTe_4^{2-}$, $Hg_2Te_5^{2-}$, $Hg_3Te_7^{4-}$, $Hg_2Te_4^{2-}$, $As_2Te_5^{2-}$, and $InTe_2^-$[4] possess structures consistent with closed-shell electronic configurations.

One particularly desirable type of 1-D conducting solid, which is analogous to a macroscopic copper wire surrounded by an organic polymer insulator, would be composed of chains of covalently bonded metals surrounded by insulating organic regions that hinder electronic coupling between the molecular wires. We report here the preparation of a semiconductive 8 Å-wide, 1-D chain composed of four different elements surrounded by insulating organic material. The synthesis, crystal structure, physical properties, and electronic structure of the first quaternary Zintl-anion material $(Et_4N)_4[Au(Ag_{1-x}Au_x)_2Sn_2Te_9]$ ($x = 0.32$), which exhibits a delocalized 1-D band structure, are discussed.

The title compound is prepared by ethylenediamine (en) extraction of a pentanary alloy of composition $K_6AuAg_2Sn_2Te_9$. Other compositions were attempted, including $K_4AuAg_2Sn_2Te_9$, but they gave either no products or significantly lower yields. After the alloy is extracted, and Et_4N^+ cations are added to the filtrate, it generally takes several months for the first crystals to appear. This is followed by a period of more rapid crystal growth. The crystal quality, and to a lesser extent the yield, vary from reaction to reaction, but no other products are detected and all crystals examined contain Au, Ag, Sn, and Te.

Crystals of $(Et_4N)_4[Au(Ag_{1-x}Au_x)_2Sn_2Te_9]$ contain unprecedented, linear, 1-D chains of composition $Au(Ag_{1-x}Au_x)_2Sn_2Te_9^{4-}$ (Figure 1) separated by Et_4N^+ cations.[5] The closest

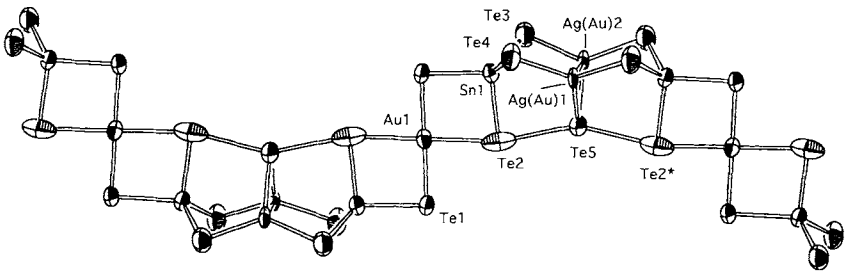

Figure 1. Structure of the 1-D $Au(Ag_{1-x}Au_x)_2Sn_2Te_9^{4-}$ chain drawn with thermal ellipsoids at the 50% probability level. In this initial model Te2 was refined as a single, fully occupied position, and the Ag1 and Ag2 positions were refined with Ag occupancy only. Selected bond lengths [Å]: Au1–Te2 2.970(6), Te2–Te5 3.187(6), and angle[°]: Te2-Te5-Te2 154.7(4).

interchain Te···Te contact is 7.0 Å. The Au atom has distorted square-planar coordination, whereas the Sn and mixed Ag/Au site show tetrahedral and trigonal-planar coordination, respectively. Structure refinement (by fixing the thermal parameter of the site and allowing the Au:Ag ratio to refine) gives 32% substitution of Au onto the Ag1 and Ag2 sites; a small stoichiometric range is apparent from refinements of other crystals. Substitution is possible since Au–Te and Ag–Te bond distances in trigonal-planar coordination are very similar.[6] From an initial refinement with a single Te2 position (see below), each Te atom is twofold coordinated if only bonds shorter than 3 Å are considered. The prominent structural feature of the polyanion is the $\{$-Au-Te-Te-Te-$\}_\infty$ strand composed of Au atoms and approximately linear Te2-Te5-Te2 units ($\sphericalangle$ Te-Te-Te = 154.7°). The two symmetry-equivalent Te2–Te5 distances are 3.187(6) Å, which is longer than a typical Te–Te single bond (2.75 Å) but much shorter than the van der Waals Te···Te contact (4.0 Å). This suggests a bonding interaction of the type observed in tellurides such as Te_{12}^{2-}, $HgTe_7^{2-}$, $Cu_4SbTe_{12}^{3-}$, and $Au_2Te_{12}^{4-}$,[7] as well as some other solid-state tellurides.[8] The Au–Te2 distance of 2.970(6) Å is much longer than Au–Te contacts (about 2.65 Å) found for $Au_2Te_{12}^{4-}$, $KAu_9Te_7^{4-}$, $K_2Au_4Te_4^{2-}$, and $Au_2Te_4^{2-}$.[9] However, the Te2

atoms have very large anisotropic displacements along the chain running parallel to the [010] direction (Figure 1). This observation is essential to understanding the electronic structure of $(Et_4N)_4[Au(Ag_{1-x}Au_x)_2Sn_2Te_9]$ discussed below.

Given the oxidation states I for Ag and Au, IV for Sn, and −II for Te, the charge on $Au(Ag_{1-x}Au_x)_2Sn_2Te_9$ is −7, which is in disagreement with the charge of −4 inferred from the crystal structure and elemental analysis. (One may consider Au atoms in square planar units such as AuI_4 and $AuTe_4$ to be Au^{3+}, but theoretical and experimental studies show that they are Au^+.[10]) In this simplified analysis, the close Te2–Te5 contacts (3.19 Å) within each linear Te_3 trimer were neglected. There is one Te_3 trimer per formula unit $Au(Ag_{1-x}Au_x)_2Sn_2Te_9$, so the charge is balanced if each Te_3 trimer is considered to possess a charge of −3. In general the formal charge of −2 is associated with an oligomeric chain Te_n^{2-} with Te-Te-Te bond angles of about 90°. A linear Te_3 trimer has three σ orbitals made up of p orbitals, that is, bonding (σ), nonbonding (*n*), and antibonding (σ*) levels (Figure 2). Both the bonding and nonbonding levels can accommodate electrons, so the maximum charge associated with a linear Te_3 trimer is −4. Since the Te_3^{3-} units in the $Au(Ag_{1-x}Au_x)_2Sn_2Te_9^{4-}$ chain have half-filled nonbonding levels, the $Au(Ag_{1-x}Au_x)_2Sn_2Te_9^{4-}$ chain should possess a half-filled band largely composed of the nonbonding levels. This is confirmed by the electronic band structure of an isolated $Au(Ag_{1-x}Au_x)_2Sn_2Te_9^{4-}$ chain (Figure 3a) calculated by the tight-binding extended

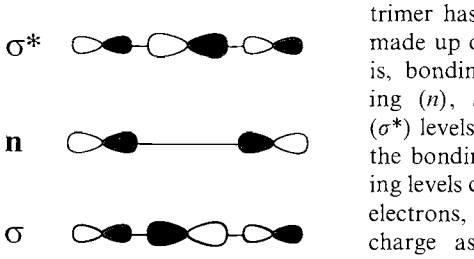

Figure 2. Three σ orbitals derived from the p orbitals of a linear Te_3 trimer.

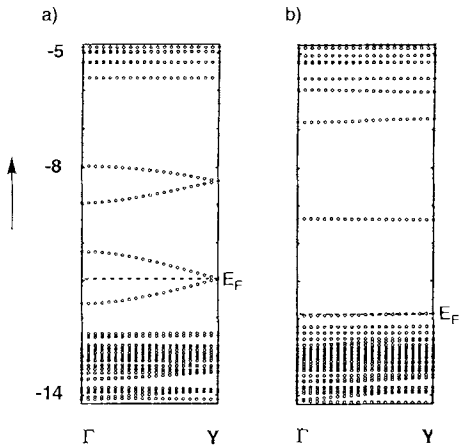

Figure 3. Dispersion relations of the electronic energy bands of an isolated $Au(Ag_{1-x}Au_x)_2Sn_2Te_9^{4-}$ chain calculated for a) the average structure in which the Te2 position is not split and b) the structure with a Peierls distortion constructed with the split positions of Te2 (see Figure 6). The horizontal, broken line refers to the Fermi level. Γ = 0 and Y = $b^*/2$.

Hückel method.[11] The repeat unit cell of the $Au(Ag_{1-x}Au_x)_2Sn_2Te_9^{4-}$ chain has two formula units (hence two Te_3^{3-} units), so the half-filled band is folded, and the Fermi level occurs at the zone edge. This band is largely composed of the σ nonbonding orbitals of the linear Te_3 trimers and the $d_{x^2-y^2}$ orbitals of the Au atoms. Since the $Au(Ag_{1-x}Au_x)_2Sn_2Te_9^{4-}$ chain has a partially filled band, one might expect $(Et_4N)[Au(Ag_{1-x}Au_x)_2Sn_2Te_9]$ to be metallic. However, since it is a 1-D band $(Et_4N)_4[Au(Ag_{1-x}Au_x)_2Sn_2Te_9]$ should be susceptible to a Peierls distortion that would open a band gab at the Fermi level.[12]

The magnetic susceptibility of $(Et_4N)_4[Au(Ag_{1-x}Au_x)_2Sn_2Te_9]$ indicates that the chain is diamagnetic and is nearly independent of temperature down to 4 K; the gram-susceptibility of approximately -2×10^{-7} emu g^{-1} is similar to that of other chalcogenide semiconductors (Figure 4a). Single crystals of $(Et_4N)_4[Au(Ag_{1-x}Au_x)_2Sn_2Te_9]$ grow to a maximum size of about $30\times30\times80\ \mu m^3$ and form mostly as clusters of crystals, thereby precluding conventional four-probe electrical resistivity measurements. Resistivity data obtained by the microwave cavity perturbation technique[13] (though confined to a small range of temperatures due to sample decomposition above about 80 °C) show, by extrapolating to 0 K and assuming that the activated conductivity is purely intrinsic, that $(Et_4N)_4[Au(Ag_{1-x}Au_x)_2Sn_2Te_9]$ is a semiconductor with a band gap of 0.45(5) eV (Figure 4b). However,

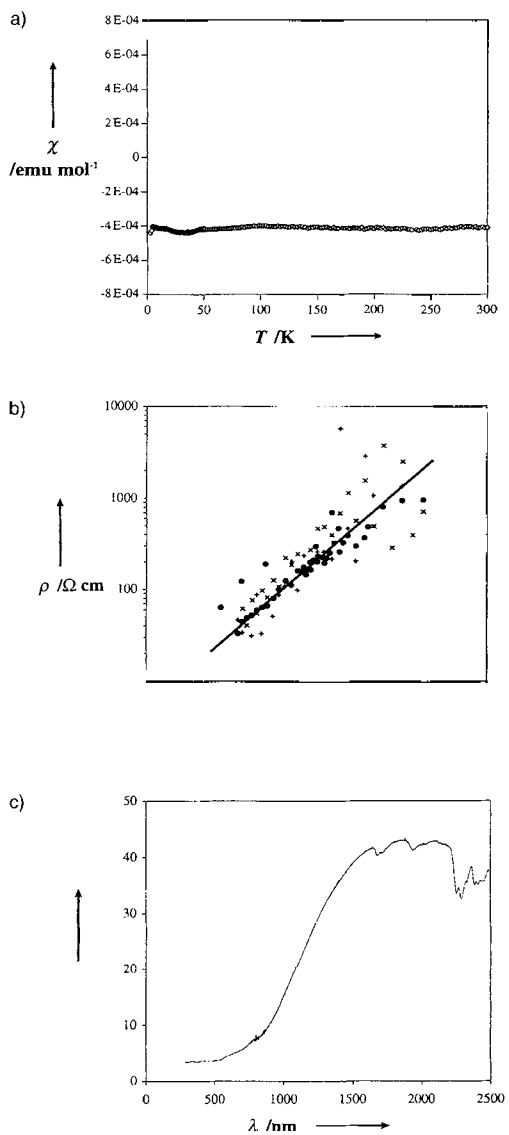

Figure 4. Physical properties of $(Et_4N)_4[Au(Ag_{1-x}Au_x)_2Sn_2Te_9]$. a) Temperature-dependence of the magnetic susceptibility χ. b) Temperature-dependent resistivity ρ measured by the microwave cavity perturbation technique. Three experiments were carried out with different quartz tube diameters [2mm (+), 1 mm (×), and 0.5mm (•)]. A band gap of 0.45(5) eV is extracted from the $\ln\rho - T^{-1}$ slope. b) Optical diffuse reflectance R versus wavelength λ of incident light illustrating the absorption band edge.

microwave absorption measures the total conductivity including extrinsic conductivity from defect-generated charge carriers. Optical diffuse reflectance measurements show a band gap of 0.95(5) eV (Figure 4c). To explain this semiconducting character, one must conclude that the $Au(Ag_{1-x}Au_x)_2Sn_2Te_9^{4-}$ chains of $(Et_4N)_4[Au(Ag_{1-x}Au_x)_2Sn_2Te_9]$ have undergone a Peierls distortion above room temperature.

A Peierls distortion that is appropriate for the half filled band of the $Au(Ag_{1-x}Au_x)_2Sn_2Te_9^{4-}$ chain makes two formula units of its repeat unit cell (Figure 1) nonequivalent, thus opening a band gap at the Fermi level. This distortion should involve primarily the displacement of the Te2 atoms, because their thermal parameter U_{22} (along the 1-D chain direction) is unusually large. Such an elongated thermal ellipsoid occurs when the real position of the Te2 atom is not at the center but close to either end of the ellipsoid.[14] In fact, the residual electron density around Te2 suggests that it is appropriate to refine Te2 as two half Te atoms (that is, Te2A and Te2B) on two independent sites along the chain. Half the electron density expected for a Te atom was placed on the two electron density peaks from the difference Fourier map (Figure 5a). Unconstrained refinements lower the residual R value, and the two independent Te positions display nearly spherical thermal ellipsoids of very similar magnitude (Figure 5b). As a result, the structure is better described by the two Te positions that are separated by 0.65 Å and occupied to 50%. In reality, either Te2A or Te2B should be 100% occupied, and the 50% occupation of both positions is a result of equal probability of populating them. The Te2A and Te2B positions give bond lengths of Au1–Te2A = 2.666(4) Å and Te5–Te2B = 2.855(4) Å, which agrees well with the values expected for Au–Te and Te–Te single bonds.

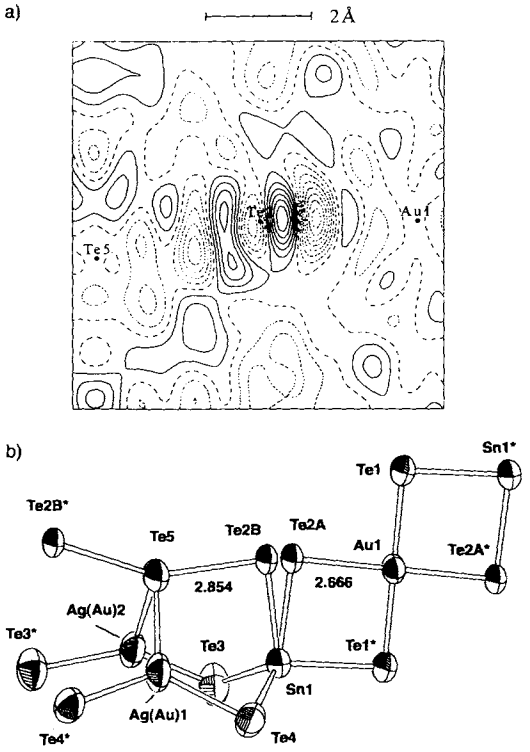

Figure 5. a) Contoured electron density difference map after refining a single, fully occupied Te2 position demonstrating peaks on either side of Te2. b) ORTEP depicting the half-occupied Te2A and Te2B positions and thermal parameters at the 50% probability level. Bond lengths [Å] within the chain: Au1–Te1 2.599(3), Au1–Te2A 2.666(4), Te2A–Te2B 0.648(5), Te2B–Te5 2.854(4), Sn1–Te2A 2.760(10), Sn1–Te2B 2.741(10), Sn1–Te3 2.707(4), Sn1–Te4 2.716(4), Ag1–Te4 2.621(3), Ag2–Te3 2.610(3), Ag1–Te5 2.724(5), Ag2–Te5 2.725(5), Ag1–Ag2 3.1028(2), Te3–Te4 4.467(5). Selected bond angle [°]: Te2B-Te5-Te2B 153.4(4).

Since a superstructure was not observed, we must assume a distortion model that is consistent with the lattice parameters and symmetry. We searched for a noncommensurate lattice change with transmission electron microscopy (TEM), but the sample decomposed rapidly in the electron beam. One would not expect any change in the X-ray data corresponding to a doubling of the cell concomitant with distortion of the $AuTe_3$ unit, because the other atoms in the 1-D chain not involved in the delocalized states (for example Ag, Sn, and two-coordinate Te atoms) are arranged such that the actual cell is twice as long as each individual $AuTe_3$ unit. No changes in unit cell parameters were observed at −160 °C. We were also unable to observe loss of the Peierls distorted state below the sample decomposition temperature of about 80 °C. On the basis of the split positions of the Te2 atoms, we consider a Peierls distortion relevant for the $Au(Ag_{1-x}Au_x)_2Sn_2Te_9^{4-}$ chain. The two formula units of its repeat unit cell can be made nonequivalent when the split positions are chosen as depicted in Figure 6. The small arrow at each Te2 indicates the choice of the split position on the left-hand side (LHS) or right-hand side (RHS) of the average position. Therefore, in Figure 6a the coordination of the LHS Au atom becomes more square planar, and that of the RHS Au atom more linear (distortion pattern A); this is reversed in Figure 6b (distortion pattern B). Except for the sense of the displacement vectors, the two patterns are equivalent.

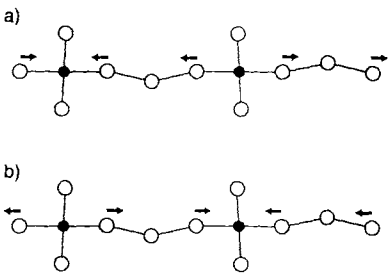

Figure 6. Two ways of using the split positions of Te2 to introduce a Peierls distortion in the $Au(Ag_{1-x}Au_x)_2Sn_2Te_9^{4-}$ chain. The filled and empty circles represent the Au and Te atoms of the $\{$-Au-Te-Te-Te-$\}_\infty$ strand. The small arrow at each Te2 atom indicates which of its two split positions (that is, the LHS and RHS positions of the average site) is chosen in the distortion patterns a) A and b) B.

Figure 3b shows the band dispersion relations calculated for the $Au(Ag_{1-x}Au_x)_2Sn_2Te_9^{4-}$ chain with the Peierls distortion defined in Figure 6a or 6b with the split Te2A and Te2B positions. As expected, the distorted $Au(Ag_{1-x}Au_x)_2Sn_2Te_9^{4-}$ chain has a band gap. (The calculated band gap is 2.5 eV and larger than those estimated from resistivity and optical measurements (0.45 and 0.95 eV, respectively). However, this is not surprising due to the semi-empirical nature of the calculation.) In the extreme case, this distortion would result in some Te···Te nonbonding contacts, as well as alternating two- and four-coordinate Au centers (from which one may suppose an average formal Au oxidation state of II from equal amounts of Au^{I} and Au^{III}) along the chain, but we do not think this extreme distortion is an important contribution to the actual electronic structure; the resulting "ionic" structure would not be expected to show the narrow bandgap and low resistivity experimentally observed.

The synthesis and characterization of the first quaternary Zintl anion, $Au(Ag_{1-x}Au_x)_2Sn_2Te_9^{4-}$, demonstrates that polymerization of anionic subunits by extraction of alkali/transition/main group alloys is a viable route to novel, low-dimensional conductive materials. Both the physical property mea-

surements and electronic structure calculations are consistent with the formation of delocalized, 1-D electronic states derived from what is formally an unpaired electron in the nonbonding orbital on a Te_3^{3-} unit through intervening Au centers. Magnetic susceptibility, conductivity, and optical measurments show that this 1-D Zintl anion exists in a Peierls distorted state exhibiting semiconducting, diamagnetic behavior. This concept of an organic-insulated conductive wire, combined with the rich structural diversity of the Zintl materials, suggest that many more materials of this type could be prepared.

Experimental Section

All manipulations were performed under helium, and en was distilled from a red solution of K_4Sn_9. An alloy of composition $K_6Ag_2Sn_2Te_9$ was prepared by fusing (about 800 °C) K_2Te (2.000 g, 9.72 mmol), Au (0.638 g, 3.24 mmol), Ag (0.698 g, 6.48 mmol), Sn (0.770 g, 6.48 mmol), and Te (2.894 g, 22.7 mmol) in a quartz tube under argon (1 atm) for 1 min with swirling. This homogeneous melt was crushed to a fine powder, extracted with en (1 g alloy per 10 mL en) for 12–24 hr, and filtered to remove undissolved solid. The dark red-brown extract was added to a vial containing a saturated solution of tetraethylammonium iodide (TEA I, 0.600 g, 2.33 mmol) in en (9–10 mL). The first crystals of $(Et_4N)_4[Au(Ag_{1-x}Au_x)_2Sn_2Te_9]$, which form as tiny, radially protruding intergrowths of black blades, appear after approximately 2–3 months and continue to form for several months thereafter. Yields are typically 1–5% by weight based on alloy; it is noteworthy that there are no other solid products. Elemental analysis calcd for $(Et_4N)_4Au(Ag_{1-x}Au_x)_2Sn_2Te_9$: C 16.17, H 3.39, N 2.36, Au 13.59, Ag 6.17, Sn 9.99, Te 48.32; found: C 16.35, H 3.57, N 2.59, Au 9.25, Ag 5.26, Sn 10.42, Te 50.49.

[5] Crystal structure data for $[N(CH_2CH_3)_4]_4Au_{1.64}Ag_{1.36}Sn_2Te_9$: orthorhombic, $a = 20.448(4)$, $b = 24.315(7)$, $c = 11.540(3)$ Å, $V = 5737(2)$ Å^3, space group *Pnma*, $Z = 4$, $\rho_{calcd} = 2.752$ g cm^{-3}, $M_r = 2376.52$ g mol^{-1}, approximate crystal dimensions = 50 × 50 × 100 mm. $\mu(Mo_{K\alpha}) = 100.18$ cm^{-1}, $\lambda(Mo_{K\alpha}) = 0.71073$ Å, $2\theta_{max} = 45°$, $T = 291(3)$ K. The total data set consists of 4219 reflections collected in the ω-scan mode; of 4218 independent reflections 1462 with $I_o > 3\sigma(I)$ were used for calculations. The data were corrected for Lorentzian, polarization, decompostion (13.5%), and absorption effects (empirical ψ-scans, transmission factors 0.75–1.00). The structure was determined by direct methods (SAPI91) followed by least-squares refinement on F with the teXsan software package. All heavy atoms were refined anisotropically, C and N atoms isotropically, and H atoms not included. Au substitution on the Ag site was accomplished by constraining both atoms to the same site in addition to constraining the anisotropic thermal parameters. The Te2 atom was split into two positions at half occupancy, but the positional and thermal parameters were allowed to freely refine. The 166 parameters were refined to $R(F) = 0.056$ and $R_w(F) = 0.057$ based on a σ weighting scheme; minimum and maximum residual electron density: −1.41 and 1.54 e$^-$ Å^{-3}. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-406539.

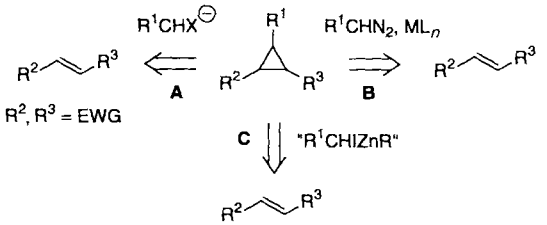
Diastereo- and Enantioselective Synthesis of 1,2,3-Substituted Cyclopropanes with Zinc Carbenoids**

André B. Charette* and Jacinthe Lemay

A significant number of natural products containing 1,2,3-substituted cyclopropanes have been isolated in the last few decades.[1, 2] Traditionally, these cyclopropane units have been prepared by a nucleophilic addition–elimination sequence on α,β-unsaturated carbonyl derivatives (Scheme 1, **A**)[3] or by a



Scheme 1. Different strategies for the cyclopropanation of olefins (EWG = electron-withdrawing group).

cyclopropanation reaction involving the transition metal catalyzed decomposition of diazoesters (**B**).[4, 5] It is clear that the diastereo- and enantiocontrol is a serious limitation in some of these methods. The use of the Simmons–Smith cyclopropanation reaction[6] to generate 1,2,3-substituted cyclopropanes is very rare, and so far no method has provided good diastereo- and enantiomeric levels (**C**).[7, 8] In this communication, we report a new method to generate 1,2,3-substituted cyclopropanes with excellent diastereo- and enantiocontrol by using substituted zinc carbenoids, and we show for the first time that functionalized zinc carbenoids[9] can be prepared and are effective cyclopropanating reagents.

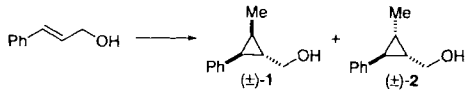
The use of substituted diiodoalkanes as precursors to substituted zinc carbenoids was first reported by Kawabata and Furukawa.[10, 11] Very modest product ratios (1.6–5.4:1) and yields (23–85%) were obtained when allylic alcohols were treated with a mixture of 1,1-diiodoethane (2.0 equiv) and Et_2Zn (1.5 equiv). Since we have already shown that the stoichiometry of the diiodoalkane and Et_2Zn is very important for optimizing diastereomeric ratios and yields,[12] we have initially surveyed different reaction conditions to optimize the diastereoselectivities in the achiral version of this reaction (Table 1). Cyclopropanes **1** and **2** were obtained in greater than 10% yield when cinnamyl alcohol was treated with 1,1-diiodoethane and Et_2Zn under Kawabata's conditions (entry 1). However, the yield, diastereoselectivity, and rate of the reaction increased dramatically if CH_2Cl_2 was used as the solvent (entry 2) or if a twofold excess of the preformed reagent[13] in CH_2Cl_2 was used (entry 3). Finally, significantly good diastereomeric ratios were also observed with five equivalents each of Et_2Zn and CH_3CHI_2 but the yield dropped to 58% (entry 4). These data clearly illustrate the importance of using a noncomplexing solvent in this reaction.

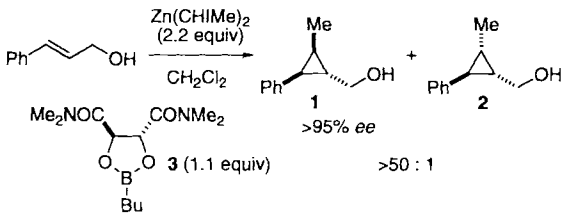
Table 1. Diastereoselective cyclopropanation of cinnamyl alcohol [a].



Entry	Et_2Zn [equiv]	CH_3CHI_2 [equiv]	Yield [%] [b]	Ratio (**1**:**2**) [c]
1	1.5	2.0 [d]	< 10	–
2	1.5	2.0	85	93:7
3	2.2	4.4 [e]	82	89:11
4	5.0	5.0	58	93:7

[a] Unless otherwise stated, all the reactions were carried out at 0 °C in CH_2Cl_2. [b] Yield of isolated product from chromatographically homogeneous material. [c] Determined by ^1H NMR spectroscopy (400 MHz) and by GC of the crude reaction mixture. [d] Solvent: *t*BuOMe. [e] The reagent was preformed prior to the addition of cinnamyl alcohol.

The addition of the chiral dioxaborolane ligand **3**[14] to the reaction had a spectacular effect on stereocontrol in the enantioselective version of this cyclopropanation reaction (Scheme 2). The treatment of a mixture of cinnamyl alcohol and

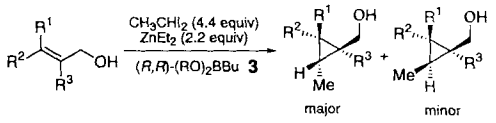


Scheme 2. Enantioselective cyclopropanation with the chiral dioxaborolane **3**.

3 with 2.2 equivalents of the preformed reagent in CH_2Cl_2 at 0 °C resulted not only in a significant increase in the diastereomeric ratio (from 93:7 to 98:2), but also gave an outstanding enantiomeric excess of the major diastereomer.[15]

Several substituted allylic alcohols were submitted to these reaction conditions, and the results are illustrated in Table 2. A particularly striking feature is that excellent diastereo- and enantioselectivities were obtained regardless of the olefin configuration. In all the cases, the relative stereochemistry of the new chiral center was *anti* to the CH_2OH group. The substantial increase in the diastereoselectivity of the reaction mediated by dioxaborolane **3** relative to the achiral version is presumed to be the result of an increase of the steric size of the CH_2OZnR group when bonded to the chiral ligand **3**.

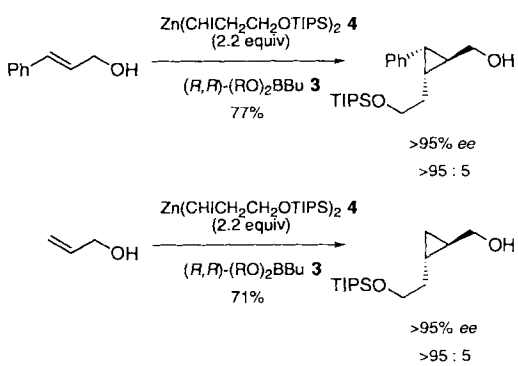
Table 2. Enantioselective cyclopropanation of allylic alcohols [a].



Entry	Allyl alcohol	*ds* [b]	*ee* [%] [c]	Yield [%] [d]
1		> 50:1	98	96
2		14:1	90	83
3		> 50:1	94	80
4		20:1	90	84 [e]
5		15:1	94	87 [e]
6		10:1	93	80 [e]

[a] All the reactions were carried out at 0 °C in CH_2Cl_2. [b] The diastereoselectivities were determined by ^1H NMR (400 MHz) and capillary GC analysis of the crude reaction mixture. [c] Determined by NMR analysis of the derived Mosher's esters (entry 2–4), by capillary GC analysis on chiral stationary phase (entry 1), or by conversion into the chiral α-methylbenzylamide. [d] Yield of isolated product from chromatographically homogeneous material. [e] The yield refers to the corresponding benzoate that was isolated by treating the crude mixture with PhCOCl.

On the basis of these results, we hypothesized that we could use functionalized iodoalkylzinc reagents in these enantioselective cyclopropanation reactions. Knochel has extensively shown that organozinc reagents are compatible with a variety of functional groups[16] but the related functionalized iodoalkylzinc reagents have never been prepared and used as cyclopropanating reagents. This variant would greatly enhance the scope of the reaction, since cyclopropanation with substituted iodoalkylzinc reagents has been limited to $CH_3CHIZnX$ and $PhCHIZnX$.[10, 11, 17] Furthermore, a variety of substituted diiodoalkanes are directly accessible by the alkylation of diiodomethane.[18] The following examples clearly show the potential of this methodology as a convergent synthesis of structurally complex, polysubstituted cyclopropanes. A single isomer was obtained when cinnamyl alcohol or allyl alcohol was



Scheme 3. Reaction of cinnamyl or allyl alcohol with **4** and the chiral ligand **3** (TIPS = triisopropylsilyl).

treated with 2.2 equivalents of **4** (prepared from 1-triisopropylsilyloxy-3,3-diiodopropane[19] and Et_2Zn) and 1 equivalent of **3** (Scheme 3). Furthermore, the diastereo- and enantioselectivity for these processes were excellent.[20]

In summary, we have developed an expedient and efficient synthesis of enantiomerically enriched 1,2,3-substituted cyclopropanes from allylic alcohols. In addition, we have presented the first cyclopropanation reaction of a functionalized iodoalkylzinc reagent. Applications of this methodology to natural product synthesis is currently underway.

Experimental Section

To a solution of Et_2Zn (113 μL, 1.1 mmol) in CH_2Cl_2 (5 mL) at 0 °C was added CH_3CHI_2 (222 μL, 2.2 mmol) over 5 min. After 10 min of stirring at 0 °C, a solution of the allylic alcohol (0.5 mmol) and (*R,R*)-dioxaborolane (**3**) (149 mg, 0.55 mmol) in CH_2Cl_2 (2 mL) was added rapidly by cannula. The ice bath was removed, and the reaction was stirred until TLC analysis showed complete consumption of the starting material (1 h). The reaction mixture was then poured into saturated aqueous NH_4Cl (20 mL), and 10% aqueous HCl (10 mL) was added. The mixture was extracted three times with ether (10 mL), and the combined organic layers were stirred vigorously with 5 M aqueous KOH (15 mL) for 12 h, washed with saturated aqueous Na_2SO_3 (15 mL), with saturated aqueous NH_4Cl (15 mL), and with saturated aqueous NaCl (15 mL), dried over $MgSO_4$, and concentrated under reduced pressure. The residue was purified by flash chromatography to afford the desired cyclopropane.

[19] Prepared in three steps from diiodomethane by the following sequence: a) LiHMDS, allyl bromide (63%); b) O_3, $NaBH_4$ (79%); c) TIPSOTf, Et_3N (94%).

[20] Quite surprisingly, the desired cyclopropane was obtained only in the presence of the chiral ligand. It is conceivable that the chiral ligand plays the important role of stabilizing the reagent. 1-Triisopropylsilyloxy-2-propene that is presumably generated by the decomposition of the carbene was isolated as the major by-product.

Generation of Alkyl(dicarbonyl)(chloro)-ruthenium Dimers in the Ruthenium-Catalyzed Addition of Alkyl Formates to Ethylene**

Sylvie Fabre, Philippe Kalck,* and Guy Lavigne*

The complex $[PPN][Ru(CO)_3(Cl)_3]$ (**1**, PPN = $(PPh_3)_2N^+$) is a convenient catalyst precursor for the hydroesterification of ethylene with methyl formate to furnish methyl propionate[1] (100% conversion, 99% selectivity, initial turnover frequency $TOF_0 = 700\ h^{-1}$).[1–3] To clarify the nature of the active species, we terminated the reaction by freezing once the maximum activity was reached. This gave a solid whose ν(CO) absorption bands [2017(s), 1945(s) cm^{-1}] appeared at slightly higher wavenumbers relative to the active catalyst solution [2003(s, br), 1918(s, br) cm^{-1}]. The solution NMR spectrum of this material indicated that it consists of a mixture of three closely related species **2**–**4**, which exhibit signals characteristic of Ru-bound ethyl and methyl groups.

$[PPN][Ru(CO)_3(Cl)_3]$ **1**

$[PPN][Ru_2(\mu\text{-}Cl)_3(\eta^1\text{-}CH_2CH_3)_2(CO)_4]$ **2**

$[PPN][Ru_2(\mu\text{-}Cl)_3(\eta^1\text{-}CH_2CH_3)(\eta^1\text{-}CH_3)(CO)_4]$ **3**

$[PPN][Ru_2(\mu\text{-}Cl)_3(\eta^1\text{-}CH_3)_2(CO)_4]$ **4**

Single crystals obtained from this mixture were shown by X-ray diffraction analysis to consist of a statistical packing of isomorphous units of these three complexes, which differ only in the nature of the alkyl groups.[4] The first of these compounds to be obtained in pure form was **2**, the crystal structure of which is shown in Figure 1.[5] This is the first ternary alkyl(carbonyl)-

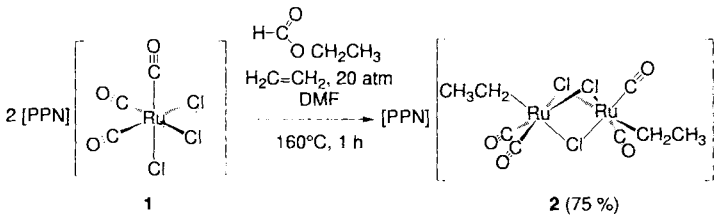
(chloro)ruthenium species reported so far. It belongs to the family of chloride-bridged, face-sharing bioctahedral complexes (FSBO).[6, 7] The present structure corresponds to the *gauche* isomer, which is produced in a strictly stereospecific manner, as indicated by solution NMR spectroscopy.

The second and third constituents of this mixture were identified as the asymmetric ethyl methyl derivative **3** and the bismethyl derivative **4** by NMR spectroscopy. This assignment was corroborated by the presence of the parent-ion multiplets in an electrospray mass spectrum of the original mixture.

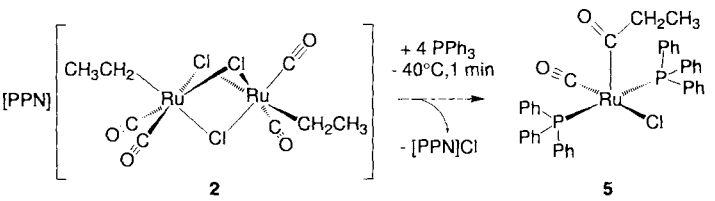
The ethyl groups in **2** and **3** presumably result from insertion of ethylene into the metal–hydrogen bond of an undetected hydrido intermediate. More surprising was the presence, in **3** and **4**, of Ru-bound methyl groups, which could be derived from methyl formate or from DMF. Evidence that they come from the alkyl formate was obtained from parallel catalytic runs with ethyl formate instead of methyl formate under otherwise identical conditions. In this way pure samples of the bisethyl derivative **2** (75% yield) were obtained for the first time, by a straightforward one-pot synthetic route. In further experiments, it was verified that **2** is only formed when both ethylene and ethyl formate are present.



1 **2** (75 %)

Significantly, when complex **2** was used as catalyst precursor in the presence of chloride ions (under experimental conditions otherwise identical to those for **1**)[1b] methyl propionate was obtained after 1 h with 94% conversion and 84% selectivity ($TOF_0 = 650\ h^{-1}$). Furthermore, the chloride ions were incorporated rapidly at 25 °C, as shown by the immediate appearance of a ν(CO) pattern similar to that of the active catalyst solution. Keeping in mind earlier observations[6] of ligand-induced interconversion between face-sharing bioctahedral, edge-sharing bioctahedral, and mononuclear octahedral complexes, we suspected that under catalytic conditions a related type of reversible transformation might be induced by halide ions or by the substrates to regenerate mononuclear alkyl species that are possibly weakly stabilized by coordinated DMF molecules. However, the chloride adduct detected by NMR spectroscopy was not isolated.

To test the ability of other nucleophiles to induce the expected cleavage, we treated **2** with triphenylphosphane. Up to four equivalents of this ligand were readily consumed within seconds above −40 °C to give exclusively the neutral mononuclear acyl complex **5** (Figure 2).[8]



2 **5**

Thus, the addition of the phosphane induces loss of a halide ion, cleavage of the bimetallic unit, and migratory CO insertion. This provides a novel and straightforward synthetic route to a known representative[9] of the family of unsaturated pentacoordinate 16-electron compounds, namely $[Ru\{C(O)R\}(CO)(PR'_3)_2X]$ (R′ = alkyl or aryl).[9, 10] The acyl ligand is coordinated in η^1 fashion in **5** but in η^2 fashion in the iodide derivative $[Ru\{\eta^2\text{-}C(O)CH_3\}(CO)(PPh_3)_2I]$.[10b] This is consistent with theoretical predictions that the chloride ion is a better ($\sigma+\pi$) electron donor than the iodide ion on the scale proposed by Caulton et al. for related π-stabilized unsaturated compounds.[11]

Alkyl complexes that result from the metal-mediated cleavage of the O–alkyl bond of an ester have rarely been detected,[12, 13] although they can be invoked as intermediates in newly reported

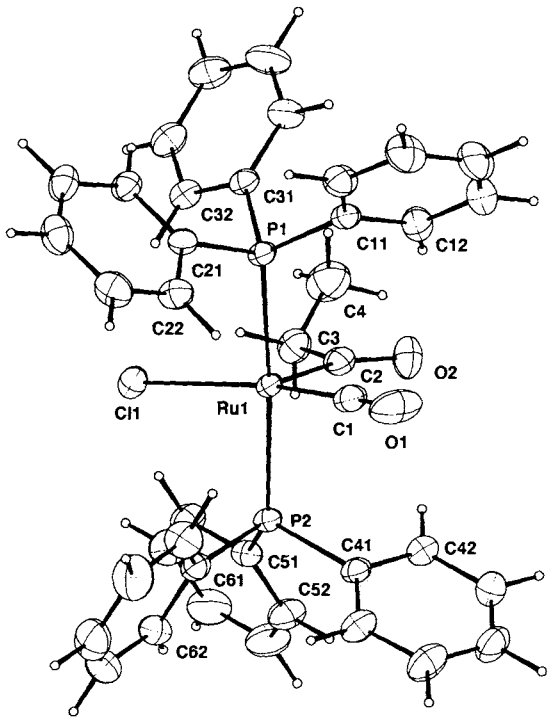


Figure 2. Perspective view of **5**. Selected interatomic distances [Å] and bond angles [°]: Ru(1)–Cl(1) 2.441(1), Ru(1)–C(1) 1.806(3), C(1)–O(1) 1.100(3), Ru(1)–C(2) 1.976(2), C(2)–O(2) 1.191(3), C(2)–C(3) 1.537(4), C(3)–C(4) 1.493(4), Ru(1)–P(1) 2.383(1), Ru(1)–P(2) 2.386(1); Ru(1)-C(2)-O(2) 129.4(2), O(2)-C(2)-C(3) 119.9(2), Ru(1)-C(2)-C(3) 129.4(2), 110.8(2), Cl(1)-Ru(1)-C(2) 115.80(8), C(2)-Ru(1)-C(1) 90.1(1), C(1)-Ru(1)-Cl(1) 154.1(1).

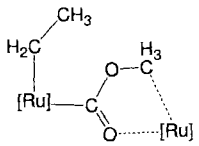
Ru-catalyzed reactions such as the selective alkylation of aromatic compounds with alkyl formates[14] or the synthesis of 2-butanone from ethylene and methyl formate.[15] The systematic and reproducible formation of such complexes in high yield by a catalytic reaction involving quantitative addition of the intact ester function to ethylene[1b] is therefore puzzling. It seems reasonable to assume that the alkyl complexes **2**–**4** are not involved in the catalytic cycle, even though they are effective catalyst precursors. It is not known at which stage of the reaction these complexes appear. If they are generated during the catalytic reaction, loss of selectivity for methyl propionate and formation of methyl acetate would be expected, as a result of transient metalation of methyl groups. However, this is not observed in our experiments.[1b] Alternatively, and more probably, they may be formed only when the catalytic reaction is terminated. The observation that the alkyl groups derived from ethylene and from the alkyl formate are found on different metal centers raises a mechanistic possibility in which the alkyl formate molecule interacts with two independent metal centers, possibly in a stepwise manner: 1) oxidative addition of the formyl C–H bond to one Ru center would give a hydrido(alkoxycarbonyl) species,[16] which can undergo rapid insertion of ethylene, normally followed by reductive elimination of methyl propionate; 2) stopping the ethylene supply might favor the intermolecular association of intermediates at different stages of their transformation, which would lead to decomposition of the ethyl(alkoxycarbonyl) intermediate by interaction of its alkoxycarbonyl group with another intermediate (Scheme 1)[17] in which sites of unsaturation result from loss of coordinated ethylene molecules.[18] This would cause metalation of the alkyl group by cleavage of the O–C-(sp^3) bond, loss of CO_2,[19] and statistical association of the resulting unsaturated fragments.



Scheme 1.

Aggregation of unsaturated mononuclear halogeno-ruthenium fragments by formation of halide bridges to give polymetallic species has been observed in few instances.[7] These polymetallic complexes, like the intermediates formed by coordination of donor solvent molecules, may be regarded as a transient reservoir for active unsaturated intermediates in a catalytic cycle.

We have thus shown that simple carbonyl(chloro)ruthenium complexes can achieve the rather difficult cleavage of the O–C-(sp^3) bond of alkyl formates and can stabilize the resulting alkyl groups, which can be subsequently undergo carbon–carbon bond-forming reactions under remarkably mild conditions.[20]

Experimental procedure

Experimental conditions for the preparation of **2**–**4** were as published [1b], except that a larger amount of **1** was used to facilitate isolation of the complexes ([formate]/[**1**] = 135), and the optional additive NEt_3 was not included.

Mixture **2**–**4**: **1** (0.5 g, 0.6 mmol) and methyl formate (5 mL, 81 mmol) in DMF (Aldrich, 99%, 15 mL) were reacted with ethylene [$p(C_2H_4)$ = 20 bar] at 160 °C. The reaction was cooled to 0 °C when the ethylene pressure had dropped to 18 atm. After depressurization, DMF was removed under vacuum, and the solid residue was recrystallized from ethanol/heptane at −20 °C to give 160 mg of white crystals.

2: As for mixture of **2**–**4**, but with ethyl formate as the substrate. Yield of isolated product: 230 mg, 75%.

When the same experiments were carried out in the absence of the alkyl formate, the only detectable species was the known intermediate [PPN][Ru(CO)$_2$(Cl)$_3$(dmf)] [1b]; conversely, in the absence of ethylene (replaced by N_2), the latter complex reacted with methyl formate to afford a hydrido species [^{1}H NMR (CD_2Cl_2): $\delta = -19.20$], still incompletely characterized.

Spectroscopic data for **2**: IR (CD_2Cl_2): $\tilde{\nu}$ = 2017 (s), 1945 (s) cm^{-1} (CO); ^{1}H NMR (CD_2Cl_2): δ = 1.30 (t, CH_2CH_3, J(H,H) = 8 Hz), 2.14 (q, CH_2CH_3, J(H,H) = 8 Hz), 7.4–7.8 (m, PPN^+); ^{13}C NMR (CD_2Cl_2): δ = 12.91 (CH_2CH_3), 21.60 (CH_2CH_3), 125–135 (PPN^+), 198.38, 197.95 (CO).

NMR data for **3** and **4** (inseparable mixture): ^{1}H NMR (CD_2Cl_2): δ = 0.79, 0.80 (s, CH_3, **3** and **4**), 2.16 (m, CH_2CH_3, **3**), 1.30 (t, CH_2CH_3, **3**, J(H,H) = 8 Hz), 7.4–7.8 (m, PPN^+); ^{13}C NMR (CD_2Cl_2): δ = −8.85, −8.89 (CH_3, **3** and **4**), 12.99 (CH_2CH_3, **3**), 21.61 (CH_2CH_3, **3**), 115–135 (PPN^+), 197.46, 197.77, 197.88, 198.29 (CO, **3** und **4**).

5: PPh_3 (110 mg, 0.40 mmol) was added to a solution of **2** (100 mg, 0.10 mmol) in CH_2Cl_2 at −40 °C. After removal of the solvent, the yellow residue was washed with methanol and recrystallized from CH_2Cl_2/hexane, giving crystals of **5** (130 mg, 68% yield). IR: $\tilde{\nu}$ = 1947 (s) (CO), 1637 (m) cm^{-1} (C=O); ^{1}H NMR (CD_2Cl_2): δ = 0.34 (t, $COCH_2CH_3$, ^3J(H,H) = 7.2 Hz), 2.22 (q, $COCH_2CH_3$), 7.3–7.5 (m, PPh_3); ^{13}C NMR (CD_2Cl_2): δ = 10.47 ($COCH_2CH_3$), 46.67 ($COCH_2CH_3$), 204.26 (t, CO, ^2J(P,C) = 14.7 Hz), 244.05 (t, $COCH_2CH_3$, ^2J(P,C) = 7.3 Hz); ^{31}P NMR (CD_2Cl_2): δ = 33.60 (PPh_3).

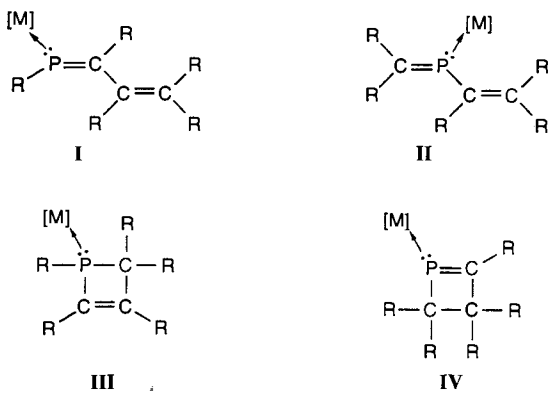
Stereoselective Synthesis and Isomerization of η^1-2-Phosphabutadiene Complexes to η^1-2,3-Dihydrophosphete Complexes**

Rainer Streubel,* Markus Hobbold, Jörg Jeske, and Peter G. Jones

Dedicated to Professor Walter Siebert on the occasion of his 60th birthday

Although various synthetic routes to η^1-1-phosphabutadiene complexes (**I**, Scheme 1)[1, 2] have been established, only one example is known of a "phospha-Wittig reaction" with isobutyraldehyde to form an η^1-2-phosphabutadiene complex (**II**).[3]



Scheme 1. η^1-1- (**I**) and η^1-2-phosphabutadiene complexes (**II**) and η^1-1,2- (**III**) and η^1-2,3-dihydrophosphete complexes (**IV**); [M] represents any metal complex fragment.

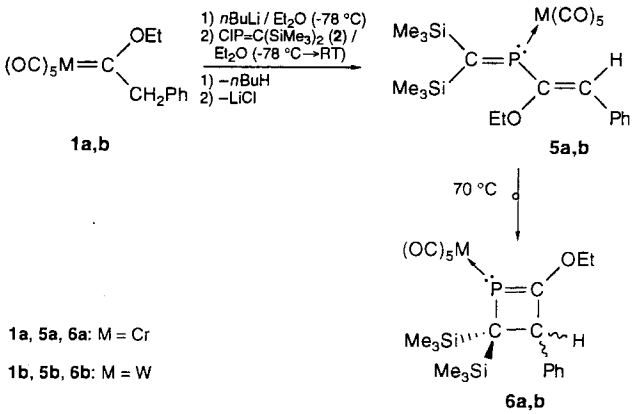
[**] Chemistry of Four-Membered Phosphorus Heterocycles, Part 2. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 1: R. Streubel, L. Ernst, J. Jeske, P. G. Jones, *J. Chem. Soc. Chem. Commun.* **1995**, 2113.

1-Phosphabutadiene complexes and isomeric η^1-1,2-dihydrophosphete complexes (**III**) are well-known synthetic units in the heterocyclic chemistry of phosphorus. Compounds of type **I** are particularly notable for their Diels–Alder reactivity and are therefore of interest for the synthesis of six-membered heterocycles,[4] whereas compounds of type **III** have become important, for example, for the construction of five-membered heterocycles.[5] In complete contrast, little is known about the chemistry of η^1-2-phosphabutadiene complexes; for instance, it is remarkable that the isomerization of these compounds to η^1-2,3-dihydrophosphete complexes (**IV**) is unknown.

Here we report the synthesis of η^1-2-phosphabutadiene complexes by the reaction of chromium- or tungsten[benzyl(ethoxy)methylene] complex anions, generated in situ from **1**, with [bis(trimethylsilyl)methylene]chlorophosphane (**2**, Scheme 2).[6]



Scheme 2. RT = room temperature.

Thermal cyclization of the η^1-2-phosphabutadiene complexes provides metal complexes with the novel 2,3-dihydrophosphete ligand.[7]

Deprotonation of **1a,b**[8] with *n*-butyllithium at −78 °C followed by addition of **2** leads smoothly to the 2-phosphabutadiene metal complexes **5a,b**, which are isolated as yellow solids in moderate to good yields. Room-temperature ^{31}P NMR spectra of the reaction solutions indicate that these P–C coupling reactions are stereoselective and form exclusively one isomer.

The proposed formulations of **5a,b** are based on the NMR spectra of their solutions (Table 1) and IR, MS, and analytical data (see Experimental Section). The ^{31}P NMR signals are observed at low field (**5a**: δ = 341.6; **5b**: δ = 283.5), and **5b** displays a ^1J(P,W) coupling constant (264.5 Hz) that corresponds roughly to that of {s-*trans*-[1-isopropyl-4-phenyl-2-phosphabutadiene-κP-]pentacarbonyl-tungsten(0)} (^1J(P,W) = 254 Hz).[3] The ^{13}C resonance signals of the butadiene carbon atoms in **5a,b** lie in the range of sp^2-hybridized carbon, which further supports the proposed formulations.[9]

The structure of **5a**, as determined by single crystal X-ray analysis,[10] shows many important features. The phenyl and ethoxy groups at the C6–C7 bond are *Z*-configurated, and the double bonds s-*trans* configured with η^1-coordination of the phosphorus atom at chromium (Figure 1). The C6–C7 and P–C16 bond lengths are 132.8(3) and 166.7(2) pm, respectively, and indicate localized double bonds.

The proposed reaction sequence for the formation of **5a,b** is shown in Scheme 3. An initial reaction of the metallaallyl anions **3a,b** with **2** that forms an M–P bond and leads to **4a,b** seems plausible, particularly since there is no evidence for prior decomposition and dissociation of **3a,b**. It cannot be unambigu-

Table 1. Selected NMR spectroscopic data [a] for **5a,b** and **6a,b**.

6b: ^{1}H NMR: $\delta = -0.03$ (s, 9H, Si(CH_3)$_3$), 0.28 (s, 9H, Si(CH_3)$_3$), 1.04 (t, ^3J(H,H) = 7.0 Hz, 3H, OCH$_2C\mathit{H}_3$), 4.15 (m_c, 2H, OCH_2CH$_3$), 4.67 (d, ^3J(H,P) = 28.8 Hz, 1H, C*H*Ph), 7.03 (m_c, 5H, Ph). ^{13}C{^{1}H} NMR: $\delta = 0.4$ (d, ^3J(C,P) = 3.7 Hz, Si(CH_3)$_3$), 2.1 (d, ^3J(C,P) = 4.6 Hz, Si(CH_3)$_3$), 14.5 (s, OCH$_2C\mathit{H}_3$), 29.9 (d, J(C,P) = 13.0 Hz, *C*Si$_2$), 64.5 (d, ^3J(C,P) = 5.5 Hz, OCH_2CH$_3$), 68.0 (d, J(C,P) = 11.1 Hz, *C*HPh), 127.9 (s, *p*-Ph), 128.5 (s, *o*-Ph), 129.4 (s, *m*-Ph), 137.8 (d, ^3J(C,P) = 13.0 Hz, *i*-Ph), 196.2 (d, ^2J(C,P) = 8.3 Hz, *cis*-CO), 198.3 (d, ^2J(C,P) = 21.2 Hz, *trans*-CO), 210.7 (d, J(C,P) = 27.8 Hz, P=*C*). ^{31}P{^{1}H} NMR: $\delta = 114.2$ (d, ^1J(P,W) = 223.9 Hz)

[a] All spectra of **5a** in $CDCl_3$, of **5b** and **6a,b** in C_6D_6, 25 °C; ^{1}H NMR: 200.1 (**5a,b** and **6b**) or 300.1 MHz (**6a**), ^{13}C NMR: 50.3 (**5a,b** and **6b**) or 75.5 MHz (**6a**), ^{31}P NMR: 81.0 (**5a,b** and **6b**) or 121.5 MHz (**6a**); the deuterated solvents were used as internal standards and 85% H_3PO_4 as an external standard.

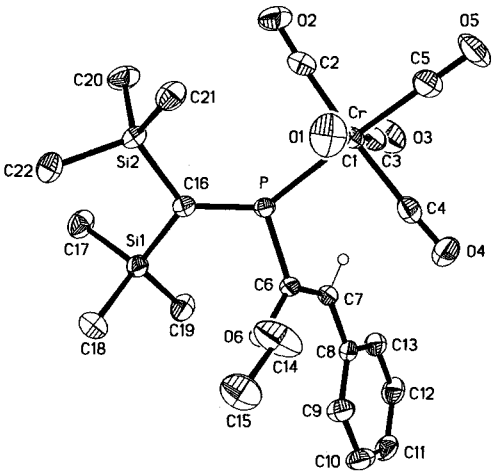

Figure 1. Molecular structure of **5a** in the crystal (ellipsoids represent 50% probability levels; all H atoms except H7 have been omitted for clarity). Selected bond lengths [pm] and angles [°]: P–W 235.09(6), P–C16 166.7(2), P–C6 182.9(2), C6–C7 132.8(3); C7-C6-P 121.08(14), C16-P-C6 107.80(9), C6-P-Cr 113.09(6), Cr-P-C16 139.09(7).

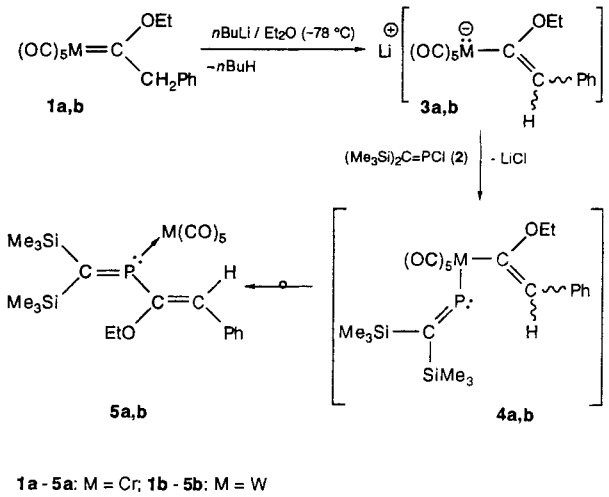
ously decided whether the configuration of the C–C double bond in **5a,b** is already determined in **3**, **4**, or during the **4** → **5** rearrangement (see ref. [11]). The final step of the reaction could represent a rare example of ligand coupling in the coordination sphere of a seven-coordinate d^4 metal (**4**) by reductive elimination, as discussed by R. Hoffmann and E. L. Muetterties.[12, 13]



1a - 5a: M = Cr; **1b - 5b**: M = W

Scheme 3. Postulated reaction sequence for the formation of **5a,b**.

Since there have been no reports on the isomerization of η^1-2-phosphabutadiene complexes, we were particularly interested in this aspect. When solutions of **5a,b** are warmed to 70 °C, formation of the η^1-2,3-dihydrophosphete complexes **6a,b** is complete after 2.5–3 h (Scheme 2). No intermediate formation of the *s-cis* isomers of **5a,b** could be detected by ^{31}P NMR spectroscopy. The constitution of **6a,b** was deduced unambiguously from solution NMR spectroscopic (Table 1), IR, MS, and analytical data (see Experimental Section).

Important information about the structure is provided by the ^{31}P NMR signals of the 2,3-dihydrophosphete ring atoms (**6a**: $\delta = 171.4$, **6b**: $\delta = 114.2$), which are shifted significantly to high field relative to those of the precursors, and the low-field ^{13}C NMR signals of the sp^2 (**6a**: $\delta = 216.3$, **6b**: $\delta = 210.7$) and sp^3 carbon atoms (**6a**: $\delta = 31.0$ (*C*[SiMe$_3$]$_2$), 67.7 (*C*HPh); **6b**: $\delta = 29.9$ (*C*[SiMe$_3$]$_2$), 68.0 (*C*HPh)); further data are presented in Table 1. The conclusion that **6a,b** contain planar rings seems justified, since otherwise the formation of diastereomers would be expected (due to ring folding and concomitant exo/endo positions of the substituents on the CHPh ring moiety).

Experimental Section

5a,b: **1a** (1.97 g, 5.78 mmol) or **1b** (3.42 g, 7.24 mmol) was dissolved in diethyl ether (55 or 72 mL) with stirring, and *n*-BuLi (1.6 M, 3.61 or 4.53 mL, 5.78 or 7.24 mmol) added at −78 °C. After the solution was stirred for 45 min, additional diethyl ether (55 or 70 mL) was added, and, after a further 20 min, **2** (1.30 g, 5.78 mmol or 1.63 g, 7.24 mmol) in diethyl ether (6 or 10 mL). The reaction mixture was allowed to warm up to RT over 2 h, stirred for 3 h, and the solvent removed in vacuo (0.1 mbar). The residue was taken up in *n*-hexane (140 or 160 mL) and filtered through celite after 30 min. After removal of the solvent, the remaining solids were washed at −50 °C with *n*-pentane (10 mL) twice and dried in vacuo (0.1 mbar). Crystallization from *n*-pentane at −30 °C gave yellow single crystals of **5a**.

5a: Yellow powder, yield 1.51 g (2.86 mmol, 49%), m.p. = 90 °C (decomp); MS (CI (NH_3), ^{52}Cr): $m/z = 529$ ([M+H]$^+$); IR (KBr, $\nu_{C=O}$): $\tilde{\nu} = 2064.8$ (vs), 1998.9 (s), 1971.8 (vs), 1937.2 (vs) cm^{-1}; correct C,H analyses.

5b: Yellow powder, yield 3.62 g (5.48 mmol, 76%), m.p. = 104 °C (decomp); MS (EI, 70 eV, ^{184}W): $m/z = 660$ ([M]$^+$); IR (KBr, $\nu_{C=O}$): $\tilde{\nu} = 2072.9$ (s), 1997.6 (m), 1967.9 (s), 1929.9 (vs) cm^{-1}; correct C,H analyses.

6a,b: A solution of **5a** (0.73 g, 1.38 mmol) in toluene (30 mL) or **5b** (0.64 g, 5.78 mmol) in *n*-hexane (70 mL) was warmed to 70 °C for 2.5 h or 3 h. The solvent was then removed in vacuo (0.1 mbar). The residue was washed at −60 °C with *n*-pentane (three times with 5 mL or two times with 4 mL) and then dried in vacuo.

6a: Pale yellow powder, yield 0.54 g (1.02 mmol, 74%), m.p. = 83 °C (decomp); MS (EI, 70 eV, ^{52}Cr): $m/z = 528$ ([M]$^+$); IR (CH_2Cl_2, $\nu_{C=O}$): $\tilde{\nu} = 2068.0$ (m), 1953.0 (vs), 1948.0 (vs), 1942.0 (vs) cm^{-1}; correct C,H analyses.

6b: Pale yellow powder, yield 0.51 g (0.77 mmol, 76%), m.p. = 84 °C (decomp); MS (EI, 70 eV, ^{184}W): $m/z = 660$ ($[M^+]$); IR (KBr, $\nu_{C=O}$): $\tilde{\nu} = 2074.4$ (s), 1992.2 (m), 1950.5 (vs), 1917.5 (vs) cm^{-1}; correct C,H analyses.

C-Terminally Modified Peptides and Peptide Libraries—Another End to Peptide Synthesis**

Michael Davies and Mark Bradley*

Peptides modified at the C-terminus have been used for many years in a variety of applications, notably as substrates and inhibitors for a variety of proteolytic enzymes. In addition, many biologically important peptides and proteins are modified at the C-terminus.

C-terminal peptide amides have been accessible for some time by utilizing a number of specifically designed linkers[1] for solid-phase peptide synthesis. Very few other C-terminal modifications are directly accessible with traditional solid-phase techniques, although the recent work of Burdick et. al.[2] has demonstrated the solid-phase synthesis of a range of *para*-nitroanilides using an aminoanilide linker followed by oxidation of the resultant *para*-aminoanilide after cleavage of the peptide from the resin. To date, specific solution-phase approaches to individual compounds, which require considerable synthetic manipulation and expertise, have been necessary. Additionally, these methods are not adaptable to combinatorial methodologies in an area where the generation of diversity would be extremely desirable.

One potential solution to this problem is to synthesize peptides in a nontraditional manner (that is, from the N- to the C-terminus).[3] One major drawback with this approach is that it risks epimerization[4] at all coupling stages due to repeated resin-bound carboxyl activation. An alternative approach would be to invert the peptide following conventional (C → N) synthesis and then modify the C-terminus. Examples of inverting resin-bound peptides are known;[5] however, no method has been reported that allows inversion, C-terminal modification, and release of the modified peptide into solution. Such a method would allow an inverted peptide library to be C-terminally modified with pharmacophores such as chloro- and acyloxymethyl ketones.[6]

We now report the methodology for the general solid-phase synthesis of C-terminally modified peptides ready for a variety of solution screening applications and a method for retaining an Edman-sequencable coding strand for resin-screening purposes. The process was analyzed by cleavage of intermediates from the resin and subsequent HPLC, MS (Electrospray and FAB), amino acid analysis, and by our recently described technique of solid-phase reaction monitoring (MALDI-TOF SPIMS).[7]

The synthetic procedure is outlined in Scheme 1. Thus Fmoc-Lys(Boc)-OH was attached to either polystyrene aminomethyl resin (0.33 $mmol\,g^{-1}$) or to TentaGel S-NH_2 (130 μm beads, 0.29 $mmol\,g^{-1}$). The Fmoc group was removed with 20% piperidine in DMF, and the α-amine reprotected with an Aloc group by means of diallylpyrocarbonate.[8] The Boc group was removed, and the highly acid-labile linker (4-(4-hydroxymethyl-3-methoxyphenoxy)butanoic acid (HMPB)[9] coupled to the

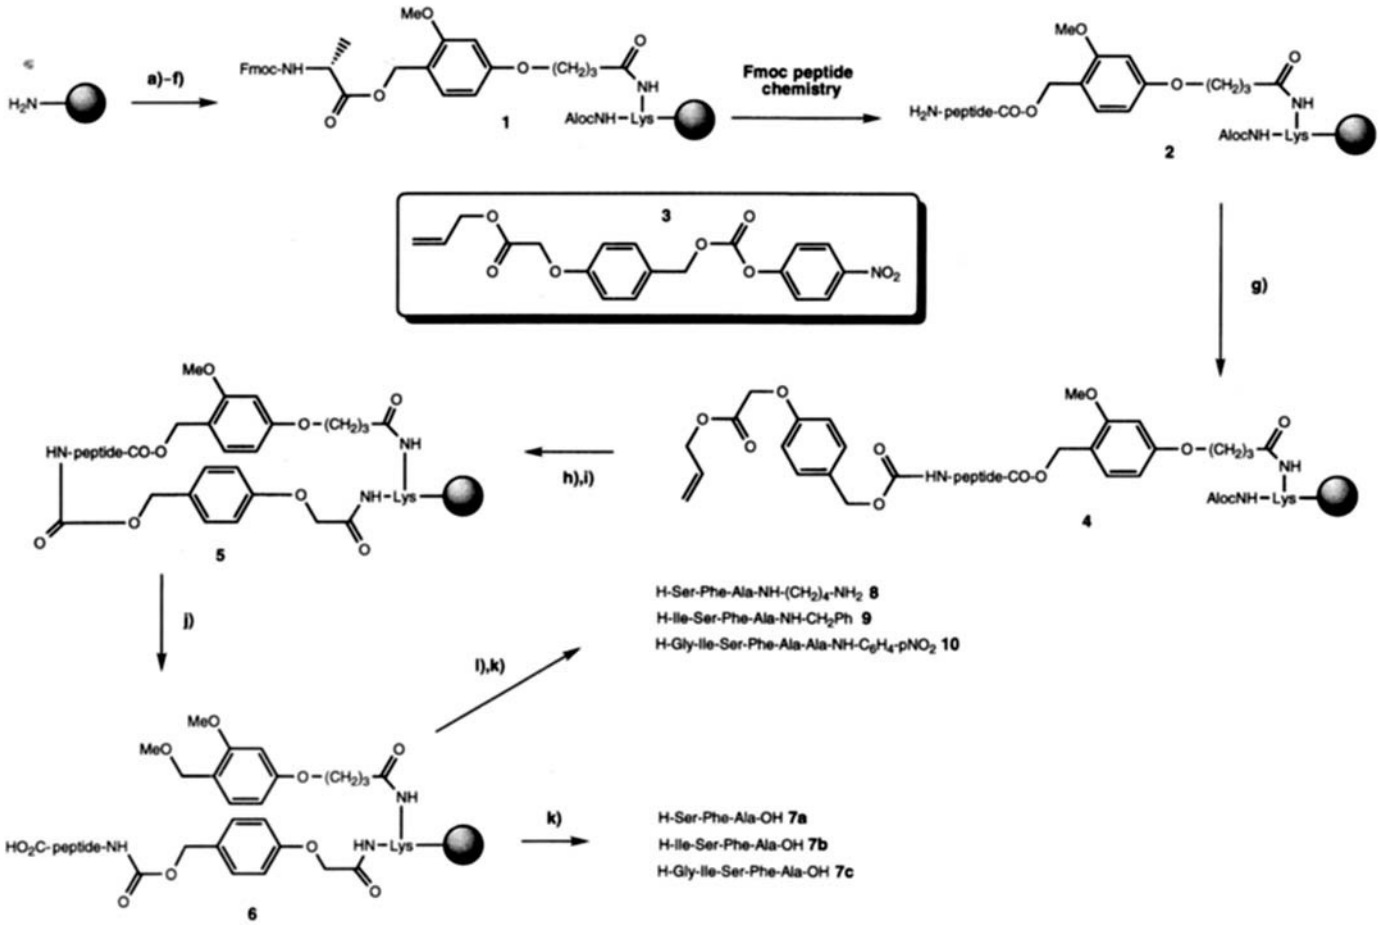

Scheme 1. a) Fmoc-Lys(Boc)-OH/DIC/HOBt; b) 20% piperidine/DMF; c) diallylpyrocarbonate/Et_3N; d) 25% trifluoroacetic acid (TFA)/CH_2Cl_2; e) (4-(4-hydroxymethyl-3-methoxyphenoxy)butanoic acid/DIC/HOBt; f) Fmoc-Ala-OH/DIC/DMAP/CH_2Cl_2; g) **3**, pyridine/DMF; h) $[Pd(PPh_3)_4]$/dimedone/CH_2Cl_2: THF 1:1 (degassed); i) PyBroP/Et*i*Pr_2N/DMAP/CH_2Cl_2/12 h; j) 1% TFA/CH_2Cl_2, 12 h, then MeOH; k) 100% TFA; l) PyBrop/RNH_2/DMAP/Et*i*Pr_2N. DIC = 1,3-diisopropylcarbodiimide; DMAP = 4-dimethylaminopyridine. The peptide chain in **2**, **4**–**6** is as follows: **a**: Ser-Phe-Ala; **b**: Ile-Ser-Phe-Ala; **c**: Gly-Ile-Ser-Phe-Ala.

ε-amino group. This linker is cleavable with 1% trifluoroacetic acid (TFA). The linker was in turn derivatized with Fmoc-alanine to give **1**. Subsequently, conventional Fmoc chemistry[10] gave the resin-bound peptides **2a**–**2c**. These were coupled to the carbonate **3** to give the resin-bound urethanes **4a**–**4c**.[11] Cleavage with 1% TFA at this stage and HPLC and MS analysis as well as analysis by SPIMS showed the success of the carbonate coupling and the differential and selective acid lability of the carboxyl and amino linkers. Aloc deprotection of the amino function was checked by ninhydrin assay,[12] and MS analysis allowed monitoring of the allyl ester cleavage. The most reliable conditions for simultaneous cleavage of both the allyl carbamate and allyl ester proved to be the use of one equivalent of $[Pd(PPh_3)_4]$ in degassed CH_2Cl_2/THF in the presence of excess dimedone.[13] Cyclization was carried out with PyBroP,[14] Et*i*Pr_2N, and DMAP for 12 hours to give the resin-bound cyclic peptides **5a**–**5c**. Treatment of **5a**–**5c** with 1% TFA for 12 hours (5.0 mL of 1% TFA in CH_2Cl_2 per 100 mg resin) gave the protected, inverted, and resin-bound peptides **6a**–**6c**. Importantly, at this stage, any peptide not attached to the resin through the urethane linker is removed by the cleavage with 1% TFA. The cyclization was followed by ninhydrin assay, and the yields determined by amino acid analysis prior to cyclization and after 1% TFA cleavage. This gave an average yield for the cyclization for the three peptides of 60%, using lysine as an internal standard. Cleavage of the unmodified peptides **6a**–**6c** from the solid support (100% TFA followed by Et_2O precipitation) gave the expected materials in excellent overall yield as the major component by reversed-phase HPLC. The resin-bound inverted peptides **7a**–**7c** were treated with PyBroP, Et*i*Pr_2N, DMAP, and either 4-Boc-aminobutylamine, benzylamine, or alanine-nitroanilide to give **8**, **9**, and **10**, respectively, following release from the resin by treatment with 100% TFA.[15]

The procedure was repeated for the tetrapeptide **7b** and to generate a 1000 compound inverted tripeptide library.[16] This time, however, two linkers (80% HMPB and 20% hydroxymethylbenzoic acid (HMBA)),[17] were coupled to the mono Aloc protected TentaGel S-NH_2 resin-bound lysine. In this case each inverted peptide was associated with a sequenceable uninverted coding attached to the bead through the HMBA linker (Scheme 2). After treatment with 100% TFA the sequence of the inverted library member could be identified by Edman sequencing of the peptide remaining on the bead. This gave the expected sequence for the tetrapeptide **7b** and was demonstrated to work successfully for five single beads chosen at random from the inverted library.

In conclusion we have developed what we believe to be a general and highly efficient method for the generation of resin-linked and liberated C-terminally modified peptides, with the inclusion of an Edman-sequencable coding strand. This methodology should find wide applicability in protease substrate synthesis and allow the generation of libraries containing

Protease-Catalyzed Peptide Synthesis from N- to C-Terminus: An Advantageous Strategy**

Frank Bordusa, Dirk Ullmann, and Hans-Dieter Jakubke*

A step-by-step peptide synthesis from the N- to C-terminus cannot be achieved with chemical coupling methods as it risks racemization due to the repeated carboxyl activation procedures. Since the ribosomal synthesis of polypeptides occurs in the N → C direction, the development of an equivalent synthesis strategy should have more than academic interest—especially in light of the fact that even the dominating, stepwise Merrifield

synthesis starting from the C-terminus cannot completely rule out partial epimerization.[1] Furthermore, it was recently demonstrated by capillary electrophoresis that 0.3–0.4% racemization resulted at every coupling step in the synthesis of a model peptide.[2] The ribosomal peptidyl transferase is only active within the ribosome, which rules out its in vitro application. Nevertheless, the reverse hydrolysis potential of proteases offers an alternative strategy.[3]

This communication introduces an enzymatic method that utilizes the cysteine protease clostripain to demonstrate the principle of a stepwise peptide synthesis in the nonconventional N → C direction with a simple model peptide as an example. To show the advantages of enzyme-catalyzed peptide synthesis, which result from the stereo- and regiospecificity of enzymes and allow mild ecological conditions without the use of side-chain protection, we chose the tetrapeptide H-Lys-Tyr-Arg-Ser-OH, which exclusively consists of trifunctional amino acids (Figure 1).

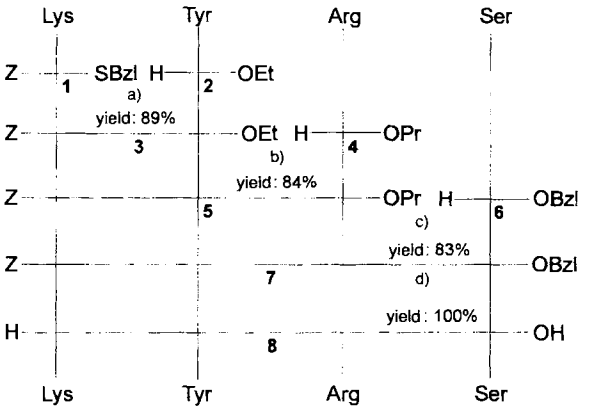

Figure 1. Scheme of the protease-catalyzed synthesis of the tetrapeptide **8**. a) and c) clostripain, 0.025 M borate buffer, pH 8.0, 25 °C, [**1**] = 8 mM, [**2**] = 24 mM, [**5**] = 10 mM, [**6**] = 50 mM; b) chymotrypsin, 0.025 mM borate buffer, pH 9.0, −25 °C, [**3**] = 10 mM, [**4**] = 70 mM; d) catalytic hydrogenation with 10% Pd.

Nucleophilic attack of the unprotected amino acid esters **2**, **4**, and **6** on the C-terminal ester group of the acyl donors **1**, **3**, and **5**, respectively, results in peptide esters **3** and **5**, which serve as acyl donors in the subsequent steps. The enzymes for the coupling steps were chosen based on their substrate specificity, which is known from previous studies of the S- and S′-subsite specificities.[4] The expected yields are mainly dictated by the S′-subsite specificity (nucleophile specificity) of the protease. Most of the studied proteases exhibit a lower nucleophile specificity for amino acid esters than amide and peptide derivatives. Consequently, such nucleophilic amino components result in low yields when used at room temperature.[5] A drastic improvement of the yield can be achieved by performing the enzymatic synthesis in frozen aqueous systems.[6] This was demonstrated for the serine protease chymotrypsin used in this study as well as the cysteine protease papain and the serine protease trypsin.[7] However, even under normal conditions clostripain exhibits an unusually high catalytic efficiency towards nucleophilic amino acid esters that is similar to its efficiency with amide derivatives. This enabled us to perform the clostripain-catalyzed steps a and c (Figure 1) in aqueous solution at room temperature. The chymotrypsin-catalyzed step b resulted in high yields when performed in frozen aqueous conditions at −25 °C. We were able to utilize clostripain as catalyst for two reaction steps due to its restrictive substrate specificity for Arg–Xaa bonds.[8] No hydrolysis occured for the Lys–Tyr bond, which is formed under kinetic control in the first step. This protease is particularly effective in the stepwise enzymatic synthesis of peptides due to its high efficiency for amino acid esters and its unusually broad nucleophilic specificity, which is not limited to proteinogenic L-amino acids.[9]

The coupling steps were optimized in preliminary experiments. We studied the influence of changes in enzyme concentration, pH, type of ester, and, in particular, the most economical ratio between acyl donor and acceptor (shown in Figure 2 for step a). The yield given in Figure 1 is not identical with the

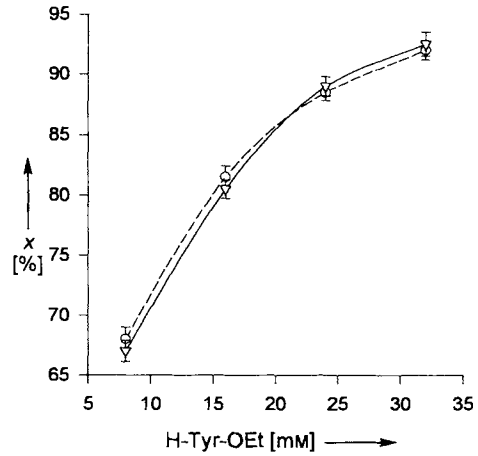

Figure 2. Influence of nucleophile concentration and pH on product yield for the clostripain-catalyzed synthesis of **3**. –▽– pH 8.0; –○– pH 9.0; [**1**] = 8 mM, 0.025 M borate buffer, 25 °C.

maximum yield but represents a compromise between the utilized excess of nucleophile and the resulting yield. Our goal was to achieve yields exceeding 80% for all synthesis steps. Our calculation is based on HPLC analyses as well as preparative yields of peptide products.[10] The error values given in Figure 2 result from the different chromophores that were considered by specific methods of analysis.[11] The analysis of all other reaction steps was straightforward for detection at $\lambda = 280$ nm. Subsequent to step c and final product purification, we removed protecting groups from **7** by catalytic hydrogenation, which occurred easily and completely. The final product **8** (total yield 62%) was characterized and identified with conventional techniques;[12] the chromatographic analysis is shown in Figure 3. The protected peptide ester **7** could be elongated in an elastase-catalyzed reaction in a frozen aqueous system, which should lead to a pentapeptide derivative that could be further extended in subsequent couplings. In principle this enzymatic strategy allows C-terminal modifications of peptides and even proteins

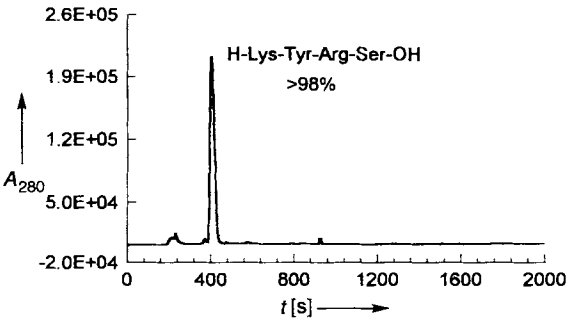

Figure 3. HPLC analysis of **8**; conditions are as given in ref. [10].

containing chiral amino acids starting from appropriate ester derivatives that could not be achieved by conventional chemical methods.

Limitations for the universal application of enzymatic peptide synthesis result from the restrictive specificity of proteases and from the risk of proteolytic cleavage of the starting materials and the product. Utilization of substrate mimetics that were originally named "inverse substrates" in trypsin-catalyzed peptide syntheses[13] and of proteolytically inactive zymogens[3] in conjunction with the results shown here offer an enzymatic strategy with emerging practical relevance.

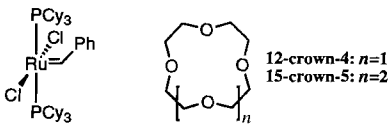
Template-Directed Ring-Closing Metathesis: Synthesis and Polymerization of Unsaturated Crown Ether Analogs**

Michael J. Marsella, Heather D. Maynard, and Robert H. Grubbs*

Ring-closing metathesis (RCM) has become an established protocol for converting dienes into corresponding cyclized adducts.[1] Recently the synthetic utility of RCM was expanded greatly by the development of catalyst **1** (Cy = cyclohexyl), which demonstrates high tolerance to a number of functional groups.[2] As with all ring-forming reactions, the RCM of medium-sized rings is determined by several factors including the kinetics of ring closing, ring strain, and competing metathesis-based polymerization. In some cases, particularly in eight-membered rings, it has proven beneficial to incorporate conformational constraints into the substrates to promote the desired RCM.[3–6] For such systems, it has been proposed that RCM is favored (in part) due to the close proximity of the olefins. To date structurally restricted conformations or hydrogen bonding have been the only reported methods for mediating olefin proximity.[3–6] Herein we present template-directed RCM, an approach that utilizes noncovalent interactions between a diene and an appropriate template to enhance the RCM of linear dienes devoid of other conformational constraints. In addition to the template-directed RCM of **2**, the activity of **1** towards the



1

acyclic diene metathesis polymerization (ADMET) of **2**, the ring-opening metathesis polymerization (ROMP) of **3**, and the template-directed depolymerization of polymer **4** to regenerate **3** will be addressed.

Yields of crown ethers derived from linear polyethers can be significantly increased when an appropriate metal-ion template is used to preorganize the substrate and promote the desired macrocyclization.[7] We anticipated that preorganization of linear polyether possessing terminal olefins about a complementary metal ion should provide the conformational restrictions required to enhance RCM. Crown ethers **3** (n = 1, 2) were chosen as the target compounds with which to test this concept due to their similarities to the known ionophores [12]crown-4 and [15]crown-5. As depicted in Scheme 1, the synthesis of **3** by RCM of **2** is subject to competing reaction pathways: 1) formation of the desired RCM product, 2) ROMP of the RCM product, and 3) ADMET of **2** to yield **4**. Side reactions occurring by ROMP and ADMET can be suppressed if the RCM is run at relatively high dilution (about 0.02 M).[4] Therefore, the RCM of **2** at 0.02 M in the presence of the appropriate metal-ion template should favor the desired RCM product **3**.

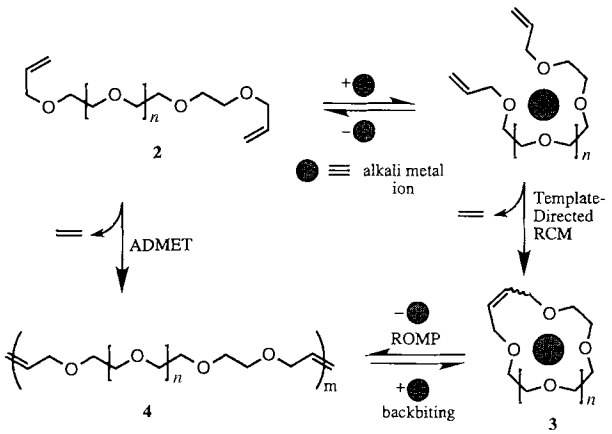
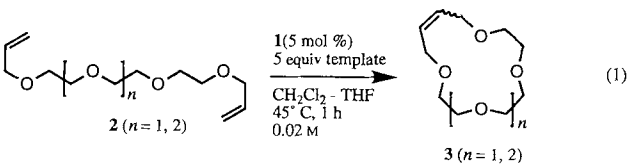


Scheme 1. Template-directed metathesis reaction between **2**, **3**, and **4**.

The results of the syntheses of **3** [Eq. (1)] are summarized in Table 1. Noting the preferential binding of Li^+ by [12]crown-4,



(1)

Table 1. Template-directed ring-closing metathesis of **2**.

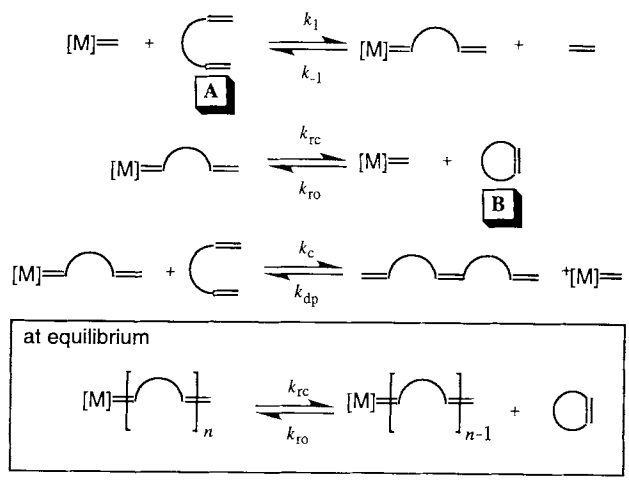
Substrate	Template	Yield of 3 [%] [a]	*cis*:*trans* ratio [c]
2 ($n=1$)	–	39	38:62
	$LiClO_4$	>95 (85) [b]	100:0
	$NaClO_4$	42	62:38
	$KClO_4$	36	36:64
2 ($n=2$)		57	26:74
	$LiClO_4$	89	61:39
	$NaClO_4$	90	68:32
	$KClO_4$	64	25:75

[a] Determined from ^1H NMR spectra of the crude reaction mixture. [b] Yield of isolated product in parentheses, see Experimental Section. [c] Determined by comparing the ^1H NMR spectrum of the ring-closed product with authentic samples of *cis*- and *trans*-**2** ($n=1$) synthesized by an independent route.

it was anticipated that the RCM of **2** ($n=1$) would afford the highest yield of **3** ($n=1$) when Li^+ is used as the template. Indeed, a yield of greater than 95% of the *cis* ring-closed product was obtained when the RCM was templated with $LiClO_4$. For the 17-membered ring **3** ($n=2$), the RCM is enhanced by both $LiClO_4$ and $NaClO_4$; both Li^+ and Na^+ ions are capable of restricting the diene to a conformation favoring RCM. In general, the ions that function best as templates to give the highest yield of ring-closed product also favor the formation of the *cis* isomer (see Table 1). This trend implies that the *cis* isomer allows the macrocycle to adopt a conformation that best accommodates the template ion. As predicted, yields of the ring-closed product are much lower in the absence of a complementary template.[8]

The close proximity of the olefins resulting from the template effect should be reflected by an accelerated rate of ring closure. Indeed, a simple kinetic analysis of the RCM reaction at equilibrium (Scheme 2) supports this proposal. By establishing $[B]_{eq} = k_{rc}/k_{ro}$, Equation (2) affords a direct relationship be-

$$\text{Yield}\,[\%] = ([B]_{eq}/[A]_0) \times 100 = (k_{rc}/k_{ro}[A]_0) \times 100 \quad (2)$$



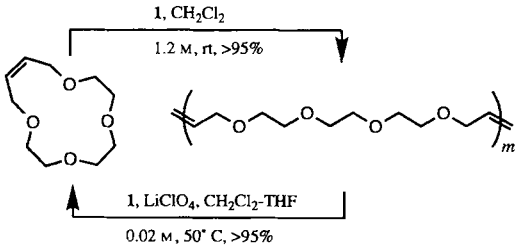
Scheme 2. Equilibrium reactions that control cyclization and polymerization.

tween the rates of the competing ring-opening and ring-closing processes for each ring size. By entering the yields of **3** from Table 1 into Equation (2) and taking $[A]_0 = 0.02\,M$, the ratio between k_{rc} and k_{ro} is larger for the templated reactions. In the case of the nontemplated ring closures the higher yield of **3** ($n=2$, 57%) versus **3** ($n=1$, 39%) most likely results from the reduced ring strain of the larger macrocycle and the larger k_{rc}/k_{ro} value for **3** ($n=2$).[4, 6, 9]

We have also explored the ADMET of **2**, ROMP of **3**, and the template-directed depolymerization of **4** (Scheme 1). Since the ADMET of **2** and the ROMP of **3** should both result in **4**, the strengths and limitations of the two routes were explored. Subjecting **2** ($n=1$) to standard ADMET conditions (5 mol% **1**, neat, 15 mTorr) at 50 °C yielded a polymer with relatively low molecular weight ($M_n = 11200$), a polydispersion index (PDI) of 3.4 (relative to polystyrene standards), and a *cis*:*trans* ratio of about 1:6.3. Isomerization of the allylic endgroups of **2** to form vinyl ethers as minor by-products was also observed and implies that catalyst degradation to a ruthenium hydride may have occurred.[10] This isomerization process is deleterious to further ADMET of **2** as the active ruthenium carbene can react with the vinyl ether to yield a species that is inert to olefin metathesis. However, ROMP of **3** ($n=1$) initiated by **1** proceeded smoothly with greater than 95% conversion into **4**. Gel permeation chromatography (GPC) and ^1H NMR spectra of **4** prepared by ROMP show $M_n = 65900$, PDI = 1.96 (relative to polystyrene standards), and a *cis*:*trans* ratio of about 1:3.7.

One key feature of olefin metathesis is that, unlike other carbon–carbon bond forming reactions, the reversible formation and breaking of a carbon–carbon double bond allows the thermodynamic product distribution to be attained. This implies that, with respect to template-directed RCM, unproductive coupling—"mistakes" that do not result in the desired product—can be "corrected" to yield the desired product if the template effect is a significant driving force. Furthermore, when dilute solutions of polymers obtained by ROMP are allowed to react with a metathesis catalyst, an equilibrium concentration of cyclic monomers is reestablished.[9] In an attempt to exploit these processes, we explored the reaction between polymer **4** and catalyst **1** in the presence and absence of Li^+. It was anticipated that the template-directed "backbiting" of **4** should yield **3** ($n=1$). In the absence of a template, backbiting should result in a complex mixture of macrocycles of varying ring size and linear oligomers. Performing the $LiClO_4$-templated degradation of **4**

under the RCM conditions employed in the conversion of **2** into **3** resulted in nearly quantitative conversion of **4** into *cis*-**3** [$n = 1$, Eq. (3); rt = room temperature]. Polymer degradation in the



(3)

absence of a Li^+ template gave about 20% combined yield of *cis*-and *trans*-**3** ($n = 1$); the remainder of the product consisted of low molecular weight polymer ($M_n \approx 9600$). In addition to demonstrating the concept of template-directed backbiting, this result illustrates the concept that if mistakes (that is, ADMET dimers) are formed during template-directed RCM of **2**, they can, in principle, be converted into **3** by this process.

We have demonstrated the utility of template-directed RCM as an entry into crown ether analogs **3**. The remarkable efficiency of this reaction is evident from the nearly quantitative yield of **3** ($n = 1$) from both the template-directed RCM of **2** as well as the template-directed backbiting of polymer **4**. We have also defined the proximity of the olefins as a parameter that controls the relative rate of RCM. The rate of ring closure can be accelerated by noncovalent interactions that preorganize the olefins into a conformation favorable for productive RCM. This concept of template-directed RCM demonstrates great potential for the synthesis of other supramolecular host–guest assemblies in which either the host or guest serves as a template for its corresponding diene-functionalized acyclic partner.[11]

Experimental Section

Typical procedure for template-directed RCM. Synthesis of **3** ($n = 1$) with $LiClO_4$: Catalyst **1** (18 mg, 0.022 mmol) and $LiClO_4$ (230 mg, 2.2 mmol) were add to THF (2.0 mL) and allowed to stir at room temperature until the $LiClO_4$ had dissolved. CH_2Cl_2 (20.0 mL) was added to the solution, and the mixture stirred in an oil bath at 50 °C. Compound **2** ($n = 1$, 100 mg, 0.434 mmol) was added with a syringe, and the solution stirred at 50 °C for 60 min. The reaction mixture was then exposed to air, and ethyl vinyl ether (≈ 0.05 mL) added. The solvent was removed in vacuo, and the crude product analyzed by ^1H NMR spectropscopy to determine the yield and *cis*:*trans* ratio of **3** ($n = 1$). Isolation of pure **3** ($n = 1$) required chromatography of the crude product (EtOAc) followed by three successive aqueous washings of solutions of **3** ($n = 1$) in Et_2O to ensure complete removal of template salt (unoptimized procedure). The solutions in Et_2O were dried over a minimal amount of Na_2SO_4 and again subjected to chromatography (Et_2O) to yield pure **3** ($n = 1$, 85% yield). Because of the slight solubility of **3** in H_2O, yields of isolated products were lower than those determined by 1H NMR spectroscopy of the crude product. ^1H NMR (300 MHz, $CDCl_3$): $\delta = 3.65-3.72$ (m, 12 H), 4.31 (d, 4 H), 5.78 (t, 2 H); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 66.77$, 68.72, 70.21, 71.77, 129.80; HR-MS calcd for $(M+H^+)$: 203.1284, found: 203.1290.

Polymerization of *cis*-**3** ($n = 1$). A solution of **1** (5.54 μmol) in CH_2Cl_2 (0.46 mL) was added to *cis*-**3** ($n = 1$, 1.554 mmol, 100 equiv), and the reaction mixture stirred vigorously at room temperature for 4.5 h. The polymerization was terminated by adding ethyl vinyl ether (≈ 0.1 mL). ^1H NMR analysis of the crude reaction mixture showed >95% conversion into polymer. The polymer was precipitated into hexanes, centrifuged, isolated, and dried under vacuum (yield 94%). (Minor impurities in the catalyst were found to be detrimental to the polymerization. These impurities can be removed by multiple washings with acetone [2].) Molecular weight determination (vs. polystyrene standards): $M_n = 65900\ g\,mol^{-1}$, $M_w = 129200\ g\,mol^{-1}$, PDI = 1.96; ^1H NMR (500 MHz, $CDCl_3$): $\delta = 3.58$ (m, 6H), 3.64 (m, 6H), 4.01 (br. d, 2H), 4.08 (br. d, 2H), 5.71 (m, 1H), 5.80 (m, 1H); ^{13}C NMR (100 MHz, $CDCl_3$): $\delta = 66.90$, 69.56, 70.69, 71.23, 129.60; elemental analysis calcd for $C_{10}H_{18}O_4$: C 59.4, H 8.97; found: C 59.17, H 9.33.

Typical procedure for the depolymerization of **4** in the presence of $LiClO_4$: A solution of **4** (371 μmol), $LiClO_4$ (1860 μmol), and **1** (1.86 μmol) in CH_2Cl_2/THF (10/1, 0.02 M) was stirred at 45 °C for 75 min. The reaction was terminated by adding ethyl vinyl ether (≈ 0.1 mL), and the mixture concentrated under vacuum. ^1H NMR and GPC analysis of the crude product showed quantitative conversion of **4** into *cis*-**3** ($n = 1$). The crude product was dissolved in CH_2Cl_2 and washed several times with deionized water. The organic layer was concentrated under vacuum and purified by column chromatography on silica gel (EtOAc) to afford *cis*-**3** ($n = 1$); yield of isolated product: 83%.

Proof of Chiral Dihydride Complexes Including Catalyst and Substrate during the Bis(phosphinite)rhodium(I)-Catalyzed Hydrogenation of Dimethyl Itaconate**

Andreas Harthun, Renat Kadyrov, Rüdiger Selke,* and Joachim Bargon*

The PHIP-NMR method[1] (PHIP = parahydrogen-induced polarization) has proven useful for detecting achiral, uncharged dihydridorhodium catalyst–substrate complexes.[2] Furthermore, hydrogenation with parahydrogen in combination with

in situ ^{1}H NMR spectroscopy identified a pairwise, partially reversible proton exchange mechanism for the hydrogenation of α,β-unsaturated carbonyl compounds[3] and styrene[4] by cationic rhodium(I) catalysts.

The PHIP-NMR method has now been used to identify dihydride catalyst–substrate complexes during the partially reversible hydrogenation of prochiral dimethyl itaconate (**1**). Dihydride complexes are of considerable interest, especially when chiral catalysts and prochiral substrates are applied. The enantioselectivity of the homogeneous hydrogenation is believed to be due to the different reactivities of the intermediate dihydrides.[5] Until now the hypothetical geometry of the dihydride intermediates for the bis(phosphane)rhodium(I)-catalyzed hydrogenation of acetamidocinnamic acid derivatives is based on molecular calculations only;[6, 7] experimental observation of such dihydrides is still pending. The potential number of expected dihydride catalyst–substrate complexes is determined by the possible geometric isomers of the catalyst–substrate complexes. In the case of substrate **1**, two or four diastereomeric catalyst–substrate complexes are possible by coordination of the double bond (*Re* or *Si*) depending on whether the bis(phosphinite)rhodium catalyst has C_2 or C_1 symmetry, respectively (Figure 1).

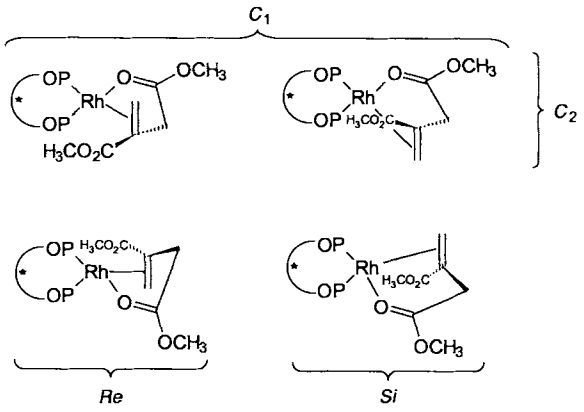

Figure 1. Number of possible catalyst–substrate complexes with the prochiral substrate **1**: Coordination to the double bond (*Re* or *Si*) results in either two or four diastereomeric catalyst–substrate complexes depending on whether the bis(phosphinite)rhodium catalyst has C_2 or C_1 symmetry, respectively.

Each of these catalyst–substrate complexes can form four dihydride complexes, assuming that the hydrogen molecule is *cis*-coordinated. If catalytic hydrogenation proceeds enantioselectively, a chiral catalyst with C_2 symmetry should yield only one dihydride complex. By contrast, a chiral catalyst with C_1 symmetry should result in two diastereomeric dihydride complexes, assuming that only one of four (or two of eight) of the relevant dihydride catalyst–substrate complexes that lead to the right enantiomer are energetically favored. We have indeed confirmed this hypothesis experimentally by the hydrogenation of **1** with the enantiomerically pure bis(phosphinite)rhodium(I) precatalysts **2a** (C_2 symmetry) or **2b** (C_1 symmetry). Comparing the experimental high-field signals in Figure 2b with those from simulations[8] verifies that the polarization pattern originates from a superposition of the signals of two different dihydride complexes (Figure 3). The individual hydride signals were assigned by selective proton-decoupling experiments,[9] which also proved that the high-field signals are indeed caused by dihydride complexes. The ^2J(H,H) coupling constant is obtained from the characteristic antiphase polarization pattern.

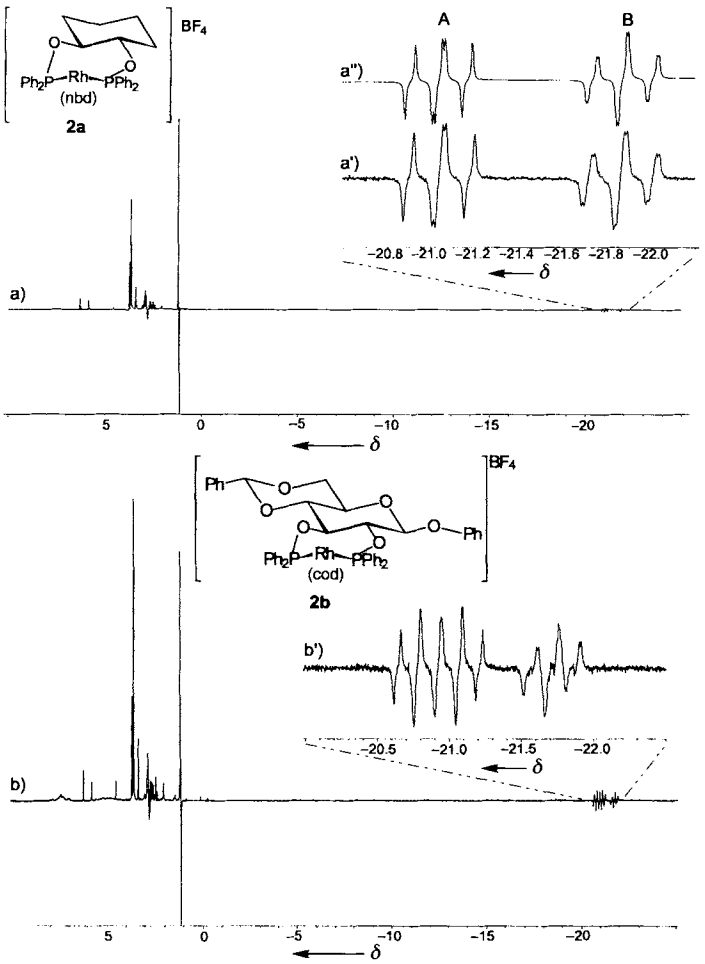

Figure 2. a) 200 MHz ^{1}H NMR spectrum recorded during hydrogenation of **1** with catalyst **2a** (C_2 symmetry) at about $-15\,^\circ$C and a p-H_2 pressure of 3 bar; a') enlarged view of the high-field region; the signals result from one dihydride catalyst–substrate complex; a") simulation spectrum; b) 200 MHz ^{1}H NMR spectrum recorded during hydrogenation of **1** with catalyst **2b** (C_1 symmetry) at about $-15\,^\circ$C and a p-H_2 pressure of 3 bar; b') enlarged view of the high-field region; the signals result from two dihydride catalyst–substrate complexes (nbd = norbornadienyl, cod = 1,4-cyclooctadienyl).

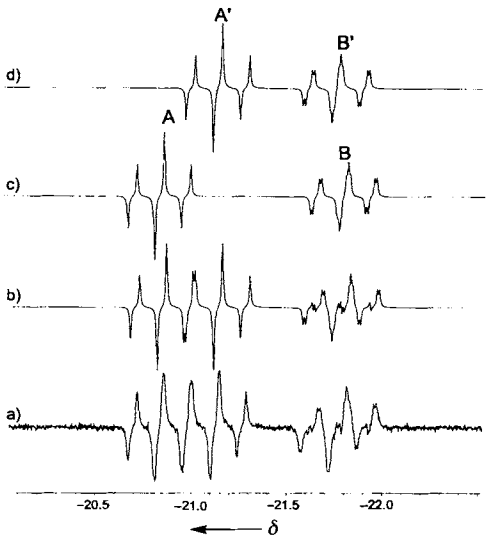

Figure 3. Verification of the NMR parameters of the observed dihydride signals by comparison with simulation spectra: a) experimental spectrum; b) addition of the simulated spectra c and d; c),d) simulations of the individual dihydride complexes. Assignment of the signals A,B and A',B' was confirmed by selective proton-decoupling experiments [9].

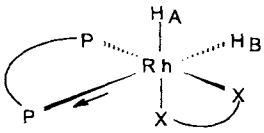
 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3610-1104 $ 17.50+.50/0

So far we cannot differentiate whether the substrate is coordinated by the *Re* or *Si* side and which of the rhodium–substrate bonds is orientated towards the dz^2 position. It seems remarkable that none of the high-field signals shows a coupling constant in the range for $^2J(H,P)_{trans}$ coupling, which is typically larger than 100 Hz in octahedral rhodium–phosphane complexes.[2] However, the polarization signals of the dihydride complexes correspond to chemical shifts and coupling constants that are typical for monohydride bis(phosphane)rhodium complexes of acetamidocinnamic acid derivatives.[10, 11] Other coupling constants lie between 26.2 Hz and 29.5 Hz, which is typical for $^1J(Rh,H)$ and $^2J(H,P)_{cis}$. Furthermore, an additional coupling of about 4 Hz can be identified for the high-field multiplets B and B'.

If one maintains the usual hexacoordinate structure of a classical dihydride, the observed coupling pattern can only be explained by a distortion of the octahedral geometry. Lengthening of the *trans* P-Rh-H bond should cause a great reduction in the value of $^2J(H,P)_{trans}$ or, in the case of bonding cleavage, complete loss of coupling. Therefore, the observed coupling constant of about 4 Hz can be assigned to $^2J(H,P)_{trans}$. Scheme 1 depicts the structure of the dihydride complex, which only takes lengthening of the Rh–P bond *trans* to H_B into account but no additional distortion of the octahedral geometry.[7]



Scheme 1. Proposed geometry of the dihydride complexes. Lengthening of the Rh–P bond *trans* to H_B [7] may explain the observed coupling constant of about 4 Hz ($^2J(H,P)_{trans}$) and the loss of a second $^2J(H,P)_{cis}$ coupling in the multiplets A,A' (X–X: dimethyl itaconate).

A strong indication for coordination of **1** at the dihydride catalyst complex is also reflected in the results of hydrogenation with the bis(phosphinite)rhodium complex **2c** (C_1 symmetry). In this case the dihydride complex is only detectable if **1** is initially, at least partially, deuterated.[3, 12] Furthermore, hydrogenation of a solution of only the precatalyst and no substrate does not lead to these polarization signals under the given reaction conditions. Further investigations to elucidate the structure of the chiral dihydride catalyst–substrate complexes are in progress.

Experimental Section

Dimethyl itaconate (Aldrich) was used without further purification. Hydrogenation (p-H_2): Parahydrogen was enriched to about 50% at 77 K and taken successively out of a U-shaped, flow-through cell filled with activated charcoal [13]. The NMR tube was filled with [D_6]acetone (1 mL, Promochem), **1** (20 μL), precatalyst (5 mg), and p-H_2 (about 3 bar). The NMR tube was then cooled for 12 s in liquid nitrogen, shaken for about 5 s, and immediately transferred to the NMR spectrometer. A ^1H NMR spectrum was recorded instantaneously with a 45° pulse [14].

Parameters used for the ^1H NMR simulation spectra of the dihydride catalyst–substrate complexes (200 MHz, [D_6]acetone): **2a**: $\delta = -21.04$ (ddd, $J = 29.2$, 26.2, $^2J(H,H) = -9.85$ Hz), -21.86 (dddd, $J = 29.2$, 26.2, $^2J(H,H) = -9.85$, $J = 4$ Hz). **2b**: A,B: $\delta = -20.78$ (ddd, $J = 27.5$, 27.5, $^2J(H,H) = -9.5$ Hz), -21.76 (dddd, $J = 29.5$, $J = 27.5$, $^2J(H,H) = -9.5$, $J = 2.5$ Hz); A',B': $\delta = -21.07$ (ddd, $J = 28$, 28, $^2J(H,H) = -9.5$ Hz), -21.71 (dddd, $J = 29.5$, 27.5, $^2J(H,H) = -9.5$; $J = 2.5$ Hz)

$S(NtBu)_4^{2-}$: A Dianion Isoelectronic to SO_4^{2-} and the Related $MeS(NtBu)_3^-$**

Roland Fleischer, Alexander Rothenberger, and Dietmar Stalke*

Dedicated to Professor Oskar Glemser on the occasion of his 85th birthday

Sulfur triimides and related anions, which are formally derived from sulfurous or sulfuric acid by partial or total replacement of the oxygen atoms by NR groups, were the focus of chemical research in the mid 1970s. Glemser et al. succeeded in the landmark synthesis of $S(NSiMe_3)_3$ from $LiN(SiMe_3)_2$ and NSF_3.[1] In the following years they presented a variety of asymmetrically substituted sulfur triimides.[2] Although many synthetic applications of sulfur–nitrogen compounds have been developed over the years,[3] their use as mono- or dianionic ligands in organometallic chemistry is still limited.[4] We recently reported the synthesis and structure of tris(*tert*-butyl)imidosulfite (an analogue of SO_3^{2-}), which can be oxidized to a stable radical.[5] Chivers et al. described tris(*tert*-butyl)imidoselenite[6a] and -tellurite.[6b] Dehnicke et al.[7] recently reported the structure of the S^{VI} dication $S(NPMe_3)_4^{2+}$. However, to our knowledge neither the synthesis nor the structure of the tetraimidosulfate, the nitrogen analogue of SO_4^{2-}, has yet been reported.

