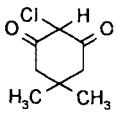
NADH-Dependent Halogenases Are More Likely To Be Involved in Halometabolite Biosynthesis Than Haloperoxidases**

Kathrin Hohaus, Annett Altmann, Wassily Burd, Ilona Fischer, Philip E. Hammer, Dwight S. Hill, James M. Ligon, and Karl-Heinz van Pée*

The detection of chloroperoxidase from the fungus *Caldariomyces fumago*[1] and the development of a simple spectrophotometric assay[2] for the detection of halogenating enzymes based on the synthetic compound monochlorodimedone (**1**) as organic substrate resulted in the subsequent isolation of a number of haloperoxidases from different organisms. All these enzymes produce hypohalogenic acid, which is the actual halogenating agent. Thus, halogenation catalyzed by haloperoxidases lacks substrate and regiospecificity.[3-4] However, investigations of the biosynthetic pathways of different halometabolites have shown that biological halogenation must be specific.[3, 5] Furthermore, the formation of fluorinated metabolites by haloperoxidases is difficult to explain, as fluoride cannot be oxidized in the haloperoxidase reaction.[6]

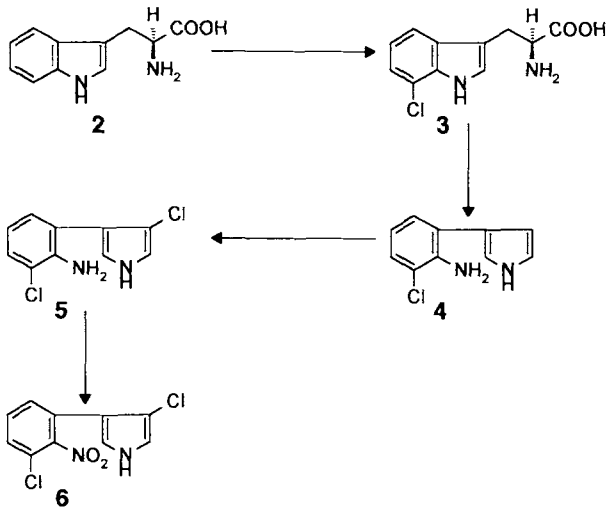


1

Recently, genetic investigations showed that haloperoxidase-type enzymes are definitely not involved in the biosynthesis of chlorotetracycline and pyrrolnitrin.[7-8] These results raise some interesting questions. What other type of halogenating enzymes could exist, and how can they be detected? It had always been assumed that the enzyme oxidizes the halide ion and that the oxidized halide reacts with the organic substrate. However, why couldn't the enzyme first react with the organic substrate in a way that would make it suitable for nucleophilic attack by the halide ion itself?

Apparently all groups working on enzymatic halogenation have ignored the fact that, if they were looking for specific enzymes, they should use the natural substrates for these enzymes and not a substrate like **1**. One reason that this approach was ignored is the lack of knowledge about the structure of these substrates. Thus, prior to the use of a "natural" substrate it had to be established that this compound actually is halogenated in vivo.

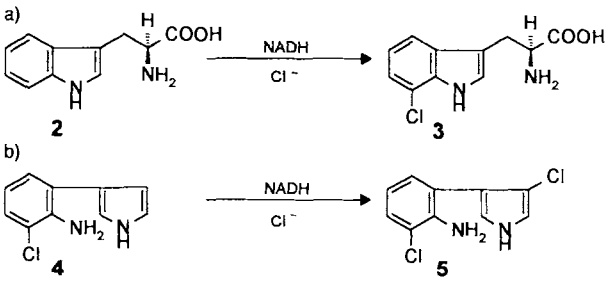
Tryptophan (**2**) would be such a substrate, if the chlorination of **2** to 7-chlorotryptophan (**3**) is the first step in the biosynthesis of the antifungal antibiotic pyrrolnitrin (**6**, Scheme 1).[9] To check this hypothesis, the growth medium of a mutant of *Pseudomonas fluorescens* blocked in the second step of pyrrolnitrin biosynthesis was analyzed. The isolated **3** was identified as the L-isomer by employing D- and L-amino acid oxidases. Thus, chlorination of the L-isomer of **2** was identified as the first step



Scheme 1. Pathway for pyrrolnitrin (**6**) biosynthesis based on the isolation of metabolites and cloning of the biosynthetic genes [9,11].

in pyrrolnitrin biosynthesis by *P. fluorescens*, and this strain therefore must contain an enzyme that catalyzes the specific chlorination of the L-isomer of **2** to the L-isomer of **3**. A second chlorination occurs later, where monodechloroaminopyrrolnitrin (**4**) is chlorinated to aminopyrrolnitrin (**5**, Scheme 1).[9]

Using the L-isomer of **2** as the substrate and a *Pseudomonas fluorescens* mutant that lacked all chromosomal pyrrolnitrin-biosynthesis genes but harbored the gene for the first step on a plasmid, we searched for tryptophan halogenase activity by means of an HPLC assay. As we did not know what kind of cofactor, if any, would be needed, a number of different cofactors were tested. The chlorinated **3** could only be detected when NADH was added to the cell-free extract (Scheme 2a).



Scheme 2. NADH-dependent chlorination of a) L-tryptophan (**2**) to 7-chloro-L-tryptophan (**3**) catalyzed by tryptophan halogenase and b) monodechloroaminopyrrolnitrin (**4**) to aminopyrrolnitrin (**5**) by monodechloraminopyrrolnitrin halogenase.

Attempts to chlorinate **2** with haloperoxidases only resulted in the formation of the oxindole derivative of tryptophan and not in a halogenated product.[10] Chemical chlorination of **2** in the 7-position is also not possible. The enzymatic chlorination of **2** can therefore be regarded as a specific and unusual reaction, although there are a number of naturally produced antibiotics that are derived from **3**.[5]

The addition of NADH to cell-free extracts of a *P. fluorescens* pyrrolnitrin-deletion mutant containing the gene coding for the enzyme that catalyzed the second chlorination step on a plasmid was also necessary for activity. Thus the halogenase chlorinating **4** to **5** is also NADH-dependent (Scheme 2b). As the oxidation of halide ions in an NADH-dependent reaction can be ruled

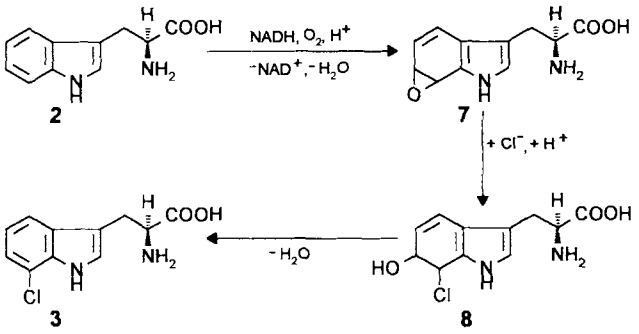
out, the NADH-dependence could be explained by the involvement of oxygen leading to the intermediate formation of an epoxide (**7**). From this enzyme-bound epoxide a halohydrin (**8**) could be formed by the incorporation of halide ion with subsequent specific removal of water (Scheme 3). Thus the organic substrate can not only be chlorinated, brominated, and iodated, but also fluorinated, depending on the specificity of the enzyme for the halide ion. No substantially different halogenating enzyme would be needed for the introduction of fluoride ions.



Scheme 3. Hypothetical mechanism for the NADH-dependent halogenation. Compounds **7** and **8** would probably not be released by the enzyme.

No enzymatically formed products other than **3** or **5** could be detected in the enzyme assays. The enzymes are specific, and tryptophan halogenase does not catalyze the chlorination of **4** or vice versa. Comparison of the amino acid sequences of the two halogenases showed no sequence homology. However, monodechloroaminopyrrolnitrin halogenase was found to be homologous to the halogenase that catalyzes the chlorination in 7-chlorotetracycline biosynthesis.[7, 11]

The newly detected NADH-dependent halogenases, in contrast to haloperoxidases, have at least some of the properties expected of specifically halogenating enzymes. It was always difficult to understand why halogenation by haloperoxidases in vitro produces halocompounds that could not be found in the organisms from which these haloperoxidases had been isolated. It is very likely that haloperoxidases are not the halogenating enzymes involved in the specific biosynthesis of halometabolites. For these reactions NADH-dependent halogenases are much better candidates. Thus, in organisms where discrepancies arise between the halometabolites produced in vivo and the products formed in vitro, the involvement of haloperoxidases should be reinvestigated and NADH-dependent halogenases sought.

Experimental Section

For the isolation of **3**, bacteria were grown in 2 L of glycerol minimal medium [9] in the presence of 8.5×10^{-5} M kanamycin and 6.2×10^{-5} M tetracycline at 30 °C for two days. As **3**, like **2**, is metabolized by a number of different pathways, it was not expected to accumulate in large amounts. Therefore the growth medium was adjusted to pH 5.3 with 1 N HCl and loaded onto an Amberlite CG-120I cation exchange column with a column volume of 25 mL, equilibrated with 0.35 M citrate buffer (pH 5.3). After elution with 1% aqueous ammonia the fractions (2.4 mL) were neutralized with 1 M acetic acid and analyzed by HPLC [12]. Fractions containing **3** were pooled, concentrated under vacuum, and desalted over a Sephadex G-10 column (column volume 5 mL). The fractions (1 mL) were analyzed by HPLC and those containing **3** were pooled and concentrated. The isolated compound was identified by comparison of its retention time, UV spectra, and mass spectra with those of authentic, synthesized **3** [13].

Oxidation of isolated **3** to 3-(3-indolyl)-pyruvic acid by amino acid oxidases was performed in a total volume of 75 µL in 0.2 M Tris/HCl buffer (pH 8.3) in the presence of 9×10^{-4} units of catalase. The reactions were started by addition of 5×10^{-1} units of D-amino acid oxidase or 5×10^{-2} units of L-amino acid oxidase. The assays were incubated at 30 °C with continuous shaking. Samples (20 µL) were analyzed at the start of the reaction, after 60, and after 90 min.

For detection of the halogenase activities, a *Pseudomonas fluorescens* mutant that lacked all pyrrolnitrin-biosynthesis genes but contained the genes for tryptophan or monodechloroaminopyrrolnitrin halogenase on a plasmid was grown for three days as described for the isolation of **3**. Cells were harvested by centrifugation, resuspended in 2 mL g^{-1} cells volume of 100 mM ammonium acetate buffer (pH 6.8) and disrupted by sonication at 2 °C for 6 min. The cell debris was removed by centifugation, and the crude extracts were used for analysis of the halogenase activities. The assays used contained the following components: 200 µL of crude extract, 20 mM NaCl, 0.2 mM **2** or **4** as the organic substrate, 2 mM cofactor, and 0.1 mM ammonium acetate buffer (pH 6.8) in a total volume of 1 mL. After incubation for 16 h at room temperature the reaction was stopped by boiling in water for 5 min in the case of tryptophan halogenase. After removal of precipitated protein by centrifugation, the assay mixture (20 µL) was analyzed by HPLC [12]. With **4** as the substrate, the assay mixture was extracted with 2 × 0.5 mL ethyl acetate. After evaporation of the organic solvent, the extracted compounds were redissolved in methanol (50 µL), and a 20 µL sample of the solution was analyzed by HPLC [14]. The products were identified by comparison of their retention times, HPLC-UV spectra, HPLC-MS spectrum in the case of **3**, and GC-MS spectrum in the case of **5** with those of authentic samples [13,15].

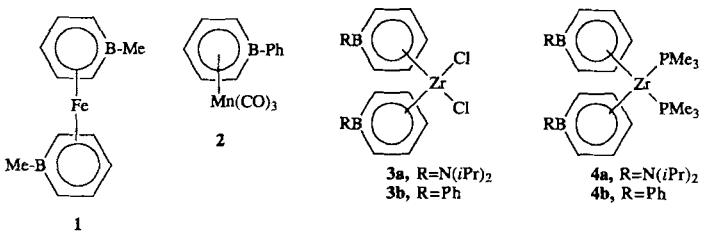
Boratabenzene Zirconium(II) Complexes: An Unusual Annulation with Ethynes**

Arthur J. Ashe III,* Saleem Al-Ahmad, Jeff W. Kampf, and Victor G. Young, Jr.

Dedicated to Professor Gerhard E. Herberich on the occasion of his 60th birthday

1-Substituted boratabenzenes can serve as six-electron, π-bound, anionic ligands towards a variety of metals.[1] The well-investigated late transition metal complexes, for example **1**[2] and **2**,[3] are closely analogous to the corresponding cyclopentadienyl metal compounds. Early transition metal complexes have been more sparingly studied. We recently reported the first zirconium(IV) boratabenzene complex **3a**, which on activation by methylaluminoxane polymerizes ethene with an activity similar to that of $[Cp_2ZrCl_2]$.[4] Since Cp_2Zr^{II} compounds are particularly useful in organic synthesis,[5] an investigation of the corresponding boratabenzene Zr^{II} complexes is appropriate. We have prepared boratabenzene Zr^{II} complex **4b** and find that the PMe_3 ligands are displaced under very mild conditions. The reaction of **4b** with ethyne involves an unprecedented ring annulation to afford complex **5**, which contains the novel ligand 4a-phenyl-8a *H*-4a-boratanaphthalene.



The reaction of **3a** and **3b**[4b] with butyllithium in ether in the presence of an excess of PMe_3 affords the zirconium(II) derivatives **4a** and **4b** in 70% and 75% yields, respectively.[5, 6] In contrast to the corresponding reactions of $[Cp_2ZrCl_2]$, neither the presumed intermediate, an (η^2-1-butene)Zr complex,[6b] nor Zr^{III}-bridged products are detected.[7] The structure of **4a** was confirmed by an X-ray diffraction study (Figure 1).[8]

Comparison of the structures **4a** and **3a**[4] illustrates the differences between Zr^{II}- and Zr^{IV}-coordinated boratabenzenes. Both molecules possess pseudo tetrahedral coordination spheres about the metal centers, which are typical of Group 4 bent metallocenes. However, the B–Zr distances (2.980(7) Å for **3a**, 2.830(3) Å for **4a**) are longer, and the B–N distances (1.396(6) Å for **3a**, 1.438(3) Å for **4a**) are shorter for the Zr^{IV} derivatives. Apparently, the more electron-withdrawing Zr^{IV} slip-distorts away from the boron atom, which is stabilized by B–N π-bonding.[4, 9] Consequently the boratabenzene ligands are η^5-bonded to the central metal in **3a** and η^6-bonded in **4a**.

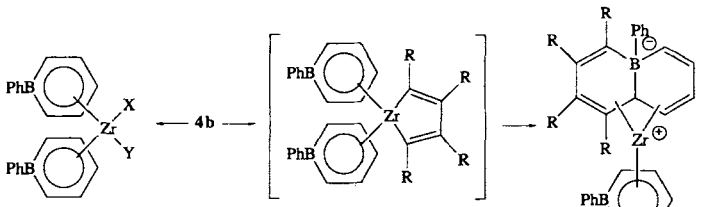
C(1), C(4), C(18), and C(21) not observed. ^{11}B NMR (115.5 MHz, C_6D_6): $\delta = 30.2$ (B1), -19.6 (B2).

[a] The spectral assignments for **5** and **9** use the crystallographic numbering scheme illustrated in Figure 2. [b] *J* values are in Hz.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3618-2014 $ 17.50+.50/0

shows two separate PMe_3 signals ($\delta = 0.58$, 0.78), which reversibly coalesce ($\delta = 0.70$) on heating to 57 °C. Thus **4b** shows rapid PMe_3 exchange.[7, 10] Both PMe_3 groups are readily displaced from **4b** by the addition of the chelating ligand 1,2-bis(dimethylphosphino)ethane to form **6** in 75% yield.[7, 10, 11] Treating **4b** with methyl iodide affords the oxidative addition product **7**,[7, 10, 11] which shows a characteristic ^{1}H NMR spectrum indicating five nonequivalent ring protons.[4a] Similarly the reaction of **4b** with diphenyl disulfide results in cleavage of the S–S bond to afford **8** in 72% yield.[12, 13] These reactions of **4b** are completely analogous to those of $[Cp_2Zr(PMe_3)_2]$ and $[Cp_2Ti(PMe_3)_2]$.



6, X = Y = $Me_2PCH_2CH_2PMe_2$
7, X = I, Y = Me
8, X = Y = SPh

5, R=H
9, R=Me

The reaction of **4b** with ethyne proceeds rapidly to produce adduct **5** as a crystalline solid in 78% yield as well as some polyacetylene. 2-Butyne reacts with **4b** in a similar manner to produce **9**, but no polyacetylenes are observed. Since the ^{1}H, ^{11}B, and ^{13}C NMR spectra of **5** are inconsistent with its formulation as the expected metallacyclopentadiene **10**,[5–7, 14] we have obtained an X-ray structure.

The crystal structural analysis of **5** reveals that two ethyne molecules have added to one of the 1-phenylboratabenzene rings to produce a novel 4a-phenyl-8a-*H*-4a-boratanaphthalene ligand (Figure 2). The zirconium atom is π-coordinated to the butadiene units C13–C16 and C24–C27 of the boratanaphthalene and η^6-coordinated to the phenylboratabenzene. Complex **5** exists as a zwitterion with a formal positive charge on zirconium center, which balances the negative charge on B2.[15] The borate structure is independently indicated by the characteristic high-field signal[16] ($\delta = -23.8$) in the ^{11}B NMR spectrum of **5**. It is particularly significant that C17 and B2 at the ring fusion are well within bonding distance to the metal (C17–Zr 2.390(7) Å, B2–Zr 2.508(7) Å). It seems likely that the electron deficiency at zirconium is partially compensated by bonding to these atoms, which is also suggested by the long B2–C17 bond (1.706(9) Å). Several electrophilic Cp_2Zr^{IV} derivatives feature similar pentacoordinated carbon atoms with C–Zr bonds in the range 2.39–2.58 Å,[17, 18] although **5** is to our knowledge the first example with a zirconium(II) center.

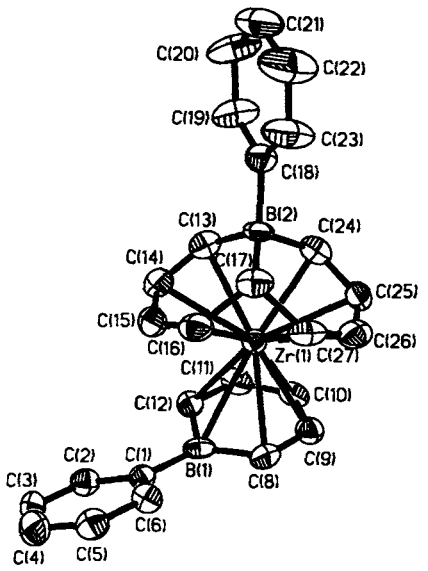


Figure 2. Molecular structure of **5** in the crystal. Selected interatomic distances [Å]: Zr–B1 2.683(7), Zr–C (boratabenzene) 2.498(7)–2.553(7), Zr–B2 2.508(7), Zr–C17 2.390(7), Zr–C(dienes) 2.401(7)–2.495(7), C–C(dienes) 1.356(9)–1.463(10), C16–C17 1.517(9), C17–C27 1.502(9), B2–C13 1.620(10), B2–C17 1.706(9), B2–C18 1.624(10), B2–C24 1.645(10).

Formation of **5** by the addition of two ethyne molecules to a boratabenzene ring is unprecedented. We speculate that the reaction proceeds "normally" to afford metallacycle **10**,[5–7, 10] which is diverted to **5** by transfer of an alkenyl unit to the electrophilic boron followed by carbometalation at the α-C atom by the pendant Zr–dienyl group. Work on this rearrangement continues in our laboratory.[19]

Experimental Section

4a: A solution of **3a** (100 mg, 0.19 mmol) and PMe_3 (150 mg, 1.9 mmol) in 20 mL of ether was treated with BuLi (0.38 mmol) in 150 μL of hexane at −78 °C. The reaction mixture was stirred for 1 h at −78 °C and then allowed to warm to 25 °C for 1 h. The solvent was removed in vacuo, and the residue extracted with pentane. On cooling to −20 °C dark green crystals of **4a** (81 mg, 70%; m.p. 195 °C) were obtained. Correct C,H,N analysis.

4b: In the same manner **3b** was converted into **4b** (84%; brown powder, m.p. 91 °C). High resolution EI-MS calcd. for $C_{28}H_{38}{}^{11}B_2P_2{}^{90}Zr$: 548.1682; found 548.1626.

6: An excess (100 μL) of 1,2-bis(dimethylphosphino)ethane was added to a solution of **4b** (100 mg, 0.18 mmol) in 8 mL of toluene. After stirring for 2 h at 25 °C the solvent was removed in vacuo. The residue was taken up in pentane, which when cooled to −78 °C afforded **6** as a brown red solid (75 mg, 75%). High resolution EI-MS calcd. for $C_{28}H_{36}{}^{11}B_2P_2{}^{90}Zr$: 546.1525; found: 546.1526.

7: A solution of **4b** (100 mg, 0.18 mmol) in 5 mL of toluene was treated with iodomethane (130 mg, 0.91 mmol) at 25 °C. After 2 h the solvent was removed, and the residue was extracted with hexane. Cooling to −20 °C afforded **8** (76 mg, 77%; m.p. 105 °C (decomp.)). High resolution EI-MS calcd. for $C_{22}H_{20}{}^{11}B_2I^{90}Zr$ ($M^+ - CH_3$): 522.9843; found: 522.9827.

8: A solution of **4b** (60 mg, 0.11 mmol) in toluene (5 mL) was treated with diphenyl disulfide (30 mg, 0.13 mmol). The reaction mixture was stirred for 2 h at 25 °C. After removal of the solvent the residue was extracted with pentane. On cooling to −78 °C **7** (50 mg, 72%) was obtained as a solid with m.p. 147 °C. High resolution EI-MS calcd. for $C_{34}H_{30}{}^{11}B_2S_2{}^{90}Zr$: 614.1022; found 614.1041.

5: A solution of **4b** (200 mg, 0.36 mmol) in toluene (10 mL) was stirred for 2 h at 25 °C under ethyne at 1 atm pressure. The solvent was removed under reduced pressure, and the residue was extracted with pentane. Cooling the extracts to −20 °C afforded **5** (100 mg, 62%) as dark red crystals with m.p. 207 °C. High resolution EI-MS calcd. for $C_{26}H_{22}{}^{11}B_2{}^{90}Zr$ ($M^+ - 2H$): 446.0955; found: 446.0961.

9: Analogously **4b** was treated with 2-butyne to give **9** (68%, m.p. 138 °C). High resolution MS calcd. for $C_{30}H_{32}{}^{11}B_2{}^{90}Zr$: 504.1737; found: 504.1747.

Practical Approaches to Analysis, Liquid Crystals, and Alkenes

Trace Analysis: A Structured Approach to Obtaining Reliable Results. Edited by *E. Pritchard, G. MacKay and U. Points*. Royal Society of Chemistry, London, 1996. XIV, 404 pp., hardcover £ 69.50.—ISBN 0-85404-417-5

Within its approximately 400 pages this book contains a lot of useful practical advice. However, it is essential that the reader should already have a certain amount of knowledge about the secrets of trace analysis.

When I started to read this book for the first time, I was struck by the abundance of information on what "trace analysis" really means. The editors have their power-play in the first three chapters. In Chapter 1 the author explains the requirements for a valid and proper trace analysis, including an outline of the possible and necessary methodologies and their characteristics. Here I do not agree with the classification of ICP-MS as a semiquantitative technique for field screening (p. 27). Also the claim that the journals *Analytical Chemistry* and *The Analyst* are all that one needs as a direct route to useful methodology and review articles in analytical chemistry is not justified. Other mothers (publishing houses) also have beautiful daughters (journals) ...

Chapter 2 is probably the most useful one in the whole monograph. All the hints and comments are extremely valuable. Unfortunately the warning at the bottom of page 44 about the use of strong acids is incomplete! Possible artifacts include, for example, effects of filtration on the concentration of PAHs in water. Likely sources of contamination during sample pretreatment are also identified.

Chapter 3 overlaps to some extent with Chapter 2, since sample preparation is again the topic. All the various digestion techniques are discussed in great detail.

Unfortunately, the following chapters provide only a superficial treatment of the subject. Chapter 4 deals with the determination of inorganic analytes, after the sample has undergone the necessary preparation steps. The most popular techniques are presented in a very general way. Here some concrete examples would have been useful. Some modern techniques such as laser-excited spectroscopy or the very successful method of total reflection X-ray fluorescence analysis are not covered. In contrast, a separate section (4.3) is entirely devoted to elemental mass spectrometry with all the known variants. On the other hand, Section 4.4, on ion chromatography, is again at a trivial level. The references given for this topic do not reflect the state of the art.

Chapter 5 ("Organic Analytes: Sample Preparation") covers more or less all the important treatment techniques, but is again not very up-to-date. Emerging methods such as solid phase extraction techniques (SPME) or immunoaffinity columns are not discussed. Here it becomes apparent that the authors' view of organic trace analysis is limited to the more conventional and well-established methods.

This is also seen in Chapter 6 ("Organic Analytes: Determination"). Recently developed techniques such as GC-AED or HPTLC-AMD are not treated. The resolution of MS techniques is given in "plates" (see Table 6.5.3)—why? A typical example, such as dioxin analysis, would have given a much better insight into the use of the various methods, especially for congener analysis (a subject that does not exist in this book!). On the other hand some practical matters, such as the safety aspects of MS, are discussed in more detail than is necessary.

The very important topic "Analysis of Speciated Elements" is treated briefly in Chapter 7, unfortunately without relating it to what has been discussed in the previous chapters. Some very general remarks are offered, for example that HPLC and GC are relatively inexpensive (Table 7.3.1). Here, a great chance to discuss exciting developments in trace analysis is wasted.

Chapter 8 is intended to bridge the gap between organic and inorganic trace analysis (if indeed there is one). Spectrophotometry is introduced at a student level. Colorimetric procedures are certainly not state-of-the-art. Luminescence is treated without introducing the advantages of time resolution. Electrochemical detection is briefly mentioned.

Chapter 8.3 treats a more modern subject, bioanalytical techniques. Enzymatic reactions, immunoassays, and PCR techniques as tools for trace analysis are discussed, and some relatively recent literature is cited.

Chapter 9 ("From Signal Processing to Reporting") is completely unnecessary. Here the reader is introduced to the formula for the standard deviation ...

The strengths of this monograph lie in the discussions of sample treatment and possible artifacts, but there are serious weaknesses in the description of the separation and detection techniques. Modern times have touched this book only slightly. It's a pity.

Introduction to Liquid Crystals. Chemistry and Physics. By *P. J. Collings* and *M. Hird*. Taylor & Francis, London, 1997. 298 pp., paperback £ 15.95.—ISBN 0-7484-0483-X

Over a century has passed since the discovery of liquid crystals in 1988. During that time liquid crystals have developed from just a scientific curiosity to become a very active interdisciplinary field of research with many technological applications. However, although there are a large number of specialized, mainly physics-oriented, monographs on the subject, there are few introductory textbooks. The interdisciplinary nature of the field is an obstacle here, as its study requires some

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

knowledge of both chemistry and physics. This book is the first in a series of monographs on liquid crystals that is planned. It is intended to serve as a general introduction suitable for both physicists and chemists. Thus the authors needed to construct a bridge between tensor algebra on the one hand and synthetic methods (transition metal catalyzed and enantioselective) on the other hand. The book's 13 chapters strike a good balance, with six that are chemistry-oriented and six physics-oriented, together with a general introduction.

The work begins with an introduction to the main classes of liquid crystals and their phase types, accompanied by a brief outline of the history. Regrettably, the latter includes no mention of the pioneering work of D. Vorländers in the period 1900–1935. Vorländers synthesized over 1100 liquid-crystalline substances (which up to 1960 still comprised 90 % of all the then known liquid crystals!), and discovered some important relationships between molecular structure and liquid-crystalline properties.

Chapter 2 deals briefly with some important physical aspects, such as order parameters, X-ray methods, and defects in liquid crystals. This is followed by five chapters which discuss in detail the most important types of mesophases and the molecular structures of the units that form them.

Structure–property relationships in calamitic liquid crystals are discussed in great detail. With the help of well-chosen examples, the authors explain very clearly how the different types of structural units, such as aromatic and alicyclic ring systems, bridging groups, and terminal and lateral substituent groups, determine the stability of the liquid crystalline phases, their types, and their special properties (dielectric properties, elastic constants, viscosity, etc.).

The chapters on discotic liquid crystals, polymeric liquid crystals, and lyotropic systems are less detailed, but they provide a good overview of typical structures and important types of phases.

The chapter on chiral liquid crystals describes not only the cholesteric and ferroelectric mesophases but also some more recent developments, including antiferroelectric, ferrielectric, TGB phases, and chiral discotic phases.

Chapter 8 reviews important methods for synthesizing a wide variety of classes of liquid crystalline materials, and this is an innovative feature of the book. The main emphasis is on modern synthetic methods such as orthometalation reactions and Suzuki cross-coupling reactions, which are illustrated by numerous examples.

The chapter entitled "Identification of Liquid-Crystalline Phases" briefly describes the use of polarization microscopy (including measurements on self-supporting films) and calorimetric methods, and explains some important distinguishing characteristics of nematic phases and different types of smectic phases. However, the choice of texture types shown as examples is disappointing and seems rather arbitrary. Also there is no mention here of the standard works by Demus and Richter and by Gray and Goodby. Furthermore, it would have been useful to include here some representative textures of the new chiral phases and of the columnar and lyotropic phases for comparison. One would also have expected to find X-ray diffraction methods included in this chapter; although the relevant theory has already been covered in Chapter 2, a brief description of typical X-ray diffraction patterns and their interpretation would have been useful.

The chapters that follow deal with dielectric and magnetic properties, instabilities, optical properties, some important theoretical approaches (the Landau–De Gennes theory, the Maier–Saupe theory, and the McMillan model), and the principles of construction of liquid crystal displays (LCDs) and a few other application devices. Thus, the book provides a survey of the many different aspects of liquid crystals, ranging from methods of synthesis to theoretical models.

An appendix contains a list of books for further reading and some selected review articles. However, there are no references to the extensive collections of data on liquid crystals that exist.

The features of this book that especially distinguish it from other introductory monographs on liquid crystals are: a) a detailed discussion of structure–property relationships for calamitic liquid crystals, b) descriptions of antiferroelectric and TGB phases, and c) the description of methods for synthesizing liquid crystals. On the other hand, many topical aspects are not covered. Some examples of those omitted are: polycatenated compounds, liquid-crystalline carbohydrate derivatives, the concept of amphotropic liquid crystals, the induction of columnar phases by charge transfer interactions, thermotropic cubic mesophases, and reentrant phases. Also, apart from one phthalocyanine derivative there is no mention of the metallomesogens, a class of liquid crystalline compounds that has grown at a remarkable rate. Moreover, the appendix contains no references to important review articles on these topics.

The formula schemes and the figures are mainly very clear and easy to understand. Exceptions are the diagrams showing columnar phases on page 12 and discotic nematic phases on page 81, both of which would be difficult for a beginner to understand. Also Figure 3.2 fails to give a clearly recognizable impression of the structure of smectic low-temperature phases, and the phase diagram for a lyotropic system on page 141 is somewhat oversimplified. It would also have been useful to include cubic phases at this point.

To summarize, this book can be strongly recommended as an excellent introduction to the interdisciplinary subject of liquid crystals. All the concepts and terms are introduced in a way that can be widely understood, and therefore one can confidently recommend the book for all readers with scientific interests. In particular, it will be valuable to both undergraduate and postgraduate students wishing to specialize in the field of liquid crystals, by giving them an initial overview of the subject and serving as an important companion to their studies. The book will also be useful to scientists who wish to gain a general overview of liquid crystals.

Preparation of Alkenes. A Practical Approach. (Series: The Practical Approach in Chemistry.) Edited by *J. M. J. Williams*. Oxford University Press, Oxford, 1996. 253 pp., ring-binding £ 29.95.—ISBN 0-19-855794-9

Alkenes are among the most important compounds in organic chemistry, since they not only function as almost universally applicable precursors and intermediates in syntheses, but are often present as structural elements in molecules that one wishes to synthesize. Every chemist who engages in synthetic work is certain to become involved with alkene groups more than once in the laboratory.

In accordance with the aims of the series *The Practical Approach in Chemistry*, of which this is the third volume, *Preparation of Alkanes* is a very useful, clear, and well produced laboratory handbook. It consists of nine chapters by various authors, together with two appendices, covering modern methods for the synthesis of alkenes.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3618-2018 $ 17.50+.50/0

Each of the first eight chapters has as its central core a very detailed description of experimental procedures, broken down into individual steps. Chapter 1 lays the foundation for the chapters that follow, and consists mainly of detailed descriptions of general methods, including especially techniques for working in inert atmospheres. It covers aspects such as setting up the apparatus, transferring materials, and determining the activity of organometallic reagents.

Chapters 2–4 deal with alkene syntheses in which the olefinic double bond is formed by bringing together two components. These methods include the highly successful Wittig reaction and its offshoots (the Horner–Wadsworth–Emmons and Horner–Wittig olefination reactions, the Schlosser and Still–Gennari variants, and the Corey–Fuchs homologization of aldehydes). These are followed in Chapter 3 by olefinations of carbonyl compounds, which are formally derived from the Wittig reaction, the role of phosphorus being fulfilled instead by another heteroatom such as silicon (Peterson), sulfur (Johnson, Julia), or boron. The treatment of olefination methods is completed by Chapter 4, which describes chromium- and titanium-mediated olefinations of carbonyl compounds, including the McMurry, Oshima–Lombardo, and Tebbe reactions, and the use of *gem*-dichromium reagents.

Chapter 5 describes strategies based on elimination and addition–elimination reactions. This is followed in Chapter 6 by methods for preparing alkenes from alkynes. As well as practical advice on performing catalytic hydrogenations of alkynes, this also includes examples of the use of metal hydrides and dissolved metals, and a description of the reduction of alkynes using diimides. To complete the treatment of approaches based on alkynes, Chapter 7 deals with reactions involving the addition of organometallic reagents, including detailed descriptions of hydro- and carbometallations using organoboron, organoaluminum, organozirconium, and organocopper reagents. The preparative part of the book ends with Chapter 8, which is devoted to the increasingly important catalytic coupling reactions, especially those involving palladium catalysts; examples described include the Stille, Suzuki, and Heck reactions.

Finally, Chapter 9 consists of a detailed summary (almost 40 pages) of synthetic methods, classified according to the types of alkenes rather than the strategies employed. The nine sections describe, for example, methods for preparing derivatives with a specified number of substituents (1–4), methods for cyclic olefins, and methods for dienes. This compilation, which does not give detailed laboratory procedures, also introduces some methods, such as the Baylis–Hillman reaction, that were not mentioned in the preceding chapters.

Each of the eight chapters dealing with preparative methods also includes a short theoretical treatment, which is mainly concerned with the configuration of the olefinic double bond created, and with the stereoselectivity of the reaction. Unfortunately, however, as in many other monographs and reviews on preparative methods, hardly any information is given about the chemoselectivity and tolerance with regard to other functions present in the molecules, including protecting groups, an aspect that is especially important in reactions of complex compounds. Another shortcoming is the absence of laboratory recipes for some important types of olefins, such as enol ethers, or for vinyltriflates and *trans*-vinylboronic acids prepared with Matteson's reagent.

To summarize, this practically oriented handbook is recommended for use by advanced students and synthetic chemists, as a resource to help with the more demanding areas of organic synthesis. It should be available in every departmental library, and especially in advanced teaching laboratories and in research groups involved in synthetic work.

Color Atlas of Biochemistry. By *J. Koolman* and *K.-H. Röhm*. Thieme, Stuttgart, 1996. 435 pp., softcover DM 49.80.—ISBN 3-13-100371-5

The *Color Atlas of Biochemistry* is an illustrated text, aimed at students of medicine and the biological sciences. It not only provides an introduction to biochemistry but also gives the reader the basic supporting knowledge of organic, inorganic, and physical chemistry necessary to gain the most from this unique book. Before discussing the contents in detail, here are a few general comments. First, the quality of the diagrams and figures, all in color, is first class. The color plates produced by Jürgen Wirth are well presented, with complex molecular graphics where necessary, and finely detailed chemical structures. Graphical representations of biochemical metabolic pathways are necessarily complex, but by a combination of color coding with astute use of figure legends the biochemical charts at the back of the book serve as an excellent reference source for any student wishing to rapidly glean the most important information from a number of key biosynthetic pathways. Secondly, the figures are all strategically placed on the page facing the relevant text, which is especially important when complex principles are being explained.

The atlas begins with a section termed *basics* and includes areas of chemistry and physical chemistry essential for a rudimentary grasp of biochemistry. These include orbital hybridization and chemical bonding, molecular structure, with explanatory paragraphs on bond polarity, hydrogen bonding, and effective atomic radii, and an excellent section on energetics and reaction kinetics.

The second section, *biomolecules*, discusses carbohydrates, lipids, amino acids and proteins, and nucleic acids. The carbohydrates subsection details the nomenclature of each of the saccharide families and discusses stereochemical aspects, amply supported by Fischer and Haworth projections. The chemistry of sugars is also outlined: redox processes, hydrolysis, acylation, and glycosylation. The lipids subsection offers an initial overview of their classification and biological roles, followed by an in-depth analysis of the biochemistry of fats, phospholipids, glycolipids, isoprenoids, and steroids. Excellent color plates help to simplify the otherwise complex area of plant and animal steroid and isoprenoid biosynthesis. The amino acids subsection comprises an overview dealing with the stereochemistry of the L and D series and a clear explanation of the pK_a values of amino-acids and proteins. The major content then outlines the importance of the peptide bond, subsequent secondary and tertiary protein structure development, and finally the function of structural and globular proteins, such as collagen, α-keratin, and insulin. The subsection discussing nucleosides and nucleotides starts with an outline of the nucleobase structures and progresses to their function. The interplay throughout the cell between the nucleic acids, DNA, mRNA, rRNA, and tRNA during transcription and translation is well illustrated.

The third section, *metabolism*, deals with the reactions involved in the interconversion of the biomolecules discussed in the previous section. The section begins with an explanation of the key role of enzymes in biosystems and includes a useful explanation of enzyme classification, something of a black art to most chemists

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3618-2019 $ 17.50+.50/0

such as ourselves. There then follows a brief outline of enzyme catalysis, with necessarily simplified views of mechanisms by which enzymes are known to effect catalysis, including transition-state stabilization, covalent catalysis, and acid–base catalysis. The discussion of mathematical modeling of enzyme kinetics and inhibition introduces the fundamentals such as the Michaelis–Menten model and the important inhibition mechanisms that a student needs to understand. The following subsection focusses on the mechanisms of metabolic regulation and includes transcriptional control with a specific example of the *lac* operon, hormonal regulation of glycogen biosynthesis, and allosteric regulation of aspartate transcarbamoylase. The biochemistry of so-called 'energy metabolism' processes is then discussed. This includes a thermodynamic profile of the phosphoric acid anhydride bond in ATP, photosynthesis, the citric acid cycle, glycolysis, the respiratory chain, ATP biosynthesis, and studies of the key enzymes as components and regulatory elements in these processes. This is followed by catabolic and anabolic metabolic processes in which carbohydrates, fats, proteins, and nucleic acids are the key components. Specific examples to note are the β-degradation of fatty acids, transamination and deamination of amino acids, purine, pyrimidine, and porphyrin biosynthesis.

Section 4, *organelles*, gives a preliminary introduction to cell structure and methods for cell fractionation, before describing in detail the functions of some of the component organelles, including the mitochondria, the cell membrane, the endoplasmic reticulum, and lysosomes. This section contains a much more detailed study of genomic function than given earlier (Section 2), with particular reference to gene technology, DNA sequencing and cloning, PCR, and RFLP.

Section 5, *tissues and organs*, forms a major part of the book and reinforces the utility of this atlas to the medical biochemistry student. The authors discuss the biochemistry and, where necessary for clarification, the relevant physiology of most of the major organ classes in the human body, including the blood, liver, kidneys, muscle, connective tissue, and brain.

Section 6, *nutrition*, presents a biochemical perspective of this area and outlines the natural sources and functions of vitamins, minerals, and trace elements in the human body.

Section 7, *hormones*, describes some examples of the different hormone classes and their mechanisms of action. Specific examples include lipophilic hormones such as the steroids involved in reproduction and metabolic control, and their biosynthesis and inactivation are described. Secondary messengers are also described in this section and clear diagrams help to delineate the mechanisms of adenylate cyclase activation and signal transduction by G proteins.

The book ends with a number of clear and very well constructed metabolic charts as mentioned earlier. For students these charts may serve to make the process of learning and memorizing these key complex biochemical transformations much less soul-destroying than from a standard text.

On the whole the book serves as an excellent visual portrayal of the key biochemical processes occurring in humans and mammals. In conjunction with other larger and more detailed works on biochemistry, this atlas supplies the necessary information for the student of biochemistry.

Molecular Modeling. Basic Principles and Applications. By *H.-D. Höltje* and *G. Folkers*. VCH Verlagsgesellschaft, Weinheim, 1996. 194 pp., hardcover DM 198.00.—ISBN 3-527-29384-1

Molecular Modelling. Principles and Applications. By *A. R. Leach*. Longman, Singapore, 1996. 595 pp., paperback £ 35.00.—ISBN 0-582-23933-8

Molecular modeling, more accurately described as computer-aided simulation of molecular properties, is now a widely used method in many areas of chemistry. When used correctly by someone with the necessary know-how, the techniques grouped together under this heading can lead to a better understanding of molecular processes, and can provide knowledge for planning experiments and for developing chemical compounds with novel properties. However, the attitudes of many scientists towards these methods are far from realistic. At one extreme there is the view that any chemist can easily use modeling methods, whereas at the other they are regarded as merely games for computer freaks, and are thought to need much further development before they can become a useful tool of chemical research. From my own observations, anyone believing the first statement usually changes sooner or later to the second. Modeling methods are of great value for the purposes mentioned above, but only in the hands of those who know how to use them effectively. On the other hand, anyone (and not only chemists) can produce meaningless colorful images on the computer screen. The two books reviewed here aim to provide their readers with the background knowledge needed to use molecular modeling techniques effectively.

Molecular Modeling. In the first book Höltje and Folkers have set out to provide a broadly-based practical introduction to molecular modeling methods. Appropriately, a distinction is made between the treatment of "small molecules" and that of proteins, and one example of each type is discussed.

The topics treated in the chapter on small molecules are: methods for generating three-dimensional atomic coordinates, methods of geometrical optimization, conformational analysis, methods for calculating molecular interaction potentials, the identification of pharmacophores, and the use of data banks. For each of these topics the authors discuss in detail the different approaches and the critical steps. The main emphasis is not on the scientific background (e.g., details of force-field calculations), but on practical aspects such as different minimization techniques, the calculation of atomic charges and of their effects, hydrophobic interactions, or the overlapping of molecules.

The introduction to the modeling of proteins describes in detail methods for predicting the structures of homologous proteins. Each of the individual steps in sequence alignment from predictions of side-chain and main-chain structures, and in the refinement of models using force field and molecular dynamics models, is briefly described. Methods for taking into account solvent effects are also described, and the authors discuss possible ways of validating a structural model that has been developed. This part of the book ends with a discussion of protein properties and of protein–ligand complexes. The only section that seems rather out of place here is the brief description of the principles of three-dimensional protein structures, which can be found in any textbook of biochemistry.

Each of the above two subject areas is illustrated by discussing an instructive example. For the small molecule case the example chosen is the simulation of a receptor binding pocket, leading to the identification of a pharmacophore. For proteins the example described in detail is the modeling of a protein–ligand com-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3618-2020 $ 17.50+.50/0

plex involved in antigen presentation by a protein belonging to MHC Class I.

This book is ideally suitable for scientists or advanced students who need a quick up-to-date overview of the methods and capabilities of molecular modeling, and who wish to be able to evaluate alternative methods in cases where there are several possible approaches. In most cases the authors have deliberately limited their treatment to brief descriptions of the various methods, leaving the reader to obtain background information and further details from the literature references attached to each chapter. This is the only aspect of the book that I would criticize, since here it would have been a great advantage to also include the titles of the papers cited. However, despite this minor complaint I hope that the book will reach a wide readership. It will be of great value in helping the reader to realistically evaluate the capabilities of these methods.

Molecular Modelling. Although the title of Leach's book is almost identical to that of the one reviewed above, the concept on which it is based is quite different. Whereas the book from the VCH publishing house has a strong practical bias with only a brief sketch of the theory, Leach has set out to present the theoretical background of molecular modeling methods.

A short introductory chapter with definitions of some important concepts is followed by one of about 100 pages containing a well written and informative, but very theoretical, treatment of quantum-mechanical models. Chapter 3 then gives a detailed account of empirical force-field models for the simulation of larger molecules. Although this subject is covered in many books on quantum-mechanical aspects, this is one of the best treatments that I have yet seen.

Chapter 4 discusses the various energy minimization techniques that are used in conjunction with both quantum-mechanical and force-field methods. The author also considers practical questions about the applicability of the techniques. Applications of modeling methods to the simulation of molecular properties are discussed in Chapter 5. The next two chapters are concerned with molecular dynamics simulation methods and Monte Carlo methods, both of which can be used to generate large numbers of states for describing the dynamics and statistics of molecular systems. The author discusses the differences between the methods, and considers the best choice for a given situation.

Chapter 8 deals with conformational analysis, including studies involving the molecular conformation space, molecular fitting methods, the use of structural data banks, and the problem of predicting conformational structures of proteins. There are many points in this chapter where one would have preferred to see the topics treated in greater depth. The last two chapters are concerned with some of the more sophisticated applications of molecular modeling methods, such as calculations of free enthalpy, the simulation of solvation processes and of chemical reactions, and the discovery or design of new molecules; aspects covered include drug design, ligand design, docking, QSAR, and lead structures.

The book is heavily biased towards theory (480 pp.) as compared with applications (about 100 pp.). Nevertheless, it clearly brings out the variety of uses of the methods. Each chapter ends with suggestions for further reading and a comprehensive list of references (including titles of publications). It is a carefully written work which is satisfying to read, and can be recommended for everyone who wishes to understand modeling methods. It should also serve as a reference source to provide essential background information when one is using modeling software packages in practical situations. It is not a suitable book for gaining a quick overview of the subject.

These two books have been written with different aims, and both fill real gaps. In many respects they are, in fact, complementary. Anyone with a serious intention to work in the field of molecular modeling should ideally use the two books in combination. On the other hand, the reader who expects to make only occasional use of these methods should rely on the book by Höltje and Folkers, while reserving the option to refer to Leach's book or to the original literature in doubtful cases. Both books have the potential to become standard works.

The development of stable alkylidene–ruthenium and alkylidene–molybdenum complexes has resulted in a significant broadening of the application potential of olefin metathesis in organic chemistry.

ANGEWANDTE CHEMIE ©WILEY-VCH

Olefin Metathesis in Organic Chemistry

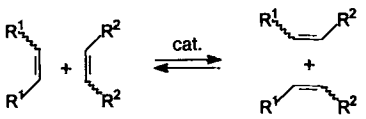
Matthias Schuster and Siegfried Blechert*

Transition metal catalyzed C–C bond formations belong to the most important reactions in organic synthesis. One particularly interesting reaction is olefin metathesis, a metal-catalyzed exchange of alkylidene moieties between alkenes. Olefin metathesis can induce both cleavage and formation of C–C double bonds. Special functional groups are not necessary. Although this reaction—which can be catalyzed by numerous transition metals—is used in industry, its potential in organic synthesis was not recognized for many years. The recent abrupt end to this Sleeping-Beauty slumber has several reasons. Novel catalysts can effect the conversion of highly functionalized and sterically demanding olefins under mild reaction conditions and in high yields. Improved understanding of substrate–catalyst interactions has greatly contributed to the recent establishment of olefin metathesis as a synthetic method. In addition to the preparation of polymers with fine-tuned characteristics, the metathesis today also provides new routes to compounds of low molecular weight. The highly developed ring-closing metathesis has been proven to be a key step in the synthesis of a growing number of natural products. At the same time interesting applications can be envisioned for newly developed variants of bimolecular metathesis. Improvements in the selective cross-metathesis of acyclic olefins as well as promising attempts to include alkynes as viable substrates provide for a vivid development of the metathesis chemistry.

Keywords: carbene complexes · heterocycles · homogeneous catalysis · metathesis · olefins

1. Introduction

Olefin metathesis is a transition metal catalyzed reaction in which formally a mutual exchange of alkylidene groups between two substituted alkenes occurs (Scheme 1). In other words, the



Scheme 1. General principle of olefin metathesis of symmetrically substituted olefins.

metathesis constitutes a catalytic method for both cleaving and forming C–C double bonds. The new developments reported here point out the large potential of this reaction type in organic synthesis. Although catalyzed C–C bond formations play an important role in synthetic chemistry, and the reaction principle has been known in polymer chemistry for a long time, thanks to the emergence of novel catalysts, olefin metathesis has recently advanced to a widely applicable synthetic method.

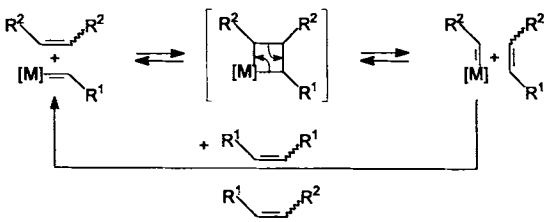
In 1955 Anderson and Merckling described the catalytic polymerization of norbornene by Ti^{II} compounds formed in situ.[1] In 1964 Banks and Bailey observed disproportionation of olefins at elevated temperatures in the presence of heterogeneous catalysts.[2] At about the same time Natta and co-workers reported the ring-opening polymerization of cyclic olefins by homogeneous catalysis.[3–5] Fundamental studies towards the understanding of this reaction were performed by Calderon et al.[6–8] and Mol et al.[9] By investigating the conversion of labeled olefins, it was demonstrated that an exchange of alkylidene groups occurs during metathesis. At first it was assumed that the alkylidene rearrangement proceeds through a bis(alkylidene)metal intermediate in which both olefin ligands are coordinated to the metal atom.[10–12] Chauvin et al. were the first to postulate that the reaction proceeds via a metallacyclobutane (Scheme 2).[13] According to these ideas,[14–17, 36]



Scheme 2. Mechanism of olefin metathesis according to the Chauvin model.

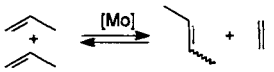
which are still valid today, olefin metathesis proceeds by a [2+2]cycloaddition between a C–C double bond and a metal–carbene complex followed by cycloreversion. The double-bond formation generally does not proceed under stereocontrol—that is, with the exclusion of numerous intramolecular reactions—and *E*/*Z* mixtures result as metathesis products. The use of 1,2-disubstituted olefins results in the formation of regioisomeric metallacyclobutane intermediates, which lead to mixtures of differently substituted products.

2. Industrial Applications

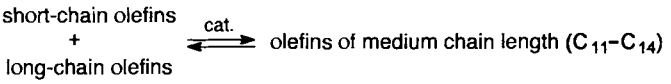
Olefin metathesis was used early on in technical processes.[18] One classical example is the Phillips triolefin process[19] (Scheme 3), in which propene is converted into a mixture of ethane and 2-butene. The reverse reaction can also be used as needed; the required butene is obtained by dimerization of ethane. Technically the most important current application of the metathesis is a partial step within the Shell Higher Olefin Process (SHOP),[20, 21] a combination process starting with ethane to produce C_{10}–C_{18} olefins. The metathesis is applied in this process to make use of the early and late distillation fractions of the nickel-catalyzed ethane oligomerization. By double-bond isomerization and subsequent metathesis, it is possible to obtain additional olefins with the desired number of carbon atoms in a cyclic controlled process (Scheme 3). Since the establishment of the SHOP in 1979 plants with a capacity of several 100000 metric tons annually have been erected.[22]

Another area of application for metathesis chemistry is the polymerization of olefins. Representative for a series of established processes, we list here only the Norsorex process[23] of the CDF-Chimie company and the Hüls–Vestenamer process (Scheme 3).[24, 25] These processes are based on the ring-opening polymerization of norbornene (Norsorex, 45000 annual tons)[22] and cyclooctene (Vestenamer), respectively. Current developments in the area of metathesis polymerization are the subject of Section 4.

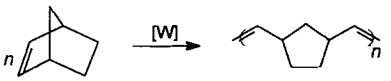
A) Phillips triolefin process



B) Shell higher olefin process (excerpt)



C) Norsorex process



D) Hüls–Vestenamer process

Scheme 3. Important technical metathesis processes.

Additional applications include preparation of neohexene (3,3-dimethyl-1-butene)[26] by reaction of 2,4,4-trimethylpentene with ethane, ring opening of cyclic olefins to α,ω-diolefins[27] as crosslinkers for the olefin polymerization, and ring expansion of cyclic olefins to cyclic diolefins containing twice the number of carbon atoms. Interesting perspectives could arise from other intensively studied reactions, including those for use in replenishing raw materials. Therefore, with metathesis reactions it is possible to convert unsaturated fatty esters[18, 28] into chain-shortened fatty acids,[29, 30] long-chain dicarboxylic acids,[31] and synthetic triglycerides.[32]

Siegfried Blechert, born 1946 in Aalborg (Denmark), studied chemistry at the Universität Hannover (Germany), and received his Ph.D. in 1974 from Prof. E. Winterfeld. After holding a research position in Gif-sur-Yvette (France) with Prof. P. Potier, he finished his habilitation at the Universität Hannover. In 1986 he held positions at the Universität Bonn and Universität Münster. After a four-year appointment as a C3 professor in Bonn, he succeeded Prof. F. Bohlmann at the Technische Universität Berlin in 1990. His research interests include the development of synthetic methods and strategies as well as the chemistry of natural and biologically active compounds.

S. Blechert

M. Schuster

Matthias Schuster, born 1963 in Bad Muskau (Germany), studied biochemistry in Leipzig (Germany) and received his Ph.D. in 1991 from Prof. H.-D. Jakubke. He received a research stipend from the Deutsche Forschungsgemeinschaft and joined Prof. C.-H. Wong's group at the Scripps Research Institute, La Jolla, CA (USA), where he investigated enzyme-catalyzed accesses to unnatural peptides and glycoconjugates. After holding a research position with Prof. S. Dieckmann at the Institut für Moleculare Biotechnologie in Jena (Germany), he is now a research fellow at the Institut für Organische Chemie der Technischen Universität Berlin.

3. Catalysts

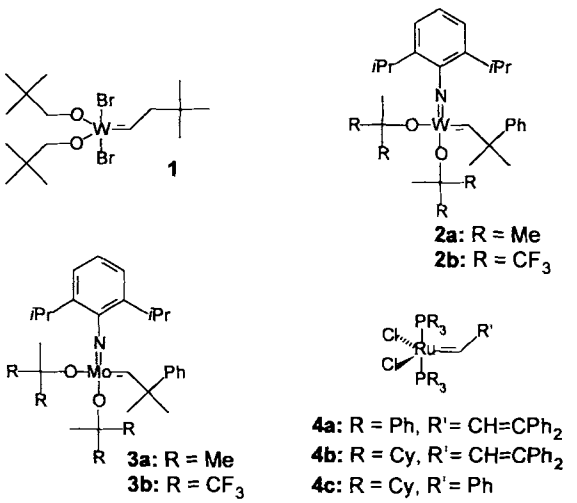
In recent decades a large number of homogeneous, microheterogeneous, and heterogeneous metathesis catalysts have been reported.[22, 33–36] Catalyst activities and reaction conditions are determined by both the catalyst type and the transition metal. The catalysis proceeds by the formation of salts or complexes of the early and late transition metals; however, abnormal reaction systems such as catalysis with irradiated silica gel surfaces have also been reported.[37]

Heterogeneous catalysts that have long been used as contacts in petrochemical metathesis include $MoO_3/CoO/Al_2O_3$, $WO_3/SiO_2/Al_2O_3$, and Re_2O_7/Al_2O_3. The reaction temperature necessary for heterogeneous catalysis is strongly dependent on the catalyst metal. Whereas the Co/Mo catalyst is active at temperatures as low as 150 °C, other systems require temperatures over 300 °C.

The "classical" complex catalysts are obtained by combining transition metal salts (WCl_6, $MoCl_5$, $ReCl_5$, etc.) and their complexes with main group organometallic compounds (for example $RAlCl_2$, SnR_4). Therefore, they can be included in the group of Ziegler–Natta type catalysts. Typical homogeneous classical catalyst systems include $WCl_6/EtOH/EtAlCl_2$, $WCl_6/Et_2O/SnR_4$, $MoCl_2(NO)_2(PR_3)_2/RAlCl_2$, and $ReCl_5/Al_2O_3$. The use of small amounts of oxygen-containing compounds (ROH, ROR, O_2) leads to an increase in activity. These catalysts are generally active at room temperature. Catalysts based on late transition metals such as ruthenium and osmium (for example $[Ru(H_2O)_6](tos)_2$; tos = $MeC_6H_4SO_3^-$) are less active than the salts of early transition metals.[38] In comparison to other systems, however, they tolerate polar functional groups including protic compounds such as water.[39] Although the classical catalysts based on transition metal salts are easily obtained, they are poorly defined with respect to the actual active catalytic component, since only a part of the metal is directly involved in the catalytic process. Their activity is therefore controllable only to a certain extent, which complicates their specific application in organic synthesis.

Important advancements in this area have been the identification of methyltrioxorhenium (MTO) as the actual catalyst precursor of the $Re_2O_7/SnMe_4$ system, and its synthesis by Herrmann and co-workers.[40, 41] Immobilized MTO on acidic metal oxide supports (for example $MTO/Al_2O_3–SiO_2$) catalyzes reactions such as the self-metathesis of allyl halides, ethers, and silanes, unsaturated carboxylates and nitriles, as well as ethenolyses and ring closing metathesis polymerization already at room temperature.[42] Herrmann recently presented another molecularly defined, surface-bound carbene precursor based on tris(neopentyl)nitridomolybdenum(VI).[43] The application spectrum of olefin metathesis to organic synthesis has been significantly expanded mainly by the introduction of stable alkylidene–metal complexes (Scheme 4).

The first catalysts of this type were obtained by Osborn[44–48] (for example **1**) and Schrock[49–53] (for example **2**) by thermal H_α abstraction. The majority of the applications described below are based on the fourfold-coordinated neopentylidene and neophylidene complexes of molybdenum (**3** in Scheme 4) introduced by Schrock and co-workers,[54] as well as the ruthenium–alkylidene compounds (**4** in Scheme 4) developed by Grubbs et al.[55–58] The stabilized alkylidene–transition metal complexes used as catalysts are correctly referred to as initiators, as they must first be converted into the actual catalytically active metal–carbene complex by alkylidene exchange with a double bond. This initiation rate is very high in the case of **3**, and strongly dependent on the substituent R′ in the case of **4**. A significant advantage of the new ruthenium catalysts such as **4c** is their high rate of initiation. The dependence of catalyst activity on the ligand is shown for **4**; **4b** shows significantly higher metathesis activity than **4a**. Both **3b** and **4c** are commercially available. In contrast to **3**, Grubbs's ruthenium–alkylidene complexes tolerate a large number of polar functional groups and are less sensitive towards humidity and oxygen. Thus, they meet a crucial criterion for application in organic synthesis. Moreover, they are more easily available by ring opening of cyclopropanes[55, 56] (**4a** and **4b**) and by carbene transfer in the presence of diazoalkanes[57, 58] (for example **4c**). The lower tolerance of the Schrock molybdenum complexes towards functional groups is often compensated by significantly higher metathesis activity, which also allows the conversion of sterically demanding double bonds. In addition to Grubbs's ruthenium(II) complexes, allyl ruthenium(IV) complexes which constitute highly active metathesis catalysts in the presence of aliphatic diazo compounds were recently introduced.[59]



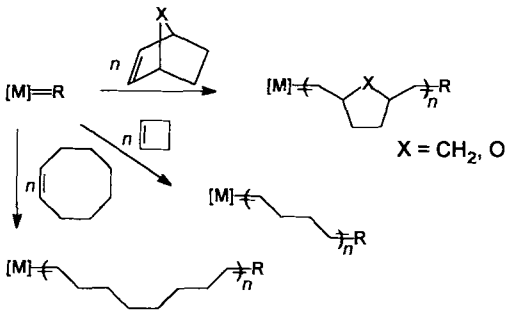
Scheme 4. Selected stable metal–carbene initiators.

In light of the repeated application of these expensive alkylidene–metal complexes, and to avoid contamination of the synthesized products with the used metal, immobilization of the catalysts on polymeric supports is an interesting concept. First studies in this area were reported by Grubbs et al.[60] based on ruthenium–carbene complexes of type **4**. The catalysts bound to polystyrene (2% divinylbenzene (DVB)) show lower metathesis rates than the corresponding soluble systems; they are, however, significantly more durable. Recently developed photoactivatable metathesis catalysts[61, 111, 112] are of great interest for application in polymerization.

4. Current Developments in Polymer Synthesis

The long established *r*ing-*o*pening *m*etathesis *p*olymerization[1] (ROMP) has been described in many re-

views.[34, 35, 61–66] The application potential of this method was greatly expanded by the development of highly active and defined alkylidene–metal complexes. In contrast to the classical catalysts, the modern alkylidene–metal initiators allow for the realization of "living" polymerizations due to their high metathesis activity and initiation rates; the metal–carbene intermediate formed during ring opening is stable on the time scale of the polymerization reaction.[35] As shown in Scheme 5,

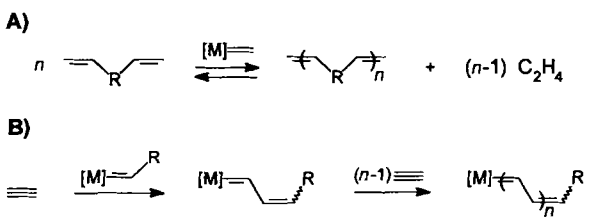


Scheme 5. "Living" ROMP of various strained cycloolefins.

the catalytic metal complex remains attached to the growing polymer chain during living ROMP. Strained cyclic olefins are used as monomers, since, due to the ring strain, the double bonds react highly selectively with the catalyst and enhance product formation.

Since the polymerization can be terminated selectively by addition of an aldehyde (for example benzaldehyde), which causes oxygen transfer to the catalyst, polymers of defined chain lengths are easily available. By alternating the addition of two or more monomers to the living chain, it is possible to synthesize defined block copolymers.[67–69]

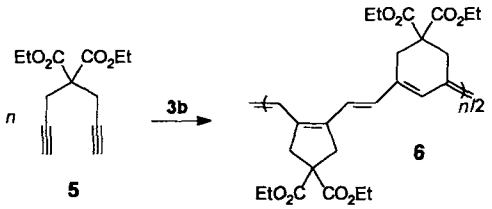
A relatively new polymerization variant is the *a*cyclic *d*iene *met*athesis[70] (ADMET) in which terminal dienes (such as 1,9-decadiene or 1,5-hexadiene) are used as starting materials. Furthermore, polymerization of functionalized[71–75] and conjugated[76] olefins was also investigated. The polymerization proceeds as a stepwise cross-metathesis of the terminal double bonds (Scheme 6A). As opposed to the ROMP, which proceeds



Scheme 6. Acyclic metathesis polymerization (ADMET) of A) dienes and B) acetylenes.

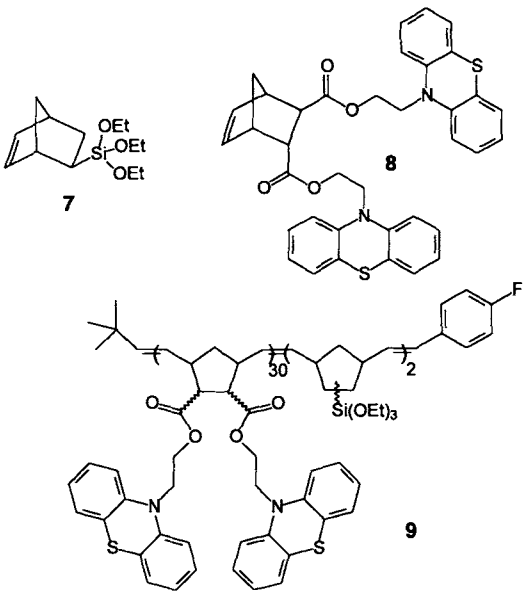
atom economically, the formation of the stoichiometric by-product ethene leads to an irreversible reaction for ADMET.[74–78] This nonliving polymerization yields products of high dispersity with (*E*) and (*Z*) double bonds.

Although metathesis of acetylenes has long been known,[79, 80] the development of the new alkylidene–metal initiators has only recently permitted living polymerizations.[81] The mechanism correlates to that proposed by Chauvin, in which conjugated metal–carbene complexes are formed.[13] When asymmetrically substituted acetylenes are used, two isomeric carbene complexes are obtained that exhibit different reactivities. An interesting variant of the acetylene polymerization is the cyclopolymerization of derivatives of 1,6-heptadiyne.[82–88] Starting from diethyl dipropargyl malonate (**5**) and **3b**, Schrock and co-workers synthesized cyclopolymer **6** with very low dispersity by living polymerization (Scheme 7).[35]



Scheme 7. Molybdenum-catalyzed cyclopolymerization of diethyl dipropargyl malonate.

Modern catalysts allow controlled construction of metal and semiconductor clusters[89–94] as well as redox-active polymers.[95, 96] The redox-active polymer **9** in Scheme 8 was

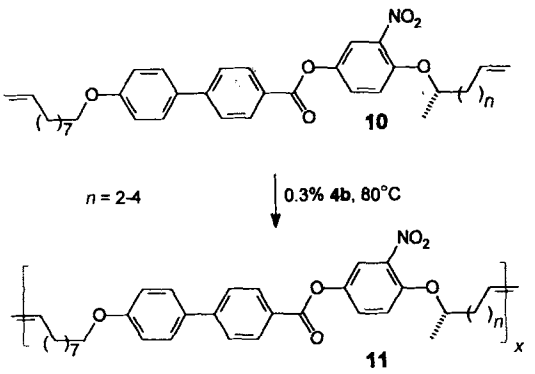


Scheme 8. Redoxactive copolymer **9**, synthesized by ROMP from **7** and **8**, that is suitable for the direct coating of electrode surfaces.

obtained by molybdenum-catalyzed copolymerization of monomers **7** and **8**.[97] While the redox-active properties of **9** can be traced back to the side chain of **8**, the triethoxysilyl functionality allows efficient and direct fixation of the polymer to the various electrode types.

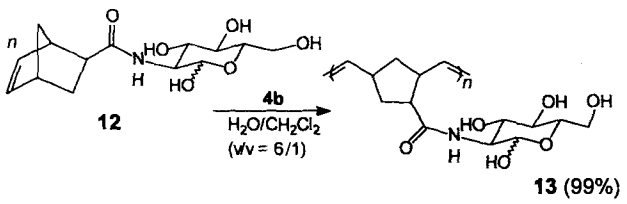
Liquid-crystal polymers are also readily available by polymerization of suitable monomers.[83, 98–104] While polymers with mesogenic side chains can be prepared by ring-opening polymerization, ADMET opens the way to main-chain liquid

crystals. One interesting application in this area is the ruthenium-catalyzed polymerization of mesogenic "α,ω-dienes" to yield oligomeric ferroelectric liquid crystals such as **11** (Scheme 9).[105]



Scheme 9. Synthesis of a main-chain liquid-crystalline polymer **11** by ADMET.

The pronounced tolerance of Grubbs's ruthenium catalyst **4b** enabled the ROMP of the unprotected, sugar-substituted norbornene **12** (Scheme 10) in an aqueous-organic two-phase system.[106] Living polymerizations with **4c** were recently reported in predominantly aqueous solutions.[107]



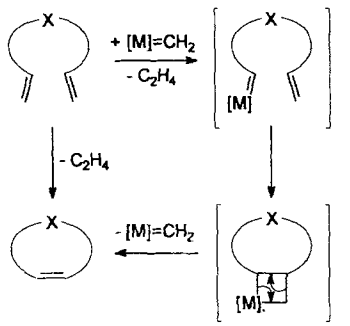
Scheme 10. Ruthenium-catalyzed ROMP of an unprotected sugar-substituted norbornene (**12**).

A fundamental problem of polymerizations is their stereochemical control. In addition to undergoing *cis*/*trans* isomerism, polymers with chiral centers adjacent to the formed double bonds can have various tacticities. By choosing specific ligands one can obtain all-*cis* and all-*trans* polymers with partly uniform tacticites. Using 2,3-bis(trifluoromethyl)norbornadiene with the hexafluoro-*tert*-butoxide catalyst **3b** led to exclusive formation of the *cis*-polymer[108] (75% tactical), while the use of the *tert*-butoxide catalyst **3a** resulted in the corresponding all-*trans* polymer ($\approx$100% tactical).[109] Furthermore, the stereochemistry can be controlled by the use of chiral catalysts. Therefore, use of the racemic form of [Mo(CHCMe$_2$Ph)(N-2,6-Me$_2$C$_6$H$_3$){BINO(SiMe$_2$Ph)$_2$}] (BINO = 1,1'-binaphthyl-2,2'-dioxy) yielded completely tactical all-*cis* poly-(dicarbomethoxynorbornadiene) and poly-[2,3-(bis)trifluoromethylnorbornadiene).[110]

Olefin metatheses can also be initiated photochemically. It was only recently discovered that sandwich complexes of the type [(η^6-arene)Ru(η^6-arene)]$^{2+}$ as well as nitrile complexes of the type [(NC–R)$_6$Ru]$^{2+}$ can be activated by UV radiation,[61, 111] and thus allow *p*hotoinduced *r*ing *o*pening *m*etathesis *p*olymerization (PROMP). Activation of the catalytically inactive sandwich complex occurs by photoinduced solvation of the metal. Since [Ru(solvent)$_6$]$^{2+}$ functions as the catalytically active complex, PROMP with ruthenium–sandwich complexes corresponds to ROMP with [Ru(H$_2$O)$_6$](tos)$_2$. To date the latter is the most active ruthenium complex for the polymerization of strained cyclic olefins in aqueous solution.[39] Activation of the nitrile complex occurs by photoinduced labilization of the extremely stable Ru–CN bond and corresponding ligand exchange. Complexes of the type [Ru(NCR)$_{6-x}$(H$_2$O)$_x$]$^{2+}$ are being discussed as catalytically active species. For both catalyst systems a nonlinear dependence of the molecular weight of the polymeric products on the monomer:catalyst ratio is observed, which is typical for nonliving polymerizations. The first PROMP based on photochemically formed catalysts of the Schrock type was also recently introduced.[112]

5. Ring-Closing Metathesis (RCM)

The intramolecular olefin metathesis of α,ω-diolefins leads to cyclic products (Scheme 11). The driving force for this transformation is the release of highly volatile ethylene. Although *r*ing-*c*losing *m*etathesis (RCM) was used relatively early for synthetic purposes, for example by Tsuji[113] and Villemin,[114] it has not become established as a method.



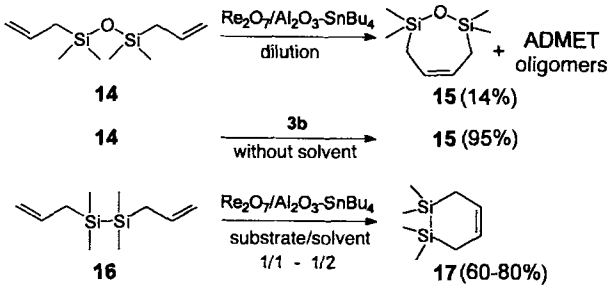
Scheme 11. Mechanism of RCM.

In recent years significant activity has been observed in this area. The versatility of the molybdenum catalysts **3b** and the ruthenium complexes **4b,c** in carbo- and heterocyclizations of very different ring sizes was demonstrated for many examples, even in the presence of diverse functional groups. Ring-closing metatheses have proven to be key steps in various total syntheses.

5.1. Synthesis of Five- to Seven-Membered Rings

Acyclic dienes can be used as substrates for metathesis polymerizations (ADMET) or ring-closing reactions (RCM). Which reaction path applies depends primarily on ring size, dilution, substrate, and catalyst. Four-membered rings cannot be obtained in this way, while five- to seven-membered rings should form readily due to their relatively low ring strain.

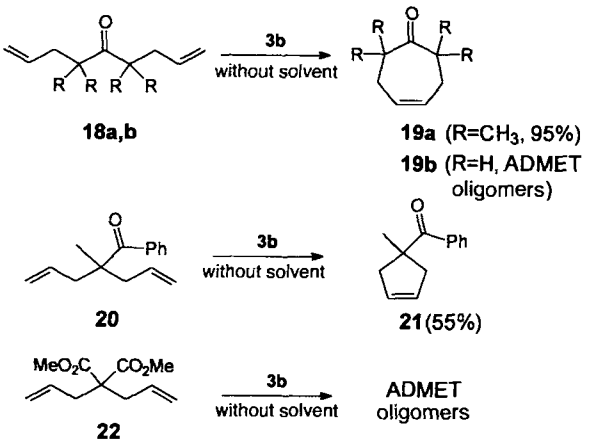
Catalyst dependency can be demonstrated with the conversion of **14** into **15** (Scheme 12). Even at high dilution the heterogeneous rhenium system affords primarily oligomers with the



Scheme 12. RCM at different dilutions.

seven-membered ring as a by-product.[115] In contrast, the homogeneous Schrock molybdenum complex cyclizes the same substrate in high yield, even without solvent.[116] The rhenium catalyst does not always fail during RCM. In fact, disilacyclohexene **17** was obtained in useful yields even at increased concentrations.[115] Instead of the corresponding five-membered ring, oligomers are again primarily formed with the same catalyst.

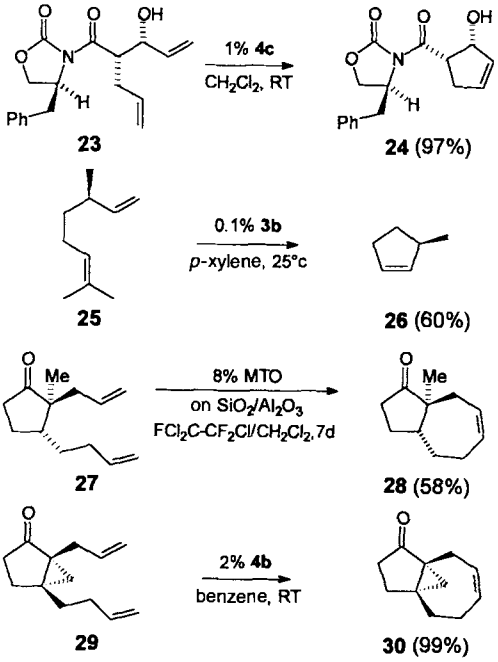
Intermolecular olefin metatheses of acyclic dienes can generally be prevented by applying the dilution principle. However, RCM at higher concentration is advantageous due to the more rapid conversion. The required dilution for a specific ring size is often strongly dependent on the substituents. Forbes et al. reported systems in which ring closure with **3b** was favored by the Thorpe–Ingold effect, and thus also possible without solvent (Scheme 13).[116] Due to the geminal dimethyl substituents, **18a**



Scheme 13. Olefin metathesis without solvent.

reacts to form the seven-membered ring **19a** in high yield, whereas **18b** reacted exclusively intermolecularly under the same conditions. The reaction paths are in agreement with results of MM2 calculations. The different reactivities of the diallyl derivatives **20** and **22**, however, are not easily predictable. Compound **20** cyclizes even in its pure form, whereas the ring closure of **22** occurs only in solution.[117]

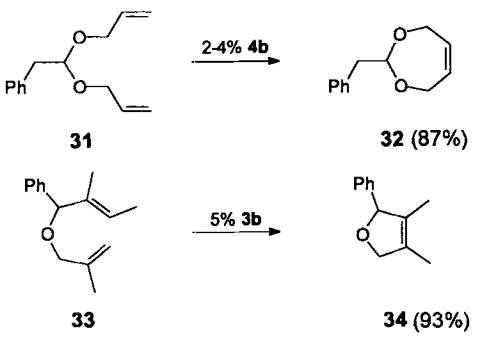
Ring-closing metatheses in which five- to seven-membered carbocycles are formed often proceed without complications; they do, however, require selection of the proper catalyst depending on functional groups as well as steric demands. A valuable resource is Grubbs's ruthenium complex **4c**. Due to its high tolerance towards substituents, it can cyclize allyl alcohol **23**, obtained by aldol addition, cleanly to the almost enantiomerically pure cyclopentenol derivative **24** (Scheme 14), which is a precursor for a carbocyclic nucleoside.[118] The optically active



Scheme 14. Carbocyclic ring closures; RT = room temperature.

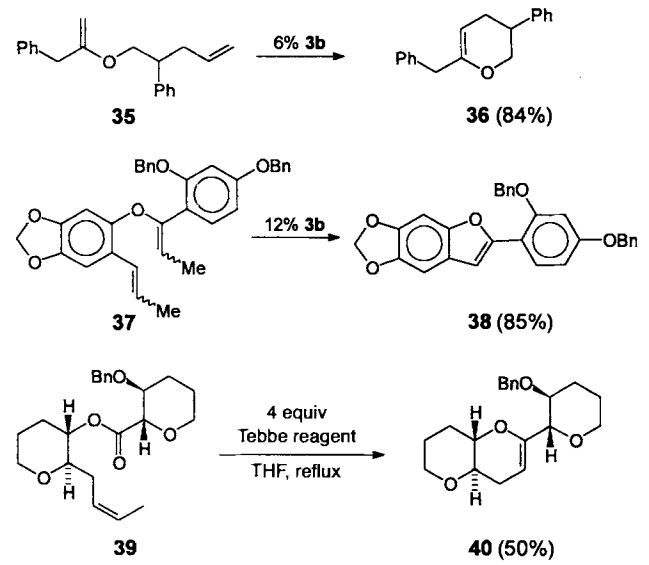
methylcyclopentene **26**, which is interesting for the synthesis of chiral polymers, was obtained by Sita with only 0.1% of the molybdenum catalyst **3b** from β-citronellene.[119] The relatively low amount of catalyst required for this reaction is presumably based on the lack of heteroatoms and the tendency of **3b** to induce the metathesis of higher-substituted olefins. Although **25** can be cyclized with **4c**, it requires higher amounts of catalyst.[117] The perhydroazulenes we prepared demonstrate the suitability of metathesis for constructing condensed ring systems.[120] In contrast to **28**, the more strained tricycle **30** cannot be obtained using MTO; with **4b**, however, it is formed nearly quantitatively.[121]

Olefin metatheses with derivatives of allyl alcohols are not unproblematic, since many catalysts are consumed by β-elimination of the generated carbene complex. The new generation of ruthenium complexes **4b** and **4c** as well as the molybdenum catalyst **3b** tolerate allyl ethers and acetals without problem, and are therefore suitable for the synthesis of cyclic ethers. The rate of RCM correlates well with the degree of substitution of the olefin substrates and with the ring size. Seven-membered rings and especially higher-substituted alkenes generally require longer reaction times. Examples for the synthesis of cyclic ethers are given in Scheme 15. Both types of catalyst are suitable for cyclization to seven-membered rings such as **32**; however, the more readily accessible and less sensitive ruthenium catalyst is generally preferred.[122] Ring-closing metatheses with di- or even trisubstituted double bonds generally require the more reactive Schrock complex **3b**.[123] The RCM to form **34** demonstrates the principle suitability of the metathesis for constructing tetrasubstituted double bonds.



Scheme 15. Synthesis of cyclic ethers.

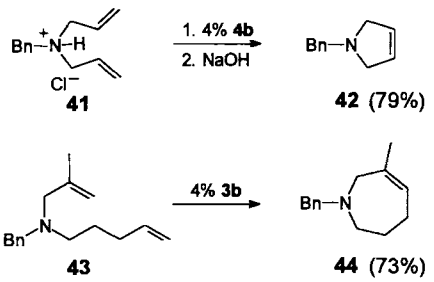
As Grubbs et al. have shown, **3b** also reacts with enol ethers. This opens versatile possibilities for the synthesis of O-heterocycles such as dihydropyran **36** or benzofuran **38** (Scheme 16).[124]



Scheme 16. Synthesis of cyclic enol ethers.

Depending on the position of the enol ether double bond, RCM can also be used for synthesizing enolizable cyclic ketones. The used enol ethers can be obtained by carbonyl olefination of the ester by the Utimoto–Takai method or with the Tebbe reagent.[125, 126] Under extreme conditions metatheses can even be catalyzed by the Tebbe reagent. Thus, one can combine olefination of an ester with RCM. Such cyclizations were recently used by Nicolaou for synthesizing ring systems of type **40**, which are interesting as they represent a subunit of naturally occurring neurotoxic polyethers.[174, 128] However, this two-step reaction in which the olefination occurs first requires an excess of the organometallic reagent. Catalytic cyclizations with **3b** to form brevetoxin subunits have been described by Clark and Kettle.[129] In contrast, **4c** is not suitable for such ring-closing reactions.

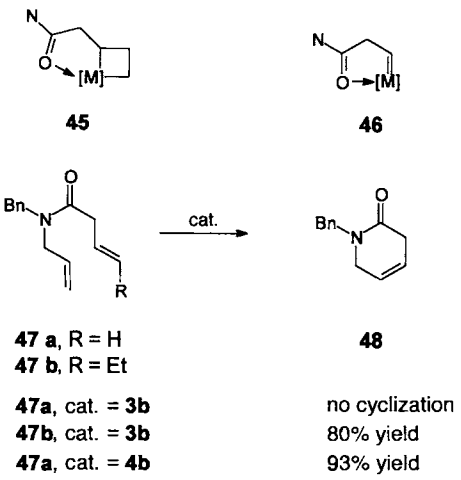
Various studies in recent years have demonstrated the usefulness of RCM for constructing N-heterocycles. Due to the importance of nitrogen-containing compounds, for instance in the synthesis of alkaloids and other biologically active substances, the method is an enrichment of synthetic chemistry. In some cases the ring-closing reactions are not unproblematic, because the catalysts may be inhibited by the complex-forming properties of amines and amides. RCM reactions with basic amines present a substantial problem, even with the use of Grubbs's ruthenium catalyst, which is relatively inert towards various functional groups. Benzyldiallylamine, for instance, could be cyclized only after conversion into the hydrochloride **41** (Scheme 17).[122] In contrast, tertiary amines are converted



Scheme 17. RCM of tertiary amines.

cleanly to N-heterocycles such as **44** with the use of the generally more sensitive Schrock complex **3b**.[130] We discovered that the catalyst-inhibiting complexation with basic nitrogen can often be suppressed by steric hindrance.

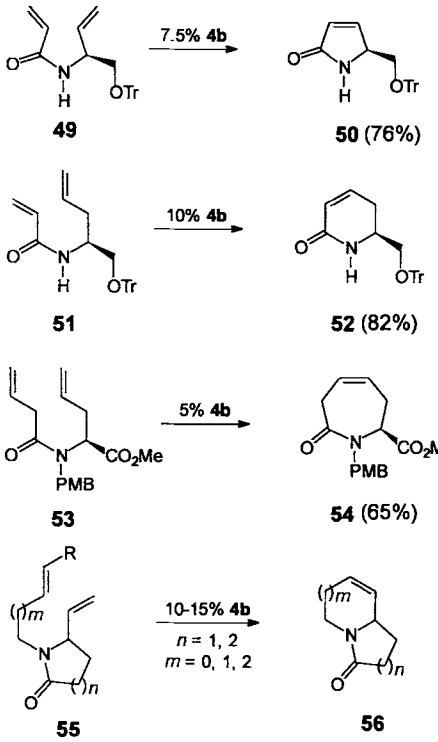
Although **3b** is very suitable for RCM of basic tertiary amines, it causes problems for the conversion of certain amides. In reactions with α,β- or β,γ-unsaturated compounds, the catalysts may become inhibited by intramolecular interaction with the carbonyl group (**45** and **46**, Scheme 18). Grubbs was able to



Scheme 18. Effects of complexating structural elements.

solve this problem by using higher-substituted double bonds.[130] The ring closing initiating first metathesis reaction can be directed by steric effects. Primary attack at the *N*-allyl group of **47b** prevents formation of an inhibiting chelating structure. However, **47a** cannot be converted with **3b**. Fortunately, the two above-mentioned catalyst types complement each other even in this case. Complexes **4b** or **4c** have considerably less problems with α,β- or β,γ-unsaturated monosubstituted amides such as **47a**, and provide **48** in good yields (Scheme 18).

In many cases Grubbs's ruthenium catalysts are active even in the presence of free NH-amides. This leads to interesting application possibilities for the conversion of amino acids and peptides.[131] However, the tolerance of these functional groups cannot be generalized. Starting with optically active vinyl and allyl glycine, we prepared various pyrrolidine and piperidine derivatives by RCM (Scheme 19),[132] and thereby discovered

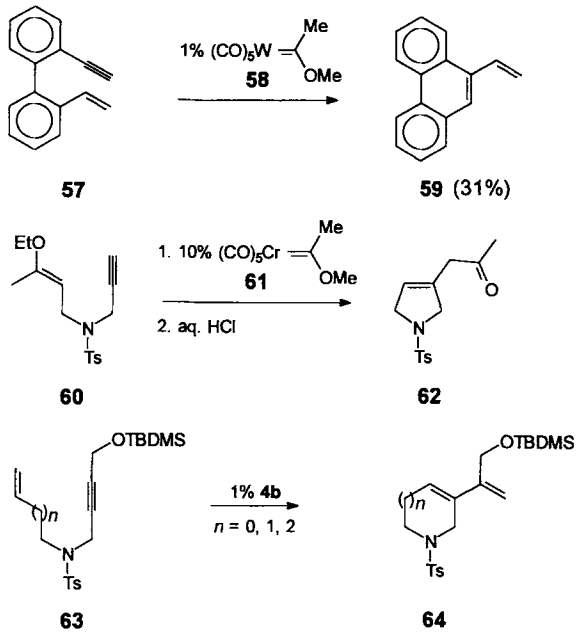


Scheme 19. Synthesis of substituted N-heterocycles; Tr = Ph_3C, PMB = *p*-$MeOC_6H_4CH_2$.

that the NH-amides **49** and **51** could be cleanly cyclized. Ring closure of such structural units is apparently favored due to steric blocking of the NH group by the neighboring trityl group. Sterically less demanding protecting groups provide significantly lower yields for RCM. Comparable effects were observed by Rutjes et al. for amino acid synthesis.[133] For cyclization of amide derivatives of allyl glycine, additional blocking of the nitrogen proved to be advantageous. For example, when the corresponding free NH compound was used instead of the *p*-methoxybenzyl-protected amide **53**, the yield of the cyclization decreased to 20%. Recently Guibé et al. also used a protected amide for synthesizing an unsaturated lactam with a six-membered ring.[134] Numerous biologically interesting alkaloids contain pyrrolizidine, indolizidine, or chinolizidine ring systems. Such structural units are also accessible by RCM. Martin et al. synthesized amides of type **55**, which provided the molybdenum-catalyzed bicyclic compounds of type **56**, from succinimide or glutarimide.[135] We were able to prepare similar bicycles with the use of **4b**; unfortunately cyclizations to yield the more strained pyrrolizidinone derivative were unsuccessful with this method.[136]

Ring-closing metatheses have also been used for synthesizing phosphorus and sulfur heterocycles.[137, 138] These functional substituents are apparently tolerated by only few catalysts. Diallylsulfide, for example, was not converted with **4c** at all. However, RCM to 2,5-dihydrothiophene proceeded smoothly with **3b**; this transformation was also described with an aryloxo(chloro)neopentylidene–tungsten complex.[138, 139]

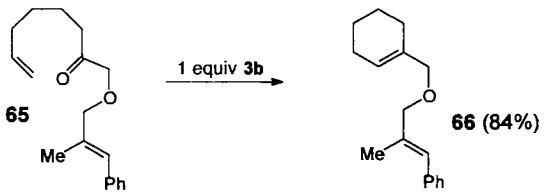
Triple bonds are also suitable probes for metathesis reactions, even though ring-closing metatheses with triple bonds are seldom. Fundamental studies were performed by Katz,[140] who was able to cyclize the rigid enyne system **57** in moderate yields using the tungsten–carbene complex **58** as the initiator (Scheme 20). A methylidene–tungsten complex presumably



Scheme 20. RCM with enynes; Ts = *p*-$MeC_6H_4SO_2$, TBDMS = *tert*-butyldimethylsilyl.

functions as the catalytically active species. Mori reported heterocyclizations with the Fischer chromium–carbene complex **61**.[141, 142] Cyclization between enol ethers and triple bonds to form five-membered rings allows regeneration of the Fischer complex. Depending on the substituents at the double bond, various enol ethers can be obtained in addition to their hydrolytic products. One positive example is the two-step transformation of **60** to **62**. More attractive is RCM of enynes of type **63**, which proceed with relatively low amounts of the catalyst and in good yields, since the required substrates are readily accessible.[143] Carbocyclizations of monosubstituted acetylene derivatives were described by Murai et al. with $[RuCl_2(CO)_3]_2$ and CO.[144]

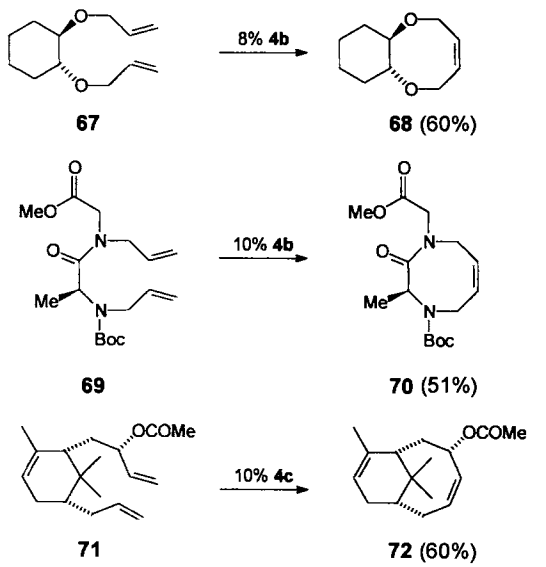
Ring-closing metatheses are also possible between an olefin and a carbonyl group (Scheme 21). Oxygen transfer to the metal during these reactions leads to inactivation of the catalyst. Therefore, the reaction is not catalytic. In contrast to the previously described olefination and metathesis sequence using the Tebbe reagent (see **39** → **40**, Scheme 16), in the case of **3b** primary attack occurs at the C–C double bond.[145] Cyclization of esters requires the more reactive analogous tungsten complex **2b**.[146]



Scheme 21. RCM with a ketone.

5.2. Synthesis of Medium-Sized and Large Rings

The efficiency of a cyclization reaction often becomes apparent in the preparation of medium-sized rings. Here also, the metathesis appears to be quite a powerful tool. A particular challenge is the synthesis of eight-membered rings, since the olefins required are often suitable monomers for competing ROMP. The balance between RCM and ROMP is certainly affected by ring strain. In the cyclization of diallylethers to eight-membered rings, Grubbs observed relatively smooth ring closure of **67** (Scheme 22), whereas the analogous *cis* compound provided the more strained eight-membered ring in only 20% yield.[147]

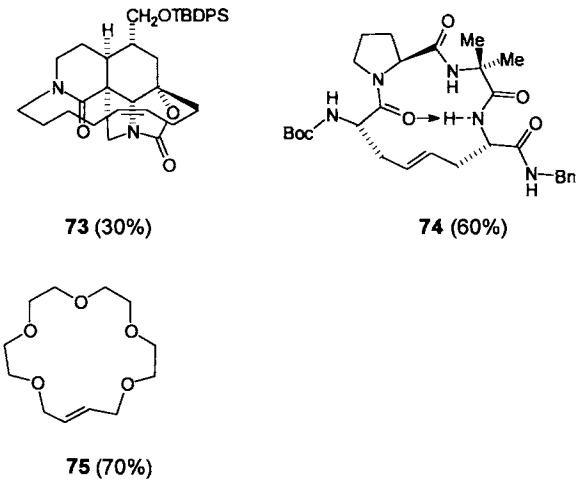


Scheme 22. Synthesis of eight-membered rings; Boc = *tert*-butoxycarbonyl.

In cyclizations which can compete with bimolecular C–C bond formations, it is absolutely crucial to maintain a high degree of dilution. A conformationally favored cyclization to an eight-membered ring, which was performed at a concentration of 0.005 M, yielded the diazocine derivative **70** in 51% yield from a dipeptide (Scheme 22). Upon replacement of the allyl amide substituent with an allyl ester under the same reaction conditions, the conformation of the substrate changed and prohibited cyclization. Grubbs et al., Martin et al., and Winkler et al. reported the use of RCM to access acozine ring systems, which are contained in many natural products.[147–150] The metathesis was also used for synthesizing various carbocycles.[147] Recently, we were able to use the ruthenium-catalyzed ring closure of **71** for synthesizing an AB-taxane system (**72**), which has a relatively strained structure due to the geminal dimethyl group and the annelation of the six-membered ring.[151]

Cyclization to an eight-membered ring does not present the biggest challenge. More problematic are ring-closing metathesis reactions to yield nine-membered rings. Barrett, Giles et al. used RCM with β-lactams in reaction with **3b** to obtain the eight-membered ring in 53% yield; the homologous nine-membered ring was obtained in only 12% yield.[152] Comparable observations were recently made by Clark and Kettle for cyclizations to form brevetoxin subunits.[153] Little is known about the synthesis of other medium-sized rings.

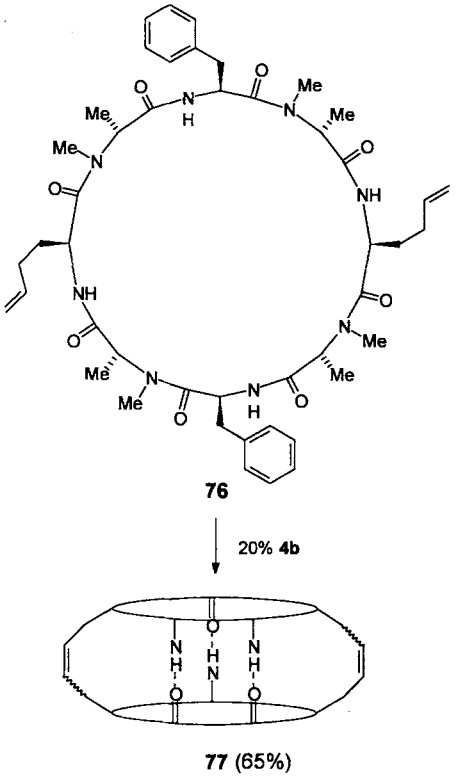
Larger ring systems are generally more readily accessible. Due to the ring size, *cis* and/or *trans* double bonds can be formed. The yields are not only dependent on the ring size, but also on the position of the resulting double bond. Ring-closing metathesis has been successfully used in the synthesis of various substance classes (Scheme 23). Despite the low yield the construction of the highly functionalized pentacycle **73**, which contains the ABCD system of the alkaloid manzamine A, is noteworthy.[154] However, the **4b**-catalyzed cyclization to the 13-membered ring required a reaction time of five days. Significantly more rapid was the ring closure to the 14-membered tetrapeptide **74** when using the same catalyst.[131] For the synthesis of the acyclic peptide, Grubbs used racemic allyl glycine. From the mixture of the four resulting diastereomers, only one cyclized. In the reaction of the pure compound with 20% **4b** at a dilution of 0.002 M, **74** was obtained in 60% yield. Beyond these conformationally favored cyclizations, Fürstner et al. described ring closure to large and very large rings starting from other substrates.[155] With small amounts of catalyst, König and Horn successfully synthesized crown ethers in good yields with only 1% **4c** at a relatively high concentration of 0.1 M.[156] Besides the 17-membered ring **75**, larger benzannelated compounds were also prepared.



Scheme 23. Macrocylic compounds prepared by RCM; TBDPS = *tert*-butylphenylsilyl.

Ring-closing metathesis was also used successfully in the area of supramolecular chemistry. Wasserman et al.[157] reported the formation of catenanes in the process of RCM to form large rings. In contrast to earlier assumptions, these reactions proceed by a statistical threading process.[158] McKervey and Pitarch

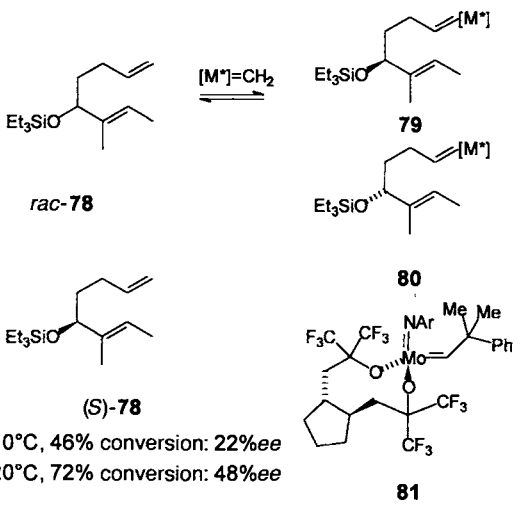
used the metathesis for synthesizing cage compounds.[159] Calix[4]arenes were converted into diethers with pentenyl bromide, and bridged by RCM. One of the largest cyclic compounds constructed by metathesis is the 38-membered ring **77**.[160] Supramolecular interactions between cyclopeptides **76** were used in the synthesis of this ring. In nonpolar solvents, these molecules arrange themselves to cylindrical arrangements by intermolecular hydrogen bonding. Based on the C_2 symmetry of the peptide unit, two diasteromeric dimer structures can be formed. In one of the diastereomers the homoallyl glycine units are in adjacent positons, which allows the noncovalent interactions to be used for the synthesis of the tricyclic cylindrical peptide **77**. The two-step reaction with **4b**, in which the last step is an RCM occured with an impressive yield of 65% (Scheme 24). Three double-bond isomers were isolated. As expected in polar solvents, no cyclizations occured due to the missing H bonds.



Scheme 24. Use of the template effect for the synthesis of peptide suprastructures.

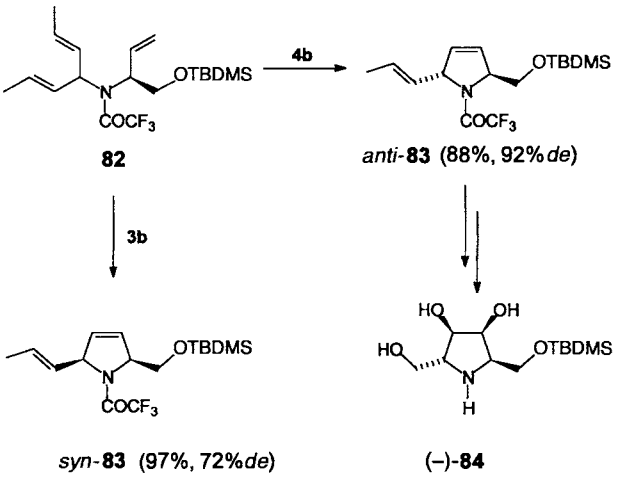
5.3 Asymmetric RCM

Due to the large synthetic potential of ring-closing metathesis, asymmetric variants are particularly important. In this area there is still a great need for development. Although chiral catalysts have been used for polymerizations, as illustrated in Section 4, the first example of an asymmetric RCM with a chiral catalyst was only recently reported.[161] This case followed the concept of converting racemates of chiral diolefins of type **78** with the chiral catalyst **81**, a modification of **3b**, into diastereomeric metal–carbene complexes (Scheme 25). Due to the different energies of the transition states resulting from the diastereomers, it was possible to achieve a kinetic racemic separation based on the different cyclization rates of **79** and **80**. The degree of substitution of the olefin controls the primary attack. In light of the *ee* values obtained to date, synthetic applications of this process are currently not envisioned.



Scheme 25. Kinetic racemic separation by olefin metathesis with **81**.

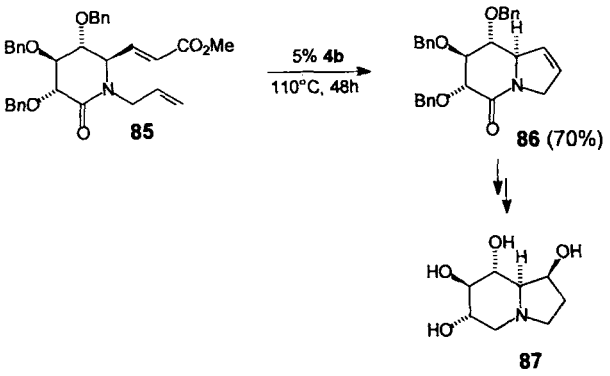
As numerous natural products and biologically active substrates contain α,α′-disubstituted heterocyclic units, we investigated the stereocontrolled construction of such systems with asymmetric RCM. In principle, an existing chiral center should control the cyclization with a prochiral diene unit. The required control of the primary attack was also achieved by using differently substituted double bonds. Surprisingly, the ring closure of **82** with **3b** afforded the product with *syn* orientation of the two substituents, while the *anti*-isomer of **83** was obtained with high diastereoselectivities when using **4b** (Scheme 26).[162] Although the catalysts lead to different ligand orientations during the metatheses, a clear explanation and predictability of the observed selectivities are not yet possible. Polyhydroxylated pyrrolidine derivatives are of interest as enzyme inhibitors. This prompted us to use this process for synthesizing the homoazasugar (−)-**84** from enantiomerically pure vinyl glycinol.[163]



Scheme 26. Catalyst-specific asymmetric RCM.

5.4 Synthesis of Natural Products

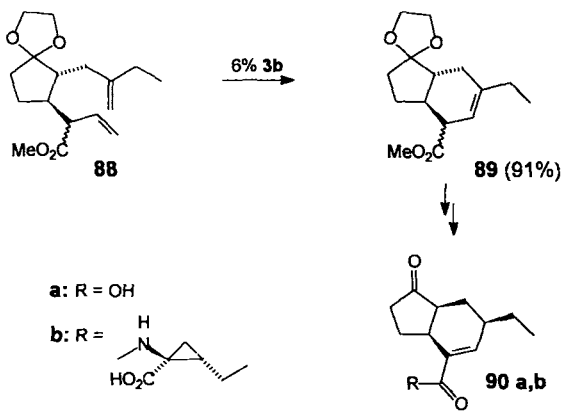
In recent years the ring-closing metathesis developed into an efficient, widely applicable method for forming C–C bonds. As a result of the pronounced tolerance to many different functional groups, the method has increasingly been used in the area of natural-product synthesis. We used RCM for synthesizing naturally occurring prolinol derivatives.[163] (+)-Castanospermin (**87**) belongs to the same family of polyhydroxylated alkaloids, which are interesting as aza analogues of saccharides. Overkleeft and Pandit synthesized lactam **85** from tetrabenzylglucopyranose.[164] This RCM, in which an acrylic ester resulting from a Wittig olefination is cleaved instead of a volatile alkene, requires relatively drastic reaction conditions (Scheme 27). The corresponding substrates with two terminal



Scheme 27. Synthesis of castanospermin (**87**).

olefins or a phenyl-substituted double bond cyclize much more readily, but are more difficult to obtain because of the competing elimination of benzyl alcohol during the Wittig reaction. The multistep introduction of the fourth OH group was accomplished by oxidation with osmium tetroxide, since epoxidations gave only unsatisfactory results.

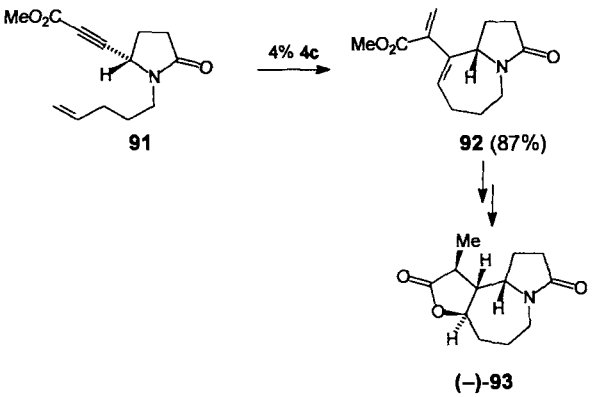
Coronatin (**90b**) is a strong phytotoxic fungus metabolite which has found new interest due to its analogy to some phytohormones. We prepared coronafacinic acid (**90a**) by metathetic ring closure of diene **88**,[165] in which the double bond is not further functionalized, but instead isomerized (Scheme 28). Due to steric hinderance, only one diastereomer of the 1:1 dia-



Scheme 28. Synthesis of coronafacinic acid (**90a**).

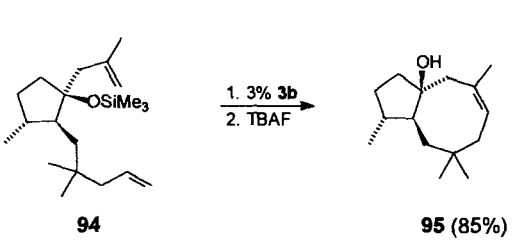
stereomeric mixture which resulted from a Michael addition could be cyclized with the ruthenium catalyst **4b**. On the other hand, with **3b** complete conversion into the bicyclic substrate **89** was achieved. During RCM with the unprotected ketone within the five-membered ring, partial carbonyl olefination was observed with simultaneous consumption of the catalyst. Deprotection, ester hydrolysis, and acid-catalyzed isomerization lead from **89** to **90a**.

Enyne metathesis to a seven-membered ring is the key step in a total synthesis of (−)-stemoamide **93**, according to Kinoshita and Mori.[166] The synthesis of the insectizidal tricyclic alkaloid starts from the acetylene ester **91**, which is obtained enantiomerically pure from pyroglutamate. Enyne metatheses with these functional groups provided poor yields in earlier studies, which was attributed to the instability of the resulting ester-substituted conjugated butadiene unit.[143] In the present case a disruption of the conjugation by steric effects was desired, and ruthenium-catalyzed RCM did in fact provide bicycle **92** in good yield, the ester group of which was used for acidic lactone annellation with $CuBr_2$ on Al_2O_3 (Scheme 29).



Scheme 29. Synthesis of stemoamide (**93**).

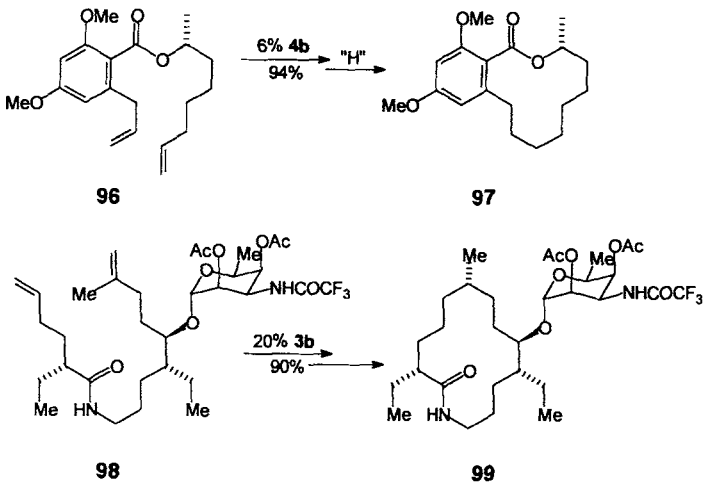
Eight-membered rings can also be prepared by olefin metathesis. Fürstner and Langemann recently reported a short synthesis of dactylol (**95**; Scheme 30), an isoprene isolated from



Scheme 30. Synthesis of dactylol (**95**); TBAF = tetrabutylammonium fluoride.

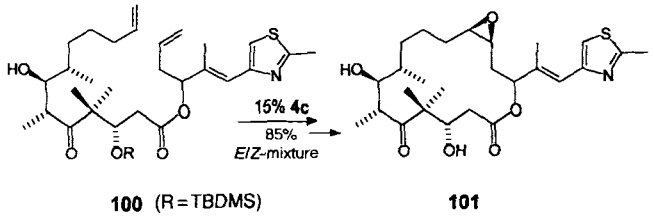
maritime organisms.[167] The precursor **94** was prepared in five steps from cyclopentenone. The synthesis of the tertiary carbinol by addition of a methallyl–cerium compound afforded an approximately 1:1 diastereomeric mixture, which was used for synthesizing 3-α-*epi*-dactylol. Protection of the OH group proved to be crucial, since the free carbinol was recovered after treatment with **3b**. It apparently deactivated the catalyst by complexation.

Ring-closing metathesis is very suitable for synthesizing large rings. Although many macrolactonization methods are known, it is attractive to prepare such compounds by olefin metathesis. The synthetic route chosen by Fürstner and Kindler to obtain (+)-lasiodiplodine (**97**) starts from enantiomerically pure propene oxide (Scheme 31).[168] The outstanding yield of 94% for the cyclization step underlines the efficiency of this ring-closing method. The resulting mixture of *E*/*Z* isomers in a ratio of approximately 2.3:1 can be combined by hydrogenation, making the 12-membered lactone **97** easily accessible. The synthesis of the 14-membered lactam fluvirucin (**99**) by Hoveyda et al. (Scheme 31) is a nice example for the highly developed status of metal-catalyzed reactions.[169, 170] This natural-product synthesis includes no less than nine transition metal catalyzed reactions. The key step, the molybdenum-catalyzed RCM of the highly functionalized diene **98**, proceeds with very good yields and affords the desired (*E*)-configurated cycloolefin almost exclusively. Subsequent hydrogenation of the relatively rigid macrocycle provides the desired stereochemical orientation of the methyl group.



Scheme 31. Synthesis of lasiodiplodin (**97**) and fluvirucin (**99**).

Epothilon A (**101**) is a promising new 16-membered macrolactone which was isolated from myxo bacteria.[171] It exhibits selective cytotoxic activity with an activation mechanism similar to that of taxol, and has therefore awakened high expectations. Soon after the publication of the complete structure, total syntheses were reported. Nicolaou et al. used an RCM as the key step.[172] The metathesis of **100** proceeds under mild conditions in 85% yield (Scheme 32), demonstrating once more the potential of the ring-closing metathesis for the construction of complex molecules. Less satisfactory is the poor *E*/*Z* selectivity, since the (*Z*) isomer necessary for the epoxidation is obtained in only 50% yield. A comparable synthetic strategy using RCM as the key step was recently reported by Schinzer et al.[173] The *E*/*Z* selectivity of the cyclization could possibly be improved by substituent effects.[174]

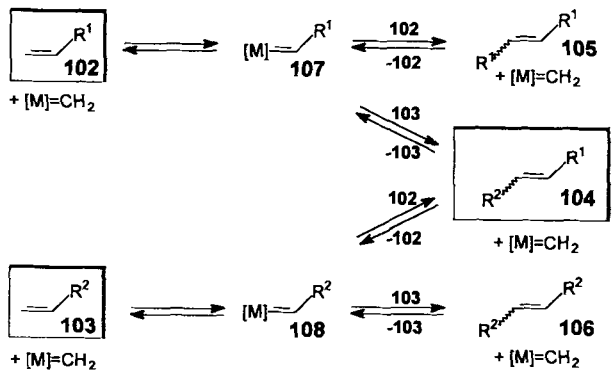


Scheme 32. Synthesis of epothilon A.

6. Cross-Metathesis

Cross-metatheses between two acyclic olefins offer interesting possibilities for synthesizing higher-substituted alkenes. The use of highly substituted asymmetric olefins is not practical because of the expected complex spectrum of products. Use of terminal olefins results in the formation of volatile ethylene as a by-product, which provides the driving force for the reaction. Therefore, almost all relevant studies to develop cross-metathesis as a synthetic method employ reactions between terminal olefins. The reaction is generally not very stereoselective.

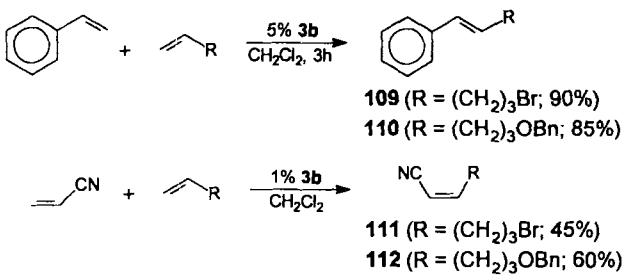
The self-metathesis of terminal olefins is a reaction which has been known for a long time for synthesizing symmetrically substituted olefins.[175–177] Every cross-metathesis of two terminal olefins **102** and **103** faces the danger that not only the desired product **104** but also the homodimers **105** and **106** form (Scheme 33). For this reason, investigations of the factors responsible for the selectivity are extremely important.



Scheme 33. General reaction scheme of the cross-metathesis of terminal olefins.

In 1988 Marciniec and co-workers published the first cross-metatheses of vinyl silanes,[178] and later of vinylalkoxy- and alkenyl-substituted silanes[179–181] with terminal alkenes, using classic ruthenium and rhodium complexes. However, these catalysts require reaction temperatures over 100 °C. Moreover, with equimolar amounts of the substrates, the dimeric silane was formed in significant yields along with the cross-product. In the case of the cross-metathesis of alkenyl-substituted vinyl silanes, self-metathesis could be suppresed only by the use of a tenfold excess of the respective coupling partner.[181]

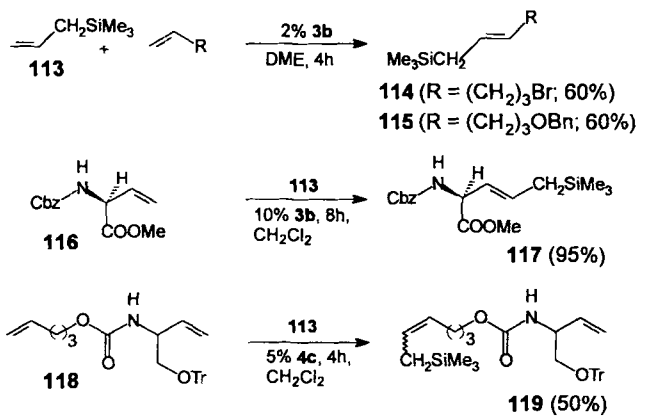
Crowe et al. performed first reactions with defined catalysts of type **3**. They described selective molybdenum-catalyzed conversions of styrene[182] and acrylonitrile[183] with a series of nonconjugated terminal olefins (Scheme 34). While cross-metathesis reactions with styrene afford the (*E*) olefin almost exclusively, the respective (*Z*) isomer predominates in the reactions with acrylonitrile. The pronounced selectivity with which these conjugated, terminal olefins react with nonconjugated



Scheme 34. Selected cross-metatheses of conjugated olefins.

olefins was first explained by the formation of a conjugated, and thus stabilized, alkylidene–metal donor from styrene or acrylonitrile (see **107** and **108**, respectively, in Scheme 33), followed by selective [2+2]cycloaddition with a "nucleophilic" isolated double bond.[183] The high selectivity of cross-metatheses of allyltrimethylsilane,[184] especially with π-substituted reaction partners, recently reported by Crowe et al. could thus be traced back to the pronounced nucleophilic character of the silane (β effect of silicon). A drawback of this model is that the results obtained with acrylonitrile and styrene are so far not transferable to other π-substituted olefins. Furthermore, we have results which suggest that not only electronic factors, but also others can control the selectivity of the reaction. For instance, we observed that 4,4-dimethylpentene, a carbon analogue of allyltrimethylsilane, shows comparable reactivities and selectivities in cross-metatheses although it lacks a β effect.[185] In addition, with the use of **3** and **4** selective cross-metatheses could be carried out between reaction partners with double bonds of comparable electron densities.

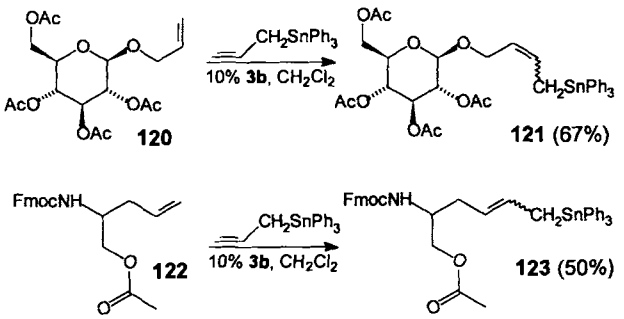
Our studies on cross-metatheses of allyltrimethylsilanes show that high yields of cross products are typically observed when the double bonds of the reaction partners are different either with regard to their steric requirements or the polarity of their substituents (Scheme 35).[185] Of practical value is the synthesis of **117**, which proceeds with high stereoselectivity. The nearly isomerization-free conversion of the strongly C,H-acidic vinylglycine derivative **116** is achievable only under the mild conditions of olefin metathesis. The preparation of **119** demonstrates the possibility of differentiating between various terminal double bonds on the basis of their steric effects. The most



Scheme 35. Cross-methatheses with allyltrimethylsilane; Cbz = benzyloxycarbonyl.

efficient catalyst in this case is the ruthenium catalyst **4c**, whereas for the conversion of the sterically demanding vinyl group in **116** the more active **3b** is necessary. In both reactions 1.5 equivalents of the silane were used. The allylsilanes that are readily available in large variety by cross-metathesis react with a large number of electrophiles either inter- or intramolecularly.[186, 187]

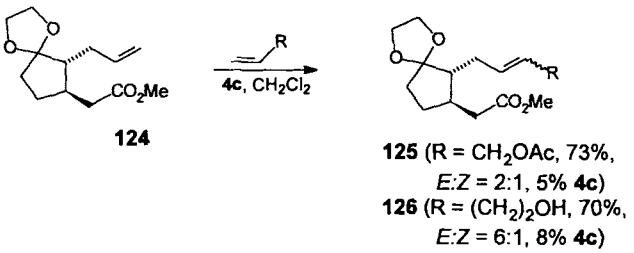
With a twofold excess of allyltriphenylstannane we were able to prepare, among others, the allylstannanes **121** and **123** shown in Scheme 36.[188] These examples demonstrate that biologically



Scheme 36. Cross-methatheses with allyltriphenylstannane; Fmoc = 9-fluorenylmethoxycarbonyl.

relevant polyfunctional structures can also be selectively converted in molybdenum-catalyzed reactions. Allylstannanes as well as allylsilanes are valuable substrates, for example in Sakurai [189, 190] and radical reactions.[191]

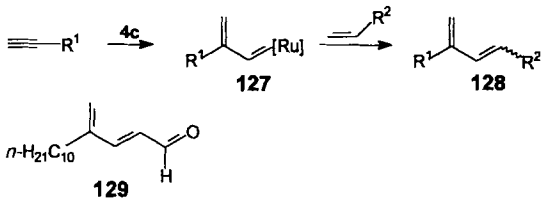
We have also used selective cross-metatheses to prepare various substituted derivatives of jasmonic acid, a highly potent plant hormone. The ruthenium-catalyzed reactions with **124** shown in Scheme 37 point towards a large synthetic potential of the cross-metathesis.



Scheme 37. Synthesis of selected jasmonic acid derivatives by ruthenium-catalyzed cross-methathesis.

To date there is no general model for the selectivity of the cross-metathesis. The reduced tendency of sterically hindered and conjugated olefins to undergo self-metathesis,[58] along with the possible precomplexation of the metal complex by heteropolar substituents, offers a viable starting point for increasing the understanding of the observed selectivities. Since the cross product can be formed by various reaction pathways, the suppression of the self-metathesis of one reaction partner alone does not allow for the proposal of a selective mode of action. On the other hand, selective cross-metatheses are often observed between olefins which completely dimerize in the absence of a partner component. The current knowledge is still insufficient for the directed use of the cross-metathesis.

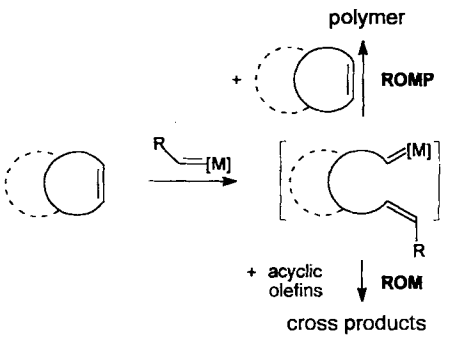
Recently, we found that cross-metatheses between monosubstituted acetylenes and terminal olefins are also possible with **4c** (Scheme 38).[192] The use of **3b** under identical reaction conditions led to the exclusive polymerization of the acetylene component (see Scheme 6B). The selectivities of the bimolecular yne–ene metatheses are surprisingly high. Disubstituted triple bonds could not be coupled. Based on the current results, we favor a reaction path in which the catalytic carbene complex attacks the triple bond in the first step (Scheme 38). The resulting conjugated metal–carbene complex **127** subsequently reacts with a double bond to form the cross product **128**. The products were isolated as *E*/*Z* mixtures. The isomerization to the thermodynamically more stable (*E*) compounds is currently under investigation. To synthesize the natural antifungal α-triticen[193] (**129**), we coupled dodecyne with allyl alcohol protected with a *tert*-butyldimethylsilyl group. The metathesis product was deprotected and directly oxidized with MnO_2 in a one-pot reaction. The desired (*E*) product was obtained exclusively in a total yield of 58%.[192]



Scheme 38. Ruthenium-catalyzed yne–ene cross-metathesis.

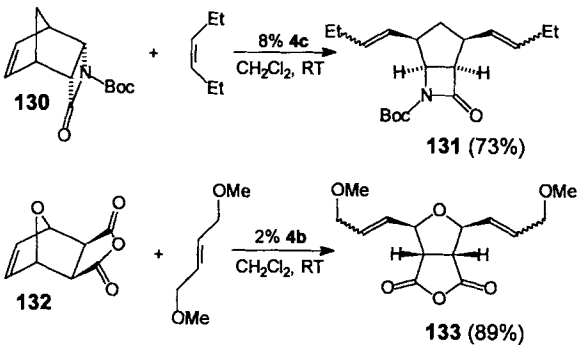
7. Ring-opening Metathesis (ROM)

The metathetic opening of strained cyclic olefins to give open-chain metal–carbene complexes provides the basis for ring-opening metathesis polymerization (ROMP). The polymerization is induced by the conversion of an intermediate metal–carbene species with another molecule of the cycloolefin (Scheme 39). In the presence of a second open-chain olefin, the same intermediate has the opportunity to react to a monomeric ring-opening product by a cross-metathesis. The benefit of this *r*ing-*o*pening *m*etathesis (ROM) is, for example, the conversion of bicycles of defined configuration into monocyclic compounds of defined configuration. In contrast to cross-metathesis, ROM proceeds atom economically.



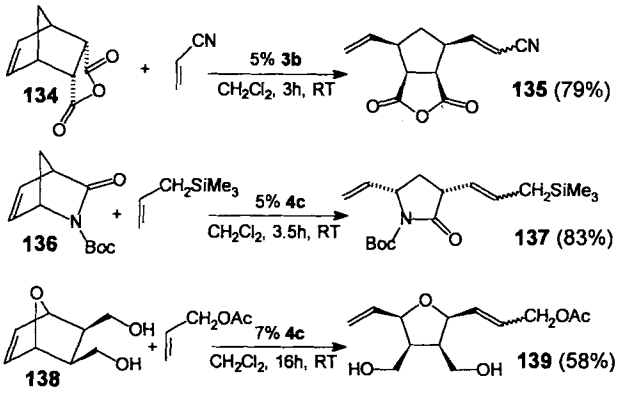
Scheme 39. Comparison between ROMP and ROM.

Since the driving force of ROM is presumed to be the ring strain of the cyclic starting materials, the first systematic investigations were performed on norbornene derivatives.[194, 195] The examples shown in Scheme 40 prove that both norbornene as well as 7-oxanorbornene derivatives **130** and **132** can be opened in high yield to the expected bicycles **131** and **133**, respectively. To suppress the polymerization of norbornene, however, it was necessary to use up to a tenfold excess of the respective acyclic component.



Scheme 40. ROM of norbornene derivatives with symmetrically substituted olefins.

Recent studies showed that the use of terminal olefins as the acyclic component alleviate the use of a large excess.[196] The molybdenum- and ruthenium-catalyzed reactions (Scheme 41) proceeded with surprising selectivity, although only equimolar amounts or up to 1.5-fold excesses of the respective terminal olefins were used. Noteworthy is also the exclusive formation of the monosubstituted diene. On the other hand, the investigated reactions generally proceeded with low stereoselectivities, that is, the *E*:*Z* ratios ranged between 5:1 and 1:6. These products represent interesting synthetic building blocks as they are highly substituted cyclopentane and furan derivatives. The selection of the catalyst is decided by the functionalities of the starting materials. While the highly reactive molybdenum initiator **3b** is required for ring opening of **134** with acrylonitrile to form **135**, it is not suitable for the conversion of **138** into **139**. In this case the ruthenium initiator **4c**, which remains active even in the presence of unprotected hydroxyl groups, was used. However, the use of silyl-protected derivatives of **138** resulted in higher

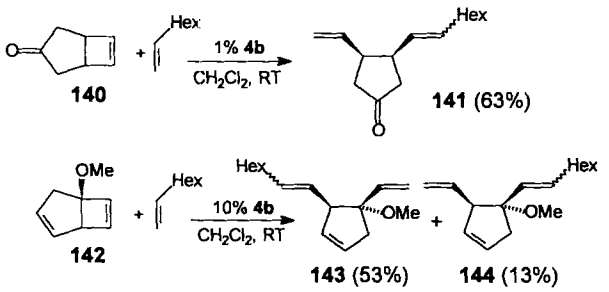


Scheme 41. ROM of norbornene derivatives with terminal olefins.

yields. The conversion of lactam **136** proceeded with surprisingly high regioselectivity. The regioisomer of the 3,5-pyrrolidinone **137** could not be detected. The application potential of the ROM is greatly increased by the possibility of performing regioselective reactions.

The high yields and the fact that no products with two disubstituted double bonds were isolated (Scheme 40) indicates that the self-metathesis of acyclic compounds can be suppressed successfully in the presence of cyclic compounds. We assume that the highly reactive methylidene–metal complex originally formed by the reaction of the alkylidene–metal initiator with the terminal olefin preferentially attacks the strained double bond of the cyclic olefin. Due to steric reasons, the resulting intermediate (Scheme 39, R = H) reacts preferentially with the acyclic component to form the observed products. Thus, the regioselectivity is caused by either steric effects during the attack of the catalytic metal–carbene complex at the double bond of the cycloolefin or a precomplexation by electron-rich heteroatoms.

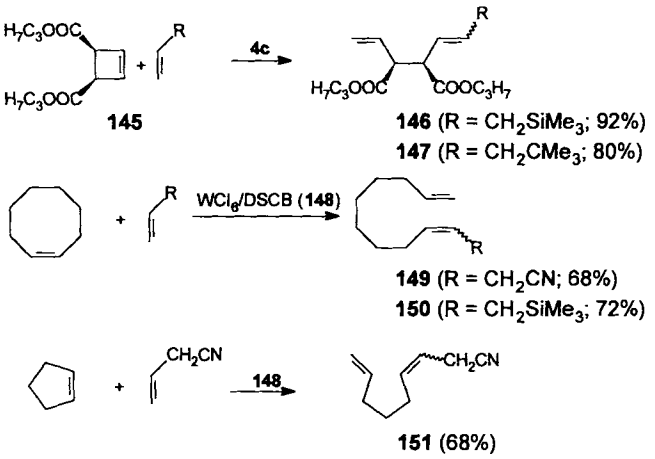
In addition to norbornenes, other strained cycloolefins were employed in ring-opening reactions.[196, 197] Snapper et al. investigated the ruthenium-catalyzed ring-opening of cyclobutene-containing bicycles to form monocyclic products (Scheme 42).[197] Here too, only small excesses of the acyclic



Scheme 42. ROM of functionalized bicyclic cyclobutene derivatives with terminal olefins.

components were used. Remarkable is the reaction of the unprotected ketone **140** to give **141**. The sterically demanding cyclobutene double bond in **142** is selectively opened by **4b** in the presence of the more accessible double bond of the cyclopentane ring to form a mixture of **143** and **144**.

We have described the formation of open-chain 1,5-dienes starting from the cyclobutene diester **145**.[196] Both allyltrimethylsilane as well as the carbon analogue 4,4-dimethylpentene react with high yields to form **146** and **147**, respectively. Similar to cyclobutene, cyclooctene represents a suitable starting material for ROM due to its ring strain. Bespalova et al. used the WCl_6/1,1,3,3-tetramethyl-1,3-disilacyclobutane cocatalyst system (**148**) for ring opening of cyclooctene to afford 1,9-dienes **149** and **150** (Scheme 43).[195] Since cyclooctene can also be opened by Grubbs's ruthenium initiators,[196] polar functionalized 1,9-dienes are also accessible by ROM. Bespalova et al. also presented the ring opening of cyclopentene by allylnitrile to yield the open-chain 1,6-diene **151**.[195] Due to the high tendency to form five-membered rings in RCM, the yield is surprisingly high. It may be possible that the disadvantage of the lower ring strain relative to the other

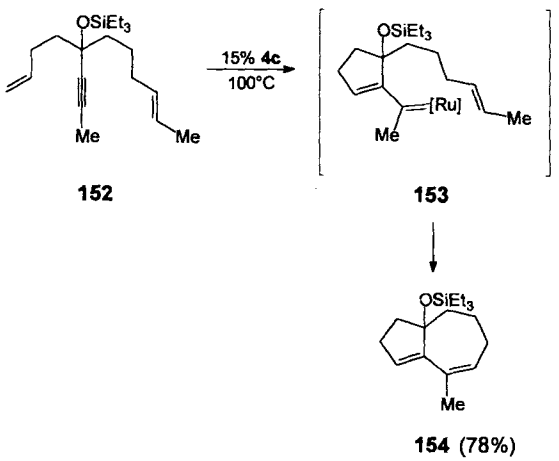


Scheme 43. ROM of monocyclic olefins with terminal olefins; DSCB = disilacyclobutane.

examined cycloolefins is compensated by the simultaneously reduced tendency towards polymerization. The catalytic ring-opening of cycloolefins, especially by terminal olefins, opens an interesting access to asymmetrically substituted acylic olefins, and therefore possesses a high synthetic potential.

8. Tandem Metathesis

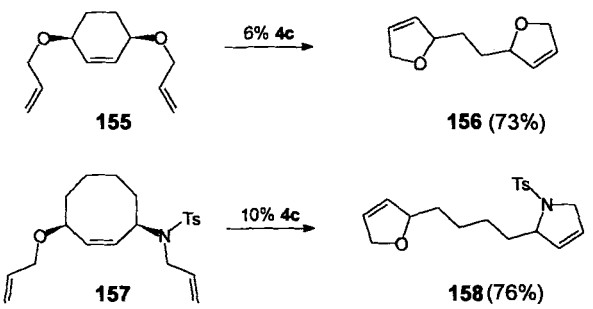
Tandem or domino reactions can shorten synthetic routes significantly and are very interesting for synthetic strategies and methods.[198] Sequences of multiple subsequent olefin metathesis reactions are also known. Grubbs reported double ring closing metatheses using dienes which lead to various bicyclic [*m*,*n*,0] systems.[199, 200] An example is the conversion of **152**, in which an enyne RCM occurs in the first step, to form the vinyl carbene complex **153**, which in the second step yields the perhydroazulene skeleton **154** by loss of propene (Scheme 44). As the reaction sequence obviously starts with the monosubstituted olefin, asymmetric dienes require differentiation between the two double bonds with different degrees of substitution. If one removes the olefinic methyl group in **152**, the tandem metathesis yields a 1:1 mixture of a [4.4.0] bicyclic and the [3.5.0] system



Scheme 44. Tandem metathesis with a dienyne.

154. Ring-closing metatheses of two olefins to form monocyclic products were found only in the case of a seven-membered ring in trace amounts. Substituent variation at the triple bond showed that bulky substituents drastically slow down the reaction, and for some functional substituents, such as $SiMe_3$ or halogens, no reaction occurs.

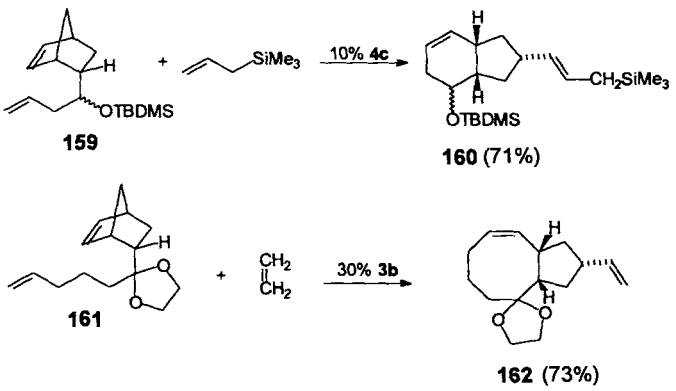
The RCM can also be combined with a ROM. Grubbs used various *syn*-configurated bis(allyl) or bis(homoallyl) ethers such as **155** in the reaction with **4c** to obtain oxygen-containing heterocyclic compounds such as **156** (Scheme 45).[201] Remarkable



Scheme 45. Tandem ring-opening/ring-closing metathesis.

in this case is the rarely observed opening of a relatively unstrained six-membered ring. This reaction, however, was carried out at high dilution to prevent bimolecular bond formation. Considering the ring system and the corresponding ring strain, various mechanisms are possible which all involve primary attack at the ring or the terminal olefin. We have used similar ring-opening/ring-closing sequences with cyclooctene derivatives for synthesizing mixed chain linked hetero- and carbocycles such as **158**.[202]

After we demonstrated that norbornene derivatives can be opened very selectively by terminal olefins,[196] we investigated the combination of this method with a RCM.[203] Norbornenes with *endo* olefinic side chains as in **159** or **161** can easily be obtained by Diels–Alder reactions with acrolein and subsequent addition to the carbonyl group. Tandem metathesis in the presence of approximately a threefold excess of another alkene affords stereocontrolled access to various bicyclic compounds such as **160** and **162** in one step (Scheme 46). Compound **159** was used as a diasteromeric mixture. In the reaction of the separated, stereochemically homogeneous compounds, however, we obtained different conversion rates and different yields. Without the use of a second olefin, only the oligomerization of the bicyclic is observed. The combination of ring opening, ring closing, and cross-metathesis provides interesting possibilities for converting readily available bridged bicyclic compounds of definite configuration into substituted [*m*,*n*,0] bicycles of defined configurations.

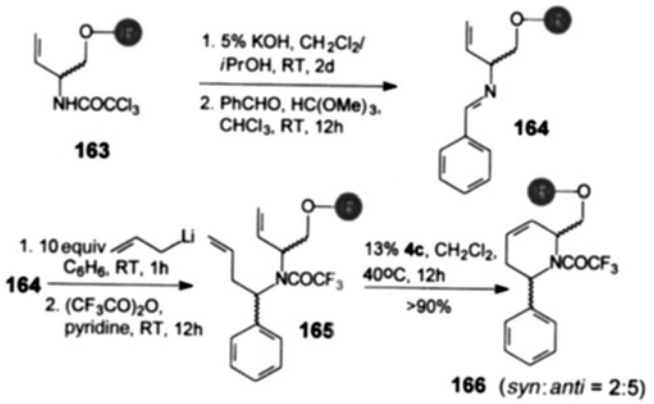


Scheme 46. Combined ring-opening/ring-closing cross-metathesis.

9. Reactions of Olefins on Solid Supports

In light of the increasing importance of combinatorial synthesis[204] for the development of biologically active substances, there is great interest in new synthetic methods on the surface of polymeric supports. The potential, especially of Grubbs's ruthenium catalysts, for the synthesis of highly functionalized heterocyclic structures by metathetic ring closures suggests applications that combine combinatorial construction of such structures with simultaneously variable modifications thereof.

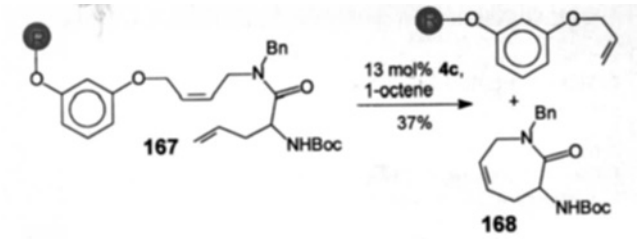
Initial studies of ruthenium-catalyzed solid-phase synthesis of heterocyclic compounds demonstrate that such a concept may be feasible.[205] We prepared functionalized precursors, such as **165**, for the RCM by sequential coupling of a polymer-bound amino alcohol, an aldehyde, and a carbon nucleophile (Scheme 47). The ruthenium-catalyzed cyclization can be carried out successfully on the polymer with high yields (>90%). By varying the individual components, it is possible to obtain differently substituted rings of various sizes.



Scheme 47. Synthesis of α,α'-disubstituted tetrahydropyridine **166** by ruthenium-catalyzed RCM (R = trityl polystyrene, 1% DVB).

Grubbs and co-workers used a tentacle polymer bound hexapeptide with two olefinic side chains as the substrate for ruthenium-catalyzed ring-closing reactions.[206] As previously observed in solution,[131] a macrocyclic structure was obtained which represents the redox-stable analogue of a loop of glutaredoxin stabilized by a disulfide bond. The avoidance of solubility problems represents a significant advantage of the cyclization of peptide systems on polymers.

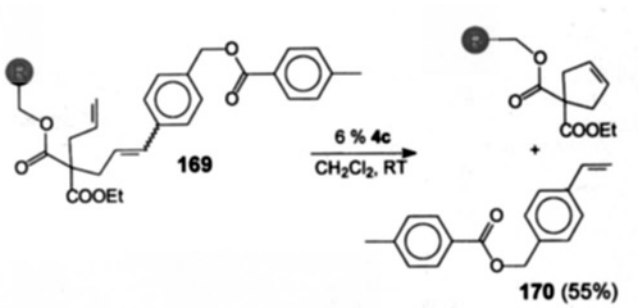
A cyclizing cleavage from the support was presented by van Maarseveen et al (Scheme 48).[207] The double bond, which functions as the linker between the resin and the component to be cleaved, is also involved in the ruthenium-catalyzed cyclization of polymer-bound **167**. This cleavage method provides the



Scheme 48. Cyclizing cleavage of polymer-bound diolefin **167** by ruthenium-catalyzed RCM (R = methylene polystyrene, 1% DVB).

concept of a "traceless" linker,[208, 209] that is, no additional polar functionalities are needed to create the link to the support. Furthermore, the cyclizing cleavage provides very pure products if the terminal double bond necessary for RCM is introduced in the last reaction step.

The catalytic performance of the cyclizing cleavage requires the use of olefinic cofactors such as ethylene or 1-octene, which can guarantee in an exchange reaction the renewed mobility of the metal that remains on the resin after cleavage. In contrast to cyclizing cleavage, when using the diolefinic linker shown in Scheme 49, the resulting cyclic compounds remain attached to

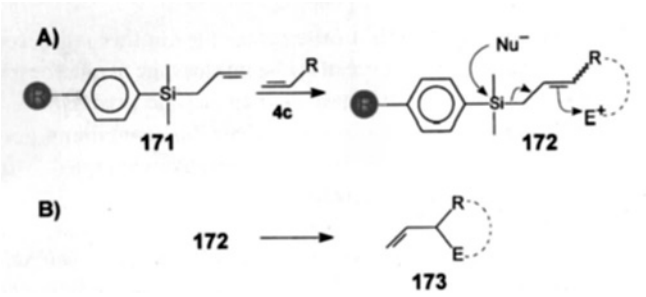


Scheme 49. Cleavage of the styrene derivative **170** by ruthenium-catalyzed cyclization of a diolefinic linker (R = polystyrene, 1% DVB).

the support.[210] Under the very mild metathesis conditions, the linker is catalytically cleaved by C–C bond breakage. The driving force of this reaction is the high tendency of formation of the resulting five-membered ring.

The interest of our group focuses not only on the ring-closing reaction but also especially on cross-metathesis with inclusion of olefinic supports. First experiments have shown that cross-metathesis between a soluble olefin and an immobilized olefin can be carried out with good yields.[205] The prerequisite for such reactions is the careful optimization of the reaction system to suppress the macrocyclic ring-closing reaction on the polymer surface. The allylsilyl polymer **171** shown in Scheme 50 can be attacked by electrophiles in solution under C–Si bond breakage (Sakurai conditions) after a terminal olefin has been catalytically attached. Since the electrophilic attack can occur either inter- or intramolecularly, a large number of open-chain as well as cyclic products of type **173** are easily accessible.[211]

The studies performed to date have shown that olefin metathesis reactions can also be carried out on polymeric supports with high yields. The potential application spectrum of metathesis ranges from binding of olefins over their further modification on the support to cleavage of the products.



Scheme 50. General scheme of A) ruthenium-catalyzed coupling of terminal olefins onto allylsilylpolystyrene (**171**) and B) inter- and intramolecular electrophilic cleavage of polymer-bound allyl silane (**172**, R = polystyrene, 1% DVB).

10. Summary and Outlook

The results discussed herein show that olefin metathesis has proven to be an efficient synthetic method, especially for the preparation of rings. Initial investigations in other areas such as the selective cross-coupling or asymmetric synthesis show promising results for future developments. For the establishment of this reaction as a broadly applicable method, however, much work remains to be done. Fundamentals have been established for the mechanistic understanding of these reactions; these, however, are still insufficient for predicting and directing chemo- and stereoselectivities. A lucrative goal is to establish metathesis as a widely applicable method for the wasteless and atom economical stereoselective synthesis of olefins. Enhanced activities can be expected in the area of olefin metathesis in the near future. The recently seen developmental rush caused by the new generation of catalysts will most likely continue. Application opportunities in organic synthesis will continue to grow, as we can count on the future development of even more active and tolerant metal complexes.

Addendum

Since submission of this review, several new publications regarding mechanistic and applied aspects of olefin metathesis have appeared. In the following, important contributions are supplemented without claiming completeness (state as of August 1997).

Investigations performed by Grubbs and co-workers[212] on the reaction mechanism justify the conclusion that catalysis by **4** is accompanied by dissociation of one phosphane ligand from the metal center. This is strongly supported by the recent isolation and characterization of a ruthenium–carbene intermediate by Snapper et al., in which one phosphane ligand is replaced by a double bond.[213] Several authors described the application of ring-closing metathesis for preparing small, polar molecules (e. g. from amino acids or β-lactams).[214–218] Fürstner et al. achieved ring closure to the ten-membered jasmine ketolactone.[219] Exploitation of templating effects has enabled the synthesis of unsaturated crown ethers as well as [*n*]catenanes[220] and topologically related systems.[221] Besides novel cross-metatheses,[222] ring-opening[223,224] and tandem reactions[225] have been reported. Noteworthy is a combinatorial approach for preparing epothilone derivatives devised by Nicolaou et al., in which the key step is cyclizing cleavage of a highly function-

alized precursor assembled on a resin.[226] Another study concentrates on the dependence of cyclizing cleavage of macrocyclic peptides on the conformation of their acyclic precursors.[227] The preparations of thymine- and penicilline-containing polymers[228, 229] are mentioned as representative examples in the area of metathesis polymerization.

We thank the co-workers listed in the references for their valuable contributions and efforts, and the Fonds der Chemischen Industrie for financial support.

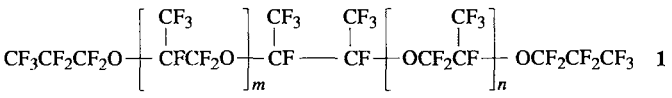
Fluorous Biphase Systems—The New Phase-Separation and Immobilization Technique

Boy Cornils*

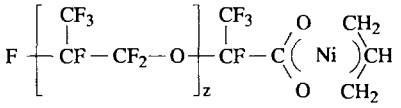
Something new is afoot in chemistry: FBS (fluorous biphase systems) is a new phase-separation and immobilization technique which makes use of the restricted and thermally controllable solubility and miscibility of perfluorinated hydrocarbons (or derivatives such as ethers or tertiary amines) and organic liquids. The method was first used in reactions with FBS-compatible, homogeneous catalysts,[1, 2] and goes back to the unpublished thesis of M. Vogt,[1] who in 1991 attempted to utilize the solvophobic properties of perfluorinated ethers of the Hostinert 216 type (structure **1**) and homogeneous catalysts dissolved therein for phase separation after successful homogeneous catalysis.



1

The actual "inventive" idea was to utilize "... the high chemical inertness of such perfluorinated compounds ..."[1] to create a medium for a variety of homogeneously catalyzed reactions, and to modify the homogeneous catalysts needed by introducing perfluorinated groups into their ligand sphere in order to make them soluble in the perfluorinated ethers. At elevated temperatures the biphase system, which contains the corresponding modified complex catalysts and the organic reactants, forms a single phase and thus provides the best conditions for the desired reaction. Since the reaction system is again biphasic upon subsequent cooling, organic reaction products and the catalysts dissolved in the FBS can be readily separated ("thermal regulation", see Figure 2). As with the oxo process of Ruhrchemie/Rhône-Poulenc[3] or the SHOP process of Shell,[4] this would have made it possible to convert the homogeneous catalyst into a "heterogenized" form and to immobilize it in an extremely effective and elegant way by means of simple phase separation without having to anchor the catalyst on solid supports (as has also been described for perfluoroalkyl-substituted supports[5]).

Following the old alchemist's rule "similia similibus solvuntur", which he cites, Vogt synthesized ligands based on hexafluoropropene oxide oligomers that gave transition metal complexes of Co, Ni, or Mn (structure **2**), which were active as



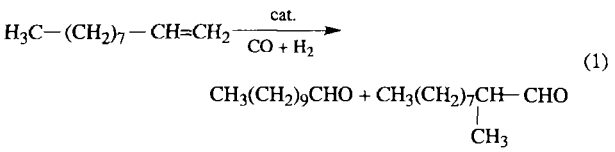
2

homogeneous catalysts and could be employed in the oxidation of cyclohexene, the polymerization and telomerization of butadiene, and the oligomerization of ethylene.

German theses which, as in the case of Vogt, do not lead to publications do not become internationally known. As a result, the phase properties of amphiphilic, perfluorinated species for solvophobic perfluorinated head groups and solvophilic hydrocarbon tail groups ("bilayer assemblies")[6] and the separation behavior of high-boiling, reactant-immiscible Fluorinert solvents[7] for etherifications, alkylations, and other reactions were described later, but clearly independent of Vogt. The same applies to work by Horváth et al. since 1994,[2, 8-10] which has the following focal points:

- Using perfluorinated solvents in FBS or FMS (fluorous multiphase systems)
- Solubilizing catalysts for homogeneously catalyzed reactions by replacing customary ligands with partially fluorinated or perfluorinated ligands
- Carrying out selected reactions, for instance hydroformylation or hydroboration,[11] as biphasic reactions catalyzed by immobilized homogeneous catalysts.[3]

Quite obviously independent of Vogt, Horváth and Rábai as well as Gladysz et al. described the genesis of the FBS methodology very logically and with virtually the same words for the hydroformylation of *n*-decene to give undecanals [Eq. (1)].



(1)

Their search for two-phase systems other than water/organic liquids—which provides the foundation for the industrially important aqueous, two-phase oxo process[8]—began with studies of solubility diagrams and the influence of intermolecular dissolution forces, as shown in Figure 1.[12]

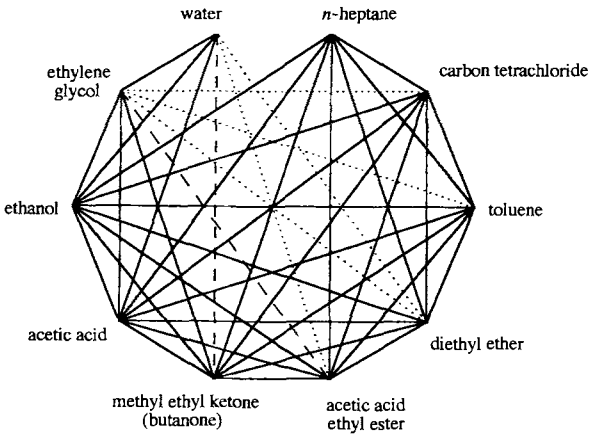

Figure 1. Miscibility diagram [12a]. Solvents not connected by a binding line are immiscible; solvents of unlimited miscibility are connected by a solid line, those of limited miscibility by a dashed line, and those of low miscibility with a dotted line.

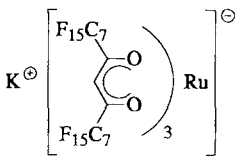
As in the case of Vogt, the substances chosen were perfluorinated hydrocarbons which are largely immiscible with organic liquids at room temperature (and thus also with the preferably oxygen-containing reaction products of customary organic syntheses). In addition, as already emphasized by Zhu,[7] they are stable to hydrolysis but nevertheless have a measurable solubilizing capability for nonpolar reactants (for example the feed olefins of hydroformylations), especially at elevated temperatures.

Taking the two-phase hydroformylation[3] as a model, the auxiliary solvent in the reaction (in this case water) should be able to dissolve the complex catalyst completely in order to retain it after phase separation and removal of the reaction products (aldehydes), and to make them immediately available for a further catalysis cycle. Therefore, as in the case of Vogt, the ligand-modified rhodium carbonyl hydrides as oxo catalysts had to be made FBS-compatible by introducing alkylene perfluoroalkyl phosphanes. Here the tailor-made "ponytail" ligands[9] are ascribed particular electronic properties which, as a result of the thermal and leaching stability of the central atom Rh, make them more suitable than Vogt's ligands. In the hydroformylation reaction, complex catalysts of type **3** modified with these ligands display satisfactory activities in the two-phase system perfluoromethylcyclohexane/toluene and an *n*:*i* ratio of about 3, which is astonishing for the use of higher olefins.[8, 10]

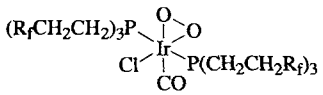
$[HRh(CO)\{P[CH_2CH_2(CF_2)_5CF_3]_3\}_3]$ **3**

The FBS complex catalysts have the general formula $[M_x\{L(R)_n(R_f)_m\}_y]$; they contain not only a hydrocarbon group R but also a fluorine-containing part R_f, which is similar to the requirements of Kunitake et al.[6] for particular two-phase structures. Incorporation of CH_2 groups between the P atom of the phosphanes and the perfluorinated R_f groups (the ponytails)[8, 9] is, according to the authors, necessary for matching reactivity and compatibility for electronic reasons.[8] The corresponding patent[10] claims catalyzed and stoichiometric reactions in addition to hydroformylations; however, the only other reactions described are oxidations of cyclohexene (to give traces of the epoxide) and of sulfur compounds (for example, diphenyl sulfide to sulfone) as well as extractions.

The FBS method of immobilizing homogeneous catalysts is also used for Rh-catalyzed hydroboration[11] (in yields of up to 95%) and for oxidation reactions. The good solubility of oxygen in the FBS auxiliary liquids, which was earlier an argument for proposing that they be used as synthetic blood substitutes,[13] indicates that they may be particularly suitable for oxidation reactions.[10] Pozzi et al.[14] used Co complexes of perfluorohydrocarbon-soluble tetraalkylporphyrins in substrate:catalyst ratios of up to 1000:1 for the epoxidation of alkenes (albeit in the presence of considerable amounts of aldehydes, preferably isobutyraldehyde, as reducing agents). For cycloolefins yields of up to 100% are reported; for 1-dodecene the yield is still 60%. As desired, the cobalt–porphyrin complex is present in the FBS phase after the reaction and can be recycled. Knochel et al.[15] described the oxidation of aldehydes to carboxylic acids and of sulfides to sulfoxides and sulfones using the Ni complexes as well as the epoxidation of carbocyclic olefins (likewise in the presence of aliphatic aldehydes) using the Ru complexes of perfluorinated diketones of structure **4**.



4



5

Also in these reactions, use is made of perfluorinated hydrocarbons as the FBS solvent; above 60 °C the reaction solution is a single phase in which the desired reaction proceeds without mass-transfer limitation. Upon cooling, the solution reverts to a two-phase system with the catalysts remaining in the FBS phase (Figure 2). According to Knochel et al.[15] the catalyst undergoes no leaching and displays only little ageing. The extent to which transition metal/oxygen complexes, as first described by Horváth and Gladysz et al.[16] for the partially fluorinated Vaska complex **5**, play a role in the oxidation is still unknown.

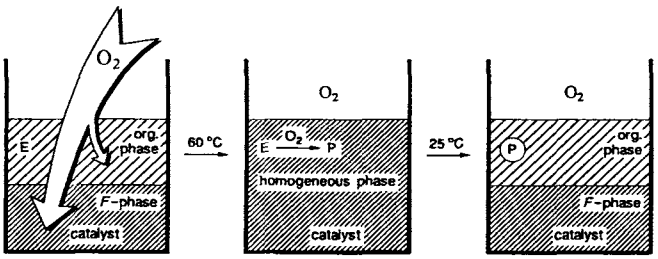


Figure 2. Principle of the FBS oxidation; E = starting material, P = product.

