are equivalent inside the C_{80} cage. To provide insight into the cage structure the ^{13}C NMR spectrum was measured at 300 K with ^{13}C-enriched $La_2@C_{80}$ (25% ^{13}C). Although the endohedral D_{2h} structure in Figure 1 suggests a total of 13 distinct ^{13}C NMR lines for 13 nonequivalent carbon atoms, only one ^{13}C NMR line was observed at $\delta = 141.61$ with satellites due to the ^{13}C–^{13}C coupling (Figure 3). Therefore, incorporation of two La atoms into various C_{80} cages was considered. Two La atoms were placed at the highest symmetry sites possible, which nevertheless led to 20, 5, 23, 22, 14, and 6 nonequivalent carbon atoms for the D_2, D_{5d}, C_{2v}, $C_{2v'}$, D_3, and D_{5h} cages, respectively. The

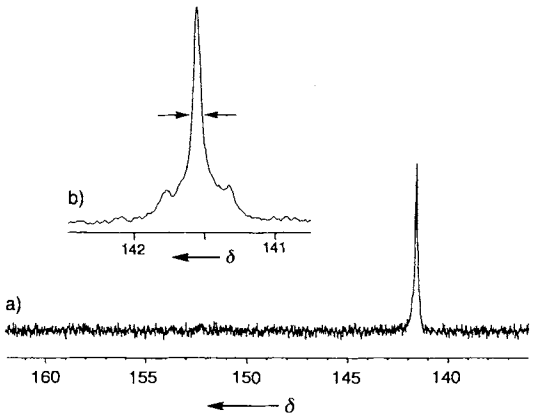

Figure 3. ^{13}C NMR spectra of $La_2@C_{80}$ in $Cl_2C_6D_4$ at (a) 150 and (b) 125 MHz. The linewidth in (b) is 0.08 ppm.

numbers of nonequivalent carbon atoms do not change, even if two La atoms are randomized uniformly. In addition, the chemical shifts should range at least over several ppm.[14] These points are not consistent with the observed ^{13}C NMR spectrum.

It is interesting that the overall symmetry is changed and increased only in the case of the I_h cage. The random motion of two La atoms inside the round I_h cage leads to two sets of slightly different carbon atoms (20 of one kind and 60 of the other). The observed linewidth of 0.08 ppm (Figure 3b) suggests that the difference in the chemical shifts is too small to be observed as two distinct lines, thereby reflecting the spherical cage. This agrees well with the small chemical shift difference of 0.07 ppm calculated for C_{80}^{6-} (I_h) at the HF – GIAO/6 – 31G// HF/6 – 31G level with the Gaussian 94 program;[15] this also supports the electronic structure of $(La^{3+})_2C_{80}^{6-}$. The presence of one or at most two lines in the ^{13}C NMR spectrum is convincing proof that two La atoms are encapsulated inside the I_h cage and circulate rapidly.

The metal motion depicted in Figure 4 is consistent with our recent calculations, which show that two La atoms can circuit the inside of the round I_h cage, since the barrier is very small (about 5 kcal mol^{-1}).[16] The presence of the barriers suggests that two La atoms can stop at the most stable positions upon a decrease in temperature. To experimentally verify this, low-temperature ^{13}C NMR measurements were carried out. At 258 K broad ^{13}C NMR signals were observed, which are ascribed to overlap of the 13 lines expected for the static D_{2h} structure (Figure 1). In addition, a single ^{139}La NMR peak, even at 258 K, supports D_{2h} symmetry for $La_2@C_{80}$ at low temperature.

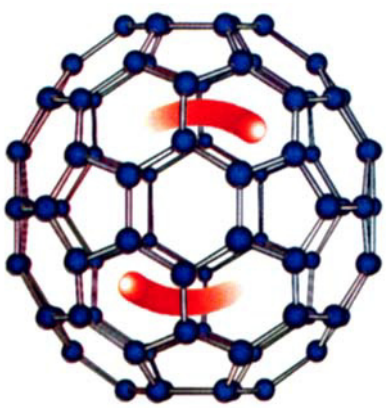

Figure 4. Circular motion of two La atoms inside the I_h cage of C_{80}.

The dynamic behavior of metal atoms should also be reflected in the ^{139}La NMR linewidth, since circulation of two La^{3+} cations produces a new magnetic field at the positions of La. Ordinarily, the interaction between La nuclear spins and the magnetic field (the spin–rotation interaction) does not contribute significantly to the relaxation time (hence, the linewidth), because molecular rotation is dominantly quenched by neighbors in solution. Since in $La_2@C_{80}$ rotation of two La atoms can be preserved due to unique cage protection, spin–rotation interaction has a drastic effect on the relaxation process and results in an increase in the linewidth upon an increase in temperature. This is quite unlike other types of relaxation.[17] Large broadening of the ^{139}La NMR linewidth was observed with increasing temperature from 305 to 363 K (Figure 5). On the other hand, narrowing of the linewidth with increasing temperature from 258 to 305 K is normal due to the overall rotation of the $La_2@C_{80}$ molecule (quadrupole-dominated relaxation).

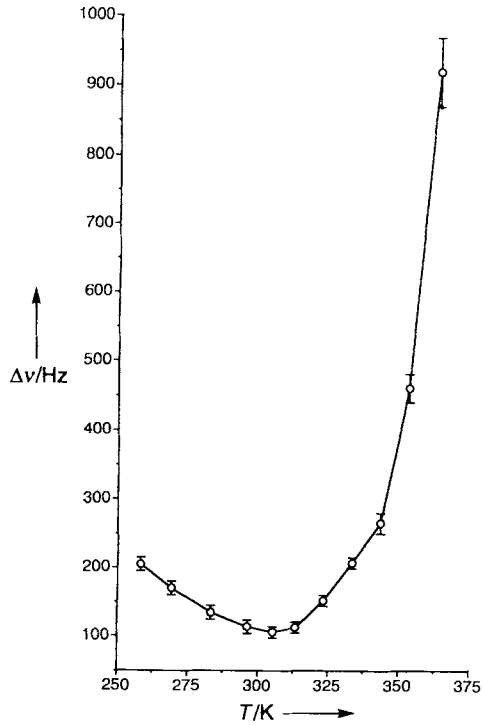

Figure 5. Linewidths $\Delta\nu$ of the ^{139}La NMR signal for $La_2@C_{80}$ as a function of temperature.

We have experimentally confirmed that two La atoms are encapsulated inside the I_h cage of C_{80}. The La atoms are not still but circulate inside the round cage even at room temperature, which is in contrast to the Sc atoms in $Sc_2@C_{84}$.[16]

Experimental Section

$La_2@C_{80}$ was synthesized and purified as reported [3]. ^{13}C-enrichment was achieved by arc-burning the lanthanum–carbon composite rods made with 90% ^{13}C-enriched amorphous carbon. $La_2@C_{80}$ (0.1 mg) was dissolved in [D_4]-*o*-dichlorobenzene under an argon atmosphere. [Cr(acac)$_3$] (acac = acetylacetonate) was added as a relaxant for the ^{13}C NMR measurements. ^{139}La NMR spectra were measured at 70.6 MHz on a Bruker DMX500 spectrometer (acquisition time 107 ms, delay time 143 ms). ^{13}C NMR spectra were obtained at 125 and 150 MHz on Varian Unity Plus 500SW, Bruker DMX500, and DMX600 spectrometers. The ^{139}La chemical shift was calibrated with 0.6 M $LaCl_3/D_2O$ as an external reference ($\delta = 0$). Chemical shifts of ^{13}C NMR were expressed downfield of the signal for the *ipso* carbon atom in *o*-dichlorobenzene as an internal standard ($\delta = 131.0$).

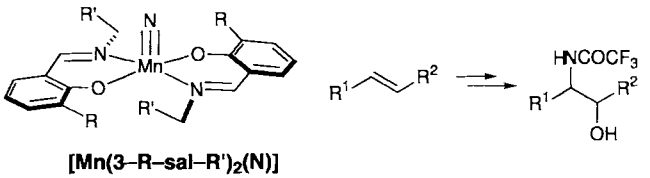
Synthesis and Structure of Novel Mn^{III} and Mn^{V} Complexes: Development of a New, Mild Method for Forming Mn≡N Bonds**

J. Du Bois, Craig S. Tomooka, Jason Hong, Erick M. Carreira,* and Michael W. Day

The numerous reaction methods for converting alkenes to epoxides or diols are of enormous value and are commonly employed in chemical synthesis.[1, 2] In contrast, far fewer methods are available for the analogous conversion of an alkene to an aziridine or an amine, despite their great potential utility.[3, 4] We are currently exploring the development of nitridomanganese systems that may be activated for N-atom transfer to alkenes. We have reported that silyl enol ethers could be aminated with [(salen)Mn≡N] complexes (salen = *N*,*N*′-bis(salicylidene)ethylenediamine dianion) in the presence of trifluoroacetic anhydride (TFAA) to give *N*-trifluoroacetylated α-amino ketones.[5] In an effort to expand the scope of this class of reagents, we have focused on the design and synthesis of novel nitridomanganese complexes. Herein we describe the preparation and X-ray crystallographic characterization of Mn^{III} and nitridomanganese(v) complexes containing Schiff bases as ligands. The generation of such Mn^{V} nitrides (Mn≡N) (Scheme 1)



[Mn(3–R–sal–R′)$_2$(N)]

Scheme 1. Schiff base nitridomanganese(v) complexes as N-atom-transfer reagents for the aminohydroxylation of alkenes.

has required the development of a mild oxidative protocol.[6, 7] Additionally, we demonstrate the ability of these nitrides to transfer a CF_3CON unit to an unfunctionalized olefin by the successful amination of styrene, a substrate which was unreactive with previously reported Mn≡N complexes.[8]

Extensive literature exists on the coordination chemistry of manganese in its divalent and trivalent oxidation states.[9] In a majority of cases, the manganese ion is observed to form bridged, multinuclear assemblies, particularly when simple bidentate ligands (e.g. carboxylates) are used.[10, 11] We were interested in examining Mn^{III} complexes containing two Schiff base ligands as precursors for the corresponding Mn^{V} nitrides. To this end, substituted salicylimine ligands (H-3-R-sal-R′) were accessed following condensation of salicylaldehydes with primary amines (75–85% yields, Scheme 2).[12] Manganese(III)

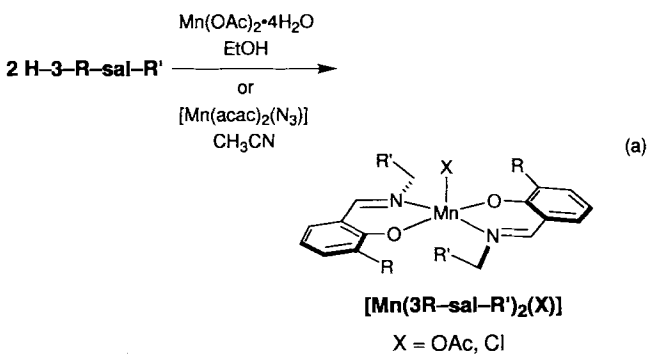
adducts of the type $[Mn(3\text{-}R\text{-}sal\text{-}R')_2(X)]$ could be formed under a variety of conditions using either Mn^{II} or Mn^{III} starting materials. In the former case, reactions were conducted open to air which led to rapid oxidation of the initially formed Mn^{II} species. The effectiveness of $[Mn(acac)_2X]$ (acac = acetylacetonate; X = N_3, Br), $[Mn(acac)_3]$, $Mn(OAc)_3\cdot 2H_2O$, $MnCl_2\cdot 4H_2O$, and $Mn(OAc)_2\cdot 4H_2O$ as starting materials for the preparation of $[Mn(3\text{-}R\text{-}sal\text{-}R')_2(X)]$ complexes was examined. In a typical experiment, treatment of two equivalents of the Schiff base with one equivalent of $Mn(OAc)_2\cdot 4H_2O$ provided the $[Mn(3\text{-}R\text{-}sal\text{-}R')_2(OAc)]$ complex as a forest green solid (65–75% yields, [Eq. (a)]). Alternatively, the acetylacetonate ligands on $[Mn(acac)_2(N_3)]$ could be exchanged with two equivalents of H-3-R-sal-R' to afford the corresponding azido species [Eq. (a)]).[13]



The structure of $[Mn(3\text{-}Ph\text{-}sal\text{-}i\text{Pr})_2(OAc)]$ was confirmed by single-crystal X-ray structure analysis (Figure 1).[14] The compound is monomeric with a distorted, octahedral Mn^{III} center in which the η^2-(OAc) ligand occupies two sites in the equatorial plane.[15] The salicylimine ligands fold towards one another creating a cleft lined by the appended phenyl rings. At the center of this cleft lies the acetate which sits on a crystallographically imposed C_2 axis. On the opposing face, the isopropyl moieties are disposed toward one another and appear to shield the backside of the manganese cation. Given the propensity of carboxylate ligands to form bridging complexes, the structure of $[Mn(3\text{-}Ph\text{-}sal\text{-}i\text{Pr})_2(OAc)]$ represents a rare example of bidentate carboxylate chelation to a single metal center.[9, 14, 16, 17]

Although small quantities (5–10 mg) of the desired nitridomanganese(v) complexes $[Mn(3\text{-}R\text{-}sal\text{-}R')_2(N)]$ could be generated upon irradiation (>18 h, Hg lamp) of the corresponding $Mn^{III}(N_3)$ compound, a more efficient preparative method was required.[5–8, 18] Initial attempts to form nitridomanganese(v) derivatives of $[Mn(3\text{-}R\text{-}sal\text{-}R')_2(X)]$ (X = OAc, Cl, N_3) using

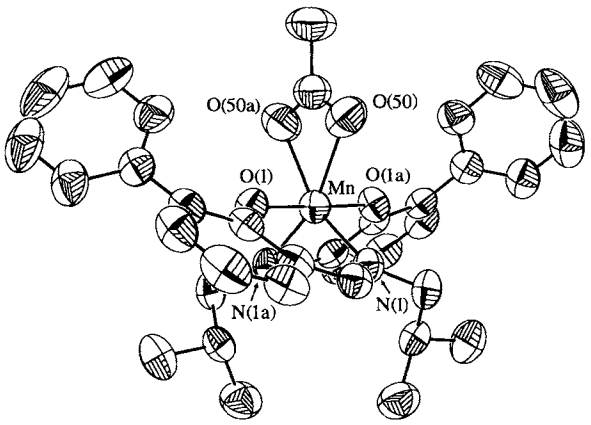


Figure 1. Crystal structure of $[Mn(3\text{-}Ph\text{-}sal\text{-}i\text{Pr})_2(OAc)]$ (ORTEP diagram displaying 50% probability ellipsoids). Selected distances [Å] and angles [°]: Mn–O(1) 1.842(12), Mn–N(1) 2.113(2), Mn–O(50) 2.212(2); O(1a)-Mn-O(1) 178.91(8), O(1)-Mn-N(1a) 91.15(6), O(1)-Mn-N(1) 89.51(6), N(1a)-Mn-N(1) 104.76(8), N(1)-Mn-O(50) 98.41(6), O(50a)-Mn-O(50) 58.43(9).

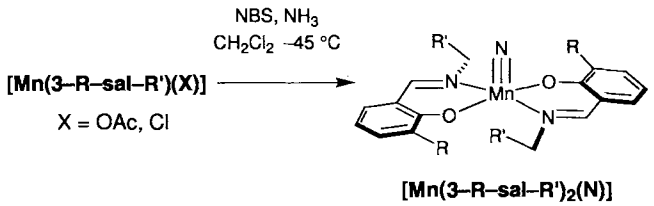
NH_4OH/Clorox bleach were, however, unsuccessful.[5, 19] We suspected that the labile Mn^{III} starting materials were not stable under the oxidizing, alkaline reaction conditions. Upon searching for a milder protocol for the synthesis of Mn≡N, we discovered that oxidation of $[Mn^{III}(3\text{-}R\text{-}sal\text{-}R')_2(OAc)]$ to $[Mn^{V}(3\text{-}R\text{-}sal\text{-}R')_2(N)]$ could be effected by using gaseous NH_3 and *N*-bromosuccinimide (NBS; 5 equiv) as the oxidant (−45 °C, CH_2Cl_2; Scheme 3).[20] At −45 °C product formation occurred



Scheme 3. Synthesis of $[Mn(H\text{-}3\text{-}R\text{-}sal\text{-}R')_2(N)]$.

immediately upon introduction of NH_3 to a solution of NBS and a Mn^{III} precursor, as noted by a slight color change. Aqueous work-up and purification using neutral Al_2O_3 (activity I) afforded the nitrido complexes as brown foams (65–70%). In all cases, single crystals were obtained by diffusing *n*-pentane into solutions of these compounds in EtOAc or benzene.

$[Mn(3\text{-}MeO\text{-}sal\text{-}Me)_2(N)]$ is one of the few crystallographically characterized nitridomanganese(v) complexes (Figure 2).[5, 6, 18, 19, 21, 22] The coordination geometry of the manganese is trigonal bipyramidal with both phenolate oxygen atoms and the nitrido ligand constituting the trigonal plane. The $Mn\text{–}N_{imine}$ bonds are substantially longer (2.02 Å) than the $Mn\text{–}O_{phenolate}$ bonds (1.87 Å) and define the two apexes of the bipyramid. Formulation of a Mn≡N bond is supported by the observed bond length of 1.54 Å as well by an IR stretch at 1047 cm^{-1}.[5, 8, 18, 19, 23]

Having developed preparative methods for the construction of nitridomanganese(v) complexes with Schiff bases as ligands, we examined these systems as nitrogen-atom-transfer reagents with unfunctionalized alkenes such as styrene **1** (Scheme 4). In a typical experiment $[Mn(3\text{-}Ph\text{-}sal\text{-}Ph)_2(N)]$ was added to a solution of TFAA and **1** (23 °C, CH_2Cl_2). The resulting unpurified reaction product was treated with an aqueous $NaHCO_3$/THF solution to afford the *N*-trifluoroacetylated amino alcohol

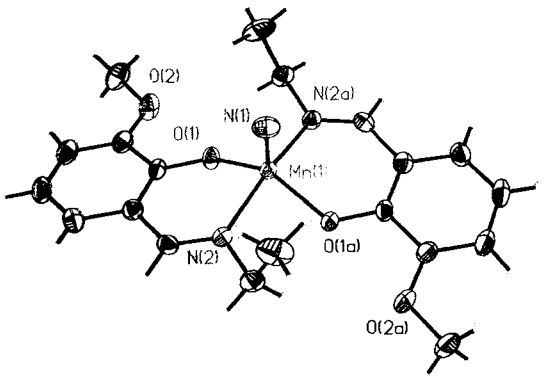

Figure 2. Crystal structure of [Mn(3-MeO-sal-Me)$_2$(N)] (ORTEP diagram displaying 50% probability ellipsoids). Selected distances [Å] and angles [°]: Mn–N(1) 1.543(4), Mn–O(1) 1.868(2), Mn–N(2) 2.023(2); N(1)-Mn-O(1) 112.51(6), O(1)-Mn-O(1a) 134.99(12), N(1)-Mn-N(2) 96.45(6), O(1)-Mn(1)-N(2) 90.46(8), O(1a)-Mn(1)-N(2) 84.61(8).

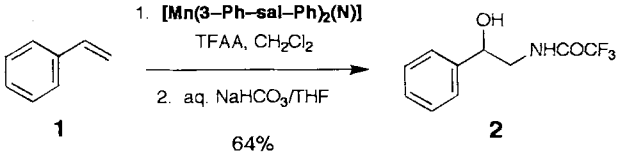

Scheme 4. Conversion of styrene **1** with [Mn(H-3-R-sal-R′)$_2$(N)] to the *N*-trifluoroacetylated amino alcohol **2**.

2. Importantly, we have found that this process can be performed with a single equivalent of styrene and one equivalent of [Mn(3-Ph-sal-Ph)$_2$(N)] to give the desired product **2** in 64% yield. The conversion of styrene to **2** with a nitridomanganese reagent is unprecedented, and thus highlights the unique reactivity which these novel systems appear to possess.

Nitridomanganese(v) complexes with Schiff bases as ligands have been prepared and demonstrated to function as potential reagents for olefin amination. Pivotal to the success of this work has been the development of new synthetic protocols for the construction of Mn^{III} Schiff base complexes and for the subsequent oxidation of these materials to the desired nitridomanganese(v) products. Extension of this methodology to encompass additional bidentate ligands and to afford alternative nitrido complexes that display greater versatility as nitrogen-atom-transfer reagents is currently under investigation.

Novel Crown Ethers with a Trithiadiazapentalene–Trithiotriuret Redox System**

Heinz Graubaum,* Franz Tittelbach, Gerhard Lutze, Karsten Gloe,* Melinda Mackrodt, Torsten Krüger, Norbert Krauss, Alfred Deege, and Heike Hinrichs

Dedicated to Professor Leonard F. Lindoy on the occasion of his 60th birthday

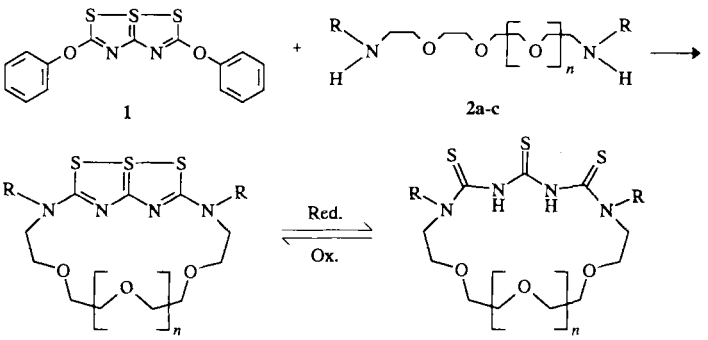
The host–guest chemistry of functionalized macrocycles offers much potential for special applications. For some time now special attention has been paid to macrocyclic compounds whose properties can be changed reversibly by both chemical and physical means.[1] This was achieved by introducing functional units like the reversibly isomerizable azo group[2] or the reversible dithiol–disulphide redox system[3] into the macrocycles. In this way a systematic modification of properties of the guest such as binding strength and binding selectivity offers new possibilities for complexation, separation, or detection of both valuable and toxic species.[4]

The assembly of heterocyclic trithiadiazapentalene units and diamino polyethers to form pentaleno crown compounds provides a new approach to the above-mentioned modification of macrocyclic host compounds for cations. The exceptional electronic structure of the trithiapentalenes also makes them very interesting building blocks for further synthesis, both in theory and in practice.[5]

In an earlier publication we showed that 2,5-bis(aryloxy)-3,3aλ^4,4-trithia-1,6-diazapentalenes[6a] are suitable for reaction with nucleophiles. The diphenyl derivative **1** reacts with α,ω-diaminopolyethers **2** in a 1:1 molar ratio to form bridged bispentalenes in high yields. These compounds can be used as starting materials for designing much larger cyclic molecules.[6b]

We now describe the synthesis of pentaleno crown ethers **3a–c** and their subsequent reduction to the corresponding thiourea derivatives **4a–c**. Furthermore, their complex-forming properties deduced from extraction and transport studies will also be discussed. The synthetic path way leads to a novel class of crown ethers that contains the trithiadiazapentalene–trithiotriuret redox system that can be used to control the recognition properties.

The compounds **3** were formed in reactions between **1** and **2** in a 1:2 molar ratio. Ring closure only occurred when the chain of the polyethers was long enough ($n \geq 1$). The structures of the pentaleno crown ether compounds **3a–c** have been elucidated



2,3,4	n	R
a	1	$CH_2C_6H_5$
b	2	CH_3
c	3	CH_3

by ^{13}C NMR spectroscopy and fast-atom-bombardment mass spectrometry (FAB-MS), and the results were confirmed by X-ray analysis[7] of compound **3b** (Figure 1).

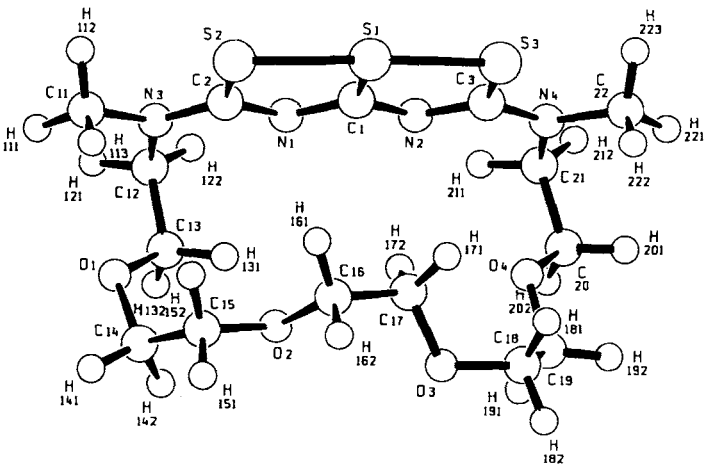


Figure 1. X-ray crystal structure of the pentaleno crown compound **3b** [7].

The macrocycles **3** can be reduced by treatment with zinc in acetic acid to form the corresponding thioureas **4**. The reoxidation is quantitative in the presence of atmospheric oxygen. As solids compounds **4** are stable in air at room temperature for several months.

Complex formation of the starting pentalene and of the new pentaleno crown compounds was investigated by liquid–liquid extraction studies with solutions of metal salt/picric acid in water and the ligand in chloroform as the liquid–liquid system.[8] The extractability of metal ions (see Figure 2 for Ag^I and Hg^{II}) by simple open-chain thiaazapentalene **1** was very low in this system. However, on introduction of **1** into a macrocyclic ring system (**3a–c**) the extractability of Ag^I and Hg^{II} increased significantly. The results for Na^I, K^I, Cs^I, Sr^{II}, Ca^{II}, Zn^{II}, Co^{II}, and Cu^{II} were comparable with that obtained in extraction studies with **1** in the same solvent extraction system. A remarkable variation in the extraction properties of the macrocyclic ring compounds **3a**, **3b**, and **3c** is observed for Ag^I and Hg^{II}. As shown in Figure 2 **3a** extracts Ag^I quantitatively into the organic phase (as picrate). In

[**] Financial support by the Akademie der Naturforscher Leopoldina (H. G.) and by the Fonds der Chemischen Industrie (H. G. and K. G.) is acknowledged. The authors wish to thank Prof. Dr. M. T. Reetz (MPI für Kohlenforschung Mühlheim) for help rendered during the transport experiments and Prof. Dr. H. Schneider (MPI für biophysikalische Chemie Göttingen) for support with the stability constant measurements. The graduate scholarship from Studienstiftung des deutschen Volkes (to M. M.) is gratefully appreciated.

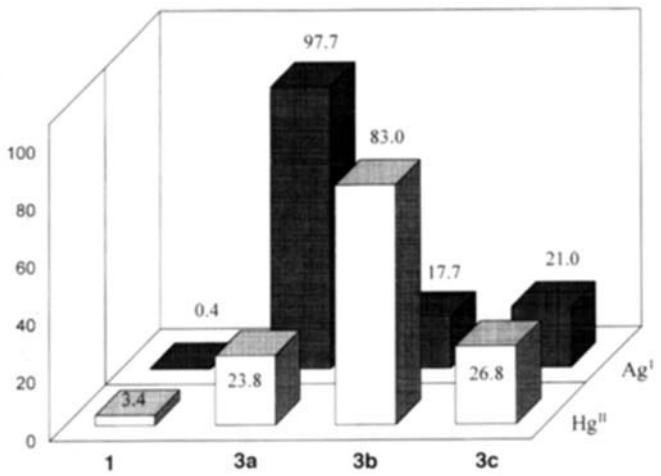

Figure 2. Liquid–liquid extraction of Ag^{I} and Hg^{II} with the open-chain trithiadiazapentalene **1** and the pentaleno crown compounds **3a–c**, $c_M = 1 \times 10^{-4}$ M ($AgNO_3$ or $HgCl_2$); $c_{HPic} = 5 \times 10^{-3}$ M; $c_L = 1 \times 10^{-3}$ M in $CHCl_3$.

contrast, only 20% extraction of Ag^{I} by the ligands **3b** and **3c** was observed.[9] The results correlate well with the order of the potentiometrically determined stability constants of the 1:1 Ag^{I} complexes with these macrocyclic ring compounds in homogeneous solutions:[10] **3a** ($\lg K_{AgL} = 6.84 \pm 0.08$) > **3b** ($4.51 \pm 0.07$) ≈ **3c** ($4.50 \pm 0.11$).

In contrast to the behavior of Ag^{I}, the Hg^{II} complex formation was optimal with the medium-sized macrocycle **3b**. In this case more than 80% of $HgCl_2$[11] was extracted. With smaller or larger macrocyclic compounds the extraction decreased significantly (25%, Figure 2).

These differences in behavior can be attributed to the different structures of the Ag^{I} and Hg^{II} complexes formed during extraction. This has been confirmed by semiempirical molecular modeling calculations of the 1:1 complexes.[12] Figure 3 shows the results of Ag^{I} and Hg^{II} complexes with compounds **3a** and **3b**. Ag^{I} formed five bonds with two nitrogen atoms of the pentalene unit and three bonds with the ether oxygen atoms of **3a**, which results in an approximately symmetrical arrangement. Since Ag^{I} forms only four longer bonds with **3b**, this complex is distinctly less favored. In the complex between **3b** and $HgCl_2$ interactions between Hg^{II} and the two nitrogen atoms of the pentalene unit and all three oxygen atoms in the macrocycle were found. In contrast, Hg^{II} coordinated with only two oxygen atoms and two nitrogen atoms of **3a**.

To determine whether bond formation with Ag^{I} and Hg^{II} depended on the oxidation state of the ligand (**3**/**4**), the macrocyclic thiourea derivatives **4** were also tested as extractants. The extraction properties of all these compounds were comparable. They extracted Ag^{I} and Hg^{II} quantitatively. This has been attributed to the change of the binding sites during complexation. Molecular modeling calculations gave some evidence that the sulfur atoms of the thiourea derivatives acted as coordination centers and that no coordination within the macrocyclic ring occurred.

In summary the new ligands uncover an interesting differentiation in the complex formation properties of Ag^{I} and Hg^{II}, which are otherwise very similar. This differentation depends on

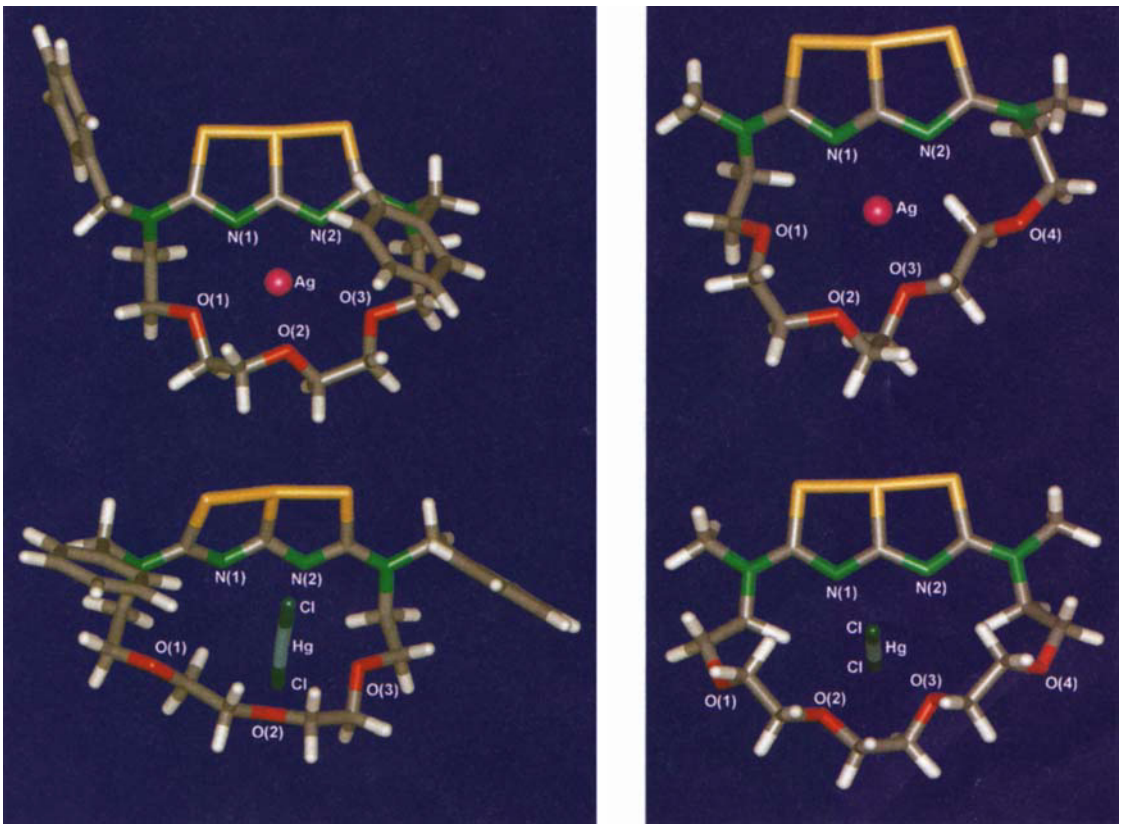

Figure 3. Structures of the complexes of Ag^{I} (top) and Hg^{II} (bottom) with **3a** (left) and **3b** (right), determined by semiempirical calculations (PM3 and ZINDO/1); selected lengths [Å]: for **3a** $Ag^{I} \cdots N(1)$ 2.25, $Ag^{I} \cdots N(2)$ 2.25, $Ag^{I} \cdots O(1)$ 2.65, $Ag^{I} \cdots O(2)$ 2.62, $Ag^{I} \cdots O(3)$ 2.80; $Hg^{II} \cdots N(1)$ 2.85, $Hg^{II} \cdots N(2)$ 2.65, $Hg^{II} \cdots O(1)$ 4.33, $Hg^{II} \cdots O(2)$ 2.31, $Hg^{II} \cdots O(3)$ 2.32; for **3b** $Ag^{I} \cdots N(1)$ 2.35, $Ag^{I} \cdots N(2)$ 2.35, $Ag^{I} \cdots O(1)$ 3.23, $Ag^{I} \cdots O(2)$ 3.01, $Ag^{I} \cdots O(3)$ 2.82, $Ag^{I} \cdots O(4)$ 4.62; $Hg^{II} \cdots N(1)$ 2.72, $Hg^{II} \cdots N(2)$ 2.76, $Hg^{II} \cdots O(1)$ 2.96, $Hg^{II} \cdots O(2)$ 2.62, $Hg^{II} \cdots O(3)$ 2.74, $Hg^{II} \cdots O(4)$ 2.97.

the size of the macrocyclic cavity and the component of the redox system. A significant change of the host selectivity is observed for the redox pairs **4b**/**3b** towards Ag^{I} and for **4a**/**3a** towards Hg^{II}. In both cases the trithiotriuret derivative binds the metal ion, but the trithiadiazapentalene does not.

Attempts to obtain crystalline complexes of the pentaleno crown ethers yielded a 1:1 complex with sodium picrate in the case of **3a** and two 1:1 complexes with ammonium rhodanide and benzylammonium perchlorate in the case of **3b**.[13] Preliminary X-ray diffraction studies on the structure of $NH_4SCN \cdot$**3b** showed that the ammonium cation is arranged symmetrically in the ring, fixed by two nitrogen atoms of the pentalene unit and four ether oxygen atoms.

Success in the synthesis and isolation of $NH_4SCN \cdot$**3b** have induced immense interest in the study of the transport properties of the compounds **3a–c** towards L-phenylalanine with the liquid membrane technique. The experimental conditions chosen were similar to those reported by Reetz et al.[14] on a system in which 3,5-bis(trifluoromethyl)benzoylboronic acid provided the synergistic effect. The results showed that the increase in the transport rates for L-phenylalanine is dependent on the cavity size of the macrocycle: **3b** ($T_R = 1037$) > **3a** ($T_R = 417.2$) > **3c** ($T_R = 74.1$).[15] The transport rate of compound **3b**, the highest among **3a–c**, is comparable with that of [18]crown-6 (T_R = 1270). Liquid–liquid extraction studies with ^{14}C-labeled L-phenylalanine have confirmed the observed trend of the transport rates of compounds **3a–c** listed above.

Experimental Section

3a–c: Pentalene **1a** (2 mmol) was stirred for 2–3 days with each of the diaminopolyethers **2a–c** (4 mmol) in chloroform (200 mL) at 25 °C. The mixture was purified by column chromatography (silica gel 60, particle size 63–100 mm, Merck) with chloroform/acetone (20/1) as eluent for phenol and chloroform/acetone (2/1) as eluent for **3a–c**. **3a**: Yield 27%, m.p. 152–154 °C; ^{13}C NMR ($CDCl_3$): δ = 49.1 (NCH_2), 56.3 127.4, 128.0, 128.8, 135.5 (benzyl-C), 66.4, 69.2, 70.2 (OCH_2), 184.0 (C-2,5), 186.8 (C-3a); FAB-MS: *m/z* (%) = 531 (48) $[M+H]^+$, 553 (48) $[M+Na]^+$. **3b**: Yield 17.5%, m.p. 135–137 °C; ^{13}C NMR ($CDCl_3$): δ = 39.2–40.2 (NCH_3), 51.1–53.8 (NCH_2), 67.0–71.9 (OCH_2), 183.4 (C-2,5), 186.0 (C-3a), FAB-MS: *m/z* (%) = 423 (48) $[M+H]^+$, 389 (14) $[M-SH]^+$. **3c**: Yield 18.8%, m.p. 66–71 °C (acetonitrile); ^{13}C NMR ($CDCl_3$): δ = 39.7–40.5 (NCH_3), 51.7–54.0 (NCH_2), 68.0–71.0 (OCH_2), 182.2, 182.8 (C-2,5), 185.7, 185.9 (C-3a); FAB-MS: *m/z* (%) = 467 (100) $[M+H]^+$, 433 (28) $[M-SH]^+$.

4a–c: Macrocycles **3a–c** (0.50 mmol) and zinc powder (150 mg) in acetic acid (5 mL) were stirred for 30 min at 25 °C under a nitrogen atmosphere. Then additional zinc powder (50 mg) was added, and the mixture stirred for 15 min. The resultant solution was neutralized with drops of a dilute solution of sodium hydrogencarbonate, extracted with chloroform, washed with water, and evaporated under vacuum. The mixture was passed through a chromatographic column (silica gel 60, particle size 63–100 mm, Merck). **4a**: Eluent heptane/acetone 1/1, yield 85%, amorphous; ^{13}C NMR ($CDCl_3$): δ = 50.3–51.7 (NCH_2), 56.7–58.5, 127.4, 128.0 128.8, 135.5 (benzyl-C), 68.2–70.8 (OCH_2), 162.4, 178.2, 180.6 (CS), FAB-MS: *m/z* (%) = 533 (62) $[M+H]^+$; **4b**: eluent heptane/acetone 4/5 to 2/5, yield 44%, m.p. 140–141 °C. ^{13}C NMR ($CDCl_3$): δ = 40.1–40.8 (NCH_3), 53.2–54.2 (NCH_2), 67.4–71.8 (OCH_2), 162.2, 179.5, 180.6 (CS), FAB-MS: *m/z* (%) = 425 (100) $[M+H]^+$; **4c**: eluent heptane/acetone 4/5 to 3/5, yield 57%, amorphous. ^{13}C NMR ($CDCl_3$): δ = 40.1–40.8 (NCH_3), 52.2–52.8 (NCH_2), 67.4–69.8 (OCH_2), 162.4, 178.2, 180.6 (CS), FAB-MS: *m/z* (%) = 469 (54) $[M+H]^+$.

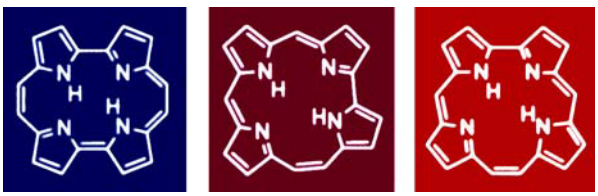
Octaethylhemiporphycene: Synthesis, Molecular Structure, and Photophysics**

Emanuel Vogel,* Martin Bröring, Steven J. Weghorn, Peter Scholz, Reiner Deponte, Johann Lex, Hans Schmickler, Kurt Schaffner,* Silvia E. Braslavsky, Martin Müller, Sigrid Pörting, Christopher J. Fowler, and Jonathan L. Sessler*

Dedicated to Professor Heinz A. Staab on the occasion of his 70th birthday

Due to its role as a naturally occurring macrocyclic motif of ubiquitous importance, porphyrin, as a molecule, has inspired the conception and synthesis of numerous novel ring systems that may be regarded as structural variants of the parent cyclotetrapyrrole. One of the focal points in the current development of this new chapter in porphyrin chemistry is framed by the seven possible "nitrogen-in" structural isomers of porphyrin.[1] These first came to light with the discovery of porphycene (**1**, Figure 1),[2] or porphyrin-(2.0.2.0).



porphycene (**1**) hemiporphycene (**2**) corrphycene (**3**)

Figure 1. The three thermodynamically most stable porphyrin isomers (with an inward-pointing N_4 coordination sphere). The colors of the still unknown parent compounds **2** and **3** correspond to those of the octaethyl derivatives; the colors of porphycene (**1**) and its octaethyl derivative are indistinguishable.

Among the isomers that were still unknown at the start of the present investigations, porphyrin-(2.1.1.0) (**2**) and porphyrin-(2.1.0.1) (**3**), called hemiporphycene and corrphycene because of their structural features, were deemed to be the most promising synthetic targets. This assessment was based on retrosynthetic analyses and the prediction from PM3 calculations that **2** and **3** should have an only slightly strained planar ring system (the relative energies of **1**, **2**, and **3** with respect to porphyrin are 1.7, 8.6, and 16.0 kcal mol^{-1}, respectively).[3]

[**] This work was funded by the Alexander von Humboldt Foundation (J. L. S. and S. J. W.), and in part by the BMBF-Verbundforschungsprojekt "Photodynamische Lasertherapie" (E. V. and K. S.) and the U. S. National Science Foundation (J. L. S.).

Recently we reported the first preparation of corrphycenes,[4a] which, despite their trapezoidal N_4 nucleus, compare favorably to the porphyrins in terms of their ability to coordinate metal ions.[4b] Since then, syntheses of corrphycenes have been reported by two other research groups.[5, 6] Therefore, the chemistry of this porphyrin isomer is apparently being studied apace. Accordingly, we focused significant attention on the synthesis of hemiporphycenes, most notably octaethylhemiporphycene (**8**) for reasons of solubility and comparability. This work had nearly been completed when H. Callot et al.[7] reported their serendipitous discovery that upon demetallation/metallation of a substituted nickel homoporphyrin two regioisomeric hemiporphycene nickel complexes were formed, one of which could be converted into the free ligand. We now present a rational synthesis of **8**, a species that has proved to be an excellent porphyrin-like tetradentate ligand.[8]

For the synthesis of **8** the tried and tested concept used for making octaalkylcorrphycenes,[4, 5] that is, generation of the tetrapyrrolic macrocycle by reductive coupling (McMurry reaction)[9] of the corresponding open-chain tetrapyrrolic α,ω-dialdehyde, in this case **6**, was followed. One possibility for preparing **6** is offered by the MacDonald condensation of 5,5′-diformyl-2,2′-bipyrrole (**5**)[10] with 5-carboxy-5′-formyl-

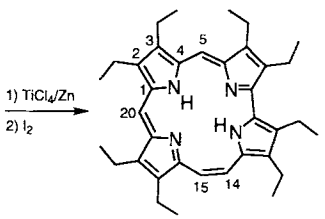
(*meso* and *rac* diastereomers)
7



8

tetraethyl-2,2′-dipyrrylmethane (**4**). However, this approach would only be practical if side reactions, such as formation of porphyrin from two molecules of **4**,[11] could be suppressed. This may be achieved by strictly adhering to the reaction conditions outlined in the *Experimental Section*. The reaction of dialdehyde **5** with aldehydecarboxylic acid **4**, obtained by saponification of the corresponding ethyl ester,[12] in the presence of perchloric acid in THF/MeOH provided a shiny, metallic-green, lacquer-like product after chromatographic workup on silica gel with CH_2Cl_2/Et_2O (4/1) as eluent. Under the assumption that the main constituent of this product was the expected (if not identified) tetrapyrrolic dialdehyde **6**, it was subjected to reduc-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3615-1651 $ 17.50+.50/0

tive coupling with titanium tetrachloride and activated zinc in THF without further purification. This approach proved to be practical, since the reaction product obtained (after oxidation with iodine or iron(III) chloride) was a solid that did contain **8** as the major component. After chromatography of this substance on silica gel with toluene as eluent and crystallization from $MeOH/CH_2Cl_2$ (5/1), pure **8** was obtained as violet cubes [m.p. 219–220 °C (20% yield)].[14] Solutions of **8** are magenta (see **2** in Figure 1) and display red fluorescence.

At a first glance one is inclined to consider the relatively facile formation of **8** by reductive coupling of the lacquer-like intermediate as indirect evidence for the existence (and presence) of dialdehyde **6**. However, as a detailed mass spectrometric analysis of the lacquer-like material showed, the bulk of the sample consisted of a compound of twice the expected molecular mass (minus two hydrogen atoms). In light of this finding the ^1H NMR spectrum, which had previously proved difficult to explain, could now be interpreted as being due to **7** (>90 %!), which exists as a mixture of the *meso* and *rac* forms. In particular the symmetrical coupling of the two halves of the molecule at the 14,14′ positions could now be readily assigned by two-dimensional NMR analysis.[15] Whereas a definitive stereochemical assignment of the diastereoisomers present in a 4:1 ratio has yet to be made, it is considered that dimer **7** most likely arises from an air-induced oxidative coupling of **6**, the presumed coupling product of **4** and **5**, in the basic reaction medium (NH_3).[16] In view of the weakness of the quadruply benzylic C14–C14′ bond in **7**, it is understandable that this bond is cleaved under the reducing conditions of the McMurry reaction, either before or after the coupling step.

Octaethylhemiporphycene (**8**) was identified as a tetrapyrrolic macrocycle that is closely related to porphyrin on the basis of structural and spectroscopic investigations, as well as its ability to complex metal ions.[8] Crystal structure analysis of **8**[17] (Figure 2) confirmed the planarity of the hemiporphycene framework inferred from PM3 calculations (maximum distance of the C and N atoms from the median plane of the framework ±0.093 Å), and clearly showed that it is an aromatic compound based on the relative bond lengths in the pyrrolic subunits ($C_\alpha-C_\beta > C_\beta-C_\beta$)[18] and the nearly complete equalization of the C–C bond lengths in the unit C⋯CH⋯C⋯CH⋯C⋯CH⋯C. The slightly increased relative energy of **8** (calculated with respect to porphyrin) is reflected by a widening of the bond angle at the *meso*-C atom C20 (131.9 versus 127.6° in octaethylporphyrin)[19] and at the C atoms of the formal double bond (134.3 and 135.5°), as well as concomitant contraction of the N2-C9-C10 and C9-C10-N3 angles (114.9 and 117.1°, respectively, versus 118.5° in octaethylporphycene).[10] Whereas the four central nitrogen atoms of porphyrins, porphycenes, and corrphycenes define squares, rectangles, and trapezoids, respectively, those in **8** describe an irregular quadrilateral in which the N⋯N distances vary between 2.627 and 3.129 Å. In the crystal the N-bonded protons can not be localized, which is in contrast to the case in solution (see NMR data below). Most likely as a result of partial disordering, these protons appear statistically distributed and show half occupancy at all four possible positions, in analogy to the behavior of porphycene.[2]

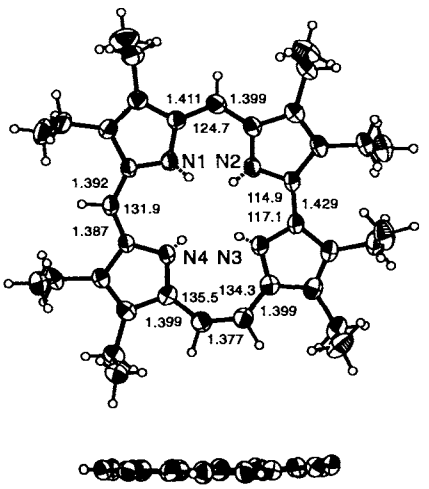


Figure 2. Crystal structure of octaethylhemiporphycene (**8**; top: view from the top; bottom: side view without ethyl substituents). Vibrational ellipsoids (40% probability) and selected bond lengths [Å] and angles [°] (standard deviations ≈0.004 Å and 0.2°); N1⋯N2 2.709, N1⋯N4 3.129, N2⋯N3 2.627, N3⋯N4 3.045 Å.

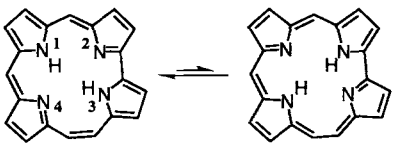
The chemical shifts in the ^1H NMR spectrum of **8** measured at room temperature (300 MHz, CD_2Cl_2/CF_2Br_2) correspond to those of porphyrin; the signals of the protons of the C_{20} perimeter appear at relatively low field (two singlets of equal intensity at $\delta = 10.11$ and 9.76, and an AB system centered at $\delta = 9.77$), whereas the signals of the N-bound protons ($\delta = -0.76$ and -2.35) appear at relatively high field. According to two-dimensional NMR experiments, octaethylhemiporphycene exists in the NH tautomeric form **8** depicted, which was shown by calculations (BLYP/3-21G and BLYP/6-31G** methods) to be the thermodynamically most stable of the six possible tautomers (one other *trans* and four *cis*).[20] The N proton that resonates at lower field is almost certainly localized on N1, since N1–H⋯N2 is expected to have a stronger hydrogen bonding interaction than N3–H⋯N4 as a result of the smaller N⋯N distance. Both NH signals are split at low temperatures into a pair of singlets (intensity ratio of the pairs 7:1), from which one can conclude that **8** is in dynamic equilibrium at room temperature with a still unidentified NH tautomer that is present in low concentration. In all likelihood **8** remains the dominant tautomer, also at low temperatures at which the equilibrium is frozen out (an unambiguous assignment of the NH singlet pairs has not yet proved possible due to instrumental limitations). The equilibrium partner of **8** is presumed to be the second *trans*-NH tautomer **8′** (Figure 3); calculations indicate



8 **8′**

Figure 3. Assumed NH tautomerism of **8** (for clarity ethyl groups have been omitted).

that this tautomer lies only 0.7–0.8 kcal mol^{-1} higher in energy than **8**, compared with the 3.5–4.5 kcal mol^{-1} energy difference between **8** and the two most stable *cis* forms.[20]

The UV/Vis spectrum of **8** shows a Soret band at $\lambda(\varepsilon) =$ 405 nm (153700), whose position (with a slightly lower extinction coefficient) almost exactly corresponds to that of octaethylporpyhrin, as well as Q bands at 484 (3900), 512 (7600), 552 (25900), 583 (9000), and 632 nm (10800).

Because of the importance of porphyrins and porphycenes in photodynamic therapy (PDT),[21, 22] it was of interest to determine the photophysical properties of **8** and to compare them with those of octaethylporphyrin (**13**), octaethylporphycene (**14**), and octaethylcorrphycene (**15**). Since **14** has a buckled ring system due to steric interactions involving the 3,6- and 13,16-ethyl groups, the planar 2,7,12,17-tetrapropylporphycene (**16**) was also considered for the sake of comparison (Table 1).

[a] Fluorescence quantum yield; $A_{max} = 0.06$; exptl error ±20% unless specified; reference solution: **16** with identical A_{max} (±0.002.) [23]. [b] Triplet energy determined by stationary phosphorescence in 1-iodopropane [24]; $\lambda_{exc} > 455$ nm. [c] Triplet (intersystem crossing) quantum yield determined by laser-induced optoacoustic spectroscopy [24, 27, 28]; $\lambda_{exc} = 570$ nm; $A = 0.05-0.2$; exptl error ±30% unless specified; calorimetric reference; I_2; all solutions saturated with N_2. The upper limit for **14** is based on the finding that the prompt heat output (α) from **14** and the reference were the same. [d] Quantum yield of $O_2(^1\Delta_g)$ determined by time-resolved $O_2(^1\Delta_g)$ phosphorescence [24, 27, 29]; $\lambda_{exc} = 570$ nm; reference: **16**; $A = 0.05-0.25$; exptl error ±20% unless specified; all solutions saturated with O_2. [e] Efficiency of $O_2(^1\Delta_g)$ formation ($S_\Delta = \Phi_\Delta/\Phi_T$). [f] Reference data see ref. [30]. [g] Not measureable. [h] Reference for all measurements; for data see [23, 24].

Of the photophysical indicators that are relevant for evaluating dyes and pigments in PDT, the fluorescence quantum yield (Φ_F) and the sensitized formation of singlet oxygen $O_2(^1\Delta_g)$ by the triplet excited state of the dye (Φ_Δ) are of primary importance.[21, 22] The Φ_F values of **8**, **13**, and **15** were significantly lower than that of **16**,[23, 24] whereas the values of Φ_T (quantum yield of the S → T intersystem crossing which leads to the triplet excited state of the sensitizer) show an inverse trend. The relatively low Φ_F values of **8**, **13**, and **15** are probably due to the greater conformational flexibility of these compounds. In the case of **8** and **13** this is reflected by increases in the rates of radiationless decay and S → T intersystem crossing. However, for **15** it is manifest only in an increase in the latter.

In the case of the nonplanar **14** radiationless decay processes dominate. Although the triplet population proved too insignificant to allow these states to be detected by laser-induced optoacoustic spectroscopy, their existence was indirectly established by observing the time-resolved phosphorescence of $O_2(^1\Delta_g)$, which is formed in small amounts. In view of its properties, which are atypical for this class of compounds, **14** was not used further as a reference compound.

The efficiency of $O_2(^1\Delta_g)$ formation ($S_\Delta = \Phi_D/\Phi_T$) corresponds to that expected for **13** and **15**, since under the prerequisite that the energy relationship of the triplet sensitizers with respect to $O_2(^1\Delta_g)$ is sufficiently exothermic, the S_Δ value for aromatic systems (including porphyrinoids)[25] will be in the range of 0.7–0.8. In contrast, the S_Δ values for **8** and **16** are unusually high.[22, 26] Therefore, from a purely photophysical perspective hemiporphycene **8** and to a lesser extent, the corrphycene **15** are potential PDT sensitizers.

Experimental Section

4: Compound **11** (7.16 g, 20 mmol) was suspended in EtOH (125 mL) under an argon atmosphere and, after treatment with a solution of NaOH (4.0 g, 0.1 mol) in water (25 mL), heated at reflux for 3 h. The mixture was cooled to room temperature and poured into ice water (600 mL). Concentrated HCl (15 mL) was added with stirring, the mixture stirred for a further 10 min, and the product that separated filtered and dried under vacuum over solid KOH. The desired **4** was obtained as a violet powder (6.47 g, yield 98%) of sufficient purity (≈95%) for use in subsequent reactions. After two recrystallizations from MeOH/THF (1/1) **4** was obtained as a colorless microcrystalline powder that decomposes without melting above 220 °C (Table 2).

7: A solution of **5** (3.0 g, 10 mmol) in MeOH/THF (10/1, 330 mL) was treated sequentially at 0 °C with 70% perchloric acid (3.5 mL) and a solution of **4** (3.3 g, 10 mmol) in THF/MeOH (2/1, 450 mL), and then left at this temperature for three days. The reaction was quenched by addition of 10% ammonia (18 mL). The mixture was treated successively with Et_2O (500 mL) and water (1200 mL), and the phases were separated. The aqueous phase was then extracted with Et_2O (50 mL). After drying the combined organic phases over K_2CO_3 and removing the solvent, the residue was suspended in cold Et_2O (100 mL) and filtered to remove solids (predominantly unchanged **5**). The solvent was removed from the filtrate under vacuum after addition of silica gel (10 g), and the solid obtained purified by column chromatography (column 20 × 4 cm) with CH_2Cl_2/Et_2O (4/1) as eluent. Octaethylporphyrin (<1%) and two small fractions of unknown composition were eluted first. Recognizable by its yellow-orange fluorescence, **7** was collected as a mixture of diastereomers from the fourth fraction. The solvent was removed, and the remaining shiny, metallic-green, lacquer-like substance used in the next step without further purification (2.54 g, yield 45%, purity >90%). NMR-spectroscopically pure **7** was obtained by subjecting the crude product to renewed chromatography followed by recrystallization from a small amount of hexane/Et_2O (10/1) at −78 °C, a process that led to great loss of product. Dimer **7**, a red, microcrystalline powder with a greenish sheen (two diastereoisomers in a ratio of 4:1), decomposes without melting above 130 °C (Table 2).

8: Activated Zn (13.1 g, 200 mmol) and CuCl (2.0 g, 20 mmol) were added to THF (350 mL) and treated dropwise with $TiCl_4$ (11.0 mL, 100 mmol). The resulting

Table 2. Selected physical data for **4**, **7**, **8**, and **11**. ^{1}H NMR: 300 MHz: ^{13}C NMR: 75.5 MHz; IR: CsI.

4: Decomp >220 °C (EtOH); ^{1}H NMR ([D$_6$]DMSO): $\delta = 12.00, 11.49, 11.06, 9.46, 3.79, 2.61, 2.57, 2.32, 2.29, 1.09, 1.01, 0.85, 0.83$; ^{13}C NMR ([D$_6$]DMSO): $\delta = 176.50, 162.14, 136.40, 135.24, 131.89, 129.23, 127.12, 122.74, 121.98, 116.60, 22.13, 17.68, 17.50, 16.54, 16.54, 16.25, 16.06, 16.06, 15.75$; IR: $\tilde{\nu} = 3268, 2967, 2931, 2871, 1654, 1625, 1576, 1491, 1462, 1445, 1354, 1278, 1261, 1147, 766$ cm^{-1}; UV/Vis (DMSO): $\lambda_{max}(\varepsilon) = 278$ (19400), 316 nm (21200); MS (EI, 70 eV): *m/z* (%): 330(60) [M^{+}].

7: Decomp >130 °C (mixture of diastereomers, crude product): 1st diastereomer (main product): ^{1}H NMR ($CDCl_3$, Al_2O_3) $\delta = 11.46$ (br. s, 2H, H20,20'), 10.34 (br s, 2H, H22,22'), 10.11 (br. s, 2H, H19,19'), 9.65 (s, 2H, H1a,1a'), 9.51 (s, 2H, H18a,18a'), 6.70 (s, 2H, H9,9'), 4.70 (s, 2H, H14,14'), 2.79 (AB *and* 4H, H2a,2a'), 2.68 (q, 4H, H7a,7a'), 2.57 (q, 4H, H17a,17a'), 2.56 (AB *and* 4H, H3a,3a'), 2.51 (AB *and* 4H, H6a,6a'), 2.35 (q, 4H, H11a,11a'), 1.96 (AB part of an ABX$_3$ system, 4H, H12a,12a'), 1.61 (AB part of an ABX$_3$ system, 4H, H16a,16a'), 1.24 (X$_3$ part of an ABX$_3$ system, 6H, H2b,2b'), 1.23 (t, 6H, H7b,7b'), 1.12 (X$_3$ part of an ABX$_3$ system, 6H, H3b,3b'), 1.11 (X$_3$ part of an ABX$_3$ system, 6H, H6b,6b'), 1.08 (t, 6H, H17b,17b'), 0.96 (t, 6H, H11b,11b'), 0.59 (X$_3$ part of an ABX$_3$ system, 6H, H16b, 16b'), 0.58 (X$_3$ part of an ABX$_3$ system, 6H, H12b,12b'); ^{13}C NMR ($CDCl_3$, Al_2O_3): $\delta = 177.54, 177.20, 171.28, 146.78, 146.67, 138.48, 136.65, 136.21, 135.47, 134.86, 129.64, 129.03, 128.78, 128.27, 127.90, 126.71, 126.71, 126.19, 116.75, 43.52, 17.96, 17.88, 17.81, 17.67, 17.49, 17.45, 17.02, 16.92, 16.92, 16.77, 15.71, 15.40, 15.22, 14.82, 14.70$; 2nd diastereomer (only prominent signals): ^{1}H NMR ($CDCl_3$, Al_2O_3): $\delta = 10.95$ (br s, 2H, H20,20'), 10.95 (br s, 2H, H22,22'). 10.67 (br s, 2H, H19,19'), 9.58 (s, 2H, H1a,1a'), 9.40 (s, 2H, H18a,18a'), 6.73 (s, 2H, H9,9'), 4.67 (s, 2H, H14,14'), ^{13}C NMR ($CDCl_2$, Al_2O_3): $\delta = 177.58, 176.78, 170.02, 117.37, 43.52$. - IR: $\tilde{\nu} = 3278, 2966, 2932, 2871, 1622, 1439, 1415, 1374, 1298, 1226, 1195, 1060, 1007, 949, 818, 771$ cm^{-1}; UV/Vis (CH_2Cl_2): $\lambda_{max}(\varepsilon) = 284$ (32400), 327 (65800), 507 nm (48200); MS (FAB): *m/z* (%): 1135 (3) [$(M+1)^+$], 1134 (1) [M^{+}], 567 (100) [$(M/2)^+$]; high-resolution-MS (FAB): $C_{72}N_{94}N_8O_4$, calcd 1134.7398, found 1134.7361.

mixture was heated at reflux for 1 h and then allowed to cool to room temperature. To the titanium reagent thus prepared was added dropwise within 10 min a solution of **7** (1.13 g, 1 mmol) in THF (180 mL). The reaction mixture was then hydrolyzed with 10 % aqueous ammonia (350 mL), and the organic phase washed with aqueous NaCl until the washings were neutral. To oxidize the coupling product, the organic phase was treated with iodine (5 g) for 5 min. Excess oxidant was separated with $Na_2S_2O_3$, and the solution subjected to conventional workup. Chromatography of the residue on silica gel (column 20 × 4 cm) with toluene as eluent produced, after separation of a green, nonuniform preliminary fraction, a violet, red-fluorescent main fraction containing **8**. Recrystallization of the product from $MeOH/CH_2Cl_2$ (5/1) provided **8** as violet cubes (m.p. 219–220 °C, yield 214 mg (20 %); Table 2).

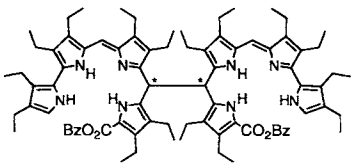
[14] If **8** is contaminated with octaethylporphyrin, the latter can be removed by converting it and **8** into the corresponding zinc complexes (10 equiv of zinc acetate in MeOH, 1 h at reflux). Chromatography of the resulting mixture on silica gel with hexane/CH_2Cl_2 (5/2) as eluent produces two fractions. The first fraction (pink) consists of the porphyrin complex, and the second (blue-green) contains octaethylhemiporphycenatozinc(II) (violet needles from $MeOH/CH_2Cl_2$ (6/1), m.p. 260–261 °C). Liberation of **8** is achieved by treatment with concentrated H_2SO_4 (room temperature, 1 h) and conventional workup.

[15] Additional support for the structure of **7** is provided by the similarity of its NMR spectrum to that of the dibenzyl ester **12**, for which an X-ray crystal structure is available (as the *rac* diastereomer).



12

[16] An alternative route to **7** that avoids the tetrapyrrolic α,ω-dialdehyde **6** could involve an initial oxidative coupling of two molecules of **4** at the *meso* position with concomitant formation of a tetrapyrrylethane, followed by condensation with **5** to give **7**. Among the evidence militating against this route is the observation that in the first step a labile product can be detected by thin layer chromatography that has a color comparable to that of **7**, and from which **7** is formed only after treatment with ammonia.

[17] X-ray crystal analysis of **8**: $C_{36}H_{46}N_4$, $M = 534.77\ g\,mol^{-1}$, crystallized from CH_2Cl_2/CH_3CN; crystal dimensions $0.40 \times 0.28 \times 0.34$ mm, triclinic, space group $P\bar{1}$, $a = 8.106(2)$, $b = 10.053(3)$, $c = 20.390(6)$ Å, $\alpha = 87.05(2)$, $\beta = 83.97(2)$, $\gamma = 66.36(2)°$, $V = 1513.6$ Å^3, $Z = 2$, $\rho_{calcd} = 1.173\ g\,cm^{-3}$; $F(000) = 580$; $\mu_{Mo} = 0.69\ cm^{-1}$; of 6555 measured reflections 4020 were observed ($F_o^2 > 2\sigma F_o^2$); $\theta_{max} = 26.95°$; $R1 = 0.0618$, $wR2 = 0.1615$. Enraf-Nonius CAD4 diffractometer (room temperature, $Mo_{K\alpha}$ radiation, $\lambda = 0.71069$ Å). The structure was solved with direct methods and refined for all observed reflections against F^2 (heavy atoms with anisotropic, H atoms with isotropic temperature factors); $wR2 = [\sum w(F_o^2 - F_c^2)^2 / \sum w(F_o^2)^2]^{1/2}$. Programs used: MolEN (Enraf-Nonius) for structure calculation and SHELXL-93 (G. M. Sheldrick, Universität Göttingen, Germany) for refinement. Calculated in the Regionales Rechenzentrum der Universität zu Köln. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100248. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

Controversial Chemists

Linus Pauling: A Life in Science and Politics. By *T. Goertzel* and *B. Goertzel*. BasicBooks, New York, 1995. XVII, 300 pp., hardcover $ 27.50.—ISBN 0-465-00672-8

Force of Nature: The Life of Linus Pauling. By *T. Hager*. Simon & Schuster, New York, 1995. 771 pp., hardcover $ 35.00.—ISBN 0-684-80909-5

Linus Pauling in His Own Words: Selections from His Writings, Speeches, and Interviews. Edited by *B. Marinacci*. Introduction by *L. Pauling*. A Touchstone Book, Simon & Schuster, New York, 1995. 320 pp., paperback $ 15.00.—ISBN 0-684-81387-4

The life, both scientific and personal, of Linus Pauling, the only person to have received two unshared Nobel Prizes, was characterized by controversy. Even within his family, which was dedicated to his success, there was no consensus: "Linus Pauling may be the closest embodiment, in this age of uncertainty, amorality, and constant conflict, of a living universal hero."—Linus Pauling, Jr.; "My father is not the great man you think he is."—Peter Pauling (both quotations from the Goertzels' book, pp. xiii and 220, respectively). Almost everything about Pauling was larger than life. The internationally acclaimed scientist, educator, humanitarian, and political activist was characterized as one of "the twenty greatest scientists of all time, on a par with Newton, Darwin, and Einstein" (*New Scientist*); as one of the two greatest scientists of the 20th century, the other being Einstein; and as the greatest chemist since Antoine-Laurent Lavoisier, the 18th-century founder of modern chemistry. His *Nature of the Chemical Bond* (1939) is considered to be one of the most influential and frequently cited scientific books of the 20th century.

The Goertzels' book, the first biography to be published since Pauling's death at age 93, is a family effort, encompassing three generations, through the assistance of Mildred Goertzel and Victor Goertzel and with original drawings by Gwen Goertzel. In 1962, more than three decades ago, writer Mildred Goertzel and psychologist Victor Goertzel began work on this biography, with Pauling's assistance, as a continuation of their work on the childhood of eminent people (*Cradles of Eminence* and *Three Hundred Eminent Personalities*). Admiring Pauling especially for his leadership of the peace movement, they thought that this biography would be "inspirational for young people who might be thinking of a career in science or involvement in worthy causes."

Because they differed with Pauling about the focus of the book (he wanted the emphasis to be on his scientific work rather than his personality), they abandoned the project for a number of years, while continuing to follow Pauling's career. They were troubled by Pauling's crusade for megadoses of vitamin C in the prevention and treatment of the common cold and later by his treatment of the president and director of the Linus Pauling Institute of Science and Medicine, Arthur B. Robinson, whom they had interviewed extensively and had come to know personally. They again resumed work on the biography, which became "more critical, less pacifist hagiography."

The Goertzels then asked their eldest son Ted, Professor of Sociology at Rutgers University with an interest in the psychosocial roots of political beliefs, to continue the project by adding more interviews and material on Pauling's later scientific research and the controversies about orthomolecular medicine. In 1991, when they learned that Pauling had prostate cancer, they decided that Ted should prepare a final manuscript because his parents' health no longer allowed their full participation and because a complete rewrite by a single author would result in a more coherent book. Ted then asked his son, Benjamin, a mathematician and Lecturer in Cognitive Science at the University of Western Australia, to help with the chapters on Pauling's scientific work, which had come to occupy a more prominent part of the biography than originally planned.

The resulting book, like Hager's biography, deals with all aspects of Pauling's life and career from his birth in Portland, Oregon on February 28, 1901 to his death from cancer on his ranch near Big Sur on August 19, 1994—his childhood; education; study of atomic and quantum physics with Arnold Sommerfeld in Munich, Erwin Schrödinger (consistently spelled Schroedinger) in Zürich, and Niels Bohr in Copenhagen; his professorships at the California Institute of Technology, the Center for the Study of Democratic Institutions at Santa Barbara, California, the University of California, San Diego, and Stanford University; his use of one science (physics) to explain another (chemsitry); his combination of quantum mechanics and X-ray diffraction to win the 1954 Nobel Prize in Chemistry "for his research on the chemical bond and its application to the elucidation of the structure of complex substances"; his seminal contributions to chemistry, quantum mechanics, X-ray crystallography, anesthesia, electronegativity, the structure of proteins and DNA, nutrition, mineralogy, nuclear physics, and immunology; his work on molecular biology and orthomolecular medicine (a name that he coined); his work for the U.S. government during World War II; his campaign against nuclear weapons testing, which earned him the 1962 Nobel Prize for Peace; his evolution, encouraged by his wife Ava Helen, from an ivory tower scientist to an ardent and articulate public spokesman on technological issues and the social responsibility of scientists; his difficulties during the McCarthy era with government committees and the refusal of his passport application; his family life; his advocacy of megadoses of vitamin C for the common cold, cancer, and AIDS, the controversial work for which he is best known to the general public (Ted Goertzel's experience in statistical research methods was helpful here in making sense of the ongoing controversies concerning vitamins and health); and his

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

founding of the Pauling Institute and his feuds and lawsuits with former collaborators.

Not content to describe these and other events, the Goertzels have evaluated and interpreted them in the context of Pauling's public and private life and the state of science at the time. Because the book is intended for a general readership, they provide much background material and diagrams by Benjamin Goertzel's wife Gwen to elucidate the complexities of quantum physics, X-ray diffraction, wave mechanics, atomic and molecular orbitals (although in Fig. 7, p. 70, the p and d orbitals are mistakenly designated as s and p orbitals), resonance, protein structures, DNA, and other technical topics needed to understand the magnitude of Pauling's scientific contributions. Inasmuch as Pauling's modus operandi was largely intuitive, they devote considerable attention to his psychological profile and personality. Their book bears signs of hasty proofreading and contains a number of misspellings of scientists' names, understandable because the authors are not chemists.

In addition to primary and secondary sources, the Goertzels have made extensive use of interviews with Pauling, his relatives, friends, colleagues, and contemporaries; the diary that Pauling kept as a boy and that of his maternal grandfather, Linus Wilson Darling; the Linus and Ava Helen Pauling Papers at Oregon State University; and the results of Pauling's Rorschach inkblot tests that he had taken as one of the subjects in Anne Roe's classic study *The Making of a Scientist* (1953). (The latter results, along with their interpretations by eight psychologists to predict Pauling's personality, appear in a unique 22-page appendix—a feature that we have not seen in any other biography of Pauling. Victor Goertzel's doctoral dissertation involved use of the Rorschach test.) The Notes (5 pp.) and Selected References (2 pp.) contain items as late as 1994 and one from 1995. Sixteen illustrations of Pauling and others are provided.

Although the Goertzels began their project with Pauling's cooperation and assistance and he was reviewing the manuscript at the time of his death, their book is in no way an authorized biography. They are critical of Pauling in many ways. For example, they contrast Herman Branson's account of the discovery of the α-helix with Pauling's account; they thoroughly examine Pauling's apparent betrayal of Arthur Robinson, his closest collaborator and disciple, who had left a promising university position to cofound the Pauling Institute; and they discuss Matthias Rath's lawsuit claiming that Pauling had taken credit for his ideas on vitamin C and heart disease.

However, the overall coherent picture of Pauling that emerges from their book is an objective but empathic one. They conclude that "Linus Pauling the man was more than Pauling the chemist and, like all human beings, had flaws as well as virtues. Despite his intensely analytical mind, he was capable of being relentlessly driven by irrational emotions, a fact that became particularly obvious in the last decades of his life. In his later years, his combativeness and defensiveness increasingly triumphed over his brilliance and creativity ... In the long run, Linus Pauling the chemist will be remembered and Linus Pauling the man largely forgotten, but it was the man who made the chemist possible." With their great psychological insights, which evaluate Pauling's weaknesses as well as strengths, the Goertzels have succeeded admirably in going beyond Pauling's public persona to portray the most famous chemist of our time as an ambitious, complex, conflicted human being who spoke his own mind and lived a long life on his own terms.

Of the four biographies of Pauling that we have read (Anthony Serafini, *Linus Pauling: A Man and His Science*, Paragon House, New York, **1989**, David E. Newton, *Linus Pauling: Scientist and Advocate*, Facts on File, New York, **1994**; and the Goertzels' and Hager's books), Hager's biography, which appeared a month later and is more than twice as long as the Goertzels', is by far the most authoritative, detailed, and comprehensive. Thomas Hager, Director of Communications at the University of Oregon, freelance science writer, and former correspondent for *American Health* and the *Journal of the American Medical Association*, is, like Pauling, a native Oregonian whose intimate familiarity with many of the locales where Pauling spent much of his youth is evident from his minute descriptions tht invoke striking, realistic images that border on the poetic.

Hager's massive but eminently readable biography is the product of five years of thorough and meticulous research, involving more than forty hours of interviews with Pauling alone; scores of additional interviews with his family members, colleagues, rivals, students, and critics; personal correspondence; manuscripts; laboratory notebooks; scientific and nonscientific publications; archival materials; and government documents, including transcripts of Congressional Committee hearings and more than 3,000 pages of recently declassified FBI files, which we have not seen utilized in other Pauling biographies.

Hager uses all these sources to sort out opinion from fact and to dispel many of the misconceptions that have surrounded Pauling throughout his long life. In general, he is somewhat less critical of Pauling than the Goertzels, but he acknowledges his fierce competitiveness, litigiousness, lack of affection for colleagues, students, children, and family members – except for his wife, who was his closest friend, confidant, and political mentor – in short, all of the complexities and inconsistencies of a creative, brilliant, and outspoken human being who was neither saint nor sinner. Hager's book is uniformally excellent in its treatment of the scientific, political, and personal aspects of Pauling's life.

Hager has left no stone unturned in ferreting out information on events from the most significant to the relatively minor. Among the topics that he discusses but that the Goertzels fail to mention and that some other biographers have neglected are: J. Robert Oppenheimer's attempt in 1929 to persuade Pauling's wife to join him on a tryst in Mexico; Warren Weaver's crucial role in providing funds from the Rockefeller Foundation to support Pauling's research; Pauling's controversy with Dorothy Wrinch over the structure of proteins; his bout with life-threatening Bright's disease (nephritis); his invention of the Pauling Oxygen Analyzer to monitor oxygen levels in submarines; and Pauling's episode of being trapped on a cliff near his cabin, which produced a severe emotional reaction, a rare occurrence for Pauling, who always kept a firm grip on his feelings since his traumatic childhood.

Hager thoroughly explores Pauling's most celebrated scientific deteat, which dashed his hopes for a Nobel Prize for Physiology or Medicine – his failure to discover the structure of deoxyribonucleic acid (DNA), the physical basis of heredity, which was reported in 1953 by James D. Watson and Francis H. C. Crick. All the participants and events in this so-called "race for the double helix" are discussed, and the reasons for Pauling's loss of the race are revealed in Hager's book in great detail. Hager even cites an incorrect article on the structure of DNA by Edward Ronwin, a former CSUF chemistry professor – a paper of which no one in our department was aware.

Hager devotes considerable space to Pauling's political activities on behalf of civil rights, nuclear disarmament, and world peace. Although Pauling accomplished great and wonderful things and acquired world renown, it is indeed unfor-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3615-1656 $ 17.50+.50/0

tunate that, because of these activities, he was denied research grants and his passport, was persecuted by the FBI and other governmental agencies, and was defended and supported only halfheartedly by the California Institute of Technology, to which he devoted almost four decades of his life, and snubbed by the American Chemical Society, which he had served as President in 1949. His battles with political enemies, although eventually resulting in his ultimate vindication, consumed much of his time and energy. As his wife expressed it, "It is just a shame for Linus to be wasting his talents in this way" (p. 520).

It is interesting to speculate as to what further discoveries Pauling might have made had he not been deflected from his goals by short-sighted, self-serving, mercenary, or jealous opponents. However, he never became embittered. In one of his last interviews (April 1, 1994), in response to our question as to how he was able to retain his positive outlook on life, he told us, "I suppose it's partially genetic ... actually the result of my having been pretty successful in my own career, and, of course, my feeling that we ought to be smart enough, we human beings, to solve our problems, whatever they are."

As Pauling states in his autobiographical introduction (completed only a few months before his death) to *Linus Pauling in His Own Words*, "Up to now ... there have been no general anthologies of my written words to provide lay readers with an overview of the many different interests that I have pursued during my lifetime." Fortunately, Barbara Marinacci, a consultant with the Pauling Institute who knew Pauling personally for many years, the sister of his son-in-law, and editor of his book *No More War!*, has produced a representative anthology of excerpts, about one-fifth published here for the first time, ranging from a sentence to several pages in length, from more than one hundred sources, including publications and a number of unpublished manuscripts, notes, and interviews.

Because her book is intended for a general rather than a scholarly readership, Marinacci has made minor editorial changes to reduce redundancies, added transitional words or sentences, and blended individual fragments. Although sources for specific fragments are not always identified, they are listed in chronological order for each of the 12 chapters in a separate section titled "Notes on Sources." Marinacci has provided an insightful preface and a useful four-page chronology summarizing Pauling's life and career, and she has inserted explanatory material (from a sentence to a page and in boldface type) between quotations to set the context.

The book is divided into three sections of three chapters each: I. The Path of Learning 1901–1922; II. The Structure of Matter 1922–1954; III. The Nuclear Age 1945–1994; and IV. Nutritional Medicine 1954–1994. This vivid self-portrait of an extraordinary scientist and humanist who possessed one of the greatest minds of our time makes a perfect complement to the Goertzels' and Hager's biographies discussed above. And until the long-awaited multivolume work-in-progress by chemist and science historian Robert J. Paradowski of the Rochester Institute of Technology, Pauling's official biographer and author of the 1972 doctoral dissertation, *The Structural Chemistry of Linus Pauling*, appears, Hager's book may be regarded as definitive.

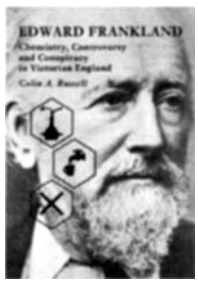
Edward Frankland: Chemistry, Controversy and Conspiracy in Victorian England. By *C. A. Russell.* Cambridge University Press, Cambridge, 1996. xx + 535 pp., hardcover $ 110.00, £ 65.00.—ISBN 0-521-49636-5

Colin A. Russell, Professor Emeritus of History of Science and Technology at the Open University, spent the first half of his career as a practicing chemist. He first encountered Edward Frankland, the most eminent chemist in Victorian Britain, more than three and a half decades ago while working on his doctoral thesis (London University, 1962) on the rise and development of valency—one of the most fundamental concepts of modern chemistry and one inextricably linked with Frankland's name. This thesis formed the basis for the first in-depth study of the subject, *The History of Valency* (Leicester University Press, **1971**). Russell learned that Frankland, who is relatively unknown today, had been born a few miles from where he and his wife and frequent collaborator, Shirley Russell, were living. In the belief that Frankland's childhood and youth were his most formative years, he delved into local history, leading to the publication of *Lancastrian Chemist: the early years of Sir Edward Frankland* (Open University Press, **1986**).



In a sense the volume under review here, the first scientific biography of Frankland, is a sequel to *Lancastrian Chemist*, but it is also complete in itself. Although Frankland himself wrote his own recollections, *Sketches from the life of Sir Edward Frankland* (privately printed, 1901; 2nd [expurgated] edition, 1902), it was incomplete and had the usual limitations inherent in any autobiography, and almost all copies of the first edition were withdrawn within months of its release. Thus the raw data for an extended biography were unavailable until Colin and Shirley Russell discovered a vast collection of Frankland papers in private hands. The Russells located and microfilmed other privately owned documents, traveling across the world in some cases. An account of their preliminary work on these and other documents that have recently come to light appeared in *Brit. J. Hist. Sci.* **1990**, *23*, 175. Not until Russell had digested this hitherto unpublished mass of material as well as primary and secondary sources from university, institutional, industrial, and governmental archives in Britain, Germany, New Zealand, and the United States, did he begin to write his latest book, which is a major new assessment not only of the life and work of "this self-made man from Lancaster alone", but also of the scientific and cultural environment in which he lived.

Edward Frankland was born on January 18, 1825 in Churchtown, Lancashire, the illegitimate son of Margaret Frankland, who had been a servant in the home of Edward Gorst, a prominent lawyer. Frankland's father was the latter's son, Edward Gorst, Jr., later also a distinguished lawyer. According to Russell, his illegitimacy, a secret that had to be suppressed, left him with a keen sense of social insecurity that contributed to his driving ambition to advance himself socially and monetarily, to be accepted by the chemical community, and to prove to himself that he had overcome his inherited disabilities, a dominant motivation throughout his life.

After attendance at eight schools and an apprenticeship in a druggist's shop in Lancaster, none of which provided him with the scientific education that he desired, at age 20 Frankland traveled to London to study systematic chemical analysis in Lyon Playfair's laboratory (a journey described with incredible attention to local color and detail in Russell's

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3615-1657 $ 17.50+.50/0

first chapter). The next year he followed Playfair as his Lecture Assistant to Putney College, where he met Hermann Kolbe, his first chemical collaborator and lifelong friend. With Kolbe he spent three months in 1847 in Robert Bunsen's laboratory in Marburg, where he met Sophie Fick from a German academic family, who became his wife in 1851 and by whom he had two daughters and two sons. A warm admiration for the German ideal of enlightened scholarship and the meritocracy of the intellect remained with Frankland all his life; he valued "the German division of Society into classes, which is here [Marburg] effected according to *mind* and not *money*."

After teaching at Queenwood College, a progressive private school, Frankland returned to Bunsen's laboratory in Marburg, where in 1849 he became the first Englishman to receive his Ph.D. In 1850 he succeeded Playfair as Professor at Putney College and became the first Professor of Chemistry at Owens College, Manchester (1851–1857), the forerunner of Manchester University. He became Lecturer in Chemistry at St. Bartholomew's Hospital (1857), simultaneously a Lecturer at the Royal Indian Military College at Addiscombe (1859–1861), Professor of Chemistry at the Royal Institution (1863–1865), and finally August Wilhelm von Hofmann's successor at the Royal College of Chemistry, a position which also made him official analyst for the London water supply (1865–1885). (Russell provides syllabuses of Frankland's courses, excerpts from his lectures, and detailed tables of his lectureships, appointments, and water analyses). Frankland's wife died in January 1874, and in May 1875, at the age of 50, he married 26-year-old Ellen Grenside, by whom he had two daughters. He was knighted in 1897 and died in Golaa, Norway on August 9, 1899.

Russell has chosen his subtitle "Chemistry, Controversy, and Conspiracy" advisedly. In chemistry, Frankland's discovery of zinc alkyls made him the true founder of organometallic chemistry, a field that he himself named and pioneered. These compounds not only were useful as reagents in synthetic organic chemistry, in which he was an acknowledged leader, but they also played a significant role in the creation of Cannizzaro's modern atomic weight system, and most importantly led Frankland to unite the radical and type theories into his crowning achievement in fundamental chemical theory—the idea that elements have a definite combining power, i.e., the concept of valency (1852). In 1866 he introduced the word "bond", a term universally used by today's chemists without realizing its originator. In his 1866 book, *Lecture Notes for Chemical Students*, he popularized the term along with his new structural formulas, which, along with his work as syllabus setter and trainer of teachers, made him one of the nineteenth century's great contributors to structural chemistry, chemical communication, and popular scientific education. In applied chemistry, Frankland established himself as one of Britain's leading academic consultants to industry and expert legal witnesses.

As "the greatest living authority on water supply", Frankland introduced into water analysis the entirely new concept of previous sewage contamination, which proved to be intensely controversial at a time when the ultimate cause of waterborne diseases was still speculative. For a number of reasons, the most important of which was probably the opposition of his chief rival August Kekulé, Frankland's claim to priority in the valency concept was mired in controversy, and more than two decades elapsed before his claim was publicly recognized. His involvement in "trade", i.e., his extensive consultancies and commercial activities, caused conflict with his fellow members of the shadowy, highly influential, all-male organization known as the X-Club, which included such luminaries as Crookes, Darwin, Huxley, and Tyndall. The agnosticism and anti-clericalism that had replaced his earlier religious beliefs and his participation in the X-Club, which was opposed to organized religion, served to estrange him further from his conventionally religious family, which was already opposed to his second marriage and his increasingly frequent absences. (Russell devotes considerable space to his troubled family relationships, making use of the papers, letters, and in the case of his older daughter Margaret the diary, of the children of his first marriage).

Frankland played a prominent role in the professionalization of chemistry in England, serving as president of the Chemical Society (1871–1873) and the newly founded Institute of Chemistry (1877–1880). Yet his "tendency to ride roughshod over proper democratic processes, to take short cuts, to form small groups of activists, and to manipulate individuals behind the scenes" and the Royal Society's horror of "trade" resulted in a conspiracy to deny the power-hungry Frankland its presidency. Also, following his death the Chemical Society and the Royal Society failed to publish a memorial lecture or death notice, respectively, either because the task was too difficult (to hide his illegitimacy Frankland had cloaked his private life in secrecy) or because his enemies wanted to deny him even posthumous honor.

Russell's thoroughly researched and meticulously documented book contains 52 illustrations and Frankland's original formulas along with their modern equivalents, and it is methodically organized into numbered sections and subsections. He is completely objective and devoid of hero worship and states: "A biographer does no one a service by implying that his subject has no faults." Although he does not hesitate to speculate about Frankland's motivations, he clearly distinguishes them from factual statements. His book considers in engrossing and fascinating detail every aspect of Frankland's life and career and is likely to prove to be a definitive biography. We heartily recommend it to both historians of science and chemists interested in the development of their science.

Laser Techniques in Chemistry. (Series: Techniques of Chemistry. Vol. 23). Edited by *A. B. Meyer* and *T. R. Rizzo*. Wiley, New York, 1995. 448 pp., hardcover $ 145.00.—ISBN 0-471-59769-4

This addition to the series *Techniques of Chemistry*, originally started by A. Weinberger, is welcome and timely in view of the continuing growth in the applications of laser spectroscopy to chemical problems, especially since no comparable survey of the field has appeared in recent years. The book contains ten articles by recognized experts, covering a selection of the most important methods. Regrettably, femtosecond spectroscopy is not included in these, but otherwise the choice of topics is excellent.

P. M. Felker contributes an article on "Fourier-Transform Nonlinear Spectroscopies". The techniques covered include stimulated emission Raman spectroscopy (SERS) with ionization detection, coherent Raman spectroscopy, and stimulated emission with fluorescence detection. The descriptions of the methods are illustrated by examples of applications to molecules and small molecular aggregates.

The article by R. E. Miller on "Near-Infrared Laser-Optothermal Techniques" gives technical details of the method and includes a good survey of the various types of detectors, with special emphasis on bolometer detectors. Examples of ap-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3615-1658 $ 17.50+.50/0

plications are described, including studies of the dynamics of photochemical reactions and of energy transfer in collisions.

The article "Direct Absorption in Supersonic Free Jets", by D. S. Perry and G. A. Bethardy, contains many technical details concerning the geometry of jets for molecular beam experiments, the design of multipass absorption cells, and the processing of experimental data. The authors describe examples of electronic and vibrational spectroscopic measurements on several systems, including clusters. The contribution on "High Resolution Optical Spectroscopy in the Ultraviolet" (O. W. Pratt et al.) gives an excellent overview of the experimental aspects, followed by some very nice examples of applications to a wide variety of problems, including studies of hydrogen-bonding, van der Waals complexes, acid–base reactions, photoionization, and the dynamics of intramolecular relaxation processes.

J. W. Hepburn contributes an article entitled "Generation of Coherent Vacuum Ultraviolet Radiation: Applications to High-Resolution Photoionization and Photoelectron Spectroscopy". As well as describing the generation of tunable VUV radiation the author devotes special attention to threshold photoelectron spectroscopy. In the article "Time-Resolved Resonance Raman in the Visible and Ultraviolet: Techniques and Applications", P. A. Thompson and A. Mathies are concerned with the details of pulsed Raman spectrometers rather than with the fundamentals of Raman scattering. The examples of applications that they describe include some interesting studies of bacteriorhodopsin and of heme proteins. A. Sengupta and M. A. Foyer contribute an article on a special topic: "Local Order and Ultrafast Dynamics in Liquids: Transient Grating Optical Kerr Experiments". This is concerned with investigations of short-range order in noncrystalline systems—liquids, melts, and glasses. The method described here affords detailed insights into these systems, although it requires some knowledge of physics to be used effectively. The article "Electric Field Effects in Molecular Systems Studied via Perisistent Hole Burning" (R. I. Personov et al.) explains the basic principles of the hole-burning method and presents examples to show how it can be used to determine molecular structures and study the orientation of molecules in Langmuir–Blodgett films. The next article, "Excited Electronic State Properties from Ground State Resonance Raman Intensities", is concerned with a special application of resonance Raman spectroscopy, and describes in detail the experimental method, the theory, and the interpretation of the results.

In the last article G. C. Walter and R. M. Hochstrasser report on very recent work, under the title "Ultrafast Vibrational Spectroscopy: Methods, Theory and Applications". They describe optical pumping probe experiments on systems of biological importance, in particular heme proteins and the reaction center of the photosynthetic process.

From this brief summary of the contents it can be seen that the work covers a substantial part of the techniques of laser spectroscopy that can be used in chemical and chemically related research. In an easily readable style, each article treats the sequence from theory to experimental method to examples. Altogether the articles provide a wealth of useful information, together with extensive literature references which are carefully chosen and up-to-date. However, this is not a book for beginners, as it assumes a lot of previous knowledge. Nor is it a reference source—for that purpose a more detailed subject index would be necessary. The book can be recommended for physical chemists whose work involves the structure and dynamics of molecules, and for physicists engaged in chemistry-related areas of research. It is an essential addition to departmental libraries.

The species barrier for the transmission of prion diseases can be overcome by generating a transgenic species (here in the center a mouse that expresses hamster prion). This is confirmed by the shortening of the incubation time for infection with the prion of the foreign species: dashed arrows indicate low or no susceptibility, whereas fat arrows imply high susceptibility for prion diseases.

Chemistry and Molecular Biology of Transmissible Spongiform Encephalopathies**

Frank Edenhofer, Stefan Weiss, Ernst-Ludwig Winnacker,* and Michael Famulok*

Prion diseases are currently in the spotlight. Among them, the Creutzfeldt–Jakob disease in humans, scrapie in sheep, and bovine spongiform encephalopathy, or mad cow disease, are most commonly known. The term "spongiform" refers to the characteristic appearance of the lesions found in affected brains. It is likely that prion diseases originate from a causative agent that replicates independently of nucleic acids. Current research assumes that a structural isoform of prion protein, the scrapie form PrP^{Sc}, is the responsible pathogen. The three-dimensional structure, but not the amino acid sequence of the isoform differs from that of the normal cellular isoform, PrP^{c}. According to a widely accepted hypothesis, the normal isoform of the protein is converted by an autocatalytic process into the scrapie form upon contact with the latter. This hypothesis has not yet been proven. However, considerable progress has been made in the last few years, which might provide answers to many open questions about prion diseases, the subject of this review.

Keywords: Creutzfeldt–Jakob disease · gene technology · prion protein · protein-only hypothesis · protein structures

1. Introduction

The "tin pest" is a remarkable phenomenon, which shows some analogies to an even more remarkable disease, the transmissible spongiform encephalopathy (TSE). TSEs are thought to be transmitted through prions, which are infectious proteinaceous particles included in fibrillous plaques in the brains of affected species. This infectious agent is probably a structural isoform of the normal cellular form, which is expressed by the host organism. This pathogen enters the host organism upon infection, finds its way to the brain, forces the cellular isoform to change its structural conformation, and converts more and more of the physiological molecules into the deadly version. The phenomenon "tin pest" appears to proceed with striking similarity: From the molten state tin solidifies as the "normal" metallic β-tin in which every Sn atom is surrounded by six other Sn atoms to form a distorted octahedron. At temperatures below 13 °C the metallic β-tin can transform into a nonmetallic isoform, the cubic α-tin, a grey powder. Normally, this transition occurs at an infinitely slow rate. However, if the β-tin is "infected" by microscopically small particles of α-tin, the latter can act as crystal seeds for the conversion of the metallic into the powdery isoform. This damaging transformation, which in case of very valuable tinware is particularly vexatious—think only of the famous Viennese "Kapuzinergruft"—spreads like an infectious disease. The name "tin pest" thus illustrates this phenomenon quite vividly.[1]

The α-tin particles of the "tin pest" phenomenon thus resemble the prions, the pathogen of the spongiform encephalopathies. These diseases include scrapie (in sheep), bovine spongiform encephalopathy (BSE), transmissible mink encephalopathy (TME), and the human forms Creutzfeldt–Jakob disease (CJD), fatal familial insomnia (FFI), Kuru, and the Gerstmann–Sträussler–Scheinker syndrome (GSS), which all give rise to amyloid depositions in the brains of affected species from which the prions can be isolated.[2, 3] A large amount, if not all, of the infectious protein particles consists of PrP^{Sc} (abbreviation for *p*rion *p*rotein *sc*rapie). The amino acid sequence and charge distribution of PrP^{Sc} is identical to that of the noninfectious isoform of this protein, the cellular prion protein PrP^{c}.[4] A significant amount of the infectious particles consists of PrP 27–30, which is generated from the precursor PrP^{Sc} by amino-terminal proteolysis. The infectious PrP^{Sc} or PrP 27–30 is assumed to transform the cellular PrP^{c} by a yet unknown mechanism into PrP^{Sc}. In this way, PrP^{Sc} propagates and finally induces the disease. The difference between PrP^{c} and PrP^{Sc} might be reflected in different tertiary structures; PrP^{Sc} possibly acts as a "seed" for the conversion of the regular cellular form, PrP^{c}, into the scrapie isoform, PrP^{Sc}, by some unknown autocatalytic process. Prions are thus unique pathogens of an infectious disease, because their propagation functions without the information contained in a nucleic acid but rather

seems to be solely determined by the amino acid sequence or tertiary structure of these proteins.

In this review we summarize the current state of prion research. The latest hypotheses concerning the replication of the pathogens of transmissible spongiform encephalopathies are presented and critically analyzed.

2. Pathology of Prion Diseases

2.1. Pathological Aberrations

The bovine spongiform encephalopathy (BSE) is the most commonly known form of transmissible spongiform encephalopathy (TSE) because of its epidemic occurrence in Britain. As a matter of fact, this kind of neurodegenerative disorder can occur in almost every mammalian species (Table 1).[5] One of the most remarkable characteristics of TSEs is the unusually long incubation period. For example, the time between infection and the first appearance of symptoms can be as long as 15 years in humans. The disease was therefore related to the "slow virus diseases" in the sixties. According to the current state of research, however, it seems unlikely that the spongiform encephalopathies are caused by viral infections (see Section 2.2.1). Because the immune system does not respond to the infection,[6] the infected organism is defenceless against the pathological changes. TSEs are neurodegenerative diseases. Consequently they display their destructive potential in the brain of the affected species. Neuropathologists diagnose TSE if the three following pathological changes are seen: 1) a spongiform change of the cortex (Figure 1), which perforates the brain, 2) a pathological proliferation of glia cells (gliosis), and 3) a loss of neuronal cells[7] linked to the deposition of an insoluble isoform of the prion protein "PrP^{Sc}". This pathological morphology in the brain of a CJD patient, for example, is accompanied by drastic disorders of body functions. In the EEG periodic anomalies are seen. After the appearance of the first symptoms such as

M. Famulok E.-L. Winnacker S. Weiss F. Edenhofer

Michael Famulok, born in Fulda in 1960, studied Chemistry at the University of Marburg, where he graduated in 1989. He carried out postdoctoral research in Cambridge, Massachusetts, and in Boston before he joined the Institute of Biochemistry at the Ludwig-Maximilians-Universität (LMU), Munich, in 1992, where he completed his habilitation in 1996. His research fields include aptamer technology, in vitro selection and in vitro evolution of ribozymes from combinatorial nucleic acid libraries, the study of nucleic acid/ligand interactions, and prion research.

Ernst-Ludwig Winnacker was born in 1941 in Frankfurt. He studied Chemistry at the ETH Zurich and graduated in 1968. Since 1980 he has held the chair of Biochemistry at the LMU, Munich. His research interests include the biochemistry of DNA repair and recombination processes, the development of vectors for gene therapy, and prions.

Stefan Weiss studied Biology at the University of Heidelberg. He graduated in the group of Roger Goody at the Max-Planck-Institut für Medizinische Forschung in Heidelberg in the field of the reconstitution of the HIV-1 initiation complex for retroviral cDNA synthesis. Since 1993 he has been working on transmissible spongiform encephalopathies at the LMU München, where he became head of the prion research group at the Genzentrum in 1995.

Frank Edenhofer was born in 1968 in Munich. He studied Chemistry at the LMU, Munich, from 1989 to 1994. In his graduate work since 1995 in the prion research group at the Genzentrum, he is working on the identification and characterization of prion cofactors and the heterologous expression of PrP^{c}.

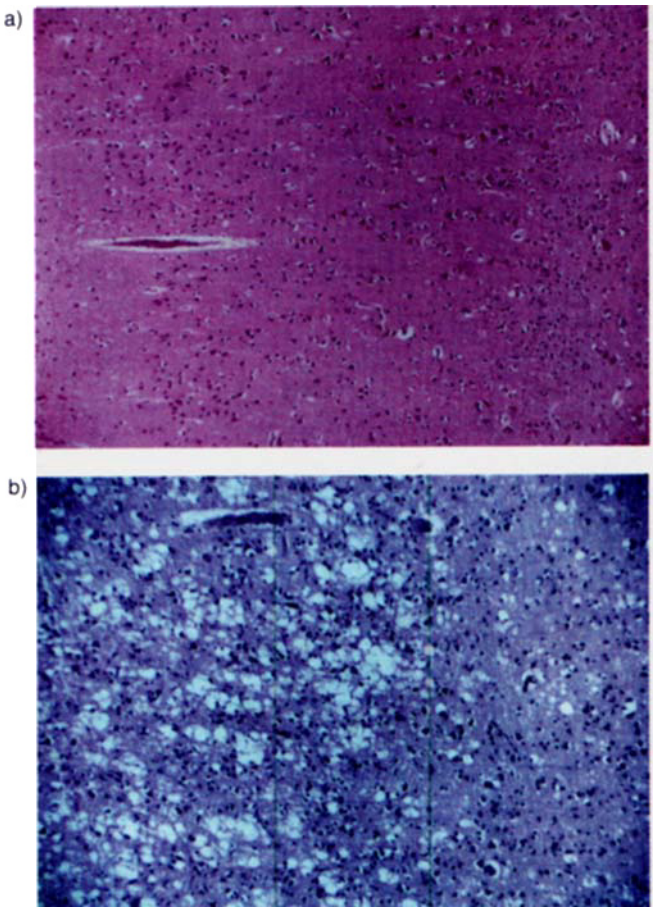

Figure 1. Thin sections of the cortex of a healthy brain (a) and of the brain of a patient who died of CJD (b). The perforation of the cortex (spongiosis means sponge-like changes) is clearly seen in this figure. We are grateful to H. A. Kretzschmar (Institute of Neuropathology, Göttingen) for providing these images.

amnesia, visual defects, and motoric malfunctions, the disease inevitably leads to death within a few months after progressive dementia. No therapeutic approaches to cure the disease exist; reliable diagnosis in a living organism is difficult.

2.2. The Pathogen

2.2.1. The Virino Hypothesis

TSEs show a number of symptoms that can be attributed to a disease caused by a viral infection. For the most commonly used mouse line C57Bl/6, for example, at least eight different TSE strains are known, which differ in specific attributes such as incubation period, nature and distribution of defects, and some other biochemical characteristics.[8, 9] The incubation periods differ when genetically identical (isogenic) mice are infected with isolated samples of different scrapie strains. These strains are passed by infection from animal to animal without loss of their specific symptoms.[10] This strain specificity within one species would argue for inheritable information and for genetic elements that contribute to the reproductive process. On the other hand, none of the experiments to isolate a virus responsible for TSE infections have yet been successful. A virus usually consists of a protein and a nucleic acid portion. The protein part protects the viral genome against external chemical and mechanical influence and in some cases helps the virus to invade the host cell. The nucleic acid represents the genetic material and therefore the infectious potential. It encodes for those proteins required for the replication of the virus in the host. Today, only a few scientists support the hypothesis of a viral transmission of TSEs (Figure 2A). For many years, the

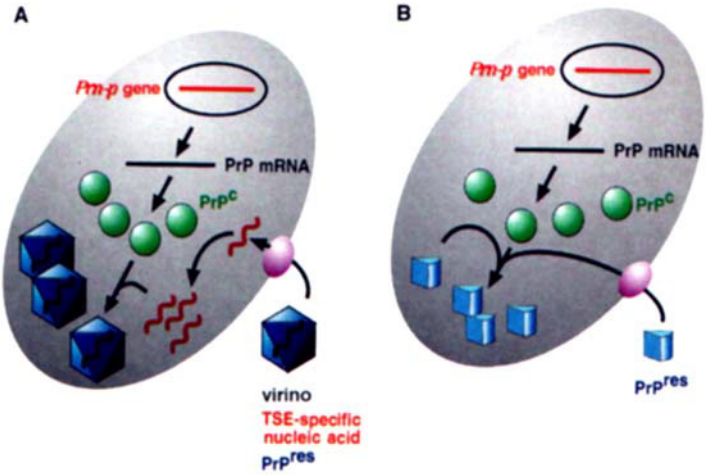

Figure 2. Models for prion propagation. A) The virino model assumes that the scrapie pathogen consists of a TSE-specific nucleic acid and the proteinase-resistant form of the prion protein PrP^{res}. The actual infectious agent, the not yet identified nucleic acid (red wavy line), is protected by packaging with PrP^{res} (blue), which has a low solubility and is extremly resistant. The virino particle invades the cell (possibly by receptor-mediated endocytosis; the putative receptor is shown in violet) and releases the nucleic acid. This nucleic acid is replicated by means of the cellular replication machinery, and the descendant molecules can associate with the cellular PrP to build new virinos. PrP^c (green spheres), which is encoded and synthesized by the host cell, is thereby converted into PrP^{res}. B) The "protein-only" model assumes that the TSE pathogen multiplies without participation of nucleic acids. The infectious particle, the prion, is identical with PrP^{res}. According to this model, exogenous PrP^{res} invades the cell (the participation of a specific receptor is likely) and converts the cellular PrP^c by direct interaction with PrP^{res}. The newly generated PrP^{res} is infectious by itself and is able to convert residual PrP^c into PrP^{res} in an autocatalytic cycle.

protagonists of the virino hypothesis—above all Laura Manuelidis (Yale Medical School) and Heino Diringer (Robert-Koch Institut, Berlin)[11]—have tried to identify such a virus without success. Diringer believes to have morphological evidence for the existence of such a virus, because in his laboratory small, symmetrical structures could be detected by electron microscopy in the brains of scrapie-infected hamsters.[12] In later experiments similar structures were indentified in the brains of deceased CJD patients.[13] These particles, which can not be detected in control tissues of healthy organisms, have a diameter of 10–12 nm. If these structures were indeed viruses, they would be much smaller than the smallest known virus, the porcine circo virus, which is 17 nm in diameter.[14]

The smallest known pathogens are viroids, small circular RNA molecules about 300 nucleotides in length, which infect plants.[15–19] The group of Detlef Riesner in Düsseldorf has carried out a systematic search for such nucleic acids in infectious scrapie samples.[20, 21] They were able to identify nucleic acids in infected preparations, but their maximum length was restricted to 80 nucleotides.[21] The genome of such a hypothetical virus or viroid would thus be considerably smaller than that of all other known viruses. Consequently, Riesner's interpreta-

tion of these results is that the existence of a scrapie-specific virus can be regarded as highly unlikely.[2, 22, 23]

2.2.2. *The "Protein-Only" Hypothesis*

The fact that no TSE virus could be detected so far is, of course, no proof that such a virus does not exist. How difficult the identification of pathogens of viral diseases can be was demonstrated, for example, by the search for a hepatitis C pathogen. It took ten years of intensive research to identify it as a virus.[24] But there is other clear evidence that nucleic acids are unlikely to be involved in the replication of TSE pathogens. Tikvah Alper et al. recognized in the sixties already that scrapie samples are resistant to nucleases and UV irradiation.[25] Usually, nucleic acids are inactivated under such conditions. Even more remarkable than these results was the fact that the scrapie pathogens lost their infectivity when they were treated with protein-denaturing agents like 8 M urea or phenol. This unusual feature of the scrapie pathogen led to the first—very cautious—speculation about the existence of infectious proteins as indicated by the title of Alper et al.'s paper:[26] "Does the scrapie agent replicate without nucleic acid?". At that time this unorthodox hypothesis could not make headway against the conventional knowledge about infectious diseases. How might an infectious agent replicate in the host without nucleic acids? Can a protein replicate itself? The classical dogma of molecular biology—the flow of genetic information from nucleic acid to protein—seems to be violated.

In 1967 J. S. Griffith was the first to suggest a possible mechanism for a self-replicating protein, which caused scrapie.[27] Stanley Prusiner of UCSF supported and extended this hypothesis by a series of experiments, which clearly showed a correlation between a protein and the observed infectivity. For example, Prusiner's group demonstrated for the first time that the infectivity of the samples increased when a specific protein contained in the samples was enriched. The concentration of this protein was found to be proportional to the titer of the infectivity in the animal.[28, 29] On the basis of these results Prusiner developed the "protein-only" hypothesis. He dubbed this new kind of pathogen as "prion", which is a short form for proteinaceous infectious particle.[30] The purification and thorough biochemical examination of this remarkable protein from the brains of affected animals was achieved by Prusiner's group after several years of intensive research. The continuing characterization of the pathogen resulted in the surprising discovery that the pathogenic protein possesses a cellular homologue. Together with the group of Charles Weissmann at the ETH Zürich they were able to clone and sequence the host gene (*Prn-p*) which encodes for PrP^c.[31, 32] This cellular prion protein, designated as PrP^c, is expressed in every normal mammal—mainly in the brain—without causing any harm to the organism. Today we know that the prion protein plays a dual biochemical role. On one hand it exists as the normal cellular form PrP^c (c for cellular); on the other hand, it can exist as a pathogenic and possibly infectious isoform PrP^{Sc} (sometimes PrP^{res}: Sc for Scrapie, res for proteinase K resistant). The PrP^{Sc} leads to death of the affected organism, whereas the biological significance of the PrP^c form is still unknown (see Section 5.3.2). A very strong argument for the protein-only hypothesis was provided by Weissmann and his co-workers, who generated transgenic mice whose *Prn-p* gene was destroyed so that they no longer expressed PrP (see Section 5.3). These so-called "PrP-knockout mice" were resistant to scrapie infections.[33] Without any doubt, the long-accepted hypothesis that the amino acid sequence of a protein is the only determinant for the biologically relevant 3D structure[34] is contradicted by the protein-only hypothesis.

Although the arguments for the protein-only hypothesis are quite compelling, a final experimental proof of the infectivity of the prion protein is still missing. The advocates of the protein-only hypothesis interpret this lack of proof as a simple preparative problem, because in purified samples only one of 10^5 PrP^{res} molecules is infectious;[22] enrichment of infectious portions is thus correspondingly difficult. Critics of the protein-only hypothesis claim that the formation of proteinase K resistant PrP^{res} is just a concomitant phenomenon, a pathological product of the infection by a not yet identified virus. This argument can be supported by experiment as well. Lasmézas et al. recently reported that mice infected with BSE samples indeed showed symptoms similar to TSE, but in 55% of the cases they could not detect proteinase K resistant PrP^{res} in the brains of the test animals.[35] These and other results show that the prion protein undoubtedly plays a central role for the pathogenesis of TSE, but until today it has not been proven that it represents the only infectious agent.

3. PrP^c and PrP^{Sc}: Differences and Common Features

The prion protein seems to be of considerable importance for the appearance of spongiform encephalopathies. In mammals as well as in some avian species the protein is expressed mainly in the brain. The prion protein is assumed to play an important biological role as is the case for many other highly conserved proteins. Various recent evidence indicates that it is important for the normal physiological function of the synapses[36] and for the long-term stability of Purkinje neurons (huge dendritic ganglial cells in the mid-layer of the cerebellum cortex),[37] as well as for the regulation of circadian rhythms and sleep patterns[38] (see Section 5.3.2. for more details).

The following statements about the composition and structure of the prion protein refer to the Syrian golden hamster, unless otherwise stated. This species is particularly suited for experimental research into TSEs, because the incubation period is only 70 days and correlates exactly with the dosage of the infectivity of the samples. According to present knowledge the characteristics of hamster PrP can be transferred with only minor modifications to PrP of other mammalian species.

3.1. Posttranslational Modifications and Infectivity

The PrP coding sequence is located entirely within an exon of the unique *Prn-p* gene.[32] Therefore, different splicing variants of PrP mRNA can be excluded. Translation of PrP mRNA leads to a PrP precursor protein of 254 amino acids in length (Figure 3). Posttranslational modification then leads to the removal of an amino-terminal signal peptide of 22 amino acids (amino

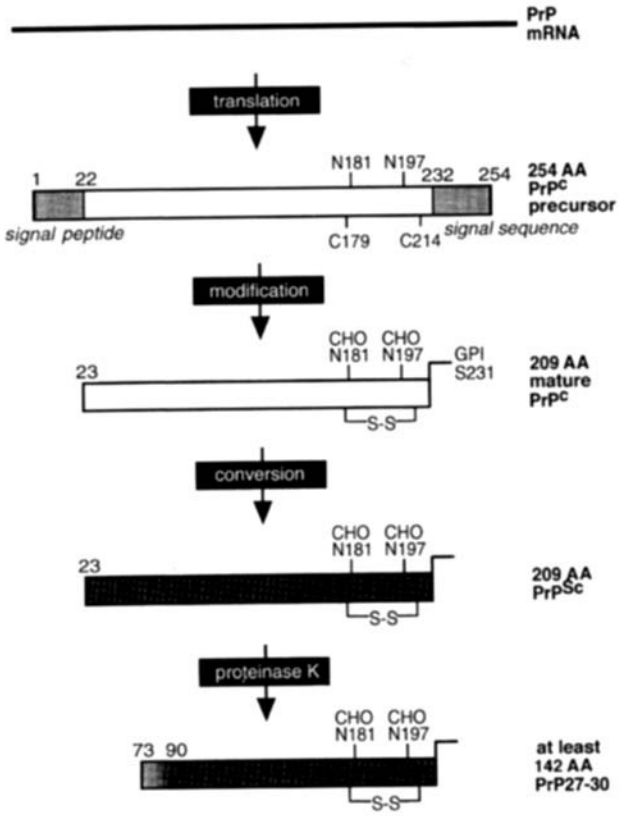

Figure 3. Maturation of PrP^c of the Syrian hamster and its conversion into the proteinase K resistant forms PrP^{Sc} and PrP 27–30. The primary structure of PrP^{Sc} does not differ from that of PrP^c. However, the two isoforms show different reactions towards proteinase K: whereas PrP^c is completely digested, PrP^{Sc} leaves a proteinase-resistant core, PrP 27–30, whose composition is not homogeneous. AA = amino acid.

acids 1–22) and of a signal sequence of 23 amino acids at the carboxy terminus (amino acids 232-254).[22] The protein contains a glycosyl phosphatidylinositol (GPI) anchor at serine 231 by which it is anchored to the cell membrane. PrP^c can be released from the cell membrane by cleavage with phosphatidylinositol-phospholipase C.[39] Characteristic for PrP is a region composed of amino acids 50–90. This region refers to five consecutive glycine- and proline-rich octapeptide sequences ("G-P repeats"). Polymorphisms within the G-P repeats have been related to hereditary forms of TSEs (see Section 4.3.2) (genetic polymorphism: differences in the genotype within a single population that cannot be explained by naturally occurring mutation rates alone). PrP is glycosylated at asparagine residues N181 and N197.[40–42] In addition, a disulfide bond forms between C179 and C214.[4, 29, 43] The resulting mature PrP, 209 amino acids in length, exists as the noninfectious form PrP^c in healthy animals. In infected hamsters the PrP^{Sc} isoform, which is generated by a yet unknown mechanism, is found as well.

Although the two isoforms PrP^c and PrP^{Sc} display the same amino acid sequence, they differ significantly from each other in many respects. As a physiological cellular protein, PrP^c does not show infectivity, whereas preparations of PrP^{Sc} do. The infectivity of prion-containing samples is maintained even in preparations treated under conditions that usually lead to inactivation of nucleic acids and most proteins; for example, incubation with formaldehyde, irradiation with UV light and X-rays, or incubation with nucleases and proteases.[31, 44, 45] The infectivity can be inhibited by heat only at temperatures above 130 °C. Infectivity is also effectively stopped by treatment with NaOH or KOH (2 N) for several hours. Incubation with proteinase K leads to the complete digestion of PrP^c, but PrP^{Sc} shows partial resistance to treatment with proteinase K.[32, 45–48] The proteinase-resistant fraction is composed of protein fragments truncated at the N-terminus and starting at amino acids between position 73 and 90. This form is also found in highly infectious preparations; it shows an electrophoretic mobility in denaturing polyacrylamide gels that corresponds to a size of 27 to 30 kDa and is therefore designated as PrP 27–30 (Figure 3). Once formed in the cell, PrP^{Sc} will not be degraded in contrast to PrP^c. The pathogenic isoform accumulates in secondary lysosomes, on the cell surface, or in the extracellular space.[49]

There is another significant physical difference between the two isoforms. PrP^c is soluble in nonionic detergents, whereas PrP^{Sc} is not. Detailed examinations of the solubility have been performed by Riesner and his group. In a recent publication they examined different ionic and nonionic detergents with respect to their ability to dissolve PrP 27–30.[50] Ultrasonication of purified infectious prion rods in the presence of 0.2–0.3% of sodium dodecylsulfate (SDS) resulted in a soluble fraction, which did not show sedimentation after ultracentrifugation for 1 h at 100000 × *g*. Relative to the infectious amyloid polymers consisting of PrP 27–30, protein in this soluble fraction contained a large number of α-helical regions and a small number of β-sheets. Furthermore, this fraction contained spherical particles with a diameter of about 10 nm and a sedimentation constant of 6 S. Each of these particles was composed of four to six PrP 27–30 molecules which, surprisingly, showed only weak or no infectivity at all. Thus, infectious preparations of soluble prion proteins could *not* be obtained in this study. When the particles were treated with 25–30% acetonitrile the α-helical regions were converted into β-sheets, as demonstrated by circular dichroism (CD) measurements. Under these conditions PrP 27–30 aggregates in nonsoluble, irregular polymers and shows partial resistance to proteinase K treatment. Insolubility and aggregation of the spheric particles treated with acetonitrile have been attributed to a conversion into β-sheets. The shape of these aggregates of PrP 27–30 clearly differs from those of the prion rods from the brains of scrapie hamsters initially used for these experiments; moreover, they did not show infectivity. As a result, protease resistance cannot necessarily be correlated with infectivity.[50]

3.2. Secondary and Tertiary Structure

The differences in the solubility of PrP^c and PrP^{Sc} might reflect differences in the secondary or tertiary structure of the two isoforms.[51] Spectroscopic data obtained by circular dichroism (CD),[52] Fourier transform infrared spectroscopy (FTIR),[53] and mass spectrometry (MS)[54] indeed provided evidence for marked differences in the secondary structure of PrP^c and PrP^{Sc}. PrP^c shows a 42% α-helical content and only 3% β-sheets, whereas PrP^{Sc} has 30% α-helical and 45% β-sheet con-

tent.[51, 52] These studies indicated that during conversion about half of the α-helical portions in PrP^c are converted into β-sheets of PrP^{Sc}.[52, 55] The mechanism by which the PrP^c is unfolded and then changed into PrP^{Sc}, however, is unknown. It is possible that the change in protein structure associated with this process requires a high activation energy.[51]

Computer models of the three-dimensional structure of the cellular PrP^c have been carried out with techniques of structure prediction such as the Chou–Fasman method or the Garnier–Osguthorpe–Robson algorithm.[56] To obtain a structural model for the Scrapie isoform, the aforementioned spectroscopic data as well as comparative analyses of the genes of various species were considered. According to this model, PrP^c contains a helix bundle of four α-helices (H1 to H4; Figure 4B, 5A).

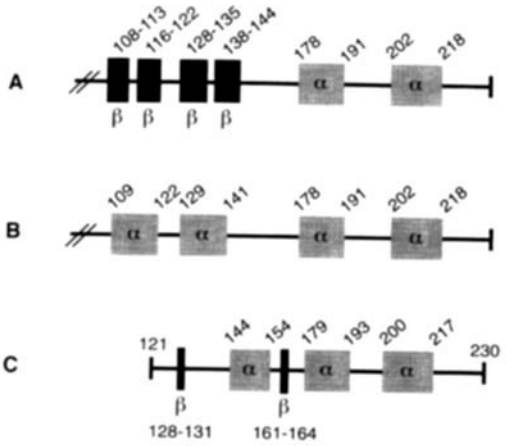

Figure 4. Secondary structures of PrP^c and PrP^{Sc}. A) Computer model of PrP^{Sc} (based on genetic data); B) computer model of PrP^c (determined by the Chou-Fasman method and the Garnier-Osguthorpe-Robson algorithm); C) schematic representation of the secondary structure determined by NMR spectroscopy. The position of the two carboxy-terminal α-helices was confirmed almost exactly by NMR spectroscopy; however the seconday structure of the domain around AA 121–178 determined by NMR spectroscopy clearly deviates from the computer model (B, C). The model proposed for PrP^{Sc} suggests a four-stranded β-sheet structure between amino acids 108 and 144 and two C-terminal helices whose position corresponds to that of PrP^c. There are no NMR data available for PrP^{Sc} due to the insolubility of the protein. (Based on data from refs. [56, 57, 61].)

H1 is formed by amino acids 109–122, H2 by amino acids 129–141, H3 by amino acids 178–191, and H4 by amino acids 202–218 (Figure 4B and 5A). The algorithm did not provide a conclusive prediction for the region comprising amino acids 23–108 in which the prion proteins contain the characteristic five octapeptide sequences in tandem orientation. For PrP^{Sc} six different structural models are suggested from a list of 10^6 initial structures. All six PrP^{Sc} models contain a four-stranded β-sheet structure which is covered by two α-helices on one side.[57] Figure 5B shows a schematic representation of these six models. Among them, model 2 correlated best with the genetic data (see Fig.4A). Accordingly, the β-sheet regions S1 to S4 are flanked by amino acids 108–113/116–122 for S1a/S1b, 128–135/138–144 for S2a/S2b, 178–184/187–191 for S3a/S3b, and 202–210/213–218 for S4a/S4b. The location of the two helices H3 and H4 corresponds to that of helices H3 and H4 in PrP^c. As suggested by this structural model, helices H1 and H2 should each convert into two

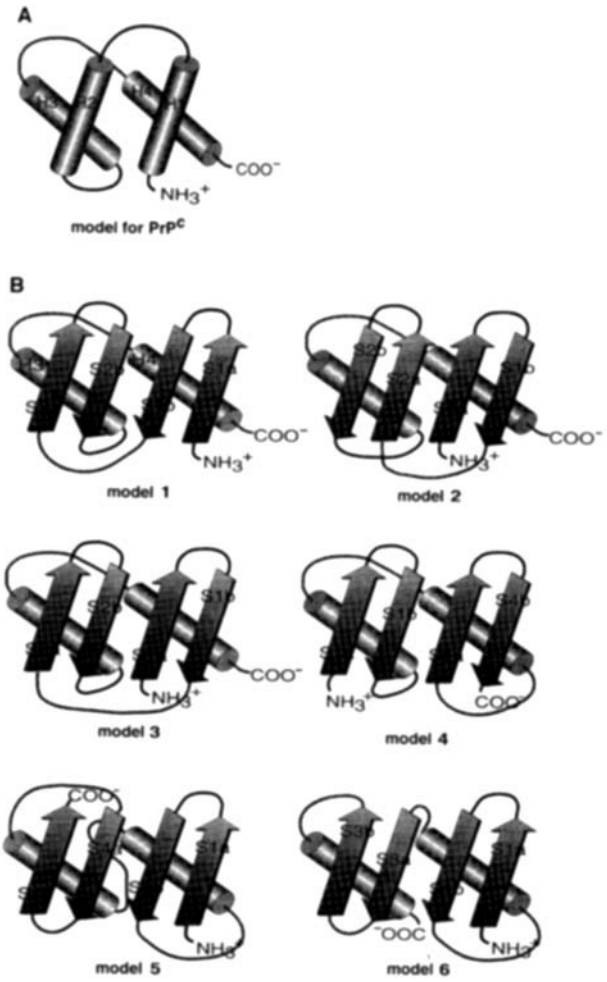

Figure 5. A) Computer-generated structural model of PrP^c modified according to ref. [57]. Two helices at a time are twisted together to form a bundle of four. B) Structural model of PrP^{Sc}. Model 2 correlates best with the genetic data of different species.

anti-parallel β-sheet structures during the structural conversion of PrP^c into PrP^{Sc}.[57]

In earlier experiments synthetic peptides of prion proteins have been examined for the aforementioned structural elements. Among four synthetic peptides which were equivalent to regions H1–H4, three exhibited only poor solubility in water. Spectroscopic data (FTIR, CD), as well as that from electron microscope images, indicated that they formed β-sheet structures and polymerized into fibrils.[58, 59] In contrast, CD and NMR experiments performed in organic solvents such as hexafluoroisopropyl alcohol (HFIP) or detergents like sodium dodecylsulfate (SDS) showed that not only H1 and H2, but also longer peptides containing these helical regions formed α-helices.[60] It therefore seems quite plausible that synthetic peptides are able to model certain aspects of the conformational differences suggested for the prion protein isoforms.

Recently the three-dimensional structure of a domain of recombinant mouse PrP^c was elucidated by NMR spectroscopy.[61] To obtain the required large amounts of protein, the mouse PrP fragment composed of amino acids 121–231 was overexpressed in the periplasm of *E. coli* cells.[62] Originally, it was attempted to express murine PrP 108–231. However, the

expression resulted in proteolytic cleavage at amino acids 112, 118, and 120. As a consequence, the protein could be obtained in stable form only from position 121. Previous studies had shown that the segment 81–231 of mouse PrP is sufficient for prion propagation in these species, indicating that the carboxy-terminal region of the protein is functionally much more important then the amino terminal region.[63] The domain PrP 121–231 used for the determination of the NMR structure lacks an extended region of the N-terminus (fragment 81–120). It is thus currently not known whether this extended region is required for the pathology of the disease or not; this domain, however, contains the majority of certain point mutations that were associated with the appearance of familial (inherited) cases of human prion diseases (see Section 4.3.2).[64]

The secondary structure of PrP121–231 determined by NMR spectroscopy is characterized by three α-helices as well as a two-stranded antiparallel β-sheet (Figure 4C). The helices are formed from amino acid residues 144–154, 179–193, and 200–217. A comparison with the structural model suggested previously[56, 57] shows that the location of H3 and H4 correlates almost exactly with that of the two C-terminal helices in the NMR studies (Figure 4). Both H2 (suggested to be formed by residues 129–141) and H1 (formed by amino acids 109–122) of the structural model are missing in the "NMR fragment". Instead, in the structure determined by NMR spectroscopy an extremely short antiparallel β-sheet structure not predicted by the structural model appeared at positions 128–131 and 161–164. This β-sheet domain in PrP^{c} might act as a seed during the conversion into PrP^{Sc}. Interestingly, the seconday structure deviates from the computer model mainly in the N-terminal region, which was heavily truncated in the fragment used for the NMR experiment (Figure 4). It remains to be seen whether the truncation of amino acids 23–120 results in significant structural changes within the N-terminus. At worst, essential elements of the prion protein may be located within this segment. The tertiary structure of PrP^{c}, determined by NMR spectroscopy, is dominated by a twisted, V-shaped arrangement of the two C-terminal helices in which the first α-helix and the β-sheet is embedded (Figure 6).

A comparison of the three-dimensional structure of PrP^{c} with a corresponding structure of the infectious PrP^{Sc} or PrP 27–30 would be interesting. However, a high-resolution, three-dimensional structure determination of the infectious prion isoforms by crystal structure or by NMR spectroscopy in solution is difficult because of the insolubility of these proteins. A technique that might lead to a structure determination of the insoluble scrapie isoform PrP^{Sc} is solid-state NMR spectroscopy. However, this requires weighable amounts of ^{13}C- or ^{15}N-labeled PrP^{Sc}, which is at present technically difficult.[65] First experiments in this direction have been carried out with a ^{13}C-enriched H1 fragment of hamster PrP, consisting of amino acids 109–122 (sequence: MKHMAGAAAAGAVV).[66] This study provided additional evidence for the ability of H1 to convert from an α-helical into a β-sheet structure. When the peptide was lyophilized from a solution of 50% acetonitrile/water, the chemical shifts in the solid-state NMR spectrum within region 112–121 were characteristic for β-sheet structures. Samples lyophilized from HFIP, on the other hand, showed chemical shifts which pointed to an α-helical secondary structure in region 113–117. A complete conversion into the α-helical form was not detected. Refolding of the α-helical into the β-sheet form was obtained after dissolving the samples in water. These results are in accordance with experimental observations that PrP can exist in different conformations. Furthermore, they correlate with structural predictions based on biological data and theoretical models which attribute to H1 an important role in determining the conformational differences between PrP^{c} and PrP^{Sc}.

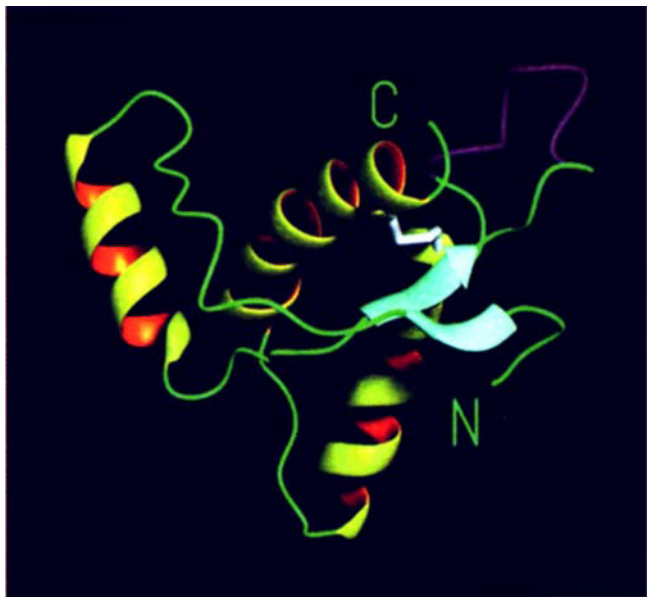

Figure 6. Structure (shown as a "ribbon diagram") of the mouse PrP^{c} fragment AA 121–231, determined by NMR spectroscopy [61]. The fragment was derived by recombinant technology from Escherichia coli. The structure contains three α-helices (yellow) and a double-stranded anti-parallel β-sheet structure (turquoise). The two C-terminal helices are mutually twisted into a V-shaped arrangement and are connected by a disulfide bond (white) between C179 (at the first turn of the second helix) and C214 (last turn of the third helix). The N-terminal helix flanked by the two β-sheet structures (turquoise) is arranged in front of this region. The short, antiparallel β-sheet structure might serve as a seed for the formation of the extensive β-sheet regions in PrP^{Sc}.

3.3. Models for the Mechanism of Prion Propagation

The next question concerns the mechanism by which the PrP^{Sc} propagates in the host cell without the involvement of nucleic acids. The protein-only hypothesis proceeds from the assumption that the PrP^{c} of the host cell is converted into PrP^{Sc} by the influence of exogenous PrP^{Sc} (which, for example, is taken in orally). The two currently competing models differ with respect to the (quaternary) structure of the infectious unit.

3.3.1. The Heterodimer Hypothesis

According to Prusiner's heterodimer hypothesis[22] PrP^{Sc}–PrP^{c} heterodimers are formed first. PrP^{c} is partially unfolded and then refolded under the influence of PrP^{Sc}, which results in the formation of a PrP^{Sc} homodimer (Figure 7A). The newly generated PrP^{Sc} can again induce the conversion of PrP^{c} in an

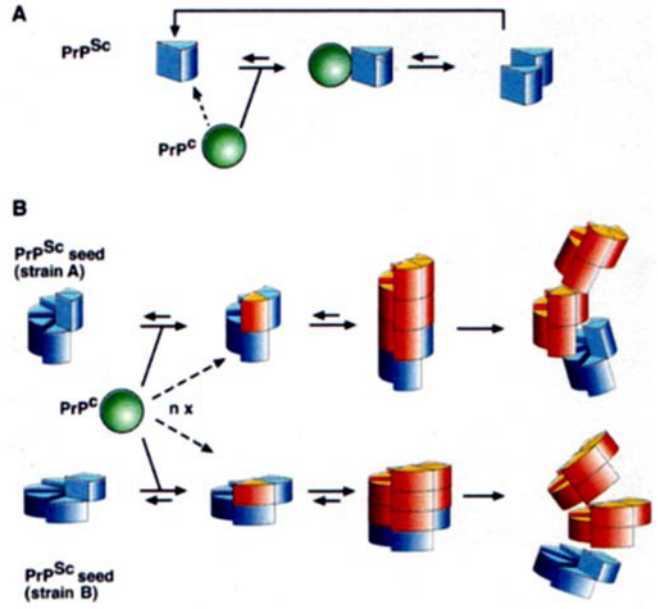

Figure 7. Models for the conversion of PrP^c into PrP^{Sc}. A) The heterodimer model [22] postulates the formation of dimers from infectious PrP^{Sc} (blue) and cellular PrP^c (green): PrP^{Sc} induces a partial unfolding of PrP^c and, subsequently, its refolding into PrP^{Sc}, which in turn can cause the formation of PrP^{Sc} in an autocatalytic process. Due to the high energy barrier of the conversion of PrP^c into PrP^{Sc} the spontaneous formation of PrP^{Sc} is very unlikely (dotted line). B) According to the model of nucleation-dependent polymerization [72, 74] the infectious unit is a PrP^{Sc}-oligomer (blue), which serves as a seed for the polymerization of PrP into fibrillous aggregates of high molecular weight. Cellular PrP (green) can successively deposit on this seed and in the process adopt its structure (red). The polymer can be separated, and the seeds generated by this process can start the nucleation-dependent polymerization again. The appearance of different scrapie strains is explained by this model as follows: every (quaternary) structure of a seed "codes" the specific characteristics of different scrapie strains (here strain A and strain B).

autocatalytic cycle. Under appropriate conditions newly formed PrP^{Sc} aggregates to furnish the fibrils or amyloid plaques that can be observed under the electron microscope. The energy barrier for the conversion of the PrP isoform is probably very high.[51] The spontaneous forms of the disease therefore only appear at an advanced age, if they appear at all (see Figure 7A; dotted line). In hereditary forms the PrP^{Sc} formation can be facilitated by specific mutations that promote the development of β-sheets. The pathological changes are probably induced either by the absence of the PrP^c form or by the massive appearance of the insoluble PrP^{Sc}.

Although this model supplies sufficient explanations for the formation of PrP^{Sc}, it leaves unanswered how *one* PrP^{Sc} can transmit *various* strains of prion diseases. As mentioned above (Section 2.2.1), even within one species different strains of PrP^{Sc} exist with clearly identifiable and inheritable characteristics.[67–70] This phenomenon argues strongly against the hypothesis that the prion propagation depends on protein factors alone without any genetic components. An explanation in this hypothesis for the hereditary propagation of the observed strain specifity without genetic information is beset with problems. Not only *two* metastable forms of the prion protein would have to exist, but also *several* PrP structures, which are each able to "code" for a specific strain. Therefore, the problem of the strain-specific transmission demanded an extension of the hypothesis and finally led to the nucleation-dependent polymerization model.

3.3.2. Nucleation-Dependent Polymerization

The idea of a seedlike growth of prion polymers was already defined in 1990 by the group of D. Carleton Gajdusek.[71] Later, Peter Lansbury et al. suggested an analogous mechanism[72, 73] and, together with Byron Caughey, developed it into the nucleation-dependent polymerization model.[74] This model differs from the heterodimer model by the assumption that an infectious unit consists of a PrP^{Sc} oligomer, which serves as a seed for the polymerization. Host PrP^c can successively deposit on this seed through a more or less unfolded transition state; on deposition it adopts the specific structure of the seed. In some kind of polymerization process, aggregated forms of PrP^{Sc} of high molecular weight are formed (Figure 7B). These aggregates can be separated again into single seeds under external influences. The main difference between this model and the previous one is that the conformation of PrP^{Sc} does not have to be an intrinsic attribute of a PrP monomer, as in the case of the heterodimer model. This difference is manifested by the experimental observation that so far no soluble, monomeric, protease-resistant, and unaggregated forms of PrP^{Sc} have been found. According to the nucleation-dependent polymerization model, the PrP^{Sc} acquires these biophysical properties only as a high molecular weight aggregate of PrP. The propagation of specific scrapie strains can be explained by this model as follows: Like in a crystal the smallest infectious unit, the nucleus, carries the information of the structure of the whole. Therefore, a PrP^{Sc} oligomer can determine the structure of the polymeric PrP aggregate (or the kinetics of its formation) by the structure of the nucleus and thereby determine the particular characteristic pathology of the various strains.

Manfred Eigen (MPI for Biophysikalische Chemie, Göttingen) recently published a detailed comparison of the two models from a kinetic point of view.[75] According to Eigen, the key difference between the models is that the nucleation-dependent polymerization model does not require a catalytic mechanism. The growth of the "crystal" is favored by the free energy, while the crystal surface gives rise to the conversion of PrP^c. In contrast, Prusiner's heterodimer model is based on an autocatalytic mechanism, but only if the dissociation of the PrP^{Sc} heterodimer is not the rate-limiting step. In the case of a slow dissociation the (auto)catalyst PrP^{Sc} would be regenerated incompletely, and the catalytic cycle would soon be terminated. A possible distinction could be the measurement of the growth rate of PrP^{Sc}; an autocatalytic mechanism would show an exponential growth, whereas the crystallization would proceed with approximately the square of time.[75]

3.4. In Vitro Conversion

In order to prove the heterodimer model, many laboratories tried hard to show a direct interaction of PrP^c with PrP^c and/or PrP^{Sc} in vitro. Proof of an in vitro conversion of PrP^c into PrP^{Sc} would confirm the protein-only hypothesis. These experiments, often designated as "key experiments" in prion research, which are based on the incubation of PrP^c with PrP^{Sc} in vitro, have failed so far. Neither was it possible to detect PrP^c/PrP^{Sc} heterodimers nor was it proven that PrP^c could be converted in

vitro by addition of PrP^{Sc}.[76] In mid 1994 Kocisko et al. reported for the first time the cell-free production of protease-resistant prion protein.[77] They used proteinase K sensitive PrP^c, radiolabeled with ^{35}S-methionine. The protein was incubated with proteinase K resistant, unlabeled PrP^{Sc}. In order to separate PrP^c from the potentially produced PrP^{Sc} the sample was treated with proteinase K. By gel electrophoresis and autoradiography they demonstrated that radioactive, proteinase K resistant PrP^{Sc} had been generated—an indication that PrP^{Sc} had emerged de novo from the labeled PrP^c (Figure 8). This experiment certainly provides necessary, but not sufficient proof for the in vitro conversion of PrP^c. That is because until now it has not been possible to show that proteinase K resistant material produced in vitro is indeed infectious. The proteinase K resistance does not necessarily correlate with the infectivity of PrP^{Sc} (see Section 3.1). In spite of this (still) missing evidence for the de novo generation of infectivity in vitro, one now has a model with which some phenomena of prion propagation can be simulated and examined. For example, even a strain-specific conversion in vitro has been demonstrated with this cell-free conversion system.[78] For that purpose, the mink-specific scrapie strains "hyper" (HY) and "drowsy" (DY) were used.[79] These TME strains were manifested originally in minks (TME = 'transmissible *m*ink *e*ncephalopathy') and can be propagated in hamsters with the particular pathology characteristic for each of them. HY- and DY-PrP^{Sc} are cleaved by proteinase K at different amino-terminal positions, from which characteristic digestion patterns of PrP fragments of variable length result, which can be detected by SDS-polyacrylamide gel electrophoresis.[79] If one uses preparations of HY-PrP^{Sc} from hamster brains for the aforementioned conversion experiments a resistant protein is produced which, after proteinase K treatment, showed a digestion pattern similar to that of HY-PrP^{Sc}. In contrast, if DY-PrP^{Sc} is used instead for the cell-free conversion of the same PrP^c-material, the characteristic DY-PrP^{Sc} pattern results.[78] These results indicate that two different conformations of the scrapie form of one prion protein can probably be forced upon a single cellular prion protein in the cell-free conversion system. These conversion experiments, therefore, serve as a model for the propagation of different scrapie strains in vitro—an important addition or alternative to the transgenic animal model.

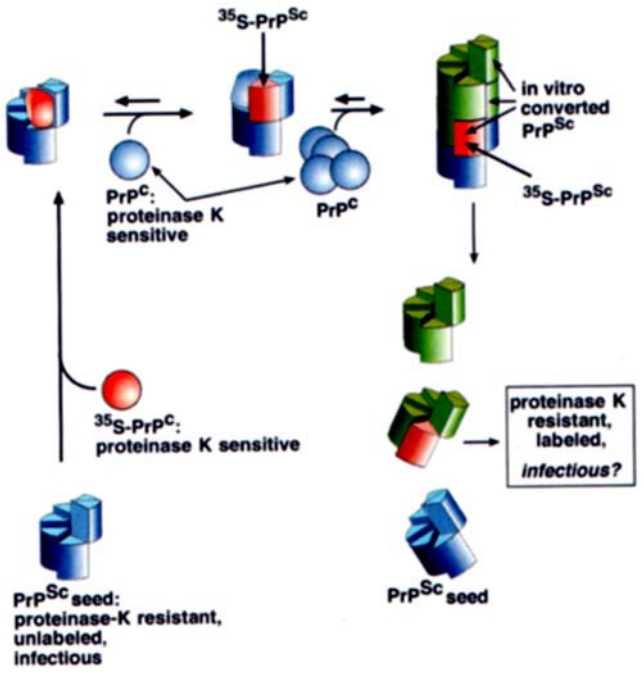

Figure 8. Cell-free production of proteinase-reistant prion protein [77, 78]. Radiolabeled PrP^c (red) is incubated with proteinase-resistant PrP^{Sc} (blue) and integrated into the polymer. In the end, a labeled, proteinase-resistant species can be detected.

3.5. More Aspects of Strain-Specific Prion Propagation

Meanwhile, experiments were carried out on transgenic mouse models[80] from which similar conclusions could be drawn to the ones of Bessen et al.,[78] who performed strain-specific in vitro conversion experiments. The mice for that experiment, abbreviated [Tg(MHu2M)],[81, 82] express a chimeric human–murine PrP gene. They were inoculated with proteinase K treated brain extracts from patients who had died from different forms of human TSE diseases. The extracts thus contained proteinase K resistant PrP^{Sc} fragments of two different human PrP strains, the sporadic Creutzfeldt–Jakob disease (sCJD) and the fatal familial insomnia (FFI; for the different human TSE forms see Section 4.3). The proteinase K treated PrP^{Sc} strains of this sort show different fragment lengths after deglycosylation: because the strain of FFI has a size of 19 kDa and the sCJD fragment 21 kDa, the two fragments can be distinguished easily by denaturing polyacrylamide gel electrophoresis. About 200 days after inoculation a PrP^{Sc} strain-specific fragment development could be observed in the mouse brains. Inoculation with the FFI strain led to the development of the 19 kDa fragment, whereas the 21 kDa fragment was obtained only after inoculation with the sCJD strain. These results led to the conclusion that the conformation of the particular PrP^{Sc} strain serves as a template for the development of PrP^{Sc} and is therefore crucial to its strain-specific characteristics. Furthermore, these experiments indicate that the diversity of the different PrP^{Sc} strains is caused by the conformation of the strain generating new PrP^{Sc}.

In a recent publication, Leslie Orgel points to another aspect that might play a role in prion propagation: "secondary nucleation".[83] Secondary nucleation can be observed, for example, in the enantiomorphic crystallization of supersaturated $NaClO_3$ solutions. If the crystallization takes place under vigorous stirring, crystals of either pure D or pure L configurations are obtained. In contrast, "undisturbed" crystallization results in almost the same amount of D and L configurated molecules in the crystals.[84] An explanation for this phenomenon is that stirring ruptures the primary crystal seed and the newly formed secondary nuclei. All developing crystals would then be "descendants" (or "clones") of the primary nucleus and would form before another primary nucleus of opposite chirality was generated. In the same way, certain details (strain specifities) of the pathology of prion diseases might be determined by secondary nucleation. Otherwise—as Orgel states—one could expect that an endogenously formed or exogenously supplied PrP^{Sc} nucleus would produce only one localized plaque. The more effective a hypothetical secondary nucleation is, the less localized the re-

sulting plaques would be. The number of developing nuclei would therefore determine the seriousness of the disease—as in the case of cancer where the severity of the disease depends on the tendency of metastasation of the primary tumor. Of course, secondary nucleation in the case of prion propagation has not yet be shown and will probably be very difficult to prove.

As discussed in greater detail later, other possibilities can explain the strain specifity of prion propagation, for example, the existence of a third component such as a strain-specific co-factor or protein X,[82] which is directly or indirectly involved in the propagation of PrP^{Sc} (see Section 5.2).

4. Epidemiology and Transmission

After close analysis of the pathogen the question arises, how are prion diseases transmitted. How could BSE in England reach epidemic proportions? What about the transmission from one species to the other? The risk of transmission of BSE to humans has, of course, important public, economic, and sanitary implications.

4.1. The Scrapie–Kuru Connection: a Historical Summary

Spongiform encephalopathies have been known since the 18th century. The oldest written record gives a description of certain peculiar behavior in sheep: at an early stage in the disease, disorientation and itching was observed in the affected animals: they scraped themselves sore at pales and trees; this is why the illness was called "scrapie" in the English speaking-world. In German-speaking countries the disease was named "Traberkrankheit", which points to the fact that affected animals progressively lose control over their body in an advanced phase, move in an uncoordinated manner ("traben"), cannot support themselves on their hind legs, and finally perish in complete paralysis. Ways of transmission of the disease and the cause of the illness remained obscure for centuries, mainly because scrapie never developed into an economic problem. The rate of infection always remained quite low—an epidemic outbreak of the disease has never been registered to date. Nowadays it has almost completely vanished in Germany, whereas only a few cases are reported in Great Britain at regular intervals.

Scientific interest arose first in this century, when William Hadlow speculated about a possible connection between the human Kuru disease and scrapie.[85] Earlier, independent of scrapie, a series of unusually slowly degenerative diseases of the central nervous system in humans such as the Creutzfeldt–Jakob disease (CJD), Gerstmann–Sträussler–Scheinker syndrome (GSS), and Kuru had been described. Kuru broke out in epidemic dimensions in the Fore, a tribe in Papua–New Guinea, and was probably transmitted by religous cannibalistic rites. D. Carleton Gajdusek succeeded in an experimental transmission of this disease to chimpanzees by injection of brain material of patients who had died of Kuru.[86] In a similar way, CJD could be transmitted to chimpanzees. The remarkably long incubation period and the pathological pattern of this neurodegeneration by spongiosis were identical in all forms of this disease. Important information about the transmissibility of scrapie resulted from experiments by J. Cuillé and P. L. Chelle, who demonstrated in the thirties that scrapie can be transmitted to healthy sheep and goats.[87] Hamsters and mice were also prone to this disease; both species are used today on a large scale for animal tests to investigate prion diseases. Nevertheless, as we will discuss later (Section 5.1), the unrestricted transmission of TSE from one species to another is not possible.

4.2. BSE—from Bonemeal to Epidemic

Because of the limited occurrence, TSE diseases in the first instance were a subject of academic interest. This changed suddenly when the first case of BSE in England was histologically confirmed in 1986.[88] Fibrils isolated from the brains of BSE-infected cattle were shown to contain a scrapie-associated protein.[89] This report was immediately followed by others. The BSE epidemic in England had its climax between 1992 and 1993 with up to 3500 new cases per month; now it has dwindled to about 500 new cases per month (Figure 9). By April 1997 a total of more than 167 300 (source: Ministry of Agriculture, Fisheries and Food [MAFF], UK) BSE cases had definitely been confirmed in England.[90] The epidemic in cattle began when in the eighties the method of meat- and bonemeal production was changed in response to economic pressures. This feed, used mainly in cattle breeding, is produced in part from sheep cadavers. In the beginning of the eighties British companies modified the sterilization temperature, lowering it from 130 °C to 110 °C. Furthermore, extractions with organic solvents were no longer performed.[91] Whether the epidemic was induced by bonemeal contaminated with scrapie (that is, the disease was transmitted from sheep to cattle) or with BSE pathogens from spontaneously affected cattle themselves (and therefore not transmitted across species) can no longer be determined with certainty. In any case the spreading of the infectious agent through feed has been confirmed as the trigger for the BSE epidemic.[91, 92] The accumulated number of BSE cases in Switzerland, which was the main importer of British bonemeal until the feed ban (July 18, 1988) on the continent, also supports this argument. BSE was detected and confirmed worldwide in 12 countries (Table 2). Besides infection through feed, even newer indications suggest that other ways of transmission, mainly from mother to calf, might be possible.[93]

A current study of the course of the BSE epidemic in Great Britain from the very beginning of the first cases to a potential epidemiological development in the future came to the conclusion that by the end of 1994 new infections by contaminated feed were almost zero, and all new cases result from horizontal (maternal) transmission.[90] Absolute numbers of new infections by this form of transmission were so small that the epidemic would vanish by the year 2001 even without slaughtering programs. In September 1996 the British government used this study as an argument to interrupt their cattle slaughtering project, which they had initiated in order to bring the epidemic under control. However, this argument neglects another important result of the study—the incubation period. It takes about five years from infection to the outbreak of the first symptoms. Since most of the cattle are killed at an age of about two years, that is, long

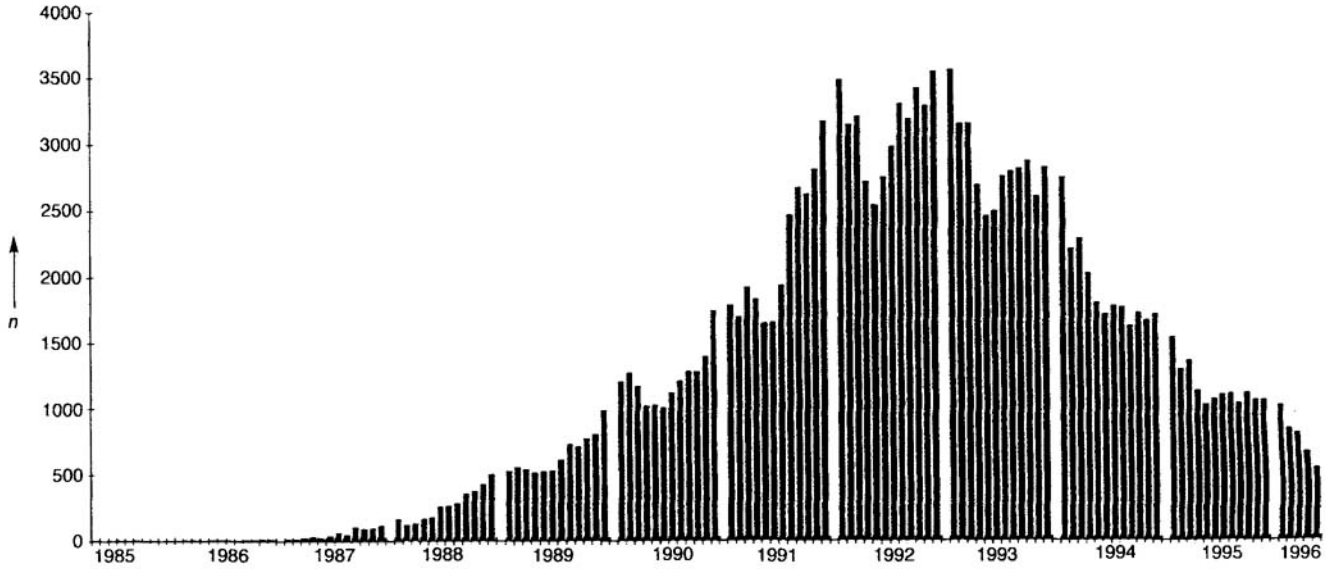

Figure 9. Confirmed cases *n* of BSE per month and year in England. The decline of the curve is traced back to the ban against meat- and bonemeal as feed and similar measures taken by the British government in 1988 and 1989. After the average incubation period of five years had passed, these measures probably led to the reduction of BSE cases.

Table 2. Appearance of BSE worldwide (data till March 1996).

Country	Number of BSE cases	Country	Number of BSE cases
Great Britain	167321 [a]	Germany	5[b]
Northern Ireland	1656	Italy	2
Switzerland	189	Oman	2
Ireland	115	Falkland Islands	1
Portugal	29	Denmark	1
France	13	Canada	1

[a] Data till April 1997. [b] Data till Januar 1997.

before the animal can be recognized as infected, infected and potentially infectious animals might get into the human food chain. Therefore absolute security can be given only if a reliable diagnosis that detects the disease long before clinical symptoms are seen is guaranteed, for example, by direct detection of the PrP^{Sc} form or the cattle prion protein (see Section 4.4).

4.3. Human Spongiform Encephalopathies

In the twenties the neurologist Hans-Gerhard Creutzfeldt[94] from Kiel, Germany, and his colleague Alfons Jakob[95] from Hamburg independently described a "strange disease of the central nervous system accompanied by remarkable anatomic findings", which led to death after an unabatable decay of brain tissue and is now known as Creutzfeldt–Jakob Disease (CJD). In the year 1936 the neuologists Josef Gerstmann and Ernst Sträussler as well as the neuropathologist I. Scheinker from Vienna observed a very similar, although rather rare, syndrome in humans.[96] They mainly observed impairments of the coordination. In contrast to CJD, in which a loss of memory and a progressive decline of intellect takes place in the beginning, the appearance of dementia in GSS patients only happens in the clinical phase. GSS is manifested by ataxia and other degeneration symptoms in the cerebellum. Histopathologically the two forms of disease, CJD and GSS, resemble each other: one could detect symptoms of degeneration connected with vacuoles (= cavities in cells with fluids like proteins or fat) as well as amyloid depositions in the brain. Such depositions are known in Alzheimer's disease as well, which, however, is not considered a prion disease. Fatal familial insomnia (FFI), another inheritable form of human prion diseases, was discovered by an American group around Pierluigi Gambetti and an Italian research group of Elio Lugaresi and Rossella Medori from the University of Bologna.[97] FFI differs from the other forms in the effect that the patients suffer from sleep disturbances in the beginning, which are followed by dementia.[98] An additional form of human prion diseases is the aforementioned Kuru disease. Among of the four human TSE forms, Kuru is the only one which is solely transmitted by infection.

4.3.1. Sporadic and Infectious Forms

Prion diseases show the remarkable characteristic that they can be caused by infections (exogenous origin) but can also originate sporadically or genetically (endogenous origin). Most cases of TSE in humans appear sporadically or are caused by transmission (for example, Kuru); however, there are cases for which genetic reasons are responsible for the outbreak of the disease as well. In humans 85% of the CJD cases occur sporadically, that is, the disease could not be traced back to a possible source of infection in these patients. A few CJD cases might be traced back to the infection with the CJD pathogen by mistake during medical treatment, for example in children who were treated with a growth hormone obtained from pituitary glands of deceased people[99, 100] (today this hormone is produced by recombinant techniques). Patients who had to undergo neurosurgery were also exposed to the risk of this iatrogenic transmission; because it was not known that the prion pathogen is extraordinarily resistant towards standard sterilization techniques (see Section 3.1), CJD was transmitted in some cases by con-

taminated instruments used in neurosurgery. Besides the iatrogenic and sporadic cases about 10% of the familial cases have a genetic dispostion, such as GSS and fatal familial insomnia (FFI).

4.3.2. *Mutations in the Prn-p Gene Locus*

Certain cases of CJD can have hereditary origin, too. Already in 1930, the physician F. Meggendorfer described hereditary cases of CJD in a family from Northern Germany. Many decades later the DNA extracted from a sample of brain tissue and conserved in celloidine was amplified by PCR and sequenced. In codon 178 within the *Prn-p* gene a GAC → AAC mutation appeared, which corresponds to an exchange of Asp178 for Asn.[101] (Figure 10).

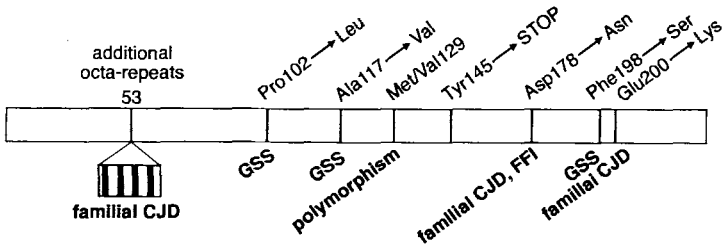

Figure 10. Mutations and polymorphisms in the human *Prn-p* gene associated with the familial form of spongiform encephalopathies. The polymorphism at position 129 seems to influence the susceptibility for vCJD, because all cases of vCJD examined so far are homozygous for Met 129.

Other mutations that were found to be associated with genetic dispositions are Glu200 → Lys, Pro102 → Leu, Ala117 → Val, and Phe198 → Ser, as well as the insertion of additional octa-repeats within the human *Prn-p* gene in position 53.[22] Position 129 appears to be of special interest as valine or methionine can appear at this site. John Collinge and his colleagues[102] from St. Mary's Hospital Medical School (London) observed a significant occurrence of Val129-homozygosity in patients who developed CJD after being treated with growth hormone from pituitary glands. At least 50% of the caucasian population is heterozygous (Met/Val) at this position. The dimerization of the prion protein, which might occur more easily in homozygous than in heterozygous patients, is possibly important for the pathogenesis of CJD. Different phenotypes of the various human TSE forms as seen, for example, in the case of CJD and FFI, seem to correlate with different genotypes. In a study in which familial TSE cases (with the exchange of Asp → Asn at position 178) were examined, it was shown that the genotype at position 129 determines the mode of pathology. Patients with Met129/Asn178 showed an FFI phenotype, whereas the Val129/Asn178 appeared in CJD patients.[103, 104] It has been suggested that the combination of the mutation in codon 178 with the polymorphism in codon 129 determines the phenotype of the disease by generating two different conformations of the prion protein.[105, 106] In the familial prion diseases the mutated forms would spontaneously adopt conformations which are determined by the mutations. A direct interaction between methionine or valine at position 129 with the asparagine at position 178 might lead to two abnormal isomers which differ in their conformation and in their pathogenic consequences. It is possible that the activation energy for the conformational change may be lowered in these mutants. Moreover, the polymorphism at position 129 also seems to be critical in a new variant of CJD, as discussed below.

The mutation Pro 102 → Leu also seems to be of great importance for the appearance of GSS. It was the first mutation identified in connection with familial prion diseases.[107, 108] Of eleven Japanese patients with GSS, all had leucine at position 102.[109] The same mutation was also found in cases of GSS in a Jewish family.[110] Interestingly, the proline at position 102 was found to be conserved in various species, which might point to an important role in the biological function of this protein (Figure 10). A rather unusual mutation within *Prn-p* was published in 1993 by a Japanese research group led by Tateishi: In one patient they found that codon 145, which normally encodes for tyrosine, was substituted by a stop-codon.[111] Accordingly, the amyloid plaques of this patient, who had initially been diagnosed for Alzheimer's disease, were analyzed to contain C-terminally truncated PrP fragments. These fragments thus lack elements of PrP thought to be important, such as glyscosylation sites, a disulfide bond, and a GPI-anchor (see Figure 3). According to recent investigations, however, it seems that the normal allele participates in the pathological process of this familial TSE form because the C-terminus of PrP could also be detected in these plaques by specific antibodies.[112]

Rather little has been published about genetic dispositions in other species. In sheep, for example, the polymorphisms at positions 136 and 171 are known to have an influence on the susceptibility to scrapie (analogously to the polymorphism at position 129 in the human gene locus). The resistance towards scrapie infection is significantly smaller in sheep with a Val136/Glu171 homozygosity than in animals with a homozygous Ala136/Arg171 genotype.[113] All these genetically determined predispositions are inheritable. With respect to the infectivity of prions, however, it is irrelevant *how* the prion disease was triggered: the prion protein from an affected brain is infectious in any case.

4.3.3. *vCJD—a Link between BSE and CJD?*

In early 1996 an English research group reported a form of CJD which had not been described until then.[114] Patients affected by the new variant ("vCJD"; by April 1997 15 patients) indeed show the usual pathological characteristics of CJD, which, however, are remarkably modified. First, with an average age of 30 years the affected patients are relatively young. Second, the average mean time from the appearance of the first symptoms to death is about 15 months, which is more than twice as long as the corresponding period in normal CJD patients. Third, the amyloid depositions or plaques show, in addition to the spongiform alterations, a characteristic morphology that had never been observed in any other case of CJD before (Figure 11). The "florid plaques" are similar to those found in Kuru patients and seem to be identical to those in Macaque apes infected with BSE.[115] These and other characteristic features (for example, lack of anomalies in the EEG of vCJD patients, homozygosity for Met129) argue for a manifestation of a new

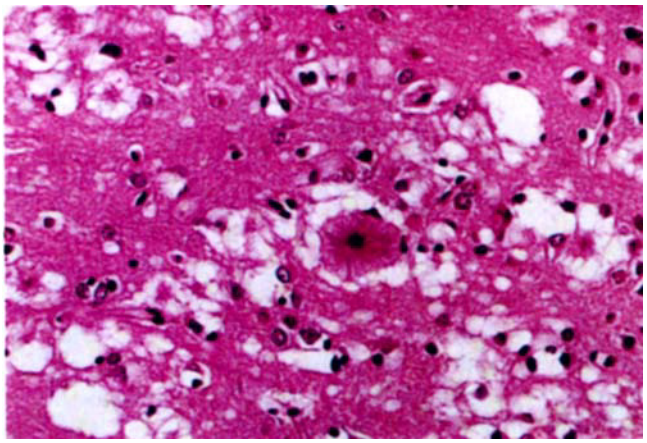

Figure 11. Thin section of the brain of a patient who died of vCJD. An especially remarkable pathological change of vCJD is the formation of florid plaques, which are surrounded by a concentric zone of spongiform changes. This picture was kindly made available by J. Ironside, University of Edinburgh.

TSE strain in humans, possibly in a direct connection with the BSE epidemic in England. Almost all vCJD patients are from England, only one patient has been reported from France.[116] It is interesting to note that France had high import quota of British beef in the relevant period; thus, certainly, a large portion of potentially infected tissue came from England to France. Recent studies confirm suspicions that BSE can be transferred to humans. Collinge and his colleagues investigated the electrophoretic mobility of PrP^{res} from preparations of different TSE cases. They looked at the fraction of proteins with different degrees of glycosylation in particular (two, one, or no glycosylation; see Figure 3) and classified these "glycoform patterns" into four groups.[117] According to this classification, type 1 and type 2 represent two different forms of sCJD. Type 3 appears only in iatrogenic cases of CJD, whereas in all vCJD cases the type 4 pattern, which had never been observed in any other CJD case, was found. BSE-affected cattle as well as macaques also showed the type 4 digestion pattern, a further indication for a causative connection between BSE and vCJD. This experimentally rather simple classification of CJD patients into four groups is, however, anything but undisputed. Parchi et al. recently reported that the method described by Collinge et al. only gave two classes of PrP^{res} in their hands.[118] Moreover, Somerville et al. could show that the "glycoform pattern" of a TSE strain described by Collinge is not necessarily stable in laboratory animals. The fraction of differently glycosylated PrP^{res} shifts upon passage of the strain from animal to animal.[119]

Closer examination of the clinical signs of vCJD raises questions about its uniqueness as well. It cannot be excluded with certainty that the striking pathological characteristics of vCJD had not already showed up before the outbreak of the BSE epidemic. Since the disease appeared so infrequently, it can be assumed that not every case of CJD was unmistakably diagnosed before the sensibilization by BSE (see Section 4.4). It is quite conceivable that there were earlier cases of vCJD that were not recognized as such, because mainly younger patients are affected. Furthermore, the appearance of florid plaques as a clear morphological criterion for the discrimination between vCJD and other CJD forms is disputable. Recently a nonfamilial case of CJD could not definitely be classified as vCJD by the aforementioned criteria; nevertheless, the autopsy of the brain of the patient revealed florid plaques. As this patient had a neurological graft of dura mater a decade before, an iatrogenic transmission could not be excluded.[120]

4.4. Diagnostic Methods

The safe diagnosis of BSE in living or symptom-free cattle is of utmost interest for economics and public health. Because of the potential threat to humans by vCJD, a diagnosis in humans is, of course, of particular importance. The aim is the development of a test to determine the status of the infection quickly, preferably by using blood or urine.

4.4.1. Present Diagnostic Methods

The early diagnosis of TSEs is restricted to the appearance of the first vague clinical symptoms or EEG anomalies, as well as the use of NMR-visualizing methods or invasive brain biopsy. In the latter method a sample of brain tissue is removed, incubated with proteinase K and then tested for the presence of proteinase-resistant PrP with an antibody. In positive cases (when the sample contains PrP^{Sc}) the brain biopsy is a relatively reliable method. To date, however, a negative diagnosis in the living organism remains difficult. A reliable diagnosis is only possible post mortem, based on the aforementioned pathological changes and immunohistological status in the brain tissue. Like in many other diagnostic systems, for example the detection of HIV, the basis of a sensitive test system would be an antibody that specifically recognizes PrP^{Sc}. It has, however, not yet been possible to develop such a pathogenic isoform-specific antibody.[121, 122] The available anti-PrP antibodies cannot distinguish between the cellular PrP form in healthy organisms and the scrapie form in the affected organism. In the immunohistochemical detection of PrP from brain slices one takes advantage of the different proteinase K sensitivities of the two protein isoforms. Proteins that can be detected by a PrP antibody after treatment with proteinase K reflect the amount of PrP^{Sc} contained in the sample. However, this test is not very sensitive; in addition, the proteinase K sensitivity does not always correlate with the infectivity of a sample (Section 3.1).

4.4.2. New Diagnostic Attempts

During the last months a number of experiments were attempted, which might constitute the basis of a diagnostic test system. We would like to discuss two of them here. A Dutch group showed that the detection of scrapie-associated PrP^{Sc} in the tonsils of sheep is possible before the first clinical symptoms appear. In the examined group of six scrapie-infected sheep they detected PrP^{Sc} at the age of 10 months, about one year before the clinical manifestation of the disease.[123] Whether this technique will work in other species is questionable. For example, in contrast to sheep, no infectivity is found in peripheric tissues in

cattle; that means that by biopsy of tonsils a detection of PrP^{Sc} would not be possible in cattle. In contrast, PrP^{Sc} was detected post mortem in the tonsils of a human vCJD case, as reported recently, although in only one case.[124]

The group of Michael Harrington does not use PrP^{Sc} itself as a diagnostic basis, but a marker protein, which is contained in the cerebrospinal fluid of CJD patients. In 1986 he and his colleagues discovered by two-dimensional gel electrophoresis that two proteins (designated p130 and p131) are found in CJD patients, which might serve as diagnostic markers. [125] Recently these proteins were indentified as degradation products of 14-3-3 proteins, and antibodies directed against them were sucessfully used in an immunoassay for CJD diagnosis.[126] Cerebrospinal fluid is taken from the spinal cord of the patients and tested for the presence of the 14-3-3 protein by SDS-gel electrophoresis and immunoblot. The required antibody can be purchased, and the test can be carried out in every biochemistry lab within a few hours. Nevertheless, this test system has a few disadvantages: the appearance of the 14-3-3 proteins is an epiphenonemon, that is, besides CJD other diseases like herpes simplex encephalopathy lead to an increased occurrence of 14-3-3 protein in the cerebrospinal fluid. The specifity in the examined group of 71 patients was therefore only 88%. The results of the application of the test in cattle were barely conclusive: only a few animals have been tested to date, and moreover, these were not infected with BSE, but with TME. This experiment revealed higher specifity concomitant with decreased sensitivity—only six of nine infected cattle were diagnosed correctly. Finally, hitherto existing data indicate that the test works only at a relatively late stage of the disease, probably not before the first clinical symptoms appear. An effective diagnostic system should respond as soon as possible after infection, so that infected cattle can, for instance, be withdrawn from the market before the epidemic can spread further.

5. Transgenic Models

In many fields of biochemisty the establishment of transgenic animal models is widely accepted for the study of molecular-biological and pathophysiological problems. Also in the case of the research into prion diseases, transgenic mouse lines led to important breakthroughs and results. One of the first animal models for prion dieseases was introduced in 1990 by Prusiner's laboratory. A mouse line was produced, into whose *Prn-p* gene a point mutation corresponding to one of the human GSS point mutations (Pro 102 → Leu; Figure 10) was introduced. As a consequence of this changed mouse genotype, it spontaneously developed neurological malfunctions, spongiform changes, and gliosis of astrocytes in the brain[127]—the three classical characteristics of transmissible encephalopathies. It had thus been possible for the first time to produce a genetically determined prion disease in mice. This neurodegeneration, induced by mutation, is hard to distinguish from experimental murine scrapie. One variation, however, is seen in these samples, which have been prepared from brains of the affected transgenic mice: they are only weakly infectious, if at all.[128] Nevertheless the transgenic "GSS mouse" not only was an important support for the protein-only hypothesis, it simultaneously opened up the exciting possibility of transfering experimental TSE studies from other species to mice. With the help of such transgenic mouse lines it is possible, for example, to examine species barriers.

5.1. Investigations of the Species Barrier

The transmission of spongiform encephalopathies from one species to the other happens, if at all, very inefficiently and with severely prolonged incubation periods. For example, when a mouse is inoculated with an infectious sample from hamster, the mouse stays alive for more than 500 days, whereas an infectious mouse sample, on average, leads to death after 140 days (Figure 12A,B). Similarly, if one tries to infect hamsters by infectious mouse preparations the hamsters survive more than 360 days, in contrast to a lifetime of 75 days after use of hamster prions (Figure 12C,D). This means that mice can be infected by hamster prions only poorly or not at all and vice versa. This species barrier seems to be caused by the different primary structures of prion proteins of the particular species;[129] the mature forms of hamster and mouse PrP, for example, differ from each other in 12 amino acids (Figure 13). In the sense of the protein-only hypothesis this means that hamster PrP^{Sc} has a much smaller influence on the conversion of mouse PrP^{c} than mouse PrP^{Sc} and vice versa. What happens if a transgenic mouse, which expresses hamster PrP^{c}, is inoculated with hamster PrP^{Sc}? The infection indeed proceeds with an incubation period of only 75 days;[130, 131] regarding scrapie susceptibility the transgenic hamster-PrP mouse responds like a hamster itself (Figure 12E).

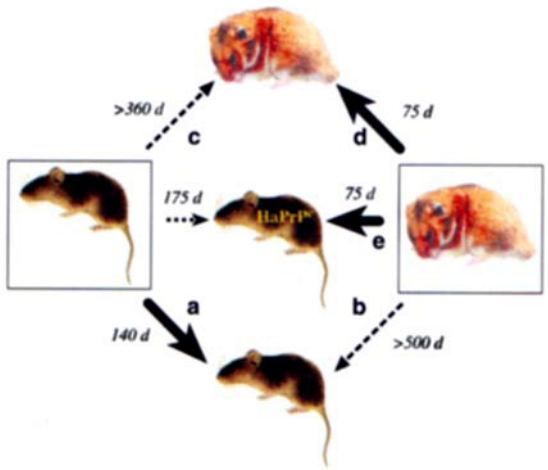

Figure 12. Species barriers and their conquest by the transgenic animal model. a) Mice inoculated with mouse-prions die, on average, after 140 days. b) Most mice survive the inoculation with hamster prions by more than 500 days in good condition. This species barrier between mouse and hamster can also be observed if hamsters are used as test animals: c) Hamsters infected by mouse prions survive, on average, longer than 360 days, whereas d) they die after 75 days if hamster prions are used for inoculation. e) The species barrier can be overcome if a transgenic mouse that expresses hamster PrP^{c} is inoculated by hamster prions. (Based on data from refs. [130, 131] and modified according to reference [150].)

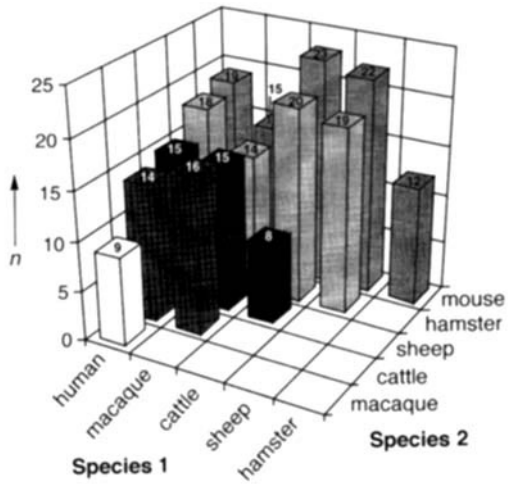

Figure 13. Deviations in the primary sequences of the mature form of PrP in selected species. The height of the columns represents the number of deviations (mutations) in the pair of species compared. The shorter a column, the more similar the PrP amino acid sequences of the two species. Whether the number of deviations between two species correlates with the extent of the species barrier is not yet clear. For clarity, the columns are drawn in different grey shades. (Based on data from ref. [129]).

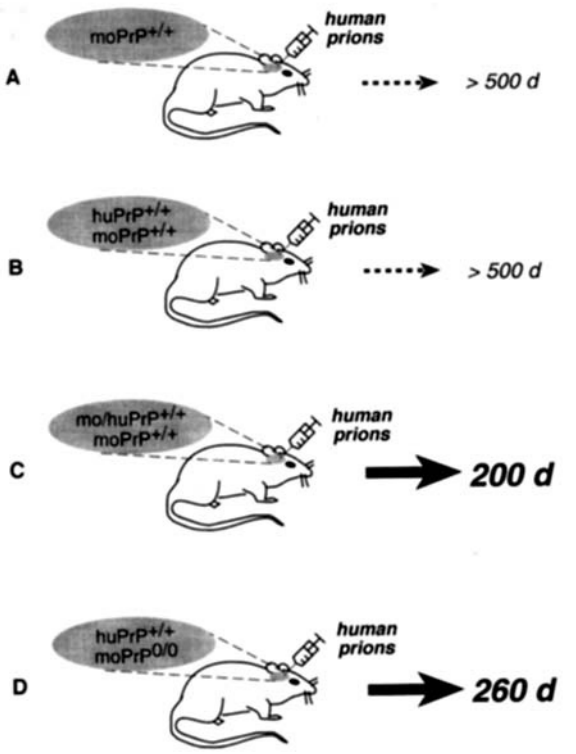

Figure 14. Inoculation experiments on transgenic mice with human prions. The genotype of the transgenic mice is symbolized by ellipses, which represent the brains: moPrP = mouse PrP, huPrP = human-PrP, mo/huPrP = PrP made of human amino acids 96–167 and the murine N- and C-terminus. A) A high species barrier exists between humans and mice: most animals survive the inoculation with human prions for more than 500 days. B) Surprisingly, the introduction of human PrP does not overcome the species barrier. C) Infection of mice by human prion material is only possible if a chimeric human–murine transgene is used. D) Mice are infected as well, if they are both transgenic for human PrP, and their mouse-PrP is switched off by knockout techniques. (Based on data from refs. [81, 82].)

5.2. The Cofactor for Prion-Propagation: Chaperoning the Prion?

Today the transgenic mouse model provides the most effective experimental possibility for analyzing species barriers in prion diseases. This model is especially suitable for examination of infection pathways to humans. Because of the species barrier, inoculation of mice with CJD material led to infection in only 5–10% of the animals after more than 500 days (Figure 14A).[81] Unexpectedly the scrapie susceptibility does not change, if transgenic human-PrP mice are used (Figure 14B). Only on introduction of a chimeric PrP, which is constructed from murine and human sequences (amino acid 96 to 167 of human, N- and C-terminus of mouse), can the transgenic mouse be made susceptible for CJD material (Figure 14C).[81] Prusiner et al. concluded from this observation that still other species-specific factors must be involved in prion propagation. This assumption was supported by the following experiment with transgenic mice: transgenic human-PrP mice can become sensitive towards CJD by knocking out the mouse-PrP (Figure 14D):[82] mice that express human PrP besides their own mouse PrP are protected against infection with human CJD material, whereas mice that express human PrP alone can be infected with CJD samples. Prusiner et al. deduced from these results the existence of a species-specific factor, which he designated as "protein X". Protein X should therefore interact preferentially with the own PrP of the species and is required for the conversion. In the transgenic mouse murine PrP competes with the human PrP^c for binding to protein X, which preferentially binds murine PrP^c, with the result that no conversion of human PrP^c is possible. Only if the mouse PrP^c is knocked out as binding partner, can protein X bind to the less preferred human PrP^c and convert it, supported by the human PrP^{Sc}.

The not yet identified protein X might act as a molecular chaperone, which lowers the activation energy for the refolding of PrP and therefore facilitates the process of conversion. Molecular chaperons are highly conserved proteins, which are involved in the folding of proteins within cells.[132] Unexpectedly, a model organism for interactions of chaperones and prion proteins was found in yeast. Although baker's yeast *Saccharomyces cerevisiae* does not express prion proteins, it contains two genetic elements that can reproduce themselves without the participation of nucleic acids: [URE3] and $[PSI^+]$.[133] $[PSI^+]$ is a prion-like aggregation of the cellular yeast protein Sup35 and replicates in yeast depending on the presence of a chaperone (Hsp104).[134] Already formed $[PSI^+]$ induces newly synthesized Sup35 to aggregate as well.[135] An attempt was made to transfer these results to prion propagation in mammals. An interaction of hamster PrP^c with a molecular chaperone (Hsp60) was indeed discoverd by applying the "Two-Hybrid" technology.[136] Experiments with scrapie-infected neuroblastoma cells in cell culture indicate that "chemical chaperones" (for example, DMSO or glycerine) might have an influence on the formation of PrP^{Sc}.[137] The final proof that a direct interaction of PrP with molecular chaperones is involved in the pathogenesis of TSE in mammals, however, is still missing.

5.3. Prion Knockout Mice

5.3.1. PrP^c is Necessary for Infection with Scrapie

The development of a mouse line in which the *Prn-p* gene is turned off was interesting in two respects. On one hand, one wanted to obtain clues for the regular biological function of PrP^c: if a specific deficiency of this $PrP^{0/0}$-mouse had been observed, conclusions might have been able to be made about the role of the missing prion protein. On the other hand, the $PrP^{0/0}$-mouse provided proof of the protein-only hypothesis. An important consequence of this hypothesis is that no propagation of PrP^{Sc} is possible in hosts which lack PrP^c and therefore the $PrP^{0/0}$-mouse would be resistant to infection with PrP^{Sc}. The $PrP^{0/0}$-mouse line developed in Weissmann's laboratory was indeed found to be resistant to scrapie infection, whereas wild-type mice under the same treatment develop the disease and die on average 140 days after inoculation.[33] In heterozygous *Prn-p*$^{0/+}$-mice the incubation period is prolonged to about 290 days; these animals are thus partially protected against scrapie infections. Therefore, the incubation period correlates with the amount of PrP^c which is expressed in the mouse brain. An important control experiment confirmed these results: the reconstitution of the *Prn-p* gene in *Prn-p*$^{0/0}$-mice led to the restoration of the susceptibility to scrapie. By introducing several copies of the *Prn-p* gene a mouse line was obtained, which overexpressed PrP^c and was, as expected, even more susceptible to scrapie infections. These mice showed a markedly reduced incubation period (60 days) relative to that of the wild-type mouse.[63]

In a collaborative effort the groups of Aguzzi and Weissmann applied another method to reintroduce the prion protein into knockout mice. Hereby, brain tissue from PrP^c-overexpressing mice was transplanted into PrP knockout mice, and these mice were used in infection studies.[138] After intracerebral inoculation with scrapie samples, the grafts showed high amounts of PrP^{Sc} together with infectivity, as well as other pathological changes characteristic for TSE. Furthermore, measurable amounts of PrP^{Sc} had gotten from the graft into the brain of the host. Nevertheless, there were no pathological changes observed in the PrP-deficient tissue—not even within the immediate surroundings of the graft. The authors concluded from these results that exogenous PrP^{Sc} does not lead to damage of the brain tissue. In contrast, PrP fragment 106–126 is toxic to neurons cultivated in vitro.[139] In the laboratory of Hans Kretzschmar, Institute for Neuropathology at the University of Göttingen, this neurotoxic effect was thoroughly analyzed. It was shown, for example, that neuronal cells of PrP-null mice did not die off in the presence of PrP 106–126.[140] This result constituted another proof that the presence of PrP^c is important for the pathogenesis of prion diseases.

5.3.2. Biological Function of PrP^c

The production of knockout cell lines has turned out to be very effective for clearing up the unknown biological function of a protein.[141] Unfortunately, the relationship between the cause (the knocked-out gene) and the effect (the phenotype) often cannot clearly be verified or has to be traced back to unspecific effects. This exactly seems to be the problem in current prion research. The PrP-knockout mouse introduced by the Weissmann group develops completely normally until the age of two years and does not show any pecularities in behavior or neurological malfunctions.[33, 142] Electrophysiological examinations performed by Collinge and co-workers led to the discovery of neuronal defects in the inhibition of synaptic $GABA_A$ receptor[36] (GABA = γ-aminobutyric acid, a neurotransmitter). This observation might explain the pathological effects resulting from the loss of functional PrP^c, but could not sufficiently be reproduced in another laboratory.[143] The reason for such a discrepancy in observation of a phenotype might be attributed to the different genetic background of the mouse strains used. Species can react to the knockout of a particular protein with increased expression of other proteins, which might compensate for the knockout under certain circumstances. The genetic background of the organism is thought to play a crucial role in such compensating effects. Different mouse sublines might therefore react differently to the knockout of PrP-expression,[144] which might explain the observed discrepancies.

In addition, another effect might have to be considered. Three research groups have reported on different phenotypes of PrP-knockout mice in the interim. Each of these knockout lines was developed by different targeting strategies. This resulted in minute differences in the genome of the knockout mouse in the vicinity of the knocked-out gene, which might be responsible for the observed deviations of the phenotype as well. For example, in the knockout mouse from the Weissmann laboratory the method chosen left part of the PrP-coding gene in. A Japanese group, on the other hand, inactivated the whole *Prn-p* gene and reported massive behavioral and neuropathological impairments in this mouse line.[37] These mice had a very insecure movements; in contrast to the wild-type they were unable to follow a straight line. The reason seemed to be the loss of Purkinje cells in the cerebellum. Purkinje cells express huge amounts of PrP and use GABA as a neurotransmitter, which might be the link to the results of the Collinge group. Tobler and co-workers recently observed a changed circadian rhythm and sleeping disorders in PrP-deficient mice.[38] This phenotype is interesting in so far as it resembles the symptoms of the human FFI (see Section 4.3). Here might be a connection to GABA as well, because GABA receptors are thought to be involved in the regulation of the circadian rhythm.[145] To confirm the specificity of the observed effects they should be neutralized by the expression of PrP^c. Moreover, isogenic mice should be used for the development of knockout lines. It therefore remains to be seen whether a clear relation between cause and effect can be found for some of the promising approaches. Because in most cases physiological effects are mediated by protein–protein interactions, the study of interaction of PrP with other cellular proteins might prove quite helpful.

6. Open Questions

According to current understanding the pathogen of the transmissible spongiform encephalopathies (TSE) is a protein

that does not require a nucleic acid for infectivity and propagation. Proof of the protein-only hypothesis by the de novo generation of infectivity in vitro after incubation of PrP^c with PrP^{Sc} is still missing. The conversion of host PrP^c into the pathogenic PrP^{Sc} seems to be the central event in the propagation of TSE. It is possible that other not yet identified cofactors take part in this process, for example a "prion receptor" or other proteins or molecules, which interact with the prion protein. It is therefore important to identify possible prion–protein interactions and to examine whether they influence the conversion of the cellular into the scrapie isoform.

Both isoforms of the prion protein differ only in their conformation as determined by CD and IR spectroscopy. Whether differences in the three-dimensional structure of different prion strains exist within one species is not clear but has to be postulated, because of the present state of knowledge, to explain certain strain-specific characteristics of prion propagation. Therefore, structural studies are in the center of research efforts to shed light into the replication mechanism of prions. The structure of a mouse PrP^c fragment identified by NMR shows the expected extended α-helical regions besides two smaller antiparallel β-sheets, which might serve as a seed for the development of β-sheet structures in PrP^{Sc}. Whether the structure of the amino-terminally truncated fragment really contains all the important domains required for the prion replication remains to be seen. Structural elucidations of PrP^{Sc} have also still not been achieved because of the difficulties connected with the low solubility of the protein.

The cell-free in vitro conversion of proteinase K sensitive PrP^c into proteinase K resistant protein material was an important step in prion research, especially with respect to the current models for prion propagation. Although the conversion is strain-specific, it proceeds relatively ineffectively and can currently be achieved only on use of a surplus of PrP^{Sc}. Whether the in vitro converted material is not only proteinase K resistant but also infectious cannot be answered yet. This question is of highest relevance for the verification of a hypothesis for prion propagation.

PrP-knockout mice are not susceptible to TSE and otherwise do not show any noticeable phenotype. The prion protein itself seems to be of no immediate benefit for the organism; the observations of the three different knockout cell lines, however, are contradictory. Maybe PrP^c participates in synaptic processes. The identification of PrP–protein interactions might suggest functional relationships in this context. The transmission of TSE is affected by species barriers, which are manifested, for example, in extended incubation periods. The reasons for the barriers are thought to be the slight differences in amino acid sequences, which result in structural differences of prion proteins of individual species. The central question whether BSE can be transferred from cattle to humans cannot be examined directly. Macaques, however, can be infected by infectious BSE material accompanied by the development of not previously observed histological characteristics. These novel pathological changes seem to be identical with those of a new variant of Creutzfeld–Jakob disease (vCJD) in humans, which appeared in England just recently. A causal relation between the BSE epidemic and this new form of TSE in humans is quite probable.

7. Concluding Remarks

"It struck me recently that one should really consider the sequence of a protein molecule, about to fold into a precise geometric form, as a line of melody written in canon form and so designed by nature to fold back upon itself, creating harmonic chords of interaction consistent with biolgical function. One might carry the analogy further by suggesting that the kinds of chords formed in a protein with scrambled disulphide bridge, ... are dissonant, but that, by giving an opportunity for rearrangement...they modulate to give the pleasing harmonics of the native molecule. Whether or not some conclusion can be drawn about the greater thermodynamic stability of Mozart's over Schönberg's music is something I will leave to the philosophers of the audience."

C. Anfinsen in *New Perspectives in Biology* (Ed.: M. Sela), Elsevier, New York, pp. 42–50.

In Anfinsen's visionary world of harmony between sequence and structure, dissonant overtones entered not only because of the results of the prion research. Experiments which were carried out with the denatured enzyme "Rubisco" (Ribulose bisphosphate carboxylase oxygenase) showed that a spontaneous renaturation into the correct structure merely by dilution with the renaturating buffer is not possible. The correct refolding can be achieved only in the presence of the chaperonin GroEL.[146] Citrate synthetase from the mitochondria of pig hearts tends to self-aggregate if the enzyme is denaturated in guanidinium hydrochloride solution and is then diluted again.[147] These and other examples show that not all proteins spontaneously fold into the thermodynamically most stable conformation, because, for example, they might be caught in a kinetic trap during the course of folding. Such proteins do indeed fold in Anfinsen's sense, but only within a protective environment.[148]

If the protein-only hypothesis is correct, the situation seems to be different for the prion protein. It can exist in at least two, maybe even more, metastable structural states.[149] The prion protein is the prototype of a structure-labile protein. By a relatively slight trigger, such as a single mutation in the *Prn-p* gene or contact with the smallest amounts of the incorrectly folded isoform, this lability is manifested in the refolding of the normal isoform. The change of one structure into the other has dramatic consequences for the organism. The understanding of "prions" and their characteristics is proceeding very rapidly—this review describes the most important progress achieved until April 1997 (a deadline we imposed on ourselves, otherwise we would not yet have completed the article because of the breathtaking development of this research field). Nevertheless, we are far from understanding the function and characteristics of this partly frightening and partly fascinating protein.

We thank H. Schätzl for critical reading of the manuscript. We are grateful to R. Glockshuber and K. Wüthrich for providing us with a picture of the NMR structure of PrP, to J. Ironside and H. Kretzschmar for the images of histological thin sections, to H. Kretzschmar and G. Ourisson for helpful discussions, and to the Deutsche Forschungsgemeinschaft and the Bundesministerium für Bildung, Forschung, Wissenschaft und Technologie (BMBF) for financial support.

Appendix 1. Glossary of the most important abbreviations and medical terms.

amyloid	pathological deposition of proteins
AA	amino acid(s)
BSE	bovine spongiform encephalopathy
CD	circular dichroism
cerebrospinal fluid	lymphoid liquid present in the medulla; secreted by the brain
chaperones	proteins that are involved in folding of cellular proteins
CJD	Creutzfeldt-Jakob disease
EEG	electroencephalogram
FFI	fatal familial insomnia
GABA	γ-aminobutyric acid
glia cells	cells of the connective tissue of the central nervous system
gliosis	pathological proliferation of glia cells
GPI	glycosyl phosphatidylinositol
GSS	Gerstmann-Sträussler-Scheinker syndrome
Octa-repeat	repeating motif of eight glycine/proline-rich AA, characeteristic for PrP
polymorphism	differences in the genotype within a single population that cannot be explained by naturally occurring mutation rates alone
prion	abbreviation for proteinaceous infectious particle
PrP	prion protein
PrP27-30	fraction of proteins truncated at the N-terminal that have an electrophoretic mobility of 27-30 kDa
PrP^{c}	cellular isoform of PrP
PrP^{Sc}, PrP^{res}	pathogenic isoforms of PrP
Purkinje cells	huge dendritic ganglial cells in the mid-layer of the cerebellum cortex
spongiosis	spongelike alteration in tissues
TSE	transmissible spongiform encephalopathy

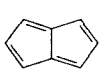
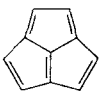
Pentalene as a Complex Ligand: New Developments in the Chemistry of Nonalternant, Highly Unsaturated Hydrocarbons

Holger Butenschön*

Compounds with annelated five-membered rings (oligo- or polyquinanes)[1,2] have generated a great deal of interest in organic chemistry under a variety of aspects. Natural products like triquinanes,[3] coriolin, hirsutene, and pentalenes or the tetraquinanes of the crinipellin-type[4] are nowadays considered classics in the biologically orientated polyquinane chemistry, while topologically remarkable compounds like dodecahedrane,[5-8] centrohexaindane,[9] or fenestrane[10,11] fascinate many chemists, who are interested in the synthesis, structure, and properties of these unusual compounds. A special role is played by the completely unsaturated compounds like pentalene (**1**) and acepentalene (**2**), whose π-electron systems are of fundamental interest with respect to the aromaticity of nonalternant unsaturated hydrocarbons.

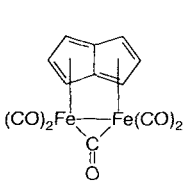


1



2

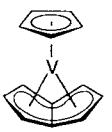
In accord with theoretical calculations[12-17] it was shown in the last twenty five years that **1** and **2** are unstable under normal conditions. De Mayo et al. and Hafner et al. prepared pentalene derivatives stabilized kinetically by substituents,[18-23] and in 1973 Hafner et al. were able to demonstrate the existence of the unsubstituted pentalene.[19] Recently de Meijere et al. reported on the identification of acepentalene (**2**) by mass spectrometry.[17] To stabilize the two compounds two further possibilities were considered: Firstly **1** and **2** could be stabilized as complex ligands in a similar way to the stabilization of cyclobutadiene as a tricarbonyliron complex forty years ago. Secondly the dianions formed by reduction of **1** and **2** should be more stable than the neutral compounds.[16,24] If the formation of such dianions, which were considered to be aromatic, were successful, they would be expected to readily undergo complexation.



3

In 1973 Hafner et al. successfully prepared the metal complex **3** of the unsubstituted pentalene (**1**) by reaction of the [2+2] dimer of **1** with $[Fe_2(CO)_9]$.[25] A substituted derivative had been prepared earlier starting from the corresponding dihydropentalene.[26] The pentalene dianion ($\mathbf{1}^{2-}$) has been known for a longer time than pentalene (**1**) itself. It was synthesized in 1962 by Katz et al. by treatment of a dihydropentalene with butyllithium,[27,28] and was also used as a ligand in some transition metal complexes.[26,29-31] The structure determined for the $\mathbf{1}^{2-}$ is planar and is in accord with that from calculations.[24] In the previously known metal complexes pentalene acts as a bridging ligand between two late transition metals.

Now Jonas et al. have reported in two remarkable publications from the Max-Planck-Institut für Kohlenforschung in Mülheim an der Ruhr on a totally new mode of complexation of the pentalene dianion in which all eight carbon atoms are coordinated to only *one* metal atom.[32,33] The authors present thermally stable and sublimable vanadium complexes of type **4**, which were prepared by treatment of $\mathbf{1}^{2-}$ with a variety of vanadocene monohalides. As expected from earlier studies this reaction proceeds with elimination of a halide and a cyclopentadienyl ligand from the vanadocene derivative. The 10 electrons that the resulting cyclopentadienylvanadium(III) fragment requires to achieve the 18-electron configuration are provided by the pentalene dianion $\mathbf{1}^{2-}$. As expected, the mononuclear pentalene vanadium complexes are obtained in high yields as diamagnetic compounds. In addition to the unsubstituted parent compound **4** the corresponding pentamethylcyclopentadienyl and indenyl complexes were prepared as well as the complex analogous to **4** bearing the 2-methylpentalene dianion.[34]



4

Some of the prepared vanadium complexes were characterized by crystal structure analyses. The outstanding feature of the three obtained structures is the folding of the pentalene ligand along the central carbon–carbon bond by 137°. Thus, the structure of the complexed ligand differs considerably from that of the planar pentalene dianion ($\mathbf{1}^{2-}$). The folding ensures that all eight coordinated carbon atoms have realistic bond lengths to the metal atom. If the ligand of the complex were planar, both central carbon atoms would be located rather closely to the vanadium atom, while the peripheral carbon atoms would be far away from it. Such a fundamental change in structure as a result of complexation to a metal is rare and impressively shows the variety of structural possibilities of cyclic π ligands.

The formation of complexes of the pentalene dianion $\mathbf{1}^{2-}$ is not restricted to the element vanadium. The authors have also

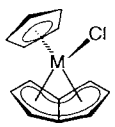
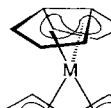
5



6: M = Ti
7: M = Zr

prepared interesting titanium, zirconium, and hafnium complexes starting from the corresponding cyclopentadienylchloro complexes.[33] For instance, the halide-free titanium complex **5** was prepared by reaction of $[CpTiCl_2]$ with $\mathbf{1}^{2-}$. Oxidation with 1,2-dichloroethane with loss of ethene leads to the Ti^{IV} complex **6**. The analogous zirconium complex **7** was synthesized directly by treating $\mathbf{1}^{2-}$ with zirconocene dichloride.

The homoleptic pentalene complexes **8**, which were obtained by treatment of **6**, zirconocene dichloride, or hafnocene dichloride with $\mathbf{1}^{2-}$, are of special interest. Moreover, it was possible to synthesize the corresponding dimethyl-substituted titanium complex **9**. Complexes **8** and **9**, which have still to be characterized by X-ray crystal structure analyses, are diamagnetic 20e complexes. The pseudotetrahedral coordination geometry was determined by comparative ^{13}C NMR studies of **8** and **9**. Temperature-dependent studies show that **9** has two distorted tetrahedral conformers that differ in terms of the distances between the methyl groups. In view of the 20e configuration it is evident that **8** (M = Zr) loses one of the pentalene ligands readily: Treatment with one equivalent of $[ZrCl_4(thf)_2]$ affords two equivalents of the distorted octahedrally coordinated 18e complex $[(C_8H_6)ZrCl_2(thf)_2]$ (**10**) in high yield.



8 (M = Ti, Zr, Hf)

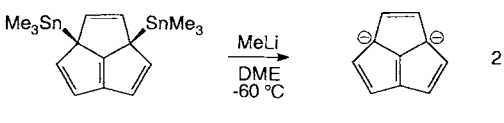
10

The fascinating results of the organometallic chemistry of pentalene (**1**) presented here lead to the question whether and to what degree does the above-mentioned acepentalene (**2**) behave analogously. Dihydroacepentalene complexes were synthesized by de Meijere et al. in 1983.[35, 36] The acepentalene dianion ($\mathbf{2}^{2-}$) was prepared by treating triquinacene in form of its potassium salt, which could not be separated from impurities, with superbases.[37] However, a short time ago the distannylated dihydroacepentalene **11** was prepared and purified by sublimation.[38] Subsequent metalation with methyllithium in dimethoxyethane (DME) at −60 °C afforded $\mathbf{2}^{2-}$ in the form of the lithium salt. The X-ray crystal structure analysis of the DME adduct shows that each DME-solvated lithium ion is located at opposite faces of the acepentalene dianion. In contrast to $\mathbf{1}^{2-}$, $\mathbf{2}^{2-}$ is not planar, but, in accord with calculations, exists in a shell-like structure with a convex and a concave surface. The chemical and structural analogy between $\mathbf{2}^{2-}$ and the ligand in the complexes **4**–**9** reported by Jonas et al. suggest that $\mathbf{2}^{2-}$ could function as ligand in transition metal complexes. Preliminary results indicate that this is indeed possible.[39]



11 **2^{2-}**

The scope of the organometallic chemistry of compounds with annelated five-membered rings has been considerably broadened by the work reported here. One eagerly awaits new developments in this interesting field between organic and inorganic chemistry. Besides the synthesis and structural characterization of these complexes there is enormous interest in the chemical reactivity, especially in terms of their suitability for catalyst systems. It appears quite fitting that in the institute, in which a chapter of chemistry history was written 40 years ago with the discovery of the Ziegler catalysts, the idea of using the new pentalene complexes as zirconocene-analogous components of modern Ziegler catalyst systems is now being pursued.

[34] According to IUPAC the anion 1^{2-} should be named dihydropentalendiide; it is obtained by double deprotonation of a dihydropentalene. The anion 1^{2-} can also be obtained from pentalene by double electron transfer and may therefore be named as pentalene dianion. In the original publications the authors prefer the graphic representation of 1^{2-} as a dianion or as a complex ligand with a formula with a closed cycle in either one of the five-membered rings. The pentalene ligand is a 10e ligand in the complexes **4**–**10**, therefore **4** should be considered as a V^{III} complex.

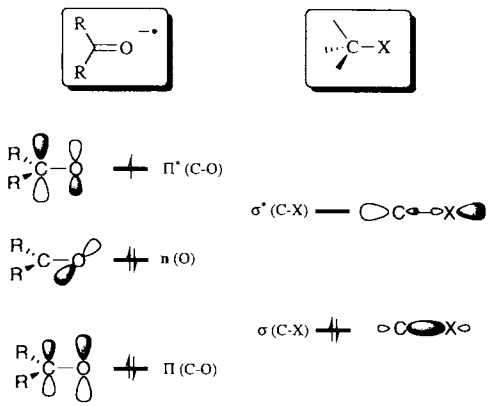
Electron-Transfer Transition States: Bound or Unbound—That is the Question!

Hendrik Zipse*

The breathtaking advances realized in the field of computational quantum chemistry within the past two decades have made it possible to reliably predict transition state structures for most reaction types in organic chemistry. The focus of controversy has moved from the characterization of typical organic reaction mechanisms, such as pericyclic reactions,[1] to more complex issues, such as reaction mechanisms in organometallic chemistry[2] or the detailed description of solvent effects. In light of this development it is quite surprising that little structural detail is available for the most elementary reaction step in chemistry, the exchange of electrons between two reaction partners. It was only recently realized that transition states for electron-transfer reactions might also have definitive structural requirements.[3] Traditionally, electron-transfer (ET) reactions were qualitatively discussed in terms of outer-sphere and inner-sphere ET.[4] These terms were originally coined for classifying ET reactions between transition metal complexes, which either occur without breaking metal–ligand bonds (outer-sphere ET) or with concomitant cleavage/formation of metal–ligand bonds (inner-sphere ET).[5] Implicit in this categorization is the assumption that little interaction exists between the electron donor and acceptor in transition states of outer-sphere ET reactions, whereas the converse is true for inner-sphere ET reactions. Exactly this assumption was challenged by Eberson and Shaik through application of the valence-bond curve-crossing model (VBCM) to thermal ET reactions in open-shell systems.[3] According to this qualitative model transition states for dissociative electron transfer between radical anions and alkyl halides is stabilized by maximum overlap between the donor SOMO (singly occupied molecular orbital) and the alkyl halide LUMO (lowest unoccupied molecular orbital), whereas the most dominant interaction for the competing S_N2 transition state is that between the donor π HOMO (highest occupied molecular orbital) and the alkyl halide LUMO. For the combination of ketyl radical anions and alkyl halides, the corresponding orbitals are shown in Scheme 1. The most important consequences of this are the following: a) Optimization of bimolecular orbital overlap is important for transition states of formal outer-sphere electron transfer. If not prohibited by steric effects, transition states for electron transfer should be bound more strongly than either the reactant or the product complexes. b) Different selection rules apply for transition states of electron transfer and nucleophilic substitution.



Scheme 1. Frontier molecular orbitals of ketyl radical anions and alkyl halides.

It already becomes apparent at this stage that the terms of inner- and outer-sphere electron transfer alone are not well suited for discussing mechanistic details in electron-transfer processes, as they do not describe the nature of the transition states involved. In general electron-transfer transition states might be characterized as "bound" or "unbound"; the latter describes a situation in which only weak interactions exist between the reactants, whereas for the former the electron donor and acceptor are in intimate contact in the transition state. Therefore, ET reactions might be of the unbound, outer-sphere type involving weakly bound transition states and avoiding formation of bound intermediates or products, or they might be of the bound, outer-sphere type in which formation of bound intermediates or products is again avoided, but the more compact transition state

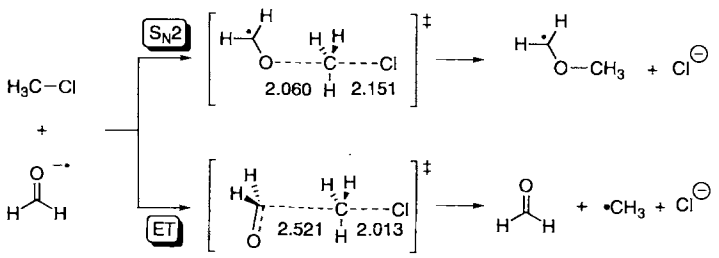
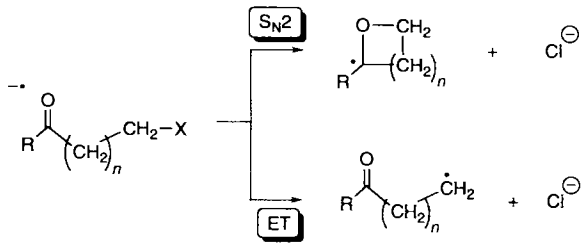
has a defined structure. An upper limit of 1 kcal mol^{-1} of electronic interaction energy is commonly assumed for unbound, outer-sphere ET transition states.[3] The distinction between unbound and bound transition states is of less importance for inner-sphere ET reactions, as basically all reactions leading to bond formation will have bound transition states. This leaves us with three categories for the classification of ET transition states: "unbound, outer-sphere ET", "bound, outer-sphere ET", or "bound, inner-sphere ET".

Can the VBCM predictions of Eberson and Shaik be verified? One of the smallest model systems amenable to quantum mechanical studies is the reaction of the formaldehyde radical anion with methyl chloride (Scheme 2).[6] The results obtained are



Scheme 2. Pathways for nucleophilic substitution and dissociative electron transfer in the reaction of formaldehyde radical anion and methyl chloride [UMP2(FC)/6 – 31+G*].

in complete agreement with the qualitative predictions of the VBCM model. The structure of the S_N2 transition state leading to the O-alkylation product is similar to that computed for other nucleophiles. The formaldehyde radical anion is oriented such that one of the carbonyl-group lone pairs points towards the methyl halide carbon atom. The transition state for electron transfer is distinctly different from that for the S_N2 alternative: the carbonyl carbon atom now aims towards the methyl group in CH_3Cl, and the distance between donor and acceptor is about 0.5 Å larger. The barrier for the electron-transfer process amounts to +5.3 kcal mol^{-1} relative to a complex of the reactants at the QCISD(T)/6 – 31+G(d)//UMP2/6 – 31+G(d) level of theory, and is 1.9 kcal mol^{-1} less than that for the S_N2 reaction. That both pathways involve significant binding between the two reactants is not only seen in the transition state structures but also in the activation entropies, which are negative and of comparable magnitude in both cases. These theoretical results nicely complement experimental studies by Kimura et al. on the competition of intramolecular substitution and electron-transfer processes in radical anions of benzoylhaloalkanes.[7] The product distribution obtained in these systems (Scheme 3, R = Ar) depends on the length of the chain connecting the carbonyl group and the halide carrier, the halide leaving group, and the solvent. For very short chains, such as $n = 1$, only electron transfer was observed, whereas an increase to $n = 2$ or 3 gives mainly nucleophilic substitution if chloride is the leaving group. This can readily be explained as the consequence of differing structural requirements for the transition states of the two competing processes. The connecting chain not only serves as a link between the two reactive centers, but also moderates the conformational space available for the relative orientation of these two groups. If the orientational preferences between the two groups are indeed as different as predicted by



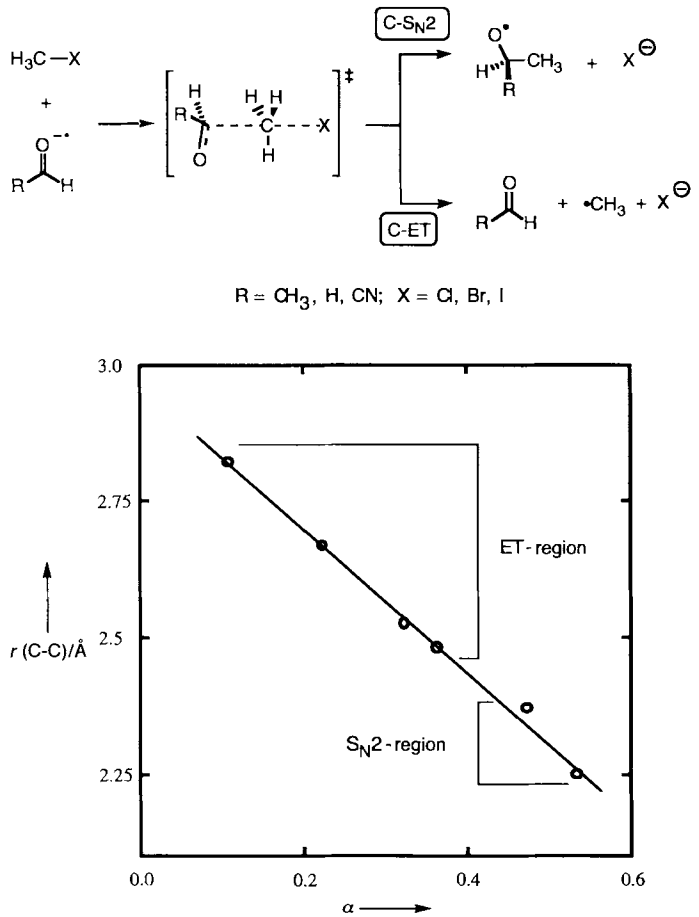
Scheme 3. Competition between intramolecular nucleophilic substitution and intramolecular dissociative electron transfer in radical anions of substituted benzoylhaloalkanes. R = H, Ar; X = Cl, Br, I; $n = 1, 2, 3$.

the theoretical model study,[6] the relative barriers for ET and substitution reactions will strongly depend on the chain length. This point was explored in more detail in another theoretical study of smaller model systems (Scheme 3, R = H, X = Cl).[8] For $n = 1$ the barrier for electron transfer is significantly lower than for nucleophilic substitution at oxygen, simply due to the fact that the ring strain is much higher in the transition state of the latter process. For $n = 2$ the S_N2 transition state can be formed much more easily, whereas the ET transition state is now burdened with excess ring strain. In agreement with experiment, the reaction now proceeds mainly by the S_N2 process. The most intriguing aspect of the experimental studies by Kimura et al. is, however, that the rate of disappearance of the initially formed ketyl radical anions correlates well with the reduction potential of the parent ketones as well as solvent polarity indicators, *irrespective* of the actual ratio between the substitution and the electron-transfer process. This observation can only be explained by assuming a *common mechanism* for both processes in the sense that fission of the C–Cl bond as well as rearrangement of the charges advance to a similar degree for both pathways.

One immediate question arising from the concept of bound outer-sphere ET transition states is whether these transition states can be bound as strongly as those of bond-forming reactions, or whether a limit exists beyond which transition state binding inevitably leads to bond formation. This question was explored in reactions of ketyl radical anion donors with methyl halide acceptors (Scheme 4).[9] Variation of the donor strength and leaving-group ability gives a series in which the reaction barrier becomes progressively larger. A mechanistic changeover from C-oriented ET to C-oriented S_N2 occurs at high barriers and short C–C distances, but all transition states can be linearly correlated with α. The parameter α is a relative measure of transition state location that, according to the Marcus equation, can be expressed as a ratio of activation- and reaction-energy contributions.[10] The clear separation between ET and S_N2 transition states illustrates that a "point of no return" exists at around 2.4 Å for the bond distance between the central carbonyl and alkyl carbon atoms. All transition states involving a C–C distance that is smaller than this limiting value lead to S_N2 products, whereas transition states with longer C–C bond distances lead to ET products. The common correlation observed for all stationary points in this study can most reasonably be explained by assuming that ET and S_N2 transition states belong to one family of related reaction mechanisms.