Here we present the syntheses and structures of tetrakis(*tert*-butyl)imidosulfate (**2**) and the related methyl tris(*tert*-butyl)imidosulfonate (**3**). In analogy to the addition of alkaline

organometallic compounds to sulfur diimides $S(NR)_2$ to yield lithium diimidosulfinates $Li(NR)_2SR'$,[8] addition of alkaline metal amides to $S(NR)_2$ yields salts of triimidosulfite $S(NR)_3^{2-}$.[5] This class of compounds provides facile access to **1** by oxidation of sulfur(IV) to sulfur(VI) with elemental bromine or iodine [Eq. (a)]. This new synthetic route is less hazardous and less time-consuming than the use of sulfur nitride trifluoride.[1]

$$[\{Li_2(t\mathrm{BuN})_3S^{IV}\}_2] + 2\,X_2 \xrightarrow{THF} \underset{\mathbf{1}}{2\,S^{VI}(N\mathrm{Bu}_3)_3} + 4\,LiX\ (X = Br, I) \quad (a)$$

$$\underset{\mathbf{1}}{S^{VI}(N\mathrm{Bu})_3} + 2\,LiN(H)t\mathrm{Bu} \xrightarrow{THF} \underset{\mathbf{2}}{[(thf)_4Li_2(N\mathrm{Bu})_4S^{VI}]} + H_2N\mathrm{Bu} \quad (b)$$

$$\underset{\mathbf{1}}{2\,S^{VI}(N\mathrm{Bu})_3} + 2\,MeLi \xrightarrow{THF} \underset{\mathbf{3}}{[(thf)_2Li_2\{(N\mathrm{Bu})_3S^{VI}Me\}_2]} \quad (c)$$

Sulfur triimide **1** reacts in THF with two equivalents of lithium *tert*-butylamide to the dilithium salt **2** and *tert*-butylamine [Eq. (b)]. Hence the reactivity of **1** is similar to that of $S(N\mathrm{Bu})_2$, which yields $[\{Li_2(N\mathrm{Bu})_3S\}_2]$ when allowed to react with two equivalents of lithium *tert*-butylamide. As in the conversion of sulfur diimides, alkaline organometallic compounds react with sulfur triimide in a very similar way. Whereas diimidosulfinates $Li(NR)_2SR'$ result from the first reaction, the latter produces triimidosulfonates $Li(NR)_3SR'$. Addition of methyllithium to a S–N double bond in **1** affords **3** [Eq. (c)]. Although the synthesis of amidodiimido sulfonic acid is known and the chemistry very well established,[9] no $RS(N\mathrm{Bu})_3^-$ fragment has yet been structurally characterized.

The crystal structure analysis[10] proves that unlike lithium sulfate, which has an infinite solid-state structure, **2** is present as discrete molecules (Figure 1);[11] thf solvation of the lithium cations prevents further aggregation. Each lithium metal is coordinated by two thf molecules and forms μ_2-bridges with two *t*BuN groups. The central sulfur atom is tetrahedrally coordinated by four *t*BuN groups. Two opposite edges of the resulting SN_4 tetrahedron are bridged by the two lithium cations. The four crystallographically independent S–N bond lengths (av 160.1 pm) do not differ significantly. The negative charge is therefore completely delocalized over the $S(N\mathrm{Bu})_4$ moiety. Due to the lithium bridging the average N-S-N angle within the LiN_2S kite-shaped rings is about 23° more acute (94.7°) than the other four N-S-N angles (117.4°).

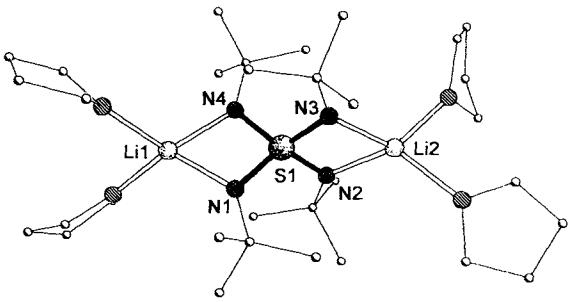

Figure 1. Crystal structure of **2**; selected bond lengths [pm] and angles [°] (standard deviations are maximum values): av S–N 160.1(3), av Li–N 195.7(6); av μ_2-bridged N-S-N 94.7(1); av nonbridged N-S-N 117.4(2).

Comparison of the S–O and S–N bond distances in related sulfur–oxygen and sulfur–nitrogen molecules reveals two major effects. Firstly, the S–O distance is on average 10 pm shorter than the corresponding S–N distance.[16] Secondly, the bonds to the sulfur atom in the oxidation state VI are 1–2 pm shorter than to those in the lower oxidation state IV (Table 1). However, the $S(N\mathrm{Bu})_3^{2-}$ ion does not seem to fit this general trend. The average S–N bond length of 165.0 pm seems to be too long when compared to the S–O bond length in SO_3^{2-} and the S–N bond length in $S(N\mathrm{Bu})_4^{2-}$. Apparently the Li–N bonds in the contact ion pairs of $[\{Li_2(N\mathrm{Bu})_3S\}_2]$ and **2** cause an elongation of the S–N bond length. In the dimeric structure of the first, each nitrogen atom interacts with two lithium cations, and the S–N bond is lengthened by 4 pm (expected value 161.0 pm: 151.0 pm in SO_3^{2-} plus 10 pm). In **2** each nitrogen atom interacts with only one lithium cation, and the S–N bond is lengthened by merely 1.1 pm (149.0 pm in SO_4^{2-} plus 10 pm). Hence, the cation induces geometrical alterations within the anion. This effect has been investigated vigorously in alkaline organometallic compounds by experimental and computational studies.[17]

Table 1. Comparison of average S–O and S–N bond lengths [pm] in related sulfur–oxygen and sulfur–nitrogen systems [a].

SO_2	[12b]	143.1	153.2	$S(N\mathrm{Bu})_2$	[15]
SO_3	[12c]	141.8	151.5	$S(N\mathrm{Bu})_3$	[1b]
SO_3^{2-}	[13]	151.0	165.0	$S(N\mathrm{Bu})_3^{2-}$	[5]
SO_4^{2-}	[13]	149.0	159.9	$S(N\mathrm{Bu})_4^{2-}$	[b]
RSO_3^-	[14]	146.8	156.1	$MeS(N\mathrm{Bu})_3^-$	[b]

[a] Lithium is the counterion for the anions. [b] This work.

The lithium salt **3**, obtained by addition of methyllithium to a S–N double bond in **1**, shows a very intriguing solid-state structure.[10] In the dimeric molecule one $MeS(N\mathrm{Bu})_3^-$ anion is coordinated to the two lithium cations (Li1 and Li2 in Figure 2), whereas the other is coordinated to only one (Li2 in Figure 2).

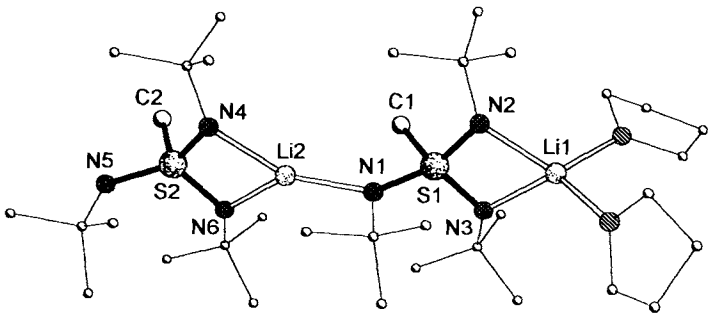

Figure 2. Crystal structure of **3**; selected bond lengths [pm] and angles [°]: S1–N1 156.2(2), S1–N2 156.3(2), S1–N3 156.7(2), S1–C1 179.6(3), S2–N4 158.1(2), S2–N5 153.5(3), S2–N6 157.5(2), S2–C2 179.9(3), av Li–N 199.3(6); N1-S1-N2 120.3(1), N2-S1-N3 97.6(1), N3-S1-N1 119.8(1), N4-S2-N5 121.0(1), N5-S2-N6 121.7(1), N6-S2-N4 97.2(1).

Li1 is tetrahedrally coordinated by two of the three nitrogen atoms bound to S1 and by two thf molecules. Li2 is trigonal-planar coordinated by the third nitrogen atom at S1 and by two nitrogen atoms of the second $MeS(N\mathrm{Bu})_3^-$ moiety. This leaves only N5 that is not coordinated to any lithium atom. Whereas the S–N(Li) bond lengths are on average 157.5 pm, the S2–N5 bond is only 153.5 pm long. As in $[\{Li_2(N\mathrm{Bu})_3S\}_2]$ the Li–N contacts in **3** cause the S–N bond to lengthen by about 4 pm. The low-temperature ^7Li NMR spectrum of **3** proves that the asymmetric structure is retained in solution.

The straightforward synthesis of tetraimidosulfates and triimidosulfonates together with their preference for forming contact ion pairs provides many applications in coordination chemistry.

Experimental Section

1: A solution of bromine (8.0 g, 50 mmol) in pentane (50 mL) was added dropwise to a solution of $[\{Li_2(NtBu)_3S\}_2]$ (14.8 g, 25 mmol) in pentane (50 mL) at −78 °C. After the reaction mixture was stirred for 1 h at room temperature, the solvent was removed in vacuo, and the crude product condensed in a cold trap. Crystallization of the resulting yellow oil from *tert*-butylamine yielded a colorless solid that melts at 57.5 °C (6.81 g, 28 mmol, 55%). ^{1}H NMR (400 MHz, C_6D_6, 25 °C): $\delta = 1.31$ (s, 27H, *t*Bu). ^{13}C NMR (100 MHz, C_6D_6, 25 °C): $\delta = 30.33$ (s, $C(CH_3)_3$), 56.99 (s, $C(CH_3)_3$).

2: *tert*-Butylamine (1 mL, 10 mmol) was added dropwise to *n*-butyllithium in hexane (6.1 mL of a 1.6 M solution, 10 mmol) at −78 °C. The reaction mixture was allowed to warm to room temperature and stirred for 30 min. A solution of **1** (1.23 g, 5 mmol) in THF (5 mL) was added at room temperature and stirred for 30 min. Crystals of **2** suitable for X-ray structure analysis were obtained from the resulting solution after storing for two days at 0 °C (yield 2.0 g, 4.2 mmol, 84%). The product decomposes at temperatures slightly higher than 200 °C. ^{1}H NMR (400 MHz, C_6D_6, 25 °C): $\delta = 1.39$, 3.53 (16H, thf); 1.42 (s, 36H, CH_3). ^{7}Li NMR (155 MHz, C_6D_6, 25 °C): $\delta = 1.49$ (s). ^{13}C NMR (100 MHz, C_6D_6, 25 °C): $\delta = 25.74$ (s, $O(CH_2)_2(CH_2)_2$), 30.51 (s, $C(CH_3)_3$), 57.31 (s, $C(CH_3)_3$), 67.90 (s, $O(CH_2)_2(CH_2)_2$).

3: Methyllithium in diethyl ether (1.25 mL of a 1.6 M, 2 mmol) was added dropwise to **1** (0.49 g, 2 mmol) in THF (5 mL). After the reaction mixture was stirred for 30 min, all the volatile components were removed. Crystals that were suitable for X-ray structure analysis were obtained from a solution of **3** in THF. The colorless dimer was isolated by filtration and drying in vacuo (yield 0.42 g, 0.6 mmol, 62%). ^{1}H NMR (400 MHz, [D$_8$]toluene, 25 °C): $\delta = 1.38$, 3.57 (16H, thf); 1.48 (s; 36H, CH_3). ^{7}Li NMR (155 MHz, [D$_8$]toluene, 60 °C): $\delta = 3.85$ (s); (−60 °C): $\delta = 3.42$(s), 4.07(s), 4.93(s).

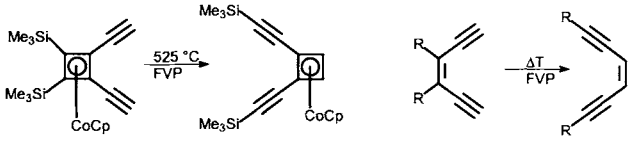
A Restitutive Bergman Rearrangement: Synthesis of a CpCo-Complexed, Tetraethynylated Cyclobutadiene**

Markus Altmann, Gaby Roidl, Volker Enkelmann, and Uwe H. F. Bunz*

The diethynylcyclobutadiene rearrangement—that is, the conversion of **1** into **2** under the conditions of flash vacuum pyrolysis (FVP)—was discovered in 1979 by Vollhardt and Fritch[1] and belongs to the larger group of Bergman rearrangements (**3** → **4**).[2–5] However, for the conversion **1** → **2** it was



1 **2** **3** **4**

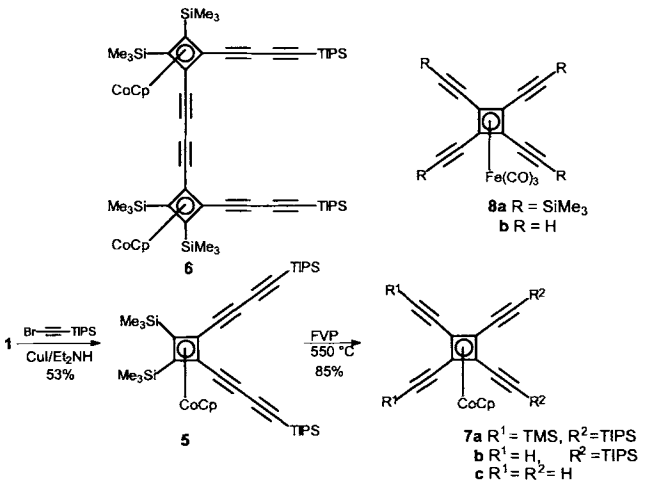
not possible to intercept intermediates with a 1,4-dehydrobenzene structure. Only **2**, in which steric strain resulting from the adjacent trimethylsilyl groups in **1** has been removed, was observed as the thermodynamic product of the system. Although this rearrangement is fascinating in a mechanistic sense, it does not seem to be particularly attractive for a purely *synthetic* purpose at first sight.

We are interested in the synthesis, chemistry, and material science of multiply ethynylated cyclobutadiene complexes and have been able to utilize Stille–Beletskaya-type coupling[6] to synthesize tricarbonyl(tetraethynylcyclobutadiene)iron.[7] However, this method is not applicable to tetraethynylated cyclobutadiene derivatives stabilized by CpCo (for example **7**, see Scheme 1), because the corresponding iodinated cyclobutadienes are not available.[8] A first experiment for the rational synthesis of **7** involving the dimerization of bis(trimethylsilyl)hexa-1,3,5-triyne over $[CpCo(CO)_2]$ led to an inseparable mixture of compounds.



Scheme 1. TIPS = triisoproplysilyl.

We decided to exploit the diethynylcyclobutadiene rearrangement of a suitably constructed precursor as a possible route to **7**. Reaction of **1** with bromo(triisopropylsilyl)ethyne under the conditions of Cadiot–Chodkiewicz coupling[9] led to the isolation of the double-coupling product **5** in 53% yield. In addition, the corresponding dimer **6** was obtained in 22% yield as a result of a mixed cross-coupling–homocoupling process.

Crystalline bisdiyne **5** was distilled through a densely coiled quartz tube (2×10^{-4} Torr, 550 °C) by heating with a heat gun. Flash chromatography (pentane, silica gel) of the product led to a compound with a considerably decreased R_f value (66%) and unchanged **5** (24%). NMR spectroscopic data of the product strongly suggest the formation of **7a** (Table 1). A dark, insoluble, and infusible thin film on the inside of the tube, probably due to decomposition of **5** during pyrolysis, must be considered to account for the mass balance (10%). The yield of **7a** was 88% based on recovered starting material. Surprisingly no other soluble products were formed. Only traces of **5** and **7a** were isolated when the pyrolysis temperature was raised to 700 °C, and a fibery, lustrous, dark solid of unknown structure formed, which is insoluble in all common organic solvents. Attempts to rearrange **5** with R = Ph (instead of TIPS) were unsuccessful; we only recovered starting material. Increasing the temperature also resulted in an infusible, insoluble, X-ray amorphous substance in low yield.

Table 1. Spectroscopic data of the newly synthesized compounds.

5: M.p. = 103 °C; IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3105, 2955, 2938, 2180, 1247, 846; ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 0.17 (s, 18H, TMS-H), 1.09 (s, 42H, TIPS-H), 4.98 (s, 5H, Cp-H); ^{13}C NMR (75 MHz, CD_2Cl_2): δ = 0.00 (6C, TMS-C), 11.49, 18.51 (18C, TIPS-C), 81.69 (5C, Cp-C), 66.69, 75.39 (4C, cyclobutadiene-C), 73.32, 77.13, 88.62, 90.75 (8C, alkyne-C); elemental analysis calcd for $C_{41}H_{65}Si_4Co$ (729.2): C 67.53, H 8.98; found C 67.68, H 8.31.

6: M.p. = 119 °C; IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3107, 2955, 2939, 2182, 1248, 848; ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 0.21 (s, 36H, TMS-H), 1.10, 1.11 (2s, 42H, TIPS-H), 5.02 (s, 10H, Cp-H); ^{13}C NMR (75 MHz, CD_2Cl_2): δ = 0.27 (12C, TMS-C), 11.76, 18.77 (18C, TIPS-C), 81.95 (10C, Cp-C), 66.55, 67.76, 75.55, 75.77 (8C, cyclobutadiene-C), 73.75, 77.36, 77.95, 80.17, 88.82, 91.08 (12 C, alkyne-C).

7a: M.p. = 88 °C; IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3104, 2955, 2948, 1450, 847; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.21 (18H, TMS-H), 1.11 (42H, TIPS-H), 4.89 (5H, Cp-H); ^{13}C NMR (75 MHz, $CDCl_3$): δ = −0.10 (6C, TMS-C), 11.51, 18.86 (18C, TIPS-C), 60.61, 61.80 (4C, cyclobutadiene-C), 84.37 (5C, Cp-C), 97.49, 98.75, 100.68, 100.70 (8C, alkyne-C); UV/Vis (CH_2Cl_2): λ [nm] = 275 (ε = 23220), 335 (ε = 4120); MS (FD) m/z = 728.2; elemental analysis calcd for $C_{41}H_{65}Si_4Co$ (729.2): C 67.53, H 8.98; found C 68.49, H 8.75.

7b: M.p. = 53 °C; IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3301, 3102, 2956, 1456, 1248, 848; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.12 (42H, TIPS-H), 3.33 (2H, alkyne-H), 4.97 (5H, Cp-H); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 11.51, 18.86 (18C, C-TIPS), 59.87, 61.61 (4C, cyclobutadiene-C), 84.33 (5C, Cp-C), 77.69, 81.90, 97.73, 100.17 (8 C, alkyne-C); MS (FD) m/z = 584.1.

7c: M.p. = 105 °C (decomp); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3302, 3103, 1245; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 3.33 (4H, alkyne-H), 4.97 (5H, Cp-H); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 59.86 (4C, cyclobutadiene-C), 82.30 (5C, Cp-C), 77.05 (4C, alkyne-C), 84.52 (4C, alkyne-C); UV/Vis (CH_2Cl_2): λ [nm] = 268 (ε = 24290), 324 (ε = 8200); MS (FD) m/z = 272.26; elemental analysis calcd for $C_{17}H_9Co$ (272.2): C 75.02, H 3.33; found C 75.20, H 4.21.

Complete deprotection of **7a** occurred in 89% yield upon treatment with Me_4NF in DMSO for 1 h at 120 °C. Subsequent flash chromatography (pentane, silica gel) furnished a yellow, crystalline material that displayed only four signals (δ = 59.9, 77.1, s; 82.3, 84.5, d) in the ^{13}C NMR and two singlets (3.33, 4.97; ratio 4:5) in the ^{1}H NMR spectrum. These analytical data can only be interpreted as the formation of **7c**. As a result, the assignment of structure **7a** was correct. In contrast to **8** (R = H), which decomposes rapidly when isolated, bright yellow **7c** is stable in the crystalline state for a couple of hours at ambient temperature and can be stored at 0 °C for several days. The sterically demanding CpCo group is responsible for the stability, which is greatly enhanced relative to that of the iron analog. To our knowledge **7c** is the most stable of all reported peralkynylated moieties with unprotected, terminal alkyne groups.[10]

The stability of **7c** as a peralkynylated π system permitted an X-ray crystal structure analysis of a suitable crystal grown from hexane. The results corroborated the molecular topology of the ligand (Figure 1).[11] There are two independent molecules in the unit cell. Whereas the bond lengths and angles in one molecule are in good agreement with known values,[12] the cyclobutadiene ring of the second shows more deviation from the tetragonal symmetry and has bond angles ranging from 86–92° and bond lengths between 1.42–1.52 Å. This is probably due to crystal packing.

K_2CO_3 in methanol deprotects **7a** cleanly to the completely air- and water-stable **7b** (R = H); the TIPS groups are not affected by these reaction conditions. The UV/Vis spectrum of **7a** shows two bands at λ = 272 and 335 nm, which are similar to those for **8** (R = TMS, λ = 259 and 296 nm). It appears that the electron-withdrawing $Fe(CO)_3$ group in **8** affects the LUMO more than the HOMO and thus shifts the observed transitions to shorter wavelengths.

We have demonstrated that rearrangement of **5** yields a complexed, tetraethynylated cyclobutadiene with absolute regiospecifity in excellent yields. The observation of a Bergman-

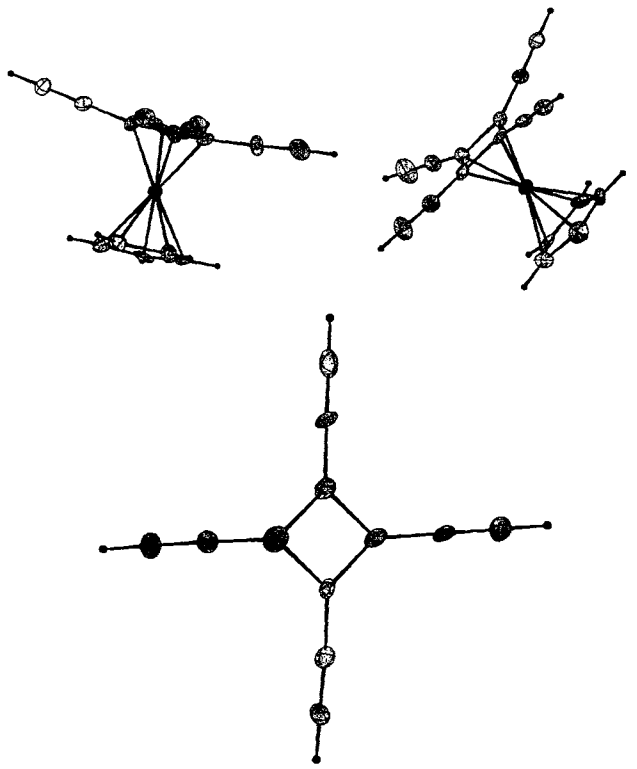

Figure 1. Top: ORTEP drawing of the crystal structure of **7c**; both independent molecules in the unit cell are shown. Bottom: View of the tetragonal hydrocarbon ligand in **7c**.

type rearrangement of a peralkynylated species is without precedence and may have wider applications, such as the formation of tetraethynylethylene derivatives from bis(butadiynylated), *Z*-configurated olefins. Examination of the reaction mechanism of this rearrangement is under way. In the future we will develop the use of **7b,c** in constructing perethynylated, cyclic, organometallic, dehydroannulenic oligomers and dendrimer-type molecules.

Experimental Section

Coupling reaction: A flame-dried Schlenk flask was charged with **1** (398 mg, 1.08 mmol) and THF (50 mL) and cooled to −78 °C. BuLi (1.38 mL, 2.20 mmol, hexanes) was added, and the reaction mixture warmed to 0 °C. CuI (419 mg, 2.20 mmol) was introduced. After 15 min the mixture was recooled to −78 °C dry propylamine and bromo(triisopropylsilyl)acetylene (10 mL) were added, and the temperature raised to 21 °C. Aqueous workup and flash chromatography (pentane, silica gel) yielded **5** (421 mg, 53%) and, as a second band, **6** (125 mg, 22%).

Pyrolysis: A coiled quartz tube (1 m × 0.008 m) was held at 550 °C and 1.5×10^{-4} mbar (dynamic) while **5** (50 mg, 68.6 μmol) was vaporized with a heating gun at 170–250 °C and distilled through the quartz tube. The products were collected in a U-tube held at ambient temperature. Flash chromatography (pentane, silica gel) yielded **5** (12 mg, 24%) and, as a second band, **7a** (33 mg, 66%).

Deprotection to **7b**: Complex **7a** (20.0 mg, 27.4 μmol) was dissolved in CH_2Cl_2 (10 mL), treated with a suspension of K_2CO_3 (500 mg, 3.67 mmol) in MeOH (3 mL), and stirred for 10 min. Aqueous workup and flash chromatography (pentane, flash silica gel) yielded **7b** (15.6 mg, 98%). **7c**: Me_4NF (300 mg, 3.22 mmol) was dissolved at 140 °C in DMSO (15 mL), and the solution cooled to 21 °C. Complex **7a** (45.0 mg, 61.7 μmol) in ethyl ether (10 mL) was added, and the mixture stirred for 2 h at 120 °C. Aqueous workup and flash chromatography (pentane, silica gel) yielded **7c** (15.0 mg, 89%).

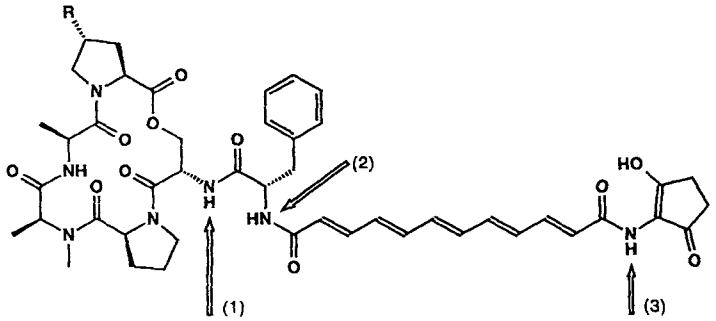
Synthesis of Enopeptin B from *Streptomyces* sp RK-1051**

Ulrich Schmidt,* Karin Neumann,
Andreas Schumacher, and Stefan Weinbrenner

The closely related enopeptins A (**1**) and B (**2**, Scheme 1) were first isolated in 1991 from the culture fluid of *Streptomyces* sp RK-1051, and their structures determined.[1] They contain a



1 R = CH_3
2 R = H

Scheme 1. Enopeptin A (**1**) and B (**2**). The amide bonds indicated by arrows were coupled in the order 1, 2, 3 (strategy 1) and 2, 3, 1 (strategy 2).

phenylalanyl cyclopeptolide connected to an aminocyclopentanedione through a dodecapentaenedioic acid residue. In contrast to the proline unit in **2**, *trans*-4-methylproline is found in **1**. Both exhibit antibiotic effects against gram-positive bacteria, especially certain strains of *Staphylococcus aureus*. The combination of a peptolide, a polyene, and a reductone in a natural product is unique. The main difficulty in the synthesis of **1** and **2** lies in coupling the three components.

Components **8** and **10** were prepared in a few steps from pentapeptolide **3**[2] (Scheme 2); the key step is the ring closure to give **7** by the pentafluorophenyl ester method that we developed.[3] Cyclopeptide **7** was obtained in 68% yield in four steps in a two-phase system of aqueous $NaHCO_3$ and CH_3Cl. Hydrogenolytic cleavage of the benzyloxycarbonyl (Z) protecting group to form **8**, acylation with Boc-phenylalanine (Boc = *tert*-butoxycarbony) to **9**, and subsequent removal of the Boc group gave **10**, which was used just as **8** for preparing **2**.

Monoesters,[4] diesters, and amides of dodecapentaenedioic acid were prepared by Horner condensation with octatrienedial (Scheme 3).[5] Derivatives **14** and **16** were used for preparing **2**; compounds **13** and **15** contain compatible protective groups that can be selectively removed.

Numerous *N*-acyl-2-aminocyclopentane-1,3-diones have been isolated as metabolic products from microorganisms,[6-16] and some simple ones have been synthesized.[17-19] However, for the synthesis of **2** only the acylation of 2-aminocyclopentanedione, whose preparation by hydrogenation of 2-nitrocyclopentanedione was improved by using PtO_2 instead of PdO,

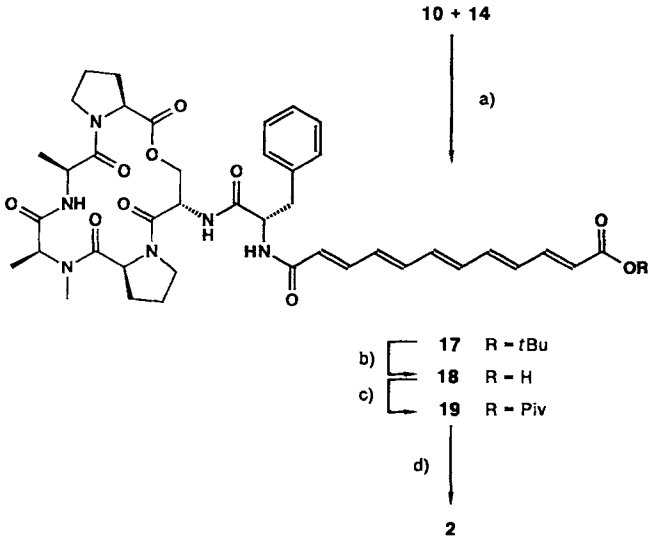
[**] Concerning Aminoacids and Peptides, part 103. Concerning Cyclopeptides, part 32. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. – Parts 102 and 31: ref. [3b].

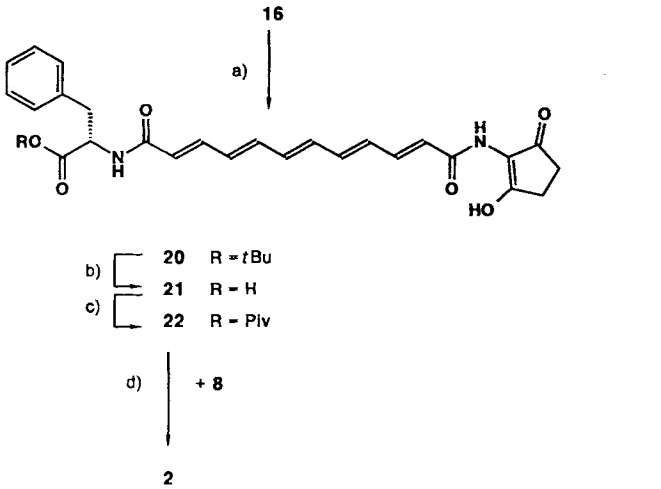
 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3610-1110 $ 17.50+.50/0

is suitable. Difficulties in the acylation of aminoreductones are due to the very low nucleophilicity of the amino group and the lability of the free amino compound, which undergoes rapid autocondensation. These problems can only be overcome with highly reactive acylation components, such as anhydrides or acid chlorides, and inverse addition.

We have prepared **2** by successive coupling of the amide bonds 1, 2, and 3 (strategy 1) and 2, 3, and 1 (strategy 2, see Scheme 1). Removing the Boc group of **9** to form phenylalanyl-cyclopeptide **10** took place only under drastic conditions. The steric hindrance of the amino group of the phenylalanine was evident from the low yield (17%) of the subsequent acylation with half ester **14** to form polyenepeptolide **17.** Coupling of **18** with the aminocyclopentanedione to **2** was only achieved by inverse reaction of the mixed anhydride **19** in 6% yield (simultaneous, dropwise addition of four equivalents each of 2-aminocyclopentane-1,3-dione hydrochloride and *N*-methylmorpholine (NMM) to a solution of **19**, Scheme 4.



Scheme 4. a) DMF, HATU, Hünig base, 0 °C, 12 h, 17%; b) CH_2Cl_2, trifluoroacetic acid (TFA), RT, 2 h; c) THF, pivaloyl(Piv)-OCl, NMM, RT, 2 h; d) DMF, 2-aminocyclopentane-1,3-dione hydrochloride, NMM, RT, 3 h; b)–d) 6%.



Scheme 5. a) THF, *i*BuOCOCl, NMM, 0 °C , 2 h; DMF, 2-aminocyclopentane-1,3-dione hydrochloride, NMM, 0 °C, 3 h, 49%; b) CH_2Cl_2, TFA, RT, 2 h; c) THF, PivOCl, NMM, 0 °C , 2 h; d) DMF, NMM, RT, 12 h; b)–d) 8%.

The mixed anhydride from phenylalanine monoamide of the polyenedioic acid **16**, and *i*BuOCOCl were converted by the inverse method with aminocyclopentanedione to **20** in 49% yield (Scheme 5). After cleavage of the *tert*-butyl ester to form **21**, the mixed anhydride **22** was prepared and coupled with peptolide **8** to form **2** in 8% yield.

The final products of the two syntheses were isolated and purified (preparative thin layer chromatography)[20] only with difficulty. The R_f value and high-resolution mass spectra were identical to that of the natural product. Due to unexplained solvent effects, the signals of the amide protons in the ^{1}H NMR spectrum (500 MHz, $CDCl_3$) deviate from those reported by Isono et al.[1] In [D_6]DMSO the chemical shifts were almost identical to those obtained for **1** in [D_6]DMSO[20] (Table 1).

Table 1. Characteristic ^{1}H NMR signals (300 and 500 MHz, [D_6]DMSO) of enopeptin A (**1**) and synthesized enopeptin B (**2**).

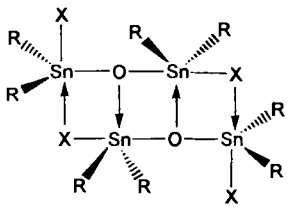
Trimethylene-Bridged Tri- and Tetratin Compounds as Building Blocks for Unusual Double and Triple Ladders

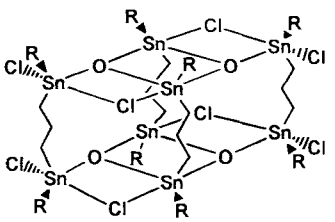
Michael Mehring, Markus Schürmann, Hans Reuter, Dainis Dakternieks, and Klaus Jurkschat*

Dedicated to Professor Adolf Zschunke on the occasion of his 60th birthday

Controlled hydrolysis of diorganotin dichlorides usually affords dimeric tetraorganodistannoxanes $[R_2XSnOSnXR_2]_2$ (X = Cl, OH) of type **A**. These compounds attract attention



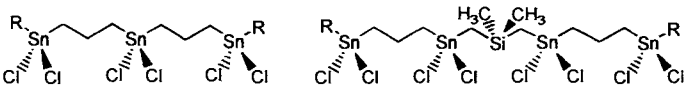
A



B

because of their interesting structural features[1-5a] and their applications as catalysts in organic chemistry.[6-11] The characteristic structural feature of this class of compounds is a planar $Sn_4Cl_4O_2$ layer with a centrosymmetric Sn_2O_2 ring, known as a ladder-type structure.[5]

We have been working for some time on the linkage of dimeric ladder units of type **A**. We have shown that the trimethylene-bridged double ladder of type **B** is formed on reaction of 1,3-bis[(trimethylsilylmethyl)dichlorostannyl]propane $[Me_3SiCH_2(Cl_2)SnCH_2]_2CH_2$ with di-*tert*-butyltin oxide $(tBu_2SnO)_3$. This result led to the question whether pillar-shaped triple and quadruple ladders can be constructed from the tri- and tetratin compounds **1** and **2**.



1 R = CH_2SiMe_3 **2**

The reaction of **1** with $(tBu_2SnO)_3$ leads in quantitative yield to **3** as colorless crystals [Eq. (a)]. The X-ray structure analysis

$$\mathbf{1} + 3/2\ (tBu_2SnO)_3 \xrightarrow[-2\ tBu_2SnCl_2]{CH_2Cl_2} 1/4\ \{[R(Cl)Sn(CH_2)_3Sn(Cl)(CH_2)_3Sn(Cl)R]O_{3/2}\}_4 \quad \textbf{(a)}$$

3 R = CH_2SiMe_3

[13] of **3** shows a triple ladder structure (Figure 1) in which three almost planar $Sn_4Cl_4O_2$ layers are linked by four trimethylene chains. The average deviation of the atoms from the central plane (0.024 Å) is smaller than that of the outer layers (0.182 Å). In analogy to **B**[12] all tin atoms are pentacoordinate and have a distorted trigonal-bypyramidal coordination environment. The solid-state structure is retained in solution. The $^{119}Sn\{^1H\}$ NMR spectrum in $CH_2Cl_2/D_2O_{cap.}$ shows four signals at $\delta = -94.0, -114.4, -134.0$, and -142.8 with an integral ratio of 2:1:2:1. The $^2J(^{119}Sn,^{117}Sn)$ coupling constants (61–65 Hz) are of the same order of magnitude as those of the dimeric

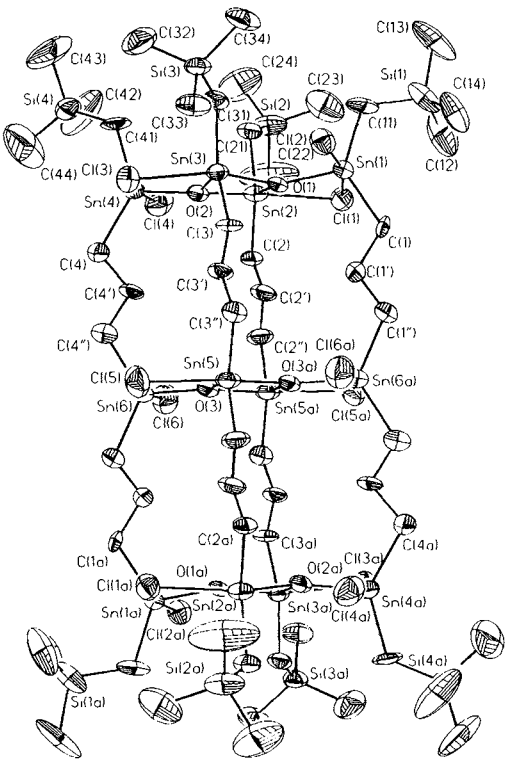


Figure 1. Molecular structure of **3** (SHELXTL-Plus, thermal ellipsoids for 50% probability). Selected bond lengths [Å] and angles [°]: Sn–$Cl_{terminal}$ 2.428(5)–2.434(6), Sn–$Cl_{bridging}$ 2.616(5)–2.783(6), Sn–O_{eq} 2.003(11)–2.032(11), Sn–O_{ax} 2.127(11)–2.155(11); O_{ax}-Sn-Cl_{ax} 150.2(3)–151.8(3), Cl_{ax}-Sn-Cl_{ax} 164.9(2)–166.1(2), Sn_2O_2 rings: O-Sn-O 73.2(4)–73.8(4), Sn-O-Sn 105.6(5)–106.3(5), Sn_2ClO rings: Sn-O-Sn 122.6(5)–130.6(6), Sn-Cl-Sn 81.53(14)–83.7(2), O-Sn-Cl 74.8(3)–78.1(3), C-Sn(1,2,3,4)-C 130.8(7)–136.4(6), C-Sn(5,6)-C 122.3(7)–123.7(7).

tetraorganodistannoxanes[14] and of the double ladder **B**. The $^{13}C\{^1H\}$ NMR spectrum, which shows two sets of five signals, is also in agreement with the triple-ladder structure.

The reaction of **2** with $(t\mathrm{Bu_2SnO})_3$ affords **4** as a colorless solid [Eq. (b)]. The crystal structure of **4** is shown in Figure 2.

$$\mathbf{2} + 2/3\,(t\mathrm{Bu_2SnO})_3 \xrightarrow[-2\,t\mathrm{Bu_2SnCl_2}]{\mathrm{CH_2Cl_2}} 1/2\ \{[(\mathrm{R(Cl)Sn(CH_2)_3Sn(Cl)CH_2)_2SiMe_2}]O_2\}_2 \quad \mathbf{4},\ \mathrm{R = CH_2SiMe_3} \qquad (b)$$

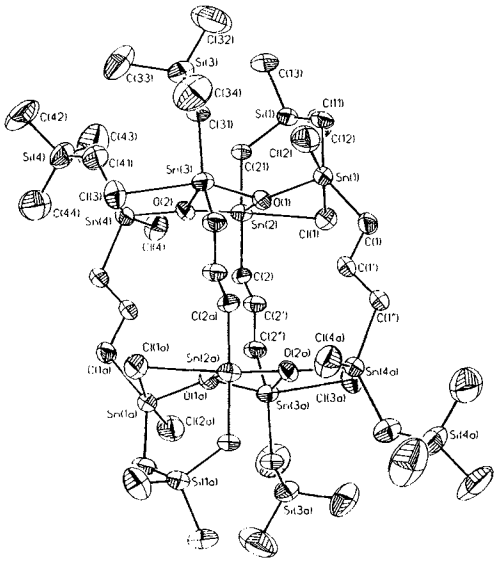

Figure 2. Molecular structure of **4** (SHELXTL-Plus, thermal ellipsoids for 50% probability). Selected bond lengths [Å] and angles [°]: Sn–$Cl_{terminal}$ 2.448(3)–2.463(3), Sn–$Cl_{bridging}$ 2.673(3)–2.781(3), Sn–O_{eq} 2.016(5)–2.055(5), Sn–O_{ax} 2.119(5)–2.145(5); O_{ax}-Sn-Cl_{ax} 148.45(14)–150.9(2), Cl(1)-Sn(1)-Cl(2) 169.02(8), Cl(3)-Sn(4)-Cl(4) 160.48(8), Sn_2O_2 ring: O-Sn-O 73.6(2), 74.1(2), Sn-O-Sn 104.0(2), 105.0(2), Sn_2ClO rings: Sn-O-Sn 115.7(2), 123.5(3), Sn-Cl-Sn 79.27(8), 82.19(8), O-Sn-Cl 75.0(2)–79.8(2), C-Sn-C 131.9(4)–141.4(3).

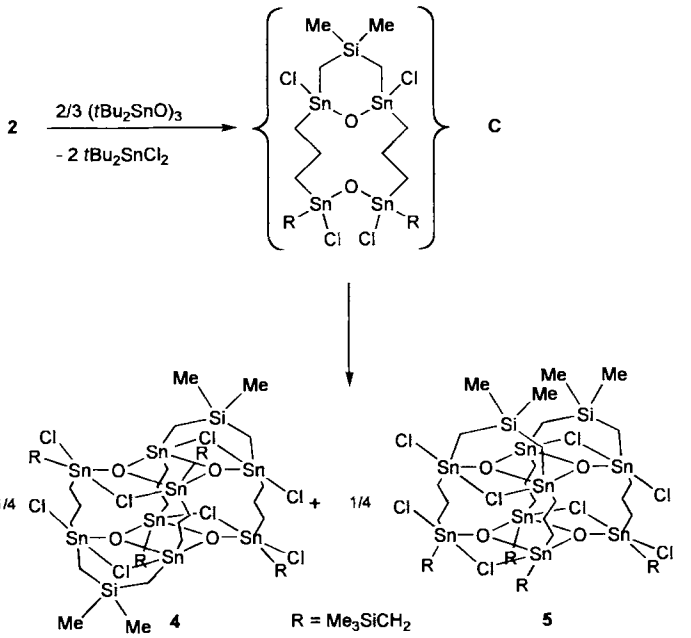
As in the double ladder of type **B**, in **4** two $Sn_4Cl_4O_2$ layers are interconnected by four trimethylene chains. Bond lengths and bond angles are similar to those in **B** and **3**. A feature of the structure of **4** is the additional linkage of two tin atoms of one $Sn_4Cl_4O_2$ layer by a CH_2-$SiMe_2$-CH_2 bridge. This results in greater distortion of the $Sn_4Cl_4O_2$ layers (average deviation of the atoms from the plane 0.260 Å) than in **3**. As with **3**, the solid-state structure of **4** is retained in solution, as is evidenced by the ^1H, $^{13}C\{^1H\}$, and $^{119}Sn\{^1H\}$ NMR spectra. The $^{119}Sn\{^1H\}$ NMR spectrum shows four signals of equal integral ratio at $\delta = -91.2$, -106.7, -129.4, and -141.7. The $^{13}C\{^1H\}$ NMR spectrum shows two equally intense sets of seven signals. Formally the formation of **4** can be interpreted as shown in Scheme 1. After formation of the bicycle **C** head-to-tail dimerization of **C** leads to **4**.

So far, the head-to-head dimer **5**, which is also expected, could only be detected by $^{119}Sn\{^1H\}$ and $^{13}C\{^1H\}$ NMR spectroscopy as a by-product of **4**. Thus, the $^{119}Sn\{^1H\}$ NMR spectrum of the crude mixture after the reaction according to Equation (b) displays, in addition to the four signals assigned to **4**, four further signals of equal integral ratio at $\delta = -99.4$, -121.3, -133.7, and -141.3. The $^{13}C\{^1H\}$ NMR spectrum of the same sample shows the signals assigned to **4** and in addition, two equally intense sets of seven signals. A solution of single crystals of **4** in $CDCl_3$ at room temperature does not show any conversion into **5**, even after several days. Thus **4** is kinetically stable and not in equilibrium with **C**.

The formation of the new ladder-type structures **3** and **4** shows the capability and limits of the concept of spacer-bridged ladders. The fact that **4** forms a "folded" double ladder instead of a quadruple ladder could be a result of additional gain of entropy by formation of the Si-CH_2-Sn-O-Sn-CH_2 six-membered chelate in the intermediate **C** (Scheme 1). We are currently investigating the influence of R and of the chain length on the formation of ladder structures of types **B** and **C**.



Scheme 1. Possible mode of formation of **4** and **5**.

Experimental Section

1: A solution of Ph_2SnCl_2 (5.15 g, 15 mmol) in Et_2O/THF (3/1, 60 mL) was added dropwise to a Grignard solution prepared from $(Me_3SiCH_2)Ph_2Sn(CH_2)_3Cl$ (20 g, 41 mmol) [16] and Mg (1.21 g, 49 mmol) in Et_2O (130 mL). The reaction mixture was heated at reflux for 12 h and then hydrolyzed. The organic layer was separated, dried over Na_2SO_4, and filtered, and the solvent was evaporated to yield an oil. This was kept for several hours at 130 °C and 10^{-5} Torr to remove all volatile by-products. The oily residue (10.6 g) was dissolved in acetone and treated dropwise under ice cooling with a solution of $HgCl_2$ (15.34 g, 56 mmol) in acetone (120 mL). The resulting PhHgCl was filtered off. The filtrate was evaporated in vacuo, and the residue recrystallized several times from hexane/CH_2Cl_2 to give **1** as a colorless solid (2.50 g, 20% yield). $^{119}Sn\{^1H\}$ NMR (111.92 MHz, $CHCl_3/D_2O_{cap}$): $\delta = 90.4$ [$^4J(^{119}Sn,^{117}Sn) = 169$ Hz], 125.6 [$^4J(^{119}Sn,^{117}Sn)$] = 171 Hz; ^1H NMR (400.13 MHz, $CDCl_3$): $\delta = 0.22$ (s, 18H, $SiMe_3$), 0.93 [s, $^2J(^1H,^{119}Sn) = 92$ Hz, 4H, $SnCH_2$], 1.86 (t, 4H, CH_2Sn), 1.99 (t, 4H, CH_2Sn), 2.39 (quint, 4H, CH_2); $^{13}C\{^1H\}$ NMR (100.63 MHz, $CDCl_3$): $\delta = 1.07$ [$^1J(^{13}C,^{29}Si) = 52$ Hz, $^4J(^{13}C,^{29}Si) = 27$ Hz, Me_3Si], 12.08 [$^1J(^{13}C,^{119}Sn) = 295$ Hz, $SnCH_2Si$], 20.87, 29.25, 29.38 (CH_2). M.p. 81–82 °C. Analysis calcd. for $C_{14}H_{34}Cl_6Si_2Sn_3$: C 20.33, H 4.11; found: C 20.40, H 4.28%.

2: A Grignard reagent was prepared from $(Me_3SiCH_2)Ph_2Sn(CH_2)_3Br$ [16] (20 g, 46 mmol) and Mg (4.5 g, 185 mmol) in Et_2O (150 mL). Excess Mg was filtered off, and $(Ph_2FSnCH_2)_2SiMe_2$ [17] (11.70 g, 18 mmol) was added in small portions. Heating at reflux for 12 h and workup analogous to **1** gave an oil, which was kept for several hours at 160 °C and 10^{-5} Torr to remove all volatile by-products. This gave $[(Me_3SiCH_2)Ph_2Sn(CH_2)_3SnCH_2]_2SiMe_2$ as yellow oil [$^{119}Sn\{^1H\}$ NMR (111.92 MHz, $CDCl_3$): $\delta = -63.7$, -64.9]. This oil (4 g, 2.79 mmol) was dissolved in acetone (30 mL), followed by dropwise addition at 0 °C of a solution of $HgCl_2$ (6.36 g, 23.44 mmol) in acetone (30 mL). The reaction mixture was stirred for 12 h, PhHgCl filtered off, and the solvent evaporated. The resulting residue was extracted for 18 h in a Soxhlet extractor with *n*-pentane (50 mL) to give a pentane-insoluble precipitate, which was filtered off, dissolved in diethyl ether, and filtered. The filtrate was evaporated in vacuo to give **2** (2.00 g, 65%) as a colorless solid.

$^{119}Sn\{^1H\}$ NMR (111.92 MHz, $CDCl_3$): $\delta = 118.0$ [$^4J(^{119}Sn,^{117}Sn) = 159$ Hz], 131.1 [^4J ($^{119}Sn,^{117}Sn$) = 169 Hz]; ^1H NMR (400.13 MHz, $CDCl_3$): $\delta = 0.18$ (s, 18H, $SiMe_3$), 0.37 (s, 6H, $SiMe_2$), 0.89 [s, $^2J(^1H,^{119}Sn) = 91$ Hz, 4H, $SnCH_2Si$], 1.04 [s, $^2J(^1H,^{119}Sn) = 79$ Hz, 4H, $SnCH_2Si$], 1.82 (t, 4H, CH_2Sn), 1.93 (t, 4H, CH_2Sn), 2.33 (quint, 4H, CH_2); $^{13}C\{^1H\}$ NMR (100.63 MHz, $CDCl_3$): $\delta = 1.00$ ($SiMe_3$), 1.19 ($SiMe_2$), 12.04, 12.44 ($SnCH_2Si$), 20.80 (CH_2), 29.27, 30.42 (CH_2Sn); $^{29}Si\{^1H\}$ NMR (59.63 MHz, $CDCl_3$): $\delta = 2.66$ [$^2J(^{29}Si,^{119}Sn) = 35$ Hz, $SiMe_3$], 5.55 [$^2J(^{29}Si,^{119}Sn) = 49$ Hz, $SiMe_2$]. M.p. 79–81 °C. Analysis calcd. for $C_{18}H_{44}Cl_8Si_3Sn_4$: C 19.60, H 3.99; found: C 19.20, H 3.92%.

3: (tBu$_2$SnO)$_3$ (225 mg, 0.30 mmol) was added in small portions to a solution of **1** (500 mg, 0.60 mmol) in CH_2Cl_2 (20 mL). After heating at reflux for 15 min, the solvent was distilled off. The residue was washed several times with *n*-hexane and recrystallized from chloroform to give **3** as colorless crystals (430 mg, 96%). $^{119}Sn\{^1H\}$ NMR (111.92 MHz, $CH_2Cl_2/D_2O_{Cap.}$): $\delta = -94.0$ [$^2J(^{119}Sn,^{117}Sn) = 65$ Hz], -114.4 [$^2J(^{119}Sn,^{117}Sn) = 62$ Hz], -134.0 [$^2J(^{119}Sn,^{117}Sn) = 65$ Hz], -142.8 [$^2J(^{119}Sn,^{117}Sn) = 61$ Hz]; ^1H NMR (400.13 MHz, $CDCl_3$): $\delta = 0.17$ (s, 36H, Me_3Si), 0.23 (s, 36H, Me_3Si), 0.85 [s, $^2J(^1H,^{119}Sn) = 120$ Hz, 8H, $SnCH_2Si$], 0.96 [s, $^2J(^1H,^{119}Sn) = 122$ Hz, 8H, $SnCH_2Si$], 1.73 (m, 16H, CH_2), 2.02 (t, 8H, CH_2), 2.11 (t, 8H, CH_2), 2.47 (m, 8H, CH_2), 2.58 (m, 8H, CH_2); $^{13}C\{^1H\}$ NMR (100.63 MHz, $CDCl_3$): $\delta = 1.21$, 1.74 (Me_3Si), 17.48, 20.34, 20.48, 20.92 ($SnCH_2Si$), 34.96, 35.56 (CH_2Sn), 35.93, 39.56 (CH_2). M.p. 297–299 °C. Analysis calcd. for $C_{56}H_{136}Cl_{12}O_6Si_8Sn_{12}$: C 22.58, H 4.56; found: C 23.12, H 4.76%.

Application of the Langmuir–Blodgett Technique to Polyoxometalates: Towards New Magnetic Films**

Miguel Clemente-León, Christophe Mingotaud,* Béatrice Agricole, Carlos J. Gómez-García, Eugenio Coronado,* and Pierre Delhaès

Soluble metal-oxide clusters (polyoxometalates) are receiving increasing interest in materials science owing to their chemical, structural, and electronic versatility.[1] Thus, because of the ability of these polyoxoanions to act as electron acceptors and to accommodate magnetic transition metal centers in their structures, they are being used as the inorganic component of conducting radical salts based on tetrathiafulvalene-type organic donors. Of particular interest is the preparation of organic–inorganic composites in which the localized magnetic moments of the polyoxometalate cluster coexist with the mobile conducting electrons of the organic network.[2–5] Other properties of these materials, such as electrochromism[6] and electrocatalysis, have been recently exploited in the preparation of conducting catalytic electrodes based on conducting polymers such as polypyrrole,[7] polyaniline,[8, 9] polythiophene[10] and poly(3-methylthiophene).[11, 12] More recently, the use of poly(*N*-methylpyrrole) with Fe^{3+}-containing polyoxometalates has provided a sensitive electrode for detection of nitrite.[13]

Here we show that organic–inorganic films containing well organized layers of polyoxoanions can be built by using the Langmuir–Blodgett (LB) technique. Such new hybrid materials could be an important step towards the creation of new supramolecular assemblies with a high degree of order and, therefore, with improved physical properties.

To prepare the LB films we used the chemically stable Keggin polyoxometalates $[X^{n+}W_{12}O_{40}]^{(8-n)-}$ [$X^{n+} = 2(H^+)$, P^V, Si^{IV}, B^{III}, Co^{II}]. All these anions have the same structure (Figure 1),

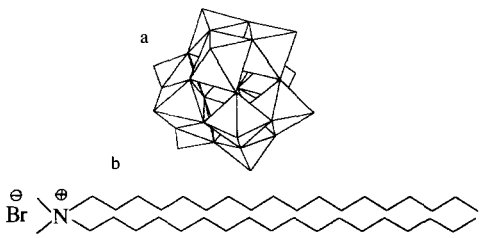

Figure 1. Polyhedral representation of the Keggin polyanions (a) and the formula of the DODA molecule (b).

but depending on the nature of X, their charge varies between -3 and -6. A monolayer of a cationic surfactant [dimethyldioctadecylammonium (DODA), see Figure 1] was used as template for adsorption of the polyoxometalates. DODA monolayers on water or sodium chloride solution exhibit a poor lipid density at the gas–water interface. Consequently it is not possible to produce ordered LB films having more than one layer from these monolayers[14] because of the strong repulsion between polar heads in the monolayer and the strong interaction of these polar heads with the water surface. In contrast, DODA monolayers on solutions containing Keggin anions lead to ordered multilayers for anion concentrations in the range 10^{-5} to 10^{-7} M. Thus, from a 10^{-6} M solution of $H_3PW_{12}O_{40}$, DODA monolayers could be efficiently deposited onto hydrophilic solid substrate with a maximum transfer ratio between 0.9 and 1 at a surface pressure of 30 mN m^{-1} and a dipping speed of 0.5 cm min^{-1}. Lowering the surface pressure or increasing the dipping speed above 3 cm min^{-1} led to a drop in the transfer ratio. These are general features for all the investigated polyanions that lead to Y-type deposits and optically defect-free LB films designated as $DODA/XW_{12}O_{40}$.[15]

Infrared linear dichroism and X-ray diffraction experiments prove the well-defined lamellar structure of these built-up films and the existence within the LB films of heteropolyoxometalates organized in monolayers. The IR spectrum of $DODA/SiW_{12}O_{40}$ LB films is shown in Figure 2. Besides the peaks at 2920, 2851, and 1467 cm^{-1} associated with the CH bonds of DODA alkyl chains, very strong peaks are observed below 1200 cm^{-1} for the polyanion vibrations. These peaks are much narrower and generally slightly shifted relative to those in the spectrum of the pure polyanions in a KBr pellet. This could be the result of a lower degree of hydration of the Keggin anions in the multilayers and/or the organization of the polyanions within the LB films. Indeed, the strong bands around 3300–3500 and 1600–1650 cm^{-1} assigned to stretching and bending modes of water are absent in the LB films. This demonstrates that the anions are largely dehydrated within the multilayers. Moreover, the observed peak shifts are surely related to the ordering and, in particular, to the presence of positively charged DODA in the film. Shifts in the Keggin IR peaks similar to those observed in the LB films have been reported by Rocchioli-Deltcheff et al.[16] for a series of Keggin salts with tetralkylammonium counter-

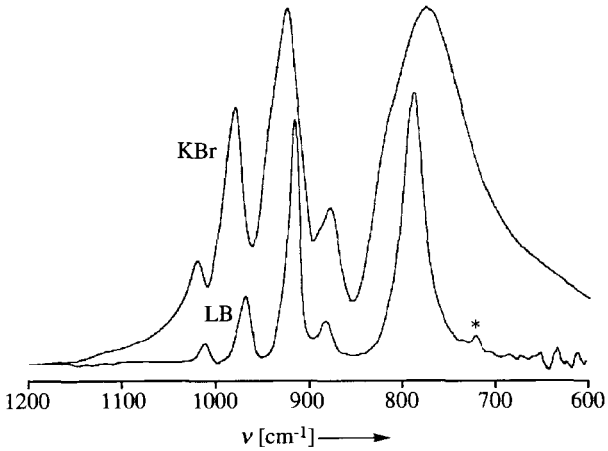

Figure 2. Infrared spectra of the $H_4SiW_{12}O_{40}$ polyanion (KBr pellet) and of a $DODA/SiW_{12}O_{40}$ LB film (20 layers) on zinc selenide. The absorbance is given in arbitrary units. The asterisk indicates the band associated with the CH_2 rocking mode of DODA.

ions. If we follow the interpretation of the frequency shift given by these authors, our results indicate that the anion–anion distance within the LB films is so large that anion–anion interactions are negligible. Another remarkable feature of the IR spectra of the $DODA/XW_{12}O_{40}$ LB films is the strong out-of-plane dichroism (Figure 3). Thus, when the IR electrical field is not

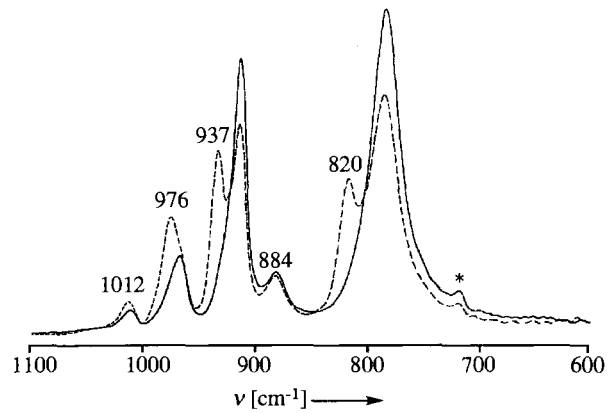

Figure 3. Infrared spectra of a $DODA/SiW_{12}O_{40}$ LB film (20 layers) on zinc selenide. The angle between the plane of the substrate and the electric field is either 0° (solid line) or 60° (dashed line). The absorbance is given in arbitrary units. The asterisk indicates the band associated with the CH_2 rocking mode of DODA.

parallel to the plane of the substrate, new peaks can clearly be seen. This result shows that the Keggin polyanions have one particular orientation (and distortion) in the multilayers, and that they can be oriented by the Langmuir–Blodgett technique. Finally, the dichroism of bands associated with the alkyl chains allows a tilt angle of the DODA chains close to 30° to be estimated for all the prepared LB films.

X-ray diffractograms of $DODA/XW_{12}O_{40}$ LB films exhibit three or four Bragg peaks. Such a number of peaks indicates that the lamellar structure of those LB films is well defined. The periodicity calculated from these data is close to 49 Å and is independent of the nature of the polyanion. From these results, one can estimate a thickness of about 10 Å for the inorganic layer. In comparison with the radius of a Keggin polyanion (ca. 5.2 Å), such a value clearly demonstrates that each inorgan-

ic layer consists of one polyanion monolayer (and not a bilayer, as would be conceivable for the Y-type transfer).

The magnetic susceptibility of a LB film was measured after deposition onto a diamagnetic substrate (see Experimental Section). As can be seen in the insert of Figure 4, the magnetic

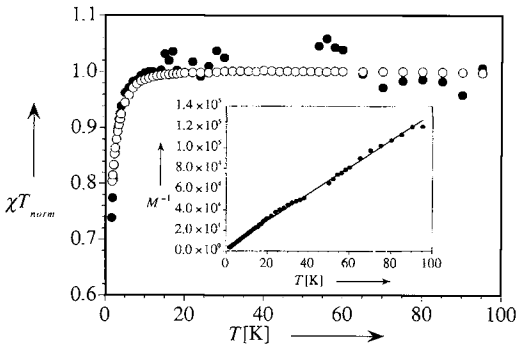

Figure 4. Plot of χT (normalized value) versus temperature for the $K_5HCoW_{12}O_{40}$ polyanion in the powder (open circles) and for the DODA/$CoW_{12}O_{40}$ LB film (full circles). Insert: reciprocal magnetization M^{-1} [emu] of the DODA/$CoW_{12}O_{40}$ LB film versus temperature. All data for the LB film are corrected for the substrate diamagnetism, and points around 40 K associated with adsorbed oxygen were deleted.

susceptibility of the DODA/$CoW_{12}O_{40}$ LB film follows the Curie law down to about 20 K, as expected from the behavior of $K_5H[CoW_{12}O_{40}]$. From such measurements and by comparison with the potassium salt, one can calculate how many paramagnetic polyanions are trapped within the LB film. The number of DODA molecules in the LB film is easily evaluated from the size of the substrate, the transfer ratio, and the molecular area at the deposition surface pressure. A comparison of these two numbers gives a ratio of DODA molecules and polyanions in the LB film close to 5 ± 1. Such a value is close to the maximum charge of the polyanion in $K_5H[CoW_{12}O_{40}](-6)$.

At low temperature, the susceptibility of this polyanion decreases (see Figure 4) because of the zero-field splitting of Co^{II} in a tetrahedral environment.[17] From such experiments, it appears that the magnetic site of such polyanions encapsulated in the LB film is weakly (or not) sensitive to the surrounding charge of the DODA molecules.

We have used the adsorption of Keggin heteropolyanions on a positively charged monolayer of DODA and the Langmuir–Blodgett technique to construct new organic–inorganic superlattices. Independent of the charge and the heteroatom in the Keggin structure, these polyanions can be organized in monolayers in well-defined LB films. For the first time, we have performed susceptibility measurements on LB films and have shown that the magnetic behavior of such an ultrathin material can be characterized by using a magnetometer. Currently we are investigating the effect of the size and shape of polyoxometalates on the formation of multilayers by using planar (Anderson type) and elongated (Dawson–Wells type) anions. The preliminary results clearly indicate that the method described in this paper can be extended to all types of polyanions or charged clusters, to give rise to new lamellar organized materials. Appropriate choice of polyoxometalate and lipid molecule should allow LB films having particular magnetic, optical, electrochromic, or electrochemical properties to be constructed.

Experimental Section

The following heteropolyoxometalates were used: $H_4[SiW_{12}O_{40}]$ (Aldrich), $H_3[PW_{12}O_{40}]$ (Prolabo); $K_5H[CoW_{12}O_{40}]$ and $K_5[BW_{12}O_{40}]$ were synthesized accordingly to literature procedures.[18–20]. Dimethyldioctadecylammonium bromide was obtained from Kodak. All commercial compounds were used without further purification. Chloroform (HPLC grade, Prolabo) was used as spreading solvent, and the lipid solutions (concentration ca. 10^{-3} M) were kept at $-18\,^{\circ}C$ during experiments to limit solvent evaporation. Built-up films were obtained by the vertical lifting method at room temperature under a continuous stream of dry nitrogen with a home-made LB Teflon trough. A barrier moved by a d.c. motor allows stepwise compression of the monolayer. After each increase of the surface pressure, the system is allowed to reach equilibrium. Steps of 2 mN m^{-1} were usually chosen. The subphase was Millipore Q-grade water with a resistivity higher than 18 MΩcm. Dipping speed was generally set to 0.5 cm min^{-1}. Films were transferred onto optically polished calcium fluoride (precoated with three layers of behenic acid if necessary) or zinc selenide for infrared linear measurements, and onto optically polished glass substrate (treated with dichlorodimethylsilane if needed) for low-angle X-ray experiments.

IR spectra were recorded on a FTIR 750 Nicolet spectrometer. The IR linear dichroism was measured to calculate the usual dichroic ratio $R = A(i = 60^{\circ})/A(i = 0^{\circ})$, where $A(i)$ is the absorption coefficient, and i is the angle between the plane of the LB film and the IR electric vector. This ratio R is related to the degree of anisotropy outside the substrate plane and allows the angle ϕ between the normal to the substrate and the dipole moment of a particular vibration [21] to be calculated with a precision of few degrees. X-ray diffraction experiments (*θ-2θ* scans) were performed with an INEL curve detector and an IBM computer for peak assignments [22]. The magnetic susceptibility was measured with a Quantum Design MPMS-5 SQUID magnetometer between 2 and 300 K. For such experiments, about 300 layers were deposited on a diamagnetic mylar sheet (0.075 × 5 × 15 mm). Two experiments (substrate alone and then substrate with the LB film) were carried out successively under the same experimental conditions (applied magnetic field 1 T). The difference gives the intrinsic magnetic susceptibility of the LB film. Experimental error on the calculated multilayer susceptibility was evaluated to be ca. 5% below 10 K, ca. 15% at 100 K, and over 30% at 300 K.

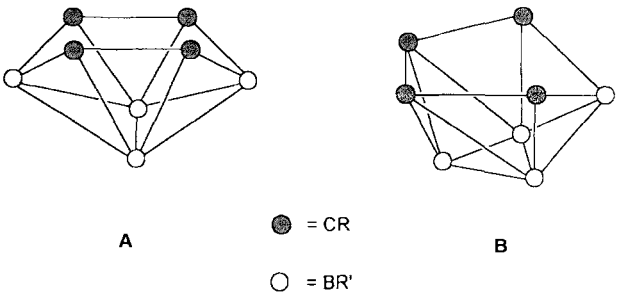
A New Route to Tetracarba-*nido*-octaboranes(8); Molecular Structure of a 6,9-Diferra-5,7,8,10-tetracarba-*nido*-decaborane(10) Derivative**

Bernd Wrackmeyer,* Hans-Jörg Schanz, and Wolfgang Milius

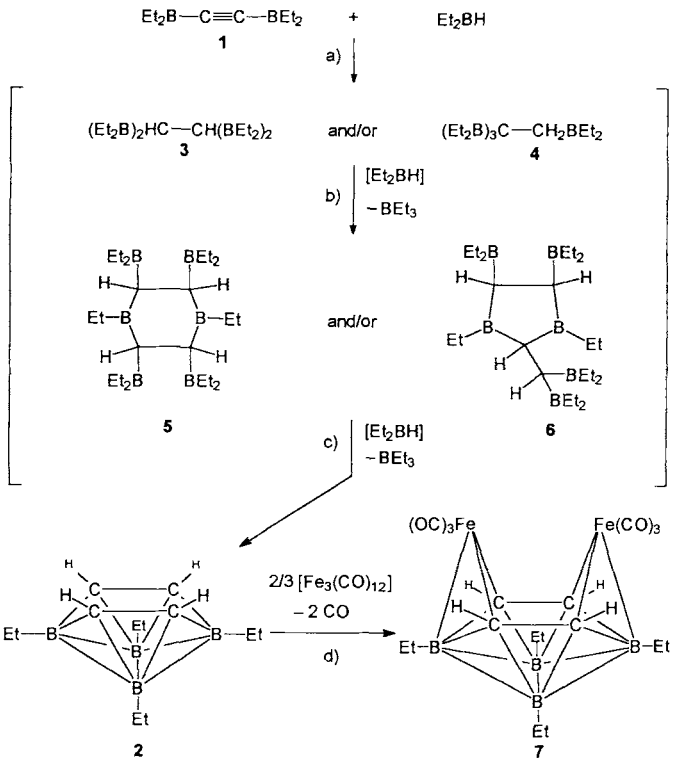
Dedicated to Professor Wolfgang Beck on the occasion of his 65th birthday

The borderline between classical and nonclassical bonding becomes particularly evident in carbon-rich carbaboranes,[1] for example in the series of frameworks *nido*-C_4B_2,[2] *nido*-C_4B_4,[3] and *nido*-C_4B_6.[4a-d] In general, the boron atoms prefer a nonclassical environment with a high order of connectivity, whereas the carbon atoms aim for lower connectivity, ideally with a coordination number of four.[1b] In the case of *nido*-C_4B_2 and *nido*-C_4B_6 examples are known for valence isomers with classical[2k-m, 4d-f] and nonclassical structures.[2a-k, 4a-d] Previous attempts at synthesizing tetracarba-*nido*-octaborane(8) derivatives met limited success with regard to a convenient, straightforward route and to a firm proposal of their molecular structure.[3] Only peralkylated or C-alkylated species were reported.[3] However, all evidence points to a choice between the nonclassical structures **A** or **B**; **A**, which has a hexagonal open face, appears to be energetically favored.[1b]



We have recently shown that hydroboration of 1-alkynylsilanes[5] or -boranes,[6, 7] carried out under controlled conditions, leads to novel carbaboranes. Here we report that the reaction of bis(diethylboryl)ethyne (**1**) with "diethylborane"[8] in diethylborane as solvent ("hydride bath")[5] affords *B*-tetraethyl-tetracarba-*nido*-octaborane(8) (**2**) as a colorless liquid that can be purified by fractional distillation. As shown in Scheme 1, step a, hydroboration of **1** leads to 1,1,2,2-tetrakis(diethylboryl)ethane (**3**) and/or the 1,1,1,2-isomer **4**, which may condense by Et_2BH-catalyzed Et_3B elimination to five- or six-membered rings such as **5** or **6** (Scheme 1, step b). The reaction of bis(trimethylsilyl)ethyne with excess Et_2BH leads to analogous ring systems with Me_3Si instead of Et_2B groups.[9] If the stereochemistry is favorable the intermediates **5** and/or **6** can again eliminate Et_3B (Scheme 1, step c) to give polycyclic compounds with either a classical structure or one of the nonclassical structures of a *nido*-cluster, as shown for **2**.

The structure of **2** follows from the complete set of ^1H, ^{11}B, and ^{13}C NMR data (see Experimental Section). Calculated (for the parent compound)[10] and experimental $\delta^{11}B$ (−14.4/−4.6 and −15.1/0.6) and $\delta^{13}C$ (133.5/120.8) values agree resonably well upon considering the different substitution pattern. The separate ^{11}B NMR signals support a rigid structure. The splitting of the ^{13}C satellites [$^1J(^{13}C,^1H) = 166$ Hz] of the ^1H(CH) NMR signal into doublets [$^3J(^1H,^1H) = 8.6$ Hz] indicates that there are two separate H-C-C-H units. This splitting does not change between 25 to 70 °C, which is again in accordance with a rigid structure for **2**.



Scheme 1.

Considering this proposed structure, reactions of **2** with suitable fragments to expand the cage structure should be promising. Therefore, we treated **2** with [$Fe_3(CO)_{12}$] as a source of $Fe(CO)_3$ fragments, which are isolobal to BH groups. As shown in Scheme 1, step d, **2** captures two $Fe(CO)_3$ fragments to give complex **7**. The proposed structure of **7** in solution is strongly supported by all spectroscopic data (see Experimental Section), and its molecular structure in the solid state was determined by X-ray structure analysis (Figure 1).[11]

The atoms Fe(6), C(5), B(1), B(3), and C(7) as well as Fe(9), C(10), B(1), B(3), and C(8) form two planes (mean deviation <4 pm), which are capped by B(2) and B(4), respectively. Since the distance between the two iron atoms is rather long [$d_{Fe(6)-Fe(9)} = 268.5(1)$ pm], strong Fe–Fe bonding interactions are unlikely. Therefore **7** posesses a hexagonal open face occupied by four carbon and two iron atoms. The C–C bond lengths are 148.2(4) pm; C–C bond lengths of other ferracarbaboranes cover a wide range from 136.7 to 158.0 pm.[12] All other bond lengths are in the usual range. The CO ligands are perpendicular to each other, as required for the isolobal relationship between $Fe(CO)_3$ and BH.

The molecular structure of **7** is derived from that of decaborane(14), *nido*-$B_{10}H_{14}$, by replacing the four boron atoms in positions 5, 7, 8, and 10 (together with the four bridging hydrogen atoms) by four CH groups, and the two boron atoms in positions 6 and 9 by two $Fe(CO)_3$ fragments. This appears to be

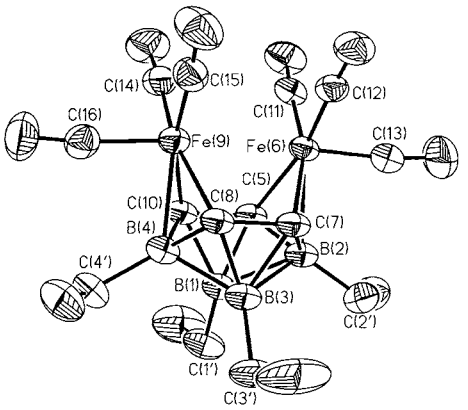

Figure 1. Molecular structure of **7** (hydrogen atoms omitted for clarity). Selected bond lengths [pm] and angles [°]: Fe(6)–Fe(9) 268.5(1), B(2)–Fe(6) 216.8(3), Fe(6)–C(5) 209.1(3), Fe(6)–C(7) 208.4(2), B(1)–B(2) 184.3(6), B(1)–B(3) 174.2(5), B(2)–B(3) 184.6(4), B(1)–C(5) 170.0(4), B(1)–C(10) 169.6(3), B(2)–C(5) 164.2(5), B(2)–C(7) 165.3(4), C(5)–C(10) 148.3(4), C(7)–C(8) 148.2(4), B(1)–C(1') 157.6(5), B(2)–C(2') 158.9(4), Fe(6)–C(11) 179.5(3), C(11)–O(1) 113.6(3); C(5)-B(1)-C(10) 51.8(1), B(1)-C(5)-Fe(6) 124.2(2), C(5)-Fe(6)-C(7) 79.5(1), C(11)-Fe(6)-C(12) 96.4(1), C(11)-Fe(6)-C(13) 90.3(1), C(12)-Fe(6)-C(13) 90.4(2).

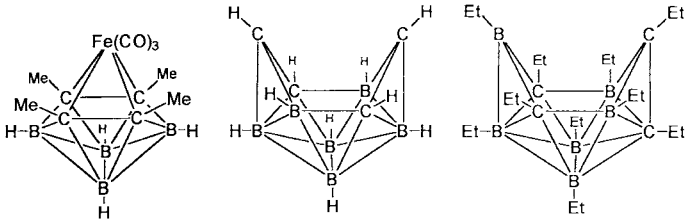
the most stable structure, since **7** is also formed in the presence of excess **2**. Heating a solution of **7** in toluene at 110 °C for 2 h or irradiating with UV light (2 h, mercury high pressure lamp TQ 718 (450 W)) does not induce noticeable decomposition or rearrangement of the polyhedral framework. A number of metallaboranes have been described with stuctures directly derived from *nido*-$B_{10}H_{14}$ by isolobal substitution of one of the four geometrically distinct types of BH groups.[13] The structure of **8** as an intermediate—with only one $Fe(CO)_3$ group—was proposed,[3b] but is unlikely in the light of the present results. Structure **9** is most likely for tetracarba-*nido*-decaborane(10),[4c] *nido*-$C_4B_6H_{10}$, which is related to **7** by replacing the $Fe(CO)_3$ fragments by BH groups. In contrast, the molecular structure of the peralkylated tetracarba-*nido*-decaborane(10) **10** is differ-



8 **9** **10**

ent,[4b] since the open face of the molecule houses only three of the four carbon atoms. However, the structure of **10** is fluxional, possibly because of the preference of that particular arrangement of carbon atoms at ambient temperature.

The availability of **2** as a reasonably stable but still reactive carbaborane opens the way to an exciting field of chemistry. The straightforward synthesis of **7** demonstrates that **2** will be an attractive reagent for the synthesis of many novel 10-vertex heteroboranes. The proximity of the metal centers in **7** is only one of numerous interesting aspects.

Experimental Section

1 [14, 15]: Bis(tributylstannyl)ethyne (30.32 g, 50.0 mmol) was added dropwise to diethylboron chloride (10.44 g, 100.0 mmol) without solvent at −40 °C over 30 min. The reaction mixture was stirred at −40 °C for 60 min, and then **1** was condensed at 10^{-3} Torr into a nitrogen-cooled trap (5.22 g, purity >80% (^{11}B NMR)). ^{1}H NMR (250.1 MHz, 25 °C, $CDCl_3$): δ = 0.86 (t, 8H, CH_2), 1.10 (q, 12H, CH_3); ^{11}B NMR (80.3 MHz, 25 °C, $CDCl_3$): δ = 72.2; ^{13}C NMR (62.9 MHz, −30 °C, $CDCl_3$): δ = 136.2 (br, B–C^{C-3}), 20.2 (br, CH_2), 9.4 (CH_3).

2: A solution of **1** (3.57 g, 21.7 mmol) in "Et_2BH" (5.0 mL, 57.1 mmol hydride) was heated at reflux for 24 h, saturated with ethene, and stirred for another 2 h to convert all B–H into B–Et bonds. After all volatile material was removed in vacuo, the residue was destilled under reduced pressure. A solution of $NaBEt_3H$ in hexane (6.022 M, 0.50 mL, 3.0 mmol) was then added to the destillate (0.97 g, >50% **2** (^{11}B NMR)). After 10 min all volatile material was removed in vacuo, the residue taken up in hexane and filtered, and the filtrate redestilled (b.p. = 79–82 °C/10^{-4} Torr) to give **2** (0.41 g, 1.93 mmol, 17.8%, purity >95% (^{11}B NMR)). ^{1}H NMR (250.1 MHz, 25 °C, $CDCl_3$): δ = 6.14 (s, 4H, CH), 0.96 (q, 4H), 0.48 (q, 4H, CH_2), 0.67 (t), 1.19 (t, 12H, CH_3); ^{11}B NMR (80.3 MHz, 25 °C, $CDCl_3$): δ = 0.6 (2B), −4.5 (2B); ^{13}C NMR (62.9 MHz, −20 °C, $CDCl_3$): δ = 120.8 (br, $h_{1/2}$ = 110 Hz (25 °C), CH), 6.4 (br), 5.0 (br, CH_2), 12.8, 10.3 (CH_3). EI-MS (70 eV): *m/z* (%) = 212 (100) [M^+], 197 (10) [M − Me]$^+$, 183 (25) [M − Et]$^+$, 155 (15) [M − Et − C_2H_4]$^+$.

7: [$Fe_3(CO)_{12}$] (0.205 g, 0.41 mmol) was added to a solution of **2** (0.131 g, 0.62 mmol) in toluene (3 mL), and the mixture heated at reflux for 1 h; the color changed from green to dark red. CH_3CN (3 mL) was then added, and the solution cooled to −20 °C. Dark red crystals of **7** (m.p. >160 °C (decomp.)) were obtained in almost quantitative yield. IR (CCl_4): $\tilde{\nu}$(CO) [cm^{-1}] = 2064 (s), 2019 (vs), 1999 (vs), 1983 (w), 1968 (m). ^{1}H NMR (250.1 MHz, 25 °C, $CDCl_3$): δ = 2.98 (s, 4H, CH), 0.82 (m, 20H, BEt); ^{11}B NMR (80.3 MHz, 25 °C, $CDCl_3$): δ = −25.4 [B(1,4)], 5.6 [B(2,3)]; ^{13}C NMR (62.9 MHz, −20 °C, $CDCl_3$): δ = 212.4 (4CO), 205.1 (2CO), 37.1 (br, $h_{1/2}$ = 26 Hz (25 °C), CH), 7.4 (br), 1.0 (br, CH_2), 9.9, 9.7 (CH_3). EI-MS (70 eV): *m/z* (%) = 492 (5) [M^+], 464 (20) [M − CO]$^+$, 436 (15) [M − 2CO]$^+$, 408 (35) [M − 3CO]$^+$, 380 (40) [M − 4CO]$^+$, 352 (90) [M − 5CO]$^+$, 324 (70) [M − 6CO]$^+$, 268 (100) [M − Fe(CO)$_3$ − 3CO]$^+$, 212 (100) [M − $Fe_2(CO)_6$]$^+$, 183 (60) [M − $Fe_2(CO)_6$ − Et]$^+$.

Liquid-Crystalline Crown Ether: Forming Columnar Mesophases by Molecular Recognition**

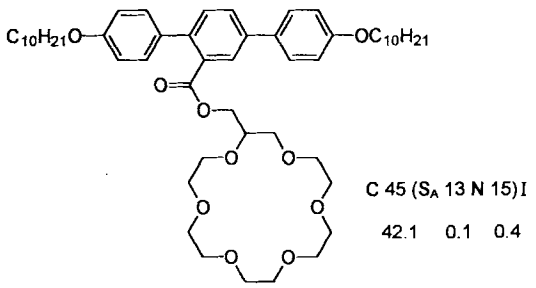
Jörg Andreas Schröter, Carsten Tschierske,* Michael Wittenberg, and Joachim Heinz Wendorff/

Dedicated to Professor Waldemar Adam on the occasion of his 60th birthday

Crown ethers are well-known for their ability to form complexes with alkali metal cations,[1] and the possiblity of combining this property with the supramolecular arrangements provided by liquid crystals has been demonstrated. Predominately nematic phases and also smectic layer structures were obtained from calamitic compounds with a crown ether moiety at one of the termini of an extended, rodlike, rigid core.[2] The isotropization temperatures of low molecular mass liquid crystals containing crown ethers decrease upon complexation with alkali metal salts,[2, 3] whereas smectic mesophases of polymeric liquid crystals crown ethers can be stabilized by complexation.[4, 5] On the other hand, columnar mesophases were induced by the interaction of heavy metal cations with multiarmed azacrowns[6–8] or by addition of alkali metal triflates to tapered-shaped crown ether derivatives.[9, 10]

We recently reported on a novel class of mesogenic compounds, in which hydrophilic functional groups such as diol or carbohydrate[11] were laterally attached to a rigid *p*-terphenyl core. Their smectic layer structures are significantly more stable than those of related nonamphiphilic mesogens, and columnar mesophases were observed for compounds carrying long, lateral polyether chains.[12] Therefore these molecules provide the possibility of changing the phase structure from layerlike to columnar with minor adjustments of the chemical structure. Here we report attempts to change the aggregation pattern of this kind of molecule by using the ability of crown ethers to specifically recognize cations.

We synthesized **1**, which consists of a rodlike 4,4″-didecyloxy-*p*-terphenyl rigid core with a laterally attached [18]crown-6 unit (Figure 1).[13] The thermotropic properties of pure **1** were



1

Figure 1. Thermotropic transition temperatures [°C] (upper line) and transition enthalpies [kJ mol^{-1}] (lower line) of pure **1**; C = crystalline solid. S_A = smectic A phase, N = nematic phase, I = isotropic liquid; values in parenthesis refer to monotropic phase transitions.

studied with polarizing optical microscopy and differential scanning calorimetry. On cooling pure **1** two monotropic liquid-crystalline phases were observed, a nematic phase (schlieren texture) and at lower temperature a smectic A phase (fanlike texture with homeotropically oriented regions). The low mesophase stability results from the significant disturbance of the rodlike molecular structure by the bulky crown ether units.

We then investigated the influence of water on the mesomorphic properties with the solvent-penetration technique.[14] The nematic phase and the S_A phase disappear in the contact region of **1** with water. In the middle concentration range only an isotropic liquid can be detected. However, another liquid-crystalline phase occurs in regions with a further increased water content. It displays a spherulitic texture between crossed polarizers, which points to a columnar mesophase. In the water-saturated sample, this induced mesophase is stable up to 22 °C.

The influence of cations on the liquid-crystalline behavior was also investigated. In principal the same behavior was observed in the contact region between **1** and 1 M aqueous KCl solution as with water. However, the induced phase was significantly more stable (up to 64 °C). Mixtures with water and with 1 M KCl solution or solutions of other K^+ salts showed the same spherulitic texture (Figure 2).

The mesophase structure that is formed by **1** in the presence of excess 1 M aqueous KCl was investigated by small-angle X-ray diffraction with a Kratky compact camera. The X-ray pattern shows several sharp reflections in the small-angle region, whose positions exclude a smectic layer structure (Figure 3). However, they can be indexed as a rectangular columnar structure (lattice parameter: $a = 4.1$, $b = 2.9$ nm, the scattering vector q is defined by $q = 2\pi/d$). The textures of systems formed from **1** and 1 M aqueous solutions of other alkali metal salts correspond to that for **1**/KCl. We therefore assume that columnar mesophases were also induced in these cases.

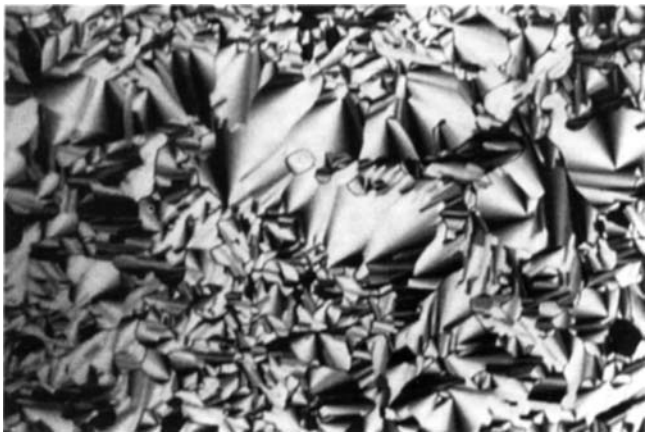

Figure 2. Optical photomicrograph of the texture of **1** saturated with 1 M aqueous KBr between crossed polarizers at 83 °C as obtained by cooling from the isotropic state.

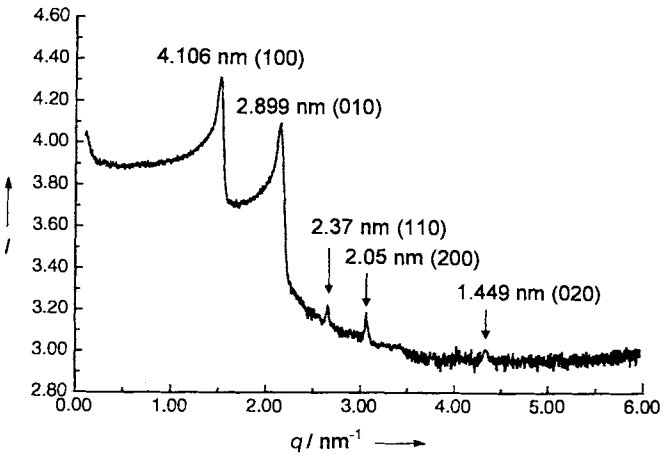

Figure 3. Small-angle region of the X-ray scattering diagram of **1** saturated with 1 M aqueous KCl at 50 °C.

The stability of the induced mesophases depends strongly on the size of the cation. Potassium ions, which fit in the cavity of the [18]crown-6 unit well, give rise to the highest clearing temperature, whereas the transition temperatures are only marginally influenced by Li^+ and Na^+. The larger cations Rb^+ and Cs^+ give lower mesophase stabilities than K^+. As seen in Figure 4, the clearing temperatures of the induced mesophases correlate very well with the stability constants of the cation/[18]crown-6 complexes in water.[15] Therefore we can conclude that the mesophases of this special kind of facial amphiphiles can be influenced by a molecular recognition process.

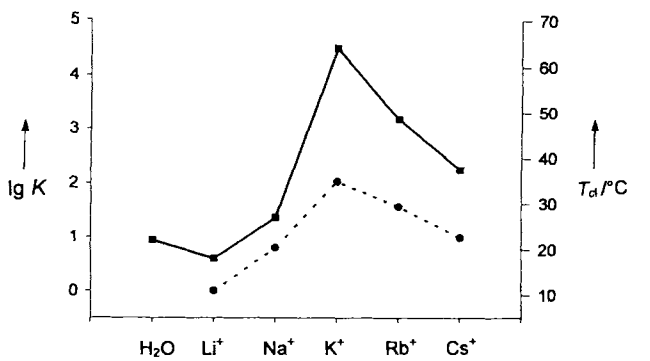

Figure 4. Dependence of the clearing temperatures T_{cl} of the columnar mesophases of the systems **1**/1 M MCl/H_2O on cation M^+ (■) and on the equilibrium constants (lg K) of the [18]crown-6/M^+ systems in water (●) [15]. The transition temperatures were obtained by polarizing microscopy.

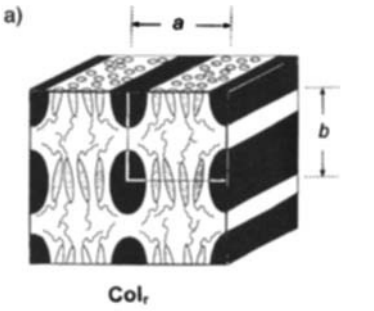
The anions also influence the mesomorphic behavior. The clearing temperatures of the systems **1** and 1 M KX increase in the order X = Cl (T_{cl} = 64 °C), X = Br (T_{cl} = 78 °C), X = I (T_{cl} = 93 °C), that is, with increasing ion radius.[16]

A possible model of the columnar mesophase is shown in Figure 5. In strong analogy to the columnar thermomesophases of facial amphiphiles with lateral polyether chains,[12] we propose a ribbon model for this columnar mesophase. The ribbons should be made up of rigid *p*-terphenyl cores that are arranged parallel to one another and separated by the hydrophilic domains of the lateral groups consisting of the crown ether moieties, the complexed ions, and the solvent molecules. The alkyl chains are molten and fill up the space between the ribbons. The observed values of the lattice parameters *a* and *b* of the Col_r phase represent the lateral distances between the centers of the ribbons[17] and the thickness of the ribbons. According to this model the ribbon may be regarded as bandlike segments of a collapsed smectic layer structure. The formation of the ribbons is caused by the segregation of hydrophilic and lipophilic units into separate regions. From the observed lattice parameters it can be concluded that more than two (about four) terphenyl units have to be arranged side-by-side in the cross-section of the ribbons. This requires that the polar lateral groups of the molecules in the middle of these ribbons cross over the neighboring calamitic terphenyl units in order to be incorporated into the polar regions. This should be possible (see Figure 5b) because the lateral crown units are decoupled from the terphenyl cores by the $COOCH_2$ spacers and because they are rather large.[18]



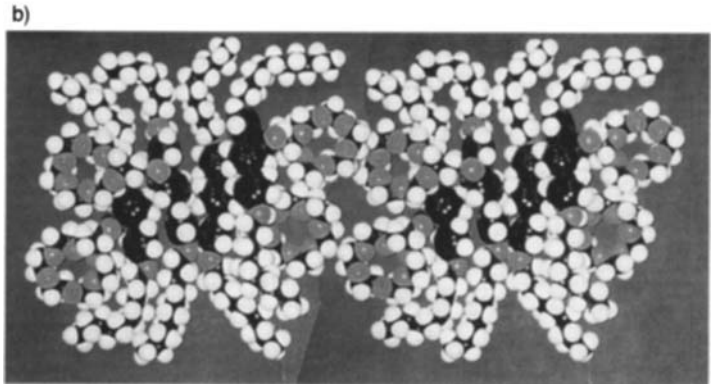


Figure 5. a) Schematic sketch of a possible ribbon arrangement of the rectangular columnar phase (Col_r). The ribbons consist of parallel *p*-terphenyl cores separated by the polar regions (crown units, water molecules, and ion pairs; black areas). b) CPK model showing a possible arrangement for the ribbons. Water molecules and ions are omitted for clarity.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3610-1120 $ 17.50+.50/0

Furthermore, this arrangement allows simultaneously the parallel organization of the rodlike molecules and the segregation of polar and lipophilic units into different regions.

A novel case of mesophase induction by self assembly directed by molecular recognition has been described. It is the first example of mesophase stabilization and induction by interaction of alkali metal cations with a low molecular weight calamitic crown compounds. It is especially remarkable, that this *rod-shaped* molecule can organize as a *columnar* mesophase. In all previously reported cases of mesophase induction by complex formation of crown ethers with alkali metal ions, columnar mesophases were only obtained with tapered-shaped molecules, that is, compounds that have a "pre-disc" shape.

[13] Obtained by esterification of 4,4″-didecyloxy-*p*-terphenyl-2′-carboxylic acid [11] with hydroxymethyl[18]crown-6 (Aldrich) in the presence of *N*-cyclohexyl-*N*′-[2-(4-methylmorpholino)ethyl]carbodiimide (Aldrich) and catalytic amounts of 4-dimethylaminopyridine. All analytical data agree with the proposed structure for **1**: ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 0.87$ (t, $J = 6.7$ Hz, 6H, CH_3), 1.21–1.51 (m, 28H, CH_2), 1.74–1.83 (m, 4H, $ArOCH_2CH_2$), 3.30 (dd, $J = 14.8$, 4.2 Hz, 1H, $OCHCH_AH_BO$), 3.37 (dd, $J = 16.8$, 6.05 Hz, 1H, $OCHCH_AH_BO$), 3.54–3.67 (m, 21H, OCH_2CH_2O, CH), 3.95 (t, $J = 6.3$ Hz, 2H, $ArOCH_2$), 3.99 (t, $J = 6.5$ Hz, 2H, $ArOCH_2$), 4.11 (dd, $J = 15.1$, 5.5 Hz, 1H, $CO_2CH_AH_B$), 4.20 (dd, $J = 16.6$, 5.05 Hz, 1H, $CO_2CH_AH_B$), 6.90 (dd, $J = 8.7$, 2.0 Hz, 2H, arom. H), 6.96 (dd, $J = 8.7$, 2.0 Hz, 2H, arom. H), 7.25 (dd, $J = 8.7$, 2.0 Hz, 2H, arom. H), 7.36 (d, $J = 8.0$ Hz, 1H, arom. H), 7.54 (dd, $J = 8.7$, 2.0 Hz, 2H, arom. H), 7.66 (dd, $J = 8.1$, 2.0 Hz, 1H, arom. H), 7.93 (d, $J = 2.0$ Hz, 1H, arom. H); MS (70 eV): m/z (%) = 862(100, $[M^+]$), 586(13), 569(8), 442(5), 429(13).

[14] These penetration experiments cannot give precise data concerning the water concentration. Related open-chain compounds can take up to 10 molequiv of water: J. A. Schröter, C. Tschierske, M. Wittenberg, J. H. Wendorff, unpublished results.

[15] R. M. Izatt, J. S. Brandshaw, S. A. Nielsen, J. D. Lamb, J. J. Christensen, D. Sen, *Chem. Rev.* **1985**, *85*, 271; R. M. Izatt, R. E. Terry, B. L. Maymore, L. D. Hansen, N. K. Dalley, A. G. Avondet, J. J. Christensen, *J. Am. Chem. Soc.* **1976**, *98*, 7620.

[16] The dependence of the clearing temperature on the anions can be caused by several influences. The equilibrium constants of the crown/M^+/X^-/water systems should depend on X^-. However, the differences are small (lg K (KCl) = 1.97; lg K (KBr) = 1.98; lg K (KI) = 1.94; Y. Liu, J. Hu, *Wuli Huaxue Xuebaro.* **1987**, *3*, 11; R. M. Izatt, K. Pawlak, J. S. Brandshaw, R. L. Bruening, *Chem. Rev.* **1991**, *91*, 1721) and cannot explain this effect. In addition, the ability to coordinate water decreases, and the lipophilic character of the anions increases in the order Cl^-, Br^-, I^-.

[17] The molecular length is 4.1 nm (CPK models). The layer thickness of the S_A phase of related 4,4″-didecyloxy-*p*-terphenyl derivatives is 3.3 nm [11].

[18] The layered organization of the terphenyl cores can tolerate rather large polar lateral substituents [11]. Therefore the crossing of the lateral substituents over the terphenyl units in the periphery should be possible. Furthermore, we have recently found columnar mesophases for facial amphiphiles in which lateral diol groups are connected through polyether chains to the rigid cores. However, columnar mesophases can only be found if the lateral hydrophilic group exceeds a certain length [12]. This means that a certain polarity and also a certain length of the lateral groups are important prerequisites for the formation of these ribbon phases.

$K_3Sb_7^{III}O_9Se_3 \cdot 3H_2O$: The First Crystalline Nanoporous Material with a Photo-Semiconducting Host Structure**

Ulrich Simon,* Ferdi Schüth, Stephan Schunk, Xiqu Wang, and Friedrich Liebau

During the nineties the preparation of nanostructured materials has evolved to an important and promising area for physicists and chemists. The topic of many developments is the designed formation of specific structures of matter, for example the generation of quantum dots, quantum wires, or multiple quantum wells, for integration into microelectronic circuits to miniaturize functional elements.[1–3]

To generate nanostructures physicists usually adopt preparation methods like electron beam lithography, which create the small from the large structure and are consequently termed "top-down" methods. However, these methods can only generate structures that have a certain size distribution, but not those of uniform size. This is a disadvantage when quantum size properties are investigated, because these properties are very sensitive to structural changes.

In order to cope with this problem, chemistry has evolved an approach that has so far attracted only little attention. Elaborately optimized synthesis and self-assembly techniques have made available nanostructured materials of uniform shape and size, which may be smaller than one nanometer. These approaches start from atomic or molecular precursors and create large from small. Thus, they are termed "bottom-up" methods. Among these materials are many metal and semiconductor clusters[4] (which in some cases are arranged in superstructures) as well as a large number of meso- to nanoporous solids. The latter consist of a host structure containing cage- or channel-type pores, or both. Guests are occluded in these voids. By far the best known solids of this kind are zeolites and zeolite-type metal oxides,[2, 5–7] in which the host structure is a porous, three-dimensional, polyhedral framework. Among the metal oxide group are mainly compounds that fulfil the structural demands of semiconductors but are electrical insulators due to their chemical composition.

Jockel (Essen) for their assistance with the impedance measurements. Financial support from the DFG is acknowledged (Li 158/29).

For some time, therefore, efforts have been made to prepare nanoporous semiconducting materials chemically.[8–10] Such substances are crystallized with templates and typical semiconducting elements such as Sn, Sb, and Se. So far, however, only template-stabilized framework structures that transform into thermodynamically more stable phases and lose their porosity upon removal of the template have been found. Here we report the synthesis of the crystalline, template-free compound **1** with a host structure consisting of one-dimensional tubular chains and discuss its thermal, optical, and electrical properties.

$K_3Sb_7O_9Se_3 \cdot 3H_2O$ **1**

Crystals of **1** are prepared hydrothermally from aqueous KOH and elemental antimony and selenium and grow as dark-red hexagonal prisms to a maximum size of 0.1 mm width and 1 mm length. Under standard conditions ($T = 298$ K, $P =$ 0.1 MPa) they are stable to air, water, methanol, ethanol, and acetic acid. The determination of the structure based on single-crystal X-ray diffraction data[11] shows that **1** is an ordered $2 \times 2 \times 1$ superstructure of the disordered structure of the natural mineral cetineite $(K,Na)_{3+x}(Sb_2O_3)_3(SbS_3) \cdot (2.8 - x)H_2O$[12] and a series of synthetic phases that are isotypic with cetineite and that have the general formula $A_6[Sb_{12}O_{18}][SbX_3]_2 \cdot (6 - mx - y)H_2O \cdot x[B^{m+}(OH)_m] \cdot y\square$ ($A = Na^+$, K^+, Rb^+; $X = S^{2-}$, Se^{2-}; and $B = Na^+$, Sb^{3+}).[13] The square in that formula represents a vacancy in the crystal structure, that is, not all of the H_2O and OH positions have to be occupied (for example after dehydration).

In the hexagonal structure of **1**, pyramidal $[SbO_3]$ groups are linked to tubular $[Sb_{12}O_{18}]$ chains (Figure 1). These tubes are

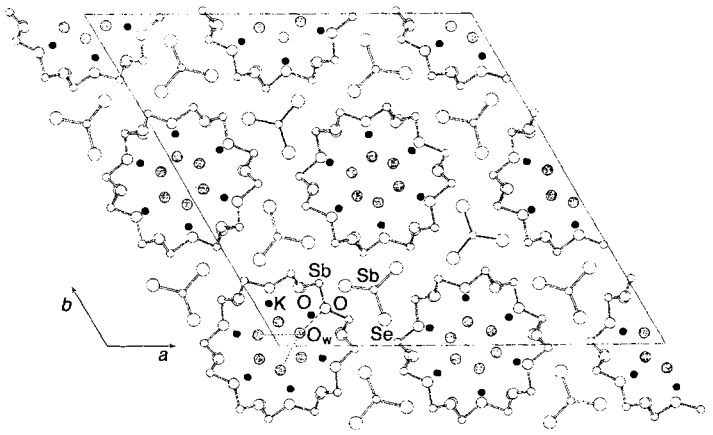

Figure 1. Projection of the hexagonal structure of **1** along the crystallographical *c* axis ($a = b = 29.260(7)$, $c = 5.6164(7)$ Å, $Z = 8$, space group $P6_3$).

then combined to form a three-dimensional nanoporous framework through weaker secondary interactions with interjacent $[SbSe_3]$ pyramids. The diameter of the tubes is about 7.0 Å, and they are lined by the K^+ ions. The central part of a tube is occupied by $[(H_2O)_6]$ octahedra, which are elongated trigonally and linked through shared faces to form a chain of octahedra. The electron micrograph in Figure 2 clearly reveals the nanoporous character of the crystal structure.

By a combination of differential thermal analysis, thermogravimetry, and X-ray diffraction it was shown that the host structure of **1** is stable up to about 570 K in air and up to 710 K in flowing nitrogen at standard pressure (0.1 MPa). At higher temperatures in air, Sb^{III} is oxidized to Sb^V and the host structure is destroyed.

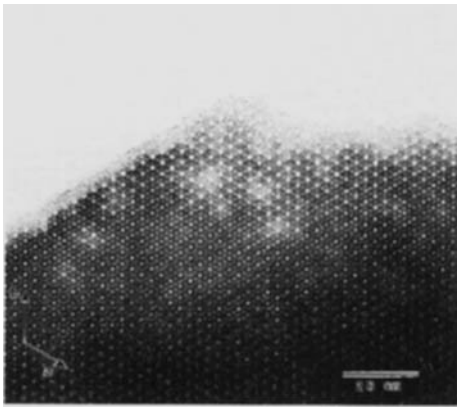

Figure 2. Electron micrograph of **1** showing the nanoporous structure.

Investigations with IR-microspectroscopy using polarized radiation and a high-vacuum sample environment were carried out on single crystals of **1** with a size of 40 μm × 200 μm. Figure 3 shows the IR spectra for radiation polarized perpendicular (top) or parallel (bottom) to the hexagonal *c* axis of the crystals. From these spectra it can be deduced that the water molecules possess a strong preferential orientation in the structure.

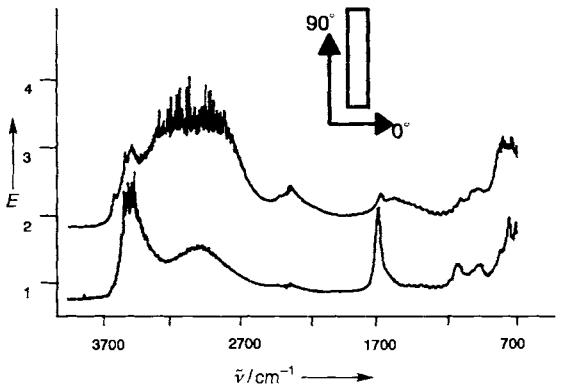

Figure 3. FTIR spectra of a crystal of **1**. The polarization plane is indicated: 0° (top) and 90° (bottom). *E* = extinction.

A striking characteristic of both spectra is the differences for the two polarization directions in the regions of the OH vibrations (at 3600–3000 cm^{-1} and at 1730–1600 cm^{-1}). The OH vibrations are caused by the water molecules occluded in the channels of **1**. The maxima of the signals occur at around 3500, 3000, and 1677 cm^{-1}. This corresponds to the symmetric and antisymmetric stretching modes and the bending mode of free water. The assignment of the high-frequency signal to the symmetric stretching mode is based upon its polarization behavior, which is identical to that of the bending mode. This shows that the two modes belong to the same symmetry.

To verify the assignment of the signals, the water was removed from the channel structure by pumping and heating. In the case of morphologically well-defined crystals, this was achieved at room temperature under high vacuum within a few seconds. In the case of crystal aggregates, which consisted of single crystals intergrown to fiber- or bundlelike units, removal of the water was possible only after grinding and sometimes only after a prolonged treatment at 620 K under vacuum. Because in all cases the IR signals mentioned above vanished under high vacuum, they can unambigiously be identified as belonging to wa-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3610-1122 $ 17.50+.50/0

ter. From the strong polarization of the signal at 1677 cm^{-1}, it can be deduced that the C_2 axis of the water molecules are preferentially aligned parallel to the crystallographic c axis of **1**. From the dichroic ratio a mean deviation of the C_2 axis from the c axis of 20–30° can be calculated.

This is in agreement with the crystallographic result based on the average structure (calculated without consideration of the superstructure reflections), according to which each oxygen atom O_w of the water molecules is attached to an oxygen atom of the tube by a short hydrogen bond of 2.67 Å (--- in Figure 1). In contrast, distances of 3.12 Å to two neighboring O_w atoms (··· in Figure 1) indicate the presence of only weak hydrogen bonds. Four such oxygen atoms connected to each other by hydrogen bonds are situated in a plane perpendicular to the c axis.

To determine the optical band gap, single crystals of **1** were studied with a microspectrophotometer (Leica MSV-SP). Figure 4 shows a UV/Vis spectrum that was recorded in transmission mode in the wavelength region between 250 and 800 nm. The solid shows a strong absorption below about 610 nm, which corresponds to the dark-red color of the crystals. This wavelength corresponds to an optical excitation energy of 2.06 eV.