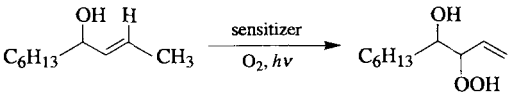
The importance of FBS for the quick separation of homogeneous catalyst and reaction product is so evident that a number of other studies have attempted to utilize the phase-separation effect even for reaction systems which do not contain transition metal catalysts. For example, Schultz et al.[17] proposed carry-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3619-2058 $ 17.50+.50/0

ing out the photoinduced singlet oxidation of cyclohexenes in this way [Eq. (2)].



(2)

Exchanging the sensitizer tetraphenylporphyrin for 5,10,15,20-tetrakis(heptafluoropropyl)porphyrin in an FBS medium produced the desired effects: increase in the chemical stability of the sensitizer towards oxidative degradation and separation of the reaction solution from the sensitizer solution, which prevents further decomposition. The increase in yield and the reduction in decomposition of the sensitizer are considerable. Curran et al.[18] used FBS systems to recover and purify liquids (typical FBS applications) in specific reactions of organic chemistry, for example, nitrile oxidations/cycloadditions, Grignard and Ugi reactions, and the Bignelli condensation.

In the wider sense catalysis in supercritical CO_2 ($scCO_2$) is also a FBS reaction, although the ability to adjust the dissolution and phase-separation behavior of $scCO_2$ by changing the pressure and temperature provides the actual impetus for their use in two-phase processes. The FBS aspect becomes involved because, as Leitner et al.[19] showed, the customary arylphosphane ligands which are important for homogeneous catalysis can only be sufficiently dissolved in $scCO_2$ if alkenylperfluoroalkyl chains are incorporated in their periphery. The catalytic properties of the parent phosphanes, and also those of their chiral derivatives, are retained (see Noyori et al.,[20] who proposed the external addition of perfluoroalkyl alcohols). In the method of Leitner et al. (see **3** and Figure 3) the solubilizers are, as in the case of Horváth et al., fixed directly to the aryl radical and thus part of the ligand. The hydroformylation of 1-octene demonstrates the effectiveness of this technique: Comparatively high conversions and *n*:*i* ratios are obtained in the homogeneous phase in $scCO_2$.

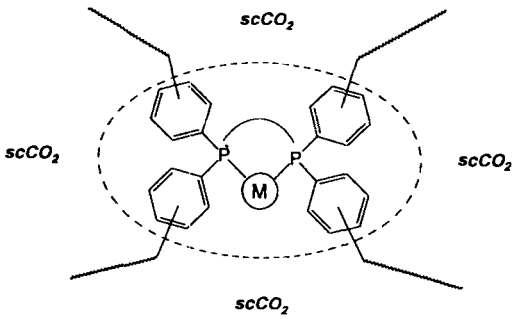


Figure 3. Catalysts with fluorine-containing ligands for use in $scCO_2$ according to Leitner et al. [19]. The "tails" on the phenyl rings represent m-$(CH_2)_2(CF_2)_6F$.

The FBS method will be secured a place in preparative organic chemistry and homogeneous catalysis in the future because its thermoselective phase behavior offers an opportunity to carry out reactions in one phase and thus homogeneously (and without serious mass transfer problems). Furthermore after cooling the mixture to separate the reaction products and by-products (and also decomposition products), the catalyst can be recycled by simple decantation. The question of the industrial importance of the FBS method is more difficult to answer. Some things do stand in the way of its wider use in industrial homogeneous catalysis: The complex catalysts are tailor-made and, like Savile Row suits, expensive; it is not so much the price of the catalytically active noble metals but rather the cost of the ligands and their recovery which becomes important. Furthermore, since they are inert fluorinated materials, ligands and FBS solvents can very easily raise questions about their presence in the atmosphere (ozone-depletion or greenhouse-warming potential of fluorine compounds) and the fate of even traces during any further processing steps (for example the hydrogenation of aldehydes to alcohols). Nevertheless, the properties of this particular type of two-phase catalysis leave no doubt that this is a spectacular but also important new development.

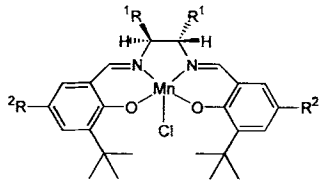
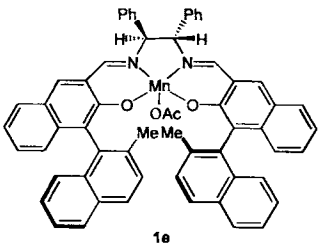
The Jacobsen–Katsuki Epoxidation and Its Controversial Mechanism

Torsten Linker*

Epoxidation reactions have been established as an important method for the formation of carbon–oxygen bonds. In 1980 Sharpless and Katsuki developed an enantioselective variant for allylic alcohols which is still one of the most elegant methods in asymmetric synthesis.[1] Over the last few years unfunctionalized olefins have also become the focal point of interest as substrates, yielding epoxides in high enantiomeric excess when the optically active (salen)manganese(III) complexes **1** designed by

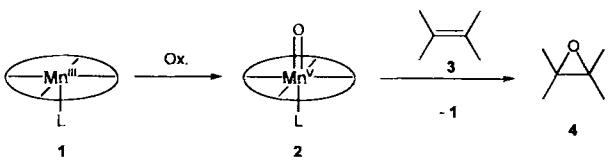


1a: R^1, R^1 = -$(CH_2)_4$-, R^2 = *t*Bu
1b: R^1, R^1 = -$(CH_2)_4$-, R^2 = OMe
1c: R^1, R^1 = -$(CH_2)_4$-, R^2 = OSi*i*Pr$_3$
1d: R^1 = Ph, R^2 = Br



1e

Jacobsen and Katsuki are used.[2] The best selectivities are achieved with *cis*-alkenes; however, recently the epoxidation of olefins having tri- and tetrasubstituted double bonds has also been successful with enantiomeric excesses of over 90%.[3] The oxidants of choice are iodosobenzene and sodium hypochlorite at room temperature as well as *meta*-chloroperbenzoic acid at −78 °C. The proposed mechanism of the Jacobsen–Katsuki epoxidation is based on investigations by Kochi et al. with achiral salen ligands, where the Mn^V–oxo complexes **2** are postulated to be the catalytically active species (Scheme 1).[4]



1 **2** **4**

Scheme 1. Formation of Mn^V–oxo complexes **2** in the Jacobsen–Katsuki epoxidation. Ox = oxidant, L = counterion or amine *N*-oxide ligand.

While the existence of analogous Cr^V–oxo complexes has been established by X-ray crystallographic analysis, the more reactive Mn^V complexes could only be speculated on. Recently, however, Plattner et al. made an important contribution to the mechanistic understanding by proving such intermediates with electrospray tandem mass spectrometry.[5]

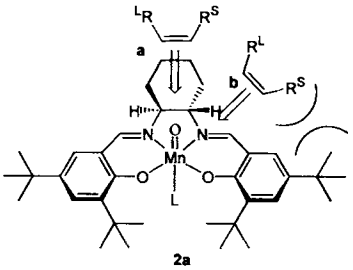
Soon after the discovery of the Jacobsen–Katsuki epoxidation, the first models were developed (which were later refined) to explain the high enantioselectivities in the transformation of *cis*-alkenes (Figure 1).[2] A side-on approach of the double bond

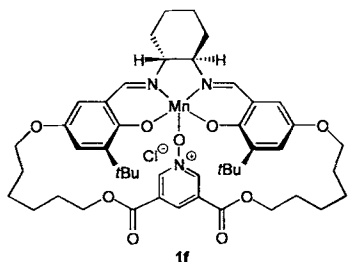


2a

Figure 1. Preferred directions of attack of alkenes **3** on complex **2**: **a** according to Jacobsen, **b** according to Katsuki.

parallel to the salen ligand is generally accepted; the sterically demanding *tert*-butyl groups shield the aryl rings. Jacobsen proposes attack from the direction of the diimine bridge (path **a**) such that the smaller substituent (R^S) is on the same side as the axial hydrogen atom of the chiral center.[2c] Katsuki favors path **b** due to π–π interactions;[2d] however, the two models differ only marginally and both explain the observed facial selectivities. Besides steric influences, the electronic character of the salen ligand also plays a decisive role. In an interesting study Jacobsen et al. found that the enantioselectivities can be increased significantly by donor substituents R^2 (in **1**), thus leading to the development of the efficient catalysts **1b** and **1c**.[6] An explanation is that the reactive manganese(v)–oxo species **2** is stabilized, and the rate of oxygen transfer is decreased. According to the Hammond postulate, this would imply a late transition state, in which the interaction between the olefin and the chiral salen ligand is more important.

The influence of additives on the reaction rate, yield, and enantioselectivity of the Jacobsen–Katsuki epoxidation was recognized early on.[7] Amine *N*-oxides proved to be the best axial coligands, because they also stabilize the manganese(v)–oxo complex **2** (Scheme 1). Recently, Jacobsen was able to impressively substantiate the importance of additives by synthesizing the (salen)manganese(III) complex **1f**.[8] While the yield and



1f

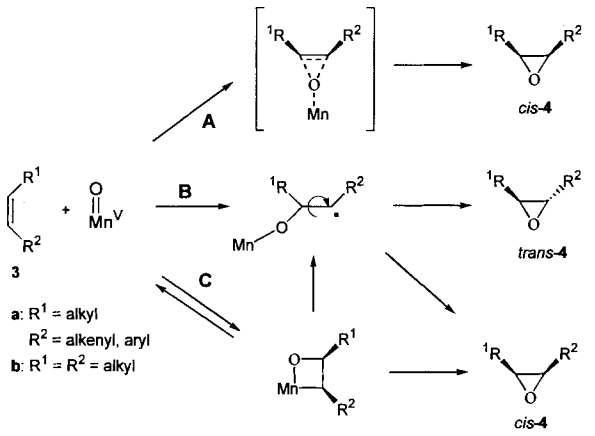
enantiomeric excess of epoxide obtained with the catalyst **1b** can be drastically increased when 4-phenylpyridine *N*-oxide (PPNO) is added, the concentration of PPNO has no influence on the reactivity of complex **1f**.

Although the factors controlling the reactivity and enantioselectivity of (salen)manganese(III) complexes **1** are now well understood, a controversy has recently erupted over the mechanism of oxygen transfer to the double bond. The concerted path **A** and pathways proceeding via radical intermediates (path **B**) and manganaoxetanes (path **C**) are under discussion (Scheme 2).



Scheme 2. Three mechanisms for oxygen transfer: **A** concerted, **B** via radicals, **C** via manganaoxetane intermediates.

Even in the first examples of the Jacobsen–Katsuki epoxidation, conjugated olefins **3a** were reported to give mixtures of *cis*- and *trans*-epoxides **4**, while the alkyl-substituted derivatives **3b** stereoselectively gave only the *cis* products. These findings were explained by evoking the concerted pathway **A** for alkyl-substituted alkenes and a radical mechanism (path **B**) for conjugated alkenes, in which rotation about the C–C single bond leads to both epoxides **4**. However, if one compares experiments with the prime example *cis*-β-methylstyrene (**3c**) under various reaction conditions, then it becomes clear that contrary to the enantiomeric excesses the diastereoselectivities are strongly dependent on the oxidant, the catalyst, and the additives (Table 1).

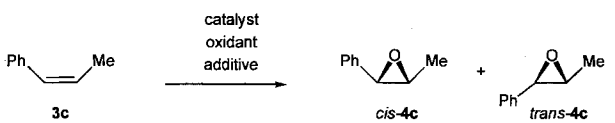


Table 1. Epoxidation of *cis*-β-methylstyrene (**3c**) with 0.04 equiv catalyst.

Entry [ref.]	Cat.	Oxidant[a]	Additive	Yield [%]	*cis*:*trans*	ee_{tot} [%][e]
1[8]	**1d**	NaOCl	4-PPNO [b]	98	95:5	81
2[8]	**1d**	MCPBA	NMO[c]	91	94:6	82
3[9]	**1a**	NaOCl	–	86	92:8	81
4[2d]	**1e**	PhIO	4-PPNO[b]	48	77:23	88
5[8]	**1d**	PhIO	4-PPNO[b]	76	75:25	72
6[9]	**1c**	NaOCl	–	86	71:29	81
7[9]	**1c**	NaOCl	CAS[d]	86	5:95	81

[a] NaOCl: in phosphate buffer/chlorobenzene; *m*-chloroperbenzoic acid (MCPBA): in dichloromethane; iodosobenzene (PhIO): in acetonitrile. [b] 0.2–0.4 equiv 4-phenylpyridine *N*-oxide (4-PPNO). [c] 10.0 equiv *N*-methylmorpholine *N*-oxide (NMO). [d] 0.2 equiv of a quaternary quinine ammonium salt (QAS). [e] $ee_{tot} = \%\,cis \times ee_{cis} + \%\,trans \times ee_{trans}$.

What is especially surprising is the high *trans* selectivity when quaternary quinine ammonium salts are added (Table 1, entry 7),[9] as it is difficult to bring this into line with radical intermediates. To date, only scant attention has been paid to the electronic interactions in the Jacobsen–Katsuki epoxidation; however, recent studies on the kinetic resolution of chiral dihydronaphthalenes have shown that polar substituents on the substrate have a strong influence on the diastereoselectivity of the reactions.[10]

The discussion on the mechanism of the Jacobsen–Katsuki epoxidation was revived by theoretical investigations conducted by Norrby, Linde, and Åkermark.[11] The diastereomeric manganaoxetanes (path **C**) were calculated with MacroModel/MM3*, and the energy differences well reflected the observed enantioselectivities. According to Scharf et al., no linear Eyring correlation should be found if these intermediates are formed reversibly.[12] Indeed, experiments by Katsuki et al. support the formation of metallaoxetanes, since inversion temperatures are found in the epoxidation of various olefins.[13] However, Jacobsen et al. question these results in a recent study and obtain a linear Eyring correlation with their salen ligands.[8] Unfortunately, the two investigations were conducted with different catalysts and under different reaction conditions, which have a significant influence on the reaction mechanism (Table 1) and thereby make comparisons rather difficult.

The epoxidation of the vinylcyclopropanes **3d–g** should provide a good indication for radical intermediates, as these "radical clocks" undergo ring-opening at a rate of approximately $10^{11}\ s^{-1}$. Jacobsen et al. published investigations with the unsubstituted vinylcyclopropane **3d** already in 1991;[14] however, an interesting paper on the phenyl-substituted derivatives **3e–g** (Scheme 3) appeared only recently.[15] Although the exclusive formation of the epoxides *cis*-**4d** according to a concerted mechanism (path **A** or **C**) was expected, the highly selective formation of the epoxides **4e** and **4f** with sodium hypochlorite without epimerization and cyclopropane ring-opening is surprising. This speaks against radical intermediates in this case and was interpreted by the authors as proof for manganaoxetanes (path **C**).[15] However, the argumentation is again based on a nonlinear Eyring correlation, which is contested by Jacobsen et al.[8] What is more striking are the different product distributions with sodium hypochlorite and iodosobenzene, something also observed in the epoxidation of *cis*-β-methylstyrene (Table 1, entries 1 and 5). The reaction conditions ap-

parently play a fundamental role in the Jacobsen–Katsuki epoxidation, so that a general mechanistic interpretation is not possible to date.

In summary, Mn^V–oxo complexes could be detected as catalytically active species in the Jacobsen–Katsuki epoxidation by electrospray tandem mass spectrometry. The synthesis of catalyst **1f** impressively demonstrates the importance of amine *N*-oxide ligands. The excellent enantioselectivities can be explained by the preferred side-on approach of the olefin. Finally, the epoxidation of phenyl-substituted vinylcyclopropanes provided evidence for radical intermediates in the *cis–trans* isomerization; however, the influence of different reaction conditions has to be taken into account. To what extent the manganaoxetanes or possibly polar intermediates play a part in the mechanism cannot be conclusively decided due to the contradictory results; further work on this point is necessary. Nonetheless, the great synthetic use of the Jacobsen–Katsuki epoxidation remains indisputable and makes this reaction one of the most important methods of asymmetric catalysis.

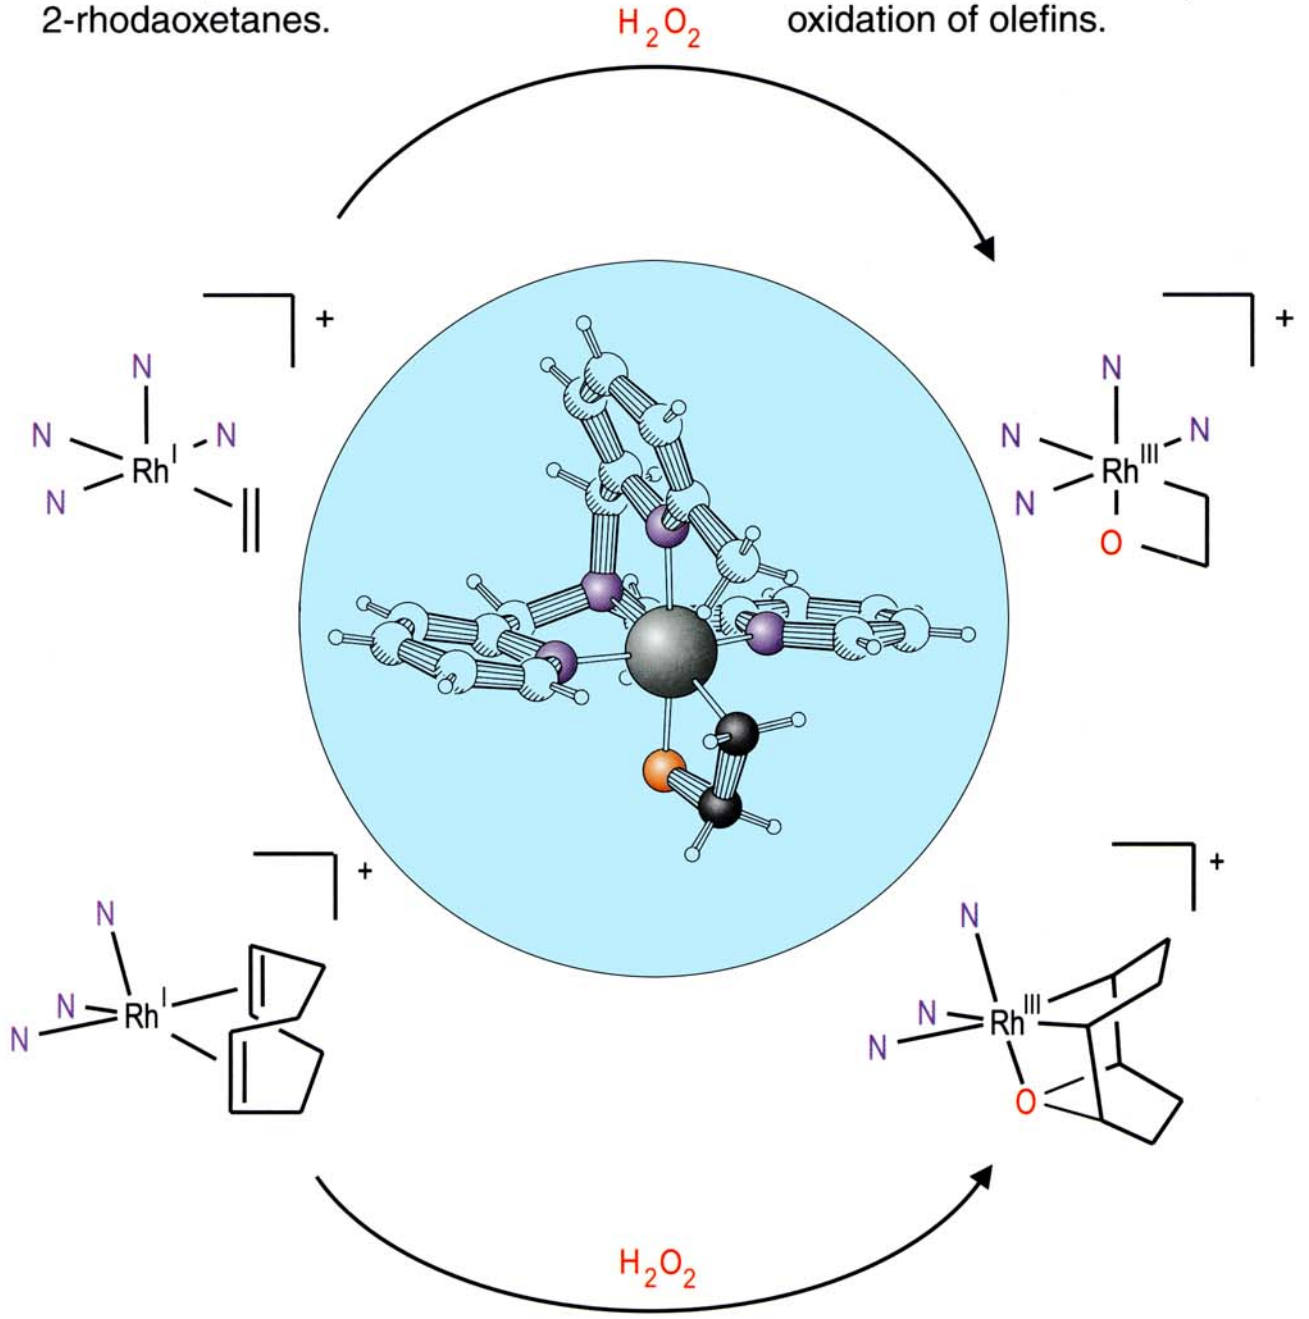
Oxidation of ethene–rhodium (I) complexes with H_2O_2 selectively leads to stable 2-rhodaoxetanes.

Such species have frequently been invoked as intermediates in the metal-catalyzed oxidation of olefins.



Analogous cyclooctadiene complexes react under the same conditions to form unprecedented Rh^{III} complexes of THF derivatives.

More about these interesting rhodium complexes is reported by Gal et al. on the following pages.

Oxidation of Rh^{I}(olefin) Fragments to 2-Rhoda(III)oxetanes**

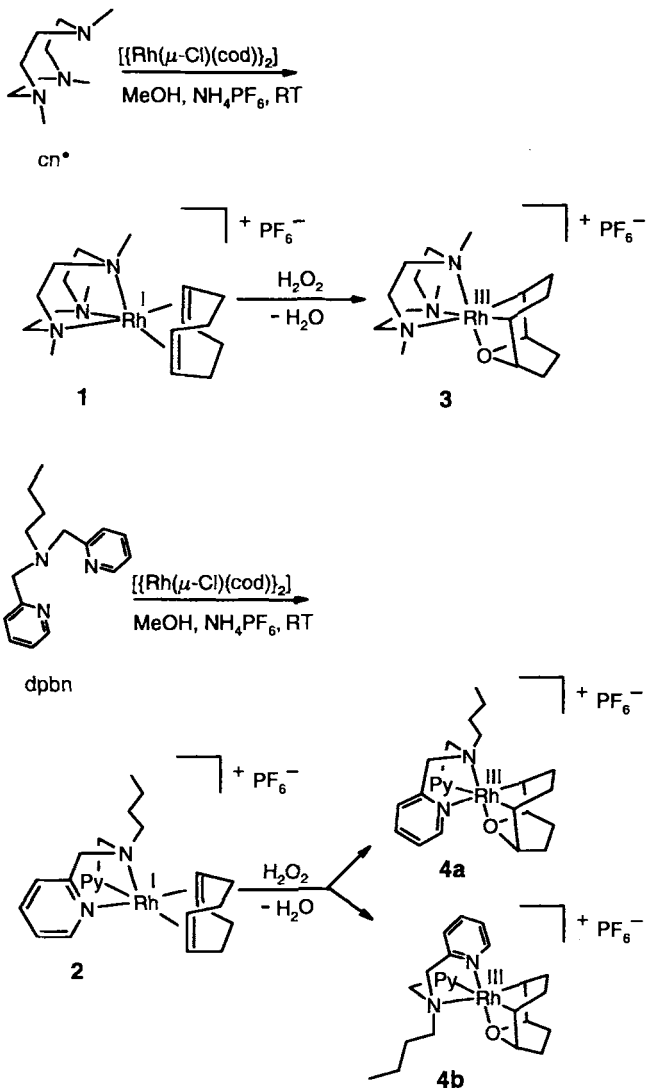
Bas de Bruin, Mark J. Boerakker, Jack J. J. M. Donners, Boukje E. C. Christiaans, Paul P. J. Schlebos, René de Gelder, Jan M. M. Smits, Anthony L. Spek, and Anton W. Gal*

The intermediacy of 2-metallaoxetanes (1,2-oxametallacyclobutanes) has been proposed in important conversions, such as the hydroxylation of olefins by $KMnO_4$, CrO_2Cl_2, or OsO_4,[1] the catalytic epoxidation of olefins,[2] and the catalytic rearrangement of epoxides to ketones.[3] Most recently, 2-metallaoxetanes have also been invoked in the Rh^{I}-catalyzed, asymmetric hydrogenolysis of epoxides.[4] Few isolated 2-metallaoxetanes are known, and those reported are stabilized by various substituents. Previous results suggest that substituents at the β-position of 2-rhodaoxetanes are required to prevent β-hydrogen elimination.[5] Substituted[6] 2-metallaoxetanes have been prepared by oxidative addition of an epoxide to a low valent metalcomplex,[4, 5b, 7] or, in the case of 2-rhoda- and 2-iridaoxetanes, by deprotonation of a β-hydroxyethyl metal halide.[5, 8] To our knowledge, the reaction of $[Ir^{I}(P_3O_9)(cod)]^{2-}$ (cod = (*Z*,*Z*)-1,5-cyclooctadiene) with dioxygen is the only example of a reaction in which a 2-metallaoxetane is obtained upon oxygenation of a coordinated olefin.[9] In this paper we describe some new $[Rh^{I}(cod)'N_3']^{+}$ ('N_3' = cn*, dpbn) and $[Rh^{I}(ethene)'N_4']^{+}$ ('N_4' = tpa, Me-tpa) complexes and their selective oxidation by H_2O_2. The $[Rh^{I}(cod)'N_3']^{+}$ complexes are oxidized to oxarhoda(III)tetracyclodecanes, possibly via 2-rhodaoxetane intermediates. Oxidation of the $[Rh^{I}(ethene)'N_4']^{+}$ complexes results in unsubstituted 2-rhodaoxetanes as isolable compounds.

The cationic five-coordinate cod complexes **1** and **2** were prepared as their PF_6^- salts (Scheme 1).[10] Compound **1** contains the rigid *fac* coordinating cn* ligand, whereas **2** contains the flexible dpbn ligand in its *fac* coordination mode.

In methanol at room temperature **1**-PF_6 and **2**-PF_6 are air-stable. Upon reaction of **1**-PF_6 with an excess of aqueous H_2O_2 (95%) in methanol, the color of the solution immediately changed from bright yellow to pale yellow. The ^1H NMR spectrum of the pale yellow powder, obtained by evaporation of the solvent, indicated quantitative conversion of **1**-PF_6 to **3**-PF_6 (Scheme 1).

Upon treatment of **2**-PF_6 with an excess of aqueous H_2O_2 (35%) in [D_6]acetone at room temperature, a reaction similar to that for **1**-PF_6 occurred. Comparison of the ^1H NMR spectrum of the resulting solution with the ^1H NMR spectrum of **3**-PF_6 in [D_6]acetone indicated the presence of two isomeric oxidation products, **4a**-PF_6 (symmetric) and **4b**-PF_6 (asymmetric) (Scheme 1), in a ratio 1:5.[11] Selective formation of the asymmetric isomer **4b** was observed when the reaction was carried out at $-10\,^{\circ}C$. We observed no isomerization of **4b** to **4a** at room temperature in [D_6]acetone.[12]



Scheme 1. Synthesis of the $[Rh^{I}(cod)'N_3']^{+}$ complexes **1**-PF_6 and **2**-PF_6, and their oxidation by H_2O_2 to **3**-PF_6 and **4a**-PF_6/**4b**-PF_6 (cn* = 1,4,7-trimethyl-1,4,7-triazacyclononane, dpbn = *n*-butylbis(pyridine-2-ylmethyl)amine).

The crystal structure of cation **3** was determined by X-ray diffraction (Figure 1).[13] The Rh^{I}(cod) fragment in **1** has been oxidized to a 6,7-oxarhoda(III)tetracyclodecane fragment that contains two Rh–C bonds and one $Rh-O_{ether}$ bond. Omission of the coordinative $Rh-O_{ether}$ bond from the nomenclature makes the fragment a 9,10-oxarhoda(III)tricyclodecane. Thus, oxidation of both double bonds of cod in the five-coordinate Rh^{I}(cod) complex **1** has resulted in a six-coordinate (9-oxabicyclo[4.2.1]nonane-2,5-diyl)rhodium(III) complex. The oxabicyclononanediyl ligand can formally be considered a tetrahydrofuran derivative. The observed oxidation reaction bears some resemblance to the stoichiometric permanganate oxidation of 1,5-hexadienes to tetrahydrofurans.[14] Though the structure of oxidation product **3** is unprecedented, it has some structural similarity to the 1,4-cycloaddition product of $[\{Rh(\mu\text{-}Cl)(cod)\}_2]$ with hexafluorobut-2-yne.[15] The coordination geometry of the rhodium atom is pseudooctahedral. The Rh–C distances (2.052 and 2.069 Å) are normal for Rh^{III}, as are the Rh–N distances. The Rh–N3 distance (2.098 Å) is shorter than the Rh–N11 and Rh–N21 distances (2.228 and 2.219 Å), reflecting

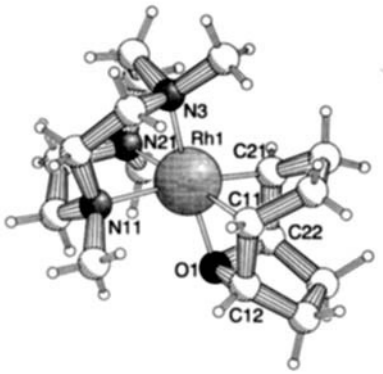

Figure 1. X-ray crystal structure of cation **3**. Selected bond lengths [Å] and angles [°]: Rh1–C11 2.069(4), Rh1–C21 2.052(4), Rh1–O1 2.077(3), Rh1–N11 2.228(3), Rh1–N21 2.219(4), Rh1–N3 2.098(3), O1–C12 1.515(5), O1–C22 1.503(5); C11-Rh1-C21 77.2(2), N11-Rh1-N3 81.87(13), N21-Rh1-N3 82.14(13), N11-Rh1-N21 80.37(13), C12-O1-C22 102.0(3), Rh1-O1-C12 92.2(2), Rh1-O1-C22 92.0(2), O1-Rh1-C11 69.81(14), O1-Rh1-C22 92.0(2), C11-Rh1-N21 173.4(2), C21-Rh1-N11 171.4(2), C11-Rh1-N3 104.2(2), C21-Rh1-N3 106.6(2), O1-Rh1-N3 173.62(13).

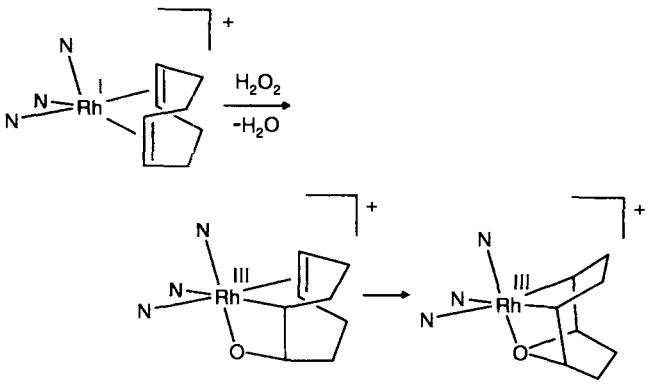
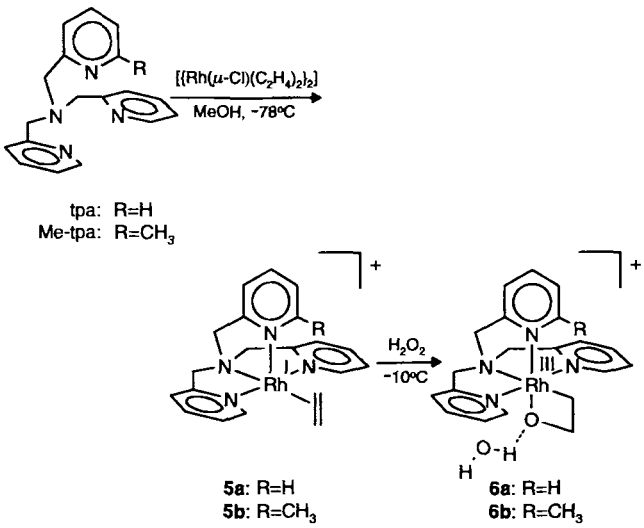


Scheme 2. Formation of oxarhoda(III)tretracyclodecanes via proposed 2-rhoda(III)oxetane intermediates.

In view of the proposed intermediacy of 2-rhodaoxetanes in the above selective oxidation of $[Rh^{I}(cod)'N_3']^+$ complexes, we argued that unsubstituted 2-rhodaoxetanes might form upon similar oxidation of $[Rh^{I}(ethene)'N_4']^+$ complexes. We therefore prepared the five-coordinate ethene complex **5a**, containing the 'N_4' ligand tpa, and studied its reaction with H_2O_2 (Scheme 3).

The color changed from yellow to pale yellow upon addition of an excess of aqueous H_2O_2 (35%) to a methanolic solution of **5a**-PF_6 at $-10\,^{\circ}C$ (Scheme 3).[17] A single compound was obtained as an off-white solid by precipitation with diethyl ether. Its ^1H NMR spectrum shows a triplet at $\delta = 4.97$ ($^3J_{H,H} = 7.5$ Hz) and a triplet with rhodium coupling at $\delta = 2.35$



Scheme 3. Synthesis of the $[Rh^{I}(ethene)'N_4']^+$ complexes **5a** and **5b**, and their oxidation by H_2O_2 to **6a** and **6b**. (tpa = tris(pyridin-2-ylmethyl)amine).

($^3J_{H,H} = 7.5$ Hz, $^2J_{H,Rh} = 2.5$ Hz), indicating the presence of a $RhCH_2CH_2O$ fragment. Further spectroscopic and analytical data led us to propose the 2-rhodaoxetane structure **6a**-PF_6 for this compound. Repeated CHN analysis and ^1H NMR spectra of samples from various experiments indicated that the product coprecipitates with water.

As we were not able to grow X-ray quality crystals of **6a**-PF_6, we also investigated the oxidation of a Rh^{I}(ethene) fragment stabilized by the monomethyl substituted 'N_4' ligand Me-tpa.[18] Stirring $[\{Rh(\mu\text{-Cl})\}_2(ethene)_2]$[19] with Me-tpa in methanol afforded **5b**-Cl, which was quantitatively oxidized in situ to **6b**-Cl by adding an excess of 35% aqueous H_2O_2. Both **6b** and **5b** could be isolated as their BPh_4 salt by precipitation with one equivalent of $NaBPh_4$.

Spectroscopic and analytical data indicated the composition **6b**-$BPh_4 \cdot 1.5H_2O$. The crystal structure of **6b**-$BPh_4 \cdot 1.5H_2O$ was determined by X-ray diffraction. It proved to be a pseudo-centrosymmetric arrangement of two cations (**6b**^{A} and **6b**^{B}), two anions, and three water molecules per unit cell. The molecular structure of cation **6b**^{A} is shown in Figure 2[13].

Two-thirds of the water molecules in the crystal are found as independent water dimers. Interestingly, one-third of the water

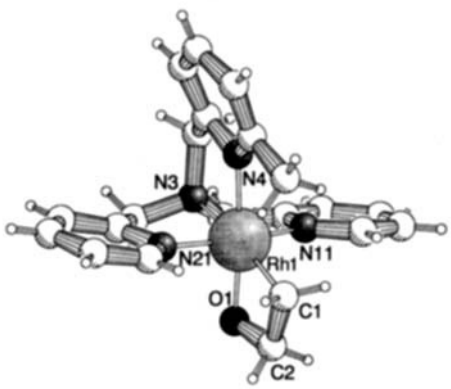


Figure 2. X-ray crystal structure of cation **6b**^{A}. Selected bond lengths [Å] and angles [°] for both cations **6b**^{A} and **6b**^{B}: Rh1–O1 2.000(5), 2.013(6); Rh1–N21 2.021(6), 2.019(8); Rh1–N11 2.045(10), 2.033(9); Rh1–C1 2.070(7), 2.075(8); Rh1–N3 2.140(8), 2.124(8); Rh1–N4 2.132(10), 2.079(13); O1–C2 1.446(10), 1.435(14); C1–C2 1.514(11), 1.49(2); O1-Rh1-C1 70.3(3), 70.0(4); C2-O1-Rh1 94.8(4), 93.5(6); C2-C1-Rh1 90.0(5), 89.4(6); O1-C2-C1 104.6(6), 106.4(7)

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3619-2065 $ 17.50+.50/0

molecules connect the cations **6b**^{A} and **6b**^{B} through two O_{water}-H$\cdots$$O_{oxetane}$ hydrogen bonds. The O_{water} atoms are also involved in a bifurcated hydrogen bond with the hydrogen atoms on the C^4 and C^5 pyridyl groups of a neighboring **6b**^{A} cation (Figure 3). The observed hydrogen bonding of H_2O to the 2-rhodaoxetane fragment parallels the frequently observed hydrogen bonds between alcohols and late transition metal alkoxides.[20]

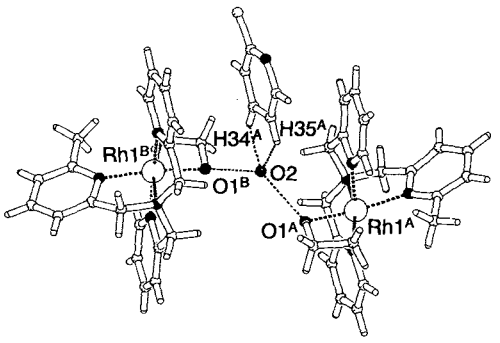

Figure 3. Hydrogen bonding interactions of the bridging water molecule as found in the X-ray structure of **6b**-$BPh_4\cdot1.5H_2O$. O1^{A} and O1^{B}: oxygen atoms of cationic 2-rhodaoxetanes **6b**^{A} and **6b**^{B}; O2: oxygen atom of bridging H_2O. Selected interatomic distances [Å]: O2–O1^{A} 2.645(6), O2–O1^{B} 2.713(7), O2–H34^{A} 1.900(15), O2–H35^{A} 2.037(11).

Rhodium–alkoxy compounds are rare. The Rh–O distances in 2-rhodaoxetane **6b** (**6b**^{A}: 2.00 Å, **6b**^{B}: 2.01 Å) are shorter than those of all the known Rh–O_{alkoxy} distances (2.01–2.11 Å),[20a, 21] including the Rh–O_{alkoxy} distance (2.10 Å) in the β,β-disubstituted 2-rhodaoxetane [RhBr{$CH_2C(Me)_2O$}-$(PMe_3)_3$] (**7**), the only 2-rhodaoxetane reported thus far.[5] The difference between the cationic **6b** and the neutral **7** seems to be the result of a weaker *trans* influence of the hard N ligand in **6b** than of the soft P ligand in **7**. A M–O distance of 1.96 Å, similar to that in **6b**, is observed for the dianionic 2-iridaoxetane $[Ir(P_3O_9)(O\text{-}cod)]^{2-}$ (**8**).[9] The C–O distances found for **6b** (**6b**^{A}: 1.45 Å, **6b**^{B}: 1.44 Å) are much shorter than the rather long C–O distance in the strained 2-iridaoxetane **8** (1.86 Å), but compare well with those in the 2-rhodaoxetane **7** (1.42 Å). The Rh–C and C–C distances in 2-rhodaoxetane **6b** compare well with the corresponding distances of **7** and **8**.[5, 9]

To our best knowledge **6a** and **6b** are the first isolated examples of unsubstituted 2-metallaoxetanes. Their formation upon oxidation of a Rh^{I}(ethene) fragment could well be relevant to a better understanding of late transition metal mediated oxidation of olefins.

Experimental Section

All procedures were performed under N_2 with standard schlenk techniques.

1-PF_6: cn* (92 mg, 0.54 mmol) and [{Rh(μ-Cl)}$_2$(cod)] [22] (134 mg, 0.27 mmol) were stirred in 25 mL MeOH for 1 h. Subsequently, NH_4PF_6 (354 mg, 2.16 mmol) was added. Partial evaporation of the solvent caused the precipitation of **1**-PF_6 as a yellow powder, which was filtered and vacuum-dried. Yield 202 mg (71%). ^{1}H NMR (200.13 MHz, [D$_6$]acetone, 298 K): δ = 3.56 (m, 4H; CH=CH), 3.1–2.85 (m, 12H; NCH_2), 3.00 (s, 9H; NCH_3), 2.46 (m, 4H; C=CCH_2-*exo*), 1.67 (m, 4H; C=CCH_2-*endo*); ^{13}C{^{1}H} NMR (50.33 MHz, [D$_6$]acetone, 298 K): δ = 74.2 (d, J(Rh,C) = 13.8 Hz; CH=CH), 58.4 (NCH_2), 51.2 (NCH_3), 30.7 (C=CCH_2). FAB-MS (*m*-nitrobenzyl alcohol (*m*-Noba)/CH_3CN): 382 $[M]^+$, 909 $[2M+PF_6]^+$. Elemental analysis calcd for $C_{17}H_{33}N_3RhPF_6$: C 38.72, H 6.31, N 7.97; found: C 38.47, H 6.22, 7.85.

2-PF_6: Prepared by a procedure similar to that of **1**-PF_6 but with the ligand dpbn [23]. ^{1}H NMR (200.13 MHz, [D$_6$]acetone, 298 K): δ = 9.20 (d, ^3J(H,H) = 5.4 Hz, 2H; Py-H6), 7.74 (m, 2H; Py-H4), 7.37–7.27 (m, 4H; Py-H5, and Py-H3), 4.62 (d[AB], ^2J(H,H) = 16.3 Hz, 2H; N-CH_2-Py), 4.25 (d[AB], ^2J(H,H) = 16.3 Hz, 2H; NCH_2Py), 4.06 (m, 2H; N$CH_2CH_2CH_2CH_3$), 3.83 (m, 4H; CH=CH), 2.65 (m, 4H; C=CCH_2-*exo*), 2.12 (m, 2H; $NCH_2CH_2CH_2CH_3$), 1.86 (m, 4H; C=CCH_2-*endo*), 1.59 (m, 2H; $NCH_2CH_2CH_2CH_3$), 1.09 (t, ^3J(H,H) = 7.4 Hz, 3H; $NCH_2CH_2CH_2CH_3$); ^{13}C{^{1}H} NMR (50.33 MHz, [D$_6$]acetone, 298 K): δ = 160.4 (Py-C2), 151.5 (Py-C6), 139.0 (Py-C4), 124.9 (Py-C3), 123.7 (Py-C5), 75.9 (d, J(Rh,C) = 13.8 Hz; CH=CH), 64.1 ($NCH_2CH_2CH_2CH_3$), 63.4 (NCH_2Py), 31.4 (C=CCH_2), 27.2 ($NCH_2CH_2CH_2CH_3$), 21.0 ($NCH_2CH_2CH_2CH_3$), 14.0 ($NCH_2CH_2CH_2CH_3$). FAB-MS (*m*-Noba/CH_3CN): 466 $[M]^+$, 1077 $[2M+PF_6]^+$. Elemental analysis calcd for $C_{24}H_{33}N_3RhPF_6$: C 47.15, H 5.44, N 6.87; found: C 46.43, H 5.33, 6.84.

3-PF_6: **1**-PF_6 (37 mg) was dissolved in MeOH (5 mL), and 35% aqueous H_2O_2 solution (0.1 mL) was added. The solution was stirred at room temperature for 1 h. Addition of Et_2O caused the precipitation of **3**-PF_6 as a light yellow powder, which was filtered, washed with Et_2O, and vacuum-dried. Yield 38 mg (100%). ^{1}H NMR (200.13 MHz, [D$_6$]acetone, 298 K): δ = 5.95 (m, 2H; OCH), 3.35–3.15 (m, 4H; NCH_2), 3.18 (s, 6H; NCH_3), 3.15–3.05 (m, 4H; NCH_2), 2.952.73 (m, 4H; NCH_2), 2.68 (m, 2H; RhCH), 2.63 (d, ^3J(Rh,H) = 1.7 Hz, 3H; NCH_3), 2.29–1.96 (m, 4H; RhCHCH_2-*exo*/OCHCH_2-*exo*), 1.53 (m, 2H; OCHCH_2-*endo*), 1.41 (m, 2H; RhCHCH_2-*endo*); ^{13}C{^{1}H} NMR (50.33 MHz, [D$_6$]acetone, 298 K): δ = 107.3 (d, ^2J(Rh,C) = 4.6 Hz; OCH), 62.3, 58.3, and 56.1 (NCH_2), 54.5 and 49.6 (NCH_3), 28.1 and 27.0 (RhCHCH_2/OCHCH_2), 21.7 (d, ^1J(Rh,C) = 23.0 Hz; RhCH). FAB-MS (*m*-Noba/CH_3CN): 398 $[M]^+$, 941 $[2M+PF_6]^+$. Elemental analysis calcd for $C_{17}H_{33}N_3ORhPF_6$: C 37.58, H 6.12, N 7.73; found: C 37.26, H 5.93, 7.65.

4b-PF_6: Prepared by a method similar to that of **3**-PF_6 except that the reaction was carried out at -10 °C. ^{1}H NMR (200.13 MHz, [D$_6$]acetone, 298 K): δ = 9.23 (d, ^3J(H,H) = 5.4 Hz, 1H; Py-H6), 8.50 (d, ^3J(H,H) = 5.6 Hz, 1H; Py-H6), 7.10–8.10 (m, 6H; Py-H4, Py-H5, and Py-H3), 6.08 (m, 1H; OCH), 6.04 (m, 1H; OCH), 4.85 (d[AB], ^2J(H,H) = 15.6 Hz, 1H; NCH_2Py), 4.67 (d[AB], ^2J(H,H) = 17.2 Hz, 1H; NCH_2-Py), 4.53 (d[AB], ^2J(H,H) = 15.6 Hz, 1H; NCH_2Py), 4.16 (d[AB], ^2J(H,H) = 17.2 Hz, 1H; NCH_2-Py), 3.90–3.45 (m, 2H; N$CH_2CH_2CH_2CH_3$), 3.42 (m, 1H; RhCH), 2.91 (m, 1H; RhCH), 2.3–2.0 (m, 4H; RhCHCH_2-*exo*/OCHCH_2-*exo*), 1.85–1.05 (m, 8H; OCHCH_2-*endo*/RhCHCH_2-*endo*/$NCH_2CH_2CH_2CH_3$/$NCH_2CH_2CH_2CH_3$), 0.91 (t, ^3J(H,H) = 7.4 Hz, 3H; $NCH_2CH_2CH_2CH_3$). ^{13}C{^{1}H} NMR (50.33 MHz, [D$_6$]acetone, 298 K): δ = 162.5 (Py_a-C2), 161.5 (Py_b-C2), 153.8 (Py_a-C6), 150.8 (Py_b-C6), 139.0 (Py_a-C4), 137.6 (Py_b-C4), 125.2 (Py_a-C3), 125.0 (Py_b-C3), 123.6 (Py_a-C5), 122.2 (Py_b-C5), 106.6 (d, ^2J(Rh,C) = 4.0 Hz; OCH_a), 105.7 (d, ^2J(Rh,C) = 4.0 Hz; OCH_b-), 66.4 ($NCH_2CH_2CH_2CH_3$), 63.3 (NCH_2-Py_a), 63.2 (NCH_2-Py_b), 28.8 ($NCH_2CH_2CH_2CH_3$), 28.2, 27.7, 26.7, and 26.6 (RhCHCH_2/OCHCH_2), 25.2 (d, ^1J(Rh,C) = 19.4 Hz; $RhCH_a$), 23.5 (d, ^1J(Rh,C) = 19.4 Hz; $RhCH_b$), 20.9 ($NCH_2CH_2CH_2CH_3$), 13.9 ($NCH_2CH_2CH_2CH_3$). FAB-MS (*m*-Noba/CH_3CN): 482 $[M]^+$. Elemental analysis calcd for $C_{24}H_{33}N_3ORhPF_6$: C 45.95, H 5.36, N 6.76; found: C 44.29, H 5.07, N 6.45.

5a-PF_6: [{Rh(μ-Cl)(ethene)$_2$}$_2$] (100 mg, 0.30 mmol) and tpa (150 mg, 0.54 mmol) were stirred in MeOH (25 mL) at -78 °C for 1 h. Subsequently KPF_6 (441 mg, 2.4 mmol) was added. Partial evaporation of the solvent caused the precipitation of **5a**-PF_6 as a yellow powder, which was filtered and vacuum-dried. Yield 200 mg (59%). In both the ^{1}H and ^{13}C NMR spectra of **5a** at 298 K, the ethene fragment is observed as two broad singlets. At 263 K the ethene fragment is observed as two double triplets in the ^{1}H NMR spectrum and two doublets in the ^{13}C NMR spectrum. ^{1}H NMR (500.14 MHz, [D$_6$]acetone, 263 K): δ = 9.43 (d, ^3J(H,H) = 4.7 Hz, 1H; Py_a-H6), 8.16 (d, 2H, ^3J(H,H) = 5.8 Hz, 2H; Py_b-H6), 7.90–7.10 (m, 9H; Py-H4, Py-H5, and Py-H3), 5.69 (d[AB], ^2J(H,H) = 15.6 Hz, 2H; NCH_2-Py_b), 5.02 (d[AB], ^2J(H,H) = 15.6 Hz, 2H; NCH_2-Py_b), 4.76 (s, 2H; NCH_2-Py_a), 2.11 (dt, ^3J(H,H) = 9.5 Hz, J(H,Rh) = 1.7 Hz, 2H; C_2H_4), 1.82 (dt, 2H, ^3J(H,H) = 9.5 Hz, J(Rh,H) = 1.7 Hz, 2H; C_2H_4); ^{13}C{^{1}H} NMR (125.77 MHz, [D$_6$]acetone, 263 K): δ = 163.9 (Py_b-C2), 159.6 (Py_a-C2), 151.9 (Py_a-C6), 151.4 (Py_b-C6), 138.1 (Py_a-C4), 137.3 (Py_b-C4), 125.2 (Py_b-C3), 124.4 (Py_a-C3), 123.1 (Py_b-C5), 122.2 (Py_a-C5), 69.6 (NCH_2-Py_b), 64.3 (NCH_2-Py_a), 27.2 (d, J(C,Rh) = 18.0 Hz; C=C), 25.0 (d, J(C,Rh) = 19.7 Hz; C=C). FAB-MS (*m*-Noba/CH_3CN): 421 $[M]^+$, 589 $([M + Na + PF_6]^+$, 393 $[M - C_2H_4]^+$. Elemental analysis calcd for $C_{20}H_{22}N_4RhPF_6$: C 42.42, H 3.93, N 9.98; found: C 40.54, H 3.60, N 9.70. The same procedure with $NaBF_4$ gave **5a**-BF_4. Calculated for $C_{20}H_{22}N_4RhBF_4$: C 47.28, H 4.36, N 11.03; found: C 47.25, H 4.46, N 10.80.

5b-BPh_4: Prepared by a procedure similar to that of **5a**-PF_6, with Me-tpa and 1 equiv $NaBPh_4$. ^{1}H NMR (200.13 MHz, CD_2Cl_2, 298 K): δ = 7.86 (d, ^3J(H,H) = 5.3 Hz, 2H; Py_a-H6), 7.55–6.65 (m, 9H; Py-H4, Py-H5, and Py-H3), 7.37 (m, 8H; BAr-H2), 7.02 (t, ^3J(H,H) = 7.4 Hz, 8H; BAr-H3), 6.87 (t, ^3J(H,H) = 7.4 Hz, 4H; BAr-H4), 5.07 (d[AB], ^2J(H,H) = 15.3 Hz, 2H; NCH_2-Py_b), 4.23 (d[AB], ^2J(H,H) = 15.3 Hz, 2H; NCH_2-Py_b), 4.11 (s, 2H; NCH_2-Py_a), 3.33 (s, 3H; Py_a-CH_3), 2.07 (br. s, 2H; C_2H_4), 1.94 (br. s, 2H; C_2H_4). FAB-MS (*m*-Noba/CH_2Cl_2): 435 $[M]^+$, 407 $[M - C_2H_4]^+$. Elemental analysis calcd for $C_{45}H_{44}BN_4Rh$: C 71.63, H 5.88, N 7.42; found: C 71.15, H 5.93, N 7.42.

6a-PF_6: **5a**-PF_6 (50 mg) was dissolved in MeOH (5 mL) and 35% aqueous H_2O_2 solution (0.1 mL) was added. The solution was stirred at -10 °C for 1 h. Addition of Et_2O caused the precipitation of **6a**-PF_6 as a pale yellow powder, which was filtered, washed with Et_2O, and vacuum-dried. Yield 51 mg (100%). ^{1}H NMR (200.13 MHz, [D$_6$]acetone, 298 K): δ = 9.03 (d, ^3J(H,H) = 5.7 Hz, 1H; Py_b-H6), 8.70 (d, ^3J(H,H) = 5.5 Hz, 2H; Py_a-H6), 8.10–7.20 (m, 9H; Py-H4, Py-H5, and Py-H3), 5.32 (d[AB], ^2J(H,H) = 15.4 Hz, 2H; NCH_2-Py_b), 5.13 (d[AB], ^2J(H,H) = 15.4 Hz, 2H; NCH_2-Py_b), 5.04 (s, 2H; NCH_2-Py_a), 4.97 (t,

^3J(H,H) = 7.5 Hz, 2H; RhCH$_2$CH$_2$O), 2.90 (s, approx. 3H; H$_2$O), 2.35 (dt, ^3J(H,H) = 7.5 Hz, ^2J(H,Rh) = 2.5 Hz, 2H; RhCH$_2$CH$_2$O); ^{13}C{^{1}H} NMR (50.33 MHz, [D$_6$]acetone, 298 K): δ = 165.4 (Py$_b$-C2), 162.6 (Py$_a$-C2), 151.9 (Py$_b$-C6), 150.9 (Py$_a$-C6), 139.4 (Py$_b$-C4), 138.4 (Py$_a$-C4), 125.9 (Py$_b$-C3), 125.1 (Py$_a$-C3), 124.6 (Py$_b$-C5), 122.2 (Py$_a$-C5), 78.8 (d, ^2J(Rh,C) = 4.0 Hz; RhCH$_2$CH$_2$O), 66.8 (NCH$_2$-Py$_b$), 64.7 (NCH$_2$-Py$_a$), 1.3 (d, ^1J(C,Rh) = 18.4 Hz; RhCH$_2$CH$_2$O). FAB-MS (*m*-Noba/CH$_3$CN): 437 [*M*]$^+$, 393 [*M* − CH$_2$CH$_2$O]$^+$. Compound **6a** appears to coprecipitate with H$_2$O: elemental analysis calcd for **6a**-PF$_6$·1.5H$_2$O (C$_{20}$H$_{25}$N$_4$O$_{2.5}$RhPF$_6$): C 39.42, H 4.14, N 9.20; found: C 38.60, H 3.62, N 9.41. The same procedure with NaBPh$_4$ gave [**6a**](BPh$_4$). Calcd for [**6a**]-BPh$_4$·1.5H$_2$O (C$_{44}$H$_{45}$N$_4$O$_{2.5}$RhB): C 57.44, H 5.79, N 7.15; found: C 67.15, H 5.43, N 7.04.

6b-[BPh$_4$]: [{(C$_2$H$_4$)$_2$Rh(μ-Cl)}$_2$] (200 mg, 0.51 mmol) and Me-tpa (320 mg, 1.05 mmol) were added to MeOH (25 mL) at −78 °C, and stirred for 1 h. A 35% aqueous solution of H$_2$O$_2$ (0.2 mL) was added, and the solution was allowed to slowly warm up to room temperature. Any undissolved material was removed by filtration. NaBPh$_4$ (0.36 mg, 1.06 mmol) in MeOH (7 mL) was added to the solution, causing the precipitation of a light yellow solid, which was collected by filtration. After recrystalization from dichloromethane/hexane, pure **6b**-BPh$_4$·1.5H$_2$O was obtained as bright yellow crystals, suitable for X-ray diffraction. Yield 654 mg (64%). ^{1}H NMR (200.13 MHz, CD$_2$Cl$_2$, 298 K): δ = 8.77 (d, ^3J(H,H) = 5.6 Hz, 2H; Py$_a$-H6), 7.80–6.50 (m, 9H; Py-H4, Py-H5, and Py-H3), 7.36 (m, 8H; BAr-H2, 7.01 (t, ^3J(H,H) = 7.4 Hz, 8H; BAr-H3), 6.86 (t, ^3J(H,H) = 7.4 Hz, 4H; BAr-H4), 4.81 (d[AB], ^2J(H,H) = 15.3 Hz, 2H; NCH_2-Py$_b$), 4.80 (t, ^3J(H,H) = 7.6 Hz, 2H; RhCH$_2$CH_2O), 4.29 (d[AB], ^2J(H,H) = 15.3 Hz, 2H; NCH_2-Py$_b$), 4.10 (s, 2H; NCH$_2$-Py$_a$), 2.90 (s, 3H; H$_2$O), 2.83 (s, 3H; Py$_a$-CH$_3$), 2.35 (dt, ^3J(H,H) = 7.6 Hz, ^2J(H,Rh) = 2.6 Hz. 2H, RhCH_2CH$_2$O); ^{13}C{^{1}H} NMR (75.47 MHz, CD$_2$Cl$_2$, 298 K): δ = 164.7 (q, ^1J(C,B) = 48.6 Hz; BAr-C1), 164.5 (Py$_b$-C2), 164.2 (Py$_a$-C2), 161.6 (Py$_a$-C6), 152.5 (Py$_b$-C6), 139.5 (Py$_b$-C4), 138.5(Py$_a$-C4), 136.8 (BAr-C2), 125.8 (q, ^3J(C,B) = 2.8 Hz; BAr-C3), 126.2 (Py$_b$-C3), 125.8 (Py$_a$-C3), 124.6 (Py$_b$-C5), 122.8 (BAr-C4), 119.6 (Py$_a$-C5), 80.6 (d, ^2J(Rh,C) = 4.2 Hz; RhCH$_2$CH$_2$O), 66.6 (NCH$_2$-Py$_b$), 65.5 (NCH$_2$-Py$_a$), 26.7 (Py$_a$-CH$_3$), 2.5 (d, ^1J(C,Rh) = 18.0 Hz; RhCH$_2$CH$_2$O). FAB-MS (*m*-Noba/CH$_2$Cl$_2$): 451 [*M*]$^+$, 407 [*M* − CH$_2$CH$_2$O]$^+$. Elemental analysis calcd for **6b**-BPh$_4$·1.5H$_2$O (C$_{45}$H$_{47}$BN$_4$O$_{2.5}$Rh): C 67.76, H 5.94, N 7.02; found: C 66.96, H 5.81, N 6.94.

[10] The structures of compound **1** and a dinuclear analogue of **2** have been determined by X-ray diffraction (as yet unpublished).

[11] Most of the ^{1}H NMR signals of **4a** are obscured by those of **4b**, yet some characteristic signals indicate its formation: ^{1}H NMR (200.13 MHz, [D$_6$]acetone, 298 K): δ = 8.95 (d, ^3J(H,H) = 5.4 Hz, 2H, Py-H6), 5.92 (m, 2H, OC*H*), 2.77 (m, 2H, RhC*H*).

[12] In solution, the η^4-cod fragment of **2** appears to be rotating fast on the NMR timescale from T = 298 K to at least 183 K. This (pseudo)rotation is interpreted as a rapid interchange of the trigonal-bipyramidal and square-pyramidal coordination geometry of **2**. The formation of the two isomers **4a** and **4b** at room temperature upon oxidation of **2** possibly results from H$_2$O$_2$ attack at both geometrical structures and the distribution results from a kinetic preference for one of them.

[13] Pale yellow crystals of **3**-PF$_6$ were obtained by slow crystallization from a saturated methanolic solution. The X-ray diffraction data were collected at 150 K on an Enraf-Nonius CAD4T diffractometer with graphite monochromatized Mo$_{K\alpha}$ (λ = 0.710730 Å). The structure was solved by the program system DIRDIF [24a], and the program PATTY [24b] was used to locate the heavy atoms. Crystal data for **3**-PF$_6$: C$_{17}$H$_{33}$F$_6$N$_3$OPRh, M_r = 543.34, monoclinic, space group $P2_1/c$ (no. 14, a = 10.2472(10), b = 13.0331(8), c = 15.5345(8) Å, β = 90.012(6)°, V = 2074.7(3) Å^3, Z = 4, ρ_{calcd} = 1.740 g cm^{-3}. All hydrogen atoms were placed at calculated positions and were subsequently freely refined. Final R indices: R_1 = 0.0441 (for 3399 reflections considered observed ($I > 2\sigma(I)$), wR_2 = 0.0929 (all data) for all 394 parameters. Crystal data for **6b**-BPh$_4$·1.5H$_2$O: C$_{45}$H$_{47}$BN$_4$O$_{2.5}$Rh, M_r = 794.56, triclinic, space group $P\bar{1}$, a = 9.3022(3), b = 11.8120(2), c = 18.3852(4) Å, α = 78.781(5), β = 88.275(3), γ = 85.428(3)°, V = 1974.99(8) Å^3, Z = 2, ρ_{calcd} = 1.336 g cm^{-3}. The X-ray diffraction data were collected at 173 K on an Enraf-Nonius CAD4 diffractometer with graphite monochromatized Cu$_{K\alpha}$ (λ = 1.541838 Å). The structure was solved by the program system DIRDIF [24a], and the program PATTY [24b] was used to locate the heavy atoms. The initial results showed severe disorder. The structure then proved to be a pseudocentrosymmetric arrangement of two cations, two anions, and three water molecules per unit cell (in spacegroup $P1$), which could be adequately refined with an inversion-disorder model in space group $P\bar{1}$. The non-rhodium atoms were subjected to restrained refinement procedures (SHELXL-93) [c]. Final R indices: R_1 = 0.0566 (for 6908 reflections considered observed ($I > 2\sigma(I)$), wR_2 = 0.1786 (all data) for all 727 parameters. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Chrystallographic Data Centre as supplementary publication no. CCDC-100377. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk)

Anion-Assisted Self-Assembly**

Matthew C. T. Fyfe, Peter T. Glink, Stephan Menzer, J. Fraser Stoddart,* Andrew J. P. White, and David J. Williams*

Dedicated to Professor Dieter Seebach on the occasion of his 60th birthday

On account of its pivotal role in several essential chemical and biological processes, anion binding and recognition[1] is currently arousing considerable attention within the domain of supramolecular chemistry.[2] Traditionally, supramolecular chemists have positioned anion recognition sites within covalent macro(poly)cyclic frameworks[3] in a preorganized[4] manner, so as to achieve strong anion binding. However, the discovery of self-assembled[5] supermolecules that are capable of binding anions has been accomplished,[6] as supramolecular science has developed. Nevertheless, to the best of our knowledge, there has been no report to date of a self-assembled anion receptor whose components are held together *entirely* by hydrogen bonds. We describe here the discovery of two novel supermolecules—self-assembled utilizing only hydrogen bonds—which display either partial or complete envelopment of PF_6^- ions in the solid state.

Recently, we reported[7] that macrocyclic polyethers form inclusion complexes, termed pseudorotaxanes,[8] of varying stoichiometries with secondary dibenzylammonium ions. In these pseudorotaxanes the ammonium ions are threaded through the macrorings and are held in place by a combination of $[N^+-H\cdots O]$ and $[C-H\cdots O]$ hydrogen bonds, with occasional assistance from $\pi-\pi$ stacking interactions. For instance, the ditopic crown ether bis-*p*-phenylene[34]crown-10 (BPP34C10) has been shown[7] to form complexes with the dibenzylammonium ion (**1**-H^+), in which two of these threadlike cations interpenetrate the macroring's void simultaneously to form (Figure 1) a double-stranded [3]pseudorotaxane. While researching these systems, we became intrigued by the possibility that higher homologues[9] of BPP34C10—specifically, the crown ethers tris-*p*-phenylene[51]crown-15 (TPP51C15) and tetrakis-*p*-phenylene[68]crown-20 (TPP68C20)—could incorporate three and four **1**-H^+ cations within their respective cavities. Moreover, on account of the increased dimensions of the circumferences of their crown ether precursors, the resultant [4]- and [5]pseudorotaxanes should possess ammonium centers ideally predisposed to associate with anions by means of hydrogen bonding and anion–dipole interactions, that is, where the macrocyclic polyethers effect supramolecular preorganization[10] of the anion binding sites. Indeed, we have found (vide infra) that the $[TPP51C15\cdot(\mathbf{1}\text{-}H)_3]^{3+}$ and $[TPP68C20\cdot(\mathbf{1}\text{-}H)_4]^{4+}$

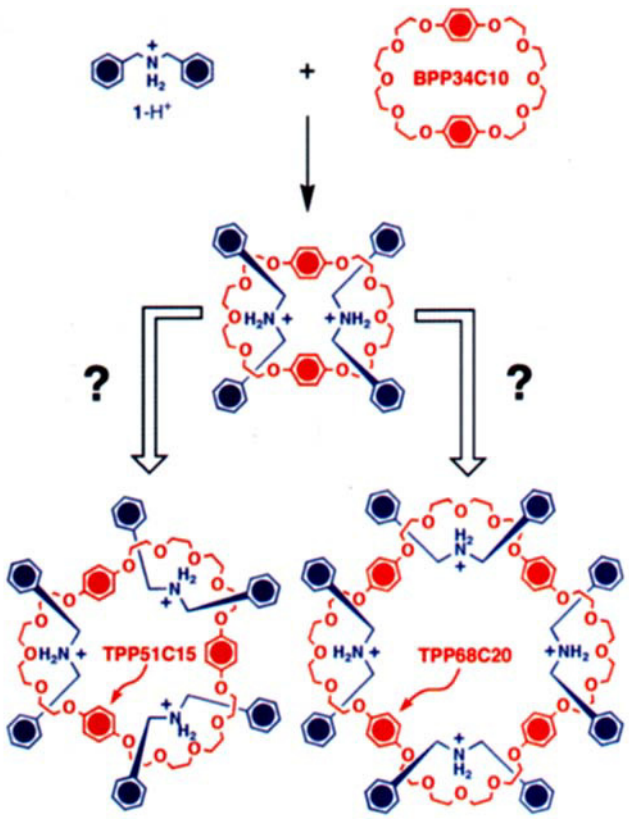

Figure 1. Complexation of the dibenzylammonium ion (**1**-H^+) with the crown ether BPP34C10 yields a double-stranded [3]pseudorotaxane. The question is: would larger macrocycles such as TPP51C15 and TPP68C20 allow the concurrent threading of three and four **1**-H^+ ions through their respective cavities?

pseudorotaxanes interact with PF_6^- ions in the solid state. Furthermore, it appears that the bound anions can dictate the overall three-dimensional topology of the pseudorotaxane complexes, thus assisting the overall self-assembly processes.[11]

TPP51C15 is capable of extracting three molar equivalents of [**1**-H]PF_6 from a suspension of a large excess of the salt in CD_2Cl_2. Since [**1**-H]PF_6 is practically insoluble in this solvent in the absence of the crown ether, this observation provides a semiquantitative guide to the likely stoichiometry of the complex. Analysis of the resulting CD_2Cl_2 solution by ^1H NMR spectroscopy reveals[12] significant chemical shift changes for the proton resonances associated with both species, indicative of host–guest complex formation. An analysis of a single crystal (obtained by liquid diffusion of *n*-hexane into a 1:3 molar mixture of TPP51C15 and [**1**-H]PF_6 in CH_2Cl_2) by X-ray crystallography[13] revealed the solid-state structure depicted in Figure 2. The complex's supramolecular architecture corresponds

to a triple-stranded [4]pseudorotaxane, in which each of the enthreaded **1**-H^+ ions is independently involved in stabilizing $[N^+-H\cdots O]$ and $[C-H\cdots O]$ hydrogen bonding interactions with TPP51C15's separate polyether loops. The macroring adopts a folded conformation with approximate C_s symmetry. A closer investigation of the location of the three PF_6^- ions reveals that one of the three anions is located almost centrally within a cleft generated by the saddlelike co-conformation[14] of the 1:3 complex (Figure 2). Complexation of this anion is achieved by a series of $[C-H\cdots F]$ hydrogen bonds to hydrogen atoms on the hydroquinone rings of the crown ether and the benzylic methylene groups of the bound **1**-H^+ ions. Hence, the crown ether participates simultaneously in both of the anion's first and second coordination spheres.[15] A noticeable feature of this binding is the order bestowed upon the bound PF_6^- ion.

This discovery of partial anion envelopment by the $[TPP51C15\cdot(\mathbf{1}\text{-}H)_3]^{3+}$ supermolecule led us to believe that the total encapsulation of anions by self-assembled pseudorotaxane superstructures of this type could be achieved with suitably expanded crown ethers. Four molar equivalents of the [**1**-H]PF_6 salt are solubilized in a CD_2Cl_2 solution containing one molar equivalent of TPP68C20. Significant changes in the chemical shifts of probe protons in both the salt and the crown ether are observed[16] in the ^1H NMR spectrum of this solution, suggesting that cation complexation is occurring in this solvent. Single crystals were obtained when a 1:4 molar solution of TPP68C20 and [**1**-H]PF_6 in CH_2Cl_2 was layered with *n*-hexane. The X-ray analysis[13] of one of these crystals reveals that, when the macrocyclic polyether is extended by an additional hydroquinone-spaced polyether loop, a crystalline aggregate results which contains two independent quadruple-stranded [5]pseudorotaxane complexes (Figure 3). The asymmetric unit also

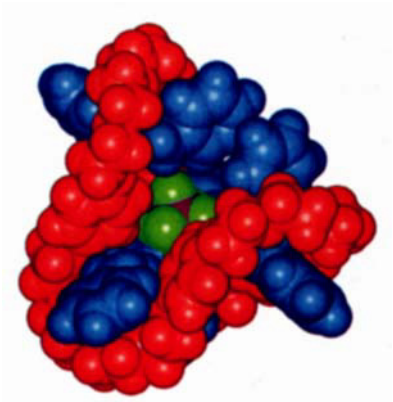

Figure 3. Space-filling view of one of the $[TPP68C20\cdot(\mathbf{1}\text{-}H)_4\cdot PF_6]^{3+}$ supermolecules formed in the solid state, illustrating both the threading of the four **1**-H^+ ions (blue) through the cavity of the macrocyclic polyether TPP68C20 (red), and the encapsulation of a PF_6^- ion (phosphorus in purple, fluorines in green) within the cavity formed by the $[TPP68C20\cdot(\mathbf{1}\text{-}H)_4]^{4+}$ complex. The $[H\cdots F]$ distances range between 2.41 and 2.73 Å; the associated $[C\cdots F]$ contacts are between 3.16 and 3.52 Å.

accommodates a pair of unassociated C_s-symmetric dibenzylammonium ions with their allied PF_6^- counterions. The two [5]pseudorotaxane complexes have essentially identical co-conformations[14]; the TPP68C20 macrocycle adopts a conformation that possesses local S_4 symmetry and resembles the seam of a tennis ball. The four dibenzylammonium ions are clipped over each of the macrocycle's four polyether loops. The tetracationic complex is stabilized by a combination of $[N^+-H\cdots O]$ and $[C-H\cdots O]$ hydrogen bonds between both the ammonium centers' hydrogen atoms and their adjacent CH_2 groups and the polyether's oxygen atoms. On the other hand, the remaining cations, which lie on the crystallographic C_s plane, are not involved in any hydrogen bonding interactions. The most striking feature of both independent [5]pseudorotaxane complexes is the siting of a single PF_6^- ion at each of their cores in ordered arrangements (Figure 3). In this case, the anion is totally encapsulated[17] by both the four hydroquinone rings, which are oriented with their planes intersecting on the phosphorus center, and the four tetrahedrally disposed, positively charged $CH_2-NH_2^+-CH_2$ regions of the four **1**-H^+ cations. The phosphorus atoms lie only about 0.3 Å from the complexes' centroids. In view of the "spherical" shape of PF_6^- ions, they tend to assume random orientations in crystal lattices. However, in this example, the anion is fully ordered—an ordering which is undoubtedly a consequence of a series of $[C-H\cdots F]$ hydrogen bonds, involving the cooperative action of hydroquinone methine and benzylic methylene hydrogen atoms which, in addition to coulombic forces, direct the physical envelopment of the anion. Thus, the self-assembled [5]pseudorotaxanes provide elegant concentric spheres of cationic and neutral ligands for the total encapsulation of the anions (Figure 4).

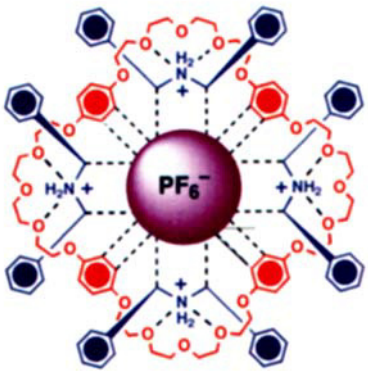

Figure 4. Cartoon representation of the $[TPP68C20\cdot(\mathbf{1}\text{-}H)_4\cdot PF_6]^{3+}$ superstructure.

It is not unreasonable to conclude that the enfolded geometries of the 1:4:1 complexes—and, indeed, the 1:3:1 complex as well—have been programmed by the negatively charged PF_6^- ions; that is, the supramolecular system could be equally well viewed as receiving its instructions from the anionic core, which are then relayed through a four-component, tetracationic, first sphere to the neutral, second-sphere ligand.

[8] Pseudorotaxanes have been defined as inclusion complexes in which one or more threadlike molecules (or ions) are encircled by one or more macrocyclic molecules (or ions) in the absence of an intercomponent mechanical or covalent bond. Consequently, pseudorotaxanes are free to dissociate into their separate components. The prefix [*n*] implies that an [*n*]pseudorotaxane is comprised of *n* components. For instance, the 1:2 complex $[BPP34C10\cdot(\mathbf{1}\text{-}H)_2]^{2+}$ depicted in Figure 1 is a double-stranded [3]pseudorotaxane.

[12] $\Delta\delta$ values for the resonances associated with the polyether's α-, β-, γ-, δ-OCH_2 and hydroquinone methine protons [solution of TPP51C15 (approximately 5×10^{-3} M) and [**1**-H]PF_6 (approximately 1.5×10^{-2} M) in CD_2Cl_2 at 20 °C]: $\delta = 0.00, -0.17, -0.29, -0.36, +0.13$.

[13] Crystal data for $[TPP51C15\cdot(\mathbf{1}\text{-}H)_3][PF_6]_3\cdot2CH_2Cl_2$, $M_r = 2004.5$, orthorhombic, $a = 19.592(1)$, $b = 25.240(1)$, $c = 20.117(3)$ Å, $V = 9948(2)$ Å^3, space group $Pca2_1$, $Z = 4$, $\rho_{calcd} = 1.338$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 23.5$ cm^{-1}, $\lambda = 1.54178$ Å, $F(000) = 4176$, $T = 293$ K, 6518 unique reflections ($\theta \le 60°$), of which 3846 were observed [$I_o > 2\sigma(I_o)$]. Final *R*-factors: $R_1 = 0.103$, $wR_2 = 0.269$ for 670 parameters. Crystal data for $[TPP68C20\cdot(\mathbf{1}\text{-}H)_4][PF_6]_4\cdot0.5(C_6H_5CH_2)_2NH_2\cdot0.5PF_6\cdot1.75CH_2Cl_2$, $M_r = 2766.4$, monoclinic, $a = 19.179(3)$, $b = 70.669(7)$, $c = 19.993(2)$ Å, $\beta = 90.55(1)°$, $V = 27096$ Å^3, space group $P2_1/m$, $Z = 8$ (two independent supermolecules), $\rho_{calcd} = 1.356$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 20.8$ cm^{-1}, $\lambda = 1.54178$ Å, $F(000) = 11532$, $T = 293$ K, 34335 unique reflections ($\theta \le 55°$), of which 20274 were observed ($I_o > 2\sigma(I_o)$). Final *R*-factors: $R_1 = 0.100$, $wR_2 = 0.269$ for 3282 parameters. Data for both structures were collected on a Siemens P4/RA diffractometer with $Cu_{K\alpha}$ radiation (graphite monochromated) using ω scans. The data were corrected for Lorentz and polarization factors, but not for absorption. The structures were solved by direct methods and refined by least-squares based on F^2. The N–H hydrogen atoms were located from ΔF maps, the C–H hydrogen atoms were placed in calculated positions. Both were allowed to ride on their parent atoms. The polarity of the $[TPP51C15\cdot(\mathbf{1}\text{-}H)_3][PF_6]_3$ superstructure was determined using the Flack parameter, which refined to 0.2(2). All computations were carried out using the SHELXTL 5.03 package. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100264. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (Fax: Int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

[14] Strictly speaking, the term "conformation" refers only to discrete molecular species. Consequently, we have used "co-conformation" to designate the different three-dimensional spatial arrangement of a) the constituent parts (e.g., host and guest) in supramolecular systems and of b) the components of interlocked molecular systems.

[15] Simultaneous first- and second-sphere coordination by macrocyclic polyethers has been noted previously in our laboratories. See: H. M. Colquhoun, S. M. Doughty, A. M. Z. Slawin, J. F. Stoddart, D. J. Williams, *Angew. Chem.* **1985**, *97*, 124–125; *Angew. Chem. Int. Ed. Engl.* **1985**, *24*, 135–136.

The Five-Stage Self-Assembly of a Branched Heptacatenane**

David B. Amabilino, Peter R. Ashton, Sue E. Boyd, Ju Young Lee, Stephan Menzer, J. Fraser Stoddart,* and David J. Williams*

The controlled creation of macromolecular chain compounds—that is, oligo- and polycatenanes—comprising mechanically linked macrocycles, which recognize each other link by link as a result of noncovalent bonding interactions is one of the most intellectually appealing goals in synthetic polymer chemistry today. Self-assembly processes[1] provide versatile means of achieving this objective, operating in the first instance by thermodynamically controlled recognition between the appropriate acyclic and cyclic intermediates, followed by kinetically controlled[2] ring closures in which both covalent and mechanical bonds are formed. Clearly, the ease of construction of the higher order catenanes becomes a function of just how efficiently additional rings can be clipped around existing ones.[3]

Previously we have reported[3] the self-assembly (Scheme 1) of a tricatenane $\mathbf{3}\cdot4PF_6$ incorporating two tris-1,5-naphtho[57]crown-15 macrocycles linked by the large tetracationic cyclophane, cyclobis(paraquat-4,4'-biphenylene). We have also shown[4] that $\mathbf{3}\cdot4PF_6$ can be employed as a template to clip on, in a stepwise manner, smaller tetracationic cyclophanes like cyclobis(paraquat-*p*-phenylene) tetracations. This approach to the construction of oligo- and polycatenanes has already yielded[4, 5] the pentacatenane $\mathbf{5}\cdot12PF_6$, dubbed olympiadane.[6] Here we report how subsequent repetitive self-assembly steps have been rendered more efficient by the use of ultrahigh pressure, leading to the isolation of a branched heptacatenene ($\mathbf{7}\cdot20PF_6$), and describe its solid-state molecular structure as determined by X-ray diffraction analysis.

When $\mathbf{3}\cdot4PF_6$[4] was treated (Scheme 1) with $\mathbf{2}\cdot2PF_6$ and **1** in *N*,*N*-dimethylformamide at 12 kbar for 6 days, the [7]catenane $\mathbf{7}\cdot20PF_6$ was isolated after chromatography in 26% yield, together with $\mathbf{5}\cdot12PF_6$ (30%) and $\mathbf{6}\cdot16PF_6$ (28%). No $\mathbf{4}\cdot8PF_6$ was obtained and only traces of $\mathbf{5}'\cdot12PF_6$ were detected.[7] The [7]catenane was characterized initially from its mass spectrum (LSI-MS) and ^{1}H NMR spectrum (see *Experimental Section*). Subsequently, single crystals of $\mathbf{7}\cdot20PF_6$, suitable for X-ray crystallography, were obtained by vapor diffusion of diisopropyl ether into an acetonitrile solution of the [7]catenane.

The X-ray analysis[8] of $\mathbf{7}\cdot20PF_6$ (Figure 1) reveals a molecular structure that fulfills every one of the anticipated design features of the interlocked molecule: all the recognition sites are

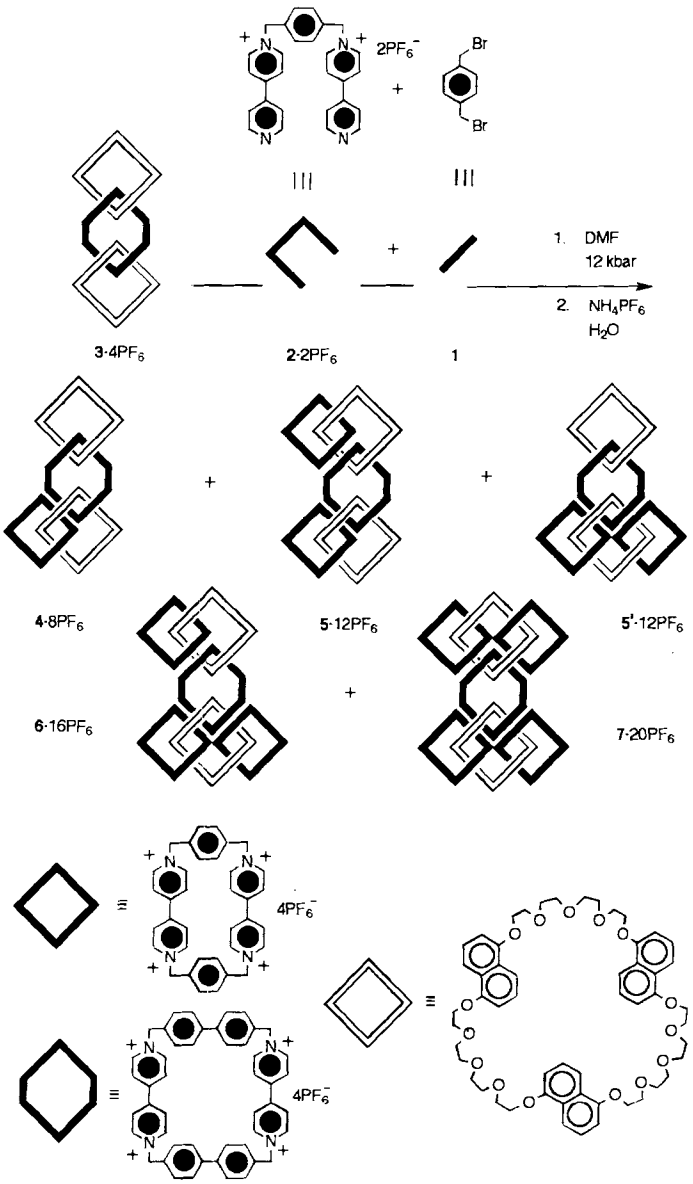

Scheme 1. The multistep template-directed syntheses of the [4]catenane $4\cdot 8\,PF_6$, two [5]catenanes $5\cdot 12\,PF_6$ (olympiadane) and $5'\cdot 12\,PF_6$, the [6]catenane $6\cdot 16\,PF_6$, and finally, the [7]catenane $7\cdot 20\,PF_6$.

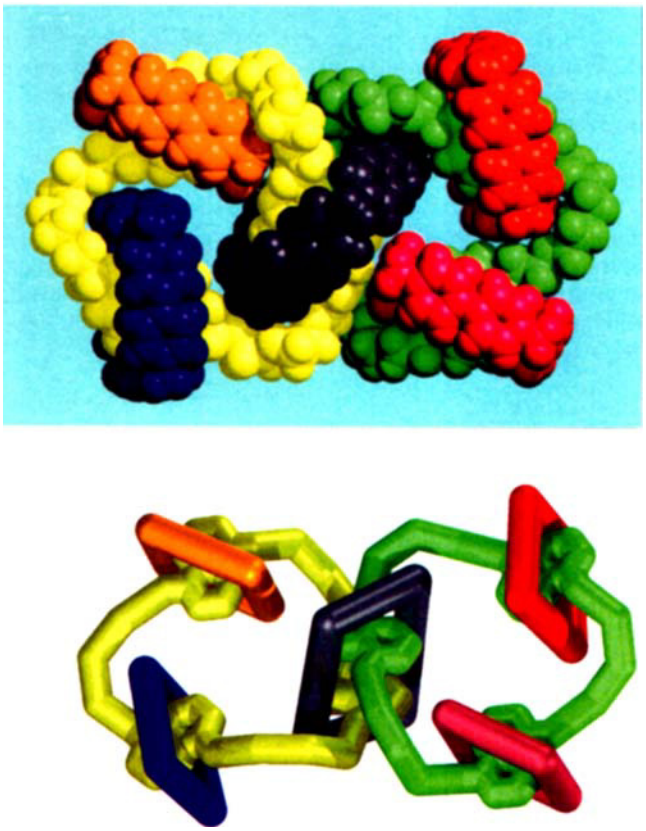

Figure 1. Top: A space-filling representation of the solid state structure of the branched [7]catenane 7^{20+}. Green and yellow: tris-1,5-dinaphtho[57]crown-15 rings; black: cyclobis(paraquat-4,4'-biphenylene) tetracation; other contrasting colors: cyclobis(paraquat-*p*-phenylene) tetracations. Bottom: A tubular representation of 7^{20+}. The pipe sections within the crown ethers define the 1,5-dioxynaphthalene rings and link the oxygen atoms of the polyether chains. Within the tetracationic cyclophanes they link the corner methylene carbon atoms. The pipe diameters are approximately 2.5 Å. This representation was generated with the Persistence of Vision (POV) package, version 3.0, on an SGI workstation.

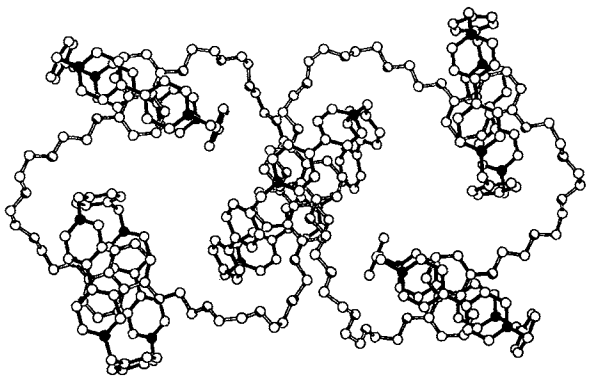

Figure 2. A ball-and-stick representation of the branched [7]catenane 7^{20+}.

utilized in a mutually compatible manner; that is, all six π-electron-rich 1,5-dioxynaphthalene units (belonging to the two discrete but identical macrocyclic polyethers) enter into π-π-stacking interactions with the π-electron-deficient bipyridinium units of all five tetracationic cyclophanes—one cyclobis(paraquat-4,4'-biphenylene) tetracation centrally located between the two macrocyclic polyethers and the other four, all cyclobis(paraquat-*p*-phenylene) tetracations, divided equally between the two macrocyclic polyethers on the periphery of the molecule (Figure 2). Although this branched [7]catenane can adopt a C_i-symmetrical arrangement, this particular symmetry is not realized in the deep violet crystals. However, despite the absence of crystallographic symmetry, the overall molecular structure deviates only marginally from this potential, centrosymmetric arrangement of the ring components. Indeed, molecular pseudosymmetry appears to dominate: the centers of the three 1,5-dioxynaphthalene rings within each of the macrocyclic polyether components define approximate equilateral triangles with sides of about 12 Å. Additionally, the inclinations of the $-OC_{10}H_6O-$ vectors of all six 1,5-dioxynaphthalene rings with respect to the average N···N axes of the bipyridinium units in their associated tetracationic cyclophanes are in a narrow range (51–54°). Furthermore, the interplanar separation between the π-π-stacked donors and acceptors throughout the molecule are bunched together between 3.37 and 3.47 Å: the sandwiched pair of 1,5-dioxynaphthalene rings within the central tetracationic cyclophane lie 3.50 Å apart. The only other arene–arene interactions[9] present within the molecule are between this sandwiched pair of rings and the orthogonally aligned, proximal

p-xylyl spacers in the tetracationic cyclophanes in the 4 and 10 o'clock positions in Figures 1 and 2: the associated ring centroid/ring centroid distances are 4.94 and 5.02 Å. The surface of the molecule has a capsular shape with nanometer dimensions of about 1.5 × 2.0 × 4.0 nm. The only extended intermolecular interaction is an off-set π-π-stacking between the peripheral *p*-xylyl rings of the pair of tetracationic cyclophanes at 4 and 10 o'clock in lattice-translated molecules.

The solid-state crystal structure of this branched heptacatenane serves as a significant marker and symbolic reminder to us of the effectiveness and efficiency of the relatively new methods of template-directed synthesis[10] where interlocked molecular compounds[5, 11] are the result of self-assembly processes[1] that are kinetically controlled.[2]

Experimental Section

7·20PF_6: 1,4-Bis(bromomethyl)benzene (**1**, 43 mg, 0.165 mmol), the dicationic salt **2**·2PF_6 (106 mg, 0.150 mmol), and the [3]catenane **3**·4PF_6 (60 mg, 0.019 mmol) were allowed to react at 12 kbar in DMF (12 mL) in an ultrahigh pressure reaction vessel for two days at 20 °C. Additional quantities of **1** (43 mg, 0.165 mmol) and **2**·2PF_6 (106 mg, 0.150 mmol) were added to the solution, and the reaction vessel was repressurized (12 kbar for four more days). The solvent was removed under vacuum, and the residue subjected to column chromatography (SiO_2; gradient elution: MeOH/2 M NH_4Cl(aq)/$MeNO_2$/DMF from 4/2/2/2 to 4/6/2/5) to afford, after counterion exchange (NH_4PF_6/H_2O), **5**·12PF_6 (30 mg, 30%), a trace of **5'**·12PF_6, **6**·16PF_6 (34 mg, 28%), and the [7]catenane **7**·20PF_6 (37 mg, 26%) as a purple solid, m.p. > 300 °C, LSI-MS: m/z = 7275, 7130, 6985, 6840, 6694, and 6549 for $[M-2PF_6]^+$, $[M-3PF_6]^+$, $[M-4PF_6]^+$, $[M-5PF_6]^+$, $[M-6PF_6]^+$, and $[M-7PF_6]^+$, respectively; ^{1}H NMR (CD_3CN, 400 MHz, 12 °C) δ = 2.28 (d, J = 7.5 Hz, 8H), 3.40–4.06 (m, 68H), 4.10–4.19 (m, 16H), 4.20–4.29 (m, 16H), 5.33–5.41 (m, 8H), 5.43 (s, 8H), 5.52–5.66 (m, 32H), 5.88 (t, J = 7.5 Hz, 8H), 6.17 (d, J = 7.5 Hz, 8H), 6.89 (d, J = 6.5 Hz, 8H), 7.08 (d, J = 6.5 Hz, 16H), 7.26 (d, J = 6.5 Hz, 16H), 7.74 (d, J_{AB} = 8.0 Hz, 8H), 7.85 (s, 16H), 7.98 (s, 16H), 8.03 (d, J_{AB} = 8.0 Hz, 8H), 8.53 (d, J = 6.5 Hz, 16H), 8.60 (d, J = 6.5 Hz, 8H), 8.87 (d, J = 6.5 Hz, 16H).

[6] X-ray crystal structure of olympiadane: R. Dagani, *Chem. Eng. News* **1996**, Sept. 2, 31. This trivial name for a pentacatenane was proposed, because it resembles the emblem of the International Olympics: N. van Gulick, *New J. Chem.* **1993**, *17*, 619–625.

[7] When the reaction was performed during 3 days at 10 kbar, some **4**·8PF_6 was isolated, along with the higher order catenanes in yields somewhat lower than those achieved for the longer and higher pressure reactions—in agreement with the kinetic regime that characterizes this self-assembly process. It is clear that the [4]-, [5]-, and [6]catenanes are intermediates on the way to the [7]catenane from the [3]catenane. There is no reason why these intermediate catenanes cannot be used for the preparation of 7·20PF_6—or indeed, other higher order catenanes.

[8] Crystal data for 7·20PF_6: $C_{300}H_{300}N_{20}O_{30}$·20$PF_6$·10$CH_3CN$·$CH_3OH$·18$H_2O$, M_r = 8327.84, triclinic, a = 24.179(1), b = 28.066(1), c = 31.108(1) Å, α = 90.04(1), β = 98.44(1), γ = 100.96(1)°, V = 20491(1) Å^3, space group $P\bar{1}$, Z = 2, ρ_{calcd} = 1.350 g cm^{-3}, μ = 0.200 mm^{-1}, T = 173 K, $F(000)$ = 8556. Data were collected with a Siemens SMART diffractometer (graphite monochromated $Mo_{K\alpha}$ radiation). The unit cell was determined by least-squares refinement of all the observed data. A total of 84390 reflections were collected up to 2θ = 52°, merged to give 55802 unique data, and of these, 18937 (2θ < 40°) reflections with $|F_o| > 4\sigma|F_o|$ were considered observed. The data were corrected for Lorentz and polarization effects but not for absorption. The structure was solved with some difficulty by direct methods with the XS module of SHELXTL 5.03. To complete the first model, solvent molecules and anions were located from electron density maps with XtalView 3.1. The ring systems and polyether linkages were then subjected to geometric restraints, and the structure refined by blocked least-squares refinement on F^2 with the observed data (2θ < 40°). All full weight anions, solvent molecules, and polyether linkages were refined anisotropically, while the remainder of the structure was left isotropic. Hydrogen atoms in the macrocyclic polyether and tetracationic cyclophane components were located in idealized positions with U(H) = 1.2 U_{eq}(C) and allowed to ride on their parent atoms. Hydrogen atoms for solvent molecules were not located. The refinement converged to give R_1 = 0.1968 and wR_2 = 0.4498 for 3748 refined parameters. The high value for R_1 is a consequence of the extensive solvation, the large number of very weak reflections, and serious and unresolved inconsistencies in the high-angle data (very asymmetric intensity distributions and negative overall U values from Wilson plots), discrepancies that necessitated weighting of the data before a solution could even be obtained and the abandoning of the data in the range 40° < θ < 52° for the refinements. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100468. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code +(1223) 336-033; e-mail: deposit@chemcrys.cam.ac.uk).

[9] In view of the limited accuracy of the data and the presence of disorder within parts of the polyether linkages, we have not carried out a detailed analysis of the possible intercomponent [CH···O] hydrogen bonding, although undoubtedly these interactions will have additional stabilizing effects on the overall molecular geometry.

Halozeotypes: a New Generation of Zeolite-Type Materials**

James D. Martin* and Kevin B. Greenwood

Solid-state chemists have followed nature's geological examples by transforming common silicate, aluminate, and phosphate building blocks into zeolitic materials with elaborate microporous frameworks.[1] These microporous materials are used as molecular sieves and catalysts that are vital to countless applications in industry as diverse as petrochemicals, personal-care products, and environmental decontamination. In spite of extensive substitution of the framework cations to fine tune the properties of such materials, zeolite-type structures with frame-

work anions other than oxide are rare.[2] The refractory nature of the metal oxides provides remarkable stability to the microporous frameworks, albeit at the expense of reactivity and tractability. For this reason there is considerable interest in the synthesis of microporous solids whose micropores incorporate reactive species that enhance reactivity,[3] and in the synthesis of microporous solids from organic[4] and inorganic/organic[5] building blocks to obtain greater control of framework design.

Here we report the development of a new generation of zeotype materials constructed from the reactive metal halide building blocks CuCl and $ZnCl_2$. These halozeotype materials represent novel non-oxide analogues of microporous aluminosilicates, and provide the foundation for new developments in host–guest chemistry for crystal engineering of chemically reactive framework building units. The halozeotypes have the general formula T_mX_{2m} (T = tetrahedraly coordinated atom, X = halide) and are constructed by linking tetrahedral cations through two-coordinate halide anions. A divalent metal halide such as $ZnCl_2$, in which the metal cation exhibits tetrahedral coordination, acts as a silicate analogue in this family of framework materials. Compounds $[A_n][Cu_nZn_{m-n}X_{2m}]$ (A = cationic template), analogues of the aluminosilicates $[A_n][Al_nSi_{m-n}O_{2m}]$, can be prepared by substituting certain Zn^{II} sites with Cu^{I} cations; an interstitial cation A^+ is required with each Cu^{I} ion to balance the charge in the framework. Although there is no evidence for binary Cu/Zn halides in the $CuCl/ZnCl_2$ phase diagram,[6] a novel family of framework materials can be prepared from the ternary system alkylammonium/copper halide/zinc halide. The materials CZX-1, CZX-2, and CZX-3 (CZX = copper zinc halide) are the first examples of halozeotypes.

$[HNMe_3][CuZn_5Cl_{12}]$ CZX-1

$[H_2NEt_2][CuZn_5Cl_{12}]$ CZX-2

$[H_2NMe_2]_n[Cu_nZn_{6-n}Cl_{12}]$ ($n = 1, 2$) CZX-3

Single crystals of CZX-1, CZX-2, and CZX-3 were grown from solutions in superheated benzene (160 °C, autogeneous pressure) with a 5:1:1 ratio (2:1:1 for CZX-3) of $ZnCl_2$, CuCl, and $HNMe_3Cl$, H_2NEt_2Cl, or H_2NMe_2Cl, respectively. The resulting materials are colorless and diamagnetic with melting points between 160 and 180 °C. The framework structures are dictated by the size and shape of the ammonium cation template. The CZX-1 framework, formed with the more symmetrical $HNMe_3^+$ template, adopts the well-known sodalite structure.[1, 7–11] The less symmetrical dialkylammonium cations $H_2NEt_2^+$ and $H_2NMe_2^+$ afford the isostructural compounds CZX-2 and CZX-3, whose frameworks exhibit novel three-dimensional channel structures.

Halozeotype CZX-1 crystallizes in the cubic space group $I\bar{4}3m$ with $a = 10.5887(3)$ Å. Refinement of the single crystal X-ray diffraction data revealed a sodalite structure (Figure 1), in which truncated octahedral metal halide cages are packed in a body-centered cubic arrangement.[12] Since the trimethylammonium cation is too small to completely fill the space inside the metal halide cage (the distance from the centroid of the cage to Cl is 4.41 Å), it is disordered over four orientations with hydrogen bonding of the N–H group to the three chloride atoms of the six-ring faces (N–Cl 3.49 Å). Halozeotype CZX-1 exhibits the smallest T-X-T angle (110.04(3)°) of all known sodalite structures;[7–11] this results in an unprecedented contraction of the cage. The T-O-T angle in oxidic sodalites ranges from 124 to 160° (145° is preferred), and in the only other nonoxide sodalite, $[P_{12}N_{24}]^{12-}$, the P-N-P angle is 125.8(4)°.[13]

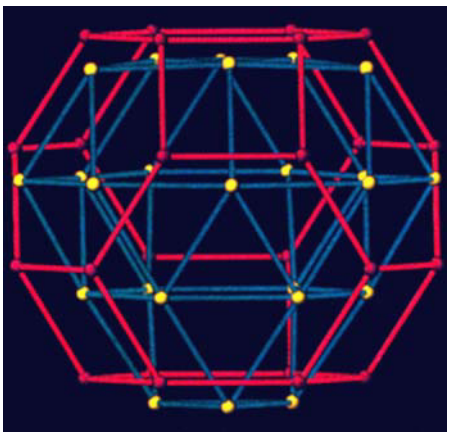

Figure 1. View of the sodalite cage of CZX-1 perpendicular to the 111 axis; T–T contacts are shown in red, and X–X contacts in blue.

To our knowledge the question of the maximal contraction of the sodalite cage has not yet been addressed, although the flexibility of the sodalite framework by T-atom substitution or thermal expansion is well documented. The angular constraints of the sodalite framework have been described by Depmeier[10] and Taylor,[11] who showed that the flexibility of the sodalite cage is a function of bond length l between the T atom and the anion, the X-T-X angle (α), the T-X-T angle (γ), and the angle by which the tetrahedra are twisted cooperatively about the $\bar{4}$ axis (φ). Thus, given the tetrahedral angle α of 109.5°, the maximum value of γ is 160.5°. This maximum expansion of the cage is obtained for $\varphi = 0°$. Structures close to this limit have been observed in several oxide-based sodalites.[7–11] However, when $\varphi = 45°$, then $\alpha = \gamma = 109.5°$. In this contracted limit, the anions form a cubic closest packed sublattice (. .ABCA. .) in which 4/16 of the anion positions are vacant. These anion vacancies provide the host cavity for the template cation(s). The sodalite cage of CZX-1 adopts just such a closest-packed structure with $\gamma = 110.04(3)°$, $\alpha = 112.82(3)°$, and $\varphi = 43.38°$. (The most highly contracted sodalite previously reported is $Zn_3As_3O_{12}^{3-}$, in which $\gamma = 123.8°$.[7])

The limits to the contraction of a sodalite cage are determined by the T–T distances u and the X–X distances m, which can be expressed as functions of l, α, and γ or φ.[14] It follows that m and u are related by the geometric limits of the sodalite cage according to Equation (a).

$$m = 2u - 2\sqrt{2}l\cos\alpha/2 \qquad \text{(a)}$$

A consequence of closest packing is that m and u must be equal. Thus, a closest-packed sodalite structure can only be obtained when $2\sqrt{2}l\cos\alpha/2$ [Eq. (a)] is greater than the radius of the X and T atoms, since the minimum value of m or u is twice the radius of the X or T atom, respectively. The radius of Si (1.55 Å) exceeds this limit. The short (Si,Al)–O distances, which range from $l = 1.58$ to 1.78 Å, define a radius limit of less than 1.29 to 1.45 Å; the oxidic sodalites are thus restricted to structures in which the T-O-T angle γ is limited to about 120°. In contrast, the longer (Zn,Cu)–Cl bond length of 2.285(1) Å defines a radius limit of 1.87 Å for a "closest-packed" sodalite with $\alpha \approx 109.5$. Chloride anions fit comfortably within this radius limit, and the van der Waals radii of copper and zinc (1.40 Å) are well below it. Whereas the most contracted structure for oxide-based sodalites is limited by T–T repulsions, the novel metal halide sodalite CZX-1 exhibits the maximum frame-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3619-2073 $ 17.50+.50/0

work contraction limited by anion–anion contacts. A similar conclusion was presented by O'Keeffe and Hyde for the structural limitations of cristobalite-like structures.[15]

Compounds CZX-2[16] and CZX-3[17] crystallize in the orthorhombic space group $I2_12_12_1$ with $a = 9.6848(5)$, $b = 9.5473(4)$, and $c = 14.0003(9)$ Å and $a = 9.5677(16)$, $b = 9.4554(12)$, and $c = 13.6435(16)$ Å, respectively. Refinement of the single crystal X-ray diffraction data revealed a novel open-framework structure (Figure 2). The dialkylammonium

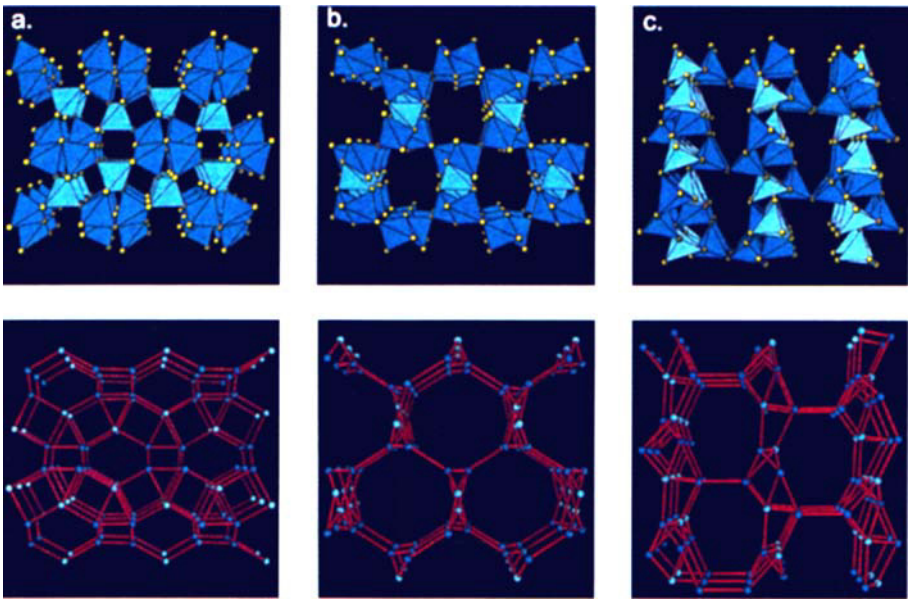

Figure 2. Polyhedral and ball-and-stick views of the open-framework structure of CZX-2 and CZX-3 a) along the *a* axis, b) along the *b* axis (the unit cell boundaries are also shown), and c) along the body diagonal. The two types of metal sites are royal blue (eightfold site) and light blue (fourfold site).

cations form hydrogen bonds with the chloride anions that form the interior of the channels (N–Cl(4) 3.25 Å × 2 and N–Cl(6) 3.21 Å in CZX-2; N–Cl(5) 3.64 Å × 2 and N–Cl(4) 3.66 Å × 2 in CZX-3) and act as templates for the formation of the open framework. In CZX-2 the ammonium cations refine to a crystallographically imposed occupancy of 50% (the methyl carbon atom is common to two diethylammonium cations), which is consistent with the ammonium:copper:zinc ratio of 1:2:5 observed by energy-dispersive X-ray spectroscopy (EDS) and elemental analysis. In contrast, the smaller dimethylammonium cation is fully occupied in CZX-3, giving an ammonium:copper:zinc ratio of 1:1:2. There are two crystallographically distinct metal sites in this framework with multiplicities of four and eight. However, it is not possible to assign uniquely the Cu or Zn cations to either site on the basis of X-ray diffraction data.

Consistent with our zeolitic analogy, frameworks CZX-2 and CZX-3 are constructed from corner-sharing tetrahedral primary building blocks. This framework structure can also be described as being constructed from three-ring secondary building units that consist of one type-one and two type-two metal sites. To our knowledge, this framework structural type has not been observed for any other zeolite-type materials. The projection of the metal framework along the *a* axis (Figure 2a) is reminiscent of a projection of the faujasite framework structure. However, the apparent six-rings and one-third of the apparent four-rings are actually projections of helical connectivity. The most open dimension of this novel framework consists of chiral channels running along the 2_1 axes parallel to the *b* axis (Figure 2b). The smallest ring that circumscribes this channel consists of eleven tetrahedra (Figure 3a). The shortest cross-channel contacts between Cl(4) and Cl(4′) are 6.34 Å for CZX-2, and 6.22 Å for CZX-3. This corresponds to free diameters of 2.9 Å and 2.8 Å, respectively, if the radius of Cl (1.7 Å) is taken into account. The Cl(6)–Cl(6′) distance is 7.87 Å for CZX-2 and 7.51 Å for CZX-3. Four eight-ring windows (Figure 3b) provide access to this primary eleven-ring channel and themselves form smaller channels along the body diagonal (Figure 2c). The smallest cross-channel contacts of this eight-ring channel between Cl(3) and Cl(3′) are 4.32 Å in CZX-2 and 4.11 Å in CZX-3. The largest remaining void in the fully occupied CZX-3 structure lies directly in the eight-ring window and also corresponds to the channel parallel to the *c* axis; the shortest void centroid to halide distance is 2.69 Å.

On investigating the microporosity of these novel frameworks we discovered that addition of methanol or water in quantities insufficient for complete solvation results in the formation of a colloidal suspension of CZX-1, CZX-2 and CZX-3. This is in contrast to $ZnCl_2$, which forms a liquid methanol solvate similar to the zinc chloride hydrates. Neither CuCl nor the known $[A]_2ZnCl_4$ phases ($A^+ = HNMe_3$, H_2NEt_2, and H_2NMe_2) absorb methanol under similar conditions. Thermogravimetric analysis (TGA) and NMR measurements indicate that up to about three equivalents of methanol can be absorbed into the framework of these halozeotypes. The frameworks with the lowest template content absorb the most methanol. Additional methanol, up to about 12–15 equivalents per framework unit ($M_6Cl_{12}^n$) are absorbed to stabilize the colloid. The size and extent of flocculation of the colloids can be controlled by the ratio of framework to solvent. Adding 40 equivalents of methanol to one equivalent of the metal halide framework gives a suspension of 100-nm particles (measured by optical microscopy), which remain suspended for days. Concentrating this suspension by removal of solvent in a

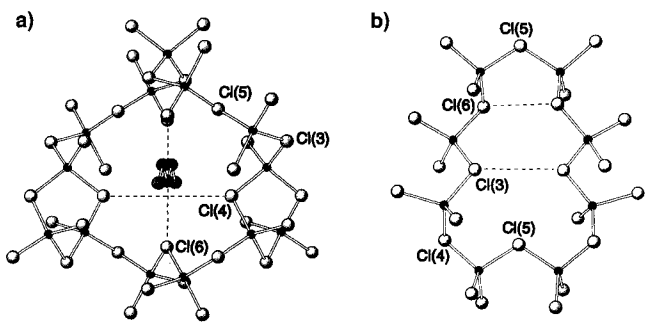

Figure 3. Ball-and-stick drawings of a) the eleven-ring that circumscribes the channels running along the *b* axis, and b) the eight-ring that circumscribes the channels running along the body diagonals in CZX-2. The location of the template cation is also shown in a).

nitrogen-filled dry-box yields a homogenous paste with the appearance and consistency of Elmer's glue. After being allowed to stand open to the dry-box atmosphere for two or three days, microcrystalline CZX-1, CZX-2, or CZX-3 was observed by Guinier X-ray powder diffraction. While the CZX frameworks are not nearly as robust as silicate frameworks, this remarkable formation of colloidal particles requires some degree of integrity of the anionic framework to yield negatively charged particles, likely $\{[A]_x[Cu_nZn_{m-n}Cl_{2m}]\}^{(n-x)-}$. (A small amount of CuCl is also observed by X-ray powder diffraction; free $ZnCl_2$ remains in the solution in methanol.) In addition, since the parent crystalline CZX materials can be grown by evaporation of methanolic colloidal suspensions, these colloidal particles are implicated as intermediates in the formation of the open-framework solids. This novel metal halide system, in which colloidal intermediates are involved in the formation of open frameworks, may also provide a useful model for understanding the growth of zeolite frameworks from sol–gel processing of colloidal suspensions.[18]

Experimental Section

All manipulations were performed under an atmosphere of dry nitrogen; CuCl and $ZnCl_2$ were freshly sublimed; benzene was distilled from sodium benzophenone and stored over 4-Å molecular sieves; and methanol was freshly distilled from magnesium methoxide. Crystalline CZX-1, CZX-2, and CZX-3 were synthesized from superheated solutions of the respective alkylammonium chloride, CuCl, $ZnCl_2$, and benzene in a 1:1:5:45 molar ratio. For example CuCl (25 mg), $ZnCl_2$ (170 mg) and $HNMe_3Cl$ (24 mg) were added to a thick-walled fused silica tube. Benzene (1.0 mL) was added to the reaction vessel with standard Schlenk techniques. The reaction mixture was frozen in liquid nitrogen and sealed with a torch, such that the reaction tube was filled to 25%. Hardened solids from which colorless single crystals could be cleaved were prepared by cooling the solutions in benzene from 160 to 60 °C at 0.01° min^{-1}. Bulk materials could also be prepared from a melt of CuCl, $ZnCl_2$, and the respective alkylammonium chloride.

Elemental analyses: CZX-1: calcd for $C_3H_{10}Cl_{12}CuNZn_5$: C 4.1, H 1.2, N 1.6; found: C 4.3, H 1.3, N 1.6; CZX-2: calcd for $C_4H_{12}Cl_{12}CuNZn_5$: C 5.4, H 1.4, N 1.6; found: C 5.3, H 1.5, N 1.4; CZX-3: calcd for $C_4H_{16}Cl_{12}Cu_2N_2Zn_4$: C 5.3, H 1.8, N 3.1; found: C 5.3, H 2.0, N 3.0.

[12] Crystal data for CZX-1: $C_3H_{10}Cl_{12}CuNZn_5$, $M_r = 876.0\ g\,mol^{-1}$, cubic, $I\bar{4}3m$ (no. 217), $a = 10.5887(3)$ Å, $V = 1187.21(3)$ Å^3, $Z = 2$, $\rho_{calcd} = 2.451\ g\,cm^{-3}$, $\mu(Mo_{K\alpha}) = 7.34\ mm^{-1}$, $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å). Data were collected at 293 K on a crystal with dimensions $0.25 \times 0.20 \times 0.14$ mm. Final cell constants were determined from a set of 24 reflections with $38 < 2\theta < 41°$. Intensity data were collected over an octant with an Enraf-Nonius CAD4 diffractometer by the $\theta-2\theta$ scan method to the limit of $\theta < 30°$. Of 986 reflections collected, 201 were unique. An absorption correction was made from empirical psi-scan data. The X-ray powder pattern indicated a sodalite structure, which was used as a starting model for the structure solution. The final refinement of 14 parameters was carried out by a full-matrix least-squares method on 191 independent reflections [$I > 1.0\sigma(I)$]. All non-hydrogen atoms were refined anisotropically. The structure refined to $R = 0.0194$ and $R_w = 0.0232$. The maximum and minimum residual electron density was 0.28 and $-0.43\ e\,Å^{-3}$.

[16] Crystal data for CZX-2: $C_4H_{12}Cl_{12}CuNZn_5$, $M_r = 890.1\ g\,mol^{-1}$, orthorhombic, $I2_12_12_1$ (no. 24), $a = 9.6848(5)$, $b = 9.5473(4)$, $c = 14.0003(9)$ Å, $V = 1294.52(12)$ Å^3, $Z = 2$, $\rho_{calcd} = 2.284\ g\,cm^{-3}$, $\mu(Mo_{K\alpha}) = 6.73\ mm^{-1}$, $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å). Data were collected at 293 K on a crystal with dimensions $0.32 \times 0.20 \times 0.10$ mm crystal. Final cell constants were determined from a set of 24 reflections with $40 < 2\theta < 46°$. An Enraf-Nonius CAD4 diffractometer data was used to collect intensity data for 3962 reflections (1887 unique) over a hemisphere by the $\theta-2\theta$scan method out to $\theta < 30°$. An absorption correction was made from empirical psi-scan data. The structure was solved by SIR92 and conventional Fourier techniques. A full-matrix least-squares calculation on 1696 independent reflections [$I > 1.0\sigma(I)$] was used in the final refinement of 44 parameters. The Cu, Zn, and Cl atoms were refined anisotropically; H atoms were not included in the refinement. The structure refined to $R = 0.0330$ and $R_w = 0.0516$. The maximum and minimum residual electron density was 1.16 and $-1.06\ e\,Å^{-3}$.

[17] Crystal data for CZX-3: $C_2H_8Cl_{12}Cu_2N_2Zn_4$, $M_r = 906.3\ g\,mol^{-1}$, orthorhombic, $I2_12_12_1$ (no. 24), $a = 9.5677(16)$, $b = 9.4554(12)$, $c = 13.6435(16)$ Å, $V = 1234.3(3)$ Å^3, $Z = 2$, $\rho_{calcd} = 2.439\ g\,cm^{-3}$, $\mu(Mo_{K\alpha}) = 6.73\ mm^{-1}$, $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å). Data were collected at 293 K on a crystal of dimensions $0.26 \times 0.14 \times 0.07$ mm. Final cell constants were determined from a set of 24 reflections with $23 < 2\theta < 28°$. An Enraf-Nonius CAD4 diffractometer was used to collect intensity data for 1231 reflections (1095 unique) over an octant by the $\theta-2\theta$ scan method out to $\theta < 25°$. The structure was solved by using the CZX-2 structure as a model and conventional Fourier techniques. A full-matrix least-squares calculation on 814 independent reflections [$I > 1.5\sigma(I)$] was used in the final refinement of 58 parameters. All non-hydrogen atoms were refined anisotropically. $R = 0.0418$, $R_w = 0.0343$. The maximum and minimum residual electron density was 0.54 and $-0.58\ e\,Å^{-3}$. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no CCD-100302 Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code +(1223) 336-033; e-mail: deposit@chemcrys.cam.ac.uk).

Binuclear Vanadium(III) Squarates with Layered and Framework Structures: Hydrothermal Synthesis and Structures of $[\{V(OH)(C_4O_4)(H_2O)\}_2]$ and $[\{V(OH)(C_4O_4)\}_2]\cdot 4H_2O$**

Kuan-Jiuh Lin* and Kwang-Hwa Lii

Studies of self-assembly of inorganic structures have blossomed during the 1990s. Supermolecules or coordination polymers with infinite two- or three-dimensional frameworks are of intense current interest[1] because of their unique physical and chemical properties, such as magnetism,[2] host–guest chemistry,[3] and catalysis.[4] Crystal engineering of supramolecular architectures based on a transition metal macrocyclic motif with rigid organic ligands has become a rapidly expanding field.[4–6] In our approach we chose as bridging ligand the squarate anion, $C_4O_4^{2-}$, together with vanadium oxide to synthesize V/O/squarate polymeric compounds with hydrothermal methods. The anion with its fourfold C=O functionality is not only a potential multiple acceptor of hydrogen bonds,[7, 8] but also can be engaged in polydentate coordination modes such as μ_2, μ_3, and μ_4 coordination.[9–11] Here we present two novel polymeric structures, **1** and **2**, where open frameworks are achieved by a combination of such interactions.

$[\{V(OH)(C_4O_4)(H_2O)\}_2]$ **1**

$[\{V(OH)(C_4O_4)\}_2]\cdot 4H_2O$ **2**

Hydrothermal reactions of NH_4Cl, V_2O_5, and squaric acid in the molar ratios 0.3:1:1 at 180 °C and 0.6:1:2 at 200 °C in water produced compounds **1** and **2**, respectively. Both were structurally characterized by single-crystal X-ray diffraction analyses.[12] The structure of **1** (Figure 1) consists of layers stacked on each other along the *a* axis with an interplanar separation of $1/a^* = 7.576$ Å. Each layer is constructed from dimers of edge-sharing $V^{III}O_6$ octahedra, which are linked by squarate anions in μ_3 mode. Within the layer, rectangular windows (3.0×6.5 Å) are surrounded by four vanadium dimers and four squarates. Adjacent layers are displaced with respect to each other such that the windows are aligned to form straight tunnels along the [101] direction. The geometry at the vanadium site is defined by two bridging OH groups, one H_2O ligand, and one oxygen donor from each of three squarates. The squarate retains a pendant group which has a somewhat shorter C=O distance than the other three substituents and an O atom that is involved in both an intra- and intermolecular hydrogen bond to the water molecule.

The structure of **2** reveals a neutral, three-dimensional framework again containing dimers of edge-sharing $V^{III}O_6$ octahedra besides the squarate anions (Figure 2). The vanadium atoms are coordinated by two bridging hydroxides and four squarates, two of which coordinate in a true μ_4 mode (to four dimers) and the other two in a μ_2/μ_2 mode (to two dimers). The binuclear cores are connected to four μ_4 squarates to form a

hydrogen-bonded water molecules are located at the intersections of the channels. The μ_4 squarate has C_{4h} crystallographic symmetry, whereas the μ_2/μ_2 squarate and vanadium dimer have D_{2h} symmetry. The window of the square channels has dimensions $\sqrt{2}a/2 \times c = 7.04 \times 7.11$ Å, which is comparable to the pore size of SAPO-40 zeolite (6.7×6.9 Å).[13] The water cluster in the *ab* plane is further hydrogen-bonded into a layer, resulting in additional eight-membered rings condensed with themselves and the four-membered rings. It is interesting to note that the O···O separation of 2.88 Å in the water tetramer compares well with the results of vibration-rotation tunneling spectroscopy[14] and of ab initio calculations.[15]

In summary, the two polymeric structures are composed of similar macrocyclic units constructed from cationic octahedral vanadium dimers and squarate anions, a new building principle for supramolecular architectures and microporous structures. The pore sizes are determined by the coordination modes of the bridging squarates: **2** provides large square channels where cyclic water tetramers are located, whereas **1** has a layer structure with rectangular windows within the layer. These first examples show that there is a great potential for the preparation of topologically unique zeolitic materials in the metal squarate system by hydrothermal methods.

Experimental Section

1: A mixture of NH_4Cl (0.60 mL, 0.5 M), V_2O_5 (0.0929 g), $H_2C_4O_4$ (0.2276 g) ($V:H_2C_4O_4$ molar ratio = 1:2), and H_2O (10 mL) was sealed in a Teflon-lined stainless autoclave (volume 23 mL), heated at 180 °C for three days, and cooled to 90 °C at 5 °C h^{-1}. The product (yellow green crystals of **1**; yield: 0.1740 g, 88% based on V), was filtered off and washed with deionized water. This compound is stable in air and insoluble in water. Monophasic crystalline material was confirmed by X-ray powder diffraction. Thermogravimetric analysis in air showed one-step weight loss of 54.41% over the temperature range 150–400 °C, which agrees well with the theoretical values of 54.1% assuming that the final decomposition product is V_2O_5. IR(KBr): $\tilde{\nu}$ = 3483 (s, OH), 3145 (br, w, H_2O), 1621 (s, pendant C=O), 1518 and 1456 (s, C=O and C=C), 1086(m), 1145(m), 861 and 843 cm^{-1} (m, V-(OH)-V).

2: A mixture of NH_4Cl (0.60 mL, 0.5 M), V_2O_5 (0.0904 g), $H_2C_4O_4$ (0.1143 g) ($V:H_2C_4O_4$ molar ratio = 1), and H_2O (10 mL) was sealed in a Teflon-lined stainless autoclave (23 mL), heated at 200 °C for three days, cooled to 150 °C at 5 °C h^{-1}, and quenched to room temperature. The product (0.1877 g), which is a mixture of dark purple crystals of **2** and an about equal amount of **1**, was filtered off and washed with deionized water. This compound is stable in air and insoluble in water. The compound retains its structure at 200 °C in air with partial loss of water molecules, and decomposes at 250 °C, as indicated from powder X-ray diffraction and thermogravimetric analysis. IR(KBr): $\tilde{\nu}$ = 3463 (m, OH), 2900 (br, w), 1500 (s, C=C and C=O), 870 cm^{-1} (m, V-(OH)-V).

Topological Bifurcation Analysis: Electronic Structure of CH_5^+ **

Dominik Marx* and Andreas Savin

CH_5^+, the product of the formal addition of a proton to methane, a stable and rigid molecule, is highly fluxional and elusive. The reason is that the electronic energy penalty to switch from one of the many degenerate eclipsed *e*-C_s global minima to another one is tiny,[1–5] the most recent best estimate being as small as 0.8 kcal mol^{-1} to the C_{2v} transition state.[5] This led to speculations that the hydrogen atoms in CH_5^+ may easily scramble in the rotational-vibrational ground state as a result of pseudorotational rearrangements.[3, 6] This picture was recently confirmed by ab initio quantum simulations in which all the nuclei of CH_5^+ were treated as quantum particles.[7] More importantly, it was demonstrated that a H_2 unit attached to the apex of a CH_3 tripod is a characteristic geometric feature of the *quantum* ground state of CH_5^+.

A fundamental question which arises is what type of chemical bonding ultimately holds such a highly fluxional molecule together. The *e*-C_s structure is commonly described as consisting

of three standard two-center, two-electron CH bonds, and one electron-deficient three-center, two-electron bond involving the carbon nucleus and the two hydrogen nuclei that form the H_2 unit.[8, 9] To what extend is this picture valid taking into account the floppiness that is present even in the ground state? We will answer this question by a topological analysis of the electron localization function ELF[10] of representative configurations sampled from ab initio quantum simulations.[7]

Let us now concisely describe some important features of the electron localization function. It can be viewed as a local measure of the Pauli repulsion between electrons in three-dimensional space due to the exclusion principle. It thus allows us to define regions of space that are associated with different electron pairs in a molecule or solid. The definition of ELF $\eta(\mathbf{r})$ is given by Equations (a)–(d), where the sum in (b) and (d) is over

$$\eta(\mathbf{r}) = \frac{1}{1 + (D/D_h)^2} \quad \text{(a)}$$

$$D = \frac{1}{2}\sum_{i=1}^{N} |\nabla\psi_i|^2 - \frac{1}{8}\frac{|\nabla\rho|^2}{\rho} \quad \text{(b)}$$

$$D_h = \frac{3}{10}(3\pi^2)^{2/3}\rho^{5/3} \quad \text{(c)}$$

$$\rho = \sum_{i=1}^{N} |\psi_i|^2 \quad \text{(d)}$$

all singly occupied one-electron (spin-) orbitals $\psi_i(\mathbf{r})$ in an N-electron system. This function is normalized to the interval between 0 and 1, and is large where the Pauli repulsion is small, that is, where two electrons with antiparallel spin are paired in space. Conversely, it is small in the regions between electron pairs. By locating the electron pairs, ELF makes a direct connection with the chemist's view of the chemical bond, often drawn as a line connecting atoms; this property of ELF is not restricted to the equilibrium structure of a molecule and can even be followed during a chemical reaction. We refer to previous work[10–13] for an in depth discussion of the properties of ELF, and in particular to Ref.[14] for an interpretation within the framework of density functional theory.

The position where ELF attains a maximum value, the attractor, can be used as an electron pair's signature. To identify a region around a maximum, one can consider all the points in space with $\eta(\mathbf{r}) \geq f$, which defines the f-localization domain; f is a positive constant smaller than the value of the maximum. This region in space can be visualized by showing the isosurface $\eta(\mathbf{r}) = f$. The isosurface surrounds only one attractor when f is close to the value of the corresponding ELF maximum. For a given value of f, several closed isosurfaces surrounding different attractors can appear. As the value of f is lowered, different spatially separated f-localization domains merge, and closed isosurfaces that contain more than one attractor appear. In other words: there is at least one path which joins different attractors as f is lowered. Of course, the isosurface encompasses all attractors, that is, all electron pairs, in the $\eta \to 0$ limit, whereas all attractors are separated in the opposite limit ($\eta \to 1$).[15]

This behavior can be visualized by a bifurcation diagram, which includes only the maxima of ELF and the saddle points where merging occurs.[16] The connectivity of these characteristic points represents the hierarchical merging pattern of the isosurfaces. By focussing on that part of the bifurcation diagram with $\eta(\mathbf{r}) > f$ one can identify the number of attractors within a particular f-localization domain, as all maxima within this domain will appear connected. This suggests that a covalent bond is the better defined the larger the difference between the ELF-maximum and the saddle point where the first merging occurs.

The usefulness of these ideas is illustrated by depicting two f-localization domains with $\eta(\mathbf{r}) \geq 0.98$ and 0.6 (Figure 1a–c) for the textbook example, methane; only the chemically relevant valence electrons are included explicitly in the calculations, and the inert core electrons are represented by pseudopotentials. There are clearly four well-separated maxima for $\eta > 0.71$ (Figure 1a), which can be assigned to the four CH bonds, whereas all four localization domains coalesce below this bifurcation value $\eta^* \approx 0.71$ (Figure 1b, c). This leads to the particularly simple bifurcation diagram displayed in Figure 1d.

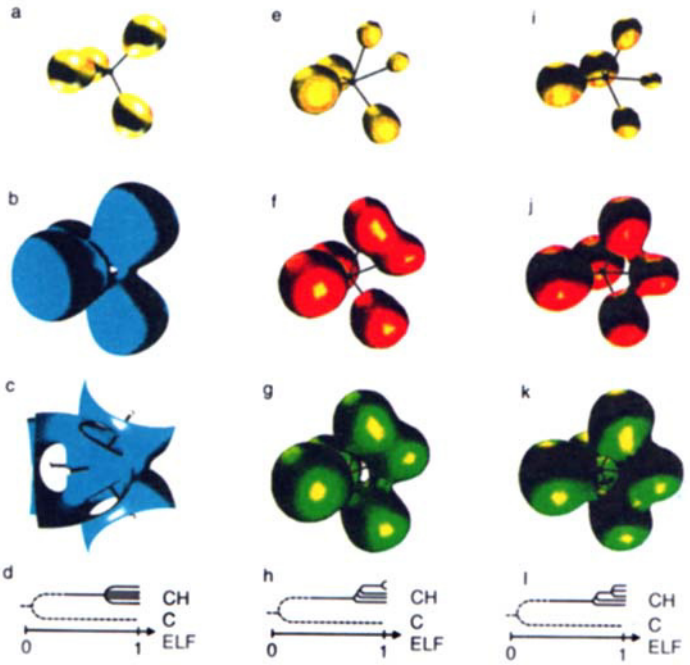

Figure 1. ELF isosurfaces ($\eta(\mathbf{r}) = f$) depicting the f-localization domains for the global minimum of methane CH_4 with $f = 0.98$ (yellow, a), $f = 0.60$ (blue, b), and $f = 0.60$ with isosurface cut open (blue, c); for protonated methane e-C_s-CH_5^+ with $f = 0.98$ (yellow, e), $f = 0.88$ (red, f), and $f = 0.70$ (green, g); for C_{2v}-CH_5^+ with $f = 0.98$ (yellow, i), $f = 0.88$ (red, j), and $f = 0.70$ (green, k). Resulting valence bifurcation diagrams for methane CH_4 (d), protonated methane e-C_s-CH_5^+ (h), and C_{2v}-CH_5^+ (l). Dotted lines (only schematic): the electrons forming the $1s^2$ shell of the carbon core are inluded in the calculations.

Moreover, the attractor structure of ELF allows disjoint spatial regions to be defined from the gradients of ELF.[12, 17, 18] From any point in space the gradient is followed to an attractor in that region, and this point is then attributed to this attractor. The collection of all the points in space that were assigned to a given attractor is called its basin. In the example of the valence shell of CH_4, space is divided into four equivalent basins corresponding to the four CH bonds. Integrating the electron density separately in these valence basins yields 1.98 electrons per basin, very close to two as expected in the idealized Lewis picture of a covalent bond; the last reported digit is assumed to be inaccurate due to the numerical integration on a finite grid. The chemically inert core basin would appear in an all-electron calculation.

The nontrivial case of the quantum-fluxional CH_5^+ can now be approached analogously. First, we have to find the characteristic ELF values at the relevant bifurcation points η^* for the two most important stationary points on the potential energy surface, namely, the e-C_s global minimum (Figure 1e–g) and the lowest energy C_{2v} transition state (Figure 1i–k). For the global minimum we find five separated maxima for $\eta \to 1$, but two localization domains around them merge already at a surpris-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3619-2078 $ 17.50+.50/0

ingly high value of $\eta^* \approx 0.97$. The resulting basin can clearly be associated with the bonding electron pair of the H_2 unit to the carbon nucleus, whereas the other three separated basins stem from the three standard two-center CH bonds in the CH_3 tripod. Integration of the electron density (from the eight valence electrons) over the basins yields values of about two electrons per basin in all four cases (1.72, 1.97, 1.98 for the CH basins, and 2.27 for the CH_2 basin with corresponding CH bonds lengths of about 1.10 Å, 1.08 Å, 1.08 Å, and 1.17 Å, respectively), so one can clearly denote the particular bond that involves two hydrogen nuclei and the carbon nucleus to be a three-center, two-electron bond.[8, 9] However, these numerical values seem furthermore to suggest that the three-center bond „needs more electrons than just two" to bind three nuclei, and that the necessary electron density is mainly „borrowed" from one particular two-center CH bond, which becomes weakened and thus is the longest of the three two-center bonds. This topological pattern is stable over a wide range on the ELF scale down to about $\eta^* \approx 0.78$, where the merging of all the valence localization domains starts. The full valence shell is finally established at $\eta^* \approx 0.7$; see Figure 1h for the resulting bifurcation diagram. Thus, we find two distinct bifurcation points η^*: the first where the two isosurfaces surrounding the two hydrogen nuclei of the H_2 unit coalesce and the second where the resulting isosurface now encompassing the H_2 unit merges with the other three isosurfaces stemming from the normal CH bonds.

The bifurcation hierarchy for the C_{2v} transition state derived from its ELF landscape (Fig. 1i–k) is topologically different (Figure 1l). At $\eta^* \approx 0.89$ three of the five localization domains merge, and the resulting basin contains four electrons (4.01) that are distributed over four centers (see ref. [5] for such a conjecture), whereas the remaining two basins with about two electrons each (1.97 and 1.96) stem from the two standard two-center, two-electron CH bonds. The full valence shell, that is, the merging of all previously separated basins, occurs at $\eta^* \approx 0.74$.

After having determined the characteristic points in the bifurcation hierarchy for the two limiting structures, we can analyze the quantum mechanical ground state of CH_5^+ including tunneling and zero-point motion effects.[7] The bifurcation analysis as outlined for the stationary points corresponding to the *e*-C_s and C_{2v} structures is applied to a statistical sample of 64 configurations obtained from previous ab initio quantum simulations.[7] We obtain for each of these configurations the ELF from electronic structure calculations based on first principles.[19] This gives access to the associated bifurcation diagrams and thus to the ELF values η^* where the two major bifurcations in the valence shell occur in each configuration. The resulting quantity of interest is a histogram or probability distribution $P(\eta^*)$ of these bifurcation points, and its broadness is entirely due to quantum mechanical tunneling and rotational-vibrational zero-point fluctuations; simulations where the nuclei are approximated as classical particles show that thermal fluctuations are negligible at low temperatures, whereas they are of similar magnitude at room temperature.[20]

The two branches of the distribution function depicted separately in Figure 2 show two prominent peaks at the bifurcation points $\eta^* \approx 0.78$ and 0.97, signaling a major contribution of C_s-like configurations to the quantum ground state of CH_5^+. Furthermore, the distribution function actually has minima at $\eta^* \approx 0.74$ and 0.89, the values that were found to characterize the bifurcation hierarchy of the ideal C_{2v} structure of CH_5^+. Thus, the electronic structure analysis based on the bifurcations of ELF clearly supports the concept of a three-center, two-electron bond that holds CH_5^+ together.

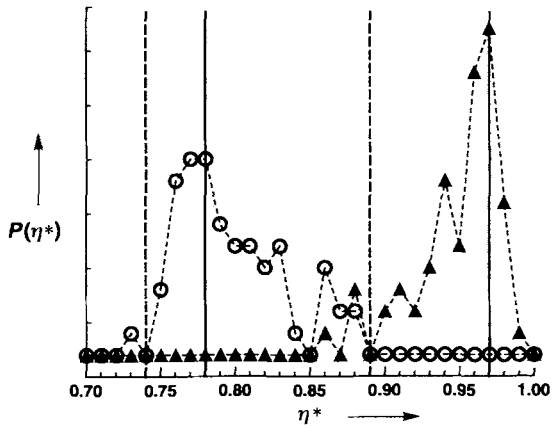

Figure 2. Distribution function $P(\eta^*)$ of the ELF bifurcation points η^* in the quantum ground state of CH_5^+; P and η^* are dimensionless quantities. The two partial distribution functions obtained from separate histograms of the bifurcation points with the largest (filled triangles) and second largest (open circles) ELF values are shown. The sum of these two contributions constitutes the full distribution function (not shown) and the connecting dotted lines are only visual guides. For the two relevant individual stationary point structures (discussed in the text and presented in Figures 1e–g and i–k) the same analysis yields necessarily very sharp peaks at two ELF values in each case: the vertical solid lines mark these four characteristic peak positions for the *e*-C_s global minimum ($\eta^* \approx 0.78, 0.97$), the dashed lines those for the C_{2v} transition state ($\eta^* \approx 0.74, 0.89$).

In conclusion, we have presented a powerful addition to the arsenal of topological analysis methods of the electronic structure of molecules that is tailored to cope with highly fluxional molecules. In particular, we have demonstrated that a three-center, two-electron bond emerges naturally from this analysis, even for the quantum ground state of such a floppy molecule as protonated methane CH_5^+. Furthermore, we believe that our method will find widespread applications in the emerging realm of ab initio simulations of molecules at finite temperatures, where one does not deal with a few high-symmetry stationary points, but with an ensemble encompassing many configurations that all deviate from ideal symmetries.

Nonclassical Shapes of Noble-Metal Colloids by Synthesis in Microgel Nanoreactors**

Markus Antonietti,* Franziska Gröhn, Jürgen Hartmann, and Lyudmila Bronstein

The controlled synthesis of colloids on a nanometer scale is important for bridging the gap between microlithography and micromechanics, which deal with structures down to 250 nm, and supramolecular chemistry, in which molecules of increasing size are built up by means of sophisticated classical chemistry. Structural design on the intermediate scale of several nanometers requires special techniques; nanomechanics would be inefficient, and classical chemical methods too complex and tedious.

Nature teaches us that effective control of structure is possible. In biomineralization, for instance, functional biomolecules (such as proteins or polysaccharides) act as templates for growing nanocrystals, platelets, and needles.[1–6] The specific interaction of these molecules with distinct crystallographic planes or sites of the growing nuclei allows control of the size, shape, and crystal structure of the inorganic product.

This approach for the nanostructuration of materials has been transferred to synthetic chemistry by utilizing Langmuir films of sparingly water soluble organic compounds to direct the growth of calcium carbonate and to tailor its crystal structure and morphology.[7] A three-dimensional biomimetic extension was described by Walsh et al., who synthesized highly defined, spongelike inorganic structures by precipitating calcium and magnesium carbonates from the microemulsion phases of nonionic surfactants.[8]

Another route to matter organized on the nanometer scale consists of controlling the intermolecular arrangement of colloids. Fendler and co-workers obtained periodic arrays of noble-metal colloids beneath or in monolayers.[9] Möller et al. generated spherical gold particles in block copolymer micelles and examined the surface patterns of drying films.[10] Andres et al.[11] and Whetten et al.[12,13] crystallized gold and silver clusters to give two-dimensional superlattices. All these alignment techniques are restricted to producing crystallike, ordered two-dimensional or three-dimensional arrays of preformed particles, but do not address the original growth process. Nevertheless, these approaches indicate what the further structural layout of nanomaterials may look like.

Currently two general strategies for particle-growth control can be distinguished.[14] In host–guest nanoscale synthesis, a cage or structure-directing molecular container is formed by supramolecular or colloidal preorganization in which the nanostructure is fabricated (exo-template approach). In the interfacial molecular recognition route, crystallization is nucleated in the proximity of a structure-directing molecule or assembly. Growth is controlled by the presence of these molecules at some of the crystal surfaces, but no imprinting of an outer shape occurs (endo-template approach).

For a broader application of these principles, simpler, nonbiogenic templates are required, and modern polymer chemistry provides some promising candidates. We here describe the use of "microgels",[15,16] spherical polymer gel particles with a well-defined diameter in the nanometer range and an adjustable chemical functionality, as exo-templates and the generation of colloid particles by chemical reactions within the microgels. The tuning parameters of the local chemical environment (cross-linking density, abundance and type of functional groups) and the related physical properties of the microgel (swellability, elasticity) were systematically varied, and the resulting structures of the colloids produced within the nanoreactors investigated.

Using the reduction of gold salts to gold colloids (the classical Faraday experiment) as a model reaction allows a simple evaluation of the experiment by the naked eye. This is because the color of metallic gold colloids is caused by collective oscillations (plasmons) of the electrons relative to the atomic cores, the energy distribution of which is sensitive to the size and shape of the colloidal particles.[17]

Figure 1 shows a selection of gold colloids in polystyrene sulfonate microgels. Variation of cross-linking density, reducing agent, and reducing conditions resulted in a variety of stable colloidal solutions with very different colors. In addition to the classical Faraday colors, Barolo red and purple, shades from bengal rose to apricot and black were obtained.

These colloids were characterized by transmission electron microscopy (TEM). Three typical morphologies obtained by varying the reduction conditions are shown in Figure 2. Fast reduction with $NaBH_4$ in water resulted in the limiting case of small spherical gold colloids located as swarms inside the microgels (Figure 2a). Decreasing the reduction rate by changing the pH ($NaBH_4$ in 0.1 N NaOH), but maintaining all other parameters, led to a second morphology: long and winding gold threads (Figure 2b). With hydrazine as a reducing agent, gold "nanonuggets" that resemble algae were formed (Figure 2c).

The estimated amount of gold in a thread or a nugget is one order of magnitude too large to have originated from the gold load of a single microgel. Dynamic light scattering before and after reduction indicated that the reaction occurred only in some of the dispersed particles, which led to a bimodal particle size distribution. That is, the colloids were nucleated in some of the microgels, while the others served as a source of gold salt which

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3619-2080 $ 17.50+.50/0

Figure 1. A selection of gold colloids prepared in polystyrene sulfonate microgels under different reaction conditions. The different colors of the solutions indicate the adjustable range of colloid sizes and morphologies. The colors yellow, red, and blue can be assigned to spherical gold particles of increasing size. All other colors are generated by the overlap of more than one plasmon resonance; this requires the presence of nonspherical particles with more than one "resonator" length.

migrated towards the growing colloids. This was confirmed by analytical ultracentrifugation, since the inclusion of a gold colloid increases the average density of the microgels. Scanning the optical density simultaneously at the wavelength of the plasmon band and at the absorption of the polymer, we found that only 15 (for the nuggets) to 20% (for the threads) of the microgels produce a colloid; the others were "empty" at the end of the reaction.

Formation of larger, more complex colloids implies that the rate of nucleation is sufficiently lower than the rate of mass transfer and growth to allow effective templating by the microgel. In the case of the nugget morphology, the microgel indeed acts as an exo-template, and the stretched polymer shell around the particles is clearly visible (Figure 2c). In the case of the nanothreads, the gold structures are significantly larger than the original microgels. Thus, the gold must have been extruded from the reaction core. The final threads are clustered and adhere to more than one microgel. It is noteworthy that, for some unknown reason, the ends of the threads usually occur in groups.

The switching between threads and nuggets upon using different reducing agents is not easy to explain. We assume that this morphology change reflects the fact that the colloid can grow at one site (thread) or many sites (nugget) as a result of the different surface binding of sodium borates and hydrazine.

The colloid morphology not only depends on the type of reduction, but also on the cross-linking density of the microgel. Higher cross-linking densities led to thinner structures as well as the formation of spherical colloids under a wider range of reac-

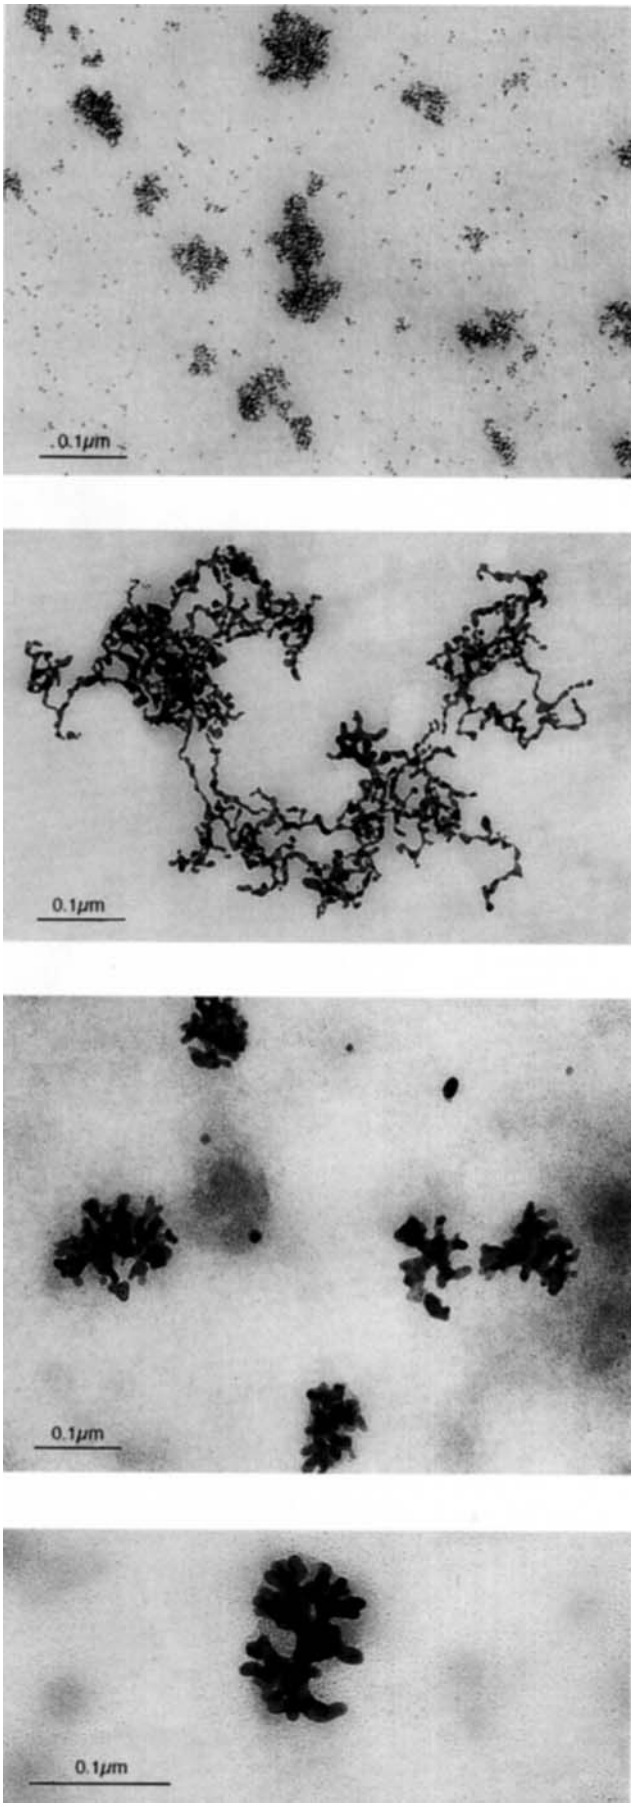

Figure 2. Transmission electron micrographs of colloids synthesized with different gels and reducing agents: a) uncontrolled particle morphology arising from fast reduction with multiple nucleation; b) threadlike morphology after slow reduction with sodium borohydride; c) nuggetlike morphology after reduction with hydrazine.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3619-2081 $ 17.50+.50/0

tion conditions, whereas the structures become thicker and less structured at lower cross-linking densities. This is due to the limitation of growth by the elastic forces of the surrounding gel matrix; that is, the particles stop growing in one direction as soon as the surrounding polymer chains are fully stretched.

Additional information was obtained from the determination of the crystallite size d_{cr} by linewidth analysis of the X-ray peaks. From the width of the Au(111) peak for the three samples shown in Figure 2, sizes of $d_{cr} = 4.5$ nm (small spheres in the microgel), $d_{cr} = 7$ nm (threads), and $d_{cr} = 25$ nm (nuggets) were calculated, which correlate well with the sizes of the colloids or the diameter of the threads observed by electron microscopy.

Further details of the inner structure of the colloids were obtained by high-resolution TEM (Figure 3). A remarkable

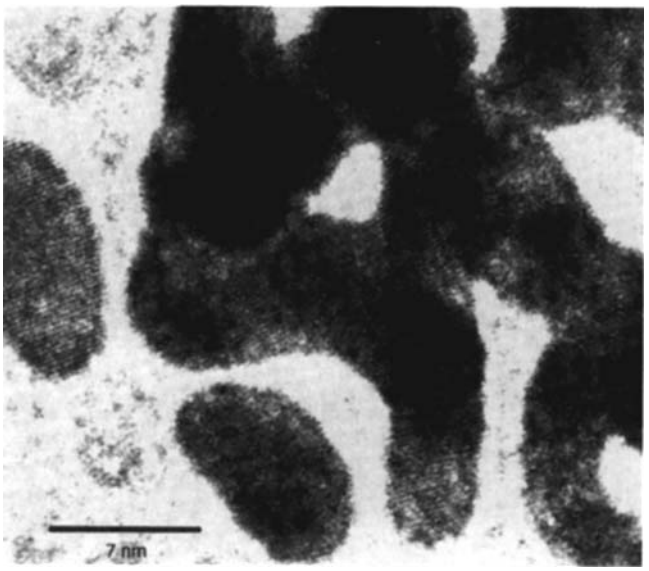

Figure 3. High-resolution electron micrographs of an end zone of the threads. The (111) crystallographic planes of the gold colloids can be seen. The correlation proves that the particles undergo directed growth rather than statistical agglomeration.

correlation of the crystallographic Au(111) planes was observed, which is apparently only weakly disturbed by the outer particle curvature. This proves that the particles grew from one nucleus, whereas the outer shape has to follow the chemical and physical structure of the microgel environment. This structure is not defect-free; grain boundaries are visible between slightly tilted regions.

We also investigated whether the use of microgel templates can be extended to control the structure of other chemically different colloids, such as oxidic colloids obtained by the precipitation of metal salts with hydroxide ions. To this end, we precipitated iron oxide under similar conditions inside the same microgels. The iron oxide does not precipitate macroscopically and is colloidally stable at pH 12, which would not be the case in the absence of the microgel. TEM revealed that again colloids with nonclassical shape, similar to the nugget morphology, are produced (Figure 4). This shows that the exo-template approach is not restricted to a particular chemistry or polymer/salt combination.

Biomineralization of iron oxides, with size and shape control, is performed by a number of living organisms, such as magnetotactic bacteria[14, 18]—this is source of inspiration. However, production of such structures is not a peculiarity of living matter, but seems to lie also within the capabilities of synthetic colloidal chemical systems.

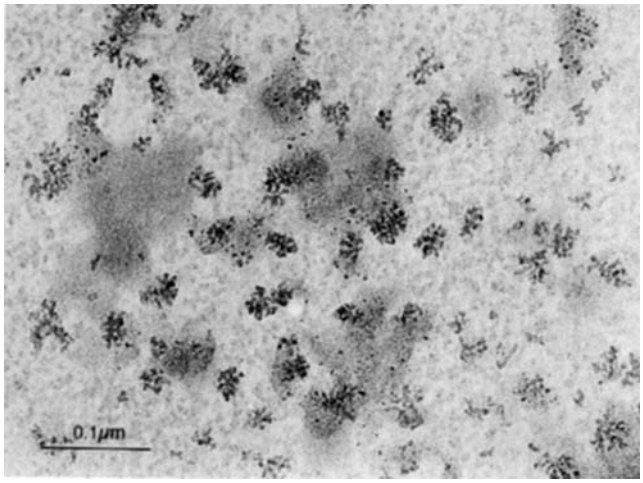

Figure 4. Transmission electron micrograph of iron oxide colloids synthesized by alkaline precipitation of iron salts in microgels. Templated, nonspherical objects are obtained.

The polymeric templates described here could potentially control properties other than size and shape. In the case of possible crystal polymorphism, the crystal structure can also depend on the microenvironment, and for binary systems, a composition control must also be considered. An extension of this set of "molecular tools" for the organized formation of matter on the nanometer scale is a topic of future experiments.

Experimental Section

The synthesis of polystyrene sulfonate microgels with defined size and cross-linking density and the characterization of their molecular properties are described elsewhere [19]. In the course of the synthesis, cross-linking density and degree of sulfonation were varied independently. For the experiments presented here, different microgels with a radius between 20 and 60 nm and cross-linking densities with one cross-link per 20 to 80 monomer units were selected.

The microgels were loaded with metal salt by mixing the aqueous solutions of microgel with the appropriate amounts of metal salts ($AuCl_3$ and $FeCl_3$; Aldrich Co.). To obtain stable systems a slight excess of negative charges is preferable; hence, ratios of Au:sulfonate slightly lower than 1:3 were employed. The colloidal stability is presumably due to enrichment of the gold salts inside the microgels, driven by osmotic forces and counterion condensation. This enrichment was required to produce the gold colloids within the microgels. No influence of the microgel template on the colloid structure is expected for nucleation in the continuous phase. The gold salt was reduced with an excess of $N_2H_4 \cdot H_2O$ or with $NaBH_4$ in aqueous solution at various pH values. Metal colloids formed immediately, as indicated by the color change. Iron oxide colloids were prepared by adding 0.1 N NaOH to solutions of $FeCl_3$ and microgel.

The colloidal solutions were characterized by static and dynamic light scattering, analytical ultracentrifugation, wide-angle scattering with linewidth analyis, and TEM. Experimental details of these techniques can be found elsewhere [20]. Samples for electron microscopy were prepared by suspension preparation. The dilute colloidal solutions were applied to a 400-mesh carbon-coated copper grid and left to dry. Electron microscopy was performed with a Zeiss 912 Omega electron microscope operating at 100 kV. High-resolution electron microscopy was performed with a Philips CM 120 equipped with Super Twin lenses at 120 kV.