The discussion of bound or unbound ET transition states is, of course, not without controversy. A new theoretical study of

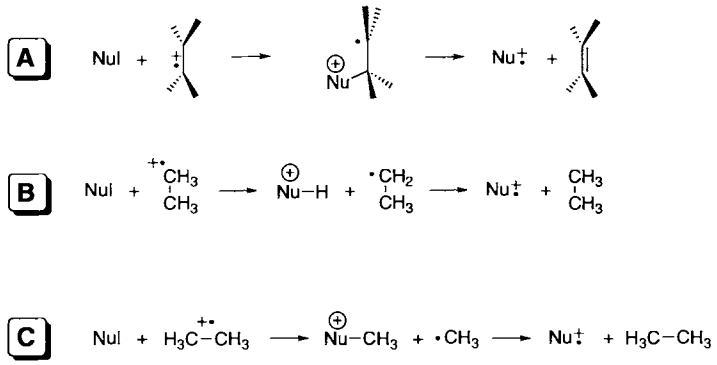
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3616-1698 $ 17.50+.50/0



Scheme 4. Correlation of the C–C bond distance in the transition state with the Marcus parameter α.

the methyl chloride/formaldehyde radical anion system by Bertran et al.[11] reports an additional transition state for electron transfer that is close to that expected for an unbound, outer-sphere ET transition state. The distance between the reactants is significantly larger in this structure, which is energetically much less favorable than the transition state for the O-alkylation pathway. A similar stationary point was found for the ET reaction of methyl fluoride and formaldehyde radical anion. Moreover, the bound ET transition state reported earlier[6] was also found in this study. However, this reaction path led to substitution products, and this stationary point has correspondingly been designated a "C-S_N2" transition state. Indeed, the situation appears to be rather delicate in that the reaction pathway leads to different products, depending on the method chosen for following the reaction. This point was reinvestigated in more detail by Shaik et al.;[12] the ET/S_N2 reaction pathway is sensitive to the coordinate system as well as the choice of wavefunction. This controversy will eventually be settled by generating the complete potential energy surface and employing more sophisticated theoretical methods. But the results obtained so far indicate a very flat potential energy surface, in which the difference between going in one or the other direction is rather small. Certainly, the actual branching ratio between the two pathways will not only depend on the reaction energetics, but on the reaction dynamics as well.

A third mechanism for electron transfer can be found in reactions of uncharged nucleophiles with radical cations of alkenes and alkanes.[13,14] In the case of the former this involves initial nucleophilic addition to the alkene radical cation and formation of a distonic radical cation (Scheme 5, type A). Homolysis of



Scheme 5. Mechanisms for inner-sphere electron transfer between uncharged nucleophiles and radical cations of alkenes (type A) and alkanes (types B, C).

the newly formed bond gives the donor radical cation and the neutral alkene as products. This sequence is a classical example for inner-sphere electron transfer between organic substrates. If the radical cation of ethane, $C_2H_6^{\bullet+}$, is used as a representative model for hydrocarbon radical cations, electron transfer to uncharged nucleophiles proceeds either through bound, outer-sphere ET transition states (for PH_3 and SH_2) or by a two-step inner-sphere process that involves stepwise transfer of $H^+/H^\bullet$ (Scheme 5, type B) or $^+CH_3/^\bullet CH_3$ (type C) redox pairs. The latter two pathways are found for NH_3 and H_2O as nucleophiles. Since the initial step of inner-sphere ET processes is simply nucleophilic attack at the hydrocarbon radical cation, we can reconfirm one major conclusion reached in the studies of anionic systems: bound transition states for outer-sphere ET and nucleophilic-substitution reactions are mutually exclusive for the same system, but both belong to the same mechanistic family in the sense that they share common structural and electronic features. Irrespective of the actual choice of ET through bound transition states, an alternative pathway also exists through unbound, outer-sphere ET transition states in these systems. This option was explored for the reaction of NH_3 and PH_3 with the ethane radical cation. In both cases the unbound transition states for outer-sphere ET are energetically less favorable than the *separated* reactants, and show a much larger distance between the two reactants (>4 Å). The pathways through unbound, outer-sphere ET transition states are thus much less attractive energetically than either of the two alternatives. In matching theoretical with experimental results it is important to consider also activation entropies, which are usually more favorable for pathways involving unbound, outer-sphere ET transition states.

Ab initio studies of small model systems predict that electron transfer cannot only proceed through the traditionally anticipated pathways involving unbound, outer-sphere or bound, inner-sphere ET transition states, but that the bound, outer-sphere ET transition state is a serious contender in many cases.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3616-1699 S 17.50+.50/0

The latter shares some of the characteristics of transition states for bond-forming reactions, such as clear stereochemical preferences and a certain proximity of the reactants. Given the dominance of ET pathways through bound transition states emanating from the theoretical studies, it appears desirable that the interpretation of experimental results proceeds under consideration of all three reaction types. The combination of complementary experimental and theoretical methods seems to be the most promising way to achieve deeper mechanistic insight into electron-transfer processes. Promising links between theoretical and experimental studies include relative activation energies and entropies of related systems as well as kinetic-isotope effects as one of the best observable descriptors of transition state structure. Even though this highlight exclusively deals with ET processes in open-shell systems, it should be noted that recent experimental results for ET processes in closed-shell substrates[15] also suggest bound, outer-sphere ET transition states. It therefore appears that the three types of ET processes described here can be used in a more general sense to categorize ET processes.

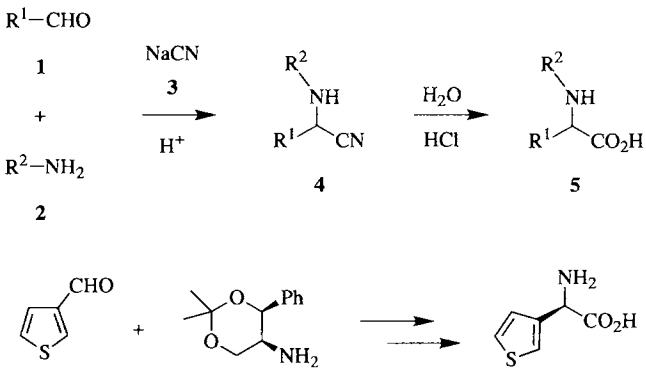
Amino Acid Derivatives by Multicomponent Reactions

Gerald Dyker*

Amino acids are one of the most important classes of naturally occurring substances and possess a variety of biological functions. The areas of application of the amino acid derivatives range from sweeteners through pharmaceuticals to crop and plant protection. Widely applicable methods for the synthesis of α-amino acids[1, 2] are of great interest especially for the construction of compound libraries by combinatorial chemistry. Multicomponent reactions as a special case of a domino process[3] are particularly fascinating since they facilitate rapid syntheses from simple building blocks.

A classic example of such a reaction is the Strecker synthesis, which has been known for almost 150 years but is still as topical as ever:[4] an aldehyde **1** (or a ketone) is condensed, using an acid catalyst, with an amine **2** and an alkali metal cyanide such as **3** to give an α-aminonitrile **4**, which can be hydrolyzed to the amino acid **5**. In recent investigations on the Strecker synthesis attempts have been made to optimize the reaction conditions[4b] and to achieve stereoselective syntheses.[4c–h] Usually chiral amines such as **7** have been employed, which can, for example, on reaction with **6** be converted to the thiophene-substituted amino acid **8**.[4c]



In Ugi's four-component condensation, imine formation from an aldehyde **1** and an amine **2** is likewise the initiating step;[5, 6] a carboxylic acid **9** and an isonitrile **10** are the other reaction components, which finally yield the bisamide **11**. Both for this reaction and the Strecker synthesis, the galactosylamine **12** is particularly suitable for carrying out a stereoselective reaction (synthesis of **13**).[4d, e, 5f] With an aminoglucopyranose as a chiral auxiliary the stereoselectivity of the reaction can be further increased.[5b] Amino acids as condensation components yield particularly impressive results. For instance, the iminodicarboxylic acid **17** can be synthesized from components **14**–**16**

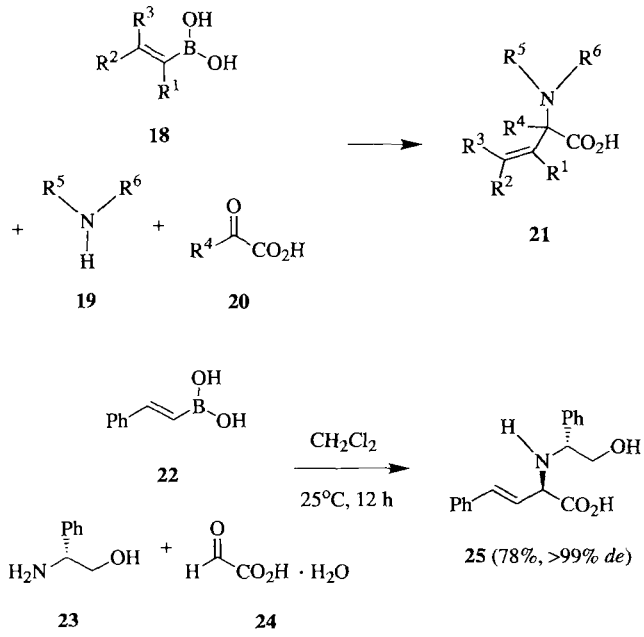
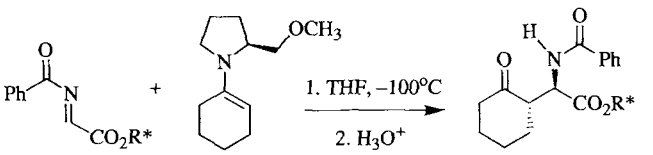
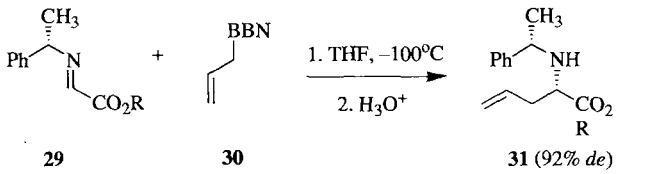
at room temperature, and obtained in excellent yield and with remarkable diastereoselectivity.[5c]

Readily available reagents were used exclusively in both the Strecker synthesis and the Ugi reaction. A convincing reaction from organometallic chemistry was a long time coming. Petasis and Zavialov now report[7a] that vinylboronic acids **18**,[7b,c] which are readily accessible and easy to handle, can participate in a three-component reaction with primary and secondary amines **19** and with α-keto acids **20**. The process, which proceeds at room temperature, leads to β,γ-unsaturated α-amino acids **21**



in good yields. The reaction of vinylboronic acid **22** with the chiral amino alcohol **23** and glyoxylic acid hydrate **24** illustrates that the reaction is not sensitive to air or humidity, can be carried out under mild conditions, and has impressive diastereoselectivity. Conceptually this new three-component reaction resembles the methods applied by Steglich, Enders et al.[8a] and Yamamoto et al.,[8b] who treated the preformed iminoesters **26** and **29** at low temperature with the electron-rich olefins **27** and **30**, respectively.[9] However, the use of boronic

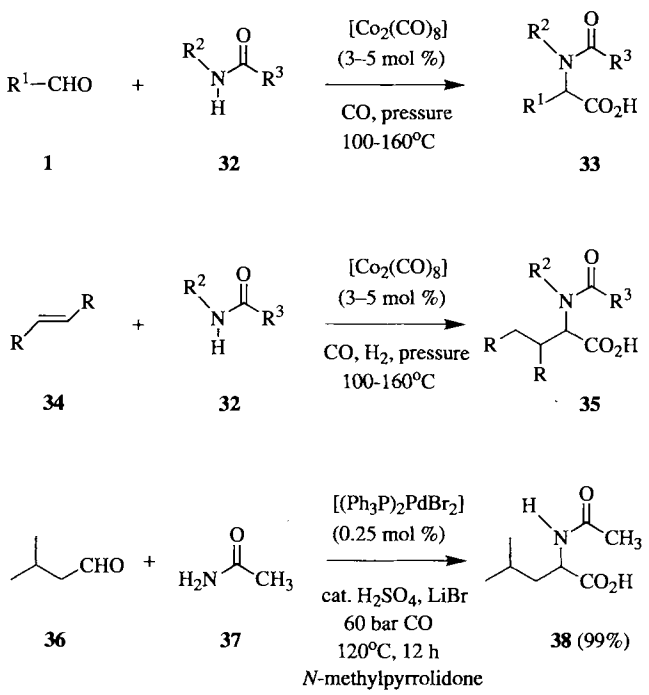




acid derivatives appears to be a versatile method with a great deal of potential. As Petasis and Zavialov note at the end of their paper unprotected amino acids and peptides, aryl boronic acids, and chiral boronates can also participate in their three-component condensation.[7a]

Transition metal catalysis also provides surprising solutions for the synthesis of amino acids by multicomponent reactions.[10] More than 25 years ago Wakamatsu et al.[11a] found that aldehyde **1** could be coupled with carboxamides **32** and carbon monoxide under pressure to give *N*-acylamino acids **33**, a process catalyzed by octacarbonyldicobalt and known as amidocarbonylation.[11b] In the presence of hydrogen the reaction conditions are suitable for hydroformylation; thus, alkenes **34** could be used in place of the aldehyde **1**.[11b] Although amidocarbonylation appears to be very favorable from an economic standpoint, it has not yet been realized in industry. The main problem concerns low catalyst efficiency, but in addition it does not appear to be possible to run the enantio/diastereoselective process with the previously applied cobalt catalysts. Beller et al. have now found[12] that amidocarbonylation of aldehydes can also be achieved by using palladium catalysts with sulfuric acid and halide ions as cocatalysts, as shown by the reaction of isovaleraldehyde **36** with acetamide **37**. This palladium-catalyzed synthesis is superior to that catalyzed by cobalt in many respects. Both the catalytic efficiency and the attainable yields are considerably higher. Several components, such as aromatic aldehydes and monoalkyl amides,[11c] which the cobalt-catalyzed method failed to convert, can now be used without any problems and, in addition, the reaction conditions required are milder: very good yields can be obtained at 80 °C and a CO pressure of only 10 bar. Most importantly, perhaps, the change

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3616-1701 $ 17.50+.50/0



of catalyst allows the possibility of controlling the process through choice of ligand and of running an enantio/diastereoselective process.

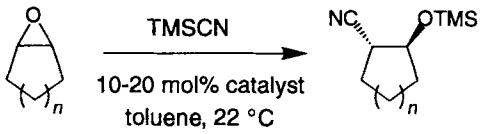
Search for Chiral Catalysts Through Ligand Diversity: Substrate-Specific Catalysts and Ligand Screening on Solid Phase**

Ken D. Shimizu, Bridget M. Cole, Clinton A. Krueger, Kevin W. Kuntz, Marc L. Snapper,* and Amir H. Hoveyda*

The development of new methods for discovering asymmetric catalytic transformations stands as an important and emerging objective in chemistry. In this context, we and others have reported protocols by which diversity strategies are used for an efficient search of chiral catalysts;[1-3] these procedures enhance the number of effective chiral ligands, and the rate at which they are identified. Here we report that 1) the ligand-discovery process can be carried out on solid support, significantly accelerating the search process, 2) the present protocol provides unique opportunities for the identification of substrate-specific catalysts, and 3) the diversity approach leads to the discovery of ligands that possess unusual properties and might have otherwise escaped detection.

Our initial studies focused on the addition of trimethylsilylcyanide (TMSCN) to *meso* epoxides [Eq. (1)]. Central to our



(1)

diversity-based strategy was the modular peptidic Schiff base system shown in Table 1.[4] Ligands were synthesized as described[1] in parallel on solid phase and subsequently cleaved for testing. Success of the diversity strategy is predicated by the number of dipeptide Schiff bases that can be fabricated simultaneously, and the rational and facile manner by which they are screened. Judicious selection of representative ligands for each of the variable positions allows efficient optimization of the epoxide-opening reaction in three stages without synthesizing and testing of every possible combination (see example in Table 2).[5]

At the outset of this investigation we realized that the ligand-screening scheme would be particularly efficient if ligand synthesis and screening could be performed directly on solid support. The critical issue in this regard was whether catalytic processes carried out under heterogeneous conditions (with an immobilized ligand) could be reliably extrapolated to the homogeneous variant.[7] Reactions with immobilized ligands can be problematic for a number of reasons: Various solid supports

contain linker units with Lewis basic sites that may interact with a transition metal. Moreover, on the solid support the aggregation state of the ligand–metal complexes, and thus the reactivity and selectivity patterns they generate, may significantly deviate from those in solution. A literature survey revealed numerous examples of transformations with differing selectivities when performed on solid rather than in solution phases.[8] Therefore, it was generally unclear whether data obtained from solid-phase studies could be reliably correlated with those in solution.[2b, 9]

To address this question, we selected 20 ligands that effect the catalytic addition of TMSCN to cyclohexene oxide with varying enantioselectivities.[10] These ligands were prepared on solid support, a portion of each sample was treated under cleavage conditions, and reaction selectivities with bound and unbound ligands were compared directly for each system. Comparison of the solid- and solution-phase reactions shows a reliable correlation, particularly for the ligands that exhibit relatively higher selectivities (Figure 1); least-squares analysis affords a line that intersects the origin. Importantly, the best ligand measured in solution (89% *ee*) is the best on the solid phase (78% *ee*) as well.

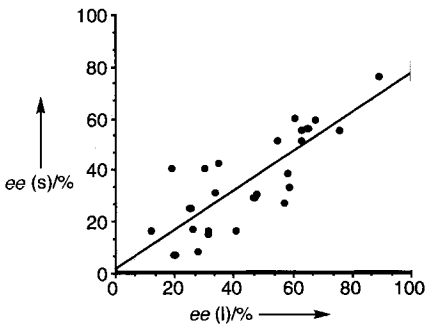

Figure 1. Correlation between solution- and solid-phase reactions (s = solid phase, l = solution phase). Each point represents a unique ligand. Reactions were run with cyclohexene oxide as the substrate (10 mol% ligand, 10 mol% $Ti(OiPr_4)$, 1 equiv of TMSCN, toluene, 4 °C).

Similar trends were observed for cyclopentene oxide (see below for further details). A correlation was measured for the selectivity pattern of 20 different ligands in the solution- and solid-phase reactions. As before, the same optimal ligand was identified when the search was carried out for both solid and solution phases. The similarity in selectivity under heterogeneous and homogeneous conditions is important as it indicates that ligand screening can be performed with immobilized ligands. This technological advance significantly facilitates the optimization procedure, since detachment of ligands from support requires several days and is the bottleneck of the process. With the latter step eliminated, peptidic Schiff bases can be prepared in six steps on solid phase in a single day, whereas the cleavage step alone requires three days. Therefore, the entire three-step screening for a substrate requires ten days on the solid phase, as opposed to one month in solution.

Our ability to examine chiral dipeptide Schiff bases on solid support leads to a notable increase in the diversity of structures that can be screened. Specifically, in our initial studies, where ligand structures were evaluated in solution, diversity was limited; amino acids with aromatic and heteroatom-containing side chains in the AA1 position proved particularly susceptible to epimerization (determined by ^{1}H NMR spectroscopy) during the cleavage process (Et_3N/DMF/MeOH 1/1/9, 3 d). Therefore, by avoiding the basic cleavage step we may access a variety of previously unavailable dipeptide Schiff bases.

The results from ligand searches on solid support bear significant implications with regard to the identity of the active Ti catalyst in the enantioselective process. In reactions performed in solution, Ti-catalyzed C–C bond formation is subject to nonlinear effects (Figure 2).[11] With cyclohexene oxide as the

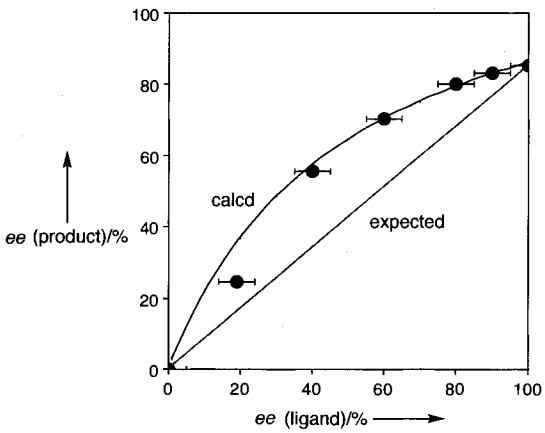

Figure 2. A positive nonlinear effect observed in the enantioselective, Ti-catalyzed addition of TMSCN to cyclohexene oxide (**12**), which was carried out with unbound ligands. The curved line is the calculated nonlinear effect [10], and the straight line the expected linear correlation.

substrate, ligand **4a** (50% optical purity) yields a product with 63% *ee* as opposed to the expected 43% *ee*. The positive nonlinear behavior suggests the existence of an equilibrium between monomeric and higher-order catalytic species.[12] Several observations suggest that the active Ti–ligand complex may be monomeric: 1) The rate of epoxide opening with ligands in solution and on a solid support are nearly the same. 2) Similar selectivities and reactivities are observed between reactions carried out in solution and on solid phase.[13]

Identification of substrate-specific catalysts differs conceptually from conventional procedures in which a single ligand–metal combination is selected and then matched to a range of substrates. As suspected from our initial studies,[1] each substrate requires a distinct ligand structure for optimal enantioselectivity when the screening protocol is applied to various *meso* epoxides (Table 3);[14] the most stereodifferentiating catalyst for one substrate is not necessarily the most desirable for all (similar to an enzyme). Whereas **4a** effects the most selective C–C bond formation for **12** (entry 2), with **10** (entry 1) peptidic Schiff base **2a** displays higher selectivity than **4a**. Chiral ligands that provide the highest level of enantiodifferentiation for seven-membered ring **8** and acyclic epoxide **14** are yet again of different constitution (entries 3 and 4). The present synthesis and screening strategy allows the search for chiral ligands to be carried out in a reasonably efficient manner, such that each individual substrate is treated as a separate case. These data raise the intriguing issue that it is perhaps unrealistic to expect that a single catalyst structure give high selectivity for the reaction of every compound of even an individual class of substrates.

Another noteworthy and unexpected feature of the results in Table 3 is that, with reactions performed in solution, ligands bearing the C-terminus Gly unit give rise to notably higher levels of selectivity.[15] This effect is particularly remarkable, since the Gly moiety (AA3) does not carry a stereogenic center, and because the original hypothesis[4] in connection with the mode of activity of these ligands primarily concerns the Schiff base unit and only the adjacent amino acid AA1. The remote and

[a] Conditions: 20 mol% $Ti(OiPr)_4$, 20 mol% ligand, 4 °C, toluene, 6–20 h. [b] The major enantiomer was identified by comparison with authentic samples of non-racemic materials; the enantioselectivities were determined with gas–liquid chromatography (GLC; BETADEX 120 column for entries 1–3, GAMMADEX for entry 4) by comparison with authentic racemic and non-racemic samples. [c] Yields of isolated products after chromatography (silica gel). [d] Determined with GLC.

positive influence of the Gly AA 3 renders these ligand structures increasingly reminiscent of enzymatic systems. Optimization of this effect through systematic ligand screening is underway and will be followed by detailed mechanistic studies.

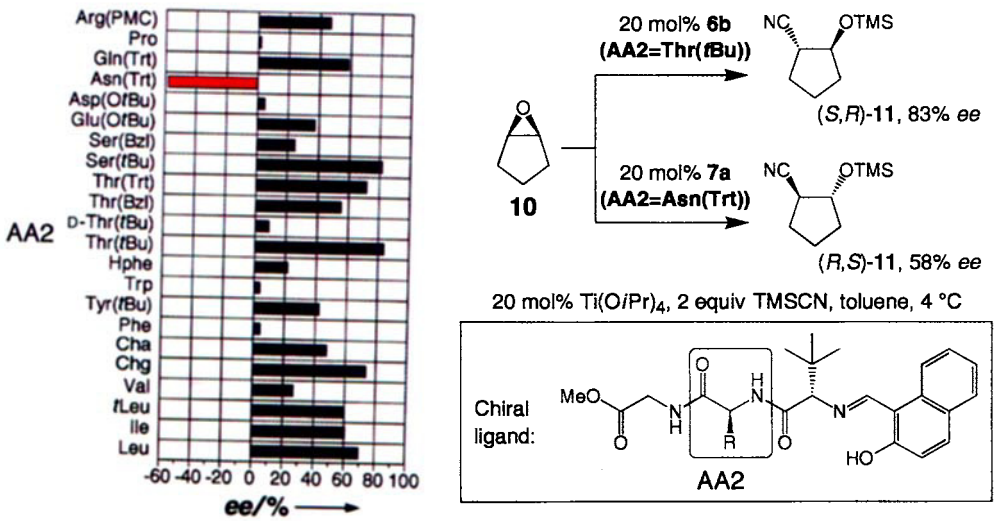
An advantage of the present method in catalyst identification is that it rapidly provides a wealth of structure-selectivity data. As the aforementioned case illustrates, this protocol can lead to the discovery of the unexpected. Another notable example in this regard was found in our search for the most enantioselective Ti–ligand complex for the reaction of cyclopentene oxide. Use of a ligand complex containing Asn(Trt) as AA 2 reverses reaction selectivity without a need for alteration of the absolute stereochemistry of the ligand stereogenic centers. This is in contrast to reactions initiated by the majority of chiral ligands for which the (*S*,*R*) product is formed predominantly. Therefore, a subtle variation in the constitution, but not the stereochemical identity, of one amino acid in the peptide framework can lead to a noteworthy reversal in enantioselectivity. In contrast to chiral ligand **2a**, which affords (*S*,*R*)-**11** with 84% *ee*, **7a** leads to the formation of (*R*,*S*)-**11** with 58% *ee* (Scheme 1). It merits mention that subtle modification of the AA 2 structure restores the original mode of selectivity; for example, the homologous Gln(Trt) as AA 2 affords the originally expected enantiomer with about 60% *ee*. The precise origin of the observed reversal in selectivity is under investigation; however, these observations give credence to our choice of individually synthesizing and testing each catalyst, as mixtures of catalysts can lead to racemic products. Further optimization of the unusual effect of **7a** may well lead to the evolution of an entirely different catalyst class of peptidic Schiff base ligands.

When **7a** is used with cycloheptene oxide **8** the "opposite enantiomer" (*R*,*S*)-**9** is again formed but with 23% *ee*; with cyclohexene oxide **12** the "usual enantiomer" (*S*,*R*)-**13** is formed with 29% *ee*. These data further underline the substrate-specific character of these peptidic catalysts. It is important to note that although structurally analogous substrates have disparate reactivity and selectivity properties, the present screening technology can rapidly match an appropriate ligand to each particular substrate without the necessity for any a priori mechanistic information.

The present protocol has a number of advantages over the more traditional methods for chiral-ligand discovery. 1) It can be carried out on a solid support; the search process is notably facilitated, and the ligand pool enriched. 2) It provides a method for searching for the most appropriate chiral ligand for a particular substrate; even structurally analogous *meso* epoxides can have dramatically different selectivity profiles. 3) The efficiency of the method permits collection of a plethora of experimental data within a short time. Unexpected observations can be made without the danger of missing important leads as a result of initial mechanistic bias; the selection process is instead strictly based on qualitative observations of the causality of variations in ligand structure. The technology and strategies disclosed here present new and effective pathways for the design, discovery, and development of new asymmetric catalytic methods in synthesis.

Experimental Section

The ligands were synthesized on WANG resin [16] (Advanced ChemTech, 0.7–0.85 mmol g^{-1} loading) as described, except that the final cleavage step was omitted [1]. The ligand–Wang conjugates were washed with toluene (10 × 1.0 mL) and



Scheme 1. Subtle variation in the functional group of chiral tripeptide Schiff bases (without altering their stereochemical identity) leads to a dramatic reversal in the enantioselectivity of the catalytic TMSCN addition to **10**. Arg(PMC) = *N*-2,2,5,7,8-pentamethylchroman-6-sulfonyl-L-arganine, Pro = L-proline, Gln(Trt) = *N*-γ-trityl-L-glutamine, Asn(Trt) = *N*-β-trityl-L-asparagine, Asp(O*t*Bu) = β-*tert*-butyl-L-asparaginate, Glu(O*t*Bu) = *O*-*tert*-butyl-L-glutamic acid, Ser(Bzl) = *O*-benzyl-L-serine, Ser(*t*Bu) = *O*-*tert*-butyl-L-serine, Thr(Trt) = *N*-trityl-L-threonine, Thr(Bzl) = *O*-benzyl-L-threonine, D-Thr(*t*Bu) = *O*-*tert*-butyl-D-threonine, Thr(*t*Bu) = *O*-*tert*-butyl-L-threonine, Hphe = L-homophenylalanine, Trp = L-tryptophan, Tyr(*t*Bu) = *tert*-butyl-L-tyrosine, Phe = L-phenylalanine, Cha = L-cyclohexylalanine, Chg = L-cyclohexylglycine, Val = L-valine, *t*Leu = *tert*-leucine, Ile = L-isoleucine, Leu = L-leucine.

dried in vacuo with toluene twice to remove any remaining solvent and water. The dried resin was weighed and used in the screening procedure. The resin-supported ligand (0.02 mmol) was placed in a dried test tube with a rubber septum under an argon atmosphere. $Ti(OiPr)_4$ (0.1 M in toluene, 200 μL, 0.02 mmol) was added and allowed to stand for 1 h. Subsequently, cyclohexene oxide (1.0 M in toluene, 200 μL, 0.2 mmol) and TMSCN (1.0 M in toluene 200 μL, 0.2 mmol) were added, and the reaction was gently agitated for 20 h (4 °C). The reaction was quenched by addition of Et_2O (1.0 mL), and the solution forced through a silica gel plug with additional Et_2O (1.0 mL). Reaction selectivity was determined by GLC analysis (BETADEX 120 chiral column).

[9] Although levels of selectivity on solid and in solution phases may correlate, they may not be reliable. This is particularly an issue if selectivites on solid phases are low (for example less than 15% *ee*). In such instances ranking of various catalyst systems in order of their effectiveness becomes increasingly dubious, since differences in selectivity are small.

[10] An initial analysis of various solvents (toluene, CH_2Cl_2, THF, Et_2O, and MeCN) indicated that the most selective and reproducible results were obtained in toluene.

[14] All reaction products in Table 3 were fully characterized by ^1H, ^{13}C NMR, and IR spectrometry, high-resolution mass spectroscopy, or combustion analysis.

[15] The effect of the glycine at AA3 was originally not appreciated and therefore went unnoted [1].

[16] FMOC-Gly-PAC resin (PerSeptive Biosystems; FMOC = 9-fluorenylmethyloxycarbonyl) may also be used to obtain similar results.

Isomers of the Elemental Composition CN_2O

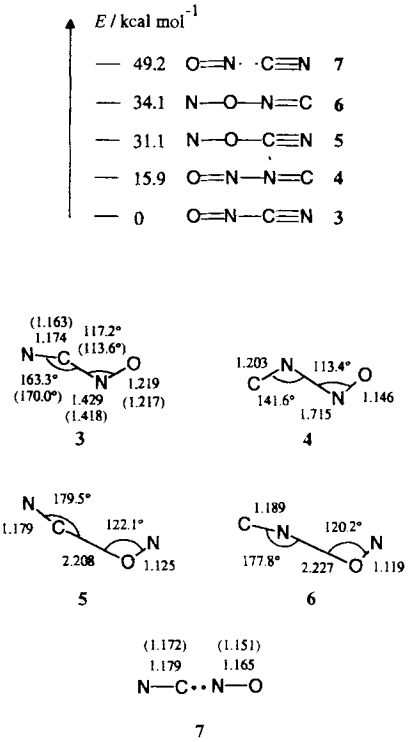
Günther Maier,* Hans Peter Reisenauer, Jürgen Eckwert, Matthias Naumann, and Michael De Marco

In our search for the still unknown molecule C_2O_2,[1] we irradiated cyanogen di-*N*-oxide (**1**) in solid argon at 10 K with light of wavelength 254 nm. Nitrosyl cyanide (**3**) was formed, probably by loss of CO from the rearrangement product **2**.[2, 3]

1 **2**

When an ArF laser ($\lambda = 193$ nm) was used, a new species with a strong IR absorption at 1837 cm^{-1} was generated instead of **3**. Since the position of this band could be reasonable for C_2O_2,[4] we attempted to determine its origin. A more precise study of the photochemistry of **3** in an argon matrix at 15 K showed that the above-mentioned absorption is not due to C_2O_2 but to isonitrosyl cyanide (**5**). To the best of our knowledge this isomer of **3** is the first "organic" isonitrosyl compound.[5]

Four ways of linking an NO group and a CN moiety are conceivable: not only **3**, which was synthesized in 1971,[6] but also nitrosyl isocyanide (**4**), isonitrosyl cyanide (**5**), and isonitrosyl isocyanide (**6**) are minima on the CN_2O energy hypersurface[7]. Their relative energies and structural data, calculated with the density functional theory (DFT) method BLYP/6-311+G*[8] in the Gaussian 94 package of programs,[9] are given in Scheme 1. This DFT method was chosen because MP2 cal-



Scheme 1. Calculated relative energies and geometries (BLYP/6-311+G*) of the CN_2O isomers **3**–**6** and the radical pair **7** (distances in Å). All CN_2O isomers possess C_s symmetry. Experimental data are given in parentheses [6b, 11].

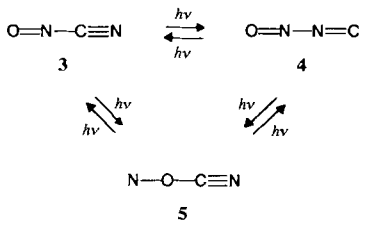
culations give less accurate results, especially for NO· and CN·.[10] According to the energy scheme, **4** should be even more easily accessible than **5**. Indeed, this species can also be generated and identified by matrix spectroscopy if **3** is irradiated with light of wavelengths greater than 570 nm instead of 193 nm.



Isomers **3**, **4**, and **5** are probably linked to each other by the radical pair **7**. However, this intermediate could not be detected, presumably because it is trapped in the matrix cage and undergoes immediate recombination. In any case, all three isomers can be interconverted photochemically; the relative ratios of the components were determined by the different UV/Vis absorptions (**3**: Figure 1c, **4**: Figure 1b, **5**: Figure 1a). Compound **3** is the preferred isomer at excitation with light of wavelength $\lambda = 254$ or 405 nm, **4** at $\lambda > 570$ nm, and **5** at $\lambda = 185$ or 193 nm. No IR bands attributable to the fourth isomer **6** were detected.

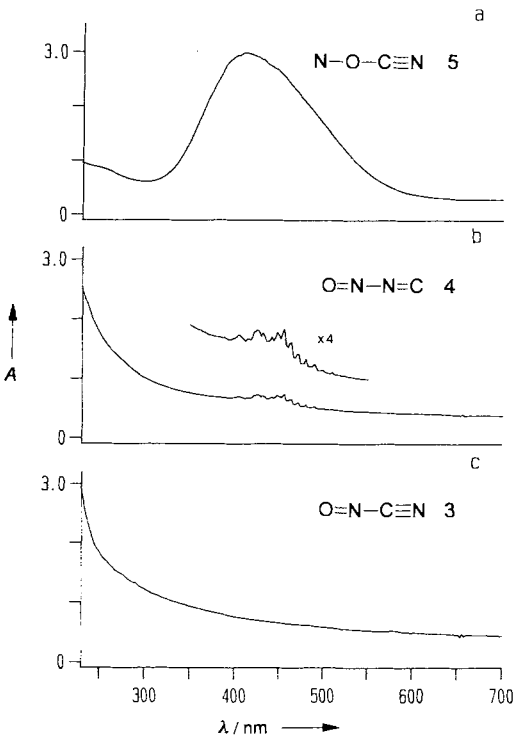


Figure 1. Experimental UV spectra of the two new isomers **5** (a) and **4** (b) as well as the starting material **3** (c) in an Ar matrix at 15 K.

For the planar molecules **3**, **4**, and **5** (C_s symmetry), six IR-active fundamental vibrations of varying intensity are expected (Tables 1–3). According to the calculation **4** should exhibit four bands in the accessible spectral range ($\tilde{\nu} > 220\ cm^{-1}$). Three of these—namely, the N–N stretching vibration at 261.0 cm^{-1}, a bending mode at 723.4 cm^{-1}, and the N–O stretching vibration at 1681.0 cm^{-1} (Figure 2b)—are readily assigned by

comparison with the theoretical predictions. Instead of a single absorption for the C–N stretching mode (ν_1) we observe a pair of bands at 1997.5 and 1967.1 cm^{-1}, which arise from anharmonic resonance with the combination mode $\nu_2 + \nu_4$. This interpretation was unequivocally confirmed by a ^{13}C-labeling experiment. Due to the resulting band shifts, the accidental degeneracy of the fundamental and combination modes is removed, and only the band for the ^{13}C–N stretch appears at 1945.9 cm^{-1}.

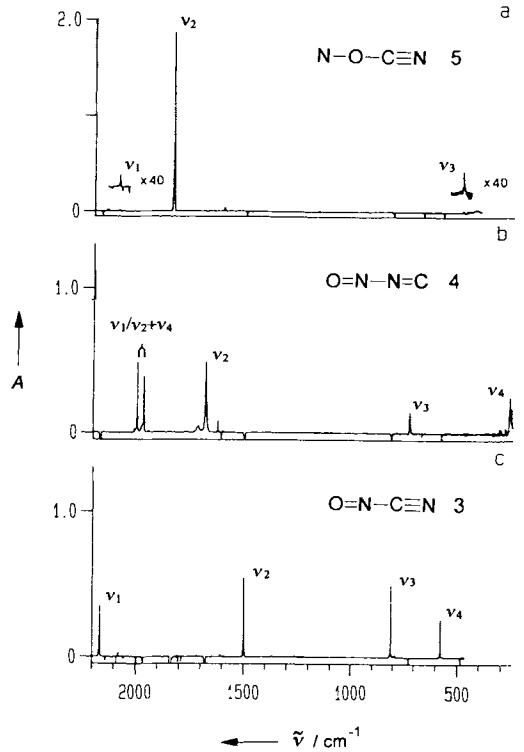

Figure 2. Experimental IR spectra of the two new isomers **5** (a) and **4** (b) as well as the starting material **3** (c) in an Ar matrix at 15 K.

The analysis of the IR spectrum of **5** (Figure 2a) is less problematic. The most intense band by far is that due to N–O stretching (ν_2) at 1836.9 cm^{-1}, the first overtone of which appears at 3650.7 cm^{-1}. The C–N stretching vibration gives rise to a weak absorption at 2086.0 cm^{-1}; the equally weak band at 485.4 cm^{-1} is due to a bending mode. We have not yet been able to definitively assign an experimental absorption to the C–O stretching transition, which should occur at the lower end of the accessible spectral range.

Two further computational results worth mentioning are the long N–N bond in **4** (1.72 Å; typical N–N single bonds are 1.4 Å) and the long O–C bond in **5** (2.21 Å; typical C–O single bonds are 1.4–1.5 Å).

It must be assumed that the conversion of **3** into an isonitrosyl isomer is not unique, but may also occur with other nitrosyl species. This is supported by the corresponding rearrangement in nitrosyl halides.[5, 12]

2,3-Dihydrothiazol-2-ylidene

Günther Maier,* Jörg Endres, and Hans Peter Reisenauer

Dedicated to Professor Peter Welzel on the occasion of his 60th birthday

There are two main approaches for investigating species that are not isolable under normal conditions: increasing their kinetic stability by introducing sterically demanding substituents and utilizing matrix-isolation techniques. The first method was successfully applied to nucleophilic carbenes by Arduengo et al.[1a, 1c] However, it later turned out that, at least for the imidazolylidenes, steric hindrance is of secondary importance.[1b] The second method, which should be suitable for detecting unsubstituted parent compounds and allows a comparison of the experimental data with quantum-chemical calculations, was not employed for this class of compounds until now.

2,3-Dihydrothiazol-2-ylidene (**2**) was selected as the target molecule for several reasons. This ring system exemplifies the nucleophilic carbene, since, as Breslow showed almost 40 years ago,[2] it is the structural element that is responsible for the activity of vitamin B_1.[3] Additionally, the catalytic activity of the thiazolium salt/**2** system is of technical interest.[4] During the recent renaissance of nucleophilic carbenes[5] 2,3-dihydro-

[*] Prof. Dr. G. Maier, Dipl.-Chem. J. Endres, Dr. H. P. Reisenauer

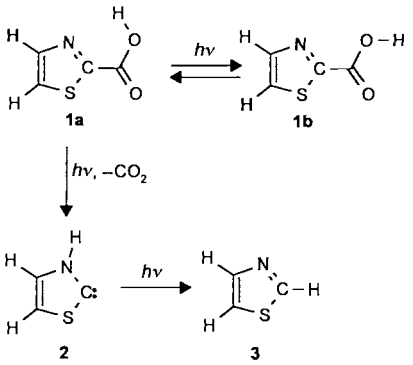
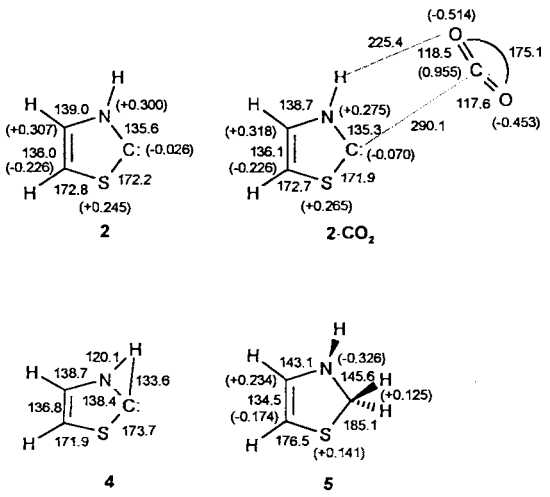
thiazol-2-ylidenes only played a minor role. The new stable carbenes of the Wanzlick–Arduengo type are derivatives of imidazole,[1a, b] imidazoline,[1c] or 1,2,4-triazole.[6] Arduengo et al. only recently reported the synthesis of a stable 2,3-dihydrothiazol-2-ylidene derivative.[7]

The standard methods for generating nucleophilic carbenes (deprotonation of the corresponding H salts) are unsuitable for matrix isolation of unsubstituted **2**. On the other hand, a precursor such as thiazol-2-carboxylic acid (**1**),[8] which might directly yield **2** upon irradiation in a matrix, would be particularly suitable. Comparison of the experimental IR spectrum of matrix-isolated **1** with the calculated IR spectrum [BLYP/6-31G(d)] shows that **1** exists as a mixture of two rotamers **1a** and **1b**. According to this calculation[9] **1a** is favored over **1b** by 1.0 kcal mol^{-1}. Hence, the intensity of the bands for **1a** in the experimental spectrum is significantly higher.



Calculations also allow an assessment of the electronic and geometric properties of the target molecule **2** and the probability of isolating it in a matrix. Whereas carbene **2** is 34.0 kcal mol^{-1} [MP4SDTQ(fc)/6-31G(d)//MP2(fc)/6-31G(d) calculation] higher in energy than the isomeric thiazole (**3**), the isomerization **2** → **3** via the transition state **4** has a considerable energy barrier of 42.3 kcal mol^{-1}. Like imidazol-2-ylidene, which was extensively analyzed by Apeloig, Schwarz et al.,[10] **2** is planar. In contrast, the nitrogen atom in the dihydro derivative **5** has a pyramidal geometry. Bond lengths and partial charges (Scheme 1) calculated for **2** (the C=C bond is longer than that in **5**, the other ring bonds are shorter, the carbene C atom bears a more negative charge, and the nitrogen and sulfur atoms bear more positive charges) indicate partial "aromatic" character, and exhibit the same trends (at least as far as the N-C-S segment is concerned) as the data obtained by Arduengo et al.[7] for highly substituted derivatives.



Scheme 1. Calculated [MP2(fc)/6-31G(d)] bond lengths and partial charges (according to Mulliken; atomic charges with hydrogens summed into heavy atoms) of carbene **2** (C_s), complex **2**·CO_2 (C_s), transition state **4** (C_1), and dihydrothiazole **5** (C_1).

When a mixture of **1a** and **1b** is exposed to light of wavelength 254 nm in an argon matrix at 10 K for 5–20 min, the bands for **1a** decrease in intensity, and those for **1b** increase. Upon prolonged irradiation (2 h) loss of CO_2 occurs (strong band at $\tilde{\nu}$ = 2332.6 cm^{-1}), and a new species that has an intense absorption at 3410.0 cm^{-1}, and must therefore contain an N–H group, is formed (Table 1). When deuterated **1** (CO_2D) is used this band shifts to 2521.9 cm^{-1} (Table 2), as expected. These observations leave little doubt that extrusion of CO_2 from **1** generates the desired product **2**. During prolonged photolysis with light of wavelength 250–420 nm (a total of 70 h) the absorptions of **2** diminish, and the known bands of **3** appear. The photoisomerization **2** → **3** enabled us to record the differ-

Table 1. Experimental IR absorptions (Ar matrix, 10 K; relative intensities are given in parentheses) and calculated [MP2(fc)/6-31G(d)] vibrational spectrum of **2**·CO_2. The five transitions at wavenumbers below 200 cm^{-1} are not listed.

[a] See fotenote [a] of Table 1.

ence spectrum depicted in Figure 1a. Comparison with the MP2(fc)/6 – 31G(d) calculated IR spectrum of **2** (Figure 1c) above 700 cm^{-1} shows good agreement within the deviations of about 5%, which is typical for this theoretical method. Between 700 and 500 cm^{-1} we observed three absorptions of rather high intensity, which is in contrast to the computed spectrum. Their origin was clarified by an experiment with $^{13}CO_2H$-labeled starting material **1**. After photolysis this isotopic marker should be found exclusively in the CO_2 fragment and cause a shift of the corresponding bands. None of the bands above 700 cm^{-1} displayed an isotopic shift. Two of the bands below 700 cm^{-1} experienced a significant shift to lower wavenumber (by 19.3 and 13.4 cm^{-1}) and, hence, must be due to CO_2 bending vibrations. The position of the third transition remained almost unchanged (shift of 4 cm^{-1}). This absorption probably originates from a ring vibration that is weakly coupled with a CO_2 bending mode. The carbon dioxide molecule, trapped after photolysis in the same matrix cage as **2**, clearly forms a complex with **2**. Therefore, the doubly degenerate bending mode of free CO_2 splits into two bands: an in-plane (666.1 cm^{-1}) and an out-of-plane vibration (614.8 cm^{-1}). The interaction of CO_2 with **2** is evidently stronger than that with the final product **3**: after complete conversion into **3**, only one broad band is observed for the CO_2 bending vibration (662.2 cm^{-1}).

Calculations [MP2(fc)/6-31G(d)] gave an energy minimum for a CO_2 complex of **2** with the geometry shown in Scheme 1. The calculated IR spectrum of **2**·CO_2 satisfactorily reproduced the spectral pattern above 700 cm^{-1}, the splitting of the CO_2 bending vibration, and the ^{13}C isotopic shifts. The orientation of the CO_2 ligand relative to **2** results form hydrogen bonding as well as an interaction between the nucleophilic carbene carbon atom and the positively polarized carbon atom of CO_2. According to theory [MP2(fc)/6-31G(d)] the stabilization energy is 5.9 kcal mol^{-1}. The complex **2**·CO_2 can be regarded as a model for the catalytic activity of 2,3-dihydrothiazol-2-ylidenes in benzoin condensations of aliphatic aldehydes, since it reveals both the nucleophilic and the electrophilic properties of **2**.

The thermal decarboxylation of carboxylic acid **1** to **3** has long been known.[11, 12] In light of the relatively high calculated activation energy for the conversion of **2** into **3**, carbene **2** generated by flash-vacuum pyrolysis of **1a** might exist long enough to be detected after immediate matrix isolation. Our attempts failed, however, and we only found the final product **3**. Nonetheless, the primary product is presumably carbene **2**. We are currently investigating whether the synthetic approach for **2** can be extended to other heterocyclic carboxylic acids.[13]

In this context, it is noteworthy that photochemically generated **2** rearranges to **3** upon warming the matrix to 60 K (accompanied by complete evaporation of the argon). It must be assumed that under these conditions the isomerization **2** → **3** does not follow the intramolecular pathway via the transition state **4** (E_A = 42.3 kcal mol^{-1}) but rather proceeds by an intermolecular hydrogen shift between two molecules of **2**.

Novel Mononuclear Vanadium Complexes Having Pentalene Ligands η^8-Bonded to a Single Metal Atom—A New Type of Coordination in Organometallic Chemistry

Klaus Jonas,* Barbara Gabor, Richard Mynott, Klaus Angermund, Oliver Heinemann, and Carl Krüger

More than sixty years elapsed between the discovery of the cyclopentadienide anion (**1**) by Thiele[1] and that of the bicyclic pentalene dianion (**2**), which Katz et al. prepared in 1962 as its dilithium salt (**5a**) by double deprotonation of 1,5-dihydropentalene (**3**)[2–4a] with butyllithium (Scheme 1).[4] The first transition metal complexes of pentalene were also synthesized during the early 1960s. Katz et al. showed that the ferrocene

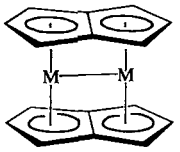
derivative bis(dihydropentalenyl)iron, synthesized from $FeCl_2$ and $Li[C_8H_7]$ (**4**), can be converted to the anionic ferrocene derivatives $Li[(C_8H_6)Fe(C_8H_7)]$ or $Li_2[(C_8H_6)_2Fe]$ by metalation with *tert*-butyllithium.[5] On the other hand, treatment of $[NiCl_2(CH_3OC_2H_4OCH_3)_2]$ or $CoCl_2$ with **5a** affords binuclear transition metal complexes with the composition $[(C_8H_6)_2M_2]$ (M = Ni, Co; yields 4–10%), for which the binuclear sandwich structure **6** has been proposed (Scheme 2).[6]

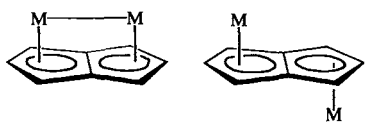


M = Ni, Co

6

Scheme 2. Proposed structure of $[(C_8H_6)_2Ni_2]$ and $[(C_8H_6)_2Co_2]$.

The structures of $[(\mu\text{-}C_8H_6)\{Ni(C_3H_5)\}_2]$,[7] the dinickel complex prepared from **5a** and allylnickel chloride, and of the binuclear complexes $[(\mu\text{-}C_8H_6)(CoCp^*)_2]$ and $[(\mu\text{-}C_8H_6)(FeCp^*)_2]$,[8] obtained by reacting **5a** with [Cp*M(acac)] (M = Fe, Co; Cp* = C_5Me_5; acac = acetylacetonate), have been confirmed by X-ray crystallography. Heterobimetallic pentalene complexes such as $[Cp^*Co(\mu\text{-}C_8H_6)Fe(\eta^5\text{-}C_8H_7)]$ and trinuclear complexes having two bridging pentalene ligands, for example $[Cp^*Fe(\mu\text{-}C_8H_6)Fe(\mu\text{-}C_8H_6)FeCp^*]$, are also known.[9] That transition metal carbonyl complexes can also be used as starting materials for the synthesis of pentalene complexes is shown by the work of Hunt et al.,[10] Hafner et al.,[11] Stone et al.,[12] and Woodward et al.[13] The pentacarbonyldiiron complex $[(\mu\text{-}C_8H_6)Fe_2(CO)_5]$ can be prepared by reacting $[Fe_2(CO)_9]$ with dihydropentalene[10a] or dimeric pentalene;[11] the reactions of the dihydropentalene derivatives C_8H_7R (R = NMe_2, C_6H_5) with $[Fe(CO)_5]$ yield $[Fe_2(CO)_5]$ complexes with substituted pentalene bridges.[10b] Stone et al.[12] employed reactions of various ruthenium carbonyl complexes with cyclooctatetraenes to form complexes having pentalene or substituted pentalene bridges. Woodward et al.[13] obtained two isomeric triruthenium complexes with $[(CH_3)_3Si]_3C_8H_3$ bridges from $[Ru_3(CO)_{12}]$ and tris(trimethylsilyl)cyclooctatriene. Thus, the only transition metal complexes that have been prepared to date that have pentalene or a derivative of pentalene as ligands are compounds of the late transition metals Ni, Co, Fe, and Ru. Without exception these are multinuclear complexes in which the bicyclic ligands, which are planar or nearly planar, act as bridges between the metal atoms (Scheme 3). We show here for

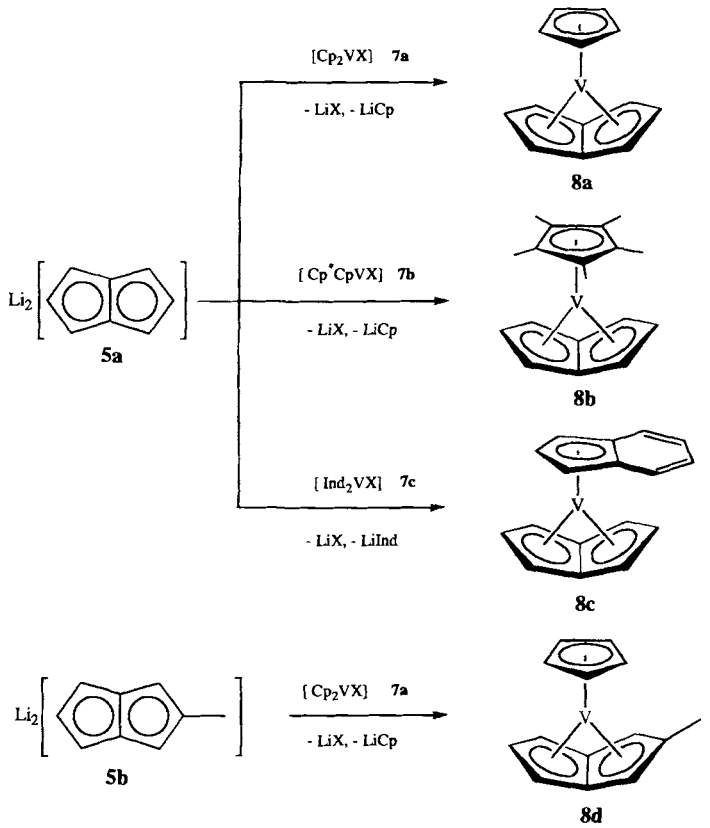


Scheme 3. Pentalene bridges in binuclear transition metal complexes as confirmed by X-ray structure analysis.

the first time that pentalene can also form complexes in which all eight carbon atoms are coordinated to a single metal atom.

The vanadium-containing starting materials used to synthesize the mononuclear vanadium pentalene complexes **8** are the vanadocene monohalides $[Cp_2VX]$ (Cp = C_5H_5; X = Cl, Br) (**7a**)[14] and their derivatives **7b** and **7c**[15] (Scheme 4). These

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3616-1712 $ 17.50+.50/0



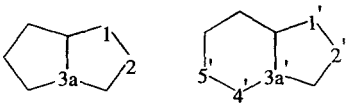
Scheme 4. Synthesis of the pentalene vanadium complexes **8**.

compounds were chosen because we knew that when the vanadium bromide compound **7a** reacts with two mole equivalents of allyllithium, the bromine atom and one of the cyclopentadienyl ligands are each replaced by an allyl group to afford the 16e complex $[CpV(\eta^3\text{-}C_3H_5)_2]$.[16] The new complexes **8**, which were prepared in high yields (80–90%) from the vanadium complexes **7** and the dilithium compounds **5a** or **5b** [17], are diamagnetic 18e complexes. They are air sensitive but can be sublimed in high vacuum at 80–100 °C without decomposition.

The compounds **8** were characterized by NMR spectroscopy and mass spectrometry (Table 1). In the ^{13}C NMR spectra of **8a–c**, three signals are observed for the pentalene ligands. The resonances appearing at highest field are those assigned to C1. Their chemical shifts (e.g., **8a**: $\delta = 84.2$) are similar to those of the Cp ligands (**8a**: $\delta = 86.9$, **8d**: $\delta = 88.4$). The signals of C2 lie to considerably lower field (e.g., **8a**: $\delta = 98.1$) and those of the bridgehead atoms C3a are found at lowest field (e.g., **8a**: $\delta = 125.9$). At 27 °C the signals of C1 (for **8d**, also of C4) and C3a are broadened for **8a–d**. The same applies to the resonances of the C atoms of the Cp ligands (**8a**, **8d**), and those of the Cp* and indenyl ligand bound to vanadium in **8b** and **8c**, respectively. For example, the line widths of these signals of **8b** are 21, 30, and 39 Hz. When the temperature is reduced the signals become narrower (9, 11, 15 Hz, respectively, −30 °C), from which follows that the line broadening is not caused by structural dynamic behavior but results from interaction with the quadrupolar vanadium nucleus. Therefore, as expected, the ^{51}V NMR spectra of these compounds are easy to measure (Table 1).

Crystals of **8a**, **8b**, and **8d** suitable for X-ray crystallography[18] were obtained by recrystallization from hexane (−30 °C). Figure 1 shows the molecular structures of the parent compound **8a**, the pentamethylcyclopentadienyl complex **8b**,

Table 1. Selected physical data of the complexes **8a–8d** [a, b]. The following numbering scheme was used for the pentalene, methylpentalene, and indenyl ligands:



8a: ^1H NMR: $\delta = 4.47$ (s, 5H, Cp), 5.02 (t, $^3J = 2.6$ Hz, 2H, H2), 5.14 (d, $^3J = 2.6$ Hz, 4H, H1); ^{13}C NMR: $\delta = 84.2$ (d, $^1J(C,H) = 184 \pm 2$ Hz, 4C, C1), 86.9 (d, $^1J(C,H) = 175 \pm 2$ Hz, 5C, Cp), 98.1 (d, $^1J(C,H) = 168$ Hz, 2C, C2), 125.9 (s, 2C, C3a); ^{51}V NMR: $\delta = -901.9$ (line width at half height 120 Hz); MS (70 eV): *m/z* [%]: 218 (M^+) [100], 153 ($M^+ - Cp$) [27], 116 ($M^+ - C_8H_6$) [13]

8b: ^1H NMR: $\delta = 1.64$ (s, 15H, CH_3), 4.53 (t, $^3J = 2.0$ Hz, 2H, H2), 4.76 (d, $^3J = 2.0$ Hz, 4H, H1); ^{13}C NMR: $\delta = 12.7$ (q, $^1J(C,H) = 126$ Hz, 5C, CH_3), 87.7 (d, $^1J(C,H) = 181 \pm 2$ Hz, 4C, C1), 102.9 (s, 5C, Cp*), 105.6 (d, $^1J(C,H) = 160$ Hz, 2C, C2), 127.4 (s, 2C, C3a); ^{51}V NMR: $\delta = -690.7$ (line width at half height 112 Hz); MS (70 eV): *m/z* [%]: 288 (M^+) [100], 273 ($M^+ - CH_3$) [16], 153 ($M^+ - Cp^*$) [42]

8c: ^1H NMR: $\delta = 4.57$ (d, $^3J = 2.5$ Hz, 4H, H1), 4.67 (d, $^3J = 2.9$ Hz, 2H, H1'), 5.09 (s, 1H, H2'), 5.80 (t, $^3J = 2.5$ Hz, 2H, H2), 6.72 and 7.06 (AA'XX' spin system, each 2H, H4' and H5'); ^{13}C NMR: $\delta = 83.6$ (br d, ^1J = (C,H) not determined, 1C, C2'), 84.3 (d, $^1J(C,H) = 172$ Hz, 2C, C1'), 87.9 (d, $^1J(C,H) = 182 \pm 2$ Hz, 4C, C1), 101.7 (d, $^1J(C,H) = 169$ Hz, 2C, C2), 111.4 (s, 2C, C3a'), 123.0 (d, $^1J(C,H) = 158$ Hz, 2C, C5'), 126.1 (s, 2C, C3a), 128.5 (d, $^1J(C,H) = 162$ Hz, 2C, C4'); ^{51}V NMR: $\delta = -597.8$ (line width at half height 176 Hz): MS (70 eV): *m/z* [%]: 268 (M^+) [100], 153 ($M^+ - C_9H_7$) [39]

8d: ^1H NMR: $\delta = 1.86$ (s, 3H, CH_3), 4.41 (s, 5H, Cp), 4.85 (t, $^3J = 2.5$ Hz, 1H, H5), 4.99 (s, 2H, H1), 5.13 (d, $^3J = 2.5$ Hz, 2H, H4); ^{13}C NMR: $\delta = 15.6$ (q, $^1J(C,H) = 127$ Hz, 1C, CH_3), 83.6 (d, $^1J(C,H) = 182 \pm 2$ Hz, 2C, C4), 86.5 (d, $^1J(C,H) = 178 \pm 2$ Hz, 2C, C1), 88.4 (d, $^1J(C,H) = 174 \pm 2$ Hz, 5C, Cp), 96.6 (d, $^1J(C,H) = 167$ Hz, 1C, C5), 116.0 (s, 1C, C2), 126.3 (s, 2C, C3a); ^{51}V NMR: $\delta = -824.1$ (line width at half height 160 Hz); MS (70 eV): *m/z* [%]: 232 (M^+) [100], 167 ($M^+ - Cp$) [7], 166 ($M^+ - Cp - H$) [9], 116 ($M^+ - C_8H_5CH_3$) [25]

[a] ^1H NMR: 300 MHz, [D$_8$]THF, 27 °C, TMS; ^{13}C NMR: 75.6 MHz, [D$_8$]THF, 27 °C, TMS. Chemical shifts measured relative to the signals of the β-methylene groups of the solvent and converted to the TMS scale ($\delta_C^0 = 25.3$, δ_H^0 1.73). ^{51}V NMR: 157.8 MHz, [D$_8$]THF, 30 °C, $VOCl_3$ (external). and the 2-methylpentalene complex **8d**. The geometrical center of the atoms C1–C5 and of C1–C3, C1*, and C2* is denoted as D1, that of C7–C9, C13, and C14 and C7–C9, C8*, and C9* as D2, and that of C9–C13 and C9–C11, C9*, and C10* as D3.

In the compounds **8a**, **8b**, and **8d** the vanadium atom has a distorted pseudo-trigonal geometry. The magnitudes of the angles D1-V-D2 and D1-V-D3 differ only slightly (148–152°), as of necessity do those of D2-V-D3 (59–61°). The V–C bond lengths within the vanadium-Cp and vanadium-Cp* moieties lie between 2.20 and 2.26 Å and in all cases V–D1 is 1.89 Å. The most prominent structural feature of the new vanadium complexes **8** is the strong folding of the pentalene or methylpentalene ligand towards the metal atom along the bond between the bridging carbon atoms. In all three vanadium complexes the angle between the plane through the atoms C7–C9, C13, and C14 (**8a**, **8d**) and C7–C9, C8*, and C9* (**8b**), respectively, and that through the plane of the atoms C9–C13 and C9–C11, C9*, and C10*, respectively, is 137°. The distances between vanadium and the C atoms of the pentalene ligands can be divided into three groups: V–C9 ≈ V–C13 (2.04–2.07 Å) < V–C8 ≈ V–C10 ≈ V–C12 ≈ V–C14 (2.20–2.23 Å) < V–C7 ≈ V–C11 (2.30–2.35 Å). The methyl substituent in **8d** causes the 2-methylpentalene ligand to be coordinated unsymmetrically to vanadium, that is within the relevant groups of bond lengths, the distances V–C14 and V–C7 in **8d** are the shortest and V–C10 and V–C11 are the longest. The methyl carbon atom C15 lies just 0.03 Å out of the mean plane of the atoms C9–C13.

We are currently carrying out further NMR studies and ab initio calculations in order to understand better the bonding situation in these novel vanadium complexes **8**.

Mononuclear Pentalene and Methylpentalene Complexes of Titanium, Zirconium, and Hafnium

Klaus Jonas,* Peter Kolb, Guido Kollbach, Barbara Gabor, Richard Mynott, Klaus Angermund, Oliver Heinemann, and Carl Krüger

In organometallic complexes, cyclooctatetraene (COT) is able to contribute up to eight π electrons, the highest number for any monocyclic hydrocarbon ligand of the series $(CH)_n$ ($n = 3–8$). Therefore, the formation of complexes of the d-block transition metals in which a cyclooctatetraene ligand is η^8-coordinated to a single metal atom is confined exclusively to the early transition metals (Ti,[1, 4a] Zr,[2] Hf,[3] V,[4] Nb,[5] Ta,[5] Mo[6]). The η^8-C_8H_8 ligands in these compounds are usually planar. In addition, numerous cyclooctatetraene complexes of the rare earth metals[7a] and the actinides[7b] are known and in these compounds the η^8-COT ligands are invariably planar.

In the preceding communication[8] we reported mononuclear organovanadium complexes in which pentalene functions as an 8e ligand. The most prominent structural feature of these mononuclear complexes is the strong folding of the bicyclic ligand towards the metal along the bond between the bridgehead carbon atoms. We wish to show that this new form of

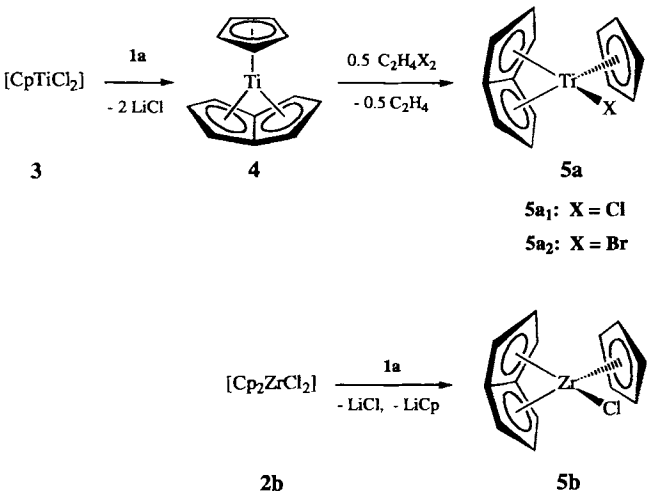
η^8-coordination can also be encountered in compounds of other transition metals and report here new mononuclear pentalene and methylpentalene complexes in which the central atom is titanium, zirconium, and hafnium.

The starting materials for the synthesis of the new titanium, zirconium, and hafnium complexes **4**–**7** are dilithiumpentalendiide (**1a**)[9] or its monomethyl derivative $Li_2[C_8H_5CH_3]$ (**1b**)[10, 11] and transition metal compounds having halide and cyclopentadienyl ligands. The metallocene dichlorides $[Cp_2MCl_2]$ (M = Ti, Zr, Hf) **2a**–**c** are commercially available and the titanium(III) complex $[CpTiCl_2]$ (**3**) is easy to prepare from $[Cp_2TiCl_2]$ (**2a**) and diisobutylaluminum chloride.[12] When $Li_2[C_8H_6]$ (**1a**) is reacted with $[CpTiCl_2]$ (**3**), both the chloro ligands are exchanged to yield the paramagnetic 17e complex **4** (Scheme 1). However, treatment of $[Cp_2ZrCl_2]$ (**2b**) with **1a** in the molar ratio 1:1 results in substitution of one chloro and one cyclopentadienyl ligand to give the 18e complex **5b**. Isostructural with this zirconium complex **5b** are the titanium compounds **5a**, which can be prepared from **4** and dichloroethane or dibromoethane, respectively (Scheme 1).



Scheme 1. Synthesis of the pentalene complexes **4**, **5a**, and **5b**.

We were able to prepare crystals of the compounds **4**, $\mathbf{5a_1}$, and **5b** suitable for X-ray crystallography.[13] The molecular structures of these compounds are depicted in Figure 1. The geometrical center of the atoms C1–C5 and of C1–C3, C1*, and C2* is denoted by D1, that of the atoms C7–C9, C13, and C14 by D2, of atoms C9–C13 by D3, and of atoms C9, C13, C7*, C8*, and C14* by D2*. In compound **4** the titanium atom has a distorted pseudo-trigonal geometry with angles at the metal of 151° (D1-Ti-D2 = D1-Ti-D3) and 58° (D2-Ti-D3). The Ti–C bond lengths, which lie between 2.33 and 2.35 Å, are typical for a $CpTi^{III}$ moiety. $[CpTi(\eta^8\text{-}C_8H_6)]$ (**4**) is isostructural with $[CpV(\eta^8\text{-}C_8H_6)]$ (**8a** in reference [8]). None of the angles at the titanium center differs by more than 2° from the corresponding one in the vanadium compound, but the metal–C distances are up to 0.12 Å longer. Here too, the distances between the metal atom and the carbon atoms of the pentalene ligand can be divided into three groups: short (Ti–C9/Ti–C13 2.08–2.13 Å), medium (Ti–C8/Ti–C10/Ti–C12/Ti–C14 2.30–2.33 Å), and long (Ti–C7/Ti–C11 2.41 Å). The angle of fold between the mean planes through each half of the pentalene ligand in **4** is 143°, which is 6° larger than in $[CpV(\eta^8\text{-}C_8H_6)]$. This angle is increased yet further by introducing an additional

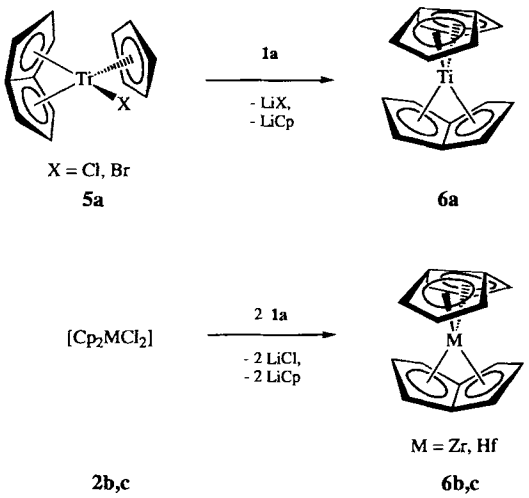
halogeno ligand; for $\mathbf{5a_1}$ an angle of 147° is found. In $\mathbf{5a_1}$ the distances between the titanium atom and the carbon atoms of the pentalene ligand are 2.12 and 2.16 Å, 2.32 and 2.43 Å, and 2.49 Å. The titanium–carbon bond lengths increase on average by about 0.05 Å in going from the Ti^{III} complex **4** to the Ti^{IV} complex $\mathbf{5a_1}$, in which the metal atom takes up a distorted pseudo-tetrahedral coordination geometry. Particularly conspicuous is the comparatively large increase in the Ti–C8 distance (**4**: 2.295(7) Å; $\mathbf{5a_1}$: 2.433(1) Å). A further striking feature is the unusually long Ti–Cl bond length of 2.512(1) Å (according to a search in the Cambridge Structure Database,[14] the average value for such bonds is 2.34 Å). The formal replacement of Ti^{IV} in $\mathbf{5a_1}$ by Zr^{IV} gives the isostructural compound **5b**. The angles at the metal center differ little from those of $\mathbf{5a_1}$ and

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3616-1715 $ 17.50+.50/0

the angle of fold of the pentalene ligand is the same as in the titanium compound **5a**$_1$ (147°). As a result of the difference in size of the metal atoms, the metal–C distances in **5b** are about 0.1 Å greater than those in **5a**$_1$.

The pentalene ligands give rise to five signals in the ^{13}C NMR spectra of the titanium compounds **5a** and of the zirconium compound **5b** (Table 1). The carbon atoms C2 and C5 are equivalent, but the positions of the signals of the bridgehead carbon atoms C3a and C6a differ by about $\Delta\delta = 7-8$ (for numbering see Table 1). Even greater differences ($\Delta\delta \leq 18$) are observed between the signals of C1 (C6) and C3 (C4).

It is particularly noteworthy that homoleptic pentalene and methylpentalene complexes of titanium, zirconium, and hafnium can also be prepared. Bis(pentalene)titanium (**6a**) was synthesized by treating **5a** in THF with one mole equivalent of **1a**. The homologous compounds **6b** and **6c** were obtained from $[Cp_2MCl_2]$ (M = Zr, Hf (**2b** and **c**, respectively)) and two mole equivalents of **1a** (Scheme 2).



Scheme 2. Synthesis of the homoleptic pentalene complexes **6**.

The preparation of bis(2-methylpentalene)zirconium (**7b**) and bis(2-methylpentalene)hafnium (**7c**) was achieved analogously by reacting **2b** or **2c** with two mole equivalents of **1b**. To prepare the corresponding titanium compound $[(\eta^8\text{-}C_8H_5CH_3)_2Ti]$ (**7a**), it was first necessary to synthesize the methyl derivative of **4**, that is, $[(\eta^8\text{-}C_8H_5CH_3)TiCp]$, from **3** and **1b**. From $[(\eta^8\text{-}C_8H_5CH_3)TiCp]$ and dibromoethane we obtained the titanium(IV) compound $[(\eta^8\text{-}C_8H_5CH_3)TiCpBr]$, which was then converted to **7a** by treating it with one mole equivalent of **1b**. We have not yet been able to prepare crystals of **6** or **7** suitable for X-ray structure analysis.

At room temperature two signals are observed in the ^{1}H NMR spectra of **6a–6c** and three in the ^{13}C NMR spectra (Table 1). The same numbers of signals are found for the complex-bound pentalene in the NMR spectra of $[CpV(\eta^8\text{-}C_8H_6)]$.[8] Also the values of the chemical shifts and the H,H and C,H coupling constants are generally comparable. Thus the pentalene ligands are η^8-coordinated and the compounds **6a–6c** have to be classified as diamagnetic "20e complexes".[15] Information on the geometrical relationship between the pentalene ligands in these complexes can be obtained from the NMR spectra of the dimethyl derivatives **7a–7c**. In each case, there are six signals for the 2-methylpentalene ligands in the ^{1}H NMR spectra measured at room temperature. Nine signals are observed in the ^{13}C NMR spectrum of **7c** but only eight in the ^{13}C NMR spectra of **7a** and **7b** because two of the nine signals are unresolved (Table 1). Thus, the axes through the bridgeheads are not parallel but lie at an angle to each other.

Table 1. Selected physical data for the new complexes **4–8** [a, b]. The following numbering scheme was used for the complex-bound pentalene and 2-methylpentalene ligands (**5**, **6**, **8**: R = H; **7**: R = CH_3):

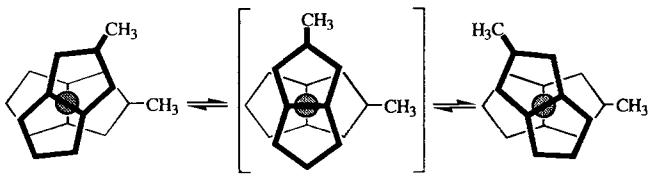
When the temperature is lowered to −80 °C, all signals in the ^1H and ^{13}C NMR spectra of **7a**[16] with the exception of the ^{13}C NMR signal of the methyl groups split into two resonances with different intensities (Table 1). All the NMR data are consistent with the titanium complex **7a** being present as two conformers (53% and 47%; Scheme 3). These conformers **I** and **II**, both of

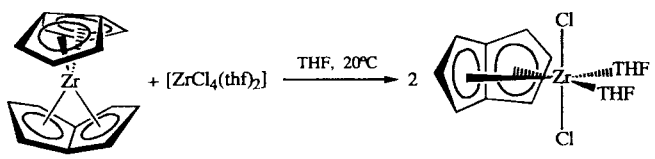


I **II**

Scheme 3. The dynamic behavior of one of the enantiomers of the C_2-symmetrical compound bis(methylpentalene)titanium (**7a**).

which have a distorted pseudo-tetrahedral coordination geometry, differ in the relative positions of the methylpentalene ligands. Conformers **I** and **II** are presumably interconverted by rotation of the ligands about the axis running through the centers of the bridges of the methylpentalene ligands and the metal atom.

When the light yellow bis(pentalene)zirconium (**6b**) is treated with $[ZrCl_4(thf)_2]$ in THF in the molar ratio 1:1, the dichloro complex **8**, which crystallizes from THF as long needles, is formed at room temperature in high yield (90%; Scheme 4).



6b **8**

Scheme 4. The synthesis of the first mononuclear "half-sandwich" complex having a pentalene ligand.

Compound **8** with its two THF ligands is an 18e complex, whereas zirconocene dichloride (**2b**), which does not bind THF, is a 16e complex. The molecular structure[17] of compound **8** is illustrated in Figure 2.

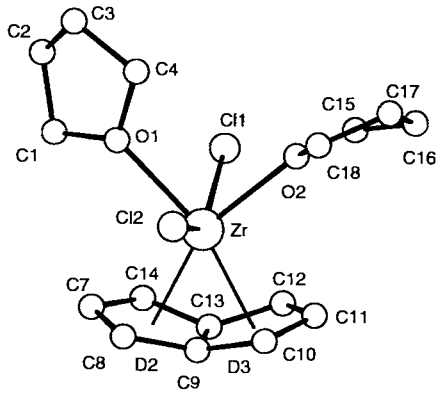


Figure 2. Molecular structure of **8** in the crystal. Selected distances [Å] and angles [°]: Zr–D2 2.107, Zr–D3 2.112, Zr–Cl1 2.595(2), Zr–Cl2 2.564(2), Zr–O1 2.303(5), Zr–O2 2.329(5), Zr–C7 2.624(9), Zr–C8 2.512(8), Zr–C9 2.261(8), Zr–C10 2.504(8), Zr–C11 2.642(9), Zr–C12 2.470(8), Zr–C13 2.257(8), Zr–C14 2.478(8); D2-Zr-O1 108.7, D2-Zr-O2 156.8, D3-Zr-O1 161.8, D3-Zr-O2 103.6, D2-Zr-Cl1 106.7(1), D2-Zr-Cl2 104.3, D3-Zr-Cl1 105.9, D3-Zr-Cl2 108.2, D2-Zr-D3 53.3, C8-C9-C10 134.4(8), C12-C13-C14 134.2(7), C8-C9-C13 107.8(7), C9-C13-C14 107.3(7), C9-C13-C12 106.0(6), C10-C9-C13 107.0(7).

In compound **8** the zirconium atom has a distorted pseudo-octahedral coordination geometry. Both axial positions are taken up by the chlorine atoms, while the equatorial sites are occupied by the geometrical centers D2 and D3 of the pentalene ligand and the oxygen atoms of the two coordinated THF molecules. D2, D3, Zr, O1, and O2 lie to a good approximation in a plane (the distances from the mean plane through Zr, D2, D3, O1, and O2 are 0.01 Å (Zr), 0.04 Å (D2), 0.04 Å (D3), 0.03 Å (O1), and 0.03 Å (O2)). This plane, which lies at an angle of 90° to that through Zr, Cl1, and Cl2, bisects the Cl1-Zr-Cl2 angle (143°). Whereas in **5b** the bond lengths Zr–C8 and Zr–C14 are markedly different, in **8** the distances between the zirconium atom and C8, C10, C12, and C14 are very similar (2.47–2.51 Å) because both sides of the pentalene ligand (that is, (C8, C9, C10 and C12, C13, C14)) lie opposite to a chlorine atom. The average value of these bond lengths is only 0.04 Å less than the Zr–C8 distance in **5b**. The angle of fold of the pentalene ligand (150°) is found to be 3° larger than that in **5b**, but the significance of this should not be overemphasized because the standard deviations of the atomic coordinates are greater (average standard deviations of the Zr–C bond lengths: 0.001 Å (**5b**), 0.008 Å (**8**)).

Some or all of the THF and chloro ligands in **8** can be replaced by various other ligands.[18] Thus, this new zirconium complex, the first mononuclear "half-sandwich" complex prepared having a pentalene ligand, plays a key role as a starting material in the newly emerging pentalene-zirconium chemistry.

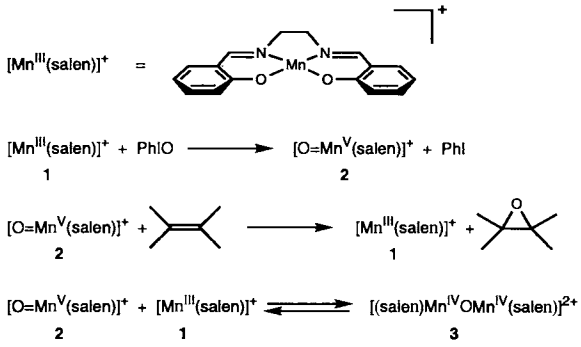
Direct Proof for O=Mn^{V}(salen) Complexes**

Derek Feichtinger and Dietmar A. Plattner*

Many first-row transition metals are able to transfer oxygen to organic substrates;[1, 2] the epoxidation of olefins is an example of particular relevance in synthesis.[3] The reactive species is usually formulated as a high-valent complex with a terminal metal–oxo multiple bond. Isolation and characterization of such complexes has been successful in only a few cases. Kochi and co-workers[4, 5] demonstrated that cationic Mn^{III} complexes of the planar tetradentate ligand salen (salen = *N*,*N*′-bis(salicylidene)ethylenediamine dianion) are highly efficient catalysts for epoxidation with a variety of terminal oxidants such as PhIO, NaOCl, MCPBA, H_2O_2, and *t*BuOOH. Based on the observed reactivities, the oxomanganese(v) complex **2** was postulated as the oxygen-transferring species. It was further suggested that the concentration of **2** is regulated by an equilibrium between the (salen)Mn^{III} complex **1** and the reactive species on one hand, and the μ-oxo bridged dimer **3** on the other. An



enantioselective version of the reaction was developed later by Jacobsen et al.[6] and Katsuki et al.[7] The observed enantioselectivities were explained by models based on a reactive oxomanganese(v) species,[6c, g] whose structure was taken to be similar to that of the analogous oxochromium complexes.[8] The catalyst of a Lewis acid catalyzed Diels–Alder reaction was also postulated to be a O=Mn^{V}(salen) complex.[9] However, in none of these cases was the reactive species isolated or characterized.

We recently reported the first direct observation of the reactive species in C–H activation by $[CpIr(PMe_3)CH_3]^+$ by means of electrospray (ES) tandem mass spectrometry.[10] In conducting these and the following experiments a slightly modified Finnigan MAT TSQ7000 mass spectrometer with an octopole/quadrupole/octopole/quadrupole setup behind the electrospray source was used.[11] This is especially suitable for detecting the short-lived species in question, since the complexes are ionic in nature; the electrospray technique allows direct transfer of ions from the authentic reaction mixtures to the gas phase.

Following Jacobsen's procedure[6d] (salen)Mn^{III}Cl was prepared by the reaction of the salen ligand with $Mn(OAc)_2 \cdot H_2O$ and LiCl under air oxidation. The complex cation $[(salen)Mn^{III}(NCCH_3)]^+$ (**1**·$NCCH_3$) was then obtained by abstraction of the chloride ligand with $AgClO_4$ in acetonitrile. Acetonitrile was chosen as the axial ligand, since our experience with a number of other manganese and iridium complexes shows that by varying the parameters of the electrospray source, it is possible to control the degree of dissociation of the neutral ligand from the complex. Electrospray of a dilute solution (about 10^{-5} M) of $[(salen)Mn^{III}(NCCH_3)](ClO_4)$ in acetonitrile yields $[(salen)Mn^{III}]^+$ (**1**, $m/z = 321$) in varying proportion to $[(salen)Mn^{III}(NCCH_3)]^+$ ($m/z = 362$). The degree of ligand loss depends on the potential applied to the tube in front of the first octopole. The oxidizing species were prepared by the two most common procedures: 1) addition of a solution of the complex to a suspension of iodosobenzene in acetonitrile, and 2) oxidation of the Mn^{III} complex with bleach in the two-phase system CH_2Cl_2/H_2O. It was experimentally confirmed that an epoxidizing species was formed by method 1. Cyclohexene was oxidized to cyclohexene oxide, as identified by gas chromatography with comparison to an authentic sample. Qualitative mass spectrometric analysis of the electrosprayed ions showed that the number as well as the nature of the detected species are substantially changed upon addition of the oxidant. Complexes **1** and **1**·CH_3CN are still present, however with strongly reduced in-

tensities. In the case of oxidation by PhIO [(salen)Mn^{III}(OIPh)]$^+$ (**1**·PhIO) is observed in low intensity.

The appearance of species whose mass is greater than that of the above-mentioned species by 16 mass units is of particular relevance. All observations indicate that these indeed correspond to the postulated oxomanganese(v) complexes. Coordination to iodosobenzene is not surprising, as Hill and co-workers found that oxidation of a (tetraphenylporphinato)Mn complex with PhIO resulted in a dimer containing one iodosobenzene molecule per Mn atom. Spectroscopic measurements pointed to axial coordination of the iodosobenzene ligands.[13, 14] In analogy to the corresponding dimer with axially coordinated azido ligands, whose constitution was confirmed by an X-ray structure analysis, an antiferromagnetically coupled μ-oxomanganese(IV) complex with a linear Mn-O-Mn arrangement was assumed.[15] In our experiments with the salen-based systems an analogous dimeric species gave rise to a prominent peak in the mass spectrum, which is in accordance with the mechanism formulated by Kochi et al.[4, 5] The signal appears at $m/z = 549$ with isotopic peaks that are seperated by one-half mass units, as is common for doubly charged ions. Further proof for the assignment of this structure comes from the daughter ion spectrum of this species (Figure 1). The dimer **3**·2PhIO fragments to **1**·OIPh ($m/z = 541$) and the oxo complexes [(salen)Mn(O)(OIPh)]$^+$ ($m/z = 557$) and [(salen)-Mn=O]$^+$ (**2**, $m/z = 321$). Small amounts of [(salen)$Mn(O_2)$]$^+$ ($m/z = 321$), which possibly has a peroxo structure, are also formed.

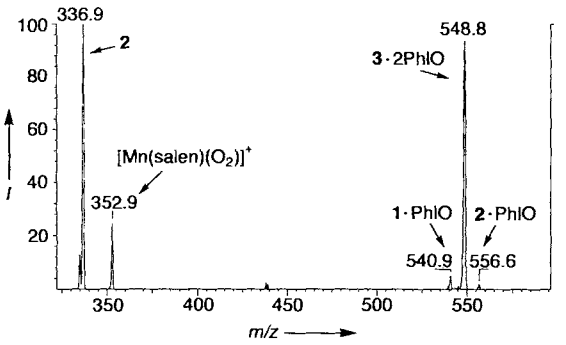

Figure 1. Daughter ion spectrum of the μ-oxo bridged, doubly charged dimer **3**·2PhIO ($m/z = 549$); I = intensity.

Strong evidence for the presence of a reactive oxomanganese(v) species is provided by collision experiments with substrates that undergo oxidation by the catalytic system in solution. When the ion corresponding to **2** is selected in the first quadrupole and then collided in the second octopole with an inert gas (about 1 mTorr of Ar) at collision energies ranging from 2 to 20 eV, no fragmentation is observed. This is in agreement with the structure of the oxo complex, because it is unlikely that all the bonds between the manganese ion and the salen ligand or the stable metal–oxo bond would fragment.[16, 17] This behavior makes it possible to establish the reactivity of the species of interest. For our oxidation experiments we chose substrates that react easily under the stated conditions in solution, that is, electron-rich olefins and sulfides.[6e] As there is no way of directly observing the oxidized products in this MS experiment, short of introducing an additional ionization step, the reactivity has to be deduced by correlating the turnover with the appearance of **1** in the daughter spectrum. At a pressure of about 0.5 mTorr of 2,3-dihydrofuran, dimethyl sulfide, or methyl phenyl sulfide in the second octopole and with collision energies of 2–5 eV, **1** was present to a considerable amount in addition to unchanged **2**. A control experiment with tetrahydrofuran as the collision gas showed no such fragmentation up to a collision energy of 20 eV.

Investigating the mechanism of the (salen)Mn-catalyzed oxidation by means of electrospray tandem mass spectrometry has proven the existence of discrete Mn^V complexes with a terminal oxo group. The reactivity of these species with respect to olefins and sulfides has been established. Moreover, a dimeric μ-oxo bridged complex could be identified as a reservoir species. Further investigations of the analogous Mn and Fe porphyrin complexes are in progress.

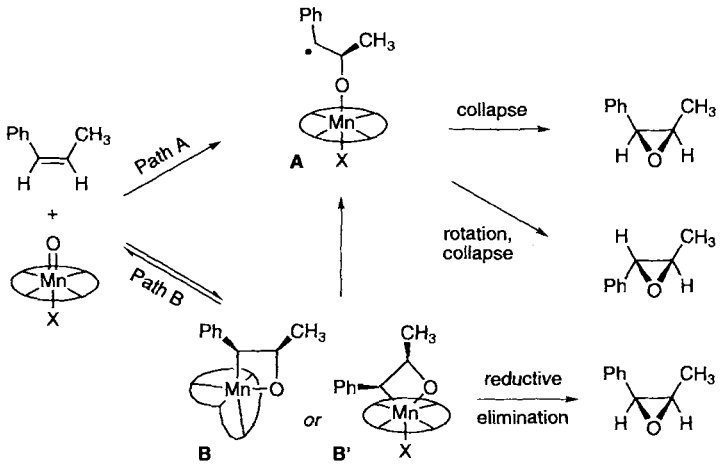
On the Viability of Oxametallacyclic Intermediates in the (salen)Mn-Catalyzed Asymmetric Epoxidation**

Nathaniel S. Finney, Paul J. Pospisil, Sukbok Chang, Michael Palucki, Reed G. Konsler, Karl B. Hansen, and Eric N. Jacobsen*

The mechanism of oxygen-atom transfer from high-valent oxometal intermediates to organic substrates has stimulated great interest as a result of its relevance to a wide range of important synthetic and biological catalytic pathways.[1] Two fundamentally different proposals have been considered: direct substrate attack at the oxo ligand with concerted or sequential C–O bond formation, and substrate attack at both the metal and oxo centers to generate an oxametallacyclic intermediate.[2] For the epoxidation of conjugated olefins catalyzed by (salen)M and M porphyrin complexes (salen = *N*,*N*′-bis(salicylidene)-ethylenediamine dianion; M = Cr, Fe, Mn), a substantial body of evidence has been accumulated that supports direct attack of olefin at the oxometal (Scheme 1, path A). This model has



Scheme 1.

been refined on the basis of stereoselectivity data to entail a side-on approach of the olefin at the oxo center to generate a radical intermediate, which in turn partitions between collapse and rotation–collapse processes to provide the observed mixture of *cis* and *trans* epoxides.[3] Recent computational[4] and experimental[5] studies purporting to substantiate the intermediacy of oxametallacycles (path B) in the (salen)Mn-catalyzed epoxidation warrant careful scrutiny, particularly since this reaction currently stands as the most effective method for the generation of optically active epoxides by oxo transfer.[1e, 6]

Here we assess the viability of such intermediates based on an analysis of the (salen)Mn coordination environment, the observed substrate scope, a computational study of representative diastereomeric radical intermediates, and the temperature dependence of enantioselection. We conclude that the radical path A remains the simplest mechanism that is consistent with all of the available data. In contrast, the oxametallacyclic mechanism fails to accomodate several crucial experimental observations, and remains both unsubstantiated and unnecessarily complicated.

The two mechanisms in question place very different constraints on the coordination environment of the manganese center throughout the catalytic cycle. Whereas the formation of a radical intermediate requires only the presence of the apical oxo ligand, formation of the proposed oxametallacycle requires that a coordination site is available for formation of the Mn–C bond, and that this coordination site is adjacent to the oxo ligand. Two critical issues are whether the (salen)Mn intermediates possess such an open coordination site during the oxo transfer steps, as required for formation of **B**, and, if not, whether the formation of oxametallacycles can be accomodated by a 7-coordinate ligand environment as in **B′**.

The first of these questions may be addressed by analyzing the effect of amine *N*-oxide additives, which have a dramatic impact on the outcome of the epoxidation reaction. Additives such as pyridine *N*-oxide influence the rate, yield, *cis*/*trans* ratio, and enantioselectivity of the (salen)Mn-catalyzed epoxidation with a range of terminal oxidants.[7] As illustrated with *cis*-β-methylstyrene addition of *N*-oxide can more than double the *cis*/*trans*-epoxide ratio, and significantly increase the chemical yield and degree of asymmetric induction (Table 1). This clearly indicates

Table 1. Epoxidation of *cis*-β-methylstyrene with various oxidants and (*S*,*S*)-**6** as catalyst.

Oxidant	Additive [e] (equiv)	*t*[h]	Conversion [%][a]	Yield [%][a]	*cis*/*trans* ratio	ee_{fac} [%][b,c]
NaOCl(aq)	4-PPNO (0.2)	0.5	100	98	19	81
NaOCl(aq)	–	2	78	62	18	71
PhIO	4-PPNO (0.2)	8.5	81	76	3	72
PhIO	–	8.5	54	2	2	69
oxone(aq)	4-PPNO (0.4)	2	98	93	15	80
oxone(aq)	–	2	18	13	10	58
oxone/K_2CO_3	NMO (2.0)	17	100	99	27	82
oxone/K_2CO_3	–	41	24	11	4	40
*m*CPBA/K_2CO_3	NMO (10.0)	0.5	100	91	16	82
*m*CPBA/K_2CO_3	–	0.5	97	41[d]	5	7

[a] Conversion, yield, and enantiomeric excess were determined by GC (see *Experimental Section*). [b] The absolute configuration of the major *cis*-β-methylstyrene oxide enantiomer is (*1S*,*2R*), and that of the major *trans*-β-methylstyrene oxide enantiomer is (*1R*,*2R*) [3h]. [c] $ee_{fac} = (x_{cis} \times ee_{cis}) + (x_{trans} \times ee_{trans})$; x = portion of *cis* or *trans* product. [d] No epoxidation was detected under these reaction conditions in the absence of **6**. [e] 4-PPNO = 4-phenylpyridine-*N*-oxide, NMO = *N*-methylmorpholine-*N*-oxide.

that the *N*-oxide additive influences the stereoselectivity of both C–O bond forming steps. Furthermore, electrochemical studies show that the presence of *N*-oxide significantly lowers the oxidation potentials for (salen)Mn complexes (Figure 1). Since oxidation to the O=Mn^V(salen) is generally rate limiting,[8] the observed rate acceleration induced by the *N*-oxide can be attributed to association of the additive with the metal center during generation of the reactive oxo intermediate. Similarly, the increase in the turnover numbers of the catalyst in the presence of *N*-oxide was taken as evidence that the additive stabilizes the highly reactive O=Mn^V(salen) by ligation after the initial oxidation.[8]

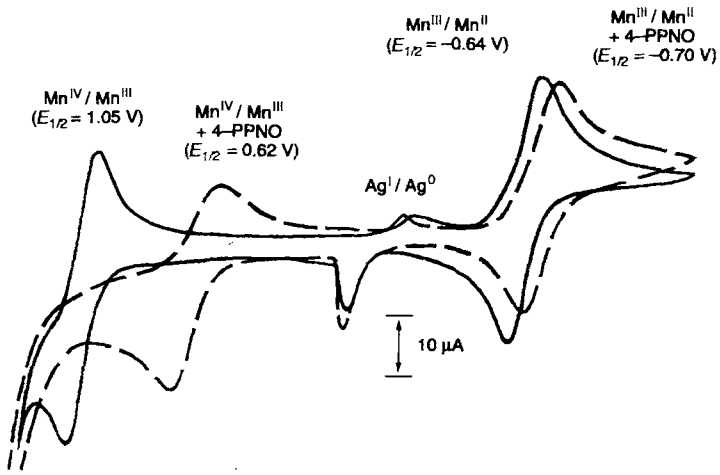

Figure 1. Cyclic voltammograms of (*R*,*R*)-**2** measured in the absence (solid line) and presence (dashed line) of 4-phenylpyridine *N*-oxide (4-PPNO, 5 equiv). Redox potentials are given relative to the saturated calomel electrode (SCE).

Further evidence that *N*-oxide additives function as axial ligands is provided by a study of catalyst **1** strapped with pyridine *N*-oxide. Figure 2 displays the X-ray crystal structure of **1** in which the tethered *N*-oxide unit is axially coordinated, as predicted, to the nearly planar (salen)Mn unit and is opposite to the chloride counterion.[9] The rate of epoxidations catalyzed by **1** is not influenced by adding 4-phenylpyridine *N*-oxide (4-PPNO; Figure 3).[10,11] For comparison, epoxidations with catalyst **2** proceed with higher conversion and at a faster rate in the presence of 4-PPNO; the combination of **2** and 4-PPNO affords results nearly identical to those obtained with catalyst **1** alone.

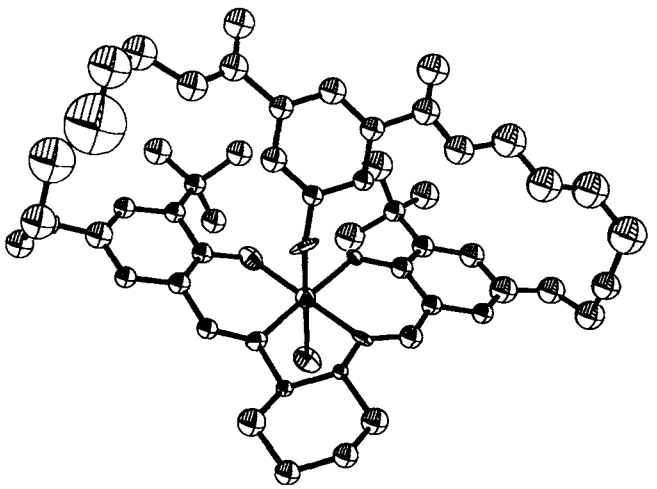

Figure 2. ORTEP representation of (*R*,*R*)-**1** (thermal ellipsoids for 50% probabilities).

These observations support a mechanism in which the *N*-oxide influences the epoxidation by axial ligation to the metal center during every step of the catalytic cycle. As a result, the relevant (salen)Mn intermediates do not possess an available coordination site for distortion of the ligand, as required for formation of intermediate **B**. Furthermore, such distortion of the (salen)Mn ligand from the square-planar disposition observed in every reported X-ray crystal structure of this class of complexes is completely unprecedented,[12] and **B** may therefore be reasonably excluded from further consideration.[13]

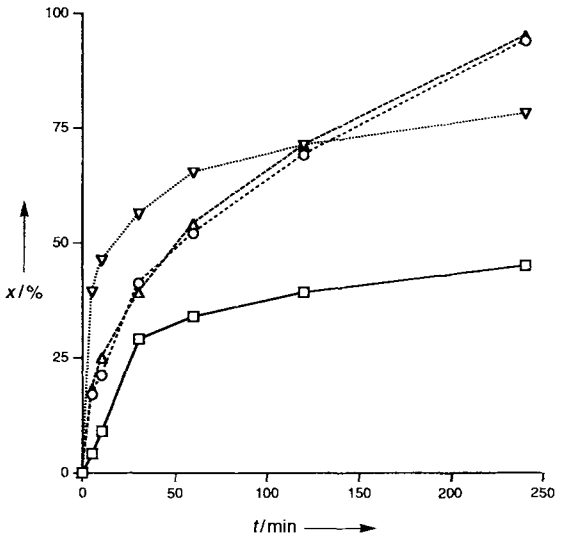

Figure 3. Plot of conversion *x* versus time *t* for the NaOCl epoxidation of styrene catalyzed by (*R*,*R*)-**1** (10 mol%; ○), (*R*,*R*)-**1** (10 mol%) and 4-PPNO (20 mol%; △), (*R*,*R*)-**2** (10 mol%; □), as well as (*R*,*R*)-**2** (10 mol%) and 4-PPNO (20 mol%; ▽).

Even cursory inspection of the alternative 7-coordinate intermediate **B′** reveals severe steric repulsions between the salen ligand and the oxametallacycle. To accomodate the observation that diastereomeric epoxides generated from acyclic *cis* olefins are epimeric at the benzylic position (see Scheme 1), the aryl-substituted olefin terminus would have to bind to the Mn center in closest proximity to the ligand plane. In light of the fact that hindered (salen)Mn catalysts such as **3** are highly active and enantioselective for the epoxidation of tri- and even certain tetrasubstituted olefins,[14] this is simply implausible.[15] The formation of oxametallacycles **B** or **B′** is thus inconsistent with a range of quantitative and qualitative experimental data, and mechanistic schemes invoking these intermediates must be regarded with skepticism.

The only experimental data presented thus far that is inconsistent with the radical mechanism is the recent report of nonlinearity in Eyring plots for the epoxidation of four olefins with a catalyst related to **2**–**5**.[5] This may indicate the presence of a reversibly formed intermediate along the reaction coordinate. However, several features complicate interpretation of this data. First, the variations in enantiomeric excess were quite small (less than 10%), rendering the changes in slope ambiguous. Second, critical experimental details—such as conversion, yield, and terminal-oxidant solubility—were missing.[16] Third, the epoxide for which the greatest effect (in terms of $\Delta\Delta G^{\neq}$) was observed, 1,2-dihydronaphthalene oxide, is known to undergo efficient kinetic resolution by a secondary oxidation pathway.[17]

In our earlier work on effective, homogenous epoxidation of olefins with *m*-chloro peroxybenzoic acid (*m*CPBA) catalyzed by (salen)Mn complexes,[8b] we observed a linear correlation of enantioselectivity and temperature for the epoxidation of styrene catalyzed by **5** over a wide temperature range. We carried out similar experiments with indene, dihydronaphthalene, and cyclooctadiene; the latter two (with styrene) are also substrates evaluated in the study by Katsuki et al.[5] The Eyring plot for the epoxidation of all four substrates catalyzed by **5** over a range of 100 degrees shows a completely linear correlation between asymmetric induction and temperature (Figure 4). The results from the *homogenous* epoxidation of these four olefins fail to reveal any sort of nonlinear behavior, and thus there is no reliable evidence suggesting existence of any reversibly formed intermediates.

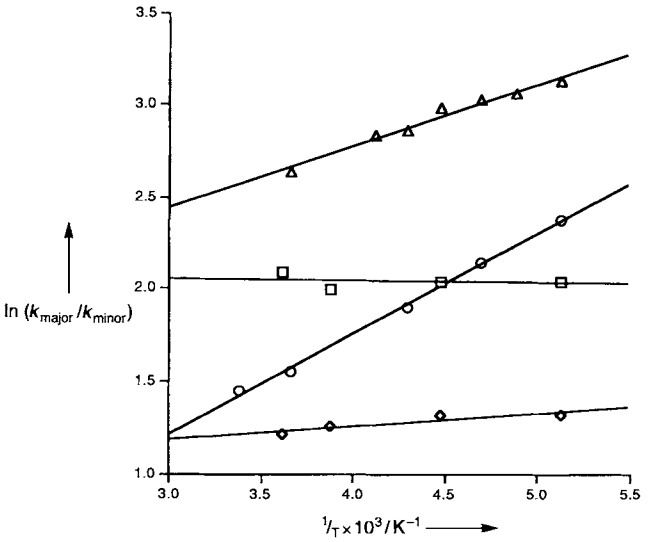

Figure 4. Eyring plots from the epoxidation of dihydronaphthalene (△), indene (□), styrene (○), and cyclooctadiene (◇) with *m*-CPBA catalyzed by (*S*,*S*)-**5**.

The simplest mechanism consistent with the observed data for (salen)Mn-catalyzed epoxidation reactions remains direct attack of olefin on an (oxo)manganese species to generate a radical intermediate, followed by ring closure to form the epoxide products. Besides adequately explaining all of the salient features of the reaction, this mechanism provides the greatest congruity with related sulfoxidation reactions[18] and biomimetic porphyrin oxidations.[3] Whereas more complicated mechanistic schemes—such as *N*-oxide ligand dissociation from the metal center during oxametallacycle formation and reassociation during epoxide formation, or the reaction of different olefins and catalysts proceeding by separate mechanisms—cannot be categorically excluded; there is no experimental evidence to support such possibilities. In what remains a fundamentally experimental discipline, it is essential to adhere to Ockham's Razor: "That which is explained with the assumption of fewer things is explained in vain by the assumption of more things."[19]

Experimental Section

Epoxidations with catalyst (*R*,*R*)-**1** were carried out following the standard biphasic epoxidation procedure [20]. Low-temperature epoxidations were conducted as described [7b], and proceeded with 20–50% conversion within 10 min; the product accounted for more than 95% of the consumed starting material. Conversion, yield, and *cis*/*trans* ratios were determined by capillary gas chromatography. Reported enantiomeric excesses are the average of at least three measurements, and were determined by either chiral capillary GC (Cyclodex-B: styrene oxide, dihydronaphthalene oxide; Gamma-TA: cyclooctadiene monoepoxide) or HPLC (Chiralcel OB: indene oxide).

Electrochemical measurements were performed at a rate of 40 mVs^{-1} on 2 mM solutions of (*R*, *R*)-**2** in CH_3CN (0.1 M Bu_4NPF_6 as the working electrolyte). The employed Pt working, Ag (vycor frit isolated) counter, and Ag/Ag^+ reference electrodes were standardized by in situ measurement of the ferrocene/ferrocenium one-electron oxidation. Redox potentials are reported relative to the saturated calomel electrode (SCE).

The semi-empirical UHF calculations described in ref. [13] were performed using the semi-empirical PM3 (tm) parameters, as implemented by the Spartan interface (Spartan version 4.0, Wavefunction, Inc., Irvine, CA (USA)). The starting catalyst conformation was derived from the crystal structure of **1** by deletion of the apical chloride and the alkyl tethers connecting the pyridine *N*-oxide to the salen aromatic rings. The phenylcyclohexanolyl fragment was appended with a fixed Mn–O bond length of 1.8 Å, and minimizations were carried out from eight different initial values for the O(salen)-Mn-O-C dihedral angle.

[13] One of the principal difficulties encountered in evaluating the radical mechanism is the question of how an essentially flat ligand system can impart such exquisite levels of enantioselectivity with a wide range of substrates. This has served as the impetus for the proposal by Norrby et al. [4] of the 6-coordinate oxametallacyclic intermediate **B**. Credence was lent to this pathway by calculations based on empirical force-field models, which predicted significant differences in energy between diastereomeric 6-coordinate (salen)Mn oxametallacycles. The documented effect of amine *N*-oxide derivatives on the epoxidation rules out such intermediates. Still, it is worth considering whether a similar computational analysis of the radical mechanism stands up well against available enantioselectivity data. We performed semi-empirical calculations of the diastereomeric radical intermediates for the epoxidation of phenylcyclohexene (PM3 (tm) parameters, Spartan version 4.0). This analysis indicates that the enantioselectivity of the epoxidation reaction may be readily ascribed to energetic differences between diastereomeric radical intermediates, and that the radical mechanism is perfectly consistent with enantioselective epoxide formation.

[14] For example, epoxidation of triphenylethylene catalyzed by **3** provides triphenylethylene oxide in 92% *ee* and 97% yield, and epoxidation of phenylcyclohexene proceeds in 88% *ee* and 67% yield: B. D. Brandes, E. N. Jacobsen, *J. Org. Chem.* **1994**, *59*, 4378. Similarly, epoxidation of 3′-bromo-2,2,3,4-tetramethylchromene employing **5** provides the corresponding chromene oxide in 96% *ee* and 84% yield: B. D. Brandes, E. N. Jacobsen, *Tetrahedron Lett.* **1995**, *36*, 5123.

[15] Similar steric arguments were made to exlude the formation of oxametallacycles in oxidations catalyzed by metal porphyrin complexes [3d].

[16] Iodosylbenzene, the terminal oxidant employed by Katsuki et al., is only sparingly soluble in organic solvents.

[17] J. F. Larrow, E. N. Jacobsen, *J. Am. Chem. Soc.* **1994**, *116*, 12129.

[18] The (salen)Mn-catalyzed oxidation of aryl sulfides proceeds with the same absolute sense of enantioinduction as for styrene derivatives: a) M. Palucki, P. Hanson, E. N. Jacobsen, *Tetrahedron Lett.* **1992**, *33*, 7111; b) K. Noda, N. Hosoya, Y. Yamashita, T. Katsuki, *Tetrahedron* **1994**, *50*, 9609. Sulfide oxidation clearly cannot proceed via oxametallacyclic or related intermediates.

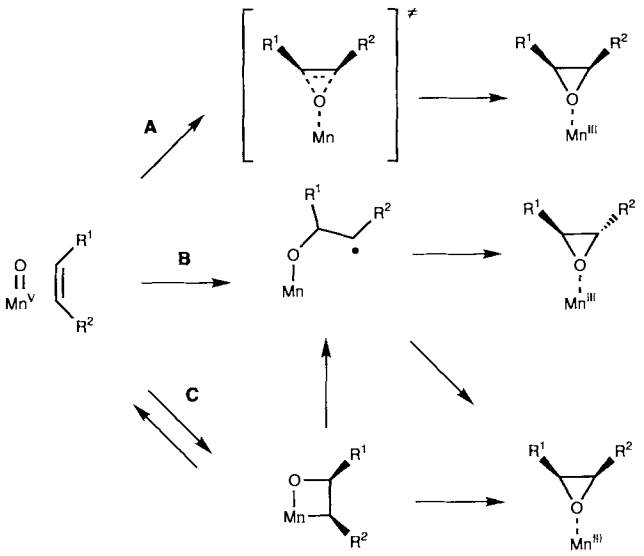
Is There a Radical Intermediate in the (salen)Mn-Catalyzed Epoxidation of Alkenes?**

Christian Linde, Moritz Arnold, Per-Ola Norrby,* and Björn Åkermark*

The mechanism for the (salen)Mn-catalyzed epoxidation of alkenes is a topic of great interest (salen = *N*,*N*′-bis(salicylidene)ethylenediamine dianion).[1] The reaction has been proposed to proceed either in a concerted manner,[2] via a radical intermediate,[1, 3] or via a manganaoxetane intermediate[4, 5] (Scheme 1). According to Jacobsen et al.[2] alkyl-substituted alkenes react concertedly (Scheme 1, pathway **A**). The *cis*/*trans* isomerization observed in the epoxidation of conjugated alkenes was taken as evidence for a radical intermediate (Scheme 1, pathway **B**).[6]



Scheme 1. Proposed mechanisms for the (salen)Mn-catalyzed epoxidation: **A**: concerted reaction ($R^1 = R^2$ = alkyl); **B**: reaction via a radical intermediate (R^1 = alkyl, R^2 = aryl, alkenyl, alkynyl); **C**: reaction via an oxetane intermediate (R^1 = alkyl, R^2 = alkyl, aryl, alkenyl, alkynyl).

Recently we suggested that the (salen)Mn-catalyzed epoxidation proceeds by reversible formation of a manganaoxetane, followed by irreversible rearrangement or ring opening, leading to the two diastereomeric products (Scheme 1, pathway **C**).[4, 7] The selectivity in the title reaction could be explained by postulating that epoxidation of conjugated alkenes mainly proceeds through an oxetane in which the conjugated carbon atom is bound to the manganese atom.[4] Katsuki et al.[5c] independently proposed a manganaoxetane intermediate to rationalize the observed nonlinear Eyring plots for relative rates of formation of the enantiomeric epoxides.[8, 9] The absence of alkene isomerization in the reaction mixture in combination with reversible formation of an intermediate suggest that any radical formation by pathway **B** (Scheme 1) is effectively *irreversible*. A concerted pathway such as **A** cannot be reconciled with the nonlinear Eyring behavior.

In the closely related epoxidations utilizing metal porphyrin complexes, strong objections were raised against the proposed metallaoxetane intermediates.[7b, 10] However, it is uncertain whether the arguments are applicable to the (salen)Mn catalysts.[11]

In analogy to the radical-probe experiments of Jacobsen et al.,[2] which were performed in a mechanistic study of the epoxidation of isolated alkenes, we investigated the catalytic epoxidation of substituted styrenes **1a**–**c**[12] to look for benzylic radicals (Scheme 2). If the mechanism of epoxidation involves a radical intermediate **4**, reaction of **1a**–**c** is expected to yield ring-opened products. A similar result is likely if a manganaoxetane intermediate **2** undergoes homolytic cleavage of the Mn–C bond. However, if **2** rearranges directly to epoxide **3** the cyclopropane unit should survive unscathed. Traps **1b** and **1c** give us the additional opportunity to study the effect of *cis*–*trans* isomerization.

For the epoxidation of **1a**–**c**, we used racemic [*N*,*N*′-bis(3,5-di-*tert*-butylsalicylidene)-1,2-cyclohexanediamine]manganese(III) chloride[13] as the catalyst. The reaction was carried out in a two-phase system of CH_2Cl_2 and a buffer solution of

a: $R^1 = R^2 = H$; **b**: $R^1 = H$, $R^2 = Me$; **c**: $R^1 = Me$, $R^2 = H$

Scheme 2. Epoxidation of **1a–c**.

aqueous hypochlorite (I),[14] and in an iodosylbenzene/benzene system (II).[3] The crude reaction mixtures were analyzed by ^1H NMR spectroscopy (Table 1).

Table 1. Results of epoxidation.

Alkene	Product	Yield of epoxide[%][a] System I[b]	System II[c]
1a	**3a**	100	57
1b	**3b**	100	83
1c	**3c**	56	54

[a] The yield was determined by ^1H NMR spectroscopy relative to an internal standard. No epimerization or oxidative-cleavage products were detected. In non-quantitative reactions (that is, with yield <100%) products resulting from opening of the cyclopropyl ring were found. [b] NaOCl used as oxidant [14]. [c] PhIO in benzene used as oxidant [3].

In system I, reaction of **1a** exclusively yielded **3a** without any traces of ring-opened products. However, in system II the yield of **3a** was only 57%. Several substituted pentenes (products from opening of the cyclopropyl ring, Scheme 2) were observed in the crude product mixture, indicating formation of a radical intermediate. Competition experiments[15] showed that the reaction rate for the epoxidation of **1a** is comparable to that for α-methylstyrene and *cis*-stilbene.

The (*E*/*Z*)-epoxide ratios for epoxidation of *cis*-stilbene in systems I and II are 23:77 and 67:33, respectively. In system II epoxidation of the trisubstituted alkene (*Z*)-α,β-dimethylstyrene yielded an (*E*/*Z*)-epoxide ratio of 35:65 plus 20% of acetophenone resulting from oxidative cleavage. Thus, if the *cis–trans* isomerization does not proceed via a radical intermediate, either of the trisubstituted radical probes **1b** or **1c** is expected to yield substantial amounts of epimerized product. In system I the reaction rates for **1b** and **1c** were similar to that for **1a**.[15] The yield of **3b** from **1b** was quantitative, whereas that of **3c** from **1c** was only 56%. In system II **1b** yielded 83% of **3b**, and **1c** 54% of **3c**. In no experiment was the known epimeric epoxide detected. For all rections in which the alkene was not quantitatively converted into epoxide, products resulting from radicals of type **4** were observed in the crude reaction mixture. The lack of epimerization product clearly shows that the intermediate radicals prefer to react by ring opening rather than by epoxide formation, as expected from measured rates of cyclopropyl ring opening for similar probes.[16]

The results indicate that initial reversible formation of a metallaoxetane (Scheme 1, pathway **C**) is the most viable mechanism for (salen)Mn-catalyzed epoxidation. Alternative proposals (Scheme 1, pathways **A** and **B**) cannot unambiguously explain either the survival of the radical probes used here or the nonlinear Eyring effects.[5c] However, it is clear that radicals can be formed under certain conditions, and it seems likely that epimeric epoxides are formed exclusively by a radical pathway. It is still uncertain whether radicals are formed directly (Scheme 1, pathway **B**) or by homolytic cleavage of the intermediate metallaoxetane. Jacobsen et al. argued that the common trend in enantioselectivities for the epimeric products indicate that they are formed from a common intermediate.[6b] Groves and Stern[17] demonstrated that epoxidation by manganese porphyrin complexes could proceed either via an oxomanganese(V) or oxomanganese(IV) species; the former pathway is stereospecific, whereas the latter yields both epimeric epoxides by radical formation.[18] Therefore, the isomerization could be rationalized as a competition between oxomanganese(IV) and oxomanganese(V) species in solution. However, in system I (Table 1) the degree of isomerization seems to depend to a very large degree on the substrate, and in particular the quantitative yields of **3a** and **3b** indicate that epoxidation of **1a** and **1b** goes cleanly via a manganese(V) oxetane. By analogy the lower yield from **1c** would be expected to be due to homolysis in a manganaoxetane, not direct radical formation. On the other hand, the lower yields in system II might well result from the presence of oxomanganese(IV) species in the reaction mixture.

The propensity of (*Z*) alkenes to isomerize is readily rationalized by pathway **C**. The steric crowding between the two (*Z*) substituents on a metallaoxetane intermediate would be significantly relieved by homolysis of Mn–C and bond rotation, but not by rearrangement to an epoxide. This effect would not be as great for an (*E*) metallaoxetane. Steric crowding in the alkene would therefore, in general, be expected to increase epimerization in the epoxidation.

We have given strong proof that (salen)Mn-catalyzed epoxidation proceeds through a metallaoxetane intermediate, which may undergo metal–carbon bond homolysis to relieve steric crowding and form a stabilized radical. Preliminary quantum chemical investigations support this mechanism.[19]

Three-Dimensional Framework with Channeling Cavities for Small Molecules: $\{[M_2(4,4'\text{-bpy})_3(NO_3)_4]\cdot x H_2O\}_n$ (M = Co, Ni, Zn)**

Mitsuru Kondo, Tomomichi Yoshitomi, Kenji Seki, Hiroyuki Matsuzaka, and Susumu Kitagawa*

The synthesis of coordination polymers with large channels or cavities is of great interest due to their intriguing structural diversity and their potential functions as microporous solids (including molecular adsorption, ion exchange, and heterogeneous catalysis).[1–10] The simple bis(monodentate) ligand 4,4'-bipyridine (4,4'-bpy) affords a variety of two- and three-dimensional frameworks when coordinated to various metal ions. $\{[Cd(4,4'\text{-bpy})_2(NO_3)_2]\cdot(C_6H_4Br_2)_2\}_n$,[3] $\{[Zn(4,4'\text{-bpy})_2]SiF_6\cdot x DMF\}_n$,[6] and $[\{Cu(cnge)_2\}_2(\mu\text{-}4,4'\text{-bpy})][BF_4]_2\cdot MeCN$ (cnge = 2-cyanoguanidine)[11] have assemblies of 2-D sheets, whereas $\{[Zn(4,4'\text{-bpy})_2(H_2O)_2](SiF_6)\}_n$,[12] $[Cu(4,4'\text{-bpy})Cl]_n$,[4] $\{[Cu(4,4'\text{-bpy})_{1.5}]NO_3(H_2O)_{1.5}\}_n$,[7] and $[Ag(4,4'\text{-bpy})\cdot NO_3]_n$ have 3-D interpenetrating structures.[10] Although the number of coordination polymers with new structural aspects is increasing, compounds that reveal functional properties characteristic of their cavities and channels are still lacking. The anion-exchange capability of the silver compound is one of a few recent instances of such properties.[10]

Here we report the synthesis and crystal structures of novel coordination polymers **1–3**, which have large micropores and can adsorb small gaseous molecules such as CH_4, N_2, and O_2.

$\{[M_2(4,4'\text{-bpy})_3(NO_3)_4](H_2O)_x\}_n$

1: M = Co, $x = 4$
2: M = Ni, $x = 4$
3: M = Zn, $x = 2$

Complexes **1–3** were prepared by the reaction of $M(NO_3)_2\cdot x H_2O$ (M = Co, Ni, Zn) with 4,4'-bpy in acetone/EtOH.[13] Complex **1** was characterized by X-ray crystallography, and the isomorphous structures of **1–3** were clearly demonstrated by their X-ray powder diffraction patterns.

Figure 1 shows the coordination around the Co center of **1** and the crystal structure along the *c* axis. The three nitrogen

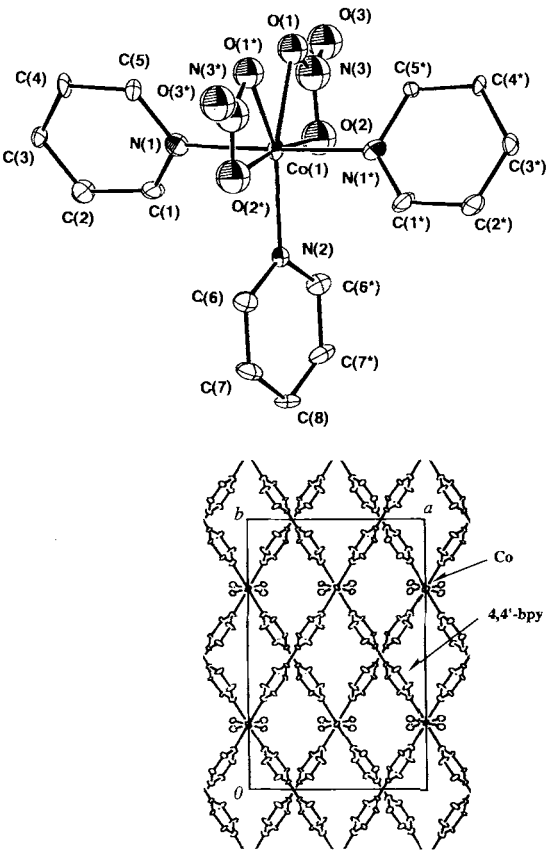

Figure 1. Top: ORTEP drawing of **1** around the Co center (ellipsoids at 20% probability); the hydrogen atoms are omitted for clarity. Selected bond distances [Å] and angles [°]: Co(1)–N(1) 2.13(1), Co(1)–N(2) 2.13(2), Co(1)–O(1) 2.23(1), Co(1)–O(2) 2.32(1); N(1)-Co(1)-N(1*) 178.2(8), N(1)-Co(1)-N(2) 90.9(4), N(1)-Co(1)-O(1) 84.5(5), N(1)-Co(1)-O(1*) 94.1(5), N(1)-Co(1)-O(2) 85.8(5), N(1)-Co(1)-O(2*) 94.3(5), N(2)-Co(1)-O(1) 140.8(4), N(2)-Co(1)-O(1*) 140.8(4), N(2)-Co(1)-O(2) 86.1(4), N(2)-Co(1)-O(2*) 86.1(4), O(1)-Co(1)-O(1*) 78.5(7), O(1)-Co(1)-O(2) 54.7(5), O(1)-Co(1)-O(2*) 133.1(6), O(2)-Co(1)-O(2*) 172.2(8). Bottom: View of the crystal structure of **1** along the *c* axis; the hydrogen atoms and nitrate anions are omitted for clarity.

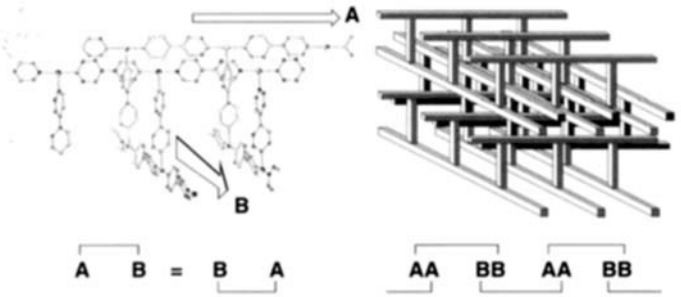
atoms from the two 4,4'-bpy molecules and the four oxygen atoms from the two nitrate anions form a distorted pentagonal bipyramid around the Co^{II} atom; N(1) and N(1*) are in the axial positions. The Co^{II} centers are bridged by 4,4'-bpy to afford infinite 1-D chains in the *ab* plane in which the pyridine rings of the 4,4'-bpy units are twisted by 38.2° with respect to each other. The chains are separated by about 10.0 Å. Two sets of arrays are

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3616-1725 $ 17.50+.50/0

observed for the 1-D chains. In one the chains are oriented at an angle of 54.8° to the *a* axis, and in the other at angle of −54.8°. The two planes that correspond to the two types of chains are designated A and B (left side of Scheme 1). The distinct planes are bound over 4,4′-bpy bridges along the *c* axis to form a double-sheet structure. The pyridine rings of the bridging 4,4′-bpy molecules are twisted by about 41.5°. Hence, each 1-D chain on the A and B planes is sterically fixed by the 4,4′-bpy unit, which acts as a pillar.



Scheme 1. Formation of the crystal structure of **1**. A section of the 3-D basic unit made up of planes A and B is shown on the left, and the result of their assembly on the right.

The assembly of these basic units is shown schematically in Scheme 1. The most characteristic feature of the resulting structure can be described as a tongue-and-groove structure (Scheme 1, right). To the best of our knowledge this type of assembly has not yet been observed in the 3-D frameworks of coordination polymers with 4,4′-bpy bridges.

The interplanar distance between A and B in the 3-D basic unit is about 11.3 Å. The nonlinked adjacent planes are separated by about 2.6 Å (A/A, B/B) and about 6.1 Å (A/B). The relatively large distance between the adjacent A and B planes creates channeling cavities along the *a* and *b* axes with dimensions of about 3 × 6 and 3 × 3 Å, respectively. These channeling cavities are occupied by water molecules, which show no significant binding interactions with the crystal framework.

The unique 3-D structures of **1**–**3** with channeling cavities prompted us to examine their gas-adsorption properties, one of the most attractive functions of microporous solids.[4, 14–16] Figure 2 shows the results of the adsorption-activity experiments of anhydrous **1**, obtained by drying under vacuum, with CH_4, N_2, and O_2. Rapid increase in the amount of adsorbed gases is shown by the increase in pressure up to 5 atm; this indicates diffusion of the gases into the cavities.[17] X-ray powder diffraction patterns confirm that there is no structural decomposition upon removal of crystal waters. Moreover, adsorption and desorption experiments with CH_4 provide the same isotherm (Figure 2), which means that there is no deformation of the crystal framework upon adsorption. The isotherms are of type I according to the IUPAC classification.[18] About 2.3 mmol of CH_4 and 0.80 mmol of N_2 or O_2 are adsorbed per 1.0 g of the anhydrous sample at a pressure of 30 atm.

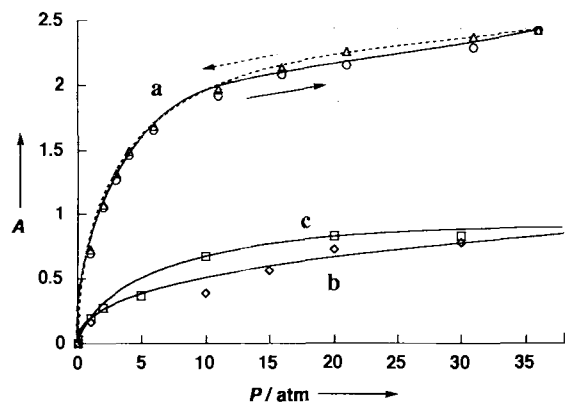


Figure 2. Isotherms for the adsorption of CH_4 (a), N_2 (b), and O_2 (c) on **1** at 298 K in the range of 1–36 atm; A = absolute adsorption in mmol of adsorbed gas per gram of anhydrous sample. In the case of CH_4 gas desorption (circles) was carried out directly after gas adsorption (triangles). Since the two isotherms are nearly identical, one can conclude that there is no structural change of the channels during gas adsorption.

An investigation of the adsorption capabilities of zeolites for several gases (CH_4, N_2, CO_2, Ar, Kr, and Xe) showed that gas affinity corresponds to cavity size.[14, 15, 19–22] Zeolites 13X and 5A show a high affinity for gases[23] and have channel dimensions of 7.4 × 7.4 Å and 4.1 × 4.1 Å, respectively, which are similar to those of **1**–**3**. In addition to structural dimensions, the specific interaction of organometallic cavity frameworks with adsorbed molecules could be controlled in the coordination polymers, which might lead to new types of adsorption properties.

Experimental Section

1: 4,4′-Bipyridine (0.82 g, 5.25 mmol) in EtOH (50 mL) was added to a solution of $Co(NO_3)_2 \cdot 6H_2O$ (0.68 g, 2.33 mmol) in acetone (50 mL), and the mixture allowed to stand for one week. The red microcrystals obtained were collected by filtration and dried in vacuo for 2 h. Elemental analysis calcd for $C_{30}H_{32}Co_2N_{10}O_{16}$: C 39.75, H 3.56, N 15.45; found: C 40.58, H 2.98, N 15.45; IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3375 (br), 1609 (s), 1536 (m), 1466 (s), 1414 (s), 1296 (s), 1219 (m), 1067 (s), 1032 (m), 1009 (m), 880 (w), 861 (w), 814 (s), 733 (m), 635 (s), 573 (m), 505 (m).

Complexes **2** and **3** were prepared analogously. **2**: Elemental analysis calcd for $C_{30}H_{32}N_{10}Ni_2O_{16}$: C 39.77, H 3.56, N 15.46; found: C 41.18, H 3.08, N 15.30; IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3385 (br), 1953 (w), 1611 (s), 1537 (m), 1494 (s), 1427 (m), 1385 (w), 1302 (s), 1224 (m), 1076 (m), 1047 (w), 1012 (m), 815 (m), 734 (w), 638 (m), 575 (w), 527 (w). **3**: Elemental analysis calcd for $C_{30}H_{28}N_{10}O_{14}Zn_2$: C 40.79, H 3.19, N 15.86; found: C 40.43, H 2.83, N 15.78; IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3406 (br), 1763 (w), 1612 (s), 1537 (m), 1415 (br), 1294 (m), 1219 (m), 1070 (m), 1030 (s), 1012 (m), 985 (w), 861 (w), 812 (s), 731 (m), 638 (m), 574 (m), 507 (m).

X-ray structure determination of **1**: All data were measured on a Rigaku AFC7R diffractometer with graphite-monochromated $Mo_{K\alpha}$ radiation and a rotating-anode generator (12 kW). The unit-cell constant was obtained from a least-squares refinement of 25 carefully centered reflections with 2θ values between 8.04 and 18.75°. The structure was solved by direct methods and refined by the block-diagonal least-squares method. Hydrogen atoms except for those of water molecules were placed at calculated positions, but their parameters were not refined. The final refinements were carried out with full-matrix least-squares techniques for non-hydrogen atoms. All calculations were performed with the TEXSAN crystallographic software package (Molecular Structure Corporation). Crystal data: $C_{30}H_{32}N_{10}Co_2O_{16}$, M_r = 906.51, orthorhombic, space group *Ccca*, a = 12.267(7), b = 19.025(7), c = 17.412(4) Å, V = 4063(2) Å^3, Z = 4, ρ_{calcd} = 1.482 g cm^{-3}, $\lambda(Mo_{K\alpha})$ = 0.71069 Å, $F(000)$ = 1856, $\mu(Mo_{K\alpha})$ = 8.96 cm^{-1}, T = 25 °C, $2\theta_{max}$ = 55.2°, of 2324 reflections measured 528 were observed ($I > 2.00\sigma(I)$), 108 parameters; R = 0.086, R_w = 0.095. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100382. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code + (1223) 336-033; e-mail: deposit@chemcrys.cam.ac.uk).

Gas-adsorption measurements for **1**: The adsorption isotherms of CH_4, N_2, and O_2 were measured by reported procedures [14, 15]. The apparatus was equipped with a Cahn R-100 electrobalance contained within a SUS steel pressure chamber that was connected with two separate lines for evacuation and adsorbate gas pressurization. Prior to adsorption measurement, to remove the solvated waters, **1** (63.1 mg, 0.074 mmol) was dried under reduced pressure at 25 °C until additional weight loss was not observed. The adsorbate gases (CH_4, N_2, O_2) were dosed into the adsorption chamber, then the change of the weight of the sample was monitored. The entire adsorption isotherms were determined by increasing the adsorbate gas pressure to a maximum of 36 atm. Gas-adsorption measurements for **2** and **3** were carried out by a similar procedure. The desorption isotherm was also obtained for CH_4 adsorption on **1**.

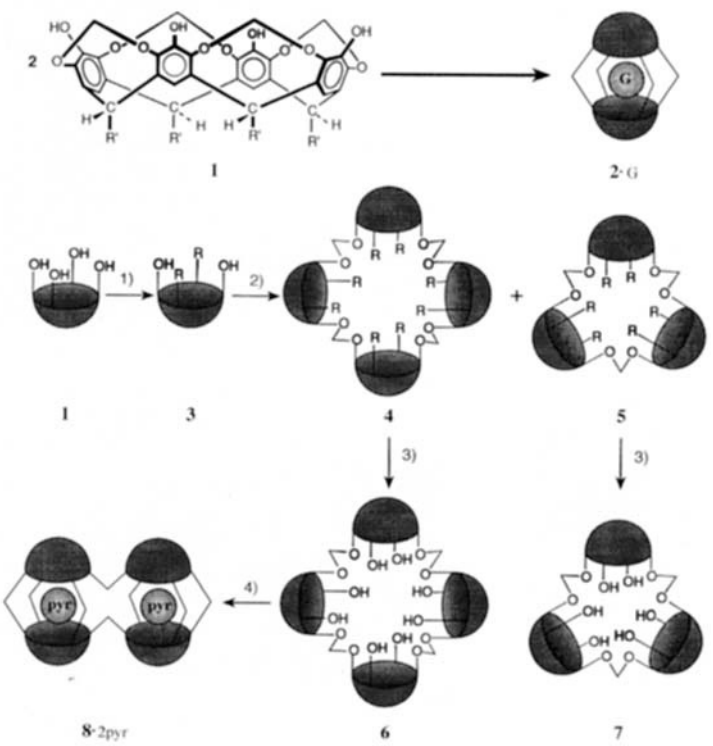
dent to use highly rigid building blocks and to seek means that limit the ways in which these units can be assembled.[3] Here we demonstrate the use of cavitands—rigid macrocycles that contain an enforced cavity—to form new, complex assemblies, most notably the first "bis(carceplex)".

It has been known for some time that two bowl-shaped molecules, cavitands or "bowls", can be linked in the presence of a suitable guest molecule to yield a closed-surface molecule, a carceplex. The guest is permanently incarcerated within the newly formed shell, akin to a ship in a bottle.[4] We studied the effects of guests as templates in the synthesis of carceplexes,[5] and found that formation of carceplex **2**·G (G = guest) is subject to a template effect that ranges one million fold. Moreover, the yields of **2**·G are as high as 87%. The formation of **2**·G demonstrates the efficient linkage of two cavitands to form a single, relatively small, closed-surface capsule (Scheme 1).



Scheme 1. Preparation of **3**–**8**. The bowls of carceplex **2**·G and bis(carceplex) **8**·2 pyr are linked through OCH_2O groups. R = $OCH_2C_6H_5$; R′ = $CH_2CH_2C_6H_5$. 1) $PhCH_2Br$, K_2CO_3, DMF, 6% yield of **3**. 2) CH_2BrCl, K_2CO_3, DMF, 15% yield of **4**, 5% yield of **5**. 3) H_2, Pd/C, 4 atm, 94% yield of **6** (based on **4**), 90% yield of **7** (based on **5**). 4) CH_2BrCl, K_2CO_3, *N*-methylpyrrolidinone, pyrazine, 74% yield of **8**·2 pyr.

A Bis(carceplex) from a Cyclic Tetramer of Cavitands**

Naveen Chopra and John C. Sherman*

One of the key goals of supramolecular chemistry is the construction of complex molecular assemblies that are composed of simple subunits or building blocks. The formation of supramolecular assemblies is common in nature and materials science, as exemplified by the braid-like structure of collagen[1] and the controlled design and engineering of crystal lattices.[2] To construct de novo assemblies of such complexity, it is prudent to use highly rigid building blocks and to seek means that limit the ways in which these units can be assembled.[3] Here we demonstrate the use of cavitands—rigid macrocycles that contain an enforced cavity—to form new, complex assemblies, most notably the first "bis(carceplex)".

Is it possible to link three or more cavitands to yield larger and/or more complex supramolecular assemblies? We report here the preparation of the first cyclic tetramer and cyclic trimer of cavitands,[6] which are potentially novel host molecules and precursors for new host molecules. To illustrate the potential of these cyclic oligomers, we also report the first bis(carceplex), which was prepared from the tetramer.

Tetrol **1** is the starting material for carceplex **2**·G and can be easily prepared in multi-gram quantities.[7] To efficiently link three or more cavitands in a cyclic array, one must limit the number of reactive sites on **1** and preclude formation of **2**·G. Both can be achieved by protecting two OH groups on opposing sides of **1**. We chose benzyl as the protecting group because of its size (it is large enough to inhibit carceplex formation), stability (the linkage remains intact upon subsequent acetal forma-

tion with $K_2CO_3/CH_2ClBr/DMF/60\,^{\circ}C$), ease of removal (by hydrogenolysis over Pd/C), and orthogonality to the acetal functionality (the acetal linkages are stable against hydrogenolysis). Treatment of **1** with 2.2 equivalents of benzyl bromide and excess K_2CO_3 in DMF gave a mixture of benzyl ethers, from which the desired bis(benzyloxy) diol **3** was isolated in 6% yield (Scheme 1). The remainder of the product mixture was subjected to hydrogenolysis over Pd/C to regenerate **1**. With this recycling method we obtained nearly quantitative conversion of tetrol **1** into diol **3**. The latter was cyclized with CH_2BrCl as a linking agent to yield a mixture of cyclic oligomers from which a cyclic tetramer of cavitands, **4**, and a cyclic trimer of cavitands, **5**, were isolated. These two cyclic oligomers were then debenzylated over Pd/C to yield tetramer **6** and trimer **7**; the latter will be discussed elsewhere.

According to the CPK space-filling molecular models, tetramer **6** has a large cavity that is complementary to molecules the size of C_{60}.[8] It could potentially form stacked arrays,[9] which could act as channels,[10] or be capped on the top and bottom with a molecule of tetrol **1** to yield a very large carceplex. Alternatively, **6** is flexible enough that the molecule can fold upon itself as described below.

Tetramer **6** was subjected to optimum conditions for the formation of carceplex **2**·G (Figure 1).[5] This includes using pyrazine as the guest, as we have found that it is the best template molecule for the formation of **2**·G.[5] The reaction proceeded smoothly to produce bis(carceplex) **8**·2pyr (pyr = pyrazine) in 74% yield. This new compound was characterized by elemental analysis, a MALDI-TOF mass spectrum (which

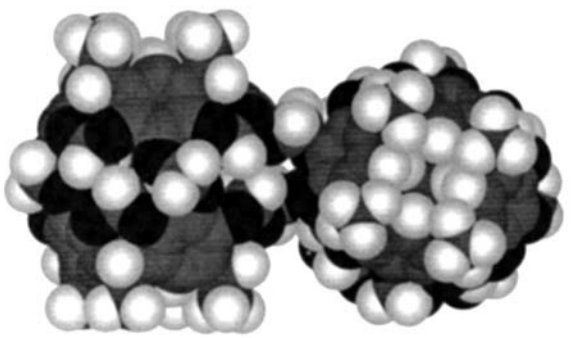

Figure 1. MM2-minimized space-filling drawing of **8**·2pyr. For clarity and simplification of the calculation, the phenylethyl pendent groups were replaced by methyl groups.

exclusively contains signals for the Na^+ and K^+ adducts), and a ^1H NMR spectrum. The latter is remarkably simple, given the size and complexity of **8**·2pyr (see *Experimental Section*). The peaks for the host were easily assigned, as was the signal for the entrapped pyrazine molecules. Integration confirms that there are two units of pyrazine per host molecule. The chemical shift of the two pyrazine molecules is shifted upfield by 4.3 ppm from its normal position in $CDCl_3$; this is typical for incarcerated pyrazine.[5, 12] Bis(carceplex) **8**·2pyr was dissolved in 1,2,4-trichlorobenzene and heated at reflux for 84 h at 214 °C with no loss of pyrazine, which demonstrates that the guests are "permanently" incarcerated. As with **2**·G the largest portal of **8**·2pyr is at the bottom of the bowls (Figure 1).[11]

MM2 molecular mechanics calculations were performed on **8**·2pyr; a space-filling drawing is shown in Figure 1. Each opposing pair of bowls was twisted by 21° with respect to one another prior to minimization, in accord with the crystal structure of **2**·G.[12] MM2 minimization of **8**·2pyr revealed a 90° twist between the two capsules.[13] Further experimental and computational studies of **8**·2pyr are currently underway, as the conformation of **8**·2G could have ramifications for intercapsule guest communication, which could be important in the development of switching devices.

Experimental Section

DMF (Fisher), HPLC-grade EtOAc (Fisher), and MeOH (Fisher) were used without further purification. *N*-methylpyrrolidinone (Aldrich) was distilled from BaO and stored over 4-Å molecular sieves, and benzene (Fisher) was dried over 4-Å molecular sieves. ^1H NMR spectra were run on a Bruker WH-400 spectrometer in $CDCl_3$ at ambient temperature using the residual $CHCl_3$ signal as a reference unless noted otherwise. "Acetal" in the NMR assignments refers to the OCH_2O linkages between the bowls; H_{in} and H_{out} refer to the diastereotopic OCH_2O linkages. Mass spectra were recorded on a Bruker Reflex MALDI-TOF (matrix assisted laser desorption ionization/time of flight) instrument in the reflectron mode. The samples were prepared by mixing the substance (5 μL of 1 mM solutions in $CHCl_3$) with the dihydroxybenzoic acid matrix (5 μL of 80 mM solutions in THF; Aldrich). A portion (0.5 μL) was applied to a MALDI-TOF target disc and allowed to dry in air for a minimum of 10 min prior to the measurement. Errors in mass accuracy are ±0.1%. Calculated molecular weights are averaged and not exact due to limited resolution. Melting points (uncorrected) were measured on a Thomas–Hoover apparatus; all compounds melt above 250 °C unless noted otherwise. Silica gel (BDH, 230–400) was used for column chromatography. Silica gel thin-layer chromatography was performed on Aldrich glass-backed plates (silica gel 60, F_{254}, 0.25 mm).

3: Tetrol **1** (3 g, 2.95 mmol), benzyl bromide (772 μL, 6.5 mmol, 2.2 equiv), and K_2CO_3 (4 g, 29 mmol, 10 equiv) were added to DMF (250 mL), and the mixture was stirred under an N_2 atmosphere for 24 h at 25 °C. The solvent was removed under vacuum and 2 M HCl (150 mL) was added to the residue. The aqueous layer was extracted with EtOAc (3 × 50 mL), and the combined EtOAc fractions were dried over $MgSO_4$ and filtered. The solvent was removed to give a viscous yellow oil, which was loaded onto a dry silica gel column. Gradient elution with EtOAc/hexanes (1/4) followed by EtOAc/hexanes (1/3), and recrystallization of the residue from $CHCl_3$/hexanes gave diol **3** (200.4 mg, 0.167 mmol, 6%) as a white solid. M.p. 157–159 °C; ^1H NMR: $\delta = 2.47$ (m, 8H, $CH_2CH_2C_6H_5$), 2.67 (m, 8H, $CH_2CH_2C_6H_5$), 4.44 (d, $J = 7.0$ Hz, 4H, H_{in}), 4.82 (t, $J = 7.9$ Hz, 4H, $H_{methine}$), 4.97 (s, 4H, $OCH_2C_6H_5$), 5.35 (s, 2H, OH), 5.86 (d, $J = 7.0$ Hz, 4H, H_{out}), 6.65 (s, 2H, *para*-H_{OH}), 6.87 (s, 2H, *para*-H_{OBn}), 7.10–7.30 (br m, $OCH_2C_6H_5$, $CH_2CH_2C_6H_5$, $CHCl_3$); MS: $m/z = 1219$ (100%) $[M + Na^+]$, 1220 calcd for $C_{78}H_{68}O_{12} + Na^+$; elemental analysis calcd for $C_{78}H_{68}O_{12} \cdot H_2O$: C 77.08, H 5.81; found: C 76.98, H 5.61.

4 and **5:** Diol **3** (297.3 mg, 0.248 mmol), CH_2ClBr (81 μL, 1.25 mmol, 5 equiv), and K_2CO_3 (261.5 mg, 1.89 mmol, 8 equiv) were added to DMF (150 mL), and the mixture was stirred under an N_2 atmosphere for 24 h at 60 °C. The solvent was removed unter vacuum, and 2 M HCl (120 mL) added to the residue. The aqueous layer was extracted with $CHCl_3$ (3 × 40 mL), and the combined $CHCl_3$ fractions were dried over $MgSO_4$ and filtered. The solvent was removed to give a viscous yellow oil, which was filtered through a pad of silica gel with $CHCl_3$. The solvent was removed under vacuum, EtOAc (50 mL) added, and the solution heated to reflux for 20 min. The suspension in EtOAc was cooled and filtered to yield tetramer **4** (45.8 mg, 0.00947 mmol, 15%). The EtOAc filtrate was then loaded onto a dry silica gel column and eluted with $CHCl_3$/hexanes (3/1). The solvent was removed, and the resulting solid recrystallized from $CHCl_3$/hexanes to give trimer **5** (15.1 mg, 0.00416 mmol, 5%).

4: ^1H NMR ([D_6]DMSO, 120 °C): $\delta = 2.50$ (br, 32H, $CH_2CH_2C_6H_5$), 2.65 (br, 32H, $CH_2CH_2C_6H_5$), 4.37 (d, $J = 7.4$ Hz, 16H, H_{in}), 4.76 (br, 16H, $H_{methine}$), 4.93 (s, 16H, $OCH_2C_6H_5$), 5.37 (s, 8H, H_{acetal}), 5.70 (d, $J = 7.4$ Hz, 16H, H_{out}), 7.36 (s, 8H, *para*-H_{acetal} or *para*-H_{OBn}), 7.38 (s, 8H, *para*-H_{acetal} or *para*-H_{OBn}); MS: $m/z = 4865$ (100%) $[M + Na^+]$, 4861 calcd for $C_{316}H_{272}O_{48} + Na^+$; elemental analysis calcd for $C_{316}H_{272}O_{48}$: C 78.46, H 5.67; found: C 78.38, H 5.60.

5: ^1H NMR: $\delta = 2.47$ (m, 24H, $CH_2CH_2C_6H_5$), 2.65 (m, 24H, $CH_2CH_2C_6H_5$), 4.36 (d, $J = 7.2$ Hz, 12H, H_{in}), 4.82 (t, $J = 7.9$ Hz, 12H, $H_{methine}$), 4.84 (s, 12H, $OCH_2C_6H_5$), 5.59 (s, 6H, H_{acetal}), 5.87 (d, $J = 7.1$ Hz, 12H, H_{out}), 6.81 (s, 6H, *para*-H_{acetal} or *para*-H_{OBn}), 6.85 (s, 6H, *para*-H_{acetal} or *para*-H_{OBn}), 7.10-7.30 (br m, $CH_2CH_2C_6H_5$, $CH_2C_6H_5$, $CHCl_3$); MS: $m/z = 3651$ (100%) $[M + Na^+]$, 3651 calcd for $C_{237}H_{204}O_{36} + Na^+$; elemental analysis calcd for $C_{237}H_{204}O_{36}$: C 78.46, H 5.67; found: C 78.20, H 5.60.

6: Tetramer **4** (98.2 mg, 0.0203 mmol) was dissolved in benzene (50 mL), MeOH (2.5 mL), and acetone (2.5 mL) in a glass bomb, and 10% Pd/C (98 mg) added. The glass bomb was subjected to high-pressure hydrogenolysis, and purification carried out as for **7** to yield tetramer **6** (78.4 mg, 0.0190 mmol, 94%). ^1H NMR ($CDCl_3$/CD_3OD 20/1): $\delta = 2.40$ (m, 32H, $CH_2CH_2C_6H_5$), 2.59 (m, 32H, $CH_2CH_2C_6H_5$), 4.31 (d, $J = 7.1$ Hz, 16H, H_{in}), 4.75 (t, $J = 7.8$ Hz, 16H, $H_{methine}$), 5.50 (s, 8H, H_{acetal}), 5.85 (d, $J = 7.2$ Hz, 16H, H_{out}), 6.58 (s, 8H, *para*-H_{OH}), 6.85 (s, 8H, *para*-H_{acetal}), 7.10–7.30 (br m, $CH_2CH_2C_6H_5$, $CH_2C_6H_5$, $CHCl_3$); MS: $m/z = 4136$ (100%) $[M + Na^+]$, 4140 calcd for $C_{260}H_{224}O_{48} + Na^+$; elemental analysis calcd for $C_{260}H_{224}O_{48}$: C 75.86, H 5.48; found: C 76.10, H 5.68.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3616-1728 $ 17.50+.50/0

7: Trimer **5** (65.7 mg, 0.0181 mmol) was dissolved in benzene (30 mL), MeOH (1.5 mL), and acetone (1.5 mL) in a glass bomb, and 10% Pd/C (66 mg) added. The bomb was subjected to three freeze–thaw cycles under vacuum, then cooled to −196 °C and opened to H_2 (1 atm) for 15 min, closed, and stirred for 48 h at 25 °C. The bomb was then cooled to −196 °C, and opened to air. The reaction mixture was thawed, added to a pad of Celite, and rinsed with THF. The solvent was removed from the filtrate under vacuum to give an off-white residue, which was recrystallized from $CHCl_3$/MeOH to give trimer **7** (50.1 mg, 0.0162 mmol, 90%). ^{1}H NMR ($CDCl_3/CD_3OD$ 20/1): δ = 2.41 (m, 24H, $CH_2CH_2C_6H_5$), 2.59 (m, 24H, $CH_2CH_2C_6H_5$), 4.31 (d, J = 7.1 Hz, 12H, H_{in}), 4.76 (t, J = 7.8 Hz, 12H, $H_{methine}$), 5.69 (s, 6H, H_{acetal}), 5.85 (d, J = 7.1 Hz, 12H, H_{out},), 6.59 (s, 6H, *para*-H_{OH}), 6.79 (s, 6H, *para*-H_{acetal}), 7.10–7.30 (br m, $CH_2CH_2C_6H_5$, $CH_2C_6H_5$, $CHCl_3$); MS: m/z = 3111 (100%) [M+Na^+], 3110 calcd for $C_{195}H_{168}O_{36}$+Na^+; elemental analysis calcd for $C_{195}H_{168}O_{36}\cdot H_2O$: C 75.42, H 5.52; found: C 75.18, H 5.66.

8·2pyr: Tetramer **6** (32.8 mg, 0.00797 mmol), K_2CO_3 (150 mg, 1.08 mmol, 135 equiv), CH_2ClBr (2.7 μL, 0.0415 mmol, 5 equiv), and 5 mol% pyrazine (626 mg, 982 equiv) were added to *N*-methylpyrrolidinone (15 mL). The reaction mixture was stirred under an N_2 atmosphere for 24 h at 25 °C and then for 24 h at 60 °C. Additional CH_2ClBr (2.7 μL) was added after the first day. The solvent was removed under vacuum, and 2 M HCl (30 mL) added to the residue. The aqueous layer was extracted with $CHCl_3$ (3 × 10 mL), and the combined $CHCl_3$ fractions were dried over $MgSO_4$ and filtered. The solvent was removed under vacuum. The residue was filtered through a pad of silica gel with $CHCl_3$ and recrystallized from $CHCl_3$/EtOAc to give bis(carceplex) **8**·2pyr (25.4 mg, 0.00587 mmol, 74%). ^{1}H NMR: δ = 2.51 (m, 32H, $CH_2CH_2C_6H_5$), 2.67 (m, 32H, $CH_2CH_2C_6H_5$), 4.07 (d, J = 7.6 Hz, 8H, H_{in}), 4.25 (d, J = 7.4 Hz, 8H, H_{in}), 4.30 (s, 8H, encapsulated pyrazine), 4.77 (t, J = 7.6 Hz, 8H, $H_{methine}$), 4.92 (t, J = 7.9 Hz, 8H, $H_{methine}$), 5.63 (s, 4H, H_{acetal}), 6.03 (d, J = 7.6 Hz, 16H, H_{out}), 6.06 (d, J = 5.8 Hz, 4H, H_{acetal}), 6.26 (d, J = 5.8 Hz, 4H, H_{acetal}), 6.51 (s, 4H, H_{acetal}), 6.87 (s, 4H, *para*-H_{acetal}), 6.91 (s, 8H, *para*-H_{acetal}), 7.02 (s, 4H, *para*-H_{acetal}), 7.10–7.30 (br m, $CH_2CH_2C_6H_5$, $CH_2C_6H_5$, $CHCl_3$); MS: m/z = 4345 (100%) [M+Na^+], 4348 calcd for $C_{264}H_{224}O_{48}\cdot(C_4H_4N_2)_2$+$Na^+$; elemental analysis calcd for $C_{264}H_{224}O_{48}\cdot(C_4H_4N_2)_2$: C 75.45, H 5.41, N 1.30; found: C 75.33, H 5.32, N 1.19.

Gas-Phase Enantiodifferentiation of Chiral Molecules: Chiral Recognition of 1-Phenyl-1-propanol/2-Butanol Clusters by Resonance Enhanced Multiphoton Ionization Spectroscopy**

Susanna Piccirillo, Cesare Bosman, Daniela Toja, Anna Giardini-Guidoni, Marco Pierini, Anna Troiani, and Maurizio Speranza*

Enantioselective complexation is a basic tool for molecular recognition. In the condensed phase chiral molecules (M) may establish short-range electrostatic, orbital, and steric interactions with suitable chiral partners (C) to form diastereomeric molecular complexes (MC), which are discriminable by virtue of their different physical and chemical properties. Determination of melting point and solubility, vapor-pressure measurements, as well as X-ray analysis[1] are commonly used to discriminate diastereomeric MC crystals. In solution calorimetric, colorimetric,[2] spectroscopic, and transport-rate measurements can be used, although the presence of the solvent may sometimes hinder their differentiation.[2, 3]

A way to eliminate this undesired interference and to evaluate the intrinsic interactions in diastereomeric MC is to extend their study to the gas phase; this, however, is by no means an easy task. Mass spectrometry has been occasionally employed to enantiodifferentiate chiral ions by complexation with suitable chiral hosts.[4] The inherent limitation of mass spetrometry to discriminate between diastereomeric or enantiomeric species demands the frequent use of isotopic markers, which may somewhat alter the relative stability of diastereomeric ion-neutral complexes.

Enantiodifferentiation of neutral chiral molecules in the gas phase can be obtained by high-resolution molecular spectroscopy of their MC complexes with chiral partners. So far there has only been one study on the laser induced fluorescence (LIF) excitation spectra of a single jet-cooled van der Waals diastereomeric MC pair.[5] Here we illustrate the first application of resonant multiphoton ionization spectroscopy (REMPI),[6] combined with time-of-flight (TOF) mass spectrometry,[7] to discriminate supersonically expanded van der Waals diastereomeric MC complexes, and to study their fundamental properties at the microscopic level. The complexes were obtained by combining a chiral chromophore, in this case (*R*)-(+)-1-phenyl-1-propanol ($\mathbf{P_R}$), with the enantiomers of 2-butanol ($\mathbf{B_R}$ or $\mathbf{B_S}$). Their MC complexes ($\mathbf{P_RB_R}$ or $\mathbf{P_RB_S}$) are expected to display different spectral signatures with respect to the electronic band origin of each pair, their appearance potential, and their vibronic bands, in particular those due to intermolecular vibrations of $\mathbf{P_R}$ with the partner ($\mathbf{B_R}$ or $\mathbf{B_S}$).[8]

The $\mathbf{P_RB_R}$ and $\mathbf{P_RB_S}$ clusters were discriminated by one-color resonance enhanced multiphoton ionization (1cREMPI) experiments, in which the complex is excited to a discrete S_1 state by absorption of one photon of frequency ν_1, and then to the continuum by absorption of several other photons with the same frequency ν_1. The 1cREMPI excitation spectra are taken by recording the TOF mass spectra of $\mathbf{P_RB_R}$ (or $\mathbf{P_RB_S}$) as a function of ν_1. The appearance potential of pure $\mathbf{P_R}$ is measured by two-color resonance enhanced two photon ionization (2cR2PI) experiments, in which the molecule is excited to a discrete S_1 state by one photon of a fixed frequency ν_1, and then ionized by a second photon of variable frequency ν_2. A value of 9.01 ± 0.01 eV is obtained for pure $\mathbf{P_R}$, which compares well with the ionization potential of 8.9 eV for benzyl alcohol at room temperature.[9]

The 1cREMPI excitation spectrum of pure $\mathbf{P_R}$ is characterized by the electronic band origin of the $S_1 \leftarrow S_0$ transition of the molecule placed at 37577 cm^{-1} and followed by two intense peaks that are shifted by 41 and 47 cm^{-1}. Other strong vibronic transitions are observed at 530, 575, 581, 629, 772, and 976 cm^{-1} from the origin. The low-frequency modes are assigned to torsional motion of the ring substituents. The other intense features are at frequencies typical for motion of the aromatic ring and ethyl or OH groups, and were not completely identified.[10]

Figure 1 reports the 1cREMPI excitation spectra of the diasteromeric pairs $\mathbf{P_RB_R}$ and $\mathbf{P_RB_S}$ around their electronic band origin. Both clusters display a complex vibronic spectrum due to numerous van der Waals vibrations, which may be coupled with low-frequency modes of the partners.[11, 12] The spectra are red shifted relative to the $S_1 \leftarrow S_0$ origin of the isolated $\mathbf{P_R}$ molecule, indicating an enhancement of binding energy for the clusters in the S_1 state relative to the S_0 state. The shifts of the most intense bands, assigned to the electronic band origin of the corresponding clusters, differ by 13 cm^{-1} as a result of a $\mathbf{P_RB_R}$-band shift of -79 cm^{-1} and of a $\mathbf{P_RB_S}$-band shift of -92 cm^{-1}. This reflects an $S_1 \leftarrow S_0$ energy gap for $\mathbf{P_RB_S}$ that is smaller than that for $\mathbf{P_RB_R}$.

The 1cREMPI excitation spectrum of the mixture with $[\mathbf{P_RB_R}]/[\mathbf{P_RB_S}] = 1$, obtained by clustering $\mathbf{P_R}$ with 2-butanol racemate, essentially corresponds to the superimposed spectra of the separate $\mathbf{P_RB_R}$ and $\mathbf{P_RB_S}$ clusters. However, when equilibration between $\mathbf{P_RB_R}$ and $\mathbf{P_RB_S}$ is favored by increasing the stagnation pressure from 2 to 5×10^5 Pa, the relative intensity of the $\mathbf{P_RB_R}$ bands increases, and that of the $\mathbf{P_RB_S}$ bands decreases by about 7%.[13] These findings corroborate molecular mechanics calculations[14] that predict that the ground-state homochiral $\mathbf{P_RB_R}$ adduct is more stable than the heterochiral $\mathbf{P_RB_S}$ adduct. Therefore, the decrease in the $S_1 \leftarrow S_0$ energy gap in going from $\mathbf{P_RB_R}$ to $\mathbf{P_RB_S}$ points to an excited state in which the stability difference of the clusters tends to be cancelled out or even reversed relative to the ground state.

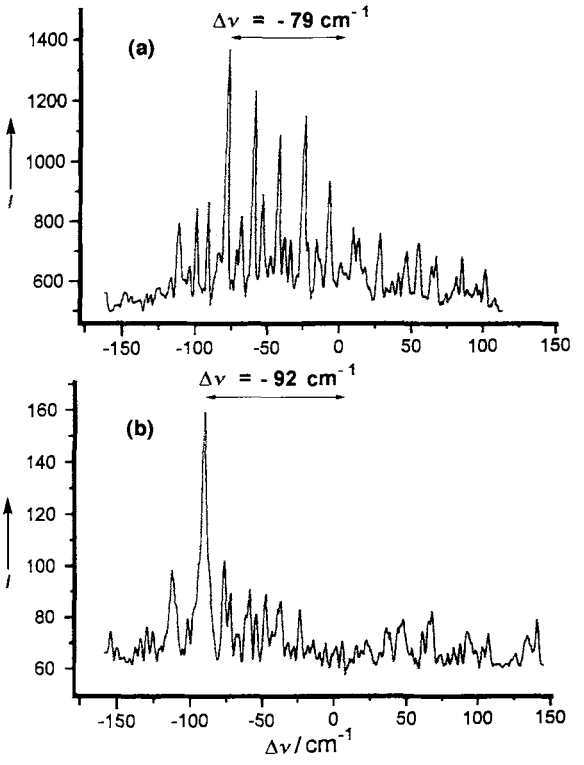

Figure 1. 1cREMPI excitation spectra of diasteromeric $\mathbf{P_RB_R}$ (a) and $\mathbf{P_RB_S}$ (b) clusters measured at $m/z = 210$ and a total stagnation pressure of 2×10^5 Pa. The origin of the frequency scale is relative to the electronic band origin of the $S_1 \leftarrow S_0$ transition of $\mathbf{P_R}$ at 37577 cm^{-1}. I = intensity (arbitrary units).

Figure 2 displays the highly reproducible 1cREMPI/TOF mass spectra of diastereomeric $\mathbf{P_RB_R}$ (Figure 2a) and $\mathbf{P_RB_S}$ (Figure 2b) complexes taken at a fixed frequency, namely at the electronic origin frequency of the corresponding cluster (Figure 1). In addition to the parent ion $[\mathbf{P_RB_R}]^+$ (or $[\mathbf{P_RB_S}]^+$) at $m/z = 210$ the spectra show the formation of fragments $[\mathbf{P_R}]^+$ ($m/z = 136$), $[\mathbf{P_RB_R} - C_2H_5]^+$ (or $[\mathbf{P_RB_S} - C_2H_5]^+$; $m/z = 181$), and $[\mathbf{P_R} - C_2H_5]^+$ ($m/z = 107$). That all these species and $[\mathbf{P_RB_R}]^+$ (or $[\mathbf{P_RB_S}]^+$) actually have the same origin is testified by their identical 1cREMPI excitation patterns.

The distinct difference between the 1cREMPI/TOF mass spectra of the diastereomers $\mathbf{P_RB_R}$ and $\mathbf{P_RB_S}$ (Figure 2a, b) provides a further tool for their discrimination. In particular the spectrum of the homochiral cluster $\mathbf{P_RB_R}$ (Figure 2a) shows a distribution of $[\mathbf{P_R}]^+ : [\mathbf{P_RB_R} - C_2H_5]^+ : [\mathbf{P_R} - C_2H_5]^+ : [\mathbf{P_RB_R}]^+ = 0.6 : 2.5 : 0.7 : 1.0$, which clearly diverges from that of the heterochiral cluster $\mathbf{P_RB_S}$ ($[\mathbf{P_R}]^+ : [\mathbf{P_RB_S} - C_2H_5]^+ : [\mathbf{P_R} - C_2H_5]^+ : [\mathbf{P_RB_S}]^+ = 1.4 : 9.7 : 3.2 : 1.0$; Figure 2b). The more extensive fragmentation observed in the spectrum of $\mathbf{P_RB_S}$ (93% ($\mathbf{P_RB_S}$) versus 79% ($\mathbf{P_RB_R}$)) is responsible for the comparatively low intensity of its 1cREMPI excitation spectrum (see Figure 1a, b), and suggests that, despite the slightly higher energy absorbed by $\mathbf{P_RB_R}$,[15] higher-energy dissociative states are more populated in heterochiral $\mathbf{P_RB_S}$ than in homochiral $\mathbf{P_RB_R}$ for the same 1cREMPI process.

The REMPI/TOF technique has been applied for the first time to enantiodifferentiate neutral chiral molecules in the gas phase. Chiral recognition is based on highly reproducible differ-

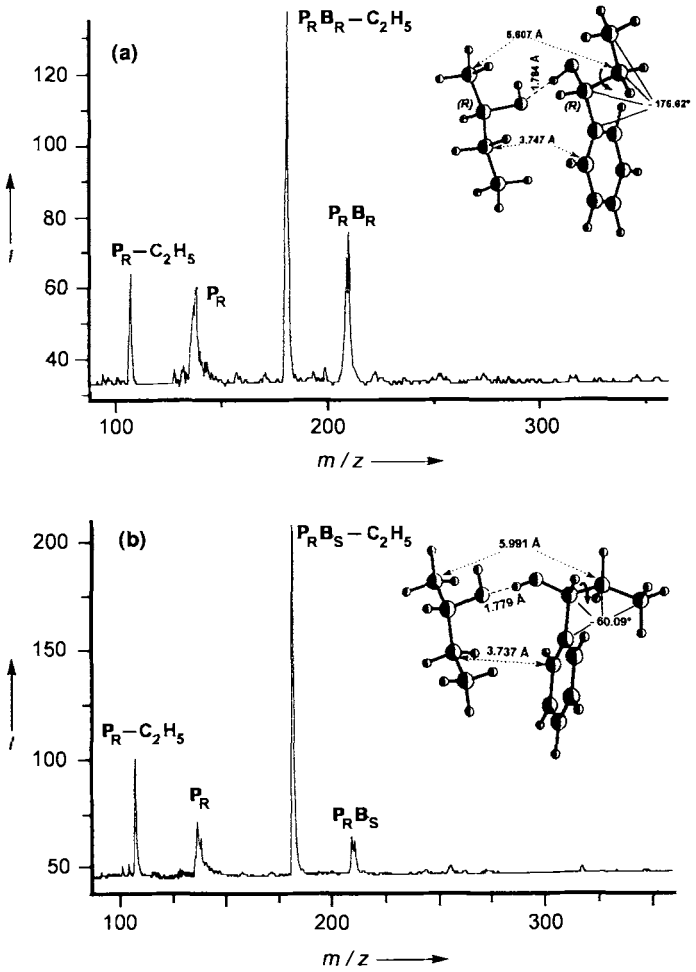

Figure 2. 1cREMPI/TOF spectra of diasteromeric P_RB_R at $\lambda = 266.68$ nm (a) and P_RB_S clusters at $\lambda = 266.77$ nm (b) at a total stagnation pressure of 2×10^5 Pa. The structures of the ground state P_RB_R and P_RB_S clusters, calculated with modified molecular mechanics (MMX), are given in (a) and (b), respectively.

ences in the photoionization fragmentation pattern of the diastereomeric clusters obtained from complexation of the chiral molecule with suitable chiral partners, and on the different bathochromic shifts of their electronic band origin relative to that of the pure chromophore. The latter indicates that attractive interactions within the clusters are more pronounced in the excited than in the ground state. Under consideration of the order of stability in the ground state, $P_RB_R > P_RB_S$, a greater stabilization of the P_RB_S cluster in the S_1 state relative to that of P_RB_R tends to cancel the stability order in the excited state. Differences in the absorption frequencies of gaseous jet-cooled species were recently used for isotope-enrichment procedures.[16] This study demonstrates that the same approach can be applied to jet-cooled diastereomeric clusters to enantiomerically enrich a racemate.

Experimental Section

The experimental setup for the generation of van der Waals clusters and their REMPI/TOF analysis was previously described [7, 11, 17]. Diastereomeric pairs P_RB_R and P_RB_S were obtained by in a supersonic beam by adiabatic expansion of a carrier gas (Ar) seeded with the corresponding alcohols (Aldrich) through a pulsed 400-μm nozzle kept at 85 °C. The molecular beam was allowed to pass through a 1-mm skimmer into a second chamber equipped with a TOF spectrometer. The laser system consisted of a frequency-doubled Nd:YAG laser ($\lambda = 532$ nm), which pumps two dye lasers. The dye frequencies were doubled and, when necessary, mixed with residual 1064-nm radiation. The ions formed by REMPI ionization in the TOF source were mass discriminated and detected by a channeltron after a 50-cm flight path.

Multipolymer-Supported Substrate and Ligand Approach to the Sharpless Asymmetric Dihydroxylation**

Hyunsoo Han and Kim D. Janda*

Since the initial solid-phase synthesis of oligopeptides by Merrifield[1] the use of polymers as supports, reagents or even catalysts for various reactions has increased.[2] Recently a high level of activity has been devoted to this field due to the application of combinatorial chemistry to drug discovery.[3] Although a resurgence of interest in polymers for organic synthesis has been seen, little effort has been paid to defining the structural

parameters of the supports. This is most evident for automated organic synthesis.

We demonstrated how a chiral ligand can be integrated onto a soluble polymeric species so that ligand-accelerated catalysis (LAC) can operate in an unhindered manner.[4] However, the converse case in which a small organic moiety is attached to a polymeric matrix has yet to be investigated. The implication of the combination of these two scenarios—immobilization of the ligand and the substrate—is that a multipolymer LAC reaction may be a feasible. We studied the influence of the structure of solid- and liquid-phase polymers on the Sharpless asymmetric dihydroxylation (AD) reaction. The outgrowth of these findings allowed us to successfully run a multipolymer Sharpless AD reaction.

A variety of supports have been used in organic synthesis.[5] Typically, they may be grouped into three categories: 1) minimal cross-linked supports that form well-solvated gels,[6] 2) porous but rigid supports with a high degree of cross-linking,[7] and 3) linear, soluble polymers that are also known as liquid-phase supports.[8] Three supports belonging to the first category, two low divinylbenzene-cross-linked polystyrene beads (Merrifield and Wang resin) and the graft copolymer polystyrene polyethylene glycol (Tentagel), were utilized. The choice of these resins was based on their fundamental differences. Merrifield and Wang resins are relatively hydrophobic matrices, whereas Tentagel is considered to be a hydrophilic tentacle polymer with more "solution-like" characteristics.[8b] The support used from the third category was polyethylene glycol (PEG). This homopolymer was enlisted because it fulfills the criteria for a third-group polymer, and its chemical reactivity differences contrasted that of Tentagel.

trans-Cinnamic acid was immobilized on the four polymeric supports (Figure 1). This ensured that the olefin was tethered as

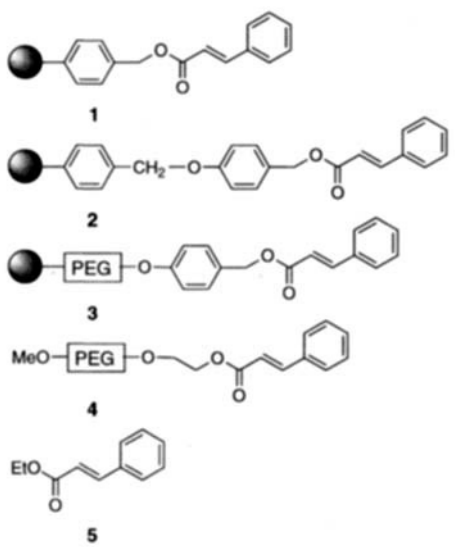

Figure 1. Polymer-bound *trans*-cinnamate esters **1**–**4** used in the Sharpless AD reaction as well as non-polymer counterpart **5**.

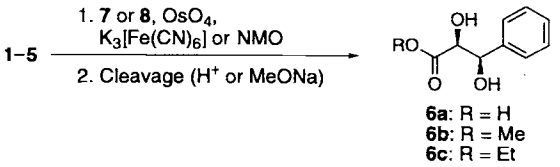
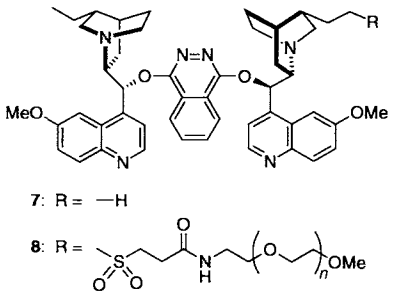
an ester on all supports, and that the overall reactivity was determined only by composition of the polymer. Because the AD reactivity of ethyl *trans*-cinnamate (**5**) using the ligand 1,4-phthalazinediyl diether hydroquinidine [$(DHQD)_2PHAL$, **7**] has been documented,[9] a direct correlation could be made between the solution and polymeric reactions [Eq. (1)].



(1)

Table 1 shows the results of the AD reaction of the four polymer-bound *trans*-cinnamate esters **1**–**4** using ligands **7** and **8**.



The amount of metal/ligand used, reaction time required for product conversion, and enantiomeric excess observed vary greatly depending on the support. The non-cross-linked liquid-phase resin **4** (Table 1, entries 6 and 10) provides the best overall results when considering reaction time and metal/ligand ratio. These results compare favorably with those from the reaction of the simple ethyl ester **5** (entry 11).

Table 1. AD reactions conducted with *trans*-cinnamate esters using ligands **7** and **8**.

Entry	Olefin	*t* [h]	OsO_4 [a]	Method [b]	Conversion [%] [c]	*ee* [%] [d]
1	**1**	72	0.01	A	–	–
2	**2**	72	0.01	A	–	–
3	**3**	24	0.01	A	3	99
4	**3**	24	0.02	A	63	98
5	**3**	24	0.10	A	96	99
6	**4**	0.5	0.10	A	100	99
7	**1**	24	0.01	B	100	88
8	**2**	24	0.01	B	100	90
9	**3**	24	0.01	B	100	87
10	**4**	24	0.008	A	80	97
11	**5**	24	0.008	A	100	97
12 [e]	**3**	24	0.02	A	60	98
13 [e]	**3**	24	0.10	A	98	98

[a] Equivalents of OsO_4 based on olefin. [ligand]/[OsO_4] = 2.5. [b] Method A: $K_3[Fe(CN)_6]$ and *t*-BuOH/water (1/1) at room temperature. Method B: NMO and acetone/water (10/1) at 4 °C. [c] Determined from the ratio of the signals of diol protons to that of the remaining olefin in the ^1H NMR spectrum. Absolute yields (entries 4–13) were between 25–85%. [d] Determined by NMR analysis of the derived bis(Mosher) ester of the diol. [e] Polymer-bound ligand **8** was used as the catalyst source ([**8**]/[OsO_4] = 2.5).

Among the three insoluble supports Tentagel (**3**) outperformed the Wang (**2**) and Merrifield resins (**1**) with $K_3[Fe(CN)_6]$ as oxidant (entries 1–5). However, the cross-linked polystyrene suppports **2** and **3** can provide a suitable environment for LAC when *N*-methylmorpholine *N*-oxide (NMO) is applied as the oxidant and acetone/water as the solvent (entries 7 and 8). It may be that supports **1** and **2** show an overall inability to support the AD reaction with $K_3[Fe(CN)_6]$ due to poor swelling properties in *t*-BuOH/water as solvent.[6] The consequences of poor swelling include limited chain mobility, which could com-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3616-1732 $ 17.50+.50/0

promise the location and distribution of catalyst and olefin within these matrices.

Somewhat unexpected was the large amount of metal and ligand that was required for the Tentagel resin (**3**) to provide a reasonable reaction time, degree of conversion, and enantioselectivity (compare entries 3–5). Interestingly, there appears to be a threshold of catalyst amount that is required for any conversion into diol to be seen (compare entries 3 and 4). We investigated this aspect further. In reaction 4 (Table 1), fresh, unbound olefin **5** (0.125 mmol) was added after 24 h along with OsO_4 (0.02 equiv based on olefin), K_2CO_3 (3.0 equiv), and $K_3[Fe(CN)_6]$ (3.0 equiv). There was only 10 % conversion of **5** into **6c** after a further 10 h. If unbound olefin **5** was used throughout the entire reaction, recharging the mixture with more **5** provided complete conversion into **6c** within 2.5 h. These results suggest that the catalyst becomes entangled in the insoluble support, thereby limiting its availability. Although resin **3** is more hydrophilic than **1** and **2**, it still must be considered as a "quasi-homgeneous" matrix that is subject to some of the same limitations as insoluble resins.

In evaluating these results we recognized that a correct combination of soluble and insoluble polymers (that is, a multipolymeric reaction) could, in principle, be suitable for AD reactions. The use of more than a single polymeric reagent and catalyst either simultaneously or consecutively was accomplished, but its exploitation has been limited to date.[10] The combination of Tentagel resin (**3**) and MeO-PEG-[$(DHQD)_2PHAL$] (**8**)[4, 11] was investigated as the multipolymer components. Entries 12 and 13 in Table 1 show that this combination of polymers can successfully support LAC. Although these two polymers are physically quite different, the outgrowth of this methodology translates into facile product separation and ligand reisolation. The significance of such technology should have direct applications to the automation of synthetic processes.[3, 12]

Experimental Section

Dichloromethane and methanol were dried over CaH_2 and powdered magnesium, respectively. Polyethylene glycol monomethyl ether (Aldrich, MeO-PEG, M_r = 5000) was dried over P_2O_5 under vacuum before use; Merrifield, Wang, and Tentagel resins were bought from Novabiochem. All other solvents and chemicals were obtained from commercial sources, and used without further purification unless stated otherwise. NMR spectra were measured on a Bruker AM-300 spectrometer.

1–4: *trans*-Cinnamic acid was coupled to each resin with the aid of coupling agents 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC)/*N*,*N*-dimethyl 4-pyridinamine (DMAP) in CH_2Cl_2. For the soluble polymer MeO-PEG, a dicyclohexylcarbodiimide (DCC)/DMAP combination was used for preparing **4**. Upon completion of reaction the urea formed was removed by filtration. Diethyl ether was added to the filtrate, and **4** separated as a white solid from the mixture. The degree of loading for each polymer was greater than 98%, determined by measuring the release of cinnamic acid and its methyl ester from the polymers with trifluoroacetic acid (TFA)/CH_2Cl_2 (v/v 95/5) and NaOMe in MeOH, respectively.

Asymmetric dihydroxylation: method A: A small aliquot of OsO_4 in *t*-BuOH (2.5% solution (wt%), see Table 1 for the amount used in each reaction) was added to a mixture of the ligand (see Table 1), $K_3[Fe(CN)_6]$ (0.250 g, 6 equiv based on olefin), K_2CO_3 (0.052 g, 3 equiv), and methanesulfonamide (0.012 g, 1 equiv) in *t*-BuOH/water (4 mL, v/v 1/1) at room temperature. After the reaction mixture was stirred for 10 min, the polymer-bound olefin (0.125 mmol, 1 equiv) was added in one portion, and the mixture further stirred for 24 h. Solid $Na_2S_2O_5$ was added(0.400 g), and the mixture stirred for an additional 5 min, filtered, and successively washed with acetone and CH_2Cl_2. The resin was dried over Na_2SO_4 under vacuum. The results of the reaction were determined by two methods: 1) The resin was suspended in TFA/CH_2Cl_2 (v/v 95/5) for 30 min. The resin was removed by filtration, and then solvent removed from the filtrate. The degree of conversion of the olefin into the dihydroxylated product was determined by NMR spectroscopy. 2) The resin was suspended in a solution of NaOMe in MeOH. The mixture was stirred for 2 h at room temperature, and the solvent removed under vacuum. The desired diol-methylester was isolated by column chromatography (silica gel; ethyl acetate/hexane 1/1). The enantiomeric excess of this product was determined by NMR analysis of the derived bis(Mosher) ester. Method B: A similar procedure to Method A was followed except acetone/water as solvent and NMO were used. The reaction mixture contained a small amount of OsO_4 in *t*-BuOH (2.5% solution, 13 μL, 0.01 equiv based on olefin), the ligand (0.0025 g, 0.025 equiv), NMO (0.022 g, 1.5 equiv), and tetraethylammonium acetate tetrahydrate (0.033 g, 1.0 equiv) in acetone/water (4 mL, 10/1 v/v) at 4 °C.

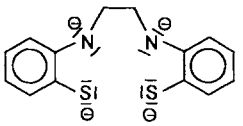
Stabilization of Iron Centers in High Oxidation State in the Mononuclear Complex [Fe^{V}(I)('N$_2$S$_2$')]**

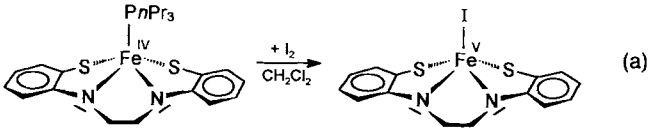
Dieter Sellmann,* Susanne Emig, and Frank W. Heinemann

Complexes containing iron centers in oxidation states higher than +III are intermediates in numerous biological oxidation processes[1] and of interest as potential catalysts for homogeneous oxidations. Discrete molecular complexes of Fe^{IV} are, however, rare,[2] and the even higher oxidation states Fe^{V} and Fe^{VI} have so far been established only for the solid-state structures of polynuclear tetraoxo ferrates such as $K_3[Fe^{V}O_4]$ and $K_2[Fe^{VI}O_4]$.[3] We have now found that Fe^{V} can be stabilized by the tetraanionic thiolate amido ligand 'N$_2$S$_2$'$^{4-}$ [=1,2-ethanediamide-*N*,*N*'-bis(2-benzenethiolate)(4 −)].



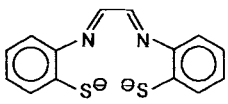
'N$_2$S$_2$'$^{4-}$

Oxidation of the readily accessible Fe^{IV} complex **1**[2a] with elemental iodine according to Equation (a) yielded **2**, which, to the best of our knowledge, is the first isolable molecular Fe^{V} complex. The lustrous crystals of **2** were dark black-brown and could be fully characterized.



1 **2** (a)

Figure 1 shows the molecular structure of **2** determined by X-ray structure analysis.[4] The crystal of **2** is composed of discrete molecules. Like the Fe^{IV} precursor complex **1**, **2** also exhibits a distorted tetragonal pyramidal structure. N and S donors form the base, and the iodo ligand occupies the apical position. All H atoms could be located, including the four H atoms of the C16–C26 bridge. This, the C16–N1 and C26–N2 distances that correspond to C–N single bonds, and the angle sums around the N atoms (N1: 360°, N2: 360.1°) confirm that the 'N$_2$S$_2$'$^{4-}$ ligand has remained intact and not undergone (oxidative) dehydrogenation to form the Schiff-base 'gma'$^{2-}$ [= glyoxal-bis(2-mercaptoanil)(2 −)].[5]



'gma'$^{2-}$

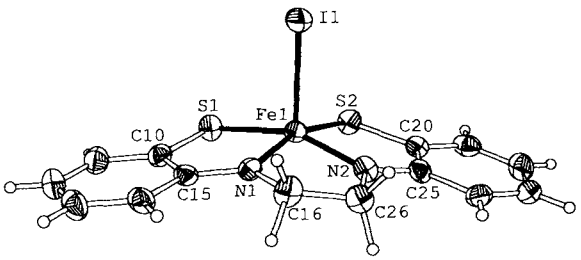


Figure 1. Molecular structure of **2**. Selected distances [pm]: Fe1–I1 255.52(9), Fe1–N1 184.2(4), Fe1–N2 185.1(5), Fe1–S1 218.1(2), Fe1–S2 218.8(2), N1–C16 146.0(6), N2–C26 145.6(6), C16–C26 150.6(8), N1–C15 133.4(7), N2–C25 134.7(7), S1–C10 171.5(5), S2–C20 172.1(6).

The Fe–S and Fe–N distances in **2** are very short and indicate S(thiolate)–Fe and N(amide)–Fe π donor bonds. Table 1 shows that the oxidation **1** → **2** does not change the [Fe('N$_2$S$_2$')] core distances, which are identical within the 3σ criterion. The Fe–I distance in **2** [255.52(9) pm] is short relative to Fe–I distances in Fe^{IV} complexes such as [Fe^{IV}(I)(L^{3-})] [259.3(2) pm; L^{3-} = pentane-2,4-dione-bis(*S*-alkylisothiosemicarbazonate)(3 −)].[2g]

Table 1. [Fe('N$_2$S$_2$')] core distances in [Fe^{IV}(P*n*Pr$_3$)('N$_2$S$_2$')] (**1**) and [Fe^{V}(I)('N$_2$S$_2$')] (**2**) [pm].

Bond	**2**	**1**[a]
Fe–N	184.7(5)[b]	184.0(6)
Fe–S	218.5(2)[b]	218.5(2)
N–C$_{aliphatic}$	145.8(6)[b]	147.2(7)
N–C$_{aromatic}$	134.1(7)[b]	134.8(8)
C–C$_{aliphatic}$	150.6(8)	154.3(13)
S–C	171.8(6)[b]	171.1(7)

[a] Complex **1** possesses crystallographically imposed C_s symmetry. [b] Averaged distances.

Complex **2** is paramagnetic. Its μ_{eff} value of 2.19 m_B at 296 K is compatible with one unpaired electron and a spin state of $S = 1/2$ and markedly distinguishes **2** from the Fe^{IV} precursor complex **1** (μ_{eff} = 2.76 m_B, $S = 1$, 295 K). The EPR spectrum of **2** shows an isotropic signal [g = 2.134, THF, 295 K; Figure 2a)], which splits anisotropically at 150 K [g_1 = 2.206, g_2 = 2.125, g_3 = 2.063; Figure 2b)]. The g value of **2** distinctly differs from that of organic radicals and is consistent with a Fe-centered unpaired electron.

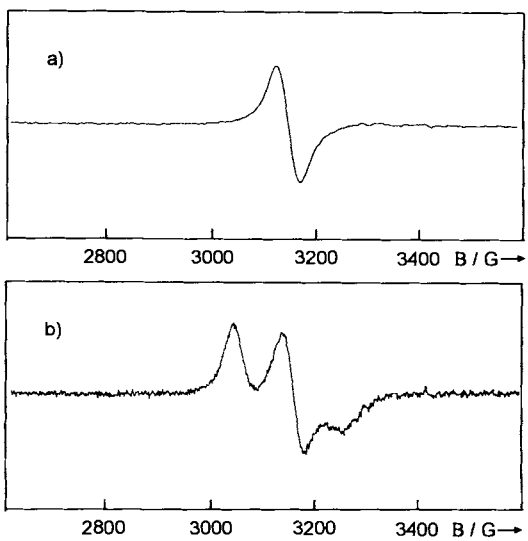

Figure 2. EPR spectra of **2** in THF at a) 295 K (g = 2.134) and b) 150 K (g_1 = 2.206, g_2 = 2.125, g_3 = 2.063).

The intense violet color of the solutions of **2** is due to a strong band at 550 nm ($\varepsilon = 33000\ L\ mol^{-1}\ cm^{-1}$, CH_2Cl_2) in the electronic spectrum of **2** (Figure 3). This band is slightly more intense than the corresponding band of **1**, but distinctly shifted to shorter wavelengths.

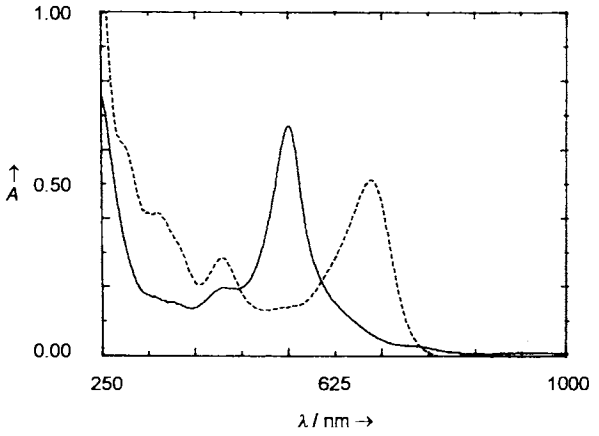

Figure 3. Electronic spectra of **2** (—) and **1** (···) in CH_2Cl_2 ($0.2\ 10^{-4}$ M, 295 K). A = absorption (arbitrary units).

The Mössbauer spectrum of **2** shows one symmetrical doublet (Figure 4). The isomeric shift of **2** [$\delta = 0.111(2)\ mm\,s^{-1}$, 4.2 K] is low, unexpectedly slightly larger than that of **1** [$\delta = 0.0396(2)\ mm\ s^{-1}$, 4.2 K], but outside the range observed

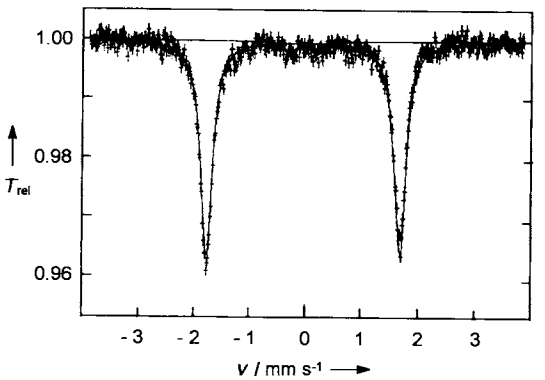

Figure 4. Mössbauer spectrum of polycrystalline **2** at 4.2 K (isomeric shift $\delta = 0.111(2)$ relative to α-Fe at 295 K, quadrupole splitting $\Delta E_Q = 3.41(5)$, line width $\Gamma = 0.125(3)$ in $mm\,s^{-1}$).

for square pyramidal $Fe^{III}(S = 1/2)$ complexes ($\delta = 0.16$–$0.38\ mm\,s^{-1}$).[6] The quadrupole splittings of both **2** [$\Delta E_Q = 3.41(5)\ mm\,s^{-1}$] and **1** [$\Delta E_Q = 3.1596(3)\ mm\,s^{-1}$] lie in the same range. Thus, the Mössbauer data do not allow an unambiguous differentiation between the oxidation states of the precursor complex **1** and the oxidation product **2**. This was rendered possible by the cyclic voltammograms. While **1** shows only two redox waves (+ 0.04, −0.86 V vs. the normal hydrogen electrode (NHE), CH_2Cl_2, 295 K), complex **2** shows three cathodic redox waves and, in addition, one anodic wave (+1.01, −0.22, −0.48, −0.77 V vs. NHE, CH_2Cl_2, 295 K, $50\ mV\,s^{-1}$; Figure 5). The cathodic waves are tentatively assigned to the redox couples Fe^V/Fe^{IV} (− 0.22 V), Fe^{IV}/Fe^{III} (− 0.48 V) and Fe^{III}/Fe^{II} (− 0.77 V). The reduction $Fe^V \rightarrow Fe^{IV}$ is irreversible, because it probably leads to release of the iodo

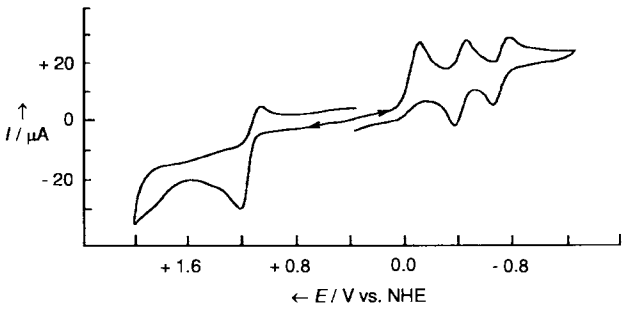

Figure 5. Cyclic voltammogram of **2** in CH_2Cl_2 (1×10^{-3} M, 0.1 M $NnBu_4PF_6$, 295 K, $50\ mV\,s^{-1}$).

ligand. In fact, the $[Fe^{IV}('N_2S_2')]$ fragment adds PR_3, $P(OR)_3$, and CN^-, but it does not add iodide.[2a, 7] The irreversible anodic oxidation wave of **2** suggests that even Fe^{VI} complexes with $[Fe^{VI}('N_2S_2')]$ cores may be accessible.

The results show that thiolate and amide donors are well suited to stabilize high oxidation states of iron. The oxidation state + v of the iron center in **2** follows from the charges of the tetraanionic $'N_2S_2'^{4-}$ and monoanionic I^- ligands. The assignment of the oxidation state is further supported by the method of preparation, the molecular structure, the magnetism, the electronic spectrum (when compared with that of **1**), and the electrochemical properties of **2**.

Iodide is a surprising ligand to find in a Fe^V complex, because FeI_3 is already unstable and instantaneously decomposes to give FeI_2 and I_2.[8] However, Fe^{IV} complexes with iodo ligands are known,[2g, h] and an important aspect to bear in mind is that the assignment of oxidation states, in a strict sense, requires completely ionic compounds. The complexes described here are covalent molecules, in which the removal of electron density from the iron center can be partially compensated by stronger iron–ligand interactions. In this regard, thiolate and amide donors with their lone pairs are perfectly suited to stabilize electron-deficient metal centers by π donation.

One question remains to be answered: why does the Mössbauer isomeric shift δ not decrease but rather slightly increase when **1** is oxidized to give **2**. The isomeric shift of complexes containing π ligands depends considerably less on changes in metal oxidation state than that of rather ionic complexes. $K_4[Fe^{II}(CN)_6]$ and $K_3[Fe^{III}(CN)_6]$, for instance, exhibit very similar δ values.[9] Furthermore, even Fe^{II} complexes such as $[AsPh_4][Fe(CN)_2(L^-)]$ [$\delta = 0.08\ mm\,s^{-1}$, 4.2 K; L^- = pentane-2,4-dione-bis(S-alkylisothiosemicarbazonate)(1 −)][2g] can exhibit isomeric shifts that are commonly observed only for Fe^{IV} complexes. Thus, the δ values of **2** and **1** can be rationalized on the qualitative basis that the isomeric shifts mainly depend on the shielding of the Fe center's s electrons. Replacing the phosphane ligand in **1** by the iodo ligand in **2**, however, is equivalent to the substitution of a π acceptor by a π donor ligand. Thus, increasing the shielding of the Fe center's s electrons in **2** by I → Fe π donation may counterbalance the removal of one d electron from the iron center in **1**.

Experimental Section

All operations were carried out under N_2 at room temperature by using standard Schlenk techniques. Solvents were dried and distilled before use. Fe^{IV} complex **1** was prepared according to literature methods [2a]. **2**: I_2 (265 mg, 1.04 mmol) was added to a green solution of **1** (510 mg, 1.04 mmol) in 20 mL of CH_2Cl_2. Black-brown microcrystals precipitated from the resultant red-violet reaction mixture. They were separated after 24 h, washed with 20 mL of CH_2Cl_2 and 30 mL of Et_2O and dried in vacuo for 1 day. Yield: 320 mg (67%). Elemental analysis calcd for $C_{14}FeH_{12}IN_2S_2$: C 36.95, H 2.66, N 6.15, S 14.09; found C 36.68, H 2.53, N 6.01,

Intra-Cavity Inclusion of $[CpFe^{II}(arene)]^+$ Guests by Cyclotriveratrylene**

K. Travis Holman, Jonathan W. Steed, and Jerry L. Atwood*

The trimeric, saucer-shaped molecule cyclotriveratrylene (CTV, **1**) forms the skeleton of the cryptophanes, a family of molecules that displays an impressive range of host–guest complexation behavior involving inclusion of neutral and cationic guest molecules within their elliptical cavities.[1] CTV itself has also been known for many years to form inclusion complexes incorporating a range of neutral guest molecules.[2] These solvates are almost invariably of the channel variety, however, in which the CTV units pack in a columnar fashion in the solid state along the crystallographic *b* axis, while guest species reside only in lattice voids caused by the inefficient packing of these columns.[3] Two distinct classes of CTV inclusion compounds have been identified based upon variations in the length of the crystallographic *b* axis and in the solid-state infrared spectra of the compounds. We have recently rationalized their differences on the basis of the hydrogen-bond-accepting properties of included guest species.[4] As a consequence of the columnar packing mode, conventional inclusion complexes of CTV are generally not as interesting as those of some derivatives (for example, CTC = cyclotricatechylene),[2] since they do not exploit the molecular cavity of this host.

We have recently demonstrated, however, that in the presence of an unusual guest, namely buckminsterfullerene, CTV may form the inclusion compounds $(C_{60} \subset CTV) \cdot 0.5\,C_{60} \cdot 0.5\,C_6H_5CH_3$[5] and $(C_{60} \subset CTV)$,[6] which are not of the column variety. Instead, the CTV cavity is occupied by a C_{60} molecule in such as way as to maximize noncovalent interactions between the electron-rich host and electron-poor fullerene. We have also reported the inclusion of both anionic and neutral guests within the cavities of organometallic CTV derivatives such as $[\{Ru(\eta^6\text{-}p\text{-cymene})\}_2(\eta^6\text{:}\eta^6\text{-CTV})]X_4$ ($X = CF_3SO_3$, ReO_4).[7] CTV has also very recently been shown to form complexes with carboranes in the solid state by formation of intermolecular CH···arene hydrogen bonds.[8]

Given the highly unusual solid-state structures observed with C_{60}, it was anticipated that this new type of inclusion within the bowl of a complex may well be observed for other relatively electron-poor guest molecules with planar π electron systems. In this regard, there is strong precedence for donor–acceptor (D–A) type interactions between appropriate organic species and organometallic sandwich complexes,[9] and these interactions often emanate as infinite one-dimensional D–A–D–A stacked arrangements in the solid state. With this as our supramolecular synthon,[10] we anticipated that a similar motif involving CTV and the appropriately chosen guest would result in a polar, one-dimensional (1D) architecture with each CTV "saucer" partially aligned. We report herein the preliminary results of a study of the solid-state inclusion of organometallic

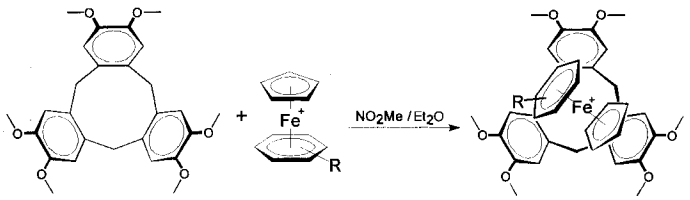
salts of the type $[CpFe^{II}(arene)][PF_6]$ ($Cp = C_5H_5$) by CTV (Scheme 1).



Scheme 1. Synthesis of the inclusion compounds **2**–**5**. R = Cl, *o*-Cl_2, *m*-Me_2, or 1,3,5-Me_3. Counterion: $[PF_6]^-$.

Diethyl ether was allowed to diffuse into solutions of CTV and $[CpFe^{II}(arene)][PF_6]$ (molar ratio 1:1) in nitromethane to afford, over a period of three weeks, large crystals of host–guest complexes **2**–**5** in excellent yields.[11] All crystallizations were performed in the dark to avoid photolysis of the arene.[12]

$[CpFe(C_6H_5Cl) \subset CTV][PF_6]$ **2**

$[CpFe(o\text{-}C_6H_4Cl_2) \subset CTV][PF_6]$ **3**

$[CpFe(m\text{-}C_6H_4Me_2) \subset CTV][PF_6]$ **4**

$[CpFe(1,3,5\text{-}C_6H_3Me_3) \subset CTV][PF_6]$ **5**

Complexes **2**–**4** are essentially isostructural and crystallize in the noncentrosymmetric space group $Cmc2_1$. The predominant feature of these structures is the formation of a 2D polar framework in the crystallographic *ac* plane based upon π-donor/π-acceptor-like interactions between the guest cation and the electron-rich arene faces of the CTV molecule (Figure 1). In each

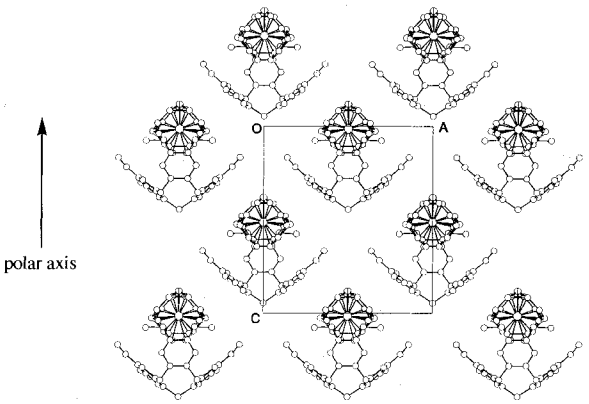


Figure 1. The polar 2D sheet structure in **2**–**4** that arises from disorder of the guest cations. Anions and arene substituents have been removed for clarity.

case the included cation is incorporated into the CTV cavity and appears to be statistically disordered across a mirror plane with the cyclopentadienyl ligands stacked against the inner ring faces of the CTV cavity. The arene portion of the cation is directed out of the cavity and interacts with the outer face of another CTV molecule in the *ac* plane. A disorder-resolved view of each included cation is shown in Figure 2a. It is this bridging function of the cation that induces the polarity along the sheet in which all of the CTV molecules are aligned in a canted fashion. The sheets then pack offset and parallel in the third dimension resulting in an overall noncentrosymmetric structure. This feature is particularly noteworthy in that a polar axis is a topological requirement for the observation of technologically useful physical properties such as second harmonic generation, piezo-, pyro-, and ferroelectric effects.[13]

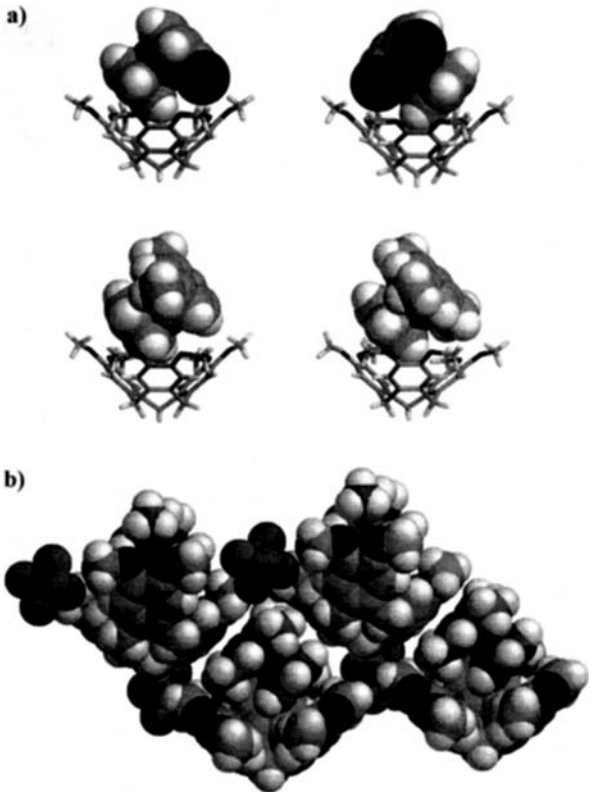

Figure 2. a) A disorder-resolved view of the host–guest complexes in **2**–**5**. b) A space-filling model of the 1D stacked arrangement in **5**. The non-hydrogen atoms of the $[CpFe(mesitylene)]^+$ guest cation have been shaded dark for clarity.

The disorder of the guest cations provide the extra dimension to the stacking array in **2**–**4**, deviating from the anticipated 1D format. The 1D architecture was realized, however, in **5**, which crystallizes in the very closely related monoclinic spacegroup *Cc*, with a β angle of only 92.0°. In this case the only difference is that the extra methyl group in $[CpFe(mesitylene)]^+$ ($[CpFe(m\text{-xylene})]^+$ has only two methyl groups) causes the arene–CTV interaction to be significantly offset relative to the corresponding interaction of the others. This is highlighted by the β angle and the longer distance between the centroids of the arene and the CTV ring (4.45 Å in **5**, 3.90–4.06 Å in **2**–**4**). Notably, the closest carbon–carbon contacts between the two C_6 rings are still of similar magnitude (Table 1). It is unclear whether this offset is due to the optimization of favorable electronic interactions between the two rings, or whether it arises in order to

minimize steric repulsions between the extra methyl group of the mesitylene fragment and the methylenic portion of the CTV molecule. The result, in any case, is loss of the cation disorder and propagation of the interaction along the predicted 1D stack (Figure 2b), rather than 2D format observed in **2**–**4**.

The host and guest seem to have little affinity in polar solvents. The visible absorption spectrum of the [CpFe(arene)][PF_6] salts in CH_3CN shows essentially no change upon the addition of up to a 50-fold excess of CTV. Furthermore, no chemical shift changes are observed for either CTV or the guest cation in the ^{1}H NMR spectrum upon the addition of up to a tenfold excess of [CpFe(ClC_6H_5)][PF_6].[14] This is not surprising considering that the association constant of various electron-rich arenes with [(mesitylene)$_2$Fe]$^{2+}$[15] are less than 2.5 M^{-1} in acetonitrile solution.[9]

The present work demonstrates a very significant extension of supramolecular chemistry involving the cavity of CTV. The formation of this type of inclusion species with electron-poor guests, in contrast to the well-known channel complexes, suggests possible applications in the engineering of crystalline materials with interesting physical properties, and in separation science. These areas are currently under investigation.[16]

Solvent-Anchored Supported Liquid Phase Catalysis: Polyoxometalate-Catalyzed Oxidations**

Ronny Neumann* and Michal Cohen

An important desired refinement of homogeneous transition metal catalyzed reactions is the heterogenization of the catalysts to achieve facile recovery and recycling of the catalyst. Two basic approaches have been used. The first is immobilization by covalent binding or adsorption of catalysts on supports.[1] This generally leads to loss of activity and selectivity with respect to the original homogeneous analog. For catalytic oxidations the polar products and oxidants react with the binding units, resulting in leaching of the metal; recent reports describe improved supported catalysts.[2] Loss of catalytic species in oxidations has been prevented by confinement within zeolites[3] or dissolution in nonvolatile siloxanes.[4] The second approach is to carry out the reaction with two liquid phases; the catalyst is dissolved in one phase (water[5] or fluorinated hydrocarbon[6]), and the product is separated into the other. Rates of such reactions are often limited by slow mass transfer.

Supported liquid phase (SPL) or supported aqueous phase (SAP) catalysis[7] combines two-phase catalysis with the use of a solid support. This hybrid technique calls for dissolution of a catalyst in a hydrophilic phase (water, ethylene glycol, or polyethylene glycol), which is then adsorbed onto a support. Although the catalyst is immobilized on a solid surface, the reaction takes place at the liquid–liquid interface. Hydroformyl-

ations,[8] Wacker-type oxidations,[9] and enantioselective hydrogenations[10] have been described.

Here we report on a new immobilization technique for homogeneous catalysts, solvent-anchored supported liquid phase catalysis. In the present application polyethers are covalently attached to silica surfaces. The bound polyether acts as a solvent and/or a complexing agent for the oxidation catalyst, in this case polyoxometalates (POM). Two different reaction modes have been described (Figure 1). In the first case the bound phase with

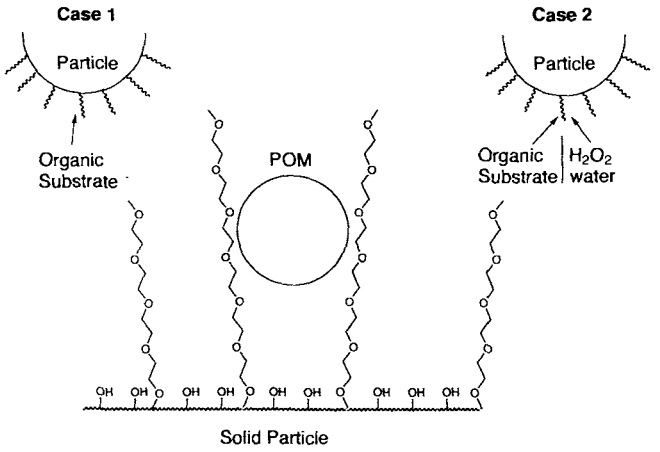

Figure 1. Illustration of the solvent-anchored supported liquid phase catalytic system. POM = polyoxometalate.