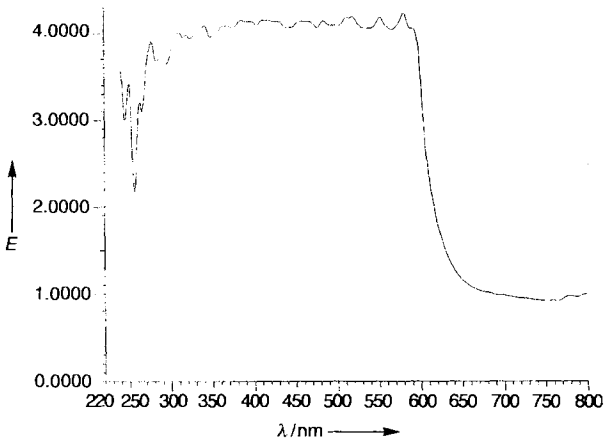

Figure 4. UV/Vis spectrum of **1** measured in transmission mode.

For measurement of the electrical conductivity, single crystals of good optical quality were fixed on a quartz support. Their ends in the c direction were fixed in contact with silver paint. Defects at the crystal surface in the contact region as well as the contacts themselves may influence the results of conductivity measurements.[14] Therefore, long crystals were selected to make sure that the contribution of the volume to the total conductivity dominates. In addition, the contacts were attached in such a way that they cover the ends of the crystals well enough to minimize the direct incidence of light in this region. Instead of d.c. measurements, impedance measurements were performed in a frequency region from 10 mHz to 10 kHz. With this method interfacial phenomena and contact resistances, for example by an oxide layer, can in most of the cases be separated from the resistance of the volume.[15]

Figure 5 shows curves of the complex impedance, which are representative of the crystals investigated. Samples were measured in the dark (a) and under illumination with white light (b) at room temperature. The measurements yield compressed semi-circles. From their low-frequency minima, the d.c. resistance R and the specific conductivity σ can be extrapolated. For the example shown here, σ_a (conductivity in the dark) is

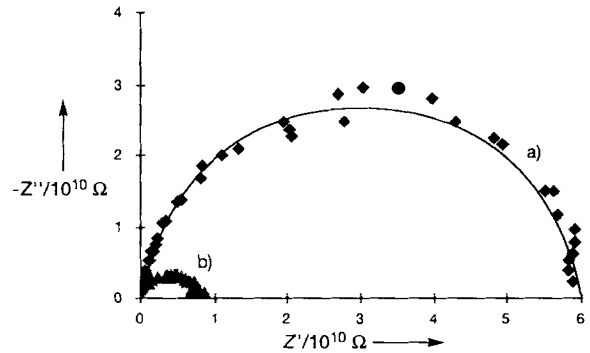

Figure 5. The complex impedance, shown in the complex plane of **1**, in the dark (a) and under illumination (b) at 298 K. The solid line represents an idealized curve fitted through the data by means of a Cole–Cole element.

2.54×10^{-9} $S cm^{-1}$ and σ_b (conductivity under illumination with light) is 1.91×10^{-8} $S cm^{-1}$. As the high-frequency ends of both curves end at the origin of the coordinate system and as only the volume of the crystal was illuminated directly, these results show that **1** is photoconducting. The H_2O guest molecules present in the structure can be excluded as the cause of this conductivity. Accordingly, as far as we know **1** is the first nanoporous semiconductor with a photosemiconducting host structure.

As at present there is no additional information on the electronic structure of **1** apart from the data presented in this work, no assignment of the optical band gap and no explanation for the basis of photoconductivity can be given. For this purpose, additional investigations, especially on the temperature dependence of the optical absorption and the conductivity, as well as on the mobility of the charge carriers, are in preparation. However, it is clear that with the synthesis and characterization of **1** a step has been made into the direction of potential applications along the lines of the predictions for the class of nanoporous semiconductors.[2, 5–7] Because of the large interior surface of dehydrated **1**, its use as a highly sensitive and chemoselective sensor appears possible. The results of this work also point to possible optoelectronic and photovoltaic applications.

Experimental Section

Synthesis of **1**: antimony (0.76 g), selenium (0.74 g), KOH (0.80 g), water (2.5 mL), and 2-aminopentane (0.5 mL) were charged into 50 mL teflon bottles, which were sealed and heated to 473 K in a steel autoclave for 4 days. The product was washed with water and methanol, filtered off, and dried in air. As the products always contained minor amounts of other phases, analytical investigations (electron beam microprobe with a CAMEBAX MICROBEAM device from Cameca) and the single crystal X-ray structure determination were carried out on crystals that were selected under the optical microscope.

Highly Efficient Synthesis of Cephalotaxine by Two Palladium-Catalyzed Cyclizations**

Lutz F. Tietze* and Hartmut Schirok

Dedicated to Professor Peter Welzel on the occasion of his 60th birthday

Cephalotaxine **1** is the parent compound of the antileukemic-active harringtonines, a group of uniquely structured pentacyclic alkaloids that were isolated from the southeast Asian yew tree of the genus *Cephalotaxus*.[1] In the harringtonines the free hydroxyl group of **1**, which itself is not biologically active, is esterified by a substituted methyl hydroxymonosuccinate. Although several total syntheses of racemic cephalotaxine have been described,[2] and even the enantiomerically pure natural product has been synthesized,[3] new synthetic approaches are especially attractive when they either surpass former methods in efficiency or allow modifications of the structure of the naturally occurring compound.

Both of these requirements are fulfilled by the method reported herein, which is used to construct the racemic intermediate **2**, which, according to Kuehne et al.,[2i] is easily converted in four steps into cephalotaxine **1** in a total yield of 75%. Retrosynthetic analysis of **2** suggests that the cleavage of the seven-membered ring would provide the spirocyclic compound **3a**, which should be available from allyl acetate **4a**. This compound can be readily obtained from **5e** und **6** by alkylation. The intramolecular Pd-catalyzed substitution of an allyl acetate with an amine has already been reported by Godleski et al.,[4] and the stereoselective construction of benzazepines by intramolecular Heck reaction from appropriate iodoarenes has been carried out with other compounds by our group.[5] The combination of both Pd-catalyzed reactions should therefore lead to a highly efficient synthesis of cephalotaxine. It had to be clarified first, however, whether the difference in reactivity between the allyl acetates and the iodoarenes is sufficient for a selective reaction process.

For the synthesis of **5e**,[6] amine **5a**,[7] readily available from piperonal, was protected with di-*tert*-butyldicarbonate to form **5b** and subsequently halogenated with iodine and silver trifluoroacetate[8] to yield **5c**. Subsequent cleavage of the *tert*-butoxycarbonyl (*t*Boc) protecting group with trifluoroacetic acid provided the known amine **5e** in 91% yield. Initially, the iodination of **5b** proved difficult. By other methods, such as the reaction with iodine and iodic acid as reported by Königstein,[9] **5c** was obtained only in very low yields. This results from the fact that the electron density of methylenedioxyarenes such as **5b** is lower than that of 1,2-dimethoxybenzene, because the steric arrangement of the methylenedioxy group restricts the overlapping of the oxygen atoms' orbitals containing nonbonding electron pairs with the π-orbitals of the arene.[10]

Alkylation of **5e** with iodide **6** (Table 1), readily available from 3-ethoxycyclopentenone in four steps, provides the secondary amine **4a**, the starting material for the double cycliza-

tion, in a yield of 80%. In contrast, alkylation of deprotonated **5b** with **6** yields only poor results. During the Pd^0-catalyzed transformation of **4a**, the reaction between the allyl acetate and the iodoaryl unit is not selective. Thus, bromoarene **4b** was synthesized in a similar fashion from **5b**; **5b** could be converted into **5d** with bromine and without the addition of silver trifluoroacetate. Reaction of the hydrochloride of **5a** with bromine in acetic acid led directly to bromide **5f** in 97% yield.[11] Intramolecular Pd-catalyzed allylic amination of **4b** afforded the spirocyclic compound **3b** in 85% yield (Table 1).[12] However, attempts to cyclize the less reactive bromoarene **3b** to **2** under normal Heck conditions were unsuccessful. Use of the palladacycle *trans*-di(μ-acetato)bis[*o*-(di-*o*-tolylphosphanyl)benzyl]dipalladium(II),[13] which we recently used successfully in an efficient total synthesis of estrones,[14] allowed for the construction of the pentacyclic **2** in 80% yield.[15] Due to the steric interactions, the intermediate palladium–aryl compound formed during the oxidative addition attacks the double bond very selectively *syn* to the nitrogen substituent, and the subsequent reductive *syn* elimination of the PdH species leads exclusively to **2**. Thus, as expected, neither a second diastereomer nor a double bond isomer were obtained. The high yield in the Heck reaction with the relatively unreactive bromoarene **3** is probably due to the fact that the low donor ability of the methylenedioxy group has a positive effect. The spectroscopic data of **2** (Table 1) agree with known values.[3]

The synthesis of **2** by two consecutive Pd-catalyzed reactions reported herein provides not only a short and highly efficient route to cephalotaxine **1** and the derived structures, the harringtonines, but should also enable a wide variation in the ring structure. Furthermore, by starting with both enantiomers of **6**, enantiomerically pure **1** and *ent*-**1** should also be accessible.

Modes for all Surfaces

Surface Analysis with STM and AFM. By *S. N. Magonov* and *M.-H. Whangbo*. VCH Verlagsgsellschaft, Weinheim, 1996. 324 pp., hardcover DM 198.00.—ISBN 3-527-29313-2

It is 15 years since the invention of scanning tunneling microscopy (STM), and applications of this technique now extend far beyond the area of classical surface physics under ultra-high vacuum conditions. STM and atomic force microscopy (AFM) are now very important methods in the materials sciences, and are used to study a wide variety of materials, not only in vacuum but also in air and in liquids. The work reviewed here is an important addition to the many books dealing with this field. It contains a clear and understandable introduction to these methods, with the emphasis on practical applications and the interpretation of STM and AFM images. It provides a good survey of the problem-solving capabilities of STM and AFM and the different types of information that they can yield.

The contents of the book can be divided into three parts, beginning with Chapters 1–4. In Chapter 1 the authors give a short introduction to the principles of STM and AFM. They explain how STM images are interpreted by considering the partial density of electron states near the Fermi level at the surface, and how the repulsion force in AFM can be described in terms of the total density of electron states at the surface. The problem of mechanical interaction between the probe tip and the specimen, and its effect on the specimen during the measurement, is also mentioned here.

In Chapter 2 the theoretical and experimental aspects of the physical processes involved in STM and AFM are examined in more detail. The mechanisms of electron transport in STM and the forces occurring in AFM are both dependent on the distance between the probe tip and the specimen, and these effects are discussed. The authors also explain how the specimen surface becomes distorted during the measurement by the strong short-range repulsion forces. Macroscopic surface deformations are described using continuum theory, whereas the description of microscopic deformations is based on the local elastic behavior of individual atoms, taking into account the nature of their bonding environment. The long-range van der Waals forces that arise mainly in the case of measurements in liquid media are discussed, as well as adhesion and capillary forces.

Chapter 3 describes in detail the principles and experimental arrangements for STM and AFM measurements with the help of diagrams and photographs. Experimental aspects of STM that are covered include the approach of the tip to the specimen, the function of the electronic feedback loop system, the properties of piezoceramic scanners, the different measurement modes using a raster with the control circuit either active or switched off ("constant interaction mode" and "constant height mode"), methods for image processing and filtering of the raw data, and techniques for damping mechanical vibrations in the microscope. The authors give practical advice on choosing the best tip material for STM measurements in different environments. The design and construction of an AFM microscope is then treated in detail, including the principles of the force measurement and materials for various types of AFM probe tips and their properties. The different measurement modes in AFM are described (in particular, "contact force mode" and "tapping mode"). Lastly the authors discuss how the resolution of STM and AFM measurements is affected by the probe tip and the sample.

Chapter 4 deals with practical aspects of STM and AFM experiments, including the limitations of these methods with regard to the surface roughness, electrical conductivity, temperature, and size of the sample. The authors discuss the optimization of tunneling parameters for investigating metals, semiconductors, and organic materials, both in vacuum and in various media, and the corresponding question of optimizing the experimental parameters for AFM measurements on various materials and in different media using either the contact mode or the tapping mode. The influence of defects on both large area scans and on scans with atomic resolution is described, and it is explained how defects can be characterized by varying the STM tunneling voltage or the AFM force setting. Some common types of artifacts in STM and AFM images are discussed and explained.

The second part of the book consists of Chapter 5 alone, treating theoretical aspects. This begins with a very elegant description of the electronic structure of solids. The band structure and the calculation of band orbital functions as linear combinations of Bloch functions according to the Hückel theory is summarized concisely in four pages. On this basis the authors then discuss the process of tunneling between two metals and between a metal and a semiconductor, with brief descriptions of the Tersoff–Hamann and other theories. They explain the simulation of STM or AFM images from calculations of the partial or total electronic state densities at the surface, respectively. Taking the surface of graphite as an example, simulated STM and AFM images produced by this method are compared with results obtained in the laboratory.

The third and longest part of the book builds on the knowledge presented in the previous chapters by discussing examples of STM and AFM experiments, so as to illustrate the basic types of problems that arise in the interpretation of STM and AFM images. Chapters 6–9 achieve this very effectively in three stages, based on measurements carried out on single crystal surfaces of various layered inorganic compounds. After a description of the crystal structures of the substances, Chapter 6 presents the first stage, consisting of results from specimens for which the electron density distribution at the surface can be obtained from band structure calculations, and in which the mechanical interaction between the probe tip and the

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3610-1127 $ 17.50+.50/0

specimen is negligible. By comparing the theoretically calculated total or partial electron density distributions at the surfaces and the corresponding crystal structure models with the structures determined from STM and AFM images with atomic resolution, the latter can be assigned to the different types of atoms or even to atomic orbitals, since no reconstructions occur on these surfaces. In Chapter 7 this concept is applied to point defects such as lattice vacancies and impurity atoms, which extend only over short distances and therefore still allow one to calculate the band structure. In the second stage the influence of defects on STM images measured with bias voltages of different signs, where it is no longer permissible to calculate the band structure, is discussed qualitatively. The results are presented in the form of tables for the convenience of readers wishing to use them in practical situations. In the third stage (Chapter 9) the authors discuss examples in which the mechanical interaction between the probe tip and the specimen causes a deformation of the specimen surface that can no longer be neglected. (These interactions are discussed in detail earlier, in Chapter 8, for STM and AFM measurements performed both in vacuum and in air.) Chapter 9 then goes on to discuss the interpretation of measurements on graphite, on thin epitaxial layers, and on various layered-compound single crystal surfaces, taking into account these deformations. For this the authors use the concept of local rigidity for individual atoms with different bonding configurations, an effect which is very nicely demonstrated by the changes in AFM images recorded with different force settings.

The last four chapters are concerned with STM and AFM studies on various organic substances. Chapter 10 describes measurements on a number of electrically conducting organic salts derived from the acceptor and donor molecules tetracyanoquinodimethane (TCNQ) and bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF). These salts form good-quality single crystals and are stable in air. First the crystal structures of the various salts are described, and some experimental problems that arise in studying them by STM and AFM are discussed. Images with atomic resolution are then interpreted on the basis of the theoretically calculated densities of electron states and the corresponding crystallographic structures, in a manner analogous to that used for the layered-compound crystals in the previous chapters.

For non-conducting compounds, STM images on a molecular scale can be obtained by depositing them on a conducting substrate. Chapter 11 describes measurements on linear and cyclic alkanes and on 4-octyl-4'-cyanobiphenyl, which were prepared in a liquid medium by adsorption on the solid substrate. The authors discuss the STM images of these ordered molecular films, which mainly have a lamellar structure and occasionally show additional long-range structures and domains with different orientations. The substrate can affect the ordering of the adsorbed molecules, and this is illustrated by comparing results obtained on graphite and on β-Nb_3I_8, two substrates with very different surface structures. STM images with molecular resolution are interpreted by using calculated electron density distributions whenever possible, taking into account the interaction of the adsorbate molecules with the substrate.

Chapter 12 is concerned with studies of the self-organized structures of organic amphiphiles, molecules with a hydrophobic end and a hydrophilic end. The principles involved in the formation of molecular aggregates such as micelles, double layers, and one-, two-, and three-dimensional supramolecular structures are briefly explained. The molecular and crystalline structures of the amphiphiles, and methods of preparing them for AFM measurements, are described. The authors discuss AFM measurements on crystalline films and supramolecular structures, and structural models for these systems are developed with the help of additional information from other experimental methods. This chapter offers the reader an interesting and easily understandable introduction to the world of self-organizing structures. Lastly, Chapter 13 begins with a brief introduction to polymer chemistry, then describes STM studies of conducting polymers and AFM studies of polymer single crystals. This is followed by an excellent description of the use of AFM for characterizing orientated and stretched polymers, which are of considerable technological interest for the development of new materials. The method yields details of their morphology, molecular structure, and structural features in the range from 1 to 100 nm. The chapter ends by describing some studies on different types of polystyrene films.

Overall this is a very good book, which is of special interest to users of STM and AFM who wish to gain a basic knowledge of these methods. The concise and easily understandable introduction concentrates on the essential experimental and theoretical aspects, and avoids burdening the reader with too much information. Up to date references to relevant published work are provided for more detailed study. The authors give valuable advice on ways of overcoming experimental problems, and the book will therefore be helpful in practical work using STM and AFM. The discussions of STM and AFM studies on different types of materials are an especially good feature of the work, being well written and very instructive. They will equip the reader with essential knowledge for the interpretation of experimental results, and they will prevent over-hasty and incorrect conclusions. The book provides a good overview of the potential applications of these methods to various materials as well as the main types of information that they can yield.

X-ray Powder Diffractometry. An Introduction. (Series: Chemical Analysis, Vol. 138.) By *R. Jenkins* and *R. L. Snyder*. Wiley, Chichester, 1996. 391 pp., hardcover $ 87.95.—ISBN 0-471-51339-3

This book sets out to provide an introduction to X-ray powder diffractometry. After the introductory chapters, which cover the production of X-rays, symmetry, and basic diffraction theory we find a very useful description of anisotropic line broadening. This is the first time the book specifically focusses upon an area where powder diffraction has made a large impact. This part of the chapter explores some of the common features that are encountered when samples give asymmetric or broadened line shapes. The discussion of residual stress and crystallite size is quite brief, but a good bibliography for more detailed reading is given. The description of available X-ray sources, diffraction equipment, and monochromatization is strongly orientated towards laboratory based systems. As the authors point out, approximately 90% of scientists using powder diffraction will use sealed tubes. However, I would have appreciated a little more information regarding developments of new and novel geometries using multilayer optics, and some more guidance regarding situations where other techniques such as the use of synchrotron radiation might be complementary.

It is not until Chapter 8 that the real value of this book becomes apparent. The description of the diffractometer align-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3610-1128 $ 17.50+.50/0

ment is clear, concise, and easily understandable. The practical experience and knowledge of both authors is quite obvious. The description here makes the book an almost essential accessory to the powder diffractometer itself, and it is worth purchasing for this section alone. The practical details and suggestions can sometimes be found elsewhere, but in some cases the advice is just not published. In addition the whole topic has been beautifully condensed and presented in one chapter, which I am sure will become essential reading.

The book has two other high spots, in the description of quantitative phase analysis, and in the methods of search match. These are two areas that are particularly in demand from industrial users of powder diffraction. The authors have taken their experience and compressed the description of the search match method into a very concise form without sacrificing essential detail. They have succeeded in writing a text that will be very useful to the majority of powder diffraction users engaged in chemical identification and quantitative analysis. Rietveld refinement as a method for quantitative analysis is mentioned, but only briefly; the reader will not find a detailed account of the extent and scope of the method in this volume. The authors do not investigate the limitations of laboratory based techniques to any great extent, nor do they provide details of the more challenging aspects of structure determination from powder data that I would have appreciated. However, as the authors point out, the book is intended to be published with a companion volume, and inclusion of too much applications material would have made the book very large.

Jenkins and Snyder have succeeded very well in producing a volume that will be useful to powder diffraction instrument libraries worldwide. The book provides almost all the essential information for obtaining the best possible experimental results from Bragg–Brentano and Debye–Scherrer diffractometers. It will be especially useful in industry, as it specifically addresses the problems that are most relevant for quality control, processing, and identification. It does not address the wider progress of powder diffraction that has made the technique capable in some cases of competing with single crystal diffraction, nor does it mention any of the specific problems associated with dynamic experiments that can be performed on laboratory based systems. However it does succeed very well in its principal aim of providing a clear and concise description of the practical aspects of laboratory based powder diffractometry. I am quite sure that the book will become a standard text to accompany powder diffractometers, and might significantly help to improve laboratory practice.

Concise Chemical Thermodynamics. By *J. R. W. Warn* and *A. P. H. Peters*. Chapman & Hall, London, 1996. 188 pp., paperback £ 15.99.—ISBN 0-412-46650-3

In this book, which is intended for students taking chemistry at the basic level, the authors have set out to present the fundamentals of thermodynamics by means of examples drawn from chemistry and chemical engineering. The book covers the main principles of thermodynamics, and develops the concepts of internal energy, enthalpy, entropy, and free enthalpy in the context of practical applications. The reader is expected to have an elementary knowledge of differential and integral calculus for functions of a single variable; however, most of the examples require only a familiarity with basic arithmetical operations. This is sufficient for an introductory treatment of thermodynamics, since those students who go on to more advanced courses can easily progress to handling the mathematics of functions of several variables. This approach has obvious advantages. It allows one to develop the subject in relation to its wide-ranging applications in chemistry without burdening students with too much mathematics and without lengthy theoretical derivations, thus providing a very direct way of gaining an appreciation of the capabilities of chemical thermodynamics.

The book contains a good selection of practical examples, including some original ones, to which the methods of chemical thermodynamics can be applied. The problems presented in the examples are well described and the methods used to solve them are clearly explained. In addition the authors provide many exercise problems, with solutions in the appendix. Many of the examples are from the recent literature, and the authors explain their significance in the context of the original publications. They are taken from a wide variety of fields, such as chemical synthesis, combustion, nuclear reactor technology, combined heat and power generation, reactions in flames, electrochemistry, corrosion phenomena, and metallurgy. In the course the reader gains insight into the wealth of existing thermochemical data and computer programs, and becomes aware of the limitations of available data.

Unfortunately, the authors' development of thermodynamic concepts such as entropy and free enthalpy does not match the quality of the practical examples. This shortcoming is most apparent in the rambling and diffuse explanations that are given in the text, usually in italic type. These sentences are no substitute for precise formulations that are essential in thermodynamics, and they only serve to fill the book with unnecessary extra pages. Hence, the presentation of thermodynamic concepts is weak, and needs to be tightened up to provide a solid basis for discussing the practical examples. Provided that these improvements are carried out the book could serve as the basis for a concise course of study in chemical thermodynamics, adding up to considerably more than just a useful collection of interesting and topical examples.

This provides an environmentally attractive process for the manu-
facture of propylene oxide.

Oxidative Transformations of Organic Compounds Mediated by Redox Molecular Sieves

Isabel W. C. E. Arends, Roger A. Sheldon,* Martin Wallau, and Ulf Schuchardt*

Dedicated to Prof. Dr. K. K. A. Unger on the occasion of his 60th birthday

Zeolites are viewed by some as the "philosopher's stone" of modern chemistry.[1] They are more or less indispensable in oil refining and petrochemicals manufacture where they are widely applied as solid acid catalysts. More recently attention has been focused on their use in the manufacture of fine chemicals. The synthetic utility of zeolites and related molecular sieves (zeotypes) has been considerably extended by the incorporation of redox metals into their frameworks. The resulting redox molecular sieves catalyze a variety of selective oxidations under mild conditions in the liquid phase. Their structural diversity—including variation of the redox metal, incorporation of metal complexes, and the size and polarity of the micropores—provides the possibility of designing tailor-made solid catalysts ("mineral enzymes") for liquid-phase oxidations with clean oxidants such as O_2, H_2O_2, and RO_2H. Hence, they have enormous potential in industrial organic synthesis as environmentally friendly alternatives to traditional oxidations employing inorganic oxidants in stoichiometric amounts. A primary aim of this review is to familiarize organic chemists with the synthetic potential of redox molecular sieves. An outline of their synthesis, structures, and chemical properties, highlighting their unique advantages, is followed by a discussion of general (mechanistic) features that influence the choice of a suitable catalyst for a particular type of oxidation. The main part of the review deals with the oxidation of various substrates of synthetic interest—such as alkanes, alkenes, (alkyl)arenes, alcohols, and amines—and emphasizes the advantages of redox molecular sieves (including selectivity and stability) over their homogeneous counterparts. New directions towards truly biomimetic solid catalysts, for example zeolite-encapsulated chiral metal complexes as heterogeneous catalysts for asymmetric oxidations, are highlighted.

Keywords: heterogeneous catalysis · metal complexes · molecular sieves · oxidations · redox chemistry

1. Introduction

The term "molecular sieve" was introduced by McBain[2] in 1932 to define porous solid materials (mainly activated carbons and zeolites) that act as sieves at a molecular level. Whereas the pore-size distribution in activated carbons is wide, it is very narrow in zeolites; this allows for highly selective discrimination of molecules on the basis of their dimensions.

Zeolites are crystalline, microporous hydrated aluminosilicates containing alkali and/or alkaline earth cations. Molecular sieves with structures analogous to those of zeolites, but with a different elemental composition, are also known. Hence, to avoid confusion we will use, in addition the general term molecular sieve, zeolite for (metallo)aluminosilicates and zeotype for analogous molecular sieves.

Zeolites are widely applied as solid acid catalysts in oil refining and petrochemicals manufacture.[3] Their use circumvents the effluent and handling problems associated with conventional mineral acids such as sulfuric and hydrofluoric acid as well as Lewis acids such as aluminum chloride, for example, in the alkylation of aromatic hydrocarbons.[4] Moreover, crystalline zeolites require milder reaction conditions than amorphous aluminosilicates, which translates to lower capital investment and increased flexibility.[5]

In contrast, applications of zeolites in the manufacture of fine chemicals has been very limited.[6] A possible explanation is that synthetic organic chemists are, generally speaking, not aware of the synthetic potential of molecular-sieve catalysts. Introduction of a redox metal[7] center into molecular sieves considerably extends their catalytic potential.[8] This review focuses on

the use of these redox molecular sieves as heterogeneous catalysts for liquid-phase oxidations of organic compounds. In fine-chemicals manufacture there is a marked trend towards replacement of stoichiometric amounts of inorganic oxidants, such as chromium(VI) and manganese(VII), with cleaner catalytic alternatives.

2. Structures of Molecular Sieves

Zeolites and zeotypes are crystalline oxides comprising corner sharing TO_4 tetrahedra (T = Si, Al, P, etc.) and consisting of a regular pore system with diameters in the range of 4–13 Å. The pore system may be one-, two-, or three-dimensional. The one-dimensional AFI structure has a pore system (diameter 7.3 Å) that can be pictured as a bundle of macaroni, whereas the FAU structure consists of three orthogonal channel systems (diameter 7.4 Å)[9] that intersect in larger cavities (diameter 13 Å, supercages).[10] As a result, the molecules can travel in all three directions. The dimensionality of the pore system can be important in the context of catalyst deactivation. Obviously a few obstructions in a one-dimensional pore system can seriously impede access to a large proportion of the internal catalytic sites, whereas alternative diffusion paths are available in two- or three-dimensional pore systems.

A zeolite with a particular topology is described by a mnemonic three-letter code[9] irrespective of its chemical composition (Table 1). The pore diameters given in Table 1 are derived from crystallographic data, and 10% should be added to obtain the limiting sizes of molecules with access to the pores.[6a] On the basis of their pore diameters molecular sieves are defined as small pore (< 4 Å), medium pore (4–6 Å), large

Roger Sheldon was born in Nottingham (UK) in 1942. He received his Ph.D. in organic chemistry in 1967 from the University of Leicester (UK) for work on organophosphorus chemistry under the joint supervision of S. Trippett and R. S. Davidson. Following postdoctoral studies with Jay Kochi in the USA on reactions of metal ions with free radicals, he joined Shell Research in Amsterdam in 1969 where he carried out reactions on various catalytic processes, in particular liquid-phase oxidations. From 1980–1990 he was the director of research and development at DSM-Andeno in Venlo (The Netherlands) where he developed an interest in the use of enzymes in enantioselective organic synthesis. In 1991 he moved to his present position as Professor of Organic Chemistry and Catalysis at Delft University of Technology. His research interests encompass homogeneous and hetereogeneous catalysis of liquid-phase oxidations, in particular by redox molecular sieves, organometallic catalysis in aqueous media, and enzymatic conversions under nonnatural conditions.

Isabel Arends was born in Huissen (The Netherlands) in 1966. She studied chemistry at the University of Leiden (The Netherlands) where she obtained her Ph.D. in 1993 in the field of radical kinetics. Thereafter she performed postdoctoral research with Keith U. Ingold at the National Research Council in Canada on alkane oxidations catalyzed by iron–biomimetic complexes. She joined the group of R. Sheldon in 1995 to study metal-catalyzed selective oxidations and, in particular, redox molecular sieves.

Martin Wallau was born in 1960 in Bad Kreuznach (Germany) and studied chemistry at the Universität Mainz (Germany) where he received his Ph.D. on zeolite-analogous gallosilicates under the supervision of K. K. Unger. In 1992 he joined the group of J. L. Guth at the Université de Haute-Alsace in Mulhouse (France) and studied the synthesis of microporous zincophosphates. This was followed by work on the analysis of organic traces in water in the group of W. Dünges at the Institut für Kernchemie der Universität Mainz. Since 1994 he is working in the group of U. Schuchardt at the State University of Campinas (Brazil). His research interests are redox molecular sieves and heterogeneous catalytic oxidations.

Ulf Schuchardt was born in Bad Sooden-Allendorf (Germany) in 1946. After obtaining his Diplom in chemistry at the Universität Marburg (Germany) in 1969, he finished his Ph.D. in 1973 at the Universität München (Germany) on transition metal complexes of boron–sulfur compounds under the supervision of H. Nöth. This was followed by work in homogeneous catalysis in the group of P. Binger at the Max-Planck-Institut für Kohlenforschung in Mülheim (Germany). In 1976 he was appointed Associate Professor of Inorganic Chemistry at the State University of Campinas (Brazil) and became Full Professor in 1987. His research interests are redox molecular sieves, homogeneous catalytic oxidation, Gif chemistry, Ziegler–Natta catalysis, strong-base catalysis, and biomass conversion.

Table 1. Pore dimensions and dimensionalities of zeotype structures.

Pore size	Structure type	Trivial names	Pore diameter [Å]	Dimensionality [a]	Adsorbed molecules

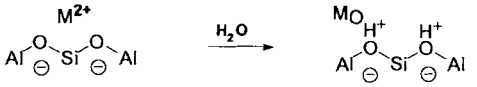
pore (6–8 Å), extralarge pore (>8 Å), and mesoporous (15–100 Å).[11]

Unlike an enzyme, the more or less rigid inorganic framework lacks the capacity to alter its topology by major conformational changes to allow induced fit of an incoming reactant molecule. However, adsorbed molecules are able to induce structural changes in the framework of molecular sieves. An increase of mean Si-O-Si angles from 146–159° in a sorbate-free MFI zeolite to 149–165° and 147–167° was found after adsorption of benzene and *p*-xylene, respectively.[6c] The reversible change of the size of the pore opening in the straight channels of MFI zeolite from 5.7 × 5.3 Å in the calcined (empty) sample to 6.2 × 4.8 Å with sorbed *p*-dichlorobenzene[6c] was also observed. Their well-defined pore system and capacity for at least small, induced structural changes enable molecular sieves to recognize, discriminate, and organize molecules with a precision of less than 1 Å.[12]

Recently different types of mesoporous (alumino)silicates, for example MCM-41, were reported.[13] They consist of a regular array of uniform, one-dimensional pores with diameters varying between 15 and 100 Å. Unlike the microporous molecular sieves, their pore walls do not possess an ordered structure, and their physico-chemical properties are similar to those of amorphous SiO_2 and Al_2O_3. Since a narrow pore-size distribution and a very high internal surface were observed for these materials,[14] selectivities similar to those of microporous molecular sieves can be expected.

3. Chemical Composition

In zeolites the centers of the TO_4 tetrahedra are occupied by silicon and aluminum atoms in a Si:Al ratio from 1:1 to ∞:1. The different valences of Si (tetravalent) and Al (trivalent) produce an overall negative charge for each incorporated aluminum atom. These negative charges are balanced by alkali and/or alkali earth cations. Whereas zeolites containing alkaline cations are weak bases, those with hydrated alkaline earth cations possess acid properties due to dissociation of adsorbed water molecules (Scheme 1). Exchange of the metal cations by protons affords strong Brønsted acids comparable in strength to sulfuric acid.[15] The acid strength increases with decreasing aluminum content, and the number of acid sites decreases.



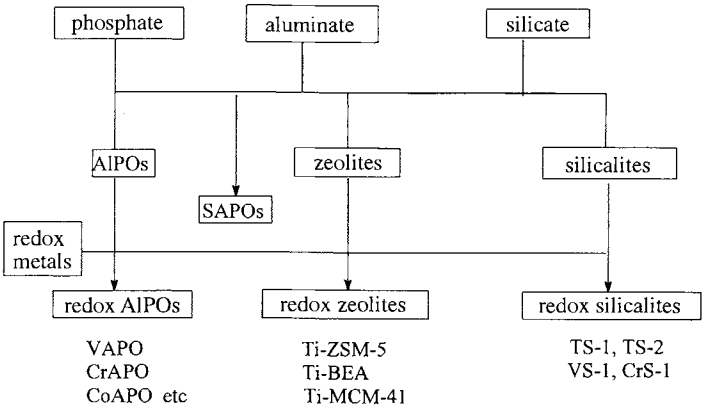
Scheme 1. Brønsted acid sites in zeolites.

The strength of the acidic sites is also influenced by the nature of the trivalent atom in the framework. Chu and Chang[16] showed that substitution of Al by B, Fe, or Ga in the framework of MFI zeolite decreases the strength of the Brønsted acid sites in the order Al-MFI > Ga-MFI > Fe-MFI ≫ B-MFI. The effects discussed above allow tailoring of basicity and acidity from weakly basic to strongly acidic.[17] Substitution of the trivalent atoms in the zeolite framework by tetravalent atoms such as silicon or titanium produces (metallo)silicalites with an electrically neutral, hydrophobic framework. The different hydrophobic or hydrophilic properties are reflected in the equilibrium adsorption isotherms for water, oxygen, and *n*-hexane.[18] The adsorption of alcohols from aqueous solutions can also be used to determine the hydrophobicity.[19] Groszek and Partyka[20] studied the adsorption of 1-butanol from an aqueous solution on different adsorbents and found the following order of hydrophobicity: alumina (0%) < MFI zeolite (Si:Al = 38:1, 73.6%) < MFI silicalite (Si:Al = 2000:1, 91%) < Graphon (activated carbon, 99.8%). The role of hydrophobicity in liquid-phase transformations catalyzed by molecular sieves is discussed in Section 6.3. Substitution of the tetravalent silicon by pentavalent phosphorous atoms produces aluminophosphates (AlPOs) and silicoaluminophosphates (SAPOs). The net framework charge of the AlPOs (P:Al = 1:1) is zero, whereas the SAPOs possess, in a defect-free framework, one negative charge for each silicon atom and show ion exchange properties and Brønsted acidity like the zeolites.[21] Table 2 illustrates the different possibilities for combining Si, Al, and P in the framework of molecular sieves along with the resulting properties.

Table 2. Chemical composition and properties of zeotype molecular sieves.

	Chemical composition	Properties
zeolite	$(Si^{IV}\text{-}O\text{-}Al^{III}\text{-}O\text{-}Si^{IV})^-$ H^+ or M^+	negatively charged framework, hydrophilic, with ion exchange and acid sites
silicalites	$Si^{IV}\text{-}O\text{-}Si^{IV}\text{-}O\text{-}Si^{IV}$	neutral framework, hydrophobic, without ion exchange and acid sites
$AlPO_4$	$Al^{III}\text{-}O\text{-}P^{V}\text{-}O\text{-}Al^{III}$	neutral framework, hydrophilic, without ion exchange and acid sites
SAPO	$(Si^{IV}\text{-}O\text{-}Al^{III}\text{-}O\text{-}P^{V})^-$ H^+ or M^+	negatively charged framework, hydrophilic, with ion exchange and acid sites

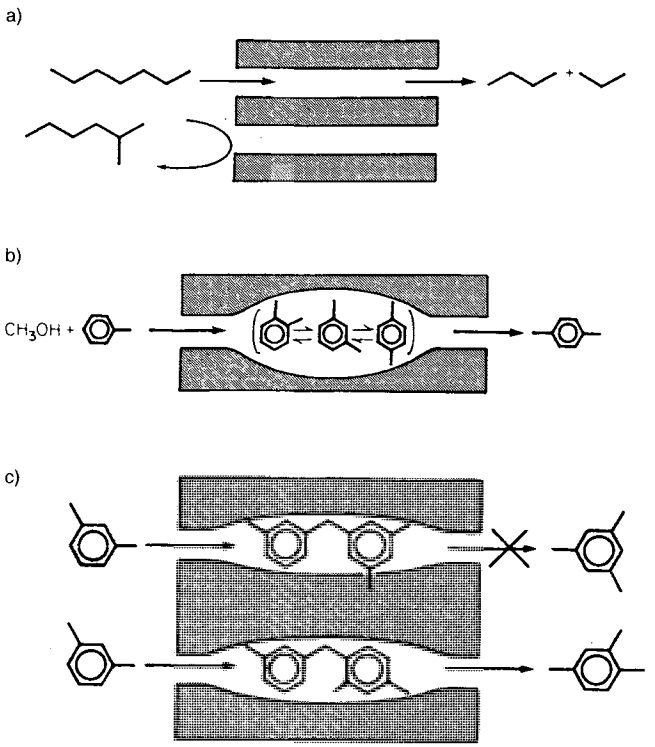
The presence of redox-active metals extends the catalytic potential of molecular sieves from acid and base catalysis to redox catalysis. For molecular sieves with redox properties the generic name "redox molecular sieve" has been coined.[22] They can be regarded as "mineral enzymes" in which the inorganic framework replaces the protein mantel of the enzyme.[23] Scheme 2 shows the various types of redox molecular sieves that are possible through the combination of Si, Al, P, and redox metals.



Scheme 2. Types of redox molecular sieves.

4. Shape selectivity

The capability of molecular sieves to organize and to discriminate molecules with high precision is responsible for their shape-selective properties.[25] Csicsery[11a,26] defined the three well-known categories of shape selectivity (Scheme 3):



Scheme 3. Shape selectivity governed by zeolites (adapted from ref. [26]): a) reactant selectivity; b) product selectivity; c) transition-state shape selectivity.

a) Reactant selectivity: only molecules that are able to enter the zeolite channels react.
b) Product selectivity: only molecules that are able to leave the zeolite channels are found in the product mixture.
c) Restricted transition-state selectivity: reaction occurs only when the required transition state can be formed in the zeolite cavities.

Shape selectivity has been mostly studied in reversible, acid-catalyzed processes.[27] Oxidation processes, on the other hand, are normally irreversible, and only reactant and/or restricted transition-state selectivity are of importance.[8c]

5. Preparation of redox molecular sieves

We can distinguish between three types of redox molecular sieve based on how they are prepared: ion exchange, framework substitution, or encapsulation.

5.1. Ion Exchange

As outlined in Section 3, zeolites and SAPOs possess a negatively charged framework. Since these negative charges are compensated by exchangeable cations, cations with redox properties can be introduced by direct ion exchange. However, the diameter of some hydrated cations can be too large to enter the pore system. This obstacle can be overcome by solid-state ion exchange.[28] This technique and its advantages have been reviewed by Karge and Beyer[29] as well as Kucherov and Slinkin.[30] Although ion exchange allows the preparation of redox molecular sieves from commercially available zeolites (such as LTA, MFI, and FAU), the presence of the metals as exchangeable extraframework cations has some disadvantages. Due to the polyvalence of the transition metal cations, disproportionation of adsorbed water will lead to acid sites in the pores (see Scheme 1), which might catalyze undesired side reactions. Moreover, the high mobility of the exchangeable cations in the pore system can lead to facile leaching of the metal cations from the pores and formation of oxide clusters, which can change the catalytic properties.

5.2. Framework Substitution by Hydrothermal Synthesis

Molecular sieves are generally crystallized from aqueous gels containing a source of the framework building elements (Al, Si, P), a mineralizer (OH^-, F^-) that regulates the dissolution and condensation processes during the crystallization, and a structure-directing template (often an organic amine or ammonium salt). These gels are transformed by allowing them to crystallize in autoclaves at temperatures between 353 and 473 K under autogenous pressure for times varying from several hours to a couple of weeks.[21,31,32]

Redox molecular sieves are similarly prepared by addition of redox-active metal cations to the synthesis gel. Substitution of Al, Si, or P in the framework by the added redox metal ion during crystallization produces framework sites. From Pauling's theory of the chemical bond,[33] framework substitution, in which the metals are coordinated tetrahedrally by four oxygen

ions, should be possible if the ratio of the radii of the cation and the oxygen anion is between 0.225 and 0.414. Table 3 lists the different structures and elements for which framework incorporation is claimed and suggests that framework incorporation is also possible for metal cations for which $r^{n+})/r(O^{2-})$ is slightly higher than 0.414. However, the oxidation state of the metal ion and, hence, the structure may be substantially different in the calcined material from that in the as-synthesized redox molecular sieve. For example, chromium-substituted molecular sieves generally contain chromium(III) in the as-synthesized material, but this is converted to chromium(VI) upon calcination. Since chromium(VI) always contains two extraframework Cr=O bonds it can only be anchored to the surface and cannot be isomorphously substituted. Similarly, the same reasoning applies to vanadium, which is generally in the tetravalent state in as-synthesized material but converted to vanadium(V) after calcination. Cobalt and manganese-substituted molecular sieves generally contain the metal in the divalent and trivalent oxidation states in as-synthesized and calcined materials, respectively. In this case, however, the metal can in principle still be isomorphously substituted in the calcined material.

Incorporation of Ti,[74] V,[75] Cr,[76] Mn,[77] and Fe[78] in mesoporous silicates of MCM-41 type has been reported. The technique used for the synthesis of mesoporous (metallo)-silicates is also applicable for the preparation of mesoporous transition metal oxides. For example, Ciesla et al.[79] and Huo et al.[80] synthesized oxides of tungsten, molybdenum, iron, lead, and antimony similar to MCM-41. The synthesis of niobotungstate[81] and vanadiophosphate[82] analogs of MCM-41 has also been described. Although these materials are potential redox catalysts, their mesopores are blocked by occluded template molecules that cannot be removed without destruction of the structure. However, Antonelli and Ying[83] recently reported the preparation of a TiO_2 analog of mesoporous MCM-41 that can be calcined without collapse of the pore structure; also the silica-containing niobotungstate contains mesopores that are at least partly accessible.[81] These approaches to prepare mesoporous transition metal oxides might lead to new redox molecular sieves in the near future.

Table 3. Framework incorporation of (redox) metals in molecular sieves.

Metal cation [a]	$r(M^{n+})/r(O^{2-})$ [33b]	Structure [ref.]	Elemental composition
Ti^{4+}	0.486	MFI [8d,e], MEL [8d,e], MTW [34], BEA [35], ZSM-48 [8d,e,36]	Ti; Si
		BEA [8d,e], MOR [8d,e,37]	Ti; Al; Si
		AEL [38], AFI [38], VFI [40]	Ti; Al; P
		AFI [39]	Ti; Si; Al; P
V^{4+}	0.421	MFI [8d,e], MEL [8d,e,41], ZSM-48 [8d,42], MTW [8e,43,44], NCL-1 [8e,45], AFI [43]	V; Si
		BEA [46]	V; Si; (Al; B)
		TON [47], EUO [47]	V; Si; Al
		AFI [8d,48], AEL [8d], VFI [40]	V; Al; P
Cr^{3+}	0.457	MFI [23,49,50], MEL [51], MTW [44]	Cr; Si
		AFI [23,52], VFI [40]	Cr; Al; P
Mn^{2+}	0.571	MTW [44]	Mn; Si
		AEL [53]	Mn; Si; Al; P
		AEL [54], AFI [55]	Mn; Al; P
Fe^{3+}	0.457	MFI [56], MEL [56], MTW [56], BEA [56,57] MOR [56], EUO [56], MTT [56]	Fe; Si
		FAU [56,58]	Fe; Al; Si
		AFI [59], VFI [40,60,61]	Fe; Al; P
Co^{2+}	0.514	MFI [62,63]	Co; Si
		AEL [64], AFI [64], FAU [65], VFI [40,66]	Co; Al; P
Cu^{2+}	0.514	MFI [67]	Cu; Si
Zn^{2+}	0.529	MFI [68]	Zn; Si
		FAU [65], AFI [55]	Zn; Al; P
As^{5+}	0.350	MFI [69]	As; Si
Zr^{4+}	0.571	MFI [70]	Zr; Si
Sn^{4+}	0.507	MFI [71], MEL [71,72], MTW [71]	Sn; Si
		AFI [73]	Sn; Al; P

[a] The valence state of the metal cations is that of the original material incorporated in the synthesis gel; when calcined, the valence state in the final material can change: V^{V}, Cr^{VI}, Mn^{III}, Co^{III}.

5.3. Post-Synthesis Modification

Incorporation of redox metals by hydrothermal synthesis requires that the procedure be optimized for each metal, which is very time consuming due to the numerous factors that influence the molecular-sieve crystallization. A further disadvantage of direct synthesis is that crystallization of some structures requires the presence of Al (for example FAU zeolite). Incorporation of Al not only produces acid sites, which must be neutralized to avoid the catalysis of side reactions, but also decreases the hydrophobicity of the catalyst, which might influence the selectivity. Isomorphous substitution of metals in the framework by post-synthesis modification allows the preparation of redox molecular sieves from commercially available molecular sieves, the properties of which are already optimized for use as catalysts. One of the first examples of post-synthesis incorporation was the preparation of high-silica FAU zeolites by their treatment with $SiCl_4$ vapor.[84] Isomorphous substitution of P by Si in zeotype aluminophosphates by treatment with $SiCl_4$ vapor has also been described.[85] The reaction of zeolites with aqueous ammonium hexafluorosilicate allows the substitution of framework aluminum by silicon.[86] Treatment of MFI and FAU zeolites with aqueous ammonium tetrafluoroborate produces boroaluminosilicates in which the B atom occupies framework positions.[87] Recently, Beyer et al. reported incorporation of silicon into framework positions previously occupied by aluminum by a solid-state reaction between NH_4SiF_6 and ammonium-exchanged zeolites.[88]

In principle such post-synthesis procedures can also be used to substitute framework atoms by redox metals. For example, Skeels and Flanigen[89] reported the substitution of Al by Fe and Ti in zeolites upon treatment with solutions of the respective ammonium fluoride salts. Use of an aqueous acidic fluoride system also allows incorporation of Sn and Cr.[90] Framework incorporation of Ti was achieved by treating a zeolite with $TiCl_4$ vapor.[91] Titanium zeolites with MFI, BEA, and FAU structures were synthesized by allowing the respective H-form to react with ammonium titanyl oxalate,[92] $TiCl_4$,[93] or $Ti(OiPr)_4$;[93] vanadium silicalite was obtained by reaction of zeolites and silicalites with MFI structure with VCl_3 vapor.[94] De Ruiter et al.[95] suggested that boron-containing structures are more suitable for post-synthesis procedures, because boron

can be extracted under extremely mild conditions from the framework to leave thermally stable, reoccupiable silanol nests. They described the preparation and deboronation of borosilicalites with MFI[96] and BEA[97] structures and the reoccupation of the silanol nests in the BEA structure with Si[97] and Ti.[98]

Future developments will show if post-synthesis procedures allow the incorporation of new redox metals. One can expect that the consecutive incorporation of different metals will lead to redox molecular sieves that cannot be obtained by direct hydrothermal synthesis.

5.4. Encapsulation of Transition Metal Complexes within Molecular Sieves

A different approach to creating novel redox-active molecular sieves is the encapsulation of transition metal complexes,[99–104] first described by Klier[105] in 1968. Such encapsulated complexes are generally referred to as "ship-in-a-bottle complexes" or zeozymes.

For encapsulation of large complexes, zeolites with FAU or EMT (hexagonal faujasite) structures have been used in most cases. They possess a supercage (diameter 13 Å) that can readily accommodate large complexes such as metallophthalocyanines. More recently, other suitable materials have become available, such as the aluminophosphate with VFI structure (VPI-5) and the gallophosphate with CLO structure.

The most reliable strategies for ensuring stable encapsulation seem to be spatial entrapment, electrostatic retention, and immobilization by low solubility (see also Sections 6.3 and 6.4). In order to maximize catalyst lifetimes, research has focused on metal complexes with oxidation-resistant ligands such as phthalocyanines, polypyridines, and aromatic Schiff bases.

In addition to adsorption or anchoring of preexisting complexes on zeolites and direct ion exchange (a recent example is reported for Cu^{II} amino acid complexes)[23b, 106] the most widely applicable synthetic methods are a) intrazeolite synthesis by complexation, b) intrazeolite ligand synthesis and complexation, and c) template synthesis.

For intrazeolite synthesis the metal complex is assembled in the zeolite cavities. In case a the ligand is small enough to diffuse through the zeolite pores, but the metal complex, once formed, is too large to diffuse out. The starting material is a transition metal ion-exchanged zeolite in which the metal ion is surrounded by H_2O, HO^-, or oxide ions of the zeolite lattice.[107–108] These are replaced by a coordinating ligand such as bipyridyl (bipy). For example, $[Ru^{II}(bipy)_2]$ and $[Ru^{II}(bipy)_3]$ in zeolite NaY have been prepared by allowing zeolite NaY, exchanged with $[Ru^{III}(NH_3)_6]^{2+}$, to react with bipyridyl.[107a, 109–110] Bipyridyl complexes of Fe,[111] Mn,[112] and Cu[113] in zeolite NaY were similarly prepared. Schiff base complexes, for example of bis(salicylaldehyde)ethylenediimine (salen), have been made by adsorption of salen into transition metal exchanged faujasites.[114–116] However, metal–salen complexes are readily leached from faujasites by protic solvents such as ethanol (see Section 6.4).[103b]

Due to their size, porphyrins and phthalocyanines need to be assembled by intrazeolitic synthesis as well (case b). There are only a few examples of porphyrin/zeolite/metal combinations, probably because of their bulkiness and difficult in situ synthesis. Nevertheless, the synthesis of tetraphenylporphyrins[117] as well as iron and manganese 5,10,15,20-tetramethylporphyrins[118] in FAU zeolite has been reported. On the other hand, examples with phthalocyanines are numerous. The metal is introduced into the zeolite, through ion exchange as carbonyl complexes or metallocenes, followed by 1,2-dicyanobenzene, which reacts at elevated temperature to form the metallophthalocyanine in the pores (Figure 1).[103a] The presence of unchelated transition metal ions can be largely avoided by using

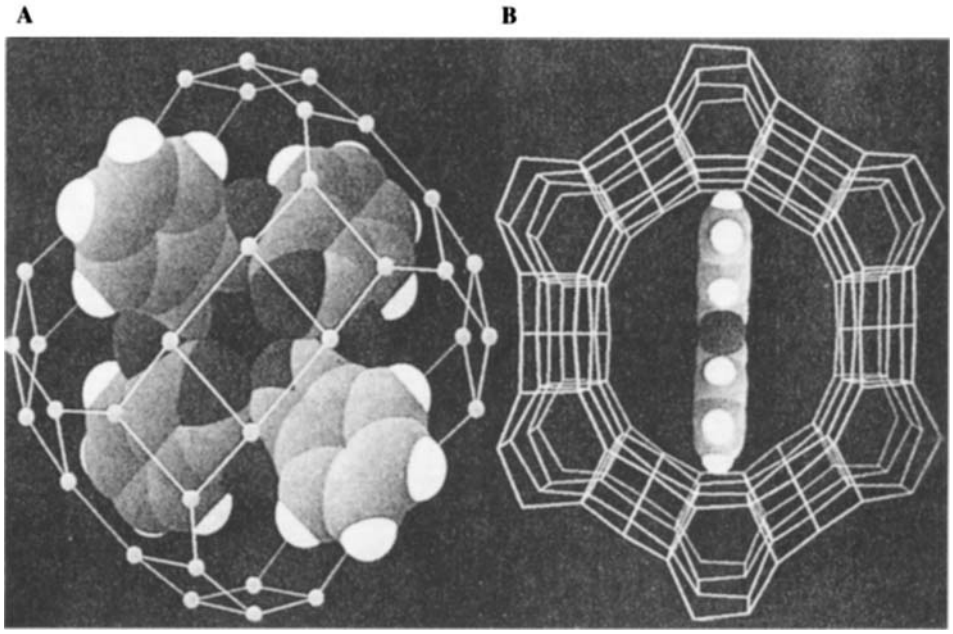


Figure 1. Molecular graphics repesentation of [Fe(Pc)] encapsulated in zeolite NaY (A) and VPI-5 (B) (adapted from ref. [120a]).

metallocenes, although a large fraction of the phthalocyanines remains metal-free. Phthalocyanine complexes have been encapsulated in FAU, EMT, and VFI sieves by intrazeolite ligand synthesis. Examples are numerous and include FePc in FAU zeolite,[119] FePc in VFI zeolite (VPI-5),[120] MnPc in FAU zeolite,[121] CoPc in EMT zeolite,[122] and CuPc in FAU zeolite.[123]

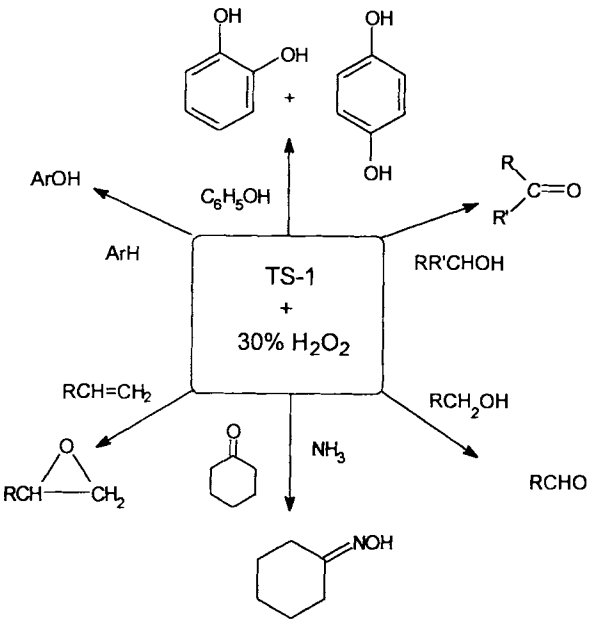
In template synthesis (case c) the metal complex, which acts as a structure-directing agent (template) during the hydrothermal synthesis, is added to the synthesis gel. A major restriction of this method is that the preformed complex must be stable during

all phases of the zeolite synthesis, that is, at high pH and temperatures. Therefore, the choice of complexes that can be made by this method is very limited. On the other hand, it has the advantage that the metal complexes have a predetermined coordination. Phthalocyanine complexes of Fe, Co, Cu, Ni, and Ru[124, 125] have been incorporated in FAU zeolite, and various metallophthalocyanines in AFI and AEL aluminophosphates[126] by the template method. The use of bipyridine and phenanthroline complexes as templates in MFI zeolites has also been claimed.[127]

6. General Considerations in Using Redox Molecular Sieves

6.1. Choice of Molecular Sieve

The molecular-sieve structure to be used for a certain reaction is determined by the size of substrate, product, and oxidant molecules. For example, the titanosilicalite with MFI structure (TS-1) catalyzes the oxidation of a broad spectrum of substrates with aqueous H_2O_2 (Scheme 4). However, its medium pore size



Scheme 4. Oxidations with aqueous H_2O_2 catalyzed by TS-1.

limits its application to relatively small molecules. The synthesis of redox molecular sieves with larger pore diameters and different chemical composition allows tailoring of the molecular sieve and optimization of the catalyst–substrate interaction. An example is the development of Ti-BEA.[8d e, 35, 92, 98] The pore dimensions of molecular sieves can be found in Table 1, and the kinetic diameters of a variety of organic molecules have been collected by Breck[31] and Szostak.[21]

6.2. Choice of Metal and Oxidant

The choice of oxidant is influenced by both economic and environmental considerations.[22a, 128] The primary oxidant should preferably contain a high percentage of active oxygen and afford a coproduct that is innocuous and/or easily recyclable. Oxidants that meet these criteria are molecular oxygen, hydrogen peroxide, and alkyl hydroperoxides such as *tert*-butylhydroperoxide (TBHP). The choice of oxidant may also be influenced by the type of oxidation mechanism involved. Catalytic oxidations can be divided into three basic categories:[22a, 128] 1) free-radical autoxidation, 2) oxidation of coordinated substrates followed by reoxidation of the reduced metal ion, and 3) catalytic oxygen transfer.

One-electron oxidants such as cobalt and manganese compounds are the most effective catalysts for free-radical autoxidations with O_2.[129] The mechanism of cobalt-catalyzed hydrocarbon autoxidation involves alkoxy and alkylperoxy radicals as key intermediates [Eq. (1)–(5)], and we assume that exactly

$$RO_2H + Co^{II} \longrightarrow RO^{\bullet} + Co^{III}OH \quad (1)$$

$$RO_2H + Co^{III}OH \longrightarrow RO_2^{\bullet} + Co^{II} + H_2O \quad (2)$$

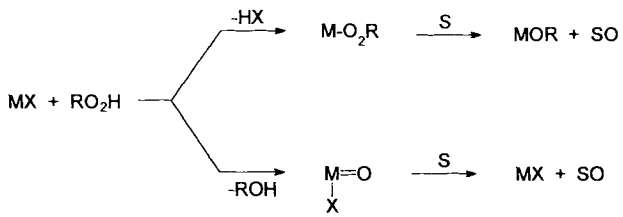
$$RO^{\bullet} + RH \longrightarrow R^{\bullet} + ROH \quad (3)$$

$$R^{\bullet} + O_2 \longrightarrow RO_2^{\bullet} \quad (4)$$

$$RO_2^{\bullet} + RH \longrightarrow R^{\bullet} + RO_2H \quad (5)$$

the same mechanism is operative in the case of a heterogeneous catalyst such as CoAPO.

Catalytic oxygen transfer is the reaction of an oxygen donor, for example H_2O_2 or RO_2H, with an organic substrate in the presence of a metal catalyst. The active oxidant in such processes may be an oxometal or a peroxometal species (Scheme 5).[22a, 128] Early transition elements (Ti, Zr, Mo, W)



Scheme 5. Peroxometal (top) and oxometal pathways (bottom).

react via peroxometal intermediates, and catalysis by late and/or many first-row transition elements (Cr, Mn, Fe) involves high-valent oxometal intermediates. Some elements, such as vanadium, react via oxometal or peroxometal intermediates depending on the substrate.[22a, 128]

A major difference between the two types of mechanisms is that in the peroxometal pathway there is no change in oxidation state of the metal ion during reaction (that is, the metal ion increases the oxidizing power of the peroxo group by acting as a Lewis acid). In the oxometal pathway, in contrast, the metal ion undergoes a two-electron reduction and is subsequently reoxidized by the oxygen donor; this is a special case of mechanism 2. This means that catalysis via oxometal intermediates can in principle be performed with molecular oxygen. Indeed, this is the major pathway observed for catalytic oxidations of

hydrocarbons in the gas phase and is known as the Mars–van Krevelen mechanism. In the liquid phase, on the other hand, it is much less common due to competition from the ubiquitous free-radical autoxidation pathway.

In short, catalytic oxidations with early transition metal ions (for example Ti^{IV}, Mo^{VI} and W^{VI}) are heterolytic in nature and require oxygen donors such as H_2O_2 or RO_2H. Examples of oxidative transformations include olefin epoxidation, sulfoxidations, oxidations of various nitrogen compounds, and alcohol oxidations. Catalytic oxidations with late and/or first-row transition metal ions can in principle be performed with oxygen donors or molecular oxygen. In both cases, however, it is often difficult to distinguish between a heterolytic, Mars–van Krevelen-type mechanism and competing homolytic pathways via alkoxy and alkylperoxy radical intermediates. Examples of oxidative transformations include side-chain oxidation of alkylarenes, allylic oxidations, and oxidations of (cyclo)alkanes. A major goal of research on catalytic oxidations is to devise catalysts that are capable of effecting a heterolytic, Mars–van Krevelen pathway in the liquid phase to the exclusion of free-radical autoxidation pathways.

6.3. Choice of Solvent

An important advantage of redox molecular sieves over other heterogeneous catalysts is that it is possible to influence which substrate molecules approach the active site by choosing a suitable combination of molecular sieve and solvent. The molecular sieve can be viewed as a second solvent that extracts the substrate molecules from the bulk solvent. Which substrate molecules are selectively extracted is determined by the size and hydrophobicity of the pores of the molecular sieve and the substrate. For example, a hydrophobic molecular sieve such as silicalite will selectively adsorb apolar hydrocarbon substrates. This is especially important in hydrocarbon oxidations where the primary products are polar molecules (alcohols, aldehydes, and ketones), which are more susceptible to oxidation than the hydrocarbon substrates. Hence, it is difficult to achieve high selectivities to primary oxidation products in homogeneous solution, but they can be improved with a hydrophobic redox molecular sieve. On the other hand, hydrophilic molecular sieves such as AlPOs, SAPOs, and zeolites selectively adsorb polar molecules.

Catalytic oxidations with H_2O_2 in homogeneous solution are in general strongly inhibited by the water present in, for example, 30% aqueous H_2O_2 or inevitably formed in the reaction. Hence, another important advantage of hydrophobic redox molecular sieves is that they are not deactivated by water, because the less polar hydrocarbon substrate and H_2O_2 are preferentially adsorbed in the micropores. In general a polar solvent such as acetone or methanol is used, which creates a single liquid phase but is not strongly adsorbed on the molecular sieve. Table 2 shows that only very highly siliceous molecular sieves are hydrophobic. Incorporation of di- and trivalent elements reduces the hydrophobicity linearly.[130] Redox silicalites containing tetravalent metal ions in framework sites (for example Ti^{IV}, V^{IV}, Zr^{IV}, and Sn^{IV}) are generally assumed to be hydrophobic. However, it was recently shown that MFI-Ti silicalite exhibits slightly hydrophilic properties that increase with Ti content.[131] Trivalent aluminum incorporated in the framework not only increases the hydrophilicity but also generates Brønsted acid sites that catalyze undesirable side reactions and must be neutralized by alkali cations to improve the catalytic properties.[132] The increase of hydrophilicity with increasing aluminum content requires the use of water-free systems with molecular oxygen or alkyl hydroperoxides as oxidant. Redox silicalites with bi- or trivalent cations in framework position (for example Cr^{III}, Fe^{III}, Mn^{II}, Co^{II}, and Cu^{II}) also contain Brønsted acid sites that should be neutralized and require a water-free system. For the strongly hydrophilic redox AlPOs and SAPOs, no (or a hydrophobic) solvent should be used to facilitate the adsorption of the apolar substrates. For polar substrates such as alcohols, the hydrophilicity of redox AlPOs facilitates their adsorption, so that they are more suitable for alcohol oxidation than redox silicalites.

6.4. Leaching of the Redox Metal Ion

A prerequisite for an industrially useful redox molecular sieve catalyst is that the metal is not leached from the internal surface of the molecular sieve during the reaction. Indeed, rapid leaching of metal ions is a general problem associated with the use of heterogeneous metal catalysts in liquid-phase oxidations. Leaching is a result of solvolysis of the metal–oxygen bonds, through which the catalyst is attached to the support (for example SiO_2, Al_2O_3), by polar molecules such as H_2O, ROH, or RCO_2H. Although the same situation is present on the (internal) surface of a molecular sieve, the metal–oxygen bonds appear to be more stable in this microenvironment. Presumably, attack of ROH on the M–O bonds is seriously hindered within the confinement of zeolite micropores. Nevertheless, it should be emphasized that, with the exception of TS-1, the long- or even short-term stability of the various redox molecular sieves towards leaching has not been unequivocally demonstrated. The definitive test for heterogeneity is to filter the catalyst during the course of the reaction at the reaction temperature and allow the filtrate to react further. If the reaction mixture is first allowed to cool to ambient temperature before filtration, readsorption of leached metal ion onto the catalyst can occur.[133]

Some molecular sieves, such as aluminophosphates, are unstable under alkaline or acidic conditions. Leaching of cobalt from CoAPO-5 is observed[64, 134] in cyclohexane autoxidation performed in acetic acid. Autoxidation of *p*-cresol catalyzed by CoAPO-5 under strongly alkaline conditions (NaOH in MeOH) leads to dissolution of CoAPO-5 and cobalt.[135] The basic conditions used for the ammoximation of ketones with NH_3/H_2O_2 catalyzed by TS-1 may also lead to leaching of titanium.[136]

Jacobs and co-workers[103b] have pointed out that a subtle interplay of various effects is responsible for the retention of metal complexes in the micropores of molecular sieves. In zeolites with cages or large channel intersections, complexes can be formed that are larger than the original, freely diffusing constituents and are locked in as a true ship-in-a-bottle. Metallophthalocyanines encapsulated in zeolite Y are classical examples of this type of complex.[119–123] Alternatively, metal complexes can be retained by electrostatic interactions with

oxide anions on the internal surface of a zeolite or even the formation of covalent bonds with surface OH groups. In cases where the complex is not truly locked into the cages or channel intersections, hydrophilic, protic solvents can be expected to leach the complex from the zeolite. Although zeolite Y-occluded metal Schiff base complexes are stable in CH_2Cl_2 they are washed out by ethanol.[103b] Apparently, the thermodynamically favorable adsorption of ethanol in zeolite Y is a strong enough driving force to cause dissociation and, hence, leaching of the metal–salen complexes from the zeolite cages. Polar protic molecules, for example alcohols and carboxylic acids, are produced in many oxidative processes.

7. Oxidation Reactions

7.1. Alkenes

Titanium silicalites with MFI and MEL structures (TS-1 and TS-2)[131, 137–141] have been extensively studied as catalysts for olefin epoxidations with H_2O_2 and/or RO_2H. TS-1, for example, is an excellent catalyst for epoxidation of olefins with aqueous H_2O_2. Even relatively unreactive olefins, such as propylene[140] and allyl chloride,[137, 140] are smoothly epoxidized under mild (40 °C in MeOH) conditions (Table 4).

Table 4. Epoxidations of olefins with aqueous H_2O_2 catalyzed by TS-1 [a].

Olefin	T [K]	t [min]	H_2O_2 conversion [%]	Epoxide selectivity [%]
propylene	313	72	90	94
1-pentene	298	60	94	91
1-hexene	298	70	88	90
1-octene	318	90	81	91
cyclohexene	298	90	10	n.d.
allylchloride	318	30	98	92
allylalcohol	318	35	81	72

[a] Reprinted from ref. [140] (copyright 1993) with kind permission of Academic Press Inc., Orlando (USA). Olefin:H_2O_2 = 5:1; n.d. = not determined.

As yet no other catalyst has been shown to be capable of emulating the remarkably high reactivity and selectivity of TS-1 for epoxidations in aqueous media. However, the scope of epoxidations catalyzed by TS-1 is limited to olefins that can be accommodated by the relatively small pores (5.3 × 5.5 Å) of the MFI structure. For example, cyclohexene is not epoxidized by this system (Table 4). Moreover, TS-1 is not active with the more bulky *tert*-butyl hydroperoxide as oxidant, and attention has been focused on the use of titanium-substituted, larger-pore zeolites as epoxidation catalysts.[35, 74, 92, 98, 132, 142–150]

Titanium-substituted zeolites with the BEA structure (7.6 × 6.4 Å) have been widely studied.[35, 92, 98, 132, 142–148] Ti-Al-β is less active than TS-1 in the oxidation of straight-chain olefins but is able to mediate the oxidation of olefins for which TS-1 is not effective, for example branched and cyclic olefins (Table 5). The major products are the monomethyl glycol ethers, which are formed by ring opening of the initially formed epoxide by the methanol solvent,[144] together with smaller amounts of rearrangement (aldehydes, ketones) and cleavage products.

Table 5. Epoxidations with aqueous H_2O_2 catalyzed by Ti-BEA and Ti-MFI [a].

Alkene	Catalyst	$v_0 \times 10^6$ [b] [mol g^{-1} s^{-1}]	Alkene conversion [mol%]	Epoxide selectivity [mol%]	H_2O_2 selectivity [%]

[d] Not determined.

Ring opening is catalyzed by the Brønsted acid sites present in Ti-Al-β. Hence, the selectivity to epoxide increased dramatically when the Brønsted acidity was neutralized by ion exchange with alkali metal acetates.[132] Ion exchange with lithium acetate resulted in an increase in epoxide selectivity from 0 to 87% in the oxidation of 1-octene at the expense of a lower conversion (27% compared to 46%, Table 6).[132]

Table 6. Epoxidation of 1-octene over ion-exchanged Ti-BEA zeolites [a].

The use of lower amounts of aluminum, for example Si:Al ratio of 300:1[146] or aluminum-free Ti-BEA,[35, 98] can also be expected to improve epoxide selectivities in this system. The activity and selectivity of Ti-BEA as an epoxidation catalyst is also strongly influenced by the solvent (Table 7). The increase in reaction rate with increasing pK_a of the solvent was explained by assuming that the solvent coordinates to the Ti center in the active site (Scheme 6).

Ti-Al-β also catalyzes epoxidations with TBHP.[144, 147] Corma and co-workers[144] obtained epoxide selectivities of 90–100% for the oxidation of alkenes with Ti-BEA in acetonitrile.

Table 7. Influence of solvent on 1-octene oxidation with H_2O_2 over Ti-BEA [a].

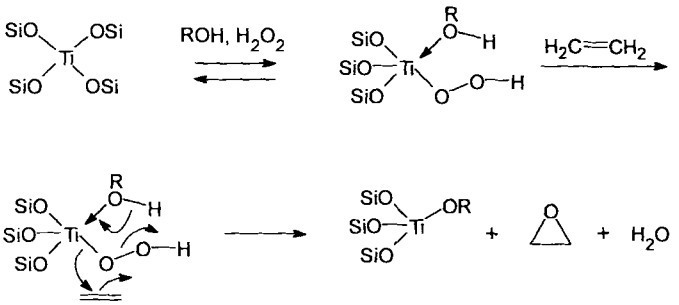
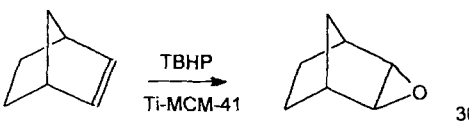


Scheme 6. Mechanism of epoxidation on titanium-substituted molecular sieves.

In hydrophobic solvents, such as chlorobenzene, or in the absence of a solvent, only nonproductive decomposition of TBHP was observed.[147] This was attributed to insufficient extraction of the hydrophobic substrate into the relatively hydrophilic cavities of Ti-BEA.[147]

Similarly, the titanium-substituted mesoporous zeolite Ti-MCM-41 has been reported to catalyze epoxidations with H_2O_2 or TBHP.[74b, 150] The bulky norbornene afforded the epoxide in 90% selectivity at 30% conversion with TBHP as oxidant [Eq. (6)].[74b] Interestingly, Ti-SAPO, which contains Brønsted

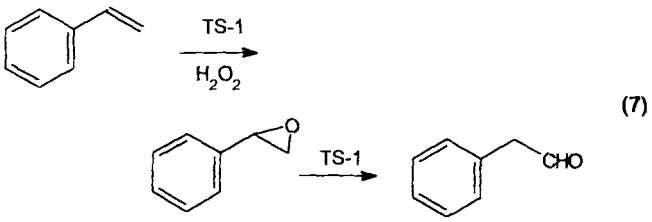


30% conversion
90% selectivity

(6)

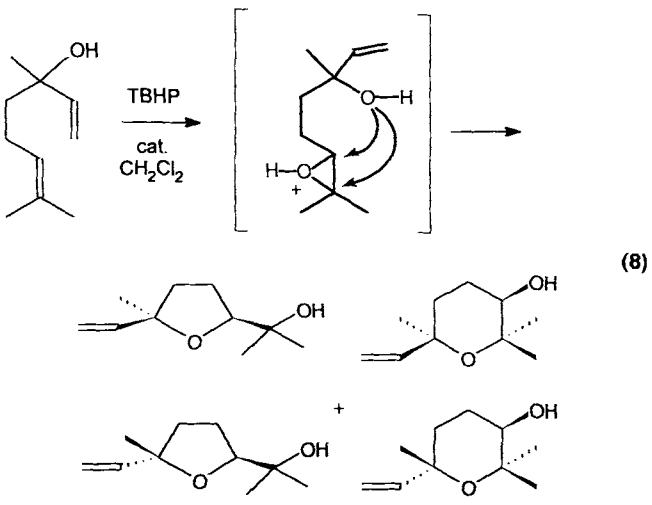
acid sites, afforded the 1,2-diol as the main product in the oxidation of cyclohexene with H_2O_2, whereas the epoxide was formed selectively (79%) with TBHP.[34, 39]

In some cases the presence of Brønsted acid sites in addition to a redox catalytic function could be an asset as it could provide the possibility of performing bifunctional catalysis, for example, epoxidation of an olefin with an in situ acid-catalyzed rearrangement to an aldehyde or ketone. Workers ar Enichem[151] have described the epoxidation of styrene, with in situ rearrangement of the initially formed styrene oxide to 2-phenylacetaldehyde [Eq. (7)], with H_2O_2 over TS-1. Similarly, Corma



(7)

and co-workers reported the oxidation of linalool to a mixture of cyclic ethers with TBHP in the presence of Ti-BEA or Ti-MCM-41 [Eq. (8)].[152] The large-pore Ti-BEA afforded a

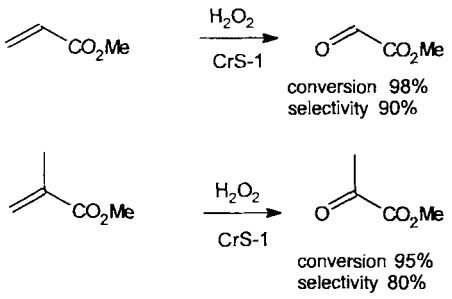


(8)

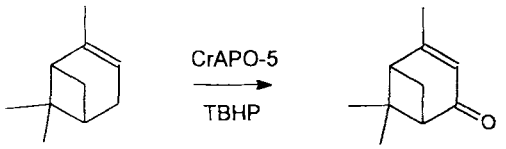
higher selectivity to the furans, whereas the mesoporous Ti-MCM-41 favored pyran formation.[152]

Other metal-substituted molecular sieves have been much less studied as epoxidation catalysts. Vanadium-substituted aluminophosphates, for example V-AFI, have been reported to catalyze selective epoxidations with TBHP.[153] However, there are serious doubts regarding the stability of this system towards leaching.[154]

Chromium-substituted silicalites with the MFI[22b, 155, 156] and MEL[157] structures catalyze the oxidative cleavage of olefinic double bonds. For example, methyl acrylate and methyl methacrylate afforded methyl glyoxylate [Eq. (9a)] and methyl



pyruvate [Eq. (9b)], respectively.[155, 156] CrAPO-5 was shown to catalyze the allylic oxidation of olefins with TBHP at 80 °C to give the corresponding enones,[158] and a variety of terpenoid substrates were oxidized to unsaturated ketones.[158] For example, α-pinene afforded verbenone in 77% selectivity [Eq. (10)]. A more recent detailed study of such oxidants catalyzed



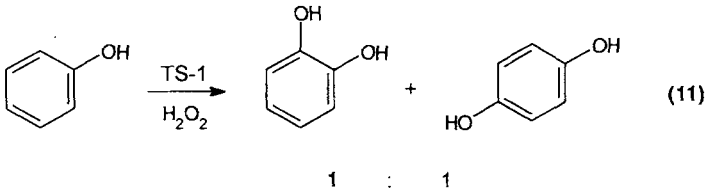
85% conversion
77% selectivity (13% alcohols)

by CrAPO-5, CrAPO-11, or CrS-1 has shown that some leaching of chromium occurs during the reaction.[133] Even though in some cases, such as with CrAPO-5, this was no more than 1% of the available chromium, this homogeneous chromium could account for most of the observed reaction. Furthermore, it was shown that leaching was due to the reaction of the framework chromium atoms with the alkyl hydroperoxide to afford soluble alkylperoxo complexes.

Ship-in-a-bottle complexes have also been used to catalyze the epoxidation or oxidation of olefins. *cis*-Bis(bipyridyl)-manganese(II) complexes, when encapsulated in zeolites X and Y, catalyze selective epoxidation of alkenes with H_2O_2. In the case of cyclohexene, epoxidation is followed by acid-catalyzed ring opening, carbon–carbon bond cleavage, and formation of adipic acid.[112, 159] By lowering the acidity of the zeolite, high yields towards epoxide can be obtained. Also Mn^{II} centers ligated by tetradentate Schiff base ligands ($salenH_2$) within zeolite NaY have been applied for selective oxidation of various alkenes.[116] Epoxides were obtained in reasonable yields with iodosobenzene as oxidant, whereas the use of TBHP mainly resulted in allylic oxidation.[116] Recently, the use of Mn- and Fe–salen complexes in BEA zeolite for the oxidation of cyclopentene and cyclohexene with H_2O_2 as the oxidant was reported.[160] Again, dicarboxylic acids were the major products.

7.2. Arenes: Nuclear Hydroxylation

Hydroxylation of phenol with H_2O_2 to catechol and hydroquinone catalyzed by MFI-Ti silicalite [Eq. (11)] was the first example of an industrial application of a redox molecular sieve; a plant producing 10000 tons per year has been in operation



1 : 1

25% conversion
92% selectivity

since 1986.[161] The ratio of hydroquinone: catechol is close to 1:1, and the selectivity based on phenol is 92% . Tuel et al.[162] showed that catechol is formed at the surface of the MFI-Ti silicalite crystals, whereas hydroquinone is formed in the channels. Poisoning of the surface sites by the formation of tar increases the hydroquinone selectivity during the reaction. With acetone as solvent, which is able to dissolve the tar from the crystal surface, they obtained a small excess of catechol. In a study of the hydroxylation of toluene, anisole, and *m*-cresol with aqueous H_2O_2 catalyzed by MFI-Ti silicalite, Bhaumik and Kumar[163] observed a negative influence of acetonitrile as the solvent, both in activity and in selectivity. The influence of solvents on the hydroxylation of phenol catalyzed by Ti and V silicalites was also investigated by Ramaswamy et al.,[164] and similar results were obtained (Table 8). Ferrini and Kouwenhoven[93] found water to be the best solvent (Table 9).

Table 8. Influence of solvents on the hydroxylation of phenol over MEL-Ti and MEL-V silicalites [a].

Solvent	Conversion [mol%]	H_2O_2 Selectivity [mol%]	Products [d] [mol%] catechol	hydroquinone	*p*-benzoquinone

V-ZSM-48,[42] MTW-V silicalite,[165] EUO-V silicalite,[47] TON-V silicalite,[47] BEA-Ti zeolite,[146] MFI-As silicalite,[69] MEL-Sn silicalite,[72] AFI-TiAPO,[38] and AEL-TiAPO[38] are also claimed to be active catalysts for the hydroxylation of phenol. In these cases catechol is the main product. Keshavaraja et al.[166] obtained *o*:*p* ratios of up to 9:1 with amorphous titanosilicates, which contain micro- and macropores, as catalyst for the hydroxylation of phenol.

Hydroxylation of benzene with aqueous H_2O_2, also catalyzed by redox molecular sieves, leads to phenol as the main product along with a small amount of *p*-benzoquinone (Table 10).[167] Phenol selectivities higher than 90% were observed with amorphous titanosilicalites[166] or mesoporous MCM-41 analogs[74a] as catalysts.

Table 10. Hydroxylation of benzene and toluene with aqueous H_2O_2 over MEL-Ti, MEL-V, and MEL-Sn silicalites [a].

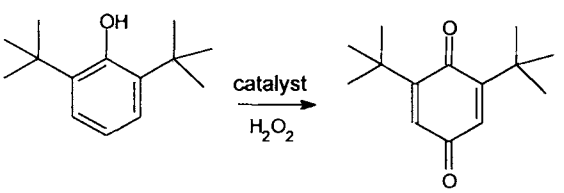
The use of large-pore or mesoporous redox molecular sieves allows oxidation of bulky aromatic molecules. Ratnasamy et al.[45, 167] showed that V-NCL-1 catalyzes the oxidation of naphthalene to afford a mixture of 1-naphthol (4%), 2-naphthol (7%), 1,4-naphthoquinone (22%), phthalic anhydride (47%), and other dioxygenates (20%).[167] Oxidation of 1-naphthol over mesoporous V-MCM-41 afforded 1,4-naphthoquinone (84%), 1,4-dihydroxynaphthalene (11%), and 1,2-naphthaquinone (5%) with a high efficiency on H_2O_2.[75, 168] Mesoporous V-MCM-41[168] and Ti-MCM-41 [74a, 169] also catalyze the conversion of 2,6-di-*tert*-butylphenol into the corresponding quinone [Eq. (12)].



(12)

	conversion	selectivity
Ti-MCM-41	83%	95%
V-MCM-41	95%	90%

7.3. Arenes: Side-Chain Oxidation

The selectivity of side-chain oxidation over ring oxidation is primarily determined by the incorporated metal. Whereas MEL-Ti silicalite catalyzes primarily nuclear hydroxylation of toluene to *o*- and *p*-cresol, MEL-V-[167, 170] and MEL-Sn-silicalites[72, 167] favor the formation of benzaldehyde and benzylalcohol. Amorphous meso- and microporous titanosilicates catalyze the oxidation of toluene with aqueous H_2O_2 to give products of side-chain oxidation and cresol in a 2.3:1 ratio.[166] EUO-V and TON-V silicalite,[165] BEA-V zeolite, and BEA-V borosilicate[46] also give mainly side-chain oxidation in the case of toluene. Side-chain oxidation is also the main reaction observed with *p*-chlorotoluene in the presence of MFI and MEL-V silicalites.[171] The use of the large-pore V-NCL-1 as catalyst[8e, 45, 172] allows the oxidation of such bulky molecules as 1,2,4- and 1,3,5-trimethylbenzene with H_2O_2. Hydroxylation at the position *meta* to the alkyl group is strongly disfavored; for 1,2,4-trimethylbenzene only benzylic oxidation is observed (substrate:H_2O_2 = 2:1, conversion 26%, alcohol:aldehyde $\approx$1:1). For 1,3,5-trimethylbenzene, however, a 13% selectivity to ring hydroxylation was found (conversion 34%), and the alcohol to aldehyde ratio was 1:2.[8e]

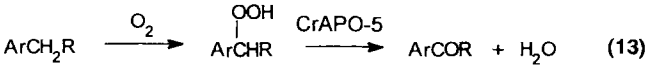
Chromium-substituted molecular sieves Cr-MFI (CrS-1) and Cr-AFI (CrAPO-5) catalyze the oxidation of aromatic side chains with TBHP (Table 11) or O_2 as oxidant[173–175] to give

Table 11. Oxidation of alkyl arenes to the corresponding ketones with TBHP catalyzed by Cr-AFI [a].

Substrate	Conversion [%]	Selectivity [%]
ethylbenzene	70	90
p-ethyltoluene	68	97
n-propylbenzene	59	93
n-butylbenzene	59	92
diphenylmethane	50	94
p-ethylanisole	13	41

[a] Reprint from ref. [203] (copyright 1994) with kind permission from Elsevier Science, Amsterdam (The Netherlands). Reaction conditions: 0.2 g catalyst; 10 mmol TBHP; 10 mL solvent; N_2 atmosphere; T = 353 K; t = 16 h; solvent = chlorobenzene.

the corresponding ketones in high selectivities. When oxidations are performed with O_2 the reaction is assumed to involve a classical free-radical autoxidation mechanism to give the corresponding benzylic hydroperoxide followed by Cr^{VI}-catalyzed decomposition to the ketone [Eq. (13)].

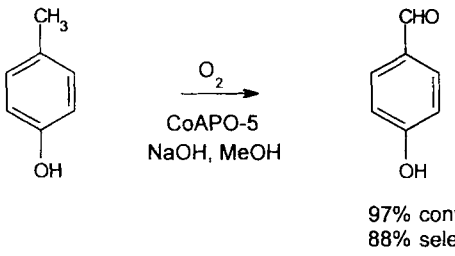


(13)

Brønsted acid sites in the catalyst can cause decomposition of the intermediate hydroperoxide to phenolic compounds that inhibit autoxidation. In some cases, for example with ethylbenzene, efficient oxidation is observed when the Brønsted acid sites in the catalyst are neutralized. Inhibition was not observed in the oxidation of tetralin and indane,[173] presumably because the intermediate hydroperoxides do not afford phenols by acid-catalyzed decomposition.

Although the Cr-AFI catalyst could be recycled several times without any loss of activity, more recent studies[133] have demonstrated that small amounts of chromium are leached from the catalyst in the presence of TBHP and could be responsible for the observed activity. Recycling of catalysts without measurable loss of activity, as reported by many authors in studies of redox molecular sieves, is not sufficient evidence for the heterogeneity of the catalytic system (see Section 6.4).

AFI-Co and AEL-Co aluminophosphates also catalyze the autoxidation of *p*-cresol to *p*-hydroxybenzaldehyde in NaOH/MeOH solution [Eq. (14)].[176] However, the aluminophosphate structure is not stable under these conditions and undergoes slow dissolution to give soluble cobalt, which is probably, at least partly, responsible for the observed catalysis.[134]



(14)

7.4. Alkanes

Following Herron's pioneering studies, ship-in-a-bottle complexes have been widely applied as biomimetic catalysts for the oxidation of alkanes.[10b, 119, 177–179] Recently, Jacobs and coworkers studied FePc encaged in FAU zeolites (FePc-Y) and VFI-APOs (FePc-VFI) as catalysts for the room-temperature oxidation of *n*-alkanes with TBHP.[120, 180] The conversions obtained with FePc encapsulated in FAU zeolite are up to 12 times higher than those obtained with the free complex.[120a] Presumably, site isolation of FePc complexes in the zeolite cages precludes catalyst deactivation by formation of oxo-bridged dimers. The turnover numbers (molar ratio of oxidized molecules:Fe complex)[120a] vary between 180 and 260 and are more than 50 times higher than those reported by Herron,[10b] who observed rapid deactivation. Whereas Herron et al.[10b, 177] obtained alcohols as main products, Jacobs et al.[120a] observed good selectivities towards ketones with increasing chain length. The ketone:alcohol ratios, which ranged from 3:1 to 10:1, suggest that the reaction occurs by a free-radical mechanism and point to the existence of diffusion control. Whereas for *n*-hexane no regioselectivity was observed, in higher alkanes the order of reactivity was C2>C3>C4>C5, presumably because the longer chains are more susceptible to steric constraints exerted by the zeolite framework. Similar results were obtained for FePc encapsulated in VFI-APOs. However, lower activity, lower ketone selectivity, and lower regioselectivities were observed.[120a] Interestingly, FePc-VFI showed no deactivation.[120a]

More recently, a 300-fold enhancement in activity of FePc-Y in alkane oxygenations was obtained by embedding FePc-Y in a hydrophobic polydimethylsiloxane membrane.[23b] The polymer probably serves to enhance the preferential adsorption of the alkane substrate and therefore increases the catalyst stability.

A second generation of metallophthalocyanines was developed by Balkus and co-workers. They used perfluorinated Ru–phthalocyanine complexes [Ru(F_{16}Pc)] encapsulated in zeolite Y to oxidize cyclohexane with TBHP.[124b, c] Their activity is superior to that of their homogeneous analogues [Ru(F_{16}Pc)] due to site isolation, and turnover numbers of 3000 per day can be reached. Moreover perhalogenation eliminates the presence of abstractable hydrogens and enhances the oxidative stability of the ligand. Ketone is the also the main product (98%) in this system, and a radical-type mechanism was suggested.

The oxidation of alkanes in the presence of framework-substituted redox molecular sieves has also been widely studied, and the systems can be divided into two basic types: those involving early transition metals (Ti and V) in combination with H_2O_2 and those involving late transition metals (Co, Mn, and Cr) in combination with O_2. All of these oxidations almost certainly proceed by free-radical mechanisms. The oxidation of unactivated alkanes with H_2O_2 catalyzed by Ti[37, 92, 138, 139, 142, 143, 167, 168, 181–191] and V[45, 75, 165, 167, 168, 170, 182, 192] incorporated in molecular sieves has been extensively studied. Mainly Ti incorporated in molecular sieves with MFI,[138, 139, 182, 183, 187, 190, 191] MEL,[167, 181, 182, 188] and BEA structure,[92, 142, 143, 185, 186] as well as V incorporated in molecular sieves with MEL structure[170, 182, 192] were studied. In early work Tatsumi et al.[183] studied the oxidation of different alkanes with H_2O_2 catalyzed by titanosilicalite (with MFI structure). They showed that the reactant selectivity of the MFI structure leads to a strong decrease in the turnover number for cyclic, branched, and higher linear alkanes relative to that for *n*-hexane. Whereas no regioselectivity was observed for linear alkanes, branched 2- and 3-methylpentane showed 100% selectivity for oxidation at the end of the linear chain. The relatively low turnover numbers observed even for *n*-hexane are probably due to the absence of a cosolvent; addition of small quantities of methanol to the reaction mixture increased the turnover number up to 5 times.[183]

Fu and Kaliaguine[181] studied the cosolvent effect in the oxyfunctionalization of *n*-hexane by aqueous H_2O_2 (30%) catalyzed by Ti silicalite (MEL). They found that oxidation of the C2 atom is favored by methanol as the solvent (Ox(C2):Ox(C3)>1:1), whereas acetone and acetonitrile favor oxidation of the C3 atoms (Ox(C2):Ox(C3)<1:1). In the presence of water the oxidation occurs statistically (Ox(C2):Ox(C3) ≈ 1:1). However, these results cannot be generalized, and the alcohol:ketone ratios observed by Tatsumi et al.[183] show that the nature of the substrate also has an important influence on the product distribution.

In addition to Ti zeotypes, V zeotypes are also active for alkane oxidations. Ramaswamy et al. observed similar activities for Ti and V silicalites in the oxidation of *n*-hexane but a remarkable difference in product distributions. Whereas Ti silicalites catalyze the oxidation of C–H bonds of secondary C atoms only, the V silicalites also mediate the oxidation of C–H bonds of primary C atoms.[45, 167, 170, 192] Furthermore, the product distribution for the oxidation of linear alkanes at the C–H bonds of secondary C atoms in the chain reflected a preference in the order C2>C3>C4 (the numbers refer to the

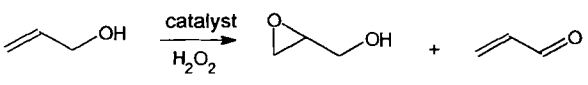
position of the carbon atom in the alkane chain).[170] Vetrivel et al.[170] proposed that oxidation of C–H bonds of primary C atoms occurs on V sites present in six-membered channels that are accessible to methyl groups but not to methylene groups. They suggested that the selectivity for oxyfunctionalization of the C–H bond of the primary C atom could be improved by partial blockage of the ten-membered channels.[170] Vanadium incorporated in large pore,[44,45,165] extra large pore,[194] and mesoporous [75,168,193] molecular sieves can also catalyze the oxidation of unactivated hydrocarbons. The lower alcohol:(aldehyde + ketone) ratio and the higher amount of polyfunctional oxygenates and lactones indicate that V silicalites are better able to oxidize than Ti silicalites and that molecular oxygen takes part in the reaction.[194]

Redox molecular sieves containing Co[64,134] and Cr[22b,173,195] have also been applied to the oxidation of alkanes. CoAPO-catalyzed autoxidation of cyclohexane without solvent gave little or no leaching,[64] whereas leaching was observed in acetic acid.[134] In the case of CrAPO, cyclohexane can be oxidized to cyclohexanone with either O_2 or TBHP.[22b,173]

7.5. Alcohols

As mentioned in Section 7.4, alcohols are the primary products of the oxidation of C–H bonds in hydrocarbons. Under the reaction conditions they can easily undergo further oxidation to aldehydes, ketones, and carboxylic acids. MFI-Ti silicalite catalyzes the selective oxidation of alcohols with aqueous H_2O_2 under mild conditions.[196,197] Secondary alcohols afforded the corresponding ketones in high yields. Primary alcohols afforded the corresponding aldehydes as the major products, but some overoxidation to carboxylic acids and esters was also observed.[197] The low reactivity of methanol towards this system allows its use as a solvent. As expected, tertiary alcohols are not oxidized but slowly converted to the corresponding alkyl hydroperoxide.[197] Ti-MFI catalyzed the oxidation of benzyl alcohol with H_2O_2 to give a mixture of benzaldehyde (75%) and benzoic acid (25%) with 90% conversion.[163] Benzoic acid results from overoxidation, and this effect was more pronounced with Cr-MFI as the catalyst and TBHP as oxidant (selectivity to benzaldehyde and benzoic acid of 40% and 55%, respectively, with 79% conversion).[198]

Different chemoselectivities were observed in the oxidation of allyl and methallyl alcohols with H_2O_2 in the presence of MFI-Ti or MFI-V [Eq. (15) and (16)].[8e,167,199] The titanium catalyst gave mainly epoxidation of the double bond, whereas the vanadium catalyst favored oxidation of the alcohol moiety. The same observation for Ti-MFI was made by Hutchings and Lee.[200,201]



(15)

V-MFI 5 : 80

AFI-Cr aluminophosphates catalyze the selective oxidation of secondary alcohols to the corresponding ketones with TBHP or O_2 as oxidant.[22b,202,203] In the latter case a catalytic amount (10 mol%) of TBHP was added to initiate the reaction. Carveol underwent chemoselective oxidation of the alcohol moiety without oxidation of the double bonds [Eq. (17)].

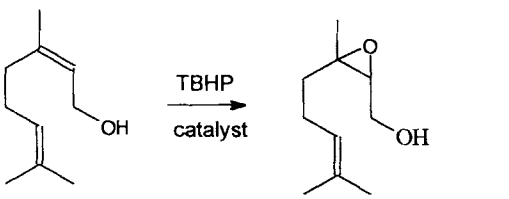
1-Phenylethane-1,2-diol underwent chemoselective oxidation of the secondary alcohol group [Eq. (18)]. These reactions are assumed to involve oxidation of the alcohol by oxochromium(VI) followed by reoxidation of the chromium(IV) compound by TBHP.

In contrast, AFI-V aluminophosphate catalyzes the selective epoxidation of allylic alcohols, such as cinnamyl alcohol[157] and geraniol,[154,157] by a peroxometal mechanism. Surprisingly, MEL-Cr silicalite was also reported to give selective epoxidation of geraniol with TBHP [Eq. (19)].[157]

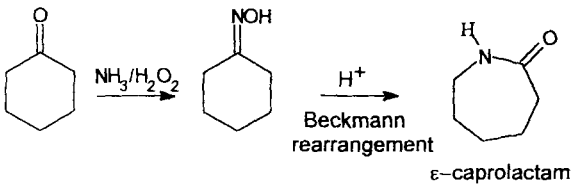


(19)

Cr-MEL 95% selectivity
V-MFI 97% selectivity

7.6. Ammonia and Amines

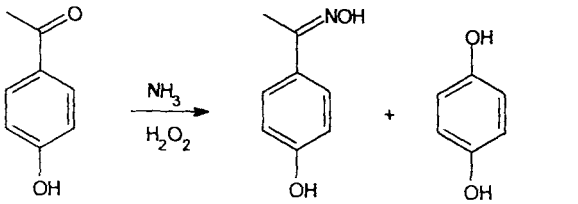
Titanium-containing molecular sieves catalyze the conversion of carbonyl compounds into the corresponding oximes in the presence of ammonia and H_2O_2.[8e,204–207] For example, ammoximation of cyclohexanone is being developed commercially as an alternative, low-salt process for the manufacture of cyclohexanone oxime, the raw material for nylon-6 manufacture [Eq. (20)].



(20)

Ammoximation of acetophenone, benzophenone, 2-butanone,[204] acetone, 3-hexanone, *p*-tolualdehyde,[8e] and benzaldehyde[8e, 204] has been described. In general, ammoximation of aldehydes is faster than that of ketones. Reddy et al. obtained the best conversion and selectivity for ammoximation of cyclohexanone to the oxime with NH_3 and H_2O_2 over MEL-Ti silicalite in the absence of solvent.[204] The reaction involves initial catalytic oxidation of ammonia to hydroxylamine followed by a noncatalytic reaction between hydroxylamine and the carbonyl compound.[207, 208] This mechanism is consistent with the observation that Ti silicalites catalyze the oxidation of ammonia to hydroxylamine selectively,[208] and that ketones that are too large to enter the molecular sieve channels are converted into oximes.[206, 207]

Recently ammoximation of cyclohexanone as well as *o*- and *p*-hydroxyacetophenone (HAP) over MFI-Ti silicalite, BEA-Ti zeolite, and Ti-ZSM-48 were studied.[206] The oxime of the latter is of interest as a key intermediate in an industrial synthesis of the analgesic paracetamol.[209] In the case of cyclohexanone, BEA-Ti zeolite and Ti-ZSM-48 gave significantly lower activity and selectivity. For BEA-Ti zeolite the presence of Brønsted acid sites could cause rearrangement of cyclohexanone oxime to ε-caprolactam, followed by polymerization to nylon-6 and blocking of the pores. In the case of *p*-hydroxyacetophenone, ammoximation competes with oxidation to hydroquinone [Eq. (21), the Dakin reaction]. Upon increasing the *p*-



(21)

HAP:H_2O_2 ratio from 1:1 to 4:1 the oxime selectivity with MFI-Ti silicalite increased from 41 to 70%. In the case of BEA-Ti zeolite the presence of water results in hydroquinone as the main product, even with high NH_3:H_2O_2 and catalyst:substrate ratios. With methanol or *tert*-butylalcohol as solvent the oxidation to hydroquinone is completely suppressed and accompanied by a lower activity. The results are similar with *o*-hydroxyacetophenone as the substrate, but a greater selectivity to forming of catechol is observed due to the possibility of intramolecular hydrogen bonding between the *o*-hydroxyl group and the carbonyl group of *o*-hydroxyacetophenone, which facilitates the attack of H_2O_2 on the carbonyl group.[206]

Primary amines are oxidized to the corresponding hydroxyl amines with H_2O_2 in the presence of titanium-containing molecular sieves,[210, 211] and secondary amines to the corresponding oximes. The activity and selectivity towards the oxime decreases with increasing size of the substrate;[210] for cyclohexyl amine a low conversion is observed over medium-pore MFI and MEL zeolites. Methanol,[210, 211] ethanol,[211] and *tert*-butylalcohol[210, 211] are suitable solvents, but the use of acetone leads to the formation of the corresponding *N*,*N*-dimethylimines (which are further oxidized to oxaziridines).[210, 211] For the oxidation of propylamine over various catalysts, MFI-Ti and MEL-Ti silicalites with aqueous H_2O_2 as oxidant gave high conversions into the oxime (Table 12). Low turnover numbers were obtained

Table 12. Oxidation of propylamine on Ti redox molecular sieves [a].

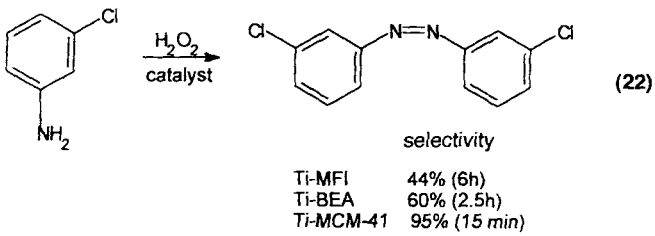
[c] Percentage of converted H_2O_2 utilized for the formation of oxime. [d] With TBHP as oxidant.

in the case of BEA-Ti zeolite, probably due to the deactivation of the active sites in this hydrophilic sieve by adsorbed water.

Titanium silicalites in combination with H_2O_2 exhibit remarkable activities and selectivities in the oxidation of anilines to symmetrical azoxybenzenes.[212] BEA-Ti zeolite and Ti-MCM-41 are also effective.[150] Interestingly, the selectivity for the formation of 3,3-dichloroazoxybenzene by oxidation of 3-chloroaniline [Eq. (22)] increases from 44% (6 h) over MFI-Ti



(22)

silicalite[212] to 60% (2.5 h) over BEA-Ti zeolite[150] to 95% (15 min) over Ti-MCM-41.[150] This clearly shows the benefits of large pore and mesoporous redox molecular sieves for the conversion of bulky substrates.

Chromium-[51] and vanadium-containing[51, 150] molecular sieves catalyze the oxidation of primary alkyl amines and anilines to the corresponding nitro compounds with high selectivities [Eq. (23), Table 13]. However, the activity of the vanadium

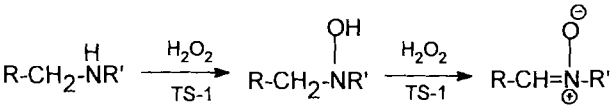
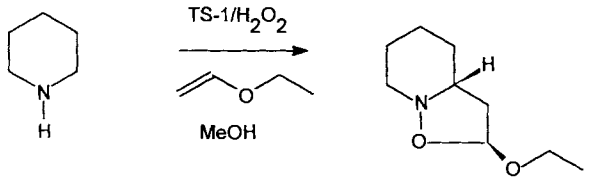
catalysts is very low.[51, 150] The MEL-Cr silicalite catalyzed oxidation of arylamines with electron-withdrawing substituents like COOH, NO_2 and CN to the corresponding nitroarenes is remarkable, because these compounds are difficult to obtain by conventional nitration methods. For the aliphatic amines no prototopic rearrangement to oximes is observed, whereas benzylamine gives benzaldoxime only.[51]

It was recently shown that oxidation of secondary amines with H_2O_2 catalyzed by redox molecular sieves allows the single-step preparation of nitrones [Eq. (24)].[213] MFI-Ti silicalite in the presence of methanol was very active and selective. MFI-V silicalite and AFI-VAPO also catalyzed the oxidaton of diethylamine to *N*-ethylideneethanamine *N*-oxide. However, their activities were only 10% of that of the MFI-Ti silicalite. The oxidation of piperidine in the presence of ethyl vinyl ether allows the synthesis of isooxazoline with 65% selectivity in a single step without isolation of the intermediate nitrone [Eq. (25)].[213]



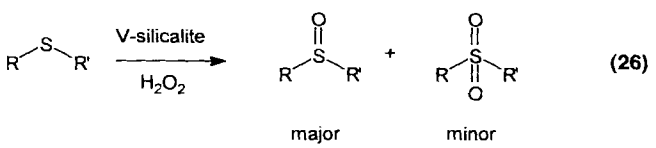
(24)



(25)

7.7. Sulfides

Kumar et al.[8e, 167, 214] have shown that Ti and V silicalites with MFI and MEL structure are efficient catalysts for the oxidation of various thioethers with H_2O_2 to give the corresponding sulfoxide along with some sulfone [Eq. (26)]. The reactivity of the thioethers as well as the sulfoxide selectivity decreases with increasing bulkiness of the substrate in the order dimethyl thioether ≫ diethyl thioether > methylphenyl thioether > ethylphenyl thioether.[214] The V silicalites were found to be more active than their Ti counterparts.[8e] Also the oxidation of dithiolanes and dithianes to sulfoxides and sulfones was observed.[8e]



(26)

Schulz-Ekloff et al.[215] have shown that Co^{II} FAU-zeolites are able to catalyze the aerobic oxidation of ethane thiol and 2-mercaptoethanol to the corresponding disulfides. The activity is markedly increased if cobalt phthalocyanine encaged in the FAU supercage is used instead.

7.8. Miscellaneous

Redox molecular sieves are active catalysts for the selective decomposition of cyclohexyl hydroperoxide to cyclohexanone.[216] The best performance was shown by AFI-CrAPO, followed by MFI-Cr silicalite and AEL-VAPO. Remarkably, other vanadium-containing molecular sieves are completely inactive (MFI-V silicalite) or only show low activity (AFI-VAPO). Cobalt-, manganese-, and titanium-containing molecular sieves were also inactive. AFI-CrAPO catalyzes this process for a number of alkyl hydroperoxides.[217] Whereas secondary hydroperoxides such as cyclohexyl- and tetralylhydroperoxide give ketones with high selectivity, tertiary alkyl hydroperoxides such as cumyl- and *tert*-butylhydroperoxide are transformed to the corresponding alcohols.

MFI-Ti silicalite catalyzes the oxidative cleavage of the C=N bond in oximes,[217] tosylhydrazones,[8e, 167, 218] and imines[218] by aqueous H_2O_2. Selectivities between 60 and 90% to the corresponding carbonyl compounds have been reported. This method can also be used to deprotect tosylhydrazones. Similarly, cleavage of oximes catalyzed by redox molecular sieves[219] offers a clean method for the synthesis of carbonyl groups not readily accessible by other means.

8. Concluding Remarks and Future Prospects

Hopefully this review has convinced the reader that the introduction of redox metals into molecular sieves produces a range of materials with enormous catalytic potential in organic synthesis. These redox molecular sieves catalyze a wide variety of synthetically useful oxidative transformations with clean oxidants—such as H_2O_2, RO_2H, and O_2—under relatively mild conditions. The pore sizes and hydrophobic or hydrophilic properties of molecular sieves endow them with special capabilities that are not possible with analogous homogeneous catalysts. Moreover, they are readily recovered by simple filtration.

Until now titanium-substituted molecular sieves have received the most attention. They are useful catalysts for processes such as olefin epoxidation, ketone ammoximation, and alcohol oxidation with 30% aqueous H_2O_2. Catalysts of varying pore size, from medium pore (TS-1) through large pore (Ti-BEA) to mesoporous (Ti-MCM-41) materials, are readily available from hydrothermal synthesis.

Incorporation of other redox metals, such as chromium, can afford catalysts for oxidative transformations that are complementary to those observed with titanium-substituted sieves, for example arene side chain oxidation and allylic oxidation of olefins (reactions that are characteristic of oxometal mechanisms). However, a caveat emptor is in order: the stability of many of these catalysts towards leaching of the redox metal has not been unequivocally demonstrated and, in many cases, should be regarded as dubious. True ship-in-the-bottle catalysts may be more stable towards leaching than framework-substituted redox molecular sieves, assuming that the complex is stable towards oxidative and/or solvolytic degradation.

Many of these redox molecular sieves exhibit high degrees of chemo- and regioselectivity. The ultimate in selectivity, however, is enantioselectivity. Hence, we expect that a future development in this area will be the design of chiral redox molecular sieves for carrying out asymmetric oxidations in intrazeolitic space. Such catalysts would indeed merit the term mineral enzymes. Encapsulation of chiral metal complexes in molecular sieves appears to be a logical approach to achieving this goal. Alternatively, chiral metal complexes may be covalently attached to the internal surface of zeolites.

Indeed, an example of the use of chiral molybdenum complexes anchored to the internal surface of a modified USY zeolite as catalysts for asymmetric epoxidation has been reported by Corma and co-workers.[220] Enantioselectivities were modest (maximum 47% *ee*), but the principle has been demonstrated and improvements are imminent. Redox molecular sieves will find broad applications as recyclable solid catalysts for selective oxidations in organic synthesis.