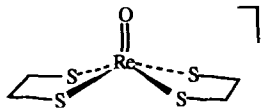
Addition of Nitriles to Metal Sulfides: Possible Insight into the Metal Sulfide Catalyzed Hydrogenation of Nitriles and Dinitrogen**

Jonathan T. Goodman and Thomas B. Rauchfuss*

The study of soluble metal sulfides provides insight into the function of biological and industrial catalysts as well as the design of new materials.[1] One remarkable aspect is the high reactivity of certain metal sulfides towards small substrates. While the binding of alkynes to metal sulfides is widely observed,[2] the corresponding addition of alkenes is relatively rare.[3] Hence, we were interested in the finding that the simple inorganic anion $[ReS_4]^-$ binds a variety of alkenes, for example ethylene [Eq. (1)].[4]

$$[ReS_4]^- + 2\,C_2H_4 + R_3NO \xrightarrow[-\,R_3N]{} \quad (1)$$

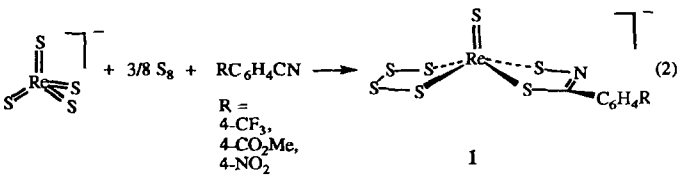


We examined the reaction of $PPh_4[ReS_4]$ with the relatively inert olefin *trans*-stilbene in the presence of sulfur in benzonitrile at reflux. Analysis of the crude reaction products by negative-ion FAB mass spectrometry revealed the presence of alkanedithiolates $[ReS(Ph(CHS)(CHS)Ph)]^-$ and $[ReS_5(Ph(CHS)(CHS)Ph)]^-$. Unexpectedly, we also observed comparable amounts of nitrile adducts $[ReS_5(NCPh)_2]^-$ and $[ReS_7(NCPh)]^-$ as well as the mixed complex $[ReS_3(Ph(CHS)(CHS)Ph)(NCPh)]^-$. We report here on this novel reaction.

Activation of nitriles by metal sulfides has been examined. Certain metal sulfides, notably WS_2 and MoS_2, catalyze the hydrogenation of nitriles.[5] The enzyme nitrogenase is also known to catalyze hydrogenation and hydrogenolysis of certain nitriles.[6] Furthermore, $[Cp_2Mo_2(S)(SH)(SCH_2S)]^+$ and MeCN react in the presence of acid to give imidothiolate $[Cp_2Mo_2(SC(=NH_2)Me)(S)(SCH_2S)]^+$,[7] a process related to the addition of H_2S to RCN.[8]

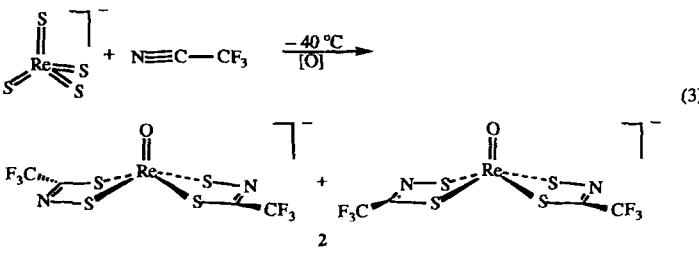
We initially focused on the reaction of $PPh_4[ReS_4]$ with S_8 and ArCN. Electrophilic substituents enhanced the rate of reaction. Thus, 4-substituted benzonitriles (X = CF_3, CO_2Me, NO_2) proved to be effective substrates, as judged by mass spectrometric and ^1H NMR spectroscopic analysis of the products. We optimized the reaction of methyl-4-cyanobenzoate with $PPh_4[ReS_4]$ in the presence of 0.5 equivalents of S_8 (see *Experimental Section*). Analysis showed the product to be $PPh_4[ReS_7NCC_6H_4CO_2Me]$. Alkene adducts of comparable stoichiometry consist of a thiorhenium(v) center bound to tetrasulfido and 1,2-dithiolato ligands.[4] The ^1H NMR spectrum of this material confirmed the 1:1 ratio of PPh_4^+ to nitrile. The IR spectrum revealed a medium-intensity band at 1602 cm^{-1}, assigned to $\nu_{C\equiv N}$, but no bands in the region normally associated with nitriles. On the basis of these results we propose that the reaction proceeds as shown in Equation (2).

We examined the connection between the nitrile adducts and the structurally related bis(tetrasulfido) complex ion $[ReS_9]^-$.[9] Under conditions employed for the formation of **1** [Eq. (2)],



$CF_3C_6H_4CN$ is unreactive towards $[ReS_9]^-$ (= $[ReS(S_4)_2]^-$). Thus, we propose that Re^{VII} is required for adduct formation; that is, a redox process takes place. In addition, solutions of PPh_4-**1** (R = CO_2Me) do not react with sulfur to give $[ReS_9]^-$.

We were unable to obtain well-formed single crystals of the aryl nitrile adducts for an X-ray structure analysis. Studies with CF_3CN[10] proved more fruitful in this regard. The interaction of this reactive nitrile with metal sulfides had not yet been studied, but the related alkyne hexafluoro-2-butyne is known to bind sulfido ligands.[11] The violet color characteristic of solutions of $[ReS_4]^-$ is rapidly discharged in the presence of CF_3CN, even at low temperatures. We conducted reactions at −47 °C with MeCN as solvent and one equivalent of *N*-methylmorpholine-*N*-oxide (NMO) as an O-atom donor. The synthesis was completed by warming the mixture to room temperature. Recrystallization of the product from ethanol/hexane afforded straw-colored crystals of $PPh_4[ReO(S_2NCCF_3)_2]$ [PPh_4-**2**, Eq. (3)].



The ^{19}F NMR spectrum of this species showed two equally intense signals at $\delta = 13.80$ and 13.95, which we attribute to *cis* and *trans* isomers. Reaction of $[ReS_4]^-$ with CF_3CN in the presence of sulfur yielded a compound that is assigned as

$PPh_4[ReS(S_2NCCF_3)_2]$ based on ^{19}F NMR and IR spectroscopy. The reaction of $[ReS_4]^-$ and CF_3CN also proceeded readily in the absence of an oxidant, but produced a complex mixture.

Single crystal X-ray diffraction analysis[12] of PPh_4-**2** confirmed the presence of ReSC=NS rings (Figure 1). The structure of the azadithiolene moieties compare well with that in

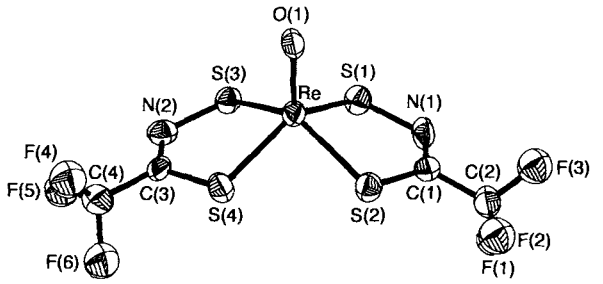

Figure 1. Structure of the anion in PPh_4-**2**. Selected distances [Å]: Re–S(2) 2.323(2), S(2)–C(1) 1.757(10), C(1)–N(1) 1.266(13), N(1)–S(1) 1.720(9), S(1)–Re 2.286(3).

$(C_5H_5)CoS_2NCPh$, which Sugimori et al. synthesized by oxidative addition of $CpCo^I$- containing compounds on preformed RCNS heterocycles.[13] Within the ReSCNS rings the Re–S distance to the nitrogen-bound sulfur atom is slightly shorter than that to the carbon-bound sulfur atom. The remaining Re–S bond lengths are similar to those seen in related Re^V–S compounds.[14]

We obtained evidence that even conventional nitriles add to $[ReS_4]^-$ in the presence of S_8. This surprising aspect was established by careful analysis of the products obtained from solutions of $PPh_4[ReS_4]$ and elemental sulfur (three equivalents) in acetonitrile, which were heated at reflux for 24 h. After removal of $[ReS_9]^-$ (≈80% yield) and a small amount of starting $[ReS_4]^-$ by fractional crystallization,[15] we obtained a crude sample in less than 5% yield that we assign as $PPh_4[ReS_7NCMe]$. The following data support this assignment: a band for $\nu_{C=N}$ at 1477 cm^{-1} in the IR spectrum, a signal at $\delta = 3.13$ (s) for the methyl group in the ^1H NMR spectrum, and negative-ion ESI MS peaks corresponding to $[ReS_7NCMe]^-$ ($m/z = 451.8$) and $[ReS_5(NCMe)_2]^-$ ($m/z = 387.9$). The aryl nitrile adducts and $[ReS_7NCMe]^-$ display very similar fragmentation patterns.

Metal sulfides are active catalysts for the reduction of nitriles.[5] We have confirmed that solutions of $[ReS_4]^-$ give very active catalysts for the hydrogenation of benzonitrile to NH_3 and dibenzylamine (typical reaction conditions: neat nitrile, 175 °C, H_2 (1000 psi), 16 h to give 75% conversion with a turnover number of about 3400). This suggests that mechanistic models for metal sulfide catalyzed hydrogenation of nitriles should consider the possibility of substrate binding at a sulfur atom. A speculative but logical extension of these findings is that similar pathways may apply to biological nitrogen fixation, which is catalyzed by clusters[16, 17] featuring highly exposed sulfido ligands.

Experimental Section

$NEt_4[ReS_4]$ was synthesized by the modification from Exxon of the procedure by Müller et al, and converted to the PPh_4^+ salt by metathesis in MeCN [18]. CF_3CN was purchased from PCR (Gainesville, FL, USA).

PPh_4-**1**, R = CO_2Me: A mixture of $PPh_4[ReS_4]$ (0.36 g, 0.55 mmol), sulfur (0.054 g, 0.21 mmol), and 4-$NCC_6H_4CO_2Me$ (2.0 g, 12.41 mmol) was held at 85 °C for 1.5 h, during which time its color changed from violet to dark brown. The product was extracted with THF (5 mL) and precipitated by cooling (yield 0.36 g, 72%). Analytically pure samples were obtained by recrystallization from THF/hexane. Elemental analysis calcd (found) for $C_{33}H_{27}NO_2PReS_7$: C 43.50 (43.47), H 2.99 (3.24), N 1.54 (1.24), S 24.63 (24.62), P 3.40 (3.14); ^1H NMR (500 MHz, CD_3CN): $\delta = 3.90$ (Me, 3H), 7.83 (m, 16H), 7.98 (m, 4H), 8.06 (Ar, 2H, $J = 0.75$ Hz), 8.36 (Ar, 2H, $J = 0.75$ Hz); ^{13}C NMR (125 MHz, [D$_6$]acetone): $\delta = 52.41$ (OMe), 118.94 (PPh, $J = 88.8$ Hz), 129.87, 130.40, 131.37 (PPh, $J = 12.9$ Hz), 131.58, 135.65 (PPh, $J = 10$ Hz), 136.34 (PPh, $J = 2.75$ Hz), 139.3, 166.85 (C = O), 181.5 (SCN); IR (KBr): $\tilde{\nu} = 1714$ (C=O), 1603 (C=N), 1278 cm^{-1} (C=O); MS (negative-ion ESI): $m/z = 571.8$ ($C_9H_7NO_2ReS_7^-$).

The above procedure applies to syntheses with 4-$CF_3C_6H_4CN$ and 4-$O_2NC_6H_4CN$: Et_4N-**1**, R = CF_3: ^1H NMR (400 MHz, CD_3CN): $\delta = 1.17$ (tt, 12H), 3.11 (q, 8H), 7.77 (d, 2H, $J = 10$ Hz), 8.42 (d, 2H, $J = 10$ Hz); MS (negative-ion ESI): $m/z = 581.7$ ($C_8H_4NF_3ReS_7^-$). Et_4N-**1**, R = NO_2: ^1H NMR (500 MHz, CD_3CN) $\delta = 1.09$ (tt, 12H), 2.98 (q, 8H), 8.28 (d, 2H, $J = 9$ Hz), 8.46 (d, 2H, $J = 9$ Hz); MS (negative-ion ESI): $m/z = 558.9$ ($C_7H_4N_2O_2ReS_7^-$).

PPh_4-**2**: A solution of $PPh_4[ReS_4]$ (0.25 g, 0.38 mmol) and NMO (0.051 g, 0.43 mmol) in CH_3CN (20 mL) was cooled to −47 °C, and treated with gaseous CF_3CN. The solution immediately assumed a brown color. The solution was allowed to warm to room temperature. After 1 h solvent was removed under vacuum from the pale yellow solution leaving yellow microcrystals, which were washed with hexane (50 mL; yield 0.28 g, 86%). Analytically pure single crystals were obtained by slow diffusion of hexane into a solution of PPh_4-**2** in ethanol. Elemental analysis calcd (found) for $C_{28}H_{20}N_2F_6OPReS_4$: C 39.11 (39.38), H 2.34 (2.28), N 3.26 (3.48), S 14.92 (14.75), F 13.26 (12.84), P 3.60 (3.47); ^{19}F NMR (CD_3CN, 376 MHz; as ext. ref. CF_3CO_2H): $\delta = 13.80$, 13.95; IR (KBr): $\tilde{\nu} = 1560$ (C=N), 1278 (CF), 1194 (CF), 1182 (CF), 1125 (CF), 960 (Re=O), 630 (CS). MS (negative-ion ESI): $m/z = 520.8$ ($C_4N_2F_6OReS_4^-$).

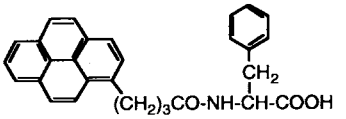
Site-Specific Photocleavage of Proteins**

Challa V. Kumar* and Apinya Buranaprapuk

Dedicated to Professor Nicholas J. Turro on the occasion of his 59th birthday

Reagents that cleave proteins with high specificity under thermal or photochemical conditions could be useful for structure–activity studies of proteins, investigation of protein structural domains, design of new therapeutic agents, and conversion of large proteins into smaller fragments that are more amenable for sequencing.[1] The proliferation of chemical nucleases in DNA-cleavage studies is an example of how reagents based on small molecules can be of use in molecular biology.[2, 3] Analogously, chemical proteases are useful for the manipulation of proteins.[1, 4, 5] Two approaches for the design of chemical proteases can be distinguished: 1) use of affinity-based reagents, and 2) covalent linking of redox-active metal complexes to specific residues of the protein with subsequent activation of the metal to achieve protein cleavage. We describe here a new reagent for the photocleavage of proteins that has a) high affinity for hydrophobic sites of proteins, b) strong absorption bands in the near-visible region, c) a long-lived singlet excited state (which is convenient for photoreactions), and d) a chromophore that has been extensively used to probe microenvironments. Use of light as a reagent in protein-cleavage reactions provides strict control of the initiation and termination of the reaction. Vanadate was used as a photoprobe for phosphate-binding sites of proteins.[6] Vanadate has a low extinction coefficient (>320 nm),[6] and high concentrations of vanadate are needed to capture a significant fraction of the incident light. The presence of several vanadium species in vanadate solutions makes it difficult to identify the photochemically active species,[6c] and vanadate induces photocleavage at many sites other than serine residues.[6d] We now observed that Py-Phe (Scheme 1) complements vanadate photochemistry and that Py-Phe induces site-specific photocleavage of bovine serum albumin (BSA) and chicken-egg lysozyme under mild conditions.[7]

The design of Py-Phe was prompted by earlier studies in our laboratory with bifunctional probes consisting of hydrophobic and hydrophilic groups separated by a linker.[8–10] Bifunctional



Py-Phe

Scheme 1. Structure of the bifunctional probe Py-Phe, which is obtained by linking 4-(1-pyrenyl)butyric acid with L-phenylalanine.

probes seek out binding sites on proteins that have an arrangement of hydrophobic and hydrophilic microenvironments with complementary interactions. Covalent linking of 4-(1-pyrenyl)-butyric acid with L-phenylalanine resulted in fluorescent Py-Phe (Scheme 1).[11] The hydrophilic carboxy functionality of Py-Phe and the amide linkage improve the aqueous solubility of the hydrophobic pyrene moiety of Py-Phe. The hydrophilic functionalities may also participate in electrostatic and hydrogen-bonding interactions. The size of the separation between the hydrophobic and hydrophilic moieties (the length of the linker) plays an important role in probe binding to proteins. Probe affinity for proteins, for example, increases with increasing linker length as well as with the size of the hydrophobic moiety.[8] The long-lived singlet excited state of the pyrenyl chromophore ($t_{1/2}$ > 100 ns), when coupled with the redox activity of amminecobalt(III) complexes, results in site-specific protein cleavage.

Studies show that Py-Phe binds to proteins. For example, the electronic absorption spectrum of Py-Phe (3 μM) is red-shifted upon binding to BSA (Figure 1). The intensities of Py-Phe absorption bands decrease with increased protein concentration;

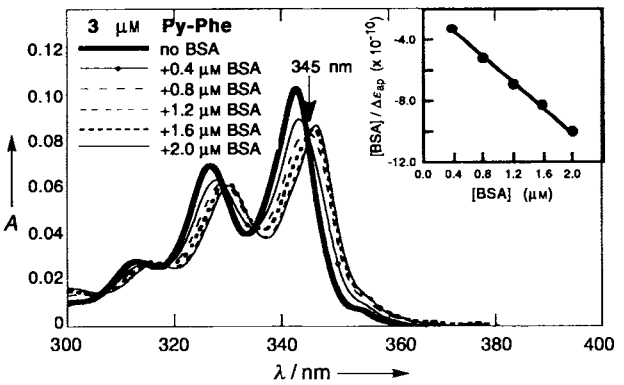


Figure 1. Absorption spectra of Py-Phe (3 μM) with and without BSA. The spectra are red-shifted by 4 nm with an isosbestic point at 345 nm. A plot of the quotient of the BSA concentration and $\Delta\varepsilon_{ap}$ versus the BSA concentration is shown at the top right corner; the estimated binding constant for the binding of Py-Phe to BSA is $(2.8\pm0.5)\times10^6\ M^{-1}$. The binding constant for the binding of Py-Phe to lysozyme is $(7\pm0.5)\times10^5\ M^{-1}$. A = absorbance.

the isosbestic point is at 345 nm. The red shift and hypochromicity indicate a hydrophobic environment around the pyrenyl chromophore.[8] The binding plot[12] derived from the absorption titration data (inset of Figure 1) provided a binding constant of $(2.8\pm0.5)\times10^6\ M^{-1}$. Binding of Py-Phe to BSA was also confirmed by circular dichroism (CD) and fluorescence spectra. New positive CD bands appeared at 330 and 345 nm when BSA (50 μM) was added to Py-Phe (50 μM), whereas the free probe had negative CD bands at 336, 351, and 360 nm. Binding of Py-Phe to BSA increases the fluorescence lifetime of Py-Phe from 106 ns (free probe, air-saturated buffer) to 125 ns (1:1 ratio of Py-Phe to BSA). Fluorescence-quenching studies indicate that Py-Phe bound to BSA is well protected from the

aqueous medium. The Stern–Volmer quenching constants obtained with CoHA (= $[Co(NH_3)_6]^{3+}$) as the quencher decrease from 1.9 mM^{-1} (free probe) to 0.25 mM^{-1} (bound to BSA). Taken together, these spectroscopic studies indicate that the probe binds to the protein through its pyrenyl moiety, which is protected from the aqueous medium by the surrounding protein matrix.

Photocleavage of BSA was achieved by irradiating into the absorption bands of the pyrenyl chromophore at 344 nm in the presence of CoHA (1, 2, and 10 mM) as an electron acceptor. Progress of the protein photocleavage was monitored by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS PAGE; 6% acrylamide, 0.4% bis(acrylamide), 13% glycerol, pH 8.4).[13] Two new bands for BSA fragments with molecular weights of 41 and 28 kDa appear in the gel (Figure 2), illustrating the high degree of specificity in cleavage. If the photocleavage were random, one would observe a smear in these lanes. No photocleavage is observed in the absence of either of the two reagents or light (Figure 2, bottom, lanes 3 and 8–10). Irradiation of BSA and CoHA without Py-Phe does not yield any fragmentation (lane 10). Similarly, irradiation of BSA in the presence or absence of Py-Phe without CoHA does not result in fragmentation (lanes 9 and 8, respectively). Py-Phe, CoHA, and light are essential for the observed photocleavage. Photocleavage with Py-Phe is also observed for lysozyme (two fragments of lower molecular weight (11 kDa, 3.5 kDa) appear), myoglobin, and carboxypeptidase, demonstrating the general nature of the methodology.

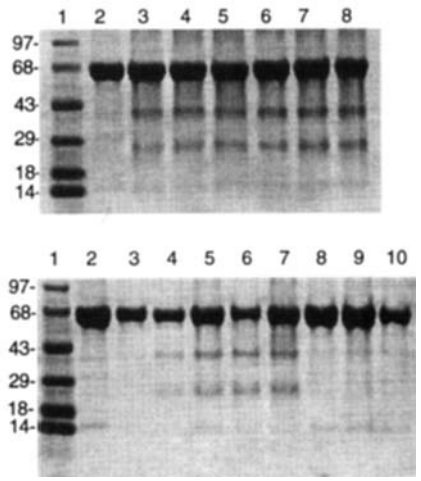

Figure 2A. Top: the gel-electrophoresis pattern of BSA under various conditions: lane 1, molecular weight standard for the mass values given on the left; lanes 2–8 contained BSA (15 μM) and Py-Phe (15 μM); lanes 3–5 also contained CoHA (1 mM); lanes 6–8 also contained CoHA (2 mM). Samples in lanes 3–5 were irradiated at 344 nm for 20, 40, and 60 min, respectively. Samples in lanes 6–8 were irradiated for 20, 40, and 60 min, respectively. The samples were run from top to bottom. Bottom: the gel-electrophoresis pattern of BSA under various conditions: lane 1, molecular weight standard for the mass values given on the left; lane 2 contained BSA (15 μM); lanes 3–7 contained BSA (15 μM), CoHA (10 mM), and Py-Phe (15 μM), and the sample was irradiated for 0, 10, 20, 30, and 60 min, respectively; lane 8 contained only BSA (15 μM), and the sample was irradiated for 30 min; lane 9 contained BSA (15 μM) and Py-Phe (15 μM), and the sample was irradiated for 30 min; lane 10 contained BSA (15 μM) and CoHA (10 mM), and the sample was irradiated for 30 min.

Use of Co^{III} complexes other than CoHA—such as chloropentamminecobalt(III) chloride, $[Co(bpy)]_3^{3+}$, or sepulchratecobalt(III) chloride—also results in the same fragments for the cleavage of BSA with Py-Phe. The cleavage most likely occurs at the pyrenyl-binding site rather than at the metal-binding site. Singlet oxygen is not involved in these reactions, as degassing of the reaction mixture does not alter or reduce photoproduct formation. Addition of sodium azide, a known singlet-oxygen quencher, does not inhibit the photoreaction. Irradiation for longer than 20 min enhances the formation of photoproducts only marginally (maximum conversion of 21% for BSA and 44% for lysozyme). The pyrenyl radical cation, generated by electron transfer from the Py-Phe singlet excited state by CoHA, may be responsible for the photocleavage. The following support this view: Py-Phe fluorescence is quenched by CoHA at a diffusion-controlled rate (4.6×10^9 $dm^3 mol^{-1} s^{-1}$), amminecobalt(III) complexes are necessary for cleavage, Py-Phe is gradually consumed in the photoreaction, and $[Co^{II}(H_2O)]_6^{2+}$ is detected at the end of the photocleavage reaction. Fluorescence from protein-bound Py-Phe is quenched by CoHA at a slower rate than that with the free probe (K_{SV} is reduced by a factor of about 8 upon binding to BSA). When Py-Phe is omitted from the reaction mixture, irradiation does not lead to protein cleavage. The pyrenyl chromophore is important in the light-absorption process and in the subsequent photoreaction. The N-terminal sequencing of the photoproducts to identify the cleavage site was not successful, which suggests possible N-terminal blockage similar to those observed with other protein-cleavage protocols.[1a–c, 6] Experiments are in progress to identify the cleavage site and the mechanistic pathways responsible for photocleavage. The appearance of two sharp bands in the gels demonstrates a single cut in the peptide backbone with a high degree of specificity. The low diffusional mobility of the pyrenyl radical cation (compared to that of the hydroxy radical)[14] and the high affinity of Py-Phe for hydrophobic and hydrophilic microenvironments in proteins may be responsible for the observed high specificity.

The equation used is $([BSA]/\Delta\varepsilon_{ap}) = ([BSA]/\Delta\varepsilon) + (1/\Delta\varepsilon K)$ where $\Delta\varepsilon_{ap} = [\varepsilon_a - \varepsilon_f]$, $\Delta\varepsilon = [\varepsilon_b - \varepsilon_f]$, K is the binding constant, $\varepsilon_a =$ (absorbance at 343 nm)/[Py-Phe], ε_b = extinction coefficient of the bound form (2.211×10^4 M^{-1} cm^{-1}), and ε_f is the extinction coefficient of free Py-Phe.

[13] The reaction mixture (0.1 mL) was irradiated at 344 nm for various lengths of time with a xenon lamp source and a monochromator (3.0×10^{-8} einsteins min^{-1} at 340 nm). Filters were used to remove stray UV light, and the band pass on the monochromator was adjusted to 10 nm. Irradiated solutions of the protein and probe were dried under reduced pressure, and the residue was redissolved in the sample buffer (0.024 mL) made of glycerol (1 mL), sodium dodecyl sulfate (3 mL, 10% aqueous solution), tris(hydroxymethyl)aminomethane hydrochloride (1.25 mL, 0.5 M), bromophenol blue (0.6 mL, 0.1% solution), and deionized distilled water (4.5 mL). The gels were run by applying a voltage of 60 V until the dye (Coomassie blue) passed through the stacking gel. The voltage was then increased to 110 V, and the gels were run for a total of 2 h; see H. Schagger, G. V. Jagow, *Anal. Biochem.* **1987**, *166*, 368.

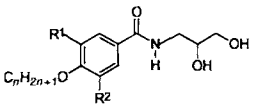
Design of Thermotropic Liquid Crystals with Micellar Cubic Mesophases: Amphiphilic *N*-(2,3-Dihydroxypropyl)benzamides**

Konstanze Borisch, Siegmar Diele, Petra Göring, Horst Kresse, and Carsten Tschierske*

Cubic mesophases are common in surfactant/solvent and lipid/solvent systems and are ordered supermolecular arrangements with isotropic physical properties. They have attracted considerable interest because of their potential use in drug release systems, as templates for the preparation of mesoporous silicates, and as models for cell fusion processes.[1] Several different cubic mesophases are observed in these systems depending on the concentration of the surfactant.[2] They can occur as intermediate phases either between lamellar and hexagonal columnar phases (bicontinuous cubic phases, V-phases) or between the hexagonal columnar phases and the micellar solutions (discontinuous cubic phases, I-phases). The first type can be regarded as interwoven networks of branched columns, the second one consists of closed micelles arranged in a cubic lattice. The interface curvature between hydrophilic regions and lipophilic regions was recognized as the key factor determining the phase type. Depending on the sign of the interface curvature either normal phases (type 1; the interface curvature is directed away from the regions with stronger cohesive interactions) or inverted phases (type 2; the interface is curved toward the regions with stronger cohesive forces) can occur.

In contrast to the large number of lyotropic systems with cubic mesophases, relatively few thermotropic compounds with cubic phases are known.[3, 4] In most cases, bicontinuous structures with body-centered cubic lattices (*Ia3d*, *Im3m*), which represent intermediate phases between columnar and smectic phases, have been proposed for these thermotropic cubic phases.[4] More recently different types of thermotropic cubic phases have been observed for amphiphilic carbohydrate derivatives.[5, 6] For some of these compounds inverted micellar cubic phases with primitive cubic lattices (*Pm3n* or *P43n*) have been found.[6] Because this type of primitive cubic phase has never been observed in thermotropic systems, their more detailed investigation should be of special interest;[7] however, the transition temperatures of these carbohydrate derivatives are rather high such that their study is hampered by decomposition. In an effort to overcome these difficulties, we decided to decrease the number of attractive hydrogen bonds in the head group regions.

Here we describe the first stable model compounds for these carbohydrate derivatives. These are amphiphiles in which one, two, or even three lipophilic alkyl chains were grafted to a hydrophilic N-(2,3-dihydroxypropyl)benzamide group (**1**–**3**). As



1, $R^1 = R^2 = H$
2, $R^1 = C_nH_{2n+1}O$, $R^2 = H$
3, $R^1 = R^2 = C_nH_{2n+1}O$

in the case of related D-glucamides,[6] three different types of mesophases were found depending on the number of alkyl chains: compound **1** with only one dodecyloxy chain, $n = 12$, forms a smectic A_d phase, a hexagonal columnar phase (Col_{H2}) is found for the double chain compound **2**, and a cubic phase was detected for compound **3** with three dodecyloxy chains (Table 1). The X-ray diffraction pattern of this cubic phase can be indexed on the basis of a primitive cubic lattice (*Pm3n* or *P43n*; $a_{cub} = 7.45$ nm at $T = 90$ °C; Table 2). Thus, simply by changing the number of lipophilic chains grafted to the aromatic linking units the supermolecular organization of these molecules can be changed from layerlike through columnar to cubic. In this respect the thermotropic mesomorphism of these compounds, which depends on the number of lipophilic chains, is analogous to the lyotropic mesomorphism of surfactant/solvent

Table 1. Transition temperatures T of the compounds **1**–**3**, $n = 12$, and lattice parameter a of their mesophases [a].

Compd.	R^1	R^2	T[°C][a]	a[nm] (T[°C])

systems. In analogy to lyotropic systems it can be expected that by increasing the number of chains the interface curvature between the segregated regions of the lipophilic chains and the polar *N*-(2,3-dihydroxypropyl)amide groups increases and gives rise to the transition from a smectic phase (S_A) through an inverted hexagonal columnar phase (Col_{H2}) to a cubic phase consisting of closed inverted micelles (Cub_{I2}).

The comparison of several homologous compounds **3** with alkyl chains of different length (Figure 1) indicates that the

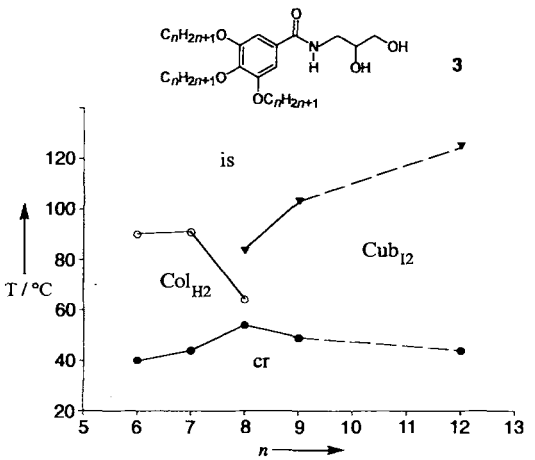

Figure 1. Dependence of the thermotropic transition temperatures T of the aminopropanediol derivatives **3** on the chain length n (● = cr/Col_{H2}, cr/Cub_{I2}; ○ = Col_{H2}/is, Col_{H2}/Cub_{I2}; ▼ = Cub_{I2}/is). Abbreviations: see Table 1.

cubic phase is destabilized on decreasing the chain length and a hexagonal columnar phase is found for the short-chain derivatives. This is in accordance with the proposed inverted micellar structure of the cubic phase. Compound **3**, $n = 8$, exhibits a cubic–columnar dimorphism. This provided the opportunity to investigate the structural changes that occur at the transition from the thermotropic columnar to the thermotropic cubic phase.[8] The hexagonal lattice parameter of the Col_{H2} phase is $a_{hex} = 3.3$ nm at $T = 60\,^{\circ}C$. The cubic phase has a primitive cubic lattice (*Pm3n* or *P43n*) with a lattice parameter a_{cub} of 6.9 nm at $T = 75\,^{\circ}C$.

In order to confirm the inverted micellar structure of the cubic phase of **3**, $n = 8$, proton conductivity investigations were carried out. If the cubic mesophase is built up by closed inverted micelles, the hydrogen bonding networks between the head groups should be located inside the micelles and therefore they should be isolated from each other by the lipophilic regions of the alkyl chains. In a bicontinuous cubic phase and in columnar phases however, the hydrogen bonding network should be extended over large distances. Since these hydrogen bonding networks can act as proton conductors, the conductivity is expected to decrease at the transition from the hexagonal columnar to the inverted micellar cubic mesophase, whereas it should remain approximately constant at the transition in a bicontinuous cubic phase. Indeed, a strong decrease in the specific conductivity is found at the transition from the hexagonal columnar phase to the cubic phase (Figure 2), which strongly supports the inverted micellar structure of this cubic phase.

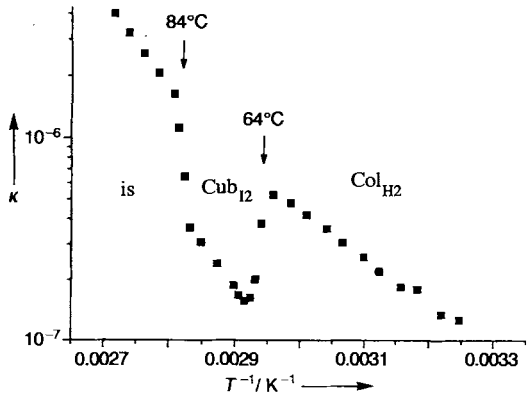

Figure 2. Dependence of the specific conductivity κ (in $AV^{-1}m^{-1}$) of compound **3**, $n = 8$, on the temperature. Measurements were carried out in a microcapacitor ($A = 2\,cm^2$, $d = 0.02$ cm) without orientation ($f = 1$ K Hz).

What shape are these closed micelles in the cubic phases? If one assumes that spherical micelles exist and that these are arranged in a primitive cubic cell, their diameter should be equal to the lattice parameter ($a_{cub} = 6.9$ nm). The length of a single molecule of **3**, $n = 8$, as estimated from CPK models under the assumption of an all-*trans* conformation of the chains is, however, only 2.2 nm and is thus significantly smaller than the radius of the spherical micelles. This contradiction between molecular size and cell dimensions is often observed in cubic phases. Therefore, Fontell et al.[9] suggested an alternative structure for lyotropic micellar cubic phases (Cub_{I1}) located between the micellar solution and the normal hexagonal phase in surfactant/solvent systems. They proposed that the cubic unit cell is built up by eight short rodlike aggregates with an axial ratio of approximately 2:1. One of these rod-shaped micelles is placed in each corner of the unit cell, one in the center, and two on each face of the cell.[10] The micelles centered at the corners and in the center should be statistically disordered or freely rotating, whereas those on the faces of the cell are only rotationally disordered.[9]

We propose that the thermotropic cubic phases of the compounds **3**, $n = 8$–12, have the same structure (Figure 3). How-

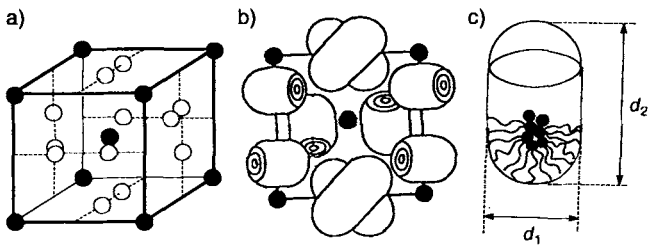

Figure 3. a) Structure of the thermotropic cubic phase Cub_{I2} of the compounds **3**, $n = 8$–12, based upon the proposal by Fontell et al. [9]. a) Arrangement of the micelles in the primitive cubic lattice. The rodlike micelles are indicated as open circles, the statistically disordered micelles at the corners and in the center are indicated by filled circles. b) View upon a face of the cubic lattice. c) Schematic representation of a rodlike micelle.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3619-2088 $ 17.50+.50/0

ever, they are built up by *inverted micelles* and appear in the *absence of any solvent*. Thus, the cubic lattice of the compound **3**, $n = 8$, should be built up by short rodlike micelles, each consisting of approximately 44 individual molecules.[11] The proposed model (Figure 3) requires that two micelles are arranged side by side at each cell face of the cubic lattice (edge length 6.9 nm). Therefore the short diameter d_1 of these rods ($d_1 = a_{cub}/2$) should not exceed 3.45 nm. In order to organize 44 molecules in each of these closed cylindrical micelles (see Figure 3) with a diameter of about 3.4 nm, these micelles should be about 5 nm long (d_2). Thus, an axial ratio $d_2:d_1$ of the order of about 1.5:1 results.[12]

Remarkably the short diameter (d_1) of the rodlike micelles in the cubic mesophase is nearly identical with the diameter of the columns in the hexagonal columnar mesophase of **3**, $n = 8$, formed at lower temperature ($a_{hex} = 3.3$ nm at 60 °C). Thus, we conclude that the short rodlike micelles of the cubic mesophase result from the collapse of the extended columns of the hexagonal columnar phase into small segments. Probably the arrangement of eight rodlike micelles in such a cubic lattice represents an energetic minimum that could be stabilized by quadrupole interactions[9] and allows an efficient packing of the molecules. If spherical micelles are formed, their packing coefficient in this arrangement would amount to only 0.52. Therefore, it is expected that spherical micelles preferably arrange in a body-centered (0.68) or in a face-centered lattice (0.74), which allow more efficient packing.

A related model was recently proposed for thermotropic cubic phases of some dendrimers.[7] A nearly spherical shape was assumed for the micelles of these cubic phases.[13] However, since both compounds differ in their chemical structure, they could not be compared directly. Further detailed investigations are necessary to elucidate the general principles for the directed design of thermotropic cubic mesophases.

[13] Two different kinds of micelles were found: spherical and tetrahedral distorted.

Absolute Sense of Twist of the C12–C13 Bond of the Retinal Chromophore in Bovine Rhodopsin Based on Exciton-Coupled CD Spectra of 11,12-Dihydroretinal Analogues**

Qiang Tan, Jihong Lou, Babak Borhan, Elena Karnaukhova, Nina Berova, and Koji Nakanishi*

Rhodopsin, the photoreceptor responsible for dim-light vision in vertebrate species, is located in the outer segment of rod cells. This membrane protein is composed of seven transmembrane α-helices and contains the 11-*cis*-retinal chromophore **1** (Figure 1), which is attached to the ε-amino group of Lys(K)296 on helix G through a protonated Schiff base (PSB).[1, 2] Glu 113 serves as a counterion to stabilize the positive charge of the PSB.[3] The 11-*cis* → *trans* isomerization triggered by light initiates changes in the protein conformation leading to a cascade of events referred to as the visual transduction process.[4] The structure of the protonated Schiff base (PSB) of 11-*cis*-retinal, with the long conjugated polyene side chain, five methyl groups, the cyclohexene ring, and the C11–C12 double bond, together with the nonplanar 6-s-*cis* and 12-s-*trans* arrangements, is ideally suited for the very subtle regulation of the pigment absorption maximum.[5] Depending on the fit of the pigment within the rhodopsin binding site, this single chromophore can cover the entire range from the UV region up to wavelengths of around 640 nm, a range most suited for the environment surrounding the organism.[5]

The UV/Vis and circular dichroism (CD) spectra of bovine rhodopsin in octyl glucoside are shown in Figure 1. Native rhodopsin ($\lambda_{max} = 500$ nm) exhibits two positive Cotton effects in its CD spectrum at 480 nm ($\Delta\varepsilon = +2.8$, α-band) and 337 nm ($\Delta\varepsilon = +9.8$, β-band). A rhodopsin incorporating a retinal analogue in which planes B and C are coplanar due to a five-membered ring (linkage of C10 and 13-methyl group) exhibit CD spectra with a negligible α-band. Similarly, the pigment formed from a retinal with coplanar A and B planes as a result of a bridged five-membered ring between the 5-methyl group and C8 showed weak β-band. Based on these findings, Ito and co-workers[6] have assigned the origin of the α- and β-bands to distortions around 12-s-*trans* and 6-s-*cis* bonds, respectively. Although the two positive Cotton effects reflect the interaction between the twisted chromophore and its environment, at this stage it is not possible to gain further information regarding the sense of twist around the 6-s-*cis* and 12-s-*trans* bonds, that is, the arrangement of planes A, B, and C in Figure 1. We have

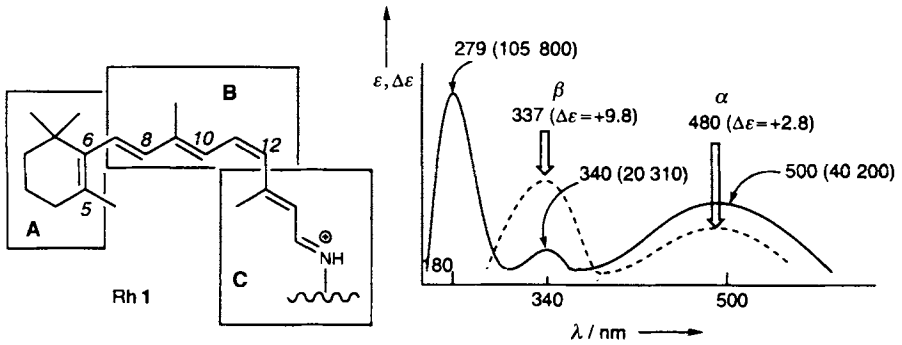

Figure 1. The 11-*cis*-retinal chromophore **1** in native rhodopsin attached in PSB form, and the UV/Vis (——, ε) and CD spectrum (– – – –, $\Delta\varepsilon$) of bovine rhodopsin in octyl glucoside.

therefore disrupted the conjugated polyene system by a single bond so that the two polyene moieties flanking the single bond would couple. The sign of the resulting bisignate couplet would reflect the twist in a nonempirical manner. Here we present data that determine the absolute sense of twist of planes B and C planes.

Previous photoaffinity labeling experiments have shown that the C3 and C4 atoms of the ionone ring lie very close to the transmembrane helix F of rhodopsin (Figure 2).[7, 8] The next essential structural feature to be clarified is the absolute sense of twist of the retinal chromophore, that is, the twists between planes A and B and planes B and C. The polyene side chain comprising C7 to C12 (plane B) is perpendicular to the axis of the transmembrane helices of rhodopsin (Figure 2). By establishing the absolute twist around the C12–C13 bond one can determine whether plane C is tilted up or down with respect to plane B. We have now established the helicity between planes B and C by incorporating 11,12-dihydroretinals into opsin and measuring their CD spectra. To our knowledge this is the first time that exciton-coupled CD spectroscopy has been applied to elucidate subtle conformational details of protein-bound substrates.

Exciton-coupled circular dichroism is observed when two or more chromophoric systems with no or only negligible molecular orbital overlap in a chiral fashion and interact through space. Hence, a twist of the polyene chain along the C12–C13 single bond in retinal bound to rhodopsin does not lead to an exciton-coupled CD band because the polyene chain is in conjugation with the rest of the molecule. However, saturation of the C11–C12 double bond in retinal breaks the chromophore into two independent conjugated systems: the triene and the protonated Schiff base (PSB) moieties. If the through-space interaction between these two chromophores in the pigment results in a couplet, then the "sign" of the split CD band should reflect the absolute twist of 11,12-dihydroretinal within the pigment binding site (Figure 3). Provided 11,12-dihydroretinal

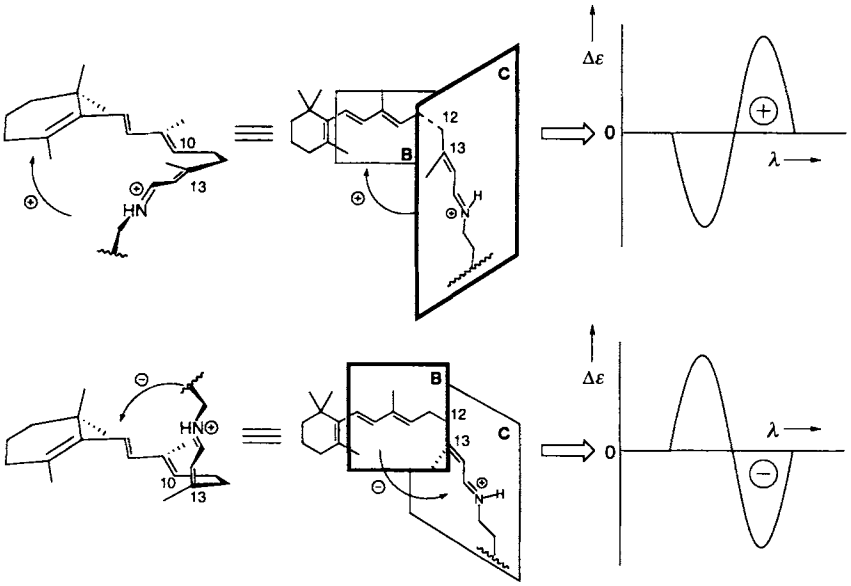

Figure 3. Absolute sense of twist between planes B and C and the predicted CD exciton couplets. The exciton-coupled CD curve is defined as positive if the sign of the first Cotton effect of the couplet at longer wavelength is positive, and vice versa.

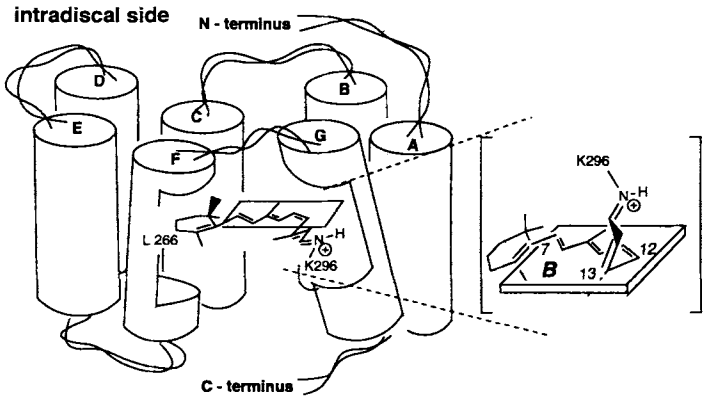

Figure 2. Schematic drawing of rhodopsin showing the location and twist of the chromophore. The residue cross-linked in the photoaffinity labeling study[7], L 266 on helix F, is indicated. The triene moiety C7 to C12 is in plane B, which is parallel to the lipid bilayer membrane. The PSB moiety is twisted around the C12–C13 bond so that it is directed toward the intradiscal side of the membrane.

adopts a conformation similar to that of 11-*cis*-retinal in rhodopsin, the exciton coupling between the triene and PSB should appear as either a "positive" or "negative" CD couplet depending on whether planes B and C assume a positive or negative twist (Figure 3).[9, 10]

The triene and enal moieties of 11,12-dihydroretinal (2H-ret, **2**)[11] absorb at 255 nm (shoulder) and 236 nm, respectively. The triene absorption of the corresponding Schiff base (2H-PSB, **3**) at 255 nm overlaps with the red-shifted PSB absorption at 270 nm (Figure 4). The UV spectrum of 11,12-dihydrorhodopsin (2H-Rh, **4**) in octyl glucoside has one broad maximum centered around 279 nm;[12] the accompanying CD spectrum shows negative and positive Cotton effects at 295 nm ($\Delta\varepsilon = -1.2$) and 275 nm ($\Delta\varepsilon = +2.5$), respectively; the difference between the extrema or *A* value is −3.7. In contrast the CD spectrum of native rhodopsin shows two positive Cotton effects (Figure 1). Thus the CD spectrum of **4** with negative and positive Cotton effects can be ascribed to the expected exciton coupling between the triene and PSB moieties, which absorb around

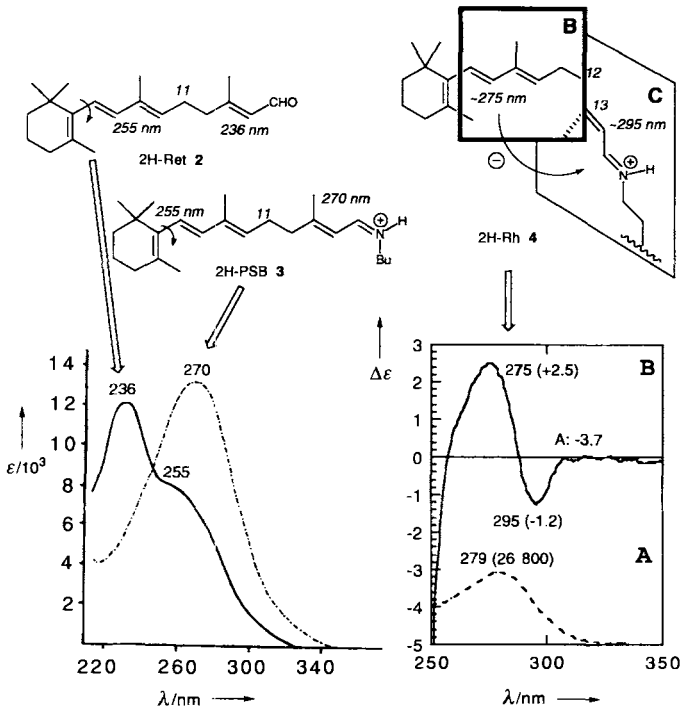

Figure 4. Left: 11,12-Dihydroretinal (**2**), its protonated Schiff base **3** obtained with *n*-butylamine, and their UV spectra in methanol. Right: Dihydrorhodopsin **4** and its UV (A) and CD spectra (B) in octyl glucoside. The chromophore analogue was bound by incubating 3.5 molequiv of analogue with a suspension of bovine opsin in 67 mM phosphate buffer (pH 7.0) at 25 °C for 5 h. All spectra were recorded in 23 mM octyl glucoside solution at pH 7.0 with opsin as a control.

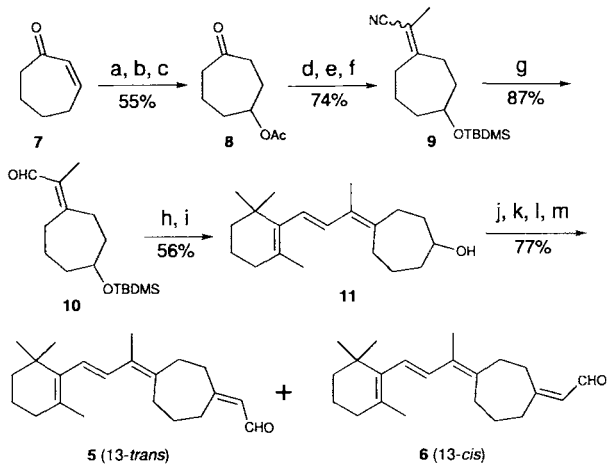
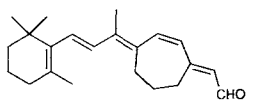


Scheme 1. Synthesis of retinal analogues **5** and **6**. a) *N*-bromosuccinimide (NBS), benzoyl peroxide, CCl_4; b) potassium acetate, 3-methyltrioctylammonium chloride (Aliquat 336), H_2O; c) H_2, Pd/C, acetic acid, CH_2Cl_2; d) diethyl 1-cyanoethyl phosphonate, NaH, THF; e) potassium carbonate, methanol, H_2O; f) *tert*-butyldimethylsilyl chloride (TBDMSCl), imidazole, DMF; g) diisobutylaluminum hydride (DIBAL-H), CH_2Cl_2, 1:1 mixture of isomers separated by column chromatography; h) *β*-cyclocitryl triphenylphosphonium bromide, potassium *tert*-butoxide, THF; i) $Bu_4N^+F^-$, THF; j) tetra-*N*-propylammonium perruthenate (TPAP), 4-methylmorpholine *N*-oxide (NMO), finely powered 4 Å molecular sieves, CH_2Cl_2; k) diethyl cyanomethyl phosphonate, NaH, THF; l) DIBAL-H, CH_2Cl_2; m) HPLC separation of 1:1 mixture of isomers[15].

275 and 295 nm, respectively. The red shift of the PSB band from 270 nm in **3** to roughly 295 nm in **4** is due to the effect of the electrostatic charges operating within the binding site[13] and is not unexpected. The extremum at 275 nm represents the positive Cotton effect of the negative couplet; the contribution from the opsin should be negligible since the CD spectrum depicted in Figure 4 is a difference spectrum between that of the pigment and that of the opsin. Thus it appears that the triene band in pigment **4** is red-shifted by 20 nm relative to the band in **3** (255 nm in methanol). This implies that the twist around the 6-s-*cis* bond in pigment **4** is smaller than in **3** in solution; in other words, planes A and B (Figure 1) adopt a more planar arrangement in the protein due to constraints within the binding site. The conclusion arising from the negative couplet of **4** is that planes B and C are twisted as depicted in Figure 4.

It is conceivable that the 11,12-dihydrochromophore is flexible and subject to many degrees of freedom, which ultimately lead to the weak amplitudes observed in the exciton-coupled CD spectra. To check the validity of the conclusion reached from studies with the dihydropigment **4**, the same set of experiments were performed with the 13-*trans*- and 13-*cis*-11,12-dihydrocycloheptatrienylidene retinal (13-*trans*-2H-ret7 **5** and 13-*cis*-2H-ret7 **6**). The synthesis of the retinal analogues is outlined in Scheme 1. After HPLC separation, **5** and **6** were characterized by their NMR and mass spectra.[14] The rationale to pursue a dihydro analogue of pigment **4** in which the conformation is locked with a seven-membered ring lies in earlier data obtained with cycloheptatrienylidene retinal (ret7 **12**). The UV and CD spectra of the pigment obtained from **12** and opsin closely resemble the UV and CD spectra of native rhodopsin.[15] It was therefore concluded that the geometry of **12** within the binding site and the corresponding protein–substrate interactions are very similar to those of 11-*cis*-retinal in the native rhodopsin. Based on these observations we felt that 13-*trans*-2H-ret7 **5** would be a more appropriate choice for a dihydro-11-*cis* locked retinal analogue of 11,12-dihydroretinal (Figure 5).



12

The enal moiety in **5** absorbs at 244 nm in methanol. The absorption of the nonplanar triene moiety was assigned to be around 266 nm (the synthetic intermediate **11** with the same triene system exhibits an absorption maximum at 266 nm) and appears as a shoulder around 270 nm (Figure 5; the UV and CD spectra of **6** are very similar). In the protonated Schiff base **13**

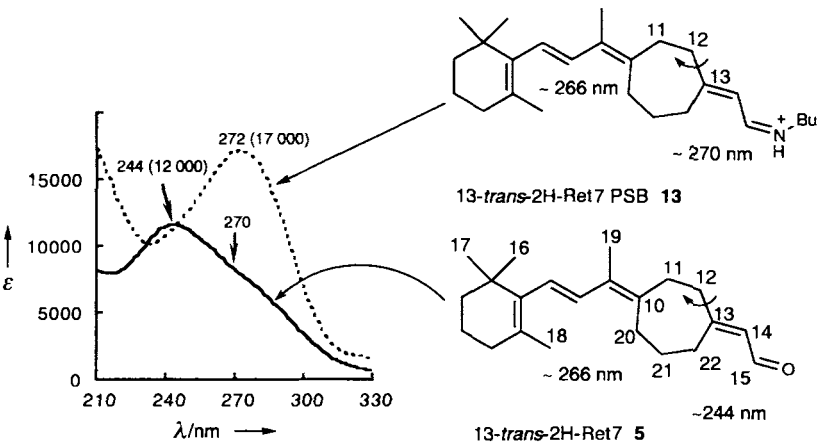


Figure 5. 13-*trans*-2H-ret7 **5**, its PSB derivative **13**, and their UV spectra in methanol. The UV spectra of 13-*cis*-2H-ret7 **6** and its PSB derivative are very similar to those of the *trans* isomer.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3619-2091 $ 17.50+.50/0

obtained with *n*-butylamine, the absorption maximum of the enal unit is shifted to around 270 nm (Figure 5) and overlaps with the triene absorption.

Rhodopsin analogues **14** and **15**, which incorporate **5** and **6**, respectively, have absorption maxima at 283 nm ($\varepsilon = 28000$) and 284 nm ($\varepsilon = 29000$), respectively (Figure 6).[16] Repeated addition of 11-*cis*-retinal to incubation mixtures of each failed to generate the native rhodopsin as determined by the absorption at 500 nm. Therefore, it was concluded that no opsin was left and the analogues bound to opsin could not be replaced by 11-*cis*-retinal.

13-*trans*-2H-Rh7 **14** exhibits a negative split CD band at 297 nm ($\Delta\varepsilon = -6.5$) and 273 nm ($\Delta\varepsilon = +5.2$; $A = -11.7$). Rhodopsin analogue **15** also shows a negative couplet with a slightly larger A value of -14.1 at similar wavelengths, 298 nm ($\Delta\varepsilon = -7.5$) and 272 nm ($\Delta\varepsilon = +6.6$; Figure 6). The bisignate CD spectra can again be ascribed to the coupling between the triene and protonated Schiff base (PSB) moieties, thus confirming the conclusion resulting from experiments with analogue **4**. To secure further support for the origin of the couplet, the amplitudes of the split CD bands of 13-*trans* and 13-*cis* isomers **14** and **15** were compared. It is known that the A value of bisignate exciton-coupled split CD curves increases as the projection angle of the two interacting chromophores approaches 70°.[9, 10] The estimated angle between the triene and protonated Schiff base moieties is roughly 60° for the 13-*cis* isomer and 20° for the 13-*trans* isomer based on molecular modeling calculations (MM2 force field).[17] This is in agreement with the observed larger A value for the 13-*cis* isomer (-14.1) relative to that for the 13-*trans* isomer (-11.7), and supports the conclusion that the observed split CD band is due to exciton coupling between the two chromophores within the binding site.

The smaller A value of the pigment incorporating 11,12-dihydroretinal (**2**), in which the 11-s-*cis* conformation is not fixed, is most probably due to the flexibility of the side chain leading to conformations in which the angles between the two interacting chromophores are smaller and/or the chromophores are more distal. Nevertheless, the fact that the CD spectrum of 11,12-dihydrorhodopsin (**4**) displays a negative bisignate curve is in agreement with the results obtained with 13-*trans*-2H-Rh7 **14** and 13-*cis*-2H-Rh7 **15**.

The experimental results indicate that the negative helicity between planes B and C is as depicted in Figure 3; they also suggest that the twist between planes A and B of chromophores bound to opsin is smaller than in the same chromophore in solution. The handedness of the arrangement of the planes B and C agrees with the theoretical prediction of Kakitani and co-workers,[18] according to which the C12–C13 bond in rhodopsin is twisted by -130 to $-150°$ when the torsion angle is measured clockwise from the planar *cis* conformation. (Han and Smith have also arrived at the same conclusion by theoretical considerations.[19]) It is remarkable that the conformation of the chromophore in the binding pocket of a large protein can be determined from the sign of the bisignate exciton-coupled split CD spectra. As mentioned above, the twist of the chromophore is reflected in the CD spectrum of the original rhodopsin by the presence of the α- and β-bands. The characteristics shape and sign of these bands are dictated by the interaction between the chromophore and the opsin binding site. Therefore, in other visual pigments that exhibit similar positive α- and β-bands, it can be postulated that the chromophoric twist along their polyene chain will be similar to that in bovine rhodopsin.

These results further demonstrate the versatility of the exciton-coupled split CD method in probing subtle conformational aspects of ligand–receptor interactions. Further studies directed toward determining the absolute sense of twist between planes A and B and clarifying the mechanism of the visual transduction process on a molecular structural basis are in progress.

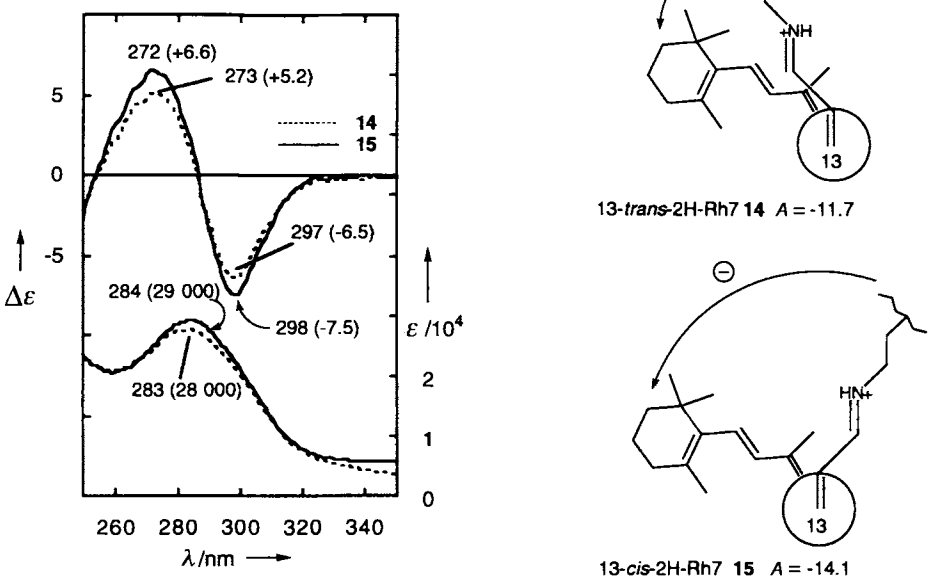

Figure 6. UV and CD spectra of 13-*trans*-2H-Rh7 **14** and 13-*cis*-2H-Rh7 **15**. The projected structures of the chromophores show that the angle between the coupled chromophores is larger for the 13-*cis* pigment, and this is reflected in the slightly larger amplitude in its CD spectrum. The chromophore analogues were bound by incubating 1.5 mol equiv of analogue with a suspension of bovine opsin in 67 mM phosphate buffer (pH 7.0) at 25 °C for 5 h. All spectra were recorded in 23 mM octyl glucoside solution at pH 7.0 with opsin as a control.

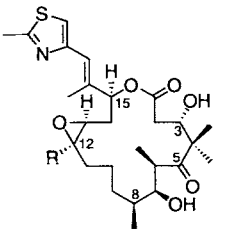
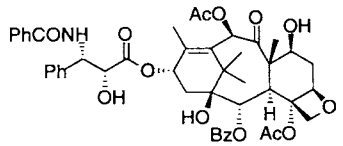
Structure–Activity Relationships of the Epothilones and the First In Vivo Comparison with Paclitaxel**

Dai-Shi Su, Aaron Balog, Dongfang Meng, Peter Bertinato, Samuel J. Danishefsky,* Yu-Huang Zheng, Ting-Chao Chou, Lifeng He, and Susan B. Horwitz

The discovery and characterization of the bacterial natural products epothilones A (**1**) and B (**2**) have evoked a great deal of interest.[1] Their high levels of cytotoxicity and their potent stabilization of microtubules are reminiscent of the biological activity of paclitaxel (**3**), a clinically valuable resource in cancer



1, R = H: epothilone A
2, R = Me: epothilone B



3: paclitaxel

chemotherapy.[2] Paclitaxel (**3**), which has been in use for the treatment of ovarian and breast carcinomas, is also being evaluated against a variety of other tumors. Nonetheless, its application is hampered by difficulties in formulation and susceptibility to multiple drug resistance (MDR). Though a massive amount of analog synthesis based on the paclitaxel structure has been accomplished, the framework appears to be intolerant to major simplification with maintenance of biological activity. To the best of our knowledge, no compound which is of a significantly lower level of structural complexity than paclitaxel has been of clinical interest as a replacement for the parent drug.

Since the epothilones are more water-soluble than paclitaxel and, in preliminary in vitro studies, seemed to perform better against several MDR cell lines, this series warranted evaluation. Our laboratory and several others have attacked the problem of the total synthesis of **1** and **2**.[3–9] This goal, in the case of **1**, was first accomplished in a stereocontrolled fashion by using a boron-alkyl Suzuki coupling strategy to establish the C11–C12

bond.[3c, e] Our total synthesis was followed by three reports of total syntheses involving nonstereoselective ring-forming olefin metathesis reactions to establish the C12–C13 bond.[3d, 4, 5] More recently, a stereoselective Wittig reaction to establish the C12–C13 bond en route to **1** has also been described.[4c]

The first synthesis of epothilone B (**2**) was accomplished in our laboratory, again, through the use of a highly stereoselective boron-alkyl Suzuki coupling reaction to form the trisubstituted olefin.[3e] A Wittig-based route, generating a mixture of olefin isomers leading to **2**, was recently reported.[4d] An important advance in the field was the stereocontrolled epoxidation of the C12–C13 double bond in desoxyepothilones A (**4**) and B (**5**) through the agency of 3,3-dimethyldioxirane.[3c–e]

While none of our syntheses described thus far are practical for the full-scale pharmaceutical development of an epothilone, they have provided more than ample quantities for biological evaluations of the natural products both in vitro and in vivo, and for early evaluations of a range of fully synthetic analogs. Presently, we are examining compounds obtained by obvious explorations of key intermediates in the total syntheses of **1** and **2**. At this writing, we have not yet generated analogs derived from extended operations on the completed natural products themselves. We have focused on structure–activity relationships (SAR) to determine zones of the molecule that are tolerant or intolerant of structural change. Such insights would be valuable in focusing studies on molecular modeling. Furthermore, it was hoped to gather in vivo data for a direct comparison of epothilone B and paclitaxel.

For the definition of the SAR of the epothilones, it is convenient to divide the structure of the drug into an acyl sector (shown arbitrarily as C1–C8), an O-alkyl sector (C9–C15), and a pendant aryl sector projecting from C15. In our preliminary SAR studies on epothilones we found that the acyl sector is rather intolerant of modification. For instance, inversion of stereochemistry at C3 ($S \rightarrow R$), or reduction at C5 results in serious abrogation of activity. Wholesale deletion of functionality at C3, C5, C6, C7, and C8 results in a loss of cytoxicity and of activity in the tubulin/microtubule system.[10] Indeed, as we recently demonstrated, a single permutation—deletion of the 8-methyl group—has a highly deleterious effect on biological function.[11] We now report that deletion of the "C9" methylene group (see the 15-membered macrolide **18**) also results in a major loss of activity in the tubulin polymerization/depolymerization assays, which have correlated rather closely with other indicators of biological function.[12]

Turning to the O-alkyl sector, we have expanded on the original[13] and subsequent findings to the effect that epothilone B (**2**) is more potent than epothilone A (**1**) with regards to tubulin polymerization/depolymerization and cytotoxicity (Figure 1 and Table 1). It was also found that the (*Z*)-desoxy compounds **4** and **5** retain a function closely comparable to their natural counterparts, **1** and **2**, respectively. Once again, the "B" precursor, compound **5**, is more active than the "A" precursor, compound **4**. Even the (*E*)-desoxy compounds **6** and **7** maintain significant biological activity, although less than that of the (*Z*) analogs, **4** and **5**, respectively.[3d, e, 4d] We now report that epothilone B is approximately 3400 times more active than paclitaxel against the resistant human leukemic cell line CCRF-CEM/VBL in cell-culture cytotoxicity studies.

The alkyl sector has been studied in greater detail.[14] Thus, substitution of an ethyl group at C12 in epothilone B is well tolerated (see compounds **8** and **12**, the ethyl versions of **5** and **2**, respectively) as are the higher homologues **10**, **13** and **14**.[15] Interestingly, biological activity is not lost in compound **11** bearing the polar acetal functionality on C12, nor in the *E*-desoxy compound **9**.[16] Further, activity is still retained, though in attenuated form, upon inversion of stereochemistry at C15 (see compound **15**). In summary, the O-alkyl sector is remarkably tolerant of modification with basic maintenance of in vitro function.

We also investigated the aryl sector.[14] Our studies indicate that this sector is also quite tolerant to permutation. For instance, the substitution of oxygen for sulfur was well tolerated. Thus, compound **16** (an oxazole rather than a thiazole) is equipotent with **4** in the tubulin polymerization assay (Figure 1)[17] as well as in cytotoxicity assays (Table 1).[18] We then studied a more drastic variant of the aryl domain with phenyl in place of the thiazolyl unit, and found that compound **17** retains 60% of the activity of **2** in the tubulin polymerization assay. Though there is a loss of one order of magnitude in the cytotoxicity assay, compound **17** is still highly cytotoxic.

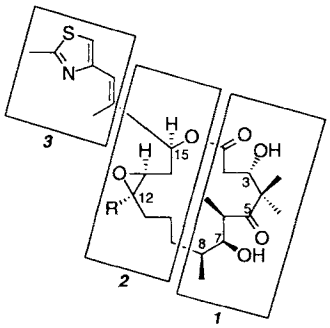
15	0.055	0.197
16	0.030	0.049
17	0.098	0.146
18	>10.0	8.95
19	>10.0	>10.0
20	3.52	1.20
21	1.80	>5.00

Given these data, we wondered whether the aryl sector is even necessary. Could it be replaced by a single hydrogen at C15? Toward this end, we prepared compound **19**. However, it has very low cytotoxicity (IC_{50} > 10.0 μM) and shows almost no activity in tubulin polymerization/depolymerization assays. We then asked whether the olefinic spacer element connecting the aromatic rings with C15 is needed. Therefore, we prepared compounds **20** and **21**. These substances showed a major loss of cytotoxicity. Accordingly, the aryl sector can now be defined with greater precision: it requires an olefinic spacer linking the lactone at C15 to an aromatic subsection which is substantially tolerant to modification.

Of course, it will be necessary to prepare and evaluate many more compounds to provide a definitive mapping of the SAR profile of this series with single carbon atom resolution. However, it is already clear that the acyl sector constitutes a "hot spot" with great sensitivity to structural change (Scheme 1). By contrast, the O-alkyl and aryl sectors exhibit significant tolerance, both in the tubulin assays and in cytotoxicity screens.

We have also initiated in vivo evaluations of the epothilones. As a first line of inquiry, we conducted a direct comparison of fully synthetic epothilone B (**2**) with paclitaxel (**3**). Since the susceptibility to drug resistance is one of the vulnerabilities of paclitaxel, we scrutinized the in vivo efficacy of the two drugs against resistant tumor tissues.[19] In the initial studies, CCRF-CEM/VBL tumor tissue was implanted subcutaneously in SCID mice. The tumor-bearing mice were treated periodically, according to a set protocol, with epothilone B (**2**, 0.7 mg kg^{-1}) and paclitaxel (**3**, 2 mg kg^{-1}). Although the concentration of paclitaxel used was higher than that of epothilone B (ca. 1.7:1 molar ratio), the reduction in tumor size was substantially greater with epothilone B at each interval of measurement (Table 2).



Scheme 1. The three arbitrarily defined sectors of the epothilones: aryl (1), alkyl (2), and acyl (3) sectors. Sector 1 is very sensitive to modifications; sectors 2 and 3 are more tolerant.

Table 2. Chemotherapeutic effect of daily treatments with epothilone B and paclitaxel in CB-17 SCID mice bearing drug-resistant human CCRF-CEM/VBL xenografts[a].

Drug	Dose [mg kg^{-1}][c]	Average tumor volume (T/C)[b] day 7	day 12	day 17	day 22
control	0	1.0	1.0	1.0	1.0
epothilone B	0.7	1.0	0.32	0.40	0.33
paclitaxel	2.0	1.0	0.60	0.58	0.70

[a] Multidrug resistant CCRF-CEM/VBL tumor tissue, 50 μL per mouse, was implanted subcutaneously on day 0. Solutions of the drugs in DMSO were injected intraperitoneally on days 7, 8, 9, 10, 14, and 15. There were seven CB-17 SCID mice in each treated group and in the control group. [b] The tumor volumes for each group on day 7 were about 1 mm^3. The average tumor volumes of the control group on days 12, 17, and 22 were 35, 107 and 278 mm^3, respectively. [c] On day 12, the average decreases in body weight due to treatment with epothilone B and paclitaxel were 2.7 and 3.4%, respectively.

In a subsequent experiment, epothilone B and paclitaxel were administered weekly (Table 3).[22] In these experiments both the sensitive (CCRF-CEM) and resistant (CCRF-CEM/VBL) tumor tissues were implanted in SCID mice. Epothilone B was given both intraperitoneally (H_2O) and intravenously (DMSO) for comparison. Epothilone B and paclitaxel show similar reduction of tumor size in treatment of the sensitive tumor (CCRF-CEM). Against the resistant tumor (CCRF-CEM/VBL), epothilone B shows a significant advantage over paclitaxel. It is also interesting to note that epothilone B is more

[a] CCRF-CEM and CCRF-CEM/VBL tumor tissue, 50 µL per mouse, implanted subcutaneously on day 0. The drugs were administered on day 5, 12, 19 (i.p. = intraperitoneally, i.v. = intravenously). There were five CB-17 SCID mice in each group. [b] On day 20 the average decrease in body weight due to epothilone B doses of 1.5 and 3.0 mg kg^{-1} was 5.0 and 6.6%, respectively. [c] The tumor volumes for each group on day 5 was about 8 mm^3. The average tumor volumes in the CCRF-CEM control group on days 10, 15 and 20 were 57, 145, 335 mm^3; those of the CCRF-CEM/VBL control group were 62, 173, and 386 mm^3, respectively. [d]–[k] A number of mice died of drug toxicity: two on day 23 (d), two on day 19 (e), three on days 13, 21, and 21 (f), three on days 6, 6, and 21 (g), one on day 24 (h), two on day 24 (i), two on day 13 (j), and four on day 6 (k).

effective against the resistant tumor tissues than sensitive tissues in these experiments.

At present, none of our analogs are more potent in vitro than the naturally occurring epothilone B (**2**), although the ethyl compound **12** is fully competitive in all comparisons thus far available. However, we have established zones of the molecule that are most likely to be responsive to molecular modification (see Scheme 1). Also, early in vivo data suggest a potentially valuable margin of advantage of epothilone B (**2**) relative to paclitaxel (**3**) against a highly resistant MDR tumor implant. In all in vivo experiments conducted so far, epothilone B and paclitaxel were equally effective in reducing the size of sensitive (CCRF-CEM) tumor tissues. While it is far too early to argue that we have demonstrated a superior alternative to paclitaxel, the data already in hand mark the epothilones as worthy of continuing interest. Our present focus is on selecting the most promising compounds for further development, and on a major restructuring of our synthesis for the preparation of any desirable compound in the series in an eminently practical fashion.

[12] Identification of the deleted carbon in compound **18** as C9 is arbitrary; it could also be looked upon as deletion of C10 or C11. For the purpose of this discussion, we look upon this compound as a "C9 deletion" corresponding to an alteration of the substituents at C8.

[14] All new analogs described here were prepared by extensions of our previously published methodology: D. Meng, P. Bertinato, A. Balog, D.-S. Su, T. Kamenecka, E. Sorensen, S. J. Danishefsky, *J. Am. Chem. Soc.* **1997**, in press.

[15] The (*Z*)-desoxy compound with *n*-hexyl at C12 was also found to have significant biological activity; however, the solubility of this compound in DMSO is very low. Therefore, the results are not included in Figure 1.

[16] Compound **9** was treated with 3,3-dimethyldioxirane to create the *trans*-epoxide, which was found to have significant biological activity. However, the absolute configuration of the *trans*-epoxide has not been determined.

[17] Microtubule protein (MTP) was purified from calf brains by two cycles of temperature-dependent assembly and disassembly[20]. The concentration of tubulin in the preparation was approximately 85%. Assembly experiments were done in the presence or absence of 10 µM drug plus MTP (1 mg mL^{-1} diluted in assembly buffer containing 0.1 M 2-(*N*-morpholino)ethanesulfonic acid (MES), 1 mM 1,2-di(2-aminoethoxy)ethane-*N*,*N*,*N*′,*N*′-tetracetic acid (EGTA), 0.5 mM $MgCl_2$, and 3 M glycerol, pH 6.6). This concentration of drug gives an approximate 1:1 ratio to tubulin dimer. Assembly was followed spectrophotometrically at 350 nm, 37 °C for 40 min, by monitoring changes in turbidity as a measure of polymer mass[21]. Aliquots (200 µL) were taken from each assembly reaction and centrifuged at 28000 rpm, 27 °C for 30 min. The amount of protein remaining in the supernatant was determined, allowing the protein concentration in the microtubule pellet to be calculated. Controls with assembly buffer or DMSO were included. The value obtained for microtubules formed with 10 µM epothilone B was defined as 100%.

[18] The cytotoxicities of test compounds were determined by the growth of human lymphoblastic leukemic cells CCRF-CEM or their sublines resistant to vinblastine and taxol (CCRF-CEM/VBL). XTT-microculture tetrazolium/fromazan assays were used. The IC_{50} values were calculated based on five or six assays at various concentrations; a median-effect plot was generated using computer software[23].

[19] The multidrug resistant CCRF-CEM/VBL tumor tissue was implanted subcutaneously to CB-17 SCID mice, and the tumor-bearing mice were treated on days 7, 8, 9, 10, 14, and 15 with 0.7 mg kg^{-1} epothilone B intraperitoneally. The average tumor sizes were reduced by 68, 60, and 67% on days 12, 17, and 22, respectively. In the parallel experiments, 2 mg kg^{-1} taxol reduced tumor size by 40, 42, and 30%, respectively.

[21] F. Gaskin, C. R. Cantor, M. L. Shelanski, *J. Mol. Biol.* **1974**, *89*, 737.

[22] Experiments were also conducted with daily (0.7 and 1.0 mg kg^{-1}) and twice daily (0.15 and 0.25 mg kg^{-1}) treatments of epothilone B. The efficacy of once and twice daily treatments with epothilone B was similar to the weekly treatments, but the drug toxicity was slightly higher.

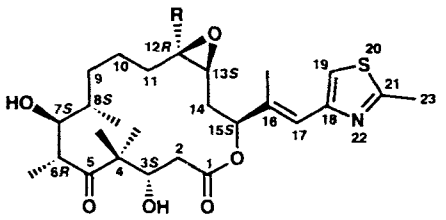
Designed Epothilones: Combinatorial Synthesis, Tubulin Assembly Properties, and Cytotoxic Action against Taxol-Resistant Tumor Cells**

K. C. Nicolaou,* Dionisios Vourloumis, Tianhu Li, Joaquin Pastor, Nicolas Winssinger, Yun He, Sacha Ninkovic, Francisco Sarabia, Hans Vallberg, Frank Roschangar, N. Paul King, M. Ray V. Finlay, Pareskevi Giannakakou, Pascal Verdier-Pinard, and Ernest Hamel

The isolation of epothilones A (**1**) and B (**2**) from the myxobacterium *Sorangium cellulosum* strain 90 by Höfle et al.[1] and the recognition of their cytotoxic action against tumor cells prompted intense research activities in chemistry and biology. In 1995 Bollag et al.[2] reported the Taxol (paclitaxel)-like mechanism of action of these compounds through induction of tubulin assembly and microtubule stabilization.[3] The recognition of their unique action against Taxol-resistant tumor cell lines[4] added to their novelty and potential importance in cancer chemotherapy. In 1996 Höfle et al. published the complete elucidation of the stereochemistry as determined by spectroscopic and X-ray crystallographic techniques.[5] Soon thereafter, a flurry of reports announced several approaches[6] to, and total syntheses of, epothilones A (**1**)[7-11,13] and B (**2**).[10,12,13] In addition to the natural products themselves, several precursors and analogues have been synthesized[7-17] and biologically investigated.[7,10,12,14,17] Notable amongst these are the 12,13-desoxy analogues (lacking the epoxide oxygen) first reported by Danishefsky et al.[7,12] and independently by ourselves,[8,10,11,13] Schinzer et al.,[9] and Höfle et al.[14] Herein we report on a) the solid-phase synthesis of several epothilone A analogues based on a combinatorial approach, b) the tubulin assembly properties of an extensive library of compounds, and c) the cytotoxic actions against breast and ovarian carcinoma cells (including a number of Taxol-resistant tumor cell lines) of a selected number of these designed epothilones. The results provide comprehensive information on structure–activity relationships of epothilones and set the foundation for their further development.



1: R = H : epothilone A
2: R = Me: epothilone B

The structures of epothilones are amenable to modification by changing the configuration of certain stereocenters, the geometry of the double bonds, the size of the rings, and the nature of their substituents. Our synthetic strategies towards these molecules were, therefore, designed on the premise of modifying these elements so as to reach optimum molecular diversity and obtain a maximum number of library members. Table 1 includes the structures of an epothilone library obtained by solution[6a,8,10,11,13,15,16,28] and solid-phase[10,28] combinatorial methods. Biological screening of these compounds was expected to lead to the establishment of sufficient structure–activity relationships to allow the next phase of the program, the design, synthesis, and identification of potential drug candidates, to proceed along a narrower track.

The strategy for the construction of a library of epothilone A analogues was based on our previously reported solid-phase synthesis[10] of epothilone A and Radiofrequency Encoded Combinatorial (REC) chemistry.[18] Scheme 1 summarizes the synthesis of a library of 12,13-desoxyepothilones A from the three key fragments generically denoted as **A**, **B**, and **C**.[19] Thus, SMART Microreactors[20] (SMART = single or multiple addressable radiofrequency tag) containing Merrifield resin were smoothly converted to Microreactors **I** by chain extension and phosphonium salt formation. Phosphonium salt resin **I** was then sorted according to the radiofrequency tag and treated with sodium hexamethyldisilazide (NaHMDS) to generate the corresponding ylides which were treated with the aldehydes **A**. The SMART Microreactors **II** were pooled for washing and subsequent deprotection and oxidation to obtain the polymer-bound aldehydes **III**. Further sorting and treatment with the dianion of the ketoacids **B** provided the polymer-bound carboxylic acids **IV** as a mixture of diastereoisomers. Resorting and esterification with alcohols **C** afforded dienes **V**. The SMART Microreactors were separately treated with $[RuCl_2(=CHPh)(PCy_3)_2]$ catalyst to simultaneously effect cyclization by olefin metathesis[6a,7a,8a,9-11,15,21,22] and cleavage of the products, leading to products as mixtures of four 12,13-desoxyepothilones A (**VII**, **VIII**, **IX**, **X**). Each mixture was identified and subjected to preparative thin-layer chromatography to provide pure compounds, which were individually deprotected by treatment with TFA in dichloromethane and then epoxidized accordingly.[6a,7b,8-11,13,15-17]

The epothilone library (Table 1) was screened for induction of tubulin assembly with 5 μM compound at 37 °C.[2] Previously tested compounds (see references in Table 1) were reevaluated for comparative purposes. Most analogues were subjected to more detailed investigation in cytotoxicity assays with human ovarian and breast cancer cells, including Taxol-resistant lines,[23] and a quantitative tubulin assembly assay that differentiates between potent taxoid compounds (Table 2).[24] It soon became apparent that compounds with assembly values below 40% in the screen yielded high EC_{50} values in the quantitative

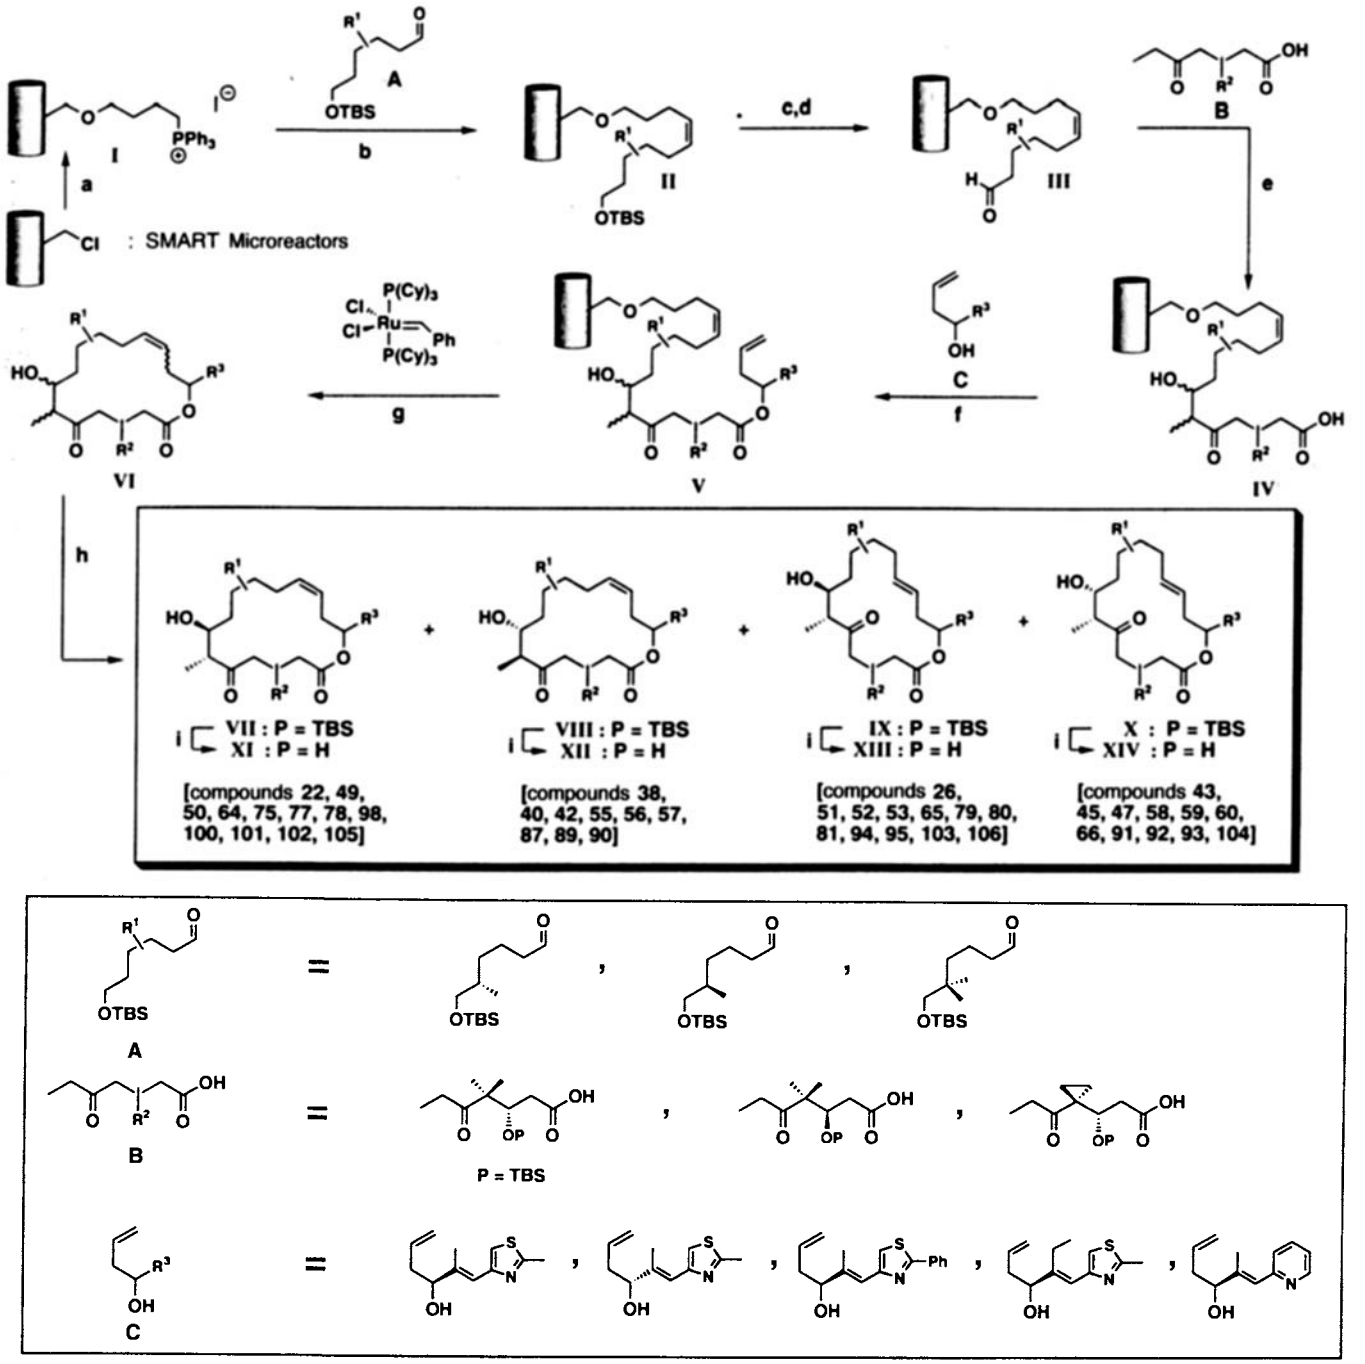

Scheme 1. Solid-phase synthesis of epothilone A analogues by a combinatorial approach. a) 1. 1,4-butanediol (5.0 equiv), NaH (5.0 equiv), nBu$_4$NI (0.1 equiv), DMF, 25 °C, 12 h; 2. Ph_3P (4.0 equiv), I_2 (4.0 equiv), imidazole (4.0 equiv), CH_2Cl_2, 25 °C, 3 h; 3. Ph_3P (10 equiv), 90 °C, 12 h; b) 1. sort SMART Microreactors (with an Accutag-100 apparatus); 2. NaHMDS (3.0 equiv), THF:DMSO (1:1), 25 °C, 12 h; 3. **A** (2.0 equiv), THF, 0 °C, 3 h (≈75% from chloromethyl polystyrene loading based on recovered aldehyde upon ozonolysis); 4. pool; c) 0.2 M HCl in THF, 25 °C, 12 h; d) $(COCl)_2$ (4.0 equiv), DMSO (8.0 equiv), Et_3N (12.5 equiv), −78 → 25 °C (≥95% for two steps, the reactions were monitored by IR analysis of polymer-bound material and by TLC analysis of the products obtained by ozonolysis); e) 1. sort; 2. **B** (2.0 equiv), LDA (2.2 equiv), THF, −78 → −40 °C, 1 h; then add resulting enolate to the resin suspended in a $ZnCl_2$ (2.0 equiv) solution in THF, −78 → −40 °C, 2.0 h (≥90%, based on recovered aldehyde upon ozonolysis); 3. pool; f) 1. sort; 2. **C** (5.0 equiv), DCC (5.0 equiv), 4-DMAP (5.0 equiv), 25 °C, 15 h (≥85% yield as determined by recovered heterocycle fragments obtained upon treatment with NaOMe); g) 1. separation of individual SMART Microreactors; 2. $[RuCl_2(=CHPh)(PCy_3)_2]$ (0.20 equiv), CH_2Cl_2, 25 °C, 48 h; h) automated HPLC (SiO_2, EtOAc/hexane, or C_{18}, H_2O/THF), or preparative thin-layer chromatography, EtOAc/hexanes. The stereochemisty at C-6 and C-7 as well as the geometry of the olefin was tentatively assigned by ^{1}H NMR spectroscopy; i) 20% TFA in CH_2Cl_2 (v/v), 25 °C, 2–12 h. The purity of individual compounds was established by ^{1}H NMR spectroscopy and HPLC. P = protecting group; TBS = *tert*-butyldimethylsilyl; DMSO = dimethyl sulfoxide; TFA = trifluoroacetic acid; LDA = lithium diisopropylamide; DCC = *N*,*N*′-dicyclohexylcarbodiimide; 4-DMAP = 4-dimethylaminopyridine.

assay and had little inhibitory effect on cell growth (only positive results shown in Table 2).

The glutamate assay was devised to test the hypothesis that taxoids more active than Taxol in tubulin assembly would also be more cytotoxic,[24] and this was validated with over fifty analogues (Hamel et al., unpublished results).[33] With the epothilones, however, the quantitative assay was less successful. A low glutamate concentration resulted in a high false negative rate in predicting cytotoxicity (data not shown), while higher glutamate concentrations (e.g. 0.7 M, Table 2) were comparable

[a] From Table 1. [b] Assay performed as described in ref. [24]; reaction mixtures contained 10 μM purified tubulin [29], 0.7 M monosodium glutamate, 5% DMSO and drug; incubation was for 20 min at room temperature and reaction mixtures were centrifuged at 14000 rpm; supernatant protein concentration was measured and the EC_{50} value is defined as the drug concentration resulting in a 50% reduction in supernatant protein relative to control values; each EC_{50} value shown is an average (standard deviations ≤20%) obtained in two to four independent assays. [c] Cell growth was evaluated by measurement of increase in cellular protein [30]. [d] The parental ovarian cell line, derived as a clone of line A2780 [31], was used to generate Taxol-resistant cell lines by incubating the cells with increasing concentrations of Taxol with verapamil [23]; the cells were grown in the presence of drug for 96 h; values shown in the table were single determinations, except for those of Taxol, **1** and **2** (average of six determinations each); the values for **1** and **2** are averages of data obtained with both synthetic and natural samples (generously provided to E. H. by Merck Research Laboratories), which did not differ significantly. [e] The MCF7 cells were obtained from the National Cancer Institute drug screening program [32]; cells were grown in the presence of drug for 48 h; each value represents an average of two determinations. [f] Relative resistance is defined as the IC_{50} value obtained for the β-tubulin mutant line divided by that obtained for the parental cell line.

to the screening assay in identifying cytotoxic analogues. If "significant" cytotoxicity is defined as an IC_{50} value below 10 nM, we identified nine analogues with activity against the breast and ovarian lines (**3**, **6**, **14**–**16**, **19**, **20**, **23**, and **25**). With the screening assay, there were no false negatives, but there were seven false positives (agents with limited cytotoxicity yielding >40% polymerization) among examined compounds. With the glutamate assay, the same results were obtained. The nine cytotoxic analogues had EC_{50} values of 3.3–13 μM, but an additional nine agents had EC_{50} values of 6.0–17 μM.

Two Taxol-resistant lines were generated from the 1A9 ovarian cells, and resistance resulted from mutations in the M40 gene, which codes for a highly expressed β_1 isotype in the parental and resistant cell lines.[23] The altered amino acids were residue 270 in the 1A9PTX10 line (Phe → Val) and 364 in 1A9PTX22 (Ala → Thr). This agreed with other observations that the Taxol binding site is on β-tubulin.[25–27] In preliminary results[10] we had reported with **1** and several analogues that 1A9PTX22 cells retained nearly complete sensitivity to epothilones, while 1A9PTX10 cells remained partially resistant to the drugs. These findings have been confirmed (Table 2). The relative resistance observed with 1A9PTX22 cells was 27-fold with Taxol and 1.0–2.7-fold with the eleven cytotoxic epothilones. With 1A9PTX10 cells, relative resistance was 23-fold with Taxol and 3.5–9.1-fold with the epothilones. The Taxol and epothilone binding sites could overlap, since **1** and **2** are competitive inhibitors of Taxol binding to tubulin polymer.[4] If one assumes that Phe270 and Ala364 interact directly with Taxol, the results with the resistant cells suggest that Phe270 is more important than Ala364 in the interaction of epothilones at the Taxol binding site.

The data in Tables 1 and 2, together with previously reported results,[1, 2, 7, 10, 12, 17] revealed important information regarding structure–activity relationships for in vitro tubulin polymerization and in vitro cytotoxicity, and lead to several conclusions. The importance of the macrocycle was confirmed by the lack of significant tubulin polymerization activity of the open-chain olefin metathesis precursor **61**. This conclusion was also reached by Höfle et al.[14] with a degradation product of epothilone A. Inversion of the configuration at C3 resulted in reduced tubulin polymerization potency. Interestingly, however, α,β-unsaturated lactones (e.g. **107** and **110**) retained significant tubulin assembly properties (Table 1) suggesting a conformational, rather than a direct binding effect for this hydroxyl group. Neither **107** nor **110**, however, exhibited significant cytotoxicity indicating an additional role for the 3-OH group. Substitution of the 4-*gem*-dimethyl with a 4,4-ethano moiety (e.g. **69** and **70**) resulted in loss of tubulin polymerization activity in all cases, pointing to the crucial importance of a proper conformation of epothilones for biological activity. Apparently the partial sp^2 character and the accompanied widening of the C3-C4-C5 angle introduced intolerable conformational changes within the macrocycle for effective interaction with tubulin. Another clear requirement for tubulin polymerization activity was the (6*R*,7*S*) configuration as revealed by the failure of all (6*S*,7*R*) stereoisomers to induce tubulin polymerization at significant concentrations (e.g. **30**, **47**, **54**–**60**, **66**, **82**–**93**, **104**, **111**, Table 1). Interestingly, there was a notable decrease in interaction with tubulin upon inversion of

Footnote to Table 1:

[a] Tubulin polymerization was determined by the filtration-colorimetric assay following the procedure of Bollag et al.[2]; purified tubulin [29] (1 mg/mL) was incubated at 37 °C for 30 min in the presence of each compound (5 μM) in MEM buffer [(100 mM 2-(*N*-morpholino)ethanesulfonic acid, pH 6.75, 1 mM ethylene glycol bis(β-aminoethyl ether). *N,N,N',N'*-tetraacetic acid, and 1 mM $MgCl_2$]; the mixture was then filtered to remove unpolymerized tubulin by using a 96-well Millipore Multiscreen Durapore hydrophilic 0.22 μm pore size filtration plate; the collected polymerized tubulin was stained with amido black solution and quantified by measuring absorbance of the dyed solution on a Molecular Devices Microplate Reader; the [%] polymerization was calculated relative to the absorbance produced by incubation with 0.5 M GTP + 10% glycerol in MEM buffer (presumed to cause 100% tubulin polymerization); these values represent the average of three experiments. [b] Refs. [1, 2, 10, 12, 17]. [c] Ref. [10]. [d] Refs. [10, 12, 17]. [e] Refs. [7, 12]. [f] Ref. [7]. [g] Ref. [17]. [h] Compounds **67** and **68** were obtained by reaction of compound **22** with OsO_4-NMO. [i] Compound **112** was prepared by desilylation of the corresponding primary *tert*-butyldiphenylsilyl ether (Ref. [11]).

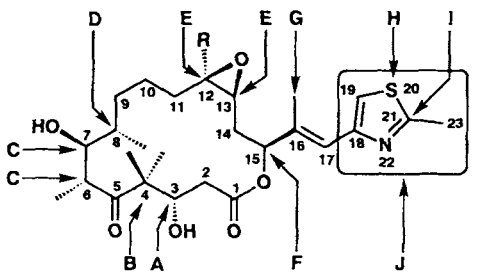
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3619-2101 $ 17.50+.50/0

the C8 methyl group (e.g. **98** vs **22**), introduction of a *gem*-dimethyl group at C8 (**100** vs **22** and **95** vs **26**), and removal of the C8 methyl group (e.g. **99** vs **22** and **96** vs **26** and **62** vs **14**). The latter observation was also made independently by Danishefsky et al.[17]

The importance of the natural (12*R*,13*S*) configuration for the epoxide was demonstrated by the general trend of the unnatural (12*S*,13*R*) epoxides to exhibit lower activities in inducing tubulin assembly (e.g. **5** vs **1**, **6** vs **4**, **7** vs **3**; although compound **6** had activities similar to those of epothilone A (**1**), but not B (**2**)). Most interestingly, both the *cis* and *trans* olefins corresponding to epothilones A and B were active in the tubulin assembly assays, and the activities of the *cis* olefins were comparable to those of the natural substances. Similar observations were independently made by Danishefsky et al.[7b, 12, 17] and Höfle et al.[14] However, we found that the *cis* and especially the *trans* olefins were significantly less cytotoxic than the naturally occurring epoxides (**22** and **26** vs **1**, **23** and **27** vs **2**). Moreover, both the α- and β-epoxides derived from the 12,13*E*-olefinic precursors exhibited considerable ability to induce tubulin assembly and inhibit cell growth (**14**, **16**, and **20** vs **1**, **15**, and **19** vs **2**; in fact, compound **15** appears to be one of the most cytotoxic analogues from those shown in Table 2).

The C12 methyl group consistently bestowed higher potency to all epothilones studied as compared to the C12 *des*-methyl counterparts (e.g. **2** vs **1** and **4** vs **3**), with the exception of compounds **14** and **15** where comparable results were obtained. Inversion of configuration at C15 led to loss of ability to induce tubulin polymerization (**64** vs **22**, **65** vs **26**). Replacement of the C16 methyl group with an ethyl group also reduced activity in the tubulin assay (**101** vs **22**, **97** vs **26**) suggesting that the methyl group may play a role in maintaining the planar conformation[5] of the side chain. The inactivity of the C16,C17 epoxides (**8**, **9**, **11**, and **12**) further supports this conclusion. The epothilone pharmacophore tolerated some heterocycle modifications. Thus, a number of oxazole derivatives exhibited activity comparable to the corresponding thiazoles (e.g. **3** vs **1**, **4** vs **2**, **16** vs **14**, **24** vs **22**, **25** vs **23**, **20** vs **18**). Furthermore, replacement of the thiazole with a 2-pyridyl moiety led only to a slight decrease in activity (e.g. **105** vs **22**, **106** vs **26**) in the tubulin assays, whereas substitution of the C23-methyl with a phenyl group yielded inactive compounds (**102**, **103**). Scheme 2 summarizes graphically the structure–activity relationships within the epothilone family of compounds as derived from these and previous studies.[1, 2, 7, 10, 12, 17]

The reported work demonstrates the power of interfacing combinatorial chemistry with chemical biology as facilitated by solid-phase synthesis, REC chemistry, and modern biological assays. Furthermore, this research should facilitate the process of drug discovery and development in the area of cancer chemotherapy.



Scheme 2. Epothilone structure–activity relationships (tubulin binding assay): A) (3*S*) configuration important; B) 4,4-ethano group not tolerated; C) (6*R*,7*S*) configuration crucial; D) (8*S*) configuration important, 8,8-dimethyl group not tolerated; E) epoxide not essential for tubulin polymerization activity, but may be important for cytotoxicity; epoxide configuration may be important; R group important; both olefin geometries tolerated; F) (15*S*) configuration important; G) bulkier group reduces activity; H) oxygen substitution tolerated; I) substitution important; J) heterocycle important.

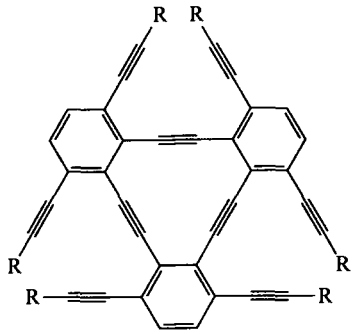
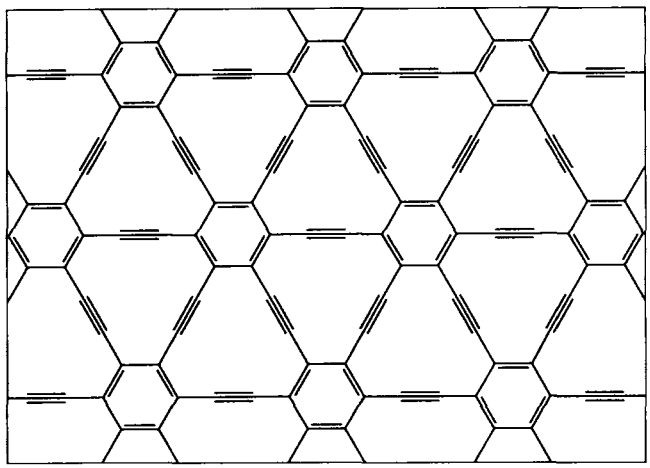
5,6,11,12,17,18-Hexadehydro-1,4,7,10,13,16-hexaethynyltribenzo[*a*,*e*,*i*]cyclododecene: Synthesis and CpCo-Catalyzed Cycloisomerization to the First Superdelocalized Oligophenylenes**

Christian Eickmeier, Heiko Junga, Adam J. Matzger, Frank Scherhag, Moonsub Shim, and K. Peter C. Vollhardt*

The title molecule ("hexaethynyltribenzocyclyne") **1a** is of great interest as a subunit of graphyne **2**,[1] a partially carbomeric[2] graphitic carbon allotrope,[3] as an extended π framework for ligating transition metals with unusual properties,[4] and as a precursor to antikekulene **3** by means of threefold CpCo-catalyzed cycloisomerization.[5] Compound **3** constitutes a much theoretically scrutinized[6] member of the as yet unknown circular phenylenes.[7]



1a, R = H
1b, R = $Si(CH_3)_2[C(CH_3)_2CH(CH_3)_2]$
1c, R = Pr
1d, R = $CH_2C_6H_{11}$



2

Compound **3** is intriguing in its juxtaposition to kekulene **4**,[8] which has the same number of rings but inner and outer π perimeters with a $4n+2$ electron count, whereas in **3**, the corresponding circuits are of the $4n$ type. However, in **4**, the annulenoid resonance forms suffer from the disruption of all benzenoid circuits and appear to be negligible contributors, as borne out by theory[6c, e, f, 9] and experiment.[8] In contrast, the nonannulenoid resonance alternatives to that depicted in **3** are all expected to be considerably destabilized by cyclobutadienoid antiaromaticity, an underlying feature of all phenylenes.[7] Thus, **3** might be a better candidate than **4** for probing the phenomenon of superdelocalization, although the notion of the

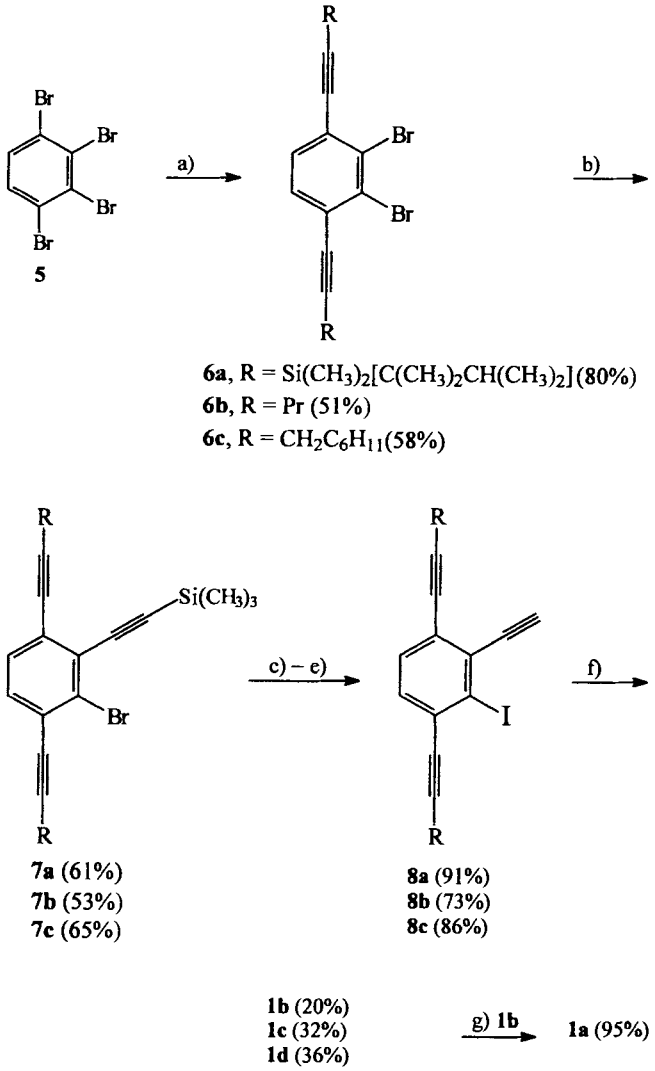
latter has been met with skepticism by some theoreticians.[6] We report here the total synthesis of **1a–d** and their reactivity in the presence of $[CpCo(CO)_2]$, which has led to the first superdelocalized oligophenylenes **9a,b** and **10a,b**.

Scheme 1 details the synthetic strategy toward **1**, which has as its cornerstone the discovery that 1,2,3,4-tetrabromobenzene



Scheme 1. a) RC≡CH, 1–2% CuI, 1–2% $[PdCl_2(PPh_3)_2]$, Et_3N, 23–60 °C, 3 d; b) $(CH_3)_3SiC_2H$, 1–2% CuI, 1–2% $[PdCl_2(PPh_3)_2]$, Et_3N, 100 °C, 4 h–2.5 d; c) BuLi, $(CH_3CH_2)_2O$, −78 °C, 30 min; d) I_2, $(CH_3CH_2)_2O$, −78 → 23 °C; e) K_2CO_3, CH_3OH or NaOH, CH_3OH or $Bu_4N^+F^-$, THF, 1 h; f) CuCl, NH_4OH, EtOH (DMSO for **8c**), pyridine, Δ, 6 h; g) $Bu_4N^+F^-$, THF, CH_3CN, 5 h.

(**5**)[10] can be regioselectively alkynylated at C1 and C4 to furnish **6**, then at C3 to give **7**, using Pd catalysis.[11] The regiochemistry of **6** was confirmed by debromination to the *p*-dialkynylbenzenes (1. *t*BuLi, 2. H_2O) and further transformations (vide infra). The bromine substituent in **7** is unsuitable for the protocol that constructs the tribenzocyclyne frame of **1**[12] and therefore was replaced by iodine. The C2-ethynyl group was selectively deprotected and cyclization of **8a–c** yielded **1b–d**.

The parent nonayne **1a** was readily accessible by desilylation of **1b**. It is relatively stable even in the solid state, and it can be conveniently handled in solution, which bodes well for its continuing elaboration into larger networks. Models show that the R groups in **1** are severely congested and indeed the X-ray structural analysis of **1d** (Figure 1)[13] reveals a severely distorted cyclyne frame with local C_2 symmetry, dihedral angles between the mean planes of the three benzene rings of 25.4, 30.8, and 31.4°, and deviations from linearity of the triple bonds within (average 174.3°, range 169.6–178.1°) and without (average 175.5°, range 171.7–179.9°) the cyclyne ring. All cyclohexyl groups adopt chair conformations. Apart from these features, the molecular structure is remarkably similar to that of the unsubstituted core system.[14b] The most noteworthy aspect of the spectral data of **1** (Table 1) is the much lower intensity of the longest wavelength UV band (π–π* transition) observed for the parent tribenzocyclyne at 290 nm ($\lg\varepsilon = 5.57$), which was associated with the rigid planarity of the latter,[14] a characteristic that is absent in **1**.

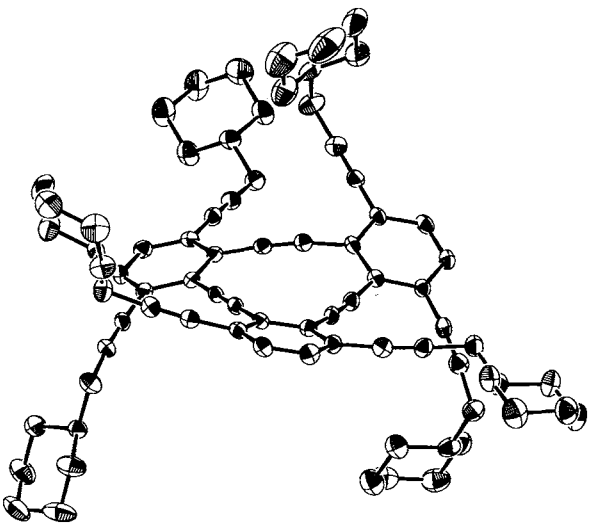


Figure 1. Molecular structure of **1d** in the crystal.

With **1a** in hand, our first concern was its potential to isomerize to **3** in the presence of $[CpCo(CO)_2]$. Calculations were encouraging in this respect, suggesting each of the three individual [2+2+2]cycloadditions to be exothermic (−14.5, −13.4, and −10.0 kcal mol^{-1} (PM3);[15a] for the last step: −31.0 kcal mol^{-1} (HF/6-31G*),[15b] −45.50 kcal mol^{-1} (B3LYP/6-31G*);[15b] comparable to the values calculated for the cyclization to angular [3]phenylene). Unfortunately, in practice, **1a** gave only insoluble dark brown powders. Suspecting lack of solubility of the target (or intermediates en route) as a potential problem in these experiments, we turned to the substituted nonaynes **1b–d**, with better, albeit not complete, success. Thus, while **1b** gave intractable mixtures, **1c** and **1d** provided **9a,b** and **10a,b**, respectively, either directly as mixtures or by a stepwise sequence (Scheme 2, Table 1).[11] The isolation of **9a,b** was possible because they cyclize noticeably slower than **1c,d**. This trend continues for **10a,b** which, despite extensive experimentation with conditions (solvent, temperature, addition rates, light sources), could not be induced to furnish the antikekulene core, but rather gave either recovered starting material or decomposition (>170 °C, sulfolane or 1-methylnaphthalene).

Because of the novelty of the "circularly" conjugated phenylenes **9** and **10**, X-ray structural determinations of **9b** and **10b** were carried out (Figures 2 and 3, respectively).[13] Similar to **1d** (Figure 1), the twelve-membered ring in **9b** is significantly (although less) distorted from planarity; the plane of the nonphenylene benzene forms an angle of 18.4° with the mean plane of the dehydro[12]annulene cycle. Unlike the parent angular

[3]phenylene,[5] the phenylene subunit in **9b** is slightly curved (dihedral angles between the mean planes of adjacent benzene and cyclobutadiene rings between 0.44 and 3.14°), a phenomenon that appears to be general.[16] In other respects, the structure of this unit, especially the pronounced bond alternation of its central benzene ring, is remarkably similar to that of the parent system; small deviations are due to the presence of the additional substituents, especially the alkyne groups which generally cause slight elongations in attached benzene ring

bonds.[1c, 3e, 14b] While the overall rigidity of the carbon frame increases noticeably when going from **1d** to **9b**, this effect is much more pronounced when continuing from **9b** to **10b** (Figure 3). The latter lies on a C_2 axis and exhibits a slightly helical angular [5]phenylene frame (dihedral angles between the mean planes of adjacent rings between 0.53 and 2.31°). The distances between the three alkyne units that would be called on in cyclotrimerization increase along the series **1**, **9**, **10**. That, along with the increasing rigidity of the structures, provides a rationale for their decreasing reactivity in the presence of [CpCo].

Because the parent angular [5]phenylene[17] could not be obtained in the form of crystals suitable for X-ray analysis and hence comparison with **10b**, the appropriately crystalline dipropyl derivative **11** (Table 1)[11] was prepared by a new, much shorter route (five steps) starting from **6a** (Scheme 3) in a variation of Scheme 1. The crystal structure of **11** is shown in Figure 4. The molecule is more pronouncedly helical than **10b** (dihedral angles between adjacent ring planes between 0.94 and 4.91°), and there is no significant contact between 5-H and 26-H (distance 2.59 Å, assuming a C–H bond length of 1.08 Å). Otherwise, the two structures are quite similar; minor deviations can be ascribed to the presence of the adjacent cyclohexylmethyl substituents and the added alkyne functions (vide supra) in **10b**. As indicated by the ^{1}H NMR data (Table 1),[17] the internal benzene rings have significant cyclohexatriene character. The bridging triple bond (C16–C16′) flattens **10b** relative to **11** and decreases the distance between the terminal benzene rings some-

what (e.g. C5–C26 in **11**: 4.69 Å; calculated for its planar conformer: 4.55 Å; C12–C12′ in **10b**: 4.06 Å). This change does not appear to greatly alter bond angles and lengths.[18] Thus, as perhaps expected, the X-ray data for **9b** and **10b** do not reveal any structural evidence for superdelocalization imparted by the bridging alkyne units.

Much more sensitive probes for such a phenomenon are UV and, especially, ^{1}H NMR measurements. Indeed, the longest wavelength maxima in the electronic spectra of **9a,b** (λ_{max} = 514 and 516 nm, respectively) and **10a,b** (554 nm) are drastically bathochromically shifted relative to those of angular [3]- (394 nm)[19] and [5]phenylene (470 nm),[17] considerably more than expected by simple substituent contributions,[7, 20] and consistent with increased antiaromaticity[21] due to superdelocalization. The latter would be expected to increase the cyclobutadienoid character of the four-membered rings, causing increased shielding of close-lying benzenoid hydrogens. Indeed, H_b in **9a,b** is shielded ($\Delta\delta$ = 0.28; all measurements in CD_2Cl_2), relative to the corresponding nuclei in angular [3]phenylene.[17] More convincingly, in **10a,b**, not only is H_b shielded ($\Delta\delta$ = 0.33) relative to the parent angular [5]phenylene (and **11**), but also the remote H_c ($\Delta\delta$ = 0.21). While H_a in **9** and **10**, respectively, appear unchanged in these comparisons, we believe that they experience the same shielding effect as H_b and H_c, since the added *ortho*-alkynyl substitution causes deshielding by $\Delta\delta \approx 0.2$ (and negligible *meta* and *para* effects).[7, 22] The operation of aromatic π-stacking effects[23] on the observed chemical shifts was ruled out by measurements at varying concentrations (5–170 mM). Moreover, the slight increase in σ-strain introduced by the alkyne bridge is unlikely to be the cause of these shieldings, since the δ(H) values of highly strained biphenylene derivatives are normal.[24]

We conclude that superdelocalization effects are operational in annelated oligophenylenes[25] of the type **9** and **10** and anticipate that they will be accentuated in **3**. The successful execution of the final cyclization step from **10** may have to rely on derivatives in which the [5]phenylene grid is rendered more flexible by chemical alteration.

Experimental Section

Cycloisomerization of **1d**: To degassed, boiling *m*-xylene (100 mL) was added within 10 s a degassed solution of **1d** (110 mg, 1.08 mmol) and $[CpCo(CO)_2]$ (41 μL, 0.324 mmol) in *m*-xylene (20 mL). The reaction mixture was irradiated with a 300 W projector lamp (60 V). After 20 min, the solvent was evaporated, and the crude product was dissolved in CH_2Cl_2, absorbed on silica gel, and chromatographed on silica gel (35 × 3 cm, 18–32 μm) eluting with hexanes/CH_2Cl_2 (20:1–10:1) to provide **9b** as an orange solid (49 mg, 45%), followed by **10b** as a red solid (5 mg, 5%).

Cycloisomerization of **9b**: A solution of compound **9b** (20 mg, 0.02 mmol) in degassed, boiling 1,2,4-trichlorobenzene (100 mL) was irradiated with a 300 W projector lamp (60 V) while a solution of $[CpCo(CO)_2]$ (7 μL, 0.055 mmol) in 1,2,4-trichlorobenzene (12 mL) was added with a syringe pump over 3 h. The solvent was evaporated and the crude product was chromatographed on a silica gel preparative TLC plate (1 mm), eluting with hexanes/CH_2Cl_2 (4:1) to provide **10b** (8.1 mg, 40%).

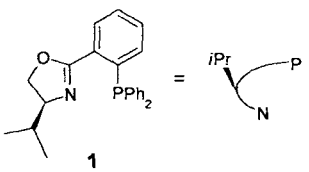
Palladium-Catalyzed Allylic Alkylation with Phosphinoaryldihydrooxazole Ligands: First Evidence and NMR Spectroscopic Structure Determination of a Primary Olefin–Pd^0 Complex**

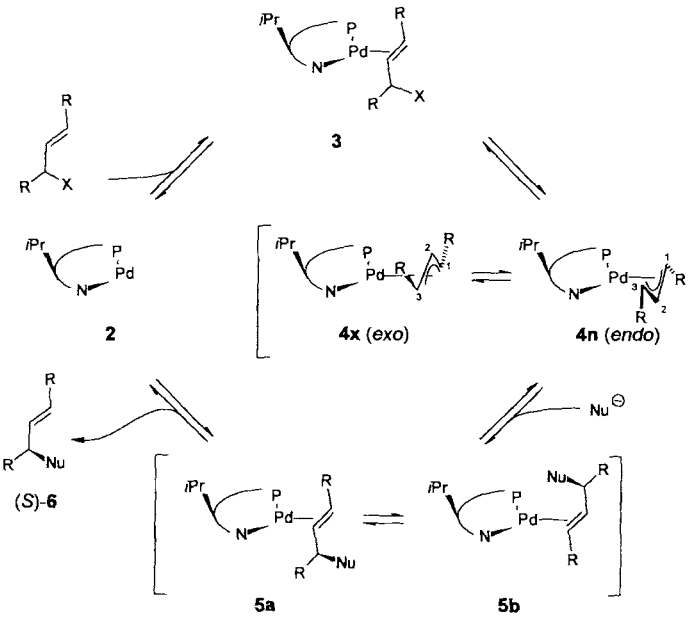
Henning Steinhagen, Michael Reggelin,* and Günter Helmchen*

Palladium-catalyzed allylic substitution reactions are well established in organic synthesis.[1] We and others showed that an enantioselective reaction can be realized with ligands containing electronically different donor centers;[2] of these, chiral phosphinoaryldihydrooxazole (phosphinooxazoline) ligands were found to be particularly useful.[3] With the prototype **1** of this ligand class it was possible to obtain substitution products with enantiomeric purity of $\geq 98\%$ from acyclic substrates.



1

The postulated catalytic cycle for the examined system is shown in Scheme 1. The cycle contains the essential intermediates **2**–**5**, of which only the easily preparable allylic complexes **4** could be characterized so far. In the case of an unsymmetrical ligand such as **1**, an *exo*- (**4x**) and an *endo*-π-complex (**4n**) are fundamentally possible; these are in equilibrium through π-σ-π rearrangement.[4] As a consequence, there are in principle four reaction pathways, of which two lead to the preferred product (*S*)-**6**. Attack of the nucleophile can occur at C-3 of **4x** or at C-1 of **4n**. In spite of contrary assumptions (early[4, 5b] and late transition state[5a]), mechanistic interpretations up to now were all based on the postulate that the first reaction pathway is the faster one. We were now able to detect a primarily formed η^2-olefin–Pd^0 complex in the catalytic cycle and unambiguously determine its conformation. Therefore, it is now possible to make a well-founded statement about a late transition state.



Scheme 1. Catalytic cycle of the Pd-catalyzed allylic substitution; R = Ph, X = OAc, Nu = $CH(COOCH_3)_2$.

Initially the stoichiometric reaction between the π-allyl complexes **4**[6] (10:1 mixture of **4x** and **4n**) and sodium dimethylmalonate (NaDMM) as a nucleophile was examined. A solution of the complexes in [D_8]THF (0.5 mL, 88 mM), prepared at room temperature, was cooled to −78 °C, and a precooled solution of NaDMM (20.3 mg, 0.132 mmol) in [D_8]THF (0.5 mL) added. The sample was allowed to warm to room temperature inside the NMR probehead, and the progress of the reaction was monitored by ^{31}P NMR spectroscopy (Figure 1).

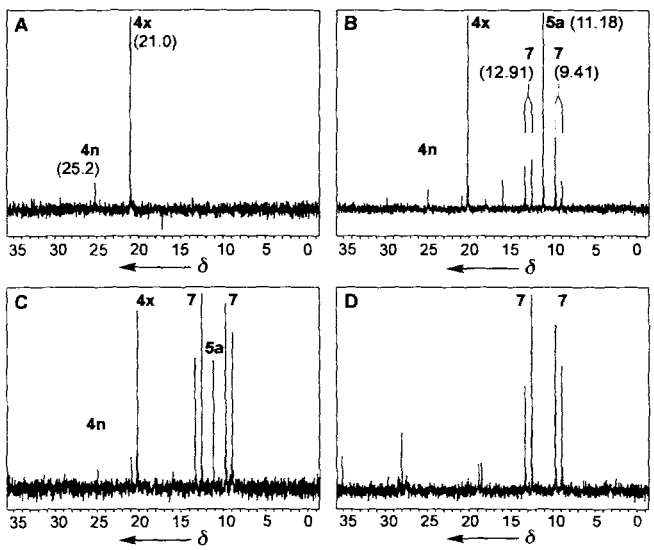


Figure 1. $^{31}P\{^1H\}$ NMR spectra recorded at various times during the reaction (161.98 MHz, −60 °C): A) equilibrating π-allyl complexes **4x** and **4n**; B–D) reaction mixtures at 370 s, 500 s, and 1 h, respectively, after addition of NaDMM.

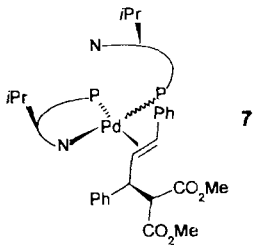
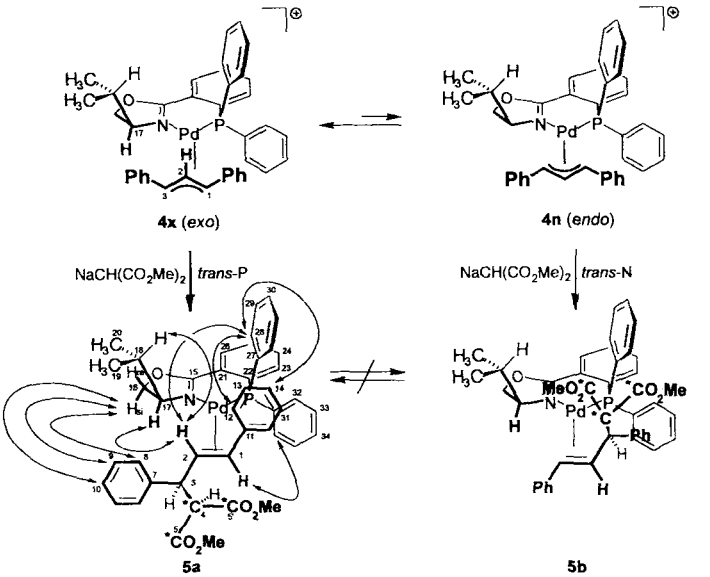
During the course of the reaction **4x** and **4n** were always in rapid equilibrium.[4] As the first new species, a compound with a singlet at $\delta = 11.18$ appeared, whose concentration reached a maximum already after 90 s before it was consumed within a few minutes. This compound is the olefin–Pd^0 complex **5a**, whose structure determination is described below. Consumption of **5a** was accompanied by the appearance of a new species with a characteristic AB spin system ($\delta_A^{corr} = 9.41$, $\delta_B^{corr} = 12.91$, $^2J_{P,P} = 128$ Hz), which was the main component after a reaction time of about one hour. We propose structure **7** for this long-lived intermediate; the precise geometry could not yet be determined.[7]



7

Only traces of the metal-free product (*S*)-**6**, which is formed from **7**, were detected in the reaction mixture when the reaction was stopped after conversion of approximately 50% of **4**. The concentration of (*S*)-**6** only increased when conversion exceeded 50%. Therefore, complex **7** is a stable by-product of the stoichiometric reaction.[8]



Scheme 2. Possible reaction pathways leading to (*S*)-**6**. The arrows mark NOE contacts between protons that were used for determining the conformation of **5a** [16]; C-4, C-5 and C-5′ are ^{13}C-labeled (99.5%).

To determine the constitution of the mechanistically meaningful transient species **5a**, the reaction was carried out with $^{13}C_3$-labeled NaDMM at -20 to $-30\,^\circ C$ and stopped after two minutes by cooling to $-78\,^\circ C$. A sample thus prepared contained about 75% of the phosphorus in the form of the olefin–Pd^0 complex **5a**,[9] and was stable for several weeks at $-78\,^\circ C$ under an inert atmosphere. This sample contained less than one percent of **7**, which is only formed at temperatures above about $-20\,^\circ C$.

Assignment of the resonances of all NMR-active nuclei was possible by use of $^{13}C_3$-labeled NaDMM and a large set of two-dimensional (2D) NMR experiments, of which only a few are described here. The starting point was a $^{31}P-^1H$ HMBC experiment[10] with a sample at $-60\,^\circ C$, which, in addition to ^{31}P correlations to aromatic protons (Scheme 2), showed correlations to protons with chemical shifts in the range of $\delta = 3-4.5$. By further analysis these could be unambiguously identified as belonging to the allyl system of the olefin–Pd^0 complex **5a** (Figure 2A: $\delta = 4.24$ (1-H), 3.23 (2-H), 3.43 (3-H)).

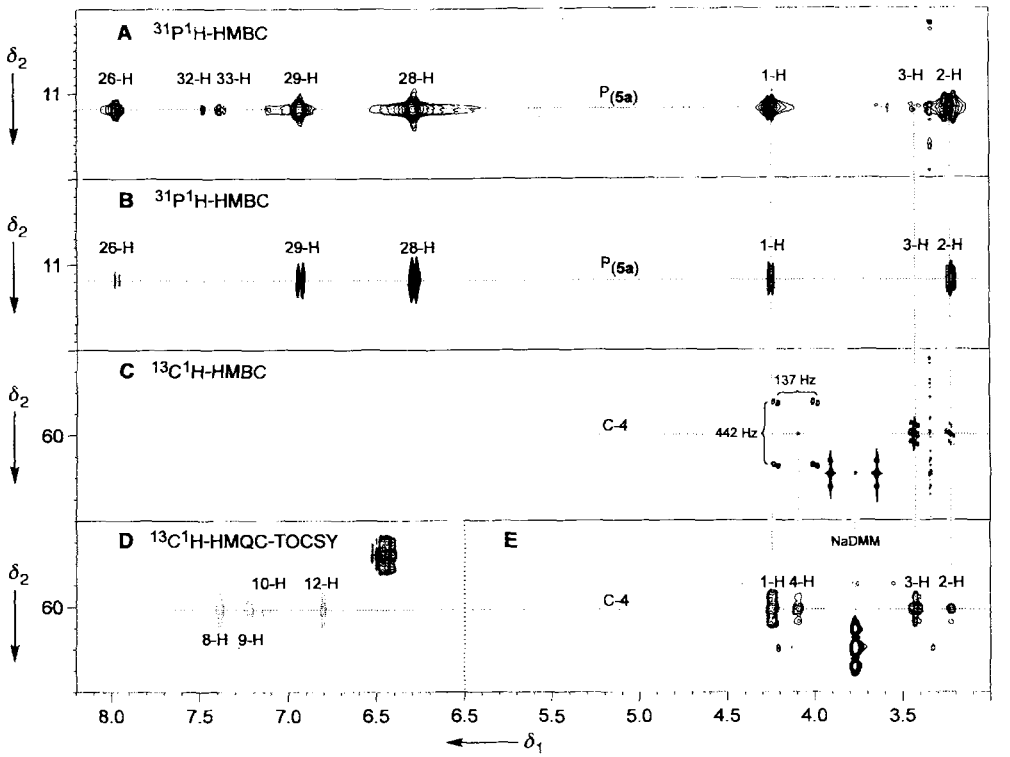


Figure 2. Sections of heteronuclear NMR spectra of **5a** ([D_8]THF, $-60\,^\circ C$): A) 400-MHz $^{31}P-^1H$ HMBC, stoichiometric reaction; B) 400-MHz $^{31}P-^1H$ HMBC, catalysis [19]; C) 600-MHz $^{13}C-^1H$ HMBC, stoichiometric reaction; D) 400-MHz $^{13}C-^1H$ HMQC TOCSY, stoichiometric reaction; the dotted crosspeaks are TOCSY-derived ROE signals between the protons of the allyl spin system and the marked aromatic protons; E) high-field region of spectrum D with a tenfold-increased contour level.

The $^{13}C-^1H$ HMBC spectrum of **5a** (Figure 2C) showed the expected $^2J_{C,H}$ and $^3J_{C,H}$ correlations between the central carbon C-4 of the malonic ester moiety and 3-H ($\delta = 3.43$) and 2-H ($\delta = 3.23$), respectively; the crosspeaks were split in the $\omega 1$ dimension due to $^1J_{C,C}$ coupling (57.3 Hz), which became apparent with ^{13}C labeling. An unusual crosspeak pattern at the position of the direct correlation ($^1J_{C,H}$) between 4-H and C-4 was of particular diagnostic value. As a consequence of ^{13}C labeling of C-4, C-5 and C-5′, marked in Scheme 2, the $^{13}C-^1H$ HMBC spectrum showed, among others, coherences that gave rise to signals at the positions $\Omega_{C-4} \pm (\Omega_{C-5} - \Omega_{C-5'})$;[11] this explained the separation of signals by 442 Hz in the $\omega 1$ dimension (Figure 2C). In addition, this provided definite proof for the assignment, because no such arrangement of nuclei could ap-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3619-2109 $ 17.50+.50/0

pear elsewhere in the molecule. By further projecting the proton spin system onto the C-4 with a HMQC-TOCSY experiment[12] (Figure 2D and E) the missing 1-H of the allylic system could be found at $\delta = 4.24$, in addition to 2-H and 3-H, which were formerly identified in the $^{13}C-^{1}H$ HMBC spectrum. The constitution of the η^2-olefin–Pd^0 complex **5a** (Scheme 2) was unambiguously determined by this analysis.[13]

The olefin–Pd^0 complex **5a** was not only found in the stoichiometric reaction but also under catalytic reaction conditions. A reaction catalyzed with 10 mol% Pd in [D_8]THF was carried out under standard conditions.[14] After a reaction time of three minutes at room temperature the mixture was cooled to $-60\,^{\circ}C$, and the $^{31}P-^{1}H$ HMBC spectrum shown in Figure 2B recorded. The characteristic P–H correlation of **5a** is apparent on comparison with Figure 2A. This proof of the presence of **5a** under catalytic reaction conditions stresses the relevance of structure determination for interpretating the mechanism.

It was also important to determine the conformation of the olefin fragment relative to the coordination plane N-Pd-P. This was achieved with the help of 2D NOESY (τ_{mix} = 200, 300, 400 ms) and 2D JS-ROESY experiments[15] (τ_{mix} = 260 ms). By quantitative analysis of NOE and ROE data, information on distances was gained[16] that is only in accordance with conformer **5a** and not **5b** (Scheme 2). For example, the NOE contact between 2-H and 17-H that appeared during the transformation of **4x** to **5a** is characteristic. The value of this NOE contact corresponds to a reduction in the distance between 2-H and 17-H by 1.4 Å[4, 17] compared to that in **4x**, which was determined by X-ray diffraction analysis.

Statements concerning the mechanism of the allylic substitution require the following plausible assumptions: a) Attack of the nucleophile NaDMM on **4x** under formation of **5a** proceeds by a "least-motion" reaction path, that is, a rotation of the allyl fragment by 30° from **4x** to **5a** is the main process. b) Rotation of the olefin fragment relative to the N-Pd-P-plane in complex **5a** is sufficiently slow, so that equilibration between **5a** and **5b** does not occur during the reaction time.[18] The second assumption is supported by experiments in which the reaction was carried out in a temperature gradient ($-78\,^{\circ}C$ to room temperature) and monitored by ^{1}H NMR spectroscopy.[19] In this experiment broadening of the resonances of **5a**, which would be expected for a dynamic exchange process, was not observed.

Under assumption b), the configuration of the more reactive allyl complex **4x** is conserved in the olefin–Pd^0 complex **5a**. Considering the known absolute configuration of the product, attack of the nucleophile *trans* to the phosphorus center at the *exo*-π-allyl complex **4x** can be derived. This result is in accordance with earlier interpretations,[4, 5] but is here based on a precisely characterized olefin–Pd^0 product complex in the Pd-catalyzed allylic substitution.

Phase Transformations and Phase Stability in Epitaxial β-GaN Films**

Achim Trampert,* Oliver Brandt, and Klaus H. Ploog

Dedicated to Professor Hans Georg von Schnering

Internal interfaces and phase boundaries determine the physical and chemical properties of low-dimensional heterostructures and nanosized composite materials. The nature of the interfaces, that is, their atomic configuration, is of fundamental importance for understanding the various material properties. In the case of GaN and its related compounds, which are of great interest because of their potential for optoelectronic devices, internal interfaces such as domain boundaries frequently occur and are believed to degrade the material's suitability for applications. Thus, the atomic structure of these interfaces is of great current interest.[1]

In general, nitrides of elements from the third main group crystallize in the thermodynamically stable hexagonal wurtzite structure (α) as well as in the metastable cubic zinc blende modification (β). First-principle calculations predict that the energy difference between these structure modifications is smallest for GaN.[2] In fact, during epitaxial growth of GaN the phenomenon of phase mixing frequently occurs and may be overcome only by choosing the appropriate growth conditions and suitable substrate materials. However, even hexagonal and cubic GaN made by state-of-the-art procedures still contain fractions of their polytypic counterparts.

Assuming that the lattice parameter ratio in the hexagonal lattice is ideal ($c/a \approx 1.633$), the wurtzite and zinc blende structures differ only in the sequence of their closed packed planes: ...γAαBβCγAαBβCγA... for the {111} planes in zinc blende and ...AαBβAαBβAαBβA... for the {00.2} basal planes in wurtzite crystals. Consequently, a structural phase transformation, introduced by a single stacking fault, would be expected to appear along the direction of closed packed planes[3] by simultaneously creating a coherent phase boundary of low energy.[4, 5] In fact, this orientation relationship has been found in GaN layers grown on (111)A- and (111)B-oriented GaAs substrates,[6] in predominantly hexagonal GaN layers on Al_2O_3,[7] and in predominantly cubic GaN epilayers on GaAs(001).[8] However, this type of phase boundary is rather unlikely in the latter case because a fault in the stacking sequence does not exist in growth direction unless the growth front is faceted. Herein we report the dominant orientation relationship between the cubic and hexagonal phases in epitaxially grown β-GaN by high-resolution transmission electron microscopy (HRTEM) and demonstrate the importance of the interface character for the cubic–hexagonal phase transformation.

The β-GaN films investigated were grown by molecular beam epitaxy on (001) GaAs substrates.[8] The nucleation and growth of these films as well as their structural quality has already been discussed in detail.[9] Figure 1 shows a typical ⟨110⟩ cross-sectional bright field TEM image and the corresponding electron diffraction pattern of the β-GaN/GaAs(001) heterostructure under consideration. The TEM experiments demonstrate the comparatively high crystalline quality of the β-GaN layer and its perfect epitaxial orientation with respect to the GaAs substrate. Stacking faults and nanotwins are the prevalent crystal defects, as is evidenced by the dark lines along the {111} planes in the bright field image (Figure 1a) and by the streaks and the weak twin spots along the ⟨111⟩ directions in the diffraction pattern (Figure 1b). These structural defects are an indirect result of the strain relief caused by the large lattice mismatch between GaN and GaAs, as discussed in more detail in reference [9].

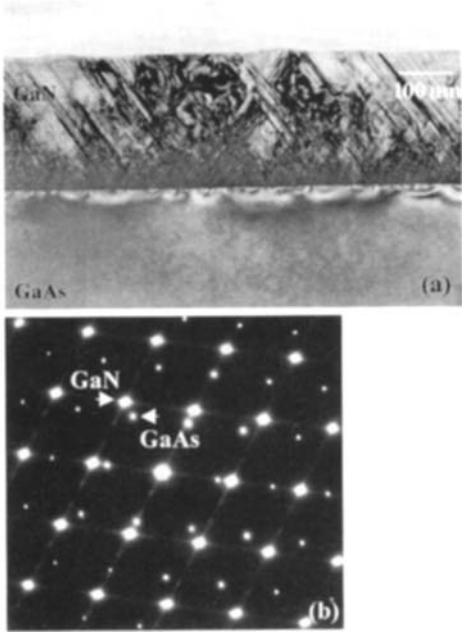

Figure 1. a) ⟨110⟩ cross-sectional bright field TEM image and b) corresponding electron diffraction pattern of the β-GaN/GaAs(001) heterostructure.

In these β-GaN layers two different kinds of hexagonal inclusions are detected. The first, which is typically of nanometer size, is located in direct vicinity of the β-GaN/GaAs heterointerface, meaning that these hexagonal inclusions are formed during nucleation. They show a random orientation with respect to the substrate, and thus, in general, their interface energy is significantly higher than that of the critical nuclei in the (epitaxial) "cube-on-cube" orientation. In fact, these hexagonal nuclei are rapidly overgrown during the subsequent coalescence process (an example is given in Figure 2). The rare occurrence of these

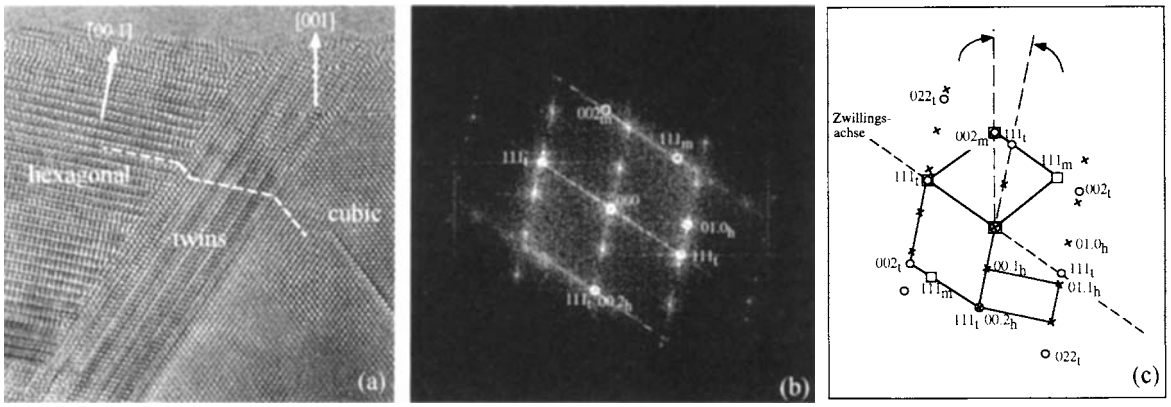

Figure 3. a) HRTEM image of a hexagonal inclusion with the specific orientation relationship to the matrix (see text). b) The corresponding Fourier spectrum: The [11.0] zone axis of the hexagonal phase and the [110] zone axis of the cubic twin are emphasized in the scheme given in (c). t = twin, m = matrix, h = hexagonal.

hexagonal inclusions implies that their influence on the layer's properties is negligible.

The second kind of hexagonal inclusions is detected within the layer and is more important than the first kind discussed above because of its apparently higher stability within the cubic matrix. Furthermore, this kind of hexagonal inclusion exhibits a specific orientation relationship to the cubic matrix: $[110]_\beta \parallel [11.0]_\alpha \measuredangle ([001]_\beta, [00.1]_\alpha) \approx 15°$.

At the first glance, this orientation seems to be arbitrary and purely accidental. However, a closer analysis reveals this orientation to be actually quite favorable. Figure 3 shows a magnified part of a HRTEM image of the interface between the hexagonal precipitate and the cubic matrix along the [11.0] and [110] zone axes respectively. The hexagonal basal plane runs parallel to closed packed planes belonging to a twinned region in the cubic layer [along the white line in Figure 3a]. The Fourier spectrum in Figure 3b directly shows the coincidence of the {111} twin and the {00.2} hexagonal reflections and also the tilt between the cubic matrix and the hexagonal inclusion. The closed packed planes of the twin can now act as seeds for the phase transformation by generating a coherent phase boundary (indicated as I in Figure 4) by simultaneously aligning the fast growing basal plane nearly parallel to the growth front and thus making the precipitate stable in the course of subsequent growth (see Figure 4). In addition, the phase boundary to the cubic matrix (indicated as II in Figure 4) is also coherent, since the {111} planes of the matrix match the {00.2} basal planes of the inclusion. Thus, this specific orientation relationship results in a phase boundary that is analogous to a cubic twin boundary except that one part of the twin is formed by the wurtzite structure.

To summarize, phase transformations from cubic to hexagonal GaN may occur due to the favorable orientation of the basal plane to the growth front. This condition is met by twinning within the cubic matrix, which aligns the closed packed planes closer to the growth front and subsequently creates a coherent phase boundary. The stability of the secondary phase is then a result of the coherent character of the phase boundaries having minimal interfacial energies.

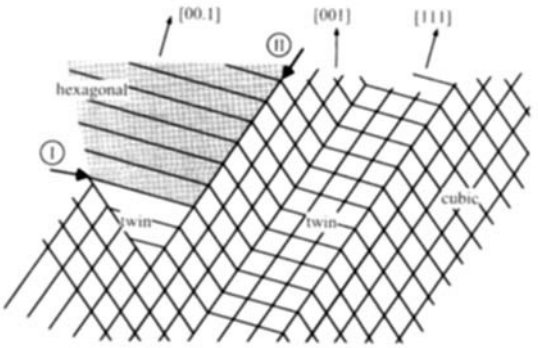

Figure 4. Schematic representation of the specific orientation between the hexagonal inclusion and the cubic matrix, which demonstrates the role of nanotwins.

[4] The energy of a crystalline interface (γ_i) can generally be subdivided into two parts (see for example ref. [5]). The first part takes into account the interaction between the atoms at both sides of the interface and is often interpreted as the coherent (chemical) interface energy (γ_i^{chem}), whereas the second portion considers the strain energy caused by the lattice mismatch (γ_i^{struc}): $\gamma_i = \gamma_i^{chem} + \gamma_i^{struc}$. In the case of a coherent GaN interface there is $\gamma_i^{struc} \approx 0$ and γ_i^{chem} should also be small because the bonding relations scarcely differ between the α- and the β-phase.[2]

Oscillation of NO_x Concentration in the Selective Catalytic Reduction of Nitrogen Oxides on Platinum-Containing Zeolite Catalysts**

Yvonne Traa, Marcus Breuninger, Beate Burger, and Jens Weitkamp*

The emission of nitrogen oxides, carbon monoxide, and hydrocarbons from spark-ignition engines can nowadays be effectively reduced with the three-way catalyst. Since diesel and lean-burn engines operate with an excess of oxygen, conventional three-way catalysts cannot be used for purifying exhaust gases from these engines. While oxidation catalysts, which are already being used in diesel engines, do reduce the amount of carbon monoxide and hydrocarbons in the exhaust gas, they do not bring about a reduction in the amount of nitrogen oxides. Since the discovery by Iwamoto et al.[1] and Held et al.[2] that the selective catalytic reduction of nitrogen oxides with hydrocarbons can be achieved in an oxidizing atmosphere (*h*ydrocarbon *s*elective *c*atalytic *r*eduction, HC-SCR), the potential of HC-SCR in the purification of exhaust gases from diesel and lean-burn engines has been intensively scrutinized. In addition to copper-containing zeolite catalysts favored earlier, platinum-containing catalysts are employed in modern research, because they are insensitive to water in the exhaust gas.[3] However, the reaction also takes place on transition metal free catalysts (for example, on γ-Al_2O_3—see below).

In 1992 Obuchi et al. observed oscillations in the concentrations of NO_x, CO_2, and CO in the product gas of the selective catalytic reduction of NO with propene on γ-Al_2O_3 in an oxidizing atmosphere.[4] Oscillations are not uncommon in heterogeneous catalysis, and the phenomenon is well-known for CO oxidation, oxidation of other substrates with O_2, and reduction of NO with CO, H_2, or NH_3.[5] In contrast, there are very few reports on oscillations for HC-SCR in a strongly oxidizing atmosphere. In addition to Obuchi et al.[4] two other groups found oscillations in such systems, namely, Halasz et al. on zeolite H-ZSM-5[6] and Cho et al. on Pt/ZSM-5.[7] Interestingly, Cho et al. were only able to observe oscillations when ^{15}NO was employed; no oscillations occurred with ^{14}NO.

In the present study, oscillations of NO_x concentration in the HC-SCR with propene on different Pt–V/H zeolites were fortuitously found. As an example, the conversion of NO_x as a function of time is depicted in Figure 1 for 2.6Pt-1.0V/H-ZSM-35 zeolite as catalyst.[8] The oscillations could only be observed at high NO_x conversion and within a temperature range of about 20 K. The temperature of the catalyst was constant within ± 1 K. C_3H_6 and CO were completely oxidized to CO_2. It can be seen from Figure 1 that the amplitude of the oscillations decreases with increasing temperature, whereas their frequency increases. The oscillations are fully reproducible, that is, they also occur on other freshly prepared Pt-V/H-ZSM-35 batches and under slightly different experimental conditions. However, on zeolite Pt/H-ZSM-35, only irregular fluctuations in NO_x conversion were noticed. Therefore, the presence of vanadium

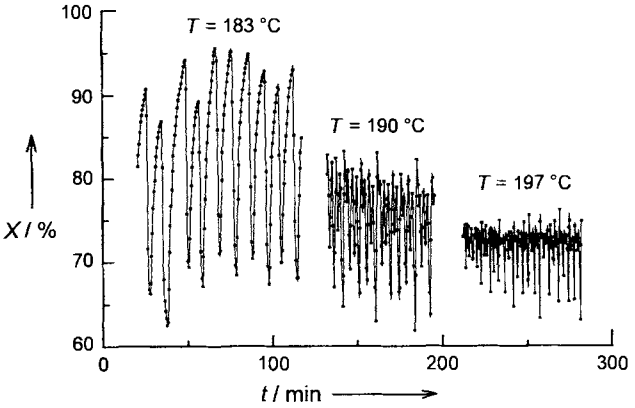

Figure 1. NO_x conversion X for HC-SCR on 2.6Pt-1.0V/H-ZSM-35 zeolite ($n_{Si}/n_{Al} = 8$) as a function of time t for different catalyst temperatures T.

seems to be important for the occurrence of regular oscillations in this system. Moreover, the oscillations are not limited to zeolite ZSM-35. They can also be observed on zeolites with other pore systems, for example on Pt-V/H-Beta and Pt-V/H-ZK-5. Figure 2 shows the dependency of the oscillation on water content for the example of 2.0Pt-1.1V/H-ZK-5 as catalyst:

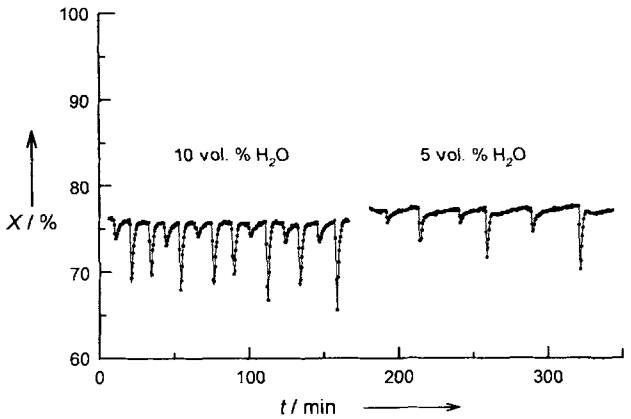

Figure 2. NO_x conversion X for HC-SCR on 2.0Pt-1.1V/H-ZK-5 zeolite ($n_{Si}/n_{Al} = 4$) for different partial pressures of water; $T_{cat.} = 189$ °C.

The amplitude and frequency of the oscillation decrease with decreasing water concentration. Without water in the feed no oscillations were observed at all. In contrast to the systems employed by Obuchi et al., Halasz et al., and Cho et al.,[4, 6, 7] who used dry model exhaust gases, the presence of relatively large amounts of water seems to be essential for the occurrence of oscillations on the catalysts described here. As Figure 3 shows, only minor changes occur in the amplitude and the frequency of the oscillation, even over a time period of 17 h.

In the literature there are different models to account for the occurrence of oscillations in HC-SCR. One possibility is the formation of carbon-containing deposits which react periodically with NO.[4] Another possibility is the slow formation of nitroxy compounds and the fast decomposition of the radicals that form from them.[6] Cho et al. interpreted the oscillations in terms of a periodic change of the catalyst between states of different catalytic activity.[7] This can be caused either by phase transitions at the platinum sites of the Pt/ZSM-5 catalyst, which are induced by NO adsorption, or by blocking of the surface by NO, which inhibits the reaction.

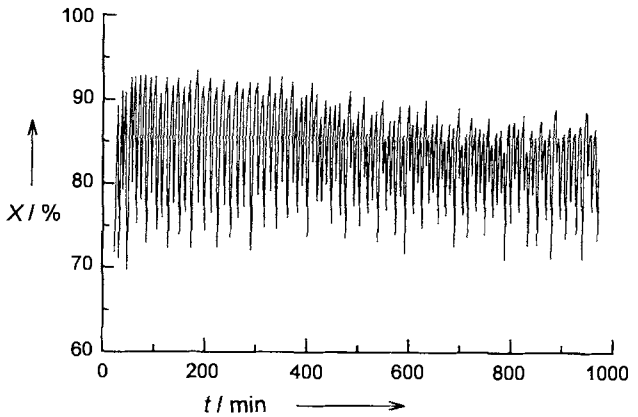

Figure 3. Long-duration experiment on 2.6Pt-1.0V/H-ZSM-35 zeolite ($n_{Si}/n_{Al} = 8$); $T_{cat.} = 187\,^{\circ}C$.

In an attempt to determine the reasons for the occurrence of the oscillations, the H-ZSM-35 samples loaded with Pt and/or V were investigated by means of temperature-programmed oxidation/reduction (Figure 4). On samples loaded with Pt or V only,

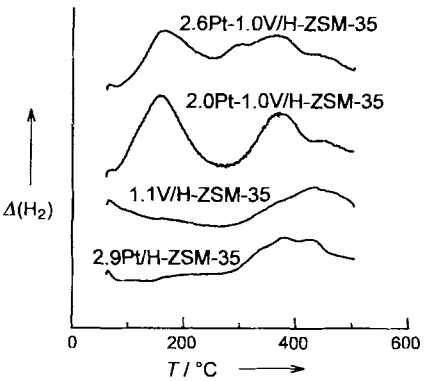

Figure 4. Results of the temperature-programmed reduction on different metal-containing H-ZSM-35 zeolites. $\Delta(H_2) = H_2$ consumption.

no significant hydrogen consumption occurred at temperatures below 300 °C. In contrast, on Pt-V/H-ZSM-35 large amounts of hydrogen were consumed already at 150 to 200 °C, that is, exactly in the temperature range in which the oscillations occur. Furthermore, the total hydrogen consumption on these bimetallic zeolites was considerably larger. From this we conclude that the reducible portion of metals in the catalyst is enhanced through synergistic effects between platinum and vanadium. Hence, it is straightforward to assume that the observed oscillations have their origin in redox reactions; this hypothesis is further supported by the simultaneous presence of oxygen and propene in the feed.