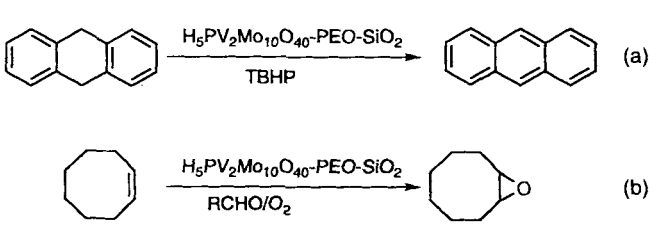
polyether (polyethylene oxide (PEO)) catalyst is in contact with a single liquid phase containing substrate. As opposed to SPL and SPA catalysis, the liquid phase here is miscible with the bound polyether, and reaction takes place within the polyether phase, thus minimizing mass-transfer constraints. The mixture appears homogeneous upon stirring but separates upon settling. In the second case the bound polyether catalyst phase is in contact with two imiscible liquid phases; one contains the oxidant, and the other the organic substrate. The supported catalyst phase is at the interphase where both reactants are soluble and meet to react.

The catalyst particles were prepared in three stages. First $(CH_3O)_3SiPhCH_2Cl$ was allowed to react with polyethylene glycol monomethyl ether (PEGME, MW = 350) or polypropylene glycol monomethyl ether (PPGME, MW = 200) to form $(CH_3O)_3SiPhCH_2O(CH_2CHRO)_nCH_3$ (**1a**: R = H; **1b**: R = Me). Then the monomer **1** was copolymerized with $Si(OCH_2CH_3)_4$ by the sol-gel method with dibutyltin dilaurate as catalyst. Finally the xerogel obtained was impregnated with the polyoxometalate catalysts to form the final catalyst assembly.

Examples that demonstrate the first reaction mode are the dehydrogenation of 9,10-dihydroanthracene with $H_5PV_2Mo_{10}O_{40}$ as catalyst[11] and 70% *tert*-butylhydroperoxide (TBHP) as oxidant [Eq. (a)],[12] and the epoxidation of cyclooctene with the same catalyst and aldehyde/O_2 as oxidant [Eq. (b)].[13]



Dehydrogenation of dihydroanthracene was carried out by mixing dihydroanthracene (0.2 mmol) in toluene (0.1 mL), 70% TBHP (0.4 mmol), and catalyst (15 mg) containing 0.002 mmol of $H_5PV_2Mo_{10}O_{40}$ at room temperature for 24 h. The silica used was 25% PEO–SiO_2. Analysis of the reaction mixture showed that the reaction was quantitative, yielding 96% anthracene and 4% anthraquinone. The catalyst was recycled without loss of activity, and no catalyst leaching or decomposition was measured by UV/Vis spectroscopy or atomic absorption, respectively. This is perhaps not surprising considering that such acidic Keggin compounds are strongly complexed by diethyl ether.[14] Therefore, the $H_5PV_2Mo_{10}O_{40}$ polyoxometalate is most likely complexed rather than simply dissolved within the PEO phase. Nonsupported $H_5PV_2Mo_{10}O_{40}$ was less effective (87% conversion) and less selective (77% selectivity with respect to anthracene). Using simply unsupported or unattached $H_5PV_2Mo_{10}O_{40}$ tetraglyme as controls did not yield a true heterogenous system, but rather a catalyst dissolved in the organic phase.

The $H_5PV_2Mo_{10}O_{40}$/PEO–SiO_2 catalyst assembly was further tested with the reaction shown in Equation (b). In typical reaction cyclooctene (5 mmol) was allowed to react with isobutyraldehyde (IBA, 10 mmol) in 1,2-dichloroethane (4 mL); the reaction was catalyzed by $H_5PV_2Mo_{10}O_{40}$/25% PEO–SiO_2 (150 mg) containing 0.0075 mmol of the POM at 23 °C under O_2 (1 atm). Figure 2 gives the reaction profile for the supported

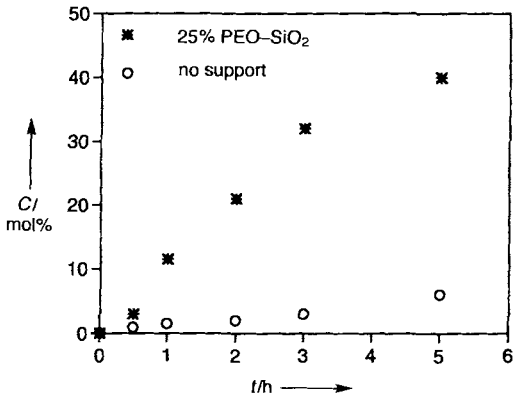


Figure 2. Oxidation of cyclooctene with isobutyraldehyde (IBA)/O_2 with supported $H_5PV_2Mo_{10}O_{40}$. Reaction conditions: cyclooctene (5 mmol), IBA (10 mmol), $H_5PV_2Mo_{10}O_{40}$/25% PEO–SiO_2 (150 mg) containing 0.0075 mmol of the POM in 1,2-dichloroethane (4 mL) at 23 °C and under O_2 (1 atm). Cyclooctene oxide was the sole product. *C* = conversion.

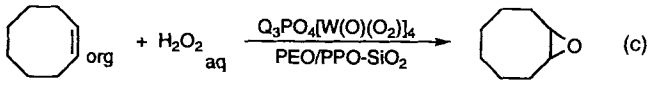
catalyst and the control experiment with the nonsupported catalyst. The advantage of using the supported catalyst is clear. Furthermore, loading of $H_5PV_2Mo_{10}O_{40}$ on the catalyst particle (constant weight) has little effect on the reaction profile. Use of other aldehydes showed the following relative reactivity normalized to IBA: $(CH_3)_3CCHO$ (2.2) > $(CH_3)_2CHCHO$ (1) > $CH_3(CH_2)_3CHO$ (0.2) ≈ $CH_3CH{=}CHCHO$ (0.015) > C_6H_5CHO (≈0). As in the previous case, the catalyst was recycled without loss of activity, and no catalyst leaching or decomposition was measurable.

The utility of solvent-anchored supported liquid phase catalysis in the second reaction mode was demonstrated by the epoxidation of cyclooctene with aqueous hydrogen peroxide with $Q_3PO_4[W(O)(O_2)]_4$ as the catalyst [Q = tetrahexylammonium; Eq. (c)].[15] In a typical reaction cyclooctene (1 mmol) and 30% H_2O_2 (2 mmol) were mixed with the catalyst (100 mg) at room temperature. The latter consisted of $Q_3PO_4[W(O)(O_2)]_4$ (0.005 mmol) on 20% PEO/PPO–SiO_2. This reaction was per-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3616-1739 $ 17.50+.50/0



formed without an organic solvent, an important ecological advantage. In this case the functionalization of the silica with the correct balance of polyethers is critical (Figure 3). Use of hydrophilic PEO yielded only low rates and conversions. Non-

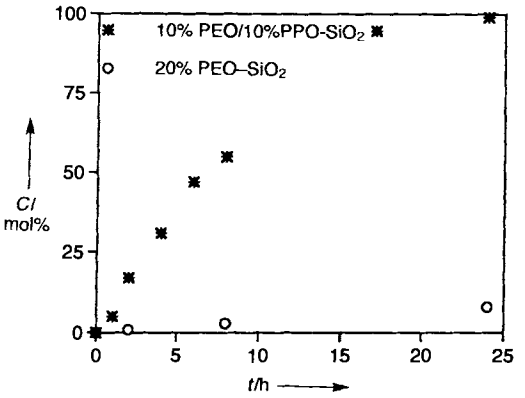


Figure 3. Oxidation of cyclooctene with 30% H_2O_2 catalyzed by supported $Q_3PO_4[W(O)(O_2)]_4$. Reaction conditions: cyclooctene (1 mmol), 30% H_2O_2 (2 mmol), $Q_3PO_4[W(O)(O_2)]_4$/20% PEO/PPO-SiO_2 (100 mg) containing 0.005 mmol of the POM at 23 °C. Cyclooctene oxide was the sole product. C = conversion.

supported $Q_3PO_4[W(O)(O_2)]_4$, that is, solid POM that is slightly dissolved in cyclooctene, was also inactive. On the other hand, a mixture of 10% PEO and 10% PPO-SiO_2 gave the optimal catalyst particle. The hydrophilic-hydrophobic balance of the catalyst particle must be adjusted to optimize the solubility of both cyclooctene and hydrogen peroxide in the polyether-bound phase. The catalyst 20% PPO-SiO_2 was almost as effective, but further increases in PPO content reduced the activity. The catalyst particle was recycled five times without loss of catalytic activity. Use of a reaction filtrate showed no catalytic species and no catalytic activity.

The new concept of solvent-anchored supported liquid phase catalysis has been introduced and demonstrated for oxidation reactions catalyzed by polyoxometalates. These new catalytic systems are more active and selective than analogous nonsupported systems, and catalytic activity is retained after recycling. Use of this technique will be expanded to other reactions and catalysts.

Experimental Section

Monomers **1** were prepared by allowing $(CH_3O)_3SiPhCH_2Cl$ (25 mmol) to react with $CH_3(OCH_2CH_2)OH$ (MW = 350; 25 mmol) or $CH_3(OCH(CH_3)CH_2)OH$ (MW = 200; 25 mmol) in acetone (100 mL) in the presence of solid K_2CO_3 (125 mmol) at reflux for 18 h. The solid salts were removed by centrifugation, and the solvent removed under vacuum. No further purification was carried out at this point. The functionalized xerogels were prepared by dissolving appropriate amounts of **1** and $Si(OEt)_4$ (in total 5 mmol) in acetone (20 mL). Water (10 equiv) and dibutyltin dilaurate (0.01 equiv) were added to initiate polymerization. The reaction mixture was held at 60 °C for three hours and left to concentrate by evaporation of solvent for two days at room temperature. The functionalized silica particles were carefully washed twice with water and ethanol and dried under vacuum. Final catalytic assembles were prepared by impregnating the polyoxometalates onto the silicates as follows: For the reaction in Equation (a) $H_5PV_2Mo_{10}O_{40}\cdot xH_2O$ (440 mg, 0.2 mmol) was dissolved in acetone (10 mL) and added to 20% PEO-SiO_2 (1.5 g), and the solvent removed. The silicate was then dried overnight under vacuum at room temperature. The procedure was identical for the reaction in Equation (b) except that $H_5PV_2Mo_{10}O_{40}\cdot xH_2O$ (165 mg, 0.075 mmol) was used. For the reaction in Equation (c) $[(C_6H_{13})_4N]_3PO_4[W(O)(O_2)]_4$ (1.04 g, 0.5 mmol) was dissolved in $CHCl_3$ (20 mL) and added to 20% PEO/PPO-SiO_2. The mixture was then treated as above.

Typical oxidations were carried out in 5-mL, magnetically stirred vials. Material quantities and reaction conditions are given in the text. The reaction mixtures were analyzed by GLC (HP 5890) with a RTX-1 column (30 m, 0.32 mm ID, 0.25 μm methylsilicone coating). The catalyst was recovered by filtration followed by washing to remove reaction remnants and drying.

Palladium-Catalyzed Regioselective Mono- and Diarylation Reactions of 2-Phenylphenols and Naphthols with Aryl Halides**

Tetsuya Satoh, Yuichiro Kawamura, Masahiro Miura,* and Masakatsu Nomura

The palladium-catalyzed substitution reactions of aryl halides and their synthetic equivalents such as aryl triflates are highly useful for the preparation of substituted aromatic compounds. In these reactions arylpalladium(II) complexes occur as common intermediates which react with various reagents including alkenes, alkynes, and a number of organometallic species to give the corresponding products.[1] While aryl halides may also react

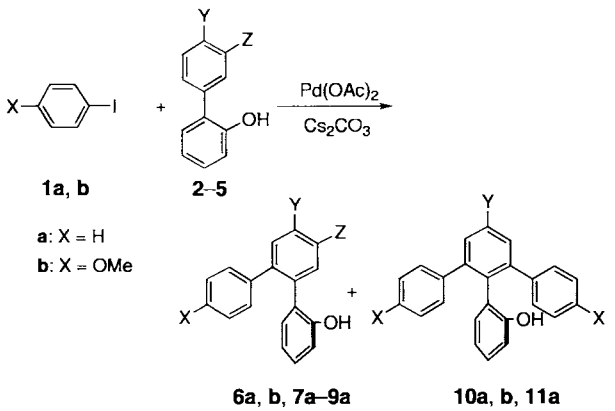
with aromatic compounds accompanied by cleavage of an aromatic C–H bond to give biaryls, only intramolecular cases are known to be generally effective.[2] Meanwhile, in the course of our study of palladium-catalyzed reactions with phenolic substrates,[3] we observed that the intermolecular cross-coupling of 2-hydroxybenzaldehydes with aryl iodides proceeded smoothly when the catalyst system $PdCl_2$/LiCl was used in the presence of sodium carbonate as base. Since the products are 2-aroylphenols, the reaction appears to involve activation of the aldehyde C–H bond.[3a] The phenolic function seems to act as a good anchor for this reaction, which suggests that arylation of other phenolic substrates should also be possible. Indeed, phenylation of 2-phenylphenol with iodobenzene was found to proceed to some extent, giving a terphenyl derivative; however, the reaction was very sluggish.[3a] We now report our new findings that when an appropriate base is employed, not only monoarylation, but also diarylation of 2-phenylphenols can take place effectively and regioselectively to afford sterically crowded 1,2,3-triarylbenzene derivatives;[4] and 1- and 2-naphthols can also be arylated.

When iodobenzene (**1a**; 1.2 mmol) was treated with 2-phenylphenol (**2**; 1.0 mmol) in the presence of $Pd(OAc)_2$ (0.05 mmol) with Cs_2CO_3 as base, a phenyl group was selectively introduced onto the 2′-position of **2** to produce 1,1′:2′,1″-terphenyl-2-ol (**6a**) in 76% yield (Scheme 1, Table 1). Other alkaline bases such as K_2CO_3 and Na_2CO_3 were much less effective than Cs_2CO_3 (25 and 13% yield, respectively, under the same conditions). When $PdCl_2$ was used in place of $Pd(OAc)_2$ the yield of **6a** was 66%. Increasing the amount of both **1a** and the base to 4 mmol led to further arylation to afford the corresponding diarylated product **10a** in 62% yield along with a minor amount of **6a** (25%). The results for the reactions of 4-iodoanisole (**1b**) with **2** and of **1a** with 2-(4-methylphenyl)phenol (**3**) demonstrate the generality of the present diarylation as well as monoarylation. In the reactions of 3′-substituted 2-phenylphenols **4** and **5** with **1a**, however, only the monoarylated products **8a** and **9a**, respectively, were formed even when an excess of **1a** was employed.

The monoarylation of **2** serves as an example in a possible mechanism illustrated in Scheme 2 (neutral ligands are omitted). Oxidative addition of aryl iodide to a palladium(0) species generated in situ followed by reaction with the phenolate forms aryl(aryloxy)palladium intermediate **A**. Then, **A** may be transformed into diarylpalladium species **B**, and the subsequent reductive elimination occurs to give the monoarylated product.[5] Coordination of the phenolic oxygen to the palladium center in **A**, similar to that in the coupling of 2-hydroxybenzaldehydes with aryl iodides,[3a] is thus considered to be the key to the effective, regioselective C–H bond activation. The second arylation may proceed by the same mechanism. The results of the reactions of **1a** with **4** and **5** suggest that a) the existence of a substituent at the 3′-position of **2** prevents the second arylation for steric reasons, and b) the transformation of **A** into **B** is feasible even when the substituent is strongly electron-withdrawing or electron-releasing.[6]



Scheme 1. Cross-coupling of **1a**, **b** with **2**–**5** (see also Table 1).

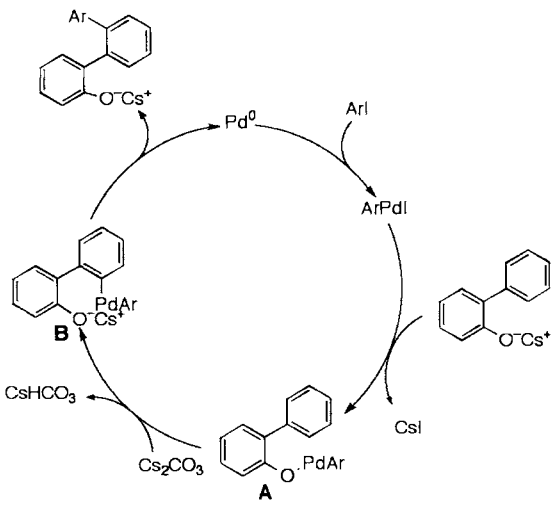
[a] Determined by gas chromatography based on ArOH used. Value in parentheses indicates yield after isolation. [b] Iodobenzene (**1a**; 2 mmol) and Cs_2CO_3 (2 mmol) were used.



Scheme 2. Possible reaction mechanism for the cross-coupling of aryl iodides with 2-phenylphenol (**2**) to afford the corresponding monoarylation product.

With the present catalytic system 1-naphthol (**12**) was monophenylated to give 8-phenylnaphthol (**13**) selectively (Scheme 3). The use of Cs_2CO_3 was also essential for the catalytic reaction to take place smoothly. It was also of considerable interest that when 2-naphthol (**14**) was treated with two equivalents of bromobenzene (**1c**) and $Pd(OAc)_2/PPh_3$, formally diphenylated compound **15** was obtained as the predominant

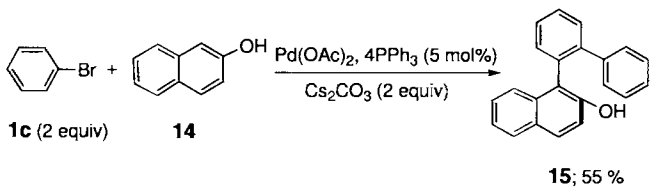
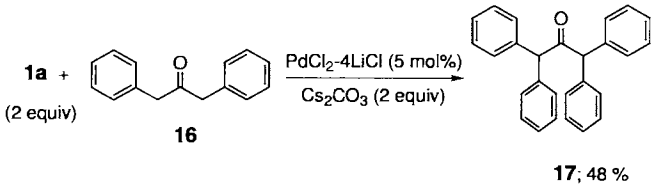
product (Scheme 4). The first step of this reaction, monophenylation at the 1-position of **14**, may involve nucleophilic attack of the corresponding naphtholate on a phenylpalladium(II) species generated in situ. Note that while palladium-catalyzed intramolecular coupling of aryl halides with enolates including phenolates is known,[7] the corresponding intermolecular version has been limited to only few reactions in which nitriles function as carbon nucleophiles.[8] Nevertheless, the present procedure was found to bring about the intermolecular cross-coupling of **1a** with 1,3-diphenyl-2-propanone (**16**) to give 1,1,3,3-tetraphenyl-2-propanone (**17**; Scheme 5).



Scheme 4. Cross-coupling of **1c** with **14**: DMF, N_2, 150 °C, 1.5 h.



Scheme 5. Cross-coupling of **1a** with **16**: DMF, N_2, 100 °C, 5 h.

Experimental Section

A mixture of **1** (1.2–4 mmol), ArOH **2–5**, **12**, or **14** (1 mmol), a palladium catalyst (0.025–0.05 mmol), Cs_2CO_3 (1.2–4 mmol), and DMF (5 mL) was stirred in the presence or absence of molecular sieves 4 Å (200 mg) under nitrogen at 100–150 °C for 1.5–44 h. After cooling, the reaction mixture was poured into dilute hydrochloric acid, extracted with ether, and dried over sodium sulfate. The product was isolated by column chromatography on silica gel using hexane/dichloromethane or hexane/ethyl acetate as eluent.

Selected data for the new products obtained are listed in Table 2. The structures were determined with the aid of ^{1}H NMR, NOE, COSY, and HOHAHA experiments. Satisfactory combustion analysis data were also obtained. Compounds **6a**[9], **13**[10], and **17**[11] are known.

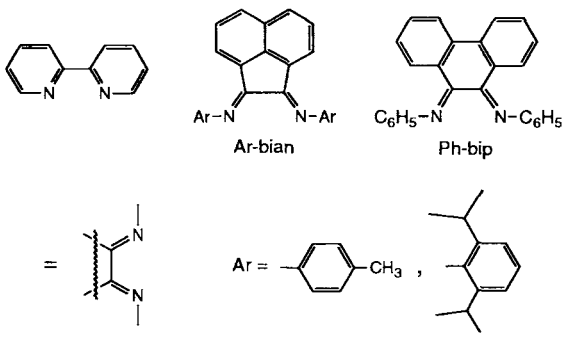
Catalytic Three-Component Synthesis of Conjugated Dienes from Alkynes via Pd^0, Pd^{II}, and Pd^{IV} Intermediates Containing 1,2-Diimine**

Ruud van Belzen, Helmut Hoffmann, and Cornelis J. Elsevier*

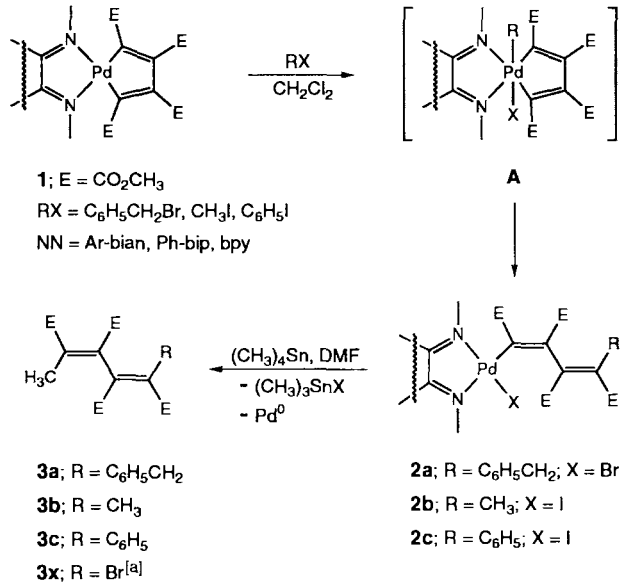
The direct synthesis of conjugated dienes from alkynes is highly desirable for forming valuable synthetic intermediates.[1] A number of methods are available for the stereoselective preparation of dienes from acetylenes,[2] but these either rely on the use of a stoichiometric amount of a reactive organometallic species (precluding the presence of sensitive substituents),[3] require more than one reaction step,[4] or start from pure stereoisomers of alkenyl compounds in cross-coupling reactions.[5] A high-yield, selective catalytic procedure for preparing conjugated "open-chain" dienes directly from acetylenes has not been described.[6]

As part of our continuing studies on carbon–carbon and carbon–heteroatom cross-coupling reactions[7] mediated by palladium compounds with ancillary, rigid, bidentate nitrogen ligands (Scheme 1), instead of the usual phosphanes, we report a new catalytic three-component synthesis of conjugated dienes by coupling of alkynes with an organic halide and tetramethyltin. Mechanistic details have been elucidated that reveal that stereospecific oxidative addition and reductive elimination at carbopalladacyclic compounds occurs, and that intermediate Pd^0, Pd^{II}, and Pd^{IV} species are involved in the catalytic cycle.



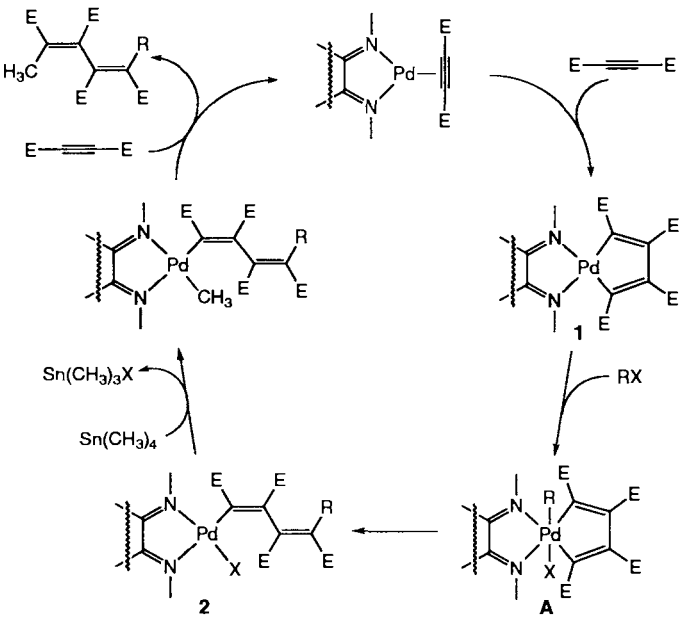
Scheme 1. Bidentate N ligands.

Palladacycles **1**[8] react with one equivalent of an organic halide (for example benzyl bromide, methyl iodide, or iodobenzene) in dichloromethane at 20 °C to give dienyl(NN-κ^2-*N*,*N*)palladium(II) halides **2**[9] (Scheme 2; NN = bis (arylimino)acenaphthene (Ar-bian), bis(phenylimino)phenanthrene (Ph-bip),[10] or 2,2′-bipyridine (bpy)). Compounds **2** are formed by a sequence of oxidative addition and reductive elimination at palladium via triorgano(NN-κ^2*N*,*N*)palladium(IV) halides **A**.[11] Reaction of **2a–c** with tetramethyltin in DMF at 60–85 °C leads to the selective formation of 2,5-difunctionalized 2,4-hexadienoates **3a–c**. Sequential addition of methyl iodide and one equivalent of Br_2 to **1** in dichloromethane results in the 2-bromo-5-methyl derivative **3x**.



Scheme 2. Stoichiometric reaction of palladacyclopentadienes **1** with organic halides and Me_4Sn. [a] With addition of Br_2 (instead of Me_4Sn) to **2b** in CH_2Cl_2 directly after its formation.

Since formation of palladacycles **1** from $[Pd(dba)_2]$ (dba = dibenzylideneacetone) and electron-poor alkynes is much faster than oxidative addition of benzyl bromide to zero-valent Pd species, and insertion of a third molecule of acetylene in **1** is slower than reaction of the organic halide with **1** to give **2**, we anticipated that a catalytic procedure for the synthesis of dienes **3** (Scheme 3), consisting of the single steps shown above, was feasible. Indeed, employing **1** as the precatalyst (or $[Pd(dba)_2]$ and an equimolar amount of Ar-bian or Ph-bip) with



Scheme 3. Proposed cycle for the three-component synthesis of conjugated dienes from alkynes, RX, and Me_4Sn catalyzed by palladium/N ligand. E = CO_2CH_3; RX = $C_6H_5CH_2Br$, CH_3I, C_6H_5I.

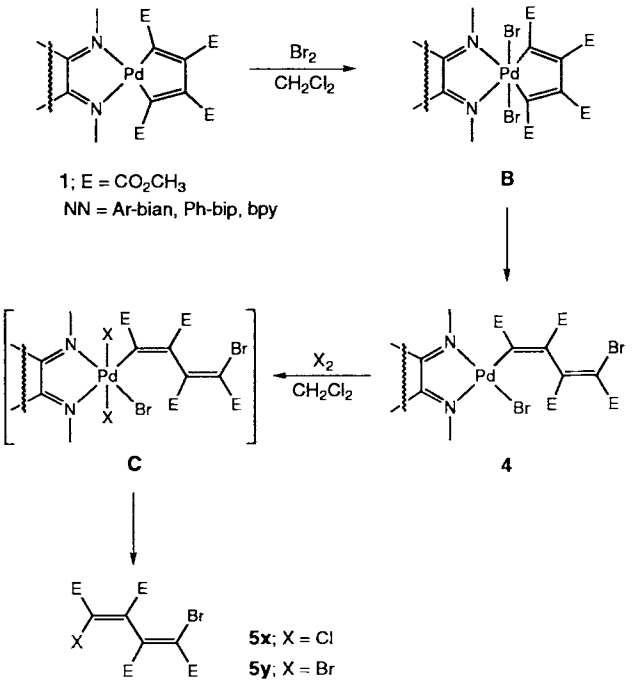
100 equivalents of dimethyl butynedioate, 50 equivalents of tetramethyltin; and 50–200 equivalents of benzyl bromide, methyl iodide; or iodobenzene in DMF at 65 °C resulted after 8–16 h in the complete conversion of the alkyne into conjugated dienes **3a–c**. DMF was selected as the solvent to obtain convenient rates, as reactions in acetonitrile and THF are sluggish, probably because transmetalation is the rate-determining step. The best results were obtained when employing [Pd(Ar-bian)] compounds as the catalyst (71–85% yields of isolated **3a–c**). 1-Dimethylamino-1,2-di(methoxycarbonyl)ethene formed as a secondary product in approximately 10% yield due to base- or palladium-catalyzed decarbonylative addition of DMF to coordinated dimethyl butynedioate.[12] This, in conjunction with the fact that the latter reaction does not occur in the absence of palladium species, points to the occurrence of zero-valent palladium species in the catalytic cycle. In the case of **3c** small amounts of the cyclotrimerization product hexamethylmellitate (4%) and 1-phenyl-1,2-di(methoxycarbonyl)-1-propene (7%)[13] formed as well. Importantly, no direct cross-coupling between the organic halide and tetramethyltin took place. We obtained palladacycles **1** containing mono- and bidentate nitrogen ligands for dimethyl butynedioate (E = CO_2Me) and hexafluoro-2-butyne (E = CF_3), but stoichiometric or catalytic reactions of methylpropynoate, phenylacetylene, and 1-octyne were unsuccessful so far.

Reactions of **1** with two equivalents of Br_2 in dichloromethane at 20 °C afforded (2*E*,4*E*)-2,5-dibromo-2,4-hexadienoates **5y** and [$PdBr_2$(NN-κ^2N,N)] (Scheme 4). Intermediate **B**, a diorganopalladium(IV) dihalide,[14] formed instantaneously and quantitatively at 200 K in CD_2Cl_2, as demonstrated by in situ ^{1}H NMR spectroscopy for NN = bis(2,6-diisopropylphenyl)bian or Ph-bip; the signals for the methoxycarbonyl groups adjacent to palladium in **B** are shifted to higher frequency by about 0.8 ppm.[15] The C_{2v} symmetry of **B** was apparent from the pair-wise equivalence of protons on the backbone of the NN ligand, the palladacyclopentadiene moiety, and the two (perpendicular) *N*-aryl groups, and from the fact that only two



Scheme 4. Stoichiometric reactions of palladacycles **1** with molecular halogen to give 1,4-dihalo-1,3-dienes via diorganopalladium(IV) dihalides **B** and organopalladium(IV) trihalides **C**.

doublets were observed for the four CH(CH_3)$_2$ groups of the bis(*N*-2,6-diisopropylphenyl)bian derivative.[16] Reductive elimination from **B** to give **4**, which could be isolated,[17] was completed in 10–15 min at 200 K.

Reaction of **4** with Br_2 gave **5y** and [$PdBr_2$(NN-κ^2N,N)], and that of **4** with PhI·Cl2 led to the chemoselective formation of 2-bromo-5-chloro-2,4-hexadienoates **5x**. The 5-chloro-2,4-hexadienylpalladium(II) chloride analogue of **4** also reacted with Br_2 to give exclusively **5x**. These results, taken together with the fact that no elimination of dibromodienes was observed from the reaction of **4** with ICl and, moreover, that such reactions could not be effected with palladium–phosphane analogues of **4**, strongly indicate the occurrence of intermediate organopalladium(IV) trihalide species **C**, from which stereospecific reductive elimination of one of the apical halogens and the dienyl moiety takes place.

Interestingly, three oxidation states of palladium are involved in the catalytic cycle. This merits further attention, especially in view of the current interest in catalytic reactions (presumably) involving palladium in high oxidation states.[11a, 14b, c, 18] Phosphane ligands are not compatible; they either react with the alkyne, or the palladium–phosphane species involved exhibit no catalytic activity whatsoever under the conditions described.

To our knowledge the procedure described here represents the first straightforward, regioselective, three-component protocol for the synthesis of conjugated dienes involving alkynes, which are themselves sensitive to nucleophilic attack. Dienes **3** and **5** obtained by this procedure may serve as building blocks, for instance in conjugate-addition, Diels–Alder, and (for **3x** and **5**) catalytic C–C coupling reactions, for example with vinyltin and boron reagents to obtain conjugated trienes and tetraenes. The drawback of the limited scope of the reaction (as far as the alkyne is concerned) may partly be overcome by modification of the substituents, including dealkoxycarbonylation.

The results obtained thus far prompt us to undertake a more detailed investigation regarding the generality and the mechanism of this convenient protocol for the catalytic synthesis of conjugated dienes from readily available starting materials.

Experimental Section

Typical procedure for the catalytic synthesis of **3**: A solution of [Pd(*p*-tolbian){C(CO_2Me)=C(CO_2Me)C(CO_2Me)=C(CO_2Me)}] (15 mg, 0.02 mmol), dimethyl butynedioate (245 μL, 2.0 mmol), Me_4Sn (180 mg, 1.0 mmol), and methyl iodide (0.6 mL, 10 mmol) in DMF (10 mL) was stirred under a nitrogen atmosphere in a closed Schlenk tube for 16 h at 65 °C. In the case of benzyl bromide or iodobenzene 1.0 mmol of the organic halide was added, and the reaction temperature kept at 85 °C. The crude reaction mixture was dissolved in dichloromethane (100 mL), washed with water (3 × 150 mL), and dried. After removal of the solvent under vacuum, a sticky solid remained, from which the organic product was extracted with diethyl ether. After chromatographic purification on silica gel (hexanes/diethyl ether 9/1) **3a** was isolated in 71%, **3b** in 85%, and **3c** in 76% yield.

Conformation Design of a Fully Flexible βII-Hairpin Analogue**

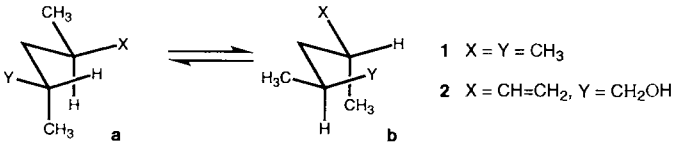
Ulrich Schopfer, Martin Stahl, Trixi Brandl, and Reinhard W. Hoffmann*

Isosteric, non-hydrolyzable analogues of secondary-structure elements of peptides are of high current interest in medicinal chemistry and serve as peptidomimetics. Such structural units yield important information on complex structure–activity relationships and are neccessary for a rational design of low molecular weight, non-peptide pharmaceutical agents.[1] Moreover, such analogues of peptide structures may be important for inducing α-helix or β-turn structures in adjacent peptide sequences.[2] Far less is known about the prerequisites for the induction of β-sheet structures, in which tertiary interactions play a decisive role. Gellman et al. pointed out that good model systems for studying the formation of β-hairpin structures are lacking.[3]

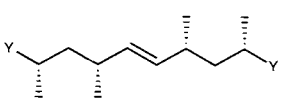
We are interested in a rational conformation design of open-chain hydrocarbon backbones that possess a strong conformational bias and yet maintain full flexibility.[4] We therefore tried to apply the principles of nature's conformation design, demonstrated in polyketide natural products, to designing new molecular backbones. We demonstrate here the value of such an approach with the design of a fully flexible β-hairpin analogue.

A β hairpin is the simplest form of an antiparallel β-sheet conformation, and is defined by a β-turn region flanked by two antiparallel peptide strands that are hydrogen bonded through the corresponding backbone CO and NH groups. Different structural types of β turns are characterized by the ϕ and ψ dihedral angles of the peptide backbone.[5] Figure 1 shows the structure of a βII-type hairpin with $\phi_1 = -60°$, $\psi_1 = 120°$, $\phi_2 = 90°$, and $\psi_2 = 0°$. The requirements that a mimic must meet are 1) a reversal in the peptide-chain direction and 2) the promotion of intramolecular hydrogen-bond formation.[2] In addition, our approach allows preservation of conformational flexibilty similar to that of the natural prototype.

Our design is based on 2,4-dimethylpentane units such as the ones nature uses in its conformation design of polyketide natural products.[4] 2,4-Dimethylpentane (**1**) is biconformational, and equally populates, to greater than 90%, two enantiomorphous and, hence, isoenergetic low-energy conformations **1a** and **1b**.



The position of the conformer equilibrium could be biased to one side by varying the substituents X and Y. In **2a** X suffers an additional *gauche* interaction, which Y does not have, and is therefore in the sterically more encumbered position. When X in **2** is a less sterically demanding vinyl group and Y a hydroxymethyl group, conformation **2a** should be preferentially populated. In fact, an equilibrium ratio **a**:**b** of about 3.5:1 was found for **2** in $CDCl_3$ solution. Therefore, **2** represents a backbone segment with a conformational preference. It can be combined with itself or other building blocks to yield larger molecular frameworks. The combination of two segments of **2** results in structure **3**, which should have a U-shaped molecular backbone that is similar to β-turn und β-hairpin moieties of peptides.



3 Y = CH_2OH **4** Y = CH_3

Simple modeling (MM3*)[6] showed that the most stable conformation of the bis(amide) **5** derived from **3** matches the shape of a βII-hairpin **8** very well (Figure 1).

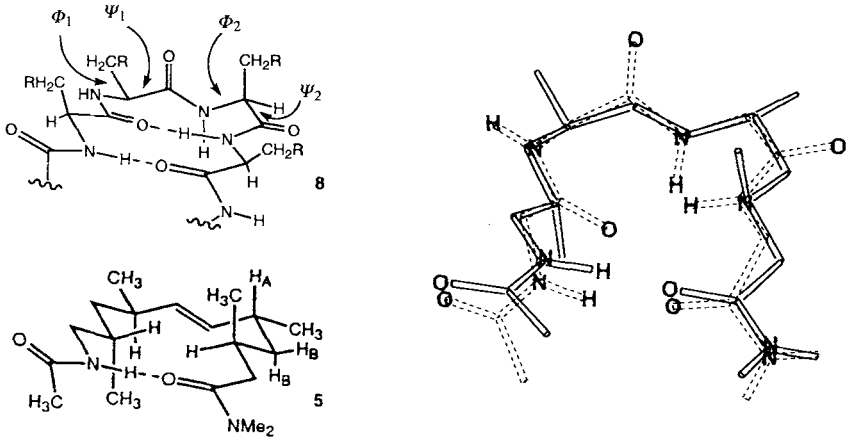

Figure 1. Superposition of the most stable conformation of **5** with a βII-hairpin **8**.

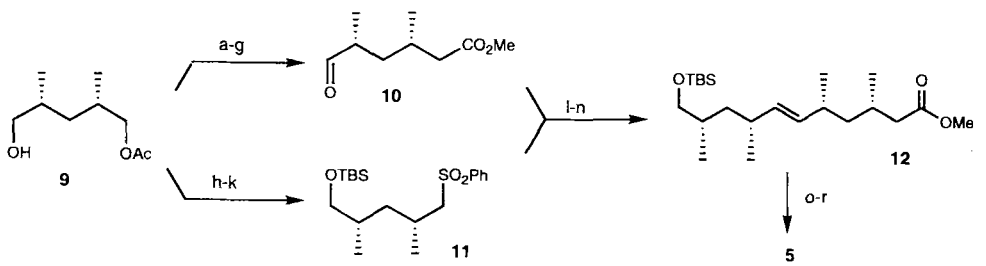
To find out whether **5** is a conformationally flexible βII-hairpin analogue, we synthesized **5** from optically active **9** (Scheme 1).[7] Compound **9** was transformed on the one hand in four conventional steps into sulfone **11**, and on the other hand in eight steps into aldehyde **10**. Julia olefination of the two components yielded alkene **12**, from which bis(amide) **5** could be obtained in four further steps.

IR and NMR spectroscopy was used to analyze the conformational properties of **5** in solution. The former is especially suited for studying intramolecular hydrogen bonds, because the transformation of hydrogen-bonded into non-hydrogen-bonded conformations is slow on the IR time scale. Both states can therefore be distinguished by separate N–H streching frequencies in nonpolar solvents. In contrast, this transformation is fast on the NMR time scale, so that the observed resonances are weighted averages of hydrogen-bonded and non-hydrogen-bonded states.



Scheme 1. a) Triisopropylsilyl chloride (TIPSCl), imidazole, 4-dimethylamino pyridine (DMAP), DMF, 50 °C, 96%; b) K_2CO_3, CH_3OH, 25 °C, 94%; c) CH_3SO_2Cl, NEt_3, CH_2Cl_2, −40 °C; LiBr, THF, 25 °C, 98%; d) NaCN, DMSO, 25 °C, 95%; e) NaOH, EtOH, 80 °C, 84%; f) CH_2N_2, Et_2O, 0 °C, 90%; g) pyridinium chlorochromate (PCC), CH_2Cl_2, SiO_2; h) I_2, PPh_3, imidazole, THF, 25 °C, 90%; i) $PhSO_2Na$, polyethylene glycol (PEG) 400, 130 °C, 91%; j) K_2CO_3, CH_3OH, 25 C, 91%; k) *tert*-butyldimethylsilyl chloride (TBSCl), imidazole, DMAP, DMF, 50 °C, 99%; l) sulfone **11**, *n*BuLi, THF, −78 °C, aldehyde **10**, 97%; m) Ac_2O, pyridine, 25 °C, 90%; n) 6% Na/Hg, CH_3OH, AcOEt, NaH_2PO_4, −30 °C, 88%; o) ClAl(Me)NMe_2, benzene, 80 °C, 95%; p) nBu_4NF, THF, 25 °C, 96%; q) CH_3SO_2Cl, NEt_3, CH_2Cl_2, −40 °C; NaN_3, DMF, 50 °C, 85%; r) PPh_3, THF, trace H_2O; Ac_2O, 25 °C, 96%.

The IR spectrum of **5** (10^{-3} M in CCl_4) shows only one sharp band, the wavenumber of which (3360 cm^{-1}) is characteristic for the N–H streching vibration of hydrogen-bonded amide protons.[8] That the preorganization of the amide groups in **5** by the hydrocarbon backbone is the origin of the predominance of the hydrogen-bonded state can be seen by a comparison with the IR spectrum of the simple ω-acetamidocarboxamide **7**. The latter shows, in addition to two bands for hydrogen-bonded NH-groups, an intensive absorption due to non-hydrogen-bonded amide protons (Figure 2). The concentration dependence of the amide proton ^1H NMR chemical shift of **5** was then determined to exclude aggregation as the cause of hydrogen bonding. From the constant value in solutions of varying concentration (10^{-1}–10^{-4} M, CCl_4) it can be unequivocally deduced that **5** is intra- rather than intermolecularly hydrogen bonded (Figure 3). In contrast, **7** exhibits a pronounced concentration dependence of the amide-proton chemical shift, which corresponds to the behavior of *N*-methylacetamide. The data clearly show that no aggregation occurs in a 10^{-3} M solution, the concentration at which the IR spectra were obtained.

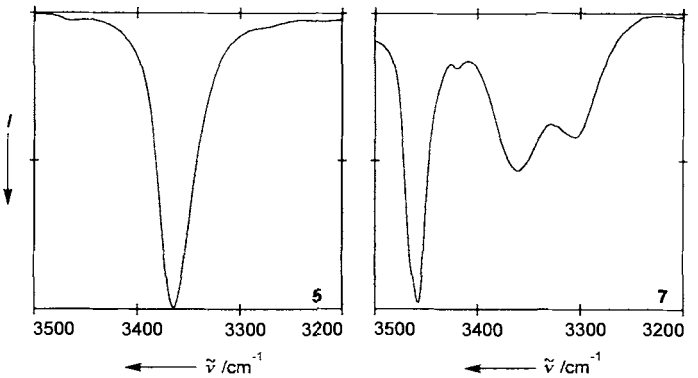


Figure 2. IR spectra (transmittance) of the bis(amide)s **5** and **7** (1 mM in CCl_4, d = 3.5 cm, NaCl): **5**, maximum at 3365 cm^{-1}; **7**, maxima at 3458, 3361 and 3305 cm^{-1}.

The conformational preference of the hydrocarbon backbone of **5** can be deduced from the vicinial ^1H–^1H NMR coupling constants. The divergence of the diagnostic[9] ^1H NMR coupling constants between H_A (Figure 1) and the two protons H_B (2.9 Hz and 10.5 Hz, $CDCl_3$) proves a pronounced conformational preference of the hydrocarbon backbone of **5**. This preference, however, is not a consequence of conformational constraints induced by the hydrogen bond: MM3* calculations show that the most stable conformation of **4** is virtually identical to that of the bis(amide) **5** (Figure 4). Therefore, the backbone conformation of **4** is already ideally suited to preorient the amide groups of **5** for formation of an intramolecular hydrogen bond. Clearly, conformation design of **5** is the origin of the spontaneous formation of the 14-membered cyclic conformation, as multiconformational **7** is converted into an essentially monoconformational

unit **5** by rational introduction of a *trans* double bond *and* four methyl groups. Simple introduction of a double bond into an ω-amido-alkyl-carboxamide does not suffice to induce a β-turn conformation, as Gellman et al.[10] showed with **6**.[11] Conclusion: **5** is not only isostructural with a βII hairpin, but also retains the conformational flexibility that is typical for peptides.

NADH-Induced Changes of the Nickel Coordination within the Active Site of the Soluble Hydrogenase from *Alcaligenes eutrophus*: XAFS Investigations on Three States Distinguishable by EPR Spectroscopy**

Arnd Müller, Andreas Erkens, Klaus Schneider, Achim Müller, Hans-Friedrich Nolting, Vicente Armando Solé, and Gerald Henkel*

Dedicated to Professor Günter Schmid on the occasion of his 60th birthday

Hydrogenases are enzymes that catalyse the reversible activation of molecular hydrogen in numerous aerobic and anaerobic microorganisms.[1] This capability has attracted increasing interest especially in view of possible applications of the catalytic principle in industrial processes or as source for "biological hydrogen" (hydrogen technology).[2]

Most of the hydrogenases known today are metalloenzymes that contain nickel and iron as essential constituents (NiFe hydrogenases) in distinction to the less widespread "iron-only" species.[1] The nickel binding site of these enzymes shows characteristic EPR signals in specific stages of the catalytic cycle indicating an uncommon redox chemistry. Thus, the nickel center is considered the site of hydrogen activation. The NiFe hydrogenase from *Desulfovibrio gigas* has recently been the focus of special attention since the crystal structure of this enzyme revealed the presence of a binuclear Ni/Fe center with cysteine sulfur bridges.[3]

The soluble NAD^+-reducing hydrogenase from the aerobic H_2-oxidizing bacterium *Alcaligenes eutrophus* H16 (E. C. 1.12.1.2) is a heterotetrameric enzyme. Composed of two heterodimeric proteins of different function ($\beta\delta$ and $\alpha\gamma$), this enzyme is of higher complexity than the "typical" heterodimeric hydrogenases.[4] In addition to the nickel center, the O_2-insensitive holoenzyme contains different iron–sulfur clusters (2Fe-2S, 3Fe-4S, 4Fe-4S) and a flavine residue (FMN) as redox-active prosthetic groups.

In this context, we were interested to learn whether and how the coordination of nickel changes upon reductive activation of the enzyme and, at the same time to tackle the question of possible structural relationships between the nickel centers of the hydrogenases from *A. eutrophus* and from *D. gigas*. To this end, high-resolution X-ray absorption spectroscopy (XAFS) was chosen as the method of choice. This technique was developed to determine the structure in the vicinity of excited atoms, and, in contrast to diffraction methods, can also be used to investigate noncrystalline systems. Thus, we characterized the soluble hydrogenase from *A. eutrophus* by XAFS analysis in three different states distuingishable by EPR spectroscopy.[5] Herein we report on the evaluation of the X-ray absorption near-edge structure (XANES) and extended X-ray absorption

fine structure (EXAFS) regions of the Ni-K edge spectra and show for the first time that the individual states differ especially in the number of sulfur atoms bound to nickel, and thereby also chemically.

Starting point of the investigation is the aerobically isolated enzyme (form 1), the nickel center of which shows no EPR signal. Treatment with NADH leads to a reduced form (form 2), which shows an EPR signal characteristic for the active enzyme ("Ni-C"). By way of contrast, the reduction of the enzyme with sodium dithionite produces a state (form 3), which possesses the EPR signals associated with reduced Fe-S clusters, but—like the oxidized form—no Ni signal.[4] The normalized X-ray absorption spectra in the region of the Ni-K edge are depicted in Figure 1, and Table 1 summarizes the results of the XANES analyses. Figure 2 shows the experimentally determined EXAFS functions.

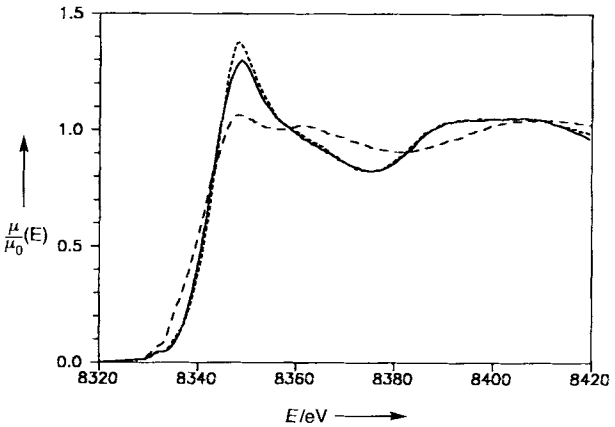

Figure 1. Normalized X-ray absorption spectra in the region of the Ni-K edge (solid line: air-oxidized; dashed line: NADH-reduced; dotted line: dithionite-reduced).

Table 1. Parameters of the normalized X-ray absorption spectra in the range of the Ni-K edge (XANES).

Enzyme form [a]	$E_{1/2}$ [eV] [b]	I_{max} [c]	A [eV] [d]
air-oxidized	8340.7	1.30	0.029
NADH-reduced	8339.6	1.07	0.035
Dithionite-reduced	8341.1	1.38	0.025

[a] See text. [b] Energy of the edge at a normalized intensity of 0.5. [c] Maximum edge intensity. [d] Integrated area of pre-edge peak.

All three investigated forms of the enzyme feature pre-edge peaks in accordance with nickel in a distorted octahedral ligand environment.[6] The edge structures of all three hydrogenase spectra also indicate an octahedral coordination of nickel. Furthermore, they suggest that nickel is predominantly coordinated by sulfur ligands after reduction with NADH (form 2), while the first coordination sphere of nickel is mainly composed of lighter atoms like nitrogen or oxygen in the other states (form 1 and form 3).

In the first step of the curve-fitting analyses based on Fourier-filtered EXAFS functions (Figure 3, $r' = 0.9-3.1$ Å), the ligand spheres of nickel were modeled by combinations of oxygen and sulfur donor functions taking into account integral occupation numbers with coordination numbers from four to six. The results confirm the characteristic differences derived from the XANES spectra in a convincing manner: while in forms 1 and 3 besides four oxygen atoms only two sulfur atoms contribute to

dures. In the case of the NADH-treated hydrogenase (form 2, Figure 3c, d), a significant improvement of the fit is achieved by distributing the directly bound sulfur atoms in a 3:1 ratio over two shells with distances of 2.20 and 2.38 Å (fit index 0.45; the fit with solely sulfur atoms yields a fit index of 0.64). The fit is further improved by adding a scatterer from the series of electron-rich 3d metals at a distance of 3.07 Å from Ni to the model (fit index 0.29). This atom is most probably an iron atom (see below). The final results of the structure refinement are listed in Table 2.[7]

Table 2. Results of the curve-fitting analysis for the Fourier-filtered EXAFS functions ($r' = 0.9-3.1$ Å).

Enzyme form [a]	N [b]	Shell	Distance [Å] [c]	$2\sigma^2$ [Å^2] [d]	Fit index

[d] Debye Waller parameter.

In contrast, the EXAFS function of the aerobically isolated hydrogenase (form 1, Figure 3a) shows features of considerably higher complexity. The strong damping behavior indicates the presence of several shells of different backscatterer atoms, which define the relatively large peak of the Fourier transform at about 3 Å (Figure 3b). Their contributions to the EXAFS are best modeled with two additional sulfur atoms at a distance of 3.02 Å and one additional metal atom 2.71 Å away from the nickel (fit index 0.41).[8] The qualitative improvement of the structural model emerges unequivocally from the development of the fit index, which amounts to 2.04 before and to 0.86 after introduction of the additional sulfur atoms. The results of the final curve-fitting analysis are summarized in Table 2.[7]

The EXAFS function of the dithionite-reduced hydrogenase (form 3, Figure 3e) resembles that of the aerobically isolated enzyme (form 1, Figure 3a). The initial two-shell model (fit index 0.89) is likewise improved by a metal atom at a distance of 2.88 Å from the nickel (fit index 0.51). However, no additional sulfur shell of physical significance comparable to that observed in form 1 can be derived from the EXAFS data. The results of the final structure refinement are listed in Table 2.[7]

Based on the results of the curve-fitting analyses, certain fundamental statements concerning the coordination of the nickel atom of the hydrogenase can be derived for all three enzyme forms, which are depicted in Figure 4. In all three cases, six ligand atoms are most likely present in a distorted octahedral arrangement around the nickel atom.

We begin the interpretation of our results with the structural model derived for the NADH-treated enzyme (form 2, Figure 4b). Here the nickel atom is surrounded by four sulfur ligands, of which three form slightly shorter bonds to the nickel than the fourth. They are supposed to be the thiolate functions of the four conserved cysteine residues of the β-subunit of the enzyme.[9] The remaining positions of the coordination octahedron are occupied by lighter atoms, which might be the oxygen atoms of bonded water molecules. The distance of 3.07 Å to the second metal atom of the active site indicates that this atom should be linked to the nickel by two bridging thiolate functions. This metal atom is assumed to be iron, since the hydrogenase from *A. eutrophus* contains—according to chemical analysis—no 3d metal other than nickel and iron.[4] Regarding the number of bridging and exogenous sulfur atoms, our proposed structure (Figure 4b) is in good agreement with the coordination of nickel in the crystallized hydrogenase from *D. gigas*. This result is especially surprising, since the crystallographically examined hydrogenase is an aerobically isolated and enzymatically inactive enzyme,[3] which shows—compared to the hydrogenase from *A. eutrophus* in its NADH-activated state—significantly different electrochemical and spectroscopic properties.[1,4]

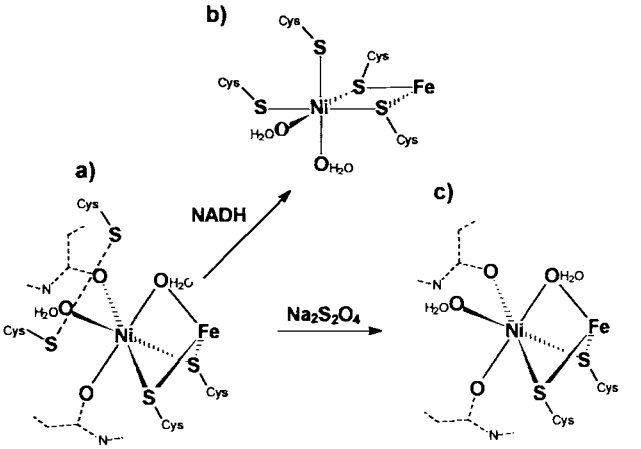

Figure 4. Schematic representations of the models for the nickel center of the hydrogenase from *A. eutrophus*: a) air-oxidized; b) NADH-reduced; c) dithionite-reduced; the assingments of O-donor functions shown here are arbitrarily chosen (see text).

In the aerobically isolated hydrogenase (form 1, Figure 4a) as well as in the preparation treated with sodium dithionite (form 3, Figure 4c), only two sulfur atoms contribute to the nickel binding. The remaining ligands are presumably nitrogen or oxygen atoms. Apart from water molecules and/or functional amino acid residues, the amide groups of the protein chains might be considered the source of these atoms.[8] In both forms the iron is 2.71 Å (form 1, Figure 4a) and 2.88 Å (form 3, Figure 4c), respectively, away from the nickel. The distinct shortening of the nickel–iron distance found here in comparison with that in form 2 (Figure 4b) strongly indicates an additional third bridge within the heterobimetallic center of the enzyme.

The contribution of a hydrogen atom to the coordination of nickel in all three enzyme forms cannot be completely ruled out by EXAFS spectroscopy, since the corresponding structural models, in which the hydrogen is modeled by an unoccupied coordination site, are still of physical significance. However, such a contribution meets the fit criteria worse than the binding situation proposed by us. The same is true for an unoccupied coordination site.

The origin of the additional cysteine sulfur atoms that contribute to the direct binding of nickel in the EPR-active state (form 2, Figure 4b) is of considerable interest. In the case of the aerobically isolated hydrogenase with only two directly bonded sulfur ligands (form 1, Figure 4a), we observe two additional sulfur atoms at a distance of 3.02 Å from the nickel, which might belong to a cystine residue. A possible reason for the ligand change within the coordination sphere of nickel upon treatment of the enzyme with NADH would be the generation of two

additional cysteine groups by reductive cleavage of the S–S bond within the cystine residue (form 2, Figure 4b; see also ref. [4d]).

According to our results the reorganization of the nickel center induced by NADH does not take place upon treatment with dithionite. This might be due to the lacking substrate properties of dithionite, which is not compatible with the NAD^+/NADH-specific binding site of the enzyme from *A. eutrophus*.

In summary, we have demonstrated that the active site of the NAD-reducing hydrogenase of *A. eutrophus* is a heterobinuclear complex with two cysteine bridges. In this respect, there are striking chemical similarities with the NiFe center of the hydrogenase from *D. gigas*. Furthermore, it was possible for the first time to detect a substantial change of the coordination of nickel upon reductive activation of a NiFe hydrogenase. Whether this property, which is characteristic for *A. eutrophus*, is also detectable in hydrogenases of other origin requires further investigations.[16] However, it should be noted that in earlier work a mechanism for the reductive activation of the hydrogenase from *A. eutrophus* specifically triggered by NADH has been proposed, which differs significantly from that of other hydrogenases.[4]

Experimental Section

Cells of *A. eutrophus* H16 (ATCC 17699; DSM 428) were heterotrophically cultivated, and the soluble hydrogenase (form 1) was isolated as described in reference [4]. The protein concentration was determined by the method described by Lowry, and the metal content was analyzed by ICP-MS. For the transformation into form 2, two independently prepared samples of the aerobically isolated hydrogenase were treated with NADH under an argon atmosphere (final concentration 15 and 30 mM NADH, respectively) and shock frozen after 10 min. Form 3 was obtained by analogous treatment with a fivefold excess of $Na_2S_2O_4$. These enzyme preparations were characterized by EPR spectra prior to the XAFS measurements (for experimental details see ref. [4b]).

The enzyme solutions used for the X-ray absorption spectroscopic investigations were concentrated by ultra-filtration in Amicon Diaflo cells (YM 100 membrane) to a concentration of about 1 mM. Inspection of the specific activity (starting activity: 80 μM reduced NAD per minute and mg enzyme; this corresponds to the 20-fold value of the in vivo activity) after the concentration step indicated no damage [4]. The samples were shock frozen and kept in a helium cryostate at 20 K during the measurements. The X-ray absorption spectra in the region of the nickel K-edge were recorded with the EXAFS spectrometer [11, 12] of EMBL (HASYLAB at DESY, Hamburg; storage ring DORIS II, 4.5 G eV, average beam current 80 mA, Si(111) double-crystal monochromator, focussing toroidal mirror, absolute calibration of the energy axis with simultaneously recorded Bragg reflections of a silicium crystal) according to reference [10].

The spectra were recorded by measuring the fluorescence radiation in a range from 8210 to 9100 eV with a 13-element solid-state detector (Canberra). The measuring time was 1–2 s per point with about 1400 points per spectrum. A total of 41 (form 1), 27 (form 2), and 28 (form 3) single scans, respectively, were averaged after individual energy calibration. Since the individual spectra did not change during the corresponding measuring sequences, we can exclude radiation damage. The EXAFS functions were isolated from the averaged spectra by literature procedures, and the determination of the background was achieved with a spline function [13]. Data evaluation was carried out with the program packages EXPROG (energy calibration and data reduction) [14] and EXCURV88 (curve-fitting procedures employing theoretical amplitude and phase functions) [15].

[7] During the final cycles of the structure refinement, the occupation numbers were kept at constant values, while a common value for E_0, the distances of the individual shells from the central atom, and the Debye–Waller parameters were refined.

[8] Recently diatomic molecules with triple-bond systems were postulated as additional ligands bound to nickel in the hydrogenase from *Alcaligenes eutrophus* on the basis of FT-IR investigations (T. M. van der Spek, A. F. Arendsen, R. P. Happe, S. Yun, K. A. Bagley, D. J. Stufkens, W. R. Hagen, S. P. J. Albracht, *Eur. J. Biochem.* **1996**, *237*, 629). A diatomic molecule in a linear arrengement (e.g. CN^- or CO), which was tentatively introduced to the structural model for that reason, did not yield any results of physical significance in the curve-fitting analysis.

A Facile Cycloisomerization for the Formation of Medium and Large Rings via Allenes

Barry M. Trost,* Pierre-Yves Michellys, and Vincent J. Gerusz

The importance of macrocycles is readily apparent by the large number of biologically significant molecules that possess such a core, be it a carbocycle or heterocycle.[1, 2] Such ring systems may be thought to represent a compromise in the attempt to introduce conformational rigidity into acyclic structures in order to enhance biological potency. In small and normal-sized rings, the limits on flexibility mean that a ligand must be just right for the receptor, otherwise it will not fit properly. Medium and large rings have well-defined conformations also; however, a number of conformations frequently will lie close in energy to the global minimum. Thus, if the design is not perfect, the molecule may still be able to adapt itself to fit the receptor without an inordinate cost in energy. Such a strategy for enhancing biopotency may be more routinely used if the methods

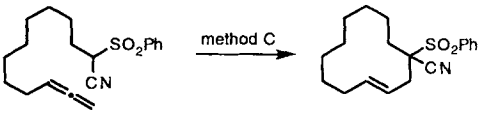
for forming such difficult-to-access ring systems were more readily available.[3] In conjunction with our interest in designing simple addition reactions, we have developed a protocol that effects addition of a pronucleophile to an allene[4, 5] in which macrocarbocycles and macrolactones ranging in size from nine to seventeen members are formed without the requirement of the usual high dilution techniques to minimize polymerization.[6]

Our initial studies examined cyclization of the allene **1**, which is easily accessed according to Equation (1). The use of the allene as a proelectrophile for the Pd^0-catalyzed reaction provides easy differentiation with other electrophilic functional groups as illustrated in this case: the allenyl iodide functions as a chemodifferentiated bis-electrophile in alkylations. In the initial efforts, we exposed **1** to a catalyst generated from 5 mol% of π-allylpalladium chloride dimer (**2**) and 12.5 mol% 1,3-bis-(diphenylphosphino)propane (**3**) in the presence of a base in THF at 100 °C (sealed tube). The choice of a bidentate ligand stemmed from earlier observations in the reactions of 1,3-dienes that monodentate ligands led to oligomerization.[7] Initial results showed that methanolic sodium methoxide (50–100 mol%) was more efficacious than potassium *tert*-butoxide. For a 0.01 M solution of the substrate in a batch reaction (that is, no slow addition), a remarkable 60–68% yield of the seventeen-membered ring **4a**[8] as a single isomer was obtained (see Table 1). The 15.5 Hz coupling of the vinyl protons (δ = 5.97 and 5.32) in the ^{1}H NMR spectrum indicates an *E* geometry. Use of 1,3-bis(2-methoxyphenylphosphino)propane as ligand gave, under similar conditions, a 47% yield of the macrocycle **4a** from **1a**.

Unfortunately, application of these conditions to other substrates proved disappointing. For example, allene **1b** gave only trace amounts of macrocycle with mainly unchanged starting material. Replacing methanolic methoxide with catalytic potassium *tert*-butoxide (1 equiv based on Pd) and 2-dimethylaminopyridine (2-DMAP, 1 equiv) had a dramatic effect on the reaction; the sixteen-membered macrocycle **4b**[8] was produced in 53% yield. Switching to 4-DMAP improved the yield to 68%. The catalytic amount of potassium *tert*-butoxide proved superfluous; the reaction proceeded similarly in its absence (method A, 2.5–5.0 mol% **2**, 6.25–12.5 mol% **3**, and 1 equiv 4-DMAP in THF at 100 °C). A full equivalent of 4-DMAP was not necessarily required. For example, cyanosulfone **1c** cyclized to **4c**[8] in 67% yield (73% based on recovered starting material (brsm)) in the presence of 3 mol% **2**, 7.5 mol% **3**, and 15 mol% 4-DMAP at a concentration of substrate **1c** of 0.01 M (method B, 2.5–5.0 mol% **2**, 6.25–12.5 mol% **3**, and 15–20 mol% 4-DMAP in THF at 100 °C).

While the last set of conditions proved to be reasonably general, we still encountered difficulties when the ring size was decreased as in substrate **1d** [Eq. (1)]. Cyclization of the latter by method B produced a 28% yield of the fifteen-membered ring **4d**.[8] Keeping in mind that *both* a proton donor and a proton acceptor are required, we added an amount of a proton donor (acetic acid, 1 equiv based on the dibasic amine DMAP; method C) and saw the yield of **4d** increase to 56%. Decreasing the ring size to twelve members still led to good yields of macrocyclization product [Eq. (2)]. In this case, the yield of **5**[8] increased

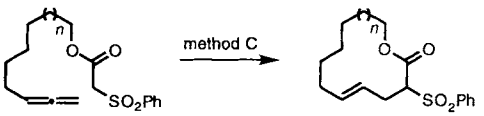


(2)

5

from 43% to 55% by running the reaction at 0.005 M rather than 0.01 M. This result suggests that, with the smaller ring size, oligomerization started to become a problem in these simple carbocycles. Only a single isomer of **5** is obtained; the 14.3 Hz coupling constant of the vinyl protons (δ = 5.68 and 5.48) suggests *trans* geometry.

The importance of macrolactones led to exploration of this cyclization for their synthesis [Eq. (3)]. Substrates for the



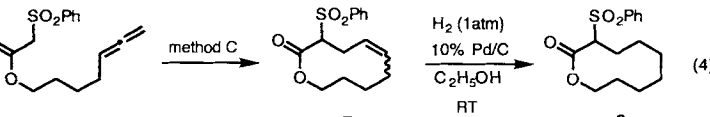
(3)

6

a: n = 6, **b**: n = 5, **c**: n = 1

macrocyclization are easily available by esterification of the requisite allenic alcohol [dicyclohexylcarbodiimide (DCC), 4-DMAP, CH_2Cl_2, room temperature (RT), 91–97% yields]. With method C, the seventeen- (**6a**[8]) and sixteen-membered rings (**6b**[8]) formed in 67% and 57% yields, respectively. The twelve-membered ring **6c**[8] also formed in a satisfactory yield of 62%. In all three cases, the single isomer formed was in the *trans* configuration, as established by proton NMR spectroscopy.

Medium-sized macrolactones pose a special problem because of their enhanced strain due to transannular effects. Interestingly, the ten-membered ring **7**[8] formed in a somewhat higher yield (82%) than the larger rings [Eq. (4)]. Unlike with the



(4)

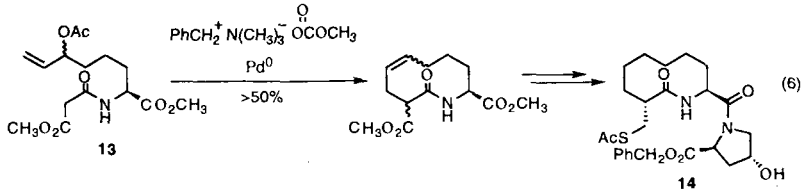
7 8

larger rings, a 1:1 mixture of two isomers was formed. That the source of the isomerism was olefin geometry was indicated by catalytic hydrogenation (87% yield) to a single macrocycle **8**[8] (m.p. 132 °C). Cyclization of **9** represents a specially interesting example, since either seven- or nine-membered rings can form [Eq. (5)]. The fact that the thermodynamically preferred *syn*-**10**

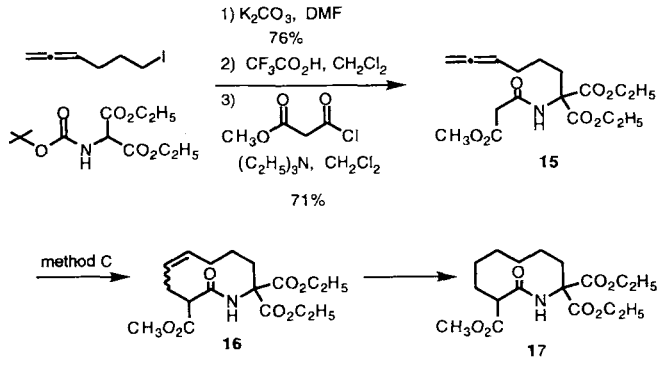
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3616-1751 $ 17.50+.50/0

should strongly favor seven-membered ring formation due to the strain of a *trans* double bond in a nine-membered ring,[9] combined with the normal kinetic preference for seven-membered ring formation,[10] would lead to the expectation that **11** should dominate.[11] Counter to this expectation, only the nine-membered ring **12** (m.p. 119 °C) formed in 65% yield, even at 0.01 M concentration of substrate. Not surprisingly, only the *Z* geometry of the product was detected as indicated by the 10.8 Hz coupling constant of the vinyl protons (δ = 5.65 and 5.37).

The efficiency by which nine- and ten-membered rings formed induced us to explore the formation of a ten-membered macrolactam as a result of a recent report of **14** as an endopeptidase inhibitor.[12] This ring system was formed by a Pd^0-catalyzed cyclization of **13** [Eq. (6)], although not without some complications. Ironically, the substrate **13** derived from an allene! As shown in Equation 7, the macrocyclization substrate **15** is readily available in a manner analogous to that of Johnson et al.[12] Subjecting a 0.01 M solution of allene **15** to what has become our "standard" conditions (method C) gave an 86% yield of macrolactam **16**[8] as a 1:1 mixture of isomers. Catalytic hydrogenation gave a single compound **17**[8] (m.p. 104–105 °C), in 85% yield. Thus, the allene cyclization not only appears to be more straightforward than that of a related allylic acetate while saving an expensive silver-promoted conversion of an allene to an allylic acetate, but does all of this in even higher yield.

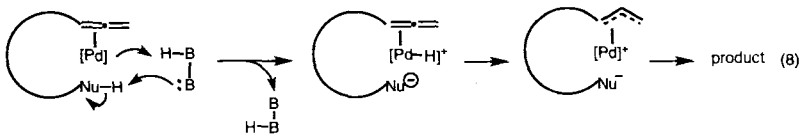


(6)



(7)

Macrocyclization with allenes as pronucleophiles appears to be a very effective way to generate normally difficult-to-form rings. The attractiveness of the methodology stems, in part, from the ease of constructing substrates because of the inertness of the allene to many standard synthetic reactions. The example of the macrolactam in which the allene served as the precursor to the allyl ester highlights this point. The remarkable efficiency by which medium-sized rings form is noteworthy. In most reactions, a plot of yield versus ring size normally has a minimum at the nine-membered ring. That is clearly not the case here. The source of the efficiency of this protocol remains to be established. It is interesting to speculate whether a bifunctional catalysis as illustrated in Equation 8 may be implicated. In any event,



(8)

this method has proven useful for carbocycles, macrolactones, and macrolactams containing from nine- to seventeen-ring members.

Crystal Structure Determination of Metaperiodic Acid, HIO_4, with Combined X-Ray and Neutron Diffraction**

Thorsten Kraft and Martin Jansen*

Dedicated to Professor Dieter Seebach on the occasion of his 60th birthday

According to textbooks on inorganic chemistry the system of iodine(VII) acids consists of the monomeric orthoperiodic acid, H_5IO_6, from which a series of oligomeric compounds $H_{6+n}I_{2+n}O_{10+4n}$ can be derived by edge-sharing of the IO_6 octahedra, and, as a terminating link, polymeric metaperiodic acid, HIO_4.[1] Besides the crystal structure of H_5IO_6, which is well-established (including the hydrogen-atom positions),[2] the proposed constitutions of iodine(VII) acids are based on insufficient experimental data. For the oligomeric periodic acids the I–O substructures of their salts are assumed to be similar to those of the free acids,[3] and in the cases of HIO_4 and $H_7I_3O_{14}$ polymeric or trimeric chains, respectively, of *trans*-edge-sharing IO_6 octahedra are proposed based on Raman spectra.[4] Attempts to grow single crystals of HIO_4 failed until now, because the compound decomposes at normal pressure, already at 105 °C, releasing oxygen and water. The development of X-ray and neutron diffraction techniques for ab initio crystal structure determination has encouraged us to investigate the structure of HIO_4 with these methods.

Microcrystalline HIO_4 was prepared by carefully dehydrating H_5IO_6 with oleum in H_2SO_4 at 50 °C. Since the reaction conditions cause the product to precipitate slowly from the homogeneous solution, the samples crystallize well despite the relatively low reaction temperature, as seen from their X-ray powder diagrams (Figure 1). The crystal structure with respect to the positions of iodine and oxygen atoms could be solved from the X-ray powder diagram; the hydrogen atoms were preliminary fixed by considering crystal-chemical evidence. Because the scattering factor of iodine is considerably higher than that of oxygen and, in particular, hydrogen, neutron diffraction techniques were necessary to complement the X-ray data. Stable refinement of the position parameters of all atoms was achieved, and the agreement between the parameter sets is satisfactory (Table 1).

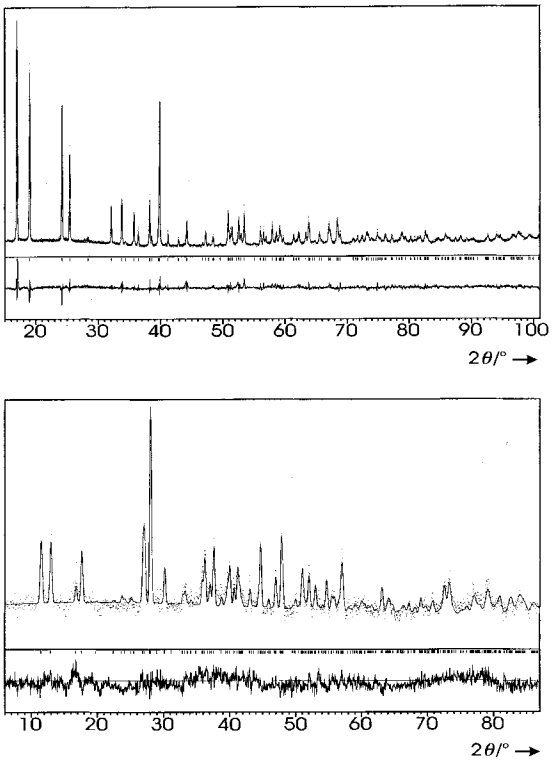

Figure 1. Observed (dotted line) and calculated (solid line) diffraction diagrams and difference profile of the Rietveld refinement (top: X-ray data; bottom: neutron data); the positions of allowed reflections are indicated by vertical lines.

Table 1. Positional parameters for HIO_4.

[a] Site occupancy of 50%. [b] From neutron diffraction data. [c] From X-ray diffracion data.

In contrast to all previously proposed structures, HIO_4 consists of one-dimensional infinite chains built up of distorted, *cis*-edge-sharing IO_6 octahedra (Figure 2). The different I–O distances of the IO_6 octahedra reflect the different crystal-chemical situations of the oxygen atoms (Figure 3). The terminal oxygen atoms show, as expected, the shortest I–O distances (184 pm). The pronounced difference between the distances to the bridging oxygen atoms (191 and 201 pm) can be easily explained in terms of the *trans* effect.

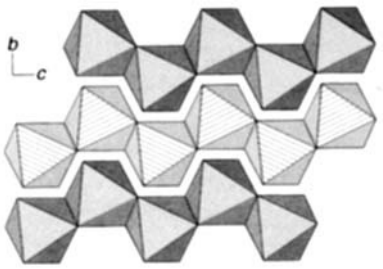

Figure 2. Chains of *cis*-edge-sharing IO_6 octahedra.

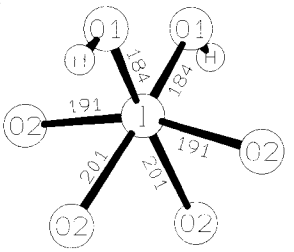

Figure 3. IO_6 octahedron; distances are given in pm.

The structural analogy to many transition metal tetrahalides, as indicated by the presence of chains of *cis*-edge-sharing octahedra, also extends on the arrangement of these structural units relative to each other. When considering the I–O substructure, isotypism to uranium tetraiodide becomes evident, that is, the oxygen atoms form a hexagonal close packing with the iodine atoms occupying a quarter of the octahedral holes.

Every polymeric chain is connected to four adjacent chains through hydrogen bonds (Figure 4; d(O···O) 269(2) pm,

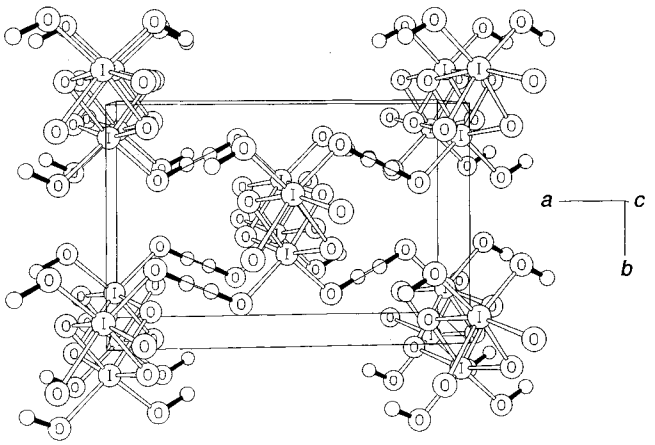

Figure 4. Connectivities between the chains through hydrogen bridges.

d(O–H) 101(3) pm, d(O···H) 169(3) pm, ∢I-O-H 112(1)°, ∢O-H···O 176(1)°). The hydrogen atoms are disordered in a double potential between the terminal oxygen atoms. This is frequently observed for linear hydrogen bonds between neutral molecules, such as in the Ih modification of ice.[7]

Until now no periodate derived from the structure of HIO_4—that is, built up by polymeric iodine–oxygen chains—is known. The structure of HIO_4 raises questions about the linkage of the iodine–oxygen polyhedra in oligomeric periodic acids. However, the crystal structure of $H_7I_3O_{14}$ does not show any new type of catenation, because this compound exists in the solid state as a stoichiometric phase containing orthoperiodic and metaperiodic acids according to the formula $H_5IO_6 \cdot 2HIO_4$.[8]

Experimental Section

HIO_4: Oleum (25%, 15 mL) was slowly added to a solution of H_5IO_6 (3 g) in concd H_2SO_4 (40 g) at 50 °C until an insoluble precipitate appeared. Upon standing for 12 h at 50 °C a voluminous precipitate separated, which was isolated by filtration under an inert-gas atmosphere. It was treated with concd H_2SO_4 (15 mL), washed with trifluoroacetic acid (5 × 15 mL) to remove traces of H_2SO_4, and finally dried in vacuo. Elemental analysis: iodine: 65.5% (calcd 66.1%), active oxygen: 27.9% (calcd 29.2%), sulfate: not detected.

Structure determination of HIO_4: After indexing [9] the X-ray powder diagram (Stoe Stadi P, $Cu_{K\alpha}$ radiation, λ = 154.051 pm) on the basis of a monoclinic system (a = 936.88(5), b = 629.59(4), c = 495.30(3) pm; β = 94.953(3)°), Cc (no. 9) and $C2/c$ (no. 15) were considered as possible space groups from the systematic absences. In both space groups the iodine- and oxygen-atom positions were determined with direct methods [10], but a crystal-chemically consistent refinement (156 reflections, 30 parameters, R = 0.0617, R_{wp} = 0.219, R_F = 0.0522 [11]) could only be achieved in the space group $C2/c$. The hydrogen bridges and, thus, the approximate positions of the hydrogen atoms were derived from crystal-chemical considerations. To verify these results optimized structure models (space group $C2/c$ with disordered H atoms and Cc with no disordering of H atoms) were refined on the basis of neutron diffraction data (λ determined to 112.704 pm [11], two-circle neutron diffractometer SV7 equipped with a linear position-sensitive JULIOS detector from the Mineralogisches Institut der Universität Bonn at the reactor FRJ2 of the KFA Jülich). The model with space group $C2/c$ was unambiguously the correct one (a = 936.60(18), b = 628.86(13), c = 495.75(19) pm; β = 94.890(15)°; 282 reflections, 27 parameters, R = 0.0185, R_{wp} = 0.336, R_F = 0.21 [11]).

Ge_9^{4-}: A Deltahedral Zintl Ion Now Made in the Solid-State**

Virginie Queneau and Slavi C. Sevov*

All known main group deltahedral clusters are made either by crystallization from solution or by direct synthesis from the elements, that is by solid-state reactions. (We exclude gaseous clusters here since they are not structurally well characterized.) Members of the first group belong to the well known class of Zintl ions and include anions of group 14 (the tetrels (Tt): Tt_9^{4-},

Tt_9^{3-}, Tt_5^{2-}, Tt_9^{2-}, and Tt_{10}^{2-}), of group 15 (the pnictogens (Pn): Pn_4^{2-}), and the mixed species $Tt_2Pn_2^{2-}$, $TrTt_8^{3-}$, and $TrTt_9^{3-}$ (Tr = element of group 13).[1-3] These clusters form when the corresponding alloy with Na or K (or mixtures of them) is dissolved in either liquid ammonia or ethylenediamine, often mixed with 2,2,2-crypt.[4] Most of these clusters have been characterized in terms of nuclearity and charge by NMR spectroscopy in solution.[5] Presumably, formation of the cluster takes place during the extraction with the solvent since no such clusters have been observed in the starting alloys.[2, 6] The group of clusters made by solid-state reactions is somewhat more diverse in terms of sizes and charges, and comprises primarily clusters of group 13 (the triels (Tr): Tr_{11}^{7-}, Tr_4^{8-}, Tr_5^{7-}, Tr_5^{9-}, Tr_6^{8-}, Tr_6^{6-}, Tr_6^{6-}, $Tr_{12}(Tr)^{11-}$, $Tr_{12}(Zn, Cd or Hg)^{12-}$, $Tr_{10}(Zn)^{8-}$, and $Tr_{10}(Ni, Pd or Pt)^{10-}$), but also includes a few species from groups 14 (Tt_4^{4-}), 15 (Bi_8^{2+}, Bi_5^{3+}, Bi_9^{5+}), and 16 (Se_4^{2+} and Te_4^{2+}).[2] These clusters are found in solid-state compounds with alkali metals as countercations (or $AlCl_4^-$ as counteranions), and are made by direct synthesis from the corresponding elements. Despite this big variety of deltahedral clusters in the two groups none has been made both by synthesis from solution and by solid-state reaction.

In Ge_9^{4-} we have found the first such species to bridge the two classes. Prior to this report the clusters of Ge_9^{4-} were structurally characterized only in the salt $[K^+\text{-222-crypt}]_6(Ge_9^{4-})(Ge_9^{2-})$, made by crystallization of a solution of a K-Ge alloy dissolved in ethylenediamine.[7] The tin-substituted isoelectronic clusters $[Ge_{9-x}Sn_x]^{4-}$ ($x = 1-8$) have been characterized in solution by ^{119}Sn NMR spectroscopy.[5] Transition metal derivatives of these and similar deltahedral Zintl ions are also known. They include $[Tt_9Cr(CO)_3]^{4-}$ (Tt = Sn, Pb), $[Sn_6\{Cr(CO)_5\}_6]^{2-}$, and the recently synthesized Ge-centered $[Ge_9Ni(PPh_3)]^{2-}$, all of which have been isolated with cryptated alkali metal cations and structurally characterized.[8] Similarly $[Tt_9PtL_x]^{4-}$ (Tt = Sn, Pb; L = ligand) have been characterized in solution by ^{119}Sn and ^{207}Pb NMR spectroscopy.[9]

We have now made the naked Ge_9^{4-} clusters in "neat" solids.[10] These solids are Cs_4Ge_9 and the isostructural Rb_4Ge_9, both made by direct synthesis from the corresponding elements (see *Experimental Section*). Ge_9^{4-} is the first deltahedral cluster of the tetrels in the solid state since Tt_4^{4-} was made more than forty years ago in A_4Tt_4 (A = alkali metal).[11] Our attempts to make similar A_4Ge_9 compounds with sodium or potassium proved unsuccessful. This supports the hypothesis that the precursor alloys used for the solution studies (traditionally made with the light alkali metals) do not contain the clusters.

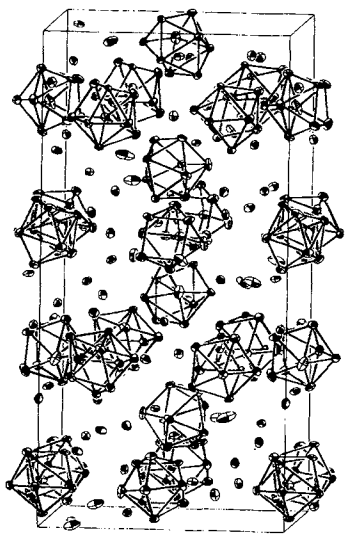

Figure 1. A general view of the tetragonal unit cell of Cs_4Ge_9 (the c axis runs vertical). Bonds are drawn between the Ge atoms of the four different Ge_9^{4-} clusters. The Cs atoms are shown isolated. All atoms are drawn with 50% thermal ellipsoids.

The structure of Cs_4Ge_9 (Figure 1) was determined by single-crystal X-ray diffraction (see *Experimental Section*). It crystallizes in the rare noncentrosymmetric $P4_1$ space group and contains four crystallographically different but otherwise very similar Ge_9 clusters A, B, C, and D. The structure can be viewed as containing quite open layers made of clusters A, B, and C, and positioned perpendicular to the c axis at $z \approx 1/12$, 4/12, 7/12, and 10/12. These layers alternate with clusters D centered along the 4_1 screw axis (the axis is at 1/2, 1/2, z) at $z \approx 5/24$, 11/24, 17/24, and 23/24. The clusters are well separated from each other by the large cesium cations positioned within and between the layers. These cations cap triangular and square faces of the clusters and also bridge some edges and "cap" some vertices. The shortest intercluster distance is 3.956(8) Å.

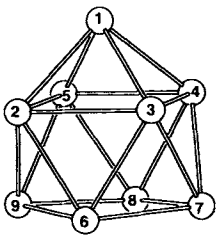

Figure 2. View of one of the four crystallographically different Ge_9^{4-} clusters (cluster A). All four clusters have the same geometry of a monocapped square antiprism. The numbering system serves for the assignment of the atoms in Table 1.

All four clusters are monocapped square antiprisms with very similar dimensions (Figure 2 and Table 1). The stoichiometry of the compounds combined with the observation that they are also electronically balanced (below), that is Zintl phases, defines the charge of each cluster as 4 − . This is also consistent with Wade's rules which predict a charge of 4 − for such *nido* species.[12] Furthermore, extended Hückel molecular orbital calculations show very similar HOMO–LUMO gaps for the four clusters at 40 electrons (2.88, 2.91, 2.91, and 3.18 eV), that is at a charge of 4 − .

Table 1. Important Ge–Ge intracluster distances for the four different clusters in Cs_4Ge_9 (at 173 K) and for Ge_9^{4-} in $[K^+\text{-222-crypt}]_6(Ge_9^{4-})(Ge_9^{2-})$ [7]. The numbering of the atoms is given in Figure 2.

Atom 1–Atom 2	Cluster A	Cluster B	Cluster C	Cluster D	Ge_9^{4-} from [7]

Ge7–Ge9	3.624(8)	3.581(8)	3.410(10)	3.543(8)	3.580(7)

The geometry of the four clusters is virtually the same as that of the Ge clusters in the K-crypt salt.[7] The distances of the latter are listed in Table 1 for comparison. Often it is difficult to distinguish between a nine-atom *closo* species (a tricapped trigonal prism) and a nine-atom *nido* species (a monocapped square antiprism). However, the four clusters in the present compound are unambiguously *nido* polyhedra according to their distances. The diagonals of the square bases, Ge6–Ge8 and Ge7–Ge9 (Table 1), which are the potential candidates for heights in even-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3616-1755 $ 17.50+.50/0

tual trigonal prisms, are quite longer than the "existing" heights, Ge3–Ge4, Ge2–Ge5 and Ge2–Ge3, Ge4–Ge5, respectively. The similarities in shape and distances between the four clusters in Cs_4Ge_9 and the one in $[K^+\text{-222-crypt}]_6(Ge_9)(Ge_9)$ support the assumption that the latter is indeed Ge_9^{4-}. This is contrary to a recent suggestion that the two clusters in the crypt-salt are both Ge_9^{3-} similar to the recently discovered Sn_9^{3-} and Pb_9^{3-} in $[K^+\text{-222-crypt}]_6(Sn_9^{3-})(Sn_9^{3-})$ and $[K^+\text{-222-crypt}]_6(Pb_9^{3-})(Pb_9^{3-})$, respectively, as well as to Ge_9^{3-} in $[K^+\text{-222-crypt}]_3(PPh_3)_3(Ge_9^{3-})$ and $[K^+\text{-222-crypt}]_3(Ge_9^{3-})$.[13]

The Cs_4Ge_9 compound is a semiconductor (or an insulator) according to its magnetic susceptibility (temperature independent and near zero, see *Experimental Section*) and its appearance (semitransparent, ruby-red color).

The Cs–Ge and Rb–Ge phase diagrams are quite uncertain especially in the regions with high alkali metal content.[14] There are conflicting reports on the number of Cs–Ge and Rb–Ge compounds. Three possible stoichiometries, A_3Ge, A_3Ge_2, and AGe_4 (A = Rb or Cs), are suggested in each phase diagram, but only CsGe and RbGe have been structurally characterized. The compounds with the stoichiometries closest to A_4Ge_9 (30.8 at.% alkali-metal) would be AGe_4 (20 at% alkali metal), which melt congruently at 990 °C and 1110 °C for Cs and Rb, respectively.

The absence of large naked clusters of group 14 in the solid state may be explained by the large ratio of nuclearity to charge. According to Wade's rules deltahedral clusters of this group will have charges of 2 –, 4 –, and 6 – for *closo*, *nido*, and *arachno* species, respectively. It is important to note that these charges are independent of the nuclearity of the cluster. The charge balancing cations therefore may not be enough to efficiently keep apart (shield) large clusters. This is especially true for the smaller alkali metals such as Na and K which have been traditionally used as countercations. The effect is even more pronounced when the corresponding tetrel is among the heaviest of the group (Sn or Pb), which results in even larger clusters. In the crypt salts the large alkali metal cryptate is sufficient to separate the clusters efficiently. The new compounds are most likely the result of the combination of large cations (cesium or rubidium) and clusters of the small germanium. Despite the relatively high nuclearity and the relatively small negative charge of 4 –, the clusters are small enough that four large cations can separate them efficiently.

Experimental Section

Synthesis: Ruby-red semitransparent Cs_4Ge_9 was initially isolated and its structure determined from a reaction of Cs, Na, Al, and Ge loaded in atomic ratio of 4:1:1:10. The mixture was heated at 800 °C for five days in sealed Nb containers closed in evacuated quartz ampules. The furnace was slowly cooled to room temperature at a rate of 5 °C per hour. After the stoichiometry of the compound was determined from the single crystal work, a single-phase product of Cs_4Ge_9 (≥ 97% according to a Guinier powder pattern) was synthesized by heating a stoichiometric mixture of the elements (in Ta containers) at 800 °C for 1 h, quenching it in cold water, and then annealing it at 300 °C for 12 days. Rb_4Ge_9 (ruby-red, semitransparent, $a = 15.154(8)$ and $c = 30.82(4)$ Å from 13 measured lines, extremely weakly diffracting) was made similarly.

Structure determination: Data were collected from a single crystal (0.15 × 0.08 × 0.08 mm) on a Siemens SMART system with monochromated $Mo_{K\alpha}$ radiation at 173 K ($2\theta_{max} = 45°$), and corrected for absorption by semiempirical methods. The structure was solved by direct methods. Full-matrix least-squares refinement on F^2 of all atoms with anisotropic thermal parameters using SHELXTL V5.0 converged with $R1 = 0.064$ for 5128 independent reflections with $I > 3\sigma_I$ ($R1/wR2 = 0.093/0.189$ for 6475 independent reflections with $I > 2s_I$) and 469 parameters. Crystal data: Cs_4Ge_9, tetragonal, $P4_1$ with $a = 15.5074(5)$, $b = 31.3997(9)$ Å, $V = 7551.0(6)$ Å^3, $Z = 16$, $\rho_{calcd} = 4.17$ g cm^{-3}, $\mu = 215.73$ cm^{-1}. The compound diffracts very poorly. Data sets collected on the Siemens diffractometer from three different crystals showed very low ratios of observed to measured reflections. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-406486.

Magnetic measurements: The magnetization of 25 mg of the Cs_4Ge_9 sample, which was obtained in near 100% yield, was measured at field of 3 T over the range of 6–295 K (Quantum Design MPMS SQUID magnetometer). The raw data, corrected for the susceptibility of the holder and the ion-core dimagnetism arising from four Cs^+ and nine Ge^{4+} ions, lay between -3.79 and -3.47×10^{-4} emu mol^{-1}. Correction for diamagnetism due to the Larmor precession of the delocalized lone pairs of electrons on cluster orbitals (-3.0×10^{-4} emu mol^{-1}) was also applied.[15] The corrected molar susceptibility is virtually zero, and fluctuates between -7.9×10^{-5} and 4.6×10^{-5} emu mol^{-1}.

[2+2] Cycloaddition Products of Tetradehydrodianthracene: Experimental and Theoretical Proof of Extraordinary Long C–C Single Bonds**

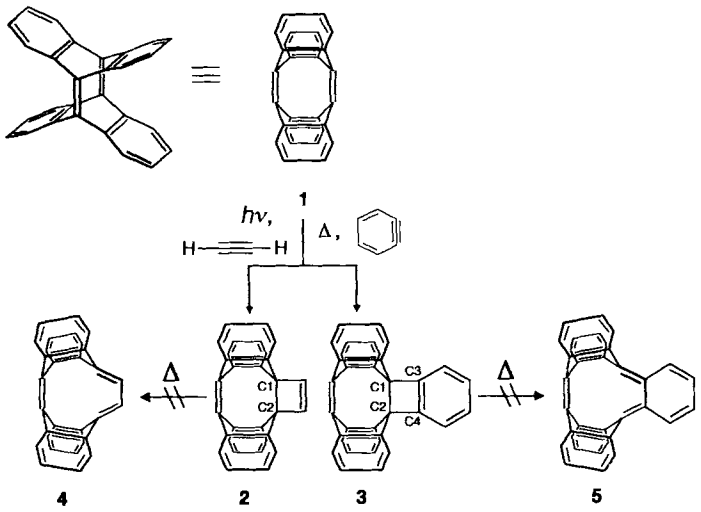
Stefan Kammermeier, Peter G. Jones, and Rainer Herges*

Dedicated to Professor George A. Olah on the occasion of his 70th birthday

C–C bonds in organic molecules can be elongated by a number of factors. Steric repulsion between bulky substituents, strain energy in polycyclic systems, and through-bond interactions are among the most important. An impressive example of extremely long C–C bonds (1.710–1.724 Å), which is the result of the interplay of several of these factors, was recently described by Toda, Tanaka, Stein, and Goldberg.[1] Other classical examples within the class of pure hydrocarbons include anthracene dimers and related compounds, in which the central C–C bonds between the anthracene units usually exceed 1.6 Å.[2] We demonstrate here with two compounds examined by both experimental and theoretical methods how the length of a C–C bond in a pure hydrocarbon can be extended to more than 1.7 Å.

The starting point for our investigations was the highly strained and reactive tetradehydrodianthracene **1**.[3] Compound **1** reacts with a number of alkenes and even with benzene in photochemical [2+2] additions to give cyclobutanes, which immediately undergo [2+2] cycloreversion yielding the product of an overall metathesis reaction.[4] The dimerizing metathesis of **1** to form a tube-shaped, conjugated hydrocarbon has also been described.[5] The driving force for the cycloreversion is the high strain energy induced by the second nonreacting bridgehead double bond in the molecular frame.

If alkynes are used as reaction partners instead of alkenes in the cycloaddition, cyclobutene derivatives are obtained as stable products. The photochemical [2+2] cycloaddition with acetylene leads to adduct **2**; the thermal addition of 1,2-dehydrobenzene gives the [2+2] adduct **3**. Electrocyclic ring opening of the cyclobutene ring in **2** and **3**, which could be expected, was not observed by spectroscopy in either case.[6] The symmetry-allowed conrotatory ring opening is probably prevented by the stiff molecular frame.[7] The reaction would have to proceed via a diradical intermediate. According to our density functional theory (DFT) calculations[8,9] at the Becke3LYP/6-31G* level,[10,11] the ring opening of **3** is thermodynamically not favored. However, in the analogous ring opening of **2** the hypothetical product **4** is only 0.3 kcal mol^{-1} less stable than **2**. We cannot exclude that small amounts of **4** may be in equilibrium with **2**, but the concentration must lie below spectroscopic detection limits. The newly formed double bonds in **4** are considerably twisted (torsion angle C2-C1-C3-C4 20°). Structure **5** is additionally disfavored by the cancellation of the aromaticity of the benzene ring. Structure **5** could not be located as a stationary point at the DFT level and probably is not a minimum on the potential energy surface.[12]



Both cycloaddition products **2** and **3** were characterized by X-ray structure analysis.[13] The central C–C single bond in the acetylene addition product **2** is 1.677(3) Å long; the corresponding bond in **3** is even longer, 1.713(2) Å (Figure 1). The remaining bond lengths and angles in the four-membered rings of **2** and

3 do not exhibit unusual values. This is also true for the annelated benzene ring in **3**. Neither the thermal factors nor the molecular packing display anomalies that would lead to systematic errors in bond lengths.

In a simplified scheme the extraordinary length of the C–C bonds can be explained by the interplay of three factors:

1. the through-bond interactions ($\pi-\sigma^*$) of the four benzene rings with the C–C single bond,
2. the strain induced by the facing, strongly pyramidalized double bond, and
3. the ring strain of the cyclobutene or the benzocyclobutene ring.

To study the effects of these factors we examined different anthracene derivatives, some of which are subject to only one or two of these factors (Table 1). The experimentally determined (X-ray crystal structure) and theoretically calculated (Becke-3LYP/6-31G* and PM3) bond lengths prove that the effects are almost additive. Only the $\pi-\sigma^*$ interaction[14] is operative in the anthracene dimer **6**; both the C9–C9′ and C10–C10′ bonds are already stretched to 1.624 Å by conjugation with the π-systems of the four benzene rings.[15] The annelation of two cyclobutane rings elongates the bonds in **8**[16,17] by 0.04 Å compared to those in **6**, and by 0.047 Å in **10** compared to those in **9**. The remarkably long bond in **7**[18] can be explained by through-bond conjugation with the C_3 bridge. The effect of the facing, strongly pyramidalized double bond becomes evident by comparing **6** with **9**, and **8** with **10**; the bond elongations are 0.024 and 0.028 Å, respectively. The effect of a cyclobutene ring is similar to that of a cyclobutane ring (cf. **10** and **2**), whereas the benzocyclobutene unit in **3** leads to an elongation of the already weak bond by an additional 0.036 Å (X-ray crystal structure) and by 0.021 Å (DFT calculations).

To our knowledge the C1–C2 bond in **3** is one of the longest, stable C–C bonds in an uncharged, pure hydrocarbon. The longest reported C–C bond so far (1.781 Å, X-ray crystal structure) was found by von Schnering et al. in a disilabicyclobutane.[19] Recently Toda and Goldberg et al. synthesized two tetraphenylcyclobutarenes, which are very similar in structure to compound **3** and which also have close to the same bond lengths, 1.710(5) to 1.724(5) Å.[1] Our calculations on a simplified model system (1,1,2,2-tetraphenylcyclobuta[*b*]benzene[20]) confirm the experimental bond lengths (1.720 Å, Becke3LYP/6-31G*). In these systems the four phenyl groups in conjugation with the long C–C single bond are almost freely rotating, and the $\pi-\sigma^*$ interaction therefore is less effective. Moreover, the strain induced by the pyramidalized double bond is lacking. However, this is obviously compensated by the strong steric repulsion of the phenyl groups.

One should expect unusual properties for such unusually long C–C bonds. In this context it is instructive to compare our systems with the simple model case of the C–C bond in ethane. An elongation of the C–C bond in ethane from 1.544 to 1.700 Å requires 6.53 kcal mol^{-1}. This is only 7% of the energy needed for complete bond cleavage (UBecke3LYP/6-31G*; a C–C distance of 2.1 Å is necessary before 50% of the dissociation energy is reached). At a C–C bond length of 1.7 Å the diradical character in ethane is also very low with 0.044 electrons in higher configurations (CAS(10,8)/6-31G*). Therefore C–C bonds of this length do not have unusual electronic properties.

The impact of the bond length on the bond strength, however, is considerable. According to our calculations (Becke3LYP/6-31G*[21]) the force constant of the long C–C bond in **3** (133.1 N m^{-1}) is less than one-third of the corresponding value in ethane (455.7 N m^{-1}). Because the frequency of a stretching vibration mainly depends on the force constant of the bond, the stretching vibration of the 1.713 Å-long C–C bond in **3** should appear at lower wavelengths than those of "normal" hydrocarbons. This is impressively confirmed by a Raman spectrum of compound **3** (Figure 2).[22] According to PM3 calculations[23]

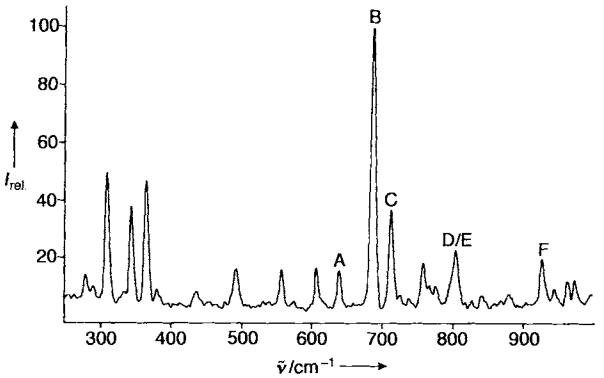

Figure 2. Experimental Raman vibrational spectrum of **3**. The labels A–F are used in the assignments in Table 2.

there are six normal modes that include the C1–C2 stretching vibration.[24] For a more reliable assignment of the theoretically calculated frequencies to the experimental Raman bands, we scaled the PM3 Raman frequencies by using a much more reliable DFT calculation (Becke3LYP/6-31G*) on a small model system.[25] The calculated frequencies of **3** were corrected by a scaling factor of 0.948. The Raman absorption with the highest intensity corresponds to the normal mode having the largest amplitude along the trajectory of our stretching vibration. According to our calculations this is also the most intensive Raman band in the region between 300 and 1000 cm^{-1}. The scaled PM3 value for the absorption is 675 cm^{-1}. Both the intensity and the wavenumber of this C–C vibration correspond well with the intense peak at 687 cm^{-1} in the experimental spectrum (Figure 2). The remaining four vibrations with A_1 symmetry can also be assigned unambiguously (Table 2). The most intense peak is thus red-shifted by more than 300 cm^{-1} relative to the Raman-active C–C stretching vibration in ethane (exp.: 995 cm^{-1}, Becke3LYP/6-31G*: 1010 cm^{-1}).

[a] Relative intensities, relative to the most intensive absorption (= 100). [b] Scaling factor: 0.948.

In agreement with our calculations the experimental data (X-ray structure analysis and Raman spectrum) show that the central C–C bonds in **2** and **3** are 1.677 and 1.713 Å long, respectively. As a consequence of the bond elongation the force constant of the bond is reduced to less than one-third of the usual value and the Raman-active C–C stretching vibration is shifted to 687 cm^{-1}. There is no reason to assume that the limit has been reached. It should be possible to stabilize even longer C–C bonds by a suitable combination of through-bond interactions, steric interactions, and ring strain, and by fixing the bond in a stiff molecular frame (to prevent subsequent reactions). Stable C–C bonds even longer than the smallest nonbonding distance of two C atoms, 1.80 Å,[26] are conceivable.

Experimental Section

2: Compound **1** (100 mg, 0.284 mmol) was suspended in acetylene-saturated benzene (120 mL) and irradiated in a quartz reactor with a high-pressure mercury lamp (150 W) for 2 h. The solvent was removed in vacuo and the residue was purified by chromatography in hexane/dichloromethane. The crude product was additionally purified by recrystallization from toluene. Compound **2** was obtained as a colorless, crystalline solid. Yield: 25 mg (31 %). M.p. 272 °C (decomp.); ^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.17 (s, 2H, olefin. C=CH), 7.14 (m, 4H, arom. CH), 6.87 (m, 12H, arom. CH); ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 150.85 (R_2C=CR_2), 144.92 (C_q), 142.65 (C_q), 137.59 (olefin. C=CH), 125.77 (arom. CH), 125.55 (arom. CH), 124.22 (arom. CH), 123.96 (arom. CH), 72.59 (aliph. C_q); IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3063, 3045, 3037, 1572, 1453, 753, 625; UV/Vis (CH_2Cl_2): λ_{max} (ε) = 230 (24500), 270 (2500), 280 nm (2000); MS (70 eV): m/z (%): 378 (100, M^+), 189 (8, M^{2+}); HRMS: calcd for $C_{30}H_{18}$: 378.1409, found: 378.1399.

3: A suspension of compound **1** (80 mg, 0.227 mmol) in benzene (50 mL) was charged with anthranilic acid (312 mg, 2.27 mmol) and 3-methylbutylnitrite (266 mg, 2.27 mmol), and the mixture was refluxed for 2 h. The solvent was removed in vacuo and the residue was purified by chromatography with hexane/dichloromethane over silica gel. In addition to a number of multiple addition products, which were not further characterized, **3** was obtained as a light yellow solid. Yield: 12 mg (12 %). M.p. 286 °C; ^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.74 (m, 2H, arom. CH), 7.66 (m, 2H, arom. CH), 7.20 (m 4H, arom. CH), 6.91 (m, 4H, arom. CH), 6.86 (m, 4H, arom. CH), 6.78 (m, 4H, arom. CH); ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 151.09 (R_2C=CR_2), 144.79 (C_q), 142.56 (C_q), 141.87 (C_q), 129.06 (arom. CH), 126.76 (arom. CH), 125.95 (arom. CH), 125.53 (arom. CH), 124.27 (arom. CH), 124.20 (CH arom.), 76.53 (aliph. C_q); IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3037, 3010, 1624, 1424, 769, 747, 722; UV/Vis (CH_2Cl_2): λ_{max} (ε) = 230 (27000), 258 (11000, sh), 270 (6000, sh), 280 nm (4200, sh); MS (70 eV): m/z (%): 428 (100, M^+), 214 (9, M^{2+}); HRMS: calcd for $C_{34}H_{20}$: 428.1565, found: 428.1564.

[24] The C1–C2 stretching vibration does not exist as a "pure" normal mode, but forms linear combinations with deformation vibrations of the molecular frame having the same symmetry (A_1 of the point group C_{2v}). Therefore there are

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3616-1759 $ 17.50+.50/0

several normal vibrations with a varying contribution of the C1–C2 stretching vibration.

[25] We chose 13,14-benzotetracyclo[4.2.2.2^{1,2}.2^{2,5}]tetradeca-3,5,7,9,11,13-hexaene as a model system. It corresponds to structure **3** in which the four benzene rings of the didehydrodianthracene framework are replaced by double bonds. A harmonic frequency analysis with the PM3 approximation and the Becke3LYP/6-31G* method was performed. A scaling factor of 0.948 for the PM3 method was determined by comparing the four normal modes with the largest contribution of the C–C stretching trajectory. The length of the corresponding C–C bond in the model system at the Becke3LYP/6-31G* level was 1.784 Å.

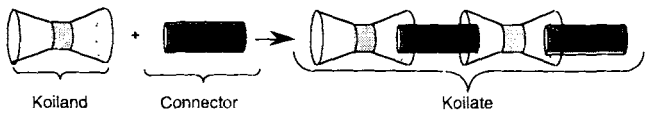
Self-Assembly of Convex and Concave Molecular Tectons to Form a Linear Molecular Array in the Solid State**

Frédérique Hajek, Mir Wais Hosseini,* Ernest Graf, André De Cian, and Jean Fischer

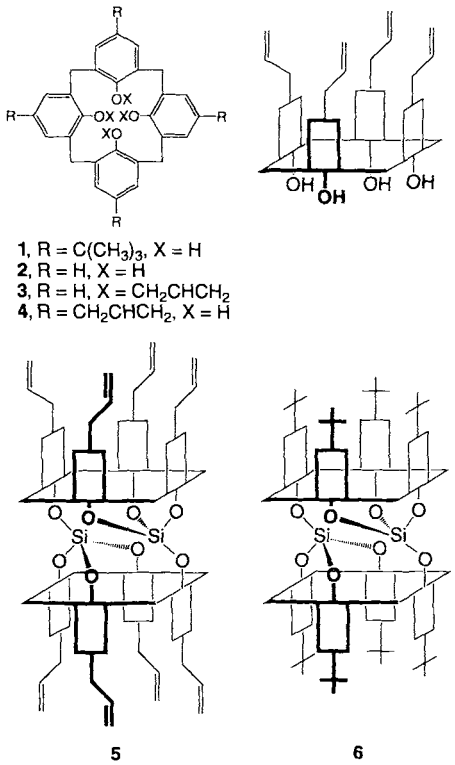
With our present level of knowledge, the complete understanding and subsequent prediction of all intermolecular interactions in the crystalline phase seems illusive. Therefore, it appears that crystal structures are not predictable.[1] However, following the statement by Jack Dunitz:[2] "A crystal is, in a sense, the supramolecule *par excellence*", one may predict some of the intermotive interactions by using proper molecular modules. The design of molecular networks in the solid state is a subject of current interest.[3] The strategy followed for the formation of molecular networks relies on a double analysis. That at the molecular level deals with the individual modules composing the solid, and the other at the supramolecular level deals with the intermotive or intermolecular interactions.[4] Obviously the latter type of analysis is more subtle. For the design and synthesis of molecular networks, the approach called molecular tectonics,[5] which is based on the self-assembly[6] of structurally defined and energetically programmed complementary tectons, seems to be viable. The most important operational concepts in molecular tectonics are molecular recognition[7] between tectons and geometrical features encoded within the framework of the tecton that allow iteration. The latter requires exoreceptor molecules possessing recognition sites that point in divergent directions.

In terms of interaction energy, hydrogen bonding[8, 9] has been used almost exclusively. However, some time ago, we proposed to use the van der Waals interactions responsible for the inclusion processes between concave and convex molecules.[10] Our approach to the preparation of linear molecular arrays (linear koilates) was based on the self-assembly of rigid and compact receptor molecules having two diametrically opposing cavities (linear koiland, from the Greek κοιλοσ, "hollow") and linear connectors with two extremities complementary to the cavities of the receptor (Scheme 1).



Scheme 1. Representation of a linear array (koilate) formed by connection of biconcave receptors (koilands) through convex molecules (connectors).

Calix[4]arene derivatives[11] appeared to be suitable components for our design of koilands. Indeed, they offer a preorganized hydrophobic pocket surrounded by four aryl moieties as well as four hydroxyl groups for further functionalization. Furthermore, the basket-type cavity of calix[4]arene derivatives has been shown to accommodate a variety of neutral guests in the solid state.[12] Our original design of koilands was based on the fusion of two *p-tert*-butylcalix[4]arenes **1** in *cone* conformation through two silicon atoms (**6** in Scheme 2).[10] This design was further extended to other calix[4]arene derivatives.[13] Examples of *p-tert*-butylcalix[4]arenes fused through other atoms have been also reported.[14]



Scheme 2. Calix[4]arenes **1**–**4** (top left) and representations of *p*-allylcalix[4]arene **4** in the *cone* conformation (top right) as well as of koilands **5** and **6** (bottom).

We used compound **6** and hexadiyne to prepare the first fully characterized linear koilate in the solid state.[15] But one could argue that, due to the presence of $CHCl_3$ molecules in the lattice, the formation of the koilate was governed by solvent molecules. To preclude this possibility and to demonstrate the generality of our approach, we describe here the formation of another linear koilate in the solid state obtained without the presence of any solvent molecules.

Calix[4]arene, in addition to the features just mentioned, presents further advantages since it can be readily modified at the *para* position with a large variety of substituents. In particular, this position may be funtionalized with allyl moieties.[16] It has been shown previously[16] that although compound **4** shows temperature-dependent conformational mobility, below room temperature it adopts a *cone* conformation. The design of the new koiland **5** possessing functional groups at both faces of the molecule was based on the double fusion of precursor **4** through two silicon atoms. The following synthetic strategy used for the preparation of compound **5**: the dealkylation of *p-tert*-butylcalix[4]arene **1**[17] afforded compound **2**, which was converted into the allyl ether **3**.[16] The latter was then transformed into the desired compound **4** by a Claisen rearrangement. The desired doubly fused compound **5** was obtained in 53% yield by treatment of compound **4** in dry THF with NaH, subsequent addition of $SiCl_4$, and column chromatography.

Since in the solid state *p*-xylene, a rigid, compact, and ditopic molecule, has been observed to form mononuclear and binuclear inclusion complexes with *p-tert*-butylcalix[4]arene[12] **1** and with the koiland **6**,[15] respectively, we investigated the formation of koilates from compound **5** as the koiland and *p*-xylene as the connector. Crystals suitable for X-ray analysis[18] were obtained from a mixture of compound **5** and *p*-xylene in excess and 2-propanol at room temperature. The crystals (space group $P\bar{1}$) are composed exclusively of **5** and *p*-xylene disposed in an alternate fashion. Both the connector and the koiland are centrosymmetric, and the latter offers two diametrically opposing cavities. The coordination geometry around the silicon atoms is tetrahedral with an average Si–O distance of 1.60 Å and an average O-Si-O angle of 109.4°. As predicted, a linear koilate forms through the interconnection of two cavities belonging to consecutive molecules of koiland **5** through the *p*-xylene molecule (Figure 1). In the crystal one can identify an assembling core, which can be defined as the inclusion of a CH_3 group of the connector within a cavity of **5**. The shortest C–C distance of 3.63 Å between the CH_3 group of the connector and one of the OH-bearing carbon atoms of the koiland at the bottom of the cavity indicates a high degree of inclusion. The formation of the α-network results from a single translation of the assembling core.

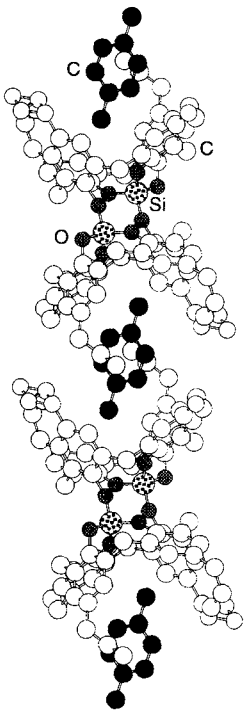

Figure 1. X-ray crystal structure of the koilate formed from compound **5** and *p*-xylene (carbon atoms in black). For clarity the hydrogen atoms are not shown.

Although the formation of the α-network was predicted, the X-ray analysis reveals another unexpected feature. Due to the high degree of rotational freedom of the allyl moieties, one cannot in fact predict their conformations in the crystal lattice. Interestingly, on examination of the lateral packing of consecutive linear koilates, we observed that among the eight allyl groups present in each koiland **5**, two of them are oriented centrosymmetrically in a peculiar manner (Figure 2). Indeed, two alkene moieties belonging to two consecutive koilands are located perfectly parallel to each other at a distance of 4.52 Å. Although this seems somewhat long, the proximity of the two double bonds suggests the possibility of interconnecting the koilates covalently by performing a [2 + 2]cycloaddition reaction in the solid state.

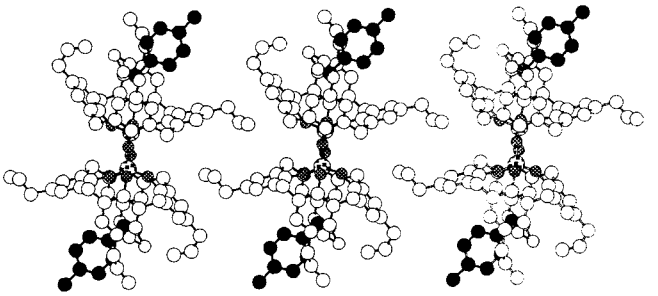

Figure 2. A section of the X-ray crystal structure of the koilate formed from **5** and *p*-xylene. The lateral packing of linear koilates leads to the parallel disposition of the allyl moieties.

In conclusion, the new koiland **5** was synthesized based on the double fusion of two *p*-allylcalix[4]arenes **4** through two silicon atoms. Koiland **5** self-assembles in the presence of *p*-xylene acting as connector to form a linear molecular array called a koilate. The formation of the koilate resulted from the encapsulation of the connector molecules by two cavities belonging to two consecutive koilands **5** and the translation of the inclusion motif.

Experimental Section

A solution of compound **4**[16] (0.42 g, 0.72 mmol) in dry THF (20 mL) was charged with NaH (0.115 g, 4.8 mmol), and the mixture was stirred under Ar for 20 h at 20 °C. $SiCl_4$ (0.1 mL, 0.87 mmol) was added in one portion, and the mixture was stirred at 20 °C for another 3 h. The solvent was removed and the solid thus obtained was purified by chromatography (SiO_2, CH_2Cl_2/hexane, 2/8) to afford **5** (0.23 g, 53%) as a white solid, which was recrystallized from $CHCl_3$/MeOH. M.p. > 300 °C, ^{1}H NMR ($CDCl_3$, 300 MHz, 20 °C): δ = 3.12 (d, $ArCH_2CH$, 4H, J = 6.7 Hz), 3.19 (d, $ArCH_2CH$, 4H, J = 6.7 Hz), 3.30 (d, $ArCH_2CH$, 8H, J = 7.2 Hz), 3.31 (d, $ArCH_2Ar$, 4H, J = 12.9 Hz), 3.37 (d, $ArCH_2Ar$, 4H, J = 13.8 Hz), 4.46 (d, $ArCH_2Ar$, 4H, J = 13.7 Hz), 4.54 (d, $ArCH_2Ar$, 4H, J = 13.4 Hz), 4.94–5.12 (m, CH_2=CH, 16H), 5.74–6.08 (m, CH=CH_2, 8H), 6.73 (s, H-Ar, 4H), 6.87 (s, H-Ar, 8H), 6.92 (d, H-Ar, 4H; J = 2 Hz); ^{13}C NMR ($CDCl_3$, 50.3 MHz, 20 °C): δ = 33.4, 34.2 (CH_2, $ArCH_2Ar$), 39.3, 39.6, 39.7 (CH_2, $ArCH_2CH$), 115.4, 115.7, 115.8 (CH_2, CH_2=CH), 128.4, 128.5 (CH-Ar), 129.7, 129.9 (CH-Ar), 129.4, 130.4, 132.8, 133.7, 134.2, 135.8 (C-Ar), 137.5, 137.7, 137.9 (CH, CH=CH_2), 145.5, 146.7, 148.9 (C-Ar, C–O); ^{29}Si NMR ($CDCl_3$, 79.49 MHz, 20 °C): δ = −112.94; FAB (*m*-nitrobenzyl alcohol matrix): *m/z* (%): 1217.4 (100) [M^+].

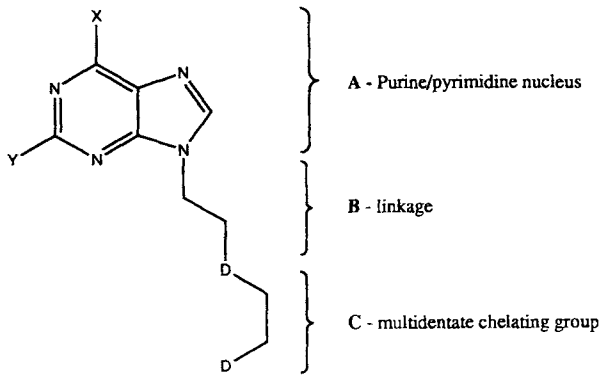
[18] Suitable crystals were obtained from a mixture of **5**, *p*-xylene, and 2-propanol. $C_{88}H_{82}O_8Si_2$: $M = 1323.8$, triclinic, space group $P\bar{1}$, $a = 12.0928(5)$, $b = 12.3615(7)$, $c = 14.0623(8)$ Å; $\alpha = 114.8(3)$, $\beta = 107.8(2)$, $\gamma = 91.5(3)°$, $Z = 2$, $\rho_{calc} = 1.23\ g\,cm^{-3}$, $\lambda(Mo_{K\alpha})$, 0.7107 Å (graphite monochromator). $R(F) = 0.051$. 3630 reflections with $I > 3\sigma(I)$ were used. The data were collected at 21 °C using a Enraf-Nonius-CAD4 automatic diffractometer and analyzed using the Enraf-Nonius SDP/VAX package. The structure was solved by direct methods. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplmentary publication no. CCDC-100399. Copies of the data can be obtained free of charge on application to the Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: Int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

Evidence for Directed Metalation: A Structural Intermediate in the Formation of a Novel C-bound Adenine Complex of Ruthenium**

Clayton Price, Mark R. J. Elsegood, William Clegg, Nicholas H. Rees, and Andrew Houlton*

The interaction of metal ions with purine and pyrimidine nucleobases is a central theme of bioinorganic chemistry.[1-3] A key objective in this field has been to establish the preferred binding sites for the different bases and these are now generally acknowledged as the endocyclic N^7 and N^1 atoms of N^9-substituted purines and the N^3 atom and the oxygen donors of N^1-blocked pyrimidines,[1, 2] sites which are all involved in hydrogen bonding interactions in the formation of base-pairs, -triples, and -quartets.

Our interest in this area is in the design of novel metalated nucleobases, in particular, those which retain the ability for base-pairing. Such compounds may, ultimately, be used as building blocks for the assembly of supramolecular structures through interactions analogous to those seen in nucleic acid chemistry.[4] Our strategy towards this has been to develop the concept of *directed metalation*.[5] With this approach the ribose group of a nucleoside is, effectively, replaced by a multidentate chelating group forming a nucleobase–ligand conjugate[6] (Scheme 1).



Scheme 1. Generalized structure of a nucleobase–ligand conjugate. X and Y = NH_2, =O or H. D = donor atom. For 9-[2-(2-aminoethylamino)ethyl]adenine (L), X = NH_2, Y = H; D = NH (NH_2).

With such a method each of the components, **A**, **B**, and **C**, can be varied allowing an extensive range of conjugates to be designed. It is anticipated that novel metalation reactions will result due to initial coordination through the multidentate chelating group **C**. Such chelation would then impose restrictions on the sites at which the metal ion could bind to the nucleobase. Here we report the synthesis and crystal structures of two ruthenium complexes of the adenine derivative L, which contains an ethylenediamine unit bound through an ethyl group to the nucleobase (see Scheme 1, D = NH (NH_2), X = NH_2, Y = H). These illustrate this concept and highlight the novel chemistry that may result with an unique example of a C-bound complex of a purine nucleobase.

Reaction of $[(dmso)_2H][RuCl_4(dmso)_2]$ (dmso = dimethyl sulfoxide) with L·HCl in methanol at reflux yields, after purification by column chromatography, two main products, **1a** and **1b** (Scheme 2). Monitoring the reaction by UV/Vis

$[RuCl_2(LH)(dmso)_2]Cl\cdot 4.5H_2O$ **1a**·4.5 H_2O

$[RuCl_2(L)(dmso)]\cdot H_2O$ **1b**·H_2O

spectroscopy and thin-layer chromatography confirmed the initial formation of **1a** followed by **1b**. Furthermore, refluxing a sample of **1a** in methanol leads to the formation of **1b**. Crystallization from saturated solutions in methanol in the case of **1a**, and water for **1b**, furnished single crystals which were analyzed by X-ray crystallography.[7]

Compound **1a** crystallizes with two independent molecules in the unit cell with similar metrical features (Figure 1). The metal ion is formally Ru^{II} and adopts an octahedral geometry with a donor set comprising {2Cl:2N:2S}. The nucleobase–ligand

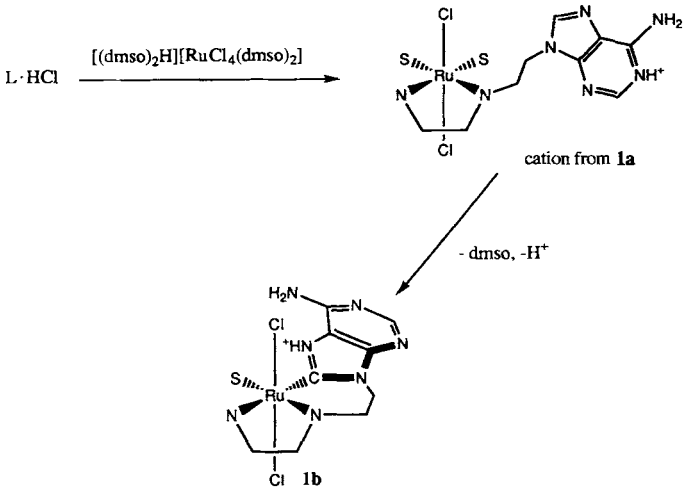

Scheme 2. Proposed reaction scheme for the formation of **1a** and **1b**. S = sulfur-bound dmso.

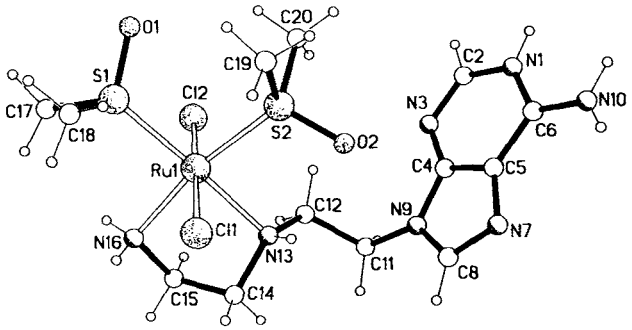

Figure 1. Molecular structure and atom labeling of the $[RuCl_2(LH)(dmso)_2]^+$ ion from **1a**. The pendant adenine lies at an angle of $\approx 65°$ to the equatorial coordination plane. Only one of the independent molecules is shown. Bond lengths [Å] around the metal, averaged over the two independent molecules, are Ru–Cl1 2.422(1), Ru–Cl2 2.415(1), Ru–N13 2.170(4), Ru–N16 2.139(4), Ru–S1 2.229(1), Ru–S2 2.237(1).

conjugate L is bound through the ethylenediamine group, leaving the adenine moiety pendant and at an average angle of $\approx 65°$ to the {2N:2S} coordination plane of the molecule. The adenine group is protonated at N^1 and participates in a variety of hydrogen bonding interactions.

In **1b** the ruthenium is similarly divalent with an octahedral coordination geometry (Figure 2). Here, however, the donor set is {2Cl:2N:S:C} with L binding in a meridional tridentate manner through the ethylenediamine group and the C^8atom of the adenine moiety. This binding mode results in five- and six-membered chelate ring formation. The adenine moiety is protonated at N^7 generating an ylide-type structure which maintains overall charge neutrality on the group.

A search of the Cambridge Crystallographic Data Base found no previous examples of $Ru-C_{(adenine)}$ complexes. A wider search for examples of purine-containing ruthenium complexes revealed a variety of binding modes; monodentate at N^7 (ethylguanine),[8] bidentate through N^7 and S^6 (mercaptopurine),[9] bridging through N^7 and N^9 (adenine),[10] and monodentate at C^8 in $[RuCl_2(NH_3)_3(caffeine)]Cl$.[11] For caffeine, N^1, N^3, and N^7 are methylated, discounting them as binding sites, while the N^3-methyl group also presents considerable steric hindrance to the large ruthenium-ammine electrophile attacking at N^9.[11, 12] *It is reasonable to assume that in this case the C^8 position* of caffeine is effectively the only available metal binding site.

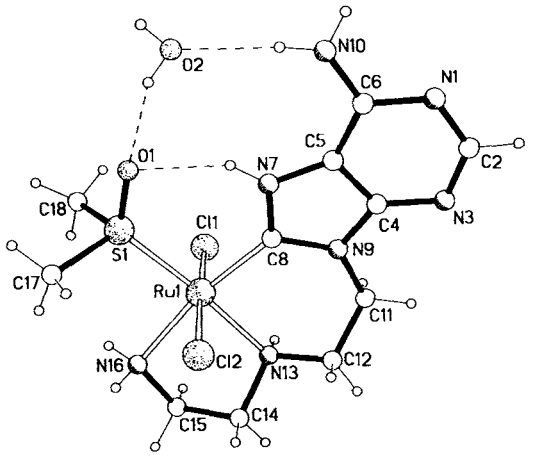

Figure 2. Molecular structure of **1b**·H_2O highlighting the five- and six-membered chelate rings. Bond lengths [Å] around the metal are Ru–Cl1 2.4181(9), Ru–Cl2 2.4209(9), Ru–S1 2.2102(9), Ru–C8 1.989(3), Ru–N16 2.208(3), Ru–N13 2.140(3).

Furthermore, despite the higher formal oxidation state of the metal, the M–C bond length is longer (2.03(1) Å) in $[RuCl_2(NH_3)_3(caffeine)]Cl$ than in **1b** (1.989(3) Å). Additional comparison can be made with the imidazolium-ylide complex *trans*-$[Ru(NH_3)_3CO(4,5\text{-dimethylimidazolium})]^{2+}$[13] which features binding analogous to that for **1b**. In this case too the Ru–C bond length is longer (2.128(4) Å). It is suggested, then, that both the metalation at C^8 and the short Ru–C bond length observed in **1b** reflect the chelating nature of ligand L and do not represent the intrinsic reactivity of adenine towards Ru^{II}.

In conclusion, the two complexes reported here highlight the role of the tethered chelating group in modifying the reactivity of nucleobases towards metal ions. The isolation of **1a** provides evidence for the principle of directed metalation and, indeed, is an intermediate in the formation of **1b**. This latter compound is the first complex to contain a C^8-metalated adenine and extends the emerging class of organometallic nucleobase derivatives that contain metal–carbon bonds derived from biomolecules,[14–16] structurally characterized examples of which, to date, have been based solely on pyrimidines.

Experimental Section

1a and **1b**: An equimolar mixture of L·HCl [5] and $[dmso_2H][trans\text{-}RuCl_4(dmso)_2]$ [17] was heated at reflux in methanol for 16 h. The reaction mixture was concentrated under reduced pressure and the crude material loaded onto a silica column. The column was eluted with methanol to give two main products **1a** (7%) and **1b** (46%) as orange and red solids, respectively. **1a**: M.p. >250 °C. UV/Vis (H_2O): λ [nm] (ε [$M^{-1}cm^{-1}$]) = 260 (8390), 300 (1160); MS: *m/z* (%): 586 (100); ^1H NMR (500 MHz, $(CD_3)_2SO$): δ = 8.20 (s, H2), 8.23 (s, H8), 7.28 (s, H10), 4.58 (ddd, H11) 4.48 (m, H11'), 3.91 (m, H12) 3.33 (m, H12') 4.48 (m, H13), 3.13 (m, H14), 2.64 (m, H14'), 2.93 (m, H15) 2.88 (m, H15') 4.47 (m, H16), 4.38 (m, H16') 3.16, 3.19, 3.22, 3.24 (s, H17–H20); ^{13}C NMR (125 MHz, $(CD_3)_2SO$): δ = 152.4 (C2), 155.8, 149.9, 118.6 (C4-C6), 140.9 (C8), 41.2 (C11), 50.6 (C12), 48.9 (C14), 42.3 (C15), 43.7, 44.0, 45.1, 45.7 (C17-C20). Crystals of **1a** suitable for single-crystal X-ray structure analysis were obtained from a saturated solution of methanol. [7] **1a**·4.5H_2O: $C_{13}H_{28}Cl_3N_7O_2RuS_2 \cdot 4.5H_2O$, $M_r = 667.04$, crystal dimensions $0.30 \times 0.29 \times 0.06$ mm^3, triclinic, $P\bar{1}$, $a = 12.7288(11)$, $b = 14.7164(12)$, $c = 16.2058(14)$ Å, $\alpha = 93.525(2)$, $\beta = 111.256(2)$, $\gamma = 110.651(2)°$, $V = 2584.2(4)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.714$ g cm^{-3}, $Mo_{K\alpha}$ ($\lambda = 0.71073$ Å), $T = 160$ K, $\mu = 1.124$ mm^{-1}. 20192 (11193 unique, $2\theta < 55°$, $R_{int} = 0.0302$) data were collected on a Siemens SMART CCD area detector diffractometer using narrow frames (0.3° steps in ω) and the absorption effects were corrected semiempirically (transmission: 0.644–0.801). The structure was solved by Patterson synthesis and refined by full-matrix least-squares on F^2 values for all data (G. M. Sheldrick, SHELXTL manual, Siemens Analytical X-Ray Instruments, Madison, WI, **1994**, version 5) to give $wR = \{\sum[w(F_o^2 - F_c^2)^2]/\sum[w(F_o^2)^2]\}^{1/2} = 0.1250$, conventional $R = 0.0525$ for F values of 8541 reflections with $F_o^2 > 2\sigma(F_o^2)$, $S = 1.055$ for 661 parameters. The asymmetric unit contains two complex cations, two chloride ions, and approximately nine molecules of water some of these disordered. All non-H atoms were refined anisotropically. Hydrogen atom coordinates were refined for N-H atoms, riding for C-H atoms, and not included for O-H; a riding model was used for all U_{iso}(H). The residual electron density extremes were 1.09 and -0.93 e Å^{-3}. **1b**·H_2O: $C_{11}H_{21}Cl_2N_7ORuS.H_2O$, $M_r = 489.39$, crystal dimensions $0.22 \times 0.17 \times 0.04$, monoclinic, $P2_1/c$, $a = 9.2067(6)$, $b = 17.1639(11)$, $c = 12.0162(8)$ Å, $\beta = 105.421(2)°$, $V = 1830.5(2)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.776$ g cm^{-3}, $\mu = 1.283$ mm^{-1}; 11279 (4148 unique, $2\theta < 55°$, $R_{int} = 0.0356$) data, transmission: 0.815–0.962. The structure was solved by direct methods. $wR = 0.0991$, $R = 0.0382$ (3295 F values), $S = 1.117$ for 232 parameters. Coordinates of H atoms on N7, N10, and O2 were freely refined, all others were riding. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100265. Synthesis of Enantiomerically and Diastereomerically Pure Cyclopentanols by Asymmetric Cyclocarbolithiation of 5-Alkenyl Carbamates**

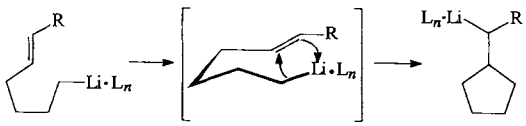
Michael J. Woltering, Roland Fröhlich, and Dieter Hoppe*

Dedicated to Professor Hans J. Schäfer on the occasion of his 60th birthday

The intramolecular carbolithiation of 5-alkenyllithium compounds has become an important alternative to cyclizations of 5-alkenyl radicals (Scheme 1) due to the high 5-*exo-trig* selectivity and the facility of further functionalization of the resulting cyclopentylmethyl anion. Recently Marek, Normant et al. described an asymmetric variant of an intermolecular carbolithiation with cinnamyl alkoxides. Enantiofacial differentiation at the attacked double bond is achieved by the (−)-sparteine-mediated addition of non-stereogenic alkyllithium compounds.[3] However, the known methods do not allow control of the absolute configuration of the attacking nucleophilic carbon center. On the other hand, a wide variety of (*S*)-configurated (α-carbamoyloxy)alkyllithium derivatives are accessible by (−)-sparteine-mediated deprotonation.[4] Despite the presence of the reactive styrene moiety, we supposed that 6-phenyl-5-hexenyl carbamates would be lithiated regioselectively at the 1-position and then undergo stereoselective nucleophilic cycloalkylation to form the appropriate cyclopentanol derivatives.



Scheme 1. Intramolecular 5-*exo-trig*-carbolithiation [1, 2]. R = H or electron-withdrawing group; L = OEt_2.

Precursors **1a** and **1b** were prepared by Wittig olefination.[5, 6] They were deprotonated with *sec*-butyllithium/(−)-sparteine (**6**) in diethyl ether at −78 °C, the reaction mixture was stirred for 20 to 30 h at this temperature, and water or an electrophilic reagent was subsequently added (Scheme 2). With exception of the carboxylic acid ester **5g**, the diastereomerically and enantiomerically pure cyclization products **5** were obtained (Table 1). Decarbamoylation of **5a** provided (1*R*,2*S*)-2-benzylcyclopentanol;[11] the collected data correspond well to that in reference [12].

Substitution at the carbamate proceeds, as expected, with retention of configuration at the carbanionic center. The cyclization shows complete 5-*exo-trig* selectivity and leads with high diastereoselectivity to the *trans*-substituted cyclopentane **5** via intermediate **4**. Electrophilic attack at the benzylic carbanionic center also proceeds with high diastereoselectivity. The absolute configuration [1*R*,2*S*,2(1*S*)] was determined from the X-ray crystal structure of diol **8**, which was generated from **5e**

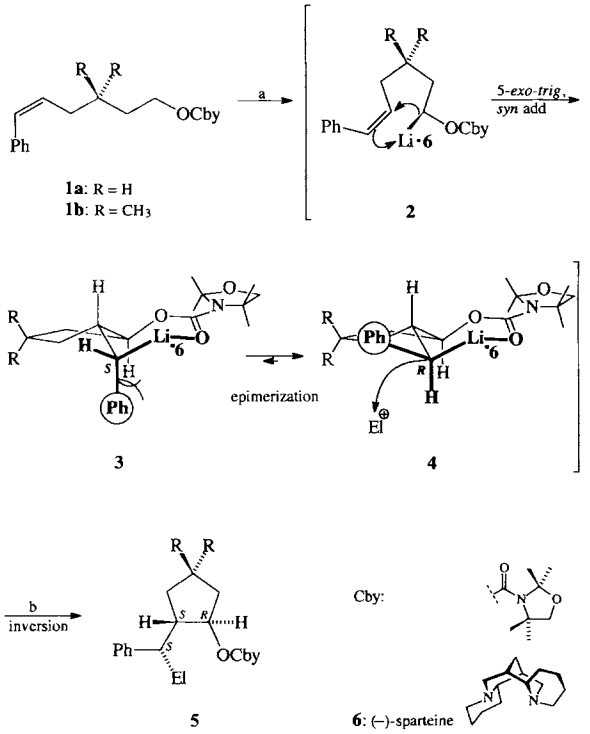


Scheme 2. Cyclocarbolithiation of **1** and scavenging reaction. a) *s*BuLi (1.5 equiv)/(–)-sparteine (**6**), Et_2O, –78 °C, 20–30 h; b) EIX, –78 °C → RT.

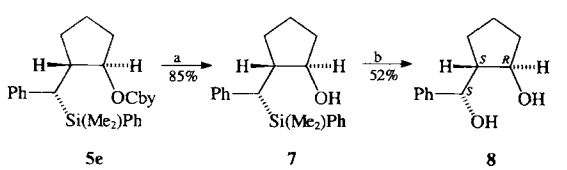
Table 1. Synthesis of cyclopentanol derivatives **5**.

Reagent	*t*[h]	EIX	Product[a]	Yield[%]	$[\alpha]_D^{20}$[b]	d.r.[f]
1a	20	HOH	**5a**	30	–20.9	>98:2
1a	26	Me_3SiCl	**5b**	32	–66.2	>98:2
1a	4	Bu_3SnCl	**5c**	14	–80.7	>98:2
1a	23	Me_3SnCl	**5d**[c]	17	–[g]	>98:2
1a	24	$PhMe_2SiCl$	**5e**	38	–79.7	>98:2
1b	23	HOH	**5f**	51	–29.0	>98:2
1b	23	CO_2	**5g**[d]	43	+19.2	92:8
1b	24	Bu_3SnCl	**5h**	30	–79.4	>98:2
1b	26	Me_3SiCl	**5i**[e]	38	–[g]	>98:2
1b	24	$PhMe_2SiCl$	**5j**	48	–59.4	>98:2

[a] Correct elemental analyses were obtained for all isolated products (C ±0.32, H ±0.26, N ±0.35 %). [b] $c = 0.96–1.01$ in CH_2Cl_2. [c] Mixture with **5a**. [d] Isolated as the methyl ester. [e] Mixture with **1b** and **5f**. [f] Determined by gas chromatography and ^1H NMR spectroscopy. [g] Not determined.

by deprotection of the hydroxy group and subsequent hydroxydesilylation (Scheme 3).[13, 14]

As stannylation, silylation, and carbonylation of several benzyllithium compounds occur with inversion of the configuration,[15–18] this can also be expected in our case. Therefore, the lithiated precursor **4** should have 2(1*R*) configuration. Since *syn* addition to the *cis* double bond leads to the primary adduct **3** with 2(1*S*) configuration, subsequent epimerization at the benzylic center is highly probable. The resulting epimer **4** is presumably thermodynamically more stable due to the equatorial position of the phenyl substituent within the bicyclic chelate. This is supported by the fact that the sequences of reactions starting from (*E*)-**1a**,**b** lead to the same diastereomers.



Scheme 3. Conversion of **5e** into diol **8**. a) $MeSO_3H$ (4 equiv), MeOH, reflux, 3 h, then K_2CO_3 (8 equiv), reflux, 20 h. b) $HBF_4 \cdot OEt_2$ (2 equiv), CH_2Cl_2, 0 °C, 10 min, then KF (2 equiv), $KHCO_3$ (10 equiv), 30% H_2O_2 (11 equiv), THF/MeOH, RT, 4.5 h.

The method described here allows the stereoselective formation of two C–C bonds and, therefore, three vicinal stereocenters of defined absolute configuration. The method might be interesting for the synthesis of cyclopentanoid natural products.[19]

Experimental Section

General procedure for cyclocarbolithiation: To **1a** or **1b** (0.5 mmol) and (–)-sparteine (0.75 mmol) in diethyl ether (3 mL) was added *s*BuLi (0.75 mmol) in cyclohexane/hexane at –78 °C, and the solution stirred for 20 to 30 h at –78 °C. The electrophile (0.75 mmol) was then added, and the reaction mixture warmed to room temperature over night. Water (3 mL) was added, the layers were separated, and the aqueous phase was extracted three times with ether. The combined organic fractions were dried over $MgSO_4$, the salts were filtered off, and the solvent removed from the filtrate in vacuo. The crude product was purified by flash chromatography on silica gel with ether/pentane.

[10] The by-products of the reactions of **1a** were the corresponding open-chain substitution product and the cyclopropane derivative resulting from intramolecular 1,3-elimination of the carbamate group. Reactions of **1b** delivered the cyclopropane derivative as well as the substrate. Therefore, in case of **1a** the yields are limited either by the rate of cyclization or the unfavorable equilibrium constant, whereas for **1b** the slow deprotonation step plays a crucial role. Other by-products were not identified.

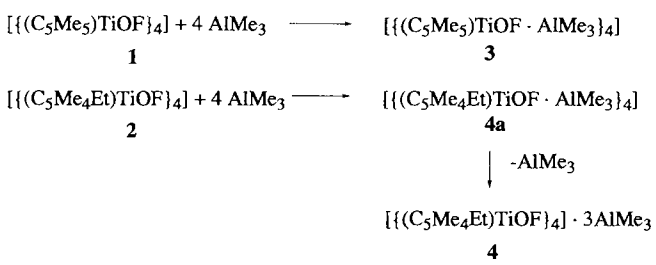
Activation of Ti–F Bonds in $[\{(C_5Me_5)TiOF\}_4]$ and $[\{(C_5Me_4Et)TiOF\}_4]$ with $AlMe_3$

Peihua Yu, Herbert W. Roesky,* Alojz Demsar, Thomas Albers, Hans-Georg Schmidt, and Mathias Noltemeyer

Dedicated to Professor Roald Hoffmann on the occasion of his 60th birthday

Substitution reactions proceed according to an S_N1 or S_N2 mechanism. For sterically shielded centers only an S_N1 mechanism is possible. It is assumed that in the latter the exit of the nucleophile can be electrophilically supported. This markedly facilitates the dissociation. Thus, C–F,[1] Si–F,[2] or P–F activations[3] have mainly been described with alkali metal and alkaline earth metal ions. Metallocenes of group 4 have been particularly intensively investigated in the last few years.[4, 5] Herein we report on the first step of a reaction of titanium fluoride oxide with $AlMe_3$.

As starting materials we chose the compounds $[\{(C_5Me_5)TiOF\}_4]$ (**1**) and $[\{(C_5Me_4Et)TiOF\}_4]$ (**2**),[6, 7] which each contain only one fluorine atom bound to each metal center. Compounds **1** and **2** were prepared by metathesis reactions from the corresponding chloride derivatives with Me_3SnF. When **1** and **2** are each allowed to react with four equivalents of $AlMe_3$ in toluene and hexane (1:1) at −10 °C, an immediate color change takes place from yellow to bright red. The solutions were stored at −20 °C, which led to red crystals of **3** and orange crystals of **4**, respectively. In the case of **4**, an intermediate is initially obtained (**4a**), which rearranges under dissociation to give **4** (Scheme 1). Both the color of the solution and that of the crystals is an indicator for the Ti–F activation in **3** and **4**.



Scheme 1.

The thermal decompositions of **3** and **4** do not afford $[\{(C_5Me_5)TiOMe\}_4]$ and $[\{(C_5Me_4Et)TiOMe\}_4]$, respectively. These compounds are only obtained when a slight excess of $AlMe_3$ is used.[8] Moreover, $(FAlMe_2)_3$ is formed. NMR and mass spectra reveal that the decomposition of **3** and **4** leads to mixtures of products containing fluorine atoms and methyl groups (MS: *m/z* 845 $[(C_5Me_5)_4Ti_4O_4FMe_2]$ and 901 $[(C_5Me_4Et)_4Ti_4O_4FMe_2]$). This confirms the lability of **3** and **4**.

The structure of **3** is shown in Figure 1. The four oxygen atoms and the four titanium atoms in this compound lie almost

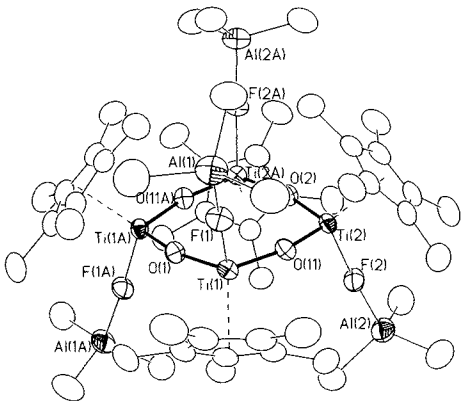


Figure 1. Crystal structure of **3**·3 toluene. Selected bond lengths [Å] and angles [°]: Ti(1)–F(1) 1.9593(13), Ti(2)–F(2) 1.9728(13), F(1)–Al(1) 1.8960(14), F(2)–Al(2) 1.8894(14), Ti(1)–O(1) 1.8282(7), Ti(1)–O(11) 1.8330(15), Ti(2)–O(11) 1.8245(15), Ti(2)–O(2) 1.8292(7); O(1)-Ti(1)-O(11) 105.24(8), O(1)-Ti(1)-F(1) 103.11(5), Ti(2)-O(11)-Ti(1) 164.67(9), Al(1)-F(1)-Ti(1) 175.90(8), Al(2)-F(2)-Ti(2) 175.62(8). The solvent molecules are not shown.

in a plane (deviation 0.02 Å). As expected the Ti–F bond lengths in **3** (av 1.965 Å) are considerably longer than those in the starting material[6] (av Ti–F 1.845 Å). Furthermore, the Ti-F-Al bond lengths (Ti–F 1.959, Al–F 1.896 Å) can be compared with the corresponding distances in $[\{(C_5H_4Me)_2TiF_2\}_3Al]$[9] (Ti–F 2.095, Al–F 1.812 Å).[10] These comparisons of the bond lengths clearly indicate that the coordinating effect of $AlMe_3$ leads to the extension of the Ti–F bonds. Moreover, the Al-F-Ti bonds are nearly linear (av 175.7°). The single-crystal structure analysis of **4** (Figure 2) shows that only three fluorine

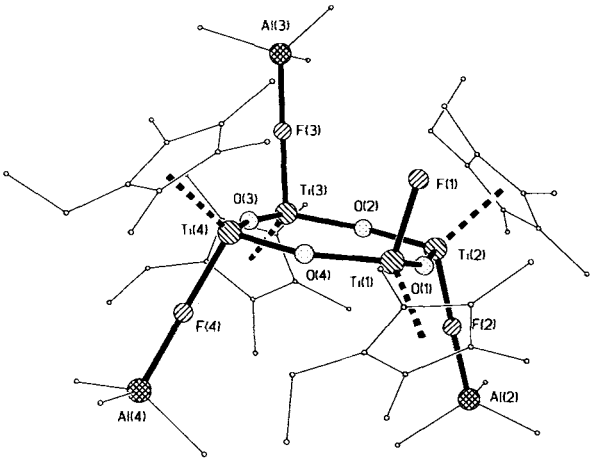

Figure 2. Crystal structure of **4**·*n*-hexane. Selected bond lengths [Å] and angles [°]: Ti(1)–O(1) 1.846(2), Ti(1)–O(4) 1.839(2), Ti(1)–F(1) 1.868(2), Ti(2)–F(2) 1.956(2), Ti(2)–O(2) 1.838(2), Ti(2)–O(1) 1.796(2), Ti(3)–O(3) 1.819(2), Ti(3)–O(2) 1.818(2), Ti(4)–O(4) 1.797(2), Ti(4)–O(3) 1.833(2), Ti(3)–F(3) 1.960(2), Ti(4)–F(4) 1.955(2), Al(2)–F(2) 1.874(2), Al(3)–F(3) 1.902(2), Al(14)–F(4) 1.876(2); Al(2)-F(2)-Ti(2) 177.55(13), Al(3)-F(3)-Ti(3) 174.58(12), Al(4)-F(4)-Ti(4) 175.48(13), O(1)-Ti(1)-O(4) 105.48(10), O(1)-Ti(1)-F(1) 103.74(10), O(4)-Ti(4)-O(3) 105.65(10), O(4)-Ti(4)-F(4) 102.11(10), O(1)-Ti(2)-F(2) 101.69(10). The *n*-hexane molecule is not shown.

atoms of the starting material **2** form coordinative bonds with three molecules of $AlMe_3$.[10] One fluorine atom (terminal) is not coordinated to $AlMe_3$ (Ti–F 1.868(2) Å), and the Ti–F bond length is correspondingly shorter than the Ti–F bond lengths with the fluorine atom in the bridging position (av Ti–F 1.95 Å). Noteworthy are the different Al–F bond lengths. Similar bond lengths are observed on one side of the ring plane (Al(2)–F(2) 1.874(2), Al(4)–F(4) 1.876(2) Å), whereas Al(3)–F(3) (1.902(3) Å) is slightly longer. Additional bond lengths and angles of **3** and **4** are given in the legends to Figures 1 and 2.

^{19}F NMR studies in solution were performed in $[D_8]$toluene at −20 °C. Initially **1** (0.1 mmol) (or **2**) was placed in an NMR tube and dissolved in $[D_8]$toluene, cooled to −20 °C, and $AlMe_3$ (0.4 mmol) was added to this solution with a syringe. The signals of the starting materials (**1**: $\delta = 64.6$, **2**: $\delta = 63.3$) disappear; they are replaced in each case by two sharp signals (intensity 1:1) that are shifted to high field, which we assign to the compounds **3** ($\delta = -132.6, -136.5$) and **4a** ($\delta = -128.2, -131.0$). These results show that the compounds are not planar in solution, as already suggested by the crystal structure analyses. Furthermore, they confirm that **4a** is initially formed in the reaction with **2**. The formation of **4** cannot be monitored by NMR spectroscopy; evidently, this compound forms by crystallization in a nonequilibrium reaction.

In summary we have shown for the first time that Ti–F bonds can be activated with $AlMe_3$. The experimental results allow conclusions and predictions for similar reactions. Furthermore, the pathways of such reactions can be readily examined by ^{19}F NMR spectroscopy.

Experimental Section

3: $AlMe_3$ (2 mL, 4 mmol, 2 M solution in *n*-hexane) was added dropwise to a stirred solution of **1** (0.87 g, 1 mmol) in toluene (30 mL) in a Schlenk tube at −10 °C. The mixture was subsequently stirred for 5 min and the tube was stored at −20 °C. Compound **3** precipitated in the form of red crystals. The mother liquor was removed with a syringe, to leave **3** (0.6 g) in 52% yield. Compound **3** is unstable at room temperature and decomposed rapidly under the formation of a yellow solid.

4: Compound **4** was prepared analogously to **3** by reacting **2** (0.93 g, 1 mmol) with $AlMe_3$ (4 mmol). The solution changed color from yellow to bright red during the addition. The solution was stored at −20 °C. This led to the formation of orange crystals, and the solution slowly changed color from red to orange. Compound **4** was obtained in 45% yield (0.51 g); it decomposed within 5 min at room temperature under an inert gas atmosphere.

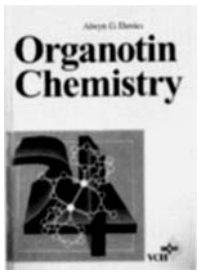
Tips and Trends in Synthesis

Organotin Chemistry. By *A. G. Davies*. VCH Verlagsgesellschaft, Weinheim, 1997. 327 pp. plus diskette, hardcover DM 248.00.—ISBN 3-527-29049-4

In the last few decades the chemistry of the heavy elements of Main Group 4 has undergone a remarkable renaissance. This has been stimulated by a growth in the use of these elements in organic synthesis, and by the discovery of many new compounds with silicon, germanium, tin, or lead (in low or high coordination states) as the central atom. These developments have been described in many monographs and review articles on organosilicon and organotin chemistry, and in two substantial works in the Wiley series *The Chemistry of Functional Groups* edited by Patai: the two-volume work on organosilicon chemistry published in 1989, and the volume on organogermanium, organotin, and organolead chemistry, which appeared in 1995 and should cover the literature up to the end of 1994. Against this background one must ask whether it is worth buying another book on organotin chemistry, whose only obvious advantage is that it is slightly more up-to-date. However, on comparing the contents with those of the recent monographs and the Patai volume mentioned above, one soon discovers that its aim is different. Whereas the other works mostly deal with a variety of individual topics, this book is essentially devoted to the preparation of organotin compounds and their reactive properties, while also covering some aspects of their use as substrates in synthetic organic chemistry.



The monograph begins by discussing physical methods of characterization and listing data. Reactions leading to the formation of compounds with tin–carbon bonds are then described, arranged in the conventional way according to the various classes of organic groups. This is followed by chapters on functionalized organotin compounds with Sn–halogen, Sn–O, Sn–N, Sn–S, Sn–Sn, and Sn–metal bonds. These derivatives occupy almost half the book, reflecting the special area of interest of the author (a professor at University College, London), whose research in the field of organotin chemistry extends over more than 30 years. The book ends with two short chapters, one on organotin radicals and radical ions and the other on tin compounds with low coordination numbers.

The author gives relatively little information about toxicological aspects or the technological applications of organotin compounds. This is a conventional book in the best sense, with a firm emphasis on the synthesis, structures, and reactive properties of organotin compounds. It has a comprehensive subject index, and an author index which enables one to quickly link each literature reference to the relevant chapter. However, the diskette that is also supplied with the book seems to me a rather pointless gimmick, since unless one has special software it yields hardly any information that is not already provided by the indexes. Perhaps the younger generation will see things differently.

The book contains few errors or inconsistencies. Occasionally the positions of alkyl substituents in aryl groups have been inadvertently interchanged. A more annoying fault is the author's tendency to cite conference reports that are virtually unobtainable, even in cases where the work has also been published in well-known journals in the same year. On the other hand, there are some passages which are more likely to raise a smile, as in the explanation of nomenclature rules in the introduction where, after reading that "... the names of the attached ligands are given in alphabetical order ...", the first example cited is "dimethyldichlorostannane". The treatment of stannaimines (more correctly: stannanimines) and stannaphosphenes in two different chapters is not consistent.

However, these minor criticisms do not detract significantly from the very positive overall impression. The book gives an excellent (although not exhaustive) overview of the synthetic aspects of organotin chemistry, based on a survey of about 1400 literature references. The standard of production is very good, with well-structured tables and an abundance of clear formula schemes, which enable the reader to quickly grasp the essence of the text. Therefore I have no hesitation in recommending this book for all organic and organometallic chemists engaged in synthetic work. It is just reasonably priced for a monograph of this kind, a point to bear in mind when deciding whether to buy it.

Hypervalent Iodine in Organic Synthesis. By *A. Varvoglis*. Academic Press, San Diego, 1996. 223 pp., hardcover £ 55.00.—ISBN 0-127-14975-9

During the last 15 years there has been a renaissance in the chemistry of hypervalent iodine compounds with oxidation states +3 or +5, resulting in a dramatic increase in the number of publications appearing. One of the main causes of this is the availability of a variety of new reagents of this type, some of which have unique chemical properties. Nevertheless, apart from a few exceptions such as the Dess–Martin reagent, hypervalent iodine compounds have not yet been able to cast off their image as belonging to a very specialized area of chemistry.

Many reviews and monographs on this subject have appeared in the last few years, and one must therefore ask whether the publication of one more book is an important event. The answer is undoubtedly yes! This book, which raises high ex-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3616-1769 $ 17.50+.50/0

pectations in view of the reputation of the Academic Press series *Best Synthetic Methods*, treats the chemistry of hypervalent iodine compounds from the standpoint of the reagents. In a masterly fashion the author presents this class of iodine compounds, often seen as a difficult and confusing subject, in a way that can be readily understood by nonspecialists. The emphasis is on the synthetic potential of hypervalent iodine compounds, with relatively little attention to the reaction mechanisms and the analytical aspects.

After a brief and succinct introduction in Chapter 1, the second chapter describes the most commonly used hypervalent iodine reagents, such as diacyloxyiodobenzene, iodosobenzene, and the iodine(V) compounds, including methods for preparing them (with detailed laboratory recipes) and some general information about their reactive properties and handling characteristics. Chapters 3–7 then describe in detail the reactions of each of the hypervalent reagents introduced in Chapter 2, subdivided according to substrates and reaction types. These cover, for example, reactions with alkenes, carbonyl compounds, and alcohols, as well as chlorination reactions and acetoxylation reactions. The most important applications are accompanied by laboratory recipes.

Chapters 8–10 cover iodine(III) compounds which formally contain two iodine–carbon bonds, with their reactions subdivided in the same way as above. The reagents described include, for example, diaryliodonium salts and phenyliodonium zwitterions. It is also pointed out here that iodine(III) intermediates can serve as substrates for C–C bond-forming reactions catalyzed by transition metals.

Chapter 11 is devoted to a brief description of the chemistry of iodine(V) compounds, with special attention to the important Dess–Martin reagent and related compounds. Finally, in Chapter 12 the author collects together an assortment of widely different reagents which he believes have the potential for being promoted to the first league of the iodine(III) compounds. Some of these, such as *o*-iodosylbenzoic acid and its derivatives, and the oxygen-bridged iodine(III) reagents, are already close to fulfilling that prediction.

The special qualities of this monograph arise from the wealth of practical advice and critical comparisons of the various hypervalent iodine reagents, with regard to their reactivities, convenience of handling, solubilities, stabilities, storage characteristics, etc. Almost every chapter contains tips and trends of a kind that are rarely found in the original publications, based on the author's detailed knowledge and years of practical experience in this field.

For the synthetic chemist, reagents emerge from the twilight into day-to-day use only when they show good chemoselectivity and have proved their capabilities in reactions involving complex multifunctional natural products or intermediates. Although the author describes some good examples of oxidation reactions for steroids, it would have been useful to devote more space to this and related aspects. Finally, one brief suggestion: The many useful laboratory recipes included in the book could have been improved still further by highlighting them with a distinctive typeface.

To summarize, the book can be thoroughly recommended as an introduction to hypervalent iodine reagents, with a strong emphasis on applications. It should be available in every chemistry department library and in laboratories engaged in synthesis.

Clausthal (Germany)

Macrocycle Synthesis. A Practical Approach. (Series: Practical Approach in Chemistry.) Edited by *D. Parker*. Oxford University Press, Oxford, 1996. 252 pp., paperback £ 29.95/hardcover £ 50.00.—ISBN 0-19-855840-6/0-19-855841-4

The idea of collecting together in a single book laboratory recipes for preparing the most important macrocycles is a good one. Supramolecular chemistry is a very active area of research which generates many short communications with a claim to be highlighted, and there is usually insufficient space to include experimental details. This book consists of nine chapters containing laboratory recipes that are designed to enable even chemists with limited preparative experience to synthesize the most important macrocycles. Most of the compounds described are important key products with a variety of uses. In supramolecular chemistry especially, success often depends on combining synthetic building blocks from different areas of investigation, and therefore this book will certainly also be very useful for chemists already engaged in research on host/guest chemistry. For these readers the fact that the editor has necessarily restricted the subject matter to a limited selection of macrocycles will be no disadvantage.

The first four chapters are concerned with the synthesis of both "classical" crown ethers and hetero-crown compounds. By introducing the most important cyclization methods they prepare the reader for the three chapters on cryptands, torands, and calixarenes that follow. Next Chapter 8 deals with spherands, hemispherands, and calixospherands, thus showing how one can link together various macrocyclic building blocks. The last chapter leads to supramolecular structures by describing syntheses of catenanes and rotaxanes which use transition-element templates.

Each chapter begins with a brief introduction. This is followed by a detailed experimental part consisting of a number of procedures varying from 6 to 19. Finally there is a short bibliography, which makes no claim to be exhaustive. Each laboratory recipe is preceded by short introductory survey or linking paragraph. The sequence of the various procedures corresponds to that of the reaction stages, thus offering a direct invitation to carry out the synthesis. All the procedures originate from well-respected groups engaged in research in the areas concerned, a fact that gives the compilation an additional appeal. Furthermore, if one is using the ring-binder version, the pages—like those of a good cook-book—stay conveniently open on the laboratory bench!

Detailed safety notes and a list of the required apparatus and materials are given at the beginning of every experimental procedure. The reactions involved are set out in clear formula schemes. The operations are described in a step-by-step manner, a style which perhaps not everyone will find ideal. Many helpful details and hints are included, but unfortunately the form of presentation leads to much unnecessary repetition. For example, a note in the first paragraph about the need to dry glassware in an electric oven appears in 39 of the 99 procedures described, varying only in the recommended temperature (from 105 to 150 °C) and time (from 30 minutes to "overnight"). Some of the paragraphs included in the experimental procedures seem unduly meticulous or unnecessary, even when one considers the fact that the book is intended for students. Thus, on page 191 it is mentioned twice (in paragraphs 14 and 18) that before the solution is concentrated in the rotary evaporator it must be transferred to a single-neck round-bottom flask. It is not until paragraph 19 that the reader, by being left to choose suitable glassware, is credited with having received a reasonably good

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3616-1770 $ 17.50+.50/0

general chemical training. Again, we find that although a "rotary evaporator with vacuum pump" (p. 97, paragraph 6) is used in nearly every case, it appears repeatedly in the list of apparatus for several of the procedures. It would have been better to include a short chapter collecting together general information about laboratory practice, which could have been placed immediately before the list of suppliers at the end of the book. The space thereby released would perhaps make it possible to list the most important spectroscopic data for the compounds described, or at least to give the relevant literature references, as is provided, for example, in *Organic Syntheses*.

However, despite these minor shortcomings, this is a very useful compilation of important synthetic methods for macrocycles, which is clearly set out and convenient to use. The detailed laboratory recipes will be helpful for organic chemists and for those working in the area of coordination chemistry, and they will undoubtedly give inspiration for the synthesis of new and interesting compounds.

Stable Carbocation Chemistry. Edited by *G. K. S. Prakash* and *P. von R. Schleyer*. Wiley, New York, 1997. 587 pp., hardcover £ 65.00.—ISBN 0-471-59462-8

Carbocations persist under conditions where the absence of nucleophiles ensures that no intermolecular reactions can occur, and the energy minimum is deep enough to prevent isomerizations. This book on such "stable" cations is based on a symposium held to mark the 65th birthday of G. A. Olah, and contains 17 articles by leading researchers in the field.

In Chapter 1 George Olah describes his pioneering work on carbocations, the importance of which was recognized by the award of a Nobel Prize in 1994. Some more recent results from Olah's laboratory, including the latest work, are reported in Chapter 4 by G. K. Surya Prakash. These include studies of carbocations with silyl groups or very bulky substituents, and of cations and dications derived from pagodane. Olah's recipe for success can be summarized very briefly as "superacids and NMR". The superacids concerned have remained virtually unchanged since the beginning (usually SbF_5 and/or FSO_3H, sometimes diluted with SO_2ClF), whereas the range of NMR instruments and techniques has greatly expanded. The isotopic-perturbation method enables one to distinguish between static and equilibrating carbocations (M. Saunders et al., Ch. 9). Similar information is obtainable by CPMAS solid-state NMR spectroscopy in amorphous SbF_5, which allows measurements down to temperatures as low as 5 K (P. C. Myrhe and C. S. Yannoni, Ch. 10). Measurements of intrinsic isotope shifts can be used for structural and conformational analysis (D. Forsyth, Ch. 9). Theoretical calculations of NMR chemical shifts (using IGLO and GIAO methods) can be used to verify proposed structural models. Theoretically calculated vibration frequencies were found to be essential for interpreting infrared spectra of carbocations in SbF_5 matrices (D. E. Sunko, Ch. 11). Such calculations have been made possible through the development of better and faster quantum-chemical methods, which yield exact structures even for quite large carbocations (P. von R. Schleyer et al., Ch. 2). The only experimental method that can give information of comparable quality is X-ray crystallography (T. Laube, Ch. 14), but unfortunately its scope is limited by the extreme difficulty of growing single crystals of carbocation salts. Calorimetric and electrochemical measurements have yielded important thermodynamic data for carbocations (E. M. Arnett and R. A. Flowers, Ch. 8). An interesting approach is the use of X-ray photoelectron spectroscopy to study carbocations at interfaces, but the account of this work is somewhat disappointing as it gives little definite information (D. T. Clark, Ch. 13).

In addition to these chapters that concentrate on methods, there are others that deal with special types of carbocations. Chapter 3 (T. S. Sorensen) is devoted to carbocations with μ-hydride bridges, Chapter 5 (H.-U. Siehl) to vinyl cations, and Chapter 6 (P. Ahlberg) to 9-barbaralyl cations ($C_9H_9^+$) and isomers thereof. Some important reactions of stable cations are also treated. These include rearrangements, especially of arenonium ions (V. G. Shubin and G. I. Borodkin, Ch. 7), alkane carbonylation reactions (J. Sommer, Ch. 15), and electrophilic substitutions of arenes (K. Shudo and T. Ohwada, Ch. 16). A topic that deserves particular attention is the enormous variety of highly selective reactions that can be performed on natural products (especially terpenes and steroids) in superacids (J.-C. Jacquesy, Ch. 17). Most of the reactions described in Chapters 15–17 do not directly involve the carbocations as such but their protonated forms or Lewis acid adducts ("superelectrophiles"). Thus even the chemistry in superacids involves reactive intermediates that can only be detected indirectly; here dications have a role similar to that of simple carbocations in nucleophilic media.

The editors have managed to avoid significant overlapping of subject matter between the contributions, and the work of the authors (and of the publishers) is of a high quality. The presentation is excellent, and there are very few misleading errors. (Examples: **26b**/p. 148, **9**/p. 167, **15**/p. 204, **2**/p. 550; in Fig. 11.7 the experimental data are missing, and in Fig. 15.5 the numbering of the curves should be interchanged.) The book gives the reader "at first hand" a comprehensive and up-to-date survey of this fascinating and highly productive area of physical-organic chemistry; the literature coverage extends up to 1995 in most cases. The ideas and methods described here also have the potential to contribute to advances in other fields. The book should be of interest to a wide readership.

Superconductivity and Chemistry

Arndt Simon*

Dedicated to Hans Georg von Schnering

The microscopic theory of superconductivity worked out by Bardeen, Cooper, and Schrieffer led to a fundamental understanding of the phenomenon. However, this theory does not provide a materials aspect. Starting from the special situation of chemical bonding in carbides and carbide halides of the rare earth metals a general view of the origin of superconductivity is developed, based on a tendency for (pairwise) localization of conduction electrons. This approach is tested in terms of special features in the electronic band structure and compared with existing physical models of electron pairing in real space. Its applicability to high-temperature superconductors discovered during the last decade is discussed.

Keywords: band structure · carbides · cuprates · lanthanoids · superconductivity

1. Introduction

In 1911, three years after successfully liquifying the last remaining "permanent" gas, helium, and thus opening a new dimension of low-temperature research, Kamerlingh-Onnes in Leiden discovered the phenomenon of superconductivity.[1] He found that the electrical conductivity of mercury below 4.2 K decreased to an unmeasurably low value within an interval of a few hundreds of a degree Kelvin. The resistance actually disappears completely. Experiments show that the induced current in a superconducting ring will still be flowing after 10^5 years.[2] One such ring can be thought of as a macroscopic analogy to the Bohr model of the atom, as the charge carriers that provide superconductivity all occupy a single quantum state and are free to move without energy loss.

A superconductor is characterized by a further property that differentiates it from a metal with zero direct current resistance: the exclusion of magnetic fields from the interior. If a superconductor is cooled in a magnetic field below its critical temperature, T_c, it will become an ideal diamagnet (Meissner–Ochsenfeld effect). Under suitable conditions a superconductor levitates above a magnet and vice versa. Only if the magnetic field exceeds the value of a critical field strength will it penetrate the superconductor, thus forcing the transition to the normal conducting state. Both the measurement of the electrical conductivity and the behavior in a magnetic field are necessary for the basic characterization of a superconductor.

[*] Prof. Dr. A. Simon
Max-Planck-Institut für Festkörperforschung
Heisenbergstrasse 1, D-70569 Stuttgart (Germany)
Fax: Int. code +(711)689-1642

For decades superconductivity occurred only at such low temperatures that cooling with liquid helium was necessary. Not until the production of metastable superconducting Nb_3Ge films (critical temperatures of 22.3 K[3] or 23.2 K[4]) more than sixty years after the discovery of the phenomenon did it become possible to enter the region of liquid hydrogen cooling. The work of Bednorz and Müller[5] in 1986 on the basis of oxocuprates started the discovery of a rapidly increasing number of superconductors, whose critical temperatures lie above the boiling point of liquid nitrogen. The current record is held by $HgBa_2Ca_2Cu_3O_{8-\delta}$, which has a critical temperature T_c of 164 K under pressure.[6]

How does current microscopic theory provide an understanding of the phenomenon of superconductivity?

2. Theory of Superconductivity

In normal metals and also superconductors in the normal conducting state above T_c the charge carriers are single electrons. These repel each other because of the Coulomb interaction between their charges. Due to structural defects as well as an exchange interaction between the electrons and lattice vibrations (electron–phonon scattering) a metal exhibits electrical resistance, which increases with temperature. It has been demonstrated simultaneously experimentally[7, 8] and theoretically[9, 10] that lattice vibrations are also important for superconductivity. The experimental proof was obtained from the variation of the critical temperature of Hg by isotope substitution.

Electron–phonon interaction under certain circumstances can cause the pairwise coupling of conduction electrons—that

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3617-1789 $ 17.50+.50/0

is, it sets up another type of charge carrier. While conduction electrons in the normal state obey Fermi statistics, and all take different quantum states, electron pairs with a total spin $S = 0$ are bosons, and must obey Bose–Einstein statistics. Therefore, they can all occupy a single quantum state. Interestingly, it was the chemist Ogg who first had the idea (prompted by the work of London[11] who interpreted the superfluidity of helium through Bose–Einstein condensation) that electron pairs are the charge carriers in superconductivity.[12, 13]

The pairing of electrons in real space is sometimes visualized in greatly simplified models[18] such as the mechanical analogy of two metal balls that roll towards one another when placed upon an elastic membrane, or, more realistically, as the dynamic polarization of the lattice by a moving electron that catches the movement of a second electron in the polarization track of the first. But even the second comparison cannot begin to describe the necessary prerequisites for superconductivity in terms of specific chemical bonding.

The microscopic theory of superconductivity[19] developed by Bardeen, Cooper, and Schrieffer (BCS theory) does not establish a relationship with real chemical systems either. The essence of this theory is shown graphically in Figure 1. An electron characterized by its wave vector $\boldsymbol{k}_1$ interacts with the lattice of positively charged ions and is scattered (new wave vector $\boldsymbol{k}_1'$), thus changing the vibrational state of the lattice. A second electron ($\boldsymbol{k}_2$) produces the initial vibration state again, and through the exchange of a virtual phonon the electrons $\boldsymbol{k}_1'$ and $\boldsymbol{k}_2'$ are coupled. The state of lowest energy corresponds to a collective state of electron pairs (Cooper pairs) formed from electrons having opposite spins and directions of their wave vectors: $+\boldsymbol{k}\uparrow\ -\boldsymbol{k}\downarrow$.

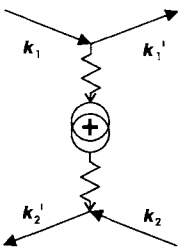

Figure 1. Schematic representation of the electron-electron interaction by the exchange of a virtual phonon. The electrons are represented by their wave vectors $\boldsymbol{k}_i$. The exchange interaction via the lattice of positively charged atomic cores is through the emission and absorption of a phonon (see text).

In the superconducting state an energy gap opens between the BCS ground state, which is derived from the paired electrons, and the excited state of the quasi free electrons ("quasiparticles"). The energy gap corresponds to a pair-breaking energy, which in BCS theory at 0 K has a magnitude of $2\Delta(0) = 3.52 k_B T_c$, where k_B is the Boltzmann constant. For the superconducting critical temperature, the following relationship is derived from BCS theory:

$$T_c = 1.14 \frac{\hbar\omega_D}{k_B} e^{-1/N(E_F)V}$$

where $\hbar = h/2\pi$, where h is Planck's constant, ω_D the Debye frequency, $N(E_F)$ the density of states at the Fermi level E_F (that is, the highest energy level of the electrons in the normal state (at 0 K)), and V the electron–phonon interaction parameter.

The results reflect the extremely simplified model that lies at the heart of BCS theory. The electronic behavior is described as isotropic, that is, the energy gap $2\Delta(0)$ is constant in all directions. Shortly after the appearance of the BCS work, it was demonstrated that many superconductors have several energy gaps, or, put in another way, are highly anisotropic. There are probably interesting consequences of this fact (see Section 7). The assumption of a Debye-type phonon spectrum as well as the restriction to weak electron–phonon coupling are also simplifications in the model that lead to many deviations between experiment and theory even with classical superconductors. Later, important extensions to the theory were made, especially those by Eliashberg[21] and McMillan,[22] which gave a better correspondence between experiment and prediction. Until now, however, BCS theory has lost nothing of its fundamental importance, as becomes clear from the fact that a new superconductor will be termed BCS-like or not. When the deviations from BCS-type behavior are large, as is the case with high-temperature superconductors, new "exotic" mechanisms are looked for. But even for this class of materials the participation of lattice vibrations on the pair exchange interaction has meanwhile been clearly shown by experiment.[23, 24]

The question arises whether the general statements of BCS theory can be associated with specific bonding situations, and whether an understanding of the physical phenomenon of superconductivity can be developed from the viewpoint of chemistry. This will be attempted in this review.

So far the electron has been described as a plane wave characterized by the wave vector $\boldsymbol{k}$, perpendicular to the wave front, as $|\boldsymbol{k}| = 2\pi/\lambda$. The electron is also a particle with momentum $\boldsymbol{p}$ and according to de Broglie $\boldsymbol{p} = \hbar\boldsymbol{k}$.

Arndt Simon was born in Dresden 1940, started his studies in chemistry at Münster University in 1960 and finished his thesis with Harald Schäfer in 1966. Since 1974 he has been director at the "Max-Planck-Institut für Festkörperforschung" in Stuttgart and, since 1975, honorary professor at the local university. His scientific interests include the investigation of metal-rich compounds (e.g. alkali metal suboxides; subnitrides of the alkaline earth metals; halides of rare earth metals with inclusions of H, B, C, N; metal clusters; concept of cluster condensation), intermetallic phases (Pauling–Simon rule), structure property relations (photoemission, magnetism, superconductivity), and structures and phase transitions of molecular crystals. These activities include apparatus development (Guinier–Simon camera). He is member of numerous academies and has received several awards (e.g., the Klemm prize 1985, Bayer prize 1987, and Leibniz prize 1990).

The Cooper pair, which corresponds to two electrons with opposite spins and momenta (that is, total momentum zero) resembles something that is known to the chemist: An electron pair, commonly symbolized by a line between two atoms in a chemical bond, depicts an "approximation" of the Cooper pair. However, there are two principle problems with such a comparison. Firstly, the Cooper pair, as part of a highly correlated state, is free to move through the lattice, in contrast to a localized electron pair. Secondly, in BCS theory the pairing of electrons occurs in momentum space,[25] a space defined reciprocally to real space ($|\boldsymbol{p}| \propto 1/\lambda$), and the Cooper pair cannot be described locally. The coherence length can be several thousand Angstroms.

Regardless of the problems just outlined, many theoretical models are derived from the assumption of real space pairing in superconductors. Schafroth,[26] in particular, followed this course in the time before Bardeen, Cooper, and Schrieffer offered their comprehensive theory. With the discovery of high-temperature superconductors, whose coherence lengths correspond to a few atomic radii, local approaches have again become more relevant.[27–29] Later a few of these ideas will be examined.

The normal state of a metal becomes unstable when an attractive exchange interaction occurs between the conduction electrons.[30, 31] Understanding the origins of the attraction in terms of chemical bonding therefore opens the door to learning about the chemical prerequisites for superconductivity. In the following chapters the C–C bond that is so familiar to every chemist will be chosen to demonstrate that an attractive exchange interaction can originate from a tendency for pairwise localization of conduction electrons ("virtual localization").

3. C_2 Units as Traps for Electron Pairs

The carbide halides of rare earth metals with the general formula $(RE)_2X_2C_2$, discovered by us some years ago,[32, 33] form layered crystals with double layers of close-packed metal atoms sandwiched between layers of halogen atoms. C_2 units are found inside the octahedral voids between metal atoms. Figure 2 shows the stacking of these layer packages, which are bonded through van der Waals forces between the halogen atoms. Two variants of the stacking sequence are known, which are identified as 1s or 3s depending upon the number of layers needed until the identity is reached.

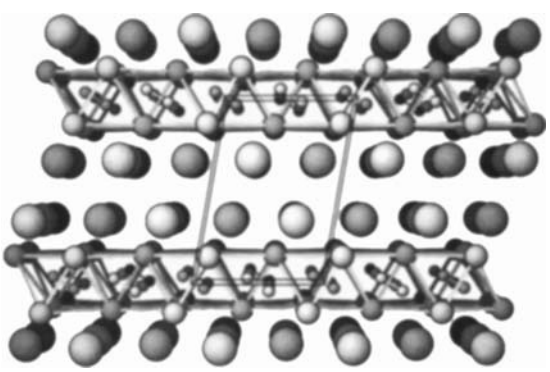

Figure 2. Projection of the monoclinic unit cell of the (1s)-layered structure of $(RE)_2X_2C_2$ in the direction of the *b* axis (*a* horizontal). The atoms, X, RE, and C are shown with decreasing size.

C_2 units have been known for a long time to occur in ionic structures. Calcium carbide is the best known example.[34] The short C–C distance of 120 pm in calcium carbide identifies the compound structurally as a derivative of ethyne in agreement with its chemical behavior. The separation distance of 128 pm[36] found in the carbide halide $Y_2Br_2C_2$ corresponds rather to that of an ethenide.[37] This classification is in accord with the ionic formulation in the Zintl-Klemm concept: $CaC_2 = Ca^{2+}(C_2)^{2-}$ and $Y_2Br_2C_2 = (Y^{3+})_2(Br^-)_2(C_2)^{4-}$. The MO examination for the C_2 units (Figure 3) shows the occupation of all the bonding MOs corresponding to a triple bond for CaC_2 and the occupation of the first antibonding MO for $Y_2Br_2C_2$. In this last case the degeneracy of the π^* levels is lost due to the monoclinic crystal symmetry and the broad spectrum of Y–Y distances (340 to 395 pm)[36] in the Y_6 octahedron that surrounds the C_2 unit.

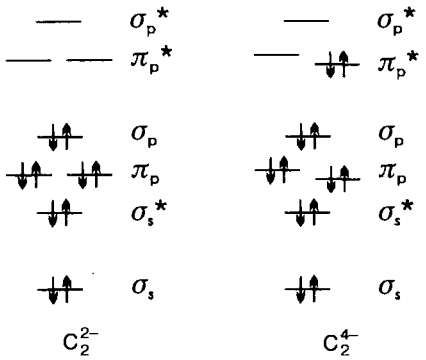

Figure 3. Schematic MO diagram of the $(C_2)^{2-}$ and $(C_2)^{4-}$ ions as found in CaC_2 and (to a first approximation) in $(RE)_2X_2C_2$, respectively. The degeneracy of the π^* levels is removed through the monoclinic crystal symmetry.

CaC_2 is an ionic crystal and insulator. The same properties could be expected for $Y_2Br_2C_2$. The compound is, however, metallic in two dimensions. As is suggested by the shortened C–C double-bond distance, backbonding from the occupied π^* MO into the empty d states of the metal atoms occurs, which in the case of the extended solid can be discerned directly from the electronic delocalization. This assumption is verified through the band structure calculations for the magnetic compound $Gd_2Cl_2C_2$.[39] The nonmagnetic compound, $Y_2Br_2C_2$, is not only metallic with a resistance in the mΩ range, but becomes superconducting at 5 K.[36, 40, 41] Superconductivity occurs similarly for the corresponding compounds, $Y_2X_2C_2$ (X = Cl, Br, I) and $La_2X_2C_2$ (X = Cl, Br).[36, 42, 43] Figure 4 shows the characteristic changes in the electric and magnetic behavior of $Y_2I_2C_2$ that occur with the transition to the superconducting state at $T_c \approx 10$ K.

The simplified discussion within the Zintl–Klemm concept portrays $Y_2Br_2C_2$ as a simple valence compound, which is only coincidentally metallic due to the covalence in the Y–C bond. The closeness to electronic localization is evident. The quasi-molecular C_2-π^* states lie near to the Fermi level, E_F. In the following, these states will be addressed as π^* states for sake of simplicity in spite of considerable π–d mixing. From our hypothesis,[41] a tendency towards a pairwise occupation of these states is the reason for attractive interactions between the conduction electrons. The phases $(RE)_2X_2C_2$ allow this assumption to be tested in a variety of ways, both experimentally and theoretically.

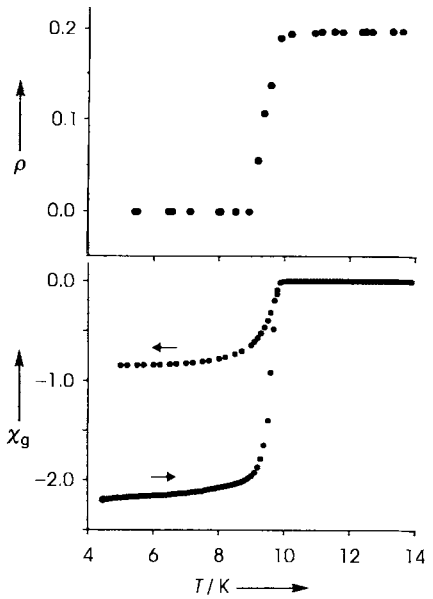

Figure 4. Transition to superconductivity in a $Y_2I_2C_2$ crystal. Top: The disappearance of the electrical resistance ρ (mΩcm); bottom: magnetization results (measured at 10 G; field cooled curve (←) shows Meissner effect; zero field cooled curve (→) displays shielding)[40]. Mass susceptibility χ_g in 10^{-2} emu g^{-1}.)

3.1. Covalence and Electron Count

From the above considerations, the mixture of C_2-π^* and metal d states is seen to be responsible for the electronic delocalization (consequence: metallic conductivity), and the presence of the C_2-π^* "MOs" at E_F is seen as the cause of the tendency for a (pairwise) localization (consequence: superconductivity). Examination of the structure in Figure 2 shows that the balance between the two effects can be easily varied by chemical means. One way is by changing the size and shape of the void for the C_2 units by exchanging halogen atoms, and thus changing the metal carbon covalence. Another way is to increase the energy of the Fermi level through the intercalation of alkali metals into the van der Waals region between the layers. In this way a direct influence on the energy of the π^* level relative to E_F is possible.

3.1.1. Halogen Exchange

Figure 5 shows the results of halogen atom substitutions for the system $Y_2(XX')_2C_2$. The substitution of Cl by I leads to approximately five percent stretching of all distances parallel to the layers, and in mixed crystals a Vegard-type behavior is found. The ratio X:X′ enables a mean halogen radius $\bar{r}_x$ to be calculated, which relates to a systematic variation in transition temperature.[36] This is equally valid if $\bar{r}_x$ is adjusted through a Cl/Br, Cl/I, or Br/I mixture. The transition temperature is $T_c = 2.30$ K for $Y_2Cl_2C_2$, and it increases monotonically through $T_c = 5.05$ K for $Y_2Br_2C_2$, to a maximum of $T_c = 11.6$ K for $Y_2I_{1.6}Br_{0.4}C_2$, decreasing again to $T_c \approx 9.7$ K for the pure iodide phase.[46] The transition temperature for the pure bromide is very sharp and reproducible, whereas T_c varies for different iodide samples, probably due to small carbon deficiencies resulting in the replacement of C_2 units with single C atoms.[43]

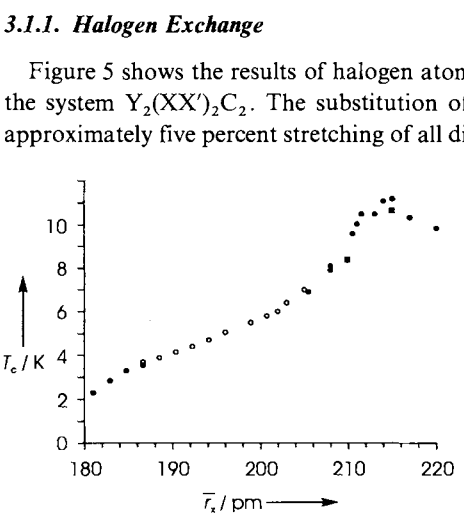

Figure 5. Critical temperature T_c for mixed crystals $Y_2Cl_{2-x}Br_xC_2$ and $Y_2Br_{2-x}I_xC_2$ (circles) as well as $Y_2Cl_{2-x}I_xC_2$ (squares), plotted against the mean halide ion radius, $\bar{r}_x$. Open and filled symbols represent 1s and 3s stacking, respectively[40].

It is interesting to note that the monotonic increase in T_c towards larger $\bar{r}_x$ values does not reflect the structural change from 1s to 3s stacking at $\bar{r}_x \approx 187$ pm, and a return to the 1s structure at $\bar{r}_x \approx 205$ pm. The difference in the layer stacking has no effect on the superconducting transition. This is a clear indication that the origin of superconductivity is to be found within the individual layers.

As shown by the change in T_c with $\bar{r}_x$ in Figure 5, the metrics in the $Y_2(X,X')_2C_2$ system can be optimized with respect to superconductivity. The maximum in T_c possibly has an interesting interpretation[46] that, however, needs substantiating. According to this interpretation the π^* level due to the bonding Y–C interaction will lie increasingly lower in energy as the Y–C separation decreases, and with the X/X′ variation the level is shifted continuously relative to E_F. Possibly the electron density of states at E_F is scanned by variation of T_c (see Section 3.4).

3.1.2. Intercalation of Alkali Metal Atoms

The consequences of the intercalation of sodium between the halogen atom layers of $Y_2Br_2C_2$ seem more clearly apparent.[47] What at first looks to be a simple increase of the Fermi level through the addition of injected electrons in the layers is nonetheless a rather complicated change. First, the intercalation reaction changes the structure from 3s to 1s stacking. This should, according to Figure 5, have no effect on the magnitude of T_c. Moreover, the intercalation leads to slight changes in the band structure, and not only the energy of the Fermi level but also that of the π^* level varies. The transition temperature increases nearly linearly with sodium content in $Na_xY_2Br_2C_2$, starting from $T_c = 5.05$ K for $x = 0$, to $T_c = 6.20$ K, the highest achievable value, for $x = 0.46$.[47] The optimal electron count per C_2 unit with regard to superconductivity lies above four electrons to be transferred from the surrounding framework. This result is interesting when compared with the optimal condition found in the carbides of the rare earth metals.

3.2. A Small Step

The explanation of the metallic properties of $Y_2Br_2C_2$ and the hypothesis concerning the origin of superconductivity for this compound is easy to test chemically on the basis of the comparison in Figure 3. If one succeeds in partially occupying C_2-π^* MOs in CaC_2, the result should be a metal, which becomes superconducting at low temperatures. The occupation is easily possible through the simple replacement of Ca^{2+} with Y^{3+}. And indeed, the golden colored, isotypic YC_2 is metallic and

becomes superconducting at approximately 4 K. This result is not new, however. The superconductivity of YC_2 was discovered in the course of extended studies on superconductivity in rare earth metal carbides.[48] In the 1970s a wealth of results was produced from compounds of the general composition $((RE)_{1-x}M_x)C_y$,[49, 50] which now can be analyzed in the light of the ideas presented here. In order to do so the given formulae have to be rewritten as $((RE)_{1-x}M_x)_{2/y}C_y$, and the number of electrons $\sum n_i$ that participate in a complete charge transfer from the metal atom framework to the C_2 unit is calculated. This number n_i is 3 for RE, 2 for Ca, 4 for Th etc. Without knowledge of the structure one already discovers important clues from the electron count. In the case of $\sum n_i \geq 8$ superconductivity will not be observed with any rare earth metal carbide. In this case the number of electrons transferred to two C atoms is sufficiently large to occupy all the antibonding MOs of a C_2 unit, and therefore only single C atoms (C^{4-}) are allowed in the structure.

In the carbides of the rare earth metals superconductivity is obviously connected to the presence of C_2 units[51] and appears only with correspondingly low electron concentrations. Plotting T_cs vs. $\sum n_i$ values for a large number of analytically well-characterized phases results in the characteristic relationships seen in Figure 6.[52] At values around $\sum n_i/C_2 \approx 4$ high critical tempera-

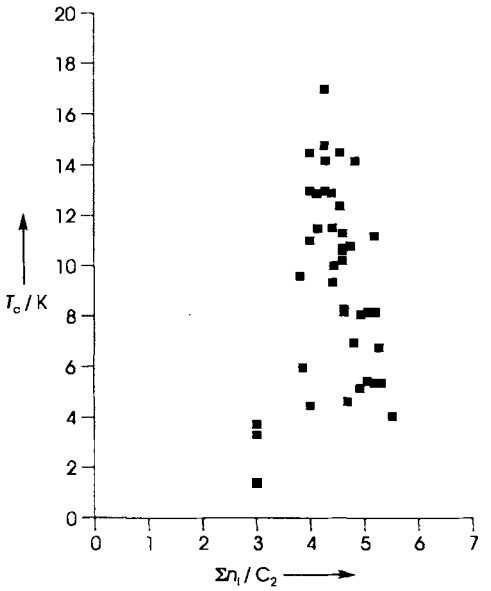

Figure 6. Critical temperature T_c for carbides of the general formula $((RE)_{1-x}M_x)_{2/y}C_2$. The abscissa represents the number of valence electrons $\sum n_i$ that are accessible to be transferred from the framework of the metal atoms to two C atoms[52].

tures appear frequently. The corresponding phases all belong to the composition $(RE)_2C_3 \equiv (RE)_4(C_2)_3$, and they crystallize in the Pu_2C_3 structure type. The maximum T_c (17.0 K) is found for the sample $Y_{0.7}Th_{0.3}C_{1.55}$, that is, with $\sum n_i/C_2 = 4.26$.[53] The characteristic electron count found for the superconductivity in the structurally completely different compound classes $(RE)_2X_2C_2$ and $(RE)_yC_2$ ($y = 1.00$ and 1.25) gives evidence for a dominant role of the C_2-π^* states in the formation of Cooper pairs in these phases.

The relationship shown in Figure 6 is reminiscent of the well-known Matthias rule,[54] although this follows a different, less chemically based electron counting procedure. The rule states that the arithmetic mean of the number of valence electrons in a superconductor is of crucial importance to the value of T_c. For mixed crystals of the transition metals, the maximum in T_c is seen to occur at approximately 4.7 and 6.5 valence electrons per atom.

The T_c dependence on the mean number of valence electrons of the A15 phases is particularly impressive. The earlier mentioned superconductor Nb_3Ge belongs to them. For this compound the valence electron concentration (VEC) is calculated as follows: VEC = $(3 \times 5 + 4)/4 = 4.75$. Through (partial) substitution of the transition metal, or alternatively, the p element, by elements with other valence electron numbers, numerous phases that show superconductivity at varying T_c values can be obtained. Figure 7 indicates that superconductors with high T_c

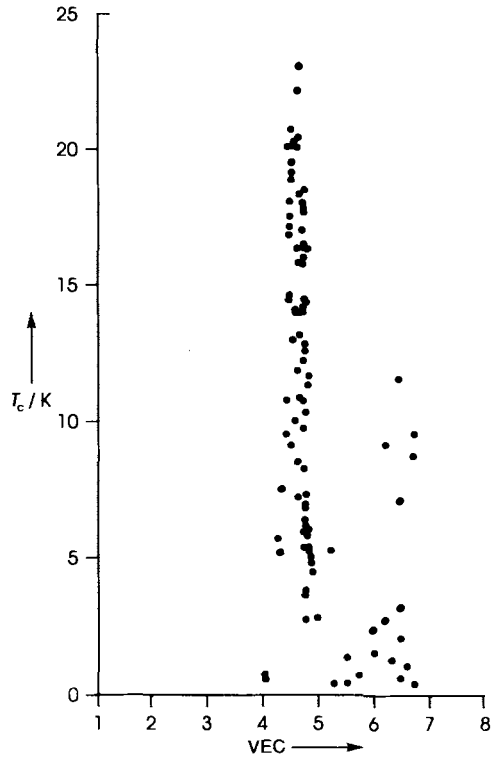

Figure 7. Critical temperature T_c as a function of the valence electron concentration (VEC) for M_3Z compounds of the A15 type (Matthias rule)[54].

values occur for VECs between 4 and 5, or alternatively, between 6 and 7. Again, the values of the valence electron concentration between the two maxima differ by about 2. A15 superconductors with high T_c values collect in rather narrow VEC ranges. The wider spread of high T_c values in Figure 6 is not that surprising when the different structural types are taken into account. One question remains open: is the shown accumulation of high T_c values for the carbides of the rare earth elements followed by a second area after a distance of two electrons/C_2 group, corresponding to the occupation of the next C_2-π^* MO in ethanides?

3.3. Similarities and Differences

The structure of α-YC_2, isotypic with CaC_2, is derived from the sodium chloride structural type by replacing the single atom anions by parallel C_2 units with $d(C-C) = 127$ pm. If layers are cut out of this structure, as is shown in Figure 8, and the broken

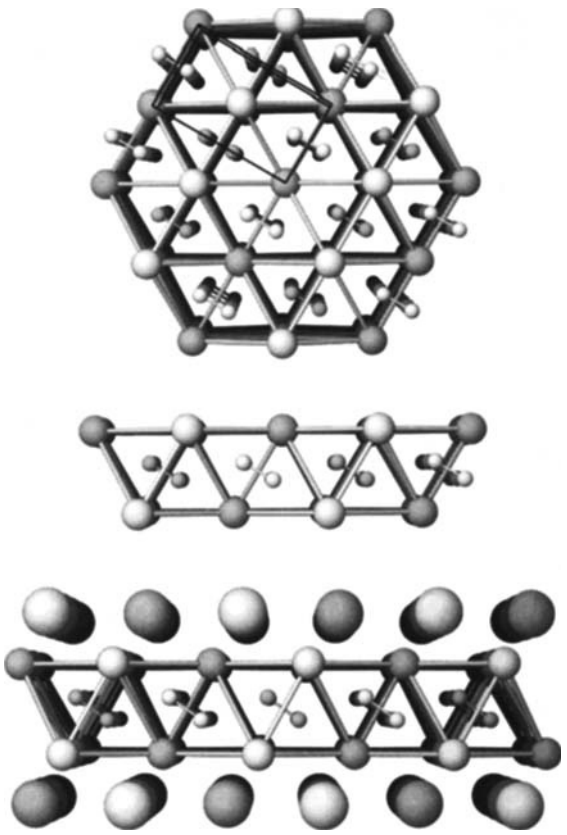

Figure 8. Topological relationship between the YC_2 and $Y_2X_2C_2$ structures. Projection of the tetragonal YC_2 structure along the a axis (top); two-dimensional layer cut from the YC_2 structure (center), which, when separated by halogen atoms, X, gives the $Y_2X_2C_2$ structure (bottom). (X, Y, C are depicted in decreasing size).

bonds replaced through Y–Br bonds, then the result is the characteristic layered structure of $Y_2Br_2C_2$.

There are close similarities between the two systems, both topologically and with regard to the assumed importance of the C_2-π^* MOs for superconductivity, but there are also large differences. Firstly, different numbers of electrons are available to be transferred from the framework to the C_2 unit, a maximum of three in the case of YC_2 and four in $Y_2Br_2C_2$. Secondly, the expected Y–Y separation is shorter in $Y_2Br_2C_2$ than in YC_2 (383 pm relative to 391 pm in α-YC_2) and, as a consequence, the practically identical C–C distance yields a shortened Y–C separation in $Y_2Br_2C_2$ (256 pm against 262 pm). An essential difference between the two compounds lies in the three-dimensional electron delocalization in YC_2, and the two-dimensional metallic character of $Y_2Br_2C_2$.

Our current knowledge of the physical properties of the two compounds will be summarized in the following. The thermodynamic properties in the superconducting state, as taken from magnetic measurements (Section 3.3.1) and heat capacity measurements (Section 3.3.2) show major differences between the two compounds. The question arises whether these differences and also the different isotope effects (Section 3.3.3) are due to the difference in dimensionality.

3.3.1. Magnetization

As mentioned earlier, superconductivity can be suppressed through a sufficiently high magnetic field. There are two types of behavior. Soft superconductors (type I) are ideal diamagnets. The magnetic field remains fully excluded from an infinitely long cylinder until a critical value H_c is reached. At H_c the magnetic field penetrates the superconductor completely, returning it to the normal conducting state. In the case of hard superconductors (type II) an increasing amount of magnetic flux penetrates the superconductor above a critical field H_{c1} and a mixed state (Shubnikov phase) develops. At H_{c2} the superconductivity within the sample is lost. The remaining superconductivity in a surface layer disappears at H_{c3}. Soft superconductivity appears for very pure elements; they display full reversibility of the magnetization. The technically important superconductors such as Nb_3Sn belong to type II.

The magnetic isotherms for YC_2[56] and $Y_2Br_2C_2$[57] measured in the superconducting state are contrasted in Figure 9. The negative magnetic polarization $-J$ decreases with increasing temperature and disappears at T_c. The curves follow very different courses for each compound. At first glance YC_2 appears to be a type I superconductor (Figure 9, top). The irreversibility of the magnetization curve after divergence from the initial line, however, is an indication of type II behavior with small and close H_{c1} and H_{c2} values.[58] The measurements on $_2Br_2C_2$ (Figure 9, bottom) show unambiguously type II behavior, with an upper critical field strength lying far above the shown measurement range. The value for H_{c2} is fifty times larger than that for YC_2.[58]

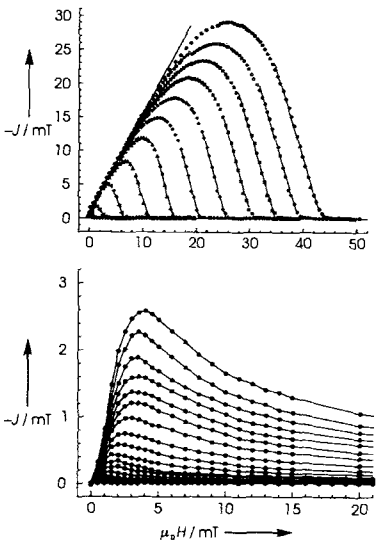

Figure 9. Isotherms of magnetization, measured on a spherical polycrystalline YC_2 sample (top, temperature from 2 K (maximum magnetization) to 4 K in steps of 0.2 K) and a compressed powder pellet of $Y_2Br_2C_2$ (bottom, $2\,K < T < 5\,K$)[56, 57].

Distinctive type II behavior is characteristic for layered superconductors and is related to the strong pinning of the magnetic flux lines between the layers.[59] By tilting a $Y_2I_2C_2$ single crystal in a magnetic field one finds the typical cusplike dependence of T_c as a function of the tilt angle, as is well known from measurements on other layered superconductors like $NbSe_2$[60] or high-temperature superconductors such as $YBa_2Cu_3O_{6.6}$.[61] Also, the magnitude of the anisotropy $H_{C2(\parallel)}/H_{C2(\perp)} \approx 5$ is comparable. The drastic change in the characteristics of the type II behavior between YC_2 and $Y_2X_2C_2$ representatives is due to the difference in dimensionality.

3.3.2. Heat Capacity

The specific heat capacity of a (nonmagnetic) metal is composed of contributions from lattice vibrations (phonons) and electrons. The lattice contribution at low temperature is usually described by the Debye T^3 law, which is derived from the

assumption of a normal spectrum of lattice vibrations within the limiting frequency ω_D. Such behavior is readily observed in the temperature range $T < 0.1\theta_D$, where the Debye temperature θ_D is defined as $\hbar\omega_D/k_B$. The contribution of the conduction electrons increases linearly with temperature; the proportionality factor γ (Sommerfeld coefficient) depends on the number of the electrons and their effective mass. With the transition to superconductivity, an ordered state is established, and the loss in entropy is evident in the well-known anomaly in the specific heat capacity. In Figure 10 the anomalies in the specific heat capacity due to superconductivity in YC_2 and $Y_2Br_2C_2$ are contrasted. The measured data are already corrected for the normal state contributions, which are readily attainable by suppression of the superconductivity by an external magnetic field.

Again large differences in the properties of YC_2 and $Y_2Br_2C_2$ arise. The specific heat capacity for the YC_2 sample (Figure 10, top)[56, 62] is a textbook example of BCS behavior with weak coupling. The fitted curve shows the expected theoretical behavior.[63] The energy gap has been calculated from experimental data, which yield $2\Delta(0) = 3.58(5)k_BT_c$, identical with the BCS value within experimental error. For $Y_2Br_2C_2$ the extrapolated Debye temperature lies at $\theta_D = 240(10)$ K. This value is considerably lower than for the hard and brittle YC_2 ($\theta_D \approx 420$ K)[63] with the three-dimensional interconnection in its crystal structure. Approaching the transition from the low-temperature side the specific heat capacity corrected for the normal state contributions increases steeply as it nears T_c, and it is only very insufficiently described by BCS weak coupling theory (Figure 10, bottom). In contrast, an excellent agreement with the predicted results of the (empirical) two fluid model[64] for (moderately) strong electron–phonon coupling is found, as is shown by the fitted curve.[57]

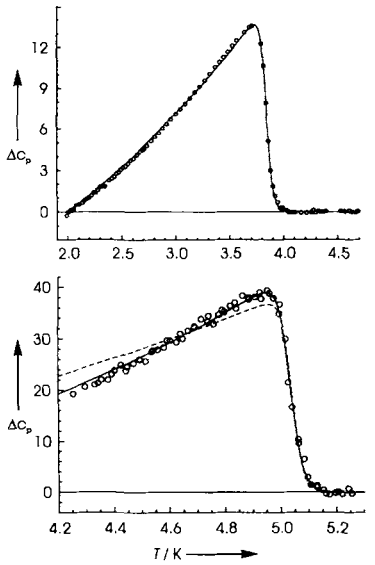

Figure 10. Difference in the specific heat capacity, $\Delta C_p(T)$ between the normal and superconducting states in mJ mol^{-1}K^{-1} as function of the temperature for YC_2 (top) and $Y_2Br_2C_2$ (bottom). While YC_2 shows nearly perfect BCS behavior (solid line), the measured points for $Y_2Br_2C_2$ deviate markedly from the fitted BCS curve (broken line) and are well fitted to the two fluid model (solid line)[40, 56, 57].

3.3.3. *Isotope Effect*

The most obvious differences in the superconducting properties of YC_2 and $Y_2Br_2C_2$ concerns the isotope effect. As is discussed in Section 2, the involvement of phonons in superconductivity was first demonstrated experimentally by the change in T_c with atomic mass through isotope substitution in Hg. With $\omega_D \propto M^{-1/2}$ the BCS theory predicts $T_c \propto M^{-1/2}$.

Because of the large atomic mass of mercury, the expected changes in T_c are rather marginal. For an average atomic mass of 199.7 the transition temperature was found at $T_c = 4.161$ K, for $M = 203.4$ it was 4.126 K. In the case of YC_2 and $Y_2Br_2C_2$ the experimental conditions are much more favorable. Assuming that the C_2 groups are crucial for the occurrence of superconductivity, one expects a change in T_c of $\Delta T_c = -0.17$ K for YC_2 and -0.20 K for $Y_2Br_2C_2$ upon substitution of ^{13}C for ^{12}C. The results[46, 62, 66] are given in Figure 11. The decrease in T_c of 0.14 K for $Y^{13}C_2$ lies near to the BCS value and demonstrates the participation of the C_2 units and their vibrations in the formation of Cooper pairs. In contrast, $Y_2Br_2C_2$ shows no isotope effect within experimental error limits. The measurements rather demonstrate the good reproducibility of the preparation (see Section 3.4).

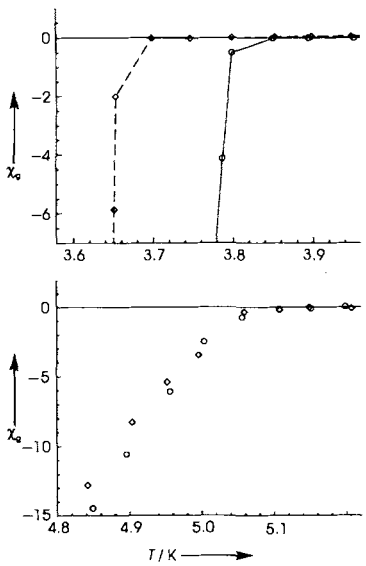

Figure 11. Isotope effects for YC_2 (top) and $Y_2Br_2C_2$ (bottom). Diamonds indicate measurements on ^{13}C samples. Circles represent measurements with the natural ^{12}C isotope mixture[46]. χ_g in 10^{-4} emu g^{-1}.

Despite the large differences between YC_2 and $Y_2Br_2C_2$ in the superconducting state, there is much evidence for a common origin of superconductivity in the two compounds. One may conclude that the special physical properties of the superconducting state are apparently of secondary importance in the search for a general connection between superconductivity and its chemical prepositions.