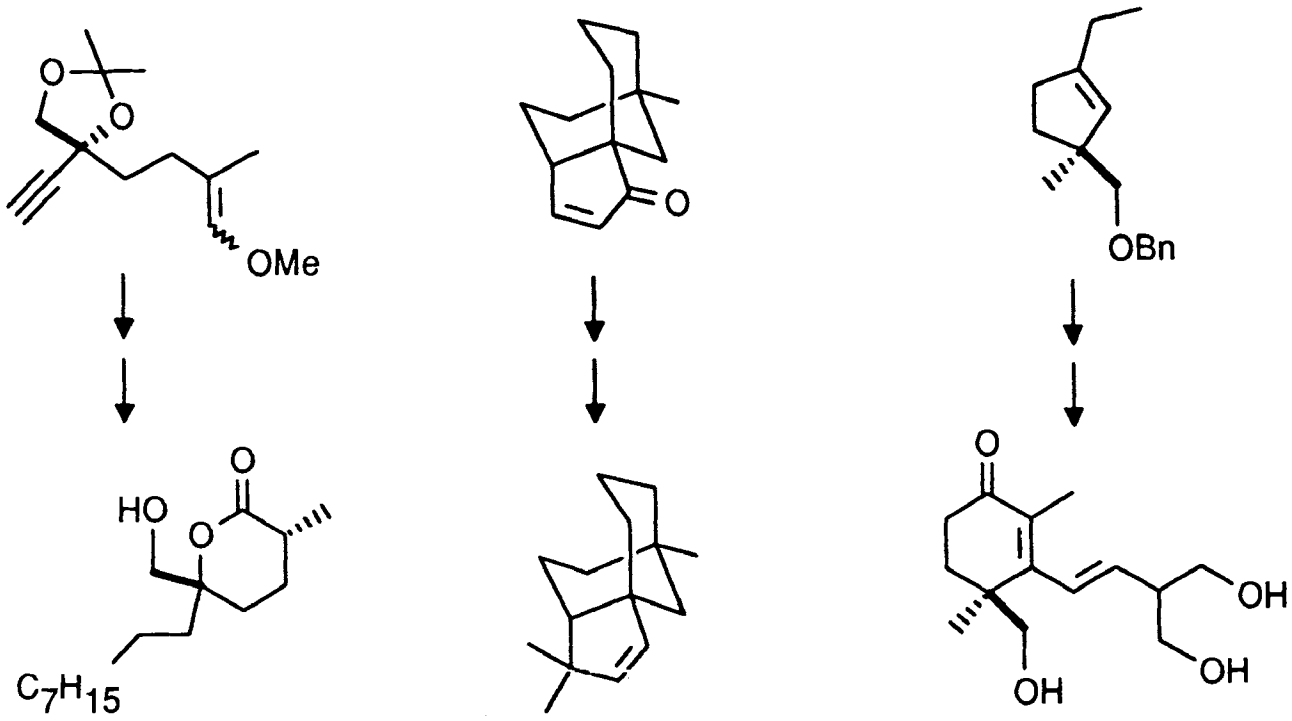
The selective formation of alkynes from aldehydes (top left) and cyclopentenes from ketones (top right) proceeds via alkenylidenes. These two reactions are being used increasingly in natural product synthesis as the pairs of starting materials and products below show.



Alkenylidenes in Organic Synthesis

Wolfgang Kirmse*

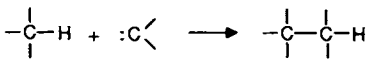
Alkenylidenes $R_2C{=}C{:}$ (= alkylidene carbenes) undergo regio- and stereoselective intramolecular C–H insertion reactions that are excellently suited for the synthesis of cyclopentenes. The 1,2-shifts occurring with R = H and R = Ar are useful for the preparation of alkynes. Alkenylidenes are efficiently generated from carbonyl compounds by diazomethylation, from vinyl halides by α-elimination, from alkynyliodonium salts by addition of nucleophiles, and from alkynes by retro-1,2-shifts. Specific applications of the various methods, particularly in the synthesis of natural products, are discussed.

Keywords: carbenes · carbenoids · cyclizations · rearrangements · synthetic methods

1. Introduction

Carbon–carbon bond formation is the basis for the construction of organic molecules. Many C–C bond-forming processes are polar—occurring between a nucleophilic and an electrophilic carbon atom [Eq. (1)]. To that end, each carbon atom must be functionalized (for example, X = halogen, Y = metal). The insertion of carbenes into C–H bonds [Eq. (2)] appears to

(1)



(2)

be more economical, since only one of the carbon atoms needs functionalization to give a carbene precursor. However, the application of reaction (2) in synthesis, particularly in cyclization reactions, is hampered by the low selectivity of many carbenes.[1] Simple alkylcarbenes react rather indiscriminately with all neighboring C–H bonds. Uniform products and acceptable yields are obtained only with rigid molecular frameworks, as exemplified by preparations of **2** from **1** (65%)[2, 3] and **4** from **3** (55%).[2, 4]

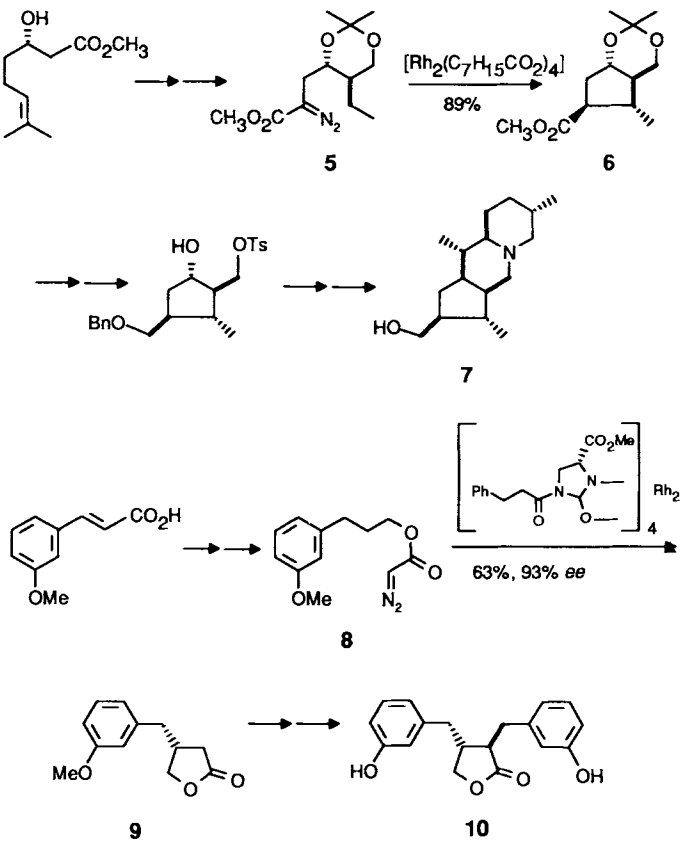
To solve the selectivity problem, various approaches have been pursued. The most advanced method involves the metal-catalyzed decomposition of diazocarbonyl compounds, most often with rhodium complexes of the type $[Rh_2L_4]$.[5, 6] A careful choice of the ligands L allows control of the regioselectivity



Scheme 1. Examples of metal-catalyzed decomposition of diazocarbonyl compounds as route to selective reactions of type (2).

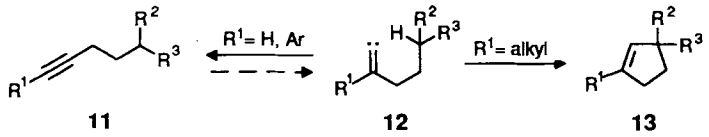
and diastereoselectivity; asymmetric induction was achieved with chiral ligands L*. Among other applications, highly selective syntheses of the dendrobatid alkaloid 251F (**7**)[6d] and of the lignan (+)-enterolactone (**10**)[6g] have been reported in which the cyclizations **5** → **6** (control of diastereoselectivity) and **8** → **9** (asymmetric induction), respectively, are instrumental (Scheme 1).

2. Alkenylidenes

An alternative approach to selective intramolecular C–H insertion makes use of alkenylidenes (= alkylidenecarbenes, **12**).[7] The regioselectivity of alkenylidene cyclizations is unsurpassed. Regardless of the substitution pattern, five-membered rings are obtained (Scheme 2).[8–11] Moreover, the configuration at chiral centers ($R^2 + R^3$) is retained.[12] However, the scope of cyclizations is narrowed somewhat by the tendency of alkenylidenes undergo 1,2-shifts with formation of alkynes **11**. Rearrangement dominates with R^1 = H,[13, 14] aryl[14–16], and halogen;[17] hydrogen atoms migrate more readily than phenyl groups.[18–20] This reaction is useful for the chain extension of aldehydes to form alkynes (RCH=O → RC≡CH) and for the preparation of diarylacetylenes. With R^1 = alkyl, alkynes are formed as by-products only at temperatures above 200 °C;[9] the RO[11, 21, 22] and R_2N[23] groups likewise show little tendency to migrate.

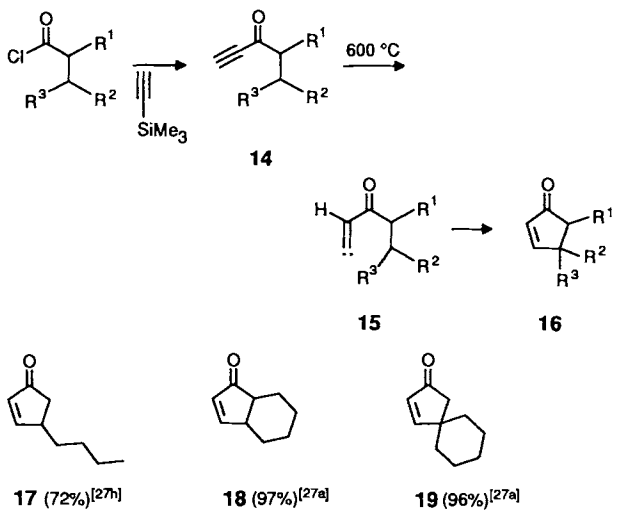


Scheme 2. Reactions of alkenylidenes.

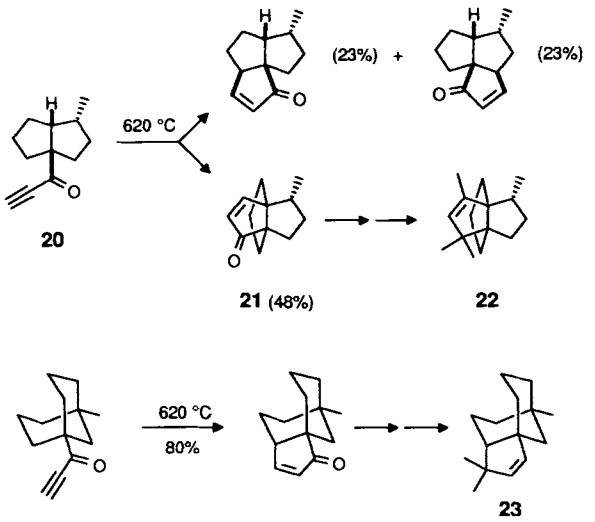
2.1. Alkenylidenes by a Retro-1,2-Shift

Since 1,2-shifts are reversible at high temperatures, alkenylidenes can be generated from alkynes[18, 24, 25] and, under certain circumstances, from cyclopropenes.[26] The retro-1,2-shift proceeds particularly smoothly with alkynones **14**, which are readily available from acid chlorides and ethynyltrimethylsilane (Scheme 3). The flash pyrolysis of **14** to give cyclopentenones **16** can be regarded as the first use of alkenylidene insertion in organic synthesis.[27] Compounds **17**–**19** exemplify the compounds that were obtained and the attainable yields.

Because of the high temperature required for the 1,2-shift **14** → **15**, the intermediate alkenylidenes **15** discriminate poorly between various types of C–H bonds.[27c] In the course of a synthesis of (±)-modhephene (**22**),[27b] the cyclization of the alkynone **20** proceeded with excellent yield, but only half of the product was the desired intermediate **21** (Scheme 4). Similar problems were encountered en route to (±)$\Delta^{9(12)}$-capnellene;[27d] however, structural constraints led to significantly more selective alkenylidene cyclizations in syntheses of (±)-albene,[27e] isomers of ptychanolide,[27f] (±)-clovene (**23**, Scheme 4),[27g] and (±)-isocomene.[27i]

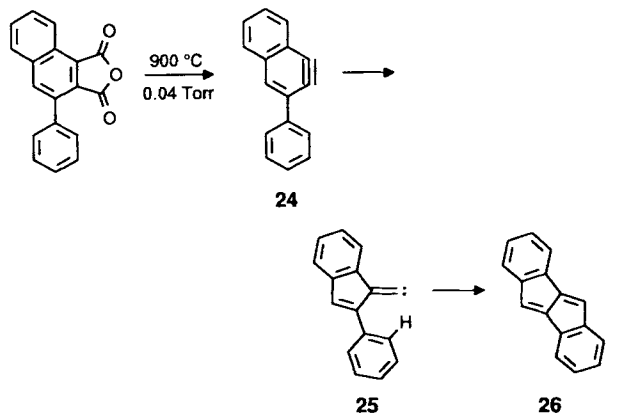


Scheme 3. Syntheses with alkenylidenes that are generated from alkynes.



Scheme 4. Natural product syntheses by alkenylidene insertion, starting from alkynes.

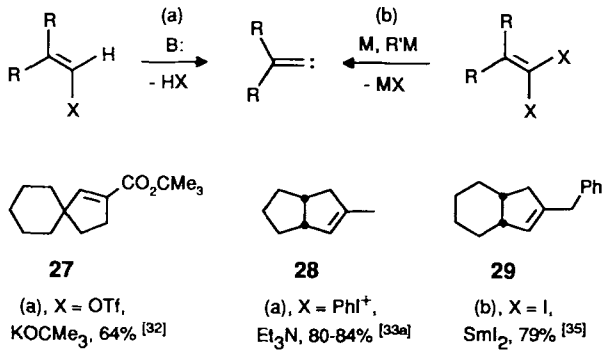
Arynes generated by flash vacuum pyrolysis (for example **24**, Scheme 5) undergo retro-1,2-shifts to give alkenylidenes (for example **25**) that insert into Ar–H bonds.[28] Polycyclic arenes such as benzo[*a*]pentalene (60%)[28c] and dibenzo[*a*,*c*]pentalene (**26**, 95%)[28a] are thus readily accessible.



Scheme 5. Aryne as precursor to alkenylidenes.

2.2. Alkenylidenes by α-Elimination

The halogen–metal exchange at 1,1-dihaloalkenes (Scheme 6) proceeds by way of carbenoids $R_2C{=}C(M)X$[29] which are stable at low temperatures; even an X-ray crystal structure



27 (a), X = OTf, $KOCMe_3$, 64% [32]

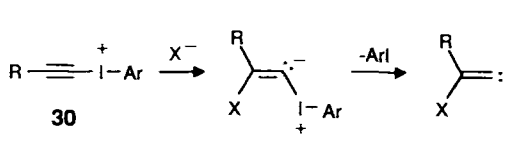
28 (a), X = PhI^+, Et_3N, 80–84% [33a]

29 (b), X = I, SmI_2, 79% [35]

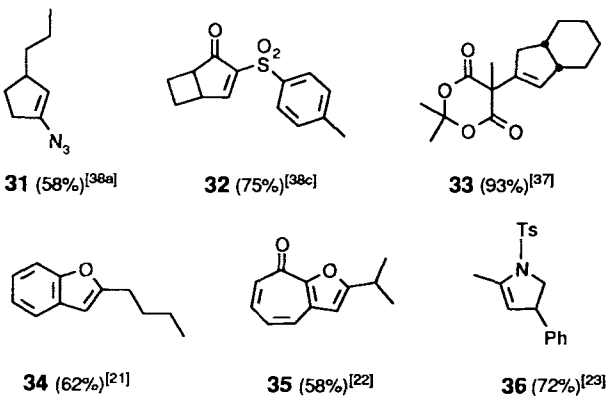
Scheme 6. Alternative pathways to alkenylidenes and examples of compounds synthesized by these routes.

could be obtained.[30] At elevated temperatures, the reactions of alkenylidenes according to Scheme 2 are observed.[29] Base-induced elimination of HX was performed on vinyl halides,[8, 9, 31] enol triflates,[14, 32] and vinyliodonium salts.[17, 33] The intramolecular C–H insertion of alkenylidenes was recognized early in these studies.[8, 9, 31] However, side reactions led to only moderate yields. More recently significant improvements were achieved, particularly by treatment of vinyl chlorides with $MN(SiMe_3)_2$ (M = K, Na)[34] and of 1,1-dihaloalkanes with SmI_2.[35] Compounds **27**–**29** illustrate the typical results of α-elimination reactions; applications in the synthesis of natural products are discussed in Section 2.4.

The addition of nucleophiles to alkynyliodonium salts **30**[36] initially produces ylides, which are trapped in protic media to give alkenyliodonium salts. Under aprotic conditions, loss of aryl iodide leads to alkenylidenes [Eq. (3)]. This elegant procedure[21–23, 37, 38] generates alkenylidenes with functional groups X that are difficult to introduce otherwise. Aside from azide (→ **31**),[38a] *p*-toluenesulfinate (→ **32**),[38c, d] and thiocyanate,[38e] the anions of 1,3-dicarbonyl compounds (→ **33**),[37, 38d] phenols (→ **34**),[21] tropolone (→ **35**),[22] and amides (→ **36**)[23] served as nucleophiles. The products **31**–**36** demonstrate the versatility and efficiency of the method, which also provided access to the frameworks of polycyclic alkaloids.[23b]



30 (3)

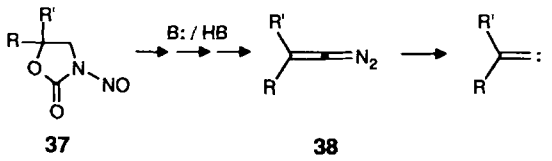


31 (58%)[38a] **32** (75%)[38c] **33** (93%)[37]

34 (62%)[21] **35** (58%)[22] **36** (72%)[23]

2.3. Alkenylidenes from 1-Diazoalkenes

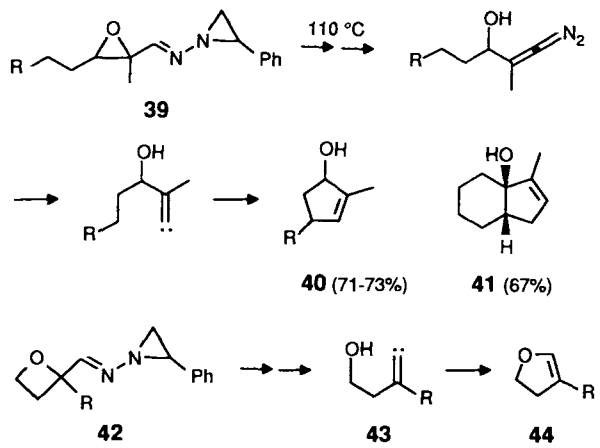
The spontaneous extrusion of nitrogen from 1-diazoalkenes is common to the reactions reviewed in this paragraph.[39] However, the methods for generating the elusive diazoalkenes differ widely. Diazo compounds are often made by alkaline cleavage of *N*-nitrosoamides.[40] If 3-nitroso-1,3-oxazolidin-2-ones (**37**) are treated analogously, elimination of H_2O and CO_2 leads to **38** [Eq. (4)].[41] As a rule, the alkenylidenes thus produced are



37 **38** (4)

scavenged by the protic (co)solvent or undergo 1,2-shifts to give alkynes (R = H, Ar).[42]

The aziridinylimines **39** decompose in toluene at reflux in close analogy to the Eschenmoser fragmentation (Scheme 7):[43]



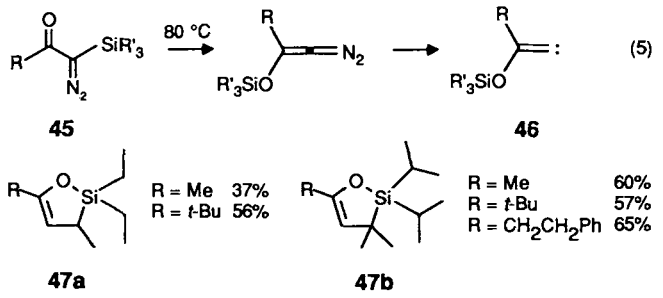
39 **40** (71–73%) **41** (67%)

42 **43** **44**

Scheme 7. Aziridynylimines as alkenylidene precursors.

Extrusion of styrene generates the diazo group; the CC double bond and the hydroxyl function arise from opening of the oxirane ring. Loss of nitrogen and intramolecular C–H insertion of the alkenylidene intermediate leads to cyclopent-2-en-1-ols (**40**) or to the cyclopentenol substructure of bicyclic compounds (for example **41**).[44] The oxetane ring of **42** opens analogously, but the homologous alkenylidenes **43** give rise to dihydrofurans **44** by O–H insertion.[45]

Warming of the α-diazo-α-trialkylsilylketones **45** induces migration of the silyl group from carbon to oxygen [Eq. (5)].

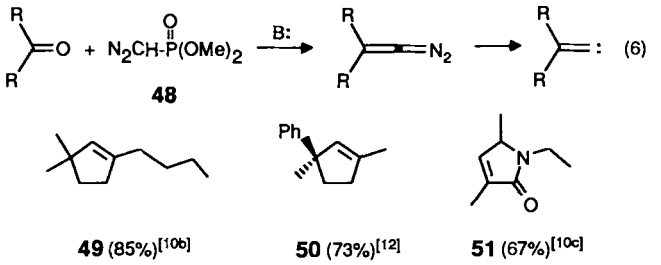


45 **46** (5)

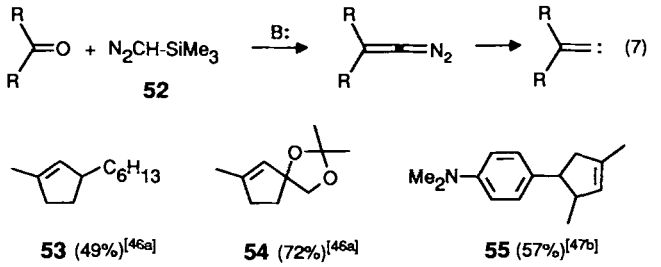
47a **47b**

Alkenylidenes **46** with trialkylsiloxy substituents are generated thus and undergo intramolecular C–H insertion with formation of the 2,3-dihydro-1,2-oxasilols **47**.[11]

More general routes to 1-diazoalkenes are available through modifications of the Horner–Emmons reaction [Eq. (6)][9, 10, 12, 15] and of the Peterson olefination [Eq. (7)].[15, 46, 47] The carbanions derived from dimethyl diazomethanephosphonate (**48**)[48] and trimethylsilyldiazomethane (**52**)[49] are added to carbonyl compounds in order to generate diazoalkenes. In contrast to **48**, **52** is commercially available. Possibly, **48** could be replaced by dimethyl 1-diazo-2-oxopropylephosphonate, which is more readily accesible.[48d] Compounds **49**–**51** are typical products for reaction (6) and compounds **53**–**55** for reaction (7). Applications of both methods for the same target molecule are rare: as exception, reaction (6) afforded 68% of **54**, while reaction (7) gave 72%.



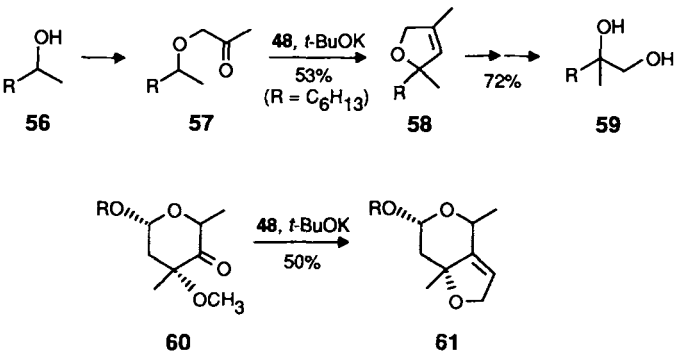
48 (6)



52 (7)

2.4. Applications in Multistep Syntheses

Reaction (6) was used for the transformation of secondary alcohols **56** into tertiary diols **59**, via intermediates **57** and **58**.[50] An analogous step, **60** → **61**, was key to the modification of natural sugars of macrolide antibiotics.[51] Complex syntheses

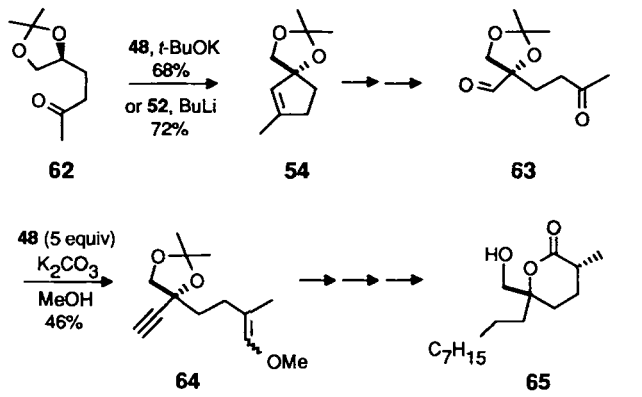


56 **57** **58** **59**

60 **61**

of 14,15-didehydroforskolin,[52] FK-506[53] and analogues,[54] (–)-discodermolide,[55] edulindiol,[56] calicheamicin analogs,[57] esperamicinone,[58] octalactin A,[59] tetronomycin,[60] and (–)-haliclonadiamine[61] involved conversion of aldehydes into homologous alkynes by means of **48**, as in the transformation **12** → **11**.

Three different reactions of alkenylidenes were utilized in a synthesis of (–)-malyngolide (**65**):[46b] The cyclization **62** → **54**,



62 **54** **63**

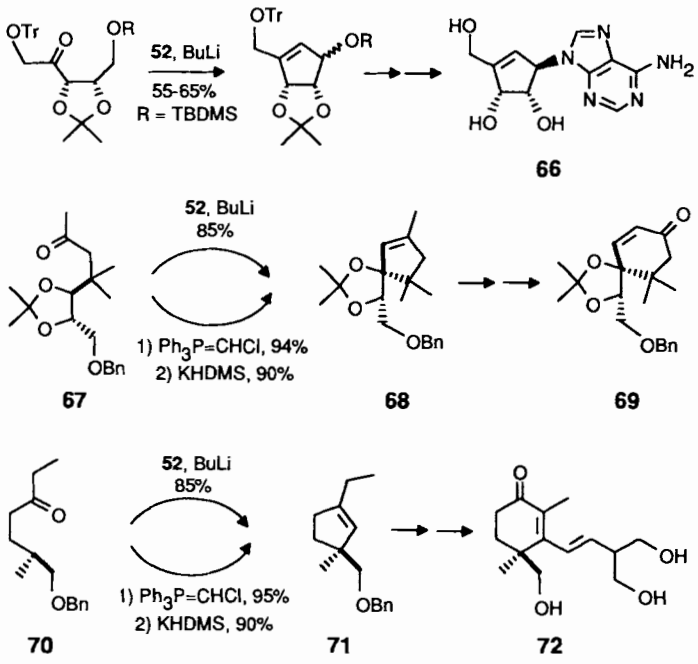
64 **65**

as mentioned above, was followed later by treatment of the ketoaldehyde **63** with excess **48** in methanol to give **64**. The one-pot reaction converts the formyl group into the alkyne (1,2-H shift of the alkenylidene intermediate) and the keto group into the vinyl ether (the alkenylidene intermediate inserts into the O–H bond of methanol). The alkyne part of **64** serves to attach the alkyl chain, while the carboxyl group of **65** originates from the vinyl ether.

Reaction (7) was employed in syntheses (Scheme 8) of (–)-neplanocin A (**66**),[46c] a synthon for the A ring of taxol (**69**),[34] and (+)-cassiol (**72**).[34b] The cyclizations **67** → **68** and **70** → **71** were also achieved by α-elimination at vinyl chlorides according to Scheme 6. Although preparation of the vinyl chlorides by the Wittig reaction is required, the yields of the two-step route were similar to those of the one-pot procedure with **52**.

3. Summary and Outlook

Alkenylidenes offer fascinating opportunities for the synthetic organic chemist. Efficient and versatile methods are now available for the generation of alkenylidenes among which the formal O/C exchange in carbonyl compounds ($R_2C{=}O$ →



Scheme 8. Natural product syntheses in which reactions of type (7) were employed.

$R_2C{=}C{:}$) is most attractive. Starting from aldehydes, alkenylidenes mediate the formation of homologous alkynes ($RCH{=}O \rightarrow RC{\equiv}CH$). If ketones are used as substrates, intramolecular C–H insertion reactions of alkenylidenes lead to cyclopentenes. Both transformations are difficult to achieve otherwise. Strict regioselectivity is a bonus of alkenylidene cyclizations. Quaternary chiral centers are readily created from tertiary precursors with retention of configuration. Preparative applications of alkenylidenes will continue to increase in number and sophistication. Improved diastereoselectivity and, if possible, asymmetric induction through chiral auxiliaries are important themes for further development.

Deposition of Data from X-Ray Structure Analyses

In order to make life easier for authors and referees the Cambridge Crystallographic Data Centre (CCDC) and the Fachinformationszentrum Karlsruhe (FIZ) have unified their procedures for the deposition of data from single-crystal X-ray structure analyses.

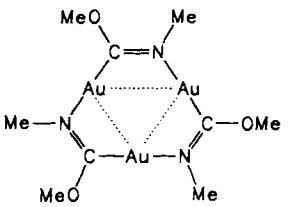
Prior to submitting your manuscripts please deposit the data for your compound(s) **electronically** at the appropriate data base, that is, at the CCDC for organic and organometallic compounds and at the FIZ for inorganic compounds. Both data bases will be pleased to provide help (see our *Notice to Authors* in the first issue of this year). In general, you will receive a depository number from the data base within two working days after electronic deposition; please include this number with the appropriate standard text (see our *Notice to Authors*) in your manuscript. This will enable the referees to retrieve the structure data quickly and efficiently if they need this information to reach their decision.

This is now the uniform procedure for manuscripts submitted to the journals *Advanced Materials, Angewandte Chemie, Chemische Berichte/Recueil, Chemistry—A European Journal,* and *Liebigs Annalen/Recueil.*

"Hyt was of Gold, and Shon so Bryghte...":** Luminescent Gold(I) Compounds

Lutz H. Gade*

Imagine isolating a solid compound on a filter frit that upon washing with an organic solvent suddenly displays intense emission of light. Bewilderment was probably the reaction of Jess Vickery in Alan Balch's group, who had prepared the known trimeric organometallic gold complex $[Au_3(CH_3N{=}COCH_3)_3]$ (**1**).[1]



1

A closer investigation of the phenomenon revealed a remarkable solvent-stimulated luminescence of solid **1**, which is triggered by contact of a liquid with crystals of the compound that previously have been irradiated with long-wavelength ultraviolet light.[***] In other words, after "charging" the sample photochemically and then removing the source of radiation, the energy thus stored may be liberated in the course of the dissolution of the surface of the crystals. That the process occurs without chemical transformation of the sample is supported by the fact that evaporation of the washings and repetition of the treatment on the solid residue produces the same effect.

Both the dissolved trinuclear complex **1** and the solid material display luminescent behavior. However, dual emission consisting of a short-lived (at 446 nm) and a long-lived component (at 552 nm) is observed in the latter. The long-lived emission, which is only observed in the solid, stems from the process responsible for the solvent-stimulated luminescence of the compound, and it was therefore suspected that the phenomenon was related to the crystal structure of the complex.

An X-ray diffraction study revealed an unusual trigonal prismatic stacking of the triangular molecules to form infinite supramolecular columns, a unique structural motif in gold chemistry but somewhat reminiscent of the discrete stacks of Pt_3 clusters discovered by P. Chini et al. more than two decades ago (Figure 1).[2] The intermolecular distance of 3.35 Å between the Au_3 units in the stacks lies within the range of attractive Au^I–Au^I contacts observed previously and indicates a certain degree of intermolecular metal–metal interaction within the supramolecular aggregate.[3] Since introduction of bulkier ligands in the Au_3 trimer, which leads to disruption of the columnar crystal structure, produces materials which do not display the solvent-stimulated emission, a relationship between the photochemical peculiarities of **1** and its crystal structure was postulated.

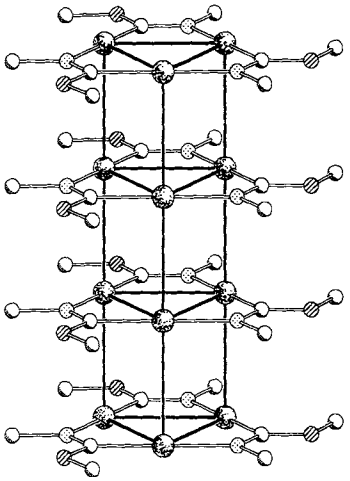


Figure 1. Stacking of the Au_3L_3 units in the crystal generating infinite trigonal columns. Intramolecular Au···Au distance 3.308 Å, intermolecular distance 3.346 Å.

It is likely that the luminescence results from sites near the surface of the crystal that are either exposed or modified by interaction with the liquid. Migration of charge through the $\{Au_3\}_n$ columns may facilitate the energy transfer from the bulk to the surface site, while domain boundaries within the crystal may function as traps, which store the energy (possibly by charge separation). Dissolution experiments of specific faces of the hexagonal single crystals (with respect to which the $\{Au_3\}_n$ stacks have a well-defined orientation) might offer further insight into the photophysics of this remarkable discovery.

This solvent-induced luminescence ("lyoluminescence") of a sample "charged" by irradiation with near-UV light, and subsequently removed from the source of radiation, is very unusual though not entirely unprecedented.[4] However, its discovery may be regarded as only the latest and most spectacular contribution to the rapidly expanding area of luminescent gold(I) compounds. In fact, in the 1970s excited-state luminescence and photochemistry of gold with $[(Ph_3P)_2AuCl]$ and other gold(I) compounds[5] was studied with the aim of developing sensitizers for photographic emulsions.[6]

It was only in the late 1980s that the groups of Balch,[7] Fackler,[8] Gray,[9] Che,[10] and others[11] began with the sys-

tematic investigation of the emission observed particularly for mono- and polynuclear gold(I) phosphane complexes. The simplest examples of emitting gold complexes are the tricoordinate trigonal-planar species of the types $[AuX(PR_3)_2]$ and $[Au(PR_3)_3]X$. The origin of the emission in these compounds has been assigned to an essentially metal-centered transition $^1A_1 \leftarrow E'(^3E'')$ $[(d_{x^2-y^2}, d_{xy}) \leftarrow p_z]$ (Figure 2).[9] The large Stokes

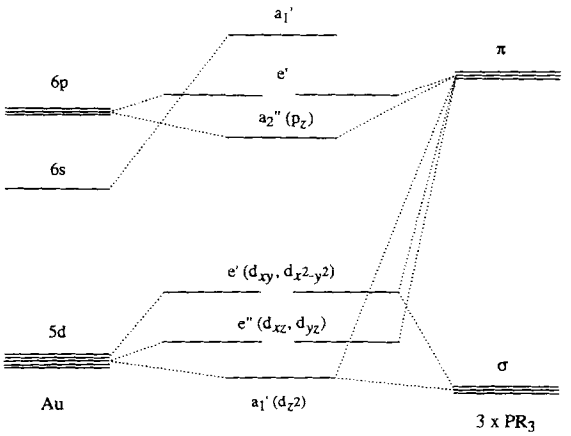

Figure 2. Frontier orbital scheme for $[Au(PR_3)_3]$. The z axis is perpendicular to the AuP_3 plane.

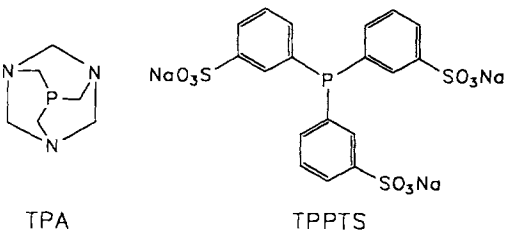
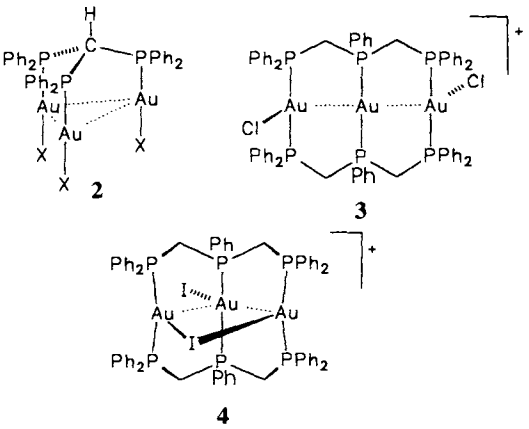
shifts and the lifetime measurements imply that the emission in these complexes is phosphorescence from the triplet state. Provided that trigonal-planar coordination is retained and water-soluble, functionalized phosphanes (Scheme 1) are employed,



Scheme 1. The water-soluble phosphanes 1,3,5-triaza-7-phosphaadamantane (TPA) and trisodium-3,3',3''-phosphanetriyltris(benzenesulfonate) (TPPTS).

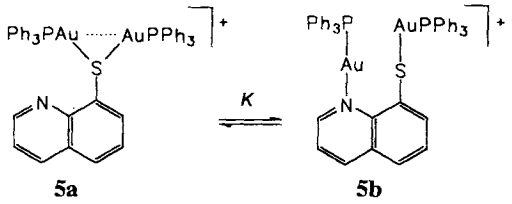
luminescence of mononuclear gold compounds may also be observed in aqueous solution as was demonstrated recently by Fackler and co-workers.[12] In the case of TPA a critical dependence of the emission on the pH of the solutions was observed. Protonation of the TPA ligand leads to disproportionation of the emitting complexes with three-coordinate metal centers into non-emitting complexes with two- and four-coordinate metal centers. The significance of the retention of the emission properties of Au^I compounds in biologically relevant media lies in its relationship to the postulate by Corey et al. that $^1\Delta_g$-O_2 quenching is relevant to the action of gold drugs in the therapy of rheumatoid arthritis.[13]

There are numerous di- and trinuclear gold complexes that show emission either in solution or in the solid state. Complexes **2**–**4** are examples studied in Che's research group (Scheme 2).[14] A characteristic of some of these species is the observation of multiple-state emission originating from thermally nonequilibrated excited states, a situation which is manifested in a pronounced temperature dependence of the emission.



Scheme 2. Selected recent examples of luminescent trinuclear phosphanegold(I) complexes **2**–**4**.

A remarkable example of the strong solvent dependence of the luminescence of a gold(I) compound in solution has been observed by Che and co-workers.[15] The quenching of the luminescence of the diauriated quinoline-8-thiolate **5** in polar solvents such as methanol and acetonitrile is attributed to an equilibrium between two forms **5a** and **5b** of the complex, of which only the former displays emission.



Significant progress in elucidating the nature of the luminescence of molecular gold compounds and its structural prerequisites has been achieved during the past five years. The combination of this property of some Au^I complexes with the other characteristic behavior of these species, namely their ability to aggregate through metal–metal contacts to form supramolecular arrays,[3b, 16, 17] holds the promise of exciting new discoveries in the photochemistry of gold compounds. These may possibly prove their utility as chemical/photochemical switches or, given the discovery in Balch's group, as energy storage devices and photochemical sensors.

Enzymes and Transition Metal Complexes in Tandem—A New Concept for Dynamic Kinetic Resolution

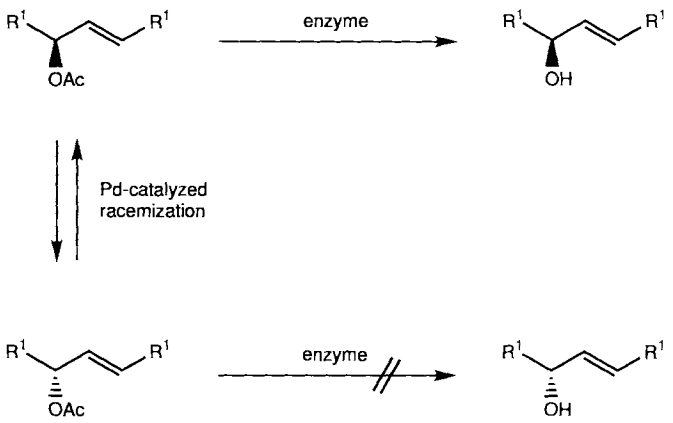
Rainer Stürmer*

The resolution of racemic compounds mediated by enzymes has become a valuable tool for the synthesis of chiral intermediates. In most cases, however, only one enantiomer of the intermediate is required for the next step in the synthesis; thus, the unwanted isomer must be either discarded or racemized for reuse in the enzymatic resolution process. Dynamic kinetic resolution is one way of avoiding this problem: the unwanted enantiomer is racemized during the selective enzymatic process and serves as fresh starting material in the resolution.

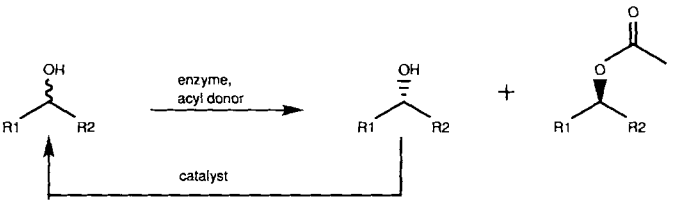
This concept has been known for a long time in pure enzymatic synthesis, for example in amino acid synthesis via hydantoins[1] or dihydrooxazoles.[2] Cyanohydrins[3] and lactols[4] are also prone to in situ racemization and may serve as substrates in kinetic resolutions. Dynamic kinetic resolution is also well known in pure chemical synthesis, as illustrated by work by Noyori et al. on the asymmetric hydrogenation of α-substituted β-keto esters. Noyori et al.[5] and Ward[6] have reviewed the chemical syntheses, and biocatalytic routes have been discussed by Faber et. al.[7]

Williams et al. have now demonstrated the compatibility of enzymes and transition metal complexes in one reaction vessel. Two examples illustrate the concept: the palladium-catalyzed racemization[8] of an allylic acetate in the presence of a hydrolase (Scheme 1), and the racemization of a secondary alcohol[9] through Oppenauer oxidation/Meerwein–Ponndorf–Verley reduction with concomitant acylation of one enantiomer with a lipase from *Pseudomonas fluorescens* (Scheme 2).

To utilize these reactions, a few conditions must be met. A selective enzyme is crucial and the organometallic catalyst must



Scheme 1. Pd-catalyzed racemization of an allylic acetate [8].



Scheme 2. Racemization of a secondary alcohol [9].

facilitate a fast racemization of the substrate. Last but not least the catalyst should not influence the enzyme in terms of selectivity and reactivity. In the ideal case the enzyme hydrolyzes one enantiomer of the allylic acetate giving rise to the allylic alcohol which itself is not susceptible to Pd-catalyzed racemization.

Scheme 3 provides a specific example of the enzymatic hydrolysis outlined in Scheme 1. The substituted allylic acetate is hydrolyzed with a lipase from *Pseudomonas fluorescens* in a phosphate buffer in the presence of 5 mol% palladium complex.

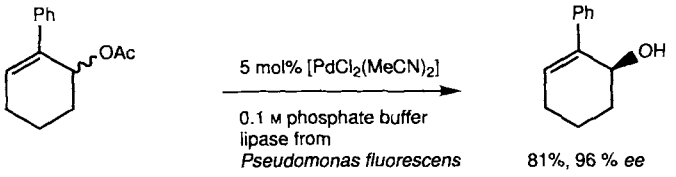
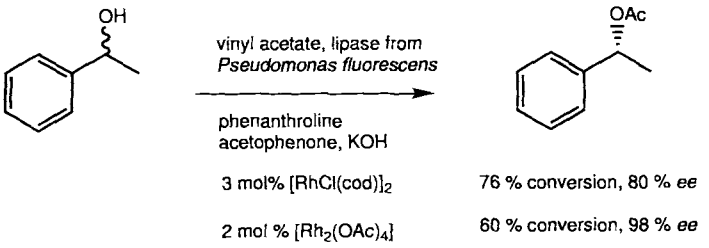


Scheme 3. Specific example for the racemization shown in Scheme 1.

After 19 days the conversion is 96% (yield is 81%) and the enantiomeric excess reaches 96%. The rate-determining step is most likely the slow Pd-catalyzed step, since 50% conversion is achieved after only two days. A more active metal complex has yet to be identified for a more practical reaction.

The reaction time in the second example (Scheme 4) is rather long as well, the rate-determining step is again the metal-catalyzed racemization. After six days the conversion is 76% with 3 mol% $[RhCl(cod)]_2$ and the enantiomeric excess reaches 80%.



Scheme 4. Specific example for the racemization shown in Scheme 2.

Theoretically, in a simple kinetic resolution the *ee* value should not exceed 32% at this specific conversion. In addition to the rhodium complex, this reaction requires acetophenone as stoichiometric hydride acceptor, phenanthroline as coligand, and potassium hydroxide as base. An *ee* value of 98% at 60% conversion (theoretical value 67%) is achieved with $[Rh_2(OAc)_4]$ without an added base after three days. Surprisingly the enzyme tolerates potassium hydroxide in amounts up to 20 mol% at elevated temperatures; however, the enantiomeric excesses are somewhat lower than those obtained in an ordinary kinetic resolution. Unselective, base- or metal-catalyzed acylation might be the reason for the somewhat lower *ee* value.

In summary a new concept for dynamic kinetic resolution has been demonstrated. There is still a long way to go to a practical system, but a first step to team up enzymes with classical organometallic catalysis has been achieved. Bäckvall et al.[10] have recently reported a substantial improvement in the described process. (*R*)-1-phenylethanol can be synthesized from the racemate in virtually quantitative yield and >99.5% *ee* by using a binuclear ruthenium complex, combined with an immobilized lipase and a specifically designed acyl donor. Furthermore no additional base is necessary and the reaction is considerably faster.

This concept was also recently extended to the resolution of phenylethylamine by Reetz et. al.[11] In this case, an immobilized lipase and ethyl acetate as acyl donor are used; the nonacylated (*S*)-enantiomer of the amine is racemized in situ by palladium on charcoal. After eight days—the metal-catalyzed racemization is again likely to be the rate-determining step—(*R*)-*N*-acetyl-1-phenylethylamine is isolated in 64% yield and 99% *ee*.

Silver–Tellurolate Polynuclear Complexes: From Isolated Cluster Units to Extended Polymer Chains**

John F. Corrigan, Dieter Fenske,* and William P. Power

Dedicated to Professor Gottfried Huttner on the occasion of his 60th birthday

The chemistry of transition metal selenolate and tellurolate complexes is a burgeoning area of research, as exemplified by a recent review by Arnold;[1] however, their utility in the synthesis of high nuclearity clusters remains virtually unexplored. We have been probing the use of bissilylated reagents $E(SiMe_3)_2$ (E = S, Se, Te) as a route into high nuclearity phosphane-stabilized copper–chalcogenide clusters. The driving force of these reactions is the generation and elimination of $SiMe_3X$ (X = Cl, OAc) and the formation of Cu–E bonds.[2] Attempts to extend this chemistry to silver have, however, met with little success as binary silver chalcogenides are preferentially formed and precipitate instead of molecular species (kinetically) stabilized by PR_3 ligands. We have recently shown that alkyltellurolate (Te*n*Bu) ligands do hold promise in the synthesis of Ag–Te clusters.[3] We now report herein our initial findings on the high-yield synthesis of silver–tellurium cluster complexes using the silylated reagent $Te(Ph)SiMe_3$.

Unlike analogous reactions with $E(SiMe_3)_2$, solutions of Ag-Cl/PR_3 remain homogenous when treated with $Te(Ph)SiMe_3$ at room temperature. Thus, addition of one equivalent of $Te(Ph)SiMe_3$ to AgCl:PEt_2Ph (1:2) results in a bright yellow solution from which crystals of **1** and **2** grow in good yield as bright yellow platelets and polyhedra, respectively (Scheme 1).

The molecular structure of **1** (Figure 1) consists of a layered arrangement of silver and tellurium atoms.[4] The cluster sits on a crystallographic threefold axis that bisects atoms Ag2, Ag3, and Ag5, and excluding the relative orientation of the phenyl rings attached to atoms Te1 and Te3, a noncrystallographic mirror plane relates the two halves of the molecule. The "top" and "bottom" layers each consist of four silver and three tellurium atoms with each Te atom functioning as a μ_3-bridge (Te–Ag = 2.867(1)–2.879(2) Å). Three of the four silver atoms in these layers are also bonded to a phosphane ligand and adopt tetrahedral geometries. The central layer comprises a planar arrangement of one Ag and three Te centers with the three phenyl rings of the tellurolate ligands also lying in this plane. The coordination environment about Te2 is noteworthy as it consists of a near linear (168.80(5)°) Ag1-Te2-Ag4 arrangement. There are no significant bonding interactions between the nine silver(I) metal sites (2.809(1)–3.126(4) Å), which is in agreement with an assigned oxidation state of +1. The packing arrangement of **1** in the lattice is such that the central $Ag(TePh)_3$ layers are all aligned resulting in a mixed aromatic-Ag-Te infinite repeat.

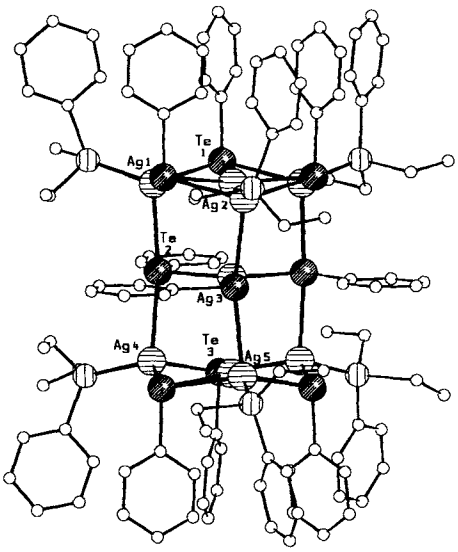

Figure 1. Molecular structure of **1**. Te atoms are drawn as dark spheres, and Ag atoms with horizontal stripes. Selected distances [Å]: Te1,3–Ag 2.867(1)–2.879(2), Te2–Ag3 2.731(1), Te2–Ag1,4 2.931(2)–2.932(2).

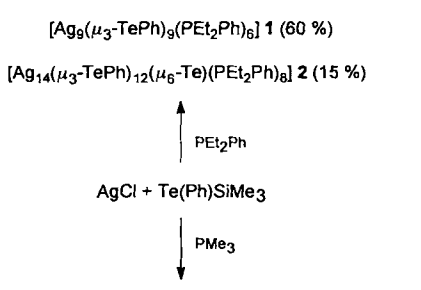

Scheme 1. The formulae for **1**–**4** showing the Ag:TeR:PR_3 ratios.

Bright yellow crystals of **2** suitable for X-ray structure analysis[4] were obtained by layering reaction solutions with additional pentane. The molecular structure of **2** is shown in Figure 2 (top) together with the atomic numbering scheme for the core atoms. The tellurium framework consists of twelve tellurolate ligands (Te1–Te8, Te10-Te13) and a central telluride (Te9) ligand; the latter arises from Te-C bond cleavage.[5] The Te–C distances in the tellurolate ligands are identical within experimental error (2.131(5)–2.145(5) Å), and the tellurium atoms each form three additional bonding interactions to the silver(I) centers of the cluster core. The overall geometry of the Te atoms consists of a nonbonded (Te···Te = 3.981(1)–5.253(1) Å), highly distorted, centered icosahedron. Thus, with atoms Te2 and Te10 at the axial vertices, the Te_5 plane Te5,6,11,12,13 deviates little from planarity (Δ_{max} = 0.15 Å), whilst atoms Te1,3,4,7,8 are irregularly arranged (Δ_{max} = 0.51 Å). The eight PEt_2Ph ligands are arranged at the corners of a cube. Of the twenty deltahedral faces of the Te_{12} icosahedron, eight are capped by Ag-PEt_2Ph units; the Ag–Te contacts range from 2.838(1) to 3.026(1) Å. The Ag–Te distances at the four-coordinate silver sites are markedly elongated in comparison to those at their three-coordinate counterparts that lie within the Te_{13} frame; the latter exhibit Ag–Te contacts ranging from 2.660(1) to 2.825(1) Å and near planar coordination around silver (sum of the angles = 359.4–360.0°). The coordination about these six silver centers is, however, highly asymmetric as invariably one

Ag, Te, and P atoms are labeled with blue, red, and green numbers, respectively.

of the Te9-Ag-Te angles lies close to 90°, not unlike the TePh-Ag-TePh arrangement observed in **1**. Similar Ag–Te distances have been observed at three-coordinate silver(I) centers in the homoleptic Ag–TeR complex $[Ag_4(\mu_2\text{-}TeC_4H_3S)_6]^{2-}$.[6] The lone telluride ligand in **2** (Te9) makes six bonding contacts to the pseudo-interstitial silver centers (Ag–Te9 = 2.768(1)-2.825(1) Å). These Ag–Te9 contacts are the longest of the three Te–Ag bonds. The combination of twelve RTe^- ligands and one Te^{2-} ligand suggests an oxidation state of +I (d^{10}) for the fourteen silver atoms, and the Ag···Ag distances (3.077(1)–3.287(1) Å) preclude strong bonding metal–metal interactions. Although a clear structural relationship between **1** and **2** is not evident at first glance, it is possible to describe the structure of **2** as composed of two molecules of **1** sharing a common Te_5 (Te1,3,9,11,13) face (Figure 2, top).

A similar reaction procedure to that described above with the smaller phosphane PMe_3 results in the formation of **3** and **4** in 20 and 40% yield, respectively (Scheme 1). Although the Ag:TeR:Te:PR_3 ratios are identical for **2** and **3**, there are marked differences in the structures of the two clusters.[4] In **3** (Figure 2, bottom), the fourteen silver centers are bridged by a combination of seven μ_3-, three μ_4-, and two μ-TeR^- ligands with a central μ_6-Te^{2-} atom (Te13). The nonbonded Te_{13} framework is best described as a centered icosahedron in which one μ_5-vertex is removed (Te1), capping instead a deltahedral face (Te2–4) resulting in a (distorted) monocapped centered octadecahedral frame (Figure 3). As in **2**, only phosphane-bonded silver centers exhibit tetrahedral coordination geometry although Ag5 and Ag8 also exhibit a fourth, weaker interaction. The Ag–Te distances associated with the two μ-TePh ligands are the shortest (on average) within the cluster (Te5–Ag = av 2.704 Å; Te6–Ag = av 2.736 Å).

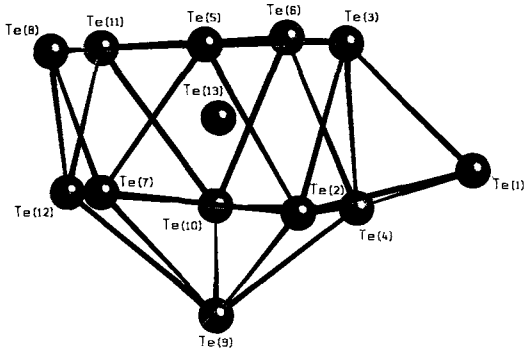

Figure 3. The Te_{13} framework in **3**.

Assuming the μ_2-TePh ligands donate three valence electrons to the cluster core, the μ_4-TePh groups each five, and the central telluride ligand six, the total cluster valence electron counts in **2** and **3** can be summed to either 212 (or 236) and 218 (or 232), respectively, dependent on whether the μ_3-TePh bridges each formally provide three or five electrons. In the absence of metal–metal bonding, fourteen 16-electron Ag centers requires a total of 224 cluster valence electrons.

In contrast to the molecular natures of **1**–**3**, complex **4** consists of an extended (polymeric), one-dimensional network in which the tellurolate ligands serve as both intra- and intermolecular bridges.[4] Complex **4** crystallizes as red needles in the monoclinic space group $C2/c$, and a crystallographic inversion center relates the two halves of the Ag_{10} cluster frame, (Figure 4) which is repeated to form the polymeric chain (Figure 5). All PhTe ligands function as μ_3-bridges, and Te3 and Te4 link the Ag_{10} units. With the exception of Ag1, which is bonded to a PMe_3 ligand and adopts a tetrahedral coordination geometry, the remaining silver centers are three-coordinate (sum of the angles = 350.3–357.2°). There is no significant difference in length between the inter- and intracluster Te–Ag contacts. The $Ag^I\cdots Ag^I$ distances (2.911(1)–3.230(1) Å) do not suggest any strong bonding interactions between the metal centers.

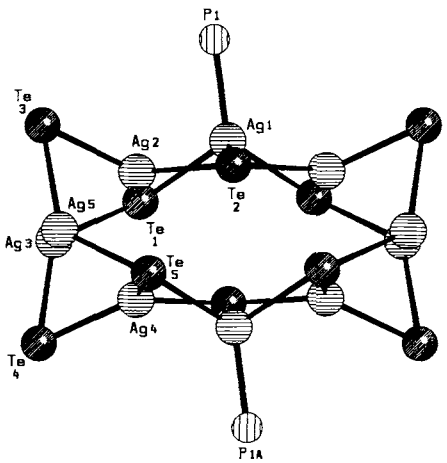

Figure 4. Structure of the $[Ag_{10}(TePh)_{10}(PMe_3)_2]$ molecular repeat unit in **4**. Selected distances [Å]: μ_3-TePh–Ag 2.746(1)–2.959(1), Ag···Ag 2.911(1)–3.230(1).

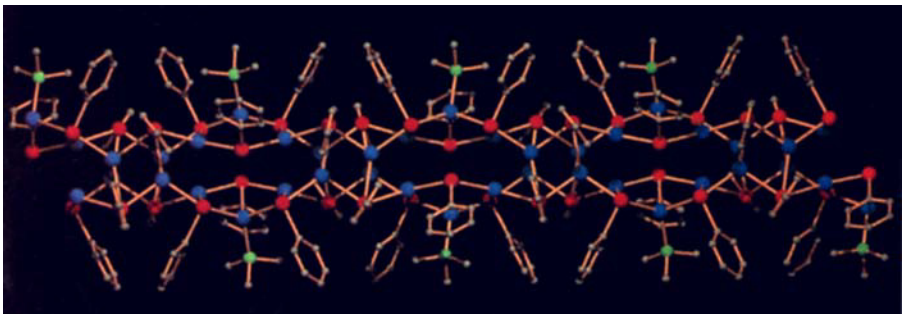

Figure 5. A side-on projection of a section of the polymer chain in **4** (Ag: blue, Te: red, P: green, C:grey).

The structural arrangement in **4** consists of a rather shell-like make-up: the inner core consists of Ag atoms only, which are enveloped by a Te/Ag layer that is in turn surrounded and stabilized by PMe_3 and Ph ligands. The phenyl rings do not show any evidence for π-stacking down the polymer chain. Bochmann and co-workers have reported a homoleptic $[Cd_2(\mu\text{-}TeC_6H_2Me_3)_2]_x$ polymer consisting of localized, tetrahedral centers.[7] More recently, Levason et al. have employed bis(telluroethers) to form ligand-bridged silver polymers with isolated Ag centers.[8] In **4**, however, the structure consists of a repeating clustered arrangement of silver and tellurium forming a AgTe "wire". Due to the high electrical and ionic conductivity exhibited by Ag_2Te,[9] the physical properties associated with **1**–**4** are under investigation.

Solid-state ^{31}P magic-angle spinning (MAS) NMR spectra obtained for **1** and **4** exhibit significant differences as anticipated from the crystallographic structures. Only one crystallographically distinct phosphorus atom is observed in the ^{31}P MAS NMR spectrum of **4**, since an inversion center relates the two phosphane ligands in the unit cell. Although this PMe_3 ligand was found to be disordered over two sites, this is not reflected in the NMR spectra.[4] This phosphorus site has a chemical shift of $\delta = -41.1$ and an "average" ^1J(Ag,P) coupling to the two silver isotopes (^{107}Ag, 51.82% and ^{109}Ag, 48.18%) of 425 Hz. This corresponds to individual values of $^1J(^{107}Ag,^{31}P) = 395$ Hz and $^1J(^{109}Ag,^{31}P) = 465$ Hz; due to the similar values and overlap of the individual resonances. In contrast, although the ^{31}P MAS NMR spectrum of **1** also exhibits a single ^{31}P NMR signal (two are anticipated based on the structural analysis), this signal is shifted to considerably higher field ($\delta = -6.6$) and has an "average" ^1J(Ag,P) of 395 Hz. Again, due to the ratio close to unity of the magnetic moments of the two silver isotopes and linewidths of the ^{31}P signals, the independent signals arising from coupling to the two isotopes (which should have values of $^1J(^{107}Ag,^{31}P) = 367$ Hz and $^1J(^{109}Ag,^{31}P) = 423$ Hz) are not resolved. The observation of only one signal in the ^{31}P MAS NMR spectrum of **1** indicates the distinct phosphorus sites are very similar. The differences in the coupling constants of **1** and **4** can be related to changes in the *s* character of the metal, under a Fermi-contact dominated model of indirect spin-spin coupling.

The ^{31}P static powder NMR spectra of **1** and **4** are dominated by chemical shielding anisotropy, or the orientation dependence of the phosphorus chemical shift within the magnetic field. Interestingly, the anisotropies, like the isotropic chemical shifts, are significantly different. The changes in the chemical shift anisotropy (and hence isotropic shifts) arise primarily from the different substituents attached to phosphorus (PEt_2Ph vs. PMe_3), but also provide some information on the character of the Ag–P bond. Compound **1** exhibits an axially symmetric chemical shift anisotropy; when the magnetic field is aligned parallel to the Ag–P bond, this orientation of the molecule gives rise to a chemical shift of approximately $\delta = 22.5$, while orientation of the molecule such that the magnetic field is oriented perpendicular to the Ag–P bond leads to a chemical shift of $\delta = -21.7$. For **4**, the sense of the anisotropy reverses, such that the unique component, corresponding to orientations of the molecule with the magnetic field lying along the Ag–P bond, occurs at a chemical shift of $\delta = -56.4$ and the orientation perpendicular to this occurs at $\delta = -34.9$. Note that the greatest change in chemical shift occurs for orientations where the Ag–P bond is aligned with the magnetic field ($\delta = 22.5$ vs. $\delta = -56.4$). This indicates the origin of the differences in isotropic chemical shift are overwhelmingly dominated by changes at the phosphorus center. The changes in shielding due to circulation of electrons through orbitals involving the Ag–P bond differ slightly from $\delta = -21.7$ to $\delta = -34.9$. This shift parallels the change in the unique component, indicating it is probably due to the change in substituents rather than any significant change in the Ag–P bonding character.

The straightforward synthesis of the phosphane-stabilized Ag–TeR complexes **1**–**4** suggests a rich and varied structural chemistry by modification of the phosphane and/or tellurolate ligands. Furthermore, the incorporation of additional interstitial Te^{2-} ligands by using the reagent $Te(SiMe_3)_2$ should result in even larger cluster frameworks. This approach to tellurolate/telluride complexes relates to the preparation of Cd/Se/SeR colloids by Steigerwald et al.[10] and is presently being pursued in our laboratories.

Experimental Section

1 and **2**: AgCl (0.24 g, 1.67 mmol) was dissolved in THF/pentane (24 mL, 1:3) with two equivalents of PEt_2Ph. Addition of $Te(Ph)SiMe_3$ (0.33 mL, 1.67 mmol) resulted in a bright yellow solution. The reaction mixture was allowed to stand and additonal pentane was added by slow diffusion to yield bright yellow plates of **1** (yield: 60%) and bright yellow polyhedra of **2** (15%). Crystals of **1** suitable for X-ray structure analysis were obtained by carrying out the reaction in C_6H_6.

3 and **4**: Typically, AgCl (0.29 g, 2.02 mmol) was suspended in pentane (25 mL) with two equivalents of PMe_3 and stirred for 40 min. $Te(Ph)SiMe_3$ (0.47 mL, 2.02 mmol) was added resulting in a turbid yellow solution. After the mixture had been stirred overnight, the pentane was removed in vacuo and the residue taken up in THF (10 mL). Slow diffusion with pentane yielded 0.27 g (40%) of **4** and varying amounts (15–20%) of **3**.

^{31}P NMR spectra were obtained on a Bruker AMX-500 spectrometer operating at 202.46 MHz. MAS was performed at 5 kHz in 4 mm ZrO_2 rotors. Contact times of 3 ms were used with ^1H 90° pulses of 3.4 μs at 500.13 MHz. Spectral widths of 120 kHz were used and samples are referenced to 85% H_3PO_4 by using an external reference sample of $NH_4H_2PO_4$.

Solvent-Stimulated Luminescence from the Supramolecular Aggregation of a Trinuclear Gold(I) Complex that Displays Extensive Intermolecular Au···Au Interactions**

Jess C. Vickery, Marilyn M. Olmstead, Ella Y. Fung, and Alan L. Balch*

We report herein the remarkable solvent-stimulated luminescence of the trimeric organometallic complex $[Au_3(CH_3N{=}COCH_3)_3]$ **1**.[1] The process involves light emission that is triggered by contact of a liquid with crystals of the compound that have been previously irradiated with long-wavelength UV light (366 nm). The emission is intense and clearly visible to the human eye. Figure 1 shows the yellow luminescence as captured photographically. To obtain this photograph, a polycrystalline sample of colorless crystals of **1** was placed on a glass frit and irradiated with a UV lamp in a darkened room. The lamp was turned off and chloroform was dropped on the crystalline sample to produce the yellow emission. Further addition of chloroform also produces subsequent emission but with diminished intensity. This process can be repeated by further charging of the sample with light, followed by the addition of several aliquots of the liquid and is

most readily observed if the liquid is rapidly removed from contact by suction below the glass frit. As the reader may suspect from this description, the phenomenon was first discovered during isolation of the complex by filtration through a conventional glass fritted filter funnel and subsequent washing of the sample with a liquid.

Similar yellow emission can be visually observed with a number of different liquids: chloroform, dichloromethane, toluene, methanol, hexane, and water. Qualitatively, there appears to be a correlation between the intensity of the luminescence and the solubility of the complex. Those liquids such as chloroform and dichloromethane in which the complex has the greatest solubility visually produce the strongest emission. The emission shown in Figure 1 is unaffected by changes in the surrounding atmosphere (air, nitrogen, argon). No overall chemical transformation appears to be involved in the emission process. If the solid sample has not been entirely dissolved during one cycle of irradiation and liquid contact, the solid will produce the same phenomenon after a second or third cycle of irradiation and liquid contact. If the liquid that has been used to trigger the luminescence is removed from the solid and evaporated to produce a sample of solid, that material displays the same liquid-triggered luminescence. Mechanical manipulation of the irradiated solid does not trigger the luminescence, and solid **1** is not triboluminescent.[2] The phenomenon described here is also distinct from that seen in solvatochromic compounds that show color changes upon exposure to the vapors of organic solvents but no light emission.[3] There is no evidence of light emission during the crystallization of **1**, so the solid does not display crystalloluminescence.[4] However, this solvent-stimulated emission may be related to lyoluminescence, in which light emission is observed from dissolution (generally in water) of solid samples previously exposed to ionizing radiation.[5] In contrast, the phenomenon reported here is a result of excitation of the sample with lower energy, near-visible light.

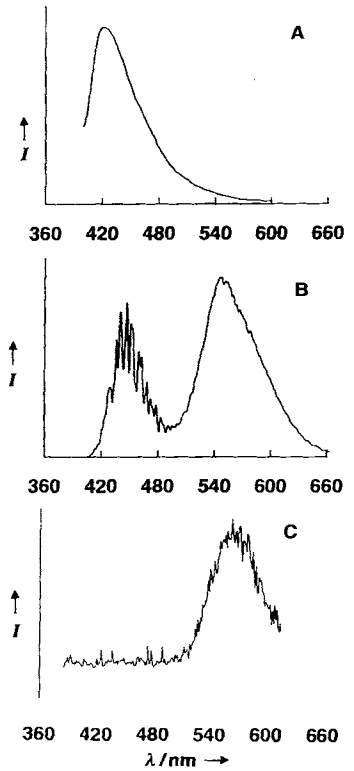

Figure 2. A) Emission spectrum from **1** in chloroform. B) Emission spectrum from a polycrystalline sample of **1**. C) Spectrum of the light emitted from a polycrystalline sample of **1** after UV irradiation and contact with a drop of chloroform.

Spectroscopic measurements on **1** in solution and as a solid shed insight into the origin of the emission. Solutions of **1** in chloroform show an emission band with a maximum at 422 nm (Figure 2A). Solid **1** shows dual emission (Figure 2B). At room temperature there is a structured, short-lived ($t \approx 1$ ms) emission at 446 nm and a broad, long-lived (triexponential, $t \approx 1.4, 4.4, 31$ s) emission at 552 nm. The yellow emission at 552 nm is readily detected by a dark-adapted human eye for tens of seconds after photoirradiation of crystalline **1**. Light emission from the solvent-triggered process arises from the solid but not from individual molecules of **1** in solution. Trace C of Figure 2 shows the emission obtained by dropping chloroform onto a sample of solid **1**. The emission band clearly corresponds to one of the bands seen in Trace B for solid **1** not to that at 422 nm seen in Trace A for individual molecules of **1** in solution. Thus the characteristics of the solid-state structure of **1** were determined in order to better understand the possible origins of its remarkable properties. Figures 3–5 show structural information for solid **1** as determined by X-ray diffraction on a single crystal that was obtained by diffusion of diethyl ether into a chloroform solution of the complex.

Figure 3 shows a view of an individual molecule of the planar trigold complex, which has $\bar{6}$ symmetry, and presents some interatomic distances. The $Au^I \cdots Au^I$ separation (3.308(2) Å) is

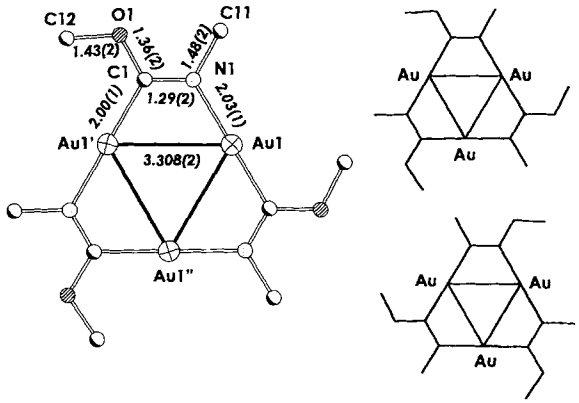

Figure 3. Crystal structure of **1**. Left: View of an individual molecule of **1** that shows some of the interatomic distances [Å]. The gold $\cdots$ gold contacts are shown as solid lines, while the conventional chemical bonds are represented by hollow lines. Right: The flip disorder that leads to two alternate positions for the methoxy-methyl groups.

shorter than 3.6 Å, and so some bonding interaction between these atoms is present within the molecule.[6] The other dimensions within the molecule conform to normal bond lengths.[7–9] There are two positions for the methoxy-methyl groups, each with 0.5 fractional occupancy. This disorder results from a flipping of the molecule between the two orientations shown on the right of Figure 3.

Individual molecules of **1** aggregate in the solid state along the *c* axis to form two types of stacks. Figure 4 shows a drawing of the more ordered stack, in which the triangles of Au^I centers are arranged to form a trigonal prismatic array. The intermolecular $Au^I \cdots Au^I$ distance is 3.346(1) Å, which is longer than the intramolecular $Au^I \cdots Au^I$ separation but still within the region, where attractive interactions between these metal centers are present. Molecules in the second, disordered stack, sit at sites of $6/m$ symmetry. Thus, there are two sets of positions for the triangles of gold atoms. Within the solid, the two stacks occur in a 2:1 ratio as shown in Figure 5, and the molecules within each stack lie in common planes.

The stacking of the triangular molecules seen here is a unique characteristic of crystalline **1**. There are a number of related triangular trigold(I) complexes,[7] but none of these show the trigonal prismatic stacking that is so prominent in **1**.[8] However, some do show pairwise association through $Au \cdots Au$ contacts. For comparison we have examined $[Au_3(C_6H_5CH_2N{=}COCH_3)_3]$, whose crystal structure reveals that it consists solely of individual molecules with no $Au \cdots Au$ contact shorter than 3.6 Å.[9] This solid does not show the long-lived luminescence that is characteristic of **1**, nor does it show

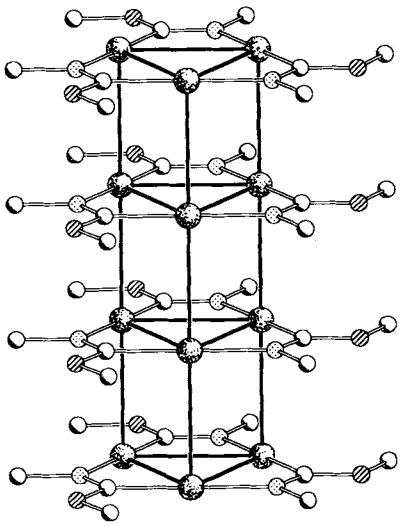

Figure 4. A drawing of the more ordered stack in crystalline **1**. The solid lines again emphasize the gold···gold contacts. The flip disorder is not included in this drawing.

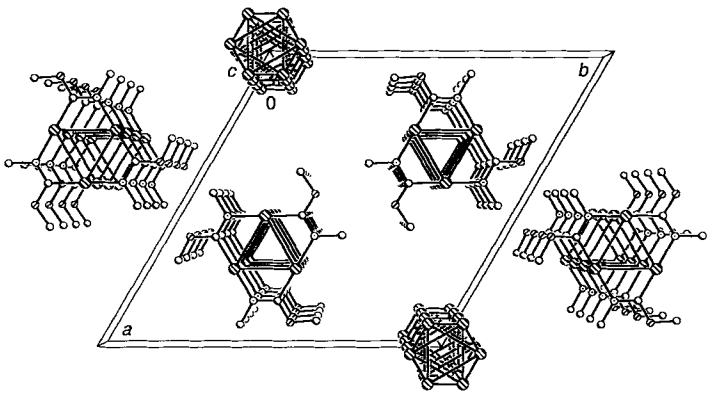

Figure 5. A view down the *c* axis of the unit cell in **1**. For clarity only the positions of the gold atoms and not the ligand atoms are shown in the more disordered stacks.

any liquid-triggered luminescence. Consequently we believe that the extended supramolecular aggregate present in the columns of molecules in **1** is important for the energy storage within the solid and may also be involved with the liquid contact triggered luminescence. Charge or electron separation may be responsible for the energy storage with emission resulting from recombination that occurs when the stacks of molecules in the solid are exposed to solvent. The remarkable luminescence shown in Figure 1 may result from sites near the surface that are either exposed by dissolution of the solid or modified through interaction with the liquid. Migration of charge through the stacks of molecules could facilitate energy transfer from the bulk to the surface. The presence of several types of disorder within this solid offers a multiplicity of sites that could function as traps and thus be responsible for the energy storage.

Further studies of the chemical, photophysical, and physical properties of **1** and related trinuclear complexes are in progress as are studies of the utility of **1** as a sensor for various liquids in remote environments and as an energy storage device.

Experimental Section

Compound **1** was prepared as described previously [1]. The emission spectrum in Figure 2C was obtained with an Olis rapid-scan spectrometer with the light beam path reversed in direction. Crystal data for colorless needles grown from chloroform/diethyl ether: crystal dimensions $0.045 \times 0.017 \times 0.016$ mm; hexagonal crystal system; space group $P6/m$; unit cell dimensions, $a = b = 19.410(4)$, $c = 3.3463(5)$ Å, $V = 1091.8(4)$ Å^3; $Z = 9$; $\rho_c = 3.683$ g cm^{-3}; $T = 130(2)$ K; $2\theta\max = 112.1°$; $Cu_{K\alpha}$ radiation ($\lambda = 1.54178$ Å); 2θ-ω scans; 1220 measured reflections, 582 independent reflections, 582 refined reflections; absorption correction with XABS2 [10], $\mu = 55.8$ mm^{-1}; max. and min. transmission factors, 0.48 and 0.34; structure solution by direct methods (SHELXTL version 5.03); refinement by full-matrix least-squares on F^2 (SHELXTL version 5.03); 33 parameters; 14 restraints; $wR2 = 0.1647$ for all data and a conventional $R_1 = 0.064$ for 498 reflections with $I > 2\sigma I$ after correction for absorption; largest difference electron density peak and hole, 2.872 and -2.117 e Å^{-3}. Crystallographic data (excluding structure factors) for the structure reported in this paper along with a discussion of the disorder have been deposited with the Cambridge Crystallographic Centre as supplementary publication no. CCDC-179-173. Copies of the data can be obtained free of charge on application to The Director CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: Int. code +(1223) 336-033; e-mail: deposit@chemcrys.cam.ac.uk).

Remarkable Template Effect of a Lewis Acidic Receptor in Intramolecular Radical Cyclizations**

Takashi Ooi, Yasutoshi Hokke, and Keiji Maruoka*

Over the last decade free-radical cyclization has developed as a powerful method for constructing ring systems by C-C bond-forming processes and it is now routinely utilized as one of the most reliable tools in organic synthesis.[1] Although the chemo-, regio-, and stereoselectivities of many classes of radical cyclizations are well understood, the full potential of this reaction including stereochemical control at the newly created centers is yet to be realized, and hence only limited structural types of cyclization products have been accessible by this reaction.[1, 2] In this context, we were interested in achieving stereoselective intramolecular radical additions to multiple bonds of halo ethers as model substrates by complexation with a rationally designed Lewis acid. Our recently developed, structurally defined aluminum tris(2,6-diphenylphenoxide) (ATPH, Figure 1)[3]

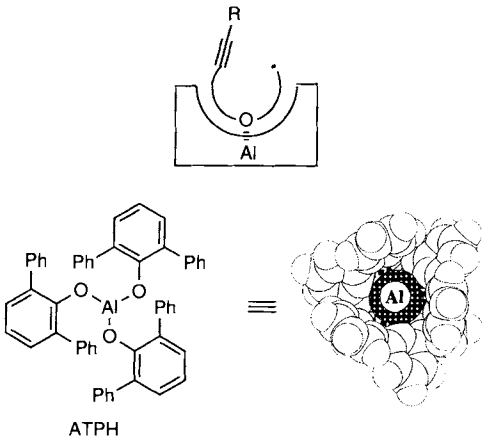

Figure 1. Template effect of a rationally designed Lewis acid such as ATPH in intramolecular radical cyclizations.

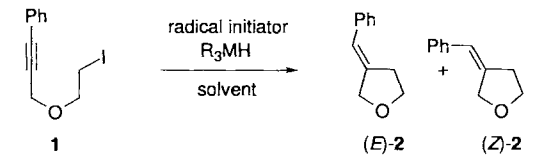
seemed quite suitable for this purpose, since it should allow an appropriate proximity of carbon radical to multiple bond in the transition state, thereby smoothly facilitating the otherwise difficult cyclization and yet reversing the stereoselectivity.

The intramolecular radical cyclization of the β-halo ether 2-iodoethyl 3-phenylpropynyl ether (**1**) was attempted in several ways (Scheme 1). Under standard radical reaction conditions



cat AIBN/Bu_3SnH/benzene, 80°C, 1h : 96% (*E*/*Z* = 50 / 50)
cat Et_3B/Bu_3SnH/toluene, −78°C, 1h : 94% (*E*/*Z* = 61 / 39)
ATPH/*cat* Et_3B/Bu_3SnH/toluene, −78°C, 1h : 99% (*E*/*Z* = 14 / 86)
ATPH/*cat* Et_3B/$(Me_3Si)_3SiH$/toluene, −78°C, 1h : 99% (*E*/*Z* = <1 / >99)

Scheme 1. Influence of the reaction conditions on the cyclization of **1** to **2**.

(catalytic amount of AIBN, Bu_3SnH, benzene, reflux) the reaction gave rise to an *E*/*Z* mixture of the cyclic ether 3-benzylidenetetrahydrofuran (**2**) in 96% yield (*E*/*Z* = 50:50).[4] The reaction of **1** with Bu_3SnH and a catalytic amount of Et_3B as radical initiator at −78 °C yielded **2** in 94% yield with higher stereoselectivity (*E*/*Z* 61/39).[5] In contrast, initial complexation of **1** with ATPH (2 equiv) in toluene and subsequent addition of Bu_3SnH (1.5 equiv) and catalytic Et_3B (0.2 equiv) afforded **2** quantitatively with a totally opposite preference of olefin geometry (*E*/*Z* = 14/86), indicating that the Lewis acidic receptor ATPH changes the conformation of the transition state in the hydrogen abstraction process (Figure 2).[6] The stereoselectivity was further improved by the use of $(Me_3Si)_3SiH$ instead of Bu_3SnH (Scheme 1).

We also examined intramolecular cyclization of the one-carbon elongated halo ether 3-iodopropyl 3-phenyl-2-propynyl

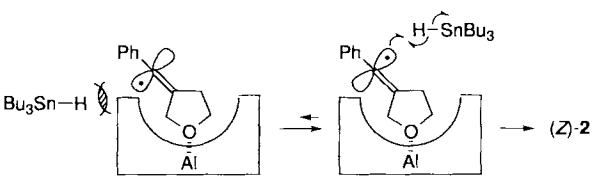


Figure 2. Hydrogen abstraction from Bu_3SnH by a π system in the presence of ATPH.

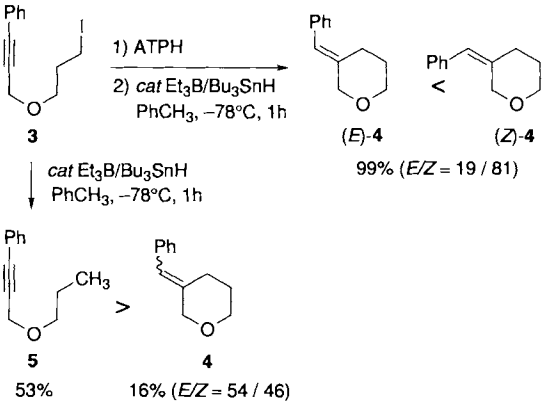
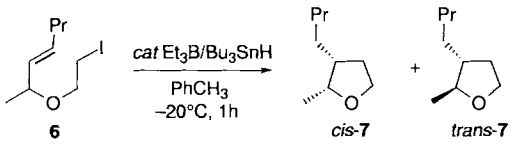
ether (**3**), which can be categorized as a heptynyl radical cyclization. Surprisingly, radical cyclization of **3** under the influence of ATPH gave the desired cyclic ether **4** as the sole isolable product in quantitative yield, whereas in the absence of ATPH the yield of **4** decreased dramatically (16%) and the reduction product **5**



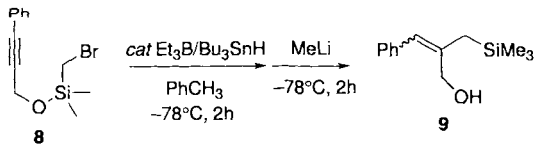
(53% yield) was formed predominantly.[4] Noteworthy is that the *E*/*Z* selectivity in the cyclization products **4** is again opposite in the presence or absence of ATPH, and that nearly perfect *Z* selectivity was also obtained with $(Me_3Si)_3SiH$, despite the significant rate retardation under similar reaction conditions (30% yield of **4**; *E*/*Z* = <1/>99 and 70% recovery of **3**). The origin of the remarkable template effect observed herein could be ascribable to the well-defined reaction environment created at the aluminum coordination center (see Figure 1); this enables appropriate proximity of the initially generated carbon radical to the triple bond in the transition state, so that the cyclization proceeds smoothly and the undesired intermolecular reduction pathway is suppressed.[7]

Encouraged by the results, we turned our attention to the diastereoselective radical cyclization of 2-iodoethyl *trans*-1-methyl-2-hexenyl ether (**6**), which proceeded in toluene at −20 °C with Bu_3SnH and a catalytic amount of Et_3B to furnish tetrahydrofurans **7** in 95% yield with excellent diastereoselectivity (*cis*/*trans* 3/97).[8] In marked contrast, initial treatment of **6**



with ATPH followed by the addition of Bu_3SnH and a catalytic amount of Et_3B at −20 °C resulted in formation of **7** almost quantitatively with totally opposite diastereoselectivity (*cis*/*trans* 92/8). This excellent *cis* selectivity is certainly unattainable under ordinary radical reaction conditions.

Our strategy has been successfully applied to the radical cyclization of [(bromomethyl)dimethylsilyl]propargyl ethers. This process is usually carried out in refluxing benzene with a catalytic amount of AIBN by slow addition of R_3SnH (R = Ph or Bu) with a syringe pump to avoid the undesired side reaction of the relatively stable α-silyl radical.[9] Indeed, an attempt to cyclize **8** in toluene by employing Bu_3SnH and a catalytic amount of Et_3B at −78 °C for 2 h without using a syringe pump and subsequent reaction of MeLi (3 equiv) at −78 °C for 2 h produced allylic alcohol **9** in only 5% yield. Interestingly, the reaction



5% (*E*/*Z* = 28 / 72)
ATPH: 70% (*E*/*Z* = 54 / 46)

with ATPH under otherwise identical reaction conditions gave rise to **9** in 70% yield, again demonstrating the ability of ATPH as an efficient template to facilitate the cyclization step.

Experimental Section

Radical cyclization of **1** in the presence of ATPH: A solution of 2,6-diphenylphenol (740 mg, 3 mmol) in toluene (5 mL) was degassed and a 2 M hexane solution of Me_3Al (0.5 mL, 1 mmol) was added at room temperature under argon. The slightly yellow solution was stirred for 30 min. After the solution had been cooled to −78 °C, **1** (143 mg, 0.5 mmol) in toluene (1 mL) was added and then Bu_3SnH (200 μL, 0.75 mmol) and Et_3B (100 μL, 0.1 mmol) were introduced sequentially. The solution was stirred at −78 °C for 1 h and then poured into an aqueous saturated solution of $NaHCO_3$. After extraction with ether, the combined ethereal extracts were dried over Na_2SO_4. Evaporation of solvents and purification of the residual oil by column chromatography on silica gel (ether/dichloromethane/hexane 1/2/16 as eluant) gave the cyclic ether **2** (79.6 mg, 0.496 mmol) as a colorless oil (99% yield, *E*/*Z* = 14/86): ^1H NMR (300 MHz, $CDCl_3$, 20 °C, TMS): δ = 7.10–7.40 (5H, m, Ph), 6.45 and 6.37 (1H, m, CH=C for *Z* and *E* isomer, respectively), 4.58 and 4.46 (2H, m, C=CCH_2–O for *Z* and *E* isomer, respectively), 4.01 and 3.90 (2H, t, *J* = 6.9 Hz, CH_2–O for *E* and *Z* isomer, respectively), 2.73–2.86 (2H, m, CH_2).

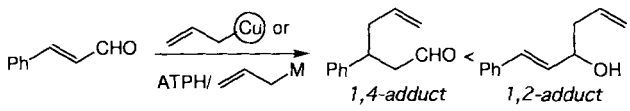
Conjugate Allylation to α,β-Unsaturated Aldehydes with the New Chemzyme *p*-F-ATPH**

Takashi Ooi, Yuichiro Kondo, and Keiji Maruoka*

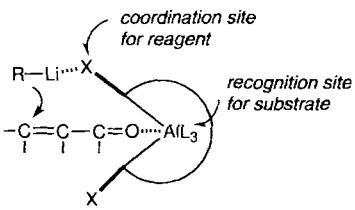
Conjugate allylation to α,β-unsaturated aldehydes is an extremely difficult, hitherto unattainable transformation in organic synthesis, and no effective procedure has yet been developed to a useful level due to the lack of a satisfactory reagent.[1, 2] Even organocopper reagents, which have been employed successfully in the conjugate alkylation to α,β-unsaturated carbonyl compounds,[3] gave very disappointing results for the conjugate allylation. For instance, the reaction of cinnamaldehyde with allylcopper or lithium diallylcuprate gave predominantly the 1,2-adduct *trans*-1-phenyl-1,5-hexadien-3-ol (Scheme 1). Our recently developed new conjugate alkylation procedure with the Lewis acidic receptor aluminum tris(2,6-diphenylphenoxide) (ATPH)[4] was also found to be less effective for the present conjugate allylation, and only the ATPH/allyllithium system gave modest 1,4-selectivity (Scheme 1). This



CH_2=$CHCH_2Cu$	: 98% (6/94)
$(CH_2$=$CHCH_2)_2CuLi$	: 98% (10/90)
ATPH/CH_2=$CHCH_2Li$	: 80% (59/41)
ATPH/CH_2=$CHCH_2MgBr$	: 96% (1/99)
ATPH/CH_2=$CHCH_2CaI$	: 92% (37/63)
ATPH/CH_2=$CHCH_2Cu$	: 70% (13/87)

Scheme 1. Preliminary attempts at the conjugate allylation to cinnamaldehyde.

tendency is contradictory, for example, to our previous observations on the ATPH/BuM system for the conjugate alkylation to cinnamaldehyde, in which the 1,4-selectivity is enhanced by changing nucleophiles (BuM) from BuLi (ratio of 1,4-/1,2-adduct 50/50) to BuMgCl (90/10) and BuCaI (98/2).[4a] After consideration of the wide availability and versatility of organolithium reagents,[5] this lack of selectivity prompted us to design a new Lewis acidic receptor possessing appropriate coordination sites for alkyllithium nucleophiles (Scheme 2).[6] Here we report the realization of such a new system by presenting the first successful conjugate addition of allyllithium reagents to α,β-un-



Scheme 2. Schematic representation of the structural requirements for a Lewis acidic receptor in order for it to be a suitable for the conjugate allylation to α,β-unsaturated aldehydes.

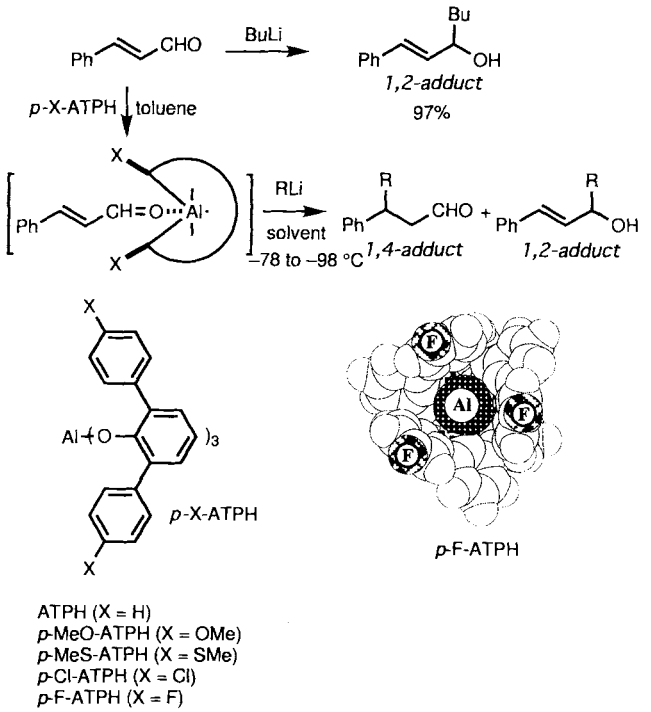
saturated aldehydes by complexation with a modified Lewis acidic receptor.

First, we examined the 1,4-selectivity of the conjugate alkylation to cinnamaldehyde with the modified ATPH/BuLi system (Scheme 3). Selected results are given in Table 1. *p*-(MeO)-ATPH and *p*-(MeS)-ATPH exhibited slightly better selectivity than ATPH (entries 2 and 3). The 1,4-selectivity was further enhanced with *p*-Cl-ATPH and *p*-F-ATPH (entries 4 and 5).[7, 8] In addition significant solvent and temperature effects on the 1,4-selectivity were observed (entries 6–10). The optimum reaction conditions for BuLi were achieved by using DME as solvent at low temperature (−98 °C) under the influence of *p*-F-ATPH in toluene. This gave the 1,4-adduct with 95% selectivity (entry 10). Here, the chelation of BuLi with DME is quite suitable for increasing the steric size of the nucleophile (BuLi) without suppressing the ability of Li^+ to coordinate to fluorine atoms of *p*-F-ATPH.[9]



Scheme 3. Conjugate addition of RLi to cinnamaldehyde in the presence of *p*-X-ATPH.

Table 1. Conjugate addition of alkyllithium compounds to cinnamaldehyde with *p*-X-ATPH compounds [a].

Entry	*p*-X-ATPH	RLi/solvent	*T* [°C]	Yield [%][b] (ratio)[c]
1	ATPH	BuLi/hexane	−78	92 (50/50)
2	*p*-MeO-ATPH	BuLi/hexane	−78	80 (55/45)
3	*p*-MeS-ATPH	BuLi/hexane	−78	91 (57/43)
4	*p*-Cl-ATPH	BuLi/hexane	−78	92 (63/37)
5	*p*-F-ATPH	BuLi/hexane	−78	87 (76/24)
6	*p*-F-ATPH	BuLi/Et_2O	−78	90 (79/21)
7	*p*-F-ATPH	BuLi/Et_2O	−98	87 (84/16)
8	*p*-F-ATPH	BuLi/THF	−78	82 (86/14)
9	*p*-F-ATPH	BuLi/DME	−78	75 (90/10)
10	*p*-F-ATPH	BuLi/DME	−98	83 (95/5)
11	*p*-F-ATPH	allyl-Li/Et_2O	−78	94 (77/23)
12	*p*-F-ATPH	allyl-Li/Et_2O	−98	87 (84/16)
13	*p*-F-ATPH	allyl-Li/THF	−78	89 (50/50)
14	*p*-F-ATPH	allyl-Li/DME	−78	75 (90/10)
15	*p*-F-ATPH	allyl-Li/DME	−98	83 (95/5)
16	*p*-F-ATPH	prenyl-Li/Et_2O	−98	82 (95/5)[d]
17	*p*-F-ATPH	prenyl-Li/DME	−98	77 (95/5)[e]

[a] The alkyllithium compounds (1.5 equiv) were added to cinnamaldehyde by complexation with the *p*-X-ATPH analogue (1.1 equiv) in toluene at −78 to −98 °C, and stirred for 15 min. [b] Yield of isolated product. [c] Ratio of 1,4-/1,2-adducts. [d] α/γ-Ratio of the conjugate adducts 10/90. [e] α/γ-Ratio of the conjugate adducts 72/28.

These results clearly demonstrate that the Lewis acidic receptor *p*-F-ATPH serves as a substrate recognition center for the aldehyde-carbonyl group as well as an effective coordination site for the nucleophile (BuLi). Thus, in this case the reactive BuLi reagent is appropriately placed in the proximity of the β-carbon atom of cinnamaldehyde to enable the smooth conjugate alkylation (Figure 1).

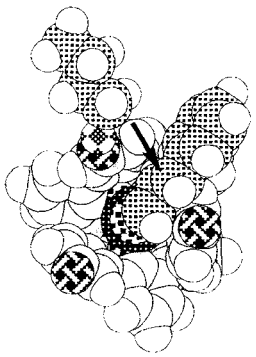


Figure 1. Proposed structure of the complex from cinnamaldehyde, *p*-F-ATPH, and BuLi, showing the favorable relative arrangement of the reaction partners for the desired conjugate alkylation.

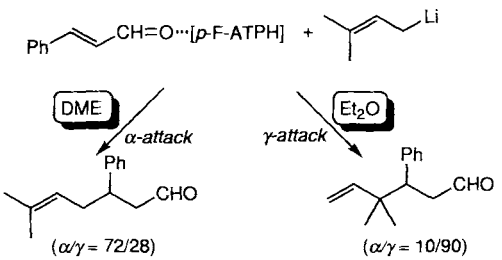
With this information at hand, the present approach was applied to the conjugate allylation to α,β-unsaturated aldehydes, which has certainly proven to be a very difficult chemical transformation by conventional methodologies including the use of the otherwise most reliable organocopper reagents.[2, 3] In fact, use of the *p*-F-ATPH/allyllithium system for the conjugate allylation to cinnamaldehyde gave better 1,4-selectivity (entries 11, 12, and 14) than the ATPH/allyllithium counterpart (see Scheme 1). Synthetically useful conjugate allylation can be realized with *p*-F-ATPH/allyllithium in DME at −98 °C (entry 15).[10] Notably, use of the more basic solvent THF resulted in significant loss of 1,4-selectivity due to the reduced ability of Li^+ to coordinate in THF to fluorine atoms of *p*-F-ATPH (entry 13).

Conjugate addition of prenyllithium to cinnamaldehyde appears to be feasible. Indeed, the reaction proceeded with excellent selectivity under optimized reaction conditions (entry 17). Noteworthy is the fact that the α/γ ratio of the conjugate adducts was profoundly influenced by the solvent (Scheme 4).[11]



Scheme 4. Effect of solvent on the conjugate addition of prenyllithium to cinnamaldehyde with *p*-F-ATPH.

Experimental Section

Conjugate addition of allyllithium to cinnamaldehyde with *p*-F-ATPH (Table 1, entry 15): A solution of 2,6-di(*p*-fluorophenyl)phenol (466 mg, 1.65 mmol, prepared as described in ref. [7]) in toluene (4 mL) was degassed, and a 1 M hexane solution of Me_3Al (0.55 mL, 0.55 mmol) was added at room temperature under argon. Methane gas evolved immediately. The resulting yellow solution was stirred for 30 min and used without purification. After the addition of cinnamaldehyde (63.1 μL, 0.5 mmol) at −98 °C, allyllithium (prepared from allyltributyltin (233 μL, 0.75 mmol) and 1.6 M hexane solution of BuLi (469 μL, 0.75 mmol) [10]) in DME (2 mL) at −98 °C was added dropwise by cannular transfer. The solution was

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3611-1184 $ 17.50+.50/0

stirred at −98 °C for 15 min and then poured into 1 N HCl solution. After extraction with ether, the combined ethereal extracts were dried over Na_2SO_4. Evaporation of solvents and purification of the residue by column chromatography on silica gel (dichloromethane/hexane 1/4 to ether/hexane 1/1 as eluant) gave the mixture of 1,4- and 1,2-adducts (72.3mg, 0.415 mmol, 83% yield) as a colorless oil. The ratio of 1,4-/1,2-adducts was determined by GLC analysis at the column temperature of 150 °C (1,4-/1,2-adducts 95/5). 1,4-adduct 3-phenyl-5-hexenal; ^{1}H NMR (300 MHz, $CDCl_3$, 20 °C, TMS): δ = 9.68 (1H, t, J = 2.0 Hz, CHO), 7.18–7.36 (5H, m, Ph), 5.59–5.75 (1H, m, CH=C), 4.90–5.06 (2H, m, C=CH_2), 3.30 (1H, quint, J = 7.3 Hz, PhCH), 2.68–2.84 (2H, m, CH_2C=O), 2.31–2.48 (2H, m, CH_2C=C).

Strong, Rapid Binding of a Platinum Complex to Thymine and Uracil Under Physiological Conditions**

Nicola Margiotta, Abraha Habtemariam, and Peter J. Sadler*

All four DNA bases adenine (A), cytosine (C), guanine (G), and thymine (T) (uracil, U, in RNA) are known to be capable of binding to metal ions through their ring N atoms and exocyclic N and O atoms. The major site of attack by platinum am(m)ine anticancer complexes is the N7 atom of guanine, which is readily accessible in the major groove of duplex DNA and is the strongest electron donor of the four bases, especially when situated next to another guanine residue.[1] Thus, over 90% of Pt is found in intrastrand G·G and A·G cross-links.[2] The N3 atom of thymine should provide a strong binding site for Pt[3] but has a high pK_a value (ca. 10),[4] and is usually inaccessible in double-stranded DNA due to involvement in A·T base pairs. Therefore cross-links involving thymine are not observed.[2] Even when the N3 atom of thymine is exposed in single strands of DNA or in thymine derivatives, reactions with Pt am(m)ine complexes are usually very slow.[5] It is of interest therefore to examine new methods of attaining kinetic control over attack by Pt on thymine bases. We report here the unusual ability of a cytotoxic platinum complex to bind strongly and rapidly to the N3 atom of thymine (and uracil) under physiological conditions.

The chloride salt of Pt^{II} complex **1**,[6] which we have used in this work, is cytotoxic to several cancer cell lines including cisplatin-resistant cells. In water it exists as a mixture of ring-closed (**1a**) and ring-opened forms. We find that **1** reacts rapidly (within minutes) with deoxythymidine 5′-monophosphate (5′-dTMP). The ^{31}P{^{1}H} NMR spectrum of a 1:1 solution of **1** and 5′-dTMP at pH* 7.1 (measured in D_2O, Figure 1) consists of

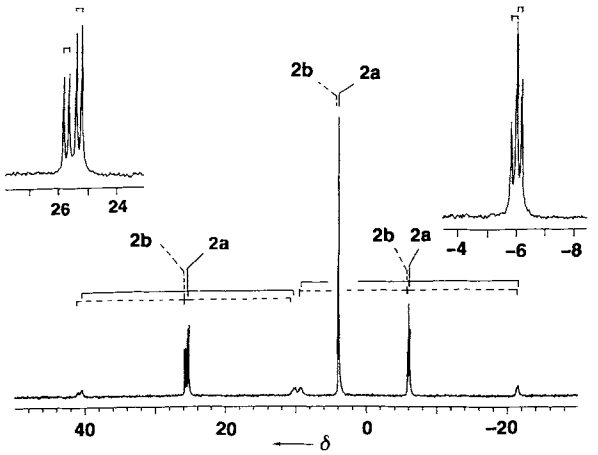

Figure 1. 109.4 MHz $^{31}P\{^1H\}$ NMR spectrum of an approximately 1:1 solution (20 mM) of complex **1** and 5′-dTMP at pH* 7.07 and 298 K, as well as the assignment of the signals to **2a** (major product) and **2b** (minor product).

three sets of peaks: one set of two doublets at $\delta = 25.4$ and 25.8 assignable to ^{31}P in a P,N chelate ring, two doublets at $\delta = -6.0$ and -5.9 assignable to ^{31}P in a P-bound ring-opened ligand, and two singlets at $\delta = 4$ due to the phosphate group of coordinated 5′-dTMP. The $^1J(^{31}P,^{195}Pt)$ values of 3327 and 3367 Hz, measured from the ^{195}Pt satellites on the high-field and low-field doublets, are typical of a ^{31}P atom *trans* to a N atom.[7, 8] In contrast, oxygen binding by 5′-dTMP would be expected to give rise to a $^1J(^{31}P,^{195}Pt)$ value of over 4000 Hz for the *trans* bond.[7, 8] The doublet splittings can be assigned to $^2J(^{31}P,^{31}P)$ couplings of about 20 Hz between the P atoms of chelated and ring-opened ligands.

In the ^1H NMR spectrum, the singlet for the 5-CH_3 group of 5′-dTMP disappears and gives rise to two new singlets shifted to high field by about $\Delta\delta = 0.2$, a shift typical for coordination of N3 to a Pt center.[9] The NMR data are consistent with the formation of **2** (charge on phosphate group ignored), in which 5′-dTMP is bound to Pt through the deprotonated N3 atom. The doubling of resonances (with relative intensities 1:1.5) can be attributed to the formation of two diastereoisomers (**2a** and **2b**) differing by 180° in rotation about the Pt–N3 bond giving head and tail conformations of coordinated 5′-dTMP. Interactions between the dangling arm amino group and coordinated dTMP (for example through phosphate or carbonyl groups) may play a role in stabilization of these isomers. Detailed molecular modeling studies will be reported elsewhere.[10]

Reactions of 5′-UMP with complex **1** followed a similar course with similar ^{31}P NMR parameters, except that the ratio of the two isomers was about 1:1. In both ^1H and ^{31}P NMR spectra, titration of 5′-dTMP or 5′-UMP with **1** gave rise to separate resonances for reactants and products, indicative of slow ligand exchange on the respective NMR timescales.

The pH*-dependent stability of the 5′-dTMP complex **2** was investigated over the range pH* 2 to 12 by ^{31}P NMR spectroscopy. Figure 2a shows that the formation of the two isomers **2a** and **2b** is characterized by a pK_a of 5.1, that is formation begins at pH* values as low as 3, and is complete by pH* 8. Displacement of coordinated 5′-dTMP at low pH* values can occur through formation of an unusual iminol tautomeric form of 5′-dTMP, as shown by Lippert and co-workers[11–13] for ammine complexes. They have also pointed out that the exocyclic oxygen atoms *ortho* to N3 can make an important contribution to steric shielding of Pt from attack. The ^1H NMR chemical shifts of the singlets assignable to the dangling arm

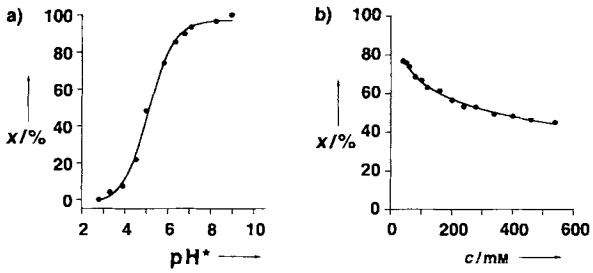

Figure 2. Graphs showing the effect of a) pH*, and b) added chloride, on the amount of bound 5′-dTMP (x) in a 1:1 solution (20 mM) of complex **1** and 5′-dTMP at 298 K. For b) the pH* value was 6.02, and hence there is incomplete binding of 5′-dTMP before Cl^- addition (see a). In both titrations the relative proportions of the two isomers remained the same and the sum has been plotted.

NMe_2H^+ groups for the isomers of **2** are markedly pH*-dependent (Figure 3) and characterized by a pK_a value of 7.8 (for both isomers), which can be associated with the deprotonation of this group.

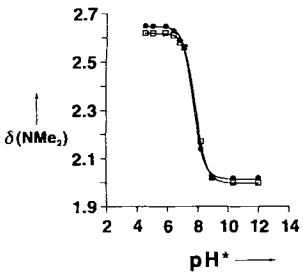

Figure 3. Dependence of the ^1H NMR peak for the dangling arm NMe_2 group of complex **2** on the pH* value. The curves are computer best fits corresponding to pK_a values of 7.71 (**2a**, major isomer •) and 7.87 (**2b**, minor isomer □).

The stability of complex **2** in the presence of added chloride ions was investigated. Figure 2b shows that addition of 0.5 M KCl displaces only about half of the bound 5′-dTMP. Therefore although the binding of 5′-dTMP to Pt is strong, it is also reversible, as we had previously found for N7-bound 5′-GMP.[6]

Finally, the ability of complex **1** to attack thymine in double-stranded DNA was investigated. The self-complementary octamer oligonucleotide d(TTGGCCAA) was chosen since it has been used extensively by Chottard et al.[14] to study the mechanism of formation of GG intrastrand cross-links by *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ and no platination of thymine has been reported to occur during reactions of the octamer with this diaqua complex.

Complex **1** was titrated into to a 2 mM solution of double-stranded d(TTGGCCAA) in 0.1 M $NaClO_4$ containing 4 mM sodium phosphate, pH 7.0 (90% H_2O/ 10% D_2O). In the 242.7 MHz ^{31}P NMR spectrum, at least four new peaks with ^{195}Pt satellites appeared near $\delta = 26$ and -7, and at least four new peaks also in the $\delta = 0$ to 1 region characteristic of DNA phosphate backbone resonances. In the 600 MHz ^1H NMR spectrum the two singlets for the thymine CH_3 groups at $\delta = 1.83$ and 1.75 gradually diminished in intensity as complex **1** was added and about seven new apparent singlets appeared (with 4 mol equiv of **1** present: $\delta = 1.42$, 1.57, 1.63, 1.68, 1.86, 1.92, 1.99). The appearance of high-field-shifted methyl peaks suggested that direct binding of Pt to the N3 atom of thymine was occurring as in the model system. Peaks at $\delta = 8.17$ and 8.15 assignable to H8 of G(3) and G(4) also decreased in intensity as **1** was added, and several new peaks appeared in the region $\delta = 7.8$ to 8.5, which probably indicates that the N7 atom of guanine is also a binding site, but the spectrum is too complex to assign without extensive further work. A sharp peak at $\delta = 13.0$ and a broader peak at $\delta = 13.75$ were assigned to the Watson–Crick H-bonded imino protons of GC and AT base-pairs, respectively. The imino protons of the AT base pairs are therefore probably exchanging more rapidly with solvent than

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3611-1186 $ 17.50+.50/0

the central GC pairs owing to end-fraying of the duplex. On reaction with **1**, the peak at $\delta = 13$ broadened. The complexity of the spectra can be attributed to binding of **1** to both thymine and guanine with similar affinities, and to binding on each of the two strands leading to a large number of possible products. Titration beyond 4 mol equiv of **1** led to precipitates which did not redissolve.