Experimental

The zeolites (ZSM-35, Beta, and ZK-5) were first transformed into their ammonium forms by ion exchange. The resulting samples were treated with aqueous solutions of $[Pt(NH_3)_4]Cl_2$ and VCl_3; the water was removed by heating after every step. Normally, the dry catalysts contained about 3 wt% Pt and 1 wt% V. The catalytic experiments were performed in a flow-type apparatus with a fixed-bed reactor at atmospheric pressure. The hydrated zeolite (200 mg) was activated in a flow of synthetic air for 1 h at 500 °C and then overnight at 450 °C. The gaseous components of the model exhaust gas were premixed in a pressure vessel, and then saturated with water vapor at 45 °C. The feed typically contained NO_x (0.02 vol%), C_3H_6 (0.06 vol%), CO (0.03 vol%), CO_2 (4 vol%), O_2 (9 vol%), and H_2O (10 vol%) in He at a flow rate of 150 $cm^3\,min^{-1}$. The product stream was analyzed for nitrogen oxides with a chemiluminescence detector; all other components were analyzed by capillary gas chromatography. Prior to the temperature-programmed reduction with H_2 (10 vol%) in Ar, the catalyst samples were oxidized in a gas stream containing O_2 (10 vol%) in He.

Multilayer Dendrimer–Polyanhydride Composite Films on Glass, Silicon, and Gold Wafers**

Yuelong Liu, Merlin L. Bruening, David E. Bergbreiter,* and Richard M. Crooks*

Organic thin films are of current interest because of their use in adhesion, corrosion passivation, sensor chemistry, photonics, electronics, and membrane chemistry.[1] Here we describe a new way to prepare thin films using functional dendrimers and a reactive copolymer that is covalently attached to a surface as a solvent-swollen, brush-like polymer. The synthesis proceeds by an alternating deposition and reaction process leading to a covalent assembly of multilayers of dendrimers contained within layers of Gantrez (poly(maleic anhydride)-*c*-poly(methyl vinyl ether) lightly cross-linked with 1% ethylenediamine). The product films are densely functionalized, semi-organized, and easily modified. The chemistry used is general, and can be extended to include the synthesis of composite interfaces using other nano- or mesoscopic surface-functionalized objects or polyfunctional molecular assemblies.

Prior syntheses of organic thin films on inorganic solids include deposition of monolayers and multilayers by self-assembly or Langmuir–Blodgett techniques,[1] deposition of polymers by adsorptive binding,[2] sequential deposition of cationic and anionic polymers, organic polymers, and inorganic sheets or mutually reactive layers,[3–9] and graft polymeriza-

tions.[8-10] The chemistry presented here combines features of these approaches for preparing thin-film composites containing highly functionalized nanomolecules in a polymeric network.

Silicon- or glass-wafer modification begins with aminosilylation.[11] The resulting aminated surface is then modified with a monolayer of Gantrez (Figure 1). Ellipsometry shows that this

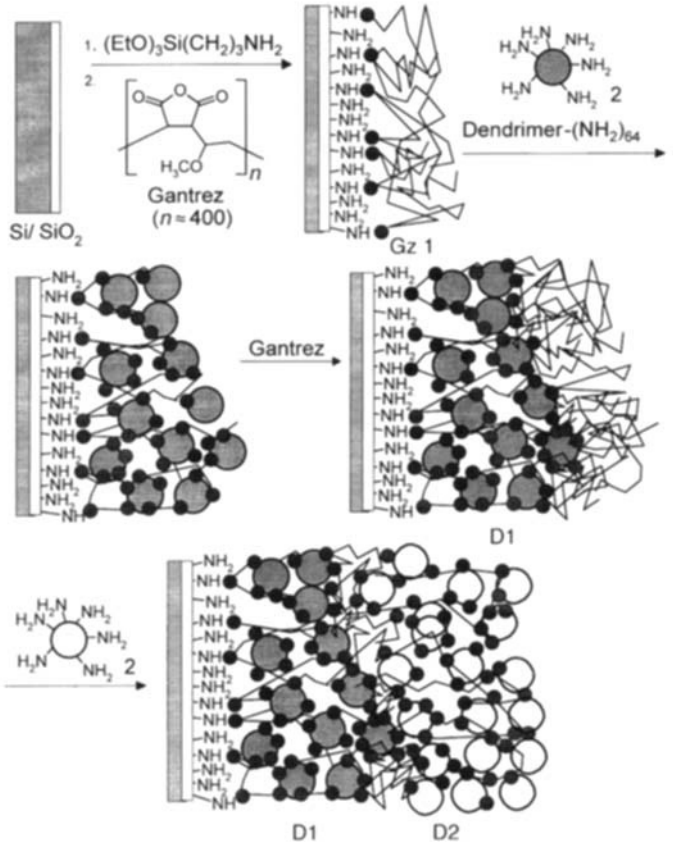

Figure 1. Schematic drawing showing the growth of multilayers of Gantrez and a PAMAM dendrimer beginning with an amino-functionalized silica/silicon-wafer surface (PAMAM = Starburst polyamidoamine). The amic acid binding sites of Gantrez are shown as smalled filled circles, and the fourth-generation PAMAM dendrimer as large filled circles (D1) or large open circles (D2).

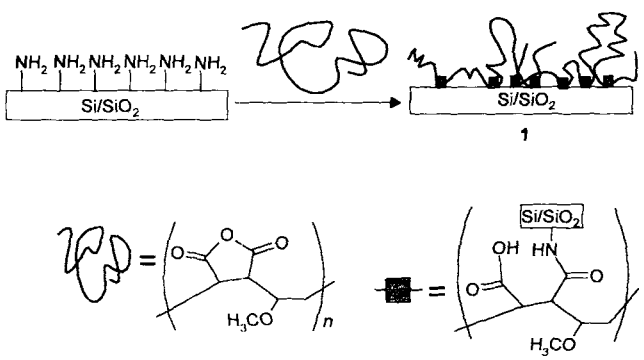
layer (Gz1) is 2.6 ± 0.4 nm thick. The silicon atoms of the underlying layer are detectable by X-ray photoelectron spectroscopy (XPS) at this stage, though the intensity of the Si_{2p} signal is attenuated from 28 to 3 atom% with silicon or from 19 to 2 atom% with glass as substrate. The Gz1 surface presumably consists of polymer chains covalently attached to the amino surface through amic acid groups at multiple sites distributed throughout the adsorbent. As Equation (1) and Figure 1 show,



(1)

this results in a polydisperse mixture (1) of random-sized loops containing unchanged anhydrides. This surface is presumably like those produced by chemisorptive binding of "sticky" polymers containing thiols or carboxylic acids to metal or metal oxide surfaces.[2, 7]

The key to this chemistry is the use of unchanged anhydride groups of these sticky surfaces for additional reactions.[7, 10] Since most of the anhydride groups of the film **1** have not reacted, the loopy brush-like polymer layer should react further, as suggested by the synthesis of cross-linked multilayer surfaces with another Gantrez derivative and 2-aminoethanol.[7] Exposure of this solvent-swollen reactive brush to a dendrimer that has terminal amino groups results in covalent attachment of multilayers of the dendrimer to the loopy brush surface through amic acids (Figure 1). Specifically, reaction of an amine-functionalized Starburst PAMAM dendrimer (**2**) with the initial Gz1 Gantrez layer yields a first-generation, dendrimer-modified surface (D1), whose ellipsometric thickness is 14.6 ± 0.4 nm (an increase of 7.9 nm). Since the fourth-generation dendrimer **2** has a diameter of 4.5 nm[12] and previous depositions of a single layer of dendrimers yields a thickness of about 4 nm,[6] a change of 7.9 nm implies that more than a single layer of dendrimer is attached in each step.

Elaboration of these surfaces by sequential deposition of Gantrez and dendrimer leads to increasingly thick films (Figure 2). Subsequent Gantrez-deposition steps (Gz2, Gz3, and

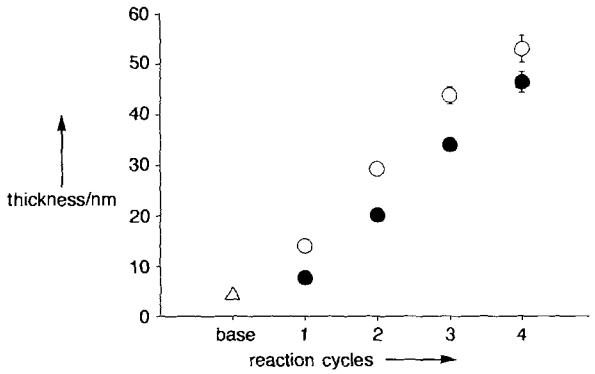


Figure 2. Ellipsometric thickness of Gantrez–dendrimer composite grafts on a silicon wafer. The thickness of the initial layer (△) includes the SiO_2 and the grafted aminopropylsilyl layer. The other data are for films after deposition of Gantrez (Gz1–Gz4, ●) and after the addition of the multilayers of dendrimer (D1–D4, ○).

Gz4) lead to larger increases in film thickness (6 nm versus 2.6 nm for Gz1). Likewise, further dendrimer additions (D2, D3, and D4) lead to larger increases in thickness (10–11 nm versus the initial increase of 7.9 nm). These increases too are in accord with addition of more than a single layer of dendrimer at the D2, D3, and D4 stages. Control experiments in which a surface without amine groups was treated first with Gantrez and then with dendrimer **2** did not lead to film growth.

XPS and IR spectroscopy as well as contact-angle analysis provide further evidence for the structure of these composite dendrimer grafts. XPS data show the disappearance of the peak due to the underlying Si atoms at the D1 stage, and changes in atom percentage that are consistent with the alternating layered structure shown in Figure 1. The anhydride-rich Gz1 and Gz2 films contain an enhanced amount of oxygen (29 atom%) and a reduced amount of nitrogen (1 atom%), while the amine-rich D1, D2, and D3 films have 19 atom% oxygen and 15 atom% nitrogen. Contact-angle measurements also cycle as film growth

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3619-2115 $ 17.50+.50/0

proceeds; the dendrimer-rich surface is more hydrophilic than the Gantrez-rich surface (Figure 3). The IR spectra also change with film growth. Bands for anhydride groups are observed at 1860 and 1790 cm^{-1} (Figure 4) for sticky films (Gz1–Gz3).

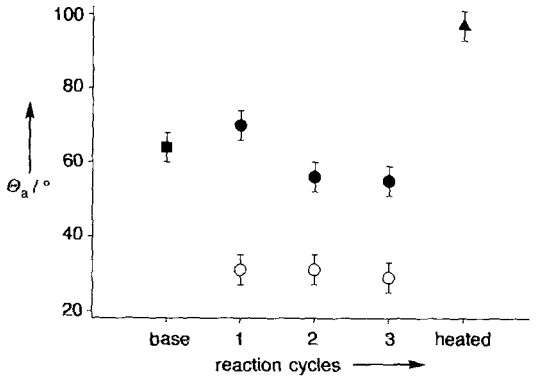

Figure 3. Contact-angle data (θ_a, water) for silicon surfaces modified with Gantrez (base, ■; Gz1–Gz3, ●) and dendrimer multilayers (D1–D3, ○) showing the cyclic changes in hydrophilicity with layer deposition and the change in hydrophilicity of layer D3 on heating (▲).

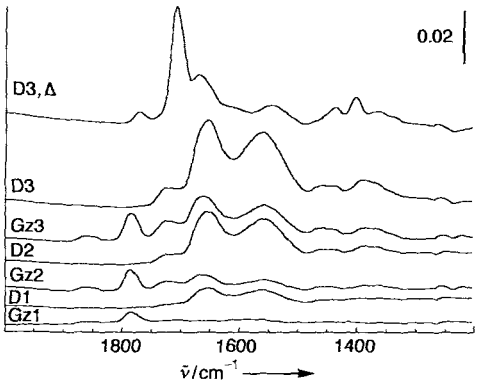

Figure 4. IR spectra (extinction) of films grafted onto silicon wafers that were polished on both sides. Spectra are shown for films after deposition of Gantrez (Gz1–Gz3) and after deposition of **2** (D1–D3) as well as for the final D3 layer after heating (D3, Δ); see text for details.

These bands disappear after addition of dendrimer **2**, and new bands for amides at 1660 and 1560 cm^{-1} appear. Moreover, the latter gradually increase in intensity as the film thickness grows. We cannot distinguish between bands for amides within **2** and bands for amides of amic acids resulting from reaction of **2** with Gantrez.

Thermal treatment of a D3 film (2 h, 120 °C) leads to a decrease of 15% in thickness and the appearance of bands for imide carbonyl groups at 1772 and 1710 cm^{-1} in the IR spectrum (Figure 4, top). We believe that imide groups form from the amic acid groups that are produced by reaction of Gantrez with the initial amine surface and with the amine-functionalized dendrimer. The IR spectrum shows that other changes occur in this film upon heating. Preliminary work with films on gold (see below) suggests that the "imidized" film is highly impermeable.

Use of a smaller second-generation Starburst PAMAM dendrimer (diameter 2.9 nm)[12] in place of the larger dendrimer **2** shows that dendrimer size may modestly affect the thickness of these multilayer films. Changes in ellipsometric thickness upon addition of the Gz1, D1, Gz2, D2, Gz3, D3, Gz4, and D4 layers were 2.3, 7.5, 4.5, 7.0, 4.6, 7.9, 5.5, and 8.5 nm, respectively.

Composite layers of **2** and Gantrez form on gold substrates upon use of an aminated base layer, which is formed by reaction of ethylenediamine with a self-assembled monolayer of 11-mercaptoundecanoic acid. In this case the D3 layer is 42.3 nm thick, as determined by ellipsometry. The D3 layer has modest blocking ability in electrochemistry experiments.[13] Heating this layer leads to an imidized film of 36.2 nm thickness that is electrochemically passivating.[13]

The chemistry described here is a new approach for the formation of thin-film composites. The coupling of a reactive surface to a polyfunctional polymer leads to a covalently attached reactive brush, that in turn allows us to incorporate multilayers of a large reactive structure (the dendrimer here) in a polyfunctional film of 40–50 nm thickness.

Experimental Section

Typical procedure for preparing a film with alternating layers of Gantrez and a polyamine dendrimer: A base layer of Gantrez on an aminopropylated glass slide was prepared by dipping the slide in a clear, pre-formed solution of Gantrez (200 mg, $M_n = 6.2 \times 10^4$, $M_w/M_n = 3.4$) and 1,2-diaminoethane (0.8 mg) in THF (4 mL). The slides were then heated in an oven at 120 °C under vacuum for 5 min. Sonication in DMF (5 min) followed by washing in THF removed any physically absorbed polymer. A dendrimer multilayer was then added to the base layer by immersing the slide in a solution of **2** in CH_3OH (10% by weight). After maintaining the slides at 25 °C for 20 min they were placed in hot THF for 5 min, washed thoroughly with CH_3OH, and dried under N_2 before being characterized by ellipsometry, XPS, and/or FT-IR spectroscopy. The next Gantrez layer was attached to the dendrimer-modified surface by allowing the dendrimer-grafted slides to react with Gantrez in THF (50 mg mL^{-1}) for 20 min with occasional heating of the reaction solution. The slides were then washed with THF and dried with N_2.

Tetra-*tert*-butyltetraborane(6) $B_4H_2tBu_4$: A Derivative in the Series B_nH_{n+2}

Andreas Neu, Theo Mennekes, Ulli Englert, Peter Paetzold,* Matthias Hofmann, and Paul von Ragué Schleyer

Dedicated to Professor Gottfried Huttner on the occasion of his 60th birthday

In the series of tetraboranes B_4H_4, B_4H_6, B_4H_8, and B_4H_{10}, *arachno*-B_4H_{10} has been known for 85 years;[1] many *arachno* derivatives of the type B_4H_8L (L = Lewis base) represent well-characterized substances.[2] B_4Cl_4[3] and B_4R_4 (R = *t*Bu),[4] derivatives of the unknown B_4H_4, have also been known for years. All four tetraboranes were investigated by theoretical methods.[5]

We report here on the synthesis of $B_4H_2R_4$, a derivative of B_4H_6. When $RBBr_2$ is reduced with Na/K alloy in toluene, $B_4H_2R_4$ is obtained in 13% yield [Scheme 1, Eq. (a)]. The two boron-bound H atoms in the product do not originate from the solvent but apparently from *t*Bu groups, since $B_4H_2R_4$ does not contain deuterium when [D_8]toluene is used. The same product is formed in 74% yield when B_4R_4[4] in THF is reduced by Na/K alloy in the presence of [18]crown-6, and the anionic intermediate subsequently protonated by HCl [Scheme 1, Eq. (b)].

The NMR spectra of $B_4H_2R_4$ reveal the presence of one type of B atom and *t*Bu group, even at −80 °C. The signals of the two framework H atoms can be observed in the $^1H\{^{11}B\}$ NMR spectrum at −80 °C, but not at ambient temperature; a corresponding cross-peak is detected in the ^1H–^{11}B HMQC NMR spectrum. The molecule gives the highest peak in the mass spectrum (2%). Although a structural model could not be refined on the basis of X-ray diffraction data[6] of crystalline $B_4H_2R_4$, the tetrahedral structure could be deduced. All experimental findings support a structure that can be derived from a tetrahedral structure by adding two bridging H atoms across the opposite edges (D_{2d} symmetry).

To confirm this structural proposal, we performed ab initio calculations at the MP2(fc)/6-31G* level[7] for B_4H_6 and $B_4H_2Me_4$ as model compounds. Three minima could be localized on the potential hyperface (Figure 1). The lowest-energy

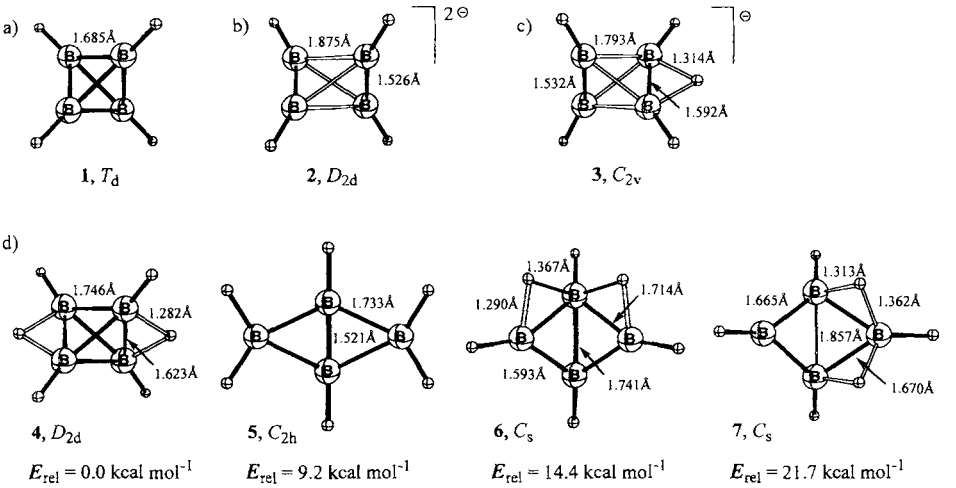

Figure 1. Geometries optimized at the MP2(fc)/6-31G* level: a) B_4H_4, b) $[B_4H_4]^{2-}$, c) $[B_4H_5]^-$, d) B_4H_6.

species corresponds to a stretched tetrahedron with two opposite hydrogen bridges (**4**, D_{2d} symmetry); the same structure is postulated for $B_4H_2R_4$. The two bridged edges (1.623 Å) are shortened and the four non-bridged edges (1.746 Å) are elongated with respect to those in B_4H_4 (1.685 Å).

Both the electron-deficient B_4H_4 and the electron-precise C_4H_4 exhibit T_d symmetry. The two *e* orbitals are unoccupied in B_4H_4 and completely occupied in C_4H_4. In the case of $B_4H_4^{2-}$, occupation of these orbitals by one electron pair causes a Jahn–Teller distortion from T_d to D_{2d} symmetry. The large difference in the B–B distances (1.526 versus 1.875 Å) is diminished by H bridges in $B_4H_5^-$ (1.592 versus 1.793 Å) and B_4H_6 (1.632 versus 1.746 Å). A similar situation is found for the tetramethyl derivatives (see Figure 2). The observed ^{11}B NMR shift of $\delta = 14.8$ is in very good agreement with that calculated for the D_{2d} structure of $B_4H_2Me_4$ with IGLO/DZ[8] ($\delta = 13.9$), leaving no doubt about the structure of $B_4H_2R_4$. The extreme change of $\Delta\delta = 120$ in the ^{11}B NMR signal by going from B_4R_4 ($\delta = 135.4$) to $B_4H_2R_4$ ($\delta = 14.6$) is worth mentioning.

Upon treating $B_4H_2R_4$ in tetrahydropyrane (L) with lithium, a bridging H atom is replaced by Li. Two solvent molecules are bound to the bridging Li atom in the crystalline product [Eq. (c)]. Only one type of BR fragment, Li cation, and cluster

$$B_4H_2R_4 + Li + 2L \longrightarrow (L_2Li)B_4HR_4 + 1/2H_2 \qquad (c)$$

H atom is recognized in the NMR spectra (^1H, ^7Li, ^{11}B, ^{13}C) of the product in [D_{10}]Et_2O. Upon cooling, the NMR signals split, and another set of signals for an isomeric product appears, which makes up one fifth of the total product at −80 °C. Two types of BR fragment as well as one type of Li cation and cluster H atom are observed for the major product at low temperature, pointing to a distorted tetrahedron of C_{2v} symmetry. The structure in which the opposite edges are bridged by an H and a Li atom is also present in the crystalline state. The coordination of

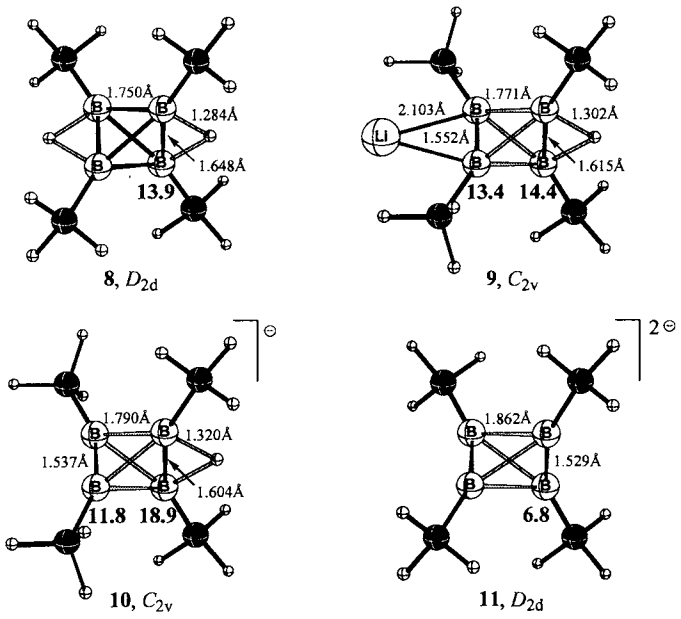

Figure 2. Geometries optimized at the MP2(fc)/6-31G* level and ^{11}B NMR shifts (boldface) calculated by IGLO/DZ for $B_4H_2Me_4$, LiB_4HMe_4, $[B_4HMe_4]^-$, and $[B_4Me_4]^{2-}$.

the Li cation by the solvent or by tetrahydropyrane remains obscure. The minor isomer observed at low temperature may represent a product that is dissociated into a solvated Li cation and the anion $[B_4HR_4]^-$; the fluctuation of the H atom between the six bridging positions, rapid even at $-80\,^{\circ}C$, results in simulated T_d symmetry in the NMR spectra. Rapid movement of the H atom and the more or less solvated Li cation apparently describes the predominating situation of LiB_4HR_4 in Et_2O at room temperature. In [D$_8$]THF as solvent, NMR signals are observed that are not principally altered upon cooling to $-80\,^{\circ}C$. These signals correspond to the minor isomer in Et_2O at low temperature. We suppose that the product dissociates into ions already at room temperature in the slightly more polar THF.

Molecules $(L_2Li)B_4HR_4$ of C_2 symmetry are found in the crystal (Figure 3). Again, the bridged edges (1.63 and 1.57 Å)

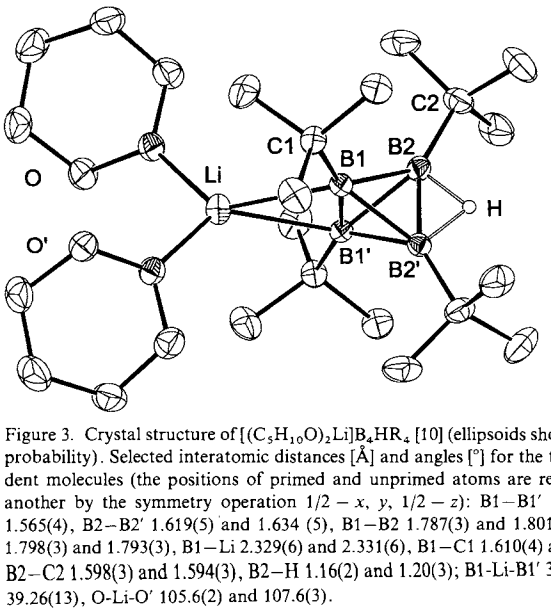

Figure 3. Crystal structure of $[(C_5H_{10}O)_2Li]B_4HR_4$ [10] (ellipsoids shown for 30% probability). Selected interatomic distances [Å] and angles [°] for the two independent molecules (the positions of primed and unprimed atoms are related to one another by the symmetry operation $1/2-x$, y, $1/2-z$): B1–B1′ 1.582(4) and 1.565(4), B2–B2′ 1.619(5) and 1.634 (5), B1–B2 1.787(3) and 1.801(3), B1–B2′ 1.798(3) and 1.793(3), B1–Li 2.329(6) and 2.331(6), B1–C1 1.610(4) and 1.620(3), B2–C2 1.598(3) and 1.594(3), B2–H 1.16(2) and 1.20(3); B1-Li-B1′ 39.79(14) and 39.26(13), O-Li-O′ 105.6(2) and 107.6(3).

are considerably shorter than the four nonbridged edges (1.79 and 1.80 Å). The calculated geometric parameters for LiB_4HM_4 (**9**, C_{2v} symmetry, Figure 2) are in accordance with the experimental values for $(L_2Li)B_4HR_4$. Only the distances between the B atoms and the Li atom are too short, as expected, since the Li atom is unsolvated in the model compound. As it is bound to the cluster by ionic forces, the influence of lithium on the cluster geometry is smaller than that of covalently bound hydrogen bridges. The ^{11}B NMR signals calculated for LiB_4HMe_4 and measured for LiB_4HR_4 at $-80\,^{\circ}C$ in ether are in excellent agreement (see Figure 2).

Closed polyhedral boranes of the type B_nH_{n+2} are in general not available. This is in contrast to the corresponding anions $[B_nH_n]^{2-}$ ($n = 6-12$), which are more or less well-known as stable salts $M[B_nH_n]$. In the larger anions $[B_nH_n]^{2-}$ ($n = 10-12$) the negative charge is distributed over a large polyhedral skeleton. The anions are therefore very weak Brønsted bases, whereas the corresponding hypothetical acids B_nH_{n+2} must be very strong acids. The basicity of the smaller anion $[B_6H_6]^{2-}$ ($pK_B = 7$) is in the range of weak but not very weak bases.[11] The basicity of a hypothetical anion $[B_4R_4]^{2-}$, in which the negative charge can only be distributed over a tetrahedral skeleton, must be very strong, since even our single-charged lithium tetraborate LiB_4HR_4 is completely protonated by the weak acid $(Me_3Si)_2NH$ to give the borane $B_4H_2R_4$. In contrast $B_4H_2R_4$ cannot be deprotonated by strong bases such as LiMe, LiBu, or K[BHEt$_3$]. We shall report on experimental and theoretical results concerning the *nido*-tetraborane $B_4H_4R_4$ and the corresponding anion $[B_4H_3R_4]^-$ in the near future.

Experimental Section

Tetra-*tert*-butyltetraborane(6): Na/K alloy (20 g) was added to dibromo-*tert*-butylborane [12] (51.30 g, 0.225 mmol) in toluene (120 mL). The mixture boiled at reflux for 15 min without additional heating, and cooled to room temperature within 3 h. The solids were then removed by filtration over a G4 frit. The volatile components were transfered from the filtrate finally at 80 °C/0.001 Torr into a condenser that was cooled to $-196\,^{\circ}C$. The volatile material was treated with butyllithium in hexane (20 mL, 1.6 M) at 0 °C. The solvent was then removed in vacuo at room temperature. After condensation of the crude product at 70 °C/0.001 Torr, colorless $B_4H_2R_4$ (2.00 g, 13%) was crystallized from acetonitrile; m.p. 112 °C. The same product was obtained by dropwise addition of tetra-*tert*-butyltetraborane [4] (100 mg, 0.37 mmol) in THF (2 mL) to a mixture of Na/K alloy (0.10 g) and [18]crown-6 (190 mg, 0,72 mmol) at 0 °C. After the insoluble components were removed by filtration, a solution of HCl in Et_2O (1 mL, 2 M) was added, the solvent removed in vacuo, and the product again dissolved in hexane. After renewed filtration, removal of hexane in vacuo, and condensation of the crude product, pure $B_4H_2R_4$ was crystallized from acetonitrile (75 mg, 74%). ^{1}H NMR (500 MHz, [D$_8$]toluene, $-80\,^{\circ}C$): $\delta = 0.85$ (br, μ-H), 1.05 (s, *t*Bu); ^{11}B NMR (160.4 MHz, [D$_8$]toluene): $\delta = 14.8$; ^{13}C NMR (125.7 MHz, [D$_8$]toluene, $-80\,^{\circ}C$): $\delta = 31.3$ (q, Me), 21.3 (br, BC).

Bis(tetrahydropyrane)lithium tetra-*tert*-butylhydrotetraborate: A mixture of lithium (40 mg, 5.8 mmol) and $B_4H_2R_4$ (200 mg, 0.73 mmol) in tetrahydropyrane (4 mL) was treated with ultrasound for 10 h. The volatile components were removed at 11 mbar, and the product dissolved in warm hexane. The hot solution was filtered over diatomaceous earth. All reaction vessels and the kieselguhr had to be dried carefully with $HN(SiMe_3)_2$. Pure product crystallized upon cooling the solution (140 mg, 42%). ^{1}H{^{11}B} NMR (500 MHz, [D$_{10}$]Et$_2$O, 22 °C): $\delta = 0.29$ (μ-H), 1.00 (s, *t*Bu), 1.53, 1.62, 3.60 (3mc, 2:1:2, CH$_2$); ^{7}Li NMR (194.2 MHz, [D$_{10}$]Et$_2$O, 22 °C): $\delta = 1.24$; ^{11}B NMR (160.4 MHz, [D$_{10}$]Et$_2$O, 22 °C): $\delta = 14,9$; ^{13}C NMR (125.6 MHz, [D$_{10}$]Et$_2$O, 22 °C): $\delta = 24.3, 27.4, 69.3$ (3t, 1:2:2, CH$_2$), 20.1 (br, BC), 34.1 (q, Me); measurements at $-80\,^{\circ}C$: ^{1}H{^{11}B} NMR: $\delta = -0.08$ (μ-H), 0.92, 1.03, 1.08 (3s, ≈5:5:2, *t*Bu), 1.57, 1.64, 1.86, 3.50, 4.11 (5mc, 1:4:1:2:2, CH$_2$); ^{7}Li NMR: $\delta = -1.21, 1.27$ (1:5); ^{11}B NMR: $\delta = 13.3, 15.5, 20.6$ (≈5:5:2); ^{13}C NMR: $\delta = 23.6, 26.7, 69.1$ (3t, 1:2:2, CH$_2$), 34.1, 33.3, 34.5 (3q); MS (Finnigan MAT 95; 70 eV): $M_{found} = 280.343$, $M_{calcd} = 280.343$ ($LiB_4HR_4^+$, 100%); elemental analysis calcd for $C_{26}H_{57}B_4LiO_2$: C 69.10, H 12.71, B 9.57, Li 1.55; found: C 68.67, H 12.75, B 9.57, Li 1.55.

[6] Crystals of $B_4H_2R_4$ exhibited measurable intensities of the reflections only at small diffraction angles. Crystal data at 243 K gave the orthorhombic space group *Pba*2 (no. 32); $a = 33.56(1)$, $b = 28.74(1)$, $c = 9.066(5)$ Å, $V = 8743(9)$ Å^3, $Z = 16$, $\rho_{calcd} = 0.832$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 2.79$ cm^{-1}, $F(000) = 2464$. Efforts to solve the structure by direct methods gave three symmetry-independent molecular fragments (substituted tetrahedra) in a general position and two fragments with crystallographic C_2 symmetry; unconstrained refinement was not possible, and refinement with rigid idealized *t*Bu groups yielded unweighted factors R of about 0.25 and large displacement parameters of the peripheral atoms. More demanding disorder models did not work because of the small number of significant intensity data. Low-temperature data could not be recorded because of a phase transition.

[7] Optimizations of energy and calculations of frequency were performed at the MP2(fc)/6-31G* level with the Gaussian 94 program: M. J. Frisch, G. W. Trucks, H. B. Schlegel, P. M. W. Gill, B. G. A New Strategy for Extending *N*-Acyl Imides as Chiral Auxiliaries for Aldol and Diels–Alder Reactions: Application to an Enantioselective Synthesis of α-Himachalene**

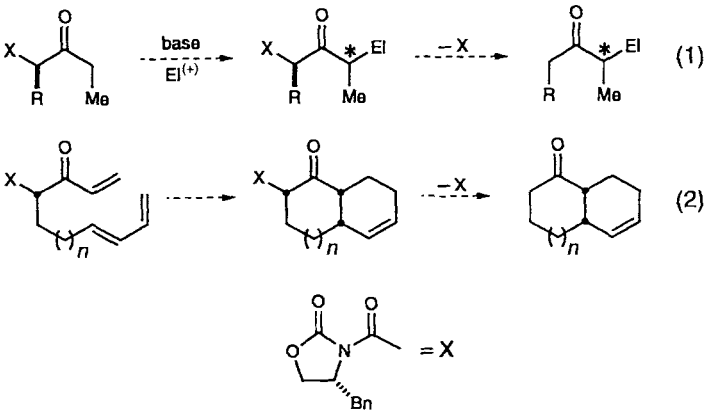
David A. Evans,* David H. Brown Ripin, Jeffrey S. Johnson, and Eileen A. Shaughnessy

The development of enantioselective transformations involving the ketone functional group continues to be a problem of general interest in asymmetric synthesis due to the ubiquity of this functionality. While chiral Lewis acids have been employed to promote enantioselective aldol and Diels–Alder reactions of carboxylic acid derivatives and aldehydes, stereocontrol is generally low in reactions of ketones due to the lack of differentiation in Lewis acid coordination to the two nonbonding electron pairs of the carbonyl group.[1] One strategy for creating a stereochemical bias in ketone-derived enolate–electrophile reactions [Eq. (1)] or in the transformations of α,β-unsaturated ketones such as the Diels–Alder reaction [Eq. (2)] has been developed. In



these processes, a stereogenic center, created by the incorporation of the removable substituent X, is positioned proximal to the trigonal carbon centers undergoing reaction, thus establishing a diastereofacial bias for the transformation. The implementation of this strategy for enolates and enolsilanes of α-trialkylsilyl ketones [Eq. (1), X = SiR_3] has been reported by Enders and Lohray,[2, 3] while Heathcock and Masamune have demonstrated that the aldol and Diels–Alder reactions of α-alkoxyketones [Eqs. (1) and (2), X = OR] are highly diastereoselective.[4]

Here we define the removable auxiliary X = COX_c (X_c = 4-benzyl-2-oxazolidinon-3-yl), which can be used in the previously described enolate bond constructions and combined with a mild hydrolysis/decarboxylation procedure to extend the utility of β-ketoimides[5] to the production of enantiopure ketones [Eq. (1)]. We also demonstrate that this strategy is applicable to the implementation of enantioselective Diels–Alder reactions [Eq. (2), X = COX_c].

We have previously demonstrated that the β-ketoimide **1**[6] undergoes metal ion dependent stereoselective *syn*-[7] and *anti*-aldol[6] reactions. In addition, the titanium enolate[8] derived

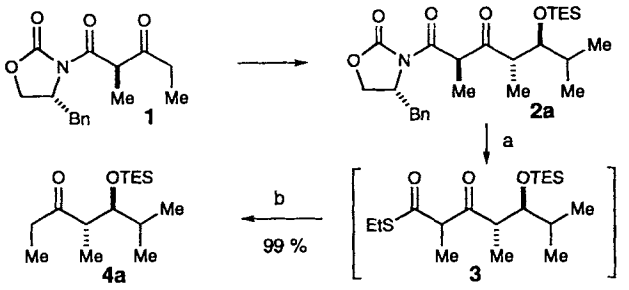
from **1** has also been shown to undergo diastereoselective orthoester acylation.[9]

The focus of the current investigation has been the development of a mild decarboxylation process that might be applied to the enolate-derived reaction products that are prone to epimerization and/or elimination.[10] A successful solution to this transformation is transesterification with ethanethiolate[11] followed by silver(I)-promoted hydrolysis/decarboxylation[12] of the resulting thioester (Scheme 1).



Scheme 1. Thiolate displacement, hydrolysis, and decarboxylation of β-oxoimide **2a**[6]: a) EtSH, KH, THF, 25 °C; b) $AgNO_3$, 2,6-lutidine, THF/H_2O (5/1), 25 °C. TES = triethylsilyl.

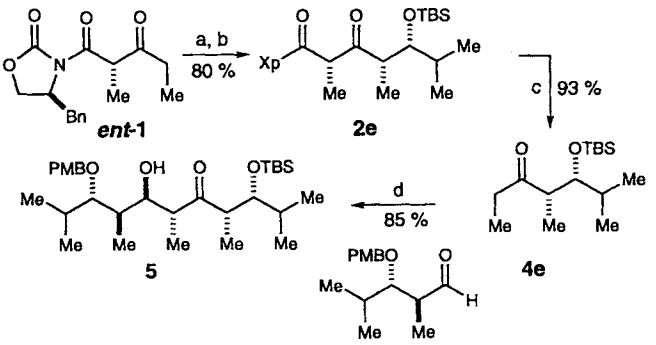
Treatment of **2a** with potassium ethanethiolate afforded a mixture of C_α-diastereomeric β-ketothioesters **3**.[13] Subjecting thioesters **3** to silver(I)-promoted hydrolysis and subsequent decarboxylation at ambient temperature provided ethyl ketone **4a** over the course of 48 hours. In most instances the reaction time may be reduced without compromising yield by mild heating during the hydrolysis step (70 °C, 3 h). The two steps may be merged into a single-flask operation (see Experimental Section). The decarboxylation of β-ketoimide-derived aldol and orthoester acylation adducts **2a–2f** was investigated using this procedure (Table 1). The mild reaction conditions accommodate the presence of ketal, silyl ether, alkene, and acetate functionalities.

Table 1. One-flask decarboxylation of representative β-ketoimide adducts[a].

Imide	Product	Yield [%][b]	*t* [h][c]
 **2b**	 **4b**	98	24
 **2c**	 **4c**	79 74	24 3[d]
 **2d**	 **4d**	88	48
 **2e**, R = TBS	 **4e**	93 92	48 3[d]
2f, R = Ac	**4f**	83	48

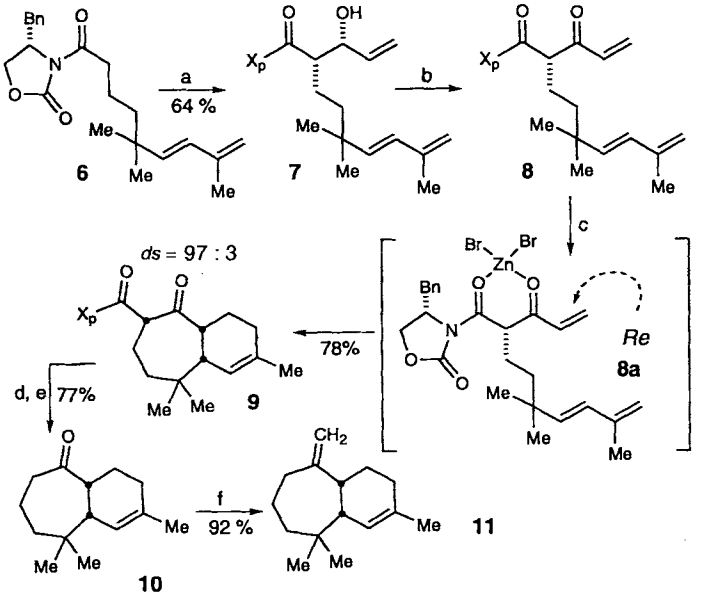
[a] X_p = (*S*)-4-benzyl-2-oxazolidinon-3-yl, X_q = (*R*)-4-benzyl-2-oxazolidinon-3-yl, TBS = *tert*-butyldimethylsilyl. [b] Yield after purification. [c] Reaction time for the hydrolysis step. [d] Hydrolysis run at reflux.

These ketone decarboxylation products are useful building blocks for the rapid synthesis of extended polypropionate chains.[14] In the example shown in Scheme 2, polypropionate **5**, containing six stereocenters, was synthesized in four steps (63 % yield) from β-ketoimide **1**; all stereocenters were formed with a combined diastereoselectivity exceeding 95 %.[14e]



Scheme 2. Strategy for the rapid assembly of polypropionate chains. a) 1. $TiCl_4$, Et_3N, 0 °C, 2. *i*PrCHO, −78 °C; b) TBSOTf, 2,6-lutidine, −78 °C; c) 1. EtSH, KH, 2. $AgNO_3$, 2,6-lutidine, H_2O; d) *c*hex$_2$BCl, Et_3N, −78 °C. OTf = trifluoromethanesulfonate, PMP = 4-methoxybenzyl.

This auxiliary-based methodology can be applied to achieve control of the absolute stereochemistry in the Diels–Alder process [Eq. (2)]. In this context, we investigated an intramolecular Diels–Alder reaction that comprises the pivotal bond construction in an enantioselective synthesis of the sesquiterpene α-himachalene (**11**).[15] Dienimide **6**, prepared in five steps from 3,3-dimethyl-4-propenal, underwent a highly diastereoselective boron-mediated aldol reaction with acrolein to afford the allylic alcohol **7** as the sole isomer (Scheme 3).[16] Compound **7** was subjected to Parikh–Doering oxidation[17] and the resulting trienone **8** was treated with $ZnBr_2$ (0 °C, CH_2Cl_2, 1.5 h) to effect cycloaddition (78 % yield, two steps) to the desired crystalline *endo* adduct **9** (97:3 diastereoselectivity), which was isolated as



Scheme 3. Enantioselective synthesis of α-himachalene (**11**). a) 1. Bu_2BOTf, *i*Pr_2NEt, isoprene, 0 °C, 2. acrolein, −78 °C; b) SO_3·pyridine, DMSO/CH_2Cl_2, *i*Pr_2NEt, −10 °C; c) $ZnBr_2$, 0 °C; d) LiSEt; e) $AgNO_3$, 2,6-lutidine, THF/H_2O, 70 °C; f) $[Cp_2Ti(\mu\text{-Cl})(\mu\text{-CH}_2)AlMe_2]$, −40 °C.

a single diastereomer by chromatography. The sense of asymmetric induction in this cycloaddition is consistent with a Lewis acid catalyzed Diels–Alder reaction on the *s-cis* $ZnBr_2$ complex **8a**.

In analogy to previous experiments, Diels–Alder adduct **9** was transformed to the corresponding β-ketothioester in 90% yield and smoothly decarboxylated (70 °C, 24 h) to afford ketone **10** in 86% yield without epimerization at the ring fusion. The synthesis was completed by treatment of **10** with Tebbe reagent[18] to afford synthetic α-himachalene (**11**) (92% yield), whose spectroscopic and analytical data are identical in all respects to literature values (^{1}H NMR, IR, TLC, $[\alpha]_D$).[15]

The removable auxiliary X = COX_c described here should prove useful in enantioselective ketone-based bond constructions. Although the methodology has been highlighted with aldol and Diels–Alder reactions, absolute stereochemical control of other transformations such as the Michael reaction should also be possible. Studies extending the scope of these concepts are currently underway.

Experimental Section

General one-flask procedure for the decarboxylation of β-ketoimides: A stirred suspension of KH (1.2 mmol) in THF (10 mL) under argon was charged with EtSH (1.3 mmol) and gas evolved. The white suspension was stirred for 1 h before a solution of β-oxoimide (1 mmol) in THF (10 mL) was added by cannula. The reaction mixture was stirred until the starting material had been consumed. To the reaction mixture was added water (4 mL) and 2,6-lutidine (10 mmol), followed by $AgNO_3$ (2.5 mmol). The reaction mixture was protected from light and stirred for two days. The pale yellow suspension was filtered through Celite with ether, and the organic solution was extracted between ether (50 mL) and aqueous $CuSO_4$ solution (50 mL). The ether layer was separated, dried over $MgSO_4$, and concentrated in vacuo. Chromatography on silica gel using an appropriate solvent mixture provided pure ketone.

One-Component Catalysts for Thermal and Photoinduced Ring Opening Metathesis Polymerization

Andreas Hafner,* Andreas Mühlebach, and Paul A. van der Schaaf

New generations of stereospecific olefin polymerization catalysts have catapulted the polymer industry into a new area. A large variety of thermoplastic materials, based on α-olefins, of well-defined tacticity and block length are expected to be commercialized in the near future.[1] A similar development can be foreseen for thermoset materials. In this respect ring opening metathesis polymerization (ROMP)[2] offers new types of polymers with attractive mechanical and electrical properties. Currently applied industrial catalysts for ROMP are multicomponent systems based on early transition metal complexes and water-sensitive alkylaluminum cocatalysts. In the mid 1980s the first well-defined, one-component catalysts for ROMP were developed by Osborn (e. g., $[WCl_2(=CHCMe_3)(OR)_2]$)[3] and Schrock (e. g., $[Mo(=CHCMe_3)(=NAr)(OR)_2]$).[4] However, these catalysts are air- and moisture-sensitive as well, and sparsely tolerate monomers bearing protic substituents, fillers, or other additives.

In contrast to early transition metal catalysts, ruthenium- and osmium-based complexes are water-stable and possess remarkable tolerance towards most functional groups.[5] Therefore, the use of these catalysts goes far beyond the classical scope of olefin-metathesis reactions.

When we started our work in the field of ROMP by studying the reactivity of $[Ru(H_2O)_6]^{2+}$, we were able to prepare polymers and copolymers from cyclic olefins containing a large variety of functional groups.[6] Using the concept of photoinduced arene displacement, we developed the first photocatalysts for ROMP (PROMP) by generating $[Ru(H_2O)_6]^{2+}$ from $[Ru(\eta^6\text{-arene})_2]^{2+}$.[7, 8] A disadvantage of these catalysts is their cationic character, which restricts their applicability to polar environments, and their moderate reactivities. Therefore, we focused our attention on more soluble and more active arene complexes of ruthenium and osmium.

In 1992 Grubbs et al. reported the synthesis of the first well-defined, metathesis-active ruthenium–carbene complex by ring opening of a substituted cyclopropene with $[RuCl_2(PPh_3)_3]$.[9]

In 1995 Noels et al. reported the in situ formation of carbene complexes from arene ruthenium phosphane complexes and (trimethylsilyl)diazomethane.[10] These studies showed that the cone angle θ of the coordinating phosphane determines the activity of the catalyst. We also investigated the photoactivity of a series of arene ruthenium phosphane and arene osmium phosphane complexes.[11]

Osmium complexes of the type $[Os(p\text{-cymene})Cl_2(PR_3)]$ (R = cyclohexyl (Cy; **1**), *i*Pr (**2**), *n*Bu (**3**), Ph (**4**), Me (**5**), $C_6H_4CH_3$-3 (*m*-Tol; **6**)) do not initiate the thermal polymerization of norbornene (NBE). However, when they were activated by UV irradiation (200-W Hg lamp, 5 min), active ROMP catalysts were obtained. The results of the photoinduced polymerization of NBE in toluene initiated by **1**–**6** are depicted in Figure 1a. Figure 1b shows the comparison of ROMP and PROMP activity for **1**.

Active photocatalysts were obtained with the sterically demanding phosphane ligands PCy_3 and $P\textit{i}Pr_3$ ($\theta = 170$ and 160°, respectively), whereas very slow or no polymerization was observed for complexes with less bulky phosphanes (PPh_3, $P\textit{n}Bu_3$, or Pme_3; $\theta = 145$, 130, and 120°, respectively). Surprisingly, **6** ($\theta = 165°$) was inactive as well.

The corresponding ruthenium complexes $[Ru(p\text{-cymene})Cl_2(PR_3)]$ (R = Cy (**7**), *n*Bu (**8**), *m*-Tol (**9**)) showed much higher reactivity for NBE polymerization;[12] none of these complexes was thermally latent towards NBE. Complex **7** was already known to initiate NBE polymerization without activation of diazomethane derivatives as cocatalyst (80% poly(NBE) after 15 min at 50 °C).[13] Both **8** and **9** yield traces of poly(NBE) after 1 h at 80 °C. However, under similar conditions **8** yields 80% poly(NBE) when irradiated for 5 min at room temperature.

The low reactivity of **6** and **9** can be explained by the work of von Philipsborn et al.[11i] The ^{187}Os NMR chemical shift for arene osmium phosphane complexes, including **1**–**6**, correlates extremely well with Toleman's steric parameters.[14] The reported θ for P*m*-Tol_3 is 165°, assuming C_{3v} symmetry, whereas a value of 150° was measured with the chemical-shift method. This can be explained by a nonsymmetrical orientation of the phenyl rings of the phosphane ligand in **9**.[15] To have direct proof for the proposed importance of the steric parameters (for example the asymmetry of the P*m*-Tol_3 ligand), X-ray structure determinations of **7** and **9** were carried out (Figure 2).[16]

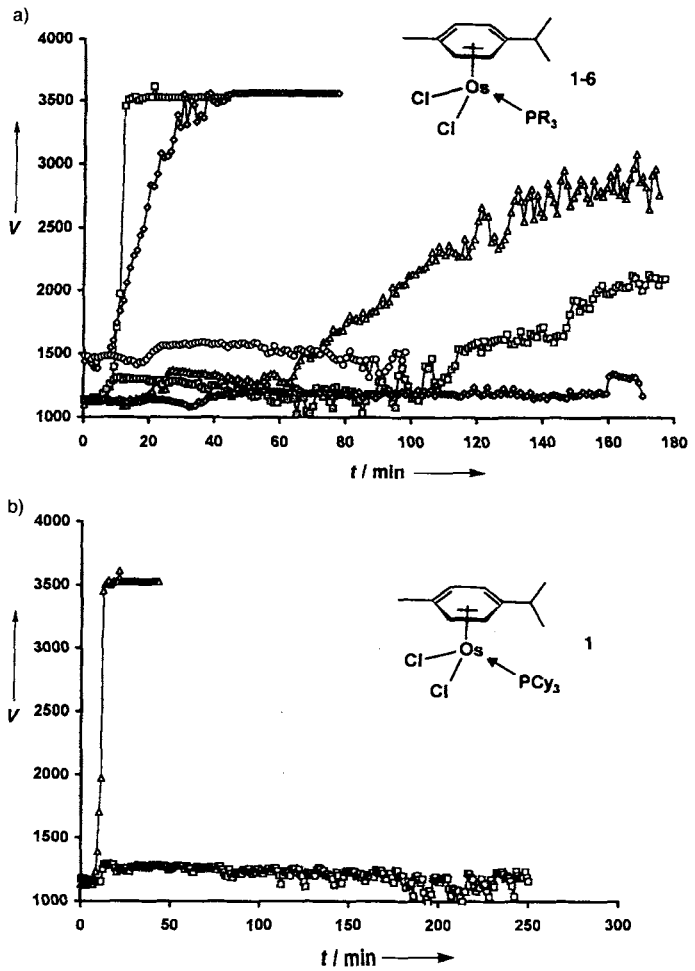

Figure 1. a) Real-time viscosimetric measurements of the photopolymerization of norbornene in toluene (10 wt%) with **1**–**6** (2 mol% each; □: R = Cy (**1**); ◇: R = *i*Pr (**2**); △: R = *n*Bu (**3**); ○: R = Ph (**4**); □: R = Me (**5**); ◇: R = *m*-Tol (**6**)). b) Thermal latency versus the photoactvity of **1** in the polymerization of norbornene (△: 30 °C, UV irradiation; □: 80 °C, without irradiation). *V* = viscosity (arbitrary units).

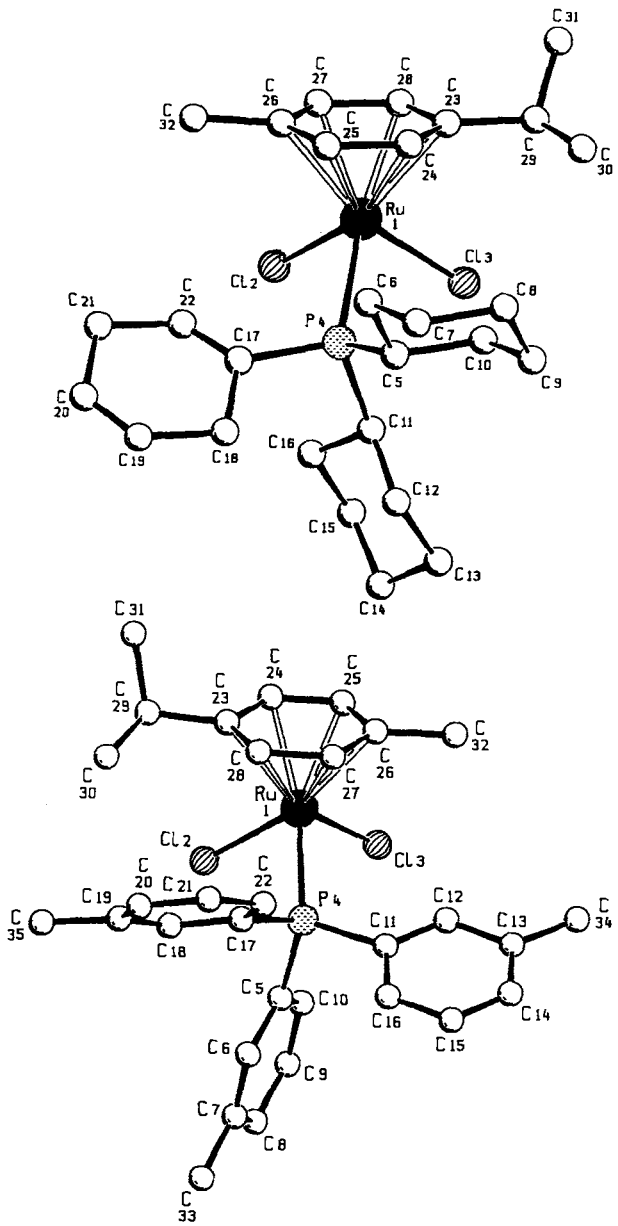

Figure 2. Molecular structures of **7** (top) and **9** (bottom); hydrogen atoms are ommited for clarity. In both cases only one of two molecules from the asymmetric unit cell is depicted.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3619-2122 $ 17.50+.50/0

The assumed asymmetry of the P*m*-Tol_3 ligand was confirmed with the molecular structure of **9**: C33 points into the ligand sphere of the phosphane, whereas C34 and C35 point outwards. The larger tilting of the *p*-cymene ring relative to the Cl-Cl-P plane in **7** (6°) than in **9** (1.5°) can be explained by the steric interaction with the more bulky PCy_3 ligand. This is also reflected by the fact that *p*-cymene is liberated at lower temperatures from **7** (150 °C) than from **8** and **9** (180 and 200 °C, respectively), as measured by differential scanning calorimetry (DSC).

By allowing **7** to react with less reactive monomers we coincidentally found that it is a very efficient catalyst for the thermal, solvent-free polymerization of dicyclopentadiene (DCPD) at temperatures above 80 °C. This was completely unexpected, since, to our knowledge, no ruthenium catalysts were known for the polymerization of DCPD. In fact, it was reported that DCPD is a poison for ruthenium-initiated ROMP.[17] Surprisingly, "solutions" of **7** in DCPD are stable for weeks at room temperature with no increase in viscosity. We think that the active species is an arene-free ruthenium phosphane complex, as described by Noels et al., formed by thermal arene displacement. Furthermore, the arene-free complexes $[Ru(PCy_3)_2(MeOH)_2Tos_2]$ (**10**) and $[RuCl_2(PCy_3)_3]$ (**11**) are also active with DCPD.[18]

Figure 3 shows a dynamic and isothermic DSC scan of the DCPD polymerization initiated with **7** (0.3 wt%). The exothermic curing reaction starts around 100 °C, and the curing heat reaches a maximum of $\Delta H = 364\ J\,g^{-1}$. This ΔH value corresponds well to the theoretical value, calculated from the ring strains of NBE and cyclopentene, for about 95% conversion and a cross-link density of 10–20% for the polymer. This cross-link density is supported by swelling experiments of poly(DCPD) in toluene (weight increase of about 100%). Another fascinating aspect of the DSC experiment is the flatness of the curve up to 100 °C, which demonstrates the excellent latency of the system at room temperature. Gel times of more than three weeks at 20 °C, 270 min at 60 °C, 102 min at 70 °C, and 38 min at 80 °C were determined with vicosimetric measurements under the conditions described above. The isothermal DSC scan at 100 °C shows a fast polymerization reaction with a peak maximum after 6 min. At this temperature the polymerization is completed after about 40 min.

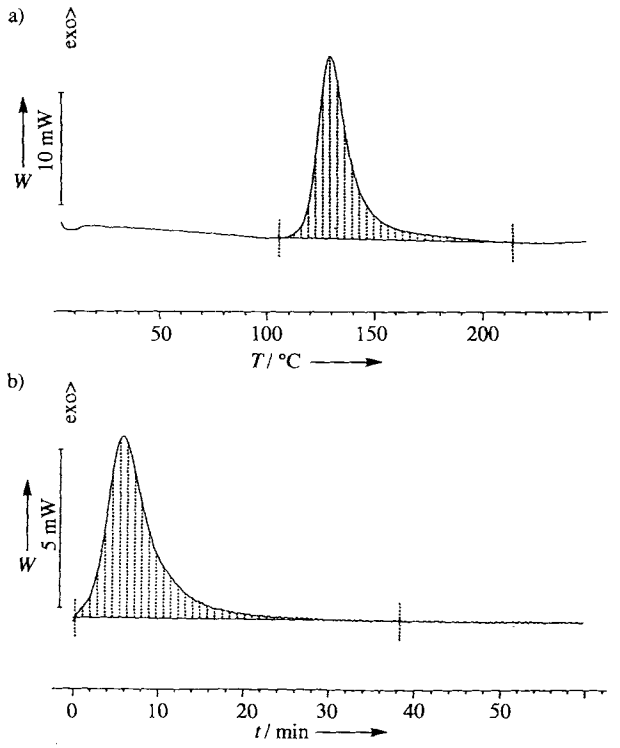

Figure 3. Dynamic (top) and isothermal DSC scan (bottom) of the polymerization of DCPD initiated by **7** (0.3 wt%). *W* = heat flow.

Due to the amazing tolerance of **7** towards impurities and water, we were able to incorporate almost any type of filler (for example SiO_2, $Al(OH)_3$, Al powder, or $CaCO_3$) in amounts of up to 70 wt%; the good electrical and mechanical properties of poly(DCPD) were thus preserved. These properties makes this system extremely interesting for new types of thermosets. For example, the dielectric constant for poly(DCPD) with quartz powder (60 wt%) is still as low as 3.3 with an E modulus of 6200 MPa. Poly(DCPD) loaded with Al powder (60 wt%) is a perfect insulator with a surface resistivity of greater than $10^{11}\ \Omega$ up to 1000 V.[19] Catalyst **7** even allows aqueous dispersion polymerization of NBE and DCPD.[20]

The good mechanical properties of this material are partially due to additional cross-linking of the cyclopentene ring. A second ring opening metathesis reaction is the accepted mechanism for the cross-linking in poly(DCPD) polymerized with early transition metal catalysts.[21] However, Wagener et al. recently reported a model study from which they concluded that cross-linking occurs by a vinyl-addition reaction.[22] To elucidate the structure of cross-linked poly(DCPD) obtained by solvent-free polymerization of DCPD with **7** (0.3 wt%), ^{13}C CP-MAS NMR spectra of the material were measured (Figure 4). Integration of the olefinic and aliphatic ^{13}C signals provided a ratio of exactly 2:3. This strongly suggests that in this case ring opening of the cyclopentene ring is the predominant cross-linking mechanismpoly(DCPD).

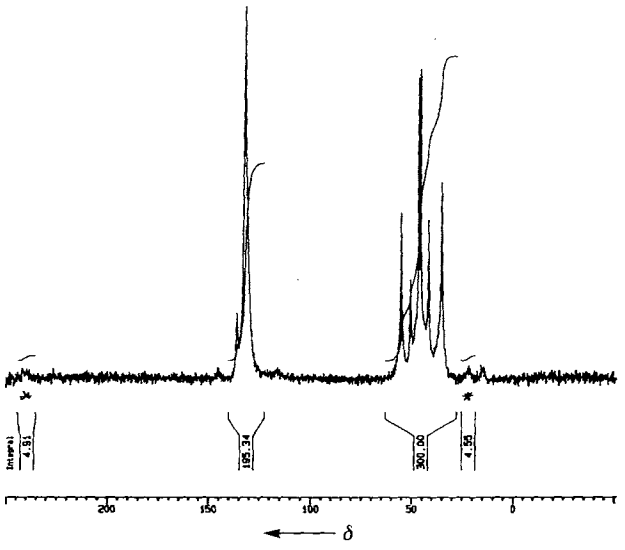

Figure 4. ^{13}CP-MAS NMR spectrum of poly(DCPD); the asterisk indicates spinning side bands.

Polymers with two double bonds per repeat unit are supposed to be oxidatively very unstable. However, almost no weight loss (<1%) was measured for 4-mm plates of unstabilized poly(DCPD) heated in air at 180 °C for 100 days. We suppose that the oxidized surface forms a dense layer which hinders O_2 penetration and therefore protects the deeper material from further oxidation. The thickness of this hard and dense oxide layer was estimated to be about 4 μm from surface-roughness and micro-hardness measurements.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3619-2123 $ 17.50+.50/0

Due to the tolerance of catalyst **7** in combination with the interesting properties of poly(DCPD), new filled or unfilled thermosets could be prepared, which should find novel applications in the field of electro casting, insulation, and tooling (among others) in the near future. Work to improve catalysts and polymer systems are ongoing.

Experimental Section

The ruthenium and osmium complexes were prepared according to literature procedures [11]. NBE was purchased from Fluka, and DCPD (technical quality, 94%) from Shell and used as received. Viscosimetric measurements were performed on a home-built, real-time viscosimeter. Gel times were recorded on a Brookfield viscosimeter, DSCs on a Mettler DSC30 with a Mettler TC11 controller, TGAs on a Mettler TG50 with a Mettler TC10A controller, and surface roughness on a Form Talysurf S3C-50. Micro hardness was determined on a Fischerscope H100. ^{13}C CP-MAS NMR spectra of a piece of poly(DCPD) that was tightly fitted into the spinner were recorded on a Bruker 400-MHz instrument with a MAS rate of 11 kHz and a pulse delay of 5 s (a pulse delay of 60 s gave an identical result).

The Amidinium–Carboxylate Salt Bridge as a Proton-Coupled Interface to Electron Transfer Pathways**

Yongqi Deng, James A. Roberts, Shie-Ming Peng, C. K. Chang, and Daniel G. Nocera*

Proton motion coupled to electron transfer is a basic energy conversion mechanism. Many proteins and enzymes function by utilizing the energy gathered along a charge-separating network to drive a proton pump, which in turn is manifested in a transmembrane chemical potential that provides the energy for the synthesis of complex biomolecules.[1] Yet some thirty years after Mitchell's initial proposal of proton translocation driven by electron transfer,[2] the mechanistic details of how the electron couples to the proton remain undefined.[1a, 3] To unravel the relationship between the proton and the electron, we have developed the following approach: electron transfer is photoinduced within photoexcitable electron donor–acceptor supramolecule complexes formed from the association of a proton transfer interface.[4] We have concentrated on asymmetric inter-

faces such as salt bridges, because they provide an important model for proton-coupled electron transfer (PCET) in biology, where reaction dynamics are modulated by coupling the charge redistribution accompanying both proton *and* electron motion to the surrounding environment.[5] Such is the case for the donor–(salt bridge)–acceptor supramolecule systems. Changes in polarity, charge, and energetics resulting from the transfer of an electron from the donor to the acceptor are augmented by the charge shift accompanying proton displacement within the salt bridge interface.

One attractive salt bridge for PCET studies is the amidinium–carboxylate interface, which models the arginine–aspartate salt bridges important to many biological structures.[6] But unlike the guanidinium–carboxylate interaction of Arg–Asp, amidinium group shows only one specific binding mode for carboxylate, thereby simplifying PCET studies. Though high association constants are characteristic of salt bridge supramolecules, an electron donor–acceptor complex assembled by such noncovalent interactions at the interface has yet to be structurally characterized. We now report the X-ray crystal structure of **1**·benzoate and show that the salt bridge is preserved in solutions of high dielectric constant. The salt bridge is maintained upon replacement of the phenyl ring by the electron-withdrawing 3,5-dinitro phenyl moiety, but with an attenuated association constant. When the porphyrin is made photoexcitable by Zn^{II} substitution of Ni^{II}, we observe an unusually slow rate of electron transfer for the porphyrinatozinc(II)–(amidinium carboxylate)–3,5-dinitrobenzene complex. Electronic spectroscopy indicates that the salt-bridge is strongly coupled to the electron transfer pathway and that it significantly influences the rate of electron transfer.

The syntheses of compounds **1** and **2** are outlined in Scheme 1. Dipyrrylmethane **5**, obtained from acid-catalyzed condensation of bromomethylpyrrole **3** and α-unsubstituted pyrrole **4**, was reduced by diborane (generated in situ by addition of BF_3 to $NaBH_4$) to give dipyrrylmethane **6**, which was then hydrolyzed and decarboxylated by heating with sodium hydroxide in ethylene glycol to give compound **7**. A modified MacDonald condensation[7] between **7** and **8** produced **9** in about 45% yield. Alcohol-derivatized porphyrin **9** was converted into vinyl porphyrin **11** by chlorination and elimination from **10** following standard procedures.[8] The vinyl group was oxidized to aldehyde **12** with osmium tetraoxide followed by sodium periodate. The aldehyde was converted into the nitrile ($\tilde{\nu}_{CN}$ at 2250 cm^{-1}) by heating at reflux with hydroxyamine hydrochloride in formic acid. After nickel complexation, **14** was converted into **1**[9] with Weinreb's reagent ($AlCl(CH_3)(NH_2)$) to deliver the amide.[10] The conversion of the Ni complex into the Zn complex can be accomplished by published procedures.[10]

The formation of the salt bridge is confirmed by X-ray crystallography of **1**·benzoate (Figure 1).[11] The relatively short N to O distances of 2.757(11) and 2.812(11) Å of the salt bridge indicates substantial stability and relatively strong hydrogen bonding ($d_{calcd}(O\cdots H) = 1.800$ and 1.874 Å). These bond lengths are usual for this type of salt bridge; according to a crystal structure analysis of the doubly hydrogen-bonded salt bridge formed between a bicyclic guanidinium unit and a carboxylate group, the N–O length is 2.85(4) and the attendant O···H bond length 1.97(4) Å.[12] An S_4 ruffling of the porphyrin ring is common for Ni^{II} porphyrin complexes and results from the contraction of the metal coordination site owing to the small size and high electrophilicity of the Ni^{II} atom.[13] The amidinium group is rotated by 42° with respect to the plane of the porphyrin ring, defined by the four pyrrole nitrogens (0.016 Å mean deviation from plane).[14] This canting of the

amidinium is not fully compensated by a counter rotation of the carboxylate, and a slight twist of 5.4° is observed within the salt bridge interface (dihedral angle defined by the planes of the CN_2 and CO_2 atoms of the salt bridge).

The amidinium–carboxylate salt bridge is very stable, and it persists in solutions, even when the dielectric constant of the solvent is high. Figure 2 shows the ^{1}H NMR spectral changes

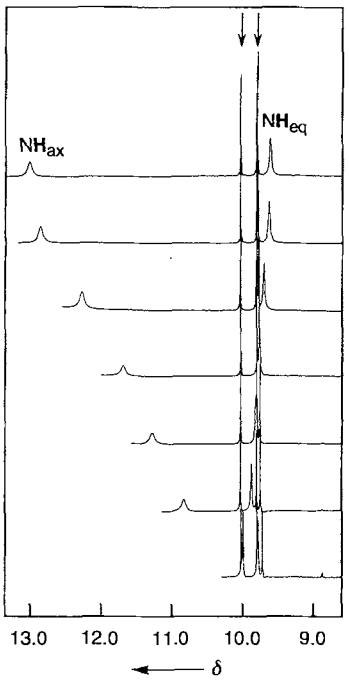

Figure 2. Selected ^{1}H NMR spectra of **1** (3.63 mM) in the presence of 0.00, 1.39, 2.08, 2.77, 4.16, 7.62, and 13.9 mM (bottom to top) tetrabutylammonium benzoate in [D_6]DMSO. The spectral range captures the signals of the amidinium protons internal (NH_{ax}) and external (NH_{eq}) to the salt bridge interface and the three *meso* protons of the porphyrin ring (indicated by arrows).

resulting from the association of the Ni^{II} porphyrin to benzoate ions in [D_6]DMSO. The chemical shift of the *meso* proton adjacent to the amidinium group at $\delta = 10.0$, and the nearly coincident singlets of two distal *meso* protons (indicated by the arrows) at $\delta = 9.8$, do not vary with addition of benzoate, indicating that π-stacking is not an important association mechanism (the *meso* protons are a sensitive measure of π-stacking in porphyrin systems[15]). As observed previously for the bicyclic guanidinium–carboxylate salt bridge,[12] a signature of salt bridge formation is the concentration-dependent downfield shift of amidinium protons involved in hydrogen bonding (NH_{ax} varies by more than 4 ppm) to carboxylate and the insensitivity of the chemical shift ($\delta < 0.5$) for the amidinium protons external to the salt bridge (NH_{eq}). A linear least-squares fit of chemical shift of the hydrogen-bonded amidinium protons vs. the carboxylate concentration, as described by Wilcox,[16] yields an association constant (K_a) of 1550(9) M^{-1} for **1**·benzoate in DMSO. A 1:1 stoichiometry of the complex is established by a Job's plot[17] of the ^{1}H NMR titration data, which shows that the optimal formation of **1**·benzoate occurs at equimolar concentrations of the amidinium and carboxylate (that is, 0.5 mole fraction). The exceptionally high association of the salt bridge accords well with Jorgensen's classification for two favorable secondary interactions that compose the hydrogen bonded interface,[18] bolstered by the stabilization imparted by the molecular recognition of the negatively charged carboxylate by the positively charged amidinium groups. When the benzoate ion is replaced by the well-known electron acceptor 3,5-dinitrobenzoate (3,5-DNBCOO$^-$), similar behavior is observed. The chemical shifts of the *meso* protons ($\delta = 9.72$) and NH_{eq} ($\delta = 9.96$) exhibit an insignificant shift upon 3,5-DNBCOO$^-$ addition ($\Delta\delta < 0.1$ over 12 mM), while NH_{ax} varies by 2 ppm over the same concentration range. However, we observe a smaller K_a of 267 M^{-1}, which is consistent with a decreased basicity of the carboxylate group conferred by the electron-withdrawing nitro groups, which results in a weaker hydrogen bonding interaction.

In less polar solvents the association constant greatly increases. Indeed the binding in CH_2Cl_2 is so high that the association can conveniently be followed by absorption spectroscopy. The Soret and Q-bands of the porphyrin undergo a blue shift immediately upon association of **1** to the carboxylate ion (λ_{max}(**1**) = 406, 530, 574 nm; λ_{max} (**1**·benzoate) = 403, 525, 570 nm; λ_{max} (**1**·3,5-DNBCOO$^-$) = 404, 526, 571 nm). Benesi–Hildebrand fits of these shifts in the absorption maxima with added carboxylate yields K_a of $5.7(11) \times 10^6$ M^{-1} and $7.7(11) \times 10^5$ M^{-1}. As above, the electron-withdrawing nitro groups engender a smaller association constant.

The perturbation of the absorption profile upon salt-bridge formation suggests that the interface is strongly coupled to the porphyrinic chromophore and correspondingly to the electron transfer pathway. When Ni^{II} is replaced by Zn^{II}, the amidinium porphyrin exhibits luminescence, which decays monoexponentially with a lifetime of 1.5 ns (λ_{exc} = 588 nm, λ_{det} = 620 nm) for **2**·benzoate in CH_2Cl_2 at 25 °C. Replacement of the benzoate ion by the 3,5-DNBCOO$^-$ ion results in luminescence quenching, and a unimolecular rate constant of 6.4×10^7 s^{-1} is calculated from the decay kinetics. This observation is consistent with electron transfer from the singlet excited state of **2** to 3,5-DNBCOO$^-$ mediated by the amidinium–carboxylate salt bridge. The electron transfer rate constant for **2** is considerably smaller than that of covalently linked Zn^{II} porphyrin donor–acceptor systems. For instance, an electron transfer rate constant of $k = 3 \times 10^{10}$ s^{-1} is interpolated from Wasielewski's data on Zn^{II}porphyrin-L-quinone (L = rigid polycyclic spacer) systems at driving forces equivalent to **2** ($\Delta G = -0.30$ eV).[19] This considerably faster rate of the covalently tethered donor–acceptor system is further augmented by its longer electron transfer distance (edge-to-edge distance: Zn^{II}porphyrin-L-quinone = 10.5 Å; **2** 7.0 Å) and hence weaker electronic coupling.

The dramatic attenuation in the electron transfer rate constant through the salt bridge may have several origins. First, the electron transfer is in the direction of the permanent dipole of the salt bridge. The presence of an internal electric field contained within the electron transfer pathway will alter the driving force of reaction relative to the isolated constituents.[20] Second, the charge shift of the electron will be stabilized by an accompanying proton shift within the salt bridge. PCET through a salt bridge therefore includes Franck–Condon factors arising from the charge shift of the electron *and* the proton coupling to the polarization of the surrounding environment.[21] Finally, differences in H-bonding strengths of the asymmetric interfaces are manifested in differences in electronic coupling efficiencies.[22] The studies reported herein thus show that salt bridges can be used to form electron transfer networks by self-assembly, and as a constituent of the electron transfer pathway, the salt bridge can profoundly affect the rate of electron transport.

[14] The structure consists of the packing of two crystallographically independent molecular complexes, one of which is shown in Figure 1. While the overall features of the two are similar (for example, hydrogen bond lengths in the second complex: 1.854(6) and 1.838(6) Å), the amidinium group of the second complex rotates 61.8° out of the porphyrin plane, and the salt bridge interface is more twisted (25.9° between the CN_2 and the carboxylate planes). Such variabilities in the solid state accentuate the high degree of rotational freedom of the salt bridge that is surely present in the solution phase.

Medicine, Membranes, and Mechanisms

Medicinal Chemistry: Today and Tomorrow. Proceedings of the AFMC Int. Medicinal Chemistry Symposium. Edited by *M. Yamakazi*. Blackwell Science, Oxford, 1996. 278 pp., hardcover £ 49.50.—ISBN 0-632-04272-9

This book contains the texts of 41 papers by industrial and academic scientists that were presented at the AFMC International Medicinal Chemistry Symposium (AIMECS 95) in Tokyo in September 1995, under the auspices of the Pharmaceutical Society of Japan. These short papers (typically 4–6 pages) touch on practically all general aspects of modern research in medicinal chemistry with relevant examples, although unfortunately they are not grouped under subject areas.

Several contributions are concerned with the isolation and characterization of biologically active natural products from various sources such as marine organisms or tropical plants, and of microbial metabolites and biologically active constituents of traditional Chinese medicines. Some of these articles also describe syntheses of natural products and their analogs. This leads into a further group of papers dealing specifically with the synthesis of biologically active natural products (e.g., inositol phosphates, brevetoxin, oligosaccharides) and with more general methods such as those that are being developed for achieving enantioselective reactions. The prospects for developing these into industrial processes based on conventional chemistry or biocatalytic reactions are discussed in relation to specific medical indications or targets. These include AIDS, diabetes, receptors for glutamates, for opiates, for angiotensin II, for prostanoids, for endothelin, and for kainates, as well as renin and DNA-gyrase inhibitors. These articles also contain sections on combinatorial synthesis and molecular diversity, on drug design and drug metabolism, polymer-bound pharmaceutical agents, drug delivery systems, and new strategies for increasing the membrane permeability of peptides.

Another group of articles is concerned with biological processes and proteins that could serve as starting points for developing new or improved therapies. These include, for example, cytokin and integrin receptors, apoptosis, the regulation of gene expression, the role of sphingoglycolipids in signal transduction, and the modulation of carbohydrates in the expression of recombinant glycoprotein therapeutic agents.

The symposium also served as a forum for official bodies: the European Commission, the United States FDA, and the Japanese Health Ministry each provided a representative to offer guidelines for the development of "orphan drugs", that is, drugs for the treatment of comparatively rare conditions, the development of which tends to be neglected on economic grounds.

This symposium report contains papers on a wide range of topics, giving it considerable variety and interest. The excellent choice of topics and presenters demonstrates the organizers' keen awareness of the latest research trends in this field. Many aspects of modern medicinal chemistry are included, but I regret that some important ones are absent, for example tumor suppressors, kinase inhibitors, and SH2 and SH3 domains. However, that is not a serious criticism. A symposium such as this one, dealing with a rapidly developing field of research, can only offer a snapshot of the current state of knowledge and development. Future snapshots will, by their very nature, emphasize different topics of special interest at the time. In accordance with its character as a symposium report, this book is mainly suitable for specialists in the field, rather than for nonspecialists who may have an interest in the subject but no close familiarity with it. It will be read with particular interest by pharmaceutical chemists seeking the latest information about developments in their area of work, and will also provide useful reading for natural products chemists and synthetic chemists, and for biologists who wish to learn whether their research is of possible relevance for medicinal chemistry, or to enrich their lectures or publications by including interdisciplinary aspects.

Basic Principles of Membrane Technology. (Second edition). By *M. Mulder*. Kluwer, Dordrecht, 1996. 564 pp., hardcover £ 174.00.—ISBN 0-7923-4247-X

"If you are tired of membranes, you are tired of life". This remark by Richard Bowen, cited in the preface of the book by M. Mulder, highlights the importance of membranes and their functions for the living cell. The ability of membranes to function as highly selective barriers is also used in industrial processes. Examples are simple particle filtration, ultrafiltration for the retention of macromolecules, or the recovery of solvents from the gas phase. This book, now available in its second edition, gives an exhaustive overview of existing membrane processes and describes the necessary fundamentals. The book is well structured and easy to understand. The figures are clear and informative. Compared to the first edition the number of pages has been increased by 200. There are three reasons for this: i) to cover recent developments new chapters have been added, for example, those on nanofiltration and membrane reactors; ii) the line spacing has been increased, resulting in better readability and clarity; iii) 80 pages with problems and solutions have been added, which is the most appealing aspect of the second edition. These exercise problems relate to the principles covered in the text. Examples are simple calculations for the design of membrane modules, considerations for the selection of suitable membranes, and more com-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

plex calculations of the transport through a membrane using different models. Examples based on everyday problems are also included: "How long will it take before a bicycle tire is flat?", or "What is the principle behind the function of Gore-tex® or Sympatex® membranes?"

The book is divided into eight chapters, varying in length between 20 and 130 pages. Each chapter has its own literature references and problems. Only a few references are from 1995, most of them are older. Here some more recent data would have been useful, including selected examples of applications of membrane processes. Some interesting examples can be found in the problems, but these are not covered by the index.

The first chapter describes the historical development and provides the basic definitions. Chapter 2 summarizes membrane materials, and Chapter 3 gives an introduction to membrane production. In Chapter 4 methods for the characterization of membranes are described. Chapter 5 summarizes different models used to describe transport through membranes. These five chapters form the first part of the book.

The second part begins with Chapter 6 which is the longest in the book (130 pages). Here various membrane processes are described, such as particle filtration, ultrafiltration, pervaporation, membrane contactors or electrodialysis, classified according to their driving forces. There is also a short section dealing with membrane reactors. Chapter 7 discusses the problem of membrane fouling. Finally, Chapter 8 describes different types of membrane modules including guidelines for their design.

To summarize, this is an excellent textbook and reference source for everyone working with membrane processes. It also gives valuable advice for the reader who has a separation problem and is looking for new approaches to solving it. But it requires careful reading—there is no 'quick solution'. Here the limited number of applications described restricts the book's usefulness. The index contains some errors: bipolar membranes can be found on page 390, not on page 277. There is no index of membrane suppliers. But a search in the Internet using the keyword 'membrane' reveals enough helpful information.

It is to be hoped that this book will be read by scientists from a range of disciplines, not solely by process engineers. However, the high price may be an obstacle to its wide distribution. Difficulties in the filtration of precipitates or the desalting of samples are typical of everyday problems that might be solved easily using appropriate membrane processes.

By the way: a bicycle tire is entirely flat after 169 days.

An Introduction to Enzyme and Coenzyme Chemistry. By *T. Bugg*. Blackwell Science, Oxford, 1997. 247 pp., softcover, £ 19.95.—ISBN 0-86542-793-3

In this book the author, Tim Bugg, has succeeded well in his aim of writing an introduction to the modes of action of enzymes and coenzymes from the standpoint of organic chemistry, and of explaining the underlying mechanisms. Concisely and in clearly understandable language, the book also provides the reader with much valuable background knowledge, which is not available elsewhere in so compact a form.

The structure of the book is well suited for such an introduction. First, in a general overview, the reader learns a little about enzyme kinetics and enzymatic reactions in general. The different types of reactions are then introduced in turn, plentifully illustrated with the help of many two-color formula schemes: hydrolytic and group transfer reactions, redox enzyme reactions, carbon–carbon bond-forming reactions, addition and elimination reactions, transformations of amino acids, and isomerase reactions. Lastly there is a chapter on nonenzymatic catalysis. A short appendix contains answers to the questions and exercises that are given at the end of each chapter.

We consider this book to be very suitable for use by students as an introduction to the various aspects of enzymatic reactions and the role of coenzymes. However, our very favorable impression on first glancing through it was modified to some extent on closer examination, as there are a number of errors that suggest a lack of care in proofreading (see the examples below). The reader already familiar with the subject would perhaps not be troubled by these, but it is especially important that the student using the book as a first introduction should be able to rely on consistent accuracy in both text and figures.

The fact that 21 proteinogenic amino acids are now known, together with their corresponding codons, should nowadays be part of every student's basic knowledge. However, it seems quite unnecessary to repeat at several places the explanation of the three-letter symbols for amino acids in the text and in the figures. The role of chaperones as "helpers" in the folding of many proteins should at least have been briefly mentioned, to avoid giving the impression that folding always occurs spontaneously (p. 12). The formula schemes do not always accurately identify all the compounds involved; it is essential to check in each case to ensure that all the reactants are shown, as the reader is likely to be confused if there are omissions. The definitions of specificity and selectivity on pages 26 and 27 do not agree with those usually found in textbooks of biochemistry and in original publications; for example, substrate specificity is normally taken to mean the selectivity of an enzyme with regard to the substrate that is converted.

A few printing errors need to be corrected in a subsequent edition of the book. In addition, however, there are numerous other mistakes and points that invite criticism, as shown by the following list:

page 4: "Many of the vitamins are in fact coenzymes ...";

page 8: the stereochemistry of the side-chain in threonine is shown wrongly (*S* instead of *R*);

pages 9 ff: the names for nucleobases, nucleosides, and nucleotides are not always used correctly;

page 16: hemoglobin is said to consist of identical subunits;

the determination of the structure of lysozyme by X-ray crystallography was the first achieved for an enzyme, not for a protein;

the statement that the active center is usually in a hydrophilic environment is over-simplified; the situation is described correctly two pages later;

page 17: the definitions of H-donors and H-acceptors given here are not the usual ones;

page 46: in giving the specific activity the protein concentration is referred to, whereas this should instead be the protein mass;

page 51: in the legend to Figure 4.5 the symbol *V* should instead be *v*;

page 66: in the first paragraph C-2 should be C-4;

page 69: the appendix does not give a solution to Problem 3;

page 87: transesterification is incorrectly printed as "*trans*-esterification", which is likely to confuse (one wonders what *cis*-esterification might mean!);

page 114: in mentioning cytochromes reference is made to Table 6.1, but the word

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3619-2130 $ 17.50+.50/0

cytochrome does not appear in the table as such, nor does it in the index;
page 229: in the statement "... the C-1 centre is designated as *S*", *R* should appear instead.

NMR of Polymers. By *F. A. Bovey* and *P. A. Mireau*. Academic Press, San Diego, 1996. 459 pp., hardcover $ 85.00.—ISBN 0-12-119765-4

The declared aim of this book is to provide an overview of the applications of NMR spectroscopy to polymer characterization. Frank A. Bovey and Peter A. Mireau have succeeded well in their objective. Naturally, in view of the enormous growth in the scope of this field, such an overview cannot cover every aspect of the current situation, and the authors make this clear in their preface. Rather than attempting an exhaustive treatment, they have set out to illustrate the range of problems in the polymer sciences that can be solved using NMR spectroscopy. The particular strength of the book lies in the adoption of this approach.

Chapter 1 explains the basic principles of nuclear magnetic resonance at a level understandable by the nonspecialist. The authors provide a good introduction to the subject, with a very broad choice of material forming a grounding in the subject that is suitable for an interdisciplinary readership. Thus we find, for example, a drawing of a cross-section through a superconducting magnet, a description of the frequency spectrum responsible for magnetic relaxation, and detailed tables of chemical shifts. A possible criticism is that some of the figures are very basic and lacking in detail, and contribute little to the reader's understanding. This applies, for example, to Figure 1.5 showing the separation of the alternating magnetic field into two counterrotating components, and Figure 1.15 illustrating the origin of the quadrupolar interaction. A necessarily brief introduction such as this cannot, of course, be expected to give the newcomer a real working knowledge. Accordingly, the later discussions of specific technique areas such as solid-state NMR spectroscopy or two-dimensional NMR methods are similarly limited to describing the most important pulse sequences and the interpretation of the resulting spectra.

Chapter 2 begins with a brief and lucid explanation of the different types of constitutional and configurational isomerism of polymers. The authors then deal with the various statistical models used to derive the sequence frequencies of the polymer chains resulting from different growth mechanisms.

In Chapter 3 the reader learns how one can determine the constitution and configuration of a polymer using high-resolution liquid-state NMR spectroscopy. This chapter achieves its purpose very well by using a large number of examples to illustrate how NMR spectroscopy can be used. These begin with regioisomerism in polythiophenes, and progress to problems such as solvent association in solutions of polymethylmethacrylate and polyvinylchloride. The reader's understanding is greatly helped by the frequent explanations of how one goes about predicting the characteristic chemical shift for a given structural element, using aids such as incremental rules, synthesizing model compounds, or recording multidimensional spectra. The authors offer many helpful hints on experimental aspects; for example, they point out that the chemical shifts of methyl groups are especially sensitive to solvent effects.

Chapters 4 and 5 contain a very wide-ranging description of the capabilities of solid-state NMR spectroscopy applied to polymers. For example, the authors explain how the chain conformations of the most important technical polymers can be deduced from features in their ^{13}C NMR spectra, how one can study long-range structures using a great variety of NMR techniques, how the molecular mobilities of the individual constituents in polymer blends can be investigated, etc., etc. The treatment is very up-to-date, as shown, for example, by the fact that a large proportion of the book is devoted to multidimensional methods. The work is rounded off by a very informative chapter on applications of NMR imaging.

The authors have been astute in their choice of topics for inclusion in these chapters. I noticed one error that has crept in: in Figure 5.1 showing the spectral density for relaxation processes, the extreme cases of very slow and very fast relaxation have been interchanged, and are opposite to those in Figure 1.8.

Which readers are most likely to benefit from this book? It does not give enough background on NMR fundamentals to enable a newcomer to the field to make effective use of the methods described. On the other hand, experienced NMR users will find nothing new here about techniques, although it may be useful in filling gaps in their knowledge of the literature. Probably those most likely to find the book useful are postgraduate students and research scientists who have a special interest in polymer science and are already familiar with NMR methods. It will make them aware of the wide variety of problems that can be investigated using NMR spectroscopy, and will bridge the gaps in their knowledge to enable them to use the techniques effectively. For these readers the outlay of $ 85.00 should prove both worthwhile and profitable.

Introduction to Medicinal Chemistry. How Drugs Act and Why. By *A. Gringauz*. WILEY-VCH, Weinheim, 1997. 721 pp., hardcover, DM 109.00.—ISBN 0-471-18545-0

Compared to the situation in other countries, the facilities for teaching medicinal chemistry in German universities, as an optional extra subject for students of organic or pharmaceutical chemistry, are somewhat rudimentary, despite the fact that many graduates hope to find work in pharmaceutical research. It is not surprising, therefore, that whereas the classical disciplines of chemistry are served by a few good quality works for each level of study, which have become established as standard textbooks, it is difficult to identify corresponding books in the area of medicinal chemistry. Alex Gringauz, the author of the book reviewed here, explains that it is intended for students of pharmaceutical and medicinal chemistry, and aims to provide an introductory overview of this specialized area of biomedical research, which is of steadily growing importance. It contains 15 self-contained chapters, the first three of which introduce the reader to the most important concepts of the molecular mechanisms involved in the activity of pharmaceutical agents. These chapters, occupying about 90 pages, explain the principles of the molecular interactions between low molecular weight compounds and macromolecular target systems, and discuss the various types of metabolic breakdown reactions undergone by medicinal compounds in the biochemical context. Unfortunately, however, the stereochemical aspects which are of such importance for pharmaceutical research are only touched on briefly.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3619-2131 $ 17.50+.50/0

After these introductory chapters the monograph becomes an encyclopedia-like collection of data, arranged according to the clinical conditions that the therapeutic substances are designed to treat. However, this arrangement of the subject matter is contrary to what one might expect in a modern textbook, as it does not correspond to current practice in pharmaceutical research. Instead we find a rather antiquated juxtaposition of often unrelated types of compounds under the following headings: agents for cancer therapy, analgesics, anti-inflammatory agents, antibiotics (two chapters consisting of 140 pages), cholinergic and adrenergic agents, cardiovascular drugs (two chapters), psychotherapeutic drugs, antihistamines, and steroids. The final chapter, entitled "New Developments and New Problems", occupies a mere twelve pages. Consequently it contains only very brief treatments of gene therapy, drug resistance, antisense technology, cytokins, and the applications of computers in pharmaceutical research.

Unfortunately, this attempt to convey the essence of pharmaceutical research fails so badly that it belongs to that generation of textbooks which cannot meet the standard of a modern works capable of motivating students. Some important aspects of this field of research are not covered at all, such as the concept of searching for lead structures and subsequent optimization, the study of structure–activity relationships in the context of the targeted receptor or enzyme, the importance of combinatorial chemistry in conjunction with high-throughput screening, and the topic of peptide mimetics, which has undergone a renaissance in the last few years. These are just a few of the topics that currently occupy organic chemists engaged in pharmaceutical research, and in relation to which this book can offer no help at all.

On a more positive note, the book deals with each of the above listed types of clinical conditions against the background of the physiological processes involved, with a wealth of detailed medical information. However, the standard of production, especially with regard to graphical layout, is much inferior to that normally found in the chemical literature. For example, the structural formulas are not numbered consecutively, and are generally of such poor quality that it is often difficult to distinguish between single and multiple bonds. Moreover, stereogenic centers are simply ignored, the orientations of substituents (e.g., in perspective representations of cyclohexane rings) are shown in ways that are very confusing and contrary to all the usual conventions, and the mechanisms of organic reactions are misrepresented to such an extent that even the experienced synthetic chemist will have difficulty in deciphering the relationship between educts and products. Here one begins to doubt whether the manuscript was ever subjected to copy-editing. It is not unusual in this book to come across hypervalent atomic centers in the structural formulas; pentavalent carbon atoms or tetravalent (neutral) nitrogen atoms are by no means rare. In the list of contents one occasionally finds a question mark instead of a page number. The overall appearance of the book in its chemical parts is more like a hastily prepared lecture manuscript than a modern textbook, and the reader will be amazed that it has been put onto the market at all in this state. When compared with other textbooks on medicinal chemistry that are currently available, such as those by R. B. Silverman or by H.-J. Böhm, G. Klebe, and H. Kubinyi, the book reviewed here cannot be recommended, either to students or to working chemists. In any case, it does not really convey the impression of a textbook intended for students; it is at best only suitable as a reference source for use by the scientist who occasionally needs information about some aspect of medicinal chemistry. Perhaps it would be fair to say, in conclusion, that Alex Gringauz's *Introduction to Medicinal Chemistry* will find few friends in the books market in view of the competition from genuine modern textbooks.

Gerhard Müller
Bayer AG, Leverkusen (Germany)

Spectra Interpretation of Organic Compounds. (Series: Spectroscopic Techniques. An Interactive Course.) By *E. Pretsch* and *J. T. Clerc*. WILEY-VCH, Weinheim, 1997. xiii, 175 pp., hardcover DM 128.00.—ISBN 3-527-28826-0

Spectroscopy is often seen by synthetic chemists as having a rather low status. It is only a slight exaggeration to say that spectroscopy is sometimes regarded as a necessary evil that one has to accept in order to meet the minimum requirements for characterizing a reaction product. Therefore it is hardly surprising that in many university chemistry departments the teaching of spectroscopy is undertaken by a lecturer for whom it is only a peripheral subject, and the students undergo an obligatory course of a minimal standard, from which they gain only a rudimentary knowledge. As a result of the low priority afforded to it, spectroscopy comes to be treated as a rather insignificant little wallflower bordering the main garden of preparative chemistry. Consequently the chemistry graduate who then moves into an industrial environment regards analysis as an overhead cost that should be minimized, so that there is a tendency, on the grounds of economy, to turn a blind eye to poor standards of analysis. Synthetic work that is not backed up by high quality analysis is worthless, and this fact is likely to be understood by the student who has learned to evaluate the capabilities of the various analytical methods. Any learning tool with the potential for helping to achieve that must be welcomed. This book by Pretsch and Clerc is the first volume in a new series from Wiley-VCH with the general title *Spectroscopic Techniques: An Interactive Course*.

The book is intended to be used as a self-study course. Its main part consists of 15 chapters, each of which is devoted to a particular compound whose structure is to be determined. These are moderately difficult exercises, with a gentle trend towards increasing difficulty in the later chapters.

Each chapter begins by showing a mass spectrum (produced by electron impact ionization), an IR spectrum (always of a solution in chloroform), a proton NMR spectrum (usually at 400 MHz, with expansions of the multiplets), and ^{13}C NMR spectra under different conditions (a normal spectrum together with DEPT-135 and DEPT-90 spectra for determining the degree of substitution). UV/vis spectral data are also given in three of the exercises, and in three other cases NMR spectra obtained in different solvents are shown.

In each case the above listed spectra are followed by a section explaining how the empirical formula can be determined from the spectroscopic data (without access to an elemental analysis or to a high-resolution mass spectrum), and how one can identify the characteristic structural groups of the unknown compound. Next it is shown how the partial structures thus obtained may be fitted together to give the required molecular structure, and how one can distinguish between possible isomeric structures. Here, however, the authors must be criticized for failing to mention the existence of two-dimensional and multidimensional NMR spectra. Surely nowadays there can hardly remain any laboratories where the structural analysis of organic compounds is carried out without the help of 2D NMR spectra! Would

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3619-2132 $ 17.50+.50/0

anyone now contemplate managing without these very informative techniques? Pretsch and Clerc do not mention 2D NMR anywhere in their book, nor do they show any H,H-COSY, H,C-HMQC, or related types of spectra.

Each chapter ends with a section headed "Comments", usually quite long, in which the authors draw attention to special points that are illustrated by the compound concerned in relation to the various spectroscopic methods. Thus, for example, they explain why a molecule containing no nitrogen can sometimes give a mass spectrum that is dominated by fragments of even-numbered mass, or why a ^{13}C spectrum recorded under the DEPT-90 conditions may contain residual signals from carbon nuclei other than those of CH fragments. Although these points only emerge at the stage where the solution to the structural problem is being discussed, the reader cannot afford to ignore them, as they include a wealth of useful information, and are in my opinion the most valuable part of the text.

The 15 exercises are followed by three short chapters headed "Additional Remarks", dealing in turn with mass spectrometry (6 pp.), infrared spectroscopy (4 pp.), and NMR spectroscopy (14 pp.). These chapters give details of the conditions under which the spectra were recorded, and some general advice about using each of the spectroscopic methods. The advice offered is certainly useful, but the notes are too brief to be really adequate, and they are not a substitute for consulting more detailed textbooks. The book ends with two further chapters, one on the SpecTool computer program (see below) and the other introducing the reader to the formula generating program ChemWindow, which allows the user to input structures to SpecTool.

The most noteworthy feature of the book, which distinguishes it from other works with a similar purpose, is the combination with a CD-ROM containing a demo version ("teaching version") of the SpecTool program together with all the spectra belonging to Chapters 1–15. The software allows one to display the spectra on the PC monitor screen and expand them at will, so that chemical shifts or wavenumbers can be read off easily and precisely. Installing the program was simple and straightforward, and it performed satisfactorily with both Windows 3.11 and Windows 95. SpecTool in its full version is a good program, and is worthy of a separate review in its own right. It contains reference data, auxiliary programms ("tools"), and examples of actual spectra for each of the above spectroscopic methods. A feature deserving special mention is the suite of methods developed by Pretsch and colleagues, which identify the key partial structures within any structural formula that is fed in, and then apply appropriate incremental relationships to estimate the ^{1}H and ^{13}C chemical shifts.

In the text of the book, whenever a problem occurs for which SpecTool contains a useful function that should help in arriving at a solution, the reader is advised of this and of how to use it. Thus, in working through the exercises, one also becomes familiar with the use of the program. However, the user may be rather disappointed with the demo version of SpecTool supplied here, as it only contains a limited selection of spectral data, namely those that are relevant to the compounds mentioned in the book (and not always all of those: for example it does not give ^{13}C NMR data for lactones, which are needed for Chapter 1). Also the chemical shift estimation works only for the examples treated in the book.

When first trying out the system I initially thought that there must be a programming error, because data or spectra displayed on the monitor screen remained for only a few tenths of a second before they were hidden by a window carrying an advertisement ("Other books in this series: ..."). However, I felt cheated on realizing that there is method in this device, which ensures that for this price one receives only a limited version. Such a sales ploy is perhaps understandable, but could it not have been handled in a more acceptable way? For example, the publishers might have offered a deal whereby one could buy the book and a full version of the program together at a special reduced price. In any case, the extravagant promise of "powerful software tools and data" on the book's cover led me to expect more than this.

The standard of production of the book is excellent, with a sturdy binding and clear type and figures. However, the CD-ROM which is supplied in a plastic sleeve attached within the book is not easy to remove without destroying the sleeve or risking scratching the disk itself. Also, the practice here of listing the chemical shifts in ^{13}C NMR spectra with four digits after the decimal point is not sensible, as the implied precision is illusory.

To sum up, the concept underlying this combined book and CD-ROM is an excellent one, and apart from the failure to cover 2D NMR spectroscopy the result is very good. The package should serve effectively to familiarize the user with the spectroscopic methods that are important in the structural analysis of organic compounds. However, the prospective buyer needs to be warned about the limitations of the facilities provided by the software, lest there should be any suggestion of deception.

Hormones were the first growth factors that were discovered to be involuntary helpers of cancer.

Both the peptidic derivatives that are already employed clinically and new peptidomimetics, as well as the growing understanding of the three-dimensional structure of the receptor, fuel the expectation of a new generation of clinically active LHRH antagonists.

Chemistry and Molecular Biology in the Search for New LHRH Antagonists

Bernhard Kutscher,* Michael Bernd, Thomas Beckers, Emmanuel E. Polymeropoulos, and Jürgen Engel

Dedicated to Professor Heribert Offermanns on the occasion of his 60th birthday

Hormones—and in particular, the sex hormones—were the first growth factors discovered to be involuntary helpers of cancer. Female breast cancer and male prostate cancer are the best known examples of tumors acknowledged to be hormone-dependent. A look at cancer statistics shows that breast cancer is still the most frequent cancer in women; in men, prostate cancer plays a similarly dominant role with increasing age. Shutting down the main production site of the sex hormones estrogen and testosterone either by removing the ovaries or by castration is a well-known and often effective therapy; however, these procedures can be problematic due to the concomittant psychological stress. Modern hormone therapy for advanced breast cancer and prostate cancer attempts to spare the patient such irreversible operative procedures for as long as possible, by using hormone antagonists, such as the LHRH antagonists, which hinder deployment of the hormone itself and thus its growth-promoting activity.

1. Introduction

The releasing hormone, gonadorelin (GnRH, synonymous with LHRH, luteinizing hormone-releasing hormone or gonadoliberin), together with its specific receptor, plays a central role in neuroendocrinology.[1] The decapeptide LHRH, discovered by A. V. Schally et al. and R. Guillemin et al.,[2] is formed in the cell bodies of hypothalamic neurons and is secreted in pulses into the blood stream. Ultimately it stimulates secretion of the sex-specific hormones in the testes and ovaries. Intensive research has revealed that specific receptors for LHRH and synthetic analogues are also present in the pituitary gland and other tissues (for example, tumor cells)[3] and organs.

Three concepts for therapeutic application have emerged. The first is the restoration of normal physiology by administration of LHRH by infusion pump to promote fertility in men and women who are infertile due to defective endogenous LHRH secretion. Second, long-lasting LHRH agonists are used in a depot form, which bring about desensitization of the pituitary receptors and thus interrupt the signal cascade. This results in a biochemical "castration", which opens up new therapeutic possibilities for hormone-dependent diseases such as prostate cancer, breast cancer, and endometriosis. Although superagonists are generally well tolerated, they have the disadvantage that hormone secretion (estrogen, testosterone) is initially stimulated before the depletion of receptors or "down" regulation can take place, and thus the illness temporarily worsens.[4] This has led to the development of the third concept: use of LHRH antagonists.[5] At present, about 5000 LHRH analogues have been synthesized worldwide and tested in vitro or in vivo.[6a–c] Whilst LHRH agonists have been on the market for about ten years (see Section 2), the LHRH antagonists that have been developed furthest are still in clinical testing (Figure 1).[7]

Complemetary to the reviews on LHRH agonists and antagonists which are already available,[8-10] this contribution covers not only the current developments in synthesis, but in addition, the establishment of the human receptor for specific characterization of substances, and presents methods and progress in the search for, and development of, peptidomimetics.

2. LHRH Peptides as Therapeutic Agents

2.1. Agonists

The first years after the discovery of the gondarelins were marked by the search for more active agonists, since their therapeutic potential as, for example, antitumor agents or in gynecology, was apparent.[5, 11] Such "superagonists" bring about a very effective reversible inhibition of the release of steriodal sex hormones. The exchange of glycine[6] of the native LHRH for other, always D-configured, amino acids, is common to all modern superagonists; some have a C-terminal ethylamide (buserelin, leuprorelin) or azaglycinamide (goserelin) residue instead of glycinamide. Eight to ten amino acids of the LHRH sequence are conserved in all clinically relevant superagonists; by exchange at a maximum of two positions, the biological activity, or hormone suppression in tumor patients, can be increased by a factor of up to 100 on subcutaneous application.[5, 11, 12] Table 1 summarizes the most important derivatives currently on the market.

Buserelin^{INN} (Profact, Suprecur), leuprorelin^{INN} (Carcinil, Enatone), triporelin^{INN} (Decapeptyl) and goserelin^{INN} (Zoladex) (trade names in Germany) are the products on the market with the highest turnover; worldwide, a turnover of about two billion

M. Bernd B. Kutscher J. Engel T. Beckers E. E. Polymeropoulos

Bernhard Kutscher, born in 1957, completed his chemistry studies in 1984 at the Universität Frankfurt (Germany) with a doctorate under the supervision of Prof. H. Kessler in the field of peptide synthesis. He then joined Degussa as laboratory manager (Laborleiter) in the research department "Pharmazeutische Chemie". Since 1987 he has headed the Department "Chemische Forschung Wirkstoffe" of ASTA Medica. Today he is responsible for the Department "Chemische Forschung". In 1992 he was appointed lecturer at the Technische Universität München and became Honorary Professor there in 1996. His fields of research include the synthesis of peptides, phospholipids and heterocycles, automation of synthesis, and combinatorial chemistry.

Michael Bernd, born in 1954, completed his doctorate in Chemistry with Professor H. Kessler at the Universität Frankfurt in 1983. In 1984 he became Laborleiter in the Department "Organische Forschung" of Degussa and in 1989 moved to ASTA Medica where he is responsible for peptide synthesis in the Department "Chemische Forschung Tumor".

Thomas Beckers, born in 1961, studied Biology specializing in Biochemistry at the Universität Frankfurt. His diploma was completed at the Max-Planck-Institut für Biophysik in Frankfurt. After graduating with a doctorate under Prof. J. Engels, Institut für Organische Chemie, Universität Frankfurt, in the field of Molecular Biology and a postdoctorate at the Massachusetts General Hospital/Harvard Medical School in the research group of Dr. B. Seed, Boston (USA), he joined the department for cancer research at ASTA Medica in the field of tumor research.

Emmanuel E. Polymeropoulos, born in Athens in 1943, obtained his doctorate in Physical Chemistry from Rutgers University, New Jersey (USA). From 1974 to 1980 he was scientific assistant in the research group of Prof. H. Kuhn at the Max-Planck-Institut für biophysikalische Chemie Göttingen (Germany) and thereafter as scientific assistant in the research group of Prof. J. Brickmann at the Institut für Physikalische Chemie der Technischen Hochschule Darmstadt (Germany) till 1984. After one and a half years at the Department of Physics of the research institute "Demokritos" in Athens he joined ASTA Medica in 1986, where he is responsible for computer applications in the Department "Chemische Forschung".

Jürgen Engel, born in 1945, completed his engineering studies at the Naturwissenschaftlich-technische Akademie in Isny (Germany) and began his studies in Chemistry at the Technische Hochschule Braunschweig (Germany) in 1969. He ended these studies in 1979 with a doctorate at the Institut für Organische Chemie der Universität Braunschweig with Prof. H. H. Inhoffen. From 1976 to 1981 he was Laborleiter in the Department "Chemische Forschung Wirkstoffe" at ASTA Medica, in 1981 head of research coordination, and in addition was promoted to head of the "Chemische Forschung Wirkstoffe" in 1982. Since 1981 he has given a series of lectures at the Universität Regensburg, where he completed his habilitation in 1985, and became Professor in 1990. In May 1993 he was appointed Honorary Professor at the Universität Dresden. Since 1996 he has been chairman of the Fachgruppe Medizinische Chemie of the Gesellschaft Deutscher Chemiker.

Table 1. Structure of LHRH, and the LHRH agonists on the market (given are only those amino acid residues that are different in LHRH).

Name (Co.)	Structure									
	1	2	3	4	5	6	7	8	9	10
LHRH	Glp[a]	His	Trp	Ser	Tyr	Gly	Leu	Arg	Pro	Gly-NH_2
Buserelin (Hoechst)						D-Ser(*t*Bu)				Gly-NHEt
Nafarelin (Syntex)						D-(2)Nal				
Leuprorelin (Abbott, Takeda)						D-Leu				Gly-NHEt
Goserelin (Zeneca)						D-Ser(*t*Bu)				Azagly-NH_2
Histrelin (Ortho)						D-His(Bzl)				Gly-NHEt
Triptorelin (Ferring)						D-Trp				

[a] Glp = pyroglutamic acid.

German marks with active compound formulations corresponding to these peptides was achieved in 1994; of this, over half belonged to the firms Abbott and Takeda with leuprorelin. A total market volume of about 2.4 billion German marks across all indications is expected at the end of the century.[12b]

Annual production of peptide pharmaceuticals is of the magnitude of less than 100 kg for buserelin and significantly over 100 kg for the market leader, leuprorelin. At this order of magnitude, these substances are only made by classical organic preparative synthesis (fragment condensation in solution). The firm Hoechst, for example, synthesizes the nonapeptide buserelin from the units Glp-His, Trp-Ser-Tyr, and D-Ser(*t*Bu)-Leu-Arg-Pro-NHEt; the tri- and tetrapeptide units are coupled to form the corresponding C-terminal heptapeptide, and then the N-terminal dipeptide is condensed with this to form the complete sequence. Control of the physicochemical process parameters, such as concentrations, precipitations, separations, reaction temperature profiles, and purification techniques, is important for successful peptide synthesis on a technical scale, since there is naturally a significant difference to those required for laboratory scale synthesis.[13a]

2.2. Antagonists

Common to the intrinsic activity of all superagonists is the initial temporary stimulation of gonadotrophin release. Soon after the use of highly active agonists became an established therapy, a search began for corresponding antagonists, which do not bring about an initial hormone release, to avoid this therapeutically counterproductive effect. A final big hurdle for clinical use of highly active anatagonists was the inherent anaphylactic potential of these peptides.

Starting from the sequence of native LHRH, the individual positions of the peptide chain were examined in rapid succession for their contribution to biological activity. Particular attention was paid to side effects. The most effective early improvements in antagonistic activity were achieved by using D-Phe^2 instead of histidine, by D-amino acids at position 6 instead of Gly^6, and the exchange of C-terminal glycine for D-Ala^{10}. Further stepwise optimization led to the sequence scheme now usual for all modern antagonists of D-Nal^1-D-Cpa^2-D-Pal^3 (Nal = 2-naphthylalanine, Cpa = Phe(4-Cl), Pal = 3-pyridylalanine) as hydrophobic cluster, plus a D-configured aromatic or aliphatic, yet hydrophilic, aminocarboxylic acid^6, and the C-terminal hydrophilic sequence Xxx^8-Pro^9-D-Ala^{10}, where Xxx is either arginine or isopropyllysine. Excellent documentation of the stepwise optimization can be found in many classical review articles.[14, 15]

Antagonists of the second generation caused formation of temporary edemas of the face and extremities in animal experiments, due in part to massive histamine release by mast cell degranulation. Cyanosis and respiratory impairment were also observed.[16] The cause of these intolerable side effects is thought to be the combination of D-arginine at position 6 with the three aromatic amino acids at the N-terminus of the sequence.[17] For the desired biological antagonist potency, an R-configured basic amino acid is necessary at position 6; A. V. Schally et al. achieved the breakthrough to highly active antagonists free of side effects with the derivatives SB-75 (INN: cetrorelix) and SB-88, by incorporating hydrophilic, nonbasic amino acids with side-chain carbamoyl functions (D-citrulline^6 (D-Cit^6), D-homocitrulline^6).[17]

The biological activity of such sequences that are free of significant anaphylactic potential is limited exclusively to R-configured amino acids at position 6; peptides with L-citrulline^6 are practically inactive in vivo due to rapid enzymatic degradation (Figure 2).[18]

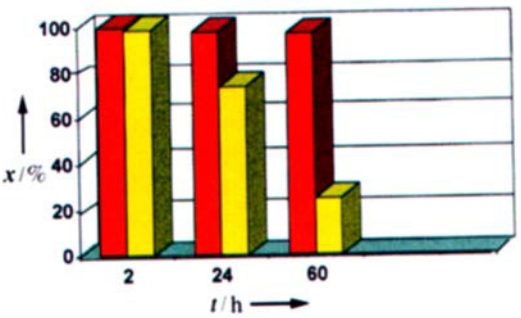

Figure 2. Stability of [D-Cit^6]SB-75 (cetrorelix; red) and [L-Cit^6]SB-75 (yellow) under the influence of human serum (HPLC peptide content x[%] over 60 h).

Today, cetrorelix is manufactured exclusively by classical fragment condensation, on a kilogram scale. Two synthesis strategies, worked out in detail and optimized over several years, proceed via either the N-terminal tripeptide (D-Nal^1-D-Cpa^2-D-Pal^3) or the C-terminal tripeptide (Arg^8-Pro^9-D-Ala^{10}) and the complementary heptapeptide (Ser^4–D-Ala^{10}) or (Nal^1–Leu^7) to the protected decapeptide with *tert*-butyl side-chain protection; the hydrochloric acid deprotection is followed by final purification by preparative HPLC. The C- and N-terminal functionalization of the acetylated decapeptide amide, nec-

essary for biological activity and to avoid rapid enzymatic degradation, is introduced at the level of the terminal tripeptide, by acetylation of the free α-amino group of naphthylalanine[1] with acetylhydroxysuccinimide, or saponification of the resulting alanine methyl ester in alcoholic ammonia.[13b,c]

Folkers et al. were able to improve active antagonists successively by consistent and systematic modifications both at the relevant sequence positions and the side-chain substituents; the most successful were complex substitutions at the positions 5, 6 and, in part, 8. Starting from antide, a highly potent but poorly water-soluble decapeptide with nicotinoyl-substituted lysine[5], or with D-lysine[6] (Scheme 1), the analogues [PicLys[5],D-(6ANic)Lys[6]]antide (= nictide where pic = picolinyl, 6ANic = 6-aminonicotinoyl), [D-3-Qal[1],c-PzACAla[5],D-PicLys[6],Arg[8]]-antide (= argtide where Qal = 3-(3-quinolyl)alanine, c-PzAC = *cis*-3(4-pyrazinylcarbonyl-aminocyclohexyl), and [PicLys[5],D-(PicSar)Lys[6]]antide (= sartide where Sar = sarcosine (*N*-methylglycine)) were synthesized and their biological activity characterized.[19-23]

Flouret et al. have reported over 104 analogues of antide, the clinical use of which is impaired by unfavorable solubility characteristics. They describe the exchange of the antide-typical nicotinoyl group for a variety of other acyl substituents, and exchange of lysine for other short-chained amino acids such as 2,3-diaminopropionic acid or 2,4-diaminobutyric acid, and the biological activity in relation to these modifications.[9] Xiao et al. have synthesized a number of active antagonists (Tx series) with unnatural amino acids at positions 5 and 6; the most active sequence Tx-44 contains the amino acid 4-(morpholinomethyl)-phenylalanine (Mop) derived from phenylalanine instead of tyrosine[5].[24-26]

An important contribution was made by Rivier et al., whose optimization led to the decapeptide "azaline" with novel modifications at positions 5 and 6, where aminotriazole-subsituted p-aminophenylalanine or lysine are positioned.[27,28] Azaline B is probably one of the most active antagonists presently available worldwide. The current status of work on the "Azaline B family" is documented in a review by Rivier.[29]

An interesting strategy for discovery of antagonists with good water solubility was published by Roeske et al.[30] Decapeptide sequences with side chain modifications of D-Glu[6] or D-Lys[6] derivatives were synthesized with strongly polar and hydrophilic groups such as taurine. The strongest antiovulatory activity (AOA) was found on substitution of D-Lys[6] with gulonic acid or D-Glu[6] substitution with tris(hydroxymethyl)aminomethane (Tris; 75 and 50% AOA, respectively, 1 μg, rat model).

Deghenghi published a highly active decapeptide sequence with minimal histamine release and good water solubility. This structure, known as antarelix, differs from SB-75 (cetrorelix) in that it has homocitrulline[6] instead of citrulline[6] and isopropyllysine[8] instead of arginine[8].[31,32] By using Lys(*i*Pr)[8], residual potential for histamine release can be further reduced.

The firm Organon is developing the antagonist ganirelix (RS-26306) under licence from the firm Syntex; this is a decapeptide with novel alkyl-modified D- and L-homoarginine units at positions 6 and 8.[33] The development of a similar forerunner derivative called detirelix (Arg[8]-ganirelix) was suspended by Syntex. With ramorelix (HOE 013), the firm Hoechst (HMR) has a peptide antagonist with a sugar–amino acid unit D-α-L-rhamnosyl-D-serine[6], that has improved water solubility; however, its biological activity is possibly insufficient for clinical use as an antitumor agent.[34,35] The firm Schering is also developing peptide antagonists, using nonproteinogenic amino acids, such as ε-dialkylated lysine or benzodiazepine aminocarboxylic acids.[36,37] ZK-157348 contains *N*-6-morpholinolysine at the positions 6 (D-Morlys) and 8 (L-Morlys); biological data have not been published.

An interesting method for the manufacture of orally administered LHRH antagonists is being pursued by the Australian firm Biotech, who are concerned with the synthesis of conjugates of antide and vitamin B_{12}. The derivatives have similar in vitro and in vivo activity to antide; however, they have much better aqueous solubility and can thus be administered parenterally.[38,39] Scheme 1 shows the relevant derivatives and known candidates for development.

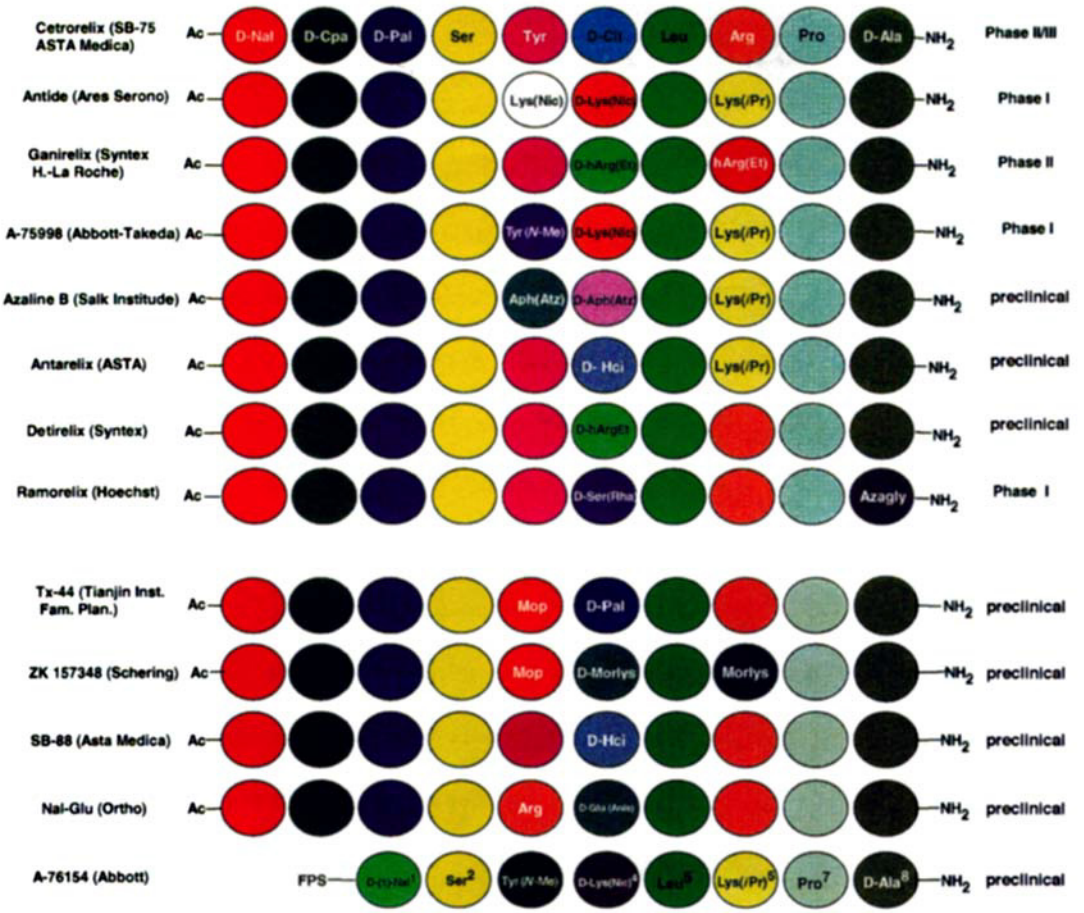
The search for peptide and peptidomimetic structures of the next (that is, the fourth) generation with improved pharmacologic activity continues undiminished worldwide. In addition to the classical indication of hormone-dependent tumor treatment, the LHRH antagonists can also be used to treat nonmalignant tissue abnormalities, for example, uterine myoma or benign prostate hyperplasia (BPH), with good prospects of success. In modern reproductive medicine, LHRH antagonists have significant advantages over the agonists used exclusively until now.

Today, the highly active decapeptides SB-88 and SB-75 (INN: cetrorelix)[40] are used in various laboratories as lead structures for the discovery of stable derivatives with good aqueous solubility and long-lasting in vivo activity. For peptide antagonists, one looks for cetrorelix analogues with modifications particularly at positions 5, 6, and 7. Nonproteinogenic amino acids, D-alkyl derivatives and amino acids with specifically altered side chains are introduced at these positions. Characteristic substitution patterns of such modifications of cetrorelix analogues are explained in Figure 3, with D-lysine[6] as an example.

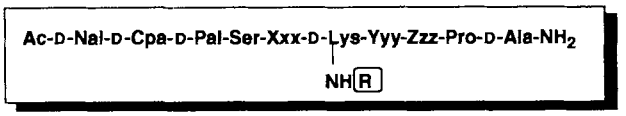
The best derivatives with the highest receptor affinities have so far been obtained by suitable modifications of the ε-amino function of D-lysine[6] with polar, hydrophilic carboxylic acids. With T-148, Schally et al. found a sequence that has bisacetyl-2,3-diaminopropionic acid bound through an amide linkage to the ε-amino function of D-lysine[6]-SB-75 and that is highly active in vitro. Sugar units of the D-glucopyranuronic acid type as D-lysine[6] side chain also give highly active antagonists with long-lasting hormone suppression in vivo.[42,43] Insertion of α-amino carboxylic acids at positions of the peptide scaffold other than position 6 also brings about stronger receptor affinity in certain cases, but has not yet achieved increased activity in vivo.[24]

D-24308, an L-Cpa[2] analogue of antarelix is a spectacular example of how reversal of chirality at a sensitive position on the molecular scaffold, which has a characteristic sequence of optically active centers, can bring about a dramatic loss of activity (Scheme 1). With exchange of D-Cpa[2] for L-Cpa[2], the biological activity is completely lost.

The work of Haviv et al. with restrictions, cyclizations and sequence truncations[44-50] is a good example of intensive research on effective antagonists. Abbott's A-76154 is an octapeptide antagonist with LHRH receptor affinity of a similar order of magnitude to that of active decapeptides such as A-75998 or "Nal-Glu".[51]



Scheme 1. Structures of LHRH antagonists (cetrorelix, the compound furthest along in clinical tests, serves as basis). $hArg(Et_2)$ = homoarginine(N^G,N^G-diethyl), Anis = anisol, Aph = *p*-aminophenylalanine, FPS = 4-fluorophenylpropionic acid, Hci = homocitrulline, Mop = morpholinomethylphenylamine, Morlys = *N*-morpholinolysine, Rha = rhamnosyl.



Xxx = Tyr or other amino acids

Figure 3. Side chain variation in (D-Lys^6)-cetrorelix analogues. Ac_2Dap = N^2,N^3-diacetyl-2,3-diaminopropionic acid.

Molecular restrictions, such as head-to-tail cyclization, can be accompanied by improved stability and duration of activity in peptides and also in heterocyclic lead structures, if the restriction includes the bioactive conformation (matched core).[52] The same applies to dimerization and partial dimerization through binding of suitable (partial) sequences, for example on the Lys^6 side chain, and also for cyclization from the C-terminus to the middle of the molecule. A multitude of cyclopeptides with LHRH sequences have been synthesized which confirm this (see Schemes 3 and 4). Their conformational properties are discussed in Section 3.

3. Structure and Conformation

Modeling of peptide systems such as LHRH as a means to explain the biologically active conformation began in the 1970s with the development of potential functions to examine energetic and entropic terms that contribute to the stabilization of the conformation of a peptide chain in solution.[53, 54] The first NMR investigations of LHRH indicated that there was no preferred conformation in solution.[55, 59, 60] Monahan et al. explained the significant difference in both in vitro and in vivo activity between [Ala^6]LHRH and [D-Ala^6]LHRH by the formation of a β-turn in the Ser^4-Tyr^5-Gly^6-Leu^7 segment of LHRH.[56] This assumption was supported by empirical conformational analyses of LHRH and analogous compounds by Momany (Figure 4).[57, 58] Substitution of the segment Tyr^5-Gly^6-Leu^7-Arg^8 by a sterically hindered β-lactam[61] as a model of a βII'-turn resulted in an LHRH-analogous compound that was more potent than LHRH both in vitro and in vivo.

Molecular dynamics (MD) simulation calculations performed by Struthers et al.[62a, b] supported the presence of a βII turn and indicated spatial separation of the hydrophobic side chains (Trp^3, Tyr^5, Leu^7), which possibly interact with a hydrophobic region of the receptor.[56] These calculations led to the synthesis of the cyclic LHRH antagonist cyclo[$\Delta^{3,4}$-Pro^1-D-Cpa^2-D-Trp^3-Ser^4-Tyr^5-Trp^6-N-Me-Leu^7-Arg^8-Pro^9-β-Ala^{10}-] (I, Scheme 2), which, however, binds more weakly to the recep-

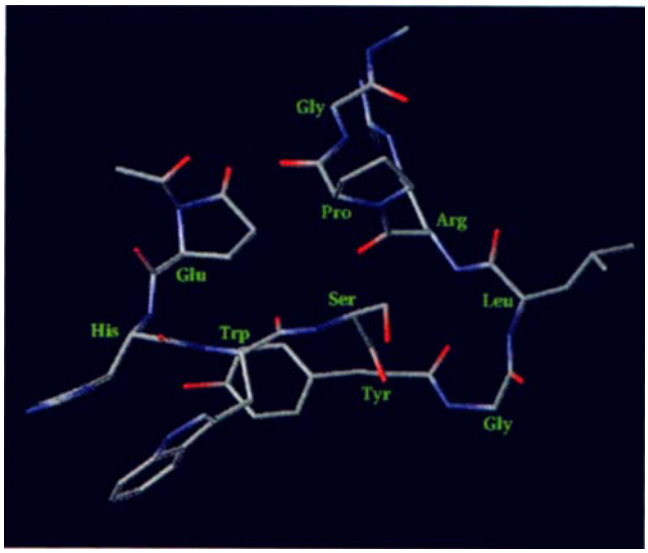

Figure 4. Conformation of LHRH, reproduced according to data in Refs. [57,58].

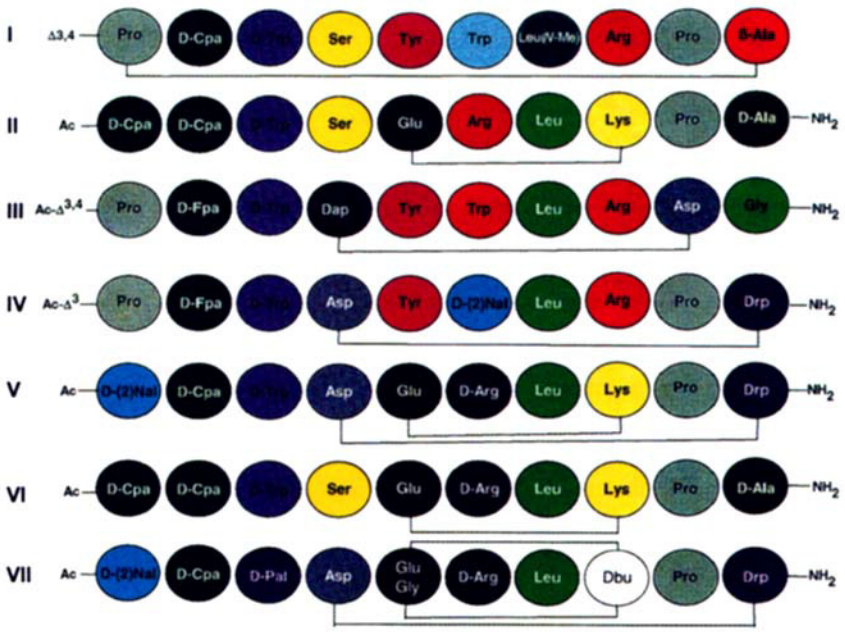


Scheme 2. Structures of cyclized LHRH analogues, whose conformations have been elucidated.

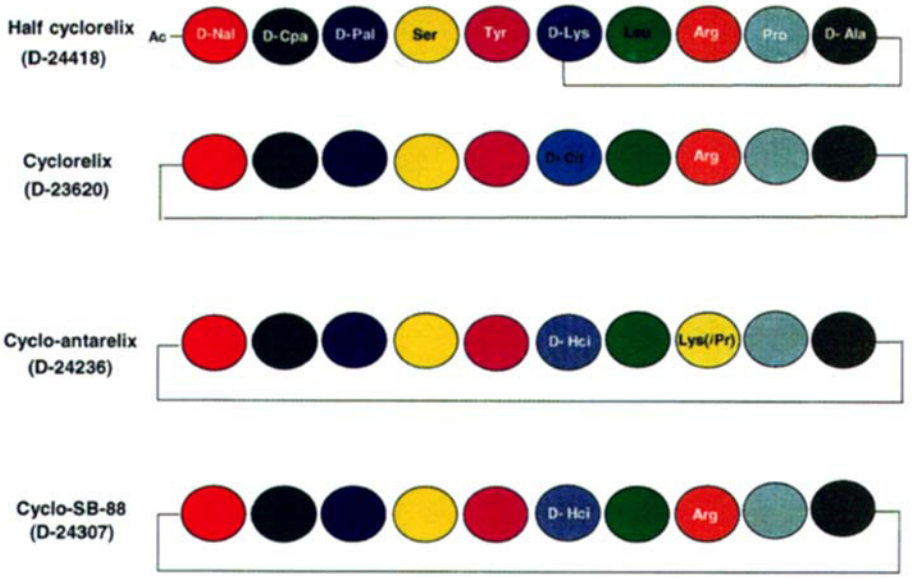
tor than LHRH itself. This compound has two βII′-turns,[63] which are formed with the help of an internal network of hydrogen bonds. This stabilizing effect was also examined by the isosteric substitution of -CH_2NH- instead of -CONH- at all amino acid positions of the antagonist [N-Ac-D-Nal[1], D-Phe[2,3], D-Arg[6], Phe[7], D-Ala[10]]-LHRH, except for position 9.[64a] These substitutions brought about a reduction or even absence of antiovulatory activity in biological tests. Such an interpretation assumes that these modifications do not lead to changed binding to the receptor. However, it is known that amide bonds of a substrate are also involved in receptor binding.[64b]

To gain a better understanding of the interaction between LHRH antagonists and the human receptor, a head-to-tail cyclization of cetrorelix to cyclic cetrorelix ("cyclorelix"), of antrarelix to cycloantrarelix, and of SB-88 to cyclo-SB-88 was carried out (Scheme 3).[65] All three cyclopeptides have significantly weaker binding than the linear derivatives (see Section 5b). NMR investigations in methanol and DMSO did not give any indication of preferred conformations for these cyclized compounds; thus no further insight into receptor-binding conformations was gained.[66] By 2D-NMR investigations of LHRH in various solvents[67] and NMR investigations of cetrorelix in DMSO, trifluoroethanol (TFE), H_2O, and H_2O/SDS (SDS = sodium dodecylsulfate),[68] preferred extended conformations were found for LHRH, and evidence was found for a possible fold in the Tyr[5]-Arg[8] segment of cetrorelix that, however, bears no resemblance to a βII′-turn.

The search for active, conformationally restricted LHRH antagonists was continued by Dutta et al.[69,70] By targeted cyclization of linear peptides, a range of cyclic derivatives was obtained, in which the side chains of the amino acids at positions 5 and 8 formed part of the ring system. The most potent compound of this group was Ac-D-Cpa[1]-D-Cpa[2]-D-Trp[3]-Ser[4]-cyclo(Glu[5]-D-Arg[6]-Leu[7]-Lys[8])-Pro[9]-D-Ala[10]-NH_2 (**II**), which showed threefold stronger ovulatory inhibition than the corresponding linear compound. As a result of conformational analysis of this antagonist and its linear analogue, bicyclic LHRH antagonists were obtained in which the amino acids 5 and 8, and also both termini, were bridged.[71] The examination of this compound led to structures in which a β-turn was present between positions 3 and 6 (Figure 5). Since the in vivo results were generally less favorable for the bicyclic peptides than for monocyclic 5–8 bridged derivatives, this was an indication that the free end groups play an important role in binding to the receptor.

Use of a novel starting point for design of LHRH antagonists was attempted by Struthers et al.;[72] based on analysis of MD simulations on **I**,[73] they suggested a receptor–binding conformation (supported by NMR investigations) for LHRH antagonists. However, in vitro results gave a K_D value greater than 100 nM for binding to the LHRH receptor, which was much higher than the K_D value of the corresponding linear compound (K_D = 0.21 nM). These findings suggest that 1) the free N- or C-terminus of the linear derivative plays an important role in receptor binding, and 2) fitting of the cyclic antagonist to the receptor binding pocket was suboptimal.

By optimization, the antagonist Ac-$\Delta^{3,4}$Pro[1]-D-Fpa[2]-D-Trp[3]-cyclo(Dap[4]-Tyr[5]-D-Trp[6]-Leu[7]-Arg[8]-Asp[9])-Gly[10]-NH_2 (**III**, Fpa = 4-fluorophenylalanine) was obtained, in which the side chains of Dap[4] and Asp[9] are bridged. The substance has a binding constant of K_D = 55 nM. The compound Ac-$\Delta^{3,4}$-Pro[1]-D-Fpa[2]-D-Trp[3]-cyclo(Asp[4]-Tyr[5]-D-(2)Nal[6]-Leu[7]-Arg[8]-Pro[9]-Dpr[10])-NH_2 (Dpr = 2,3-diaminopropionic acid, **IV**)[74,75] was synthesized by bridging amino acids 4 and 10, whereby a βII′-turn in segment 5-6-7-8 is stabilized by two hydrogen bridges. The influence of incorporation of L-Tic (Tic = tetrahydroisoquinoylalanine) at various positions of the linear antagonist Ac-D-Nal[1]-D-Cpa[2]-D-Pal[3]-Ser[4]-Tyr[5]-D-Pal[6]-Leu[7]-Arg[8]-Pro[9]-D-Ala[10]-NH_2 was also examined, with molecular mechanics cal-



Scheme 3. Cyclized analogues of cetrorelix and structurally related compounds (code numbers).

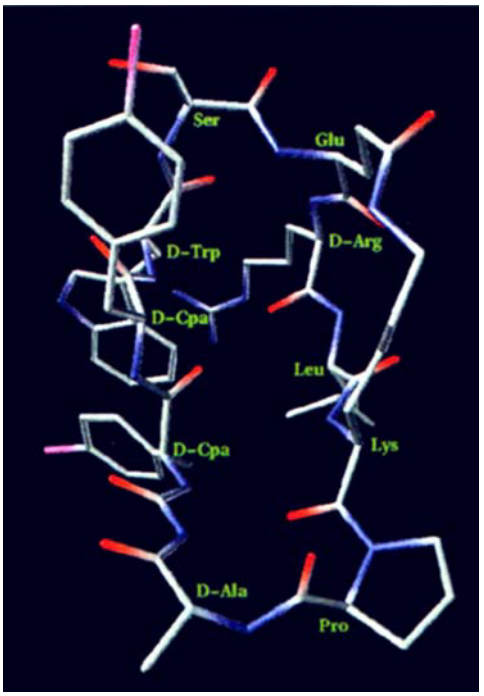


Figure 5. Conformation of the antagonist bicyclo(1-10/5-8)(-D-Cpa^1-D-Cpa^2-D-Trp^3-Ser^4-cyclo(Glu^5-D-Arg^6-Leu^7-Lys^8)-Pro^9-D-Ala^{10}-), reproduced according to the data in Ref. [71].

culations.[76] Substitution of D-Tic at position 6 seems to contribute to the maintenance of a βII′-turn. It is known that a D-amino acid flanked by L-amino acids is a strong βII′-turn inducer. The D-amino acid then occupies the $i+1$ position. D-Pro, which is the natural counterpart of D-Tic, exerts a particularly strong effect.[76b] Further mimetic models for βII-turns were discussed by Rizo and Gierasch in a review article on theoretical considerations of conformationally restricted peptides.[77]

N-methylation of α-amide bonds in LHRH agonists[78] and antagonists[45] has the surprising effect of converting some agonists into antagonists. In the majority of cases, the N-methylated agonists were less active than the corresponding nonmethylated compounds. All Tyr^5(*N*-Me) derivatives of antagonists had surprisingly good aqueous solubility. In particular, for the sequence Ac-D-(2)Nal^1-D-Cpa^2-D-(3)Pal^3 - Ser^4 - Tyr^5(*N* - Me) - D - Lys-(Nic)^6-Leu^7-Lys(*i*Pr)^8-Pro^9-D-Ala^{10}-NH_2 (A-75998), the conformational change was crucial for both solubility and binding affinity to the receptor. On N-methylation, the ratio of *cis*/*trans* isomers is changed and hydrogen-bridge formation is not possible, which leads to poorer association or aggregation. In addition, a hydrogen bridge, which normally contributes to stabilization of the βII-turn, is broken by the methylation. A further development was attempted by Liff et al., who tried to bring about targeted changes in the conformation of LHRH-analogous compounds by methylation of C_α atom centers.[79] However, such substitutions have not resulted in any significant conformational changes.

Comprehensive conformational analyses of native LHRH and of LHRH agonists and antagonists were performed by Nikiforovich and Marshall.[80, 81] A high flexibility was established for LHRH, in agreement with previous NMR investigations on linear peptides of corresponding chain length. Due to the function of Gly as a D-amino acid, the fragment Tyr^5-Gly^6-Leu^7-Arg^8 has a preferred conformation, yet without forming a marked βII-turn. Calculations indicate different conformations for agonists and antagonists in segment 5–8. However, the geometry of the N-terminal tripeptide was similar for agonists and antagonists.

A further attempt to determine the "biologically active conformation" of LHRH and analogues was made with NMR and MD investigations on the conformationally restricted bicyclic antagonist bicyclo(4-10/5-8)[Ac-(2)Nal^1-D-Cpa^2-D-Trp^3-Asp^4-Glu^5-D-Arg^6-Leu^7-Lys^8-Pro^9-Dpr^{10}]-NH_2 (**V**).[82] The existence of a βII′-turn in segment 5–8 (D-Arg at $i+1$ position) could be shown here. The additional 5–8 ring closure changed the conformation of the 4–10 bridge in the original monocyclic compound only slightly.

NMR investigations on a series of cyclized LHRH antagonists and their linear analogues (best cyclic antagonist: Ac-D-Cpa^1-D-Cpa^2-D-Trp^3-Ser^4-cyclo(Glu^5-D-Arg^6-Leu^7-Lys^8)-Pro^9-D-Ala^{10}-NH_2, **VI**) resulted in a structure with a β-turn present in segment 3–6, as in Refs. [71, 83]. In addition, the side chains 1 and 10 were now in direct proximity to one another, due to the existence of a network of hydrogen bridges. These cyclic compounds showed higher potency in the antiovulation assay (AOA) than the corresponding linear peptides.

Recent results on putative binding conformations of LHRH antagonists were obtained by Rizo et al. in a study of the bicyclic antagonist bicyclo(4-10/5,5′-8)(Ac-D-(2)Nal^1-D-Cpa^2-D-Pal^3-Asp^4-Glu^5(Gly)-D-Arg^6-Leu^7-Dbu^8-Pro^9-Dpr^{10}-NH_2) (**VII**, Dbu = 2,4-diaminobutyric acid).[84] This antagonist has a βII-turn at amino acids 5–6, a βI′-turn at 6–7 and a βII-like

turn between Pro^9 and the side chain of Dpr^{10}. Comparison with the results in Ref. [82] clearly shows that 4-10/5-8 bicyclic structures—despite double restriction—can adopt many conformations.

Until now, cyclized LHRH agonists and antagonists have not shown any significantly better biological activity than linear derivatives. It is clear that the termini must be free to take part in binding to the receptor. Although NMR investigations and MD simulations indicate the existence of a β-turn in segment 5–8 or 3–6, the high flexibility of oligopeptides remains the main problem in the search for the biologically active conformation and in optimization of structure–activity relationships. It is becoming more and more obvious that new methods are needed to solve this problem.

4. Receptor Assays

4.1. The Pituitary LHRH Receptor—A Representative of the Rhodopsin-Like G-Protein-Coupled Family of Serpentine Receptors

Although the hypothalamic peptide luteinizing hormone-releasing hormone was isolated and its sequence determined in 1971 by A. V. Schally and coworkers,[2, 85] the corresponding cDNA was not successfully cloned until 1984. This coded for the precursor protein of 92 amino acids, from which the decapeptide is formed by proteolytic processing.[86] Almost another ten years of intensive research passed until in 1992, various research groups managed to clone the high affinity receptor for LHRH from the murine gonadotrophic αT3-1 cell line.[87, 88] This immortalized murine pituitary cell line shows relatively high LHRH receptor expression, which enabled isolation of the cDNA by expression cloning in oocytes of *Xenopus laevis*.[87, 89–91] Based on the murine LHRH receptor cDNA sequence, the homologous cDNA genes of human, rat, cow, and sheep receptors were subsequently cloned.[92–97] The homology of the murine receptor to that of the rat is 97% and to the human receptor 89%. The pituitary high-affinity receptor for LHRH belongs to the rhodopsin-like family of G-protein-coupled 7-helix receptors, which are also described as serpentine receptors (a review is given in Iismaa et al.[98]). Further representatives of this family are the receptors for the peptides somatostatin, thyrotropin-releasing hormone (TRH), cholecystokinin (CCK), neurokinins A and B, and Substance P.[99] The cDNA of the human LHRH receptor codes for a protein of 328 amino acids. It is striking that the receptor has practically no C-terminal cytoplasmic domain (only two amino acid residues) and that the "signature sequence" typical for many G-protein-coupled receptors is changed from DRY^{140} to DRS^{140}.[100] Complementary to the LHRH cDNA, the chromosomal gene of the human receptor, composed of three exons and two introns, was recently cloned.[101] LHRH induces dose-dependent synthesis of the "second messenger" D-*myo*-inositol-1,4,5-triphosphate ($InsP_3$) and a biphasic rise in the intracellular calcium [Ca_i^{2+}] both in cultivated gonadotrophic pituitary cells and in the αT3-1 cell line (Figure 6).[102] Since these signals could not be inhibited by pertussis toxin, participation of the G_i and G_o subfamily of trimeric G-proteins could be excluded.[103] Recent work on the gonadotrophic αT3-1 cell line shows, however, that signal transmission following activation of the receptor takes place through a G protein of the subtype G_q/G_{11} and is thus coupled by phospholipase C subtype β (PLCβ) to the inositol phospholipid signal pathway.[104] The heterologously expressed LHRH receptor is also functional in recombinant cell systems, that is, stimulation with agonists leads, after G-protein coupling, to synthesis of $InsP_3$.[105, 93]

4.2. The Human LHRH Receptor—Cloning, Heterologous Expression and Recombinant Systems for Testing LHRH Antagonists

Cloning of the human receptor is of great importance for discovery and characterization of potent LHRH antagonists for clinical application, and this has become possible with the development of relevant, simple test systems. In the past, an initial in vitro characterization of peptide LHRH antagonists was done with classical receptor-ligand binding tests with iodinated LHRH derivatives, which mostly use crudely purified membrane fractions from the rat pituitary.[106, 107] Since a species-dependent binding of LHRH derivatives has been reported by various authors, this was a pragmatic method although not without problems.[97, 108–109] In particular, species-specific binding might be the case for nonpeptide receptor ligands, since these probably

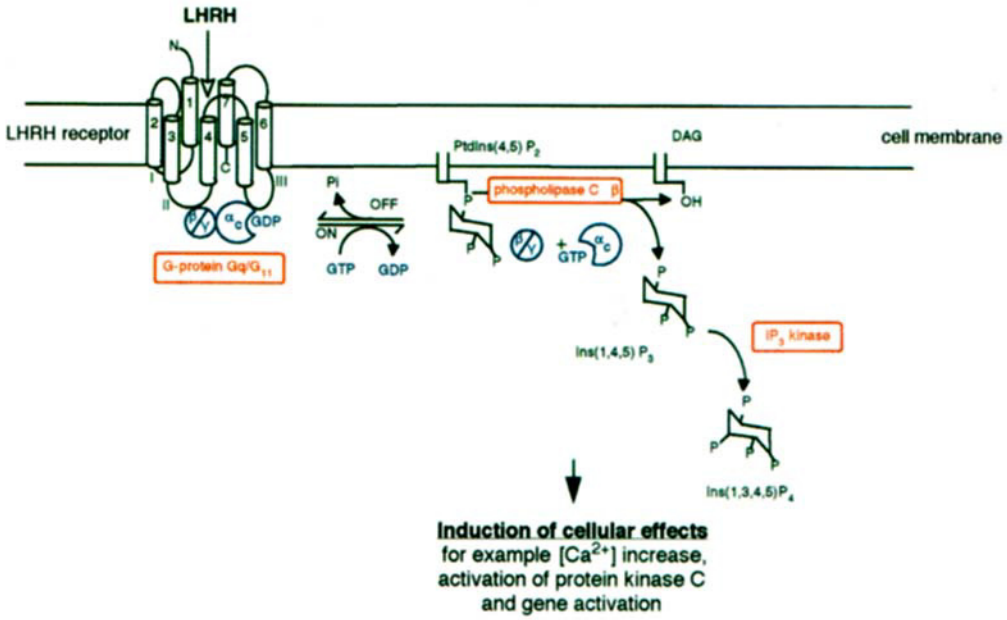

Figure 6. Simplified representation of the signal transduction pathway of the LHRH receptor. DAG = diacylglycerol.

interact with nonconserved amino acids outside the peptide-binding pocket of the receptor protein. This was shown for the neurokinin-1 receptor, for example, with Substance P as endogenous ligand and chemically very diverse, antagonistic, non-peptide compounds.[110] Taking this into consideration, the human LHRH receptor was thus stably expressed in different mammalian cell lines such as murine L cells. The individual cell clones overexpressing the receptor were isolated, and a pharmacological characterization/validation of the test system was performed with receptor–ligand binding tests on intact cells under physiological conditions, with the authentic hormone and relevant LHRH superagonists and antagonists.[105] A multitude of further structurally diverse peptide LHRH antagonists were tested with this system in displacement binding experiments with [^{125}I]-cetrorelix. The results for both clinically relevant and cyclized peptides are discussed in Section 5 (see also Figure 8).

In addition to the determination of binding affinity, expressed as the dissociation constant K_D [nM], the functional characterization of a ligand is also of importance. In early work, cultivated primary cell cultures from, for example, chicken pituitary, were used for this purpose, and agonist-stimulated or antagonist-inhibited release of luteinizing hormone (LH) was measured in a radioimmunoassay (RIA).[109] This reliable but complicated method has been simplified by determination of intracellular messenger substances such as $InsP_3$ in permanent cell lines or, alternatively, in suitable reporter gene test systems. In Figure 7a, detection of $InsP_3$ following stimulation with LHRH and with the superagonist [D-Trp^6]LHRH is shown as an example of the use of recombinant cell lines overexpressing the human LHRH receptor. The agonist-stimulated signal is dose-dependently reduced to the level in unstimulated cells, using an antagonist such as cetrorelix (Figure 7b).[105]

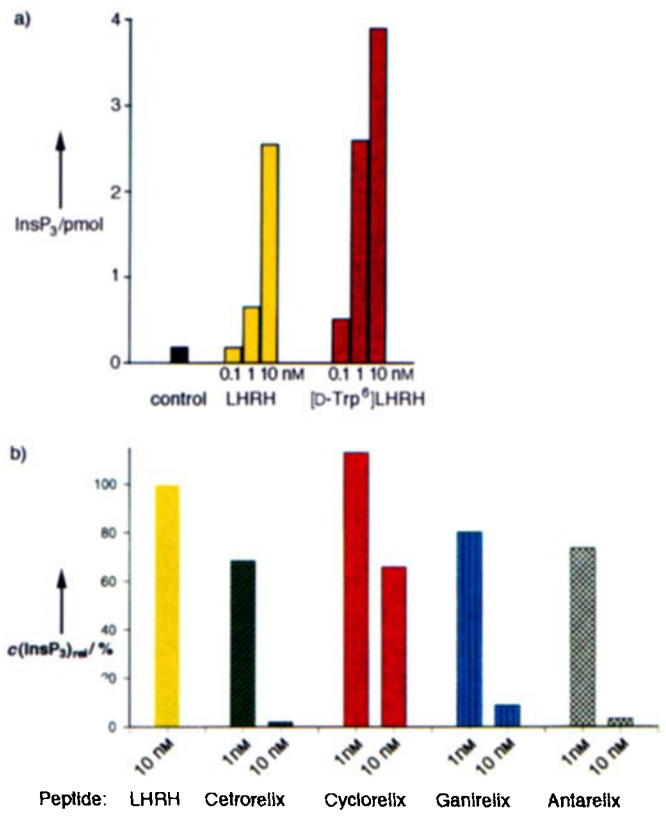

Figure 7. Functional characterization of peptide LHRH antagonists. a) Stimulation of $InsP_3$ synthesis by LHRH or by the superagonists [D-Trp^6]LHRH (triporelin/decapeptyl) in murine L cells, which overexpress the human LHRH receptor. The $InsP_3$ concentration is given for 4×10^6 cells; cells not stimulated with peptide are shown as control. b) Inhibition of stimulation by 10 nM LHRH by various antagonists (1 nM and 10 nM). The cellular $InsP_3$ concentration $c(InsP_3)_{rel}$ [%] is given relative to the maximum $InsP_3$ concentration specifically induced by 10 nM LHRH (100% corresponds to 7.63 pmol and 11.68 pmol $InsP_3$, respectively, per 4×10^6 cells).

At present, selected peptides are being tested in vivo by measuring the testosterone concentration in male rat serum. Here, a single subcutaneous application of a potent LHRH antagonist leads to persistent testosterone suppression. According to our current knowledge, the activity in animals generally correlates well with the binding affinity determined in vitro on human receptors. In cases where no in vivo activity was observed despite high binding affinity, the peptide probably had pharmacokinetic characteristics that played a decisive role. In the future, transgenic animals will also be very important for in vivo testing.

5. Comparative Studies

5.1. Comparison of Clinically Relevant Antagonists

The binding affinity and also the functional characteristics of certain, in part clinically relevant, peptide LHRH antagonists have been tested on the human LHRH receptor. The antagonists tested were cetrorelix (SB-75, D-20761), SB-88 (D-20455), antide (Serono), antarelix (D-23234), ganirelix (Organon/D-24598), and a truncated-sequence antagonist from Abbott, (ProNHEt)-A-76154 (D-24710). The binding affinity was determined as the dissociation constant K_D [nM] with suitable displacement binding tests with [^{125}I]-cetrorelix as labeled ligand and various concentrations of the peptide to be tested (Figure 8 and Table 2). Cetrorelix showed the highest affinity for the human receptor, followed by its analogue SB-88.

Selected peptide antagonists were tested with a functional assay in the cell line used for the radioligand binding tests (see Figure 7b). Here, inhibition of $InsP_3$ synthesis induced by 10 nM

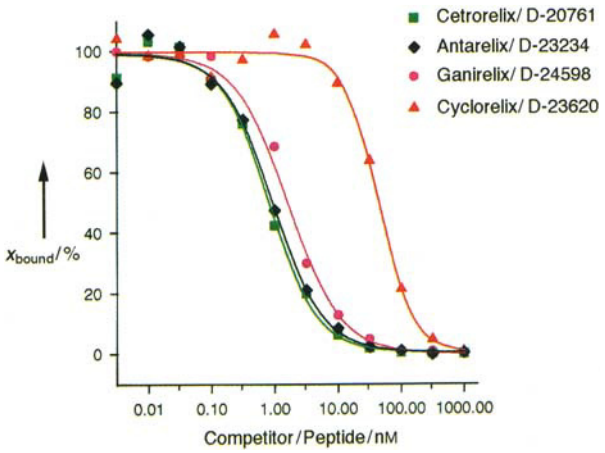

Figure 8. Binding affinity of selected peptide LHRH antagonists. Dose–response curves of competitive binding tests with [^{125}I]-cetrorelix as labeled ligand are given for cetrorelix (K_D = 0.18 nM), antarelix (K_D = 0.26 nM), ganirelix (K_D = 0.45 nM), and cyclorelix (K_D = 9.81 nM). Evaluation of many experiments and a comparison of the binding affinities are shown in Tables 2 and 3.