3.4. Chemical Bonding

The description of chemical bonding for the C_2 units in carbides and carbide halides, as outlined in Figure 3, refers to discrete molecular entities. In the solid the interaction of a multitude of these units in connection with the corresponding covalence of the carbon–metal bonds (p–d mixing) produces a band-type broadening of the energy levels. It needs to be tested whether in a detailed description of the bonding the crux of the hypothesis is retained, namely, that band states with quasi-molecular C_2-π^* character at the Fermi surface can cause a tendency for pairwise localization of conduction electrons. With regard to the validity of band structure arguments, a misunderstanding should be avoided right away. A metal in the superconducting state represents a highly correlated, many-electron system, which, by its nature, excludes any description with one-electron approximations. In the following the emphasis is merely to search the band structure in the normal state for special features that set the conditions for superconductivity at low temperature. In order to be able to follow the arguments the

essentials for the description of the chemical bonding in a solid will be introduced first. There are many sources that explain the electronic band structure to the chemist, and only a few can be mentioned here.[67-69]

If we stay with carbon and consider π bonding in the hydrocarbons ethene, the cyclopropenyl cation, cyclobutadiene, the cyclopentadienide ion, benzene etc., the number of MOs is equal to the number of C atoms. A hypothetical ring composed of 10^{23} carbon atoms, that is, a quasi-infinite chain, is characterized by a sequence of extremely closely spaced levels, that is, an electron band. The combination of the atomic wave functions for the lowest energy state is all-bonding, the highest all-antibonding in character. As Figure 12 indicates, the density of states $N(E)$ increases towards both the top and the bottom of the band.

The all-antibonding combination of the atomic wave functions with alternating sign can be described with the shortest possible wavelength, $\lambda = 2a$ (a = atomic spacing), and the all-bonding combination is described with an infinitely long wavelength. The wave vector $\boldsymbol{k}$ is therefore the positional parameter for an electron in the band of allowed states. With $|\boldsymbol{k}| = 2\pi/\lambda$, k changing from 0 to π/a, the band has a characteristic dispersion, as shown in Figure 12. The more states in an energy interval the flatter the band becomes, as is seen when $k \rightarrow 0$ (zone center or Γ point) and $k \rightarrow \pi/a$ (zone boundary). In the chosen example the band is filled with two electrons per C atom, and it is therefore half filled in the case of the chain $(CH)_{n\rightarrow\infty}$.[70]

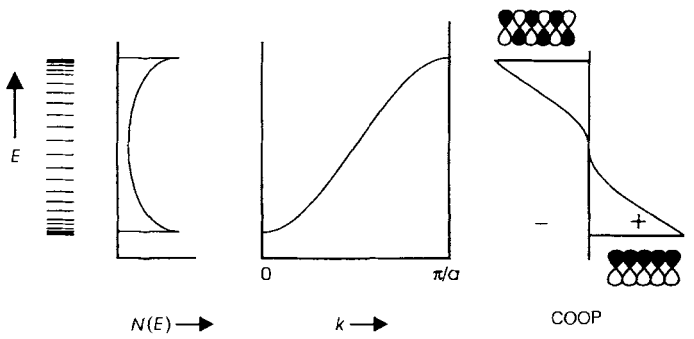

Figure 12. Schematic representation (from left to right) of the MO sequence for the π-like interaction in a polyene, the density of states $N(E)$, the dispersion k of the electronic band, and the chemical characterization of the band states with regard to the interaction between nearest neighbors ("crystal orbital overlap population", COOP). The bottom of the band corresponds to all-bonding, the top to all-antibonding combinations of the AOs[68].

The slope of the band at the Fermi level is a measure of the velocity v of the conduction electrons. Using the equations $E = mv^2/2$ and $p = mv$, one obtains $E = p^2/2m = \hbar^2k^2/2m$, and through differentiation one gets $dE/dk = \hbar^2k/2m = \hbar v$. A large slope of the conduction band at E_F corresponds to a high velocity of the conduction electrons,[71] and a horizontal band at E_F corresponds to a Fermi velocity $v_F \rightarrow 0$ in the special direction of k.

The electronic band structure describes the chemical bonding in momentum space (reciprocal space). A useful aid for the transformation of this description into real space is provided by the COOP formalism (crystal orbital overlap population),[72] which allows the analysis of the band character with respect to bonding, nonbonding, or antibonding interactions between selected atoms. According to the above discussion, the band character in the chosen example of π-type interaction between adjacent C atoms develops from bonding via nonbonding to antibonding with increasing energy (Figure 12).

The discussion of the bonding in a chain with the additional restriction to a single electronic band serves well as an introduction to the concepts and ideas. Band structures of three-dimensional crystals are naturally much more complicated. Normally they are portrayed in the form of the density of states $N(E)$ as a projection of all the band states on the energy axis. The dispersion of the bands is only shown in certain symmetry directions, and the specific zone boundaries are labeled with letters.

In Figure 13 the electronic density of states for $Y_2Br_2C_2$ as calculated with the Extended Hückel method[73, 74] is shown

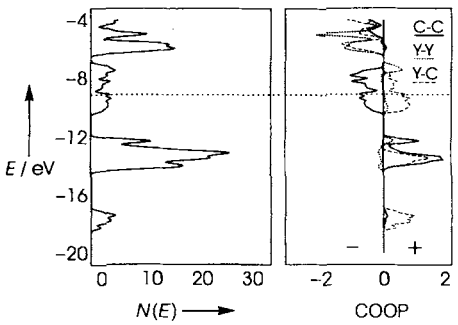

Figure 13. Band structure calculation for $Y_2Br_2C_2$ in the Extended Hückel approximation. On the left the total density of states $N(E)$ (also known as DOS) is given; right is the COOP analysis for the C–C (solid line), Y–C (dotted line), and Y–Y (dashed line) exchange interaction between nearest neighbors. The dotted horizontal line corresponds to E_F.

together with the COOP analysis for C–C and C–Y interactions between nearest neighbors. Concentrating on the energy range around the Fermi level, the structure at E_F is recognized as having antibonding C–C and bonding C–Y character. In accord with earlier results of band structure calculations on $Gd_2Cl_2C_2$[39] and newer ones on further $(RE)_2X_2C_2$ representatives,[75] the structure at E_F can be assigned to the C_2-π^* states which mix strongly with the Y-d states. At E_F a local maximum in the density of states appears, giving evidence of a flat band. The individual bands with their dispersions give a clue about the origin of this maximum.

In Figure 14 the results of self-consistent band structure calculations in various directions are presented.[76, 77] The results have already been described and discussed in more detail.[36] Here, only the character of the band states of the conduction electrons is of interest. The conduction bands cross E_F several times, partly with large gradients corresponding to high conduction electron velocity, and partly very flat at E_F, that is, a Fermi velocity that tends towards zero. The small dispersion in the direction from Γ to A (perpendicular to the layers) is a trivial consequence of the two-dimensionality of the structure of $Y_2Br_2C_2$. However, the special situation is due to the fact that the flat band occurs exactly at the Fermi level.

The orbital character of each of the two conduction bands in the so called "fat band" representation is given in Figure 14. The line width is proportional to the indicated orbital contribution. Because the contribution of the C_2-π^* is of particular inter-

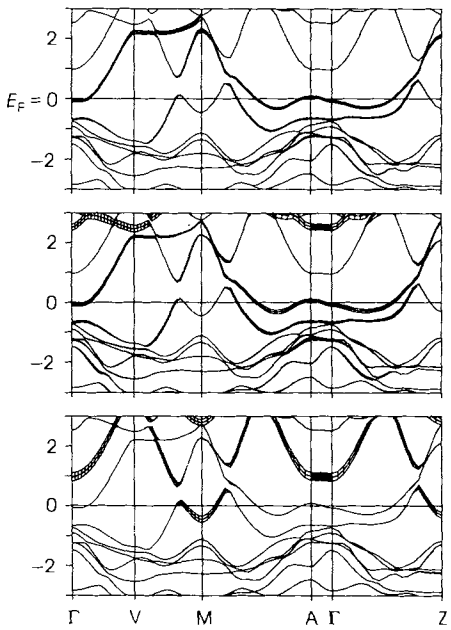

Figure 14. Representation of the dispersion of the bands for $Y_2Br_2C_2$ in the energy range close to the Fermi level, calculated self-consistently according to the TB-LMTO-ASA method ($E_F = 0$ eV). The prominent orbital contributions to the band structure are indicated in the form of "fat bands" (from top to bottom: C_2-π^*_{xz}, Y-d_{xz}, Y-$d_{x^2-y^2}$)[36].

est here, the linear combinations of the atomic orbitals in the C_2 unit were formed with z pointing in the direction of the C–C axis. It is obvious that the steeply crossing band at M and Z (zone boundaries in the plane of the layers) has strong $Yd_{x^2-y^2}$ character, while the C_2-π^* contribution mixed with Yd_{zx} determines the flat band. These results corroborate the naive approach that a tendency towards pairwise localization of conduction electrons should be connected to the C_2-π^* MOs.

The special course of the flat band is interesting, because a saddle point at the Γ point is formed. The band rises in the direction of A and falls (almost) perpendicularly towards Z.[36] Saddle points at E_F are well known from the classical layered superconductors, like niobium and tantalum dichalcogenides,[78] and also from the layered high T_c superconductors found with oxocuprates.[79] The existence of such saddle points—van Hove singularities[80]—was repeatedly discussed in connection with the origin of superconductivity in these layered compounds.[81–85] With the appearance of a van Hove singularity, the critical temperature follows an expression similar to that from BCS theory; however, the Debye temperature, $\theta_D = \hbar\omega_D/k_B$, is replaced by the Fermi temperature, $\theta_F = E_F/k_B$. Electron–phonon coupling therefore looses its importance for electron pairing, and because of the large value of θ_F in comparison with θ_D (and because of the higher density of states at E_F) higher critical temperatures are possible than in the BCS scenario. Therefore, van Hove singularities are possibly of particular relevance for high-temperature superconductivity (see Section 7). The replacement of θ_D with θ_F in $Y_2Br_2C_2$ should make the isotope effect disappear, as is actually observed in the case of this compound.

Despite the missing carbon isotope effect in $Y_2Br_2C_2$, it can be demonstrated unambiguously that vibrations of the C_2 units couple to the conduction electrons in a special way. In "frozen phonon" calculations the band structure is calculated for a slightly deformed lattice. The static distortion corresponds to a snapshot of the dynamic displacements of the atoms caused by a lattice vibration. As is obvious from Figure 15, small changes

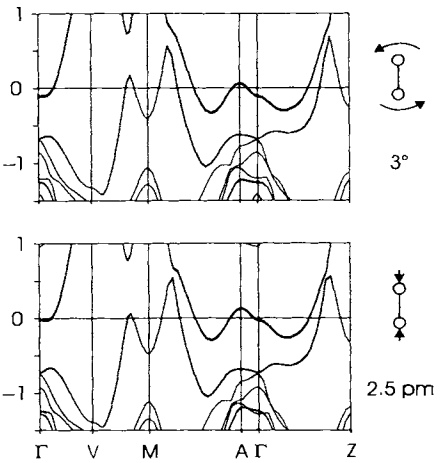

Figure 15. "Frozen phonon" calculations for the band structure changes in $Y_2Br_2C_2$. The changes in position and size of the C_2 units are shown to the right (fat band representation for the C_2-π^*_{xz} part, $E_F = 0$ eV)[36].

in the C atom positions influence the position of the flat C_2-π^* bands relative to E_F significantly. The band structure has been calculated for Γ phonons, that is, identical changes to all C_2 units. These changes are an increase of the C–C distance by 2.5 pm and a tilt of the C_2 units by 3° in the *ac* plane. As expected, the expansion of the C_2 unit weakens the antibonding interaction, and the π^* level decreases in energy. However, the rotation of the C_2 unit also leads to a drastic change due to the change in C–Y covalence. The C_2 units obviously form a charge reservoir that experiences a permanent dynamic alternation.

The carbides MC_2, with M = Ca, RE, Th, were the repeated subject of band structure calculations,[86–89] which aimed at understanding the transition from CaC_2 to ThC_2 type structure as well as explaining the stability of the CaC_2 type itself.[35] As expected, the self-consistently calculated band structure of YC_2[90] (Figure 16) showed no bands flat through the entire zone as in the case of the layered compound $Y_2Br_2C_2$. The density of states at E_F has again C-p and Y-d character, and it is high, but still does not show a maximum. Nevertheless, special features are closely related to those found for $Y_2Br_2C_2$. Because of the tetragonal symmetry of YC_2, the C_2-π^* bands become degenerate. They have a large amount of Y-$d_{xy,yz}$ character, and they approach E_F horizontally at the zone boundary. These bands are only flat at the zone boundary and otherwise cross the Fermi level steeply in the neighborhood of the center Γ. The pure Y-$d_{x^2-y^2}$ band, too, is steep at E_F. The three-dimensional YC_2 therefore also shows the characteristic juxtaposition of different kinds of conduction electrons as seen before: those which are highly mobile (itinerant), and those which have a disappearing Fermi velocity. The latter fill band states that come from the C_2-π^* MOs.

If one stays within the frame of BCS theory, the density of states $N(E_F)$ and the coupling constant V enter the exponent of the expression for T_c as the decisive parameters. Figure 15 illus-

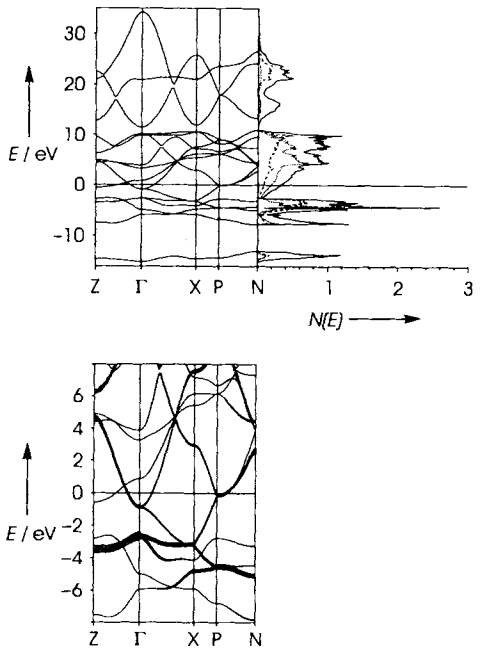

Figure 16. Self-consistently calculated band structure of YC_2 (top left), projected and total density of states (dashed: C-p, dotted: Y-d; top right, $N(E)$ in (eV·spin·formula unit)$^{-1}$), and fat band representation of the C_2-π^* part of the band around $E_F = 0$ eV (bottom)[90].

trates the coupling between vibrations of the C_2 units and the conduction electrons in the superconductors discussed here, and a high density of states results in flat bands at E_F. The example of YC_2 indicates that these bands may be highly dispersive and only need to be flat at E_F within a small interval Δk. In this context a long known fact should be remembered, namely, that a high density of states at the Fermi level leads to structural instability. A lattice that distorts statically implies localization of charge carriers. Structural instability and superconductivity compete.

4. Itinerant Electrons and Local Pairs

According to our hypothesis the origin of superconductivity is related to a tendency for a pairwise localization of some of the conduction electrons, without causing a structural phase transformation. The band structure is characterized by the simultaneous presence of steep bands and extremely flat band portions at the Fermi level, and the pairwise attractive interaction between conduction electrons results from a local attraction caused by special atomic arrangements, such as those of the C_2 units in the carbides and carbide halides of the rare earth metals. This local approach is somehow in contrast to the present general opinion, and particularly the large coherence lengths in the superconducting state are used as a main argument against it.

As already mentioned, the theory of superconductivity on the basis of local exchange interactions has regained some popularity due to the discovery of high-temperature superconductivity and the short coherence lengths that are observed there. Particularly revealing is a physical modeling and extension[27, 91–93] of the chemical view presented here, which is based on an interaction of local pairs with itinerant electrons. The model rests on a two band picture with one broad band **a** that is populated with single electrons (fermions) as in a normal metal and one very narrow band **b** that contains locally paired electrons (bosons).

The electrons in band **a** shield the far-reaching Coulomb interaction between the pairs in band **b** and suppress any structural phase transition. The superconductivity in this model system involves the electrons of the broad band **a** in the long-range pair interaction of an indirect nature, and the microscopic mechanism of superconductivity depends on the relative position of bands **b** and **a**, that is, on their relative degree of occupation. If **b** lies below **a** (or rather E_F?), band **b** is occupied by local pairs, which can move by virtual excitation of pairs of electrons with opposite momenta and spins in band **a**. The mechanism resembles the exchange interaction between local magnetic moments by polarization of the electron gas put forward by Rudermann, Kittel, Kasuya, and Yosida (RKKY).[94]

The maximum values for T_c are obtained when band **b** lies exactly at the Fermi level. The exchange interaction between the local pairs in the narrow band and the itinerant electrons in the broad band also couples the electrons in **a** to form Cooper pairs. The condensation of all pairs produces the superconducting state. If band **b** lies above the Fermi surface, electrons in **a** with opposite momenta and spins couple through the virtual transition to local pair states of the empty band **b**. This case leads to BCS-type behavior and $2\Delta(0) = 3.52 k_B T_c$.[27]

5. Prediction

The special features in the electronic band structures of carbides and carbide halides of the rare earth metals are viewed as a characteristic "fingerprint" for superconductivity. Because of its qualitative character and the restriction to electronic criteria only, quantitative predictions cannot be expected. Using the fingerprint in the search for new superconductors is, however, also of great enough interest. A new superconductor[95] discovered in the chemical neighborhood of the compounds discussed before serves as an example.

During extensive phase studies on boride carbide halides of the rare earth metals[96, 97] we obtained the new compound $Ce_9Br_5(CBC)_3$. The structure is shown in Figure 17. The chemical bonding can be described in a simplified way as $(Ce^{3+})_9(Br^-)_5(CBC^{7-})_3e^-$ according to the Zintl-Klemm concept. The bent CBC units, which occur as discrete anions, are electronically isovalent with SO_2. From much experience with other rare earth metal compounds the electron surplus is expected to

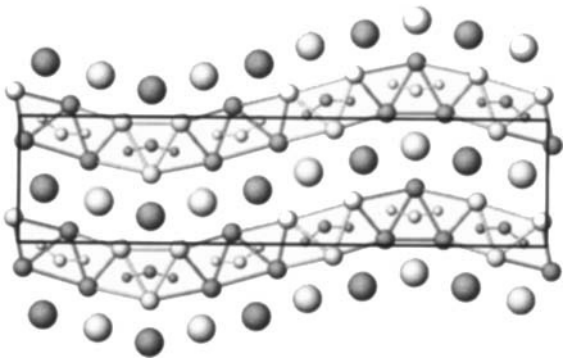

Figure 17. Projection of the orthorhombic structure of $Ce_9Br_5(CBC)_3$ in the direction of the b axis (a horizontal). The atoms Br, Ce, B, and C are shown with decreasing size[95].

be used for metal–metal bonding. Because of the partial occupancy of a M–M bonding band a "true" metal should result.

The results of Extended-Hückel calculations (Figure 18) are in agreement with this simplified view of chemical bonding as

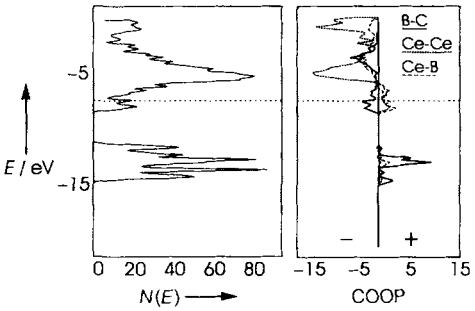

Figure 18. Band structure of $Ce_9Br_5(CBC)_3$ calculated in the Extended Hückel approximation (left: total density of states, right: COOP for the indicated interactions between nearest neighbors; dotted horizontal line: E_F).

well as with the resulting metallic properties. One finds a maximum of the density of states at the Fermi level, and the COOP analysis shows the bands at E_F to be of Ce–Ce and B–Ce bonding character on one side and of B–C antibonding character on the other. The local maximum at E_F gives evidence for the existence of a flat band with effectively nonbonding character due to the backbonding from occupied antibonding states of the molecular anion into the metal d states. With the exception of significant M–M bonding, there are many similarities in the bonding between $Ce_9Br_5(CBC)_3$ and $Y_2Br_2C_2$, and one is tempted to search for the existence of superconductivity. Of course, a superconducting transition is not expected for the magnetic compound of cerium containing Ce^{3+} ions ($4f^1$ configuration). Luckily the nonmagnetic isotypic La compound can also be prepared; moreover, the band structure exhibits the same characteristic feature at E_F despite the differences in the electronic energy levels of Ce and La, and the slightly different lattice parameters. $La_9Br_5(CBC)_3$ is a superconductor, as is demonstrated by the disappearance of resistance at 6 K, and the simultaneous change to diamagnetism.

The self-consistently calculated band structure of $La_9Br_5(CBC)_3$ is shown in Figure 19. The Fermi level is crossed by a multitude of steep bands. One of the degenerate bands at E_F is again almost dispersionless. As expected, the direction from S to R where the band is flat corresponds to the *c* direction. The flat band has both BC_2-π^* and La-$d_{xz,yz}$ character. As in the case of the C_2 units, the conduction electrons also couple with specific "molecular" vibrations of the CBC unit. The bending vibrations, especially, change the position of the flat band greatly and should therefore be of importance to the superconductivity.

In contrast to the recently discovered boride carbide halides, the boride carbides of the rare earth elements have been known for a long time. The compound $La_5C_2(CBC)_2$ is particularly interesting here. It can be formulated, according to the Zintl-Klemm concept, as $(La^{3+})_5(C_2)^{4-}(CBC^{5-})_2e^-$, and it contains C_2 units beside linear CBC units which are isoelectronic to CO_2.[98] The compound is superconducting at 6.9 K.[99] This is the parallel to the much studied superconductor $(RE)Ni_2B_2C$[100, 101] with (also linear) BCB units. An examination of the electronic structure must show whether the presence of the C_2 units, or possibly, the CBC groups is important for the appearance of superconductivity in the d-metal-free compound $La_5C_2(CBC)_2$.

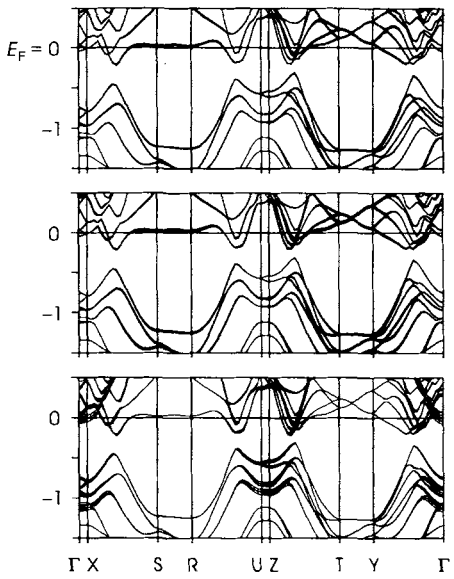

Figure 19. Self-consistently calculated band structure of $La_9Br_5(CBC)_3$ for the bands lying around the Fermi level at $E_F = 0$ eV. From top to bottom the contributions of the BC_2-MOs (approximate π^*), the La-$d_{xz,yz}$, and La-$d_{x^2-y^2}$ orbitals are emphasized in the fat band representation [95].

6. Orbital Topology

When the fingerprint of superconductivity is reduced to the condition of "steep bands beside parts of bands with vanishing slope at the Fermi level", the consideration of specific bonding conditions, which has been distinctly addressed for the systems discussed so far, is lost. The question of the symmetry of the band states, as is necessary for superconductivity, remains open. What kind of atomic orbitals in which combinations produce the condition for superconductivity?

Krebs sought an answer to this question in a series of papers, first addressing the question selectively,[102] and later more generally.[103, 104] He was of the opinion that the prerequisite for superconductivity must be a partially occupied band formed by the atomic orbitals in such a way that the electrons can move in at least one direction without finding planar or conelike nodes.[102] Such systems are δ-bonded linear chains of d-metal atoms, as in Nb_3Sn (compare Section 7). The all-bonding combination—the argument has at its basis a representation of the bands at the Γ point—creates tubes along the chain with the same sign of the atomic wave functions (ψ_+ and ψ_-) in each. Absence of nodes in the total function naturally characterizes bonding with s electrons, and one would therefore expect superconductivity to occur with alkali metals. However, these show no superconductivity under normal pressure, where they are s metals. Nevertheless, the s electrons, in spite of their large radial extension and the resulting width of the bands and consequently low density of states, were assumed to be of special importance for superconductivity. The idea found no acceptance, and the publication of the last manuscript was rejected. In a theory developed ten years later,[105] essentials of the idea were applied.

The starting point of the considerations was the idea of Weisskopf,[106] who, in order to visualize the Cooper pair, put forward the real space model of a moving conduction electron that leaves a polarization trace behind it, which produces an interaction with a conduction electron moving in the opposite direction. The polarization trace ("long thin tube"), according to Johnsson and Messmer,[105] is produced in adjacent tubes or layers with alternating positive and negative sign of the wave function, which as regions of p–π bonding or bonding through d_{z^2} orbitals in a layer as well as d–δ bonding in a chain can be identified with the node-free areas of the total function according to Krebs. For the d–δ bonded chain, for example, this produces tubes from the Ψ_+ and Ψ_- contributions of the atomic wave functions, which each construct bonding systems of mutually antibonding character adjacent to one another. The electrons in each are assigned spin ↑ and spin ↓. This "antiferromagnetism" of the conduction electrons[107] describes the bonding state for the singlet electron pair. The description corresponds to the original suggestion by Schafroth of characterizing Cooper pairs as "quasi-molecules".[108, 109]

The occurrence of such tubes is not restricted to explicitly one-dimensional structures. As an illustration of the basic idea[105] the construction of the tubes for a body-centered cubic lattice of a transition metal, plotted as the Γ point configuration with the all-bonding δ interaction along the *z* axis is shown in Figure 20. Niobium, the metal with the highest critical temperature of all the element superconductors ($T_c = 9.3$ K), crystallizes in this structure, and interestingly, the concentration of the electrons is just large enough to provide a near coincidence of the triply degenerate $d_{xy,xz,yz}$ band at the Γ point with the Fermi level.[110] By definition, the band has zero slope at Γ.

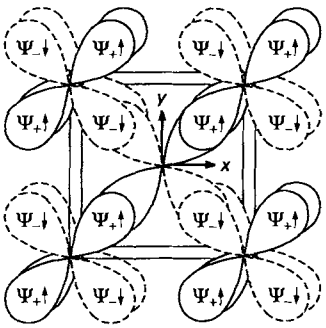

Figure 20. Depiction of the δ bonding in the body-centered cubic crystal of niobium. The combination of the d_{xy}, d_{xz}, and d_{yz} orbitals give a triply degenerate band, which nearly coincides with the Fermi level at the Γ point. The figure is taken from ref. [105] where the regions of different sign of the wave function are associated with opposite spins.

The band degeneracy at the Fermi level is the cause of a Jahn–Teller or pseudo Jahn–Teller effect: the conduction electrons couple with atomic displacements to remove the degeneracy. The dynamic Jahn–Teller coupling between conduction electrons and lattice lead to formulas for T_c and other superconductivity parameters that resemble those derived from the BCS theory. The model thus represents a real space analogue to coupling of electrons through virtual phonons. In the quantitative formulation of the theory, the degree of the dynamic displacement of the atoms is a function of two parameters, which quantify, on one hand, the distance between the tubes or layers with differing signs of the wave function, and on the other hand, the strength of the bonding in the tubes and layers. These parameters set the field for structural phase transformations (with static Jahn–Teller effect) and superconductivity (if the Jahn-Teller effect stays dynamic). Critical temperatures and isotope effects are predicted for simple elemental and compound superconductors with an impressive accuracy.[105]

When one applies the theory qualitatively to the carbides and carbide halides of the rare earth metals, one meets fundamental problems. For $Y_2Br_2C_2$ node-free tubes parallel to the *b* axis are easily constructed. These are made of, on one side, bonding combinations of C-p_x and Y-d_{xz} orbitals, and on the other side, very weak δ bonding involving the Y-d_{xz} orbitals.[88] This configuration corresponds to that of the Γ point, and it is indeed part of the flat, although not degenerate, band at E_F in the band structure. In contrast, the corresponding construction for YC_2 does not correlate with the band structure, because no electronic states at E_F lie at the Γ point, and it is only at the zone edge in the 111-direction (P point) that the conduction band becomes flat and touches the Fermi level. The example, as many more, demonstrates the difficulties in connecting this interesting real space model with the description of chemical bonding in momentum space. We are working on an extension of the model to general points in momentum space.

7. To Higher Temperatures

Superconductivity is known to exist in more than ten thousand materials. Here the term material refers to the complete spectrum of pure metals, structurally and analytically defined chemical compounds, mixed crystals, alloys, and phase mixtures. So there are many different materials on which to test the presented ideas about the necessary prerequisites in chemical bonding for superconductivity to occur. Perhaps the most investigated compounds are the technically important A15 phases, which before 1986 were termed high-temperature superconductors.

The cubic structure is characterized by three nonpenetrating linear chains of transition metals, all mutually orthogonal (Figure 21). With decreasing temperature, the equivalence of the

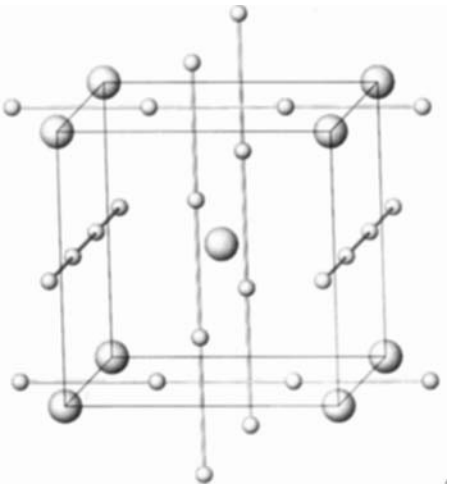

Figure 21. Unit cell of Nb_3Sn (A15 type). The linear chains, orthogonally oriented to one another, of Nb atoms are emphasized.

chains is lost through structural phase transformations before superconductivity appears. The band structure[111, 112] for the tetragonal Nb_3Sn (Figure 22) shows a degenerate extended flat band at the Fermi level around the Γ point corresponding to δ-type interaction in the chain, which is closely related to the bonding in discrete complexes with multiple metal–metal bonds known to every chemist.[113]

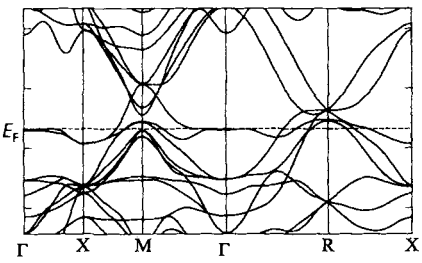

Figure 22. Band structure of tetragonal Nb_3Sn with an extended flat band at the Fermi level[112].

In the past decade, three classes of superconductors were discovered; the critical temperatures of some of them are way above the critical temperatures of conventional superconductors that had been optimized over decades. These are oxobismuthates, fullerides (sometimes called fullerites), and oxocuprates. The high critical temperatures gave physicists hope that new mechanisms would be discovered, or at least that a better understanding would be gained of the nature of electron–electron coupling in these systems where it must be very pronounced. For some chemists the proximity to normal valence compounds, different from metallic elements and intermetallic phases, was of interest as it allows the use of familiar terms and notions like oxidation number, coordination, etc. in discussing superconductivity.

7.1. Oxobismuthate Superconductors

The superconducting bismuth oxides crystallize in the perovskite structure, or in structures closely related to it. The arrangement of the atoms in this very simple structure is depicted in Figure 23. In the compound $BaBiO_3$, Bi has the unusual oxidation state +IV. At room temperature the unit cell is doubled

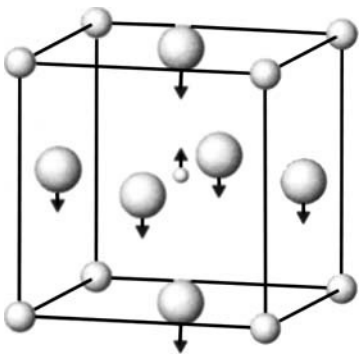

Figure 23. Unit cell of the perovskite-type structure. The arrows show the Γ point displacements for the ferroelectric mode in $BaTiO_3$. The O, Ba, and Ti are depicted in decreasing size.

and distorted to monoclinic. It contains two types of Bi atoms in differently sized coordination polyhedra.[114] As the compound is a semiconductor the bonding can be described by the formula $(Ba^{2+})_2(Bi^{3+})(Bi^{5+})(O^{2-})_6$, and the complicated static distortion can be easily related to the localization of two electrons at the Bi^{3+} ion with the "lone pair" configuration. Such an interpretation remains contradictory, though. From band structure calculations[115] there is hardly any difference between the charges of the Bi atoms ($\approx 3.9+$ and $\approx 4.1+$). The naive assignment of integral oxidation numbers leads to the argument that the specific deformation of the structure resulting in nonequivalent Bi atoms—corresponding to a charge density wave (CDW)—can be suppressed through the partial replacement of Bi with Pb as Pb^{4+}, since its closed electron configuration prefers a regular coordination octahedron, which would stabilize the structure. In fact, the (tetragonal) mixed crystal $BaPb_{0.75}Bi_{0.25}O_{3-\delta}$ shows no CDW transition; it is metallic and becomes superconducting below 13 K.[117] The compound should be seen as an important predecessor of the actual high-temperature superconductors. In an analogous way, the stabilization of the undistorted structure is obtained through an increase of the relative amount of Bi^{5+} ions, which again have a closed shell ($5d^{10}6s^06p^0$) configuration. This is achieved, accompanied by a change in the charge carrier concentration, by partial replacement of Ba with K. Cubic $Ba_{0.6}K_{0.4}BiO_3$ shows superconductivity at $T_c \approx 30$ K.[118]

The proximity of these superconductors to ferroelectrics, for example, the technically important $BaTiO_3$, is evident. The characteristic lattice vibration shown in Figure 23, which becomes soft in the zone center, is responsible for the ferroelectric behavior of barium titanate. The resulting static deformation—chemically it is due to a distortion in the direction of a titanyl cation, TiO^{2+}—produces parallel dipole moments in all unit cells. These moments can be reversed by an external electric field, in analogy to the magnetic moment in a ferromagnet. The instability of the cubic structure is due to the configurational instability of the O^{2-} ion,[119, 120] which is reflected in its nonlinear atomic polarizability. It is reasonable to associate a (dynamic) deformation of the same type as in $BaTiO_3$ with the superconductivity in oxobismuthates.[121, 122] In contrast to the valence-stable Ti^{4+}, the intermediate valence system Bi^{3+}/Bi^{5+} can react sensitively with a tendency to pair localization with a pseudooctahedral environment.[123] Thus, to the configurational instability of the O^{2-} ion is added a vibronic coupling due to the presence of a lone pair at Bi^{3+}. In a lattice dynamics model[124, 125] the common origin of ferroelectricity and superconductivity in these systems, which has also been empirically recognized,[126] has been demonstrated.

The superconducting oxobismuthates are looked upon as representative examples for systems that are composed of local pairs next to itinerant electrons as considered in Section 4.[127] Indeed the band structure calculated for the approximate composition $Ba_{0.5}K_{0.5}BiO_3$ (Figure 24)[128] shows a broad conduction band formed from Bi-6s and O-2p orbitals, which becomes very flat with the formation of a saddle point at E_F in X.

The element bismuth itself could serve as a very obvious example of the role of local pairs in superconductivity. Under ambient conditions it has a structure[129] formed from corrugated layers of hexagons, where each Bi atom has three nearest

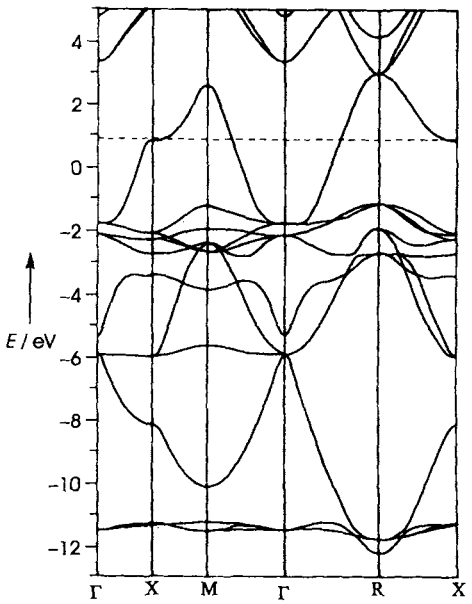

Figure 24. Band structure of $Ba_{0.5}K_{0.5}BiO_3$ with flat Bi-6s/O-2p bands at E_F (dashed horizontal line) at point X [128].

neighbors in its own layer (307 pm) and three in an adjacent layer (353 pm). Its noncentric position in the trigonal antiprism can be interpreted in terms of a localization of the stereoactive nonbonding electron pairs, in agreement with the semimetallic properties, which classifies Bi close to a (degenerate) semiconductor. Under pressure the structure becomes highly symmetrical—first cubic primitive, then body-centered cubic. The charge carrier concentration is many times larger than in the ambient pressure form, that is, the localization of the nonbonding electron pairs is lost in the high-pressure forms. However, the tendency towards localization through dynamic deformation of the atomic surroundings apparently still remains, and leads to superconductivity with critical temperatures up to $T_c = 8.5$ K.[130] Also, deposition of Bi from the gas phase on a cold substrate at 4 K yields a film that is superconducting up to 6 K.[131] The film recystallizes upon warming to 20 K and no longer shows superconductivity when cooled again. Obviously, the "locking in" of the electron pairs is apparently avoided in the case of amorphous Bi. This last example once again stresses the relevance of local effects to superconductivity, as do several other amorphous superconductors.[132]

7.2. Fulleride Superconductors

Graphite becomes superconducting on intercalation of alkali metals. The critical temperatures are, however, very low ($T_c \approx 0.5$ K for C_8K).[133] In contrast, the intercalation of alkali metals in the other allotrope of carbon, fullerene C_{60}, produces critical temperatures of over 30 K.

C_{60} is a semiconductor. After reaction with alkali metals, poorly conducting metals are obtained, and at the composition A_3C_{60}, superconductivity appears. This was first discovered in K_3C_{60} (critical temperature $T_c \approx 18$ K)[134] The critical temperature increases with the size of the alkali metal atoms. Rb_3C_{60} and Cs_2RbC_{60} are superconducting at 29 K and 33 K, respectively.[135] Higher values such as $T_c = 45$ K[136] for the combination $Rb_{2.7}Tl_{2.2}C_{60}$ have still to be reproduced. The maximum alkali metal content is reached at A_6C_{60}, and it produces, along with A_4C_{60}, semiconducting behavior.

The phase relations and the structures of the alkali metal fullerides are complicated. The structure of the A_3C_{60} phases appear relatively simple at first sight. The molecules show a cubic close packing, with an occupation of both the octahedral and tetrahedral voids by the cations ($BiLi_3$-type structure). However, because of an orientational disorder of the quasi-spherical anions, the structure is still unknown in detail.[137-139]

The band structure of C_{60} looks like that typical of a molecular crystal. The broadening of the MOs to bands is only slight, and groups of bands are therefore well separated by large forbidden gaps. The valence bands correlate with the HOMO with h_u character, and the conduction bands are derived from the LUMO with t_{1u} character. Upon intercalation, the electrons of the alkali metal atoms are transferred almost completely to the C_{60} molecules to form triply charged anions; the Fermi level is thereby raised, and the LUMO consequently becomes partially occupied. The MO diagram of the C_{60} molecule[140] is very exactly known. However, as the relative orientations of the molecules in the solid cannot be determined unambiguously because of orientational disorder, the specific interaction of the molecules are not exactly known, and the band structure that results therefore remains uncertain. Calculations have been performed for different ordered structural models, assuming one single orientation of all anions, or two or four different orientations.[140-142] It is tempting to show the best fitting result, which is characterized by steeply crossing bands beside an extended flat band at E_F. However, it would have no evidential value.

Despite this lack of detailed knowledge of the crystal structures and the resulting problems of describing the bonding in the solid, there seems to be agreement that the superconductivity in fullerides can be understood within the framework of conventional theories.[143, 144] Such a statement can not be made for the oxocuprate superconductors.

7.3. Oxocuprate Superconductors

Experiments and theories of high-temperature superconductivity are described in tens of thousands of original papers and in a number of books. The problems in understanding the superconductivity of oxocuprates begins with the exact chemical compositions. The first high-T_c superconductor found was based on La_2CuO_4, made metallic and superconducting by the substitution of cations in $La_{1.85}Ba_{0.15}CuO_4$.[5, 145] Later it was shown that with an excess of oxygen of the order of one percent, superconductivity occurs also in the unsubstituted compound $La_2CuO_{4.04}$.[146, 147] The oxygen content, in particular, is frequently unknown in the investigated multicomponent phases. The second problem affects the crystal structures, that even at room temperature can often be described only approximately, because they are modulated with long periodicities as in (EA)-Bi-Cu-O and (EA)-Tl-Cu-O systems (EA = alkali earth metal)[148, 149] and, like the previously described fullerides,

elude an exact description in terms of the band structure. Even in homogeneous single crystals structural and electronic phase separations are observed at low temperatures.[149-153] These produce extremely complicated features in the real structure that are puzzling with respect to their importance for superconductivity. From the point of view of physics, the oxocuprates differ from the oxobismuthates in the presence of magnetic ions. Antiferromagnetic interactions between the Cu^{2+} ions might therefore be involved in the emergence of superconductivity in these materials.

$YBa_2Cu_3O_{7-\delta}$ is possibly the most completely characterizable and best examined high-T_c superconductor.[154, 155] The unit cell of $YBa_2Cu_3O_7$ is shown in Figure 25. It is characterized

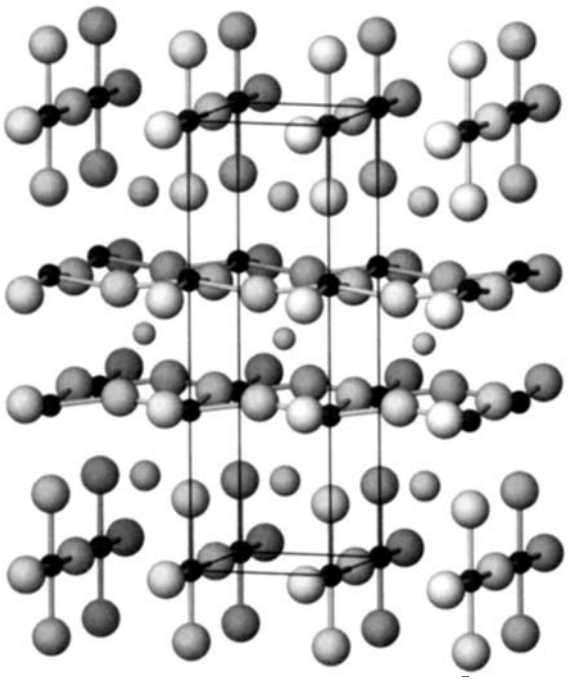

Figure 25. Unit cell of $YBa_2Cu_3O_7$. The CuO_2 layers around the Y atoms, and the CuO_3 chains next to the Ba atoms are highlighted (dark small spheres Cu, the others Y, Ba, O with increasing size).

by the CuO_2 layers with their typical deviation from planarity, which enclose the Y^{3+} ions, and the CuO_3 chains between the layers next to the Ba^{2+} ions.[156] Starting from an assignment of Cu^{2+} in the layers and Cu^{3+} in the chains,[158] one arrives at an intermediate valence and metallic conductivity through a partial charge compensation between layers and chains.

The O atoms between the Cu atoms in the chains can be easily removed. By complete removal ($\delta = 1$) the chain is left with CuO_2 dumbbells containing Cu^+. The composition would suggest all copper in $YBa_2Cu_3O_{6.5}$ to be Cu^{2+}; however, this is not true as indicated by the metallic conductivity of this phase. Given enough time, a crystal develops an ordered array of alternating filled CuO_3 and depleted CuO_2 chains accompanied by a doubling of the a axis.[159, 160] With the formula $YBa_2Cu_3O_{6.67}$, the order is two filled following one empty chain with a tripling of the a axis.[161] The seemingly simple chemical compound $YBa_2Cu_3O_{6.5}$ is therefore a mixed valence phase[162] with crystallographic ordering in different coordinations for Cu in the +I, +II, and +III oxidation states. Beyond this, an intermediate valence adds to the mixed valence and leads to the electronic delocalization by charge transfer. With the successive removal of the oxygen atoms, the critical temperature decreases from $T_c = 93$ K for $\delta = 0.1$ to an extended plateau around 60 K for $0.3 \leq \delta \leq 0.5$ and reaches 0 K for $\delta = 0.6$.[163] At this value the phase becomes semiconducting. Antiferromagnetism, first occurring at $\delta = 0.75$, has a maximum ordering temperature T_N of 500 K at $\delta = 0$.[164]

Mixed valence with the special feature of involving oxidation states differing by 2 and antiferromagnetism in a system with strong correlations indicate quite different kinds of electron localization. Whether one of them, or both, are responsible for the formation of Cooper pairs is still an open question.[165] Interestingly, a valence change from Cu^+/O^{2-} to Cu^{3+}/O^{2-} (or $(CuO)^+$)[158] can be compared to the situation with the carbide examples. In the carbides the metal-d bands interact with the filled antibonding π^* MOs of the anion, and in the doped oxocuprates the reverse interaction of the empty antibonding $d_{x^2-y^2}$ level of Cu^{3+} with the filled oxygen p band exists.

As is shown in Figure 26 for two special sections of the band structure of $YBa_2Cu_3O_7$, the electronic structure is again characterized by bands with large dispersion besides very flat band portions at E_F.[79, 167-169] This structure differs from those of the examples discussed before in the multiple occurrence of both types of band. The saddle point close to X has also been verified experimentally[170] by angle-dependent photoemission studies, and it is the basis for arguments that explain the high critical temperature within the theory of the van Hove singulari-

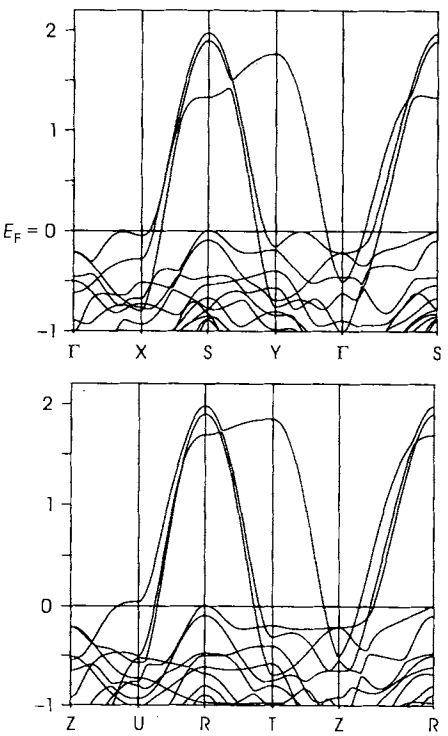

Figure 26. Band structure of $YBa_2Cu_3O_7$. Planes are parallel to the layers passing through the zone center (top) and through the zone edge (bottom)[168]. The band maximum at $E_F = 0$ eV at point S has essential contributions from O-2p and Cu-d_{xz} orbitals from those atoms forming the CuO_3 chains. Obviously, the chains do not only represent charge reservoirs but participate in the formation of Cooper pairs.

ty.[84, 171] One can also argue in terms of an interplay of the electrons in different flat bands at E_F, which increases the critical temperature. The energy gap in the superconducting state is very anisotropic.[172–175] If one represents it through a spectrum of discrete values taken from IR reflectivity measurements, the observed critical temperature can be derived without the assumption of an unconventional mechanism.[176] Perhaps one complicates matters when searching for a chemical understanding of superconductivity in high-temperature superconductors. Maybe what Hans Georg von Schnering called "virtual valence instability" in a paper on new superconductors[177] is easier to grasp in the simpler low-T_c superconductors.

8. Concluding Remarks

The understanding of superconductivity from a chemical point of view, as developed from special examples, leads to the conclusion that a tendency to pairwise localization of conduction electrons must occur. The prerequisite is the occurrence of steep electronic bands at the Fermi level as well as bands that display maxima, minima, points of inflection, or saddle points at E_F in order to provide a vanishing Fermi velocity to part of the conduction electrons. This condition is obviously necessary, though not sufficient, as clearly shown by the competition between superconductivity and structural phase transformation or magnetism.

Hardly any physical phenomenon has had so much work dedicated to it as the disappearance of the electrical resistance in a metal—in fact, even decades before the final (accidental) discovery of superconductivity. Probably every thought that one may now develop about the phenomenon of superconductivity has already been considered and written down somewhere. The earlier cited work of London from 1938[11] about Bose–Einstein condensation, which refers to superfluidity and superconductivity serves as a good example of this statement. "The well known formula for the electrical conductivity $\sigma \approx (l/v)_{Av}$ would yield the value $\sigma \approx \infty$ in the case where a finite fraction of all particles has zero velocity. . . .In general (particularly in the case of Fermi statistics, and also in the case $T > T_0$ for the Bose statistics) one is accustomed and entitled to disregard the few particles. . . In the case of Bose degeneracy ($T < T_0$), however, we are not allowed to neglect the *finite fraction* of particles with $v = 0$. . . One may say the 'conductivity' viz. the *fluidity*. . . becomes infinite. . ., and this abruptly, as soon as $T < T_0$." The large spatial extension of these "particles" is a consequence of their vanishing momentum.

In this work the introduced ideas are born from chemistry and carried some way into physics. Entirely independent of the topic superconductivity, one meets an interesting aspect. The term "tailor-made" is frequently used in modern chemistry when we put into use our knowledge of structures and structural increments in real space, to build molecules, supramolecular assemblies, and solids with desired properties. A "tailoring" in momentum space up till now is restricted to a few questions raised about chemically trivial materials, such as how to make the indirect band gap semiconductor silicon a direct one. Could it be that there is a large open field of research for chemists in constructing desired band structure features?

My group contributed numerous results to the work reported here. In particular, I would like to thank Peter Adler, Kyungsoo Ahn, Michael Bäcker, Annette Bussmann-Holder, Shuiquan Deng, Claudia Felser, Thomas Gulden, Rüdiger Henn, Jürgen Köhler , Reinhard Kremer, and Hansjürgen Mattausch for their contributions and many helpful discussions. The help of Claudia Kamella with the drawings and of Brendan Gibson in the translation of the text is gratefully acknowledged.

[25] Pairing is described in momentum space. Momentum space and real space transform into one another, as is obvious to a chemist from X-ray scattering. There is the visual approach in real space with only limited power of prediction (lattice planes acting as mirrors, Bragg equation) and the much more abstract but comprehensive approach in momentum space (reciprocal lattice, Laue equations).

[43] The (spurious) superconductivity mentioned in ref. [41] of $Lu_2Cl_2C_{2-x}$ could not be reproduced. It is due to impurities; see also ref. [44]. With luthetium the phase Lu_2Cl_2C, which contains no C_2 units, is the only accessible product [45]. $Y_2I_2C_2$ always yields smaller T_c values when prepared from educts in the stoichiometric ratio [46], as a part of the carbon apparently reacts with the Ta ampoule.

The three-dimensional representation of the ELF isosurface for methyl acetate (top) and sections corresponding to the planes drawn as well as to those parallel to the plane through the carbonyl group uncover many details about the distribution of electron density and can therefore contribute to supporting qualitative concepts and models. This is true not only for molecules but also for solids.

ELF: The Electron Localization Function**

Andreas Savin,* Reinhard Nesper,* Steffen Wengert, and Thomas F. Fässler

Dedicated to Professor Hans Georg von Schnering

The chemical bond is always considered from different points of view, depending on the classes of compounds or on the chemical and physical aspects to be examined. In both cases, descriptions of the chemical bond are chosen that are appropriate for the particular research or application. Therefore, there are significant differences in the understanding as what constitutes chemical bonding. This is acceptable in practice but proves to be a hindrance for true interdisciplinarity. The concept of the chemical bond offers a firm basis upon which to forge links not only within chemistry but also to all related sciences. The general desire and the growing necessity for interdisciplinary collaboration requires a careful treatment of these concepts and, if possible, a tightening and standardization to a level that is widely acceptable and beneficial. In the age of tremendously fast development of computers and computer science, we believe that the electron localization function (ELF) provides a new description of the chemical bond for almost all classes of compounds. Its graphical language earns it the ultimate qualification for enhanced interdisciplinarity.

Keywords: bond theory · electron localization function · structure elucidation

1. The Electron Localization Function—ELF

Chemistry—as we know it—without the Pauli principle is inconceivable. This principle is deeply rooted in so many chemical concepts that the connection is frequently neglected; for instance, the systematics of the periodic table, steric hindrance, and the covalent bond. The Pauli principle itself is also presented in various ways. In books on quantum mechanics it is often described as a property of the wave function, which needs to be antisymmetric with respect to interchange of electrons. From textbooks on chemistry one recalls mostly the fact that orbitals can be occupied by at most two electrons. The Pauli principle is reflected in the expression for the total energy of a system both in an energy-lowering part (the exchange term) and a larger energy-raising contribution, which can be found indirectly in the kinetic energy. The following explanation is usually used: The energetically higher canonical orbitals occupy the same space as the ones lower in energy but they must have additional nodal planes (in order to meet the criterion of orthogonality) and therefore a steeper behavior. Their appearance strongly resembles a growing precipitous landscape. The slope is expressed mathematically by the derivative; the latter can be found in the formula for the kinetic energy T [Eq. (1)], where φ_i are the orbitals and n_i their occupation numbers.

$$T = \int \frac{1}{2} \sum_i n_i |\nabla \varphi_i|^2 d^3r \qquad (1)$$

The Pauli principle has been used as a basis for the explanation of many chemical concepts. For example, Gillespie's explanation of his rules.[1] In this article we will show that most of these chemical concepts can be described very well with the electron localization function (ELF). The relationship of ELF with older concepts will be emphasized first.

Artmann was the first to introduce a formulation similar in concept to ELF.[2] In quantum mechanics, the sum of squares of the N-particle wave function corresponds to a probability density. Therefore he searched for the maximum of this quantity and found it to occur where the chemist imagines the bonds; for instance, in the case of the methane molecule, he observed four valence electron pairs arranged tetrahedrally around the carbon atom.[*] Examinations of the sum of the squares of the wave function are quite interesting but difficult to perform in practice (see for example ref. [3]). Lennard-Jones recognized that only two electrons of equal spin and therefore only two coordinates

[*] Artmann used an approximate valence electron wave function composed of hybrid orbitals.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3617-1809 $ 17.50+.50/0

are necessary for the examination of the Pauli principle, a significant simplification on the work of Artmann. Lennard-Jones found that space is divided into regions according to the Pauli principle. If an electron resides in a given region, the other stays away from that region. More precisely, if an electron resides at a place $\vec{r}$, the probability of finding an electron in the surrounding region $B(\vec{r})$ is clearly diminished. B remains practically unchanged as long as $\vec{r}$ stays in that region. The interaction of all particles under the condition of energetic stability defines the division into regions and is therefore always dependent on the system.

Even electrons with opposite spin avoid each other. This fact cannot be attributed to the Pauli principle and the effect is usually smaller by an order of magnitude. This is the reason why a given electron permits the presence of another with opposite spin in its region: the region is therefore occupied by a pair of electrons. Such a formation of pair regions corresponds exactly to the picture proposed by Kossel eighty years ago.[4]

Lennard-Jones went one step further in assigning every pair region a localized orbital. Such orbitals have only very small values outside their assigned regions. Sometimes they are denoted "chemical orbitals" because of their proximity to chemical definitions based on electron pairs (bond, lone pair of electrons) and therefore they are very useful. In addition, they can be used in the calculation of measurable quantities on equal footing with the common (delocalized, canonical) orbitals. The symmetry behavior of localized orbitals is different from that of canonical orbitals. By applying a symmetry operation, the latter (in the absence of degeneracy) always transform into themselves (except for the sign), whereas the former may be interchanged. In the ethene molecule the canonical (σ, π) orbitals are frequently considered. Their linear combination yields two equivalent localized orbitals often regarded as the C–C "banana bonds", which are interchanged upon reflection in the atomic plane.[*] The generation of localized orbitals can be problematic in symmetry groups allowing degeneracy: In practice just a minimal numeric effect can determine the localization. This can be seen, for example, in the benzene molecule[5] in which nine (six σ and three π) electron pairs are available. On the other hand it

[*] There are also localized orbitals that correspond to the C–H bonds and the 1s cores; they are interchanged for example upon inversion.

A. Savin

R. Nesper

S. Wengert

T. F. Fässler

Andreas Savin was born in 1950 in Bukarest, Romania, where he studied chemistry and received his diploma in 1973. He completed his PhD thesis in 1983 under the supervision of Professor H. Preuss at the Universität Stuttgart, where he also performed his habilitation. Between 1983 and 1993 he worked at the Universität Stuttgart, where he also lectured from 1985 onwards, and at the Max-Planck-Institut für Festkörperforschung. In 1993 he moved to the Centre National de la Recherche Scientifique in Paris. Since 1995 he has lectured at the Université Pierre et Marie Curie, Paris. His main areas of interest are density functional theory and the electron localization function as well as Monte-Carlo procedures and the application of quantum chemical methods.

Reinhard Nesper, born in Elze/Hannover, Germany, in 1949, studied chemistry at the Universität Münster and then moved to the Max-Planck-Institut für Festkörperforschung in Stuttgart where he received his PhD thesis under the supervision of Professor von Schnering. Apart from a period of research with Professor Roald Hoffmann at Cornell University in 1984, he was a member of the scientific staff at the Max-Planck-Institut Stuttgart from 1978 to 1990. In 1989 he received his habilitation at the Universität Stuttgart and in 1990 he accepted the chair of inorganic chemistry at the ETH Zürich. His main areas of interest are solid-state chemistry, structure determination, and the electronic structure of solids as well as new materials, nanostructures, structure–property relationships, and models for structure formation.

Steffen Wengert was born in Heilbronn, Germany, in 1964. He studied chemistry at the Universität Stuttgart where he also carried out his diploma thesis in theoretical chemistry. He then moved to the ETH Zürich to work with Professor Nesper and subsequently completed his PhD thesis on the topic of "experimental and theoretical solutions to fundamental problems in Zintl compounds" in spring 1997.

Thomas F. Fässler, born in Bad Waldsee/Reute, Germany, in 1959, studied chemistry and mathematics in Konstanz. In 1988 he received his PhD for work on transition metal cluster compounds under the supervision of Professor G. Huttner in Heidelberg. During a period of research at the University of Chicago with Professor J. Burdett he carried out fundamental theoretical studies on chemical bonding at metal surfaces. Since 1991 he has been carrying out work at the ETH Zürich towards his habilitation. His research interests are focused at the interface between molecular and solid-state chemistry, and involve the synthesis, structural characterization, and the study of the electronic properties of soluble Zintl ions, Zintl phases, and intermetallic compounds.

is not possible to generate nine equivalent regions on the six-membered ring (this is only compatible with three- or ninefold rotation axes, not with a sixfold axis). A similar situation arises for clusters such as the cage of $[B_6H_6]^{2-}$ in which seven pairs of electrons are available, which is incompatible with the icosahedral symmetry of the anion. Unfortunately, this problem appears frequently in solid phases.

The homogeneous electron gas represents an extreme case. Here, the pair region must also show a translational invariancy due to the translational symmetry of the Hamiltonian operator. To understand this phenomenon the analogy to resonance structures is quite helpful. Here, the best compromise is an average of the extreme cases.

Therefore, we will return to the original treatment by Lennard-Jones. He reduced the probability density of two electrons mathematically upon integrating over all coordinates of the remaining $N-2$ electrons. The resulting quantity (the pair density) is a function of the coordinates of two electrons, a six-dimensional function that is too complicated for our three-dimensional concept of the chemical bond that we want to develop here. A possible solution is to reduce the examination to a single electron, that is to consider the electron density. Its partitioning into contributions from different atomic orbitals is very common. The latter are not precise in the original formulation (Mulliken population analysis[6]) leading to a certain arbitrariness, which can be restricted by additional regulations such as those introduced by Davidson or Ahlrichs and co-workers.[7, 8] An additional variant is obtained by the use of "natural" bonding orbitals.[9] Bonding relationships are also discussed in terms of differences between molecule (or crystal) densities and those of atoms and ions. Nowadays, spherical atoms,[10] formerly used as a reference, can be substituted by nonspherical ones.[11] Finally, the elegant procedure of Bader and co-workers with no reference systems at all should be mentioned: only the density ρ as a function of the positional coordinates and their derivatives is used.[12] The Pauli principle can, of course, be found in the electron density, which is certainly different for bosons at a given potential. A clear connection is not easily discernible. For that reason we return to the pair density for the moment.

A solution, and at the same time a direct precursor to the electron localization function described in this article, was found by Luken and Culbertson.[13] They studied the modification of the region $B(\vec{r})$ upon substituting the point $\vec{r}$ by a neighboring point. It is small in the pair region, but becomes predominant on leaving the region (cf. the investigations of Lennard-Jones) and, as a consequence, these changes can serve in the determination of the borders of the pair region. An overlap integral is used to measure the change.

Becke and Edgecombe proposed the examination of the Taylor expansion.[14] They used the fact that for small distances $s = |\vec{r} - \vec{r}'|$ only the second derivative of the pair density P (spherically averaged around $\vec{r}$) for electrons of equal spin is important [Eq. (2)] and therefore the examination can be restricted to the value $C(\vec{r})$ which is dependent on $\vec{r}$.

$$P(\vec{r},s) = \frac{1}{2}s^2 C(\vec{r}) + \ldots \tag{2}$$

The simplest form of a wave function satisfying the Pauli principle, is the Slater determinant. In this case C can be expressed by Equation (3); thus, the electron density [Eq. (4)] as well as the sum $\sum_i n_i|\nabla\varphi_i|^2$ over the orbitals φ_i at $\vec{r}$ can be calculated.

$$C(\vec{r}) = \frac{1}{2}\sum_i n_i|\nabla\varphi_i|^2 - \frac{1}{8}\frac{|\nabla\rho|^2}{\rho} \tag{3}$$

$$\rho = \sum_i n_i|\varphi_i|^2 \tag{4}$$

Becke and Edgecombe proposed two additional scaling rules:
1. The homogenous electron gas is used as a reference. In this system, C depends only on the electron density [Eq. (5)].

$$C(\vec{r}) \rightarrow C_h(\vec{r}) \sim \rho^{5/3} \tag{4}$$

2. The introduction of a value which is defined between zero and one. Whereas this second scaling is convenient for comparison of numerical data, it does not play a decisive role (see Sections 2–6).

Becke and Edgecombe named the scaled function the *electron localization function* (ELF) [Eq. (6)]. ELF has its highest

$$\mathrm{ELF} = \left\{1 + \left[\frac{C(\vec{r})}{C_h(\rho(\vec{r}))}\right]^2\right\}^{-1} \tag{6}$$

value ($\rightarrow 1$) if $\vec{r}$ is within the pair region (where P does not change very much and C is small). On the other hand, ELF is small when $\vec{r}$ is close to the border between two pair regions.[15] In a homogeneous electron gas ELF has everywhere the value 1/2.

In solid-state physics the homogeneous electron gas is commonly used as a reference system. Another reason is the aforementioned average of extreme cases, which occurs in homogenous systems leading to an average picture. The value C_h can also be introduced independently from the homogeneous electron gas.[16] Instead of a Taylor expansion, Dobson proposed the integration over a small sphere,[17] leading to the number of electrons of equal spin in the surrounding of the reference electron. Thus, Equation (2) changes to give Equation (7).

$$\int_0^R \frac{1}{2}s^2 C(\vec{r}) 4\pi s^2 \,\mathrm{d}s + \ldots = \frac{1}{2}\frac{4\pi R^5}{5}C(\vec{r}) + \ldots \tag{7}$$

The radius of the spheres can be made position dependent, which keeps the number of reference electrons in a sphere with radius R unchanged. Equation (8) is valid for small spheres

$$\int_{V_{\mathrm{sphere}}} \rho(\vec{r}+\vec{s})\,\mathrm{d}^3 s \approx \rho(\vec{r})\frac{4\pi R^3}{3} + \ldots \tag{8}$$

around $\vec{r}$, where $R \sim \rho^{-1/3}$ and the number of electrons around the reference electron [see Eq. (7)] is proportional to $C(\vec{r})/\rho^{5/3}$ and $C(\vec{r})/C_h(\rho(\vec{r}))$.

It is evident from the definition of ELF in Equation 6 that the scale has been established more or less arbitrarily. This fact is irrelevant in graphical representations as the numerical scale is transformed into a (arbitrary) color scale or is shown in the form of isosurfaces (selected arbitrarily in three-dimensional representations). No information is lost as electron pairs and the chemical bond are first and foremost examined qualitatively. It must be mentioned that qualitative statements can also be described mathematically (for example the catastrophe theory of R. Thom,[18] which was used by Bader and co-workers[12] in analyzing the density). We now want to comment on this aspect in connection with ELF.[19] As we have decided to focus on the

characterization of pair regions, those regions where ELF exhibits maxima are of special interest. Mathematically, it is known that the positions of maxima may be sought by examining the first derivative of a function. For ELF they are fulfilled by the first derivatives of C/C_h; thus, for this property the second scaling rule is irrelevant. ELF can have several maxima. The positions of these maxima are denoted as *attractors*. The next step is the division of space by considering the path of steepest ascent (the gradient of ELF) from every point in space. If an attractor is found along this path, the point is assigned to it. All points in space from which this attractor is reached form its *domain* (Wirkungsbereich, WB). Thus, we obtain a more precise definition of the "pair regions".

Another way to analyze ELF is to examine the spatial region (the *f-localization domain*) in which ELF $\geq f$ is valid, where f is a constant.[19, 20] For larger values of f there is only one attractor in each of the f-localization domains. At a certain (smaller) f-value different f-localization domains come into contact at a single point (an ELF saddle point; again only the relation C/C_h is important because we are dealing with the first derivative). Smaller values of ELF lead to a merging of these localization domains: here the f-localization domain contains more than one attractor. The f-interval, where only one attractor in the f-localization domains exists (the difference of the ELF values at the maximum and the saddle point), is characteristic of the bond. The separation between the core and valence regions is more sharply defined than the separation observed within the valence shell. In particular, the separation of the regions of double-bond pairs is weak.[21]

Of course, quantitative statements can also be obtained with ELF. Quantifications of charge, volume, etc. can be determined. A total electron number can be obtained upon integration of the electron density in a certain domain (see Section 4.2). ELF yields electron numbers that are usually in agreement with chemical intuition, for example two for a region assigned to a pair of electrons. On the other hand, special electron numbers appear due to the above-mentioned overlap effects, such as $\approx 3/2$ for the C–C bond in benzene or ≈ 8 for the valence shell of the Ne atom.[22] Remarkably in ionic solids, ELF predicts electron numbers that correspond to those derived from formal charges.[23]

The precision of the determination of such electron numbers is interesting. According to the Heisenberg uncertainty principle, the above-mentioned numbers can only be considered as mean values. But it is possible to get average deviations. These deviations are relatively small when dealing with atomic cores, whereas for valence electrons they are larger.[21] More sophisticated calculations show that the partition obtained by ELF resembles the one yielding the smallest uncertainty.[24]

Although ELF is currently only obtainable from calculations, it is, in principle, possible to derive ELF from experimental data. Certainly, the evaluation of the sum of the squares of the wave function (and the pair density) according to the postulates of quantum mechanics is a possibility; but this is more difficult to realize. Therefore, we want to show how ELF can be determined from the electron density alone, and in the following we present a definition of ELF equivalent to that given before.[25]

A computational method that is successfully applicable for molecules as well as for solids is based on the (exact) density functional theory defined by Kohn and Sham.[26] Therein the ground state energy is exclusively determined from the electron density. The terms in the energy expression can either be easily calculated from the density (the classical interaction of the charge distribution), or sufficiently approximated (the exchange and correlation energy). However, the construction of the kinetic energy can cause difficulties if the Pauli principle is neglected. In the density functional theory defined by Kohn and Sham, the kinetic energy of a hypothetical system T_s with identical density but no interaction between the particles is calculated instead of the kinetic energy from Equation (1). This leads to a simplification and the ground state function is (usually) a Slater determinant so that the orbitals in Equations (1) and (4) are not singly or doubly occupied (i.e.: $n_i = 0$, 1, or 2).

If the Pauli principle is ignored, it has been shown[27] that all electrons will occupy the orbital of lowest energy, which is defined by $\varphi_i = \sqrt{\rho(\vec{r})/N}$ (N = electron number). Therefore it is possible to evaluate the increase in kinetic energy that occurs on consideration of the Pauli principle [Eq. (9)].

$$\Delta T = \int \left[\frac{1}{2} \sum_i |\nabla \varphi_i|^2 - \sum_i \left| \nabla \sqrt{\rho(\vec{r})/N} \right|^2 \right] \mathrm{d}^3 r \qquad (9)$$

Upon applying the same scalings used for ELF (electron gas, interval (0,1)), the integrand yields a local value that corresponds exactly to the expression of the ELF formula [Eq. (6) with Eqs. (3)–(5)]. These orbitals, which yield the exact density, are not easily obtained from the electron density, but this is possible with several algorithms and programs (see, for example, ref. [28]).

To investigate the role of approximations in ELF calculations, densities (and no other information) determined by exact calculations on small atoms were used. ELF values were obtained that fortunately do not differ significantly from the Hartree–Fock (HF) and density functional calculations that are routinely carried out.[29] Even rather simple methods, such as the extended Hückel method (EHMO), reveal the characteristic features of ELF.[16, 30, 31] There are other interpretations of ELF but all of them are based on the Pauli principle.

2. Fundamental Studies of the Chemical Bond

In the first publications on the practical applications of ELF, the ability of the function to generate easily understood pictures of the chemical bond for many different chemical systems was demonstrated.[32] Subsequently, many more chemical systems have been examined, all of them substantiating this result: ELF yields very meaningful, easily understandable, and visually informative patterns of the chemical bond. In this section we want to analyse some typical chemical bonding forms with ELF. We will demonstrate how ELF portrays these forms, and the similarities and differences to other existing methods will be highlighted. It has been shown that pictures obtained with ELF by using different theoretical calculation methods are qualitatively comparable (see Section 1). Here, we present results obtained by using the relatively simple extended Hückel approximation[33] and the more sophisticated ab initio linear-muffin-tin orbital method (LMTO).[36]

A single krypton atom serves as an example to explain the shell structure of atoms in the ELF pattern. Figure 1a shows

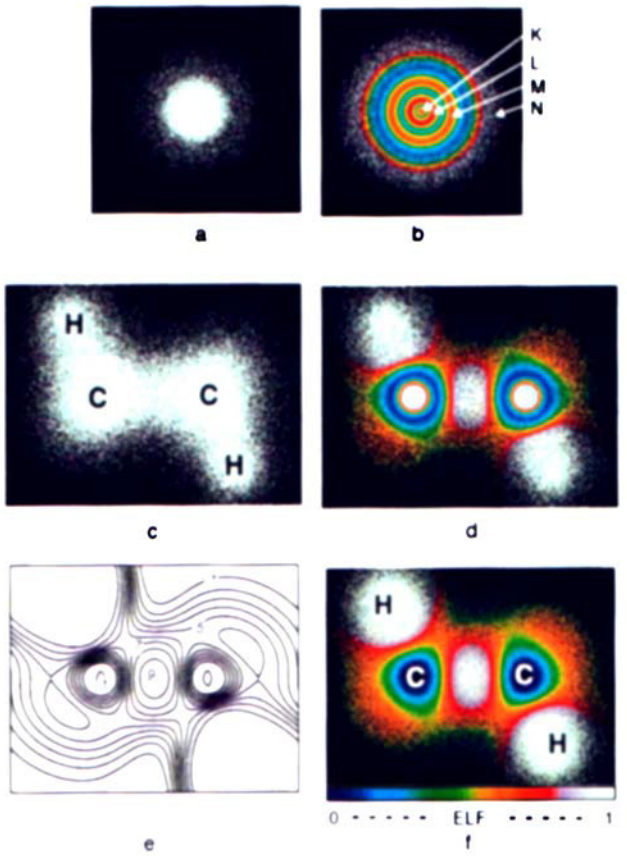

Figure 1. Distribution of electron density a) in a section through a krypton atom, c) in a section through an ethane molecule and coloring with ELF b) and d), respectively, based on HF calculations. The color scale for all such ELF representations corresponds to that given in Figure 1 f. e) and f) Representation of ELF for the EHMO valence electron calculation of ethane with contour lines and the corresponding ELF representation with colored valence electron density, respectively.

only the electron density for the free atom, whereas in Figure 1 b this point pattern is colored according to the ELF values. Thus, in such two-dimensional graphical representations the electron density (as a density of points) and the ELF values (coded in a color scale in analogy to a geographical map) are depicted simultaneously. High ELF values (approximately 0.8 to 1.0) are colored white; the series descends through brown and yellow to green for middle ELF values (ca. 0.5). The lower end of the scale is represented by blue and violet.[39] Of course, it is possible to reproduce ELF in two dimensions by using contour line diagrams. In three-dimensional representations, isosurfaces are shown for each chosen ELF value.

Four separate localization shells with varying degrees of contraction and compactness can be recognized in the krypton atom. In the course of our discussion we will focus on the regions that can be assigned to either atomic cores or to valence electrons. Figures 1 d–f depict the ELF representations for sections through the ethane molecule along the C–C bond. It is known that the electron density is poorly structured (Figure 1 c), whereas all chemical details of the structure can clearly be discerned in the ELF representation: the C atom cores and the C–C as well as the C–H bonding regions. The latter are diffuse and also show the H positions. In the EH valence electron calculation (Figure 1 f), regions of low localization appear instead of the C-atom cores. A similar result is obtained with calculations using pseudopotentials. In such calculations, the problem is restricted to the quantum mechanical treatment of valence electrons, while interactions with the core electron density are substituted by effective potentials. Figure 1 e depicts ELF in terms of a contour line diagram.

In the series ethane, ethene, and ethyne (Figure 2) differences between covalent single, double, and triple bonds are clearly seen.[40] This is valid for both representations: the two-dimensional (2D) cross sections in Figures 2 a, c, e, and g as well as the three-dimensional (3D) isosurfaces in Figures 2 b, d, f, and h. It

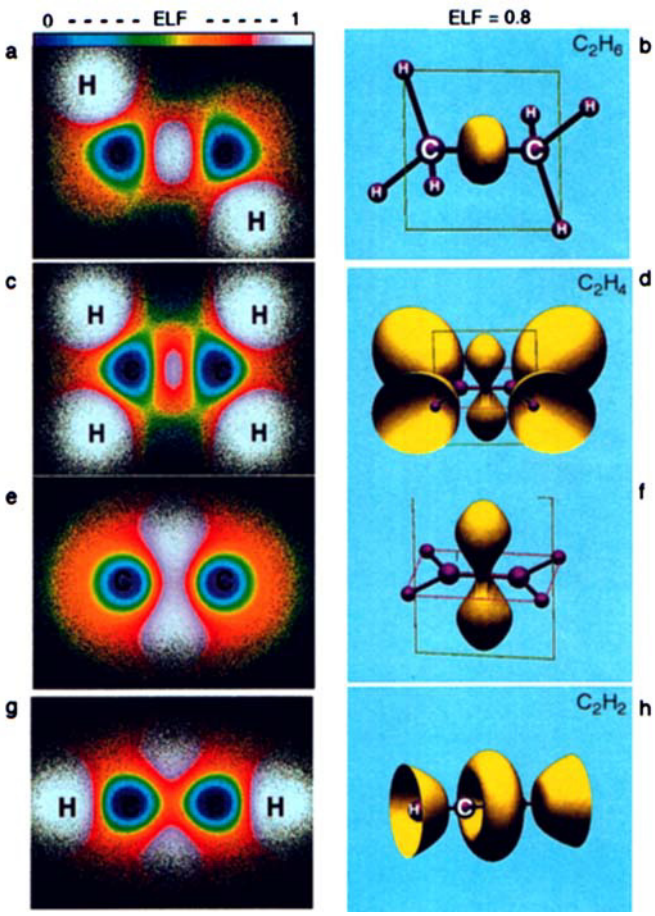

Figure 2. Left: 2D cross sections (EHMO calculations) through the molecules a) ethane, c) and e) ethene, and g) ethyne. Right: 3D representations of ELF isosurfaces with ELF = 0.8, b) ethane, d) and f) ethene, and h) ethyne. The planes around the hydrogen atoms are either not shown or only cut.

should be pointed out here that the number and form of the localization regions are strongly dependent on the choice of the isovalue. An isovalue of ELF = 0.8 has proven to be a useful standard for the classical valence compounds; this corresponds to the white-orange border in the 2D cross sections. In both representations an increasing contraction of the σ-like region along the C–C axis is observed with the increase of bond order. The 3D representation of ethyne gives the impression that only a localization torus is present. HF calculations using a double-zeta basis set and polarization functions[29] show that this is correct in principle. With both methods (EH, HF) the highest electron density is found on the core–core connecting line (Figure 2 g) but the highest ELF values are found outside (Figure

2f). The torus obtained from EH calculations is more distinctive. In conclusion, this result corroborates the formally equivalent descriptions of double bonds previously formulated by Pauling:[41] the banana or bent bonds and the σ-π-bonding model.

In electron-rich compounds, lone pairs of electrons play an important role in structure formation. Their structure-directing influences are summarized by the rules of Nyholm and Gillespie (VSEPR model[1]). These rules have been used successfully for decades and although they are more or less intuitive, only recently have quantifications been attempted.[42]

Figure 3 shows the 3D ELF isosurfaces for PF_3, SF_2, ClF_2^-, and ClF_3. As expected, the geometrical distributions of lone

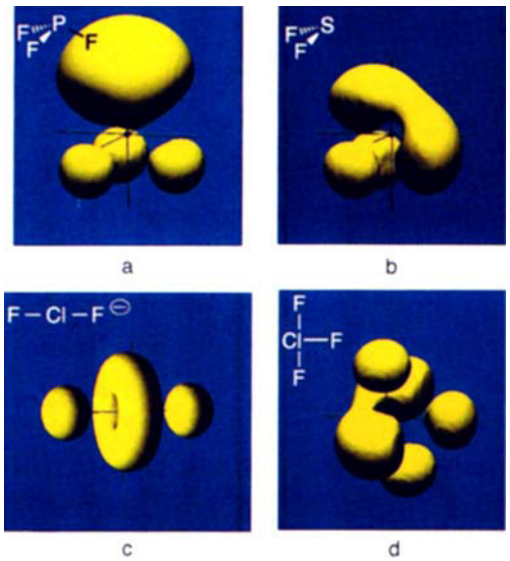

Figure 3. 3D representations of ELF isosurfaces with ELF = 0.8 for molecules differing in the number of lone pairs (based on EHMO calculations): a) PF_3; b) SF_2; c) ClF_2^-; d) ClF_3. The positions of the fluorine ligands (within the yellow ELF regions) can be taken from the given structure formulae. The central atom is located at the origin of the coordinate system shown in each figure.

pairs of electrons and bonding electron pairs and ligands correspond in principle to the VSEPR model: extended regions of lone pairs of electrons and relatively compact, almost spherical localizations around the F ligands. A closer inspection of the latter reveals a division in regions of element–F bonds and lone pairs of electrons at the F center.[16, 32] The contraction of the lone pairs of electrons is very evident in going from the relatively extended region at P in PF_3 to the compact torus at Cl in ClF_2^-.[43] The exceptional *anti*-position of the lone pairs of electrons both in SF_2 and ClF_3 is more distinctive than expected from the VSEPR model.

The topological similarity between ethyne C_2H_2 (Figure 2h) and ClF_2^- (Figure 3c, ref. [44]) is also interesting. These units are clearly distinguished by chemists but they are equivalent with respect to the attractor model (see Section 1). In other words, the attractor may be bonding (C–C bond) as well as nonbonding around the Cl atom. In this sense it is possible to deduce a hierarchical relationship even for these two simple species (ref. [121], see Section 7.2): the topology of the attractors is the same but the chemical structure realized therein is diversely complex.

In addition to the examination of the real electron space, cores, bonds, and lone pairs and their mutual interactions, become visible in simple molecules. In organic chemistry these interactions are understood by using qualitative concepts. Methyl acetate CH_3COOCH_3 serves as an example (Figure 4).[40] The three-dimensional representation of the ground

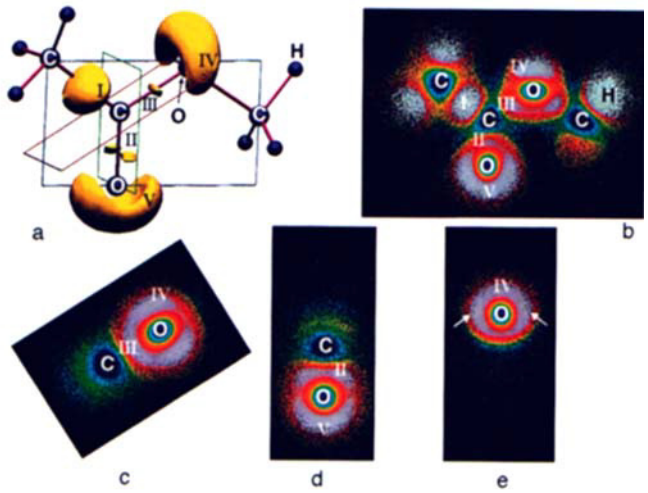

Figure 4. a) 3D representation of the ELF isosurface ELF = 0.85 (EHMO calculations) for methyl acetate. The regions around the hydrogen atoms are not included. For ELF = 0.80 the regions of the lone pairs (IV and V) are no longer separated from the neighboring C–O bonding regions (III and II, respectively). b)–e) 2D cross sections through different planes: b) through the plane drawn in blue in (a); c) through the plane drawn in red in (a); d) through the plane drawn in green in (a); e) through the plane parallel to that drawn in (d), which contains the oxygen atom of the ester.

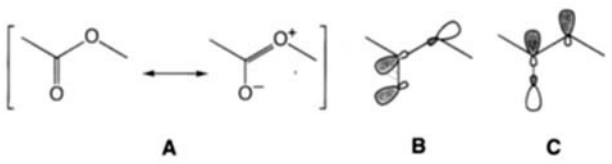
state conformation contains an ELF isosurface showing extended localization domains for the lone pairs of the carbonyl and the oxygen atom of the ester. In addition there is a relatively extended region that includes the C–C bond (for clarity the C–H bonds were not included in the calculation of ELF). On the other hand, the regions of C–O single and double bonds are comparatively strongly contracted but show the expected distributions with respect to the core–core bond lines. ELF sections were calculated for planes through the molecule (Figures 4b–e). The cut through the C–O ester bond perpendicular to the molecular plane (Figure 4c) shows a broadening in the bond region in agreement with a double-bond contribution as given in Scheme 1A. Such an ELF analysis is helpful in the assignment of resonance formulae. Furthermore, a n-σ* anomeric effect is expected between the lone pair at the carbonyl oxygen atom and the σ bond to the ester oxygen atom (Scheme 1B). This should lead to a deformation of the ELF distribution around the oxygen atom of the carbonyl group, as can indeed be seen (Figure 4b, regions II and V merge asymmetrically). However, the n-σ* interaction in the ester bridge (Scheme 1C) is not supported by ELF, though the difference in the comparable sections through the oxygen atoms is striking (Figure 4b region V and Figure 4e region IV). The ELF distribution at the oxygen atom of the ester has a slight p-characteristic (the local maxima facing each other in region IV of Figure 4e, marked with arrows), which may be interpreted in terms of a reduction of the s part of the lone pairs (Scheme 1C).

Investigations of carbosilanes proved ELF to be a powerful tool in the comprehension of complicated bonding systems. It was shown for 1,3-disilacyclobutane that there is no (not even



Scheme 1. Bonding features in methyl acetate.

weak) bond between the two Si centers in spite of a relatively short interatomic distance. Therefore an alternative interpretation was necessary: the Si–C bonds appear as bent bonds in the ELF analysis, and they can be interpreted in terms of a bent bond between two building blocks, which differ in size but retain tetrahedral angles at the cores. From this description it follows that the relatively short Si–Si distance is a geometrical consequence of the bent Si–C bond.[45] Analogously, the bond shortening in C_2H_4 compared with that in C_2H_6 was previously explained by Pauling with the assumption of bent bonds.[41]

2.1. Covalent versus Ionic

The division of chemical bonds into homopolar or primarily ionic bonds has proved to be very useful in the language and comprehension of chemistry. Naturally, the ideal covalent bond is simply defined in element–element bonds but, strictly speaking, only when the surroundings of both bonding partners are identical. The ideal ionic bond with a complete charge transfer does not exist. In general, a bonding interaction intermediate to ionic and covalent bonds is observed: a polar bond.[46]

The definition of the range of influence for ELF attractors permits a new formulation of ionicity in which the delimitation and mutual significance of covalent and ionic parts is simplified.[47] First, a qualitative impression is gained upon analyzing the form of the attractors. If they are more spherically distributed around the cores either a more ionic or a van der Waals interaction is present. If the covalency of a bond increases, the migration of the attractor becomes more distinctive between the centers until a totally symmetric topology is achieved in the ideal covalent case. The position of the attractor between the centers can quantitatively be used to define the extent of polarity of a chemical bond.[48] As long as the attractor lies on the line connecting the cores and can be separated from the cores themselves by a trajectory, and the attractor does not circumscribe the core, a situation is reached that is usually described as polar covalency. An ionic formulation is suitable if the attractor is close to the core region of one of the atoms and no longer on the connecting line. One must take into account that no clear separation is possible.

The combination of the division of the electron density according to Bader[12] and ELF in domains (WBs) is a second way for a complete quantitative description of the chemical bond. The actual charges of the atoms can be determined by the partition of the density in ranges of atomic influence. The covalent contribution of the bond is obtained by the number of electrons in the mutually shared electronic range of influence and attractor (partition of ELF). This is illustrated in Section 4.2 with the results of calculations on several intermetallic phases.

2.2. ELF in Simple Crystal Structures

The investigation of structure and chemical bonding is frequently carried out with a small number of ELF plots, where series of structures can visually be compared. In this way the language of ELF can be learned "simply", asking the basic question: "what happens if...?". Figure 5 illustrates ELF for sections through simple structure types with primitive cubic arrangements and their AB variant, the rock salt structure, (Figures 5a–d), as well as the diamond structure and its AB variant, the zinc blende structure (Figures 5e–h). The ELF obtained from LMTO calculations on the isoelectronic series silicon ("SiSi"), AlP, MgS, and NaCl are shown. The corresponding hypothetical modifications are given in quotation marks.

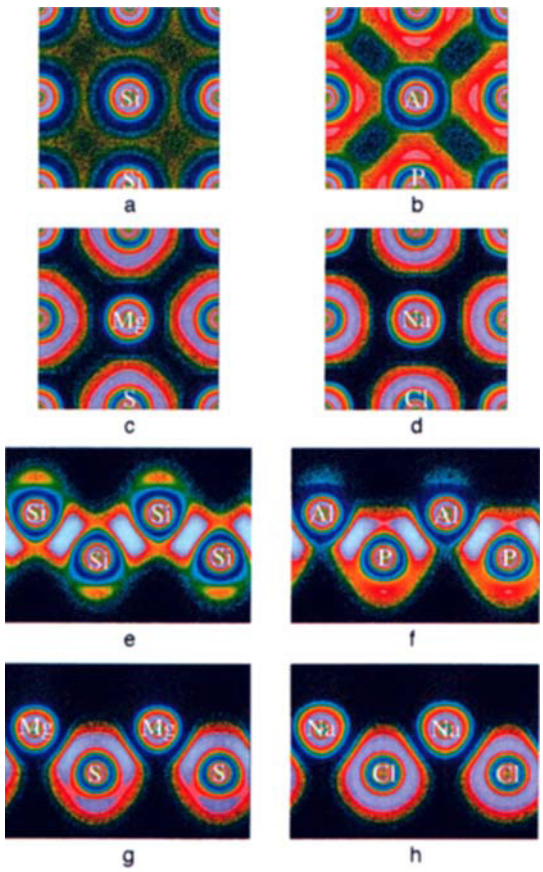


Figure 5. ELF sections (based on LMTO calculations) for the (100) surface of a) a hypothetical primitive cubic structure of silicon, as well as for the rock salt structure for b) AlP, c) MgS, and d) NaCl. The increasing concentration of regions of high ELF values on spherelike shells around the cores is evident. e)–h) Actual and hypothetical modifications of diamond structure: e) silicon, f) AlP with a clearly increased bond polarity, g) MgS with polarized "S^{2-} ions", and h) NaCl with clearly separated but still polarized anions.

"Silicon" in a primitive cubic arrangement would be really lost in a metallic state: the valence electrons are totally delocalized over that region which is not covered by the cores (Figure 5a). A localization of ELF ~ 0.7 is rather high with respect to the free electron gas (ELF = 0.5). For the corresponding "AlP" phase, ELF provides an almost perfect example of a polar bond: it increases in a wedge-shaped fashion from the Al core to the phosphorus atom, where it merges with five other

equivalent localization domains (Figure 5b). It should be mentioned that the individual localization regions can be separated by trajectories of minimal function values (orthogonal trajectories). This can be used for the division into domains (WBs) and for subsequent quantitative evaluations (see Section 4.2).

For MgS, ELF indicates a more ionic structure. The soft S^{2-} ions are polarized, resulting in an octahedral distortion of the spherical symmetry (Figure 5c). In NaCl, a region of high localization with nearly spherical symmetry is found around the anion (Figure 5d). If a corresponding division of ELF is made, no attractors can be found between the Na and Cl atom pairs. Rather an alignment of the attractors is found as expected on the basis of the VSEPR or ligand field theory.[49] The six attractors around the chloride ion are directed precisely between the Na neighbors. Whether the disappearance of the attractors from the line connecting interatomic centers is suitable for a sharp separation of polar-covalent and ionic bonds must be further investigated as very polar π or δ interactions cause similar effects.

From the general evolution of the localization in the former case it can be concluded that an increase in the localization in the vicinity of certain attractors leads simultaneously to its decrease in the interstitial regions. With respect to the free electron gas, whose density is totally uniform and revealed by the green coloring in ELF (see Section 1), a more or less distinctive localization of electrons takes place in every structure. In the primitive cubic packing of identical atoms (Figure 5a), the proximity to the electron gas is even more pronounced. For example, Savin showed a dramatic alteration of the localizations with different valence electron numbers in the fcc structure. For calcium (2e per atom) the localization regions are in the octahedral holes, whereas in aluminum (3e per atom) the regions of highest localization are always found between the Al pairs[50] (see Figure 12o). On average, the localization for silicon in the bonding region is even higher but the distribution is distinctively less structured than in the aluminum case.

In compounds exhibiting the diamond structure (Figure 5e–h), localized regions are only present in sections of ELF along the plane diagonal of the unit cell ([110]). In this series the localization maximum is again shifted stepwise along the core–core connecting line towards the more electronegative atom. The position of the ELF maximum can be used to measure the extent of the polarity of the bond. Even for "NaCl", a considerable deviation from the spherical symmetry of the anions is observed (Figure 5h). Examination of the plots reveals that AlP appears to be predominantly covalent, whereas "MgS" and "NaCl" are more ionic, because of an increasing spherical distribution of the localization around the anions. In "NaCl" the appearance of a strongly polarized anion is predominant. In AlP and MgS it is possible to clearly distinguish between the regions of localization of high ELF values. For the more ionic compounds, such distinctions are hardly or often not possible. The immediate impression gained from these ELF representations confirms those gleaned from chemical intuition.

Similar ELF investigations of the diamond structure for the elements carbon, silicon, germanium, and tin also show interesting trends; a reduction of localization in the two-electron–two-center bond, while the localization in the interstitial region increases continuously.[25] The comparison of α- with β-tin clearly verifies that in the latter a much lower localization is present than in the diamond modification.[25]

2.3. Bonds between Metals

One faces the metallic bond as if one is meeting an alien: with suspicion, lack of understanding, and a certain respect. The actual meaning of the term "metallic bond" is complex with many variations and we will examine it in more detail in Section 4. First we consider the smallest metal aggregations, biatomic clusters[16] such as $[Re_2(CO)_{10}]$, $[W_2(CO)_8]^{4-}$, and $[Mo_2Cl_8]^{4-}$. The question is: may bonds between transition metals be resolved as well as those between main group elements?

According to the 18-electron rule $[Re_2(CO)_{10}]$ and $[W_2(CO)_8]^{4-}$ should have one and two metal–metal bonds, respectively. Four metal–metal bonds are expected in $[Mo_2Cl_8]^{4-}$. Figures 6a–c present the structures of these clusters with the accompanying 3D ELF isosurfaces as calculated with the EH method. As expected, for $[Re_2(CO)_{10}]$ a rotationally symmetric localization is found between the metal centers that is relatively small compared to the localization regions around the CO ligands (Figure 6a). This holds also for the two other clusters: the corresponding localization regions are very compact in spite of the contribution of 4d and 5d states. This is generally observed

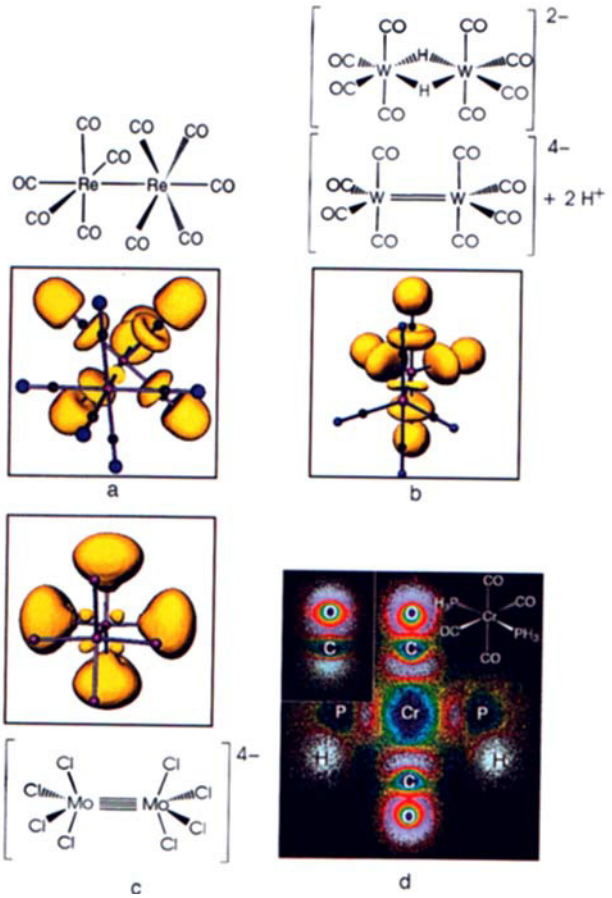

Figure 6. 3D representation of the isosurface ELF = 0.80 for molecules with a) metal–metal single, b) metal–metal double, and c) metal–metal quadruple bonds (EHMO calculations). d) 2D section through a plane in $[Cr(CO)_4(PH_3)_2]$ and 2D cross section through a free carbon monoxide molecule (insert).

in systems containing transition metals. As a rule, regions of ELF with high contributions of d states are rather small both with respect to the ELF values and the volume.

In the case of $H_2[W_2(CO)_8]^{2-}$, a π-like distribution between the metal centers is indeed observed in the deprotonated form $[W_2(CO)_8]^{4-}$ (Figure 6b). Of course, in this case the double bond is aligned in this special way only because the arrangement of the CO ligands breaks the degeneracy of the two possible π states. The two possible formulations $2H^+ + [(CO)_4W{=}W(CO)_4]^{4-}$ and $[(CO)_4W(\mu_2\text{-}H)_2W(CO)_4]^{2-}$ again show the hierarchical relationship, which is evident at the ELF attractor: the attractor is able to accommodate electrons as well as atoms and ions or multicentered groups without changing the topology of the total system.

For $[Mo_2Cl_8]^{4-}$, ELF shows four localization regions around the line connecting the M centers. This can be understood in terms of four bent bonds (Figure 6c). Taking into account that the point group D_{4h} allows only a twofold degeneracy, a principal difficulty arises, which also appears in the MO description of methane. The problem is that we do not have a "natural sense" for degeneracy caused by symmetry. At first the chemistry student is surprised at the strange partitioning of spherical symmetry into one s, three p, five d, seven f etc. representations but this is quickly accepted. It is a matter of debate whether $[Mo_2Cl_8]^{4-}$ actually "believes" its electronic structure may be reduced into irreducible representations. It must be emphasized that ELF always provides a picture that corresponds to the full symmetry of the respective group. This property is reminiscent of the symmetry-adapted hybrids of the VB theory, but it must be stressed that in contrast, ELF is always unambiguous.

Finally the ELF at the ligands is also worth mentioning. A comparison of the CO groups in Figures 6a, b reveals an extended region that surrounds the polar triple bond and the lone pair around oxygen. In $(H^+)_2[W_2(CO)_8]^{4-}$ it is smaller and more round, whereas the region between W and C atoms is more extended. Figure 6d shows the sections of ELF through an isolated CO molecule and in the octahedral complex $[Cr(CO)_4(PH_3)_2]$. Clear displacements of the localization regions are found when the free and bound CO molecules are compared. Here, the differences between a strong CO–Cr and a normal donor P–Cr bond are evident. Similar results were obtained recently by Kaupp in the analysis of two-center carbonyl clusters with terminal and bridging CO ligands.[51]

To substantiate this result we carried out EH calculations on the following series: free CO, $[CO{-}Cr(CO)_5]$, and $[CO{-}Cr(CO)(PH_3)_4]$ (Figure 7[52]). A distinct bonding effect between chromium and the CO ligand is expected and can clearly be seen by comparing the left part and the center of Figure 7. In $[CO{-}Cr(CO)_5]$ the attractor lies on the Cr–C bond axis (center), whereas in $[CO{-}Cr(CO)(PH_3)_4]$ this axis is surrounded by a torus (right), which indicates the presence of π-bonding contributions. In the first case the metal–ligand backbonding is relatively weak because the Cr center has to distribute its electrons evenly onto six ligands; thus, the σ character is dominant.

From these examples it is evident that in organic molecules (Section 2, Figure 4) as well as in complexes, weak effects such as changes in the behavior of backbonding become directly visible with ELF.

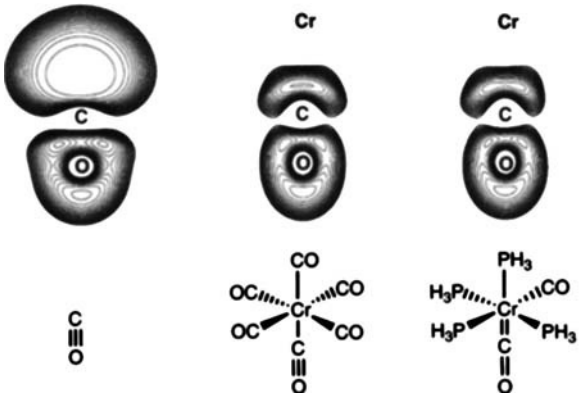

Figure 7. Contour line representations of the ELF (EHMO calculations) through a free CO molecule (left), CO complexed in $[Cr(CO)_6]$ (center), and in *cis*-$[Cr(CO)_2(PH_3)_4]$ (right) with the corresponding valence line formulae.

2.4. Clusters, Multicenter Bonds, and the Principle of Duality

The boranes, carboranes, and naked clusters (especially those of the heavier elements of group 14) form deltahedral clusters that may be understood with the aid of Wade's rules.[53] Here, terminal lone pairs and terminal bonds on the cluster are separated from the framework states as one- or two-center states. The framework bonds can be formally described as local three-center interactions in the sense of closed three-center bonds.[54] However, this leads to problems because, as a rule, there are more triangles than occupied framework states in *closo* deltahedrons. Here, a kind of inverse problem to that discussed in both the examination of multiple bonds (Section 2.3) and benzene (Section 1) arises. This forces the formulation of mesomeric structures, that is formulations coinciding with the phenomenon of delocalization (at least in the conventional sense).

What pictures are provided by ELF with regard to framework electrons and framework–ligand interactions, and how do ELF distributions change with respect to the number of framework electrons?

The first ELF examination of boron clusters revealed a pronounced duality between the polyhedral framework and the localization regions. The latter form the dual tetrahedron for the tetrahedral B_4H_4 framework, a cube for the octahedral $B_6H_6^{2-}$ ion, and a pentagonal dodecahedron for the icosahedral $B_{12}H_{12}^{2-}$ ion.[30] Recently theoretical studies based on experimental investigations were carried out on B_9X_9 (X = Cl, Br, I), the findings from which add further support to this interpretation.[55]

Figure 8c shows ELF for a $B_6H_6^{2-}$ cluster.[16] The localization regions above the planes are clearly seen and simultaneously a noticeable localization appears above the edges. A systematic study of ELF versus the number of framework electrons n_G reveals localization regions that are either spherical ($n_G = 2$, Figure 8a), concentrated above planes ($n_G = 8$, Figure 8b), distributed above planes and edges ($n_G = 20$, Figure 8d, Wade's framework electron number), or only above the edges ($n_G = 20$, Figure 8d). For main group element clusters, twenty electrons corresponds to a strongly antibonding situation. If d states are present at the metal centers up to twelve orbitals must be occupied before antibonding states are reached. The $[Mo_6Cl_8]^{4+}$ group found first in $MoCl_2$[62] has 24 framework electrons and

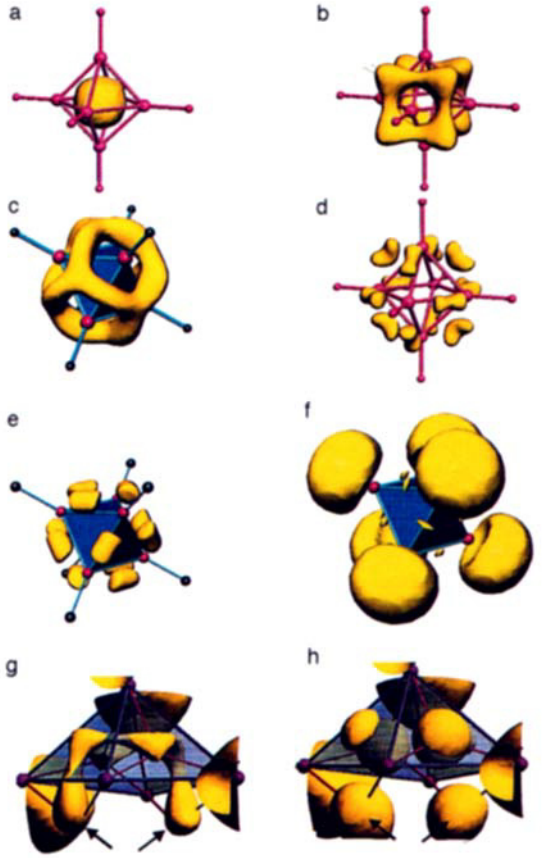

Figure 8. 3D representations of the ELF = 0.80 isosurface for different cluster molecules (EHMO calculations). a)–d) Octahedral clusters with different numbers of framework electrons n_G, each calculated with the parameters used for the calculation of $B_6H_6^{2-}$. For details see text. e) $[Sn_6H_6]^{4+}$ as a model for $[Sn_6(Cr(CO)_5)_6]^{2-}$. f) The corresponding hypothetical $[Sn_6]^{2-}$ ion without transition metals. g) and h) ELF isosurfaces of the square-pyramidal clusters $[Zr_5Cl_{12}(PMe_3)_5]^{4-}$ and $[Zr_5Cl_{12}(PMe_3)_5H_4]$, respectively, together with the structure of the Zr_5 cluster unit. The Cl and PMe_3 ligands are omitted for clarity. The arrows mark the positions of the bridging hydrogen atoms. In addition to the spherical localization regions of the four hydrogen atoms, h) shows two smaller regions that are found in the unoccupied triangular planes. The ELF isosurfaces of the isoelectronic and formally fourfold deprotonated cluster in g) are very similar: four almost equal regions above the triangular planes and two distinctive ones above the open plane of the cluster. See text for details.

is representative of the latter situation. For such systems variable numbers of framework electrons ranging from 19 to 24 have been verified experimentally.[56]

The duality relationship was already pointed out in investigations of metal carbonyl clusters[51] and for clusters in intermetallic phases.[57] Again, this is only valid for certain numbers of framework electrons, for example for main group element clusters with electron numbers close to those predicted by Wade's rules.

There are typical examples of octahedral clusters with different electron counts (Figures 8a–d) that sometimes contain condensed rather than isolated polyhedra. The ELF distribution with two framework electrons is shown in Figure 8a. The octahedral Li_6C group is an example of such a two-electron system, for which a totally symmetric lithium-centered framework state has been calculated.[58] To our knowledge, the eight-electron case (Figure 8b) has never been observed. Here, the duality between the framework structure and ELF is most evident. Wade's electron number for the octahedron is achieved with 14 electrons, whereas the 15e and 16e systems are realized in the well known clusters $[Nb_6X_{12}]^{3+}$ and $[Nb_6X_{12}]^{2+}$, respectively. Here, almost equally pronounced localization regions above planes and edges of the polyhedron are found as well, but with a slight accentuation above the planes. Clusters with 19 to 24 framework electrons like Nb_6I_{11}, HNb_6I_{11},[59,60] the Chevrel phases,[61] and $[Mo_6X_8]^{4+}$ are examples of 20e systems with very distinctive concentrations of regions of high localization above the edges of the polyhedra (Figure 8d). The shape of the localization regions in $B_6H_6^{2-}$ as well as in $[Zr_6Cl_{18}]^{8-}$ and $[Nb_6Cl_{18}]^{4-}$ (14 and 16 framework electrons, respectively) is almost identical. With regard to the framework atoms, the localization regions are located outside of the B_6 cluster, but inside of the clusters in the other two metal polyhedra.[52,66] Two possible reasons for this are: first, the different size of the polyhedra and the relation of orbital expansion to edge length, and second, the different interactions and repulsions between ligands and framework electrons.

Several examples of clusters with different numbers of valence electrons exist. For instance, $[AuPR_3]_4^{2+}$[63,64] and Li_4^{2+} contain two framework electrons, B_4Cl_4 and C_4R_4 eight, and Si_4^{4-} and P_4 twelve. A corresponding spherical distribution is found in ELF. Four localization regions above the planes and six above the edges[16] may be seen in ELF and can be interpreted in terms of bent bonds over the planes.[45,67,68] As in the dinuclear metal complexes mentioned previously (Section 2.3), the mutual distribution of ligands and localization regions of the framework is also apparent here: if the ligands are electron-rich octet systems, the ligands and localization regions avoid each other. Here, a kind of higher hierarchical level of the ligand field theory is found. The form and the number of the attractors is not only determined by the type of the occupied framework states, but also by the type of the ligands and their distribution. Therefore, it should be possible to transfer effects like the Jahn–Teller distortion and ligand-field induced changes, which are well understood for mononuclear metal complexes, to topologically related larger systems, that is on a higher hierarchical level. This was carried out many years ago on M_6 clusters such as M_6X_8 and M_6X_{12} by Simon.[56] ELF is especially suitable for the observation of such effects in real space.

Figures 8e and f show the comparison of the clusters $[Sn_6H_6]^{4+}$ and the hitherto unknown naked cluster $[Sn_6]^{2-}$; the former is used as a model for the recently published cluster $[Sn_6(Cr(CO)_5)_6]^{2-}$. It is clearly seen that electrophilic ligands are bound at the cluster vertices (Figure 8f). Further ligands would approach the localization regions of the framework. If there are ligands at the edges and vertices of the cluster, localization regions are found at the faces. This is validated experimentally. In $H_7Th_6Br_{15}$, seven of the eight planes of the octahedron are occupied statistically by H atoms. Presumably, they can easily tautomerize above the localization regions on the plane centers and would as such be carried along the localization regions by an "overhead cable".[30] Experimental and theoretical examinations carried out on the $B_6H_7^-$ ion verify such behavior.[69,70] According to quantum mechanical calculations, the two H atoms in $H_2B_9Br_9$ with *anti*-conformation are distributed over two planes of the B_9 polyhedron.[55]

Protons bound on cluster surfaces often give rise to problems in structure determination as illustrated in the following example. A compound containing octahedral Zr_6 clusters was ini-

tially published as $[Zr_6Cl_{14}(PR_3)_4]$,[71] and subsequently proven to be $[Zr_6Cl_{14}(PR_3)_4H_4]$.[72] In the structure determination of $[Zr_5Cl_{12}(PR_3)_5H_4]$, which features a square-pyramidal Zr_5 framework, the position of the protons were determined crystallographically.[73] Two of the protons are located in opposite triangular planes of the Zr_5 pyramid and two protons bridge the opposite edges of the open square plane (Figures 8g and h). Whereas the positions in the triangular planes are located in or above the center of the Zr_3 triangles for reasons of symmetry, there are more degrees of freedom for possible positions above the edges. The ELF investigation of the fourfold deprotonated cluster $[Zr_5Cl_{12}(PR_3)_5]^{4-}$ (Figure 8g) shows four local maxima in the triangular planes and two very pronounced localization regions caused by a slight asymmetrical distribution of the chlorine and phosphane ligands. Their centers correspond exactly to the crystallographically determined positions of the hydrogen atoms.[52] The localization regions are determined only by the electronic structure of the cluster framework and the remaining ligands, independently from the basis functions of the hydrogen atoms used in the calculation. More about the use of ELF in making predictions of structures is given in Section 6.

3. Zintl Phases: Semiconducting Compounds

In the semiconducting compounds M_aX_b (M = metal, X = semimetal) two fundamental chemical classes are united: metals and insulators. In this "symbiosis", the latter component dominates as is reflected in electron structures that are, nearly without exception, described in terms of localized electronic states. In fact, the majority of compounds in this enormously diverse class obey the $(8-N)$ rule, that is, only two-electron–two-center bonds and lone pairs of electrons are possible states for the valence electrons. Therefore, the electronic structure may be qualitatively determined directly from the topology. As a rule, the connection of semimetals X to give oligo- and polymeric Zintl anions $(X_m)^{n-}$ as well as the coordination of these Zintl anions, which are surrounded by M^{n+} ions through their lone pairs of electrons, may be easily understood from an electrostatic point of view.

The connection pattern is a structural solution to the average connectivity of the X atoms that results from the average valence electron number at X determined from the $(8-N)$ rule. Bonds and lone pairs form sp^3, sp^2, or sp hybrid-like arrangements around the X atoms with more or less pronounced deviations from the ideal angles as predicted by the Nyholm–Gillespie rules. If there are different structural solutions for the same stoichiometry and the number of valence electrons, the details of the electron structure and a detailed knowledge of the long-range interactions is of interest. Then, local distributions, diffusiveness or compactness, polarizability, and total expansion of local electron density may be important. Only the latter values can be qualitatively and quantitatively examined in three dimensions with ELF.

3.1. Lone Pairs of Electrons in Zintl Phases

The crystal structures of $Ca_{14}Si_{19}$ ($Ca_3Si_{4.071}$) and Ca_3Si_4 differ significantly despite having almost identical formulae and being in thermodynamic equilibrium at 1270 K.[74] Therefore, a phase transformation is not present here, but a peritectic transformation of the low-temperature (LT) phase Ca_3Si_4 into the high-temperature (HT) phase $Ca_{14}Si_{19}$.

Both compounds contain the bicyclic Si_9 unit (Figure 9a) that appears in $Ca_{14}Si_{19}$ as a sixfold connected building unit $R_6[Si_9^{14-}]$ and in Ca_3Si_4 as a threefold connected unit $R_3[Si_9^{17-}]$. It seems to be that at low temperatures a higher charge can be accumulated in individual regions than at higher temperatures; the distribution of charges and bonds in space becomes more regular at higher temperatures. The average Ca–Si bond lengths of 3.18 and 3.19 Å in the LT and HT phase, respectively, are hardly distinguishable, which is attributable to the almost equal formal overall charges. Apart from the connectivity of the Si frameworks, the Ca atoms have very similar chemical environments with respect to the lone pair electrons.

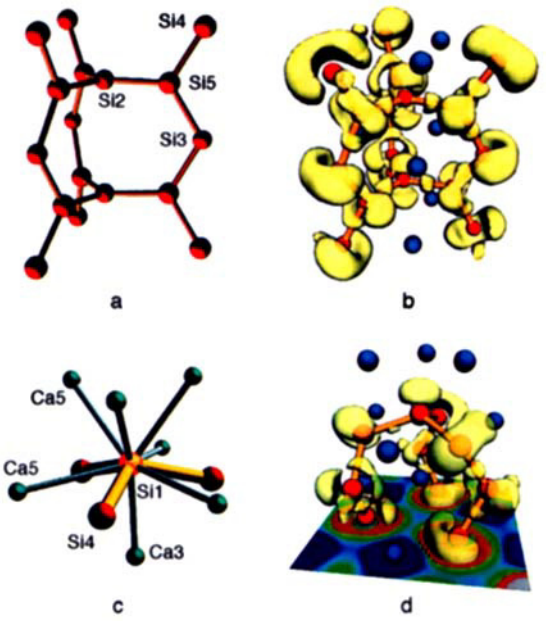

Figure 9. a) Bicyclic unit in $Ca_{14}Si_{19}$ containing the planar Si3-Si4-Si5 chain and planar three-coordinate silicon atoms (Si2, Si5). b) 3D isosurface (ELF = 0.80, based on LMTO calculations) showing very large attractor regions (yellow) for the lone pairs at the two-bonding Si centers and a p-characteristic at the three-bonding Si atoms. c) Bent cap $Si1(Si4)_3$ in Ca_3Si_4. In comparison to that in b), the Ca coordination changes slightly at the Ca5 positions and markedly at Ca3; in this case Ca3 occupies the center of the Si arrangement. d) An enlarged section of the 3D ELF isosurface shown in c) with a similar characteristic distribution of the large lone pair regions. See text for details.

Up to this point, ELF does not significantly enhance our understanding of the structural topology. What is clearly seen with ELF are the enormously extended regions for the lone pair of electrons at the two-bonding Si atoms, which fill the large void that is not occupied by the two bonding neighbors in a horseshoe geometry (Figure 9b). The mutual positions of neighbors and localization regions reveal a relatively good packing of all attractor regions, that is either atomic cores, bonding electrons, or lone pairs (see Figure 9b). In contrast, at the central Si2 atom, which adopts a trigonal-planar coordination, the lone pair clearly has p character. This is also observed at the other three-bonding Si atoms of Si5 type, but the localization regions of the three bonds and the lone pairs are not fully resolved (see Figures 9b and d). Figure 9b clearly shows that

the lone pairs aligned along the Si3-Si5-Si4 chain avoid each other. Furthermore, the lone pairs do not point directly towards the Ca cations (blue spheres) in the inner region of the fragment. A small change in position of the three-bonding Si1 in Figure 9c is accompanied by an immediate spatial change of the lone pair electron, which now shows a sp^3 geometry (Figure 9d). Therefore it can no longer take part in the coordination of Ca3. On the other hand, Ca3 polarizes the three two-bonding Si centers located at the same plane such that the localization regions of their lone pairs deviate from the usual horseshoe form. Overall, it is remarkable that the horseshoe-like lone pairs circumscribe very large spatial regions around the two-bonding Si atoms, perhaps exceeding the effect expected from VSEPR theory. In the 2D cross section of Figure 9d, the cation–polyanion interaction is clearly seen between the yellow localization region and the blue Ca center. The central region of the lone pair is directed towards the Ca atom. We believe that a more extensive spatial examination of this kind with the aid of ELF will lead to a deeper comprehension, because many attractors relevant in structural chemistry become visible in their mutual relations.

The relationship between electron localization regions and cation distribution becomes even more apparent in $Ca_7Mg_{7.25}Si_{14}$,[74–76] because there are two different cations with completely different structural and chemical functions. The compound contains isolated octet Si^{4-} anions and planar Si_{12} groups stacked in an eclipsed manner in the [001] direction (Figure 10a). The regular distribution of large Ca cations around the Si_{12} unit and of the Mg centers at terminal and isolated Si atoms is clearly seen. Despite the large interunit distance of $c = 4.40$ Å, there is a weak interaction that develops between the π states of the Si_{12} group. Such interactions have recently been verified for many polyanionic arrangements of silicon. Band structure calculations on different structures confirm these results.[31] The corresponding EH band structure of $Ca_7Mg_{7.25}Si_{14}$ shows the large dispersion of the π^* bands in the c^* direction by which the semiconducting characteristic of the bulk of the band structure is overshadowed by a one-dimensional metallic conductivity (Figure 10c, see ref. [31]). This effect is not identifiable in the form of a localized interaction in the ELF, as it is evidently a weak interaction. The quantum mechanical analysis supports a formulation that corresponds only approximately to the Zintl–Klemm formalism, namely $(Ca^{2+})_7(Mg^{2+})_{7.25}[Si^{4-}]_2[Si_{12}^{20.5-}]$. Nevertheless, all ocupied electronic states must be assigned to the silicon anions. Even the conduction band is centered at Si. Therefore, such compounds can be described as metallic Zintl phases. ELF clearly depicts those localization regions that are well understood according to the Zintl–Klemm concept.

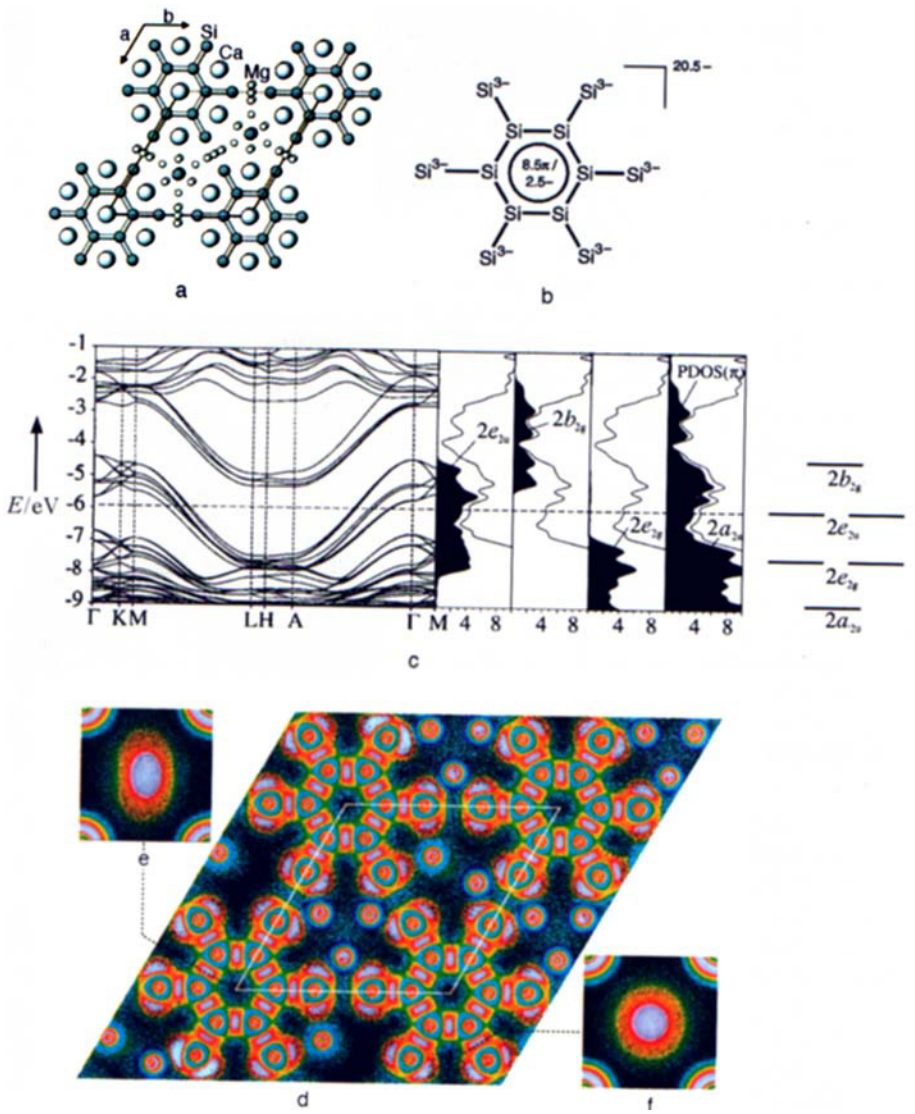

Figure 10. a) Structure of $Ca_7Mg_{7.25}Si_{14}$ containing isolated Si^{4-} anions and planar Si_{12} units. b) Schematic Lewis formula of the planar $Si_{12}^{20.5-}$ Zintl anion. c) EHMO band structure (left), density of states (DOS, center, in states per cell and eV), and MO scheme (pattern) of the π orbitals of $Ca_7Mg_{7.25}Si_{14}$ close to the Fermi level. The band structure reveals bands with large dispersion intersecting the Fermi level. These bands give rise to the metallic nature of $Ca_7Mg_{7.25}Si_{14}$ and are composed of the π^* states (e_{2u} symmetry) of the Si_6 ring (left DOS). The comparison between the total DOS (black line) and the DOS of all π states beautifully reveals that despite the metallic conductivity all occupied electronic states are centered on silicon. d) ELF (LMTO) cross section containing Si_{12} rings and several Mg centers. The plot is perpendicular to the c axis of the crystal structure. e) and f) ELF of cross sections of an intraring bond and a terminal bond, respectively, in the Si_{12} ring.

An interesting bonding structure can be found in the ELF of the highly charged oligomeric anion $Si_{12}^{20.5-}$. Figure 10d shows the pattern of the Si–Si bonds and the localized lone pairs. Remarkably, the lone pairs clearly interact with the small Mg^{2+} ions, whereas the larger Ca^{2+} ions interact more with the bonding electron pairs and the π system (not shown). This result was also observed in other structures.[31, 74] The relatively complicated band structure (Figure 10c) can thus be brought into a readily interpretable form (Figure 10d) with the aid of ELF.

The 68.5 valence electrons of the $Si_{12}^{20.5-}$ unit occupy the first twelve σ bonds and form the $6 \times 3 = 18$ lone pairs. The remaining 8.5 electron pairs occupy three π-bonding and two π*-antibonding states. The latter contribute to the conduction band (Figure 10c). Therefore, a π-bonding contribution remains that is unambiguously located in the ring as seen in the bond cross sections shown in Figures 10e and f. The intraring bonds are ecliptically distorted. A distribution of the π-bonding contribution over the whole silicon framework is also conceivable, but such a phenomenon is not observed. The planarity of the polyanions and the absence of significant distortions of the bonding structure in spite of partial occupancy of π* states is conspicuous here, and has also been observed in numerous other cases of planar Zintl anions. This is due to the relatively high formal and therefore comparatively high effective charges that can only be distributed equally when very delocalized π* states are generated.[77] Any distortion would lead to an irregular charge distribution, which evidently could not be stabilized by given cation fields.

The structure of the ternary silicide $Ba_2Mg_3Si_4$ contains Si_2 pairs and Si_6 chains.[31] The latter are in the *cis–trans* conformation and planar. The all-*trans* chain is well known for the compounds MSi (M = Ca, Si, Ba), which crystallize in the chromium boride structure type.[78–80] In $Ba_2Mg_3Si_4$ it is conceivable that the *cis* conformation is only present when Mg centers are coordinated to one of the Si centers. The Mg atoms are always in the *exo*- and the large Ba atoms in the *endo*-position to the chain (Figure 11 top). The center of the *trans* connection (of the chain) is always surrounded by four large metal atoms, whereas the highly charged terminal Si centers are always stabilized by four Mg atoms (in both cases only two of these atoms are seen in the figure). This coordination pattern is also found at the Si_2 pair (Figure 11 top). Furthermore, an ecliptic packing of Zintl anions along the *c* axis of the unit cell is present here. Even in this case it is not possible to formulate a completely saturated system with respect to charge balance: $(Ba^{2+})_4(Mg^{2+})_6(Si_2^{6-})(Si_6^{14-})$ and $(Ba^{2+})_4(Mg^{2+})_6(Si_2^{4-})(Si_6^{16-})$ represent possible formulations of $Ba_2Mg_3Si_4$. In the former case, the six-membered chain is unsaturated (e.g. $[Si-Si-Si=Si-Si-Si]^{14-}$ with 36 valence electrons), in the latter a $[Si=Si]^{4-}$ pair is proposed. Now we want to address the following questions with the aid of ELF:

1. Are there double bonds in Zintl phases and if so, where?
2. What dictates the conformation of the Si_6 chain?
3. Why is there a conspicuous accumulation of Mg centers at the terminal Si atoms?

To answer the first question ELF for a plane perpendicular to the *c* axis of the structure was analyzed (Figure 11 top). The small representations in the lower part of the figure are sections through Si–Si bonds that are correspondingly indicated in the picture above. There is a rotationally symmetric Si–Si bond in the Si_2 unit that is centered with respect to the interatomic vector (Figure 11, I). It clearly features the characteristics of a σ bond. On the other hand, the central bond in the chain shows an elliptical form and is more extended (Figure 11, II). The Ba atoms come closer to the extended bond, which leads to an enhanced coordination of the π bond. The next bond is markedly distorted towards the Mg centers and shows an elliptical shape in the central, relatively compact region (Figure 11, III). Finally, the bond to the terminal Si atom is almost rotationally symmetric and reveals hardly any π character (Figure 11, IV). This ELF analysis suggests the simplified formulation $[Si-Si\cdots Si\cdots Si\cdots Si-Si]^{14-}$ for the Si_6^{14-} ion. A more detailed analysis of the underlying band structure calculations confirms this formulation. Thus, $Ba_2Mg_3Si_4$ may be formulated $(Ba^{2+})_4(Mg^{2+})_6(Si_2^{6-})(Si_6^{14-})$.[31]

The second question can be answered in light of the geometrical arrangement of cations and lone pairs. Upon comparing the position of the Ba_2Mg_2 groups around bond III with the alignment of the participating Si centers, it is clearly seen that both lone pairs are oriented towards the Mg centers and away from the Ba centers. Therefore, a local *cis* conformation results. In the bonds exclusively coordinated by Ba cations (I, II, and IV), the lone pairs are in the *trans* position, which allows a symmetrical interaction with the cations.

Figure 11 shows that most of the lone pair electrons are oriented towards the Mg centers. It is thus the Mg and not the Ba centers that play the dominating role in dictating the coordination geometry. Therefore it is clear that assuming an equal proportion of cations to anions, the Mg^{2+} ions are able to stabilize higher charges in Zintl anions. This can be predominantly attributed to the higher Coulomb effect. It was previously shown that this structure-directing effect of the Mg cations can be used for controlling the variety of Zintl anions in the solid state.[31, 74, 81]

Finally the spherically symmetric ELF distribution around all metal centers, where only a shell-like structure is visible, should be mentioned, that is, the metal centers act almost as perfect cations. This will be further quantified in Section 4.2. The effective charges of the metal centers are smaller than $q = +2$; however, this is not important as they only stabilize the electronic states of the anions.

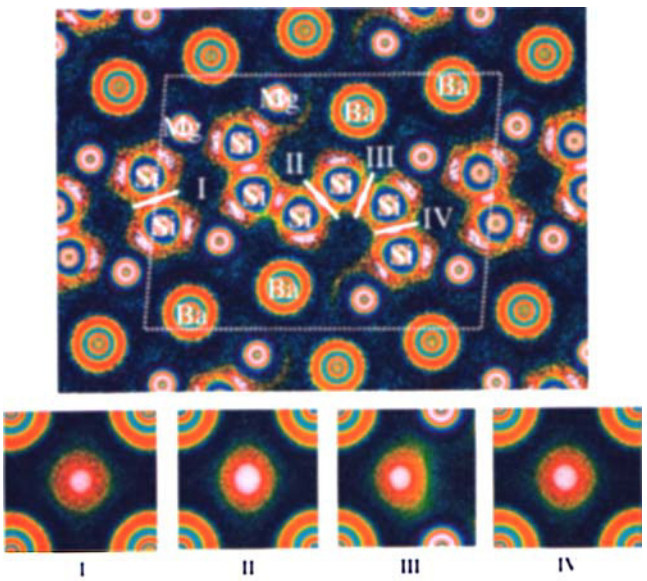

Figure 11. Top: ELF plot (LMTO) of the (010) plane in the new Zintl phase $Ba_2Mg_3Si_4$ [31] that contains Si_2 pairs and Si_6 chains. As in Figure 10, the direct relationship between the Mg centers and the lone pair electrons is demonstrated, whereas the coordination of the Ba cations at the Zintl anions is less pronounced. According to the determined stoichiometry one of the Si_n Zintl anions must contain π contributions. Bottom: The ELF cross sections of the bonds labeled above clearly show that only the six-membered chain contains π contributions. These contributions are very distinctive in the central bond II, weaker in III, and almost absent in IV.

Table 1. Classes of chemical compounds, typical building groups, and chemical interactions.

No.	Class of compound	Basic units	Type of interaction
I	van der Waals packings metal packings	atoms, molecules	van der Waals metallic
II	alloys	atoms, clusters, simple structures	covalent and delocalized
III	intermetallic phases	polyhedra, nets, partly complex structures	covalent, ionic, and delocalized
IV	Zintl phases, semiconductors	isolated, oligomeric, and polymeric ions	covalent, ionic
V	insulators	ions, valence polymers	covalent, ionic
VI	coordination compounds	molecules, complexes, and clusters	covalent, ionic
VII	H-bridging systems	polar molecules, valence polymers	covalent, ionic
VIII	composite	combinations of classes I–VI	

4. Intermetallic Compounds

In the past twenty years a great number of novel solid-state inorganic compounds have been synthesized, leading to a deeper understanding of structure–property relationships; thus, we are now able to face intermetallic compounds with new ideas and concepts. The evident conflict between more or less uniform structures of many metallic elements and their often quite complex compounds highlights complicated aspects of the chemical bond, which, however, are gradually being unraveled thanks to the development of theoretical methods. A significant difficulty in transferring classical valence concepts to compounds of classes II and III (Table 1) is their unique structural chemistry and topological form. Obvious relations exist only to boranes and clusters. The definition of intermetallic compounds as a unified family is not so simple; an encompassing theory is not at hand, especially considering the smooth transition to the semiconductors on the one hand and to the alloys on the other, the diverse expressions of the chemical bond, and the extraordinarily rich and varied structural chemistry. Older classifications such as that of B. Pearson (molar volumina, portion of the total energy in the band structure, framework or hybrid-framework structures, ref. [82]) are generally useful but definitely limited with regard to a deeper understanding of the chemical bond. Even the successful division into structure maps does not lead to true understanding.[83]

Also in this context, investigations with ELF led to completely new qualitative but also quantitative insights. We will show in the following sections how the chemical bond in intermetallic phases may be analyzed with ELF. To this end we studied two principal classes of compounds: Type A) those with more homopolar networks and type B) those with cluster-building units.

4.1. ELF in Intermetallic Phases

Figure 12 shows ELF calculations on a series of substances that reveals a transition from the semiconducting compounds to intermetallic phases and to metals in the following order: α-Si, $CaAl_2Si_2$, $SrAl_2$, $BaAl_4$, $CaAl_2$, and α-Al.[84] We assign these phases to type A. The general change in the ELF shows a development of strongly structured, contracted localization regions to distributions revealing not only distinctive structuring but considerably smaller differences between the extrema. The very high localizations (white regions) decrease proportionally and vary strongly in form and extension. Simultaneously, a change from clearly defined two-center localizations (α-Si, $CaAl_2$, $SrAl_2$) to the coexistence ($BaAl_4$) of two-center (Figure 12i, broad white spots) and multicenter bonds (Figure 12i, small white spots) as well as antibonding interactions (Figure 12j) occurs. The differences in bond lengths in $BaAl_4$, however, are not so dramatic and sometimes counterintuitive: the shortest distance is found for the five-center–six-electron bond (272.5 pm), whereas the two-electron–two-center bond is slightly longer (278.4 pm). An Al–Al distance of 305 pm is indicative of antibonding interactions (Figure 12j) and is quite close to the Al–Al distance in α-Al (286.3 pm). A discussion about bond lengths and bond strengths inevitably fails here.[85] It should be noted that even in $SrAl_2$ and $BaAl_4$ some localization regions show rather high ELF values and therefore yield corresponding integrated electron numbers (see Section 4.2).

The Laves phase $CaAl_2$ and α-Al belong to the class of substances clearly classified as metals; however, distinct localization regions are also present that may be understood in terms of covalent pair interactions even in the case of α-Al. The conspicuously complex structural chemistry of Al compounds, including quasicrystals, is expressed in the highly symmetric cubic closed packing of the metal. A similar case is found in $CaAl_2$, but only for the Al–Al interactions; the Ca–Al contacts are more ionic (Figure 12l,m). There are no Ca–Ca bonding contributions in spite of the diamond-like Ca substructure. Furthermore, all cases show a relatively spherically symmetric distribution of core and very weak valence localization (blue colored) around the large Ca, Sr, and Ba metal atoms, which indicates ionic character. This has been confirmed by quantitative analyses (see Section 4.2).

4.2. Quantitative Investigations

In structural chemistry, geometrical parameters as well as those deduced from topology and composition such as coordination numbers, bond strength, and formal charges have been used for a long time to classify compounds. With skillfully chosen division procedures, model systems are obtained that are sometimes amazingly resilient, but with well-defined limits. More precise statements about, for example, effective or partial charges, or valence electron distributions require other defini-

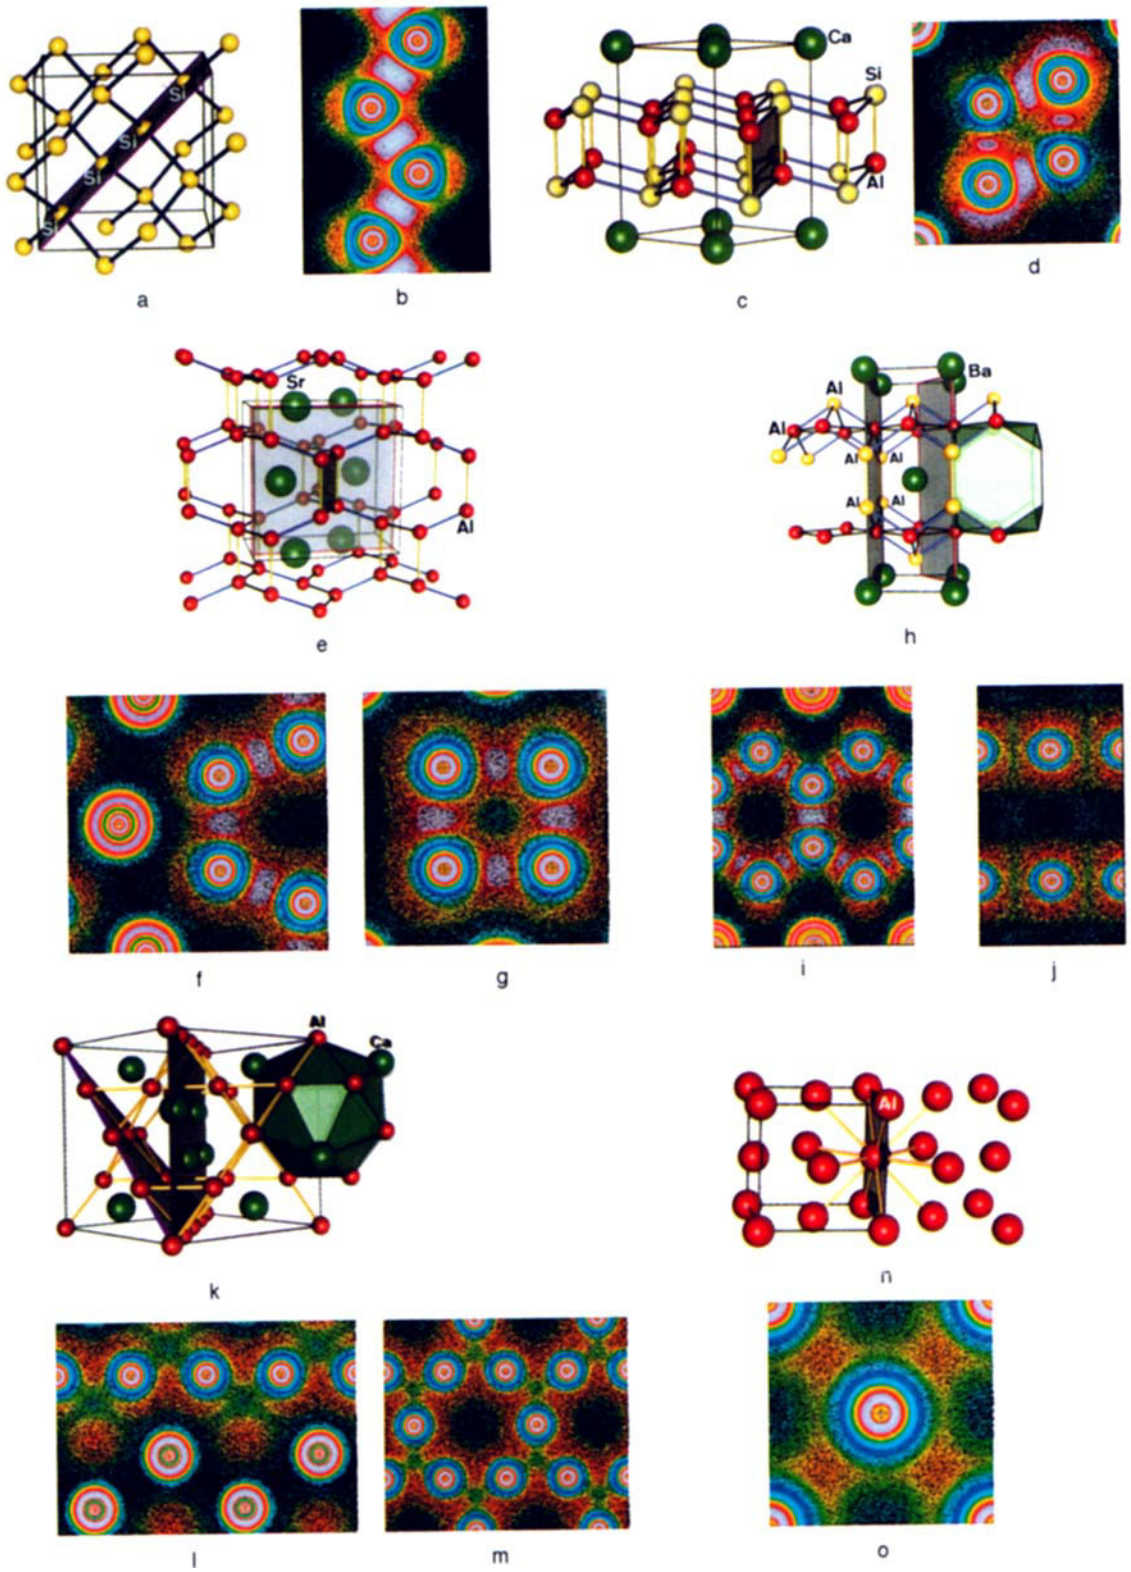

Figure 12. Structure and ELF representations (based on LMTO calculations) of selected 2D cross sections of the following structures: a), b) α-silicon, c), d) $CaAl_2Si_2$, e)–g) $SrAl_2$, h)–j) $BaAl_4$, k)–m) $CaAl_2$, n), o) α-Al. This series is representative for the transition from valence compounds to metals.

tion schemes and as such lead to different results. In principle, centers which are meaningful in structural chemistry, such as the so-called attractors (molecules, complexes, atoms, centers of bonds, etc.) and their domains (WBs) are defined.[21, 85] The most basic model is that of rigid spheres that do not completely fill the space. The simplest, and for the most part volume-preserving domain (WB) division was proposed by Voronoi and Dirichlet[86] in the 19th century and used by Niggli and Laves for crystal chemical investigations.[87, 88] The domains (WB) are restricted by the construction of convex polyhedra around the attractors. A sufficient number of planes are erected on the interatomic vectors so that the polyhedra are completely

closed. The division point on the vector can be chosen according to radius relation criteria and is critical. Even the volume-preserving power plane method[89] is not free from that arbitrariness. Furthermore, the restriction of domains (WBs) by planes is a relatively rough approximation.

As mentioned, domains (WBs) of single atoms or ions are obtained upon the division of electron density according to the method of Bader.[12] A corresponding division with ELF yields electronic domains (WBs) for atom cores (only in the case of all-electron calculations), lone pair electrons, bonds, and bonding contributions such as in cluster compounds with delocalized three-center bonds (e.g. boranes). Both the atomic and electronic domains (WBs) can be used for integration of incremental values such as partial charges, ionicity of bonds, and number of electrons per interaction center per attractor.

The domain (WB) regions for the electron density in α-Al, α-Si, and $CaAl_2$ in the form of three-dimensional envelopes are shown in Figures 13a, c, and g, respectively. Whereas a euclidean polyhedron (rhombic dodecahedron) is obtained for aluminum, the border planes for the atomic cells of α-Si and $CaAl_2$ are bent. A comparison of the edges of the polyhedra for the euclidean division (Figure 13f) and the division of orthogonal trajectories according to Bader[12] (Figure 13e) clearly reveals different results due to the restriction to planar borders in the former case.

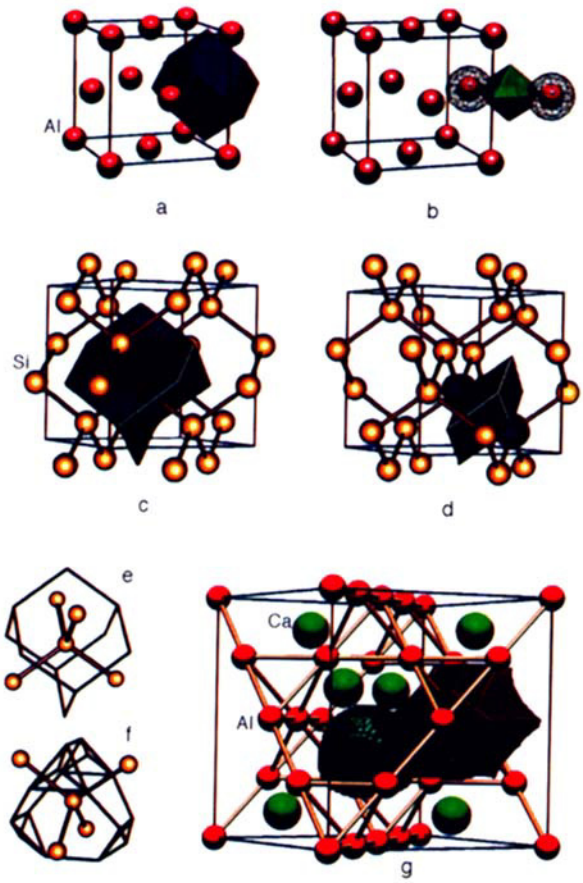

Figure 13. Domain (WB) divisions for quantitative partitioning of electron densities ρ [12] (a, c, g) and ELF (b, d). a), b) Al; c), d) Si; g) $CaAl_2$. The bonding regions in b) and d) appear either as a distorted octahedron (α-Al, green) or as a rhombus (α-Si, dark green). e) The atomic domain (WB) in α-Si may be described as a saddle polyhedron with bent boundary planes. The comparison of the topology of edges of this polyhedron with that obtained by a geometrical division method f) [89] reveals distinctive differences.

The clearly structured domain (WB) of Al in $CaAl_2$ is striking (red) (Figure 13g). It appears to be polarized by an almost spherical core region around Ca (green). This implies that significant ionic bonding contributions are present in the $CaAl_2$ Laves phase as evidenced by a relatively hard cation ($Ca^{\delta+}$) and a very soft anion ($Al_2^{\delta-}$) and thus covalent Al–Al interactions may be assumed. The quantitative investigations confirm this impression convincingly (see Table 2). Figures 13b and d show the divisions for the corresponding ELF.

Figure 14 displays the course of the trajectories in the two-dimensional sections in Figure 12; each picture shows the division of the electron density (atomic regions, top) and the division of the ELF (electronic regions, bottom). A comparison of both regions reveals a certain duality in the sense that where attractors are found in ELF, trajectories are present in the electron density and a minimum is found for the electron density at bond critical points along the interatomic vector. Furthermore, in $CaAl_2Si_2$, $SrAl_2$, $BaAl_4$, and $CaAl_2$ only one attractor is found for the alkaline earth metals and it is at the core position. This

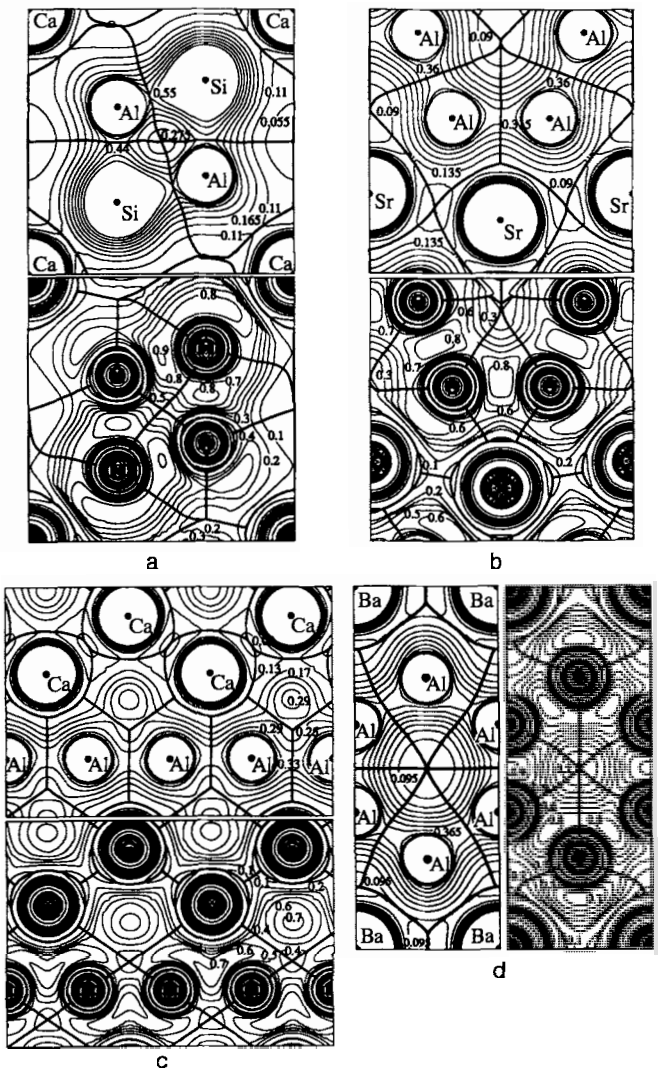

Figure 14. Contour line diagrams (thin black lines) with orthogonal trajectories that indicate the course of space divisions (thick black lines) in pairs for the electron density (top) and ELF (bottom) for a) $CaAl_2Si_2$, b) $SrAl_2$, c) $CaAl_2$, and d) $BaAl_4$ (LMTO calculations). The values given in Table 2 are obtained by separately integrating each domain (WB).

coincidence of atomic and electronic domains is indicative of the presence of quasi-ions in all cases. Furthermore, it is interesting that the domains (WB) in electron density and those of the cores in ELF are almost equal in form and extension for the electropositive metals Ca, Sr, and Ba. In Figure 14 these dual relations between ρ and ELF as well as the corelike form of the electronic domains at Ca, Sr, and Ba are emphasized.

Some quantitative values of this domain (WB) analysis are given in Table 2. The division of ρ yields partial charges q (difference between the number of valence electrons in the neutral atom and the N_e(at.) values) that are about the same with respect to the electropositive metals for the intermetallic phases $SrAl_2$ and $CaAl_2$ ($q(Ca) \approx q(Sr) \approx 1$). Suprisingly, the charge does not increase in $BaAl_4$ ($q(Ba) \approx +0.7$) although the concentration of the more electronegative component Al is doubled. As expected the calcium atom in $CaAl_2Si_2$ carries a higher charge ($q(Ca) \approx +1.3$). However, the high positive charge of aluminum ($q(Al) \approx +1.3$) in this phase is unexpected. Actually, aluminum and silicon form a network with clearly covalent bonding contributions that are expressed in the ELF in the form of separable electronic attractors (see Figure 14a). The term "polar covalency" can be used to describe $CaAl_2Si_2$ with the formulation $(Ca^{\alpha+}[Al^{\beta+}Si^{\gamma-}]_2)$, whereas the interaction between Ca centers and $[Al_2Si_2]$ has pronounced ionic character.

Table 2. Quantification of the electron density and the ELF over domain (WB) divisions: N_e(at.): Number of electrons for atomic domains (WB); N_e(al.): Number of electrons for electronic domain (WB) and ELF attractor.

Compound	atomic cell	N_e(at.)	electronic cell	N_e(el.)	distance [pm]
α-Al	Al atom	3.01	Al–Al	0.5	286.3
$CaAl_2$	Ca atom	0.99			
	Al atom	3.50	Al–Al	1.30	284.2
$SrAl_2$	Sr atom	1.01	Al–Al	2.13	279.9
	Al atom	3.51	Al–Al	2.01	278.6
			Al–Al	1.60	293.0
$BaAl_4$	Ba atom	1.33	Al–Al	2.05	278.4
	Al atom	2.57	Al–Al	1.45	272.5
	Al atom	3.75	Al–Al	-	305.2
$CaAl_2Si_2$	Ca atom	0.77	e_2-pair	1.96	
	Al atom	1.46	Al–Si	1.67	248.9
	Si atom	6.18	Al–Al	1.00	257.2
α-Si	Si atom	4.03	Si–Si	2.02	235.1

The effective electron numbers per domain (WB) reveal the influence of the corresponding attractor (bond, formula unit). Domain (WB) regions with approximately two electrons include the Si–Si bond, one of the three kinds of Al–Al bonds in $SrAl_2$, as well as the lone pair in $CaAl_2Si_2$ (Table 2). The integration of another Al–Al bond in $SrAl_2$ yields slightly more than two electrons; the cross section through this bond shows an elliptic form of the ELF. A weak π-bonding contribution seems to be present, but it does not appear to influence the bond length. Similar effects have also been found in Zintl anions of silicon.[31, 74, 75, 81] Smaller integrated electron numbers indicate multicenter bonds (see $BaAl_4$) or polar bonds with a corresponding Coulomb contribution.

The quantitative results summarized here reveal ELF to be very suitable for the examination of intermetallic phases. The function is particularly valuable because the rules of valency do not hold here and there is no other comprehensive bonding theory yet. However, according to the few ELF investigations to date it is evident that the exceptional feature of intermetallic phases is a mixture of a wide variety of bonding forms.

4.3. $CuAl_2$ and Its Variants

The $CuAl_2$ structure is the aristo structure type of a great number of intermetallic phases. Pt_3Ga_7, $PdSn_3$, $PtSn_4$, $PtPb_4$, $RhBi_4$, and $PdGa_5$ are isotypical to or derived from the $CuAl_2$ structure. All these compounds can be classified under type B (see Section 4). They feature a common building element, namely square antiprisms of main group elements E, which are interconnected[92, 93] in various ways through E–E, T–E, and T–T bonds (T = transition element). Examination of the local chemical bond with ELF reveals the development of totally different, strongly bound partial fragments especially in the E partial structure,[95] which are accompanied by a noticeable localization within the square antiprisms. In $CuAl_2$, for example, there are strong bonds between the Al pairs connecting the prisms.[96] This is reminiscent of the strong bonds between boron polyhedra and the terminal two-electron–two-center bonds in boron clusters, and of the Ga_2 pairs in the structure of α-Ga.[94] These bonds are sections of two interpenetrating graphite-like networks.[96]

The lone pairs of electrons in $PtPb_4$ and $RhBi_4$ are located on the main group elements that are oriented according to the topology of simple periodical nodal surfaces (PNSs).[95, 97] Such a surface-active behavior of inert pairs of electrons is known, for example, from the work of Andersson, Galy et al.,[98] and has also been interpreted by using PNS.[99] In $PdGa_5$, the Ga_4 squares emerge as the more strongly bound units and, according to quantitative analyses, four electrons (i.e. two bonds) are distributed over the four-membered groups.[95] Furthermore, weak Pd–Ga interactions were found described in the sense of a "real" metallic bond. It was shown here that different interactions are spatially separated and that this division can be simply visualized with the aid of a PNS.[95]

5. ELF of Surfaces

The surface structures of many substances are unknown today. The reconstruction and passivation of surfaces are crucial phenomena that determine, for example, reactivity, thermal stability, crystal growth, electrolytical, and sintering characteristics. With regard to the specific control of these phenomena and to the access to nanotechnology, mechanistic bonding and dynamic models become extremely important, particularly because the surface area becomes more important as the particles become smaller.

Scanning probe methods enable exciting new insights in surface phenomena, and with scanning tunnel microscopy (STM) it is possible to generate images of surfaces at subatomic resolution. The corresponding images cannot easily be interpreted, because they depend on many factors such as composition of the probe tip, surface covering, bias voltage, and the density of

states close to the Fermi level for the surface.[100] The latter means that only a part of the electronic structure of the surface is explored. For this reason it is interesting to carry out theoretical modeling of surfaces not only with calculations of partial electron densities (PED) alone but also with the ELF. Spatial representations that may also be calculated for surfaces are obtained with both methods and both are able to reproduce aspects of STM images.

Today, surfaces of silicon single crystals are among the most well defined and thoroughly examined surfaces. The (100) surface of silicon has been frequently and controversially discussed. It is known that a 2×1 surface reconstruction takes place, but there is no agreement as to whether the dimer formation is symmetrical or unsymmetrical (Figure 15a).[101, 102] The results of the theoretical investigations depend on the quality of the calculation and there is no consensus yet as to which model is superior. However, it is possible to draw direct topological comparisons between experiment and models with the PED and the ELF. Figure 15b shows the corresponding density of states (DOS) close to the Fermi level (E_F) of the three surface situations depicted in Figure 15a. It is clearly seen that in both cases the reconstruction (formation of dimer) leads to a decrease of the DOS at E_F. Figure 15c reveals the total valence electron densities (TEDs, top), the partial electron densities (PEDs) for unoccupied states ($E_F \leq E \leq (E_F + 3\,eV)$ center), and the PED for occupied states close to E_F ($((E_F - 3\,eV) \leq E \leq E_F$, bottom) for the same three situations. The accompanying 2D ELF cross sections calculations are presented in Figure 15d for quantum mechanical states occupied up to $E_F + 3$ eV (top) and for the states occupied up to E_F (bottom). Figure 15e shows the accompanying three-dimensional isosurface representations of ELF, whose exact form depends on the ELF value. Since ELF is always determined over all occupied states, the images obtained from the detection of the unoccupied (virtual) states (tunnel current from the tip to the surface) and occupied states (reversed tunnel current) must be simulated with the calculation of a slightly reduced or neutral system (Figure 15e bottom).

The comparison of calculated images with those measured (Figures 15f and g) for both directions of bias voltage shows interesting differences, which are discussed in reference [101]. Figure 15f shows the STM picture at positive bias voltage (electrons move from the tip to the surface) and therefore a reproduction of the unoccupied states (conduction band) of the surface.[103] This corresponds to Figures 15c center, 15d top, and 15e top. The result for the reversed bias voltage (electrons move from the surface to the tip) is presented in Figure 15g. The correlation to the calculated Figures 15c bottom, 15d bottom, and 15e bottom is clear.

At this point it must be stressed that

1. the TED is not sufficiently structured for a good explanation of these observations,
2. the PED are well structured and subtly differentiable but change significantly with small variations of the energy window $[(E_F - \Delta E), E_F]$ (like the STM pictures upon change of the bias voltage),
3. the ELF shows a situation intermediate to TED and the PED, that is it is well structured and considers all occupied states.

The advantage of ELF is that it not only provides an accurate reproduction of the spatial distribution but also a detailed image of the chemical bond and, particularly here, of dangling bonds at the surface. This is rarely possible with the other methods. Therefore ELF provides necessary and sufficient information for the analysis of STM images. It must be emphasized that there is no theoretical basis up to now for a relation between ELF and the STM experiment.

6. Localization Patterns in Interstitial Space

Nowadays, diffraction methods constitute a most important part of the determination of structure–property relationships. However, in some cases X-ray diffraction methods face nontrivial problems if, for example, super- or noncommensurate structures are to be determined, if twinning or disorder phenomena demand very sophisticated approaches, or if very light atoms must be resolved in the presence of strong X-ray scatterers.

Semiconducting compounds such as Zintl phases can in general be rationalized by the application of simple bonding concepts.[104] If, however, unusual or unexpected moieties occur it is not always certain whether they actually exist or are just an artifact of an erroneous structure determination.[105, 106] The existence of a geometrical void in such a structure is expected to arouse suspicion, but it cannot be used as a sure indicator for an overlooked atom or group of atoms. The "free" space may be generated for electronic reasons, for example as a packing space for lone pairs that are tightly bound to specific atoms, or of more or less free electrons as in electrides, intermetallic compoundss, and metals. The ELF is an extraordinarily useful sensor, especially for such problems in structure determination.[107]

Several times we have alluded to hierarchical relations in the sense that an ELF attractor also represents electrophilic particles such as protons. Mostly, these special attractors can be assigned to a part of the atomic structure. We should point out that ELF enables the visualization of patterns in interstitial space in such regions that cannot be associated with single atoms. The following four examples illustrate that such patterns, which indicate weakly bound but still spatially localized electrons, are in many cases indicative of overlooked atoms and thus may be of considerable importance for verifying the correctness of a structure.

6.1. Suboxides of Zintl Phases

To corroborate our findings concerning ELF we analyzed with LMTO band structure calculations[36] Zintl phases that contain light heteroatoms X in addition to mononuclear and oligomeric Zintl anions.

Compound Ca_4Sb_2O[108] was first described as a binary calcium antimonide Ca_2Sb[109] (Figure 16a), an assertion corrected shortly thereafter by the authors. The structure contains isolated Sb^{3-} ions and thus the compound can only be a valence compound, as expected, if an additional X^{2-} anion is present. The additional anion was identified as O^{2-} coordinated octahedrally by six calcium atoms. Surprisingly, the calculation of the ELF for Ca_4Sb_2 (without the O atom!) generates one and only

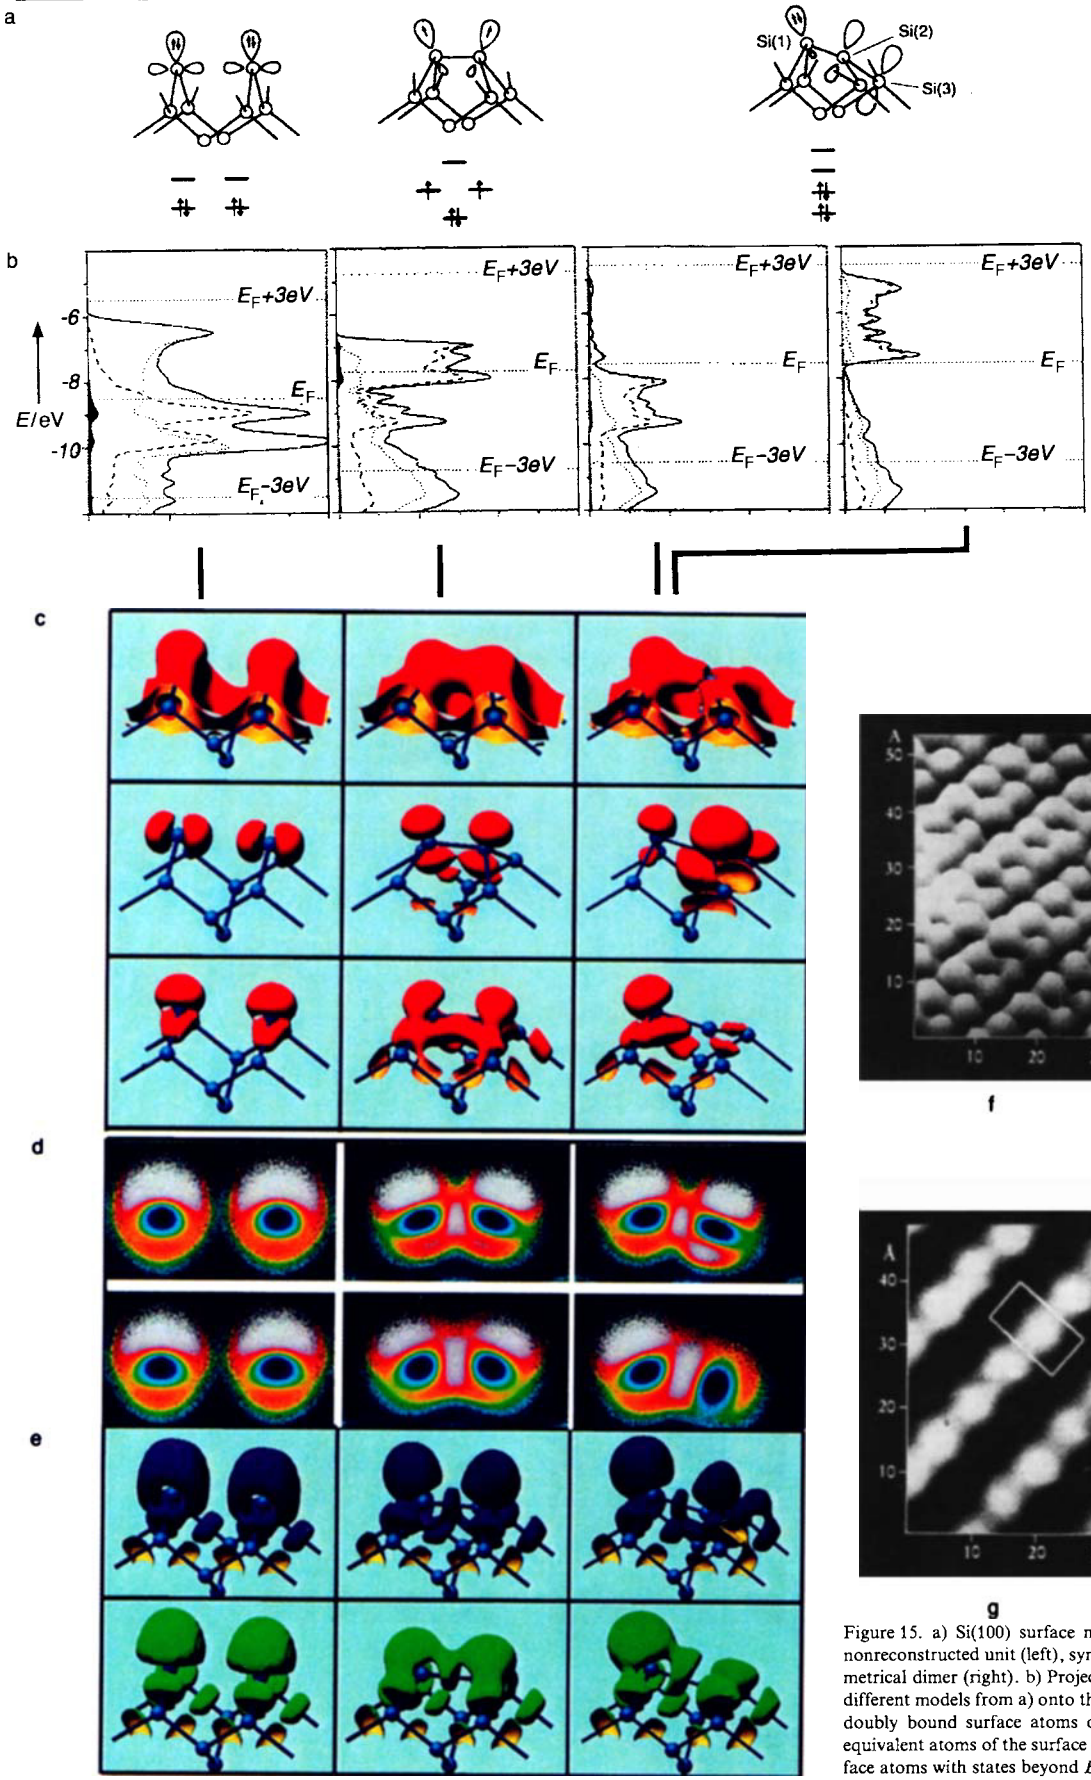

Figure 15. a) Si(100) surface models containing dangling bonds: nonreconstructed unit (left), symmetrical dimer (center), and asymmetrical dimer (right). b) Projections of the density of states of the different models from a) onto the surface atoms. From left to right: doubly bound surface atoms of the nonreconstructed unit, both equivalent atoms of the surface layer of the symmetrical dimer, surface atoms with states beyond E_F, and the atoms slightly below the surface with states above E_F. c) 3D representations of isosurfaces of TED (top row), PED of states in the energy region from E_F to $E_F + 3$ eV (second row), and PED in the region from $E_F - 3$ eV to E_F (third row). d) and e) 2D and 3D representations, respectively, of ELF with electronic occupation up to E_F (corresponding to the electron number of Si, bottom row), and with electronic occupation of the states up to $E_F + 3$ eV (corresponding to the formation of a further electron pair at the surface atoms, top row). f) STM image of the unoccupied surface states (positive bias voltage). g) STM image of the occupied surface states (negative bias voltage).

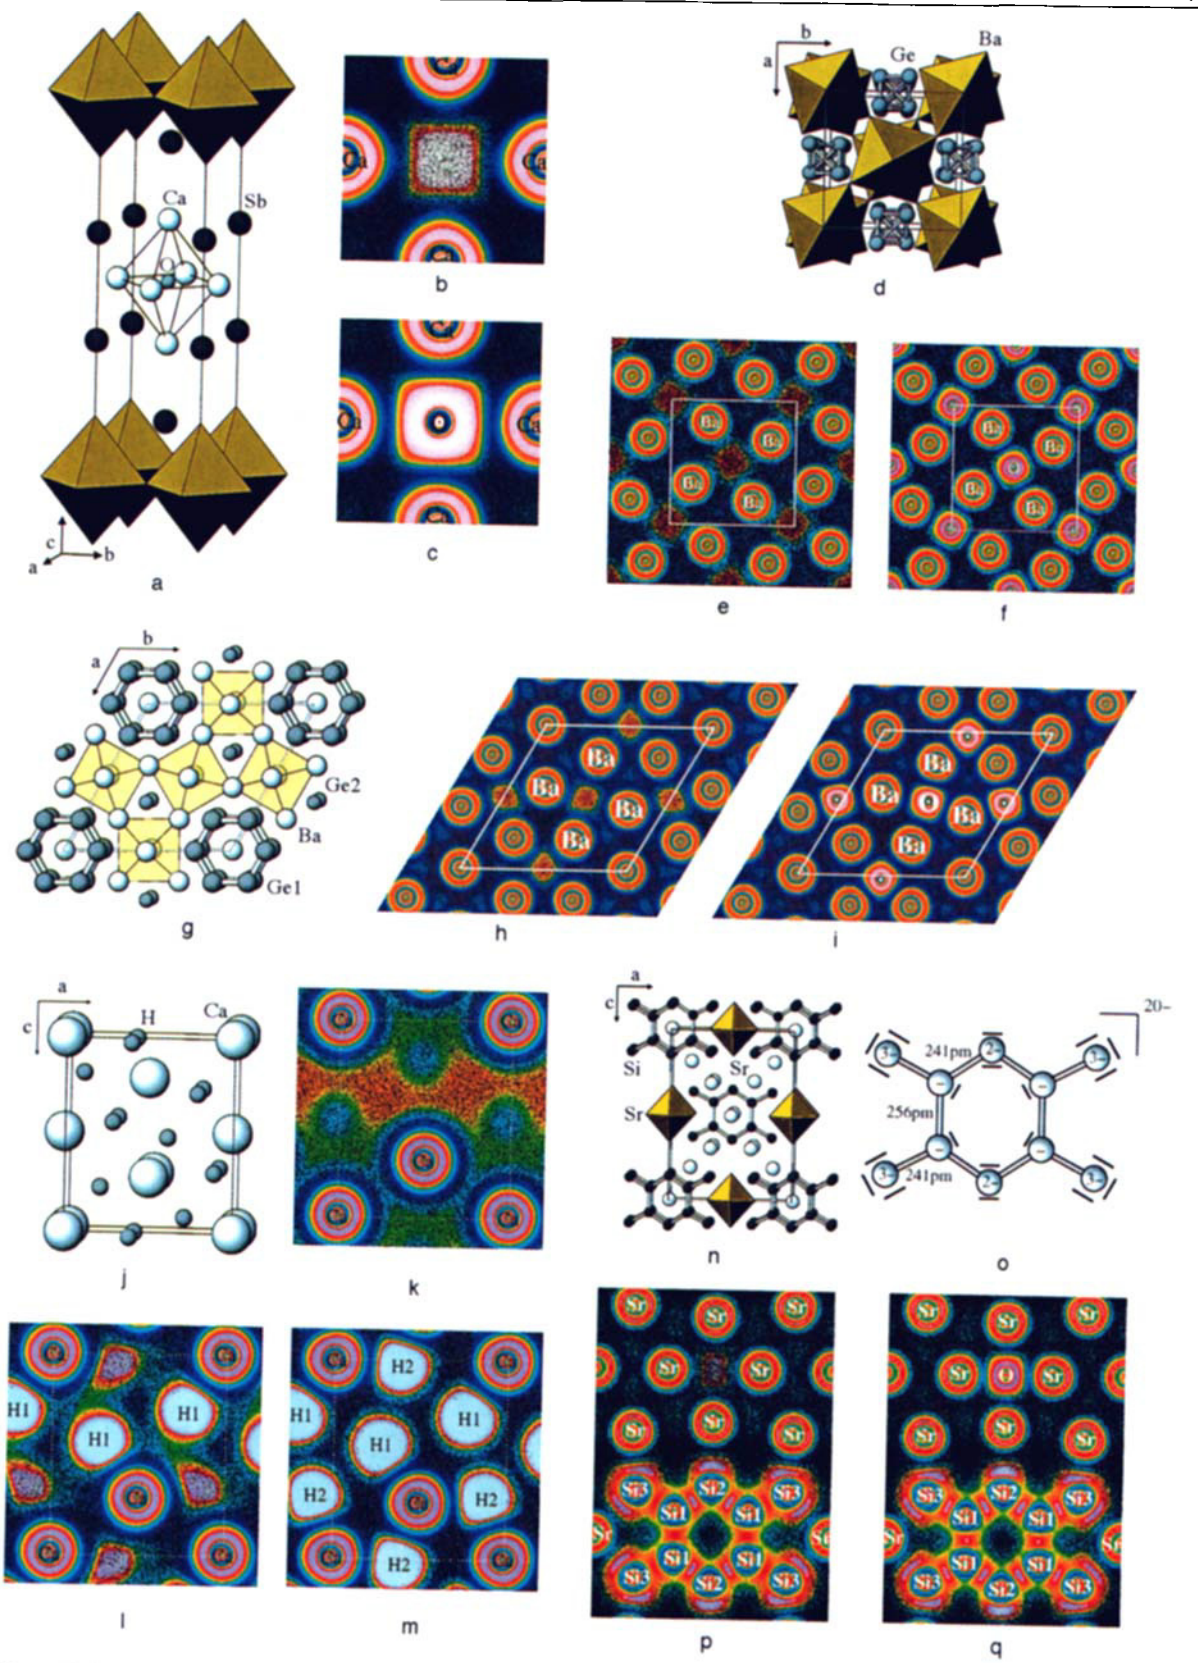

Figure 16. Structures and representative ELF (LMTO) cross sections with and without interstitial atoms (see text): a) structure of Ca_4Sb_2O, b), c) cross sections of the empty Sr_6 octahedron (ELF of the empty octahedron suggests the presence of the heteroatom) and with interstitial O atom, respectively; d) structure of Ba_3Ge_4X, e), f) cross sections of the empty Ba_6 octahedron and with interstitial O atom, respectively; g) structure of $Ba_3Ge_7O_3$ h), i) cross sections of the empty Ba_6 octahedron and with interstitial O atom, respectively; j) structure of CaH_2, k)–m) ELF of the Ca partial structure, with only one crystallographically unique H atom, and with all H atoms, respectively; n)–q) "SrSi" (second modification), n) structure with empty Sr octahedra [79], o) planar Zintl anion $[Si_{10}]^{(20-x)-}$, p) ELF cross section containing a Si_{10} unit and a Sr_6 octahedra; q) like p) but with O as a heteroatom corresponding to the $Sr_{10}Si_{10}O$ composition.

one additional localization region, which lies at the center of the Ca_6 octahedron (Figure 16b, white area). After introduction of the O atom into the calculation, an ELF is yielded that clearly displays the O atom with its core regions (Figure 16c). It is remarkable that despite the use of the different electron counts similar localization patterns are found for Ca_4Sb_2 ($\{8+10\}e$) and Ca_4Sb_2O ($\{8+10+6\}e$).

Quite recently, von Schnering et al. synthesized derivatives of barium germanides that contain Ba_6X octahedra and typical Zintl anions of germanium.[110, 111] In Ba_3Ge_4X there are Ge_4^{4-} tetrahedra (Figure 16d) and in $Ba_{10}Ge_7X$ planar Ge_6^{10-} rings occur. The ELF distributions without the heteroatoms X show localization patterns that are exactly at those positions that are occupied by X atoms or X groups. Figures 16e, f, h, i display the corresponding ELF sections through the Ba_6 octahedra without (Figures 16e, h) and with the X atoms (Figures 16f, i, X = O). The ELF displays the sites of the heteroatoms quite convincingly. According to the Zintl–Klemm concept and band structure calculations, X^{2-} units such as O^{2-}, C_2^{2-}, NH^{2-} are expected in these sites.[112]

The so-called second modification of "SrSi" (Figure 16n), which has never been confirmed experimentally, contains a very interesting Zintl anion, a planar $[Si_{10}]^{20-}$ unit with quite a peculiar variation in Si–Si bond lengths.[113] One would expect a formal charge distribution for this Zintl anion like that depicted Figure 16o. However, the Si1–Si1 bond lengths (256 pm) are so much longer than the other two (Si1–Si2 241 pm, Si1–Si3 241 pm) that this explanation seems quite suspect. A closer inspection reveals that the Sr atoms form an empty octahedron. The ELF treatment reveals a localization pattern (white spots in the structural section in Figure 16p) consistent with the assumption of σ bonds between Si1 and Si2. The lone pairs are indicated by white clouds of high ELF value located at expected positions.

The long Si1–Si1 bond has unusually low ELF values. More remarkable, however, is the center of the single Si1–Si3 bond (241 pm), for which a white region is to be expected, if the electron structure shows no peculiarities, and thus obeys the Zintl–Klemm concept (Figure 16o).[104]

Even more surprising is the large localization region between the four Sr atoms in the upper middle of Figure 16p. Two additional Sr atoms above and below that plane generate a distorted octahedron that shows a remarkable contraction compared with the neighboring Sr groups on the left and right side. Too high an accumulation of charge on the Zintl anion could lead to the formation of a cage orbital[106] in the Sr_6 octahedron. In this case, SrSi would belong to the class of electrides. The center of the octahedron, however, is an ideal position for an electronegative heteroatom such as oxygen. The corresponding distances (4×245, 2×285 pm) coincide very well with the Sr–O distances found in SrO (6×257 pm, ref. [114]) and in $SrTiO_3$ (12×276 pm, ref. [115]). The presence of a heteroatom would also explain the failed attempts to synthesize this "SrSi" modification from rigorously purified elements.[116] Neither the EH nor the LMTO investigations on the hypothetical phase $Sr_{10}Si_{10}O$ reveal a band gap at the Fermi level indicating a semiconductor. Therefore, there is no preferred valence electron number that allows for the more electronegative neighbors of oxygen, such as fluorine, nitrogen, or carbon, to act as heteroatoms.[117] In the meantime, it has been shown on numerous Zintl phases that a limited capacity for accumulation of charge in highly charged Zintl anions leads to a planar geometry and a partially occupied π system. For the binary "SrSi", there are unusually high Sr contributions to a few bands below the Fermi level. This is quite unusual according to our experience.

A LMTO calculation with oxygen in the void position leads to an ELF that shows a surprisingly smooth distribution of white bond regions in the Si_{10} framework (Figure 16q), and the Sr contribution below the Fermi level disappears. We would like to emphasize that it was not obvious at the outset that a removal of two electrons from the Si partial structure to the O^{2-} ion would generate a, by our standards, very reasonable σ-bonded structure that is understandable with the quantum mechanical ELF analysis.

6.2. Determination of Hydrogen Positions in Hydrides

The following example, CaH_2,[119, 120] is important because, in general, hydrides present a problem in structure determination. Quite frequently, such compounds are microcrystalline and thus single-crystal investigations cannot be performed. Furthermore, hydride positions may not be found by X-ray analysis because of the small scattering factor of hydrogen.

To follow the typical procedure adopted in the determination of a hydride structure, the CaH_2 structure was analyzed with the ELF starting with the pure Ca substructure. Figures 16j—m display a section of the structure that contains atom positions Ca, H1, and H2. In Figure 16k the ELF is shown for the pure Ca substructure, that is without electron pair acceptors. There is a weak but significant localization (yellow spot) that includes the position of H2. If now one H atom is added and located at that site, a new localization spot that coincides with the position of H1 becomes clearly visible (Figure 16l). Actually this second localization region is already distinct in the ELF for the Ca substructure, but only equally as strong as a neighboring position unoccupied by H. These two weaker localization regions can be clearly distinguished after an antisymmetrical introduction of the first H atom on the observed position.[119] Therefore, this second localization region is clearly observable in a subsequent ELF calculation (Figure 16l).

The ELF of the complete structure (Figure 16m) beautifully reveals the ionic character of this hydride: there are only low ELF minima between the atoms. Nevertheless, a significant polarization is visible, especially of the hydride ions but also of the Ca^{2+} ions, which includes deviations from the spherical symmetry.

We must emphasize that this new way for the determination of missing atom positions is less reliable if the substructure reveals a higher symmetry than the complete structure, because the quantum mechanical calculation represents only a given symmetry. For example, starting from the magnesium position in MgH_2, an isolated localization cloud is obtained that indicates an interstitial region.[21, 31] But this region only represents the center of a region containing two hydride ions and does not permit any further geometrical specifications. Starting with such information, further methods in optimizing geometry can successfully lead to a complete structural model.

There are many indications that ELF describes the chemical bond in molecules, clusters, and extended structures in such a differentiated way, that, in general, regions of high ELF values can be understood as nucleophilic centers. With ELF it is possible to find missing atoms in incomplete structures, and in fact, as in CaH_2, even the positions of the major component and not only of a few of overlooked atoms.

7. Outlook

7.1. The Chemical Bond in Intermetallic Phases

Quite recently, a highlight by J. C. Schön appeared in this journal dealing with the chemical bond.[90] Therein an article by Burdett et al.,[91] and especially the following statement, was critically discussed: "... that the 'metallic bond' as a separate term with equal weight to the other three traditional schemes[*] should be abandoned" and "certainly it does not have a mathematical framework distinct from the other three categories ...". Equivalently, the metallic bond does not represent a special type of chemical bond because previously known bonding types appear simultaneously in the corresponding structures and band structures should be used in the classification.[91] The rebuttal of Schön praised the usefulness of the usual forms of description of the metallic bond and criticized Burdett et al. for focussing on only one method (EH) for the calculation of band structures.

We believe that both authors are certainly correct, but the essential things that are governed by the term metallic bond are not yet fully understood. In our ELF investigations on intermetallic phases, definite localized bonding structures are found, mostly coexisting with ionic interactions, two-electron–two-center, two-electron–three-center, multielectron–multicenter bonds, as well as lone pair electrons, and conducting electrons. Here, clear separations between bonding forms, as known from valence compounds, can no longer be drawn. Furthermore, intermetallic phases sometimes show a very complicated structural chemistry. This proves that the coexistence of totally different bonding forms leads to a new structure chemical quality, where local and cooperative effects arrange themselves in very specific ways. The metallic bond might be one of the most homogeneous of all bonding classes with respect to differences in localization, but at the same time one of the most complex regarding the variety of bonding forms that are simultaneously present in a structure.

Evidently, the metallic bond may be explained by using a combination of classical bonding concepts but there is no reason to reject its definition as an independent class. It is important that an independent phenomenon is described here that is valid for many substances. The essence of a system is not simply the sum of its parts. We believe that the essence of the characteristic features of metals and intermetallic phases as an independent class is not yet clear, but ELF will contribute significantly to this end.

7.2. Hierarchy

A totally general relation in the construction of chemical and presumably all other structures emerged from the analysis of the chemical bond with the aid of ELF: there is a hierarchical correlation between structures of equal basic topology. For example, there is a correlation between the structures of diamond, cristobalite, and $Li_{10}P_4N_{10}$.[120] Every C atom in the diamond structure is substituted by a SiO_4 tetrahedron in cristobalite and by a $P_4N_{10}^{10-}$ unit in $Li_{10}P_4N_{10}$. It is important here that the correlated structures belong to the same symmetry group or correspond to group–subgroup relations. The central sites, the positions of the C atoms in the diamond structure, are invariant attractors, whereas other structural elements are located at those sites in each of the accompanying structures. The chemical correlation between the building groups may change completely, but the topology of the structure invariant attractors (the center of gravity of the structure elements) is always preserved. In the mathematical sense, it is unimportant whether distortions of the complete structure (e.g. change of the angles, change of unit cell dimensions) occur as long as the number of principle neighbors around each invariant attractor remains unchanged.

Von Schnering has demonstrated "hierarchical relationships" in a great number of such hierarchical families.[121] Now, with the aid of ELF, localization regions of electrons may be introduced in such hierarchical relationships and thereby, surprising new correlations have been found. It seems that attractor structures, which are obtained from electron distributions using ELF, are also formed by atoms, molecules, or clusters. This was already demonstrated in individual cases, for example the attachment of hydrogen atoms at attractors of transition metal complexes and boranes (see Section 2.4).

This correlation seems to be most important for the structural relations of intermetallic phases, oxides, and fluorides found by O'Keeffe and Hyde.[122] In many cases the atomic distribution in intermetallic phases is identical or very similar to the cation distribution in oxides and fluorides. In 1991, one of us pointed at the misinterpretation of this correlation by O'Keeffe and Hyde, namely in the sense of large cations.[82] At the time an explanation was given correlating the electronic domains in intermetallic phases with the anion positions of oxides and fluorides.[82] So far, ELF investigations increasingly confirm this assumption and its unexpected scope. It seems that there are correlations between localization regions of electrons and many atomic or molecular structures. Further systematic investigations are necessary for the confirmation of this statement. We were surprised that this method can be reversed for the localization of missing atoms in uncompletely determined structures.

Such correlations have been occasionally observed[121, 123, 124] but not yet amalgamated into a general concept. The calculation of the ELF may be quite useful for a classification of this kind.[21] In this respect, the observed ELF patterns provide not only compound- or structure-specific information but gain a general topological significance.

[15] According to Equations (3) and (6) within a certain space of very low density, ELF may adapt high values that are physically meaningless. For example, in the Be atom ELF has the value one at $\rho \to 0$ ($r \to \infty$). Principally, these difficulties may be removed by the definition of an effective ELF′ as $\{1+[(C(\vec{r})+\varepsilon)/C_h(\rho(\vec{r}))]^2\}^{-1}$, where $\varepsilon = 2.87 \times 10^{-5}$ is chosen so that for $\rho \leq 10^{-3}$ bohr^{-1} ELF′ adapts smaller values than 0.5. Well-Rounded Research: Nanotubes through Self-Assembly

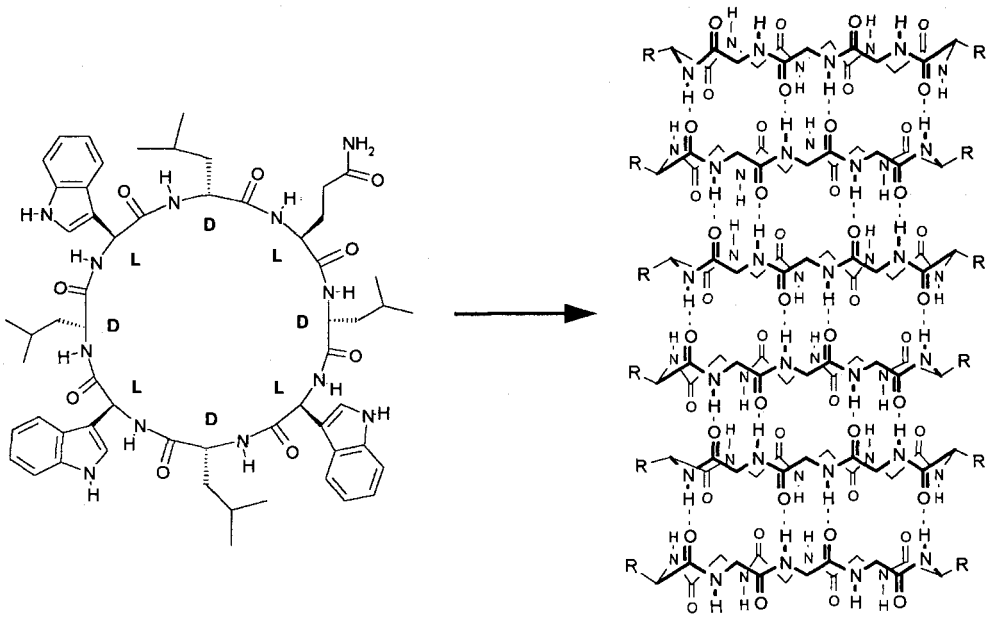
Burkhard König*

Tube-shaped structures with nanometer dimensions are currently being reported from completely different fields of chemistry: on one hand, carbon chemists keep surprising us with new shapes[1] and properties[2] of carbon nanotubes; on the other, synthetic chemists are introducing highly functionalized nanotubes, which are of some interest as models for biological ion channels. This account is concerned with topical developments in the latter field.



Scheme 1. Cyclic peptides of alternating chirality spontaneously form nanotubes. For reasons of clarity most side chains were omitted.

The construction of synthetic nanotubes is achieved through self-assembly of suitable subunits. Among the various possibilities for such self-alignment, stacking of macromolecules is a particularly promising starting point. As early as 1974, DeSantis and co-workers predicted a roughly planar structure for cyclopeptides made up of alternating D and L amino acids.[3] In this conformation the amide chain would be oriented at a right angle to the plane of the macrocycle; thus the carbonyl groups would be set in ideal positions for the formation of intermolecular hydrogen bonds between the stacked rings. The side chains would protrude outwards in the D/L motif to give an open channel whose diameter is determined only by the number of amino acid residues. Based on this model, Lorenzi et al. constructed cyclopeptides consisting of D- and L-valine units in 1987; however, their low solubility prevented structure investigations.[4] A breakthrough was then achieved in 1993 by Ghadiri's group with the octapeptide *cyclo*[-(D-Ala-Glu-D-Ala-Gln)$_2$-].[5] The glutamic acid residue renders this compound soluble in alkaline media; stacking to form nanotubes occurs after acidification (Scheme 1). The more hydrophobic side chains in *cyclo*[-(Trp-D-Leu)$_3$-Gln-D-Leu-] even enabled the construction of a transmembrane ion channel with a proton transport activity similar to that of gramicidin A or amphotericin B.[6] Measurements of single-channel conductivity showed fast transport of sodium and potassium; the channel's pore diameter of 7.5 Å led to weak potassium selectivity.[7]

Larger cyclopeptides yield nanotubes with a larger inner diameter.[8] Thus, macrocycles with ten to twelve amino acid residues result tubes in whose cavities molecules can be transported. The pore size of the channel leads to exclusion selectivity: A nanotube built from cyclic decapeptides with 10 Å diameter is permeable by glucose, whereas a tube of cyclic octapeptides is not.[9]

The biological activity of self-assembling transmembrane channels has now been determined by in vitro assays. These channels are antibacterially active against gram-positive strains and cytotoxic in a test with human kidney cells.[7]

Not only cyclopeptides are suitable for the construction of nanotubes. Stacked cyclodextrins[10] also form tube-shaped structures with inner diameters of up to 1.3 nm, as has just been proved by Stoddart, Williams, and co-workers through X-ray structure analysis (Figure 1).[11] The similarity of the design principles used here is striking: the cyclodextrin macrocycles

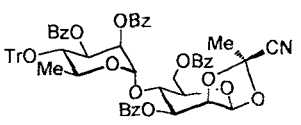
consist of alternating D and L sugar units! A whole series of new cyclodextrin derivatives from alternating D and L rhamnopyranose and D and L mannopyranose units has been presented by this research group (Scheme 2). Among these are also the first

	n	R^1	R^2
1-MM	3	CH_2OH	CH_2OH
1-RM	3	Me	CH_2OH
2-RM	4	Me	CH_2OH
1-RR	3	Me	Me
2-RR	4	Me	Me
3-RR	5	Me	Me
4-RR	6	Me	Me
5-RR	7	Me	Me

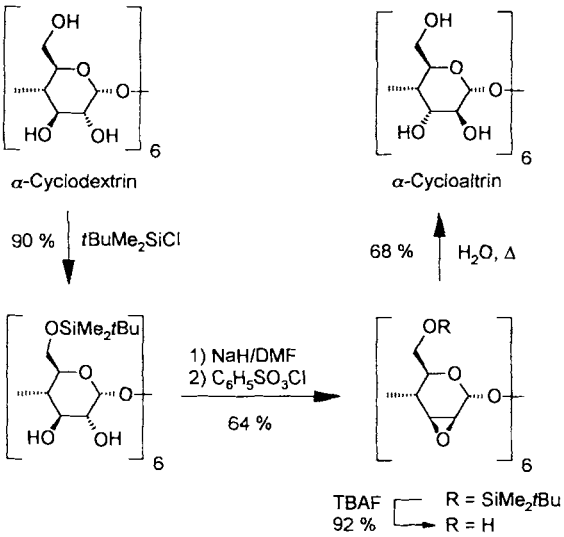
Scheme 2. D/L-Cyclooligosaccharides synthesized so far. **M** = mannopyranose, **R** = rhamnopyranose.

achiral cyclic oligosaccharides (**RR** and **MM** derivatives) as well as the largest cyclooligosaccharide known to date (5-**RR**) with 14 sugar units. The synthesis of the cyclodextrin analogues **1-RM** and **2-RM** succeeded efficiently by polycondensation–cycloglycosylation of the disaccharide **1**, in which the cyanoethylidene group serves as glycosyl donor and the trityloxy function as glycosyl acceptor. The key intermediate **1** is available in 15 steps from L-rhamnose and D-mannose.



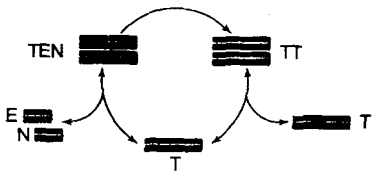
1

The results obtained by Fujita, Lichtenthaler, and coworkers show that cyclooligosaccharides with sugar units other than glucose do not necessarily have to assemble as tubes. Via the 2,3 anhydro compound as intermediate, α and β cycloaltrin were obtained from the corresponding cyclodextrins (Scheme 3).[12] The X-ray structure analysis of the α cycloaltrin revealed a highly unusual structure with alternating $^1C_4/^4C_1$ chair conformations and a cavity open on only one side. Instead of the now impossible formation of tubes, the layers lie on top of each other in a staggered way with water molecules in the gaps.



Scheme 3. Synthetic sequence leading from α-cyclodextrin to α-cycloaltrin. TBAF = tetrabutylammonium fluoride.

Other than with ion channels, it is not the inner void, but the groups pointing outwards that are crucial for the function of a tube-shaped self-replicating system[13] built up on the base of α-helical peptides (Scheme 4). For this purpose a peptide consisting of 32 amino acids whose sequence resembles the GCN4



Scheme 4. Schematic representation of the minimal autocatalytic reaction cycle of a self-replicating, α-helical peptide. The peptide fragments E and N are preorientated at the template T through hydrophobic, interhelical interaction. The amide bond formation leads to an identical copy of the template, which further accelerates the peptide ligation in the autocatalytic cycle.

leucine zipper region was used. Ghadiri and co-workers showed that this compound catalyzes its own formation by accelerating amide bond formation between appropriate peptide strands. The most important interaction responsible for the specific interhelical recognition between template and reactant is the hydrophobic interaction of the leucin and valine residues, which increases due to electrostatic forces. If this interaction is interrupted, for example, through the addition of guanidinium hydrochloride or through exchange of a valine or leucine residue for alanine, the autocatalysis comes to a standstill.

The above-mentioned examples show impressively how fast the development of functional nanostructures on the base of molecular recognition is progressing.[14] Even if the complexity falls far short of that of biological self-assembly processes like the RNA-induced formation of the coat of the tobacco mosaic virus from 2130 identical proteins, the next step might already lead to applications in nano- and microtechnology.

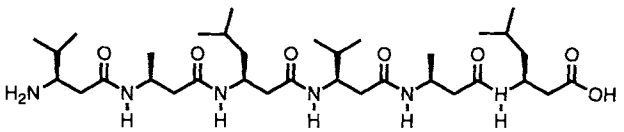
β-Peptides: Novel Secondary Structures Take Shape

Ulrich Koert*

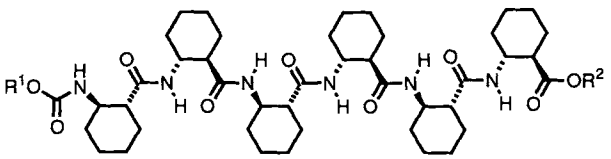
The prerequisite for the biological function of any protein is the folding of the peptide strand composed of α-amino acid residues into the corresponding active conformation. Important intermediates during the folding process are domains having a particular secondary structure. Secondary structures of α-peptides have been studied intensively; the most common structural themes are the α-helix and the β-sheet. Is the occurrence of secondary structures limited to α-peptides only?

Recent results from the groups led by D. Seebach[1–3] and S. Gellman[4, 5] show that β-peptides[6] such as **1** and **2** also may



H-(β-HVal-β-HAla-β-HLeu)$_2$-OH

1



2

form well-defined, remarkably stable secondary structures. The required β-amino acid building blocks are accessible, for example, by Arndt–Eistert homologation of the corresponding α-amino acids.[1]

Seebach et al. examined β-peptides of type **1**.[1–3] NMR studies in solution (MeOH, pyridine) prove the presence of a helical secondary structure (Figure 1 A, B). An oligomer containing only six β-amino acid residues forms a stable helix! With α-peptides, a stable secondary structure usually occurs first for the 15–20-mers. Exceptions are shorter homo-α-peptides and α-peptides containing proline or 2-amino-2-methylpropanoic acid

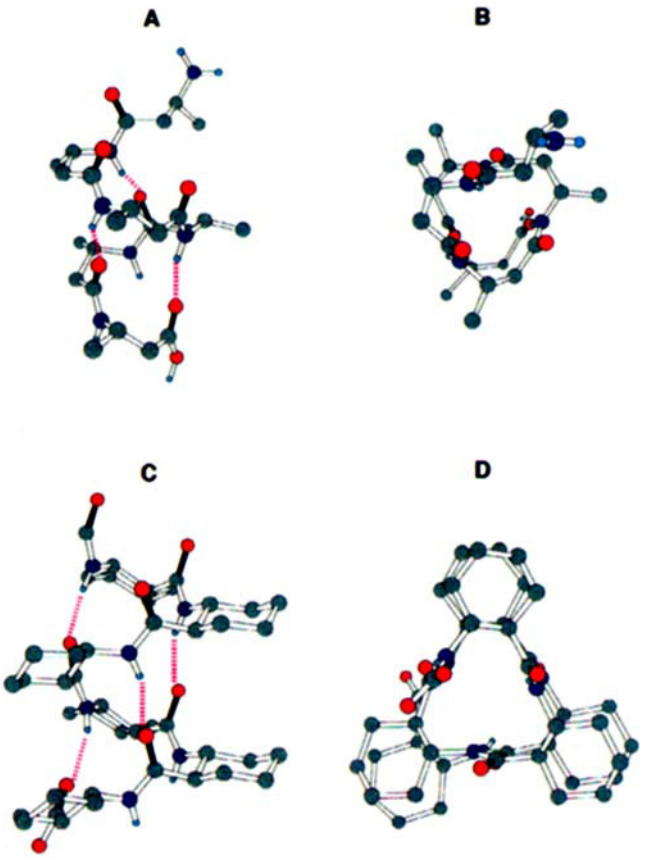


Figure 1. 3_1-Helices of the β-peptides **1** and **2**; respective side views (A and C) and views along the helix axis (B and D). The intramolecular hydrogen bonds are drawn in violet. For clarity, only one carbon atom in each side chain in A and B is shown.

(Aib). Gellman et al. proved the presence of an almost identical secondary structural motif in type **2** β-peptides by X-ray structure analysis and conformational studies in solution (Figure 1 C, D).[4] The new helical secondary structure is stabilized by hydrogen bonds forming a 14-membered ring (the α-helix contains 13-membered rings). Exactly three amino acid residues are required to form one turn of the helix. Therefore the new secondary structure is designated a 3_1-helix. The known α-helix with 3.6 α-amino acids per turn is a 3.6_1-helix.

An α-peptide composed of naturally occurring L-α-amino acids forms, with respect to its helical sense, a 3.6_1-*P*-helix. In contrast, a β-peptide like **1** made of homologated L-α-amino acids forms a 3_1-*M*-helix (Figure 2).

How much stereochemical "information" in the β-peptide is necessary to establish the new secondary structure? Gellman

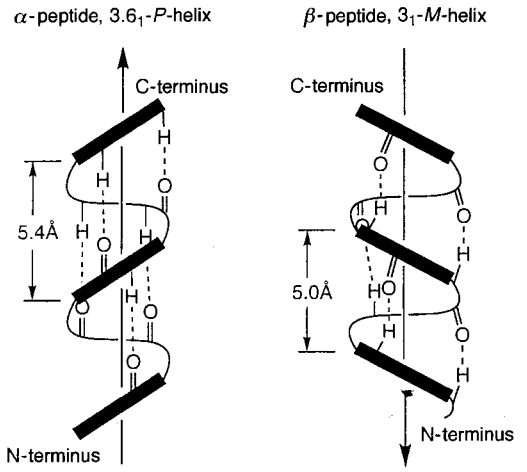

Figure 2. Schematic representation of the helix of a peptide composed of L-α-amino acids (left) and one composed of L-β-amino acids (right). The arrows follow the helix dipoles. The α-peptide is depicted as a 3.6_{13}- or α-helix (*P* configuration with 3.6 α-amino acid residues per turn and a pitch of 5.4 Å). β-peptides consisting of homologated L-α-amino acids form a 3_{14}-helix (peptide nomenclature) or 3_1-helix (crystallographic notation) of *M* configuration (3 β-amino acid residues per turn and a pitch of 5.0 Å).

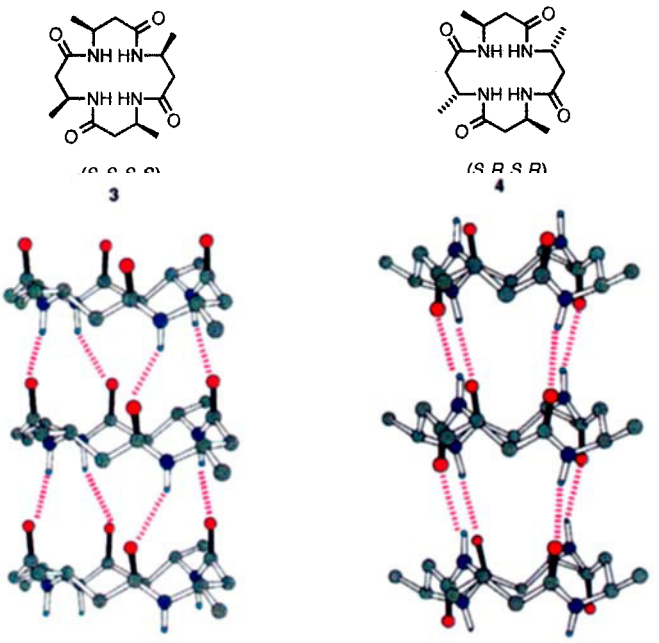

Figure 3. Side view of the solid-state structures of the cylindrical stacks made up of the cyclopeptides **3** (left) and **4** (right). The intramolecular hydrogen bonds are depicted in violet.

et al. attribute the stability of their 3_1-helix to the conformational rigidity of the cyclohexane rings.[4] Van Gunsteren and Seebach et al. used molecular dynamics calculations to show that the single stereogenic center in their β-amino acids already causes a stable folding pattern. The 3_1-helix, stable at 298 K, unfolds when heated to 350 K. Within only 200 ps the helical conformation is re-established![7] Without stereogenic centers in the β-peptide backbone, the formation of a 3_1-helix is not preferred.[1, 2]

The *trans*-substituted cyclohexane ring in Gellman's β-amino acids has a strong influence on the formation of the hydrogen bonds making up the 14-membered ring in the 3_1-helix. When the corresponding *trans*-substituted cyclopentane β-amino acid is employed, an altered helix with 12-membered-ring hydrogen bonds results.[5]

In addition to the linear β-peptides, Seebach et al. synthesized cyclic β-peptides such as **3** and **4** and studied their conformations.[8] In the solid state these cyclo-β-peptides form cylindrical stacks stabilized by hydrogen bonds (Figure 3). In the (*S*,*S*,*S*,*S*) tetramer **3**, the amide bonds are orthogonal to the ring plane and all point in the same direction. In the (*S*,*R*,*S*,*R*) tetramer **4**, the orthogonal amide bonds alternatingly point in opposite directions. These cylindrical stacks display structural similarities with the nanotubes investigated by Ghadiri et al.[9] and by Sun and Lorenzi.[10]

Summarizing the structural results, one can say that β-peptides are at least as good candidates for protein folding as their counterparts in the world of β-peptides. This fact raises the following, thrilling question: what kinds of interactions exist between the world of α-peptides and that of β-peptides? Seebach et al. report that peptides composed of β-amino acids have not yet been found to have mutagenic properties and that β-peptides are stable against various peptidases.[11] Another interesting question with respect to β-peptides concerns the evolution of life: why do we live in an α-peptide and not in a β-peptide world?

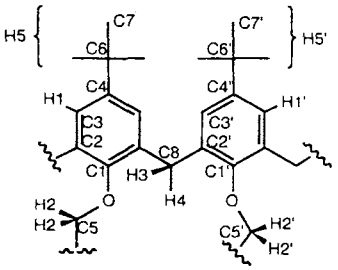
Calix[4]tube: A Tubular Receptor with Remarkable Potassium Ion Selectivity**

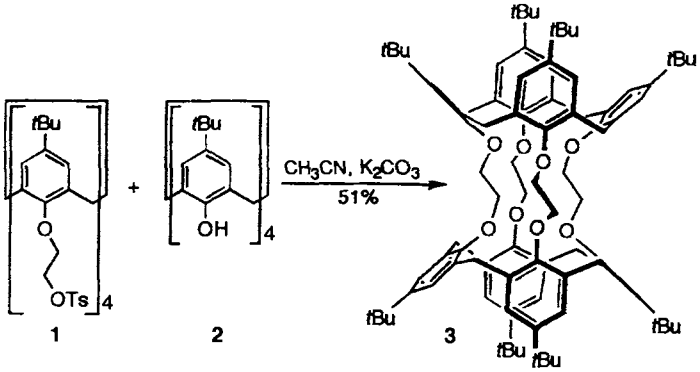
Philippe Schmitt, Paul D. Beer,* Michael G. B. Drew, and Paul D. Sheen

Potassium channel proteins have been investigated intensely in the last decade and a great deal of information about their structure/function relationships has been elucidated.[1] A very exciting, and still controversial, aspect focuses on how these proteins transport potassium ions through the cell membrane at high rates and with almost perfect selectivity (K^+ transported 1000 times more efficiently than Na^+).[2] The region of the channel pore responsible for the selection of the alkali metal ion, termed the selection filter, contains a square-planar array of four converging tyrosine residues.[3] The results of experimental and ab initio studies suggest that an *en face* cation-π interaction between K^+ ions and the arene surfaces of the tyrosine residues could be determinant for such a unique selectivity pattern.[4]



Despite the involvement of numerous research groups in the development of synthetic channels,[5, 6] it appeared to us that a biomimetic approach focusing in particular on the selection of alkali metal ions had not been fully investigated. In an effort to accredit the cation–π interaction hypothesis, we designed a novel biomimetic calix[4]arene-based tubular receptor whose access to metal cations may be controlled by filtering gates based on a square-planar array of arene surfaces.[7]

The template-driven condensation of the *p-tert*-butyl-calix[4]arene **2** with the pertosylated derivative **1**[8] in acetonitrile furnished the novel calix[4]tube **3** in fairly good yields (Scheme 1). Surprisingly this compound was found to be insoluble in all common organic solvents with the exception of chloroform and carbon tetrachloride. After crystallization from a chloroform/benzene mixture, **3** was submitted to crystal structure analysis (Figure 1) and found to exhibit C_i symmetry in the solid state.[9] The molecule contains two calix[4]arene units in a flattened, C_2-symmetrical *cone* conformation. Within the same calixarene macrocycle, each phenyl ring intersects the plane of the four methylene carbon atoms at angles of 89.6(2), 41.3(2), 87.3(2), and 43.7(2)°, respectively. It is noteworthy that the ethylene linkages alternate in two different geometries. Two of them present an *anti*-like conformation (O-C-C-O torsion angle



Scheme 1. Synthesis of the calix[4]tube **3**.

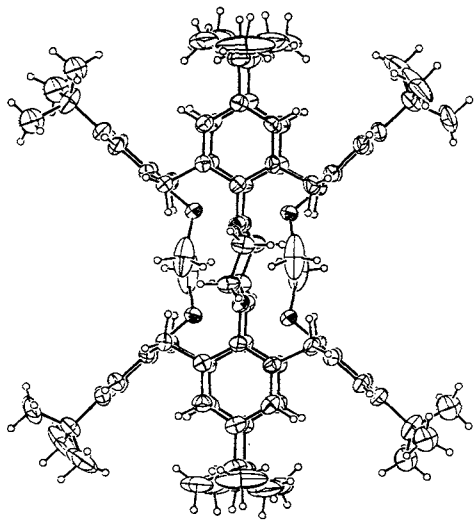


Figure 1. Crystal structure of the centrosymmetric calix[4]tube **3** in $3 \cdot 2.5\,C_6H_6$, with ellipsoids at 30% probability. Hydrogen atoms are included with small arbitrary radii. The benzene solvent molecules are not shown.

of 161.2(6)°), whereas the remaining two display a *gauche*-type conformation (O-C-C-O torsion angle of 47.8(8)°). As a consequence of this particular arrangement, the central cage composed of eight oxygen atoms is unsuitable to form an inclusion complex.