The conclusion that complex **1** can bind to both thymine and guanine bases with similar affinities is supported by NMR spectroscopic investigations of mixtures containing both 5′-dTMP and 5′-dGMP at pH* 7.19. At a Pt/5′-dTMP/5′-dGMP mol ratio of 0.5:1:1 (20 mM), 35% of the 5′-dGMP and 18% of the 5′-dTMP were bound, and at a mol ratio of 1:1:1 50% of each nucleotide was bound.

There are few precedents for the rapid reaction of Pt complexes with thymine bases. The strong *trans* effect of P in square-planar Pt^{II} complexes[15] is probably important, and indeed Bandoli et al.[16] have reported that the dinuclear complex $[\{(dppf)Pt(\mu\text{-}OH)\}_2]^{2+}$ (dppf = 1,1′-bis(diphenylphosphino)-ferrocene) forms an N3-bonded 1-methylthymine (1-Me-T) complex in dimethylformamide (dmf), dimethyl sulfoxide, or acetonitrile, and determined the X-ray crystal structure of $[(dppf)Pt(1\text{-Me-T-H}_{-1})(dmf)]^+$, but the reactions were slow (complete in about 14 h at ambient temperature). However, they also found[17] that *cis*-$[Pt(PMe_3)_2]^{2+}$ is unreactive towards 1-Me-T in water unless 2 mol equiv of NaOH was added, emphasizing the role of the base in facilitating the removal of the proton at N3. In the present case the dangling arm amino group may play a role in enhancing removal of this proton. Compounds of the type **1** provide significant scope for control of chelate ring-opening, gating of ligand exchange, and base-specificity of attack on DNA or RNA which are being further explored.

Experimental Section

5′-UMP and 5′-dTMP were purchased from Sigma. Complex **1** was prepared and characterized as previously described in ref. [6]. The 8 mer oligonucleotide d(TTGGCCAA) was purchased as an HPLC-purified sodium salt from OSWEL DNA Service (University of Southampton).

Measurements of pH were made using a Corning 145 pH meter equipped with an Aldrich microcombination electrode calibrated with Aldrich buffer solutions of pH 4, 7 and 10. Values of pH* were adjusted with 1 M DNO_3 or NaOD as appropriate.

NMR spectra were recorded on the following instruments: JEOL GSX270, Bruker AM400, Bruker DRX500 and Varian INOVA600 using 5 mm tubes. The chemical shift references were sodium trimethylsilylpropanoate (through internal dioxan at $\delta = 3.744$; ^{1}H NMR), and 85% H_3PO_4 (external; ^{31}P NMR). Typical acquisition conditions for ^{1}H spectra were: 45–60° pulses, 2.5 s relaxation delay, 64–256 transients, final digital resolution 0.2 Hz per point. When necessary the water resonance was suppressed by presaturation, or the WATERGATE pulsed field gradient sequence [18]; for ^{31}P spectra: 50–90° pulses, 512–2048 transients, and a final digital resolution of 3–5 Hz per point.

For the experiments with d(TTGGCCAA), microliter aliquots of a 40 mM solution of complex **1** (in the same solvent as used for the oligonucleotide: H_2O/D_2O 9/1, 4 mM phosphate, 0.1 M $NaClO_4$, pH 7.0) were added in steps to give totals of 0.5, 1, 2, and 4 mol equivalents.

Titration curves were fitted to the Henderson–Hasselbalch equation with the program KaleidaGraph (Synergy Software, Reading, PA, USA) on a Macintosh computer.

Formation of Isobenzenes by Thermal Isomerization of 1,3-hexadiene-5-yne Derivatives**

Henning Hopf,* Harald Berger, Gerhard Zimmermann,* Uta Nüchter, Peter G. Jones, and Ina Dix

The cyclization of 1,3-hexadiene-5-yne (**1**) to benzene (**3**),[1] first described in the late 1960s, has proven in recent years to be a useful reaction for preparing bowl-shaped, nonalternating polycyclic arenes (fullerene fragments).[2a–c] The activation parameters for the formation of **3** from **1** were determined, and the electrocyclic formation of 1,2,4-cyclohexatriene (**2**, isobenzene) was suggested as the first step.[3] As this highly reactive benzene isomer has recently been prepared by treatment of the dibromocarbene adduct of 1,3-cyclopentadiene with methyllithium at −30 °C by Christl et al.,[4] the question arises whether **2** and its derivatives are also thermally accessible from **1** and related hydrocarbons. The experiments described here show that this is indeed the case.

When a 1:1 mixture of *cis*- and *trans*-**1** and styrene (**4**) is heated to 200 °C in an ampoule, 70% of the dienyne and 30% of the trapping reagent are consumed after 90 min (GC analysis of the pyrolysate with fluorobenzene as internal standard). The products obtained are **3** (3%), addition products (homo- and codimers and trimers, 68%), polymers (29%), and cracking gases (traces; Scheme 1). The fraction with the addition prod-

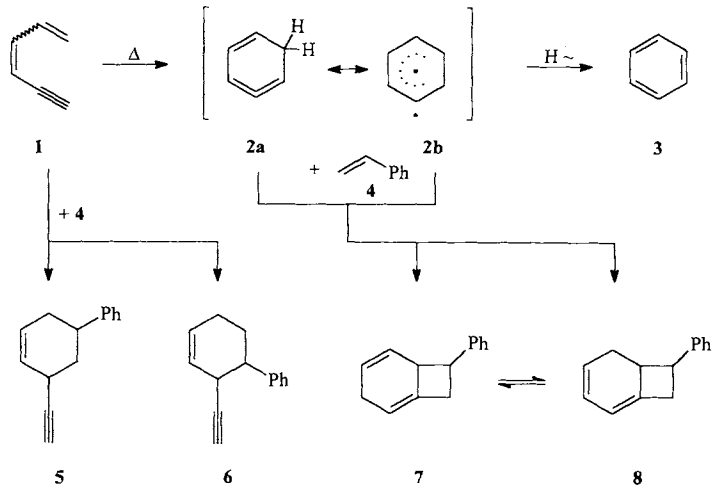


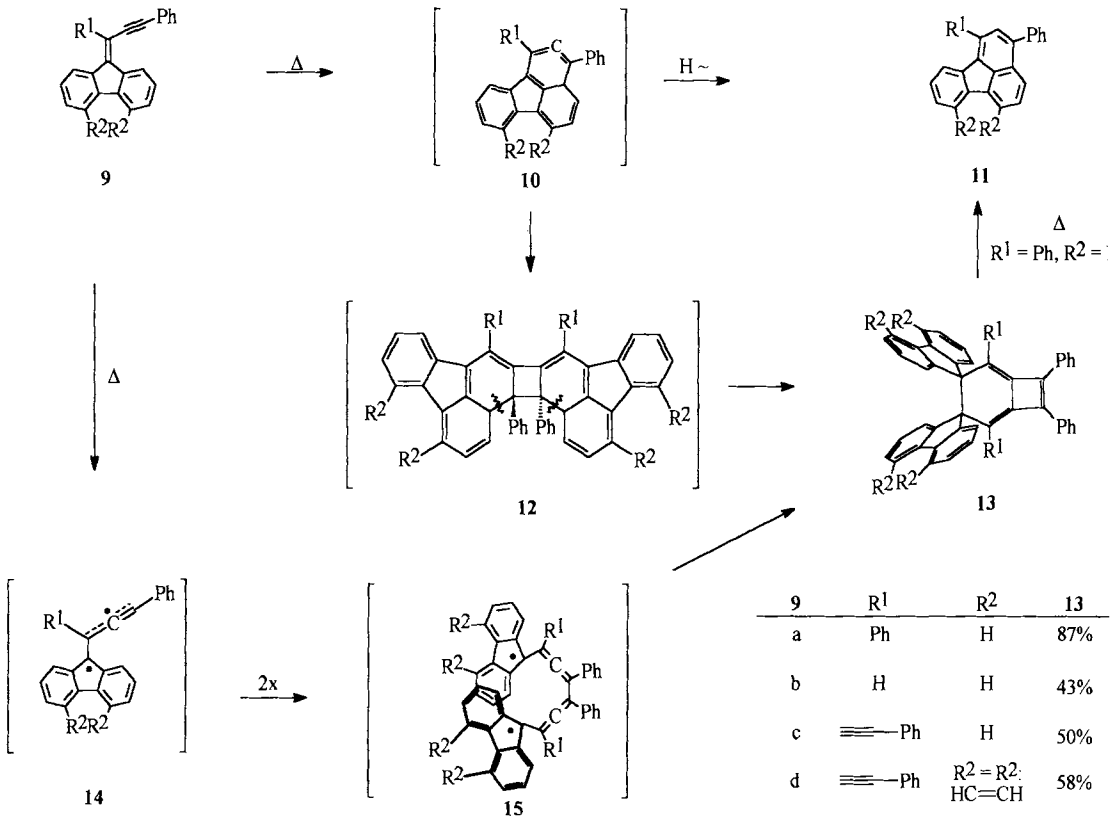
Scheme 1. Thermal isomerization of 1 and trapping experiments with 4.

ucts consists of about 35 compounds, of which 22 are obtained in amounts of less than 1%. The main part of this fraction is made up of the two Diels–Alder regioisomers **5** and **6** (48%, 1:1 ratio) and also the products of the [2+2] cycloaddition of **2** and **4**, 7-phenylbicyclo[4.2.0]octa-1,4-diene (**7**) and 7-phenylbicyclo[4.2.0]octa-1,3-diene (**8**), which are present in a ratio of 7:3 (6%).

The structure of **7** was assigned by comparison with the authentic hydrocarbon, first synthesized by Christl et al.[4] In addition to the 1:1 adducts **5**–**8**, the main fraction contains $C_{20}H_{20}$ hydrocarbons, which are formed from two molecules of **1** and one molecule of **4**, and $C_{22}H_{22}$ compounds, which require one molecule of **1** and two molecules of **4** for their formation (46%). The structures of these compounds have not yet been determined. If **4** is not added to the reaction mixture, **7** and **8** cannot be detected in the pyrolysate. Christl et al. have shown[4] that **7** and **8** are in thermal equilibrium at 130 °C; regioisomers of **7** and **8** are not obtained. At temperatures below 180–190 °C and above 260–270 °C the cycloadducts **7** and **8** are not detectable. In the first case ($T \leq 190$ °C) the available thermal energy is apparently insufficient to overcome the activation barrier of 30 kcal mol^{-1}[3] for the electrocyclization, and in the second ($T \geq 260$ °C) the reaction of **2** to form **3** by a hydrogen shift and the cycloreversion reaction of **7** and **8** are probably so strongly favored that both codimers cannot be detected (by GC/MS analysis). Therefore, only a narrow temperature range remains in which isobenzene formation can be determined by trapping reactions.

After the formation of **2** by thermal isomerization of **1** had been experimentally confirmed, several hydrocarbons containing the hexadienyne structure,[5a–c] including dibenzofulvenes **9a–d**, were synthesized and thermally converted. When **9a**, either neat or dissolved in toluene, is heated to 250 °C, the 1,3-diphenylfluoroanthene **11** expected in analogy to the reaction of **1** → **3** is formed, but only in trace amounts (2%; Scheme 2). The main product is the dimer **13a** (87%), whose structure was established by spectroscopy (see Table 1) and an X-ray structure analysis of the 1,2-dichloroethane bis(solvate) (Figure 1).[6] The elongated C9–C9′ bond (163.8(8) pm) in the cyclohexadiene ring is probably attributable to steric congestion at these carbon atoms.

Heating **13a** to 350 °C results in rearrangement to yield **11** (80%), which is also obtained from **9a** under these drastic conditions (350 °C, 70%).[7] These isomerizations are best explained by the existence of the isobenzene intermediate **10**. After its formation by electrocyclization of **9**, **10** can react in analogy



9	R^1	R^2	13

Scheme 2. Thermal isomerization of the condensed arenes **9a–d** with 1,3-hexadiene-5-yne substructure.

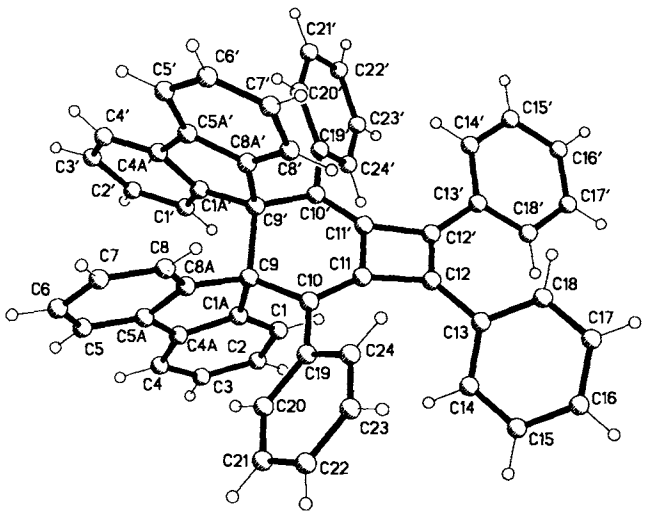

Figure 1. Crystal structure of **13a** (without solvent). Radii are arbitrary. Selected bond lengths [pm]: C9–C9′ 163.8(8), C9–C10 154.5(7), C10–C11 133.3(8), C11–C12 148.7(8), C9′–C10′ 154.3(7), C10′–C11′ 133.2(8), C11′–C12′148.3(7), C11–C11′ 149.2(9), C12–C12′ 138.2(9).

to the well-documented [2 + 2] cycloadditions of allenes to give **12**, which undergoes a stabilizing bond reorganization (cleavage of the weakest bonds in **12**, marked with wavy lines, and C–C bonding at the five-membered ring of the fluorenyl unit) to yield **13a**. Alternatively, a hydrogen shift in **10**, which is favored at higher temperatures, is possible, as was the case with the parent compound (see above). Presumably, the reaction of **13a** → **11** also proceeds via **10**. However, at these temperatures a decoupling of the exocyclic double bond of the starting material is also feasible (thermal *cis–trans* isomerization of **9**). The resonance-stabilized diradical **14** thus formed could dimerize to **15**, which can react to **13a** by cyclization and conversion of the bis(allene) unit to a bis(methylene)cyclobutadiene group.[9] Dimer formation is not restricted to **9a**, as is demonstrated by the isomerization–dimerization of **9b–d** to **13b–d**, whose structures were proven spectroscopically (Table 1) and by comparison with data obtained for **13a**.

These experiments show that isobenzenes are by no means exotic intermediates; they are in fact easily accessible by different routes. It is conceivable that such benzene isomers are also intermediates in the formation of condensed arenes by high-temperature pyrolysis of alkynes. This is particularly likely when ring-closing reactions of 1,3-hexadiene-5-ynes by 1,6-C,H insertion of alkenylidenecarbene intermediates, which dominate at temperatures above 800 °C, are disfavored because of conformational constraints, and it is also probable for the carbene obtained from **9a** by a 1,2-phenyl shift.[12] In the future, dimers of type **13** should systematically be sought when pyrolyzing aromatic hydrocarbons with 1,3-hexadiene-5-yne substructure.[14]

Table 1. Spectroscopic data for **13a–d**.

13a: ^{1}H NMR (400 MHz, $CDCl_3$): δ = 8.16 (m, 1H), 7.47 (m, 1H), 7.40 (m, 2H), 7.16 (m, 1H), 7.11 (d, 1H), 7.04 (m, 4H), 6.87 (dt, 1H), 6.77 (m, 3H), 6.49 (d, 2H), 6.29 (t, 1H), 5.35 (d, 1H); ^{13}C NMR (100.1 MHz, $CDCl_3$): δ = 151.7, 147.9, 145.0, 142.0, 141.5, 139.2, 137.7, 132.9, 128.8, 128.6, 128.3, 128.0, 127.8, 127.0, 126.9, 126.6, 126.5, 126.4, 126.1, 125.0, 124.2, 119.5, 118.0, 66.1; IR (KBr): $\tilde{\nu}$ = 3056 (w), 3029 (w), 1443 (m), 1026 (w), 768 (m), 739 (s), 696 cm^{-1} (s).

13b: ^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.85 (m, 2H), 7.38 (m, 5H), 7.16 (br. s, 3H), 6.97 (br. s, 3H), 5.71 (s, 1H); ^{13}C NMR (100.1 MHz, $CDCl_3$): δ = 145.5, 141.2, 140.9, 133.3, 129.1, 128.7, 127.7, 127.4, 126.1, 126.0, 118.9, 111.5, 61.3; IR (KBr): $\tilde{\nu}$ = 3060 (w), 3031 (w), 1443 (m), 759 (m), 734 (s), 698 cm^{-1} (m).

13c: ^{1}H NMR (400 MHz, $CDCl_3$): δ = 8.23 (dd, 2H), 7.94 (br. s, 1H), 7.45 (m, 4H), 7.34 (br. s, 3H), 7.08 (m, 4H), 6.68 (dd, 3H), 6.07 (br. s, 1H); ^{13}C NMR (100.1 MHz, $CDCl_3$): δ = 148.1, 144.5, 141.7, 132.0, 130.9, 129.7, 129.1, 128.4, 127.9, 127.8, 123.2, 106.7, 97.5, 87.6, 63.8; IR (KBr): $\tilde{\nu}$ = 3060 (w), 3031 (w), 3019 (w), 1595 (m), 1488 (s), 1474 (m), 1446 (s), 766 (s), 753 (s), 739 (s), 688 cm^{-1} (s).

13d: ^{1}H NMR (400 MHz, $CDCl_3$): δ = 8.18 (dd), 7.40 (m), 7.00 (br. m), 7.00–6.90 (m), 6.38 (dd), 5.90 (br. m); ^{13}C NMR (100.1 MHz, $CDCl_3$): δ = 148.6, 144.9, 137.8, 132.2, 130.8, 129.6, 129.1, 128.4, 128.2, 127.8, 127.7, 127.5, 126.9, 124.8, 123.6, 123.2, 122.4, 106.6, 97.4, 87.9, 66.1; MS (70 eV): *m/z* (%) = 804 (100) [M^+], 727 (33) [$M - C_6H_5$], 402 (20) [M^{2+}], 400 (20) [$(M - 2H)^{2+}$], 278 (25) [$C_{22}H_{14}$], 189 (62) [$C_{15}H_9^+$], 78 (95) [$C_6H_6^+$]

Experimental Section

9a–d: Compounds **9a** and **9c** were prepared by reaction of 9-trimethylsilylfluorene-9-yllithium with 1,3-diphenylpropynone and 1,5-diphenyl-1,4-pentadiyne-3-one [10], respectively, in Et_2O at −40 °C (69% and 57%). Derivative **9b** was obtained from fluorene-9-ylidene triphenylphosphane and 3-phenylpropynal in $CHCl_3$ (70%), and **9d** from cyclopenta[*def*]phenanthrenyllithium and 1,5-diphenyl-1,4-pentadiyne-3-one [10] in THF (75%).

9a: m.p. 118 °C (116 °C) [13]; ^{1}H NMR (400 MHz, $CDCl_3$): δ = 8.87 (m, 1H), 7.63 (m, 1H), 7.55 (m, 4H), 7.49 (m, 3H), 7.36 (m, 6H), 7.22 (m, 1H), 6.86 (dt, 1H), 6.46 (d, 1H); ^{13}C NMR (100.1 MHz, $CDCl_3$): δ = 140.7, 140.4, 140.1, 138.2, 137.5, 131.7, 129.0, 128.9, 128.8, 128.5, 128.4, 127.4, 126.6, 125.5, 124.9, 122.5, 122.2, 119.4, 102.4, 92.2; IR (KBr): $\tilde{\nu}$ = 3056 (w), 3030 (w), 2180 (w), 1567 (w), 1488 (w), 1442 (s), 782 (s), 757 (s), 728 (s), 694 (s), 687 cm^{-1} (s).

9b: m.p. 91–92 °C; ^{1}H NMR (400 MHz, $CDCl_3$): δ = 8.58 (d, 1H), 7.65 (m, 3H), 7.59 (m, 2H), 7.37 (m, 6H), 7.25 (dt, 1H), 6.76 (s, 1H); ^{13}C NMR (100.1 MHz, $CDCl_3$): δ = 144.2, 140.7, 139.4, 138.2, 136.9, 131.6, 129.3, 129.1, 128.8, 128.6, 127.4, 127.2, 124.9, 123.3, 120.3, 119.8, 119.7, 103.7, 100.9, 88.7; IR (KBr): $\tilde{\nu}$ = 3049 (w), 2923 (w), 2183 (w), 1619 (w), 1440 (m), 840 (s), 728 (s), 688 cm^{-1} (s).

9c: m.p. 137 °C; ^{1}H NMR (400 MHz, $CDCl_3$): δ = 8.70 (d, 2H), 7.65 (m, 6H), 7.41 (dd, 6H), 7.36 (dt, 2H), 7.30 (dt, 2H); ^{13}C NMR (100.1 MHz, $CDCl_3$): δ = 145.2, 140.3, 137.5, 131.8, 129.5, 129.1, 128.6, 127.5, 125.5, 122.9, 119.6, 101.3, 97.9, 88.9; IR (KBr): $\tilde{\nu}$ = 3052 (w), 3029 (w), 2186 (w), 1448 (m), 1442 (s), 779 (w), 752 (s), 720 (s), 683 cm^{-1} (s).

9d: m.p. 210 °C; ^{1}H NMR (400 MHz, $CDCl_3$): δ = 8.52 (d, 2H), 7.82 (d, 2H), 7.81 (s, 2H), 7.73 (m, 4H), 7.64 (t, 2H), 7.45 (m, 8H); ^{13}C NMR (100.1 MHz, $CDCl_3$): δ = 146.7, 136.4, 135.8, 131.9, 129.6, 128.6, 128.0, 127.4, 125.8, 125.1, 123.2, 122.8, 103.9, 97.3, 88.4; IR (KBr): $\tilde{\nu}$ = 3036 (w), 2186 (w), 1489 (s), 1441 (s), 822 (s), 755 (s), 689 cm^{-1} (s).

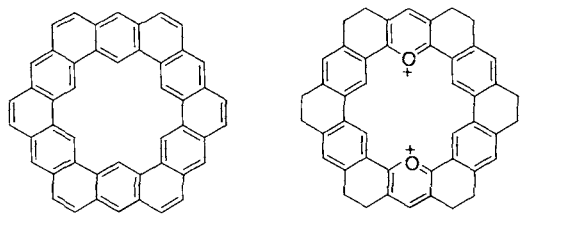
[14] Such a situation occurs in, for example, the case of 7,10-diethynylfluoroanthene, which rearranges to form corannulene under the conditions of flash vacuum pyrolysis [2a].

Synthesis of 3,9,15,19,21,23-Hexaazakekulene

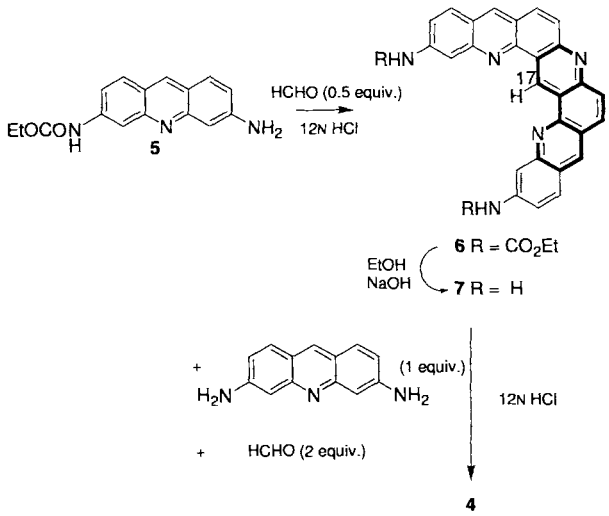
Arnaud Tatibouët, Richard Hancock, Martine Demeunynck,* and Jean Lhomme

Kekulene (**1**) was synthesized by Diederich and Staab in 1978[1] as the first member of a series of compounds designated as cycloarenes or coronaphenes. The electronic structure (annulenoid or benzenoid) of **1** is intriguing.[2a] ^{1}H NMR results[2b] and a very recent theoretical study[2a] indicate the benzenoid structure. Synthesis of cycloarenes is a challenging problem, and only very few molecules have been described. Dodecahydro-18,21-dioxoniakekulene[3] (**2**) and dodecahydrohexaazakekulenes[4] **3** are the only heteroaromatic analogues of kekulene prepared so far.

In the course of investigating the synthesis of heterocyclic Tröger's bases,[5] we studied the reactivity of 3-aminoacridine with formaldehyde and observed the formation of a new, fully unsaturated heptacycle, acridino[3,4-*j*]benzo[*b*]-1,7-phenanthroline.[6] On the basis of this result, we designed a strategy for preparing 3,9,15,19,21,23-hexaazakekulene (**4**), in which the nitrogen atoms are located alternatively at the inner and outer perimeters of the cycloarene.



Compound **4** could be constructed by condensation of three molecules of proflavine (3,6-diaminoacridine) with three molecules of formaldehyde. Proflavine has to first be monoprotected to avoid polymerization. We used the ethoxycarbonyl protecting group, since it is stable in the strongly acidic conditions required for the condensation reaction. Monoprotected proflavine (6-amino-3-(ethoxycarbonylamino)acridine, **5**)[7] slowly reacted with paraformaldehyde in 12 N HCl to give 2,14-di(ethoxycarbonylamino)acridino[3,4-*j*]benzo[*b*]-1,7-phenanthroline (**6**) in 84% yield after 3 weeks (Scheme 1). The stoichiometry of the reaction was crucial, as formation of **6** required only one equivalent of formaldehyde for two proflavine molecules. An excess of formaldehyde would lead to different compounds (analogues of Tröger's base, tetrahydroquinazoline, or dihydrooxazine derivatives).[5] The ^{1}H NMR spectrum of **6** is characterized by the strong deshielding of the internal H-17 proton, which appears at $\delta = 11.3$.



Scheme 1. Synthesis of hexaazakekulene **4**.

Removal of the ethoxycarbonyl groups was achieved under basic conditions (EtOH, NaOH) to give 2,14-diaminoacridino[3,4-*j*]benzo[*b*]-1,7-phenanthroline (**7**) in 68% yield. This polar compound was analyzed by ^{1}H NMR spectroscopy in deuteriated trifluoroacetic acid ([D]TFA); the H-17 proton appears as a singlet at $\delta = 12.24$.

To obtain the hexaazakekulene **4**, stoichiometric amounts of **7** and proflavine were allowed to react with two equivalents of paraformaldehyde in 12 N HCl. After the mixture was stirred at 50 °C for one week, there was total disappearance of **7** (HPLC). The mixture was basified, and a dark brown residue, which was analyzed by ^{1}H NMR spectroscopy and mass spectrometry, was obtained. The ^{1}H NMR spectrum ([D]TFA) indicated the presence of one major product, later identified as the desired hexaazakekulene **4**, and several by-products. The mass spectrum confirmed the formation of **4** ($m/z = 606$ [M^+]) along with two compounds of higher mass ($m/z = 815$ and 829).[8] Since **4** is insoluble in most organic solvents, pure product can be obtained by extensive washings of the solid reaction mixture with CH_2Cl_2, MeOH, and DMF. Elemental analysis was performed three times, and the data are in agreement with structure $4 \cdot 10H_2O$ ($C_{42}H_{18}N_6 \cdot 10H_2O$); the water molecules could not be removed by extensive drying in vacuo. High-resolution mass

spectrometry of **4** dissolved in TFA (positive ion FAB) showed a signal at $m/z = 607.1631$, which corresponds to the calculated value of 607.1671 for $C_{42}H_{18}N_6$ $[M+H]^+$. The ^1H NMR spectrum ([D]TFA) of **4** contains only four signals in a 1:1:2:2 ratio: a singlet at $\delta = 12.98$, corresponding to the inner protons (H-20, H-22, and H-24), a singlet at $\delta = 9.90$ (H-6, H-12, and H-18), and two doublets at $\delta = 9.39$ and 8.98 for the twelve remaining protons. UV/Vis and fluorescence spectroscopy was carried out on **4** dissolved in $CHCl_3$/TFA (98/2). The solution shows absorptions at $\lambda_{max} = 429$, 404, 383, 332, and 249 nm and exhibits an intense blue fluorescence. The fluorescence emission was observed between 420 to 560 nm with maxima at 452, 481, and 514 nm (excitation at 331 nm). This new compound is insoluble in most organic solvents but exhibits low solubility in strong acids (methane sulfonic or trifluoroacetic acid), probably due to protonation of **4**.

We have prepared the first fully unsaturated heterocyclic analogue of **1**. The results of the mass spectrometry analysis indicate that the strategy used for synthesizing **4** should be also successful for preparing "expanded" heptaazahelicenes.[8]

Experimental procedure

6: Paraformaldehyde (0.026 g, 0.9 mmol) was added to a solution of **5** [7] (0.5 g, 1.8 mmol) in 12 N HCl (100 mL), and the mixture stirred at 50 °C for three weeks. The solution was then added dropwise to 10 N NaOH. The solid was filtered, washed with water and methanol, and dried (0.42 g, 0.75 mmol, 84% yield). An analytically pure sample was obtained by flash chromatography on silica gel (ethyl acetate); m.p. = 320 °C. ^1H NMR (200 MHz, [D$_6$]DMSO): $\delta = 11.30$ (s, 1H, H-17), 10.27 (s, 2H, 2 NH), 9.00 (s, 2H), 8.65 (s, 2H), 8.27 (d, 2H, $J = 9.4$ Hz), 8.18 (d, 2H, $J = 8.9$ Hz), 7.98 (d, 2H, $J = 9.4$ Hz), 7.85 (d, 2H, $J = 8.9$ Hz), 4.27 (m, 4H, CH_2), 1.35 (t, 6H, CH_3); ^{13}C NMR (100 MHz, [D$_6$]DMSO): $\delta = 153.56$, 151.07, 148.28, 147.035, 141.50, 135.73, 131.88, 129.34, 128.98, 127.08, 124.67, 123.22, 122.98, 120.46, 113.35, 60.62, 14.43; UV/Vis (EtOH): λ_{max} (ε) = 427 (7700), 362 (37400), 332 (41600), 280 (41300), 257 (71000); HR-MS (positive ion FAB, *m*-nitrobenyl alcohol matrix): calcd m/z: 556.1985, found: 556.1972 $[M+H]^+$.

7: A solution of **6** (1.6 g, 2.9 mmol) in EtOH (100 mL) and 10 N NaOH (10 mL) was stirred at 90 °C for 24 h. After the solution had cooled to room temperature, **7** was precipitated by addition of water. The solid was filtered, washed with water, methanol and diethyl ether, and dried (0.81 g, 1.9 mmol, 68% yield). An analytically pure sample was obtained by flash chromatography on silica gel (ethyl acetate); m.p. > 320 °C; elemental analysis calcd for $C_{27}H_{17}N_5 \cdot 1H_2O$: C 75.51, H 4.46, N 16.31; found: C 74.94, H 4.37, N 15.86; ^1H NMR (200 MHz, [D]TFA): $\delta = 12.24$ (s, 1H, H-17), 9.40 (s, 2H), 9.05 (d, 2H, $J = 8.8$ Hz), 8.62 (d, 2H, $J = 9.1$ Hz), 8.38 (d, 2H, $J = 8.8$ Hz), 7.72 (m, 4H,); ^{13}C NMR (100 MHz [D$_6$]DMSO): $\delta = 151.68$, 151.11, 150.22, 147.07, 135.56, 132.13, 129.47, 129.27, 125.23, 124.63, 120.98, 120.81, 120.59, 104.65; MS (positive ion FAB): $m/z = 412$ $[M+H]^+$.

4: A mixture of 7 (0.102 g, 0.25 mmol), proflavine (0.053 g, 0.26 mmol), and paraformaldehyde (0.015 g, 0.5 mmol) in 12 N HCl (30 mL) was stirred at 50 °C for 7d. After the solution had cooled, it was basified with diluted NH_4OH. The solid was filtered, washed with water, and dried (0.105 g). Washing the solid with CH_2Cl_2 (3 × 40 mL), DMF (3 × 40 mL), and MeOH (3 × 40 mL) provided pure **4** (0.017 g, 0.028 mmol, 10% yield), m.p. > 320 °C. ^1H NMR (200 MHz, [D]TFA): $\delta = 12.98$ (s, 3H, H-20,22,24), 9.9 (s, 3H, H-6, H-12, H-18), 9.39 (d, 6H, $J = 9.9$ Hz), 8.98 (d, 6H, $J = 9.9$ Hz); UV/Vis ($CHCl_3$/TFA 98/2): λ_{max} (ε) = 429 (13000), 404 (18900), 383 (18000), 332 (63700), 249 (62600); HR-MS (positive ion FAB): calcd $m/z = 607.1671$, found: 607.1631 $[M+H]^+$; elemental analysis calcd for $C_{42}H_{18}N_6 \cdot 10H_2O$: C 64.12, H 4.87, N 10.68; found: C 63.74, H 5.13, N 10.91.

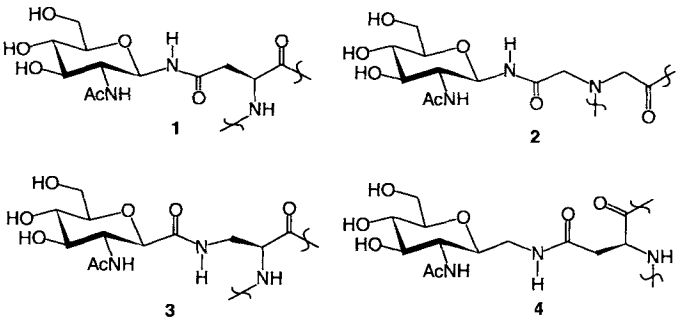
Stereoselective Synthesis of a C-Glycosidic Analog of *N*-Glucoasparagine**

Fred Burkhart, Matthias Hoffmann, and Horst Kessler*

Dedicated to Professor Hans Paulsen on the occasion of his 75th birthday

In drug design glycopeptides are of interest for the modification of biologically active peptides. Recent investigations revealed that the attachment of carbohydrates to peptides improves bioavailability,[1] increases resistance to proteases,[2] improves water solubility,[3] or enables them to penetrate the blood–brain barrier.[4] Most synthetic glycopeptides contain the natural O- or N-glycosidic linkage between the sugar residue and the peptide backbone.[5] To improve the metabolic stability, C-glycosidic amino acids[6] are of interest because the carbon–carbon linkage at the anomeric center should increase the stability towards enzymes, acid, or base. Herein we present the synthesis of a C-glycosidic amino acid whose structure is analogous to that of N^4-(2-acetamido-2-deoxy-β-D-glucopyranosyl)-L-asparagine (Asn(β-GlcNAc) **1**). Already existing analogs are the glycopeptoid **2**,[7] the retroamide **3**, which was recently described by our group,[8] and the C-glycosidic analog **4**.[9]



The key step in the synthesis described here is the coupling of the glycosyl dianion **10** with aldehyde **8**. Reactions of different glycosyl dianions with simple electrophiles have shown that a direct glycosylation is difficult and therefore the formation of a C–C bond with an aldehyde seemed most practical.[10] The

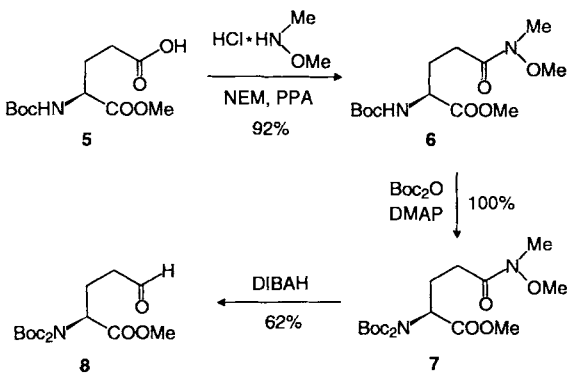
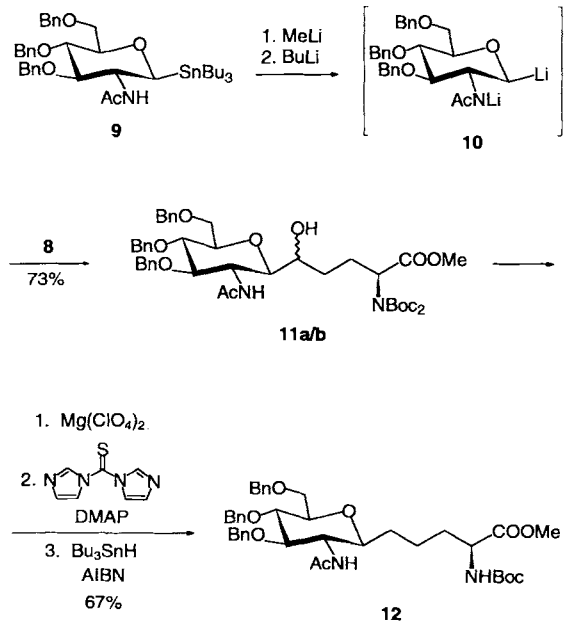
synthesis of the aldehyde **8** started from the *tert*-butoxycarbonyl(Boc)-protected methyl glutamate **5**, which was transformed into the Weinreb amide **6**[11] by using *N*,*O*-dimethylhydroxylamine hydrochloride, *N*-ethylmorpholine (NEM) and propylphosphonic acid anhydride (PPA) as coupling reagent. To prevent the protonation of the dianion **10**, the NH-proton was replaced by a second Boc-protecting group.[12] Subsequently, the protected Weinreb amide **7** was transformed into aldehyde **8** by reduction with diisobutylaluminum hydride (DIBAH).



To generate dianion **10**, the tin compound **9**[8] was first deprotonated with methyllithium and then transmetalated with butyllithium.[13] After addition of the aldehyde **8**,[14] the two diastereomeric C-glycosidic amino acids **11a,b** were obtained in equimolar amounts in a total yield of 73%. During this reaction no epimerization at the α-carbon atom was observed. After one Boc-protecting group had been removed with magnesium perchlorate,[15] the hydroxy group was transformed with 1,1′-thiocarbonyldiimidazole and 4-(dimethylamino)pyridine (DMAP) to give the corresponding thiocarbonyldiimidazole.[16] The subsequent radical reduction with tributyltin hydride and 2,2′-azobisisobutyronitrile (AIBN) gave the desired C-glycosylated amino acid **12** in 67% yield[17] with pure β-configuration at the C-1.[18]



The described procedure offers an easy access to a new C-glycosylated amino acid. The orthogonally protected building block can be prepared in few steps and good yields on a multigram scale.

Synthesis and Characterization of the Carbide Cubane Cluster $[Fe_3(CO)_9Te_4(\mu_3\text{-}CTeBr_4)]$ with an Unusual Tetrahedral CTe_4 Unit**

Jeffrey R. Eveland and Kenton H. Whitmire*

Clusters of transition metal carbonyls with the Group 16 element tellurium have been studied extensively in recent years.[1] A wide variety of cluster compounds have been produced.[2] Complexes with polytelluride ligands[1] as well as those in which the tellurium center possesses bonds to halide ions are also known.[3] We have recently reported the synthesis of some interesting complexes between tellurium chloride and iron carbonyl from the reaction of **1** with SO_2Cl_2,[4] and are pursuing reactions of clusters of main group elements and transition metals, containing other halogenated molecules. We now report that reaction of **1** with CBr_4 leads ultimately to the unusual tellurium–iron carbide cluster **3**.

$[Te_2Fe_3(CO)_9]$ **1**

$[Te_2Fe_2(CO)_6]$ **2**

$[Fe_3(CO)_9Te_4(\mu_3\text{-}CTeBr_4)]$ **3**

The reaction of **1** with CBr_4 in MeCN in a ratio of 2:1 first yields **2** in 96% yield (based on Te) along with $FeBr_2$. The addition of more than one additional equivalent of CBr_4 yields, after standing at −20 °C for 3–4 weeks, **3** as a dark red crystalline solid in 63% yield (based on Te). Compound **3** is insoluble in most organic solvents, but dissolves in DMSO. It is exceedingly unstable in solution, decomposing to metallic precipitates within 3–5 minutes, but is indefinitely stable in the solid state. Analysis for carbon monoxide content gave results consistent with the formula derived from the structural study.[5] The infrared spectrum of this compound in DMSO showed three absorption maxima at 2067, 2027, and 1981 cm^{-1} consistent with C_{2v} symmetry at the iron centers, and is similar to those reported for other Te–Fe cubane systems.[6]

Compound **3**·2MeCN crystallizes in the orthorhombic space group *Pcmn* (No. 62), and as the cluster resides on a mirror plane half of the molecule is unique (Figure 1). The structure is best described as a cubane consisting of an Fe_3Te_4C core in which the carbon atom is bonded additionally to a square-planar $TeBr_4$ unit. The Te–Br bond lengths (av. 2.665 Å) are in the same range as those found for related Te^{IV} compounds with terminal Br ligands such as $[PhTeBr_3]_2$ and various salts of $[TeBr_6]^{2-}$ (range: 2.50–2.72 Å).[7] The Te–Fe distances (av. 2.606 Å) lie in the range generally found in compounds with an iron–tellurium cubane core geometry.[8] The cubane geometry for a variety of clusters between main group elements and transition metals is well established, but the carbide unit as a vertex is, to our knowledge, unique. It is also the only structurally characterized example we are aware of in which carbon is bonded to four Te atoms.

The cluster core may be viewed as a site-voided cuboidal structure in which a vacant iron site has been filled by a carbide unit. Such a site-voided cuboidal system is common in iron–sulfur chemistry, many derivatives of this type having been prepared, but it is unknown for iron–tellurium compounds.[9] It is interesting to note, for comparison, that the room temperature decomposition of **2** has also been postulated to lead to a cubane structure. That product has been identified as $Te_4Fe_4(CO)_{12}$ based upon elemental analyses, but the insolubility of that compound has hindered its full structural characterization (the lack of solubility is similar to that of other structurally characterized cubane compounds).[3] Alternatively, that product could be a polymeric complex formed by opening of the Te–Te bond.[3] The mechanism by which **2** is converted into **3** is unclear, although a process involving oxidative addition of C–Br bonds to Te (or across the Te–Te bond) of **2** is plausible. What is noteworthy, regardless of the mechanism, is that CBr_4 has oxidized Te, formally in oxidation state 0, to Te^{IV}.

The carbon atom serves as a two-electron donor to the external $TeBr_4$ Lewis acid and also as a two-electron donor to the cluster's electron count; it is thus an isolobal replacement for the $Fe(CO)_3$ group. Work is in progress to determine whether the $TeBr_4$ group may be displaced to generate a reactive carbide cluster vertex.

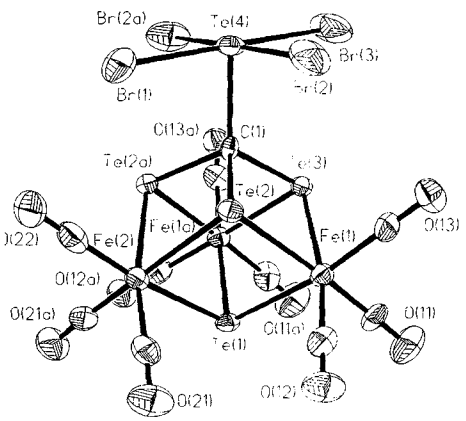

Figure 1. Structure of the cluster portion of **3**·2MeCN (thermal ellipsoids at 50% probability level) showing the atom labeling scheme. Selected bond lengths (Å) and angles (°): Te(1)–Fe(1) 2.614(1), Te(1)–Fe(2) 2.604(2), Te(2)–Fe(1) 2.608(1), Te(2)–Fe(2) 2.596(1), Te(2)–C(1) 2.186(7), Te(3)–Fe(1) 2.603(1), Te(3)–C(1) 2.179(10), Te(4)–C(1) 2.179(10), Te(4)–Br(1) 2.669(2), Te(4)–Br(2) 2.666(1), Te(4)–Br(3) 2.660(2); Fe(1)-Te(1)-Fe(2) 95.06(4), Fe(1)-Te(1)-Fe(1A) 98.14(6), Fe(1)-Te(2)-Fe(2) 95.41(5), Fe(1)-Te(2)-C(1) 87.3(3), Fe(2)-Te(2)-C(1) 90.0(2), Fe(1)-Te(3)-Fe(1A) 98.70(6), Fe(1)-Te(3)-C(1) 87.6(2), Br(1)-Te(4)-Br(2) 91.62(3), Br(1)-Te(4)-Br(3) 179.86(3), Br(1)-Te(4)-C(1) 84.1(3), Br(2)-Te(4)-Br(2A) 176.58(7), Br(2)-Te(4)-Br(3) 88.38(3), Br(2)-Te(4)-C(1) 89.63(3), Br(3)-Te(4)-C(1) 95.7(3), Te(1)-Fe(1)-Te(2) 83.80(4), Te(1)-Fe(1)-Te(3) 81.45(4), Te(2)-Fe(1)-Te(3) 81.98(4), Te(1)-Fe(2)-Te(2) 84.24(5), Te(2)-Fe(2)-Te(2A) 79.74(5), Te(2)-C(1)-Te(2A) 99.2(4), Te(2)-C(1)-Te(3) 103.1(3), Te(2)-C(1)-Te(4) 115.4(3), Te(3)-C(1)-Te(4) 118.1(5). Symmetry transformation to generate atoms labeled with a: $x, -y+3/2, z$.

Experimental

2: Compound **1** (1.02 g, 1.51 mmol) and CBr_4 (0.23 g, 0.77 mmol) were weighed together into a Schlenk flask under a nitrogen atmosphere. The solids were dissolved in MeCN (40 mL), and the solution stirred for 2 hours, after which it was filtered through diatomaceous earth. The product was then precipitated by addition of ether (250 mL) and isolated by filtration. It was thoroughly dried under vacuum to give pure **2**, which is soluble in THF, CH_2Cl_2, MeCN, Me_2CO, only slightly soluble in ether, and insoluble in hexanes. The compound is unstable in solution and decomposes over a period of several hours at room temperature. Yield: 0.78g, 96% (based on Te). IR (MeCN): $\tilde{\nu}_{CO}$ = 2061 (m), 2020 (vs), 1982 (ms, br) cm^{-1}. ^{13}C NMR ([D$_8$]THF, 295 K): δ = 210.6 (s, CO). MS (CI positive-ion MS): m/z (M^+) 537.

3: Compound **1** (1.01g, 1.50 mmol) and CBr_4 (0.99 g, 2.99 mmol) were weighed together into a Schlenk flask under a nitrogen atmosphere. The solids were dissolved in MeCN (40 mL), and the solution stirred for 2 hours, after which it was filtered through diatomaceous earth. The solution was allowed to stand for up to

three weeks at −20 °C. This procedure yielded a mixture of dark cubic crystals of **3**·2MeCN and a brick-red powder. The powder was partially removed by swirling the solution and decanting the fine powder suspension. This was repeated several times with fresh MeCN to give nearly pure **3**. The crystals were separated manually from the remainder of the powder to give analytically pure **3**·2 MeCN. Yield: 0.53 g (63% based on Te). Compound **3** is insoluble in most common organic solvents but does give unstable solutions in DMSO. IR (DMSO): $\tilde{\nu}_{CO}$ = 2067 (vs), 2027 (s), 1981 (m, sh) cm^{-1}. Analysis calcd for **3**·2MeCN: 6.1 mmol CO per gram. Found: 6.2 mmol CO per gram.

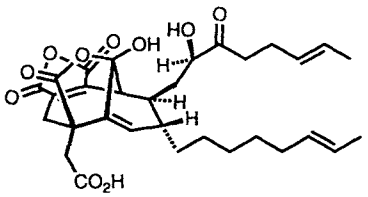
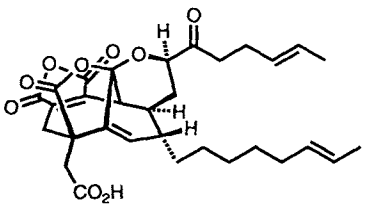
Synthesis of the Bicyclic Core of CP-225,917 and CP-263,114 by an Intramolecular Diels–Alder Reaction**

K. C. Nicolaou,* Michael W. Härter, Lee Boulton, and Bernd Jandeleit

CP-225,917 (**1**) and CP-263,114 (**2**) are two structurally unusual natural products that were recently isolated from an unidentified fungus by a Pfizer research group.[1, 2] These molecules—which contain bicyclo[4.3.1]dec-1(9),4-dien-10-one, maleic anhydride, and γ-lactol ring systems—are both novel and challenging to synthetic chemists. Their biological activity includes inhibition of squalene synthase[1, 3] and Ras farnesyl transferase.[1, 4] Therefore, they constitute intriguing lead compounds for the development of useful agents for medical intervention, particularly for lowering cholesterol levels[5] and for cancer chemotherapy.[5, 6] Their presumed biosynthesis[1, 2] and mode of action add to their appeal as synthetic targets, since they provide additional opportunities for contributions to biology and medicine. Here we report an approach to the novel bicyclic core of these naturally occurring substances based on an intramolecular Diels–Alder reaction.[7]



1 CP-225,917



2 CP-263,114

Inspection of the structures of **1** and **2** reveals that the basic carbon skeleton can be reduced to model system **3** (Scheme 1), which contains the key and challenging bicyclic core as well as anchor groups for elaborating the remaining functionalities and side chains. Applying a retro Diels–Alder reaction to **3** leads to the open-chain triene **4** as a potential precursor (Scheme 1). Since the absolute stereochemistry of **1** and **2** is not yet known, this issue was put aside for now. The construction of **4** was guided by the strategic bond disconnections shown in Scheme 1 and involved a nucleophilic acylation reaction[8] and a directed aldol condensation.[9]

Scheme 2 summarizes the synthesis of **3a**,**b** from 1,4-butanediol (**5**). Monosilylation of **5** with NaH and *tert*-butyldimethylsilyl chloride in THF proceeded in 90% yield to afford the corresponding hydroxysilyl ether **6**, which was smoothly oxidized to aldehyde **7** with SO_3·pyridine/DMSO/Et_3N. Alkylation of **7** via its *N*-cyclohexylimine derivative **8** with LDA and

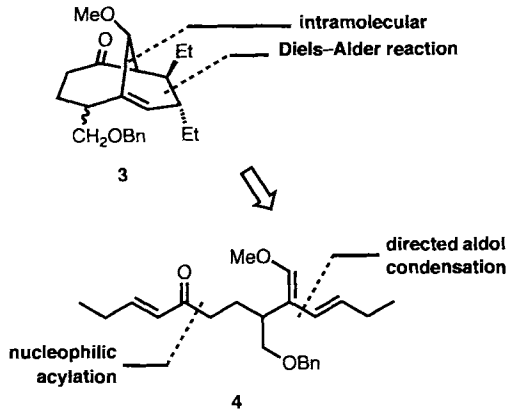

Scheme 1. Model compound **3** and the retrosynthetic analysis.

allyl bromide (**9**) furnished **10**, which was reduced with $NaBH_4$ in methanol to afford primary alcohol **11** (58% overall yield from **7**). After benzylation of **11**, the terminal olefin was cleaved with ozone/Ph_3P to give aldehyde **13** in 84% yield. Formation of the imine of **13** by reaction with cyclohexylamine in benzene under anhydrous conditions followed by anion generation, condensation with *n*-butanal (**15**), and acidic workup furnished aldehyde **16** in 74% overall yield as a mixture of isomers (*E*:*Z* ca. 1:1). Methylation of **16** with Me_2SO_4 in the presence of KH and HMPA proceeded smoothly to afford diene **17** in 96% yield as the single geometrical isomer. Desilylation of **17** with TBAF in aqueous THF led to alcohol **18**, which was converted to the corresponding iodide **19** with I_2/Ph_3P/imidazole in 78% yield. Finally, reaction of **19** with the lithio derivative of the TMS-protected cyanohydrine **20**,[4] followed by exposure to TBAF in aqueous THF led to triene **4** via **21** in 86% overall yield (see Table 1).

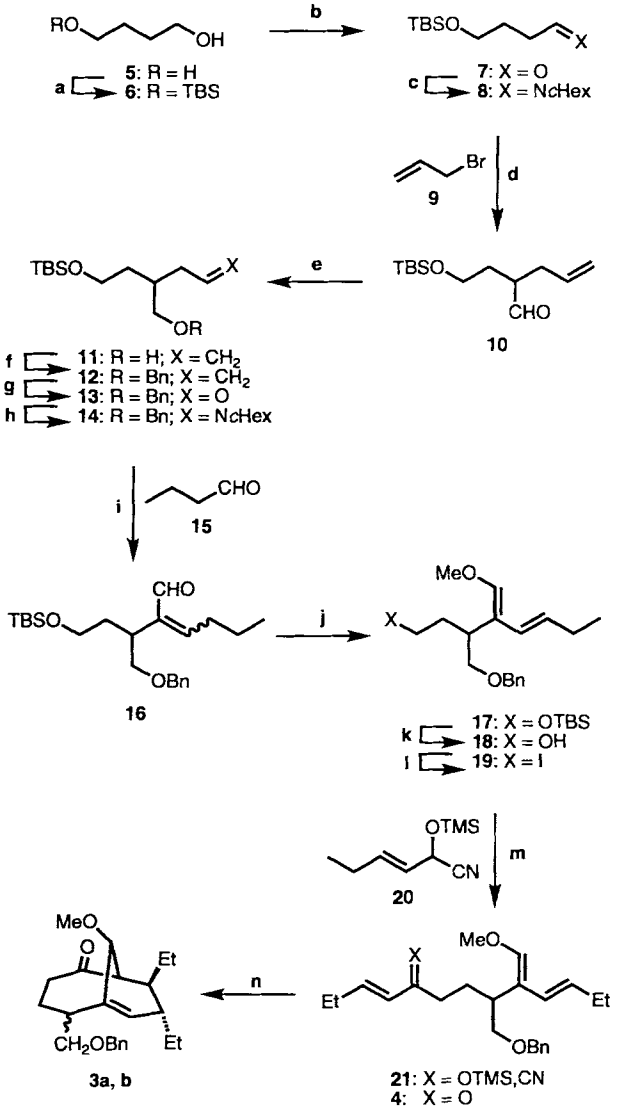
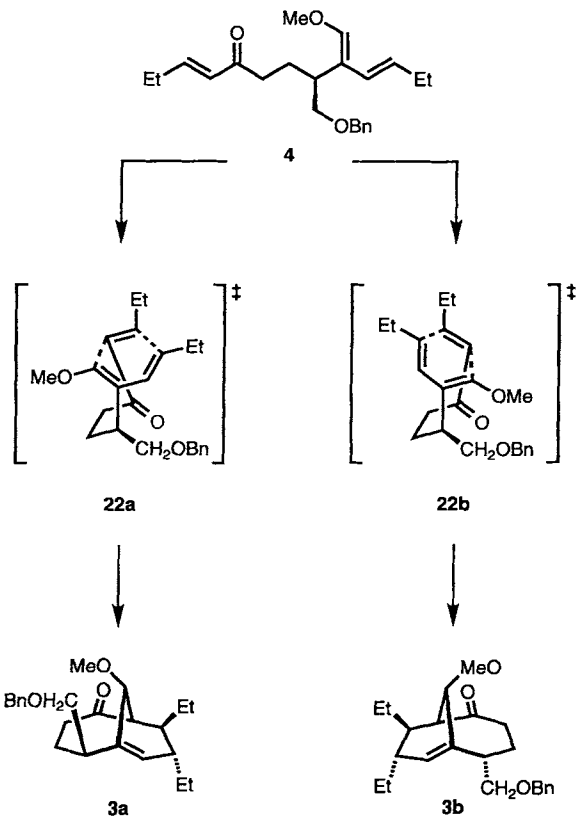


Scheme 2. Synthesis of the bicyclic core of CP-225,917 (**1**) and CP-263,114 (**2**). Reagents and reaction conditions: a) TBSCl (1.0 equiv), NaH (1.05 equiv, 60% dispersion in mineral oil, washed with hexane), THF, 0 °C, 2 h, 90%; b) SO_3·pyridine (3.0 equiv), DMSO (8.0 equiv), Et_3N (5.0 equiv), CH_2Cl_2, 0 °C, 3 h, 80%; c) cyclohexylamine (1.05 equiv), 4 Å molecular sieves, benzene, 22 °C, 15 h; d) LDA (1.0 equiv), THF, −5 °C, 0.5 h, then **9** (1.1 equiv) in THF, −78 → 22 °C, 15 h; e) $NaBH_4$ (2.0 equiv), MeOH, 22 °C, 10 min, 58% over 3 steps; f) BnBr (1.1 equiv), NaH (1.1 equiv, 60% dispersion in mineral oil, washed with hexane), nBu_4NI (0.25 equiv), DMF, 0 °C, 15 h, 88%; g) O_3, CH_2Cl_2, −78 °C, then excess Ph_3P, −78 → 22 °C, 15 h, 84%; h) cyclohexylamine (1.05 equiv), 4 Å molecular sieves, benzene, 22 °C, 15 h, 98%; i) LDA (1.05 equiv), THF, −5 °C, 0.5 h, then **15** (1.5 equiv) in THF, −78 → 22 °C, 4 h, then 6% oxalic acid in H_2O, 22 °C, 0.5 h, 74%; j) KH (2.0 equiv, 35% dispersion in mineral oil, washed with hexane), DME, 0 °C, 0.5 h, then Me_2SO_4 (2.0 equiv) in HMPA, 0 °C, 0.5 h, 96%; k) TBAF (1.5 equiv), THF/H_2O 95/5, 22 °C, 3 h, 96%; l) I_2 (1.2 equiv), Ph_3P (1.5 equiv), imidazole (2.0 equiv), CH_2Cl_2, 22 °C, 5 min, 78%; m) **20** (2.0 equiv), LiHMDS (2.0 equiv), THF, −78 °C, then immediately 0 °C, 30 min, TBAF (2.0 equiv), THF/H_2O 95/5, 0 °C, 5 min, 86%; n) Me_2AlCl (0.5 equiv), CH_2Cl_2, −10 °C, 40 min, 86%, two isomers in a ratio of about 3:1. TBSCl = *tert*-Butyldimethylsilyl chloride, THF = tetrahydrofuran, DMSO = dimethyl sulfoxide, LDA = lithium diisopropylamide, DMF = *N*,*N*-dimethylformamide, DME = 1,2-dimethoxyethane, HMPA = hexamethyl phosphoramide, TBAF = tetra-*n*-butylammonium fluoride, LiHMDS = lithium hexamethyldisilazide.

Although **4** was rather stable under thermal conditions (toluene, 110 °C, several hours), it smoothly underwent intramolecular Diels–Alder reaction in the presence of Me_2AlCl in CH_2Cl_2 at −10 °C. The resulting mixture of cycloadducts **3a, b** was chromatographically separated (silica gel, 6% acetone in hexane). The components **3a** and **3b** (R_f 0.25, 66% yield and R_f 0.28, 20% yield, stereochemistry unassigned) are presumably formed via the favored transition states **22a** and **22b**, respectively (Scheme 3). Variation of the substituents on the backbone of **4** and of the reaction conditions and catalyst is expected to improve the stereochemical outcome of the cycloaddition reaction, as desired for a total synthesis of the target molecules.



Scheme 3. Favored Diels–Alder transition states **22a** and **22b** leading to **3a** and **3b**, respectively (a racemic mixture was used; only one enantiomer is shown).

The chemistry described defines a possible strategy for the total synthesis of **1** and **2**, and opens the way for construction of simpler biological mimics of this class of compound for biological investigations.

Metal-Free Bacterial Haloperoxidases as Unusual Hydrolases: Activation of H_2O_2 by the Formation of Peracetic Acid**

Martin Picard, Jürgen Gross, Ellen Lübbert, Sabine Tölzer, Susanne Krauss, Karl-Heinz van Pée, and Albrecht Berkessel*

Dedicated to Professor Waldemar Adam on the occasion of his 60th birthday

Haloperoxidases catalyze the formation of hypohalites from hydrogen peroxide and chloride, bromide, or iodide [Eq. (1)].

$$H_2O_2 + Hal^- \underset{\text{Hal: I, Br, Cl}}{\overset{\text{haloperoxidase}}{\rightleftharpoons}} OHal^- + H_2O \qquad (1)$$

The electrophiles thus formed are able to halogenate suitable organic substrates[1–3] and can thus play an important role in the biosynthesis of halogenated natural products. Haloperoxidases can also catalyze the transfer of oxygen from hydrogen peroxide to organic substrates such as olefins or thioethers.[4] Therefore, this class of enzymes has been intensively studied with respect to preparative transformations, for example, the asymmetric epoxidation of olefins and sulfoxidation of thioethers.[4] Furthermore, hydrogen peroxide is a readily available, mild, and environmentally friendly terminal oxidant.

Most haloperoxidases require a cofactor to catalyze the redox reaction shown in Equation 1. The type of cofactor is used to classify these enzymes into heme-containing, vanadium-containing, and metal-free haloperoxidases. So far only the heme-containing haloperoxidases have proven suitable for preparative applications, for example the chloroperoxidase from the fungus *Caldariomyces fumago*.[4] Although good yields and enantioselectivities could be achieved with some substrates, for a wider application the limited stability of this enzyme (temperature, cosolvents, pH, H_2O_2) is a serious drawback.

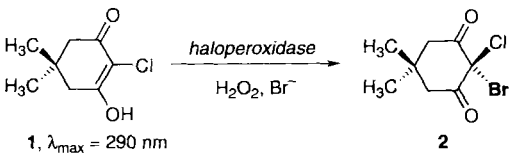
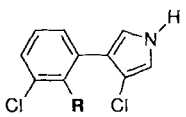
About ten years ago, van Pée et al. described the first metal-free haloperoxidases from bacteria: the chloroperoxidases from *Pseudomonas pyrrocinia* (CPO-P)[5] and from *Streptomyces aureofaciens* Tü24 (CPO-T).[6] The monochlorodimedone assay was used to trace the haloperoxidase activity [Eq. (2)]. In this



1, λ_{max} = 290 nm — **2** (2)

assay, the loss of extinction of the enolone band of the substrate 2-chlorodimedone (**1**) is followed spectrophotometrically at $\lambda = 290$ nm.[7]

In further publications, the halogenating activity of these enzymes was also shown for natural substrates, for example, in the course of the biosynthesis of the antimycotic pyrrolnitrin **4**.[5, 8] In the presence of hydrogen peroxide, CPO-P/CPO-T do not only catalyze the introduction of the two chlorine atoms, but also effect the oxidation of the amino group of the precursor **3** to the nitro group in pyrrolnitrin **4**.[9]

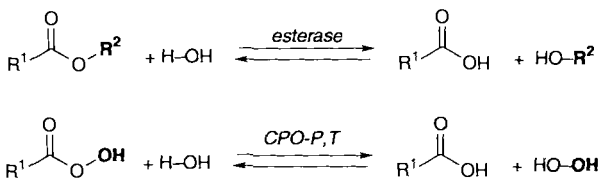


3: R = NH_2
4: R = NO_2

Since CPO-P und CPO-T were characterized as very stable enzymes, they appeared to be interesting potential catalysts for preparative applications.[5, 6] At the beginning of our investigations, the mechanisms of catalysis of heme- and vanadium-containing enzymes were relatively clear.[1-3] In contrast, the mode of action of the metal-free enzymes was absolutely unknown. One hypothesis involved the intermediary formation of a methionine sulfoxide in the enzyme's active site.[10] However, a recent X-ray structural analysis[11] on the bromoperoxidase A2 from *Streptomyces aureofaciens* (ATCC 10762) rendered this proposal unlikely. Instead, the X-ray crystal structure revealed the presence of the "catalytic triad" Ser-His-Asp in the enzyme's active site. The question arose how this catalytic triad, which normally catalyzes the hydrolysis of ester and amide bonds,[12] can activate hydrogen peroxide! Herein we describe first our attempts to use the chloroperoxidases from *Pseudomonas pyrrocinia* and *Streptomyces aureofaciens* (CPO-P, CPO-T) as catalysts for oxidation reactions and second our experiments aimed at the clarification of the mechanism of catalysis of the above enzymes. We present a mechanistic proposal that is able to explain all experimental data available so far.

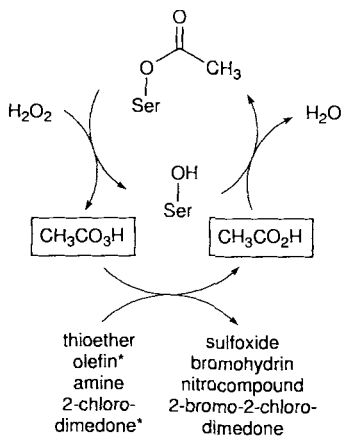
The following was observed when CPO-P und CPO-T were used as oxidation catalysts: a) Formation of halohydrins: In the presence of hydrogen peroxide and bromide, styrene, (*E*)-β-methylstyrene and 1,2-dihydronaphthalene were converted rapidly and quantitatively. By comparison with authentic samples, all reaction products were identified as the expected bromohydrins, for example 2-bromo-1-phenylethanol in the case of styrene. Quite remarkably, all bromohydrins were formed as racemic mixtures. When bromide was exchanged for chloride, chlorohydrins did not form analogously. b) Epoxidation of olefins: We found that neither CPO-P nor CPO-T catalyzed the epoxidation of olefins with H_2O_2. No reaction occurred with either electron-rich (styrene, 1,2-dihydronaphthalene) or electron-deficient olefins (*E*-crotonic or *E*-cinnamic acid, 2-cyclohexenone, 2-isopropylidenecyclopentanone). (c) Oxidation of thioethers: CPO-P und CPO-T catalyzed the quantitative conversion of thioethers such as methyl, ethyl, and octyl phenyl sulfide, to afford the corresponding sulfoxides. The sulfoxidations, too, afforded totally racemic products. d) Oxidation of aniline derivates: In the presence of hydrogen peroxide and CPO-P or CPO-T, 2-, 3- and 4-chloroaniline were smoothly converted into the corresponding nitrobenzenes.

The formation of racemic products does not suggest an oxidation within the enzyme's active site. On the contrary, these results point to a diffusible oxidizing entity. CPO-P and CPO-T are active only in acetate or propionate buffer, and not, for example, in phosphate buffer. The enzymatic activity is a function of the buffer concentration and shows saturation characteristics (not depicted). Thus, it seemed that the oxidation of halide does not take place in the active sites of CPO-P and CPO-T. Instead, an enzyme-catalyzed equilibration of hydrogen peroxide with acetate (propionate) affording peracetate (perpropionate) appeared much more likely. As mentioned above, the active site of the enzyme contains the catalytic triad of serine esterases. As shown in Scheme 1, the hydrolysis of an ester (top equation from left to right) closely resembles the reaction of a carboxylic acid with H_2O_2 (bottom reaction from right to left).



Scheme 1. Comparison of ester hydrolysis with the reaction of a carboxylic acid with H_2O_2.

According to this hypothesis, the peracid formed in very low stationary-state concentration oxidizes thioethers to sulfoxides and bromide to bromine, which accounts for the formation of halohydrins from olefins. Analogous to the mechanism of serine esterase catalyzed ester hydrolyses, the hydroxyl group of the "catalytic" serine would be acetylated during turnover (Scheme 2).[12] Indeed, the X-ray crystal structure of the haloperoxidase from *Streptomyces aureofaciens* (crystallized from acetate buffer) showed additional electron density in the vicinity of this hydroxyl group which was interpreted as an acetate residue.[11]



Scheme 2. Postulated mechanism of the catalysis by metal-free haloperoxidases. The conversion of substances indicated by an asterisk requires the presence of bromide.

The assumption of an enzyme-catalyzed formation of peracetic acid as the diffusible oxidizing entity is further supported by the following observations: a) Incubation of CPO-T with H_2O_2 in acetate buffer and subsequent ultrafiltration yielded a protein-free filtrate that gave a positive monochlorodimedone assay (Figure 1). b) All the oxidations (formation of halohydrins, sulfoxidation) that can be performed with H_2O_2 and CPO-P/CPO-T took place in just the same way when dilute peracetic acid was used. This is true for the peroxidase assay shown in Equation 2, too. It is well-known that peracids oxidize bromide to bromine,[13] and that the Br_2 transforms **1** into **2**

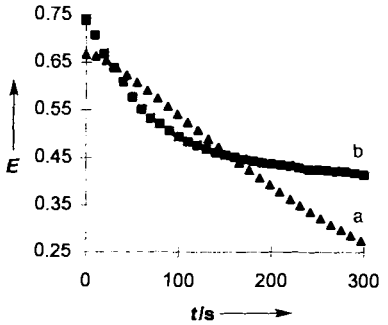

Figure 1. Monochlorodimedone assay in acetate buffer in the presence of NaBr with a) CPO-T and H_2O_2 and b) the protein-free ultrafiltrate obtained from the incubation of CPO-T with H_2O_2 in acetate buffer. E = extinction.

[Eq. (2)] and effects the formation of halohydrins from olefins in aqueous medium. c) Under the reacton conditions employed, dilute peracetic acid did not effect the epoxidation of olefins (see above). d) In the presence of H_2O_2/chloride, the enzymes CPO-P/CPO-T did not give a positive monochlorodimedone assay.[5,6] In the presence of peracetic acid and chloride, no positive assay was observed either. e) Phenylmethanesulfonyl fluoride (PMSF) is a well-known inhibitor for serine-proteases und -esterases. Its inhibitory activity results from the sulfonation of the serine-hydroxyl group in the active site.[14] PMSF also inhibits oxidation reactions catalyzed by CPO-P and CPO-T. As an example, the inhibition of CPO-T (monochlorodimedone assay, Eq. 2) as a function of time and acetate concentration is shown in Figure 2.

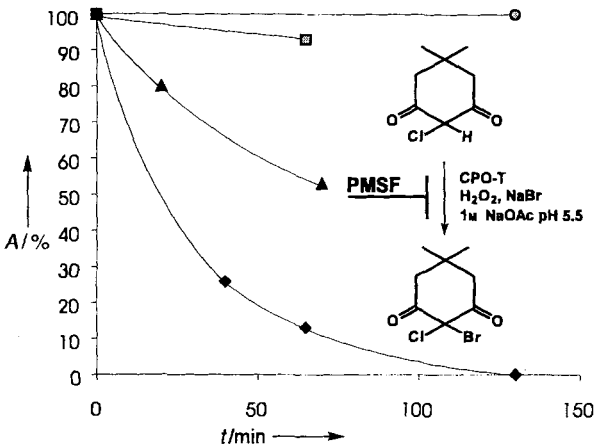

Figure 2. Time course of the inhibition of the oxidizing activity of CPO-T by PMSF in water and in sodium acetate buffer. o Control CPO-T/water, □ control CPO-T/buffer, • inhibition CPO-T/water, ▲ inhibition CPO-T/buffer; t = incubation time, A = relative activity.

Obviously, the irreversible inhibition by PMSF proceeded much faster in water than in acetate buffer.[15] This effect can easily be explained by the competition of acetate with PMSF in the reaction with the serine hydroxyl group in the enzyme's active site.

Until now, all attempts to prove the presence of peracetic acid in the equilibrium mixture by spectroscopic techniques were frustrated by its low equilibrium concentration relative to the much higher contents of water and acetate. With this in mind, we decided to prove the enzyme-catalyzed equilibration *starting from peracetic acid* (second Equation in Scheme 1, from left to right). Indeed, this approach proved successful: When an approximately 30 mM solution of peracetic acid in 1 M acetate buffer (pH 5.5) was acidified to pH = 1 and extracted with ether, the presence of peracetic acid in the extract could unambiguously be proven by high-resolution CI-MS. When CPO-T was added to the same solution of peracetic acid in acetate buffer, and the same extraction procedure was carried out, the HR-CI-MS of the extract did not show the presence of peracetic acid! As a control experiment, the equivalent amount of trypsin was added instead of CPO-T: No measurable decrease of the peracetic acid concentration took place within hours.

Our mechanistic hypothesis implies that the haloperoxidases CPO-P/CPO-T should have esterase activity as well. We confirmed this assumption with 4-nitrophenyl acetate as substrate: at 20 °C and pH 5.5, the ester was hydrolyzed rapidly, whereas no reaction occurred in the absence of the enzymes. The observed esterase activity is in agreement with the categorization of the (structurally characterized) bromoperoxidase from *Streptomyces* as an α/β-hydrolase.[11] Similar to the irreversible inhibition of the enzymatic activity by PMSF (see above), the hydrolysis of 4-nitrophenyl acetate in acetate buffers of higher concentration proceeds more slowly than at lower acetate concentrations: For example, changing from 0.05 M to 0.5 M decreased the rate of reaction to about one quarter. Clearly, the hydrolytic activity of CPO-P/CPO-T was also inhibited by PMSF.

If the catalytic triad of CPO-P and CPO-T catalyzes the equilibration between acetate/H_2O_2 and peracetic acid, other serine-esterases should be able to do the same.[16] We checked this assumption on chymotrypsin, trypsin, elastase, alkaline protease from *Streptomyces griseus* and acetylcholine esterase from *Torpedo californica*. Whereas the first four enzymes proved inactive in the monochlorodimedone assay [Eq. (2) and MS-experiment, see above], the acetylcholine esterase showed a catalytic activity comparable to that of CPO-T. However, the former enzyme was rapidly and irreversibly deactivated by H_2O_2.

Our investigations have shown that the oxidizing activity of the metal-free bacterial haloperoxidases CPO-P and CPO-T is in fact due to an unusual hydrolase activity, namely, the formation of peracetic acid from acetate and hydrogen peroxide (Schemes 1 and 2). Thus, we have introduced a novel enzymatic system (besides lipases[17]) for the in situ activation of hydrogen peroxide by peracid formation.

Experimental Section

General: Chloroperoxidase from *Streptomyces aureofaciens* Tü24 (CPO-T) was isolated from pHM621-containing *S. lividans*. CPO-P from *Pseudomonas pyrrocinia* was isolated from pHW321-containing *E. coli* [18,19]. Chymotrypsin, trypsin, elastase, and acetylcholine esterase from *Torpedo californica* were purchased from Sigma, and protease alkaline from ICN. *n*-Octyl phenyl sulfide and all sulfoxides were prepared according to literature procedures [20,21]. The identification of the reaction products was done by comparison with authentic samples.

Enzyme-catalyzed oxidations (typical experiments): Standard assay for haloperoxidase activity according to Hewson and Hager [7] with monochlorodimedone (44 μM), H_2O_2 (7.2 mM), NaBr (82 mM) in 1 M acetate buffer, pH 5.5, 25 °C (this reaction was also used for the serine-hydrolases stated in the text): The reaction was started by the addition of the enzyme and followed spectrophotometrically at λ = 290 nm. The analysis of the solution for low-molecular weight oxidant was done as follows: CPO-T and H_2O_2 were incubated in acetate buffer for 30 min, then the enzyme was removed by ultrafiltration (Centricon-10, *Amicon*). The filtrate (500 μL) was added to a solution (500 μL) of monochlorodimedone (88 μM) and NaBr (164 mM) in 1.0 M acetate buffer (pH 5.5). The reaction was followed spectrophotometrically. Formation of bromohydrins: 1 M sodium acetate buffer (3.0 mL, pH 4.0), 1,4-dioxane (0.5 mL), *tert*-butyl alcohol (0.5 mL), 1 M NaBr (1.0 mL), H_2O_2 (30%, 150 μL), and the olefin (100 μmol) were homogenized by sonication (10 s). The reaction was started by the addition of 4 u (determined by the monochlorodimedone assay) of CPO-P or CPO-T and performed at 50 °C (3 h). The reaction mixture was extracted with ether (5 mL, 60 s sonication), and the ether phase was analyzed by GC and GC/MS. Control experiments were carried out in the same way, but without the addition of enzyme. Epoxidation of olefins: As described under bromohydrin formation, but without addition of NaBr. Under these conditions, no transformation of the olefins was observed. *Oxidation of thioethers*: 1 M sodium acetate buffer (4.0 mL, pH 5.5), 1,4-dioxane (1.0 mL), H_2O_2 (150 μL, 30%) and the thioether (100 μmol) were homogenized by sonication (10 s). The reaction was started by the addition of 8 u (determined by the monochlorodimedone assay) CPO-P or CPO-T and carried out at 22 °C (2 h). The reaction mixture was extracted with ether (5 mL, 60 s ultrasound treatment), and the ether phase was analyzed by GC, GC/MS, or HPLC (*n*-octyl phenyl sulfide). Control experiments were carried

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3611-1198 $ 17.50+.50/0

out in the same way, but without the addition of enzyme. Oxidation of amines: 2-, 3-, or 4-chloroaniline (78 μM), H_2O_2 (44.4 μM), and 1 M sodium acetate buffer (pH 4.5). The reaction was started by the addition of 0.5 u (determined by the monochlorodimedone assay) CPO-P or CPO-T to 1 mL of the mixture. The reaction was carried out at 30 °C (3-chloroaniline: 30 min; 2-, 4-chloroaniline: 50 min). The products were identified by HPLC-coinjection.

Oxidations with peracetic acid: Under identical experimental conditions, peracetic acid was used instead of H_2O_2/enzyme, (200 μmol CH_3CO_3H instead of 150 μmol H_2O_2). In the monochlorodimedone assay, peracetic acid was used in a concentration of 72 μM (instead of 7200 μM H_2O_2).

Proof of the enzymatic transformation of peracetic acid by mass spectrometry: sector-field mass spectrometer Jeol JMS-700 MS, high-resolution CI-MS with isobutane as reactant gas, positive ion mode, resolution $R = 8000$, accumulation of 5–10 scans of the accelerating voltage (m/z 56–90, 8 s per cycle), quasi-molecular ion $[M+H]^+$ (calcd. for $C_2H_5O_3$: 77.0239, found: 77.0261), internal mass calibration with ions derived from isobutane and the solvent. Aliquots (2.5 mL) of a 37 mM solution of peracetic acid in 1 M sodium acetate buffer (pH 5.5) were a) incubated with 5.5 mg (ca. 50 u) CPO-T for 10 min at room temperature (RT), b) incubated with 5.5 mg trypsin for 1 h at RT, or c) kept at RT without the addition of enzyme. The solutions were then acidified with H_2SO_4 to pH 1 and extracted with ether (1 mL). The extracts were concentrated to approximately 50 μL in a stream of N_2 and introduced into the mass spectrometer through the reference inlet. Whereas peracetic acid was clearly present in approximately the same concentration in experiments (b) and (c), no peracetic acid could be detected by MS in the extract from (a). Furthermore, whereas the pungent smell of peracetic acid persisted in the experiments (b) and (c), this typical odor vanished immediately after the addition of enzyme in experiment (a).

Hydrolase activity (typical experiments): The enzymes were added to a solution of 0.1 μmol *p*-nitrophenylacetate in 2.0 mL 1 M sodium acetate buffer (pH 5.5) and 10 μL *tert*-butyl alcohol. The reaction was followed by the decrease of extinction at $\lambda = 317$ nm.

Inhibition experiments: In a typical experiment, 0.04 u CPO-T (determined by the monochlorodimedone assay) in 500 μL of water or sodium acetate buffer (pH 5.5, various concentrations) were incubated with a solution of PMSF (4 μmol) in *tert*-butyl alcohol (20 μL) at 50 °C. The remaining enzymatic activity was determined at various incubation times as described above.

Synthesis of Rotaxanes by Brief Melting of Wheel and Axle Components

Mirko Händel, Marcus Plevoets, Sven Gestermann, and Fritz Vögtle*

Dedicated to Professor Sigrid D. Peyerimhoff on the occasion of her 60th birthday

In 1995 we synthesized the first amide-type rotaxanes by forming the amide bond of the axle in the presence of the wheel.[1] The triphenylmethyl stoppers used were sterically demanding enough to prevent wheels of type **1**[2] from slipping off the axle. We have been searching for a way to thread such a macrocycle onto a preassembled axle by using a "slipping approach" analogous to that described previously for other types of rotaxanes.[3] In the course of this research we have synthesized amide-type rotaxanes **2** by simply melting the preassembled wheel and axle components for about one minute.

In order to synthesize amide rotaxanes in this way (Scheme 1), it is necessary to tune the size complementarity of stoppers and wheels. At high temperatures the wheel must be able to slip over the bulky stoppers onto the axle, whereas at low temperatures the barrier should be high enough to prevent the reverse process, thus resulting in stable mechanical bonding between wheel and axle. A synthesis in which wheels were slipped over triphenylmethyl stoppers did not appear promising to us, since even when such rotaxanes are heated to 100 °C in tetrachloroethane no disassembly into a wheel and axle is observed.[4] Hence in order to investigate a "slipping-on" process we synthesized axles **3** with smaller di-*tert*-butylphenyl stoppers, which according to space-filling models should pass through the cavities of wheels like **1** more readily.[5] Attempts to slip tetralactams **1** onto the *meta*-phenylene axle **3α** in high boiling solvents like tetrachloroethane were not successful: We recovered most of the starting materials **1a** and **3α**, but did not detect the rotaxane **2aα**.

Thus, it appeared reasonable not to work under solvent conditions any longer but to turn to experiments in the melt in order to increase the concentration and to achieve higher temperatures. Furthermore, instead of **3α** we employed the slightly longer axle **3β** in order to reduce the steric hindrance between the wheel and axle.[3b] The pulverized components **1a** and **3β** were melted down in a tube heated to 350 °C with a hot air

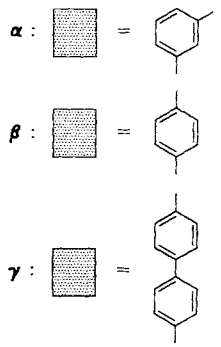

Scheme 1. Synthesis of amide rotaxanes **2** from preassembled wheel and axle components.

blower for one minute. Upon quenching the hot tube in cold water the melt instantly solidified. The desired rotaxane **2a**β was detected by mass spectrometry and thin layer chromatography; a sample of **2a**β synthesized by the traditional threading method was used as a reference.[2] The reaction products were not isolated because the slipping process was improved further by using **3**γ, an even longer axle containing a biphenyl unit. The rotaxane **2b**γ was isolated in 3% yield after melting the tetralactam cycle **1b** and this axle; more than 50% of the starting materials were recovered. The product **2b**γ was characterized by FAB mass spectrometry and ^{13}C and ^{1}H NMR spectroscopy; the ^{1}H NMR spectrum shows typical high-field shifts of the biphenyl signals from $\delta = 7.98$ and 8.23 in the free axle **3**γ to $\delta = 7.12$ and 7.55 in the rotaxane **2b**γ (Table 1).

Table 1. Physical and spectroscopic data of **2c**γ and **2b**γ.

The overall yield was improved by considering the following: If as we propose, the construction of the rotaxane involves a slipping process,[6] more rotaxane should be formed not only by using an elongated axle but also by enlarging the cavity of the wheel. However, the latter change must not be so great that the slipping off process is favored and the stability of the rotaxane is reduced. The cycle **1c** containing one sulfonamide unit appeared to be a suitable candidate,[7] because this wheel should possess a slightly larger cavity due to the fact that the C-S(O_2)-N bond lengths are slightly longer than the C-C(O)-N bond lengths in the tetralactam macrocyle **1b**. Indeed, rotaxane **2c**γ could be isolated in 8% yield. Surprisingly, **2c**γ disassembles (in DMF solution) into the starting materials (wheel and axle) within several days. Plots of the respective concentrations against time revealed that this reaction follows first-order kinetics as expected for reactions of this type: the half-life is about 80 h at room temperature.

Unlike the rotaxane **2c**γ, the (narrower) rotaxane **2b**γ undergoes no significant change when left to stand in DMF at room temperature for one week. However, after this sample had been heated to 50 °C for 24 h, a considerable portion (15%) of the wheel was found to have slipped off the axle. Besides the enlargement of the wheel by using methylene groups,[3a, b] it is also possible to fine tune the steric effects at the rotaxane/pseudorotaxane border by incorporating sulfonamide groups.[8]

Our results indicate that it should be possible to develop fast and simple melting syntheses for other[9] and new rotaxane types, for example, those without amide bonds. A comparison of rotaxanes prepared by using donor/acceptor complexes[3c] with other rotaxanes that are statistically synthezised by a slipping process[3a, b] could be used to determine the effective diameter of the wheel cavity and the effective size of the stoppers.[10] This could be useful for designing further rotaxane syntheses. Furthermore, it should be possible to adjust the mechanical barriers for the synthesis and disassembly (into wheel and axle) of rotaxanes by tuning the size complementarity of

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3611-1200 $ 17.50+.50/0

stoppers and wheels. This could be important for measuring the hydrogen-bonding strength between wheel and axle, and for the application of mechanical bonds in polymers,[11] in which a temperature-dependent change of the relationship between structure and property is desired.

Experimental Section

The typical procedure for the synthesis of rotaxanes by melting down wheel and axle is exemplified by the preparation of rotaxane **2cγ**: Wheel **1c** (200 mg, 0.2 mmol) was carefully mixed with axle **3γ** (123 mg, 0.2 mmol). Portions of 20–30 mg of this mixture were poured into glass tubes, melted by heating to 350 °C for a short time with a hot-air blower, and subsequently quenched in cold water [12]. The solidified melt was dissolved with a mixture of chloroform and methanol (5/1). The combined crude products were purified by column chromatography. M.p.: 240 °C; $R_f = 0.6$ (dichloromethane/ethyl acetate, 20/1, silica gel 40–63 μm); yield 25 mg (8%).

[4] We thank Dipl.-Chem. R. Jäger for providing substances and for fruitful discussions.

[5] We know from experience that Stuart/Briegleb models of large molecules are often too flexible, whereas CPK models are usually too rigid.

[6] It is conceivable that at high temperatures the rotaxane construction takes place by a bond cleavage (e.g. CO–NH) and subsequent threading and recombination. The fact that we could not find any catenanes refutes a mechanism of bond cleavages in the wheel, particularly since the number of the amide bonds (although sterically more hindered) is twice the number of those in the axle. Furthermore we could not find any thermal/pyrolytic cleavage/recombination of amide bonds in the literature apart from transamidations, which proceed by addition and elimination at 200 °C: H. R. Kricheldorf, E. Leppert, G. Schilling, *Makromol. Chem.* **1975**, *176*, 1629.

[7] S. Ottens-Hildebrandt, T. Schmidt, J. Harren, F. Vögtle, *Liebigs Ann.* **1995**, 1855.

[8] Pseudorotaxanes are compounds with a mechanical bond between wheel and axle in which the stopper groups are not sterically demanding enough to hold the wheel on the axle.

[12] We have also tried to synthesize these rotaxanes by slowly heating corresponding mixtures of wheel and axle in an oil bath (to 320 °C). This led to decreased yields of the corresponding rotaxanes and increased portions of by-products.

A Convenient Way to Novel Fe^{IV} Complexes with Mixed N/S/P Coordination Spheres and "Innocent" Ligands**

Dieter Sellmann,* Susanne Emig, Frank W. Heinemann, and Falk Knoch

Dedicated to Professor Walter Siebert on the occasion of his 60th birthday

Iron complexes with high-valent Fe^{IV} centers are discussed as reactive intermediates in numerous enzymatic processes that are catalyzed, for instance, by heme peroxidase, cytochrome P450, methane monooxygenase, ribonucleotide reductase, isopenicillin N synthase, and other enzymes.[1] The diversity of these reactions suggests that also a rich nonbiological Fe^{IV} chemistry should be accessible.[2] However, only a few ligands proved to be sufficiently oxidation resistant and able to stabilize Fe^{IV} centers. These ligands are mainly tetrapyrrolic ligands[3] and other N_4 donor ligands[2, 4] or ligands with sulfur donors.[5] We have now obtained Fe^{IV} complexes with a mixed N/S/P coordination sphere from readily accessible starting materials in a remarkably easy way. The one-pot reaction according to Equation (1) yields the Fe^{IV} complexes $[Fe^{IV}(PR_3)(L)]$ in yields of more than 85%.

Equation (1) shows that the oxidation $Fe^{II} \rightarrow Fe^{IV}$ is accompanied by a deprotonation of the amine functions in the LH_2^{2-} ligand and formation of the tetraanionic L^{4-} ligand [LH_4 = 1,2-ethanediamide-*N*,*N*′-bis(2-benzenethiol). The reaction initially

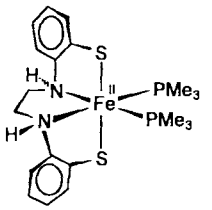
[**] Transition-Metal Complexes with Sulfur Ligands, Part 122. We thank the late Prof. G. Ritter and E. Giese for the Moessbauer measurements. Part 121: D. Sellmann, A. Hennige, *Angew. Chem.* **1997**, *109*, 270–271; *Angew. Chem. Int. Ed. Engl.* **1997**, *36*, 276–278.



2

yields suspensions of $[Fe^{II}(LH_2)]$ complexes. Upon contact with air, the color of these suspensions turns from brown into deep blue-green, and the respective Fe^{IV} complexes precipitate as red-violet microcrystals. The primary formation of Fe^{II} complexes was proved by isolation and characterization of $[Fe^{II}(PMe_3)_2(LH_2)]$ (**2**).[6]

The complexes resulting according to Equation (1) exhibit largely analogous properties. $[Fe^{IV}(PnPr_3)(L)]$ (**1**) has been characterized comprehensively, and is readily soluble in common solvents (THF, CH_2Cl_2) yielding deep blue-green solutions. The color is attributed to a strong band at 684 nm in the UV/Vis spectrum (CH_2Cl_2), which is assigned to a ligand-to-metal charge transfer (LMCT) transition. Complex **1** is paramagnetic ($\mu_{eff} = 2.76\ \mu_B$, 295 K, solid state). The magnetism is appropriate for two unpaired electrons and an "intermediate-spin" d^4 Fe^{IV} center with a $S = 1$ ground state[4b, c, 5a] and gives rise to paramagnetically shifted signals in the ^1H NMR spectrum of **1**. The ^1H NMR spectrum and likewise the $^{13}C\{^1H\}$ NMR spectrum of **1** indicate that **1** possesses C_s symmetry; thus, the molecular structure determined by X-ray structure analysis for the solid state (Figure 1) is retained in solution.[7]

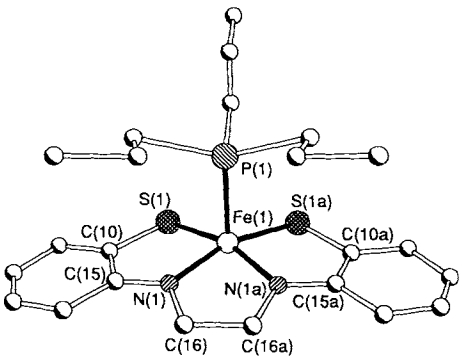


Figure 1. Molecular structure of **1** (H atoms omitted). Selected distances [pm]: Fe(1)–P(1) 220.2(3), Fe(1)–S(1) 218.5(2), Fe(1)–N(1) 184.0(6), N(1)–C(15) 134.8(8), N(1)–C(16) 147.2(7), C(16)–C(16a) 154.2(13), S(1)–C(10) 171.1(7).

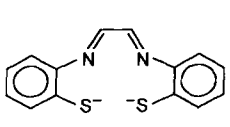
Complex **1** possesses crystallographically imposed C_S symmetry and a distorted tetragonal pyramidal Fe center. The Fe–N distances (184.0(6) pm) are similar to those in reported Fe^{IV} amido complexes (d(Fe–N) = 186–192 pm)[4b, c, g] and are distinctly shorter than in the related $[Fe^{II}(L^1)(L^2)(LH_2)]$ complexes ($L^1 = PR_3$; $L^2 = CO$, PR_3; d(Fe–N) = 206–209 pm).[6b] Because Fe–N distances longer than 200 pm correspond to Fe–N single bonds,[8] the distances in **1** indicate Fe–N multiple-bond character. Similar arguments hold for the Fe–S distances (218.5(2) pm). Comparably short Fe–S distances are found in square-pyramidal $[Fe^{IV}(PMe_3)(o\text{-}C_6H_4S_2)_2]$ (218.5 pm), which exhibits an average Fe–S bond order of 1.5.[5a] The angle sums of 360° around the N atoms corroborate the amide character of the N donors. In addition, the averaged N–C and C–C distances in the $N-C_2H_4-N$ bridge of the L^{4-} ligand exclude the formation of the Schiff base ligand glyoxal-bis(2-mercaptoanil)(2–) (L^{*2-}), which can potentially form from LH_2^{2-} by dehydrogenation.[9]



L^{*2-}

The zero-field Moessbauer spectra of **1** consist of one doublet at 298 K and 4.2 K (Table 1, Figure 2). The low isomer shifts δ and the large

Table 1. Moessbauer parameters of **1**.

T [K]	δ [mm s^{-1}] [a]	ΔE_Q [mm s^{-1}] [b]	Γ [mm s^{-1}] [c]
298.0	−0.0442(20)	3.0226(40)	0.2285(63)
4.2	0.0396(2)	3.1596(3)	0.2361(5)

[a] δ Isomer shift relative to α-iron at 298 K. [b] ΔE_Q Quadrupole splitting. [c] Γ Linewidth.

and the large quadrupole splitting ΔE_Q, which is nearly temperature independent, are consistent with a five-coordinate Fe^{IV} ($S = 1$) center in a tetragonal-pyramidal coordination.[2, 4a, b, g, 5a] The Moessbauer data rule out resonance structures such as **B** and **C** for the [Fe(L)] core of **1**, which suggest an intramolecular redox reaction between the Fe center and the ligand.

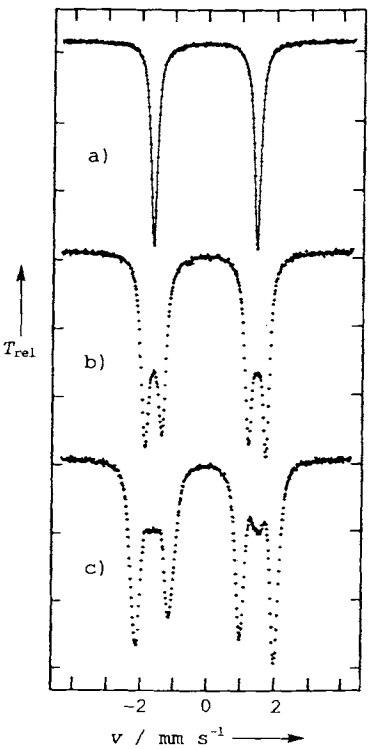


Figure 2. Moessbauer spectra of polycrystalline **1** at 4.2 K; a) in the zero-field, b) in an applied field of 2.5 T, and c) in an applied field of 5.0 T.

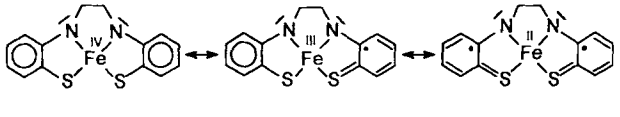
The resonance structures **B** and **C** would implicate that the L ligand is a dithiolene-type "noninnocent" ligand that, due to the $S = 1$ magnetism of **1**, coordinates either as a monoradical a Fe^{III} ($S = 1/2$) center or as a diradical a Fe^{II} ($S = 0$) center. However, Fe^{III} ($S = 1/2$) complexes and Fe^{II} ($S = 0$) complexes exhibit isomer shifts δ in the ranges of 0.16 to 0.38 mm s^{-1} and 0.18 to 0.51 mm s^{-1},[10] which is quite different from the isomer shift of $\delta = 0.0396(2)$ mm s^{-1} for **1**.



A B C

Finally, the high-valent character of the Fe center is also revealed by the cyclic voltammogram of **1** (Figure 3). It displays two quasireversible redox waves at +0.04 V and −0.86 V (CH_2Cl_2, vs. NHE). They are assigned to Fe^{IV}/Fe^{III} and Fe^{III}/Fe^{II} redox couples and appear at relatively positive potentials when compared with the corresponding redox waves of the related complex $[Fe^{IV}(PMe_3)(o\text{-}C_6H_4S_2)_2]$ (− 0.31 V, −1.07 V, vs. NHE; acetone).[5a]

The results show that novel Fe^{IV} complexes are readily accessible from simple starting materials. To the best of our knowledge, **1** and its analogues are the first Fe^{IV} complexes with a mixed N/S/P coordination sphere. Spectroscopic and structural data corroborate the results accumulated over the past years that 1,2-benzenedithiolate or the related *o*-aminothiophenolate behave as quite usual dithiolate or aminethiolate ligands.[5a, 9b] These ligands show no tendency to break up their aromatic

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3611-1202 $ 17.50+.50/0

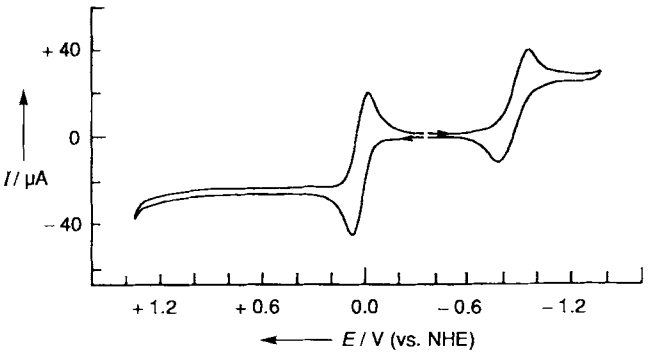


Figure 3. Cyclic voltammogram of **1** in CH_2Cl_2 (1×10^{-3} M; 1×10^{-1} M $NnBu_4PF_6$, $v = 0.02\ Vs^{-1}$).

systems by release of electrons from the benzene rings in order to become "dithiolene-type" ligands. The data rather indicate that the stabilization of Fe^{IV} centers by "hard" N and "soft" S donors is essentially due to π donation from the amide and thiolate functions and rule out "noninnocence" of the L^{4-} ligand, if something like "innocence" of ligands exists at all!

Experimental Section

All operations were carried out under N_2 at room temperature by using standard Schlenk techniques. Solvents were dried and distilled before use. LH_4 was prepared according to literature methods [11]. **1**: To a yellow solution of LH_4 (280 mg, 1 mmol) in THF (5 mL) and MeOH (25 mL) a 1 N solution of LiOMe (2 mL, 2 mmol) in MeOH, $FeCl_2 \cdot 4H_2O$ (200 mg, 1 mmol), and $PnPr_3$ (1 mL, 5 mmol) were added. The resulting brown suspension was stirred for 1.5 h in contact with air and for 2 h under N_2. The precipitated red-violet microcrystals of **1** were separated, washed with MeOH (50 mL), H_2O (30 mL), and Et_2O (20 mL), and dried in vacuo for 1 d. Yield: 440 mg (90%). Elemental analysis of $C_{23}H_{33}FeN_2PS_2$ (488.48): Calcd C 56.55, H 6.81, N 5.73, S 13.13; found C 56.32, H 6.78, N 5.72, S 12.97; ^1H NMR (269.6 MHz, $CDCl_3$): $\delta = 19.30$, 12.13 (2 s, 4 H; C_2H_4), 8.09, 5.87 (2 d, 4 H; C_6H_4), 7.01, 4.95 (2 t, 4 H; C_6H_4), 0.85–0.6 (m, 6 H; CH_2), 0.47 (t, 9 H; CH_3), (−0.4)–(−0.6) (m, 6 H; PCH_2); $^{13}C\{^1H\}$ NMR (67.70 MHz, CD_2Cl_2): $\delta = 157.6$, 140.1, 123.4, 122.9, 120.6, 115.6 (C_6H_4), 51.7 (C_2H_4), 25.4, 15.9, 15.1 ($P(C_3H_7)_3$); MS (FD, CH_2Cl_2): $m/z = 488$ [M^+]; UV/Vis (CH_2Cl_2): λ_{max} (ε) = 339 (10500), 373 (11000), 441 (9900), 684 (25800); $\mu_{eff} = 2.76\ \mu_B$ (295 K); CV (CH_2Cl_2, 295 K, 0.1 M $NnBu_4PF_6$; E vs. NHE [V]): $E^{0\prime}$ +0.04 ([**1**]^0/[**1**]$^-$), $E^{0\prime}$ −0.86 ([**1**]$^-$/[**1**]$^{2-}$).

[7] X-ray crystal structure analysis of **1** was made on a Siemens P4 four-circle diffractometer ($Mo_{K\alpha}$ radiation, $\lambda = 71.073$ pm, graphite monochromator, $T = 200$ K, ω scan, $3° \leq 2\theta \leq 54°$). The structure was solved by SHELXTL-PLUS and refined by using the program package SHELXL93. The non-hydrogen atoms were refined anisotropically. All hydrogen atoms were located in the difference Fourier map and refined with fixed isotropic displacement parameters. **1**: $C_{23}H_{33}FeN_2PS_2$, crystals from THF/MeOH, $0.50 \times 0.30 \times 0.20$ mm^3, orthorhombic, space group *Pnma*, $a = 826.6(3)$, $b = 1510.6(4)$, $c = 1926.3(5)$ pm, $V = 2.405(12)$ nm^3, $\rho_{calcd} = 1.35$ g cm^{-3}, $Z = 4$, $R_1 = 0.0613$, $wR_2 = 0.1336$, 3305 measured reflections, 2741 independent reflections, 771 observed reflections [$F > 4.0\sigma(F)$], 139 refined parameters. With greater accuracy the molecular structure of [Fe(PPh_3)(L)] was also determined by X-ray crystal structure analysis. The relevant parameters of [Fe(PPh_3)(L)] are nearly identical with those of **1**. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository numbers CSD-406037 (**1**) and CSD-406038 ([Fe(PPh_3)(L)]).

New Motifs in Aurophilic Self-Assembly: Synthesis and Structures of $[Au(NH{=}CMe_2)_2]CF_3SO_3$ and $[Au(C{\equiv}CSiMe_3)(CN\,tBu)]$**

José Vicente,* María-Teresa Chicote,* María-Dolores Abrisqueta, Rita Guerrero, and Peter G. Jones*

The triflate salt of the complex $[Au(NH_3)_2]^+$ prepared by Mingos et al.[1, 2] reacts very slowly with acetone to give the first iminogold(I) complex $[Au(NH{=}CMe_2)_2]CF_3SO_3$ (**1**, Scheme 1).

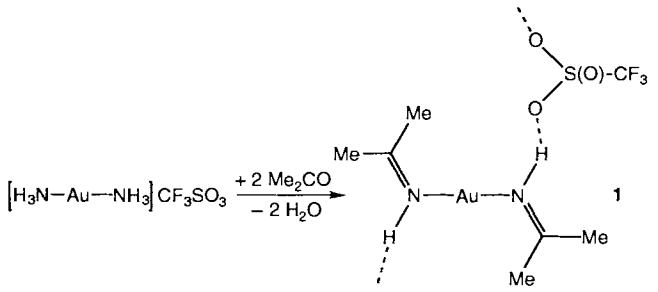

Scheme 1.

In contrast to N-substituted ketimines (RN=CR′R″), NH-ketimines are, with the exception of the diaryl derivatives, unstable compounds that cannot be prepared by simple methods. Thus, direct synthesis of NH-ketimines from ketones and ammonia requires an ammonium chloride catalyzed reaction at 50 bar pressure and 120 °C,[3a] or high temperature stabilization in the HZSM-5 zeolite supercage (up to 520 K).[3b] The difficulties associated with preparing and handling these compounds are such that few metal complexes containing acetimine, such as **1**, are known.[4] Recently, one tri- and one tetrametalated carbodiimide have been reported.[5]

The crystal structure of **1** (Figure 1)[6] contains two independent formula units but three independent gold atom positions

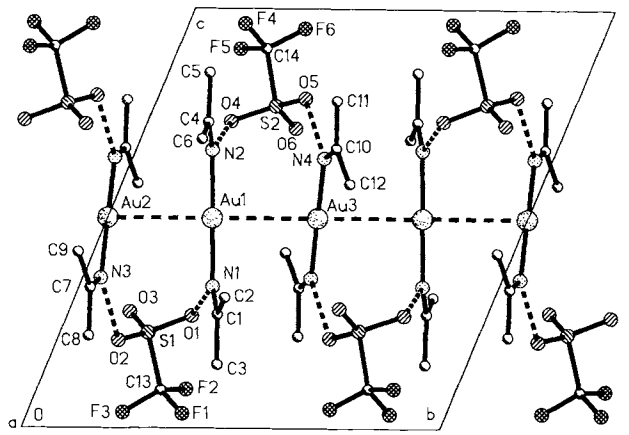

Figure 1. Crystal structure of **1** projected down the *x* axis. Only the asymmetric unit is numbered. H atoms are omitted for clarity. Secondary interactions (aurophilic and hydrogen bonds) are indicated by broken bonds. Selected bond lengths [Å] and angles [°]: Au1–N1 2.017(5), Au1–N2 2.018(2), Au1–Au2 3.1663(5), Au1–Au3 3.1705(5), N1–C1 1.285(8), N2-C4 1.271(7); N1-Au1-N2 178.7(2), Au2-Au1-Au3 153.346(10), other N-Au-N and Au-Au-Au 180° by symmetry.

(Au2 and Au3 lie on inversion centers). A polymeric chain of $[Au(NH{=}CMe_2)_2]^+$ ions is formed through short Au···Au contacts (3.1663(5), 3.1705(5) Å; Au2-Au1-Au3 153.346(10)°, other Au-Au-Au 180°); additionally, four independent hydrogen bonds are formed between the anions and the NH groups of the acetimine ligands (N···O 2.89–2.91 Å and N–H···O 158–167° (Scheme 1). Short Au···Au interactions occur in many Au^I complexes,[7] and the phenomenon is called aurophilicity, a term coined by Schmidbaur.[8] It has been estimated that aurophilic contacts are of similar energy to hydrogen bonds (ca. 7 kcal mol^{-1}).[9] As far as we are aware, there are only two complexes in which Au···Au contacts occur exclusively among cationic species, the pentameric complex $[Au(pyridine\text{-}2\text{-}thione)_2]ClO_4$[10] and the dimeric complex $[Au(NH_2tBu)(PMe_3)]BF_4$.[11] Complexes $[AuL_2][AuX_2]$ (L = pyridine, X = Cl, Br, I)[12] are tetrameric and show one cation–cation and two cation–anion interactions: $[AuX_2]^-$ $[AuL_2]^+ \cdots [AuL_2]^+ \cdots [AuX_2]^-$. Therefore, it seems that aurophilicity can only compensate for a limited number of cation–cation repulsions. In the case of **1**, the additional outer-sphere coordination of the anion through hydrogen bonds may be responsible for the attainment of polymerization. A similar situation occurs in $[Au(NH_3)_2]Br$,[1] in which NH···Br hydrogen bonds exist, but only pairs of mutually perpendicular cations are observed.