Table 2. Binding affinity of clinically relevant peptide LHRH receptor antagonists[a].

Peptide	Binding affinity K_D[nM]
LHRH	3.610±0.89 (4)
Cetrorelix (D-20761)	0.202±0.03 (10)
SB88 (D-20455)	0.209±0.002 (2)
Antarelix (D-23234)	0.233±0.04 (3)
Antide (Bachem)	0.360±0.13 (3)
Ganirelix (D-24598)	0.405±0.04 (2)
[Pro^8-NHEt]A-76154 (D-24710)	2.371±0.69 (2)

[a] The binding affinity of the peptide LHRH antagonists was determined in a displacement binding test with [^{125}I]cetrorelix as labeled ligand. The dose–response curves and the dissociation constants $K_D \pm \sigma_n$ (n = number of experiments, in parentheses) were calculated with the program EBDA/Ligand 3.0[133]. The binding affinity of the authentic LHRH ligand is shown for comparison.

LHRH was measured at antagonist concentrations of 1 nM and 10 nM. In this test, cetrorelix is also the most effective inhibitor of secondary messenger formation.

5.2. Comparison of Cyclized Antagonistic LHRH Derivatives

Several cyclized peptide LHRH antagonists were tested for binding affinity to the human LHRH receptor: cyclized cetrorelix ("cyclorelix", D-23620), cycloantarelix (D-24236), cyclo-SB-88 (D-24307) and partially cyclized cetrorelix ("half-cyclorelix", D-24418). The binding affinities, calculated as dissociation constants K_D [nM], are summarized in Table 3. All cyclopeptide analogues of the potent antagonists show significantly weaker binding than the linear precursors.

Table 3. Binding affinity of cyclized peptide LHRH receptor antagonists[a].

Peptide	Binding affinity K_D[nM]
Cyclorelix (D-23620)	12.87±3.1
Cyclo-Antarelix (D-24236)	13.64±1.69
Cyclo-SB88 (D-24307)	24.74±10.57
Halbcyclorelix (D-24418)	10.41±0.27

[a] The binding affinity of the cyclized LHRH antagonists was determined in a displacement binding test with [^{125}I]cetrorelix as labeled ligand. In each case two experiments were performed. The dose–response curves and the dissociation constants $K_D \pm \sigma_n$ (n = number of experiments, here $n = 2$) were calculated with the program EBDA/Ligand 3.0[133].

6. LHRH-Receptor Modeling

It has not yet been possible to determine the structure of a receptor coupled to a G-protein. Knowledge of the molecular structure and the functionality of the receptor has only been obtained by targeted mutagenesis experiments.[111–113] Molecular modeling offers the opportunity to obtain an approximate, three-dimensional structure of a receptor. Hoflack et al. have suggested a model for binding and activation of the gonadothyrotrophin hormone at the receptor.[114] A model of the LHRH receptor was outlined by Kühne et al.,[115] which is based on the well-known crystal structure of bacteriorhodopsin[116] and on material published on bovine rhodopsin.[117–118] The amino acids of the human LHRH receptor were positioned on the seven transmembrane helices of bacteriorhodopsin by means of homology modeling. The extracellular turns were modeled in the same way with data from the Brookhaven Protein Bank.[119] The orientation of the helices was fixed by hydropathy studies. Following energy minimization of the entire model with the AMBER force field, an MD simulation was performed over 100 ps. The model structure was stable under the conditions of this simulation; the relative orientation of the seven helices to each other changed little. In addition, the proline-containing helices formed the bend typical for such structures (Figure 9). This model could give information about the biologically active conformation of LHRH agonists and antagonists and thus facilitate the way to optimization of structure–activity relationships.

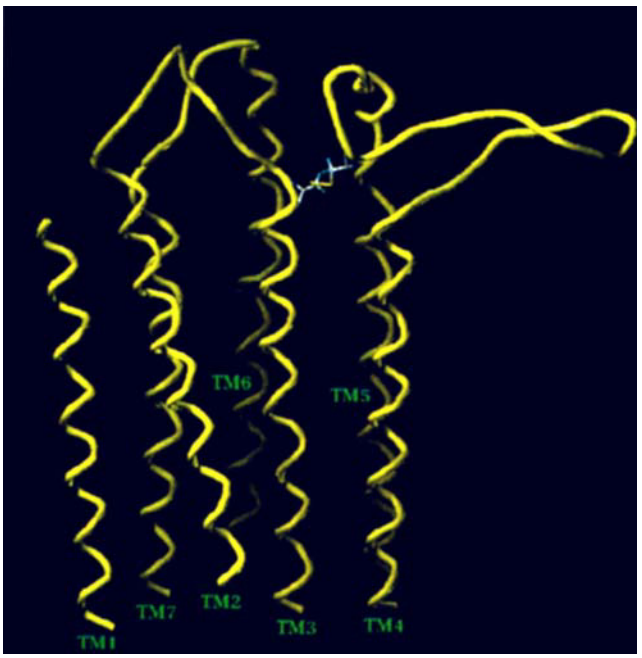

Figure 9. Energy-minimized structure of the human LHRH receptor model.

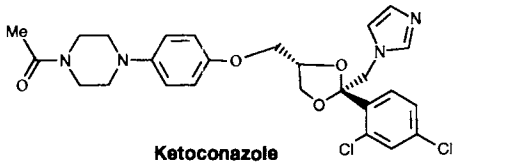
7. The Search for Peptidomimetics for the LHRH Receptor

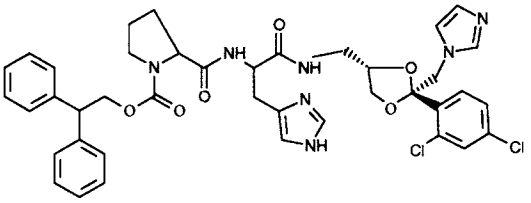
The search for peptidomimetic substances to replace peptides as active substances is being undertaken worldwide; prominent examples are angiotensin II antagonists such as Losartan, and (substituted) benzodiazepinones as high affinity ligands for the somatostatin receptor. Literature on the endothelin receptor antagonists (Ro 46-2005, L-744453), growth hormone analogues (MK-0677), CCK antagonists (MK-329), bradykinin B_2 receptor antagonists (Win-64338), and Substance P antagonists (CP-99994) is rapidly expanding.[120–124] Intensive efforts are being made particularly in the area of fibrinogen receptor antagonists, to replace the native Arg-Gly-Asp sequence ("RGD") and to obtain active substances that can be administered orally.[125]

For some years, increased efforts have also been made to find substances with affinity to the LHRH receptor that do not have

the characteristic substance-specific properties and also disadvantages of peptides (short half-life, lack of bioavailability), yet have a high binding affinity. Ideally, such substances should be able to be administered orally, be sufficiently stable in the organism, and possess favorable pharmacological parameters comparable to peptide antagonists. Clinical investigations of the influence of the antimycotic ketoconazole on prostate cancer and testosterone suppression indicate that it may have a LHRH-mimetic effect.[126, 127] Further investigations by the firm Abbott showed weak antagonistic activity both in vitro and in vivo for ketoconazole and modified analogues (Scheme 4); however, the biological activity of such derivatives is most probably not mediated mainly by LHRH antagonism.[128, 129]



Ketoconazole



Ketoconazole partial skeleton with dipeptide unit

Scheme 4. LHRH mimetics based on the ketoconazole partial structure [128,129].

A multitude of publications on stabilization and modification of peptide sequences (pseudo-peptides) with the help of mimetic structures, for example, the use of *N*-alkyl amino acids, cyclization and sequence truncation without loss of activity, originate from Abbott.[51, 45, 78, 130]

Complex, highly substituted nitrogen heterocycles such as those published by the firm McNeillab (Scheme 5) seem to have LHRH antagonistic potential.[135] In patent literature, Takeda describe benzodiazepines, benzodiazepinones, heterocyclic benzo-substituted alkylamines, and recently, thienopyridine carboxylic acid derivatives as LHRH receptor antagonists with receptor-binding inhibition at submicromolar concentrations, suitable amongst other uses as antitumor agents for hormone-dependent tumors.[131, 133] A lead structure from the latter substance class is currently in extensive pharmacological trials.

ASTA Medica is also developing substances with potential as antagonistic LHRH mimetics. Based on our work with sequence-truncated and cyclized peptides, both short-chain cyclopeptides and low molecular weight mimetics based on condensed heterocyclenes are being synthesized and evaluated. This strategy is confirmed by recent publications from the firm Takeda, who report cyclopentapeptides with affinity to the human LHRH receptor of the order of $IC_{50} = 0.07\ \mu M$.[134] The search for lead structures is facilitated and further accelerated by the use of compound libraries and high-throughput screening systems.[136, 137]

8. Conclusions and Outlook

LHRH agonists are well-established, high-turnover pharmaceuticals with the main area of application in tumor therapy and gynecology. Despite an early start to the search and intensive worldwide research activity, no LHRH antagonists are on the market today; cetrorelix, with its improved selectivity, high stability, and long-lasting action, is in an advanced stage of development and thus has the best chance of being the first LHRH antagonist to be launched.

With the help of molecular biology, human receptor assays have been established and functional tests developed, so that targeted optimization and characterization of clinically relevant antagonists can follow. Intensive conformational analyses on both linear and cyclized antagonists have not yet delivered any strategy for enhancing the activity or bioavailability. Despite advanced formulation technologies, the goal of a simple, economical, easily administrable form has not yet been adequately achieved in this research area. Assuming similar activity characteristics, peptidomimetics are, in general, superior with respect to cost of manufacture and method of application to the peptide derivatives on which they are based; with the available methods and lead structures, the search for these pharmacologically important substances will certainly be intensified in the future, so that the fourth generation of LHRH derivatives will meet the challenges of modern pharmaceutical research.

We would like to thank H. Kessler, Technische Universität München, for many NMR spectroscopic investigations and for suggestions during drafting of the manuscript, and A. V. Schally, Tulane University, New Orleans, for the introduction to the topic of endocrinology and his constant support. The cooperation with H. Michel and M. Reiländer, MPI Frankfurt, and with G. Krause and R. Kühne, Forschungsinstitut für molekulare Pharmakologie Berlin, in the field of the human LHRH receptor was supported by a project of the Bundesministerium für Bildung und Forschung (BMBF No. 0310697).

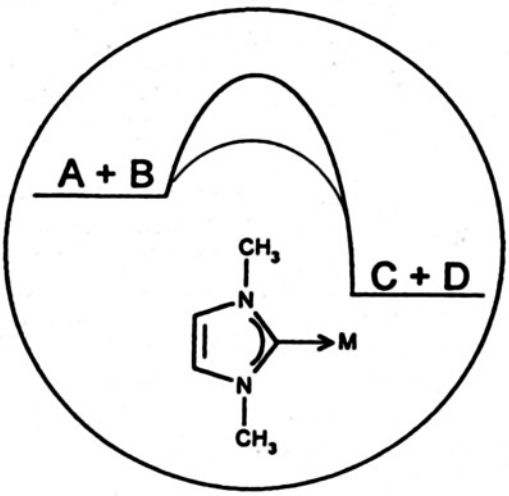
A downhill energy pathway leads from methylene to isolable heterocyclic carbenes such as 1,3,4-triphenyl-4,5-dihydro-1*H*-1,2,4-triazol-5-ylidene and 1,3-di-R-dihydroimidazolylidene.

These heterocyclic carbenes form complexes or covalent compounds with the elements marked in the periodic table.



Several of the metal complexes can be successfully used as homogeneous catalysts, as indicated by the schematic representation of the energy profile.

N-Heterocyclic Carbenes**

Wolfgang A. Herrmann* and Christian Köcher

Dedicated to Professor Heribert Offermanns on the occasion of his 60th birthday

The chemistry of N-heterocyclic carbenes has long been limited to metal coordination compounds derived from azolium precursors, a development that was started by Öfele and Wanzlick in 1968. Since free carbenes are now available through the work of Arduengo (1991), a renaissance in this little-recognized area of chemistry has occurred. A leading motive is the advantage of N-heterocyclic carbenes as ligands in organometallic catalysts, where they extend the scope of application reached by phosphanes (functionalized, chiral, water-soluble, and immobilized derivatives). The present review summarizes the state of the art with regard to synthesis, structure, bonding theory, metal coordination chemistry, and catalysis. Chelating, functionalized, chiral, and immobilized ligands can be generated and attached to metal centers in straightforward procedures under mild conditions. A wealth of new chemistry is thus opened. It is also shown how carbenes derived from imidazoles and triazoles behave as ligands in catalysis. It is reasonable to assume that N-heterocyclic carbenes surpass the ubiquitous phosphanes as ligands in a number of organometallic catalytic reactions.

Keywords: carbenes · heterocycles · homogeneous catalysis · metal complexes

1. Introduction

Carbenes have played an important role in organic chemistry ever since the first firm evidence of their existence. While much of the early chemistry of these laboratory curiosities was established in the 1950s by Skell,[1] it was Fischer and his students who introduced carbenes into inorganic and organometallic chemistry in 1964.[2] Suffice it to say that metal carbenes have become quite significant, particularly in organic synthesis, catalysis, and macromolecular chemistry.[3–6] Shortly after the discovery of the first authentic metal–carbene complexes of type **1**, two little-recognized reports by Öfele (Technische Universität München)[7] and Wanzlick et al. (Technische Universität Berlin)[8] appeared that described complexes **2** and **3** with N-heterocyclic carbenes as ligands. These complexes, which at that time were highly unusual compounds, were both obtained from imidazolium salts and metal-containing precursors of sufficient basicity to deprotonate the organic substrate. In the first case a carbonylmetalate was used, while the mercury complex resulted simply from the metal acetate [Eqs. (1), (2)].

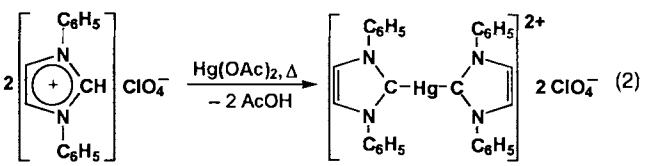
(1)



(2)

Öfele and his students established several basic features of this chemistry before Arduengo opened the access to free, isolable N-heterocyclic carbenes in 1991.[33] According to Equation (3),

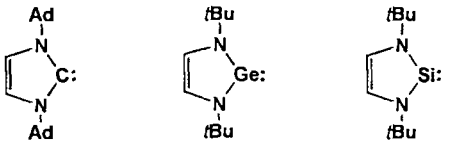
deprotonation of the imidazolium ion is effected by NaH and catalytic amounts of KO*t*Bu or the DMSO anion. Although this methodology has its limitations with regard to substituent R, Arduengo's work proved that a carbene of type **4** is in principle thermodynamically stable. At roughly the same time we synthesized the crystalline divalent germanium(II) congener **5** from diimine *t*BuN=CH–CH=N*t*Bu, lithium, and germanium(II) chloride.[10] As a result of this discovery Denk et al. and Lappert et al. successfully synthesized the stable silylenes **6** by reduction of the corresponding silicon(IV) cyclodiamides with potassium.[11] Compound **5** proved to be a successful precursor for chemical vapor deposition (CVD) of amorphic germanium.[134–137]



4 **5** **6**

Based on earlier work in the Munich laboratory,[12a–e] we suggested that N-heterocyclic carbenes **4** would exhibit ligand properties similar to those known from electron-rich phosphanes. This led to the conclusion that an equally rich coordination and catalysis chemistry should arise from these pronouncedly C-nucleophilic compounds.[13] Experimental evidence has increasingly been keeping track with our predictions.

1.1. The Way to Isolable Carbenes

There has been continued and growing interest in persistent intermediates since the days of Gomberg.[14, 15] However, almost no efforts were made to isolate carbenes, and stable "ylidene carbenes" were only recently isolated. Carbene intermediates such as dihalocarbenes are now well established in synthetic chemistry.[1, 16, 17] Carbenes are uncharged compounds with a divalent carbon atom and two unshared electrons, which can be assigned to two nonbonding orbitals in different ways. For this reason, the chemistry of carbenes, nitrenes, and arynes is similar in many respects.

1.1.1. Hybridization and Structure

Depending on spin multiplicity and ground state, the (electronic) structure of a given carbene varies as follows: If the carbene has a nonlinear structure with an sp^2-hybridized carbon atom, the structures of the singlet ground state and the triplet state compare to that of carbenium ions $(CR_3)^+$ and free radicals $^{\bullet}CR_3$, respectively. For the triplet state and excited singlet states linear structures with sp-hybridized carbon atoms also need to be considered.[18] A nonlinear triplet ground state is experimentally established for the majority of carbenes; singlet-state dihalocarbenes and carbenes with oxygen, sulfur, or nitrogen substituents are exceptions.

1.1.2. Triplet Carbenes

Electrophilic carbenes $:CR^1R^2$ with substituents R^1 and R^2 that are not electron donors were originally regarded as being too reactive to be isolated. As these triplet carbenes cannot be stabilized through thermodynamic effects, they have to be rendered unreactive by steric protection. Considerable progress was made by Tomioka et al., who stabilized diphenylcarbenes with methyl or chloro substituents in *ortho* positions. Whereas laser flash photolysis (LFP) of phenyl(2,4,6-tris-*tert*-butylphenyl)diazomethane yielded a nascent singlet carbene which intramolecularly inserted into a *tert*-butyl C–H bond before undergoing intersystem crossing, LFP in the presence of the triplet sensitizer benzophenone produced a transient triplet carbene.[19] In 1995 they synthesized 2,2′,4,4′,6,6′-hexabromodiphenylcarbene (**7**),

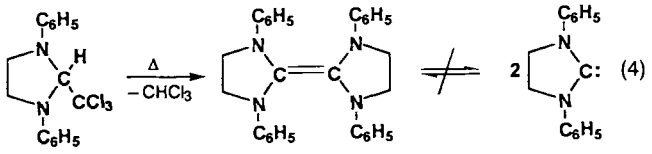
Wolfgang A. Herrmann, born in 1948, recieved his organometallic academic education with E. O. Fischer (Munich, Germany), H. Brunner (Regensburg, Germany), and P. S. Skell (Pennsylvania, USA) before becoming a professor at Regensburg (1979) and Frankfurt (1982). In 1985 he was appointed the chair professor of inorganic chemistry at the Technische Universität München as the successor to E. O. Fischer. His research focuses on homogeneous catalysis with a strong emphasis on synthesis, spectroscopy, and structures. He has authored about 450 scientific publications, 38 patents, and a number of review articles. He holds honorary doctoral degrees and has received numerous scientific awards. In 1996 he became president of the Technische Universität München.

W. A. Herrmann

C. Köcher

Christian Köcher, born in 1968 in Munich, studied chemistry at the Technische Universität München. For his Diplomarbeit in the group of W. A. Herrmann he investigated functionalized derivatives of C_{60}. This year he finished his dissertation "New Ways to N-Heterocyclic Carbenes and their Transition Metal Complexes—Applications in Homogeneous Catalysis". He is coauthor of eight publications and five international patents.

triplet carbene (ESR spectroscopy), again by photolysis of the parent diazo compound. In glassy (77 K) and completely fluid (120 K) 2-methyltetrahydrofuran, **7** is stable without significant decomposition. The crystalline compound can be kept at room temperature.[20]



8 **8a** **9** (4)

1.1.3. Singlet Carbenes: Heteroatoms at the Divalent Carbon

Heteroatom donor groups on a carbene center render the originally degenerate orbitals on carbon unequal in energy, thus enhancing the nucleophilicity of the carbon atom and the thermodynamic stability. The singlet–triplet splitting correlates with increasing electronegativity of the π-donor substituents X and Y in carbenes of the type :CXY. Although several combinations of heteroatoms (O, S, N) are conceivable, only singlet carbenes with two nitrogen atoms (amino groups) were isolated as crystalline compounds so far ("carbon diamides"). These singlet carbenes have a pronounced low-energy HOMO and a high-energy LUMO.[21] Because of the lower electronegativity of carbon, they are stronger electron-pair donors than amines. The electron-accepting capability is more significant than that of boranes (electronegativity!). Since the amino groups are π-donating (mesomeric) and σ-withdrawing (inductive), 2,3-dihydro-1*H*-imidazol-2-ylidenes benefit from a "push–pull" effect.[22, 23] Although the methoxy and trifluoromethyl groups also display push–pull stabilization, methoxy(trifluoromethyl)carbene, $CH_3O(CF_3)C$:, is unstable at room temperature and electronically indiscriminant upon reaction with different alkenes.[24] Dialkoxycarbenes could be generated in situ by thermolysis of, for example, 2,2-dialkoxy-Δ^3-1,3,4-oxadiazolines,[25] and amino(chloro)carbenes by deprotonation of Vilsmeier reagents such as chloromethylene iminium salts;[26] however, attempts at their isolation resulted in dimeric or oligomeric products.

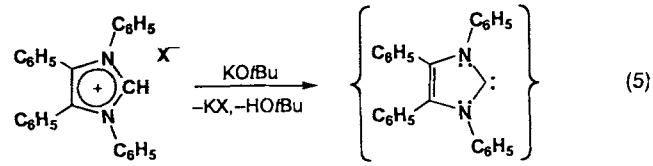
Therefore, the extent of "stability" and "aromaticity" (for 6π-electron systems) of free carbenes and their homologues depends on the point of view. For preparative chemistry kinetic stability is crucial. Stable N-heterocyclic carbenes are being studied for several reasons. Structure, reactivity, and theoretical understanding of these highly Lewis basic (one of the strongest known neutral bases) and nucleophilic molecules are of interest per se. Moreover, stable ylidene carbenes are used to prepare main group and transition metal complexes, although there are several in situ methods for synthesizing metal ylidene complexes without having to isolate free carbenes or their equivalents.

1.1.4. N-Heterocyclic Singlet Carbenes

In the early 1960s Wanzlick et al. investigated saturated and unsaturated heterocyclic carbenes.[27] The focus was first put on C–C-saturated molecules of type **9**. Imidazoline **8**, one possible precursor of **9**, was obtained from the reaction of 1,2-dianilinoethane with chloral; it underwent thermal α-elimination of chloroform. The resulting product dimerized, however, to yield the electron-rich olefin **8a** as a colorless crystalline compound [Eq. (4)]. Reactions with oxygen, water, nitromethane, and cyclopentanone confirmed the nucleophilic properties of what was incorrectly described as a "monomeric carbene". Cross-coupling experiments with differently substituted "dimers" showed that they are not in equilibrium with their monomers. Most notably, Lappert et al. developed a general synthesis of metal–carbene complexes by treatment of electron-rich (Wanzlick) olefins with transition metal complexes such as chlorotris(triphenylphosphane)rhodium(I). It is interesting that this particular rhodium complex catalyzes the metathetical cleavage of electron-rich olefins.

Numerous five- and six-membered heterocyclic cations display CH-acidic properties and base-catalyzed H–D exchange. The *N*-methylbenzthiazolium cation was most easily deprotonated by triethylamine in *N*,*N*-dimethylformamide or acetone, as shown by Wanzlick, Vorsanger, and Hünig. Once again, only the electron-rich olefin could be isolated in place of the free carbene,[28] but numerous transition metal complexes have become known since.

Wanzlick et al. recognized that aromatic resonance structures in unsaturated N-heterocyclic five-membered rings contribute to carbene stability. Free carbenes, such as 1,3,4,5-tetraphenyl-2,3-dihydro-1*H*-imidazol-2-ylidene (**10**), were generated by deprotonation of imidazolium salts with KO*t*Bu [Eq. (5)] and then allowed to react with isothiocyanates or

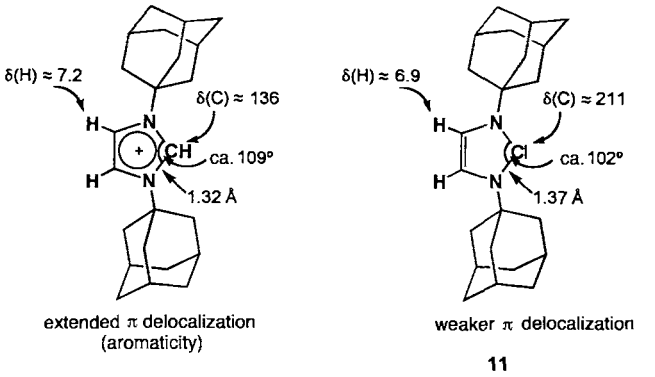


10 (5)

metal-containing precursors.[29, 30] Although Wanzlick et al. were so close to carbenes, they lacked the luck needed to isolate them.[31] Gleiter and Hoffmann pointed out that the ground state of a carbene will be a singlet state if the energy difference between the σ and π orbitals is greater than 2 eV, and that this splitting may be achieved by interaction of the unoccupied carbene p orbital with an aromatic system of $(4n+2)$ π electrons.

1.1.4.1. Synthesis and NMR Spectroscopy

In 1895 Nef announced that the isolation of methylene would be his next challenge.[32] After he and many others failed, however, no one believed any longer that carbenes would ever be isolated. Only the careful investigations by Arduengo et al. yielded the surprise of stable, crystalline (ylidic) carbenes almost one hundred years later.[33] For example, 1,3-diadamantyl-2,3-dihydro-1*H*-imidazol-2-ylidene (**11**; Figure 1) was obtained as



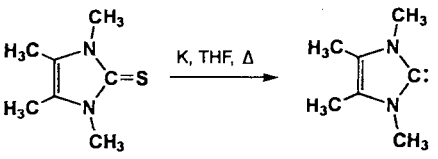
11

Figure 1. Geometric and spectroscopic parameters of the first isolated free carbene **11** and the corresponding imidazolium ion.

a colorless, crystalline solid by deprotonation of 1,3-diadamantylimidazolium iodide with NaH in the presence of catalytic amounts of DMSO anion [see Eq. (3)].

The thermal stability of solid **11** is surprising (melting point 240–241 °C without decomposition). In contrast, decomposition occurs rather quickly at room temperature in solution. To obtain reasonable rates for the deprotonation, catalytic amounts of either KO*t*Bu or the DMSO anion have to be applied, since sodium hydride and potassium hydride (and in most cases also the imidazolium salt) are insoluble in THF. Alternatively, stoichiometric amounts of KO*t*Bu may be used, but the less volatile *tert*-butyl alcohol is generated in place of hydrogen. Major progress in the synthesis was achieved with liquid ammonia as solvent: Deprotonation with sodium hydride or potassium amide occurred quickly and quantitatively in a homogeneous phase, and provided carbenes that were not previously accessible, such as oxygen-, nitrogen-, and diarylalkylphosphino-functionalized or chiral carbenes.[34]

Kuhn et al. reported a versatile two-step approach to thermally stable, alkyl-substituted N-heterocyclic carbenes.[35] To give an example, reducing 1,3,4,5-tetramethylimidazol-2(3*H*)-thion with potassium in boiling THF yielded analytically pure 1,3,4,5-tetramethyl-2,3-dihydro-1*H*-imidazol-2-ylidene [**12**, Eq. (6)] after filtration and removal of the solvent under vacuum.



(6)

12

The thiones were accessible through condensation of *N*,*N*′-dialkylthioureas with 3-hydroxy-2-butanone. 1,3,4,5-Tetramethylimidazol-2(3*H*)-thione was obtained in a stoichiometric mixture with the pentamethylimidazolium ion when 1,3,4,5-tetramethyl-2-(methylthio)imidazolium iodide was reduced with potassium. The only drawback to this technique is the thermal lability of 2,3-dihydro-1*H*-imidazol-2-ylidenes in solution, which is dependant on the nature of the substituents R on nitrogen. The same problems are encountered upon generation of free carbenes under "Arduengo conditions".

1,3-Disubstituted ylidenes with aryl residues (*p*-tolyl, *p*-chlorophenyl, and 2,4,6-trimethylphenyl; m.p. 157 (decomp), 154 (decomp), and 153 °C (decomp), respectively) or higher alkyl groups (*tert*-butyl, cyclohexyl, adamantyl) and 1,3,4,5-tetramethyl-2,3-dihydro-1*H*-imidazol-2-ylidene (m.p. 109 °C) are colorless crystalline solids; 1,3-dimethyl-2,3-dihydro-1*H*-imidazol-2-ylidene is an oily liquid.[36] Under an inert-gas atmosphere they can be kept in the solid state for months at −30 °C. 1,3-Dicyclohexyl-2,3-dihydro-1*H*-imidazol-2-ylidene does not fully decompose upon heating at 160 °C for 24 h. In solution they are stable to approximately 50 °C for several hours; this is even valid for 1,1′-(1,2-ethylene)-3,3′-dimethylbis(2,3-dihydro-1*H*-imidazol)-2-ylidene.[37] As long as the solid carbenes or their solutions are colorless, they are very pure and contain no decomposition products. (Slightly colored solutions, from yellow to orange, are in most cases NMR spectroscopically pure.)

It was clear from the constitution of the stable, sterically unencumbered ylidenes named above that not kinetic (steric hindrance) but rather thermodynamic stabilization (electronic structure) is the essential feature. Two electronic effects deserve consideration. Firstly, the difference in electronegativity of nitrogen and carbon accounts for the (−I) inductive σ effect, which stabilizes the pair of unshared electrons in the in-plane carbene orbital. Secondly, the unoccupied p orbital yields a π-resonance interaction; in the ylidic resonance structures the nitrogen atoms donate their lone pairs to carbon (+M effect). Steric hindrance quite certainly contributes to stability, but the electronic situation in the N-C-N moiety seems to be crucial.

Imidazolium salts, which are promising solvents for two-phase catalysis,[38–40] are electron-rich heteroaromatic compounds. Hence, the ^{13}C NMR shift of the N-C-N sp^2 carbon (which later becomes the carbene center) appears at $\delta \approx 137$. The $H^4(H^5)$ ring protons and the CH-acidic H^2 proton resonate at $\delta = 7.9-7.3$ and 8–10, respectively (Figure 1).

Free 2,3-dihydro-1*H*-imidazol-2-ylidenes are also diamagnetic. The divalent carbon atoms resonates at rather low field ($\delta = 210-220$ in $[D_8]$THF). The substituents on nitrogen exert only little influence (!) on the chemical shift. The $H^4(H^5)$ ring protons typically resonate at $\delta = 6.9-7.0$. However, in 2,3-dihydro-1*H*-imidazol-2-ylidenes with aryl residues adopting a roughly coplanar arrangement (no *ortho* substituents!), anisotropic effects of the aryl substituents account for chemical shifts at $\delta = 7.6-7.8$.[36] Deprotonation of the imidazolium salts to the corresponding 2,3-dihydro-1*H*-imidazol-2-ylidenes entails a significant high-field shift of the $H^4(H^5)$ proton resonances in the case of N-alkyl substitution. This indicates a different magnetic anisotropy of the ring system, which is consistent with a decrease in 6π-electron delocalization.[41]

1.1.4.2. Isoelectronic Congeners

π Backdonation also contributes to the stability of isoelectronic stable nitrenium and phosphenium ions LN^+ and LP^+ (L = *N*,*N*-di-*tert*-butyl-1,4-diaza-2-butene or -butane).[42, 43] Isoelectronic Group 13 congeners, for example N-heterocyclic gallium and aluminum complexes containing the fragments

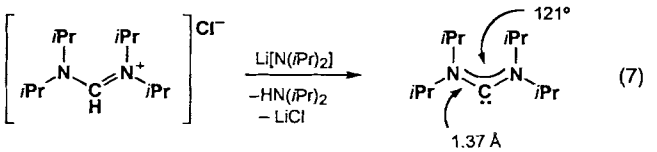
$NR_2Ga(R)NR_2$ and $NR_2Al(R)NR_2$, were experimentally verified with 1,4-diazabutadiene (DAB) ligands.[44,45] They are either stabilized by intramolecular coordination of a hemilabile dimethylamino side group or by dimerization. Alkyl- and aryl-substituted diyls $:E[CH(SiMe_3)_2]_2$ and $:E(2,4,6\text{-}t\text{Bu}_3C_6H_2)_2$ (E = Ge and Sn), which are monomeric in solution, were studied earlier;[46,47] in the meantime numerous compounds are known.[141] Stability and resistance to dimerization or insertion reactions once again reach a maximum for N-heterocyclic ring systems containing the DAB fragment and a Group 13–15 element.[10,11]

1.1.4.3. Solid-State Structures

The solid-state structures of 2,3-dihydro-1*H*-imidazol-2-ylidenes and representatives of C–C-saturated and acyclic carbenes were extensively studied by X-ray and neutron diffraction techniques. In the case of 2,3-dihydro-1*H*-imidazol-2-ylidenes, the N-C-N angles at the divalent carbon atom are all within a narrow range (±1°). For ylidenes with methyl, *p*-tolyl, or adamantyl substituents $R^1(R^3)$ on nitrogen, the carbenic angles are 101.5(1), 101.2(1), and 102.2(2)°, respectively.[33,35,142] These data are in excellent agreement with predictions for prototypical singlet ($^1A'$) carbenes bearing π-donor substituents (CF_2: F-C-F 102°).[48] These angles are significantly smaller than the typical range known for imidazolium salts (108.5–109.7°).[49] It was established for 1,3-diadamantyl-2,3-dihydro-1*H*-imidazol-2-ylidene that the $C^2-N^1(N^3)$ bonds (1.37 Å) are longer than in the imidazolium cation (1.33 Å). Considering this together with a slight elongation of the $N^1(N^3)-C^4(C^5)$ bonds, it was concluded that π delocalization is less pronounced in 2,3-dihydro-1*H*-imidazol-2-ylidenes than in imidazolium cations.

1.1.5. Acyclic carbenes

The success story of stable carbenes culminated in 1996 when Alder et al. synthesized bis(diisopropylamino)carbene (**13**), the first stable acylic carbene, by C-deprotonation of *N*,*N*,*N*′,*N*′-tetraisopropylformamidinium chloride with lithium diisopropylamide (LDA) in THF [Eq. (7)].[50] It is more sensitive to oxygen



(7)

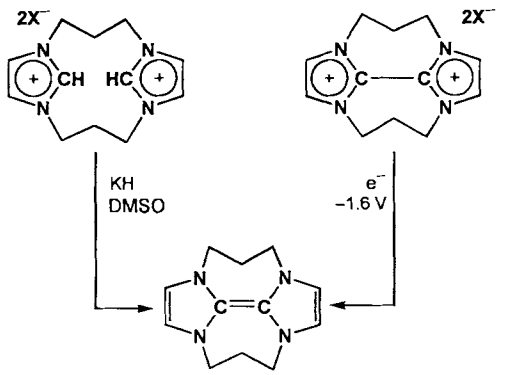
13

and moisture than the cyclic congeners. The N-C-N (121.0°) angle is significantly larger than in 1,3-dimesityl-1*H*-imidazolidin-2-ylidene (104.7°) and ylidene **11** (102.2°). The barrier to N–C rotation gives proof of substantial double-bond character.[50] The ^{13}C NMR chemical shift of the divalent carbon atom in **13** is shifted downfield by about 40 ppm relative to that for the divalant carbon atom in 2,3-dihydro-1*H*-imidazol-2-ylidenes and downfield by 10 ppm relative to that for **15** (see below).

1.2. Monomer or Dimer? The Singlet–Triplet Gap

1.2.1. C–C-Unsaturated Carbenes

After carbon monoxide and isocyanides, unsaturated N-heterocyclic carbenes have the largest singlet–triplet gap (about 85 kcal mol^{-1} according to ab initio calculations) of any divalent carbon compounds.[51] They show no tendency to dimerize, which is in contrast to their C–C-saturated analogues. Despite the predicted (thermodynamic) lability for tetraazafulvalene, the formal dimer **14** of 2,3-dihydro-1*H*-imidazol-2-ylidenes with a genuine double bond was isolated by Chen et al. by deprotonation of a doubly trimethylene-bridged diimidazolium salt [Eq. (8)] and structurally characterized.[52] The bond energy was



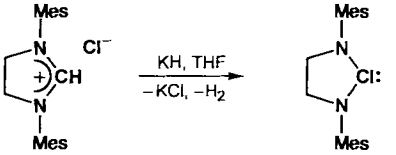
(8)

14

estimated to be 4±3 kcal mol^{-1}. The tetramethylene-bridged analogue, however, readily converts into the corresponding dicarbene. Monobridged and untethered imidazolium salts exist in the monomeric ylidene form after deprotonation and show no tendency to dimerize. Thummel et al. independently reported that **14** is accessible by bulk electrolysis (−1.6 V) of the corresponding doubly tethered diimidazolium salt in acetonitrile.[55] Doubly tethered benzo- and naphtho-2,3-dihydro-1*H*-imidazol-2-ylidene dimers which are reluctant to undergo C–C bond cleavage were also obtained through bulk electrolyis. It has long been recognized that enetetramines are strong reducing agents. For example, 2,2′-dibenzo-2,3-dihydro-1*H*-imidazolylidene shows the first ionization potential at about 6 eV and is easily oxidized to the corresponding dication.[54]

1.2.2. C–C-Saturated Carbenes

The singlet–triplet gap becomes smaller upon saturation of the C–C bond, since five-center six-electron (5c-6e) π delocalization as a stabilizing factor is no longer possible. As dimers of saturated carbenes, electron-rich olefins **8a** were used by Lappert et al. to prepare imidazolidine–carbene metal complexes. In 1995 Arduengo et al. succeeded in synthesizing imidazolidine-2-ylidene **15**, a stable and crystalline monomer of the electron-rich olefins [Eq. (9)].[55]



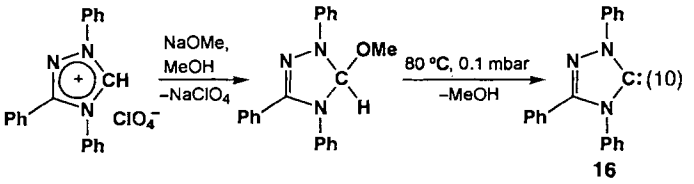
(9)

15

2,3-Dihydro-1*H*-imidazol-2-ylidenes, ylidene **15**, and the acyclic diaminocarbene **13** were synthesized by deprotonation of amidinium salts. This showed that the different degree of aromaticity in the precursor has no first-order effect on deprotonation in this special case. Semiempirical calculations (AM 1 method) suggest that the proton affinities of similarly substituted representatives of all three systems vary by less than 1% of the absolute values.[50]

1.2.3. Triazole-Derived Carbenes

The first crystalline triazole-derived carbene, 1,3,4-triphenyl-4,5-dihydro-1*H*-1,2,4-triazol-5-ylidene, was not prepared by deprotonation of the highly protic triazolium salt, because the latter forms—in contrast to imidazolium salts—(isolable) 5-methoxytriazoles upon treatment with NaOMe.[56] 4,5-Dihydro-1*H*-1,2,4-triazol-5-ylidene **16** was obtained at 80 °C and 0.1 mbar by endothermic elimination of methanol from the corresponding 5-methoxytriazole in the solid state [Eq. (10)].

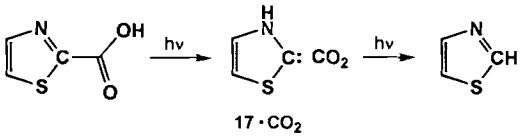


16

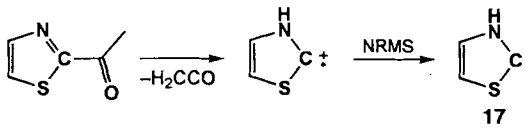
The bond lengths N^1–C and N^3–C (1.351(3) and 1.373(4) Å) are much shorter than expected for a single bond. This result and ab initio calculations indicate strong interaction of the filled nitrogen 2p orbitals with the unoccupied carbon 2p orbital. As in the case of imidazole-derived carbenes, no dimers are formed in solution. Ylidene **16** decomposes unspecifically above 150 °C (differential scanning calorimetry/thermogravimetry (DSC/TG) studies). 1,3,4-Triphenyl-4,5-dihydro-1*H*-1,2,4-triazol-5-ylidene is the first carbene to be commercially available (ACROS). Cyclic voltammetry and ESR measurements demonstrated that **16** can be reversibly reduced to the corresponding radical anion.[57] Density functional theory (DFT) calculations on the spin density in the most stable structure of the radical anion suggested that the single electron is delocalized between the N^2–C^3 double bond and the adjacent phenyl substituent.

1.2.4. Thiazole-Derived Carbenes

Substituted 2,3-dihydrothiazol-2-ylidenes as well as the unsubstituted parent compound as a thiazole tautomer were investigated experimentally and by quantum chemical calculations only very recently. These compounds are close analogues of the intermediate involved in enzymatic C–C bond forming and breaking transformations catalyzed by thiamin (vitamin B_1). The parent species were characterized by matrix-isolation techniques as well as in the gas phase: Prolonged irradiation (254 nm) of thiazol-2-caboxylic acid in an argon matrix (12 K) yielded unsubstituted 2,3-dihydrothiazol-2-ylidene (**17**) with loss of CO_2 [Maier et al.; Eq. (11)].[58] The analysis of calculated and measured IR spectra together with ^{13}C labeling experiments confirmed the formation of **17**·CO_2. Ylidene **17** isomerized, probably by an intermolecular pathway, to thiazole under further irradiation or upon heating to 60 K. Dissociative electron ionization (EI) of acetyl-2-thiazole yielded the 2,3-dihydrothiazol-2-ylidene radical cation, from which neutral ylidene **17** was generated by neutralization-reionization mass spectroscopy [Eq. (12); Schwarz and Terlouw et al.].[59]

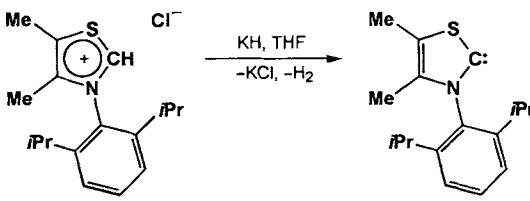


17·CO_2



17

The geometric parameters and energies of neutral thiazole, 2,3-dihydrothiazol-2-ylidene, and the corresponding radical cations were calculated using the hybrid DFT option. Ylidene **17** is 31.5 kcal mol^{-1} less stable than thiazole; the energy barrier is 72.4 kcal mol^{-1}. The calculated geometry of planar **17** (1*A'*)[59] is in perfect agreement with the X-ray diffraction data of 3-(2,6-diisopropylphenyl)-2,3-dihydrothiazol-2-ylidene (**18**), the first stable crystalline 2,3-dihydrothiazol-2-ylidene synthesized by Arduengo et al. through deprotonation of the corresponding thiazolium chloride with potassium hydride in THF [Eq. (13)].[60] With 104.2° the angle at the carbene carbon



18

atom (S-$C_{carbene}$-N) is again smaller than in the azolium ion (112.0°). As for other singlet carbenes, the bond lengths between C2 and the heteroatoms are greater than those in azolium salts. Monomeric 2,3-dihydrothiazol-2-ylidenes with sterically less demanding groups on nitrogen can be observed in solution at low temperature but are prone to fast dimerization. With **18** an equilibrium between a stable carbene and its dimer was observed for the first time in the presence of a protic acid catalyst.

1.2.5. Functionalized Chiral and Multidentate Carbenes

N-Heterocyclic carbenes form a plethora of metal complexes, either over carbenes, which are formed by deprotonation of CH-acidic imidazolium salts, or by in situ deprotonation by metal-bound basic ligands (e. g. amides, alkoxides, or acetate; see Section 5). Free carbenes with oxygen, nitrogen, and diarylalkylphosphino donors in the side chain(s) or with chiral residues were synthesized in our group using the particularly beneficial liquid-ammonia route (Figure 2).[34, 61, 62] When the

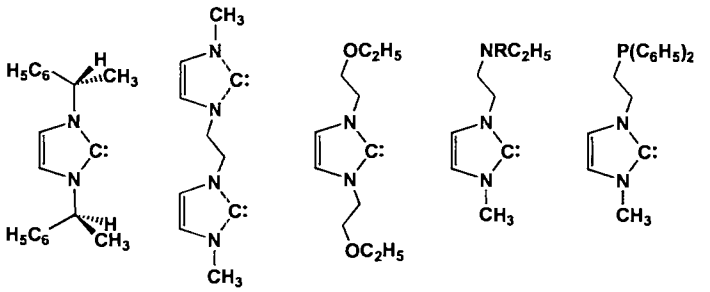


Figure 2. Side chain functionalized, chiral, and multidentate 2,3-dihydro-1*H*-imidazol-2-ylidenes.

imidazolium salts were deprotonated in a mixture of liquid ammonia and aprotic polar solvents such as THF, the desired carbene was obtained in exellent yield and purity; in most cases the reaction went to completion within about 30 min at −40 °C. Many otherwise inaccessible carbenes have thus been prepared.

As two-electron ligands, carbenes are related to ethers, amines, isonitriles, and phosphanes with regard to their coordination chemistry. Chelating derivatives are of special interest. Asymmetric precursors are accessible from commercially available starting materials in four-step syntheses with yields of up to 90%.[63] Because of the rigid geometry of the planar five-membered rings, the optimum number of atoms forming an appropriate chelate ligand does not match that found with diphosphanes or diamines. Methylene-bridged 2,3-dihydro-1*H*-imidazol-2-ylidenes and 1,2,4-1*H*-triazol-5-ylidenes form six-membered rings upon metal complexation. However, the natural bite angle of 78–79° found in transition metal complexes (W, Pd) of these ligands is exactly that of 1,1′-bis(diphenylphosphino)methane (four-membered ring).[63, 64] At rhodium centers this dicarbene exhibits a bridging coordination mode.[65] In ethylene-bridged 2,3-dihydro-1*H*-imidazol-2-ylidenes an unfavorable eclipsed conformation of the hydrogen atoms in the ethylene bridge also favors dinuclear structures.[37] With an *o*-xylylene backbone (C_4), however, bidentate ligands well suited for chelating metal coordination on Rh were obtained.[66] In addition to phenyl- and naphthylethyl-substituted carbenes, other chiral 1,3-di-R-2,3-dihydroimidazol-2-ylidenes and complexes thereof were prepared in our group. Enantiomerically pure acetylated 1,1′-bis(1-hydroxyethyl)ferrocene reacted with imidazole under retention of configuration at the pseudobenzylic positions. Chiral diimidazolium salts were obtained after alkylation. Differrocenyl-substituted imidazolium salts were synthesized from enantiomerically pure 1-ferrocenylamine by a ring-closure synthesis.[67] Complexes of chelating oxazoline/carbene donors are available by a simple general route from 2-amino alcohols.[119]

A tripodal carbene ligand of the Trofimenko type, tris(2,3-dihydro-1*H*-imidazol-2-ylidene)borate, resulted from deprotonation of the corresponding precursor salt with *n*BuLi/*n*-hexane in THF. The homoleptic hexacarbene–iron complex **19** resulted from subsequent treatment with $FeCl_2$ (Figure 3).[68] Another tridentate carbene ligand, [1,3,5-{tris(3-*tert*-butyl-2,3-dihydro-1*H*-imidazol-2-ylidene)methy}-2,4,6-trimethyl benzene] (**20**), was isolated as a solid. Inter- or intramolecular interactions of the carbene groups with each other were not found.[69]

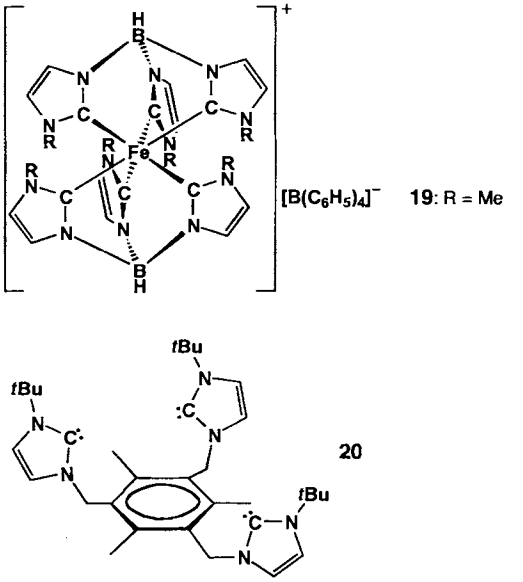

Figure 3. Tridentate carbenes as ligands in the hexacarbene complex **19** and as free carbene **20**.

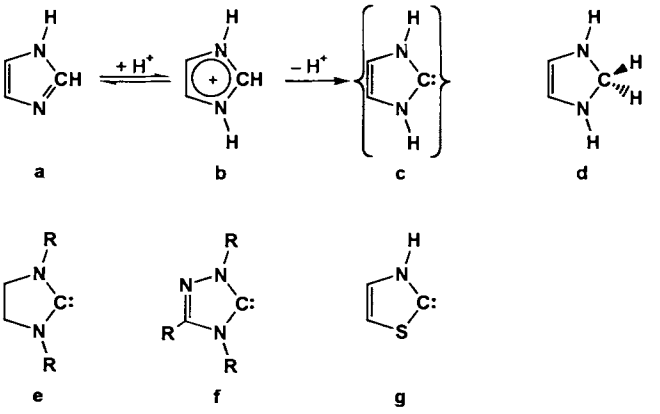
1.3. Nomenclature of Ylidenes

The suffixes of the systematical names of heterocyclic compounds are determined by the kind of heteroatoms in the ring. The first differentiation is made between a ring system containing at least one nitrogen atom and all other heterocyclic rings. Five-membered rings containing at least one nitrogen atom have the suffixes -olidine (saturated ring systems), -oline (ring containing one double bond), and -ole (ring containing the maximum number of double bonds).

The N-heterocyclic ylidenes first isolated by Arduengo are formal tautomers of 1*H*-imidazole **a**. Protonation of 1*H*-imidazole at the basic N3 position and subsequent deprotonation of the resulting 1,3-dihydroimidazolium ion **b** at the C^2 center yields the 1,3-dihydrosubstituted ylidene **c**. The number of π electrons (six) remains unchanged. The addendum -ylidene refers to compounds in which two hydrogen substituents are replaced by two electrons or one pair of electrons. The parent compound of **c** (**d**) is unequivocally described as 2,3-dihydro-1*H*-imidazole. Thus, **c** is called 2,3-dihydro-1*H*-imidazol-2-ylidene. As **d** represents a ring system with only one double bond, it may also by called an imidazoline (see above). Although the



name imidazoline by itself comprises other tautomers, 1,3-di-R-imidazoline-2-ylidene is unequivocal for compounds of type **c**. The names 1,3-di-R-2,3-dihydro-1*H*-imidazol-2-ylidene and 1,3-di-R-imidazoline-*2*-ylidene are synonymous here because of the substitution pattern of imidazole-derived carbenes with (organic) substituents in positions 1 and 3, and the carbenic center at the C^2 atom. Definitely not correct, however, is the name "1,3-di-R-imidazol-2-ylidene". N-heterocyclic ylidenes of type **e** with a saturated C–C bond are correctly called 1,3-di-R-2,3,4,5-tetrahydro-1*H*-imidazol-2-ylidenes or 1,3-di-R-imidazolidine-2-ylidenes. Triazole-derived carbenes of type **f** are 1,3,4-tri-(R)-4,5-dihydro-1*H*-triazol-5-ylidenes, and thiazole-derived **g** 2,3-dihydro-thiazol-2-ylidenes.

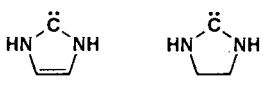
2. Electronic Structure of N-Heterocyclic Carbenes, Silylenes, and Germylenes

2.1. Singlet–Triplet Gap in Methylene

Due to a small HOMO–LUMO gap, the energy difference between the singlet and triplet states can be very small or even negative because of the energy gain from increased exchange interaction in the triplet state. It was experimentally verified that the parent carbene $:CH_2$ has a triplet ground state. This fact has served as a reference for various ab initio methods, since the contribution of electron correlation in singlet and triplet states is significantly different, and an accurate value for the singlet–triplet gap can be calculated only by using large basis sets and extensive configuration interaction (CI).[70]

2.2. π Delocalization in N-Heterocyclic Carbenes

In their first theoretical work Dixon and Arduengo calculated singlet–triplet splitting and proton affinity of unsubstituted 2,3-dihydro-1*H*-imidazol-2-ylidene by ab initio methods (singlet: TCSCF, triplet: ROHF).[71] With 79.4 kcal mol^{-1} the energy gap is nearly twice as large as that of $:CF_2$ (calcd: 45, found: $\approx$57 kcal mol^{-1}). On the other hand, the proton affinity is estimated to be about 250 kcal mol^{-1}, making 2,3-dihydro-1*H*-imidazol-2-ylidenes one of the strongest organic Brønsted bases known. Interestingly, this value is larger then that for $:CH_2$ (205 kcal mol^{-1}), whereas $:CF_2$ has a lower proton affinity (172 kcal mol^{-1}). It was concluded that a) **A** is similar to $:CF_2$ and b) ylidic resonance structures do not dominate. An analysis of the MP2 wavefunction using the localized orbital approach provided a similar conclusion:[72] The stability of **A** is due to σ donation of charge to the nitrogen atoms, whereas π backdonation plays only a minor role.



A **B**

This point of view was reconfirmed.[73] The electron distribution of perdeuterated tetramethyl-2,3-dihydro-1*H*-imidazol-2-ylidene was determined experimentally by neutron and X-ray diffraction. In addition, the electron density was calculated by DFT methods using a gradient-corrected function. Experimental and theoretical electron distributions matched each other very well. Based on contour line diagrams of the electron density, the authors reestablished their picture of similarity between $:CF_2$ and **A**. The "egg-shaped" density at the carbenic carbon resembles that of $:CF_2$ and was interpreted as significant electron deficiency above and below the molecular plane. Accordingly, contour plots 70 pm above the molecular plane showed separate maxima for the two nitrogen atoms and one for the C–C double bond, which was interpreted as a lack of π delocalization in the N-C-N fragment and a separated double bond. The authors concluded that the stability of 2,3-dihydro-1*H*-imidazol-2-ylidenes must be due to kinetic hindrance because of electrostatic repulsion between the localized π electrons and an attacking nucleophile.

The above-mentioned theoretical studies judged N-C-N π delocalization to be of minor importance. However, it is a necessary prerequisite for an aromatic type of delocalization in the 6π-electron system in **A**. The appartent difference in the stability of isolated **A** and **B** provoked skepticism of this point of view.

Avoiding the question of aromaticity, Thiel et al. attributed the difference between **A** and **B** to the larger singlet–triplet separation in **A** entailing a higher barrier to dimerization.[74] However, the reason for the higher singlet–triplet gap in the unsaturated system **A** remains unexplained.

2.3. Aromaticity

On the basis of (hypothetical) isostructural and isodesmic reactions, the relative thermodynamic stability of a given set of species can be estimated. Sauers therefore verified the influence of heteroatoms in heterocyclic 6π-electron carbenes.[75] The aromatic stabilization energy (ASE) is the negative of the isodesmic reaction energy in Equation (14) (including the zero point energy correction).

$$AH_2 + B \longrightarrow A + BH_2 \qquad (14)$$

Significant stabilization for the 6π-electron system can be achieved with two nitrogen atoms. In contrast, two oxygen atoms, with higher electronegativity than N and S, afford the lowest stabilization. This rules out stabilization merely by σ effects, as proposed by Cioslowski.[72] Consequently, as long as 6π-electron delocalization plays a role, N-C-N π delocalization must also be present.

Two profound theoretical studies by Heinemann et al.[76] as well as Frenking and Böhme[77] came to essentially the same conclusion. It was demonstrated that, even in systems such as pyridine or pyrrole, the analysis of electron-density contour plots 70 pm above the molecular plane exhibit the same features of "separated" π electron density above the individual nuclei.[77] Therefore, the method of density mapping employed by Arduengo et al. is not very reliable for analyzing the presence of electron delocalization.

The isodesmic reaction energies in Equation (15) are very interesting.[76] For R = NH_2 (the plane of the NH_2 frag-

$$R_2C: + CH_4 \longrightarrow R_2CH_2 + H_2C: \qquad (15)$$

ments is perpendicular to the carbene plane) the reaction energy of about 20 kcal mol^{-1} demonstrates the stabilization with respect to singlet methylene due to the higher electronegativity of the nitrogen atoms. However, in a completely planar conformation, where π delocalization from the nitrogen lone pairs into the "empty" carbene p-type orbital is possible, this stabilization energy is increased by 70 kcal mol^{-1}. Thus, π backdonation dominates carbene stabilization. Addition of a CH_2-CH_2 bridge increases the stabilization by only 6 kcal mol^{-1}, whereas the unsaturated CH=CH linkage effects an additional stabilization of 26 kcal mol^{-1} with respect to the planar aminocarbene. This demonstrates a significant stabilization effect of the double bond and indicates the presence of a certain degree of cyclic electron delocalization. On the other hand, this stabilization is small compared to that originating from N-C-N π delocalization.

Thermodynamic calculations led to two main conclusions: a) The major contribution to carbene stabilization is due to $p\pi-p\pi$ electron donation from the two nitrogen atoms to the carbene carbon atom, and b) the unsaturated cyclic carbene **A** is about 20 kcal mol^{-1} more stable than the saturated analogue **B**.

2.4. Heterocyclic Silylenes and Germylenes

Because of their similarity, silylenes and germylenes were studied in parallel to the carbene by a number of methods mentioned above.[11, 21, 73, 76–79] Arduengo et al. concluded that the electron-density distribution of silylenes and germylenes differs significantly from that of carbenes, and resembles chelation of a Group-14 element by a DAB ligand.[73] However, numerous thermodynamic calculations performed in various studies led directly to the conclusion that also silylenes and germylenes are stabilized by $p\pi-p\pi$ delocalization.[76, 77] On the other hand, 6π-electron delocalization was judged to be present but less pronounced than in carbene **A**. As an example, an isodesmic reaction energy affords an increased thermodynamic stability of about 9 kcal mol^{-1} for the unsaturated silylene with respect to the cyclic saturated analogue (about 20 kcal mol^{-1} for the carbene).[76]

2.5. Magnetic Properties

The thermodynamic calculations clearly demonstrated the increased stability of the 6π-electron system. However, this was only an indication for aromaticity but no proof. A large anisotropy between in-plane and out-of-plane magnetic susceptibility is known to be a good indicator for ring currents, and therefore a good measure for what is meant by "aromaticity". It should be noted here that there are at least two noncompatible scales of aromaticity.[80]

Heinemann et al. as well as Frenking and Böhme calculated magnetic susceptibilities. They pointed out that the absolute values of susceptibility are not very accurate, but the relative parallel and perpendicular components should be reliable.[77] A reference value of $\Delta\chi = 50$ was given for pyridine. As expected the 6π-electron carbene **A** is "less aromatic" than pyridine with an anisotropy $\Delta\chi$ of only 28, which is nevertheless much larger than the value of $\Delta\chi = 9$ for **B**. The protonated imidazolium cation has a slightly higher anisotropy of $\Delta\chi = 31$. It is reasonable to conclude that cyclic electron delocalization in **A** is less developed as in, for example, benzene or pyridine, as expected for five-membered heteroaromatic rings.[80] However, there is a distinct difference between **A** and **B**, which suggests a relation between cyclic electron delocalization and increased thermodynamic stability.

2.6. Chemical Shielding Tensor

In addition to these studies that focus on the electronic structure of 2,3-dihydro-1*H*-imidazol-2-ylidene, a number of theoretical investigations concerning experimental properties were performed. The chemical shielding tensor of carbenes was calculated based on the local density functional and Hartree–Fock (HF) theories,[41] and compared with the experimental CP-MAS solid-state NMR spectra of 1,3,4,5-tetramethyl-2,3-dihydro-1*H*-imidazol-2-ylidene. The large chemical shielding anisotropy at the carbene carbon atom could be reproduced by all theoretical methods. Because of a large deshielding component of the tensor in the molecular plane orthogonal to the lone pair, the resonance for the carbene carbon atom appears at very low field. This tensor element is dominated by a paramagnetic (deshielding) contribution arising from a low-lying $n \rightarrow \pi^*$ transition. This large deshielding paramagnetic contribution is missing in the shielding tensors of the doubly bonded carbon atoms C^4 and C^5 of **A** and also for the protonated carbene carbon C^2 in the imidazolium cation AH^+, which indicates the absence of π delocalization in the N-C-N fragment (carbenic structure). However, this reasoning is somewhat misleading, since the presence of such a large paramagnetic contribution is not necessarily due to different π^* energy levels. The most significant difference between the carbenic carbon atom C^2 in **A** and the carbon atoms C^4 and C^5 as well as the C^2 center in the imidazolium cation is the fact that the lone pair is replaced by a significantly stabilized electron pair forming the C–H bond. The extent of paramagnetic contribution is proportional to the inverse of the energy difference of the related transition. Therefore, this contribution will be much larger for carbene carbon atoms, for which the $n \rightarrow \pi^*$ transition has a low energy gap, than for other cases for which the equivalent $\sigma \rightarrow \pi^*$ transition out of the C-H bond will have a much larger energy gap and therefore a much smaller paramagnetic contribution. Exactly this kind of simplified picture was established to explain the difference between the ^{13}C NMR chemical shielding tensors of benzene and the *ipso* carbon atom of phenyllithium.[81]

2.7. Photoelectron Spectroscopy

Since photoelectron spectra can shed light on the electronic structure of molecules, the whole series of isolated, cyclic 6π-electron carbenes, silylenes, and germylenes was investigated.[21] Density functional calculations were employed to explain the experimental data. Based on Koopman's theorem on the Kohn–Sham orbitals and using first-order time-dependent per-

turbation theory, the spectra could be simulated very well. The most important feature is the fact that, in contrast to the Si and Ge homologues, the lowest-energy ionization process is the removal of an electron from the in-plane lone-pair orbital which appears as the HOMO in the DFT calculation. The next two bands correspond to π-type orbitals of the five-membered ring.

The HF orbital energies for all carbenes, silylenes, and germylenes show a π-type HOMO, and that the second highest molecular orbital (HOMO − 1) is that for the in-plane lone pair.[76] The question of why the classical Koopman's theorem is violated only in the case of the 6π-electron carbene then appears. In fact, it implies that the errors in neglecting electron correlation in the HF wavefunction and electronic relaxation upon ionization cancel out. This apparently does not apply to carbenes. These deficiencies can be overcome by using correlated ab initio methods to calculate also the energy of the radical cation: Ionization energies of **A** were reproduced very well with respect to both order and absolute value at the PUMP4/6-31G(d) or CCSD(T)/6-31G(d) level of theory. The analysis revealed that significant relaxation of the wavefunction occurs upon removing an electron from the in-plane lone pair, which results in increased electron delocalization. This is in line with the increased aromaticity of the cationic imidazolium, for which charge density of the former lone pair is diminished by "adduct formation" with a proton. The authors concluded that the in-plane electron density acts as a barrier that reduces the extent of cyclic electron delocalization. Because of the energy gained upon removing an electron from the lone pair, this ionization appears to be the lowest-energy ionization process. This fact was confirmed by the Kohn–Sham orbital energies.

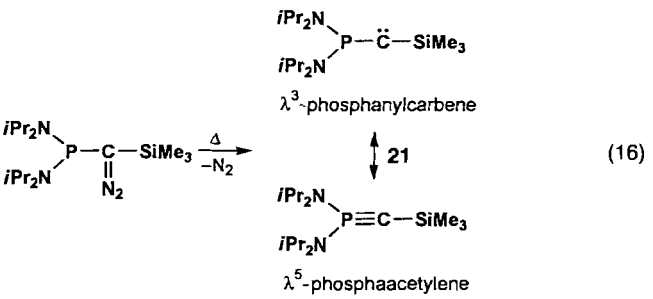
3. Reactivity

Whereas triplet carbenes exhibit radical-like reactivity, singlet carbenes are expected to show nuleophilic and electrophilic reactivity due to the σ-type lone pair and the vacant p orbital. As a result of small HOMO–LUMO gaps, carbenes are very reactive. One of the most intriguing and controversial questions regarding the reactivity and stability of 2,3-dihydro-1*H*-imidazol-2-ylidenes, imidazolidine-2-ylidene, and bis(diisopropylamino)ylidene focuses on their electronic structure. The theoretical investigations discussed above, however, concluded that unsaturated as well as saturated N-heterocyclic carbenes of the imidazole type benefit very well from π donation from the adjacent amino groups; this is equivalent to a contribution of the two ylidic mesomeric structures to the electronic structure of diaminocarbenes.

It is doubtful whether much can be learned about the behavior of transient, highly reactive singlet carbenes by studying the stable ones. Transient carbenes generally react with unsaturated nucleophiles such as allenes, acetylenes, arenes, or olefins. Following Skell's theory the spin multiplicity of the carbene correlates with the stereochemistry of cyclopropanes resulting from [1 + 2] cycloadditions to olefins.[82, 83] However, it has long been known that nucleophilic carbenes in which the singlet state is stabilized by interaction of the vacant π orbital with a delocalized π system do not react with nucleophilic olefins (e. g. hexene) but with electrophilic olefins such as fumaric esters. This rule is confirmed by 2,3-dihydro-1*H*-imidazol-2-ylidenes, which do not undergo electrophilic reactions like insertions or cycloadditions; furthermore, they can be handled in typical donor solvents including THF, liquid ammonia, or acetonitrile. 2,3-Dihydro-1*H*-imidazol-2-ylidene adducts are also reluctant to add to nucleophiles. This shows that the pπ LUMO lies rather high in energy as a result of nitrogen lone pair conjugation, thus decreasing the electrophilic character of the carbene carbon atom. The stability of 2,3-dihydro-1*H*-imidazol-2-ylidenes with respect to dimerization (nucleophilic perpendicular attack of one singlet carbene at the vacant out-of-plane orbital of another singlet carbene) suggests that the term "carbene" is misleading.[30]

3.1. Bertrand's Carbene

Ab initio calculations indicate that Bertrand's phosphanylsilylcarbenes $[(R_2N)_2P](SiMe_3)C{:}$ (R = *i*Pr (**21**), *c*-C_6H_{11}) and the more temperature-sensitive phosphanylphosphoniumcarbenes $[\{(iPr_2N)_2P\}\{P(iPr_2N)_2H\}C{:}]X$ are best regarded as λ^5-phosphaacetylenes with polar P^+-C^- multiple bonds [Eq. (16)]; reactivity typical for λ^3-phosphanylcarbenes results.[51, 84, 85] The P-C-P angle in $[(iPr_2N)_2PCP\{(iPr_2N)_2H\}]^+$ (165°) is significantly larger than that expected for singlet carbenes. A singlet–triplet energy seperation of only 3 kcal mol^{-1} was computed. However, reactivity typical for carbene is known, for example, for intramolecular insertion into C–H bonds, stereospecific cyclopropanation with electron-poor olefins (dimethyl fumarate), addition to aldehydes to yield oxiranes, [1 + 1] addition to isocyanides to yield ketene imines, and concerted or stepwise (cyclo)additions to nitriles to give 2*H*-azirins and 1,2-λ^5-azaphosphetes, respectively.[86]



(16)

3.2. Basicity and Nucleophilicity

The basicity following the concept of Brønsted–Lowry and the nucleophilicity of 2,3-dihydro-1*H*-imidazol-2-ylidenes were examined by Alder et al. With $pK_a = 24$ in $[D_6]$DMSO (fluorene: $pK_a = 22.9$; 2,3-benzofluorene: $pK_a = 23.5$) 1,3-diisopropyl-4,5-dimethyl-2,3-dihydro-1*H*-imidazol-2-ylidene is a stronger base than 1,5-diazabicyclo[4.3.0]non-5-ene (DBN), 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), and proton sponges but weaker than phosphazene bases.[87] The rate of proton transfer between a free carbene and its conjugate acid is close to the exchange limit at room temperature, but the carbene is too

nucleophilic for synthetic applications as a strong base due to a sterically unhindered conformer which is only slightly higher in energy than the preferred congested conformer. The ratio of elimination to substitution in the reaction with 2-bromopropane (20:80) is similar to that for DBN and DBU. Proton exchange between the acyclic bis(diisopropylamino)carbene and its conjugate acid is much slower due to steric hindrance; this may also explain the stability of the acyclic carbene, for example, towards dimerization.

3.3. N-Heterocyclic Carbenes as Nucleophilic Catalysts

N-Heterocyclic carbenes acting as nucleophiles have manifold catalytic applications in synthetic chemistry as well as in nature: Breslow showed in the context of ylidene-catalyzed benzoin condensations[88] that the vitamin B_1 enzyme cofactor thiamin (**22**), a naturally occurring thiazolium salt, plays a key role in biochemistry (Figure 4).[89] As thiamin diphosphate (the

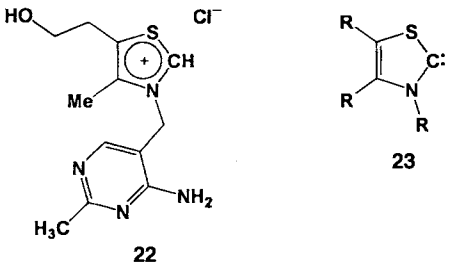


Figure 4. Structure of thiamin (**22**) as well as the framework of the corresponding catalytically active 1,3-dihydrothiazol-2-ylidene **23**.

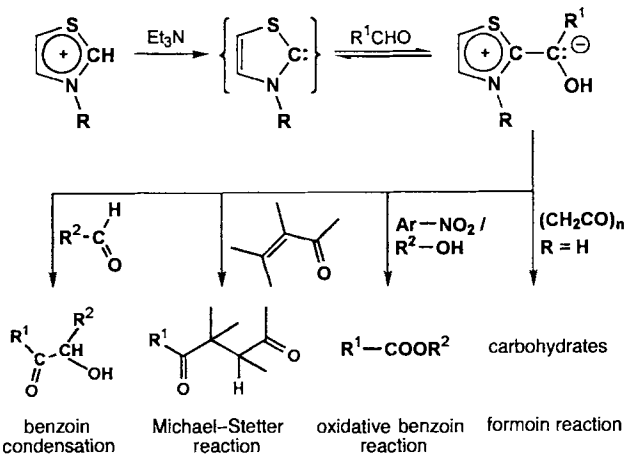
coenzyme of pyruvate decarboxylase), it catalyzes the decarboxylation of pyruvic acid to active acetaldehyde as well as the benzoin condensation of benzaldehyde. In basic aqueous buffers the active catalyst of this reaction is a 2,3-dihydrothiazol-2-ylidene of the form **23**. Stetter recognized that aliphatic aldehydes that undergo aldol condensation in the presence of cyanides are activated for a benzoin-type condensation upon addition of ylidene catalysts.[90-92]

2,3-Dihydro-1*H*-imidazol-2-ylidenes and 4,5-diyhdro-1*H*-1,2,4-triazol-5-ylidenes also found catalytic applications in organic synthesis, for example in the benzoin condensation of higher aldehydes to α-hydroxyketones, the oxidative benzoin condensation of aldehydes, alkohols, and aromatic nitro compounds to yield esters, and selective formoin reactions of formaldehyde to give C_2 to C_6 building blocks.[93] The catalytic activity and selectivity of a given system composed of a 1,3-heteroazolium salt and a base correlated nicely with the kinetic acidity of the 1,3-heteroazolium salt. The transient formation of dimers was ruled out. Nucleophilic ylidenes also served as catalysts in the Michael–Stetter reaction (Scheme 1). In this "umpolung" reaction yielding 1,4-dicarbonyl compounds, a nucleophilic heterocyclic ylidene attacks an aldehyde; the generated acyl carbanion equivalent then adds to α,β-unsaturated ketones in a 1,4 manner. Intramolecular variants of this reaction provided furanones, pyranones, and chromanones. Asymmetric variants of ylidene-catalyzed benzoin condensations and

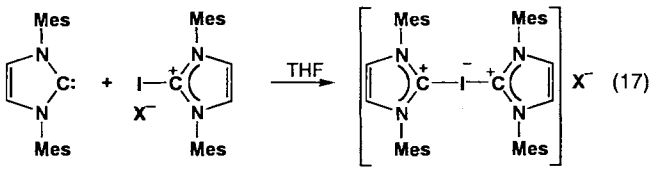


Scheme 1. Organic transformations of aldehydes catalyzed by N-heterocyclic ylidenes.

Michael–Stetter reactions were achieved using chiral triazolium salts as catalyst presursors.[94]

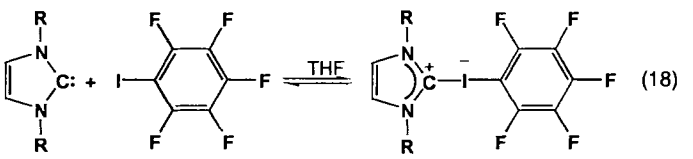
3.4. N-Heterocyclic Carbenes as Lewis Bases

The transition metal coordination chemistry of 2,3-dihydro-1*H*-imidazol-2-ylidenes is discussed in detail in Section 5. 2,3-Dihydro-1*H*-imidazol-2-ylidenes form stable adducts with soft and weak Lewis acids, such as iodine, in which the carbenes,[9,95] just like tertiary phosphanes, act as pronouncedly basic σ donors. The nearly linear arrangement together with other structural and spectroscopic data of the imidazole moiety suggest a hypervalent (10e-I-2c) central iodine atom (I^-) with an expanded I···I bond and a positively charged imidazole moiety of slightly augmented π delocalization. 2-Iodo-1,3-dimesitylimidazolium iodide further reacted with 1,3-dimesityl-2,3-dihydro-1*H*-imidazol-2-ylidene to give almost linear cationic bis(carbene) adducts of hypervalent iodine with only slightly different C–I bond distances [Eq. (17)].[96]



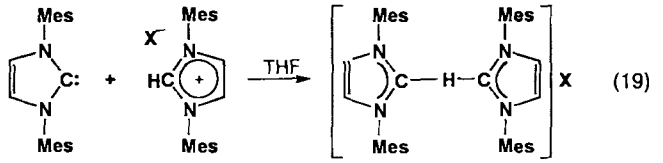
X = I, $[B(C_6H_5)_4]$

Adducts (1:1) of 2,3-dihydro-1*H*-imidazol-2-ylidenes with iodopentafluorobenzene[9] also display a characteristic linear arrangement [Eq. (18); R = adamantyl]. Increased π delocaliza-



tion in the imidazole ring indicates a formal charge assignment opposite to that in halonium methylides. These halonium methylides ($RX^+ \leftarrow {}^-CR_2$) with a small C-X-C angle are typically formed from reactions of electrophilic carbenes with halogen centers.

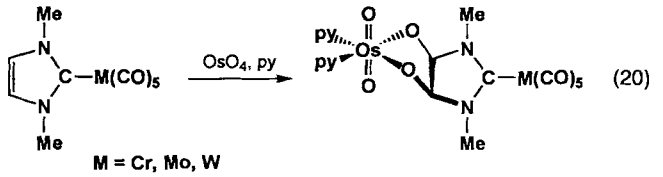
Upon complexation to a Lewis acid, electron density at C^2 decreases, and ylidic mesomeric structures become more important. In this sense a (hetero)aromatic imidazolium salt is an adduct of free carbene with the strongest Lewis acid, a proton. By allowing 1,3-dimesityl-2,3-dihydro-1*H*-imidazol-2-ylidene to react with the corresponding imidazolium salt, a linear 3c–4e C-H-C hydrogen bridge is formed [172.5°; Eq. (19)].[97] This



X = PF_6, CF_3SO_3

"proton complex" has two significantly different C–H bond lengths (202.6(45) versus 115.9(45) pm, X-ray diffraction). It was suggested that mesityl substituents favor the formation of homoleptic bis(carbene) adducts because of the "cavity" seen in the structure of the 2,3-dihydro-1*H*-imidazol-2-ylidene.

There is only one example of backbone functionalization of N-heterocyclic carbenes. A new type of bimetallic complex was obtained by *cis*-osmylation of the isolated double bond of 1,3-dimethyl-2,3-dihydro-1*H*-imidazol-2-ylidene in $[M(CO)_5$(carbene)] (M = Cr, Mo, W) with osmium tetraoxide [Eq. (20)]. Upon oxidation the ylidene ligand becomes slightly more nucleophilic. There is no interaction between Os^{IV} and Cr^0, as seen from cyclic voltammetry.[98]



M = Cr, Mo, W

3.5. Electronic Properties of N-Heterocyclic Carbene Ligands

It has been standard textbook knowledge for several decades that divalent carbon species $:CR^1R^2$ exhibit σ-donor and π-acceptor properties upon binding to transition metals. In principle, a "double bond" situation represented in formula **1** results, depending somewhat on the nature of R^1 and R^2. In all cases, however, metal–carbon bonds shorter than single bonds in metal–alkyl complexes are present. Unfortunately, there is only little thermodynamic data on metal–carbene bonds. With regard to the reactivity of the metal-bonded carbon fragment, the literature discriminates between electrophilic (Fischer) and nucleophilic (Schrock) carbenes.[2] In many cases the carbene (alkylidene) ligand can be transferred to other substrates; cyclopropanation and metathesis of olefins are probably the most prominent examples.[3] A general reaction scheme is not easy to produce since particularly the nature of the metal influences the reactivity of the carbene. However, metal–carbene complexes often react with cleavage of the metal–carbon bond. For this reason the common carbenes $:CR^1R^2$ (R^1, R^2 = H, alkyl, aryl, alkoxy, amino) are not considered as ligands that would survive the standard reaction conditions of organometallic catalysis.

The quite distinctive role of diamino-substituted carbenes (singlet ground state) was anticipated in coordination chemistry, and the classification into "Fischer-" and "Schrock-type" complexes ($[Cr(CO)_5\{C(OMe)Ph\}]$ and $[(\eta^5\text{-}C_5H_5)_2Ta(CH_3)(CH_2)]$, respectively) does not hold for N-heterocyclic carbenes of the imidazole and imidazolidine series. At first glance these may be classified as Fischer-type compounds which are formally derived from rather "soft" nucleophilic carbenes and are susceptible to nuleophilic attack at the carbene carbon.

Conventional carbenes are rather weak σ donors. Their bonding to metals depends on pronounced π backbonding; metals in low formal oxidation states therefore prevail in this domain of coordination chemistry. The CO stretching frequencies in metal–carbonyl complexes are a sensitive probe for electronic ligand properties. The differences between single-faced two-electron ligands in a series of isoelectronic compounds $[M(CO)_nL]$ can be derived from the IR spectra. The ratio of σ donors to π acceptors (that is, the electron density induced at the metal center) of $Fe(CO)_4$-bonded heteroatom-substituted carbenes increases in the order $:C(OR)R < :C(NR)R < :C(NR)_2$ ≙ imidazolidine-2-ylidene ≙ 2,3-dihydro-1*H*-imidazol-2-ylidene (see Table 2).

The stretching frequencies of the *trans*-CO ligands in carbene complexes $[M(CO)_nL]$ are identical within the limit of error with those of imidazolidine-2-ylidene and 2,3-dihydro-1*H*-imidazol-2-ylidene complexes (Table 1 and 2). The latter induces a remarkably higher electron density at the metal center than the basic trimethylphosphane.[12a, 65]

[a] 1,3-Dimethyl-2,3-dihydro-1*H*-imidazol-2-ylidene.

"Conventional" carbene ligands such as alkoxy(alkyl)-carbenes are similar in their bonding properties (with respect to low-valent metals) to carbon monoxide, and N,O-heterocyclic carbenes may also act as π acceptors.[12c–e] N-heterocyclic carbenes, however, very much resemble electron-rich alkylphosphanes and N donors such as nitriles and pyridine.[12a, b]

4. Main Group Element and Rare Earth Metal Complexes

With this background it was not surprising that metals incapable of π backbonding also coordinate these N-heterocyclic carbenes as nucleophilic two-electron ligands, which are in this sense similar to the distant relatives amines and ethers. Both the genesis of these complexes and their structural data suggest that they could be viewed as donor adducts, just like ammonia and ether complexes.

4.1. Alkaline Earth Metals and Zinc

The chemistry of beryllium shows unique aspects among the alkaline earth metals, since Be^{2+} is one of the hardest Lewis acids known. Tetrahedral adducts of the formula $BeCl_2 \cdot L_2$ formed upon treatment of $BeCl_2$, a polymer in the solid state, with donors. Use of the sterically unencumbered 1,3-dimethyl-2,3-dihydro-1*H*-imidazol-2-ylidene (L^{Me}) resulted in the formation of complexes $BeCl_2(L^{Me})_2$ and [$BeCl(L^{Me})_3$]Cl (Figure 5).[99] An X-ray diffraction analysis of the latter showed

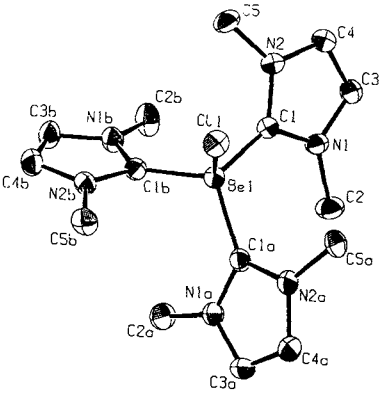

Figure 5. Structure of the cation $[BeCl(L^{Me})_3]^+$ in the chloride salt.

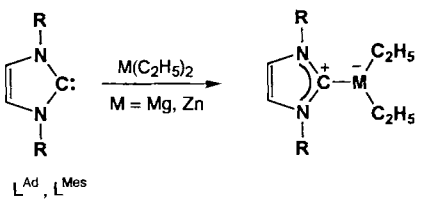
distorted tetrahedral coordination at the beryllium atom. With 1.822(3) (1.807(3) Å) the $Be-C_{carbene}$ distances are in the range of Be–alkyl or Be–aryl single bonds (1.708(6)–1.85(3) Å), and under consideration of the different ionic radii they can be compared to Be–O and Be–N bonds. The Be–Cl bond (2.083 Å) is significantly longer than in other tetravalent complexes and in $BeCl_2$. An excess of free carbene did not displace the second chloride ion. Complete solvation to yield dicationic complexes was only observed for $[Be(H_2O)_4]^{2+}$ and $[Be(NH_3)_4]^{2+}$.

Monomeric and dimeric 1:1 adducts of Mg^{2+} and Zn^{2+} were obtained from the reaction of diethyl zinc and diethyl magnesium with 1,3-diadamantyl- and 1,3-dimesityl-2,3-dihydro-1*H*-imidazol-2-ylidene (L^{Mes}, L^{Ad}) [Eq. (21)].[100] The solid-state

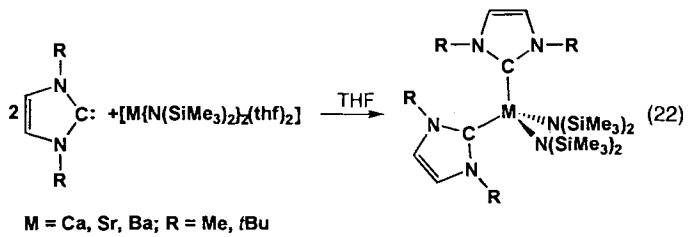


L^{Ad}, L^{Mes} (21)

structure of $(C_2H_5)_2Zn \cdot L^{Ad}$ shows trigonal-planar coordination at zinc. The angle between the coordination sphere of zinc and the imidazole plane is 81.6°. Mesityl groups do not provide as much steric protection as adamantyl groups, as seen in the dimeric magnesium adduct $(C_2H_5)_2Mg \cdot L^{Mes}$ with bridging ethyl groups. The ^{13}C NMR resonances of the imidazole C^2 nuclei are shifted upfield by 25–30 ppm. There is evidence that in THF the trivalent adducts are coordinatively saturated by THF.

The metal–donor bonds are predominately ionic and more labile in complexes of the heavier analogues of beryllium and

magnesium. 2,3-Dihydro-1*H*-imidazol-2-ylidene complexes of calcium, strontium, and barium were nevertheless obtained for bis(trimethylsilyl)amides $[M\{N(SiMe_3)_2\}_2(thf)_2]$ (M = Ca, Sr, Ba) upon displacement of the two THF molecules by two equivalents of 1,3-dimethyl-2,3-dihydro-1*H*-imidazol-2-ylidene [Eq. (22)]. The solubility and stability of the adducts decrease



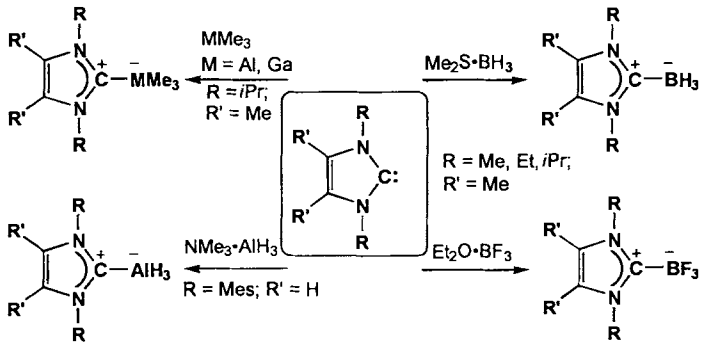
(22)

M = Ca, Sr, Ba; R = Me, *t*Bu

from calcium to barium. Whereas the calcium and strontium adducts can be isolated in the solid state at −36 °C, the barium adduct is stable only in solution. For the barium adduct a dissociation equilibrium is observed. Upon complexation to strontium and barium the resonances of the carbene centers are only slightly shifted to higher field (δ = 198 and 203, respectively).[101]

4.2. Boron, Aluminum, and Gallium

Borane adducts with (formally) neutral carbon donors such as carbon monoxide, isonitriles, or phosphane ylides are well established. Since conventional carbene complexes show pronounced metal-to-ligand π backdonation, electron-poor (coordination) fragments are not well suited for stabilizing carbene ligands. However, N-heterocyclic carbenes do not depend on backdonation due to delocalization of the nitrogen lone pair; 1:1 adducts with BH_3 or BF_3 (Scheme 2) are thermally stable



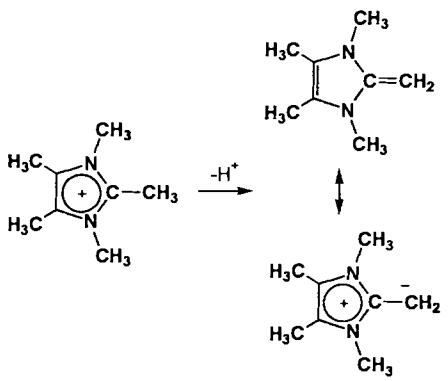
Scheme 2. Adducts of 2,3-dihydro-1*H*-imidazol-2-ylidenes and Lewis acids MR_3 (M = Al, Ga; R = H, Me), BH_3, and BF_3.

and can even be sublimed without decomposition. The ^{11}B NMR chemical shift of 1,2,3,4-tetramethyl-2,3-dihydro-1*H*-imidazol-2-ylidene → BH_3 at δ = −35 is typical for ylide–borane adducts, and between that of amine– and phosphane–borane adducts. The $^1J(^1H,^{11}B)$ coupling constant, however, is very similar to that of the anionic analogue $[(C_6H_5)BH_3]^-$. Both X-ray analysis and ab initio calculations on these borane adducts imply alternating bond lengths and only weak π interactions between the N-C-N moiety and the C–C π systems within the five-membered rings.[102] When 1,3-dialkyl-2,3-dihydro-1*H*-imidazol-2-ylidenes were allowed to react with 2-bromo-2,3-dihydro-1*H*-1,3,2-diazaboroles, borolylimidazolium salts formed under displacement of the halide.[143] Borane adducts are also known for N,O-heterocyclic carbenes.[144] A silylene–borane adduct was reported recently.[145]

When 1,3-bis(2,4,6-trimethylphenyl)-2,3-dihydro-1*H*-imidazol-2-ylidene was allowed to react with $H_3Al\cdot NMe_3$, a 1:1 adduct with AlH_3 formed.[103] The upfield shift of the ^{13}C NMR signal for the carbenoid carbon center is, agreement with π delocalization, even more pronounced (δ = 175.3; parent carbene: δ = 219.7; imidazolium salt: $\delta \approx 136$). 1,3-Diisopropyl-4,5-dimethyl-2,3-dihydro-1*H*-imidazol-2-ylidene adducts with Me_3Al or Me_3Ga are also stable. The metal–$C_{carbene}$ bonds in the monomeric, tetrahedrally coordinated adducts are significantly longer than the metal–C_{methyl} bonds (Al–$C_{carbene}$ 2.124(6) Å; Al–C_{methyl} 1.940(5) and 2.062(7) Å). In the trimethylaluminum dimer, Al_2Me_6, the Al–C_{bridge} bond length is 2.14(1) Å (3c–2e alkyl bridge), and a distance of 1.97(1) Å is found for the Al–$C_{terminal}$ bonds.[104]

4.3. Carbon and Higher Homologues

The pronounced ability of the N-heterocyclic fragment to take on a formal positive charge is demonstrated by ylidic olefins (exocyclic C_{ylide}–C bond), which form upon deprotonation of pentamethylimidazolium salts [Eq. (23)]. The chemical

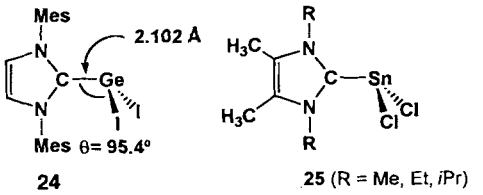


(23)

reactivity of the methylene carbon atom in $C_8H_{14}N_2$ and the strong shielding in the ^{13}C NMR signal (δ = 40.2) reveal high electron density on the methylene carbon atom and extended charge separation.[105a] The exocyclic double bond is extremely polarized due to a combination of the enamine structure and π delocalization; it acts as a strong ylidic donor towards boranes and metal–carbonyl complexes.[105b,c] In these complexes the exocyclic double bond is clearly bound to the metal in the otherwise unusual end-on mode. This ylidic olefin also allowed the preparation of mono adducts with 4f elements such as La^{III}, Nd^{III}, and Y^{III} from $Ln[N(Me_3Si)_2]_3$ (Ln = La, Nd) and $[(C_8H_8)Y(C_5Me_5)]$, respectively. Whereas coordination to low-valent metal–carbonyl complexes ($[M(CO)_5(C_8H_{14}N_2)]$, M = Mo, W) entails a significant high-field shift of the

methylene carbon resonance ($\Delta\delta \approx 45$), there is almost no change in the exocyclic ylidic bond upon coordination to lanthanide ions.[105d] Like these ylidic olefins, the 2-iminoimidazolines[146a] with exocyclic C_{ylide}–NH bonds display interesting chemistry.[147b,c]

Similar to organophosphanes, N-heterocyclic carbenes form stable adducts with carbon disulfide. In the crystal structure the plane of the CS_2 fragment is perpendicular to the five-membered ring (decoupled π systems).[105e,f] Strongly polarized structures are most clearly observed in the mono adducts $GeI_2 \cdot L$ (**24**, L = 1,3-dimesityl-2,3-dihydro-1*H*-imidazol-2-ylidene) and $SnR_2 \cdot L$ (**25**, L = 1,3-diisopropyl-4,5-dimethyl-2,3-dihydro-1*H*-



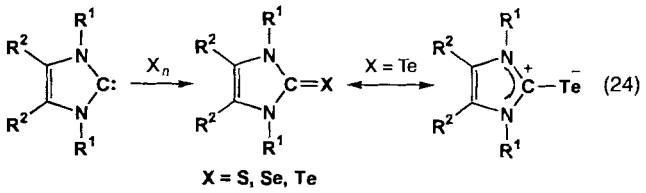
imidazol-2-ylidene; R = Cl, 2,4,6-iPr$_3$C$_6$H$_6$), which were used as models for the dimerization of singlet carbenes along a non-least-motion pathway.[106,107] The heavier main group elements show pronounced pyramidalization of the coordination sphere (sum of angles at Ge 290°, at Sn 282°, C-Ge-I 95.4 and 100.1°) and the two halves of the adducts are twisted with respect to one another. The ^{13}C NMR resonance of the carbene carbon atom in the GeI_2 adduct is shifted upfield by 61 ppm, and the N-C-N angle opened from 101.4 to 107.0°. Long C–Ge and C–Sn distances (2.102 and 2.290(5) Å, respectively) suggest that the adducts be described as Lewis acid–base adducts. Tetravalent dicarbene adducts of the less Lewis acidic $SnCl_2$ with sterically unencumbered carbenes are very insoluble.

The chemistry of hypervalent silicon compounds is dominated by complex anions with sixfold coordination. Substituents are in most cases negatively charged organic alkyl or aryl residues or fluoro, alkoxy, or hydrido ligands. A new way of forming element–carbon bonds was opened with the isolation of nucleophilic carbenes. The reaction of carbenes with main group element halides may yield several possible products (Scheme 3): a) neutral or ionic compounds resulting from simple adduct formation or displacement of a halide ion, or b) reduction of the central element with formation of 2-haloimidazolium ions. Lewis acidic silanes such as tetrachlorosilane as well as diaryl- or dialkyldichlorosilanes form monomeric and neutral pentavalent 1:1 adducts with 2,3-dihydro-1*H*-imidazol-2-ylidenes. The $SiCl_4$ adducts are rather labile. The less Lewis acidic trimethylsilanes Me_3SiCX are inert or, such as Me_3SiI, form ionic 2-(trimethylsilyl)imidazolium salts.[107]

The tendency to form complexes is more pronounced for tetravalent tin than for silicon. Pentavalent tin adducts are prepared from diphenyldichlorostannane. The solid-state structure of $Sn(C_6H_5)_2Cl_2 \cdot L$ (L = 1,3-diisopropyl-4,5-dimethyl-2,3-dihydro-1*H*-imidazol-2-ylidene) shows that the three organic substituents adopt the equatorial positions of a distorted trigonal bipyramid. With 2.179(3) Å the Sn–$C_{carbene}$ bond is longer than the Sn–Ph bonds (2.122(5) and 2.139(3) Å). The ^{119}Sn NMR resonance is shifted to higher field by about 30 ppm relative to that of the phosphane adducts.[107] Allowing 1,3-dimesityl-2,3-dihydro-1*H*-imidazol-2-ylidene to react with suitable phosphorous precursors yielded adducts with two- and six-coordinate phoshorus centers ($L^{Mes} \cdot PF_4Ph/L^{Mes} \cdot PPh$) which were also structurally characterized.[147]

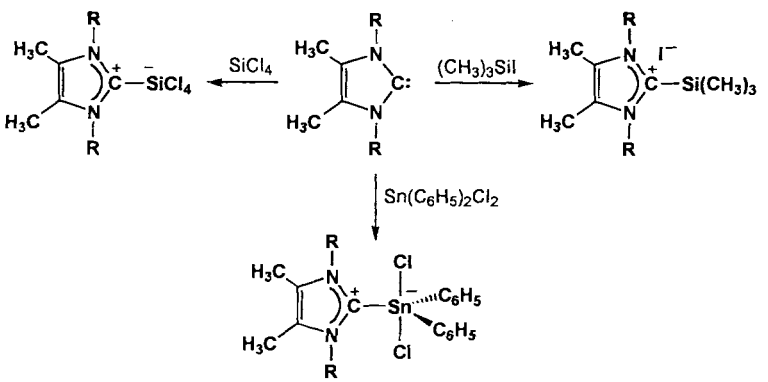
4.4. Sulfur, Selenium, and Tellurium

Ylidic structures with a positively charged imidazolium group have spotlighted a new perspective in organotellurium chemistry. In general the existence of tellurocarbonyl compounds such as telluroaldehydes or telluroketones can only be proven by stabilization with metals. In contrast, 2,3-dihydro-1*H*-imidazol-2-ylidenes readily react with elemental sulfur, selenium, and tellurium to form stable adducts [Eq. (24)].[108] According to



(24)

the crystal structure analysis the formal C_{ylide}–Te double bond is almost as long as a single bond (2.087(4) Å). The stability of this compound, in contrast to the analogous selenium compound, results from the decrease in double-bond character. The signals in the ^{125}Te and ^{77}Se NMR spectra of the telluro- and selenoimidazolines, respectively, resonate upfield with respect to that of other chalcocarbonyl compounds. This shielding is explained by π delocalization. Oxidation of the sulfur imidazoline with iodine yields a charge-transfer complex; in the cases of the seleno and telluroimidazolines, however, structures with covalent bonds are formed; the latter exists as a dimer. Chalcogenoimidazolines also serve as ligands in transition metal complexes.[148]



Scheme 3. Possible reactions of 4,5-dimethyl-2,3-dihydro-1*H*-imidazol-2-ylidene with main group elements. R = Me, Et, *i*Pr.

1,3,4-Triphenyl-4,5-dihydro-1*H*-1,2,4-triazol-5-ylidene similarly reacts with chalcogenes such as oxygen, sulfur and selenium to give the respective triazolinone, triazothion, and triazoselenone. The free triazolylidene also inserts into the O–H, N–H, and S–H bonds of alcohols, amines, and thiols, but no case of insertion into C–H bonds has been reported yet.[109] Reaction with protonation or alkylation occurs with acids and trialkyoxonium salts, respectively. The products formed from reaction with activated double bonds such as those in fumaric and maleic esters, amides, and nitriles suggest [2+1] cycloaddition with subsequent 1,2-hydrogen shift. Nonactivated double bonds are not attacked. Heterocumulenes (e. g. CS_2, $C_6H_5N{=}C{=}O$, and $C_6H_5N{=}C{=}S$) are also susceptible to nucleophilic attack by the triazol-derived carbene.

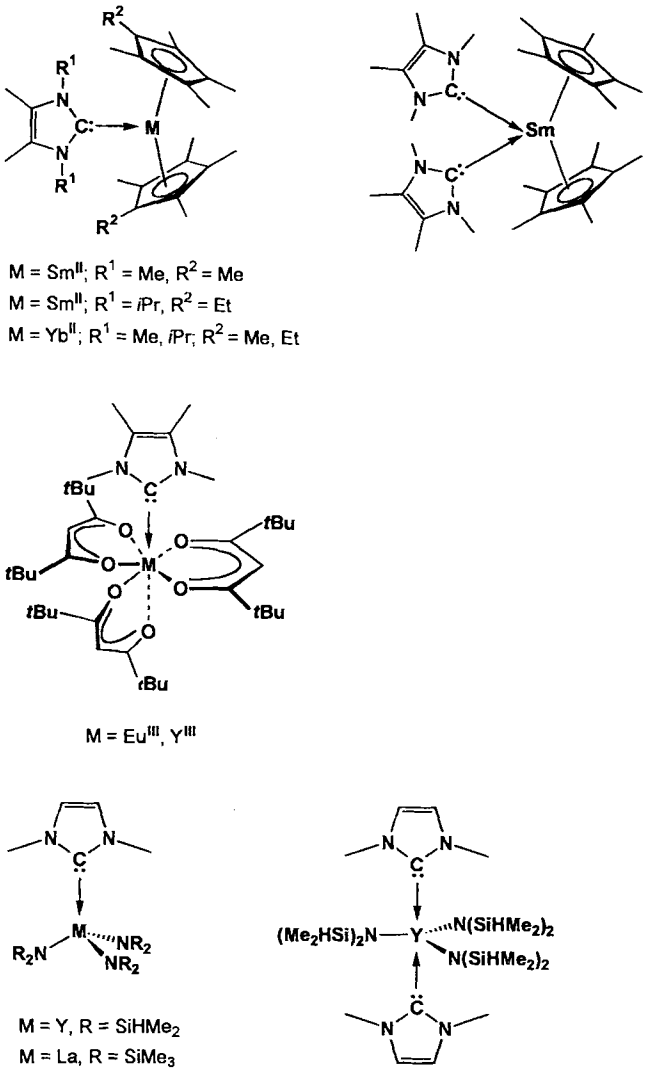
4.5 Rare Earth Metals

Until a few years ago isonitriles were the only neutral ligands in organolanthanide chemistry that coordinate through just one carbon atom. In view of the isolation of stable alkaline earth metal complexes of nucleophilic carbenes, it was not surprising that rare earth metals, which are nearly incapable of π backbonding, also coordinate N-heterocyclic carbenes (Scheme 4). 2,3-Dihydro-1*H*-imdidazol-2-ylidenes are not reduced by cyclopentadienyl precursors of Yb^{II} or Sm^{II}: 1,3,4,5-Tetraalkyl-2,3-dihydro-1*H*-imidazol-2-ylidenes readily replace the THF molecule in $[(\eta^5\text{-}C_5R_5)_2M^{II}(thf)]$ (M = Yb, Sm). The mono- and bis(carbene) adducts obtained $[(\eta^5\text{-}C_5R_5)_2Yb^{II}(L)]$ and $[(\eta^5\text{-}C_5R_5)_2Sm^{II}(L)_n]$ ($n = 1$ or 2) are more stable to air and moisture than the THF adducts.[110–113]

In the solid-state ^{13}C NMR spectra of the diamagnetic and thermally very stable ytterbium complexes, the resonances for the ligating carbon atom are shifted to higher field by only 10 ppm with respect to that of the free carbenes. Solid-state structures were determined in two cases. With 2.552(4) and 2.598(3) Å the $Yb{-}C_{carbene}$ bond lengths in the pseudotrigonal complexes are in the range of "elongated single bonds".[111, 112] The analogous monocarbene samarium(II) complexes are also high-melting stable solids. Addition of a second equivalent of 1,3,4,5-tetraalkyl-2,3-dihydro-1*H*-imidazol-2-ylidene to $[(\eta^5\text{-}C_5Me_5)_2Sm^{II}(L)]$ yielded the bis(carbene) adduct $[(\eta^5\text{-}C_5Me_5)_2Sm^{II}(L)_2]$. The X-ray structure analysis of this complex shows pseudotetrahedral coordination and rather long metal–$C_{carbene}$ bonds (2.837(7) and 2.845(7) Å). With 101.1(6) and 101.9(6)° the internal valence angles $N\text{-}C_{carb}\text{-}N$ are very close to that for free carbenes.[110]

Seven-coordinate monocarbene adducts of Eu^{III} and Y^{III} were prepared from the dionato precursors $[Eu(thd)_3]$ and $[Y(thd)_3]$ (thd = 2,2,6,6-tetramethylheptane-3,5-dionate).[110] In the ^{13}C NMR spectrum the former $C_{carbene}$ in $[Y(thd)_3L]$ resonates at $\delta = 199.4$ with a $^1J(Y,C)$ coupling constant of 33 Hz. Although the metal–carbene bond lengths are longer for lanthanides than for s-, p-, and d-block metals, the carbene does not dissociate on the NMR time-scale. With 2.663(4) Å the $Eu{-}C_{carbene}$ bond length in $[Eu(thd)_3L]$ is similar to Pr^{III}–C and Sm^{III}–C distances in isonitrile complexes.

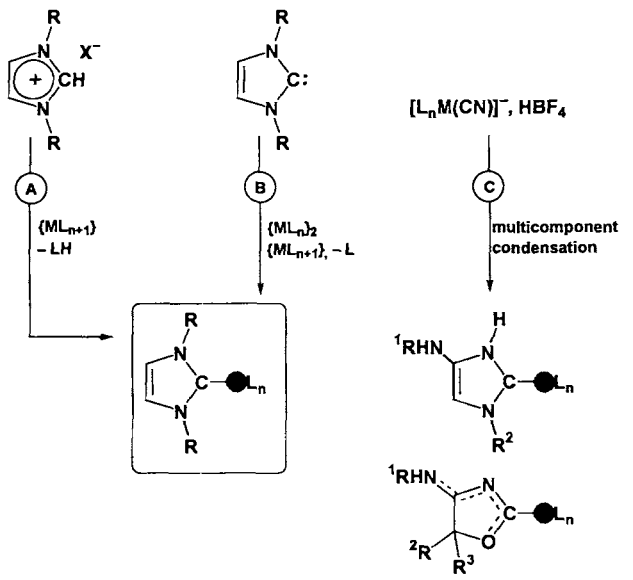
Lanthanide amides (with or without additional donors such as THF) are also versatile starting compounds for carbene complexes. Addition of one or two equivalents of 1,3-dimethyl-2,3-dihydro-1*H*-imidazol-2-ylidene to $[Y\{N(SiHMe_2)_2\}_3(thf)_2]$ yielded $[Y\{N(SiHMe_2)_2\}_3(L^{Me})]$ and $[Y\{N(SiHMe_2)_2\}_3(L^{Me})_2]$, which were both structurally characterized. The $Y{-}C_{carbene}$ distances are 2.55(1) and 2.648(8)/2.671(9) Å, and in the range of elongated Y–C single bonds. The bond lengths compare well to other lanthanide–carbene distances. Monocarbene adducts of lanthanum $[La\{N(SiMe_3)_2\}_3(L^{Me})]$ are available from $[La\{N(SiMe_3)_2\}_3]$.[114, 115]



Scheme 4. Complexes of 2,3-dihydro-1*H*-imidazol-2-ylidenes and rare earth metals.

5. Transition Metal Complexes

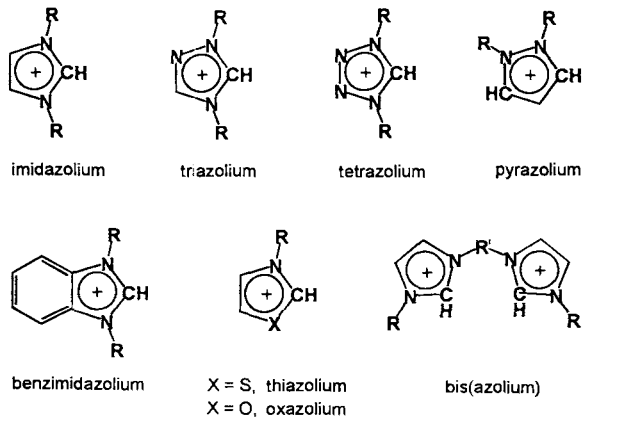
Transition metal complexes of heterocyclic carbenes are accessible by three different routes (Scheme 5). Most common is the treatment of simple metal salts or coordination compounds (neutral, cationic, or anionic) with azolium precursors (route A). The coordination properties of the anion X^- determine whether it enters the inner coordination sphere of the resulting carbene complex; the most commonly employed azolium iodides normally yield iodo complexes in which the iodide



Scheme 5. Synthesis of transition metal carbene complexes by A) in situ deprotonation of azolium salts, B) reaction with free N-heterocyclic carbenes, or C) reaction with anionic metal–cyano complexes

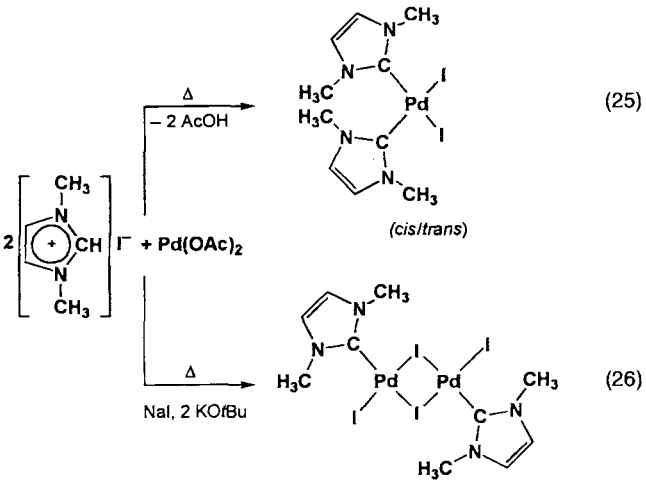
has replaced other ligands (e. g. chloride, bromide, acetate, carbon monoxide).

This is certainly not the case when non- or weakly coordinating anions are employed, for example tetraphenylborate or hexafluorophosphate. In some cases the metal complexes act as a reducing agent for imidazolium salts (evolution of hydrogen). The scope of heterocyclic carbenes which can be directly generated at metal centers is more varied following route A because of the broad variety of CH-acidic, cationic heteroaromatic compounds (Scheme 6).



Scheme 6. Heteroaromatic azolium salts which can be deprotonated in situ to give coordinated N-heterocyclic carbenes.

It is useful to have a basic ligand in the precursor that effects deprotonation of the azolium salt. C-Deprotonation of azolium salts is also feasible with (anionic) carbonylmetalates, which are normally generated through typical Hieber base reactions. Both variants were reported in 1968 for the first time: Wanzlick's homoleptic mercury(II) carbene complex and Öfele's chromium(0) complex were already mentioned [see Eqs. (2) and (1)]. Palladium(II) complexes were prepared similarly from the metal acetate [Eqs. (25) and (26)].[13, 116]



(25)

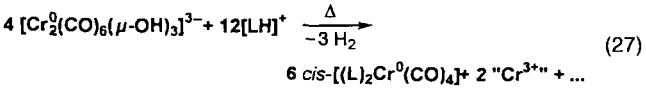
(26)

Öfele pointed out that this procedure is not limited to imidazolium salts. Also triazolium, tetrazolium, benzimidazolium, and even the less acidic pyrazolium salts yield complexes of the respective N-heterocyclic carbene ligands. Other metal bases from elements of Groups 6–8 were identified as suitable precursors, for example metalates of chromium, molybdenum, and tungsten, some of which contain μ-hydroxo or μ-alkoxo bridges (Table 6). In the case of the di- and tetranuclear complexes, the acidic azolium protons are not transferred to the hydroxy or methoxy ligands but reduced to hydrogen [Eq. (27)].[63]

Table 6. Multinuclear Group-6 metalates capable of reducing azolium salts with formation of carbene ligands.

		Metal M	Product [a]
dinuclear	$[M_2(CO)_{2n}]^{2-}$	Cr, Mo, W	$[M(CO)_5L]$
	$[M_2(CO)_6(\mu\text{-}OH)_3]^{2-}$	Cr	$[M(CO)_4L_2]$
	$[M_2(CO)_6(\mu\text{-}OH)_3]^{3-}$	Mo, W	$[M(CO)_4L_2]$
tetranuclear	$[M_4(CO)_{12}(\mu\text{-}OMe)_4]^{4-}$	Cr, Mo, W	$[M(CO)_4L_2]$

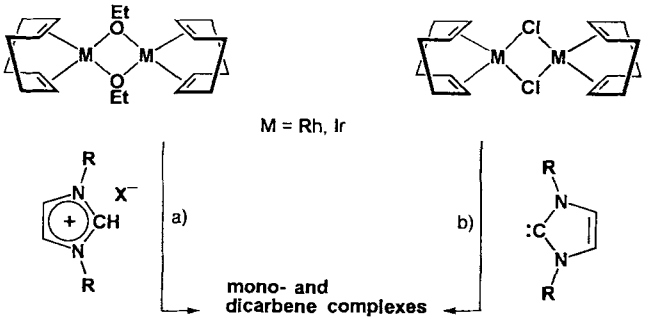
[a] L = carbene ligands derived from imidazole, triazole, tetrazole, benzimidazole, or pyrazole.



(27)

$K[Re_2(CO)_6(\mu^2\text{-}OR)_3]$ was successfully applied to synthesize dicarbene complexes *fac*-$[Re(CO)_3(L)_2I]$, and $Na_2[Fe_2(CO)_8]$ was a suitable precursor for carbene complexes of the type *trans*-$[Fe(CO)_3L_2]$ and *cis*-$[Fe(CO)_3(L-L)]$. Again the metal precursor was partially oxidized during the synthesis.[63]

A variety of rhodium and iridium complexes were synthesized from easily available μ-alkoxy complexes and azolium salts. Carbene-complex formation is exclusively effected by proton transfer to the metal-bound ethoxy group (Scheme 7). The reactions seem to be thermodynamically controlled, as further acidic protons in the azolium unit did not inhibit carbene-complex formation. Even when an excess of base and azolium salt was employed, neutral monocarbene complexes of the type [M(η^4-1,5-cod)LX] (M = Rh, Ir; cod = cyclooctadiene) are formed selectively in almost quantitative yield.[65] On the other hand, free carbenes displaced the halide ligands to yield cationic complexes of the type $[Rh(\eta^4\text{-}1,5\text{-cod})L_2]^+X^-$ (Scheme 7). The acidic protons are therefore transferred to metal-bound ethoxide groups exclusively. However, cationic dicarbene complexes are also accessible when the imidazolium halides are first transferred to imidazolium ethoxides salts with potassium ethoxide in ethanol (2-ethoxyimidazoles are not observed).[62]



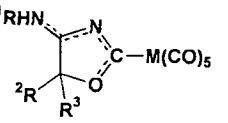
Scheme 7. Mono- and diylidene complexes of Rh and Ir are accessible a) directly from metal alkoxides and azolium salts or b) from free N-heterocyclic ylidenes and dinuclear μ-chloro complexes.

According to route B in Scheme 5, nucleophilic N-heterocyclic carbenes may replace other ligands, for example a two-electron ligand (such as halide, carbon monoxide, or acetonitrile) in the complex. From carbonyl complexes such as $[M(CO)_6]$ (M = Cr, Mo, W), $[Fe(CO)_5]$, or $[Ni(CO)_4]$, one or two molecules of carbon monoxide are displaced. Further substitution requires photolytic conditions.[12a, b]

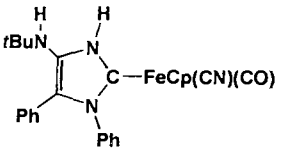
Two-electron donors are displaced by 2,3-dihydro-1*H*-imidazol-2-ylidenes in smooth reactions from the adducts $[(Me_2S)MCl]$ (M = Cu, Ag, Au), $[MCl_4(thf)_2]$ (M = Ti, Zr, Hf), $[MCl_4(py)_2]$ (M = Nb, Ta), and $[VCl_2(tmeda)_2]$.[150] Free N-heterocyclic carbenes thus act as conventional two-electron donors, and react with a broad variety of precursors. Bridging moieties of dinuclear precursor complexes are split by the carbene. Dinuclear halo- or acetato-bridged complexes of Ru, Os, Rh, Ir, and Pd yield mononuclear carbene complexes in excellent yields.[13, 34, 37, 61]

Acyclic carbenes with heteroatoms can be generated at the metal centers by transforming other C-bound ligands, for example isonitriles [Eqs. (28), (29)]. Nucleophilic attack of an alcohol or an amine at the electrophilic carbon atom starts the reaction sequence.[117] The four-component condensation (4CC) following route C, established by Fehlhammer et al., yielded the ligand framework of 2,3-dihydro-1*H*-imidazol-2-ylidene. Metal complexes of hydrogen cyanide (normally generated from anionic metal–cyano precursors) were treated successively with an aldehyde, an isocyanide and an amine to form (ring-substituted) N-heterocyclic carbene complexes. Because of the isolobal analogy between an oxygen atom and a ML_5 d^6 transition metal complex fragment, this route represents the organometallic analogue of Ugi's 4CC reaction to hydantoins.[118] The same principle can be employed to generate oxazolidine-derived carbenes bound to transition metals by a 3CC [2+1+2] cycloaddition of hydrogen isocyanide metal complexes, isocyanides, and carbonyl compounds [see Eq. (28)].[119, 120]

$$[M(CN)(CO)_5]^- + HBF_4 + CNR^1 + R^2R^3C{=}O \xrightarrow[-BF_4]{3\,CC} \quad (28)$$



$$[Cp(CN)_2(CO)Fe]^- + CNtBu + PhCHO + PhNH_3Cl \xrightarrow{4\,CC} \quad (29)$$

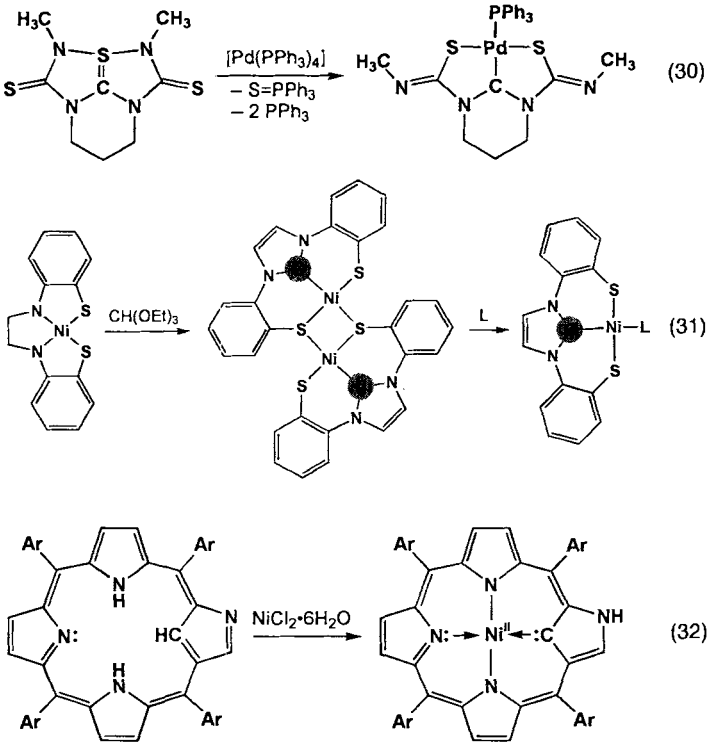


Less general routes were mentioned in the recent literature. For example, Matsumara reported that palladium und rhodium complexes of six-membered 2,6-diazocarbenes result in a most peculiar manner from 10-S-3-tetraazapentalene derivatives [Eq. (30)].[121] Sellmann et al. obtained nickel and platinum complexes with tridentate dibenzenethiolate-imidazolidine-2-ylidene ligands according to Equation (31).[122] Furthermore, Ghosh discussed the analogy between the "N-disordered porphyrines" [Eq. (32), Ar = p-Tolyl] and Arduengo carbenes.[123]

6. Structural Chemistry

The structure of bis(1,3-dimethyl-2,3-dihydro-1*H*-imidazol-2-ylidene)mercury(II) perchlorate was determined[151] three years after its synthesis by Wanzlick in 1968.[8] In the twenty years since 1971 only a few solid-state structures of this type were reported in the literature. On the other hand, there are many examples of structurally characterized complexes with C–C-saturated carbene ligands not considered in this review.

The data rather suggest a bonding order near, or even below, one. In comparison to Schrock- and Fischer-type carbene complexes, imidazole-derived ylidenes show long metal–carbon bonds. This is expected from the contribution of the ylidic resonance structures to the free 2,3-dihydro-1*H*-imidazol-2-ylidenes. Significant metal-to-carbon backdonation can only be observed in linear homoleptic bis(1,3-dimesityl-2,3-dihydro-1*H*-imidazol-2-ylidene) complexes $[M(L^{Mes})_2]$ of of zero-valent nickel and platinum. The $Ni-C_{carbene}$ distances are 0.15 Å shorter than in $[Ni(CO)_2(L^{Mes})_2]$, which cannot be



explained with the decrease in coordination number from four to two. A barrier to rotation has not been observed for the metal–carbene bond, which is in agreement with single-bond character. The position of the carbene ligands relative to the remaining complex fragment is strongly influenced by packing effects: For $[W(CO)_5L]$ three different rotamers with an eclipsed, a staggered, and an intermediate arrangement are structurally characterized for nearly identical carbene ligands.[61]

The structures of free 2,3-dihydro-1*H*-imidazol-2-ylidenes, as determined by X-ray and neutron diffraction, all show nearly identical geometries (Table 7). Considering a 3σ limit of error for X-ray and neutron diffraction data, the only difference worth discussing is an increase of about 2° in the ring angle N-$C_{carbene}$-N upon metal coordination. Whereas the geometric details of free and metal-bound carbenes hardly differ from each other, the structures of azolium cations are very different. In accordance with an increase in π delocalization in the five-membered ring upon protonation, the N–C bond lengths decrease and the C=C bond lengths increase. The angles in the ring become more similar. Apart from the C–C double bond all structural parameters of the carbene ligands are between those of the two extreme structures.

A dependence of the ring parameters on the metal is seen when the average bond lengths are considered (Figure 6).

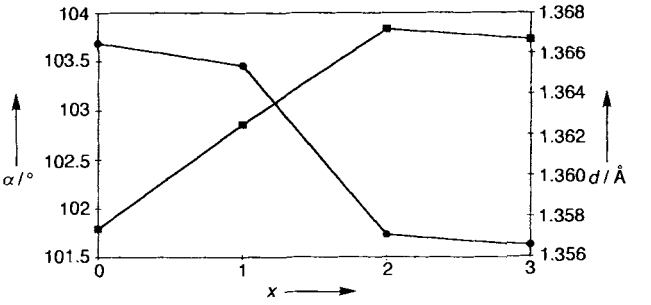


Figure 6. Averaged values of the $C_{carbene}$–N bond lengths d (circles) and the N-$C_{carbene}$-N angles α (squares) as a function of the metal from the transition metal series x. The first column ($x = 0$) lists the values for free carbenes [115].

Whereas isolated data are not meaningful, the trend in Figure 6 is more elucidating: Angle N-$C_{carbene}$-N increases for the heavier metals, while the $C_{carbene}$-N bond length decreases. This supports the general rule that metal–carbon bonds become stronger when going from 3d to 4d and 5d transition metals.

7. Catalysis

Applications of C–C-unsaturated N-heterocyclic carbenes as ligands in metal-containing catalysts were disclosed in a series of patents (1994). Previous investigations on catalytic properties were limited to C–C-saturated derivatives, but no advantage over the standard metal–phosphane catalysts was achieved.[124, 125] A recent publication on the Heck olefination sparked renewed interest in the catalysis-related aspect of carbenes.[13] Reactions such as hydroformylation, hydrogenation, isomerization, furan synthesis,[126] and olefin metathesis were investigated. The synthesis of chiral 2,3-dihydro-1*H*-imidazol-2-ylidene complexes and their application in asymmetric catalysis was another important development.

7.1. Hydrosilylation of Alkenes and Alkynes

The hydrosilylation of terminal alkenes catalyzed by rhodium–carbene complexes such as $[RhCl(\eta^4\text{-}1,5\text{-cod})L]$, $[RhCl(PPh_3)_2L]$, and $[RhCl(CO)(PPh_3)L]$ led to selective anti-Markovnikov addition of the silane [Eq. (33)].[124, 125] The

$$C_6H_{13}CH{=}CH_2 + HSiX_3 \xrightarrow{cat.} C_6H_{13}CH_2{-}CH_2SiX_3 \quad (33)$$

$X = OC_2H_5, C_2H_5, \ldots$

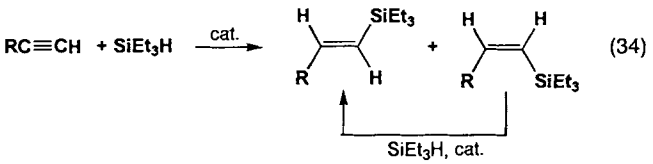
hydrosilylation products were obtained in yields of up to 98%, depending on the silane and the rhodium–carbene catalyst.

Table 7. Average bonding parameters of the 2,3-dihydro-1*H*-imidazol-2-ylidene system (see text; distances in Å, angles in °) [115].

	$C_{carbene}$–N	N–C	C–C	N-$C_{carbene}$-N	$C_{carbene}$-N-C	N-C-C
free carbene	1.367	1.390	1.335	101.8	112.8	106.3
carbene ligand [a]	1.360	1.384	1.329	103.5	111.4	106.9
imidazolium ion	1.322	1.374	1.345	109.2	108.2	107.2

Other rhodium(I) catalysts, for example $[RhCl(PPh_3)_3]$, gave lower yields. Conjugated dienes with rhodium–carbene catalysts yielded mixtures of 1,4- and 1,2-addition products, while $[RhCl(PPh_3)_3]$ led to pure 1,4-isomers.

In the hydrosilylation of alkynes[127] [Eq. (34)] the product distribution depended on the reaction conditions and the catalyst. With the rhodium(I) carbene complexes $[RhCl(\eta^4\text{-}1,5\text{-cod})L]$ and $[RhCl(PPh_3)_2L]$, silane addition gave mixtures of *cis* and *trans* adducts. Upon further heating in the presence of both the catalyst and the silane, complete *cis* → *trans* isomerization occurred.

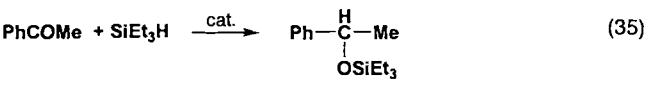


(34)

The rates of the hydrosilylation of alkynes increased in the presence of air and/or ultraviolet light. For example, irradiation of a mixture of phenylacetylene, triethylsilane, and catalyst $[RhCl(\eta^4\text{-}1,5\text{-cod})L]$ effected quantitative conversion within one hour, whereas in the absence of ultraviolet irradiation or the catalyst no reaction was observed. No such effects were seen for $[RhCl(PPh_3)_3]$.

7.2. Hydrosilylation of Ketones

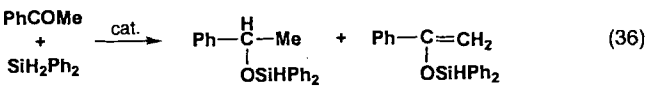
The hydrosilylation of ketones according to Equation (35) is of synthetic interest, since this reaction followed by hydrolysis



(35)

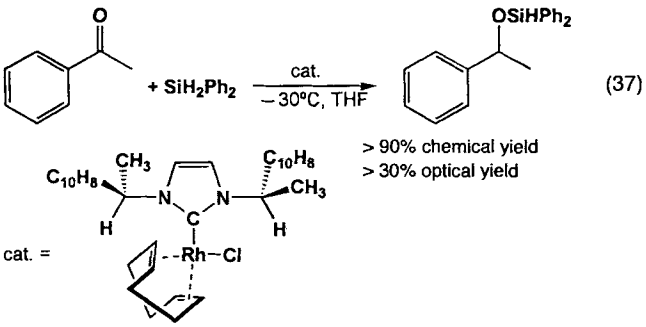
of the resulting silylether is a mild route for reducing ketones to secondary alcohols. The use of triethylsilane requires relatively high temperatures. $[RhCl(\eta^4\text{-}1,5\text{-cod})L]$, $[RhCl(PPh_3)_2L]$, $[RhCl(CO)L_2]$, and several ruthenium–carbene complexes were tested as catalysts.[124, 125] The rhodium complexes proved to be efficient catalysts. Only the dicarbene complex $[RhCl(CO)L_2]$ was rather unreactive; the mixed phosphane–carbene derivative $[RhCl(PPh_3)_2L]$ showed the best performance (98% conversion, 4 h, 100 °C). The nature of the N substituent on the carbene ligand also effected the catalytic activity, indicating that the carbene ligand is indeed involved in the catalysis. Ruthenium(II) complexes are less active.

The reaction temperatures could be significantly lowered if diphenylsilane was used as the silylating agent [Eq. (36)]. However, with some catalysts considerable amounts of the silyl enol ether side product formed.[125] The best results were obtained with the monocarbene complex $[RhCl(\eta^4\text{-}1,5\text{-cod})L]$ (*N*-phenyl derivative, 98% conversion, 24 h, 25 °C). Increasing number of carbene ligands lowered the yields.



(36)

Treating silanes with a rhodium(I) carbene complex in the absence of another substrate resulted in coupling to disilanes. This reaction was exploited for the synthesis of disilanes.[125] The asymmetric version of the catalytic hydrosilylation is particularly interesting. For example, prochiral ketones are converted into optically active secondary alcohols. Although chiral carbene complexes were synthesized by Lappert et al. in a multistep approach, they failed to generate significant enantiomeric excesses. Therefore, our recently published asymmetric hydrosilylation of acetophenone [Eq. (37)] represents the first successful asymmetric catalysis using chiral metal–carbene complexes.[128, 129]



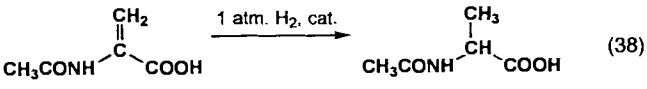
(37)

The synthesis of the chiral carbene complex is straightforward: the C_2-symmetrical imidazolium salt is synthesized in one step from enantiomerically pure α-naphthylethylamine and directly converted into the catalytically active rhodium–carbene complex (alkoxo route). With this chiral rhodium complex as catalyst, the hydrosilylation of ketones proceeds smoothly, even at low temperatures (–30 °C); asymmetric inductions over 30% (not optimized) are obtained.[128]

Although the enantiomeric excesses are subject to improvement, they are not influenced by the amount of catalyst or the degree of conversion. It should be mentioned that a free carbene ligand reacts with a hydrosilane with insertion into the Si–H bond. If there were free ligands present in the reaction mixture, they would be irreversibly destroyed and the enantiomeric excess would then decrease in the course of the reaction. It can therefore be taken for granted that the metal–carbene bond is kinetically inert under the reaction conditions.

7.3. Hydrogenation of Olefins

Mixed carbene–phosphane complexes, for example $[RhCl(PPh_3)_2L]$ and $[Ru(Cl)L(PPh_3)_2]$, are so far the most active of the carbene-containing catalysts for the hydrogenation of olefins. Hydrogenation of C–C double bonds proceeds smoothly under atmospheric pressure [Eq. (38)].[125]

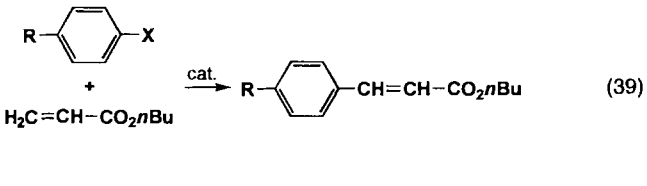


(38)

The hydrogenation of olefins catalyzed by rhodium(I) carbene complexes is being investigated further in our group.[130] Preliminary results suggest that carbenes are best combined with other ligands that lower the electron density at the metal center and dissociate in solution to generate coordination sites for the respective substrate ("hemilabile coordination"). This is plausible, since the activation of H_2 proceeds more readily when rather strong p-accepting phosphanes, for example pyrollyl phosphane, are employed.[131] Combined phosphane–carbene complexes, however, exhibit pronounced stability under the conditions of catalysis.

7.4. Heck Olefination

The application of palladium complexes $[PdL_2I_2]$ as catalysts for the Heck olefination of aryl halides according to Equation (39) has been subject to intense research.[13] The new catalysts are extraordinarily stable with respect to heat, moisture, and oxygen. Kinetic studies show that they become very active after a short induction period: Treatment with reducing agents yielded Pd(0) derivatives which are the true active spiecies (Figure 7) and have remarkable long-term stability in the Heck



(39)

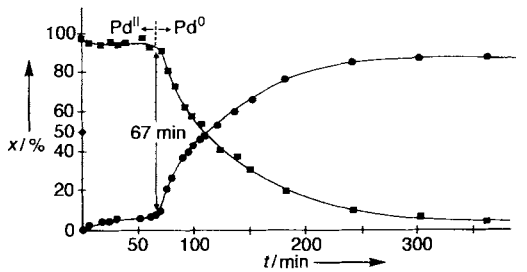


Figure 7. Palladium(0) carbene complexes as active species in the Heck olefination with the example of the reaction of 4-bromoacetophenone (squares) with *n*-butyl acrylate to form *n*-butyl-(*E*)-4-acetylcinnamate (circles). Hydrazine hydrate was added after 67 min; x = concentration.

olefination. No colloidal palladium was observed. These properties make carbene complexes of this type suitable for the activation of chloroarenes.

Enders et al. reported the synthesis of chiral palladium–carbene complexes and their application in asymmetric Heck reactions. However, they have not yet obtained significant optical inductions.[116]

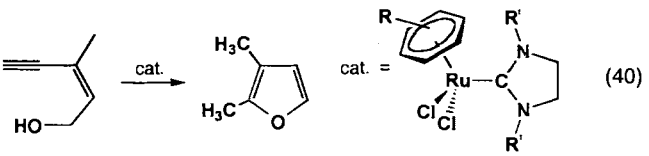
7.5. Hydroformylation

Rhodium(I) phosphane complexes are commonly used as catalysts in the hydroformylation of olefins. To avoid decomposition of the complex and to obtain a good ratio of linear to branched products, a large excess of phosphanes (up to 1000-fold) is required. Stoichiometric rhodium triphenylphosphane complexes slowly decompose under the conditions of a catalytic hydroformylation.

In contrast, since the long-term stability of rhodium(I) carbene complexes—for example $[RhCl(\eta^4\text{-}1,5\text{-cod})L]$, $[RhCl(PPh_3)_2L]$, or $[RhCl(CO)L_2]$—is much higher , they can be used without ligand excess; this is quite an advantage over conventional catalysts. However, the higher electron density at the metal entails reduced activities in comparison with triphenylphosphane complexes (e. g. $[RhH(CO)(PPh_3)_3]$). Higher activities in combination with long-term stability were observed in the case of mixed rhodium carbene phosphane complexes.[132] All experimental observations lead to the conclusion that the carbene ligands remain at the metal center during the catalytic cycle.

7.6. Furan Synthesis

In 1996 Dixneuf et al. reported an interesting application of ruthenium(II) carbene complexes of the general type [Ru(*p*-cymene)Cl_2L].[126] In a catalytic reaction (*Z*)-3-methylpent-2-en-4-yn-1-ol was converted into 2,3-dimethylfuran [Eq. (40)].



(40)

The reactivity of the catalyst is strongly dependent on the nature of the carbene ligand. Best results were obtained with a benz-2,3-dihydro-1*H*-imidazol-2-ylidene derivative.

7.7. Olefin Metathesis

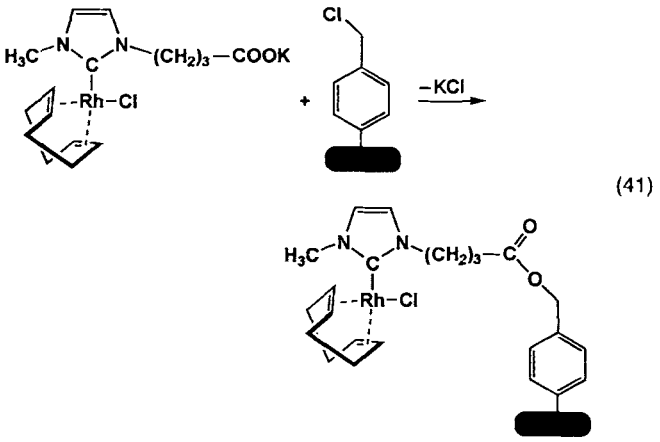
Ruthenium(II) carbene complexes were successfully employed as catalysts in olefin metathesis. The bond between ruthenium and the N-heterocyclic carbene carbon atom does not react with strained cyclic olefins; norbornene is not polymerized with [Ru(*p*-cymene)Cl_2L]. This suggests that the carbene acts as a stabilizing "spectator ligand". The ruthenium catalyst has a high activity in the metathesis of norbornene (turnover number (TON) at room temperature >8000) only when an alkylidene moiety is generated with trimethylsilyldiazomethane. Functional groups as in *exo*/*endo*-bicyclo-[2.2.1]hept-5-en-2-acetate are tolerated (TON >100).[62] Ruthenium(II) complexes with N-heterocyclic carbenes are similar to analogous complexes with basic phosphanes, for example [Ru(*p*-cymene)$Cl_2(PCy_3)_3$], in their catalytical performance. Further work in our laboratories is in progress.[133]

7.8. Conclusions

N-Heterocyclic carbene complexes exhibit promising properties for a number of catalytic reactions in organic chemistry. The

cheap synthesis of imidazolium salts makes them attractive for industrial applications. Since the strong σ-donating abilities of the carbene ligands lead to increased electron density at the metal centers, heterocyclic carbenes can generally be seen as alternatives and extensions to more basic phosphanes.

Since this new class of catalysts feature strong metal–carbene bonds, immobilization techniques have a realistic chance for catalytic applications; the first results are now available. A number of methods to immobilize either the imidazolium salt or a preformed catalyst have been tested. For example, the coupling of a functionalized rhodium(I) carbene complex with a Merrifield resin works well [Eq. (41)]. Many different functionalized



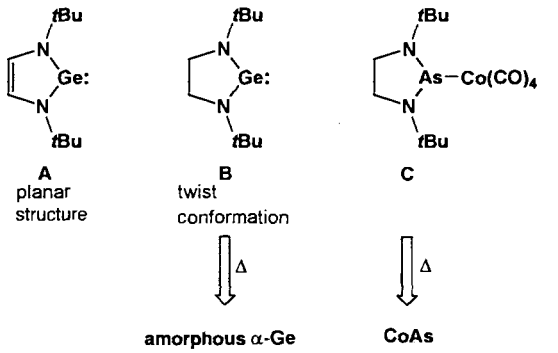
(41)

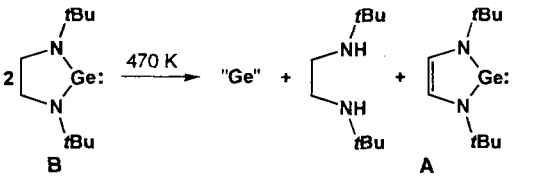
metal–carbene complexes with amino, ester, ether, hydroxy, and keto groups were synthesized for the purpose of subsequent attachment to organic and inorganic polymers.[135]

8. Chemical Vapor Deposition (CVD) of Germanium

Photoelectron spectroscopy (PES) and thermolytic studies opened an interesting application of the C–C-saturated cyclogermylene (**B**, Scheme 8) in materials science.[10, 134] The compound yielded [Ge/GeH] layers, isobutylene, HCN, and (possibly) isobutane but no hydrogen upon heating to 900 K, and [Ge/GeH] layers, **A**, and *N*,*N*′-bis-*tert*-butylethylenediamine upon heating to 470 K (Scheme 8).

A comprehensive CVD study by Veprek et al. established that these cyclogermylenes are suitable precursors for generating thin films of amorphic α-germanium by MOCVD (sublimation at about 40 °C/0.25 mbar).[135–137] Depending somewhat on the nature of the support meterial, germanium coatings began growing around 245 °C. At lower temperatures selective deposition of germanium on silicon patterned with SiO_2 was possible. To demonstrate the selectivity, silicon wafers covered with 1.8 μ thick patterned SiO_2 were used. The contact holes were filled at a substrate temperature of 230 °C with germanium without any deposition onto the SiO_2 surface. X-ray diffraction analysis showed that all films were amorphous without detectable crystallite (sensitivity about 1 vol%). The dark conductivity of the germanium film on SiO_2 ("ball-like film") reached values of 6.6×10^{-3} S cm^{-1}. This relatively high value and low activation





Scheme 8. Germylenes as a source for depositing α-Ge films by CVD.

energy of 0.20 eV are due to the dendritic-like nature of these films. The compact films deposited on clean SiO_2 surfaces had a relatively high dark conductivity (7.2×10^{-4} S cm^{-1}, 25 °C) and activation energy (0.25 eV). Hydrogen contents were around 0.2 atom%.

The decomposition of cyclogermylene **B** follows a bimolecular mechanism: One germanium atom is deposited, while an equivalent amount of the C–C-unsaturated derivative **A** is formed together with the diamine. The precision of this decomposition seems to arise from a predissociative bond lengthening along with the occupation of antibonding orbitals residing at germanium approaching the surface. This corresponds to a weakening of the Ge–N bonds and consequently promotes decomposition. The same feature was recognized in the case of the arsenic–cobalt heterobimetallic compound **C** (Scheme 8), which formed thin films of cobalt arsenide under CVD conditions at temperatures as low as 210 °C.[138] Electron micrographs showed uniform films, energy dispersive X-ray spectroscopy and electron spectroscopy confirmed their bulk composition, and powder diffraction patterns and conductivity measurements proved the crystallinity and electrical properties. As in the case of germanium above, impurities due to carbon, oxygen, and nitrogen were below 1%.

9. N-Heterocyclic carbenes—Quo vadis?

Heterocyclic carbenes of the imidazole, triazole, and thiazole families are no longer laboratory curiosities, since general avenues for synthesis have been opened following Arduengo's discovery of stable, isolable carbenes. A specific strength of these compounds is their universal capability to coordinate to metal centers, ranging from electron-rich transition metals (e. g. Pd^0, Rh^I) to electron-poor main group metal cations (e. g. Be^{2+}) and high oxidation state metals such as Ti^{IV}, Nb^V, and Re^{VII}.

Considering this versatility, N-heterocyclic carbenes surpass even phosphanes in that pure σ donation suffices to form stable "adducts" with certain metals and nonmetals—just as for amines and ethers. In addition, unexpectedly stable bonds are formed with catalytically relevant metals, as exemplified by the palladium(0) carbene complexes that easily survive temperatures as high as 140 °C under the harsh conditions of catalytic Heck coupling reactions.

These specific ligand properties make N-heterocyclic carbenes ideally suited for redox-dependent catalytic cycles because they tolerate rather different electronic situations. The future is thus seen in homogeneous catalysis. Effects to be expected from ligand functionalization are far from being explored. Side chains containing hemilabile phosphorus, nitrogen, and oxygen functionalities should trigger the chemistry at the metal center and, at the same time, enhance the catalyst's stability.

Chelating dicarbenes have already been verified in the free state and attached to metal centers. Water-soluble and immobilized derivatives may bridge the gap between homogeneous and heterogeneous catalysis. Finally, chiral derivatives will exploit the advantageous flexibility of composition, not least because simple ring syntheses are available. Chiral carbenes synthesized from α-phenylethylamine, glyoxal, and formaldehyde work reasonably well as part of a rhodium(I) complex in asymmetric hydrosilylation, but can certainly be improved by generating a fixed geometry (no rotation around the N–C bonds). We do not think that the planar core geometry of this class of ligands, as compared to the conical geometry of phosphanes, will reduce the efficiency of chirality transfer, not least because of the chance to synthesize bulky, chelating derivatives. It is reasonable to assume that N-heterocyclic carbenes will extend the well-established phosphanes as catalyst ligands, both alone and in combination with the latter.

What have we learned from the foregoing discussion? There are three major reasons why N-heterocyclic carbenes enter a new era in chemistry thirty years after the landmark publications of Wanzlick[8] and Öfele:[7] a) They are available as free compounds from an efficient general route (deprotonation of azolium salts in liquid ammonia), thus making a plethora of substituted, functionalized, chiral, or immobilized derivatives important in catalytic applications accessible. b) They are compatible with literally any type of main group and transition metal element of the periodic table, both in low and high formal oxidation states. However, the syntheses of catalytically relevant metal complexes does not depend on the availability of the free carbenes, but rather rests on several indirect ways to convert an azolium precursor into the metal-bound carbene. c) They form highly efficient catalysts with certain metals; palladium(II) complexes of the type $[PdL_2X_2]$ were first used successfully in the Heck-type C–C coupling,[13] and another example is the enantioselective hydrosilylation.[128]

We conclude that N-heterocyclic carbenes have long been an overlooked class of catalytically relevant ligands in coordination chemistry. Although Wanzlick pointed out in his very first publication (1968) that nucleophilic carbenes are "close relatives of isonitriles" (!), they have always been viewed as curiosities. Their renaissance in the past several years, however, justifies the assessment that they will play a major role in tomorrow's organometallic chemistry.

The authors are grateful to Dr. K. Öfele (Technische Universität München) for his continuous participation in our research related to N-heterocyclic carbenes. We acknowledge generous support by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. The (former) students Dr. M. Elison, Dr. J. Fischer, Dr. G. R. J. Artus, Dr. D. Mihalios, C.-P. Reisinger, G. M. Lobmaier, Dr. O. Runte, M. Steinbeck, T. Weskamp, R. Eckl, M. Prinz, and G. Gerstberger deserve our gratitude for their experimentally skillful contributions to our work on the coordination chemistry of N-heterocyclic carbenes and their applications in catalysis. We thank Dr. R. Schmidt and Dr. L. J. Goosen for contributions to the manuscript.

Deposition of Data from X-Ray Structure Analyses

In order to make life easier for authors and referees the Cambridge Crystallographic Data Centre (CCDC) and the Fachinformationszentrum Karlsruhe (FIZ) have unified their procedures for the deposition of data from single-crystal X-ray structure analyses.

Prior to submitting your manuscripts please deposit the data for your compound(s) **electronically** at the appropriate data base, that is, at the CCDC for organic and organometallic compounds and at the FIZ for inorganic compounds. Both data bases will be pleased to provide help (see our *Notice to Authors* in the first issue of this year). In general, you will receive a depository number from the data base within two working days after electronic deposition; please include this number with the appropriate standard text (see our *Notice to Authors*) in your manuscript. This will enable the referees to retrieve the structure data quickly and efficiently if they need this information to reach their decision.

This is now the uniform procedure for manuscripts submitted to the journals *Advanced Materials, Angewandte Chemie, Chemische Berichte/Recueil, Chemistry—A European Journal,* and *Liebigs Annalen/Recueil.*

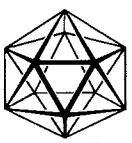
The Direct Synthesis of a *closo*-Borate from Elemental Boron

Lars Wesemann*

The significance of the icosahedron in the chemistry of boron is certainly unique. Whereas Platonic forms such as tetrahedra, octahedra, and cubes are known as structures of a diverse range of very different compounds, the icosahedron is a characteristic structural motif for boron and its compounds. The known element modifications[1] of boron all contain B_{12} icosahedra, which in α-rhombohedral boron are linked together through three-center bonds and through usual two center bonds in such a way that a near cubic face-centered packing of B_{12} icosahedra is formed. β-Rhombohedral boron has a considerably more complicated structure with 105 boron atoms per unit cell; the central icosahedron in this case is surrounded by twelve additional icosahedra. The modification of boron that was earlier designated as α-tetragonal boron should be described as boron carbide or boron nitride, in which four B_{12} icosahedra and two heteroatoms are present per unit cell.

In the boron-deficient borides the boron atoms are either isolated or linked one- or two-dimensionally, whereas the boron-rich borides all have a three-dimensional covalent linkage of the boron atoms. Icosahedra occur as a structural motif for the linkage of the boron atoms in several of these borides (B_4C, B_6P, B_6O, SiB_6, α-AlB_{12}, γ-AlB_{12}).[2]

In the chemistry of the boranes, which began with the pioneering investigations by Stock,[3] a regular icosahedron is found for the *closo*-borate $[B_{12}H_{12}]^{2-}$ (**1**).



$[B_{12}H_{12}]^{2-}$

1

Of the structures of the *closo*-borates the regular, closed deltahedra $[B_nH_n]^{2-}$ with $n = 6-12$ are known; the icosahedron is the upper limit ($n = 12$). The relationship between the structure of the boranes and the number of electrons in their frameworks shows that the *closo*-borates with n framework atoms have $2n + 2$ electrons.[4] For closed, dodecagonal heteroboranes, which can be derived formally by the exchange of a BH unit of the $[B_{12}H_{12}]^{2-}$ ion (**1**) for a heteroatom or a substituted heteroatom, the descriptive term icosahedron is now used despite their lower symmetry. The best known compound of this class of substances is *o*-carborane ($C_2B_{10}H_{12}$); however, syntheses are also known for other disubstituted as well as a large number of monosubstituted icosahedra.[5] An icosahedron of the higher homologue $[Al_{12}iBu_{12}]^{2-}$ was prepared in a surprising reaction by the reduction of diisobutylaluminum chloride.[6]

Although there is a close structural relationship between elemental boron and the icosahedral dodecaborate dianion $[B_{12}H_{12}]^{2-}$ (**1**), no synthesis of such a *closo* cluster directly from the element was known. As starting materials for the synthesis of the icosahedral polyborate dianion $[B_{12}H_{12}]^{2-}$ (**1**), which was isolated for the first time by Hawthorne et al. in 1960,[7] either smaller borane clusters and sodium boranate[8] or sodium borates or boron oxide are used in the presence of sodium and hydrogen.[9] The chemistry of **1** and other polyhedral boranate ions has become more significant because these compounds show potential for application in cancer therapy. The large effective nuclear cross section of the ^{10}B isotope for capture of thermal neutrons is used to achieve a localized destruction of the cell by the products of the nuclear reaction. Boron-rich soluble compounds such as the polyhedral borates are particularly promising for such medical applications.[10]

Many examples are known for the substitution of the hydrogen atoms in the *closo*-borate ion; the derivatization to give a halogen compound has been described for monosubstitution up to persubstitution.[11] The isolation and characterization of a B_{12} icosahedron that is completely substituted by selenium atoms and has the composition $[B_{12}(BSe_3)_6]^{8-}$ (**2**) (Figure 1) was recently described by Krebs et al.[12]

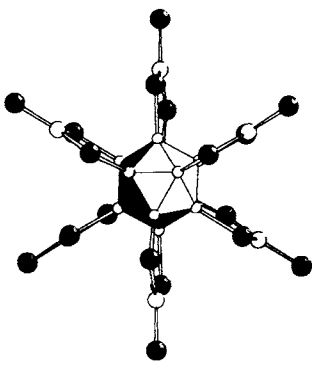


Figure 1. Structure of the anion of $Cs_8[B_{12}(BSe_3)_6]$ (o = B, • = Se).

It is not the complete substitution but rather the synthesis from elemental boron that is surprising. Hitherto, the reactions typical for solid-state chemistry have described the dissolution of boron network structures to give boron compounds completely substituted by chalcogen atoms. These products highlight the novel remarkable structural principles; the boron

atoms reside in trigonal-planar and tetrahedral environments, coordinated by chalcogen atoms. The short reaction times are considered as a possible explanation for the formation of the unusual cluster **2**, which obeys Wade's rules. Future experiments will surely determine whether this substance is an intermediate on the way to selenium borates. The bridging substituents in **2**, which in this form are not known for boron clusters, lower the icosahedral symmetry to D_{3d}. In the solid state the anion only shows crystallographic inversion symmetry. A substituent that bridges two neighboring atoms of the icosahedron framework, as in the cluster anion described here, was reported for an annelated six-membered ring at the azadodecaborane by Paetzold et al. and at the *o*-carborane by Wade et al.[13] The bridging of two neighboring boron atoms by a triazenium ligand has been confirmed for two open derivatives.[14]

The fascination of compound **2** originates on the one hand from its aesthetically pleasing structure and on the other from its synthesis, which reveals a direct link between the element boron and a substituted borane cluster.

Biosynthesis of Taxol

Jürgen Rohr*

Yew trees contain a broad spectrum of biologically active compounds.[1] Indeed "slips of yew" were already esteemed as important ingredients of certain recipies by well-known "chemists" in Elizabeathen literature (Shakespeare: Macbeth IV, I).[1b,c] Today, interest in yews is concentrated mostly upon taxol (**1**, paclitaxel),[2a] a novel cytostatic occurring in the bark of the Pacific yew *Taxus brevifolia*. Taxol, related taxoids, and the semisynthetically prepared taxotère (**2**, docetaxel)[2a] are antimitotic agents. They presumably[2b] stop the growth of cancer cells by stabilizing the mitotic spindles through inhibition of the depolymerization of their major component, tubulin. The hollow spindle fibers play an essential role in mitosis (cell division), since they pull the two chromosomes to opposite poles of the cell. Epothilone[3] is another natural product with this mode of action.[2b,3] Taxol and taxotère are successfully used for the treatment of a variety of solid tumors, in particular ovarian and breast cancer, even in advanced stages.

The problem hindering wider application of this promising drug has been its limited supply from its original source. Only 100–170 mg of taxol can be isolated from one kilogram of bark, and the slow-growing yews (a tree needs about 200 years to reach its full size) have to be cut down (ca. 1000 trees for 1 kg of taxol). The treatment of only one cancer patient requires at least 3 g, and approximately 50000 patients die each year of ovarian and breast cancer in the USA alone.[1,4]

An alternative source that preserves natural resources and is currently used for both taxol and taxotère is semisynthesis. 10-Deacetylbaccatin III (**3**) and baccatin III (**4**) are extracted from regenerable twigs of various yew species and then converted to taxotère (**2**) and taxol (**1**), respectively, through the linkage of the synthetically prepared side chains.[4,5] Taxol has also been prepared by a number of total syntheses,[4,6] but none of these are realistic for commercial production. In the most recent, and conceptually most attractive approach, which was devised by P. A. Wender et al. (the so-called pinene route),[6d] the overall yield is ten times that of the first taxol syntheses.