Interestingly, on the NMR time scale, this conformational symmetry is conserved in solution. The ^1H and ^{13}C NMR spectra of **3** in deuterated chloroform are consistent with the freezing of the calixarenes in a flattened *cone* conformation. All the signals, with the exception of those for the methylene groups, are split into two singlets of equal intensity. Moreover, the ^1H NMR spectra were found to be temperature independent up to 55°C. The absence of any coalescence or even peak broadening, features indicative of a time-averaged D_{4h} symmetry, suggests the calix[4]tube **3** is an extremely rigid molecule in solution.

As a consequence of the solubility limitations of **3**, a mixture of deuterated chloroform and methanol (8:2) was employed as solvent for the NMR spectroscopic investigations of the complexation of metal ions by **3**. Solid alkali metal iodide (10 μmol ($\approx$10 equiv)) was added to 1 mL of a solution of the calix[4]tube in this solvent mixture ([**3**] = 1 mM) at 25°C. The samples were sonicated briefly and ^1H NMR spectra were recorded at various times.

Compound **3** underwent a dramatic change when treated with potassium iodide. Within the first hour after mixing, the initial spectrum disappeared and was replaced by a new set of peaks suggestive of an increase of the ligand symmetry (Figure 2). The

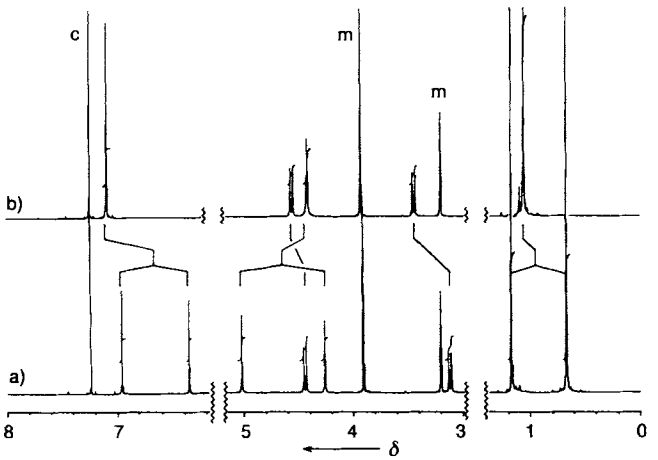

Figure 2. ^{1}H NMR spectrum of **3** [500 MHz, $CDCl_3/CD_3OD$ 4/1 (v/v)]: a) pure, b) with 10 equivalents of solid potassium iodide (c, m: solvent peaks corresponding to chloroform and methanol, respectively).

structural degeneracy of **3** after K^+ complexation, characterized by a fourfold symmetry along the molecule's main axis, is consistent with the opening of the binding cavity driven by the complexation of the potassium ion within the cage consisting of eight oxygen atoms.

Analogous experiments with other alkali metal iodides (LiI, NaI, RbI and CsI) failed to exhibit any significant cation uptake. Estimated by integration of the NMR signals, less than 7% of **3** was complexed after more than three days in presence of 10 equivalents of RbI; in the cases of LiI, NaI, and CsI the complexation after three days was less than 5% (Figure 3). Such a preference for potassium ions over any of the other alkali metal ions is remarkable for a synthetic receptor.[10]

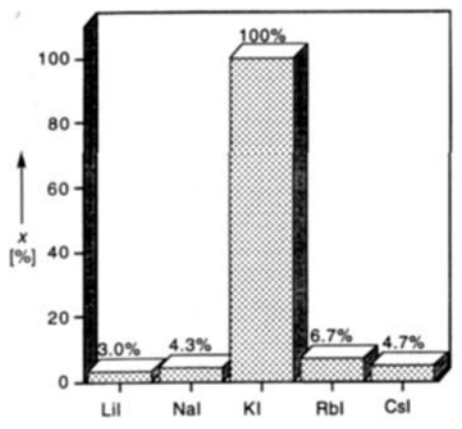

Figure 3. Uptake of alkali metal ions by **3** after treating its chloroform-methanol solution (4/1, [**3**] = 1 mM) with 10 equivalents of alkali metal iodide. The complexation ratio x was determined by integration of the ^{1}H NMR spectra after the samples had been left to stand for 90 h. In the case of KI, equilibrium was reached within an hour.

To investigate the potassium complexation process quantitatively, the uptake of 1 μmol of KI ([KI] = 10^{-3} M) by one equivalent of **3**, in homogeneous solution at 25 °C, was monitored as a function of time. After 24 h the system was evaluated to have reached equilibrium (86% of **3** was complexed), the formation of a 1:1 complex was established, and a stability constant of 4×10^4 L mol^{-1} was estimated. The complexation halftime, defined by the time necessary for the system to reach half the equilibrium conversion ratio, was measured to be 18 minutes. Although these are preliminary results, this experiment reveals the complexation process is kinetically slow and may be a consequence of an important intramolecular reorganization necessary for the cation uptake.

Comparison of the chemical shifts values of **3** and of its potassium complex (**4**), shows in general low-field shift deviations of all the calix[4]arene-related peaks ($\Delta\delta$ *t*-Bu: +0.923, Ph: +0.426, CH_2: +0.216), whilst the signals of the ethylene protons exhibit an average high-field variation (− 0.228, Figure 2). This feature is consistent with a displacement of the electron density of the ligand towards the molecule's equatorial plane caused by the close proximity of the positive charge of the complexed metal ion.

The geometry of the complex was confirmed by X-ray analysis.[11] As predicted by NMR spectroscopy, **4** is highly symmetrical and contains an approximate C_4 element of symmetry along the main axis of the molecule. All ethylene linkages present a *gauche* conformation (O-C-C-O torsion angles vary from 51.7 to 68.00°) and the potassium ion is located at the center of a slightly flattened cube; the K−O distances range from 2.759(6) to 2.809(6) Å (Figure 4). The angles of intersection of the phenyl rings with the mean plane of the four methylene carbon atoms vary between 64.6(2) and 67.9(2)°.

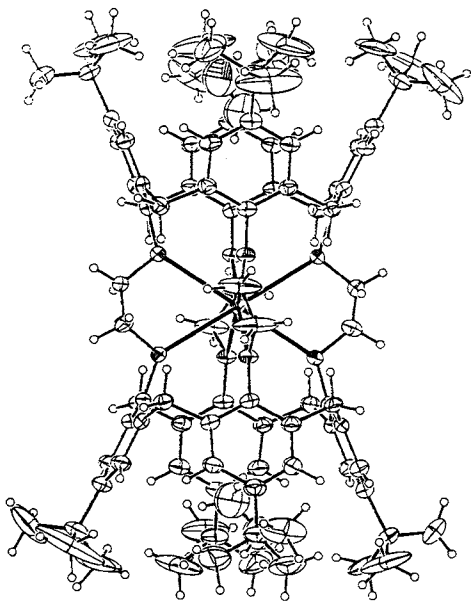

Figure 4. Structure of the K^+ complex **4** of the calix[4]tube **3** in crystals of **4**·I·3 $CHCl_3$·4 CH_3OH·H_2O. A potassium ion is located in the center of **3**, and two methanol molecules in the cone cavities. Ellipsoids are drawn at 30% probability. Hydrogen atoms are included with small arbitrary radii. The chloroform and water solvent molecules are not shown.

Of relevance to K^+ selective channel transportation, the assumption that the calixarene units provide the preferred cation-accessing gates was tested by using constrained molecular mechanics calculations.[12, 13] Preliminary calculations suggested that indeed the complexation of the potassium ion would require an activation energy about 10 kJ mol^{-1} larger by accessing the cavity across rather than along the main axis of the molecule and may involve a prior weak complexation of the cation in the calixarene cone (Scheme 2).[14] Our current efforts are directed in the collection of experimental evidence of such a behavior and in the derivatization of **3** as a potential new class of membrane-spanning compounds.

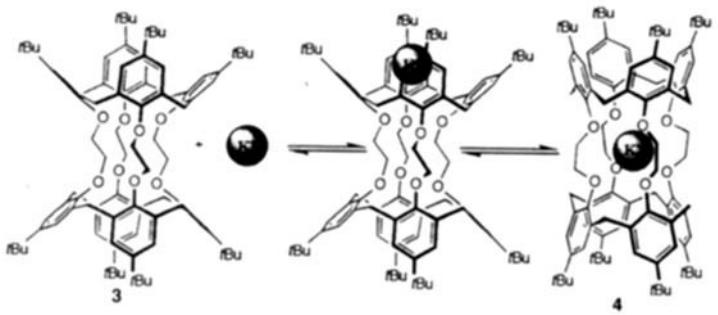

Scheme 2. Schematic representation of the uptake of K^+ ions by **3** based on molecular mechanics calculations.

Experimental Section

3: A suspension of *p-tert*-butyl-calix[4]arene (451 mg, 0.70 mmol) and potassium carbonate (480 mg, 3.5 mmol) in dry acetonitrile (100 mL) was stirred under nitrogen. After 2 h at room temperature, **1** (1 g, 0.70 mmol) was added and the reaction mixture brought to reflux for five days. The solvent was then removed in vacuo and the solid suspended in a 1:1 ethanol-water mixture. The suspension was heated to reflux overnight and hot filtered. The crude mixture was then dissolved in chloroform (50 mL) and the solution carefully paper filtered to yield a clear solution to which acetone (40 mL) was added. Filtration of the microcrystalline material obtained after the solution had been allow to stand for a few hours, followed by its drying in vacuo yielded **3** (500 mg) as an analytically pure product (51%). ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C): δ = 7.09 (s, 8H; H1/H1′), 6.48 (s, 8H; H1/H1′), 5.15 (s, 8H; H2/H2′), 4.57 (d, ^3J(H,H) = 13 Hz, 8 H; H3), 4.39 (s, 8 H; H2/H2′), 3.25 (d, ^3J(H,H) = 13 Hz, 8 H; H4), 1.31 (s, 36H; H5/H5′), 0.80 (s, 36 H, H5/H5′); ^{13}C NMR (125 MHz, $CDCl_3$, 25 °C): δ = 156.0 (C1/C1′), 152.8 (C1/C1′), 144.5 (C2/C2′), 144.3 (C2/C2′), 135.1 (C4/C4′), 131.9 (C4/C4′), 125.5 (C3/C3′), 124.8 (C3/C3′), 73.0 (C5/C5′), 72.5 (C5/C5′), 34.1 (C6/C6′), 33.5 (C6/C6′), 32.4 (C8), 31.7 (C7/C7′), 31.0 (C7/C7′); C,H,Cl analysis ($C_{96}H_{120}O_8 \cdot CHCl_3$): calc.: C 76.58, H 8.02, Cl 6.99; found: C 76.32, H 8.17, Cl 8.09.

[9] Crystal data for **3**·2.5C_6H_6: crystal dimensions: 0.25 × 0.25 × 0.20 mm, triclinic, $P\bar{1}$, a = 10.286(12), b = 14.803(14), c = 19.01(2) Å, α = 75.70(1), β = 83.66(1), γ = 64.91(1)°, V = 2541(5) Å^3, Z = 1, ρ_{calcd} = 1.044 mg m^{-3}, $2\theta_{max}$ = 50.180, $\lambda(Mo_{K\alpha})$ = 0.71073 Å, T = 293(2) K. 7510 independent reflections were measured on a MARresearch Image Plate, and data processing including Lorentzian polarization were carried out using the XDS program (W. Kabsch, *J. Appl. Crystallogr.* **1988**, *21*, 916). The structure was determined by direct methods by using the SHELX86 program (G. M. Sheldrick, Universität Göttingen, **1986**) and anisotropically refined on $|F^2|$ using the Shelxl program (G. M. Sheldrick, Universität Göttingen) with non-hydrogen atoms given anisotropic thermal parameters. Hydrogen atoms were included in calculated positions with anisotropic thermal parameters set to 1.2 times those of the atom to which they were bonded. One of the *tert*-butyl groups was disordered. Compound **3** and one of the benzene molecules (which is given 50% occupancy) had crystallographically imposed $\bar{1}$ symmetry. No absorption correction was carried out. The final R and wR^2 values are 0.0850 and 0.2387, respectively, for 3239 data with $I > 2\sigma(I)$. Largest peak and hole in the final difference were 0.588, −0.375 e Å^{-3}, respectively [11 b].

Coordination Arrays: Tetranuclear Cobalt(II) Complexes with [2 × 2]-Grid Structure**

Garry S. Hanan, Dirk Volkmer, Ulrich S. Schubert, Jean-Marie Lehn,* Gerhard Baum, and Dieter Fenske

A major goal in inorganic supramolecular chemistry is the self-assembly of polynuclear coordination arrays through the suitable design of ligands and choice of metal ions in order to generate well-defined architectures in a controlled fashion.[1] In

addition to the novel physicochemical properties that such entities may present, they are potentially interesting as components of functional nanostructures.

We have recently investigated three fundamental types of metal ion coordination arrays: racks $[n]R$,[2, 3] ladders $[2n]L$,[4] and grids $[m \times n]G$,[5] where the nuclearity of different species is given by $[n]$, $[2n]$, and $[m \times n]$ (n represents the rank) and where the ligand components are oriented more or less orthogonal to each other. Two-dimensional gridlike structures are of particular interest as their architectures may serve as a basis for the construction of information storage devices.[6] Such arrays of metal ions could represent ion dots that might be addressable photo- or electrochemically; they would be of still smaller size than quantum dots[7] and would form spontaneously by self-assembly—microfabrication would therefore not be required.[1]

To form "orthogonal" coordination arrays one may either combine tetrahedrally coordinated metal ions and bidentate ligands (such as 2,2′-bipyridine derivatives)[4, 5] or octahedrally coordinated metal ions and tridentate ligands (such as 2,2′:6′,2″-terpyridine units).[2, 3] For both of these combinations the ligands are arranged in a more or less perpendicular fashion as required for the construction of grid-type complexes. However, by using metal ions presenting octahedral coordination rather than those which prefer a tetrahedral[5, 8] environment, one may expect a wider variety of interesting physical and chemical properties.[9] We describe here the synthesis, characterization, and electrochemical properties of the $[2 \times 2]G$ Co^{II} complexes **1a–c** based on the bis-tridentate ligands **2a–c**.

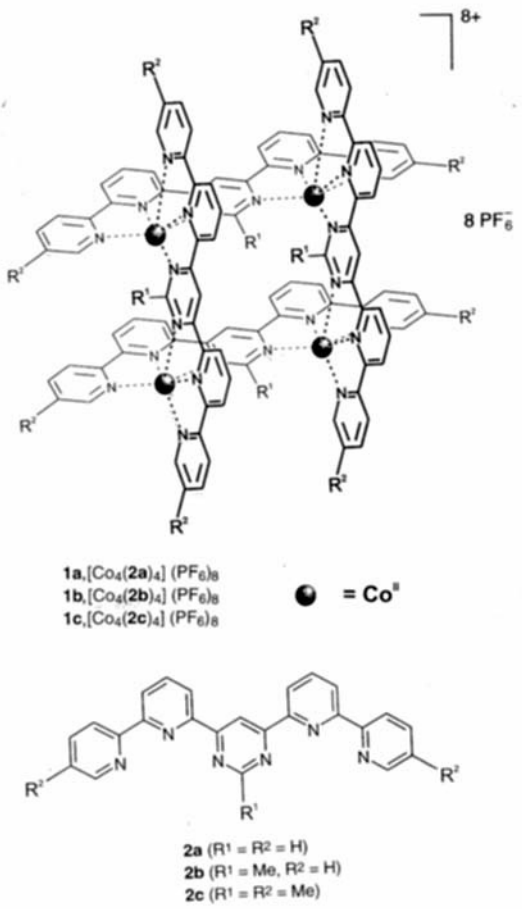
Ligands **2a–c** were synthesized by Stille cross-coupling reactions between stannyl bipyridines and dichloropyrimidines.[10] The ligands vary in the substitution at the 2-position of the central pyrimidine ring (R = H, Me) and at the 5-position of the terminal pyridine ring (R = H, Me). The steric effect of the substituent in the pyrimidine 2-position was previously shown to influence the relative disposition of ancillary ligands in $[2]R$-diruthenium(II) complexes.[2] The 5-methyl groups on the terminal pyridine ring in **2c** were introduced to allow functionalization of the grid-type structure for incorporation into more complex systems.

Mixing equimolar amounts of cobalt acetate tetrahydrate and ligands **2a**, **2b**, or **2c** in methanol at reflux led to the assembly of the $[2 \times 2]G$ tetracobalt(II) complexes **1a–c** in high yields (typically ranging from 80 to 85% after precipitation as their PF_6^-, AsF_6^-, or SbF_6^- salts). The elemental analyses of **1a–c** indicate a 1:1 ligand-to-metal ratio.

The electrospray mass spectrum of **1b** shows only the peaks from multiply charged cationic species, due to loss of the hexafluorophosphate counteranions. It unequivocally confirms the grid structures in solution, in agreement with data from analytical ultracentrifugation studies.[11]

Slow diffusion of methanol into saturated acetonitrile solutions of the complexes gave crystalline materials. Single crystals of the complex $[Co_4(\mathbf{2b})_4](SbF_6)_8$ of sufficient quality were obtained, and its structure was determined by X-ray crystallography.[12, 13]

The asymmetric unit contains a single cation and eight SbF_6^- counteranions of which two are highly disordered (Figure 1). The complex cation is composed of four ligands **2b** and four cobalt cations arranged in a $[2 \times 2]$-grid-type structure of distorted D_{2d} symmetry. The metal ions lie almost perfectly in a plane (mean deviation of 0.13 Å) and form a slightly distorted square (angles of 88.8–91.4°) with Co,Co distances of 6.41–



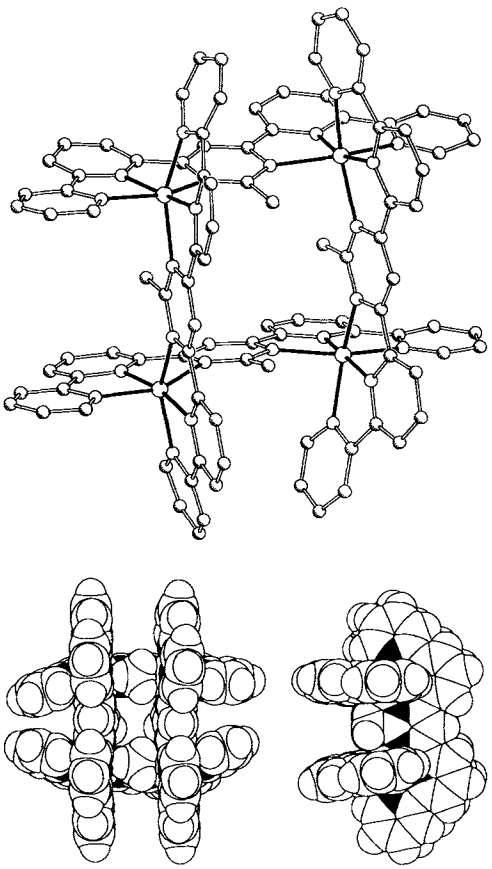


Figure 1. Crystal structure of the tetranuclear $[2 \times 2]$-grid-type complex cation $[Co_4(\mathbf{2b})_4]^{8+}$ of **1b**. Top: ball-and-stick representation (hydrogen atoms omitted for clarity); bottom: two views in space-filling representation.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3617-1843 $ 17.50+.50/0

6.52 Å. They display a distorted octahedral coordination to two perpendicularly oriented ligand fragments. The average Co,N distances are 2.10 (pyridine-N) and 2.23 Å (pyrimidine-N); the average Co,Co distance is 6.35 Å. The complex cation is roughly a parallelipiped with almost parallel walls and dimensions $20 \times 20 \times 14$ Å (total volume 5600 Å^3).

The self-assembly of the [2 × 2]-grids complies with the principle of "maximum coordination site occupation"[1, 14] and may further be rationalized in terms of the appropriate design of the ligand and choice of its dimensional properties, which exclusively lead to the generation of the closed grid structure instead of a coordination polymer. Indeed, the formation of the latter is hindered by the steric repulsion that would arise between the partially overlapping terminal pyridines in the polymeric structure.

The degree of metal–metal interaction in polynuclear complexes is highly dependent on the nature of the bridging ligand.[15] Ligands **2a** and **2b** were previously shown to mediate electronic interactions between the metal ions within [2]*R*-Ru^{II} rack-type complexes.[2, 3] In the present grid complexes, each Co^{II} ion is connected at a distance of 6.5 Å to its two nearest neighbors through the pyrimidine moities, whilst the Co^{II} ion at the opposite corner is farther away (Co$^{II}\cdots$Co^{II}: 9.2 Å).

Interaction between the metal ions may be indicated by the redox properties of the complexes. Complex **1a** undergoes reversible oxidations of the cobalt centers at + 0.46, + 0.66, and + 0,91 V (vs. SCE in DMF).[16] These values are more positive than those found in $[Co^{II}(terpy)_2](PF_6)_2$.[17a] The first four reductions at − 0.14, − 0.24, − 0.44, and − 0.83 V are ascribed to the Co$^{II}\rightarrow$Co^{I} reduction process and occur at a less negative potential than those of $[Co^{II}(terpy)_2](PF_6)_2$[17a] and of a related dinuclear Co^{II} complex of sexipyridine.[17b] The next four reversible one-electron reductions are ascribed to ligand-localized reductions at − 0.83, − 1.09, − 1.33, and − 1.77 V. Complexes **1b** and **1c** also undergo multiple redox processes.[13]

As a first approximation the observed trends in electrochemical behavior may be explained by the high charge of the tetranuclear Co^{II} grids, which—just for electrostatic reasons—makes these complexes easier to reduce than their mononuclear counterparts. In addition, the electronic interactions between the metal ions may make a significant contribution to the altered redox potentials of the Co^{II} ions. Magnetization studies on compound **1b** indicate an antiferromagnetic exchange interaction between the Co^{II} ions.[18]

The UV spectra of the complexes **1a–c** in acetonitrile show broad and highly intense absorption bands at 275 and 345 nm, which may be assigned to nonresolved, ligand-centered (LC) $\pi-\pi^*$ transitions. In the visible region, the broad bands centered between 440–450 nm are assigned to Co^{II}–bipyridine MLCT transitions, and the broad shoulder at about 550 nm could be due to a Co^{II}–pyrimidine MLCT transition.

The present results demonstrate the directed synthesis of [2 × 2]-grid-type coordination arrays of octahedrally coordinated metal ions by a simple, yet efficient self-assembly approach. This approach is general and has been applied to other metal ions to generate grids of Ni^{II}, Zn^{II}, Cd^{II}, and Cu^{II}.[13] The appropriate shape of the ligands ensures a rigid and discrete spacing between the metal ions. The physicochemical properties of complexes **1a–c** indicate that electronic interactions exist between the Co^{II} ions and that coordination arrays of grid type may be suitable building blocks for the construction of molecular information storage devices. For instance, single grids embedded into a highly ordered monolayer might be individualy addressable by altering their redox state with the tip of a scanning–tunneling microscope. Another strategy could be the construction of devices in which the metal ions within the coordination arrays form magnetic domains. Investigations of higher ranking racks, ladders, and grids containing different bridging groups as well as other transition metal ions are being pursued.[19]

Designed Self-Generation of an Extended Helical Structure From an Achiral Polyheterocyclic Strand**

Dario M. Bassani, Jean-Marie Lehn,* Gerhard Baum, and Dieter Fenske

The generation of helical chemical entities requires specific structural and conformational features. The helicity in the molecular chains of proteins and nucleic acids as well as in the supramolecular strands of self-assembled hydrogen-bonded polymers[1] results from the presence of an asymmetrically substituted carbon atom in the backbone components. Numerous organic molecules present helical characteristics.[2] The helicity of self-assembled metal complexes, the helicates, rests on the design of the ligands and on the choice of the coordinating metal ion.[1]

Helicity induction into a molecular or supramolecular strand thus requires encoding of structural and conformational information through suitable design of the components. This is the case for a new structural motif reported recently, that led to the formation of a helical structure from a nonchiral linear molecule.[3] It is based on the preference of 2,2′-bipyridine for a *transoid* conformation[4] and relies on the combination of three basic features: 1) an alternating sequence of pyridine and pyrimidine units, 2) the linkage of these units at specific positions, and 3) the *transoid* conformation adopted by the single bonds linking the units. The combination of these features is illustrated in **A** for a species composed of six alternating pyridine–pyrimidine heterocycles. A molecule of this type (**1**, Scheme 1) adopts a helical structure in solution and in the solid phase.[3] We now report the synthesis and structure elucidation of compound **3**, composed of thirteen alternating pyridine–pyrimidine units. Its preference for the helical conformation **3A** demonstrates the generality of the principle outlined above.

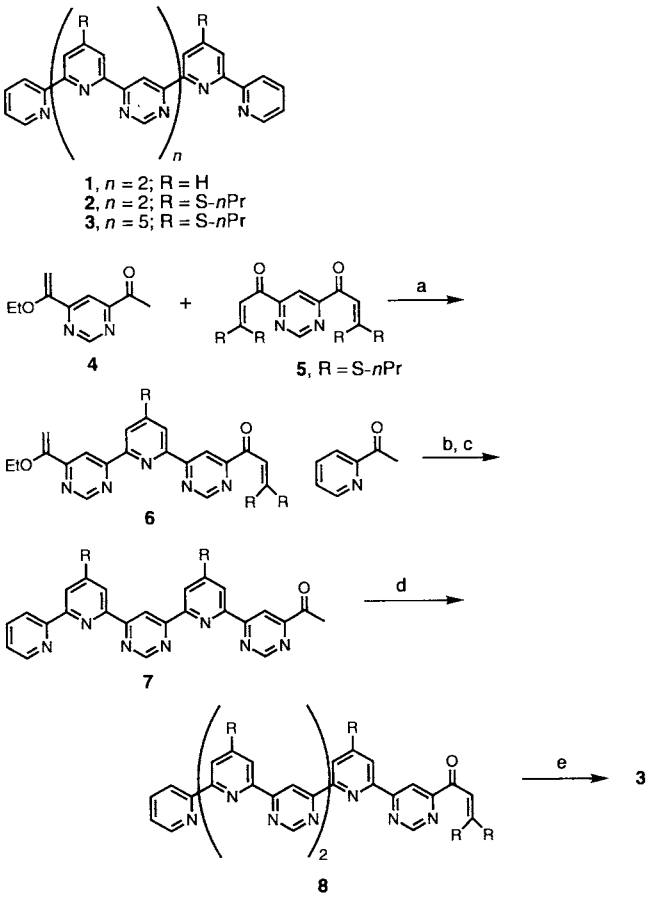
The synthesis of **3** was accomplished by a combination of tin-mediated cross-coupling reactions and Potts's synthesis of 2,6-disubstituted pyridines (Scheme 1).[5] Compound **4** was prepared in three steps from 4,6-dichloropyrimidine and α-ethoxyvinyltributyltin[6] Construction of other symmetrical and unsymmetrical pyridine–pyrimidine sequences, such as **2**, is possible with different combinations of **4**, **5**, and **6**.[7]



Scheme 1. a) 1. *t*BuOK, DMSO, RT; 2. NH_4OAc (44%). b) 1. *t*BuOK, **6**, THF, RT; 2. NH_4OAc (53%). c) HCl_{aq} (70%). d) 1. *t*BuOK, **5**, THF, RT; 2. NH_4OAc (46%); e) 1. *t*BuOK, **7**, THF (reflux); 2. NH_4OAc (47%).

The use of α-oxoketene dithioacetals in the preparation of **3** has the advantage over other syntheses of substituted pyridines that one of the thioalkyl groups is retained in the incipient pyridine heterocycle after ring closure. Thus, **3** incorporates six thiopropyl side chains, which contribute to its solubility in organic solvents such as chloroform. The presence of substituents in the C-4 position of the pyridines is not expected to interfere with helication, as they are oriented outwards from the helix.

The structure of **3** in solution may be deduced from ^1H NMR studies. The assignments shown in Figure 1 were determined by combining the results from COSY and ROESY NMR experiments. Nevertheless, protons corresponding to the trisubstituted pyridines (H5, H6, H9, H10, H13, and H14) could not be unambiguously assigned. The high upfield shifts observed for the terminal pyridine H2 and H3 are indicative of significant shielding by nearby heterocycles. Strong NOE interactions are observed in the ROESY NMR spectrum between H4 and H8, H8 and H12, and H12 and H16. This is consistent with a helical conformation in which the pyrimidine C5 carbon atoms point towards the interior and the thiopropyl side chains towards the exterior of the helix. The interior cavity is lined alternately with pyridine nitrogen atoms and pyrimidine C–H groups. Such a structure places H2 and H3 above a central pyridine ring, which could account for their significant upfield chemical shifts. It also corresponds to an all-*transoid* conformation about the single bonds connecting the heterocyclic subunits. It is thus assumed that, in solution, **3** adopts the helical conformation **3A** with two turns.

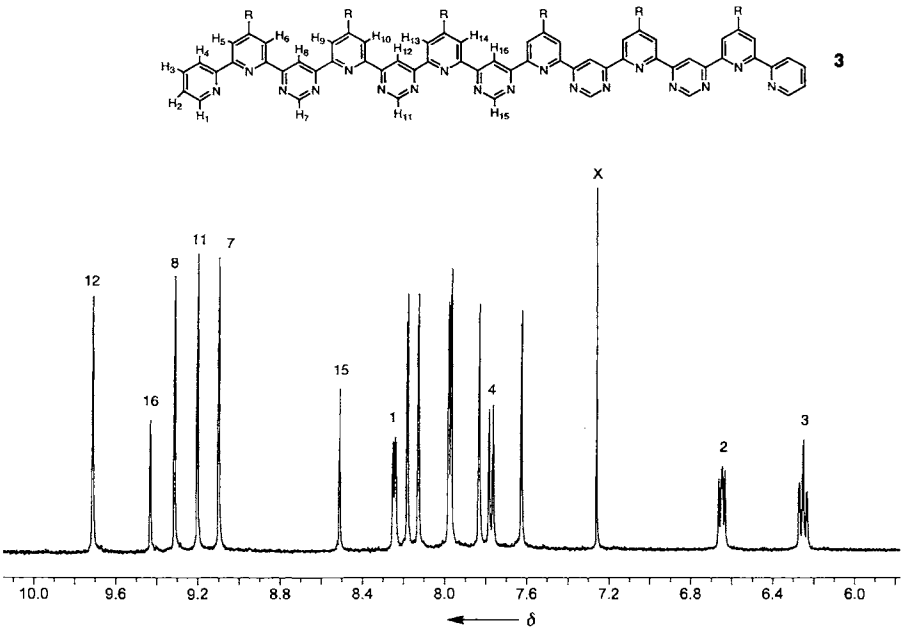

Figure 1. Portion of the 400 MHz ^{1}H NMR spectrum of **3** in $CDCl_3$ showing the signals from aromatic residues. Signal assignment is shown above the relevant peak and was deduced from COSY and ROESY NMR experiments.

Further evidence for the helical nature of **3** is provided by its fluorescence spectrum (Figure 2). The overlap of the pyridine rings gives rise to some rather unusual electronic interactions between the aromatic residues. Thus, upon excitation of dilute

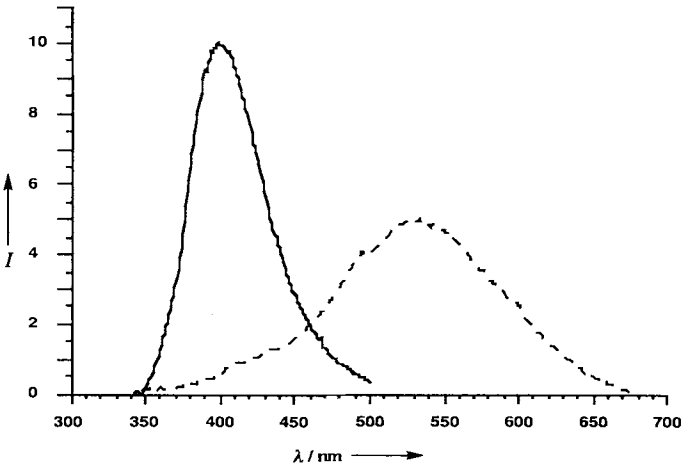

Figure 2. Fluorescence emission spectra of **2** (solid line) and **3** (dashed line) in dichloromethane upon excitation at 280 nm; I = relative intensity ($c \approx 1 \times 10^{-5}$ M).

solutions of **2** in dichloromethane at 280 nm, pyridine-like fluorescence is observed at about 400 nm. However, excitation of **3** under similar conditions results in the observation of a broad, structureless band at 540 nm and only weak residual pyridine fluorescence. The band at longer wavelengths is attributed to emission from intramolecular pyridine excited state dimers (excimers); these dimers result from the self-organized stacking of the pyridine residues in the helix. The lack of excimer fluorescence in **2** despite the overlap of the terminal pyridines may be attributed to an unfavorable geometry, or to their greater mobility because **2** only forms one turn of a helix. Fluorescence emission at 550 nm has been reported to occur in polypyridine polymers and was assigned to excimer formation.[8]

The crystal structure of **3** is shown in Figure 3 (see opposite page) and unambiguously identifies the solid-state structure as helical.[9] The unit cell is centrosymmetric and contains four molecules of **3** (two enantiomeric pairs) and eight molecules of acetonitrile. In the crystal structure the molecules are stacked one above the other along a central axis, thus forming long channels, a feature of interest for ion channel design. Each molecule possesses a twofold rotation axis passing through the central pyrimidine. The pyridine–pyrimidine torsional angles are between 8.0° and 14.0°, whereas the two terminal pyridines are offset by only 3.5°. The structure possesses an interior void of 2.6 Å diameter and a helical pitch of 3.75 Å.

Stabilization of the helical conformation **3A** may also involve favorable aromatic stacking interactions in addition to the preference for a *transoid* geometry about the single bonds.[4] The latter may be attributed to electrostatic repulsion between the nitrogen dipoles and steric repulsion between the CH groups in the *cisoid* conformation. The helical structure adopted by *m*-deciphenyl in the solid state[10] may also result from favorable stacking interactions.

The present results demonstrate the generality of the principle of helicity induction in chains of alternating pyridine–pyrimidine heterocycles. This spontaneous formation of a helical superstructure also represents a molecular self-organization process directed by the structural and conformational information encoded in the polyheterocyclic strand and operating through intramolecular nonbonded interactions, in the same way as supramolecular self-organization is based on intermolecular recognition events and noncovalent interactions.[1] One may envisage combining intra- and intermolecular interactions to induce self-organization of complex chemical architectures on both the molecular and supramolecular levels.

Analysis of the Bonding in $[Ni_5(\mu_5\text{-}S)(\mu_2\text{-}SR)_5]^-$, an Unprecedented Pentanuclear Sulfide Cluster**

Fu-Wah Cheung and Zhenyang Lin*

In the past decade, much progress has been made in the synthetic chemistry of metal chalcogenide clusters.[1-6] These clusters can act as model compounds for the active sites of certain metalloproteins and metal sulfide catalysts.[7] They also exhibit many interesting structural types and bonding modes. Chalcogen atoms in metal chalcogenide clusters can occupy terminal or bridging positions (μ_n, $n = 2$–6). The existence of numerous coordination modes of chalcogenide ligands gives rise to the question whether they are part of the polyhedral framework. In other words, the electronic structures of these clusters is difficult to describe. As Dance and Fisher noted in their review,[1] the diversity of compositions and structures known for metal chalcogenide clusters makes the establishment of a relationship between the observed geometry and bonding theory a true challenge.

Such relationships have been established for boranes and metal carbonyl clusters: in the 1970s, Williams and Wade[8-9] formulated well-known $n+1$ rule, which describes the relationship between the structure of boranes and carboranes and the number of skeletal electrons. Subsequently, Wade and Mingos[9-11] recognized the similarities between the bonding in these main group clusters and that in many transition metal carbonyl clusters. Since then, the geometries of these various clusters have been systematized by a set of rules known collectively as the polyhedral skeletal electron pair theory (PSEPT), which describes the relationship between the skeletal structure and the total number of valence electrons in clusters.[11] Other rules have also been put forward to account for these structural relationships.[12,13] While these rules have proved helpful in understanding the structure and bonding of transition metal carbonyl clusters, they can not readily be extended to metal chalcogenide clusters.[14] For example, the recently synthesized pentagonal cluster **1** formally contains nickel atoms of oxidation state +1.2. A formal nickel oxidation state of +1.6 is found in $[Ni_{20}Se_{12}(SeMe)_{10}]^{2-}$,[3] although this cluster contains similar $Ni_5(\mu_5\text{-}Se)$ structural units. A simple description of the bonding in these compounds was regarded as impossible.[3]

Here we describe a simple bonding model, based on the or-

bital interaction concept,[15] for the unprecedented pentagonal cluster **1**. We hope that this analysis will serve as a foundation for a similar orbital interaction concept that will explain the bonding situation in all Ni–S and Ni–Se clusters.

On examining the structure of the $[Ni_5S(StBu)_5]^-$ cluster, one can see that each nickel metal atom is bonded to two *tert*-butyl sulfide ligands. In other words, $[Ni_5S(StBu)_5]^-$ can be regarded as being derived from five ML_2 fragments (M = Ni, L = *t*BuS ligand) and a μ_5-S capping atom. The molecular orbitals of an ML_2 fragment are shown in Figure 1a. The frontier orbitals of the fragments that are involved in the metal–metal interaction are depicted with their orbital lobes. Because of the high 3d–4p promotion energy, the contribution of the p_z orbital to the metal–metal bonding is ignored in the following discussion of the orbital interactions for the sake of simplicity. Figure 1b

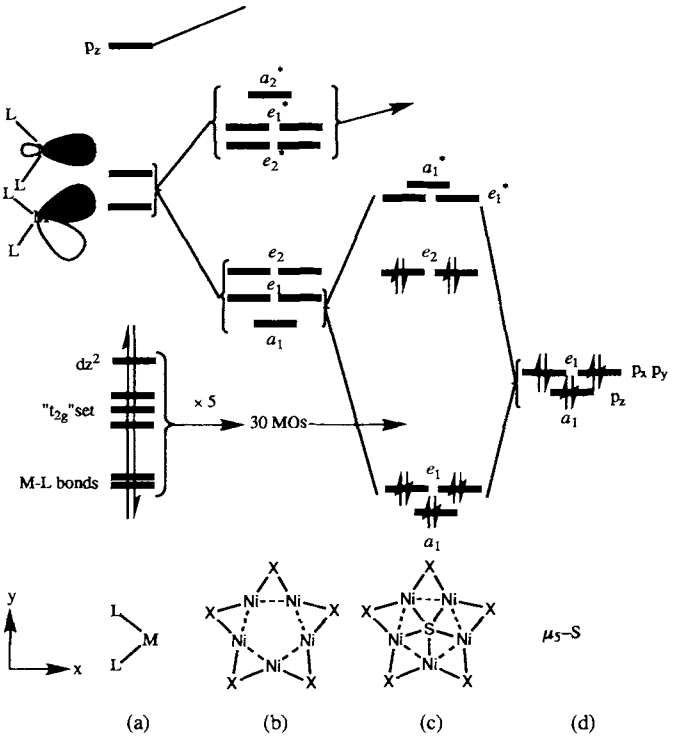

Figure 1. MO diagrams for $[Ni_5S(StBu)_5^-]$ in which *S*t*Bu* groups are represented by X. a) Frontier orbitals of an ML_2 fragment; b) orbitals of Ni_5X_5; c) orbitals of Ni_5SX_5; d) p valence orbitals of the capping μ_5 sulfur atom.

shows the energy levels of the molecular orbitals (MOs) derived from the linear combinations of five ML_2 fragment orbitals. In the lower part of the MO diagram, 30 MOs are derived mainly from the M–L σ bonds (two per fragment)and the t_{2g} and d_{z^2} orbitals. These 30 orbitals are fully occupied and, therefore, their contributions to the metal–metal bonding can be neglected. The interactions of the frontier orbitals of the five fragments gives rise to five bonding ($a_1 + e_1 + e_2$) and five antibonding ($a_2^* + e_1^* + e_2^*$) MOs. The five metal–metal bonding orbitals correspond formally to the five metal–metal edge bonds.

Figure 1c shows the resulting MO energy levels for $[Ni_5(\mu_5\text{-}S)(\mu_2\text{-}StBu)_5]^-$. In the point group C_{5v}, the orbitals of the capping sulfur atom have the transformation properties of $a_1(p_z)$ and $e_1(p_x, p_y)$ symmetries (see Figure 1d). The sulfur p_z orbital is of appropriate symmetry to interact strongly with the a_1 orbital of the pentagonal fragment. Similarly, the p_x and p_y orbitals of sulfur are of appropriate symmetry to interact strongly with the e_1 orbitals. As a result of the interaction between the pentagonal $[Ni_5(\mu_2\text{-}StBu)_5]$ fragment and the capping μ_5-sulfur atom, three ($a_1 + e_1$) of the five metal–metal bonding orbitals stabilize the three p orbitals of the capping sulfur atom, and three additional antibonding orbitals are generated (see Figure 1c). The e_2 orbitals remain nonbonding as there are no orbitals of the same symmetry on the capping atom. A preliminary MO calculation[16] on the model compound $[Ni_5(\mu_5\text{-}S)(\mu_2\text{-}StBu)_5]^-$ showed that the e_2 orbitals are indeed the HOMOs (Figure 2). The HOMO–LUMO gap is 0.28 au, which is remarkably large.

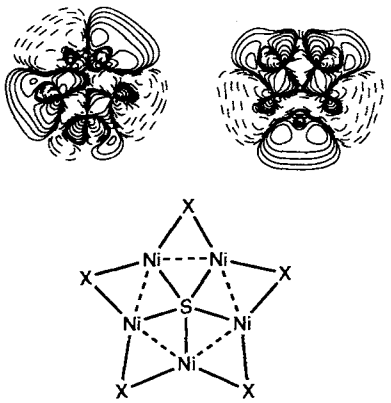

Figure 2. Contour maps of the two HOMOs (e_2) of the $[Ni_5(S(SH)_5]^-$ cluster complex. The contours of the plots decrease by a factor of 1/2, and the lowest contour is 0.000976563.

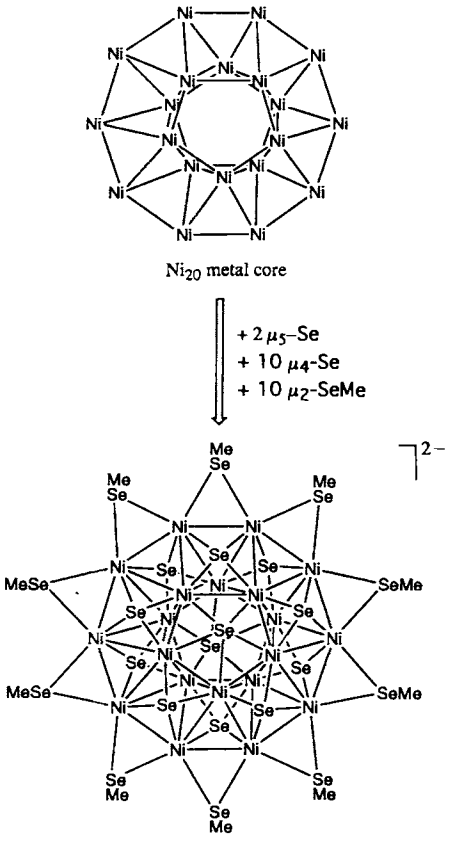
The $[Ni_5S(StBu)_5]^-$ cluster has 70 valence electrons. Figure 1b shows that the 30 molecular orbitals are completely filled with 60 electrons. These 60 electrons do not take part in $Ni\text{–}S_{capping}$ and M–M interactions. Therefore, ten valence electrons are available for $Ni\text{–}S_{capping}$ and M–M bonding. If these extra ten valence electrons are excluded, one would expect each Ni atom to have a d^8 electron configuration. When the ten valence electrons are added, six electrons are formally assigned to the capping S^{2-} ligand. The remaining four electrons, which occupy the e_2 metal–metal bonding orbitals, should be assigned to the five Ni atoms. Each nickel atom therefore has formally 8.8 d electrons ($d^{8.8}$ configuration), and a formal mean oxidation state of +1.2 can be assigned. As discussed above, because the p_z orbital of each Ni atom is hardly involved in the bonding, the $[Ni_5S(StBu)_5]^-$ cluster actually fulfills the 16-electron rule.

Based on the analysis of $[Ni_5S(StBu)_5]^-$ complex, we can now describe the bonding in the novel selenolato-bridged nickel cluster **2** (Scheme 1).[3] The central unit of the $[Ni_{20}Se_{12}(SeMe)_{10}]^{2-}$ anion is a pentagonal Ni_{10} antiprism in which the two pentagonal faces are capped by two μ_5-Se ligands. The remaining ten nickel atoms form a ten-membered ring that encompasses the pentagonal antiprism and in which the nickel atoms bridge the edges along the prismatic axis. The ten μ_4-Se ligands cap the square faces formed by the Ni_{20} metal core. Five of them are above the ten-membered ring, and the other five are below the ring (see Scheme 1). In such an arrangement, the central antiprismatic unit of the $[Ni_{20}Se_{12}(SeMe)_{10}]^{2-}$ complex can be regarded as a combination of two $[Ni_5(\mu_5\text{-}Se)(\mu_2\text{-}Se)_5]$ units, similar to the above-mentioned $[Ni_5(\mu_5\text{-}S)(\mu_2\text{-}StBu)_5]^-$ complex.

The outer Ni_{10} ring is bridged by ten μ_2-SeMe groups, and therefore each nickel atom in the Ni_{10} ring is coordinated by two $SeMe^-$ and two Se^{2-} ligands in a distorted tetrahedral fashion. If the metal–metal interaction between the two pentagonal

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3617-1848 $ 17.50+.50/0



Scheme 1.

units and that between the central Ni_{10} antiprismatic unit and the encompassing ten-membered ring are weak, one would expect that the bonding in the $Ni_5(\mu_5\text{-S})$ unit in the Ni_{20} cluster should be similar to that of the $[Ni_5(\mu_5\text{-S})(\mu_2\text{-S}t\text{Bu})_5]^-$ cluster. In other words, if the three building blocks [two $Ni_5(\mu_5\text{-S})$ units and one Ni_{10} ten-membered ring] are simply connected by the ten μ_4-Se bridging ligands and no metal–metal interactions occur, an oxidation state of +1.2 can be assigned to each Ni atom of the central pentagonal antiprismatic unit. As $[Ni_{20}Se_{12}(SeMe)_{10}]^{2-}$ contains 20 Ni atoms with a total charge of +32, each Ni atom in the ten-membered ring should have a formal oxidation state of +2.0. If we examine the structure of $[Ni_{20}Se_{12}(SeMe)_{10}]^{2-}$ in detail, this bonding description seems quite plausible, as the Ni–Ni distances within each of the two pentagonal $Ni_5(\mu_5\text{-Se})$ units (ca. 2.47 Å) are much shorter than those between the two $Ni_5(\mu_5\text{-Se})$ units (ca. 2.62 Å).[3] The Ni–Ni distances within the Ni_{10} ten-membered ring (ca. 2.57 Å) and between the Ni_{10} ten-membered ring and the two pentagonal $Ni_5(\mu_5\text{-Se})$ units (ca. 2.53 Å) are also noticeably longer. The assignment of a formal oxidation state of +2.0 for each Ni atom in the ten-membered ring is also reasonable, since several trinuclear Ni clusters, for example $[Ni_3S(S\text{Bu})_3(CN)_3]^{2-}$,[6] $[Ni_3S(SMe)_6]^{2-}$,[17] $[Ni_3S(SCH_2C_6H_4CH_2S)_3)^{2-}$,[18] and $[Ni_3S(SPh)_6]^{2-}$,[19] contain tetrahedrally coordinated Ni^{II} centers.

A preliminary ab initio calculation[16] on $[Ni_{20}(\mu_5\text{-Se})_2(\mu_4\text{-Se})_{10}(\mu_2\text{-SeH})_{10}]^-$ gave net atomic charges of +0.12 and +0.23 for the inner Ni atoms [those in the two $Ni_5(\mu_5\text{-Se})$ pentagonal units] and the outer Ni atoms (those in the ten-membered ring), respectively. This result supports the above conclusion that the outer Ni atoms have a higher atomic charge than the inner ones. The bonding similarity between the two $Ni_5(\mu_5\text{-Se})$ pentagonal units of this Ni_{20} cluster and the $[Ni_5(\mu_5\text{-S})(\mu_2\text{-SR})_5]^-$ cluster is also supported by their similar net atomic charges. The net atomic charge of the Ni atoms in the latter is +0.15.

In summary, contrary to the common belief that a simple description of the bonding situation in the Ni–S(Se) clusters is not possible, we have demonstrated that the cluster $[Ni_5S(S\text{Bu})_5]^-$ can be understood in terms of a schematic MO diagram; $[Ni_5S(S\text{Bu}^t)_5]^-$ has a total number of 70 valence electrons and thus obeys the 16-electron rule. Based on the mean oxidation number of nickel atoms in $[Ni_5S(S\text{Bu})_5]^-$, $[Ni_{20}Se_{12}(SeMe)_{10}]^{2-}$ can be regarded as containing ten Ni atoms of oxidation state +1.2 and ten of oxidation state +2. We are now examining other Ni–S(Se) clusters such as $[Ni_5Se_4Cl_2(PEt_2Me)_6]$,[2] $[Ni_8S(SC_4H_9)_9]^-$[5] and $[Ni_{12}(S_2)_6S_8]^{3-}$[20] to determine whether we can find a simple bonding description for them.

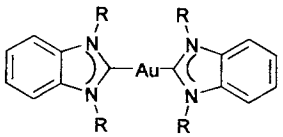
A Facile Synthesis of Unusual Liquid-Crystalline Gold(I) Dicarbene Compounds**

Kwang Ming Lee, Ching Kuan Lee, and Ivan J. B. Lin*

Self-assembly of molecules through weak forces such as hydrogen bonds and hydrophobic and electrostatic interactions to form supramolecular aggregates has become a major research area in recent years.[1] While conventional liquid crystals (LC) are one aspect of this subject,[2] metal-containing liquid crystals (metallomesogens, MLCs) provide new possibilities for varying the structure and properties such as color and polarizability.[3] Designing stable MLCs remains a challenge. Many MLCs decompose at the clearing point; their applications are therefore limited. We are interested in the chemistry of gold(I). Gold(I) compounds are used in medicine, they exhibit remarkable photophysical properties, and aurophilic interactions are important in the construction of supramolecules. The above reasons and the inherent thermal stability of metal complexes of 1,3-disubstituted imidazol-2-ylidene (imy) led us to investigate the synthesis of liquid-crystalline bis(1,3-dialkylbenzimidazol-2-ylidene)gold(I) bromide $[\{(C_nH_{2n+1})_2\text{-bimy}\}_2Au]Br$ ($n = 12, 14, 16$).

Gold(I) carbene compounds have been prepared by methods such as addition of alcohols or amines to coordinated isocyanides,[4a,b] carbene transfer from tungsten complexes,[4c] alkylation of gold(I)-2-pyridine or gold(I)-2-thiazole,[4d] and other, unexpected methods.[4e] In these methods, bases such as KO*t*Bu, NaH, or LiBu were used, solvents had to be dried, and reactions had to be carried out under a dry nitrogen atmosphere. Initially, we attempted to synthesize compounds **1** by treating salts of the 1,3-dialkylbenzimidalozolium cation $[(C_nH_{2n+1})_2\text{-bim}]^+$ with AgOAc, NaH, or LiBu in dry THF. However, yields were low, and care had to be taken to avoid extensive decomposition. In the last decade, we have used phase-transfer catalysis (PTC) techniques in the synthesis of metal ylides[5] and the hydrolysis of Pt–dppm compounds (dppm = $Ph_2PCH_2PPh_2$);[6] therefore, the idea of using PTC to synthesize **1** seemed logical. It turns out that PTC is an excellent synthetic route to **1**. Thus treatment of $Au(SMe_2)Cl$ with $[(C_nH_{2n+1})_2\text{-bim}]Br$ ($n = 12, 14, 16$) under PTC/OH^- conditions leads to the formation of **1** in greater than 80% yield.



$[((R)_2\text{-bimy})_2Au]Br$ **1** ($R = C_nH_{2n+1}$, $n = 12, 14, 16$),

The structure[7] of cationic $[\{(C_{16}H_{33})_2\text{-bimy}\}_2Au]^+$ is shown in Figure 1. Each molecular cation has four alkyl chains, which are "perpendicular" to the bimy rings and which all point in the same direction. That this must not necessarily be so is illustrated by pyridinium salts[8] and a cyanine dye.[9] If the plane formed by two bimy rings and a gold atom is regarded as a table top, then the molecular geometry of the cation resembles a table with four slightly distorted legs. Each table top forms Br···O bridges, and this results in a herringbone-like arrangement in the plane. Interdigitation of two such planes, with interpenetrating alkyl chains, produces a bilayer of about 22 Å thickness; stacking of bilayers gives a lamellar structure (Figure 2) with a repeating lamellar spacing of about 26 Å and an Au···Au distance of 3.66 Å. Along the normal plane (i.e., along the *c*-axis), the table tops exhibit columnar stacking. Two of the four alkyl chains of a molecular cation are more highly distorted to allow better packing and stronger hydrophobic interations between interpenetrating chains. Structures of gold–bis(imy) com-

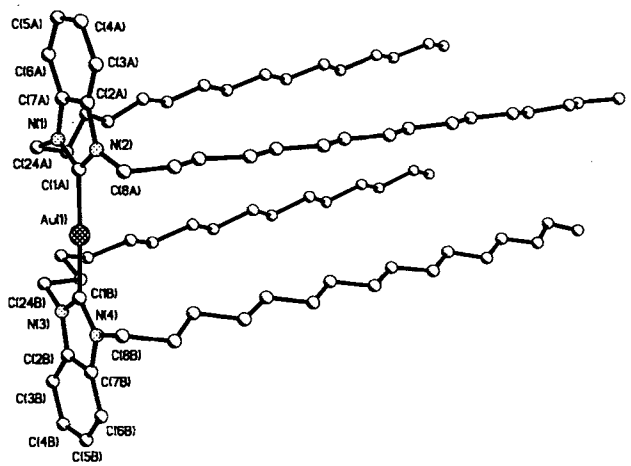


Figure 1. Structure of the cation of **1** ($n = 16$) with partial atom numbering. Hydrogen atoms of the alkyl chains have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Au(1)–C(1A) 2.03(2), Au(1)–C(1B) 2.02(2), N(1)–C(1A) 1.36(2), N(1)–C(7A) 1.40(3), N(2)–C(1A) 1.36(2), N(2)–C(2A) 1.38(2), C(2A)–C(7A) 1.44(3), N(3)–C(1B) 1.35(2), N(3)–C(2B) 1.39(2), N(4)–C(1B) 1.40(2), N(4)–C(7B) 1.40(2), C(2B)–C(7B) 1.43(3); C(1A)-Au(1)-C(1B) 176.5(12), N(1)-C(1A)-N(2) 113(2), C(1A)-N1-C(7A) 101(2), C(1A)-N(2)-C(2A) 109(2), N(1)-C(7A)-C(2A) 113(2), N(2)-C(2A)-C(2A) 104(2), N(3)-C(1B)-N(4) 108(4), C(1B)-N4-C(7B) 109(2), C(1B)-N(3)-C(2B) 109(2), N(4)-C(7B)-C(2B) 105(2), N(3)-C(2B)-C(7B) 108(2)

pounds with short *N*-alkyl chains and Au–Au distances of 3.37 and 3.23 Å have been reported.[10]

Examples of gold(I) MLCs are rare.[11] These gold(I) MLCs require high temperatures for the transition into the liquid-crystalline phase and have narrow mesophase temperature ranges and low thermal stability. In contrast, the ionic gold dicarbenes presented here have relatively low transition temperatures (Table 1, determined by differential scanning calorimetry, DSC)

Table 1. Transition temperatures [°C] of complexes **1** ($n = 12, 14, 16$) [a]; in parentheses: ΔH [kJ mol^{-1}].

n	K		M		I

and high thermal stability. For example, compound **1** ($n = 14$) undergoes the transition from crystal (K) to LC phase at 93 °C (at 76 °C on cooling), and the mesophase has a range of 70 °C; decomposition occurs only above 240 °C. The mesomorphic structure of **1** ($n = 14$) was studied by X-ray diffraction (XRD) and polarized optical microscopy (POM). The XRD spectrum of a nonoriented LC sample is characterized by a series of intense reflections and another set of relatively weak reflections around a diffraction angle 2θ of 9° (Figure 3). The former set of

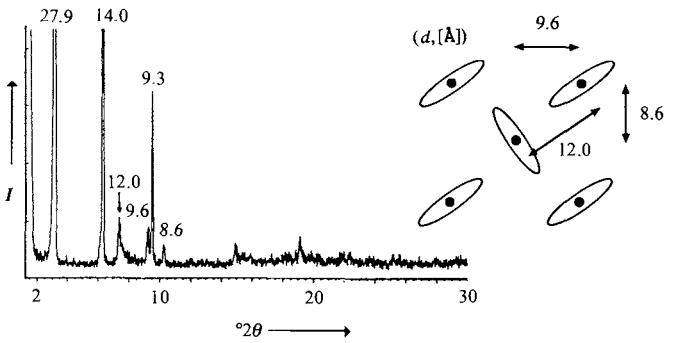

Figure 3. X-ray diffraction spectrum of **1** ($n = 14$) at 120 °C, showing the ordering of repeating layers and the order within the layers. A schematic representation of the latter is also given.

reflections is related to the stacking period of the layers, and the latter set is indicative of ordering of the molecules within the layers. The strong reflections yield a repeating layer distance of 27.9 Å. The three weak reflections at 12.0, 9.6, and 8.6 Å result from the herringbone order in the layers (Figure 3). Therefore, results of XRD investigations suggest that the mesomorphic structure of **1** ($n = 14$) is a layer structure with order in the layers; that is, a lamellar β phase. A POM investigation of the mesophase at 160 °C shows irregularly shaped dendrites, which on further cooling (140 °C) form the mosaic texture (Figure 4) typical for a lamellar β phase. The mesophase deduced from XRD and POM studies is similar to those found for 1,2,ψ,ω-*n*-alkanetetraols.[12]

We have synthesized liquid-crystalline gold dicarbenes under very mild PTC/OH$^-$ conditions. The ease of formation of gold carbene compounds suggests the possible formation of metal carbene compounds under physiological conditions. These thermally stable and highly ordered liquid-crystalline compounds are the first example of gold(I) dicarbene compounds in which a lamellar β mesophase is formed by the unusual interdigitation of long alkyl chains. The formation of this mesophase is the result of a compromise between aromatic π interactions, hydrophobic interactions of alkyl chains, and hydrogen-bonding forces between the anions and C–H hydrogen atoms. Currently we are investigating derivatives of bimy and imy salts with chiral anions or substituted *N*-alkyl chains, to produce ferroelectric systems.

Cyclic "Acetylenosaccharides"—Novel Cyclodextrin Analogues**

Roland Bürli and Andrea Vasella*

Analogues of cyclodextrins (CDs) with a designed shape, size, and electrostatic potential of the cavity are of interest as specific host molecules. An incisive change of the cavity of the CDs is attained, for example, by changing the configuration and/or the conformation of the repetitive unit.[2] Substitution of one or several of these units by non-saccharide moieties also leads to a profound change of the cavity, as demonstrated by the "glycophanes".[3]

Diethynylated carbohydrates in which the angle between the ethynyl substituents is lower than 180° are potential building blocks for the preparation of cyclic "acetylenosaccharides".[4] A large number of such monomeric building blocks is conceptually available by changing the constitution (position of the ethynyl substituents, pyranose or furanose form, mono- or oligosaccharide) and/or the configuration. Several coupling steps are required for the preparation of cyclic "acetylenosaccharides" from a given monomer; homo- and/or heterocoupling leads to constitutional isomers of a specific ring size. 1,4-*cis*-Diethynylated glucopyranose derivatives should lead to cyclodextrin analogues;[5] this monomer has the same configuration as the repetitive unit of the CDs and is connected at the same positions of the tetrahydropyrane units, albeit by butadiyne units.

An efficient synthesis of the D_2-symmetric cyclotetramer **8**, which is prepared by homocoupling the 1,4-*cis*-diethynylated glucopyranose **1**, is presented in Scheme 1. Two additional macrocycles, the D_3-symmetric cyclohexamer **9** and the D_4-symmetric cyclooctamer **10** were isolated as by-products.

The readily available[5] mono-*C*-silylated dialkyne **1**[1] was converted to the butadiyne **2** in a yield of 83% by homocoupling under Glaser conditions;[6] the trimer **3** was isolated as a by-product (9%). Base-catalyzed desilylation of the dimer **2** led to the butadiyne derivative **4**, which was added to a solution of $Cu(OAc)_2$ in pyridine over a period of 10 h; separation by chromatography of the cyclooligomers (**5** (68%), **6** (7%), and **7** (1.8%)) and subsequent deprotection with HCl in methanol led to the cyclotetramer **8**, the cyclohexamer **9**, and the cyclooctamer **10**. The ^{1}H and ^{13}C NMR spectra of the macrocycles **8**, **9**, and **10** show signals for one monomeric unit only, as expected for the D_n symmetry. The molecular weights of **8**, **9**, and **10** were determined by mass spectrometry. The NMR spectra are very similar to each other; this finding and the mass spectra data indicate that the octamer **10** is not a catenane.[7]

The chemical shift (^{1}H NMR, D_2O) for the C*H* signals of the cyclotetramer **8** does not significantly depend on the concentration (0.1 mM $< [8] <$ 1 mM), suggesting that **8** does not strongly self-assemble in water. Similarly as for the CDs, the solubility[8] of the macrocycles **8**, **9**, and **10** in water depends strongly on their size. Thus, the concentration of a saturated solution of the tetramer **8** is 3.1 mM, while that of the hexamer **9** rises to 117 mM and that of the octamer **10** drops to 2.8 mM. Remarkably, a suspension of the cyclooctamer **10** in methanol forms a gel upon ultrasonication. The smaller homologues, **8** and **9**, do not show a similar tendency towards gelation.

The cyclotetramer **8** crystallized as needles from a mixture of H_2O, methanol, and diethyl ether. In spite of the small size of the crystals, the structure of **8**, albeit only isotropically refined,

[**] Oligosaccharide Analogues of Polysaccharides Part 13. We thank the Swiss National Science Foundation and F. Hoffmann-La Roche AG, Basel, for generous support, and Dr. B. Schweizer for the X-ray analysis. Part 12: ref. [1].

was determined by X-ray analysis.[9] The unit cell consists of two independent molecules. As expected from MM3* calculations, the butadiyne groups are not in one plane. The average distances between the four butadiyne groups (7.4 and 11.4 Å) correspond approximately to the expected values (MM3: 7.8 and 11.2 Å). There are five molecules of water in the cavity of the cyclotetramer and one outside of it. The molecules of **8** are stacked to form antiparallel tubes (Figure 1).

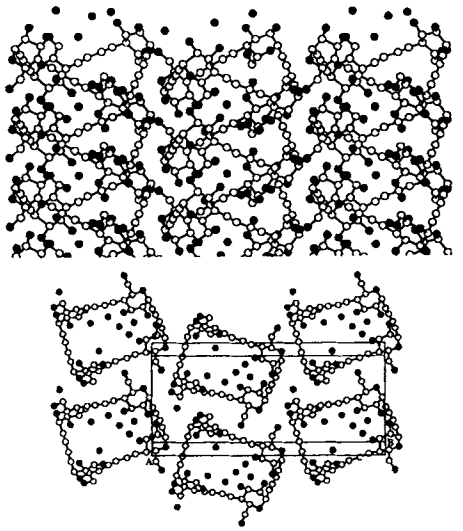

Figure 1. Crystal structure of the cyclotetramer **8**. Top: Side view; bottom: plan view.

The cyclotetramer **8** binds adenosine in aqueous solution. We determined the dissociation constants and the binding free energies of **8** with D- and L-adenosine[10] by ^{1}H NMR spectroscopic titrations in D_2O (Table 1).[11] The high-field shift of the signal of C(2)-H upon addition of adenosine suggested that the aromatic part of adenosine is bound in the cavity of **8**, while the ribosyl moiety is still solvated. This is supported by the fact that the free energies of binding for the complexes between D- and L-adenosine with **8** do not differ significantly.

Table 1. Association constants K_a and binding free energies $-\Delta G°$ from ^{1}H NMR binding titrations for 1:1 complexes of **8** with D- and L-adenosine at 296 K in D_2O [a].

Guest	K_a [L mol^{-1}]	$-\Delta G°$ [kcal mol^{-1}]	Degree of saturation [%]
D-adenosine	40	2.1	70
L-adenosine	32	2.0	66

[a] Titrations in buffered D_2O solutions (pD = 6.8, $[K_2DPO_4] = [KD_2PO_4]$ = 1.35 mM) at constant ion-strength ([NaCl] = 1.35 mM); [**8**] = 1 mM, [guest] varied. The association constants were obtained by nonlinear least-squares curve fitting of the titration data [12]. Accuracy of the K_a values is about ±12%.

Experimental Section

Treatment of **4** with $Cu(OAc)_2$ in pyridine: A solution of **4** (1.32 g, 2.01 mmol) in pyridine (10 mL) was added over a period of 10 h to a solution of $Cu(OAc)_2$ (18.3 g, 0.1 mol) in pyridine (1.45 L) at 50°C under N_2. The mixture was stirred for 19 h and then the solvent was evaporated. The residue was suspended in AcOEt and a saturated aqueous NH_4Cl solution was added. The solids were filtered off and washed with AcOEt. The aqueous layer was extracted (3 × AcOEt). The organic layers were dried ($MgSO_4$) and the solvent was evaporated. Chromatographic purification of the crude product (toluene/AcOEt 9/1 → 4/1) gave **5** (0.894 g, 68%), **6** (90 mg, 7%), and **7** (24 mg, 1.8%) as colorless solids.

5: R_f: 0.30 (toluene/AcOEt 2/3 (v/v)); m.p. 106–107.5°C; $[\alpha]_D^{25} = 152.7$ ($c = 0.48$, $CHCl_3$); ^{1}H NMR (200 MHz, $CDCl_3$; coupling constants in Hz): $\delta = 5.09$ (br. d, $J = 5.8$, 1H; H-6), 4.96 (br. d, $J = 6.7$, 1H; MeOCH), 4.85 (br. d, $J = 6.7$, 1H; MeOCH), 4.77 (br. d, $J = 7.1$, 1H; MeOCH), 4.70 (br. d, $J \approx 7.1$, 1H; MeOCH), 4.68 (s, 2H; $MeOCH_2$), 4.10 (br. ddd, $J \approx 1.8$, 4.0, 10.5, 1H; H-2), 3.93 (br. t, $J \approx 10.0$, 1H; H-4), 3.91 (br. dd, $J \approx 4.0$, 11.2, 1H; H-1), 3.81 (br. dd, $J \approx 1.8$, 11.2, 1H; H′-1), 3.55 (dd, $J = 5.8$, 9.6, 1H; H-5), 3.52 (s, 3H; CH_3O), 3.40 (s, 6H; 2 CH_3O), 2.93 (br. t, $J \approx 10.4$, 1H; H-3); ^{13}C NMR (50 MHz, $CDCl_3$): δ = 98.51, 97.97, 96.98 (3 t, 3 $MeOCH_2$), 78.80, 76.23 (2 d, C-4, C-5), 74.99, 74.80 (2 s, 2 $C\equiv C$), 73.65 (d, C-2), 72.99 (s, $C\equiv C$), 69.28 (d, C-6), 68.67 (s, $C\equiv C$), 66.74 (t, C-1), 56.45, 56.32, 55.44 (3 q, 3 CH_3O), 37.44 (d, C-3); MALDI-MS: 1327 ($[M + Na]^+$); elemental analysis: calcd for $C_{64}H_{88}O_{28}$: C 58.89, H 6.79; found: C 59.05, H 6.70.

Organometallic Chemistry under Hydro(solvo)thermal conditions: Synthesis and X-ray structure of $(Ph_4P)_2[Mn_3(CO)_9(S_2)_2(SH)]$, $(Ph_4P)[Mn_2(CO)_6(SH)_3]$, and $(Ph_4P)_2[Mn_4(CO)_{13}(Te_2)_3]$**

Songping D. Huang,* Chunqiu P. Lai, and Charles L. Barnes

Hydrothermal, or more generally, hydro(solvo)thermal syntheses may be defined as chemical reactions carried out in superheated water or organic solvents at sub-, near, or supercritical conditions.[1-3] The rapid transport ability of the solvent under such conditions often leads directly to crystal growth of the product similar to the formation of many mineral crystals in nature.[4] Thus far, the hydro(solvo)thermal synthesis has found numerous applications in solid-state chemistry and materials science.[5-6] Use of a similar concept to carry out organometallic reactions in sealed ampoules or autoclaves at elevated pressures and temperatures has opened up a new avenue for organometallic cluster chemistry.[7-8] In this report, we describe three novel cluster compounds **1**–**3**, obtained from

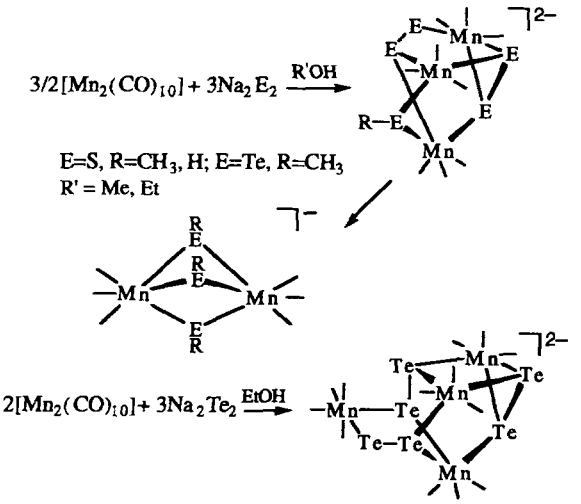
$(Ph_4P)_2[Mn_3(CO)_9(S_2)_2(SH)]$ **1**

$(Ph_4P)[Mn_2(CO)_6(SH)_3]$ **2**

$(Ph_4P)_2[Mn_4(CO)_{13}(Te_2)_3]$ **3**

ethanothermal synthesis. The formation of these compounds provides insight into the reaction pathways dictated by the solvent under the solvothermal conditions.

The reaction of $[Mn_2(CO)_{10}]$ with Na_2S_2 and ethanol in the molar ratio 1:4:80 in a sealed tube at 85 °C for 1.5 h gave **1**. When the same reaction was carried out for 80 hours, **2** was obtained. Compound **3** was synthesized analogously from the reaction of $[Mn_2(CO)_{10}]$ with Na_2Te_2 and ethanol in the molar ratio 1:2:50 (Scheme 1). The structures of **1**, **2**, and **3** were determined by single-crystal X-ray analyses.[9] The $[Mn_3(CO)_9(S_2)_2(SH)]^{2-}$ anion in **1** contains a triangle of Mn atoms bridged by two disulfide S_2^{2-} and a hydrosulfide HS^- ligand (Figure 1). The two disulfide ligands adopt different coordination modes: one is μ_3-η^1,η^1,η^1-bridging and the other μ_3-η^1,η^1,η^2-bridging. The hydrosulfide acts as a μ_2-ligand. The H atom on the monosulfide could not be located from the difference Fourier electron density map of the X-ray diffraction data. Its presence is implied by other experimental evidence (vide infra). The cluster possesses idealized C_s molecular symmetry with the mirror plane through O8/C8/Mn3/S5/S4/S1/H1. Each Mn atom is coordinated to three S atoms and three *cis* CO groups in an approximately octahedral environment. The observed Mn–Mn distances [3.523(1)–4.048(1) Å] preclude any metal–metal bonding. All Mn atoms are assigned a formal oxidation state of +I. The average Mn–S bond length of 2.372(7) Å is comparable to those of 2.34–2.38 Å found in $[Mn_4(S_2)_2(CO)_{15}]$.[10] The S–S distances of 2.076(2) and 2.055(3) Å can be considered normal single bonds.[11]



Scheme 1. Synthesis of the cluster anions 1–3.

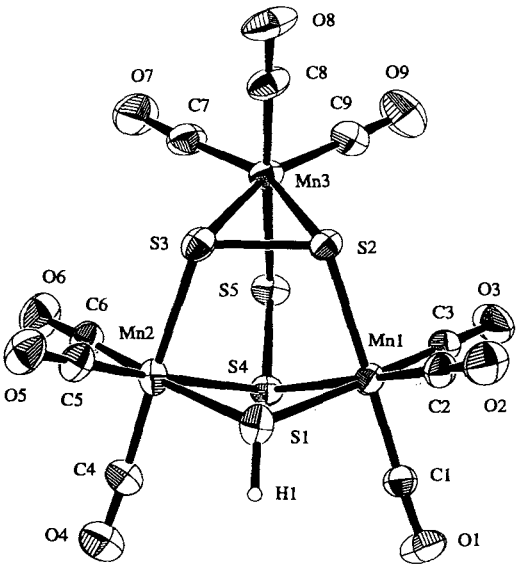


Figure 1. ORTEP representation of the structure of $[Mn_3(CO)_9(S_2)_2(SH)]^{2-}$. Selected bond lengths [Å] and bond angles [°]: Mn1–S1 2.408(2), Mn1–S1 2.402(2), Mn1–S2 2.372(2), Mn1–S4 2.349(2), S2–S3 2.076(2), S4–S5 2.055(3) Å; S1-Mn1-S2 88.10(7), S1-Mn1-S2 79.68(6), Mn1-S4-Mn2 96.82(6).

The $[Mn_2(CO)_6(SH)_3]^{2-}$ anion in **2** (Figure 2) is formed by two Mn^I centers bridged by three μ_2-HS^- ligands. The octahedral coordination of each of the Mn atoms is completed by three *cis* CO groups. Atom S1 is situated on the crystallographic twofold axis, which causes positional disorder of the attached H atom. Thanks to the high quality X-ray data collected at low temperature with the SMART diffractometer, both H1 and H2 atoms were located from the difference Fourier electron density map. The S–H bond lengths and bond angles were refined satisfactorily. Furthermore, three weak peaks at 2527, 2495, and 2478 cm^{-1} found in the FT-IR spectrum are attributable to the bridging ν(S–H) vibrations.[12] The molecule approaches D_{3h} symmetry if the H atoms are omitted. The Mn–Mn distance of

Campana of Siemens Analytical X-ray Instruments, Madison, WI (USA) for collecting the low-temperature X-ray diffraction data for 2.

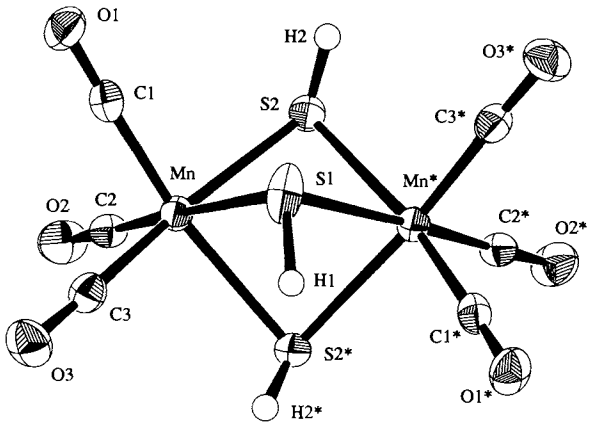

Figure 2. ORTEP representation of the structure of $[Mn_2(CO)_6(SH)_3]^-$. Selected bond lengths [Å] and bond angles [°]: Mn–S1 2.3978(9), Mn–S1 2.4091(7) or 2.4176(7), S1–H1 1.38(5), S2–H2 1.15(5) Å; S1-Mn-S2 81.51(2) or 81.33(2), S2-Mn-S2 82.47(3), Mn-S1-H1 111(2) or 99(2), Mn-S2-H2 117(2) or 99(2).

3.154(1) Å suggests no metal–metal bonding interactions. The average Mn–S bond distance of 2.408(6) Å is slightly longer than that in **1**.

Figure 3 is the ORTEP representation of the $[Mn_4(CO)_{13}(Te_2)_3]^{2-}$ anion in **3**. It consists of an $Mn(CO)_4$ and three Mn-

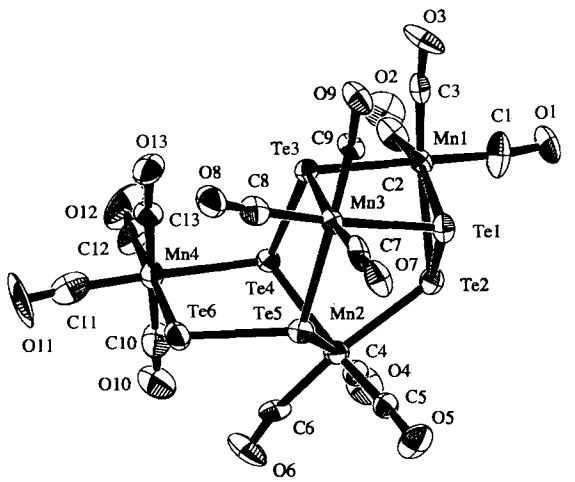

Figure 3. ORTEP representation of the structure of $[Mn_4(CO)_{13}(Te_2)_3]^{2-}$. Selected bond lengths [Å] and bond angles [°]: Te1–Mn1 2.684(4), Te3–Mn1 2.643(4), Te5–Mn2 2.662(4), Te6–Mn(4) 2.717(5), Te1–Te2 2.723(3), Te3–Te4 2.777(2); Te1-Mn1-Te2 61.1(1), Te1-Mn1-Te3 84.1(1), Te2-Mn2-Te4 89.3(1), Te2-Mn2-Te5 98.5(1), Mn1-Te1-Mn3 94.3(1), Mn2-Te4-Mn(4) 112.9(1).

$(CO)_3$ fragments bridged in an unusual fashion by three ditelluride Te_2^{2-} ligands. First, three $Mn(CO)_3$ fragments and three ditelluride Te_2^{2-} ligands define a $[Mn_3(CO)_9(Te_2)_3]^{2-}$ cluster core, reminiscent of the $[Mn_3(CO)_9(S_2)_2(SH)]^{2-}$. The minor change in bonding mode of a Te_2^{2-} unit in **3** stems from the need to accommodate another Mn center: atom Te4 is detached from Mn3 so that Te4 and Te6 can form new bonds with the $Mn(CO)_4$ fragment while Te3 is connected to Mn3 instead. Two of the ditelluride Te_2^{2-} ligands in **3** are bound to three, and the third Te_2^{2-} ligand to four Mn centers. Their coordination modes can be designated as $\mu_3,\eta^1,\eta^1,\eta^2$-bridging for $\{Te1–Te2\}^{2-}$, $\mu_4,\eta^1,\eta^1,\eta^1,\eta^1$-bridging for $\{Te3–Te4\}^{2-}$, and $\mu_3,\eta^1,\eta^1,\eta^1$-bridging for $\{Te5–Te6\}^{2-}$. All the Mn atoms can be assigned the formal oxidation state +1 and are in approximately octahedral environments with either *cis* C_{3v} or C_{2v} local symmetry. The Mn···Mn distances range from 3.91 to 5.41 Å, thus excluding any possibility of metal–metal bonding. The average Mn–Te bond lengths of 2.665(7) Å is comparable to those of 2.676(1) and 2.671(1) Å found in *cis*-{[Na([18]crown-6)]·2THF}$[Mn(CO)_4(TePh)_2]$.[13] The Te–Te bond lengths are, on average, 2.75(2) Å and can be considered normal single bonds.[14]

Attempts to use IR and ^1H NMR spectroscopy to confirm the presence of the SH^- ligand in **1** have thus far been unsuccessful. The ν(S–H) vibrational modes may be too weak to be detected.[12] On the other hand, a trace amount of acid or base in solution has been known to cause exchange broadening and collapse of the SH^- proton NMR signal in other metal hydrosulfide complexes.[15] The hydrosulfide ligand in **1** is formulated as a result of the following observations: 1) If the monosulfide ligand were not protonated, mixed valence would have to be invoked for the Mn centers in **1**. However, magnetic susceptibility measurements showed that the compound is diamagnetic, which is supportive of an assignment of the precise formal oxidation state +1 to the Mn atoms; 2) the control reactions carried out in superheated MeOH gave **4** and **5**, the methylated analogues of **1** and **2**, as confirmed by single crystal X-ray

$(Ph_4P)_2[Mn_3(CO)_9(S_2)_2(SCH_3)]$ **4**

$(Ph_4P)[Mn_2(CO)_6(SCH_3)_3]$ **5**

analyses.[16] The cluster ions $[Mn_3(CO)_9(E_2)_2(ER)]^{2-}$ (E = S, R = CH_3, H; E = Te, R = CH_3)[17] are formed by attack of the solvent (MeOH or EtOH) on the coordinated monochalcogenide ligands because of the nucleophilicity or Lewis basicity of such atoms.[7] However, tellurium is unable to follow the same course of reaction if protonation is required. This is consistent with the lower Lewis basicity of telluride relative to sulfide. Instead, the monotelluride ligand is replaced by a ditelluride ligand, and the structure expands to include an extra $Mn(CO)_4$ fragment. Therefore, we speculate that **1** and **3** are probably formed by the same pathway, but the ultimate structure is controlled by the need to satisfy the electronic requirements of the monochalcogenide ligand. This leads to either methylation, protonation, or replacement of the monochalcogenide with a dichalcogenide in this position.

Pure **1** failed to react with EtOH to give **2**. The formation of the latter may have involved, besides EtOH, some unidentified intermediate species generated in situ. We have also been unable to prepare **1**, **2**, or **3** from the refluxing ethanol solution. Kolis and co-workers have shown that the solution reaction between $[M_2(CO)_{10}]$ (M = Mn or Re) and K_2E_x (E = S, Se; x = 2–4) in DMF gives the E_4^{2-}-containing dimers $(Ph_4P)_2[M_2(E_4)_2(CO)_6]$.[18] Heating of the latter in DMF leads to the formation of homoleptic $(Ph_4P)_2[M(E_4)_2]$.[18] All this underscores the intrinsic difference of the chemistry under hydro(solvo)thermal conditions and that at ambient temperatures and pressures.

Experimental Section

Na_2S_2 and Na_2Te_2 were prepared by treating a stoichiometric amount of sulfur (or tellurium) with sodium metal in liquid ammonia. Other reagents were used as obtained. All the manipulations were carried out under a dry nitrogen atmosphere in a Labconco glovebox.

1: A sample of $[Mn_2(CO)_{10}]$ (40 mg, 0.1 mmol), Na_2S_2 (44 mg, 0.4 mmol), and Ph_4PBr (252 mg, 0.6 mmol) was ground and mixed thoroughly in a mortar with a pestle. The reagents were loaded into a thick-walled Pyrex tube (~25 cm long). After addition of EtOH (0.4 mL), the tube was frozen with liquid N_2, evacuated, and sealed with a flame. The tube was heated at 85 °C for 1.5 h to afford orange single crystals of $(Ph_4P)_2[Mn_3(CO)_9(S_2)_2(SH)]$. Analytically pure crystals can be isolated in 34% yield by washing with ethanol and diethyl ether. Mid-IR spectrum in the CO region: $\tilde{\nu}$ = 1999(sh), 1972(s), 1955(s), 1900(sh), 1878(s), and 1859(sh) cm^{-1}.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3617-1855 $ 17.50+.50/0

2: This compound was prepared analogously except that the sealed tube was heated at 85 °C for 80 hours. Orange-yellow, cube-shaped single crystals were isolated in 70% yield. Mid-IR spectrum in the CO region: $\tilde{\nu}$ = 1994(s), 1910(sh), 1898(s), 1884(s), and 1863(sh) cm^{-1}.

3: The sealed Pyrex tube containing $[Mn_2(CO)_{10}]$ (80 mg, 0.2 mmol), Na_2Te_2 (120 mg, 0.4 mmol), Ph_4PBr (252 mg, 0.6 mmol), and 0.4 mL EtOH was heated at 85 °C for 14 hours. After washing with ethanol and diethyl ether, black single crystals of **3** were separated by hand in about 55% yield. Mid-IR spectrum in the CO region: $\tilde{\nu}$ = 2030(s, sharp), 1962(vs, broad), 1929(s, shoulder), 1883(s, multiple) cm^{-1}. Semi-quantitative elemental analysis by SEM-EDAX: P/Mn/Te = 1/2.07/3.11.

Satisfactory C and H analyses were obtained for **1** and **2**. The phase identity and homogeneity of the three compounds was confirmed by comparing their experimental X-ray powder diffraction patterns of bulk material with those of calculated from the single crystal X-ray data.

A Five-Atom Molecule which Enantiomerizes in a Single Step via Chiral Transition States **

Michael Mauksch and Paul von Ragué Schleyer*

Dedicate to Professor Kurt Mislow

Racemizations of chiral molecules do not necessarily involve achiral transition states or intermediates. A rubber glove, turned inside out by stripping it from the right hand, will then fit the left without going through a symmetric representation. Mislow demonstrated in 1955[1] an enantiomerization involving only chiral intermediates along the whole path (termed a "chiral path") in dissymmetric biphenyl derivatives.[2, 3]

Other enantiomerizations along chiral paths, involving one or more reaction steps, are known. The stereomutation of phosphoranes substituted with five different groups by the Berry pseudorotation mechanism,[4] which proceeds through five steps (that is, four intermediate configurations and five transition states), the enantiomerization of triarylamines ("molecular propellers") by a sequence of three two-ring flips,[5, 6] correlated rotation of "gear" systems such as appropriately substituted bis-(9-tripticyl)-methane,[7] as well as the internal rotation of Mislow's biphenyl,[1, 2] are examples with complicated, many atom molecules. A recently synthesized chiral knot from single-stranded DNA may enantiomerize without even being able to assume any achiral conformation.[8] The racemizations of a number of *o,o'*-bridged biphenyls are more recent single-step examples.[9]

The simplest possible asymmetric enantiomerization of a real molecule would require only five atoms as well as a single reaction step, that is, without an intervening minimum.[10] The goal of this research was to locate a chemically feasible possibility with a chiral path of minimum energy and a low barrier. The demonstration of such an example computationally did not prove to be easy.

As the stereomutation of methane has been computed to occur via a nonplanar transition state (a $CH_2 \cdot H_2$ complex),[11] the hypothetical chiral isotopomer CHDTMu (Mu = muonium, a hydrogen-like particle) might enantiomerize by an asymmetric path. This barrier for CH_4, although below the H_2 elimination threshold, was computed to be very high (107 ± 2 kcal mol^{-1} and 5 ± 1 kcal mol^{-1} at 0 K) above the CH dissociation energy.[11] We have not been able to find any chiral five-atom methane-based molecule (for example CHFClBr, recently dis-

cussed by Quack et al[12]) with a low barrier to chiral enantiomerization. SiH_4 (and its chiral isotopomer, SiHDTMu) has a more complex potential energy hypersurface (PES) than methane.[13] Stereomutation involves a high-lying isomer (a perpendicular $SiH_2 \cdot H_2$ complex, 50.3 kcal mol^{-1} higher in energy at BECKE3LYP/6-311++G(2d,2p)), which can rotate internally (barrier 2.2 kcal mol^{-1}) and exchange the H atoms through a parallel $SiH_2 \cdot H_2$ transition state. However, the barrier of 55.3 kcal mol^{-1} for obtaining this $SiH_2 \cdot H_2$ intermediate from the SiH_4 ground state is 2.1 kcal mol^{-1} higher than the dissociation into SiH_2 and H_2 at 0 K.[13]

Moreover, like the last example, most completely chiral enantiomerization paths in five atom systems involve more than one step.[14, 15] Four examples, representing three different connectivities, illustrate this further here: "tetrahedral" HDTSiLi (**1**), "branched" HFNOH (**2**), and HFPSH (**3**), as well as "linear" HSOOH (**4**) (see Figures **1**–**3** and also see Table **1**). The computations were carried out with the GAUSSIAN 94 program at the BECKE3LYP/6-311G** level (see Table 1).[16]

Table 1. BECKE3LYP/6-311G** total energies E/E_h, zero point energies (ZPE) and ZPE-corrected relative energies E_{rel} [kcal mol^{-1}] of stationary points on the potential energy surfaces of molecules **1**–**4**.

[a] See Figures 1–3. [b] H_3SiLi represents the chiral derivative HDTSiLi, which should have a similar potential energy surface.

The lithium in **1** is ionically bound, and, unlike a halogen substituent, is relatively mobile. For chiral HDTSiLi (represented in Figure 1 by H_3SiLi) SiH_3 inversion (**1a** → **1c** → **1b**) and the more facile migration of the Li^+ ligand (**1b** → **1d** → **1a**) participate in the enantiomerization.[17] The two minima **1a** and **1b** are interconnected by two transition states, **1c** and **1d**. The racemization barrier (energy difference between **1a** and **1c**) is 24.0 kcal mol^{-1}, that is, much smaller than for the methane[11] or silane[13] isotopomers, or for CHFClBr.[12]

The "branched" connectivity, considered earlier,[14, 15] is illustrated here by HFNOH (**2**, Figure 2**a**) and HFPSH (**3**, Figure **2b**). Both enantiomerizations pass through two separate

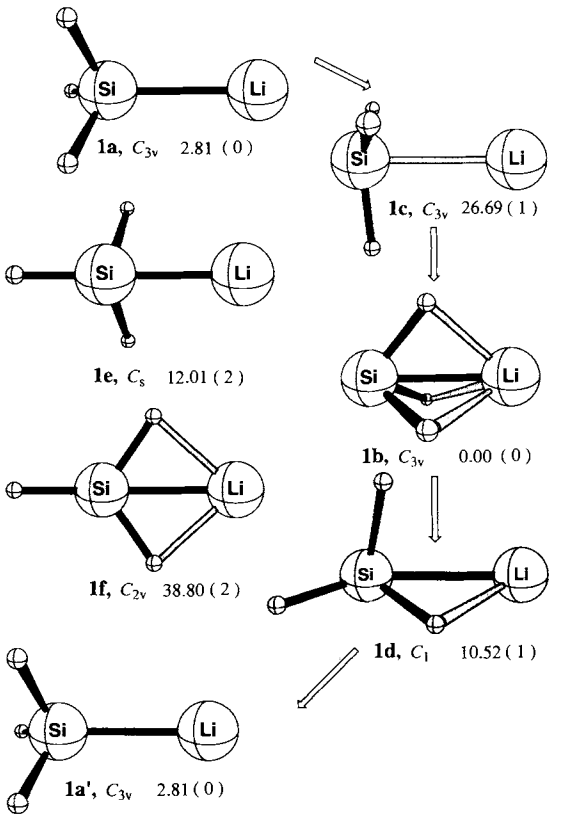

Figure 1. Schematic representation of two-step racemization of HDTSiLi, **1a**↔**1a'**, via the lower energy inverted minimum **1b**. Point groups are shown for the parent H_3SiLi species; relative energies are at B3LYP/6-311G** (Table 1) and the number of imaginary frequencies (NIMAG) are given in parenthesis. The steps involve pyramidal inversion at silicon (via transition state (TS) **1c**) and migration of Li^+ (via TS **1d**). The more symmetrical alternative (**1e**) is higher in energy and has NIMAG = 2. The planar geometry **1f** (also with NIMAG = 2) does not compete energetically. The relative energies (vs. **1a**) are given below the structures in kcal mol^{-1} (including zero point vibrational correction).

chiral transition states for the inversion at nitrogen (**2c**, barrier for the rate-determining step 27.6 kcal mol^{-1}) or phosphorus (**3c**, barrier 53.9 kcal mol^{-1}), and for the rotation around the N–O (**2d**) or the P–S bonds (**3d** (clockwise rotation) and **3e** (counterclockwise), which have nearly the same energy).[14] Both HFNOH and HFPSH have two planar conformations, but these are second-order saddle points, considerably higher in energy than the chiral inversion transition states.

The enantiomerization of the helical conformation of HOOSH, **4a** (Figure **3**) can occur by two separate rotations around the O–S and the O–O bonds and involves four chiral transition states **4c**–**f** (and their enantiomers). Of these, the transition states for O–S bond rotation are highest in energy (8.18 kcal mol^{-1} for **4d** and 7.00 kcal mol^{-1} for **4b**), but lie somewhat below the planar second-order saddle points **4h** (9.03), **4g** (8.51), **4i** (9.50) and **4j** (15.24 kcal mol^{-1}). The overall racemization barrier is thus 7.0 kcal mol^{-1} at 0 K. We assumed that this PES would be simplified if the hydrogen atoms were replaced by divalent atoms that were joined together.

Indeed, the facile interconversion ("pseudorotation") of C_2 and C_s conformations of cyclopentane,[18–21] S_5,[22] and other[18] five-membered rings suggested possible one-step enantiomerization candidates. Pentaatomic five-membered rings without any nonplanar achiral conformations require at least three different chemical elements, appropriately placed, to provide five differentiable chemical environments. *cyclo*-SeSSOS (**5**), although unknown, should fulfill this condition, as

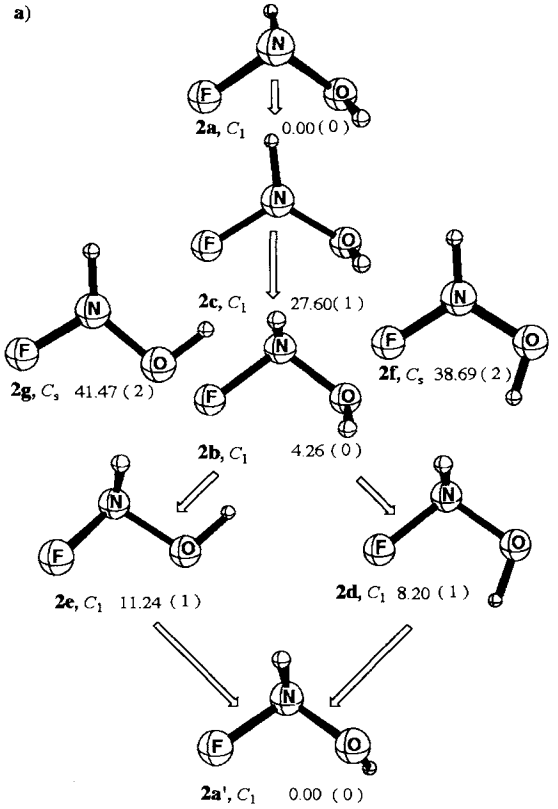

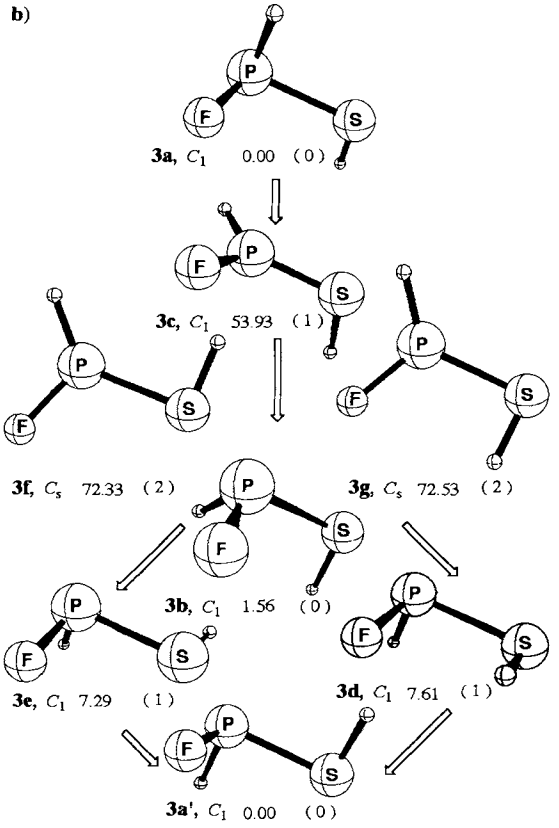

Figure 2. Two examples of another five-atom molecule connectivity: NHFOH (**2**, a) and PHFSH (**3**, b). Transition states **2c** and **3c** belong to inversion, **2d,e** and **3d,e** to rotation processes. The planar forms **2e,f** and **3e,f** do not take part in the enantiomerization. The energies given are relative to the most stable structure.

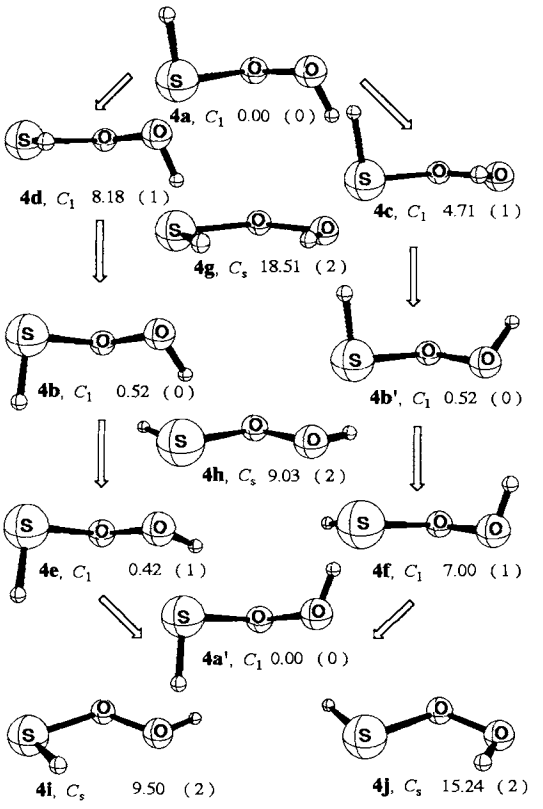

Figure 3. HOOSH (**4**) serves as example for a chiral five-atom chain. The two-step enantiomerization of the global minimum, helical **4a** (shown schematically), involves the intermediate **4b** (0.84 kcal mol^{-1} above **4a**). The two pathways involve TSs **4c**–**4f**. The four planar conformations, **4g**–**4j** (also shown) are second-order saddle points.

its enantiomerization is predicted to proceed along a completely chiral reaction path in only one step! This was demonstrated by computations at several different levels of ab initio and density functional theory (HF/3-21G*, HF/6-31G*, B3LYP/6-31G*, and B3LYP/6-311G*); all give similar geometries and relative energies (Table 2).

The enantiomers **5a**, **5a'** and the transition states **5b**/**5b'** are shown in Figure 4. The racemization barrier of *cyclo*-SeSSOS is only 6.2 kcal mol^{-1} (at BECKE3LYP/6-311G* + ZPE). In contrast, the achiral planar **5c** is a second-order saddle point with a high relative energy (31.8 kcal mol^{-1}). Hence, inversion by ring flattening should not occur. Two enantiomerically related minimum-energy reaction pathways connect the chiral structures (**5a**, **5a'**). The truly chiral character of the path is confirmed by results of HF/3-21G(*) intrinsic reaction coordinate (IRC) computations, plotted in Figure 5.[22] Full geometry optimizations, starting from the endpoints of the IRC paths, gave both enantiomers (with identical energies). The asymmetry of the energy profile results from the chirality of the transition state. Figure 5 also depicts some of the intermediate structures along one of the two enantiomeric racemization pathways.

The low-energy stereomutation pathways of the pentacyclic system **5a** contrasts, for example, with the conceivable one-step enantiomerization of chiral methane derivatives, which have high racemization barriers.[12–14] The verification of a single-step chiral inversion of a five-atom molecule is an experimental challenge.

[22] The similar activation barriers (5.7 kcal mol^{-1} at HF/3-21G(*) and 6.2 kcal mol^{-1} at BECKE3LYP/6-311G*) justifies the use of the more economical HF/3-21G(*) level for the IRC calculation. Also see [23] for a similar method of evaluation. The isomeric *cyclo*-SeOSSS (the C_1 global minimum is 10.8 kcal mol^{-1} less stable than **5a** at BECKE3LYP/6-31G*) behaves similarly and will be discussed in a full paper. Trials with five-membered rings comprising other combinations of chalcogen atoms did not succeed (PES searches led to three-membered rings, for example).

Proton-Dependent Monomer–Oligomer Interconversion of Metal Complexes**

Naohide Matsumoto,* Yukiko Mizuguchi, Genjin Mago, Shingo Eguchi, Hitoshi Miyasaka, Toshio Nakashima, and Jean-Pierre Tuchagues*

Metal-directed self-assembly processes like formation of catenanes and helicates by spontaneous assembly of oligo-2,2′-bipyridine strands and metal ions have attracted much interest in recent years.[1] As a further development of this fascinating area of supramolecular chemistry, metal complexes capable of reversibly interconverting between monomers and self-assembled oligomers by inputting external information (afforded, for example, by protons, electrons, or photons) would be of the utmost interest. Indeed, they could afford new functional materials with a switching ability, and in more specific cases the ability to sequester/release guest molecules or ions according to the delivered external information, provided the polydentate ligand is properly designed to induce the formation of a monomeric species that exhibits the following building block characteristics:[2] a) potential donor ability at a suitable external site of the chelating ligand; b) potential acceptor ability at a vacant or substitutable metal coordination site; c) building process from monomeric into oligomeric species and reverse dismantling process both triggered by appropriate external signals; d) for the more specific case of sequestering/release of guest molecules or ions, presence of one or more cavities in the resulting oligomeric molecular structure, cooperatively determined by the steric restriction provided by the ligand frame and the coordination geometry required by the metal ion.

We are currently investigating whether polydentate ligands including an imidazole moiety can be used to synthesize metal complexes capable of exhibiting such monomer–oligomer interconversions through self-assembly.[3] We report here the pH-controlled interconversion of the Cu^{II} complex of 2-(4-imidazolyl)-ethylimino-6-methylpyridine (HL) between the protonated monomer $[Cu(HL)Cl_2]$ (**1**) and the self-assembled deprotonated cyclic hexamer $[\{Cu(L)\}_6](ClO_4)_6$ (**3**). As an example of the structural tuning afforded by the metal ion, the protonated monomeric Pd^{II} complex with the same ligand [Pd(HL)Cl]Cl (**2**) and the self-assembled deprotonated cyclic tetramer $[\{Pd(L)\}_4](ClO_4)_4$ (**4**) are also described.

Monomeric complexes **1** (light-green crystals) and **2**·H_2O (yellow needles) were synthesized by reacting $CuCl_2 \cdot 2H_2O$ and $PdCl_2 \cdot 2H_2O$, respectively, with HL (1:1 metal-to-ligand molar ratio) in methanol. When the pH value of MeOH, MeOH/H_2O, or H_2O solutions of **1** is raised by addition of NaOH, a color change from green to blue is observed. The pH dependence of the electronic spectra obtained upon dropwise addition of aqueous NaOH to the methanolic solution of **1** up to an equimolar **1**:NaOH ratio has been studied. The original spectrum of **1** (d-d absorption at 750 nm) changes to that of a unique new species (**3**, d-d absorption at 640 nm), and an isosbestic point occurs at 690 nm. Conversely, when an aqueous HCl solution is added to the resulting solution of **3** the intensity of the d-d band absorption at 640 nm decreases and that of the d-d band around 750 nm increases, while the green color is restored.[4] Although the color change of complex **2** from yellow to orange upon increase of the pH value did not afford significant spectral changes, NMR spectroscopy clearly indicates the formation of a unique new species (**4**). The complexes **3** (deep-blue crystals) and **4** (orange crystals) were quantitatively prepared as their perchlorate salts.

The crystal structures of complexes **1**–**4**[5] afforded an illuminating picture of the proton-dependent conversion between the appropriate monomer and imidazolate-bridged copper hexamer (**1**↔**3**) or palladium tetramer (**2** → **4**). The ORTEP drawings of the monomeric protonated complexes **1** and **2** and deprotonated imidazolate-bridged cyclic hexamer **3** and tetramer **4** are shown in Figures 1 and 2), respectively. Clearly, the driving force for these monomer–oligomer interconversions is the deprotonation/protonation of the imidazole moiety of the polydentate ligand that switches alternately from the protonated tridentate state to the deprotonated tetradentate one according to the proton supply (Scheme 1). Thus, the metal ion determines the nuclearity of the oligomeric species through its coordinative requirements: although the ligand environment of the metal ion is close to square planar in both oligomers, Cu^{II}, which has the flexibility to assume square planar, tetrahedral, and intermediate geometries, accommodates a cyclic hexanuclear array of $[CuL]^-$ building blocks in **3**, while Pd^{II} which has not such flexibility imposes a cyclic tetranuclear array of $[PdL]^-$ moieties in **4**.

A more detailed picture of the structural changes associated with these monomer–oligomer conversions is afforded by comparative examination of the metal coordination sphere for complexes **1**–**4**. The trigonal basal plane of the pentacoordinate Cu^{II} atom in the protonated monomeric complex **1** comprises two Cl^- ions and the central imine-nitrogen atom of the tridentate ligand, while its imidazole- and pyridine-nitrogen donors occupy the apical coordination sites. On the other hand, each Cu^{II} ion of the deprotonated imidazolate-bridged cyclic hexamer **3** essentially assumes a square-planar coordination geometry involving the three imine-nitrogen donor atoms of a tetradentate ligand and the imidazolate-nitrogen donor atom of the adjacent unit. However, the monomer–hexamer interconversion does not involve a Cu^{II} valence interconversion because the above-mentioned Cu^{II} pentacoordination is not retained when **1** is

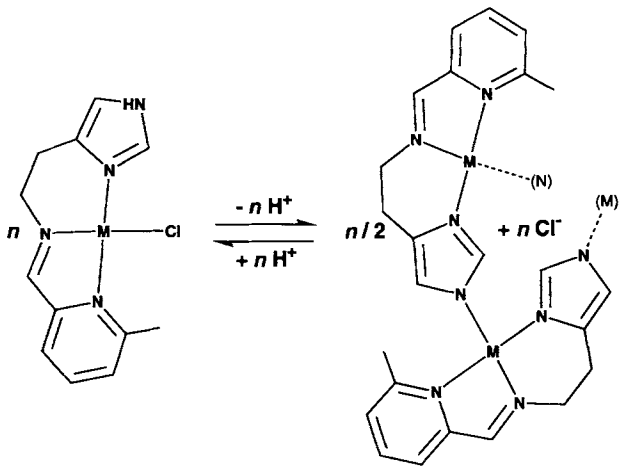

Scheme 1. Protonation and deprotonation of the imidazole moiety of the polydentate ligand L.

dissolved: electron spectroscopy reveals that the $[CuN_3Cl_2]$ chromophore observed in the solid state is converted to the $[CuN_3Cl]$ chromophore in solution.[4] Consequently, the reorganization of the coordination sphere is minimized to a Cl^-/N^- ligand exchange upon monomer–hexamer interconversion. The same is true for the monomer–tetramer interconversion of the palladium complex. The Pd^{II} coordination geometry is square planar in **2** and **4**, and the coordination sphere reorganization is identical to that described for conversion of **1** to **3**.

The reversible interconversion between **1** and **3** was confirmed by potentiometric pH titration. In water at 25 °C, the degree of proton dissociation α calculated by Bjerrum's method increases from 0 to 1 for the titration of the monomer leading to the formation of the hexamer and decreases from 1 to 0 for the reverse titration; this affords superimposable α vs pH curves. The apparent dissociation constant K_d is expressed by Equation (a), where $[Cu(L^-)]^{tot}$ is defined by Equation (b), and the pK_d value by Equation (c). A pK_d value of 8.59 ± 0.01 is obtained

$$K_d = [Cu(L^-)]^{tot}[H^+]/[Cu(HL)] \quad (a)$$

$$[Cu(L^-)]^{tot} = [Cu(L^-)] + 6[\{Cu(L^-)\}_6] \quad (b)$$

$$pK_d = lg\{[Cu(HL)]/([Cu(L^-)]^{tot}[H^+])\} \quad (c)$$

for both forward and reverse titrations. The potentiometric pH titration of the Pd^{II} monomer **2** showed different behavior. Prior to the titration of the monomer, the initial potential indicated that approximately 17% of the imidazole protons were already dissociated. In the course of the forward titration the degree of dissociation of the imidazole protons increased to $\alpha = 1$. In the reverse titration, 80% of the protons did not associate to the nitrogen atoms of the imidazole moiety, indicating that the cyclic Pd^{II} tetramer **4** does not dissociate as easily as the Cu^{II} cyclic hexamer **3**. A pK_d value of 4.50 ± 0.01 was obtained from the forward titration of the Pd^{II} monomer **2**, based on the assumption given in Equation (d).

$$[Pd(L^-)]^{tot} = [Pd(L^-)] + 4[\{Pd(L^-)\}_4] \quad (d)$$

The reversibility of the overall monomer–oligomer conversion depends on the reversibility of reactions I and II. Re-

$$M(HL) \rightleftharpoons M(L^-) + H^+ \quad (I)$$

$$nM(L^-) \rightleftharpoons \{M(L^-)\}_n \quad (II)$$

action I is an intrisically reversible ligand-dependent reaction in which the nature of the metal ion determines only the pH range of the proton dissociation. On the other hand, the reversibility

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3617-1861 $ 17.50+.50/0

of reaction II depends exclusively on the relative stabilities of $M(L^-)$ and $\{M(L^-)\}_n$; these stabilities depend on the metal as well as on the association state n of the final oligomeric species.

The complex cation of **3** has a tubular shape with a cylindrical cavity parallel (radius ca. 4 Å) to the pseudo C_3 axis. A constriction in the middle of the cylindrical cavity delimitates two half-cavities. Each set of three copper atoms that is involved in the construction of one of these half-cylinders defines one of the two faces of a compressed copper octahedron constructed exclusively from next-nearest copper atoms. Three vacant coordination sites for each such set of three copper atoms define an approximately equilateral triangle, suggesting that a molecule or anion with three trigonally arrayed (donor) atoms may be conveniently hosted in each half-cavity. We are currently evaluating the potential use of this reversibly self-assembling cyclic hexamer in host–guest chemistry, monitoring the size of the cavity through ligand modifications, and studying the relationship between the nature of the metal atom and the nuclearity with an extensive range of metal ions.

Experimental Section

1: 6-Methyl-2-pyridinecarboxyaldehyde (242 mg, 2 mmol) in methanol (20 mL) was treated with a neutralized (1 M NaOH, 4 mL) solution of histamine dihydrochloride (368 mg, 2 mmol) in MeOH (20 mL). $CuCl_2 \cdot 2H_2O$ (340 mg, 2 mmol) in methanol (20 mL) was then treated with the solution of the ligand and the pH was adjusted to 7–8. The resulting green solution was filtered and allowed to stand for several days. The precipitated green crystals were filtered off, washed with acetone, and dried in air.

2·H_2O: Yellow needles: same synthetic procedure as for **1** except that the pH was adjusted to 3–4.

3·$4CH_3CN \cdot 2H_2O$: A 1 M NaOH solution (2 mL) and $NaClO_4$ (244 mg, 2 mmol) in methanol (10 mL) were added to a solution of **1** (2 mmol) in water-methanol. After the mixture had been allowed to stand for several days, deep blue crystals appeared, which were filtered off and dried in air. Recrystallization from CH_3CN-H_2O gave blue prismatic crystals overnight (90% yield).

4·EtOH: Orange crystals (75% yield): same procedure as for **3**.

Correct elemental analyses were obtained for all compounds.

Potentiometric pH titrations were carried out in a thermostated bath at 25 °C and under a 99.9995% N_2 atmosphere. Extra pure grade water was used (resistivity $\rho > 18.0$ MΩ). The GS-5015c electrode and the potentiometer used in these experiments were supplied from TOA Co. Ltd, Tokyo. The standard electrode potential (E_0) was first determined by Gran's plot method [6]. About 50 mL of a solution (ionic strength 0.15) containing metal complex (0.2 mmol) and sodium chloride was titrated with a solution containing 0.10 M NaOH and 0.05 M NaCl. Immediatedly after the forward titration the resulting solution was titrated back with a solution containing 0.10 M HCl and 0.05 M NaCl. The electrode potentials were converted into proton concentration scale ($-\log[H^+] = (E_0(\text{mV}) - E(\text{mV}))/59.15$) and the degree of dissociation, α, was calculated by Bjerrum's method for the forward and reverse titrations, respectively [7].

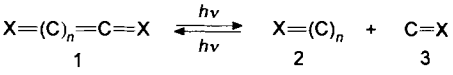
2-Thioxoethen-1-one (O=C=C=S)**

Günther Maier,* Hans Peter Reisenauer, and Raimund Ruppel

Generally, upon irradiation in an argon matrix at 10 K dioxides,[1, 2] sulfide oxides,[3] and disulfides[4] of carbon (**1**; X = O, S) decompose into the fragments **2** and **3**.[5] In the



case of the sulfide oxides only CO and no CS is formed as leaving group. Since the fragments remain embedded in the matrix cage the reverse reaction **2** + **3** → **1** can also be triggered upon irradiation with light of the appropriate wavelength.[2–4] Even the photocleavage of matrix-isolated C_2S_2 (**5**) is reversible;[6] hence, we tried to synthesize the elusive C_2O_2 (**7**) in

the same manner.[7, 8] However, our attempts failed even though with diisocyanate O=C=N–N=C=O[7] we had the ideally suited precursor to produce two CO molecules in the same matrix site. Thus, since the photoaddition of two CS molecules occurs readily, whereas the corresponding dimerization of two CO does not, the behavior of the mixed pair CO/CS should be of particular interest, and herein we report our findings on this system.

The carbon monosulfide needed for the photoreaction was generated by exposing a CS_2/Ar mixture (1/100) to a microwave discharge.[9] It was deposited on a CsI window cooled to 10 K together with the same volume of a CO/Ar mixture (1/5). The concentrations applied were much higher than those necessary for a good matrix isolation; however, this is a statistical prerequisite for a significant fraction of the CS molecules to be trapped in the direct vicinity of a CO molecule. After irradiation of the resulting matrix with 254-nm light (a wavelength at which CS has a strong absorption band), several new IR absorption bands were detected and assigned to C_2OS (Figure 1). Simultaneously, the intensity of the CS band diminished by about 5%,

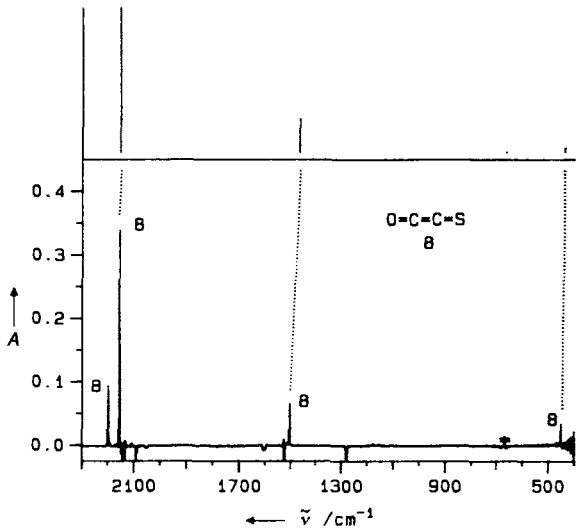

Figure 1. Calculated (BLYP/6-311+G*; top) and experimental (Ar matrix, 10 K, bottom) IR spectrum of thioxoethenone **8**. The experimental spectrum is a difference spectrum of the photoreaction **8** → **4** + **6**.

a corresponding decrease in the intensity of the CO band could not be detected due to the huge initial concentration. During a subsequent short irradiation with 313-nm light the bands of C_2OS listed in Table 1 disappeared and could be recovered again with 254-nm light. The UV spectrum recorded after exposure of a CO/CS matrix to 254-nm light showed a new absorption with vibrational fine structure in the range between 280 and 320 nm with a maximum at 306 nm. The behavior of this UV transition paralleled that of the IR bands during the reverse reaction with 313-nm light. Therefore, this absorption must be attributed to C_2OS (**8**).

In addition to the absorption bands for C_2OS, the described irradiation gave rise to bands attributable to the formation of minor quantities of C_2S_2.[4c] Lower CO concentrations led to higher yields of C_2S_2. In all experiments COS was formed as an additional by-product, presumably as a photoproduct of CO and S atoms present in the matrix.

To facilitate an assignment of the IR bands of C_2OS quantum mechanical calculations were conducted. We employed the MP2(full), MP4(full), CCD, CCSD, and CCSD(T) methods

Table 1. Calculated vibrational spectrum (harmonic approximation) of thioxoethenone **8** (BLYP/6-311+G*) and experimentally observed IR absorptions (Ar matrix, 10 K, relative intensities in parentheses).

[a] Absolute intensity: 445 km mol^{-1}. [b] Estimated from combination bands.

implemented in the GAUSSIAN 94[10] package of programs in combination with the basis set 6-31G* as well as the density functional approaches BLYP and B3LYP with the 6-31G* and 6-311+G* basis sets. In all cases the following two molecular structures were located as minima on the C_2OS hypersurface: a linear thioxoethenone in a triplet state and a transoidally bent singlet molecule with identical connectivity. ^3C_2OS was always lower in energy, the singlet–triplet gap (including zero point vibrational energies) ranged between 5.4 and 16.3 kcal mol^{-1} depending on the method. A comparison of the calculated IR spectra with those obtained experimentally showed a good correlation with respect to the position of the bands and their intensities, particularly for the linear triplet molecule. This is consistent with Hund's rule, which predicts a triplet ground state for linear C_2OS.

Three stretching vibrations and two degenerate bending modes are expected for the linear C_2OS molecule. The stretching vibrations ν_1 and ν_2 are directly observable (2156 and 1505 cm^{-1}, respectively). The ν_3 vibration could not be detected, which is consistent with the theoretical prediction of an extremely low intensity. Its approximate position (ca. 685 cm^{-1}) can be deduced from the observed combination bands. One of the bending vibrations (ν_4) appears at 452 cm^{-1}. It is essential to note for a correct assignment of the measured IR absorptions that the second strongest band at 2200 cm^{-1} originates from a combination of the fundamentals ν_2 and ν_3. An anharmonic resonance of this combination band with ν_1 leads to an increase in the intensity of the combination band.

To substantiate these findings an analogous experiment with ^{13}C-labeled carbon monoxide containing about 10% ^{18}O was conducted. In all cases, the measured isotopic shifts of the IR bands corresponded with the calculated ones for linear triplet C_2OS. The correlation was less satisfactory for the distorted singlet C_2OS. This is most apparent for the shift of the fundamental ν_2: All computations predict a shift of about 3 cm^{-1} for ^3C_2OS; the experimental value is 3.4 cm^{-1}. In contrast, this absorption band should not shift at all in the corresponding singlet molecule. The resonance of the combination vibration $\nu_2 + \nu_3$ with the fundamental ν_1 virtually disappears in O=^{13}C=C=S. Therefore, the intensity of the higher band decreases sharply.

2-Thioxoethen-1-one (**8**) can thus be generated in a photochemically induced addition of CS to CO. This reaction is reversible. C_2OS, which probably possesses a triplet ground state, is stable under matrix conditions. Our results are in accordance with the findings of Schwarz et al., who by neutralization reionization mass spectrometry identified C_2OS[11] but not C_2O_2[12] as a viable species in the gas phase.

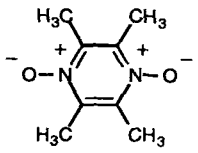
Pyrazinedioxide–Tetracyanoethylene Arrays in the Solid State—New Donor–Acceptor Interactions for Crystal Engineering**

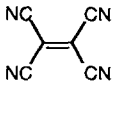
Melinda L. Greer, Byron J. McGee, Robin D. Rogers, and Silas C. Blackstock*

Molecular recognition forms the basis of supramolecular chemistry[1] and, in the solid state, of crystal engineering.[2] Of the intermolecular interactions commonly employed as crystal engineering synthons,[3] neutral organic donor–acceptor (DA) attractions[4] have remained relatively rare. Recent findings[5,6] of TCNE/azooxide complexes (TCNE = tetracyanoethylene) prompted our further investigation of heterocyclic *N*-oxides as donors for the preparation of dimensionally ordered organic DA crystals. The first examples, crystalline pyrazinedioxide–TCNE arrays, are reported here.

Pyridine *N*-oxides are known to give colored solutions with TCNE.[7] However, these mixtures typically decompose on standing, and no structurally characterized DA complexes in this series have previously been reported. Recently we found that mixtures of 2,3,5,6-tetramethylpyrazine-*N*,*N*′-dioxide (TMPDO)[8] and TCNE in solution yield chemically stable purple solutions (λ_{max} = 524 nm in CH_2Cl_2, 500 nm in CH_3CN) from which crystalline $(TMPDO)_2TCNE$ solids may be isolated.



TMPDO



TCNE

The visible absorption of TMPDO/TCNE solutions is assigned to a charge-transfer (CT) excitation of the 1:1 DA complex. Benesi–Hildebrand analysis[9] of TMPDO/TCNE mixtures in CH_2Cl_2 yields a complex formation constant K_f of $1.4(2)\,M^{-1}$.[10]

Cooling of purple TMPDO/TCNE mixtures in CH_3CN affords deeply colored $(TMPDO)_2TCNE$ crystals. Two polymorphs of the solid crystallize and may be prepared independently as purple needles (at short times) or red prisms (at longer times). As indicated by these crystal equilibration results at 253 K, the red crystals are thermodynamically favored, and the purple crystals are a kinetic product at this temperature in CH_3CN. UV/Vis data for the $(TMPDO)_2TCNE$ solids (Nujol mulls) and for the complex in solution are shown in Figure 1.

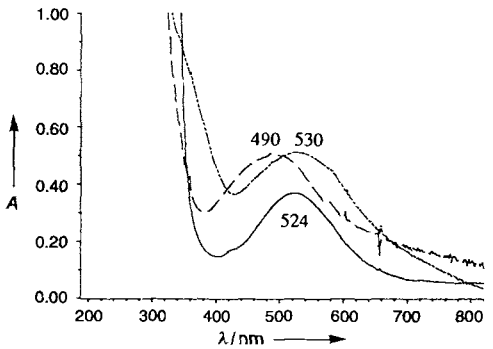


Figure 1. UV/Vis spectra of TMPDO (1.9 mM) and TCNE (51.2 mM) in CH_2Cl_2 (—), as well as of red (– – –) and purple crystals of $(TMPDO)_2TCNE$ (—·—).

The purple $(TMPDO)_2TCNE$ crystal is composed of infinite double strands in which intermolecular O–C attractions are apparent between donor and acceptor (Figure 2).[11] The O–C contacts are 2.769(2) and 2.914(2) Å, much shorter than the sum of atomic van der Waals radii[12] (3.22 Å). In this array TCNE molecules, located on inversion centers, are the rungs of a TMPDO-railed ladder. We postulate that electrostatic forces and HOMO–LUMO overlap between the TMPDO oxygen

atoms, and the TCNE olefin carbon atoms contribute to a weak DA "bond", which provides cohesion for the strand formation in the lattice. Accordingly, the donor oxygen atoms are positioned at the four π^* lobes of the TCNE LUMO in a rectangular "ligand field" about the electron-poor alkene. Intraladder π stacking of TMPDO donors occurs at van der Waals distance (3.4 Å from plane to plane). Slipping of the π-stacked donors by about 1.3 Å along the ladder axis creates head-to-tail NO dipolar alignment across the ladder and skews the ladder superstructure slightly. Adjacent ladders close-pack in a staggered arrangement (Figure 2).

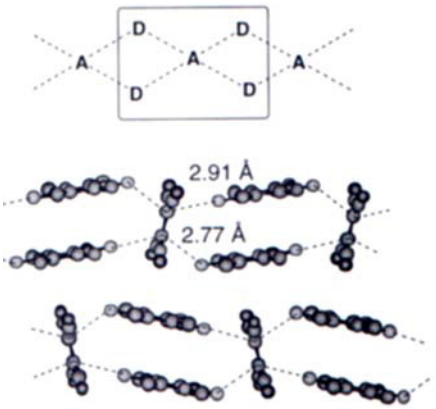

Figure 2. Schematic representation of the DA connectivity in the ladder array in purple crystals of $(TMPDO)_2TCNE$ (top) as well as a ball-and-stick drawing of two adjacent ladder chains (bottom).

Polymorphic red $(TMPDO)_2TCNE$ crystals form a topologically different DA array, which possesses 2D D–A connectivity (Figure 3).[13] Here, each TCNE "binds" four TMPDO donors (as for the purple array) and each TMPDO donor bridges a unique pair of TCNE molecules, creating a web-like D_2A "sheet". A pinwheel arrangement of four donors about each TCNE acceptor is observed. Distances between TMPDO oxygen atoms and TCNE olefinic carbon atoms are 2.849(2) and 2.764(2) Å. The web sheets are not planar but sinusoidal in profile and stack in a closest-packing arrangement. The web itself comprises fused eight-molecule rings, made of four TMPDO donors and four TCNE acceptors.

At 363–373 K red $(TMPDO)_2TCNE$ crystals change irreversibly to purple without melting.[14] Room-temperature UV/Vis spectroscopy[15] and (most convincingly) powder X-ray diffraction analysis of the crystals before and after heating verify the irreversible web to ladder supramolecular transformation.[16, 17] Representative powder X-ray diffractograms are shown in Figure 4. Topologically, the red web network may be viewed as a cross-linked ladder array, and thus the thermal process may be considered a reverse cross-linking of the lattice. Because the spacing between TCNE units [18] and the donor–oxygen positions[19] about TCNE are quite similar in the two polymorphs, a web-to-ladder transition requires only slight molecular reorientation in the solid. The mechanism for isomerization of the array minimally involves pivoting (one end migration) of half the TMPDO donors and rotation of alternate TCNE acceptors.

The NO···C interactions of azaaromatic *N*-oxides with TCNE reported here constitute a new functional group interaction in the solid state, whose potential application to crystal engineering appears promising, especially in view of the wide structural diversity of this donor group.[20, 21] A common struc-

tural feature of these $(TMPDO)_2TCNE$ arrays is rectangular four-site O–C binding at the TCNE olefinic carbon atoms, which appear to interact through their π^* lobes. The topological requirement for DA complexation at the *N*-oxide center is more flexible, allowing the formation of both ladder and web (cross-linked ladder) DA arrays in the $(TMPDO)_2TCNE$ crystals as the N-O-C angle flexes.

Experimental Section

TMPDO (2.58 g, 69%, m.p. 498 K (493 K [22])) was prepared by treatment of 2,3,5,6-tetramethylpyrazine (2.95 g, Aldrich) in CH_2Cl_2 (50 mL) with potassium peroxomonosulfate (66.6 g, 5 equiv; OXONE, Aldrich) in H_2O (400 mL) with vigorous stirring at 298 K for 24 h. TCNE (Aldrich) was purified by multiple sublimation (373 K, 0.05 mm Hg) through activated charcoal. Conditions for the Benesi–Hildebrand analysis: [TMPDO] = 1.90 mM; [TCNE] = 18.7, 34.0, 51.1, 66.4, 75.7, and 90.6 mM. Purple crystals of $(TMPDO)_2TCNE$ were prepared by cooling a mixture of TMPDO (40 mM) and TCNE (20 mM) in CH_3CN to 253 K for 2–5 h. Red prismatic crystals of $(TMPDO)_2TCNE$ were prepared analogously, after 2–3 d crystallization.

Crystal X-ray diffraction was performed on a Siemens SMART diffractometer with CCD area detection at 293 (purple [11]) and 173 K (red [13]) with monochromatic $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å). Solution and refinement (against $|F^2|$) were performed with SHELXTL. No absorption correction was employed. Hydrogen atoms were placed in calculated positions (0.95 Å from the methyl carbon atom with tetrahedral angles). They were given torsional freedom and their thermal parameters were set to $1.2 \times U_{eq}$ of the bonded carbon atom. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100438. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code + (1223) 336-033; e-mail: deposit@chemcrys.cam.ac.uk). Powder $Cu_{K\alpha}$ X-ray spectra were obtained on a Rigaku powder diffractometer.

In Search of Molecular Ratchets**

T. Ross Kelly,* Imanol Tellitu, and José Pérez Sestelo

The creation and the control of movement are fundamental aspects of dynamics on both macroscopic and microscopic levels. Much current interest is focused on constructing molecular scale analogues of macroscopic devices, in part because of the intellectual challenge, but also because of their potential applications in nanotechnology.[1] We now report the results of an effort to synthesize the first molecular ratchets. The work was undertaken partly as a result of a continuing[1a] interest in molecular devices, but it also serves to demonstrate that macromechanical principles do not always transfer to the molecular scale.

In their simplest form, ratchets consist of three components (Figure 1): a) a toothed ratchet wheel, b) a pawl that prevents unintended rotation of the ratchet wheel, and c) a spring that holds the pawl in place. Both the tension of the spring and the contours of the ratchet wheel and pawl determine the ease (and direction) of rotation.

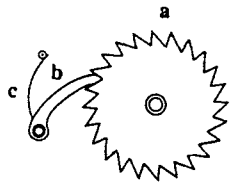

Figure 1. A simple ratchet: a) toothed wheel, b) pawl, c) spring.

In the present instance a triptycene[2] was chosen as the ratchet wheel and helicenes[3] as the pawls and springs. The two molecular "ratchets" are **1**[4] and **2**. Molecular modeling calcu-

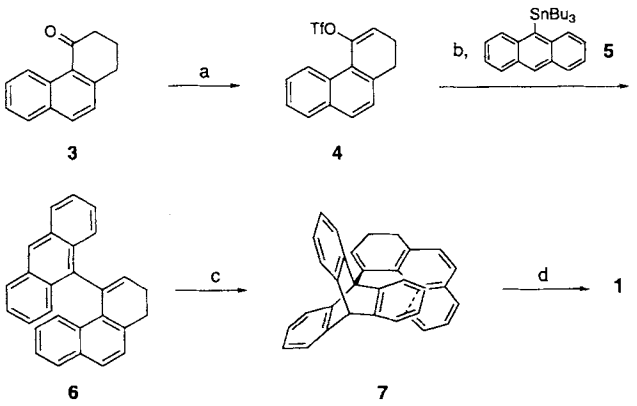
lations[5] indicated unexpectedly—at least to us—that the [3]helicene spring and pawl in **1** present a greater barrier to rotation (ΔH calculated to be 27 kcal mol^{-1}) than the [4]helicene in **2** ($\Delta H = 22$ kcal mol^{-1}).

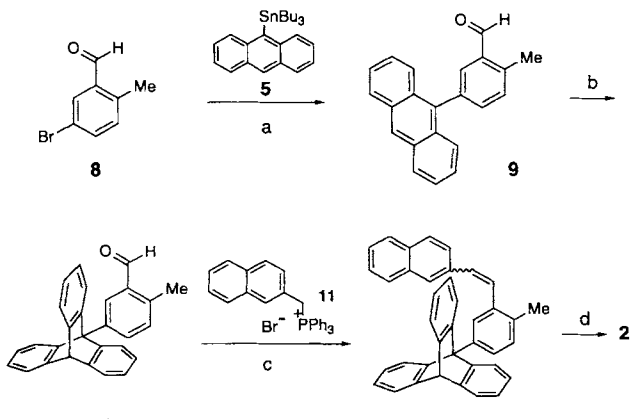
Compound **1** was prepared from the known ketone **3** (Scheme 1).[6] Conversion of **3** to the enol triflate **4** and palladium-catalyzed coupling with anthracenyl stannane **5**[1a] gave **6**.[7]



Scheme 1. a) $(F_3CSO_3)_2O$, 2,6-lutidine, CH_2Cl_2, 0 °C, 77%; b) $[Pd(PPh_3)_4]$, LiCl, dioxane, 120 °C, sealed tube, 3 d, 55%; c) benzyne, dioxane, reflux; d) 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ), C_6H_6, reflux, 53% (overall yield for steps c and d).

Addition of benzyne[8] across the 9,10 positions of the anthracene in **6** generated the triptycene unit **7**; dehydrogenation[9] of **7** completed the synthesis.[10]

Compound **2** was synthesized by the route in Scheme 2. Palladium-catalyzed coupling of bromoaldehyde **8**[11] with stannane **5** gave **9**, which was converted into triptycene **10** by addition of benzyne.[8] Wittig reaction of the aldehyde group in **10** with the ylide from **11**[12] delivered an *E*/*Z* mixture of stilbenes **12**. Irradiation[3, 13, 14] through Pyrex of a benzene solution of **12** with a medium pressure (100 W) mercury lamp under argon in the presence of I_2 (1 equiv) and excess propylene oxide generated



Scheme 2. a) $[Pd(PPh_3)_2]Cl_2$, dioxane, 130 °C, sealed tube, 60 h, 60%; b) benzyne, dioxane, reflux, 68%; c) *n*-BuLi, THF, −78 °C, 84%; d) *hv*, 54%.

2[15] in 54% yield. The methyl group blocks photocyclization in the undesired, but otherwise less hindered direction.

The ^{1}H NMR spectra of **1** and **2** indicate that at room temperature rotation around the triptycene/helicene bond is frozen in both compounds, but that the topology of the two is distinctly different. In particular, the ^{1}H NMR spectrum of **1** reveals a plane of symmetry; two (but not all three) of the rings of the triptycene unit are equivalent. The phenanthrene component of **1** is therefore either planar or exists as a rapidly racemizing mixture of two helical enantiomers.[4] Even at 160 °C, ^{1}H NMR spin polarization transfer experiments[16] reveal no detectable rotation within two seconds of polarization, which indicates a barrier ($\Delta G^{\neq}$) to rotation in excess of 27 kcal mol^{-1}.

The ^{1}H NMR spectrum of **2** recorded at room temperature reflects an absence of symmetry; all three rings of the triptycene are nonequivalent. At 160 °C, however, peak-broadening of triptycene (but not helicene) resonances indicates slow rotation. Extrapolation, based on analogy to our earlier work,[1a] suggests a coalescence temperature of about 220 °C, which corresponds to $\Delta G^{\neq} \approx 25$ kcal mol^{-1}, a value that is corroborated by the studies described below, and which is reassuringly close to the calculated barrier ($\Delta H^{\neq}$ not $\Delta G^{\neq}$) of 22 kcal mol^{-1}. We suggest that the barrier to rotation in **2** is smaller than in **1** because in **2** the interaction between the one-ring-longer helicene and the blade of the triptycene prevents the molecule from relaxing to as stable a ground state conformation (relative to the energy maximum) as is accessible to **1**.

The remaining question is whether **2** functions as a ratchet; that is, whether rotation of the triptycene is uni- or bidirectional. Given the helicity of the [4]helicene in **2**, it is not surprising that the calculated[5] energy diagram (Figure 2) for rotation around the triptycene/[4]helicene bond in **2** is decidedly asymmetric. Clockwise rotation ($\alpha = 0 \rightarrow 120°$) has a more gradual energetic slope than counterclockwise rotation ($\alpha = 120 \rightarrow 0°$).

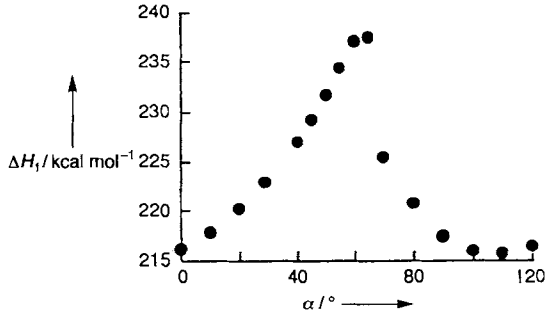


Figure 2. Calculated energy diagram (AM1 [5]) for rotation around the triptycene/[4]helicene bond. Clockwise rotation of the triptycene in **2** corresponds to a rotation from $\alpha = 0$ to $\alpha = 120°$.

One should be able to establish the direction of rotation of the triptycene in **2** by using isotopically labeled rotamers of **2**, but their synthesis, rotamer separation, and structure determination would be very laborious. Fortunately, the spin polarization transfer NMR technique[16] affords the same information at a small fraction of the effort. In short, if a system is conformationally mobile, but that mobility is slow on the NMR time scale, the spin of a slowly conformationally mobile atom can be polarized, and after an appropriate time an assay will show where (if anywhere) that polarization has moved to.

In the present case in which a single rotamer has an experimentally determined half-life of about 0.17 sec at 160 °C, the barrier ($\Delta G^{\neq}$) to rotation is approximately 24.5 kcal mol^{-1}. Thus, if one selectively polarizes one of the three H_a, H_b, and H_c protons (see **13** in Figure 3) and—after appropriate time de-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3617-1867 $ 17.50+.50/0

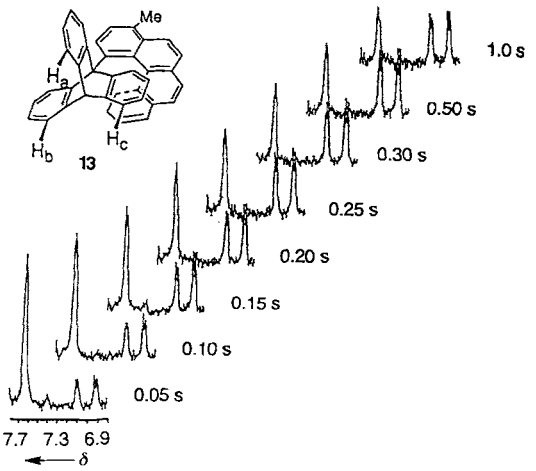

Figure 3. Results of spin polarization transfer experiment in [D$_6$]DMSO at 160 °C (calibrated temperature). The resonances for H_a, H_b, and H_c (see **13**) appear at $\delta = 7.6$, 7.1, and 6.9 (not necessarily respectively). The spin of the proton resonating at $\delta = 7.6$ was polarized, and transfer of that polarization was monitored over time.

lays—assays for the location of that polarization, a clearcut distinction between predominantly unidirectional rotation and bidirectional rotation is available. In the first case, a disproportionate share of the polarization that has moved should be transferred to a resonance for only one of the two other protons. In the second case, the polarization that moves should be transferred equally to the remaining two resonances.

Spin polarization of one (see **13**) of the three H_x protons in **2** was achieved with a selective 180°-pulse–delay–observe sequence. As is evident from Figure 3, the triptycene rotates clockwise and counterclockwise to the same extent. Control experiments polarizing the spin of each of the other two H_x protons gave equivalent results.[17] The asymmetry of the rotational energy curve in Figure 2 is thus deceptive: In contrast to mountain climbing, it is only the height of the summit, not the steepness of the terrain that matters. The chemical principle of microscopic reversibility prevails.

The current study also provides experimental corroboration of a theoretical, thermodynamic analysis of a ratchet and pawl by the physicist Richard Feynman.[18]

In conclusion, the synthesis of triptycene[4]helicene **2** successfully incorporates into a single molecule the essential components of a simple ratchet: the asymmetric combination of a ratchet wheel, a pawl, and a spring. Tantalizing as models of **2** are, the experimental demonstration that **2** rotates equally in both directions illustrates the perils of extrapolating from macroscopic to molecular scales. It follows that molecular units such as **2** cannot by themselves be used to induce unidirectional rotation in an isothermal environment. Nonetheless, their ability to modulate the barrier to free rotation should make them useful components of more complex systems such as molecular motors and machines.

The Donor-Stabilized $[PS_2]^+$ Ion**

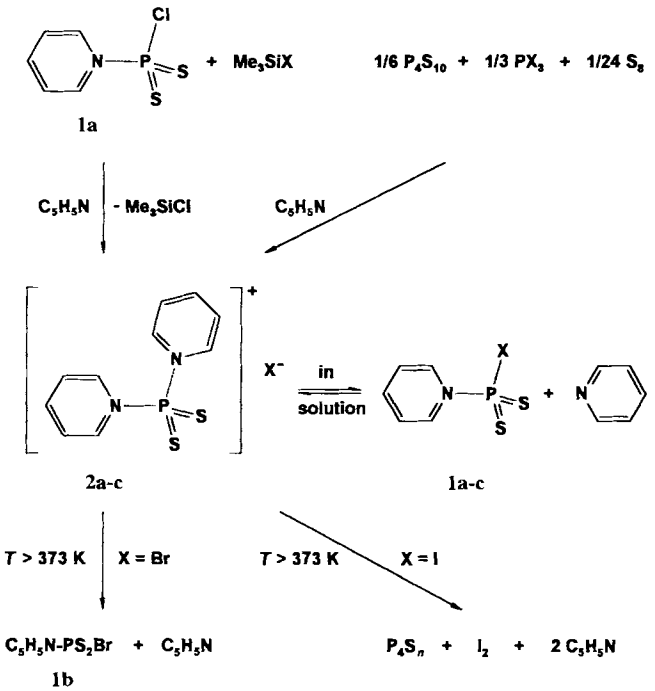
Manfred Meisel,* Peter Lönnecke,
Arnd-Rüdiger Grimmer, and Dirk Wulff-Molder

Dedicated to Professor Roger Blachnik on the occasion of his 60th birthday

Within the scope of our investigations on donor-stabilized dithiometaphosphoric acid halides $(C_5H_5N)PS_2X$ (**1**, X = halogen) we have varied the amine donor function and/or the halogen substituents to determine the influence of these ligands on bonding and reactivity. Our attempts to synthesize the hitherto unknown iodo compound $(C_5H_5N)PS_2I$ (**1c**) surprisingly resulted in the formation of the donor-stabilized $[(C_5H_5N)_2PS_2]^+$ ion with a tetracoordinate phosphorus center.

Trimethyliodosilane and $(C_5H_5N)PS_2Cl$ (**1a**) presumably react in pyridine under the formation of $[Me_3Si(C_5H_5N)]^+$ ions[1] and strongly nucleophilic iodide ions, which are able to substitute the chloride ion in **1a**. In an equilibrium reaction the iodide of the intermediate **1c** is replaced by pyridine because of its stronger basicity, and the dipyridine(dithio)phosphonium iodide $[(C_5H_5N)_2PS_2]I$ (**2c**) is formed, which can also be synthesized by the reaction of P_4S_{10}, PI_3, and sulfur in pyridine as solvent (Scheme 1). In a similar reaction the nucleophilic degradation of P_4S_{10} with pyridine in the presence of $PSBr_3$ led to the formation of the corresponding dipyridine(dithio)phosphonium bromide $[(C_5H_5N)_2PS_2]Br$ (**2b**).

NMR investigations on **2b** and **2c** in acetonitrile indicate an equilibrium of the species **1** and **2** in solution (Scheme 1). This equilibrium shifts progressively from left to right for the series



Scheme 1.

I, Br, Cl and lies for X = Cl completely on the side of **1a**, which is attributed to the decreasing basicity on going from the chloride to the iodide.

As a result of one-bond coupling of phosphorus with the ^{14}N quadrupole nucleus the ^{31}P NMR signal is split into a triplet when the compounds **1b** and **1c** are dissolved in acetonitrile.[2] Comparable spectra are recorded for $(C_5H_5N)PS_2F$ and **1a**.[3] This finding is remarkable, because the low symmetry of **1** and the great difference in the electronegativities of the halogen substituents should encourage an effective quadrupole relaxation. In contrast to this no comparable effect has been observed for the more symmetric $[(C_5H_5N)_2PS_2]^+$ ion, and only a singlet is visible in the ^{31}P NMR spectrum. The $^1J(^{31}P,^{14}N)$ coupling constants increase linearly with decreasing electronegativity of the halogen substituent X in the series $(C_5H_5N)PS_2X$ (X = F, Cl, Br, I; Figure 1). In solution[2] and in the solid state[4] the isotropic chemical shifts of **2b** and **2c** are comparable; thus, $[(C_5H_5N)_2PS_2]^+$ ions exist both in the solid state and in solution.

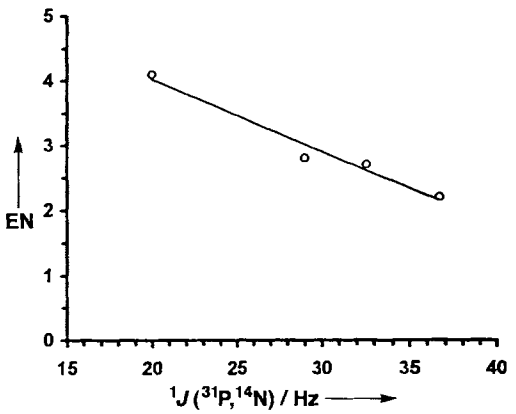


Figure 1. $^1J(^{31}P, ^{14}N)$ coupling constants of the dithiometaphosphoric acid halides $(C_5H_5N)PS_2X$ (X = F, Cl, Br, I) as a function of the electronegativity (EN) of the halogen substituents.

For the discussion of the bonding the anisotropy of the chemical shift has been taken into account.[4] A comparison of the tensor data for the iodide **2c** and the bromide **2b** shows only small differences; thus, the bonding at the phosphorus center is expected to be nearly the same in both compounds. This is in accordance with the structure parameters[5, 6] estimated for **2b** and **2c**. Both tensors show an unusual, extremely large span Ω value of approximately 500 ppm. A span of this magnitude had never been observed in noncyclic phosphorus–sulfur compounds. Evidently, the tetrahedral symmetry of the distribution of the bonds, which is realized, for example, in the $[PS_4]^{3-}$ ion, is extremely distorted. In the present case of an exactly or approximately axial tensor the orientation of the tensor axis can be given in relation to the symmetry axis of the respective molecule or ion.[7] Thus, the bisector of the S-P-S angle—as the twofold axis of the $[PS_2]^+$ cation—coincides in a good approximation with the symmetry axis of the ^{31}P shielding tensor. From the negative sign of the span it can be deduced that the direction of the strongest shielding (δ_3) as $\delta_\parallel$ coincides with the bisector of this angle; therefore, the double-bond character is concentrated in the PS_2 plane.

The single-crystal X-ray structure analysis of **2b**[5] and **2c**[6] (Figure 2) enabled us to attain deeper insights into the bonding. P–N single bonds normally range from 169 to 175 pm. For the $[(N_3)_2PS_2]^-$ ion, whose molecular geometry is similar to that of the $[(C_5H_5N)_2PS_2]^+$ ion, a normal P–N distance of 173 pm had

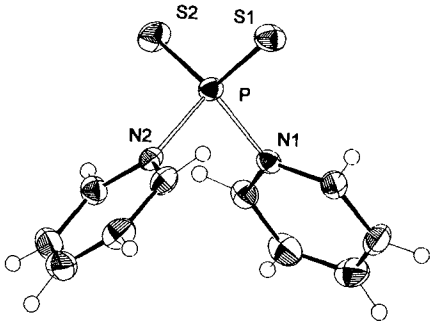

Figure 2. Structure of the $[PS_2(NC_5H_5)_2]^+$ ion (ORTEP, ellipsoides with 50% probability). Selected bond lengths [pm] and angles [°] for the bromide **2b**/iodide **2c**: P-S1 191.9(2)/191.7(2), P-S2 191.0(2)/191.1(2), P-N1 176.8(14)/183.1(3), P-N2 187.4(13)/183.1(3); S1-P-S2 123.75(9)/124.85(8), N1-P-N2 94.2(2)/93.1(2), N1-P-S1 107.6(4)/108.55(9), N1-P-S2 108.8(4)/108.56(9), N2-P-S1 109.6(5)/108.55(9), N2-P-S2 108.8(4)/108.56(9).

been determined.[8] The P–N bond lengths for **1a** (184.9 pm),[9] **2b** (177 pm and 187 pm),[5] and **2c** (both 183.1 pm)[6] lie outside this normal range and should therefore be regarded as weak coordinative P–N bonds. P–S single bonds range between 203 and 217 pm, P–S double bonds between 188 and 198 pm, and for the $[PS_2]^+$ ion calculations predict a value of 182–187 pm.[10] The P–S distances for **2b** and **2c** (191 and 192 pm) demonstrate the double-bonding character of these P–S units. The P–Br and P–I distances (490.7(2) and 503.4(2) pm, respectively) are clearly longer than the sum of the respective van der Waals radii. S-P-S bond angles of phosphorus sulfides usually lie between 100 and 115°. Initial predictions on the structure of the PS_2 species were based on the results of IR spectroscopic investigations and MNDO calculations.[10, 11] The S-P-S bond angle increases in the series $[PS_2]^-$ ion (IR: $\sphericalangle \leq 118°$), $[PS_2]^{\cdot}$ radical (IR: $\sphericalangle \leq 127°$, MNDO: $\sphericalangle \leq 143°$), and linear $[PS_2]^+$ ion. The experimentally observed S-P-S angle for the $[(C_5H_5N)_2PS_2]^+$ ion is about 124° and demonstrates the change of the bonding towards that of the free $[PS_2]^+$ ion.

Compounds **2b** and **2c** are stable at room temperature. Under vacuum **2c** decomposes above 100 °C to give pyridine, elemental iodine, and phosphorus sulfides such as P_4S_7, P_4S_9, and P_4S_{10}, which have been detected by NMR spectroscopy. In addition, this decomposition process was confirmed by mass spectrometry. In contrast, **2b** (as well as **2c**) decomposes under the same conditions, but only one mole of pyridine is split off and the compound is transformed into **1b**. This behavior can be explained on the basis of the two different P–N distances determined for **2b** (see above).[5]

Unlike **2b**, compound **2c** is not hygroscopic and is relatively stable towards dry air. Both compounds are sensitive towards moisture, and **2c** decomposes under decolorization of the bright yellow substance to yield $[(C_5H_5N)PS_2]_2O$, pyridine hydroiodide, and other, unknown decomposition products. Solutions of **2b** and **2c** are extremely sensitive towards moisture and can be handled only under an inert gas atmosphere.

$[NO_2]^+$ and $[NS_2]^+$ are stable, linear cations that occur in a number of compounds. $[PO_2]^+$ is still unknown, but $[PS_2]^+$ had been detected by mass spectrometry.[12] Since **2c** readily eliminates pyridine and iodine, it could conceivably be used as a starting material for the synthesis of compounds with isolated $[PS_2]^+$ ions.

Experimental Section

All operations were carried out under an inert gas atmosphere by using standard Schlenk techniques.

2b: $SPBr_3$ (5.1 g, 16.8 mmol) in dry pyridine (250 mL) and P_4S_{10} (3.74 g, 8.4 mmol) were heated until reflux. The hot solution was filtered and then allowed to cool to room temperature. After 15 h pale yellow crystals of **2b** could be separated from the mixture. These were washed with toluene, recrystallized from dry pyridine, and dried in vacuum. Yield: 15.5 g (92%). Elemental analysis: Calcd.: C 36.05, H 3.03, N 8.41, P 9.30, S 19.24, Br 23.98; found: C 35.47, H 3.42, N 8.28, P 8.85, S 18.04, Br 23.72.

2c: a) P_4S_{10} (2 g, 4.5 mmol), PI_3 (3.7 g, 9 mmol) and sulfur (0.29 g, 9 mmol) were dispersed in pyridine (200 mL) and heated to reflux. The hot dark red solution was filtered and allowed to cool to room temperature. Bright yellow crystals of **2c** were obtained after 48 h, which were washed with toluene and dried in vacuum. Yield: 8.3 g (81%). b) $PyPS_2Cl$ (4 g, 19 mmol) in pyridine (200 mL) was treated with Me_3SiI (3.81 g, 19 mmol) and heated until the precipitate had dissolved. The hot dark red solution was filtered and allowed to cool to room temperature to yield crystals of **2c**, which were washed with toluene and dried in vacuum. Yield: 4.1 g (58%). Elemental analysis: Calcd.: C 31.59, H 2.65, N 7.37, P 8.15, S 16.86, I 33.38; found: C 31.51, H 2.77, N 7.57, P 8.20, S 16.97, I 33.29

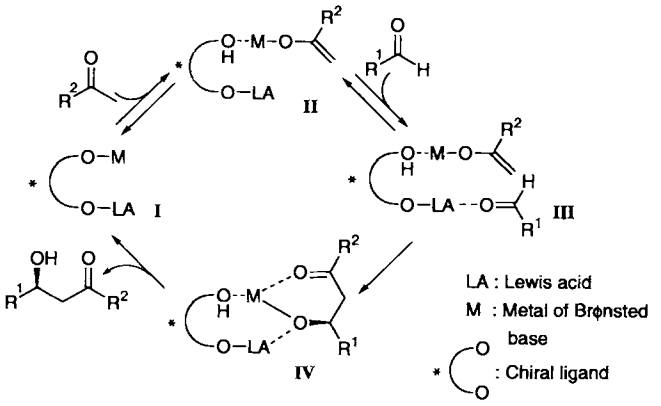
Direct Catalytic Asymmetric Aldol Reactions of Aldehydes with Unmodified Ketones

Yoichi M. A. Yamada, Naoki Yoshikawa, Hiroaki Sasai, and Masakatsu Shibasaki*

The aldol reaction is one of the most powerful of carbon–carbon bond-forming reactions, and the development of a range of catalytic asymmetric aldol-type reactions has thus proven to be a valuable contribution to asymmetric synthesis.[1] In all of these asymmetric aldol-type reactions, however, pre-conversion of the ketone moiety to a more reactive species such as an enol silyl ether, enol methyl ether, or ketene silyl acetal is an unavoidable necessity. Development of a direct catalytic asymmetric aldol reaction, starting from aldehydes and *unmodified* ketones is thus a worthwhile endeavor.[2] Such reactions are known in enzyme chemistry:[3] the fructose-1,6-bisphosphate and dihydroxyacetone phosphate (DHAP) aldolases are characteristic examples. The mechanism of these is thought to involve cocatalysis by a Zn^{2+} ion and a basic functional group in the enzyme's active site; the latter abstracts a proton in proximity to a carbonyl compound while the former functions as a Lewis acid to activate the second carbonyl component. These aldolases can thus be thought of as multifunctional catalysts displaying both Lewis acidity and Brønsted basicity, so making possible efficient catalytic asymmetric aldol reactions under typically mild in vivo conditions. An analogous cooperative mode of action can be seen in reactions mediated by any of several heterobimetallic asymmetric catalysts having both Lewis acidity and Brønsted basicity, which have been developed by our research group.[4, 5]

We speculated that it might be possible to develop a direct catalytic asymmetric aldol reaction of aldehydes with unmodified ketones by employing catalysts like **I** (Scheme 1). A



Scheme 1. Catalytic cycle of the direct catalytic asymmetric aldol reactions.

Brønsted base unit (OM) of catalyst **I** could deprotonate an α-proton of a ketone to generate the metal enolate **II**, while at the same time a Lewis acid unit (LA) could activate an aldehyde to give **III**. These reaction partners might react in the chelation-controlled, asymmetric environment to afford a β-keto metal alkoxide (**IV**). Proton exchange between the metal alkoxide moiety and a hydroxy proton of the aryl unit or an α-proton of a ketone could then generate an optically active aldol adduct with regeneration of the catalyst **I**. We now wish to report the first example of such a reaction,[6] in which we have obtained optically active aldol adducts in up to 94% *ee*.

We were initially concerned that our heterobimetallic asymmetric catalysts would be ineffective at promoting aldol reactions as a result of their rather low Brønsted basicity and were thus pleased to find that aldol reactions of the desired type proceeded quite smoothly with $LaLi_3$tris(binaphthoxide) (LLB)[4d] as catalyst (Figure 1). As shown in Table 1, when the

[a] (*R*)-LLB and addition of 1 equiv of H_2O to LLB; see ref. [10]. [b] The reaction was carried out at −30 °C.

direct catalytic asymmetric aldol reaction of pivalaldehyde (**1a**) with 5.0 equivalents of acetophenone (**2a**) was carried out in the presence of 20 mol% of (*R*)-LLB and 1.0 equivalent of H_2O (relative to LLB) in THF at −20 °C for 88 h, we obtained the desired adduct **3a**[7, 8] in 43% yield with 89% *ee* (entry 1).[9] Anhydrous LLB was more efficient than hydrated LLB, affording **3a** with 88% *ee* in 76% yield after stirring for 88 h (entry 2).[10] Furthermore, the use of 1.5 equivalents of **2a** gave **3a** with 87% *ee*, albeit in 43% yield (entry 3), and increasing the amount to 10 equivalents afforded **3a** with 91% *ee* in 81% yield after stirring for 91 h (entry 4).[11]

Following on from these results we turned our attention to broadening the range of substrates. The reaction of **1a** with **2b** at −20 °C proceeded satisfactorily to give **3b** with 76% *ee* in 55% yield (entry 5), as did the reaction of **1b** with **2a** at −20 °C to afford the aldol adduct **3c** with 69% *ee* in 90% yield (entry 6). The achievement of efficient catalytic asymmetric aldol reactions of aldehydes with α-hydrogen atoms clearly represents a much greater challenge than for cases such as those above, since self-aldol products can easily be produced as by-products. However, the reaction of cyclohexanecarbaldehyde (**1c**) with **2a** proceeded smoothly without significant self-aldol of **1c**. Thus, after optimization, the reaction of **1c** with 8.0 equivalents of **2a** in the presence of 20 mol% of LLB gave **3d** with 44% *ee* in 72% yield, with no detectable self-condensation products of **1c** (entry 7).[12, 13] The reaction of isobutyraldehyde (**1d**) also proceeded smoothly, giving **3e** with 54% *ee* in 59% yield at −30 °C (entry 8). The reaction of hydrocinnamaldehyde (**1e**), which possesses two α-hydrogen atoms, with **2a** proved more difficult; **3f** was obtained with 52% *ee*; however, the yield was low (28%) due to the formation of self-condensation by-products (entry 9).

Aldol reactions that utilize acetone (**2c**) as a starting material are generally difficult to control. However, in this case the reaction of aldehyde (**1b**) and 10 equivalents of **2c** with LLB gave **3g** with 74% *ee* in 82% yield (entry 10), the reaction of **1a** with 10 equivalents of **2c** at −20 °C product **3h** with 73% *ee* in 53% yield (entry 11), and the reaction of **1b** and 50 equivalents of 2-butanone (**2d**) at −20 °C adduct **3i** with excellent *ee* (94%) in 71% yield (entry 12).[14, 15] Acetone and 2-butanone are widely used as solvents and are much cheaper than the corresponding enol silyl ethers and/or methyl enol ethers, which are used as substrates in the catalytic asymmetric Mukaiyama aldol reaction;[1] the use of large excesses of ketone can thus be justified in this particular case.

As outlined above (Scheme 1) in these reactions the lanthanum atom is believed to function as a Lewis acid and a lithium binaphthoxide moiety as a Brønsted base. The nature of the coordination of the aldehyde appears to be of first importance, as the accompanying activation makes possible a smooth reaction of the hypothetical LLB enolate (**II**), which on the basis of pK_a values can be expected to be present at only low concentrations, and also enables control of the orientation of the aldehyde and so facilitates the enantioselective reaction. To determine the extent of coordination between aldehydes and the lanthanum cation we carried out a ^{1}H NMR study on a mixture of $PrLi_3$tris(binaphthoxide) (PrLB)[4d] and **1a** (Figure 2).[4a] The propensity of Pr complexes to induce upfield shifts is known,[16] and in fact reaction of **1a** with **2a** in the presence of (*R*)-PrLB gave (*S*)-**3a** in 79% *ee*, indicating that Pr-containing catalysts are also a reasonable model for those containing La in terms of chemical reactivity. In the relevant ^{1}H NMR spectra the chemical shift of the formyl hydrogen of **1a** appears at $\delta = 9.37$ in THF; however, when 20 mol% of PrLB was added, an upfield shift of this signal to $\delta = 9.27$ was observed. In contrast, adding 60 mol% of the dilithium salt of (*R*)-binaphthol alone gave no detectable chemical shift of **1a**, and moreover, reaction of **1a** with **2a** catalyzed by this salt gave *rac*-**3a**. These results clearly indicate that coordination of the aldehyde to Pr is indeed occurring, allowing activation and stereocontrol to occur as proposed.[17]

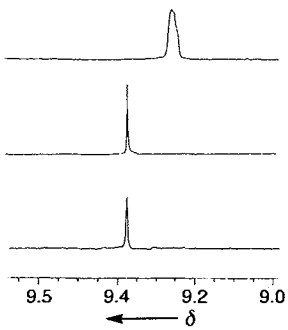

Figure 2. Chemical shift of the formyl hydrogen in **1a** in THF (bottom) as well as in the presence of 60 mol% of (*R*)-dilithium binaphthoxide (center), and 20 mol% of (*R*)-PrLB (top).

In conclusion, we have succeeded in carrying out the first catalytic asymmetric aldol reaction of aldehydes with unmodified ketones by using heterobimetallic multifunctional catalysts. Although the present catalytic asymmetric reaction is still being developed, the results reported here should provide a solid foundation for further work.

Experimental Section

General procedure: To a stirred solution of (*R*)-LLB (0.10 mmol) in THF (1.67 mL) was added 2-butanone (**2d**, 25 mmol) at −20 °C. After 30 min, 2,2-dimethyl-3-phenylpropanal (**1b**, 0.50 mmol) was added to the solution, which was then stirred for 185 h at −20 °C. The reaction was quenched by adding 2 mL of 1 N HCl and extracted with Et_2O (3 × 10 mL). The combined organic layers were washed with brine and dried over Na_2SO_4. The solvent was removed under reduced pressure, and the residue purified by flash chromatography (SiO_2, Et_2O/hexane 1/12) to give (*S*)-**3i** with 94% *ee* in 71% yield.

[9] The enantiomeric excess of all the aldol adducts was determined by HPLC analysis with DAICEL CHIRALPAK AS, AD, or CHIRALCEL OJ; absolute configurations were determined to be (*S*)-form. Absolute configurations of **3b**, **3c**, **3g**, and **3i** were determined by Mosher's method: J. A. Dale, H. S. Mosher *J. Am. Chem. Soc.* **1973**, *95*, 512–519.

[10] To (*R*)-LLB in THF was added 1.0 equiv of H_2O in THF (1.0 M) to give hydrated (*R*)-LLB, which had been found to be a more effective catalyst for previously reported catalytic asymmetric nitroaldol reactions [4b].

[11] Results with 5 or 10 mol% of (*R*)-LLB: 42% yield, 77% *ee* and 52% yield, 88% *ee*, respectively.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3617-1872 $ 17.50+.50/0

[12] Results with 20 mol% of other catalysts at −20 °C: $LaNa_3$tris(binaphthoxide) (LSB)[4a] in THF (16%, 13% *ee*), LaK_3tris(binaphthoxide) (LPB)[4c] in THF (49%, 0% *ee*), AlLibis(binaphthoxide) (ALB)[4b] in THF (quite low yield), LLB in toluene (25%, 31% *ee*), LLB in CH_2Cl_2 (33%, 15% *ee*), LnLB where Ln = Pr, Sm, Gd, Dy, or Yb in THF (low *ee* values), LLB* in THF (B* = 6,6′-bis((triethylsilyl)ethynyl(binaphthoxide)) (low *ee*), 6,6′-dibromo(binaphthoxide) (low *ee*), 6,6′-dimethoxy(binaphthoxide) (low *ee*)).

[13] The moderate yield is mainly due to the low reactivity of LLB. A small amount of dehydrated product was detected.

[14] A trace amount of 4-hydroxy-3,5,5-trimethyl-6-phenyl-2-hexanone was detected.

[15] The reaction of benzaldehyde and 8 equiv of **2a** in the presence of 20 mol% of (*R*)-LLB at 198 h gave the desired aldol adduct with only 3% *ee* (*S*) in 41% yield, but the reaction under the same conditions except in the presence of $YbLi_3$tris((*R*)-binaphthoxide) ((*R*)-YbLB) instead of (*R*)-LLB gave the aldol product with 36% *ee* (*R*) in 47% yield.

[16] Review: A. F. Cockerill, L. O. Davies, R. C. Harden, D. M. Rackham, *Chem. Rev.* **1973**, *73*, 553–588, and references therein.

[17] It is unlikely, even if the aldehyde coordinates to a Li atom of the Pr complex, that proximity to the Pr or the positioning of the formyl C–H in the shielding region of the naphthyl ring could produce a shift of such magnitude, as no such chemical shift is observed in the presence of LLB.

Synthesis and Crystal Structure of Phosphorus(v) Nitride α-P_3N_5**

Stefan Horstmann, Elisabeth Irran, and Wolfgang Schnick*

Dedicated to Professor Hans Georg von Schnering

Polymeric nonmetal nitrides are of considerable interest for the development of inorganic materials.[1] Among the binary members of this class of compounds dimorphic boron nitride (BN) and silicon nitride (Si_3N_4) have gained significance. Their potential applications include use as substrate for semiconductors (Si_3N_4) and as high-temperature materials (for example crucibles made of hexagonal BN or valve tappets and turbochargers made of Si_3N_4).

Chemically and structurally related phosphorus(v) nitride P_3N_5 was assumed to be built up by a polymer network structure of connected TN_4 tetrahedra (T = B, Si, P) similar to that of cubic BN and Si_3N_4. The crystal structures of BN and Si_3N_4 have already been investigated in detail.[1] However, no structural model of P_3N_5 was available in spite of many intensive efforts,[2, 3] because neither monocrystalline nor pure polycrystalline samples of P_3N_5 had been obtained. In our recently developed synthesis of phosphorus(v) nitride [Eq. (1)] we always obtained mixtures of the polymorphs α- and β-P_3N_5, which were characterized by electron diffraction (ED), high-resolution transmission electron microscopy (HRTEM), EXAFS (extended X-ray absorption fine structure) spectroscopy, and ^{31}P and ^{15}N solid-state NMR spectroscopy.[3]

[**] This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft (project SCHN 377/2-2, and Gottfried-Wilhelm-Leibniz-Programm), the Bundesministerium für Bildung, Wissenschaft, Forschung und Technologie in the Verbundprojekt "Erforschung kondensierter Materie" (project 03-SC4 BAY), and the ESRF Grenoble. The authors thank Dr. P. Pattison (ESRF, Grenoble) for his help during the synchrotron experiment.

We have now synthesized single-phase α-P_3N_5 by thermal condensation of tetraaminophosphonium iodide $[P(NH_2)_4]I$ according to Equation (2).[4] The NH_4I atmosphere that develops during the decomposition of $[P(NH_2)_4]I$ evidently is significant for the formation of ordered α-P_3N_5, because heavily disordered P_3N_5 is formed when $[P(NH_2)_4]Cl$ is used under comparable experimental conditions. During our procedure α-P_3N_5 is formed as a microcrystalline, beige powder, which is insoluble in common solvents as well as in hot acids and alkaline solutions.

$$3[P(NH_2)_4]I \xrightarrow{825\,^\circ C} P_3N_5 + 3NH_4I + 4NH_3 \quad (2)$$

The crystal structure of α-P_3N_5 was determined and refined on the basis of powder X-ray diffraction data. Due to numerous overlapping peaks the resolution of conventional powder diffractometers (typical full width of half maximum height (FWHM) of the peaks: 0.09°) did not allow us to deconvolute the diffraction pattern of α-P_3N_5. Therefore we performed powder diffraction investigations with higher resolution by using synchrotron radiation at the European Synchrotron Radiation Facility in Grenoble (ESRF, Beamline BM1, typical FWHM: 0.03°). We could index the powder pattern obtained unambiguously (Figure 1) and the structure was determined by direct methods and refined by the Rietveld method (Table 1, see Experimental Section).

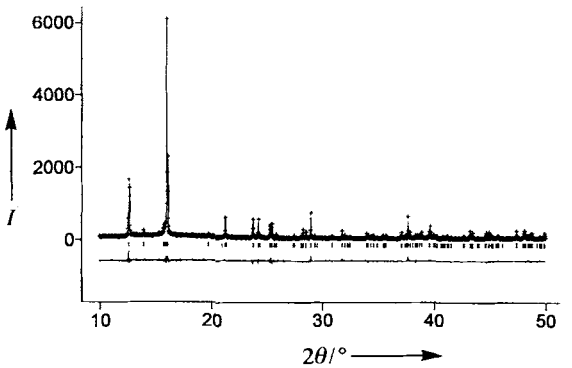

Figure 1. Observed (crosses) and calculated (line) X-ray powder diffraction pattern as well as difference profile of the Rietveld refinement of α-P_3N_5 (only section until $2\theta = 50°$ is shown). Possible positions of the peaks are marked by vertical lines. The powder pattern was obtained at the ESRF, Grenoble, on the Beamline BM1 (λ = 99.963(4) pm).

In the solid state α-P_3N_5 has a three-dimensional network structure of connected PN_4 tetrahedra (Figure 2). As a consequence of the molar ratio P:N = 3:5 two fifths of the nitrogen atoms ($N^{[3]}$) are bound to three neighboring P atoms and the remaining nitrogen atoms ($N^{[2]}$) to two P atoms according to

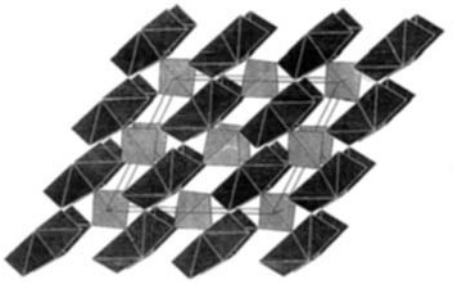

Figure 2. Crystal structure of α-P_3N_5, view along [010]. Crossing zweier single chains (black), in which the PN_4 tetrahedra are linked alternately through common corners and edges, are connected by addional PN_4 tetrahedra.

$^3_\infty[P_3^{[4]}N_3^{[2]}N_2^{[3]}]$.[*] Thus the coordination resembles that in silicon dioxide ($^3_\infty[Si^{[4]}O_2^{[2]}]$) and in silicon nitride ($^3_\infty[Si_3^{[4]}N_4^{[3]}]$). Examples of $N^{[3]}$ connections recently have been proven in P_4N_6O[5] and $K_3P_6N_{11}$,[6] while in less condensed phosphorus nitrides (molar ratio P:N $\leq$1:2) exclusively terminal $N^{[1]}$ and simple bridging $N^{[2]}$ are found.[1] On the other hand, in higher condensed nitridosilicates[7] numerous examples of $N^{[3]}$ connections between Si tetrahedral centers are known (e. g. $Ca_2Si_5N_8$, $Ce_3Si_6N_{11}$), and surprisingly even $N^{[4]}$ connections were found in nitridosilicates ($MYbSi_4N_7$, M = Sr, Ba).[8]

In α-P_3N_5 zweier single chains occur parallel to [110] and [1$\bar{1}$0], in which the PN_4 tetrahedra are connected alternately through edge- and corner-sharing. These zweier single chains are linked together through additional vertex-sharing PN_4 tetrahedra. First indications of the edge linkage of the tetrahedra already appeared during the analysis of the EXAFS spectrum of α-P_3N_5, in which an interatomic distance of about 250 pm was determined.[3] This corresponds to the transannular P$\cdots$P distance in P_2N_2 rings. In almost all known condensed phosphorus(v) nitrides the PN_4 tetrahedra are connected exclusively through common corners.

A similar connection through edge-sharing has only previously been observed in the phosphorus(v) nitride oxide P_4N_6O[5] and in the phosphorus(v) nitride imide HP_4N_7.[9] Among nitridosilicates examples of an analogous connection through edge-sharing SiN_4 tetrahedra include $Ba_5Si_2N_6$[10] and $BaSi_7N_{10}$.[11] "Fibrous" SiO_2 was assumed to contain edge-sharing SiO_4 tetrahedra;[12] however, this statement has not yet been confirmed by using modern experimental techniques.

The network structure of connected PN_4 tetrahedra in α-P_3N_5 could be characterized by analogy to condensed silicates by the specific distribution of the occurring P_nN_n ring sizes.[13] All ring sizes with the exception of $n = 3$ are found in α-P_3N_5. In contrast, analogously condensed Si_3N_3 rings often occur in highly condensed nitridosilicates (Si:N $>$1:2).[7]

The P–N bond lengths (151–174 pm) and the P-$N^{[2]}$-P bond angles (142–170°) vary in ranges typical of phosphorus(v) nitrides.[1] The sum of the angles at the $N^{[3]}$ center is 360°; therefore, these N atoms must be considered as sp^2 hybridized. According to the experience gained with nitridosilicates, P–$N^{[2]}$ distances (151–160 pm) are significantly shorter than P–$N^{[3]}$ distances (164–174 pm). However, due to the specific properties of the chemical bond between P and N the assumption of a double bond is not justified. Thus, polar character of the bond must be responsible for the observed bond shortening.[14]

α-P_3N_5 crystallizes in a new and unprecedented structure type. However, isotypic compounds of the other polymeric nonmetal nitrides built up by TN_4 tetrahedra (T = B, Si), cubic BN and Si_3N_4, exist. The crystal structure of cubic BN corresponds to the sphalerite type and Si_3N_4 crystallizes analogously to phenakite Be_2SiO_4. Hypothetical $BeSi_2O_5$ would be isoelectronic to P_3N_5. However, in the corresponding region of the quasi-binary system BeO–SiO_2 only vitreous phases and no crystalline compound of the given composition are found. Among the hitherto known binary compounds of the formula type A_3X_5 (e. g. Ti_3O_5, V_3O_5, Ta_3N_5, Si_3Mn_5, Si_3W_5) there are no examples that are isotypic to α-P_3N_5. Here higher coordination numbers of either 6 (Ti_3O_5, V_3O_5, Ta_3N_5, Si_3Mn_5) or 8 (Si_3W_5) are found for the A atoms.

On the basis of the solved crystal structure of α-P_3N_5 we are now working on the determination of structural models for β-P_3N_5 and disordered P_3N_5. The HRTEM[3] results show that similar to the situation in the polytypes of SiC[15] the different stacking variants are based on the same structural modules, which are linked in different ways.

Experimental Section

For the synthesis of α-P_3N_5 [$P(NH_2)_4$]I (200 mg, 0.9 mmol) was transferred under argon into the lower end of a quartz ampoule 30 cm in length and the opening was connected with a bubble counter filled with paraffin. Then the lower end was heated to 825 °C in a tube furnace for three days. Ammonia, which formed according to Equation (2), escaped through the bubble counter, and ammonium iodide precipitated at the wall of the ampoule. The product was obtained as a beige solid (12.0 mg) that remained at the bottom of the ampoule (yield: 24.5%). Elemental analysis by Mikroanalytisches Labor Pascher, Remagen, Germany, calc.: P 57.0, N 43.0; found: P 56.8, N 42.7%. The absence of hydrogen (N-H) was checked by IR spectroscopy.

The diffraction investigations with synchrotron radiation were carried out in Debye–Scherrer geometry. The sample was enclosed in a glass capillary (diameter 0.3 mm). A wavelength of 99.963(4) pm was selected by a Si(111) single crystal monochromator, and also a Si(111) crystal was used as analyzer. A scintillation counter was used, and the measured diffraction intensities were normalized for storage ring decay by a ionization chamber monitor. The diffraction pattern was indexed unambiguously by the programs ITO [16] and TREOR-90 [17] (de Wolff figure of merit M_{20} = 131). On the basis of the systematic absences the space groups *Cc* (No. 9) and *C2/c* (No. 15) were considered. The program EXTRA [18] was employed to extract 184 integrated intensity data and these were used as input for the program SIRPOW.92 [19] for the structure determination by direct methods. As a result all P and N could be localized immediately. The refinement (program system GSAS [20]) was carried out with the space group *Cc*. On the basis of the same topology space group *C2/c* would require unusual bond angles P-N-P of 180° and the assumption of structural disorder. P_3N_5: *Cc*, a = 812.077(4), b = 583.433(4), c = 916.005(5) pm, β = 115.809(1)°, Z = 4, $F(000)$ = 320, μ = 5.283 mm^{-1}, measured range 10° $\leq 2\theta \leq$ 97.4°, 17203 data points, 699 observed reflections, 22 positional parameter refined, wR_p = 0.113, R_p = 0.091, R_F = 0.060. At the beginning of the calculation scaling factor, lattice constants, zero point shift, and background were refined. The profile was fitted by a pseudo-Voigt function [21] and its asymmetry corrected according to reference [22]. As compared to the unit cell of α-P_3N_5 [3] derived on the basis of electron diffraction data, the here mentioned metric results from the transformation matrix (0, 0, 1/2; 0, −1, 0; 1, 0, −1/2). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, on quoting the depository number CSD-406599.

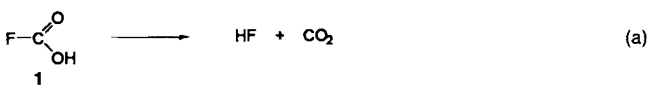
Preparation, NMR, and Ab Initio/IGLO/GIAO-MP2 Study of the Elusive Protonated Fluoroformic Acid and Fluorocarbonyl Cation**

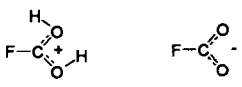
George A. Olah,* Arwed Burrichter, Thomas Mathew, Yashwant D. Vankar, Golam Rasul, and G. K. Surya Prakash*

Fluoroformic acid, the monofluoro derivative of carbonic acid, is a proposed intermediate in the oxidation of fluorocarbons[1] and ozonolysis of fluoroalkenes.[2] Considerable interest has been focused on its potential role in the depletion of the ozone layer in the stratosphere.[3, 4] Fluoroformic acid has recently[5] been observed in the gas phase by neutralization–reionization mass spectrometry (NMRS). All attempts to prepare fluoroformic acid in solution have so far failed. According to a chemistry textbook,[6] fluoroformic acid cannot exist in condensed phases because of its autocatalytic decomposition to HF and CO_2 [Eq. (a)].



(a)

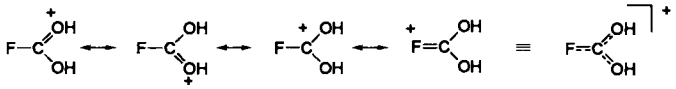
The structure and decomposition pathways of fluoroformic acid have been investigated in a number of theoretical papers.[2, 7–10] While neutral FCOOH was found to be unstable, its conjugate acid and base, protonated fluoroformic acid $[FC(OH)_2]^+$ and fluoroformate ion $[FCO_2]^-$, respectively, are expected to be considerably more stable due to resonance stabilization (Scheme 1).



Scheme 1. Resonance stabilization of the conjugate acid and base of fluoroformic acid.

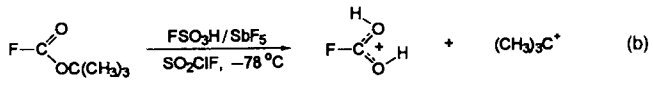
Seppelt et al. have recently[11] prepared and characterized stable salts of the fluoroformate anion by reaction of CO_2 with dry quaternary ammonium fluorides such as Me_4NF. The fluoroformate anion was found to be remarkably stable under anhydrous conditions in aprotic solvents such as dry acetonitrile and has been characterized by ^{13}C and ^{19}F NMR and IR spectroscopy.

Similar to the fluoroformate anion, protonated fluoroformic acid $[FC(OH)_2]^+$ is expected to be significantly resonance-stabilized, involving backdonation (p–p interaction) from oxygen as well as fluorine nonbonded electron pairs (Scheme 2). Wiedmann and Wesdemiotis previously obtained evidence for protonated fluoroformic acid in the gas phase through dissociative ionization of ethyl fluoroformate.[5] We now report the first preparation and characterization of protonated fluoroformic acid $[FC(OH)_2]^+$ in the condensed phase under superacid stable ion conditions, the results of ab initio calculations of its structure and energetics, and the ^{13}C and ^{19}F NMR chemical shifts calculated by IGLO[12] and GIAO-MP2[13] methods together with a comparison with the experimental NMR data.



Scheme 2.

Protolytic ionization of *tert*-butyl fluoroformate in fivefold excess of FSO_3H/SbF_5 (1/1 molar solution; Magic Acid) in SO_2ClF as solvent at −78 °C resulted in a deep yellow solution [Eq. (b)]. The 75 MHz ^{13}C NMR spectrum of the solution



(b)

at −78 °C (Figure 1) clearly showed the formation of the *tert*-butyl cation $[(CH_3)_3C]^+$ (δ = 334.3 (C^+, *s*), 41.4 (CH_3, *q*)), as well as two well-resolved doublets at δ = 157.8 (*d*, $J_{C,F}$ = 321.0 Hz) and 117.5 (*d*, $J_{C,F}$ = 322.4 Hz). We assign the peak at δ = 157.8 to protonated fluoroformic acid $[FC(OH)_2]^+$, which is deshielded by $\Delta\delta$ = 14.6 relative to its progenitor *tert*-butyl fluoroformate [δ = 143.2 (*d*, $J_{C,F}$ = 285 Hz)]. Similar results were obtained in the even stronger fluoroantimonic acid medium (HF/SbF_5). The carboxyl carbon of $[FC(OH)_2]^+$ is shielded relative to those of protonated carbonic acid $[C(OH)_3]^+$ (δ = 165.4),[14] protonated formic acid $[HC(OH)_2]^+$ (δ = 177, 174),[15] and protonated acetic acid $[CH_3C(OH)_2]^+$ (δ = 193.0).[15]

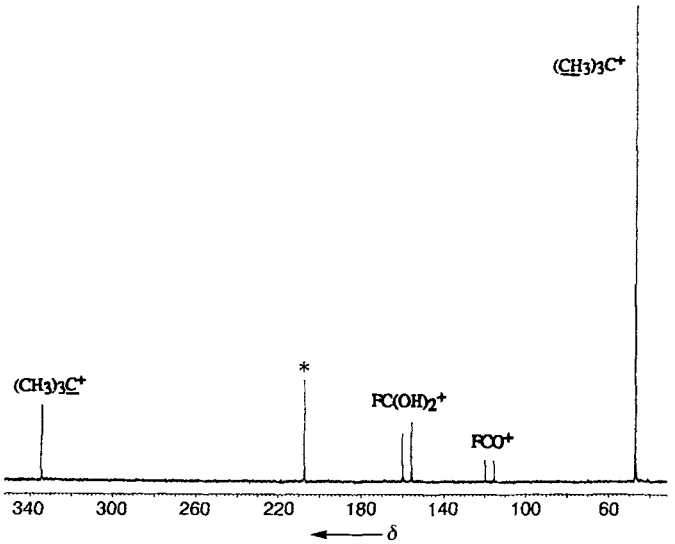

Figure 1. ^{13}C NMR spectrum (75 Hz) of the ionization of *tert*-butyl fluoroformate in FSO_3H/SbF_5 in SO_2ClF as solvent at $-78\,^{\circ}C$ (the peak marked with an asterisk is due to [D_6]acetone as external standard).

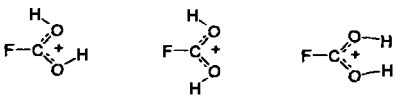
O-Protonation of fluoroformic acid could result in three different isomers of protonated fluoroformic acid (Scheme 3). However, only the *cis–trans* isomer was observed by ^1H and ^{13}C NMR spectroscopy under the experimental conditions. The 300 MHz ^1H NMR spectrum of the solution at $-78\,^{\circ}C$ exhibited two peaks at δ^1H 8.95 (*s*) and 8.88 (*s*) in a 1:1 ratio, besides the peaks resulting from the acid system [FSO_3H/SbF_5 ($\delta = 12.91$) and H_3O^+ ($\delta = 9.66$)]. The magnetic nonequivalence of the two protons is in accordance with a *cis–trans* structure and indicates the restricted rotation about the C···OH^+ bond. The ^{19}F NMR spectrum of the solution recorded at $-78\,^{\circ}C$ showed a signal at $\delta = -4.7$. This value agrees with the GIAO-MP2 calculated ^{19}F NMR chemical shift of $\delta = -0.4$ (see Table 2).



Scheme 3.

The additional doublet observed at $\delta = 117.5$ ($J_{C,F} = 322.4$ Hz) in the ^{13}C NMR spectrum is assigned to the hitherto elusive fluorocarbonyl cation $[FCO]^+$. In an attempt to dehydrate $[FC(OH)_2]^+$ further to $[FCO]^+$, the reaction mixture of protonated fluoroformic acid was allowed to warm up to $-10\,^{\circ}C$ and kept at this temperature for twelve hours. Subsequent NMR analysis of the sample at $-78\,^{\circ}C$, however, showed a substantial decrease in the intensity of both peaks at $\delta = 157.8$ and 117.5. The calculated ^{19}F NMR chemical shift for $[FCO]^+$ at GIAO-MP2 level is $\delta = -96.7$ (see Table 2). We could not conclusively locate this signal in the ^{19}F NMR spectrum, because it overlapped with strong absorptions of the acid system (FSO_3H/SbF_5), but the observed doublet in the ^{13}C NMR spectrum is clearly due to coupling with fluorine. Previous[16] attempts to obtain $[FCO]^+$ by ionization of oxalyl fluoride with SbF_5/SO_2ClF were been unsuccessful, although the other halocarbonyl cations ($[XCO]^+$, X = Cl, Br, I) were generated in this way.

As further support for the experimental observations, the structures, energies, and NMR chemical shifts of the protonated and diprotonated fluoroformic acid and fluorocarbonyl cation, and the protonated fluorocarbonyl dication $[FCOH]^{2+}$ were calculated. Structures were optimized at the MP2/6-31G** level, and improved energies were obtained at the MP4(STDQ)/6-31G**//MP2/6-31G** + ZPE level.[17] The calculated geometry of fluoroformic acid (**1**) is in agreement with previously reported results.[5] Three minimum structures (**2**–**4**) were located for O-protonated fluoroformic acid $[FC(OH)_2]^+$. In accordance with the experimental results, the *cis/trans* isomer **2** (C_s) was found to be the global minimum on the $[FCO_2H_2]^+$ potential energy surface, but only 0.5 and 6.1 kcal mol^{-1} more stable than *cis–cis* isomer **3** (C_{2v}) and *trans–trans* isomer **4** (C_{2v}), respectively (Table 1). Protonation of FCOOH (**1**) to form $[FC(OH)_2]^+$ (**2**) is calculated to be exothermic by 171.3 kcal mol^{-1}. We have also located the transition states **5** and **6** for the interconversion of structure **2** into **3** and **4**, respectively, and the rotational barriers for these conversions were calculated to be 12.1 and 13.4 kcal mol^{-1}. Therefore, interconversion of *cis–trans*, *cis–cis*, and *trans–trans* isomers does not seem feasible, despite their similar energies. The calculated C–F bond in **2** is only 0.057 Å (4.2%) shorter than in **1**, indicating very little p–p backdonation of a fluorine nonbonded electron pair (Figure 2). There seems to be no O-H-F intramolecular hydrogen bonding in **2**, as the distance between F and H is 2.342 Å.

Table 1. Energies, zero-point vibrational energies (ZPE)[a], and relative energies [b].

[a] ZPE in kcal mol^{-1} at the MP2/6-G31G** level, scaled by a factor of 0.93. [b] Relative energies based on MP4(SDTQ)6-31G**//MP2/6-31G** + ZPE.

The ^{13}C and ^{19}F NMR chemical shifts were calculated by IGLO (basis set II) and correlated GIAO-MP2 (basis set tzp/dz) methods based on MP2/6-31G** geometries (Table 2).[18] The ^{13}C NMR chemical shift of protonated fluoroformic acid $[FC(OH)_2]^+$ (**2**), calculated with GIAO-MP2, is $\delta = 170.6$, which is 12.8 ppm downfield from that of the experimental data ($\delta_{exp} = 157.8$). Calculated $\delta^{13}C$ values of the other two isomers (168.9 for **3** and 170.3 for **4**) are very close to that of **2**. On the other hand, the calculated $\delta^{13}C$ shift of diprotonated fluoroformic acid (**7**, 160.5) is shifted 10.1 ppm downfield relative to the calculated value of the monoprotonated species **2**, but very close to the experimenal data of $[FC(OH)_2]^+$. The $\delta^{13}C$ signal of $[FCO]^+$ (**10**) calculated with GIAO-MP2 is 124.5, which agrees with the observed experimental shift of $\delta_{exp} = 117.5$. Interestingly, calculated $\delta^{13}C$ value of the protonated fluoroformyl dication $[FCOH]^{2+}$ (**11**) is 116.6, which is also very close to the experimenal data of $[FCO]^+$. Similar results were obtained with the IGLO program (see Table 2). However, $[FCOH]^{2+}$ is ex-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3617-1876 $ 17.50+.50/0

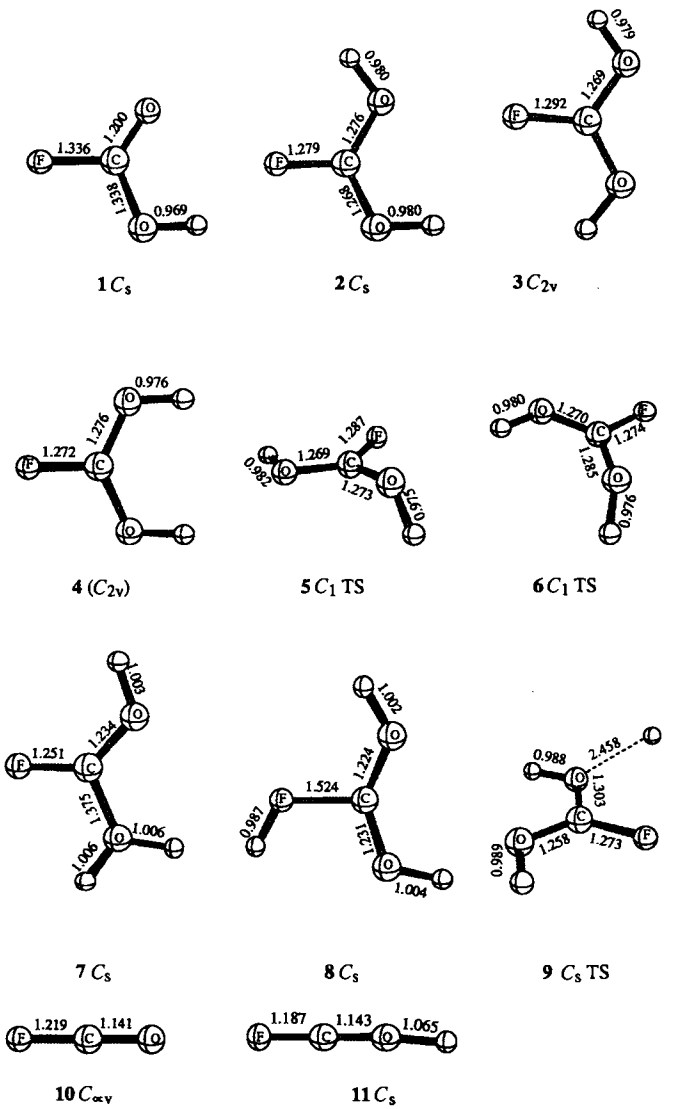

Figure 2. MP2/6-31G**-calculated structural parameters of free and protonated fluoroformic acid, as well as the fluorocarbonyl cation and its protonated forms.

pected to dissociate into $[FCO]^+$ and H^+, as it is 70 kcal mol^{-1} more unstable than these products.

The potential further protonation of **2** to diprotonated fluoroformic acid, a gitonic[19] fluorocarboxonium dication, was also investigated. Considerable interest has been focused recently on such highly electron-deficient superelectrophiles,[20] as they might play an important role in many superacid-catalyzed reactions, as well as in biological processes.[21] Based on experimental and theoretical studies, we recently[22] suggested the intermediacy of diprotonated trifluoroacetic acid $[CF_3C(OH_2)OH]^{2+}$ in the protolytic cleavage reaction of CF_3COOH with FSO_3H/SbF_5. For diprotonated fluoroformic acid, the O,O-diprotonated dication **7** was found to be the global minimum on the potential energy surface. Interestingly, O,F-diprotonated dication **8** was calculated to be a stable minimum. However, structure **8** is 25.4 kcal mol^{-1} higher in energy than structure **7**. Significantly, protonation of $[FC(OH)_2]^+$ (**2**) to form dication **7** was calculated to be endothermic by only 3.3 kcal mol^{-1}. We have also located the transition state **9** for protodissociation of **7** into **2**. Structure **9** lies 70.1 kcal mol^{-1} above structure **7**. Thus, dication **7** has a very high kinetic barrier for protodissociation. Although diprotonated fluoroformic acid could not be observed as a persistent species in NMR studies under the experimental conditions (even in fluoroantimonic acid medium), a limited diprotonation equilibrium could exist in the superacid solution. Gitonic dications (or related protosolvated cations) are energetic, reactive intermediates and should be differentiated from persistent, long-lived, relatively stable intermediates.

Table 2. Experimental and calculated ^{13}C and ^{19}F NMR chemical shifts [a].

$[L_3Ni(\mu\text{-}L)_3NiL_3](AsF_6)_4$, (L = $N{\equiv}SF_2NMe_2$), a Dinuclear Nickel Complex with Bridging Thiazyl(dimethylamide)difluoride Ligands**

Ulrich Behrens, Jan Petersen, Enno Lork, Paul G. Watson, and Rüdiger Mews*

Dedicated to Professor Alois Haas on the occasion of his 65th birthday

The coordination chemistry of ligands with sulfur–nitrogen triple bonds has been investigated for a number of years, and all of the results to date show that the ligands NSX (X = F, Cl),[1–4] NS^+,[3,5] and NSF_3[6,7] coordinate "end-on" through the nitrogen atom.

Thiazyldialkylamides NSF_2NR_2 (R = Et,[8] Me,[9] R_2N = piperidine[10]) have been known since the work of Glemser, Meyer, and Haas.[8] The donor properties and coordination possibilities of the nitrogen atom of the $N{\equiv}S^{VI}$ system are dramatically improved by exchanging one of the sulfur-bound fluorine atoms of NSF_3 for the more strongly electron-donating R_2N group.[11] Thus, for example, although only two NSF_3 ligands can coordinate to the Ag^+ ion to form the unstable $[Ag(NSF_3)_2]^+$ ion,[12] a stable silver complex can be prepared by addition of three $NSF_2(NMe_2)$ ligands [Eq. (a)].[7]

$$\underset{\mathbf{1}}{Ag[AsF_6]} + 3\,\underset{\mathbf{2}}{NSF_2NMe_2} \longrightarrow \underset{\mathbf{3}}{[Ag(NSF_2NMe_2)_3][AsF_6]} \qquad (a)$$

In **5**, which can be formed from **4** and **2** according to Equation (b), the central Co^{II} atom is surrounded by a regular tetrahedron of ligands, in contrast the corresponding NSF_3 complex $[Co(NSF_3)_4(FAsF_5)_2]$ shows octahedral geometry.[7] In **7** [Eq. (c)]

$$\underset{\mathbf{4}}{[Co(OSO)_4(FAsF_5)_2]} + 4\,\mathbf{2} \longrightarrow \underset{\mathbf{5}}{[Co(NSF_2NMe_2)_4](AsF_6)_2} + 4SO_2 \qquad (b)$$

$$\underset{\mathbf{6}}{[Ni(OSO)_6][AsF_6]_2} + 6\,\mathbf{2} \longrightarrow \underset{\mathbf{7}}{[Ni(NSF_2NMe_2)_6](AsF_6)_2} + 6SO_2 \qquad (c)$$

as many as six $N{\equiv}S^{VI}$ ligands are attached to one central atom. The $[Ni(NSF_2NMe_2)_6]^{2+}$ ion has C_i symmetry as shown in Figure 1.[13]

By using the correct stoichiometry of **6** and **2**, the binuclear complex **8** can be isolated in almost quantitative yield [Eq. (d); L = $N{\equiv}SF_2NMe_2$].

$$2\,\mathbf{6} + 9\,\mathbf{2} \longrightarrow \underset{\mathbf{8}}{[L_3Ni(\mu\text{-}L)_3NiL_3](AsF_6)_4} + 12SO_2 \qquad (d)$$

Complex **8** is the first example in which the thiazyl nitrogen atom is fixed in a bridging position. Two $[Ni(NSF_2NMe_2)_6]^{2+}$ octahedra are connected by a common face formed by three nitrogen atoms of the thiazyl triple bond to give a dimeric complex $[Ni_2L_9]^{4+}$ (Figure 2). The Ni–N distances to the terminal nitrogen atoms (204.2(9)–208.6(9) pm) are significantly shorter than those to the bridging nitrogen atoms (213.2(8)–219.2(8) pm). The geometry of the terminal Ni-N-S bonds (d(SN) = 137.6(9)–141.1(9) pm, Ni-N-S angles 143.7(6)–164.9(7)°) varies slightly more than that of the bridges, in which the Ni-N-S angles range between 124.0(5) and 139.5(5)° and the S–N distances between 141.8(9)–142.9(8) pm.

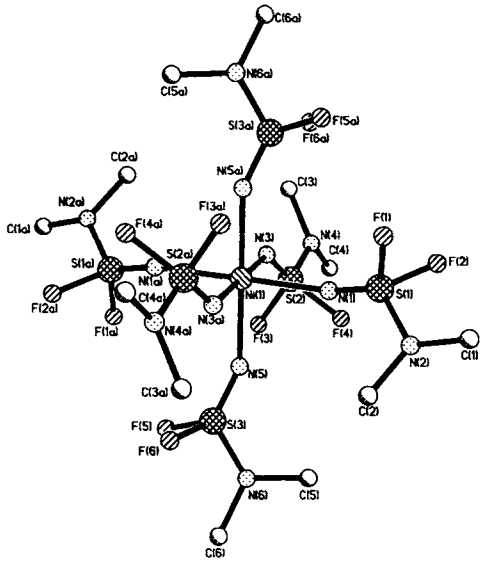

Figure 1. Structure of the cation of **7** with selected bond lengths [pm] and angles [°]: Ni–N 207.1(4)–211.5(4), (av 209.2); N≡S 139.1(4)–140.9(4), (av 139.7); S–N 155.6(4)–157.7(4), (av 156.7); S–F 153.5(3)–156.9(3), (av 156.0); Ni-N-Ni 88.2(2)–91.8(2); Ni-N≡S 138.3(2)–155.0(3), (av 147.6); N≡S-F 115.7(2)–119.4(2), (av 117.9), F-S-F 91.0(2)–92.1(3), (av 91.4); N-S-F 98.2(2)–103.6(2), (av 100.6); N≡S-N 120.4(2)–124.8(3), (av 122.5). The sums of the angles at the nitrogen atoms of the dimethyl amino group range between 353.3 and 357.8°.

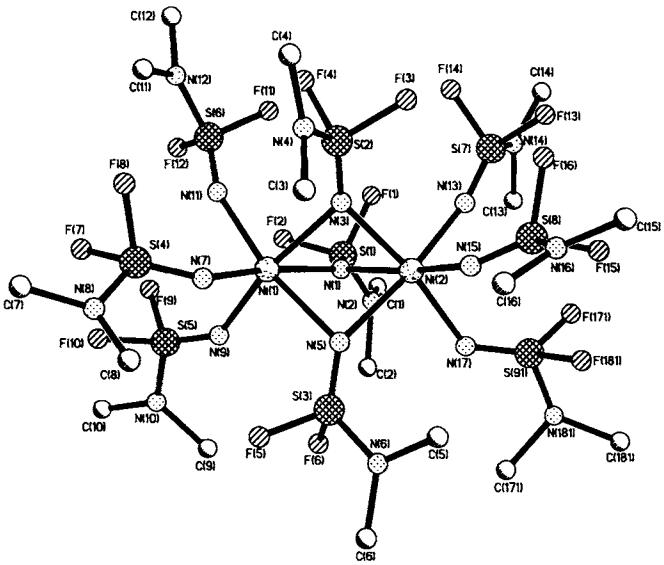

Figure 2. Structure of the cation of **8**.

Complexes of type **8** with isolated $[Ni(\mu\text{-}N)_3Ni]$ units are rare, to our knowledge only one analogous complex (with three bridging 1,1-N_3 groups) has been structurally characterized.[15] In the related $[Ni(N_3)(tmeda)]_\infty$[16] (tmeda = *N,N,N',N'*-tetramethylethylenediamine) the $[(tmeda)Ni(\mu\text{-}1,1\text{-}N_3)_3Ni(tmeda)]$ units are linked by 1,3-azido bridges, forming a polymeric structure.

The Ni_2N_3 cluster in **8** (Ni(1)-N-Ni(2) angle 86–87°, d(Ni(1)–Ni(2)) 296.7(4) pm) is very similar to the known example.[15] Complex **8** is paramagnetic at room temperature.[17]

Experimental Section

7 and **8**: Freshly prepared $[Ni(SO_2)_6](AsF_6)_2$ (1–2 mmol) was dissolved in SO_2 (10 mL) in a two-legged thick-walled glass vessel at −30 °C. The stoichiometric amount of ligand, also dissolved in SO_2 (10 mL) was added. A color change to light green (**7**) and to yellow (**8**) indicated immediate reaction, and the mixture was stirred for 1 h in order to complete the reaction. The product was obtained in quantitative yield after removal of the solvent.

7: NMR ($SO_2/CD_2Cl_2/CFCl_3$/TMS/309 K): $\delta(^1H) = 7.8$ (s, br); $\delta(^{19}F) = 51.3$ (s, br, SF_2); IR: $\nu_{NS} = 1508\ cm^{-1}$ (vs, br). Elemental analysis: calcd: Ni 4.87, S 15.96; found: Ni 4.74, S 16.2.

8: NMR ($SO_2/CD_2Cl_2/CFCl_3$/TMS/309 K): $\delta(^1H) = 8.6$ (s, br), $\delta(^{19}F) = 55.1$ (s, br, SF_2); IR: ν_{NS} 1553, 1531 cm^{-1} (vs, br). Elemental analysis ($C_{18}H_{54}As_4F_{42}N_{18}Ni_2S_9$): calcd: Ni 5.79, S 14.24; found: Ni 5.84, S 14.3.

Single crystals of **7** suitable for structural analysis were obtained after removal of the solvent and pumping off of excess ligand under vacuum. Single crystals of **8** were grown by slow removal of SO_2 from a solution of the complex in SO_2/diethyl ether at ambient temperature.

[13] X-ray crystal structure analysis of **7** ($C_{12}H_{36}As_2F_{24}N_{12}NiS_6$), $M_r = 1205.44$; crystal dimensions $0.8 \times 0.4 \times 0.3\ mm^3$; orthorhombic, space group *Pbca*, $a = 1303.2(3)$, $b = 1263.5(3)$, $c = 2499.3(5)$ pm, $V = 4.115(2)\ nm^3$, $Z = 4$, $\rho_{calcd} = 1.946\ Mg\,m^{-3}$, $\mu = 2.511\ mm^{-1}$. A single-crystal suitable for X-ray analysis was fixed to a glass fiber with Kel-F oil and measured at −100 °C on a Siemens P4 four-circle diffractometer (graphite monochromator, $Mo_{K\alpha}$ radiation, $\omega/2\theta$ scan). Of the 5876 measured reflections ($2.39° < \theta < 27.5°$) 4687 independent reflections remained after averaging. The structure was solved by direct methods. The refinement calculations converged at $wR_2 = 0.1316$ (refinement against F^2) for all 4687 reflections and 267 variables ($R1 = 0.0514$ for 2851 reflections with $I > 2\sigma(I)$). Heavy atoms were assigned individual anisotropic deflection parameters. Hydrogen atoms were calculated with a riding model and common isotropic temperature factors. A difference Fourier synthesis indicated no residual electron density beyond $+730\ e\,nm^{-3}$ and $-929\ e\,nm^{-3}$. The structure solution and preparation of the drawings were performed with the SHELXTL program package [18], the refinements with the program SHELXL-93 [19·20].
[14] X-ray crystal structure analysis of **8** ($C_{18}H_{54}As_4F_{42}N_{18}Ni_2S_9$), $M_r = 2026.43$; crystal dimensions $0.6 \times 0.4 \times 0.3\ mm^3$; triclinic, space group, $a = 1190.8(2)$, $b = 1375.3(3)$, $c = 2313.7(5)$ pm, $\alpha = 77.40(3)$, $\beta = 75.51(3)$, $\gamma = 64.50(3)°$, $V = 3.2847(11)\ nm^3$, $Z = 2$, $\rho_{calcd} = 2.049\ Mg\,m^{-3}$, $\mu = 3.018\ mm^{-1}$. A single-crystal suitable for X-ray analysis was fixed to a glass fiber with Kel-F oil and measured at −100 °C on a Siemens P4 four-circle diffractometer (graphite monochromator, $Mo_{K\alpha}$ radiation, $\omega/2\theta$ scan). 12076 reflections were measured ($2.62° < \theta < 25°$). The structure was solved by direct methods. Due to twinning in the crystal, some reflections lay so close to each other that they appeared with greater than normal intensity. These reflections had to be removed from the data set before the final refinement. 912 of the 12076 reflections were deleted under the following criteria: $F_o^2 > F_c^2$ and $F_o^2 > 3\sigma(F_o^2)$. 10379 reflections were obtained after averaging of the remaining 11164 intensities. The final refinement calculations converged at $wR_2 = 0.2296$ (refinement against F^2) for 10379 reflections and 905 variables ($R1 = 0.0873$). Heavy atoms were assigned individual anisotropic deflection parameters. Hydrogen atoms were calculated with a riding model and common isotropic temperature factors. A difference Fourier synthesis indicated no residual electron density beyond $+1872\ e\,nm^{-3}$ and $-885\ e\,nm^{-3}$. The structure solution and preparation of the drawings were performed with the SHELXTL program package [18], the refinements with the program SHELXL-93 [19·20].

In Vitro Selection without Intervening Amplification**

Joseph Smith and Eric V. Anslyn*

Aptamers to medically important targets have potential value as drug leads.[1] Currently, aptamer selection procedures are typically limited to unmodified DNA and RNA. When modified oligomers are incorporated, the selection procedure is terminated after just one round of amplification since polymerases will not tolerate most chemically modified mononucleotides.[2] However, if the modified nucleotides are not part of the random region that is amplified by the polymerase chain reaction (PCR) after each selection, they would not disturb the amplification. Unfortunately, using such a method would require reincorporation of the modified oligomers into the library after each selection cycle, making the method quite tedious. This limitation would be circumvented if the screening process did not involve amplification during each selection cycle, but instead relied on a single amplification of the random region after the final round of selection. If the modified region was separated from the random region by a PCR primer (Scheme 1), then the successful

Scheme 1. Representation of the DNA aptamers found.

aptamer could be resynthesized in a manner similar to that used to produce the original library. In addition, such a recursive selection without intervening amplification should yield high-affinity aptamers in a fraction of the time required for in vitro selection. Although we do not describe the use of modified nucleotides here, we introduce three requirements for in vitro selection without intervening amplification and demonstrate its viability.

We envisioned three minimal conditions that must be met before in vitro screening of oligonucleotide libraries can be achieved without intervening amplification. First, the number of copies of ligand-binding sequences must be great enough to survive iterative small losses during the entire process. Second, the ratio of signal to noise (ratio of ligand-binding to nonspecific binding sequences) must increase with every round of screening until the noise is totally overwhelmed. Since the signal is not amplified, the noise must be capable of being repetitively reduced until signal strength is greater than noise level. The third condition is that the amplification after the last selection round must be sufficiently effective so that polymerases can make enough copies of the few surviving sequences for eventual identification. As an initial test of the concept, iterative screenings for aptamers to ATP were performed without amplification. We used ATP since it has been previously targeted;[3] hence we could compare our new method to the literature method for in vitro selection. Steps from the new method and the traditional method are schematically summarized in Figure 1.