As expected, the self-assembly of neutral mononuclear complexes [AuXL] through Au···Au contacts occurs much more frequently than between charged complexes. Depending largely on the steric demand of the ligands, common arrangements are dimers,[13,14] polymeric single[13c,15] or double[16] chains, or bidimensional sheets.[13c,17] As far as we are aware, there exists only one oligomer unsupported by bridging groups, the tetramer of [AuCl(piperidine)], based on a square of gold atoms.[18] We have now synthesized a new member of this family of aurophilic oligomers, **2** (Figure 2), a tetramer that displays

$[Au(C{\equiv}CSiMe_3)(CN\,tBu)]$ **2**

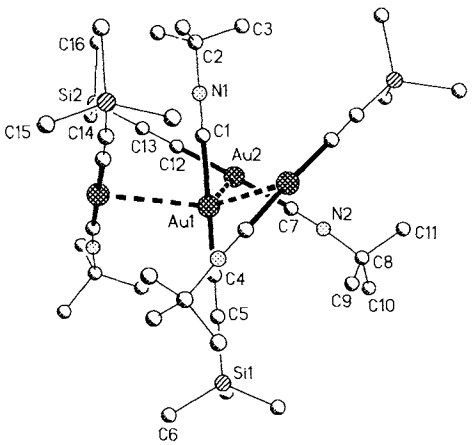

Figure 2. Crystal structure of **2**. Only the asymmetric unit is numbered. H atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Au1–C4 1.95(5), Au1–C1 1.98(5), Au1–Au2 3.1244(10), Au2–C7 1.96(3), Au2–C12 2.02(2), N1–C1 1.17(5), N2–C7 1.15(3), C4–C5 1.18(6), C12–C13 1.21(3); C4-Au1-C1 180.0, C7-Au2-C12 177.9(10), Au2-Au1-Au2′ 116.32(2).

a new aurophilic motif. The crystal structure of **2**[19] shows a central molecule (based on Au1) lying on a crystallographic threefold axis, with three others (based on the general Au2) connected to it by Au···Au contacts of 3.1244(10) Å. The central gold atom Au1 lies 0.61 Å out of the plane formed by the other three gold atoms. The repulsion between the bulky $SiMe_3$ and *t*Bu groups is avoided by rotation of the peripheral molecules by 121° (with respect to the central one; angle between the vectors C1···C4 and C7···C12). The isolated "aurophilic three-coordination" found at the central gold atom is also, we believe, unprecedented; in refererence [13c] an extended pseudo-hexagonal array is described, and in reference [16] a "ladder" in which two of the three contacts are very long at 3.72 Å. In all the other gold complexes in which three or more atoms are in contact, aurophilic one- or two-coordination is observed.

Mixed alkynyl–isocyanide complexes are of considerable interest because of their luminescent properties[14] and liquid crystal behavior.[20] Rigid-rod gold-containing polymers, which are formed by using diisocyanides and diacetylides, have recently

been reported.[21] These complexes were prepared by allowing $[Au(C{\equiv}CR)]_n$ to react with the isocyanide, whereas complex **2** is obtained by reacting $HC{\equiv}CSiMe_3$ with [AuCl(CN*t*Bu)] in NEt_3.[22]

Experimental Section

1: A solution of $[Au(NH_3)_2]CF_3SO_3$ (100 mg, 0.26 mmol) [2] in acetone (20 mL) was stirred for 95 h in the dark. The resulting solution was filtered through $MgSO_4$ and concentrated in vacuum to 2 mL. Diethyl ether (20 mL) was added to precipitate **1** (85 mg) as a white solid which was filtered off, washed with diethyl ether (5 mL), and air-dried. Yield: 85 mg, 70%. M.p.: 134 °C (decomp.). Λ_M (acetone, 4×10^{-4} mol L^{-1}) = 126 Ω^{-1} cm^2 mol^{-1}. IR $\tilde{\nu}$(NH) = 3215(s), $\tilde{\nu}$(C = N) = 1663, 1647 (s) cm^{-1}. ^1H NMR (200 MHz, [D$_6$]acetone): δ = 2.39 (d, Me, 3H, ^4J(H,H) = 1.2 Hz), 2.46 (s, Me, 3H), 10.28 (br, NH, 1H). Elemental analysis: calcd for $C_7H_{14}AuF_3N_2O_3S$: C 18.27, H 3.07, N 6.09, S 6.97; found: C 18.10, H 2.99, N 6.11, S 7.20.

2: $HC{\equiv}CSiMe_3$ (100 mg, 1.02 mmol) was added to a suspension of [AuCl(CN*t*Bu)] (308 mg, 0.976 mmol) in NEt_3 (5 mL), and the resulting mixture was stirred for 22 h. The suspension was filtered and washed with water (5 mL). The solid was dissolved in CH_2Cl_2 (10 mL) and the solution was filtered over $MgSO_4$. Partial evaporation of the solution (ca. 1 mL) and addition of *n*-hexane (20 mL) gave **2** as a white solid. Yield: 134.4 mg, 36%. M.p.: 110 °C. IR: $\tilde{\nu}$(C≡N) = 2230, $\tilde{\nu}$(C≡C) 2062 cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$): δ: 0.14 (s, Me_3Si, 9H), 1.53 (s, *t*Bu, 9H). $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): δ = 0.77 (s, Me_3Si), 29.73 (s, *t*Bu), 58.53 (s, CMe_3), 109.71 (s, Si-C≡), 140.00 (s, Au-*C*≡C), 147.02 (t, Au-*C*-N, ^1J(C,N) = 20 Hz). Elemental analysis: calcd for $C_{10}H_{18}AuNSi$: C 31.83, H 4.81, N 3.71; found: C 31.37, H 4.69, N 3.67.

[6] Crystal data: **1**, $C_7H_{14}AuF_3N_2O_3S$, M = 460.23, triclinic, space group $P\bar{1}$, a = 9.1365(8), b = 12.223(2), c = 13.8305(12) Å, α = 68.397(8), β = 75.006(6), γ = 89.263(10)°, V = 1393.6 Å^3, Z = 4, ρ_{calcd} = 2.193 Mg m^{-3}, $F(000)$ = 864, $\mu(Mo_{K\alpha})$ = 10.7 mm^{-1}, T = −100 °C. Data collection and reduction: A colorless needle (0.32 × 0.08 × 0.06 mm) was mounted in inert oil and transferred to the cold gas stream of a Siemens P4 diffractometer. A total of 5056 reflections were collected to 2θ = 50° by the ω-scan technique, of which 4809 were independent (R_{int} = 0.021). An absorption correction based on ψ scans gave transmission factors 0.79–0.89. Structure solution and refinement: The structure was solved by the heavy-atom method and refined anisotropically on F^2 (program SHELXL-93, G. M. Sheldrick, Universität Göttingen). Similarity restraints (168) were employed for displacement parameters of neighboring light atoms. Hydrogen atoms: rigid methyl groups, others riding. The final $wR(F^2)$ was 0.044 for all reflections, with a conventional $R(F)$ of 0.027; S = 0.84, max. $\Delta\rho$ = 0.63 e Å^{-3}, max. Δ/σ = 0.004. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100059. Electron Transfer Induced C–S Bond Cleavage in Rhenium and Technetium Thioether Complexes: Structural and Chemical Evidence for π Back-Donation to C–S σ* Orbitals**

Gregory E. D. Mullen, Michael J. Went, Sigrid Wocadlo, Anne K. Powell, and Philip J. Blower*

The ability of tertiary phosphane ligands to act as π-acceptor ligands is well-established. It has been suggested that a model in which P–C σ* orbitals are the primary contributor to the π-acceptor capacity of the phosphane ligand is a more useful description of the back-bonding than the model in which the phospho-

Kennard, *Chem. Design Autom. News* **1993**, *8*, 1 and 31–37.

rus d orbitals are the primary acceptor. This is supported by structural[1] and computational evidence.[2, 3] The analogy between tertiary phosphanes and thioethers suggests that thioethers too may act as π acceptors in transition metal complexes,[4] although the relative instability of thioether complexes has been an obstacle to substantive investigation of the bonding. At issue are whether thioethers possess significant π-acceptor properties, and whether C–S σ^* orbitals have a significant role in the description of the back-bonding, if it exists. The relative scarcity of suitable thioether complexes has in the past prevented experimental verification of theoretical calculations, but in the last decade a large series of homoleptic hexathioether complexes has become available with the macrocyclic ligand 1,4,7-trithiacyclononane (9S3).[5] This has led to an accumulation of spectroscopic evidence for π acidity of thioether ligands.[5] If C–S σ^* orbitals participate in this bonding structural manifestations would also be expected.

Here we describe structural trends in $[M(9S3)_2]^{n+}$ (where M are metals from Groups 7–12 in the first, second, and third rows of transition elements, and $n = 1-3$) complexes, which support the notion that C–S σ^* orbitals accept electron density from metal-based orbitals, leading to lengthening of C–S bonds. We also describe complexes in which this back-bonding induces complete C–S bond cleavage under mild conditions to release ethene.

Figure 1 shows the scatter in a plot of C–S bond lengths in the complexes $[M(9S3)_2]^{n+}$. Data from all published $[M(9S3)_2]^{n+}$ complex crystal structure determinations are included, except

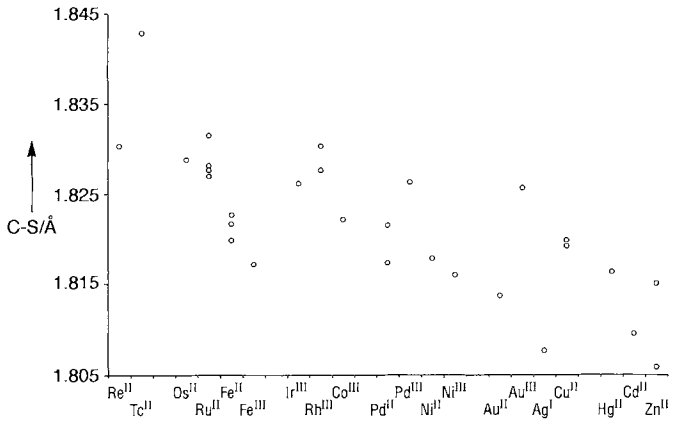

Figure 1. Scatter diagram relating mean C–S bond length for all C–S bonds within a complex with periodic group of the metal. Where a structure determination has been performed more than once, or more than one independent molecule appears in the unit cell, each molecule/structure determination is included separately.

for the Pt^{II} and Co^{II} complexes for which large (> 0.02 Å) estimated standard deviations (e.s.d.'s) in the C–S bond lengths and poor R-values are reported. All C–S bond distances included have e.s.d.'s of between 0.004 and 0.020 Å. A total of thirty structure determinations from the Cambridge Crystallographic Data Centre were included. There is a clear correlation between the mean C–S bond length of the coordinated thioether groups and the position in the periodic table. Within a given group, C–S distances in the first row metal complexes are usually the shortest. There is no clear correlation between C–S bond length and the overall charge on the complex. By assigning an idealized octahedral geometry to the complexes (Figure 2) and identifying the d orbitals as of $\sigma(d_{z^2}$ and $d_{x^2-y^2}$, that is, those with e_g symmetry) and $\pi(d_{xy}, d_{xz}, d_{yz}$, that is, those with t_{2g} symmetry) symmetry with respect to the M–S bonds, it is seen

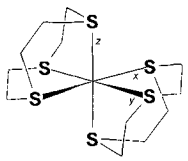

Figure 2. General idealized octahedral structure of $[M(9S3)_2]^{n+}$ complexes, showing assignment of Cartesian axes, which closely match the M–S bond axes.

that the t_{2g} orbitals are completely filled, and hence capable of back-donation, in all except the Tc^{II}, Re^{II}, and Fe^{III} complexes, which are d^5 systems. Thus far, π-back-bonding is therefore a plausible explanation of the trend in C–S bond lengths, because increasing d-orbital energy would be expected to increase back-donation (since within the d block of the periodic table the energy of the valence d orbitals increases as the group number decreases).

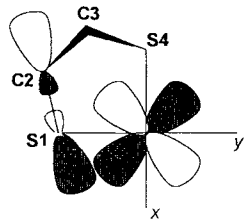

Figure 3. Diagram to show spatial overlap between in-plane C–S σ^* and metal t_{2g} orbitals. S1, C2, S4, and the metal atom are coplanar. C3 lies out of this plane, reducing effective overlap of the C3–S4 σ^* orbital with the metal d_{xy} orbital.

This view is only tenable if the orientation of the C–S bonds allows significant spatial overlap of the C–S σ^* orbital and the donor (t_{2g}) orbital on the metal. Figure 3, which is representative of all the chelate rings in all the complexes except those of Pd^{II} and Au^{III} (which have highly elongated axial metal–sulfur bonds), shows that this is indeed the case. Each thioether group, and each chelate ring, has one of its two C–S bonds lying in the plane of a filled t_{2g} orbital. The C–S σ^* orbital associated with this bond therefore overlaps spatially with a filled d orbital. The other C–S bond in the same thioether group cannot overlap as effectively with a filled d orbital. Inspection of all the complexes by molecular graphics methods (QUANTA, version 4.1[6]) indicates that *every* thioether group in *every* complex has one C–S bond in a suitable plane and one not. Moreover, for the metals towards the left hand side of the series (higher d-orbital energies), the average "in-plane" C–S bond is significantly longer than the average "out-of-plane" bond (Figure 4), consistent with greater occupancy of the C–S σ^* orbital of the in-plane bonds than of the out-of-plane bonds. The difference between the average in-plane and the average out-of-plane bond lengths diminishes as the d-orbital energy decreases towards the right of the series, as would be expected (Figure 4).

The trends observed suggest that the lower the group number of the metal, the longer the C–S bond, because d-orbital energy

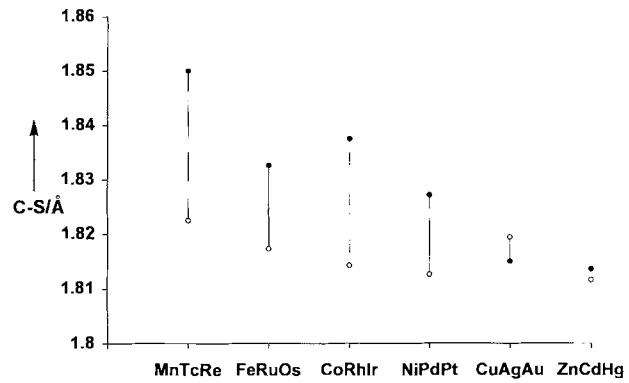

Figure 4. Correlation of average C–S bond lengths (in-plane ●, out-of-plane ○) with periodic group number. Data are averaged for all metals in the same group to give only one in-plane and one out-of-plane value per group.

increases. Indeed, the complexes of the metals from the lowest group number considered, Tc^{II} and Re^{II}, have C–S bonds that are amongst the longest, despite having one less electron in the t_{2g} orbitals than all other complexes in the series. As this trend continues, at some point C–S bond lengthening might be sufficient to cause complete cleavage of the bond. This is indeed observed: reduction of yellow $[Re(9S3)_2]^{2+}$ [7] in water with ascorbic acid, at room temperature, immediately induces cleavage of two C–S bonds of one 9S3 ligand to give ethene and the yellow-brown rhenium(III) dithiolate complex $[Re(9S3)(SCH_2CH_2SCH_2CH_2S)]^+$ in 90% yield of the isolated BF_4 salt [Eq. (a)]. The structure of the product has been determined by X-ray crystallography[8] and is shown in Figure 5 together with pertinent bond lengths and angles. The structural dimensions indicate nearly ideal octahedral coordination, with very little change relative to $[Re(9S3)_2]^{2+}$ except for the loss of ethene.

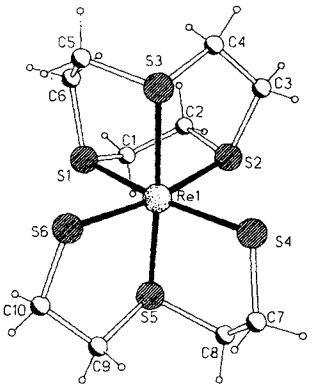

Figure 5. Structure of $[Re(9S3)(SCH_2CH_2SCH_2CH_2S)]^+$. Pertinent bond lengths (Å): Re–S1 2.436(2); Re–S2 2.463(2); Re–S3 2.393(2); Re–S4 2.256(2); Re–S5 2.346(2); Re–S6 2.272(2); S1–C1 1.822(8); S1–C6 1.829(9); S2–C2 1.819(9); S2–C3 1.818(9); S3–C4 1.847(9); S3–C5 1.830(8).

$$[Re(9S3)_2]^{2+} + e^- \longrightarrow \text{"}[Re(9S3)_2]^{+}\text{"} \longrightarrow [Re(9S3)(SCH_2CH_2SCH_2CH_2S)]^+ + C_2H_4 \quad (a)$$

The ethene was collected quantitatively and identified by gas chromatography/mass spectrometry. We have also shown that the analogous yellow technetium complex $[Tc(9S3)_2]^{2+}$ [9] behaves similarly, giving the pink complex $[Tc(9S3)(SCH_2CH_2SCH_2CH_2S)]^+$. That the C–S cleavage is simply the consequence of electron transfer to $[M(9S3)_2]^{2+}$, and not a more complex reaction involving ascorbic acid specifically, was demonstrated when the same products were isolated from the reaction of the rhenium complex with various other reducing agents including metallic zinc and chromium (in the case of rhenium) or stannous chloride (in the case of technetium). Similarly, if $[Re(9S3)_2]^{2+}$ is reduced electrochemically at a platinum electrode, bubbles of ethene can be seen to evolve at the electrode surface. A search for ethene production by similar ascorbate treatment of 9S3 complexes containing metals further to the right in the d-block (Rh^{III}, Fe^{II}) failed to find ethene. It thus appears that addition of the sixth electron to the t_{2g} orbitals causes the back-donation to become so strong that occupancy of the C–S σ^* orbital is enough to cancel the C–S bond and release ethene, provided the t_{2g} orbitals have high enough energy. Fast-atom-bombardment (FAB) mass spectroscopy indicates that further loss of ethene molecules from $[Re(9S3)(SCH_2CH_2SCH_2CH_2S)]^+$ occurs in the spectrometer: peaks appear at 519 (M^+, 100%), 491 ($M^+ - C_2H_4$), 463 ($M^+ - 2(C_2H_4)$), 435 ($M^+ - 3(C_2H_4)$), 403 ($M^+ - 3(C_2H_4) - S$), and 375 ($M^+ - 4(C_2H_4) - S$). The precursor complex $[Re(9S3)_2]^{2+}$ also undergoes serial losses of ethene in the FAB mass spectrometer.

The combined structural and chemical patterns described here provide compelling experimental evidence to support the computational arguments not only that the thioether ligand acts as a π-acceptor ligand in thioether complexes (especially where the d orbitals of the metal have relatively high energy) but also that the ligand π-acceptor orbitals have considerable C–S σ^* character and can accept sufficient electron density to achieve complete C–S bond cleavage.

Experimental Section

Structural parameters were obtained from the Cambridge Crystallographic Data Centre. To identify in-plane and out-of-plane C–S bonds, the pictures of the structures were assembled and studied on computer (Iris Indigo^2 workstation, Silicon Graphics).

Synthesis: To a solution of $[Re(9S3)_2][BF_4]_2$ (200 mg, 0.27 mmol) in water (5 mL) was added L-ascorbic acid (80 mg, 0.45 mmol). After stirring for 2 h the red-brown solid was collected and dried in vacuo. Recrystallization from water gave $[Re(9S3)(SCH_2CH_2SCH_2CH_2S)][BF_4]$ (140 mg, 86%) in the form of crystals suitable for X-ray analysis. Elemental analysis calcd: C 31.7, H 5.3; found: C 31.6, H 5.2.

Highly Enantioselective Reduction with Novel, Bridged NADH Models**

Nobuhiro Kanomata* and Tadashi Nakata

An L-lactate dehydrogenase that requires the coenzyme NADH catalyzes enantioselective reduction of pyruvate to L-lactate in anaerobic glycolysis. The enzymatic environment in this reaction fulfills the most important factors for asymmetric

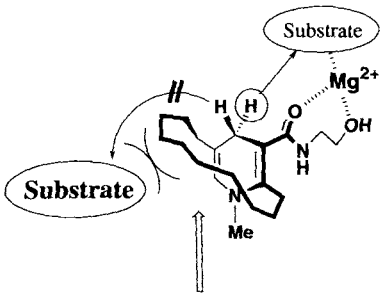
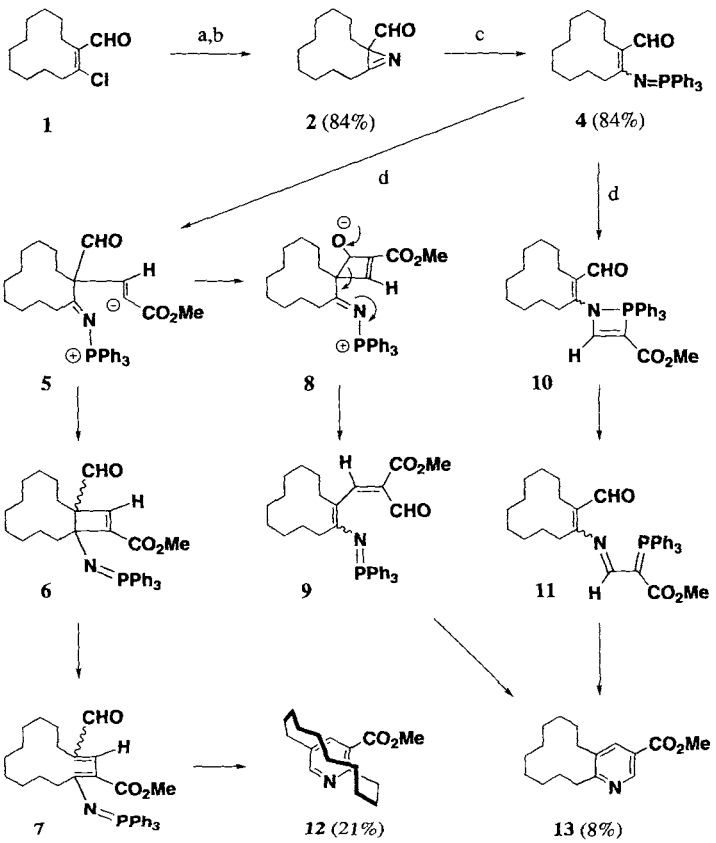
induction: stereoselective transfer of one of the diastereotopic hydrogen atoms in NADH to achiral substrates and controlled orientation of substrate approach (*re*- or *si*-face selectivity for the substrates). Many organic and bioorganic chemists have been challenged to mimic this biochemical reaction with various NADH models[1–7] that aid in reducing pyruvate analogs with high enantioselectivity. Interpretation of the enzymatic function in asymmetric reduction with coenzyme NADH led us to design novel, bridged NADH models[8] with an [*n*](2,5)pyridinophane (parapyridinophane) skeleton[9] as promising candidates for recyclable compounds that induce high enantioselectivity. The oligomethylene chain bridging the 2- and 5-positions of a dihydronicotinoyl ring would behave as an "enzyme wall" that allows the substrates to approach from the opposite side exclusively (Scheme 1). We describe here the syntheses of homochiral, bridged NADH models and their outstanding ability to reduce methyl benzoylformate, an analog of pyruvic acid, with high enantioselectivity.



Scheme 1. Protection of one side of the dihydronicotinoyl ring in bridged NADH model compounds by the oligomethylene bridge.

The synthesis of the bridged nicotinate **12**, a key synthetic intermediate toward NADH models **16**, is outlined in Scheme 2. *cis*-2-Chlorocyclododecene-1-carboxaldehyde (**1**)[10] was treated with sodium azide and a catalytic amount of lithium chloride to give azirine **2**[11] and *trans*-2-azidocyclododecene-1-carboxaldehyde (**3**)[12] in a 61:39 ratio.[13] Subsequent irradiation of the mixture in chloroform resulted in conversion of **3** into **2** (84% yield based on **1**). The thermal ring-opening reaction of **2** with triphenylphosphane proceeded in toluene at reflux to give the iminophosphorane **4**[14] in 84% yield. The ^{1}H NMR spectrum of **4** shows that it is a mixture of *cis* and *trans* isomers in a ratio of about 1:3, based on their aldehyde signals at $\delta = 10.66$ (0.25 H) and 9.87 (0.75 H), respectively.[15]



Scheme 2. Synthesis of nicotinates **12** and **13**. a) NaN_3, LiCl (cat.), H_2O, THF, RT, 5 h; b) *hν* (Pyrex), $CHCl_3$, RT, 8 h; c) PPh_3, toluene, Δ, 3 h; d) methyl propiolate (10 equiv), toluene, 140 °C, 12 h.

Methyl [10](2,5)pyridinophane-3-carboxylate (**12**) was synthesized from **4** and methyl propiolate (10 equivalents) in toluene at 140 °C. The desired product was obtained in 21% yield along with its *ortho*-bridged isomer **13** (8%). The structures of these compounds were deduced by ^{1}H and ^{13}C NMR and mass spectroscopy (see Table 1). The ^{1}H NMR spectrum of **12** shows that one of oligomethylene protons ($\delta = 0.13$) is located in a shielded area above the pyridine ring. Furthermore, all the bridge protons appear as independent signals, in accordance with a nonsymmetric structure. This indicates that **12** has a parapyridinophane skeleton with no flipping (jump-rope rotation) of the oligomethylene bridge on the NMR time scale. All other spectroscopic data agree with the proposed structure of **12**. As for **13**, geminal methylene protons of the oligomethylene bridge afford identical chemical shifts due to the symmetrical structure, which is in contrast to **12**.

The postulated pathways for this novel pyridine-formation reaction are also depicted in Scheme 2. Enamine-type addition of **4** to the β position of methyl propiolate provided intermediate **5**; intramolecular addition on the C=N and C=O bonds produced cyclobutene intermediates **6** and **8**, respectively. Spontaneous ring opening of **6** and **8** generated (vinylimino)phosphoranes **7** and **9**, which underwent intramolecular aza-Wittig reactions to give pyridines **12** and **13**. Formation of a portion of **13** can also be explained by initial cycloaddition of methyl propiolate to the N=P bond of **4** to give **10**. Subsequent cycloreversion of **10** and intramolecular Wittig reaction of **11** afforded **13**. Similar pyridine formation occurred in the reaction of **4** with dimethyl acetylenedicarboxylate (2 equivalents) to give both isomers of *ortho*-bridged 3,4- and 2,3-pyridinedicarboxylates (5% and 14%, respectively) in addition to [10](2,5)pyridinophane-3,4-dicarboxylate (14%). Formation of the two *ortho*-bridged nicotinates suggests that there are also two independent routes from **4** to **13**.

Conversion of **12** into the NADH models **16** was accomplished by transformation of the ester to an amide followed by *N*-alkylation and selective reduction of the pyridinium rings (Scheme 3). Hydrolysis of **12** with lithium hydroxide afforded the corresponding nicotinic acid (81%), and the amide formation reaction with (*S*)-valinol gave diastereomeric nicotinamides **14**, which were separated to give (*S,S*)-**14** and (*R,S*)-**14** in 48% yield each. Once purified these compounds are stable enough at room temperature that no flipping of the oligomethylene bridge occurs. This is in contrast to 2,8-dithia[10](2,5)pyridinophane,[9d] which undergoes racemization. Thermal interconversion between (*S,S*)- and (*R,S*)-**14** is observed in toluene at reflux and reaches equilibrium after 8 h to give a nearly 1:1 mixture. This phenomenon is remarkably useful for the selective preparation of homochiral **14**, since repeated "separation and interconversion" could result in either (*S,S*)- or (*R,S*)-**14**.

The structure of (*S,S*)-**14** was unequivocally solved by X-ray crystallographic analysis of colorless plates obtained by recrystallization from ethyl acetate (Figure 1).[16] The interesting feature of the structure is that the thermal vibration of the

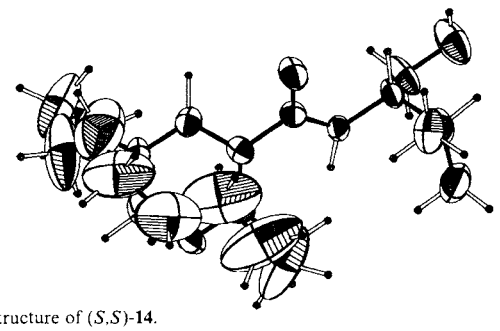

Figure 1. Crystal structure of (*S*,*S*)-**14**.

oligomethylene bridge is more dynamic than that of the pyridine and amide moieties. This result agrees with our design that the oligomethylene bridge would function as the bulky, shielding wall against substrate approach.

N-Alkylation of (*S*,*S*)- and (*R*,*S*)-**14** with methyl iodide afforded the corresponding *N*-methylpyridinium iodides (*S*,*S*)- and (*R*,*S*)-**15a** in quantitative yields. Regioselective 1,4-reduction of **15** by the biphasic reaction with aqueous sodium dithionite in dichloromethane resulted in the formation of (*S*,*S*)- and (*R*,*S*)-**16**.[17]

The bridged NADH models **16** were found to effect an excellent level of biomimetic reduction. The reaction of **16** with methyl benzoylformate was carried out in the presence of magnesium perchlorate in acetonitrile (Table 2). Stirring the reac-

Table 2. Reaction of methyl benzoylformate with **16** [a].

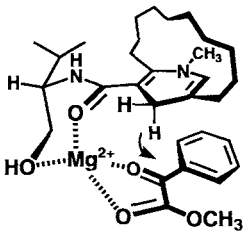
[a] Reaction conditions: 1.0 equiv **16**, 0.9 equiv methyl benzoylformate, 1.0 equiv $Mg(ClO_4)_2$, MeCN. [b] The enantiomeric excess was determined chromatographically with a Chiralcel OJ HPLC column (Daicel Chemical Technologies).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3611-1209 $ 17.50+.50/0

tion mixture for 5 days at room temperature in the dark resulted in the desired hydrogen transfer from (*S,S*)-**16** to methyl benzoylformate, which occurred enantioselectively to afford (*R*)-methyl mandelate with 99% *ee* (64% yield) and the corresponding homochiral N-methylpyridinium perchlorate (*S,S*)-**15b** (66% yield; Table 2, entry 1). It is noteworthy that the rate of the reaction raised remarkably with increasing reaction temperature without significant decrease of enantioselectivity. The reactions were complete within 24 h at 50 °C and within 6 h at 75 °C to give (*R*)-methyl mandelate with 99% *ee* and 98% *ee*, respectively (entries 2 and 3).



Scheme 4. Proposed transition state for the reduction of methyl benzoylformate with (*S,S*)-**16** in the presence of Mg^{2+}.

The estimated transition state for the asymmetric reduction with (*S,S*)-**16** is illustrated in Scheme 4. The ternary complex[18] in which magnesium perchlorate chelates to methyl benzoylformate beneath the bridged NADH model, since the top side of the model is blocked by the oligomethylene chain, rationalizes the enantioselectivity. The reactions of bridged NADH models proceeded stereospecifically. Reduction with (*R,S*)-**16** resulted in the formation of (*S*)-methyl mandelate with 97% *ee* at room temperature and 98% *ee* at 75 °C (64% and 63% yields, respectively; entries 4 and 5). Inoue et al.,[5a] Vekemans et al.,[2b] and Combret et al.[3b] studied the temperature effect of their NADH-model reactions and reported more or less decreased enantioselectivity with higher temperatures. The NADH model without a chelating group reported by Vekemans et al. reduced benzoylformate to mandelate in 95% optical yield at −25 °C, which dropped to 66% at 25 °C. Therefore, the chelating group derived from (*S*)-valinol in **16** apparently assists in stabilizing the ternary complex even at higher temperatures, as is reflected in the unique temperature independency of the enantioselectivity.

For reactions with NADH models with chiral amide moieties, the enantioselectivity of the asymmetric reduction is considerably dependent on the absolute configuration of the amide groups.[1a, 3, 4] Davies et al. reported NADH models with both a chiral amide group and a chiral ferocenyl group designed for selective shielding of their dihydropyridine rings.[4] However, there seems to be both matched and mismatched combinations between the two auxiliary groups, and, although the matched NADH models gave mandelate with 97–98% *ee*, the mismatched ones only gave 15–16% *ee*. On the other hand, in the case of **16** both diastereomers induced high enantioselectivity, which is strictly subject to the absolute structure of the solid parapyridinophane moieties. Therefore, the amide group derived from (*S*)-valinol does not behave as a "chiral auxiliary group" but simply as a "tight chelating group", and the absolute configuration has nothing to do with the selectivity. The salts **15b**, recovered by chromatography on silica gel, could be recycled to produce **16**, since the bridged NAD^+/NADH model system retains its plane chirality throughout the redox reaction. Consequently, the bridged NADH models designed from enzymatic environment successfully controlled both the direction and the orientation of substrate approach to induce high enantioselectivity in the biomimetic reactions.

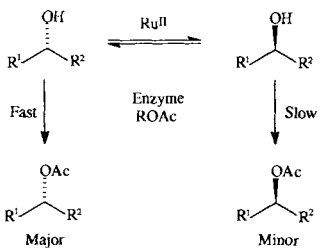
Enzymatic Resolution of Alcohols Coupled with Ruthenium-Catalyzed Racemization of the Substrate Alcohol**

Anna L. E. Larsson, B. Anders Persson, and Jan-E. Bäckvall*

Dedicated to Professor Henri B. Kagan

The resolution of racemic compounds by enzyme-catalyzed reactions has become a powerful tool in organic synthesis.[1, 2] In particular, processes for hydrolysis of esters and acylation of alcohols have been successfully employed. One limitation with classical enzymatic resolution is that the reactions are associated with a maximum yield of 50% based on the racemate. In order to overcome this limitation the substrate could be continuously racemized during the resolution process; this would lead to efficient use of all of the starting material. This approach has attracted some interest recently, and a few applications have been reported.[2–6]

During our studies on ruthenium-catalyzed hydrogen transfer reactions we observed that alcohols undergo fast isomerization at the α-carbon leading to racemization or epimerization.[7–9] Attempts to use chiral ligands in order to obtain ruthenium-catalyzed asymmetric transfer hydrogenations were hampered by the racemization of the product,[10] and this has also been observed by others using the same catalytic system.[11] In connection with previous enzyme studies in our group[12] we decided to investigate enzymatic resolution of racemic alcohol mixtures coupled with the above-mentioned racemization. In this communication we report on the successful enzymatic resolution of alcohols under substrate-racemizing conditions (second-order asymmetric transformation[13]) (Scheme 1).



Scheme 1. Enzymatic resolution under substrate-racemizing conditions.

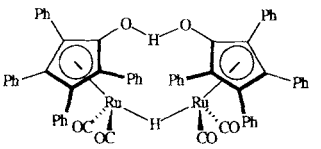
[**] We would like to thank Dr. Ratan. L. Chowdhury who performed the initial studies on the racemization of alcohols. *Candida antarctica* component B Lipase (Novozym 435) was a gift from Novo Nordisk A/S, Denmark. Financial support by the Swedish National Science Research Council is gratefully acknowledged.

Catalytic amounts of $[(PPh_3)_3RuCl_2]$ (**1**) epimerized *cis*-2-methylcyclohexanol and racemized enantiomerically pure α-methylbenzyl alcohol ((+)-(*R*)-**3**). For an efficient isomerization it was necessary to use a ketone as a cocatalyst to promote the ruthenium-catalyzed hydrogen transfer reactions.[9a] Consequently, the corresponding ketones, 2-methylcyclohexanone and acetophenone, were used. The epimerization of *cis*-2-methylcyclohexanol proceeded with a moderate rate,[14] whereas the racemization of (+)-(*R*)-**3** took only 4 h with 2 mol% of the catalyst in the presence of base (Scheme 2). The latter reaction was quite sensitive, and in some of the reactions the catalyst was deactivated and racemization stopped.

Because of the problems with the reproducibility of catalyst **1** we turned our attention to ruthenium catalyst **2**.[15] This catalyst

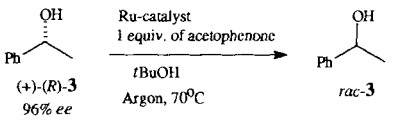
$[(PPh_3)_3RuCl_2]$

1



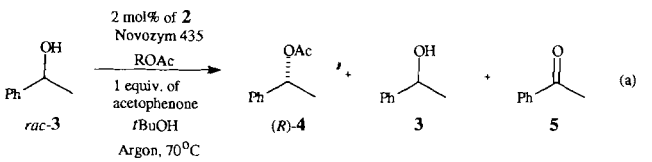
2

has been found to be less sensitive and can be used over longer reaction periods without being deactivated.[9c, d] Reaction of (+)-(*R*)-**3** in the presence of 2 mol% of catalyst **2** and 1 equivalent of acetophenone in *t*BuOH at 70 °C led to a complete racemization in 45 h (Scheme 2).



Scheme 2. Ruthenium-catalyzed racemization of (+)-(*R*)-**3**. Reaction conditions: 2 mol% of **1**, 10 mol% of NaOH, 4 h or 2 mol% of **2**, 45h.

The ruthenium-catalyzed racemization of (+)-(*R*)-**3** was combined with an enzyme-catalyzed transesterification with *Candida antarctica* component B lipase (Novozym 435 = N-435).[16] The use of catalyst **1** in combination with the enzyme and the acyl donor gave poor results, and the rapid racemization with this catalyst could not be reproduced in the presence of the enzyme. Combination of catalyst **2** and the enzyme worked better (Eq. (a) and Table 1). We first tried vinyl acetate as the



acyl donor. Although a complete conversion of the alcohol took place, only about 50% of the acetate was obtained, because the acetaldehyde formed when using this acyl donor reacts as a hydrogen acceptor and oxidizes the substrate alcohol to ketone.[17]

The use of isopropenyl acetate, from which acetone is formed in the acylation step, showed the same phenomenon but to a lesser extent than for vinyl acetate. In this case 72% of the substrate was converted into (*R*)-α-methylbenzyl acetate ((*R*)-**4**), and the remaining 28% was oxidized (Table 1, entry 2). The

Table 1. Results of the enzymatic resolution of α-methylbenzyl alcohol (*rac*-**3**) coupled with ruthenium-catalyzed racemization with catalyst **2** [a].

Entry	ROAc (equiv)	*t* [h]	(*R*)-**4**:**3**:**5** [b]	*ee* of (*R*)-**4** [%]
1	 (5.5)	17	50:0:50	>99.5 [c]
2	(5)	24	72:0:28	>99.5 [d]
3	 (3)	70	88:12:0	>99.5 [d]
4 [e]	 (3)	87	100:0:0 92% yield of isol. (*R*)-**4**	>99.5 [d]

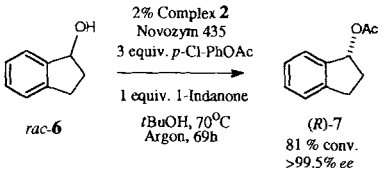
[a] The reactions were performed on a 2 mmol scale with 2 mol% of complex **2**, 1 equiv of acetophenone, 50 mg of Novozym 435 and the acyl donor (ROAc) in *t*BuOH (5 mL) at 70 °C under argon. [b] The conversion and ratio of products were determined by ^{1}H NMR and GC. The relative amount of acetophenone (**5**) formed has been corrected for the amount of added acetophenone. [c] The *ee* value was determined directly on (*R*)-**4** by chiral HPLC on a Chiralcel OD-H column with 5% *i*PrOH in hexane (0.5 mL min^{-1}). [d] The *ee* value was determined on the corresponding alcohol to (*R*)-**4** (namely, (+)-(*R*)-**3**), by chiral HPLC under the same conditions as for the acetate. [e] The reaction was run on half the scale as in [a] (1 mmol).

production of 2-propanol was confirmed by GC analysis. The product was hydrolyzed, and the enantiomeric excess of the alcohol was determined and found to be greater than 99.5%.

To further improve the efficiency of the resolution, an acyl donor that does not interfere with the ruthenium catalyst was required. Alkenyl acetates should therefore not be used, since they produce carbonyl compounds. Also esters producing an alcohol with protons in the α position should be avoided, since such an alcohol will compete with the substrate for the ruthenium catalyst. We therefore considered the use of an aryl acetate, which should be reasonably activated to favor acyl transfer from the phenol to the alcohol substrate. The phenol produced from this acyl donor should not interfere with the ruthenium. Phenyl acetate was not active enough in the transesterification reaction, but halogenated derivatives, *p*-chlorophenyl acetate and 2,4,5-trichlorophenyl acetate were excellent acyl donors in the enzyme-catalyzed acylation of *rac*-**3** with enzyme N-435.

The combination of ruthenium catalyst **2**, *p*-chlorophenyl acetate, and enzyme N-435 in the reaction of *rac*-**3** gave enantiomerically pure (*R*)-**4** (>99.5% *ee*) and in high conversion (Table 1, entries 3 and 4). In the best case the conversion of *rac*-**3** into enantiomerically pure acetate (*R*)-**4** was greater than 99% (>99.5% *ee*).

In preliminary studies racemic 1-indanol (*rac*-**6**) was allowed to react with *p*-chlorophenyl acetate in the presence of the enzyme and ruthenium catalyst **2**. An 81% conversion into the acetate (*R*)-**7** with >99.5% *ee* took place [Eq. (b)].



(b)

An advantage with these chlorophenyl acetates is that the rate of the transesterification can be adjusted by varying the number of halogen atoms to match the rate of a metal-catalyzed racemization of a given alcohol.

During the course of our work on this project Williams et al. reported a related study on metal-catalyzed racemization of alcohols combined with enzymatic resolution.[6b] They used another lipase (from *Pseudomonas fluorescens*) and a rhodium-catalyst for their second order asymmetric transformation. Their best results were 76% conversion with 80% *ee* and 60% conversion with 98% *ee*. We obtained a high conversion of enantiomerically pure product, and in addition explored alternative acyl donors that are compatible with the racemization catalyst.

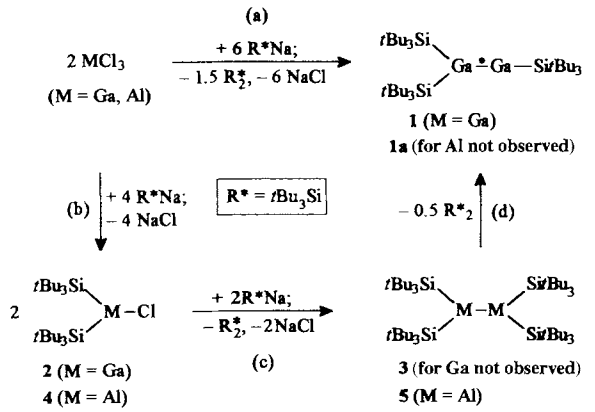
Tris(tri-*tert*-butylsilyl)digallanyl (tBu$_3$Si)$_3$Ga$_2$: A New Type of Compound for a Heavy Group 13 Element**

Nils Wiberg,* Kerstin Amelunxen, Heinrich Nöth, Holger Schwenk, Wolfgang Kaim, Axel Klein, and Thomas Scheiring

Dedicated to Professor Walter Siebert on the occasion of his 60th birthday

Compounds of the boron homologues M = Al, Ga, In, and Tl usually exhibit the composition R_3M (R = inorganic or organic substituent) and, hence, contain M in the oxidation state III.[1] It has been known for about ten years that these elements also form donor-free, uncharged molecular compounds of composition R_2M and RM, in which the metal is in oxidation states II and I, respectively.[2] The latter species, however, tend to disproportionate ($6\,RM \rightarrow 3\,R_2M + 3\,M \rightarrow 2\,R_3M + 4\,M$), a process that can only be inhibited by the use of bulky substituents R.[2, 3] Here we report a gallium compound of the composition R_3M_2 (R = tBu$_3$Si = "supersilyl"; M = Ga), which represents a novel type of compound for a boron homologue with the metal in an oxidation state between I and II.[4, 5]

An unexpected reaction is observed when $GaCl_3$ is allowed to react in pentane at room temperature with tBu$_3$SiNa(THF)$_2$ ("supersilyl sodium/tetrahydrofuran(1/2)") in a molar ratio of 1:3. In addition to hexa-*tert*-butyldisilane ((tBu$_3$Si)$_2$ "superdisilane") and NaCl, the tris(tri-*tert*-butylsilyl)digallium radical (**1**, "trisupersilyldigallanyl") is formed [Eq. (a) in Scheme 1].



Scheme 1.

An intermediate reaction product is chlorodisupersilylgallane (**2**), which is formed by the reaction of $GaCl_3$ and tBu$_3$SiNa(THF)$_2$ in pentane in a molar ratio of 1:2 [for unknown reasons it is also observed for a molar ratio of 1:1; Eq. (b) in Scheme 1] and can be isolated as lemon-yellow crystals. Supersilylsodium reacts with **2**, presumably according to tBu$_3$SiNa + (tBu$_3$Si)$_2$GaCl → tBu$_3$Si$^\bullet$ + NaCl + (tBu$_3$Si)$_2$Ga$^\bullet$ to form the radicals tBu$_3$Si$^\bullet$ and (tBu$_3$Si)$_2$Ga$^\bullet$. For steric reasons, these two radicals cannot combine to form (tBu$_3$Si)$_3$Ga but only tBu$_3$Si–SitBu$_3$ and **3** [see Eq. (c) in Scheme 1]. Digallane **3** cannot be observed since it presumably undergoes rapid conversion into **1** by loss of tBu$_3$Si$^\bullet$ [see Eq. (d) in Scheme 1]. However, there are also other possibilities for the conversion of tBu$_3$SiNa and **2** into **1**.[6]

The intermediate existence of **3** is supported by the reaction of $AlCl_3$ (as the etherate) in heptane at room temperature with three molar equivalents of tBu$_3$SiNa. In analogy to Equations (b) and (c) in Scheme 1, this reaction proceeds via the colorless species (tBu$_3$Si$_2$)AlCl (**4**, 69%) to yield red (tBu$_3$Si)$_2$Al–Al(SitBu$_3$)$_2$ (**5**, 11%).[7] Neither heat nor UV irradiation can induce **5** in heptane to form a radical **1a**, which would be analogous to **1**. Instead, colorless solutions result, which, based on their ESR spectra, do not contain radicals.

(tBu$_3$Si)$_2$Ga^{II}Ga^{I}(SitBu$_3$) crystallizes from pentane at –23 °C as air- and moisture-sensitive, blue-black, rhombic crystals. It decomposes at 55 °C. The X-ray structure analysis (Figures 1 and 2)[8] shows a planar $Si_2Ga^{II}Ga^{I}$ and a nearly linear $Ga^{II}Ga^{I}Si$ framework (sum of the angles $SiGa^{II}Si + SiGa^{II}Ga^{I} + SiGa^{II}Ga^{I} = 359.6°$; Ga^{II}-Ga^{I}-Si 170.0°). The plane defined by the slightly bent $Ga^{II}Ga^{I}Si$ group is approximately perpendicular to the $SiGa^{II}Si$ plane. The Ga–Ga bond length (2.42 Å) is comparatively short, which indicates a bond order of more

[**] Compounds of Silicon, Part 113; Sterically Overloaded Supersilyl Compounds, Part 12. This research was supported by the Deutsche Forschungsgemeinschaft. Parts 112 and 11: N. Wiberg, A. Wörner, K. Karaghiosoff, D. Fenske. *Chem. Ber.* **1997**, *130*, 135.

than one (compare $r(Ga-Ga) = 2.54$ Å in $R_2Ga-GaR_2$; R = $(Me_3Si)_2CH$ or 2,4,6-$iPr_3C_6H_2$[9, 10]). The bonding of the Ga atoms can be described in the following simplified manner: Ga^{II} is sp^2 hybridized, and Ga^{I} is sp hybridized. The bonding Ga–Ga σ molecular orbital, which is formed by the interaction of one hybrid orbital each from Ga^{II} and Ga^{I}, is occupied by two electrons. The bonding Ga–Ga π molecular orbital, which is formed by the interaction of the p_z orbitals of the two Ga atoms, is occupied by one electron. As a result the bond between the Ga atoms has a formal bond order of 1.5. The radical **1** can also be viewed as the adduct of $tBu_3Si^{\bullet}$ with the as yet unknown disupersilyldigallene (disupersilyldigallanediyl), $tBu_3Si-Ga=Ga-SitBu_3$.

Under normal conditions, **1** is a metastable inorganic radical. This stability most likely stems from the fact that the radical electron can occupy a low-energy π state and is, therefore, controlled by, among others, electronic effects.[11] The steric bulk of the supersilyl group also plays a role in stabilizing the radical by preventing the formation of a radical dimer and its subsequent reaction products.

Although **1** cannot be observed with NMR spectroscopy, ESR spectroscopy can be used[12] and is not only an important tool for determining the structure (interaction of an unpaired electron with two chemically different Ga atoms), but also a method for rapidly identifying **1** as a radical (Figure 3).

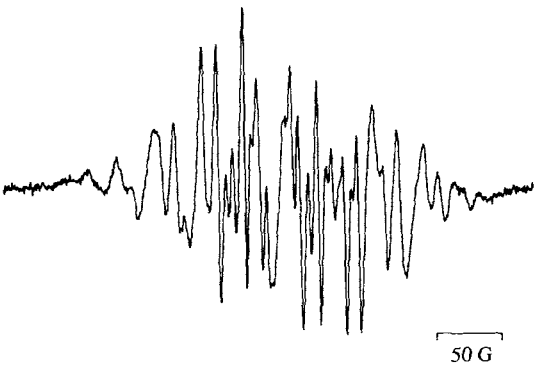

Figure 3. ESR spectrum of **1** in *n*-pentane.

The natural isotopic composition (^{69}Ga: 60.1%, nuclear spin $I = 3/2$; ^{71}Ga: 39.9%, $I = 3/2$) and the ratio of 1.27 for the nuclear *g* factors in favor of ^{71}Ga theoretically result in a total of 64 resonance lines, of which the outer lines are much broader than the inner lines (and those from a simulation with constant line widths, not shown). The reason for this known effect[13] is the comparatively slow rotation of the heavy, stretched molecule in solution, as a result of the large moment of inertia. Therefore, the presumably strong anisotropic contributions of the *g* factor and hyperfine tensors, which stem from the π character of the radical electron, are not completely averaged out at room temperature (time scale of ESR spectroscopy: 10^{-6}–10^{-8} s).[14] The hyperfine coupling constants $a_1(^{69}Ga/^{71}Ga) = 5.0/6.4$ mT and $a_2(^{69}Ga/^{71}Ga) = 3.2/4.1$ mT are in the range observed for related radical anions $R_2Ga-GaR_2^{-}$.[13, 15] In both cases, variations can be explained by a small mixing of s-orbital contributions into the π molecular orbital. In the case of **1**, this could result from the observed deviations from ideally linear $Ga^{II}Ga^{I}Si$ geometry. Although it is tempting to assign the larger a_1 couplings to Ga^{I}, the present data do not allow such definitive identification.

Experimental Section

1: $tBu_3SiNa(THF)_2$ [16] (3.135 mmol) in pentane (10 mL) was rapidly added dropwise to a solution of $GaCl_3$ (0.184 g, 1.045 mmol) in pentane (10 mL) at −30 °C. As the mixture warmed to room temperature, the initially formed yellow suspension (undissolved NaCl, dissolved **2**) began at about 0 °C to change to green and finally to intense blue. After removal of the volatile components, the residue was placed in pentane (30 mL), the white precipitate (NaCl) removed by filtration, and the resulting solution reduced in volume to about 10 mL. Within 12 h at −23 °C, colorless crystals of $(tBu_3Si)_2$ precipitated, which were removed by decanting the blue solution. Blue-black blocks of **1** formed from the mother liquor after 5 d at −23 °C (110 mg, 0.15 mmol, 14.4%); m.p. 55 °C (decomp). In solution, **1** cannot be observed by NMR spectroscopy. It has not yet been possible to obtain a satisfactory elemental analysis.

2: $tBu_3SiNa(THF)_2$ [16] (1.893 mmol) in pentane (5 mL) was added dropwise to a solution of $GaCl_3$ (0.333 g, 1.893 mmol) in pentane (10 mL) at room temperature. A white precipitate (NaCl) formed immediately. After removal of the volatile components, the residue was placed in pentane (30 mL), and the lemon-yellow solution filtered to remove NaCl. Light yellow platelets of **2** precipitated within 12 h at −23 °C (0.347 g, 0.688 mmol, 73% based on tBu_3SiNa). By an analogous method, **2** was formed from $GaCl_3$ and tBu_3SiNa in a molar ratio of 1:2. M.p. 132–135 °C; ^1H NMR (C_6D_6, TMS, internal): $\delta = 1.31$ (s, 6 *t*Bu); $^{13}C\{^1H\}$ NMR (C_6D_6, TMS, internal): $\delta = 25.67$ (6 CMe_3), 32.59 (6 CMe_3); ^{29}Si NMR (C_6D_6, INEPT, TMS, external): $\delta = 33.6$; MS: $m/z = 445$ $[(M - C_4H_9)^+]$, 268 $[(M - tBu_3SiCl)^{\cdot+}]$; elemental analysis calcd for $C_{24}H_{54}Si_2GaCl$ (504.0): C 57.19, H 10.80; found: C 56.83, H 10.84.

[2] See N. Wiberg, K. Amelunxen, H. Nöth, M. Schmidt, H. Schwenk, *Angew. Chem.* **1996**, *108*, 110; *Angew. Chem. Int. Ed. Engl.* **1996**, *35*, 65, and references therein.

[3] Donor-containing, uncharged molecular compounds of uni- and divalent boron homologues M, such as $[AlBr_2(MeOPh)]_2$, $[AlBr(NEt_3)]_4$, and $[GaBr_2(dioxane)]_2$, as well as compounds with cations M^+ or anions $[M_2X_6]^{2-}$, such as $Ga_2[Ga_2Br_6]$, $In_2[In_2Br_6]$, and TlCl [1], are also more stable towards disproportionation.

[4] The radicals formed by UV irradiation of $R_2Al-AlR_2$ (R = $(Me_3Si)_2CH$) should be formulated as $R_2Al^{\bullet}$ (short-lived) and $R_3Al_2^{\bullet}$ (long-lived); a symmetrical structure $(RAl-\mu R-AlR)$ is proposed for $R_3Al_2^{\bullet}$ [9].

[5] Gallium also exhibits a noninteger oxidation state in the uncharged, albeit not donor-free molecular species $Ga_5Cl_7(OEt_2)_5$: D. Loos, H. Schnöckel, D. Fenske, *Angew. Chem.* **1993**, *105*, 1124; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1059. The same is true for $Trip_6In_4$ (Trip = 2,4,6-$iPr_3C_6H_2$), which is obtained from $Trip_4In_2$ and Li (formation and subsequent dimerization of $Trip_3In_2^{\bullet}$): P. J. Brothers, K. Hübler, H. Hübler, B. C. Noll, M. M. Olmstead, P. P. Power, *Angew. Chem.* **1996**, *108*, 2528; *Angew. Chem. Int. Ed. Engl.* **1996**, *35*, 2355. Noninteger oxidation states are also found in charged Al and Ga compounds such as $(RAl)_{12}^{2-}$, $(RAl)_6^{-}$, $(RAl)_5^{2-}$, and $(RGa)_3^{2-}$ [1, 9, 11].

[6] For example, a reaction such as $R^*Na + R_2^*GaCl \rightarrow R^* + NaCl + R_2^*Ga \rightarrow R_2^* + NaCl + R^*Ga$ results in the gallium(I) species R*Ga (R* = tBu_3Si), which can add to R_2^*Ga to form **1**. Insertion of the gallium(I) compound R*Ga into the Ga–Cl bond of remaining starting material R_2^*GaCl is also possible; the $R_2^*Ga-GaClR^*$ formed undergoes subsequent dehalogenation by R*Na to form **1**.

[7] According to the X-ray structure analysis, **5** (orthorhombic, space group *I*4, lattice constants $a = b = 15.4455(5)$, $c = 13.1749(5)$ Å) is structurally analogous to $(tBu_3Si)_2M-M(SitBu_3)_2$ (M = In, Tl [2], mutually perpendicular Si_2Al planes) and contains a relatively long M–M bond: Al–Al 2.75, Al–Si 1.70 Å; Si-Al-Si = 128.0°; Si-Al-Al-Si = 90° (N. Wiberg, K. Amelunxen, H. Nöth, I. Krossing, unpublished results). For further R_2M-MR_2 compounds, see ref. [2, 9].

[8] X-ray structure analysis of **1**: Siemens P4 diffractometer, $Mo_{K\alpha}$ radiation, graphite monochromator, CCD area detector, crystal (0.2 × 0.3 × 0.35 mm) mounted in perfluoroether oil, $T = 183$ K, $C_{36}H_{81}Ga_2Si$, $M_r = 737.72$, blue-black rhombus, monoclinic, space group $C2/c$ (no. 15), $a = 62.368(6)$, $b = 12.7238(1)$, $c = 23.1295(4)$ Å, $\beta = 109.39(1)°$, $V = 17313.9(4)$ Å^3, $Z = 8$, $\rho_{calcd} = 1.132$ gcm^{-3}, $\mu = 1.349$ mm^{-1}, $F(000) = 6416$; data collection: 10 s per frame, φ steps of 0.30, $-81 \le h \le 81$; $-16 \le k \le 16$; $-28 \le l \le 28$; $2\theta_{max} = 58.5°$; of 47491 reflections collected, 16174 were independent and 7834 considered observed ($4\sigma(I)$). Semiempirical absorption correction (min./max. transmission = 0.551/0.733); $R_1 = 0.0687$, $wR_2 = 0.1183$, $GOF(F^2) = 1.188$; largest residual electron density: 1.119 e Å^{-3}. The weighting factor $w^{-1} = \sigma^2 F_o^2 + xP + yP$ with $P = (F_o^2 + 2F_c^2)/3$; $R_1 = \sum||F_o| - |F_c||/\sum|F_o|$; $wR_2 = \{\sum[w(F_o^2 - F_c^2)^2]/\sum[w(F_o^2)^2]\}^{1/2}$. The structure was solved by direct methods (SHELXTL, version 5). All non-hydrogen atoms were refined an-

[11] In the case of the cyclotrigallane dianion $(RGa)_3^{2-}$ (R = 2,6-$Mes_2C_6H_3$), which can be isolated as the sodium salt, electrons also occupy a π molecular orbital (the anion is formally an aromatic $(4n+2)$ electron system with $n=0$, r(Ga–Ga) = 2.44 Å): X.-W. Li, W. T. Pennington, G. H. Robinson, *J. Am. Chem. Soc.* **1995**, *117*, 7578. See also $R_2M-MR_2^-$ with M = Al, Ga, and R = $(Me_3Si)_2CH$ [9].

[12] This behavior clearly indicates the radical character of the compound (which also follows from its structure) and excludes $(tBu_3Si)_2Ga-GaH(SitBu_3)$ as a possibility for **1**. This was confirmed by reduction of the radical to $(tBu_3Si)_2Ga-Ga(SitBu_3)Na(thf)_3$, which can be observed by NMR spectroscopy (X-ray structure analysis: H. Nöth, J. Knizek, unpublished results).

[13] W. Uhl, U. Schütz, W. Kaim, E. Waldhör, *J. Organomet. Chem.* **1995**, *501*, 79.

[14] Lowering of the g factor from 2.0023 (free electron) to 1.9947, which is also observed for free radicals of the type $R_3E^{\bullet}$ (E = Group 14 element [15]), stems from the existence of closely spaced excited states with nonvanishing orbital momenta and from the spin-orbit coupling constant of Ga.

Lithiation of a Simple Amine with a Large Excess of *n*-Butyllithium: The Remarkable Product $(Ph_2NLi)\cdot[Ph(C_6H_4Li)NLi]_2\cdot(nBuLi)_2\cdot(Et_2O)_4$**

Robert P. Davies, Paul R. Raithby, and Ronald Snaith*

Lithiation reactions are extremely important in organic synthesis.[1] The natures and structures of lithiating reagents employed (RLi, especially lithium alkyls and amides) have been investigated extensively over the past twenty years.[2] Recent efforts have switched somewhat to examination of how lithiations actually occur. For example, in a reaction between RLi and an organic precursor R'H where R' contains a functionality of some sort (e.g., a C=O or P=O unit), the initiation step was found possibly to involve complex formation between the reactants.[2d, 3] Other work has concentrated on what might be termed the propagation step. In particular, reactions between RLi and twofold stoichiometric excesses of secondary amines (R'_2NH) have led to complexes between lithium amides and amines $(R'_2NLi\cdot HNR'_2)_n$; that is, half of the amine is lithiated, but the remainder that awaits its own lithiation is coordinated to the lithium amide produced thus far.[4] In this study, we posed the question the other way round: what happens if an amine R'_2NH is treated with an excess of a lithiating reagent RLi? We deliberately chose a simple system: *n*BuLi + Ph_2NH. We also used initially a gross excess of the organolithium (6:1 *n*BuLi:Ph_2NH rather than just, say, 2:1). The surprising and high-yield product of this reaction, carried out in cyclohexane/ether, is in fact **1**.

$2(Ph_2NLi)\cdot[Ph(C_6H_4Li)NLi]_2\cdot(nBuLi)_2\cdot(Et_2O)_4$ **1**

Treatment of a cyclohexane solution of Ph_2NH with a sixfold excess of *n*BuLi at room temperature gave a white precipitate instantaneously. The solid dissolved on warming in Et_2O, and crystals of **1** were obtained from this solution in about 20% yield for the first batch. More prolonged refrigeration of the solution improved the yield to about 50%. In light of the subsequent identification of the product, a repeat synthesis using the correct stoichiometric proportions (Ph_2NH:*n*BuLi 3:7) gave a yield of about 75% (see *Experimental Section*). The ^1H NMR spectrum of the product was complex, especially in the aromatic-proton region; however, the presence of Et_2O ligands and of *n*Bu groups was readily apparent. The precise identity of **1** was proven by X-ray crystallography.[5]

The solid-state structure of **1** is shown in Figure 1. Its *R* factor is quite high, in part because of disorder in the peripheral ligand groups and in part because the solid undergoes a phase change at low temperatures, necessitating data collection at 193 K rather than at the usual 153K. This limits discussion of bond lengths in any detail; nonetheless the key structural features are clear. The structure consists of three interconnected components: 1) on the left of Figure 1 an $(nBuLi\cdot OEt_2)_2$ dimeric unit containing a C(53)Li(5)C(57)Li(6) ring, 2) on the right a diphenylamide monoanion whose nitrogen center [N(3)] is formally associated with Li(4), and 3) a central unit consisting of two dilithiated amides each of type $Ph(C_6H_4Li)NLi$; that is, these Ph_2NH precursor molecules have been lithiated not only at N [N(1) by Li(3), N(2) by Li(2)] but also at one of their *ortho*-CH ring positions [C(18) by Li(1), C(12) by Li(7)].

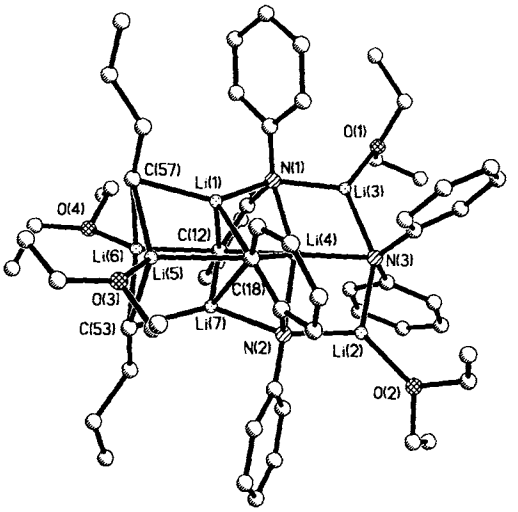

Figure 1. Molecular structure of **1**. Hydrogen atoms have been omitted for clarity, and disorder among the *n*-butyl and ethyl groups is not shown.

The connectivities within these three components are fairly straightforward. In 1) the butyl αC–Li bond lengths within the puckered C_2Li_2 ring average 2.268 Å, broadly comparable to the lengths found in the parent $(nBuLi)_6$ [average C–Li 2.159,

2.270 Å][6a] and in the dimeric complex (nBuLi·tmeda)$_2$ [range 2.215(11)–2.227(9) Å; tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine].[6b] In 2) the N(3)–Li(4) distance of 2.131(13) Å is quite standard for lithium amide structures.[2c, d] A similar comment applies to the central unit 3) regarding the N-lithiated portions, the interatomic distances being 1.994(14) [N(1)–Li(3)] and 1.99(2) Å [N(2)–Li(2)]. The formally C-attached Li^+ ions of this central unit each exhibit a short C–Li contact [Li(1)–C(18) 2.187(12), Li(7)–C(12) 2.193(13) Å] with an *ortho* C of one of the dianions, and a longer attachment [Li(1)–C(12) 2.530(14), Li(7)–C(18) 2.506(13) Å] with an *ortho* C of the other dianion. In this way, a puckered C_2Li_2 ring is formed [Li(1)C(18)Li(7)C(12)]. Finally, these Li^+ ions also interact with one amide N atom apiece [Li(1)–N(1) 2.051(13), Li(7)–N(2) 2.031(12) Å].

Of more interest are the ways in which these three components interlock. The (nBuLi·OEt_2)$_2$ ring is joined to the central dilithiated unit by means of four C–Li contacts, two from the butyl α-C atoms to the Li^+ ions on *ortho* C atoms [C(57)–Li(1) 2.15(2), C(53)–Li(7) 2.166(14) Å] and two in a reciprocal manner from the *ortho* C atoms to the Li^+ ions of the (nBuLi)$_2$ ring [C(12)–Li(6) 2.370(14), C(18)–Li(5) 2.42(2) Å]. Connections between the central dilithiated unit and the $Ph_2N(3)Li(4)$ unit are more complicated. The N-attached Li^+ ions of the central unit bind to N(3) [Li(2)–N(3) 2.095(14), Li(3)–N(3) 2.106(14) Å]. In addition, Li(4) is bonded to the N centers of the central dilithiated units [Li(4)–N(1) 2.087(12), Li(4)–N(2) 2.112(12) Å] and to the lithiated *ortho* C atoms of these units [Li(4)–C(12) 2.465(13), Li(4)–C(18) 2.367(13) Å]. Overall, therefore, Li(4) is five-coordinate, and the other cations in **1** either four- [Li(1),(7); Li(5),(6)] or three-coordinate [Li(2),(3)].

Apart from these unusual structural features, **1** is a unique and, in many respects, surprising product. With regard to its incorporation of nBuLi, several other systems are known in which lithiated (therefore, presumably, rather polarized) molecules form complexes with the lithium reagents used to produce them. Specifically for nBuLi, a 1:1 reaction with 1,3-(Me_2NCH_2)$_2$-2,4,6-Me_3C_6H (= RH) gave initially (RLi)$_2$·(nBuLi)$_2$,[7a] and a similar reaction with 2,4,6-$tBu_3C_6H_2Br$ (= Mes*Br) afforded (Mes*Li)$_2$·(nBuLi)$_2$ and (Mes*Li)$_2$·(nBuLi)$_2$·Mes*Br.[7b] However, in these cases the products were attributed to sluggish reactions between the organic molecules and nBuLi (which is not present in excess); that is, they could be seen as stable intermediates which, along with "free" nBuLi, will lithiate the residual organic component in time. The case of **1** is very different: **1** is produced quickly and in high yield from a reaction employing a deliberate excess of nBuLi. A closer analogy is thus perhaps the reaction between $PhCH_2CN$ in TMEDA with two equivalents of lithium diisopropylamide (LDA).[8] This produces PhCHCNLi·LDA·2tmeda, which has been termed a QUADAC (QUAsi DiAnion Complex).[8, 9] Such species have been sought in order to explain the fact that, while (supposed) dilithiation of an organic molecule followed by treatment with electrophiles (E^+) often leads successfully to disubstituted products, the envisaged dilithium species (if they exist) have proved difficult to isolate. A QUADAC provides an alternative mechanism: its reaction with one equivalent of E^+ followed by an internal lithiation and subsequent substitution by the second equivalent would lead to the final organic product. Again though, **1** is different. It is not a QUADAC: two of the three Ph_2NH molecules provided *have* been dilithiated and, further, the incorporated excess lithiating reagent (nBuLi) is not adjacent to the monolithiated Ph_2NLi unit but separated from it by the dilithiated amides. This ordering of the three components may explain the failure to dilithiate the Ph_2NLi unit, but why this arrangement is found is not immediately obvious. What is clear is that **1** is an exceptionally favored product, being formed even when 3 equivalents of Ph_2NH are treated with over 19 equivalents of nBuLi (5 mmol:32 mmol).

Finally, and leading on from comments just made, the real surprise in this study is that reaction of excess nBuLi with Ph_2NH has led to dilithiation of (some of) the amine. As noted in the opening paragraph, the reverse approach—treating lithiating reagents with excess amine—has led to lithium amide·amine complexes, for example, Ph(2-pyr)NLi·hmpa·HN(2-pyr)Ph[4a] (2-pyr = 2-pyridyl, HMPA = hexamethylphosphoramide) and ($C_5H_{10}NLi$·HNC_5H_{10})$_4$ ($C_5H_{10}NH$ = piperidine).[4b] It was envisaged that this study would produce a monolithium amide·nBuLi species. To that end, Ph_2NH was chosen as the amine: with no functionalities or "directing groups", it seemed an unlikely candidate for anything more than monolithiation at the N atom. And yet dilithiation of some (in fact, two-thirds) of the Ph_2NH molecules has occurred in **1**—why not of all remains a puzzle—and it has occurred quickly, at room temperature, and in high yield. This is significant given that in reactions with a formal 1:1 or 1:2 ratio of organic precursor to lithium reagent, it is common for synthetic chemists to employ a slight excess of the lithium reagent.[1]

These findings also raise interesting points about the true reaction mechanisms of multilithiation reactions (what lithiates what?). Furthermore using large excesses of lithiating reagents promises to allow syntheses of some interesting polylithium aggregates. We are pursuing all of these points.

Experimental Section

Synthesis of **1**: Initially a solution of diphenylamine (0.85 g, 5 mmol) in cyclohexane (8 mL) was treated at room temperature with a large excess of *n*-butyllithium (20 mL of a 1.6 M solution in hexane, 32 mmol). This produced immediately a white precipitate, which dissolved on addition of Et_2O (2 mL) and slight warming. Partial (about 50%) removal of solvent and refrigeration (5 °C, 2 days) gave colorless cubic crystals of **1**. Yield of first batch: 21%. More prolonged refrigeration gave further crystals (52% after 4 days). A repeat of the reaction with 5 mmol of Ph_2NH and 11.7 mmol of nBuLi (3:7) gave **1** in 75% yield. M.p. >300 °C; satisfactory C,H,N,Li analysis for $C_{60}H_{86}Li_7N_3O_4$; ^{1}H NMR (C_6D_6, 250 MHz, 25 °C): δ = −0.55 (m, br, 4H, RCH_2Li), 0.3–1.9 (m, br, 14H, BuLi), 0.72 (t, 24H, Et_2O), 2.90 (q, 16H, Et_2O), 6.75 and 7.21 (m, 28H, ArH).

Hardcover. DM 148,-. ISBN 3-527-29288-8

Catalysis occupies a pivotal position in the physical and biological sciences.

As well as being the mainstay of the chemical industry, it is the means of effecting many laboratory syntheses and the root cause of all enzymatic processes.

This book is an eminently readable introduction to the fundamental principles of heterogeneous catalysis. Written by world-renowned experts, it explains the vocabulary, grammar and literature of catalysis from the laboratory-oriented model study through to the operating plant.

Didactically skillful and using many lucidly designed figures, the authors present an insightful exposition of all important concepts, new developments and techniques in this rapidly advancing field.

From the contents:
Fundamentals of Adsorption/ Characterizing Catalysts and Their Surfaces/ Significance of Pore Structure and Surface Area in Heterogeneous Catalysis/ Poisoning, Promotion, Deactivation and Selectivity of Catalysts/ Catalytic Process Engineering.

Illuminate Your Data

Data Analysis for Chemists. Applications to QSAR and Chemical Products Design. By *D. Livingstone*. Oxford University Press, Oxford, 1996. 239 pp., hardcover £ 40.00.—ISBN 0-19-855728-0

This is neither a student textbook nor a theoretical work on statistical methods. It is a concise, highly informative, and skillfully written practical handbook on the planning of experiments, the processing and analysis of data, computational methods, the construction and interpretation of quantitative models, and the presentation of results.

The contents are divided conveniently into nine self-contained chapters arranged in a logical sequence. This provides the reader with a clearly understandable framework, so that the various methods are seen in the context of an overall scheme. Another helpful feature is the appendix, which lists the available software for data analysis in the form of tables.

Chapter 1 is an introduction in which frequently used descriptors for molecular and physicochemical properties are highlighted by boxes within the text.

Chapter 2 deals with an important topic which often tends to be given insufficient attention: the design of experiments and the choice of compounds and variables. Methods such as single-factor design, fractional-factorial design, and *D*-optimal design are described, and strategies for choosing appropriate compounds are suggested.

Chapter 3 describes pretreatment methods, such as scaling or reduction, that are applied to raw data before analysis.

Chapter 4 is concerned with methods for visual presentation of multidimensional data. As well as the traditional linear methods for data reduction some newer nonlinear methods are described.

The remaining chapters deal with a wide variety of techniques for analyzing data. First the author discusses the methods based on "unsupervised learning". These methods depend solely on the distribution of the properties parameters, and do not require any reference data such as biological activities or other quantities.

The classification of objects in multidimensional space by the clustering method is described. The types of problems encountered in using this method are illustrated very well by taking a number of different sets of data as examples. The methods of factor analysis and principal components analysis are described and compared. The classical regression analysis methods (simple, multiple, and nonlinear) are treated in somewhat greater detail, and the problem of accidental correlations is discussed.

Chapter 7 deals with discrimination analysis and with methods based on the use of latent variables, such as SIMCA, PCR, and PLS; the difficulties of interpreting latent variables are also discussed.

Chapter 8 is concerned with methods for treating sets of data involving multiple biological activities.

In the last chapter the author discusses the application of artificial intelligence methods to the analysis of data. In a densely concentrated, but nevertheless easily understandable treatment, he describes the use of expert systems for the calculation of distribution coefficients, for predicting toxicity, and for investigating chemical reaction pathways. The reader is also given an insight into the processes that occur in artificial neuronal networks.

To summarize, this book will be especially useful to the nonspecialist, as it gives a clear description of the various methods of analysis and their advantages and disadvantages.

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Photochemistry. (Series: Oxford Chemistry Primers). By *C. E. Wayne* and *R. P. Wayne*. Oxford University Press, Oxford, 1996. 92 pp., paperback £ 5.99.—ISBN 0-19-855886-4

The books of the *Oxford Chemistry Primers* series are intended as introductions to the various branches of the field for students reading chemistry at a basic level or as their main subject. Thus, in this volume with the very general title *Photochemistry*, one hopes to find an interesting survey covering both "classical" and more "modern" photochemical reactions. However, a brief glance through the book reveals that the aspects of photochemistry that concern the chemist with an interest in synthetic applications form only a minor part of the contents, the main emphasis being on photophysics and fundamental principles.

The book begins with a detailed introduction to the basic principles of photochemistry, covering the physical-chemical fundamentals, the different types of possible reaction pathways, and experimental methods, thus providing the student with the essential background knowledge for understanding photochemical reactions.

In Chapter 2 the different types of photochemical reactions are considered in more detail. However, the reader interested in synthetic applications may find this 20-page treatment rather disappointing. The subdivision of this chapter into 13 sections devoted to different reaction types or general characteristics seems not always appropriate, particularly since it leads to some inevitable repetition. An arrangement of the subject matter according to compound classes would have been more convenient. Also the appearance of the reaction schemes is somewhat spoiled by the lack of consistency in the format and by small errors. The discussions of individual reactions could have been improved by devoting more attention to mechanistic aspects, and this would have helped the reader to understand the examples described. The description of the photochemistry of carbonyl groups in the individual sections seems rather inadequate. Although the most important reactions, such as the Norrish I and Norrish II

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3611-1219 $ 17.50+.50/0

cleavage reactions, and the Yang and Paternò–Büchi reactions, are in fact described, they are not always mentioned by name. Separate sections are devoted to photoaddition and photocyclization reactions and reactions with oxygen, but no distinction is made between photooxygenation and photooxidation.

Chapter 3 is entirely devoted to photophysics, although the treatment of this topic involves some unavoidable repetition and references to Chapter 1. Deactivation processes are discussed, first by use of the Jablonski diagram, then in more detail in several sections devoted to specific aspects, with the help of figures and comments in the margin. Processes such as bimolecular physical deactivation (quenching) and radiation emission (fluorescence and phosphorescence) are described, as well as the important radiationless monomolecular deactivation processes of intersystem crossing (ISC) and internal conversion (IC). Other phenomena discussed include intermolecular energy transfer and chemiluminescence (which is formally a reverse photochemical reaction).

Chapter 4 is concerned with the kinetics of photochemical reactions, with particular emphasis on the determination of quantum yields and the use of the Stern–Volmer equation. Unfortunately the lengthy discussion of these topics is not easy to follow. In order to understand the mathematical treatment of the systems chosen as examples the reader will need the help of an advanced textbook of physical chemistry.

On the other hand, the last two chapters, which deal with photochemistry in natural systems and with applied photochemistry, are well written and very interesting.

Despite a few weaknesses the book is, on the whole, of an acceptable standard, and it will therefore be useful to students for consolidating the subject matter of a lecture course and providing a deeper understanding. The clarity of the presentation suffers a little from the fact that some parts of the text are too compressed, and the rather sparsely distributed figures offer only a limited aid to the reader's understanding. On the other hand, the wide margin and the notes emphasizing important points help to lighten the style of presentation a little. The individual chapters do not contain literature references; a list of references is included at the end, but it is too brief. Also the list of contents and the rather mediocre subject index are less comprehensive than one would have liked. It would have been useful to include some exercise problems for individual work, so as to enable the student to apply what has been learned.

Although the individual books of the *Oxford Chemistry Primers* series are attractively priced, it must be borne in mind that one would have to buy a large number of titles to assemble a complete textbook. Moreover, the individual volumes vary considerably in quality and in the level of treatment of their topics. It should also be remembered that most good textbooks of organic or physical chemistry already include a separate chapter on photochemistry, and therefore it appears that the book reviewed here is suitable only as supplementary background reading in greater depth for students majoring in chemistry.

Electrochemical Phase Formation and Growth. By *E. Budevski, G. Staikov, and W. J. Lorenz.* VCH Verlagsgesellschaft, Weinheim, 1996. 450 pp., hardcover DM 198.00—ISBN 3-527-29422-8

This book treats the physicochemical foundations of the electrochemical deposition of metals on metallic substrates. Structural aspects related to the surface thermodynamics of crystalline solids and to deposition kinetics are emphasized. After a short general introduction, the structural elements like adatoms, steps, and kinks are described, and the probability according to thermodynamic models of their occurrence as well as their influence on the transfer reaction of metal ions from the electrolyte are discussed. All essential mechanisms pertinent to the relationship between surface structure and deposition kinetics are treated comprehensively.

A major part of the book is devoted to underpotential deposition, that is, to the adsorption of metals on foreign metal substrates. In this field, much progress was made recently with the application of scanning tunneling microscopy. Thermodynamic models of adsorption isotherms are described which take into account the structural aspects. However, the influence of the adsorbate on the thermodynamic properties of the solid substrate is neglected. Kinetics and mechanisms of adsorption including two-dimensional phase transitions and formation of two- and three-dimensional alloys are discussed in detail.

The chapter on the initial steps of the deposition of three-dimensional crystals treats equilibrium shapes, the classical and atomistic theories of nucleation proceeding by various mechanisms with or without prior underpotential deposition, and the corresponding experiments. It is an unexpected result that the sizes of the critical nuclei calculated from the two theories agree well, even if the nuclei are too small to justify the classical theory.

The chapter on Growth of Crystalline Faces is mainly devoted to the remarkable experiments of Budevski and his co-workers on nucleation and growth of two-dimensional layers of silver on essentially dislocation-free silver surfaces. Not only the mean deposition rates are discussed, but also their statistical variations in time and space. It is shown that silver is deposited not via adatoms, but directly at steps, as for metals of higher melting points. The same specific edge energies are obtained from the nucleation kinetics and from the kinetics of pyramidal growth at screw dislocations.

Finally, practical aspects of electrocrystallization are considered. One finds short remarks on the deposition of metals on semiconductors and polymers, and on the deposition of alloys, semiconductors and oxides. Apart from conventional techniques, several modern methods are described such as pulse- or laser-induced deposition, and those for nanostructuring of surfaces.

The appendix contains a list of the systems for which underpotential deposition was investigated, theoretical considerations regarding, for example, the ideally polarizable electrode (neglecting its solid state properties) and the computation of adsorption isotherms. The bibliography quotes more than 800 publications apart from about 250 references to the underpotential systems. However, some papers are listed several times. The glossary of symbols and abbreviations used extensively in the text is quite helpful. One regrets serious deviations from IUPAC rules. For instance, the current density should be denoted by j and not by i, which is reserved for current, and the specific surface energy by γ and not by σ, reserved for surface charge density. Apart from misprints, regrettably also in equations and references, one occasionally finds careless choices of words like energy instead of Gibbs energy, or: "The exchange current density is a thermodynamically well defined quantity".

The book is an excellent introduction to the theoretical and experimental aspects of the electrocrystallization of pure metals. The electrodeposition of alloys, elementary and compound semiconductors, oxides, sulfides, etc. not treated ade-

quately can be understood on the basis of the theory of metal deposition. There is still a great need for further research on these topics. "Electrochemical Phase Formation and Growth" is recommended to all who want to inform themselves about the latest advances of electrocrystallization.

The Chemistry of *C*-Glycosides. (Tetrahedron Organic Chemistry Series. Vol. 13.) By *D. E. Levy* and *C. Tang*. Elsevier, Oxford, 1995. 291 pp., paperback £ 30.00.—ISBN 0-08-042081-8

Methods for the synthesis of *C*-glycosides have undergone a phase of rapid development during the last few years. Anyone who wishes to keep in touch with progress in this area should take a look at the book reviewed here, in which D. E. Levy and C. Tang present a comprehensive survey, covering in eight chapters almost every aspect of the chemistry of *C*-glycosides, illustrated by many examples.

The first chapter briefly reviews the nomenclature of these compounds and their occurrence in nature, and discusses their pharmacological importance and biological activity. The subsequent chapters then treat in great detail the different types of reactions for preparing *C*-glycosides, with numerous examples. However, the authors' use of the expressions "electrophilic substitutions" (in Chapter 2) and "nucleophilic sugar substitutions" (in Chapter 3) could lead to misunderstanding, as they fail to explain clearly in each case whether the sugar moiety acts as an electrophile or as a nucleophile, or is attacked by an electrophile or a nucleophile. The expression "sugar ring formations" in Chapter 7 also seems a rather poor choice of words.

Chapter 2, which is devoted to the sugar components as electrophilic species, is by far the longest. Much emphasis is placed on the importance of the cyanoglycosides, which have many potential synthetic applications, since the CN function can be readily converted to other functional groups to give, for example, carboxylic acid amides, carboxylic acids, or amines. Thus the cyanoglycosides are also ideal precursors for synthesizing *C*-glycosyl-amino-acids and *C*-glycosyl-heterocycles. The authors also explain how, by reacting glycosyl halides or epoxides with lithium cuprates, one can introduce alkyl groups and synthesize simple *C*-glycosides.

Chapter 3 describes the use of C_1-lithiated sugar units as nucleophiles for preparing *C*-glycosides. Metallation reactions such as hydrogen–metal exchange at the anomeric center of a glycal are treated in special detail.

Chapter 4 deals with the arylation reactions of glycals with benzene or with arenes having groups such as alkoxy or halogens as substituents. These are usually carried out in the presence of palladium(II) acetate.

The main topic of Chapter 5 is the formation of anomeric radicals and their coupling with acrylonitrile. Some more recent developments on this theme, such as intramolecular variants, are also described.

Chapter 6 is concerned with syntheses of *C*-glycosides based on rearrangement reactions of the Wittig and Claisen types or on cycloadditions. Special attention is given to 1,3-dipolar cycloaddition reactions for synthesizing heterocyclic *C*-glycosides, with many illustrative examples.

In Chapter 7 the authors treat in considerable detail the synthesis of *C*-glycosides by a Wittig reaction of a glucose followed by cyclization induced by a base or a halogen. The chapter also discusses "classical" routes to *C*-glycosides based, for example, on Diels–Alder or hetero-Diels–Alder reactions.

Lastly, Chapter 8 deals with the synthesis of *C*-disaccharides and *C*-trisaccharides. Here the authors describe how the methods already discussed in Chapters 2–7 are applied to a number of more complex syntheses, which are treated in chronological order, beginning with the first synthesis of a *C*-disaccharide in 1983 and continuing through to 1994.

The book is completed by a comprehensive index to help the reader who wishes to use the work as a reference source. In addition each chapter has a detailed list of literature references.

When the time comes to revise the book for a second edition, the opportunity should be taken to re-draw the structural formulas in a uniform style, avoiding the mixing of steric and conformational forms of presentation. Some errors in the first edition (e.g., in Schemes 1.4.7 and 7.3.3) also need to be corrected.

A particular strength of the book is the wealth of examples that are presented. It should be read by everyone whose work involves carbohydrate chemistry, or who has an interest in the subject and wishes to quickly gain an overview of the chemistry of *C*-glycosides.

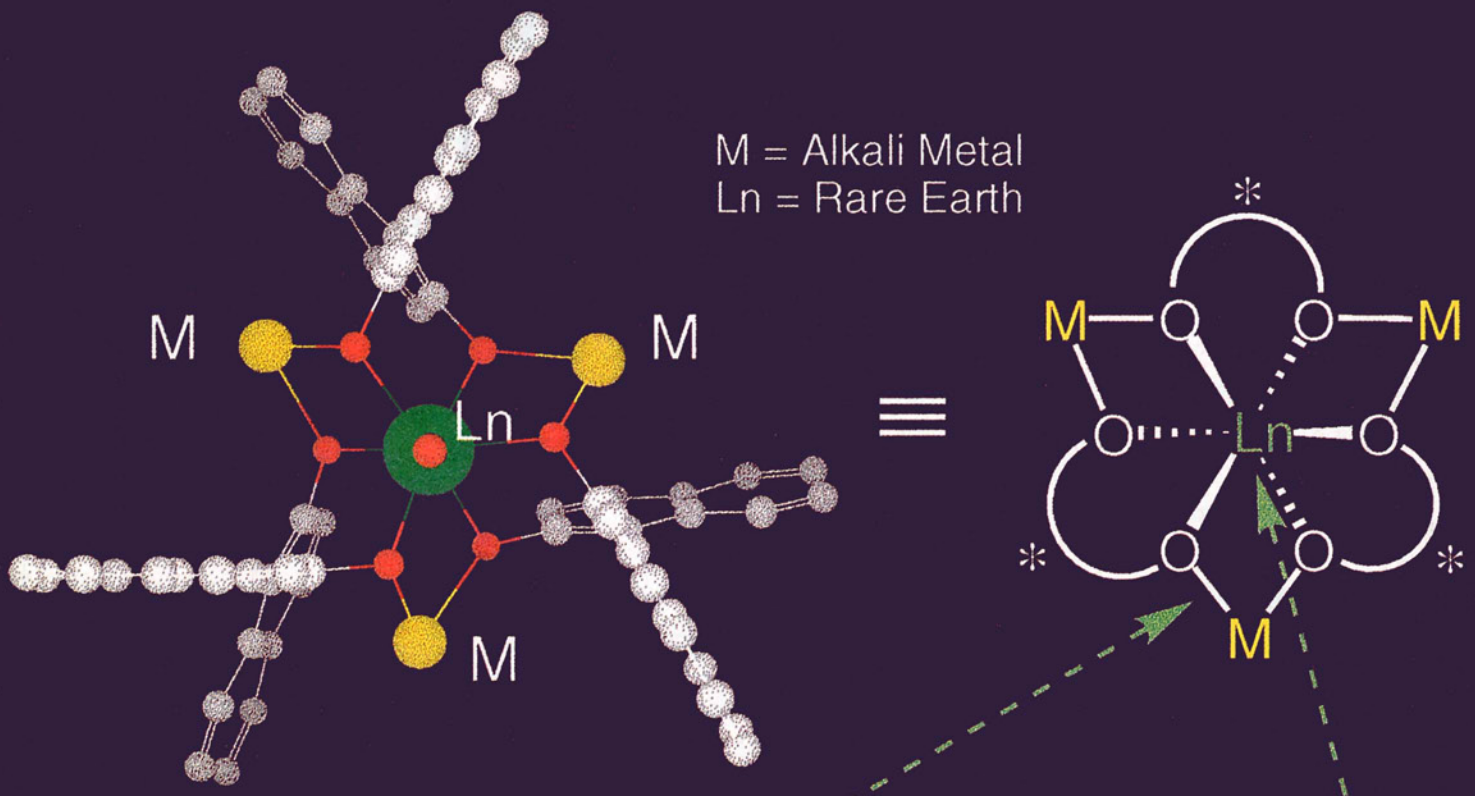
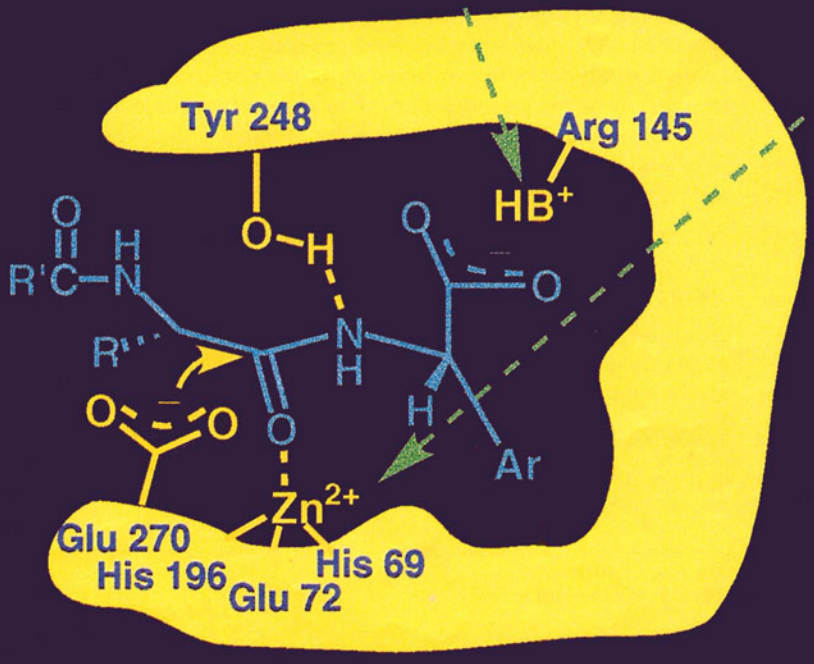
Heterobimetallic Multifunctional Catalysts



Brønsted Base

Lewis Acid



Enzyme Carboxypeptidase A with a Substrate

Asymmetric Catalysis with Heterobimetallic Compounds

Masakatsu Shibasaki,* Hiroaki Sasai, and Takayoshi Arai

This review focuses on a new concept in catalytic asymmetric reactions that was first realized for the use of heterobimetallic complexes. As these heterobimetallic complexes function as both a Brønsted base and as a Lewis acid, just like an enzyme, they make possible a variety of efficient catalytic asymmetric reactions. This heterobimetallic concept should prove to be applicable to a variety of new asymmetric catalyses. The first part of this review describes the development of rare earth–alkali metal complexes such as LnM_3tris(binaphthoxide) complexes (LnMB, Ln = rare-earth metal, M = alkali metal), which are readily prepared from the corresponding rare-earth trichlorides or rare-earth isopropoxides, and their application to catalytic asymmetric synthesis. By using a catalytic amount of LnMB complexes several asymmetric reactions proceed efficiently to give the corresponding desired products in up to 98% *ee*: LnLB-catalyzed asymmetric nitroaldol reactions (L = Li), LnSB-catalyzed asymmetric Michael reactions (S = Na), and LnPB-catalyzed asymmetric hydrophosphonylations of either imines or aldehydes (P = K). Applications of these heterobimetallic catalysts to the syntheses of several biologically and medicinally important compounds are also described. Spectral analyses and computational simulations of the asymmetric reactions catalyzed by the heterobimetallic complexes reveal that the two different metals play different roles to enhance the reactivity of both reaction partners and to position them. From mechanistic considerations, a useful activation of the heterobimetallic catalyses was realized by addition of alkali metal reagents. The second part describes the development of another type of heterobimetallic catalysts featuring Group 13 elements such as Al and Ga as the central metal. Among them, the AlLibis(binaphthoxide) complex (ALB) is an effective catalyst for asymmetric Michael reactions, tandem Michael–aldol reactions, and hydrophosphonylation of aldehydes.

Keywords: aluminum · asymmetric catalysis · bimetallic complexes · homogeneous catalysis · lanthanides

1. Introduction

The synthesis of optically active chiral compounds, which play an important role in the development of medicines and materials such as liquid crystals,[1] is one of the most fascinating aspects of modern organic synthesis. Of the methods available for preparing such compounds, catalytic asymmetric synthesis has attracted the most attention. Although catalytic antibodies or structurally modified enzymes are now becoming available,[2] molecular catalysts, in particular homogeneous-phase molecular catalysts, have the great advantage that their structures can be structurally modified to improve their efficacy. Many catalytic asymmetric syntheses with organotransition-metal compounds or main-group organometallic compounds have been carried out.[3] The respective characteristic chemical reactivities and Lewis acidities play a crucial role in the key steps.

In 1989 we became interested in using amphoteric $Zr(OtBu)_4$ for developing a new class of basic asymmetric catalysts.[4] This led to the development of exciting heterobimetallic asymmetric catalysts with conceptually new chemical reactivities.[5] A key feature of enzymes is their ability to position substrates in proximity to each other and to enhance their reactivities by appropriately positioning the reacting functional groups in the asymmetric environment.[6, 7] Heterobimetallic asymmetric catalysts promote many reactions efficiently through a synergistic cooperation between two different metals and a chiral template in a manner analogous to that seen in enzymatic processes involving metal-ion cocatalysis.[5] Here we describe the development of heterobimetallic asymmetric catalysts and their application in many asymmetric reactions, and consider future possibilities for the use of this type of catalyst.

2. Basicity of Zirconium(IV) *tert*-Butoxide and Rare-Earth(III) Isopropoxides

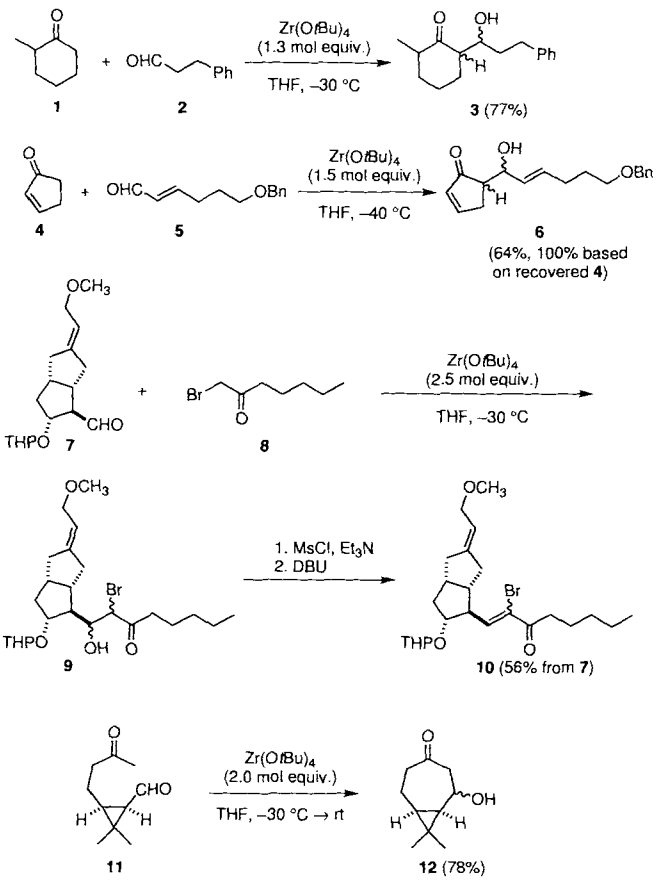
We began out studies with an investigation of the direct preparation of zirconium enolates from ketones with $Zr(OtBu)_4$ and their aldol reactions. As expected the reactions proceeded

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3612-1237 $ 17.50+.50/0

smoothly to give aldol products, indicating that the zirconium enolates were formed directly (Scheme 1).[8] However, these reactions proceeded efficiently only when stoichiometric amounts of $Zr(OtBu)_4$ were used. Several unsuccessful attempts to carry out catalytic aldol reactions with $Zr(OtBu)_4$ were made. We envisioned that rare earth metal alkoxides would be stronger bases than Group 4 metal alkoxides due to the lower ionization potentials (about 5.4–6.4 eV) and lower electronegativities (1.1–1.3) of rare-earth elements.[9] This enhanced basicity would then increase the utility of rare earth metal alkoxides with respect to catalytic organic synthesis.[10] We found for the first time that rare earth metal alkoxides are suitable for use as a base in aldol reactions. Furthermore, the *catalytic* use of these alkoxides is feasible, which suggests the possibility of developing basic asymmetric catalysts from rare earth metal alkoxides.[11] The results are shown in Scheme 2.

3. Design and Development of Basic Asymmetric Catalysts

We began by designing basic asymmetric catalysts of type A, which were prepared from $LnCl_3$ (Ln = Y or La) and optically active bidentate diol derivatives such as **20**[12] (Scheme 3). Although the structures of the type A catalytic species were still open to conjecture, we went ahead and used them in a series of catalytic asymmetric reactions. Treatment of **18** with a type A yttrium catalyst in THF at −52 °C for six days gave **19a** in 60% yield and 52% *ee* (Scheme 4).[11] However, the optical purity of isolated **19a** was *reduced* when further exposed to the type A catalyst at −30 °C. This suggests that the product undergoes an



Scheme 1. Aldol reactions with $Zr(OtBu)_4$; THP = tetrahydropyranyl, Ms = methanesulfonyl, DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene.

M. Shibasaki

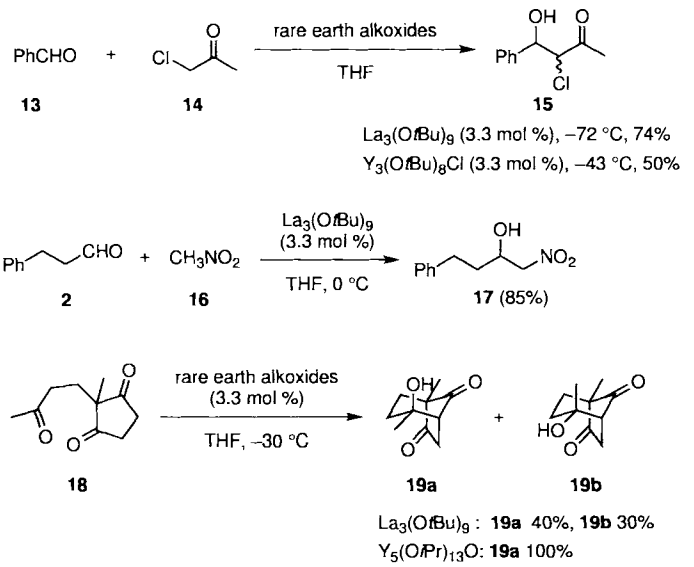
H. Sasai

T. Arai

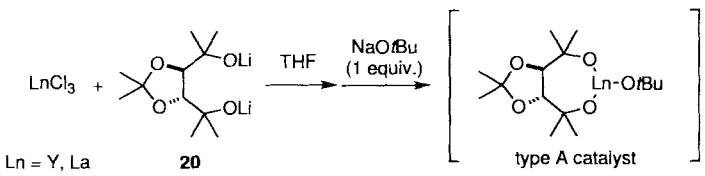
Masakatsu Shibasaki, born in 1947 in Saitama, Japan, received his Ph.D. from the University of Tokyo in 1974 under the direction of the late Professor Shun-ichi Yamada before doing postdoctoral studies with Professor E. J. Corey at Harvard University. In 1977 he returned to Japan and joined Teikyo University as an associate professor. In 1983 he moved to Sagami Chemical Research Center as a group leader, in 1986 to Hokkaido University as a professor, and in 1991 to the University of Tokyo as a professor. He was a visiting professor at Philipps-Universität Marburg, Germany in 1995. He has received the Pharmaceutical Society of Japan Award for Young Scientists, Inoue Academic Prize, and the Fluka Prize "Reagent of the Year 1996". His research interests are asymmetric catalysis, including asymmetric Heck reactions and reactions promoted by asymmetric heterobimetallic complexes, and the medicinal chemistry of biologically significant compounds.

Hiroaki Sasai, born in 1956 in Tokyo, Japan, received his Ph.D. from Keio University in 1985 under the direction of Professor Tetsuo Suami before joining Professor Shibasaki at Sagami Chemical Research Center. In 1988 he moved to Hokkaido University as an assistant professor and in 1992 to the University of Tokyo. In 1994 he joined the University of California, Los Angeles as a visiting scholar to engage in computational analysis of enantioselective reactions with Professor K. N. Houk. He is now an associate professor at the University of Tokyo. He has received the Daicel Award in Synthetic Organic Chemistry, Japan, the Pharmaceutical Society of Japan Award for Young Scientists, and the Fluka Prize "Reagent of the Year 1996".

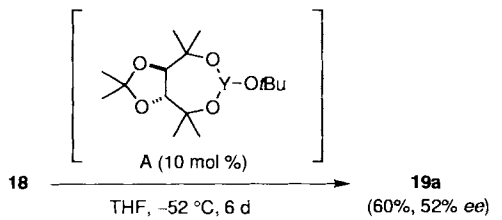
Takayoshi Arai, born in 1968 in Hokkaido, Japan, received his M. S. from the University of Tokyo in 1994 where he became an assistant professor in 1995 while enrolled in a Ph.D. course. He received the Sankyo Award in Synthetic Organic Chemistry, Japan.



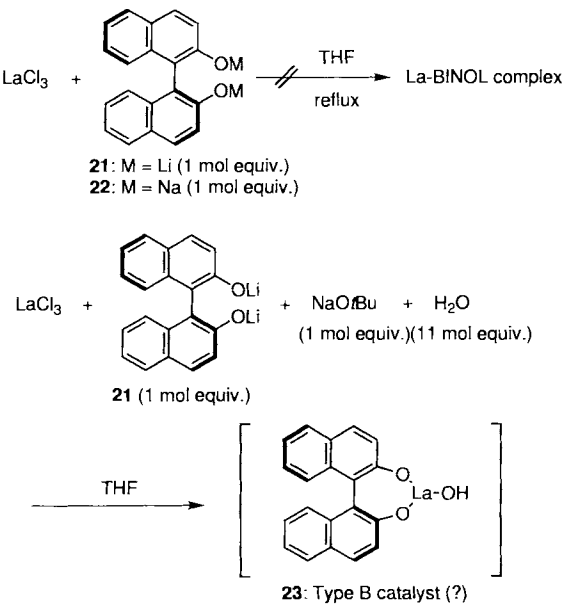
Scheme 2. Aldol reactions catalyzed by rare-earth alkoxides.



Scheme 3. Preparation of type A asymmetric catalysts.

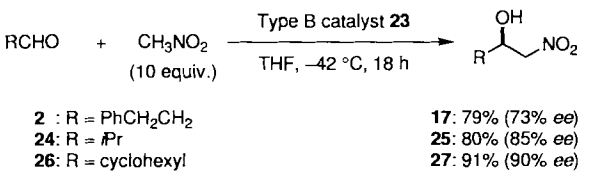


Scheme 4. Asymmetric intramolecular aldol reaction catalyzed by yttrium alkoxide (type A).



Scheme 5. Preparation of type B asymmetric catalysts. The structure given for **23** is the proposal at the start of the investigations.

undesirable retroaldol reaction. We next examined the nitroaldol (Henry) reaction, which also proceeded efficiently in the presence of a catalytic amount of rare earth metal alkoxides. Specifically, by using type A catalysts the reaction of **2** with nitromethane (**16**) gave the desired nitroaldol; however, no asymmetric induction was observed. The ^{13}C NMR spectrum of a mixture of the asymmetric catalyst and nitromethane clearly shows that an undesired exchange of the asymmetric ligand for (acidic) nitromethane occurs to produce an achiral nitronate. More acidic bidentate asymmetric diols are required to suppress this ligand exchange; therefore, optically active 2,2′-dihydroxy-1,1′-binaphthyl (BINOL) was used. Based on the results shown in Scheme 2, we decided to use La as the central metal. However, the reaction of *anhydrous* $LaCl_3$ with the dialkali metal salts of BINOL **21** (M = Li) and **22** (M = Na) in THF did not proceed even at reflux temperature. In contrast to our expectations, the reaction of anhydrous $LaCl_3$ with the dialkali metal salts of BINOL proceeded smoothly in the presence of a small amount of water, and we succeeded in preparing the best asymmetric catalyst for nitroaldol reactions with a 1:1 ratio of **21** to $LaCl_3$ (Scheme 5).[13] Although NaOH could be used instead of NaO*t*Bu, as expected, we recommend using a solution of NaO*t*-Bu in THF, if only for convenient measurement of the exact amount added. With the catalyst prepared above, we succeeded in carrying out the first catalytic asymmetric nitroaldol reaction (Scheme 6; the amount of catalyst is not given since its structure is unknown).[11]



Scheme 6. Asymmetric nitroaldol reactions catalyzed by type B catalysts.

The rare-earth metals are generally regarded as a group of 17 elements with similar properties, especially with respect to their chemical reactivity. However, in the case of the above-mentioned catalytic asymmetric nitroaldol reaction, we observed pronounced differences both in reactivity and in enantioselectivity among the rare-earth metals.[14] For example, when benzaldehyde (**13**) and nitromethane (**16**) were used as starting materials, the corresponding Eu complex gave **28** in 72% *ee* (91% yield) in contrast to 37% *ee* (81% yield) in the case of the La complex of type B (– 40 °C, 40 h). The unique relationship between the ionic radii of the rare-earth metals and optical purities of the nitroaldols is depicted in Figure 1. These results suggest that small changes in the structure of the catalyst (about 0.1 Å in ionic radius of the rare earth cation) cause a drastic change in the optical purity of nitroaldols produced. Although nitroaldol reactions are regarded as equilibrium processes, no detectable retro-nitroaldol reaction was observed in the asymmetric nitroaldol reactions catalyzed by a Ln/BINOL complex.

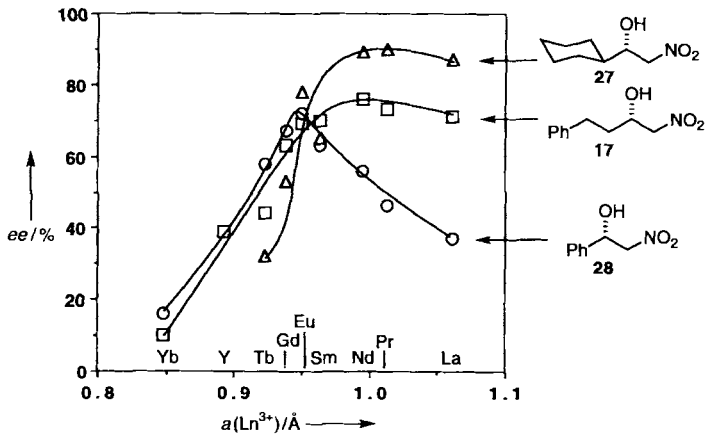


Figure 1. Dependence of the optical purity of nitroaldol derivatives on the ionic radii *a* of the rare-earth elements in the catalyst.

We were very interested in determining the structure of the type B catalyst. Although, we first speculated that it was made up of a hydroxyl complex, such as **23**, laser-desorption/ionization time-of-flight (LDI-TOF) mass spectrometry revealed that the structure is a heterobimetallic complex consisting of one lanthanum and three lithium atoms as well as three BINOL moieties (Figure 2). Although LDI-TOF MS has a mass accuracy of about $\pm 0.1\%$, the proposed structural framework was strongly supported by the similarity of the mass spectra to those of other rare-earth complexes; rare-earth elements have their own atomic weights and isotope abundance distributions.