Further sources for taxol production are (endophytic) fungi such as *Taxomyces andreanae*,[7a] *Fusarium*, *Penicillium*, and *Phoma*, and *Alternaria alternata* ssp. *Taxus hicksii*, which have

1: R = , R' = CH_3CO

2: R = , R' = H

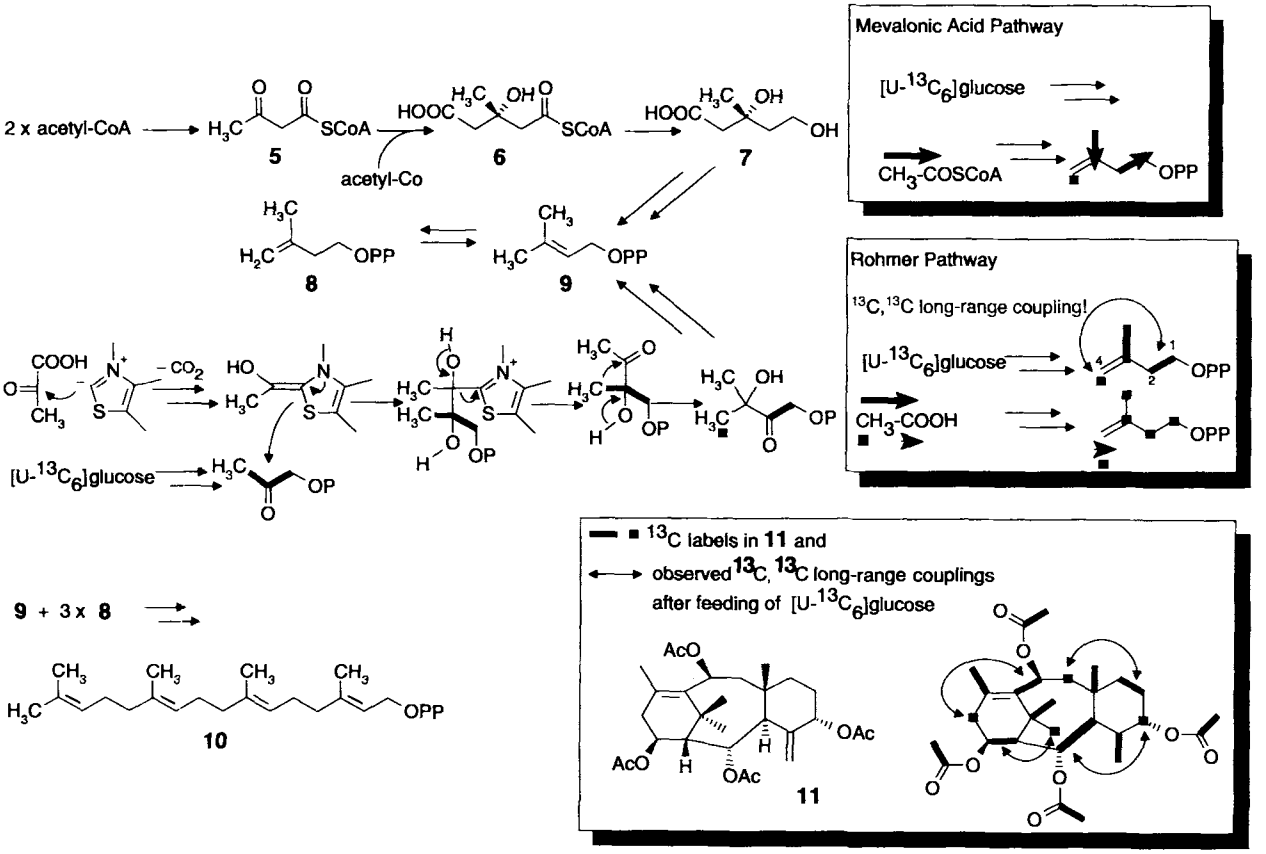
3: R = H

4: R = CH_3CO

been isolated from the Pacific yew and *Taxus hicksii*, respectively.[7a,b] These organisms probably "learned" to biosynthesize taxol from the tree by horizontal gene transfer.[7c] The fermentation of *Alternaria alternata* yields about 116 mg of taxol per liter.[7b] Further sources being developed include plant tissue cultures (production rates of roughly 55 mg of taxol per liter per week are already reached[7d]) and cell-free biosynthesis.[8] For the optimization of such complex biochemical systems exact information on taxol biosynthesis and its enzyme apparatus is essential, and recently tremendous advances in this area have been achieved.[9–18]

Initial information on the biogenetic origin of the taxol molecular frame was gained through radiolabeling studies by Zamir et al. using *Taxus baccata* and *Taxus canadensis*.[9b] The expected precursors were found: phenylalanine (for the side chain), acetate (for the acetyl residues), and mevalonate (**7**, for the taxane frame). However, the incorporation rates of mevalonate turned out to be very low, and no further degradation studies were undertaken to pinpoint the exact sites of incorporation (see below). Further biosynthetic hypotheses were suggested based on molecular modeling studies and on the structures of isolated side products.[9c]

More exact biosynthetic studies have been reported only recently, and virtually nothing was known about early stages in taxol biosynthesis up until 1995. These studies were led by R. Croteau et al. partially in collaboration with H. G. Floss and R. M. Williams[10,12–15]. The Munich-based teams headed by M. H. Zenk et al. and A. Bacher et al. also contributed interesting results.[10] The first step in the biosynthesis of the taxane diterpenoid frame is the formation of the common building block geranylgeranyl diphosphate (**10**). In this context it was surprising that the taxane frame is not of mevalonoid origin.[10] In incorporation experiments using cell cultures of *Taxus chinensis* with [U-$^{13}C_6$]glucose, [1-^{13}C]glucose, and [1,2$^{13}C_2$]acetate the labeled acetate reached only the acetyl residues (NMR analysis), but not the tricyclic taxane ring frame. The labeled glucose, in contrast, was incorporated in the acetyl groups as well as in the frame of taxol-related compound taxuyunnanine C (**11**, Scheme 1). Especially interesting was the analysis of long-range $^{13}C,^{13}C$ couplings in **11** after the incorpo-



Scheme 1. The classical mevalonic acid and Rohmer's "non-mevalonoid" biosynthetic pathway to isopentenyl pyrophosphate (**8**) and dimethylallyl pyrophosphate (**9**). The labeling pattern in taxoid **11** after the incorporation of [U-$^{13}C_6$]glucose and especially the observed $^{13}C,^{13}C$ long-range couplings within each isoprenoid unit indicate that the taxane skeleton is biosynthesized by a "non-mevalonoid" pathway.

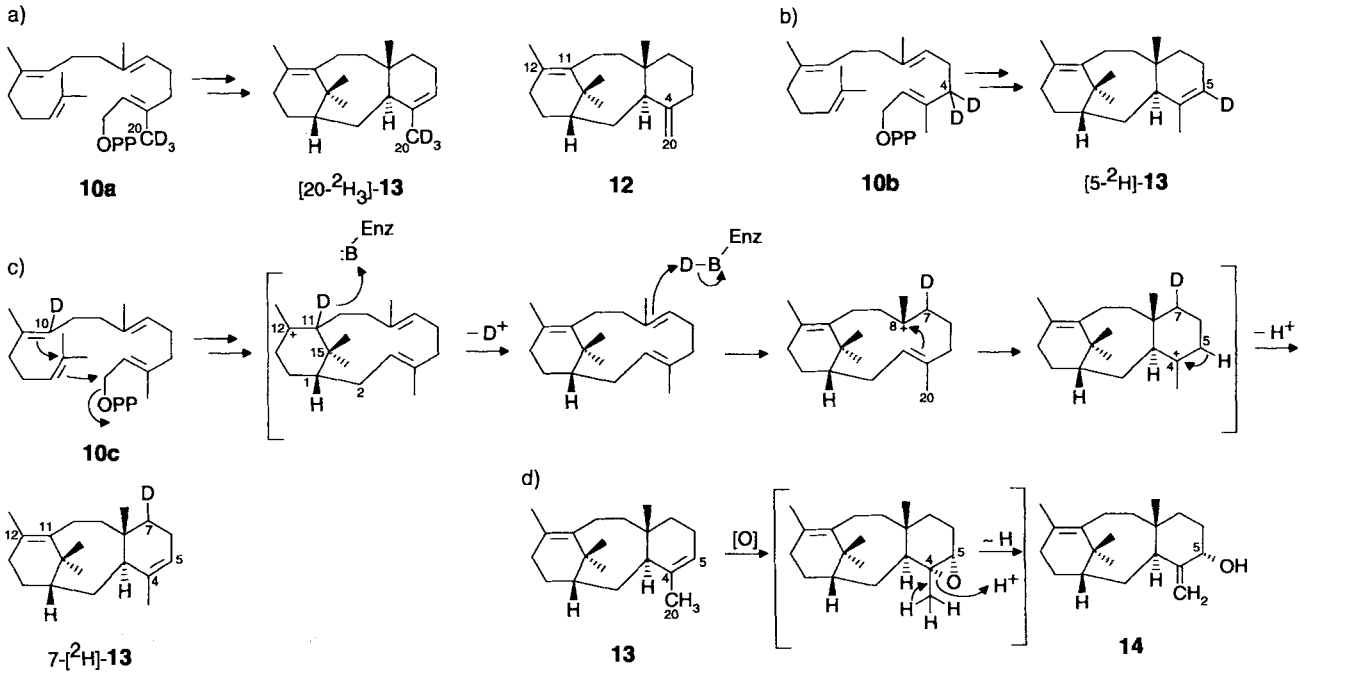
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3620-2191 $ 17.50+.50/0

ration of [U-$^{13}C_6$]glucose, since this proved that a C_3 precursor rearranges intramolecularly during the formation of each isoprene unit. This is not consistent with the classical mevalonate pathway,[11a] but remarkably resembles the alternative biosynthetic pathway for isoprenoids recently recognized by M. Rohmer et al. as predominant for the biosynthesis of hopane triterpenoids and ubiquinones in eubacteria (Scheme 1).[11b]

The fundamental building blocks of all isoprenoids, including terpenes such as geranylgeranyl diphosphate (**10**), are isopentenyl pyrophosphate (IPP, **8**) and dimethylallyl pyrophosphate (DMAPP, **9**). These are biosynthesized via acetoacetyl-CoA (**5**), 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA, **6**) and mevalonic acid (MVA, **7**). IPP **8** and DMAPP **9** are in an isomerase-mediated equilibrium. This leads to a labeling pattern showing the same incorporation rates everywhere when [1,2-$^{13}C_2$]acetate or [U-$^{13}C_6$]glucose is used (Scheme 1). In the alternative pathway discovered by Rohmer et al.[11b] IPP and DMAPP are constructed presumably via thiamine-activated acetic aldehyde (which is generated in the course of pyruvate decarboxylation) and dihydroxyacetone phosphate. Cleavage of the thiamine residue is followed by a rearrangement (CH_3 shift) and further reductions, and dehydration and phosphorylation steps (Scheme 1). The characteristic labeling pattern of IPP **8** and DMAPP **9** biosynthesized in this way is principally similar to that arising from the classical pathway when [U-$^{13}C_6$]glucose serves as the source of the isotopic label. But typically one finds different incorporation rates for the carbons of the C_2 and C_3 precursors and characteristic $^{13}C,^{13}C$ long-range couplings between the carbons of the former C_3 precursor within each isoprenoid unit which are separated due to the rearrangement. In contrast to their classically assembled counterparts, alternatively biosynthesized IPP **8** and DMAPP **9** cannot be labeled directly by acetate (one finds either no clear label at all or "scrambling", i.e. indirect incorporation after further metabolism, Scheme 1). This pathway may be in effect in many other organisms,[11c] possibly also in humans, since cholesterol inhibitors such as the HMG-CoA reductase inhibitors compactin and mevinolin (lovastatin) do not disturb the biosynthesis of ubiquinone which is essential for mitochondrial respiration.

The first committed biosynthetic step towards the construction of the tricyclic taxane skeleton is catalyzed by taxadiene synthase, an enzyme responsible for the formation of three C–C bonds.[12] Its final product is taxa-4(5),11(12)-diene **13** and not the isomeric 4(20),11(12)-diene **12** (Scheme 2), which had been favored due to the common occurrence of such taxanes (e.g. **11**). Feeding experiments with [1-^{3}H]geranylgeranyl diphosphate proved that **13** is the first cyclization product. The radiolabeled taxa-4(5),11(12)-diene was converted further into baccatin III (**4**), taxol (**1**), and other taxanes, which proved its role as a biosynthetic intermediate. A cell-free enzyme system was used in these experiments which was prepared from four-year-old *Taxus brevifolia* saplings.[12] After this success the responsible taxadiene synthase was sought. To find the genes encoding this enzyme, DNA primers were constructed based on known conserved gene fragments of putative related terpene cyclases. Amplification of two of these primers by polymerase chain reaction (PCR) yielded a DNA fragment 83 base pairs (bp) in length, whose sequence was homologous to that of a cyclase. A cDNA library of *Taxus brevifolia* DNA was then screened, and one of the hybridizing cDNA fragments was expressed in *E. coli*. The resulting protein (862 amino acids, 98303 g mol^{-1}) proved to be the desired taxadiene synthase and catalyzed the cyclization of geranylgeranyl diphosphate (**10**) to give taxa-4(5),11(12)-diene **13**. This work paved the way for more detailed studies of the mechanisms of this important key enzyme in the taxol biosynthesis.[13]

A taxa-4(20),11(12)-diene intermediate and its rearrangement into the thermodynamically more stable **13** could be ruled out



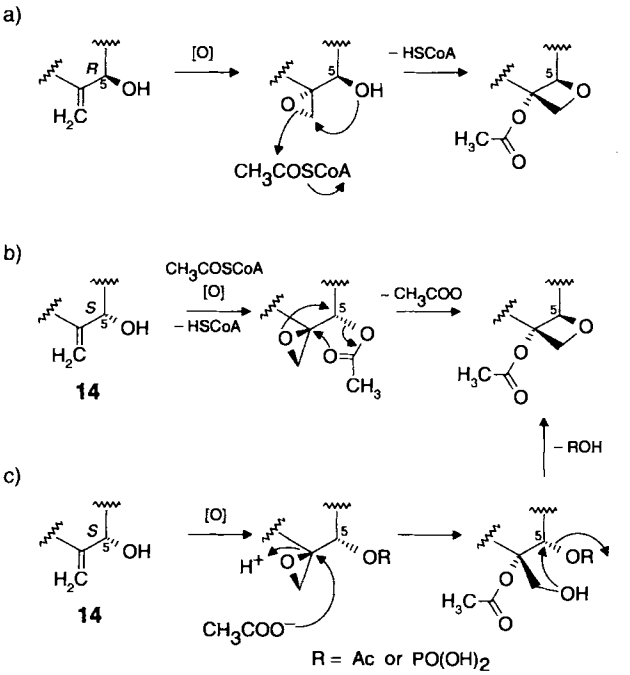
Scheme 2. Experiments with taxadiene synthase (see text for details). The taxa-4(5),11(12)-diene **13** oxygenase reaction: 4,5-α-epoxidation and subsequent rearrangement to give taxa-4(20),11(12)-dienol **14**.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3620-2192 $ 17.50+.50/0

conclusively, since all three deuterium atoms of [20-$^2H_3$]-geranylgeranyl diphosphate (**10a**) were retained during the taxadiene synthase reaction (Scheme 2a). In other work one deuterium atom disappeared when taxadiene synthase was fed [4-$^2H_2$]geranylgeranyl diphosphate (**10b**). This is a clear indication of a direct H^+ abstraction at C-5, and thus direct formation of **13** (Scheme 2b). Particularly interesting was the conversion of [10-^{2}H]geranylgeranyl diphosphate (**10c**), which yielded **13** labeled in the 7-position. This result proves that the C-11/C-15 and the C-1/C-2 connections are made prior to the formation of the C-3/C-8 bond, since the abstraction of one of the protons from C-11 (this was 10-H in **10**) leading to the formation of the C-11/C-12 double bond must occur prior to its reconnection at C-7. This last step generates the cation that enables formation of the last C–C bond in the biosynthesis of the tricyclic taxane skeleton, namely the one between C-3 and C-8. The resulting cation (at the 4-position) undergoes H^+ abstraction from C-5 and the C-4/C-5 double bond of taxa-4(5),11(12)-diene **13** is formed (Scheme 2c).[14]

The biosynthetic conversion of taxa-4(5),11(12)-diene **13** into taxol (**1**) requires extensive oxidative modification of the taxane skeleton, all in all eight oxygenation steps, including the formation of the important oxetane ring. Recently, the first and perhaps most important of these oxygenation steps has been elucidated,[15] namely the 5α-hydroxylation catalyzed by taxadiene-5-hydroxylase. This occurs with the simultaneous shift of the double bond from the 4,5- to the 4,20-position. The enzyme responsible, taxa-4(5),11(12)-diene-5α-hydroxylase could be characterized as a membrane-bound, NADPH-dependent, P450 oxygenase that uses molecular oxygen. Cell-free preparations from *Taxus brevifolia* saplings and cell cultures from *Taxus cupsidata* containing this oxygenase catalyze the reaction of radiolabeled [^{3}H]- and [20-$^2H_3$]taxa-4(5),11(12)-diene. The latter experiment showed a loss of one deuterium in agreement with the shift of the double bond into the 4,20-position. The former experiment allowed access to radiolabeled taxa-4(20),11(12)-dien-5α-ol **14**, which was shown to be a true biosynthetic intermediate by conversion into 10-deacetylbaccatin III (**3**) and taxol (**1**). The absolute configuration of alcohol **14** at the 5-position (5α and not 5β) was proven by TLC comparison with the diastereomers prepared by total synthesis.[15]

The proof that **14** is a biosynthetic intermediate of taxol (**1**) immediately following **13** and that the 5α-hydroxylation is the first oxygenation step and accompanied by the shift of the double bond gave rise to interesting mechanistic consequences, especially regarding the formation of the oxetane ring in **1** and related taxanes. The formation of the oxetane ring always was postulated to be initiated by epoxidation of the 4,20-double bond.[16] This is also the reason why taxa-4(20),11(12)-diene **12** was favored for such a long time as a biosynthetic intermediate (see above). There is evidence[15a] that the rearranged dienol **14** is formed by 4,5-epoxidation of **13** and subsequent opening of this epoxide along with H-migration (Scheme 2d). The observed formation of a 4,20-olefin along with the 5-hydroxylation confirms all the hypotheses favoring 4,20-epoxidation as the first step in the formation of the oxetane ring. The configuration in **14** (5α-OH) and in the oxetane moiety of **1**, however, exclude a direct intramolecular attack of the 4,20-epoxide by the 5-OH group (Scheme 3a). Instead, a more complicated acetate

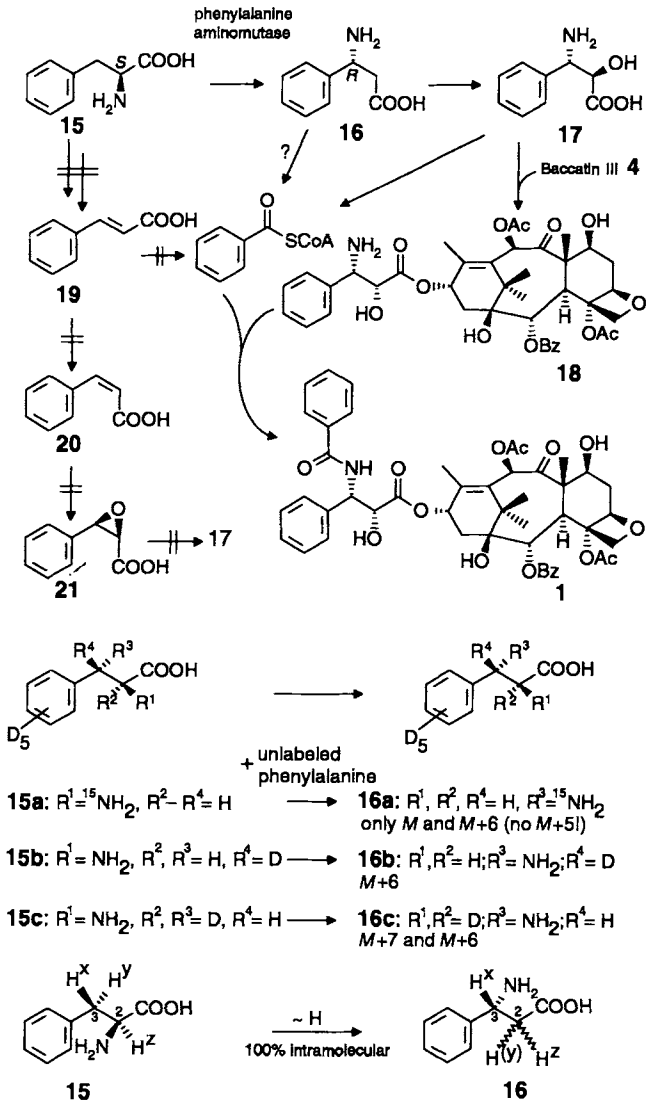


Scheme 3. Alternative mechanisms for the formation of the oxetane ring in **1**. The stereochemistry in taxadienol **14** and the oxetane ring in **1** exclude direct intramolecular opening of the epoxide (as shown in a)). The alternatives shown in b) and c) are still open.

rearrangement with concomitant opening of the epoxide and an S_N2 reaction at C-5 must be considered (Scheme 3b). It is still unclear whether this is an intramolecular acetate migration (Scheme 3b) or an intermolecular acetate opening (Scheme 3c).

The route from taxa-4(20),11(12)-dien-5α-ol **14** to taxol (**1**) is still quite long and for the most part unexplored. Late steps in the biosynthesis in which the taxol side chain is assembled were examined intensively by H. G. Floss et al. The side chain derives entirely from the biogenetic building block phenylalanine (**15**).[9, 17] Debenzoyltaxol **18** is an intermediate, the last one in the long biosynthetic cascade leading to **1**. One reaction that has been never detected before in biosyntheses in plants, a phenylalanine aminomutase reaction, plays a key role in the formation of the side chain from phenylisoserine (**17**), which is essential for the antitumor activity of taxol. In this reaction phenylalanine (**15**) is turned into the corresponding β-amino acid **16** through the 1,2-shift of the amino group (Scheme 4). Another plausible alternative via cinnamic acid (**19**), its isomerization (to the (*Z*) isomer **20**), epoxidation (to **21**), and final ring opening with concurrent amination could be ruled out because of negative incorporation experiments with [$^2H_5$]-**19** and analogously labeled (*Z*)-epoxide **21**. The reaction of the interesting enzyme phenylalanine aminomutase has since been examined closely with cell-free extracts from *Taxus brevifolia* cambial tissue cultures by using selected isotopically labeled precursors and analyzing the products by mass spectrometry. An experiment with [$^2H_5$,^{15}N]phenylalanine (**15a**) showed that the migration of the amino group from the α- to the β-position is strictly intramolecular, since addition of unlabeled **15** yielded only **16**, which gives rise to the molecular ion M^+ and $M+6$, but never $M+5$.[17b] Also the steric course of the reaction could

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3620-2193 $ 17.50+.50/0



Scheme 4. Late steps in the biosynthesis of taxol (**1**). Both arene rings of the side chain derive from phenylalanine (**15**), which is first rearranged into the corresponding β-phenylalanine (**16**). The alternative path via cinnamic acid (**19**) was ruled out (see text for details). Designed experiments to examine the mechanisms of the phenylalanine aminomutase reaction lead to the stereochemical course shown and a strict intramolecular course of reaction.

be determined. Conversion reactions of [3*R*-^{2}H]- and [2*S*,3*R*-$^2H_2$]-labeled phenylalanine (**15b** and **15c**, respectively) showed that the reaction proceeds with retention of the pro-*R* hydrogen at the 3-position and (partial) migration of the pro-*S* hydrogen from C-3 (in **15**) to C-2 of **16** (Scheme 4).[17b] The biosynthesis of the benzoate residue of the side chain is also performed differently in *Taxus brevifolia* than in other plants, in which a route via cinnamic acid (**19**) is preferred. Incorporation experiments with [$^2H_5$]-β-phenylalanine gave in part double incorporation, as indicated by the $M+10$ peak in the mass spectrum. Thus, the benzoyl group must also be constructed via β-phenylalanine (**16**) (or phenylisoserine (**17**)).

Although many questions regarding the biosynthesis of taxol (**1**) are still unanswered, recent results have pinpointed "bottlenecks" in the pathway. The primary time-consuming, rate-limiting key reactions are the taxadiene synthase and the subsequent oxygenase reaction. Now it is necessary to accelerate these reactions, taking advantage of well-established gene technological methods. A functioning transformation system to amplify the necessary genes coding the biosynthesis of the rate-limiting enzymes and to transform the enhancer genes that regulate certain biosynthetic steps has been already established.[18] It is based on the mutagenic bacterium *Agrobacterium tumefaciens*, a common tool for the targeted mutation of plants. With such methods, the chances are good that the rate of taxol production in plant tissue cultures can be stimulated further. Alternatives include targeted mutations of taxol-producing fungi for further increase of the taxol biosynthesis, and the development of an organism-independent, cell-free enzyme system,[8] a strategy currently under investigation.[8c]

EVENTS

Announcing the

XXIII International Symposium on Macrocyclic Chemistry

Macrocycles in Academe and Industry

June 7th–12th, 1998
Turtle Bay, Hawai

Imaging, Chelation, Catalysis, Molecular Recognition, Sensing.
Poster Presentations Currently Being Accepted.

Site of symposium is the Turtel Bay Hilton on the North Shore of the Island of Oahu. Activities of interest include golf, surfing, and tennis. An excursion to the Polynesian Center is planned. Organized by Jonathan Sessler, Eric Anslyn, and Eiichi Kimura.

To acquire registration and poster contribution forms please write: Eric V. Anslyn, Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin TX 78712, or e-mail anslyn@ccwf.cc.utexas.edu.

Immobilization of Platinated and Iodinated Oligonucleotides on Carbon Nanotubes**

Shik Chi Tsang, Zijian Guo, Yao Kuan Chen, Malcolm L. H. Green, H. Allen O. Hill, Trevor W. Hambley, and Peter J. Sadler*

Rapid advances in biotechnology are making major contributions to our understanding of health and disease, stimulating much current interest in designing novel systems for detecting abnormalities and for delivering (bio)chemicals to target diseases with limited side effects. In this context, the development of techniques for the study of molecular recognition is particularly important in the area of biochemical sensing, drug delivery, and gene therapy. For example, there has been recent interest in anchoring DNA onto a solid surface so that it may function as a chemical recognition agent for complementary DNA or for specific proteins.[1]

Carbon is the most common support material for the immobilization of biomolecules because of its strength, stability, and electrical conductivity.[2] However, only a limited amount of work on the structure and morphology of biomolecules adsorbed onto carbon materials has been reported. Recently discovered nanotubes have fullerene-type structures of concentric tubular carbon layers and a prominent central cavity 30–60 Å in diameter. This novel form of carbon has a higher electrical conductivity than graphite[3] and can be prepared on a gram-scale by high-temperature arc vaporization of graphite electrodes.[4, 5] We report here the synthesis and immobilization of small, platinated and iodated DNA oligomers and their immobilization on carbon nanotubes. These heavy-atom-labeled oligomers readily scatter electrons, which allows indirect visualization by high-resolution transmission electron microscopy (TEM).

Carbon nanotubes were prepared as previously reported.[6] TEM examination of the nanotube-rich distillate showed it to consist of fiberlike nanotubes (about 30%) and graphitic particles (about 70%). The TEM images of the tip region showed that the carbon tubes invariably had closed ends. In order to investigate whether DNA could be trapped inside nanotubes, opened nanotubes were prepared by treatment with HNO_3, and most of the surface acidic groups were removed by heat treatment.[7] TEM examination of the sample showed that more than 80% of the tubes were selectively opened in the cap region[8] and that the internal cavities were clean and empty.

The nanotubes were then treated with a DNA duplex labeled with a heavy atom, which could be clearly seen by the TEM technique. For this purpose a self-complementary 14-mer (**I**)

d(5'A-T-**G**-**G**-T-A-G-^{I}**C**-T-A-^{I}**C**-^{I}**C**-A-T3') **I**

containing 5-iodocytosine (^{I}C) and a GG pair, which could be labeled with chelated *cis*-$[Pt(NH_3)_2]^{2+}$ was chosen. The ^{1}H NMR spectrum of this oligonucleotide over the pH range of 4.4 to 7 (H_2O/D_2O (9/1), 0.1 M $NaClO_4$) showed 5 to 11 peaks in the region $\delta = 11.5-13.5$, typical of imino NH protons in Watson–Crick base pairs.[9] The duplex (**II**) was platinated specifically at G(3)·G(4) by treatment with 0.9 equivalents (i.e., ca. one Pt per duplex) of a solution containing equimolar amounts of *cis*-$[Pt(H_2O)_2(^{15}NH_3)_2]^{2+}$ and *cis*-$[PtCl(H_2O)(^{15}NH_3)_2]^{+}$, the reactive hydrolysis products of the anticancer drug cisplatin.[10] The reaction was monitored by [^{1}H,^{15}N] HSQC 2D NMR spectroscopy.[11, 12] The diaqua complex reacted very rapidly to give the GG chelate, and no monofunctional aqua intermediates were seen, whereas the monoaquamonochloro complex gave rise to two monofunctional intermediates *cis*-$[PtCl(NH_3)_2$(G3-N7)] and *cis*-$[PtCl(NH_3)_2$(G4-N7)] (Figure 1). One of the monofunctional adducts predominated,

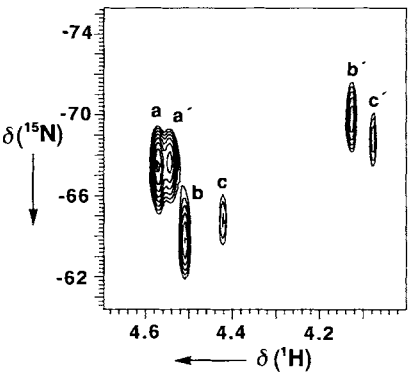

Figure 1. Two-dimensional [^{1}H,^{15}N] NMR spectrum recorded 12 h after mixing duplex **II** with 0.9 equiv of a solution of *cis*-$[Pt(H_2O)_2(^{15}NH_3)_2]^{2+}$ and *cis*-$[PtCl(H_2O)(^{15}NH_3)_2]^{+}$. At the end of the reaction (about 72 h) only peaks **a** and **a'** were present, which are assignable to the nonequivalent Pt-NH_3 ligands in the GG chelate Pt-**II**. Peaks **b**, **b'**, and **c**, **c'** are assignable to the monofunctional intermediates platinated at G(3) or G(4) (two peaks in each case: NH_3 *trans* to N7 and Cl).

an effect which has been observed recently for a 14-mer DNA oligonucleotide duplex.[12] After three days the GG chelate was the only final product detected by [^{1}H,^{15}N] NMR spectroscopy. The presence of about ten resonances in the imino region of the ^{1}H NMR spectrum suggested that the duplex structure of **II** was retained after platination, as is usual for such adducts.[10] The model of Pt-**II** shown in Figure 2 serves to indicate the position of the heavy atoms in this duplex.

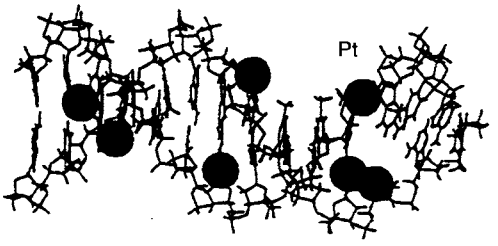

Figure 2. B-DNA model of Pt-**II** showing the positions of the heavy atoms (artificially enlarged; unlabeled heavy atoms are iodine atoms).

Both closed and opened nanotubes were treated with Pt-**II**. Figure 3 shows closed nanotubes (with graphitic layers) entirely embedded beneath a layer of amorphous material. A small amount of the amorphous material could be due to contamination of the sample during preparation and transfer, and local electrical charges induced by the electron beam could lead to the attraction of amorphous material inside the microscope chamber. However, contamination by such a large quantity of amorphous material on nanotube surfaces such as those shown in Figure 3 has never been observed. Nanotubes treated similarly

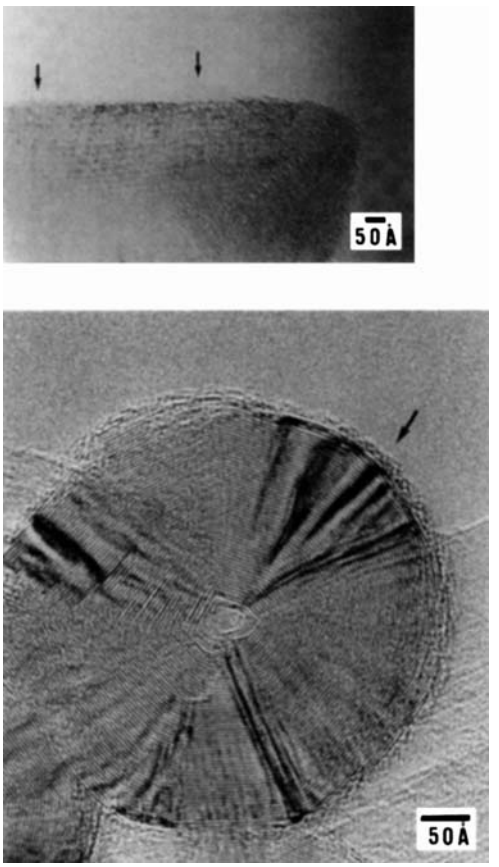

Figure 3. TEM images of closed nanotubes after treatment with Pt-**II**. Top: side view; bottom: an end. The arrows indicate adsorbed layers of amorphous material (DNA) on the surface.

but without the presence of Pt-**II** showed clear surfaces free of contamination. X-ray dispersive analysis (EDX) indicated that adsorbed material contained Pt, P, I, Cl, Na, and some Ca. We therefore infer that the amorphous surface layer is due to Pt-**II** (and $NaClO_4$). The immobilized material gave IR absorption peaks at 1630 cm^{-1} (NH_2 bending mode), 1097 cm^{-1} (phosphate backbone), 1000–1400 cm^{-1} (nucleobases), and 800 cm^{-1} (deoxyribose), typical of DNA.[13]

Good contrast from the amorphous material was obtained in some TEM images. This may arise from the heavy elements Pt and I, which scatter electrons more readily than the background. The amorphous material tended to cover the nanotube surface very evenly with an average thickness of 7–13 Å, although some larger aggregation patches were also observed (Figure 3, top). This indicates that the material interacts strongly with the carbon surface and has good surface-wetting properties. The strong binding was illustrated by the fact that material was still observable on open nanotubes (2 mg) after treatment with Pt-**II** (1 mL of a 3 μM solution) for 24 h and followed by incubation in water for 24 h. The adsorption of duplex **II** was studied by UV spectroscopy (see Experimental Section). Even after washing, about 25 μg of **II** (46% of added DNA) was adsorbed onto 2 mg of closed tubes and 12 μg of **II** (22% of added DNA) onto open tubes. The material washed off the tubes was shown to be double helical DNA by melting experiments. The greater adsorption of DNA onto closed nanotubes is consistent with the introduction of negative charges on the surface after oxidation of the tubes.

No clear image of the surface adsorbed DNA was obtainable, perhaps because of radiation damage. Blurring of images due to beam-induced specimen movement and charging has been reported previously.[14] Nevertheless the fairly uniform thickness of adsorbed molecules (7–13 Å) indicates excellent surface recognition properties. The large major groove of B-DNA results in it having a regular cross-section and is consistent with the observed two-dimensional width variation of 7–13 Å, being dependent on the projection angle and position relative to the electron beam. Thus, the surface layer coating the nanotubes is likely to be double-stranded helical DNA. DNA on some inert surfaces (for example, glass) can have a similar morphology as in bulk aqueous solution.[15] Some TEM pictures appeared to show the presence of highly coiled Pt-**II** trapped inside open nanotubes with filling along the entire length of the tube but in a discontinuous manner. Presumably when the tubes were dried and water was removed, the DNA anchored to the internal surface in a regular fashion. The included materials appeared to form long aggregates inside the nanotubes.

We have previously reported[6] immobilization of proteins and enzymes in and on the nanotubes and now anticipate that carbon nanotubes with their well-defined structures, defect-free surfaces and tubular morphology may be of general utility in the study of molecular recognition processes including biomolecule–carbon interactions of importance to the design of biosensors.

Experimental Section

Chemicals: The iodinated oligonucleotide I was supplied by OSWEL DNA Service (University of Southampton). *cis*-$[PtCl_2(^{15}NH_3)_2]$ was synthesized by a standard method [16], and the solution of *cis*-$[Pt(H_2O)_2(^{15}NH_3)_2]^{2+}$ and *cis*-$[PtCl(H_2O)(^{15}NH_3)_2]^{+}$ was prepared by treating *cis*-$[PtCl_2(^{15}NH_3)_2]$ with 1.5 equiv of $AgNO_3$ for 24 h followed by removal of AgCl. Carbon nanotubes were prepared by the arc vaporization method [6]. Open tubes were obtained by suspending closed tubes in HNO_3 and heating at reflux for 4 h [8]. The open tubes were washed thoroughly with H_2O, dried in air at 100 °C, and heated at 700 °C for 4 h to remove most of the surface acidic groups [7]. Immobilization was carried out by mixing 0.5 mL of a 0.5 mM solution of Pt-**II** (as used for NMR) with 2 mg of closed or opened tubes. To avoid DNA damage, no sonication was used. Typically the sample was preconcentrated under vacuum, and a droplet of the suspension was placed on a copper grid (400 mesh) covered with perforated carbon film. Tubes for the control experiments were treated in the same way except for the absence of added Pt-**II**.

Instruments: DNA samples were characterized by UV, IR, NMR, and HRTEM. UV spectra were recorded on a Perkin Elmer Lambda 16 spectrometer in 1 cm cells and a PTP-1 Peltier temperature programmer. The NMR spectra were recorded on Varian UNITY plus-500 and UNITY-600 spectrometers fitted with pulsed-field-gradient modules. ^1H chemical shifts were internally referenced to TSP ($Me_3Si(CD_2)_2CO_2Na$), and the ^{15}N shifts to 1.5 M NH_4Cl in 1 M HCl. The 2D [^1H, ^{15}N] HSQC spectra (optimized for $J(N,H) = 72$ Hz) were recorded as previously reported [11,12,17] with the sequence of Stonehouse et al. [18]. The electron micrographs were recorded on JEOL 4000EX and 2000FX high resolution microscopes. The accelerating voltages were adjusted to 200 kV in all cases. The microscopes were operated at their optimum defocusing conditions. In order to reduce contamination, short illumination times (less than one minute), low beam intensity, and improved vacuum by use of liquid nitrogen traps were employed. Energy X-ray analysis (EDX) was used to confirm the presence of Pt and I on nanotubes treated with Pt-**II**.

UV studies of DNA adsorption: Open or closed nanotubes (2 mg) were incubated with 1 mL of a 7 μM solution of duplex II in 0.1 M $NaClO_4$ for 24 h at ambient

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3620-2199 $ 17.50+.50/0

temperature with occasional agitation. The supernatant was separated by ultrafiltration (Centricon, Amicon, cut-off 30 kDa, 6 h at 15 °C). The nanotubes were then washed with water (0.6 mL), and the separation was repeated. In a control experiment (to check for adsorption of DNA onto the membrane filter), DNA solution was added to the ultrafiltration tube in the absence of nanotubes, and the separation and washing steps carried out as before. DNA concentrations were determined from the absorption at 260 nm. The recovery of DNA in the control experiment was >87%. A second set of experiments was carried out with 0.1 M $NaClO_4$ to wash the tubes, and then melting curves for the desorbed DNA were determined by UV.

Molecular modeling: A bifunctional Pt adduct was constructed on one strand of a B-DNA model with the HyperChem program [19] and restrained energy minimization, followed by docking of the ammine ligands in an appropriate geometry. This produced a model of the bifunctional adduct similar to those obtained with Newton–Raphson energy minimization and a force field developed for Pt/DNA interactions [20]. Iodine atoms were then added to the 5-positions of each cytidine base.

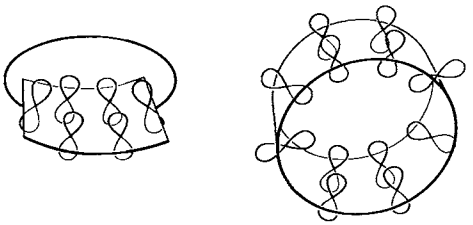
Beltlike Aromatic Hydrocarbons by Metathesis Reaction with Tetradehydrodianthracene**

Stefan Kammermeier, Peter G. Jones, and Rainer Herges*

One of the main motivations for the synthesis of cyclophanes is the preparation and investigation of compounds in which the π-electron system is spherically deformed by the introduction of bridging ligands (Scheme 1, left).[1] Fully conjugated belt- and



Scheme 1. Spherically deformed π systems in a cyclophane (left) and in a beltlike conjugated system (right).

tubelike structures can be viewed as an extreme example of such a deformation (Scheme 1, right).[2] The p orbitals in these structures are perpendicular to the surface of a cylinder and their inner lobes point towards the axis of the cylinder. To date, three such systems have been prepared by conventional synthesis and isolated as stable compounds.[3–5] Formally, the nanotubes generated by vaporization of carbon[6] and chemical vapor deposition (CVD)[7] also belong to this class of compounds.

Our approach to the synthesis of molecular belts and tubes is based on the ring enlargement metathesis[8] of tetradehydrodianthracene **1** (TDDA).[9] Scheme 2 illustrates the molecular unit construction system employed. a) Bianthraquinodimethanes are obtained starting from TDDA **1** and noncyclic alkenes;[3] b) cyclophanelike, bridged bianthraquinodimethanes are available from TDDA and cyclic alkenes;[3] c) tubelike anthracene-9,10-bisylidenes, which are connected by quinoid double bonds, can be constructed by dimerizing metathesis;[4] and d) bianthraquinodimethanes bridged by conjugated chains are formed from [*n*]annulenes.[3] The double bonds in the bridge of these beltlike conjugated systems should again be able to undergo metathesis with TDDA. This should provide access to larger conjugated systems composed of anthracenylidene units connected by quinoid double bonds and diene units in an alternating sequence. We now report on the synthesis of the smallest of these beltlike, fully conjugated systems which has 20 carbon atoms in its perimeter ($n = 0$, Scheme 2d).

In principle, cyclobutadiene, the smallest [*n*]annulene, would be suitable for the synthesis of the conjugated, bridged bianthraquinodimethane. Cyclobutadiene can be generated in situ[10] and also undergoes [2+2]cycloadditions;[11] however,

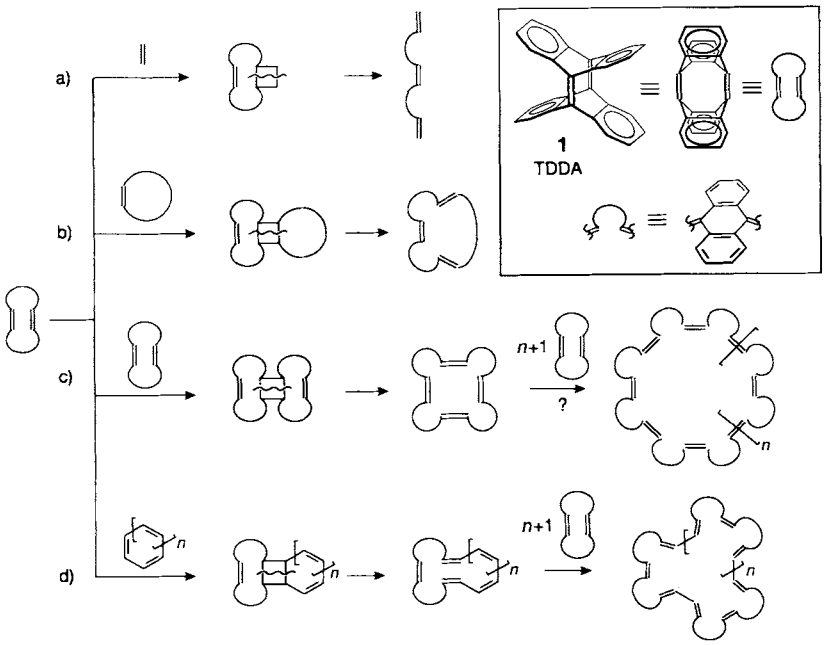
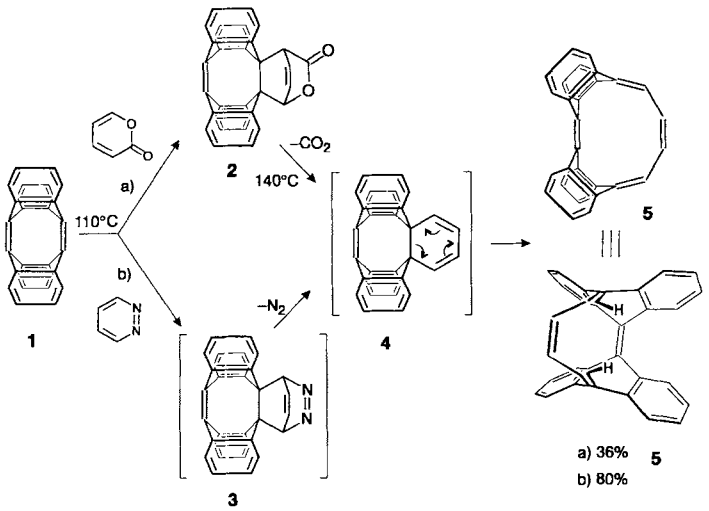


Scheme 2. Molecular unit construction system for the synthesis of molecular belts and tubes.

we chose the more comfortable detour via α-pyrone and 1,2-diazine. Both dienes react with TDDA **1** in boiling toluene yielding the Diels–Alder adducts **2**[12] and **3**, which eliminate CO_2 and N_2, respectively (Scheme 3). Electrocyclic ring opening results in the desired product **5** ("Kammermeierphane 1"[13]). In contrast to **3**, adduct **2** can be isolated and characterized.

According to the X-ray analysis (Figure 1),[14] the bridging ethene unit in **5** is *syn* with respect to the two quinoid double bonds. The C_s-symmetrical structure is also in agreement with a thermochemically allowed electrocyclic ring opening of **4**.



Scheme 3. Synthesis of "Kammermeierphane 1" **5** by reaction of **1** with a) α-pyrone and b) 1,2-diazine.

The sterically easily accessible double bond in the bridging part of **5** can serve as the reaction partner in a second metathesis reaction with TDDA **1**. Photochemically induced metathesis of **1** with **5** (benzene, 150W high-pressure mercury lamp, quartz filter,[15] room temperature, 1 h) directly leads to cyclophane **6** ("Kammermeierphane 2"[13]), which has the molecular formula $C_{60}H_{36}$ (Scheme 4).

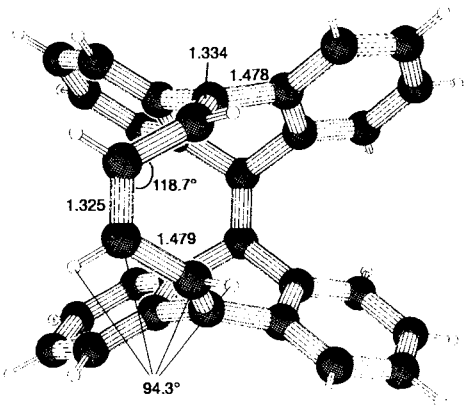


Figure 1. X-ray crystal structure of **5**.

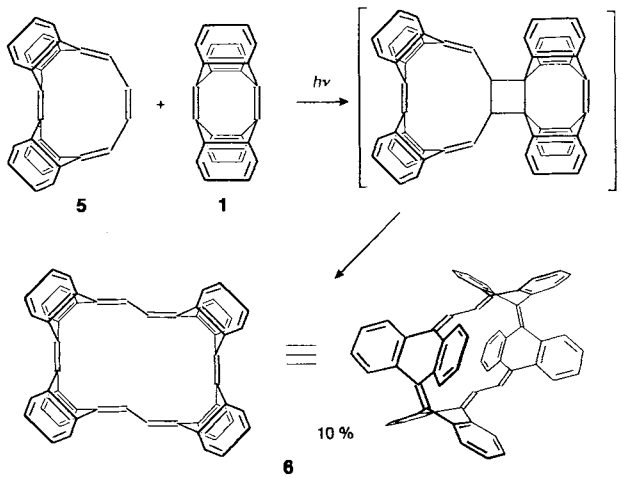

Scheme 4. Synthesis of **6** by metathesis of **1** with **5**.

Compound **6** is composed of two bianthraquinodimethane units, which are connected by C–C bonds such that a fully conjugated beltlike system is formed. The structure of **6** can be viewed as a subunit of a (5,5)-armchair nanotube.[16] According to AM1 calculations[17] and simple considerations based on space-filling models, the 1,3-butadiene units in the bridge must have s-*trans* configuration (C_{2h}). The s-*cis*/s-*trans* (C_1) and s-*cis*/s-*cis* (C_{2v}) configurations are not possible for steric reasons and would be highly strained. The NMR spectra confirm the C_{2h}-symmetrical structure. Because the structure itself prevents rotation about the single bonds, **6** has a rigid conformation. According to AM1 calculations the cavity of the approximately rectangular tube has dimensions of 7.9 × 4.8 Å. Figure 2 shows the calculated van der Waals surface of **6**. Based on the strategy illustrated in Scheme 2, it should be possible to synthesize larger belt- and tubelike π systems.

Experimental Section

2: A solution of **1** (100 mg, 0.284 mmol) and α-pyrone (82 mg, 0.852 mmol) in toluene (60 mL) was heated at reflux for 30 h. During the reaction two portions of α-pyrone were added (82 mg each). The solvent was removed in vacuo and the residue was purified by chromatography with hexane/ethyl acetate 2/1 on silica gel

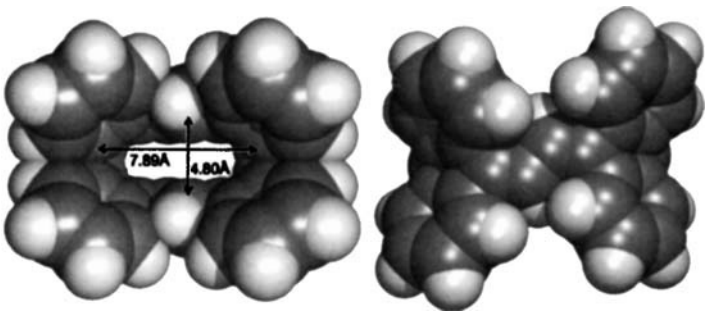

Figure 2. AM1-calculated van der Waals surface of "Kammermeierphane 2" **6** ($C_{60}H_{36}$).

(R_f = 0.37). Compound **2** was obtained as a colorless solid. Yield: 90 mg (71%). M.p. 229 °C (decomp); ^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.72 (m, 1H; CH, arom.), 7.58 (m, 1H; CH, arom.), 7.17 (m, 6H; CH, arom. and CH=CH), 6.90 (m, 10H; CH, arom.), 5.95 (dd, J = 4.3 Hz, J = 2.9 Hz, 1H; CH, saturated), 4.39 (dd, J = 5.1 Hz, J = 2.7 Hz, 1H; CH, saturated); ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 174.16 (C=O), 150.76 (C_q), 150.76 (C_q), 147.95 (C_q), 147.29 (C_q), 147.26 (C_q), 146.95 (C_q), 144.38 (C_q), 143.56 (C_q), 143.09 (C_q), 142.87 (C_q), 133.43 (CH=CH), 132.23 (CH=CH), 126.79 (CH, arom.), 126.51 (CH, arom.), 126.38 (CH, arom.), 126.38 (CH, arom.), 126.38 (CH, arom.), 126.12 (CH, arom.), 125.98 (CH, arom.), 125.21 (CH, arom.), 125.21 (CH, arom.), 125.07 (CH, arom.), 124.78 (CH, arom.), 124.71 (CH, arom.), 124.10 (CH, arom.), 123.93 (CH, arom.), 123.56 (CH, arom.), 123.56 (CH, arom.), 79.04 (CH, saturated), 66.12 (C_q, saturated), 61.78 (C_q), 49.46 (CH, saturated); IR (KBr): $\tilde{\nu}$ = 3061, 3037 cm^{-1} (m, C–H, arom.), 1754 (s, C=O), 1634 (w, C=C, olef.),1451 (s, C=C, arom.), 1361 (m), 1181 (m), 1019 (m), 768 (s, C–H, arom.); UV/Vis (CH_2Cl_2): λ_{max} (ε) = 230 (20100), 272 (1700, sh), 280 nm (1200, sh); MS (70 eV): m/z (%): 448 (47) [M^+], 404 (100) [$M^+ - CO_2$]; C,H analysis ($C_{33}H_{20}O_2$): calcd C 88.36, H 4.50; found C 88.06, H 4.90.

5 (Kammermeierphane 1): Method a from Scheme 3: Thermolysis of **2**: A solution of **2** (106 mg, 0.237 mmol) in xylene (50 mL) was heated at reflux for 16 h. After removal of the solvent in vacuo the residue was purified by chromatography on silica gel with hexane/dichloromethane 2/1. **5** was obtained as a colorless solid. Yield: 54 mg (51%). M.p. 242 °C; ^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.58 (m, 2H; CH, arom.), 7.47 (m, 2H; CH, arom.), 7.19 (m, 2H; CH, arom), 7.07 (m, 6H; CH, arom.), 6.96 (m, 4H; CH, arom.), 6.45 (m, 2H; HC=C), 5.86 (m, 2H; HC=C); ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 142.20 (C_q), 140.56 (C_q), 140.12 (C_q), 139.96 (C_q), 136.59 (C_q), 136.00 (C_q), 130.00 (CH, arom.), 126.84 (CH, arom.), 126.71 (CH, arom.), 126.53 (CH, arom.), 126.42 (CH, arom.), 125.75 (CH, arom.), 125.19 (CH, arom.), 125.19 (CH, arom.), 124.56 (CH, arom.), 121.44 (CH, arom.); IR (KBr): $\tilde{\nu}$ = 3061, 3035, 3013 cm^{-1} (m, C–H, arom, olef.), 1633 (m, C=C, olef.), 1450 (s, C=C, arom.), 768 (s, C–H, arom.); UV/Vis (CH_2Cl_2): λ_{max} (ε) = 230 (41000), 272 nm (20400, sh); MS (70 eV): m/z (%): 404 (100) [M^+], 200 (10); C,H analysis ($C_{32}H_{20}$): calcd C 95.02, H 4.98; found C 94.81, H 5.04.

Method b from Scheme 3: Diels–Alder reaction of **1** with 1,2-diazine: A solution of **1** (100 mg,0.284 mmol) and 1,2-diazine (350 mg, 4.38 mmol) in toluene (70 mL) was heated at reflux for 20 h. After removal of the solvent in vacuo the residue was purified by chromatography on silica gel with hexane/dichlormethane 2/1 (R_f = 0.26). **5** was obtained as a colorless solid. Yield: 92 mg (80%).

6 (Kammermeierphane 2): A solution of **5** (40 mg, 0.010 mmol) and **1** (53 mg, 0.015 mmol) in benzene (120 mL) was irradiated in a quartz reactor for 3 h. The solvent was removed in vacuo and the residue was purified by chromatography on silica gel with hexane/dichloromethane 2/1 (R_f = 0.08). After further purification by HPLC (PSS-SDV gel 100 Å, 10 mm, $CHCl_3$) the product was recrystallized from toluene. **6** was obtained as a lemon-yellow solid. Yield: 7 mg (10%). M.p. 380 °C (decomp); ^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.79 (m, 8H; CH, arom.), 7.54 (m, 4H; CH, arom.), 7.27 (m, 4H; CH, arom.), 7.16 (m, 16H; CH, arom.), 6.82 (s, 4H; CH, olef.); ^{13}C NMR (100.6 MHz, CS_2/C_6D_6 10/1): δ = 140.55 (C_q), 139.96 (C_q), 139.45 (C_q), 138.56 (C_q), 136.17 (C_q), 135.70 (C_q), 128.72 ($CHR=CR_2$), 128.67 (CH, arom.), 127.55 (CH, arom.), 127.16 (CH, arom.), 126.20 (CH, arom.), 125.57 (CH, arom.), 124.91 (CH, arom.), 123.39 (CH, arom.), 122.98 (CH, arom.); IR (KBr): $\tilde{\nu}$ = 3090, 3060, 3028 cm^{-1} (m, C–H, arom, olef.), 1644 (m, C=C, olef.), 1451 (s, C=C, arom.), 769 (s, C–H, arom.); UV/Vis (CH_2Cl_2): λ_{max} (ε) = 230 (56000), 246 (58000), 316 (27000), 358 nm (60000); MS (70 eV): m/z (%): 756 (100) [M^+]; HRMS: calcd for $C_{60}H_{36}$: 756.2817, found: 756.2815.

[12] This proves the high reactivity of TDDA **1** in [4+2]cycloadditions. Under these conditions reactions of α-pyrone with even very reactive dienophiles like maleic anhydride do not proceed with more than 50% yield: E. Pfaff, H. Plieninger, *Chem. Ber.* **1982**, *115*, 1967–1981, and references therein.

[13] Named after one of the authors, Stefan Kammermeier.

[14] Crystal structure analysis of **5**: **5**·$CHCl_3$, $C_{33}H_{21}Cl_3$, M_r = 523.85, monoclinic, space group $P2_1/n$, a = 799.2(1), b = 2137.7(3), c = 1477.4(2) pm, β = 90.06(1)°, V = 2.5242 nm^3, Z = 4, ρ_{calcd} = 1.378 Mg m^{-3}, $F(000)$ = 1080, $\mu(Mo_{K\alpha})$ = 0.39 mm^{-1}, T = −100 °C. A colorless plate 0.5 × 0.5 × 0.3 mm was mounted in inert oil and brought into a stream of cold gas in the diffractometer (Siemens, P4). 4772 Reflections were registered up to 2θ = 50° by ω-scans, of which 4438 were independent (R_{int} = 0.023). The structure was solved with direct methods and refined anisotropically versus F^2 (program SHELXL-93, G. M. Sheldrick, Universität Göttingen). Hydrogen atoms were considered using a riding model. The final $wR(F^2)$ value was 0.129 for all reflections, with conventional $R(F)$ = 0.050; S = 0.95, max. $\Delta\rho$ = 592 e nm^{-3}. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100360. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: Int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

[15] The π–π* transition of TDDA lies at 280 nm. With a Pyrex filter the irradation time is much longer due to absorption of light with wavelengths <300 nm.

Organic-Soluble Neutral and Ionic Indium Siloxane Cages: Potential Precursors for Indium-Containing Silicates**

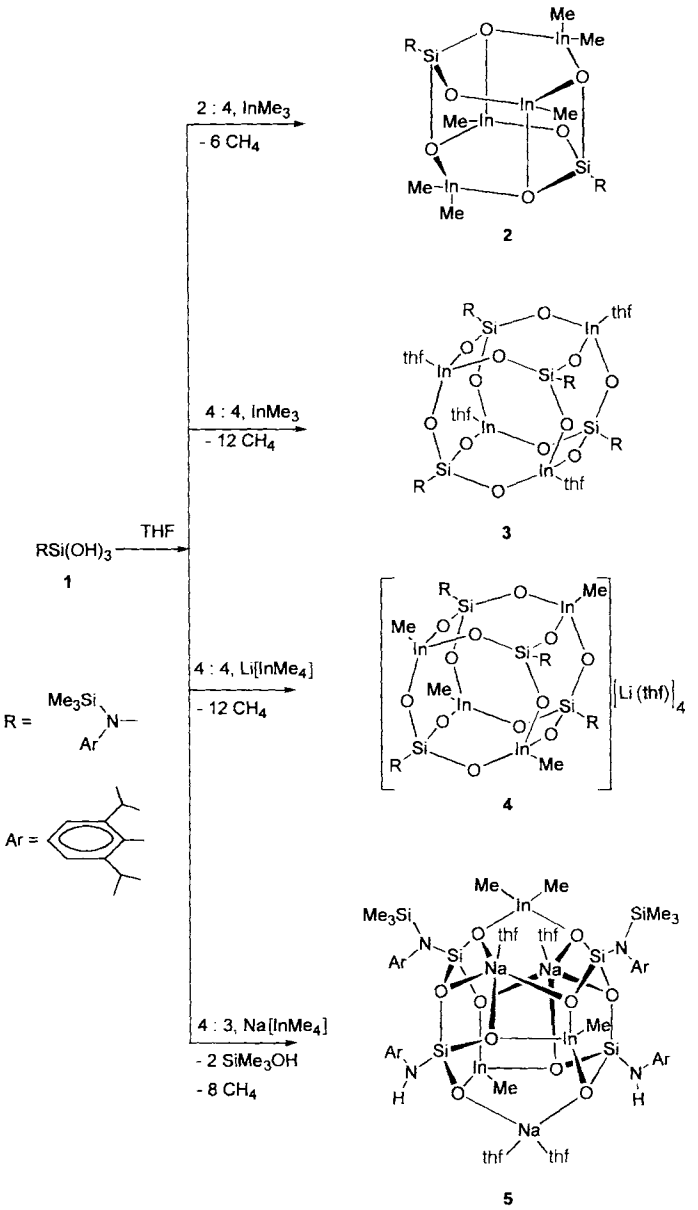
Andreas Voigt, Mrinalini G. Walawalkar, Ramaswamy Murugavel, Herbert W. Roesky,* Emilio Parisini, and Paolo Lubini

Dedicated to Professor Achim Müller on the occasion of his 60th birthday

Zeolites and metal-doped zeolites have attracted increasing attention from chemists and material scientists because of their excellent catalytic and ion exchange properties, which also find wide applications in the chemical industry. While aluminum-containing silicates have been well known and studied over the decades, there has been a recent upsurge in the study of Ga-doped molecular sieves and phosphate compounds in the light of their usefulness in catalytic conversions.[1-3] In spite of the widespread applications of Al and Ga zeolites, there are only a very few reports on the synthesis or on the catalytic activity of In-containing zeolites.[4] Studies on In-based zeolites warrant attention in the light of their recently reported utility in the catalytic reduction of nitrogen oxides (NO_x),[4] a process that has implications in cleaning up exhaust gases of combustion engines.

Studies on metallasiloxanes are also important because of their ability to act as model compounds for complex zeolite systems.[5] Starting from a series of stable silanetriols we have synthesized a range of metallasiloxanes incorporating metals such as Al, Ga, Sn, Ti, Zr, Ta, and Re that exhibit novel structural features.[6, 7] In particular, silanetriols are excellent starting materials for three-dimensional Al- and Ga-containing siloxanes, which could function as models for zeolites.[8] Continuing our efforts in the utilization of stable and discrete silanetriols for the preparation of useful metallasiloxanes, we report here on the first successful synthesis of new polyhedral indium siloxanes **2**–**5** (Scheme 1) that are soluble in common organic solvents such as pentane, diethyl ether, THF, and toluene. While the reaction between **1** and $InMe_3$ in the ratio 1:2 results in the partial elimination of methyl groups on indium leading to the drum-shaped In–siloxane **2**, a 1:1 reaction between the same reactants under similar conditions leads to the complete elimination of all the methyl groups on indium and the isolation of the cube-shaped In–siloxane **3**. The reactions between **1** and the ionic alkylindium compounds $Li[InMe_4]$ and $Na[InMe_4]$ lead to the ionic In–siloxanes **4** and **5**, respectively (Scheme 1).

The reaction leading to the Na–In–siloxane **5** is particularly interesting. The formation of this product should have proceeded by a self-condensation of the silanetriol **1** resulting in the tetrahydroxydisiloxane $[(OH)_2RSi]_2O$ and water.[9] This process is presumably catalyzed by highly ionic reactants such as $Na[InMe_4]$ in the reaction medium.[10] Evidently, the reactive $N-SiMe_3$ bonds in the initially formed In–siloxane are partially hydrolyzed over the period of crystallization (ca. three months) to yield the siloxane **5**, which contains NHAr groups.



Scheme 1. Synthesis of indium siloxanes **2**–**5**.

All the new In–siloxanes have been characterized based on their analytical, spectroscopic (IR, ^1H and ^{29}Si NMR), and mass spectrometric (EI MS) data. In addition the solid-state structures of **2**, **4**, and **5** have been unambiguously established by single-crystal X-ray diffraction studies.[11] In the case of **3**, it has so far not been possible to obtain suitable single crystals. The spectroscopic data are consistent with the structural formulation of all the compounds. The EI mass spectra of all compounds yield molecular ion peaks or the peaks due to loss of solvent molecules or methyl groups. Three ^{29}Si NMR signals are observed for the three different types of silicon centers in **5** ($\delta = -73.9$, -72.8, and 2.3); the spectra of all the other compounds show only two ^{29}Si NMR signals corresponding to the $SiMe_3$ and SiO_3 moieties.

The molecular structure of the heterosiloxane **2** (Figure 1) can best be described as a cylindrical-drum whose top and bottom faces are made up of six-membered In_2O_3Si rings. The side faces

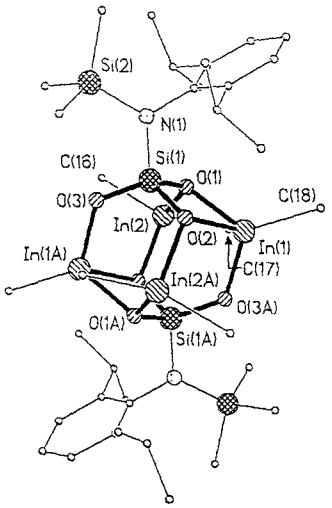

Figure 1. Molecular structure of **2** in the crystal. Selected bond lengths [Å] and angles [°]: In(1)–O(1) 2.148(6), In(1)–O(2) 2.150(6), In(1)–C(18) 2.100(9), In(1)–O(3A) 2.033(6), Si(1)–O(1) 1.654(6), Si(1)–O(2) 1.666(6), Si(1)–O(3) 1.590(6), Si(1)–N(1) 1.722(7), In(2)–C(16) 2.136(6), In(2)–C(17) 2.132(10); O(1)-In(1)-O(2) 71.0(2), O(1)-In(1)-O(3A) 97.8(2), O(2)-In(1)-O(3A) 100.1(2), C(16)-In(2)-C(17) 136.9(4).

are composed of two such six-membered rings (existing in a boat conformation) in addition to two planar four-membered InO_2Si rings. The shape of the $In_4O_6Si_2$ framework in compound **2** is similar to that observed for the previously characterized Al and Ga analogues.[8] Given the differences in the covalent radii of the metal atoms, the In–O distances (2.11 Å) are longer than the Ga–O (1.91 Å) and Al–O (1.83 Å) distances in the corresponding compounds. As a consequence, the internal O-M-O angles of the drum also decrease on going from Al to In. The In–O distances in **2** are comparable with the values reported for $[\{InC(Me_3Si)_3\}_4O(OH)_6]$ (2.12 Å)[12a] and $[\{In(OH)(O_2PPh_2)Me(py)\}_4]$ (2.23 Å) (py = pyridine).[12b]

Both **3** and **4** are made up of a central $In_4O_{12}Si_4$ cubic core (Scheme 1). In the ionic compound **4** (Figure 2), four of the six faces of the $In_4O_{12}Si_4$ cube are further surrounded by Li^+ ions. Although the overall shape of the cage appears to be comparable to that of the Al analogue,[8b] the substitution of Al by In seems to provide a greater flexibility to the cubic core. In particular, the chair conformation for the four eight-membered $In_2O_4Si_2$ rings facing the coordinated Li^+ ions is absent in the other two faces of the cage. Also there is a pronounced deviation from regular tetrahedral coordination of the four-coordinate In atoms. The Li^+ ions adopt a nearly ideal square-pyramidal coordination geometry. As a consequence of the *side-on* coordination of the oxygen atoms to the Li^+ ions, the cubic cage is slightly squeezed along the axis perpendicular to the plane defined by these four lithium ions. The conformation adopted by the N-bonded ligands in **2** and **4** is almost identical; owing to the bulkiness of the isopropyl groups, the aromatic ring is forced to lie perpendicular to the Si-N-Si plane.

The molecular structure of In–siloxane **5** is made up of a central $In_3Na_3O_{10}Si_4$ core that resembles the shape of a bird-cage (Figure 3). Two formal $[\{N(Ar)(SiMe_3)\}O_2(\mu\text{-}O)O_2Si(NHAr)]^{4-}$ ligands coordinate to two $[InMe]^{2+}$, one $[InMe_2]^+$, and three Na^+ moieties. There are two InO_3Si_2 six-membered

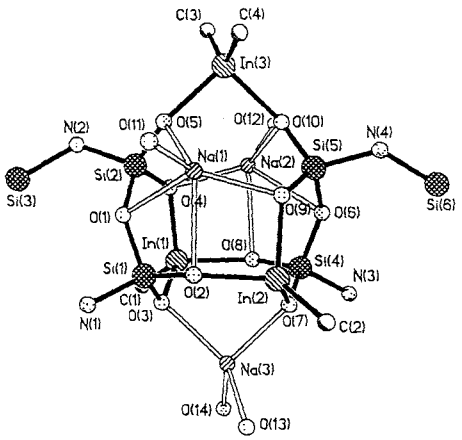

Figure 3. Structure of the central core in **5** in the crystal. Selected bond lengths [Å] and angles [°]: In(1)–O(3) 2.078(5), In(1)–O(4) 2.069(5), In(1)–O(8) 2.080(5), In(1)–C(1) 2.144(8), Si(1)–O(1) 1.640(5), Si(1)–O(2) 1.606(5), Si(1)–O(3) 1.619(5), Na(1)–O(1) 2.647(5), Na(1)–O(2) 2.512(6), Na(1)–O(5) 2.313(6), Na(1)–O(9) 2.310(6), Na(1)–O(11) 2.295(6); Si(1)-O(1)-Si(2) 141.4(3), Si(1)-O(2)-In(2) 137.4(3), Si(1)-O(3)-In(1) 123.2(3).

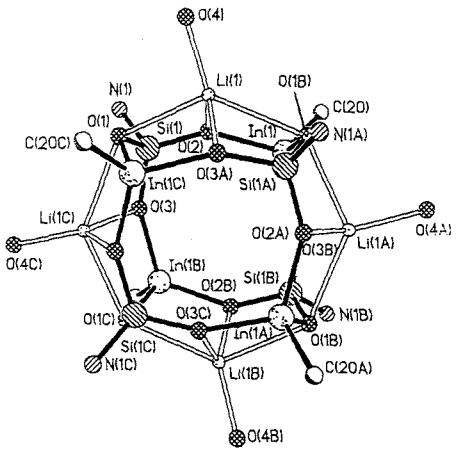

Figure 2. Structure of the central core in **4** in the crystal. Selected bond lengths [Å] and angles [°]: In(1)–O(2) 2.036(3), In(1)–O(1B) 2.068(3), In(1)–O(2A) 2.056(3), In(1A)–C(20A) 2.131(4), Si(1)–O(1) 1.609(3), Si(1)–O(2) 1.618(3), Si(1)–O(3) 1.615(3), Li(1)–O(4) 1.953(8), Li(1)–O(1B) 2.561(10), Li(1)–O(2) 1.933(8), Li(1)–O(3A) 1.974(8); O(2)-In(1)-O(2A) 115.65(11), O(2)-In(1)-O(1B) 92.19(12), O(2A)-In(1)-O(1B) 95.21(12).

rings in the molecule that are linked by two In-O-Si bridges. All the oxygen atoms in the molecule are triply bridging (μ_3) the In, Na, and Si centers. All In atoms have a tetrahedral coordination sphere.

While the two pentacoordinate Na^+ ions (bonded to four cage oxygen atoms and one THF molecule) have an approximate square-pyramidal geometry, the third Na^+ ion is tetrahedrally coordianted by two cage oxygen atoms and two THF molecules. There are two distinct types of Si–O distances in the molecule: the Si–O(Si) bonds are considerably longer (av 1.65 Å) than the Si–O(In) bonds (av 1.60 Å). All the In–O distances are nearly equal; the average value is 2.08 Å. The Na–O distances in the molecule vary from 2.28 to 2.66 Å.

In summary, small variations in the reaction conditions and the choice of starting materials has allowed us to prepare indium siloxanes with different polyhedral structures, which would potentially model the In–silicate frameworks. Furthermore, the hydrolyzable functionalities make compounds **2**–**5** promising starting materials for the synthesis of new synthetic In-containing zeolites under mild conditions or by sol–gel processes.

Experimental Section

2: A solution of $InMe_3$ (1.60 g, 10 mmol) in *n*-hexane/THF (10 mL/5 mL) was added to a suspension of **1** (1.64 g, 5 mmol) in *n*-hexane (40 mL) at room temperature. The resulting clear solution was heated under reflux for 2 h and then slowly allowed to cool to room temperature to yield colorless crystals of **2** after two days. Yield 2.45 g (82%); MS (EI, 70 eV): *m/z* (%): 1198 (20) [M^+], 1183 (100) [M^+ − Me]; ^{1}H NMR ($CDCl_3$): δ = − 0.10 (s, 6H; In*Me*), 0.04 (s, 12H; InMe_2), 0.30 (s, 18H, SiMe_3), 1.32 (m, 24H; CHMe_2), 3.57 (m, 4H; C*H*Me$_2$), 7.05 (s, 6H; aromat.); ^{29}Si NMR ($CDCl_3$): δ = −70.9 (SiO_3), 6.3 ($SiMe_3$); IR (Nujol): $\tilde{\nu}$ = 1500, 1317, 1260, 1249, 1180, 1106, 1043, 1014, 969, 955, 905, 875, 838, 802, 752, 688, 613, 542 cm^{-1}; elemental analysis (%) calcd for $C_{36}H_{70}In_4N_2O_6Si_4$: C 36.1, H 5.8, N 2.4; found: C 35.1, H 5.2, N 2.1.

3: A solution of $InMe_3$ (0.80 g, 5 mmol) in *n*-hexane/THF (10 mL/5 mL) was added to a suspension of **1** (1.64 g, 5 mmol) in *n*-hexane (40 mL) at 60 °C. After the evolution of methane gas ceased, the heating was continued for an additional 1.5 h. The solvent was removed in vacuo to afford **3** as a white solid which was purified by crystallization from hot *n*-hexane. Yield 2.43 g (95%); MS (EI, 70 eV): *m/z* (%): 2045 (10) [M^+], 1756 (100) [M^+ − 4THF]; ^{1}H NMR ($CDCl_3$): δ = 0.15 (s, 36H; SiMe_3), 1.26 (m, 48H; CHMe_2), 1.28 (m, 16H; OCH_2CH_2), 3.46 (m, 16H; OCH_2), 3.74 (m, 8H; C*H*Me$_2$), 7.10 (m, 12H; aromat.); ^{29}Si NMR ($CDCl_3$): δ = −72.4 (SiO_3), 6.4 ($SiMe_3$); IR (Nujol): $\tilde{\nu}$ = 1499, 1321, 1258, 1180, 1109, 1046, 1012, 968, 954, 908, 879, 836, 801, 755, 656, 617, 551, 474, 443, 397 cm^{-1}; elemental analysis (%) calcd for $C_{72}H_{136}In_4N_4O_{16}Si_8$: C 51.9, H 7.7, N 3.2; found: C 50.1, H 7.1, N 2.9.

4: A solution of LiInMe$_4$ [13] (0.91 g, 5 mmol) in *n*-hexane/THF (10 mL/5 mL) was slowly added to a suspension of **1** (1.64 g, 5 mmol) in *n*-hexane (40 mL). The reaction mixture was heated under reflux for 1.5 h and then allowed to cool to room temperature. From this solution, colorless crystals of **4** were obtained after two days. Yield 2.27 g (85%), MS (EI, 70 eV): *m/z* (%): 1844 (5) [M^+ − 4THF], 1770 (100) [M^+ − 4THF − $SiMe_3$]; ^{1}H NMR (C_6D_6): δ = − 0.15 (s, 12H; In*Me*), 0.15 (s, 36H: SiMe_3), 1.23 (m, 16H; OCH_2CH_2), 1.37 (m, 48H; CHMe_2), 3.54 (m, 16H; OCH_2), 3.82 (m, 8H; C*H*Me$_2$), 7.12 (m, 12H; aromat.); ^{29}Si NMR ($CDCl_3$): δ = −75.9 (SiO_3), 5.8 ($SiMe_3$); elemental analysis (%) calcd for $C_{80}H_{148}In_4Li_4N_4O_{16}Si_8$: C 45.0, H 6.9, N 2.6; found: C 44.3, H 6.4, N 2.4.

5: A solution of Na[InMe$_4$] [13] (0.59 g, 3 mmol) in *n*-hexane/THF (10 mL/5 mL) was slowly added to a suspension of **1** (1.31 g, 4 mmol) in *n*-hexane (40 mL). The reaction mixture was heated under reflux for 1.5 h and and then allowed to cool to room temperature and left to crystallize. The colorless solution turned brown over three months with the formation of large colorless single crystals of **5**. Yield: 0.94 g (40% based on 1); m.p. 200 °C (decomp), MS (EI, 70 eV): *m/z* (%): 1839 (2) [M^+ − 3Me], 1695 (3) [M − 3Me − 2THF], 162 (100) [iPr$_2$C$_6$H$_3$NH$_2$ − Me]; ^{1}H NMR (C_6D_6): δ = − 0.77 (s, 12H; In*Me*), 0.41 (s, 18H; SiMe_3), 1.23 (d, ^3J(H,H) = 6.8 Hz, 24H; CHMe_2), 1.29 (d, ^3J(H,H) = 6.8 Hz, 24H; CHMe_2), 1.40 (t, ^3J(H,H) = 6.4 Hz, 16H; OCH_2CH_2), 3.45 (t, ^3J(H,H) = 6.4 Hz, 16 H; OCH_2), 4.04 (sept., 4H; C*H*Me$_2$), 4.14 (sept., 4H; C*H*Me$_2$), 6.82–7.20 (m, 12H; aromat.); ^{29}Si NMR (C_6D_6): δ = −73.86 (SiO_3), −72.76 (SiO_3), 2.30 ($SiMe_3$); IR (Nujol): $\tilde{\nu}$ = 1319, 1256, 1245, 1185, 1099, 1049, 1019, 941, 919, 834, 801, 720, 592, 546, 515, 462 cm^{-1}; elemental analysis: calcd for $C_{74}H_{132}In_3N_4Na_3O_{14}Si_6$: C 47.2, H 7.1, N 3.0; found: C 46.8, H 7.3, N 2.6. The observed low values of carbon analysis for **2**–**5** are due to the formation of silicon carbide during the combustion process.

The Distortive Tendency of Benzene π Electrons: How Is It Related to Structural Observables?**

Avital Shurki and Sason Shaik*

Many computational experiments have demonstrated that benzene π electrons tend to distort to a localized D_{3h} structure, while the final D_{6h} symmetry is determined by the σ framework.[1a] However, the notion of π distortive tendency would have remained elusive without experimental probes. Although the exalted b_{2u} frequency of the $^1B_{2u}$ excited state was recently pointed out as such an observable,[1b, 2] there is still a need for a more "chemical" observable which can be associated with π distortive tendency. Structure is an essential chemical observable, and the recent exciting syntheses of cyclohexatriene motifs[3, 4] (for example **1**, in which there is strong bond alternation)[3b] pose an excellent opportunity for drawing a link between π distortive tendency and structure as well as predicting novel structures.

Our approach for establishing the requisite link between π distortive tendency and structural probes relies on the struc-

tural patterns of the ground state and the $^1B_{2u}$-like excited state. These two states for benzene derivatives are described as the bonding and antibonding combinations of the Kekulé structures (Scheme 1).[1b, 5]. Thus, they arise from avoided crossing,

Scheme 1. Description of the ground state and the $^1B_{2u}$-like excited state of benzene as the linear combinations of Kekulé structures.

that is, resonance mixing along the bond alternation distortion mode (b_{2u} for benzene[1b]), and are two twin states which are expected to exhibit mirror-image behavior along the bond-alternating mode. We therefore decided to compute[6] the properties of these two states for the target molecules **1**[3b] and **2**.[8] The

$R_2 = 1.438$Å
$\phi = 102.3°$

ground states ($^1A'_1$ and $^1A'$, respectively) were calculated at the restricted Hartree–Fock (RHF) level, the Møller–Plesset (MP2) level, and the hybrid density functional theory (DFT) level B3LYP. Calculations with the latter two methods were used to ascertain that the localization of the bonds is not due to the deficiency of the RHF method.[9] The $^1B_{2u}$-like excited states ($^1A'_1$ and $^1A'$, respectively) were calculated at the *c*onfiguration *i*nteraction with single excitations (CIS) level, which proved useful for these states.[10] The results are collected in Table 1.

In agreement with experiment (entry 1) and previous computations,[3b, c] our results (entries 2–7) show that the ground state of **1** exhibits significant bond alternation. In contrast, the calculations of the $^1A'_1$ excited state (entries 8–11) reveal a very small bond alternation, which is one order of magnitude smaller than in the ground state. Therefore, unlike the cyclohexatriene structure of the ground state of **1**, the $^1B_{2u}$-like excited state, which arises from $\pi \rightarrow \pi^*$ promotion is almost symmetrical. What are the origins of this structural switch?

Table 1. Experimental and calculated angles ϕ [°], bond lengths R_1 and R_2 [Å], and bond length alternations ΔR for **1** in the ground and exited states [a].

Entry	Method	ϕ	R_1	R_2	ΔR

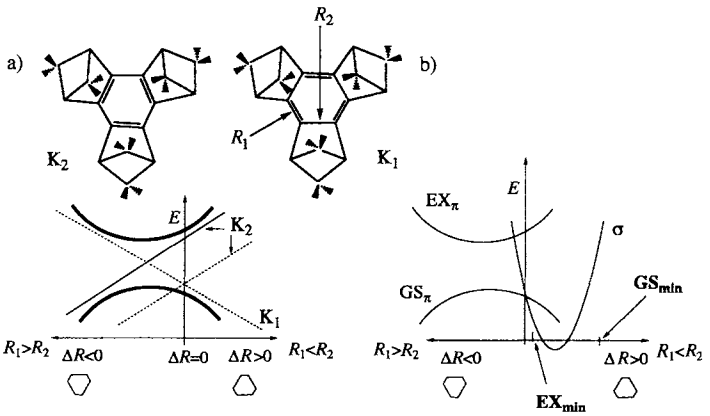
[a] See the formula of **1** for definitions of R_1, R_2, and ϕ; $\Delta R = R_2 - R_1$. [b] Virtually identical to the results from MP2 and DFT calculations in ref. [3b]. [c] This state is the $^1B_{2u}$-like state of benzene (Scheme 1).

Scheme 2 provides a model for this behavior of the two states. Scheme 2a shows the behavior of the Kekulé structures contain-



Scheme 2. Behavior of the π and σ energy curves of **1** along the bond-alternation coordinate; see text for details.

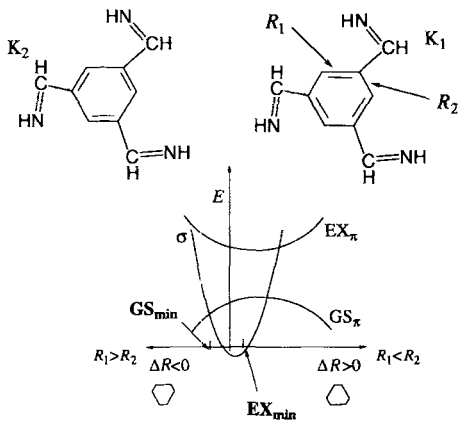
ing only π electrons, K_1 and K_2, along the bond-alternation coordinate.[1b] The dashed lines describe the situation for benzene, for which the Kekulé structures cross at $R_1 = R_2$ ($\Delta R = 0$). In **1** the C–H bonds and the C–C Walsh orbitals of the bicyclic moieties lie above and below the benzene unit, and therefore have a repulsive interaction with the π orbitals. This effect is stronger in K_2, and, hence, K_2 rises in energy relative to K_1, as shown by the solid thin line in Scheme 2a. This displacement of K_2 shifts the crossing point of the two Kekulé curves to a geometry were $R_1 > R_2$ ($\Delta R < 0$). By resonance mixing the Kekulé structures avoid the crossing and form the delocalized ground and excited states represented by the solid thick lines in Scheme 2a. The lower π curve, which is the bonding combination of the two Kekulé structures (that is, the ground state), has a maximum at $R_1 > R_2$ ($\Delta R < 0$). The upper π curve describes the excited state, which is the antibonding combination of the two Kekulé structures and possesses a minimum at $R_1 > R_2$ ($\Delta R < 0$) above the ground-state maximum.

Scheme 2b shows the two π curves (GS_π and EX_π) along with the σ curve. As discussed previously,[1a, 11–13] due to angular strain the σ minimum is located at $R_1 < R_2$ ($\Delta R > 0$), and ΔR increases as the endocyclic angle ϕ decreases from the ideal value of 120° in benzene. Furthermore, as we demonstrated,[1a] since the distortion caused by the σ electrons is small, the σ minimum lies very close to the D_{6h} geometry ($\Delta R = 0$). Thus, were it only a σ effect, the ground state of **1** would exhibit marginal bond alternation. The total energy of the ground state is determined by the sum of the σ curve, which has a minimum, and the π curve, which has a maximum. This sum will shift the ground-state minimum (GS_{min}) relative to the σ minimum to a higher degree of bond alternation in the sense $R_1 < R_2$ ($\Delta R > 0$). In contrast, the total energy of the excited states is the sum of σ and π curves with minima. As a consequence, the minimum of the excited state (EX_{min}) will be an average of the σ and π minima and possess a much lower degree of bond alternation relative to the ground-state minimum, if at all. Therefore, the opposite behavior of the ground state and its twin covalent excited state derive from the avoided crossing of the π curves and is associated with the tendency of π electrons in the ground state to distort, which is enhanced by the repulsive interaction with the bicyclic bridge. If the GS_π curve had a minimum like the

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3620-2206 $ 17.50+.50/0

ES_π curve, the bond alternation would have also been marginal in the ground state.

The model can now be applied to **2**. Here, σ repulsion between the NH moieties and the *ortho* hydrogen atoms of the benzene ring will increase angle α and decrease angle ϕ. According to previous studies,[1a, 11, 12] the σ minimum will be shifted very slightly[1a] in the direction of $R_1 < R_2$ ($\Delta R > 0$; Scheme 3).



Scheme 3. Behavior of the π and σ energy curves of **2** along the bond-alternation coordinate; see text for details.

The π interaction of the C=NH groups with the benzene moiety will now raise K_1 relative to K_2. Following the same argument as for Scheme 2a, this π effect will shift the avoided crossing of the π curves to $R_1 < R_2$ ($\Delta R > 0$), which is precisely opposite to the situation with molecule **1**. The ground state, which is the sum of a σ curve with a minimum and a π curve with a maximum, will attain a minimum (GS_{min}) to the left of the σ minimum where $R_1 > R_2$ ($\Delta R < 0$). In contrast, the excited state, which is a sum of two curves with minima, will have a minimum (EX_{min}) between the two minima ($\Delta R > 0$).

This prediction is supported by the computational data presented in Table 2. The ground state has a small (negatively signed) bond alternation, that is, $\Delta R < 0$, while the twin excited state alternates in the opposite direction. Thus, as predicted by the qualitative model, this small but opposite alternation of the ground state and its twin excited states is a result of the π electronic behavior along the bond-alternating mode.

Table 2. Calculated angles ϕ [°], bond lengths R_1 and R_2 [Å], and bond length alternations ΔR for **2** in the ground and exited states [a].

[a] See the formula of **2** for definitions of R_1, R_2, and ϕ; $\Delta R = R_2 - R_1$. [b] This state is the $^1B_{2u}$-like state of benzene (Scheme 1).

This link between distortion and structure can be quantified. Assuming that the total energy is the sum of π and σ energies which have a parabolic behavior in the bond-alternation coordinate ΔR, one obtains Equation (1), in which k represents the corresponding force constants. The quantities δR are shifts relative to the minimum of the σ curve on the ΔR coordinate[14]. Since $k_\sigma > k_\pi$, the denominator is always positive irrespective of the sign of k_π. The numerator depends on the sign of k_π. Due to the avoided-crossing mechanism, which generates the π curves, k_π is negative for the ground state and positive for the excited state. Consequently, the structural distortion $\delta R_{(\sigma+\pi)min}$ will be opposite for the two states. Moreover, since the denominator is small for the ground state ($k_\pi < 0$) and large for the excited state ($k_\pi > 0$), Equation (1) predicts that the ground state will undergo significant bond alternation upon appropriate constraints (for example, as with **1**), whereas the corresponding twin excited state will hardly alternate and virtually conserve local D_{6h} symmetry. These predictions, which are supported by the quantitative calculations, are amenable to experimental scrutiny.

$$\delta R_{(\sigma+\pi)min} = k_\pi \delta R_\pi / (k_\pi - k_\sigma) \quad (1)$$

At the onset we stated the importance of linking the distortive tendency of the π electrons to a chemical observable. The work reported here steps toward this goal by drawing a simple and predictive relationship between π distortion and bond-alternation patterns in the ground and covalent excited states (Scheme 1) of constrained and perturbed benzene derivatives. This, together with the vibrational characteristics of the bond-alternating mode in the two states of benzene,[1, 15] provide well-defined observables for probing the balance between the σ and π electrons in benzene and its derivatives.

[14] The variable δR is defined as $\Delta R - \Delta R_{\sigma\,min}$. Using this definition and parabolic equations for the energy curves, one obtains $E_\sigma = 0.5k_\sigma(\delta R)^2$ for the σ curve, and $E_\pi = 0.5k_\pi(\delta R - \delta R_\pi)^2 + \text{const}$ for the π curve; δR_π is the deviation of the maximum or minimum of the π curve from the σ minimum at $\delta R = 0$. The curve of the total energy E_{tot} (the sum of σ and π energies) is then given by $0.5k_\sigma(\delta R)^2 + 0.5k_\pi(\delta R - \delta R_\pi)^2 + \text{const}$, and its minimum by Equation (1).

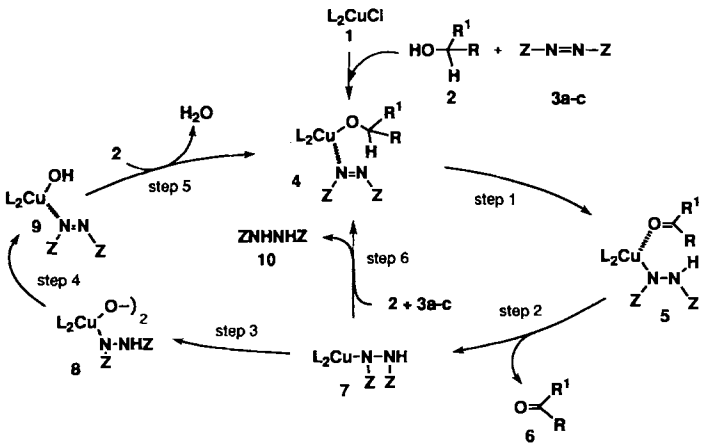
Anaerobic Copper-Catalyzed Oxidation of Alcohols to Aldehydes and Ketones**

István E. Markó,* Masao Tsukazaki, Paul R. Giles, Stephen M. Brown, and Christopher J. Urch

We recently reported on an efficient, copper-catalyzed oxidation of alcohols to carbonyl compounds that uses oxygen or air as the ultimate, stoichiometric oxidant.[1] In light of the extensive research on copper chemistry[2] and some of our own mechanistic studies,[3] we proposed the catalytic cycle depicted in Figure 1.



R, R¹ = alkyl, aryl, H; **3a**: Z = COOEt, **3b**: Z = COO*i*Pr, **3c**: Z = COO*t*Bu; L_2 = phen

Figure 1. Proposed mechanism for the copper-catalyzed oxidation of alcohols.

In this catalytic process, we assumed that the reaction of CuCl·phen (phen = 1,10-phenanthroline) with the alcohol **2** and azodicarboxylate **3** forms the ternary complex **4**. This copper(I) derivative **4** then undergoes an intramolecular hydride transfer reaction leading to complex **5** and the formation of a carbon–oxygen double bond.[4] Release of the bound carbonyl compound **6** generates the hydrazidocopper(I) system **7** which, in the presence of oxygen, is subsequently oxidized to the binuclear copper(II) complex **8**.[5] Homolytic cleavage of the peroxo linkage, enables the second intramolecular hydrogen-atom transfer of the catalytic cycle, which affords the hydroxycopper(I) derivative **9** and leads to the regeneration of the key diazo functionality. Addition of alcohol **2** with concomitant loss of water leads to reformation of the loaded catalyst **4** and a new catalytic cycle ensues.

As this mechanism suggests, in the absence of the azo derivatives **3**, little if any turnover was observed.[6] The key role played by the azodicarboxylates **3** (DEAD: Z = COOEt, DIAD: Z = COO*i*Pr and DBAD; Z = COO*t*Bu) is apparent from the catalytic cycle. They act both as hydride acceptors in step 1 and also as ligands for the metal in the various complexes involved in the oxidation process. The continuous regeneration of **3** in the presence of oxygen ensures efficient turnover.

In order to gain more information on the hydride transfer (step 1) and thereby to substantiate our proposed mechanism, we decided to perform some experiments in the absence of oxygen. Under these anaerobic conditions, the conversion of alcohol **2** into carbonyl compound **6** should stop once the azo derivative **3** has been reduced. Reoxidation of the intermediate copper–hydrazine complex **7** to the active species **4** cannot occur and the reaction should cease after **3** is consumed.[7] An equimolar quantity of hydrazine **10** should also be produced in this process. For catalysis to still take place under these anaerobic conditions, a ligand exchange between the hydrazidocopper(I) complex **7**, alcohol **2** and azo compounds **3** should operate with simultaneous generation of hydrazine **10** (step 6).[8]

To test these hypotheses, we performed some initial experiments on *p*-chlorobenzyl alcohol **11**. The most important results are displayed in Table 1.

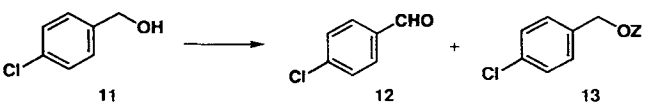


Table 1. Influence of the azo derivative **3** on the copper-catalyzed, anaerobic oxidation of alcohols [a].

Entry	Z	**3** [mol%]	Conversion [%] [b]	Ratio **12**/**13** [c]
1	COO*t*Bu	10	11	>99/<1
2	COO*t*Bu	50	42	>99/<1
3	COO*t*Bu	120	>99 [d]	>99/<1
4	COO*i*Pr	120	81	36/64
5	COOEt	130	73	26/74

[a] 20 °C; other conditions see Experimental Section. [b] Determined by ^{1}H NMR spectroscopy. [c] Determined by ^{1}H NMR spectroscopy and by capillary gas chromatography. [d] Aldehyde **12** was isolated in 82% yield.

Addition of one equivalent of alcohol **11** to a suspension containing 5 mol% CuCl·phen, 10 mol% DBAD **3c**, and 10 mol% K_2CO_3 in toluene, in the absence of oxygen, led to the partial transformation of **11** into aldehyde **12** (11% conversion, Table 1, entry 1). Raising the quantity of DBAD **3c** (50 mol%) used resulted in an increase in the yield of the aldehyde (entry 2). Finally, when DBAD **3c** (1.2 equiv) was used, a quantitative conversion was observed and high yields of *p*-chlorobenzalde-

hyde **12** were obtained (Table 1, entry 3). One equivalent of $DBADH_2$ was also produced in this last reaction. Whilst the use of one equivalent of DIAD **3b** also resulted in complete consumption of **11**, the mixed carbonate **13** was now the major product (Table 1, entry 4). The amount of **13** increased even further when DEAD **3a** was employed instead of DIAD **3b** (Table 1, entry 5). Thus, to avoid the undesired formation of carbonate **13**, a bulky carboalkoxy residue is required on the azo derivatives **3**. DBAD **3c** therefore appears to be the best adjuvant and all subsequent oxidations were performed with this diazo compound.[9]

In addition to substantiating our proposed mechanism, the anaerobic, copper-catalyzed oxidation system proved to be particularly useful for the laboratory-scale oxidation of a wide variety of alcohols into the corresponding carbonyl derivatives (Table 2).

As can be seen from Table 2, primary, secondary, allylic, and benzylic alcohols can all be smoothly oxidized to the corresponding aldehydes and ketones in excellent yields. Sensitive products, such as geranial and neral are not isomerized under the reaction conditions (Table 2, entries 3 and 4, respectively). Remarkably, benzoin is oxidized to benzil with virtually no competitive C–C bond cleavage (Table 2, entry 9).[10] Importantly, optically active β-amino alcohols are oxidized to the corresponding β-amino aldehydes without any detectable racemization (Table 2, entry 10), which demonstrates the mildness of the reaction conditions.[11] In contrast to the aerobic oxidation system[1] in which two equivalents of K_2CO_3 were required for optimum catalytic activity, only a small amount of K_2CO_3 (10 mol%) is necessary in our anaerobic version. Remarkably, in all cases studied so far, complete conversion of the alcohol to the carbonyl derivative took place. This situation is different in the aerobic process in which the presence of oxygen hampers complete transformation of primary alcohols to aldehydes.[12]

In summary, we have established a new, efficient copper-catalyzed anaerobic protocol for the oxidation of a wide range of alcohols into carbonyl compounds under mild conditions. In addition, these studies support our proposals for the mechanism of such Cu-catalyzed oxidations and form the foundations for the development of this interesting oxidation system.

Table 2. Anaerobic, copper-catalyzed oxidation of alcohols [a].

Experimental Section

Typical procedure for the oxidation of 2-undecanol to 2-undecanone: CuCl (5 mg, 0.05 mmol) and 1,10-phenanthroline (9 mg, 0.05 mmol) were mixed in dry toluene (5 mL) and the mixture was stirred for 10 min at room temperature. K_2CO_3 (14 mg, 0.10 mmol), DBAD **3c** (230 mg, 1.00 mmol), and 2-undecanol (172 mg, 1.00 mmol) were added successively and the mixture was heated at 70 °C for 3 h. After cooling to room temperature, the mixture was diluted by adding Et_2O (5 mL) and filtered through a pad of celite. Evaporation of the solvent under vacuum afforded a crude product that was further purified by column chromatography (EtOAc/hexane 1/20) to give pure 2-undecanone (142 mg, 84%).

[6] In the absence of azo derivatives **3** highly active benzylic alcohols undergo some aerobic oxidation to the corresponding aldehydes. For example, using 5 mol% CuCl·phen, 200 mol% K_2CO_3, benzene, 80 °C, and bubbling O_2 through the reaction mixture, a 60% conversion of *p*-chlorobenzylalcohol into *p*-chlorobenzaldehyde can be achieved. Allylic substrates gave much lower conversions (<30%) and aliphatic alcohols are virtually inert under these conditions. No reaction is observed with any of these substrates under anaerobic conditions, in the absence of the azo derivatives **3**.

[7] The intermediacy of complex **7** in the aerobic oxidations was supported by the following observations: 1) independently generated hydrazido complex **7** (CuCl·phen/DBADH$_2$/NaH) proved to be unreactive under anaerobic conditions; 2) passing O_2 through the reaction mixture containing **7** and alcohol **2** restored the catalytic activity, and good yields of aldehyde **6** were again obtained.

[8] This new catalytic cycle, involving steps 2 and 6, is in some ways reminiscent of analogous oxidation shunts that take place in aerobic bacteria placed under anaerobic conditions.

[9] The oxidation of alcohols with azodicarboxylates has been previously reported: F. Yoneda, K. Suzuki, Y. Nitta, *J. Org. Chem.* **1967**, *32*, 727–729. Control experiments were therefore performed to establish the need for copper salts in our anaerobic oxidation procedure. Thus, under our reaction conditions, no aldehyde or ketone could be detected in the absence of the CuCl·phen catalyst, even when phenanthroline was added as an activating base. Moreover, certain reactive alcohols were oxidized partially by CuCl·phen in the absence of the azo derivative **3**, though only in moderate yields.

[10] With most oxidants, α-hydroxyketones are oxidized with concomitant cleavage of the C–C bond: a) R. C. Larock, *Comprehensive Organic Transformations*, VCH, New York, **1989**, pp. 604–615; b) R. A. Sheldon, J. K. Kochi, *Metal-Catalyzed Oxidations of Organic Compounds*, Academic Press, New York, **1981**; c) G. Procter in *Comprehensive Organic Synthesis*, *Vol. 7* (Eds.: B. M. Trost, I. Flemming, S. V. Ley), Pergamon, Oxford, **1991**; d) W. S. Trahanovsky, *Oxidation in Organic Chemistry*, *Part A–D*, Academic Press, New York.

[11] See for example M. T. Reetz, M. W. Drewes, A. Schmitz, *Angew. Chem.* **1987**, *99*, 1186–1188; *Angew. Chem. Int. Ed. Engl.* **1987**, *26*, 1141–1143.

[12] This difference appears to be due to competitive autooxidation of the aldehyde to the corresponding carboxylic acid by oxygen at high conversions of the alcohol. See also ref. [9b].

Electron-Density Relaxation and Oppositely Signed Reaction Constants in Dual Substituent Parameter Relationships in Dediazoniation Reactions**

Rainer Glaser,* Christopher J. Horan, and Heinrich Zollinger*

Dedicated to Professor Dieter Seebach on the occasion of his 60th birthday

The reasons why relationship between σ and ρ in the Hammett equation [Eq. (1)][1] has been fairly well applicable since 1935 to several thousand heterolytic reactions of substituted benzene derivatives are by no means obvious. In the Hammett equation, the constants σ and ρ represent a combination of field (inductive) and resonance effects (mesomeric). One can therefore conclude that in all of these reactions both effects influence the reactivity in the same direction and to the same relative extent. This is indeed the case if one evaluates the same kinetic data with a dual substituent parameter (DSP) treatment, as, for example, developed by Taft and co-workers [Eq. (2); subscripts F and R indicate field and resonance effect contributions, respectively, to reaction rate constants k_X of X-substituted benzene derivatives relative to that of the unsubstituted compounds (k_0)].[2] Effects of electronic substituent can be classified[3a] into those that are associated with the substituent's polarity (I_σ, F, π_s, π_F) and those that are assigned to the substituent's ability to transfer charge (R, σ_π).[3b] This classification relates the substituent constants σ_F and σ_R in Equation (2) to polarity and charge-transfer factors, as indicated in Equation (3).

$$\lg(k_X/k_0) = \sigma\rho \quad (1)$$

$$\lg(k_X/k_0) = \sigma_F\rho_F + \sigma_R\rho_R \quad (2)$$

$$\lg(k_X/k_0) = (\text{polarity})\rho_F + (\text{charge transfer})\rho_R \quad (3)$$

The substituent constants in the Hammett equation are assumed to be independent of the reaction.[4] Dual substituent parameter treatments can thus be regarded as a necessary consequence of the two classes of intrinsic substituent effects. Experience shows that in the large majority of cases the ratio $\rho_R/\rho_F = \lambda \approx 1$. We estimate that values of λ larger than 1.1 or smaller than 0.9 (but still positive) are present in fewer than 10% of all equilibria and rates for which a Hammett relationship was tested. This result seems surprising, as the field and resonance effects are, in principle, considered to be independent of each other. There are, however, sixteen reactions with opposite signs for ρ_F and ρ_R, that is, λ is negative.[5] Examples are dediazoniations of benzenediazonium ions in water, 1,2-dichloromethane, and trifluoroethanol; these reactions all show $\rho_F < -3.5$, $\rho_R > +2.2$, and $|\rho_F| > |\rho_R|$.

Due to our interest in the structure of benzenediazonium ions,[6] the nature of C–N dative bonding,[7] and its dediazoniations,[5–8] we investigated the theoretical basis for the opposing influences of the field and resonance effects on dediazoniation of *para*-substituted benzenediazonium ions *para*-X-C_6H_4-N_2^+ (**1a**, X = H; **1b**, X = NH_2; **1c**, X = NO_2) to the respective *para*-substituted phenyl cations **2a–c** (see Figure 1). Zollinger interpreted the opposite signs of the reaction constants ρ_F and ρ_R by proposing that the cleavage of the σ bond between the N_2 lone pair and the sp^2 LUMO of **2** is slowed by inductively withdrawing substituents and should give rise to a substantial negative field reaction constant ρ_F. If N–C σ bonding is reinforced by C → N π backbonding, a positive reaction constant ρ_R is plausible, since dissociation leads to an increase in π density on the phenyl fragment and brings π-electron density closer to the substituent. While this interpretation cannot be demonstrated experimentally, it is possible to examine it with electronic structure methods. We carried out electron-density analyses of the unimolecular dissociations **1**→**2** + N_2 (X = H, NH_2, NO_2).

Our objectives here are to show that the reaction constants of the dediazoniation reactions are consistent with the hypothesis of combined C←N σ dative and C→N π backdative bonding. Furthermore, we want to learn about the mechanisms by which two important substituents affect electronic structure. The electron-density analysis is based on the topological features of total electron densities, which are observable in the quantum me-

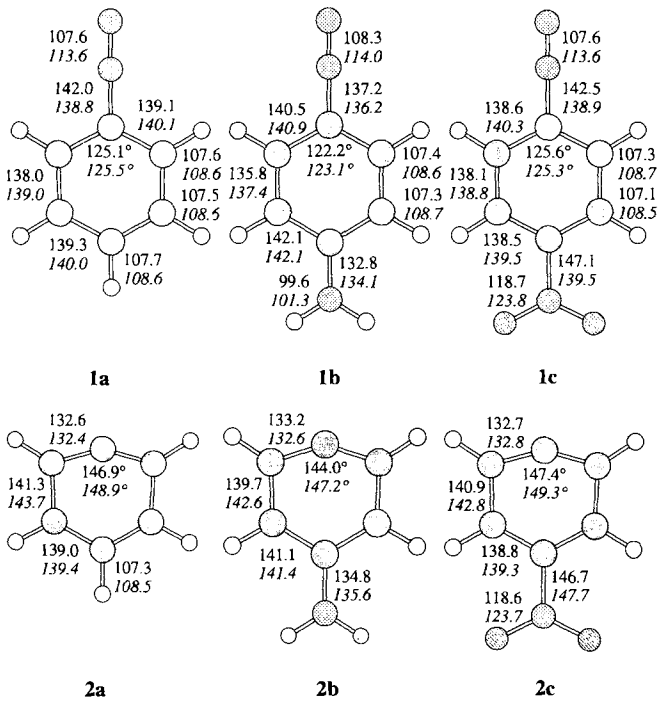

Figure 1. Structural parameters for **1a–c** and **2a–c** calculated at the levels RHF/6-31G* and MP2(full)/6-31G* (in italics). The *para* subsituent is H, NH_2, and NO_2, respectively. The bond lengths are given in pm.

chanical sense. We also determined the σ and π components of the atom populations. Although these components are not observable, the concept of σ/π separation is successful and central to all models invoking dative and backdative bonding. In essence, our analysis links shifts in electron density in the σ and π systems with the reaction constants ρ_F and ρ_R. This approach differs slightly from Topsom's formulation,[3] in which we would weigh π_σ and π_F with ρ_R. Ideally, an analysis of this relatively clear and qualitatively explainable case[5] of a reaction with opposing field and resonance effects may lead to an understanding of why thousands of equilibria and reactions can be explained with the simple Hammett equation and show an almost constant ratio of the two effects ($1.1 > \lambda > 0.9$).

Structures along the dissociation pathways of **1a–c** were optimized at the RHF/6-31G* level,[9, 10] and vibrational analyses were carried out for stationary structures. These dissociations proceed without an activation barrier, as in other diazonium ions.[6, 7] Zero point energy corrections to binding energies were scaled by a factor of 0.9135.[11] Geometries of stationary structures were refined at the MP2(full)/6-31G* level; the molecular models are shown in Figure 1. More reliable binding energies were computed at the levels up to QCISD(T,fc)/6-31G*//MP2(full)/6-31G* (Table 1).

Table 1. Binding energies and corrections of the vibrational zero point energy (VZPE) of **1** [a, b].

X	Reaction	RHF //RHF	Δ(VZPE)	MP2 //MP2	MP3(fc) //MP2	MP4(fc) //MP2	QCISD(T) //MP2
H	**1a** → **2a** + N_2	107.22	−19.72	161.78	139.96	143.52	134.81
NH_2	**1b** → **2b′** + N_2	141.18	−19.05	199.75	178.02	177.86	165.67
NO_2	**1c** → **2c** + N_2	118.82	−19.30	180.12	154.87	160.73	150.93

[a] All values were calculated with the 6-31G* basis set. All energies are given in kJ mol^{-1}. [b] The Δ(VZPE) values need to be added to the reaction energies to obtain approximate reaction enthalpies: $\Delta H = \Delta E + \Delta(\mathrm{VZPE})$.

The C_{2v} structures **1a–c** are minima on the potential energy hypersurface, and **2a** and **2c** also prefer C_{2v} symmetry. However, a C_{2v} structure is not a minimum for **2b**. The most stable structure, labeled **2b′**, is nonplanar and chiral (C_1 symmetrical), and it appears advantageous for reducing ring strain at C_{ipso}. Structures **2b′** and **2b** are nearly isoenergetic, and the distortions do not play a role until late stages in the dissociation. Although we report binding energies for **2b′** in Table 1, we consider **2b** for the remaining discussion. The structural differences between **1a** and **1c** are minor (within 1 pm and 1°; Figure 1), while the effects of push–pull interaction are clearly manifest in **1b**. The structural relaxation upon N_2 dissociation is steady for all substituents X, and the major structural consequences are common. The main event concerns the rehybridization of C_{ipso} upon heterolysis: The $C_{ipso}-C_{ortho}$ bond lengths shorten dramatically (by 0.06–0.08 pm), and the angle at C_{ipso} increases. Systematic studies of X/N_2^{+2} systems showed that binding energies computed at the MP3 level or higher that include vibrational zero point energies reproduce experimental gas-phase binding energies nearly quantitatively.[12] The good agreement between the data measured in the gas phase and in solution[13, 14] suggests that primarily intrinsic properties of **1** are important in the solution chemistry. The binding energies of **1b** and **1c** are higher than for **1a**. The NH_2 and NO_2 groups are overall both electron-withdrawing groups, and are expected to destabilize the phenyl cation more than the diazonium ion. But why is the dissociation of **1b** more endothermic than that of **1c**? One might expect the opposite, since the nitro group is more electron-withdrawing, and because the π donor might better compensate for the electron deficiency in the σ framework. Therefore, qualitative considerations of **2** require significant differences in the electronic structures of **1b** and **1c** that provide an extra stabilization to **1b**. This realization leads to the idea of push–pull stabilization of spacer-connected π-donor–acceptor systems.

Topological electron density analyses[15, 16] at the RHF/6-31G* level were carried out for stationary structures **1a–c** and **2a–c** and the associated reaction pathways; important results are shown in Figures 2 and 3. In general, aliphatic and aromatic diazonium ions are best thought of as carbenium ions closely associated with an N_2 molecule that is internally polarized in the fashion $N_\alpha^{\delta-}-N_\beta^{\delta+}$. This bonding model implies C–N dative bonding instead of covalent C–N bond formation with charge transfer, as suggested by the formal Lewis notation. With a combination of theory and experiment, we have shown that the idea of a carbenium ion within the diazonium ion is fully warranted.[17, 18] The integrated phenyl charge of **1a** is +0.974, and the N_2 group is nearly neutral and polarized ($q(N_\alpha) = -0.540$, $q(N_\beta) = +0.558$). The charge distributions in the CN_2 regions of **1a** and **1c** are similar (Figure 2, top), and, as expected, **1c** exhibits a slightly higher positive N_2 charge.

In **1b** the charge $q(H_2N-Ph)$ exceeds +1, and a negatively charged N_2 group occurs as the result of strong C→N π backdonation of 0.338 electrons. This backdonation is about half as much in **1a** (0.211) and **1c** (0.185). For all ions **1**, the N → C σ donation is the same, and the σ charge hardly varies from 0.231. The charge transfer associated with C–N bonding in **1** can thus be described by a bonding model that involves N→C σ donation and C→N π backdonation of about equal magnitudes (Scheme 1). The H_{para} atom in **1a** acts like the other aromatic H atoms to delocalize positive charge to the periphery of the molecule, while the X groups are negatively charged in **1b** and **1c**. The NH_2 group is a π donor (0.156 electrons), but overall it withdraws 0.475 electrons! The NO_2 group withdraws in total 0.531 electrons, of which 0.063 is due to π withdrawal.

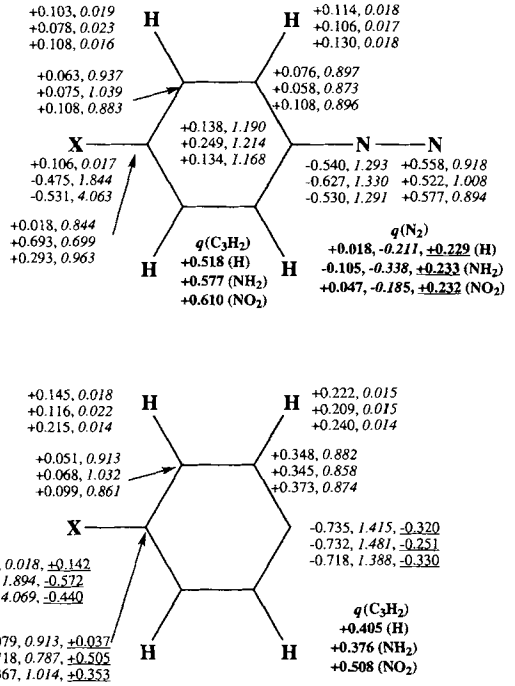

Figure 2. Integrated atom and fragment charges as well as populations (RHF/6-31G*) for **1a–c** and **2a–c**. The π populations are given in italics, and σ charges are underlined.

σ dative interaction between the N_2 lone pair and the vacant σ orbital of the phenyl cation

π backdative bonding between a π orbital of the phenyl cation and the π* orbital of the N_2 group

Scheme 1. Schematic representation of the primary MO interactions associated with N→C σ dative and C→N π backdative bonding in diazonium ions.

The density shifts show enhance C→N π backdative bonding in **1b**, but the electronic mechanism is more complex than the simplistic π-pushing picture and leaves the amino group very negative. The σ density of the N_2 group is changed slightly, but that of C_{ipso} is depleted; these events should strengthen N → C σ dative bonding in **1b**. Therefore, both components of the C–N interaction are enhanced in **1b**. Compared to **1a**, the total changes in the charge of the N_2 group in **1c** are very similar to the changes in the π system. The NO_2 group leads to depletion of π density at C_{meta}, C_{ipso}, and N_β. These density shifts suggest that the NO_2 group hardly affects N→C σ dative bonding but weakens C→N π backdative bonding. The electron-density analysis suggests that C–N bonding is enhanced in **1b** and weakened in **1c**; the C–N bond lengths in **1a–c** are perfectly consistent with this trend.

Our analysis of the phenyl cations **2** focused on the C_3H_2 fragment and showed that its overall positive charge is greatly diminished during dediazoniation: by 0.113 for X = H, by 0.102 for X = NO_2, and by as much as 0.201 for X = NH_2. The σ-hole formation causes such extreme polarizations in the σ system that the majority of the positive charge is located on the other half of the molecule! Interestingly, the population analysis of **2** assigns a negative charge to C_{ipso} and large positive charges to the *ortho*-CH groups. These atom populations reflect C_{ipso}–C_{ortho} bond polarization toward C_{ipso} and, with the zero-flux surfaces at a greater distance from C_{ipso}, an expanding C_{ipso} basin.[7a, b] The topological analysis of the electronic relaxation along the dissociation path shows that the associated population changes at C_{ipso} reflect primarily inductomeric effects on the location of the C_{ipso}–C_{ortho} partitioning surface.[16]

The plots in Figure 3 depict the changes in C–N bonding during heterolysis of **1a**; similar plots were obtained for the

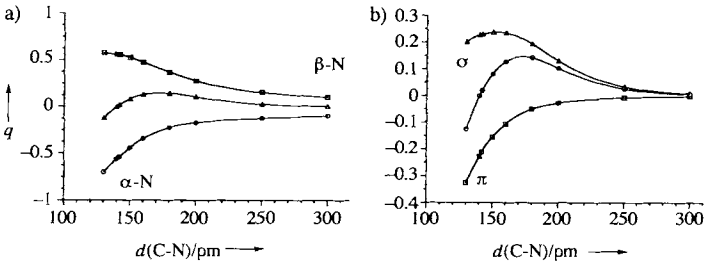

Figure 3. Variation of the charge q of a) the N atoms and b) the N_2 group as well as the σ and π components of the charge for **1a** along the unimolecular dissociation pathway as a function of the C–N bond length. The top and bottom curves describe the different components, and the middle curve describes the corresponding combination.

substituted systems. The dissociation is essentially complete when the bond length d(C–N) is about 300 pm. The charges of N_α and N_β change steadily, and the negative charge at N_α drops faster than the positive charge at N_β. Consequently, the charge of the N_2 group goes through a maximum around d(C–N) = 175 pm. Cleavage of the C–N bond may increase (X = H, NO_2) or decrease (X = NH_2) the overall positive charge on the phenyl fragment. Irrespective of their charge in the equilibrium structures **1a–c**, the N_2 groups become more positive in the early phase of the dissociation, reach a maximum charge of 0.1–0.2 at d(C–N) ≈ 175 pm, and then smoothly become neutral in the later stages. The value $q_{max}(N_2)$ for the NO_2-substituted system exceeds that of the parent system; $q_{max}(N_2)$ of the NH_2-substituted ion is the lowest. Our analysis illustrates in a compelling way that the C→N π backdative bond breaks earlier than the N→C σ dative bond.

These results are consistent with and provide additional support for the electron density based model that describes C–N bonding in diazonium ions by synergistic C←N σ dative and C→N π backdative bonding. The analysis provides a straightforward theoretical basis for interpretating the oppositely signed DSP relationship and, in addition, furnishes details about the electronic structure that cannot be deduced from physical-organic studies alone. For example, the kinetic analysis does not answer the question as to whether the negative reaction constant ρ_F is due to positive charge being transferred from the diazo function onto the phenyl fragment (e. g. Lewis notation) or whether it is merely the result of charge shifts within the phenyl fragment (as we show). Only the theoretical analysis reveals how C–N bonding is achieved. The kinetic analysis quantifies substituent effects on the overall energy difference between reagents and products, which form the basis for deducing stabilization mechanisms. Theory allows one to pinpoint

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3620-2212 $ 17.50+.50/0

these mechanisms by providing independent information on both. While the overall charge of the phenyl fragments in **1** and **2** differ relatively little, the extreme polarizations in the σ systems of the phenyl cations cause a pronounced shift of positive charge from the C_3H_2 fragment into the other half of the molecule. We consider this electron density shift responsible for the negative reaction constant ρ_F. The phenyl ring gains π density upon dediazoniation, which is consistent with the positive reaction constant ρ_R.

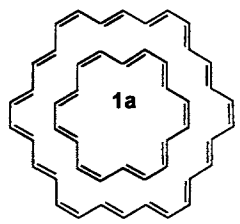
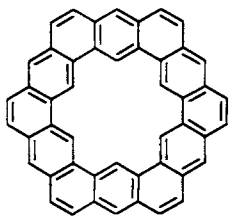
Hexavinylogous Porphyrins with Aromatic 30 π-Electron Systems**

Christian Eickmeier and Burchard Franck*

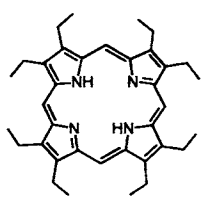
The seminal work of Sondheimer et al. on the synthesis of cyclic conjugated compounds, including the aromatic [18]annulene (**1a**), culminated with the preparation of [30]annulene (**1b**).[1] Although **1b** follows the $(4n+2)$ rule[2] for aromatic systems, it is unstable. Perfect conformational stabilization of a C_{30} perimeter is achieved in kekulene **2** synthesized by Staab and Diederich.[3] However, the π-electron sextets of its annelated benzene rings do not allow the formation of a conjugated 30 π perimeter. Recently it has been shown with numerous examples that planar cyclopolyenes can be stabilized by insertion of pyrrole units,[4–7] but no aromatic compound corresponding to [30]annulene (**1b**) has been synthesized so far.



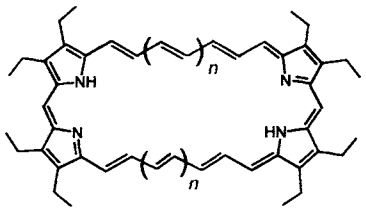
1b



2



3



4: $n = 0$
5: $n = 1$

After we had found that the *tetravinylogous* porphyrin **4** has a stable aromatic 26 π-electron system,[8] the question arose whether the stabilizing effect of the pyrrole units would be sufficient for a *hexavinylogous* porphyrin **5**, which has a conjugated perimeter corresponding to the [30]annulene (**1b**) of Sondheimer et al.[1] One serious impedement was that the synthesis of **5** would have to proceed via the highly reactive pyrrylpolyene **11** (Scheme 1).

We report here on the first synthesis of a hexavinylogous porphyrin **5** with an aromatic 30 π-electron system. In addition to its importance for the understanding of aromaticity, this octaethyl[30]porphyrin is also of practical interest, as its parent compound, octaethyl[18]porphyrin **3**,[9] is the most extensively used porphyrin in chemistry and medicine.

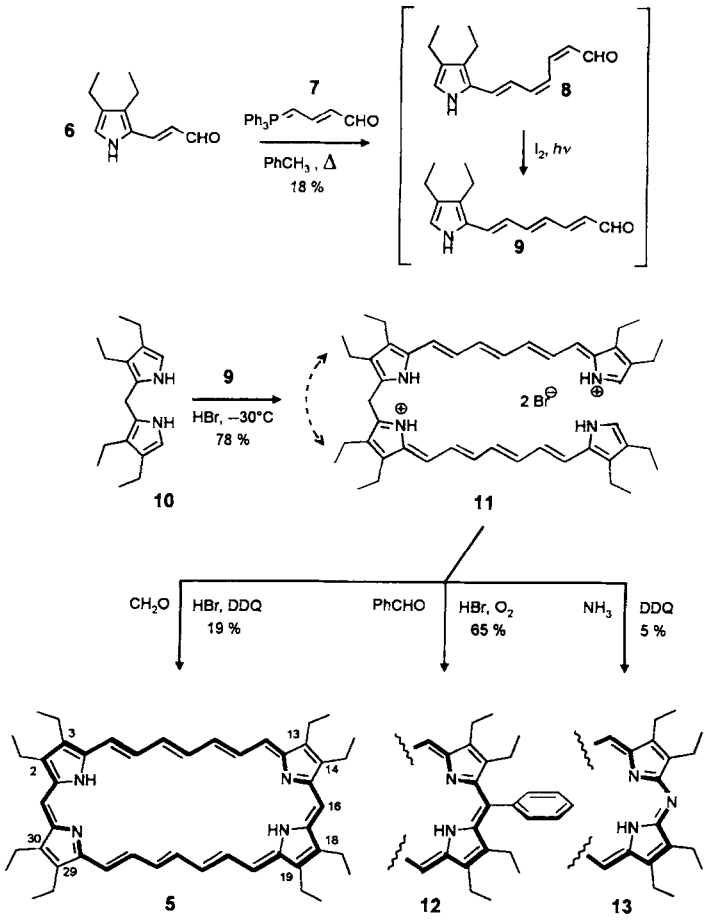

Scheme 1. Synthesis of the hexavinylogous biladiene **11** and its cyclocondensation to give the octaethyl[30]porphyrins **5**, **12**, and **13**[13].

The key building block for the synthesis of the octaethyl[30]porphyrin **5** was the hexavinylogous biladiene bishydrobromide or bilaoctaene **11** (Scheme 1). The deep green bishydrobromide **11** was prepared starting from pyrrylacrolein **6**[4c, 10] by chain extension through Wittig reaction with phosphorane **7**[11] and acid-catalyzed condensation with dipyrrylmethane **10**.[12] 7-(3,4-Diethylpyrrol-2-yl)hepta-2,4,6-trienal **8**/**9** was obtained as a mixture of the (4*E*) and (4*Z*) isomers, from which the (all-*E*) product **9** was separated as rust-colored reddish crystals by column chromatography (silica gel, ether/cyclohexane 2:1) and recrystallization (ether/*n*-hexane). The oily (4*Z*) isomer **8** yielded a further amount of **9** by isomerization with iodine/*hv* (24 h, daylight).

The bilaoctaene salt **11**, which contains two heptavinylogous amidine structures, is stable to air but decomposed in solution. Its cyclocondensation with formaldehyde was achieved in methanol/HBr. After subsequent in situ dehydrogenation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ), 2,3,13,14, 18,19,29,30-octaethyl[30]porphyrin(7.1.7.1) (**5**)[14] was isolated and purified by twofold flash chromatography[15] (silica gel, CH_2Cl_2/MeOH 10:1). Compound **5** is deep violet in solution, and despite its limited stability as a solid and in solution, it could be completely characterized.[13] The considerably more stable 16-phenyl[30]porphyrin **12** was obtained by acid-catalyzed condensation of biladiene **11** with excess benzaldehyde.[13] In this case air oxidation sufficed for the dehydrogenation of the initially formed cyclic intermediate. After column chromatography (silica gel, CH_2Cl_2/MeOH 20:1) **12** was obtained as thin green needles. As in earlier investigations[4g, 7] the high yield of 65% can be explained by the favored hairpin-type conformation of **11**, which results from steric repulsion of the ethyl groups in the dipyrrylmethane unit (indicated with an arrow in Scheme 1; "helical effect"[4g]). Of the new [30]porphyrins, the 16-aza-[30]porphyrin **13**[13] is the least stable. Its synthesis required careful optimization of the conditions for the condensation of the biladiene salt **11**: NH_3/MeOH at room temperature in the presence of a stoichiometric amount of DDQ.

Although the [30]porphyrins **5** and **12** have limited solubility, their ^{1}H NMR spectra could be recorded in [D_6]dimethylsulfoxide/[D_1]trifluoroacetic acid ([D_6]DMSO/[D_1]TFA); the observed diatropic ring current effects provide proof of aromacity (Figure 1). For **5** the maximum difference $\Delta\delta$ in the chemical shifts of the inner (H_c) and outer (H_a) protons is 23.7. This value is slightly lower than that of the [26]porphyrin **4** ($\Delta\delta = 24.1$),[8] and indicates that extending the conjugated perimeter from **4** to **5** does not result in a further increase of aromaticity, as expressed by the diatropic ring current effect. Thus we conclude that the planar stabilization of annulenes through four pyrrole units ends with the 30π perimeter **5** because of its two long C_7 bridges.

Further evidence for the interdependence of the ring current effect and planarity of the ring system can be gained from the δ values of 16-phenyl-[30]porphyrin **12** (Figure 1). The maximum

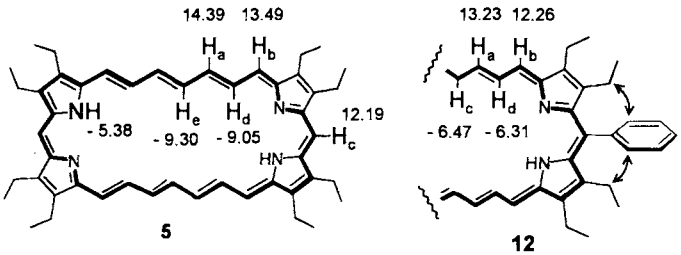

Figure 1. ^{1}H NMR chemical shifts of [30]porphyrin **5** and 16-phenyl-[30]porphyrin **12**[13].

difference $\Delta\delta$ in the chemical shifts of the inner (H_c) and outer protons (H_a) amounts to 19.7, which is four units less than for **5**. In agreement with earlier results[16] this may be explained by distortion of the 30π perimeter due to interactions of the phenyl group with adjacent ethyl groups.

It can be concluded that even [30]annulene systems are aromatic and follow E. Hückel's $(4n+2)$ rule[2] when they are stabilized and held planar. The stabilization of the [30]π systems in **5**, **12**, and **13** by insertion of four pyrrolic units follows the porphyrin model in nature.

The Crystal Structure of Aziridine**

Norbert W. Mitzel,* Jürgen Riede, and Christoph Kiener

Dedicated to Dr. C. Arnold Beevers on the occasion of his 89th birthday

The structure of the aziridine molecule in the gas phase is well established by microwave spectroscopy[1] and electron diffraction[2] studies. Ab initio calculations on aziridine confirm most of the experimental results.[3] The structures of crystalline, substituted aziridines, elucidated by X-ray diffraction, deviate from these results in some cases.[4] We report here on the crystal structure determination of this simplest nitrogen heterocycle at low temperature.

The toxic, extremely carcinogenic, and teratogenic free aziridine, which tends to polymerize spontaneously (potentially explosively), was prepared following a known synthetic procedure[6] starting with β-aminoethylsulfate. It was purified by repeated distillation and condensed into a thin-walled glass capillary. A single crystal was grown by carefully cooling the melt after generation of a suitable seed crystal. X-ray diffraction intensities were collected at 145 K and analyzed following established procedures.[7]

Aziridine crystallizes with three independent molecules in the asymmetric unit, which show very similar geometries. As in crystalline oxirane studied by Luger et al.,[8] aziridine is an equilateral triangle (Figure 1), although the bond lengths are significantly longer in aziridine [average values aziridine/oxirane: C–C 1.462(2)/1.438(4) Å, C–N and C–O 1.467(2)/1.431(4) Å, respectively]. Cyclopropane, also isoelectronic, shows even longer C–C distances of 1.500 Å on average,[9] which suggests that the ring bond lengths are primarily dependent on the electronegativity of the heteroatom.

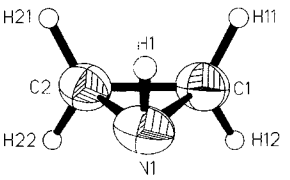

Figure 1. Molecular structure of aziridine in the crystal at 145 K. Selected bond lengths and angles for the three independent molecules: C–C 1.459(1), 1.465(2), 1.463(2) Å; C–N 1.463(2), 1.464(2); 1.469(2), 1.470(2); 1.465(2), 1.468(2) Å; C-N-C 59.8(1), 59.8(1), 59.8(1)°; N-C-C 60.1(1), 60.1(1); 60.1(1), 60.2(1); 60.0(1), 60.2(1)°.

Using all available lone pairs of electrons and hydrogen atoms, aziridine forms a hydrogen-bonded chain aggregate (Figure 2). In contrast to crystal structures of other very small secondary amines like F_2NH, which shows a zig-zag arrangement of molecules ABAB, the chains of aziridine follow an ABCABC motif with three molecules per repeat unit, although an ideal N–H···N angle of 180° cannot be attained (the N–H···N angles are 157, 179, and 161°). Two molecules are oriented toward one side of the chain axis, while the third one points in the other direction. The cavity generated on the side of the latter molecule is filled by a symmetry-equivalent molecule from the neighboring chain.

A comparison of the structure of aziridine in the crystal and in the gas phase (Table 1) shows that the molecule suffers no

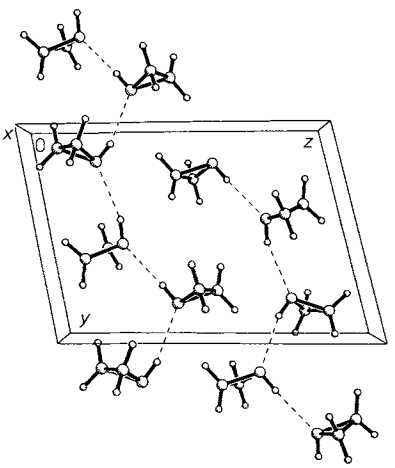

Figure 2. View of the hydrogen-bonded molecules in the crystal showing the ABCABC arrangement in the chains. The intermolecular N–N distances are 3.085(2), 3.069(2), and 3.082(2) Å.

significant structural distortions on incorporation into the crystal lattice. Even the electron density maxima, which roughly represent the positions of the hydrogen atoms bound to nitrogen, are described by C-N-H angles that are only marginally different from the gas-phase values (Table 1).

To our knowledge, the best ab initio calculations of the structure of aziridine were performed at the SCF/6-31G(d) level of theory in 1989.[3] The predicted C–C and C–N bond lengths differ significantly from the experimental values (Table 1). Consequently, we conducted calculations at much more sophisticated levels of theory. As expected, the deviations decrease when the effects of electron correlation are taken into consideration. Already at the MP2/6-31G* level of theory good results are obtained, which deviate only slightly from those calculated at QCISD/6-311 + G**, the highest level applied (Table 1). In particular the calculated C–N distance and C-N-H angle are much more realistic.

A rigid-body correction[11] of the results of the crystal structure analysis with all the anisotropic displacement parameters of one molecule yields average C–N and C–C bond lengths of 1.474 and 1.469 Å, respectively. These values are very close to those calculated and determined by microwave spectroscopy. However, even after application of these corrections, the aziridine C–C bond in the crystal is shorter than the C–N bond, whereas microwave spectroscopy and theory both indicate the C–C distance to be the longer one. The remaining deviations can be explained at least in part by the fact that X-ray diffraction analysis measures the maxima of electron density rather than the average nuclear positions, which may be significantly different, in particular in the presence of light atoms and in extreme bonding situations. Nevertheless, the descriptions of the molecular structure of the simplest nitrogen heterocycle are now consistent in the solid state and gas phase, and according to theory.

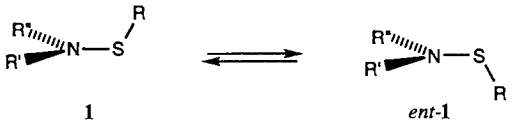
The Chiral S–N Axis in Sulfenamides: Enantiomeric Resolution, Direct Demonstration of Optical Activity, and Kinetics of Interconversion**

Merav Ben-David Blanca, Eric Maimon, and Daniel Kost*

Sulfenamides **1** have a chiral ground-state geometry (when $R'' \neq R'$), since the R-S-N and the average R′-N-R″ planes are mutually perpendicular.[1] Interconversion of the enantiomers (**1**⇌*ent*-**1**) takes place by rotation about the S–N bond [Eq. (1)], which constitutes a stereolabile chiral axis. The factors



1 *ent*-**1** (1)

affecting the magnitude of the rotational barrier have been known for some time:[2] a) electron-withdrawing groups in the substituent R attached to the sulfur atom, and b) steric hindrance in the rotational transition state. Barriers ranging from 10 to 22 kcal mol^{-1} have been reported.[1] Sulfenamides with barriers that are high enough to permit potential isolation of stereoisomers at ambient temperature were described, however no resolution was attempted.[3, 4]

Here we describe the preparation of the *stereostable* sulfenamide **6**, and the direct demonstration of its chirality by enan-

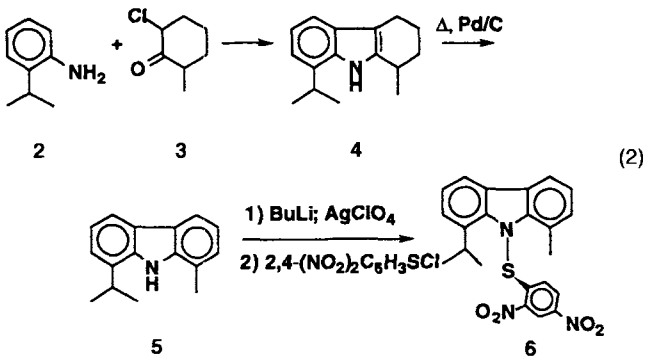
tiomeric resolution and measurement of circular dichroism (CD) spectra.[5] Furthermore, the determination of the rate constants for enantiomer interconversion over a wide range of temperatures is described. Sulfenamide **6** was prepared according to Equation (2). The ^1H and ^{13}C NMR spectra of **6** at ambient



temperature feature separate signals for each of the diastereotopic isopropyl methyl groups, which confirms the chiral ground-state geometry of **6**.

The Gibbs energy of activation for rotation about the S–N bond was determined by the coalescence of the methyl signals in the ^1H NMR spectrum ([D_5]nitrobenzene) to be $\Delta G^{\neq} = 21.0\ kcal\,mol^{-1}$ at 417 K;[6] this is insufficient for isolation of the rotamers at room temperature. However, the enantiomers were resolved at 0° by HPLC on a chiral column, and immediately cooled and stored in liquid nitrogen. The CD spectra of the enantiomers of **6** in the HPLC eluents are shown in Figure 1 (bottom) along with the corresponding UV spectrum of the racemate (top), which is identical to the UV spectrum of the

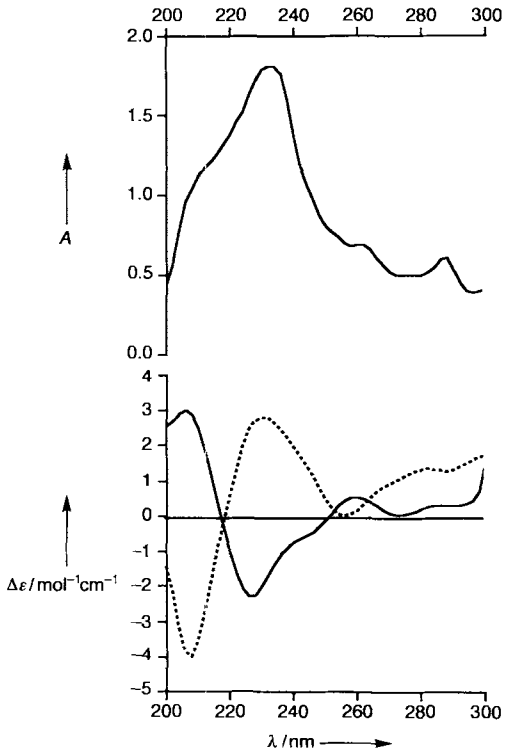


Figure 1. CD spectra for the enantiomers of **6** at 0° (bottom), and the corresponding UV spectrum of the racemic mixture (top).

enantiomers. The approximate mirror-image shapes of the superimposed CD spectra confirm the enantiomeric nature of the components. This constitutes the first direct observation of optical activity due to restricted rotation about a S–N single bond, and renders this bond a stereogenic axis.[7]

Relatively rapid racemization took place during the CD measurements, as manifested by the variation in the CD spectra with time (Figure 2). A first-order rate constant of $k = 0.0028\ s^{-1}$

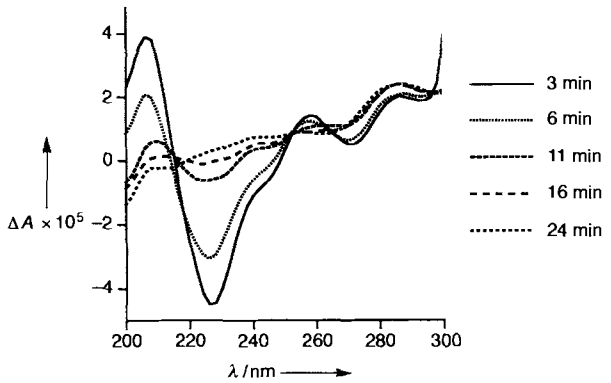

Figure 2. Decay of CD spectrum of **6** at 0° as a function of time; concentration of the initial sample: 8.91×10^{-5} M.

was obtained from the linear correlation of $\ln(\Delta A)$ versus time, and extrapolation to $t = 0$ s afforded the differential absorbances ($\Delta A = A_L - A_R$) of the pure enantiomer. The total concentrations of the solutions, determined from their UV spectra after racemization, were used to calculate the molar differential absorbances at maximum and minimum points on the CD spectrum (Table 1). Several Cotton effects were found that correspond to the UV maxima of **6**.

Table 1. Bands in the CD spectrum of **6** at 0 °C [a]: differences in the molar absorption coefficients of left- and right-handed circularly polarized light.

Wavelength [nm]	$\Delta\varepsilon$ [$cm^{-1}M^{-1}$] [b]
206	+3.79
226	−4.33
258	+0.58
270	−0.62
286	+0.39
310	+1.38

[a] Obtained by extrapolation of ΔA values to $t = 0$; concentration: 8.91×10^{-5} M in 2-propanol/hexane (3/7), pathlength: 0.2 cm. [b] CD Cotton effects are sometimes reported in terms of molar ellipticity [θ], which may be obtained from $\Delta\varepsilon$ values by multiplying by 3298.2 and is expressed in $10^3\,cm^2\,mol^{-1}$ (ref. [7b], p. 1005).

To obtain accurate values for the activation enthalpy and entropy, rate constants at four additional temperatures were measured by NMR magnetization transfer using the selective inversion recovery technique.[8] Selective inversion was applied to one of the isopropyl methyl signals (at temperatures below the coalescence temperature), and variations of the inverted and the unperturbed signals back to their equilibrium intensities were followed as a function of the delay time τ between the inversion and the observation pulses. The unperturbed signal first decreased in intensity as a result of kinetic magnetization transfer from the inverted methyl signal, and then returned exponentially to its steady-state intensity (Figure 3). This behav-

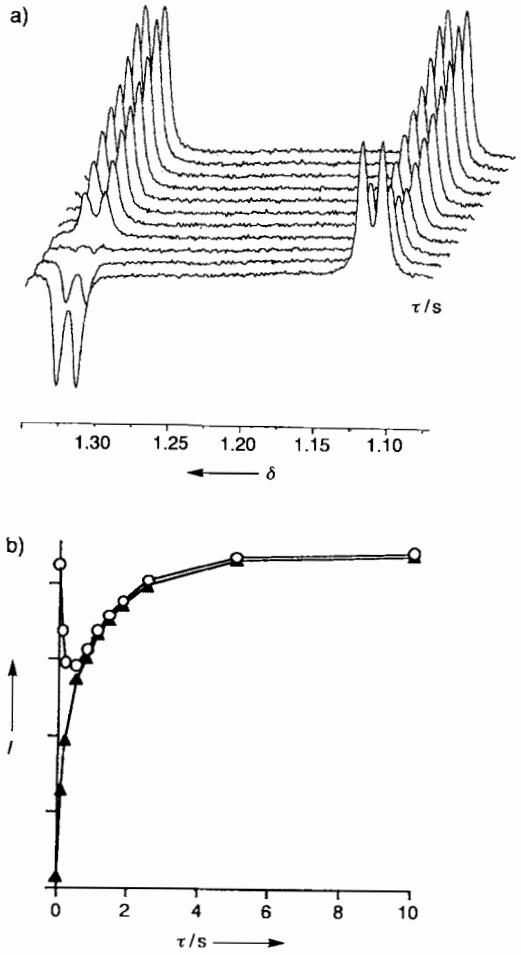

Figure 3. Selective inversion recovery ^{1}H NMR spectra (500 MHz, [D$_5$]nitrobenzene) of the isopropyl methyl region of **6** at various delay times τ between 0.01 and 10 s at 360 K; a) time-dependent presentation of the measured spectra; b) plot of signal intensities versus delay time τ; I = intensity in arbitrary units.

ior is described by Equations (3) and (4) and their linear solutions [Eq. (5), (6)]. (k = first-order rate constant; T_1 = spin-lattice relaxation time, I_A, I_B = signal intensities.)

$$\frac{dI_A}{dt} = \frac{1}{T_1}(I_A^\infty - I_A) + k(I_B - I_A) \quad (3)$$

$$\frac{dI_B}{dt} = \frac{1}{T_1}(I_B^\infty - I_B) - k(I_B - I_A) \quad (4)$$

$$\ln\left(1 - \frac{I_A + I_B}{I_A^\infty + I_B^\infty}\right) = -\frac{t}{T_1} \quad (5)$$

$$\ln\frac{I_B - I_A}{I_B^0 - I_A^0} = -\left(2k + \frac{1}{T_1}\right)t \quad (6)$$

The graphic solutions of Equations (5) and (6) at four temperatures are presented in Figures 4a and 4b, respectively. The excellent linear relationships indicate the precision of the method for kinetic measurements. The first-order rate constants for rotation about the S–N bond (k) and the spin-lattice relaxation times T_1 were obtained from the slopes of the lines (Table 2). The relaxation times compare well with T_1 values obtained at the corresponding temperatures by the conventional (nonselective) inversion recovery method.

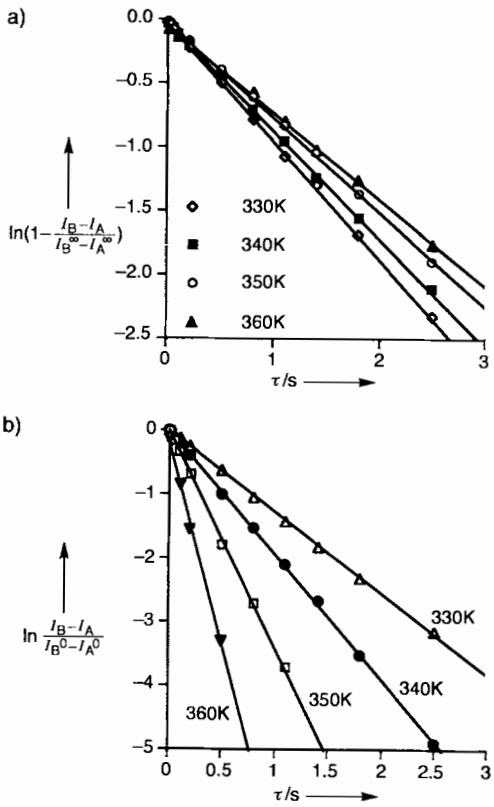

Figure 4. Graphic solution of Equations (5) (a) and (6) (b) from the inversion recovery experiments at four temperatures (see text).

Table 2. Rate constants for rotation about the S–N bond and spin-lattice relaxation times for **6** obtained by selective inversion recovery experiments.

T [K]	k [s^{-1}]	T_1 [s] (selective)	T_1 [s] (nonselective)
330	0.17	1.09	1.00
340	0.55	1.18	1.17
350	1.34	1.40	1.39
360	3.47	1.49	1.50

The rate constants determined by the coalescence and magnetization transfer methods over a wide temperature range were correlated in an Eyring plot as $\ln(k/T)$ versus $1/T$. A perfect linear correlation was obtained (correlation coefficient 1.000), from which the enthalpy and entropy of activation were calculated: (21.7 ± 0.4) kcal mol^{-1} and (3.7 ± 1.0) cal mol^{-1} K^{-1}, respectively.

The rate constant obtained at 0° from the decay of the CD spectrum was left out of the correlation because it was much too high. This was evident earlier from the observation that, although HPLC resolution was achieved at 0° without significant racemization over 22 min, the optical activity decayed almost completely over the same period of time. Since the CD measurement was carried out under adequate temperature control, it seems that the rate of enantiomer interconversion is increased by the influence of the light beam.[9]

Experimental Section

1-Isopropyl-8-methylcarbazole (**5**) was synthesized from **3** [10] (0.07 mol) and 2-isopropylaniline (**2**, 0.14 mol) according to a literature procedure [11] via **4** followed by Pd/charcoal dehydrogenation [12]. Compounds **4** and **5** were purified by chromatography over silica gel and obtained in 55 and 60% yields, respectively (m.p. 57–58 and 79–81 °C, respectively (petroleum ether (40–60)). To a solution of **5**

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3620-2218 $ 17.50+.50/0

(0.8 g, 36 mmol) in THF at -20° under nitrogen was added *n*BuLi in hexane (2.5 M, 1.5 mL, 36 mmol) with stirring. The reaction mixture was cooled to -78°, and $AgClO_4$ (0.74 g, 36 mmol) in THF added. After 30 min a solution of 2,4-dinitrobenzenesulfenyl chloride (0.84 g, 36 mmol) in THF was added dropwise. The temperature was allowed to rise to room temperature, and stirring maintained for 20 h. The solid residue was removed by filtration, and the filtrate purified by chromatography on silica gel with petroleum ether (40–60)/CH_2Cl_2 (3/1) as eluent. Compound **6** was obtained in 46% yield (0.7 g); m.p. 145–146° (methanol); HRMS (CI) calcd for $C_{22}H_{20}N_3O_4S$ ($M+1$): 422.117; found: 422.119.

Resolution of **6**: $T = 0^{\circ}$, Chiralpak-AD column (25 × 0.46 cm) packed with dimethylphenylcarbamoylamylose from DAICEL Chemical, hexane/2-propanol (7/3), Waters 996 HPLC instrument. Retention times of the enantiomers: 8.5 and 21.5 min.

Selective inversion was applied by the sequence of hard pulses: $\pi/2 \rightarrow 1/2\Delta\nu \rightarrow \pi/2$ on resonance with one of the methyl signals.