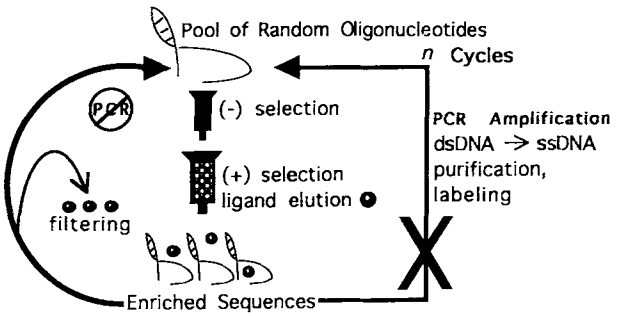

Figure 1. Schematic representation of the new and traditional in vitro selection methods. The "no PCR" sign is only meant to imply a lack of PCR during the selection cycles since a final PCR step is still required. ● = ATP, (−) selection indicates an acetate-agarose precolumn, and (+) selection indicates an ATP-agarose column. dsDNA = double-stranded DNA, ssDNA = single-stranded DNA.

The first condition of recursive selection without amplification was satisfied with the synthesis of a library of DNA oligonucleotides containing an 18-nucleotide random region,[4] which after labeling and purification yielded roughly 17800 copies per distinct sequence. Six cycles of selection were then performed without any intervening amplification (see the Experimental Section).

As mentioned in reference to the second condition, noise reduction is of paramount importance in this method. Therefore, the radioactive decay (in counts per minute (cpm)) was measured after each selection cycle to monitor the progress of the procedure (Table 1). The initial library had a total activity of 4.2×10^7 cpm. After the first selection round, the ATP-eluted oligonucleotides had an activity of near 10^5 cpm, less than 0.25% of the original quantity loaded. Since almost all the sequences lost during selection are likely oligonucleotides that do not bind the target, this serves as an estimate of noise. After the second cycle, the activity of the ATP-eluted DNA had dropped to about 600 cpm. Retained noise was again reduced over 99%. For later cycles no measurable radioactivity above background could be detected. Since the amount of signal was unknown, we could not determine at this point in the selection whether the second condition had been met.

Table 1. Review of the six cycles of selection. cv = column volumn, fb = folding buffer (300 mM KCl, 5 mM $MgCl_2$, 20 mM Tris, pH 7.5).

Cycle	DNA	cpm	Pre-column (300 µL)	ATP-agarose (2.5 mM, 800 µL)	Ligand elution
1	300 µL fb	4.2×10^7	2 cv fb	+5 cv fb	3 mL, 5 mM ATP in fb
2	10 mL 30 µM ATP in fb	1×10^5	1 cv fb	+2 cv fb	fb
3	fb	600	fb	fb	fb
4–5	fb	–	fb	fb	fb
6	fb	–	fb	fb	3 mL, 10 mM ATP in fb

The third condition was met using the "rare-DNA PCR" protocol created specifically for the amplification of DNA with a low number of copies.[5] The effective range of the optimized amplification protocol is reported to be from 1 to 20000 molecules of DNA as the initial substrates. Also, rare-DNA PCR has been used to quantitate less than ten molecules of herpes simplex viral DNA in a reaction that also had 100 ng of contaminating nonviral DNA as background.[6] Although use of a single amplification at the end of an in vitro selection protocol requires more cycles than if each selection cycle is followed by amplification, the former has the advantage that it should introduce less replication bias in the final populations than the latter.[7]

After the rare-DNA protocol was performed (see the Experimental Section), the amplified DNA was cloned and ten clones were sequenced. Three sequences had duplicates. There were obvious homologies among the three with two consensus regions. Figure 2 shows the base pairing of these sequences based on Huizenga's and Szostak's postulated general sequence[3] for an ATP DNA aptamer. Indeed, according to the number of flanking base pairs stabilizing the guanine-rich regions of the sequences, the order of ATP affinity found correlates with the predictions of Huizenga and Szostak.

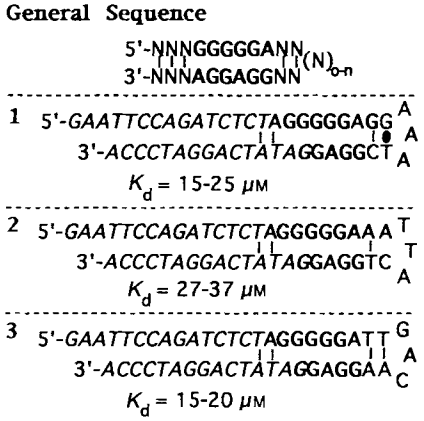

Figure 2. Base pairings based on the proposed general sequence for an ATP DNA aptamer[3]. The sequences in bold are thought to form two stacked guanine quartets. The italicized sequences are parts of the fixed primer regions. The methods of isocratic elution[8], membrane diafiltration[1b, 3], and equilibrium gel filtration[9] were used to determine the dissociation constant for the ATP–aptamer complex. ● indicates a non-Watson–Crick base pair.

The original method of Huizenga and Szostak proceeded through several rounds of screening, amplifying, isolating ssDNA, radiolabeling, and purifying before a DNA population was developed with moderate affinity to ATP.[3] After 17 clones had been sequenced, no consensus sequence was found. One clone was chosen for a series of truncation experiments wherein the ATP-binding domain was localized to a region 42 nucle-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3617-1880 $ 17.50+.50/0

otides in length. In vitro "evolution" was done on this region at 30% mutagenesis, and four more rounds of in vitro selection followed before this second population was cloned. From these sequences, a consensus region was discovered. Certainly though this work is a pioneering achievement in the field, it is an example of how the conventional protocol is significantly more involved than that presented here.

In summary, a novel in vitro selection protocol has been designed to take advantage of a combinatorial library of small size that has multiple copies of every distinct sequence. The method condensed the many days of a typical screening strategy to less than two days. This was a proof-of-concept experiment that showed that the new method succeeds by creating a large number of copies of individual sequences in the initial random pool, consistently reducing the level of nonspecific binding sequences per selection round, and effectively amplifying the few surviving sequences.

Since only the original synthesized sequences were used for all the screenings, the technique should allow for the iterative in vitro selection of modified oligonucleotides that previously could not undergo this powerful process.[10] Hence, this method should significantly increase the power of the in vitro selection method and is the direction that we are currently investigating.

Experimental Section

The DNA library[4] (31 mg) was labeled at the 5'-end with [γ-^{32}P]ATP, purified by gel chromatography, and suspended in 300 mL of folding buffer (300 mM KCl, 5 mM $MgCl_2$, 20 mM Tris, pH 7.5). After cooling down to room temperature following denaturation at 75 °C, the ^{32}P-labeled DNA was loaded onto an acetate-agarose precolumn (300 µL), which was attached directly to a 2.5 mM ATP-agarose column (800 µL, Sigma). The precolumn was washed with 600 µL of buffer, and the eluted DNA was allowed to equilibrate on the ATP-agarose column for 10 min. The precolumn was discarded after a single use as were all subsequent columns. After equilibration, the ATP-agarose column was washed with 4 mL of folding buffer to elute unbound or weakly bound oligonucleotides. The retained DNA was eluted with 3 mL of the ATP elution buffer (5 mM ATP in folding buffer) and collected in 500 µL fractions.

In order to perform another round of selection, the ATP had to be removed. Hence, the eluted fractions were collected directly into Microcon-3 microcentrifuge devices (3000 D cutoff, Amicon). After membrane diafiltration, about 98% of the total ATP was removed. The filtered fractions were then pooled, and folding buffer was added until a final volume of 10 mL was attained. The concentration of contaminating ATP concentration was 30 µM for the DNA sample, which was over 80 times more dilute than that of the 2.5 mM ATP-agarose column. Each cycle of selection started with a new set of stacked affinity columns, i.e. a precolumn attached to a ligand column. The screening cycles for the ATP aptamers are summarized in Table 1.

The rare-DNA PCR was performed as follows: On the last cycle the DNA was eluted from the ATP-agarose column with 3 mL of 10 mM ATP in 20 mM Tris, pH 7.5. This last fraction was precipitated twice from ethanol, and the PCR reagents (50 mM KCl, 8 mM $MgSO_4$, 10 mM $(NH_4)_2SO_4$, 20 mM Tris, pH 8.8 at 25 °C, 200 µM dNTPs, 0.1% Triton X-100, 20 units of Deep Vent (exo-) DNA polymerase, 0.5 µg 5'-primer, 0.5 µg 3'-primer) were added. Thermal cycling (94 °C for 45 s; 42 °C for 90 s; 60 °C for 45 s; 45 cycles) was done in a microcentrifuge tube that had first been irradiated with UV light. A positive control containing a dilute solution (~20000 molecules) of a 52-mer, and a negative control containing no DNA also underwent the same amplification protocol. Gel electrophoresis after amplification showed DNA in all lanes except the negative control.

The Synthesis of Enantiopure ω-Methanoprolines and ω-Methanopipecolic Acids by a Novel Cyclopropanation Reaction: The "Flattening" of Proline**

Stephen Hanessian,* Ulrich Reinhold, and Gabriella Gentile

Proline occupies a prominent position in the hierarchy of natural amino acid constituents of mammalian proteins.[1] As part of a peptidic motif, its unique structure results in secondary amide bonds, leading to important conformational and functional consequences.[2] For example, the well-known *cis–trans* isomerism in prolylamides is associated with vitally important biological phenomena and functions, such as protein folding,[3] hormone regulation,[4] recognition,[5] and transmembrane signaling[6] to mention a few. The importance of *cis–trans* conformational changes is manifested by the role that peptidyl prolyl isomerases such as the immunophilins play in immunoregulation.[7] Proline has also figured prominently as a component of therapeutic agents,[8] in drug design,[9] and in probing enzyme activity.[10]

Conformationally constrained analogues of proline have been used extensively in connection with peptidomimetic research.[11] Although 2,3- and 3,4-methanoprolines have been

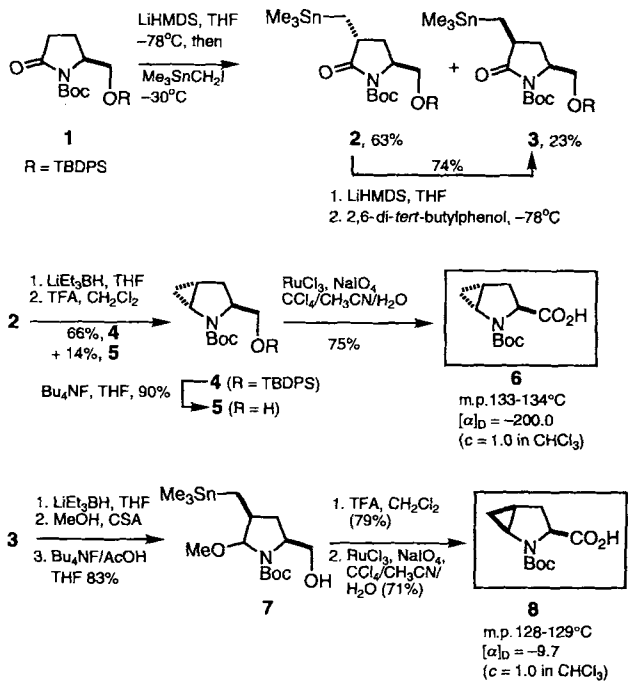
described,[12, 13] the 4,5-methanoprolines are relatively unexplored.[14] Furthermore, structural investigations that study the consequences of introducing strain and its effects on the configuration and stability of amide linkages are not available to compare such systems to their proline counterparts.

We describe herein highly stereocontrolled syntheses of the diastereomeric 4,5-methano-L-prolines and 5,6-methano-L-pipecolic acids by a novel intramolecular cyclopropanation reaction of iminium ions and the extension of the methodology to other congeners.[15, 16]

Treatment of the readily available lactam **1**[17a] with lithium hexamethyldisilazide (LiHMDS) and Me_3SnCH_2I gave the α-alkylated products **2** ($[\alpha]_D = -15.3$, $c = 0.43$ in $CHCl_3$) and **3** ($[\alpha]_D = -16.0$, $c = 1.23$ in $CHCl_3$) in 63% and 23% yields, respectively (Scheme 1). The *syn*-isomer **3** could be easily obtained



Scheme 1. TBDPS = *t*-BuPh$_2$Si, TFA = trifluoroacetic acid, Boc = *tert*-butoxycarbonyl, CSA = camphor-10-sulfonic acid.

by treatment of the enolate from **2** with the proton source 2,6-di-*tert*-butylphenol.[18, 19] Generation of the hemiaminal from **2** and treatment with TFA led to the (4*R*,5*R*)-methanopyrrolidine derivative **4** ($[\alpha]_D = -69.3$, $c = 1.41$ in $CHCl_3$), which was smoothly deprotected to **5**, and the latter oxidized to give the crystalline (4*R*,5*R*)-methano-*N*-Boc-L-proline in excellent overall yield.

Similar treatment of the *syn*-isomer **3** gave the diastereomeric crystalline acid **8** via its methylaminal derivative **7**. The structures and conformations of **6** and **8** in the solid state were unambiguously confirmed by single-crystal X-ray analysis. Table 1 lists selected torsion angles for compounds **6** and **8**, where considerable "flattening" of the pyrrolidine ring is observed relative to *N*-Boc-L-proline,[20] particularly in the case of **6**. The flattening of the pyrrolidine ring in **6** is also manifested in the root-mean-square value of 0.003 Å for the C_β and N atoms from the plane defined by C_β,C_γ,C_δ, and N (0.013 Å in **8**). The lowest deviation of 0.018 Å in the case of *N*-Boc proline was found for C_α and C_γ atoms in the plane C_α,N,C_δ,C_γ; in this case C_β was distinctly above the plane (0.521 Å). This differs substantially

Table 1. Selected torsion angles and root-mean-square deviations from fitted atoms in a given plane of X-ray crystal structures, and ^{13}C NMR chemical shifts ($CDCl_3$).

	N-Boc-L-proline [20]	**6**	**8**

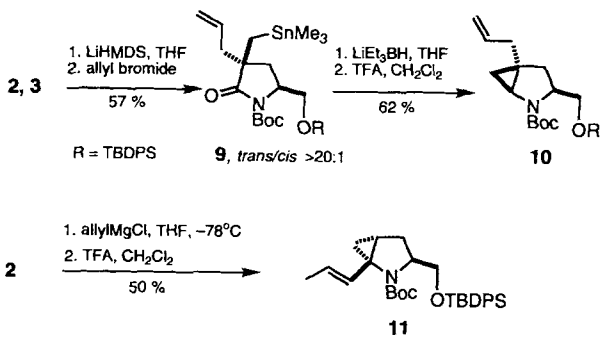
τ(C$_\alpha$C$_\beta$)	+31	+4.8	+15.3
τ(C$_\beta$C$_\gamma$)	−35	−2.6	−11.4
τ(C$_\gamma$C$_\delta$)	+24	−0.7	+2.9
τ(C$_\delta$N)	−4	+4.1	+7.6
τ(BocNC$_\alpha$CO$_2$H)	−72	−64.0	−67.1
rms deviation of fitted atoms	0.018 C$_\alpha$, N, C$_\delta$, C$_\gamma$	0.003 C$_\beta$, C$_\gamma$, C$_\delta$, N	0.013 C$_\beta$, C$_\gamma$, C$_\delta$, N
	δ(*cis*/*trans*)	δ(*cis*/*trans*)	δ(*cis*/*trans*)
COOH	178.35/176.60	177.7/175.5	179.1/176.1
NC=O	153.95/155.39	157.1/154	155.7/154.1
C$_\alpha$	58.8	60.8/60.1	59.5/59.1
C$_\beta$	30.75/29.53	32.0	31.5/29.1

from **6** and **8**, in which the out-of-plane carbon atom was the one bearing the carboxyl group (0.082 Å and 0.235 Å respectively).

Intermediates **2** and **3** could also be subjected to further stereocontrolled branching leading to the α-C-allyl derivative **9**, which upon controlled reduction and acid-catalyzed destannylation led to the branched 4,5-methano-L-proline precursor **10** ($[\alpha]_D = +4.3°$, $c = 0.72$ in $CHCl_3$; Scheme 2). Treatment of **2**

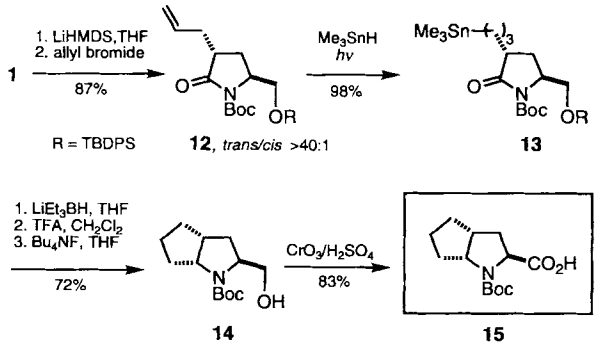


Scheme 2.

with allylmagnesium chloride, followed by trifluoroacetic acid (TFA), led to the (*S*)-5-(2-propenyl)-4,5-methano-L-proline derivative **11** ($[\alpha]_D = -27.0$, $c = 0.57$ in $CHCl_3$) on migration of the double bond. Compounds **10** and **11** represent uniquely functionalized precursors to constrained ω-methanoprolines.

The versatility and generality of the intramolecular carbocyclization reaction with appended trimethylstannylalkyl groups via incipient iminium ions can be demonstrated in the synthesis of bicyclic proline congeners (Scheme 3). These compounds are related to the antihypertensive agent ramipril.[21] A highly stereoselective allylation of the enolate from **1** gave **12** ($[\alpha]_D = -45.0$, $c = 1.0$ in $CHCl_3$), which was subjected to a photoinduced trimethylstannylation[22] to give **13** ($[\alpha]_D = -23.6$,

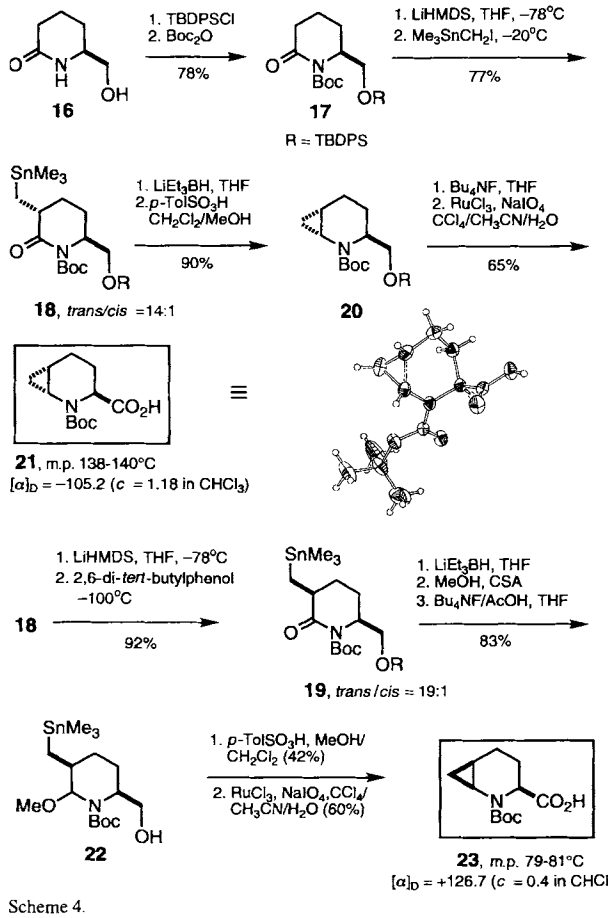
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3617-1882 $ 17.50+.50/0



Scheme 3.

$c = 0.92$ in $CHCl_3$). Formation of the hemiaminal, followed by acid-catalyzed cyclization and deprotection, led to the bicyclic prolinol derivative **14** ($[\alpha]_D = -97.3$, $c = 1.38$ in $CHCl_3$). Finally, oxidation under Jones conditions gave the immediate precursor to the *N*-Boc-(4*R*,5R)-ramipril diastereomer **15** (m.p. 61–63 °C; $[\alpha]_D = -126.7$, $c = 0.46$ in $CHCl_3$).

It is also of interest to view compounds **6**, **8**, **10**, and **11** as precursors to constrained analogues or precursors to L-pipecolic acid. The extension of the cyclopropanation reaction to the pipecolic acid series is shown in Scheme 4. Trimethylstannylmethylation of the lithium enolate derived from the readily available **17**[23] gave the *anti*-isomer **18**. Reduction to the hemiaminal and acid-catalyzed cyclization led to **20** ($[\alpha]_D = -56.0$, $c = 1.02$ in $CHCl_3$), which was deprotected and oxidized to the crystalline (5*R*,6*S*)-methano-*N*-Boc-L-pipecolic acid **21** (m.p. 138–140 °C; $[\alpha]_D = -105.2$, $c = 1.17$ in $CHCl_3$). Epimerization of **18** to the *syn*-isomer **19** by diastereoselective protonation, followed by functional group manipulation as described above, led to the crystalline diastereomeric (5*S*,6*S*)-methano-*N*-Boc-pipecolic acid **23** (m.p. 79–81 °C; $[\alpha]_D = -126.7°$, $c = 0.40$ in $CHCl_3$). The structure of crystalline **21** was unambiguously established by X-ray analysis. It is of interest to note that while the proline derivatives **6** and **8** adopt a *cis*-*N*-Boc proline orientation in the solid state (Table 1), the corresponding 4,5-methanopipecolic acid analogue **21** exhibits a *trans* orientation (Scheme 4). The presence of *cis* and *trans* isomers of **6** and **8** in $CDCl_3$ was evidenced by the corresponding ^{13}C NMR shifts, as in the case of *N*-Boc-L-proline (Table 1).



Scheme 4.

Pipecolic acid is an important constituent of the immunosuppressive agents FK-506[24] and rapamycin,[25] in which its α-ketoamide portion is intimately involved in an "active complex" with the target enzyme.[26] It is also involved in the metabolism of L-lysine, an essential amino acid for mammalian growth and development.[27] Functionalized pipecolic acids are also considered strained analogues of lysine with applications in drug design and peptidomimetic research,[28] as well as in the inhibition of L-pipecolate oxidase.[27]

It is our belief that the replacement of L-proline and L-pipecolic acid by conformationally altered ring variants represented by the methano congeners described in this work could have important consequences in biological recognition, in *cis–trans* conformational changes, in the susceptibility of the secondary amide bonds to enzymatic cleavage, and in related processes or phenomena. Studies that address these issues will be reported in due course.

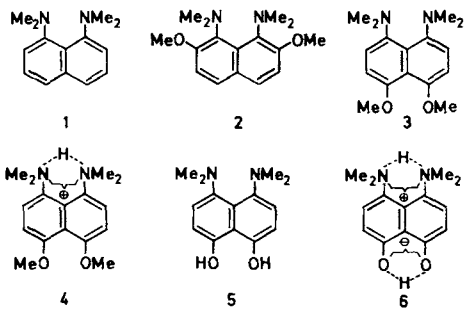
1,8-Bis(dimethylamino)-4,5-dihydroxynaphthalene, a Neutral, Intramolecularly Protonated "Proton Sponge" with Zwitterionic Structure**

Heinz A. Staab,* Claus Krieger, Gisela Hieber, and Klaus Oberdorf

The interaction of basic groups in close proximity to each other may lead, as in the case of 1,8-bis(dimethylamino)-naphthalene (**1**), to unusually high basicities ("proton sponges").[1] The influences of gradually changed distances and orientations of the basic centers as well as of inductive, mesomeric, and steric effects on the basicity of such compounds have been thoroughly studied.[2] In comparison to the basicity of **1** [$pK_a \approx 12.1$ (H_2O); 7.5 (DMSO)],[3] that of 2,7-dimethoxy-1,8-bis(dimethylamino)naphthalene (**2**) is found to be increased by four powers of ten [$pK_a \approx 16.1$ (H_2O); 11.5 (DMSO)].[3] To separate the mesomeric effect of the two methoxy groups from their steric effect on the dimethylamino groups, we were interested in **3**, an isomer of **2** in which the two methoxy groups are not in the 2,7-positions but in the opposite *peri*-positions. In fact, 1,8-bis(dimethylamino)-4,5-dimethoxynaphthalene (**3**) is considerably less basic [$pK_a \approx 13.9$ (H_2O); 9.3 (DMSO)] than the isomer **2**, indicating that the main reason for the high basicity of **2** is the steric effect of the methoxy groups in *ortho*-positions to the dimethylamino groups. Irrespective of this primarily intended basicity comparison of **2** and **3**, the synthesis of **3** should allow the easy preparation of the corresponding 4,5-dihydroxy compound **5**, which by intramolecular proton displacement may lead to a new type of neutral, yet zwitterionic "proton sponge" (formula **6**).



For the synthesis of **3**, 1,8-dihydroxynaphthalene[4] was methylated to give 1,8-dimethoxynaphthalene, which was nitrated (conc. nitric acid, glacial acetic acid/dichloromethane, 9:5) to yield 1,8-dimethoxy-4,5-dinitronaphthalene (39%; m.p. 278 °C); the isomeric 2,5-dinitro product (m.p. 151–153 °C) was separated by chromatography on silica gel with dichloromethane as eluent. Catalytic hydrogenation (10% Pd/C, tetrahydrofuran (THF), 20 °C) resulted in the formation of 1,8-diamino-4,5-dimethoxynaphthalene (97%; m.p. 83–95 °C, decomp), which was N-methylated according to the method of Quast et al.[5] to give **3** (71%; m.p. 75 °C, from *n*-hexane/ethyl

acetate 4:1); reaction with hydrogen bromide in ethyl acetate furnished **3**·HBr (m.p. 313 °C). Cleavage of the methoxy groups of **3** with boron tribromide in dichloromethane yielded the hydrobromide of 4,5-bis(dimethylamino)-1,8-dihydroxynaphthalene (**5**·HBr, 59%; m.p. 177–180 °C), which on treatment with the equivalent amount of lithium diisopropylamide in DMSO/cyclohexane gave **5** (83% yield; m.p. 212 °C, decomp). Analytical data and the molecular mass determined are in accord with structure **5**. In fact, however, both ^{1}H NMR and X-ray structure analysis clearly demonstrate that we did not obtain **5**, but the zwitterionic isomer **6**.

Figure 1 shows the structure of **3**, Figure 2 that of the cation **4** of the hydrobromide of **3**. Similar to the structure of the original naphthalene proton sponge **1**,[6] the naphthalene skeleton in **3** is not planar but shows a twist around the C(4a)–C(8a) axis. In **3** this twist is more pronounced than in **1**, due to the additional two methoxy groups in the *peri*-positions 4 and 5. The side view along the long axis of the naphthalene unit (Figure 1, bottom) demonstrates that in each of the two pairs of

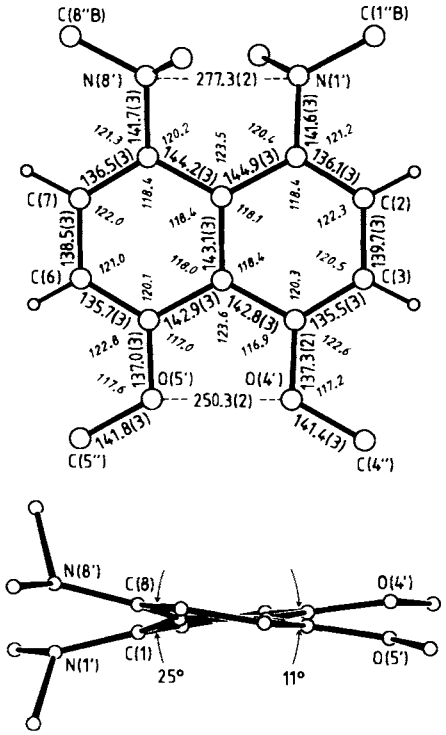

Figure 1. X-ray crystal structure of **3**; view perpendicular to the central bond of the naphthalene unit (top) and view along the long axis of the naphthalene unit (bottom).

peri-substituents the groups avoid short contacts by deviating in opposite directions. In addition, the methyl groups of the dimethylamino and methoxy substituents reduce close contacts by rotation around the bonds to the *peri*-positions. Nevertheless, the N···N distance, 277 pm, is similar to that in **1**, and the O···O distance between the methoxy groups, 250 pm, is considerably shorter than the sum of the van der Waals radii of oxygen (ca. 280 pm). The methoxy groups are oriented exactly in the plane of the neighboring naphthalene π-systems; thus, the mesomeric effect of the methoxy substituents is fully active like in **2**.

Protonation of **3** results in the formation of the strong intramolecular N···H···N hydrogen bond in **4** (Figure 2). The naphthalene system including the bonds to the four substituents

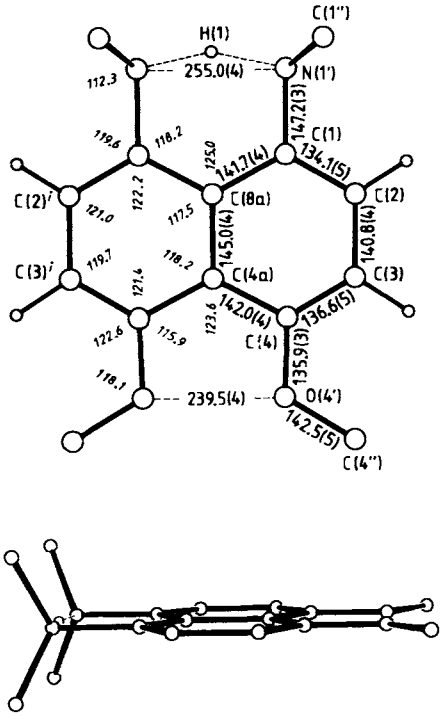

Figure 2. X-ray structure of **4** (of **3**·HBr); view perpendicular to the central bond of the naphthalene unit (top) and view along the long axis of the naphthalene unit (bottom).

is now completely planarized, leading to a shortening of the N···N and O···O distances to 255 and 239 pm, respectively.

The most interesting result of the present study, however, concerns the structure of the compound obtained from **3** by cleavage of the two methoxy groups; 1,8-bis(dimethylamino)-4,5-dihydroxynaphthalene (**5**) was expected. Both the elemental analysis and the mass spectrum (molecular ion peak $m/z = 246$ as base peak) are in full agreement with structure **5**. However, the ^{1}H NMR data (500 MHz, [D$_6$]DMSO, 303 K) disprove this structure. In addition to the signals at $\delta = 2.93$ (12 H, NMe_2), 6.06 (d, $J = 8.4$ Hz, 2 H, 2,7-H), and 7.37 (d, $J = 8.4$ Hz, 2 H, 3,6-H) there are *two* strongly downfield-shifted signals at $\delta = 18.10$ and 19.30, which each correspond to one proton. The slightly broadened signal at $\delta = 18.10$ is due to a N···H···N hydrogen bond (nuclear Overhauser effect with the NMe_2 substituents); the signal at $\delta = 19.30$, then, must be assigned to an O···H···O hydrogen bond. Apparently, cleavage of the methoxy groups in **3** does not lead to dihydroxynaphthalene **5**, but rather to the isomeric zwitterion **6**, which contains the N···H···N hydrogen bond with positive charge typical of protonated proton sponges. The signal at $\delta = 19.30$, then, corresponds to the O···H···O hydrogen bond carrying the negative charge of the zwitterion.

The result of the X-ray structure analysis of **6** shown at the top of Figure 3 confirms the presence of an intramolecularly protonated proton sponge, which due to the zwitterionic structure is an overall neutral molecule. The zwitterionic structure determines the crystal packing (Figure 3, bottom). Along the crystallographic *a*-axis the molecules of **6** are arranged in a type of belt, with the positive parts of the zwitterions facing the negative parts of their neighbors. This belt is coordinated with a corresponding second belt, in which the zwitterions are oriented in the opposite direction. In this "double belt" the positive parts of the zwitterions of one belt are roughly opposite the negative parts of the neighboring belt. Figure 4 shows in a per-

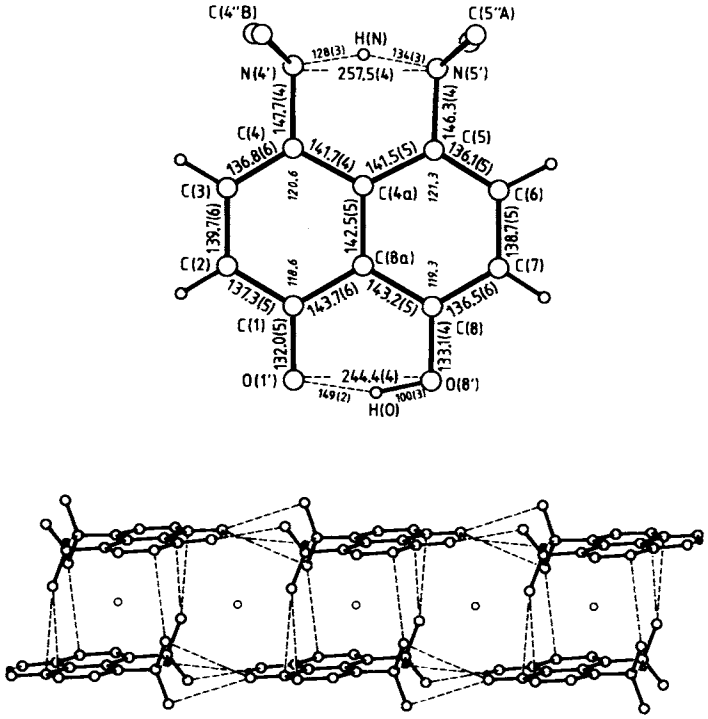

Figure 3. X-ray crystal structure of **6**; top view (top; bond lengths in pm, standard deviations in units of the last digit). The bottom view shows a section of the arrangement of **6** in a double belt (for details see text).

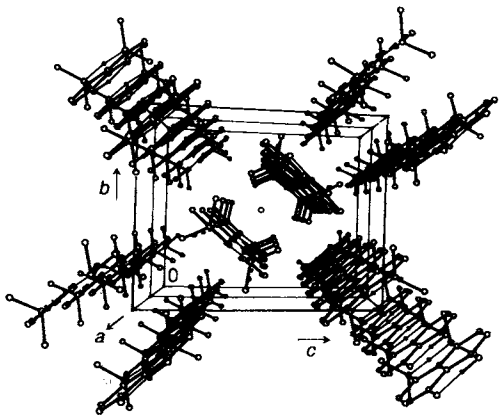

Figure 4. Crystal packing of **6** in perspective view along the crystallographic *a* axis.

spective view that an ensemble of such double belts is oriented along the *a* axis of the crystal. This very interesting crystal packing of the zwitterion **6** prompts further studies of anisotropic crystal properties.

Experimental Section

Analytical data of the synthesized compounds: 1,8-Dimethoxy-4,5-dinitronaphthalene: Correct elemental analysis; ^{1}H NMR (360 MHz, [D$_6$]DMSO, 303 K): δ = 4.05 (s, 6H, OCH_3), 7.26 (d, J = 9.0 Hz, 2H, H-2,7), 8.44 (d, J = 9.0 Hz, 2H, H-3,6). 1,8-Dimethoxy-2,5-dinitronaphthalene: Correct elemental analysis; ^{1}H NMR (360 MHz, $CDCl_3$, 303 K): δ = 4.02 (s, 3H), 4.15 (s, 3H), 7.00 (d, J = 8.9 Hz, 1H), 7.92 (d, J = 9.5 Hz, 1H), 8.41 (d, J = 8.9 Hz, 1H), 8.52 (d, J = 9.5 Hz, 1H). 1,8-Diamino-4,5-dimethoxynaphthalene: Correct high-resolution mass spectrum; ^{1}H NMR (360 MHz, [D$_6$]DMSO, 303 K): δ = 3.69 (s, 6H, OCH_3), 5.19 (br. s, 4H, NH_2), 6.55 (d, J = 8.2 Hz, 2H, H-2,7), 6.68 (d, J = 8.2 Hz, 2H, H-3,6). **3**: Correct elemental analysis; correct high-resolution mass spectrum; ^{1}H NMR (360 MHz, [D$_6$]DMSO, 303 K): δ = 2.64 (s, 12H, $N(CH_3)_2$), 3.76 (s, 6H, OCH_3), 6.82 (d, J = 8.4 Hz, 2H, H-3,6), 6.89 (d, J = 8.4 Hz, 2H, H-2,7). **5**·HBr: Correct elemental analysis; ^{1}H NMR (500 MHz, [D$_6$]DMSO, 303 K): δ = 3.04 (d, J = 2.2 Hz, 12H, $N(CH_3)_2$), 6.92 (d, J = 8.4 Hz, 2H, H-2,7), 7.86 (d, J = 8.4 Hz, 2H, H-3,6), 18.61 (br. s, 1H, N···H···N). **6**: Correct elemental analysis; correct mass spectrum; ^{1}H NMR (500 MHz, [D$_6$]DMSO, 303 K): δ = 2.93 (d, J = 2.2 Hz, 12H, $N(CH_3)_2$), 6.06 (d, J = 8.4 Hz, 2H, H-2,7), 7.37 (d, J = 8.4 Hz, 2H, H-3,6), 18.10 (br. s, 1H, N···H···N), 19.30 (s, 1H, O···H···O).

Alanyl PNA: Evidence for Linear Band Structures Based on Guanine–Cytosine Base Pairs**

Ulf Diederichsen*

The stability of a DNA double strand is based on the formation of hydrogen bonds between the nucleobases guanine and cytosine, and between adenine and thymine, as well as base stacking and hydrophobic interactions.[1] In addition, the influ-

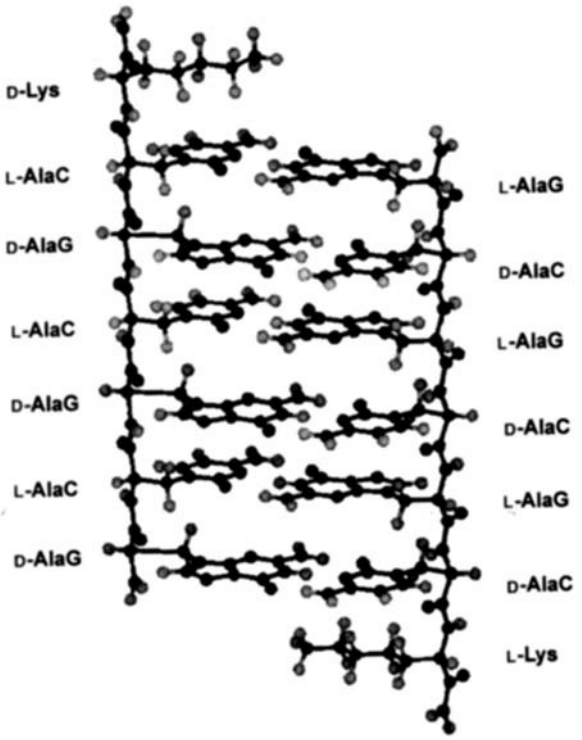
[**] This work was supported by the Deutsche Forschungsgemeinschaft (Di 542/2-1), the Fonds der Chemischen Industrie, and the Leonhard-Lorenz-Stiftung. I am grateful to Professor H. Kessler, Garching, for generous support.

ence of the backbone is important: the pairing mode and geometric requirements for a base pair are restricted for topological reasons, whereas charge repulsion of the phosphodiester groups seems functionally important[2] but has a destabilizing effect. The influence of the backbone on the stability of the double strand can be illustrated by comparing the UV melting temperature of the self-pairing DNA oligomer $d(GC)_3$ ($T_m = 47\,^\circ C$)[3] with that of the homo-DNA oligomer $dd(GC)_3$ ($T_m = 58\,^\circ C$);[4] the latter contains 2′,3′-dideoxyglucopyranosyl sugar moieties and pairs in approximately linear double strands. This stabilization is mainly due to entropic effects. Reduction of charge repulsion, however, should be important for the stabilization of double strands containing *N*-(2-aminoethyl)glycine peptide nucleic acids (PNAs) in the order DNA/DNA < PNA/DNA < PNA/RNA < PNA/PNA.[5] We introduced a new kind of PNA oligomer that forms linear double strands and also lacks charge repulsion (Scheme 1).[6] Alanyl amino acids with



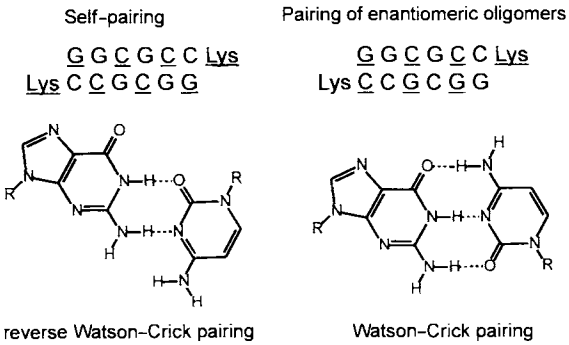
Scheme 1. Model of a linear alanyl PNA double strand (Insight II; Biosym/MSI): The regular peptide strands have alternating configuration, and thus the PNA in β-sheet conformation is repetitive in each nucleo amino acid. The Watson–Crick pairing G/C hexamer is shown with antiparallel strand orientation and nucleo amino acids with the same configuration forming a base pair. The distance between two base pairs is 3.5 Å. The lysine amide at the C-terminal end was introduced for solubility reasons.

nucleobases connected at the β-position of the side chain can be oligomerized to form a regular peptide strand. These oligomers, which have nucleo amino acids of alternating configuration are repetitive with the backbone in β-sheet conformation and able to form linear double strands based on nucleobase recognition. In the series of alanyl PNA oligomers presented here the pairing of guanine and cytosine shows remarkably high stability and selectivity, as was predicted from model studies. We also found an unexpected sequence-dependent formation of a bandlike, higher order structure.

The oligomers described herein were prepared by solid-phase peptide synthesis (SPPS),[8] purified by HPLC (RP-C18), and characterized by electrospray ionization mass spectrometry (ESI-MS),[9] circular dichroism (CD), and in a few cases by ^{1}H NMR spectroscopy. A C-terminal lysine amide was introduced for solubility reasons. The pairing stabilities were investigated by UV melting curves. The temperature-dependent sigmoidal increase of the absorption corresponds to the destacking of the nucleobases. In order to study the G–C pairing we first examined oligomer **1** (AlaG = β-(guanin-9-yl)alanine, AlaC = β-(cytosin-1-yl)alanine, D-configurated amino acids are underlined), because this sequence usually provides an antiparallel double strand based on six Watson–Crick G–C base pairs (Scheme 2). Neither pairing with parallel strands nor double

H-(AlaG-AlaG-AlaC-AlaG-AlaC-AlaC)-Lys-NH_2 **1**

H-(AlaG-AlaG-AlaC-AlaG-AlaC-AlaC)-Lys-NH_2 *ent*-**1**



Pairing mode	Possible geometries	
Watson-Crick	antiparallel, homochiral	parallel, heterochiral
reverse Watson-Crick or Hoogsteen	antiparallel, heterochiral	parallel, homochiral

Scheme 2. Dependence of the G–C pairing mode on strand orientation and configuration. In addition, the Hoogsteen mode is possible at pH 4.5 (G = β-(guanin-9-yl)alanine, C = β-(cytosin-1-yl)alanine).

strand formation with G–G, C–C base pairs is likely.[10] In analogy to the A–T pairing discussed earlier[6] formation of antiparallel double strands of alanyl PNA based on the G–C Watson–Crick pairing mode requires that the nucleo amino acids forming the base pair have the same configuration (homochiral). Changing the pairing mode from Watson–Crick to Hoogsteen[11] or to reverse Watson–Crick provides a suitable geometry for antiparallel self-pairing. Therefore, the complex formed from oligomer **1** and its enantiomer *ent*-**1** (Watson–Crick pairing) is expected to be more stable than the self-pairing strands (reverse Watson–Crick pairing).

The pairing stabilities determined by UV spectroscopy (Figure 1) are in agreement with our model: for the self-paired complex of oligomer **1** a melting temperature of $T_m = 40\,^\circ C$ was observed, whereas the complex from a 1:1 mixture of the enantiomeric oligomers **1** and *ent*-**1** showed denaturation at $T_m = 58\,^\circ C$. The Watson–Crick mode is stabilized by three hydrogen bonds, the reverse Watson–Crick mode only by two. The double-strand stability as observed is remarkably high for the pairing of hexamers.

We expected similar UV melting curves when the GGCGCC hexamer sequence was replaced by the G/C alternating oligomers **2** and *ent*-**2**. The self-pairing complex of the G/C

H-(AlaG-AlaC)$_3$-Lys-NH_2 **2**

H-(AlaG-AlaC)$_3$-Lys-NH_2 *ent*-**2**

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3617-1887 $ 17.50+.50/0

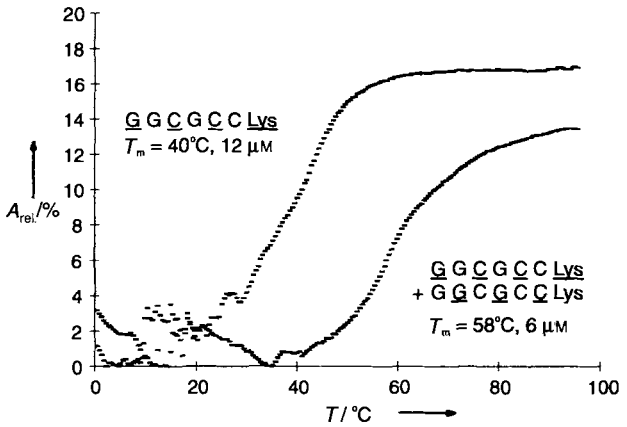


Figure 1. Melting curves of **1** and an equimolar mixture of **1** and *ent*-**1** (260 nm, 0.1 M NaCl, 0.01 M Na_2HPO_4/H_3PO_4, pH 7).

alternating hexamer **2** did indeed have the stability of T_m = 37 °C at 6 μM as expected (Figure 2). Increasing the concentration to 12 and 22 μM resulted in slightly higher stability (at least a bimolecular process) and a strong shift of the hyperchromicity from 15% to 40 and 90%, respectively.

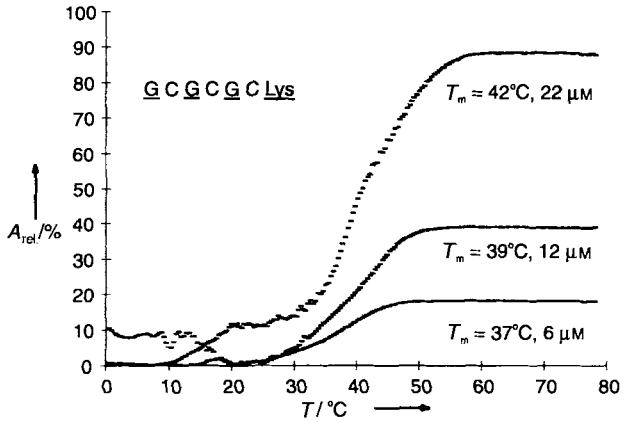

Figure 2. Melting curves of **2** at different concentrations (260 nm, 0.1 M NaCl, 0.01 M Na_2HPO_4/H_3PO_4, pH 7).

The pairing of an equimolar mixture of the enantiomeric hexamers **2** and *ent*-**2** had a stability exceeding that of the corresponding oligomers **1** and *ent*-**1** by 17 °C (Figure 3) and also showed concentration-dependent melting temperatures and hyperchromicities (6 μM: T_m = 75 °C, 50% hyperchromicity; 11 μM: T_m = 79 °C, 150% hyperchromicity).

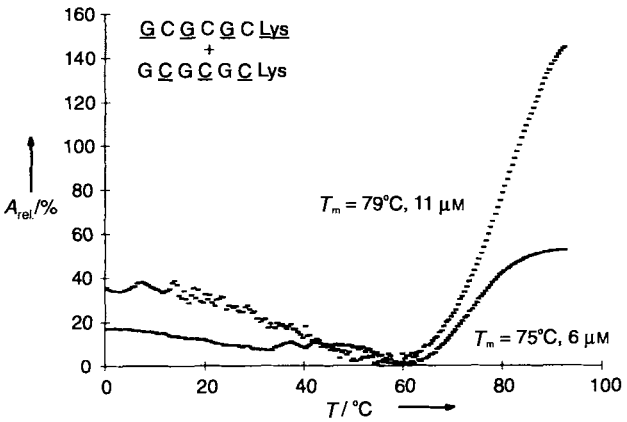

Figure 3. Melting curves of an equimolar mixture of **2** and *ent*-**2** at different concentrations (260 nm, 0.1 M NaCl, 0.01 M Na_2HPO_4/H_3PO_4, pH 7).

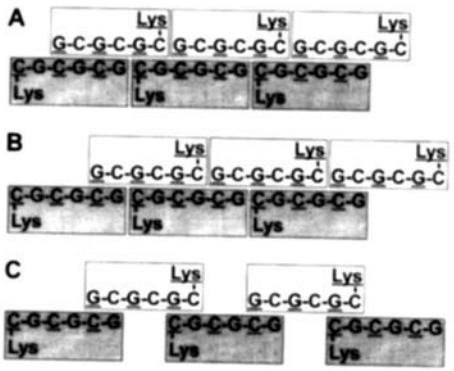
Oligomers **1** and **2** differ only in their sequence; they should be identical with respect to number of base pairs and pairing mode. The enormous increase of hyperchromicity of oligomers with alternating G/C sequence indicates the formation of higher order structures. In fact, only G/C alternating oligomers have the potential to form overlapping band structures (Scheme 3).



Scheme 3. Possible organization of G/C alternating hexamers in linear, bandlike higher order structures. Overlap as shown in A provides the highest amount of G–C pairs.

Each oligomer can form four Watson–Crick base pairs with an enantiomeric hexamer and in addition two base pairs with a second oligomer. Model studies indicate that by a slight twist of the hexameric strand steric interactions of the C-terminal lysine amide with the neighboring strand can be avoided. This twist favors the formation of four additional hydrogen bonds: two between the ε-amino group of lysine and the guanine (N7, O6) of the neighboring oligomer and two between the NH and the carbonyl groups of the peptide strands overlapping with the lysine amide. This model is feasible for all pairing modes. For self-pairing complexes of G/C alternating oligomers (reverse Watson–Crick mode) the stabilization in higher order structures seems to work only at higher concentrations.

To further prove this model we examined the shorter oligomers **3** and *ent*-**3**, which still should be able to aggregate into bands with a 2+2 overlap. For self-pairing of the tetramers we observed a melting temperature of T_m = 12 °C (10% hyperchromicity), whereas the UV melting curve of the enantiomeric mixture provided T_m = 52 °C (28% hyperchromicity; Figure 4), which again suggests formation of a

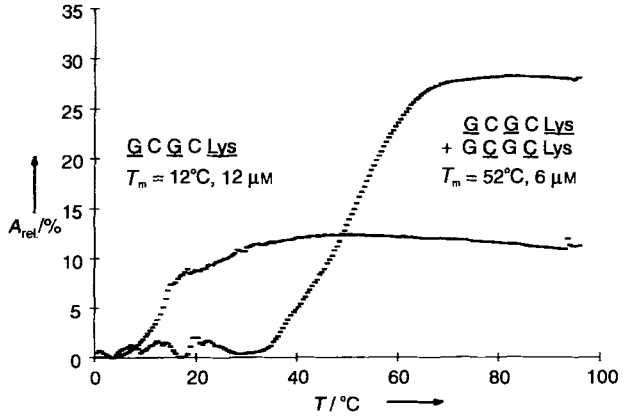


Figure 4. Melting curves of **3** and an equimolar mixture of **3** and *ent*-**3** (260 nm, 0.1 M NaCl, 0.01 M Na_2HPO_4/H_3PO_4, pH 7).

H-(AlaC-AlaG-AlaC)-Lys-NH$_2$ *ent*-**5**

independent as is the absorption of the trimers alone (not shown). Formation of a pairing complex by only three G–C base pairs therefore is not feasible.

Three pairing modes can be identified for G/C hexamers: Watson–Crick for the pairing of enantiomeric oligomers (T_m = 58 °C), reverse Watson–Crick in the case of self-pairing (T_m = 40 °C), and the Hoogsteen mode at pH 4.5 (T_m = 23 °C). The observed selectivities as well as comparison of the pairing stabilities of A–A and A–T pairing (T_m = 31 °C and T_m = 25 °C)[6] are in agreement with our model of alanyl PNA pairing in linear double strands. Although the plane of base pairs is oriented orthogonal to the backbone, the experimental results indicate that the strand orientation, configuration of the nucleo amino acids forming a base pair, and pairing mode are dependent on each other. Based on the evidence for organization of G/C alternating oligomers in band structures, we are currently examining the template-directed oligomerization of G/C alanyl PNA oligomers.

[10] U. Diederichsen, unpublished results.
[11] At pH 4.5 cytosine is protonated at N3 and can form a Hoogsteen base pair with guanine. At pH 4.5 both the hexamer **1** and the mixture of the enantiomeric oligomers I and *ent*-I had a melting temperature of T_m = 23 °C (4% hyperchromicity). This indicates that the Hoogsteen mode is irrelevant for G–C pairing in alanyl PNA at pH 7. The higher stability of the self-pairing complex compared to that of the pairing of the enantiomeric oligomers is in agreement with the selectivity requirements (Scheme 2).

Stable Free Dianionic Silicon–Carbon Clusters

Andreas Dreuw, Thomas Sommerfeld, and Lorenz S. Cederbaum*

Many prominent inorganic dianions, such as CO_3^{2-}, SO_4^{2-}, and SO_3^{2-}, known from the solid state are unstable with respect to electron loss in the gas phase.[1, 2] The question as to whether there are small molecules capable of compensating the electrostatic repulsion of two electrons and thereby of forming stable free dianions has been examined theoretically and experimentally. In the meantime several stable free dianions are known,[3, 4] and the smallest of these that have been detected directly in a mass spectrometer are C_7^{2-} [5] and $S_2O_6^{2-}$.[6]

From a theoretical point of view the smallest dianions predicted to be long-lived are the trigonal-planar alkali metal halides MX_3^{2-} (M = alkali metal, X = F, Cl, Br), which can be understood in the framework of an "ionic model".[7, 8] In addition, carbon clusters of the type C_n^{2-} ($n \geq 7$) have been examined at a high level of theory.[9, 10] The results of these studies showed that the smallest stable dianion of this class, C_7^{2-}, has a trigonal-planar structure[11] instead of the expected linear one.

We report herein on dianionic silicon–carbon clusters and focus on the smallest stable cluster from this class. In the following, we first describe the principal differences between the theoretical examination of neutral and dianionic clusters and the theoretical methods used in our calculations. Then we discuss the structures of two stable dianionic silicon–carbon clusters and compare them with structures of typical neutral species.

We begin with the principal differences between the theoretical examination of neutral molecules and dianions. Isolated neutral molecules possess an infinite number of bound states, that is, all electrons can be bound. Thus, a typical goal in their theoretical study is to find the electronic ground state and the lowest minimum on the potential energy surface (PES). In contrast, the theoretical examination of the general stability of a dianion is more difficult, since it is by no means clear whether a dianionic system exists at all. The principal questions pertaining to the examination are whether the given system can bind the two extra electrons, that is whether electronic stability is given, and whether the system is structurally stable, that is whether stability with respect to fragmentation is present. Thus, the theoretical investigation of a given dianion includes the examination of both the electronic stability and the stability with regard to fragmentation.

Let us turn to the quantum chemical methods used to calculate the electron-detachment energy (EDE). The geometries of the examined systems were optimized at the HF-SCF level of theory (HF = Hartree–Fock, SCF = self-consistent field) by using a Gaussian-type double-ζ basis set (dz(sp, d/2d)[12] augmented with additional diffuse and polarization functions, and all presented structures were found to represent local minima, that is their harmonic vibrational frequencies showed real values. A detailed study of the basis sets showed that the additional functions are necessary to account for the diffuse character of the outer valence orbitals of an anion, whereas it is not necessary to apply larger basis sets, such as a triple-ζ basis set because this, has only small effects on the results. For example, the vertical EDE of the dianion **1** is 1.77 eV at the level of Koopmans

Theorem (KT)/dz(sp,d/2d) and 1.81 eV when the enlarged analogous triple-ζ basis set (tz(sp,d/2d)) is used. The adiabatic EDE behaves in the same way and is 0.59 eV at the ΔSCF/dz(sp,d/2d) level compared with 0.61 eV at the ΔSCF/tz(sp,d/2d) level (see Table 1). The effects on the geometries are also minimal; in all cases the observed bond length changes were less than 0.002 Å.

The EDE values can now be obtained in two ways. On the one hand, the EDE can be obtained directly by so-called direct methods. We have employed Koopmans Theorem[13] and the outer valence Green's function (OVGF)[14, 15] approach. The OVGF values represent an improved "orbital energy", which contains orbital relaxation and correlation effects. On the other hand the EDE can be obtained indirectly by calculating the difference in the total energies of the dianion and the monoanion. These indirect methods are also referred to as Δ methods. In our calculations we have used ΔSCF/dz(d,sp/2d) and ΔSDCI (SDCI = singles doubles configuration interaction). We note that the positive EDE indicates that a system is electronically stable.

We present here the results of our calculations on the dianionic silicon–carbon clusters SiC_6^{2-} (**1**) and $Si_2C_6^{2-}$ (**3**). Several smaller dianionic Si–C clusters of general formula SiC_4^{2-} and SiC_5^{2-} were examined but we found no electronically stable isomers. SiC_6^{2-} (**1**) seems to be the smallest dianion of this class capable of binding both excess electrons. We have located several minima on the SiC_6^{2-} PES that have similar total energies, but only **1** represents a stable free dianion. This isomer consists of a central Si atom and three terminal C_2 units. Dianion **1** has the closed-shell $^1A'$ electronic ground state and shows D_{3h} symmetry (Figure 1). At the SCF/dz(d,sp/2d) level the C–C bonds (1.243 Å) show significant triple bond character, whereas the Si–C bonds (1.759 Å) possesses mainly single-bond character.

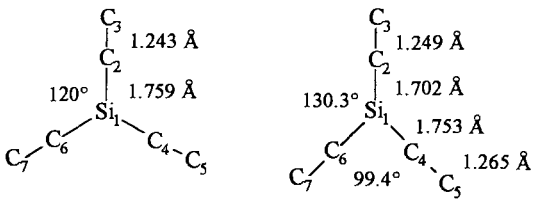

Figure 1. Stable SiC_6^{2-} dianion **1** (D_{3h} symmetry) and its corresponding monoanion **2** (C_{2v} symmetry)

The calculation of possible fragment energies showed that owing to the covalent character of the Si–C bonds and the resulting high binding energy, fragmentations of **1** into two singly negatively charged fragments can be excluded. In contrast, the electronic stability of dianion **1** is not guaranteed. The vertical EDE is 1.77 eV at the level of KT, 1.08 eV at the ΔSCF level, 1.27 eV at the correlated ΔSDCI level, and 1.24 eV according to an OVGF calculation (Table 1). The Overestimation of the EDE by 0.5 to 1.0 eV by Koopmans Theorem is typical. Taking orbital relaxation into account within an ΔSCF calculation leads to a decrease of the EDE, whereas correlation effects within a ΔSDCI or OVGF calculation tend to stabilize the dianion and to increase the EDE.

The adiabatic EDE is obtained by calculating the difference between the total energies of the dianion and the separately optimized monoanion **2** that shows C_{2v} symmetry. At the employed levels of theory the adiabatic EDE is clearly positive (Table 1). Since the dianion **1** is both vertically and adiabatically

Table 1. Vertical and adiabatic electron-detachment energies of the dianions **1** and **3**.

Theoretical method	EAE/eV	
	1	**3**
vertical		
KT	1.77	1.55
ΔSCF	1.08	1.12
ΔSDCI	1.27	1.10
OVGF	1.24	0.98
adiabatic		
ΔSCF	0.59	0.73
ΔSDCI	0.86	0.75

stable with respect to electron loss, and stable with respect to fragmentation, it should be possible to observe it in a mass spectrometer.

Let us now consider the $Si_2C_6^{2-}$ dianion. As for the SiC_6^{2-} system we found only one electronically stable isomer but in contrast to the branched structure of **1** the $Si_2C_6^{2-}$ dianion **3** exhibits a chainlike geometry. Dianion **3** has a ^1A electronic ground state and a C_2 symmetrical structure (Figure 2). The

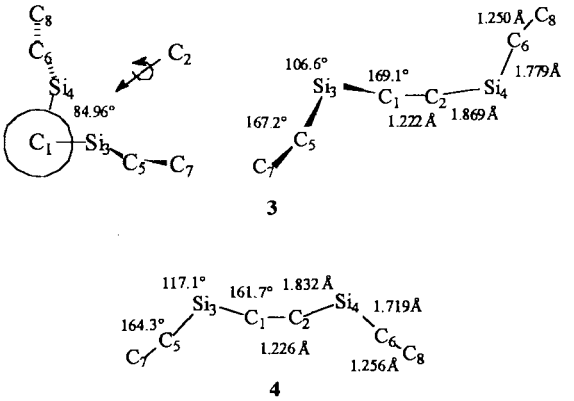

Figure 2. Stable $Si_2C_6^{2-}$ dianion **3** (C_2 symmetry) from two perspectives and its corresponding monoanion **4** (C_{2v} symmetry)

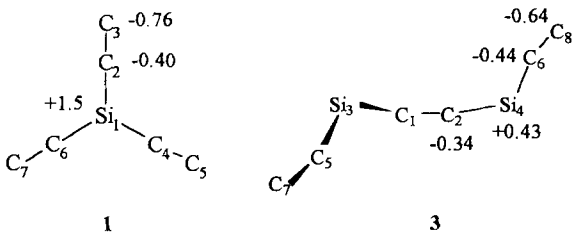
C–C bond C_1–C_2 (1.222 Å) and the bonds C_5–C_7, C_6–C_8 (1.250 Å) can be identified as C–C triple bonds, whereas the Si–C bonds (1.779 and 1.869 Å) have essentially single bond character (Figure 2). As for all chainlike structures we have examined the chain is folded at the silicon atoms. In dianion **3** the angle at the silicon atom is 106°, that is close to the tetrahedral angle. The vertical EDE of dianion **3** is 1.55 eV at the level of KT, and 1.12, 1.10, and 0.98 eV at the ΔSCF, ΔSDCI and OVGF levels respectively (Table 1). The adiabatic EDE has been calculated with respect to a geometrically optimized monoanion with C_{2v} symmetry (**4**); it is clearly positive (Table 1). Based on the sums of possible fragment energies and the arguments presented above, fragmentation can be excluded as a relevant decomposition channel. Thus, we predict that dianion **3** will be long-lived and observable in a mass spectrometer.

Let us now discuss the structures of the stable isomers **1** and **3** from a more general point of view. From the investigation of several classes of free dianions it has been established that stable dianions can roughly be divided into two groups. On the one hand, there are strictly linear or chainlike structures in which the negative charge is mainly localized at the ends of the chain, and the chain itself is essentially neutral. We call this class the "linear neutral group". The most prominent examples are dianions of

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3617-1890 $ 17.50+.50/0

aliphatic dicarboxylic acids $^-OOC-(CH_2)_n-COO^-$,[16] and the linear isomers of the carbon clusters C_8^{2-} and C_{10}^{2-}.[10] On the other hand, there are many dianions that form compact structures. These clusters are characterized by a positively charged central atom or group and several electron-withdrawing substructures that enforce the binding of the two extra electrons. We denote this group as the "compact polarized group". The previously mentioned alkali metal halides MX_3^{2-} belong to this group. These dianions have a positively charged central metal atom and three negatively charged halide ligands. The stability of the MX_3^{2-} dianions can be understood in terms of the electrostatic forces present.[7, 8] Another example is the starlike, stable $C(C_2)_3^{2-}$ cluster, which despite its homonuclear, covalent bonding character belongs to the "compact polarized group", since the central carbon atom is clearly positively polarized (+ 0.4) and the negative charge is evenly distributed over the three terminal electron-affinitive C_2 units.

We can now assign the Si–C dianions **1** and **3** to theses groups. The Mulliken charge distribution (Figure 3) shows that the central silicon atom of dianion **1** is positively polarized and



1 3

Figure 3. Mulliken charge distribution of the dianions **1** and **3**.

the three C_2 units carry the negative charge. Thus, the dianion SiC_6^{2-} (**1**) belongs to the group of "compact polarized dianions". The stability of such systems can be explained as follows: The high symmetry (D_{3h}) allows an even distribution of the two negative charges over three electron-affinitive C_2 units. Thus, each "ligand" has to bind effectively less than one electron, the center can be positively polarized, and a favorable electrostatic pattern arises. For dianion **1** the difference of the electronegativities of the elements silicon and carbon additionally favor this charge distribution, such that the positive charge at the central position is increased in comparison with the analogous homonuclear C_7^{2-} cluster. In summary dianion **1** is stabilized, because the polarization of the atoms due to the difference in electronegativities works in the sense of the "ionic model". This is not the case if the silicon atom is not in the central position of the cluster, but in the position of the ligands. In such a case the polarization due to the difference in electronegativities contrasts the favorable charge distribution and indeed all these isomers are not stable with respect to electron autodetachment.

In contrast, the dianion $Si_2C_6^{2-}$ (**3**) belongs to the "linear neutral group". The Si atoms of dianion **3** are likewise positively polarized due to the difference in electronegativities, but there is virtually no difference to the corresponding neutral molecule. In addition, the associated negative charge of the carbon atoms in the center of the molecule (C_1 and C_2) is only slightly smaller in the neutral molecule than in the dianion. Thus, the additional electrons of the dianionic system are mainly bound to the terminal alkyne groups C_5-C_7 and C_6-C_8. Therefore, the picture of dianion **3** resembles that of a neutral chain with the negative charges localized at the ends. Clearly, the stability of dianion **3** originates from the sufficiently large distance between the two extra electrons and not from a stabilization in the sense of the "ionic model".

Finally, let us compare the structures of dianionic Si–C clusters with those of typical neutral Si–C clusters. In neutral carbon-rich systems the Si atoms are placed mainly at the outer positions such that the number of strong C–C bonds is maximized.[17] In contrast, in dianionic species the Si atom is in the central position. This phenomenon is directly related to the criteria of stability of dianions. In contrast to neutral species, electronic stability is the most important requirement for the existence of a given dianion. For example, there are several energetically more favorable isomers of dianion **1**, such as a linear chain with the silicon at the outer position. These structures are stable with respect to fragmentation, but they are not stable with respect to electron autodetachment. Thus, the position of the Si atoms, and thereby the whole geometrical structure, is not controlled by a total energy criterion, but by the necessity to bind both extra electrons.

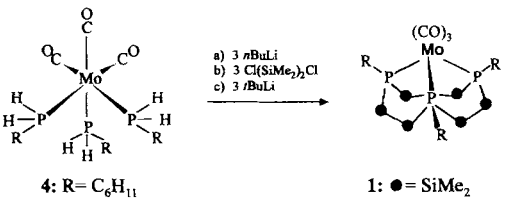
Multidentate, Cyclic Phosphorus Ligands with a Silicon–Phosphorus Backbone: Template Synthesis of a 1,4,7-Triphospha-2,3,5,6,8,9-hexasilacyclononane and a 1,3,5,7,9,11-Hexaphospha-2,4,6,8,10,12-hexasilacyclododecane**

Matthias Driess,* Markus Faulhaber, and Hans Pritzkow

Dedicated to Professor Malcolm Chisholm

Multidentate, cyclic ligands containing nitrogen, oxygen, sulfur, or phosphorus donor atoms play an important role in the coordination chemistry of transition metals. They are more suitable than acyclic chelating ligands for the synthesis of complexes with a rigid stereochemistry and with defined redox and magnetic properties. In such complexes the metal is often completely shielded from one side, while the "free" coordination space on the other side can be forged into almost any shape in order to attain a high selectivity. This has already been substantiated by numerous investigations of macrocycles with nitrogen[1] and sulfur atoms as hard and soft donor centers,[2] respectively; however, only a few phosphorus macrocyclic ("phosphacrown") ligands[3] are known to date. The need for such ligands is great, since they are "sterochemically superior" to the analogous acyclic phosphane ligands. However, preparative access to cyclic phosphanes is still very limited. For example, the synthesis of analogues of 1,5,9-triazacyclododecane (tacdo) and 1,4,7-triazacyclononane (tacn) is either difficult or has not been achieved to date. Recently, a template synthesis of a 1,5,9-triphosphacyclodecane[4] was reported. An alternative way to cyclic triphosphorus ligands is the facile synthesis of 1,3,5-triphospha-2,4,6-trisilacyclohexanes, which can also serve as efficient crown ligands, as we have already demonstrated with the synthesis of tricarbonyl metal complexes.[5] 1,4-Diphospha-2,3,5,6-tetrasilacyclohexanes were synthesized by using a metal center as the template.[6] However, larger Si_nP_m skeletons with $n+m>6$ were not known previously. Here we report the template synthesis of the first homologue of tacn, the 1,4,7-triphospha-2,3,5,6,8,9-hexasilacyclononane derivative in complex **1**, and on the unusual "fusion" of two 1,3,5-triphospha-2,4,6-trisilacyclohexane derivatives **2** (Cy = cyclohexyl) in the coordination sphere of Cu^I and Ag^I ions to form the 1,3,5,7,9,11-hexaphospha-2,4,6,8,10,12-hexasilacyclododecane ligand in the complexes **3a** and **3b**.

The starting material, the tris(phosphane) complex *fac*-[Mo(CO)$_3$(PH$_2$R)$_3$] (**4**, R = C_6H_{11}), which is readily obtained from the treatment of [Mo(CO)$_3$(NCMe)$_3$] with three equivalents of RPH$_2$, was lithiated in a surprisingly uniform one-pot reaction with *n*BuLi in THF at $-70\,^\circ C$; subsequent silylation with 1,2-dichlorotetramethyldisilane followed by cyclo-condensation with *t*BuLi produced the desired complex **1** in 48% yield as



4: R = C_6H_{11} **1**: ● = $SiMe_2$

ocher crystals. The chemical composition was confirmed by mass spectrometry and satisfactory C,H analyses. Surprisingly, the ^{1}H NMR spectrum reveals that the novel Si_6P_3 ligand on the metal is *not* coordinated in a highly symmetrical fashion (C_{3v}): four types of methyl protons at $\delta = 0.4$, 0.5, 0.7, and 1.0 are observed for the Si_2Me_4 bridges. The assignment of these resonance signals to CH, CH_2 (cyclohexyl groups), and CH_3 substituents was verified by a gradient 1D-HMQC NMR experiment (HMQC = Heteronuclear Multiple Quantum Correlation). If **1** had C_{3v} symmetry, only two signals would be observed for the Si_2Me_4 protons. In this case the methyl groups orientated *syn* and *anti* to the Mo center would be arranged in an ecliptical conformation. Apparently, a *gauche*-type conformation of the Me groups in the Si_2Me_4 bridges in **1** is more favorable; this results in different environments for all four Me groups. A singlet at $\delta = -100.2$ is observed in the ^{31}P NMR spectrum. The IR spectrum contains two bands for the CO stretching vibrations at $\tilde{\nu}$ 1837 (s) and 1927 (br) cm^{-1}, which is in agreement with a local C_{3v} symmetry of the [Mo(CO)$_3$] fragment. Though the Si_6P_3 ligand can be released in low yields by the treatment of **1** with multidentate nitrogen and other phosphorus ligands (detected by ^{31}P NMR spectroscopy), it has not yet been isolated.

A new method of constructing cyclic P_6 ligands is offered by the reaction of the P_3 ligand **2**,[7] which can be readily obtained in high yields, with the strongly Lewis-acidic Cu and Ag triflates [M(OSO$_2$CF$_3$)] (M = Cu, Ag). These reactions, which were carried out at $-30\,^\circ C$ in toluene, produce a clear solution. Evaporation of the solvent, subsequent extraction with toluene, and crystallization affords the complexes **3a,b** as colorless, extreme-

3b: M = Ag

ly air-sensitive solids. The formation of these complexes is surprising, because silylphosphanes with Cu^I or Ag^I salts usually react to form metal-rich Cu/P or Ag/P clusters.[8] Complexes **3a,b** are diamagnetic, are hardly soluble in aromatic, aliphatic, or ethereal solvents, and gradually decompose to form [(CyH$_2$P)$_3$M(OTf)] (M = Cu: $\delta(^{31}P) = -85$, M = Ag: $\delta(^{31}P) = -100$), which strongly limits their characterization by NMR spectroscopy. In the ^{31}P NMR spectrum of **3b** there was at least a very broad resonance signal at $\delta \approx -140$ with $^{31}P,^{107/109}Ag$ couplings ($J \approx 2600$ Hz), whereas none was observed for **3a** because of the quadrupole broadening by the $^{63/65}$Cu nuclei ($I = 3/2$). The structures of the complexes were determined unambiguously by single-crystal X-ray diffraction analyses[9] (Figure 1), and their compositions were confirmed by correct C,H analyses. The isotypic compounds crystallize in

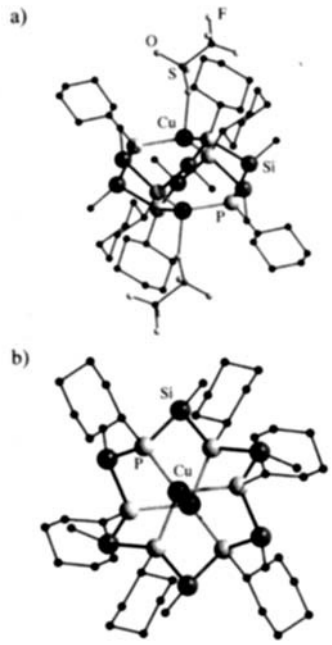

Figure 1. a) Molecular structure of **3a** in the crystal. Compounds **3b** and **3a** are isotypical. Selected distances [Å] for **3a**: Cu–O 2.192(4), Cu–P 2.345(2), 2.348(2), 2.349(2), P–Si (averaged) 2.253(2), P–C (averaged) 1.880(4), Si–C (averaged) 1.851(5). Selected distances [Å] for **3b**: Ag–O 2.507(10), Ag–P 2.510(2), 2.517(2), 2.519(2), P–Si (averaged) 2.257(2), P–C (averaged) 1.874(5), Si–C (averaged) 1.826(6). b) Side view of **3a** along the Cu–Cu axis. The triflate ligands on Cu are not depicted for reasons of clarity.

the triclinic space group $P\bar{1}$. The crownlike Si_6P_6 ligand binds two metal centers, and the M–M distance is 3.521 Å (**3a**) and 3.455 Å (**3b**), which indicates no M–M bond. The M–P distances lie in a narrow range (**3a**: 2.345, 2.349(2) Å; **3b**: 2.510, 2.519(2) Å) and are only slightly longer than those values found in other tris(phosphane)-substituted copper(I)[10] or silver(I)[11] complexes. The unremarkable and only slightly different Si–P distances in **3a** and **3b**, as well as the M–P distance, implies an almost ideal tetrahedral coordination of the Si and P atoms, with somewhat smaller bonding angles on the phosphorus than on the silicon centers as expected. The metal centers, each coordinatively saturated, display a severely flattened tetrahedral environment (sum of the P-M-P angles: **3a** 348.7; **3b** 349.8°).

The high symmetry of the complexes is apparently conserved in solution, since only one type of SiH proton for the potentially stereogenic SiHMe bridge is observed in the ^{1}H NMR spectrum of **3b**. The mechanism of formation of **3a,b** is not yet known. We assume that the metal-template-controlled, multistep fusion of **2** is mainly initiated by two factors: firstly by the thermodynamically favorable tridentate coordination of the Cu^I or Ag^I ion with phosphorus, and secondly, by the ring strain in **2**, which favors a ring extension. On the other hand, the oxidative addition to a reactive intermediate with a d^8-M^{III} center, which, for example, could be formed by the insertion of an M^I ion into a Si–P bond, is very unlikely. NMR spectroscopy gives no hint of any intermediates. Since the electrophilic metal centers in **3a,b** lie embedded in an element–organic pocket, and the triflate group is an excellent nucleofugal leaving group, **3a,b** should be particularly suitable for selective reactions and for mechanistic investigations, such as the isolation of intermediates during the insertion of unsaturated organic substrates into copper(I)–element or silver(I)–element bonds. The relevant investigations and experiments on the liberation of the Si_6P_6 ligand in **3a,b** by decomplexation with other chelate ligands is currently in progress.

Experimental Section

1: A solution of **4** (1.3 g, 2.5 mmol) in THF (80 mL) was treated at −70 °C with a solution of 2.5 M *n*BuLi (3 mL, 7.5 mmol) in hexane. The mixture was warmed to −30 °C. Subsequently, 1,2-dichlorotetramethyldisilane (1.6 g, 7.5 mmol) in THF (20 mL) was added dropwise at −70 °C. The solution was warmed to room temperature, then re-cooled to −70 °C and a solution of 2.0 M *t*BuLi (3.75 mL, 7.5 mmol) in pentane was added to complete the reaction. After partial evaporation of the solvent at room temperature under vacuum (10^{-2} Torr), the residue was extracted with toluene (20 mL). Concentration of the solution to 3 mL gave **1** as ocher crystals. Yield: 48% (1.0 g, 1.2 mmol). M.p. 211 °C (decomp.); ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.4 (s, SiMe), 0.5 (s, SiMe), 0.7 (s, SiMe), 1.0 (s, SiMe), 1.1 (d, CH-Cy, ^2J(H,P) = 6 Hz), 1,15 (m, CH_2-Cy), 1.35 (m, CH_2-Cy) 1.65 (m, CH_2-Cy); ^{31}P NMR (36 MHz, $CDCl_3$): δ = −100.2 (s); IR (toluene): $\tilde{\nu}$ (CO) = 1837 (s), 1927 (br.) cm^{-1}; MS (EI, 70 eV): m/z(%) = 872 (M^+, 19), 844 ($(M-CO)^+$, 54), 816 ($(M-2CO)^+$, 20), 761 ($(M-CO-C_6H_{11})^+$, 8), 733 ($(M-2CO-C_6H_{11})^+$, 100).

3a: Ligand **2** (455 mg, 0.9 mmol) was treated at −30 °C in toluene (30 mL) with CuOTf·0.5 C_6H_6 (Aldrich; 180 mg, 0.4 mmol). The volume was reduced to ca. 5 mL, and colorless, very air-sensitive crystals were obtained after several days. Yield: 74% (395 mg, 0.3 mmol). M.p. 148 °C (decomp.).

3b: In an analogous synthesis to **3a**, ligand **2** (1.0 g, 2.2 mmol) was treated with AgOTf (Aldrich, 0.51 g, 2.00 mmol) to afford **3b** as colorless crystals. Yield: 85% (1.2 g, 0.83 mmol). M.p. 134 °C (decomp.); ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.7–2.3 (m, Me and C_6H_{11}), 5.4 (s, Si-H); ^{31}P NMR (36 MHz, $CDCl_3$): $\delta \approx -143$ (br., $J(^{31}P,^{105/107}Ag) \approx 2600$ Hz).

$[Sn_6(PR)_6]$, $[Sn_3(PR)_2Cl_2]$, and $[Cu_{24}(PR)_{12}]$ (R = Triorganosilyl): New Tin and Copper Phosphanediyl Clusters**

Matthias Driess,* Stefan Martin, Klaus Merz, Vassili Pintchouk, Hans Pritzkow, Hansjörg Grützmacher, and Martin Kaupp

Dedicated to Professor Gottfried Huttner on the occasion of his 60th birthday.

Although monometallic diorganophosphanes MPR_2 containing s-, p-, and d-group metals have been widely investigated, very little is known about the structure of phosphanes with two metal atoms attached to the phosphorus (phosphanediides or phosphanediyl complexes) M_2PR (R = alkyl, aryl, silyl). These complexes show a much greater tendency to oligomerize than the metal diorganophosphanides.[1, 2] We recently reported the structure of the first ionic phosphanediyl heteroaggregates **A**[3] and **B**,[4] whose Li, P frameworks can be described as a close packing of Li cations and RP dianions.

$[(RP)_8Li_{18}O]$ $[(RP)_2Li_4(RF)_2]$

A : R = iPr$_2$(2,4,6-Me$_3$C$_6$H$_2$)Si **B** : R = iPr$_2$(2,4,6-iPr$_3$C$_6$H$_2$)Si

Here we describe the molecular tin(II)-phosphanediyl clusters **1** and **2** as well as the first neutral phosphanediyl-bridged copper cluster **3**, which has no additional terminal donor ligands attached to the Cu(I) center. Compounds **1**–**3** represent new structural motifs for M_2PR aggregates (phosphanediides), with stronger covalent M–P bonds than the Li–P bonds in **A** and **B**. Attractive M–M dispersion forces also contribute to the bonding in **3**.

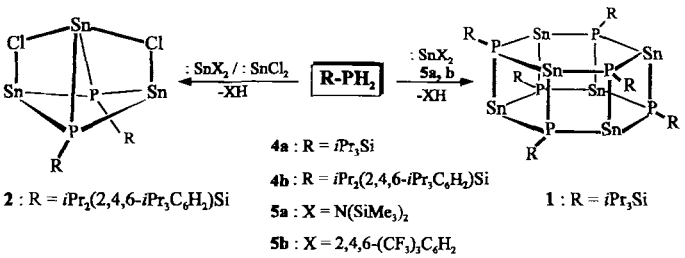
The Sn_6P_6 cluster **1** can be synthesized by two different Brønsted acid–base reaction pathways. The reaction of the primary silylphosphane **4a** with diaminostannanediyl **5a** in a molar ratio of 1:1 in hexane results in an 89% yield of black-red crystals of **1**. Bis[2,4,6-tris(trifluoromethyl)phenyl)]stannanediyl **5b** can also be used as the Sn^{II} source, whereby **1** and 1,3,5-tris(trifluoromethyl)benzene (^{19}F NMR spectroscopy) are obtained in practically quantitative amounts.



Single-crystal X-ray structure analysis[5] revealed that **1** crystallizes with triclinic symmetry and with two independent half molecules in the unit cell. Since the two molecules differ only very slightly, we will discuss only one form. The molecule has $\bar{1}$ symmetry and forms a distorted hexagonal Sn_6P_6 prism with σ^3,λ^2-coordinated tin and σ^4,λ^3-coordinated phosphorus centers (Figure 1). The atoms P1, P2, P3 and Sn1, Sn2, Sn3 are located just 0.09 Å above (phosphorus) and below (tin) the best hexagonal plane. The average Sn–P bond lengths of 2.626 (3) Å in the Sn_3P_3 plane are only slightly longer than the corresponding Sn–P bond lengths between the two Sn_3P_3 planes (2.665(3) Å). The endocyclic angles at the three symmetry-independent Sn centers are practically identical. For example, the sum of the angles around the Sn1 atom is 276.29(9)° with P1-Sn1-P2a 86.99(9), P3-Sn1-P1 100.76(10) and P3-Sn1-P2a 88.54(9)°. The larger endocyclic angles at the phosphorus atoms are a result of the bulky silyl group attached to the phosphorus. The angles are approximately the same for all three phosphorus centers: for P1 90.19(9) (Sn3a-P1-Sn1), 90.77(10) (Sn3a-P1-Sn2), and 139.13(11)° (Sn1-P1-Sn2).

The Sn–P bond lengths and the endocyclic angle at the tin are virtually the same as the values observed for dimeric[6] and hypercoordinated diphosphinostannanediyl.[7] Monomeric V-shaped $Sn(PR_2)_2$ derivatives (P-Sn-P approximately 97°) have, however, shorter Sn–P bond lengths (average distance 2.567(1) Å).[8] Of particular interest is the unusual highfield position of the ^{31}P NMR singlet signal with Sn satellites at $\delta = -475.2$, with a comparatively low value of $^1J(^{31}P, ^{117/119}Sn) = 708$ Hz. The low solubility of **1** made it impossible to obtain a ^{119}Sn NMR spectrum. DFT-IGLO calculations (density functional theory with individual gauges for localized orbitals)[9] on the parent compound $H_6Sn_6P_6$ (**1***), taking spin–orbital corrections explicitly into account, show that spin–orbital splitting of the 5p orbital of the tin plays a significant role in the unusual high field shift of the ^{31}P resonance. Although calculations without the spin–orbital correction yield a value ($\delta(^{31}P) = -274$) at relatively high field; including the spin–orbital contribution (−80) leads to a further high-field shift to $\delta(^{31}P) = -354$. Because of the amount of computer time required, only a medium-sized basis set was used;[9] experience has shown that the spin–orbital correction is then clearly underestimated. It is therefore probable that the remaining discrepancy between the calculated and experimental values for the high field position of **1** is also due to spin–orbital effects. Calculations at the same level carried out on Sn-

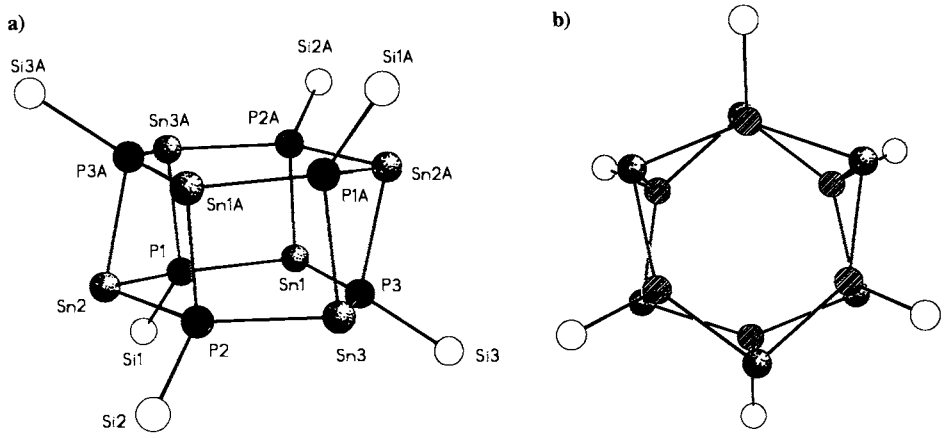

Figure 1. a) Molecular structure of **1** in the crystal. Only one of the two independent molecules in the unit cell is shown, as they can hardly be distinguished. For clarity, the alkyl groups have been omitted. Selected bond lengths [Å] and angles [°]: Sn1–P1 2.611(3), Sn1–P3 2.642(3), Sn1–P2a 2.654(3), Sn2–P1 2.613(3), Sn2–P2 2.628(3), Sn2–P3a 2.669(3), Sn3–P3 2.631(3), Sn3–P1a 2.671(3), Sn3–P2 2.634(3), P1–Si1 2.262(4), P2–Si2 2.269(4), P3–Si3 2.271(4); P1-Sn1-P3 100.76(10), P1-Sn1-P2a 86.99(9), P3-Sn1-P2a 88.54(9), Si1-P1-Sn1 106. 03(13), Si1-P1-Sn2 105.93(13), Sn1-P1-Sn2 139.13(11), Si1-P1-Sn3a 126.59(14), Sn1-P1-Sn3a 90.19(9), Sn2-P1-Sn3a 90.77(10). b) Projection of the Sn_6P_6 cluster in **1** along the Sn_3P_3 rings.

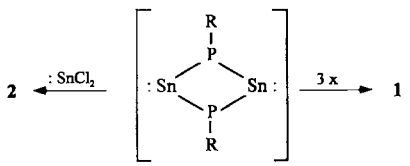
$(PH_2)_2$ gave a value of $\delta(^{31}P) = -105$, with a much lower spin–orbital contribution of -26. This is in good agreement with experimental values obtained for derivatives ($\delta(^{31}P) = -102$ to -121)[8]. The strong influence of the spin–orbital coupling on the ^{31}P chemical shift of **1** (**1***) is a result of the relatively large Sn-P-Sn angles within the Sn_3P_3 ring. This means that the phosphorus 3s orbitals contribute particularly strongly to the Sn–P bonds in the Sn_3P_3 ring and permit a very efficient transfer of the spin–orbital effect from the two neighboring Sn centers.[10a] The mechanism of formation of **1** is unknown. The Sn_6P_6 framework is possibly built up by a stepwise association of three dimeric $(RPSn)_2$ intermediate molecules (Scheme 1).



C

Scheme 1. Formation of **1** and **2** from the hypothetical intermediate C.

The formation of a $(RPSn)_2$ molecule as an intermediate is very probable when the following reaction is considered: the diaminostannanediyl **5a** reacts with the bulky silylphosphane **4b** in the presence of $SnCl_2$ to form the unusual cluster $Sn_3P_2Cl_2$ (**2**), which is isolated as yellow crystals in 44% yield. The crystal structure of **2** has been determined and can be described[5] as a complex of the Sn_2P_2 intermediate **C** and $SnCl_2$ (Scheme 1), where the Cl atoms and the phosphanediyl groups act as μ_2- and μ_3-bridging ligands (Figure 2). This description is in agreement with the observation that $SnCl_2$ cleaves off from **2** under mass spectrometry conditions (electron impact ionization (EI), 70 eV). The Sn–P bond lengths in **2** show only slight variations from one another (average 2.622(3) Å) and are virtually identical with those in **1**. The Cl3-Sn2-Cl4 angle is 159.6(1)° and the (somewhat different) Sn2–Cl distances in the $SnCl_2$ dumbbell are approximately 0.3 Å longer than the Sn1–Cl3 (2.583(3) Å) and Sn3–Cl4 bond lengths 2.565(3) Å), which can be explained by higher coordination of the Sn2 atom.

Veith et al. obtained similar complexes (though polymeric in the crystalline state) from the reaction of the four-membered cyclodiazastannanediyl with SnX_2 (X = Cl, Br).[11] The ^{31}P NMR spectrum of **2** shows a singlet with Sn satellites at $\delta = -122.4$ ($^1J(^{31}P, ^{117/119}Sn) = 1037$ Hz). The calculation of the ^{31}P chemical shift[9] of the parent compound $H_2P_2Sn_3Cl_2$ (**2***) gave a value of $\delta = -52$, with a spin–orbital contribution of only -22. The low spin–orbital contribution for **2*** relative to **1*** is due to the large difference in Sn-P-Sn angle, which implies differing amounts of s character of the phosphorus center in the P–Sn bond[10b]. When the reaction is carried out without $SnCl_2$, a deep red solution is formed that has only one singlet signal with Sn satellites ($^1J(P,Sn) = 793$ Hz) at $\delta = -440.5$ in the ^{31}P NMR spectrum, which can be interpreted without doubt as the corresponding Sn_6P_6 cluster. **1** and other derivatives do not react with $SnCl_2$.

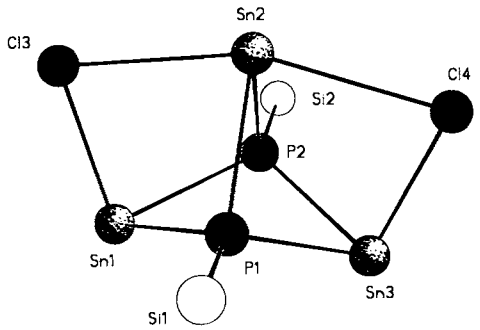


Figure 2. Structure of **2** in the crystal. Selected bond lengths [Å] and angles [°]: Sn1–Cl3 2.583(3), Sn3–Cl4 2.565(3), Sn2–Cl3 2.889(3), Sn2–Cl4 2.947(3), Sn1–P1 2.630(3), Sn1–P2 2.620(3), Sn2–P1 2.636(3), Sn2–P2 2.619(3), Sn3–P1 2.617(3), Sn3–P2 2.614(3), P1–Si1 2.304(4), P2–Si2 2.303(4); Cl3-Sn2-Cl4 159.60(9), P1-Sn2-P2 72.65(9), Cl3-Sn1-P2 88.45(9), Cl3-Sn1-P1 88.59(9), P1-Sn1-P2 72.73(9), P2-Sn2-P1 88.59(8), Si1-P1-Sn2 122.27(11), Si1-P1-Sn1 129.51(12), Si1-P1-Sn3 126.65(12).

A neutral copper phosphanediyl cluster with no additional terminal donor ligands on the copper was prepared for the first time in the synthesis of **3**. Its structure as $(Cu_2PR)_{12}$ (R = Me_2-(*i*PrMe_2C)Si) is very different from that of the dialkali metal phosphanediides, even though it also has a monvalent metal center.[3,4] Cluster **3** forms when **4c** is heated with $[\{CuO tBu\}_4]$ (**6**) in toluene at 60 °C and was isolated in 81% yield, as dark red crystals that are only sparingly soluble.

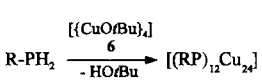

Figure 3 shows the structure of **3**[5] as a cluster of 24 Cu atoms surrounded by 12 triorganosilylphosphanediyl groups. The 24-atom cluster consists of three planar Cu_6 rings and two peripheral Cu_3 rings that all lie parallel to one another. The twelve RP fragments cap alternately the Cu_4 faces of the Cu_{24} polyhedron resulting in five-fold coordinated P centers. The Cu–P and Si–P bond lengths lie within the expected range. The structure of the

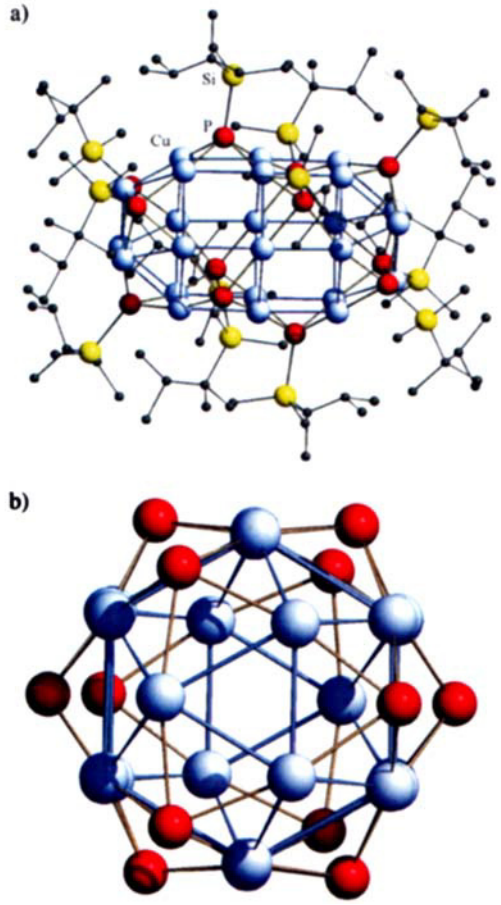

Figure 3. a) Structure of **3** in the crystal. Selected average bond lengths [Å] and angles [°]: Cu–P 2.226(3), Cu–Cu 2.733(2), P–Si 2.239(3); P-Cu-P 164.67(10). b) Projection of the $Cu_{24}P_{12}$ cluster of **3** along the parallel Cu_3 and Cu_6 rings. Cu: blue, P: red.

Cu_{24} polyhedron agrees with that of the recently described $[Cu_{24}(NPh)_{14}]^{4-}$ anionic cluster and can be discussed in an analogous fashion.[12] The construction principle of parallel stacks of hexagonal and trigonal Cu layers to form a polyhedron has also been observed for other Cu clusters.[13]

Experimental Section

1: Silylphosphane **4a** (1.32 g, 7.3 mmol) was added to a solution of **5a** (3.2 g, 7.3 mmol) in 20 mL hexane at 0 °C and then stirred at room temperature for about 2 h. The volatile components were removed under vacuum (10^{-2} Torr) at 25 °C, and the residue was dissolved in about 5 mL hot toluene. Black-red crystals of **1** precipitated upon cooling. Yield: 2.0 g (1.08 mmol, 89%). M.p. = 297 °C (decomp.). ^{1}H NMR (C_6D_6, 200 MHz): δ = 0.98 (d, 108 H, Me, J(H,H) = 5.9 Hz), 1.16 (sept, 18 H, C*H*Me$_2$, J(H,H) = 5.9 Hz); ^{31}P NMR (81 MHz): δ = −475.2 (s, ^1J(P,Sn) = 708 Hz). Correct C,H analysis. Compound **1** was also obtained in quantitative yield by heating **4a** (1.32 g, 7.3 mmol) with an equimolar amount of **5b** in toluene at 90 °C (5 h).

2: Aminostannanediyl **5a** (2.1 g, 4.78 mmol) was added to a suspension of dried $SnCl_2$ (1.0 g, 5.27 mmol) in 50 mL benzene and then treated with **4b** (dissolved in 5 mL benzene). The mixture was heated for 8 h at 60 °C. After cooling, the product crystallized in the form of a yellow solid. Yield: 1.17 g (1.04 mmol, 44%). M.p. = 181 °C (decomp.). ^{1}H NMR (C_6D_6, 200 MHz): δ = 0.91 (pseudo t, 36 H, Me), 1.12 (br. sept, 3 H, C*H*Me$_2$), 1.16 (sept., 3 H, CHMe$_2$, J(H,H) = 5.9 Hz); ^{31}P NMR (81 MHz): δ = −122.4 (s, ^1J(P,Sn) = 1037 Hz); MS (EI, 70 eV): m/z(%) = 1124 (M+, 12), 934 ($(M - SnCl_2)^+$, 6), 774 ($(M - i\mathrm{Pr}_2(i\mathrm{Pr}_3C_6H_2)\mathrm{SiP})^+$, 28), 317 ($(i\mathrm{Pr}_2(i\mathrm{Pr}_3C_6H_2)\mathrm{Si})^+$, 100). Correct C,H analysis.

3: A stirred solution of **6** (0.45 g, 0.82 mmol) in 20 mL toluene was allowed to react with **4c** (0.58 g, 3.29 mmol) and then heated for 5 h at 60 °C. The product crystallized from the deep red solution after cooling to room temperature. Yield: 0.4 g (0.14 mmol, 81%). M.p. = 214 °C (decomp.). Correct C,H analysis.

Eight-Coordinate [Bis(oxyiminodiacetate)-titanium(IV)]$^{2-}$ and Nine-Coordinate [Bis(oxyiminodiacetate)aquazirconium(IV)]$^{2-}$; Variation in Coordination Mode in Amavadin-Like Complexes**

Spencer M. Harben, Paul D. Smith, Roy L. Beddoes, David Collison, and C. David Garner*

The synthesis and single-crystal X-ray characterization of $[NH_4][NMe_4][V(hida)_2]$, $(hida)^{3-}$ = oxyiminodiacetate,[1] was important in the development of our understanding of the structure of amavadin ($H_2[V(S,S\text{-hidpa})_2]$, $(hidpa)^{3-}$ = oxyimino-2,2′-dipropionate),[2] the form in which vanadium is accumulated in *Amanita muscaria*. We have confirmed the nature of isolated amavadin,[3] which possesses a novel, eight-coordinate structure. Each $(hidpa)^{3-}$ ligand binds to vanadium through two unidentate carboxylate groups and an η^2-N,O moiety; the two η^2-N,O groups are mutually *trans* and oriented at about 90° to one another. The relative orientations of the two η^2-N,O groups define the Δ and Λ isomers at the stereogenic metal center; amavadin as isolated contains an equal mixture of the two diastereoisomers, $[\Delta,\Lambda\text{-V}(S,S\text{-hidpa})_2]^{2-}$.[3] We have extended this chemistry to other early transition metals, including Mo,[4] Nb, and Ta.[5] Herein we report the synthesis and characterization of $(hida)^{3-}$ complexes of the Group 4 metals Ti and Zr, which further develops the coordination chemistry of the oxyiminodicarboxylate ligands.

The complexes **1** and **2** have been prepared in situ in H_2O, isolated as colorless crystals, and characterized by X-ray crystallography (Figures 1 and 2).[6] Each compound contains Δ and

$[Ca(H_2O)_4][Ti(hida)_2]\cdot 2H_2O$ **1**

$[Ca(H_2O)_5][Zr(hida)_2(H_2O)]$ **2**

Λ isomers of the anions within the crystal lattice. The anion of **1** possesses the same structure as that reported for the complexes of $(hida)^{3-}$ and $(hidpa)^{3-}$ with V^{IV}, V^{V},[1,3] Mo^{V},[4] Nb^{V}, and Ta^{V}.[5] Most of the Ti–O and Ti–N bonds (Figure 1; av. Ti–O_C 2.083, Ti–N 2.075) are similar in length to the equivalent bonds of the V^{IV} complex (av. V–O_C 2.067, V–N 2.003) and longer than those observed for the V^{V} complex (av. V–O_C 1.951, V–N 2.022), but the Ti–O_N bond length of 1.943(4) Å is shorter than that in either of these comparable complexes (V^{IV} av. 1.975 Å, V^{V} av. 1.970 Å; the other Ti–O bond length is 1.975(5) Å). The Zr^{IV} coordinates to two $(hida)^{3-}$ ligands in a manner similar to that of Ti^{IV} but with significantly longer bonds (Figure 2, av. Zr–O_C 2.239, Zr–N 2.227, Zr–O_N 2.125 Å). A water molecule (O16) is also coordinated to the zirconium center and located in a plane between O5 and O6 (Figure 2); consequently, the Zr^{IV} center is nine-coordinate, a unique structural feature for this class of bis-ligand complexes with $(hida)^{3-}$ and $(hidpa)^{3-}$.

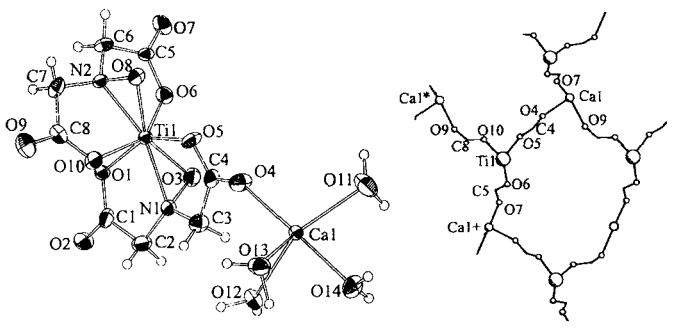

Figure 1. Left: ORTEP view of the asymmetric unit $[Ca(H_2O)_4][\Delta\text{-Ti(hida)}_2]$ in the crystal. Selected bond lengths [Å] and angles [°]: Ti1–O1 2.079(5), Ti1–O5 2.087(5), Ti1–O6 2.077(5), Ti1–O10 2.089(5), Ti1–O3 1.975(5), Ti1–O8 1.943(4), Ti1–N1 2.071(5), Ti1–N2 2.078(5); N1-Ti1-O3 40.6(2), N2-Ti1-O8 41.0(2). Right: schematic representation of the metallacycle in the crystal lattice.

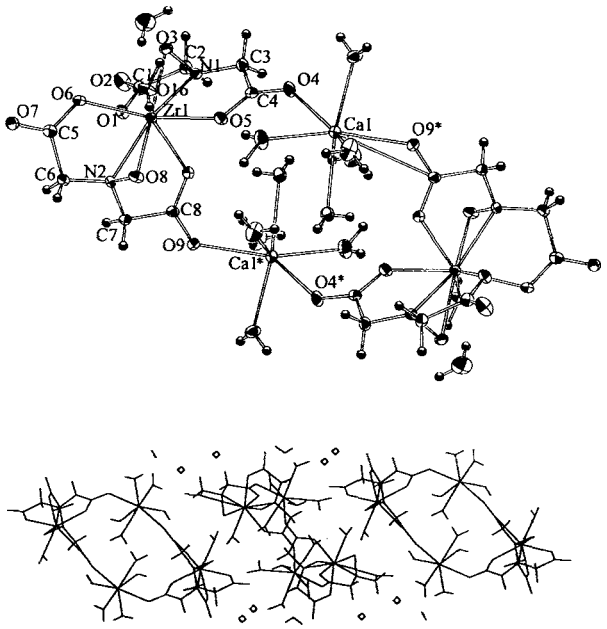

Figure 2. Top: ORTEP view of the metallacycle of $[Ca(H_2O)_5][Zr(hida)_2(H_2O)]$ in the crystal. Selected bond lengths [Å] and angles [°]: Zr1–O1 2.224(4), Zr1–O5 2.240(4), Zr1–O6 2.243(3), Zr1–O10 2.247(4), Zr1–O3 2.126(4), Zr1–O8 2.124(4), Zr1–N1 2.229(4), Zr1–N2 2.225(4), Zr1–O16 2.262(4); N1-Zr1-O3 38.1(1), N2-Zr1-O8 38.2(1). Bottom: packing of the metallacycles in the crystal lattice; water molecules are represented as ◇ and ∧; the plot was obtained with the program PLUTON [11].

If the amavadin-like coordination geometry is considered to be an octahedron in which a pair of *trans* vertices are occupied by the η^2-N,O groups, the extent of distortion from a regular geometry is related to the size of the metal. Thus, the dihedral angle between the two (η^2-N,O)M groups increases, the *trans* angle O1-M-O5 (for the carboxylate oxygen atoms of the same ligand) decreases, and the *cis* angle O5-M-O6 (involving the carboxylate oxygen atoms of different ligands) increases as the size of the metal increases (see Table 1 and Figure 3). This increase in distortion ultimately leads to the ligation of an H_2O molecule in the case of the Zr^{IV} ion. Figure 4 shows a space-filling diagram for $[Ti(hida)_2]^{2-}$ and $[Zr(hida)_2(H_2O)]^{2-}$, illustrating the ligation of the H_2O molecule between the two bonding carboxylate oxygen atoms. Nine-coordination is novel for Zr^{IV} in coordination chemistry, but coordination numbers higher than eight are known for organometallic Zr^{IV} complexes.[8]

The crystal structure of the Ti complex **1** contains 24-membered rings formed from three $[Ti(hida)_2]^{2-}$ anions and three $[Ca(H_2O)_4]^{2+}$ cations (Figure 1); each $[Ti(hida)_2]^{2-}$ binds to three $[Ca(H_2O)_4]^{2+}$ units through the carbonyl oxygen atoms

Table 1. Dihedral angle (α) between the two {MNO} groups, and the O1-M-O5 (β) and O5-M-O6 (γ) angles for the $[M(hida)_2]^{n-}$ complexes.

M/ionic radius [pm][10]	α [°][a]	β [°] [b]	γ [°]
V^V/54 [3]	86.6	159	107
V^{IV}/58 [1]	87.7	157.3(1)	103.9(2)
Ti^{IV}/60.5	92.7	149.8(2)	115.8(2)
Nb^V/64 [5]	98.3	148.6(2)	119.8(2)
	95.1	148.8(2)	119.4(2)
Ta^V/64 [5]	98.4	149.4(5)	118.4(4)
	96.9	148.7(4)	119.3(4)
Zr^{IV}/72*	101.3	135.2(1)	146.1(1)

[a] The angle between the N atom of one η^2-N,O group and the O atom of the second η^2-N,O group. [b] In $[Zr(hida)_2(H_2O)]^{2-}$ the *trans* O6-M-O10 angle and the *trans* O1-M-O5 angle are equivalent within the estimated standard deviations.

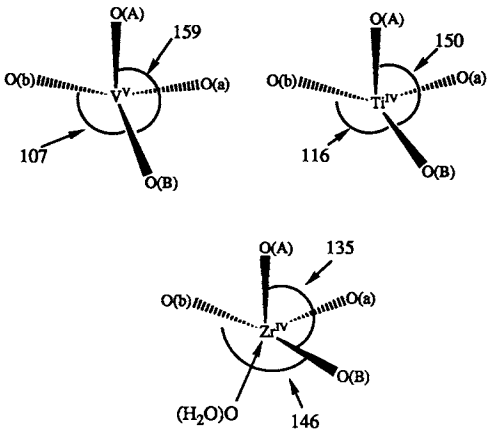

Figure 3. Schematic representation of the four ligating carboxylate oxygen atoms in the $[M(hida)_2]^{n-}$ complexes, viewed perpendicular to the N–O bond axis (not shown), illustrating that as the size of the metal ion increases ($V^V < Ti^{IV} < Zr^{IV}$) the *trans* angle O(A)-M-O(B) (O(A) and O(B) belong to the same ligand) decreases and the *cis* angle O(B)-M-O(b) between the two ligands increases on one side of the molecule ultimately leading to the ligation of an H_2O molecule in the Zr complex.

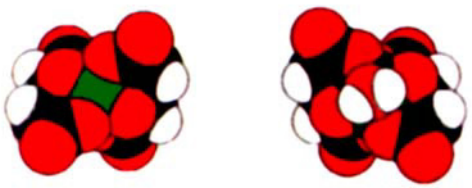

Figure 4. Space-filling model of $[Ti(hida)_2]^{2-}$ (left) and $[Zr(hida)_2(H_2O)]^{2-}$ (right). Red = oxygen, black = carbon, blue = nitrogen, and green = metal; the plot was obtained with the program PLUTON [11].

(Ca–O4 2.375(5), Ca–O7 2.402(5), Ca–O9 2.419(5) Å) and is part of three separate metallacycles. Each Ca^{2+} is seven-coordinate, binding to four H_2O molecules and a single carboxylate oxygen atom from each of three $[Ti(hida)_2]^{2-}$ anions. The crystal lattice is built up from these rings containing common segments as a distorted honeycomb configuration, in which each metal atom is a node of the irregular hexagons (see Figure 1). In Zr complex **2**, two anions are linked by two cations to form 16-membered metallacycles (Figure 2). As in the Ti^{IV} system, each $[Zr(hida)_2(H_2O)]^{2-}$ binds to the $[Ca(H_2O)_5]^{2+}$ cations through the carbonyl oxygens (Ca–O4: 2.400(4), Ca–O9: 2.374(4) Å). However, unlike the Ti^{IV} compound **1** in which the macrocycles are connected through the Ti and Ca units, the rings containing Zr and Ca are discrete. Hydrogen bonding is observed within the rings, and further hydrogen bonding links these metallacycles to form an extended structure (Figure 2, bottom). The rigidity of these extended structures is manifest in the low thermal parameters and R values obtained in the crystal structure determinations at room temperature.

Experimental Section

1: $[TiO(acac)_2]$ (0.131 g, 0.5 mmol) was added to a solution of H_3hida [9] (0.148 g, 1 mmol) in H_2O (10 mL). The resultant mixture was stirred at 22 °C for 16 h. $CaCl_2$ (0.055 g, 0.5 mmol) was added, and the solution stirred for a further 10 min. The solution was concentrated under reduced pressure (to about 3 mL), filtered into a Schlenk tube, a layer of *i*PrOH (15 mL) carefully added, and the Schlenk tube was left to stand at 22 °C. After several days, colorless bipyramidal crystals formed (yield 0.159g, 65%). Elemental analysis calcd for $C_8H_{20}N_2O_{16}CaTi$: C 19.68, H 4.13, N 5.74; found (%): C 19.90, H 4.09, N 5.54.

The Zr compound was prepared analogously from $[Zr(acac)_4]$ (0.244 g, 0.5 mmol), H_3hida [9] (0.148 g, 1 mmol), and $CaCl_2$ (0.055 g, 0.5 mmol). A layer of THF (15 mL) above the reaction solution (3 mL) produced, after several days at 22 °C, colorless tabular crystals (yield 0.127 g, 48%). Elemental analysis calcd for $C_8H_{20}N_2O_{16}CaZr$: C 18.07, H 3.67, N 5.33; found (%): C 18.07, H 3.79, N 5.27.

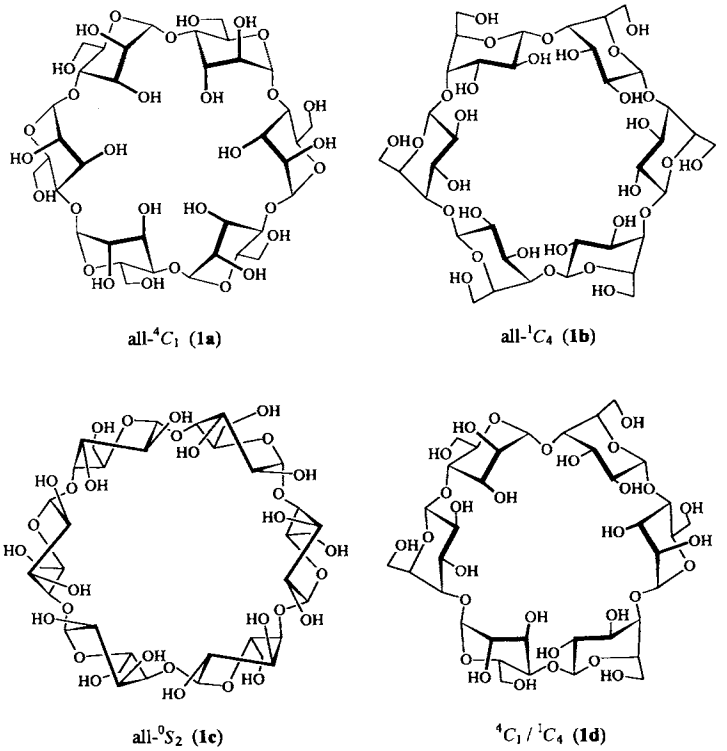
Synthesis, Structure, and Conformational Features of α-Cycloaltrin: A Cyclooligosaccharide with Alternating $^4C_1/^1C_4$ Pyranoid Chairs**

Yasuyoshi Nogami, Kyoko Nasu, Toshitaka Koga, Kazuko Ohta, Kahee Fujita,* Stefan Immel, Hans J. Lindner, Guido E. Schmitt, and Frieder W. Lichtenthaler*

The wealth of knowledge that has accumulated on the starch-derived cyclodextrins and their unique ability to form inclusion complexes[1] is contrasted by a peculiar paucity of data on cyclooligosaccharides composed of sugars other than glucose.[2] Except for certain cyclofructins, obtainable by bacterial action on the polysaccharide inulin,[3] all of the non-glucose cyclooligosaccharides presently known have been acquired synthetically and require laborious multistep procedures to assemble the linear oligosaccharide from its monosaccharide units in a form suitable for cycloglycosylation. In this way, α(1 → 4)-linked cyclooligosaccharides composed of D-mannose[4] (α-, β-, and γ-cyclomannin), of L-rhamnose[5] (α-cyclorhamnin), and of alternating D-mannose/L-rhamnose units[6] have been prepared, yet in such minute amounts as to preclude investigations into their inclusion complex behavior. Molecular modeling studies on α-cyclomannin[7] and its 6-deoxy L-analogue α-cyclorhamnin[2] showed that their axially disposed 2-OH points away from the cavity; thus they fairly closely resemble α-cyclodextrin in backbone structure, cavity dimensions, and lipophilicity patterns. The same, in fact, is to be expected for the cyclohexasaccharide with alternating D-mannose and L-rhamnose units. For a cyclogalactin composed of six β(1 → 4)-linked galactopyranose residues, molecular modeling revealed an α-CD-like geometry, yet a distinctly different lipophilicity distribution such that hydrophobic surface regions at the primary hydroxyl face are substantially enlarged.[7]

More profound changes in shape, cavity dimensions, and guest binding properties are to be anticipated for cyclooligosaccharides with axially disposed 3-OH groups in the pyranoid rings—α-cycloallin for example—as these would be directed towards the interior of the cavity, resulting in considerable steric congestion, which is likely to be released by deformation of the $^4C_1$ chairs. Topologically even more interesting appears to be α-cycloaltrin, as the $^4C_1$ and $^1C_4$ conformations of α-altropyranoid chairs are very similar in stability[8] and, hence, in a macrocyclic array several conformations could be formed, such as the all-$^4C_1$ (**1a**) or all-$^1C_4$ forms (**1b**), or even more likely in solution, an equilibrium between the two, that passes through the skew $^0S_2$ geometries (**1c**) of the pyranoid rings (Scheme 1).

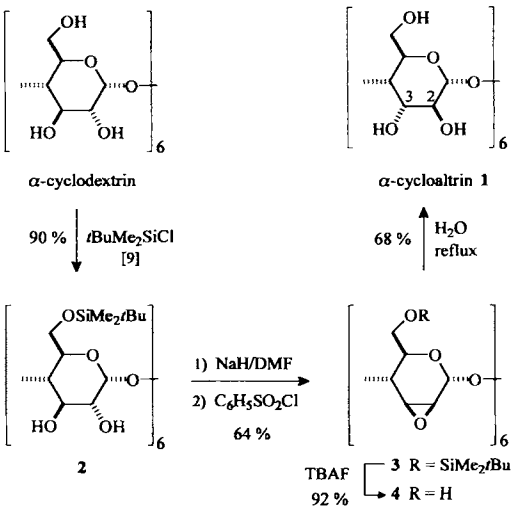
In context with our studies on non-glucose cyclooligosaccharides,[2] we report on a straightforward synthesis of α-cycloaltrin



Scheme 1. Molecular geometries for α-cycloaltrin (**1**), a cyclooligosaccharide composed of six α(1 → 4)-linked D-altropyranose residues. In aqueous solution, a dynamic equilibrium prevails between forms **1a**–**1c**, and various other intermediate conformations; in the solid state, the structure is that of **1d**, comprising a unique alternating sequence of $^4C_1$ and $^1C_4$ altropyranoid chair forms.

(**1**) from α-cyclodextrin its molecular geometries in the solid state, revealing a unique alternating sequence of $^4C_1$ and $^1C_4$ chairs (**1d**), and in solution, in which a dynamic equilibrium of the type **1a** ⇌ **1c** ⇌ **1d** prevails.

The conversion of α-cyclodextrin into **1** started with protection of the six primary hydroxyl groups by the *tert*-butyldimethylsilyl moiety (→ **2**[9]). Ensuing deprotonation of the secondary hydroxyls in **2** by treatment with NaH in DMF was followed by the addition of benzenesulfonyl chloride, which not only effected selective 2-*O*-sulfonylation but, concomitantly, displacement of the 2-sulfonyloxy group by the vicinal 3-OH to elaborate the key intermediate, the 6-*O*-protected 2,3-anhydro-α-cyclomannin (**3**, 64%). Deblocking with TBAF/THF yielded



Scheme 2. Synthesis of **1** from α-cyclodextrin.

4 (92%), which simply by refluxing in water was converted into **1** and isolated by reversed-phase chromatography (68%). The overall yield for the four-step sequence is a satisfactory 36%, but is lower than the conversion of β-cyclodextrin into its all-*altro* analogue (52%[10]), obviously reflecting the lesser steric strain, and hence cleaner reactions, in the cycloheptamer.

Cycloaltrin **1** crystallized with 21 water molecules and is thus embedded in a water matrix in the solid state. Its X-ray structural analysis[11] not only gave evidence of the water molecules built into the crystal lattice (Figure 1), but revealed the unique

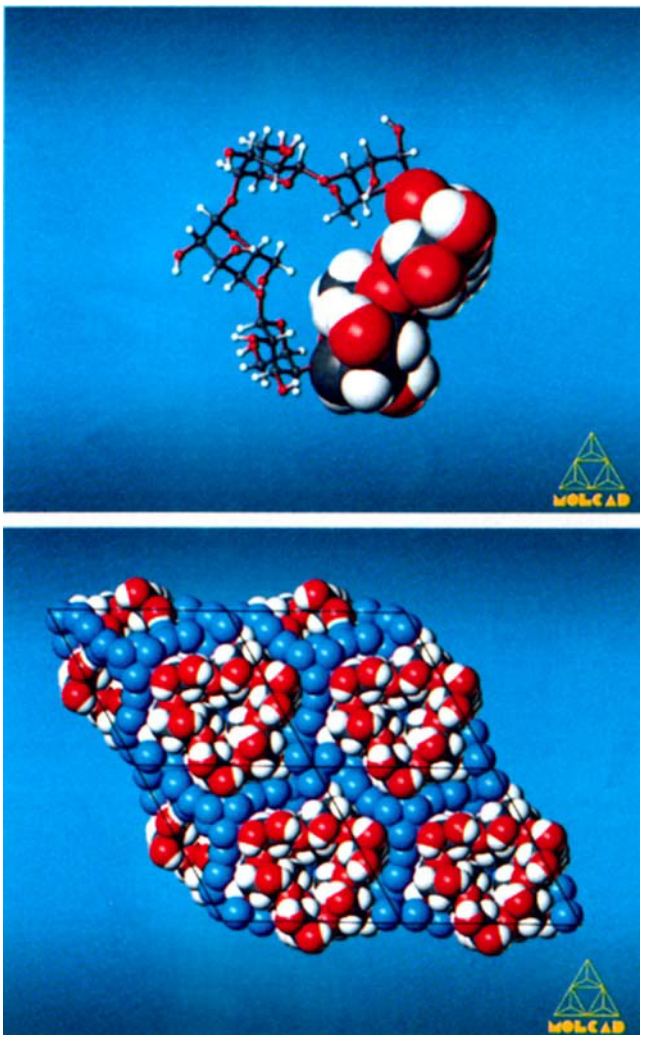

Figure 1. Structure of cyclo-α(1 → 4)-D-altrohexaoside (α-cycloaltrin, **1**) [12]. Top: Ball-and-stick model of the alternating sequence of $^4C_1$ and $^1C_4$ chair conformations of altropyranoid rings; in this way the macrocycle is constructed from three banana-shaped disaccharide units, one of which is depicted in a space-filling representation. Bottom: The macrocycle has a compact, disklike topology, devoid of a cavity and is embedded in a water matrix (**1**·21 H_2O); the disks are stacked in offset layers.

conformational features of the altropyranoid rings: neither the all-$^4C_1$ form **1a** or the all-$^1C_4$ form **1b** is adopted, nor one of the various nonchair conformations conceivable (for instance, **1c**); instead, the altrose units display alternate $^4C_1$ and $^1C_4$ altropyranoid chair conformations (Figure 1, top), entailing the macrocycle to be made up of three banana-shaped disaccharide portions. The molecules are disk-shaped, devoid of a cavity, and stacked in transposed layers (Figure 1, bottom), the space in between being occupied by water molecules.

The closeness of the chair conformations to the ideal is remarkable: nearly perfect geometry in the $^1C_4$-portions with O_4 and C_6 in a fairly antiparallel disposition (167.5°) and with the six pyranoid ring torsion angles in the 52–58° range. The $^4C_1$ chairs, by contrast, are less ideal, as the C_1-C_2-C_3-C_4 torsion angle (−45.7°) reveals some flattening at C-2 and C-3, whilst O_1, O_2, and O_3 are still in a fairly antiparallel disposition (O_1-C_1-C_2-O_2 166.2°, O_2-C_2-C_3-O_3 166.5°). Another salient feature of the structure is the different orientations of the 6-OH groups relative to the pyranoid rings: *gauche–trans* disposition ($\omega = 55.7°$[13]) in the three $^1C_4$ forms in which the CH_2OH groups are directed towards the outside of the macrocycle versus a *gauche–gauche* arrangement ($\omega = -66.8°$[13]) in the three $^4C_1$ forms in which their equatorially disposed CH_2OH groups point towards the center of the macrocycle, thereby closing it (Figure 2). Accordingly, the disk-shaped molecule has a shallow

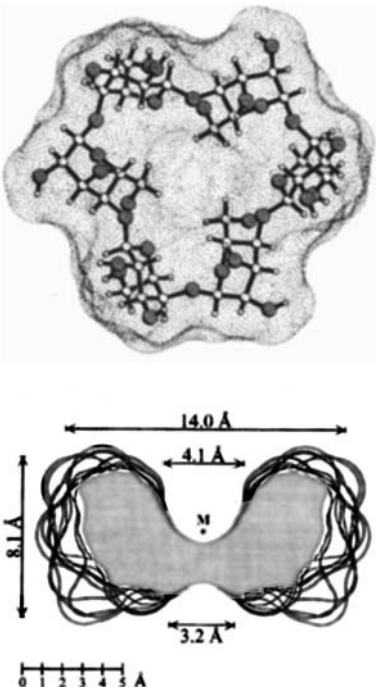

Figure 2. Top: Calculated [12] contact surface (in dotted form) of the solid-state structure of **1** with inserted ball-and-stick-model. The three equatorial hydroxymethyl groups of the $^4C_1$ altropyranoses are directed towards the macrocycle's interior, thereby closing it. Bottom: Cross-sections through the contact surface of **1** (2-OH/3-OH side up) and approximate molecular dimensions; surface contours were obtained for a plane perpendicular to the macrocycle's mean plane through successive 10° rotation steps around the geometrical center *M* and subsequently superimposed.

indentation on one side, and a pronounced hole-like depression on the other. Provided that this disk-shaped, solid-state structure of **1**, already embedded in a water matrix, is retained in aqueous solution, not only separate sets of NMR signals should be observed for the $^4C_1$ and the $^1C_4$ portions, but also distinctly different coupling patterns for the respective pyranoid ring protons as revealed by the calculated *J* values (Table 1).

The high resolution ^1H and ^{13}C NMR spectra of **1** in D_2O,[14] however, unambiguously provide only one set of signals for both the altropyranoid hydrogen atoms and the carbon atoms, and the ^1H coupling constants are an average of those calculated for the $^4C_1$ and $^1C_4$ conformations (Table 1); moreover, the observed *J*-values correlate surprisingly well with those calculated for the all-skew (twist-boat) $^0S_2$ geometry of **1c**, which, in

[a] Angles from the solid-state structure of **1**. [b] Data calculated for the global energy minimum (all-skew form) from HTA simulations. [c] Calculation based on the Karplus-type dependence of H-C-C-H torsion angles on coupling constants, including the electronegativity effect of the substitution pattern by use of the generalized Haasnoot equation [15].

fact, emerges from extensive HTA calculations[16] as the global energy minimum structure. Favored over the $^4C_1/^1C_4$ solid-state geometry by as much as 36 kJ mol^{-1}—a major portion of this energy gain undoubtedly stems from hydrogen bonding between the 2-OH of one altrose moiety to the O-3 of the next—this all-skew form features a cavity that pierces the disk (Figure 3) and a pyranose tilt inverse to that of the cyclodextrins.

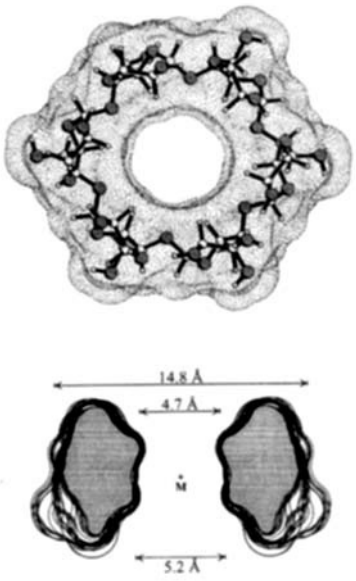

Figure 3. The all-skew (twist-boat) $^0S_2$-geometry of α-cycloaltrin (**1**) emerging from HTA simulations [16] as the global energy minimum structure. Top: Contact surface. Bottom: The contour plots reveal a cavity whose conicity is inverse to that of the cyclodextrins.

Whether, however, the all-skew form **1c** is adopted in aqueous solution—in HTA simulations molecules are in vacuum rather than surrounded by a solvation shell—remains open. If prevalent in aqueous solution, its cavity is conceivably filled with water. Thus not only the six primary, but also the 12 secondary hydroxyl groups are likely to satisfy their hydrogen bonding requirements towards the solvent rather than intramolecularly. This results in a tightly associated first water shell around **1**, which will have to follow any geometry changes within the macrocycle. This hydration sphere could readily be characterized by molecular dynamics (MD) simulations in water, but contributed little to unraveling the nature of the $^4C_1 \rightleftharpoons {}^1C_4$ scrambling observed in the NMR spectra, since on subjection to a 600 ps MD simulation in a box of water,[17] not only the geometry of the hydrated all-skew $^0S_2$ form (**1c**), but also that of the solid-state $^4C_1/^1C_4$ structure **1d**, remained in their respective geometries (Figure 4). Accordingly, no appreciable flexing

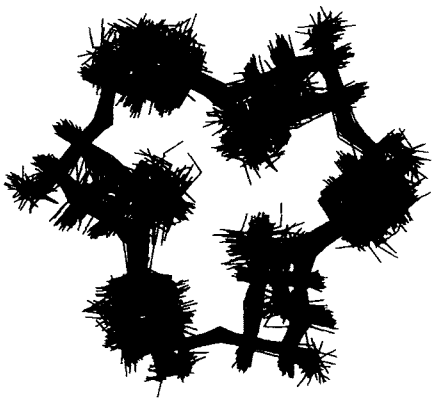

Figure 4. Superimposition of 60 α-cycloaltrin snapshot-geometries taken in 10 ps intervals from a 600 ps molecular dynamic simulation [17] on an assembly comprising α-cycloaltrin in a box of 606 water molecules.

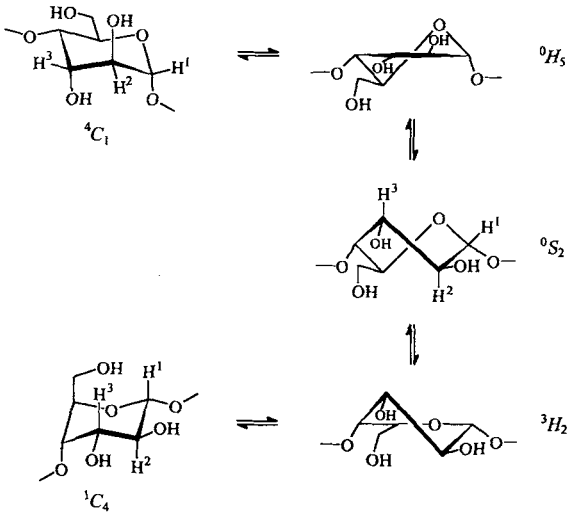
or flip over of the pyranoid chairs or skew forms to alternate topologies takes place within a 600 ps time frame; that is, profound conformational changes like the flipping from $^4C_1$ to $^1C_4$ within the macrocycle are comparatively slow, and require the 10^6 times longer, millisec time frame of NMR spectroscopy to become observable.

The temperature-dependent ^1H and ^{13}C NMR studies proved to be more meaningful in determining the nature of the conformational changes occurring in aqueous solutions of **1**:[14] the coupling constant $J_{2,3}$ of 8.2 Hz at 30 °C in D_2O decreases to 7.6 and 7.1 Hz at 20 and 4 °C, respectively, thereby narrowing the well-separated signal for 3-H; more profound effects are observed for the C-4 and C-5 signals, which, like all other carbon atoms, give rise to sharp singlets at 30 °C but show substantial broadening at 4 °C, which indicates the onset of "freezing out" certain conformations the $^4C_1 \rightleftharpoons {}^1C_4$ equilibrium. Consequently, in water, α-cycloaltrin does not adopt a fixed geometry, such as the all-$^0S_2$-form; rather, the D-altropyranoid rings, tied up in a macrocyclic "straitjacket", adopt a variety of conformations within the $^4C_1 \rightleftharpoons {}^0S_2 \rightleftharpoons {}^1C_4$ pseudorotational "turntable" (Scheme 3), and this necessarily in a coordinated way: flexure of one altropyranoid chair into the intermediate skew $^0S_2$-form via half-chair transition states forces the two adjoining altrose chairs to follow suit, thereby eliciting a consecutive "rolling around" in the probably elliptically distorted macrocycle. NMR data provide an averaged picture thereof and give evidence through the comparatively large $J_{1,2}$ and, particularly, $J_{2,3}$ couplings that the position of the equilibrium in water at 30 °C lies pronouncedly on the $^1C_4 \rightleftharpoons {}^0S_2$ side.

Experimental Section

3: To a solution of NaH (0.40 g, 10.8 mmol) in anhydrous DMF (40 mL) was added **2** (1.0 g, 0.6 mmol) [9], and the mixture was kept under N_2 at 60 °C for 2 h. After cooling, benzenesulfonyl chloride (568 μL, 4.32 mmol) in anhydrous DMF (10 mL) was injected followed by stirring at room temperature for 30 min. Filtration and flash chromatography on a silica gel column (4 × 15 cm) with benzene/EtOAc (4/1, 250 mL) afforded 600 mg (64%) of **3**; m.p. 203 °C (decomp.); $[\alpha]_D^{16} = +70.1$ ($c = 0.36$ in THF). ^1H NMR (500 MHz, $CDCl_3$, relevant data): $\delta = 3.11$ (d, 1H, 2-H), 3.32 (d, 1H, 3-H), 3.56 and 4.24 (two d, 1H, 6-H_2), 3.64 (d, 1H, 4-H), 3.93

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3617-1901 $ 17.50+.50/0



Scheme 3. The chair/half-chair/skew pseudorotational "turntable" between D-altropyranoid rings in $^4C_1$ and $^1C_4$ conformation [18]. Due to the comparatively large $J_{1,2}$ and $J_{2,3}$ values found for **1** (4.7 and 8.2 Hz, respectively, in D_2O), the conformational equilibrium in aqueous solution lies on the $^1C_4 \rightleftharpoons {}^3H_2 \rightleftharpoons {}^0S_2$ side.

(m, 1H, 5-H), 5.16 (s, 1H, 1-H), $J_{1,2}$ and $J_{3,4} = 0$, $J_{2,3} = 3.7$, $J_{4,5} = 11.5$ Hz. MS: $[M^+]$ not detectable. Elemental analysis calculated for $C_{72}H_{132}O_{24}Si_6$: C 55.78, H 8.58; found: C 55.55, H 8.68.

4: A 1 M solution of Bu_4NF in THF (4.6 mL) was added to a solution of silyl epoxide **3** (1.0 g, 0.65 mmol) in anhydrous THF (90 mL) under N_2, and the mixture was stirred at 40 °C for 4 h. Concentration in vacuo, addition of methanol (10 mL), and cooling in a refrigerator overnight resulted in a precipitate: 511 mg (92%) of **4**; m.p. 166 °C (decomp.); $[\alpha]_D^{18} = +83.6$ ($c = 0.34$ in DMSO). ^1H NMR (500 MHz, [D_5] pyridine): $\delta = 3.40$ (d, 1H, 2-H), 3.67 (d, 1H, 3-H), 4.10 (m, 1H, 5-H), 4.30 (m, 2H, 6-H_2), 4.47 (d, 1H, 4-H), 5.57 (s, 1H, 1-H), $J(1,2)$ and $J(3,4) = 0$, $J(2,3) = 3.5$, $J(4,5) = 11.6$ Hz; FAB-MS: m/z: 865 $[M^+]$.

1: A solution of epoxide **4** (1.0 g, 1.14 mmol) in distilled water (250 mL) was heated at reflux for 5 days. Concentration of the mixture in vacuo and chromatography on a reversed-phase column (Merck Lobar, size C) with water yielded **1** (765 mg (68%); m.p. 215 °C (decomp.); $[\alpha]_D^{20} = +70.5$ ($c = 0.3$ in H_2O). ^1H NMR (800 MHz [14], D_2O, 30 °C): $\delta = 3.91$ (dd, 1H, 6-H_a), 4.00 (m, 2H, 2-H, 6-H_b), 4.03 (dd, 1H, 3-H), 4.14 (dd, 1H, 4-H), 4.44 (sext, 1H, 5-H), 4.95 (d, 1H, 1-H), $J_{1,2} = 4.73$, $J_{2,3} = 8.19$, $J_{3,4} = 3.71$, $J_{4,5} = 5.32$, $J_{5,6a} = 3.60$, $J_{5,6b} = 3.46$, $J_{6,6} = 12.42$ Hz. ^{13}C NMR (200 MHz [14], D_2O, 30 °C): $\delta = 63.05$ (C-6), 71.98 (C-3), 73.26 (C-2), 76.07 (C-5), 79.65 (C-4), 105.53 (C-1). FAB-MS: m/z: = 973 $[M + H^+]$), 995 $[M + Na^+]$.

[11] Crystal structure analysis of **1**: $C_{36}H_{60}O_{30} \cdot 21\,H_2O$, $M_r = 1351.18$, hexagonal, space group $P6_3$, $a = b = 17.241(3)$, $c = 13.323(2)$ Å, $V = 3430(1)$ Å^3, $Z = 2$, $\rho = 1.268$ g cm^{-1}, $\mu(Mo_{K\alpha}) = 0.115$ mm^{-1}, crystal dimensions $0.5 \times 0.15 \times 0.125$ mm, $T = 293$ K. Of 12711 reflections collected on a STOE IPDS diffractometer, graphite-monochromated $Mo_{K\alpha}$ ($\lambda = 0.71069$ Å) radiation, 2253 are independent ($R_{int} = 0.0284$). The structure was solved by direct methods (SHELXS-86) and successive Fourier difference synthesis. Refinement (on F^2) performed by full-matrix least squares method with SHELXL-93. $R(F)$ 0.0568 for 2036 reflections with $I \geq 2\sigma I$, $wR(F^2) = 0.1604$ for all 2253 reflections ($w = 1/(\sigma^2(F_o^2) + (0.1189P)^2 + 0.57P)$; $P = (F_o^2 - 2F_c^2)/3$. All non-hydrogen atoms (except one oxygen atom of the solvent water molecule) were refined anisotropically. Hydrogen atoms on the cycloaltrin were considered in calculated positions with the 1.2 U_{eq} value of the corresponding bound atom. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100196. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code +(1223) 336-033; e-mail: deposit@chemcrys.cam.ac.uk).

[16] High-temperature annealing (HTA) calculations were performed with a force field program specially adapted to carbohydrates, comprising application of the verlet integrator in the MD simulation program CHARMM with a time step of 1 fs at constant temperature and dielectric constant $\varepsilon = 1$. Every 1000 fs the respective conformation from the MD trajectories at 1200 K (4059 ps) was allowed to cool down to 300 K with a rate of 10 K fs^{-1}, was held there for an additional 1100 fs, and was subsequently fully energy-minimized by an adapted Newton–Raphson algorithm of the CHARMM22 program package with a convergence criterion of 10^{-7} kcal mol^{-1}. For **1**, a total of 2736 (67%) different conformers (corresponding to 16416 altrose units) underwent geometry analysis.

[17] The CHARMM force field with **1** in the center of a truncated octahedron ($V \approx 16400$ Å^3) was used for the MD simulations, and the remaining empty space was filled with water molecules.

Selenoboratoborates $[B_{12}(BSe_3)_6]^{8-}$: A New Class of Chalcogen-Substituted Icosahedral Boron Clusters

Jörn Küper, Olaf Conrad, and Bernt Krebs*

Dedicated to Professor Hans Georg von Schnering

Binary and ternary boron–sulfur and boron–selenium compounds are accessible through high-temperature solid-state syntheses starting from the elements or binary components. This novel class of compounds, which has been established over the past two decades, shows some remarkable structural principles and interesting physical properties. For instance, there are compounds with trigonal-planar coordinated boron atoms such as isolated BS_3^{3-} ions,[1,2] dinuclear strained B_2S_2 four-membered ring systems $B_2S_4^{2-}$,[3] trinuclear $B_3S_6^{3-}$ ions,[2,4-6] dinuclear $B_2S_5^{2-}$ ions with trithiadiborolane rings,[7] octanuclear porphin-analogous B_8S_{16} molecules, and planar two-dimensional polymers formed by interconnected B_2S_2 and B_3S_3 rings.[4,8,9] Thioborates with tetrahedral coordination of the boron atoms show a structural diversity that ranges from chains of corner-sharing tetrahedra over layers of corner- and edge-sharing tetrahedra[10,11] to three-dimensional macrotetrahedra.[4,12-17] Lithium and silver thioborates such as $Ag_6B_{10}S_{18}$, $Li_5B_7S_{13}$, and $Li_9B_{19}S_{33}$ are particularly interesting for use as fast ionic conductors. The only known example of a compound with an isolated BSe_3^{3-} ion is Tl_3BSe_3.[1] In all other reported selenoborates a tetrahedrally coordinated boron atom is present. They form polymeric chain structures with spirocyclically fused B_2Se_3 and B_2Se_4 rings.[11]

The novel chalcogenoborate $Cs_8[B_{12}(BSe_3)_6]$ was obtained from cesium selenide, boron, and selenium by means of high-temperature synthesis. It contains the first B_{12} icosahedron completely saturated with chalcogen ligands (Figure 1). Thus, unlike in all previous chalcogenoborate syntheses, the B_{12} icosahedron is preserved rather than being fragmented by nucleophilic attack. The linkage of trigonal-planar BSe_3 units to an intact B_{12} fragment may be interpreted as an intermediate of the stepwise formation of the "conventional" selenoborates. Evidently, this was not recognized because of the long reaction times in earlier experiments.

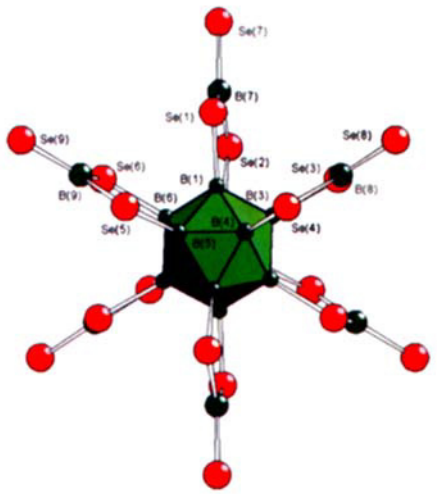

Figure 1. Crystal structure of the $[B_{12}(BSe_3)_6]^{8-}$ ion in cesium hexaselenoborato-*closo*-dodecaborate. Average bond lengths [Å]: B–B 1.783 (range: 1.753(12)–1.803(12)), B(cluster)–Se_{endo} 1.996 (range: 1.981(8)–2.011(8)), B(trig.)–Se_{endo} 1.979 (range: 1.952(8)–1.999(8)), B–Se_{exo} 1.902 (range: 1.886(8)–1.913(8)). Average antipodal B–B distance 3.39 Å.

The unusual cluster $Cs_8[B_{12}(BSe_3)_6]$ contains centrosymmetric, molecular $[B_{12}(BSe_3)_6]^{8-}$ units. Trigonal-planar selenoborate entities functioning as bidentate ligands complete the B_{12} icosahedron to form a persubstituted *closo*-dodecaborate ion. The complex $[B_{12}(BSe_3)_6]^{8-}$ ions are linked through Cs^+ ions (Figure 2), which are eight- and ninefold coordinated by selenium atoms.[22] Thus, the cesium hexaselenoborato-*closo*-dodecaborate is the first representative of a new type of boron cluster compounds.

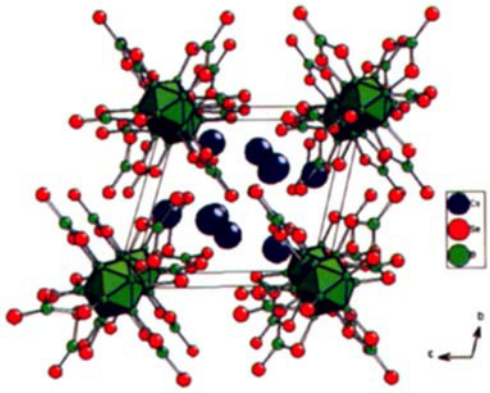

Figure 2. Unit cell of $Cs_8[B_{12}(BSe_3)_6]$. Average Cs–Se distance [Å] in eightfold coordination (Cs(1), Cs(2), Cs(3)) 3.737 (range: 3.533(2)–3.953(2)), and in ninefold coordination (Cs(4)) of the metal atoms 3.941 Å (range: 3.675(2)–4.405(2)).

The electronic counts of the selenium-substituted dodecaborate unit and the hydro-*closo*-dodecaborate are identical. The *closo* cluster contains $2n + 2$ binding electrons for the B_{12} unit and therefore obeys Wade's rules for cluster compounds. Six negative charges are located on the terminal selenium atoms, leaving two negative charges on the central cluster. The comparison between six pairs of hydride ligands in the *closo*-$[B_{12}H_{12}]^{2-}$ ion and the six B–Se_{exo} units present here reveals that each of the latter formally contributes an additional electron, resulting in an overall charge of -8. The antipodal boron–boron distances differ very little due to the symmetrical arrangement of the BSe_3 units (Figure 1). The two types of boron–selenium bonds in the chelate-type B_3Se_2 rings are almost the same length (B(cluster)–Se 1.996 Å and B(trig.)–Se 1.979 Å), whereas the B–Se bonds to the exocyclic selenium atoms, which carry a large portion of the negative charge of the $[B_{12}(BSe_3)]^{8-}$ ion, are significantly shorter (1.902 Å) (Figure 1).

The $[B_{12}(BSe_3)_6]^{8-}$ ion is of additional general interest because of the complete substitution of the *closo*-borate by non-hydrogen atoms. To date this is only known for a few perhalogenated and perhydroxide-substituted *closo*-dodecaborates.[23-26] Replacement of the hydride ligand atoms by selenium-containing substituents has been shown to yield $[B_6(SeCN)_6)]^{2-}$, a per-substituted *closo*-hexaborate.[27] Monosubstituted selenocyanatoborates provided the first indications of the ability of selenium to coordinate to a B_{12} icosahedron.[28]

These results open the way to a series of investigations, which, on the one hand should contribute to the understanding of the steps involved in the reaction of boron with chalcogens, and on the other should provide access to a new field of interesting materials, for example, by replacement of selenium by its homologue sulfur. The size of the selenoboratoborate ion is particu-

larly interesting with regard to its use with small cations like Li^+, Ag^+, or Cu^+ to synthesize new ionic conductors. Another strategy for synthesizing polyhedric chalcogenoborates is conceivably available by starting from metal borides with preformed B_{12}, B_6, or other clusters rather than from elemental boron.

Experimental Section

All experiments were carried out in a dry nitrogen atmosphere in a glove box.

$Cs_8[B_{12}(BSe_3)_6]$ was prepared by reacting stoichiometric amounts of dicesium monoselenide (from elemental Cs and HgSe), boron (powdered, amorphous, purity 95%, Alfa-Ventron), and selenium (powdered, purity 99%, Merck) in a molar ratio of 2:9:7. In a quartz glass ampoule coated with glassy carbon the reaction mixture was heated up to 700 °C for 2 h and subsequently annealed (10 h at 600 °C, 24 h at 400 °C, 120 h at 200 °C). Powder diffraction of the resulting pale gray crystalline product showed only traces of impurities. A colorless crystal was chosen for single-crystal X-ray structure determination.

The Self-Assembly of a Switchable [2]Rotaxane**

M.-Victoria Martínez-Díaz, Neil Spencer, and J. Fraser Stoddart*

Catenanes and rotaxanes are molecular compounds[1] that hold considerable promise for use in molecular devices as a consequence of the relative movements of their ring and dumbbell-shaped components. Initially researchers learned how to make simple rotaxanes,[2] followed by degenerate rotaxanes with molecular shuttling characteristics,[3] and eventually nondegenerate rotaxanes whose dynamic properties could be addressed selectively with external stimuli of a chemical, electrochemical, or photochemical nature to induce them to behave as molecular switches.[4] However, to our knowledge, no constitutionally asymmetric, two-site [2]rotaxane that exhibits 100% selectivity for one of the binding sites between ring and dumbbell-shaped components has yet been reported. Here, we describe the self-assembly of a [2]rotaxane that possesses two very dissimilar cationic binding sites within its dumbbell-shaped component—specifically, a secondary dialkylammonium center and a bipyridinium unit—each of which shows different affinities[5] toward dibenzo[24]crown-8 (DB24C8), the ring component of the [2]rotaxane. We also report the pH-controlled shuttling of the DB24C8 ring between the two very different recognition sites, or "stations", in this simple molecular shuttle.

The [2]rotaxane **2**-H·3PF_6 was self-assembled (Scheme 1) by using a template-directed threading approach.[6] A pseudorotaxane[7, 8] [DB24C8·**1**-H][PF_6]$_2$ was formed initially in solution between the DB24C8 and **1**-H·2PF_6,[9] which already contains the ammonium center and a stopper (3,5-di-*tert*-butylbenzyl) to prevent unthreading of the ring. Subsequently a single stoppering reaction with 3,5-di-*tert*-butylbenzyl bromide led to the formation of the bipyridinium dicationic unit and the dumbbell-shaped component.[10]

The ^{1}H NMR spectrum of **2**-H·3PF_6 recorded in CD_3COCD_3 at 20 °C shows signals corresponding to the formation of a [2]rotaxane. The spectrum (Figure 1b) demonstrates that the DB24C8 ring binds selectively with the secondary dialkylammonium center, since the characteristic resonance at $\delta = 4.87–4.85$ for the four CH_2 protons adjacent to the NH_2^+ group is observed. These protons experience a downfield shift of about $\Delta\delta = 0.2$ upon association with DB24C8: compare the

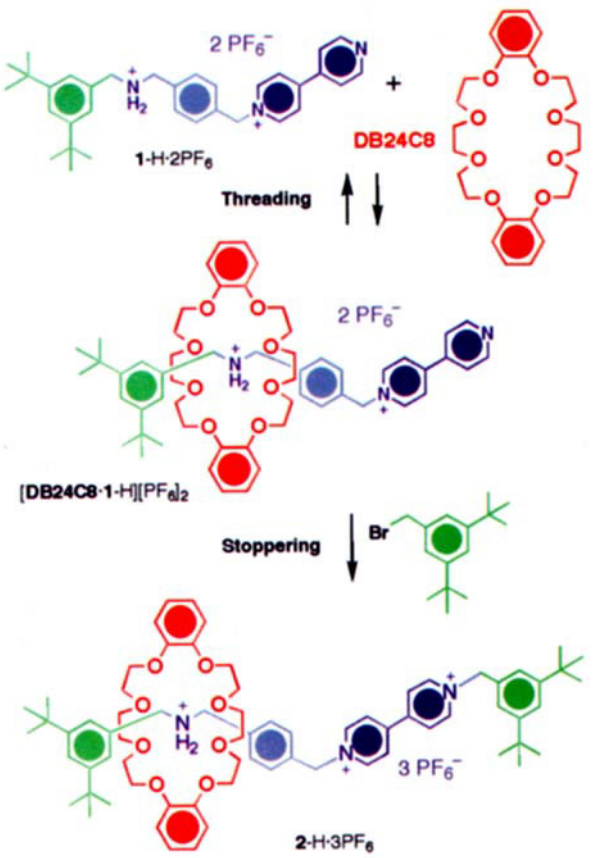

Scheme 1. The self-assembly approach to the [2]rotaxane **2**-H·3 PF_6: threading followed by stoppering.

^{1}H NMR spectrum (Figure 1a) of the dumbbell-shaped compound **3**-H·3 PF_6 with that of the [2]rotaxane **2**-H·3 PF_6 (Figure 1b). This selective binding was confirmed by one-dimensional ^{1}H NMR NOE doubled-pulsed field-gradient spin-echo experiments[11]—GOESY (gradient enhanced nuclear Overhauser effect spectroscopy)—carried out at 400 MHz at room temperature. Selective irradiation of the protons (C) on the *para*-xylyl spacer closest to the NH_2^+ center showed that, in addition to the expected intramolecular NOEs, intercomponent NOEs with some of the OCH_2 protons in the DB24C8 were observed. Since the two faces of the crown ether are diastereotopic, NOEs are observed with protons on only one of its faces. The same effect was noted when the protons in *ortho* positions (A) in the stopper closest to the NH_2^+ center were irradiated selectively. Moreover, since association and dissociation between the NH_2^+ center and DB24C8 is expected to be slow on the ^{1}H NMR time scale,[8] we should observe another set of signals for a second translational isomer if the DB24C8 ring resides anywhere else along the dumbbell-shaped component other than on the NH_2^+ center. In order to establish that the [2]rotaxane **2**-H·3 PF_6 exists as a single translational isomer, a solution of **2**-H·3 PF_6 in CD_3COCD_3 was cooled down to −80 °C. Since no additional set of resonances could be detected, it may be concluded that the DB24C8 ring is bound to the NH_2^+ center with a selectivity of at least 98% in the temperature range between −80 °C and +31 °C.

One reason for the synthesis of interlocked molecules, such as the [2]rotaxane **2**-H·3 PF_6 incorporating an NH_2^+ center and a bipyridinium unit, is to develop them as pH-sensitive or electrochemically driven molecular switches. Since we have established that the potentially mobile component of **2**-H^{3+}—that is the

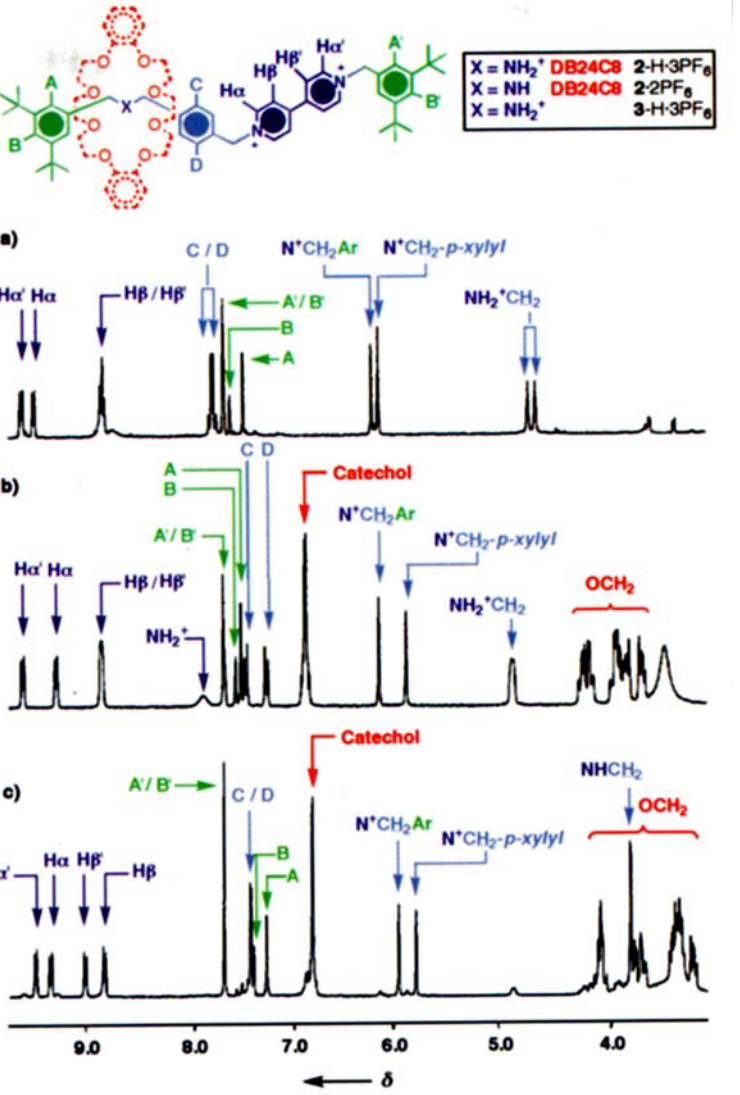

Figure 1. Partial ^{1}H NMR spectra (300 MHz, CD_3COCD_3, room temperature): a) the dumbbell-shaped compound **3**-H·3 PF_6 (ca. 7 mM); b) the [2]rotaxane **2**-H·3 PF_6 (ca. 4.7 mM); c) the deprotonated [2]rotaxane **2**·2 PF_6, after addition of 1.5 μL (2.4 mol equiv) of iPr_2NEt to the solution.

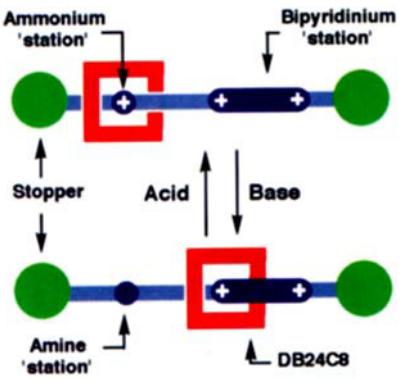
DB24C8 ring—resides initially on the NH_2^+ station, it should be possible (Scheme 2) to deprotonate the NH_2^+ center with base and "drive" the ring to the bipyridinium station. The choice of



Scheme 2. A cartoon of the switchable [2]rotaxane **2**-H·3 PF_6 showing how the motion of the ring component (red) is driven by deprotonation or reprotonation of the ammonium/amine station in the dumbbell-shaped component (blue and green). The fact that the DB24C8 component interacts asymmetrically with the bipyridinium station is conveyed by the off-center location of the ring with respect to the station.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3617-1905 $ 17.50+.50/0

the base for deprotonation of the NH_2^+ center was not straightforward, since the bipyridinium unit is very sensitive to nucleophilic bases. Addition of a slight excess of a number of bases (e.g. 2,6-lutidine, dibenzylamine, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), quinuclidine, hexamethyldisilazane, diisopropylethylamine) to a CD_3COCD_3 solution containing equimolar amounts of DB24C8 and benzyl viologen and dibenzylammonium hexafluorophosphate allowed us to identify an appropriate base for triggering this molecular switching action of **2**-H^{3+}. The deprotonation can be followed by ^1H NMR spectroscopy by noting the disappearance of the multiplet assigned to the CH_2 protons adjacent to the NH_2^+ center. The stability of the bipyridinium dication was monitored by checking the signals for the α-CH and β-CH bipyridinium protons. In the presence of weak bases, such as 2,6-lutidine or dibenzylamine, although the benzyl viologen is stable, the NH_2^+ center is not deprotonated. Upon addition of a much stronger base, such as DBU, or a nucleophilic one such as quinuclidine, deprotonation does occur but the solution turns dark green, indicating the decomposition of the benzyl viologen. Eventually we found that diisopropylethylamine is the ideal base. The ^1H NMR spectrum (Figure 2b) shows that total deprotonation of the NH_2^+ center occurs, while the benzyl viologen is left intact—its resonances only being broadened in the presence of iPr_2NEt. Addition of trifluoroacetic acid (TFA) to this solution results in the reprotonation of the dibenzylamine (Figure 2c) and the recovery of the 1:1 complex between the dibenzylammonium cation and DB24C8. Despite the success of this association–dissociation experiment, no remarkable changes in the ^1H NMR spectrum that might indicate complex formation between the benzyl viologen and DB24C8 were observed. Moreover, the solution remained pale yellow all the time. Since the complex between dibenzylammonium hexafluorophosphate and DB24C8 is colorless, the pale yellow color of the 1:1:1 mixture may be a consequence of charge transfer interactions between the catechol rings of the DB24C8 and the viologen dication.[12] Clearly, once the NH_2^+ center is deprotonated, the affinity of the DB24C8 ring for the viologen is so low that most of the crown ether remains uncomplexed in solution.

This observation poses several questions: can the lack of binding be overcome in a rotaxane in which the DB24C8 ring cannot be expelled from the molecule once the NH_2^+ center is deprotonated? Would it be possible to oblige the DB24C8 ring to associate[12] with the bipyridinium unit in a cliplike manner? In order to test this hypothesis, an excess of iPr_2NEt was added to a solution of **2**-H·3PF_6 in CD_3COCD_3. Immediately, a change in the color of the solution from colorless to yellow was observed, indicative of charge transfer interactions between the catechol rings of the DB24C8 ring and the bipyridinium dication.[12] Moreover, the ^1H NMR spectrum (Figure 1c) of **2**·2PF_6 shows dramatic changes in chemical shifts relative to those for **2**-H·3PF_6 (Figure 1b)—especially in the resonances for the bipyridinium and *para*-xylyl protons—indicating that the DB24C8 ring interacts in an asymmetric fashion with the bipyridinium station. ^1H NMR spectra of the deprotonated [2]rotaxane **2**·2PF_6 from −80 °C to +31 °C in CD_3COCD_3 at 400 MHz revealed that the DB24C8 ring resides *exclusively* on the bipyridinium station. Although the spectrum broadens below −40 °C, no additional set of resonances for another translational isomer are observed. On subsequent addition of TFA to the CD_3COCD_3 solution of the [2]rotaxane **2**·2PF_6, we demonstrated that the system is reversible, since the recorded ^1H NMR spectrum once again shows signals for the translational isomer in which the macrocycle resides on the NH_2^+ station.

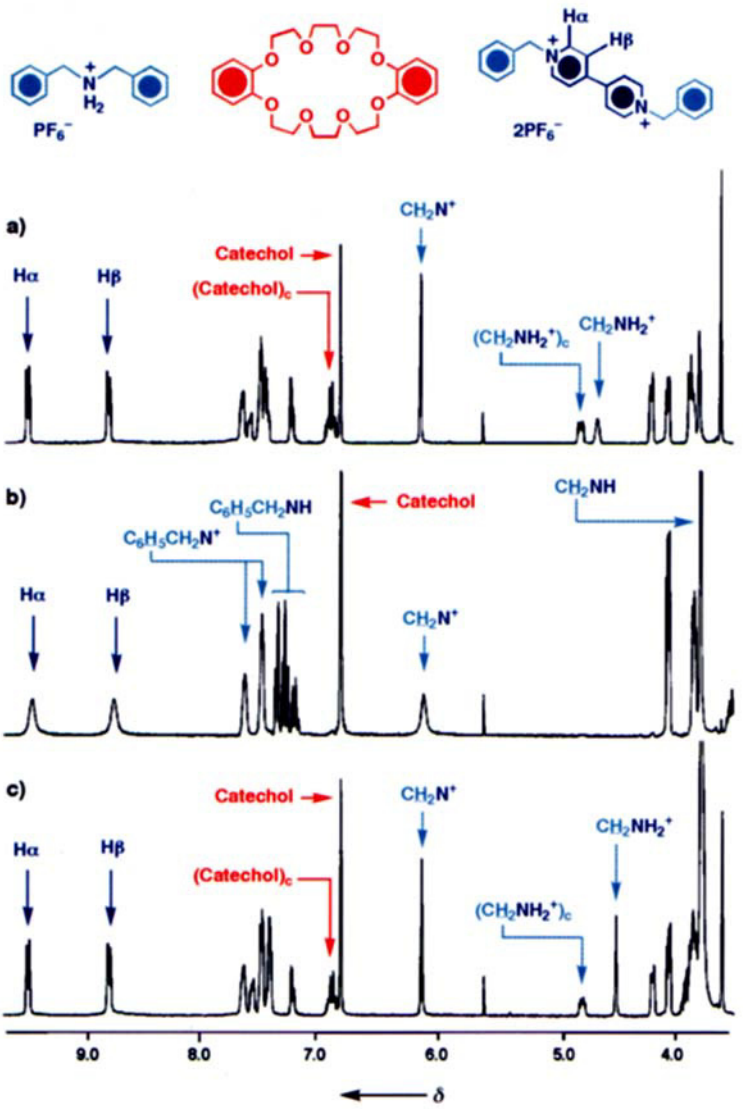


Figure 2. Partial ^1H NMR spectra (300 MHz, CD_3COCD_3, room temperature): a) an equimolar mixture of dibenzylammonium hexafluorophosphate, DB24C8, and benzyl viologen bis(hexafluorophoshate) (ca. 10 mM); b) after addition of 2 μL (1.4 mol equiv) of iPr_2NEt to the CD_3COCD_3 solution, and c) after subsequent addition of 2 μL (3.2 mol equiv) of TFA to the basic solution. The subscript *c* is used in the annotation to indicate signals corresponding to the 1:1 complex formed between the NH_2^+ cation and DB24C8.

In conclusion, we have shown that the dethreading and rethreading of the [2]pseudorotaxane[8] formed between the dibenzylammonium cation and DB24C8 can be controlled chemically by the addition of iPr_2NEt or TFA. However, after the dibenzylammonium cation is deprotonated, complexation of the crown ether with the benzyl viologen also present in the solution is not observed. In order to obtain an efficient switching process in which the bipyridinium dication is bound by the DB24C8 ring upon the transformation of the NH_2^+ center into a neutral amino group, a new [2]rotaxane **2**-H^{3+} was synthesized; in this compound the DB24C8 ring is bound mechanically to a dumbbell-shaped component incorporating both a secondary dialkylammonium center and a bipyridinium dicationic unit. The [2]rotaxane **2**-H·3PF_6 constitutes the most selective switchable molecular shuttle reported to date. When the NH_2^+ center is protonated, the DB24C8 ring resides *exclusively* on this station. The affinity of the crown ether for this NH_2^+ center is decreased dramatically upon the addition of a nonnucleophilic base such as iPr_2NEt—which deprotonates the NH_2^+ center—

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3617-1906 $ 17.50+.50/0

and the DB24C8 ring moves to the bipyridinium station. The process is reversible upon addition of TFA, which reprotonates the NH_2^+ center.

Experimental Section

2-H·3PF_6: A solution of 3,5-di-*tert*-butylbenzyl bromide (300 mg, 1.06 mmol) in $CHCl_3$ (5 mL) was added to a stirred suspension of **1**-H·2PF_6 (150 mg, 0.195 mmol) and DB24C8 (200 mg, 0.446 mmol) in $CHCl_3$ (15 mL). The suspension was heated under reflux for 4 days until it became a clear solution. Upon cooling, the reaction mixture was concentrated in vacuo to give a solid residue, which was purified by column chromatography (SiO_2; gradient elution with CH_2Cl_2/MeOH in the proportions 1/0, then 9/1 and then 7/1) to afford a pale yellow solid and characterized as the hydrochloride salt **2**-H·2Cl (97 mg, 40%). After counterion exchange (NH_4PF_6/H_2O/Me_2CO), **2**-H·3PF_6 was isolated as a beige solid (116 mg, 95%); m.p. 169–173 °C; ^{1}H NMR (300 MHz, CD_3COCD_3, 20 °C): δ = 9.55 (d, 2H), 9.23 (d, 2H), 8.80 (d, 2H), 8.79 (d, 2H), 7.62 (s, 3H), 7.51 (s, 1H), 7.46 (s, 2H), 7.41, 7.21 (AA'XX' system, 4H), 6.86–6.83 (m, 8H), 6.14 (s, 2H), 5.88 (s, 2H), 4.87–4.85 (m, 4H), 4.22–3.58 (m, 24H), 1.30 (s, 18H), 1.23 (s, 18H); FABMS (*m*-NBA): *m/z* 1420 [M – PF_6]$^+$, 1275 [M – 2PF_6]$^+$, 1129 [M – 2PF_6 – HPF_6]$^+$.

[9] Compound **1**-H·2PF_6 was prepared in good overall yield (49%) as follows: 3,5-di-*tert*-butylbenzaldehyde was condensed with methyl 4-aminomethylbenzoate, and the resulting imine was reduced in situ with $NaBH_4$ to give the secondary amine. After reduction of the ester function with $LiAlH_4$ and subsequent reaction of the alcohol derivative as hydrochloride salt with an excess of $SOCl_2$, the benzylic chloride in the form of the hydrochloride salt was obtained. Reaction of this compound with a fourfold excess of 4,4'-bipyridine and subsequent counterion exchange (NH_4PF_6/H_2O/Me_2CO) gave **1**-H·2PF_6.

[10] The dumbbell-shaped component of the [2]rotaxane **2**-H·3PF_6 was prepared as compound **3**-H·3PF_6 (Figure 1) in its own right by treating **1**-H·2PF_6 (50 mg, 0.065 mmol) with 3,5-di-*tert*-butylbenzyl bromide (100 mg, 0.35 mmol) in MeCN (10 mL). The reaction mixture was transferred to a Teflon ultrahigh pressure reaction vessel and subjected to a pressure of 12 kbar at 50 °C for 5 days. After removal of the solvent, the crude product was purified by column chromatography (SiO_2: gradient elution with CH_2Cl_2/MeOH 9/1 and then MeOH/2 M NH_4Cl/$MeNO_2$ 7/2/1). After counterion exchange (NH_4PF_6/H_2O/Me_2CO), the dumbbell-shaped compound **3**-H·3PF_6 was isolated as a beige solid (48 mg, 66%). M.p. 187–193 °C (decomp.); ^{1}H NMR (300 MHz, CD_3COCD_3, 20 °C): δ = 9.53 (d, 2H), 9.42 (d, 2H), 8.78 (d, 2H), 8.76 (d, 2H), 7.74, 7.70 (AA'XX' system, 4H), 7.61 (s, 3H), 7.56 (s, 1H), 7.43 (s, 2H), 6.20 (s, 2H), 6.14 (s, 2H), 4.70 (s, 2H), 4.63 (s, 2H), 1.30 (s, 18H), 1.28 (s, 18H); FABMS (*m*-NBA): *m/z* 972 [M – PF_6]$^+$, 827 [M – 2PF_6]$^+$, 681 [M – 2PF_6 – HPF_6]$^+$.

Isocyanates Yesterday's News? Think Again!

Chemistry and Technology of Isocyanates. By *H. Ulrich*. Wiley, New York, 1996. 489 pp., hardcover £ 80.00.—ISBN 0-471-96371-2

It is now nearly 150 years since the first synthesis of an isocyanate by Wurtz in 1848. In this book *Chemistry and Technology of Isocyanates,* Henri Ulrich deals with a subject that forms the basis for the 6 Mt/year production of polyurethanes. These are among the most important of polymeric materials, not only in terms of the quantities produced but also because of the enormous variety of polyurethane products and the ability to tailor their properties for different uses.

For this work of almost 500 pages the author has chosen a straightforward and effective structure, dividing it into two main parts: monoisocyanates and diisocyanates. These are subdivided according to the other functional groups present, the synthesis of the compounds, and their reactions. In both parts of the book the chemistry of the isocyanates is described in detail, but in a very effective and concise form, illustrated by over 1100 reaction schemes, mostly with several stages. There are also 80 tables listing reaction parameters. The enormous amount of factual information, taken from almost 2500 publications, is skillfully presented in a form that makes for easy reading, with particular attention to the latest developments in the chemistry of isocyanates. The following is a brief outline of the chapters, mentioning a few highlights.

The treatment of monoisocyanates occupies two-thirds of the book. It ranges over all the areas in which isocyanates are used in agricultural and pharmaceutical chemistry, by dealing with compounds that have aryl, alkenyl, halogen, carbonyl, thiocarbonyl, sulfur, or phosphorus functionalities in addition to the isocyanato group. Thus, for example, the phosphorus-containing compounds offer an elegant route to phosphaheterocycles. Also [2+2]-, [2+3]-, and [2 + 4]-cycloaddition reactions of isocyanates are important for the synthesis of N-heterocycles and alkaloids.

Although phenolic monoisocyanates are of some importance in polymer chemistry, diisocyanates play the dominant role in the polymer area. The two market leaders, MDI and TDI, currently have a combined annual production of about 2.5 Mt, with a strong upward trend. These two, together with other aromatic and nonaromatic diisocyanates, form the basis for the many different polyurethane plastics. The author adds interest to the chapter by including, on page 428, some fascinating highlights from the history of polyurethanes.

Ulrich also treats the synthesis of isocyanates in great detail. With regard to the phosgene-based processes, diphosgene and triphosgene have become important as alternatives to phosgene, whereas nitrene intermediates have become established in the area of non-phosgene processes. The proposed route whereby nitroarenes are allowed to react with carbon monoxide may have the potential to become a low-cost alternative. Processes based on the reactions of isocyanates have special advantages for large-scale industrial production, since addition reactions do not generate waste emissions. This subject of environmental considerations is treated in a short additional section following the two main ones. Here the author discusses on the one hand accident risks and the toxicity and safety aspects of isocyanate chemistry, and on the other hand the use of feedstocks from renewable sources, such as furfural.

Even in such an excellent work as this, there are a few minor details that could be improved. The summary tables 10, 12, 13, and 40–42 in Part 1 and 19–22 in Part 2 should include the relevant literature references, which would allow the reader to extract the required information more quickly. Perhaps this improvement could be incorporated into a second edition of the book, which one hopes will appear in due course.

The author has benefited from discussions with many experts throughout the world and with relevant manufacturers, and this has contributed significantly to the great value of the work. The book is written in such a way that it can be understood by any chemist, but by virtue of the wealth of detailed information provided it will be most useful to specialists working in the area of isocyanate chemistry. It is emphatically recommended for the latter readers, and also for those who intend to become professionally involved in this field, or who wish to gain a more detailed knowledge of it.

Dictionary of Renewable Resources. Edited by *H. Zoebelein*. WILEY-VCH, Weinheim, 1997. 320 pp., hardcover DM 198.00.—ISBN 3-527-30075-9

In recent years there has been increasing interest in renewable raw materials as feedstocks for the chemical industry. The use of such materials could save fossil resources, improve the CO_2 balance in the atmosphere, help to reduce agricultural surpluses, and lead to new products with biocompatible properties. Although there has been some progress in using renewable resources, no real breakthrough has yet occurred. Hans Zoebelein, the editor of this book, writes in his introduction: "Today renewable resources are in an active stand-by situation". For many years he played a prominent and active role in this field in the chemical industry, and worked on several committees set up to study the subject. His introduction to the book, which discusses in detail the present situation regarding the use of renewable feedstocks and examines the prospects for future developments, is well worth reading. The advantages and disadvantages of

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3617-1909 $ 17.50+.50/0

fossil and renewable raw materials are carefully weighed in the balance.

The main part of this *Dictionary of Renewable Resources* lists and explains a large number of concepts and terms connected with the (sometimes confusing and diverse) subject. The book is intended to be of interest to a broad readership. This includes not only chemists, bioscientists, and process technologists in industry and universities, but also others with backgrounds as varied as agriculture, administration, and policy making, who have an interest in the subject and can benefit from reading the book.

Under the appropriate headings the *Dictionary* explains and discusses renewable resources of both plant and animal origins, and intermediates made from these. For the named chemical compounds the book gives information about their origin and occurrence, extraction, use, chemical structure, and physical properties. Chemical reactions are given under the headings of the individual compounds obtained from the raw materials, sometimes with equations, and the uses of the derivatives are explained.

Economic aspects are also covered in detail, as is evident from the inclusion of entries such as "Starch, EC market" or "Starch industry, world". Data on tonnages produced are also included in many cases. Each article includes carefully chosen cross-references to related entries, and in addition there is usually a short list of literature references. Another nice feature is that each subject heading is also accompanied by a German and a French translation. However, one needs to know the English term in order to find a particular topic.

The editor has recruited appropriate experts from industry and universities to write the contributions on the various specialist areas, thus ensuring competence throughout. This has resulted in a well-balanced coverage of the different aspects.

It is unfortunate that, in contrast to the otherwise high standard of the book and the excellent quality of production, insufficient care has been taken with the structural formulas. The figures are very inconsistent in style, and are even unclear in a few cases. The large number of errors in the formula diagrams is especially annoying. In this first edition of the work it would have been desirable to make the reader aware of the errors in the formulas, for example by including an erratum page. These errors need to be corrected in a future edition and the formulas should be redrawn in a uniform style.

Nevertheless, on the whole we can thoroughly recommend the book. It will undoubtedly be a very useful work of reference for many people in industry and universities who are involved in the area of renewable raw materials. It will serve as a rapid source of information on many different aspects of the subject, which is not available anywhere else in such a clear and concise form.

Exercises in Synthetic Organic Chemistry. By *C. Ghiron and R. J. Thomas.* Oxford University Press, Oxford, 1997. 139 pp., hardcover £ 40.00.—ISBN 0-19-855944-5

In this book the authors have collected together a selection of 82 total and partial syntheses. These are presented in the form of reaction schemes which are incomplete, so that they serve as exercise problems. In some cases the reader's task is to propose suitable reagents and reaction conditions whereby a desired product can be synthesized, starting from familiar compounds as educts. In others the situation is reversed, by specifying the reagents and inviting the reader to name the end-product. With each synthesis the authors also include suggestions for points that could be discussed, and they refer the reader to recent review articles relating to the key steps. However, there is an inconsistency in one respect: whereas in their preface the authors mention retrosynthetic analysis as being an extremely useful tool for planning a synthesis, they simply leave it at that, providing no examples. In a book of exercises such as this, it would certainly have been appropriate to give a retrosynthetic analysis before the exercise itself, thus affording the reader a preliminary overview of the task.

Unfortunately there is no subject index, which would have made it easier to find material on a particular topic. An index would also allow one to make better use of the well-chosen literature references, so as to get a quick overview of the latest synthetic methods.

The exercises chosen by the authors are of a high and demanding standard, and the syntheses often include a particularly clever key step, or have some other elegant feature. The synthetic targets chosen are mainly natural products of widely different kinds, such as steroids, macrolides, alkaloids, and even taxol. Thus the book tests and extends the reader's knowledge of the areas of heterocyclic chemistry, rearrangement reactions, organometallic chemistry, arenes, and even to some extent carbohydrate chemistry.

But the reader will not achieve very much by merely using this book on its own, because for didactic reasons the answers to the interesting synthetic exercises are not included! Instead, as the authors explain, the reader is referred to the original publications to arrive at a solution, so that there can be no temptation to cut short the exercise by simply looking up the answer. Consequently one must be prepared to make trips to the library, or alternatively to refer to textbooks to find solutions to the simpler problems.

The choice of material and the manner of presentation are undoubtedly suitable for use by a wide readership, from advanced students to experienced chemists. The book could provide exercise material for use in the weekly synthetic seminars that are obligatory in many research groups, or for some other form of group work.

The book is not intended for private study. There would be little motivation to use it in that way, as it does not lend itself to adaptation from the exercise concept on which it is based. To benefit fully from the book one needs a tutor or moderator who can lead the discussion of the exercises on the basis of a knowledge of the original publications.

Grundlagen der Elektrochemie. By *W. Schmickler.* Vieweg, Braunschweig/Wiesbaden, 1996. 214 pp., paperback DM 58.00.—ISBN 3-528-06755-1

The chemical discipline of electrochemistry is of growing importance in many areas of the fundamental and applied sciences. Energy production and conversion, sensor technology, materials science, and many other branches of science and technology make use of electrochemical processes and industrial techniques. As in other analogous situations, the introduction of electrochemistry into these fields has been accompanied by a diversification of the discipline itself. With regard to mechanistic studies, much effort is currently being devoted to investigating the process of electron transfer at an electrode and the great variety of associated chemical reactions, including synthetic applications. Another topical area of study is the role of the electrode–electrolyte interface in electrochemical processes.

The author of this book is mainly concerned with the latter aspect of electrochemistry, the role of surfaces, including the microscopic characterization of the phase boundary. According to his view, as explained in the preface, kinetic studies have not advanced significantly since the 1970s. One might well disagree with that, but nevertheless the appearance of a textbook on electrochemistry in German, incorporating modern developments in this interdisciplinary science, is an event of great interest.

Schmickler takes as his starting point the central concept of the thermodynamic potential and the structure of electrolyte solutions. He then goes on to discuss the phase boundary between a metal and the electrolyte, adsorption (involving a specific interaction between the electrode and constituents of the electrolyte), and electron transfer (treated phenomenologically using the Butler–Volmer kinetic model and its variants, and "theoretically" on the basis of the Marcus–Hush kinetic model). The discussion is then widened to include semiconductor electrodes, and the models are tested against a number of experimental systems. This is followed by three chapters dealing with electrode surface reactions of increasing complexity: gas evolution, the deposition or dissolution of metals, multistage reactions, corrosion. The treatment then moves on to the liquid–liquid interface and liquid electrodes. By far the most familiar example of the latter is the mercury drop electrode, which was the subject of the only Nobel Prize awarded to an electrochemist (Heyrovský in 1959). The book ends with a discussion of mass transport at an electrode and the analytical techniques based on such processes.

From a superficial standpoint it is pleasing to find here detailed figures that are clear, informative, and not over-elaborate. The text contains some printing errors (not many, and mostly confined to the later chapters), but unfortunately there are also some vague or inaccurate statements [examples: "... die Reaktion ist sehr unsymmetrisch" (p. 67); "... so dass der Strom durch ein Maximum fliesst" (p. 193); the word "langsam" (slow) to describe a current (p. 188)]. More seriously, there are occasional errors in symbols, formulas, and equations which alter the meaning, a shortcoming that is especially regrettable in a basic textbook. Sometimes different symbols are used for the same quantity, for example the concentration in the bulk solution is variously denoted by c^0 or c^b.

Schmickler's approach, which is certainly to be welcomed, is to present even complex relationships by deriving them from simple considerations and models. This enables the reader to understand the significance of the essential mathematical "equipment" of electrochemistry, which older textbooks often treat in a way that discourages the student. Usually the technique works well (e.g., in Chapter 11 on the deposition and dissolution of metals), but occasionally the author takes the process too far. For example, the explanation of the nonstationary method of cyclic-voltammetry by relating it to the limiting stationary case would have been better avoided (and, moreover, the formation of the peak is *not* due to the disappearance of the surface concentration but to a depletion in the diffusion layer and an increase of this layer's thickness).

In a basic textbook it is, of course, appropriate to cite only a few key publications, which can then provide a way into the extensive primary literature. However, in a book which frequently emphasizes recent developments in electrochemistry, it is surprising that the references given for some areas of research that have been most active in recent years are limited to very old publications. For example, those for Chapters 7 (theory of electron transfer reactions) and 12 (complex reactions) are all from the 1950s and 1960s, apart from a 1974 review on normal coordinate analysis.

As explained in the preface, this book is a considerably revised translation (from English into German) of the author's *Interfacial Electrochemistry*. It turns out that in the course of this revision certain chapters, including some on surface methods, have been omitted, while new sections on mass transport have been added. Since the author repeatedly emphasizes the surface aspects of electrochemistry, which in my view is exactly where the book's main strength lies, the reason for this choice is not altogether clear. It would have been better to retain the reference to interfaces in the title of the German version, so as to make it clear that this treatment of the "Grundlagen der Elektrochemie" does not include, for example, the (also important) subject of electrochemically induced homogeneous reactions. The title as it stands could lead one to expect more from the book than it actually contains.

Apart from the shortcomings mentioned above (which should certainly be corrected by the author and the publishers), this is a moderately priced volume which offers an overview of the important subject of electrochemistry at interfaces, and it is suitable not only as an introduction but also for advanced students. In this respect, I am shure that there is a demand for such a text book.

Cell-Mediated Immunity in Virus Infections (Nobel Lecture)**

Peter C. Doherty*

Introduction

Many key concepts concerning the nature of immunity have originated from the very practical need to control virus infections. This year, 1996, has been designated the "Year of the Vaccine" commemorating the 200th anniversary of Edward Jenner's vaccination of James Phipps with cowpox virus, and the subsequent challenge with smallpox virus. Insight into the nature of viruses, and how viruses interact with mammalian cells, has evolved since the turn of the century. Our concepts of immunity developed concurrently, beginning with Pasteur's treatment of Joseph Meissner with "aged" rabies virus. Antibody-mediated protection conferred by attenuated, live yellow-fever virus won the Nobel Prize for Max Theiler in 1951. Perhaps the most exciting area of immunology when I graduated from the University of Queensland Veterinary School in 1962 was the nature of virus neutralization,[1] a topic that is still being resolved with the monoclonal antibody (mAb) technology originated by Georges Köhler and César Milstein (Nobel Prize 1985). Crystallographic analysis of influenza virus neuraminidase-mAb complexes and variants of neuraminidase selected by mAbs led to the clear demonstration that Ig molecules normally bind to tertiary structure on proteins.[2]

The present award is for our discovery[3–6] from experiments with lymphocytic choriomeningitis virus (LCMV) that the nature of T cell mediated immunity (CMI) is essentially different, focusing on the recognition of cell-surface major histocompatibility complex (MHC) glycoproteins that have been modified as a consequence of infection (see Figure 1). My intention here is to place these findings in historical context and to develop some aspects to the present day in the context of viral immunity and pathology.

The Australian School of Viral Pathogenesis and Immunity

The strengths in both virology and immunology at the John Curtin School of Medical Research (JCSMR), where we did the LCMV experiments, were a direct consequence of themes developed in Australia by F. M. (Sir Mac) Burnet. Over a period of more than twenty years, Sir Mac built the Walter and Eliza Hall Institute (WEHI) in Melbourne into a major international center for virus (particularly influenza) research. In the late 1940s the only person working there on another virus disease was Frank Fenner, who at Burnet's suggestion studied the epidemiology and pathogenesis of ectromelia (mousepox). Following Burnet's demonstration that ectromelia could be titrated by pock assay on chick chorioallantoic membrane, Fenner did careful quantitative studies of virus distribution in a range of tissues.[7] His conclusion was that the virus replicated initially at the site of inoculation in the dermis, then the regional lymph nodes, then generalized via the liver and spleen, and again to the skin, where it produced a smallpox-like rash. He also noted that delayed-type "allergy" appeared earlier than the serum antibody. In 1949 Fenner became Head of the Department of Microbiology in the JCSMR at the Australian National University, which had just been formed largely as a consequence of initiatives taken by Sir Howard (later Lord) Florey (Nobel Prize 1945). Fenner built a very strong center for virology research.

In 1957, having just enunciated the clonal selection theory,[8] Burnet abandoned virology and redirected the work of the WEHI to basic immunology, a focus continued with great distinction by his protégée G. J. V. Nossal. Nossal recruited J. F. A. P. Miller, who established a strong program in T cell immunology that was to have a major influence both locally and on the international scene. Many of the leading WEHI virologists joined Fenner's department in Canberra. One of the few remaining in Melbourne was G. L. Ada, who switched to immunology. Gordon Ada then moved to Canberra in 1968, replacing Fenner who had become Director of the JCSMR. By the time that I arrived the microbiology department in Canberra had a strong research effort in immunology, interfacing with the virologists remaining from the Fenner era.

Fenner's ectromelia model was subsequently pursued at the JCSMR in two ways that were to influence our discovery. The first was that C. A. Mims made extensive use of fluorescence microscopy to define patterns of virus growth in different organ sites,[9] helping to keep the general area of whole-animal viral pathogenesis alive through the 1960s when most virologists (following Ender, Weller, and Robbins, Noble Prize 1954) turned their attention to in vitro tissue culture systems. Fenner's final contribution to experimental viral immunology was to recruit R. V. Blanden back to Australia from the Trudeau Institute, where he had been working with George Mackaness (a Florey

trainee and former JCSMR scientist) on CMI in bacterial infections.[10] Bob Blanden applied the approaches that he had developed with Mackaness to the ectromelia model, using both adoptive transfer experiments and depletion with anti-thymocyte serum to show the crucial role of T lymphocytes in controlling the infection.[11-13]

I had followed Mim's papers for many years and returned to Australia from Edinburgh at the end of 1971 to work with him. He had warned me that he might be moving to a Chair in Microbiology in London, and left before the end of 1972. I inherited his laboratory, his technician (Gail Essery), and the LCMV model that had been brought to Canberra some years before by Fritz Lehmann-Grube. Rolf Zinkernagel arrived in 1973 to work with Blanden on CMI in Salmonellosis. Due to space requirements Gordon Ada moved Rolf into the laboratory with me, which is how our collaboration started. Rolf was later to use our experimental data for his Ph.D. thesis but, though I helped him with the writing, the relationship was always as equal colleagues rather than supervisor and student.

Early Experiments with LCMV and the Discovery of MHC Restriction

My initial focus with the LCMV model was to combine contemporary T cell immunology approaches with the capacity to quantitate inflammatory pathology[14] by counting cells in mouse cerebrospinal fluid (CSF), using a CSF tap technique that I had learned from R. I. Carp.[15] This proved to be a very powerful approach (Figure 2), providing strong support for the theme developed initially by W. P. Rowe and J. E. Hotchin (and later by D. H. Gilden, G. A. Cole, and N. Nathanson) that clinical LCM is an immunopathological disease.[16-18] The most visually satisfying experiment done at this time was to use Evan's blue injection to show that the virus-immune T cells were causing a total breakdown of the blood-brain barrier to protein, an experiment that reaches back to the dye studies of Paul Ehrlich (Nobel Prize 1908). Much of this work never appeared in the primary literature and was only published[3] in an article that G. Möller requested for *Transplantation Reviews*. This also carried the first, tentative description of the MHC-restriction finding.

The formal collaboration with Rolf Zinkernagel started when I suggested that we might look to see if the CSF cells that I was obtaining (Figure 2) from clinically affected mice could be shown to have cytotoxic T lymphocyte (CTL) activity. Having worked in Lausanne he was very familiar with the ^{51}Cr-release assay that was being used so effectively by J.-C. Cerottini and K. T. Brunner[19] to study alloreactivity, and had tried (unsuccessfully) to apply the approach to the Salmonella model. The CTL assay had already been used with spleen cells from LCMV-infected mice by M. B. A. Oldstone, O. Marker, M. Volkert, and colleagues.[20, 21] Fortuitously, we were using H-2^k-compatible CBA/H mice and L929 fibroblasts (L cells) as a source of T lymphocytes and virus-infected targets, respectively. The first experiment worked beautifully, and we were able to show that the lytic activity was mediated by Thy-1 positive cells.[22]

At about this time, the very active group of cellular immunologists that made up Gordon Ada's weekly "bible class" had been discussing recent publications on immune response (Ir) gene effects from B. Benacerraf (Nobel Prize 1980) and D. H. Katz at Harvard, which used a very complex in vivo mouse model of T cell/B cell collaboration.[23] We later read of the experiments of E. Shevach and A. Rosenthal at NIH, Bethesda, Maryland, USA, who were looking at the Ir gene question using in vitro stimulation of guinea-pig T cells.[24] The paradigm[25] in this East Coast USA immunology axis was that the Ir genes, which had been mapped to the I-region (now MHC class II) between the loci for the "strong" transplantation antigens (H-2K and H-2D, now MHC class I), encoded all (or part of) the "enigmatic" T cell receptor (TCR). This interpretation would probably have quickly been revised when it became apparent that the Ir gene product (Ia antigen) was expressed on macrophages.[26]

We then saw a report by H. McDevitt, G. R. Mitchell, and M. B. A. Oldstone that there was an "Ir gene" effect in the LCM immunopathology model.[27] This stimulated us to accumulate all the mouse strains that were available in Canberra (CBA/H, BALB/c, and C57BL/6J) to see if we could correlate the level of CTL activity with the H-2 type. The big surprise was that only the H-2^k T cells were lytic for the MHC-compatible, LCMV-infected L cells.[3, 4] We had no appropriate H-2^b or H-2^k cell lines available, so we used primary peritoneal macrophages[28] to

Peter C. Doherty was born in 1940 in Australia. He studied veterinary medicine at the University of Queensland, Australia. From 1963 to 1967 he was at the Animal Research Institute in Brisbane, Australia, and from 1967 to 1971 at the Department of Experimental Pathology of the Moredun Research Institute in Edinburgh, Scotland, where he finished his Ph.D. in 1970. After a position as a Research Fellow in the Department of Microbiology at the John Curtin School of Medical Research at the Australian National University in Canberra, he became a Professor at the Wistar Institute in Philadelphia, PA, USA. In 1982 he went back to Canberra, this time as Professor and Head of the Department of Experimental Pathology. He has been the Chairman of the Department of Immunology at the St. Jude Children's Research Hospital in Memphis, TN, USA since 1988, and, in addition, Adjunct Professor of the Departments of Pathology and Pediatrics of the College of Medicine at the University of Tennessee in Memphis since 1992. He has been awarded numerous scientific fellowships and awards including the Paul-Ehrlich-Preis in Germany, the Gairdner Foundation International Award in Canada, The Albert Lasker Medical Research Award in the USA, and the 1996 Nobel Prize for Medicine and Physiology.

provide a source of LCMV-infected targets to demonstrate reciprocal exclusion of T cell recognition. The next important experiment was with the H-K^kD^d A/J mouse strain,[29] establishing that CTL recognition mapped to H-$2D^d$ and (perhaps) to H-$2K^k$. Later studies on immunodominance hierarchies[30, 31] were to show us how lucky we had been to have a system available where both the H-2K and H-2D alleles were associated with a potent LCMV-specific CTL response. The basic findings with LCMV were rapidly replicated for ectromelia by Bob Blanden's student Ian Gardner.[32] Bob also used his contacts as a more established immunologist to bring in a range of H-2 recombinant and mutant mouse strains over the next 12–18 months that were used (with both the LCMV and ectromelia models) to map virus-specific CTL effector function to the MHC class I alleles.[33, 34] The more detailed description of the actual experiments, the preceding history of the MHC, and the way that the TCR repertoire develops during ontogeny are covered in the accompanying article by Rolf Zinkernagel.[35]

The "Single TCR Altered Self" Hypothesis

Right from the time that we made the discovery[3–6] we considered that there might be two possible explanations for our findings (Figure 1). The first was based on the "TCR"-type

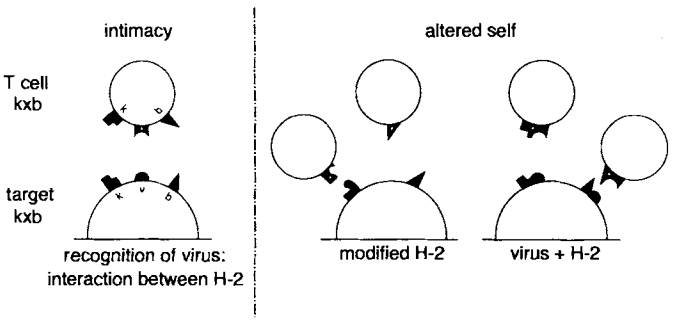

Figure 1. Formulation of the "single T cell receptor altered self" hypothesis. It was published in the second article that appeared in *Nature* [4] about a year after the initial experiment showing MHC restriction of CTL activity. In this paper we discredited the "intimacy" model, which argued that there might be some form of "like–like" interaction between H-2 glycoproteins expressed on the T lymphocyte and the target cell. The experiments and the intellectual context are dealt with in much greater detail in the accompanying article by Rolf Zinkernagel [35].

hypothesis of Katz and Benacerraf, which was formulated as the various dual-recognition models proposed through the 1970s and early 1980s. The second was that the virus was in some way modifying the MHC molecule,[4–6] either by complexing with it on the cell surface or by inducing some other (perhaps allosteric) change. This idea of an "altered-self" molecule recognized by a single TCR seemed reasonable for virus-infected cells, though we were a bit perturbed when the recognition of "minor" histocompatibility antigens was later shown to obey the same rules.[36, 37] Evidence against the dual-recognition model as originally stated (like–like interaction) came from adoptive transfer studies, where we showed that LCMV-primed T cells from H-2 heterozygous mice ("AxB" F1) that would kill virus-infected A and B target cells partitioned into "clonotypes" lytic for A + v (v = virus) alone or B + v alone following further stimulation in irradiated, virus-infected mice of type A or B, respectively.[5] Later variants of "two-receptor" models got around this problem by arguing that the postulated recognition molecules seeing A or B molecules were themselves clonally excluded.

The single TCR altered self hypothesis allowed us to assign a biological role to the strong transplantation antigens, and to explain alloreactivity, Ir gene hierarchies, and the extreme polymorphism of the MHC. We believed from the outset that we had found the mechanistic basis of immunological surveillance of self, though we used the term in a somewhat different context[5, 6, 38, 39] from that employed by Lewis Thomas and Burnet in their discussion of susceptibility to cancer.[40] Many people did not accept the altered-self idea, including some of our colleagues in the JCSMR group.[34] It was to remain controversial and regarded as heretical by most T cell immunologists for the next ten years or so (discussed in ref. [41·42]). The two-receptor models that were generally favored continued, however, to have the problem that they offered no satisfactory generalization that would accommodate alloreactivity and the Ir gene mechanism.

The resolution of the dilemma came with the finding of A. R. Townsend, A. J. McMichael, and colleagues that the class I MHC molecules present viral peptides processed by the "endogenous" pathway.[43] This, together with the publication of the three-dimensional structure of a class I MHC molecule by P. Bjorkman, J. L. Strominger, D. C. Wiley et al[44] and the definition of the two-chain TCR by M. M. Davis, S. Hedrick, T. Mak, J. Allison, P. Marrack, J. Kappler, S. Tonegawa, and others,[45] put the final nail in the coffin of the various "dual-receptor" TCR models. The recent characterization of the tertiary structure of the TCR provides a very satisfactory conclusion to the debate that started with the altered-self hypothesis.[46, 47]

The LCMV Model and T Cell Targeting In Vivo

The MHC restriction of CTL effector function indicated from the outset that the virus-immune T cell must interact directly with the virus-infected target cell. This had already been obvious for alloreactivity, but no one had suggested that the strong transplantation antigens were in any way involved in the immune response to pathogens. Thinking about CMI in infectious diseases had been very much constrained by experiments with *Listeria monocytogenes*, which emphasized the need for T cells in macrophage recruitment and activation.[10] The numbers and the status (in terms of heat shock–protein mRNA expression) of monocyte/macrophages that localize to the lungs of mice infected with an influenza A virus are, for example, clearly a function of the concurrent $CD4^+$ and/or $CD8^+$ T cell response.[48] Macrophages activated during the T cell mediated elimination of LCMV or ectromelia virus can rapidly destroy *L. monocytogenes*.[49]

The MHC-restriction findings with in vitro CTL assays were quickly translated into the in vivo situation. One of the reasons that the LCMV model was so powerful was that we had a very clean in vivo system for analyzing an inflammatory process. Unlike many viruses, LCMV causes little damage and the levels of "background" cellular infiltration independent of the T cell response[3, 50] are low (Figure 2). Combining this with the ca-

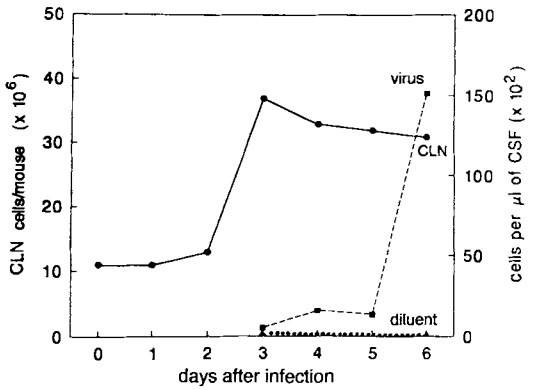

Figure 2. The finding that led to the discovery of MHC restriction was the demonstration that the inflammatory population recovered from the CSF of mice with clinical LCM contains potent CTL effectors [22]. The data shown is from a much later experiment [50], which illustrates the massive influx of cells (dashed line) into the CSF accompanying the onset of CTL activity between days 5 and 6 after infection of the central nervous system. Also shown (solid line) is the preceding increase in cellularity (fourfold) of the cervical lymph nodes (CLN).

pacity to quantitate very accurately by counting cells in the CSF allowed us to determine rapidly by adoptive transfer experiments that the same rules apply for T cell recognition in vitro and in vivo. This was shown for differences in MHC haplotype, particular MHC class I alleles and for H-2 mutant mice.[34, 51, 52]

The interpretation that the T cell must bind directly in vivo to the virus-infected target rather than just to an appropriate antigen-presenting stimulator cell has, however, continued to be subject to challenge. The alternative idea is that cytokines released as a consequence of such interactions are the key effector molecules, an idea that seems to work for the control of a hepatitis virus transgene by interferon-mediated mechanisms.[53] So far this hepatitis model seems to be unique. Adoptively transferred LCMV-immune T cells only caused severe meningitis in virus-infected, chimeric mice when the appropriate MHC restriction element was present on virus-infected epithelial cells in the brain. Neither secondary stimulation of the virus-specific CTL populations in lymphoid tissue nor interaction with inflammatory monocyte/macrophages in the site of pathology were alone sufficient to cause the massive cellular extravasation characteristic of LCM.[54–56]

Perhaps the final indication that the LCMV-immune effector CTL must interact directly with virus-infected CNS epithelia in vivo has come from experiments with perforin −/− mice, which failed to develop the classical symptoms of T cell mediated immunopathology.[57] Cytokine-mediated mechanisms may, however, be responsible for the chronic wasting disease[58–60] that develops in LCMV-infected CD8 "knockout" (−/−) mice and $CD8^+$ T cell deficient mice[61] that are −/− for β2-microglobulin (β2-m), the light chain of the MHC class I glycoproteins. Both these genetically manipulated mouse strains mice are unable to clear LCMV, leading to a persistent confrontation between virus-infected stimulators and the immune $CD4^+$ population. The studies with LCMV and other experiments with respiratory viruses (see below) indicate that the effector mechanisms used by $CD4^+$ and $CD8^+$ T cells to deal with viruses are fundamentally different.

The Non-Self Component: Analysis with Respiratory Viruses

The division of labor in the LCMV experiments at the JCSMR was that Rolf Zinkernagel did the in vitro CTL analysis, while I was responsible for the in vivo immunopathology experiments and for writing the manuscripts with, of course, the benefit of his immediate and constant critique. I thus used respiratory infection with the parainfluenza type 1 virus, Sendai virus, to develop a facility with the CTL assay,[62] and to confirm that MHC restriction was true for more than LCMV and the pox viruses.[27, 32, 63] I returned to the Sendai model[64, 65] years later at St Jude Children's Research Hospital, principally because of the molecular virology expertise available in the laboratory of A. Portner.

When I moved to the Wistar Institute (Philadelphia, USA) in mid 1975, it quickly became apparent that the animal facility was not sufficiently secure to allow extensive experimentation with LCMV, which can easily induce clinically "silent" infections in mouse colonies. The CTL response to Sendai virus was being studied by others at the Wistar, so I took the opportunity to collaborate with W. E. Gerhard on the analysis of T cell mediated immunity to the influenza A viruses (Figure 3).

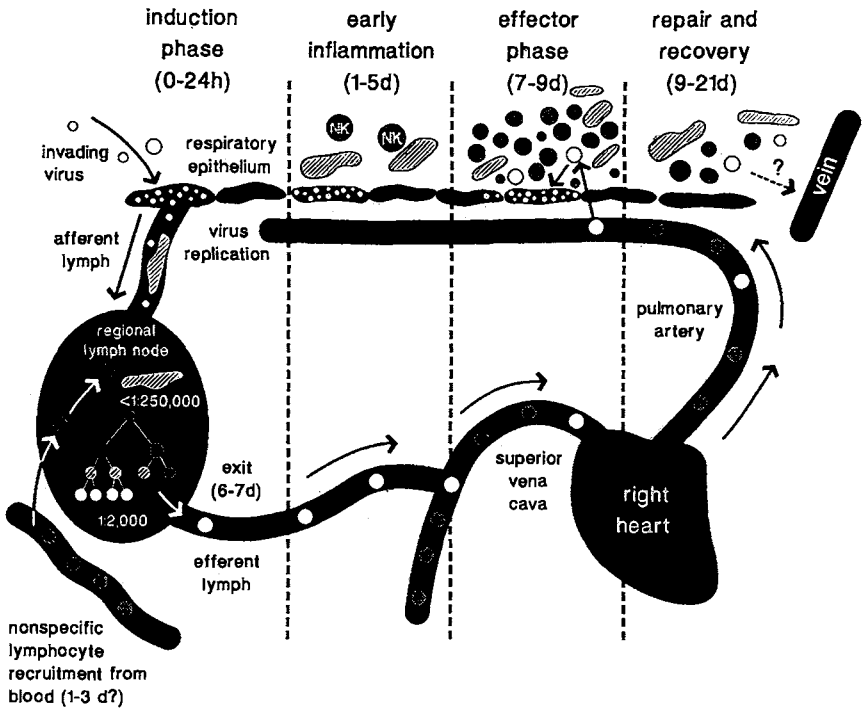

Figure 3. The various events occurring in the respiratory tract and regional lymph nodes are illustrated for mice infected with an influenza A virus or with Sendai virus [64, 98, 83]. Infectious virus cannot generally be recovered from the lung subsequent to day 9 after infection. The $CD8^+$ and $CD4^+$ T cells are responsible for most of the monocyte/macrophage recruitment [48]. The $CD8^+$ set predominates in the inflammatory exudate, but most of these lymphocytes are memory T cells specific for other antigens. Probably less than 1:100 are reactive to the inducing pathogen [99]. Potent CTL effectors and large numbers of cytokine-producing cells are found mainly in the virus-infected lung.

Walter Gerhard had learned his influenza virology at the Institut für Immunologie in Basel from Stephen Fazekas de St. Groth,[1] who had formerly been a leading figure in Fenner's virology department at the JCSMR.

The aim was to exploit "recombinant" influenza A viruses to dissect the other half of the T cell specificity equation, for viral components rather than for MHC glycoproteins. The so-called recombinants result from growing two different influenza A viruses concurrently in the one cell.[66] The eight segments of the influenza genome repackage to give novel variants, the mechanism responsible for the phenomenon of "antigenic shift". The principal focus of immunology-related influenza research, which tends to focus on vaccine studies, was on the viral hemagglutinin (H) and neuraminidase (N) glycoproteins. These virion surface proteins are subject to the antibody-mediated selection pressure that results in "antigenic drift", a further mechanism that can give rise to novel pandemic strains.

We thought that by using serologically distinct variants such as the H1N1 and H3N2 viruses, which do not cross-neutralize, we would be able to map CTL activity to H or N, both of which are expressed on the plasma membrane of the virus-infected cell. The aim then was to use "drifted" variants to map fine specificity. The initial experiments were done by my first graduate student, R. B. Effros, and were later pursued by my second student, J. R. Bennink. Much to our surprise, Rita found that the CTL response for these two viruses was almost totally cross-reactive.[67, 68] Though we were unaware of it at the time, similar findings were being recorded in B. A. (Ita) Askonas's laboratory at the National Institute for Medical Research in London.[69] Our findings with LCMV had induced Ita to drop her long-term studies of the B cell responses to concentrate on virus-specific T cell mediated immunity. Her laboratory was to make an enormous contribution over the next ten years.

Though we failed at this stage to define the nature of the antigenic entity recognized by the influenza specific CTL, these early experiments further supported the conclusion from the MHC restriction analysis that the specificity profiles of T and B lymphocytes are fundamentally different.[34, 70] In addition, we quickly established that exposure to any one influenza A virus will prime T cell memory for a secondary response (Figure 4) to any other influenza A virus.[68, 71] This meant that infection with a "drifted" or "shifted" influenza A virus in an adult person is likely to proceed in the context of a secondary CTL response and a primary humoral response. The albeit imperfect protection conferred by influenza-specific memory T cells[72–74] probably explains why young to middle-aged adults are generally much less likely to die from influenza than are small children or elderly people. These results were quickly confirmed for other viruses that had, after the influenza experiments, also been found to induce CTL specificity profiles that were not predicted by serological analysis.[75]

Other significant experiments that were done with the influenza model at about this time were the extension of MHC restriction to the rat model[76] and, most importantly, the clear demonstration by A. J. McMichael in Askonas's laboratory that this is also true for humans.[77] Further pursuit of this unpredicted cross-reactivity for the influenza viruses led to A. Townsend's (again from the Askonas's laboratory) seminal finding[43, 78] that MHC class I restricted T cells are responding to a peptide derived from the influenza nucleoprotein (NP), which finally explained the molecular mechanism underlying our altered-self hypothesis (Figure 1) and started the whole field of antigen processing in the "endogenous" compartment. Analysis at the Wistar Institute by Jack Bennink and J. R. Yewdell with recombinant vaccinia viruses also showed that much of the CTL recognition in the influenza model is directed at internal components of the virus.[79]

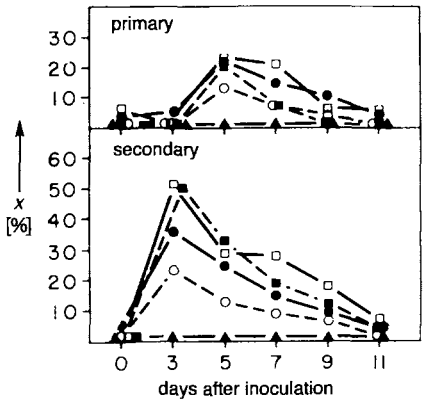

Figure 4. Immunologically naive (primary) CBA/J (H-2^k) mice, or mice that had been infected with the PR8 (H1N1) influenza A virus 52 days previously (secondary), were challenged with the HK × 31 (H3N2) influenza A virus [68]. Spleen cells were assayed (100:1) at the intervals shown on H-2 compatible targets infected with a range of influenza A viruses or with an influenza B virus (triangles). Both the enhanced kinetics and potency of the recall response are very apparent. Later experiments with HK × 31 infection of C57BL/6J (H-2^b) mice have shown very little CTL activity in lymphoid tissue following primary exposure [98]; x = specific ^{51}Cr release.