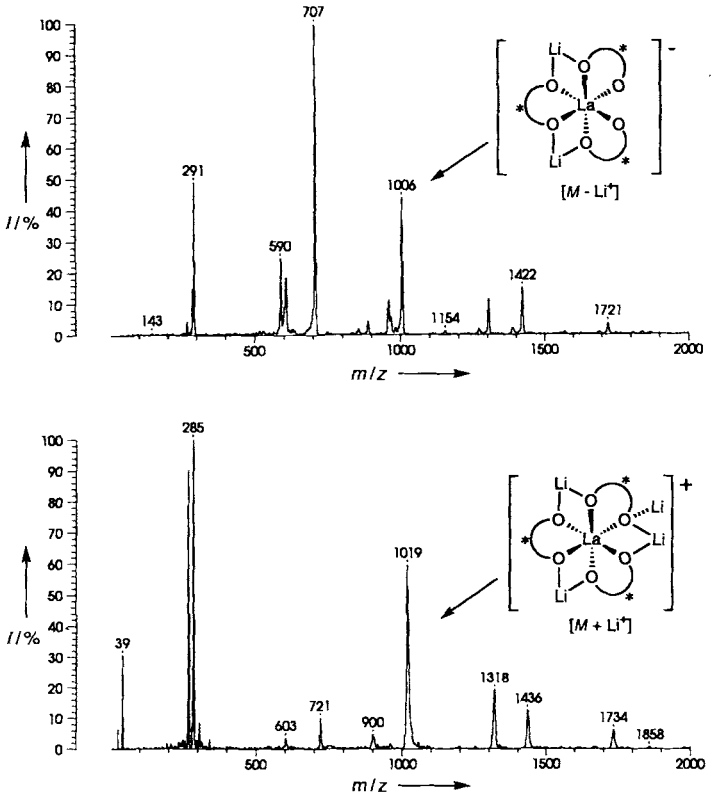

Figure 2. Negative (top) and positive ion LDI-TOF mass spectra (bottom) of the La/Li/BINOL complex.

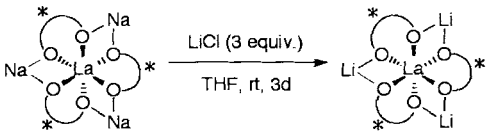
Several unsuccessful attempts were made to obtain an X-ray quality crystal of a rare-earth complex. One reason for the low crystalline character might be contamination by LiCl in the catalyst solution. We therefore turned our attention to preparing crystals under lithium-free conditions. Starting from rare-earth trichlorides (including $LaCl_3$), disodium (*R*)-binaphthoxide (**22**), NaO*t*Bu, and H_2O several rare-earth complexes could be crystallized from THF. Elemental analyses suggested a stoichiometry of $LnNa_3$tris(binaphthoxide)$\cdot 6THF \cdot 2H_2O$, which was confirmed by X-ray crystallographic analyses of La, Pr, Nd, and Eu complexes. Figure 3 shows a photograph of four crystals and the corresponding X-ray structures of four rare earth/Na/BINOL complexes (LnSB, S = Na).[15,16] X-ray crystallography showed that these crystals have almost the same structure, and that the distance of the atoms around the center from the central rare-earth metal are different. Since each rare earth/(*S*)-BINOL complex has an chiral center at the metal, the (*S*)-BINOL complex can exist as a diastereomer. Nevertheless, La, Pr, Nd, and Eu complexes starting from (*S*)-BINOL exist only in the Λ configuration. This is perhaps due to the greater thermodynamic stability of this configuration over the Δ form.

All the above-mentioned LnSB crystals show mass patterns similar to those of Ln–Li BINOL complexes, even though they contain sodium instead of lithium. LnSB complexes are basic and act as catalysts for the nitroaldol reaction. However, the nitroaldols thus obtained were mostly racemic mixtures. We expected lithium-containing heterobimetallic complexes to be more effect asymmetric catalysts for nitroaldol reactions and prepared them by treating LnSB with three equivalents of LiCl in THF at room temperature for three days (Scheme 7). Under



Scheme 7. Preparation of LLB from LSB.

these conditions, complete exchange of sodium for lithium was achieved, as detected by LDI-TOF MS. These lithium-containing heterobimetallic catalysts give almost identical results in catalytic asymmetric nitroaldol reactions to those achieved with the same catalyst directly prepared from $LnCl_3$. The oligomeric structure of the catalysts in the reaction mixture is supported by slightly positive asymmetric amplification.[13,17] Therefore, the effective asymmetric catalyst for nitroaldol reactions is the $LnLi_3$tris(binaphthoxide) complex (LnLB). What, then, is the role of NaOH in the catalyst preparation? NaOH acts as a buffer and neutralizes HCl generated by the reaction of $LaCl_3$ with H_2O. Furthermore, the presence of H_2O accelerates catalyst formation (Scheme 8).

After successfully determining the structure of the LnLB complex and the role of H_2O in catalyst formation, we attempted to optimize the conditions for preparing LLB. After much experimentation, we found that treatment of $LaCl_3 \cdot 7H_2O$ with 2.7 molar equivalents of **21** and NaO*t*Bu (0.3 mol equiv.) in THF at 50 °C for 50 h gave the LLB complex most efficiently (Scheme 9).[18] Alternatively LLB can be prepared from

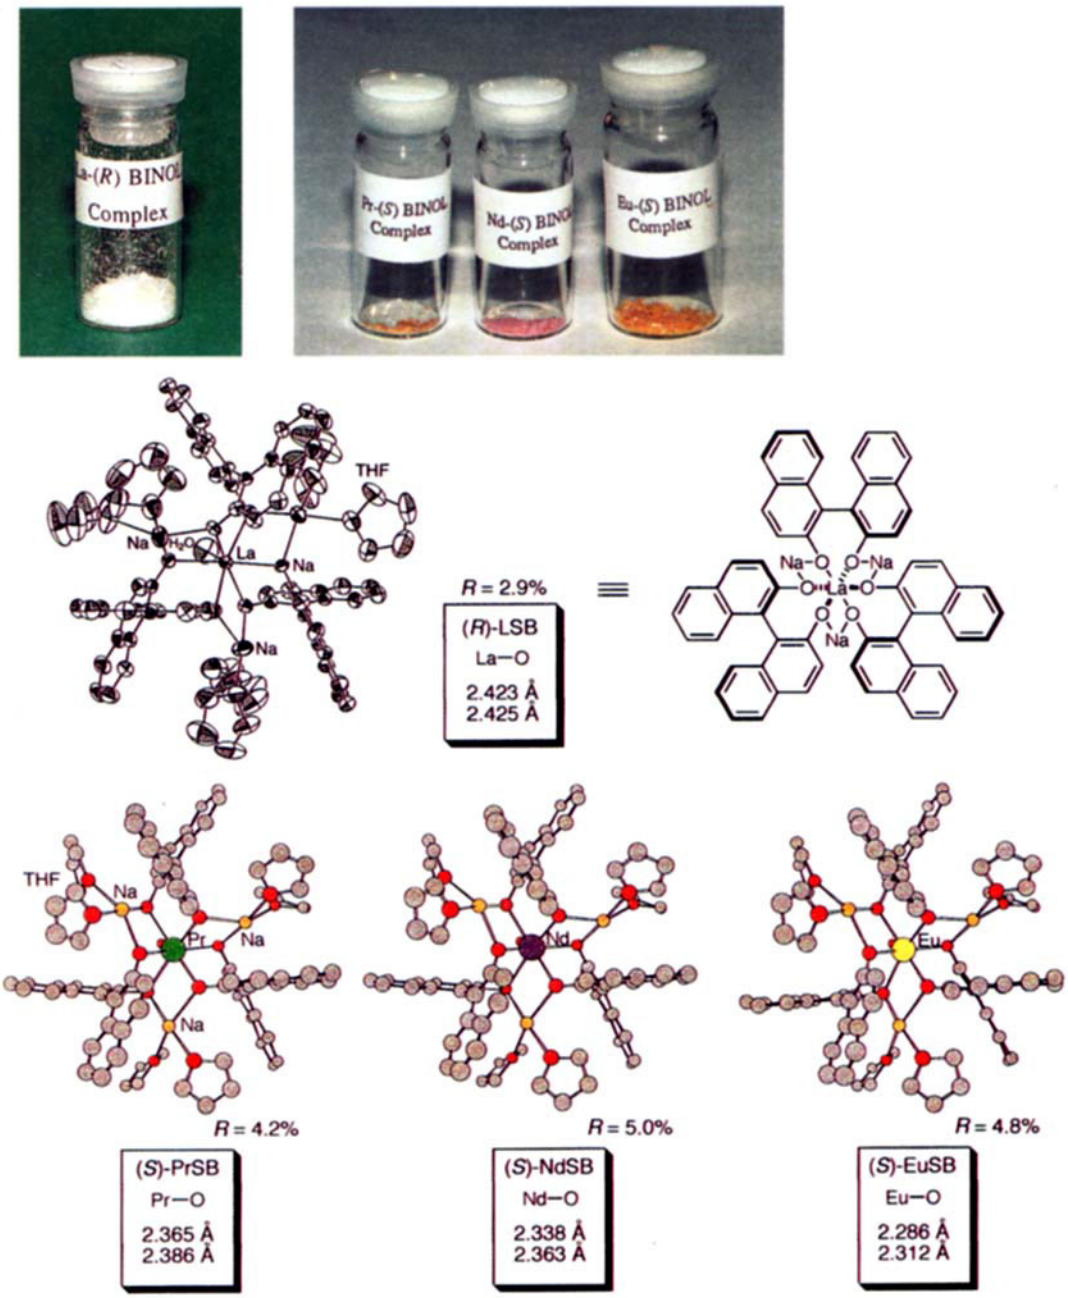


Figure 3. X-ray quality crystals of rare earth/Na/BINOL complexes (LnSB; top) and their structures (middle and bottom).

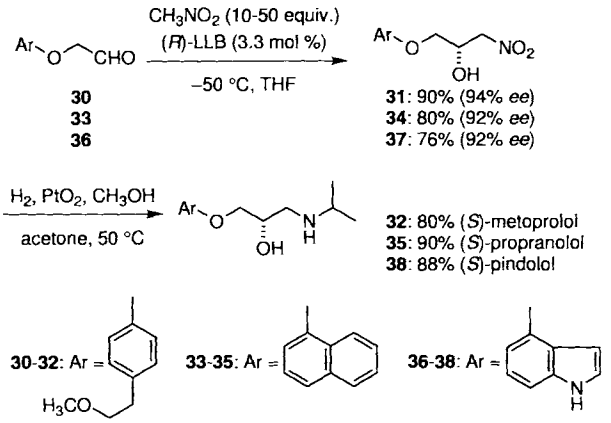
at 0 °C. Interestingly, the addition of one equivalent of water to LLB improves the catalyst's activity.[15] With these two procedures a variety of heterobimetallic asymmetric complexes such as PrLB, NdLB, SmLB, EuLB, GdLB, and YbLB were prepared efficiently. These heterobimetallic asymmetric complexes, including LLB, are insensitive to oxygen and stable in organic solvents that contain small amounts of water (such as THF, CH_2Cl_2, and toluene).

4. Catalytic Asymmetric Nitroaldol Reactions with Nitromethane

The nitroaldol (Henry) reaction is a powerful synthetic tool and is utilized for constructing numerous natural products and other useful compounds.[20, 21] In early results we discovered the first example of a general and effective catalytic asymmetric nitroaldol reaction that proceeds efficiently in the presence of 3.3 mol% of LLB (Scheme 6). THF appears to give the best results as far as solvent effects are concerned. Until this discovery no reports of asymmetric nitroaldol reactions, including noncatalytic varieties with a stoichiometric amount of asymmetric base, had appeared. The nitroaldols are readily converted into β-amino alcohols and/or α-hydroxy carbonyl compounds. Examples of the effective application of the LLB-catalyzed nitroaldol reaction include convenient syntheses of three kinds of optically active β blockers (Scheme 10).[14, 22–24] Using ten

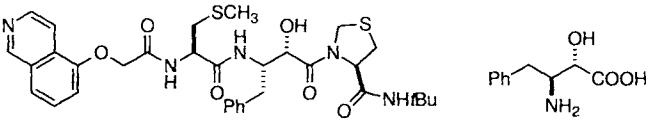


Scheme 10. Asymmetric syntheses of β blockers with (*R*)-LLB as catalyst.

equivalents of nitromethane and **36** at −50 °C in the presence of 3.3 mol% of (*R*)-LLB catalyst resulted in nitroaldol **37** in 76% yield and 92% *ee*.

Reductive alkylation of **37** to **38** was accomplished in 88% yield by PtO_2-catalyzed hydrogenation in the presence of five equivalents of acetone in methanol. (*S*)-(−)-pindolol (**38**) was thus synthesized in only four steps from 4-hydroxyindole.[23] Interestingly, the nitroaldols **31**, **34**, and **37** have the (*S*) absolute configuration when (*R*)-LLB is used. Therefore, the nitronates react preferentially at the *Si* face of the aldehydes. This is opposite to the enantiofacial selectivity that might be expected on the basis of previous results (see Scheme 6) and suggests that the presence of an oxygen atom at the β position has a great influence on the enantiofacial selectivity.

Furthermore, diastereoselective catalytic nitroaldol reactions of optically active α-amino aldehydes with nitromethane in the presence of LLB were found to proceed with high diastereoselectivity.[25] The adducts (3-amino-2-hydroxy-1-nitro derivatives) are attractive intermediates for the synthesis of unnatural *erythro*-amino-2-hydroxy acids, which are important components of several biologically active compounds. For example, the promising HIV-protease inhibitor KNI-272 (**39**)[26] contains (2*S*,3*S*)-3-amino-2-hydroxy-4-phenylbutanoic acid (*erythro*-AHPA, **40**) as a subunit (Scheme 11). As shown in Table 1,



39: KNI-272 **40**

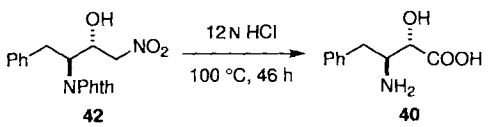
treatment of *N*-phthaloyl-L-phenylalanal (**41**, Phth = phthaloyl) with nitromethane at −40 °C in the presence of (*R*)-LLB (3.3 mol%) gave practically a single stereoisomer of (2*R*,3*S*)-2-hydroxy-4-phenyl-3-phthaloylamino-1-nitrobutane (**42**) in 92% yield (>99:1 *erythro*-selectivity). The enantiofacial selectivity for the C2 hydroxyl group of **42** agrees with results previously observed in enantioselective nitroaldol reactions for non-β-oxaaldehydes with LLB. Interestingly, reaction of the (*S*)-aldehyde **41** with nitromethane and the (*S*)-LLB complex as a catalyst, led to the reduced diastereoselectivity. Conversion of the nitroaldol adduct **42** into **40** was achieved in 80% yield by a one-pot reaction (Scheme 12).



Scheme 12. Synthesis of *erythro*-AHPA (**40**).

LLB-type catalysts are also able to promote diastereoselective and enantioselective nitroaldol reactions starting from prochiral materials. However, in preliminary work LLB gave unsatisfactory results in terms of both diastereoselectivity (*syn*:*anti* ratio between 63:37 and 77:23) and enantioselectivity (<78% *ee*).[22] We therefore focused our attention on synthesizing a novel asymmetric catalyst. We first prepared a number of complexes from $La(OiPr)_3$, butyllithium (three equivalents),

and (*R*)-BINOL derivatives (three equivalents) in which certain positions were substituted by alkyl, alkenyl, alkynyl, aryl, and/or cyano groups. Their utility as asymmetric catalysts was assessed by a nitroaldol reaction of nitromethane with hydrocinnamaldehyde (**2**). Whereas complexes derived from 3,3'-dimethyl-BINOL[27] and 3,3'-bis(trimethylsilyl)BINOL[28] gave racemic **17**, and the catalyst derived from 3,3'-dihydroxy-4,4'-biphenanthryl (BIPOL)[29] provided **17** in only 39% *ee*, substitution at the 6,6'-position of BINOL proved effective for obtaining superior asymmetric catalysts.[30] The structures of these rare earth/Li/6,6'-disubstituted BINOL complexes are similar to that of the (*R*)-LLB complex (as elucidated by ^1H and ^{13}C NMR; Scheme 13). Table 2 shows the results of the nitro-

results of the nitroaldol reaction at −40 °C for 91 h in THF with 3.3 mol% of catalyst and ten equivalents of nitromethane. Using catalysts **43e**–**43i** routinely provided nitroaldols with optical purities superior to that of adducts obtained with LLB.

Another advantage was conferred by introducing 6,6'-substituents to BINOL. In general, catalytic asymmetric syntheses of fluorine-containing compounds are rather difficult.[31] In collaboration with Iseki and Oishi (Daikin Industries, Tsukuba, Japan) we found that the catalytic asymmetric nitroaldol reaction of rather unreactive α,α-difluoroaldehydes proceeded satisfactorily with heterobimetallic asymmetric catalysts generated from 6,6'-bis((triethylsilyl)ethynyl)BINOL (Table 3).[32] The (*S*) configuration of the nitroaldol adduct **45** showed that the nitronate reacted preferentially on the *Si* face of aldehyde in the presence of (*R*)-LLB. In contrast, (*R*)-LLB generally causes

attack on the *Re* face. Therefore, enantiotopic face selection for α,α-difluoroaldehydes is opposite to that for nonfluorinated aldehydes. The stereoselectivity for α,α-difluoroaldehydes is identical to that of β-oxaaldehydes, suggesting that the fluorine atoms at the α position have a great influence on enantioface selection.

5. Diastereoselective and Enantioselective Nitroaldol Reactions

With more effective asymmetric catalysts in hand, we applied the catalysts **43f** and/or **43g** in diastereoselective nitroaldol reactions. On the centennial of the discovery of the nitroaldol reaction in 1895,[20] we found that in all cases high *syn* selectivity and enantioselectivity were obtained with 3.3 mol% of the new catalysts (much higher than with LLB; Table 4).[33] Structurally simple aldehydes such as hexanal, which has no neighboring group to assist asymmetric induction, gave nitroaldols in high optical purity. The optical purities of the minor *anti* adducts were lower than those of the *syn* adducts, indicating that the former were *not* generated by epimerization of the nitro group. In fact, treatment of the *syn* adducts with catalysts such as LLB and its derivatives resulted in near-quantitative recovery of the starting materials with unchanged optical purities. The *syn* selectivity in the nitroaldol reaction can best be explained as arising from steric hindrance in the bicyclic transition state—as can readily be seen in the Newman projection. This suggests that the transition state leading to the *syn* adduct is the more favorable (Scheme 14).[33] In the favored transition state, the catalyst is believed to act simultaneously as a Lewis acid and as a Lewis base at different sites. In contrast, the nonchelation-controlled transition state affords *anti* adducts with lower optical purities.

The *syn*-selective asymmetric nitroaldol reaction was successfully applied to the catalytic asymmetric synthesis of *threo*-dihydrosphingosine (**70**), which elicits a variety of cellular responses by inhibiting protein kinase C (Scheme 15).[34] Nitroaldol reaction of hexadecanal (**68**) with three equivalents of nitroethanol gave the corresponding nitroaldol adducts in high *syn* selectivity (91:9; 78% yield); the *syn*-adduct **69** was obtained with up to 97% *ee*. The LLB-catalyzed reaction under similar conditions

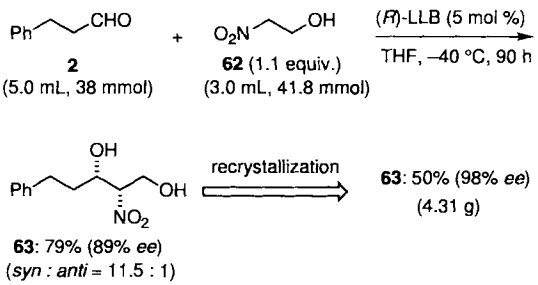
proceeded only slowly to give a 86:14 ratio of the *syn* and *anti* adducts in 31% yield and with lower optical purity (83% *ee*). Hydrogenation of **69** in the presence of 10% of Pd on charcoal afforded **70** in 71% yield.

The reason for the positive effects 6,6′-substitution on BINOL is not yet clear. Nevertheless, introduction of 6,6′-bis-(trialkylsilyl)ethynyl substituents suppresses undesired ligand exchange between nitroalkane and BINOL completely, which occurs in the case of LLB (albeit in only tiny amounts). This chemical phenomenon was brought to our attention by the following observation: Although an excess of nitroalkanes is in general required for efficient nitroaldol reactions, in the case of nitroethanol about one equivalent of the nitroalkane is sufficient. The undesired ligand exchange clearly becomes uncompetitive and is therefore avoided. Even using unmodified LLB gives high diastereoselectivity and enantiomeric excess by a practical synthetic procedure (Scheme 16).[35]



Scheme 16. Practical procedure for the synthesis of **63**.

6. Second-Generation LLB Catalysts

Catalytic asymmetric nitroaldol reactions promoted by LLB or its derivatives require at least 3.3 mol% of asymmetric catalyst for efficient conversion; even so, the reactions are rather slow. Is it possible to reduce the required amount of asymmetric catalysts and/or accelerate the reactions? Consideration of the possible mechanism for catalytic asymmetric nitroaldol reactions is clearly required to formulate an effective strategy (Scheme 17). Although the lithium nitronate is first generated, there is a significant possibility that the aldehyde coordinates to La first. We strove to detect the postulated intermediate **I** by various methods. However, these attempts proved to be unsuccessful, probably owing to the low concentrations of **I**. This might be ascribable to the presence of an acidic OH group in close proximity. To remove a proton from **I** we added almost one equivalent of base to the LLB catalyst. After many attempts, we found that 1 mol% of second-generation LLB (LLB-II, prepared from LLB), one equivalent of H_2O, and 0.9 equivalents of butyllithium efficiently promoted catalytic

asymmetric nitroaldol reactions. Moreover, use of LLB-II (3.3 mol%) accelerated these reactions. Other bases such as NaO*t*Bu, KO*t*Bu, and Ca(O*i*Pr)$_2$ gave less satisfactory results (Table 5).[36]

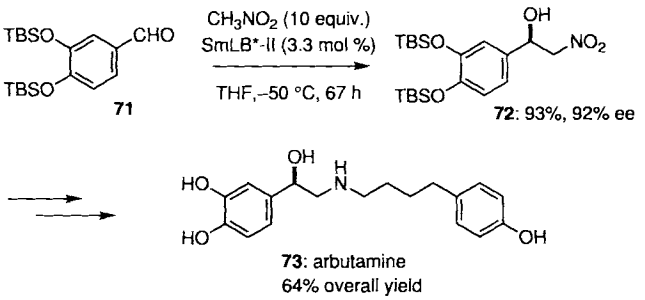
10	**62** + **2**	**43g**-II (1)	154	−50	**63**	76 (94/6)	96

[a] LLB-II = LLB + H_2O (1 equiv.) + BuLi (0.9 equiv.); **A** = LLB + H_2O (1 equiv.) + BuLi (2 equiv.); **43g**-II = **43g** + H_2O (1 equiv.) + BuLi (0.9 equiv.).

The structure of LLB-II has not yet been unequivocally determined. However, we propose that it is a complex of LLB and LiOH. A proposed reaction course for an improved catalytic asymmetric nitroaldol reaction is shown in Scheme 18. Treatment of the lithium nitronate (0.9 mol%, generated from nitropropane and butyllithium) with **43g** (1 mol%), **2**, and nitropropane (**59**) under conditions similar to those described above gave comparable results (59% yield, *syn*:*anti* = 94:6, 94% *ee*). This suggests the presence of a heteropolymetallic intermediate **II**. Although a molecular-ion peak was not observed, a fragment-ion peak for the complex of LLB and lithium nitronate was seen at *m*/*z* = 816 by FAB-MS.

These results suggest quite interesting chemical phenomena, namely the tight complexation of LLB and LiOH and the high rate of aggregation between LLB and lithium nitronates. With the second-generation LnLB catalyst consisting of 6,6′-bis((trimethylsilyl)ethynyl)BINOL and Sm, we succeeded in an efficient catalytic asymmetric synthesis of arbutamine (**73**; Scheme 19), a useful β agonist.[37,38]



Scheme 19. Catalytic asymmetric synthesis of arbutamine (**73**); SmLB*-II = $SmLi_3$tris[(*R*)6,6′-bis{(trimethylsilyl)ethynyl}binaphthyloxide] + H_2O (1 equiv.) + BuLi (0.6 equiv.).

7. Catalytic Asymmetric Hydrophosphonylations of Aldehydes

In recent years α-hydroxy phosphonates have attracted much attention due to their wide-ranging biological activity[39] and their usefulness as synthetic intermediates for other biologically important α-substituted phosphoryl compounds.[40] Although the biological activities of the latter depend on their absolute configuration,[41] syntheses of optically active phosphoryl compounds have only recently begun to be studied in detail.[42] Shibuya et al. and Spilling et al. have independently reported[43,44] enantioselective hydrophosphonylations of aldehydes with LLB. However, the purity of the LLB catalyst used appeared to be rather low. Therefore, we reinvestigated the catalytic asymmetric hydrophosphonylation with LLB. In the presence of 10 mol% of LLB, hydrophosphonylation of benzaldehyde (**13**) and cinnamaldehyde (**85**) with 1.3 equivalents of dimethyl phosphite in THF at −40 °C gave the corresponding α-hydroxy phosphonates **74** and **86** in 76% *ee* (79% yield) and 72% *ee* (78% yield), respectively.[45] Shibuya et al. and Spilling et al. reported that hydrophosphonylation of **13** with LLB prepared in their groups gave the corresponding α-hydroxy phos-

phonates in less than 30% *ee* under similar conditions.[43, 44] Upon slow addition of the aldehydes the enantiomeric excesses of both **74** and **86** at −40 °C were increased to 83% *ee* (73% yield) and 79% *ee* (88% yield), respectively. As solvent, THF again gave the best results. Representative results obtained at −78 °C are summarized in Table 6.[45]

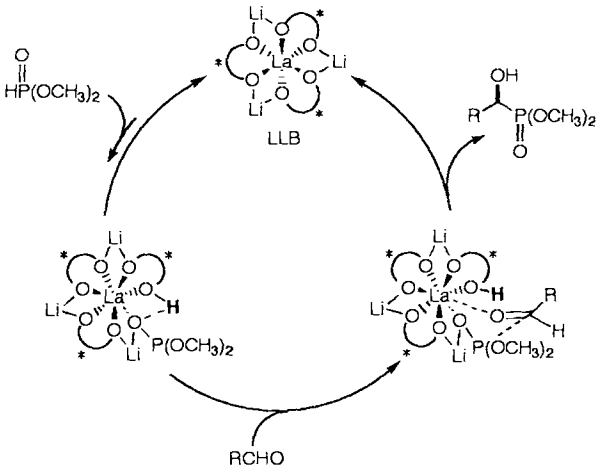
12	**65**	$CH_3(CH_2)_3CH_2$	**91**	8	88	61

[a] The aldehyde was added in one portion.

In the catalytic asymmetric hydrophosphonylation reactions, neither 6,6′-bis((triethylsilyl)ethynyl)BINOL nor LLB-II gave a significant improvement in the results. The effects of slow addition of the aldehydes on the enantioselection can be explained as follows: Heterobimetallic catalysts such as LLB are believed to activate both nucleophiles and electrophiles. For the hydrophosphonylation of relatively unreactive aldehydes, the activated phosphite can only react with aldehydes that are precoordinated to the La atom. In the case of reactive aldehydes such as **13** and **85**, the Li-activated phosphite may be able to undergo a competing reaction with the unactivated aldehyde. If such aldehydes are added in one portion, the enantiomeric excess of the product will be reduced. In contrast, slow addition of aldehyde has the effect of maximizing the ratio of activated to unactivated aldehyde present in solution. This allows enough time for the catalytic cycle to complete and regenerate the catalyst, and the aldehyde activation is facilitated. Reactive aldehydes should, therefore, be added slowly in order to avoid the side reaction that proceeds without activation of the aldehyde by LLB (Scheme 20).

8. Catalytic Asymmetric Diels–Alder Reactions

Catalytic asymmetric Diels–Alder reactions have attracted great attention over the past two decades.[46] Can LLB-type complexes form effective catalysts for such processes? These complexes are multifunctional asymmetric catalysts that show both Brønsted basicity and Lewis acidity. Nevertheless, we decided to examine the use of LLB-type catalysts acting as asymmetric Lewis acids alone in a range of catalytic reactions. This idea led naturally to the development of catalytic asymmetric Diels–Alder reactions with the LLB-type catalyst.[47]



Scheme 20. Proposed catalytic cycle for asymmetric hydrophosphonylation.

Table 7 shows some representative results for reactions of **92** and cyclopentadiene (**93**). Interestingly, addition of [12]crown-4 to the reaction medium resulted in the formation of the adduct **94** with much lower enantiomeric excess. This suggests that the lithium cations play a key role in activating the dienophile.

9. Catalytic Asymmetric Michael Reactions Promoted by LSB

Catalytic asymmetric Michael reactions are one of the most important synthetic methods for obtaining asymmetric centers.[48] In particular, 1,3-dicarbonyl compounds are highly promising Michael donors for the enantioselective construction of carbon–carbon bonds. Although LSB (L = La, S = Na) is ineffective as an asymmetric catalyst for nitroaldol reactions,[15] it is effective in the catalytic asymmetric Michael reaction of various enones with malonates to give Michael adducts in up to 92% *ee* and almost quantitative yield (Table 8).[16, 49] In general the use of THF as a solvent gave the best results, whereas in the case of the LSB-catalyzed reaction of *trans*-chalcone (**105**) with **100** the use of toluene was essential to give **106** in good enantiomeric excess. An investigation of the effects of the central metal for the reaction of **105** with **100** showed that LSB is the best catalyst for catalytic asymmetric Michael additions.

What is the origin of the catalytic activity and mode of enantioselectivity in LSB-catalyzed Michael reactions? To clarify the

nature of the interaction between the enone and the asymmetric catalyst, the complexation was studied by ^{1}H NMR spectroscopy. The chemical shift of the α proton of cyclohexenone (**95**) was observed upon mixing it with the asymmetric bimetallic complexes (Figure 4). It is well-known that, in general, praseodymium complexes induce an upfield shift, whereas europium complexes induce a down-field shift.[50] Ordinary Lewis acids such as $La(OTf)_3$ and Et_2AlCl also induce a downfield shift. Complexation with LSB induced a small downfield shift of the signal for the α-proton of **95**, and PrSB, a moderately effective asymmetric catalyst for Michael reactions, induced a large upfield shift. For EuSB or LLB, which gave only near-racemic Michael adducts, the ^{1}H NMR spectra show no changes in chemical shift of the α proton of **95**. These NMR studies indicate

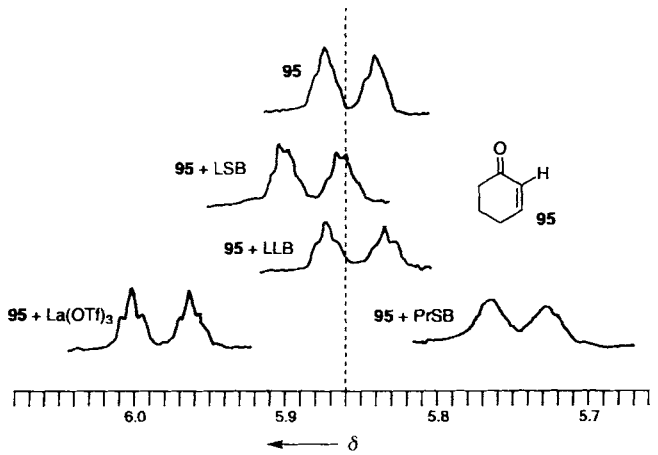

Figure 4. Chemical shift of the α proton in cyclohexenone (**95**).

that the carbonyl group of the enone is coordinated to the La and/or Pr atom in the LnSB molecule, whereas the enone does not coordinate to either LLB or EuSB. These changes of chemical shift were observed even in the presence of **100**. This chemical phenomena described might be understood by considering the differing dihedral angles of binding of the BINOL moiety to the center metal.

With the X-ray structure of LnSB as a reference point, computational simulations of the enantioselection process were carried out with Rappé's universal force field (UFF).[16, 51] With **95** coordinated to the La metal cation, the plane of the cyclohexenone ring should be almost parallel to the closest naphthyl ring system. This facilitates attack by the coordinated sodium enolate of **100** to give Michael adduct **101** (Scheme 21). UFF calculations and conformational searching for models of the pro-(*R*) and pro-(*S*) adducts clearly indicates that the (*R*)-LSB complex coordinates better as a pro-(*R*) than a pro-(*S*) adduct ($\Delta E = 4.9$ kcal mol^{-1}). LSB can therefore generate an intermediate such as that shown at the top of Scheme 21, which gives a high enatiomeric excess. The resulting sodium enolates of the optically active Michael adducts abstract a proton from an acidic OH group to regenerate the LSB catalyst (Scheme 22). Therefore, the basic LSB complex also acts as a Lewis acid and controls the orientation of the carbonyl function to activate the enone to attack. The multifunctional nature of the LSB catalyst makes possible the formation of Michael adducts with high enantiomeric purity even at room temperature.

In both catalytic asymmetric Michael reactions and nitroaldol reactions, the enones and aldehydes appear to coordinate to the rare-earth metal. Why is LSB more effective for catalytic asymmetric Michael reactions, and LLB more effective for catalytic asymmetric nitroaldol reactions? Although the reason is still unclear, we assume that slight differences in bond lengths in chelate structures such as **I** and **II** as well as in the bite angle for the BINOL moiety caused by varying the alkali metal are responsible for this effect.

LSB was next applied to a catalytic asymmetric Michael reaction in which the asymmetric center is induced on the side of the adduct originating from the Michael donor. The reaction of **107** with **108** in THF and 10 mol% of LSB gave **109** with 23% *ee*, whereas the reaction in toluene afforded **109** with 75% *ee* (Table 9). When the amount of LSB was reduced to 5 mol%, the enantiomeric excess of **109** declined to 25% *ee*. In an attempt to offset this decline while still maintaining the lower level of catalyst we examined the effects of slow addition of **107**. As expected, the use of syringe-pump methods gave **109** with a high enantiomeric excess. In marked contrast, the asymmetric Michael reaction in toluene catalyzed by 5 mol% of LSB in CH_2Cl_2 gave **109** in 89% yield and with 91% *ee* without the need for slow addition. Moreover, the reaction was not so affected by the choice of rare-earth metal.[52]

Slow addition of the β-keto ester and use of CH_2Cl_2 as solvent are generally quite effective methods for preventing reduction of enantiomeric excess for the various Michael adducts (Table 10). On the other hand, malonates give adducts with high enatiomeric purity regardless of the solvent used.[16] These results can be rationalized by comparing the p*K*a of a β-keto ester with that of a malonate; the former is significantly more acidic. Therefore, the concentration of the resulting Na–enolate can be expected

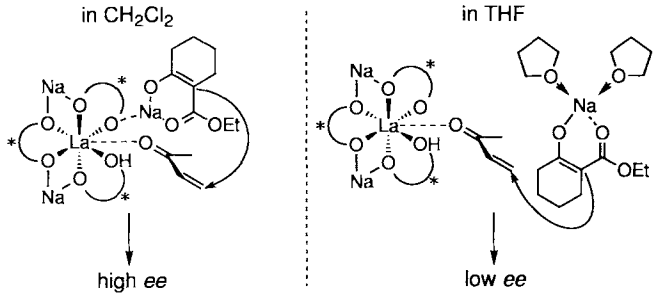
to be greater in the case of the β-keto ester. Furthermore, this Na–enolate will react with an enone more slowly than the Na–enolate derived from a malonate. We suggest that this combination of more rapid formation and longer lifetime increases the likelihood of dissociation of the Na–enolate from the chelated ensemble to give a product of lower enantiomeric purity. In less



Scheme 23. Proposed mechanism for the asymmetric Michael reaction catalyzed by LSB.

polar CH_2Cl_2 the Na–enolate would, even in this case, remain part of the ensemble to afford the product with a high enantiomeric excess (Scheme 23). Slow addition of the β-keto ester also acts to limit undesired ligand exchange between BINOL moieties and the Michael donor.

In both types of catalytic asymmetric Michael reactions, the use of either second-generation LSB or LSB-type catalysts derived from 6,6′-substituted BINOL did not resultant in significantly improved results.

10. Catalytic Asymmetric Hydrophosphonylation of Imines Promoted by Rare Earth/Potassium/BINOL Catalysts (LnPB)

α-Aminophosphonic acids are interesting compounds for designing enzyme inhibitors. Mimicking tetrahedral transition states of enzyme-mediated peptide-bond hydrolyses led to the successful design and synthesis of phosphonamide-containing peptides as a promising new class of proteinase inhibitors.[53] In the case of α-hydroxy phosphonic acids, the absolute configuration of the α carbon strongly influences the biological properties. Several methods for synthesizing optically active α-aminophosphonic acids have been published.[54] We succeeded in developing the first catalytic asymmetric hydrophosphonylation of imines with LnK_3tris(binaphthoxide) complexes (LnPB) to give optically active α-aminophosphonates in modest to high enantiomeric excesses.[55]

We first examined the possibility of a catalytic asymmetric hydrophosphonylation of imine **125** with dimethyl phosphite and catalytic amounts of heterobimetallic complexes. These reactions proceed at 60 °C only in the presence of a stoichiometric amount of the heterobimetallic complexes; LPB and LSB proved to be more effective than LLB. To increase the reactivities of the imines, we examined the reaction of **127** under various conditions. In contrast to **125**, the reactions proceeded at room temperature in the presence of even a catalytic amount of the heterobimetallic complexes, in particular LPB. Treatment of **127** with 1.5 equivalents of dimethyl phosphite and 10 mol% of LPB in THF/toluene (1/7) at room temperature for 96 h gave α-aminophosphonate **128** with 96% *ee* in 70% yield. In the case of imine **129**, use of 5 mol% of LPB gave **130** with 92% *ee* in 82% yield. The slightly weaker coordination of amine **130** to the La atom with respect to that of **128** improves the catalyst turnover. Several imines were converted effectively to the corresponding optically active α-aminophosphonates (Table 11). In contrast, in the case of imine **137** use of the GdK_3tris(binaphthoxide) complex (GdPB) gave a better result, and for **139** the use of *p*-methoxyaniline as the imine component and PrPB proved most effective.

The proposed mechanism of this catalytic asymmetric hydrophosphonylation is shown in Scheme 24. The first step is

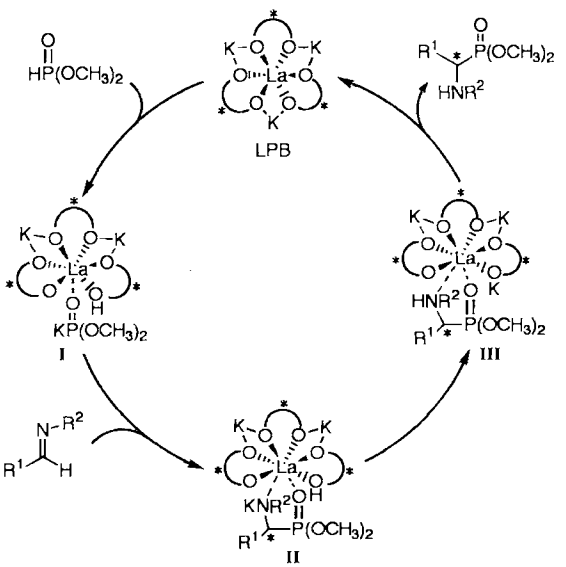
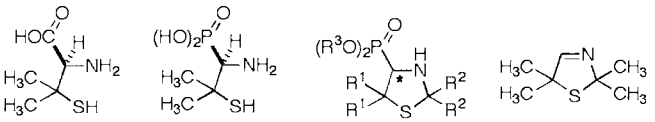
[a] All reactions were performed in the presence of five equivalents of dimethyl phosphite except entries 7 and 8 (1.5 equiv.). A: 60 °C in THF; B: room temperature in THF; C: room temperature in THF/toluene (1/7); D: 50 °C in THF/toluene (1/7).



Scheme 24. Proposed catalytic cycle for the asymmetric hydrophosphonylation catalyzed by LPB.

deprotonation of dimethyl phosphite by LPB to generate potassium dimethyl phosphite, which immediately coordinates to the strongly oxophilic rare-earth metal to give **I**.[56] Compound **I** then reacts with an imine to give an optically active potassium salt of the α-aminophosphonate, which results in an α-aminophosphonate and LPB by a proton–exchange reaction. This completes the catalytic cycle and provides the desired asymmetric hydrophosphonylation. This mechanism reveals why LPB is the best catalyst for catalytic asymmetric hydrophosphonylations of imines. Once again, neither the use of LPB-II nor LPB derivatives derived from modified BINOLs gave better results.

We also examined the hydrophosphonylation of cyclic imines. The 4-thiazolidinylphosphonates **145**, which may be regarded as N,S-protected phosphonic acid analogs of L-penicillamine (**143**), have been described as biologically active compounds[57] and were first prepared in racemic form by addition of dialkyl phosphite to the C=N bond of 3-thiazolines such as **146** (Scheme 25).[57, 58] Several attempts at the diastereoselective



Scheme 25. Structure of L-penicillamine (**143**), its phosphonic acid analog **144**, and its synthetic intermediates.

synthesis of 4-thiazolidinylphosphonates have been made by addition of stoichiometric amounts of chiral phosphites.[59] In collaboration with Martens and Gröger (Universität Oldenburg, Germany) we succeeded in developing an efficient *catalytic* asymmetric hydrophosphonylation of cyclic imines. Some representative results are shown in Table 12.[60]

With the use of 20 mol% of LPB in THF/toluene (1/7) at room temperature, only a modest enantioselectivity of 61% *ee* (53% yield) was observed for the formation of the desired **147** after 144 h (Table 12, entry 1). The efficiency of the reaction was improved by increasing the reaction temperature to 50 °C. We thereby obtained **147** in nearly unchanged chemical yield and enantioselectivity but in a reduced reaction time (50 h, entry 2). Additional efforts to increase the efficiency of the reaction by investigating the influence of further lanthanoid metal components in the catalyst structure were carried out at 50 °C. A great increase in the enantiomeric excess (up to 97%) and good chemical yields were obtained with Sm, Gd, or Dy (entries 4–6). In addition, the desired phosphite adduct (*R*)-**147** was obtained with both excellent enantioselectivity (96% *ee*) and high chemical yield with the (*R*)-YbPB complex as the heterobimetallic lanthanoid catalyst (entry 7), a complex which also shows highly effective catalytic properties with respect to the reaction rate. By carrying out the phosphite addition with YbPB catalyst at room temperature **147** was obtained in 86% chemical and 98% *ee* (entry 8). This is the highest enantioselectivity so far observed for a catalytic asymmetric hydrophosphonylation.

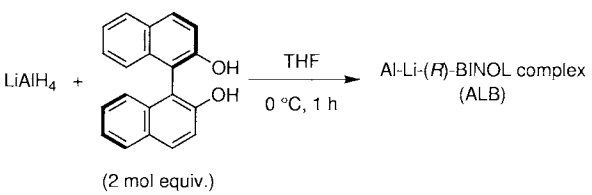
11. Other Heterobimetallic Asymmetric Complexes and Their Use in Catalytic Asymmetric Reactions

As discussed above, mechanistic studies of LnMB-catalyzed reactions, in particular of LSB-catalyzed Michael reactions, have revealed that LnMB acts as a base catalyst (through the OM moiety) and, at the same time, shows Lewis acid character (through the Ln center). This makes highly enantioselective reactions possible and suggests that extension of the heterobimetallic concept to central metals other than rare earth could lead to new heterobimetallic asymmetric catalysts with novel functionality.

We first developed an amphoteric asymmetric catalyst assembled from aluminum and an alkali metal.[61] In an initial attempt to prepare the AlLibis(binaphthoxide) complex (ALB), diisobutylaluminum hydride (1.0 M solution in THF) was treated with two equivalents of (*R*)-BINOL in THF at 0 °C for 0.5 h, and the resulting solution further treated with one equivalent of butyllithium (1.73 M solution in hexane) at 0 °C for 0.5 h. The new asymmetric catalyst produced (10 mol%) was highly effective in the Michael reaction of **95** with dibenzyl malonate (**96**) to give **97** with 98% *ee* and 46% yield at room temperature. The same catalyst could be prepared more efficiently from $LiAlH_4$ and two equivalents of (*R*)-BINOL (Scheme 26). This catalyst (10 mol%) provides high yields of **97** with greater than 99% *ee*; excellent yields of the various Michael adducts **149**, **150**, **101**, and **103** in enantiomeric excesses ranging from 91% to 98% *ee* were also observed (Table 13).[62] This is the highest enan-



Scheme 26. Preparation of the Al/Li/(*R*)-BINOL complex (ALB).

Table 13. Asymmetric Michael reactions catalyzed by an Al/M/bis[(*R*)-binaphthoxide] complex (AMB)

tiomeric excess so far reported for catalytic asymmetric Michael reactions.[48, 62] Although LLB and LSB complement each other in their ability to catalyze asymmetric nitroaldol and Michael reactions,[15, 16] Al/M/(*R*)-BINOL complexes (M = Li, Na, K, and Ba)[63] are more useful for catalytic asymmetric Michael reactions (entries 3–6).

With these excellent results in hand, we then unequivocally determined the structure of ALB by X-ray crystallography (Figure 5).[36, 62] The complex has a tetrahedral geometry around the aluminum center with an average Al–O distance of 1.75 Å. The long Li–O(1) distance of 2.00 Å is indicative of the ionic character between Li^+ and $[Al(BINOL)_2]^-$.

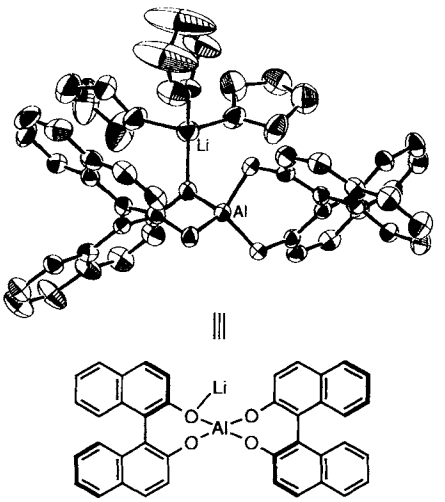

Figure 5. Crystal structure of ALB: $[C_{40}H_{24}AlLiO_4]\cdot 3THF$.

Since the electronegativity of lithium (1.0) is smaller than that of aluminum (1.5), a lithium enolate should be generated preferentially from a malonate derivative. However, the role of aluminum in this reaction is not understood well, and an ^{27}Al NMR study was performed to study the interaction between the enone and aluminum.[62] One broad signal was observed for the ALB at $\delta = 75$ (S_0). Upon addition of three equivalents of cyclohexenone (**95**), two additional signals were obtained at $\delta = 40$ (S_1) and 23 (S_2). The latter signal became stronger and was a major peak under conditions of the Michael reaction. This is strong evidence for an octahedral arrangement of six magnetically equivalent ligands around the aluminum cation in a solution in THF since all shifts are upfield relative to S_0.[64] These NMR studies clearly indicate that the carbonyl groups of the enones coordinate to the aluminum center. Consequently, this ALB acts as a heterobimetallic multifunctional asymmetric catalyst,[16] which makes possible efficient Michael reactions even at room temperature.

The above-mentioned mechanistic considerations suggest that the reaction of a lithium enolate derived from a malonate derivative with an enone should lead to an intermediary aluminum enolate. Further studies were carried out to obtain direct evidence of such an aluminum enolate in an effort to find a way to enhance its influence on the chemical fate of the Michael adducts. On the basis of the electronegativity of aluminum, protonation of the aluminum enolate should be slower than for the corresponding lithium, sodium, and/or lanthanoid enolates. Is it possible that such an aluminum enolate could be trapped by an electrophile such as an aldehyde? As anticipated, the reaction of cyclopentenone (**4**), diethyl methylmalonate (**148**), and hydrocinnamaldehyde (**2**) in the presence of 10 mol% of ALB gave the three-component coupling product **151** as a single isomer in 91% *ee* (64% yield; Table 14). The use of LLB, LSB,

Table 14. Tandem Michael–aldol reactions.

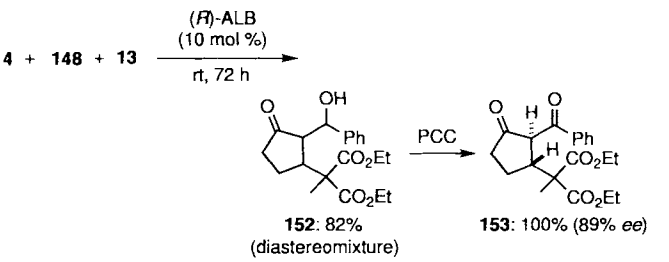
[a] Inseparable mixture. [b] Lithium-free.

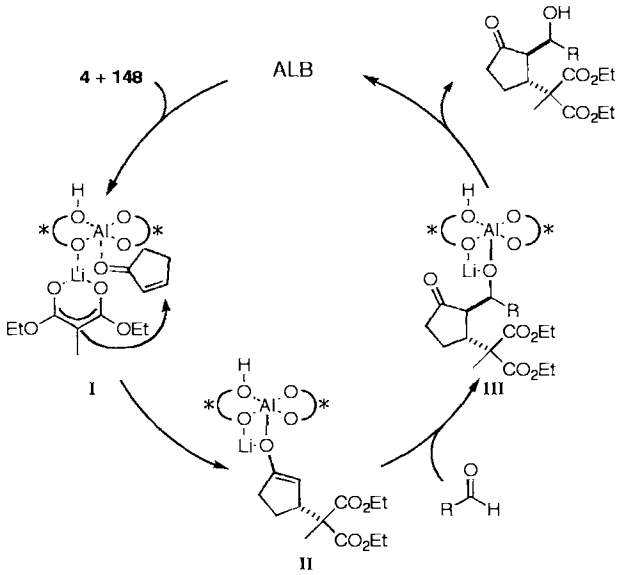
and/or a lithium-free La/BINOL complex[49] gave very unsatisfactory results for the same three-component coupling reaction. This is probably due to the lanthanum enolates being more reactive towards the acidic proton. Moreover, the use of benzaldehyde (**13**) instead of hydrocinnamaldehyde (**2**) gave the three-component coupling product **152** in 82% yield (Scheme 27). Although **152** was a mixture of diastereomers, oxidation gave the corresponding diketone derivative **153** as a



Scheme 27. Three-component coupling reaction with benzaldehyde (**13**) as an electrophile; PCC = pyridinium chloro chromate.

single isomer in 89% *ee*. This is the first example of a catalytic asymmetric tandem Michael–aldol reaction.

We can describe the reaction pathway in these three-component coupling reactions as follows (Scheme 28): The reaction of



Scheme 28. Possible mechanism for the asymmetric tandem Michael–aldol reaction catalyzed by ALB.

diethyl methylmalonate (**148**) with the ALB gives the corresponding lithium enolate **I**, which reacts with cyclopentenone (**4**, precoordinated to aluminum) to give the aluminum enolate **II** in an enantioselective manner. Further reaction of **II** with aldehyde leads to alkoxide **III**. Although it is unclear whether the aluminum or the lithium alkoxide is generated, **III** may then abstract a proton from an acidic OH group to give the three-component coupling product and regenerate the ALB, thereby completing the catalytic cycle. This reaction was successfully used in the catalytic asymmetric synthesis of 11-deoxy-$PGF_{1\alpha}$ (**155**; Scheme 29).[65]

Having developed an efficient catalyst, we next examined the hydrophosphonylation of aldehydes with ALB as a catalyst, as described for LLB (see Table 6).[66] As shown in Table 15, ALB is also effective at generating α-hydroxyphosphonates from aldehydes, especially those with an electron-withdrawing substituent. ALB and LLB can thus be used in a complementary

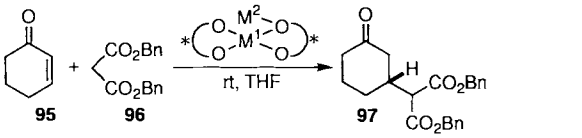
manner for asymmetric catalysis of the hydrophosphonylation of a wide variety of aldehydes.

In an attempt to develop other asymmetric heterobimetallic catalysts with advantageous functions, we attempted to prepare heterobimetallic asymmetric catalysts with either B, Ga, or In as the central cation. Whereas B/alkali metal/BINOL complexes do not promote the reaction of **95** with **96** at room temperature, the Ga/Na/BINOL (GaSB) and In/K/BINOL complexes (InPB) are effective catalysts for asymmetric Michael reactions; GaSB is superior to InPB in terms of enantioselectivity (Table 16). The

Table 16. Asymmetric Michael reaction of **95** with **96** catalyzed by a heterobimetallic asymmetric catalyst (10 mol%).



Entry	M^1	M^2	*t*[h]	Yield[%]	*ee*[%]
1	B	Li	17	0	-
2	B	Na	21	0	-
3	B	K	15	0	-
4	Ga	Li	43	71	49
5	Ga	Na	143	45	98
6	Ga	K	44	50	86
7	In	Li	24	77	2
8	In	Na	95	25	10
9	In	K	168	61	84

GaSB catalyst was prepared from $GaCl_3$, NaO*t*Bu (4 equiv to $GaCl_3$), and (*R*)-BINOL (2 equiv to $GaCl_3$) in THF/Et_2O. The structure consisting of one Ga atom, one Na atom, and two molecules of BINOL was determined by ^{13}C NMR spectroscopy and LDI-TOF mass spectrometry (Scheme 30). As expected, using almost one mole excess of NaO*t*Bu did not reduce the optical purity of the Michael adducts but did enhance the reactivity of the catalyst. Whereas the asymmetric Michael reaction of **95** with **96** catalyzed by 10 mol% of GaSB required 143 h at room temperature to give **97** with 98% *ee* in 45% yield, treatment of **95** and **96** with 10 mol% GaSB and 9 mol% NaO*t*Bu at room temperature for only 21 h gave **97** with 98% *ee* in 87% yield (Table 17). Addition of the sodium salt of dibenzyl

14	**156**	ALB	C	72	83	96

[a] A: NaO*t*Bu; B: $LiN(Si(CH_3)_3)_2$; C: sodium malonate. [b] Two molar equivalents of NaO*t*Bu. [c] Three molar equivlents of NaO*t*Bu.

malonate (9 mol%) instead of NaO*t*Bu gave an almost identical result (96% *ee*, quantitative yield). The asymmetric Michael reaction of **4** with **96** in the presence of 10 mol% of GaSB and 9 mol% of NaO*t*Bu also proceeded smoothly to give **150** with 98% *ee* in 96% yield (room temperature, 22 h). Moreover, an effective catalytic asymmetric synthesis of **157** was also realized for the first time (>99% *ee*, 79% yield). Typical time courses for the Michael reaction of **95** with **96** in the presence of GaSB, GaSB + NaO*t*Bu, or NaO*t*Bu are shown in Figure 6. The reaction was found to be kinetically controlled, as treatment of racemic **97** with GaSB or GaSB/NaO*t*Bu resulted in only racemic **97**. GaSB- and GaSB/NaO*t*Bu-catalyzed reactions were second-order for up to about 70% of the reaction (linear correlation coefficient $r > 0.998$). The calculated rate constants for the GaSB- and GaSB/NaO*t*Bu-catalyzed reactions were $k_{GaSB} = 0.031\,M^{-1}h^{-1}$ and $k_{GaSB/NaOtBu} = 1.78\,M^{-1}h^{-1}$, respectively (Figure 7). As expected, reaction of **95** with **96** in the presence of 10 mol% of the sodium salt of dibenzyl malonate at room temperature for 12 h gave racemic Michael adduct **97** in 91% yield. These results clearly suggest that the sodium

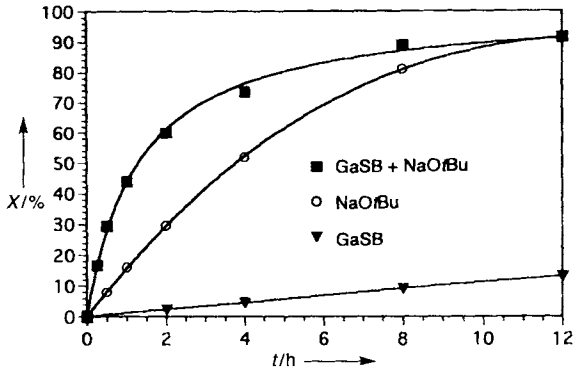

Figure 6. Typical time courses of the asymmetric Michael reaction of cyclohexenone (**95**, 392 mM) with dibenzyl malonate (**96**, 392 mM) in THF in the presence of 10 mol% of catalysts at 24 °C; X = conversion.

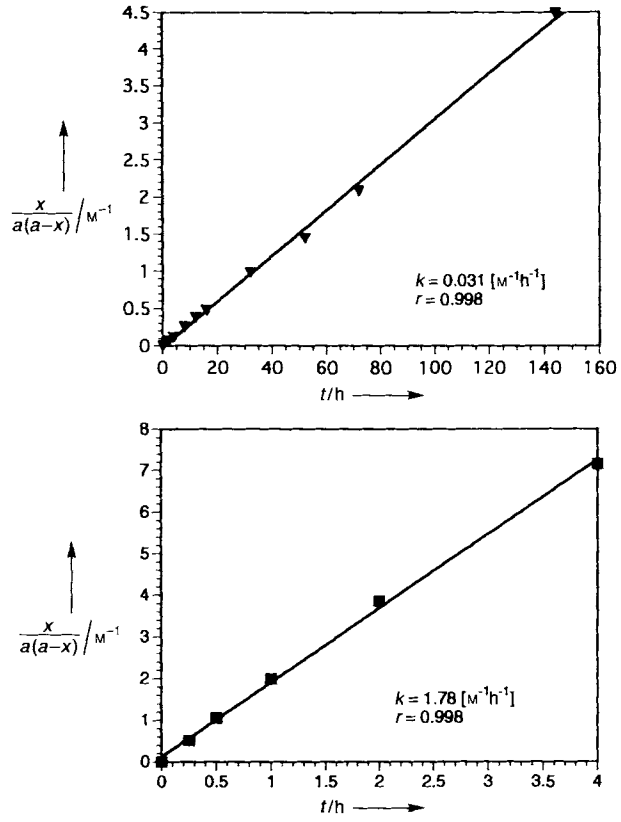

Figure 7. Kinetic analysis of GaSB- (top) and GaSB/NaO*t*Bu-catalyzed asymmetric Michael reactions of **95** with **96** (botton); a = initial concentration of **95** or **96**, x = concentration of **97**.

salt of dibenzyl malonate binds to GaSB more quickly than it reacts with the enone (as observed in the LLB case) to produce Michael adducts with high enantiomeric excess. No free sodium dibenzyl malonate should therefore be allowed to be present in the reaction medium. From the above assembly the malonate anion can be transferred to cyclohexenone with an enantiomeric excess similar to that in the case of GaSB itself. This result suggests that cyclohexenone also coordinates to the Ga metal center under the conditions described above.[62, 67] The usefulness of this activation strategy has also been demonstrated for catalytic asymmetric Michael reactions promoted by ALB (Table 17, entries 10–14). ALB-

and ALB/Na–malonate-catalyzed reactions are also second-order ($r > 0.995$). The calculated rate constants of the ALB- and ALB/Na–malonate-catalyzed reactions are $k_{ALB} = 0.273\ M^{-1}h^{-1}$ and $k_{ALB/Na-malonate} = 1.66\ M^{-1}h^{-1}$, respectively (Figure 8).

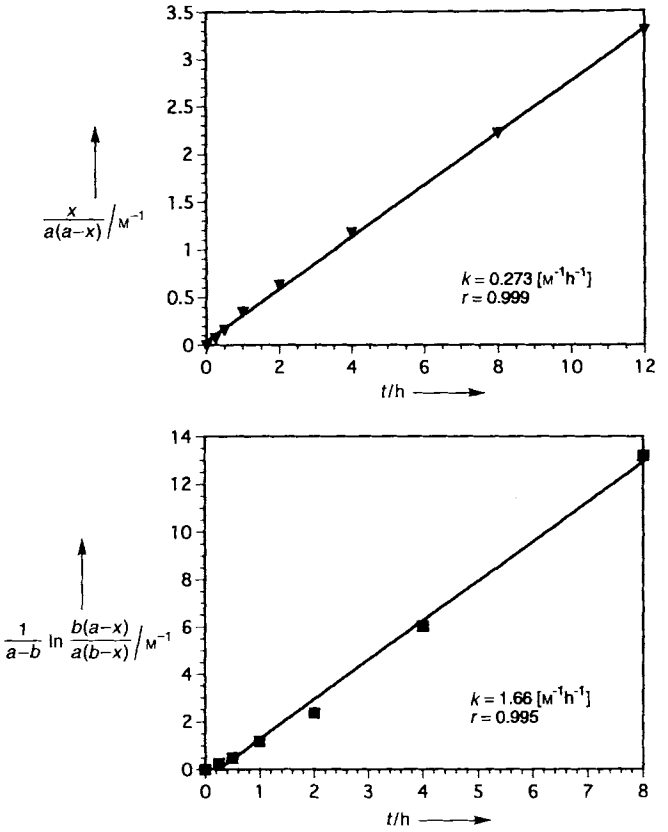

Figure 8. Kinetic analysis of ALB- (top) and ALB/Na–malonate-catalyzed asymmetric Michael reactions of **95** with **96** (bottom); a = initial concentration of **95** (= 444 M), b = initial concentration of **96** (484 M), x = concentration of **97**.

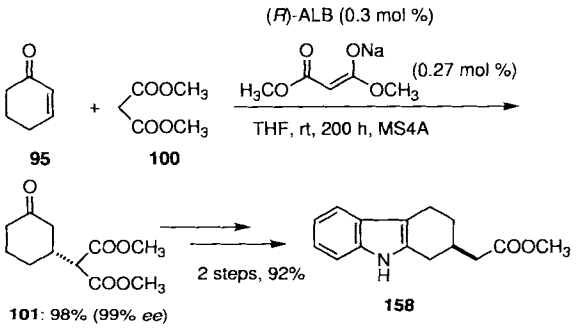
This strategy also made possible the use of 0.3 mol% ALB for efficient catalytic asymmetric Michael reactions (Scheme 31). The Michael adduct **101** (99% *ee*) was converted into the tricyclic compound **158** in 92% overall yield with a Fischer indole synthesis as the key step. Such tricyclic compounds should prove to be attractive intermediates for the catalytic asymmetric synthesis of various indole alkaloids.[68]



Scheme 31. Synthesis of the indole derivative **158**. The key step is a Michael reaction catalyzed by ALB (0.3 mol%) and sodium malonate (0.27 mol%).

12. Summary and Outlook

We have succeeded in developing conceptually new heterobimetallic asymmetric catalysts such as LnMB, AMB, and GaMB. These catalysts function as both Brønsted bases and Lewis acids making possible various efficient catalytic asymmetric reactions in a manner analogous to enzyme chemistry. Several such catalytic asymmetric reactions are now being investigated for potential industrial applications. Successful development of the heterobimetallic concept has opened up a new field in asymmetric catalysis, and a wide range of applications may well ensue. We have clearly obtained good preliminary results for catalytic asymmetric aldol reactions,[69] catalytic asymmetric epoxidations of α,β-unsaturated ketones,[70] and catalytic asymmetric epoxide opening reactions.[71] The heterobimetallic asymmetric complexes discovered so far are applicable only to reactions that proceed in the presence of a base. Is it possible to develop nonbasic heterobimetallic asymmetric complexes that promote a variety of reactions in a highly enantioselective manner? Such reactions might include, for example, activation of olefinic double bonds followed by a nucleophilic addition. If this proves to be possible, the usefulness of the heterobimetallic concept would be greatly increased. Moreover, the heterobimetallic concept may perhaps be extended to an analogous *homo*-bimetallic concept. Development of a variety of asymmetric complexes that exist as oligomers may be possible, and, by obtaining positive cooperation between two identical metal centers in these asymmetric oligomers, many conceptually new asymmetric reactions might become feasible.

The research reviewed in this paper was possible only through the dedication, enthusiasm, and creativity of scores of co-workers, whose names are acknowledged on the publications from our laboratory cited here.

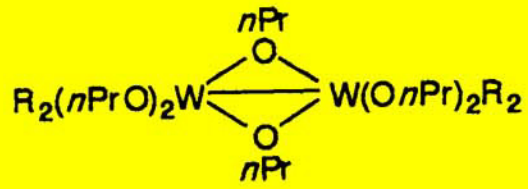
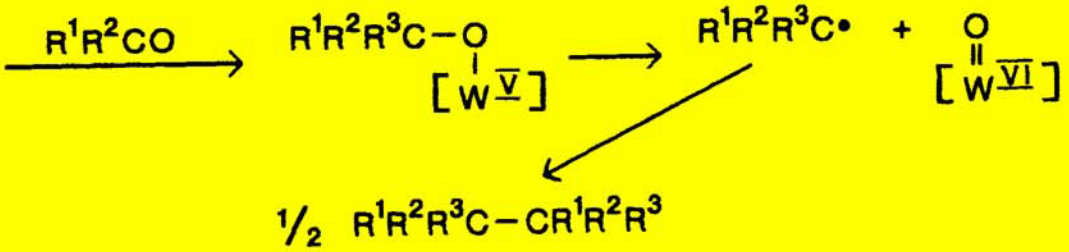
Deposition of Data from X-Ray Structure Analyses

In order to make life easier for authors and referees the Cambridge Crystallographic Data Centre (CCDC) and the Fachinformationszentrum Karlsruhe (FIZ) have unified their procedures for the deposition of data from single-crystal X-ray structure analyses.

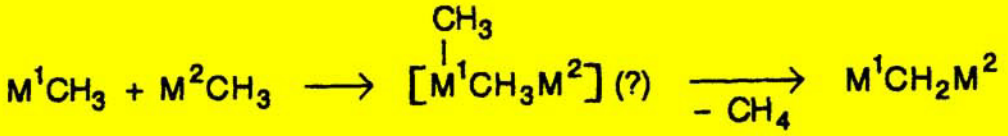
Prior to submitting your manuscripts please deposit the data for your compound(s) **electronically** at the appropriate data base, that is, at the CCDC for organic and organometallic compounds and at the FIZ for inorganic compounds. Both data bases will be pleased to provide help (see our *Notice to Authors* in the first issue of this year). In general, you will receive a depository number from the data base within two working days after electronic deposition; please include this number with the appropriate standard text (see our *Notice to Authors*) in your manuscript. This will enable the referees to retrieve the structure data quickly and efficiently if they need this information to reach their decision.

This is now the uniform procedure for manuscripts submitted to the journals *Advanced Materials, Angewandte Chemie, Chemische Berichte/Recueil, Chemistry—A European Journal,* and *Liebigs Annalen/Recueil.*

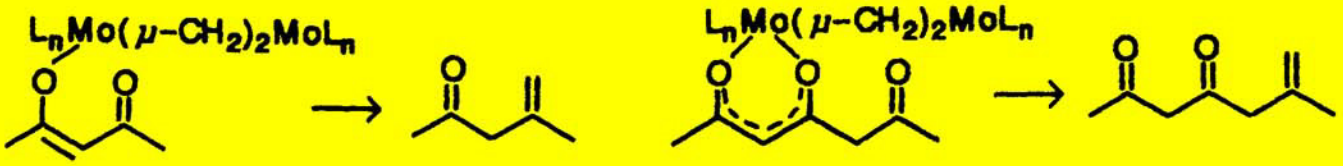


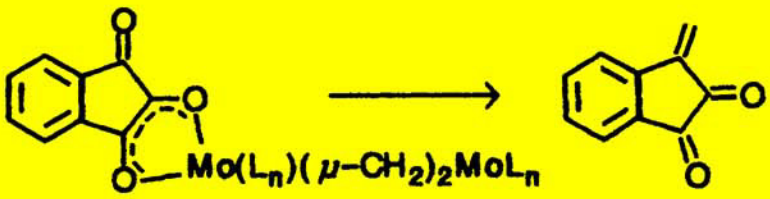


Additive – reductive carbonyl dimerization (top) is possible by using novel organotungsten reagents ...



$(M^1 = MoL_n, WL_n; M^2 = MoL_n, WL_n, AlL_n)$





... and highly regioselective carbonylmethylenations (bottom) can be achieved with μ-methylenemolybdenum reagents, which are readily accessible by a spontaneous transformation of a methyl ligand into a μ-methylene ligand (middle).

Novel Reactions of Organomolybdenum and Organotungsten Compounds: Additive–Reductive Carbonyl Dimerization, Spontaneous Transformation of Methyl Ligands into μ-Methylene Ligands, and Selective Carbonylmethylenation**

Thomas Kauffmann*

Hitherto there was no reaction known that permits transformations of R^1R^2-CO → 0.5 $R^1R^2R^3C$–$CR^1R^2R^3$ in one step. This type of additive–reductive carbonyl dimerization is now possible using alkoxy(alkyl)tungsten(v) complexes with aromatic, heteroaromatic, or α,β-unsaturated aldehydes and ketones. When a corresponding phenyl complex was employed in a test experiment, it was revealed that an aliphatic ketone could be used as the substrate in this reaction. A second interesting type of reaction is the transformation of CH_3 ligands into μ-CH_2 ligands, which occurs during the treatment of MeLi or Me_3Al with molybdenum or tungsten chlorides (oxidation states VI and V, for Mo additionally IV) at low temperatures with liberation of CH_4. Here, the question arises as to whether the intermediate involved has a terminal CH_2 ligand (Schrock carbene complex) or a μ-CH_3 ligand (CH_3 bound by a two-electron three-center bond to two metal atoms). Of all the μ-CH_2 complexes obtained, those which were synthesized by the action of MeLi on molybdenum chlorides can be recommended as reagents for carbonylmethylenation of aldehydes and ketones. They display high selectivity, very low basicity, a surprising resistance to protons, they are readily available, can be easily modified and, as regards their selective behavior, they have been investigated more thoroughly than other readily accessible carbonylmethylenation reagents of comparable selectivity. The results of NMR spectroscopic investigations on the structure of the μ-CH_2 complexes, and associcated reaction mechanisms are discussed. A survey of carbonylmethylenation reagents, which have been reported in the literature, permits comparisons to be made with carbonylmethylenating molybdenum and tungsten complexes.

1. Introduction

The large number of transition metals and the resulting virtually immeasurable number of theoretically possible alkyl derivatives necessitates repeated comparative investigations of alkyl transition metal compounds.[2–4] In 1982 my co-workers and I began research in this field, and concentrated for a prolonged period on the elements molybdenum and tungsten (other main topics see refs. [5, 6]). Preceding this were reports on reactions of nucleophilic alkylating reagents with WCl_6: Thiele[7] and other authors[8] had treated WCl_6 with Me_2Zn, Me_2Hg, Et_4Sn, or $n$$Bu_3B$ and obtained crystalline complexes of $RWCl_5$ (R = Me, Et, nBu), which rapidly decomposed at room temperature. On the other hand, Wilkinson et al.[9] had treated WCl_6 with MeLi or Me_3Al and synthesized Me_6W, which explosively decomposes at room temperature to liberate three equivalents of CH_4. However, analogous experiments to obtain defined compounds by alkylation of $[Mo_2Cl_{10}]$, remained unsuccessful at first.[10] In 1975 Muetterties[11] found that on treating WCl_6 with Me_2Zn there is elimination of α-H to liberate CH_4 (does not contain D if treated in deuterated solvents), and a species is produced that can catalyze olefin metathesis and therefore probably contains a terminal CH_2 ligand. In analogy to their syntheses of alkylideneniobium(v) and -tantalum(v) complexes, Schrock and Clark[12] attempted to synthesize alkylidene complexes by reaction of neopentyllithium with $[Mo_2Cl_{10}]$ or WCl_6. However, they obtained dimers of alkylidyne complexes as a result of double α-H elimination, and so they turned to indirect synthesis (by transalkylidenation) of alkylidenetungsten complexes. Eventually Wilkinson et al.[13] obtained the alkylidene complex $[(Me_3SiCH_2)_3Mo{=}CHSiMe_3]$ along with $[(Me_3SiCH_2)_2Mo{\equiv}CSiMe_3]$ after treatment of $[Mo_2Cl_{10}]$ with excess Me_3SiCH_2Li. Thus, alkyl derivatives of high-valent Mo and W repeatedly demonstrated a powerful tendency towards α-H elimination. The publication by Muetterties,[11] mentioned above as well as in Section 3.4, can be regarded as the starting point for the investigations described in Sections 3 and 4. On

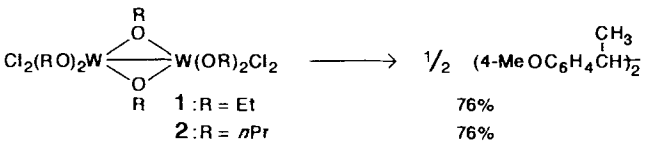
[**] Organomolybdenum- and Organotungsten Reagents, Part 7. Part 6: [1].

account of its novelty the additive–reductive carbonyl dimerization discovered during that work is the first topic to be discussed in this review.

2. Additive–Reductive Carbonyl Dimerization (ARCD Reaction)

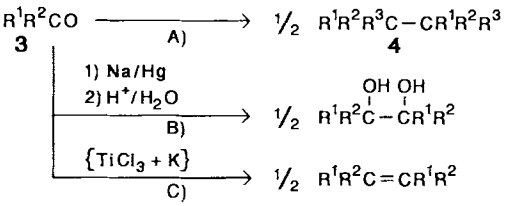
2.1. Characterization of the Reaction

During investigations as to whether alkoxy groups inhibit the transformation of a methyl ligand into a μ-methylene ligand (see Section 3), the known W^V complexes **1**[14–18] and **2**[16,18] as well as the W^{VI} complexes $(MeO)_4WCl_2$[19] and $(MeO)WOCl_3$[20] were each treated with two equivalents of MeLi per tungsten atom, and then with 4-methoxybenzaldehyde (Scheme 1). Whilst in the case of the W^{VI} complexes the expect-



Scheme 1. Discovery of the additive–reductive carbonyl dimerization [21,22a]. Conditions: 1) 4 MeLi, THF, $-78 \rightarrow 20\,^{\circ}C$ in 1 h, 2) $4\text{-}MeOC_6H_4CHO$, 3 h at 66 °C; *meso*:*rac* = 1:1.

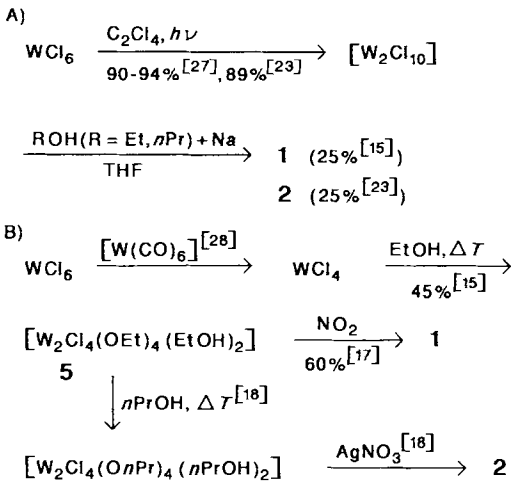
ed carbonylmethylenation product was obtained (see Table 4), treatment of **1** and **2** both produced good yields of equimolar amounts of *meso*- and *rac*-2,3-bis(4-methoxyphenyl)butane.[21] This reductive coupling, discovered by J. Jordan,[21,22a] can be used with other aromatic aldehydes as well as aromatic ketones, conjugated enones, and benzoic acid derivatives. Not only that, the MeLi can be replaced by other organolithium compounds and Grignard reagents.[22b,22c,23] Thus, a new type of reaction had been discovered, which—for aldehydes and ketones as the substrates—is described by the general Scheme 2A. This reaction supplements the reductive carbonyl dimerization to produce glycols[24] (Scheme 2B) and that to alkenes using low-valent titanium[25a] (McMurry reaction; Scheme 2C) or low-valent tungsten.[25b,32] Prior to this, in order to convert **3** → **4**, it was necessary to treat **3** with an organolithium or Grignard compound, the alcohol obtained by hydrolysis was then isolated, followed by reductive dimerization with $\{3\,TiCl_3 + LiAlH_4\}$[26].



Scheme 2. Additive–reductive carbonyl dimerization (A, reagents see Scheme 1 and text) and two further kinds of reductive carbonyl dimerization together with reagents (B,C).

2.2. Preparation and Properties of the Reagents

We synthesized[23] chlorides **1** and **2** using the two-step method of Brubaker et al.[15,16] from WCl_6 via $[W_2Cl_{10}]$[27] (Scheme 3A). On account of the unsatisfactory yields from the

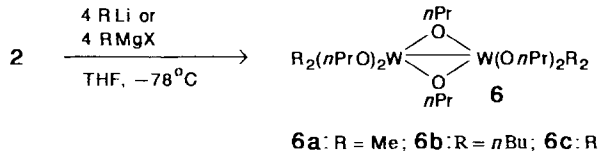


Scheme 3. Synthesis of reagents **1** and **2**.

second reaction step, Scheme 3B presents a three- and four-step synthesis for **1** and **2**, respectively, via WCl_4[28] and **5** from Cotton et al.,[17,18] which they regard as the most favorable pathway. However, they do not give the yields for each step. Additionally, there is a third synthesis[29] starting from $[W(CO)_6]$, which leads to the key compound **5** in three steps (not all yields given).

Complexes **6**, the actual reagents for the ARCD reaction, were each prepared from the tetrapropoxy complex **2** (Scheme 4), which is produced in somewhat better yields than **1**.

Thomas Kauffmann was born in Reutlingen, Germany, in 1924. He began to study chemistry in 1947 at the Universität Würzburg, and was a student of Clemens Schöpf at the Institut für Organische Chemie der Technischen Hochschule Darmstadt. Since 1965 he has been Professor of Organic Chemistry at the Universität Münster (Emeritus Professor in 1990). His main research interests have focused on sodium hydrazide as a reagent in organic synthesis, hetarynes, homocoupling by organocopper compounds, 1,3-anionic cycloaddition, preparative application of the areno-analogy principle, organoelement–lithium and organotransition metal reagents for organic synthesis, chele- and anticheleselectivity.



Scheme 4. Synthesis of the reagents **6** [23]. Reaction time for MeLi 15 min, for alkylLi 30 min, for PhLi and Grignard compounds 45–60 min.

During the reaction of **2** with four equivalents of MeLi there is a change of color from dark red to green with complete consumption of MeLi (detected by ^1H and ^{13}C NMR spectroscopy) to furnish a tetramethyl complex. This complex was assigned the structure **6a** for the reasons which follow: no gas was evolved on methylation, which points to the preservation of the oxidation state W^V. The ^1H NMR spectrum[22b, 23] displays four singlets of almost equal intensity, these arise from the CH_3 ligands, and indicate, as in **2**, the presence of bridging and nonbridging propoxy groups with an intensity ratio of 1:2. The sharpness of all the NMR signals indicates that the solution is diamagnetic, and therefore a W–W bond is present in **6a**. It is striking that the transformation of a methyl ligand into a μ-methylene ligand (see Section 3), which has been repeatedly observed for methyl derivatives of Mo^V, Mo^{VI}, W^V, and W^{VI}, does not take place with **6a**. This is discernible by the lack of evolution of CH_4[22b] on warming.

In analogy to MeLi, **2** was also treated with four equivalents of RLi (R = Et, *n*Pr, *n*Bu, *i*Bu, *s*Bu, Me_3SiCH_2, and Ph) as well as with some Grignard reagents.[23] With the exception of MeMgBr as the reagent, a color change from dark red to green occurred, which had already been observed for MeLi (see above). Therefore, it can be assumed that the transmetalation process is substantially complete and the individual complexes, which are analogous to **6a**, have been formed. Correspondingly, when the green reaction solutions were treated with aldehydes and ketones, alcohols of type R^1R^2CHOH or $R^1R^2R^3COH$ were either not produced at all or only in small amounts (see Table 3). In those cases in which a small amount of alcohol did form, this could have been due to only the first phase of the ARCD reaction having taken place. Experiments to isolate **6a** and analogous complexes (see Table 3) were not successful because of the extreme thermolability of these compounds. The approximate decomposition temperatures of the proposed complexes **6a–c** (Scheme 4) were determined to be −40,[22b] −55,[22c] and −70 °C,[22c] respectively (see reference [23]). Rapid decomposition occurs at these temperatures, and the color of the reaction solution changes from green to red. Slow decomposition of **6a** had already been established at −78 °C,[22b, 23] and, even at −40 °C, there is no evolution of CH_4. Nothing is known about the decomposition reaction.

2.3. Range of Application and Limits of the Reaction

2.3.1. Compound 6a as a Reagent

2.3.1.1. Aldehydes and Ketones as Substrates

Table 1 presents reactions in which the substrates were added to the thermolabile reagents at about −78 °C. As with benzaldehyde, **6a** also reacts with other aromatic aldehydes as well as with aromatic ketones according to Scheme 2A to give the ARCD product, generally with a good yield. The reaction with aldehydes and ketones containing OH, Cl, F, OMe, or NMe_2 groups reveals a great tolerance towards functional groups. This makes the reaction attractive for synthetic applications, because difunctionalized, and therefore readily modified ARCD products, are now accessible. One of the difunctionalized products, 2,3-bis(4-hydroxyphenyl)-2,3-dimethylbutane (Table 1, entry 8), exhibits anti-estrogen properties and can inhibit the growth of mammary tumors.[30] The nitro group is not tolerated.[23] An essential limitation of the range of application of the methylating ARCD reaction with **6a** (in contrast to the phenylating ARCD reaction with **6c**) is that the carbonyl group must be conjugated with an unsaturated group (this was tested for aromatic groups and C–C double bonds; see Tables 1 and 2). If this is not the case, only the carbonyl group is methylated to yield the corresponding alcohol.[23] If the conjugated, unsaturated group is a phenyl unit, only the ARCD product is formed. If, on the other hand, the carbonyl group is linked to a 2-furyl, 2-thienyl, or 2-(*N*-methyl)pyrrolyl group, or a C–C double bond (Table 2), isomeric compounds ("rearranged ARCD products") are also produced in addition to the ARCD product (**7**, **9–12**). Their structures (**8**, **13**, **14**) were elucidated (Table 2, entries 1 and 6) and are given in Scheme 5. In the reactions of furfural

Table 1. Reaction of **6a** with aldehydes and ketones R^1R^2CO in a 1:1 mole ratio [23]. Conditions: THF, −78 to 66 °C in 1 h, then 3 h at 66 °C, followed by hydrolysis with 2N NaOH at 20 °C [23]. The unconverted carbonyl compound could not be recovered from any of the reactions.

Entry	R^1	R^2	Yield [%] $(MeR^1R^2C)_2$	MeR^1R^2COH

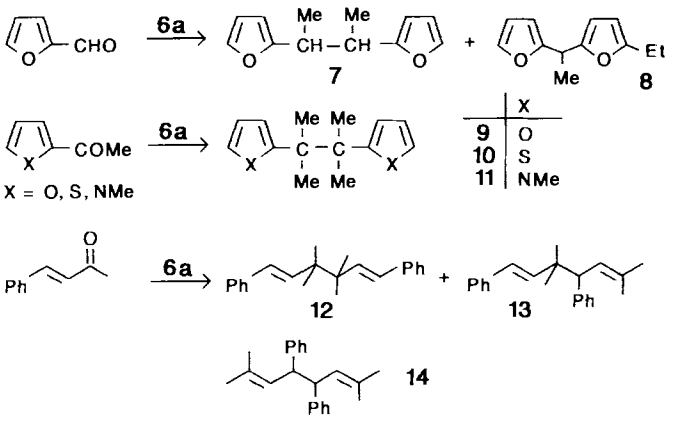
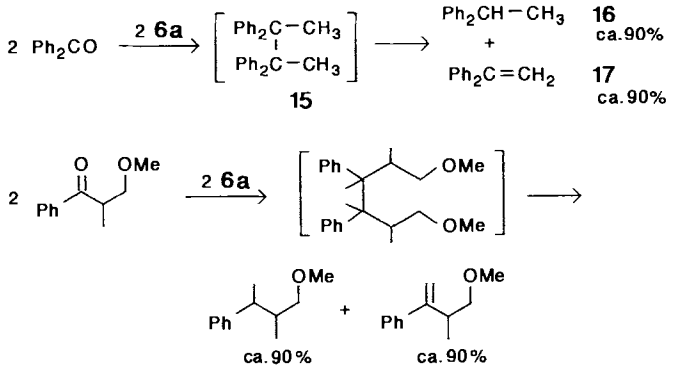
7	2-cyclohexenone		86 [c]	0

[a] Two diastereomers in the ratio of about 1:1. [b] Structure not elucidated. [c] Separation of the ARCD product and the isomers did not succeed. [d] The given structure is based on ^1H NMR spectroscopy and GC/MS analysis.



Scheme 5. Additive–reductive carbonyl dimerization with heteroaromatic carbonyl compounds as well as with an α,β-unsaturated ketone [23].

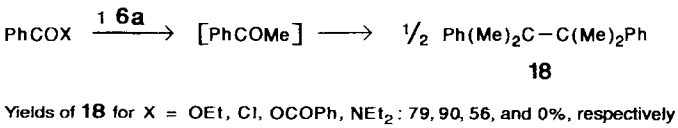
and heteroaromatic ketones (Table 2, entries 1–4) there is only *one* rearranged product (structure not elucidated) which is only produced in minor amounts compared to the ARCD product, so that these ARCD reactions still remain attractive for syntheses. In contrast, the reactions of cinnamaldehyde and conjugated enones (Table 2, entries 5–7) furnished several rearranged ARCD products. Therefore, these reactions are not recommended for preparative use. In the case of benzophenone and a further ketone (Scheme 6), a disproportionation product was obtained instead of the ARCD product. The ARCD product **15** from benzophenone disproportionates on warming to 1,1-diphenylethane (**16**) and 1,1-diphenylethene (**17**).[31]



Scheme 6. Disproportionation of ARCD products [23].

2.3.1.2. Benzoic Acid Derivatives as the Substrate

Compound **6a** reacts with ethyl benzoate, benzoic anhydride, and benzoyl chloride to give 2,3-dimethyl-2,3-diphenylbutane (**18**). Here there is initial formation of acetophenone by nucleophilic substitution, which then undergoes the ARCD reaction (Scheme 7). The unsuccessful reaction with *N*,*N*-diethylbenzamide indicates the limits of the surprisingly high nucleophilic activity of **6a** towards carbonyl compounds.



Yields of **18** for X = OEt, Cl, OCOPh, NEt_2: 79, 90, 56, and 0%, respectively

Scheme 7. Additive–reductive carbonyl dimerization of benzoic acid derivatives [23]. Two equivalents of **6a** were used for the reaction with benzoic anhydride; side product: 2-phenyl-2-propanol (20%). *N*,*N*-Diethylbenzamide was recovered in 90% yield.

2.3.2. Further Compounds of Type 6 as Reagents

ARCD reactions in which the alkyl group is transferred are also possible with good yields, even if the structural prerequisite for β-H elimination is present (Table 3, entries 1–6). This considerably widens the range of application of the ARCD reaction. The surprisingly low tendency towards β-H elimination, for example, in **6b**, which is in contrast to *n*-butylation products of $WOCl_3$, $WOCl_4$ (see Section 3.1), or WCl_6[32], corresponds to the disinclination of **6a** to form μ-CH_2 ligands from CH_3 ligands by α-H elimination (cf. Section 3.2). The tetraphenyl complex **6c** is also suitable for use as an ARCD reagent (Table 3, entries 8–10). It is particularly interesting that cyclohexanone, that is a substrate with an isolated keto group, also produces the ARCD product (Table 3, entry 9). From these results it can be expected that other carbonyl compounds (aldehydes, ketones, carboxylates, carboxylic acid anhydrides, and acyl chlorides) containing saturated hydrocarbon groups can also take part in a phenylating ARCD reaction. Not only that, it should be possible to employ other reagents in which the phenyl group of **6c** is replaced by other aryl groups.

Table 3. Reaction of reagents of type **6**, prepared according to Scheme 4, with aldehydes and ketones R^1R^2CO in a 1:1 mole ratio [23]. The yields and degrees of recovery given in parentheses apply to the case when **6** was synthesized with RMgX, the others to when it was synthesized with RLi. Reaction conditions as in Table 1.

Entry	R in **6**	R^1	R^2	Yield [%] $(R^1R^2R^3C)_2$	Yield [%] $R^1R^2R^3COH$	Recovery [%]

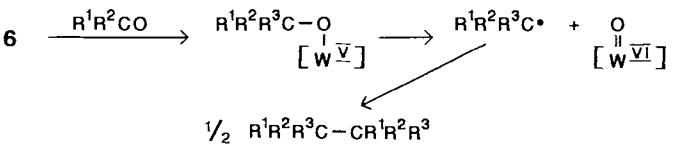
[a] Not determined. [b] Instead of the ARCD product its disproportionation products **16** and **17** were each obtained with 67% yield.

2.4. Mechanistic Discussion

The radical mechanism postulated for the ARCD reaction with aldehydes and ketones is given in Scheme 8.[23] This mechanism is supported by the following: a) The reaction only proceeds with the tetramethyl reagent **6a** if the carbonyl group of



Scheme 8. Postulated mechanism of additive–reductive carbonyl dimerization [23].

the substrate is conjugated with an unsaturated group; this leads to mesomeric radical stabilization. b) The reaction is also possible with an aliphatic ketone, if the tetraphenyl reagent **6c** is employed. c) The radical mechanism explains the occurrence of the "rearranged ARCD products" in the reactions given in Table 2, because the mesomeric radicals which are produced, can couple on both the primary radical center and in the allyl or pentadienyl position.

In a process which conforms with Scheme 8, the homolysis of the O–C bond is aided by mesomeric stabilization of the organic radical, as well as by the mesomeric interaction between the resulting electron-withdrawing oxo ligands and the electron-donating propoxy ligands. The following observations indicate a process in which the resulting radicals are in close proximity to one another, as in species **19**, and are within the effective domain

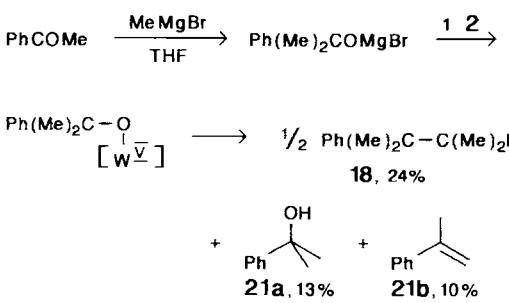
of the concomitantly formed organometallic species or in a solvent cage. a) In the ARCD reactions with **6a**, there were no cases observed of H-transfer from the solvent THF onto the postulated radical intermediate $R^1R^2\dot{C}CH_3$ (formation of $R^1R^2CHCH_3$ without the simultaneous formation of $R^1R^2C{=}CH_2$). b) The elimination of an H atom in an α position to the radical center was not observed (formation of $R^1R^2C{=}CH_2$ without the simultaneous formation of $R^1R^2CHCH_3$). c) Normally, there is a total absence of disproportionation of $R^1R^2\dot{C}CH_3$ (nonformation of equivalent amounts of $R^1R^2CHCH_3$ and $R^1R^2C{=}CH_2$) as well as yields of the ARCD product of up to 94%. In those cases in which the two central C atoms of the ARCD product are chiral centers (for example, Table 2, entry 1), the ratio of the *meso* form to the *rac* form is always about 1:1, as is usual for a radical process. This lack of stereoselectivity is a powerful argument against an electrocyclic process via transition state **20**. The fact that the ARCD product **18** from acetophenone is also accessible using the pathway given in Scheme 9, in which the methylating step is carried out on acetophenone instead of on **2**, is also in agreement with the mechanism given in Scheme 8. However, the low yield and the side products **21a** and **21b** make this second pathway of additive–reductive carbonyl dimerization appear to be relatively unfavorable.

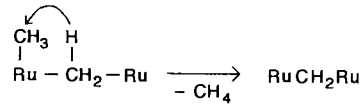


Scheme 9. Additive–reductive carbonyl dimerization with reversed course of reaction [23].

3. Spontaneous Transformation of Methyl Ligands into μ-Methylene Ligands in Complexes Containing High-Valent Molybdenum or Tungsten

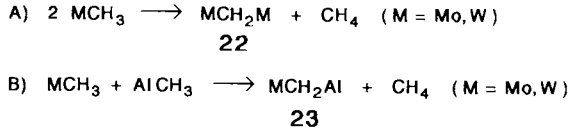
3.1. Formation of μ-CH_2 Complexes after Methylation of Molybdenum and Tungsten Chlorides with MeLi or Me_3Al

In 1978 Wilkinson et al[33] isolated the complex $[(Me_3P)_3Ru(\mu\text{-}CH_2)_3Ru(PMe_3)_3]$ after treating the quadruply bridged Ru^{II},Ru^{III} complex $[Ru_2(O_2CMe)_4]Cl$, or a further Ru^{II},Ru^{III} derivative, with excess Me_2Mg. They assumed that the μ-CH_2 ligands had been formed by α-H transfer via μ-CH_3 ligands (Scheme 10).[33] The transformation of a μ-CH_3 ligand into a μ-CH_2 ligand had been discovered only shortly before by Calvert and Shapley[34] on an Os cluster.



Scheme 10. Proposed mechanism for the formation of the μ-CH_2 ligands of a Ru complex [33]. The ligands not taking part in the reaction are omitted.

In our investigations, which were prompted by an observation by J. Sander,[35a] we found more than twenty examples for the transformation of CH_3 into μ-CH_2 ligands according to Scheme 11A and 11B:[1,36–43] treatment of MeLi or Me_3Al



Scheme 11. Transformation of CH_3 ligands into μ-CH_2 ligands in the reactions given in Tables 4–6 as well as in Section 4. The ligands not taking part in the reaction are omitted.

with Mo^V, Mo^{VI}, W^V, and W^{VI} chlorides[44] (see Tables 4–6) in THF or Et_2O at low temperatures produces methylmolybdenum and -tungsten complexes. On warming these complexes they liberate CH_4 and largely convert into thermolabile complexes containing μ-CH_2 ligands in the partial structures **22** and **23**, respectively, and can carbonylmethylenate aldehydes and ketones[1,36–42] (Tables 4–6 as well as Section 4). In some cases this ligand transformation could be proved qualitatively by NMR spectroscopy (Sections 3.2 and 3.3), and for molybdenum chlorides, it could be determined quantitatively by the measurement of the amount of CH_4 liberated in combination with the determination of the number of CH_2 groups transferred to the aldehyde groups (Table 6). Since at least 0.75–0.96 carbonylmethylenating μ-CH_2 ligands were formed per liberated CH_4 molecule, the CH_4 can only be formed at most in minor amounts by the reduction of the molybdenum chloride. The reactions according to Scheme 11 not only proceed in THF or Et_2O but also in chlorobenzene, toluene, cyclohexane, or in *n*-pentane, as can be discerned by the liberation of CH_4 and the formation of a carbonylmethylenating complex. The reactivity of the species formed in these solvents is not

Table 4. Reactions for the detection of CH_2 ligands by methylenation according $RCHO \rightarrow RCH{=}CH_2$ in THF. So far, they have only been published in dissertations. MeLi was added to the chloride at about −78 °C, followed by addition of the aldehyde (0.5 equivalent per molybdenum or tungsten atom). Unless otherwise stated, the mixture was then warmed to 20 °C over a period of 18 h. Corresponding reactions of aldehydes and ketones with $[Mo_2Cl_{10}]$, $MoOCl_3$, $MoOCl_4$, $WOCl_3$, and $WOCl_4$, in which very good yields were often obtained: see references [36–41] and Section 4.

restricted by any relatively strongly bound THF or Et_2O ligands. Thus, they are capable of attacking C–C double bonds and allylic H atoms. The reactions resulting from this occur either as a secondary reaction after a carbonylmethylenation (olefin dimerization, olefin metathesis), or instead of a carbonylmethylenation (cyclization, isomerization). For further information on these reactions see references [22n, 22o, 35d, 35k, 42, 43].

3.2. Further Details on the μ-CH_2 Complexes Formed by the Reaction with MeLi

Optimization of the reaction of MeLi with molybdenum and tungsten chlorides to give carbonylmethylenating reagents revealed that the most favorable ratio is two equivalents of MeLi per molybdenum or tungsten atom. Since it is highly probable that 1,3-dimolybda- or 1,3-ditungstacyclobutanes are formed (see below), the individual reagents are represented within brackets and each contain *two* molybdenum or tungsten atoms. The methylation step has been investigated for the reagents $\{2\,MoOCl_3 + 4\,MeLi\}$,[38] $\{2\,WOCl_3 + 4\,MeLi\}$,[22h] and $\{2\,WOCl_4 + 4\,MeLi\}$:[22h,44] ^1H NMR spectra were measured directly after mixing the components in $[D_8]$THF at low temperature (in the first case −30 °C, otherwise about −70 °C). The signal at $\delta \approx -1.98$ is absent, which indicates the complete consumption of MeLi. For each reagent there are two singlets present (δ = 0.96/0.79, 0.92/0.69, and 0.95/0.73, respectively), which lie in the range expected for metal-bound methyl groups. As the temperature is raised these signals disappear, whilst the intensity of the CH_4 signal at $\delta \approx 0.23$ increases and signals of μ-CH_2 ligands appear. The methylation products, which must have Lewis acidic properties, are incapable of methylating aldehydes and ketones at low temperature in THF (formation of stable reagent–THF complexes?; see references [45,46]). On warming these primary products CH_4 is liberated (for amounts see Table 6). Whilst this process is complete at about 20 °C for the molybdenum reagents, the tungsten reagents must be warmed to about 45 °C, although partial liberation of CH_4 starts below 20 °C. The chronological course of the CH_4 elimination for $\{2\,MoOCl_3 + 4\,MeLi\}$ as an example, is described in reference [38].

Because of the high thermal lability of the carbonylmethylenating species (determination of the time-dependent loss of activity in the case of $\{2\,MoOCl_3 + 4\,MeLi\}$:[38]) attempts at isolation were unsuccessful. However, NMR measurements lead to a clear idea of the structure.[22g,22h,37,38,43] Taking into account the method of formation, the carbonylmethylenating action (see Section 3.1), the low basicity, and the surprising resistance to protons (see Sections 4.2 and 4.4; the latter results exclude compounds with $MoCH_2Li$ or WCH_2Li bridges), the complexes must either contain terminal CH_2 ligands or a μ-CH_2 ligand (CH_2 bound to two metal atoms). NMR spectroscopy helped to decide between these two possibilities.[37,38] The ^{13}C NMR signals (Table 7) and ^1H NMR signals[37,38,22h,35b]—which all disappear on addition of aldehydes or ketones to the reaction solution, whilst at the same time signals of terminal alkenes appear—all lie in the range (Scheme 12)[33,47–50] which is typical for μ-CH_2 ligands in small rings. Signals of terminal CH_2 ligands did not appear. ^1H NMR signals, which appeared suspiciously close to the range characteristic for terminal CH_2 ligands (δ = 9–11), can be plausibly explained by hydrogen bonds, as demonstrated in references [37,38]. A direct comparison is possible by using the complex obtained from $\{2\,WOCl_4 + 4\,MeLi\}$: whilst its μ-CH_2 ligand produces a ^1H NMR signal at δ = 3.5 (broad),[22h] the proton signals of the terminal CH_2 ligands of $[(Me_3P)_2Cl_2(O)W{=}CH_2]$ are found at δ = 12.34 and 11.47.[51] The coupling constants $^2J_{H,H}$, which are caused by the μ-CH_2 groups of the carbonylmethylenating

molybdenum complexes,[37, 38] each amount to about 14.4 Hz. Therefore, they correspond to the coupling constants for geminal protons in four-membered ring systems (10–14 Hz[52a]). Taking into account the formation with liberation of one equivalent of CH_4 per molybdenum or tungsten atom, the quotients $(CH_2)_{tf}/CH_4$ given in Table 6 along with the presence of μ-CH_2 ligands detected by spectroscopy, implies that the complexes obtained according to Scheme 13 are 1,3-dimolybda- or 1,3-di-

tungstacyclobutanes or their oligomers. The presence of a metal–metal bond in complexes **24** is very probable on account of the diamagnetism (generally very sharp NMR signals) of the reaction solutions obtained from Mo^V and W^V chlorides.

An in-depth analysis of the ^{13}C (Table 7) and ^1H NMR data substantiates the idea that 1,3-dimetallacyclobutane structures are present. 1) ^{13}C NMR: **A** affords only one signal (Table 7). In analogy to **25**[49] (C and H atoms of the μ-CH_2 ligands are each equivalent), **A** could be centrosymmetric **26** with four THF ligands in axial positions. Two ^{13}C NMR signals are observed for **B**–**E** and each can be explained by the presence of two *cis*/*trans* isomers: the NMR data of **B** (discussed here as an outsider) support the complexes *cis*- and *trans*-**27**, which are centrosymmetric with regard to the equatorial ligands Cl and O. The Me_3Si groups give rise to the isomerism in an analogous manner to the *t*Bu groups in comparable Zr complexes.[50] In **C**–**E** the two ^{13}C NMR signals can be interpreted by the presence of *cis*- and *trans*-**28**, *cis*- and *trans*-**29**, and *cis*- and *trans*-**30**, respectively, whose isomerism is caused

by the axial chlorine ligands. The assumption that there are two THF ligands in *cis*- and *trans*-**30** is consistent with the fact that the carbonylmethylenating activity of **E** towards benzaldehyde is drastically reduced on addition of one equivalent of Ph_3As or Ph_3P per molybdenum atom (Table 8). Evidently, the loosely bound THF ligands are replaced by strongly bound ligands, which either hinder or prevent the coordination of the oxygen atom of the aldehyde group to the molybdenum atom. In this context it is interesting that the carbonylmethylenating activity of **F** (= **31**), which is presumed to contain four THF ligands, is not restricted by the addition of one equivalent of Ph_3As or Ph_3P per molybdenum atom (Table 8). More than two ^{13}C NMR signals were observed for **F** and **G**. Evidently, these two each are a relatively complicated product mixture, which can be explained by the fact that in the resulting complexes **31** and **32** the Cl and O and Cl and

Table 8. Inihibition of carbonylmethylenation reaction PhCHO → $PhCH{=}CH_2$ in THF (−78 → 20 °C in 18 h; 0.5 PhCHO per molybdenum atom) by the addition of potential ligands at about −78 °C [22f, 64].

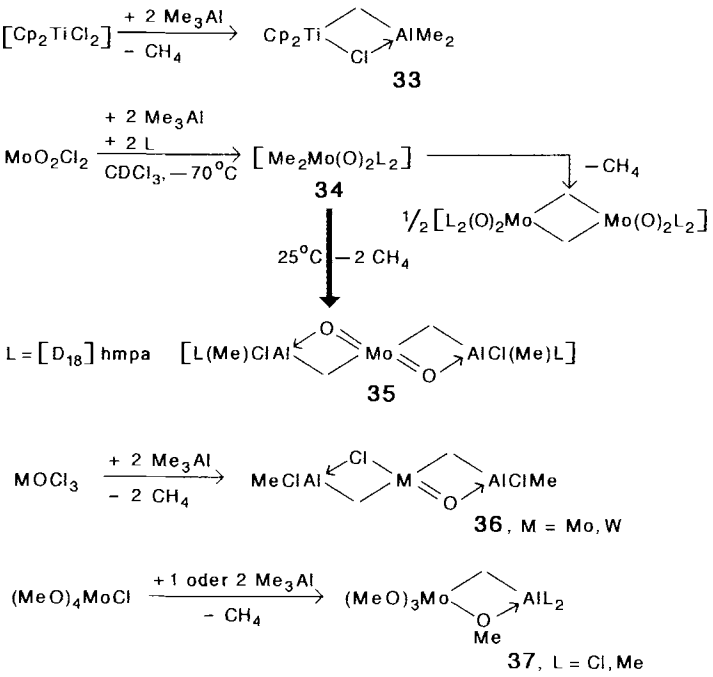
MeO ligands, respectively, are not only in equatorial but also in axial positions. In **F** the oligomerization of the primarily formed complexes **31** must also be considered as the reason for the numerous nonequivalent μ-CH_2 carbon atoms.[38] 2) ^{1}H NMR: The ^{1}H NMR data[22h, 35b, 37, 38] has been analyzed for **B**, **C**, **E**, and **F** and is in agreement with the proposed structures *cis*- and *trans*-**27**, *cis*- and *trans*-**28**, *cis*- and *trans*-**30** and **31**, respectively.[37, 38, 35b]

Reactions of $[Mo_2Cl_{10}]$, analogous to those in Scheme 13, were not possible with alkyllithium compounds other than MeLi: the use of *n*BuLi or *n*-hexyllithium suppresses the formation of 1,3-dimolybdacyclobutanes by β-H elimination,[22d] and in the reaction of neopentyllithium with Mo_2Cl_5 double α-H elimination occurs instead of single.[12] If Me_3SiCH_2Li is treated with $[Mo_2Cl_{10}]$, an alkylidene complex is formed together with an alkylidyne complex by single or double α-H elimination, as described in Section 1.[13] Accordingly, the mixture of the reaction products olefinize benzaldehyde only to a small degree (9% β-(trimethylsilyl)styrene).[22i] Furthermore, the reaction of $WOCl_3$ with two equivalents of Me_3SiCH_2Li (THF, 20 °C) and subsequent treatment with benzaldehyde produces the carbonylolefination product only in unsatisfactory yields (21% *cis*- and 11% *trans*-β-(trimethylsilyl)styrene).[35b]



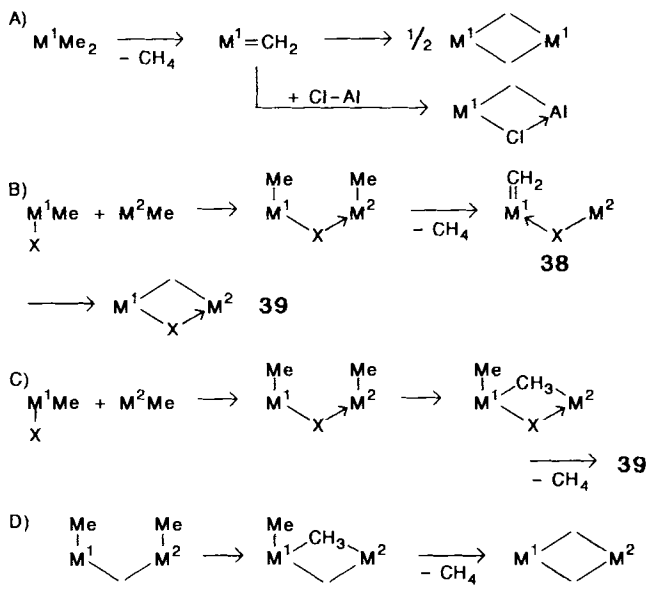
Scheme 14. Tebbe reagent (**33**) and the postulated formation of similarly structured μ-CH_2 complexes with molybdenum or tungsten as the transition metal.