Synthesis of a Triiodide-Like Pentamesityltritellurium Cation by Addition of Dimesityltelluride to the Remarkably Electrophilic Trimesityltelluronium Ion**

Jörg Jeske, Wolf-Walther du Mont,* and Peter G. Jones

Dedicated to Professor Manfred Weidenbruch on the occasion of his 60th birthday

It has been observed that linear Te_3 building units in some nonclassical polytellurides and polytelluride-chelate complexes[1–5] are analogous to the I_3^- ion. This raises questions such as whether matrix effects or metal coordination are essential[3] for the existence of such Te_3 units and whether the hypervalent Te_3 units and the I_3^- ion also show similar reactivities. Answers to such questions could be provided by a model reaction in which linear Te_3 units would be formed from Te_1 and Te_2 units with "normal" valencies. Calculations of a hypothetical Te_3^{n-} ion, under the assumption of a Te–Te bond length of 307.7 pm (Te coordinated in a linear manner in the $[CsTe_6]^{2-}$ layer of Cs_3Te_{22}),[6] predict linear structures for $n = 3-5$.[7] The Te_3^{4-} ion, which is isoelectronic with I_3^-,[3, 7] can be formally obtained by the addition of Te^{2-} to Te_3^{2-}, but has not yet been detected either in the solid state or in solution. In contrast, the first cationic pentaaryl derivative of the hypothetical Te_3^{4-} ion has proved to be remarkably stable. The synthesis of $[Mes_5Te_3]^+$ described herein exploits the pronounced electrophilic character of the ditelluronium ion $[Mes_3Te_2]^+$; it readily undergoes addition to Mes_2Te (**1**) (Mes = 2,4,6-trimethylphenyl). Normally telluronium cations interact only very weakly with tellurium nucleophiles,[8] but the Lewis acidity of the divalent tellurium atom in the triaryldittelluronium ion $[Mes_3Te_2]^+$ is strongly increased by the proximity of the neighboring telluronium center. Although corresponding trialkyldisulfonium ions $[R_2SSR]^+$[9] can be used as reagents for the transfer of RS^+ units,[10] they avoid violating the octet rule by cation–anion interaction[11] or by the addition of further dialkyl sulfide. The stable ditelluronium salt $[Mes_3Te_2][SbF_6]$ (**2**) was synthesized by coordinating **1** with the $[MesTe]^+$ ion, which was produced in situ from dimesityldittelluride, silver hexafluoroantimonate, and bromine [Eq. (a)].

$$2\,\underset{\mathbf{1}}{Mes_2Te} + Mes_2Te_2 + Br_2 \xrightarrow[-2\,AgBr]{+2\,AgSbF_6} 2\,\underset{\mathbf{2}}{[Mes_2TeTeMes][SbF_6]} \qquad (a)$$

The description of the ditelluronium ion in **2** as a mesitylenetellurenyl cation $MesTe^+$ donor-stabilized by the Lewis base **1** is supported by the interaction of the cation in **2** with the SbF_6^- counterion in the solid state (see crystal structure).[12] The structure of the cation in **2** is fundamentally different from the structures of the original ditelluride[13] and from those of known disulfonium ions.[11] In **2**, two cations and two anions form ring-shaped units through secondary Te···F interactions (Figure 1). The coordination geometries of the two tellurium atoms in **2** can be described as pseudo trigonal-bipyrami-

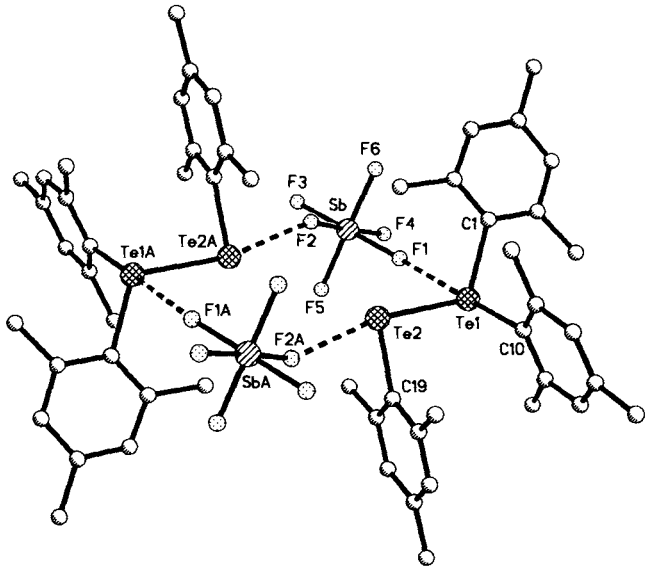

Figure 1. Crystal structure of **2**. Symmetry operators for the equivalent A: $1-x$, $2-y$, $1-z$; Te1–Te2 276.45(5), Te1–F1 308.9(3), Te2–F2A 276.8(3) pm; C1-Te1-Te2 112.76(12), C10-Te1-F1 175.65(12), Te2-Te1-C10 95.34(11), Te2-Te1-F1 88.94(6), C19-Te2-Te1 86.18(12), Te1-Te2-F2A 168.27(9), C19-Te2-F2A 83.01(14)°.

dal when the Te–F contacts are taken into consideration. Relative to Te1 (*one* lone pair of electrons, 10-Te-4[14]), the neighboring F atom is in an apical position (C10-Te1-F1 175.6°) and the neighboring divalent Te2 atom is in an equatorial position. The T-shaped geometry is clearly apparent from the coordination sphere of Te2 (Te1-Te2-F2A 168.3°, Te1-Te2-C19 86.2°, C19-Te2-F2A 83°). This is because the divalent tellurium atom in the α position in **2** has an appreciably stronger contact with the counterion than the telluronium center, which formally carries the charge (Te2–F2A 276.8 pm, Te1–F1 308.9 pm). This surprising phenomenon distinguishes the cation in **2** clearly from disulfonium ions and permits a comparison with the known acceptor behavior of iodophosphonium ions. For example, in solid [tBu$_3$PI][BF$_4$], donor–acceptor interactions exist between the F atoms of ordered tetrafluoroborate ions and the iodine atom of the onium center, whereas P···F contacts do not occur.[15] The F2A···Te2-Te1 (n $\rightarrow \sigma^*$) interaction is accompanied by a Te–Te bond length that is approximately 6 pm longer than that in Mes$_2$Te$_2$.[13] As a consequence, the d(Te1–Te2) and d(Te2–F2A) bonds are almost the same length. The strong cation–anion interaction in **2** indicates the pronounced electrophilic character of the Te atom in the α position to the telluronium center. Red-black **2** reacts smoothly with excess **1** by addition to Te2 to form the brown-red **3** [Eq. (b)], which contains the new pentaaryltritellurium cation. Compound **2** can therefore be described as a salt of a tellurenyl cation that is, despite coordination with a diaryltelluride nucleophile, still not saturated.[16, 17]

$$\underset{\mathbf{1}}{\text{Mes}_2\text{Te}} + \underset{\mathbf{2}}{[\text{Mes}_2\text{TeTeMes}][\text{SbF}_6]} \longrightarrow \underset{\mathbf{3}}{[(\text{Mes}_2\text{Te})_2\text{TeMes}][\text{SbF}_6]} \qquad \text{(b)}$$

The compound **3** is much more soluble in dichloromethane than **2**, which enabled the ^{125}Te NMR spectrum in solution to be measured. The two Mes$_2$Te groups in the cation in **3** are magnetically equivalent. The varying degrees of broadening of the two ^{125}Te NMR signals from **3** and the absence of Te–Te coupling indicate dynamic exchange equilibria in solution. When a further equivalent of **1** is added, no separate signals for **1** and the terminal Te atoms in **3** are observed. This means that fast exchange of coordinated **1** with free **1** occurs at room temperature. Crystals of **3** contain [Mes$_5$Te$_3$]$^+$ and SbF$_6^-$ ions and CH$_2$Cl$_2$ (Figure 2). The cation of **3** contains an almost linear Te$_3$ unit. The Te–Te bond lengths differ by about 7 pm but they are both clearly longer than the single bond in **2**. The one

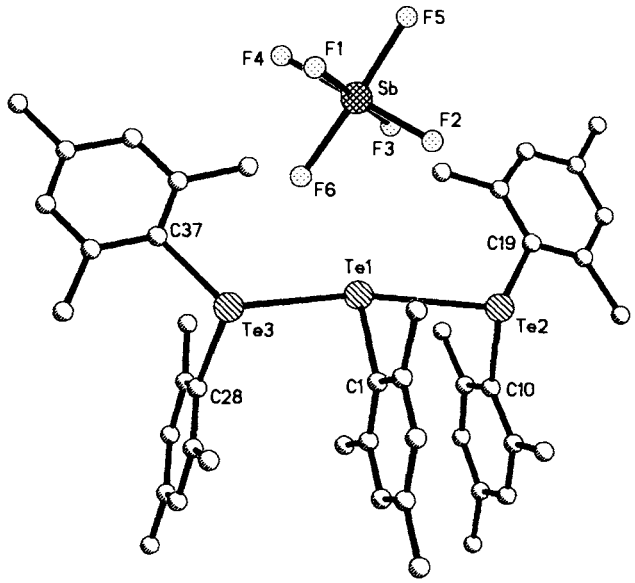

Figure 2. Crystal structure of **3** (without dichloromethane). Te1–Te2 304.91(10), Te1–Te3 297.91(10) pm; Te2-Te1-Te3 159.51(3)°; shortest distance to the fluorine atoms; Te1–F3 390.9(11), Te3–F6 358.3(15) pm.

Te···F contact in **3** (Te3–F6 358.3 pm) is much longer than those in **2** and is accompanied by a shortening of the neighboring Te–Te bond (Te3–Te1 297.9 pm); the other Te–Te bond is correspondingly longer (Te1–Te2 304.9 pm). The average Te–Te bond length in **3** (301.5 pm) is one of the shortest Te–Te distances known for linear Te-Te-Te units (for example the I_5^+-analogous Te_5^{4-} ion of NaTe: linear: d(Te–Te) 308 pm, terminal: d(Te–Te) 282 pm.[1, 18] Therefore the cation in **3** is undoubtedly a slightly asymetric cation similar to triiodide, in which the valence shell of the central tellurium atom is expanded to contain 10 electrons. Compound **3** is the first organotellurium compound with a "hypervalent" Te$_3$ unit.

The addition of **1** to **2** to form **3** represents the first well-defined combination of two eight-electron tellurium species to form a linear ten-electron Te$_3$ species. The smooth access to **2** and **3** and the remarkable acceptor properties of the cation in **2** raise expectations that ditelluronium ions could be of significance for the synthesis of new cationic organotellurium compounds and for doping experiments. The formation of **3** is analogous to the known reaction of iodine with iodide. Similar bonding characteristics (homonuclear n $\rightarrow \sigma^*$ donor–acceptor interaction or 3-center-4-electron bonding) and the kinetic lability of the stable Te$_3$ unit in **3** show how closely related the unusual properties of many polytellurides, the significance of which has only become clear within the past ten years, are to the known phenomena of iodine chemistry.

Experimental Section

2: Mes$_2$Te (**1**) (0.55 g, 1.5 mmol) and Mes$_2$Te$_2$ (0.49 g, 0.75 mmol) in dichloromethane (30 mL) were oxidized with bromine (0.12 g, 0.75 mmol) and then allowed to react with AgSbF$_6$ (0.5 g, 1.5 mmol) in dichloromethane (5 mL). The initially brown solution turned blood-red immediately and silver bromide slowly precipitated. The reaction was allowed to proceed to completion in the dark for 1 h at room

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3620-2220 $ 17.50+.50/0

temperature with stirring, then the precipitate was removed by filtration. Hexane (50 mL) was added to the now brown solution and the product was obtained as a violet-brown powder. Crystals suitable for X-ray structure analysis were obtained by using the diffusion method (dichloromethane solution/hexane). Yield: 0.94 g (74%); m.p.: 189 °C (decomp), $C_{27}H_{33}F_6SbTe_2$; $M = 848.50\ g\,mol^{-1}$, calcd.: C 38.22, H 3.92; found: C 38.37, H 4.03; ^1H NMR (CD_2Cl_2): $\delta = 7.05$ (2H), 2.34 (6H), 2.32 (3H); ^{125}Te NMR: no signal was observed because of low solubility; positive-ion FAB-MS (NBA): *m/z* (%): 741 (5, $[Mes_3Te_3]^+$), 613 (40, $[Mes_3Te_2]^+$), 494 (22, $[Mes_2Te_2]^+$), 368 (100, $[Mes_2Te]^+$), 248 (24, $[MesTe^+ - H]^+$), 119 (70, Mes^+); negative-ion FAB-MS: *m/z* (%): 494 (7, $[Mes_2Te_2]^-$), 472 (2.5, $[Sb_2F_{12}]^-$), 235 (100, $[SbF_6]^-$), 216 (2, $[SbF_5]^-$), 197 (2, $[SbF_4]^-$).

3: **2** (0.43 g, 0.5 mmol) and **1** (0.25 g, 0.7 mmol) were taken up in dichloromethane (2 mL) by warming and subsequently crystallized at -18 °C to give crystals suitable for X-ray structure analysis. The transparent red-brown needlelike crystals obtained by filtration crumbled to a brown powder after drying in vacuum (yield, melting point, and elemental analysis refer to the solvent-free substance). Yield: 0.45 g (74%); m.p.: 169 °C (decomp), $C_{45}H_{55}F_6SbTe_3$; $M = 1214.47\ g\,mol^{-1}$; calcd.: C 44.50, H 4.56; found C 44.64, H 4.48; ^1H NMR (CD_2Cl_2): $\delta = 7.04$ (2H), 2.32 (6H), 2.30 (3H); ^{125}Te NMR (CH_2Cl_2/C_6D_6): $\delta = 854$, 388, (20% excess of 1: 842, 385); positive-ion FAB-MS (NBA): *m/z* (%): 741 (2, $[Mes_3Te_3]^+$), 613 (40, $[Mes_3Te_2]^+$), 494 (14, $[Mes_2Te_2]^+$), 368 (100, $[Mes_2Te]^+$), 248 (20, $[MesTe^+ - H]^+$), 119 (55, Mes^+); negative-ion FAB-MS: *m/z* (%): 494 (7, $[Mes_2Te_2]^-$), 472 (3, $[Sb_2F_{12}]^-$), 235 (100, $[SbF_6]^-$), 216 (2, $[SbF_5]^-$), 197 (2, $[SbF_4]^-$).

The First Di-μ_3-hydroxo-Bridged Tetramanganese(II) Complex**

Lutz Stelzig, Bruno Donnadieu, and Jean-Pierre Tuchagues*

Tetranuclear manganese complexes are currently of interest as models for the manganese cluster in the oxygen-evolving center (OEC) of photosystem 2 (PS2) for which four manganese centers per active site have been proposed.[1] In terms of the synthesis of model complexes for the various states of the OEC, the coordination of water or its derivatives (OH^- or O^{2-}) to a tetranuclear manganese cluster is of great significance. Many manganese complexes containing hydroxo, oxo, and peroxo bridges have been synthesized.[2] However, only two hydroxo-bridged tetranuclear manganese complexes that include $Mn^{I}(\mu_3\text{-}OH)$[3a] and $Mn^{IV}(\mu_2\text{-}OH)$[3b] bonds are known. This communication describes **1**, the first tetranuclear manganese(II) complex including bridging μ_3-hydroxo ligands.

$[Mn_2(L)(OH)(thf)]_2 \cdot 2THF$ **1**

LH_3 = 1,5-bis(3,5-dinitrosalicylideneamino)pentan-3-ol)

LH_3 has proven a suitable ligand for the synthesis of di- and tetranuclear metal complexes; in particular, a tetranuclear μ_3-oxo-bridged manganese(III) complex based on the unsubstituted analogue, 1,5-bis(salicylideneamino)pentan-3-ol ($L'H_3$), has been previously reported by Mikuriya et al.[4] Under strictly anaerobic conditions, reaction of twice the molar amount of $Mn(OAc)_2 \cdot 2H_2O$ with LH_3 in a methanolic sodium hydroxide solution leads to a very air-sensitive orange compound. Subsequent crystallization of this orange powder from THF/pentane yielded **1** as well-shaped, orange-red crystals.

The molecular structure[5] of the tetranuclear complex **1** (Figure 1) shows that the trianionic pentadentate ligand L bridges two Mn^{II} ions through its alkoxo oxygen atom. Each Mn^{II} is additionally bonded to one azomethine nitrogen and one phenolate oxygen atom of L. A hydroxo bridge further stabilizes the two Mn^{II} centers of each dinuclear unit. The structure of complex **1** is best viewed as two layers of dinuclear subunits linked by two bridging phenolate-O atoms of L and two μ_3-OH^- ions. The bis-dinuclear molecule is located at a crystallographic inversion center. Different coordination spheres for the two man-

ganese atoms in the same subunit result from the weak binding of a THF molecule at the remaining apex of the Mn1 coordination octahedron. Consequently, Mn2 is in a square-pyramidal environment of one N and four O atoms, whereas Mn1 has donor set of one N and five O atoms.

The Mn1 $\cdots$ Mn2 distance of 3.166(3) Å is mainly dominated by the ligand bite angle. The Mn1 $\cdots$ Mn1′ distance involving bis-hydroxo-bridged metal centers (3.281(3) Å) is very close to those involving hydroxo-phenoxo-bridged metal centers (Mn1 $\cdots$ Mn2′ = Mn2 $\cdots$ Mn1′ = 3.278(3) Å). The Mn2 $\cdots$ Mn2′ distance (5.547(7) Å) is the largest Mn $\cdots$ Mn separation inside the Mn_4 unit.

The bond lengths between Mn and μ_3-OH oxygen atoms range from 2.106(3) Å (within a dinuclear layer) to 2.203(3) Å (between dinuclear layers). These values are in agreement with those previously reported for $Mn^{II}(\mu_2\text{-OH})_2Mn^{II}$ bonds[2b] and for the $Mn^{II}\mu_2$-OH bond of a $Mn^{II}(\mu_2\text{-OH})(\mu_2\text{-OAc})_2Mn^{III}$ complex,[2h] and longer than that reported for a $Mn^{II}(\mu_2\text{-OH})Mn^{II}$ bond.[2f] On the other hand, these $Mn^{II}(\mu_3\text{-OH})Mn^{II}$ bonds are significantly longer than the $Mn^{III}(\mu_3\text{-O})Mn^{III}$ bonds (1.89–1.94 Å) in the related $[Mn_4(L')_2(\mu\text{-O})_2(CH_3COO)_2]$ complex.[4] The oxidation state of the manganese ions and the presence of the hydroxo bridges are deduced from stoichiometric considerations and the good correspondence with established Mn–O bond lengths; furthermore, the hydroxide proton is easily located in difference Fourier maps as a result of the hydrogen bond between the oxygen atom of uncoordinated THF molecules and the bridging hydroxo anions. A broad and weak band at 3400–3500 cm^{-1} in the IR spectra of **1** is unambiguously attributable to a $\tilde{\nu}_{O-H}$ stretch. This observation is in agreement with the presence of a hydrogen bond between the hydroxide anion and the oxygen of the uncoordinated THF molecule, which should broaden and exert a downfield shift on the hydroxide $\tilde{\nu}_{O-H}$ stretch, usually a relatively sharp absorption in the 3520–3688 cm^{-1} range.[2a–c, g, 3a] However, due to the possible presence of water, unambiguous assignment of this $\tilde{\nu}_{O-H}$ stretch requires labeling experiments. The band at 558 cm^{-1} may be attributed to the $\tilde{\nu}_{Mn-OH}$ stretch.

The X-band powder spectra of complex **1** exhibit a temperature-independent (from 300 to 80 K) and featureless broad resonance with a g value of about 2. The broadness of this isotropic EPR absorption is consistent with the presence of magnetically interacting manganese(II) ions in the solid state.[6] The X-band EPR spectra of the compound in DMF/toluene glasses at 100 K exhibit a resonance without fine or hyperfine features centered at $g \approx 2$, indicating that the tetranuclear structure is retained in solution.

The magnetic susceptibility of complex **1** has been measured betweem 300 and 2 K. The μ_{eff} value per Mn center is lower than the spin only value at 300 K and decreases from 5.56 to 2.31 μB at 2 K, indicating overall antiferromagnetic coupling of the $S = 5/2$ spin systems of the Mn^{II} ions in complex **1**.

The vacant coordination site at the Mn2 center may be of interest in oxidation reactions. Air oxidation, for example, proceeds rapidly with formation of a not yet structurally characterized solid. Oxidation reactions of related compounds containing acetate anions yield tetranuclear, mixed-valence, methoxo-bridged Mn^{II}_2/Mn^{III}_2[7] or oxo-bridged Mn^{III}_4[4] compounds. As the nature of the oxidized complex is considerably influenced by the salicylaldimine ring substituents of L, it is expected that **1**, which bears strongly electron-withdrawing nitro groups, may be oxidized to a mixed-valent tetramanganese(II)/(III) complex.

Experimental Section

A solution of NaOH (0.06 g) in MeOH (20 mL) was added to a suspension of the ligand[4] (0.252 g, 5×10^{-4} mol) in MeOH (20 mL). The reaction mixture was stirred until dissolution was complete. The resulting solution was added dropwise to a methanolic solution of $Mn(OAc)_2 \cdot 2H_2O$ (0.244 g, 10^{-3} mol in 10 mL) and stirred for 24 h. The orange precipitate was suction filtered, washed with MeOH and Et_2O, and dried under vacuum. Yield: 260 mg (65%) of a complex which analyzed well for $Mn_2(L)(OH)(MeOH)_2$. Orange-red crystals of **1** suitable for X-ray diffraction where grown by vapor diffusion of pentane into a THF solution of **1**. IR, EPR, and magnetic measurements were carried out on ground crystals of **1**.

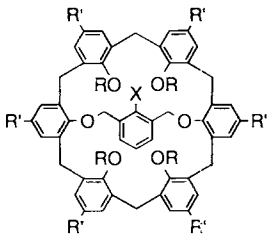
Isolation and X-ray Crystallographic Analysis of a Stable Selenenic Acid**

Toshiyuki Saiki, Kei Goto, and Renji Okazaki*

Selenenic acids (RSeOH) play a central role in the oxidation and reduction processes of organoselenium compounds, for example, in the *syn* elimination of selenoxides, the reduction of seleninic acids, and the oxidation of selenols and diselenides.[1] They are also of great interest from a biological point of view as illustrated by a number of reports that postulate the intermediacy of a selenenic acid in the catalytic cycle of glutathione peroxidase[2] and its synthetic model compounds.[3] However, despite the importance of selenenic acids, much of our knowledge on their chemistry has been derived in quite an indirect and speculative fashion because of their extremely high instability; they are known to undergo a rapid disproportionation to form the corresponding diselenides and seleninic acids. Several areneselenenic acids stabilized by coordination to *ortho*-nitro,[4] -carbonyl,[5] or -amino groups[3c] have been reported to be observable, but only in solution.[6] Even the employment of the 2,4,6-tri-*tert*-butylphenyl group, one of the most effective steric protection groups, cannot prevent the disproportionation of a selenenic acid.[7] Thus, to date, no selenenic acid has been isolated in pure form,[8] and the development of a new methodology to stabilize this important but elusive species has long been awaited.

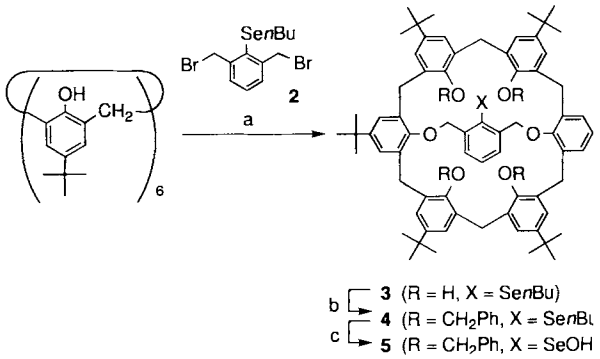
Herein we report the synthesis and structure of the first isolable selenenic acid. In this work we have applied the recently developed 1,4-bridged calix[6]arene **1**[9,10] as a reaction environment; we had previously verified the usefulness of **1** as a stabilizing environment for a reactive species by incorporating a sulfenic acid functionality (X = SOH) into the calixarene **1** as a probe.[9b]



1

The reaction of *p-tert*-butylcalix[6]arene with selenide **2** under basic conditions afforded a bridged calix[6]arene **3** bearing a butylselanyl group on the bridge (Scheme 1). Treatment of **3** with benzyl bromide in the presence of NaH gave the tetrabenzyl ether **4** as the main product. Oxidation of **4** by *m*-chloroperoxybenzoic acid (*m*CPBA) followed by thermolysis in toluene (80 °C, 2 h) afforded the selenenic acid **5**, which was isolated by silica gel chromatography as colorless crystals (74%).

Compound **5** was fully characterized by NMR and IR spectroscopy, as well as FAB mass spectrometry, and elemental analysis. The ^{77}Se NMR spectrum ($CDCl_3$) revealed a signal at $\delta = 1134$ and the ^{1}H NMR spectrum showed the signal of the hydroxyl proton at $\delta = -0.05$ (readily exchangeable with D_2O), suggesting that it is highly shielded by the calix[6]arene macrocycle. The ^{1}H NMR spectrum of **5** is consistent with the *cone* conformation and hardly changes up to 130 °C: it shows essentially the same features as those in the spectrum of the *cone*



Scheme 1. Synthesis of selenenic acid **5**. a) KOH, THF/DMF (80%); b) NaH, $PhCH_2Br$, THF/DMF (59%); c) *m*CPBA, CH_2Cl_2, then toluene, 80 °C, 2 h (74%).

conformer of its bromide analogue (X = Br instead of SeOH).[9d] The OH absorption in the IR spectrum (CH_2Cl_2) was observed at 3523 cm^{-1}, indicating the absence of significant intramolecular hydrogen bonding.

The structure of **5** was established by X-ray crystallographic analysis (Figure 1).[11] This is the first X-ray structure analysis

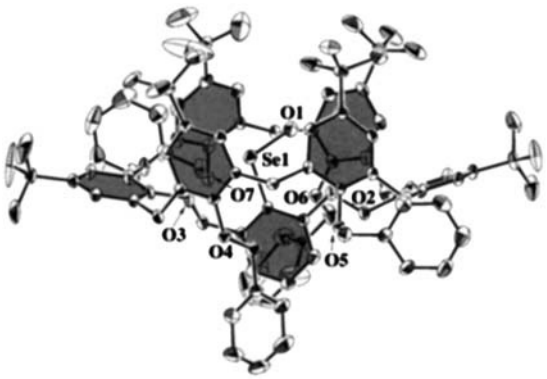


Figure 1. Crystal structure of **5** (ORTEP drawing; thermal ellipsoids at 20% probability level). The aromatic rings of the calix[6]arene macrocycle and that of the bridging unit are shaded.

of a selenenic acid. The SeOH functionality is deeply buried in the cavity of the *p-tert*-butylcalix[6]arene macrocycle with a *cone* conformation; evidently this situation is unfavorable for the intermolecular processes that normally lead to its decomposition. The distance between the selenium atoms on the neighboring molecules is more than 10 Å, indicating that there is no intermolecular interaction between the SeOH functionalities. The Se1–O1 bond length is 1.763(7) Å, which is almost the same as that of the Se–O single bond in benzeneseleninic acid.[12] The distances between O1 and O2–O7 lie between 3.88 and 6.21 Å, and are thus much longer than the average distance of hydrogen-bonded HO···O (2.72 Å),[13] clearly showing the lack of hydrogen bonding between the OH group and the atoms O2–O7 also in the solid state. The Se1–O3 distance is 2.64 Å, which is significantly shorter than the sum of the corresponding van der Waals radii (3.42 Å).[14] The atoms O3, Se1, and O1 adopt a nearly linear arrangement (bond angle 168°). These structural parameters indicate the existence of the nonbonding interaction between the Se1 and O3 atoms of **5** in the solid state.[15]

Selenenic acid **5** is remarkably stable both in the crystalline state and in solution. Even after **5** had been heated at 120 °C for 5 h in $CDCl_2CDCl_2$, no decomposition was observed. Considering that 2,4,6-*tert*-butylbenzeneselenenic acid disproportion-

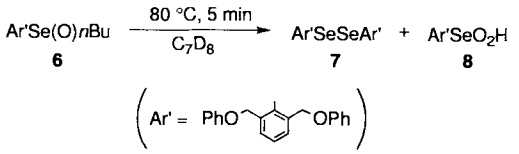
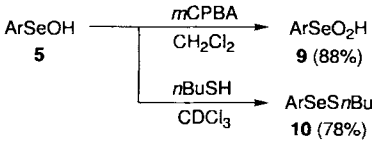
ates completely within 2 h in 4% D_2O/CD_3CN at 25 °C,[7] this stability of **5** is remarkable. In order to clarify its origin, a control experiment was carried out using selenoxide **6**, which does not have the macrocyclic structure (Scheme 2). Upon heating at 80 °C for 5 min in [D_8]toluene, **6** decomposed to afford diselenide **7** and seleninic acid **8**; the intermediary selenenic acid Ar'SeOH was not detected. After separation, **7** and **8** were isolated in 59 and 28% yields, respectively. These results clearly indicate that the high stability of **5** is caused by the steric protection, and not the coordination by the *ortho* substituent.



Scheme 2. Control experiment with the selenoxide **6**.

The reaction of **5** with *m*CPBA (1.2 equiv) or 1-butanethiol (10 equiv) afforded the corresponding seleninic acid **9** (88%) or selanyl sulfide **10** (78%), respectively (Scheme 3), indicating that **5** retains its reactivity as a selenenic acid although it has the unprecedented stability.



Scheme 3. Reactions of selenenic acid **5**.

In summary, an isolable selenenic acid was synthesized for the first time by taking advantage of the bridged calix[6]arene framework, and its structure was determined by X-ray crystallographic analysis. This stable compound should enable us to elucidate the chemistry of selenenic acids directly.

Experimental Section

To a solution of **4** (282 mg, 0.18 mmol) in CH_2Cl_2 (5 mL) was added a solution of *m*CPBA (80%, 47 mg, 0.22 mmol) in CH_2Cl_2 (4 mL) at 0 °C. After the mixture had been stirred at the same temperature for 2 h, it was washed with 5% aqueous $NaHCO_3$ and dried over anhydrous $MgSO_4$. After removal of the solvent, the residue was heated in toluene (9 mL) at 80 °C for 2 h. After removal of the solvent, the residue was separated by chromatography ($SiO_2/CHCl_3$:hexane = 1:1) to give **5** (204 mg, 74%) in the form of colorless crystals. M.p. 168 °C (decomp); ^{1}H NMR (500 MHz, $CDCl_3$): $\delta = -0.05$ (s, 1H; SeOH), 1.04 (s, 36H; *t*Bu), 1.44 (s, 18H; *t*Bu), 3.24 (d, $^2J = 14.3$ Hz, 2H; $ArCH_2Ar$), 3.34 (d, $^2J = 15.3$ Hz, 4H; $ArCH_2Ar$), 4.21 (s, 4H; $ArCH_2OAr$), 4.47 (d, $^2J = 11.9$ Hz, 4H; $PhCH_2O$), 4.500 (d, $^2J = 14.3$ Hz, 2H; $ArCH_2Ar$), 4.501 (d, $^2J = 15.3$ Hz, 4H; $ArCH_2Ar$), 4.58 (d, $^2J = 11.9$ Hz, 4H; $PhCH_2O$), 6.44 (t, $^3J = 7.3$ Hz, 1H), 6.81 (d, $^4J = 2.3$ Hz, 4H), 6.99–7.007 (m, 8H), 7.012 (d, $^3J = 7.3$ Hz, 2H), 7.08–7.11 (m, 8H), 7.13–7.17 (m, 4H), 7.20 (d, $^4J = 2.3$ Hz, 4H), 7.29 (s, 4H); ^{13}C NMR (125 MHz, $CDCl_3$): $\delta = 26.9$ (t), 31.3 (t), 31.5 (q), 31.7 (q), 34.17 (s), 34.19 (s), 72.7 (t), 74.7 (t), 124.2 (d), 124.7 (d), 125.9 (d), 126.0 (d), 127.0 (d), 127.5 (d), 127.9 (d), 128.5 (d), 131.9 (s), 132.1 (s), 133.8 (s), 135.1 (s), 137.7 (s), 137.9 (s), 144.4 (s), 145.6 (s), 152.2 (s), 152.6 (s); ^{77}Se NMR (95 MHz, $CDCl_3$): $\delta = 1134$; IR (CH_2Cl_2): $\tilde{\nu} = 3523$ cm^{-1} (OH); HR-MS (FAB): calcd. for $C_{102}H_{114}O_7{}^{80}Se$ 1530.7730; found: 1530.7737; elemental analysis (%): calcd for $C_{102}H_{114}O_7Se \cdot H_2O$: C 79.09, H 7.55, Se 5.10; found: C 79.31, H 7.53, Se 4.72. The NMR signals were assigned by HH-COSY, CH-COSY, and differential NOE experiments.

[11] Crystal data for **5**: $C_{102}H_{114}O_7Se$, $M_r = 1530.98$, crystal dimensions $0.80 \times 0.30 \times 0.20$ mm, crystal system triclinic, space group $P\bar{1}$, unit cell dimensions $a = 12.949(4)$, $b = 28.743(8)$, $c = 12.230(2)$ Å, $\alpha = 96.90(2)$, $\beta = 101.55(2)$, $\gamma = 78.70(2)°$, $V = 4357(1)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.167$ g cm^{-3}, $2\theta_{max} = 55.2°$. The intensity data were collected at 296 K on a Rigaku AFC5R diffractometer with $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å), the scan mode being ω. Of the 20951 reflections which were collected, 20064 were independent. The linear absorption coefficient μ for $Mo_{K\alpha}$ radiation is 4.9 cm^{-1}. An empirical absorption correction using the program DIFABS [16] was applied that resulted in transmission factors ranging from 0.81 to 1.00. The data were corrected for Lorenz and polarization effects. The structure was solved by heavy-atom Patterson methods (PATTY [17]) and expanded by using Fourier techniques (DIRDIF94 [18]). The non-hydrogen atoms were refined anisotropically. Hydrogen atoms except that of the SeOH group were included but not refined. Full-matrix least-squares refinement based on F weighted with $1/\sigma^2(F_o)$ gave final values $R = 0.063$ and $wR = 0.066$ for 5001 observed reflections [$I > 3.00\sigma(I)$] and 991 variable parameters. Maximum/minimum residual electron density: 0.81/ −0.55 e Å^{-3}. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100401. Anti-Markovnikov Functionalization of Olefins: Rhodium-Catalyzed Oxidative Aminations of Styrenes**

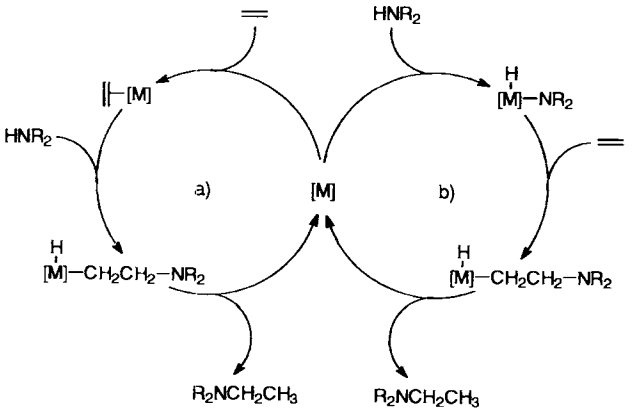
Matthias Beller,* Martin Eichberger, and Harald Trauthwein

Amines and their derivatives are of great importance for organic chemistry as natural products, pharmacological agents, fine chemicals, and dyes. Despite the many uses for amines, the direct addition of ammonia as well as primary and secondary amines to olefins has not been investigated in detail.[1] The advantage of direct aminations of olefins over classical methods[2] is that in principle no coupled products are formed, that is every atom from the starting material is still present in the product molecules (100% atom economy).

Aminations of olefins catalyzed by transition metals can follow two different paths (Scheme 1):[3] a) coordinative binding

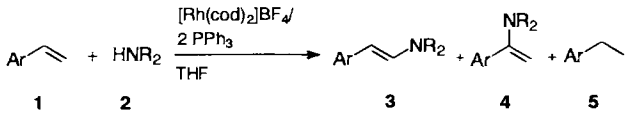


Scheme 1. Transition metal catalyzed amination of olefins as exemplified by ethene. a) The first step is the coordinative binding of the olefin to the metal center. b) The first step is the insertion of a metal complex into the N–H bond.

of an olefin, for example ethene, to the central atom of an electron-poor metal complex activates the olefin for a direct attack of the amine; b) oxidative insertion of an electron-rich metal complex into the N–H bond of an amine leads to the corresponding amidohydrido complex with subsequent insertion of an olefin into the metal–nitrogen bond.

Both paths present several problems, and to date, there is no broadly applicable method for the catalytic amination of olefins. Rhodium-catalyzed aminations of ethene and norbornene are well-known,[4–6] as are palladium-catalyzed intramolecular aminations of amines and amides[7] as well as recently developed hydroaminations in the presence of lanthanoid complexes.[8] The metal complexes previously employed for transition metal catalyzed aminations are not very active, and some of the aminations only progress intramolecularly. In addition the Markovnikov products are always favored when unsymmetrical olefins are used. An exception is the intramolecular oxidative amination of *o*-aminostyrene, in which for reasons of ring strain in the product only attack at a terminal position is possible.[9]

Here we report on a catalytic system which for the first time enables regioselective intermolecular oxidative anti-Markovnikov aminations of different olefins with secondary amines. Because of the significance of the pharmacologically important structural unit $ArylCH_2CH_2NR_2$[10] we examined the reaction of styrene with amines. During the course of a catalyst screening we discovered that rhodium complexes with the general formula $[RhL_4]X$ (L = olefin, phosphane, $X = BF_4^-$) surprisingly catalyze the selective formation of the enamines **3**, that is of the anti-Markovnikov products (Scheme 2)!



Scheme 2. Rhodium-catalyzed regioselective oxidative amination of styrenes. Ar = aryl; R = alkyl, aryl; cod = (*Z*,*Z*)-1,5-cyclooctadiene.

Formally this is an oxidation of the olefin, similar to the Wacker process.[11] Hydrolysis of the enamines leads to phenylacetaldehydes that are regioisomeric to the products of a Wacker oxidation. The reaction conditions were optimized for the model reaction between styrene and piperidine. In the presence of 2.5 mol% $[Rh(cod)_2]BF_4$ and two equivalents of triphenylphosphane in THF, the desired product *N*-styrylpiperidine **3** (Ar = Ph, R_2 = pentane-1,5-diyl) is obtained after 20 h in 55% yield. According to the ^1H NMR spectrum the *E* isomer is formed exclusively ($^3J = 14$ Hz). Hydrogenation of styrene leads to ethylbenzene **5** as a further main product. The other possible amination product, the Markovnikov regioisomer **4**, was not detected. Brunet et al. obtained the Markovnikov product of oxidative amination as main product besides the product of the hydroamination reaction when styrene and aniline were converted in the presence of $[\{RhCl(PEt_3)_2\}_2]$/lithium anilide.[12]

The reaction of piperidine with styrene is catalyzed not only by $[Rh(cod)_2]BF_4$, but also by the corresponding norbornadiene (nbd) complex $[Rh(nbd)_2]BF_4$. More strongly coordinating anions such as halide ions suppress enamine formation. Likewise no reaction takes place when $[\{RhCl(cod)\}_2]$/2 PPh_3 is used as a catalyst. The addition of phosphane to the cationic olefin–rhodium complex is essential, as only traces of the product are obtained without PPh_3. The optimal phosphane–rhodium ratio is 2:1. Besides triphenylphosphane, electron-rich, sterically less demanding phosphanes such as tri-*n*-butylphosphane or tri-*p*-tolylphosphane are highly suitable catalyst ligands. On the other hand, chelating phosphorus and amine ligands completely inhibit the reaction. The choice of solvent is also crucial to the productivity of the catalytic system. The best results are obtained in THF. As expected, the use of polar and coordinating solvents such as dimethyl sulfoxide or dimethylacetamide significantly reduces the activity.

To examine the range of applications for this method, different amines and olefins were transformed under optimized conditions. Table 1 shows that a series of secondary amines can be used for oxidative aminations. The highest reactivity is displayed by cyclic and acyclic aliphatic amines, but *N*-methylani-

line, whose nucleophilicity is strongly reduced because of the phenyl ring, can also be made to react.

Surprisingly, electronically different substituents at the aryl ring can significantly influence the efficiency of the reaction (Table 2). Thus a methyl group clearly increases the yield,

Table 2. Variation of olefins in the reaction with piperidine [a].

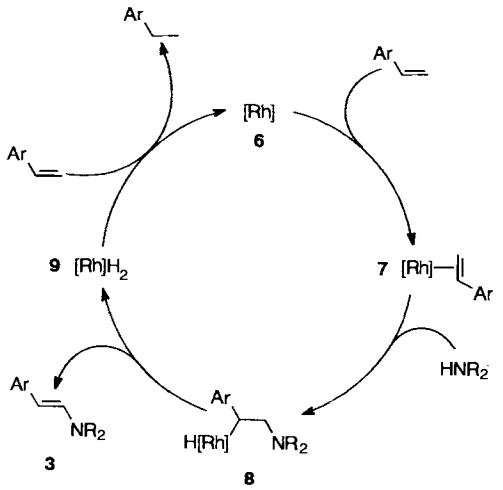
4-trifluoromethylstyrene	14	6	14
acrylamide	18	- [d]	-

[a] Ratio of styrene:amine 4:1, 2.5 mol% $[Rh(cod)_2]BF_4$/2 PPh_3 relative to amine, 20 h reflux in THF. [b] The yield was determined by gas chromatography by percentage area. [c] The yield was determined by gas chromatography using an internal standard. The values in parentheses correspond to yields of isolated product. [d] The yield of the hydrogenated product could not be determined by gas chromatographic methods as the retention time coincides with that of acrylamide.

whereas a methoxy group in the 4-position decreases it. A further methoxy group in 3-position only has a negligible influence on the yield. Distinctly lower yields of enamine are obtained with electron-poor styrenes. Therefore electronic reasons also seem to be responsible for the low reactivity of 4-vinylbiphenyl.

Preliminary experiments aimed at broadening the spectrum of suitable olefins showed that functionalized olefins also undergo the reaction. For example, acrylamide, which without catalyst selectively reacts in a Michael reaction resulting in the hydroamination product, can be transformed into the enamine in 18% yield; however, the hydroamination product is also detected. In principle, further functionalized aliphatic olefins should be convertible into enamines.

The oxidative amination and the simultaneous hydrogenation of a further olefin molecule make a mechanism similar to that of the oxidative silylation seem plausible (Scheme 3).[13] We postulate that the catalytically active species **6** reacts with the olefin, leading to the formation of the η^2 complex **7**. Nucleophilic attack of the amine on the thus activated olefin affords the Rh–alkylamine compound **8**; β-H elimination then leads to the Rh–H species **9** and the enamine **3**. The active species **6** is then reformed from **9** and a further olefin molecule. Interestingly, only the styrene is hydrogenated, which can be explained by its easy hydrogenability.[14] Unlike in the palladium-catalyzed oxidative amination with benzoquinone as an oxidant, the



Scheme 3. Postulated mechanism of the oxidative amination. Ar = aryl; R = alkyl, aryl.

olefin added in excess serves as an oxidizing agent. The yield of enamine falls with decreasing styrene–amine ratio.

We have thus developed a method that for the first time allows oxidative aminations of simple olefins. The resulting enamines are reactive intermediates that can be further transformed;[15] thus, in future new cascade processes should become possible. The excellent regioselectivity of the reaction is of particular importance, as it provides evidence that transition metal catalyzed reactions of simple olefins with nucleophiles in the anti-Markovnikov sense are possible.

Experimental Section

All experiments were carried out under exclusion of air and moisture. The chemicals were dried according to standard procedures and stored under N_2 or argon. $[Rh(cod)_2]BF_4$ was prepared according to reference[16].

Procedure for the catalysis experiments: $[Rh(cod)_2]BF_4$ (45.0 mg, 0.11 mmol) and PPh_3 (58.0 mg, 0.22 mmol) were suspended in THF (10.0 mL) under argon. Addition of the amine (4.40 mmol) afforded a yellow solution to which the olefin was added. Subsequently the mixture was heated to reflux for 20 h. The reaction mixtures were then either distilled or hydrogenated to the corresponding alkylamines (48 h, 1 bar H_2, 0.5 g 5% Pd/C). After the hydrogenation catalyst had been removed by filtration, the solvent was removed in vacuo and the residue was taken up in dichloromethane (20.0 mL). After extraction with 5% HCl (3 × 20.0 mL) the combined aqueous phases were carefully brought to pH 9 by using NaOH pellets and then extracted with dichloromethane (3 × 20.0 mL). The combined organic phases were dried over magnesium sulfate. After the solvent had been removed in vacuo, the product was purified by column chromatography and dried in high vacuum. The products were characterized by ^1H NMR and (DEPT)^{13}C NMR spectroscopy as well as by GC-MS. The yields with respect to the amine were determined after gas chromatography with hexadecane as internal standard.

$[Ru_{20}H_4Cu_6Cl_2(CO)_{48}]^{4-}$: A New High Nuclearity Copper–Ruthenium Cluster**

Michael A. Beswick, Jack Lewis, Paul R. Raithby,* and M. Carmen Ramirez de Arellano

Mixed-copper alloys are of interest as catalysts, particularly in the selective reforming of petroleum naptha fractions to aromatic hydrocarbons.[1] We have recently embarked on the study of high nuclearity mixed-metal ruthenium–copper carbonyl clusters, and the three cluster anions characterized so far, $[Ru_8H_2Cu_7Cl_3(CO)_{24}]^{2-}$, $[Ru_{12}H_2Cu_6Cl_2(CO)_{34}]^{2-}$, and $[Ru_{12}Cu_4Cl_2C_2(CO)_{32}]^{2-}$ all have different Ru:Cu ratios, 8:7, 2:1, and 3:1, respectively.[2] These mixed-metal clusters illustrate the use of copper cations as linking agents in the formation of high nuclearity mixed-metal clusters. We now report the synthesis and structure of the highest nuclearity ruthenium–copper carbonyl hydrido cluster $[Ru_{20}H_4Cu_6Cl_2(CO)_{48}]^{4-}$, so far characterized crystallographically.

The reaction of the dianion $[Ru_{10}H_2(CO)_{25}]^{2-}$ with excess $[Cu(MeCN)_4]^+$ in CH_2Cl_2 in the presence of $[Bu_4N]OH/H_2O$ and $[(Ph_3P)_2N]Cl$, with stirring at room temperature, leads after purification by thin-layer chromatography to the isolation of **1** in 60–70% yield. Complex **1** was initially

$[Bu_4N]_4[Ru_{20}H_4Cu_6Cl_2(CO)_{48}]$ **1**

characterized by spectroscopy,[3] but in order to establish the structure of the complex a crystal structure analysis was undertaken. Crystals suitable for X-ray analysis were grown from the layered diffusion of ethanol into a solution of **1** in CH_2Cl_2.[4]

The structure of the tetraanion of **1** (Figure 1) may be viewed as two decaruthenium clusters sandwiching the hexacopper cluster metal core. The geometry of the decaruthenium units in cluster **1** is different from that observed in the precursor dianion $[Ru_{10}H_2(CO)_{25}]^{2-}$.[5, 6] This geometry can be viewed as the condensation of two octahedra through the triangular face Ru2-Ru3-Ru4, generating three butterflies, one of which is capped. This is very similar to the metal core geometry found in $[Ru_{11}H(CO)_{27}]^{3-}$[6, 7] but in this case two of the butterflies are capped. In the cluster precursor $[Ru_{10}H_2(CO)_{25}]^{2-}$ the geometry is that of two trigonal bipyramids fused to an octahedron. The ruthenium metal core arrangement in the anion of **1** has not been observed previously for decanuclear clusters, although the use of Group 11 metals has been shown to introduce a polarity into ruthenium metal frameworks, generating metal geometries not observed in homometal clusters.[8] The Cu_6 metal core may be described as two tetrahedra fused through a common edge (Cu(1)–Cu(1a)) the center of which is the crystallographic center of symmetry.

The central section of the metal core is reminiscent of that in $[Ru_{12}H_2Cu_6Cl_2(CO)_{34}]^{2-}$, which consists of four fused octahredra; in the case of **1** a further four Ru atoms have condensed on each end. Two chloride ligands each symmetrically bridge two of the copper atoms in the Cu_6 core. The distance between the Cu centers bridged by the two chloride ligands is 2.840(5) Å, and the shortest Cu–Cu distance is between the two central copper atoms Cu(1) and Cu(1a) (2.440(6) Å). The structure of the tetraanion of **1** has 12 asymmetrically bridging carbonyl ligands, each Ru_{10} unit containing six.

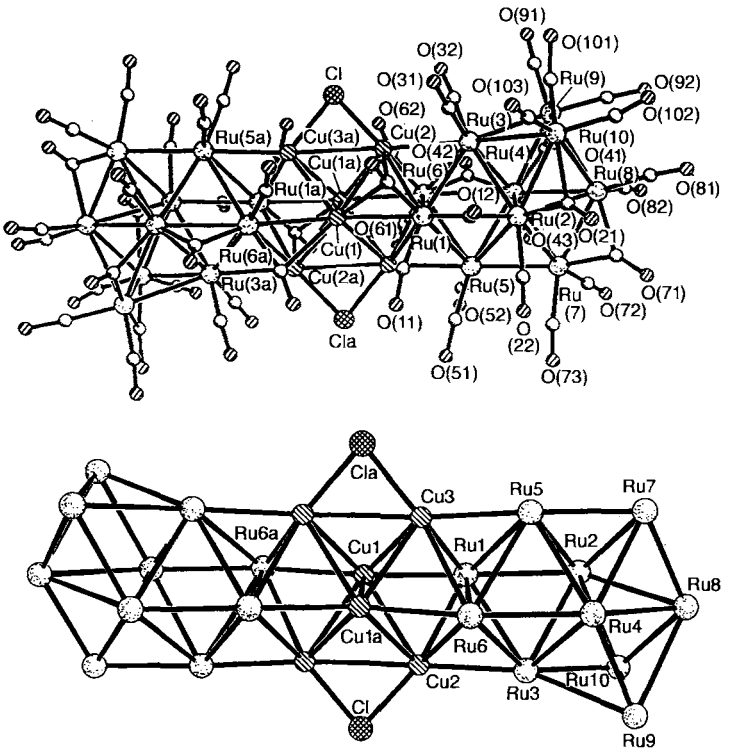

Figure 1. Top: Structure of the anion of **1** showing the atom numbering scheme. Selected bond lengths [Å] and angles [°]: Ru(1)–Cu(1) 2.595(4), Ru(1)–Cu(2) 2.667(5), Ru(1)–Cu(3) 2.720(4), Ru(1)–Ru(2) 2.835(3), Ru(1)–Ru(3) 2.882(3), Ru(1)–Ru(5) 2.994(3), Ru(1)–Ru(6) 3.073(3), Ru(2)–Ru(3) 2.852(4), Ru(2)–Ru(4) 2.855(3), Ru(2)–Ru(5) 2.806(3), Ru(2)–Ru(7) 2.836(4), Ru(2)–Ru(8) 2.837, Ru(2)–Ru(10) 2.807(4), Ru(3)–Cu(2) 2.657(4), Ru(3)–Ru(4) 2.851(3), Ru(3)–Ru(6) 2.924(3), Ru(3)–Ru(9) 2.916(3), Ru(3)–Ru(10) 2.960(3), Ru(4)–Ru(5) 2.842(4), Ru(4)–Ru(6) 2.860(3), Ru(4)–Ru(7) 2.823(4), Ru(4)–Ru(8) 2.885(3), Ru(5)–Cu(3) 2.608(4), Ru(5)–Ru(6) 2.937(4), Ru(5)–Ru(7) 2.697(4), Ru(6)–Cu(2) 2.678(4), Ru(6)–Cu(3) 2.715(4), Ru(6)–Cu(1a) 2.615(4), Ru(7)–Ru(8) 2.685(4), Ru(8)–Ru(9) 2.925(4), Ru(8)–Ru(10) 2.924(4), Ru(9)–Ru(10) 2.798(4), Cu(1)–Cu(2) 2.668(5), Cu(1)–Cu(3) 2.674(5), Cu(1)–Cu(1a) 2.440(6), Cu(1)–Cu(2a) 2.647(5), Cu(1)–Cu(3a) 2.631(5), Cu(2)–Cu(3a) 2.840(5). Cu(2)–Cl 2.229(7), Cu(3)–Cl 2.244(7); Cu(3)-Cl(a)-Cu(2a) 78.8(2). The atoms denoted "a" are related to the atoms with the same number through the center of symmetry. Bottom: The metal core geometry of **1** showing the position of the chlorine ligands.

If the decaruthenium units are each considered to have a formal 4 − charge, that is $[Ru_{10}H_2(CO)_{24}]^{4-}$, the two chloride ions contribute a 2 − charge, and each of the six copper atoms is in a formal +I oxidation state, then the overall charge on the cluster is 4 − , consistent with the presence of the four $[Bu_4N]^+$ ions. As in the precursor $[Ru_{10}H_2(CO)_{25}]^{2-}$ and the related anion $[Ru_{11}H(CO)_{27}]^{3-}$ the four hydrides in the anion of **1** could not be located from the structural analyses[6] or from potential energy calculations.[9] However, the presence of a strong, but broad, ^{1}H NMR signal at $\delta = -5.00$, in a similar position to that observed in the anion $[Ru_{11}H(CO)_{27}]^{3-}$,[7] is consistent with the presence of hydrides that are undergoing a dynamic process. Attempts to carry out low-temperature NMR studies were unsuccessful because of the poor solubility of **1** at lower temperatures. The assignment of four hydrides to the anion of **1** is consistent with the ^{1}H NMR data, the charge assignment to the cluster and the precursor complexes, and follows the trends observed in the synthesis of other high nuclearity, mixed-metal clusters in this series.[2]

Experimental Section

1: $[(Ph_3P)_2N]_2[Ru_{10}H_2(CO)_{25}]$ (100 mg) in CH_2Cl_2 (50 mL) with $[Et_4N][OH]/H_2O$ (100 mg), excess $[Cu(MeCN)_4][BF_4]$ (250 mg), and $[(Ph_3P)_2N]_2Cl$ (100 mg) was stirred for 10 min. The mixture was filtered hot and the volume reduced to 10 mL under vacuum. The mixture was separated by thin-layer chromatography with CH_2Cl_2 as eluent.

Cationic Metallatricarbadecaboranyl Analogues of Metallocene Antitumor Agents: Synthesis, Structure, and Antineoplastic Activity of $[1\text{-}(\eta^5\text{-}C_5H_5)Fe\text{-}2\text{-}Me\text{-}2,3,4\text{-}C_3B_7H_9]^+[X]^-$ Salts ($X^- = AsF_6^-$, SbF_6^-)**

Michael D. Wasczcak, Christian C. Lee, Iris H. Hall,* Patrick J. Carroll, and Larry G. Sneddon*

The success of the antitumor reagent cisplatin[1] has stimulated the search for new metal complexes having cytotoxic properties. Studies of metallocenes of the general formulae $[(\eta^5\text{-}C_5H_5)_2MX_2]$ and $[(\eta^5\text{-}C_5H_5)_2M]^+[X]^-$[2] continue to show promise. We report here the synthesis, structure, and bioactivity of new types of hybrid cationic ferratricarbadecaboranyl analogues of ferrocenium complexes that demonstrated significant cytotoxicity and inhibition of topoisomerase II activity.

The synthesis[3] of the ferrocene analogue **1** [Eq. (a)] illustrates that the *nido*-[6-Me-5,6,9-$C_3B_7H_9$] tricarbadecaboranyl

$$[(\eta^5\text{-}C_5H_5)Fe(CO)_2I] + Na[6\text{-}Me\text{-}5,6,9\text{-}C_3B_7H_9] \xrightarrow{-2CO,\ -NaI} closo\text{-}[(\eta^5\text{-}C_5H_5)Fe\text{-}2\text{-}Me\text{-}2,3,4\text{-}C_3B_7H_9] \quad \mathbf{1} \qquad (a)$$

cage can, like the cyclopentadienyl ligand, coordinate to transition metals as a monoanionic six-electron donor. However, tricarbadecaboranyl complexes have higher chemical, oxidative, and thermal stabilities than their cyclopentadienyl analogues.[3] They are also less prone to hydrolytic metal–ligand cleavage, which can deactivate metallocenes under biological conditions. These observations suggested that cationic ferratricarbadecaboranyl complexes might, like the ferrocenium cation,[4, 5] exhibit significant bioactivity.

Oxidation of **1** with silver ion gave quantitative formation of the paramagnetic ferratricarbadecaboranyl cation [Eq. (b)].

$$\mathbf{1} + AgX \longrightarrow [1\text{-}(\eta^5\text{-}C_5H_5)Fe\text{-}2\text{-}Me\text{-}2,3,4\text{-}C_3B_7H_9][X] + Ag^0 \qquad (b)$$

$$X = AsF_6^- \ (\mathbf{1}^+\cdot AsF_6^-)$$
$$X = SbF_6^- \ (\mathbf{1}^+\cdot SbF_6^-)$$

As shown in Figure 1 for $\mathbf{1}^+\cdot AsF_6^-$,[6] crystallographic determination of both salts established that the complexes are hybrid ferratricarbadecaboranyl analogues of the ferrocenium cation, in which the iron atom is sandwiched between the planar cyclopentadienyl ring and the puckered six-membered face of the tricarbadecaboranyl ligand. The cage structure of $\mathbf{1}^+$ is remarkably similar to that of **1**,[3] with only a shortening of the Fe–C3 (by 0.02 Å), Fe–C4 (by 0.04 Å), and Fe–B7 bond lengths (by 0.05 Å). The lengthening of Fe–C_5H_5(centroid) from 1.69 Å in **1** to 1.75 Å in $\mathbf{1}^+$ suggests removal of an electron from an Fe–C_5H_5 bonding molecular orbital.[7]

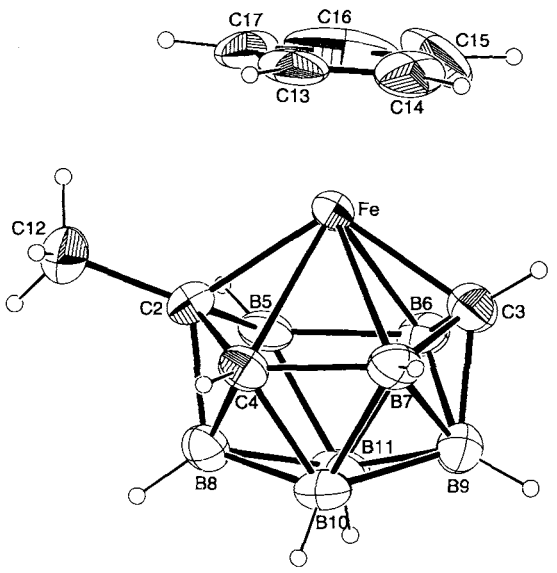

Figure 1. ORTEP view of the crystal structure of the cation in $1^+ \cdot AsF_6^-$.

Both $1^+ \cdot AsF_6^-$ and $1^+ \cdot SbF_6^-$ demonstrated selective cytotoxicity in certain cultured tumor cell lines, and produced more effective ED_{50} values than 5-fluorouracil (5-FU), 6-mercaptopurine (6-MP), β-cytosine arabinoside (Ara-C), etoposide (VP-16), and hydroxyurea standards.[8] The best ED_{50} values for $1^+ \cdot AsF_6^-$ were obtained for human HeLa uterine carcinoma (0.90 $\mu g mL^{-1}$), human lung bronchogenic MB-9812 (1.83 $\mu g mL^{-1}$), and A431 skin cells (1.32 $\mu g mL^{-1}$), while $1^+ \cdot SbF_6^-$ gave best activities for murine L-1210 leukemia (0.75 mg mL^{-1}) and P388 lymphocytic leukemia cells (1.49 $\mu g mL^{-1}$). The two salts also demonstrated excellent activity in the $Tmolt_3$ leukemia cell line, (2.39 and 2.59 $\mu g mL^{-1}$, respectively). The neutral compound **1** also showed significant activity for P388 (1.80 $\mu g mL^{-1}$), HL-60 lymphoma (2.41 $\mu g mL^{-1}$), $Tmolt_3$ (2.41 $\mu g mL^{-1}$), HeLaS^3 (1.50 $\mu g mL^{-1}$), and A431 skin cells (2.73 $\mu g mL^{-1}$). It is significant that the complexes had different activity than the corresponding $[(\eta^5\text{-}C_5H_5)_2Fe]^+[X]^-$ ($X^- = AsF_6^-$ or SbF_6^-) salts or ferrocene.[9]

Complexes $1^+ \cdot SbF_6^-$ and $1^+ \cdot AsF_6^-$ were examined for their effects on DNA, RNA, and protein synthesis in L-1210 cells. Use of $1^+ \cdot SbF_6^-$ (100 μM, 1 h) resulted in reductions of 92% for ^{3}H-thymidine incorporation into DNA, 59% for ^{3}H-uridine incorporation into RNA, and 32% for ^{3}H-leucine incorporation into the protein. Use of $1^+ \cdot AsF_6^-$ (100 μM, 1 h) caused 22% reduction in RNA synthesis, but no reduction in DNA and protein synthesis.[9]

Most significantly, the complexes inhibited L-1210 DNA topoisomerase activity. Salt $1^+ \cdot SbF_6^-$ afforded an IC_{50} value of 68.7 μM, and $1^+ \cdot AsF_6^-$ a value of 78.17 μM with inhibition of DNA synthesis. These values are in the range provided by the standard VP-16 (22.5 μM), but the complexes exhibited a different mode of action, since L-1210 DNA protein linked breaks were not produced by the metal compounds themselves at 100 μM. Yet, when incubated with VP-16 at 40 μM there was a 25% increase in breaks over those observed for VP-16 alone. The metal complexes inhibited topoisomerase II phosphorylation by protein kinase C from 59 to 64% at 30 min. The suppression of topoisomerase II phosphorylation is positively linked with increased DNA fragmentation and apoptosis. These metal salts thus offer a different mode of action for regulating topoisomerase II activity.

The initial bioactivity results strongly suggest that the tricarbadecaboranyl analogues of other more potent metallocene antitumor agents, such as the early transition metal compounds $[(\eta^5\text{-}C_5H_5)_2MX_2]$,[2] *should exhibit significant and selective anticancer activities. The syntheses and bioactivities of corresponding metallatricarbaboranes, including* $[(RC_3B_7H_9)_2MX_2]$ *and* $[(\eta^5\text{-}C_5H_5)(RC_3B_7H_9)MX_2]$ *are currently being investigated.*

Experimental Section

$1^+ \cdot AsF_6^-$ and $1^+ \cdot SbF_6^-$: Under a nitrogen atmosphere, of $AgAsF_6$ (0.122 g, 0.41 mmol) or $AgSbF_6$ (0.221 g, 0.61 mmol) suspended in dry Et_2O (10 mL) was added dropwise to solutions of **1** (0.016 g, 0.06 mmol and 0.024 g, 0.09 mmol, respectively) in Et_2O (10 mL). The precipitates were isolated by filtration, and washed with Et_2O and CH_2Cl_2. Recrystallization from CH_2Cl_2 gave air-stable, purple-pink crystals of $1^+ \cdot AsF_6^-$ (0.026 g, 0.06 mmol) and $1^+ \cdot SbF_6^-$ (0.043 g, 0.09 mmol) in quantitative yields. $1^+ \cdot AsF_6^-$: elemental analysis: calcd: C 24.26, H 3.84; found: C 23.98, H 3.50; IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3122s, 2579s, 2554s, 1450m, 1428s, 1391m, 1273m, 1196w, 1164w, 1122m, 1105m, 1096m, 1061w, 1015w, 967m, 954w, 932w, 904w, 875m, 860m, 830m, 706vs; UV/Vis (CH_2Cl_2): λ_{max} [nm] (ε [$M^{-1}cm^{-1}$]) = 538 (1060), 360 (2894), 242 (25265). $1^+ \cdot SbF_6^-$: elemental analysis: calcd: C 21.95, H 3.48; found: C 21.89, H 3.35; IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3120s, 3036m, 2579vs, 1452m, 1429s, 1390m, 1272m, 1164w, 1123m, 1094m, 1059m, 1021m, 952m, 874s, 860m, 827m, 789w, 752w, 723m, 677s, 650vs, 521w; UV/Vis (CH_2Cl_2): λ_{max} [nm] (ε [$M^{-1}cm^{-1}$]) = 538 (356), 358 (1450), 244 (11535).

Cytotoxicity assay: The four salts ($1^+ \cdot AsF_6^-$, $1^+ \cdot SbF_6^-$, $[Cp_2Fe]^+AsF_6^-$, $[Cp_2Fe]^+Sb_6^-$), controls, standards, and **1** were tested for cytotoxic activity by homogenizing the drugs (1 mM) in 0.05% Tween 80/H_2O. Solutions were sterilized through an acrodisc filter (0.45 μM). The cell lines were maintained by standard techniques. The National Cancer Institute (NCI) protocol was used to assess the cytotoxicity [10]. Values for cytotoxicity are expressed as ED_{50} in $\mu g mL^{-1}$, that is, the concentration of the compound inhibiting 50% of the cell growth after 3 d. Growth of solid tumor cell lines was determined with crystal violet/methanol and assessed at 580 nm in a plate reader [11].

Incorporation studies: ^{3}H-labeled precursors (2 μCi) were incorporated into 10^6 L-1210 lymphoid leukemia cells over 60 min. The reaction was stopped with cold acids and filtered [12]. Incorporation into DNA, RNA, or protein was expressed in dpm per 10^6 cells. Drugs were incubated at concentrations of 25, 50 and 100 μM.

Topoisomerase inhibition studies: P4 phage knotted DNA was isolated by the method of Liu et al [13]. L-1210 topoisomerase II was isolated and the enzyme activity determined according to Miller et al. [14]. The drugs were measured at concentrations of 0–100 μM over 1 h with VP-16 as a standard. IC_{50} values (50% inhibition of protein content) were determined by densitometry.

Enhanced α-CH Acidity and Reactivity of Lewis Acid–Base Complexes in the Gas Phase**

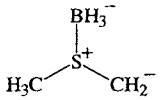
Jianhua Ren, Derek B. Workman, and Robert R. Squires*

Lewis acid catalysis provides a powerful means for accelerating many different types organic and organometallic reactions, and recent work with chiral Lewis acids has demonstrated the tremendous potential of this approach for catalytic asymmetric induction.[1] A key component of the general mechanism for Lewis acid catalysis is the coordination of the substrate and the resulting activation of its reactive site(s).[2] This activation may take the form of, inter alia, enhanced electrophilicity of a carbonyl group, increased Brønsted acidity of α-C–H bonds or amplified dienophilicity of an alkenyl moiety in the substrate. We are interested in developing quantitative models for the activation of Lewis acids, and in the use of gas-phase ion chemistry techniques for determining the changes in fundamental physical properties such as acidity, basicity, and bond energy that accompany coordination of a molecule by a Lewis acid. Herein we examine the gas-phase negative-ion chemistry of a series of prototype Lewis acid–base complexes: Me_2SBH_3, Me_3NBH_3, Me_3PBH_3 and Et_3NBH_3. We show that the α-CH acidities in the complexes are up to 20 kcal mol^{-1} higher than in the uncomplexed molecules, and that deprotonation of such α-CH groups produces stable, dipole-stabilized carbanions.[3] Coordination by BH_3 is also shown to switch-on substitution and elimination reactions involving the alkyl groups of the Lewis bases that are either kinetically or thermodynamically inaccessible to the uncomplexed molecules.

The experiments were carried out at room temperature in a flowing afterglow-triple quadrupole apparatus.[4] The gas-phase reaction between OH^- and the head vapors sampled from a 10 M solution of Me_2SBH_3 in Me_2S produces an ion with the formula $C_2H_8BS^-$ [Eq. (1)], in addition to a series of $B_nH_m^-$

$$Me_2SBH_3 + OH^- \rightarrow C_2H_8BS^- + H_2O \quad (1)$$

($n = 1-3$; $m = 4-10$) ions derived from the diborane present in the sample mixture. Likely structures for this ion are either the carbanion **1**, formed by simple deprotonation of Me_2SBH_3, or the alkylborate ion **2**, which could result from rearrangement.



1

2

Ab initio calculations carried out at the G2(MP2) level of theory[5] predict that **2** is lower in energy than **1** by 28 kcal mol^{-1}, but unimolecular rearrangement of **1** to **2** by a 1,2-borane shift has an energy barrier of 30 kcal mol^{-1}.

We have carried out collision-induced dissociation (CID) and ion–molecule reaction experiments with the product of reaction (1) in order to identify its structure. Authentic isomer **2** was synthesized independently from the reaction between B_2H_6 and $CH_3SCH_2^-$ (formed by deprotonating Me_2S with NH_2^-). Low-energy CID of both $C_2H_8BS^-$ and the authentic $MeSCH_2BH_3^-$ ion under identical conditions in the triple quadrupole analyzer yields two different fragment ion spectra (Figure 1). Three product ions are common to both spectra, but the relative intensities are quite different. For example, loss of methyl radical is the dominant fragmentation for $C_2H_8BS^-$ (Figure 1a), while it

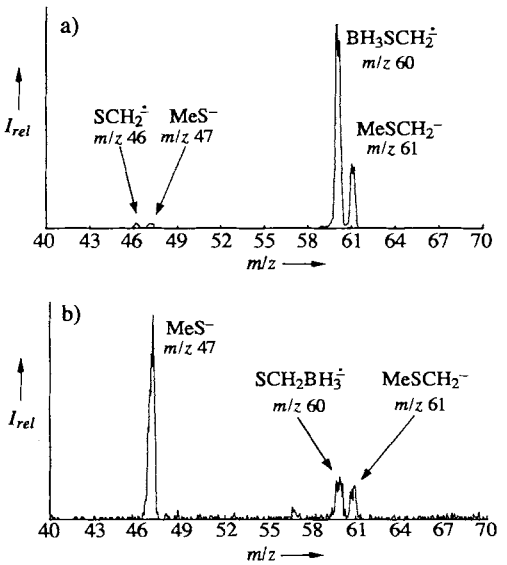


Figure 1. CID spectra of a) $MeS(BH_3)CH_2^-$, the product of reaction (1), and b) $MeSCH_2BH_3^-$, which is produced by reaction of $MeSCH_2^-$ with B_2H_6. The argon target pressure was 7×10^{-5} Torr and the center-of-mass collision energy was 3.5 eV.

is only a minor channel for ion **2**, which fragments mainly by heterolytic cleavage to give MeS^- (Figure 1b). The qualitative differences between these two CID spectra clearly indicate that the $C_2H_8BS^-$ ion formed in reaction (1) is not the alkylborate isomer **2**.

The most compelling evidence in support of structure **1** comes from the results of H/D exchange experiments.[6] Reaction of $C_2H_8BS^-$ with either D_2O or CH_3OD in the flow tube results in a maximum of five sequential H/D exchanges (Figure 2). This is clearly indicative of the structure **1**, which has five exchangeable hydrogen atoms. In contrast, the authentic $MeSCH_2BH_3^-$ ion does not undergo any H/D exchange because it has no hydrogen-bearing carbanionic sites.

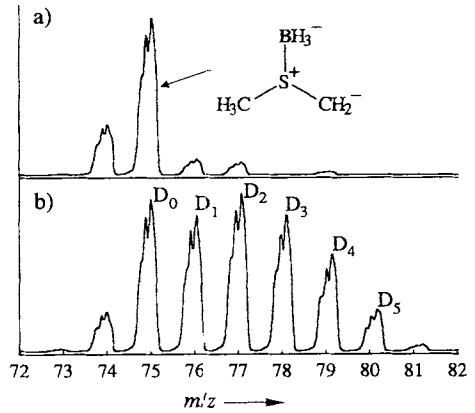

Figure 2. Mass spectra that illustrate the H/D exchange reaction between $MeS(BH_3)CH_2^-$ and D_2O. a) Spectrum without D_2O, b) spectrum after addition of D_2O; D_0, D_1 etc. denote how many H atoms were replaced by D atoms.

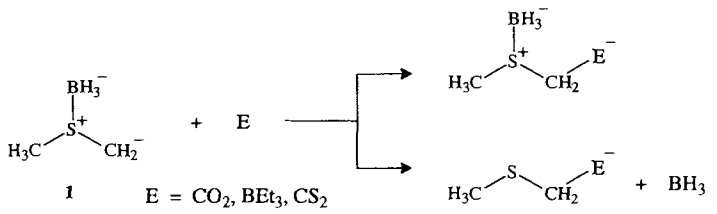
Structure **1** is further confirmed by the occurrence of "electrophile switching" reactions of $MeS(BH_3)CH_2^-$ with other Lewis acids such as CO_2, BEt_3, and CS_2 (Scheme 1). For instance, the $MeS(BH_3)CH_2^-$ ion reacts with CO_2 and BEt_3 to



Scheme 1. Reactivity of the product of reaction (1) with electrophiles.

produce adducts and electrophilic substitution products, whereas only substitution occurs with the stronger Lewis acid CS_2. In contrast, isomer **2** is completely unreactive with these reagents. Thus, the CID results and the observed reactivity indicate that deprotonation of Me_2SBH_3 in the gas phase produces a stable carbanion, $MeS(BH_3)CH_2^-$.

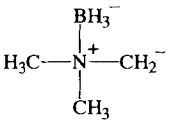
The original motivation for this study derives, in part, from our earlier observation[7] that Me_2SBH_3 was readily deprotonated by anionic bases that are too weak to deprotonate uncomplexed Me_2S (ΔH_{acid} = 393.2 kcal mol^{-1}).[8] This means that the α-CH acidity of Me_2S increases upon borane coordination at the sulfur atom. To quantify the extent of the acidity enhancement, we determined the gas-phase acidity of Me_2SBH_3 by the bracketing method.[9] Reactions of Me_2SBH_3 with a series of anionic bases having known basicities,[8] and reactions of $MeS(BH_3)CH_2^-$ with a series of acids having known gas-phase acidities gave consistent behavior with respect to the preferred direction for proton transfer [Eq. (2)].

$$Me_2SBH_3 + A^- \rightleftharpoons MeS(BH_3)CH_2^- + HA \quad (2)$$

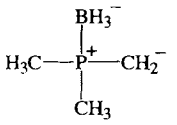
The bracketing results indicate $\Delta G_{acid} = 364.3 \pm 2.0$ kcal mol^{-1} for the gas-phase acidity of Me_2SBH_3, which corresponds to $\Delta H_{acid} = 372.5 \pm 2.0$ kcal mol^{-1} at 298 K.[10] The predicted acidity obtained from G2(MP2) calculations, ΔH_{acid} = 373.4 kcal mol^{-1}, is in good agreement with the experimental results.

Thus, Me_2SBH_3 is a stronger acid than uncomplexed Me_2S by 20 kcal mol^{-1}, which corresponds to a difference in acid dissociation equilibrium constants of about 10^{15}. The gas-phase acidity of Me_2SBH_3 is virtually identical to that of the isoelectronic molecule dimethyl sulfoxide (DMSO, ΔH_{acid} = 373.5 kcal mol^{-1}),[8] and the enhancement relative to Me_2S probably originates from the same dipolar effects as with DMSO.[11] G2(MP2) calculations give C–H bond energies for Me_2S and Me_2SBH_3 of 94.5 and 98.7 kcal mol^{-1}, respectively, whereas the electron affinities for the radicals $MeSCH_2^{\bullet}$ and $MeS(BH_3)CH_2^{\bullet}$ are computed to be 13.8 and 38.6 kcal mol^{-1}, respectively. Therefore, most of the acidity enhancement is due to the increase in electron affinity of $MeSCH_2$ that accompanies complexation by BH_3.

Analogous results are obtained for the volatile amine and phosphane complexes, Me_3NBH_3 and Me_3PBH_3, respectively. Both species can be deprotonated by anionic bases to yield product ions that display reactivity consistent with the dipole-stabilized carbanions **3** and **4**, respectively. For example, car-



3



4

banions **3** and **4** both undergo up to eight H/D exchanges upon reaction with added D_2O, and both ions undergo electrophilic addition and/or switching reactions like those shown in Scheme 1. The observation of carbanion **3** is significant since the uncomplexed α-aminocarbanion $Me_2NCH_2^-$ is unknown, and is believed to be thermodynamically unstable with respect to electron detachment.[12] Organolithium reagents analogous to the ion **4** have found use as organic synthons for the asymmetric synthesis of C_2-symmetric *P*-chiral diphosphanes.[13]

Acid–base bracketing measurements give gas-phase acidities (ΔH_{acid}) for Me_3NBH_3 and Me_3PBH_3 of 393 ± 2 and 374 ± 2 kcal mol^{-1}, respectively. Therefore, borane coordination leads to acidity increases of more than 11 kcal mol^{-1} for Me_3N ($\Delta H_{acid}(Me_3N) > 404$ kcal mol^{-1}),[14] and 17 kcal mol^{-1} for Me_3P ($\Delta H_{acid}(Me_3P)$ = 391.1 ± 2.1 kcal mol^{-1}).[15] The acidity enhancements in these complexes are similar to that found for Me_2SBH_3, and their absolute acidities are essentially the same as those calculated (B3LYP/cc-pVTZ) for the isoelectronic amine and phosphane oxides: $\Delta H_{acid}(Me_3NO)$ = 389 kcal mol^{-1} and $\Delta H_{acid}(Me_3PO)$ = 375 kcal mol^{-1}.

Borane coordination at the heteroatom also enhances the reactivity of the pendant alkyl groups. This is shown, for example, by the occurrence of a novel S_N2 reaction between F^- and Me_2SBH_3 [Eq. (3)], and by a Hoffmann-like elimination reaction that occurs when Et_3NBH_3 reacts with OH^- [Eq. (4)].

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3620-2231 $ 17.50+.50/0

$$Me_2SBH_3 + F^- \rightarrow MeSBH_3^- + CH_3F \quad (3)$$

$$Et_3NBH_3 + OH^- \rightarrow Et_2NBH_3^- + H_2C{=}CH_2 + H_2O \quad (4)$$

For comparison, F^- is completely unreactive in the gas-phase with uncomplexed Me_2S, and OH^--induced ethylene elimination from uncomplexed Et_3N is actually endothermic by 14 kcal mol^{-1}[8] and does not occur at room temperature. The absence of $Me_2NBH_3^-$ as a product from the reaction between OH^- and Me_3NBH_3 indicates that $Et_2NBH_3^-$ must be formed by elimination rather than substitution. In neither of the above reactions is the proton abstraction product observed.

In conclusion, complexation of methyl sulfides, methylamines, and methylphosphanes with BH_3 causes a dramatic increase in the gas-phase acidity of the α-C–H bonds, amounting to 11–20 kcal mol^{-1}. Deprotonation of borane Lewis base complexes in the gas phase produces stable carbanions that do not rearrange to the more stable "borate" forms. Borane coordination at a heteroatom is also found to enable new reactions of the attached alkyl groups, such as α-substitution and β-elimination.

[15] S Ingemann, N. M. M. Nibbering, *J. Chem. Soc. Perkin Trans. 2*, **1985**, 837. Grabowski, et al. report a value of 384.2 ± 3.2 kcal mol^{-1} based on bracketing experiments (J. J. Grabowski, P. D. Roy, R. Leone, *ibid.* **1988**, 1627). However, B3LYP/cc-PVTZ and CBS-4 calculations using an isodesmic reaction approach predict $\Delta H_{acid}(PMe_3)$ = 390 kcal mol^{-1}, in support of the higher value.

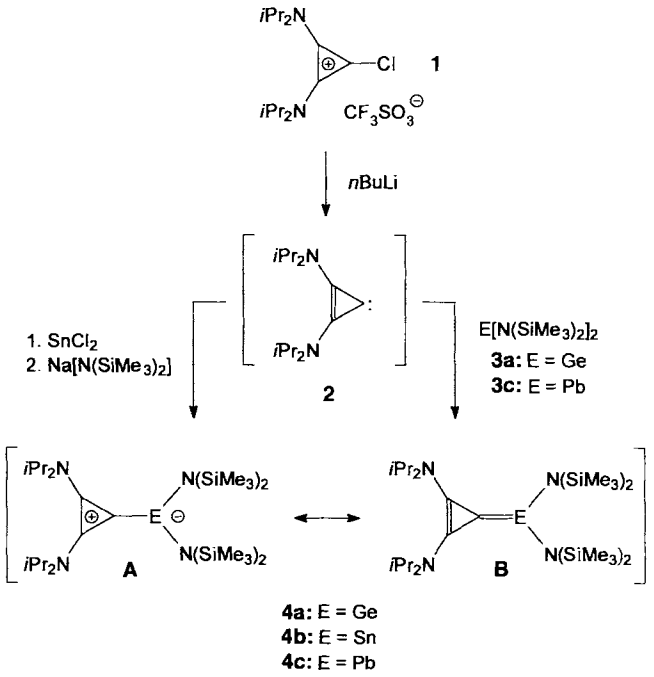
Cyclopropenylidene Adducts of Divalent Germanium, Tin, and Lead**

Herbert Schumann,* Mario Glanz, Frank Girgsdies, F. Ekkehardt Hahn, Matthias Tamm,* and Alexander Grzegorzewski

Dedicated to Professor Wolfgang Beck on the occasion of his 65th birthday

Adducts of nucleophilic carbenes[1] (especially imidazol-2-ylidenes[2]) with main group Lewis acids have been studied intensively in recent years.[3] In the course of our work on ligands containing cycloheptatrienylium[4] and cyclopropenylium[5] rings we became interested in the coordination chemistry of bis(dialkylamino)cyclopropenylidenes, which according to calculations[6, 7] have a stability comparable to imidazol-2-ylidenes. Whereas cyclopropenylidene transition metal complexes[8] have been known for many years,[8] analogous derivatives with main group elements have not yet been described.

The bis(dialkylamino)cyclopropenylidene (**2**) can be obtained from cyclopropenylium salts like **1** by treatment with *n*-butyllithium. At low temperature **2** forms a stable lithium adduct that



can be used directly for the synthesis of carbene complexes.[5, 7, 8b] Thus, the reaction of **2** with the bisamides **3a** and **3c** affords the cyclopropenylidene complexes **4a** and **4c**, respectively. The analogous tin compound **4b** is synthesized by reaction of **2** with $SnCl_2$ followed by amidation of the intermediate

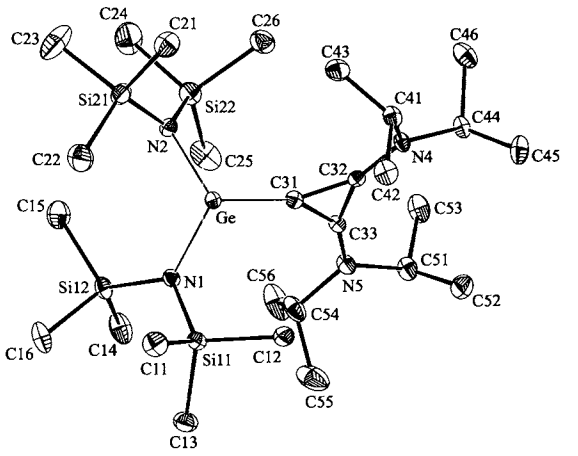
carbene adduct. Compounds **4a–c** are isolated as thermally stable yellow crystals, which are soluble in aprotic solvents such as tetrahydrofuran and diethyl ether and in aromatic and aliphatic hydrocarbons. In the crystalline state the monomeric complexes **4** have a trigonal-pyramidal structure (Figure 1, top) with the E atom (E = Ge, Sn, Pb) on top and the two silylamine-N atoms and the carbene-C atom forming the basal plane of the pyramid (Figure 1, bottom). The plane defined by the three-membered carbene ring approximately includes the nitrogen



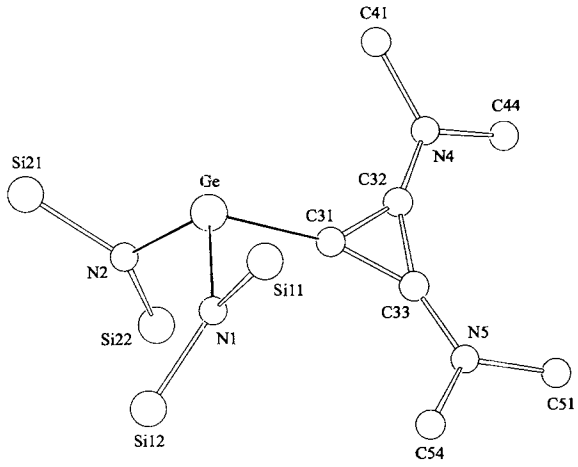


Figure 1. Top: ORTEP drawing [11] of **4a** (thermal ellipsoids at the 30% probability level); compounds **4b** and **4c** have analogous structures. Bottom: Schematic ORTEP drawing [11] of **4a** (all methyl groups have been omitted for clarity). Selected bond lengths [pm] and angles [°] [12]: Ge–C31 208.5(3), Ge–N1 199.1(3), Ge–N2 196.5(3); N1-Ge-C31 98.67(12), N2-Ge-C31 98.65(12), N1-Ge-N2 105.67(11). **4b**: Sn–C31 230.3(9), Sn–N1 221.2(7), Sn–N2 215.7(7); N1-Sn-C31 95.1(3), N2-Sn-C31 94.3(3), N1-Sn-N2 110.5(3). **4c**: Pb–C31 242.3(8), Pb–N1 230.1(7), Pb–N2 230.8(7); N1-Pb-C31 95.0(2), N2-Pb-C31 91.9(2), N1-Pb-N2 110.2(2).

and secondary carbon atoms of the *iso*-propyl groups. The distances between the E atom and the carbene-C atom are appreciably longer than those in "true" germaethenes (180/183 pm)[9] and stannaethenes (202 pm)[10] and fall in the range expected for single bonds. This indicates a bond type best described by the ylidic resonance structure **A**, which corresponds to that in imidazol-2-ylidene adducts,[3a–c] rather than the metallaethene structure **B**.

Comparison of the molecular structures of the adducts **4** with the compound **3**[16] reveals only slight changes in the N-E-N angles upon coordination of the carbene ligand, whereas the E–N distances show the expected lengthening. Resonance stabilization of the carbene ligand is clearly indicated by the equivalence (3σ) of the C–C bonds (137–139 pm). The exocyclic C–N distances (133–134 pm) are significantly shorter than typical C–N single bonds.

The ^{1}H NMR spectra of complexes **4** below $-60\,^\circ$C exhibit four multiplets for the methine protons and four doublets for the methyl protons of the *iso*-propyl groups, which are all magnetically inequivalent due to hindered rotation around the N–C(ring) and E–C bond axes. As the temperature increases the signals broaden, and at room temperature only two very broad resonances are observed for the CH_3 groups. As the exchange processes are concurrent, it is not possible to determine the coalescence temperatures. The ^{13}C NMR signals for the ring carbon atoms in **4a–c** are observed at $\delta \approx 145-150$ and fall in the range typical for cyclopropenylium compounds.[5, 7] In imidazol-2-ylidenes the carbene-C resonance is shifted significantly to higher field upon coordination.[3a–c] Here, an analogous trend is purely speculative, as a free cyclopropenylidene **2** has not yet been isolated and characterized by NMR spectroscopy. Comparison of the ^{119}Sn NMR resonance signals in **3b** ($\delta = 766$)[17] and in **4b** ($\delta = -45$) indicates strong shielding of the tin nucleus by interaction with the carbene ligand.[3b, c] The new compounds presented here illustrate that nucleophilic bis(dialkylamino)cyclopropenylidenes could be interesting alternatives to the intensively studied imidazol-2-ylidenes.

Experimental Section

1 [18], **3a**, and **3c** [19] were prepared according to published procedures. NMR spectra were recorded on Bruker AMX-200 and AMX-400 instruments. Microanalyses were performed on a Perkin-Elmer Series II CHNS/O 2400 analyzer.

4a: A solution of *n*BuLi (3.5 mL of a 1.6 M solution in hexane, 5.6 mmol) was added dropwise to a stirred suspension of **1** (2.35 g, 5.6 mmol) in THF (70 mL) at $-78\,^\circ$C. After the mixture had been stirred for about 15 min, solid **3a** (2.20 g, 5.6 mmol) was added in small portions to the clear solution. The reaction mixture was allowed to warm up to 25 °C and was subsequently stirred for 12 h. After removal of the solvent the residue was suspended in hexane (70 mL) and filtered. The solution was concentrated to about 35 mL, and yellow crystals of **4a** were obtained at $-78\,^\circ$C. Yield 2.15 g (61%). M.p. (0.1 mbar) 125 °C (decomp); ^{1}H NMR (400 MHz, C_6D_6, 25 °C): $\delta = 1.23$ (br. s, 120 Hz, 12H; $CHCH_3$), 0.86 (br. s, 120 Hz, 12H; $CHCH_3$), 0.47 (s, 36H; $SiCH_3$); ^{1}H NMR (400 MHz, C_7D_8, $-73\,^\circ$C): $\delta = 4.95$ (m, 1H; $CHCH_3$), 3.92 (m, 1H; $CHCH_3$), 2.88 (m, 1H; $CHCH_3$), 2.74 (m, 1H; $CHCH_3$), 1.39 (d, ^3J(H,H) = 5.7 Hz, 6H; $CHCH_3$), 1.09 (d, ^3J(H,H) = 5.8 Hz, 6H; $CHCH_3$), 0.77 (d, ^3J(H,H) = 6.1 Hz, 6H; $CHCH_3$), 0.67 (d, ^3J(H,H) = 6.0 Hz, 6H; $CHCH_3$), 0.57 (s, 36H; $SiCH_3$); ^{13}C NMR (100.64 MHz, C_6D_6, 25 °C): $\delta = 145.45$ (CC_2), 144.62 (CC_2), 52.50 (250 Hz; $CHCH_3$), 49.26 (250 Hz; $CHCH_3$), 22.51 (120 Hz; $CHCH_3$), 21.70 (120 Hz; $CHCH_3$), 6.74 ($SiCH_3$); elemental analysis calcd (%) for $C_{27}H_{64}GeN_4Si_4$ (629.76): C 51.50, H 10.24, N 8.90; found: C 51.84, H 10.01, N 8.47.

4b: A solution of *n*BuLi (3.9 mL of a 1.6 M solution in hexane. 6.22 mmol) was added dropwise to a stirred suspension of **1** (2.61 g, 6.2 mmol) in THF (70 mL) at $-78\,^\circ$C. After the mixture had been stirred for about 15 min, solid $SnCl_2$ (1.18 g, 6.2 mmol) was added in small portions to the clear solution. The reaction mixture was allowed to warm up to 25 °C and was subsequently stirred for 12 h. $Na[N(SiMe_3)_2]$ (2.27 g, 12.3 mmol) was added and the mixture was stirred for another 12 h. Compound **4b** was isolated as described for **4a**. Yellow crystals of **4b** are obtained from hexane at $-78\,^\circ$C. Yield 2.30 g (55%). m.p. (0.1 mbar) 137 °C (decomp); ^{1}H NMR (400 MHz, C_6D_6, 25 °C): $\delta = 1.26$ (br. s, 75 Hz, 12H; $CHCH_3$), 0.85 (br. s, 75 Hz, 12H; $CHCH_3$), 0.49 (s, 36H; $SiCH_3$); ^{1}H NMR (400 MHz, C_7D_8, $-61\,^\circ$C): $\delta = 4.87$ (m, 1H; $CHCH_3$), 3.91 (m, 1H; $CHCH_3$), 2.80 (m, 2H; $CHCH_3$), 1.38 (d, ^3J(H,H) = 6.3 Hz, 6H; $CHCH_3$), 1.09 (d, ^3J(H,H) = 6.1 Hz, 6H; $CHCH_3$), 0.78 (d, ^3J(H,H) = 6.8 Hz, 6H; $CHCH_3$), 0.68 (d, ^3J(H,H) = 6.2 Hz, 6H; $CHCH_3$), 0.57 (s, 36H; $SiCH_3$); ^{13}C NMR (50.32 MHz, C_6D_6, 25 °C): $\delta = 150.17$ (CC_2), 146.66 (CC_2), 51.13 (120 Hz; $CHCH_3$), 49.73 (120 Hz; $CHCH_3$), 21.89 (100 Hz; $CHCH_3$), 7.09 ($SiCH_3$); ^{14}N NMR (28.91 MHz, C_6D_6, 25 °C): $\delta = -316.7$, -353.1; ^{29}Si NMR (79.49 MHz, C_6D_6, 25 °C): $\delta = -3.03$; ^{119}Sn NMR (149.21 MHz, C_6D_6, 25 °C): $\delta \approx -44.69$; elemental analysis calcd (%) for $C_{27}H_{64}N_4Si_4Sn$ (675.86): C 47.98, H 9.54, N 8.29; found: C 46.76, H 8.85, N 7.90.

4c: **4c** was prepared from **1** (1.16 g, 2.8 mmol), *n*BuLi (1.8 mL of a 1.6 M solution in hexane, 2.8 mmol) and **3c** (1.45 g, 2.8 mmol) by a procedure similar to that for **4a**. Yield 1.66 g (79%) of yellow crystals. M.p. (0.1 mbar) 135 °C (decomp); ^{1}H NMR (400 MHz, C_6D_6, 25 °C): $\delta = 1.20$ (br. s, 120 Hz, 12H; $CHCH_3$), 0.81 (br.

s, 120 Hz, 12H; $CHCH_3$), 0.47 (s, 36H; $SiCH_3$); ^1H NMR (400 MHz, C_7D_8, $-61\,^\circ C$): $\delta = 4.92$ (m, 1H; $CHCH_3$), 3.95 (m, 1H; $CHCH_3$), 2.84 (m, 1H; $CHCH_3$), 2.78 (m, 1H; $CHCH_3$), 1.32 (br. s, 15 Hz, 6H; $CHCH_3$), 1.16 (br. s, 15 Hz, 6H; $CHCH_3$), 0.84 (br. s, 15 Hz, 6H; $CHCH_3$), 0.75 (br. s, 15 Hz, 6H; $CHCH_3$), 0.60 (s, 36H; $SiCH_3$); ^{13}C NMR (100.64 MHz, C_6D_6, 25 °C): $\delta = 148.53$ (C_3), 50.71 (400 Hz; $CHCH_3$), 21.46 (175 Hz; $CHCH_3$), 6.89 ($SiCH_3$); elemental analysis calcd (%) for $C_{27}H_{64}N_4Si_4Pb$ (764.37): C 42.43, H 8.44, N 7.33; found: C 42.54, H 8.45, N 6.66.

On the Mechanism of the McMurry Reaction**

Martin Stahl, Ulrich Pidun, and Gernot Frenking*

The use of low-valent titanium reagents for the reductive coupling of carbonyl compounds is an important synthetic technique in organic chemistry. Although an impressively broad range of alkenes is accessible by this method, for a long time only a few mechanistic details were known and only in the last few years have experiments shed new light on the mechanism. The current status of research in this field has recently been described in a review article.[1]

Typically the reaction is conducted with $TiCl_3$ as the source of titanium and a reducing agent such as $LiAlH_4$, Zn/Cu, or Mg. It was long believed that highly dispersed Ti^0 particles are initially formed and that the carbonyl coupling proceeds heterogeneously on their surface via ketyl radical intermediates.[2–4] New experiments by Fürstner et al. and Bogdanović et al., however, indicate that when the coupling is performed with Zn/Cu in dimethoxyethane (DME), a different reaction path is followed.[5, 6] They propose a nucleophilic rather than a radical mechanism, as depicted in Scheme 1.[1]

Because the postulated intermediates **1**–**4** have not been characterized experimentally and the energetics of the reaction course suggested by Fürstner and Bogdanović are not known, we have carried out quantum mechanical calculations of the proposed reaction profile by means of density functional theory (DFT)[7] using formaldehyde as a model carbonyl compound. All intermediates and transition states have been located on the singlet potential energy surface and confirmed by frequency calculations. The transition states have been further characterized by calculating the intrinsic reaction coordinates (IRC).[16]

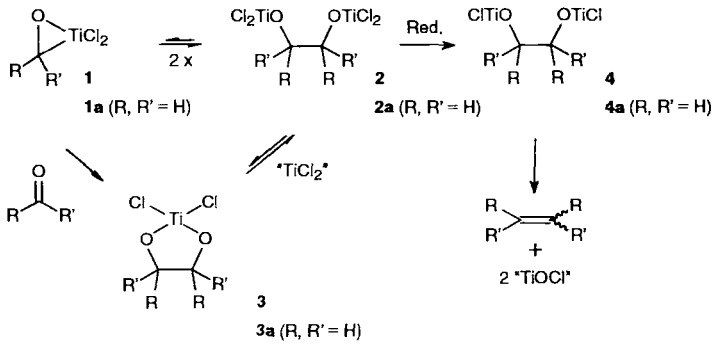
Frenking, *Organometallics*, **1997**, in press.



Scheme 1. Nucleophilic reaction mechanism for the McMurry reaction proposed by Fürstner and Bogdanović [1].

Three key experimental observations led to the formulation of the Ti^{II} complex **1** as the starting point for the proposed nucleophilic mechanism: a) Pure $TiCl_3$ in DME is not reduced by Zn/Cu. b) Reduction takes place only after addition of the carbonyl compound. A complex between $TiCl_3$ and the carbonyl compound has been observed by IR spectroscopy, and it has been shown that only one reduction equivalent is consumed per equivalent of titanium.[6] c) The resulting complex **1** has been formulated as a side-on coordinated carbonyl complex, since at low temperatures reaction mixtures can be quenched with D_2O to yield the corresponding secondary alcohol deuterated in the α-position.[6] Side-on coordinated formaldehyde complexes of early transition metals are known[17] and have frequently been observed to undergo C–C coupling reactions.[17, 18] In our calculations the only minimum found for the complex of CH_2O with $TiCl_2$ is indeed the side-on coordinated structure **1a** (Figure 1), which has pseudotetrahedral coordination at titanium. The C–O bond length of 1.399 Å is considerably closer to the length of a typical C–O single bond (1.43 Å[19]) than to the length of the C–O bond in free formaldehyde (1.21 Å[20]). The term titanaoxacyclopropane is thus justified and the formal oxidation state IV can be assigned to the titanium atom.

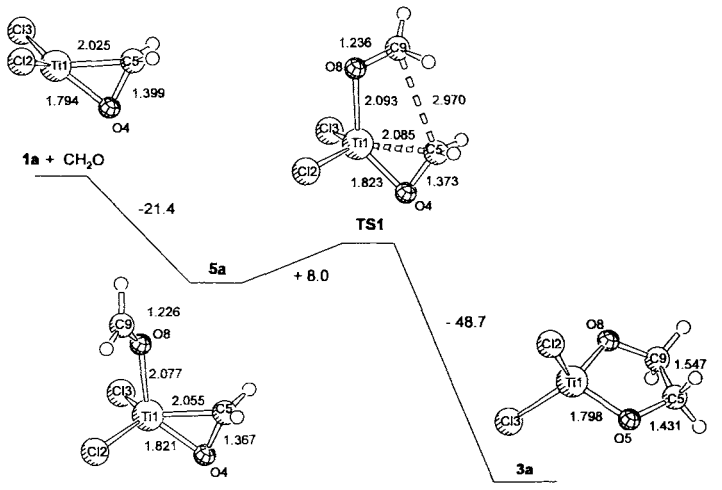


Figure 1. Energy profile and structures of stationary points in the pathway for intramolecular C–C coupling; bond lengths [Å] and reaction energies [kcal mol^{-1}] corrected for zero-point vibrational energies at the B3LYP/II level.

At room temperature the reaction can be quenched with water to yield the pinacol.[6] This has been rationalized by the formation of the pinacolate complex **2**, in which the Ti centers must have the formal oxidation state III, since only one reduction equivalent per equivalent of titanium is consumed up to this stage. A reversible disproportionation reaction to give a Ti^{IV} pinacolate complex **3** and a Ti^{II} compound of low solubility is observed.[6] While Fürstner and Bogdanović consider the pathway **1** → **2** to be the C–C bond forming process, we have found that the reaction **1** → **3** is energetically accessible as well. Figure 1 shows the structures and the energy profile for the reaction **1a** + CH_2O → **3a**. The complex **1a** acts as a Lewis acid towards another molecule of formaldehyde to yield structure **5a**. This complex is the only energy minimum in which two CH_2O molecules are coordinated to a $TiCl_2$ fragment. Structures with two side-on or two end-on coordinated molecules of formaldehyde could not be located. The formation of the adduct **5a** is exothermic by 21.4 kcal mol^{-1}. A series of linear synchronous transit (LST) optimizations showed that the addition of formaldehyde to **1a** takes place without an activation barrier. The end-on coordinated formaldehyde can rotate with a barrier of only 2.9 kcal mol^{-1} about the Ti–O bond, describing a semicircle above the $TiCl_2$ moiety. The transition state structure of this rotation (not shown in Figure 1) is C_s-symmetric with an antiperiplanar arrangement of the two carbon atoms. At the same time rotation of the end-on coordinated formaldehyde about the O–Ti axis towards the other carbon atom, combined with rotation around the C–O bond, leads to the transition state **TS1** for the formation of the pinacolate complex **3a**. This step has an activation barrier of only 8.0 kcal mol^{-1}. The long C–C bond (2.97 Å) in **TS1** and the only slight elongation of the Ti1–C5 and O8–C9 distances indicate an early transition state, which is in agreement with the Hammond postulate. Reaction **5a** → **3a** is exothermic by 40.7 kcal mol^{-1}. The product pinacolate complex **3a** has a nonplanar five-membered ring with an O-C-C-O dihedral angle of 31.1° and a C–C distance of 1.547 Å, typical of a C–C single bond.[19]

The results of the calculations for the intermolecular C–C coupling by means of the dimerization reaction 2 × **1a** → **2a** (Scheme 1) are shown in Figure 2. The highly unsymmetric transition state **TS2** was located for the C–C coupling step leading to the dimetalated pinacolate **2a**. One of the two titanaoxacyclopropanes **1a** almost retains its ground state geometry, while the other has a widened Ti-O-C bond angle to allow for the bond formation between the two carbon atoms. At the same time the coordinative unsaturation of the titanium atom is compensated by one of the chlorine ligands (Cl3) of the first reaction partner, which now forms a bridge between the two titanium atoms. The C–C distance of 2.171 Å and the significant pyramidalization at C10 show that this is a rather late transition state compared to **TS1**. IRC calculations prove that complex **6a** must be formed before the dimerization can occur. Intermediate **6a** is 15.9 kcal mol^{-1} more stable than two molecules of **1a**. The activation barrier for the C–C coupling step **6a** → **2a** is 27.1 kcal mol^{-1}, which means that the overall reaction has an activation barrier of 11.2 kcal mol^{-1}. The pinacolate complex **2a** is 24.0 kcal mol^{-1} lower in energy than **6a**. The most striking feature of the pinacolate **2a** is the long Ti–Ti distance of 2.813 Å. The weak Ti–Ti bond[21] leads to a closed-shell electron configuration for **2a**, while the postulated intermediate **2** (Scheme 1) was originally formulated without a Ti–Ti bond.[6] Despite careful searching, no other energy minimum structure of **2** was found. In particular, we could not locate a diradical structure on the potential energy surface.[22] This is in agreement with the fact that in ESR studies of the reaction course signals for paramagnetic species could not be observed.[23]

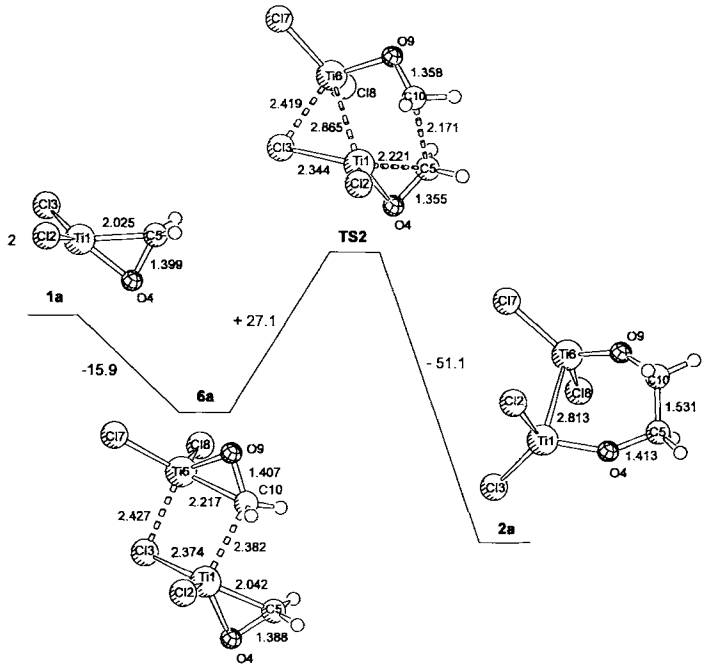

Figure 2. Energy profile and structures of stationary points in the pathway for intermolecular C–C coupling; bond lengths [Å] and reaction energies [kcal mol^{-1}] corrected for zero-point vibrational energies at the B3LYP/II level.

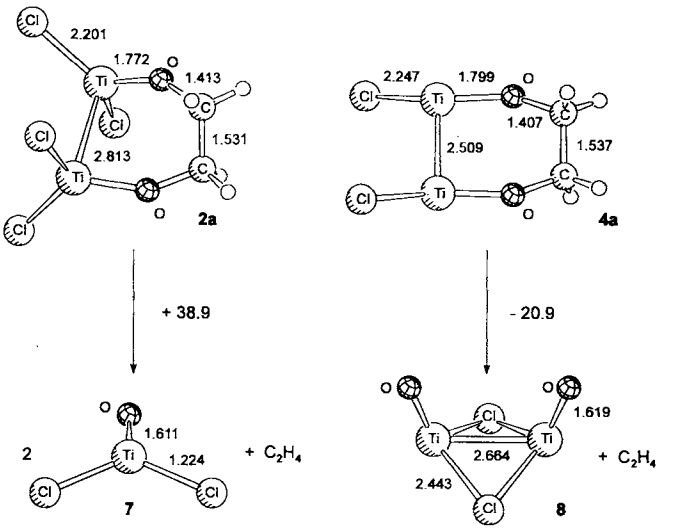

Figure 3. Comparison of the ethylene elimination reactions of the pinacolate complexes **2a** and **4a**; bond lengths [Å] and reaction energies [kcal mol^{-1}] corrected for zero-point vibrational energies at the B3LYP/II level.

The theoretical reaction profiles for the intramolecular (Figure 1) and intermolecular (Figure 2) closed-shell C–C coupling reactions indicate that both pathways should be possible. The calculated energies favor the intramolecular mechanism. It may depend on the reaction conditions whether there is a sufficient proportion of uncomplexed carbonyl compound available which can then react easily via **5a** to **3a**. The energetics of the reaction will also be influenced by solvent molecules stabilizing the ground and transition state structures to different extents.

The final reaction step of the proposed mechanism is the reduction of the pinacolate complex to the alkene. A very recent experimental study of a related C–C coupling reaction with UCl_4 and Li/Hg as the reducing agent showed that the alkene is formed directly from the mononuclear pinacolate complex of UCl_4 corresponding to **3** (Scheme 1).[24] However, experimental evidence proved unequivocally that in the case of titanium the direct formation of the alkene from **3** can be excluded.[25] Therefore, the dinuclear complex **2** must be an intermediate in the alkene-forming process. Furthermore, it is known that when Zn/Cu is used as a reducing agent, the formation of the alkene takes place only if a further reduction equivalent is consumed per equivalent of titanium and that the titanium finally precipitates as $TiClO(ZnCl_2)_{0.93}$.[6] It was suggested that further reduction, **2** → **4** (Scheme 1), takes place prior to dissocation of the alkene.[6] To test this hypothesis we calculated the energetics of the elimination of ethylene from the Ti^{III} compound **2a** and from the Ti^{II} species **4a** (Figure 3). Compound **4a** has a significantly shorter Ti–Ti bond (2.509 Å) than **2a**, indicative of a Ti–Ti double bond. The calculations predict that the reaction **2a** → ethylene + $2TiOCl_2$ (**7**) is strongly endothermic by 38.9 kcal mol^{-1}, while the reaction **4a** → ethylene + $Ti_2O_2Cl_2$ (**8**) is exothermic by 20.9 kcal mol^{-1}. No energy minimum structure corresponding to a $TiOCl_2$ dimer could be located. Even though the calculated energies are not exact reaction energies, because they may be significantly influenced by solvent effects and the solubility of the inorganic products, the calculations indicate that formation of ethylene from a Ti^{II} pinacolate is energetically clearly favored over the Ti^{III} pinacolate pathway.

Although our results do not rule out that the McMurry reaction may follows a radical pathway under different reaction conditions, the calculations presented here support the interpretation of the experimental results of Fürstner and Bogdanović[1, 5, 6] in terms of a nucleophilic mechanism. The calculations show that a closed-shell nucleophilic pathway for the C–C coupling step is a reasonable mechanistic hypothesis. In particular, intermediates **1**–**4** which have hitherto been postulated only, were characterized as energy minima **1a**–**4a** on the potential energy surface, and the energy profile of the postulated reaction course was found to be favorable.

[7] All calculations were performed with the program package Gaussian 94[8]. The geometries were optimized at the DFT[9] level by means of the Becke three parameter hybrid method (B3LYP)[10]. The accuracy of the B3LYP method is well known[11]. Calculations at the MP2 level of theory gave similar geometries and relative energies as the B3LYP calculations. For titanium, we used a (small core) nonrelativistic effective core potential (ECP) with a (441/2111/41) basis set for the twelve valence and outer-core electrons[12]. For chlorine, we also used an ECP in combination with a (31/31/1) basis set for the seven valence electrons[13]. For carbon, oxygen, and hydrogen a 6-31G(d) basis set was employed. This is our standard basis set II[14]. Frequency calculations were performed at the same level of theory. Zero-point energies were used unscaled[15]. The calculated total energies [Hartree] and zero-point vibrational energies [kcal mol^{-1}] of all stationary points are: **1a**: −202.79952, 20.6; CH_2O: 114.49822, 16.8; **5a**: −317.33510, 39.4; **TS1**: −317.32200, 39.2; **3a**: −317.40519, 42.7; **6a**: −405.62620, 42.3; **TS2**: −405.58359, 42.7; **2a**: −405.66890, 45.1; **7**: −163.50559, 3.4; **4a**: −375.43133, 42.7; **8**: −296.87155, 6.0; $TiCl_2$: −88.16417, 1.4; $H_2C{=}CH_2$: −78.58582, 32.1.

Sb_8R_4, R = $(Me_3Si)_2CH$—A Polycyclic Organostibane**

Hans Joachim Breunig,* Roland Rösler, and Enno Lork

Dedicated to Professor Gottfried Huttner on the occasion of his 60th birthday

Whereas several examples of monocyclic organostibanes are known,[1] polycycles of the type Sb_nR_m ($n > m$, R = monovalent substituent) have not yet been described. Polycyclic structures have been observed, however, for polyantimonides and their derivatives.[2]

Since monocyclic stibanes can be stabilized kinetically by bulky substituents, it seemed appropriate to try to protect polycyclic stibanes in a similar way. Attempts to produce polycycles by methods analogous to those applied for organophosphorus polycycles[3] by reactions of magnesium and mixtures of $RSbCl_2$ [R = *t*Bu, $(Me_3Si)_2CH$)] and $SbCl_3$ in the molar ratios 3:1, 1:1, or 1:3 were, however, unsuccessful. When a 3:1 mixture was used the known Sb_4 monocycles were formed.[1a,c,d] In the other cases no ring formation was observed; only insoluble black solids were obtained.

Yellow crystals of the polycycle Sb_8R_4 (**1**) (R = $(Me_3Si)_2CH$) have now been obtained as a product of the previously described[1c] reaction of $RSbCl_2$ with magnesium filings in tetrahydrofuran, in which a variation of the work-up conditions was crucial. When the main product, Sb_4R_4, is separated by chromatography before crystallization, the novel polycycle is obtained from a fraction that also contains Sb_3R_3, SbR_3, and Sb_7R_5 (**2**). The yield of **1** and **2** is small, but the synthesis is very reproducible. The pathway of the reaction is not yet known. A thermal decomposition of Sb_3R_3 to give **1** or **2** and SbR_3 may be assumed, which corresponds to reaction patterns known in phosphorus chemistry.[3]

According to an X-ray structure analysis of **1**[4] (Figure 1), the eight Sb atoms form a tricyclic cage consisting of Sb_5 monocycles sharing common edges. The alkyl substituents occupy

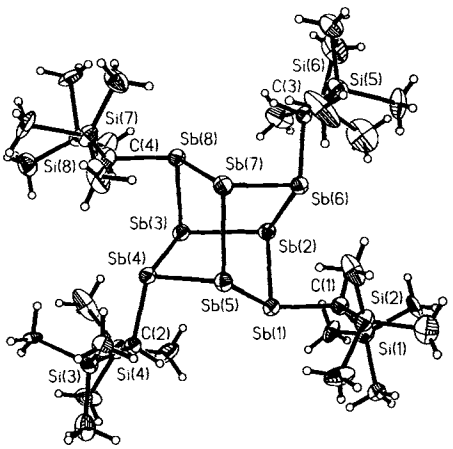

Figure 1. Structure of **1** in the crystal. Selected bond lengths [pm] and angles [°]: Sb(1)–Sb(2) 281.0(4), Sb(2)–Sb(3) 281.4(3), Sb(3)–Sb(4) 285.2(4), Sb(4)–Sb(5) 278.4(4), Sb(5)–Sb(1) 284.3(3), Sb(5)–Sb(7) 281.9(3), Sb–C (mean) 220; C(1)-Sb(1)-Sb(2) 96.2(8), C(1)-Sb(1)-Sb(5) 110.2(7), Sb(2)-Sb(1)-Sb(5) 99.65(10), Sb(3)-Sb(2)-Sb(6) 109.66(10), Sb(3)-Sb(2)-Sb(1) 91.22(10), Sb(1)-Sb(2)-Sb(6) 87.32(10).

1,3-positions in a *trans* orientation to each other in the five-membered rings, which each adopt an approximate envelope conformation. The structure of **1** can be derived from a Sb_4 tetrahedron that is bridged on four edges with SbR groups. Therefore a close relationship exists between **1** and realgar, As_4S_4, whose structure is explained by insertion of sulfur atoms into four As–As bonds of a tetrahedral As_4 molecule. The structure of **1** cannot be derived from a known modification of antimony; however, it corresponds to the P_8 cage in Hittorf's phosphorus. Thus, **1** supplements the structural patterns of organophosphorus polycycles since the analogous octaphosphanes P_8R_4[5] have not yet been investigated crystallographically.

The distances and angles in the structure of **1** display wider variations than those in monocyclic organostibanes. The Sb–Sb bond lengths are approximately equal only between antimony atoms bearing no alkyl substituents (av 281.7 pm). In the [Sb–Sb(R)-]$_4$ skeleton there is a systematic variation of shorter [278.4(4)–281.0(4) pm] and longer distances [284.3(3)–286.1(4) pm]. In the four-membered ring $(SbR)_4$ (R =

$(Me_3Si)_2CH$) the differences between the Sb–Sb bond lengths (282.2–286.6 pm) are considerably smaller. The bond angles at the antimony atoms of **1** range between 84.66(9)° and 113.2(7)°. A similar wide range of Sb–Sb bond lengths and bond angles has also been observed in other antimony clusters, such as the anions Sb_7^{3-} [2d] or $[Sb_7M(CO)_3]^{3-}$ (M = Cr[2b], Mo[2a]). The differences in the distances and angles of **1** cause some deviations from the geometry of the realgar structure. This is apparent for the antimony atoms Sb(1), Sb(4), Sb(8), and Sb(6) bearing alkyl substiuents. They are not exactly situated in a plane; the deviations from the best plane are between −39.1 and 38.6 pm. The nonbonding distances between the antimony atoms without alkyl substituents [Sb(2)–Sb(5), Sb(2)–Sb(7), Sb(3)–Sb(5), Sb(3)–Sb(7)] vary only little between 429.0 and 432.3 pm. This corresponds quite well to the idealized geometry of the realgar type. A detailed examination of the structure of the five-membered rings reveals some deviations from an ideal envelope conformation. The atoms Sb(2), Sb(3), Sb(4), and Sb(5), for example, are not exactly in a plane either; the deviations from the best plane vary from −21.4 to 20.9 pm.

Apart from crystallographic analysis, mass spectrometry is also suitable for detecting the novel polycycles. In the chemical ionization mass spectrum, in addition to **1**, Sb_7R_5 (**2**, $R = (Me_3Si)_2CH$) was also detected through the intensive group of signals of the molecular ion. Attempts to determine the structure of **2** by X-ray structure analysis or NMR spectroscopy have not yet been successful. Analogous phosphorus compounds of the type P_7R_5 have the bicyclic norbornane structure.[3]

Experimental Section

All operations were carried out with strict exclusion of air in an argon atmosphere. Al_2O_3 was heated under reduced pressure and loaded under argon.

A solution of $RSbCl_2$ [R = $(Me_3Si)_2CH$] [6] (1.58 g, 4.5 mmol) in THF (20 mL) was added dropwise within 30 min with stirring to magnesium filings (0.15 g, 6 mmol) in THF (5 mL) activated with $BrCH_2CH_2Br$. The dark brown mixture was stirred for 1 h, the solvent was removed at reduced pressure, and the residue was washed three times with portions of petroleum ether (100 mL). The extracts were combined, concentrated to a volume of 10 mL, and separated by chromatography with petroleum ether on Al_2O_3 (Al_2O_3 neutral according to Brockmann, activity Super I, particle size 0.063–0.200 mm; column 8 × 1.5 cm). The first, intensely orange fraction contained $(SbR)_4$ (yield 0.76 g, 60%). The second, less intensely colored fraction was concentrated to a volume of 10 mL under reduced pressure. It contained $(SbR)_3$ as main component as well as SbR_3 and the polycycles **1** and **2**. Small yellow crystals of **1** were obtained when the concentrated solution was stored at −27 °C for two months (MS (CI, positive-ion mode, NH_3): **1**: *m/z* :1608–1612 [M^+]; **2**: *m/z*: 1643–1658 [M^+H]).

Chemoenzymatic Synthesis of Fluorescent N-Ras Lipopeptides and Their Use in Membrane Localization Studies In Vivo**

Herbert Waldmann,* Michael Schelhaas, Edgar Nägele, Jürgen Kuhlmann, Alfred Wittinghofer,* Hans Schroeder, and John R. Silvius*

Dedicated to Professor Heribert Offermanns on the occasion of his 60th birthday

The lipidation of proteins, specifically the covalent attachment of a myristoyl group to an N-terminal glycine, and the S-palmitoylation and S-alkylation of cysteines by farnesyl or geranylgeranyl moieties, is among the most important modifications of proteins in nature.[1] Lipoproteins play decisive roles in numerous biological processes; in particular they are critically involved in the transduction of hormonal and mitogenic signals across the plasma membrane and from there towards the nucleus. For instance, the transmembrane G-protein-coupled receptors are S-palmitoylated, the heterotrimeric G-proteins are N-myristoylated, S-palmitoylated, and S-farnesylated, nonreceptor protein tyrosine kinases are N-myristoylated and S-palmitoylated, and the Ras proteins carry S-palmitoyl- and S-farnesyl groups. In addition, numerous further membrane-associated proteins are lipidated, for example the enzyme NO_x-synthetase,[2] and various viral envelope proteins[3] are S-palmitoylated.

Due to the important biological roles of lipid-modified proteins, the study of protein lipidation and its biological significance is at the forefront of biological research.[1] Correct lipidation of G-protein-coupled receptors[4] and the Ras proteins (vide infra) is known to be important for the proper execution

of their biological functions. However, the general biological significance of different lipid groups, in particular their possible roles in biological signal transduction processes, is largely unclear and the subject of numerous hypotheses.[1] Furthermore, the detailed knowledge of the requirements for either transient or stable insertion of lipopeptides into biological bilayers may help in the design of drugs that influence pathological signal transduction processes such as those employing oncogenic Ras.

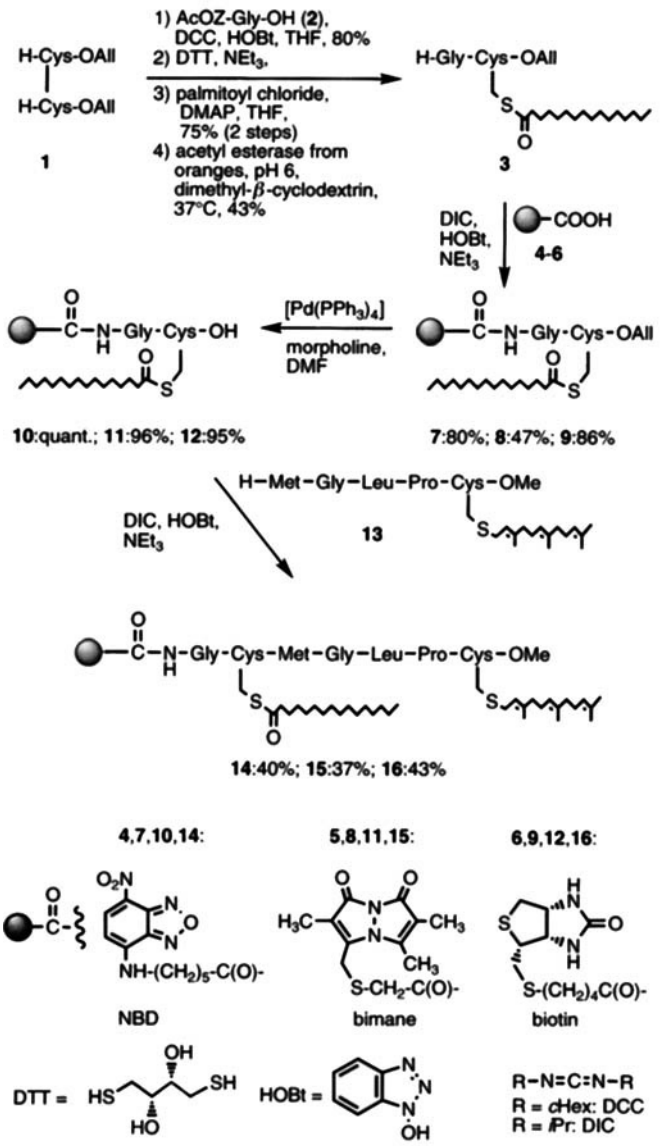
For the study of such phenomena by a combination of biophysical[5] and cell-biological[6] methods[7] useful reagents are lipidated peptides that contain the lipid groups and amino acid sequences of their parent lipoproteins, and also carry labels by which they can be traced in biological systems (i.e. fluorescent labels that can be detected by fluorescence microscopy).

We report here on an efficient method for the synthesis of fluorescent-labeled lipopeptides and on their application in the study of the specific membrane localization of lipopeptides and lipoproteins by means of membrane fusion/fluorescence microscopy and microinjection/confocal laser fluorescence microscopy.

For the development of a new synthetic, flexible method for the construction of differently lipidated peptides we have drawn from our previous experience in the construction of acid- and base-labile S-palmitoylated and S-farnesylated Ras lipopeptides.[8] The Ras proteins, a class of membrane-bound lipidated proteins that convey signals sent by growth factors further towards the nucleus, are often involved in malignant transformation.[9] They can fulfill their biological roles in the normal and the transformed state only if they are lipidated.[9]

The differently labeled N-Ras heptapeptides **14**–**16**, **17**, and **18** were chosen as target compounds. In retrosynthetic analysis they were divided into differently labeled N-terminal dipeptides and a constant C-terminal pentapeptide **13**, which carries an acid-labile farnesyl sulfanyl group (Scheme 1). Peptide **13** can be constructed in high yield by enzymatic removal of the N-terminal *p*-acetoxybenzyloxycarbonyl (AcOZ) group[8a] or base-mediated cleavage of the fluorenylmethoxycarbonyl (Fmoc) group[8c] as key steps. The synthesis of the selectively deprotected, S-palmitoylated peptides **14**–**16** is complicated by the pronounced base-lability of the sulfanylcarbonyl group. Thus, we found that in S-palmitoylated peptides these groups hydrolyze spontaneously even at pH 7 in aqueous solution.[8b] We now report that S-palmitoylated peptides can be synthesized efficiently by the combination of Pd^0-mediated cleavage of an allyl ester[10] for deprotection of the peptide chain at the C-terminus and enzymatic removal of an AcOZ group[8a] for unmasking at the N-terminus.

Thus, cystine (bis)allyl ester **1** was condensed with AcOZ-glycine **2** to give the corresponding peptide in high yield. After reductive cleavage of the disulfide bond by means of dithiothreitol (DTT), the sulfanyl groups were palmitoylated and then the N-terminal AcOZ residue was cleaved by means of the enzyme acetyl esterase from oranges to deliver the selectively unmasked, S-palmitoylated dipeptide allyl ester **3** in a straightforward manner. Dipeptide **3** was then condensed with different labels. The fluorescent 7-nitrobenz-2-oxa-1,3-diazolyl (NBD) and bimanyl groups were introduced with reagents **4** and **5**, respectively, and **3** was also coupled to the biotin derivative **6**. The fully masked peptides **7**–**9** were then treated with $[Pd(PPh_3)_4]$ in the presence of morpholine as an allyl-accepting nucleophile to give the selectively deprotected, fluorescent-labeled dipeptides **10**–**12** in high yields. In the N- and the C-terminal deprotections no undesired side reactions occurred. Thus, the conditions for the enzymatic cleavage of the AcOZ residue and the allyl ester are so mild that neither an attack on the base-sensitive thioester group nor a base-induced β-elimination[8] occurs. Finally, **10**–**12** were condensed with the N-terminally deprotected pentapeptide **13** to give the desired, differently labeled, S-farnesylated and S-palmitoylated N-Ras heptapeptides **14**–**16**. Similarly, the NBD-tagged heptapeptides **17** and **18** were prepared. In addition, the farnesylated pentapeptide **13** was coupled with NBD-aminocaproic acid **4** to give the labeled peptide **19** (Scheme 2).



Scheme 1. Chemoenzymatic synthesis of the labeled, farnesylated and palmitoylated N-Ras lipopeptides **14**–**16**.

The NBD- and the bimanyl-labeled peptides can be detected directly in biological systems and in vitro model systems by fluorescence microscopy and fluorescence spectroscopy. The biotin label can be traced with the protein streptavidin, which is also available in a fluorescent-labeled form or can be modified with colloidal gold, thus facilitating the study of model lipoproteins by fluorescence microscopy and electron microscopy.[11]

One of the prevailing questions in the study of the biological roles of the lipidation of proteins is whether particular lipidation motifs target lipoproteins to specific membranes.[5–8] Thus, the observation that several proteins in the plasma membrane carry farnesyl residues, whereas proteins in intracellular membranes

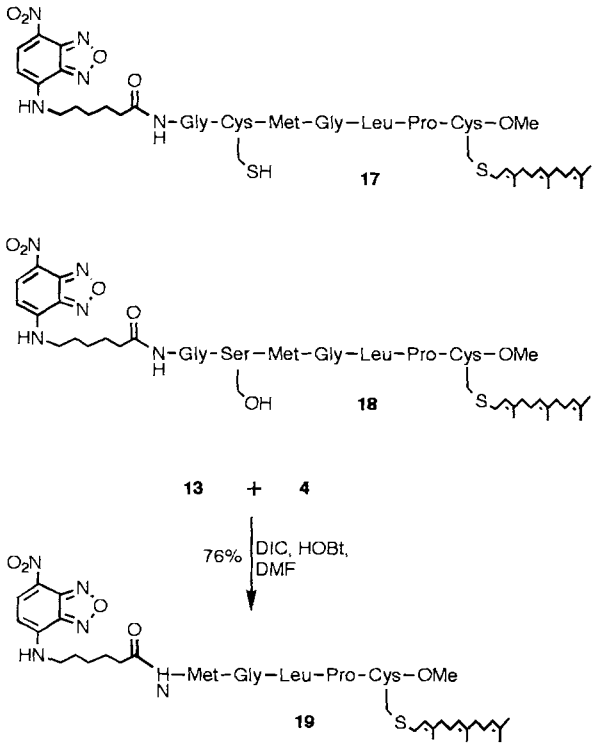

Scheme 2. Synthesis of the labeled farnesylated N-Ras peptides **17**–**19**.

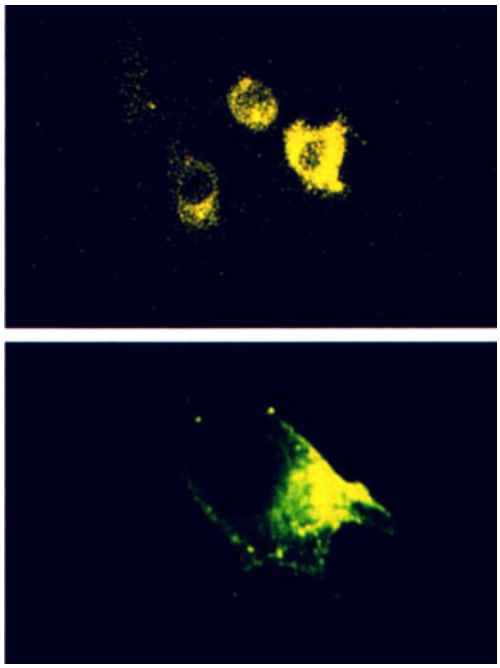

Figure 1. Fluorescence micrographs of NIH-3T3 fibroblast cells. Top: After microinjection of pentapeptide **19**; bottom: after microinjection of heptapeptide **14**. The top micrograph shows that **19** is not localized to the plasma membrane; the bottom micrograph indicates that **14** is localized in the plasma membrane.

are often geranylgeranylated (e.g. the Rab proteins[12]) has raised the notion that S-farnesylation might serve to target lipidated proteins specifically to the plasma membrane, for example by interactions with respective receptors.[1, 13]

To address this question and to determine whether the different lipidation motifs and amino acid sequences present in the Ras model peptides **14**, **17**, **18** and **19** determine a specific localization of the probes in a particular subcellular membrane, in particular the plasma membrane, the labeled peptides were subjected to in vivo studies. In one set of experiments the exclusively farnesylated and non-palmitoylable NBD-labeled pentapeptide **19** and the palmitoylated and farnesylated NBD-labeled lipoheptapeptide **14** were microinjected into NIH-3T3 fibroblast cells. After 30 min the distribution of the peptides in the cells was investigated by means of confocal laser fluorescence microscopy. The image obtained for **19**, shown at the top of Figure 1, demonstrates that the peptide is not localized in the plasma membrane. At the bottom of Figure 1 the corresponding result for **14** indicates clearly that the doubly modified peptide is specifically located in the plasma membrane. In the micrograph the fluorescence intensity is highest in the membrane around the site of injection (large yellow spot) and extends from there into the membrane of the dendrites of the cell. Several notable "hot spots" seem to represent compartments of the plasma membrane that are particularly enriched with the lipidated peptide.

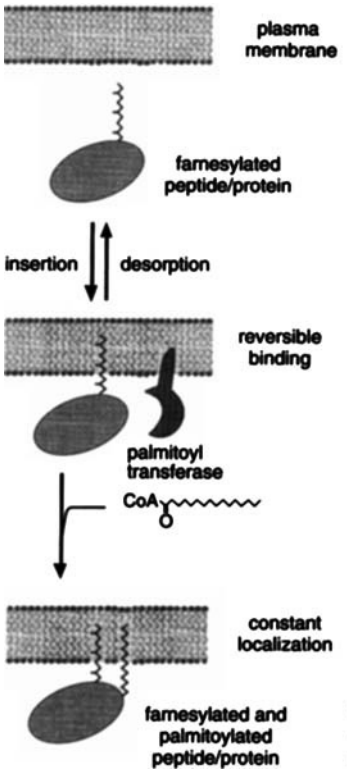
In a second set of experiments the palmitoylation of the lipopeptides **17** and **18** was studied, and the subcellular locus at which this reaction occurs was determined. To this end, cultured CV-1 fibroblasts were incubated with [^{3}H]palmitic acid and sonicated vesicles (composed of phosphatidyl choline extracted from egg yolk and 1-palmitoyl-2-oleoyl phosphatidylethanolamine in a ratio of 90:10) loaded with lipopeptides.[6] The palmitoylation of the fluorescent peptides after fusion of the vesicles with the cell membrane was determined by extraction of the fibroblast cells and analysis by two-dimensional thin-layer chromatography and scintillation counting.[6] Visualization of the S-acylated peptide spot by fluorescence employing peptide **14** as reference compound revealed that the N-Ras peptide **17**, which contains a farnesylated and an unacylated cysteine, was readily S-acylated in the fibroblasts and thereby converted into the palmitoylated and farnesylated lipopeptide **14**. In contrast, the serinyl lipopeptide **18** was not acylated under these conditions at all.

The subcellular locus of S-acylation of **17** was examined by fluorescence microscopy.[6] After incubation of CV-1 fibroblasts with lipid-loaded vesicles and selective extraction of unacylated peptide, inspection of the cells revealed a preferential accumulation of fluorescence, that is, the S-acylated lipopeptide **14**, in the plasma membrane. To determine whether the peptide might have been acylated at an intracellular membrane, for example in a compartment of the endoplasmatic reticulum or of the Golgi apparatus, and then rapidly transferred in the S-acylated form to the plasma membrane, presumably by vesicular membrane transport,[14] the experiments were carried out at different temperatures. However, neither at 37 °C (at which vesicular transport is regular) nor at 15 °C (at which vesicular transport of materials from the Golgi to the plasma membrane is strongly suppressed[15]) was fluorescence detected in the Golgi apparatus or trans Golgi compartments. At both temperatures fluorescence accumulated in the plasma membrane. Given the additional fact that doubly lipid-modified peptides like **14** exhibit negligible rates of spontaneous transfer between distinct membranes[5, 6] (as opposed to lipopeptides like **19** carrying only a farnesyl group, which rapidly exchange between different membranes), these observations suggest that the plasma membrane is itself a major site of cellular S-acylation. In contrast, cells incubated with the serinyl-peptide **18** showed little residual fluorescence.

These in vivo experiments with the labeled N-Ras peptides support the mechanism for the selective subcellular localization

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3620-2240 $ 17.50+.50/0

of lipoproteins recently proposed by Silvius et al.[5] (Scheme 3). According to this mechanism, the farnesylated but unacylated N-Ras C-terminal heptapeptide **17** (as well as the analogous pentapeptide **19**) can diffuse freely between different membranes. Upon S-acylation of **17** (which is not possible for **19**) in



Scheme 3. Proposed model for the targeting of lipoproteins to the plasma membrane by S-palmitoylation.

a given cellular membrane compartment the now doubly lipidated peptide can no longer be transferred between different membranes. It is thus localized to the membrane where the S-acylation reaction takes place, which in the case of the N-Ras peptide is the plasma membrane. The injected, doubly modified conjugate **14** might be rapidly incorporated into the plasma membrane near the injection site and remain there due to the anchoring influence of two lipid groups. In addition, it could undergo enzymatic[16] or nonenzymatic (vide supra) deacylation on sulfur and subsequent repalmitoylation at the plasma membrane during the time of assay.

This model should also be valid for the co- and posttranslational modification of membrane-bound lipid-modified proteins by S-farnesylation and S-palmitoylation, in particular of the Ras proteins themselves. According to this model the specific localization of lipoproteins in particular membranes would not only be determined by the first lipid group introduced in the course of their biosynthesis, but even more by the attachment of the second lipid residue at the site at which the protein remains localized. The recent identification of a plasma membrane bound protein S-acyltransferase,[17] which acylates the free cysteine in the farnesylated C-terminal hexadecapeptide of N-Ras, and similarly positioned cysteine residues in full length H-Ras strongly supports this notion.

This model of "kinetic targeting" does not address the participation of transport proteins that might be involved in the membrane targeting of lipoproteins. However, it explains how very small regions of proteins such as Lck, Fyn, and H- and N-Ras containing S-acylation sites are both necessary and sufficient for targeting to the plasma membrane when they are introduced artificially into chimeric or mutated proteins.[18] Also, a recent study has concluded that the protein Fyn is targeted to the plasma membrane by a kinetic-targeting mechanism based on acylation at that membrane[19] just as was observed for simple lipopeptides that are S-acylation substrates and that resemble the termini of proteins such as Fyn and Lck.[6]

[20] NIH-3T3 cells were grown in Dulbecco's Modified Eagle Medium (DMEM) supplemented with 10% fetal bovine serum (Gibco) in a humidified CO_2 (7.5%) incubator at 37 °C. Microinjections were performed in culture medium buffered with 20 mM Na-HEPES, pH 7.4. For injections a Zeiss Microinjection Workstation (AIS) was used along with thin borosilicate glass capillaries with filaments (Hilgenberg) having a diameter of ≤ 0.5 µm at the tip. Distribution of the fluorophore was observed 30 min after injection with a confocal laser scanning microscope (CLSM) based on the MRC 500 system (BioRad) with an excitation wavelength at 488 nm.

Bimetallic Nanoparticle Catalysts Anchored Inside Mesoporous Silica**

Douglas S. Shephard, Thomas Maschmeyer, Brian F. G. Johnson,* John Meurig Thomas,* Gopinathan Sankar, Dogan Ozkaya, Wuzong Zhou, Richard D. Oldroyd, and Robert G. Bell

There has been considerable interest in the formation, structure and further exploitation of the catalytic activity of bimetallic particles ever since Sinfelt et al.[1] demonstrated the powerful, catalytic, reforming properties of alumina-supported Ru–Cu, Pt–Ir, and Pt–Re ensembles. With the advent[2, 3] of readily preparable mesoporous solids possessing pore diameters in the range 25 to 100 Å and the feasibility[4–6] of inserting "single-site" centers that are catalytically active (such as Ti^{IV} ions anchored through Si–O bonds) in atomically well-defined locations inside such mesopores, the incentive for extending such strategies to the insertion of bimetallic nanoparticles is high. One of the key aims in this work has been the design and production of discrete, supported bimetallic particles of well-defined and tuneable atomic composition; another is to secure the clusters to the support in such a way that they are prevented from sintering.

In this communication we report: a) the synthesis and characterization of a novel Ag_3Ru_{10} complex anion $[Ag_3Ru_{10}C_2(CO)_{28}Cl]^{2-}$ (**2**) from Ag^+ ions and $[Ru_5C(CO)_{14}]^{2-}$ (**1**); b) the adsorption of **2** onto the inner walls of the mesoporous silica (MCM-41), with a pore diameter of about 30 Å,[7] together with spectroscopic proof that it retains its integrity; c) the subsequent thermolytic conversion of the bound complex $[Ag_3Ru_{10}C_2(CO)_{28}Cl][AsPh_4]_2$ (**2**) into discrete nanoparticles that have been shown (by bright-field and annular dark-field high-resolution electron microscopy and extended X-ray absorption fine structure (EXAFS)) to be firmly anchored inside the siliceous mesopores; and finally d) the performance of the nanoparticles as a catalyst for the hydrogenation of hex-1-ene.

Several important criteria influence the choice of bimetallic cluster precursor for the production of supported nanoparticles. First, the protective sheath surrounding the organometallic precursor must be readily removable (for **2** mild thermolysis is sufficient to activate and secure the bimetallic particles). Second, to ensure an even distribution of the precursor over the surface of the support the sheath must undergo favorable interactions with the functional groups on the surface, the solvent, and the counterion. The interaction with the surface must be stronger than that involved both in solvation and between the precursor species, so that aggregation into small molecular crystallites on the surface is suppressed, as these may sinter on removal of the CO sheath. Anionic carbonyl clusters[8] fulfill these criteria; their interaction with the MCM-41 surface is between the Si-OH group of the surface and the OC-M group,[9] and the intermolecular coulombic repulsion prevents aggregation prior to thermolysis. A loading corresponding to about 0.2 occupancy of the internal volume (127 mg PPN-**2** per 427 mg MCM-41) was used for both the microscopy and catalysis experiments (PPN = $^+N(PPh_3)_2$).

The selected anionic bimetallic cluster **2** was fully characterized before deposition inside the mesoporous silica. According to a single crystal X-ray analysis of $[Ph_4As]_2$-**2** (Figure 1) the dianion is composed of two $Ru_5C(CO)_{14}$ units linked by three

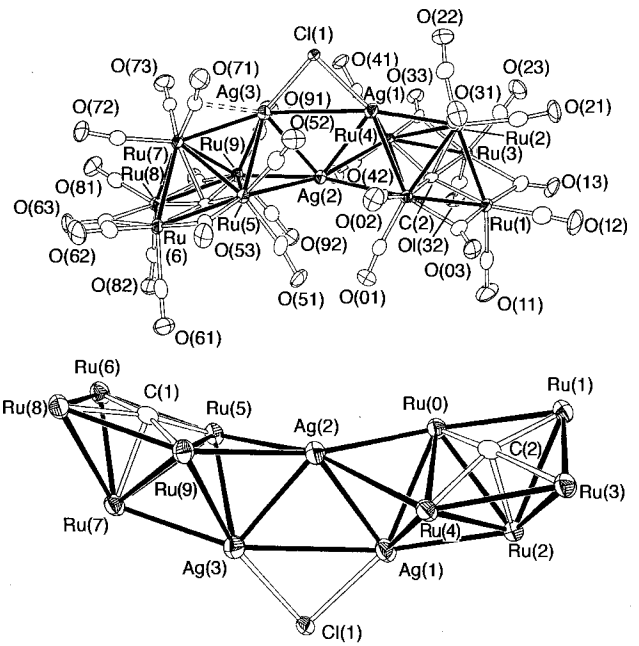

Figure 1. The molecular structure of **2** in the crystal. Top: the full dianion; bottom: $Ag_3Ru_{10}C_2$ core. Selected bond lengths [Å] and standard deviations (in parentheses): Ru0–Ru1 2.7753(10), Ru0–Ru2 2.8580(10), Ru0–Ag2 2.8587(10), Ru0–Ag1 2.9645(10), Ru0–Ru4 3.1078(10), Ru1–Ru3 2.7877(11), Ru1–Ru2 2.8296(10), Ru2–Ru3 2.8173(11), Ru2–Ag1 2.8411(10), Ru2–Ru4 2.8922(11), Ru3–Ru4 2.7708(10), Ru4–Ag1 2.8366(10), Ru4–Ag2 3.0507(10), Ru5–Ru6 2.7795(11), Ru5–Ru7 2.8669(10), Ru5–Ag3 2.9646(10), Ru5–Ag2 3.0613(10), Ru5–Ru9 3.0756(11), Ru6–Ru8 2.7633(11), Ru6–Ru7 2.8534(10), Ru7–Ru8 2.8173(12), Ru7–Ag3 2.8419(10), Ru7–Ru9 2.8852(10), Ru8–Ru9 2.8061(10), Ru9–Ag3 2.8279(11), Ru9–Ag2 2.9181(10), Ag1–Cl(1 2.501(2), Ag1–Ag2 2.8199(11), Ag1–Ag3 3.3498(10), Ag2–Ag3 2.7949(10), Ag3–Cl1 2.486(2).

silver atoms in a triangular arrangement, which is in turn bridged by a chlorine atom. The Ru–Ru contacts in the bimetallic core lie in the unusually broad range between 2.7633(10) and 3.1078(10) Å (cf. $Ru_5C(CO)_{15}$),[10] the two longest distances arising between two basal ruthenium atoms bridged by silver atoms [Ru0–Ru4 3.1078(10) Å, Ru5–Ru9 3.0756(10) Å]. Consequently the geometries of the two pentaruthenium moieties of the anion are distorted from those of regular square pyramids. The silver atoms occupy two distinct environments (see Figure 1) and form an isosceles triangle with two short sides and one long side, which is bridged by the chlorine atom [Ag1–Ag2 2.8199(11) Å, Ag2–Ag3 2.7949(10) Å, Ag1–Ag3 3.3498(10) Å].

The chemical integrity of the cluster accommodated inside the MCM-41 was established by IR (Nujol mull) and EXAFS spectroscopies (Table 1). The major bands in the infrared spectrum were somewhat broader and shifted to lower energy (by about 3 cm^{-1}), which may be due to interactions with the pore wall. The structural parameters extracted from the EXAFS analysis (Ru and Ag K-edges) correspond well to those established from the single crystal X-ray structure.

Activation and anchoring of adsorbed **2** on the MCM-41 support was achieved by heating the sample under dynamic

vacuum [10^{-4} Torr] for 1 hr at 473 K, during which the sample turned from pink to grey. Upon thermolysis, the CO-stretching region in the IR spectrum became featureless, and the interatomic distances as well as the coordination numbers changed dramatically as determined by EXAFS measurements obtained in situ in a custom made cell.[11] The K-edge EXAFS data, corresponding Fourier transformations, and calculated fits for Ru and Ag are given in Figure 2. The data were modeled bearing in mind the propensity of the bimetallic particle to contract and rearrange on losing its CO sheath. The structural parameters extracted from the analysis of the EXAFS spectra are summarized in Table 1. The Ag K-edge EXAFS data establish the bimetallic nature of the cluster, since, in addition to Ag–Ag interactions at 2.92 Å, the metal–metal distance of 2.81 Å, in between the bulk metal–metal distances for Ru-Ru (2.65 Å) and Ag-Ag (2.92 Å) is consistent with a Ag–Ru contact. Ru–Ru scattering is the dominant feature in the Ru K-edge data and the inclusion of a Ag–Ru shell does not result in a statistically meaningful improvement. However, we have been able to refine one combined model to both Ru and Ag K-edge data sets simultaneously using the XFIT (for Windows 95) suite of programs.[17] This procedure clearly confirms the presence of Ag–Ru contacts and establishes beyond doubt the bimetallic nature of the particles. This result highlights the importance and need of EXAFS measurements of both metals in bimetallic systems, as concentration on the Ru data only would not have been able to establish the bimetallic nature of the particles. In addition, the simultaneous two edge data refinement represent a major step forward in the structural elucidation of particles for which one scatterer dominates.

In addition to the metal–metal contacts, there is clear evidence of the light scatterer oxygen, in the case of Ag at a distance of 2.30 Å (close to a covalent Ag-O bond) and in the case of Ru at a distance of 2.53 Å (most likely associated with a surface oxygen, as such anchoring metal–O distances have been observed in other supported catalysts and zeolitic materials[12]). These structural features are consistent with the model of the carrier-bound bimetallic cluster shown in Figure 3, which is about 12 Å across. It should be noted that the interatomic dis-

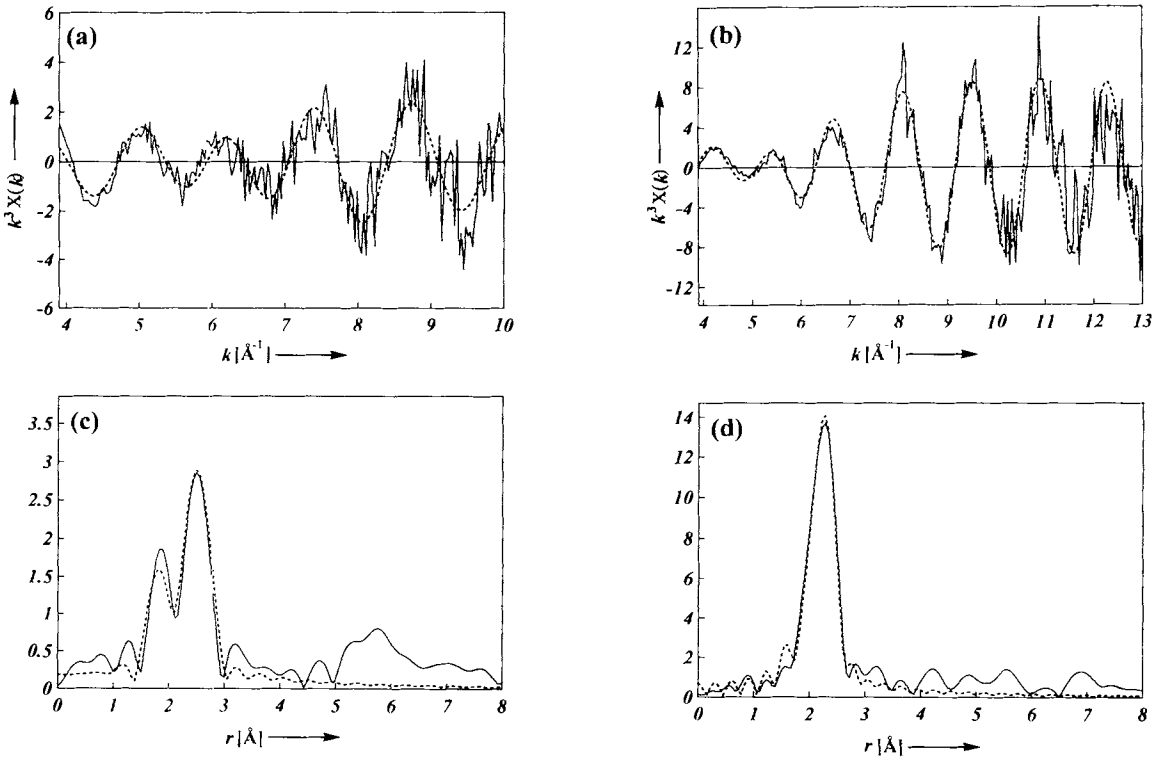

Figure 2. EXAFS data for **2** after thermolysis (Ag K-edge (a) and Ru K-edge (b)), and their Fourier transforms (Ag K-edge (c) and Ru K-edge (d)). Solid lines represent observed data, and dashed lines the fitted curves. The fits shown are obtained from simultaneous two-edge refinement.

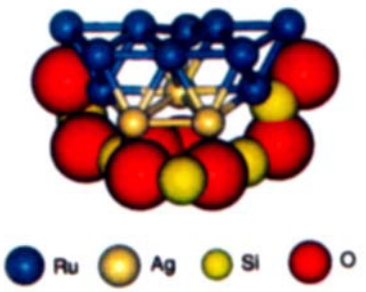

Figure 3. A possible structure of nanoparticles of the bimetallic catalyst anchored inside MCM-41 generated from **2** by thermolysis (see text).

tances of the metal atoms are larger than expected for small metal particles and approach those of the bulk metals. This may be due to the surface interaction with the particle and their bimetallic nature. Different starting clusters can yield contractions,[13] possibly pointing to different particle shapes (for example, spherical versus flat, yielding contraction and expansion, respectively).

Conventional high-resolution electron microscopy (*JEOL* 200CX TEM microscope) of the heat-treated material yielded the bright-field image shown in Figure 4, viewed perpendicular

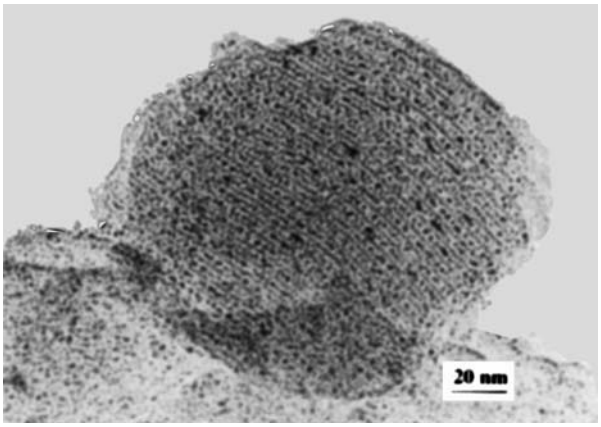

Figure 4. A bright-field HRTEM micrograph of **2** after heat-treatment showing alignment of particles (about 15 Å inddiameter) inside the channels.

to the pore axis. The uniform distribution of the bimetallic nanoparticles, aligned along the channels, is clearly discerned.[14] A scanning transmission electron microscope (STEM, *Vacuum Generators HB501* equipped with a field-emission gun) yielded the high-resolution, annular-dark-field (so-called *Z* contrast) image (Figure 5, top left) and the bright field image (Figure 5, top right). Electron-induced X-ray emission maps (Figure 5, bottom) further confirm the spatial uniformity of the distribution of the nanoparticles.[15]

The catalytic performance of the activated, supported bimetallic particles was tested for hydrogenation of hex-1-ene to hexane. Initial experiments show a high selectivity (in excess of 99%) and a turnover frequency of at least 6300 mol hexane per mol $[Ag_3Ru_{10}]$ per hour.[16]

Experimental Section

Synthesis of **2**: Reaction of $[Ru_6C(CO)_{15}]^-$ [18] with $AgBF_4$ (3 equiv) and $(Ph_3)_2NCl$ (PPN-Cl, 1 equiv) or $(Ph_3)_4AsCl$ (TPACl) in dichloromethane gave a ruby red solution within 10 min. The reaction was monitored by infrared spectroscopy in the $\tilde{\nu}$(CO) region, which showed the growth of a new set of bands at 2053 (s), 2024 (vs), 2001 (vs), and 1830 (br s) cm^{-1}. Addition of a small amount of hexane/ether gave a deep red precipitate showing the same profile in the $\tilde{\nu}$(CO) region. In a similar synthesis in which no Cl^- was added, a similar red solution was

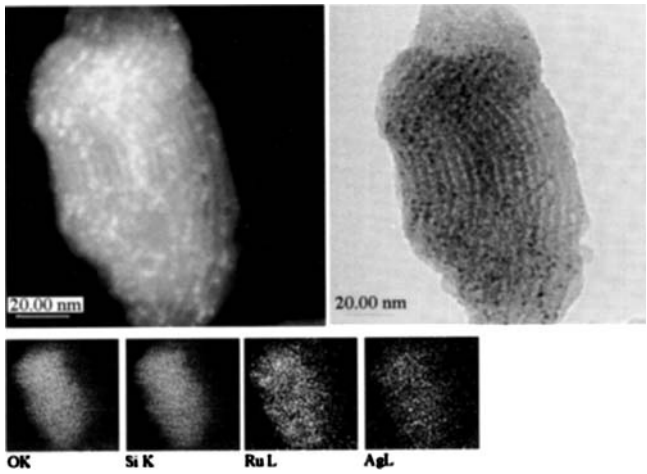

Figure 5. High-resolution annular dark-field (*Z* contrast) and bright-field scanning transmission electron micrographs (top left and right, respectively) of adsorbed PPN-**2** in MCM-41 after heat treatment at 150 °C for 1 h. Bottom: Electron-induced X-ray emission maps of the same sample.

produced; however, the resulting compound has proved difficult to isolate and characterize. Positive fast atom bombardment (FAB) mass spectrometry also showed only peaks assignable to the presence of PPN^+ or TPA^+, whilst negative FAB mass spectrometry of the PPN salt gave broad peaks at *m/z* 2718, 2550, 2178, and 2011. The highest peak was tentatively assigned to $\{[Ru_5C(CO)_{14}]_2Ag_3Cl \cdot PPN\}^-$ (calcd 2717), whilst the peak at 2178 corresponds to $\{[Ru_5C(CO)_{14}]_2Ag_3Cl\}^-$ (calcd 2178). Elemental analysis gave 31.18% C, 1.20% H, 0.00% N (calcd for $C_{78}H_{40}Ag_3As_2Cl_1O_{28}Ru_{10}$ gives 31.81% C, 1.37% H).

Crystals of the TPA salt of **2** suitable for a single crystal X-ray diffraction study were grown from a solution mixture of dichloromethane/ethylacetate into which pentane was allowed to diffuse at about 253 K. Crystal data for $[Ag_3Ru_{10}C_2(CO)_{28}Cl][Ph_4As]_2$: $C_{79}H_{42}Ag_3As_2Cl_3O_{28}Ru_{10}$, $M = 3039.63$, triclinic, space group $P\bar{1}$, $a = 14.6991(5)$, $b = 26.1473(8)$, $c = 12.7729(4)$ Å, $\alpha = 102.146(2)$, $\beta = 112.439(3)$, $\gamma = 82.522(2)°$, $U = 4429.1(2)$ $Å^3$, $\rho_{calcd} = 2.272$ $g\,cm^{-3}$, $Z = 2$, $Mo_{K\alpha}$ radiation, $\lambda = 0.71069$ Å, $\mu = 3.206$ mm^{-1}, $T = 153(2)$ K. Data were collected on a Rigaku AFC7 image plate diffractometer for an RS 3000 coated, rapidly cooled crystal of dimensions $0.40 \times 0.30 \times 0.10$ mm, mounted directly from solution (T. Kottke, D. Stalke, *J. Appl. Crystallogr.* **1993**, *26*, 615) by the θ/ω method ($3° < 2\theta < 50°$). Of a total of 23085 reflections collected, 13750 were independent ($R_{int} = 0.0642$). The structure was solved by direct methods (SHELXTL PLUS, SHELXL-93, Göttingen Univeristy, **1993**) and refined by full-matrix least-squares analysis on F^2 with $R_1(F > 4\sigma(F)) = 0.0603$ and wR_2(all data) = 0.1724. H atoms were placed in calculated positions and allowed to refine riding on their C atoms. Largest peak/hole in final difference map: 3.677/ − 2.085 e $Å^{-3}$. Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100617. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

Adsorption of PPN-**2** into MCM-41: PPN-(**2**) was slurried in ether with MCM-41 (3:10 *m/m*) for 48 h in which time the white mesoporous silica became pink in color. The ether was removed by filtration and the solid dried under high vacuum [0.01 mmHg] at ambient temperature.