Latterly, the nonlethal respiratory infections have emerged as the experimental system of choice for analyzing localized, transient viral infections.[80–83] These models have the advantage that it is easy to obtain both the regional lymphoid tissue and the inflammatory cells from the pneumonic lung by bronchoalveolar lavage (BAL). There is also no obvious way that either the virus or the viral genome can persist after infection with such negative strand RNA viruses,[84] which is important when we are considering the difficult area of T cell memory [85].

Some recent experiments addressed again the question of T cell targeting in vivo that we had analyzed earlier with the LCMV model (Figure 2). Using adoptive transfer protocols and bone marrow radiation chimeras made between β2-m $-/-$ and $+/+$ mice, we showed that the clearance of Sendai virus depends on the $CD8^+$ effector T cells interacting directly with virus-infected, MHC class I^+ respiratory epithelium.[86] The opposite conclusion was reached concerning the capacity of $CD4^+$ T cells[87–89] to control influenza virus infection in the absence of the $CD8^+$ subset: Expression of the MHC class II glycoproteins that target the $CD4^+$ T cells is not essential in the respiratory tract.[90] More recent experiments performed by David Topham are confirming the theme developed by Walter Gerhard[91] that complete clearance of the virus by $CD4^+$ T cells requires the concurrent presence of antibody-forming cells.

Quantitating Inflammation and T Cell Mediated Immunity

The essence of the virology-based approach to pathogenesis has always been quantitation, a theme that was started by Mac Burnet with his various plaque assays and continued by Cedric Mims for the fluorescence microscopic localization of virus-infected cells in different organ sites.[9] Measuring the inflammatory process that is the consequence of CMI has, however, traditionally been (at best) semiquantitative. The classical delayed-type hypersensitivity foot-pad swelling assay is a very blunt instrument.

Analyzing Inflammation

My early experience in ultrastructural pathology and immunocytochemistry[92, 93] resulted in an intense curiosity concerning the nature of the lymphocyte populations that invade into tissue sites of virus growth (Figure 5). The experiments that

Figure 5. My interest in the nature of virus-specific CMI was stimulated by the experimental studies of louping-ill encephalomyelitis that Hugh Reid and I did with sheep at the Moredun Research Institute, Edinburgh [92–94]. The electron micrograph shows cells of undetermined identity extravasating from a capillary into the brain parenchyma. Lymphocyte invasion into tissue sites of virus growth is the central feature of CMI.

H. W. Reid and I did with the sheep louping-ill (tick-borne flavivirus) model at the Moredun Research Institute in Edinburgh led to the conclusion that antibody-forming cells were extravasating into the CNS and were responsible for a substantial, in situ virus-specific Ig response.[92, 94] Much later studies by D. E. Griffin have shown that such locally produced antibody controls Sindbis virus infection of mouse brain.[95]

The dual frustrations with morphological approaches are the lack of functional analysis and the difficulty of quantitation, though my current perception is that there is a great need to focus more attention on the anatomical localization of events in immunity that is only possible with microscopy-based protocols. My early attempts at quantitating inflammatory pathology caused me to seize on the CSF tap technique that Richard Carp[15] had developed to look for enzymatic activity in CSF from scrapie-infected mouse brain and apply it to the study of viral meningitis (Figure 2). Experiments with this simple model induced us to develop the LCMV-specific CTL assay, and allowed the later in vivo dissection of MHC-restricted T cell effector function. The capacity to measure statistically significant differences for quite small effects enabled us to operate with unique sensitivity in the in vivo situation.[3, 34] However, because the approach was technically demanding and only really useful with the LCMV model, nobody else adopted this analytical system. The other, great advantage of being able to obtain inflammatory cells directly from the CSF (or from the lung by the BAL) is that the lymphocytes do not need to be freed from tissue by enzymatic techniques. This has been of great benefit for later experiments concentrating on flow cytometric analysis and FACS separation to define functional T cell subsets,[56, 96, 97] experiments that were first started for LCMV (with R. Ceredig in Canberra) and have been a major focus of the respiratory infection studies[98, 99] in Memphis (Figure 3).

Measuring the T Cell Response

Though the in vitro ^{51}Cr-release CTL assay provides numbers, the precursor (p) frequencies that give comparable levels of lytic activity (both during the course of in vivo infection or as a consequence of in vitro culture) can vary enormously.[100, 101] The potency of the $CD8^+$ CTL set in the BAL population from mice with influenza pneumonia is, for example, apparently equivalent by day 10 after infection for $CD4^+$ T cell deficient MHC class II $-/-$ mice and for MHC class II $+/+$ controls.[101, 102] However, the CTLp numbers in both the BAL and regional lymph nodes are much lower for the MHC class II $-/-$ mice, and virus clearance may be slightly delayed. The much smaller CTLp pool in the MHC class II $-/-$ mice is almost totally consumed to provide the level of CTL effector function needed to deal with the infection. A conclusion based on the CTL data alone that the absence of the $CD4^+$ set does not greatly modify the magnitude of the $CD8^+$ T cell response would thus be misleading. Careful kinetic analysis is essential in these in vivo pathogenesis studies.

We first realized this when we tried to quantitate the Ir gene hierarchy that we discovered for the MHC class I alleles H-2K^k, H-2K^b, and H-2D^b with the influenza A viruses.[30, 31] The situation here is that the CTL response associated with H-2D^b + NP peptide is dominant in mice that express H-2K^b, but apparently absent when H-2K^k is present. The same thing happens with vaccinia virus. Jack Bennink and I tried hard to work out the underlying mechanism, using thoracic duct cannulation and negative selection in vivo to remove the alloreactive T cells,[103] a very tedious protocol that we learned from J. A. Sprent. The lack of any useful resolution is a good example of the fact that (though important insights can be generated) molecular mechanisms cannot ultimately be worked out by biological experiments. My current guess is that H-2K^k must greatly out-compete H-2D^b for binding some constant molecule involved in the MHC class I antigen processing pathway,[104] though not to the extent that H-2D^b + NP peptide is no longer present at sufficient levels to be recognized by the appropriate effector CTL on an H-K^{k}D^b target cell.

When J. A. Owen joined the laboratory in Philadelphia she took on the task of developing a quantitative limiting dilution analysis (LDA) for determining influenza virus specific CTLp frequencies,[105] an approach that has been central to my research program over the subsequent years. Judy Owen and Michelle Allouche then applied this technique to the H-2K^{k}D^b hierarchy problem and found that, for mice that had been primed a month or more previously, the CTLp numbers specific for influenza virus components expressed in the context of H-2K^k and H-2D^b may be fairly comparable.[106] Recent experiments with this experimental system by R. A. Tripp in Memphis indicate that the reason that the H-2K^k-restricted CTL effectors are preferentially generated is that this component of the response emerges more quickly.

The Rate Problem in Immunology

The preceding is a good example of one of the major difficulties that we face in developing a detailed understanding of immunity. How do we measure the true kinetics of responses in terms of lymphocyte generation and loss, and in the context of transit times through the various tissue sites that are sampled? A major insight developed from studies with superantigens was that the majority of the T cells that proliferate following such stimulation die as a consequence.[107, 108] We initially thought that this was not the case for "conventional" antigens, such as influenza virus or Sendai virus epitopes, largely because sequential LDA studies indicated a remarkable constancy (Figure 6) in CTLp frequencies (1:2–3000 cells in a lymph node) from about day 7 after infection through to long-term memory.[85, 99, 109] This was somewhat different from the situation that was concurrently being described for LDA studies with LCMV by Rafi Ahmed,[110] but we agreed that the difference was probably due to the fact that systemic LCMV infection undoubtedly gives a much greater antigenic stimulus.

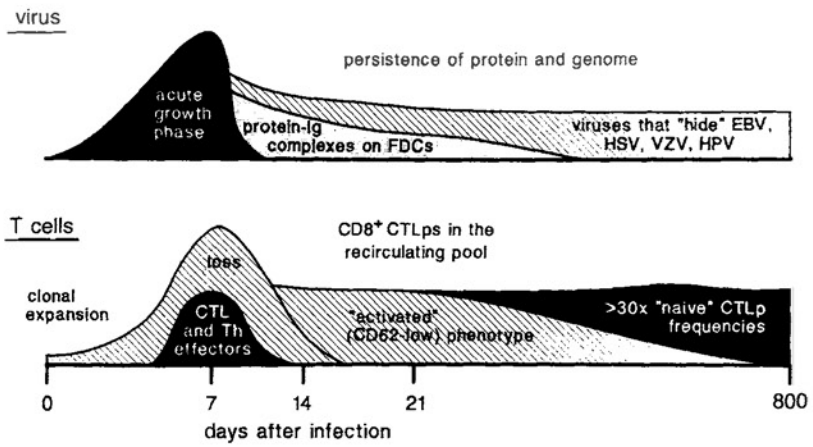

Figure 6. Virus: Replication of the negative strand RNA viruses is generally terminated by the immune response within 7–10 days [84, 118], with the only trace of the infectious agent generally being the long-term maintenance of protein–Ig complexes on the surface of follicular dendritic cells [110]. These do not seem to be necessary for the maintenance of influenza-specific CD4$^+$ T cell memory [119], but are probably essential for B cell memory. Other pathogens, such as the herpes viruses, may persist in a latent form in neurons or B lymphocytes, and periodically reactivate into lytic phase [120]. T cells: Clonal expansion of the CD4$^+$ THp and CD8$^+$ CTLp during the acute phase of the response is greatly in excess of the numbers required to generate the cytokine-producing TH or effector CTL populations that deal with the infection. Many of the CTLp, in particular, either die or are excreted, and CTLp frequencies may remain remarkably stable thereafter for the life of a laboratory mouse. However, the activation phenotype of these T cells may (as first shown by Sam Hou [121]) change with time.

The thymidine analogue bromodeoxyuridine (BrDU) incorporates into the DNA of multiplying cells and causes the formation of toxic thymidine dimers following exposure to bright light, a protocol that was used many years ago to "suicide" in vitro stimulated T cells.[111] Ralph Tripp found that loading proliferating T cells with BrDU in vivo led to the same effect when the lymphocytes were exposed to the laser beam of the flow cytometer.[112] Use of this protocol indicates that the CTLp numbers generated during the acute phase of the response to an influenza A virus are more than tenfold in excess of what would be expected from estimates of CTLp frequencies (Figure 6). Some of these T cells will give rise to the CTL effectors that are found in the virus-infected respiratory tract, but it seems that many others are lost. Measuring a virus specific CD8$^+$ T cell response by effector CTL assays takes no account of the CTLp numbers that are generated. However, the more extensive quantitation of CTLp frequencies shows only the balance between CTLp generation and loss, and does not give a true estimate of the real magnitude of an acute host response. This is less a problem with T cell memory, where the cell populations are turning over at a much slower rate.[113]

Homeostasis: On the Edge of Chaos?

The above experience, together with trying to understand the nature of T cell memory, has left me with the conviction that the major challenge for cellular immunology is to develop a much clearer understanding of lymphocyte homeostasis.[114] In the past many of us would have followed Burnet's insight that the balance between responsiveness and tolerance is the key question, but recent studies (particularly with transgenic mice) have clarified the issues, blurred the distinction, and made the tolerance–response mantra less compelling.[115] It could be argued that tolerance–response is simply a more refined statement of the homeostasis problem, but language conditions perceptions, and defining the area in this way focuses attention solely towards antigen and away from the more physiological mechanisms and quantitative considerations that are also likely to be enormously important.

An obsession with homeostasis is dangerous territory, as it has led in the past to some of the least useful and expensive efforts in immunology. Even so, it may be time for our experimentally based discipline to take greater cognizance of the contribution that can be made by theoreticians, particularly those who are more mathematically inclined. A good example of the way that quantitative analysis can contribute to the development of better predictive models has been provided by recent determinations of the numbers of virus-infected cells[116] in people infected with the human immunodeficiency virus (HIV). Influenza virus specific memory CD8$^+$ T cells seem to show a remarkable constancy in frequency over a very long period (Figure 6). Is this an example[117] of a

chaotic system? Now that we are starting to generate useful numbers, we need the help of people whose business is numbers.

Conclusions

The need to deal with pathogens has driven the evolution of the vertebrate immune system, so it should not be surprising that experiments with infectious agents have often illuminated key elements of the underlying mechanisms. The discovery of MHC restriction and the development of the single TCR altered self hypothesis is a classical example of how interfacing different scientific disciplines and ways of thinking, an inevitable consequence of studying viral pathogenesis, can lead to a major paradigm shift. The progress that was made over the subsequent ten years, and the intellectual directions that were followed as a consequence of this simple, operational hypothesis tell us a great deal about the power of ideas. This is not to decry the importance of technology. Our success depended totally on the availability of the ^{51}Cr-release CTL assay and inbred mouse strains, both of which had been developed to study alloreactivity. The experiments were done in the context of an experimental framework that was being used to dissect T cell responsiveness, the immunopathology of LCMV infection, and the nature of CMI to *L. monocytogenes* and ectromelia virus. The local intellectual environment was strong, and heavily focused on the then current forefront of immunology research. Being isolated in those pre-fax and e-mail days in Australia was a great advantage, as it allowed time to discuss and to think things through. We had outspoken and informed local critics, the freedom and resources to pursue our own ideas, and were given full credit for our efforts. Those of us who have senior roles in science need to do everything possible to ensure that comparable opportunities and environments remain available to young scientists.

My research career has been supported by the taxpayers of Australia, the United Kingdom, and the United States, the National Multiple Sclerosis Societies of the USA and Australia, and by the American Lebanese Syrian Associated Charities who provide much of the funding for St. Jude Children's Research Hospital. I would have achieved nothing without the devotion and encouragement of my wife, Penny, who is my best friend and critic. I owe a very great deal to my students, fellows, colleagues, and collaborators over the years.

Cellular Immune Recognition and the Biological Role of Major Transplantation Antigens (Nobel Lecture)**

Rolf M. Zinkernagel*

The Original Experiment on T cell Specificity

While Immunology began as an attempt to understand immunity against infectious disease, in the 1960s and early 1970s it was largely preoccupied with antibody and T cell responses against easily available foreign protein antigens or chemically defined small molecules (haptens).[1] The mechanisms of graft rejection of foreign organs were also intensively studied, although the biological function of the highly polymorphic, major transplantation molecules coded by the major histocompatibility complex (MHC and HLA in humans, H-2 in mice)[2, 3] was largely unclear. Only a few people studied immunity against infectious agents. The Department of Microbiology at the Australian National University in The John Curtin School of Medical Research in Canberra, headed by G. Ada, was one place where virologists and immunologists worked together on antibacterial and antiviral T cell mediated immunity, particularly on the capacity of immunized cytotoxic $CD8^+$ T cells to destroy either virus-infected or allogeneic target cells in vitro. Peter C. Doherty from Brisbane, who had returned to Australia from Edinburgh at the end of 1971, was working in this Department. He was interested in inflammatory cell responses in the brain against virus infections. When I arrived in Canberra in early 1973 I started working on *Listeria* bacteria with R. V. Blanden and joined forces with Peter to work on cell-mediated immunity to the lymphocytic choriomeningitis virus (LCMV).[4–6] I had come from an institute that was involved in establishing the ^{51}Cr release assays by T. Brunner and J. C. Cerottini in Lausanne, Switzerland,[7, 8] and I therefore attempted to establish the cytotoxicity assay against LCMV in the same way as R. V. Blanden, N. A. Bowern, and I. Gardner were using it to monitor cellular immune responses against ectromelia virus (mouse pox) in mice.[9] Because many papers on cytotoxic T cell responses against LCMV had already been published by various groups[10, 11] and since studies had already been carried out on mouse pox in Canberra by R. V. Blanden's group, members of the Department were sceptical that we should and could run with the strong competition. Although we had some initial problems because of our limited experience with LCMV we successfully established the test with some help from I. D. Gardner. We then used this test to find out whether inflammatory cells in the cerebrospinal fluid of mice infected intracerebrally with LCMV were cytolytic in vitro and whether there was a correlation between cytotoxic T cell activity and severity of choriomeningitis. P. C. Doherty was very good at collecting a few microliters of cerebral spinal fluid from the cisterna magna of a mouse. I miniaturized the ^{51}Cr release assay to be able to measure the activity of such small numbers of cells in microwell plates. These experiments revealed that cytotoxic T cells specifically destroying LCMV-infected target cells could be found in the cerebral spinal fluid of normal mice, but not in that of nude mice lacking a thymus and T cells; this implied that T cells probably also destroyed infected meningial and ependymal cells in vivo and that this was the essential pathogenic mechanism causing lethal choriomeningitis. These findings were published in the *Journal of Experimental Medicine* in March 1973.[12] In this journal a paper by M. B. A. Oldstone, H. O. McDevitt, and collaborators had just appeared, showing that mice with different major histocompatibility gene complexes (H-2) differed with respect to their susceptibility to LCM disease after intracerebral infection.[13] We therefore checked whether a correlation existed between the virus-specific cytotoxic T cell activity in mice and their susceptibility to disease. Six to eight mice of each inbred and cross-bred strain available at the School were infected intracerebrally with LCMV. Two of each were sacrificed when the first mice became sick on day 7 after infection, to test antiviral cytotoxic T cell activities in spleens (Table 1). The remaining mice were monitored for the development of lethal disease during the next ten days. While all the mice died of choriomeningitis by day 10, surprisingly only some strains of mice generated virus-specific cytotoxic T cell activity that was measurable in our in vitro assay (Table 1). This result either signaled that cytotoxic T cells had nothing to do with lethal choriomeningitis, or, alternatively, that our test was in some way inadequate. The latter interpretation proved to be correct: We had used mouse L-929 cells infected with LCMV as target cells to assess cytotoxic T cell activities. This was a fibroblast cell line used by virologists at the John Curtin School of Medical Research to quantifiy viruses by a plaque assay (determination of plaque-forming units (pfu)).[14] Since this was the

[a] Normal mice (**I**) as well as mice lacking a thymus that therefore have no T cells and were given a thymus graft under the kidney capsule (**II**) were infected with LCMV intracerebrally. All mice died, except those that had no T cells (**II**, no. 1), because of the lethal $CD8^+$ T cell mediated LCMV-specific immune reaction. The fact that mice without functional T cells survived shows that the noncytopathic LCMV does not cause disease directly. The LCMV-specific cytotoxic T cells lysed infected target cells that have the same MHC molecules (**I** no. 1; immune T cells from infected CBA mice) ($H\text{-}2^k$) lysed infected L929 fibroblast cells ($H\text{-}2^k$) [15]. The MHC of the thymus determines which MHC is recognized by mature T cells. The experimental group **II**, no. 2, shows that ($H\text{-}2^k \times H\text{-}2^d$) mice with a thymus $H\text{-}2^k$ generated virus-specific T cells that lysed virus-infected $H\text{-}2^k$ target cells, but not infected $H\text{-}2^d$ cells [75]. There are, however, experimental exceptions to this rule (**II** no. 4). Thymus-deficient nude mice ($H\text{-}2^d$) reconstituted with an $H\text{-}2^k$ thymus generated $H\text{-}2^d$-restricted T cells [76].

only mouse-cell line usually used in the Department, along with a Vero-cell line derived from monkeys or the BHK-cell line derived from hamsters, we chose it to provide target cells in the virus-specific, cytotoxic T cell assays. By chance, and fortunately, the mice that were most commonly used in the Department were of the CBA strain, while the L cells had been derived from a closely related mouse strain C3H some 50 years earlier. Also by chance, both mice possessed the same MHC molecules ($H\text{-}2^k$). Our critical test now revealed that LCMV-immune spleen cells from all mice that possessed the $H\text{-}2^k$ haplotype (as do, for example, CBA mice), including cross-breeds with $H\text{-}2^k$ mice, lysed L929 ($H\text{-}2^k$) cells infected with the virus, but did not lyse uninfected targets, or those infected with a third-party virus; all spleen cells derived from immunized mice that were not of the $H\text{-}2^k$ type failed to do so.[15]

Two additional experiments carried out within the next few weeks promptly confirmed these findings. It was important to show that LCMV-immune lymphocytes from non-$H\text{-}2^k$ strains of mice were able to lyse LCMV-infected target cells of the corresponding MHC type. This did not prove to be easy, because the other available mouse-cell lines in the Department, such as the $H\text{-}2^d$ mastocytoma P815 or the $H\text{-}2^b$ thymoma EL4, could not be infected with LCMV. Because of my work with R. V. Blanden on *Listeria*—which infects macrophages and is essentially controlled by cell-mediated activation of macrophages as shown by G. B. Mackaness[16]—we tried to use macrophages directly isolated from peritoneal washings of mice as target cells for these tests. Macrophages adhered well to plastic and could be readily infected and labeled with ^{51}Cr. Proper criss-cross experiments showed that LCMV-immune T cells from $H\text{-}2^b$ mice lyse LCMV-infected macrophages of $H\text{-}2^b$ origin but not those of other H-2 types, and vice versa. The report on these findings was sent off via J. Humphrey as a letter to *Nature* in early December;[15] it was accepted in January 1974 and published in April 1974. The first public presentation of our data outside Australia was at a Keystone meeting, in Squaw Valley (California), attended by A. Cunningham in February and a Brook Lodge meeting (Kalamazoo, Michigan) attended by G. Ada in March 1974. A letter sent back to Canberra by A. Cunningham summarized data from G. M. Shearer showing that TNP-specific (TNP = trinitrophenyl), cytotoxic T cells lysed syngeneic TNP-lated targets more efficiently than allogeneic TNP-lated targets; these data were submitted to the *European Journal of Immunology*[17] at about the time our report appeared in *Nature*. Obviously, the two findings had emerged independently.

Rolf M. Zinkernagel was born in 1944 in Basel. After studying medicine (1962–1968) in his home town, he was postdoctorate fellow there (1969–1970) and at the institute for Biochemistry at the University of Lausanne (1971–1973). His doctoral studies as Visiting Fellow (1973–1975) at the Australian National University in Canberra were followed by a position as Assistant Associate and Full Professor at the Department of Immunopathology, Scripps Clinic, in La Jolla, California (1976–1979), and simultaneously (1977–1979) as Adjunct Professor in the Department of Pathology at the University of California, San Diego. Since 1979 he has occupied the chair of Experimental Pathology at the UniversitätsSpital, University of Zürich, and became Director of the Institute of Experimental Immunology in 1992. He has received many awards, such as the Paul-Ehrlich Prize in Germany (1983), the Gairdner Award in Canada (1987), the Albert-Lasker Medical Research Award in the USA (1995), before he won the Nobel Prize for Medicine and Physiology last year.

Interpretations of the Data

The biological function of MHC and of transplantation antigens was largely unknown in the early 1970s. Their function was obviously not simply to frustrate transplantation surgeons. Transplantation antigens have been defined by P. A. Gorer,[18] and by G. D. Snell,[19] based on the work of C. Little, L. Strong, and others, who had developed many inbred strains of mice in order to be able to define the rules of transplantation and rejection of tissue and cell grafts (reviewed by J. Klein[2]). Hematologists, particularly J. Dausset[3] and J. J. van Rood et al.,[20] defined lymphocyte surface antigens in humans as being similar to red blood cell antigens and called them human lymphocyte antigens (HLAs). Once many patients had been typed for their transplantation antigens it became apparent that several disease susceptibilities were somehow linked to the transplantation antigen types. It was revealed in studies by B. Benacerraf et al.,[21] and later in great and critical detail by H. O. McDevitt and coworkers[22,23] and by F. Lilly et al.,[24] that inbred strains of guinea pigs and mice differed in their responses to some of the model antigens or tumors studied. Because of the availability of well-defined inbred strains of mice, this was readily mapped to the MHC and even to subregions of the MHC in mice by H. O. McDevitt et al.[25] In the early 1970s, transplantation antigens were widely discussed because of these findings. MHC polymorphism was thought either to prevent mutual parasitism or transmission of tumor cells,[26] or to prevent viruses or other pathogens from mimicking transplantation antigens and, therefore, from eliminating the species;[27-29] alternatively, it was proposed that transplantation antigens functioned as enzymes or as generators of antibody diversity.[30] A most fascinating proposal had been formulated by H. S. Lawrence in 1959.[31] He proposed that infectious agents complexed with transplantation antigens and formed a (self + x) complex—a fantastically prophetic view of what was to be found later!

There is no doubt that the experiments that were to reveal the essential role of MHC and T cell recognition in all depended upon the foundation built by tumor and transplantation immunologists. Without inbred and MHC (H-2) - congenic or H-2 mutant mouse strains, as developed by G. D. Snell[19] and D. W. Bailey[32] and coworkers, respectively, this problem would not at the time have been accessible to analysis. There is also no doubt that MHC-restricted T cell recognition would have been discovered by others, with a different approach, a few years later. This would certainly have happened once cloned effector T cells were developed by M. H. Schreier, H. Hengartner, H. von Boehmer, and C. G. Fathman,[33,34] when T cell hybridomas were developed by J. W. Kappler, P. Marrack et al., or when T cell receptors were first successfully analyzed by J. W. Kappler, P. Marrack et al., and J. P. Allison et al.[35-37] and then were molecularly defined by M. M. Davis et al. and T. W. Mak et al.[38,39]

From our very first experiments showing the double specificity of cytotoxic T cells for MHC and virus, we immediately knew that we had discovered something important. Our results were not the only ones that hinted at the biological role of major transplantation antigens, and they fitted several observations made during 1972/1973. In addition to the suggestions from cytotoxic T cell studies with leukemia, ectromelia, and LCM viruses,[9,40,41] there were the experiments by B. Kindred and D. C. Shreffler,[42] who had reported that H-2-incompatible T-helper cells transfused to T cell deficient nude mice were not able to help nude B cells make antibodies. Also, P. J. McCullagh and D. H. Katz, T. Hamaoka, and B. Benacerraf had shown that histoincompatible B cells and T cells did not interact successfully to produce a good IgM-to-IgG switch.[43,44] In parallel experiments with inbred strains of guinea pigs, A. S. Rosenthal and E. M. Shevach analyzed antigen-specific, proliferative T cell responses and found them only when primed T cells and antigen-presenting cells were from guinea pigs with the same MHC type.[45] Most of these experiments were, however, complicated and difficult to interpret, because the mixing of T cells and B cells or antigen-presenting cells (APCs) of different MHC type initiated allogeneic mixed lymphocyte reactions, resulting in nonspecific signals. These findings were, therefore, only accepted with hesitation by immunologists; this changed when our data appeared. The simplicity of the in vitro viral assays, the parallel observation by G. M. Shearer with TNP,[17] and its easy reproducibility by R. V. Blanden, I. D. Gardner et al. with ectromelia virus,[46] by U. Koszinowski and H. Ertl with vaccinia virus,[47] by E. Simpson, R. D. Gordon, and L. E. Samelson, and H. von Boehmer et al. with the male H-Y-antigen,[48,49] and by M. J. Bevan with various minor histocompabibility antigens[50] all helped to convince immunologists of the general character of MHC-restricted T cell recognition. Also MHC-restriction of T cell recognition was soon confirmed in vivo to be also important for antiviral protection transmissible from immune to naive recipients by immune T cells. By 1977 A. J. McMichael and coworkers in B. A. Askonas's laboratory showed that cytotoxic T cells specific to human influenza virus were HLA-restricted,[51] as did E. Goulmy et al. for male antigen H-Y-specific cytotoxic T cells.[52]

Our results triggered heated discussions in the Department. We thought that the virus somehow altered the normal cells' MHC molecules and that this virus-specific alteration was recognized by cytotoxic T cells in a similar way to that of foreign transplantation antigens. Everyone's imagination and intellect was stimulated to come up with a more general, simpler, and more convincing explanation for the findings. Discussions were particularly lively because at the same time K. J. Lafferty and A. J. Cunningham developed their ideas on second signals necessary to induce responses against foreign transplantation antigens,[53] G. Ada and R. V. Blanden were studying other virus-specific T cell responses, L. Pilarski and P. Bretscher were thinking about B cell responses and signal requirements along the two-signal theories of P. Bretscher, M. Cohn, and R. E. Langman,[54,55] and C. Parish, I. D. Gardner, I. Ramshaw, A. Happle, S. Kirov, W. Davidson, M. Dunlop, and Y. Rosenberg, working on B cell and T cell response in various virus infections, were discussing the role of enzymes modifying carbohydrates or other self-surface structures to explain the experiments.

Further analysis

According to our interpretation, our findings signified that virus infection somehow caused alterations of transplantation

antigens on the cell surface by forming a complex between the viral antigen and MHC molecules, by undefined structural alterations, or by complexing both, and that these alterations were recognized by T cell receptors (Figure 1).[56] Foreign transplantation antigens (so-called alloantigens) could thus be viewed as a genetically altered form of self-transplantation antigens. This view differed from the then-favored possibility that lymphocytes and target cells interacted mutually through transplantation antigens (see Figure 1A), that is, H-2^k interacted best with H-2^k, H-2^b best with H-2^b molecules in a symmetrical like–like complementarity. This intimacy model was soon excluded by the "F_1-experiment" showing that virus-specific, cytotoxic T lymphocytes from heterozygote (H-2^k × H-2^b) F_1 mice consisted of at least two subpopulations, one of each being specific for infected H-2^k, and the other for infected H-2^b targets. Since both MHC types were codominantly expressed on the lymphocyte surfaces of all host cells, this indicated that some T cell receptors of one T cell subpopulation were probably specific for H-2^k-plus-virus and the other subpopulation was specific for H-2^b-plus-virus (Figure 1B).

Further experiments together with R. V. Blanden carried out with the help of mouse geneticists (including C. S. David and H. O. McDevitt in the U. S. A.) showed that the H-2D and H-2K regions coding for class I MHC molecules were involved in virus-specific, cytotoxic T cell recognition.[46] These findings separated the MHC-restricted recognition by virus-specific, cytotoxic T cells from the MHC class II (Ia) antigen-linked immune response phenomena regulating interactions between T cell and B cell, or T cell and macrophage. Analysis of cytotoxic T cell interactions in vivo causing lethal immunopathology,[57] antiviral protection,[58] and protection against *Listeria monocytogenes*[59] all confirmed that MHC restriction was also valid in vivo.

In our second letter to *Nature*, we therefore concluded that T cells might function essentially by surveying the integrity of transplantation antigens. Recognition of cell surface alteration due to virus infection, chemical modification, or genetic differences (that is, alloantigens) may then be accommodated within the same model. A general hypothesis was formulated in *Lancet* in 1975,[60] which stated explicitly that the function of the major histocompatibility molecules is to signal modifications of self-MHC to the immune system.

What we had discovered and tried to explain for cytotoxic T cells, we also extended to helper T cells, proposing that they might recognize antigen-induced modifications of Ia (as the MHC class II molecules were called at the time) on macrophages and B cells. Importantly, the results offered an explanation of the reasons for the extensive polymorphism of MHC molecules; it minimized both the possibility that some cell-destroying pathogens failed to cause immunogenic modification and the risk of there being general unresponsiveness in a population. Obviously, what was unknown at the time was that MHC molecules or transplantation antigens are the antigen-presenting molecules that are recognized as a complex with the antigenic peptide. This became known in the subsequent ten years, mostly thanks to the work of E. R. Unanue et al.[61] and H. M. Grey and co-workers[62] for class II antigens, as well as to the particularly revealing and eye-opening work of A. R. M. Townsend.[63] He showed that class I molecules of virus-infect-

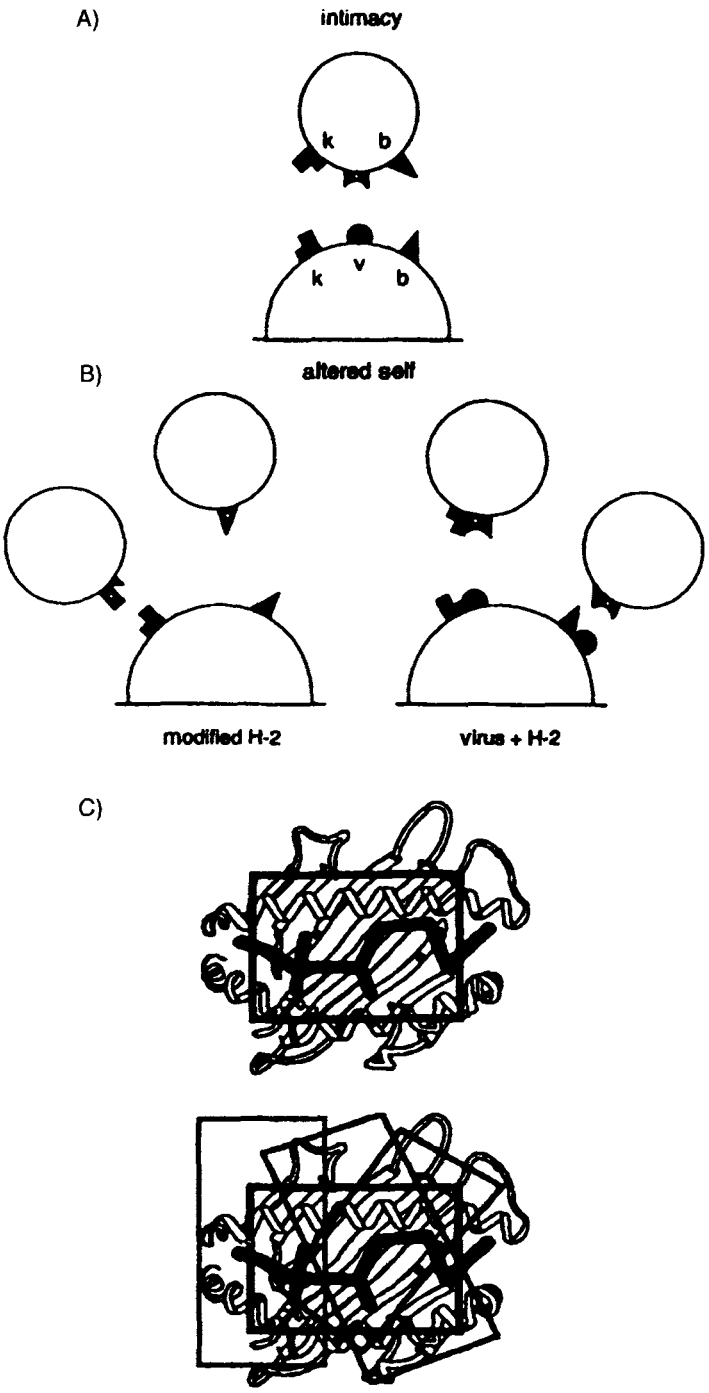

Figure 1. Models originally proposed to explain MHC-restricted T cell recognition. The idea that T cell and target cell come close enough through interactions with MHC molecules (A) was disproven by the demonstration that in H-2^k × H-2^b mice, an F1 cross between H-2^k and H-2^b mice, only two specific T cell populations were present, one specific for virus plus H-2^k and a second for virus plus H-2^b. Therefore T cell receptors were either specific or the virally modified MHC molecule where neither details of either virus antigen nor MHC molecules were recognized in original form (B), or T cells were specific for a complex formed between MHC molecule and viral antigen, and the T cell receptor recognized parts of the viral antigen and parts of the MHC molecule (C). It is now clear (in 1996) [69, 70] that the T cell receptor is composed to two chains Vα and Vβ that recognize a viral peptide presented by the MHC molecule [63]. What is still unclear (C) is whether the T cell receptor, here drawn as a square, interacts with the peptide plus MHC complex always in the same directed fashion, so that certain hypervariable regions of the receptor always interact with corresponding parts of the peptide or of the two MHC domains forming the groove, or whether alternatively the receptor interacts with the complex formed by MHC plus peptide in many possible random ways. (Reproduced with permission of Macmillan Magazines Ltd. from *Nature* **1974**, *251*, 547, and *JAMA* **1995**, *274*, 1070.

ed cells present peptides, 9–10 amino acids in length, to virus-specific cytotoxic T cells. Similar results were obtained by J. Maryanski and coworkers.[64] These peptides became very real when they were first eluted from target cells by the group of H. G. Rammensee.[65] Peptides were also soon shown to be involved in antitumor CTL responses by T. Boon's group.[66] All became convincingly clear in the classical studies of P. J. Bjorkman, J. L. Strominger, D. C. Wiley et al. in 1987, when the X-ray cristallography of class I HLA molecule revealed the peptide binding cleft.[67, 68] It is probably not only by chance that within a few weeks of the news of the Nobel Prize 1996 for specificity of the cell-mediated immune response, the first studies appeared in *Science* and *Nature*, revealing the X-ray structure of the complete complex of the T cell receptor, MHC class I molecule, and bound peptide by I. A. Wilson and by D. C. Wiley and their co-workers.[69, 70] What is still unclear (in 1996) is, which part of the T cell receptor (TCR), and whether always corresponding parts of the TCR, recognized the peptide and the MHC molecule in the same general position (Figure 1).[71, 72]

Implications

The Role of the Thymus in MHC-Restricted T Cell Repertoire Selection

Experiments first published by M. J. Bevan at MIT[73] and conducted in parallel in my laboratory at Scripps with the help of G. N. Callahan, G. Dennert and J. Klein signaled a role of thymic MHC in selection of the MHC-restricted T cell specificity.[74, 75] Reconstitution of lethally radiated H-2^b recipient mice with bone-marrow stem cells of (H-2^k × H-2^b) F_1 origin resulted in bone-marrow chimeras that were tolerant of H-2^k and H-2^b; when immunized, these chimeras reacted against H-2^b plus minor histocompatibility antigens, or, in our experiments, against H-2^b plus virus only (Table 1). This indicated that MHC-restricted T cells were specifically selected during T cell maturation according to the MHC expressed in the thymus. This was formally shown when MHC-restricted T cell specificity was studied in mice that lacked a thymus and therefore did not have mature T cells. When these mice of (H-2^k × H-2^b) F_1 type were given a thymus of fetal H-2^k origin, they eventually generated effector T cells that recognized virus-infected H-2^k, but not infected H-2^b target cells. Surprisingly, thymus-deficient nude mice given a histoincompatible thymus generated T cells that were specific for the nude mice's MHC,[76] but in general the MHC (apparently of the radio-resistant part of the thymus) selected the restriction specificity of virus-specific cytotoxic T cells.

These thymus and bone-marrow-grafting experiments had an immediate impact on clinical medicine by providing rational rules for the reconstitution of immunodeficiency disease. Accordingly, it is not only necessary to deplete T cells in order to avoid lethal graft-versus-host disease, but in addition, the host and the transplanted bone-marrow cells and the host's own or the transplanted thymus grafts must share MHC molecules. Otherwise, T cells capable of recognizing antigen-plus-MHC molecules on infected epithelial, mesenchymal cells, macrophages, or the corresponding B cells would not develop and function appropriately in such reconstituted hosts. These rules for positive selection of T cells according to the MHC of the thymus were subsequently elegantly—and even more convincingly—confirmed with T cell receptor transgenic mice, by H. von Boehmer and collaborators.[77] Subsequently, several other groups also analyzed transgenic TCR-expressing mice—D. Y. Loh et al. with an alloreactive T cell receptor[78] and H. P. Pircher, H. Hengartner, T. W. Mak, and K. Bürki et al. with an LCMV-specific receptor;[79] others used a variety of additional specificities.

New Vaccines

The recognition that peptides derived from viruses, bacteria, or classical parasites are presented to T cells via MHC class I or class II molecules immediately suggested that instead of live, and therefore potentially harmful, infectious agents, peptides could possibly be used as vaccines to induce T cell responses.[80] This was first formally shown for virus-specific peptides in studies by M. Schultz, P. Aichele, and H. Hengartner,[81] (Table 2, Figure 2) and then by C. J. Melief, W. M. Kast, and co-workers.[82] The main problem that slowed things down after the discovery of the key role of peptides by A. R. M. Townsend[63] was the fact that the half-life of such peptides is usually short, and protective T cells could therefore only be induced with the help of adjuvants that guaranteed the relatively slow, long-term release of peptides, triggering T cells over a prolonged period.[83] Peptide treatments were first shown to prevent experimental allergic encephalitis (EAE) under various conditions.[84, 85] More recently, the capacity of peptides to induce cytotoxic T cells so exhaustively and completely that they are deleted has been shown by D. Kyburz, P. Aichele, H. P. Pircher,

Table 2. The role of antigen localization, dose, and time on positive and negative vaccination [a].

vaccination	Infection with				
	cytopathic viruses		noncytopathic viruses		
	localized	generalized	localized		generalized
			choriomeningitis	subcutaneous	
none	survival	death	death	disease	disease but survive (virus eliminated)
positive	protection	protection	protection (virus eliminated)	disease (shorter)	death or protection (virus eliminated)
negative by "exhaustion"	disease and death dependent upon critical role of cytotoxic T cells		treated mice do not develop disease and survive but do not eliminate virus (develop carrier status)

H. Hengartner et al. and D. Moskophidis et al.[86–89] T cells were either induced or exhausted, depending on the relative amount and kinetics of the available antigen within a recipient mouse (Figure 2). Thus, with too much peptide, specific T cells

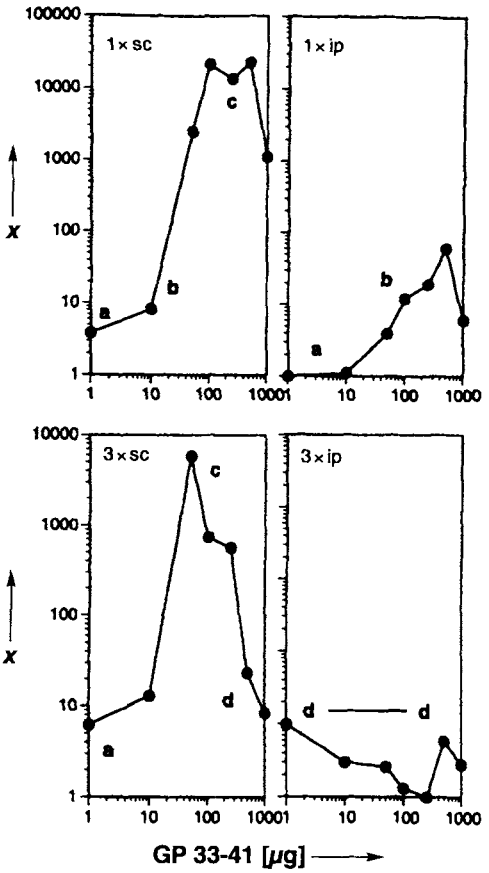

Figure 2. The role of antigen localization and of dose and time on T cell responses: The LCMV glycoprotein peptide GP33–41 presented by MHC class I D^b in C57BL/6-H-2^b mice was used as vaccine. Its half-life in vivo is $\ll$ 12 hours; protection was compared with controls in this experiment to assess T cytotoxic specific, LCMV specific cytotoxic T cell immunity; the x-fold protection relative to the untreated control (x) was titrated against amount of peptide given with adjuvans either once or 3 times subcutaneously (s.c.) or once or 3 times in intraperitoneally (i.p.). No induction was seen if the antigen is available in too small amounts (a), or for too short a period of time (b). Induction of a protective immune T cell response occurs if sufficient antigen is available for long enough (c). If, however, too much antigens spread throughout the organism for a long time causing excessive induction of all inducible T cells, exhaustion/deletion of all specific T-cells results (d). Adapted from ref. [88 b].

could be deleted for aslong as the peptide persisted—even permanently in the case of a thymectomized host. This signaled the possibility of a "negative" vaccination strategy (Figure 2, Table 2): Instead of increasing T cell precursor frequencies to enhance protection (positive vaccination), one could also reduce or delete T cells by means of excess peptides (negative vaccination).[90] The latter possibility may allow the immunopathological T cells that cause disease to be exhausted and deleted. Although one such example has been documented in an MHC class I specific, immunopathological, T cell mediated, transgenic diabetes model,[87] attempts to achieve the same in already primed hosts, before or after initiation of disease, have only met with partial success.

T Cell Epitope Escape Mutant Viruses

It could be expected that noncytopathic viruses would mutate the 9–10 amino acid peptides recognized by T cells in the context of the crucial MHC class I antigen. Mutation of this peptide, so that either its presentation by MHC molecules or its recognition by T cells is no longer possible, could help viruses to escape immune surveillance. A first example of this possibility was found by chance when H. P. Pircher, D. Moskophidis, H. Hengartner, et al. analyzed T cell receptor transgenic mice that expressed a T cell receptor specific for the LCMV glycoprotein peptide 33–41 presented by the MHC class I (D^b) molecule (Figure 3).[91, 92] When we infected such mice in the footpad we found a very early swelling reaction caused by immunopathological cytotoxic T cell response by day 2 to 4, which, however, waned, and a second CTL-mediated response was measurable after day 8 (Figure 3). When this unexpected

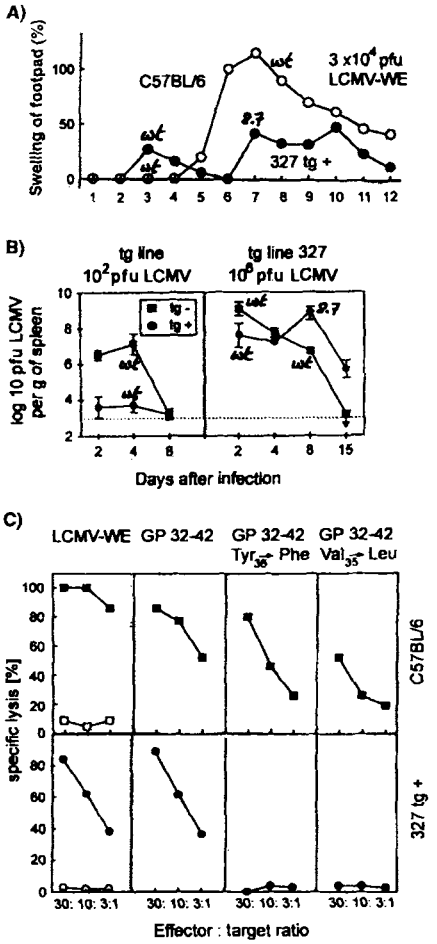

Figure 3. Selection of cytotoxic T cell epitope escape mutants in T cell receptors of transgenic (TCR-tg327) mice. LCMV-WE wildtype (wt) was injected into the footpad (A). The control C57BL/6 developed the expected $CD8^+$ T cell dependent footpad swelling by day 6 or 7; the TCR-tg327 mice exhibited an early swelling caused by the tg-TCR specific for LCMV-GP 33–41 plus D^b. This early response selected a mutant virus 8.7 by about day 7–8, that induced a swelling reaction by the endogenous non-tg T cells specific for other peptides. The virus titers found in the spleen of mice is infected with a low (10^2 plaque-forming units (pfu)) or a high (10^6 pfu) dose of LCMV-WE (B). The cytotoxic T-cell activity found in control C57BL/6 or TCR-tg327 mice on day 8 is shown in C. The peptides of the T cell epitope escape variant virus are not recognized by the tg-TCR, but are still partially (Tyr → Phe) or not (Val → Leu) recognized by effector T cells from control C57BL/6 mice. (Summarized from ref. [91].)

double peak of the T cell mediated footpad swelling reaction was analyzed further, it became clear that the virus had mutated by day 6 of infection; it no longer expressed the original gp 33–41, but exhibited various mutations within this epitope, presented by the MHC class I (D^b) molecule.[91] Apparently the vehement, virtually monoclonal, antiviral $CD8^+$ T cell response in the TCR-transgenic mouse had quickly selected the T cell epitope mutant virus that had escaped the transgenic T cells. A similar mutant virus that escaped the T cell response has subsequently also been found in patients infected with HIV by R. E. Phillips, A. J. McMichael, and co-workers[93] and in HBV-infected patients by A. Bertoletti et al.[94]

Associations between MHC and Disease

The link between some disease susceptibilities and certain HLA types was one of the first findings signaling the important role of MHC molecules in immunity.[95, 96] These diseases are often of autoimmune or immunopathological nature and are often linked to HLA class I, rather than class II, molecules.[97] The critical role of modified MHC molecules in T cell recognition explained why different allelic forms of MHC are randomly distributed in the population and made it likely that infectious agents and their peptides are presented by at least one of the four to ten MHC molecules expressed by an individual; this minimizes the possibility that a virus escapes immune surveillance, endangering survival of the entire population. The fact that some differences with respect to antigenicity and immunogenicity are linked to the MHC and correlate directly with different strengths of the T cell responses shows that different MHC molecules directly determine and regulate resistance to diseases.

Obviously, cytopathic viruses must be controlled efficiently by the immune system, otherwise the host species dies. Therefore, hosts with non-responder or non-presenting MHC molecules have probably been eliminated long ago by natural selection, leaving only high responders to survive. In contrast, for noncytopathic viruses, diseases are not caused by the infectious agent itself, but rather by the damaging effect of protective T cell responses. Because such agents do not directly cause disease, they do not exert a direct selective pressure on survival. But since these viruses may induce immunopathological cytotoxic T cell responses, differences in MHC may influence the severity of the disease. In fact, many of the diseases exhibiting some association with MHC have an aura of being autoimmune or immunopathologically mediated. This has been directly shown for known noncytopathic viruses (Table 3).[97, 98]

As pointed out above, one of the motivations for testing various mouse strains for cytotoxic T cell activity, resulting in the discovery of MHC-restricted T cell recognition was the variable and weak evidence of susceptibility differences of mice to lethal choriomeningitis that somehow correlated with MHC (Table 4). The comparison of a slowly replicating neurotropic strain of LCMV (UBC-A) with a rapidly replicating viscerotropic isolate UBC-B characterized by C. J. Pfau et al.[99] revealed a dramatic and strict correlation with MHC. After intracerebral infection of mice, UBC-A virus caused death in all recipients, irrespective

Table 3. Association between MHC and disease, reflecting $CD8^+$ T cell mediated immunopathological reaction against host cells infected with noncytopathic LCMV [a].

Mouse strain	A. Maximal increase of serum transaminases after intravenous infection with LCMV (pfu): T cell mediated hepatitis				B. Mortality after intracerebral infection with LCMV	
	WE_{UBC} A		WE_{UBC} D		WE_{UBC} A	WE_{UBC} D
	10^2	10^6	10^2	10^6		
BI0.G H-2D^{q}L^q	–	–	–	++	100%	100%
BI0.BR H-2D^k	–	–	++	±	100%	0%

Mice were infected intravenously with the indicated doses of LCMV WE_{UBC} A or D. Maximal increases of serum transaminases were indicated as follows: - less than threefold, +10–20-fold, ++ greater than 100-fold. Damage of liver cells or of choriomeningeal or ependymal cells caused by LCMV-specific $CD8^+$ T cells. In absence of $CD8^+$ T cells, no immunopathology is seen.

C. Role of virus characteristics increasing likelihood to establish persistent LCMV-infection in mice	
Virus parameters	Increased replication rate, increased resistence to interferons, loss of T cell epitopes by mutation, increased tropism for lymphohemopoietic cells.
Host parameters	Decrease in relative interferon levels, loss of presenting MHC class I molecules (e.g., BALB/c-dm2 mice), partial loss of $CD8^+$ T cells (e.g., DBA/2 mice), loss of T-help cells, lack of IL-2.

[a] Data from refs. [98, 100, 101].

Table 4. Transmission of protective immunity from mother to offspring [a,b].

	preexistent antibodies	"activated" T cells
placenta	maternal antibodies transmissible except with chorioepithelial double layered placenta (bovine)[b]	nontransmissible, danger of host-versus-graft disease and rejection
milk	transmissible through gut of offspring (temporarily) passive protection in gut[b]	evidence poorly analyzed
function	altruistic: protection of offspring against infectious diseases during the period of T cell immunodeficiency and protection of mothers during pregnancy	egoistic: protection of original host against spread of noncytopathic infectious agents (control of immunopathology and tumor cells within host)

[a] Because of MHC-restriction of T cell recognition, T cell maturation in offspring is slow and starts after birth to prevent graft-versus-host disease. During this period of physiological immunoincompetence, transfer of maternal antibody-memory is essential for protection of offspring against many infections. [b] Data from refs. [106a].

of MHC. UBC-B caused immunopathological disease in all those possessing the MHC class I H-2D^{q}L^q allele but not in the others.[98, 100] Furthermore, the susceptibility of mice to becoming persistently infected virus-carriers could be linked by D. Moskophidis et al. to the absence of class I MHC molecules that were able to present the critically important dominant immunogenic viral peptide.[101, 102] These studies, in addition, demonstrated that virus dose and virus strain (including T cell epitope variants) also played an important role in the overall virus–host balance and in MHC–disease association.

Thus association between MHC (in humans HLA) and disease may not be found readily for acute cytopathic viral or bacterial infections, because natural selection has favored good combinations between virus and MHC–presenter.[90] In contrast, for noncytopathic viruses, the selection pressures are much weaker and various virus–host immune response balances resulting in more or less immunopathological disease are acceptable for species survival. Because cytotoxic and protective T cell responses directly depend upon class I MHC presentation of peptides, susceptibility to consequential disease may correlate directly with the MHC class I allele, depending upon the localization of infection (choriomeningitis vs. establishment of a virus-carrier status).[98, 101]

One may therefore extrapolate that at least some autoimmune diseases may eventually turn out to be caused by immunopathological T cell responses against viruses that are poorly cytopathic or noncytopathic[95, 96] (Figure 3, 4). Hepatitis B, C, or D virus infections or possibly immunodeficiency virus (HIV) infections in man may represent this type of chronic infection leading to a protective but immunopathological T cell response, causing MHC-regulated immunopathologic disease. Alternatively, infectious agents that are either unknown or not yet recognized may be involved initially in triggering the disease by immunopathological or autoimmune mechanisms. For example, it is suspected that also common cytopathic viruses may be involved in the pathogenesis of some autoimmunity diseases (Figure 4 and 5). Infections of MHC class-I-positive epithelial or

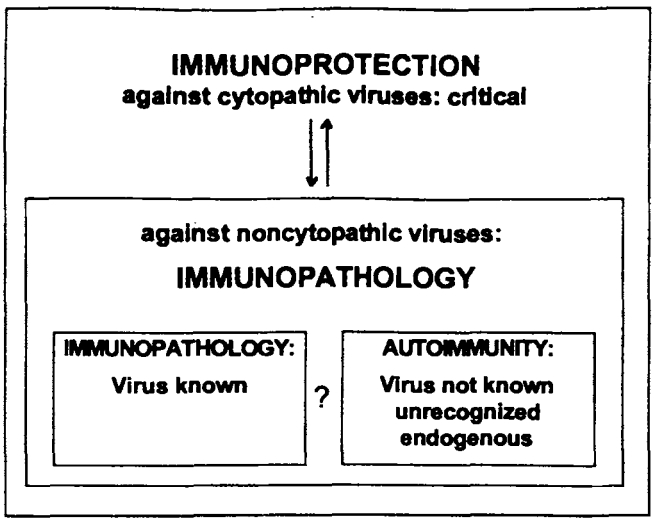

Figure 4. Immunoprotection and immunopathology: Efficient immunoprotection is mandatory for survival of the host infected with a cytophatic virus. Since noncytophatic viruses do not cause cell damage directly, pathology is caused by immune mechanisms. If the virus is not recognized or is unknown, the disease may be mistaken as an autoimmune disease.

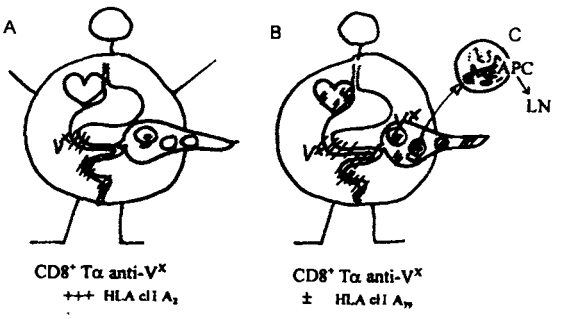

Figure 5. Autoimmunity induced by viruses: If a cytopathic or noncytopathic virus is stopped early enough by MHC class I-(HLA-cl I A_2)-restricted effector T cells (A), sensitive target cells are not destroyed. If the protective HLA-cl I A_{39}-restricted T-cell response is slow (B), virus may reach sensitive target organs and cells that may be destroyed directly or induce disease by T cell mediated immunopathology, that is, T cells cause release of self antigen (S). The self-antigen may then be picked up and presented by APC (C) and in the local lymph node or in the spleen induce autoimmune CTL T cells or autoantibodies. Autoantibody production needs T-help that may be provided by newly induced CD4$^+$ T cells specific either for viral antigens that are linked to self-antigens or for so far segregrated immunologically ignored self-antigens.

neuroendocrine cells should be controlled primarily through CD8$^+$ T cells; their efficiency will, therefore, not only determine the extent and kinetics of destruction of infected host cells, but also whether an autoimmune T cell and B cell response against such sequestered self-antigens is induced.

The reason for MHC class I linkage of autoimmune diseases is, therefore, probably in some diseases that the autoimmune effector T cells are class I restricted (Figure 4), and in other situations that modulations of common or unrecognized infections by the efficiency of class-I-restricted effector T cells may indirectly regulate autoantibody responses (Figure 5).

Consequences for Immunological Memory

The discovery that T cell specificity monitored MHC molecules, that it was positively selected in the thymus, and that this explained the transplantation reaction offered a basis for understanding the role of protective immunological memory. Immunological memory by B and T cells is an important hallmark of immunity and has been exploited successfully by vaccinations.[103–106] However, before vaccinations were used, the idea of immunological memory had no raison d'être. One could argue that if a host dies during the primary infection, he does not need an immunological memory. Also, if he survives the primary infection, he does not need memory, because the system has proven itself efficient. What then is the function of immunological memory? The first and most critical one is transfer of immune antibodies of the mother to protect offspring during the phase of maturation of the immune system after birth, the second is to protect mothers from infections during pregnancy.[106] I will only discuss the first aspect further here.

Calves are born without antibodies because, as for all vertebrates, the immune system is not yet mature enough to produce its own antibody response (Table 4).[106a] In addition, in calves maternal antibodies cannot be transmitted because of the complete doubly layered placenta. All protective antibodies are transmitted in colostral milk from the mother within 24 hours of

birth. If this does not happen, the calf dies within a few weeks as a result of common bacterial infections.

Why then are newborn vertebrates immunoincompetent (Table 4)? My explanation is that because of MHC-restricted T cell recognition, T cells of the fetus should not mature, so as not to endanger pregnancy or cause graft-versus-host disease against maternal MHC molecules.[90, 106] The passively acquired antibodies provide protection during the critical period after birth, during which T cell and B cell maturation slowly takes place over 3–6 months in humans, or four weeks in mice. Since maternal antibodies must cover a wide spectrum of relevant infectious agents that may not be encountered during pregnancy, immunological memory carried by antibodies is mandatory for at least two reasons. Firstly, pregnancy is relatively short compared to the time taken for the host to reach sexual maturity, and therefore antibody memory must be developed over a long period. Secondly, the relevant infections must not occur during pregnancy, because many infections cause damage to and abortion of the foetus.

Evidence has been found in various models and infections that antigens persist both in antibody–antigen complexes and exposed on follicular dendritic cells to maintain antibody responses for many years (Table 5), so that levels of transmissible protection are guaranteed.[107–109]

Table 5. Memory B cells are not protective, whereas preexistent neutralizing levels protect naive recipients against cytopathic infectious agents [a].

Adoptive transfer to naive mice	Booster immunization 2 days before challenge infections	Result of challenge infection
B-cells, naive or normal	no	disease
	yes	disease
"primed" or memory B cells	no	disease
	yes	disease
immune serum with neutralizing antibodies	no	protection
	yes	protection

[a] Data from results of experiments performed in mice with vesicular stomatitis virus (VSV) of refs. [108, 115].

What then is the role of T cell memory? Memory T cells are probably necessary to maintain memory B cells but this is not yet certain. Although increased precursor frequencies of T cells provide some protection, which should suffice to protect mothers during pregnancy, there is a second very important aspect of T cell memory. T cells are critical for controlling persisting noncytopathic viruses that hide in peripheral epithelial or mesenchymal cells and prevent them from reemerging to trigger T cell mediated, immunopathological disease (Tables 4). There is good evidence available now that these protective T cells are also maintained by antigens,[106, 110, 111] although this simple notion is very controversial at the present time.[102, 112, 113] Thus, low levels of ongoing T cell responses reflect antigen-driven, activated effector T cells and not special memory T cells. These serve to protect the host itself and not progeny; these egoistic protective memory T cells cannot be transmitted, due to MHC differences between mother and offspring (Table 4).

Taken together, the summarized evidence suggests that because of MHC-restricted T cell recognition, which causes the transplantation reaction, prolonged physiological immunodeficiency of the offspring is necessary; protection during the period of maturation of the immune system is provided by passively transferred, altruistic antibodies, which necessitate a mandatory antigen-driven elevated antibody level in mothers (Table 4).

Conclusions

In the complex balance between viruses and hosts, T cells play an important role that varies with different host and viral characteristics. The unexpected finding—by chance and also as a matter of course on collaboration between immunologists, geneticists, and virologists—of MHC-restricted T cell recognition has triggered a great number of important subsequent studies by many other groups, resulting in an excellent molecular understanding of T cell recognition of viral-infected target cells. These combined findings have helped to improve the understanding of both immunological specificity and immunological memory. They have furthered our understanding of disease pathogenesis and made possible applications of the acquired knowledge for improving protective immunity and for diminishing immunopathological T cell responses.

Small Glossary

allogen	a substance that stems from another individual of the same species
CTL	cytotoxic T lymphocytes
cytopathic effect	degenerative change in infected cells due to the replication of viruses (formation of giant cells, lysis of cells, etc.)
APC	antigen-presenting cells
EAE	experimental allergic encephalitis
HLA	human lymphocyte antigens (coded by the major histocompatibility complex (MHC)); the MHC controls the transplantation or histocompatibility antigens
H-2	histocompatibility-2, coded by the H-2 gene region (= stronger histocompatibility complex, MHC of the mouse); H-2 controls the transplantation or histocompatibility antigens; the Class 1 antigens are gene products of the K and D region
LCM	lymphocytic choriomeningitis
Listeria monocytogenes	gram-positive, rodlike bacteria without spores that cause the infectious disease Listeriose, which can be tranmitted between animals and humans; the disease can be acute or chronic, with sepsis, meningitis, or often also only as an influenza-like infection or even unnoticed
MHC	major histocompatibility complex
LCMV	the lymphocyte–choriomeningitis virus infects rhodents and occasionally humans; it can attack cells of the meninges and the nervous system without damaging them
TCR	T cell receptor (specific on a T cell)

Looking back over the past 28 years of my professional life since graduating from medical school and marrying my wife, Kathrin, I must admit that life has been very good to me. I was given the chance to work and spend time with many excellent scientists and good friends as well as many eager young students and postdocs. I am part of a caring family, I have the luck to discover new things every once in a while; furthermore, I am paid a salary for enjoying re-searching (in the true sense of the word) the secrets of nature. I thank my families, my mentors, and my

collaborators for all these years. I would also like to thank the Universities of Basel, Zürich, and Lausanne, and especially the John Curtin School of Medical Research, Professor G. Ada, and R. V. Blanden. I am also greatly indebted to the Australian National University in Canberra, the SCRIPPS Clinic and Research Foundation in La Jolla (California), the U. S. National Institutes of Health, the Canton of Zürich, the Swiss Federal Government, the Swiss National Science Foundation, the University of Zürich, and the Fondation Jeantet for their generous financial support.

Inorganic Cauliflower: Functional Main Group Element Dendrimers Constructed from Phosphorus- and Silicon-Based Building Blocks

Dietrich Gudat*

Increased interest in synthetic mesoscopic systems and nanostructures has triggered the rapid development of the chemistry of dendrimers and cascade molecules.[1] Dendrimers are oligo- or polymeric molecules with a treelike, branched backbone, which are constructed in discrete generations by repetitive synthetic cycles. They exhibit interesting properties such as monodispersity, frequently spherical molecular shape, a high degree of internal order, and an accumulation of peripheral functional groups. Although at first mainly dendrimers with organic skeletons were studied, later, dendritic complexes and organometallic compounds and, more recently, main group cascade molecules from silicon- and phosphorus-based building blocks have come to the fore. The incorporation of these elements was stimulated by the availability of a large number of highly reactive monomers suitable for both the assembly of the molecular frame and the attachment of peripheral functional groups. A further advantage of phosphorus-containing dendrimers is that ^{31}P NMR spectroscopy can be applied to directly monitor the construction process.

The known silicon-containing dendrimers may be classified according to three principal categories: silicones and carbosilanes with skeletons of (SiO) and (SiC_n) fragments, respectively, and oligosilanes with pure Si backbones. Silicone dendrimers were obtained as the earliest examples of Si-containing cascade molecules in the late 1980s by the groups led by Zhdanov and Masamune. Starting from $MeSiCl_3$, Zhdanov et al.[2] constructed a dendrimer with 24 $Si(OEt)_2$ end groups by iterative reaction with **1** and subsequent $SOCl_2$-promoted exchange of terminal EtO groups by Cl substituents. Masamune et al.[3] chose the oligosiloxane **2** as the initiator core. The terminal SiH groups were oxidized to SiOH moieties, which were then coupled to the extension unit **3**. Two reiterations of this sequence yielded a third-generation dendrimer ($M \approx 15$ kDa) with 24 SiH end groups, which should be suitable for further functionalization.

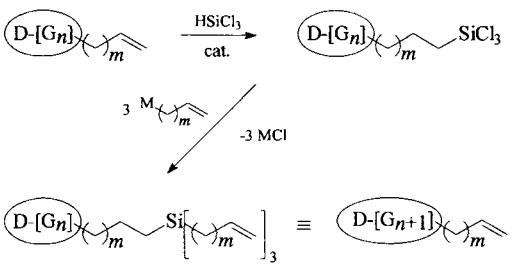
An efficient procedure for the generation of carbosilane dendrimers was reported shortly afterwards by van der Made and van Leeuwen[4] and later extended by other groups.[5] Starting from polyfunctional ω-alkenylsilanes as cores, new generations are assembled in two steps by hydrosilylation and subsequent ω-alkenylation (Scheme 1). By deliberate variation of the



Scheme 1. Construction of carbosilane dendrimers by successive hydrosilylation/alkenylation. D-[G_n]–X denotes a dendrimer of generation n with end groups X.

branch cell multiplicities (e.g. by replacement of $HSiCl_3$ by $HSi(Me)Cl_2$) and segment lengths of each generation (by using alkenyl chains of different lengths) dendrimers can be designed with specific dimensionality and compactness.[4b] Mazerolles et al. recently showed[6] that this procedure can also be used to construct germanium dendrimers up to the second generation; the controlled assembly of still larger molecules has been prevented so far by partial decomposition and side reactions of reactants under the reaction conditions.

Approaches to dendritic polysilanes were elaborated independently by the research groups of Lambert and Sekiguchi. Lambert et al.[7] prepared **4** by chlorinating demethylation of $MeSi(SiMe_3)_3$ and treatment of the resulting product with $LiSi(SiMe_3)_3$. Sekiguchi et al.[8] obtained **7** from the tetrasilanes **5** by repeated cleavage of terminal Si–C bonds with CF_3SO_3H and coupling of the resulting silyl triflates with the lithiosilanes **6** (Scheme 2). Crystal structure determinations revealed that **7** has a rather open, starfishlike molecular structure, whereas **4** is more compact owing to its higher degree of branching. In polysilane **4** the coordination spheres of the inner Si atoms are also distorted due to steric overcrowding.[7] According to UV/Vis studies, the optical properties of both compounds are similar to those of linear oligosilanes.

A growing interest in the functionality of silicon dendrimers is documented by first reports dealing with the linkage

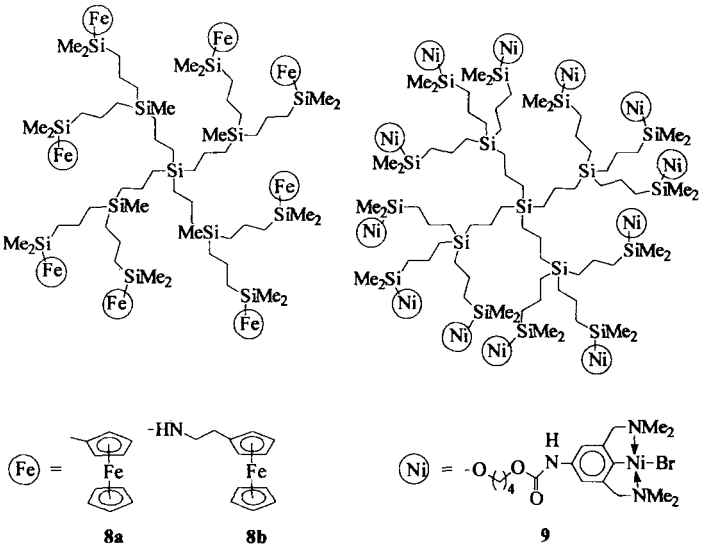
of reactive transition metal fragments to the surface of small dendritic carbosilanes. With the exception of a single report describing the attachment of $Cr(CO)_3$ moieties to terminal phenyl groups,[9] the metal fragments have been anchored by coupling to Si–Cl bonds, either directly or through an additional linker. Examples of this synthetic strategy are the preparation of redox-active ferrocene derivatives and nickel complexes such as **8a**, **b**[10] and **9**,[11] respectively. Complex **9**

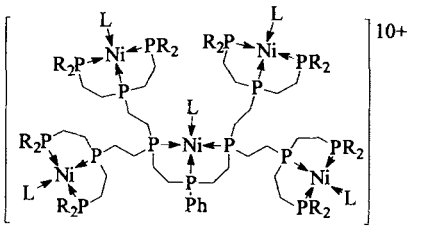


8a **8b** **9**

was successfully employed as a catalyst in Kharasch additions; although its activity was somewhat reduced, its behavior was similar to that of analogous monomeric catalysts. The potential use of SiH_3-terminated carbosilane dendrimers as SiC precursors rather than the explicit exploitation of their terminal functionalities stimulated the synthesis of these compounds by means of hydrogenation of $SiCl_3$-substituted derivatives.[5b] Pyrolysis studies revealed that even if larger dendrimers of this type are in principle suitable as preceramic materials, their use does not lead to any significant improvements that would justify the expensive synthesis.

The structural and functional diversity of dendrimers constructed from phosphorus-based building blocks owes largely to the existence of both neutral and charged framework structures. Rengan and Engel obtained the first charged cascade molecules, polyphosphonium salts in which the three to five dendrons are composed of $[P^+(C_6H_4CH_2)_3]$ repeat units and carry up to 40 positive charges.[12] Reduction of the P=O moiety in the core of such a phosphonium cascade molecule afforded a dendritic phosphane, which is capable of coordinating a metal fragment in the center rather than on the surface, as was demonstrated by the formation of a AuCl complex.[12c]

Neutral phosphorus dendrimers were first reported by the research group headed by Majoral[13] and, shortly afterwards, by the groups led by DuBois and Labarre. DuBois et al.[14] prepared dendritic oligophosphanes by repetitive addition of vinyl phosphonates to primary phosphanes and subsequent reduction of the ester groups to regenerate PH_2 termini; saturation of the outermost PH_2 groups was finally achieved by addition of monovinylphosphanes. The largest molecules of this kind (15 phosphane groups) was treated with $[Pd(MeCN)_4]^{2+}$ to give as the main product the complex **10**, which was found to



10

catalyze the electrochemical reduction of CO_2 to CO with a rate and selectivity comparable to that attained with analogous monomeric Pd complexes. Similar reactivities were also observed for a mixed Si/P dendrimer accessible from fourfold addition of $HP(CH_2CH_2PPh_2)_2$ to tetravinylsilane and subsequent reaction with $[Pd(MeCN)_4]^{2+}$.

Labarre et al.[15] exploited the functionality of cyclophosphazenes for the generation of highly branched, spherical dendrimers with $N_i = 6$ and $N_b = 5$.[16] Their synthesis started with the exhaustive substitution of hexachlorocyclotriphosphazene by long-chain α,ω-diamines to give a hexamine ("sexapus"), whose terminal amino groups were then capped with new phosphazene "flagstones". This two-step reaction sequence could be reiterated to construct cascade molecules up to the fifth generation, although with increasing molecular size an increasing portion of incompletely substituted side products was noted. Even though these impurities could be removed by chromatography, the analytical data reported for the products give no unequivocal information about possible structure defects (e.g. the growing together of different dendrons, or cyclization reactions), which may lead to polydisperity and molecular weights lower than the theoretically predicted value of approximately 1830 kDa. The authors suggested that the risk of impurities resulting from incomplete reactions might be minimized by a modified reaction sequence in which an existing flagstone is first capped with a sexapus and then with a cyclotriphosphazene to give two new dendrimer generations in two steps.

The largest push so far in the development of phosphorus dendrimers was initiated by the preparation of dendritic polythiophosphoryl amides, whose construction was described by Majoral et al. based on two different reaction sequences starting from aldehyde-based building blocks (Scheme 3). In the first

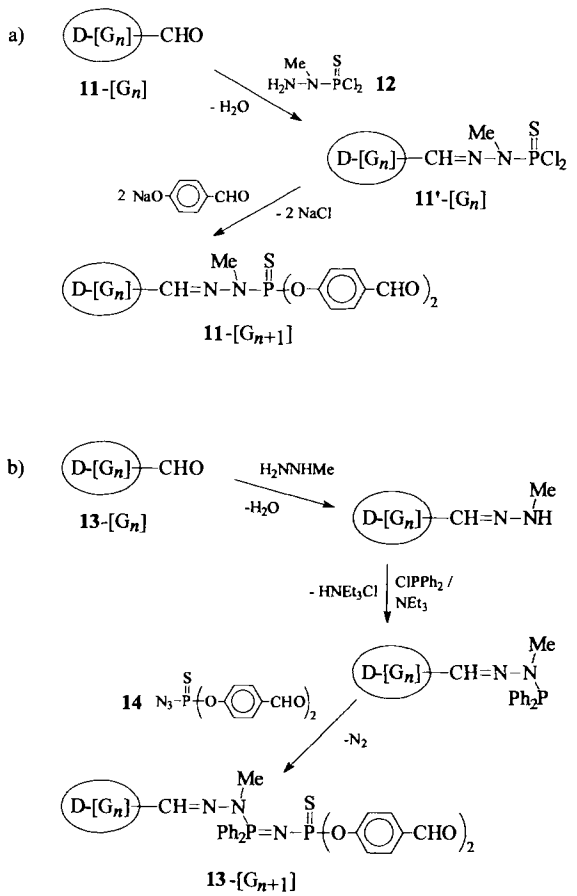
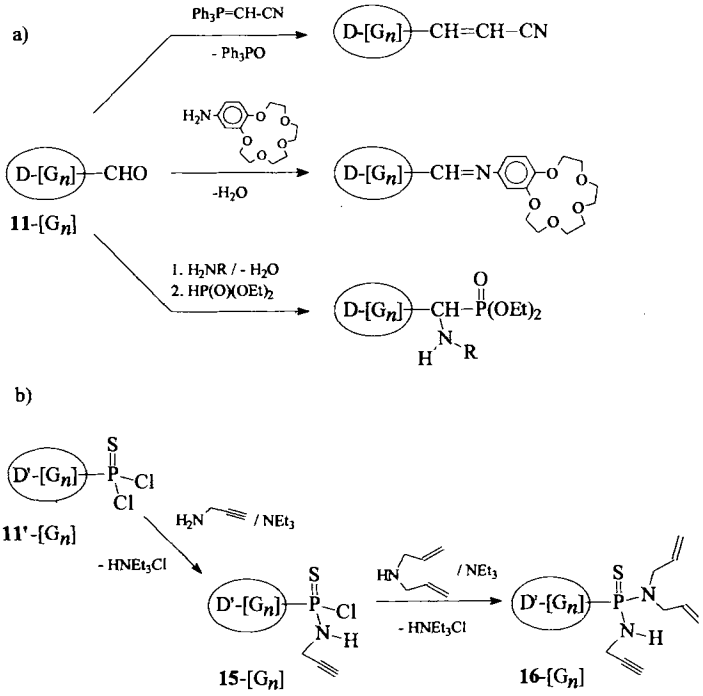


Scheme 3. a),b) Two reaction sequences for the synthesis of thiophosphoryl dendrimers.

addition of phosphonates[21] is possible almost regardless of the size (generation) of the dendrimer. Some examples demonstrating the power of these reactions for the introduction of new functional groups are collected in Scheme 4a. At present investigations of analogous transformations of $P(S)Cl_2$ end groups



Scheme 4. Functionalization of dendrimers containing a) aldehyde end groups and b) thiophosphoryl end groups.

case a new generation is assembled in two steps by Schiff condensation with the hydrazinothiophosphoryl dichloride **12**, followed by substitution of the Cl groups by the sodium salt of 4-hydroxybenzaldehyde.[13] In the second procedure[17] new generations are formed in three steps by reaction with methylhydrazine, conversion of the formed hydrazone into an aminophosphane (or alternatively[18] Mannich reaction with Ph_2PCH_2OH), and final Staudinger reaction with the thiophosphoryl azide **14**. Since both sequences begin and end with compounds having CHO end groups, their combination affords an easy access to layered block codendrimers with generations of different chemical constitution.[18] Owing to the low degree of branching ($N_b = 2$), large segment lengths, and the ready separation of coproducts, thiophosphoryl dendrimers with three, four, or six dendrons, good solubilities, and large theoretical molecular masses (> 3000 kDa for **11**-[G_{12}]) were easily accessible.[13, 17–19] Confirmation of the calculated molecular masses by mass spectrometry was feasible for first- and second-generation dendrimers,[19] but failed for larger derivatives; however, ^1H and ^{31}P NMR spectroscopic studies indicated that even for the largest molecules any deviations from monodispersity are too small for the observation of structural defects due to incomplete reactions.[13, 17, 19–23]

The highly reactive end groups prove not only useful for backbone construction, but also for the modification of surface groups. Thus, Majoral et al. demonstrated that conversion of peripheral CHO groups in Schiff or Wittig reactions[19, 20] or by are mostly confined to aminolysis and alcoholysis reactions.[20a, 22] A noteworthy finding here is that by appropriate adjustment of reaction conditions the two chlorine atoms of each phosphoryl unit may be replaced successively by two different functional groups.[22] This reaction permits the first directed synthesis of polyfunctional dendrimers such as **15** and **16**, which carry up to four different end groups at the tip of each branch and may, for instance, allow the simultaneous binding of several different chemically active substrates in close proximity (Scheme 4b).

Special attention has been paid to dendrimers with phosphane end groups, which are accessible by the Mannich condensation of hydrazones having NH or NH_2 groups with Ph_2PCH_2OH (Scheme 5a). The potential of these dendrimers to act as mono- or bidentate ligands was confirmed by the syntheses of a number of transition metal complexes.[23] The successful methylation of the Pd complex **18a** with Cp_2ZrMe_2 or MeMgBr to give **18b**, and its further conversion into **18c** and **18d** by sucessive insertion of CO and norbornene into the M–C bonds are impressive examples of synthetically relevant organometallic reactions conducted on the surface of an inorganic dendrimer (Scheme 5b).[23b] Further applications of these and similar reactions in synthetic and catalytic transformations are interesting prospects. After the phosphane surfaces of dendrimers of type **17b** had been covered with between 48 (**17b**-[G_3]) and ca. 3000 AuCl moieties (**17b**-[G_{10}]) the resulting complexes could be visualized directly by electron microscopy. Single dendrimer mol-

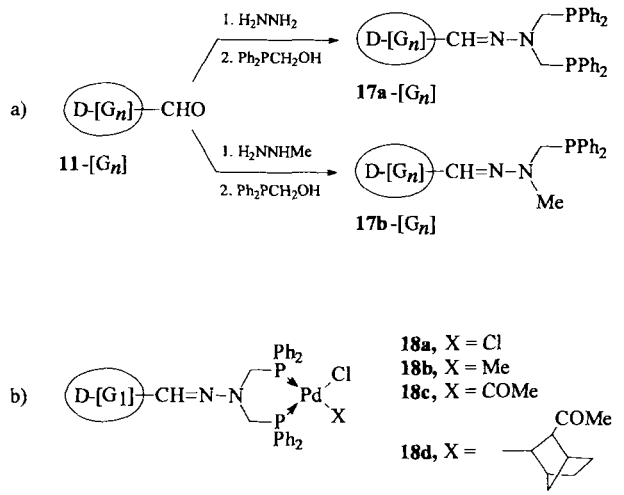
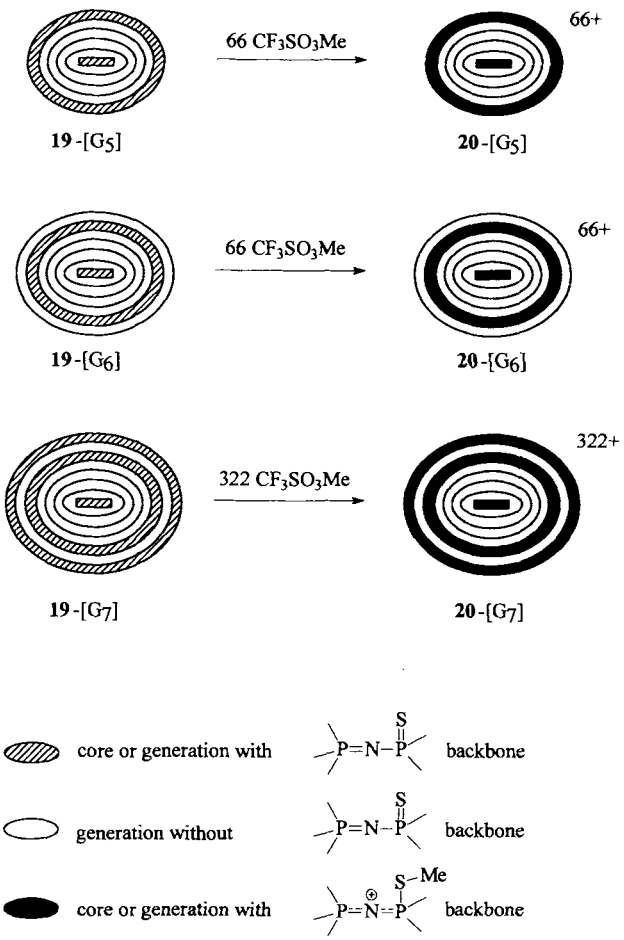


Scheme 5. a) Syntheses of phosphane-functionalized dendrimers and b) dendrimer palladium complexes **18**.

ecules were found with spherical shapes and sizes between 6 [**18b**-[G_3]) and 15 nm [**18b**-[G_{10}]); up to the fifth-generation dendrimer the size increased regularly by 1.5 nm per layer.[23a, c]

^{1}H and ^{31}P NMR spectroscopic studies indicate that for all the surface reactions of thiophosphoryl dendrimers studied a quantitative displacement of end groups within the spectroscopic detection limit can be reached.[19–23] In only a few reactions was a decrease of reaction rates with increasing dendrimer size noted;[20] no generation-dependent variations of the chemical reactivities were detected for the rest. In addition, Majoral et al.[18] were recently able to demonstrate that the inner structures of large thiophosphoryl dendrimers are sufficiently open to allow functionalization even in inner layers. They found that tiered block dendrimers such as **19** react with methyl trifluoromethanesulfonate under regioselective S-alkylation of (Ph_2)-P=NP(S) moieties to give polycations **20**, in which the charges are arranged in well-defined layers at the surface, in the core, in inner cells, or a combination thereof (Scheme 6). Alkylation of the core unit was proven unequivocally by ^{31}P NMR spectroscopy for dendrimers up to the sixth generation. In contrast, for **19**-[G_7] only alkylation of the fourth and seventh layer was ascertained, while the signals of the core evaded spectroscopic detection. The most noteworthy feature of this reaction is not only that the initiator core of an inorganic dendrimer of sixth generation is accessible for defined chemical reactions,[18] but the high chemoselectivity which results in unambigous discrimination between the two types of P=S moieties present. This result suggests that the differences in the reactivity of individual functional groups on the surface and in the interior are comparatively small and paves the way for the further development of organometallic chemistry not only on the surface, but also in interior of dendrimers.

In the study of inorganic dendrimers the focus has also shifted from pure skeleton construction to the preparation of functional molecules.[1c] Earlier studies of functionalities were mostly centered on the consequences of cooperative effects resulting from the accumulation of many functional groups on the surface (e.g. multielectron transfer processes). In the future aspects like the immobilization or fixation of reagents and catalysts on polymers with the aim of facilitating separation from reaction



Scheme 6. Polyalkylation reactions of thiophosphoryl dendrimers.

mixtures (for instance, in two-phase or membrane reactors[11]), or the exploitation of "multiply" functionalized dendrimers having several different types of surface groups may gain importance. Another promising area is the application of specific host–guest interactions for the chemoselective control of reactions at interior functionalities, which may lead to the development of novel synthetic reagents or catalysts.

A Chemical Concept for the Treatment of Tay–Sachs Disease

Thomas Kolter*

Tay–Sachs disease belongs to a group of hereditary human diseases in which lipids accumulate in the lysosomes of the cells due to a degradation disorder. With one exception, a causal treatment of these often fatal sphingolipid storage diseases is not possible. Recently, lipid storage was retarded in the central nervous system of an animal model of Tay–Sachs disease with the aid of a low molecular weight inhibitor of glycosphingolipid biosynthesis, *N*-butyldeoxynojirimycin (**1**) (Scheme 1).[1]

Sphingolipidoses

Sphingolipid storage diseases (Scheme 2) are relatively rare hereditary disorders in which at least one step in sphingolipid degradation is deficient.[2, 3] Sphingolipids, components of cell membranes, fulfill functions on the surface of eukaryotic cells that to date have been only partially clarified.[4] They consist of a membrane anchor of ceramide (*N*-acyl-D-*erythro*-sphingosine) and a hydrophilic headgroup, which can be a saccharide or a phosphorylcholine. Sphingolipid biosynthesis[5] starts with the amino acid L-serine and palmitoyl coenzyme A at intracellular membranes. From there the sphingolipids are transported to the plasma membrane to be internalized by endocytosis after a certain time and to be degraded in the digestive system of the cells, the lysosomes.[6] In contrast to phospholipids, for example, sphingolipids are degraded in a strictly sequential manner. Nearly of every of these degradation steps is associated with an inherited defect that gives rise to a human disease. As a consequence of the impaired degradation, undegraded sphingolipids accumulate in the lysosomes and lead to the destruction of certain cells. Since the degradation proceeds at membrane surfaces, activator proteins are needed in addition to hydrolytic enzymes to mediate the interaction between membrane-bound lipid substrates and water-soluble hydrolases. The clinical pictures of sphingolipidoses are rather heterogeneous. Often they are man-

ifested as mental illnesses that start in early childhood and lead to death of the patients within a few years. However, mild forms of diseases are also known, which do not involve the nervous system, and the patients have a normal life span.

The pathogenesis of these diseases depends essentially on two factors.[2] The expression of glycosphingolipids is cell-type-specific. The gangliosides, for example, glycosphingolipids containing sialic acid, are predominantly found on neuronal cells, so that their accumulation leads to the loss of these cells and impairment of the function of the central nervous system. The other factor is that the course and the severity of the disease depend on the residual enzymatic activity of the gene product in the lysosomes.[7] In general, a complete deficiency leads to an early onset and a severe course of the disease. Many mutations, however, only lead to a partial loss of enzymatic activity. A residual activity of only a few percent can be sufficient to delay the onset of the disease and cause a mild course of the disease.[7]

Tay–Sachs Disease

Human Tay–Sachs disease is characterized by the onset of neurological symptoms in early childhood, rapid progression of the disease, and the death of the patients usually by the age of four years.[8] The earliest symptoms begin within the first three to five months of life. Motoric weakness is evident; patients are extremely startled by sudden sounds since inhibitoric neurons die faster than excitatoric neurons. By the age of six to ten months attention decreases and vision diminishes. Neurological disorders continue until the death of the patients. In Tay–Sachs disease the α-subunit of the enzyme β-hexosaminidase A is defective. β-Hexosaminidase A, which is a heterodimer containing an α- and a β-subunit, cleaves off terminal β-glycosidically linked *N*-acetylglucosamine and *N*-acetylgalactosamine residues from charged and uncharged glycoconjugates. The natural substrate of β-hexosaminidase A is the ganglioside GM2, which is negatively charged under physiological conditions. For GM2 degradation in vivo, the additional presence of a cofactor, the GM2 activator protein, is necessary. Uncharged substrates like the glycolipid GA2 can also be cleaved by β-hexosaminidase B with the subunit composition β_2. Mutations in the β-chain of the hexosaminidases can lead to the loss of both isoenzymes, hexosaminidases A and B, which in humans results in Sandhoff's disease.

The Concept

The new approach is based on the idea that the severity and onset of these diseases are governed by the ratio of residual lysosomal activity and substrate influx into the lysosome.[7] As long as the biosynthesis of substrates continues, the pathological accumulation of substrates in the lysosomes proceeds. Since substrate influx into the lysosomes should be reduced by inhibition of sphingolipid biosynthesis, it should be possible to positively influence the severity as well as the onset of these diseases with the aid of synthetic inhibitors. This approach assumes that a definite residual activity of the enzyme is present in the lysosomes, which is especially the case in juvenile and adult patients.

The Animal Model

The animal model of Tay–Sachs disease was obtained by targeted disruption of the gene of the α-chain of β-hexosaminidase A in murine embryonic stem cells.[9, 10] The animal model of Sandhoff's disease, in which the β-chain of the hexosaminidases A and B are inactivated, has also been described.[11] While both variants of GM2 gangliosidoses mentioned above are only slightly different in the human phenotype, the animal models show drastic differences in severity and course of the disease. Mice with deficient β-hexosaminidase A (the Tay–Sachs mice) are phenotypically normal. They show a mild accumulation of GM2 in the central nervous system, but do not express the neurological symptoms characteristic for Tay–Sachs disease in humans. In contrast, mice with deficient β-hexosaminidase B (Sandhoff mice) develop severe neurological disorders, and the life span of the animals is greatly reduced. The reason for this is the difference in the specificity of sialidase in mice and humans.[11] Mouse sialidase accepts GM2 as a substrate and converts it to GA2. For humans this metabolic pathway is of no significance. GA2 can be degraded by the still-intact β-hexosaminidase B, so that despite the complete loss of β-hexosaminidase A the metabolic barrier is in part circumvented (Scheme 3). Only the loss of both isoenzymes, hexosaminidases A and B, leads to the symptoms corresponding to Sandhoff's disease in humans. Although the mouse sialidase can still convert GM2 to GA2, GA2 cannot be further degraded, since the responsible enzyme, β-hexosaminidase B, is also deficient. For a biosynthetic inhibitor to be useful in the treatment of sphingolipidoses, the degrading system within the lysosomes of the cells should have a certain residual activity. In the animal model of Tay–Sachs disease such a residual activity is present for the degradation of the storage substances through the mouse sialidase, although no intact β-hexosaminidase A can be formed. In this respect the animal model used for the evaluation of the compound is not suitable for studying the effect of the treatment on the symptoms of the disease. But it is particularly well-suited for studying the alteration of morphological parameters of the disease.

The Effect

Through oral application of the inhibitor, serum concentrations of 50 μM are maintained; the same level is also measured in humans who received compound **1** during antiviral therapy.[12] This concentration is sufficient to reduce GM2 storage by 50% (compared to that in untreated mice) after twelve weeks of treatment. In contrast to the findings in untreated mice, cytoplasmic membrane structures due to deposited lipid were hardly detected in the neurons of mice treated for sixteen weeks. The work shows that the compound is well-tolerated, passes the blood–brain barrier,[13] and reaches sufficiently high concentrations in the nervous system to inhibit glucosylceramide formation to the desired extent.

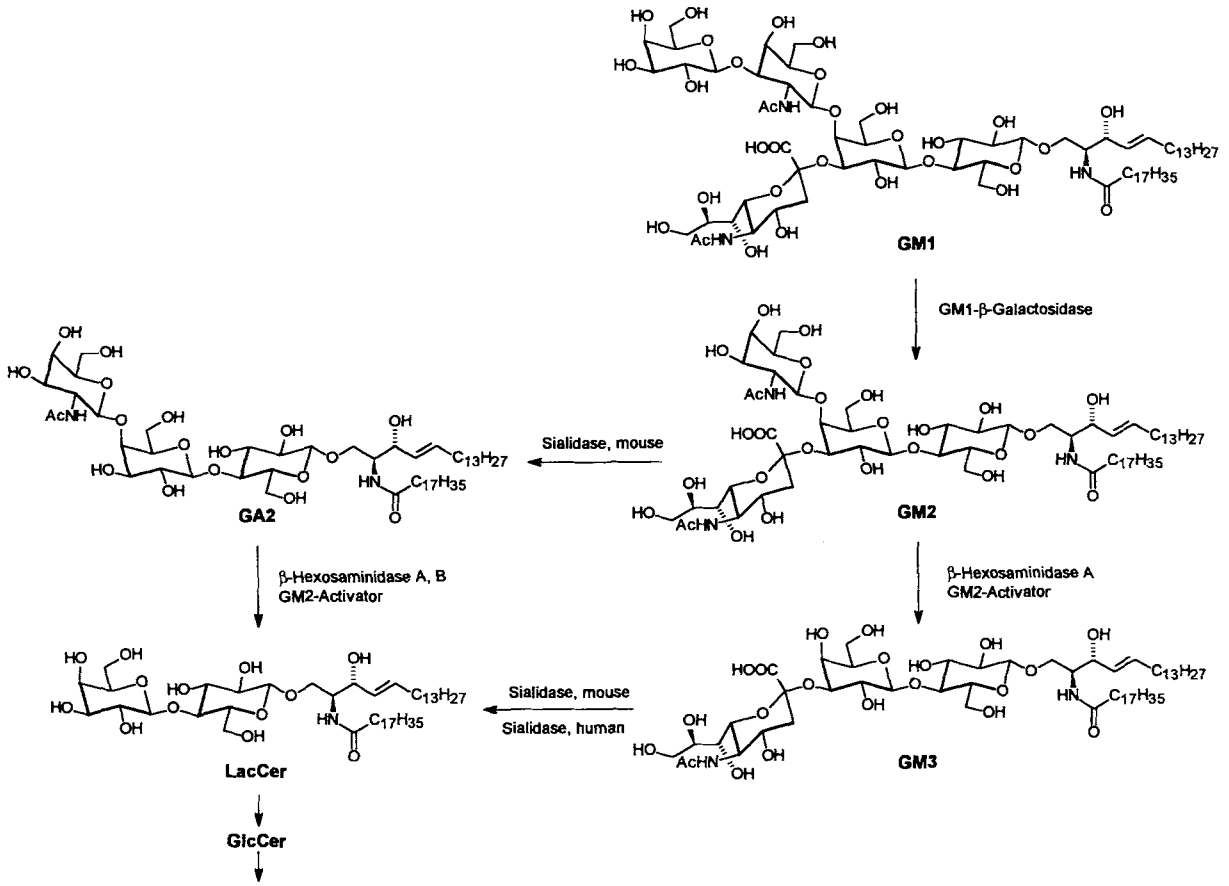

Scheme 3. Degradation pathways for ganglioside GM1 in humans and mice[11].

The Inhibitor

Compound **1** inhibits the glycosyltransferase[14] that transfers glucose from uridine diphosphate-glucose to ceramide (Scheme 1) with an IC_{50} value of 20 μM.[15] The mechanism of the inhibition of the glycosyltransferase by alkylated iminosugars like **1** is not known.[16] However, it is reasonable to assume that the nitrogen atom, which is positively charged under physiological conditions, imitates the carboxonium ion in the transition state of the glycosyltransferase reaction. It can be expected that the mechanism of glycosyltransferases corresponds to the mechanism of glycosidases with the difference that the carbohydrate residue is not transferred to water but to the nucleophilic center of another glycosyl acceptor.[17] In both cases, the enzyme-stabilized intermediate is a carboxonium ion generated by departure of the substituent at the anomeric center. Therefore, **1** should serve as a transition state analog of both the transferase and the glycosidase reaction. Indeed, **1** has been known for some time to be a potent inhibitor of α-glucosidase I and II (IC_{50} = 0.36 μM).[16] Compound **1** is also an inhibitor of HIV replication in vitro; apparently it interferes with the posttranslational processing of viral glycoprotein N-glycosidically linked glycans. Therefore, the compound is neither a particularly potent nor selective inhibitor of glucosylceramide formation, which apparently does not affect its utility.

Structure–activity relationships revealed that the minimum length of the alkyl chain necessary for inhibition of the transferase is three C atoms, and that a chain length of C_4 to C_6 is optimal. Compounds with longer chains led to improved inhibition in vitro, but also had cytotoxic properties in vivo.

Several low molecular weight inhibitors of sphingolipid biosynthesis are known.[18] Inhibition of biosynthesis upstream from glucosylceramide formation can be accompanied by immune suppression or the formation of toxic metabolites.[18] Ceramide-based inhibitors of glucosylceramide formation may interfere with sphingomyelin formation or with ceramide-dependent signal transduction. A compound with improved selectivity compared to that of **1** is the derivative with D-galacto configuration (IC_{50} = 40 μM),[19] which results in little to no inhibition of glycosidases like β-gluco- and β-galactocerebrosidase and α-glucosidase I and II. This compound, however, has not been investigated in the animal model. The results obtained with the alkylated iminosugars are also of importance because attempts at developing potent and selective inhibitors of glycosyltransferases have as yet been of limited success.

Outlook

To date, a causal therapy of sphingolipidoses has been successful only for patients having the adult form (type I) of Gaucher's disease. Here, the central nervous system is not involved due to the high residual activity of the deficient enzyme, the glucosylceramidase. In this very expensive enzyme replacement therapy the patients receive infusions of chemically modified glucocerebrosidase. Gene therapy based approaches and

 © WILEY-VCH Verlag GmbH D-69451 Weinheim. 1997 0570-0833/97/3618-1958 $ 17.50+.50/0

bone marrow transplantations did not lead to the desired success. This underlines the importance of this new approach, in which an orally available and well-tolerated compound has potential for the treatment of an entire group of diseases. Inhibition of glucosylceramide formation should be suitable for the treatment of other sphingolipidoses in which glycosphingolipids are stored that are biosynthetically derived from glucosylceramide and in which residual enzymatic activity is found in the lysosome. Of particularly importance is the ability of the title compound **1** to pass the blood–brain barrier. Owing to its oral availability and low toxicity, the development of **1** constitutes considerable progress towards the treatment of this group of severe diseases.

Enzyme Models Based on Molecularly Imprinted Polymers with Strong Esterase Activity**

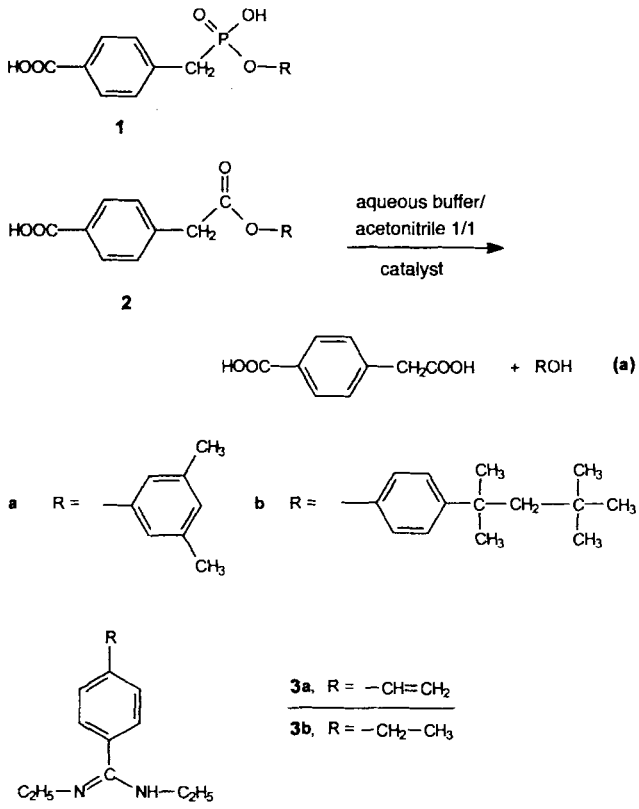
Günter Wulff,* Thomas Gross, and Rainer Schönfeld

Enzyme models have roused great general interest[1] since they could be used as efficient synthetic catalysts, and also serve to test theories and hypotheses of enzyme research. Thus, the thesis that the catalytic activity of enzymes relies on the preferred binding of the transition state of the reaction, which was first postulated by L. Pauling[2a] and later justified by W. P. Jencks,[2b] was confirmed by experiments with enzyme models based on transition state imprinted antibodies.[3] For example, a phosphonic ester, as a transition state analogue of the alkaline ester hydrolysis, was used as hapten to generate antibodies that catalytically accelerate the hydrolysis of carboxylic esters by a factor of 10^3–10^4.

We have described a method for obtaining specific microcavities in cross-linked polymers by molecular imprinting.[4, 5] Cross-linking polymerization takes place around a molecule that is used as a template; this is similar to the previously assumed mechanism for the generation of antibodies. The template is then split off, leaving behind an imprint of defined shape and bearing functional groups in specific positions, which are accessible for interaction. This method should be suitable for creating transition state imprinted enzyme models. So far, attempts to design enzyme models with esterase activity by imprinting, for example with phosphonic esters, were disappointing.[6] The attainable acceleration factors of 1.6–2, in one case 6.7, are not satisfying, especially since in most cases neither Michaelis–Menten kinetics nor competitive inhibition or turnover were observed.

The results of others[7] and numerous experiments performed in our laboratory indicate that the transition state analogous shape of a cavity does not alone cause a strong catalytic effect; additional effective groups are necessary. Furthermore, in catalytically active antibodies the correctly positioned functional groups also play an important role in the catalytic mechanism. S. J. Benkovic et al.[8] established that the guanidine group of the amino acid arginine is decisive for the positioning and fixation of the phosphonic monoester during the formation of an antibody, and is also important for the catalysis of the alkaline ester hydrolysis. We have now developed polymerizable amidines[9, 10] and used them as anchor or catalyst groups. Detailed investigations on the interaction of amidines with carboxylic acids and phosphonic acid monoesters showed that, for example, *N*,*N*′-diethyl(4-vinylphenyl)amidine forms readily soluble complexes with very high association constants with both classes of substances. In contrast to the monomer and its hydrochloride, in which the ethyl groups can be (*E*) or (*Z*) configurated, the ethyl groups of the complex are exclusively (*E*) configurated.[11]

Phosphonic acid monoester **1**, which can be prepared in four steps from methyl 4-chloromethylbenzoate in good yields, was used as a transition state analogue of the alkaline ester hydrolysis of **2** [Eq. (a)]. In nonpolar solvents **1a** reacts with two equivalents of amidine **3a** to form the bis(amidinium) complex nearly quantitatively (NMR spectroscopy; see Scheme 1, top). This



salt is copolymerized in the presence of an inert solvent (THF) with a large excess of ethylene dimethacrylate as cross-linker. About 90% of the template can be split off, leaving cavities containing two amidine groups (Scheme 1, middle). Owing to the high binding constants stoichiometric amounts of the anchor groups can be used, so that all the amidine groups are within the cavities. A larger excess of the anchor group is almost always required for other noncovalent interactions.

The hydrolysis of ester **2a** according to Equation (a) was performed in a 1:1 solution of buffer (pH 7.0, 7.6, and 9.0) and acetonitrile in the presence of the polymer prepared with **1a** (see Table 1). For comparison hydrolysis was performed at each pH

Table 1. Relative reaction rates for hydrolysis of **2a** and **2b** in the presence of different catalysts.

Substrate	pH	k[min^{-1}][a]	Relative reaction rate: Neat solution	Solution + **3b**	Polymer imprinted with **3a**·benzoate	Polymer imprinted with **1a** or **1b**
2a	7.0	$8.9 \cdot 10^{-7}$	1.0	1.5	10.9	49.0
2a	7.6	$9.2 \cdot 10^{-7}$	1.0	2.4	20.5	102.2
2a	9.0	$4.2 \cdot 10^{-6}$	1.0	1.9	4.7	17.6
2b	7.6	$3.1 \cdot 10^{-6}$	1.0	n.b.	n.b.	81.4
2b	9.0	$2.3 \cdot 10^{-6}$	1.0	2.0	14.9	52.4

[a] Reaction rate k refers to the reaction in buffer/acetonitrile (1/1) without addition of amidine or polymer. This value is defined as 1.0.

in a neat solution, in solution with addition of amidine **3b** (equivalent to the amount of amidine groups within the polymer), and with a polymer that was imprinted with the benzoate of **3a** (a polymer containing statistically distributed amidines without microcavities behaves similarly to the solution of the amidine). The reaction at 21 °C was followed with HPLC on a RP8 column with UV detection at 238 nm. All compounds in Equation (a) and the added internal standard propiophenone

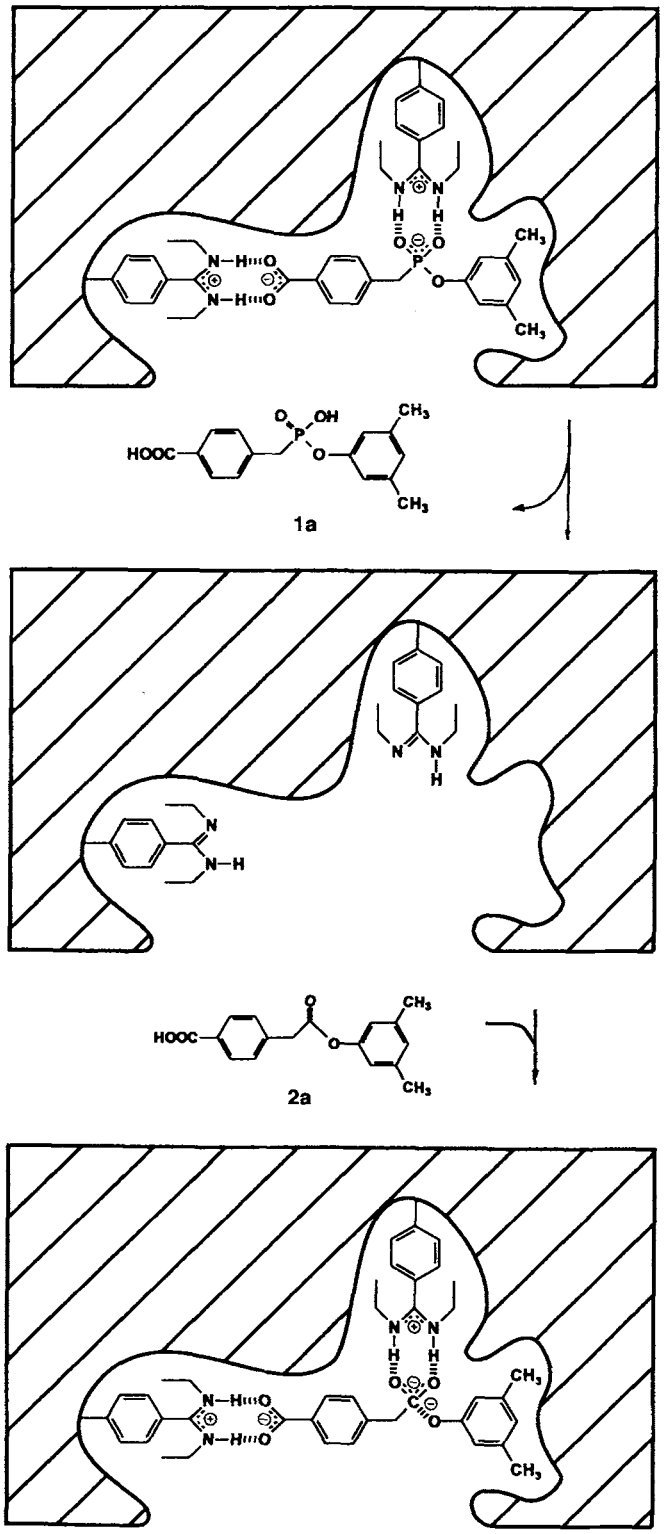

Scheme 1. Schematic representation of a microcavity that was imprinted by the polymerization of bis(amidinium) salt of **3a** with the transition state analogous template **1a** (top). A cavity bearing two *N,N'*-diethylamidine groups remains after removal of the template **1a** (middle). The alkaline hydrolysis of ester **2a** is catalyzed by the polymer that stabilizes the transition state of the reaction (bottom). See also frontispiece of the communications section.

could be completely separated ("baseline-separated"). For the kinetics the formation of homoterephthalic acid was monitored, and the specific reaction rates were calculated from the initial reaction rates.

As in the case of investigations with the catalytic antibodies, the reaction rates given are relative. The rate for hydrolysis in solution at the same pH without addition of a catalyst is defined as 1.0. The amidine **3b** in solution shows a relatively small effect, whereas the acceleration by the polymer imprinted with **1a** is unusually strong, and the reaction rate at pH 7.6 increases by more than 100-fold. Even the polymer imprinted with **3a**·benzoate causes a distinct acceleration by a factor of 20. The polymer imprinted with structurally related template **1b** also shows a strong acceleration (80-fold) of the hydrolysis of the corresponding ester **2b**.

These are by far the strongest catalytic effects for ester hydrolysis achieved with this approach up to now. The activity is only one to two orders of magnitudes lower than that of catalytic antibodies, which is not a big difference considering the fact that we used insoluble polymers with rigid structure and "polyclonal" cavities. It should also be pointed out that in our case only nonactivated phenol esters were employed, in contrast to the strongly activated 4-nitrophenyl esters used in nearly all other investigations.

It is of great interest to assay if this model also shows other typical enzyme characteristics. Therefore, the kinetics of systems with strongly varying substrate:catalyst ratios were measured. Hydrolysis with the polymer imprinted with **1a** reveals typical Michaelis–Menten kinetics with saturation kinetics, while hydrolysis with the neat solution and the solution with **3b** both show a linear relationship between reaction rate and concentration (Figure 1). Surprisingly, even the polymer imprinted with **3b**·benzoate shows a certain substrate saturation.

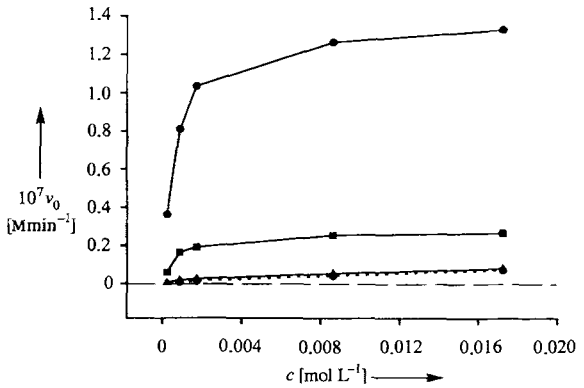

Figure 1. Michaelis–Menten plot for the hydrolysis of ester **2a** in a 1:1 mixture of aqueous buffer (pH 7.6) and acetonitrile at 21 °C in the presence of different catalysts (plot of initial reaction rate v_0 versus substrate concentration c): —●— polymer imprinted with **1a**, —■— polymer imprinted with benzoate, —▲— amidine **3b**, - - ● - - no catalyst.

The double-reciprocal Lineweaver–Burk plot in Figure 2 indicates strong substrate bonding with a Michaelis constant of $K_m = 0.60$ mM. The turnover number is relatively small ($k_{cat} = 0.8 \times 10^{-4}$ min^{-1}), but a turnover unequivocably takes place. Figure 2 also shows that the transition-state analogue **1a** is a very effective competitive inhibitor; its affinity for the imprinted polymer ($K_i = 0.025$ mM) is clearly higher than that of the substrate. Unfortunately the product, homoterephthalic acid, is also a competitive inhibitor, and probably responsible for the small turnover number observed.

The selectivity of our enzyme models is also remarkable. The cross-selectivity of the polymers imprinted with **1a** and **1b** at pH 9.0 is shown in Table 2. The determination of the rates of alkaline hydrolysis of **2a** and **2b** with both polymers proves that

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3618-1963 $ 17.50+.50/0

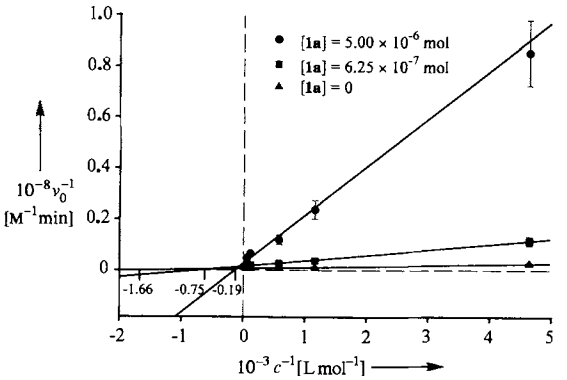

Figure 2. Double-reciprocal Lineweaver–Burk plot of initial reaction rate v_0^{-1} versus substrate concentration c^{-1}. Different concentrations of the competitive inhibitor **1a** were added in two cases. Intersections at $1/v_0 = 0$ provide the $-1/\alpha K_m$ values shown, from which K_i can be determined.

Table 2. Relative reaction rates for the hydrolysis of **2a** and **2b** catalyzed by polymers imprinted with **1a** and **1b** (pH 9) (cross-equilibration).

Substrate	Solution	Imprinted with **1a**	Imprinted with **1b**	Factor
2a	1.0	17.6	11.8	1.5
2b	1.0	40.6	52.4	1.3

each polymer hydrolyzes its "own" substrate significantly better (factor of 1.3–1.5), although both are phenol esters, and the cavities have only a slightly different shape caused by the small structural differences on the aromatic rings.

Experimental Section

General procedure for synthesizing the imprinted polymers: Template **1a** (0.5 equiv), **1b** (0.5 equiv), or benzoic acid (1 equiv) is added with azobis(isobutyronitrile) (1%) to a mixture of ethylene dimethacrylate (87.6 wt%), methyl methacrylate (4.1%), and **3a** (8.3%, 1 equiv). The solution is diluted with the same volume of tetrahydrofuran as the porogen. Polymerization proceeds at 60 °C for 70 h in a fused ampoule. After the polymer is ground, it is washed with methanol in a Soxhlet apparatus for 24 h. The template molecules are then split off by two equilibrations with 0.1 N aqueous NaOH/acetonitrile (1/1). Split-off percentages (typically 90%) are determined by HPLC. The hydrolysis is investigated after adding a solution of **2a** or **2b** (500 μL, 0.01 M) along with benzophenone or propiophenone as internal standard to buffer/acetonitrile (1/1, 5 mL ; phosphate buffer pH 7.0 and 7.6, glycine/NaOH buffer pH 9.0]. The amount of the polymer is based on the number of free cavities. The hydrolysis is monitored at 21 °C by HPLC (RP8 column, UV detection at 238 nm) and referenced to the amount of originating homoterephthalic acid.

A Polyoxo–Polyolato Complex of Tantalum(v) with a Double Adamantane-Like $[Ta_7O_{12}]^{11+}$ Core**

Kaspar Hegetschweiler,* Thomas Raber, Guido J. Reiss, Walter Frank, Michael Wörle, Antonio Currao, Reinhard Nesper, and Thomas Kradolfer

In their highest oxidation state, some of the early transition metals, such as V, Nb, Ta, Mo and W, have a pronounced tendency to form polynuclear, oxo-bridged aggregates in aqueous solution.[1] Polyoxometallate anions like $[V_{10}O_{28}]^{6-}$, $[M_6O_{19}]^{8-}$ (M = Nb, Ta), $[Mo_7O_{24}]^{6-}$, $[Mo_8O_{26}]^{4-}$ and $[H_2W_{12}O_{40}]^{6-}$ are well known representatives of this type. The formation of polynuclear complexes is currently being intensively investigated, since such species can be regarded as discrete intermediates in the process of hydrolytic polymerization, which starts from a mononuclear species and leads to the solid oxide.[2] The question arises whether the structural principles of the resulting solid can already be recognized in such intermediate species. A novel molecular architecture of a polynuclear oxo complex would thus be of special interest, since it could open routes to new materials. We have recently demonstrated that polyalcohols with a tripodal arrangement of the hydroxy groups are particularly suitable for stabilizing such polynuclear oxo complexes in solution,[3] since the coordinated polyalcohols shield the periphery of the complex and thus prevent further aggregation. Starting with $[Ta(tdci)_2]^{5+}$ (**1**, tdci = 1,3,5-trideoxy-1,3,5-tris(dimethylamino)-*cis*-inositol) as the mononuclear precursor, this strategy has now been used to prepare a heptanuclear complex having a unique, purely "inorganic" Ta_7O_{12} core with a double adamantane-like structure.

The cation **1** is readily formed by the reaction of $TaCl_5$ with tdci in methanol. It can be isolated in solid state as a hydrated pentachloride.[4] In aqueous medium, the mononuclear species is stable for a few days, thus affording a convenient means of investigating the solution properties. Potentiometric titrations

and NMR measurements established that a total of six protons can be abstracted upon addition of base.[5] Around pH 6, the doubly deprotonated complex is formed. It can be isolated as a crystalline material. The X-ray structure analysis[6] confirmed the presence of a mononuclear complex (Figure 1). The hydroxy

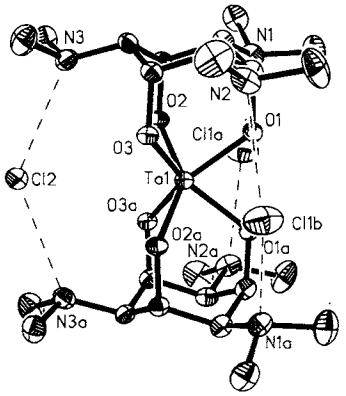

Figure 1. Structure of $[H_{-2}Ta(tdci)_2]^{3+}\cdot 3Cl^-$ (displacement ellipsoids at 50% probability level). The Ta atom is placed on a twofold axis. Main interatomic distances [pm]: Ta–O1 199.2(4), Ta–O2 197.1(3), Ta–O3 198.3(3).

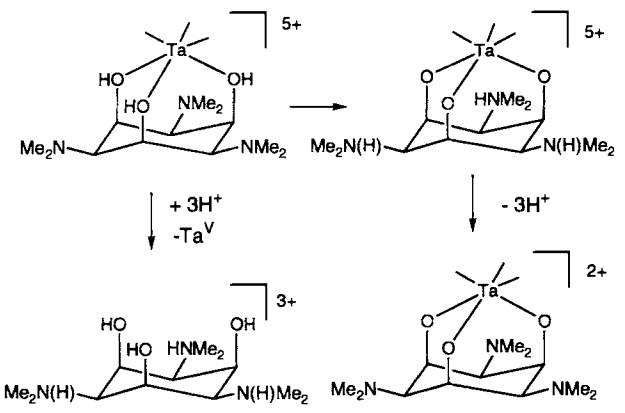
groups of tdci are all deprotonated on coordination to Ta^V, but this does not determine the overall charge of the complex, since internal proton transfer to the peripheral amino groups can occur, leading to a zwitterionic form of the ligand (Scheme 1).[7]



Scheme 1.

The coordination geometry of Ta^V, which is trigonal prismatic rather than octahedral, is somewhat unexpected,[8] and obviously arises from the interactions of the protonated amino groups with the three Cl^- counterions.

Under neutral conditions, **1** reacts slowly to give the heptanuclear hydrolysis product according to Equation (a). All 24

$$7\,[H_{-2}Ta(tdci)_2]^{3+} + 12\,H_2O \longrightarrow [H_{-11}Ta_7O_{12}(tdci)_6] + 5\,H_3tdci^{3+} + 3\,H_2tdci^{2+} \quad (a)$$

protons released upon deprotonation of the 12 water molecules are taken up by the liberated tdci. Additionally, by analogy with the mononuclear species **1**, the dimethylammonium groups of the coordinated tdci ligands are weakly acidic, which allows further deprotonation of the complex and thus a change of the overall charge in the range +11 to −7. At pH 7, upon addition of ethanol, the neutral complex $[H_{-11}Ta_7O_{12}(tdci)_6]$ (**2**) crystallizes as a hydrate. The crystal structure is shown in Figure 2.[9]

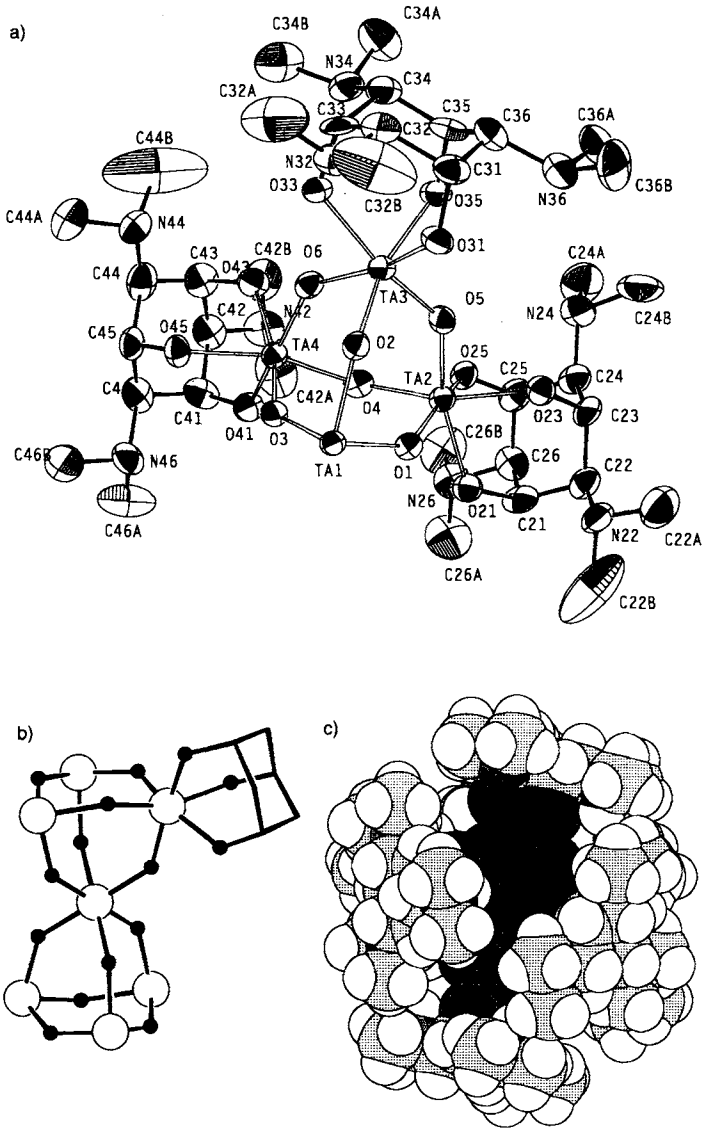


Figure 2. Structure of $[H_{-11}Ta_7O_{12}(tdci)_6]$ (**2**). a) ORTEP view with numbering scheme (ellipsoids at 50% probability). Only the asymmetric unit of the complex is shown for clarity. The second, symmetry-equivalent part of the molecule is generated by inversion on Ta1. b) Representation of the Ta_7O_{12} core with double adamantane structure (oxygen: small, black spheres, Ta: large open spheres). The coordination of the peripheral tdci ligands is indicated for one Ta atom, but the three dimethylamino groups have been omitted for clarity. c) Space filling model: Ta, O, N, C, and H are represented by spheres with decreasing darkness in this order. The Ta–O distances [pm] fall in the range of 198.1(9)–198.3(10) for Ta1, 190.3(10)–195.1(10) for the other $Ta-O_{oxo}$ bonds, and 203.2(10)–205.9(10) for the $Ta-O_{alkoxo}$ bonds [8].

The central Ta1 is connected to six additional Ta atoms by six μ_2-oxo bridges. These peripheral Ta atoms are themselves linked by six additional oxide ions. The structure of the entire Ta_7O_{12} core is exclusively made up of fused six membered Ta_3O_3 rings in chair conformation, and this gives rise to the Ta_7O_{12} double adamantane skeleton, in which Ta1 occupies the common vertex of two Ta_4O_6 cages. Each of the six peripheral Ta atoms is coordinated to another tdci ligand, which significantly distorts the octahedral TaO_6 geometry.[8]

The Ta_7O_{12} core and the eighteen oxygen atoms of the coordinated tdci ligands form a Ta_7O_{30} structure, which can be regarded as an aggregate of seven TaO_6 octahedra. It is noteworthy that these octahedra are all connected by common vertices. This is in contrast to most of the previously described

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3618-1965 $ 17.50+.50/0

polyoxo metalates in which the linking of the coordination octahedra occurred mostly through common edges. In the above mentioned $[Ta_6O_{19}]^{8-}$ ion the central oxygen atom has a coordination number of 6, which leads to a much more compact structure. However, in **2** all twelve oxygen atoms have a coordination number of 2, which obviously results in a much more open structure. The higher porosity of this structure is clearly reflected by the cavities formed by the Ta_4O_6 cages (Figure 3).[10]

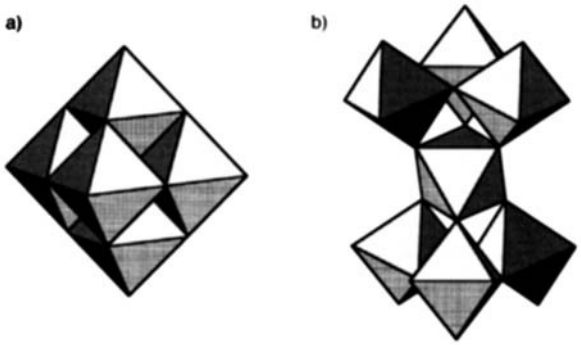

Figure 3. Representation of the coordination polyhedra for $[Ta_6O_{19}]^{8-}$ (a) and the Ta_7O_{30} structure observed in $[H_{-11}Ta_7O_{12}(tdci)_6]$ (**2**) (b). The figures are drawn for maximal symmetry (O_h and D_{3d}), as expected for the two complexes in solution.

The formation of a single tetranuclear M_4O_6 adamantane core is well known [11] and has been established for a variety of metal centers, including Ta^V as $[Ta_4F_{12}O_6]^{4-}$.[12] However, to our knowledge, the M_7O_{12} double-adamantane structure has not previously been described. With a view to controllable construction of new structures, it would be of particular interest to understand the factors that determine the structural motifs in such a continuing polymerization reaction. The peripheral ligands are obviously of crucial significance due to both steric and electrostatic effects. The rigid tdci ligand is restricted to facial coordination, and the bulky dimethylamino groups demand a comparatively large molecular surface leading to the rather open structure observed in the complex core. Moreover, the ability of the 18 dimethylamino groups to serve as a reservoir of protons is also important, as it allows a facile adjustment of the overall charge by simple protonation–deprotonation reactions and thus avoids an unfavorable, highly charged molecular surface.

[4] The C,H,N,Cl analysis is consistent with the formula $[Ta(tdci)_2]Cl_5 \cdot 5.5H_2O$. FAB$^+$-MS: $[Ta(tdci)_2 - 4H]^+$ (100%), $[Ta(tdci)_2Cl_2 - 2H]^+$ (30%).
[5] pK_a values (25.0 °C, 0.1 M KCl): 4.5, 5.7, 7.2, 9.3, 10.5, 11. 2. In the ^{1}H NMR spectrum (D_2O) a closely linear dependence of the chemical shifts on pD is observed in the range $3.8 < pD < 12.9$. Below pD 3.5 the shifts remain constant; δ for pD 3.0 and pD 13.0: 5.77 and 5.18 (6H), 3.79 and 2.11 (6H), 3.17 and 2.37 (36H).
[6] Crystals of $[1 - 2H]Cl_3 \cdot 9H_2O$ (the composition $C_{24}H_{70}Cl_3N_6O_{15}Ta$ was confirmed by C,H,N-analysis) disintegrate upon exposure to air. A crystal of approximate dimensions $0.22 \times 0.12 \times 0.12$ mm was therefore sealed in a glass capillary. Space group $C2/c$, $a = 2319.6(4)$, $b = 1448.8(3)$, $c = 1211.8(2)$ pm, $\beta = 91.62(1)°$, $V = 4070(1) \times 10^6$ pm^3, $Z = 4$, $\rho_{calcd} = 1.583$ Mg m^{-3}. Data were collected on a Siemens-P4 four-circle diffractometer at 293(2) K, $Mo_{K\alpha}$ radiation ($\lambda = 71.073$ pm), $\mu = 2.964$ mm^{-1}, graphite monochromator, numerical absorption correction (min./max. transmission = 0.072/0.461); $2\theta_{max}$: 50.00°. Of 4234 measured reflections 3448 independent reflections were used for the refinement of 284 parameters, structure solution by direct methods (SHELXS-86). All non-hydrogen atoms were refined in the anisotropic mode (full-matrix, least-squares calculations based on F^2). All H-atoms were located and included in the final refinement (SHELXL-93) with either appropriate constraints or on fixed positions as found in the difference Fourier map (H_2O molecules). $R = 0.0382$ ($F_o^2 > 2\sigma(F_o^2)$), $wR_2 = 0.0683$ (all data). Residual electron density $+0.78/-0.50$ e Å^{-3} [13].
[7] The deprotonation of the hydroxy groups is indicated by the short Ta–O bonds. Moreover, the difference Fourier synthesis did not show any electron density in proximity to these oxygen positions. There was, however, additional electron density in proximity to the nitrogen atoms, which could be interpreted as hydrogen atomic positions. In agreement with the elemental analysis, the crystal structure analysis did not give any indication of the presence of additional chloride ions, even if partial occupancy was considered. To achieve the correct charge balance, a 2:1 disorder of protonated and deprotonated amino groups had therefore to be considered. This conclusion was further supported by refined occupancy factors of the hydrogen atoms, which gave a mean value of 2/3, and the rather large displacement parameters of the Cl^- ions, which can be interpreted as a consequence of disorder in the three N–H···Cl···H–N bridges. The rather high pK_a values and the NMR data indicate that the zwitterionic form is also present in solution.
[8] The sum of the Ta–O bond valences of 5.06 for $[1 - 2H]Cl_3 \cdot 9H_2O$ and 5.07–5.23 for the Ta^V centres of $2 \cdot 38.67H_2O$, all fall in the expected range: I. D. Brown, D. Altermatt, *Acta Crystallogr. Sect. B*, **1985**, *41*, 244.
[9] Crystals of the composition $2 \cdot 38.67H_2O$ disintegrate rapidly upon exposure to air. A crystal of approximate dimensions $0.4 \times 0.4 \times 0.25$ mm was therefore sealed in a glass capillary together with its mother liquor: space group $P\bar{1}$, $a = 1759.0(6)$, $b = 1885.7(6)$, $c = 1889.6(7)$ pm, $\alpha = 96.95(3)$, $\beta = 114.32(3)$, $\gamma = 113.91(3)°$, $Z = 1$ (for $Ta_7C_{72}H_{228.33}N_{18}O_{68.67}$), $V = 4900(3) \times 10^6$ pm^3, $\rho_{calcd} = 1.258$ Mg m^{-3}. Data were collected on a STOE IPDS image plate system at 293(2) K, $Mo_{K\alpha}$ radiation ($\lambda = 71.073$ pm), $\mu = 3.957$ mm^{-1}, graphite monochromator; $2\theta_{max}$: 52.1°. Of 34522 measured reflections 17668 independent reflections were used for the refinement of 752 parameters, structure solution by direct methods (SHELXS-86), no absorption correction. All non-hydrogen atoms except some disordered solvent molecules were refined in the anisotropic mode (SHELXL-93, full-matrix least-squares calculations based on F^2). H(–C) atoms were placed at calculated positions. $R = 0.0652$ ($F_o^2 > 2\sigma(F_o^2)$), $wR_2 = 0.0220$ (all data). Residual electron density $+2.18/-1.98$ e/Å^{-3} [13].
[10] The cavity formed by the six oxygen atoms and four tantalum atoms of the adamantane cage of **2** is not large enough to accommodate an additional atom. The mean distance from the center of the cage to the oxygen atoms is 196 pm and to the tantalum atoms is 222 pm. However, some minor displacements of the oxygen positions are sufficient to enlarge the cavity in such away that there is space for an additional oxide ion. A corresponding structure of an $In_4(OH)_6$ adamantane cage with an oxide ion in the center has been described: S. S. Al-Juaid, N. H. Buttrus, C. Eaborn, P. B. Hitchcock, A. T. L. Roberts, J. D. Smith, A. C. Sullivan, *J. Chem. Soc. Chem. Commun.* **1986**, 908.

Clusters from Vertex- and Face-Sharing Adamantane-Like Units: A New Topology for Multinuclear Complexes**

Euan K. Brechin, Steven G. Harris, Simon Parsons, and Richard E. P. Winpenny*

The discovery of novel metal polyhedra remains one of the chief goals in the synthesis of multinuclear complexes, as new structures may lead to novel properties. The adamantane-like structure featuring a central M_4O_6 core has been reported for the 3d-metals from Ti to Fe;[1-9] however, it remains comparatively rare, and only a dozen or so examples are known. Compounds containing this core have never been reported for later 3d-metals, and only one example exists where adamantane units are linked into higher nuclearity clusters; this is a hexairon complex reported by Nair and Hagen[10] in which two adamantanes share a common edge. Here we report the first nickel and cobalt complexes that contain M_4O_6 units, which are also the first examples of vertex- and face-sharing adamantanes.

Reaction of "$Ni(OH)_2$" with 2.1 equivalents of 6-chloro-2-hydroxypyridine (Hchp) at 130 °C under N_2 gives a green paste, which, after drying in vacuo, can be crystallized from MeCN/MeOH to give green crystals. Structural determination[11] reveals a heptanuclear nickel complex $[Ni_7(chp)_{12}Cl_2(MeOH)_6]$ (**1**, Figure 1). The central Ni site (Ni1) lies on a crystallographic inversion center and is the shared vertex of two Ni_4O_6 adamantanes; the O atoms are provided by the chp ligands. The central Ni atom is bound to six oxygen atoms derived from chp ligands that form chelates with the "basal" Ni sites in the structure. Each basal Ni atom is chelated to one further chp and bound to a bridging O-donor from the chp chelating to a neighboring basal nickel atom. These three chelating chp ligands lie virtually coplanar with the Ni_3 base. Thus chp donors occupy five coordination sites on each basal nickel; the sixth site is occupied by a molecule of MeOH in each case. These three terminal MeOH ligands form strong H-bonds to chloride ions [$\bar{d}$(O···Cl) = 3.11(4) Å] stemming from the nickel chloride used to prepare "$Ni(OH)_2$".

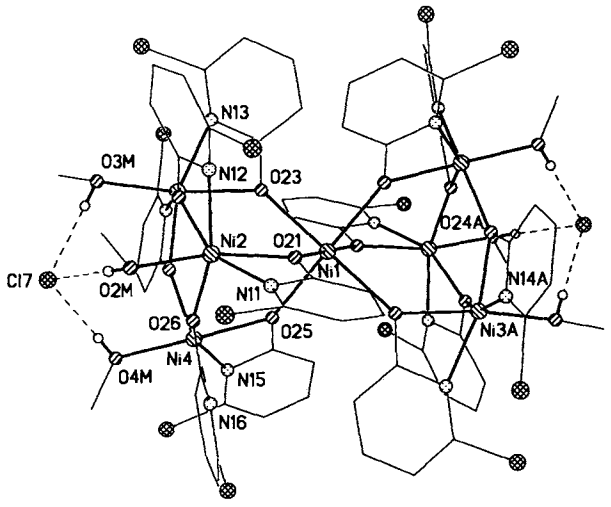

Figure 1. The structure of **1** in the crystal. The structure of **2** is extremely similar in the crystal. Bond length ranges [Å] (in square brackets data for **2**): Ni1–O 2.337–2.369, other Ni–O 2.002–2.145 [1.976–2.165], Ni–N 2.066–2.105 [2.050–2.116], (av. estimated standard deviation (esd): 0.007 [0.010]). Bond angle ranges [°]: *cis* at Ni1 89.4–90.6, *cis* at other Ni 63.2–108.5 [85.8–94.2], *trans* at other Ni 152.6–169.3 [157.0–171.0] (av. esd 0.3 [0.4]).

If the same procedure is utilized, but the nickel chloride is treated with sodium methoxide prior to reaction to produce "$Ni(OMe)_2$", another heptanuclear complex, $[Ni_7(OH)_2(chp)_{12}(MeOH)_6]$ (**2**), can be crystallized. Structure determination[11] shows that a very similar cluster has formed. Again a central Ni atom, disposed on an inversion center and bound to six O donors derived from chp ligands, is the shared vertex of two Ni_4 cages; however, in **2** the ideal adamantane cages are distorted by the presence of a μ_3-hydroxo ligand (O1H) linking the three Ni sites in the basal plane. These three Ni sites are now dissimilar. Ni2 is bound to two chelating chp ligands, the μ_3-OH, and a chp oxygen atom that is μ_2-bridging to Ni3; the pyridine-N donor of this chp ligand forms a hydrogen bond to a MeOH ligand. Ni3 is bound to one chelating chp, the μ_3-OH, μ_2-oxygen atoms from two chp ligands, and a terminal MeOH ligand. Ni4 is bound to one chelating chp, the μ_3-OH, one μ_2-O(chp), and two terminal MeOH ligands.

To remove the influence of MeOH from this chemistry, a similar product was crystallized from MeCN only (see *Experimental Section*). Structure determination[11] revealed a nonanuclear cage $[Ni_9(OH)_2(chp)_{16}(MeCN)_2]$ (**3**, Figure 2), in which a central six-coordinate nickel atom (Ni1) again lay on a symmetry element—in this case a twofold axis. A very similar heptanuclear cage to that in **2** is present, in which a μ_3-OH ligand bridges the three Ni sites, Ni2, Ni3, and Ni4, within the basal plane. However, the absence of MeOH ligands has led to a slightly larger cage, and an additional $[Ni(chp)_3]^-$ unit containing Ni5 is attached to one edge of the triangular base.

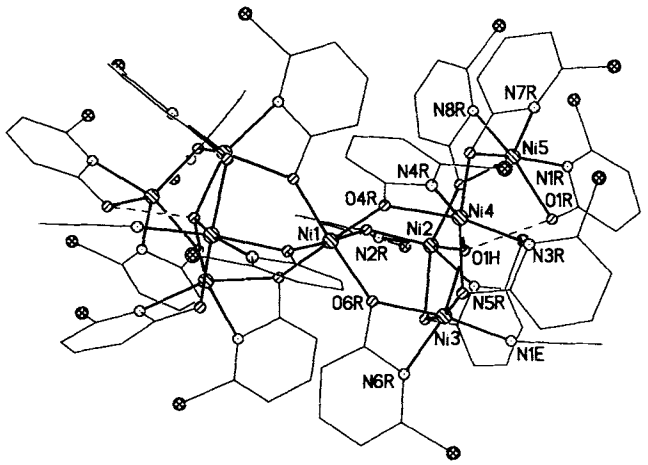

Figure 2. The structure of **3** in the crystal. Bond length ranges [Å]: Ni–O 2.011–2.198, Ni–N 2.053–2.109 (esd 0.005). Bond angle ranges: *cis* at Ni1 85.1–95.3, *trans* at Ni1 175.8–177.7, *cis* at other Ni 62.7–109.4, *trans* at other Ni 148.8–169.6 (esd 0.2).

The three Ni sites in the base are again distinct. Ni2 and Ni4 are identical, bound to two chelating chp ligands, the μ_3-OH ligand, and the μ_2-O-atom that attaches the $[Ni(chp)_3]^-$ unit to the cage. Ni3 is unique, bound to one chelating chp, the μ_3-OH ligand, two μ_2-O-donors from chp ligands chelating to Ni2 and Ni4, and a terminal MeCN ligand.

The reaction that produced **3** was repeated with cobalt in place of nickel. The nonanuclear cage compound $[Co_9(chp)_{18}]$ (**4**) crystallized from EtOAc in a form suitable for structure determination[11] (Figure 3). The cage has crystallographic D_{3d}

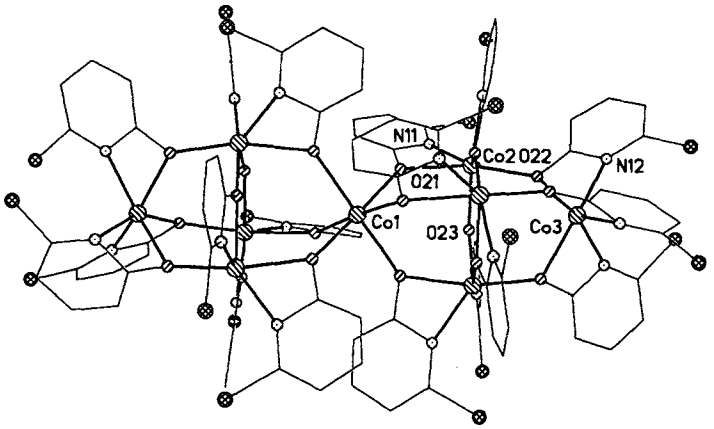

Figure 3. The structure of **4** in the crystal. Bond length ranges [Å]: Co1–O 2.316, Co2–O 2.026–2.211, Co2–N 2.122–2.126, Co3–O 2.185, Co3–N 2.126 (esd 0.007). Bond angles: *trans* at Co1 175.6, *cis* at Co1 85.3 and 91.6, *trans* at Co2 165.3 and 167.2, *cis* at Co2 61.4–132.3, *trans* at Co3 151.9, *cis* at Co3 62.1–104.3 (esd 0.3).

symmetry, and the central cobalt, Co1, lies on both a threefold axis (which also passes through Co3) and a twofold axis. The cage containing four adamantane units is clearly related to the three nickel cages. Two of the adamantane units share Co1 as a common vertex; two additional units share the basal planes (Co2 and symmetry equivalent atoms) with Co3 (and symmetry equivalent) as vertex. The three crystallographically unique Co sites are chemically distinct. Co1 is bound to six O-donors in an identical manner to the central metal sites in **1**–**3**. Co2 is bound to two chelating chp ligands, one μ_2-O atom from a further chp ligand within the basal plane, and one μ_2-O donor that attaches the Co3 vertex to the cage. Co3 is chelated to three chp ligands in *fac* geometry; each O-donor bridges to the Co atoms of the basal plane. A comparison of **4** with **1** shows that the three terminal MeOH ligands and the H-bonded chloride ion have been replaced by a $[Co(chp)_3]^-$ moiety, leaving the connectivity of the heptanuclear metal core unchanged.

Metal coordination geometries in **1**–**4** can be related to an octahedron, with one exception. In each cage the central metal site has a regular geometry (range for *trans* angles 175.8–180.0°; for *cis* angles 85.1–95.3°), whereas the other metal sites are distorted by the narrow bite angle of the chelating chp ligands (range for Ni cages: *trans* angles 148.8–171.0°; for *cis* angles 62.5 to 109.7°). For **4** the distortion at Co2 is so large (only two angles approaching a typical *trans* value at about 166°) that an octahedral description becomes difficult to maintain and the geometry is best described as irregular.

The metal-to-metal distances within the adamantane units vary from 3.808 to 4.143 Å for the nickel cages and 3.742 to 4.116 Å for **4**. The metal-to-ligand bond lengths vary greatly depending on the metal site. The M–O lengths to the central metal in structures **1** and **4** are long, varying from 2.316 to 2.369 Å. The length of these bonds led us to examine the possibility that this site was occupied by Na rather than Ni or Co; however, refinement of the structure with a Na atom in place of Ni1 or Co1 produced physically meaningless results. Analytical data strongly support the formulae given, as does mass spectrometry. Fragments of the three Ni cages are observed in fast atom bombardment mass spectrometry (FAB-MS) which are very close to the molecular ion in mass, and for **4** peaks are seen for fragments containing five Co centers, which would not be feasible if the central metal site were not a cobalt atom. There is no straightforward explanation for the observed bond lengths at this site; steric crowding can be ruled out as the equivalent sites in **2** and **3** have normal bond lengths, as do all other metal sites in the four structures (range for Ni–N 2.050–2.116; for Ni–O 1.976–2.198; for Co–O 2.026–2.211; for Co–N 2.122–2.245 Å).

We have previously stated that the coordinative flexibility of pyridonates and the presence of heteroleptic ligand sets are important factors in the formation of high nuclearity arrays of these ligands;[12] however, **4** is a fascinating exception to this rule in that it is homoleptic, and each pyridonate ligand in the cluster has an identical coordination mode. The homoleptic chp complex of the heavier Group 9 metal rhodium has been reported by Cotton et al.,[13] and the dimer $[Rh_2(chp)_4]$ contains a Rh–Rh single bond. Compound **4** is a beautiful example of the complicated arrays that 3d-metals must adopt to avoid forming metal–metal bonds, and certainly this is a further factor contributing to the novel cages formed by 3d-metals with simple bridging ligands.

Experimental Section

1: Hydrated nickel chloride (1 g, 4.2 mmol) was treated with NaOH (2 equiv) in water (20 mL) to give a green precipitate of nickel hydroxide, which was dried in vacuum. Hchp (1.088 g, 8.4 mmol) was added, and the mixture heated to 130 °C under N_2 for 2 h to produce a paste. This paste was dried in vacuum for 1 h before being dissolved in 1:1 MeCN/MeOH. Green crystals grew over 2 days. Yield: 30%. Elemental analysis calcd (found) for $C_{66}H_{60}Cl_{14}N_{12}Ni_7O_{18}$: C 35.7 (35.6), H 2.71 (2.50), N 7.58 (7.40), Ni 18.5 (17.8)%. FAB-MS: *m/z*: 2181 $[Ni_7(chp)_{12}Cl(MeOH)_6]^+$, 1921 $[Ni_7(chp)_{11}(MeOH)_3]^+$, 1862 $[Ni_6(chp)_{11}(MeOH)_3]$, 1830 $[Ni_6(chp)_{10}(MeOH)_6]^+$, 1734 $[Ni_6(chp)_8(MeOH)_4]^+$, 1605 $[Ni_6(chp)_9(MeOH)_3]^+$, 1509 $[Ni_6(chp)_8(MeOH)_4]^+$, 1477 $[Ni_6(chp)_8(MeOH)_3]^+$, 1413 $[Ni_6(chp)_8(MeOH)]^+$, 1348 $[Ni_6(chp)_7(MeOH)_3]^+$, 1284 $[Ni_6(chp)_7(MeOH)]$, 1205 $[Ni_3(chp)_8]^+$, 889 $[Ni_2(chp)_6]^+$, 573 $[Ni(chp)_4]^+$, 503 $[Ni_2(chp)_3]^+$, 375 $[Ni_2(chp)_2]^+$.

2: Synthesis as for 1, using NaOMe in place of NaOH and MeOH in place of H_2O. Crystals grew after 2 days. Yield: 25%. Elemental analysis calcd (found) for $C_{66}H_{62}Cl_{12}N_{12}Ni_7O_{20}$: C 36.3 (36.0), H 2.84 (2.71), N 7.71 (7.63)%. FAB-MS: as for **1** except peak at *m/z* 2180 assigned as $[Ni_7(chp)_{12}(OH)_2(MeOH)_6]^+$.

3: Synthesis as for **1**, except MeCN alone was used for crystallization. Crystals grew after 1 day. Yield: 80%. Elemental analysis calcd (found) for $C_{84}H_{56}Cl_{16}N_{18}Ni_9O_{18}$: C 37.3 (37.3), H 2.07 (2.00), N 9.33 (9.30)%. FAB-MS: *m/z*: 2490 $[Ni_9(chp)_{13}(OH)_2]^+$, 2174 $[Ni_8(chp)_{13}(OH)_2]^+$, 1602 $[Ni_7(chp)_9(OH)_2]^+$, 1526 $[Ni_6(chp)_9(OH)]^+$, 1288 $[Ni_4(chp)_8(OH)]^+$, 1205 $[Ni_3(chp)_8]^+$, 889 $[Ni_2(chp)_6]^+$, 572 $[Ni(chp)_4]^+$.

4: Synthesis as for **1**, except that cobalt was used in place of nickel, and crystallization was from EtOAc and gave pink crystals after 1 week. Yield: 9%. Elemental analysis calcd (found) for $C_{90}H_{54}Cl_{18}Co_9N_{18}O_{18}$: C 38.0 (37.7), H 1.90 (1.89), N 8.86 (8.80), Co 18.7 (17.8)%. FAB-MS: *m/z*: 1522 $[Co_4(chp)_{10}]^+$, 1323 $[Co_5(chp)_8]^+$, 1264 $[Co_4(chp)_8]^+$, 1195 $[Co_5(chp)_7]^+$, 1136 $[Co_4(chp)_7]^+$, 820 $[Co_3(chp)_5]^+$, 632 $[Co_2(chp)_4]^+$, 573 $[Co(chp)_4]^+$, 504 $[Co_2(chp)_3]^+$, 445 $[Co(chp)_3]^+$, 316 $[Co(chp)_2]^+$.

[11] Crystal data for **1**·1.7 MeCN: $C_{71.4}H_{65.1}Cl_{14}N_{13.7}Ni_7O_{18}$, $M_r = 2310$, triclinic, $P\bar{1}$, $a = 13.706(7)$, $b = 15.216(9)$, $c = 15.431(8)$ Å, $\alpha = 60.68(5)$, $\beta = 67.15(4)$, $\chi = 69.33(4)°$, $V = 2532$ Å^3, $Z = 1$ (the molecule lies on an inversion center), $\rho_{calcd} = 1.515$ g cm^{-3}, $T = 220.0(2)$ K, crystal size $0.51 \times 0.19 \times 0.16$ mm, $\mu(Cu_{K\alpha}) = 5.33$ mm^{-1}. Crystal data for **2**: $C_{66}H_{62}Cl_{12}N_{12}Ni_7O_{20}$, $M_r = 2180$, monoclinic, $P2_1/n$, $a = 12.502(4)$, $b = 19.917(6)$, $c = 17.601(4)$ Å, $\beta = 106.23(2)°$, $V = 4208$ Å^3, $Z = 2$ (the molecule lies on an inversion center), $\rho_{calcd} = 1.720$ g cm^{-3}, $T = 220.0(2)$ K, crystal size $0.31 \times 0.27 \times 0.19$ mm, $\mu(Mo_{K\alpha}) = 1.99$ mm^{-1}. Crystal data for **3**: $C_{84}H_{56}Cl_{16}N_{18}Ni_9O_{18}$, $M_r = 2701$, monoclinic, $C2/c$, $a = 31.570(3)$, $b = 12.784(2)$, $c = 25.371(3)$ Å, $\beta = 101.160(10)°$, $V = 10046$ Å^3, $Z = 4$ (the molecule lies on a twofold axis), $\rho_{calcd} = 1.786$ g cm^{-3}, $T = 220.0(2)$ K, crystal size $0.23 \times 0.16 \times 0.16$ mm, $\mu(Cu_{K\alpha}) = 6.33$ mm^{-1}. Crystal data for **4**·3 EtOAc: $C_{102}H_{78}Cl_{18}Co_9N_{18}O_{24}$, $M_r = 3108$, rhombohedral, $R\bar{3}c$, $a = 18.298(2)$, $c = 67.570(8)$ Å, $V = 19593$ Å^3, $Z = 6$ (the molecule lies on 32 site), $\rho_{calcd} = 1.581$ g cm^{-3}, $T = 220.0(2)$ K, crystal size $0.16 \times 0.16 \times 0.04$ mm, $\mu(Cu_{K\alpha}) = 12.695$ mm^{-1}. Diffraction was very weak, and $Cu_{K\alpha}$ radiation was used for higher intensity. Data were collected with a Stoë Stadi-4 diffractometer equipped with an Oxford Cryosystems low-temperature device. Absorption corrections were applied with Ψ-scan data for **2** and **3** (min./max. transmission: for **2** 0.413/0.594; for 3 0.193/0.343), with SHELXA for **1** (min./max. transmission: 0.165/0.637), and with DIFABS (N. Walker, D. Stuart, *Acta Crystallogr. Sect. A* **1983**, *39*, 158) for **4** (min./max. transmission: 0.176/0.604). All structures were solved by direct methods (SHELXTL, G. M. Sheldrick, Universität Göttingen, **1993**) and completed by iterative cycles of ΔF syntheses and full-matrix, least-squares refinement against F^2 (SHELXTL). Hydrogen atoms were included in all structures in calculated positions, riding on parent C atoms, with $U(H) = 1.2\,U_{eq}(C)$ for chp H atoms and $U(H) = 1.5\,U_{eq}(C)$ for methyl-H atoms. For **1** there were partially occupied, diffuse solvent regions, which were modeled in the manner described by van der Sluis and Spek (*Acta Crystallogr. Sect. A* **1990**, *46*, 194). All non-H atoms were refined with anisotropic displacement parameters: for **1**, 529 parameters, $wR2 = 0.2729$ for 7366 unique data ($2\theta \le 120°$), $R1 = 0.0890$ for 4284 observed reflections, $F_o > 4\sigma(F)$, largest residual difference peak and hole were, respectively, 0.984 and -1.437 e Å^{-3}; for **2** 535 parameters, $wR2 = 0.2220$ for 5474 unique data ($2\theta \le 45°$), $R1 = 0.0827$ for 2899 observed reflections, $F_o > 4\sigma(F)$, largest residual difference peak and hole were, respectively, 0.612 and -0.899 e Å^{-3}; for **3** 655 parameters, $wR2 = 0.1524$ for 7213 unique data ($2\theta \le 120°$), $R1 = 0.0602$ for 4810 observed reflections, $F_o > 4\sigma(F)$, largest residual difference peak and hole were, respectively, 0.496 and -0.504 e Å^{-3}; for **4** 285 parameters, $wR2 = 0.2496$ for 2729 unique data ($2\theta \le 120°$) and 305 restraints, $R1 = 0.0771$ for 1404 observed reflections, $F_o > 4\sigma(F)$, largest residual difference peak and hole were respectively, 0.700 and -1.317 e Å^{-3}. Crystallographic data (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 100219. Synthesis, Structure, and Oxidation of Donor-Stabilized Gallium(I) Iodide: $Ga_8I_8 \cdot 6PEt_3$**

Clemens U. Doriat, Markus Friesen, Elke Baum, Achim Ecker, and Hansgeorg Schnöckel*

Dedicated to Professor Wolfgang Beck on the occasion of his 65th birthday

Gallium halides with low-valent gallium have been the subject of intensive study in the fields of solid-state chemistry and molecular compounds.[1] The readily available gallium(II) halides—which are present as gallium(I/III) halides as solids[2] and in donor-free solvents[3] but as genuine gallium(II) species[4] with Ga–Ga bonds ($Ga_2X_4 \cdot 2D$) in donor-containing solvents D—occupy a special position among the gallium halides because they can be used, for example, as starting materials in the synthesis of organic gallium(I) compounds.[5] The mixed-valent $Ga_5Cl_7 \cdot 5OEt_2$ is a peculiarity in which the Ga centers are formally present in the oxidation state 1.5.[6]

A binary Ga^I halide, that is, a compound that contains no Ga^{III} ions, has not yet been structurally characterized. Although solid GaI could be prepared some years ago and its stoichiometric composition substantiated with subsequent reactions,[7] a structure determination of a solid GaX compound remained elusive. As we have been studying donor-stabilized AlX species[8] prepared by cocondensation methods for some time, and were successful in confirming the presence of both AlBr[9] and AlI[10] with planar Al_4 rings ($Al_4X_4 \cdot 4NEt_3$), it was reasonable to consider experiments with analogous GaX systems. We report here the synthesis and structure determination of the first donor-stabilized GaI compound.

Condensing gaseous GaI (31 mmol, prepared from Ga and HI at about 900 °C)[11] with PEt_3 (48 mmol) and toluene (1.05 mol) at −196 °C and then thawing the matrix results in an orange-red solution, from which an orange solid precipitates at −50 °C. The ^{31}P NMR spectrum of the solution (300 MHz, external standard 85% H_3PO_4) shows a downfield-shifted signal at $\delta = -7.2$ in addition to that for free PEt_3 ($\delta = -19.7$).[12] Analysis of the solid (yield about 65%), which decomposes above 133 °C under disproportionation to metallic gallium and $GaI_3 \cdot PEt_3$,[13] gives a Ga:I:PEt_3 ratio of approximately 1:1:0.75. Recrystallization from benzene provides yellow, hexagonal crystals that are suitable for a crystal structure analysis (Figure 1).[14]

The compound, $Ga_8I_8 \cdot 6PEt_3$ (**1**), has a planar eight-membered ring of Ga atoms that is bridged by two I atoms to form a doubly transannular Ga_2I_2 ring. Thus, two of the eight Ga atoms reach the coordination number 4; the remaining six Ga atoms reach this coordination number by binding to one I atom and one PEt_3 donor ligand. The eight Ga–Ga distances (2.47 Å) are of almost equal length. This value seems reasonable when compared to known Ga–Ga distances in compounds of the type $Ga_2X_4 \cdot 2D$ (2.39–2.42 Å for X = Cl, Br),[4] because the radius of the Ga^I ion should be larger than that of the Ga^{II}

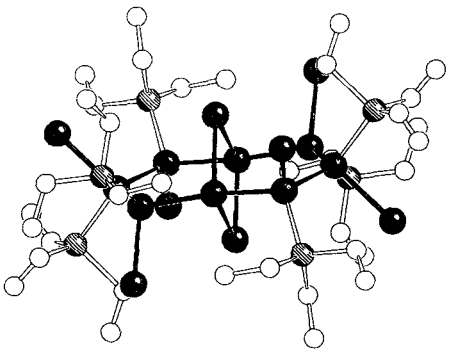

Figure 1. Molecular structure of **1** in the crystal (H atoms omitted). Selected bond lengths [Å] ($d_{min}/d_{max}/\bar{d}$): Ga–Ga 2.4584(11)/2.4726(11)/2.4656), Ga–I_{term} 2.6483(9)/2.6757(10)/2.6648), Ga–I_{br} 2.8522(9)/2.8922(9)/2.8722), Ga–P 2.412(3)/2.428(2)/2.422.

ion. The Ga–I distances are long, as expected for a Ga^I compound: 2.65 Å and 2.87 Å for terminal and bridging I atoms, respectively. The Ga–P distances of 2.42 Å also lie within the expected range; however, they are slightly longer than the Al–P distances in $Al_4I_4 \cdot 4PEt_3$ (2.40 Å).[15] The I-Ga-I angle in the four-membered ring is 98°. The environment of the Ga atoms in the four-membered ring is approximately linear with respect to their neighbors in the Ga_8 framework (168°), whereas the remaining Ga-Ga-Ga angles are about 115°. Thus, the eight-membered metallacycle formally consists of two expanded five-membered rings that are connected to one another. The iodine bridges give the illusion of a shared Ga–Ga "bond";[16] however, the distance of 3.76 Å between these two Ga atoms indicates a nonbonding interaction.

The question of why an eight-membered ring is formed instead of the four-membered rings observed in AlX species is currently being studied by quantum chemical methods.[17] Preliminary results indicate that, in addition to electronic effects, the steric influences of the ligands are of particular importance to the stabilization of the four-membered rings. Therefore, instead of a hypothetical compound $Ga_4I_4 \cdot 4PEt_3$, the sterically less strained $Ga_8I_8 \cdot 6PEt_3$ (**1**) is formed. The isolation of an amine-stabilized $(GaI)_n(NEt_3)_m$ species has been unsuccessful. This system can avoid the electronic and steric forces (stronger Ga-donor interactions weaken the Ga–Ga bonds) in two ways: disproportionation, which begins at low temperature and for $Ga_2I_4 \cdot 2NEt_3$ (**2**) leads to a new donor-stabilized Ga_2I_4 species,[18, 19] or partial oxidation, which would result in relaxation of ring strain in the case of the undetected $Ga_8I_8 \cdot 6NEt_3$.

The latter reaction took place as we attempted to crystallize $Ga_8I_8 \cdot 6NEt_3$ at low temperature to avoid disproportionation. Upon storage at −78 °C traces of oxygen inadvertently came into contact with the solution of GaI. This led to partial oxidation to $Ga_8I_8O_2 \cdot 6NEt_3$ (**3**), a compound with Ga ions in the average oxidation state 1.5. Unfortunately the crystals of **3** thus obtained were only of moderate quality for a crystal structure analysis. The synthesis could not yet be repeated; apparently a very small, defined amount of O_2 must be dosed over a long period of crystal growth. The geometry of the $Ga_8I_8O_2$ species as determined from the X-ray data is shown in Figure 2.[20] Despite the moderate *R* value the geometry of **3** can be regarded as being confirmed.[21]

As expected the Ga–Ga distances in **3** (248–252 pm) are longer than those in the nonoxidized PEt_3-stabilized species, as the relatively strong Ga–N interactions ($d_{Ga-P} = 242$ pm, $d_{Ga-N} = 212$ pm) destabilize the Ga_x system. The $Ga_8I_8O_2$ framework can be described as two near-planar Ga_4O rings

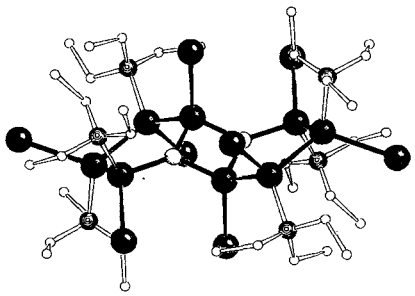

Figure 2. Molecular structure of **3** in the crystal (H atoms omitted). Selected bond lengths [Å] (d_{min}/d_{max}): Ga–Ga 2.478(3)/2.518(3), Ga–O 1.874(11)/1.959(10), Ga–I 2.606(2)/2.670(2), Ga–N 2.12(2)/2.16(2).

connected by a four-membered Ga_2O_2 ring ($d_{Ga-Ga} = 286$ pm); the three Ga atoms bound to a single O atom almost lie in a plane (sum of angles 355°).

The cyclic GaI oligomer **1** is the first structurally characterized gallium(I) halide. The confirmation of a primary product in the oxidation of $Ga_8I_8 \cdot 6D$ with O_2 gives an indication of the strain in this unusual ring system. In addition to its importance for the systematics of structural chemistry, the synthesis of **1** may be of interest for further reactions in Ga^I chemistry.

[15] A. Ecker, Dissertation, Universität Karlsruhe (Germany), **1996**.

[16] Attempts to open the iodine bridge by addition of excess PEt_3 gave no evidence for the existence of species of the formula $(GaI \cdot PEt_3)_n$. Instead, **1**·2 toluene was isolated in crystalline form. The molecular structures of **1** and **1**·2 toluene in the crystal do not differ significantly. **1**·2 C_7H_8: monoclinic space group $P2_1/n$, $a = 17.370(10)$, $b = 11.888(6)$, $c = 20.172(9)$ Å, $\alpha = \gamma = 90$, $\beta = 91.06(6)°$, $V = 4164.7(37)$ Å^3, $Z = 2$.

[17] The results obtained so far for the energy values (TURBOMOLE; DFT-RI/SVP; BP 86 parametrization: K. Eichkorn, O. Treutler, H. Öhm, M. Häser, R. Ahlrichs, *Chem. Phys. Lett.* **1995**, *240*, 283–290) confirm the experimental findings. Formation of an eight-membered ring system analogous to **1** from two four-membered Ga or Al rings according to Equation (a) is exothermic for $GaI \cdot PH_3$ (about 200 kJ mol^{-1}). For the corresponding $AlI \cdot NH_3$ oligomer the energy balance is almost zero.

$$2\,M_4I_4 \cdot 4D \rightleftharpoons M_8I_8 \cdot 6D + 2D \qquad (a)$$

Despite the considerable effort involved in the calculation, the results are purely preliminary, as only the simple PH_3 and NH_3 groups were used as donors. Sterically demanding substituents could have a decisive influence on the energy balance, especially in the case of the "forced" Ga_8 system ($d_{Ga-Ga} = 247$ pm; $d_{Al-Al} = 266$ pm in $Al_4I_4 \cdot 4D$).

[18] $Ga_2I_4 \cdot 2AsEt_3$ was the first structurally characterized compound of this type: B. Beagley, S. M. Godfrey, K. J. Kelly, S. Kungwankunakorn, C. A. McAuliffe, R. G. Pritchard, *Chem. Commun.* **1996**, 2179–2180. The Ga–Ga bond of 242.8 pm in this compound is considerably shorter than that in **2** (249 pm). This is in agreement with strengthening of the Ga-donor interaction and resulting weakening of the Ga–Ga bond in **2**.

[19] Crystal structure analysis of **2**: $C_{12}H_{30}Ga_2I_4N_2$ ($M_r = 849.42$); monoclinic space group $P2_1/c$, $a = 7.888(2)$, $b = 14.906(3)$, $c = 19.554(4)$ Å, $\alpha = \gamma = 90$, $\beta = 95.57(3)°$, $V = 2288.3(8)$ Å^3, $Z = 4$, $R1 = 0.0579$ ($F > 4\sigma(F)$), weighted R value (all data): $wR2 = 0.1150$ [14b].

[20] Due to the poor quality of the crystal the caliber of the experimental data and, thus, also of the structural analysis was only moderate. (One of the solvent molecules in the crystal could not be localized.) Crystal structure analysis of **3**: $C_{36}H_{90}Ga_8I_8N_6O_2$ ($M_r = 2212.13$); crystal dimensions $0.4 \times 0.3 \times 0.2$ mm; $T = 200$ K; monoclinic space group $C2/c$, $a = 19.411(4)$, $b = 13.979(3)$, $c = 27.340(6)$ Å, $\alpha = \gamma = 90$, $\beta = 103.45(3)°$, $V = 7215(3)$ Å^3, $Z = 4$, $\rho_{calcd} = 2.066$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 6.393$ mm^{-1}, empirical absorption correction, ω-scan mode ($\Delta\omega = 1.5°$), $3 \le 2\theta \le 50°$; 6279 independent reflections (4783 with $F > 4\sigma(F)$) were measured on a four-circle diffractometer (STOE STADI4; $Mo_{K\alpha}$ $\lambda = 0.71073$ Å, graphite monochromator); the structure was solved by direct methods (SHELXS-86) [22]; full-matrix refinement of 302 parameters according to the least-squares method against $|F^2|$ (SHELXL-93) [23]; the positions of hydrogen atoms were calculated. The molecule has an inversion center. Weighting scheme: $w^{-1} = \sigma^2 F_o^2 + (0.0561\,P)^2 + 411.140\,P$, with $P = (F_o^2 + 2F_c^2)/3$; $R1 = 0.0890$ ($F > 4\sigma(F)$):, weighted R value (all data): $wR2 = 0.2047$, max/min residual electron density: 2.185/ −1.045 e Å^{-3} [14b].

[21] The molecular geometry of **3** described here was also determined for $Ga_8I_8O_2 \cdot 6PEt_3$ (**4**). Crystals of **4** were obtained by treating a solution of GaI in PEt_3 and toluene with a N_2/O_2 mixture at 0 °C. Due to the poor quality of the crystals a precise structural analysis was not possible in this case either. However, the framework structure of **3** was unequivocally confirmed. **4**: triclinic space group $P\bar{1}$, $a = 12.065(5)$, $b = 12.736(4)$, $c = 13.981(4)$ Å, $\alpha = 89.49(3)$, $\beta = 68.54(3)$, $\gamma = 70.32(3)°$, $V = 1866.5(8)$ Å^3, $Z = 1$. The molecule has an inversion center.

Bi_7RhBr_8: A Subbromide with Molecular $[\{RhBi_7\}Br_8]$ Clusters**

Michael Ruck*

Dedicated to Professor Hans Georg von Schnering

The recently discovered ternary subhalides of bismuth are not only chemically, but also structurally remarkable compounds.[1] One example is $Bi_{5.6}Ni_5I$, the unusual structure of which consists of decagonal tubes of Bi and Ni atoms, and the I atoms intercalated between the tubes.[2] Another compound that belongs to this ternary system is $Bi_{12}Ni_4I_3$. It is composed of ribbons of face-sharing, trigonal $\{NiBiBi_{6/3}\}$ prisms, similar to those found in the intermetallic compound Bi_3Ni.[3] Both $Bi_{13}Pt_3I_7$ and Bi_4RuI_2 are based on different building principles: $Bi_{13}Pt_3I_7$ is composed of Kagomé networks of $\{PtBi_{8/2}\}$ cubes alternating with layers of I atoms and tetraiodobismuthate(III) chains,[4] while Bi_4RuI_2 has a columnar structure with face-sharing, square $\{RuBi_{8/2}\}$ antiprisms.[5]

In contrast to these metal-rich subiodides, which contain one- or two-dimensional intermetallic substructures, the distinctly halogen-richer subbromide Bi_7RhBr_8 reported here consists of discrete molecular clusters of the same composition (Figure 1).[6] These clusters are ordered within the monoclinic crystal structure into an almost perfect hexagonal close packing ($c/a = 1.739 \approx \sqrt{3}$ and $b/a = 1.613 \approx \sqrt{8/3}$) (Figure 2).

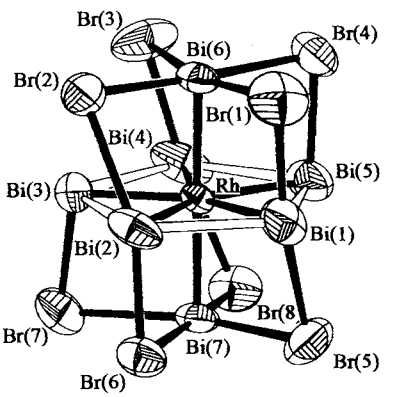

Figure 1. Molecular structure of a $[\{RhBi_7\}Br_8]$ cluster in the crystal (the ellipsoids represent 90% probability). Selected distances [pm] and angles [°]: Rh–Bi(1) 273.2(2), Rh–Bi(2) 273.8(2), Rh–Bi(3) 274.9(2), Rh–Bi(4) 274.2(2), Rh–Bi(5) 271.9(2), Rh–Bi(6) 273.5(2), Rh–Bi(7) 271.9(2) Bi(1)–Bi(2) 326.6(2), Bi(2)–Bi(3) 322.8(2), Bi(3)–Bi(4) 319.1(2), Bi(4)–Bi(5) 320.3(2), Bi(5)–Bi(1) 319.4(2), Bi(1)–Bi(6) 381.3(2), Bi(1)–Bi(7) 388.2(2) Bi(6)–Br(1) 289.7(3), Bi(6)–Br(2) 287.6(3), Bi(6)–Br(3) 296.2(3), Bi(6)–Br(4) 301.0(3); Bi(1)-Rh-Bi(2) 73.32(6), Bi(2)-Rh-Bi(3) 71.08(7), Bi(3)-Rh-Bi(4) 71.05(5), Bi(4)-Rh-Bi(5) 71.81(5), Bi(5)-Rh-Bi(1) 71.73(6), Bi(6)-Rh-Bi(7) 178.91(7).

In this novel $[\{RhBi_7\}Br_8]$ cluster seven Bi atoms are arranged as a pentagonal bipyramid with a Rh atom in the center. The apical Bi atoms are surrounded by four Br atoms in a square-planar environment. Each of these Br atoms is also coordinated to one Bi atom of the central five-membered ring, and two of the five equatorial Bi atoms are coordinated to only one Br atom. The squares are staggered, so that the $\{RhBi_7\}$ bipyramid is enclosed by a distorted, square Br_8 antiprism. The whole mole-

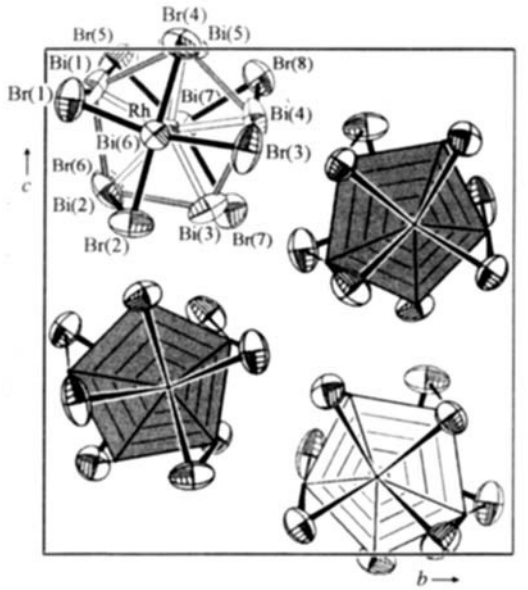

Figure 2. Projection of a part of the crystal structure of Bi_7RhBr_8 onto the b,c plane. The cluster units given in a darker shade are closer to the observer by $\Delta x = 0.5$. (The ellipsoids represent 90% probability).

cule does not display any symmetry dictated by the space group; however, the inner $\{RhBi_7\}$ polyhedron has almost D_{5h} symmetry. The equatorial Bi atoms and the central Rh atom only deviate by a maximum of 1 pm from the average plane defined by these six atoms. If the Br atoms are now taken into consideration, only a two-fold rotational axis through the Rh and the Bi(4) atoms remains from the elements of pseudo-symmetry.

The Br atoms of neighboring molecules are as far apart (d[Br(1)–Br(5′)] = 366.0(3) pm) as those in Bi_6Br_7 (d[Br–Br] ≥ 347.1 pm)[7] and in $BiBr_3$ (d[Br–Br] ≥ 356.8 pm).[8] Together they form gently undulating nets parallel to the (100) plane (Figure 3), which are described by the $3^2434 + 3^34^2 + 3^44 + 3^54$ (1:1:1:1) representation of Schläfli.[9]

The distances between the apical and the equatorial Bi atoms in the $[\{RhBi_7\}Br_8]$ cluster lie in the range 381.3(2) to 391.1(2) pm, so direct interaction can hardly be expected. The smallest distances between the apical Bi atoms of neighboring molecules are of a similar size. In spite of the differing types of coordination of the Br atoms, the distances between the Bi

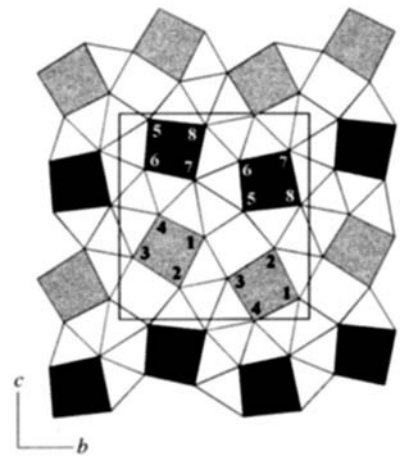

Figure 3. Projection of one of the gently undulating networks of Br atoms in the structure of Bi_7RhBr_8 onto the b,c plane. The numerals represent the number of the Br atom at the junction. The squares formed by the Br atoms of one molecule are shaded, differing in the gray tone according to the set of the atoms involved.

atoms in the five-membered ring only differ slightly (319.1(2)–326.6(2) pm). Consequently, the corresponding Bi-Rh-Bi angles also lie in a very narrow range about the ideal value of 72°. The distances between the Rh atom and all seven surrounding Bi atoms lie between 271.9(2) and 274.9(2) pm. From a comparison with the binary Bi–Rh phases (α-Bi_2Rh: coordination number (CN) = 6, $\bar{d}$[Bi–Rh] = 272 pm;[10] β-Bi_2Rh: CN = 7, $\bar{d}$[Bi–Rh] = 281 pm;[11] α-Bi_4Rh: CN = 8, $\bar{d}$[Bi–Rh] = 280 pm[12]) it is evident that the "disintegration" of the intermetallic structure gives rise to stronger bonds between the transition metal atom and the Bi atoms in the subhalide.

An analysis of the boundary conditions for a regular pentagonal-bipyramidal arrangement highlights a further aspect of the atomic arrangement in the $[\{RhBi_7\}Br_8]$ molecule: in an ideal pentagonal bipyramid with equally sized ligands (radius r_L) at a distance d from the central atom (radius r_Z), the ten apical edges have a length of $\sqrt{2}d = 1.4142\,d$ and the five equatorial edges are $2 \sin 36°\, d = 1.1756\,d$. The ratio of the two edge lengths is 1.2030. For the ligands to be in contact a radius of $r_L = \sin 36°\, d = 0.5878\,d$ is necessary. The maximum radius of the central atom then is $r_Z = (1 - \sin 36°)\,d = 0.4122\,d = 0.7013\,r_L$. In the $[\{RhBi_7\}Br_8]$ molecule, the quotient of the average apical and equatorial edge lengths is 1.201, which is in agreement with an almost ideal pentagonal bipyramid. From the average distance between the Bi atoms and the central Rh atom of 273.3 pm, a radius of the Bi atoms of $r_L = 160.6$ pm and a maximum radius of the Rh atom of $r_Z = 112.7$ pm can be calculated. Since the sum of the covalent radii of the Bi atom (146 pm) and of the Rh atom (125 pm) is 271 pm, which only differs slightly from the observed average Bi–Rh distance, a division of the distance into the respective covalent radii is possible. However, the Bi atoms are then no longer in contact on the basis of the hard sphere model.

The interactions between the Br atoms and the atoms Bi(3) and Bi(5) are only apparently weaker than those between the Br atoms and the other Bi atoms in the five-membered ring. The sums of the bond orders calculated according to the method of Brese and O'Keeffe[13] differ only slightly, even when only an isolated $[\{RhBi_7\}Br_8]$ molecule is considered. However, the interactions between the molecules contributes up to an additional 20% (Table 1). The shortest intermolecular Bi–Br distances of 350.8(3) pm resemble the intramolecular distances. The spatial linkage of the almost spherical molecules that results from this similarity is probably of great importance for the ordered, crystalline structure of the compound.

The sum of the bond orders of the apical Bi atoms also clearly differs from that of the Bi atoms of the five-membered ring: although the Bi–Br bond lengths are similar, the greater number of contacts here leads to an approximate doubling of the sum of the bond orders. If the contributions for the single Bi

Table 1. Sum of the bond orders $\sum_{Br} v_{Bi-Br}$ for the Bi–Br interactions in Bi_7RhBr_8. The total sum is split up into the intra- and intermolecular contributions. Only distances smaller than 400 pm were considered. Bond valence parameter $R_{Bi-Br} = 262$ pm.

Atom	$\sum v_{intra}$	$\sum v_{inter}$	$\sum v_{total}$
Bi(1)	0.844	0.040	0.884
Bi(2)	0.811	0.160	0.971
Bi(3)	0.761	0.134	0.895
Bi(4)	0.740	0.147	0.887
Bi(5)	0.732	0.131	0.863
Bi(6)	1.717	0.032	1.749
Bi(7)	1.673	0.027	1.700
Bi(1) to Bi(5)			4.500
Bi(1) to Bi(7)			7.949

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3618-1972 $ 17.50+.50/0

atoms are added, then for the Bi_5 ring the sum of the bond orders is $V_{Bi(1-5)} = \sum_{Bi(1-5)}\sum_{Br} v_{Bi-Br} = 4.50$, and for all seven Bi atoms $V_{Bi(1-7)} = 7.95$. As a result, the sum of the valences of the eight Br atoms and consequently the compensation of the electrostatic charges is almost perfect.

Since the electronegativities of Bi and Rh only differ slightly, covalent bonds between these atoms can be regarded as almost nonpolar. Thus, the central Rh atom should be essentially neutral. If it is assumed that there are seven Bi–Rh single bonds, then the Rh atom has $9 + 7 = 16$ valence electrons. However, in such a calculation the Bi atoms have not been assigned integral oxidation states, but rather values of 8/9 for the equatorial and 16/9 for the apical atoms. In order to avoid fractional oxidation states, Bi_7RhBr_8 can be alternatively formulated as $(Bi^{I})_5(Bi^{II})_2Rh^{-I}(Br^{-I})_8$; note that the Rh atom has been assigned a formal negative charge.

The results of band structure calculations at the extended Hückel level[14] also point to a low negative partial charge on the Rh atom. According to these calculations, the highest occupied and the lowest unoccupied state are distinctly separated in energy (Figure 4), although the band gap is smaller than ≈ 1.7 eV, which is in agreement with the black color of the compound.

The interactions between the central Rh atom and the surrounding Bi atoms are almost exclusively bonding below the band edge, while above it they are strongly antibonding. Again, the equatorial atoms Bi(1) to Bi(5) must be differentiated from the apical atoms Bi(6) and Bi(7): as a result of antibonding contributions, the integration of the overlap population (COOP) curves up to the Fermi level gives a lower positive overlap population of the Rh atom with the equatorial Bi atoms than with the apical atoms. The weaker bond to the central atom, however, is compensated for by an additional, homoatomic bond in the five-membered ring: the Bi–Bi interactions between the atoms in the five-membered ring (distances < 330 pm) are all bonding and those between the equatorial and the apical Bi atoms (distances > 330 pm) are all nonbonding.

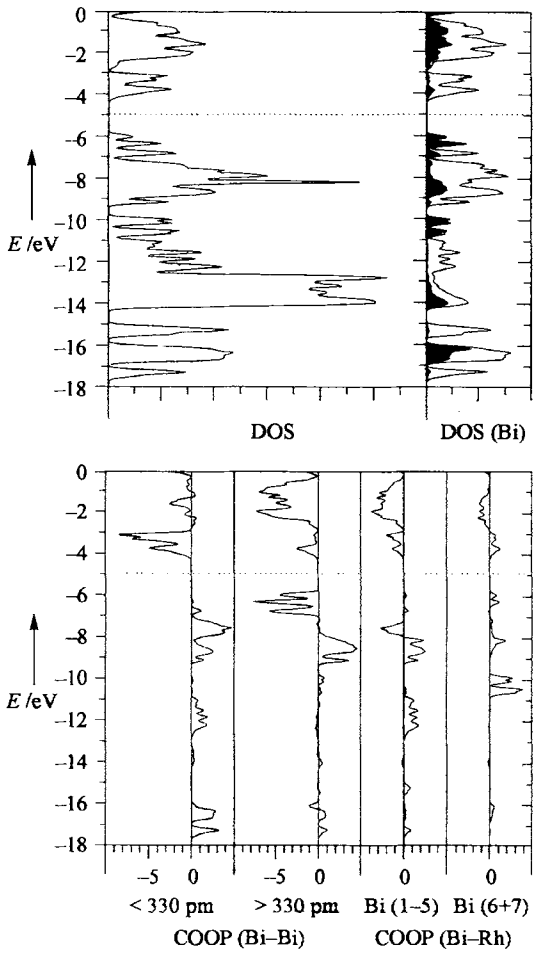

Figure 4. Density of states (DOS) and the projected DOS of the Bi atoms as well as selected overlap populations (COOP) for Bi_7RhBr_8. The dotted line represents the Fermi level. The shaded areas of DOS(Bi) represent the contributions of the apical atoms Bi(6) and Bi(7). The energetically low-lying Bi–Br bonding states at about −22.5 eV have been omitted.

Experimental Procedure

Synthesis of Bi_7RhBr_8: in an evacuated quartz glass ampoule a mixture of the elements (molar ratio Bi:Rh:Br = 7:1:8; $BiBr_3$ can be used instead of Br_2) was heated to 1270 K over a period of 1 h, and subsequently, without a longer tempering phase, cooled to RT over a period of 8 h. Attached to the walls of the ampoule were platelike crystals with a metallic luster, which were contaminated with $BiBr_3$. The impurity was sublimed out of the crystals by storage of the ampoule in a temperature gradient of 520 K to 350 K for 1 d. The black, lustrous platelets of Bi_7RhBr_8 can be left in the air for several weeks without any visible decomposition.

Sc_2Te: A Novel Example of Condensed Metal Polyhedra in a Metal-Rich but Relatively Electron-Poor Compound**

Paul A. Maggard and John D. Corbett*

Dedicated to Professor Hans Georg von Schnering

The earlier transition-metal chalcogenides have both extended the boundaries of solid-state chemistry and challenged our understanding of stability, structure, and bonding. Some recent examples of metal-rich chalcogenides of Group 4 and 5 metals are Ti_9Se_2,[1] Zr_3Te,[2] Hf_3Te_2,[3] Ta_3S_2,[4] and Ta_2Se.[5] Highly reduced binary compounds of the earliest transition metals Sc, Y, La have been limited to a few halides and to the monochalcogenides (NaCl-type), which may be significantly substoichiometric.[6] Only a few truly binary halides are known (Sc_7Cl_{10}, Y_2X_3, and LaI).[7] No phase diagrams exist for any of the scandium or yttrium chalcogenides, and the only binary Sc–Te phases reported are Sc_2Te_3 and ScTe.[8] This situation clearly results from a lack of investigation of these quite refractory compounds. This article describes the first example, Sc_2Te, an exceptional chalcogenide with respect to the nature of its metal–metal bonding.

A [010] projection of the Sc_2Te structure down the short (3.919 Å) axis is given in Figure 1. Both a large complex chain unit and a simple zigzag chain of scandium are evident. The Sc–Sc distances vary from 3.05 Å upward with no distinctive breaks, but the justification of the 3.5 Å limit for "bonds" marked in Figure 1 will be given later. Considerably closer contacts and tighter bonding are found within the larger Sc chain, which is detailed in Figure 2 with atomic numbering and independent distances (the Sc6–Sc6 and Sc4–Sc4 bonds lie on centers of symmetry). The central building block emphasized by the darker bonds is the same as can be visualized in Sc_7Cl_{10}[7] as well as in several interstitial derivatives such as Pr_3I_3Ru,[9] namely, the familiar pairs of quasi infinite chains of distorted *trans*-edge-sharing metal octahedra (for example, (1,1)-5-(6,6)-6) that are further cocondensed through sharing of Sc6–Sc6 side edges. (The choice of Sc1–Sc6 (3.49 Å) as the shared edges and Sc5, Sc6 (d = 3.52 Å) for the apices of the compressed octahedra is fairly arbitrary (see below). The y coordinates around the periphery of the double chain alternate between $^1/_4$ and $^3/_4$.)

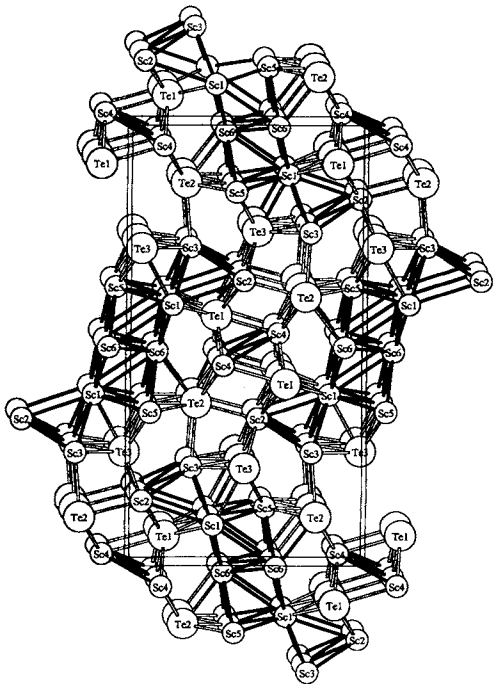

Figure 1. A view of the unit cell of Sc_2Te along [010] (Sc: small circles, Te: large circles). Bonds are drawn for d(Sc–Sc) < 3.50 Å and d(Sc–Te) < 3.15 Å. All atoms lie on mirror planes at $y = {}^1/_4, {}^3/_4$.

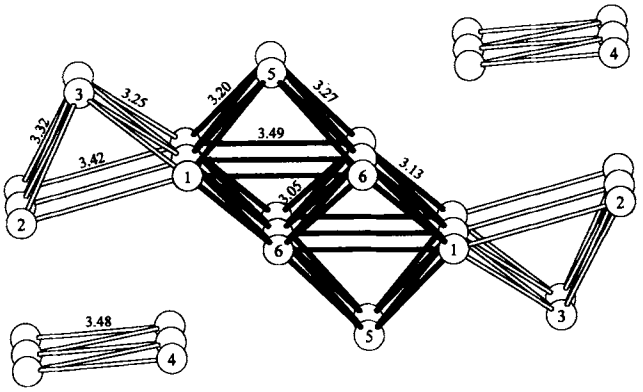

Figure 2. The highly condensed scandium chain and two zigzag chains with atomic labeling and independent distances ($\sigma \leq 0.005$ Å). Inversion centers lie on the Sc6–Sc6 and Sc4–Sc4 bonds.

The shortest Sc–Sc distances in the structure lie within the double chain (3.05–3.27 Å). Surprisingly, these values range from the same length to about 0.1 Å shorter than those in Sc_7Cl_{10}, while both the shared *trans*-edge Sc1–Sc6 and the repeating unit of the chain are about 0.4 Å longer. The first difference may reflect the presence of the Sc2, Sc3 appendages or the bonding within the chain (see below), whereas the increased chain repeat of 3.92 Å logically derives from the larger diameter of closed-shell Te. (An alternate description in terms of metal tetrahedra 1-5-6-6 that are more loosely coupled along the chains is more consistent with observed distances but less useful for comparison with other structures.) There are no short Te–Te separations, so their problematic bonding is not a concern. The metal environments of all tellurium atoms are monocapped trigonal prisms, and Sc–Te distances range between 2.86 and 3.14 Å, less than nearly all Sc–Sc distances.

Generally, the nonmetal-to-metal ratios in metal-rich compounds seem to be the major factor in determining structure, more overtly than electron counts. Although the similar double metal chains in Sc_7Cl_{10} [$= Sc^{3+}(Sc_6Cl_{10})^{3-}$] are easy to assess in terms of average oxidation state (+1.17), a similar partitioning in the more complex Sc_2Te is not very clear. The double-chain framework described above is further augmented by edge-sharing square pyramids (Sc1, Sc2, Sc3; open bonds in Figure 2) that also share Sc1–Sc1 edges along the double chains. The Sc–Sc distances within these appendages are the same or longer (3.25, 3.32, 3.42 Å) than in the double-chain core, befitting the greater amount of tellurium bound to these atoms. The anion-poorer nature of Sc_2Te also allows closer approaches of the metal building blocks. Finally, the 3.48 Å repeat in the Sc4–Sc4 zigzag chain is somewhat larger than within the augmented

double chain and closer to what we assign as interchain separations (3.53(× 2) Å for Sc4–Sc6, 3.67 Å for Sc4–Sc1, 3.68 Å for Sc4–Sc2, and beyond). However, all of these are well segregated by crystal orbital overlap populations (COOP, see below). The larger Sc–Sc separations appear to be attributable to matrix effects and the shortage of bonding electrons.

A novel way to view the Sc_2Te result is as a dissociation product of the metal frameworks in electron-richer chalcogenides of later transition metals with comparable stoichiometries. For example, the metal network in Ta_2Se contains layers of an interpenetrating body-centered cubic (bcc) structure for Ta, as in the element,[5] and similar but more condensed frameworks appear in Ti_8S_3[10] and Ti_9Se_2.[1] Related building blocks can also be perceived in Ti_2S, Zr_2S, Zr_2Se (all the Ta_2P-type),[11] and Hf_3Te_2.[3] A similar feature can be generated from Sc_2Te if each Sc4 is moved toward Sc6 in the closer chain: extended pairs of condensed Sc4-5-6-1 cubes centered by Sc6. The Sc2, Sc3 portions may be further fragments of what was once a sheet.

Extended Hückel calculations have been carried out for the full structure at 48 k points.[12] The total density of states (DOS) shows a Te p-orbital-based valence band (with some Sc mixing through covalency) between about −14.0 and −10.8 eV. A large conduction band (Figure 3) is generated almost entirely

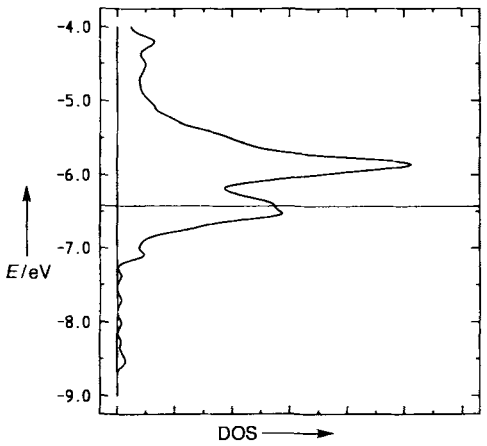

Figure 3. The total densities of states (DOS) for the conduction band in Sc_2Te.

from Sc 3d orbitals, with only traces of Te p orbitals in the upper reaches. Six small DOS features between −7.0 and −8.5 eV all originate with the Sc1–Sc5, Sc1–Sc6, Sc5–Sc6, and Sc6–Sc6 intracluster bonding interactions. The Fermi energy for such an electron-poor compound falls low in the band near −6.4 eV, while the Sc–Sc COOP functions show that the states remain bonding up to about −6.0 eV. (In contrast, all bonding states are occupied in Hf_3Te_2.[3]) The compound appropriately exhibits a Pauli-like paramagnetism ($\chi_{M(298)} = 3.4 \times 10^{-4}$ emu mol^{-1}) and is logically presumed to be a metal.

Interesting features of the bonding are revealed by differences in pairwise Sc–Sc Mulliken overlap populations (MOP) as a function of distance. These emphasize the strength and delocalization of the metal bonding in the double chain region, especially among Sc1, Sc5, and Sc6, and the contrasting weakness of all bonding about Sc4. In fact, directly following the 0.306–0.172 MOP for the three shortest Sc–Sc separations (Figure 2) are those for the longish Sc1–Sc6 separation across the octahedral waist (3.49 Å, MOP 0.166) and for Sc5–Sc6 between its vertices (3.52 Å, 0.170; not interconnected in Figure 2 for clarity). Next is that for the shorter Sc5–Sc6 bond (3.27 Å, 0.146) on the periphery of the chain. These contrasts presumably reflect an enhanced electron concentration and delocalization *within* the chains and suggest a reason for the marked compression of the octahedra across Sc5–Sc6. Still lower populations order fairly well with increasing distances, including those within the Sc1, Sc2, Sc3 appendages (0.119–0.069). Another irregularity appears for the Sc6–Sc6 and Sc3–Sc3 interactions along the chain (0.050–0.040), even at 3.92 Å! Finally, the longish 3.48 Å Sc4–Sc4 separations in the zigzag chains have an MOP of only 0.026, followed by still lower populations for all interchain Sc4–ScX contacts. Thus bonding of Sc4 to all other scandium atoms appears to be weak and not an important part of the stability of this compound. Naturally, Sc4 and Sc2 have, in contrast, the largest Sc–Te overlap populations. A charge flow among the rather different types of scandium atoms from Sc–Sc and Sc–Te bonding is reflected in the relative MOP: largest for Sc6 and Sc1, least for Sc4 and Sc2.

Other highly reduced Group 3 chalcogenides of this type are under study, for example, the result of condensation of four chains of edge-sharing octahedra into four-blocks in Sc_9Te_2.[13] A rich and novel chemistry of these chalcogenides is expected by virtue of the conflicts between the electron-poor but metal-rich characteristics.

Experimental Section

Sc_2Te_3 [8] was prepared by reaction of Sc and Te (2:3) in fused SiO_2 at 900 °C for 72 h. A pressed pellet of Sc_2Te_3 and Sc foil with a Sc_2Te stoichiometry was arc-melted for 20 s per side, sealed into a tantalum tube, allowed to react in a vacuum furnace at 1125 °C for 72 h, and cooled at 5 °C h^{-1} to 850 °C. The structure was determined from crystals in the product, which was later shown to be single phase Sc_2Te according to its Guinier pattern [14].

Direct Solid-Phase Glycosylations of Peptide Templates on a Novel PEG-Based Resin**

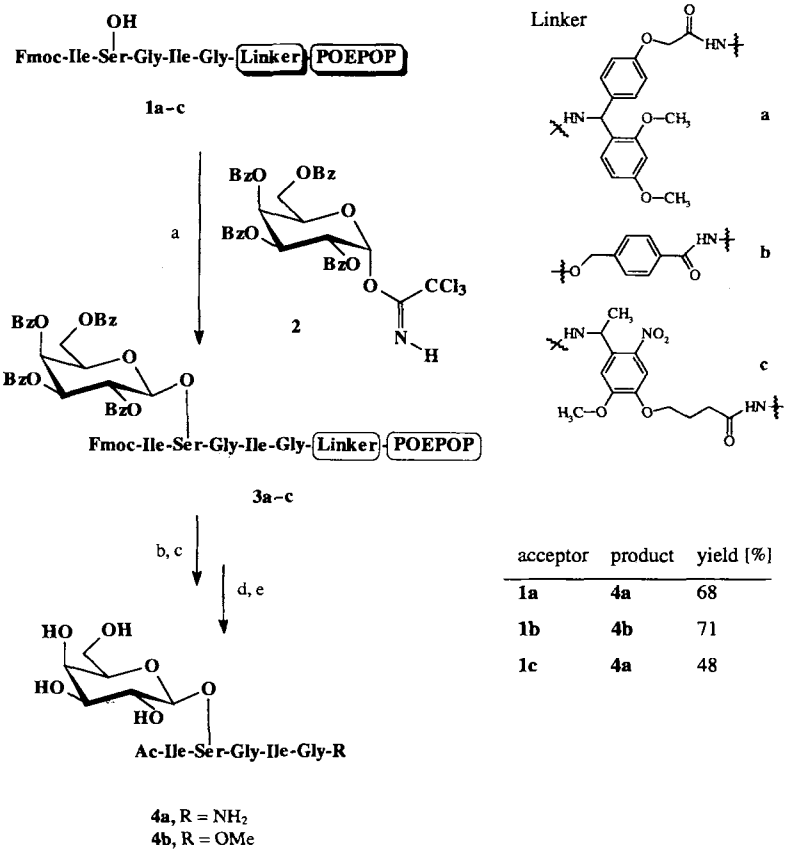
Axel Schleyer, Morten Meldal,* Renil Manat, Hans Paulsen, and Klaus Bock

Currently the most efficient method to synthesize glycopeptides is by solid-phase synthesis with glycosylated amino acid building blocks.[1–5] However, this method requires the preparation of a new glycosyl amino acid building block for each sugar incorporated. For the generation of a multitude of glycopeptides with variation of both sugar and peptide, it might be more efficient to couple the sugar directly and stereoselectively to the free hydroxyl groups of amino acid side chains on the resin-bound peptides. Thus, libraries of libraries could be produced by glycosylation of a preformed peptide library.

It has been demonstrated that solid-phase bound glycopeptides and oligosaccharides with free hydroxyl groups on the oligosaccharide moiety could be glycosylated with different glycosyl trichloroacetimidates.[6, 8] In contrast, attempts to glycosylate free hydroxyl groups of Thr or Ser in peptides bound to a PEGA resin, Tenta Gel, Polyhipe, and Macrosorb with a Rink linker, as well as polystyrene with a Wang linker, have not been successful.[6] However, a recent report described the glycosylation of N-terminal Thr in a tripeptide on solid-phase, albeit in very low yield.[7]

Systematic studies have demonstrated that the properties of the polymer support can have a large influence on the outcome of solid-phase reactions,[9] so such supports cannot be considered a rigid and inert material in the reaction.[10] The support interacts with reactive intermediates and has a significant role in the solid-phase reaction. With the desire to develop polymeric supports with an optimally balanced hydrophilic–hydrophobic character, a new class of cross-linked polymers, the polyethylene glycol polyacrylamide (PEGA) resins, have been introduced for peptide[11] and glycopeptide[1–5] synthesis. Even though these supports were found to be excellent for glycopeptide synthesis with glycosyl amino acid building blocks,[12] it would be preferrable to eliminate the amide backbone from the polymer matrix to facilitate a larger range of organic reactions. This has led to the development of inert PEG cross-linked resin, namely polyoxyethylene–polyoxypropylene (POEPOP), where all the amide linkages present in PEGA are replaced by fairly stable ether linkages, while the optimized balance of hydrophilic–hydrophobic character is retained.[13] PEG-OH was converted into a mixture of mono- and diepoxylated PEG with epichlorohydrin and polymerized by bulk anion-catalyzed polymerization in the presence of *t*BuOK to yield the POEPOP resin. The product was granulated by passing the wet, swollen polymer through a 1 mm sieve. Gel phase ^{13}C NMR showed a high degree of incorporation of PEG into this type of resin. After acid wash and rinsing the polymer support was dried under high vacuum for 24 h and used in the solid-phase synthesis.

A simple pentapeptide was synthesized as a solid-phase glycosyl acceptor on the POEPOP resin with three different linkers that were attached to the resin through a glycine residue to the resins hydroxy groups: **1a** was prepared with Rink linker,[14] **1b** with hydroxymethyl benzoic acid, and **1c** with a UV-labile linker[15] (Scheme 1). The dried acceptors **1a–c** were glycosylated with perbenzoylated galactopyranosyl trichloroacetimidate (**2**, 8 equiv)[16] in dichloromethane over a few pellets of molecular sieves with slow agitation at room temperature to afford the resin bound glycopeptides **3a–c**. These standard reaction conditions were also used for all the reactions described below. Cleavage of small resin aliquots and TLC analysis of the



acceptor	product	yield [%]

product showed the glycosylation to be complete within 24 h. After completion of assembly, N-terminal acetylation, cleavage from the resin, and deprotection, the corresponding glycopeptides **4a** and **4b** were obtained in 48–71% yield (based on the acceptor peptide). A ROESY connectivity between Gal^{H1} and $Ser^{H\beta}$ confirmed the glycosidic linkage (Figure 1). In all three cases quantitative glycosylation could be achieved. The lower yield (48%) of the glycopeptide synthesized on the UV-labile-linker was due to side reactions during the UV-cleavage.

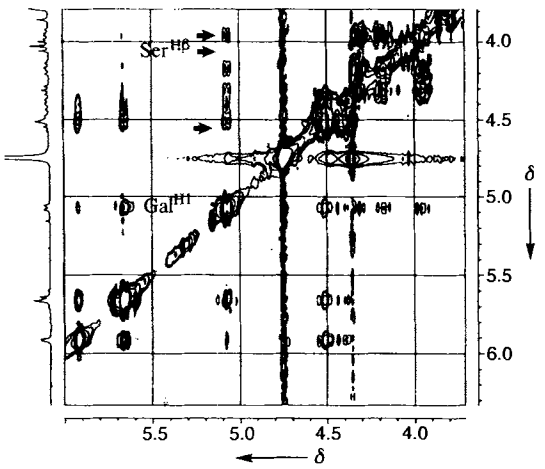

Figure 1. ^{1}H NMR ROESY spectrum of Ac-IS(Bz_4Gal-β)GIG-NH_2. The cross-peaks of the anomeric proton (δ = 5.1) and the $Ser^{H\beta}$ (δ = 3.95 and 4.2) indicates the connectivity between Gal^{H1} and $Ser^{H\beta}$. Fmoc = 9-fluorenylmethoxycarbonyl.

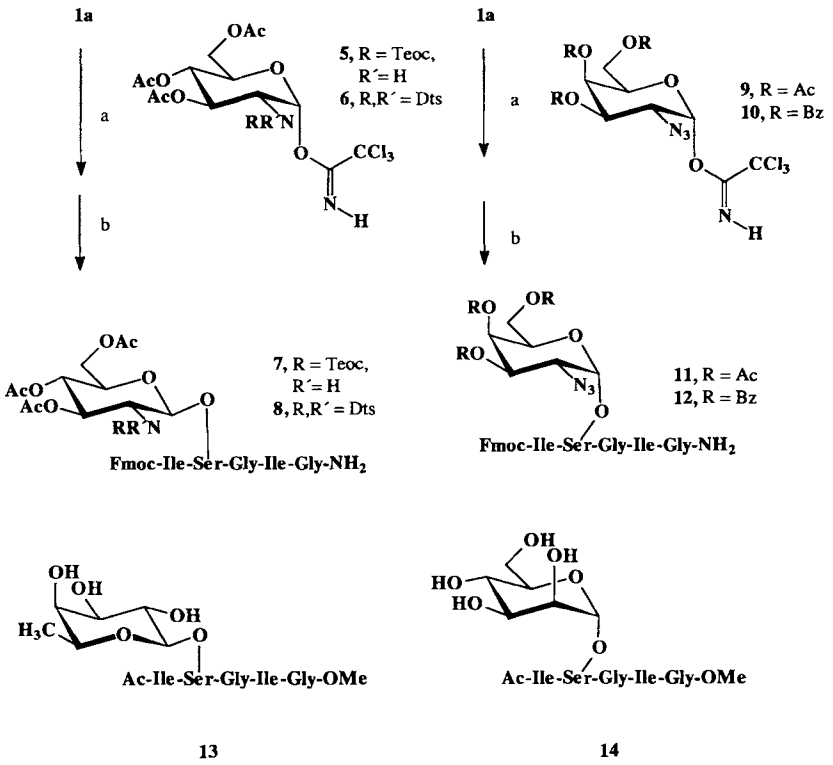

Scheme 2. Stereoselective β- and α-glycosylations of peptides with amino sugars on solid phase with TCAs and TMS-OTf. a) 0.1 equiv TMSOTf in CH_2Cl_2, b) TFA/H_2O, HPLC. β-L-Fucopyranoside (**13**) and α-L-mannopyranoside (**14**) were prepared analogously.

The protection of the 2-amino group of the 2-aminoglucopyranosyl donors is important, since the stereoselectivity of the β-glycosylation and deprotection under mild conditions has to be controlled. The trichloroethoxycarbonyl (Teoc) and the *N*-dithiasuccinyl groups (Dts) are best suited for this 2-amino protection. The acceptor peptide **1a** was glycosylated for 1.5 h (monitored by thin-layer chromatography (TLC)) with the protected 2-amino-2-deoxyglucopyranosyl trichloroacetimidates **5**[17,18] and **6**[19,20] (5 equiv, Scheme 2), and the products were cleaved with 95% trifluoroacetic acid (TFA). The corresponding protected *N*-acetyl-2-amino-2-deoxy-β-D-glucopyranosyl peptides **7** and **8** were obtained in a yield of 53% and 74%, respectively.

The perbenzoylated and peracetylated 2-azido-2-deoxy-α-D-galactopyranosyl trichloroacetimidates **9** and **10** were selected as glycosyl donors to form an α-linkage between the 2-acetamido-2-deoxy-α-D-galactopyranose and acceptor peptide **1a**. The 2-azido-2-deoxyglycosyl donors did not undergo neighboring group participation in the 2-position and led to the corresponding α-glycosylated products. After glycosylation for 2.5 h (monitored by TLC), cleavage with 95% TFA afforded the corresponding protected glycopeptides **11** and **12** in yields of 41% and 78%, respectively (based on the acceptor).

Glycosylation of acceptor **1b** was performed with 8 equivalents of the peracetylated trichloroacetimidates of D-mannose (1 h) and L-fucose (30 min) with trimethylsilyltrifluoromethanesulfonate (TMSOTf, 0.1 equiv) in CH_2Cl_2 at room temperature. Cleavage of the Fmoc group with piperidine in DMF, followed by N-acetylation and treatment with MeOH/NaOMe at pH 9–10, gave cleavage from the resin, and the corresponding glycopeptides **13** and **14** were isolated in 68% and 62% yields, respectively (based on the acceptor).