3.3. Further Details on the μ-CH_2 Complexes Formed by the Reaction with Me_3Al

The reactions of the carbonylmethylenating complexes formed by reaction of Me_3Al with molybdenum and tungsten chlorides (Tables 5 and 6), via the methylation products detected by NMR spectroscopy,[22k, 22o] exhibited the following differences to the corresponding reactions with MeLi: a) In many cases approximately *two* equivalents of CH_4 per molybdenum or tungsten atom were liberated, and the carbonylmethylenating complexes formed transferred more than one CH_2 group (maximum 1.84) per molybdenum or tungsten atom (see Table 6). b) The solutions formed from Mo^V chlorides as well as from $WOCl_3$ by action of Me_3Al are paramagnetic. c) The complexes obtained with Me_3Al are highly sensitive to protons and are unsuitable for the carbonylmethylenation of hydroxy ketones. d) Their carbonylmethylenating activity can be enhanced by addition of a base (see Table 5) as found for the Tebbe reagent (**33**, Scheme 14)[53, 54] and a Zr–Al complex of similar structure.[50] These observations leave little doubt that complexes containing aluminum have been formed. Accordingly, during experiments to isolate the complex resulting the reaction of MoO_2Cl_2 and two equivalents of Me_3Al, a yellow, amorphous solid complex containing aluminum precipitated from the THF solution at 0 °C. A suspension of this solid in THF methylenated benzaldehyde.[42] The formation of the carbonylmethylenating complex from MoO_2Cl_2, two equivalents of Me_3Al, and two equivalents of $[D_{18}]$HMPA in $CDCl_3$ was monitored by ^{1}H NMR spectroscopy[1, 35j] (in the case of Mo^V and W^V chlorides the formation of paramagnetic solutions prevents such investigations): on mixing the components at −78 °C a singlet appears at $\delta = 0.81$, which is assigned to the dimethyl complex **34**, since it disappears on warming and the same signal ($\delta = 0.81$)[22d] was observed during the reaction of MoO_2Cl_2 with two equivalents of MeLi at −70 °C in $[D_8]$THF. At 10 °C the first μ-CH_2 signals appear. After 1 h at 25 °C the spectrum exhibits not only very weak μ-CH_2 signals ($\delta = 5.7$–5.0 and 10.8–10.1), which are characteristic of 1,3-dimolybdacyclobutanes, but also a very intense singlet at $\delta = 5.34$. This lies in the region typical for μ-CH_2 ligands in small rings (see Scheme 12) and is in agreement with structure **35**, which was postulated on the basis of the way of formation (liberation of 1.9 CH_4) and reactivity (CH_2 transfer rate = 1.5; see Table 6).[1, 42] The remaining carbonylmethylenating Mo–Al and W–Al complexes, which were obtained from reactions in reference [1] and Table 5, are also assigned cyclic structures[1] (e.g. **36** and **37**) on the basis of the results described above as well as their high aldehyde versus ketone selectivity (usually > 94:6; see reference [1]).

3.4. Discussion of the Mechanism

The discussion of the mechanism of the ligand transformations described in Sections 3.1–3.3, which exhibit parallels to the formation of the Tebbe reagent,[53] is headed by the question as to the identity of the intermediate species involved. According to Scheme 15A or 15B it is a terminal CH_2 ligand, and according to Scheme 15C or D it is a μ-CH_3 ligand (CH_3 bound by a two-electron three-center bond to two metal atoms). The argument against a complex with a terminal CH_2 ligand (Schrock carbene complex) as the intermediate product stems from the fact that during the formation of the μ-methylenemolybdenum complexes described in Sections 3.1 and 3.2, the carboxylic acid chlorides, or carboxylates, or benzyl chloride added to the reaction mixture are not attacked. Schrock carbene complexes are usually not inert to such electrophiles (cf. references [54–56]). In addition, the high aldehyde versus ketone selectivity found in competition experiments (see Table 5 and Section 4.3) does not support the theory of an intermediate



Scheme 15. Possible mechanisms for the transformation of CH_3 ligands into μ-CH_2 ligands. A and B: Complexes with terminal CH_2 ligands as intermediate products. C and D: Complexes with a μ-CH_3 ligand as the intermediate product. M^1 = Mo, W; M^2 = Mo, W, Al; X = Cl, OMe, O. For X = O, $H_2C{=}M^1{-}O{-}M^2$ is produced instead of **38** for mechanism B (bond between M^1 and O is covalent instead of dative in **38**).

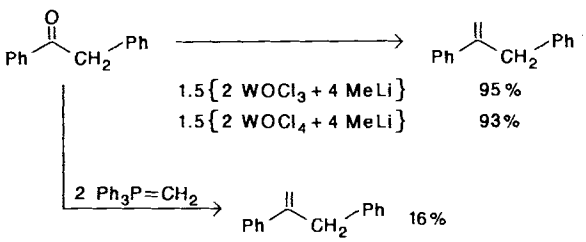
Schrock carbene complex, because in these experiments μ-CH_2 complex formation did occur in the presence of the added ketoaldehyde or aldehyde–ketone mixture. Support for the formation of the μ-CH_2 ligand from a primarily formed μ-CH_3 ligand, in an analogous manner to the μ-CH_3 → μ-CH_2 transformation reported in reference [34], comes from the fact that the elimination of a proton from a μ-CH_3 ligand should be more favorable than from a CH_3 ligand. The possibility of facilitating α-H elimination by primary μ-CH_3 formation was already pointed out in 1975 by Muetterties.[11] In addition, the intermediate formation of MCH_3M or MCH_3Al bridges (M = Mo, W) is very plausible on account of the electron deficiency on the high-valent molybdenum and tungsten atoms as well as the $AlCH_3Al$ bridges in $(Me_3Al)_2$. It also agrees with the results from the reaction with MeLi: the tendency to form a carbonylmethylenating complex on going from Mo^V chlorides to $MoCl_4$[22d] decreases (see e.g. Table 6) and was not even observed for $MoCl_3$, β-$MoCl_2$, and α-$MoBr_2$.[22d] The same question arises for the formation of the Tebbe reagent (**33**): not only the mechanism following the principle of Scheme 15B, which was postulated by Grubbs et al.[57], but the mechanism according to Scheme 15C need to be considered.

4. Application of μ-Methylenemolybdenum and -tungsten Complexes as Lewis Acidic, Selective Carbonylmethylenating Reagents

In contrast to the intensive efforts to optimize the stereoselectivity of carbonylolefinations, relatively little was undertaken to confer high regioselectivity to this important C–C coupling reaction (see Section 4.9). Of all the carbonylmethylenating μ-CH_2 complexes described in Section 3, the 1,3-dimolybdacyclobutane type in particular display high selectivity. Also the low basicity of these compounds and the corresponding tungsten complexes proved to be advantageous in carbonylmethylenations. In an analogous manner to the Lewis acidic alkylation reagents $RTiX_3$[58] these reagents also offer the possibility of varying the selectivity within certain limits by variation of the electronegative ligands on the molybdenum or tungsten atoms (reaction of various chlorides according to Scheme 13 or ligand exchange on the μ-CH_2 complexes).

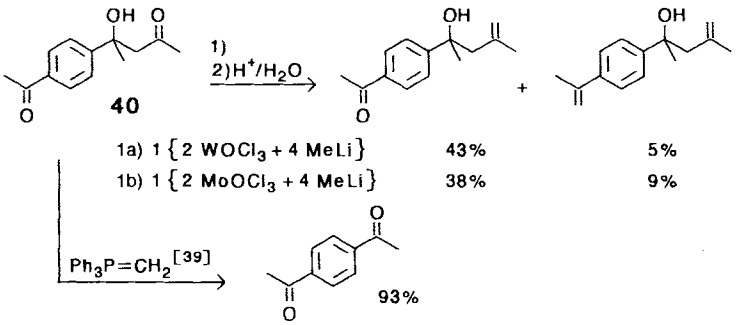
4.1. Carbonylmethylenation of Base-Sensitive Ketones

The low basicity of the complexes obtained according to Scheme 13 permits carbonylmethylenation of readily enolizable ketones.[22h, 35e] Scheme 16 gives an example, and a comparison



Scheme 16. Methylenation of a readily enolizable ketone. Conditions: THF, −78 → 45 °C in 18 h [22h].

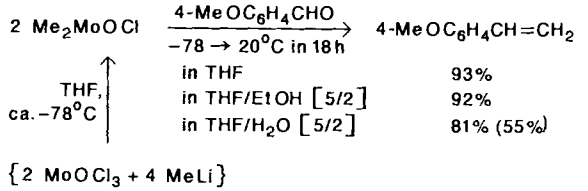
with $Ph_3P{=}CH_2$ as methylenating reagent. Whilst $Ph_3P{=}CH_2$ or MeMgBr or even the weakly basic $[MeCrCl_2(thf)_3]$[59] lead to the rapid cleavage of the base-sensitive ketone **40** by a retro-aldol reaction, {2 $WOCl_3$ + 4 MeLi} and {2 $MoOCl_3$ + 4 MeLi} are capable of methylenating **40**, and this with high regioselectivity[22j, 39] (Scheme 17).



Scheme 17. Highly regioselective monomethylenation of an extremely base-sensitive hydroxy diketone. 1a) THF, −78 → 45 °C in 16 h [22j]. The second possible monocarbonyl methylenation product was not formed. 1b) THF, −70 → 20 °C in 12 h [22j, 39].

4.2. Carbonylmethylenation in Protic Media

The carbonylmethylenating activity of {2 $MoOCl_3$ + 4 MeLi}, {2 $MoOCl_4$ + 4 MeLi}, and {$[Mo_2Cl_{10}]$ + 4 MeLi} is restricted only to a surprisingly small degree by water, ethanol, or other alcohols. This permits carbonylmethylenation in aqueous or alcoholic media, which was hitherto not possible (for examples see Scheme 18 and reference [40a]) and which could be useful for hydrophilic substances. As was to be expected for these results, {2 $MoOCl_3$ + 4 MeLi} smoothly methylenates 2-, 3-,

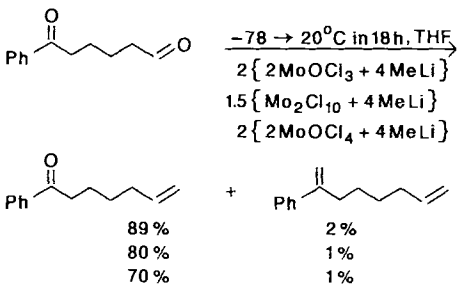


Scheme 18. Methylenation of aldehydes in protic media [40a]. The yield given in parentheses was obtained when the reagent solution was added at 0 °C instead of at −78 °C. This lower yield is attributed to the thermolability of the carbonylmethylenating complex.

and 4-hydroxybenzaldehyde (to give the alkene in 89, 86, and 56% yield, respectively[22e]) as well as hydroxy ketones (see Section 4.4). Even glyceric aldehyde (suspended in THF) is a suitable substrate (affords alkene in 41% yield).[35e] It can be concluded that the mechanism of carbonylmethylenation in aqueous or alcoholic media involves nucleophilic substitution of chlorine ligands for hydroxy or alkoxy ligands on the 1,3-dimolybdacyclobutanes. This has already been reported for the analogous reaction of EtOH with $[Mo_2Cl_{10}]$ to give $(EtO)_2MoCl_3$ under similar conditions,[60] and corresponds to the fact that the carbonylmethylenating activity of the reagents is usually somewhat weakened in aqueous or alcoholic media.

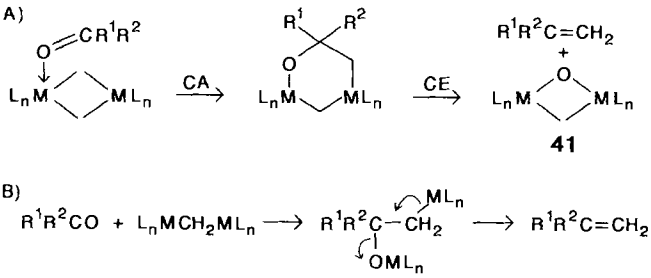
4.3. Aldehyde Versus Ketone Selectivity ("Aldehyde Selectivity")

In intermolecular[37,39] and intramolecular competition experiments (Scheme 19), the carbonylmethylenating 1,3-dimolybdacyclobutanes exhibit an aldehyde selectivity that is



Scheme 19. Stringent aldehyde-selective monomethylenation of a keto aldehyde [37,39]. The second possible monocarbonyl methylenation product was not formed in each case.

higher than that of 1,3-ditungstacyclobutanes as well as that of the Mo–Al or W–Al complexes described in Section 3.3. The discernible agreement here with the high aldehyde selectivity of alkyl transition metal reagents (metal e.g. Ti^{IV},[61] Cr^{III}[59]) is readily understood if it is supposed that the 1,3-dimolybdacyclobutanes, which represent specific alkyl transition metal reagents, react with the carbonyl compounds without previous separation into complexes with terminal CH_2 ligands according to the cycloaddition (CA)—cycloelimination (CE) mechanism[37] in Scheme 20A. This mechanism is similar to that represented in Scheme 20B, in which the aldehyde-selective geminal dimetalliomethanes (see Section 4.9) carbonylolefinate. Since in the methylenation of aldehydes—but not of ketones—with 1,3-dimolybdacyclobutanes, more than 0.5 CH_2 groups



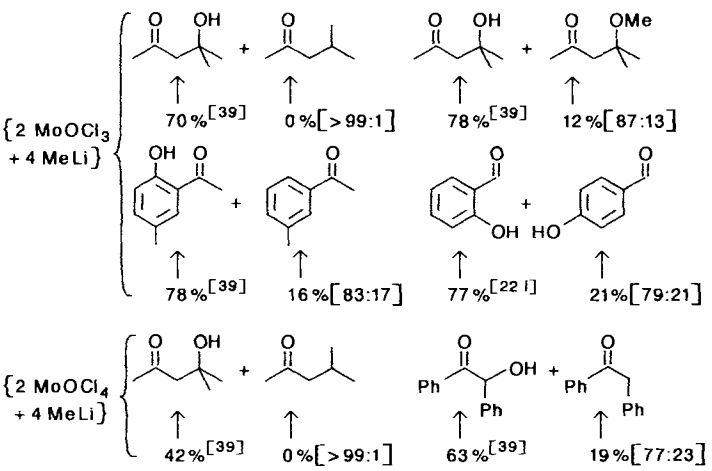
Scheme 20. Carbonylmethylenation according to CA–CE mechanism [37] and the proposed mechanism [82] for carbonylmethylenations with open-chain dimetalliomethanes.

per molybdenum atom are often transferred (see for example the first two experiments given in Table 6), it is reasonable to assume that 2,4-dimetallaoxetanes **41** (Scheme 20A) also have carbonylmethylenating activity.[38] Accordingly, in the methylenation of propanal with $\{[Mo_2Cl_{10}] + 4\ MeLi\}$ in *n*-pentane, $MoOCl_3$ (intense IR bands at 950 cm^{-1}) was detected as the inorganic end product.[22g,38]

4.4. Cheleselectivity

4.4.1. 1,3-Dimolybda- and 1,3-Ditungstacyclobutanes

In alkylations of keto groups with alkyl transition metal reagents, the basic groups (HO, MeO, Me_2N, MeS) in the α or β position exercise an accelerating effect on the reaction. This permits alkylations with a high cheleselectivity (for a definition of the term see reference [5]). If $\{2\ MoOCl_3 + 4\ MeLi\}$ or $\{2\ MoOCl_4 + 4\ MeLi\}$ are treated with the substrate pairs in Scheme 21, the hydroxyl group displays a powerful accelerating effect. This neighboring group effect, which also permits the very regioselective monomethylenation of the hydroxy diketone **40** in Scheme 17, is explained[39] by primary esterification of the hydroxyl group by 1,3-dimolybda- and 1,3-ditungstacyclobutanes containing chlorine ligands, and cleavage of HCl (cf. Scheme 28). The carbonylmethylenation then follows in-

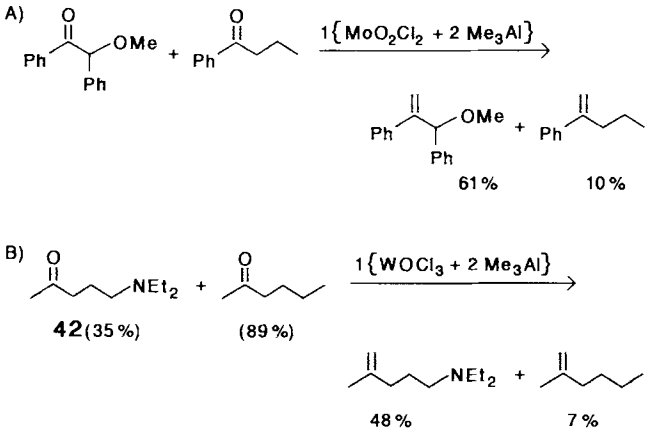


Scheme 21. Cheleselectivity of 1,3-dimolybdacyclobutane reagents in intermolecular competition reactions. Mole ratio reagent:substrates = 1:1:1; THF, −78 → 20 °C in 18 h. Numbers under the arrows: yields of the carbonylmethylenation product; in square brackets: selectivity. For details on the recovery of the substrate see reference [39].

tramolecularly and therefore with a favorable entropy term. Evidently, a covalent bond between the reagent and the substrate is necessary, because the methoxy group or the dialkylamino groups do not accelerate the reaction when 1,3-dimolybda- and 1,3-ditungstacyclobutanes are used, but rather have a retarding effect (see Scheme 24). The solvent was varied in competition reactions of $\{2\ MoOCl_3 + 4\ MeLi\}$ with a β-hydroxy ketone/ketone pair and it was found that the cheleselectivity increases in the order $CH_2Cl_2 < THF < MeO(CH_2)_2OMe$, that is with increasing basicity of the solvent (Table 5 in reference [39]). The reagents $\{2\ WOCl_3 + 4\ MeLi\}$ and $\{2\ WOCl_4 + 4\ MeLi\}$ are normally less suitable for selective carbonylmethylenation of hydroxy ketones than the corresponding molybdenum reagents.

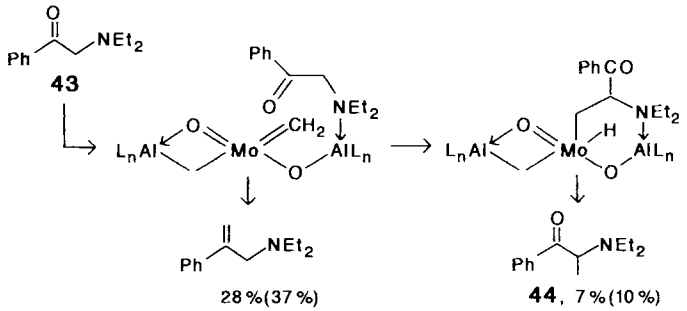
4.4.2. *Mo–Al and W–Al Reagents*

In competition reactions of α-methoxyketone/ketone pairs with $\{MoO_2Cl_2 + 2\ Me_3Al\}$ there is a clear preferential methylenation of the functionalized ketone (for examples see Scheme 22 and reference [1]), whilst there is no such preference



Scheme 22. Cheleselective carbonylmethylenation with $\{MoO_2Cl_2 + 2\ Me_3Al\}$-[22k] and $\{WOCl_3 + 2\ Me_3Al\}$ [22o]. Conditions: THF, $-70 \rightarrow 20\,^{\circ}C$ in 12 h; mole ratio reagent:substrates = 1:1:1. The yields of ketone recovered are given in parentheses.

discernible for hydroxy ketone/ketone pairs. An amine-N atom in a β or γ position to the keto group often drastically retards the carbonylmethylenation with $\{WOCl_3 + 2\ Me_3Al\}$. This has been attributed to the formation of stable complexes.[1] On the other hand, an electron-donating atom in a δ position to the keto group has a marked promoting effect on the carbonylmethylenation of **42** with $\{WOCl_3 + 2\ Me_3Al\}$ (Scheme 22) as well as of $MeCO(CH_2)_2COMe$ and $MeCO(CH_2)_2CO_2Et$ with $\{MoOCl_3 + 2\ Me_3Al\}$.[1] For the carbonylmethylenation of ketones that contain an electron-donating atom in an α or β position to a keto group, it is proposed that there is an active terminal CH_2 ligand which was formed by ring-opening (Scheme 23). Clear evidence in support of this mechanism is the α-methylation of **43** $\rightarrow$ **44**,[1] also given in Scheme 23, as well as analogous α-methylations.[35j] The latter is an alternative reaction to carbonylmethylenation, and can only be readily explained by a combination of C–H insertion and reductive elimination. The

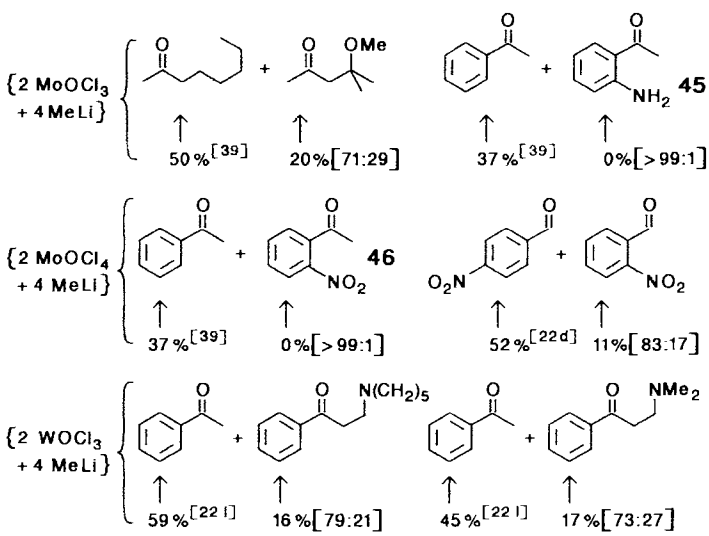


Scheme 23. Proposed mechanism for carbonylmethylenation and also the alternative α-methylation of **43** with $\{MoO_2Cl_2 + 2\ Me_3Al\}$ [1]. Conditions: THF, $-78 \rightarrow 25\,^{\circ}C$ in 18 h [1, 22k]. The yields given in parentheses are those for the corresponding reaction with $\{MoO_2Cl_2 + 2\ Me_3Al + 2\ HMPA\}$.

addition of a base (HMPA,[62] Ph_3P) (cf. Table 5) has a distinct promoting effect on the carbonylmethylenation reaction with Mo–Al and W–Al reagents, and offers further support for the ring-opening mechanism. This effect has also been reported for the Tebbe reagent[54] and a Zr–Al complex of similar structure[50] and is in these cases, without a doubt, caused by ring-opening.

4.5. Anticheleselectivity

The intermolecular competition reactions given in Scheme 24 with 1,3-dimetallacyclobutane reagents reveal that methoxy,



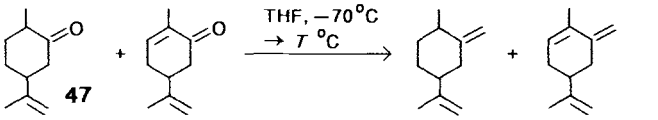
Scheme 24. Anticheleselectivity of 1,3-dimetallacyclobutane reagents in intermolecular competition experiments. Reaction conditions and other information as in Scheme 21.

amino, dimethylamino, piperidino, and nitro groups retard the carbonylmethylenation of an aldehyde or keto group in the α or β position (for further examples see reference [39]). Whilst retardation in the case of **45** can be explained by the +M effect of the amino group, there must be other reasons for this for **46** (– M effect of the nitro group) and for the other remaining cases. The moderate anticheleselectivity observed in competition reactions with ketone/methoxy ketone as well as ketone/

dialkylamino ketone pairs is similar to the anticheleselectivity observed in the corresponding reactions of transition metal carboxylates and of dimeric allyl and cyanomethyl transition metal reagents, which are probably dimeric. In these cases it is attributed to steric hindrance.[5, 63] This interpretation is suggested for the 1,3-dimetallacyclobutanes with bulky THF ligands. In addition, deactivating complexation could also be involved. In **45** and **46** the inhibiting action of the amino and nitro group, respectively, is so great that even in individual experiments there is no carbonylmethylenation. There is little doubt that stable substrate–reagent complexes have been formed here.[39] Apart from these exceptions, the functionalized aldehydes and ketones listed in Scheme 24 reacted with the cited reagents in single experiments to give good yields of the methylenation products.

4.6. Ketone–Enone Differentiation

The reagents given in Scheme 25 can differentiate well between **47** and carvone. The reagent {2 $MoOCl_3$ + 4 MeLi} was particularly selective. The unconverted ketone was recovered in high yields.[39]

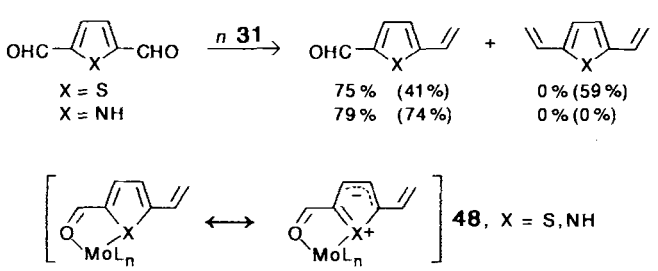


{2 $MoOCl_3$ + 4 MeLi}	T = 20	58%	3% [95:5]
{2 $MoOCl_3$ + 4 MeLi}	T = 50	60%	5% [92:8]
{2 $WOCl_3$ + 4 MeLi}	T = 50	65%	10% [87:13]

Scheme 25. Ketone–enone differentiation with 1,3-dimetallacyclobutane reagents [35g, 39]. In square brackets: selectivity.

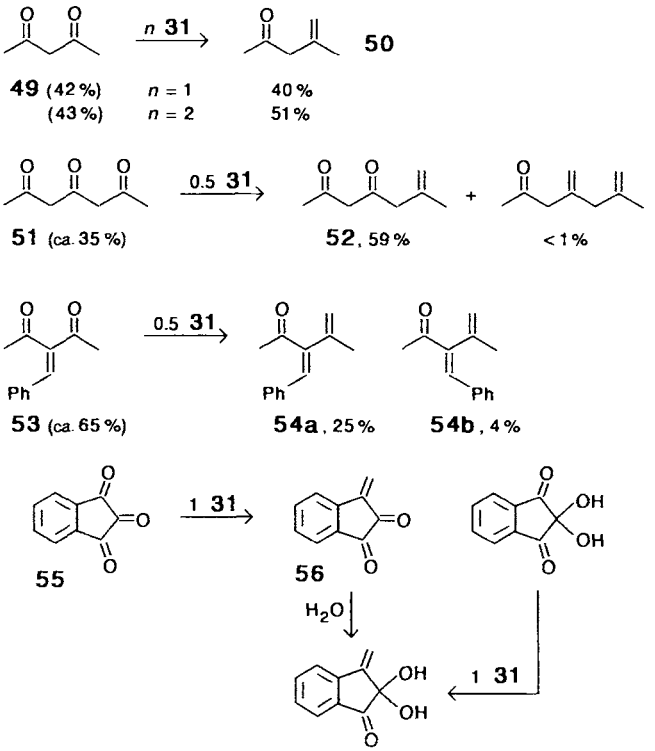
4.7. Highly Selective Monomethylenation of Dialdehydes, Diketones, and Triketones

Thiophene- and pyrrole-2,5-dicarboxaldehyde can be monomethylenated with extreme selectivity if less than an equimolar amount of {2 $MoOCl_3$ + 4 MeLi} (**31**) is used (Scheme 26). In the case of pyrrole-2,5-dicarboxaldehyde the reaction stops at the monomethylenated stage, even if an equimolar amount of reagent is used. The deactivation of the second aldehyde group by the +M effect of the heteroaromatic moiety cannot be the crucial factor, because thiophene- and pyrrole-2-carboxaldehyde are smoothly methylenated by {2 $MoOCl_3$ + 4 MeLi}



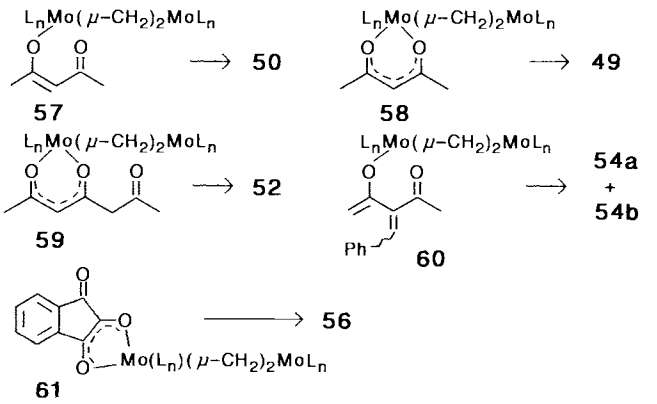
Scheme 26. Monomethylenation of dialdehydes with {2 $MoOCl_3$ + 4 MeLi} (**31**) in THF, −78 → 20 °C in 18 h [22e, 35h, 35i]. Yields given: values not in brackets are valid for $n = 0.5$, values in brackets for $n = 1$.

(mole ratio 1:1 and 2:1, respectively) to 2-vinylthiophene (78%) and 2-vinylpyrrole (95%), respectively.[22e] Therefore, it is probable that during monomethylenation a complex of type **48** is formed in which the electrophilicity of the remaining aldehyde group is greatly diminished (cf. the retardation of carbonylmethylenation of 1,2-diketones in Section 4.8). The reagent **31** reacts with di- and triketones **49**, **51**, **53**, and **55** (Scheme 27)



Scheme 27. Monomethylenation of diketones **49** [35h,43] and **53** [22m,43] as well as the triketones **51** [22m,43] and **55** [43,67]. Conditions: THF, −78 → 20 °C in 18 h. Compound **56** was the only product of the reaction of **55**, and was only detected qualitatively. The yields in parentheses give the amount of substrate recovered.

with high selectivity to give the monomethylenated products **50**,[35h] **52** [22m] (along with traces of a dimethylenated product), **54a,b** [22m] and **56**,[64] respectively. In the case of the triketones, a peripheral keto group is methylenated.[43] The reagent employed demonstrates a particular affinity towards hydroxy ketones (see Section 4.4). Therefore, it is proposed that **49** (if solvent-free it is enolized to 76.4%[65]), **51**, and **53** react to give molybdenum enolates **57**, **59**, and **60**, respectively (Scheme 28), so that only one free keto group remains which can be methylenated. Since diketone **49** was recovered in 43% yield after treatment with excess reagent and subsequent addition of water, (second experiment in Scheme 27) then it is probable that not only **57** was produced, but the endiolate **58** as well, in which both keto groups are protected against methylenation. Surprisingly, methylenation of the cyclic 1,2,3-triketone **55** does not take place in the middle position, which is particularly electrophilic, but exclusively at a peripheral group.[43, 64] This can be explained by the formation of a stable 1,2-diketone complex (**61**), which probably methylenates a similar type of complex in which there is still a free keto group (cf. Scheme 29 B) The open-chain 1,2,3-triketone PhCOCOCOPh is not methylenated by **31**



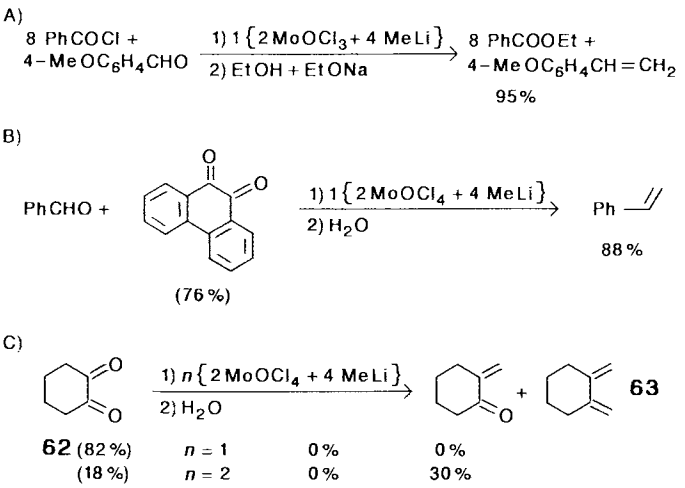
Scheme 28. Postulated intermediates for the highly selective reactions of Scheme 27.

but degraded by decarbonylation to benzil.[22m] The extremely selective monomethylenations in Scheme 26 and 27 illustrate the extent of the proficiency of a methylenating reagent if it can form quasi-aromatic complexes with the substrate.

4.8. Tolerated and Nontolerated Functional Groups

4.8.1. 1,3-Dimolybdacyclobutanes as reagents

Representatives of the compound classes RCOCl,[39,66] $RCOOOCR$,[22d] R^1COOR^2,[43] $RCONMe_2$,[43] ArCOCOAr,[22d,64] $ArNO_2$,[22d] $RCH{=}CH_2$,[43] $RCH{=}CH{-}CH{=}CH_2$[37] as well as the individual compounds $Ph_2C{=}C{=}O$,[35j] PhCN,[35c] $PhC{\equiv}CPh$,[22d] PhCl,[22n] $PhCH_2Cl$,[64] and CH_2Cl_2[35f,38] were not permanently altered on reaction in THF with the reagents obtained from $[Mo_2Cl_{10}]$, $MoOCl_3$, and $MoOCl_4$ according to Scheme 13. The corresponding tungsten reagents have not been well investigated. In some cases (e.g. aromatic nitro compounds; see Section 4.5) there may be some fairly stable reagent–substrate complexes formed, from which the substrate is released unchanged on addition of water. Since acyl chlorides are usually more powerful electrophiles than aldehydes, their resistance to the molybdenum reagents is surprising.[39,66] Intermolecular competition reactions reveal that the carbonylmethylenation of 4-methoxybenzaldehyde or acetophenone are not hampered by acyl chlorides, even in excess (Scheme 29 A[39]). This is similar to the inertness of Lewis acidic methyl transition metal reagents[66] such as $MeTiCl_3$ and $MeNbCl_4$ towards acyl chlorides. However, it does contrast with the behavior of carbonylmethylenating reagents such as $Ph_3P{=}CH_2$ and $[Cp_2Ti{=}CH_2]$ (formation of $[RCOCH_2PPh_3]Cl$[67] or $[RC(=CH_2)OTi(Cp)_2Cl]$[54]) and is informative with regards to the mechanism of carbonylmethylenation with molybdenum reagents (see Section 4.3). In addition, they do not react with carboxylates, benzyl chloride, benzonitrile, and tolan. This differentiates them from $[Cp_2Ti{=}CH_2]$ and other complexes containing terminal CH_2 ligands which attack these substrates.[54–56] The aromatic 1,2-diketones benzil and 9,10-phenanthrenequinone are not methylenated by one equivalent of $\{2\ MoOCl_3 + 4\ MeLi\}$ or $\{2\ MoOCl_4 + 4\ MeLi\}$ (recovery of the ketone 80–90%), and 9,10-phenanthrenequinone does not inhibit the methylenation of benzaldehyde with



Scheme 29. Resistance of acyl chlorides [22e,39] and 1,2-diketones [22d,35h] towards carbonylmethylenating molybdenum reagents in THF, $-78 \rightarrow 20\,^{\circ}C$ in 18 h. The yields in parentheses give the amount of diketone recovered.

$\{2\ MoOCl_4 + 4\ MeLi\}$[22d] (Scheme 29 B). The aliphatic 1,2-diketone **62** is also remarkably resistant towards $\{2\ MoOCl_4 + 4\ MeLi\}$, because there is no carbonylmethylenation with only one equivalent of reagent. Only when two equivalents are used, does this reaction proceed with low yields[35h] (Scheme 29 C). Since the sole product is the bismethylenated **63**, the first methylenation step is evidently slower than the second. The behavior of the 1,2-diketones, as well as the formation of benzil from PhCOCOCOPh, mentioned in Section 4.7, leave little doubt that thermodynamically stable 1,2-diketone–reagent complexes are formed in which the keto groups are protected against methylenation. Azomethynes, epoxides, and nitrosobenzene have proved to be nonresistant towards carbonylmethylenating 1,3-dimolybdacyclobutanes. Azomethynes are "azomethyne-methylenated" in moderate yields by $\{[Mo_2Cl_{10}] + 4\ MeLi\}$, whilst aromatic epoxides are deoxygenated and aliphatic epoxides are converted to α-chlorohydrines.[35c,43] Nitrosobenzene is inexplicably altered by $\{2\ MoOCl_3 + 4\ MeLi\}$.[35c,43]

4.8.2. $\{MoO_2Cl_2 + 2\ Me_3Al\}$

This reagent is optimal for the methylenation of aldehydes. However, in THF at about 20 °C, it proved to be resistant towards acyl chlorides, ethyl carboxylates, nitriles, phenyl isothiocyanate, azobenzene, and diphenyl sulfone.[35j] Nevertheless, it did reduce diphenyl sulfoxide to diphenyl sulfide.[35j]

4.9. Comparison of Reported Carbonylmethylenating Reagents

With regard to their aldehyde versus ketone selectivity, low basicity, relatively high resistance towards protons, and ready availability, carbonylmethylenating reagents of the 1,3-dimolybdacyclobutane type are clearly superior to strongly basic carbonylmethylenating reagents. These include the classical reagents such as $Ph_3P{=}CH_2$,[68] $Ph_2(O)PCH_2M$ (M = Li, Na),[69] and Me_3SiCH_2Li,[70] (which are linked to the names of

Table 9. Non- or weakly basic carbonylmethylenating reagents reported in the literature. Category A: weak, selective nucleophiles (substrates: aldehydes and ketones). Category B: strong nucleophiles (substrates: additionally carboxylates, carboxamides, and lactones).

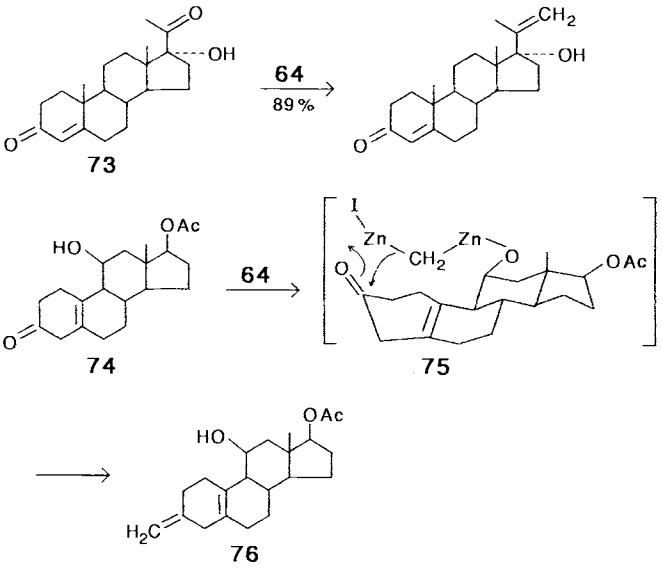
[a] + Represents good aldehyde versus ketone selectivity. [b] Structure proposed by the authors. [c] TMEDA = tetramethylethylenediamine.

Wittig, Horner, and Peterson) along with Ph_3MCH_2Li (M = Ge, Sn, Pb),[71] Ph_2MCH_2Li (M = As, Sb, Bi),[71] $PhSCH_2Li$,[72] and $PhSeCH_2M$ (M = Li, Na).[73] A superior alternative are the non- or weakly basic, weakly nucleophilic carbonylmethylenating reagents **64–72** listed in Table 9: the reagents **66**, **67**, **70**, and **71**[74,75] synthesized by us, along with similar, modified Peterson[74] and Horner reagents[75] can methylenate with high aldehyde selectivity and in good yield, however, they are relatively difficult to obtain. On the other hand, the reagents **64**,[76–78] **65**,[79] **68**,[80] and **72**,[81] which also appear to be dimetalliomethanes,[82] are serious competition for the reagents of 1,3-dimolybdacyclobutane type because of their straightforward preparation, nonexistent or low basicity, and their proven selectivity. However, this is only partly true for **65**.

Compound **64**, prepared by Hashimoto et al.[76] (THF, 6 h, 40 °C) and by Fried et al.[77] (Et_2O, 4 h, 78 °C) by reaction of CH_2I_2 with a Zn–Cu couple, methylenates aldehydes (yield 18–61%), but does not attack either ketones or methyl benzoate in THF.[76] In Et_2O it also methylenates ketones, but only in good yields if the reaction is supported by a sterically favorable hydroxyl group.[77,78] This permits the highly regioselective methylenation of **73** in high yields (Scheme 30). The reaction **74** → **76** (yield not mentioned) demonstrates that the assisting hydroxyl group may be situated several bonds away from the keto group in a folded ring system. In analogy to the hydroxyl-promoted Simmons–Smith reaction of allyl and homoallyl alcohols (see reference [77]) as well as to the hydroxyl-promoted carbonylmethylenations described in Section 4.4, it is proposed that there is a similar covalent fixation of the reagent as in species **75**.[78] If reagent **64** is used, the cyclopropanation of the primarily formed vinyl group can occur as an interfering side reaction. The Fried–Hashimoto reagent **64**, which has incited little interest to date, is certainly a good alternative or supplement to the molybdenum reagents with an affinity for hydroxy ketones (Section 4.4). Admittedly, its range of application has not been sufficiently well investigated. The reagents **65**[79] ("Oshima–Lombardo reagents"[79c]), derived from **64**, have recently been the subject of an exhaustive review by Stille.[79c] They are suitable for the methylenation of ketones and display ketone versus carboxylic acid selectivity. However,



Scheme 30. Hydroxyl group promoted carbonylmethylenation with the Fried–Hashimoto reagent [77, 78].

they are unsuitable for the methylenation of aldehydes, because reductive coupling of the carbonyl function occurs as a competing reaction.[79c] A hydroxyl group in an α position to the keto group distinctly retards methylenation with **65**, X = Br,[83] whilst a β-positioned group does not.[84] The reagents **68**[80] and **69**[80] are, in contrast to **65**, equally suitable for the methylenation of aldehydes and ketones, and are distinguished by high aldehyde versus ketone selectivity. If the carbonyl group of dodecanal is protected in situ by $Ti(NEt_2)_4$, as according to Reetz et al.[85], **69** methylenates exclusively the 4-dodecanone (95% alkene), which is also present in the reaction mixture.[80] Whether the chromium reagent **72** introduced by Takai et al.[81] methylenates with stringent aldehyde selectivity, does not appear to have been tested. However, because of the high aldehyde selectivity of the analogous reagents $\{Me_3SiCHBr_2 + n CrCl_2\}$[86] and $\{CHI_3 + n CrCl_2\}$[87] this selectivity can be presumed. Using the readily available chromium reagents of type $\{alkylCHHal_2 + n CrCl_2\}$ (**77**), Takai et al.[81] were able to undertake the important jump from regio- and

chemoselective carbonylmethylenation to the corresponding carbonylalkylidenation. β-H Elimination, which destroys the reagents, apparently does not occur to a high extent at low temperatures. However, the yield of the alkylidenation (*E*-selective) of ketones with **77**, R = *n*Pr, *i*Pr, *t*Bu is regarded as "rather low" (in the example given for **77**, R = *n*Pr, +cyclododecanone: 15% yield and 75% recovery of the ketone), whilst this limitation does not apply to aldehydes and the reaction of **77**, R = Me with ketones.[81] Carbonylalkylidenations (good yields; *E*- and aldehyde selective) are also possible with the reagents introduced by Knochel and Normant[88] {allylZnBr + 1-alkenylMgBr + $BF_3 \cdot OEt_2$}. Because of the particular method of reagent preparation only specific alkylidene groups are transferable.

The non- or weakly basic, strongly nucleophilic carbonylmethylenating reagents **33** and **78**–**80**, listed in the lower part of Table 9, can carbonylmethylenate not only aldehydes and ketones but also carboxylates and carboxamides as well as lactones. They can only be regarded as an alternative to 1,3-dimolybdacyclobutanes if the weak basicity of the reagent is important (readily enolizable aldehydes and ketones as well as aldehyde and ketones with α-positioned stereocenters as substrates). Because of the high nucleophilicity of these reagents, high aldehyde selectivity or selectivity by hydroxyl group assistance can be expected to a lesser degree than in reagents of category A in Table 9. The Tebbe reagent (**33**),[53] frequently used to methylenate carboxylates and carboxamides as well as lactones, is not very aldehyde selective.[22l] It is deactivated by hydroxyl groups in the substrate and reacts with bases to give the highly reactive, less selective, carbonylmethylenating Grubbs reagent **78**. This reagent can also be produced by the thermolysis of titanacyclobutanes.[54] The carbonylmethylenating reagent **79**, introduced by Takai et al.,[89] does not differentiate between aldehydes and ketones (for corresponding alkylidenations see reference [89a,b]). The authors assume that the active species of **79** is a complex with a terminal CH_2 ligand, and demonstrated that traces of lead in the zinc used were a prerequisite for the high nucleophilicity of **79**.[89c] The carbonylmethylenating reagent **80**, described by Petasis et al.,[90a] does not appear to methylenate by primary formation of **78**, but by complexation on the carbonyl group, subsequent methyl transfer and elimination of CH_4. Apparently, aldehyde selectivity, which not is expected on the grounds of the high reaction temperature required for **80**, was not reported. Corresponding alkylidenations are possible with $[Cp_2TiR_2]$ (R = groups which do not contain any β-H atoms).[90b–d] The ketone-methylenating reagent $\{[Cp_2TiCl_2] + Me_2Zn\}$,[91] which has not been well investigated, should probably be assigned to category B in Table 9.

5. Conclusion and Future Prospects

Thermolabile complexes $[R_2(n\text{PrO})_2W(\mu\text{-O}n\text{Pr})_2W(O n\text{Pr})_2R_2]$ (**6**; R = Me, Et, *n*Pr, *n*Bu, *i*Bu, *s*Bu, Me_3SiCH_2, Ph) were obtained in situ by nucleophilic substitution with organolithium or Grignard compounds from the reported $[Cl_2(n\text{PrO})_2W(\mu\text{-O}n\text{Pr})_2W(O n\text{Pr})_2Cl_2]$ (**2**). They react with aromatic, heteroaromatic, or α,β-unsaturated aldehydes and ketones: $R^1R^2CO \rightarrow 0.5\ R^1R^2R^3C{-}CR^1R^2R^3$. Hitherto, this had not been possible in one step. In an orientating experiment with R = Ph, such an additive–reductive carbonyl dimerization (ARCD reaction, for postulated mechanism see Scheme 8) was also successful on an aliphatic ketone. Complex **6**, R = Me, converts benzoic acid derivatives into $Me_2PhC{-}CPhMe_2$. In order to make the ARCD reaction interesting for applications in organic synthesis, it is still necessary to improve the accessibility of **2** or analogous alkoxy compounds, and to sound out the possibility of converting aliphatic aldehydes and ketones into ARCD products with reagents **6**, R = Ar.

The CH_3 complexes prepared at low temperature by action of MeLi or Me_3Al on chlorides of high-valent molybdenum and tungsten display a great tendency to eliminate CH_4 and transform into thermolabile, carbonylmethylenating μ-CH_2 complexes. This transformation of a methyl ligand into a μ-methylene ligand has been monitored qualitatively by NMR spectroscopy, and has also been quantified by a combination of gas measurement and yield determination during carbonylmethylenation reactions (Table 6). Depending on whether they were methylated with MeLi or Me_3Al, the μ-CH_2 ligands are present either in MCH_2M or in MCH_2Al bridges (M = Mo, W). The NMR data of some μ-methylenemolybdenum and -tungsten complexes permitted detailed structural proposals. The μ-methylenemolybdenum complexes, easily accessible by treatment with MeLi, have a high selectivity potential as readily modified, Lewis acidic carbonylmethylenating reagents that are surprisingly insensitive towards protons. An examination of the literature for Section 4.9 revealed that they have been more intensively investigated as regards their selective behavior than other carbonylmethylenating reagents of comparable selectivity. The selectivity of the molybdenum complexes exerts itself above all in reactions with keto aldehydes, hydroxy ketones, dialdehydes, di- and triketones, and is partly based on the formation of quasi-aromatic cyclic compounds in which one or two carbonyl groups are blocked. Attention should also be paid to carbonylmethylenating μ-methylenemolybdenum and -tungsten complexes obtained from reaction with Me_3Al, and which are regarded as bicyclic. They have a particular affinity towards keto groups which contain a basic atom in the δ position. Future research will confirm or disprove the proposed structures of **26**–**32** as well as **35**–**37** of μ-CH_2 complexes and the probable mechanism of the methyl → μ-methylene ligand transformation. Future investigations will show whether particular examples of the molybdenum and tungsten complexes described here prove to be suitable as selective carbonylmethylenating reagents in organic synthesis.

I have tried to present the experimental work carried out by my co-workers cited in the references and which was discussed in our "Friday meetings". I would like to thank all who participated in this work for their great commitment and many intelligent, original contributions. Furthermore, my thanks go to the Deutsche Forschungsgemeinschaft, the Volkswagen-Stiftung, and the Fonds der Chemischen Industrie for their financial support.

Free or Not, That Is the Question: Silyl and Germyl Cations in Condensed Phases

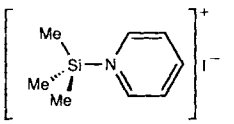
Johannes Belzner*

"Even after a very short experience, it was evident that the corresponding derivatives of the two elements showed very considerable differences in their chemical properties...".[1] The two elements that F. S. Kipping, one of the fathers of organosilicon chemistry, was talking about are carbon and silicon. One notable difference is, for instance, the pronounced instability of compounds with triply substituted silicon. With the synthesis of persistent disilenes and silenes in 1981, which showed that compounds with triply bonded silicon may well be sufficiently stable to allow their isolation, the question arose whether this would also be true of silyl cations.[2] Everything seemed favorable: silicon is more electropositive than carbon and should therefore be better able to stabilize a positive charge. Ab initio calculations confirm this: the reaction enthalpy of the isodesmic reaction (1) for R = H is -57.4 kcal mol^{-1} at the MP2(FC)/6-31G*

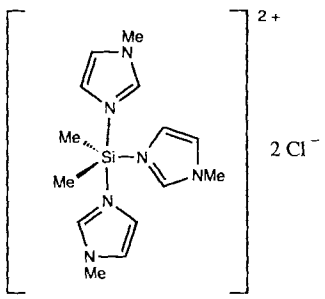
$$RSiH_2^+ + RCH_2{-}H \longrightarrow RSiH_2{-}H + RCH_2^+ \quad (1)$$

level of theory; this shows that $[SiH_3]^+$ is thermodynamically significantly more stable than the methyl cation.[3a] In agreement with these findings, it is easy to generate silyl cations in the gas phase, where the chemistry of these species has been explored thoroughly over the years.[4] But what about silyl cations in condensed phases, that is, in solution or in the solid state? Silyl cations were postulated early on as short-lived intermediates in the reactions of organosilicon compounds, but conclusive evidence for their existence was missing.[5] More recent studies especially kinetics have, however, provided evidence for a positively charged silicon intermediate in solution;[6] nevertheless, the structures of these intermediates could not be deduced from the experimental results. Not surprisingly, many efforts were aimed at synthesizing and characterizing stable silicon analogues of carbenium ions in solution and in the solid state. Kipping's aforementioned differences between silicon and carbon compounds again became apparent:[1] all reactions and techniques successfully used for the generation and isolation of stable carbenium ions[7] failed for silyl cations. Why?

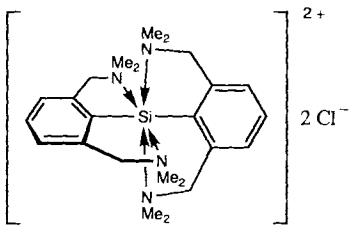
The principle difference between silicon and carbon in their compounds is the tendency of silicon to react with Lewis bases with expansion of its coordination sphere. If neutral silicon already displays a tendency for higher coordination numbers, what is to be expected of electron-deficient compounds like silyl cations? Their proverbial "voracious appetite"[8] for nucleophiles of any kind has been not exaggerated in view of the computed stability of coordination complexes of silyl cations with noble gases.[3a] This "appetite for electrons" is also reflected in the existence of numerous stable highly coordinated silyl cations. The structure of such a compound, pyridine adduct **1**, was determined in 1983 for the first time; the dative Si–N bond causes pyramidalization of the otherwise planar silyl cation.[9a] Even the isolation of doubly charged cations like **2**[9b] or **3**[10] is possible, provided they are stabilized by coordination to a base.



1



2



3

The observed ^{29}Si NMR shift to relatively high field showed clearly that the positive charge is not localized on silicon, but is transferred to the coordinated group. These species may be more appropriately called silyl ammonium ions. The formation of the 2-silanorbornyl cation **5**, which is stable in toluene for several weeks after formation by hydride abstraction from silane **4** [Eq. (2)], shows that the C–C double bond can also satisfy the appetite of the silyl cation for electrons.[11]

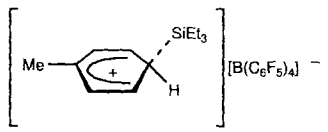
4 5 (2)

How should one proceed experimentally to avoid nucleophilic attack on a newly formed silyl cation? Three complementary strategies of proven value for the generation of stable carbenium ions are available: 1) The use of counterions and solvents of very low nucleophilicity to reduce the chance of nucleophilic attack on the cationic silicon center. 2) Sterically demanding substituents at the silicon center should hamper the approach of a nucleophile. The problem here is that silicon is larger than carbon, so that substituents which effectively shield a carbon center from nucleophiles of a certain size may allow the same nucleophile to reach a silicon center. 3) A third possibility is to stabilize the silyl cation thermodynamically by substitution with NR_2 or SR groups, the electron lone pairs of which should, in principle, be capable of back-bonding into the empty silicon p orbital. However, the corresponding stabilization energies, calculated for Equation (1) for different substituents R, are much smaller than for the analogous carbenium ions.[3, 12]

In spite of extensive utilization of these three strategies, especially in the groups of J. Lambert, G. A. Olah, and C. Reed, no complete success was achieved for a long time in the search for persistent silyl cations in condensed phases. Lambert et al., for instance, reported that hydride abstraction from silanes R_3SiH (R = Ph, MeS, EtS, *i*PrS) by trityl perchlorate leads to silyl perchlorates for which NMR data, molecular mass determination, and conductivity measurements in sulfolane and acetonitrile seem to imply the existence of ionic structures.[13] In contrast, Olah et al. showed by using ^{35}Cl and ^{29}Si NMR spectroscopy that—at least at concentrations around 0.12 mol L^{-1}—the perchlorate group in $Ph_3SiOClO_3$ is bound covalently to silicon through an oxygen atom.[14a] Furthermore, they suggested that Lambert et al.'s results, derived from measurements in highly diluted solutions, were corrupted by inevitable hydrolysis at these concentrations.[14b] Subsequently, Lambert et al. tried to refute these objections,[15] and the quarrel over the question of whether water was really present in these systems, and if so how much, would have continued if the introduction of less nucleophilic anions such as $[B(C_6F_5)_4]^-$[16] or the halogenated carboranes $[CB_9Br_5H_5]^-$[17a] and $[CB_{11}Hal_6H_6]^-$ (Hal = Cl, Br, I)[17b, c] had not advanced the chemistry of silyl cations.

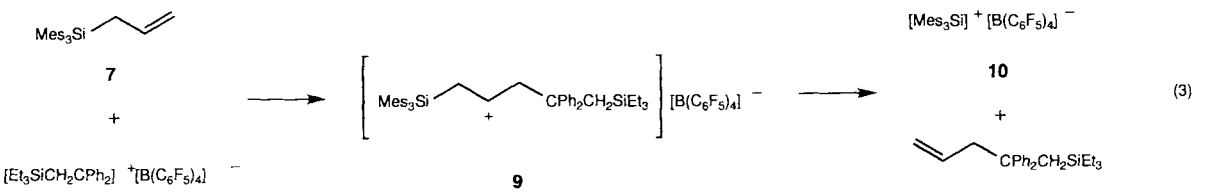
There was great excitement in 1993 when Lambert et al. reported the isolation of a silyl cation "with no coordination to anion and distant coordination to solvent".[18] Undoubtedly, the anion, and especially its fluorine substituent, was so remote from the silicon center in the solid-state structure of $[Et_3Si]^+[B(C_6F_5)_4]^-$ that a bonding interaction could be excluded with certainty. However, two toluene molecules per unit cell were incorporated into the crystal on recrystallization. The shortest distance between the silicon center and the aromatic *para*-carbon atom was 218 pm, which is significantly longer than the average Si–C bond length, typically between 186 and 191 pm. This, together with the observation that the geometry of the toluene molecule is only slightly distorted, led Lambert et al. to call this a compound a silyl cation with a weakly coordinated toluene molecule. Many objected immediately:[19] the pronounced pyramidalization of the Et_3Si fragment was completely inconsistent with the description of a silyl cation. The solid-state structure, however, correlated very well with a computed structure of the σ-Wheland complex **6**, the intermediate for electrophilic attack of $[Et_3Si]^+$ on toluene[19a, b]; alternatively, an η^1-bonded π complex was suggested. The main argument against a silyl cation is that the experimentally determined ^{29}Si NMR chemical shift (δ = 81.8 in toluene), which is shifted very far to high field relative to the calculated shift of $[Me_3Si]^+$ (δ = 355), is close to the computed chemical shift of $\delta = 60$[19b] for a $[Me_3Si\cdots toluene]^+$ complex (δ = 82.1 for $[Et_3Si\cdots toluene]^+$[19d, e]). It was argued that the coordinative interaction between the silyl cation and toluene is stronger than initially assumed by Lambert et al.,[19c] and that the positive charge was mostly transferred from the silicon center onto toluene. Based on the ^{29}Si NMR chemical shift as a criterion for the "freedom of a silyl cation", there is no doubt that the compounds $[R_3Si]^+[CB_{11}Hal_6H_6]^-$ (R_3Si = Et_3Si, iPr_3Si, tBu_3Si, and tBu_2MeSi), all of which display ^{29}Si NMR resonances in the range of δ = 105–115, are not "free" silyl cations. X-Ray structure analyses also showed that in these compounds the anion is coordinated through its halogen atom to the silicon center in the crystal. Based on the ^{29}Si NMR chemical shifts and geometric parameters such as the C-Si-C bond angle, the cationic character was estimated to be around 55–70%.[17b, c] At times the concept of a free silyl cation seemed to be a reason for a quarrel over terminology; nowadays there is a consensus that the transition between coordinated and free silyl cations is continuous. The crux of the matter is how to define and how to realize such a free silyl cation, whatever its definition may be.



6

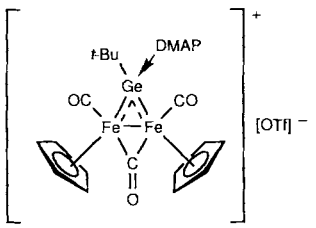
Three ethyl groups, as used by Lambert et al., certainly do not provide optimal shielding for the silicon center. It seemed obvious to use kinetically stabilizing substituents such as mesityl groups whose *ortho*-methyl substituents should hinder the approach of, at least, the large nucleophiles. However, the otherwise so useful hydride abstraction method (i.e., the reaction of a silane with a trityl salt) could then become difficult. Since the silicon center in the starting material is sterically shielded by the mesityl substituents, it may be difficult for the trityl cation to remove hydride from the silane. This is indeed the case: trimesitylsilane does not react with trityl salts, even on prolonged heating. Lambert et al.[20] have now used a surprisingly simple trick to solve this problem. The allyltrimesitylsilane **7** operates as if the allyl substituent were a "rip cord" [Eq. (3)] that aids in liberating the silyl cation. Electrophile **8** reacts with the allylic double bond, which is located in the accessible outer region of the sterically crowded silane **7**. As a consequence, the Si–C bond β to the carbenium ion **9**, already weakened by hyperconjugation, breaks. The larger the angle at the silicon center due to

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3612-1278 $ 17.50+.50/0

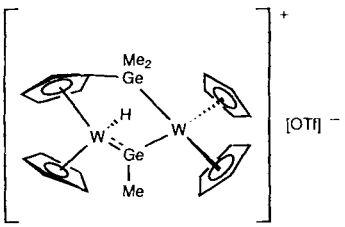


steric hindrance, the faster the bond cleavage. Compound **10**, obtained by this technique, has a ^{29}Si NMR signal at $\delta = 225.5$ in benzene. This record value, which agrees well with the computed chemical shift of $[Ph_3Si]^+$ ($\delta = 208.9$), shows that the positive charge is mostly if not completely localized on the silicon center. The chemical shift is practically the same in other solvents. Upon addition of acetonitrile, the ^{29}Si NMR signal moves to higher field ($\delta = 37.0$); thus this nucleophile is small enough to bypass the mesityl substituents and reach the silicon center. In any event, the NMR data have to be interpreted as an indication that no solvent interaction occurs in aromatic solvents. A weak coordination with the anion cannot be excluded completely but seems unlikely.

In contrast to the (almost) never-ending story of silyl cations, very little has been reported on the experimental generation of stable germyl cations. Cation **11**, which contains an alkyl group and two transition metal fragments as substituents, is stabilized by coordination with a Lewis base.[21] The short Ge–W bond in complex **12** demonstrates that the positive charge at the triply



11



12

coordinated germanium center is delocalized by back-bonding to the tungsten atom.[22] The combination of steric shielding and electronic stabilization has now made it possible to isolate another germyl cation.[23] The Ge_3 moiety in **13** is a slightly distorted triangle whose edges are between a Ge–Ge double and a Ge–Ge single bond length in the solid state. These structural parameters suggest that the positive charge is delocalized over the three-membered ring. This delocalization, together with steric shielding by the large silyl substituents, suppresses nucleophilic attack at the cation. Compound **13** is best described as a germanium analogue of the smallest Hückel aromatic system, the cyclopropenylium ion. This confirms the results of ab initio studies which predicted that the $[Ge_3H_3]^+$ ion is a local minimum. Its aromatic stabilization energy of 31.9 kcal mol^{-1}, however, is considerably smaller (by 26.8 kcal mol^{-1}) than that of the cyclopropenylium ion.[24] Thus, despite all differences, germanium cannot deny its relationship to carbon: the aromaticity principle is valid in both cases, albeit to varying degrees.

[1] F. S. Kipping, *Proc. R. Soc. London, Ser. A* **1937**, *159*, 139–148.
[2] Just as difficult as the search for a stable silyl cation in condensed phases is the search for a proper name for this class of compounds, acceptable to all researchers involved. While silyl cations were named siliconium ions (which was consistent since carbenium ions were designated as carbonium ions at that time) in what is probably the first publication postulating a silicon analogue of a carbenium ion as an intermediate [F. C. Whitmore, L. H. Sommer, J. Gold, *J. Am. Chem. Soc.* **1947**, *60*, 1976–1977], this name is now commonly used for cationic silicon complexes with a coordination number higher than four. Since then the terms silylenium ion, silicenium ion, or silylium ion have been used for triply coordinated positively charged silicon compounds. The latter name is also suggested by IUPAC [G. J. Leigh, *Nomenclature of Inorganic Chemistry*, Blackwell Scientific Publishing, Oxford, **1990**, p. 106]; alternatively, the term silyl cation is suggested.

Combinatorial Chemistry for the Synthesis of Carbohydrate Libraries

Prabhat Arya* and Robert N. Ben*

The use of combinatorial libraries in the identification and elucidation of structure–activity relationships has become a powerful tool in the pharmaceutical sector.[1] Traditionally, novel lead compounds were obtained as natural products from a number of sources including extracts from plants, animals, insects, or microorganisms. When an extract shows a desired biological activity, the active compound is identified, isolated, and then subjected to further biological testing. Optimization of the chemical structure to enhance biological activity is a labor-intensive, time-consuming process, which dictates that each new structure be independently synthesized. This overall approach has made the development of new therapeutics a very lengthy and expensive process.

In contrast, combinatorial chemistry has provided an attractive alternative to these traditional synthetic approaches since it allows for the synthesis of a large number of structurally diverse compounds within a short period of time. The approach utilizes a large array of building blocks that are systematically assembled in such a way that all possible combinations are represented. Typically, a solution or solid-phase approach may be used in conjunction with either a "split" or "parallel" synthetic strategy. Although the technology required to assemble a small molecule library is not new, combinatorial chemistry was not fully exploited until recently, since efficient methods for screening such libraries were virtually nonexistent. Many of these screening strategies, as well as technical aspects of combinatorial chemistry, have been summarized in several well-written reviews.[2]

Unlike for protein–protein and nucleotide–protein interactions, progress in understanding the role of cell-surface carbohydrates in biological and pathological processes has been slow.[3] Although comparatively little is known about these weak, noncovalent interactions between cell-surface carbohydrate ligands and various protein receptors, they form the basis of recognition events that are fundamental to a vastly diverse range of biological and pathological processes. For instance, interactions of this nature have been implicated in cell-to-cell communication, bacterial and viral infections, chronic inflammation, cancer/metastasis formation, and rheumatoid arthritis.[3]

Oligosaccharides are very complex and diverse, which makes their synthesis both labor-intensive and expensive. As a result, the discovery of new biologically active oligosaccharide ligands is a complicated problem. This aside, even when a promising compound has been identified, optimization to enhance activity is difficult and time-consuming. The synthesis of oligosaccharide libraries by a combinatorial approach offers a feasible solution to these problems.

In contrast to peptide and nucleotide libraries, preparation of an oligosaccharide library is not a facile process. It is complicated by the issues of stereochemistry at the anomeric position and the fact that multiple hydroxyl groups are present. Traditionally, these groups would be dealt with using a less than elegant orthogonal protection–deprotection strategy. As an alternative, Hindsgaul et al[4a] demonstrated a random glycosylation approach for forming small di- and trisaccharide libraries. This strategy utilizes a glycosyl donor, which is protected with only one type of protecting group, and a glycosyl acceptor in which all hydroxyl groups are unprotected (Scheme 1). Hindsgaul et al. coupled the benzylated glycosyl donor **1** to the disaccharide **2**, which has six free hydroxyl groups. After three hours at room temperature, a complex mixture was obtained in which about 30% of acceptor **2** was fucosylated. Separation of the mixture with reverse-phase chromatography furnished individual trisaccharides, which were analyzed by NMR spectroscopy. Analysis confirmed that all six expected products were present in yields of 8–23%. Ideally, a statistical mixture would contain 17% of each product.

In an alternate solution-phase approach, a latent–active glycosylation method was developed by Boons and co-workers (Scheme 2).[4b] This strategy uses a glycosyl donor (**4**) and a

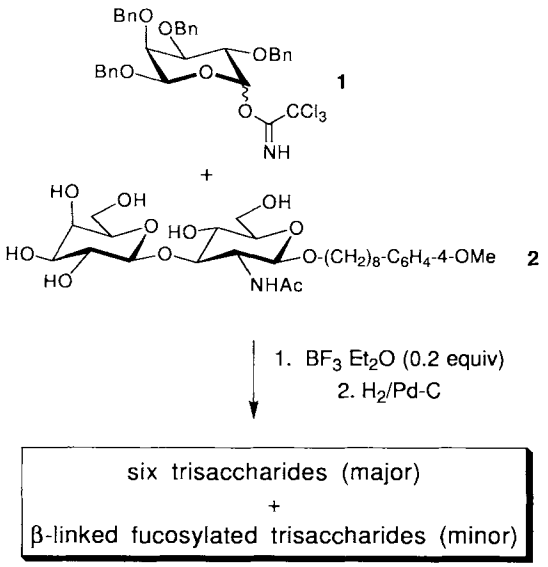
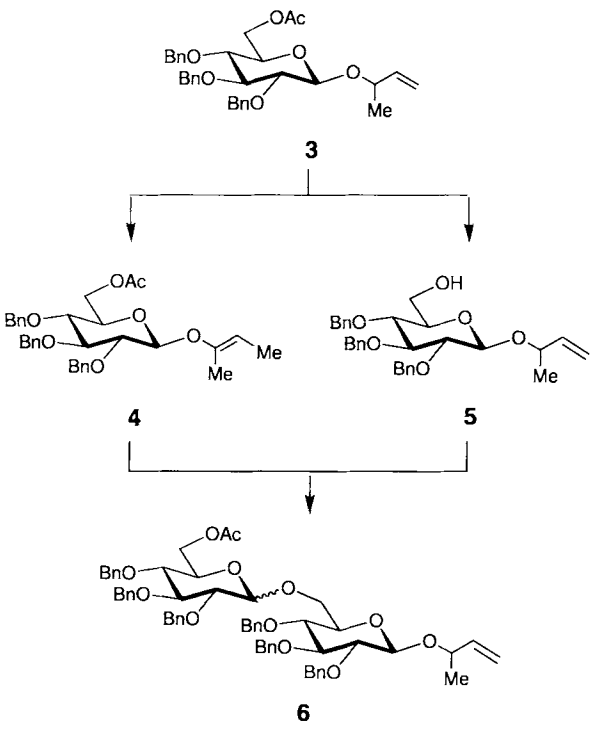


Scheme 1. Random glycosylation according to Hindsgaul et al.



Scheme 2. Latent-active glycosylation approach by Boons et al.

glycosyl acceptor (**5**); the two are derived from a common building block (**3**). Coupling of **4** and **5** produced a disaccharide (**6**), which could be deacetylated and allowed to react with other glycosyl donors in a combinatorial manner. Boons et al. demonstrated the feasibility of such a strategy by synthesizing a small trisaccharide library containing anomeric mixtures that were purified by gel-filtration column chromatography.

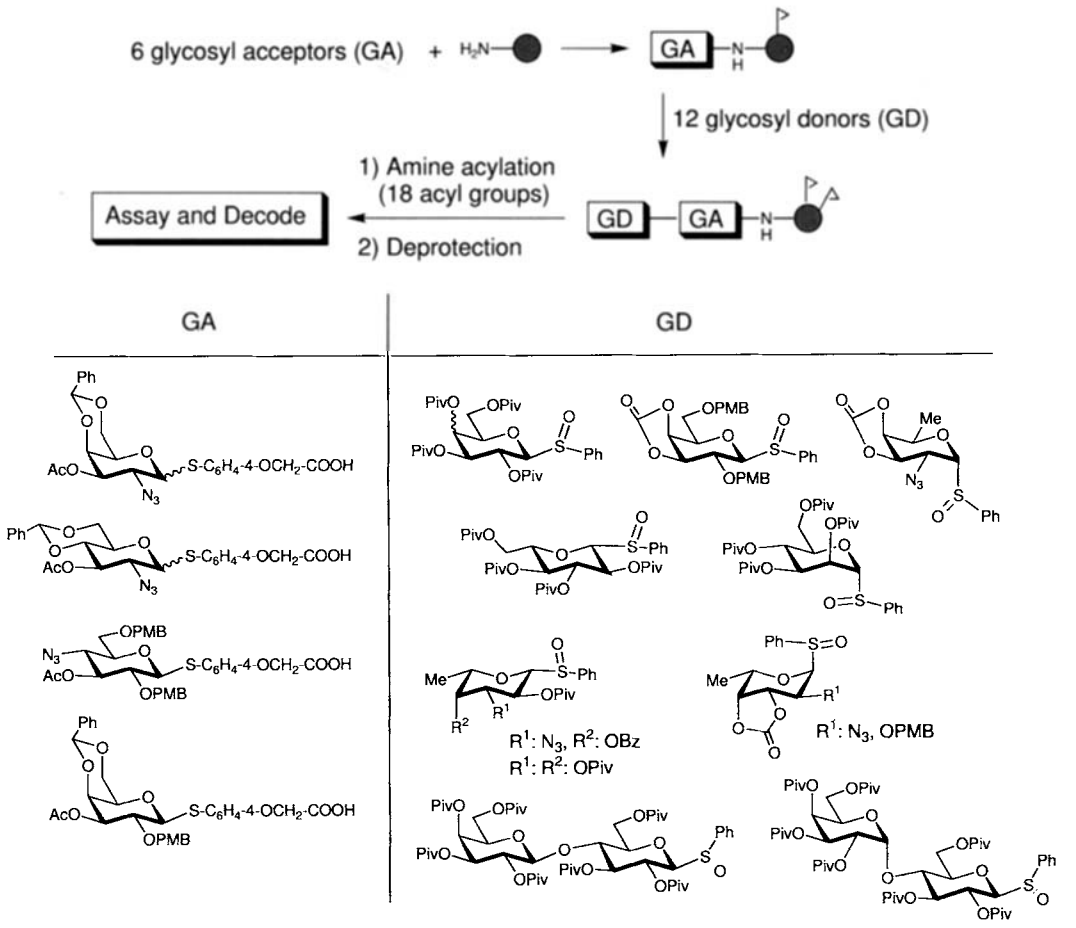
Another important discovery in the area of combinatorial synthesis with di- and trisaccharides was made by Kahne and co-workers at Princeton.[4c] Their approach utilized solid-phase technology to synthesize a saccharide library (Scheme 3). This was especially challenging, since bonds between monomers must be formed in high yields for a solid-phase approach to be successful. This is not trivial, as most high-yielding coupling reactions in carbohydrate chemistry are not general in nature.[5]

Kahne et al. employed a novel coupling procedure that utilized anomeric sulfoxides as glycosyl donors. Such compounds are attractive intermediates, since they can be activated at low temperatures independent of other protecting groups, and give nearly quantitative yields (about 90%) in solid-phase synthesis.[5b] A sizable library with approximately 1300 di- and trisaccharides, possessing a diverse array of linkages, was synthesized in three steps. The approach, which utilized a split and mix synthesis, first involved the separate coupling of six different monomers onto TentaGel resin beads. Next, twelve glycosyl sulfoxide donors were coupled separately to mixtures of beads containing the six monomers. The beads were then combined, and the azido group on the glycosyl acceptor was reduced to an amine. At this point, the beads were divided again into eighteen groups and allowed to react with various acylating reagents. Finally, all the protecting groups were removed.

To screen the library a colorimetric assay was performed with a lectin. The library containing approximately 1300 compounds was exposed to biotinylated lectin, streptavidin-linked alkaline phosphatase, and stained with "nitro blue tetrazolium" (= 2,2′di-*para*-nitrophenyl-5,5′-diphenyl-3,3′-(3,3′-dimethoxy-4,4′-diphenylene)ditetrazolium chloride). The beads that were stained exhibited the greatest degree of binding and were removed with the aid of a simple light microscope. Remarkably, only 0.3% (25 beads) were stained, and of these thirteen had the same disaccharide core acylated with various hydrophobic groups. The remaining twelve hits were discarded, since none of these compounds exhibited any degree of commonality. Surprisingly, the natural ligand for the lectin was not identified as a hit even though it was present in the library. Through separate experiments it was proven that all of the thirteen hits were, in fact, better ligands than the natural substrate.

As pointed out by Kahne et al. it is very interesting that the lectin discriminates so well in its binding of certain di- and trisaccharides. One of the paradoxes of carbohydrate binding is that carbohydrate-binding proteins may bind different substrates in solution but function with remarkable specificity in cell-to-cell recognition. This work also emphasized that the presentation of the saccharide on the surface of the bead is also critical to lectin binding, since solution-affinity experiments demonstrated that both the natural ligand and all thirteen compounds identified as hits bind the lectin in the solution phase. This is indeed surprising, since presentation effects complicate most on-bead screening techniques.

The random-glycosylation techniques by Hindsgaul et al., the latent-active glycosylation by Boons et al., and solid-phase methodology by Kahne et al. now make the synthesis of di- and trisaccharide combinatorial libraries a feasible process. Furthermore, a colorimetric assay can make the screening of such libraries facile and efficient, since the same approach could be applied to other lectins. There can be little doubt that these recent advances in di- and trisaccharide combinatorial chemistry will have a great impact in the understanding of cell-surface interactions and aid in the design of polyvalent compounds that inhibit these interactions.



Scheme 3. Di- and trisaccharide library from Kahne et al. using split and mix synthesis and screening on a solid phase.

Although these recent advances facilitate the synthesis of di- and trisaccharide combinatorial libraries, the synthesis of oligosaccharide libraries (such as tetrasaccharides and higher derivatives) is still quite challenging. This is largely due to the fact that the present glycosylation methods are not quantitative. Therefore, more efficient, quantitative glycosylation methods as well as improved separation techniques need to be developed before the combinatorial synthesis of oligosaccharide libraries is feasible.

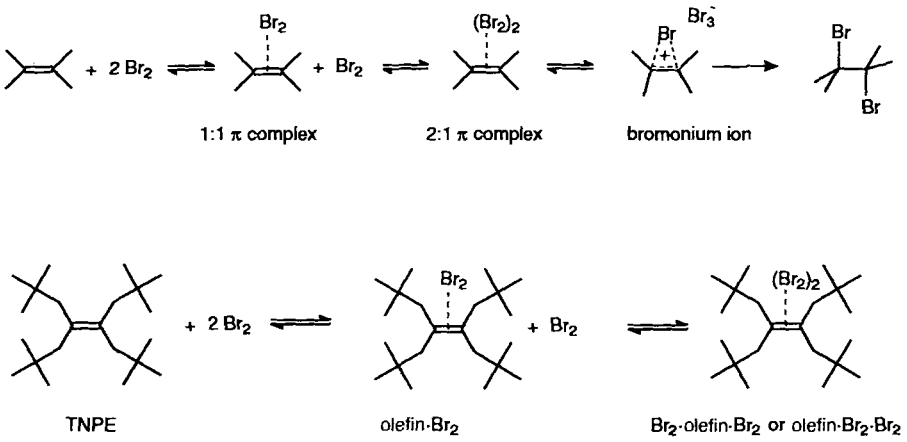
Spectroscopic Detection and Theoretical Studies of a 2:1 Bromine–Olefin π Complex**

Roberto Bianchini,* Cinzia Chiappe, Dieter Lenoir,* Peter Lemmen, Rainer Herges,* and Jörg Grunenberg

Dedicated to the memory of Giuseppe Bellucci



Scheme 1.

Bromine–alkene 1:1 π complexes are the first (and usually short-lived) intermediates in electrophilic bromination.[1] Thermodynamic and spectroscopic properties of these complexes have been investigated in a variety of cases in which the very rapid subsequent reactions (formation of a bromonium ion and the backside attack of Br^-) are hampered, as in sterically hindered,[2] cage,[3] and strained[4] olefins. In the reaction of bromine with cyclohexene[5] and with (*E*)-2,2,3,4,5,5-hexamethylhex-3-ene[6] in 1,2-dichloroethane (DCE), however, the intermediacy of a second bromine–alkene π complex with a 2:1 stoichiometry was inferred on the basis of thermodynamic evidence. There are indications that the 2:1 complex has to be interposed between the 1:1 complex and the bromonium ion as an additional intermediate in electrophilic bromination reactions[7] (Scheme 1). Recently G. Maier and S. Senger found evidence that such a 2:1 complex is also formed by cocondensation of ethylene with an excess of bromine in an argon matrix at 10–20 K.[8]

We now report the first direct UV-spectroscopic detection of a 2:1 bromine–olefin complex. Theoretical investigations reveal the structure of the so far elusive species. Suitable candidates for our studies are highly hindered olefins, which prevent a close approach of bromine and thus formation of the bromonium ion, such as tetraneopentylethene (TNPE). TNPE was first synthesized and studied by Olah et al. and indeed was claimed not to react with bromine.[9] We recorded first the UV spectra of a series of solutions containing low concentrations of Br_2 ($2-5\times10^{-3}$ M) and a variable excess of TNPE (0.4–0.05 M) in the 260–400 nm range in a 10–35 °C temperature interval. A new absorption band centered at 270 nm, whose intensity is almost linearly correlated to the olefin concentration, was observed. From these spectrophotometric data we calculated the thermodynamic and spectroscopic parameters of the 1:1 complex (Table 1). In a second set of measurements, we registered the spectra of solutions containing 1.5×10^{-2} M TNPE and 2.35–0.4 M Br_2 in DCE. At these massive bromine concentrations, deviations from Beer's law are apparent starting between 340 and 260 nm, probably at least partly due to dimerization of the halogen itself.[10] In order to avoid interferences from this process, we recorded the difference of the absorbance of TNPE–Br_2 mixtures and pure Br_2 solutions each at the same Br_2 concentration.[11] Fitting of this second set of spectrophotometric data proved that in addition to the 1:1 complex a 2:1 complex was formed. The new absorption band (ε_{max} = 2535 $M^{-1}cm^{-1}$ at 310 nm, Figure 1) does not overlap with that

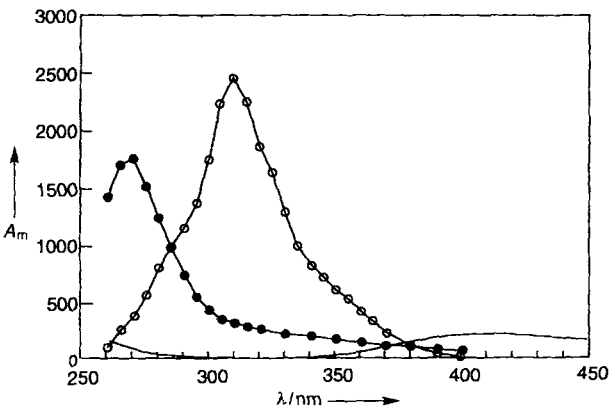


Figure 1. UV spectra of the 1:1 (•) and 2:1 complex o of bromine with tetraneopentyl ethene in dichloroethane as compared with free bromine (—). A_m = molar absorption.

of the well-known 2:1 ionic species, the bromonium–tribromide ion pair (ε_{max} = 48000 $M^{-1}cm^{-1}$ at 272 nm)[3a,12] and provides the first direct demonstration of the existence of a 2:1 π complex.

The thermodynamic data reported in Table 1 account well for the elusiveness of the weak complex. While the charge transfer (CT) band of the 1:1 complex can be easily detected even in dilute solutions of bromine and TNPE, molar concentrations of bromine are needed to form the 2:1 complex in measurable concentrations. The thermodynamic values of the 1:1 complex are in good agreement with results of similar systems that were recently reported.[4–6] The enthalpy of formation $\Delta_R H$ of the 2:1 complex of −1.6 kcal mol^{-1} (Table 1, note [a]) almost exactly matches that inferred from the kinetic approach to the fast

Table 1. Thermodynamic parameters for the 1:1 and 2:1 bromine–TNPE π complexes.

Br_2–TNPE Complex	$\Delta_R H$ [kcal mol^{-1}]	$\Delta_R S$ [cal mol^{-1} K^{-1}]	K_f (25 °C)	K_f (10 °C)	% at equilibrium (10 °C) 0.4 M TNPE 2×10^{-2} M Br_2	% at equilibrium (10 °C) 1.5×10^{-2} M TNPE 2.0 M Br_2
1:1	−3.5 (1.1)	−11.1 (3)	1.6 (0.4)	2.2 (0.5)	46	37
2:1 [a]	−5.1 (2.1)	−17.2 (12)	1.0 (0.5)	1.6 (0.7)	0.5	54

[a] These values refer to the equilibrium TNPE + 2 Br_2 → TNPE·$(Br_2)_2$. For TNPE·Br_2 + Br_2 → TNPE·$(Br_2)_2$ the values are as follows: $\Delta_R H = -1.6$ kcal mol^{-1} and $\Delta_R S = -6.1$ cal mol^{-1} K^{-1}.

reaction of (*E*)-2,2,3,4,5,5-hexamethylhex-3-ene[6] with Br_2 in DCE ($\Delta_R H = -1.5$ kcal mol^{-1}). The small contribution to the entropic factor ($\Delta S = -6.1$ cal mol^{-1} K^{-1}) can be attributed to a large degree of conformational freedom of the second bromine molecule (see Figure 2).

^{1}H and ^{13}C NMR spectra recorded at bromine concentrations of a similar range as used in the UV experiments did not exhibit measurable changes in the chemical shifts of either the vinylic carbons or the allylic protons. Raman spectra of pure TNPE and TNPE/Br_2 solutions (in CCl_4) are identical.[13] This indicates that the reaction of the title olefin with bromine indeed stops at the stage of the 2:1 complex. In agreement with Olah's report no bromonium ion or even olefin dibromide is formed. The second complex therefore is of the Mulliken outer type.[4]

The structure of 1:1 olefin–bromine complexes is known to be of "T-type".[14] However, a number of different spatial arrangements of an olefin with two bromine molecules is conceivable. Since the experimental data do not provide direct information on the structure of the new 2:1 complex we performed an exhaustive search on the energy hypersurface of the parent system: ethene + 2 Br_2 to find the energetically most favorable arrangement. Two different theoretical methods were applied to secure the reliability of our computational results. Density functional theory (DFT)[15] at the B3LYP/6-31 + G* level[16, 17] and ab initio MP2/6-31 + G* calculations[18] were used to optimize three different structures of 1:1, ten conceivable structures of 2:1 complexes, and five different structures for bromine dimers. Two minima for each system were found.[19] Energies and geometries of the six structures are given in Table 2 and Figure 2.

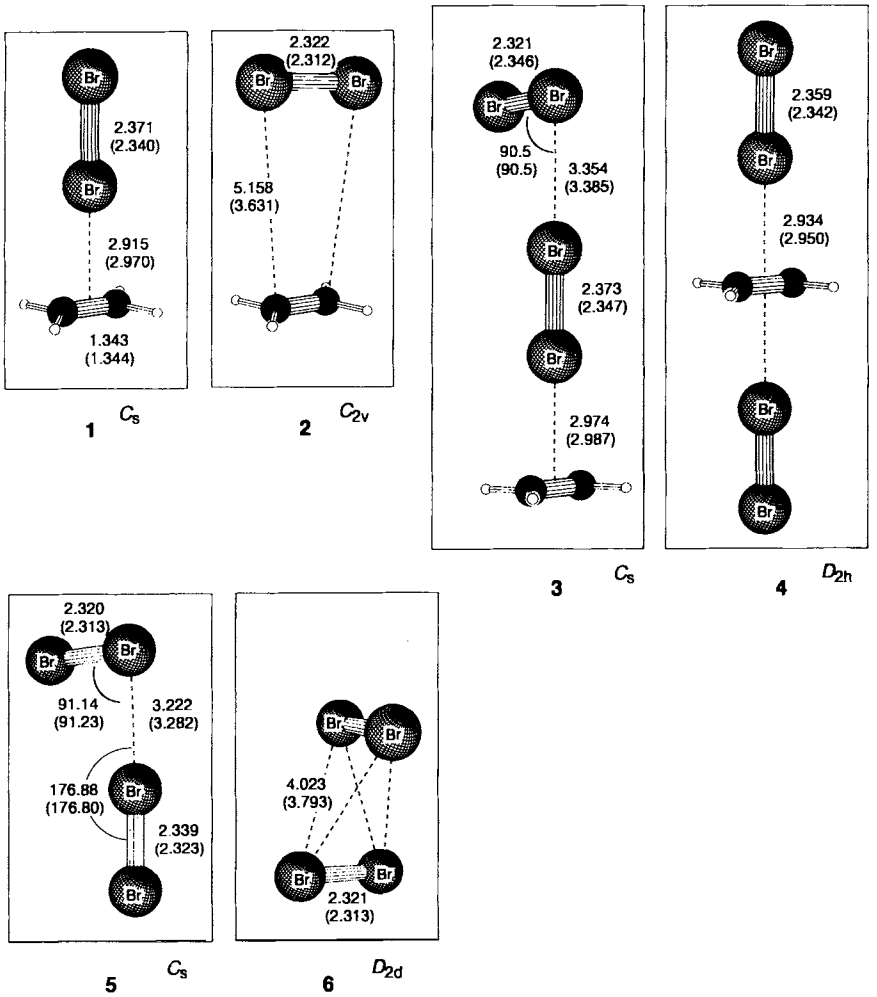

Figure 2. Structures of the 1:1 complexes **1** and **2** and the 2:1 complexes **3** and **4** between bromine and ethene, as well as the bromine dimers **5** and **6**, optimized by density functional theory (B3LYP/6-31 + G*) and ab initio methods (MP2/6-31 + G* in parentheses); bond lengths are given in Å, and angles in°.

The most stable 1:1 complex is of the well-known T-type(**1**).[13] Surprisingly we found a second minimum. Structure **2**, however, s a very weak complex ($\Delta_R H \approx 1-2$ kcal mol^{-1}). Among the 2:1 complexes structures **3** and **4** are the only minima on the energy hypersurface. In structure **4** both sides of the π system of ethene interact with bromine (Br_2·olefin·Br_2 complex). In structure **3** the second bromine is bound to the first bromine (olefin·Br_2·Br_2 complex). The midpoint of the C=C bond, the two Br atoms of the first bromine molecule, and one Br atom of the second bromine almost lie in line. The remaining Br atom approximately forms a 90° angle with respect to this line. According to a frequency analysis of **3** there is almost free rotation of the second bromine atom around this axis and a very small force constant for bending of the 90° angle (Figure 2, structure **3**).

In principle both structures **3** and **4** have to be considered as candidates for a 2:1 complex in the parent system. The energy difference between them, even though in favor of **3**, is too small for an unequivocal assignment within the accuracy of our calculations ($\Delta\Delta_R H =$ 0.37 kcal mol^{-1} at B3LYP/6-31 + G* + ZPE and 0.17 kcal mol^{-1} at MP2/6-31 + G* + ZPE; see Table 2). The situation in the tetraneopentyl-substituted system, however, is less ambiguous. Even though the TNPE system is too large to be calculated with ab initio methods or DFT, the effect of the bulky substituents can be reliably estimated. Steric hindrance low-

Table 2. Relative energies (E_{rel}) and enthalpies of formation ($\Delta_R H$) of the complexes **1**–**6**, calculated from density functional theory and ab initio methods, in [kcal mol^{-1}]. E_{rel} is given relative to the more stable structure of each pair of isomers. $\Delta_R H$ values are based on the reactants bromine and ethylene. Numbers of imaginary frequencies (nimag) were obtained by harmonic frequency calculations at the DFT level.

Structure	1:1 Complexes		2:1 Complexes		Bromine dimers	
	1 C_{2v}	**2** C_{2v}	**3** C_s	**4** D_{2h}	**5** C_s	**6** D_{2d}
E_{rel} (B3LYP)[a]	0.0	3.72	0.0	0.36	0.0	1.03
E_{rel} (MP2)[b]	0.0	3.25	0.0	0.16	0.69	0.0
nimag[a]	0	0	0	0	0	0
$\Delta_R H$ (B3LYP)[c]	−4.85	−1.13	−9.79	−9.42	−4.90	−3.87
$\Delta_R H$ (MP2)[d]	−5.07	−1.82	−11.36	−11.19	−5.29	−5.98

[a] B3LYP/6-31+G*. [b] MP2/6-31+G*. [c] B3LYP/6-31+G*+ZPE. [d] MP2/6-31+G*+ZPE.

ers the enthalpy of complexation of the first bromine with the π system of the olefin by about 1 kcal mol^{-1} (relative to unhindered cyclohexene). Such interactions are operative in complexes of the type of structure **1** (olefin·Br_2·complex) and **4** (Br_2·olefin·Br_2 complex). However, the neopentyl substituents hardly affect the bromine–bromine interaction of the type of structure **3** (olefin·Br_2·Br_2 complex), because the second bromine molecule and the olefinic carbons are more than 8 Å apart (see PM3-calculated structure[20] in Figure 3).

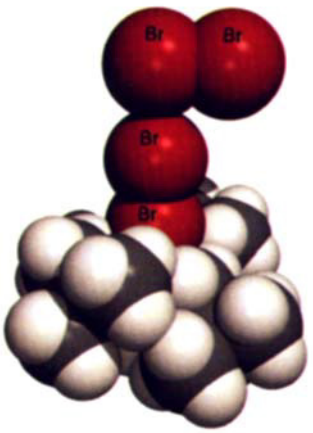

Figure 3. PM3-calculated structure of the olefin·Br_2·Br_2 complex of tetraneopentyl ethene (TNPE) with two bromine molecules.

Based on our ab initio and DFT calculations on the parent system and assuming a steric effect of the neopentyl substituents of 1 kcal, the olefin·Br_2·Br_2 complex should be about 1.4 kcal mol^{-1} more stable than the Br_2·olefin·Br_2 complex (which is inherently less stable by about 0.4 kcal mol^{-1} and which suffers twice from steric hindrance). The theoretically estimated absolute value for the formation enthalpy of olefin·Br_2·Br_2 including steric effects (9–11 kcal mol^{-1}), however, is still about 5 kcal mol^{-1} larger than the experimental value (5.1 ± 2.1 kcal mol^{-1}, Table 1), whereas $\Delta_R H$ of olefin·Br_2 after correction for steric factors almost exactly matches the experiment. A deviation of 5 kcal mol^{-1} is beyond the error limit of our theoretical calculations. The reason for the discrepancy between theory and experiment is probably due to the fact that at the large Br_2 concentrations (0.4–2.35 M) used in the experiment, bromine dimerizes to a considerable extend.[10] Our calculations predict the two minima **5** and **6** as conceivable bromine dimer structures (Table 2, Figure 2). DFT and ab initio methods do not concur on which would be more stable. Structure **5** is favored by orbital interactions and **6** on dispersion energy grounds. However, since the bromine dimer is known to be polar, structure **6** can be excluded. The enthalpy of dimerization according to the equation: 2 $Br_2 \rightarrow Br_2 \cdot Br_2$ was calculated to be 4.9 kcal mol^{-1} (B3LYP/6-31+G*+ZPE) and 5.3 kcal mol^{-1} (MP2/6-31+G*+ZPE). For the reaction olefin + Br_2·Br_2 → olefin·Br_2·Br_2, theory ($\Delta_R H$ = 3.9 kcal mol^{-1} at B3LYP/6-31+G*+ZPE and 5.3 kcal mol^{-1} at MP2/6-31+G*+ZPE) and experiment ($\Delta_R H = 5.1 \pm 2.1$ kcal mol^{-1}) are in excellent agreement.

Further evidence favoring olefin·Br_2·Br_2 over Br_2·olefin·Br_2 is provided by the small entropy of formation of the 2:1 complex. This is probably due to the large degree of conformational freedom of the second bromine molecule in olefin·Br_2·Br_2 as opposed to that in Br_2·olefin·Br_2 and olefin·Br_2 where the bromine is directly bound to the olefinic π bond.

Bromine not only forms a 1:1 but also a 2:1 complex with TNPE in DCE. The thermodynamic data of both species were determined by UV-spectroscopy. According to our theoretical calculations the 2:1 complex has an olefin·Br_2·Br_2 type structure as shown in Figure 3. The intermediacy of such a 2:1 complex well accounts for the second-order dependence on [Br_2] in the kinetics of electrophilic bromination reactions.[5] Moreover, charge separation and hence formation of the bromonium–tribromide ion pair (olefin·Br_2·Br_2 → olefin·Br^+ + Br_3^-) is favored by the assistance of the second bromine. In the TNPE system this process is inhibited by the steric hindrance of the neopentyl substituents and therefore the 2:1 species can be detected in the equilibrium. Such 2:1 complexes most probably are of general importance as intermediates in electrophilic bromination reactions.

Experimental Section

TNPE was prepared as described [9] and purified by flash chromatography on silica gel with hexane as eluent (yield 53%). Recrystallization from ethanol at −20 °C yielded colorless crystals (m.p. 64–65.5 °C; ref. [9] 59 °C).

All the spectrophotometric measurements were carried out on a Cary 2200 UV/Vis spectrophotometer fitted with a Haake D8 thermostat. Freshly prepared prethermostated solutions of TNPE and Br_2 at the appropriate concentrations were rapidly mixed, and their spectra measured after 5 minutes of further thermal equilibration inside the cell holder. In the first set of experiments (170 spectrophotometric data), the concentrations after mixing were: Br_2 5×10^{-3} M; TNPE 0.4, 0.31, 0.29, 0.18, 0.1, and 0.05 M. In the second set of experiments (170 data) the spectra of 1.5×10^{-2} M TNPE and 2.35, 2.13, 1.64, 1.25, 1.0, 0.74, 0.5, and 0.4 M Br_2 were recorded in a thermostated cell (0.01 cm path length). Measurements were taken every 5 nm in the 260–400 nm range. Wavelengths shorter than 260 nm could not be used, because of considerable absorption by the excess of either TNPE or Br_2. Unlike with other tetrasubstitued, hindered, or strained ethenes (see refs. [2–4, 6]) no side reaction occurred. Solutions started to exhibit some change after only 30 minutes in the worst case. An already described [21] nonlinear least-squares procedure was applied to fit the spectrophometric data. The first set of data (high excesses of TNPE) was processed to obtain data for the 1:1 complex. The results of this fitting (formation enthalpy and entropy, molar absorptivities at each examined wavelength) were taken as fixed values in the second fitting (large excess of Br_2). In both fittings about 30 fitting parameters, including the molar absorptions of the complexes at each examined wavelength, were used besides the formation enthalpies and entropies. The root mean-square deviation of the fitting was 0.05 in absolute units. The highest correlation coefficient between ΔH and ΔS of 0.981 is acceptable considering the small temperature interval used (10–35 °C).

NMR experiments: TNPE (0.1 M): ^{1}H NMR (400 MHz, CD_2Cl_2, 15 °C): δ = 0.94 (s, $(CH_3)_3C$)), 1.80 and 2.53 (d, CH_2). ^{13}C NMR (100.6 MHz, CD_2Cl_2, 15 °C): δ = 31.13 ($3CH_3$), 34.23 (quat. C), 46.32 (CH_2), 135.40 (C=C). Both ^{1}H and ^{13}C spectra remained unchanged upon addition on an excess of Br_2 (up to 2.5 M).

[7] In both reactions apparent negative activation energies (E_{app}) were found, due to the exothermic formation of the 1:1 Br_2–olefin complex as the first reactive species. However, their negative enthalpy of formation did not fully account for the negative E_{app}. Therefore, the occurrence of a second bromine–alkene complex (2:1) with an enthalpy and entropy of formation of approximately $-3.2\ kcal\,mol^{-1}$ and $1.5\ cal\,mol^{-1}\,K^{-1}$ was suggested.

Enantioselective Formation of Double and Triple Helicates of Silver(I): The Role of Stacking Interactions**

Christophe Provent, Sujatha Hewage, Guy Brand, Gérald Bernardinelli, Loïc J. Charbonnière, and Alan F. Williams*

Dedicated to Professor Werner Haerdi on the occasion of his 70th birthday

The formation of helical complexes or helicates by simple mixing of ligands and metal ions has attracted considerable attention in recent years as a prototypical self-assembly reaction.[1, 2] Although these complexes are chiral, the combination of achiral ligands and metal cations leads generally to racemic mixtures. Enantiospecific synthesis of helicates has been achieved by incorporation of a chiral element in the bridge between the two metal centers,[3] into the template of a tripodal[4] or bipodal[5] ligand system, or by the introduction of a chiral substituent at the extremity of a biscatechol ligand.[6] In this communication we show how enantiospecificity may also be achieved by the use of the readily accesible chiral oxazoline (dihydrooxazole) unit as a ligand, and how the nature of the group introducing the chirality can dramatically influence the structure.

Some years ago we reported that ligand **1** forms a double helical complex $[Cu_2(\mathbf{1})_2]^{2+}$ with copper(I)[7] in which each copper center is approximately linearly coordinated by two benzimidazole moieties, one from each ligand. Ligands such as **2** were originally developed by Nishiyama and others[8–10] for enantioselective catalysis, and are closely related to **1**; they should therefore form double helicates with ions such as Cu^I and Ag^I that are subject to linear coordination. Models showed that the configuration of the oxazoline group determines the configuration of the helix: an *S,S* ligand such as **2** will form the *P* or *Δ* helix (Scheme 1), since in the alternative *M* helix the oxazoline substituents would prevent the binding of the second ligand strand.

^1H NMR titration of a solution of (*S,S*)-2,6-bis(4′-benzyl-oxazolin-2′-yl)pyridine (**2**) in [D_3]acetonitrile with $AgBF_4$ showed initial formation of a complex of stoichiometry $[Ag(\mathbf{2})_2^+]_n$; on addition of more Ag^I ions the peaks broadened, narrowing again for a 1:1 metal-to-ligand ratio, after which the spectrum remained sharp even in excess of silver. This is consistent with formation of a complex $[Ag(\mathbf{2})^+]_n$. Electrospray (ES) mass spectrometry of solutions of $[Ag(\mathbf{2})^+]_n$ in acetonitrile showed peaks at *m/z* 505.3 ($[Ag(\mathbf{2})^+]_n$, base peak), 901.4 ($[Ag(\mathbf{2})_2]^+$), and 1097.3 ($\{[Ag_2(\mathbf{2})_2](BF_4)\}^+$). Examination of the isotopic abundances of the peak at *m/z* 505.3 showed the peak separation of 0.5 units typical of a doubly charged species, confirming the presence of the complex $[Ag_2(\mathbf{2})_2]^{2+}$; however, the isotopic distribution pattern suggested that a small amount of $[Ag(\mathbf{2})]^+$ was present, which we attribute to fragmentation in the mass spec-

trometer since the ^1H NMR spectrum shows the presence of only one complex; the observation of only one diastereomer confirms the enantioselectivity of helix formation. Finally the CD spectrum changes dramatically on complex formation: the free ligand shows a weak negative band at 296 nm ($\Delta\varepsilon = -0.4\,L\,mol^{-1}\,cm^{-1}$), whereas the complex $[Ag_2(\mathbf{2})_2]^{2+}$ shows a strong positive band at 301 nm ($\Delta\varepsilon = 10.15\,L\,mol^{-1}\,cm^{-1}$), corresponding to a new shoulder in the UV/Vis spectrum attributed to a metal-to-ligand charge transfer transition ($\Delta\varepsilon = 1547\,L\,mol^{-1}\,cm^{-1}$).

The X-ray structure analysis[11] of crystals of $[Ag_2(\mathbf{2})_2](BF_4)_2$ obtained by diffusion of diethyl ether into an acetonitrile solution shows a double helical structure similar to that of $[Cu_2(\mathbf{1})_2]^{2+}$, but with *P* (*M*) helicity (Figure 1a), in which **2** acts

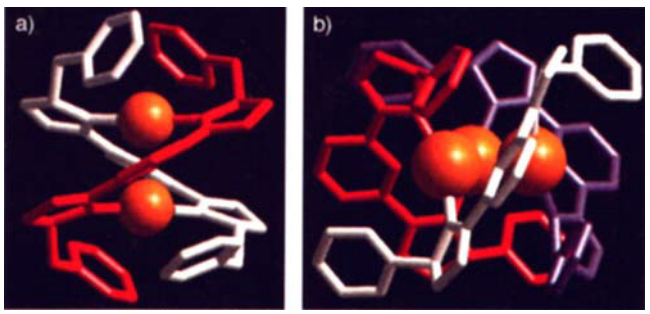

Figure 1. a) View of $[Ag_2(\mathbf{2})_2]^{2+}$ perpendicular to the helical axis. b) View of $[Ag_3(\mathbf{3})_3]^{3+}$. The crystallographic threefold axis is perpendicular to the equilateral triangle formed by the three silver atoms. Both views were generated with the Cerius2 program.

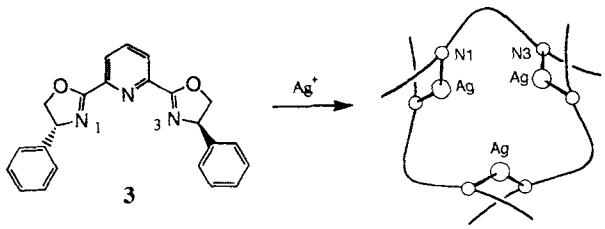
as a bismonodentate ligand. The silver(I) ions are linearly coordinated by two oxazoline-N atoms (av Ag–N 2.18(2) Å, N-Ag-N 177(2)°), the pyridine units lying much further away (av Ag–$N_{pyridine}$ 2.82(5) Å). The Ag–Ag distance of 2.985(1) Å is slightly longer than the Cu–Cu distance in $[Cu_2(\mathbf{1})_2]^{2+}$ (2.854(2) Å),[7] probably as a result of the relative size of the Ag ion. The complex has approximate D_2 symmetry with pseudotwofold axes passing through the silver ions and through the pyridine rings. The phenyl groups may be regarded as extending the ligand strand and are slightly inclined to the helical axis; one group shows a weak stacking interaction with the pyridine ring of the second ligand (interplane angle 12.8°, average distance 3.62 Å) but the others show no stacking interaction.

Replacement of **2** by the ligand (*R*,*R*)-2,6-bis(4′-phenyloxazolin-2′-yl)pyridine (**3**) would be expected to give the *M* double helix, but the X-ray structure determination of the colorless tetrahedral crystals obtained by diffusion of benzene into a solution of the compound in acetonitrile showed the formation of $[Ag_3(\mathbf{3})_3](BF_4)_3$ (Scheme 2).[11] The complex (Figure 1b) has



3

Scheme 2. (*R*,*R*)-bis(phenyloxazolinyl)pyridine **3** forms a triple helicate with Ag^I ions.

crystallographic C_3 symmetry, and consists of an equilateral triangle of silver ions (Figure 2), with the ligands bridging the sides of the triangle. Each ligand binds through the

oxazoline-N atoms (av Ag–N 2.16(2) Å), the pyridine rings again lying much further away (Ag–$N_{pyridine}$ 2.65(2) and 2.82(5) Å). The coordination of the silver ion is not strictly linear (angle N-Ag-N 153.3(6)°), and the Ag–Ag distance of 3.001(2) Å is close to that of $[Ag_2(\mathbf{2})_2]^{2+}$. Each ligand binds to one metal from below the plane of the silver atoms, and to a second metal from above the plane. The structure may thus be considered as a triple helix in which the ligands wrap around the threefold axis and are held in place by coordination to the Ag_3 triangle; by virtue of the configuration of the ligand, only *P* helices are found in the crystal. Alternatively, it may be considered as a toroidal helix similar to the pentameric species described recently by Lehn et al.,[12] in which the three silver ions define a polygon, with the ligands wrapping around the sides of the polygon. In the double helical structure of $[Ag_2(\mathbf{2})_2]^{2+}$ the bond linking the substituent to the oxazoline ring is directed roughly along the helical axis, but in the triple helical complex $[Ag_3(\mathbf{3})_3]^{3+}$ this bond is equatorial and thus perpendicular to the helical axis. This allows a strong stacking interaction between the strands, the pyridine rings lying almost parallel to the phenyl substituents of the two other ligands (interplane angles

4.9(1) and 6.1(1)°; average interplane distance 3.37(9) and 3.44(11) Å).

The Ag–N bond lengths are not significantly different in the two complexes, and the conformations of the bis(oxazoline)pyridine units are virtually superimposable in $[Ag_2(\mathbf{2})_2]^{2+}$ and $[Ag_3(\mathbf{3})_3]^{3+}$. The only reasonable explanation of the remarkable difference in structure is the existence of the stacking interaction in $[Ag_3(\mathbf{3})_3]^{3+}$; although stacking interactions have frequently been observed in helicates,[1, 2] this is to our knowledge the first example in which their absence or presence appears to modify the structure. We may note that although the complexation of the silver ion by the ligands provides the thermodynamic driving force for the assembly, the use of monodentate ligands gives a freedom of rotation around the Ag–N bond that is absent in the case of complexation of a metal by bi- or tridentate ligands; it is therefore possible for the system to rearrange itself in such a way as to maximize the secondary stacking energy without imposing too great a strain upon the coordinate bond. This contrasts with a previous study in which the formation of double or triple helices with a given ligand was controlled by the metal ion coordination preference.[13] The close stacking in $[Ag_3(\mathbf{3})_3](BF_4)_3$ results in a very compact structure that crystallizes in a cubic space group, and has a crystal density 8% greater than $[Ag_2(\mathbf{2})_2](BF_4)_2$. In solution, however, the trimeric cation appears to be unstable, the ES mass and ^{1}H NMR spectra suggesting that partial dissociation to $[Ag_2(\mathbf{3})_2]^{2+}$ occurs. This question is currently being investigated.

Experimental Section

Ligands **2** and **3** were prepared according to references [8,9]. In a typical procedure for the preparation of complexes, the ligand (0.5 mmol) in dichloromethane (5 mL), and $AgBF_4$ (0.5 mmol) in methanol (5 mL) were mixed and stirred for 15 min. The solution was evaporated to dryness, and the residue taken up in acetonitrile (5 mL). After filtration to remove the insoluble material, crystals were obtained by diffusion of diethyl ether.

Palladium-Catalyzed Sixfold Alkenylation of Hexabromobenzene: An Interesting Case of Self-Organization**

Peter Prinz, Annegret Lansky, Thomas Haumann, Roland Boese, Matthias Noltemeyer, Burkhard Knieriem, and Armin de Meijere*

Dedicated to Professor Fabian Gerson on the occasion of his 68th birthday

Hexasubstituted benzene derivatives with six functional side chains have attracted considerable interest for various reasons over the last two decades.[1, 2] One elegant route to such molecules, which has been developed and extensively used by Astruc,[3] is the sixfold alkylation of hexamethylbenzene activated as an $FeCp^+$ complex under basic conditions. Hexakis(trimethylsilylethynyl)- and hexakis(trimethylsilylbutadiynyl)benzene were readily prepared by sixfold alkynylation of hexabromobenzene with palladium–copper cocatalysis.[4] Although palladium-catalyzed sixfold alkenylation of hexabromobenzene