This method of synthesizing glycopeptides would be more versatile and useful for the synthesis of glycopeptide libraries if more than one free hydroxyl group on the peptide backbone could be glycosylated simultaneously. Therefore, four different acceptor peptides **15a–d** were synthesized in a combinatorial approach. After cleavage of the Fmoc group the obtained free amine was benzoylated with benzoic acid, *O*-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium tetrafluoroborate (TBTU) and *N*-ethyl morpholine (NEM) in THF (Scheme 3). Each of the compounds were first glycosylated in two cycles with perbenzoylated D-galactosyl trichloroacetimidate (**2**, 4 equiv, 24 h) under the standard conditions determined above. The resin was washed carefully with dichloromethane and treated with TFA (95%) for 90 min to remove any remaining *tert*-butyl ether groups. After washing with dichloromethane and drying, the acceptor resin was subjected to a second glycosylation with two cycles of peracetylated L-fucosyl trichloroacetimidate (4 equiv, 30 min). Cleavage from the resin with NaOMe yielded the four different glycopeptides **16a–d**. The products were separated by preparative reversed phase HPLC and were analyzed by one- and two-dimensional ^{1}H NMR spectroscopy and matrix-assisted laser-desorption time-of-flight mass spectrometry (MALDI-TOF-MS). The products contained the expected β-galacto- and β-fucosylated glycopeptides (Table 1).[21]

The method of solid-phase glycoslation on POEPOP resin is a powerful tool for synthesizing a variety of glycopeptides and a valuable alternative in many respects for the introduction of one or several monosaccharides into a peptide template. On Rink-linker-bound glycosyl acceptor peptides, stereoselective β-glycosidation with perbenzoylated or peracetylated trichloroacetimidates of galactose, 2-deoxy-2-dithiosuccimidoglucopyranose and 2-deoxy-2-trichloroethoxycarbamido-D-glucopyra-

nose gave the corresponding glycopeptides in high yields after cleavage. The protected β-galactopyranosyl peptide was deprotected in solution to yield the unprotected D-galactopyranosyl peptide. With perbenzoylated or peracetylated 2-azido-2-deoxy-α-D-galactopyranosyl trichloroacetimidate, the corresponding α-glycosylated products were formed in good yields.

On peptides attached through a HMBA-linker, glycosylation reactions with peracetylated trichloroacetimidates of L-fucopyranose, D-mannopyranose, and D-galactopyranose afforded the corresponding unprotected glycopeptides upon cleavage with NaOMe. *tert*-Butyl ether protecting groups were sufficiently stable when short glycosylation times could be employed. Longer reaction times resulted in some cleavage of *t*Bu, particularly from *tert*-butyl esters (data not presented). Use of temporary *t*Bu-protection of some serine hydroxy groups led to quantitative glycosylation of a model library consisting of four different octapeptide templates with two different glycosyl acceptor sites. The peracetylated trichloroacetimidates of L-fucose and D-galactopyranose were used in two sequential glycosylation steps to produce the four different unprotected glycopeptides obtained after cleavage from the resin.

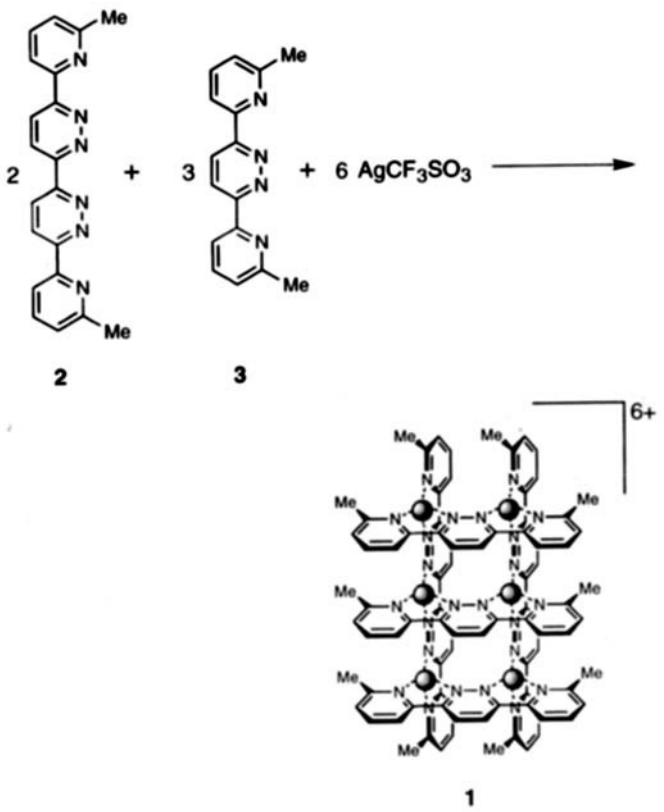
a single step from a mixture of suitably tailored molecular components.[1-4] The generation of multimetallic arrays by metal ion directed self-assembly is especially interesting in this respect, as the presence of metal ions may endow the resulting inorganic architecture with novel redox, optical, magnetic, and other properties. Recent examples from this class of compounds include helicates,[3, 5] cages,[6] rotaxanes,[7] and grids.[8, 9] The formation of a [3 × 3]G silver grid[8] demonstrated the feasibility of self-assembling two-dimensional square [$n \times n$] arrays of metal ions ($n = 3$), which may be considered as ion dots. Following the generation of [$n \times n$]G symmetrical grids, their rectangular [$m \times n$]G counterparts are especially attractive synthetic targets, as they constitute a potentially much larger class of compounds, and may therefore present a greater diversity of properties and possible applications.

We herein report the formation of the first example of the rectangular grid **1**, which spontaneously and preferentially self-assembles upon combination of tri- and ditopic ligands **2** and **3** with $AgCF_3SO_3$ in a 2:3:6 stoichiometric ratio in nitromethane (Scheme 1); minor amounts of the corresponding square grids



Scheme 1. Self-assembly of the rectangular [2 × 3]G grid complex **1**; the spheres represent Ag^I ions.

are also found (see Scheme 2). The structural formulation of the product as **1**·$(CF_3SO_3)_6$ is based on elemental analysis, X-ray crystallography, and ^1H, ^{13}C, and ^{109}Ag NMR spectroscopy. The product incorporates a two dimensional [2 × 3]G rectangular array of six silver(I) ions, and therefore represents the first member of a homologous series of [$m \times n$]G rectangular grids ($m \neq n$).

The ^1H NMR spectrum[10] of the solution obtained by dissolving **2**, **3**, and $AgCF_3SO_3$ in a 2:3:6 ratio in CD_3NO_2 gave the first indication of structure **1**. The spectrum is clean and free from overlapping bands. Ligand **2** is situated in a single chemical and magnetic environment, as indicated by five aromatic signals in a 2:2:2:2:2 ratio, which correspond to the H3, H4, and H5 protons of the outer pyridine rings and the H4′ and H5′ protons of the inner pyridazine rings. Ligand **3** appears as two sets of signals in a 2:1 ratio, each set comprising four bands due to the H3, H4, and H5 protons of the pyridine rings and the equivalent H4′/H5′ protons on the pyridazine ring. This pattern is consistent with two outer and one inner ligands **3** in **1**. The CH_3 protons give three peaks in a 6:6:3 ratio, which is also indicative of **2** in a single and **3** in two different environments in a ratio of 2(**2**):2(**3**):1(**3**). In addition, the pyridazine H4′/H5′ singlet of the inner **3** ligand is shifted upfield relative to that of the outer two **3** ligands. This shielding effect is what would be expected for protons on a ring situated within structure **1**. The ^{109}Ag NMR spectrum shows two signals in a 2:1 ratio corresponding to four outer and two inner Ag^+ ions, respectively.

An X-ray crystal structural determination[11] of the reaction product confirmed the structure as **1**·$(CF_3SO_3)_6$ (Figure 1). The

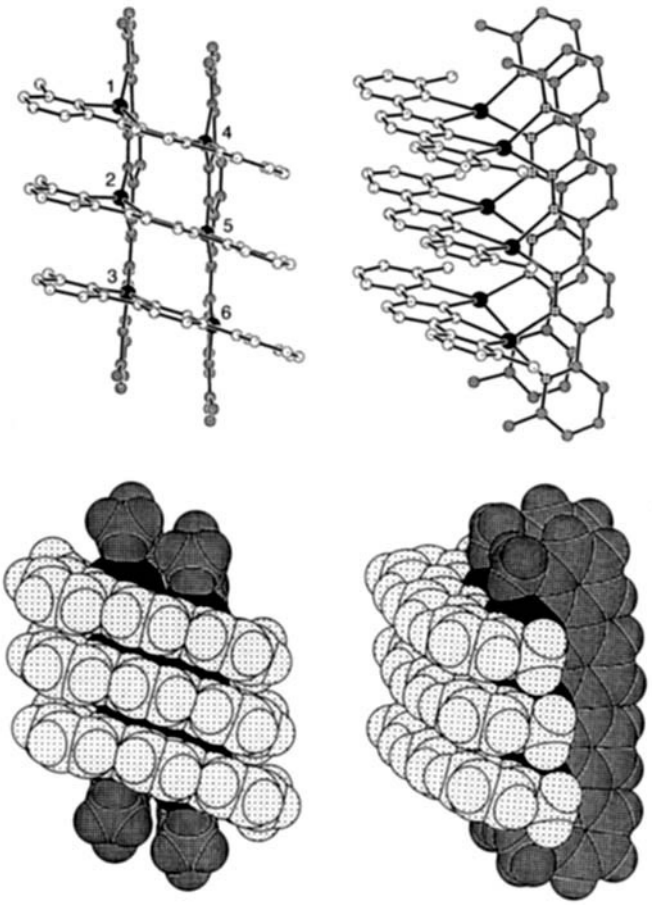


Figure 1. Two views of the crystal structure of the self-assembled [2 × 3]G rectangular grid $[Ag_6(\mathbf{2})_2(\mathbf{3})_3]^{6+}$ (**1**): ball-and-stick (top) and space-filling representations (bottom).

crystals consist of $[Ag_6(\mathbf{2})_2(\mathbf{3})_3]^{6+}$ ions, uncoordinated triflate anions, as well as nitromethane and water molecules. The six silver ions in **1** are arranged in the form of a 2 × 3 rhombohedrally distorted rectangular matrix. The dihedral angle described by the rhombus (between the mean planes of ligands **2** and **3**) is about 66°, and the average Ag–Ag separation is 3.75 Å. The vertex silver ions Ag1, Ag3, Ag4, and Ag6 lie almost in a plane with distances Ag1–Ag4 3.79, Ag1–Ag3 7.63, Ag3–Ag6 3.72, and Ag4–Ag6 7.45 Å, and inner angles Ag4-Ag1-Ag3 65 and

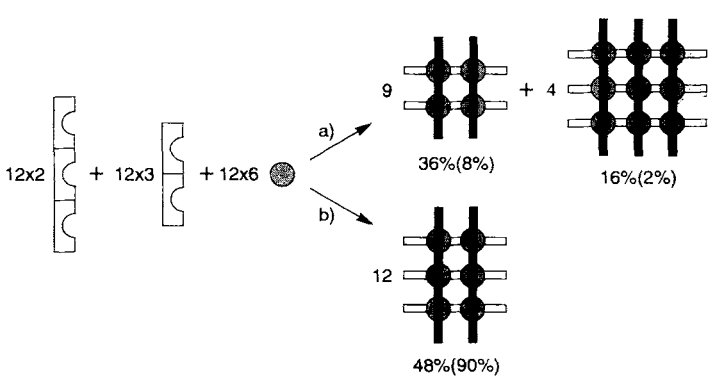
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3618-1979 $ 17.50+.50/0

Ag1-Ag4-Ag6 115°. The six silver ions define a slightly U-shaped surface along the longer axis of **1**, in which Ag2 and Ag5 lie 0.19 and 0.25 Å, respectively, above the mean plane through Ag1, Ag3, Ag4, and Ag6. All the silver ions possess a distorted tetrahedral coordination polyhedron with an average dihedral angle of 71° between the N-Ag-N planes of ligands **2** and **1**. The four vertex silver ions are each coordinated to two pyridine and two pyridazine nitrogen atoms (mean Ag–N 2.30 Å), and the two central Ag ions to one pyridine and three pyridazine nitrogen atoms (mean Ag–N 2.35 Å). This situation is reflected in the ^{109}Ag NMR spectrum of **1**, in which the signal due to the vertex Ag ions is shifted downfield by $\Delta\delta = 59$ ppm from that of the central Ag ions. This is in agreement with the chemical shifts observed for a [3 × 3]G nonasilver grid.[8]

The five ligands in **1** are divided into two sets comprising two units of **2** and three units of **3** lying above and below the mean plane through the six Ag^I ions. Each ligand forms a slightly twisted blade conformation due, in part, to the summed effects of intra-ligand steric repulsions (maximum dihedral inter-ring twist angle 12°). The average distance between the ligand mean planes is 3.36 Å and therefore slightly larger than the van der Waals contact distance of about 3.4 Å. The overall dimensions of **1** are 15.19 × 11.07 Å, which places the grid just within the nanostructural domain. The shortest distance between the grid cations within the crystal lattice is 3.4 Å.

The spectroscopic and crystallographic evidence unambiguously supports the identity of the product from the reaction of **2**, **3**, and $AgCF_3SO_3$ in a 1:1.5:3 ratio as that of hexanuclear rectangular [2 × 3]G grid **1** both in solution and in the solid state. Complex **1** forms spontaneously by the self-assembly of eleven particles, that is, five ligand components of two types and six silver ions. On the basis of the instructions contained in the ligands and the coordination algorithm of the metal-ion connectors, the mixed-component process by which a rectangular grid is generated represents a step further in complexity in terms of information content with respect to the formation of symmetric [$n \times n$]G grids, which involves only a single ligand species.

The preferential formation of a mixed-ligand entity is especially noteworthy, as the system made up of **2**, **3**, and Ag^+ in a 1:1.5:3 ratio has the potential to give three different product distributions (Scheme 2): 1) statistical distribution, 2) homo ligand recognition in which ligands only recognize individuals of their own identity to yield [2 × 2]G and [3 × 3]G symmetrical grids, and 3) hetero ligand assembly, that is, selective association between ligands of different type resulting in the generation of **1**. Upon completion of the reaction, **1**·$(CF_3SO_3)_6$ coexists in CD_3NO_2 with a mixture of 8% $[Ag_4(\mathbf{3})_4](CF_3SO_3)_4$ and 2% $[Ag_9(\mathbf{2})_6](CF_3SO_3)_9$, as indicated by the ^{1}H NMR spectrum of the solution. This ratio appears to be independent of concentration. Helicate mixtures exhibit either partial or exclusive homo ligand recognition.[14, 15] The preference for hetero over homo ligand recognition in the case of **1** may derive in part from an avoidance to form the [3 × 3]G complex, which possesses the least stable metal–ligand coordination site, that is, the central $Ag(pyridazine)_4$ unit. Solvation and thermodynamic considerations also play a role. An understanding of the factors which result in a preference for hetero over homo ligand assembly will be of great importance for the future design of disymmetric metal-ion arrays.



Scheme 2. Possible self-assembly pathways for **2**, **3**, and Ag^+ in a 2:3:6 ratio: a) homo and b) hetero ligand selection; statistically expected values and actual yields (in parentheses) are given for both cases.

The successful preparation of **1** opens the way to metal ion mediated self-assembly of nonsymmetric [$m \times n$]G ion grids ($m \geq 2$, $n \geq 3$, and $m \neq n$ for m and n binding sites). Because such disymmetric grids must, by definition, be mixed-ligand species, they present a larger variety of possible combinations of the ligands involved than their symmetric [$n \times n$]G congeners. Therefore, they could find a greater number of applications, for example as components within a futuristic information storage and processing nanotechnology. To uncover and exploit the novel physicochemical properties that such systems may possess, detailed investigations into electronic, magnetic, surface chemical, and interfacial behavior will be necessary. Furthermore, methods for the fabrication of polynuclear architectures of higher dimensionality and techniques for their incorporation into larger organized superstructures may also be envisioned.

Experimental Section

Nitromethane (3 mL) was added to **2** (0.026 g, 7.64×10^{-5} mol), **3** (0.030 g, 1.14×10^{-4} mol), and $AgCF_3SO_3$ (0.059 g, 2.30×10^{-4} mol), and the mixture subjected to brief ultrasonication. All suspended solids rapidly dissolved to give a yellow solution, which was stirred at room temperature for 36 h and then filtered. The solvent was removed under reduced pressure. The remaining solid was suspended in benzene (8 mL), homogenized by brief ultrasonication, isolated by filtration under vacuum, washed with excess benzene, and dried in the air and then under vacuum at 2×10^{-6} mm Hg and 70 °C. The yellow powder obtained (yield 0.114 g, 99%) could be either pure **1**·$(CF_3SO_3)_6$ or a mixture with the square grids; it was recrystallized quantitatively from nitromethane/benzene [10, 11].

1·$(CF_3SO_3)_6$: ^{1}H NMR (CD_3NO_2, 500 MHz, 25 °C): $\delta = 9.146$ (d, $J(5',4') = 9.4$ Hz, H5′ (**2**)), 9.081 (d, $J(4',5') = 9.4$ Hz, H4′ (**2**)), 8.774 (s, H4′ (outer **3**)), 8.575 (s, H4′ (inner **3**)), 8.264 (d, $J(3,4) = 8.2$ Hz, H3 (**2**)), 8.171 (d, $J(3,4) = 8.0$ Hz, H3 (outer **3**)), 7.977 (t, $J(3,4,5) = 7.9$ Hz, H4 (**2**)), 7.914 (t, $J(3,4,5) = 7.9$ Hz, H4 (outer **3**)), 7.816 (d, $J(3,4) = 8.0$ Hz, H3 (inner **3**)), 7.691 (t, $J(3,4,5) = 7.9$ Hz, H4 (inner **3**)), 7.438 (d, $J(5,4) = 7.7$ Hz, H5 (**2**)), 7.353 (d, $J(5,4) = 7.7$ Hz, H5 (outer **3**)), 7.211 (d, $J(5,4) = 7.7$ Hz, H5 (inner **3**)), 2.373 (s, CH_3 (inner **3**)), 2.258 (s, CH_3 (**2**)), 2.244 (s, CH_3 (outer **3**)). All of the protons assigned represent a symmetric pair of protons on each ligand. ^{13}C NMR (CD_3NO_2, 75 MHz, 25 °C): $\delta = 161.20$, 161.01, 160.83, 158.11, 156.38, 155.28, 153.70, 147.26, 147.05, 145.82, 142.91, 142.20, 142.16, 132.37, 132.31, 131.23, 131.08, 129.98, 129.90, 129.50, 123.81, 123.30, 123.17; 28.40, 27.53, 27.38 (CH_3); 124.59, 120.34 ($CF_3SO_3^-$); ^{109}Ag NMR (CD_3NO_2, 18.625 MHz, 25 °C): $\delta = 572.63$ (Ag, vertex), 513.12 (Ag, central); elemental analysis calcd for $C_{94}H_{74}Ag_6F_{18}N_{24}O_{18}S_6$: C 37.52, H 2.48, N 11.17; found: C 37.35, H 2.61, N 11.32.

[10] ^{1}H NMR spectral assignments were made on the basis of ^{1}H–^{1}H ROESY and COSY measurements. The spectra of the crude and recrystallized materials were identical, indicating that the different grid species present equilibrate. In addition, mixing preformed [2 × 2] and [3 × 3] square grids in the correct ratios generates an equilibrium solution giving the same NMR spectrum. The fact that the species has higher symmetry in solution (NMR spectroscopy) than in the solid state (crystal structure analysis) may be attributed to fast exchange between the two rhombohedral enantiomers, as noted previously [8].
[11] Yellow crystals were grown by slow diffusion of benzene into a solution of **1**·$(CF_3SO_3)_6$ in nitromethane at 20 °C. Crystal data for $\{2[Ag_6(\mathbf{2})_2(\mathbf{3})_3]\cdot 12(O_3SCF_3)\cdot 2C_6H_6\cdot 7H_3CNO_2\cdot 1C_6H_{14}\}$: crystal size 0.1 × 0.1 × 0.2 mm; STOE-IPDS diffractometer with graphite monochromater, $T = -80$ °C, $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å); monoclinic, space group $P2/n$, $a = 29.961(6)$, $b = 21.534(4)$, $c = 38.827(8)$ Å, $V = 25032(9)$ Å^3, $Z = 4$, $\mu = 1.128$ mm^{-1}, $F(000) = 13092$, $\rho_{calcd} = 1.753$ Mg m^{-3}, $M_r = 6604.99$, $2\theta_{max} = 48°$. The primary structure was solved and refined by direct methods (SHELXS-92) [12]. All non-hydrogen atoms except those of some heavily disordered solvent molecules were refined anisotropically (SHELXL-93) [13]. A riding model starting from calculated positions was employed for the hydrogen atoms; due to disorder no hydrogen positions were calculated for solvent molecules. Of 107065 reflections measured 38400 were independent (R(int) = 0.0659), of which 38368 were employed in the refinement of 3795 parameters. Triflate ions and solvent molecules partially show heavy disorder, which could be successfully modeled by use of geometry restraints (planarity, chemically equivalent 1,2-/1,3-distances, and "anti-bumping" principles) and ADP restraints (rigid-bond, similarity, and isotropy). $O_3SCF_3^-$ ions: restraints on S-O (1.42 Å), S-C (1.82 Å), and C-F (1.32 Å) bond lengths. For disordered triflate ions displacement parameters of fluorine and oxygen positions were equated for each split position by means of constraint. N-C and N-O distances in nitromethane were fitted to target values of 1.55 and 1.20 Å, respectively; benzene molecules were refined as variable metric groups; C-C bonds in *n*-hexane were fitted to target values of 1.54 Å. The structure was refined against F^2 (full-matrix-block least squares). Weighting scheme: $w^{-1} = \sigma 2(F_o^2) + (0.0939P)^2 + 172.5727P$, with $P = (F_o^2 + 2F_c^2)/3$, $R1 = 0.0732$ ($F > 4\sigma F$) and $wR2 = 0.2146$ (all data), GOF ($F^2 = S$) = 1.106, max/min residual density +2.34/−1.25 e Å^{-3}, $(R1 = \sum||F_o| - |F_c||/\sum|F_o|$, $wR2 = [\sum w(F_o^2 - F_c^2)^2/\sum wF_o^4]^{1/2}$, GOF = $S = \{\sum[w(F_o^2 - F_c^2)^2]/(n-p)\}^{1/2}$, where n = no. of reflections, and p = no. of parameters). Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100391. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code +(1223) 336-033; e-mail: deposit@chemcrys.cam.ac.uk).

New Copper Telluride Clusters by Light-Induced Tellurolate–Telluride Conversions**

John F. Corrigan and Dieter Fenske*

There is currently considerable interest in the chemistry of metal selenolate and tellurolate complexes,[1] driven in part by their potential utility as single-source precursors for semiconducting binary- and ternary-phase materials.[2] Homoleptic $[M(ER)_2]$ (M = metal, E = chalcogen) complexes decompose with elimination of ER_2 and formation of the corresponding binary solid materials "ME".[3a] Studies in this area have included chalcogenolate complexes of Group 12 elements,[3] and recent efforts have focused on related lanthanide,[4] early transition metal,[5] and main group complexes.[6]

Despite the abundance of research activity in this area, structural reports detailing the manner in which the molecule → bulk transformation occurs are scarce. Arnold et al. described the Lewis base induced conversion of early transition metal selenolate and tellurolate complexes into selenide- and telluride-containing molecules as the first step towards extended solids from molecular precursors.[5] Piers and co-workers also detailed the reversible elimination of dialkyl tellurium from permethyl scandocene tellurolates to yield the dimeric telluride complex $[(Cp^*_2Sc)_2(\mu\text{-Te})]$ ($Cp^* = C_5Me_5$).[7] We set out to exploit this reactivity to access high nuclearity metal telluride clusters. Here we report on the elimination of $TePh_2$ from the phosphane-stabilized copper(I) tellurolate **1**, and its concomitant condensation to yield the mixed telluride/tellurolate cluster **2**.

$[Cu_6(\mu\text{-TePh})(\mu_3\text{-TePh})_5(PEtPh_2)_5]$ **1**

$[Cu_{50}(\mu_3\text{-TePh})_{20}Te_{17}(PEtPh_2)_8][PEtPh_3]_4$ **2**

CuCl readily dissolves in ethers with excess phosphane. When a solution of CuCl and PPh_2Et (1:2) in THF/Et_2O is allowed to react with the silylated tellurium reagent $Te(Ph)SiMe_3$, a yellow, homogenous solution forms, from which yellow crystals of **1** grow in high yield (80–88%) after layering with *n*-heptane [Eq. 1].[8] The molecular structure of **1**[9] (Figure 1) consists of

$$CuCl + 2\,PEtPh_2 + Te(Ph)SiMe_3 \xrightarrow[-Me_3SiCl]{THF/Et_2O} \underset{\mathbf{1}}{[Cu_4(TePh)_6(PEtPh_2)_5]} \quad (a)$$

a nonbonded octahedral array of tellurolate ligands (Te···Te 4.035(1)–4.576(1) Å) that each bridge three Cu sites with the exception of Te3, which forms only two Cu–Te bonds. The μ-TePh–Cu distances (av 2.560(1) Å) are noticeably shorter than their μ_3 counterparts (2.577(1)–2.700(1), av 2.652(4) Å).

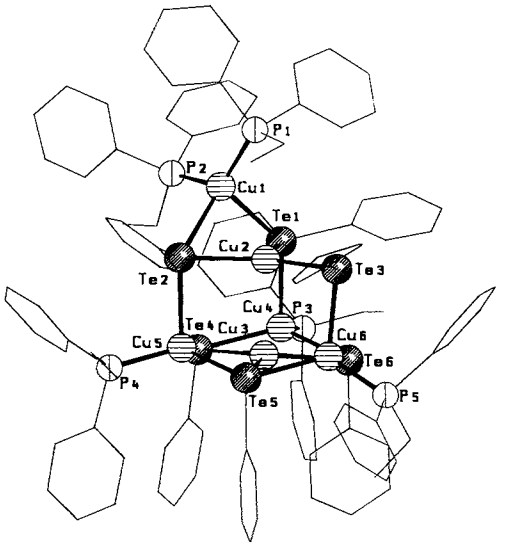

Figure 1. Molecular structure of **1** in the crystal. Important bond lengths and angles are discussed in the text. Te atoms are illustrated as dark spheres, and Cu atoms as spheres with horizontal hashing.

Four of the copper atoms adopt tetrahedral geometries, either with one phosphorus and three tellurium atoms (Cu4–C6) or two Cu–Te and two Cu–P bonds (Cu1). Atoms Cu2 and Cu3 lie in opposite deltahedral faces of the Te_6 octahedron (maximum deviation 0.22 Å, sum of angles 357.8–360.0°). The oxidation state I (d^{10}) can be assigned to the metal centers, and a cluster valence electron count of either 98 or 88, depending on whether the μ_3-TePh ligands are described as five- or three-electron donors, respectively, can be derived. Cluster **1** is related to the recently published homoleptic hexanuclear copper selenolate complex $[Cu_6\{Se(2,4,6\text{-}iPr_3C_6H_2)\}_6]$, in which the Cu^I atoms lie on the faces of a Se_6 antiprism.[10]

We were unable to observe any signals in the ^{125}Te NMR spectrum of **1**; room-temperature $^{31}P\{^1H\}$ NMR spectra display a broad singlet at $\delta = -10.3$. Solutions of **1** are bright yellow and exhibit an intense, broad absorbance band at $\lambda_{max} = 287$ nm ($\varepsilon = 72000$) and a weaker one at $\lambda_{max} = 397$ nm ($\varepsilon = 13500$). The d^{10} electronic configuration at Cu and the high extinction coefficients of these transitions suggest a charge transfer type process. However, intraligand transitions cannot be ruled out for the higher energy band. Upon exposure to light these solutions gradually darken to a brown color, and after four days the bands at 287 and 397 nm are no longer observed. When **1** is dissolved in benzene, brown platelets of the mixed telluride/tellurolate cluster $[Cu_{50}(\mu_3\text{-TePh})_{20}Te_{17}(PEtPh_2)_8]^{4-}$ crystallize over the course of several days as the $[PEtPh_3]^+$ salt (yield 50%); the cation arises from the originally coordinated phosphane ligands.[8] In contrast, solutions of **1** in benzene that are protected from light show no evidence of darkening even after several weeks at room temperature.

A projection of the cluster core determined by X-ray analysis is shown in Figure 2.[9] Although the plate-like crystals scattered

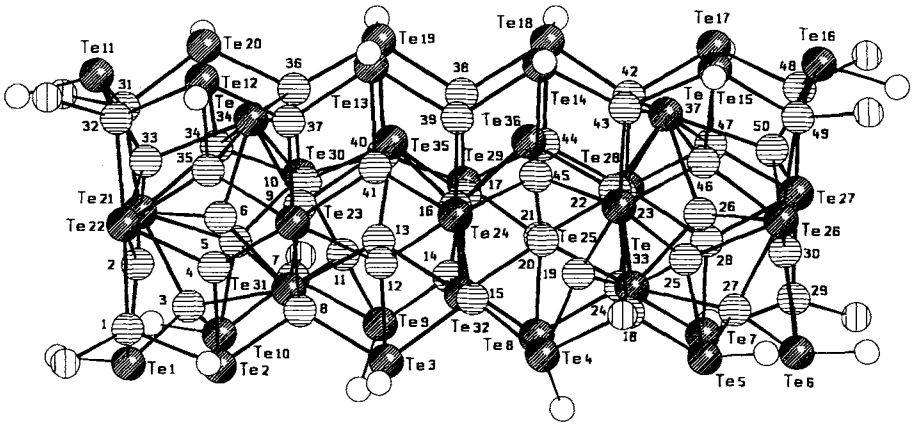

Figure 2. Molecular structure of **2** in the crystal. Important bond lengths and angles are discussed in the text. For clarity all C atoms, with the exception of the *ipso*-C atoms bonded to the tellurolate ligands, have been omitted.

only weakly—which adversely affected the intensity and quality of the data—all carbon atoms, with the exception of those bonded to the disordered $[PEtPh_3]^+$ counterions P11 and P12, could be localized in the difference Fourier maps.[9] The striking feature of the cluster core is the manner in which the tellurium ligands are arranged: the molecule consists of "top" and "bottom" μ_3-TePh layers (Te1–Te10 and Te11–Te20, respectively) with a central telluride layer (Te21–Te30). Sandwiched between these are the 50 copper atoms along with the remaining 7 telluride ligands. The combination of 20 $Te(Ph)^-$ and 17 Te^{2-} ligands accounts for the presence of the four phosphonium ions in the asymmetric unit when an oxidation state of I is assigned to the copper centers. Cluster **2** is diamagnetic, which is in agreement with the above description. The stoichiometric ratio of Cu:Te in **2** is in contrast to the nonstoichiometry observed in more spherical, closely packed Cu/Te clusters[11] but parallels observations on related high-nuclearity Ag/Te/TeR clusters.[12]

The 20 phenyltellurolate ligands are each bonded to three copper atoms (Te–Cu 2.525(4)–2.969(4) Å) and, in conjunction with the eight coordinated $PEtPh_2$ ligands, serve to stabilize effectively the inner CuTe core. The telluride ligands that form the middle Te_{10} layer act as μ_6 and μ_7 bridges between the copper sites to which they are bound with distances between 2.521(4) and 2.983(4) Å. The seven remaining Te^{2-} ligands (Te–Cu 2.561(3)–3.142(4) Å) function as μ_6, μ_7, and μ_8 bridges. Evidence for the presence of $TePh_2$ in reaction solutions, which accounts for the presence of telluride ligands in **2**, was confirmed with $^{125}Te\{^1H\}$ NMR spectroscopy; a signal at $\delta = 688$ was observed.[13] Arnold et al. recently reported the isolation and structural characterization of the mixed telluride/tellurolate clusters $[Ln_5Te_3\{TeSi(SiMe_3)_3\}_9]$ (Ln = La, Ce) by the decomposition of homoleptic metal tellurolate precursors and concomitant generation of $Te[Si(SiMe_3)_3]_2$.[4d]

The Cu···Cu distances in **2** (2.463(5)–3.022(5) Å) are consistent with the oxidation state I assigned to these centers,[14] and their coordination geometries vary from (distorted) trigonal planar to tetrahedral. Despite the layered nature of both **2** and the binary material Cu_2Te,[15] the arrangement in the latter consists of ditelluride (Te_2^{2-}) units and formal Cu–Cu bonds. Therefore, it bears little resemblance to the arrangement observed in **2**.

Although we have yet to isolate any intermediates in the reaction of **1** to **2**, $^{31}P\{^1H\}$ NMR spectra of solutions from which **2** crystallize display broad signals in the range of $\delta = +2$ to -12, suggesting the presence of additional cluster species. Clues into the reaction pathway may be gleaned from the isolation and structural characterization[9] of the dodecanuclear mixed telluride/tellurolate complex **3**,[8] which is the only crystalline

$[Cu_{12}(\mu_6\text{-Te})_3(\mu_3\text{-TePh})_6(PPh_3)_6]$ **3**

product obtained (yield 40%) from reactions analogous to that for **1** but with the ligand PPh_3 under normal daylight conditions (Figure 3). The cluster, not unlike **2**, consists of two tellurolate and a central telluride layers with the 12 Cu atoms lying either slightly above (Cu11, Cu41) or within (Cu21, Cu31) the deltahedral faces of the nonbonded tellurium framework. There are two crystallographically independent but chemically equivalent molecules per asymmetric unit which lie on crystallographic threefold axes.[9] The Te_9 polyhedron consists of two Te_6 octahedra sharing a common face composed of the three telluride ligands. It is thus easily viewed as the product of condensation of two $(PhTe)_6$ units in **1**.

We are currently exploring the general applicability of photolytic methods for the generation of high nuclearity metal/chalcogenide/chalcogenolate clusters and nanoparticle complexes.

[8] Elemental analyses: calcd values (found): $[Cu_6(TePh)_6(PEtPh_2)_5]$ (**1**), $C_{106}H_{105}P_5Cu_6Te_6$: C 47.50 (47.44), H 3.95 (3.83); $[Cu_{50}(TePh)_{20}Te_{17}(PEtPh_2)_8][PEtPh_3]_4$ (**2**), $C_{312}H_{300}P_{12}Cu_{50}Te_{37}$: C 30.42 (30.45), H 2.45 (2.42), P 3.02 (2.80); $[Cu_{12}(Te)_3(TePh)_6(PPh_3)_6]\cdot 1.5C_6H_6$ ($\mathbf{3}\cdot 1.5C_6H_6$), $C_{153}H_{129}P_6Cu_{12}Te_9$: C 45.21 (44.61), H 3.20 (3.15).

[9] Data for the crystal structure analyses were collected with a Stoe IPDS imaging plate diffractometer ($Mo_{K\alpha}$, $\lambda = 0.71073$ Å). $C_{106}H_{105}P_5Cu_6Te_6$ (**1**) at 193 K: yellow polyhedron, $0.40\times0.30\times0.23$ mm, $M = 2680.6$, monoclinic, space group $P2_1/n$, $a = 17.891(4)$, $b = 23.891(5)$, $c = 23.735(5)$ Å, $\beta = 90.39(3)°$, $V = 10145(4)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.755$ g cm^{-3}, $\mu = 3.051$ mm^{-1}, $2\theta_{max} = 52°$; of 41727 reflections collected 18291 were independent ($R_{int} = 0.0433$) and 15469 observed with $F_o > 4\sigma(F_o)$. The structure was solved by direct methods and refined on F^2 using SHELXTL software. Data were corrected for Lorentzian and polarization effects. No absorption corrections were performed. All atoms were refined anisotropically, and hydrogen atoms were included as riding on their respective carbon atoms (1108 parameters). Final $R = 0.0461$ ($wR_2 = 0.1124$) and GOF = 1.111; max/min residual electron density = 2.37/ −1.23 e Å^{-3}. $[C_{232}H_{220}P_8Cu_{50}Te_{37}][C_{20}H_{20}P_4]\cdot 2C_6H_6$ ($\mathbf{2}\cdot 2C_6H_6$) at 200 K: brown platelet, $0.22\times0.22\times0.02$ mm, $M = 12475.6$, monoclinic, space group $P2/c$, $a = 35.986(4)$, $b = 19.955(2)$, $c = 57.004(8)$ Å, $\beta = 106.83(1)°$, $V = 39181(8)$ Å^3, $Z = 4$, $\rho_{calcd} = 2.115$ g cm^{-3}, $\mu = 5.439$ mm^{-1}, $2\theta_{max} = 40°$; of 101160 reflections collected 35173 were independent ($R_{int} = 0.1083$) and 23318 observed with $F_o > 4\sigma(F_o)$. The structure was solved and refined as for **1**; however, only Cu, Te, and P atoms were anisotropically refined (1562 parameters). All phenyl rings were refined as rigid groups, and hydrogen atoms were not included. $[PEtPh_3]$ cations P(10)–P(12) were disordered over inversion centers. P–C and C–C distances about these cations were refined with common values. Not all C atoms about these counterions could be localized. Final $R = 0.0777$ ($wR_2 = 0.2102$) and GOF = 1.11; max/min residual electron density = 1.97/ −1.14 e Å^{-3}. $C_{144}H_{120}P_6Cu_{12}Te_9\cdot 1.5C_6H_6$ ($\mathbf{3}\cdot 1.5C_6H_6$) at 200 K: green hexagonal plate fragment, $0.27\times0.19\times0.04$ mm, $M = 4064.3$, trigonal, space group $R\bar{3}$, $a = 28.049(1)$, $c = 71.959(4)$ Å, $V = 49029(4)$ Å^3, $Z = 12$, $\rho_{calcd} = 1.652$ g cm^{-3}, $\mu = 3.204$ mm^{-1}, $2\theta_{max} = 45°$; of 28704 reflections collected 12849 were independent ($R_{int} = 0.0674$) and 9119 observed with $F_o > 4\sigma(F_o)$. The structure was solved and refined as for **1**; however, solvent atoms C(1S)–C(6S) were isotropically refined (1034 parameters). Final $R = 0.0598$ ($wR_2 = 0.1667$), GOF = 1.036; max/min residual electron density = 1.70/ −0.91 e Å^{-3}. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100373. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

Difluorovinylidene, $F_2C{=}C{:}$**

Jürgen Breidung, Hans Bürger,* Carsten Kötting, Rodion Kopitzky, Wolfram Sander,* Michael Senzlober, Walter Thiel,* and Helge Willner*

Vinylidenes $R^1R^2C{=}C{:}$ rearrange so rapidly to alkynes $R^1C{\equiv}CR^2$, which are more stable by 35–45 kcal mol^{-1}, that they could be detected directly only in few cases. The singlet carbenes $H_2CC{:}$ and $FHCC{:}$ were characterized in the gas phase by means of the vibrational progression in the photoelectron (PE) spectra of the anions H_2CC^- [1, 2] and $FHCC^-$.[3] The immediate rearrangement of 1-H-vinylidenes into alkynes by 1,2-H shift is rendered possible by a very low activation barrier[2] calculated to be 2–4 kcal mol^{-1}.[4, 5]

In contrast, the isomerization of $F_2C{=}C{:}$ (difluorovinylidene, **1**) to $FC{\equiv}CF$ (**2**) is impeded by a considerably higher barrier of 35–40 kcal mol^{-1}. The planar, antiaromatic species **A** is the transition state for the corresponding 1,2-F shift.[6] Surprisingly, in spite of this kinetic stabilization there is no direct evidence yet for **1** beyond that based on the vibrational frequencies (see Table 1)[3] measured in the 351.1 nm PE spectrum

of F_2CC^- and assigned with the assistance of ab initio calculations.[7] Experiments to generate **1**, by IR excitation of $F_2C{=}CHF$[8] and $F_2C{=}CHCl$[9] in the gas phase with a CO_2 laser or Hg $6(^3P_1)$ photosensitized decomposition of $F_2C{=}CHF$,[10] yield the geminal elimination products HF and HCl. However, singlet **1**,[10] the presumed intermediate, either adds across the C=C bond of the parent olefin,[7, 10] or by H abstraction[9] immediately forms stable products whose constitution proves the intermediacy of **1**.

This conclusion is further supported by the formation of a mixture of $F_2CC^{12}CO$, $F_2CC^{13}CO$ and ^{13}CO when difluoropropadienone (**3**) with [1-^{13}C] isotopic enrichment is photolyzed in an Ar matrix doped with natural CO ($\lambda > 185$ nm). UV irradiation ($\lambda = 240$ nm) of **3** in an N_2 matrix yields small amounts of difluorodiazoethene F_2CCNN (**4**).[11] Upon flash pyrolysis of difluoromaleic anhydride at 825–975 °C both **2** and **3** are formed, whereas **1** is not obtained.[12] These previous studies suggest that it might be possible to detect and characterize **1**, for example in a matrix in the absence of possible reactive partners, but hardly as a product of photochemical elimination processes.

Our efforts to convert **2**[13] into **1** thermally either by heating to 1100 °C, or by passing over hot Pt wool, failed; only undecomposed **2** was trapped in an Ar matrix at 15 K. We therefore attempted to generate **1** by photochemical isomerization of **2**. A noble gas matrix at low temperature seemed to be more favorable for this purpose than the gas phase, since in the matrix bimolecular trapping reactions and surface-catalyzed back reactions are suppressed. Infrared spectroscopy is apparently particularly suited for the detection of **1**, since the matrix IR spectrum of **2** is well known.[14]

The location of the IR absorptions of **1** has been estimated from ab initio CCSD/DZP calculations[7, 15] by scaling the harmonic wavenumbers with a factor of 0.95. To obtain more reliable ab initio predictions without empirical corrections we recalculated the harmonic wavenumbers at the higher correlated CCSD(T) level using the significantly larger cc-pVQZ basis and determined the anharmonicity corrections to the wavenumbers from the anharmonic MP2/TZ2Pf force field.[15–20] The ab initio predictions are collated in Table 1, columns 1 and 2.

We have recorded the UV/Vis spectrum of gaseous and matrix-isolated **2** in order to determine the wavelength best suited for photochemical conversion of **2** into **1**. Figure 1 illustrates that **2** has an absorption maximum ($\lambda < 200$ nm) with a flank at longer wavelengths. In the UV gas spectrum this flank extends

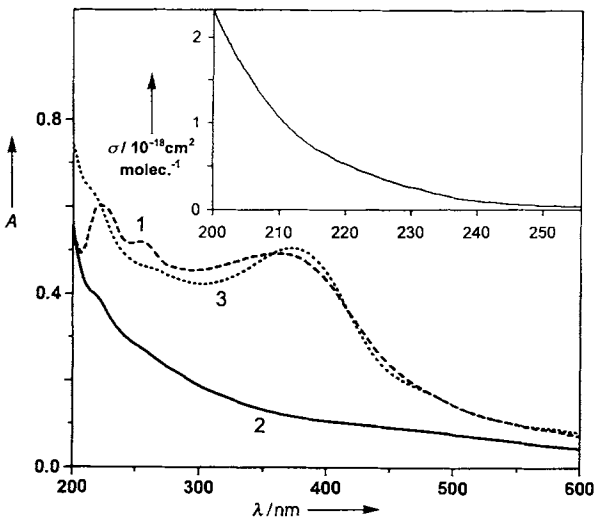

Figure 1. Matrix UV/Vis spectra (A = Absorbance): 1: After 193 nm irraditation of **2**. 2: Compound **2** before irradiation. 3: After irradiation of the carrier of spectrum 1 with $\lambda > 230$ nm. Insert: gas phase spectrum of **2**.

to approximately 250 nm (Figure 1, insert). Irradiation of matrix-isolated **2** with a high-pressure mercury lamp (Heraeus TQ 150, $\lambda > 230$ nm) produced a slow decay of **2** with formation of numerous IR absorption bands, whose number increased with prolongated irradiation. Among the absorptions those typical of **1** at 1672, 1267, and 918 cm^{-1} were discernible, but they only reached low stationary intensity.

Irradiation of matrix-isolated **2** at 10 K with a pulsed ArF laser (Lambda Physik, model COMPex 100; $\lambda = 193$ nm, repetition rate 1 Hz, about 80 mJ per pulse) yielded a photolysis product, which, according to the difference IR spectrum (Figure 2a), revealed absorption bands almost exclusively of the single species ①. These absorptions whose relative intensities did not change grew at the expense of the disappearing **2**. After optimization of the photolysis (5000 pulses) the transformation of **2** into a quasi-stationary equilibrium was completed to more than 90% (Figure 2b).

Altogether six new absorptions were observed, the wavenumbers and relative intensities of which are listed in Table 1,

Table 1. Wavenumbers $\tilde{\nu}$ [cm^{-1}] of the infrared spectra of $F_2C{=}C$: and F_2CS.

		1 Theory		1 Experiment		SCF_2

column 4. The assignment of five of these bands to the fundamentals $\nu_1-\nu_4$ and ν_6 of planar difluorovinylidene **1** with C_{2v} symmetry follows unambiguously from a comparison with ab initio predictions of vibrational frequencies and intensities (Table 1, column 2). The excellent agreement of observed and predicted vibrational spectra and the trapping reactions described below ascertain that difluorovinylidene **1** is the exclusive product of the 193 nm photolysis of **2**.

The IR absorption at 1245 cm^{-1}, which is the second most intense, is assigned to the combination $\nu_2+\nu_5$ belonging to the same species b_1 as ν_4 at $\tilde{\nu}_{eff}=1267\ cm^{-1}$, with which it interacts by anharmonic ("Fermi") resonance. Exactly the same situation is met in the closely related SCF_2 molecule (Table 1, column 5).[21] Here a pair of absorptions assigned to $\nu_4/\nu_2+\nu_5$ at 1190 and 1219 cm^{-1} (gas phase)[21] is observed; the intensity ratio is about 3:2 and compared to the spectrum of **1** the relative position of ν_4 and $\nu_2+\nu_5$ is inverted.

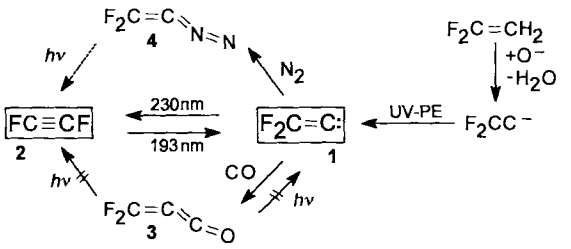
Assuming that the transition moment of ν_4 is very large relative to that of $\nu_2+\nu_5$ (cf. Table 1, footnote [f]), the anharmonic resonance of ν_4 with $\nu_2+\nu_5$ can be deperturbed by means of the observed relative intensities (100:46). The coupling term W_{245} is determined to be 10.25 cm^{-1} (analogous value of 13 cm^{-1} for SCF_2), which is in excellent agreement with the ab initio prediction (10.81 cm^{-1} from the corresponding cubic force constant, MP2/TZ2Pf). The deperturbed vibrational frequencies $\tilde{\nu}^*$ are $\tilde{\nu}_4{}^*=1260$ and $(\tilde{\nu}_2+\tilde{\nu}_5)^*=1252\ cm^{-1}$ (ab initio: 1284 and 1249 cm^{-1}). The vibrational fundamental, which could not be observed for experimental reasons, is calculated from $\tilde{\nu}_2=918\ cm^{-1}$ and an estimated anharmonicity constant χ_{25} of 0 (ab initio: $-0.34\ cm^{-1}$) to be $\tilde{\nu}_5=(1252-918)\ cm^{-1}=334\ cm^{-1}$.

The photochemical transformation **2** → **1** may also be monitored by the UV/Vis spectrum (Figure 1). Upon irradiation of **2** with an ArF laser (193 nm) in an Ar matrix whose concentration was higher than that employed for the IR experiment, the UV absorption of **2** changed, and new maxima at $\lambda=228$ and 254 nm emerged, which were assigned to **1** (Figure 1 (1)). Under the given experimental conditions additional products absorbing at $\lambda=380$ nm were formed, which were retained when **1** was converted back into **2** by irradiation with $\lambda>230$ nm (Figure 1 (3)). Quantitative reconversion was achieved by irradiation with a high-pressure mercury lamp (Osram HBO, 500 W, $\lambda>230$ nm) for merely 15 minutes. This behavior explains why irradiation of **2** with $\lambda>230$ nm produces **1** in a photostationary equilibrium only in very low concentration.

The previous experiments of Brahms and Dailey[11] suggest that **1** would react in a matrix with CO to yield **3** and with N_2 to form **4**. To prove this we have photochemically generated **1** from **2** in an Ar matrix doped with 1% CO or 1% N_2 at 10 K. Under these conditions **1** is sufficiently separated from CO or N_2 that they coexist in the matrix. On annealing the matrix at 35–42 K a synchronous depletion of the IR absorptions of **1**, and growth of those of **3** and **4** is observed.[22]

While **3**, as reported,[11] is "pseudo" inert towards irradiation with $\lambda=254$ nm, **4** decomposes to **2** and N_2 under these conditions. The transformation of **2** isolated in a matrix in contact with N_2 into **1** by irradiation at $\lambda=193$ nm could not be repeated, because N_2 and **1** rapidly react to form **4**, which then immediately decomposes to N_2 and **2** (Scheme 1).

As the essential result of the present investigation we stress that matrix-isolated difluorovinylidene **1** can be made by 193 nm excimer laser photolysis of difluoroethyne **2**. It is protected against isomerization to **2**, which is more stable by about 30 kcal mol^{-1}, by a substantial barrier (calculated to be ca. 35 kcal mol^{-1}). Nevertheless **1** is so reactive that addition of CO



Scheme 1.

and N_2 occurs at temperatures as low as 10 K. Previous attempts to generate **1** by photofragmentation of other precursors failed, because **1** reacted immediately, even in a matrix, with other concomitantly formed photofragments or precursors. All vibrational fundamentals of **1** have been determined experimentally, ν_5 by an indirect method. Their frequencies are in excellent agreement with those from high-level ab initio calculations.

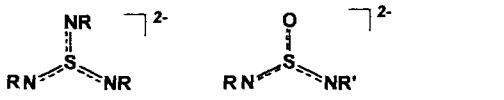
Self-Assembly of Thirty-Six Atom Clusters ($Li_{12}S_6O_6N_{12}$) Containing Diazasulfite Anions**

Justin K. Brask, Tristram Chivers,* Masood Parvez, and Gabriele Schatte

Recently there has been considerable interest in alkali metal derivatives of polyimido anions of p-block elements, for example $[Sb(NR)_3^{3-}]$ ($R = PhCH_2CH_2$),[1a] $[Sb_2(NCy)_4^{2-}]$,[1b] and $[E(NR)_3^{2-}]$ (**1**, R = *t*Bu; E = S,[2] Se,[3] Te[4]). In addition to the novelty of their cluster structures, the anions themselves are potentially important reagents for the incorporation of main group elements into chalcogen–nitrogen rings [4b] and the development of the coordination chemistry of anionic polyimido ligands.[5] The dimeric dilithium derivatives of the dianions $[E(NtBu)_3^{2-}]$ (E = S, Se, Te) all adopt distorted hexagonal prismatic structures.[2–4] The replacement of one (or more) of the bulky NR groups in the anions of these clusters by the isoelectronic oxo ligand may have significant structural consequences, but the diazasulfite anions $[OS(NR)(NR')]^{2-}$ (**2**) are unknown. We describe here the syntheses of dilithium derivatives of the bis(*tert*-butylimido)sulfite dianion, $[OS(NtBu)_2]^{2-}$ (**2a**), and the (*tert*-butylimido)(trimethylsilylimido)sulfite dianion, $[OS(NtBu)(NSiMe_3)]^{2-}$ (**2b**), which adopt unique cluster structures derived from the aggregation of hexagonal prisms and eighteen atom cages, respectively.



The reactions of the chalcogen diimides, *t*BuN=E=N*t*Bu, with two equivalents of LiNH*t*Bu produce the dianions $[E(NtBu)_3]^{2-}$ (E = S, Se, Te) in excellent yields.[2–4] By analogy, the treatment of *tert*-butylsulfinylimine, *t*BuNSO, or trimethylsilylsulfinylimine, Me_3SiNSO, with two equivalents of lithium *tert*-butylamide leads to hexameric dilithium bis(*tert*-butylimido)sulfite **3** and hexameric dilithium (*tert*-butylimido)-(trimethylsilylimido)sulfite **4**, respectively [Eq. (a), cf. reac-

$$6\,RNSO + 12\,LiNHtBu \xrightarrow{C_7H_8} [\{Li_2[OS(NtBu)(NR)]\}_6] + 6\,H_2NtBu \quad (a)$$

3, R = *t*Bu

4, R = $SiMe_3$

tions of RNSO with other bases, e.g. $Li[N(SiMe_3)R']$, which lead to mixed sulfurdiimides, RNSNR'].[6]

A crystal structure determination of **3** revealed a remarkable arrangement of thirty-six atoms of main group elements in a $Li_{12}N_{12}O_6S_6$ cluster with a central Li_6O_6 core, which comprises two parallel, six-membered Li_3O_3 rings in their chair conformations (Figure 1).[7, 8] The cage structure consists of six pyramidal $[OS(NtBu)_2]^{2-}$ ions (mean bond angles: NSN 104.2(5)°, OSN 101.6(4)°); the oxygen atom of each of these ions participates in the formation of the central Li_6O_6 core with Li–O distances in the range 1.86(2)–2.20(2) Å. In addition, one nitrogen atom of each $[OS(NtBu)_2]^{2-}$ ion is attached to one Li atom of the Li_6O_6 core with Li–N distances in the range 1.91(2)–2.15(2) Å. The mean S–O and S–N distances of 1.587(7) and 1.625(9) Å imply bond orders of 1.44 and 1.46,[9] respectively, in reasonable agreement with the values of 1.33 expected for these bonds in the resonance hybrid **2**. The six sulfur atoms are all three-coordinate, as expected for the pyramidal $[OS(NtBu)_2]^{2-}$ ion, and all oxygen atoms are four-coordinate. However, this novel structural arrangement results in different coordination environments for the N*t*Bu ligands as well as the Li atoms. All the N atoms are four-coordinate with the exception of N6 and N11, which are three-coordinate. The atoms Li3, Li4, Li5, and Li7 of the Li_6O_6 core are four-coordinate, whereas the remaining Li atoms of the Li_6O_6 core and the other six Li atoms are three-coordinate.

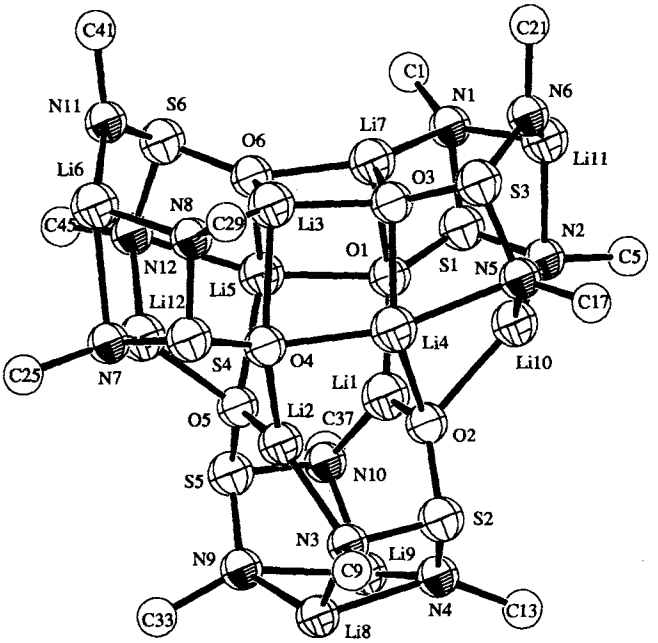


Figure 1. Crystal structure of $[\{Li_2[OS(NtBu)_2]\}_6]$ (**3**) with the atomic numbering scheme. For clarity only the α-carbon atoms of the *t*Bu groups are shown. The range and mean values of selected bond lengths and bond angles are given in the text.

Hexagonal prismatic arrangements based on A_6X_6 clusters are well known,[10–16] and the dimers $[\{Li_2[E(NtBu)_3]\}_2]$ are examples of such structures involving $A_4B_2X_6$ cores.[2–4] The thirty-six atom cluster **3** can be visualized to result from the trimerization of three $Li_4S_2N_4O_2$ ($A_4B_2X_4Y_2$) hexagonal prisms through their Li_2O_2 faces (Figure 2). To our knowledge **3** is the first cluster derived from the aggregation of hexagonal prisms. The $[\{Li_2[OS(NtBu)_2]\}_6]$ cluster **3** has C_2 symmetry; the C_2 axis passes through the center of the [Li3-O3-Li7-O6] square. As a result, there are six inequivalent environments for both the Li atoms and the *tert*-butyl groups. Therefore, six resonances of equal intensity are expected in both the ^1H and the ^7Li NMR spectra. However, very complex sets of both ^1H and ^7Li resonances are observed in C_7D_8 solution throughout the temperature range 183–298 K (see Experimental Section for details) suggesting a dissociative equilibrium, for example according to Equation (b) (cf. $[\{Li_2Sb_2(NCy)_4\}_2]$).[17]

$$[\{Li_2[OS(NtBu)_2]\}_6] \rightleftharpoons [\{Li_2[OS(NtBu)_2]\}_4] + [\{Li_2[OS(NtBu)_2]\}_2] \quad (b)$$

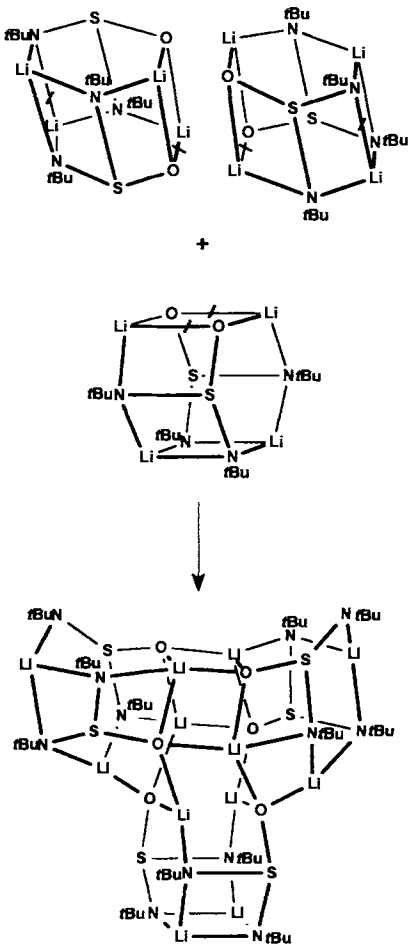

Figure 2. Schematic representation of the formation of the hexameric cluster **3** by the trimerization of $Li_4S_2N_4O_2$ hexagonal prisms (only the α-carbon atoms of the *t*Bu groups are shown for clarity). The designation + indicates the bonds broken in this process.

A comparison of the ^1H and ^7Li NMR data for **3** in C_7D_8 solution with the corresponding data for **4** suggest a different structure for **4**. Indeed, a crystal structure determination of **4** revealed a second unique arrangement for the thirty-six atom cluster in which two $Li_6N_6O_3S_3$ cages are joined by their Li_3O_3 faces (Figure 3).[8, 18] The dimerization of two $Li_6N_6O_3S_3$ cages is depicted schematically in Figure 4. Structurally similar eighteen-atom (A_9X_9) cages are known for the nonamers $[(t\text{Bu-MO})_9]$ (M = Al, Ga)[15, 19] and $[Na(OtBu)_9]$.[20] In **4** each $Li_6N_6O_3S_3$ cage contains three pyramidal $[OS(NtBu)(NSiMe_3)]^{2-}$ ions arranged to form two six-membered rings (Li_3N_3 and Li_3O_3) linked by three SN(R) units. A channel resulting from the parallel arrangement of these six-membered rings passes through the center of the molecule (viewed down the S_6 axis). The lithium atoms in the Li_3N_3 ring are three-coordinate, whereas those in the Li_3O_3 ring are four-coordinate. The crystal structure exhibited disorder in which the N-bonded silicon and carbon atoms were scrambled over all positions, and no distinctions could therefore be made about their positions (see ref. [18]). The solvent toluene molecules were also highly disordered, and the structure analysis thus had high *R* values. The mean values and ranges for important bond lengths and bond angles for **4** are summarized in the caption to Figure 3.

Although it is not possible to define the positions of the silicon and α-carbon atoms from the structure determination due to the disorder, they can be assigned by using the ^1H and ^7Li NMR data for **4**. The ^7Li NMR spectrum of **4** in C_7D_8 at 23 °C shows four well-resolved resonances of approximately equal intensity, and the ^1H NMR spectrum shows two equally intense resonances for the *t*Bu as well as for the $SiMe_3$ groups. In view of the S_6 symmetry of the $Li_{12}S_6N_{12}O_6$ cluster in **4** the ^1H NMR spectrum should exhibit two resonances, one singlet for the *t*Bu groups and one singlet for the $SiMe_3$ groups. The analysis of the NMR results is consistent with the presence of the two clusters **4a** and **4b** in which the nitrogen atoms of the Li_3N_3 rings are attached to either $SiMe_3$ or *t*Bu groups (Figure 4). Apparently **4a** and **4b** are present in equal amounts in solution. Each of these two molecules should exhibit two ^7Li NMR resonances of equal intensity consistent with the finding of four resonances of approximately equal intensity in the ^7Li NMR spectrum of **4**.

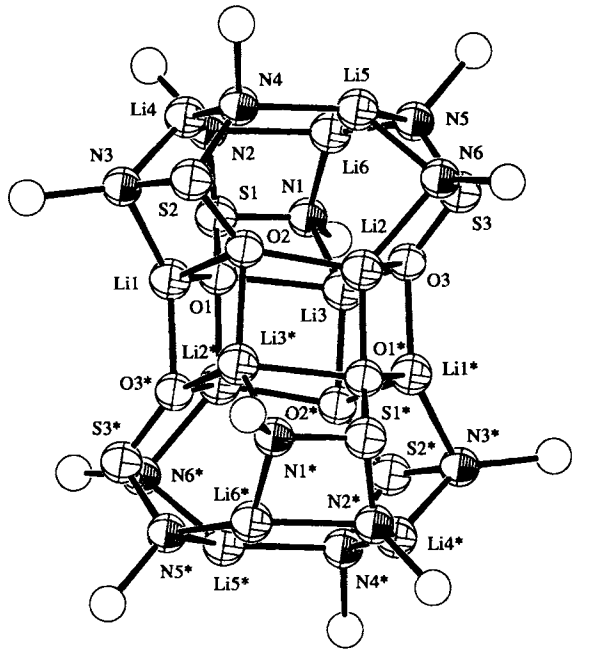

Figure 3. Crystal structure of $[\{Li_2[OS(NtBu)(NSiMe_3)]\}_6]$ (**4**). For clarity only the α-carbon atoms of the *t*Bu groups and the Si atoms of the $SiMe_3$ groups are shown. Mean bond lengths [Å] and bond angles [°]: S–O 1.546(13), S–N 1.62(2); N-S-N 102.4(9), O-S-N 101.1(1). The Li–O and Li–N bond lengths are in the ranges 1.87(4)–2.17(4) Å and 1.89(4)–2.14(4) Å, respectively.

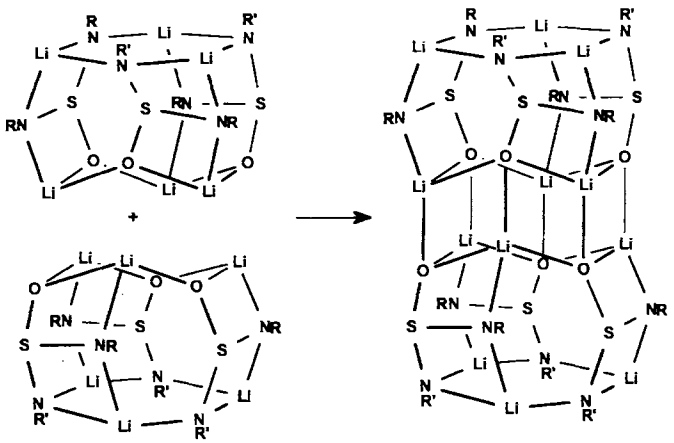

4a, R = $C(CH_3)_3$, R' = $Si(CH_3)_3$
4b, R = $Si(CH_3)_3$, R' = $C(CH_3)_3$

Figure 4. Schematic representation of the formation of the hexameric cluster **4** by the dimerization of $Li_6S_3N_6O_3$ cages.

In summary, we have prepared two examples of the novel diazasulfite ion $[OS(NtBu)(NR)]^{2-}$. Their dilithium derivatives are hexameric and represent the first examples of main group element clusters formed by the aggregation of either hexagonal prisms or eighteen atom cages. The self-assembly of these thirty-six atom clusters is envisaged to occur by oligomerization of smaller clusters through their Li_xO_x faces ($x = 2$ or 3). Consequently, the replacement of two NR groups in $[S(NR)_3]^{2-}$ by two oxygen atoms is likely to produce more highly associated clusters. This possibility and the effects of subtle changes to the size of the R/R′ groups on the aggregation of $\{Li_2[OS(NR)(NR')]\}$ units are under investigation.

Experimental Section

3: A slurry of LiHN*t*Bu (7.21 g, 91.2 mmol) in toluene (15 mL) was added dropwise to a stirred, yellow solution of *t*BuNSO [21] (5.43 g, 45.6 mmol) in toluene (75 mL) at −78 °C. The reaction mixture turned orange. After 1 h at −78 °C, it was allowed to warm slowly to 23 °C to give a transparent, pale yellow solution. All volatiles were removed under dynamic vacuum, and the off-white precipitate was washed with *n*-hexane (10 mL). The yield of **3** was 7.93 g (6.47 mmol, 85%); m.p. 210 °C (decomp.). IR (KBr, Nujol): $\nu\sim$ [cm^{-1}]: above 1000 (N*t*Bu groups), 960–977 (S–N stretching vibrations), 814–837 (S–O stretching vibrations) [22]; ^{1}H NMR (400 MHz, C_7D_8/C_7H_8, TMS in $CDCl_3$): δ(25 °C) = 1.37–1.11 (12 signals), δ(−90 °C) = 1.59 (very broad); ^{7}Li NMR (400 MHz, C_7D_8/C_7H_8; standard: 4 M LiCl in D_2O)]: δ(25 °C) = 0.68– −2.03 (7 signals), δ(−90 °C) = 0.14– −2.86 (6 signals). Satisfactory C,H, N analysis.

4: A yellow solution of Me_3SiNSO [23] (0.536 g, 3.96 mmol) in toluene (10 mL) was added dropwise to a stirred slurry of LiHN*t*Bu (0.626 g, 7.92 mmol) in toluene (20 mL) at 0 °C. After 0.5 h at 0 °C, the mixture was allowed to warm to 23 °C to give a transparent, bright yellow solution, which was stirred for a further 3.5 h. All volatiles were removed under dynamic vacuum, and the oily yellow residue was washed with *n*-pentane (10 mL) to give a white solid. The yield of $[Li_2S(O)(NtBu)(NSiMe_3)]_4$ was 0.707 g (3.21 mmol, 81%); m.p. 207 °C (decomp.). IR (KBr, Nujol): $\nu\sim$ [cm^{-1}]: above 1000 (Me_3Si and N*t*Bu groups), 951–894 (S–N stretching vibrations), 856–831 (S–O stretching vibrations); ^{1}H NMR (200 MHz, 23 °C, C_7D_8, TMS in $CDCl_3$): δ = 1.41 (18 H, s, *t*Bu), 1.32 (18 H, s, *t*Bu), 0.37 (18 H, s, Me_3Si), 0.28 (18 H, s, Me_3Si); ^{7}Li NMR (200 MHz, 23 °C, C_7D_8; standard: 4 M LiCl in D_2O): δ = 2.79, 2.15, 1.64, 1.39. Satisfactory C,H, N analysis.

[7] Colorless, square-pyramidal crystals of **3** were obtained by recrystallization from toluene at −8 °C (6 weeks). Crystal data for **3**: $(C_8H_{18}N_2OSLi_2)_6 \cdot 2.5\ C_7H_8$, M_r = 1455.44, monoclinic, space group $P\ 2_1/n$ (No. 14), a = 14.416(8), b = 24.718(9), c = 24.676(11) Å, b = 95.15(5)°, V = 8757(7) Å^3, Z = 4, ρ_{calcd} = 1.104 g cm^{-3}, $\mu(Mo_{K\alpha})$ = 0.205 mm^{-1}, $\lambda(Mo_{K\alpha})$ = 0.71069 Å, T = −123(1) °C, $F(000)$ = 3140. Data were collected on a Rigaku AFC6S diffractometer on a colorless prism (0.7 × 0.5 × 0.5 mm^3) mounted directly from the solution (toluene solvation was maintained) into a glass capillary tube (i.d. 1.0 mm) by the $\omega - 2\theta$/scan method ($2° < \theta < 25°$). Of a total of 15896 collected reflections, 15465 were independent (R_{int} = 0.057), 3553 were observed [$I > 2\sigma(I)$], and 15384 reflections were used to refine 897 parameters. Maximum and minimum of the final difference Fourier synthesis: 0.325 and −0.401 e Å^{-3}. The structure was solved by direct methods (SAPI91, Fan Hai-Fu, Rigaku Corp., Tokyo, **1991**). The data were corrected for absorption, Lorentz, and polarization effects. The non-hydrogen atoms were allowed anisotropic temperature factors. The H-atoms were included at geometrically idealized positions with CH distances of 0.95 Å. For each asymmetric unit, which contains 12 Li atoms and six $(NtBu)_2SO$ groups, there are 2.5 molecules of toluene; one of the toluene molecules lies on a special position and is disordered. The C atoms of the toluene were constrained to be regular hexagons and the hydrogen atoms of the disordered solvate ignored. Refinement by full-matrix, least-squares calculations on F^2 converged at R = 0.079 (for the observed reflections) and R_w = 0.217 (all data) with $R = \sum||F_o| - |F_c||/\sum|F_o|$ and $R_w = [\sum w(|F_o|^2 - |F_c|^2)/\sum w(F_o^2)]^{\frac{1}{2}}$, $w = [\sigma^2(F_o^2) + (0.131P)^2 + 16.3897P]^{-1}$ and $P = (F_o^2 + 2F_c^2)/3$ (SHELXL-92) [24].

[8] Crystallographic data (excluding structure factors) for the structures **3** and **4** reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-406170 (**3**) and CCDC-100287 (**4**). [18] Crystals of $\mathbf{4} \cdot 2C_6H_5CH_3$ were obtained by recrystallization from toluene at −17 °C (3 weeks). Crystal data for **4**: $(C_7H_{18}N_2OSSiLi_2)_6 \cdot 2C_7H_8$, M_r = 1505.84, monoclinic, space group $P\ 2_1/n$ (No. 14), a = 15.560(4), b = 19.728(6), c = 15.629(8) Å, β = 104.24(3)°, V = 4650(3) Å^3, Z = 2, ρ_{calcd} = 1.075 g cm^{-3}, $\mu(Mo_{K\alpha})$ = 0.268 mm^{-1}, $\lambda(Mo_{K\alpha})$ = 0.71069 Å, T = −103(1) °C, $F(000)$ = 1616. Data were collected on a Rigaku AFC6S diffractometer on a colorless prism (0.50 × 0.40 × 0.15 mm^3) mounted directly from the solution on a glass fiber coated with epoxy resin. Of a total of 8822 reflections, 8494 were unique (R_{int} = 0.085), 2188 were observed [$I > 3.00\sigma(I)$] and used to refine 283 parameters. The structure was solved by direct methods and expanded using Fourier techniques [25]. The S, O, N, and Si/C positions were refined anisotropically, while the remaining carbon and hydrogen atoms were refined isotropically. The silicon atoms of the Me_3Si groups and the carbon atoms of the *t*Bu groups were scrambled over all positions. Therefore, these positions were refined as Si with partial occupancy factors leading to electron populations corresponding to three Si and three C atoms over six sites. No distinctions could be made about the positions of C and Si atoms, and hence C–C and Si–C distances are not typical. The solvent molecules were highly disordered; therefore the C atoms with partial occupancy factors were included at fixed positions. Hydrogen atoms were included but not refined. Refinement converged at R = 0.125 and R_w = 0.084.

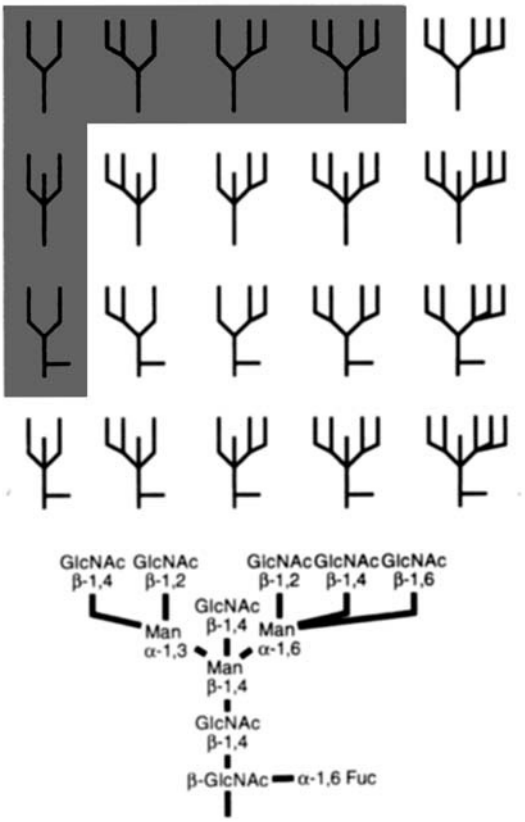
A Modular System for the Synthesis of Complex *N*-Glycans**

Carlo Unverzagt*

The aparagine-bound oligosaccharides found in glycoproteins (*N*-glycans) vary in their degree of branching, the terminal sugars, and the substitution of the core pentasaccharide.[1] A divergent combination of the possible linkages leads to thousands of related oligosaccharide structures. This phenomenon is also known as microheterogeneity.[2] Therefore, glycoproteins can be viewed as natural libraries, whose elements are very similar but show a high degree of diversity in the detailed structures. Complex *N*-glycans are classified by the number of branches, ranging from two to five, and by characteristic substitutions of the core pentasaccharide (Scheme 1). In the case of the pharmaceutically important glycoprotein hormone erythropoietin (EPO), the in vivo biological activity[3] of the glycoform with tetraantennary *N*-glycans was significanty greater that that of biantennary structures.



Scheme 1. Twenty individual basic structues can be distinguished for complex *N*-glycans. They result from a combination of five different degrees of branching (first row) with core substitutions by "bisecting" GlcNAc residues (second row) or core fucosylation (third row), or both modifications (fourth row). Seven examples of this class of compounds (in the grey box) were synthesized by a flexible system of oligosaccharide building blocks.

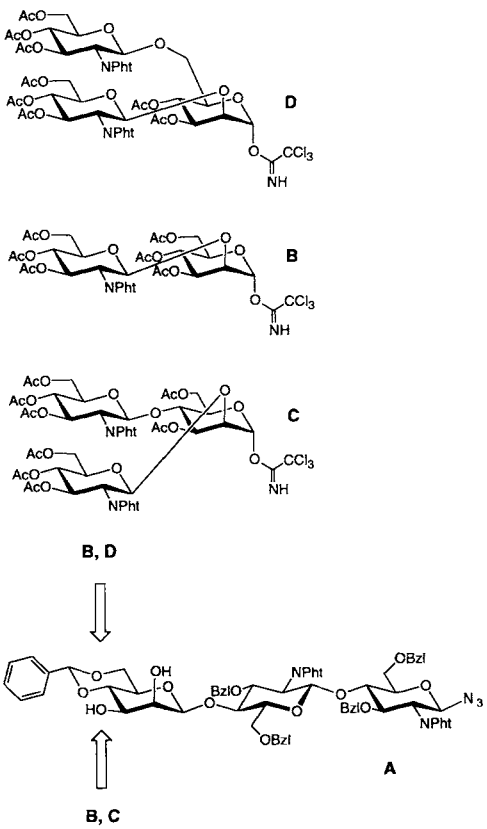
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Leonhard-Lorenz-Stiftung. I would like to thank the Hoechst AG and Boehringer Mannheim for funding, and Prof. Dr. H. Kessler for his generous support.

Up to now the synthesis[4] of biantennary sialylated *N*-glycans[5] was only demonstrated in a few examples. Partial structures of complex tri- and tetraantennary *N*-glyans were chemically synthesized.[6] Entire multiantennary *N*-glycans are only accessible in small amounts by tedious isolation procedures[7] from natural sources or by semisynthesis.[8] The biosynthesis of *N*-glycans is carried out stepwise by a number of glycosyltransferases, however, only a few of the *N*-acetylglucosaminyltransferases[2c] responsible for branching have been cloned and overexpressed. In the course of this work a series of modular building blocks which provide access to synthetic tri- and tetraantennary *N*-glycans was devised (Scheme 2).



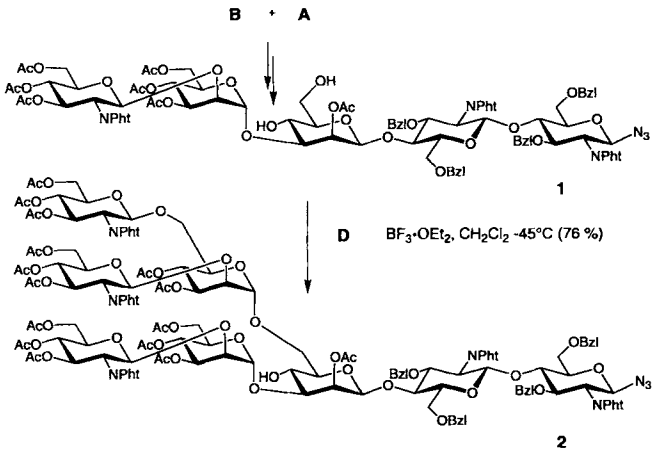
Scheme 2. The building blocks **A**–**D**; Pht = phthaloyl.

A new strategy was developed recently to obtain biantennary *N*-glycans by chemical synthesis.[9] Starting from core trisaccharide **A** (Scheme 2), positions 3 and 6 of the central β-mannosyl residue were glycosylated regio- and stereoselectively[5c] using donor **B**. Subsequent elongation of the carbohydrate chains by enzymatic synthesis gave sialylated biantennary *N*-glycans.[5c] The concept of double regioselective glycosylation of **A** could be extended and applied to the synthesis of the tri- and tetraantennary *N*-glycans **2**, **5**, and **6**. The products shown in Schemes 3 and 4 represent the most frequently found branching patterns for *N*-glycans. Together with **A** and **B** the newly synthesized trisaccharide building blocks **C** and **D** form a modular system. This allowed the multiple use of valuable intermediates to obtain various basic structures of *N*-glycans. A crucial requisite for the success of this concept was the optimized protecting-group pattern of the building blocks, and the high reactivity at the connection points provided by the vicinal diol structure of the acceptors.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3618-1989 $ 17.50+.50/0

The temporary allyl and benzyl groups required for the synthesis of **C**[10] und **D**[13] were replaced by acetate groups. Benzyl functionalitites in the mannosyl part of the donors may lead to β-configured side products during glycosylation.[6c] The three α-configured imidates **B**–**D** follow the same protecting-group pattern which was expected to facilitate deprotection of these parts of the molecule.

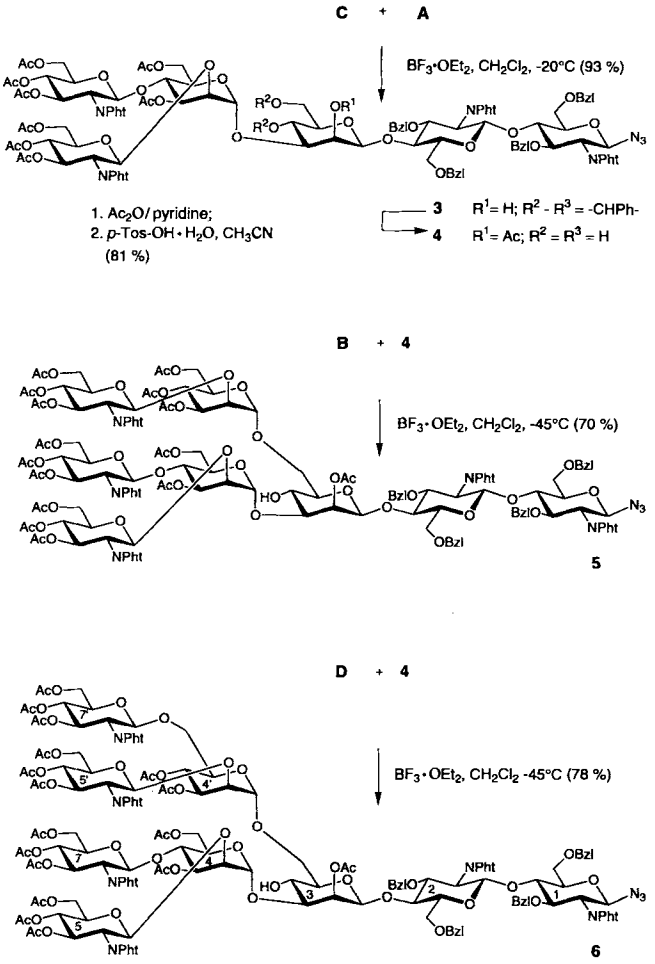
Pentasaccharide **1** was obtained as an intermediate[5c] during the synthesis of biantennary *N*-glycans starting from core trisaccharide **A** and donor **B** (Scheme 3). Elongation of pentasaccharide **1** with the imidate **B** gave the heptasaccharide in 73% yield. To achieve selective reaction at the primary hydroxyl group, the glycosylation was performed under dilute conditions. Otherwise overreaction at the second OH functionality occurred. As an initial test of the glycosylating properties of the branched and thus sterically more demanding trisaccharide imidate **D**, the coupling with pentasaccharide **1** was examined. Activation of the imidate **D** under dilute conditions with $BF_3 \cdot OEt_2$ gave the triantennary octasaccharide **2**[16] in 76% yield (Table 1). The α-1,6-linked product was formed selectively. This was confirmed by the characteristic downfield shift of the ^{13}C NMR signal for C-6^3 (60.4 → 66.3) and a C-1,H-1 coupling constant[17] of 176.2 Hz for C-$1^{4'}$, which is typical for α-mannosides.



Scheme 3. Synthesis of **1** and **2**.

A steric hindrance during the regioselective glycosylation at OH-3^3 of the core trisaccharide **A** with the branched donor **C** was not observed. The coupling to hexasaccharide **3** proceeded with an unexpectedly high yield of 93%(Scheme 4). The newly formed α-1,3-linkage was verified by NMR spectroscopy: the signal for C-3^3 of **3** is shifted from $\delta = 69.9$ to 78.0, and J(C-1,H-1) is 172.7 Hz for C-1^4. Acetylation of the free hydroxyl group in **3** followed by debenzylidenation with *p*-toluenesulfonic acid gave the hexasaccharide diol **4**. These conditions permitted acidic acetal cleavage without affecting the numerous acetyl groups. Subsequently, the linear donor **B** was coupled with the acceptor **4** to the triantennary octasaccharide **5**[16] in 70% yield (Table 1). The presence of the branched mannoside in the 1,3-arm of **4** did not affect the reaction at the primary OH group.

The sterically most demanding glycosylation of the hexasaccharide acceptor **4** also proceeded regio- and stereoselectively with the trisaccharide building block **D** (Scheme 4). Nonasaccharide **6**,[16] a partial structure of tetraantennary *N*-glycans, was obtained in 78% yield (Table 1). Others have reported difficulties in the formation of glycosidic linkages using branched donors.[18]



Scheme 4. Synthesis of **3**–**6**.

Surprisingly, a comparison of the glycosylation yields showed that under identical conditions the branched trisaccharide imidates **C** and **D** gave even higher yields than the linear disaccharide **B**. It may be assumed that the reactivity of the trisaccharides **C** and **D** is lower than that of **B**, and, because of the slower rearrangement to the unreactive trichloroacetamides,[19] higher yields are obtained. However, higher yields should only be observed when steric hindrance is not increased. Therefore, combining donors **C** and **D** with the complex acceptors carrying two adjacent OH groups is favored from a steric point of view. The protected compounds **1**–**6** were purified by flash chromatography and characterized by NMR spectroscopy with HMQC, HMQC-COSY, HMQC-DEPT, HMQC-TOCSY, TOCSY, and NOESY experiments.[20]

The often problematic removal of phthalimido groups was examined for compound **6**, which was converted into the water-soluble nonasaccharide **7** in three steps (Scheme 5). A one-pot reaction with ethylenediamine in *n*-butyl alcohol[21] followed by an acetylation–deacetylation sequence proceeded smoothly, as seen previously for the deprotection of the biantennary parent compound.[5c] Solid-phase extraction furnished the deprotected nonasaccharide **7**[16] in high yield. The remaining protecting groups in the chitobiosyl part are strategically valuable. They allow the construction of glycoconjugates through an *N*-glycosidic bond at the anomeric center, and facilitate purification by reversed-phase HPLC.[5c]

An additional extension of this flexible synthesis concept was demonstrated recently by incorporation of a modified building block **A**, which led to core-fucosylated *N*-glycans.[22] Further-

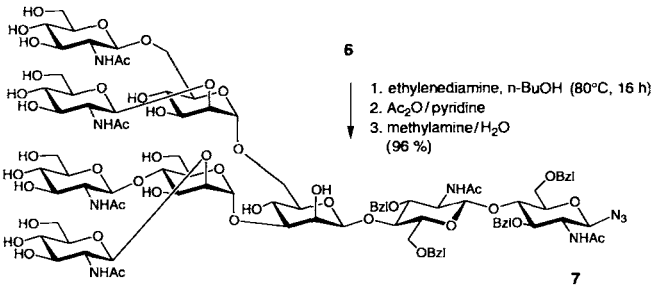
[a] NBA = *m*-Nitrobenzyl alcohol, Pht = phthaloyl.

more, the glycosylation of the free OH-4^3 functionality of the heptasaccharide[5c] obtained from compounds **A** and **B** gave access to the class of "bisecting" *N*-glycans.[23]

For the first time the most frequently found basic structures of *N*-glycans could be assembled by a single synthetic scheme. The versatile building blocks **A**–**D** provide an efficient chemical equivalent for the modular structure of these natural oligosaccharides. In the future this will facilitate the synthesis of those *N*-glycans that display biological functions and are difficult to isolate. The final compounds were obtained in high yields throughout. After removal of the majority of the protecting groups, the synthetic *N*-glycans are accessible for functionalization at the anomeric center and enzymatic elongation of the oligosaccharide portion.



Scheme 5. Selective cleavage of the protecting groups: synthesis of **7**.

Phosphorus(v) Nitride Imide HP_4N_7: Synthesis from a Molecular Precursor and Structure Determination with Synchrotron Powder Diffraction**

Stefan Horstmann, Elisabeth Irran, and Wolfgang Schnick*

The ammonolysis of phosphorus(v) chloride (PCl_5) leads to chlorine-rich compounds such as $[NPClNH_2]_x$ or to totally substituted compounds such as $[NP(NH_2)_2]_x$, depending on the reaction temperature and the distribution ratio NH_3:PCl_5.[1] Already in the last century a polymeric compound HPN_2 was postulated to be the final product of substitution and condensation.[2–4] However, the ammonolysis of PCl_5 leads to countless oligomeric and polymeric phosphazenes; no single-phase and well-defined product HPN_2 was obtained. Pure and crystalline HPN_2 was synthesized recently by heterogeneous pressure ammonolysis of phosphorus(v) nitride [Eq. (a)].[5] Phosphorus(v)

$$P_3N_5 + NH_3 \xrightarrow{580\,^\circ C} 3\,HPN_2 \qquad (a)$$

nitride imide (HPN_2) has the framework structure $^3_\infty[(PN_{4/2})^-]$ built up of PN_4 tetrahedra linked by corner-sharing through all four vertices. This structure, which is also found in $LiPN_2$,[6] is derived from the isosteric β-cristobalite type.[5] The hydrogen atoms are bound in an ordered manner to half of the nitrogen atoms.[7]

We recently obtained the novel phosphorus(v) nitride imide HP_4N_7[8] by the reaction of P_3N_5 with ammonium chloride in closed, thick-walled quartz ampoules [Eq. (b)]. However, X-ray

$$4\,P_3N_5 + NH_4Cl \xrightarrow{820\,^\circ C} 3\,HP_4N_7 + HCl \qquad (b)$$

powder diffraction measurements indicate that HP_4N_7 is not formed as a single-phase product by this reaction. Furthermore, since it was not possible to obtain single crystals of HP_4N_7, the crystal structure could not yet be elucidated. This structure is nevertheless of particular interest, because HP_4N_7, in addition to P_3N_5, is one of a few highly condensed phosphorus(v) nitrides (molar ratio P:N > 1:2). Therefore, the structure of HP_4N_7 should not be analogous to that of silicates.

We thank Dr. D. E. Cox and Dr. Q. Zhu (NSLS, Brookhaven) for their help during the synchrotron experiment, and Dr. R. Dinnebier (Lehrstuhl Kristallographie, Universität Bayreuth) for discussions during the structure refinement.

While systematically investigating the development of molecular precursors for the synthesis of well-defined, crystalline nonmetal nitrides (molecular preorganization[9, 10]), we obtained $(NH_2)_2P(S)NP(NH_2)_3$ (**1**).[11] According to thermoanalytical investigations diphosphazene **1** loses H_2S already at 145 °C with formation of amorphous poly(aminoiminophosphazene)s. In contrast, the pyrolysis of **1** in closed pressure ampoules at 750 °C (see Experimental Section) leads to pure and crystalline HP_4N_7 [**2**; Eq. (c)]. During this procedure phosphorus(v) nitride imide

$$\underset{\mathbf{1}}{2\,(NH_2)_2P(S)NP(NH_2)_3} \xrightarrow{750\,^\circ C} \underset{\mathbf{2}}{HP_4N_7} + 2\,H_2S + 5\,NH_3 \qquad (c)$$

(**2**) is formed as a microcrystalline, colorless powder. It is stable in a nonoxidizing atmosphere up to 800 °C; further increase of temperature leads to loss of NH_3 and formation of P_3N_5. HP_4N_7 is insoluble in common solvents as well as in hot acids and alkaline solutions.

The determination and refinement of the crystal structure of HP_4N_7 were based on powder X-ray diffraction data. The measurements were made with synchrotron radiation at the National Synchrotron Light Source in Brookhaven, USA (Beamline X7A). The powder pattern obtained (Figure 1) could be indexed unambiguously, and the structure determination by direct methods as well as the subsequent Rietveld refinement were successful (see Experimental Section).

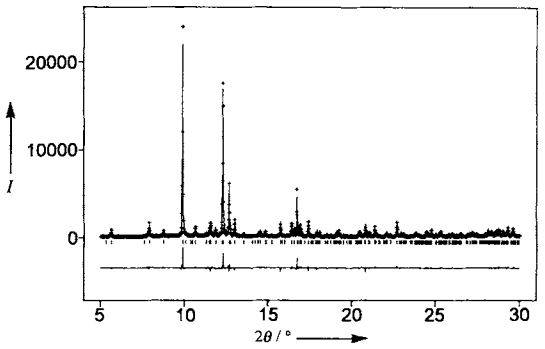

Figure 1. The observed (crosses) and calculated X-ray powder diffraction pattern (line) as well as the difference profile of the Rietveld refinement of HP_4N_7 (only the section until $2\theta = 30°$ is shown). The possible positions of the peaks are marked by vertical lines. The powder pattern was obtained at the National Synchrotron Light Source (NSLS) at Brookhaven, USA, on the Beamline X7A ($\lambda = 69.906$ pm). I = intensity in counts.

Solid HP_4N_7 is made up of a three-dimensional network structure of connected PN_4 tetrahedra, according to $^3_\infty[(P^{[4]}_4N^{[2]}_5N^{[3]}_2)^-]$ (Figure 2). Whereas in β-cristobalite-analogous HPN_2[5] the nitrogen atoms are only bound to two phosphorus atoms ($N^{[2]}$), in HP_4N_7 there are also nitrogen atoms connected to three phosphorus atoms ($N^{[3]}$).[*] The situation resembles that in phosphorus(v) nitride $^3_\infty[(P^{[4]}_3N^{[2]}_3N^{[3]}_2)]$.[12] In HP_4N_7 there exist pairs of edge-sharing PN_4 tetrahedra. This structural motive has so far only been found in P_3N_5[12] and P_4N_6O.[13] In the nitridosilicates $Ba_5Si_2N_6$[14] and $BaSi_7N_{10}$[15] analogous edge-sharing pairs of tetrahedra are found, while in oxosilicates a comparable edge linkage has not yet been confirmed.

The three-dimensional network structure of HP_4N_7 may be separated into two different open-branched zweier single chains (Figure 3). The main cords of both arrangements are built up of corner-sharing PN_4 tetrahedra; in one case the branch results by

[*] The superscripted numbers in square brackets define the coordination number of the element.

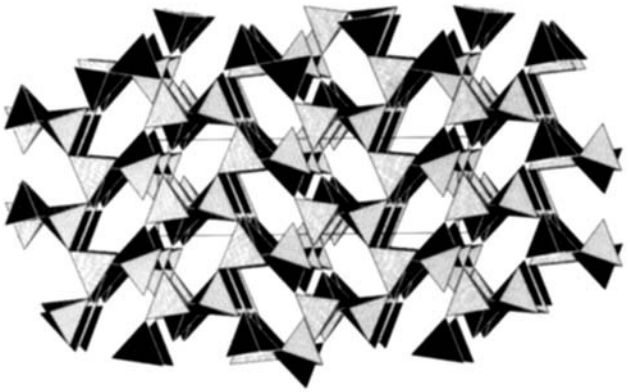

Figure 2. Crystal structure of HP_4N_7 as viewed along [001]. Open-branched zweier single chains, in which the PN_4 tetrahedra are linked alternately through common corners and edges, are connected by further PN_4 tetrahedra. The pairs of tetrahedra resulting from edge-sharing are shown in black.

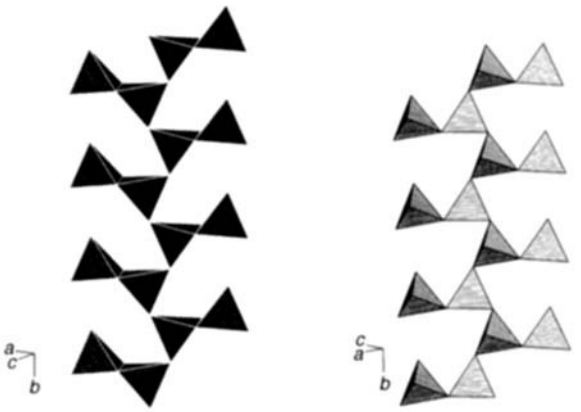

Figure 3. Two different open-branched zweier single chains of PN_4 tetrahedra are found in HP_4N_7. Branching results from edge-sharing (left) and corner-sharing (right).

edge-sharing, and in the other by corner-sharing. The whole network is formed from the alternating arrangement and vertex-sharing of these cords. As in α-P_3N_5[12] all ring sizes P_nN_n with the exception of $n = 3$ are found in the P–N network of HP_4N_7. In contrast, analogously condensed Si_3N_3 rings often occur in highly condensed nitridosilicates (Si:N > 1:2).[16]

Though P_4N_6O and HP_4N_7 are isoelectronic, different three-dimensional network structures exist in the solid-state topologically.[17] However, in the case of silicon, Si_2N_2O[18] and Si_2N_2NH[19] are homeostructural.

Although we used synchrotron radiation for the X-ray structure analysis based on powder data, we could not localize the hydrogen-atom positions. However, based on structure-chemical estimations[20] conclusions of the probable hydrogen-atom positions are possible. On average the bond lengths $P-N^{[2]}$ (152.6(7)–166.9(6) pm) are shorter than the corresponding values for $P-N^{[3]}$ (164.7(8)–172.2(7) pm). This effect occurs similarly in P_3N_5[12] and nitridosilicates.[16] The angular sum of the nitrogen atoms bonded to three phosphorus atoms is nearly 360°; therefore, these $N^{[3]}$ atoms must be considered as sp^2-hybridized. These circumstances as well as the analysis of the valence sums and effective coordination numbers[20] point to no further demand of coordination for the $N^{[3]}$ atoms. Two of the four crystallographically independent $N^{[2]}$ atoms possess largely saturated bond valences; only the remaining nitrogen atoms are suitable for bonding to hydrogen atoms. These nitrogen atoms are similar, and emerge into channels along [001] built up of P_6N_6 rings. It is possible that all hydrogen atoms are bound intrinsically disordered to these nitrogen atoms.

We are currently synthesizing DP_4N_7 to prove the postulated hydrogen-atom positions as well as their order and dynamic behavior by neutron diffraction. In the case of DPN_2, the corresponding order in the hydrogen-atom positions has recently been described.[7] The proposed arrangement of the hydrogen atoms in channels of HP_4N_7 leads to the supposition that phosphorus(v) nitride imide is suitable as a proton conductor. In the case of HPN_2, orientating measurements[21] have already shown remarkable thermal proton conductivity. The advantage of phosphorus(v) nitride imides over traditional proton conductors might be their chemical and thermal stability.

Experimental Section

HP_4N_7: $(NH_2)_2P(S)NP(NH_2)_3$ (100 mg, 53.2 mmol) was transferred under an argon atmosphere to a quartz ampoule ($d = 15$ mm, wall thickness 2 mm). The ampoule was sealed off to a length of 12 cm, and heated for 3 d in an electrical tube furnace at 750 °C. The colorless solid product remained at the bottom of the ampoule (45.7 mg, 20.3 mmol, 76.3%). Elemental analysis by Mikroanalytisches Labor Pascher, Remagen, Germany (calcd): P 55.1% (55.6%), N 40.6% (43.9%). IR (1 mg substance per 500 mg KBr): $\tilde{\nu}$ = 3089 (NH), 1338, 1262, 938 (PN), 778, 691, 651, 549, 473 cm^{-1} (framework).

The diffraction investigations with synchrotron radiation were carried out in Debye–Scherrer geometry. The sample was enclosed in a glass capillary ($d = 1.0$ mm). A wavelength of 69.906 pm was maintained by a Ge(111) double-crystal monochromator, and a Ge(220) crystal used as analyzer. A scintillation counter was used, and the measured diffraction intensities were normalized for storage ring decay by an ionization chamber monitor. The diffraction pattern was indexed unambiguously with the programs ITO [22] and TREOR-90 [23] (de Wolff figure of merit $M_{20} = 45.9$). The space group $P2_1/a$ (no. 14) resulted from the systematic extinctions. With the program EXTRA [24] 1574 integrated intensity data were extracted, and used as input for the program SIRPOW.92 [25] for structure determination by direct methods. As a result, all P and N could be localized immediately. The atomic coordinates were refined with the program system GSAS [26]. HP_4N_7: $P2_1/a$, (no. 14), $a = 1507.95(2)$, $b = 480.304(6)$, $c = 710.722(8)$ pm, $\beta = 92.191(1)°$, $Z = 4$, $F(000) = 440$, $\mu = 1.333$ mm^{-1}, measured range $4 \le 2\theta \le 60°$, 5500 data points, 1689 observed reflections, $wR_p = 0.082$, $R_p = 0.063$, $R_F = 0.038$. At the beginning of the calculation the scale factor, lattice constants, zero point, and background were refined. The profile was fitted by a pseudo Voigt function [27], and its asymmetry corrected according to ref. [28]. A total of 33 atomic parameters were refined; the thermal ellipsoids of all P atoms were refined independently, and those of N atoms as dependent on each other. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, Germany on quoting the depository number CSD-406655.

Trimethylplatinum Triflate: A Versatile Building Block in Coordination Chemistry**

Sabine Schlecht, Jörg Magull, Dieter Fenske, and Kurt Dehnicke*

The well-known trimethylplatinum compounds $[\{Me_3PtX\}_4]$ (**1**; for example, X = Cl, Br, I, N_3, OH)[1] form very stable, relatively inert heterocubane structures, in which Pt and X atoms occupy alternate corners of slightly distorted cubes. In contrast to **1**, we have found the previously reported[2] but structurally uncharacterized trimethylplatinum triflate **2** to be a versatile reagent in coordination chemistry. Its tetrameric structure (Figure 1)[3] can be "deaggregated" successively into trimeric, dimeric, and momomeric complexes by bases of various strengths (Scheme 1).

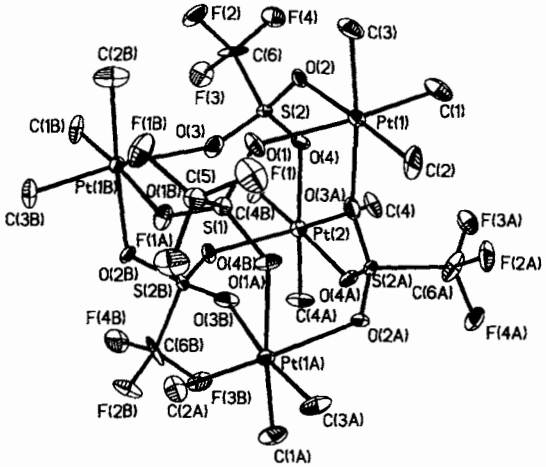

Figure 1. Crystal structure of **2**. Selected average bond lengths [pm] and angles [°]: Pt–C 200(3), Pt–O 227(2), S–O 144(2); C-Pt-C 91.2(12), O-Pt-O 87.4(7), Pt-O-S 138.8(12), O-S-O 113.9(10).

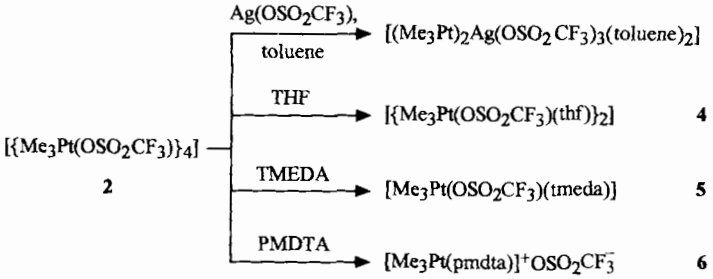

Scheme 1. Deaggregation of **2**. TMEDA = *N,N,N',N'*-tetramethylethylenediamine; PMDTA = *N,N,N',N'',N''*-pentamethyldiethylenetriamine.

This is associated with a change in the donor function of the triflate ions from μ_3 to μ_2 to nonbridging O coordination. Known examples of these types of coordination are **7**, with μ_3 and μ_2 coordination, which leads to chain formation,[4] **8**, which exhibits μ_2-coordination of a bicapped heterocubane,[5] and **9**, which contains monodentate triflate ion.[6]

$[Cu(O_3SCF_3)(\text{cyclohexene})]_\infty$ **7**

$[Cu_4(OH)_4(O_3SCF_3)_2\{N(py)_3\}_4]^{2+}$ **8**

$[Me_2Au(H_2O)(O_3SCF_3)]$ **9**

The structure of **2** is stretched relative to the heterocubane structure of **1**, and the platinum atoms of **2** are bridged by oxygen atoms of the triflate ion in a μ_3 fashion. Due to the weak donor strength of the triflate ions[7] the resulting Pt–O bonds of average length 228 pm are significantly longer than those in $[Me_3PtOH]_4$[8] (222 pm). The associated weakening of the Pt–O bonds is reflected in the relatively low-field position of the ^{1}H NMR resonance[9] for the methyl groups in the *trans* position ($\delta = 1.36$) and the large coupling constant $^2J(^1H, ^{195}Pt) = 81.6$ Hz.[1] This also explains the deaggregation of **2** by the very weak Lewis base silver triflate to give the trinuclear complex **3**, in which three triflate ions each bridge the platinum atoms of two Me_3Pt fragments through two μ_2-O atoms (Figure 2). One oxygen atom of each of two triflate ions, O(6) and O(9), is bonded to a silver ion, the coordination sphere of which is completed by two η^2-coordinated toluene molecules. This bonding mode, which has often been observed in arene complexes of silver,[10] is the reason for the relatively long Ag–O bonds of 250.7 and 245.5 pm in **3**. The ^{1}H NMR spectrum indicates a slightly increased electron density at the Me_3Pt

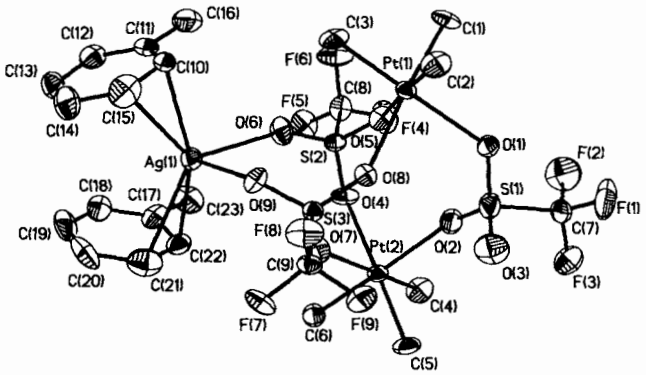

Figure 2. Crystal structure of **3**. Selected (sometimes averaged) bond lengths [pm] and angles [°]: Ag1–C10 239.2(11), Ag1–C15 257(2), Ag1–C21 268(2), Ag1–C22 238.5(12), Ag1–O6 250.7(8), Ag1–O9 245.5(8), Pt–C 200.3(12), Pt–O 226.9(7), S1–O3 147.1(10), other S–O 143.1(8); O6-Ag1-O9 84.4(3), Ag1-O6-S2 150.1(6), Ag1-O9-S3 128.3(5), Pt-O-S 138.1(5) C-Pt-C 89.1(6).

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3618-1994 $ 17.50+.50/0

unit ($\delta = 1.28$) and correspondingly weaker coupling to the platinum atom [$^2J(^1H,^{195}Pt) = 79.4$ Hz].

With the somewhat stronger Lewis base tetrahydrofuran, **2** can be deaggregated to the dimeric complex **4**, which according to the crystal structure analysis[3] (Figure 3) contains a centrosymmetric, corrugated $Pt_2O_4S_2$ eight-membered ring, in which the platinum atoms are additionally coordinated by the O atom of a THF molecule. The Pt–O(THF) bond (222.9 pm) is slightly shorter than the Pt–O bonds to the triflate ions (227.2 pm on average), which are very similar to those in **2** and **3**. In **4** only two of the three O atoms of each triflate ion capable of coordinating are actually used for coordination. However, the corresponding S–O bonds of the bridge, with lengths of 144.6 and 145.6 pm, are only marginally longer than the nonbridging S–O bond (143.0 pm), and this indirectly reflects the weak donor strength of the triflate ion. In spite of the different donor strengths of triflate and THF, the ^{1}H NMR data of the Me_3Pt unit in **4** differ only slightly from those of **3** and show one set of signals for the methyl groups at 293 K ($\delta = 1.29$, $^2J = 80.7$ Hz). At 193 K (CD_2Cl_2, 500 MHz) two sets of signals are observed at $\delta = 1.09$ (3H, $^2J = 81.0$ Hz) and 1.21 (6H, $^2J = 76.7$ Hz), as required by the molecular symmetry.

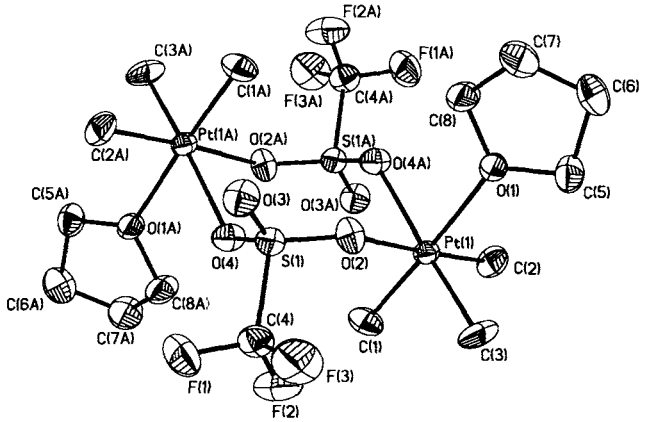

Figure 3. Crystal structure of **4**. Selected (sometimes averaged) bond lengths [pm] and angles [°]: Pt–C 201.9(6), Pt–O1 222.9(4), Pt–O2/4 227.2(4), S1–O3 143.0(4), S1–O2/4 145.1(4); C-Pt-C 89.3(3), O1-Pt1-O2 82.9(2), O1-Pt-O4A 82.4(2), O2-Pt1-O4A 87.6(2), Pt-O-S 134.7(1), O-S-O 114.7(3).

The reaction of **2** with the strong chelating base TMEDA leads to the monomeric complex **5**, in which the triflate ion is monodentate (Figure 4). Surprisingly, the Pt–O bond (232.1 pm) is now significantly longer than those of complexes **2**–**4**, which contain bridging triflate ions. Because of this very weak coordination of the triflate ion, the ^{1}H NMR signals of the Me_3Pt group are broadened by intramolecular dynamic processes at room temperature.[11] On cooling to 253 K they split into two sets of signals at $\delta = 0.79$ (3H, $^2J = 82.9$ Hz) and 1.01 (6H, $^2J = 67.2$ Hz), which are shifted upfield relative to those of **4**. The triflate ion is therefore readily substituted on reaction of **2** with the trifunctional base PMDTA to give the complex cation **6**, in which the Me_3Pt group gives rise to two sets of resonances in the ^{1}H NMR spectrum at $\delta = 0.66$ (3H, $^2J = 65.1$ Hz) and 0.80 (6H, $^2J = 68.7$ Hz). Their significant high-field shift is in good agreement with the strong donor capacity of PMDTA.

Polycyclic Aromatic Hydrocarbons in the Nanometer Range**

Benedikt Schlicke,
A.-Dieter Schlüter,*
Petra Hauser, and Jürgen Heinze

Both the discovery of fullerenes with all their exciting aspects[1] and the improved understanding of optoelectronic properties of polycyclic aromatic hydrocarbons (PAHs) as well as other unsaturated molecules[2] have considerably stimulated research on unsaturated compounds of all sorts. A few years ago, a two-step methodology for the synthesis of fully unsaturated, double-stranded polymers was established, which uses Diels–Alder (DA) polyaddition of unsaturated, bifunctional monomers followed by dehydration or dehydrogenation of the initially resulting prepolymer.[3,4] This chemistry has now been used to push the size of extended, yet monodisperse and structurally well-defined PAHs to its (present) limits. We report here on the synthesis of the novel PAHs **6** and **7**, which contain 19 and 29 condensed five- and six-membered rings, respectively, as well as their chemical, electrochemical, and optical characterization.

The synthetic strategy involves the bifunctional central building block **3** and its linear extension by DA end-capping reactions with cyclopentadienones **4b**[5] and **5**. Compound **3** was synthesized from **1**[3d] and bisaryne precursor **2**.[6] The more extended analogue of the cyclopentadienone derivative **4**, compound **5**, was synthesized by cycloaddition between diene **4a** and the dienophilic group of compound **1**. This cycloaddition proceeds at a significantly higher rate than the self-addition[3c,d] of the DA monomer **1**. This may be explained in terms of a reduced DA reactivity of the cyclopentadienone moiety in **1** as compared with that in **4a** presumably due to the substitution of the latter with electron-withdrawing ester groups in this inverse DA reaction. The very minor amounts of oligomers of **1** formed during synthesis of **5** (<2%) were removed in the workup, which gave the isolated target compound in a yield of 91%. In the final step, two equivalents of **4b** and **5** were treated with the central building block **3** to afford the PAHs **6** and **7**, respectively. They were easily purified by column chromatography and obtained in yields of 85 and 92%, respectively. Due to the substitution with dodecyl chains, these quite extended, flat (tabular) molecules show an exceptionally high solubility in common organic sol-

vents like chloroform, toluene, and THF at room temperature. For example, at room temperature CH_2Cl_2 dissolves 5.0 gL^{-1} of **6** (1.8 $mmol L^{-1}$) and 4.5 gL^{-1} of **7** (1.1 $mmol L^{-1}$). The NMR spectra are in agreement with the proposed structures, including the integrals, which show correct proportions. The laser-desorption time-of-flight (LDI-TOF) mass spectra show the molecular ions at 2778 (**6**) and 4024 kDa (**7**) and no higher signals.[7] Compound **7** gives a correct elemental analysis.[8] Gel permeation chromatography (GPC) elution curves referenced to polystyrene standard are monomodal and give $M_n(\mathbf{6}) = 3380$ ($M_w/M_n = 1.02$) and $M_n(\mathbf{7}) = 4280$ ($M_w/M_n = 1.03$).

Compounds **6** and **7** were studied by cyclic voltammetry (Table 1).[9] Experiments were carried out in tetrahydrofuran

Table 1. Redox potentials ([V] vs. Ag/AgCl) of compounds **6** and **7** [a].

	Reduction						Oxidation			
	$E^6_{1/2}$	$E^5_{1/2}$	$E^4_{1/2}$	$E^3_{1/2}$	$E^2_{1/2}$	$E^1_{1/2}$	$E^1_{1/2}$	$E^2_{1/2}$	$E^3_{1/2}$	$E^4_{1/2}$
6	−3.10	−2.92 [b]	−2.00	−1.82	−1.50	−1.40	+0.89	+1.28	+1.54	
7	−2.55	−2.42	−2.16	−2.04	−1.41 [b]	−1.13 [b]	+0.85	+1.21	+1.34	+1.52

[a] The cyclic voltammograms were recorded in THF/$TBAPF_6$ (reductions) and CH_2Cl_2/$TBAPF_6$ (oxidations) at −40 °C (scan rate: 200 mVs^{-1}; TBA = Tetrabutylammonium). [b] Two-electron transfer steps.

(reductions) and dichloromethane (oxidations) under superdry conditions. With **7** the onset of reduction and oxidation shifts to lower energies than that with **6**. Compound **6** can be reduced to the heptaanion and **7** to the octaanion within a relatively small potential range (Figure 1). Fullerenes cannot be reduced further

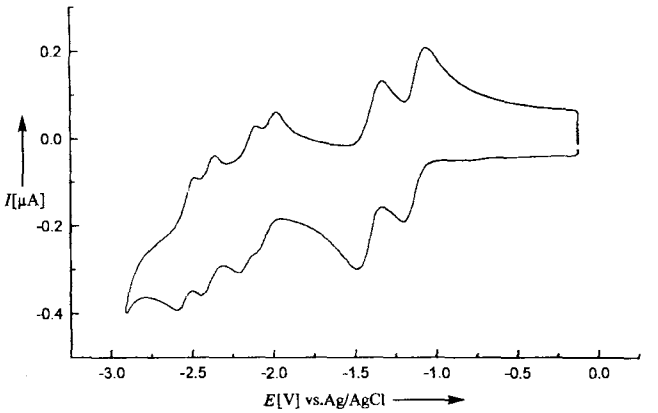

Figure 1. Reduction part of the cyclic voltammogram of compound **7** in THF/$TBAPF_6$ at −40 °C (scan rate: 200 mVs^{-1}).

than the hexaanions.[1, 10] Persistent trications and tetracations can be generated for species **6** and **7**, respectively. The redox states are stable. Their lifetimes are at least in the range of seconds. During reduction two-electron transfer steps take place up to the tetraanion, whereas for the oxidation well-separated one-electron transfer steps are observed. This is surprising because typically the energetical order of reduction and oxidation is symmetrical.

Some optical properties of **6** and **7** are summarized in Table 2. The absorption bands at longest wavelength (^1L_a) have a typical vibronic pattern (Figure 2). The fluorescence spectra show small Stokes shifts, indicating a high rigidity of the molecules.[11] The fluorescence quantum yield is high for the shorter and surprisingly weak for the longer arene.[12] The apparent lifetime of the excited states (τ) lies in the range of ns as for anthracene and perylene.[13]

Table 2. Absorption and emission maxima, fluorescence quantum yields (Φ_F), Stokes shifts, and lifetimes of the excited state (τ) of compounds **6** and **7**.

	Color	Absorption λ_{max} [nm]	lg ε	Emission λ_{max} [nm]	Φ_F	Stokes shift [nm]	τ [ns]
6	red	582	5.28	597	0.81	17	2.76

We have devised a facile route to monodisperse PAHs of 3.0 (**6**) and 4.5 nm (**7**) length,[14] which, regardless of their considerable size, can be handled and characterized (Table 3) like any low molecular weight compound. To our knowledge PAH **7** is the most extended, fully characterized aromatic compound known today.

[7] The LDI-TOF spectra of **6**, **7**, and other related compounds show, besides the molecular ion peak (low intensity), patterns of signals with a Gaussian type distribution at somewhat lower masses (relatively high intensity). The peaks of these patterns are separated by a constant $m/e = 28$ Da. The reason for this finding is not yet understood. A possible systematic distribution of molecular weights caused by an inadvertent employment of reagents with an even distribution of methylene groups in the alkyl chains is unlikely. The alkyl chains are introduced into the whole sequence as bromides and alcohols (see Refs. [3d, 5]), the purity of which was greater than 98% (checked by (GC)).
[8] Despite several attempts we were not able to get correct analytical data from compound **6**; the values for H were always slightly too small.

Efficient Synthesis of Ganglioside GM2 for Use in Cancer Vaccines**

Julio C. Castro-Palomino, Gerd Ritter,*
Sheila R. Fortunato, Stefan Reinhardt, Lloyd J. Old,
and Richard R. Schmidt*

A number of carbohydrate antigens that are expressed on human cancer cells on glycolipids and glycoproteins are considered attractive targets for immunotherapy with monoclonal antibodies and vaccines.[1] Examples include the gangliosides GM2, GD2, GD3, *O*-acetyl-GD3, and fucosyl-GM1, the neutral glycosphingolipid globo-H, the T, Tn, and sTn epitopes expressed on glycoproteins, and the Le^Y epitope expressed on both glycolipids and glycoproteins. Of these potential targets, ganglioside GM2 is of particular interest, because a) GM2 is expressed on the cell surface of a number of human cancers, including melanoma, sarcoma, and renal cancer;[2] b) GM2-reactive antibodies (mouse and human polyclonal and monoclonal antibodies) are cytotoxic in vitro against $GM2^+$ human cancer cells;[3,4] c) GM2 is immunogenic in humans due to the presence of naturally occurring low-titer IgM serum antibodies against GM2,[4] to the relative ease of isolating GM2 monoclonal antibodies from humans,[5] and to the induction of GM2 antibodies in melanoma patients following immunization with GM2-containing vaccines;[3,4,6–8] d) the presence of GM2 antibodies in melanoma patients appears to be associated with an improved survival rate and a longer disease-free interval;[4] and e) no deleterious side effects associated with an immune response to GM2 have been observed.[4]

Various approaches for inducing an immune response against $GM2^+$ cancer cells in melanoma patients have been pursued, including immunization with GM2-expressing tumor cells,[7] with purified GM2 mixed with various immunological adjuvants,[3,4] and more recently, with vaccines consisting of purified GM2 chemically conjugated to an immunogenic carrier protein.[6] Antibodies induced by whole cell vaccines or GM2 adherent to bacillus Calmette Guerin (BCG) were generally of the IgM isotype (low-titer, short-lived, and nonboostable), consistent with a T-cell-independent immune response.[3,4] In more recent studies vaccination with GM2 chemically conjugated to keyhole hemocyanin (KLH) and mixed with QS21, an adjuvant of the saponin family, resulted in more strongly cytotoxic IgM antibodies and the frequent induction of IgG antibodies against GM2 in ELISA (enzyme-linked immunosorbent assay).[6,8] However, the majority of the IgG antibodies against GM2 failed to react with GM2-expressing human cancer cells.[8] This could be due, among other explanations, to the induction of IgG antibodies against GM2 epitopes that are hidden or buried on the cell surface, possibly as a consequence of the particular vaccine formulation.

The GM2 used in these studies was derived from mammalian tissues (e.g., bovine brain, cat Tay–Sachs brain, or human melanoma). However, extraction and purification of GM2 from tissue bears the risk of biological contamination. In addition, mammalian tissue-derived GM2 comprises a mixture of different molecular species, mostly varying in the ceramide moiety. For systematic clinical vaccine development, a consistent source of a single, well-defined, synthetic GM2 species would be desirable, particularly for vaccines to be used in large groups of patients. We have therefore developed a practical method for the chemical synthesis of ample quantities of GM2 oligosaccharide building blocks and GM2 ganglioside for use in GM2 cancer vaccines.

The strategies pursued in previous GM2 syntheses[9–11] follow the GA2 or the GM3 route,[12] which is also employed here (Scheme 1). The most important synthetic problems in this endeavor are a) convenient generation of a suitable lactose building block, b) α-selective attachment of a sialyl donor to the 3b-hydroxyl group of this lactose constituent, c) high-yield β-selective attachment of an N-protected galactosamine residue to the low-reactive 4b-hydroxyl group of the GM3 trisaccharide intermediate, and d) convenient transformation of the N-protected galactosamine residue into the *N*-acetyl-galactosamine constituent. Problems (a)–(d) can be solved by means of build-

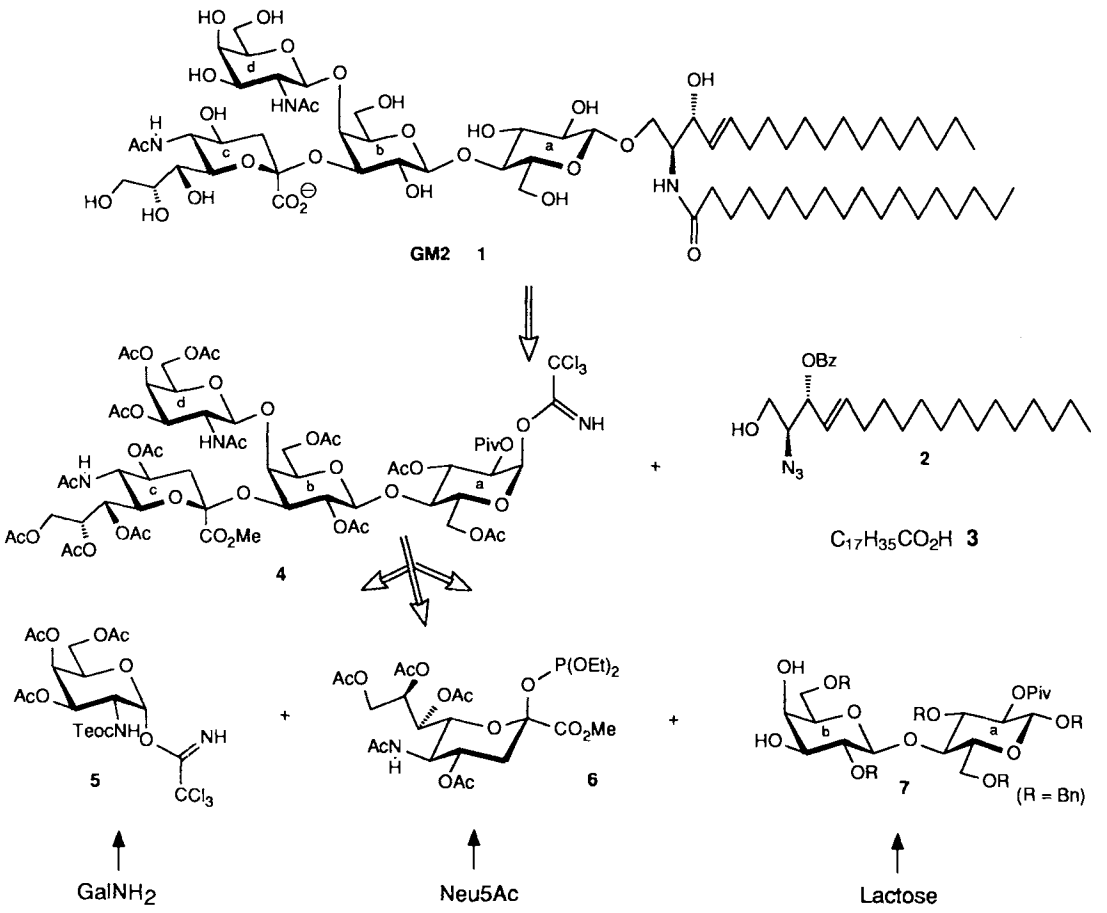
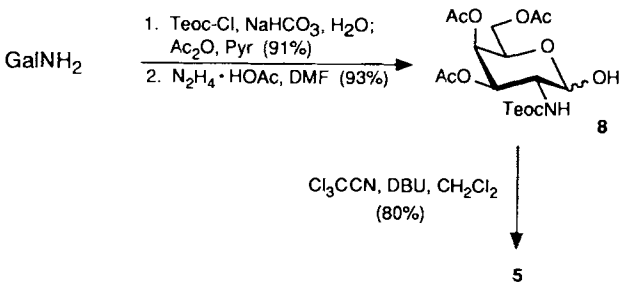


Scheme 1. Retrosynthesis of GM2 (**1**).

ing blocks **2**,[13] **3**, and **5**–**7**, which constitute tetrasaccharide intermediate **4**.

After investigating various galactosamine donors, we selected *N*-trichloroethoxycarbonyl(Teoc)-protected trichloroacetimidate **5**,[14] which was obtained from galactosamine in three convenient steps via the 1-O unprotected intermediate **8** in high yield (Scheme 2). This procedure avoided the tedious azidogalactose production[11,12] and the difficult removal of *N*-phthaloyl protecting groups in the presence of Neu5Ac residues, required in previous GM2 syntheses.[9,10] Simple treatment of *N*-Teoc-containing compounds with Zn/acetic anhydride leads to direct replacement of *N*-Teoc by an acetyl group.[15] The known diethyl phosphite derivative **6**[16] was employed as Neu5Ac donor.

The 3b,4b-O-unprotected 2a-*O*-pivaloyllactose residue **7**[17] facilitates the desired consecutive regioselective attack at the 3b- and then at the 4b-hydroxyl group, because of the very different



Scheme 2. Synthesis of the trichloroacetimidate **5** (Pyr = pyridine).

reactivities of these groups. The number of steps required for the reported synthesis of **7**[17] was greatly reduced by employing 1a,2a-*O*-silyl-group migration[18] for the regioselective introduction of the 2a-*O*-pivaloyl group. Isopropylidenation of lactose[19] and then silylation with thexyldimethylsilyl chloride (TDS-Cl) in the presence of base led to 1-*O*-silylated 3b,4b-*O*-isopropylidenelactose **9** (Scheme 3), which can be conveniently obtained also via the per-O-acetyl derivative of 3b,4b-*O*-isopropylidenelactose.[20] Benzylation of **9** with benzyl bromide and NaH as base in DMF leads to reversible silyl-group migration between the 1a and 2a oxygen atoms. Owing to the high nucleophilicity of the oxide oxygen atom of the β anomer, **10** is directly obtained from these intermediates in good yield by an irreversible anomeric *O*-alkylation process[18,21]. Removal of the 2a-*O*-silyl group with tetra-*n*-butylammonium fluoride (TBAF) in THF, pivaloylation, and acid-catalyzed cleavage of the isopropylidene group furnished target molecule **7** in high yield.

Reaction of sialyl donors with 2,3,4-*O*-unprotected galactosyl residues provides generally good α-glycosylation results. This is usually not found for 3,4-*O*-unprotected galactose derivatives.[16,22] Investigations with donor **6** and acceptor **7** and various catalysts showed that tin(II) triflate in acetonitrile at $-40\,^{\circ}C$ leads to high α selectivity ($\alpha:\beta = 9:1$) and good yields of GM3 intermediate **11** (Scheme 4); at room temperature sialoside yields of up to 80% were obtained with a slightly higher content of the β anomer ($\alpha:\beta = 4:1$); the α product **11** can be separated by flash chromatography in high purity. Subsequent glycosylation with donor **5** gave the desired tetrasaccharide in almost quantitative yield. Replacement of the Teoc group

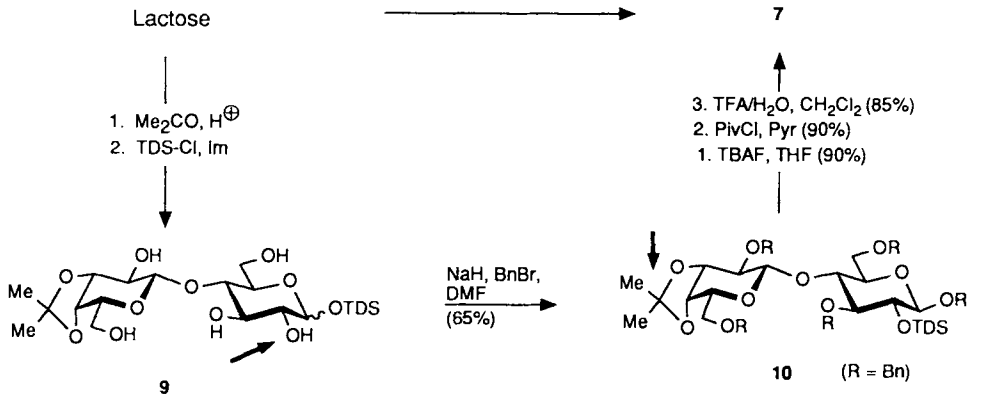
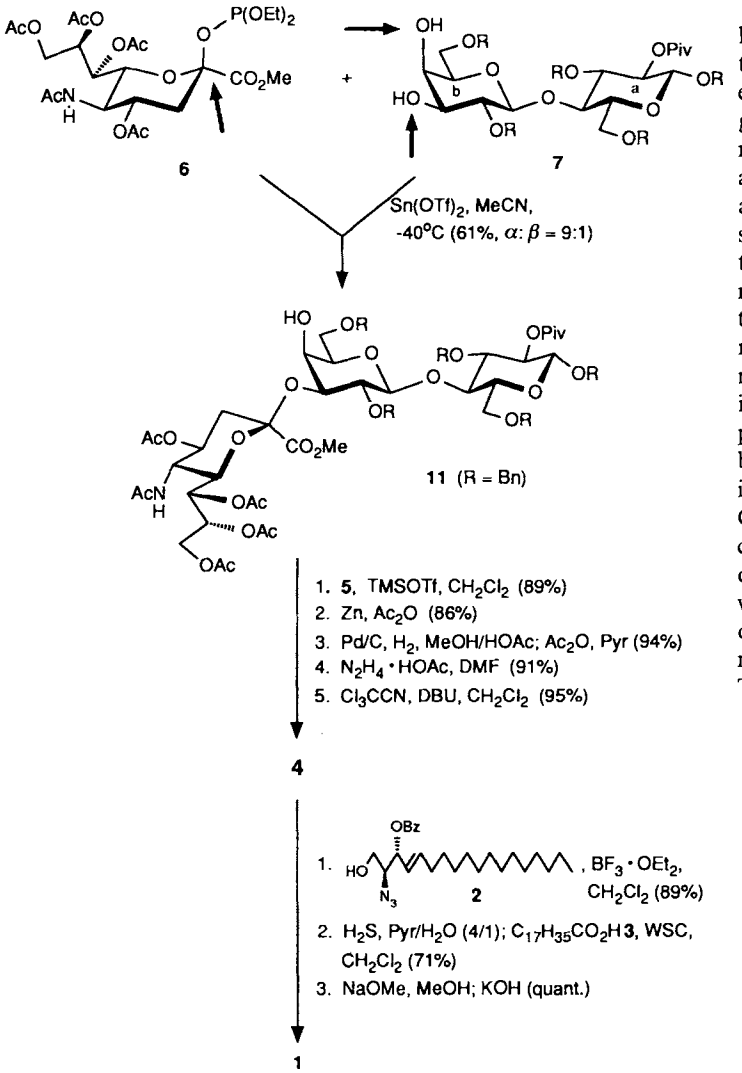


Scheme 3. Synthesis of the pivaloyllactose **7**. Im = imidazole, Piv = pivaloyl, TFA = trifluoroacetic acid. For synthesis of **7** from lactose, see also ref. [17].



Scheme 4. Synthesis of GM2 (**1**) from the building blocks **6**, **7**, **5**, and **2**. Tf = F_3CSO_2, TMS = trimethylsilyl, WSC = water-soluble carbodiimide [*N*-(3-dimethylaminopropyl)-*N'*-ethylcarbodiimide hydrochloride].

by an acetyl group with Zn/Ac_2O proceeded smoothly. Hydrogenolysis with Pd/C in MeOH/HOAc, followed by treatment with Ac_2O in pyridine led to replacement of all *O*-benzyl groups by *O*-acetyl groups. All subsequent procedures followed our previously introduced standard methods:[12] regioselective removal of the anomeric *O*-acetyl group with $N_2H_4 \cdot$HOAc and then treatment with CCl_3CN in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) as base afforded tetrasaccharide donor **4**. Application of the "azidosphingosine glycosylation procedure"[13] to azidosphingosine derivative **2**,[13] transformation of the azido into the amino group, attachment of the stearoyl residue (or other acyl group; see below), and then removal of all protective groups under basic conditions furnished target molecule **1** that was identical to previously synthesized material.[8, 9]

The availability of a GM2 oligosaccharide building block in large quantities by chemical synthesis facilitates the construction of GM2 gangliosides with different defined ceramide moieties and novel GM2 neoglycoconjugates for use as immunogens in GM2 vaccines. For instance, we have synthesized by this methodology GM2 having fatty acids of various lengths (capric acid, stearic acid, and lignoceric acid) in the ceramide moiety, and we have linked GM2 oligosaccharide to a short lipophilic spacer molecule (azidohexanol) to facilitate further conjugation to carrier molecules. To identify potential serological differences resulting from the composition of the lipid moiety, we tested these compounds and GM2 derived from bovine brain for their reactivity with a number of serological reagents (including mouse and human monoclonal antibodies against GM2, rabbit immune serum with GM2 reactivity, and sera from melanoma patients who had been immunized with vaccines containing bovine-brain GM2) by ELISA, dot blot immune stains, and immune thin-layer chromatography. We found that synthetic GM2 with stearic acid or lignoceric acid and sphingosine in the ceramide moiety was serologically indistinguishable from GM2 derived from bovine brain (Figures 1 and 2). However, GM2 with a ceramide containing a shorter fatty acid (e.g., capric acid) or GM2 oligosaccharide linked to azidohexanol showed dramatically reduced reactivity towards GM2-reactive antibodies. This suggests that ceramide containing a fatty acid longer than

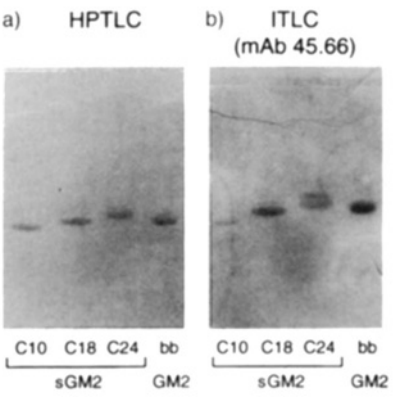


Figure 1. Reaction of a human monoclonal GM2 antibody (mAb 45.66) from a patient with malignant melanoma with synthetic GM2 containing capric acid (C10sGM2), stearic acid (C18sGM2), lignoceric acid (C24sGM2), or GM2 derived from bovine brain (bbGM2). The amount of ganglioside spotted per lane was 1 mg. The TLC was developed in chloroform/methanol/$CaCl_2$ (0.2%) in H_2O (55/45/10 v/v/v) and treated with hybridoma supernatant 45.66 diluted 1:10 with phosphate-buffered saline. Specific reactivity was made visible by using an anti-human IgM antibody conjugated to horseradish peroxidase and diaminobenzidine (b). Gangliosides were stained with orcinol/H_2SO_4 after immunostaining (a).

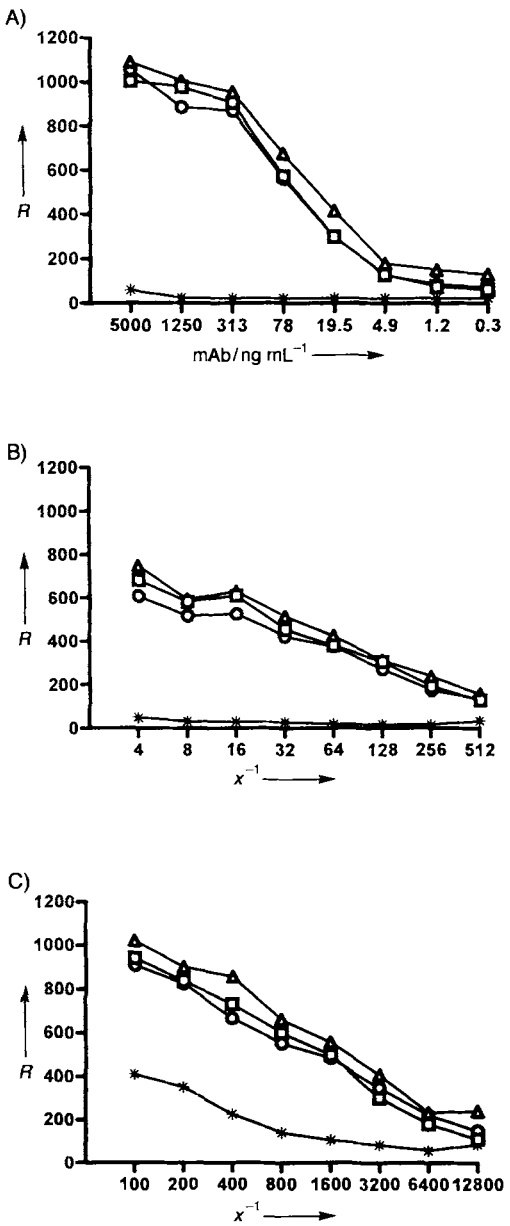

Figure 2. ELISA reactivity of GM2 antibodies with synthetic GM2 containing C10:0 (•), C18:0 (○), or C24:0 (△) fatty acid or with bovine brain-derived GM2 (□). A) Mouse monoclonal antibody 10.11 (purified IgM). B) Human monoclonal antibody 45.66 (tissue culture supernatant, IgM). C) Serum of a melanoma patient immunized with bovine brain-derived GM2-KLH/QS21 vaccine (IgG). No reactivity was observed with control antibodies or other gangliosides. Method: 200 pmol GM2 were incubated with varying amounts of GM2 antibody, and reactivity was quantitated by using Fitc-conjugated species, isotype specific secondary antibodies, and a microplate fluorospectrometer.

ten carbon atoms is required for full and specific immune recognition of GM2. Based on this observation, we have now prepared GM2–KLH conjugate vaccines by using synthetic GM2 containing stearic acid. Clinical trials with these vaccines will be initiated in the near future in patients with advanced malignant melanoma. By utilizing fully synthetic GM2, which is structurally well defined and free of biological contaminants, we hope to come a step closer towards our goal of developing a safe and efficient vaccine able to induce consistently a high-titered and long-lived cytotoxic antibody response in cancer patients.

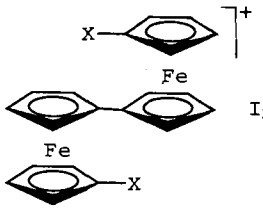
Effects of Environment on Intramolecular Electron Transfer in Mixed-Valence 1′,1‴-Dinaphthylmethyl(biferrocenium) Triiodide: Structural and ^{57}Fe Mössbauer Characteristics**

Teng-Yuan Dong,* Xiao-Qian Lai, Zhi-Wei Lin, and Kuan-Jiuh Lin

Electron transfer in chemical[1] and biological[2] systems has received considerable attention in the last few years. Recent studies of electron transfer in mixed-valence biferrocenium complexes **1**–**6** revealed that the environment surrounding a cation is perhaps the most important factor in determining the rate of intramolecular electron transfer.[1c, 3] Complexes **1**–**6** give unusual temperature-dependent Mössbauer spectra.[4] At temperatures below 77 K they each show two doublets, one for the Fe^{II} and one for the Fe^{III} site (electron-transfer rate $< 10^7\ s^{-1}$). In each case the two doublets move together upon increasing temperature and eventually become a single "average-valence" doublet. Hendrickson et al. suggested that the temperature dependence of the Mössbauer spectrum is due to the onset of lattice dynamics associated with the triiodide counterions and alkyl substituents.[4] At low temperatures (< 100 K) all parts of the crystal lattice of the complex are static. As the temperature is increased, the thermal energy formed could be sufficient to trigger a cooperative phase transition in the crystal lattice.[3a] A crystallographic phase change was not observed in **1**–**6**; we believe that the transition may be described in terms of a gradual (second-order) change with temperature.



1 X = H
2 X = CH_3
3 X = C_2H_5
4 X = n-C_3H_7
5 X = n-C_4H_9
6 X = benzyl
7 X = 1-naphthylmethyl

The mixed-valence complex **6** has two distinct crystallographic phases that show that the electron-transfer rates are extremely sensitive to changes in the crystal lattice.[3a] Two different crystalline morphologies (needle and platelike crystals) of **6** were found. The needle crystal in the triclinic space group $P\bar{1}$ shows a Mössbauer spectrum characteristic of a valence-detrapped electronic structure down to 25 K. The platelike crystal in the space group $P2_1/n$ shows a valence-trapped Mössbauer spectrum up to 300 K. However, because of the poor quality of the diffraction data and disorder in the triiodide anion, a satisfactory refinement of the structure was not obtained. Here we report on **7**, the first mixed-valence complex in two crystallographic phases with satisfactory structural refinements. Compound **7** was formed from **8** via **9** and **10** (see Experimental Section).

[**] This work was supported by the National Science Council (NSC86-2113-M-110-003) and National Sun Yat-Sen University.

Dark crystals in the triclinic space group $P\bar{1}$ were formed when a solution of **7** in CH_2Cl_2 was slowly concentrated.[5] An ORTEP plot of the molecular structure is given in Figure 1a. The refinement of the structure imposed inversion centers on both the cation and the triiodide anion. Thus, the two ferrocenyl moieties are crystallographically equivalent. The average Fe–C distance of 2.059(5) Å is intermediate to values for ferrocene (2.045(1) Å)[6] and the ferrocenium ion (2.075(1) Å).[7] The distances from the iron atom to the planes of the Cp ligands (1.668(2) and 1.676(2) Å) are also between the corresponding values for ferrocene (1.65 Å)[6] and the ferrocenium ion (1.70 Å).[7] The plane of the Cp ring forms a dihedral angle of 4.4° with the fulvalenide plane, and the two Cp rings in each ferrocenyl moiety are not perfectly eclipsed but rotated relative to one another by 7.0°.

Dark crystals in the monoclinic space group $P2_1/n$ were obtained when a layer of hexane was allowed to diffuse slowly into a solution of **7** in CH_2Cl_2.[5] The molecular structure is shown in Figure 1b. The two metallocene moieties in the cation are not equivalent. The average Fe1–C distance (2.052(4) Å) and the Fe1–Cp distance (1.660(4) Å) indicate that the iron in this metallocene is in the oxidation state II. In contrast, the average Fe2–C (2.086(5) Å) and Fe2–Cp distances (1.693(4) Å) indi-

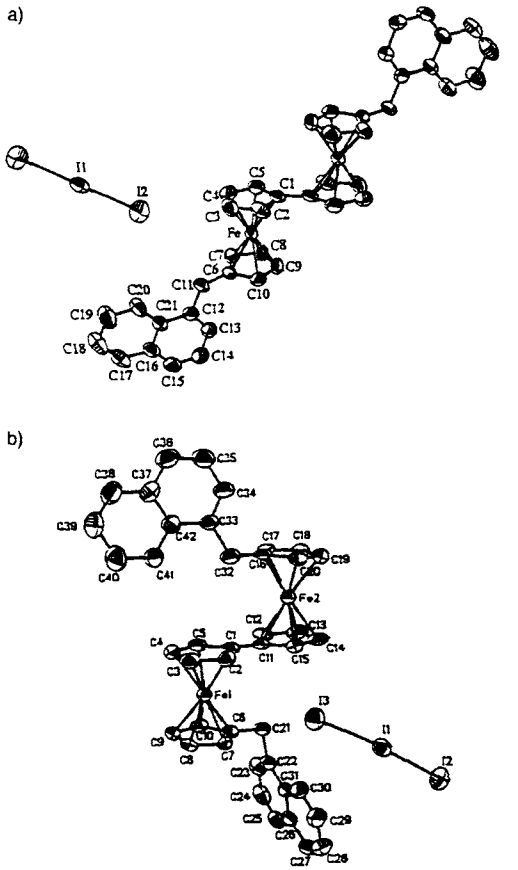

Figure 1. a) ORTEP plot of the crystal structure of **7**, space group $P\bar{1}$. Selected distances [Å] and angles [°] (standard deviations are given in parentheses): Fe–C1 2.090(5), Fe–C2 2.055(6), Fe–C3 2.039(6), Fe–C4 2.046(6), Fe–C5 2.050(6), Fe–C6 2.074(5), Fe–C7 2.043(5), Fe–C8 2.053(6), Fe–C9 2.064(6), Fe–C10 2.073(6), I1–I2 2.8936(8); I2-I1-I2 180. b) ORTEP plot of the crystal structure of **7**, space group $P2_1/n$. Selected distances [Å] and angles [°]: Fe1–C1 2.053(6), Fe1–C2 2.054(7), Fe1–C3 2.067(7), Fe1–C4 2.056(7), Fe1–C5 2.028(7), Fe1–C6 2.065(6), Fe1–C7 2.046(6), Fe1–C8 2.043(6), Fe1–C9 2.055(6), Fe1–C10 2.043(6), Fe2–C11 2.129(6), Fe2–C12 2.095(7), Fe2–C13 2.047(7), Fe2–C14 2.050(7), Fe2–C15 2.079(7), Fe2–C16 2.126(7), Fe2–C17 2.091(7), Fe2–C18 2.067(7), Fe2–C19 2.069(7), Fe2–C20 2.1107, I1–I2 2.89(1), I1–I3 2.932(1); I2-I1-I3 176.31.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3618-2002 $ 17.50+.50/0

cate that the iron in this metallocene is in the oxidation state III. The two Cp rings associated with Fe1 and Fe2 are not quite parallel; the dihedral angles are 2.1 and 5.5°. Furthermore, the two Cp rings associated with Fe1 and Fe2 are nearly eclipsed with average staggering angles of 3.0 and 2.3°.

A comparison of the structural features of the two different crystallographic phases of **7** is interesting. The naphthylmethyl substituents on the Cp rings are situated differently. The two nonequivalent naphthylmethyl groups in the cation of the $P2_1/n$ phase show a cisoid conformation relative to the fulvalenide ligand; this is similar to other dialkyl mixed-valence biferrocenium triiodide salts.[4, 8, 9] In the case of the cation of the $P\bar{1}$ phase the two equivalent naphthylmethyl groups show a transoid conformation relative to the fulvalenide ligand. Consequently, the packing arrangement of the cations and anions of **7** in the $P2_1/n$ phase is different from that in the $P\bar{1}$ phase. In the case of the latter the packing arrangement can be described as columns of cations and anions developing approximately along the *a* axis. In $P2_1/n$ phase the packing arrangement has a layer structure. Furthermore, it appears that the naphthylmethyl substituents lead to further slippage of the cations from the steplike stacks seen in dialkyl biferrocenium cations.

In the $P\bar{1}$ phase the I_3^- anion is at the inversion center and shows a symmetric structure. The I–I bond length is 2.8936(8) Å. In the case of the $P2_1/n$ phase the I_3^- anion is asymmetric (I1–I2 2.895(1), I1–I3 2.932(1) Å). In other words, the I3 atom carries more negative charge and shows I2–I1···I3$^-$ character. Furthermore, the I_3^- anion is not quite linear. In the $P\bar{1}$ phase an intermolecular phenyl–phenyl (π–π) interaction is observed between adjacent cations.

These structural characteristics are consistent with the results of the Mössbauer studies. The variable-temperature ^{57}Fe Mössbauer spectra of the two different crystallographic phases are shown in Figures 2 and 3. The ^{57}Fe Mössbauer spectrum of the $P\bar{1}$ phase at 80 K shows two doublets (Fe^{II}, ΔE_Q = 1.610 mms^{-1}; Fe^{III}, ΔE_Q = 0.818 mms^{-1}), which is characteristic of a valence-trapped cation in which the rate of intramolecular electron transfer is less than 10^7 s^{-1}.[10] The two doublets move together as the temperature is increased, and finally become a single average doublet (valence-detrapped) at about 130 K. On the other hand, the sample of the $P2_1/n$ phase exhibits a Mössbauer spectrum that is characteristic of a valence-trapped cation which remains trapped even at 300 K (Fe^{II}, ΔE_Q = 2.085 mms^{-1}; Fe^{III}, ΔE_Q = 0.407 mms^{-1}; Figure 3). The differences in the ^{57}Fe Mössbauer spectral properties of the two phases of **7** are attributable to differences in the molecular conformation around the mixed-valence cation. The crystal structure analysis of the $P\bar{1}$ phase shows that the environment of the cation is symmetric with respect to the two iron ions; rapid electron transfer is therefore possible. The asymmetric environment of the cations in the $P2_1/n$ phase energetically favors one valence state over the other, and, as a consequence, slow electron transfer results.[11]

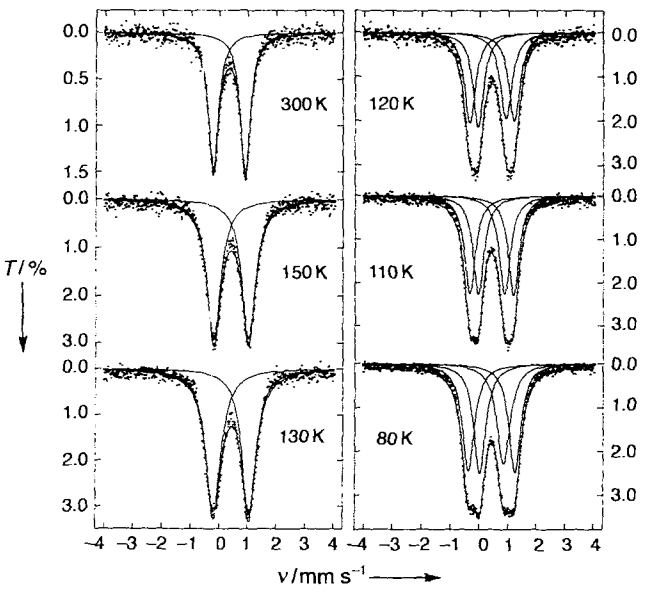

Figure 2. Variable-temperature ^{57}Fe Mössbauer spectra of **7** in the $P\bar{1}$ phase; T = transmission, v = velocity.

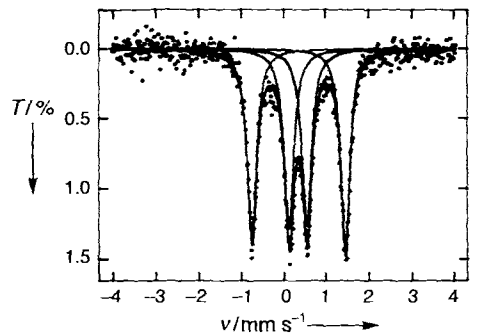

Figure 3. ^{57}Fe Mössbauer spectra of **7** in the $P2_1/n$ phase at 300 K.

The observations for the mixed-valence cation **7** definitively show that the crystallographic properties of the lattice play an important role in controlling the rate of electron transfer. There are several cases known in chemical and biological systems in which sluggish solvent–molecule motion and lattice dynamics can dramatically affect the rate of electron transfer.[1a, 12] In biological systems conformational changes of protein and the motion of amino acid groups have been suggested as providing control and specificity in electron transfer between proteins.[2] Our observation is an interesting result, which shows that the crystallographic properties can turn the electron transfer on or off.

Experimental Section

1′-Naphthoyl-1-bromoferrocene (**8**): Dibromoferrocene [13] (1.72 g, 5 mmol) was placed in a freshly dried flask (250 mL), and dried under vacuum at 2 Torr and 30 °C for 4 h. Dry THF (20 mL) and then butyllithium (3.15 mL, 1.6 M in hexane) were added under N_2. The solution was stirred at −25 °C for 30 min, during which 1-lithio-1′-bromoferrocene gradually precipitated. 1-Naphthylnitrile (5 mmol) was then added, and the solution stirred at −25 °C for another 25 min. Water (20 mL) was added, and the mixture extracted with CH_2Cl_2 (50 mL × 2). The combined extracts were dried over sodium sulfate and concentrated under reduced pressure. The residue was purified by chromatography on a column of neutral alumina (activity grade II). Elution with hexane gave fractions containing dibromoferrocene and bromoferrocene. Further elution with ethylacetate/hexane (1/25) provided the desired **8** in 20 % yield. ^{1}H NMR (300 MHz, $CDCl_3$, TMS): δ = 8.25 (t, 1H), 7.94 (m, 2H), 7.77 (d, 1H), 7.53 (m, 3H), 4.87 (s, 2H), 4.60 (s, 2H), 4.45 (s, 2H), 4.19 (s, 2H); MS (40 eV): m/z (%) = 418, 420 (100) [M^+].

Reduction of **8** to 1′-naphthylmethyl-1-bromoferrocene (**9**): Small portions of $AlCl_3$ were carefully added with stirring to a mixture of **8** and $LiAlH_4$ in dry ether. After 1 h the solution became yellow. An excess of H_2O was added, and the ether layer isolated, washed with H_2O, and dried over $MgSO_4$. After removal of the solvent the crude product was purified by chromatography on neutral Al_2O_3 with hexane as eluant. The first fraction contained the desired **9** in 71 % yield. ^{1}H NMR (300 MHz, $CDCl_3$, TMS): δ = 8.10 (d, 1H), 7.85 (t, 1H), 7.72 (d, 1H), 7.44 (m, 4H), 4.38 (t, 2H), 4.19 (s, 2H), 4.16 (s, 2H), 4.08 (t, 2H); MS (40 eV): m/z (%) = 404, 406 (100) [M^+]; m.p. 113.5–114.5 °C.

1′,1‴-Dinaphthylmethylbiferrocene (**10**): A mixture of **9** (1 g) and activated copper (5 g) was heated under N_2 at 120 °C for 24 h. After the mixture was cooled to room temperature, it was repeatedly extracted with CH_2Cl_2 until the extracts were colorless. The extracts were concentrated and purified by chromatography. The first fraction eluted with hexane yielded starting material. Further elution with CH_2Cl_2 afforded the desired **10** in 78% yield, which was recrystallized from hexane/

benzene. ^{1}H NMR (300 MHz, $CDCl_3$, TMS): $\delta = 7.94$ (d, 2H), 7.81 (t, 2H), 7.66 (d, 2H), 7.48 (m, 4H), 7.31 (m, 2H), 7.08 (d, 2H), 4.42 (s, 4H), 4.30 (s, 4H), 4.01 (s, 8H), 3.79 (s, 4H); MS (40 eV): m/z (%) = 650 (100) [M^+]; m.p. 170.0 °C (decomp).

7: A stoichiometric amount of I_2 in benzene/hexane (1/1) was added to a solution of **10** in benzene at 0 °C. The resulting dark green crystals were isolated by filtration and washed with cold hexane. A better crystalline sample was prepared by slowly concentrating a solution of **7** in CH_2Cl_2 (method 1) or by slowly diffusing hexane into a solution of **7** in CH_2Cl_2 (method 2). Microanalyses of the two different preparations were identical within experimental error. Elemental analysis calcd for **7** ($C_{42}H_{34}Fe_2I_3$): C 50.91, H 3.14; found: C 51.02, H 3.53 (method 1); found: C 50.99, H 3.55 (method 2).

[5] The X-ray structures of **7** ($C_{42}H_{34}Fe_2I_3$, $M = 1031.14$) were determined at 298 K. a) Crystals were obtained by slowly concentrating a solution of **7** in CH_2Cl_2: triclinic, space group $P\bar{1}$, $a = 9.836(2)$, $b = 10.418(2)$, $c = 10.638(3)$ Å, $\alpha = 62.83(1)$, $\beta = 86.06(1)$, $\gamma = 69.74(1)°$, $V = 904.5(4)$ Å^3, $F(000) = 497$, $\lambda(Mo_{K\alpha}) = 0.71073$ Å, $\mu = 3.391$ mm^{-1}, $Z = 1$, $\rho_{calcd} = 1.893$ g cm^{-3}. Data were collected on an Enraf Nonius CAD4 diffractometer in the range $2.16 < \theta < 22.42°$ (of 2356 reflections collected 1973 were independent). The structure was solved by heavy-atom methods, and refined, based on F^2, by full-matrix least-squares techniques. All non-hydrogen atoms were refined anisotropically, and hydrogen atoms were included in calculated positions and allowed to ride on the relevant carbon atom. Final residuals were $R1 = 0.0354$ and $wR(f^2) = 0.0875$ for 2356 unique data with $I > 2\sigma(I)$. Absorption corrections were made with empirical ψ rotation. b) Crystals were obtained by slowly diffusing hexane into a solution of **7** in CH_2Cl_2: monoclinic, space group $P2_1/n$, $a = 17.286(5)$, $b = 9.188(7)$, $c = 23.069(4)$ Å, $\beta = 93.44(2)°$, $V = 3658(3)$ Å^3, $F(000) = 1988$, $\lambda(Mo_{K\alpha}) = 0.71073$ Å, $\mu = 3.355$ mm^{-1}, $Z = 4$, $\rho_{calcd} = 1.873$ g cm^{-3}. Data were collected in the range $1.43 < \theta < 22.43°$ (of 4764 reflections collected 4764 were independent). The structure was refined as described above. Final residuals were $R1 = 0.0348$ and $wR(f^2) = 0.0980$ for 3289 unique data with $I > 2\sigma(I)$. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. $[Ru(Ph)(CO)(PtBu_2Me)_2]^+$: A Unique 14-Electron Ru^{II} Complex with Two Agostic Interactions**

Dejian Huang, William E. Streib, Odile Eisenstein,* and Kenneth G. Caulton*

In a number of molecular settings the ligand $PtBu_2Me$ (L) is very bulky, even in comparison to $PiPr_3$ and PCy_3 (Cy = cyclohexyl). Thus, this ligand significantly diminishes the enthalpy of addition of PhCCPh and even compact MeNC to $[Ru(CO)_2L_2]$, and this phosphane spontaneously and completely dissociates from $[Ru(CO)_2L_3]$.[1] The two *t*Bu groups have a similarly large influence, for example, on promoting *ortho* metalation of $[Ir(H)_2X(PtBu_2Ph)_2]$ to form $[IrHX(PtBu_2Ph)\{\eta^2\text{-}P(C_6H_4)tBu_2\}]$, and in causing even this 16-electron complex to eliminate $PtBu_2Ph$.[2] Indeed, phenyl metalation is accompanied by metalation of the *t*Bu carbon atoms. We reported that $[RuH(CH_3)(CO)(PtBu_2Me)_2]$ loses methane already at −40 °C with metallation of a *t*Bu group.[1] We report here that $PtBu_2Me$ is the phosphane which leads to a remarkable example of two agostic aliphatic interactions with a single metal center.

Essential to this observation is the production of a metal center with two empty valence orbitals. This is tantamount to the synthesis of a 14-valence-electron complex. Our approach to this goal is halide removal from a 16-electron complex. For optimum electrophilicity in a 14-electron complex, it is desirable to exclude π-donor ligands from the coordination sphere. This also diminishes the possibility of loss ("quenching") of unsaturation by dimerization through halide bridges (e.g., $[L_nM(\mu\text{-}Cl)_2ML_n]$). Unlike in the case of $[Ru(CO)(NO)L_2][BAr'_4]$ (L = $PtBu_2Me$, Ar' = 3,5-$(CF_3)_2C_6H_3$),[3] which can be made by salt metathesis of $[RuCl(CO)(NO)L_2]$ with $Na[BAr'_4]$, $Na[BAr'_4]$ does not remove Cl^- from $[Ru(Ph)Cl(CO)L_2]$. Replacement of Cl^- in $[Ru(Ph)Cl(CO)L_2]$ by OTf^- with AgOTf ($OTf^- = CF_3SO_3^-$) also fails. However, $[Ru(Ph)Cl(CO)L_2]$ can be transformed into $[Ru(Ph)F(CO)L_2]$ quantitatively by salt metathesis with CsF in acetone. Reaction of $[Ru(Ph)F(CO)L_2]$ with one equivalent of Me_3SiOTf affords $[Ru(Ph)(OTf)(CO)L_2]$ in quantitative yield. Subsequent reaction with $Na[BAr'_4]$ in dichloromethane at 20 °C (5 min) gives $[Ru(Ph)(CO)L_2][BAr'_4]$ in quantitative yield [Eq. (1)].

$$[Ru(Ph)F(CO)L_2] \xrightarrow{Me_3SiOTf} [Ru(Ph)(OTf)(CO)L_2] \xrightarrow[-NaOTf]{Na[BAr'_4]} [Ru(Ph)(CO)L_2][BAr'_4] \quad (1)$$

The ^{1}H NMR spectrum (CD_2Cl_2, 20 °C) of $[Ru(Ph)(CO)L_2][BAr'_4]$ shows only three broad signals for the phenyl-ring

protons. In contrast, five phenyl-proton signals appear for the five-coordinate $[Ru(Ph)X(CO)L_2]$ species reported here, indicating that phenyl-ring rotation is slow on the ^1H NMR time scale.[4] Two *t*Bu virtual triplets reveal that the molecule has a rigid, nonplanar geometry with two mutually *trans* phosphanes. The CO stretching frequencies (1958 cm^{-1}) of this complex in CD_2Cl_2 or fluorobenzene are identical, indicating the lack of solvent coordination to Ru. This very high ν(CO) value is consistent with a very electron-poor metal center. The other species in Equation (1) have ν(CO) values from 1890 to 1921 cm^{-1}. Additionally, two bands at 2722 and 2672 cm^{-1} are observed in the two solvents.[5] These two bands, which are in the stretching-frequency range of agostic C–H bonds, suggest that there are agostic interactions in this complex. However, attempts to observe the agostic protons by ^1H NMR spectroscopy in CD_2Cl_2 failed, even at −60 °C.[6]

To have conclusive evidence of an agostic interaction and the structure of this complex, a single crystal grown from a solution of fluorobenzene layered with pentane at room temperature was selected for an X-ray diffraction study. The crystal structure[7] of $[RuPh(CO)L_2][BAr'_4]$ confirms that the $[BAr'_4]^-$ anion does not bind directly to Ru, and shows a nonplanar geometry for the $Ru(C_{ipso})(CO)P_2$ moiety; this resembles an octahedron in which two *cis* ligands are missing (Figure 1). The phosphanes are transoid (∢ P-Ru-P 167.9°), and the CO and phenyl C_{ipso} atom *cis* (∢ C-Ru-C 93.5°). There is no evidence for agostic *ortho* phenyl interactions with Ru ($Ru\text{-}C_{ipso}\text{-}C_{ortho}$ 121 ± 4°); this phenyl ligand is therefore monohapto bound. However, the complex cation shows two agostic C-H-Ru interactions, one from one *t*Bu group of each phosphane. The shortest $Ru\text{–}C_{phosphane}$ distances are 2.87 Å (to C13) and 2.88 Å (to C28), which are within the range for strong agostic interactions.[8] Consequently, Ru-P-C angles are smaller when agostic interactions are involved: ∢ Ru1-P10-C11 (98.1(3)°) is 28° smaller than ∢ Ru1-P10-C15 (126.1(4)°), and ∢ Ru1-P20-C25 (96.6(3)°) is 25° smaller than ∢ Ru1-P20-C21 (121.7(6)°). In contrast, normal ∢ Ru-P-CMe_3 angles are typically around 115°. It is also true that the P-C-CH_3 angles for the which the CH_3 group is involved in an agostic interaction (C13 and C28: 103.3(11) and 104.2(12)°, respectively) are among the smallest in this molecule. While the C–C bonds in which the agostic methyl groups participate are not significantly longer than other C–C bonds, P–C bonds involving agostic *t*Bu groups are 3–4 σ (0.06 Å) longer than those to non-agostic *t*Bu groups. Thus, agostic interactions form primarily by angular deformation at P and C, but there is some evidence that P–C bonds may be "soft" enough to be lengthened.

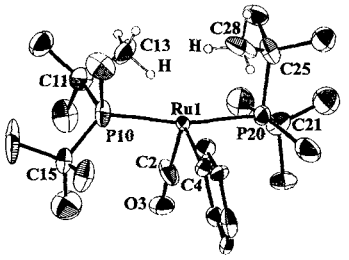

Figure 1. ORTEP diagram of the crystal structure of $[Ru(Ph)(CO)L_2]^+$. Hydrogen-atom positions are modeled. Only the hydrogen atoms of agostic methyl groups are shown, and these are idealized (C–H 1.05 Å, staggered conformation); Ru–C2 1.799(14), Ru–C4 2.058(12) Å.

The two agostic interactions formally provide four electrons to two vacant Ru orbitals. The occurrence of two (not one) agostic interactions in this cation reveals the reluctance of retaining even a 16-electron count in the absence of a π-donor ligand. Finally, since an intramolecular agostic interaction is evidently preferred to interaction with F, H or the π system of $[BAr'_4]$, this anion is quite effective at being "inert". The preference for *t*Bu over methyl C–H as donor must be attributed to the better steric approach of the former (giving a five-membered ring) than the latter (giving a four-membered ring). In summary, the existence of two agostic interactions in this complex reveals that this Ru^{II} complex is a strong Lewis acid but a weak π base.

The structure of the model complex $[Ru(Ph)(CO)(PH_3)_2]^+$ was optimized by density functional theory (DFT) calculations (B3LYP) with no symmetry constraint using the Gaussian 94 package (Figure 2).[9] The objective was to determine the inherent structural preferences of Ru and of the phenyl group (*ortho* agostic or not) in the absence of the influence of bulky phosphane substituents. The minimum-energy geometry is that of an octahedron with two empty *cis* sites. The calculated P-Ru-P and $OC\text{-}Ru\text{-}C_{ipso}$ angles are 176.6 and 97.4°, and the experimental values 167.9 and 93.5°, respectively. This shows that the (nonintuitive)[10] nonplanar structure of Ru and the four attached atoms is not caused by the two agostic interactions observed in $[Ru(Ph)(CO)(PtBu_2Me)_2]^+$. Instead, a d^6 configuration prefers a bent ML_4 structure with one angle close to 90°. This permits the three occupied metal d orbitals to be nonbonding (versus antibonding). The ligands with the strongest *trans* influence, CO and phenyl, prefer a position *trans* to an empty site. This structure keeps the (two) LUMOs, directed *trans* to CO and to phenyl, at a relatively high energy and, thus, makes the species persistent. The CO ligand (π* orbital) stabilizes two of the occupied d orbitals, but it (and the cationic charge) prevents oxidative addition of any C–H bond onto the metal. The slight twist (18°) of the phenyl ring out of the $OC\text{-}Ru\text{-}C_{ipso}$ plane observed in the crystal structure of $[Ru(Ph)(CO)(PtBu_2Me)_2]^+$ is not reproduced by the calculation involving PH_3, and is attributed to the *t*Bu and methyl substituents of the experimental species. The optimized structure shows no agostic interaction involving the *ortho*-phenyl hydrogen atom adjacent to the empty coordination site (Ru–H 2.84 Å). A phenyl ring is apparently too rigid to be a good *ortho* agostic donor to the metal to which it is σ bonded.

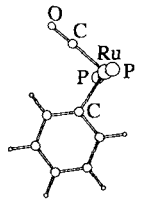

Figure 2. Calculated structure of $[Ru(Ph)(CO)(PH_3)_2]^+$; selected structural parameters: Ru–C(O) 1.83, Ru–C(Ph) 2.03, Ru–P 2.42 Å, ∢ Ru-C-O 178.9°.

$[Ru(Ph)(CO)L_2][BAr'_4]$ is highly air-sensitive. However, it is thermally stable up to 100 °C (eight hours in $[D_8]$toluene). It reacts with H_2 (CD_2Cl_2, 20 °C) within the time of mixing to form benzene, HL^+, and several other phosphane-containing products. The reaction with Me_3SiCCH occurs within the time of mixing at 25 °C (in CH_2Cl_2) to produce exclusively $PhCCSiMe_3$ and $[Ru\{\eta^3\text{-}(Me_3Si)CH{=}CHC{=}CH(SiMe_3)\}(CO)L_2][BAr'_4]$[11] in quantitative yield (Scheme 1). Since $[Ru(Ph)(CO)L_2^+]$ is a weak π base, it is unlikely to undergo oxidative addition. We therefore propose that this reaction undergoes a sigma bond metathesis mechanism in a highly selective way. This shows that agostic interactions in no way suppress the reactivity of this operational equivalent of a 14-electron species.

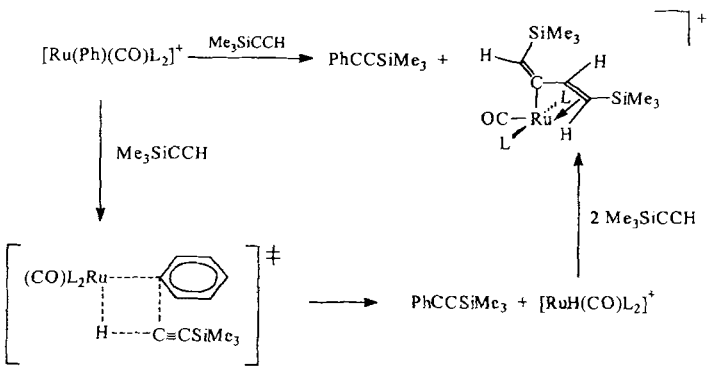

Scheme 1.

Experimental Section

[Ru(Ph)Cl(CO)L_2]: A solution of [RuHCl(CO)L_2] [12] (2.0 g, 4.1 mmol) and $HgPh_2$ (2.9 g, 8.0 mmol) in toluene (40 mL) was heated at reflux for 12 h and freed of volatile components [13]. The residue was extracted with pentane ($\approx$120 mL), and the extract evaporated to dryness to afford a crude product. Recrystallization from methanol gave dark orange crystals. Yield 1.92 g (83%). ^{1}H NMR (C_7D_8, 20 °C): δ = 8.32 (d, J = 7.2 Hz, 1H, *ortho*-H), 7.31 (d, J = 7.2 Hz, 1H, *ortho*-H), 6.78 (m, 1H, *para*-H), 6.69 (m, 2H, *meta*-H), 1.44 (virt. t, N = 5.4 Hz, 6H, PMe), 1.04 (virt. t, N = 12 Hz, 18H, P*t*Bu), 1.02 (virt. t, N = 12 Hz, 18H, P*t*Bu); N = ^3J(P,H) + ^5J(P,H); ^{31}P{^{1}H} NMR (C_7D_8, 20 °C): δ = 34.0 (s); IR (C_6D_6): $\tilde{\nu}$(CO) = 1902 cm^{-1}.

[Ru(Ph)F(CO)L_2]: [Ru(Ph)Cl(CO)L_2] (200 mg, 0.36 mmol) and CsF (100 mg, 0.66 mmol) were mixed with acetone (5 mL) and stirred for 12 h. The mixture was filtered, and the residue washed with pentane. The combined filtrate was evaporated to dryness in vacuo. The crude product was recrystallized from pentane (− 40 °C). Yield 150 mg (77%). ^{1}H NMR (C_6D_6, 20 °C): δ = 8.44 (d, J(H,H) = 6.6 Hz, 1H, *ortho*-H), 7.50 (d, J(H,H) = 8.1 Hz, 1H, *ortho*-H), 6.92 (m, 1H, *para*-H), 6.90 (m, *meta*-H), 6.83 (m, *meta* H), 1.31 (virt. t, N = 5.7 Hz, 6H, PCH_3), 1.08 (virt. t, N = 13.2 Hz, 18H, P*t*Bu), 0.99 (virt. t, N = 12.6 Hz, 18H, P*t*Bu); ^{31}P{^{1}H} NMR (C_6D_6, 20 °C): δ = 42.0 (d, J(P,F) = 24 Hz); ^{19}F NMR (C_6D_6, 20 °C): δ = −124.5 (t, J(P,F) = 24 Hz, Ru−F); IR (C_6D_6): $\tilde{\nu}$(CO) = 1890 cm^{-1}.

[Ru(Ph)(OTf)(CO)L_2]: [Ru(Ph)F(CO)L_2] (150 mg, 0.28 mmol) was dissolved in cyclohexane (10 mL), and Me_3SiOTf (54 µL, 0.28 mmol) added. The mixture was stirred for 10 min and then freed of volatile components. Recrystallization from a solution in toluene layered with pentane gave orange crystals. Yield 110 mg (58%). ^{1}H NMR (C_6D_6, 20 °C): δ = 8.0 (d, J(H,H) = 7.8 Hz, 1H, *ortho*-H), 7.31 (d, J(H,H) = 7.8 Hz, 1H, *ortho*-H), 6.90 (t, J(H,H) = 7.4, 1H, *para*-H), 6.73 (m, 1H, *meta*-H), 6.72 (m, 1H, *meta*-H), 1.50 (br s, 6H, PCH_3), 1.04 (virt. t, N = 13.2 Hz, 18H, P*t*Bu), 0.76 (virt. t, N = 13.2 Hz, 18H, P*t*Bu); ^{31}P{^{1}H} NMR (C_6D_6, 20 °C): δ = 40.5 (s); ^{19}F NMR (CD_2Cl_2, 20 °C): δ = −77.7 (s, O_3SCF_3); IR (C_6D_6): $\tilde{\nu}$(CO) = 1921 cm^{-1}.

[Ru(Ph)(CO)L_2][BAr$'_4$]: [Ru(Ph)(OTf)(CO)L_2] (150 mg, 0.22 mmol) and NaBAr$'_4$ (201 mg, 0.23 mmol) were mixed in fluorobenzene (5 mL) in a Schlenk tube under argon. The mixture was shaken for 10 min and then centrifuged. The liquid was transferred to a Schlenk flask in a glovebox under argon and layered with pentane. After 2 d red crystals were obtained. Yield 160 mg (52%). ^{1}H NMR (CD_2Cl_2, 20 °C): δ = 7.73 (s, 8H, BAr$'_4$), 7.57 (s, 4H, BAr$'_4$), 7.15 (br s, 2H, Ph), 7.01 (br s, 2H, Ph), 6.88 (m, 1H, *para*-H), 1.22 (virt. t, N = 4.8 Hz, 6H, PCH_3), 1.18 (virt. t, N = 13.2 Hz, 18H, P*t*Bu), 1.12 (virt. t, N = 14.4, 18H, P*t*Bu); ^{19}F NMR (CD_2Cl_2, 20 °C): δ = − 65.2 (s, BAr$'_4$); ^{31}P{^{1}H} NMR (CD_2Cl_2, 20 °C): δ = 41.4 (s); IR (CD_2Cl_2 or fluorobenzene): $\tilde{\nu}$(CO) = 1958, $\tilde{\nu}$(C−H(agostic)) = 2722, 2672 cm^{-1}; elemental analysis calcd for $C_{57}H_{59}BF_{24}OP_2Ru$: C 48.59, H 4.22; found: C 48.61, H 4.10.

Solution Structures of a Pair of Stable Hexaaminecobalt(III/II) Conformers**

Peter Comba* and Achim F. Sickmüller

Dedicated to Professor Gottfried Huttner on the occasion of his 60th birthday

Hexaaminecobalt(III) complexes generally are yellow, and their redox potentials clustered around (− 0.2 ± 0.25) V (aqueous solutions, versus standard hydrogen electrode (SHE)). Some highly strained species were reported with "extremely" low ligand fields, in which the first d–d transition ($^1A_1 \rightarrow {}^1T_1$) is shifted from about 480 nm (20800 cm^{-1}) to about 510 nm (19600 cm^{-1}), and the redox potentials up to about + 0.3 V. The recent report[1] of an exciting blue hexaaminecobalt(III) cage compound with a $^1A_1 \rightarrow {}^1T_1$ transition at 600 nm (16700 cm^{-1}) and a redox potential of + 0.84 V (versus SHE) beats all records, and indeed opens an entirely new area of hexaaminecobalt(III) chemistry and ways of changing electronic and structural properties of metal complexes profoundly. Also of interest is the fact that this challenging new compound occurs in two forms which appear to be conformers of similar stability. The second species is a "normal" yellow hexaaminecobalt(III) complex with a $^1A_1 \rightarrow {}^1T_1$ transition at 480 nm (20800 cm^{-1}) and a redox potential not far from 0 V versus SHE. The X-ray structure of the yellow form was determined, but not that of the blue species.[1] There are two important questions addressed here: a) What are the structural differences between the yellow

and blue conformers? b) What causes the unprecedented shift of over 4000 cm^{-1} in the ligand-field band and of about 800 mV in the redox potential?

The structure of the yellow conformer is shown in Figure 1b. The calculated structure is in excellent agreement with the experimental data (see below). The three pairs of methyl substituents on the annular six-membered chelating rings are oriented towards the periphery of the complex, leading to a twist (skew-boat) conformation of these rings. The orientation of each of these rings is such that they are quasi perpendicular (oblique) to the C_3 axis through the metal center and the two trigonal planes defined by the "caps" of the cage ligand (*ob* conformations). The configuration of the coordination polyhedron of the computed molecule is Δ, and that of each of the six nitrogen donors (S); the two caps have the same orientation. As a result, the symmetry of the complex is D_3, and the overall geometry of the conformer may be described as $twist_3$-D_3ob_3. Simple geometric considerations suggest that the corresponding lel_3 conformer would have a cavity that is elongated along the C_3 axis. Structural studies on smaller cage complexes, which are based on ethane-1,2-diamine and have five-membered chelating rings, support this idea.[2] Therefore, an lel_3 conformer would have a larger cavity, leading to longer Co–N bonds and, thus, a weaker ligand field and a preference for the larger cobalt(II) ion, that is, to a more positive redox potential. Qualitatively, these are the properties of the blue conformer.

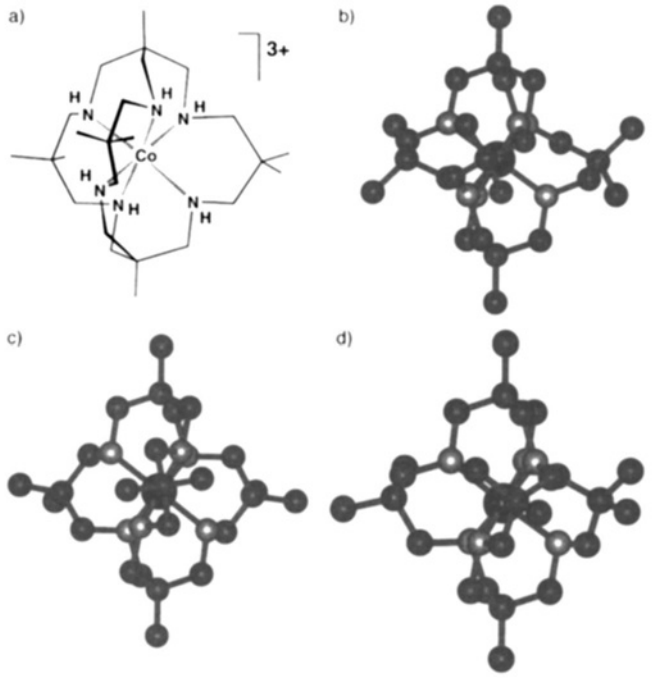

Figure 1. a) Lewis structure and computed structures of the most stable isomers: b) $twist_3$-D_3ob_3, c) $twist_3$-D_3lel_3, and d) $chair_3$-C_3.

These ideas were tested by computing various possible conformers of the hexaaminecobalt(III) cage compound. The calculations were restricted to the most important geometries. Conformers containing six-membered chelating rings in different geometries and structures including mixed chiralities at the nitrogen donors (R and S) were neglected, because they are distorted and high in energy. The strain energy minimized structures were obtained with the MOMEC program[3] and the corresponding force field.[4] Since the expected long cobalt(III)–amine bonds are outside the allowed interpolation limit of force-field calculations,[5] a Morse potential was used to model these stretching interactions.[6–8] The strain energies and the computed Co–N distances are assembled in Table 1, together with those for the reduced cobalt(II) species. It emerges that the $twist_3$-D_3ob_3, $twist_3$-D_3lel_3, and $chair_3$-C_3 cobalt(III) conformers are the most stable. The first two conformers have skew-boat conformations for all three six-membered chelating rings, and the third one has the three six-membered chelating rings in chair conformations.

Table 1. Calculated metal–ligand distances and strain energies of the most stable conformers.

Conformer	Co^{III}–N (Co^{II}–N) [Å]	Strain energy $H_{Co^{III}}$ ($H_{Co^{II}}$) [kJ mol^{-1}]
$twist_3$-D_3ob_3	1.985[a]	279.01
	(2.124)	(238.40)
$twist_3$-D_3lel_3	2.046	281.8
	(2.224)[b]	(177.11)
$chair_3$-C_3	2.031	268.77
	(2.189)	(190.37)
$twist_3$-C_2lel_2ob	2.008	312.1
	(2.204)	(194.42)

	(2.219)	(201.47)

[a] Observed [1]: 1.990 Å. [b] Observed [1]: 2.235 Å.

The electronic transitions and redox potentials of all conformers listed in Table 1 were also computed based on the strain energy minimized structures using MM-AOM[5, 9–11] and MM-Redox[5, 7, 13] calculations. These are given in Table 2. The calculated redox potentials and electronic transitions of the $twist_3$-D_3lel_3 and $twist_3$-D_3ob_3 conformers are in excellent agreement with the experimental data of both the yellow and blue species, which are also listed in Table 2.

Table 2. Calculated [a] and observed redox potentials [1] as well as ligand-field transitions of the three most stable and the two isolated conformers.

			344
$twist_3$-D_3lel_3	2.046	+0.89	612
			416
$chair_3$-C_3	2.031	+0.49	583
			402
orange	1.990	~0	480
			350
blue	–	+0.84	600
			370

[a] $E^\circ = \{[(H_{Co^{III}} - H_{Co^{II}})/64.818] - 0.724\}$ V [7].

The good agreement between the computed and the observed structural data for the yellow isomer and for the reduced form of the blue isomer as well as the agreement between observed and computed spectroscopic and electrochemical properties are a strong basis for the structural assignment of the blue cobalt(III) hexaamine compound. This supports our view that the combination of force-field calculations with the simulation of d–d absorption spectra and/or redox potentials, based on the computed structures, is a reliable tool for the determination of structures of cobalt(III) hexaamines in general.

[8] Due to the strongly elongated bonds the compounds modeled here are the first examples of cobalt(III) hexaamines for which an anharmonic potential is required, and for which this may be accurately parameterized. The quality of the parameters is based on structural data, including that of the yellow isomer and a set of cobalt(III) amines with moderately long bonds, and on the computed ligand field and redox properties (see below and ref. [7]).

[13] Ligand-induced steric strain is not the only contribution to the redox potential of coodination compounds, and other effects have been discussed in detail [5, 7]. The admittedly simplistic approach used here was shown to lead to valuable results for hexaaminecobalt(III/II) couples [7].

$Ln_3Au_2Al_9$ (Ln = Dy, Tb): Heteronuclear versus Homonuclear Bonding in Intermetallic Phases**

Karen J. Nordell and Gordon J. Miller*

Dedicated to Professor Hans Georg von Schnering

Main-group intermetallic phases can be classified into three groups based on the valence electron concentration (VEC) per atom: Hume–Rothery phases with VEC < 2, Zintl phases with VEC > 4, and compounds with 2 < VEC < 4 whose structures cannot be rationalized by any simple electron-counting rules. Compounds of these three classes display a rich variety of structures and compositions ranging from close-packed structures with wide phase widths to valence compounds containing covalent two-center, two-electron bonds.[1] Many of these intermetallic phases offer chemists the challenge of complex structural features such as fractional and mixed site occupancies, site preferences, vacancy ordering, and structural phase transitions.

In addition to careful crystallography, calculations of electronic structure are essential for understanding the structures of these compounds. To explore the connection between VEC and structure type for the compounds between the Hume–Rothery phases and the Zintl phases, we focused on the synthesis, characterization, and determination of electronic structure of new ternary aluminum-rich intermetallic phases with 2 < VEC < 4.

The electronic structures of several binary aluminides—for example $BaAl_4$,[2a] $CaAl_4$,[2b] and $LaAl_3$[2c]—were investigated recently. These studies suggest phase stability within narrow ranges of VEC, and optimization of Al–Al bonding according to their calculated overlap populations. The ternary compound $BaCu_xAl_{13-x}$ ($5 < x < 6$) has the $NaZn_{13}$ structure, in which Ba atoms are surrounded by a $^3_\infty[Cu(Cu_y\text{-}Al_{12-y})]$ ($4 < y < 5$) cubic framework of Cu-stuffed icosahedra with randomly arranged Cu (ca. 33%) and Al atoms (ca. 67%). This is an example of a ternary aluminide whose VEC maximizes the bonding within the $^3_\infty[Cu_5Al_8]$ network, as observed in its overlap populations. These theoretical results provide justification for attractive Al–Al, Cu–Al, and Cu–Cu interactions in these intermetallic phases. When the more electronegative Au is used instead of Cu, we also observe a different structure that is related to the $BaAl_4$ structure.

While $BaAl_4$ represents one of the most prolific structural types,[3] isostructural compounds involving main-group metals are restricted to VEC ≤ 3.5.[4] The rare-earth elements (except Eu) do not form binary aluminides of composition $LnAl_4$ in this structural type (VEC = 3.75); rather, they form Ln_3Al_{11}.[5] Low-temperature $\alpha\text{-}Ln_3Al_{11}$ (Ln = La, Ce, Pr, Nd) has a body-centered orthorhombic structure which undergoes a phase transition (above 976 °C for La_3Al_{11}) to $\beta\text{-}Ln_3Al_{11}$ ($Ln\square_{0.33}Al_{3.67}$), a tetragonal $BaAl_4$ structural type with ordered vacancies. The structure of $\alpha\text{-}Ln_3Al_{11}$ is also closely related to that of $BaAl_4$ (Figure 1). The reason that these rare-earth elements form

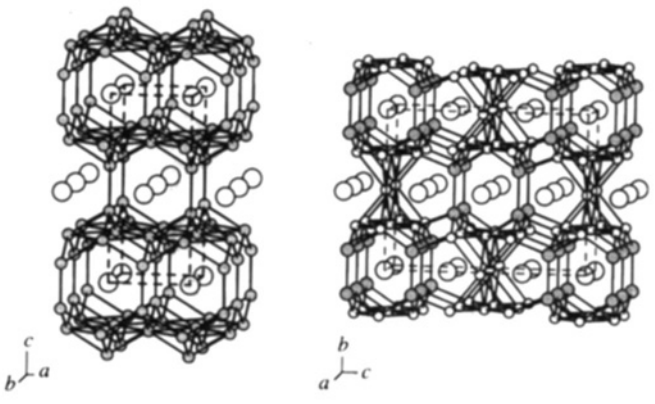

Figure 1. Left: structure of $BaAl_4$; large open circles Ba and small gray circles Al. Right: structure of $Dy_3Au_2Al_9$ ($\alpha\text{-}La_3Al_{11}$); large open circles Dy, small open circles nearly exclusively Al, and large gray circles 48% Au and 52% Al.

Ln_3Al_{11} rather than $LnAl_4$ is probably a combination of several factors including cation size and electron count. In the ternary rare-earth/Au/Al systems $LnAu_xAl_{4-x}$ ($x = 1\text{–}1.5$, Ln = La–Tb) with VEC = 3.0–3.25 form the $BaAl_4$ structure if Au and Al are disordered, but form the $BaNiSn_3$ structural type if the Al atoms are ordered.[6a] $LnAu_xAl_{4-x}$ ($x = 1.5\text{–}2$, Ln = La–Tb) with VEC = 2.75–3.0 are reported to form the $CaBe_2Ge_2$ structural type.[6b] We observed several rare-earth gold aluminides (e.g., $EuAu_{0.75}Al_{3.25}$, VEC = 3.125) that form the $BaAl_4$ structural type with no ordering of the Au and Al atoms.[6c]

We prepared the new compounds $Ln_3Au_2Al_9$ (Ln = Dy, Tb)[7] from their elements in an arc welding furnace. Both crystallize in a ternary derivative of the α-La_3Al_{11} type. According to single crystal X-ray diffraction studies, $Dy_3Au_2Al_9$ crystallizes in the space group *Immm* with $a = 4.265(1)$, $b = 9.952(2)$, and $c = 12.563(4)$ Å (see Table 1).[8] Several crystallites of

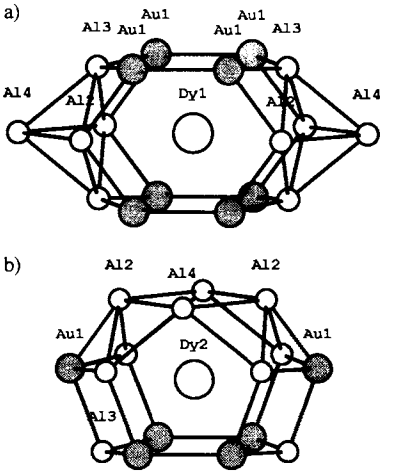

Figure 2. a) Structure of the 18-vertex elongated rhombic dodecahedron around Dy1. Au1 atoms are shown, but Al1 are not. Distances [Å] between Dy1 and framework atoms: Dy1–Au1 3.238(1), Dy1–Al2 3.555(2), Dy1–Al3 3.275(2), Dy1–Al4 4.971(3). Bond lengths [Å] within the framework: Au1–Au1 2.767(2), Al1–Al1 2.13(2), Au1–Al1 2.452(1), Au1–Al3 2.509(2), Au1–Al2 2.484(2), Al1–Al2 2.625(1), Al4–Al3 2.931(4), Al4–Al2 3.009(3). Bond length Dy1–Al1 3.067(7) Å (not shown). b) Structure of the 16-vertex polyhedron around Dy2. Au1 atoms are shown, but Al1 are not. Selected distances [Å]: Dy2–Al1 3.130(9), Dy2–Au1 3.204(1), Dy2–Au2/Al2 3.143(3), Dy2–Al3 3.148(3), Dy2–Al4 3.1474(9).

$Dy_3Au_2Al_9$ were analyzed with energy-dispersive spectroscopy in a Jeol 6100 scanning electron microscope, which indicated that Dy, Au, and Al were the only elements present in the sample. Magnetic-susceptibility measurements of $Dy_3Au_2Al_9$ showed Curie–Weiss paramagnetism with an effective moment of 18.54(4) μ_B per formula unit (for $T > 100$ K), which corresponds to three noninteracting Dy^{3+} centers (f^9) or 10.70 μ_B per Dy atom.[9]

$Dy_3Au_2Al_9$ forms the α-La_3Al_{11} structural type whose body-centered orthorhombic unit cell contains two formula units, or 28 atoms, and is related to $BaAl_4$ (see Figure 1). In $BaAl_4$, sheets of square pyramids are linked together along the *c* axis by direct connections between apex atoms, which results in 18-vertex polyhedra surrounding the Ba atoms. Calculations suggest that these linkages are two-center, two-electron bonds.[2a] In α-Ln_3Al_{11} the unit cell is three times larger, and two of the apex–apex connections have been condensed to single atoms (Al4), which have square-prismatic coordination and account for the deficiency in Al (the composition is $Dy_3Au_2Al_9$ and not "$Dy_3Au_2Al_{10}$"). This difference from $BaAl_4$ also leads to the disruption of the square network of Al atoms (the bases of the square pyramids) into ribbons along the *a* axis. There are two types of polyhedra surrounding the Dy atoms: 1) an elongated rhombic dodecahedron composed of 18 Al and Au atoms surrounding the Dy1 atoms on the corners and body center of the cell (Figure 2a) and 2) an irregular polyhedron composed of 16 Al and Au atoms encapsulating each Dy2 atom (Figure 2b). The large gray atoms in Figure 2 (labeled Au1), which represent averaged positions of the Au1 and Al1 atoms (see Table 1), form a cube around the Dy1 atom and are occupied by 48.4(3)% Au and 51.6(3)% Al.

Extended Hückel calculations[10] were performed on $Ln_3Au_2Al_9$ to examine the electronic structure of this compound and to help understand the mixing of Au and Al within the structure. Valence atomic orbitals of Y were selected to mimic Dy without its localized 4f orbitals, since the ionic radius of Y^{3+} (0.93 Å) is similar to that of Dy^{3+} (0.99 Å). Usually we can treat these elements as classical cations (Ln^{3+}); we included them in the calculation with the shortest Dy–Al and Dy–Au distances of 3.067(7) and 3.204(1) Å, respectively. To initially investigate the electronic structure of the aluminum-rich framework, we considered the homonuclear $^3_\infty[Al_{11}]^{n-}$ framework from α-La_3Al_{11} with an electron count of 38, which is appropriate for $Ln_3Au_2Al_9$. Mulliken populations were calculated for each atomic position: 3.676 (8*n*), 3.374 (4*h*), 3.266 (8*l*), and 3.512 (2*d*). For 42 electrons per formula unit, the electron count appropriate for La_3Al_{11}, the Mulliken populations are 3.900 (8*n*), 3.653 (4*h*), 3.810 (8*l*), and 3.853 (2*d*). The position with the largest population for both electron counts is 8*n*. Using Mulliken populations for the $^3_\infty[Al_{11}]^{n-}$ framework as a guide for the atomic ordering in the ternary compound, the positions with the largest Mulliken populations would be those most likely occupied by the atoms with the largest electronegativity.[11] The Pauling electronegativity of Au is 2.4, and that of Al 1.5. In the ternary compound $Dy_3Au_2Al_9$ this 8*n* position is occupied by 48.4(3)% Au and 51.6(3)% Al.

Since the X-ray diffraction experiment indicated no special ordering of Au and Al atoms on the 8*n* position, calculations were performed on model structures in which the Au and Al atoms were arranged with either homoatomic (Au–Au and Al–Al) or only heteroatomic (Au–Al) contacts. The partial density of states (DOS) curve for the $^3_\infty[Au_2Al_9]^{9-}$ framework in $Ln_3Au_2Al_9$ and the crystal orbital overlap population (COOP) curve for the Au1–Al1 contacts are shown in Figure 3. The Fermi energy lies in an area of nonzero DOS, and falls in the region of the crossover from bonding to antibonding levels in the Au1–Al1 COOP curve, which indicates near optimization of the bonding at this VEC. The total energy of the structure with only heteroatomic contacts is 0.5 eV per formula unit lower than that of the structure with homoatomic contacts.[12] Having two such bonding contacts per formula unit with only heteroatomic Au-Al contacts places an upper limit of two gold atoms per formula unit. These results indicate that there may be a range in composition of $x = 0$–2 for $Ln_3Au_xAl_{11-x}$; we are currently investigating this point. The stability of heteroatomic contacts may also be a factor in the ordered $LnAu_xAl_{4-x}$ ($x = 1.5$–2, Ln = La–Tb),[6b] which form the $CaBe_2Ge_2$ structure type in which there are only heteroatomic contacts for $x = 2$, or Au-Al and Al-Al contacts for $x < 2$. Given the large

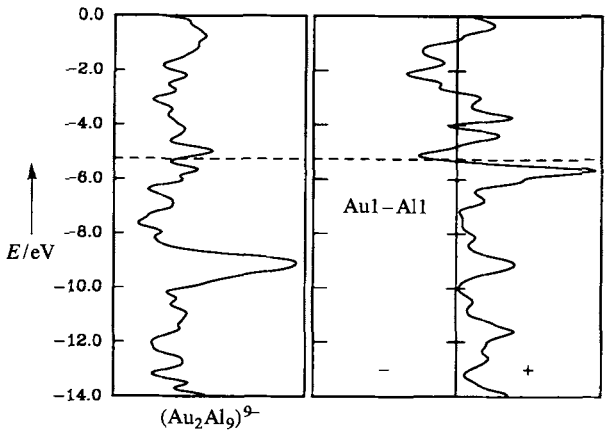

Figure 3. Left: Partial DOS curve for the $^3_\infty[Au_2Al_9]^{9-}$ framework of $Y_3Au_2Al_9$. Right: The COOP curve for the Au1–Al1 interaction, which shows the nearly optimal filling of bonding orbitals (+) and leaves the antibonding orbitals unfilled (−). The Fermi energy (dotted line) is at −5.21 eV.

DOS at the Fermi energy, we are also exploring electronic instabilities in these phases, in particular "$Y_3Au_2Al_9$", for a possible superconducting or structural phase transition.

Experimental Section

$Dy_3Au_2Al_9$ and $Tb_3Au_2Al_9$ were synthesized by allowing the elements to react in an argon-filled arc welding furnace with a zirconium getter for further atmosphere purification. Dysprosium and terbium (Materials Preparation Center, Ames Lab, 99.0%) as well as aluminum wire (Aesar 99.95%) and foil were cut into stoichiometric amounts in an argon-filled glovebox. The aluminum foil was used to wrap the metals into a small ball for transfer to the arc welding chamber. In the X-ray powder pattern no lines except those of the $Dy_3Au_2Al_9$ pattern and the silicon standard were observed. Samples that were annealed in niobium foil and evacuated fused silica at 800 °C for several weeks showed no structural change.

$[NH_4]_3[Ir(S_4)(S_6)_2]$: A Reevaluation of Hofmann and Höchtlen's Report of $[NH_4]_3[Ir(S_5)_3]$ from 1904**

Thomas E. Albrecht-Schmitt and James A. Ibers*

Dedicated to Professor Hans Georg von Schnering

Hofmann and Höchtlen were among the first to synthesize polysulfidometalates. In seminal work they reported on a number of novel compounds including $[NH_4]_2[PtS_{15}]\cdot 2H_2O$[1,2] and $[NH_4]_3[IrS_{15}]$.[2] Sixty-six years later $[NH_4]_2[PtS_{15}]\cdot 2H_2O$ was shown by single-crystal X-ray diffraction to be $[NH_4]_2[Pt(S_5)_3]\cdot 2H_2O$.[3] When a reaction mixture containing $[NH_4]_2[Pt(S_5)_3]$ is acidified to about pH 9.4, a second complex forms; from analytical data the complex was formulated as $[NH_4]_2[PtS_{17}]\cdot 2H_2O$.[4] Presumably the anion in this complex is either $[Pt(S_5)(S_6)_2]^{2-}$ or $[Pt(S_5)_2(S_7)]^{2-}$.[4]

Whereas the chemistry of $[PtS_{15}]^{2-}$, initiated by Hofmann and Höchtlen, was subsequently pursued and clarified, the chemistry of their $[IrS_{15}]^{3-}$ anion was not investigated until our recent studies of reactions between Ir^I and Ir^{III} complexes and polychalcogenides. We isolated the α-$[Ir(Se_4)_3]^{3-}$,[5,6] β-$[Ir(Se_4)_3]^{3-}$,[6] $[Ir(S_6)_3]^{3-}$,[6] and $[Ir(NCCH_3)_2(Se_4)_2]^{1-}$ anions;[6] with the exception of the latter, all have Pt^{IV} analogues.[7–9] We found that under certain conditions a polysulfidoiridate other than $[NH_4]_3[Ir(S_6)_3]$ could be isolated. We now report the synthesis and X-ray crystal structure of this product, $[NH_4]_3[Ir(S_4)(S_6)_2]$. We demonstrate that this is the material Hofmann and Höchtlen characterized as $[NH_4]_3[IrS_{15}]$ in 1904.

When $IrCl_3\cdot n H_2O$ is allowed to react with 25 wt% $[NH_4]_2S_n$ in water at 30–50 °C, the major product is $[NH_4]_3[Ir(S_6)_3]\cdot H_2O\cdot 0.5CH_3CH_2OH$.[6] However, after isolation of

this product, the mother liquor can be cooled to yield small amounts of $[NH_4]_3[Ir(S_4)(S_6)_2]$ in the form of brown, polycrystalline hemispheres. If 20 wt% $[NH_4]_2S_n$ is employed the product is predominantly $[NH_4]_3[Ir(S_4)(S_6)_2]$ as small red plates. When $RhCl_3 \cdot nH_2O$ is allowed to react under identical conditions $[NH_4]_3[Rh(S_5)_3] \cdot 3H_2O$ is the only product isolated.[10, 11]

The $[Ir(S_4)(S_6)_2]^{3-}$ anion (Figure 1), which has crystallographically imposed twofold symmetry, has the $\Lambda\lambda\lambda\delta$ conformation. This and its enantiomer $\Lambda\delta\delta\lambda$ are the expected conformations.[6, 9] The geometry about the Ir atom is a distorted octahedron with S-Ir-S bond angles ranging from 85.5(2) to 98.8(2)°, comparable to those of other octahedral polychalcogenometalates.[6, 8] The Ir–S and S–S bond lengths are within expected[6] ranges of 2.347(5) to 2.367(4) and 2.042(9) to 2.079(9) Å, respectively.

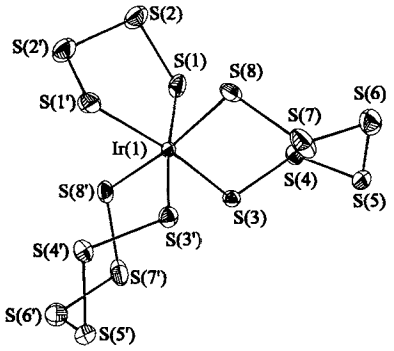

Figure 1. Structure of the $[Ir(S_4)(S_6)_2]^{3-}$ anion; ellipsoids for 50% displacement are shown.

Hofmann and Höchtlen's formulation of their product as $[NH_4]_3[IrS_{15}]$ was based upon the assumption that $[NH_4]_2S_n$ contained polysulfide exclusively in five-atom chains,[1] and upon accurate and reproducible elemental analyses.[1, 2] Although their work from 1904 was carried out a decade before the discovery of X-ray diffraction, they did report sufficient crystallographic data to enable us to establish beyond doubt that their product was $[NH_4]_3[Ir(S_4)(S_6)_2]$, that is $[NH_4]_3[IrS_{16}]$. They reported that their product crystallized in the tetragonal system as octahedra with interplanar angles of 52.30° for (001):(111) and 68.40° for (111):($\bar{1}$11).[2] The assignment of {111} to octahedral faces is arbitrary though standard in mineralogy in the absence of information about the space group. In fact, if we assign the octahedral faces as {101}, then from our unit-cell measurements the interplanar angles are calculated to be 51.60° for (001):(101) and 67.31° for (10$\bar{1}$):(011). There is thus excellent agreement between the interplanar angles reported by Hofmann and Höchtlen from room-temperature measurements and those calculated from our unit cell obtained at 113 K. There is no doubt that $[NH_4]_3[IrS_{15}]$ is $[NH_4]_3[Ir(S_4)(S_6)_2]$, and that all references to the former compound are in error.

Individual crystals of $[NH_4]_3[Ir(S_4)(S_6)_2]$ are enantiomerically pure, but, since batches of single crystals fail to rotate polarized light and since Ir^{III} complexes are kinetically inert,[12, 13] other crystals contain anions in the $\Lambda\delta\delta\lambda$ conformation. Thus, $[NH_4]_3[Ir(S_4)(S_6)_2]$ is an example of a material that undergoes spontaneous resolution. It is interesting that such crystals were available a decade before Werner's classic paper from 1914,[14] in which he resolved the first completely inorganic chiral compound.

Remarkably, Hofmann and Höchtlen briefly described the existence of small, orange plates as a second product from their reaction. $[NH_4]_3[Ir(S_6)_3]$, which we characterized,[6] crystallizes as orange plates.

Hofmann and Höchtlen's seminal work in this field was characterized by superb elemental analyses, reproducible reaction conditions, and thorough descriptive analysis of isolated products. The incorrect formulation of $[NH_4]_3[IrS_{16}]$ as $[NH_4]_3[IrS_{15}]$ simply resulted from a low S analysis, a problem also noted for $[NH_4]_3[Rh(S_5)_3] \cdot 3H_2O$.[11] By analogy to Rh^{III} and Pt^{IV} chemistry,[4, 10, 11] the existence of $[NH_4]_3[Ir(S_5)_3]$ is entirely plausible. But neither the remarkable chemistry of Hofmann and Höchtlen from 1904 nor the present chemistry provides evidence for its existence.

Experimental Section

$[NH_4]_3[Ir(S_4)(S_6)_2]$ was prepared by allowing $IrCl_3 \cdot nH_2O$ (1.000 g), dissolved in water (10 mL), to react with $[NH_4]_2S_n$ (30 mL), which was prepared by dissolving sulfur (5 g) in 20 wt% $(NH_4)_2S$ (30 mL) at 50 °C. The resultant deep red solution was stirred at 50 °C for 1 h, and then filtered through a plug of celite. The filtrate was divided into two portions, each of which was layered with ethanol/2-propanol (1/1, 40 mL). Crystals were usually observed after 24 h. The mother liquor was decanted, and the crystals were washed with CS_2 and 2-propanol. By appearance, three different products were formed: orange octagonal plates, small red crystals, and brown polycrystalline masses. The orange plates were previously shown to be $[NH_4]_3[Ir(S_6)_3] \cdot H_2O \cdot 0.5\,CH_3CH_2OH$ [6]. The other two products were both identified as $[NH_4]_3[Ir(S_4)(S_6)_2]$ by means of Raman spectroscopy and energy-dispersive X-ray spectroscopy (EDX). The ratio of $[NH_4]_3[Ir(S_6)_3] \cdot H_2O \cdot 0.5\,CH_3CH_2OH$ to $[NH_4]_3[Ir(S_4)(S_6)_2]$ was approximately 1:4, as determined by manual separation of the crystals. The total yield was 1.430 g ($\approx$ 57%). Semiquantitative EDX ratios of Ir:S for $[NH_4]_3[Ir(S_6)_3] \cdot H_2O \cdot 0.5\,CH_3CH_2OH$ and $[NH_4]_3[Ir(S_4)(S_6)_2]$ were recorded on a Hitachi S-4500 SEM, since standard elemental analyses can be misleading and inaccurate for polysulfidometalates [4, 11].

X-ray structure analysis of $[NH_4]_3[Ir(S_4)(S_6)_2]$: red, irregular blocks, crystal dimensions $0.16 \times 0.17 \times 0.13$ mm, tetragonal, D_4^8-$P4_32_12$, $Z = 4$, $a = 12.009(2)$, $c = 15.154(3)$ Å, $V = 2186(1)$ Å^3 ($T = 113$ K), Enraf-Nonius CAD4 diffractometer: $\theta_{max} = 49.94°$, $Cu_{K\alpha}$, $\lambda = 1.54056$ Å, ω-scan mode; of 2487 reflections measured 1121 were independent and included in the refinement. The data were corrected for Lorentz–polarization and absorption effects (empirical method), $\mu = 261$ cm^{-1}. The structure was solved by the Patterson method [15], and refined anisotropically on F^2 by full-matrix least squares [16]; 101 parameters, $R_w(F^2) = 0.120$, $R_1 = 0.054$ for 929 reflections with $F_o^2 > 2\sigma(F_o^2)$, absolute structure parameter $-0.07(5)$, residual electron density 1.12 e Å^{-3}. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the depository number CSD-406601.