HRTEM of activated **2**: The dry sample ground in air was deposited on a copper grid with a carbon film, transferred to a Jeol TEM-200CX electron microscope operating at 200 kV, and kept in the microscope vacuum overnight. The images were recorded at 49000-fold magnification.

The EXAFS data were analyzed with the XFIT (for Windows 95) [17] and EXCURVE suites of programs. The simultaneous refinement of two edges was performed with XFIT (WIN95). The S_0^2 parameters were taken from the single-edge refinements and held constant. The σ^2 parameters were constrained to be equal for the silver and ruthenium atoms. Two E_0 parameters were included in the model, one for silver and one for ruthenium. All parameters (coordination numbers, distances, E_0, and σ^2 values) were refined simultaneously. The precise fitting protocol and theoretical underpinning will be published elsewhere.

Hydrogenation of hex-1-ene: A 200 mL teflon-lined autoclave equipped with a magnetic follower was charged with catalyst (20 mg), hex-1-ene (3.0 mL), and H_2 (65 atm). The ensemble was heated to 393 K for 4 h, after which the vessel was cooled to ambient temperature, and the contents were analyzed by ^1H NMR to reveal greater than 99% conversion to *n*-hexane.

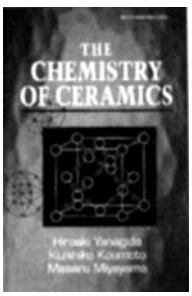
Modern Materials

The Chemistry of Ceramics. Edited by *H. Yanagida, K. Kuomoto and M. Miyayama.* John Wiley & Sons, Chichester, 1996. 263 pp., hardcover £ 19.99.—ISBN 0-471-96733

Engineering ceramics or high-performance ceramics are playing an increasingly important role in the development of new technologies, especially in the fields of microelectronics and telecommunications, automotive and turbine engineering, power generation, medical technology, and special materials such as cermets. In this book, which is an English translation of the second edition of a monograph first published in 1993, the editors' main aim was to present the basic chemistry and physics of this new class of constructional materials. The detailed engineering and technical aspects of ceramics, such as processing methods or fracture mechanics, are only touched on at an elementary level.



The work consists of just four chapters, resulting in a structure that is clear and easy to grasp. The first chapter is an introduction which explains the special importance of ceramic materials, reviews their history and the present situation, and considers the potential for future developments.

The second chapter describes the characteristic solid state structures of ceramics and glasses. The crystal structures are classified according to the coordination number and the arrangement of the ions. Point defects and dislocations, which are of fundamental importance for understanding the relevant powder processing technology and the properties of polycrystalline materials, are treated in detail. The microstructures of both dense sintered and porous materials in molded components are then described, and are related to their properties. Surface structures are discussed, first in a general way, then with special reference to thin films, fibers, and interfaces.

For a thorough understanding of solid state syntheses and the properties of the resulting materials it is essential to have a detailed knowledge of the different reactions that can occur in ceramics, especially at high temperatures. Therefore the third chapter begins by concentrating on phase equilibria, phase diagrams, and phase transformations. Diffusion and mass transport in solids, and the many different types of reactions that solids can undergo with gases or liquids, are treated in detail. These discussions then provide the basis for a section devoted to the sintering processes that play a key role in the compaction of ceramic powders, and make possible the manufacture of a variety of technologically important refractory materials. The development of suitable sintering methods has made it possible to produce a whole range of new synthetic ceramics with especially valuable properties, such as those based on barium or aluminum titanates, zirconium dioxide, silicon nitride, and silicon carbide. As well as dealing with the purely physical fundamentals of sintering, the chapter also describes the most important technological compaction processes. This part ends with a description of processes for manufacturing ceramic powders, thin films, fibers, porous structures, and composite materials.

The final chapter is devoted to the physical properties of ceramic materials in relation to their technological applications. These are discussed under the headings of thermal properties (melting point, coefficient of expansion, thermal conductivity), electrical and magnetic properties, and optical, mechanical, and chemical properties. The treatment of electrical and magnetic properties is quite detailed, but some of the other properties, such as corrosion behavior, are only covered rather superficially. A more extensive and thorough treatment of these aspects in a future edition would add further to the generally very favorable impression given by this monograph.

In its structure and content *The Chemistry of Ceramics* is an excellent textbook which provides a good treatment of the fundamental relationships between the structure and properties of modern technical ceramics. It can therefore be recommended unreservedly for chemistry students specializing in solid state chemistry, and for students of materials science subjects and applied mineralogy.

CVD of Nonmetals. Edited by *W. S. Rees Jr.* VCH Verlagsgesellschaft, Weinheim, 1996. 424 pp., hardcover DM 238.00.—ISBN 3-527-29295-0

This book is a further addition to those recently published by VCH Verlagsgesellschaft on the topical theme of chemical vapor deposition (T. Kodas, M. Hampden-Smith, *The Chemistry of Metals CVD*, 1994; A. C. Jones, P. O'Brien, *CVD of Compound Semiconductors*, 1996).

Chapter 1 is a short introduction which explains how the book should be used, and briefly summarizes the basic principles of physical and chemical gas phase deposition techniques. The reader wishing to gain a deeper insight should consult the more advanced literature listed in the bibliography. The topics treated in the main text are: superconductors (Ch. 2, D. L. Schulz and T. J. Marks), nonmetallic (transparent) conductors (Ch. 3, T. Gerfin and K.-H. Dahmen), compound semiconductors (Ch. 4, G. S. Tompa), insulators (Ch. 5, A. R. Barron), and structured ceramics and composites (Ch. 6, W. J. Lackey). The book ends with a chapter by G. E. Kräuter and W. S. Rees entitled "Other Materials", in which the authors have carefully gathered together all the topics that would not naturally fit in under any of the other headings.

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

A focus of considerable interest in this area, as in CVD methods generally, is the chemistry of the starting materials. On this aspect one is helped by the very detailed documentation that the editor has provided, with about 1230 literature references extending up to 1993/94. The book is intended for a heterogeneous readership with backgrounds in different disciplines. Thus the users are likely to include, among others, synthetic organometallic chemists, electrical engineers, and solid state physicists whose common interest is an involvement in the design and manufacture of novel types of microelectronic components.

The chapter on superconductors is especially interesting and well written. The established systems such as Nb_3Ga and Nb_3Sn are compared with the new ceramic high temperature superconductors (Section 2.4, pp. 67–132). The problems of producing these materials from organometallic precursors by CVD or VPE (vapor phase epitaxy) are discussed in detail. For example, Section 2.4.1.2 (pp. 71 ff) considers "Limitations of Alkaline Earth β-Diketonate Complexes for HTS CVD", and describes recent developments (e.g., the use of an alternative precursor for the barium component). The comparison of different methods for introducing the relatively involatile precursors (β-diketonates and β-ketoiminates) is well worth reading. The following section, "Conducting Materials", is mainly concerned with TiN, In_2O_3, SnO_2, and ZnO. There is an interesting and useful description of the recently clarified mechanistic details of the breakdown of the tetrakis-dialkylamidotitanium precursor to give TiN or TiN_xC_y, a reaction which depends critically on the process conditions (thermal CVD with or without NH_3, or plasma methods). This part of the book is highly recommended; it is well structured and carefully written, and is ideally suitable to be adapted for use in undergraduate courses related to materials chemistry. Aspects such as the interaction between the surface and the chemistry of the gas phase, the effects of different process conditions (reactor type, means of energy supply), positionally selective deposition, prenucleation in the gas phase, purity, electrical and morphological properties, mechanisms that incorporate carbon, transamination, labeling studies, and plasma chemistry, are treated concisely but thoroughly. For completeness CVD of compound semiconductors is briefly discussed in Chapter 4. However, this subject is already covered by some other excellent monographs (examples are those mentioned above and: G. B. Stringfellow, *Organometallic Vapor Phase Epitaxy*, Academic Press, 1989). The book does not cover new trends in the chemistry of precursors. Chapter 5 deals with the important topic of the deposition of electrically insulating layers, and also extends the analogy to discuss "chemically insulating" films, such as diffusion barriers and passivating layers. The materials discussed include SiO_2, Al_2O_3, AlN, and Si_3N_4.

Chapter 6 describes methods for deposition from the gas phase onto ceramic fibers and various types of composites, for example porous materials treated by chemical vapor infiltration. Here again the deposited materials are mainly oxides of aluminum, zirconium, and tin, and in some cases SiC. Thus, from the chemical point of view there is little here that is new. Instead the emphasis is on aspects such as reactor design, a very detailed description of the processes involved, and the analysis of the morphology and materials properties of the layers produced.

Chapter 7, which occupies the last 20 pages of the book, presents an interesting collection of research results taken from the widely scattered sources in the literature. These relate to a wide variety of deposited substances, from metal fluorides via metal carbides to metal tellurides.

On the whole the book has been carefully written and produced. However, the quality of the figures is not consistently good, and a few are disappointingly crude in appearance; for example one may contrast Figure 1-3 with Figure 6-1. It is also noticeable that the literature coverage only extends to about 1993/94, and is mainly concentrated within the years 1988 to 1993. There are scarcely any references to more recent developments from 1995 onward. Nevertheless, the work is a useful additional resource, both for molecular chemists with an interest in this field and for users of vapor deposition, and will provide them with quick and convenient access to the literature on CVD of nonmetals.

Roland A. Fischer
Anorganisch-chemisches Institut
der Universität Heidelberg (Germany)

Introduction to glass science and technology. By *J. E. Shelby*. Royal Society of Chemistry, Cambridge, 1997. 244 pp., paperback £ 18.95.—ISBN 0-85404-533-3

This book, written by a well recognized glass scientist, is intended as an introduction for students or beginners. The material is limited to what can be covered in a single semester of course work, and assumes no more than a general knowledge of physical and inorganic chemistry. Depending on the extent of prior knowledge, the reader will therefore find that some chapters can be read more quickly than others. Each of the ten chapters of the book, with one exception, ends with a concise summary. The bibliography is necessarily short, due to the brevity of monography although somewhat one-sided, and the index is sufficiently detailed.

The first two chapters deal with the principles of glass formation and glass melting, including technological aspects such as the formation of bubbles or inhomogeneities. Immiscibility and phase separation is discussed in a separate chapter. The attempt to elaborate the structures of glasses in only 37 pages is obviously only possible in a very limited way. Although the author emphasizes that he wants to restrict himself to general principles (including the trivial statement: "... the author now proposes the Fundamental Law of Structural Models: 'no model can be considered to be valid unless that model can explain *all* of the available data' "), he does not always meet this claim, and sometimes loses himself in details that are out of place in a book of this kind. For example, there are mini-subchapters on rare earth alumino/galliosilicate glasses, fluorogermanate glasses, and $ZnCl_2$ glasses. Instead a little more space could have been allocated to the treatment of organic and metallic glasses, which are given only half a page each. The viscosity of glass-forming melts is treated in a fairly general way in the following chapter, which also includes a section on viscosity measurement techniques. The next chapter discusses the influence of composition, thermal history, phase separation and crystallization, radiation exposure, and pressure on the density and thermal expansion behavior of glasses. Under the heading "Transport Properties", a concise general introduction to the fundamentals of diffusion is followed by discussions of ionic diffusion, ion exchange, ionic conductivity, chemical durability, weathering, gas permeation, and diffusion. In the chapters on mechanical and optical properties a more detailed discussion of how these are related to the structure and composition of glasses would have been desirable. The title of the final chapter, "Glass Technology", is rather misleading, as it deals with forming methods. Its 12 pages are definitely insufficient to give more than a rough overview. For example, the one page on sol–gel processing is hardly enough to give the uninformed reader a clear impression of this method.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3620-2248 $ 17.50+.50/0

In summary, the author has succeeded in writing a comprehensible introduction to glass science. The diagrams are clear, and the use of physical and chemical formulas is restricted to an essential minimum. Of course, one can have different opinions on the weighting of the different topics in such a book. The book cannot be recommended as a *textbook* on glass, but, in accordance with the intentions of the author, as an introductory overview dealing with all important aspects.

Chemistry of Powder Production. (Series: Powder Technology.) By *Y. Arai.* Chapman & Hall, London, 1996. 281 pp., hardcover £ 69.00.—ISBN 0-412-39540-1

This book is an English translation of the original Japanese version published in 1987. Consequently it does not cover the latest methods for the production and characterization of powders, but describes conventional and well-established methods. The book can therefore best serve as an introduction to powder technology, which now plays an increasingly important role in the manufacture of high-performance materials such as polymers, metals, and ceramics. Materials in powder form are also important in the areas of pharmaceuticals and agricultural products. A large proportion of modern industrial manufacturing involves the production and processing of raw materials in powder form.

The book consists of five chapters covering the basic principles of the production of powders and measurements of powder properties. The main part of the contents is arranged under three subject areas: the physical properties of powders (Chapter 3), the production of powders (Chapter 4), and methods for the measurement and analysis of powder properties (Chapter 5).

Chapter 1 is an excellent introduction, which begins by discussing what is meant by a powder, and goes on to give a definition. According to this, powders can be regarded as a fourth state of matter alongside the three aggregated states: gas, liquid, and solid. The powder state has features in common with all the latter three. The essential differences between a powder and a bulk solid are discussed in terms of their characteristic physical properties. Lastly, the author explains the distinction between powders and granular materials on the basis of their typical particle size ranges.

Chapter 2 discusses powder specifications by considering various examples: ceramic sintering powders, powders for magnetic applications (e.g., sound recording), and pigment powders for use in plastics, paints, and paper. The different combinations of properties needed for each of these three areas of application are described. In each case the author explains how the critical properties of the powder (e.g., sintering behavior, magnetic induction at saturation, coloring power) are affected by the size and/or shape of the particles.

Chapter 3 is concerned with the fundamental physical properties of powders. The main aspects treated are particle size, structure, surface energy, and surface properties such as adsorption behavior, wettability, and catalysis. Mechanochemistry, i.e. the influence of mechanical energy input on the physical and chemical properties of powders, is also included here.

Chapter 4 deals with methods for manufacturing powders. A distinction is drawn between purely physical processes, such as comminution or milling, and the thermal decomposition of inorganic or organic metal salts to yield finely-divided ceramic powders, where the chemical decomposition reactions determine the constitution of the product. Another important topic discussed is the precipitation of solids from liquid phases (especially solutions). The chapter deals with the mechanistic details of nucleation, or of processes where a precipitate is laid down on a substrate, as well as crystal growth, hydrolysis of metal alkoxides, and hydrothermal reactions. Next the author discusses the production of powders by gas phase reactions, with special attention to the thermodynamics of the formation of oxide and non-oxide powder particles from the gas phase. The chapter ends by considering the internal structure of the solid phase, and discusses solid state reactions, a fundamental understanding of which is important in the production of ceramics from powders.

Having thus dealt with the production of powders, the final chapter is devoted to their properties, which are of crucial importance for technological applications. The physicochemical methods used for studying the properties of powders are discussed in detail. The central topics are particle size analysis and the measurement of surface properties (wetting energy, surface energy, heat of adsorption, zeta potential, and surface activity).

Considering the book as a whole, its special virtues are the orderly arrangement of the material and the easily understandable presentation of the main features. At the end of each chapter is a list of references which includes the most important original papers on the subjects covered. However, it is unfortunate that the chapters are not as up-to-date as they should be. If the translation from the Japanese had been combined with a thorough revision and enlargement, the result would have been an up-to-date standard work of great value for both teaching and research. Bearing in mind this limitation, the book can be recommended mainly for advanced or postgraduate students of chemistry, mineralogy, or materials science, who wish to learn about the fundamentals of powder technology, and more particularly about the production, characterization, and properties of inorganic powders.

Ralf Riedel

Darmstadt (Germany)

Hydrocarbon Resins. By *R. Mildenberg, M. Zander* and *G. Collin.* WILEY-VCH, Weinheim, 1997. 179 pp., hardcover DM 198.00.—ISBN 3-527-28617-9

Synthetic hydrocarbon resins consist of rather complex oligomers and monomers which are derived from coal tar, cracked petroleum, and turpentine feedstocks. Such resins—frequently consisting of complicated reaction products and blends of numerous compounds—find many applications in formulated multicomponent systems such as adhesives, coatings, printing inks, packaging, sealants, paints, wood protection treatments, surface modification treatments, foundry industry chemicals, mineral oil additives, flooring, etc.

The authors of the book *Hydrocarbon Resins* have compiled information about raw materials, production processes, methods of characterization, and chemical and physical properties of hydrocarbon resins, excluding natural resins. Special emphasis is placed upon applications and opportunities for improving performance of formulated products in specific end uses. The aim of the book is to provide background information on hydrocarbon resins for chemists, engineers, applications technologists, and sales personnel, who are concerned with production and quality control of products involving hydrocarbon resins.

The book is organized in nine chapters: 1. terminology (2 pp.); 2. raw materials

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3620-2249 $ 17.50+.50/0

for the manufacture of resins such as indene–cumraone resins, petroleum-based resins, dicyclopentadienes, or polyterpenes (14 pp.); 3. resin manufacture including resin modification (21 pp.); 4. resin structure and properties (34 pp.); 5. applications (80 pp.); 6. chemical composition and resin selection (6 pp.); 7. quality and quality assurance (2 pp.); 8. toxicology and legal aspects (4 pp.); 9. economic aspects (4 pp.). Instead of writing a concise manual, the authors have preferred to summarize their extensive practical experience. The applications section describes some specific formulations, and offers advice on incorporating hydrocarbon resins in formulated products.

In conclusion, this very specialized book represents a valuable asset for everybody who does not have hands-on experience with hydrocarbon resins and is planning to exploit the potential of hydrocarbon resins in formulated systems or to solve quality control problems. Unfortunately, there are only 46 literature references, which is not adequate to give access to more detailed information on specific topics.

Rolf Mülhaupt
Institut für Makromolekulare Chemie
der Universität Freiburg (Germany)

Chemometrics in Environmental Analysis. By *J. W. Einax, H. W. Zwanziger* and *S. Geiss*. WILEY-VCH, Weinheim, 1997. 384 pp., hardcover DM 238.00.—ISBN 3-527-28772-8

Chemometrics is a relatively new discipline that is undergoing great developments, not least in its applications to environmental analysis using automated multielement and multicomponent instrumental methods. Modern analytical techniques generate a vast amount of data, and to digest this and arrive at a description of complex environmental processes requires powerful mathematical and statistical methods. For this reason, chemometrics is important to everyone working in the area of environmental analysis.

From the first chapter the reader learns that chemometrics may be defined as a chemical discipline in which mathematical and statistical methods are used to design measurement procedures and experiments or to choose the best alternatives, and then to analyze the resulting data so as to extract the maximum amount of chemical information. From this definition one can already form a first impression of the potential applications of chemometrics.

The book is divided into two main parts. The first part consists of five chapters that are essentially concerned with methods, dealing with the mathematical fundamentals of chemometrics and illustrating these with examples from environmental analysis. The second part (four chapters) is more problem-orientated, and describes applications of chemometrics, dealing in turn with specific types of problems related to the interpretation of analytical data or with sampling strategies.

About one-half of the first part is devoted to methods for the analysis of multivariate data and of time series. As well as graphical methods such as box–whisker plots, Chernoff diagrams, and time series plots, the authors describe in detail the most important mathematical methods (cluster analysis, principal components analysis, factor analysis, multivariate variance analysis, smoothing and filtering, regression and correlation techniques, ARIMA modeling, etc.). The methods are illustrated and put into a practical context by including examples of applications in environmental analysis, with numerical data (e.g., comparative studies of analytical results from different laboratories, or the variation with time of the nitrate concentration in a drinking water reservoir). This makes the book especially interesting for the analyst who has not yet begun to make serious use of chemometrics.

This first part also familiarizes the reader with all the important aspects of the statistics of experimental data, factorial and sequential design of experiments, and the planning of sampling procedures. Designing a system to give truly representative sampling is a very important aspect of environmental analysis, and accordingly it is considered in more detail, with up-to-date practical examples, in the second part.

The second part of the book, entitled "Case Studies", has separate sections devoted to the three main environmental matrices: atmosphere, hydrosphere, and pedosphere. These are followed by a further section on the applications of chemometrics in food research and in optimizing an analytical method. Each section begins by describing a topical problem in environmental analysis, then explains how various chemometric methods can be used to plan the sampling procedure, analyze the data output, and interpret the results. The chapter on the pedosphere (soil) contains a discussion of the problems that arise in studying the deposition of heavy metals, including the planning of methods for representative sampling, the minimum number of samples needed, and comparing the burden of pollutants at different sites. The chapter describes how these problems are approached using chemometric methods such as principal components anaysis, MANOVA, and discrimination analysis. From this part of the book the reader gains an appreciation of the scope of chemometrics, and is prompted to refer back to the first part to learn more about the methods applied here.

Each chapter includes a list of references, extending up to 1995 in most cases. This should be useful also for readers who already have a good knowledge of chemometrics.

In summary, this is a very clearly written and easily readable book. The typesetting is clear, including the mathematical formulas, and the figures help the reader's understanding, although they are not of a uniformly high quality. It can be thoroughly recommended for all analytical chemists who wish to learn about chemometrics and its applications to environmental analysis, without having to work only through a rigorous mathematical description of the methods.

Christian Zwiener
Engler-Bunte-Institut der Universität
Karlsruhe (Germany)

Inorganic Chemistry. An Industrial and Environmental Perspective. By *T. W. Swaddle*. Academic Press, San Diego, 1997. 428 pp., hardcover $ 65.00.—ISBN 0-12-678550-3

Writing a new book on inorganic chemistry is an ambitious task, as there are already such a large number of comprehensive treatments of the subject. Nevertheless, Thomas W. Swaddle has set out to do just that. He teaches as Professor of Inorganic Chemistry at the University of Calgary (Canada), and this is his second book on the subject. Although it was originally conceived as a textbook for undergraduates, the author intends that in its now completed form it will also enable a broader public to appreciate the role of inorganic chemistry in modern life and its importance for industry and care of the environment, as well as being a convenient reference source for scientists, technologists, and students.

The 19 chapters cover a wide range of topics in general and inorganic chemistry. As well as explaining important concepts of thermodynamics and kinetics, the book contains several rather theoretically oriented chapters discussing the crystal structures of metals and salts, the main types of defects present in non-ideal solids, and some aspects of electrochemistry and complex chemistry. The author

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3620-2250 $ 17.50+.50/0

then builds on this basic knowledge by describing the types of inorganic reactions that occur and their practical applications, such as the separation and refining of metals, corrosion and corrosion protection, the principles of batteries and fuel cells, and the manufacture of industrial diamonds. The reader is introduced to topics such as zeolites and their uses in washing powders and as catalysts, and to inorganic fertilizers, building materials, and different types of explosives, to mention just a few examples. Catalytic processes are discussed in detail in the chapters on "Inorganic Solids as Heterogeneous Catalysts" and on "Organometallics". Some examples of other topics covered in the book are water treatment processes, the greenhouse effect, the depletion of the ozone layer caused by the use of CFCs, and technologies for reducing emissions of sulfur and nitrogen oxides in flue gases.

The standard of writing and production is excellent. The principles are clearly explained and are illustrated by interesting examples. Consequently the book makes agreeably easy reading and invites browsing. At the end of each chapter there are some exercise problems and a very comprehensive list of references for further reading, enabling the reader to build on the foregoing material. On the other hand, the discussions are often rather superficial and seldom go much beyond providing a basic knowledge. The choice of topics seems a little haphazard and could not be described as comprehensive. The reader seeking an overview of the most important compounds of a particular element, or of the different processes for manufacturing a given product, will be disappointed in many cases. Moreover, finding such information is made more difficult by the fact that the material is not arranged under elements or compound classes. For example, α-sulfur (S_8), polysulfanes, and polythioacids appear in Chapter 3 ("Catenation: Inorganic Macromolecules"), oxides of sulfur in Chapter 8 ("The Atmosphere and Atmospheric Pollution"), and sulfates in Chapter 9 ("N, P and K in Agriculture"). The manufacture of sulfur and sulfuric acid is described in Chapter 10 ("Sulfur and Sulfur Compounds"), but the main emphasis in this chapter is on paper manufacturing processes based on sulfur compounds. Lastly we find sulfides in Chapter 17 ("Extractive Metallurgy"). Many inorganic substances, including some that are of great technological importance, are not covered at all. Thus, although Chapter 3 treats diamond and the fullerenes in great detail, some other forms of carbon such as graphite and carbon black are mentioned only briefly or not at all.

To summarize, this book can provide the newcomer to inorganic chemistry with a good first insight into a variety of interesting topics, but it cannot be recommended as a comprehensive textbook nor as a work of reference.

Steffen Hasenzahl
Degussa AG, Hanau (Germany)

NMR Data Processing. By *J. C. Hoch* and *A. S. Stern*. John Wiley & Sons, Chichester, 1996. 196 pp., hardcover £ 50.00.—ISBN 0-471-03900-4

Pulsed nuclear magnetic resonance spectroscopy generates time domain signals that have to be transformed to obtain a spectrum. The present book shows in a convincing manner that there are other ways of doing this besides the usual Fourier transformation, and that they can sometimes even yield better results.

The book begins with a flashy introduction about NMR signal processing, featuring Richard Ernst, 26 years before his Nobel Prize award, performing the first pulsed Fourier transform NMR measurement. It is pointed out that the signal processing methods now used in multidimensional NMR spectroscopy have only become possible as a result of the breathtaking development of computer performance during the last 20 years. The time domain signal or free induction decay (FID) is then introduced.

Chapter 2 deals with the fundamentals of digitization in the time and amplitude domains in the context of Fourier transformation, and introduces all the important concepts such as the Nyquist frequency, aliasing and folding, and Parceval's theorem, which are discussed using only a minimum of mathematics. The fact that the FID and the spectrum form a Fourier pair has a number of important consequences that are discussed. These include, for example, the relationship between sampling rate and spectral range, the equivalence between phase correction in the spectrum and a shift of the time coordinate in the FID, and between convolution of the spectrum and multiplication of the FID by a time-dependent function, and the Hilbert transform which, when applied to the real component of the spectrum, allows one to restore the imaginary component (provided that no information has been discarded). This chapter is really great for the reader who wishes to understand how Fourier transformation works, without having to deal with more mathematics than is absolutely necessary.

Chapter 3 gives some examples, with special emphasis on zero-filling and apodization. The different functions that can be used, and their relative merits with regard to resolution versus signal-to-noise enhancement, are discussed. Some topics that have only come into prominence quite recently, such as oversampling, are also covered. Phase correction, quadrature, baseline, and solvent-induced artifacts are treated at length. However, modified pulse sequences for reducing such artifacts are only mentioned briefly, as detailed treatments would be beyond the intended scope of the book. There is also a subchapter dealing with the transformation of multidimensional data.

In Chapter 4 we move on to non-FT methods of signal processing, which have now been in use for over ten years. One such method is linear prediction, which again is introduced with only a minimum of mathematics. The underlying principle is explained and the most important equations are given. The two alternative modes of linear prediction are described. In the first of these, linear prediction of the FID in the forward or backward direction is used to generate a new FID which, after conventional Fourier transformation, yields a spectrum with improved resolution, and possibly also improved signal-to-noise ratio. The second mode is the direct evaluation of the spectrum by linear prediction (parametric approach). The most important recipes are discussed (least squares, Hankel–SVD method, minimum variance estimate, Burg method). The chapter could profit from the inclusion of more figures; for example, the regularization could have been explained more clearly with the help of a figure. Another criticism is that only one example is given to show the result of applying linear prediction to a two-dimensional COSY experiment. The fact that linear prediction is widely used in multidimensional NMR spectroscopy is not obvious from this book.

Chapter 5 is devoted to the maximum entropy reconstruction method (MaxEnt), an area in which the authors are themselves actively involved. The method is introduced using a lot of mathematics in a concise form. The underlying principle, in which a synthesized spectrum is fitted to match the experimentally observed FID, is clearly explained. The many examples will be a valuable aid for the reader who is mainly interested in the application of the MaxEnt method. In contrast to apodization methods and Fourier transformation, the MaxEnt method can achieve an increase in the signal-to-noise ratio at the same time as improving the

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3620-2251 $ 17.50+.50/0

resolution. This seemingly paradoxical situation is explained with the help of examples. MaxEnt is able to make use of preknowledge about the spectrum, such as the expectation of a particular line shape or of certain coupling constant values, and provides deconvoluted spectra accordingly. This is also possible in principle with FT methods, but in that case it would amount to division of the FID by the time domain function of the known spectral feature, and in many cases the result would be numerically unstable due to a division by zero. MaxEnt, by contrast, compares the spectrum with the FID, so that the procedure amounts to multiplying the time domain function of the spectrum by that of the known spectral feature, thereby avoiding such numerical instabilities. The chapter also contains many examples illustrating how the MaxEnt treatment can overcome problems of truncated FIDs, poor resolution, and low signal-to-noise ratio. Finally, the potential advantages of nonlinear sampling of the FID are discussed. Nonlinear sampling is not compatible with the FT method, but with MaxEnt reconstruction it becomes possible, since the FID is compared with the time domain function of the spectrum (a feature which also allows one to deal with partially corrupted FIDs). Nonlinear sampling is recommended for acquisition of multidimensional data that achieve good resolution.

Chapter 6 describes some emerging methods that have not yet entered the practice of NMR spectroscopy. Those discussed include "iterated soft thresholding", "smoothing by wavelets", and Bayesian techniques. However, it is not clear why the latter methods should be included under this heading, as they are already in use.

Finally, Chapter 7 reviews procedures for the visualization of the results of data processing, for extracting quantitative data, and for error analysis. This chapter is not well integrated with the main body of the book. However, it contains valuable information about matters such as the pitfalls of integrating peak areas in multiple dimensions, the use of color in plotting results, and suggestions for error analysis as applied to peak integrals, peak positions determined from spectra, etc.

Altogether the book is easy to read, and is valuable for NMR spectroscopists who wish to learn more about the processing of the data. It covers all the modern approaches that are available in commercially available software packages, and will help inexperienced users to apply them. The examples are mainly from solution state NMR, but the spectroscopist using high-resolution solid state techniques will find the book equally beneficial. I can therefore recommend it for all NMR laboratories as an aid to ensuring that the data generated are processed in the most effective way.

Christian Griesinger
Institut für Organische Chemie
der Universität Frankfurt a. M.
(Germany)

Handbook of Palladium-Catalyzed Reactions. By *J.-L. Malleron, J.-C. Fiaud,* and *J.-Y. Lagros.* Academic Press, San Diego, 1997. 304 pp., in ring-binder with demo diskette £ 50.00.—ISBN 0-12-466615-9

Transformations catalyzed by palladium are among the most important of all organometallic reactions. Many highly efficient syntheses based on palladium-catalyzed reactions have been developed during the last 30 years. Some important examples are the allylic alkylations due to Trost and Tsuji, and the palladium-catalyzed cross-coupling reactions developed by Heck, Stille, Negishi, and Suzuki. The versatility of palladium-catalyzed reactions is of interest not only for use in basic research (asymmetric catalysis, etc.) but for enabling the synthetic chemist to prepare classes of compounds that present difficulties due to their complexity or sensitivity. This handbook is intended mainly for those wishing to carry out syntheses using such reactions.

The work is based on a palladium data base covering more than 3000 publications (there is an accompanying demo diskette), which was originally set up by one of the authors, Dr. J.-L. Malleron of Rhone-Poulenc-Rorer. The actual handbook contains over 2500 literature references (extending up to November 1995), which relate to 84 different palladium-catalyzed reactions. For convenience these reactions (numbered RXN1 to RXN84) are not only listed in the table of contents but are shown in a diagrammatic form and cross-referenced to the list, so that the reader can find a desired reaction very quickly. The detailed descriptions of the individual reactions are linked to the latter system. First the reaction mechanism (taken from a recent publication) is shown diagrammatically, and this is followed by data on the reaction itself (substrate, substitution pattern, nucleophile, leaving group, etc.). For the more complex reactions a detailed reaction scheme is usually shown. This allows the reader to pick out the most interesting example from his or her standpoint, and to obtain additional information from the cited literature as necessary.

This handbook can be thoroughly recommended for everyone concerned with palladium-catalyzed reactions.

Database of Palladium Chemistry. Reactions, Catalytic Cycles and Chemical Parameters on CD-ROM. By *J.-L. Malleron* and *A. Juin.* Academic Press, San Diego, 1997. $ 875.00.—ISBN 0-12-466760-0

The complete version of the *Database of Palladium Chemistry* is a collection of data on the best known catalytic reactions of organopalladium chemistry. It covers the literature up to May 1996 and lists 3481 reactions, classified under 85 reaction types. This review is based on a demo version of the database containing just a representative sample of the reactions that are included in the full version of the data bank, while offering the user the same facilities.

The user can access the data bank in three different ways as described in detail below.

a) In the first mode nothing is specified. One obtains a list of all the available reactions, which can then be worked through in sequence. However, considering the large number of reactions listed, this method is hardly suitable as a way of searching for information on special topics.

b) As a second alternative one can specify a given type of reaction, which produces a list of reactions that one can then search through for information on the aspect of special interest. For each reaction one obtains key information in a clearly set out form. Thus, one sees at a glance the reaction scheme, the solvent used, the catalyst and ligands (but no clear explanation of the abbreviations used for the ligands, at least in the demo version), the reaction conditions, and the yield. There are also comments on the reaction, which contain information about the purpose of the investigation, any other examples that are known, and relevant review articles if these exist. The picture is completed by a reference to the original

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3620-2252 $ 17.50+.50/0

publication describing the example of the reaction. In addition it is possible to request information about the catalytic cycle on which the reaction is based and the relevant reaction parameters (substrate, substitution pattern, nucleophile, leaving groups, etc.). The catalytic cycle and the list of reaction parameters can also be found in identical form in the *Handbook of Palladium-Catalyzed Organic Reactions*.

c) Probably the most effective way of using the data bank is by means of the various search facilities that are provided. These allow one to specify keywords relating to the solvent, catalyst, reaction conditions, ligands, yield, and authors. By carrying out a search with two or more simultaneous criteria one can limit the number of matching reactions that it produces and thus arrive more quickly at the required data. One can also perform a search in which these criteria are combined with a chosen reaction scheme described by using the ISIS/Draw facility. In fact, however, it is often advantageous to use such a reaction scheme by itself, either by searching directly for the reaction that the scheme depicts, or by carrying out a search to list all those reactions in which the structures of the educt and product are present as subunits. In another type of situation one's interest might lie not in a particular reaction but in reactions that involve a given substrate. In that case the program allows one to specify the substrate structure together with a reaction arrow and obtain a list of all reactions in which that structure is present, either in its own right or as a subunit. In a similar way one can also carry out a search to find a synthesis giving a particular product.

Thus, the *Database of Palladium Chemistry* provides a toolkit that affords the user rapid access to important information of all kinds. Furthermore, the data bank is to be kept up-to-date by continually adding new reactions, typically at a rate of 500–700 each year. That prospect will be of great interest to everyone concerned with organopalladium chemistry.

Protein and Peptide Analyis by Mass Spectrometry. Edited by *J. R. Chapman*. (Series: Methods in Molecular Biology, Vol. 61.) Humana Press, Totowa, 1996. 350 pp., hardcover $ 69.50.—ISBN 0-896-03345-7

J. R. Chapman has already edited several successful books on mass spectrometry. The present book of 21 chapters is concerned with applications of modern mass spectrometric methods to the analysis of proteins and peptides.

In the first, introductory chapter P. Roepstorff gives a short summary of the past and present development of mass spectrometry. Here also the work of the late Michael Barber, 'father' of FAB ionization, to whom the book is dedicated, is honored. Then follows an introduction to mass spectrometry by Chapman, in which soft ionization methods, mass analyzers, and modern techniques such as MS/MS are explained.

The choice of the topics of the subsequent chapters is well balanced and covers many current analytical problems in protein chemistry. However, special problems of synthetic peptide chemistry, such as the characterization of synthetic peptides or analytical problems of combinatorial chemistry, are not discussed. Some of the topics dealt with in detail are the determination of the primary structure of proteins by tandem mass spectrometry, by low- and high-energy CID, PSD or ladder sequencing, mass spectrometric fingerprinting for the identification and characterization of proteins, determination of post-translational modifications (determination of the disulfide bridges), and the analysis of glycopeptides and protein conjugates. Also quantitative aspects are discussed in one chapter (quantitative analysis of neuropeptides). Further chapters deal with the secondary structural analysis of proteins, the determination of noncovalent (supramolecular) interactions of proteins, the computer-assisted analysis of mass spectra, and the identification of proteins by means of protein databases.

Since the chapters have been written by different authors (all of whom are recognized experts in the field of biochemical mass spectrometry), one might expect some overlapping and repetition. Fortunately, however, this is not the case. The individual chapters are on different and well-demarcated topics, and repetitions are rare (one of the few exceptions: a table containing the masses of the amino acid residues appears both in Chapter 12 and in Appendix III).

In accordance with their increasing importance for protein analysis, the two modern soft ionization techniques of electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI) are treated most thoroughly. Nevertheless, the classical methods such as SIMS und FAB have not been forgotten.

As usual for books of the series *Methods in Molecular Biology*, each chapter is organized in sections entitled 'Introduction', 'Materials', 'Methods', and 'Notes'. These sections contain much advice and many practical tips, so that the scientist with the required analytical equipment at his disposal can put the particular method into practice right away in his own laboratory. At the end of each chapter is a bibliography, which also, commendably, includes very recent literature (up to the year 1996). In addition the appendix contains over 180 further references, most of them from 1995.

The text is well illustrated by numerous figures and tables and contains only a few typing errors (e.g., p. 322, 'Vat' instead of 'Val'; p.327, 'Tryp' instead of 'Trp'). The subject index could be more detailed. Some terms, such as 'FTMS' or 'ion trap', which occur in the text, are not listed here.

The book provides the protein chemist with comprehensive information about the capabilities of modern mass spectrometry for biopolymer analysis. Because it is also helpful for practical applications in the laboratory (for example in explaining which detergents interfere with the analysis of proteins by ESI-MS), it can be recommended unreservedly for all scientists working in the field of protein chemistry. Before one picks up this book, however, one should take seriously the warning that Chapman gives in the preface: 'the use of mass spectrometry might be habit-forming'!

The chiroptical contributions from the chiral addition pattern of higher fullerenes greatly dominate those from the chiral addends, as shown by CD spectra of the diastereoisomeric bis-adducts formed in the reaction of bis[(*S*)-1-phenylbutyl] 2-bromomalonate with C_{70} in the presence of base.

The Covalent Chemistry of Higher Fullerenes: C_{70} and Beyond

Carlo Thilgen, Andreas Herrmann, and François Diederich*

Dedicated to Professor Dieter Seebach on the occasion of his 60th birthday

Although higher fullerenes are not yet available in larger amounts, their accessibility, like that of C_{60}, has gradually improved since the early days of fullerene chemistry. Today, many of the soluble larger carbon cages can be purchased either in pure form or as isomeric mixtures. In particular, pure C_{70} is available in preparative amounts from fullerene soot without the need for tedious separation by high-performance liquid chromatography; this has had a major impact on the progress of the chemistry of this higher fullerene. Over the last years C_{70} has been functionalized in many ways, and pure derivatives of even the larger, more complex carbon spheres C_{76}, C_{84}, and recently also C_{78}, have been isolated and characterized. From the collected body of data, first general principles of reactivity and selectivity begin to emerge for these fullerenes, which are all less symmetric than C_{60}. Important information is provided by multiple additions to higher fullerenes, in which certain isomers are formed with a remarkable selectivity that exceedes that observed for C_{60}. A particularly attractive aspect is the chirality of certain allotropes and many derivatives. Although the chirality of fullerene derivatives is not restricted to the larger carbon cages, it was sofar mostly explored through their chemistry and can be related to different structural characteristics. A recently proposed system allows simple specification by a single descriptor of the configuration of chiral fullerenes and fullerene derivatives with a chiral functionalization pattern, including highly branched carbon frameworks with a multitude of possible stereogenic centers.

Keywords: carbon allotropes · chirality · fullerenes · reactivity

1. Introduction

Shortly after the discovery of the bulk fullerene soot production process by Krätschmer, Huffman, and co-workers[1] and the isolation of macroscopic quantities of C_{60} and C_{70}, evidence for soluble carbon molecules with more than 70 carbon atoms was obtained.[2] Together with C_{70}, these homologues of C_{60} are designated as "higher fullerenes". Isolation of single species proved to be difficult due not only to their structural similarity and the occurrence of isomerism, but also to their low abundance in the soot.[3, 4]

Whereas simple protocols are available for isolating pure C_{60}[5, 6] and C_{70},[7] separation of higher fullerenes is based on multistage chromatography.[2–4] Currently, pure species are available in quantities of up to 100 mg by high-performance liquid chromatography (HPLC) of fullerene-soot extract that has been previously depleted of most of the far more abundant C_{60} and C_{70}.[8, 9] The first isolation of D_2-C_{76}[10] and C_{78}[11],

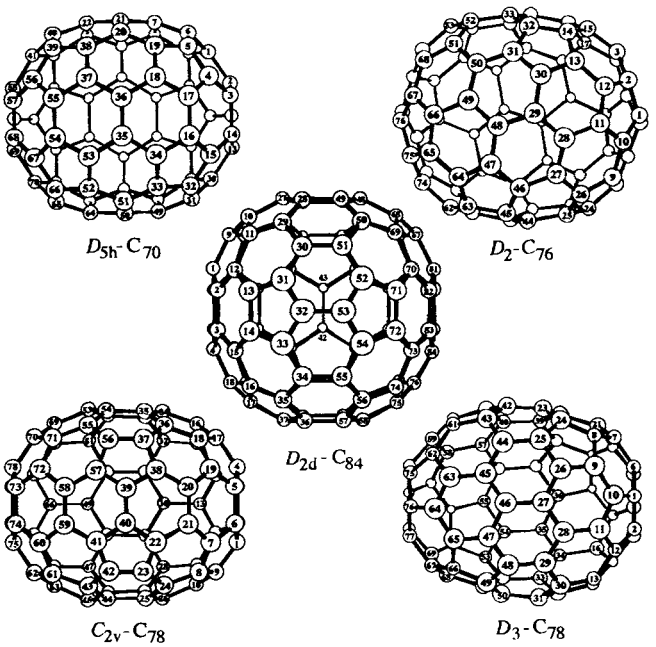

Figure 1. Five higher fullerenes of which pure derivatives have been isolated: D_{5h}-C_{70}, D_2-C_{76}, C_{2v}-C_{78}, D_3-C_{78}, and D_{2d}-C_{84}. The atoms are numbered according to refs. [13, 14].

which could be separated into two isomers of C_{2v} and D_3 symmetry (Figure 1), was achieved by HPLC on a polymeric C18 reversed-phase column. Preparative-scale separation was subsequently improved considerably by using π-acidic stationary phases, of which the Buckyclutcher I column developed by Welch and Pirkle merits particular mentioning.[12]

Even though the number of possible isomers increases dramatically with fullerene size,[15] unambiguous structural assignment based on ^{13}C NMR spectroscopy or X-ray crystallography was possible for D_2-C_{76},[10, 16, 17] C_{2v}-C_{78},[11, 16, 18] D_3-C_{78},[11, 16, 18] C'_{2v}-C_{78},[16, 18] and D_{2d}-C_{84} (Figure 1).[19] If rigorous experimental assignment of an isomer is impossible, calculations of heats of formation in conjunction with ^{13}C NMR spectroscopy may provide a structural lead. This was the case for the isolated fullerenes D_2-C_{80},[20] C_2-C_{82},[18] and D_2-C_{84} (obtained as a mixture with D_{2d}-C_{84}).[4, 16, 18]

Due to their hollow cage structure, C_{60} and higher fullerenes can form endohedral inclusion compounds with metal ions[21] or noble-gas atoms.[22] Depending on the size of the cavity, up to three metal ions can be incarcerated. Preparative amounts of the first helium compounds He@C_n (n = 60, 70, 76, 78, 84) were produced by heating fullerene samples at about 600 °C under a high He pressure ($\approx$2700 atm).[23, 24] Based on energetic considerations, different mechanisms have been discussed for the incorporation of He atoms.[25] ^3He NMR spectroscopy revealed strong and specific magnetic shieldings of ^3He atoms inside the cages of different fullerenes and their covalent derivatives; this gave rise to a unique resonance for each compound measured so far.[26, 27]

Although the covalent chemistry of the most abundant fullerene, C_{60}, developed fastest after 1990 and led to a rich variety of tailor-made building blocks for materials and biological applications,[28–31] investigations into the chemical reactivity of the higher fullerenes also made enormous progress in recent years. Of particular interest are the understanding of chemo- and regioselectivity of covalent derivatizations as well as the structural aspects related to chirality.[32, 33]

2. Chirality of Fullerenes and Their Derivatives

Many higher fullerenes are chiral.[3, 4, 16, 18, 20, 32] With increasing cage size, the number of chiral isomers increases rapidly: Of the 5 isomeric C_{78} structures obeying the isolated pentagon rule (IPR), 2 are chiral, whereas there exist 10 chiral representatives among the 24 IPR-satisfying isomers of C_{84}.[15, 32] These compounds are among the rare examples of chiral element modifications, and the enantiomers of D_2-C_{76}, D_3-C_{78}, and D_2-C_{84} could be separated in small amounts.[34, 35]

Functionalized fullerenes can be chiral even if they are derived from achiral parent cages. Depending on the origin of their chirality, four classes of chiral fullerene compounds can be distinguished.[32, 33]

1) All inherently chiral fullerenes and their derivatives.
2) Chiral adducts obtained by functionalizing achiral fullerenes in such a way that stereogenic elements are exclusively located in the addends.
3) Fullerene derivatives with an inherently chiral functionalization pattern, that is, the addends create a chiral addition pattern on an achiral fullerene core irrespective of the addends being identical or different.
4) Fullerene derivatives with a noninherently chiral addition pattern that is chiral due only to differences in the addends.

Carlo Thilgen was born in Luxembourg in 1961. He received his Ph.D. from the Universität Bonn in 1990, and was a postdoctoral fellow of NATO and the Government of Luxembourg at the University of California at Los Angeles (UCLA) with François Diederich. Since 1993 he has been a research associate at the Eidgenössische Technische Hochschule (ETH) Zürich. His current research focuses on the stereochemical aspects of fullerene functionalization.

C. Thilgen

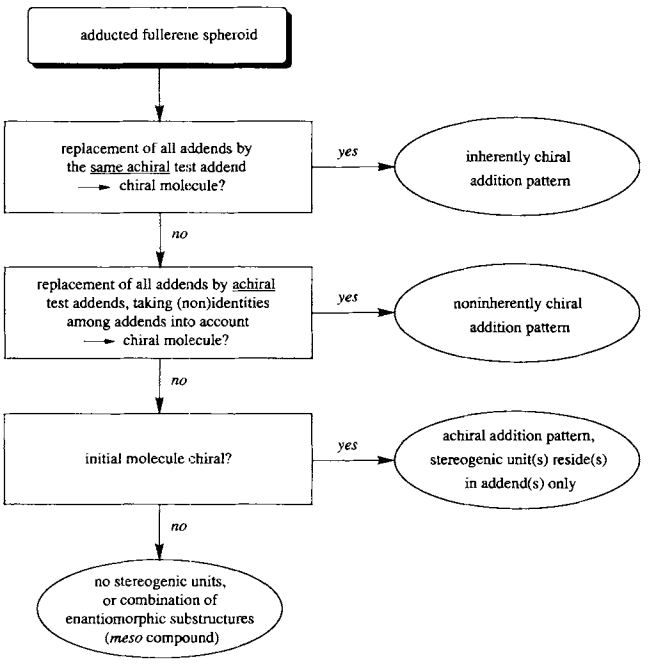
A. Herrmann

F. Diederich

Andreas Herrmann was born in Karlsruhe, Germany in 1969, and studied chemistry at the Universität Karlsruhe and the Ecole Européenne des Hautes Etudes des Industries Chimiques de Strasbourg (EHICS). In 1997 he received his Ph.D. at the ETH Zürich, where he was working on the chemistry and chiroptical properties of higher fullerenes and their derivatives. Since March 1997 he has been employed at Firmenich SA in Geneva, Switzerland.

François Diederich was born in Ettelbrück, Luxembourg, in 1952 and received his Ph.D. in 1979 at the Universität Heidelberg. Following postdoctoral studies at UCLA from 1979 to 1981, he was a research associate at the Max-Planck-Institut für medizinische Forschung in Heidelberg. After his Habilitation in 1985 he joined the faculty of the Department of Chemistry and Biochemistry at UCLA where he advanced to full professor of organic and bioorganic chemistry in 1989. Since April 1992 he has been a professor of organic chemistry at the ETH Zürich.

A compound can belong to several of the above classes when different stereogenic elements are superimposed in the same molecule. From a slightly different viewpoint, adducts of both chiral and achiral parent fullerenes can be usefully classified as outlined in Scheme 1.



Scheme 1. Flow diagram for classifying different types of fullerene-spheroid chirality by applying a simple, stepwise substitution test. Checking the structure resulting after each step for chirality quickly reveals the type of addition pattern of the starting structure.

The configurational description of compounds in categories 1, 3, and 4 by application of the Cahn, Ingold, and Prelog (CIP) rules[36] can be excessively complicated, especially when there is a multitude of stereogenic centers within the highly branched carbon framework. For this reason, we proposed a new system that allows configurational specification of chiral spheroids by a single descriptor, regardless of the degree of functionalization.[33] It is based on the fact that the numbering schemes proposed for fullerenes, which can be developed with a set of rules from their structure,[37] are themselves chiral (helical) and thus constitute an ideal reference for differentiating between enantiomeric carbon cages. Whereas two isometric, mirror-symmetric numbering schemes can be applied to an achiral parent fullerene, a unique scheme is associated with a specific enantiomer of an inherently chiral carbon spheroid.[37] Similarly, for a chiral derivative resulting from a specific addition pattern of an achiral parent fullerene, there is a unique numbering pattern leading to the lowest set of locants[38] for the addends. Depending on whether the direction of this numbering from C(1) over C(2) to C(3) is clockwise (*C*) or anticlockwise (*A*), the descriptors are ^{f}C or ^{f}A, respectively (f = fullerene; Figure 2).[33]

3. Reactivity and Regioselectivity in the Functionalization of Higher Fullerenes

Fullerene bonds are located either between two six-membered rings (6–6 bonds) or between a six- and a five-membered ring (6–5 bonds). In buckminsterfullerene, C_{60}, primary addition takes place preferentially at 6–6 bonds, which have higher double bond character.[28, 29] Whereas buckminsterfullerene contains only a single type of 6–6 bond, C_{70} contains 4, C_{76} 15, C_{2v}-C_{78} 18, and D_3-C_{78} 10. This leads to a growing number of possible adduct isomers with increasing fullerene size and decreasing symmetry.

In general, the mode of addition to higher fullerenes is similar to that of C_{60}:[28, 29] Whereas nucleophilic and carbene addition, hydrogenation, formation of transition metal complexes, and cycloadditions give rise to 1,2-adducts, most radical reac-

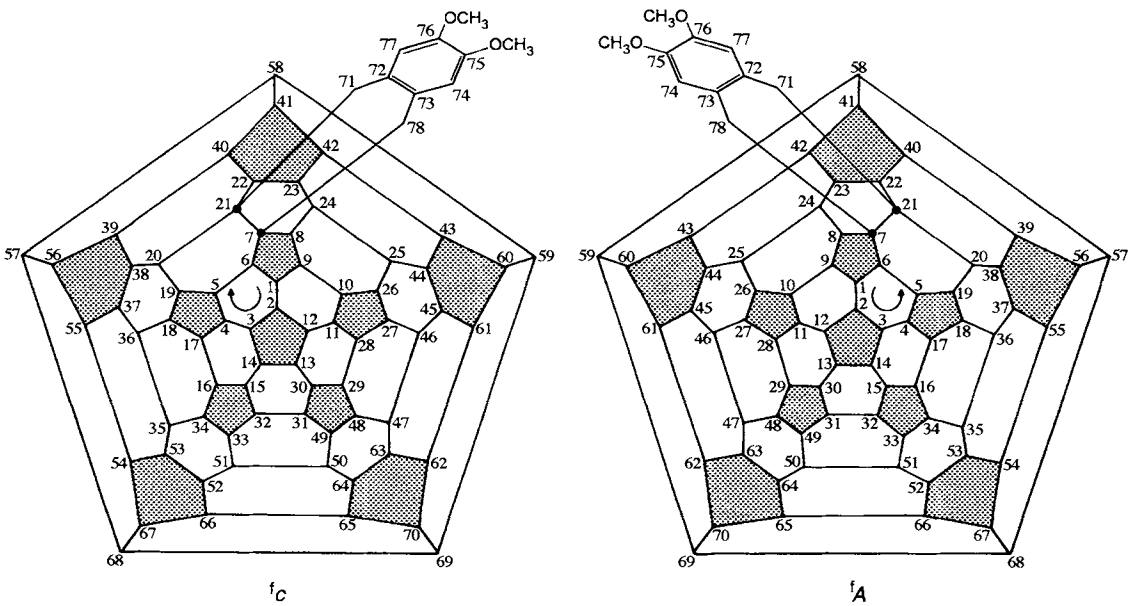


Figure 2. Schlegel diagrams of the enantiomers of 75,76-dimethoxy-7,21-(methano[1,2]benzenomethano)[70]fullerene, a C_{70} adduct with an inherently chiral addition pattern. Interchanging the numbering schemes and, therefore, the descriptors would afford the locant set 8,24 for the addend(s), which, being higher than 7,21, is unacceptable.

tions, for example halogenations, occur as intrahexagonal 1,4-additions, especially if sterically demanding groups are introduced. With C_{60}, 1,4-addition results in at least one double bond within a five-membered ring; this situation is energetically unfavorable in fullerene structures.[39] However, some of these energetic costs may be compensated by a reduction in steric interactions.

Bond reactivities in higher fullerenes can be estimated by considering π bond orders[13,40] or the local spheroid curvature,[34,41] which is expressed as pyramidalization angles of the corresponding carbon atoms.[42] To make simple predictions of the expected isomeric product distributions, we consider a qualitative model for evaluating local curvature.[8] As the latter results from incorporation of pentagons into a network of hexagons, the reactivity of a 6–6 bond should increase with the number of surrounding five-membered rings and a decrease in their distance to the 6–6 bond being considered. According to this description, the most strained bonds in C_{70} and C_{76} are located at the poles (type α, surrounded by type β), whereas the flatter equatorial region contains a number of different, less curved bonds (Figure 3).

Figure 3. Pyracylene substructures (shaded) with the three most curved fullerene bond types α, β, and γ at their center (marked with a cross).[8]

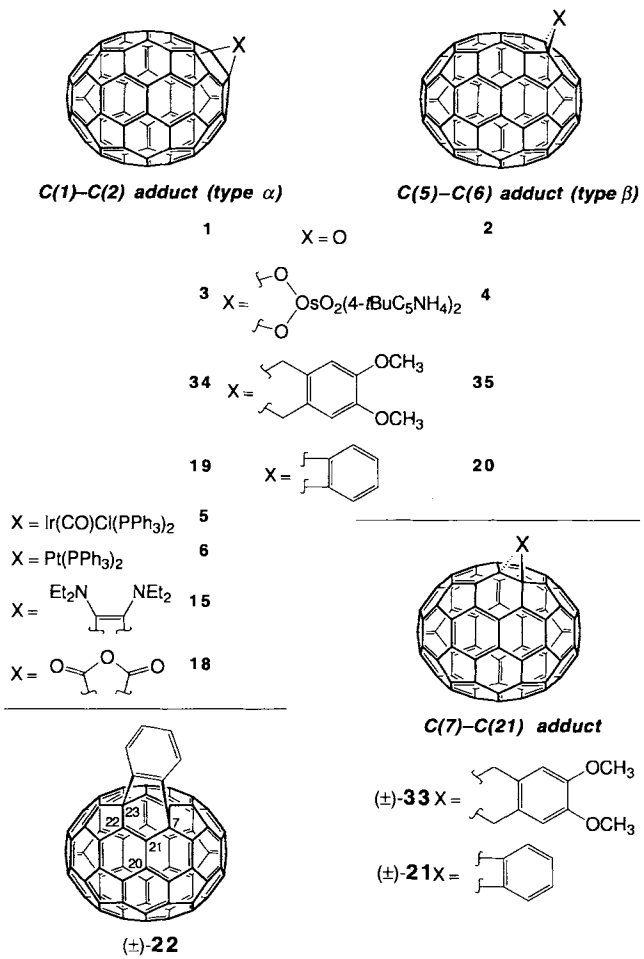
4. Functionalization of C_{70}

4.1. Oxidation Reactions

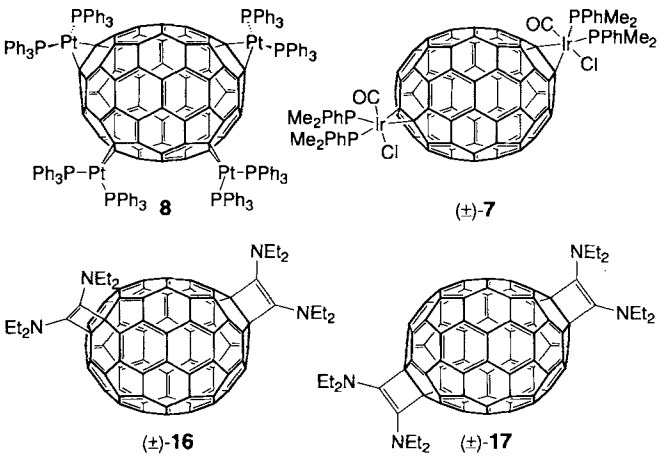
The first derivative of a higher fullerene described in the literature was the epoxide $C_{70}O$, which formed as a by-product during fullerene-soot production in the presence of traces of oxygen.[2,43] It is conveniently generated by the reaction of C_{70} with oxidizing agents such as dioxygen,[44,45] ozone,[46] or *m*-chloroperbenzoic acid.[47] As evidenced by X-ray crystallography of an iridium complex obtained from the isomeric epoxide mixture **1** and **2**,[48] oxygen addition occurs at the most curved α- and β-type bonds in the polar region of the fullerene (Scheme 2). This characteristic addition pattern was also observed for the osmylation of C_{70} to yield the mono-osmates **3** and **4** in a ratio of approximately 2:1.[41]

4.2. Transition Metal Complexes

Transition metal complexes of fullerenes are characterized by reversible, thermodynamically controlled association and a pronounced tendency to form crystals suitable for X-ray analysis. As illustrated for mono-adducts **5**[49] and **6** (Scheme 2)[50] as well as bis-adduct (±)-**7** (Scheme 3),[51] there is a high selectivity for η^2-complexation by Ir and Pt at the bonds nearest the pole of C_{70}. The addition patterns seen in the chiral bis-adduct (±)-**7** and the C_{2v}-symmetrical tetrakis-adduct **8**[52] were also realized in functionalizations with C-nucleophiles (see Section 4.8).



Scheme 2. Mono-adducts of C_{70} with bridging addends, and their isomeric distribution. All chiral adducts are represented by a single enantiomer only.

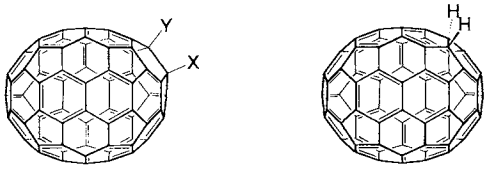


Scheme 3. Bis-adducts of C_{70} with an inherently chiral functionalization pattern resulting from addition to α-type bonds at opposite poles as well as a C_{2v}-symmetrical tetrakis(platinum) complex. Only a single enantiomer is shown in each case.

4.3. Hydrogenation

As in the case of C_{60},[28,53] 1,2-addition is preferred over 1,4-addition for the hydrogenation of C_{70} despite eclipsing interactions between vicinal hydrogen atoms on the carbon spheroid. Two isomeric bis-adducts, **9** (major product) and **10**,

were formed by the reaction of C_{70} with diimide[54] or $BH_3 \cdot THF$[55] (Scheme 4). Conversion of the less stable **10** into a mixture of **9** and **10** by Pt-catalyzed equilibration allowed experimental determination of the corresponding difference in free energy as (1.4 ± 0.2) kcal mol^{-1}.[55] Diimide reduction of



9 X = Y = H
36 X = CH_3, Y = H
37 X = H, Y = CH_3

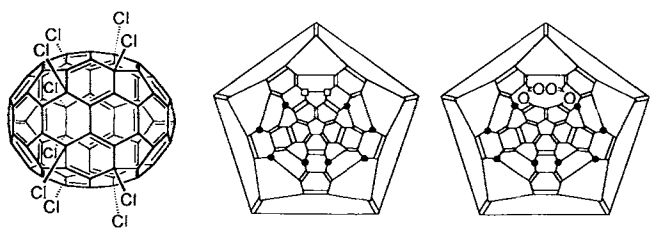
10

Scheme 4. Isomeric hydrogenation and hydromethylation products of C_{70}.

C_{70} also afforded the tetrahydro[70]fullerenes 1,2,3,4-$C_{70}H_4$ and (±)-1,2,5,6-$C_{70}H_4$, in which all four hydrogen atoms are located at adjacent positions in one of the six-membered rings of the polar corannulene substructure.[54] Although a number of more highly hydrogenated derivatives of C_{70} bearing 8, 10, 12,[16, 56] 30,[57] or 36[58] hydrogen atoms as well as a mixture of hydrogenated higher fullerenes[59] were generated by various methods, in no case was a conclusive structural assignment possible.

4.4. Halogenations

Possibly due to crystal packing effects, solid C_{70} is more reactive towards fluorination than C_{60}.[60, 61] As revealed by mass spectrometry, the reaction with F_2[60–63] or the more selective MnF_3[64] affords $C_{70}F_{38}$,[60, 61, 64] $C_{70}F_{40}$,[62] and $C_{70}F_{52}$[63] as prominent species of high symmetry (^{19}F NMR spectroscopy). Fluorofullerenes are sensitive towards moisture or solvents.[61, 63] An S_N2' mechanism was proposed for nucleophilic attack, for example by OH^- or H_3CO^-, which clearly cannot take place from the back side of the fluorinated carbon atoms of the fullerene shell.[65] The most interesting halide of a higher fullerene is the well-characterized $C_{70}Cl_{10}$, which was obtained by Taylor and co-workers as a single C_s-symmetrical isomer (**11**) in the reaction of C_{70} with ICl (Scheme 5).[14] Presumably



11

11 • = C-Cl, □ = C-Cl
12 • = C-Ph, □ = C-Ph
13 • = C-Ph, □ = C•

14 • = C-Ph

Scheme 5. $C_{70}Cl_{10}$ (**11**), $C_{70}(Ph)_{10}$ (**12**), $C_{70}(Ph)_8$ (**13**), and oxidative cage opening of **13** yielding the C_s-symmetrical bis(lactone) **14** with an eleven-membered ring in the fullerene shell. The two representations on the right are Schlegel diagrams.

taking place by a radical mechanism, 1,4-addition leads to sterically favorable "*para*" relationships of the Cl atoms in a belt of adjacent six-membered rings with only one vicinal ("*ortho*") neighborship.[14, 66] In addition, all double bonds are exocyclic to the five-membered rings.

4.5. Chemistry of $C_{70}Cl_{10}$

$C_{70}Cl_{10}$ is an interesting starting material for further chemical transformations. In analogy to $C_{60}Cl_6$, $C_{70}Cl_{10}$ undergoes Friedel–Crafts alkylation with benzene/$FeCl_3$ to yield $C_{70}Ph_{10}$ (**12**) via the octakis-adduct $C_{70}Ph_8$ (**13**), which contains an intrapentagonal double bond.[67] A by-product of this reaction, fullerenol $C_{70}Ph_9OH$ is formed by nucleophilic substitution of another intermediate, $C_{70}Ph_9Cl$, by water.[68]

When left in CCl_4 under air for several weeks, **13** is spontaneously oxidized to the C_s-symmetrical bis(lactone) $C_{70}Ph_8O_4$ (**14**; Scheme 5) with an eleven-membered hole in the fullerene cage.[69] It presumably results from insertion of two oxygen atoms into σ bonds followed by oxidative cleavage of the adjacent, electron-rich intrapentagonal bis(enol ether) double bond.

4.6. Addition of Radicals

Studies with C_{60} showed that, for reasons of allylic stabilization, the unpaired electron resulting from radical attack is preferentially located at the position α to the addition site.[28] With five different types of carbon atoms in its shell, C_{70}, which seems to have a somewhat lower affinity for radicals than C_{60},[70] can give rise to a maximum of five isomeric mono-adducts. Three were detected with ESR spectroscopy for the addition of alkyl or Cl_3C radicals,[71, 72] up to four for H, aryl, and F_5C_2 radicals,[72–75] and all five for H_3CO[76] and F_3C radicals.[74] Whereas structural assignments are in general difficult, calculations on $HC_{70}^{\bullet}$ regioisomers indicate that attack at the equator is the most unlikely.[72, 74, 75, 77]

4.7. Cycloadditions

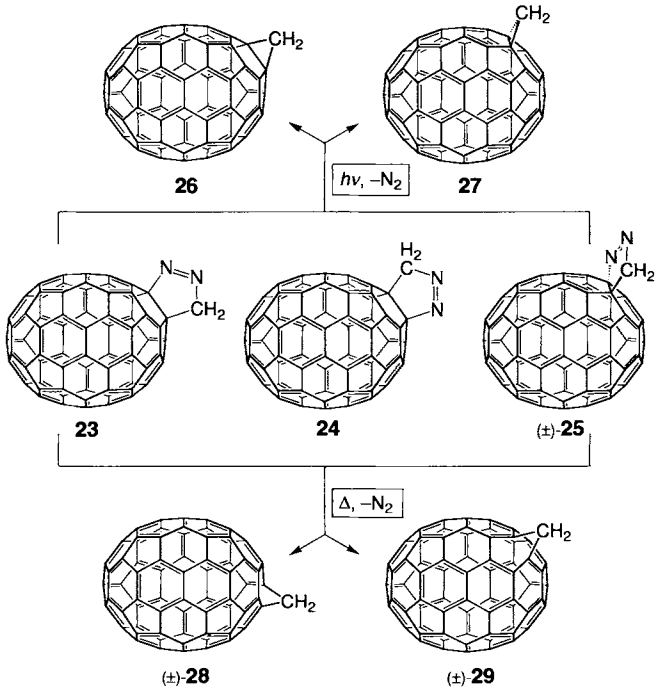
Together with the addition of C-nucleophiles, cycloadditions represent the most important reaction for the formation of C–C bonds with the fullerene framework.[28, 29, 78] Ando and coworkers described a [2+1]cycloaddition in which they treated C_{70} with photochemically generated bis(2,6-diisopropylphenyl)silylene.[79] As in most cycloadditions with this fullerene, the reaction occurred selectively at the C(1)—C(2) (α) and C(5)—C(6) (β) bonds in a 2:1 ratio.

Zhang and Foote reported [2+2]cycloaddition of ethynediamines and thioethynamines to C_{70} and, for the former, obtained a single mono-adduct isomer (**15**; see Scheme 2) in addition to a mixture of two chiral bis-adducts ((±)-**16** and (±)-**17**; see Scheme 3). This demonstrated a remarkable selectivity for attack at the most curved bonds of type α nearest the poles.[80] After self-sensitized photooxygenation of the mixture, the authors obtained the tetrakis(carboxamide) corresponding to (±)-**16**. Starting from a thioethynamine α-type mono-adduct,

photooxidative cleavage to a thioester amide followed by acid treatment afforded **18** as the first fullerenedicarboxylic acid anhydride.

Up to ten equivalents of benzyne readily add to C_{70}.[81, 82] ^1H and ^{13}C NMR spectroscopic analysis of the generated monobenzeno[70]fullerene mixture revealed the formation of three out of four possible 6–6 bond cycloadducts (**19**, **20**, and (±)-**21**, see Scheme 2); no reaction occurred at the equatorial biphenyl-type bond C(20)–C(21). A fourth, presumably transequatorial 1,4-adduct in which C(7) and C(23) are bridged ((±)-**22**) is a fullerene analogue of triptycene. In contrast to [2+2]cycloaddition at the equatorial C(20)–C(21) bond, [4+2]cycloaddition leading to (±)-**22** does not generate new double bonds in the five-membered rings. Furthermore, by taking into account the high reactivity of α-type bonds and possible steric interactions, as well as avoidance of intrapentagonal double bonds, a structure was proposed for the decakis(benzeno) adduct.[82] Its π system includes five benzenoid six-membered rings and is a substructure of the $C_{70}Cl_{10}$ chromophore.[14, 66] [2+2]Cycloadditions between carbon spheres seem to be the origin of polymers produced from C_{70} films upon irradiation or application of high temperature and pressure.[83]

Methanofullerenes can be obtained by [3+2]cycloaddition of diazo compounds to 6–6 bonds and subsequent photochemical or thermal extrusion of N_2 from the intermediate pyrazolines.[28, 29, 84] Two regioisomeric pyrazolines, **23** and **24**, arise from addition at the α-type bond C(1)—C(2), and a racemic mixture of a third constitutional isomer ((±)-**25**) with a noninherently chiral addition pattern is obtained from addition to the β-type bond C(5)–C(6) (12:1:2 ratio; Scheme 6).[85] The same isomerism was found by Meier et al.[86] and Irngartinger et al.[87] for the reaction of isonitrile oxides with C_{70}, and by Yamago and Nakamura for the addition of a dipolar trimethylenemethane derivative generated by thermolytic ring opening of a methylenecyclopropane derivative.[88]

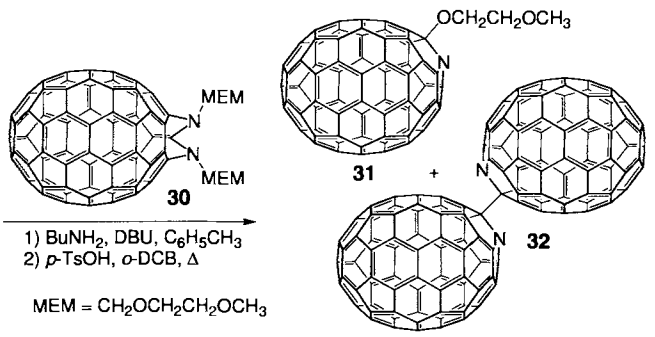


Scheme 6. Photochemical N_2 extrusion from diazomethane adducts of C_{70} **23**, **24**, and (±)-**25** yields 6–6 closed methanofullerenes **26** and **27**, whereas the corresponding thermal process generates the 6–5 open derivatives (±)-**28** and (±)-**29**.

Irradiation of the mixture of pyrazolines **23**, **24**, and (±)-**25** yielded methanofullerenes **26** and **27** (7:1) with a closed transannular 6–6 bond in addition to minor amounts of a third constitutional isomer ((±)-**28**), whereas thermolysis of the same mixture gave (±)-**28** and (±)-**29** (4:1) with an open transannular 6–5 "bond".[85] As to the mechanism of this combination of N_2 extrusion and rearrangement, thermolysis of the corresponding pyrazolo[60]fullerene was proposed to give a 6–5 open methanofullerene by an orbital symmetry controlled [$\pi^2s+\pi^2s+\sigma^2s+\sigma^2a$] reaction, whereas photolysis to a 6–6 closed methanofullerene proceeds by a diradical mechanism.[89]

Similar to the reaction of diazomethane, [3+2]cycloaddition of alkyl azides to C_{70} afforded three constitutionally isomeric triazolines, of which the regioisomer analogue of **23** predominated.[90, 91] Subsequent thermal elimination of N_2 under formation of N-bridged compounds showed a preference for the 6–5 open analogues of (±)-**28** and (±)-**29** over the 6–6 closed isomers corresponding to **26** and **27**.[90]

Twofold addition of azide yielded C_s-symmetrical **30** with two bridged, adjacent 6–5 open "bonds" (Scheme 7).[92, 93] Compound **30** is a suitable starting material for the macroscopic



Scheme 7. Generation of aza[70]fullerene derivatives from a geminally N-bridged precursor.

synthesis of aza[70]fullerene derivatives **31** and **32**, provided that facile deprotection of the N-bridges is possible.[93] Whereas **31** could be well characterized, **32** gave no ^1H NMR signal, as expected, and its solubility was too low to obtain sufficient ^{13}C NMR data; it did however provide a UV absorption typical for a 1,2-dihydro[70]fullerene. In analogy to $(C_{59}N)_2$,[93, 94] the mass spectra of **32** showed only a peak for half of the dimeric structure.

Wilson and Lu found that *N*-methylazomethine ylide adds under formation of fused *N*-methylpyrrolidines not only to the reactive α- and β-type bonds of C_{70}, but, to a minor extent, also to the C(7)–C(21) bond.[95] This led to an addition pattern previously seen in Diels–Alder adduct **33** (see Scheme 2).[8] The transequatorial 1,4-addition mode of **22** (see Scheme 2) was also suggested[82] for the product of the photochemically induced addition of 1,1,2,2-tetramesityl-1,2-disilirane to C_{70}.[96]

We investigated the regioselectivity of the Diels–Alder [4+2]cycloaddition of 4,5-dimethoxy-*o*-quinodimethane to C_{70} and C_{76}.[8] In the case of C_{70}, three out of four possible 6–6

adducts ((±)-**33**, **34**, and **35**) were isolated and unambiguously assigned by ^{13}C NMR or variable-temperature ^{1}H NMR spectroscopy. Boat-to-boat interconversion of the newly formed cyclohexene ring is fast on the NMR time scale around 80 °C, and the spectroscopically observed average symmetry of the adducts changes upon crossing the coalescence temperature T_c. A unique symmetry combination at $T<T_c$ and $T>T_c$ allowed structural assignment of all three isolated constitutional isomers. The two most abundant products were **34** and **35** (Scheme 2), and their structures were confirmed by X-ray crystallography.[97] The third, minor constitutional isomer (±)-**33**, formed by addition to the C(7)–C(21) bond, has an inherently chiral addition pattern which is also found in other adducts of C_{70}.[82, 95] Addition at the equatorial C(20)–C(21) bond did not occur.

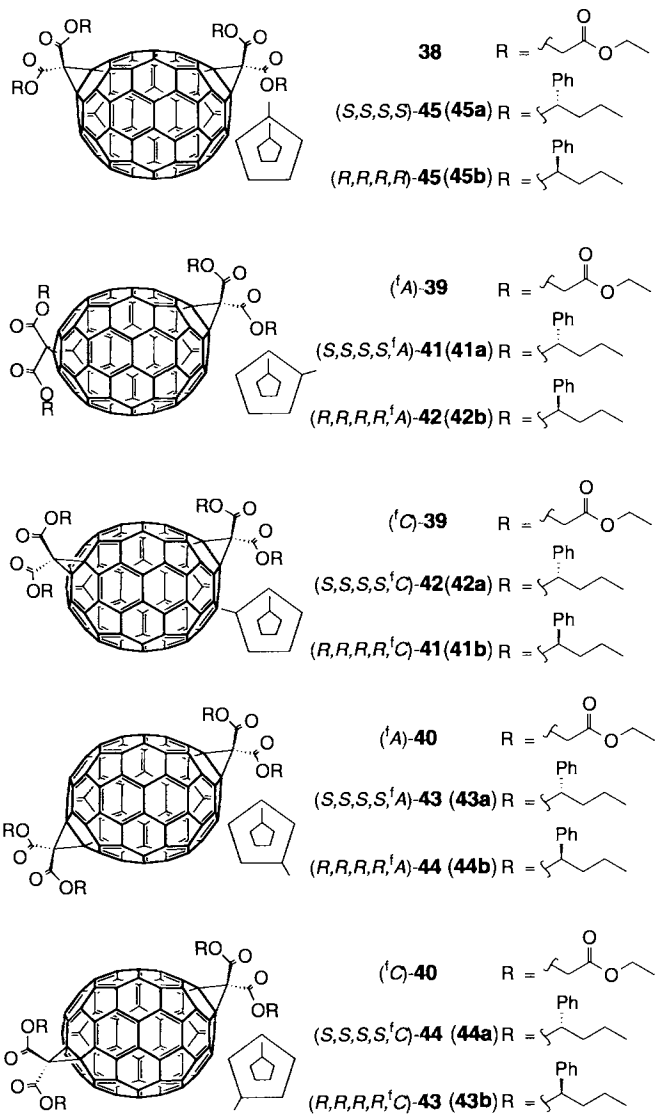
Cyclopenta-1,3-dienes readily and reversibly add to C_{70}.[98–100] An interesting method for purifying C_{60} and C_{70} was developed by Rotello and Nie; it takes advantage of the differential reactivity of the two fullerenes towards a silica gel supported cyclopentadiene.[101] An [8 + 2]cycloaddition of 8-methoxyheptafulvene to an α-type bond of C_{70} was reported by Daub and co-workers in addition to Diels–Alder reactions with electron-rich Danishefsky dienes.[102]

4.8. Addition of Nucleophiles

Kinetically controlled nucleophilic 1,2-additions to C_{70} followed by quenching with an electrophile display a particularly high selectivity for the polar α-type C(1)–C(2) bond.[103–107] This can be rationalized by the preference of the sp^3-hybridized carbanionic center, which develops in the transition state α to the site of nucleophilic attack,[28] for a region of high curvature. Hirsch and co-workers found that hydroalkylations or hydroarylations, in which the carbanion resulting from nucleophilic attack is quenched by a proton as electrophile, afford two isomers (e. g. **36** and **37**; see Scheme 4) by addition to the C(1)–C(2) bond.[103, 108]

In one of the most practical methanofullerene syntheses, the Bingel reaction,[104] attack of 2-bromomalonate carbanions on the fullerene is followed by intramolecular halide displacement. Starting from phosphonium[109] or sulfonium ylides,[105, 110] a similar addition–elimination mechanism also yields methanofullerenes. The Bingel reaction shows high preference for monofunctionalization of C_{70} at the C(1)–C(2) bond, and we selected it for studying the formation of multiple adducts of higher fullerenes.[9, 106] Our objective was to learn about the changes in chemical reactivity and physical properties which occur when the conjugated fullerene chromophore is reduced as a result of increasing functionalization.[111]

The X-ray crystal structures of C_{70} mono-adducts **34** and **35** revealed that the electronic configuration at the unfunctionalized pole closely resembles that of the parent fullerene.[97] As a consequence, second Bingel[106, 112] or other[51, 80] additions to C_{70} take place at the unfunctionalized pole (see Schemes 3 and 8).[97] If both malonate addends are achiral, three constitutionally isomeric bis(methano)fullerenes are formed: an achiral (C_{2v}-symmetrical **38**) and two chiral compounds (C_2-symmetrical (±)-**39** and (±)-**40**) that are obtained as pairs of enantiomers with an inherently chiral addition pattern.[106] The analogous addition of bis[(*S*)-1-phenylbutyl] 2-bromomalonate leads to a superimposition of the chirality of the addend and, when present, that of the core functionalization pattern. This affords a total of five optically active isomers, two constitutionally isomeric pairs of C_2-symmetrical diastereoisomers (**41a, 42a** and **43a, 44a**) as well as a third constitutional C_2-symmetrical isomer (**45a**).[106] All these and the products **41b**–**45b** resulting from addition of the respective (*R,R*)-configured esters could be separated by HPLC on silica gel.[113] As a consequence, ten pure, optically active compounds were obtained; they include five pairs of enantiomers, four with an inherently chiral fullerene functionalization pattern and chiral side chains (**41a, b, 42a, b, 43a, b, 44a, b**), and one with stereogenic units in the addends only (**45a, b**). Inherently chiral addition patterns lead to very strong Cotton effects in the circular dichroism (CD) spectra,[106, 114–116] which is in contrast to sole perturbation of achiral fullerene chromophores by chiral addends.[32, 106, 117, 118] Furthermore, identical core functionalization patterns lead to



Scheme 8. Different combinations of inherently chiral or achiral [70]fullerene functionalization patterns and chiral or achiral addends. The addition patterns are schematically represented by Newman-type projections along the C_5 axis of the C_{70} framework; the inner pentagon corresponds to that nearest the viewer.

(nearly) the same spectra irrespective of the side chain configuration. This is nicely illustrated by the spectra of diastereoisomeric bis-adducts ($S,S,S,S,^{f}A$)-**43** and ($S,S,S,S,^{f}C$)-**44**, which have enantiomeric addition patterns and display nearly mirror-image shapes since the chiroptical contributions from the chiral addition pattern of the fullerene greatly dominate those from the chiral addends (Figure 4b).[106] A characteristic band around 460 nm was observed in the CD spectra of all C_{70} adducts with an inherently chiral functionalization pattern and may be helpful in assigning absolute configurations.[113]

Further functionalization of the major bis-adducts **38** and (±)-**39** with diethyl bromomalonate yielded tetrakis-adducts **46** and (±)-**47**, respectively, in addition to the intermediate tris-adducts (Scheme 9, top).[106] Once C_{70} bis-adducts are formed, further addition must take place in a hemisphere that is already functionalized. For steric and probably also electronic reasons, this does not occur at another α-type bond. Instead, an addition mode similar to that of a second bromomalonate addition to C_{60}, which preferentially occurs at an equatorial bond, is observed. Given the two alternatives corresponding to this relative arrangement in a C_{70} hemisphere, the next addition takes place at a β-type bond rather than at bond x in the less curved equatorial region (Scheme 9, bottom), thus leading to tris- and tetrakis-adducts.[106] Compared to C_{60},[119,120] C_{70} shows higher selectivity in multiple nucleophilic additions.[106,108]

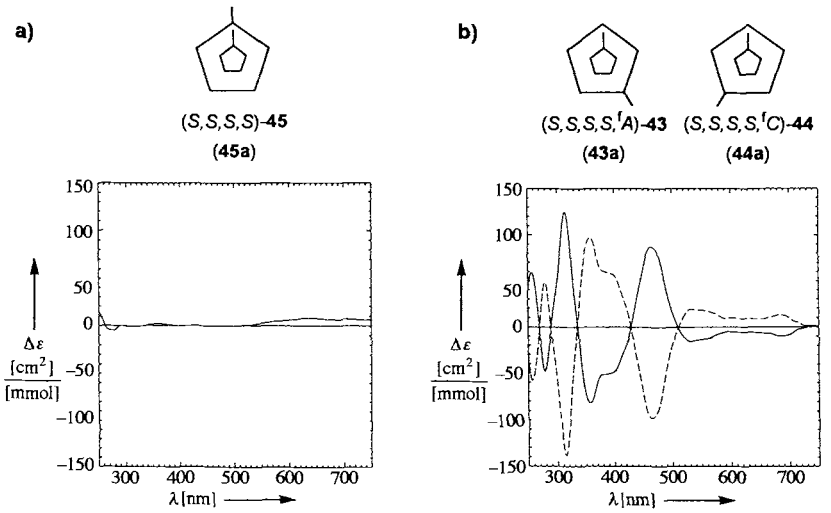


Figure 4. CD spectra of a) **45a** and b) the diastereoisomeric bis-adducts **43a** and **44a**. The Cotton effects shown by **43a** and **44a**, which have an inherently chiral addition pattern, are much larger than those observed for **45a**, in which the achiral fullerene chromophore is only perturbed by the chiral side chains. In addition, the spectra of **43a** and **44a** with their enantiomeric fullerene addition patterns display near mirror-image shapes despite the fact that the molecules are diastereoisomers.

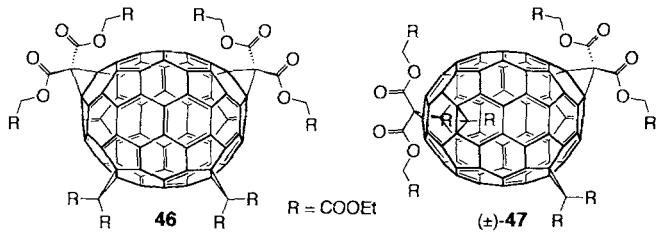
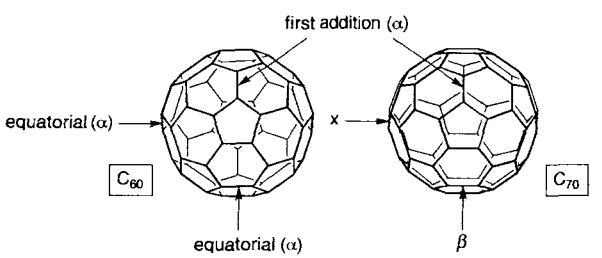


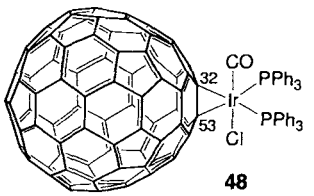


Scheme 9. C_2- and C_{2v}-symmetrical tetrakis-adducts of C_{70} as well as a comparison of the modes of second intrahemispheral addition for C_{60} and C_{70}. In C_{60}, the second addition preferentially takes place at one of the two different equatorial bonds (both of type α). In C_{70}, the same favorable relative addend arrangement can be realized by addition of a second nucleophile either at the marked bond of type β or in the less curved equatorial region (bond x). Of the two possibilities, only the former was observed.

5. Functionalization of the Fullerenes Beyond C_{70}

The chemistry of the fullerenes beyond C_{70} is much less explored, and, other than for the derivatives derscribed in this review, product mixtures from ozonation[46], hydrogenation[59], and methylenation[121] have been reported. Making use of the asymmetric Sharpless osmylation, Hawkins et al. achieved a small-scale kinetic resolution of D_2-C_{76}, D_3-C_{78}, and D_2-C_{84}.[34,35] No racemization of C_{76}, or of D_2-C_{84} by Stone–Wales rearrangements[122] via D_{2d}-C_{84}, occurred below 700 °C and upon UV irradiation.[35]

By selective crystallization of [{η^2-(D_{2d}-C_{84})}Ir(CO)Cl(PPh_3)$_2$] (**48**) from a mixture of D_{2d}-C_{84} and D_2-C_{84}, Balch et al. obtained the first isomerically pure adduct of [84]fullerene (Scheme 10).[19] Fluorination of a higher fullerene mixture yielded $C_{70}F_x$ ($x = 44-56$), $C_{78}F_y$ ($y = 54-60$), and $C_{84}F_z$ ($z = 56-62$).[123] The difluorinated anions $C_{72}F_2^-$, $C_{74}F_2^-$, $C_{76}F_2^-$, and $C_{78}F_2^-$ were produced in Knudsen-cell mass-spectrometric experiments.[124–127]

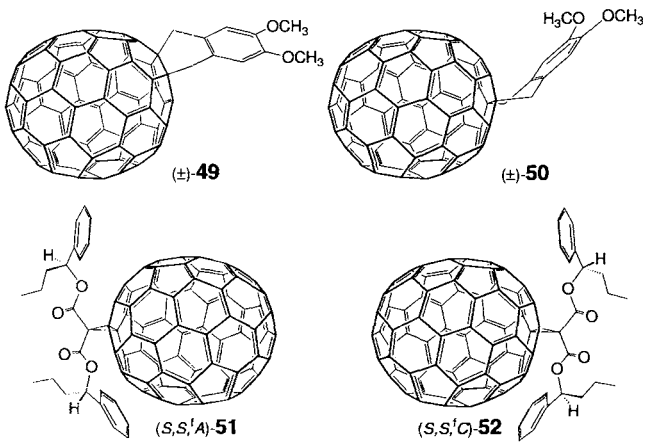


Scheme 10. Formula of the first isomerically pure adduct of [84]fullerene.

Photochemically induced addition of 1,1,2,2-tetramesityl-1,2-disilirane to endohedral metallofullerenes such as La@C_{82}, Gd@C_{82}, La_2@C_{80}, and Sc_2@C_{84} yielded isomeric mixtures of mono-adducts.[128] In contrast to the empty cages, most of the more strongly electron-accepting metallofullerenes also react thermally with this disilirane.

5.1. Diels–Alder Addition and Nucleophilic Addition to C_{76}

At least six isomers were formed by the addition of 4,5-dimethoxy-*o*-quinodimethane to D_2-C_{76}.[8] ^{1}H NMR spectroscopy, together with consideration of bond reactivities modulated by local curvature, led to the tentative assignment of the C_1-symmetrical C(2)–C(3) adduct structure (±)-**49** (Scheme 11) resulting from attack at the polar α-type bond to the major



Scheme 11. Isolated mono-adducts of C_{76} for which confident structural assignments were possible.

product, which was isolated in pure form. Based on similar reasoning, the structure of the C(1)–C(6) adduct (±)-**50** formed by attack at another α-type bond, was assigned to a C_2-symmetrical mono-adduct, which was isolated as a mixture with two C_1-symmetrical isomers.[8]

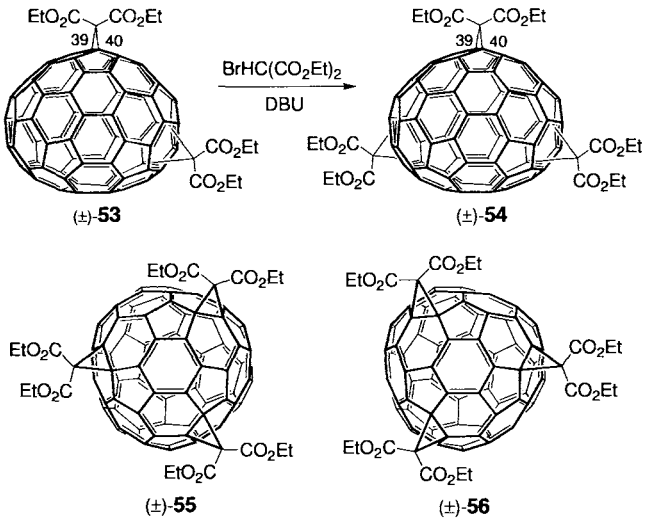
In a Bingel reaction of C_{76} with an (*S,S*)-configured 2-bromomalonate, superimposition of the chirality of the addend and that of the inherently chiral fullerene mainly yielded three constitutionally isomeric pairs of diastereoisomeric mono-adducts, two of C_1, and one (**51**, **52**) of C_2 symmetry (Scheme 11; ratio approximately 8:7:1).[115] All six compounds were isolated by HPLC, and represent the first optically pure adducts of an inherently chiral fullerene. UV/Vis, CD, and ^{13}C NMR spectra showed distinct similarities for isoconstitutional stereoisomers, thus allowing facile identification of the three pairs. The CD spectra of these derivatives of an inherently chiral fullerene display very pronounced Cotton effects with maximum Δε values ($\approx 250\ cm^2\ mmol^{-1}$)[115] that are twice as high as those[106] measured for optically active adducts of achiral fullerenes with a chiral addition pattern.

According to the local curvature model for bond reactivities, the minor C_2-symmetrical diastereoisomeric pair (**51,52**) most probably results from addition to the α-type bond C(1)–C(6) that is intersected by a C_2 axis of D_2-C_{76}. This leaves another α bond (C(2)–C(3)) for malonate addition leading to one of the C_1-symmetrical pairs; the third C_1-symmetrical constitutional isomer must arise from addition to a bond located in a less curved region. The fact that a minor product results from α-bond addition, whereas reaction at a less curved bond leads to a major adduct, indicates that other factors, such as electronic effects, contribute to the regioselectivity in C_{76} and possibly other higher fullerenes.[115]

5.2. Nucleophilic Addition to C_{78}

Cyclopropanation of a 3:1 isomeric mixture of C_{2v}-C_{78} and D_3-C_{78} with about two equivalents of diethyl 2-bromomalonate showed high reactivity of these fullerene isomers, since at least eight tris-adducts, colored from green to brownish yellow in CH_2Cl_2, were formed as main products in addition to two C_1-symmetrical bis-adducts.[9] Most of the adducts were isolated in a pure state by HPLC and characterized by UV/Vis and ^1H and ^{13}C NMR spectroscopy, as well as mass spectrometry. A minor fraction of mono-adducts consisting of at least four isomers could not be analyzed in detail.

In the case of the tris-adducts, three isomers displayed higher symmetry than C_1 and could therefore be unambiguously assigned to the C_{78} isomer from which they arose. By comparing the spectra obtained for a C_2-symmetrical tris-adduct of C_{2v}-C_{78} to those of the bis-adducts, three possible structures ((±)-**53**) were proposed for one of the C_1-symmetrical bis-adducts that is the direct precursor to the corresponding tris-adduct (±)-**54** (Scheme 12). A common addend position in



Scheme 12. Proposed structures for a C_2-symmetrical tris-adduct of C_{2v}-C_{78} ((±)-**54**), its bis-adduct precursor ((±)-**53**), and a C_3-symmetrical tris-adduct of D_3-C_{78} ((±)-**55** or (±)-**56** are possible).

(±)-**53** and (±)-**54** can be identified as the γ-type bond C(39)–C(40) at the intersection of the mirror planes of the parent fullerene. For the second addend, one out of three positions within the same six-membered ring containing one bond of type α and two of type β is most likely.[9] Considerations of π bond orders[13] that take into account steric effects predict C(9)–C(10) and C(69)–C(70) to be the most likely positions for the second and third addends in (±)-**54** (see Figure 1).

Two constitutionally isomeric structures, (±)-**55** or (±)-**56** (Scheme 12), were finally proposed for a pure C_3-symmetrical tris-adduct of D_3-C_{78}; both show the same relative pairwise arrangement of addends that is observed within a hemisphere of tris- and tetrakis-adducts of C_{70} (see Scheme 9).[9] This functionalization pattern (equatorial in C_{60}) therefore seems to be commonly realized in multiple adducts of fullerenes. According to considerations of π bond orders,[13] (±)-**56** should be formed preferentially. Even though a mixture of two C_{78} isomers was used as the starting material for the syntheses, most products were chromatographically isolated as (racemic) single isomers and represent the first pure adducts of C_{2v}-C_{78} and D_3-C_{78}. Reversible functionalization may therefore be a useful method for separating isomers of higher fullerenes.[19]

6. Conclusions

The chemical reactivity of C_{70} is becoming increasingly understood. Noteworthy is the general tendency for additions at 6–6 bonds in areas of highest local curvature near the poles, and for bis-additions at 6–6 bonds in opposite hemispheres. Furthermore, the pronounced regioselectivity in multiple additions exceeds that observed for C_{60}.

Although the number of studies concerning the reactivity of higher fullerenes beyond C_{70} is still small, it appears that relatively few mono-adduct isomers are formed despite the large number of potentially reactive 6–6 bonds. Also, the regioselectivity in multiple additions to the C_{78} isomers is quite remarkable. Many of these features cannot be satisfactorily explained by sole differences in bond reactivities resulting from differences in local curvature (C-atom pyramidalization) or steric effects. Rather, electronic effects must additionally be taken into account, and the consideration of π bond orders was proposed as a different way of looking at reactivities of fullerene bonds. Furthermore, the view of fullerenes as having the reactivity of simple alkenes with isolated double bonds might need significant adjustment. From the chemistry of higher fullerenes known today, it emerges that the different "double bonds" cannot be considered as independent. Further elucidation of the interrelationships between bonds in fullerene π systems has to be the object of future investigations, which, however, still await easier availability of the higher fullerenes.

Fullerene chirality is a novel chapter in stereochemistry that has largely been developed in work on higher fullerenes and their covalent derivatives. Hopefully, the remarkable, yet poorly understood chiroptical properties of fullerenes with chiral addition patterns will attract the interest of theoretical chemists in the future.

This work was supported by the Swiss National Science Foundation. We also thank Hoechst AG for samples of pure C_{70} and fullerene-soot extract enriched in higher fullerenes.

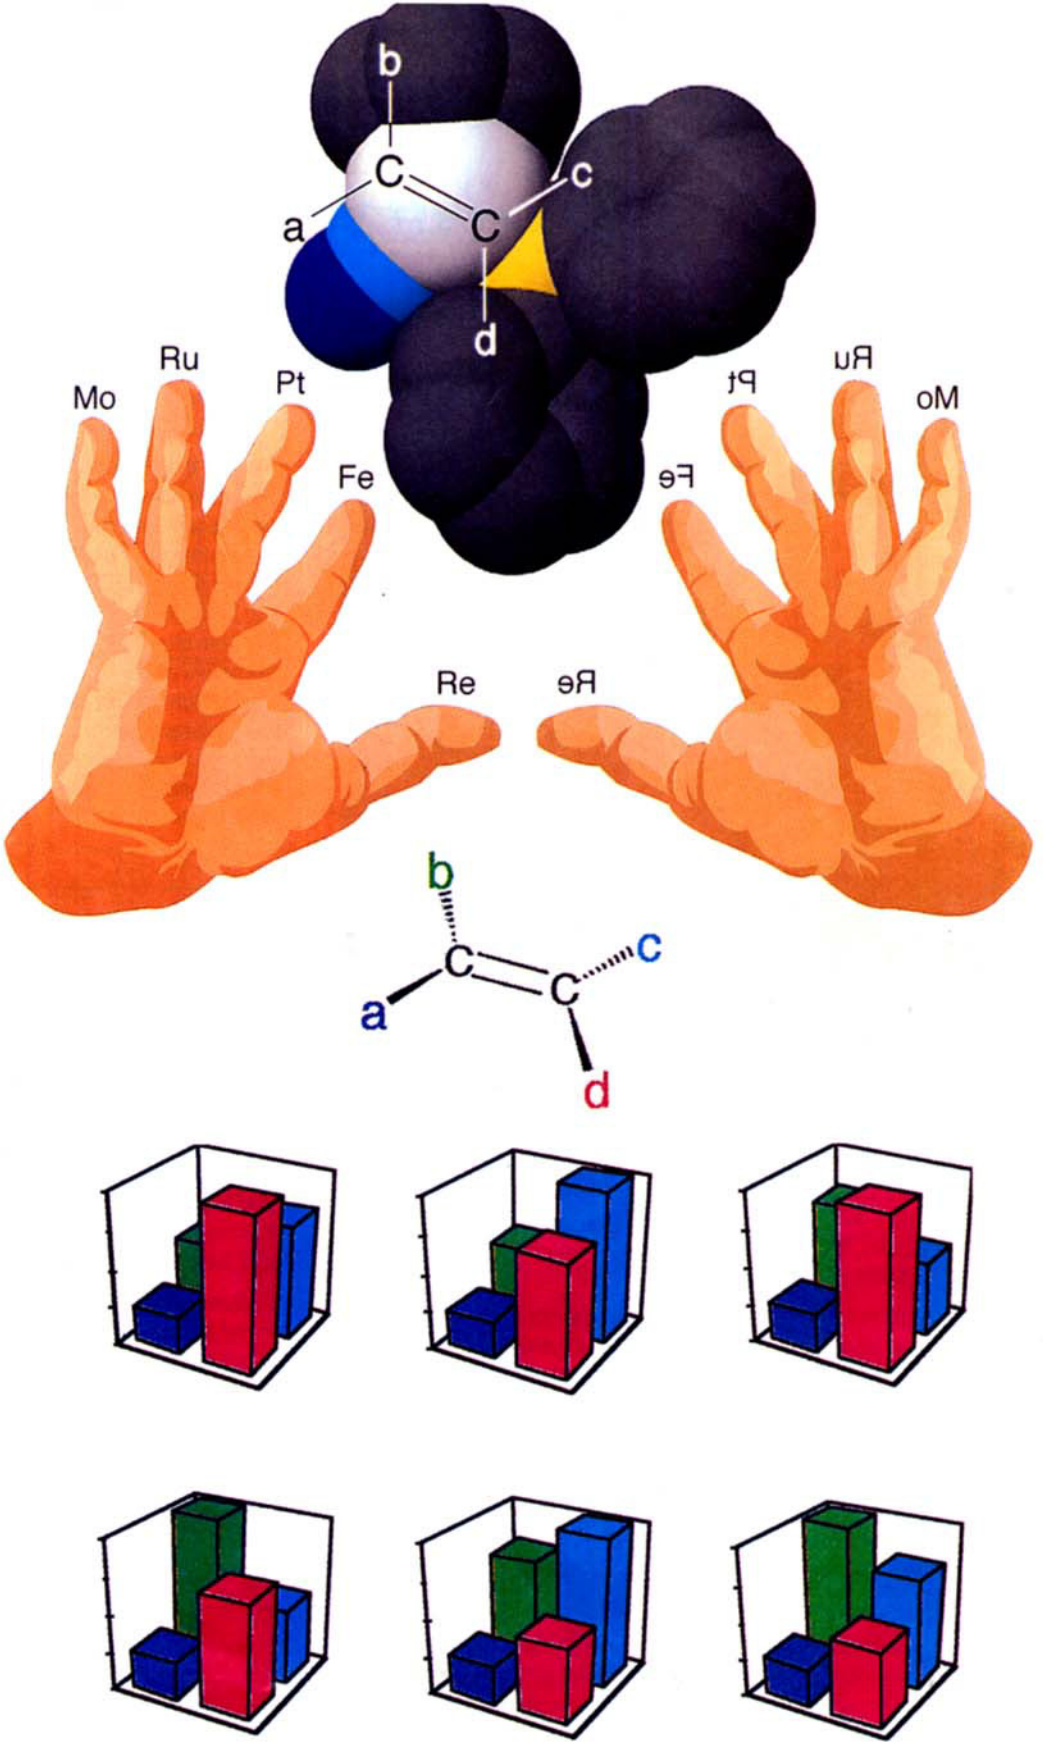
Deposition of Data from X-Ray Structure Analyses

In order to make life easier for authors and referees the Cambridge Crystallographic Data Centre (CCDC) and the Fachinformationszentrum Karlsruhe (FIZ) have unified their procedures for the deposition of data from single-crystal X-ray structure analyses.

Prior to submitting your manuscripts please deposit the data for your compound(s) **electronically** at the appropriate data base, that is, at the CCDC for organic and organometallic compounds and at the FIZ for inorganic compounds. Both data bases will be pleased to provide help (see our *Notice to Authors* in the first issue of this year). In general, you will receive a depository number from the data base within two working days after electronic deposition; please include this number with the appropriate standard text (see our *Notice to Authors*) in your manuscript. This will enable the referees to retrieve the structure data quickly and efficiently if they need this information to reach their decision.

This is now the uniform procedure for manuscripts submitted to the journals *Advanced Materials, Angewandte Chemie, Chemische Berichte/Recueil, Chemistry—A European Journal,* and *Liebigs Annalen/Recueil.*



$[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]^+$ and analogons unsaturated chiral complexes (see element symbols along the fingertips) can form two diastereomeric adducts with prochiral alkenes, aldehydes, and ketones. The ratio of these diastereomers is a measure of the chiral recognition, symbolized by the hands, of the reaction partners. The rhenium complex mentioned is depicted above the hands (Re: light gray, P: yellow, N: light blue, O: dark blue, Ph, Cp: dark gray). The selectivity of alkene complexation can be analyzed (and predicted) by considering the sizes of the substituents a–d on the alkene and correlating them with the steric conditions in the chiral complexes, which can be represented with three-dimensional bar graphs.

Enantioselective Synthesis with Lithium/(−)-Sparteine Carbanion Pairs

Dieter Hoppe* and Thomas Hense

Dedicated to Professor Dieter Seebach on the occasion of his 60th birthday

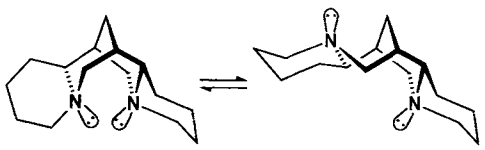
"Chiral carbanions"—that is, enantiomerically enriched lithium–carbanion pairs in which the carbanionic center carries the chiral information—were regarded until recently as "exotic species." In the past ten years it has become clear that they can, in fact, play a meaningful role in enantioselective synthesis, since substitution for lithium occurs here stereospecifically, usually with retention of configuration. They are also more readily and commonly accessible than was originally assumed. The trick lies in the use of lithium cations with chiral ligands, whether in the form of alkyllithium species used as bases in kinetically controlled, enantiotopically discriminating deprotonation, or in thermodynamically controlled equilibration in configurationally labile epimeric ion pairs. The lupine alkaloid (−)-sparteine has shown itself admirably suited as a chiral bidentate ligand, and its efficiency and breadth of application are so far unsurpassed. This contribution constitutes an overview of the preparation of chiral reagents, covering primarily "umpoled" synthons such as homoenolates, 1-oxyalkanides with a broad pattern of substitution, and α-aminobenzyl anions.

Keywords: asymmetric synthesis · chiral building blocks · lithium · (−)-sparteine

1. Introduction and Delineation of the Problem

In a series of reviews that also provide insight into the fundamental contributions of his research group, D. Seebach has since 1969 popularized the concept of "reactivity umpolung."[1] As a consequence, the synthetic chemist has acquired not only a simple tool for the rational planning of syntheses, but has also been stimulated in the search for new synthetic building blocks. A higher standard has been achieved particularly in the case of reagents for carbanionic synthons of the d^1 and d^3 type, which now leaves little to be desired with respect to controlling reactivity and various levels of selectivity. Seebach has repeatedly noted that the reactivity and selectivity of carbanionic reagents is heavily dependent on the nature of the counterion and the structure of the relevant aggregates.[2] It will become clear in what follows that it is precisely the apparent disadvantage of most d^1 and d^3 reagents—a lack or at least a weakening of resonance stabilization, and thus restricted accessibility—that lends new qualities to these species.

The carbanionic center of a lithium–carbanion pair in the vicinity of +M substituents seeks to achieve a pyramidal and therefore potentially chiral configuration; in this way it is able, under appropriate conditions, to act as a carrier of chiral information, thereby opening the way to new strategies for enantioselective synthesis. Chiral ligands attached to the cation—here primarily the alkaloid (−)-sparteine (**1**) (Scheme 1)—have shown themselves to be astonishingly efficient aids.



1A **1B**

Scheme 1. Conformations of (−)-sparteine (**1**).

In nonpolar solvents lithium salts of carbanions form tight ion pairs, usually present as dimers, tetramers, and occasionally also higher aggregates.[2, 3] The lithium cation usually prefers an approximately tetrahedral coordination geometry saturated by four donor ligands. It is thus tempting to provide the cation with chiral, enantiomerically pure ligands and to hope that stereoselectivity will be introduced in reactions with achiral, prostereogenic substrates. For purposes of clarity our first "thought experiment" will involve a bidentate, C_2-symmetric ligand[4, 5] and a η_1-bound anion; in addition, we will consider a monomeric ion pair. The ion pair **A** bears an achiral alkanide residue; that means that any chiral induction must be due to the chiral cation (Scheme 2). If both components of the ion pair (the cation as well as the anion) are chiral, the result is the pair of epimers **B** and *epi*-**B**. The consequences will be explored in more detail.

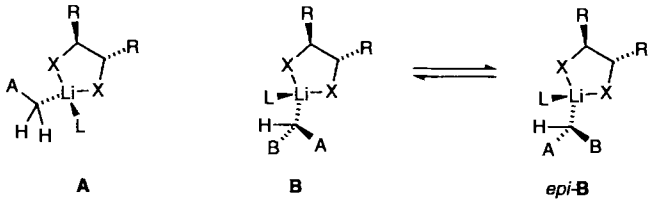
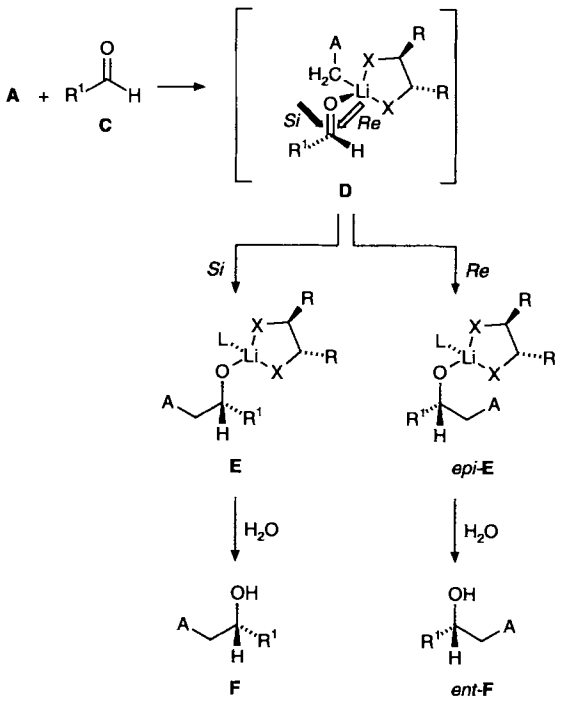


Scheme 2. Types of chiral lithium–carbanion pairs. X is, for example, OR, NR_2; L is, for example, OEt_2, THF; A,B are C- or heterosubstituents.

A is already in a position to "recognize" enantiotopic faces and groups in prochiral[6] reaction partners, since it will proceed through diastereomorphic transition states, which will in principle be energetically nonequivalent (Scheme 3). This is apparent in complex **D**, comprising a combination of **A** and **C**: the previously enantiotopic faces *Re* and *Si* are now diastereotopic in the intermediate **D**, and the alkanide residue ACH_2^- will be transferred at different rates to form the adducts **E** and *epi*-**E**. Hydrolysis leads finally to the enantiomers **F** and *ent*-**F**, one of which will be present in excess.[7] Scheme 4 depicts several examples from the early stages of the development of this technique.

A similar problem is posed when **A** interacts as a chiral base with the prostereogenic substrate $A-CH_2-B$: in this case the enantiotopic groups *pro-S*-H atom H_s and *pro-R*-H atom H_R must display different reactivities. Insofar as the resulting ion pairs **B** and *epi*-**B** are configurationally stable under the reaction conditions and substitution occurs stereospecifically (that is, with either retention or inversion), the enantiomeric relationship **G**:*ent*-**G** reflects directly the result of enantiotopic differentiation between H_S and H_R (Scheme 5). Thus, the newly created stereocenter at the carbanionic C atom determines the stereochemistry of substitution.

However, with few exceptions (which will be discussed later), configurational stability of the carbanionic intermediate cannot be assumed;[15] the ion pairs **B** and *epi*-**B** are subject to equilibration. Scheme 6 summarizes the possible situations, where for simplicity only stereoretentative substitution is illustrated. Under the simplifying assumption that $k_R \approx k_s > k_{epi}$, the ratio **G**:*ent*-**G** corresponds to the position of equilibrium **B**:*epi*-**B**. Especially fortunate circumstances obtain when one of the diastereomers **B** or *epi*-**B** crystallizes, so that in the reaction mixture essentially only one diastereomer arises. This special case of a dynamic kinetic resolution through crystallization is also referred to as "asymmetric transformation of the second order."[16] An additional limiting case—kinetically controlled



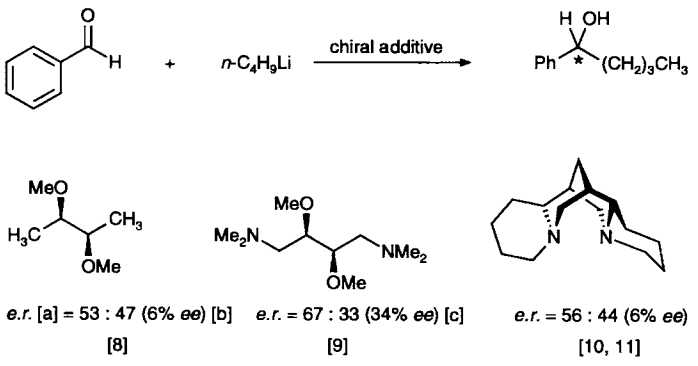
Scheme 3. Enantiofacial selection in a prochiral carbonyl compound on use of an ion pair containing an achiral residue.

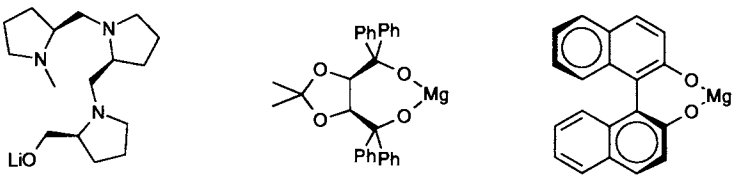
Dieter Hoppe, born in Berlin in 1941, worked as a chemical technician in Hannover before beginning his chemistry studies at the University of Göttingen in 1965. He received his doctorate in 1970 with U. Schöllkopf, submitting a dissertation on metalated isonitriles and completed his habilitation there in 1977 with a topic drawn from the realm of β-lactam chemistry. From 1977 to 1978 he was a postdoctoral fellow with R. B. Woodward at Harvard University in Cambridge (Massachusetts). After serving as a Privatdozent at the University of Göttingen he accepted a call to a C-4 professorship at the University of Kiel in 1985. Then followed a call to the University of Münster (1992), after a call he had declined to Hamburg (1991). His work was recognized in 1993 with an Otto-Bayer Award. He is a coeditor of "Synthesis." His areas of research relate to the development of stereoselective and especially enantioselective synthetic methods based on carbanion chemistry.

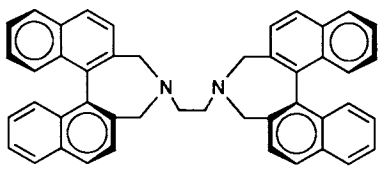
D. Hoppe

T. Hense

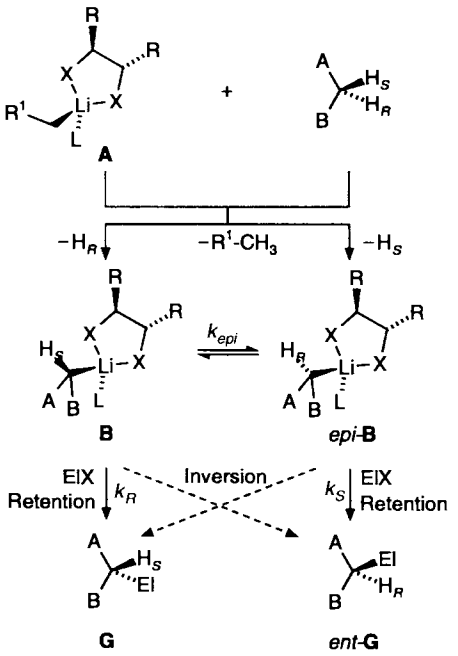
Thomas Hense, born in 1964 in Oldenburg, began his studies in 1987 in Münster, and joined the research group of D. Hoppe in 1992. He completed his dissertation in 1996 on the subject of kinetic resolution of racemates through (−)-sparteine-induced deprotonation. In 1997 he entered upon a postdoctoral appointment with J. Otera in Okayama (Japan) in the field of enantioselective catalysis.



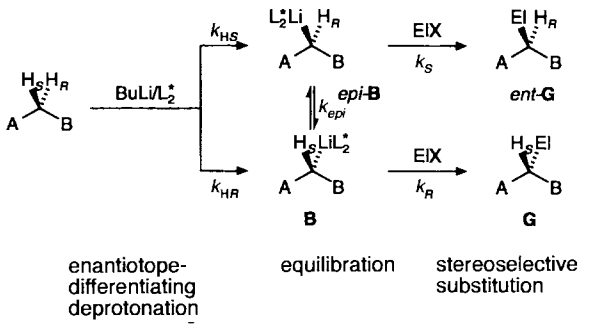




Scheme 4. Addition of complexes of *n*-butyllithium and chiral ligands to benzaldehyde with differentiation between enantiotopic faces. [a] *e.r.* = enantiomeric ratio; [b] 2.0 equivalents of ligand utilized; [c] with 9 equivalents, 86% *ee* was achieved; [d] With butylmagnesium chloride.



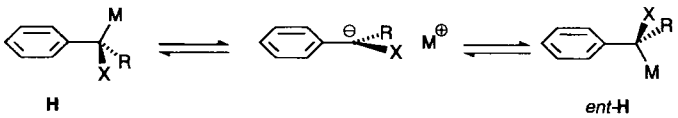
Scheme 5 Deprotonation of a prochiral CH acid ACH_2B by a chiral base and stereoselective substitution of the epimeric ion pairs.



Scheme 6. Limiting cases in the substitution of chiral ion pairs.

stereoselective substitution with dynamic kinetic resolution[16a, c, d]—occurs when the rate constants k_R and k_S differ greatly, and k_{epi} much larger than these. In this limiting case (e.g., $k_R \gg k_S > k_{epi}$), the enantiomeric ratio **G**/*ent*-**G** is determined solely by the quotient k_R/k_S.[17]

It should also be recalled that achiral carbanions, which in the ground state are planar and which bear three different substituents at the carbanionic center, become chiral in the course of interacting with a cation (Scheme 7). Since exchange of the



Scheme 7. Chiral tight ion pairs and their racemization via achiral separated ion pairs.

cation between the enantiotopic faces on the "top" and "bottom" of the benzylmetal compounds **H** and *ent*-**H** normally occurs with exceptional ease, enantiomerically enriched ion pairs are subject to rapid racemization, as demonstrated by D. J. Cram.[18] However, if the cation is provided with a configuratively uniform ligand, the result is epimeric, configurationally stable ion pairs, to which the above argument applies.

Thus, the areas of application for chiral lithium carbanions in enantioselective synthesis can be subdivided according to the effective mechanisms:

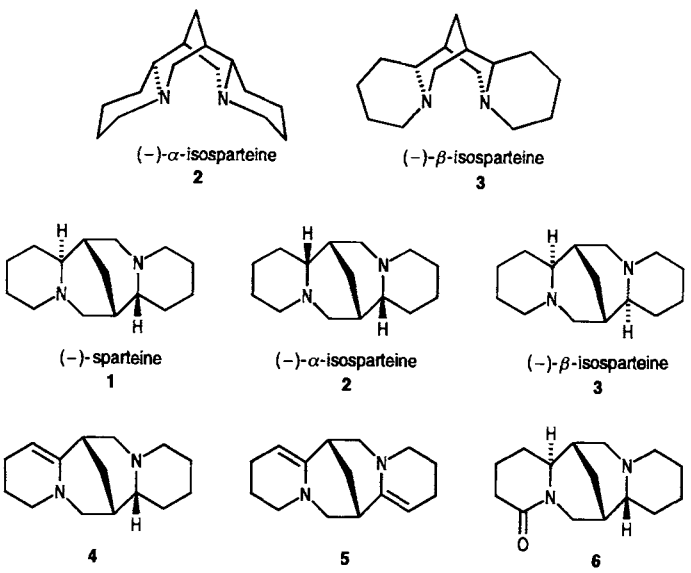
1. Enantiofacial selection with achiral carbanions bearing a chiral cation.
2. Kinetically determined enantiotopic selection through deprotonation by a chiral base.
3. Thermodynamically controlled selection between epimeric ion pairs.
4. Kinetically controlled selection between diastereomeric ion pairs during a substitution step.

We will also discuss and then utilize the complications that arise out of interaction with other stereocenters that may be present.

2. (—)-Sparteine-Modified Ion Pairs—Early Experiments and Disappointments

The alkaloid (−)-sparteine[19] (**1**) is extremely well-suited to the chiral modification of cations in carbanion pairs,[20] because in the only slightly more energy-rich conformation **1A** (see

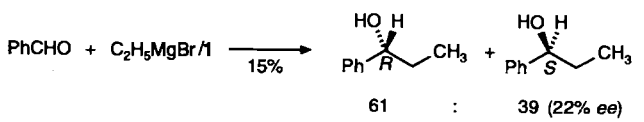
Scheme 1)[21] it can function as a bidentate ligand. (−)-Sparteine is available in large quantity and is obtained through the extraction of certain papilionaceous plants such as Scotch broom.[22] In contrast to its diastereomers[23] (−)-α-isosparteine (**2**) and (−)-β-isosparteine (**3**) (Scheme 8) it deviates



Scheme 8. Various sparteine diastereomers, along with starting material **6** and intermediates **4** and **5** for semisynthetic transformations.

slightly from C_2-symmetry; it is true that **2** and **3** also occur naturally, but they are best obtained by isomerization of (−)-sparteine (**1**) via the dehydro derivatives **4** and **5**.[24] (+)-Sparteine (*ent*-**1**) has been described as a constituent of the shrub *Sophora pachycarpa C. A. Mey*.[25] It is most conveniently obtained in the form of the racemic lactam *rac*-lupanine (**6**) by extraction of seeds of the bitter lupine *Lupinus albus*, followed by racemate resolution through the salt of (−)-camphor-10-sulfonic acid and finally by deoxygenation to give *ent*-**1**.[26] All the sparteine diastereomers can be easily recovered from alkaline suspensions as a result of their low water solubility.

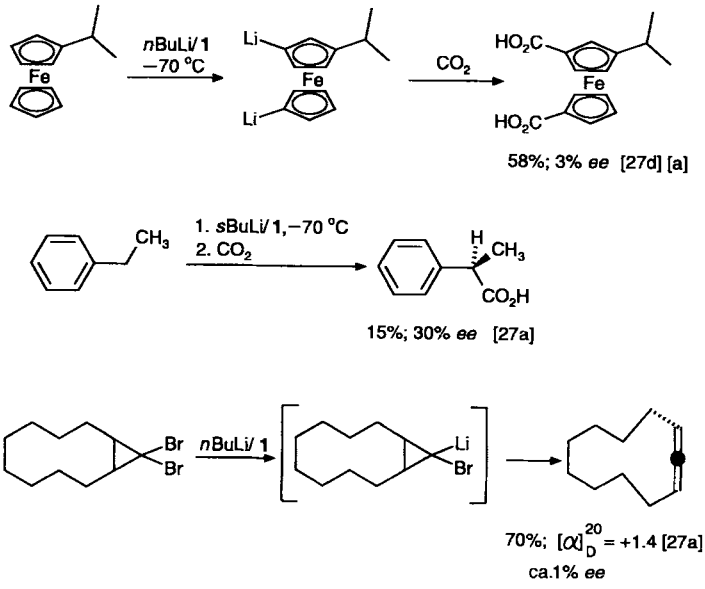
Nozaki, Aratani, Toraya, and Noyori[10, 27] first studied the suitability of (−)-sparteine (**1**) as a chiral additive in carbanion reactions in the years 1968–70 (Scheme 9). The greatest enan-



Scheme 9. Early attempts at (−)-sparteine-mediated nucleophilic alkylation of benzaldehyde. [10, 27a]

tiomeric excess (22% *ee*) was achieved by addition of ethylmagnesium bromide/**1** to benzaldehyde.[10, 27a] The procedure they utilized is only of historical significance,[28] since today efficient catalytically asymmetric methods are known for nucleophilic alkyl transfer.[7a, h, o, 29]

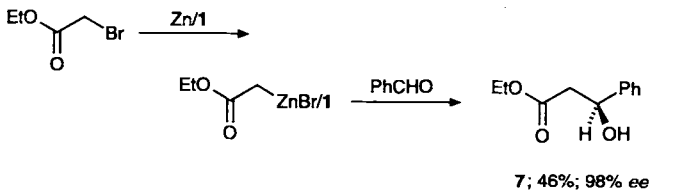
Other early applications relate to the asymmetric lithiation of isopropylferrocene[27c, d] and ethylbenzene,[27a] as well as attempts at rearranging cyclopropyl carbenoids;[27a, b] the best results achieved in each case are illustrated without comment in Scheme 10.



Scheme 10. Early applications of (−)-sparteine-mediated lithiation. [a] The configuration is unknown.

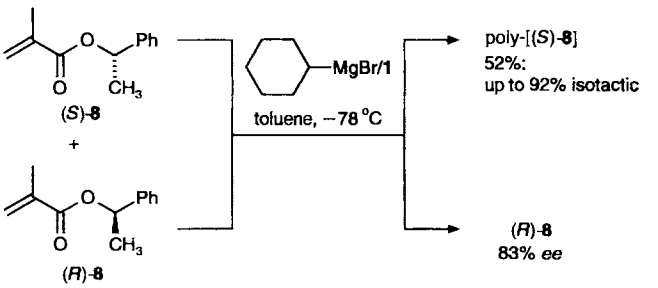
Only very small enantiomeric excesses have been observed in (−)-sparteine-mediated conjugate addition to enones,[30] allylation utilizing palladium catalysis,[31] methyltitanium trichloride addition to alkanals,[32] and the acylation of lithiomethyl *p*-tolyl sulfoxide.[33]

An astonishingly high chiral induction of 98% *ee* was achieved in the case of **7** by M. Guetté, J.-P. Guetté, and J. Capillon in the Reformatzky reaction of ethyl bromoacetate and benzaldehyde in the presence of (−)-sparteine[34] (Scheme 11). However, the authors themselves and others as well[35, 36] established, for unknown reasons, much lower *ee* values with substrates that differ only slightly.



Scheme 11. (−)-Sparteine-catalyzed Reformatzky reaction [34a].

(−)-Sparteine-modified alkyllithium and alkylmagnesium complexes found early application in stereoselective anionic polymerization.[37, 24b] Remarkable in this context is the reaction of racemic 1-phenylethyl methacrylate (*rac*-**8**) with cyclohexylmagnesium bromide/(**1**), as well as with other Grignard complexes (Scheme 12). Under kinetic resolution, (*S*)-**8** is largely transformed into isotactic poly(methacrylate), whereas (*R*)-**8** remains behind.[24b].



Scheme 12. Anionic polymerization of a methacrylic acid ester with kinetic resolution via (−)-sparteine [24b].

Kinetic ^{1}H NMR studies by Fraenkel et al. document relatively slow ligand exchange in dialkylmagnesium/(−)-sparteine complexes.[38]

The metal complexes of (−)-sparteine and its isomers display a strong tendency toward crystallization. This has permitted corresponding X-ray crystal structure analyses of various Grignard compounds,[39] an allylpalladium complex,[40] and several transition-metal salts.[41]

White, Raston, et al. solved the structure of the (−)-sparteine complex with (methylphenylphosphinyl)methyllithium[42] (**9**), which crystallized as a dimer, and that with 1-pyrid-2-yl-1-(trimethylsilyl)methyllithium[43] (**10**), which can be regarded as an azaallyllithium derivative. The structure of α-isocyanodiphenylmethyllithium/**1**/2THF (**11**) was characterized by Boche et al. (Scheme 13).[44] It is interesting that here lithium

seeks contact with the isonitrile C atom, but not with the carbanionic center. The bond lengths between lithium and the (nonequivalent) N atoms of (−)-sparteine are quite variable: 202–216 pm and 206–221 pm. The structures of additional lithium complexes that possess stereogenic carbanionic centers are discussed in Section 3.

3. Enantioselective Syntheses with Configurationally Labile Lithium/Sparteine-Carbanion Pairs

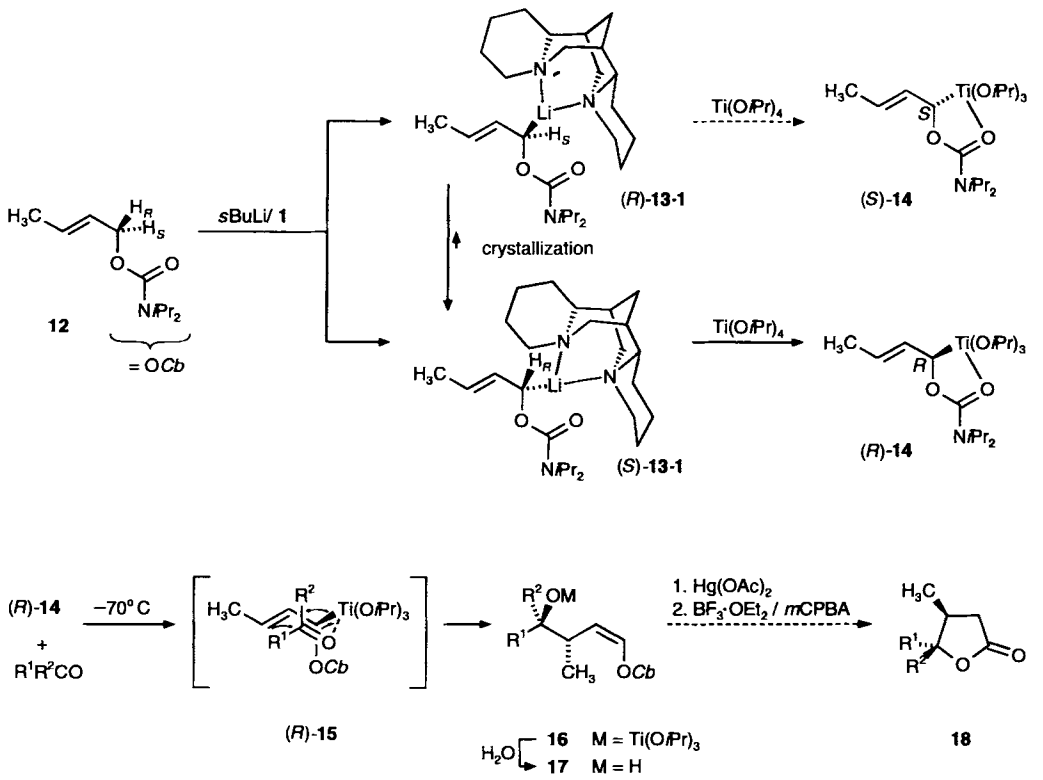
3.1. Lithiated Allyl Carbamates and Enantioselective Homoaldol Reactions

We established in 1985 that enantiomerically enriched secondary 2-alkenyl diisopropylcarbamates can be deprotonated with retention of configuration using butyllithium.[45] This formed the basis for an enantioselective variant of the homoaldol reaction.[46] Not aware at the time of the previously described sparteine efforts, O. Zschage began in 1988 a diplom a thesis[47] with the task of deprotonating the (*E*)-2-butenyl carbamate **12** in the presence of (−)-sparteine instead of the ordinarily employed achiral complexing agent *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA), and subsequently investigating the resulting capture products with respect to possible enantiomeric excesses. We anticipated that the chiral base *sec*-butyllithium/(−)-sparteine would distinguish between the enantiotopic protons *pro*-*R*-H and *pro*-*S*-H in the methylene groups. In that case, one of the epimeric ion pairs (*R*)-**13**·**1** or (*S*)-**13**·**1** should be generated in excess, which would be discernible from a corresponding enantiomeric excess in the capture product **14** (Scheme 14, Table 1).

It quickly became apparent that the deprotonation here is not kinetically controlled, but the process is nevertheless extremely efficient.[52,48] In the very first experiment deprotonation with *sec*-butyllithium/(−)-sparteine (**1**) in isopentane/cyclohexane and addition of tetra(isopropoxy)titanium[53] to the suspension of the organolithium intermediate, followed by 2-methylpropanal, led to the (*Z*)-*anti*-configured homoaldol adduct **17a** [R^1 = $CH(CH_3)_2$] with 83% *ee*. Because of the complete 1,3-chirality transfer[54] during carbonyl addition, the titanated intermediate (*R*)-**14** must have been present here with the same enantiomeric excess, corresponding to the diastereomeric excess in the (−)-sparteine complex **13**·**1**. Nevertheless, the reaction at first proved not to be reproducible; only a nearly racemic product was subsequently isolated. In contrast to the successful experiment, crystallization failed to occur after deprotonation. Our suspicion was confirmed that dynamic kinetic racemate resolution[55] occurred in the course of crystallization; the epimeric (*R*)- and (*S*)-**13**·**1** are in equilibrium in solution, and one diastereomer crystallizes preferentially. A certain amount of cyclohexane is required for the crystallization, however, and this had been introduced in sufficient quantity into the first experiment only due to the use of a *sec*-butyllithium solution in isopentane/cyclopentane with the unusually low concentration of 0.5 M. An optimized procedure, in which a defined quantity of cyclohexane was added to the hexane solution and *n*-butyllithium was employed as the base, resulted unambiguously in substitution products with 90–94% *ee*.[55]

Metal exchange occurs under the refined conditions[55] with complete inversion of configuration, and the titanium intermediate (*R*)-**14** is configurationally stable up to at least −40 °C. Thus the epimeric ratio of (*S*)- and (*R*)-**13**·**1** determines the enantiomeric ratio of the homoaldol adducts **17**/*ent*-**17**. The stereoselectivity is predominantly reagent-controlled; that is, equally good results are achieved for the "mismatched pair"[16c,d,56] with chiral aldehyde components.[57,58]

The crystalline suspension of (*S*)-**13**·**1** can also be trapped with retention of optical activity using trialkyltin chloride (Scheme 15).[55] This results, with low regioselectivity and about 80% *ee*, in a mixture of the α-adduct (*S*)-**20** (inversion) and the γ adduct (*S*)-**19** from an *anti*-S_E' reaction. However, stannylation of the titanium intermediate (*R*)-**14** leads with high efficiency to the (1*Z*,3*R*)-configured stannane **19**, from which the tributylstannyl derivative (*R*)-**19b** is obtained with about 95% *ee*.



Scheme 14. Dynamic kinetic racemate resolution in the (−)-sparteine-induced deprotonation of **12**; lithium–titanium exchange and enantioselective homoaldol reaction [48, 51, 52, 55].

[a] Nonoptimized preparation of **13**·**1**. [b] Not determined. [c] A different oxidation method was utilized; see text.

The stannanes **19** are storable homoenolate reagents that are activated by the addition of titanium tetrachloride (Scheme 16, Table 2).[55, 59, 60] All indications suggest a stereospecific tin–titanium exchange (similar to that shown by Marshall for tin–tin exchange[61]) to give a trichlorotitanate, and pericyclic *syn*-S_E' addition of the latter to the aldehyde. Starting with stannane (*R*)-**19** one obtains the enantiomerically enriched homoaldol adduct **22**, whereas the antipode (*S*)-**19** leads to *ent*-**22**. Thus, both series of enantiomers are accessible via this Lewis acid mediated variant from the same lithium intermediate (*S*)-**13**·**1**. The strength of the variant lies in a smooth reaction with sterically demanding ketones.

The extension of thermodynamically controlled asymmetric lithiation with a subsequent homoaldol reaction to the diisopropylcarbamates of (*E*)-2-hexen-1-ol, 3-methyl-2-butenol, or (*E*)-3-trimethylsilyl-2-butenol provided only modest enantiomeric excesses (41–76% *ee*), because optimized conditions for the crystallization had not yet been established.[48]

[a] See text.

In collaboration with Boche et al. it proved possible to obtain an X-ray crystal structure analysis of sparteine complex **23**·**1** (Figure 1).[63] This revealed the (*1S*)-configuration at the carbanionic center and verified our earlier assumptions regarding the structure of lithioallyl carbamates: they are monomeric even in the crystalline state, because the lithium cation is offered optimal preconditions for four-fold coordination in the α-position. The allylic system is η^1-bonded, and the electron-donating carbamoyl oxo group and the nitrogen atom of the tertiary diamine function as residual ligands. Firm attachment of the cation at the α-position is the key to high γ-selectivity in the course of carbonyl addition. This also causes the observed torsional stability in most cases of the β,γ-double bond[64] and presumably contributes much to increasing the barrier to racemization in chiral lithium derivatives.

The lithiated secondary 2-alkenyl and 2,4-alkadienyl carbamates **24** and **25** (Scheme 17), readily accessible in enantiomerically enriched form, are configurationally stable below $-70\,^{\circ}C$;[45] to our knowledge they represent the first known examples of allyllithium derivatives with configurationally

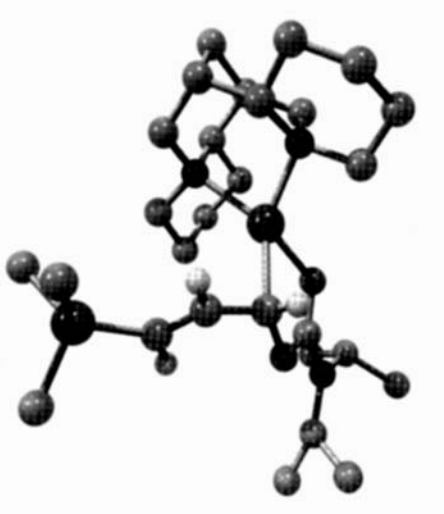

Figure 1. X-Ray crystal structure analysis of η^1-[(1*S*,2*E*)-1-(*N*,*N*-diisopropylcarbamoyloxy)-3-trimethylsilyl-2-propen-1-yl]lithium·(−)-sparteine (**23**·**1**)[63]. All hydrogen atoms have been omitted, with the exception of H-1 and H-2. (C Atoms gray, O atoms dark gray, N atoms black).

24 **25**

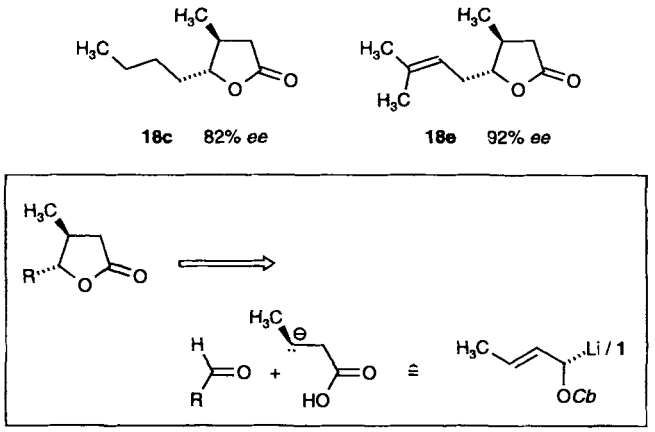
Scheme 17. Configurationally stable alkenyl carbamates **24** and **25**. L_2 = TMEDA.

stable stereogenic, metal-bearing C atoms. As we reported in 1990, the enantiomerically enriched lithium derivative **24** can be obtained not only from the optically active carbamate, but also with *sec*-butyllithium/(−)-sparteine under kinetic resolution of the corresponding racemic allyl carbamate **24** (H for Li/L_2 in *rac*-**24**).[59,60] The rich chemistry of the compound[45,60,65] and **25**,[66] as well as their analogues, is governed by their torsional behavior; further discussion of this point would exceed the bounds of this review, however.

The value of the enantiomerically enriched homoaldol adducts in stereoselective synthesis extends far beyond formal hydrolysis to carbonyl compounds; numerous stereoselective transformations of the (*Z*)-vinyl carbamate group have been developed by P. Kocienski as well as by us.[67] Oxidative deblocking[71] of adduct **17c** or **17e** (Table 1) leads to completion of the syntheses of (+)-quercus lactone A[52,48] (**18c**) and (+)-eldanolide (**18e**).[50] This procedure is readily transferable to the synthesis of diverse γ-lactones (Scheme 18).

3.2. Benzyllithium Compounds

Primary and secondary benzyl *N*,*N*-dialkylcarbamates are deprotonated with the same ease as the corresponding allyl esters.[72] Whereas the lithium derivatives of chiral secondary benzyl carbamates are configurationally stable at $-70\,^{\circ}C$, this is not true for lithiated primary benzyl carbamates, although the "Hoffmann test"[57] for the complex **27**·TMEDA demonstrates



Scheme 18. Synthesis of optically active β-methyl-γ-lactones by enantioselective homoaldol reactions [50].

increased stability at the microscopic level.[73] This can also be concluded from the following series of experiments: Benzyl *N*,*N*-diisopropylcarbamate (**26**) was deprotonated with *sec*-butyllithium/(−)-sparteine in ether at −78 °C, and after 4 h the epimeric mixture of ion pairs **27**·**1** was trapped by introduction of carbon dioxide into the homogeneous reaction mixture (Scheme 19). After esterification with diazomethane one isomer

hexane (solid)	(50%)	95 : 5	(90% *ee*)
hexane (solution)	(18%)	69 : 31	(38% *ee*)

Scheme 19. Investigations into the configurational stability of lithiated benzyl carbamates.

lates the mandelic acid derivatives (+)-(*S*)-**28** and (−)-(*R*)-**28** with only 14% *ee* in favor of (*S*)-**28**. Under identical experimental conditions but with hexane as the solvent crystallization occurred, and (+)-(*S*)-**28** was formed with 82% *ee*. In a third experiment the solution was separated from the crystalline mass, and the two were treated separately; the enantiomeric excesses amounted to 38% and 90% *ee*, respectively.

It is thus very probable that the lithium complexes equilibrate even at −70 °C, and that here also the crystallization of one epimer leads to a dynamic resolution. The configuration of the favored ion pair has not been established with certainty; since we have found inversion in carboxylation of a similar complex (**29**, CH_3 for 1-H),[74a,b] there are strong arguments for the (*S*) configuration.[75, 76]

P. Beak et al. succeeded in carrying out stereoselective lithiation of a series of benzyl systems; the results are collected along with an extensive discussion of the mechanistic aspects in a recent review.[17]

N-Methyl-3-phenylpropionamide (**30**) reacts with two equivalents of butyllithium/(−)-sparteine to give the dilithium derivative **31**·**1**,[77] which leads with various electrophiles to amides substituted at the benzyl position with 60–94% *ee* (Scheme 20). Similar results were achieved when **30** was prepared first in the absence of (−)-sparteine (**1**) and the latter was added only subsequently. This argues in favor of equilibration between the epimers **31**·**1**, a suspicion that has recently been verified.[78] On the other hand, racemization-free lithiodestannylation/silylation proved successful with the enantiomerically enriched stannane **32f** to give silane **32a**; under these reaction conditions the carbanionic intermediate was configurationally stable. It is noteworthy that reaction in this case can be carried out in THF without displacement of (−)-sparteine.[77b] Equally efficient are transformations of the 2-methoxyphenyl derivative; adducts of the type **32** (2-$MeOC_6H_4$ for C_6H_5) offer the possibility of transformation into enantiomerically enriched coumarins.[77b]

Scheme 20. Enantioselective substitution of *N*-alkyl-3-phenylpropionic acid amides [77].

As in the case of **31**·**1**, configurational stability at −78 °C was demonstrated for a series of additional benzyllithium–(−)-sparteine complexes. Warming of the reaction mixture is required to cause epimerization. This opens up interesting pathways for controlling stereoselectivity, as will be demonstrated.

M. Schlosser and D. Limat[79] discovered that *N*-Boc-*N*-methylbenzylamine (**33**) is smoothly deprotonated by *sec*-butyllithium/(−)-sparteine (Scheme 21). The resulting enantiomeric excess and the direction of chiral induction depend not only on the solvent and electrophile, but also on the length of time the

Scheme 21. Enantioselective lithiation and substitution of *N*-Boc-*N*-methylbenzylamine (**33**) [79]. [a] The same excess enantiomer is formed in ether.

reagent was kept before quenching it. Only after about 2 h at −75 °C is maximum enantiomeric excess achieved; exchange of hexane for THF causes the configuration of the product to be reversed, and precipitation of a solid is observed in THF after 1 h.

Through deprotonation and subsequent carboxylation of (*S*)-[1*D*]**33** with *sec*-butyllithium/TMEDA[80] it was established that the ion pair was configurationally labile in all the solvents employed at 75 °C. The ratio of the ion pairs **34·1** and *epi*-**34·1** is therefore thermodynamically determined.[81] Boche et al. conducted an X-ray crystal structure analysis on the *N*-pivaloyl derivative **36·1** and found it to possess the (1*S*)-configuration (Figure 2).[82] What is the cause of the solvent-dependent stereoselectivity of the substitution step? The authors suspect that in both cases an ion pair with the (*S*)-configuration is present, but the stereoselectivity in the substitution step is reversed under the influence of the solvent. However, all the results are also consistent with the following interpretation: The predominant ion pairs in hexane and ether solution possess a reversed configuration relative to the aggregate obtained through THF crystallization, and the substitution step follows the same configurational pathway in each case.

Beak et al. describe a (−)-sparteine-mediated lithiation of *N*-Boc-*N*-(*p*-methoxyphenyl)benzylamine (**37**), followed by enantioselective alkylation or addition to carbonyl compounds and imines (Scheme 22).[83] In a formal sense the *pro-S* H atom

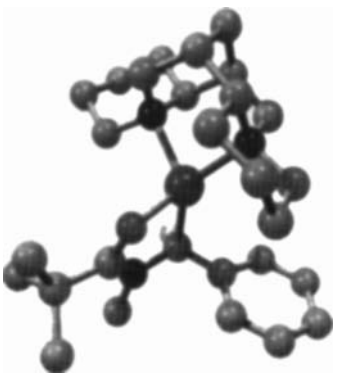

Figure 2. X-Ray crystal structure analysis of α-(*N*-methyl-*N*-pivaloylamino)-benzyllithium·(−)-sparteine (**36·1**)[82]. All hydrogen atoms have been omitted with the exception of the benzylic hydrogen atoms. (C atoms gray, O atoms dark gray, N atoms black).

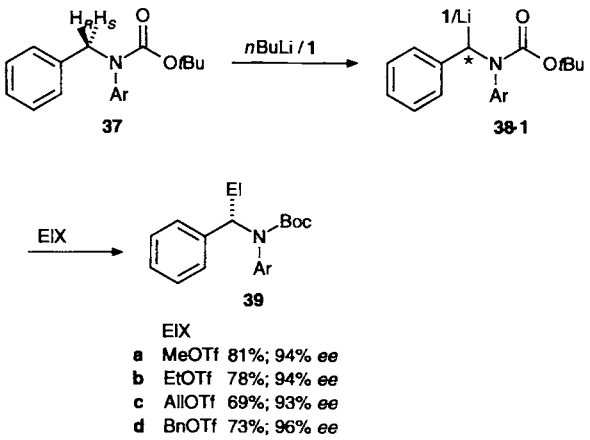


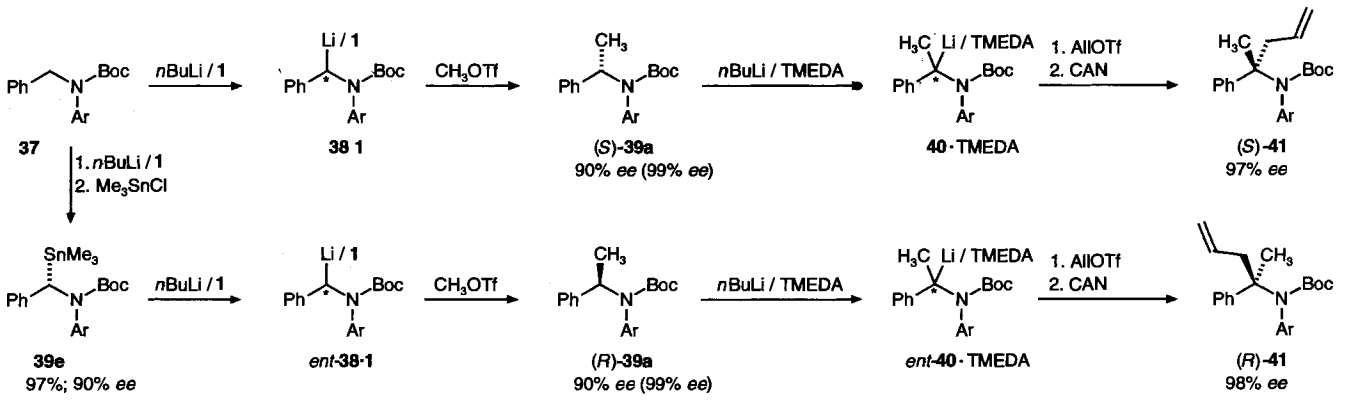
Scheme 22. Enantioselective lithiation and substitution of *N*-Boc-*N*-(*p*-methoxyphenyl)benzylamine (**37**) [83]. Ar = 4-MeO-C_6H_4; Tf = F_3CSO_2; All = CH_2=$CHCH_2$.

in **37** is substituted, and the resulting enantiomeric excesses in most cases range around 95% *ee*.

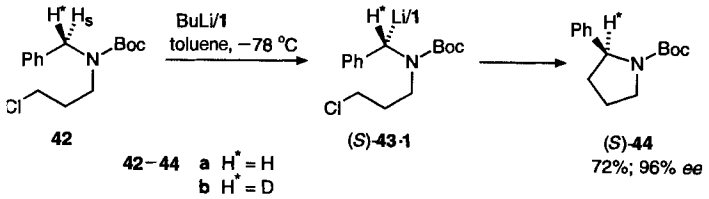
The configuration of the dominant intermediate **38·1** is unknown.[84] As we have previously demonstrated for a lithiated benzyl carbamate,[74a] it can be reversed by stannylation–delithiostannylation (Scheme 23).[83] It is important to note here that the intermediates complexed with (−)-sparteine are configurationally stable. It follows that one can obtain the oppositely configured tertiary amines (*S*)- and (*R*)-**41** by the same sequence of methylation, deprotonation, and alkylation, with subsequent oxidative deblocking.[83a]

In the case of the *N*-Boc-*N*-(3-chloropropyl)benzylamine **42a** it proved possible to show with the aid of the (*R*)-deuterium derivative **42b** that the (−)-sparteine reagent preferentially abstracts the *pro-S*-proton in **42a** (Scheme 24).[85] Intramolecular cycloalkylation of the (*S*)-configured lithium derivative **42a·1** to pyrrolidine (*S*)-**44a** occurs very rapidly, and therefore virtually free of racemization. Alkylation with stereoretention is an astonishing fact.[75] The reaction is transferable with comparable efficiency to a whole series of arylmethyl- and heteroarylmethylamines of the type **42**.

N,*N*-Diisopropyl-2-ethylbenzamide (**45**) was transformed by P. Beak et al. into the (−)-sparteine–lithium complex **46·1**[86]

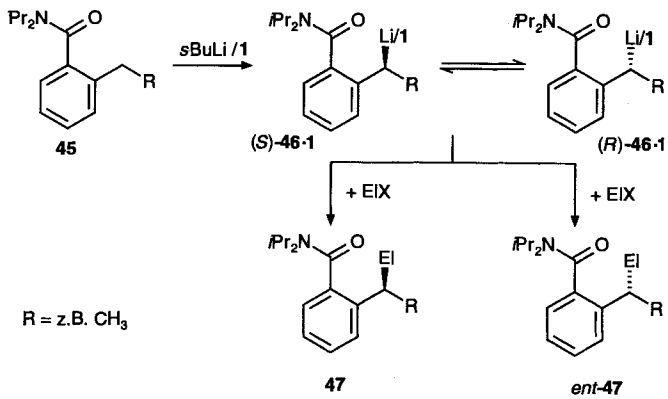


Scheme 23. Enantiodivergent synthesis of tertiary benzylamines [83a]. CAN = $(NH_4)_2Ce(NO_3)_6$; Ar = p-$MeOC_6H_4$.



Scheme 24. Synthesis of (*S*)-*N*-Boc-2-phenylpyrrolidine by intramolecular substitution [85].

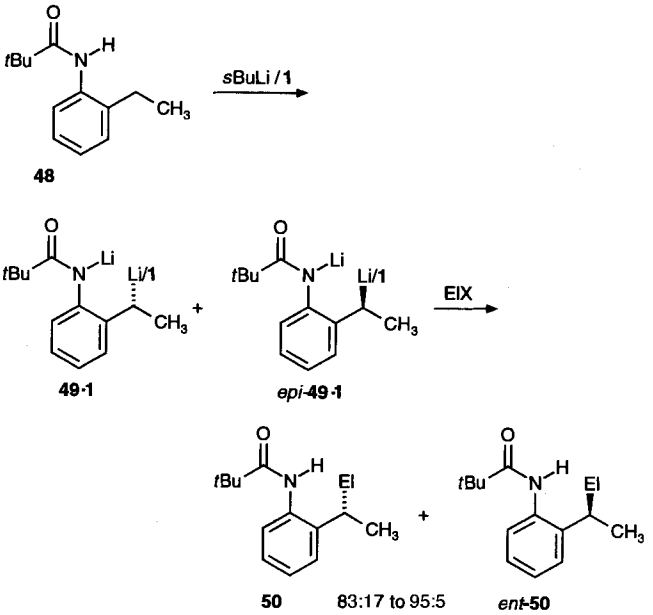
and then alkylated. All experimental indications are that the rare case of dynamic kinetic resolution (Scheme 6) has been realized.[87] The epimers (*R*)- and (*S*)-**46**·**1** are in equilibrium, and one [presumably (*S*)-**46**·**1**] reacts preferentially. In the process, substitutions with alkyl halides and alkyl tosylates take opposite courses (Scheme 25). No such strong dependence on the leaving group[75] had previously been observed for alkylating agents.



Scheme 25. Enantioselective lithiation and substitution of 2-alkyl-*N*,*N*-diisopropylbenzamides [86·87].

The (−)-sparteine complex of the dilithium salt of 2-ethyl-*N*-pivaloylaniline (**49**·**1**) is configurationally stable at −78 °C. Only after equilibration between the epimers **49**·**1** and *epi*-**49**·**1**, which occurs upon raising the temperature, does electrophilic substitution lead to good enantiomeric excesses[88] (Scheme 26).

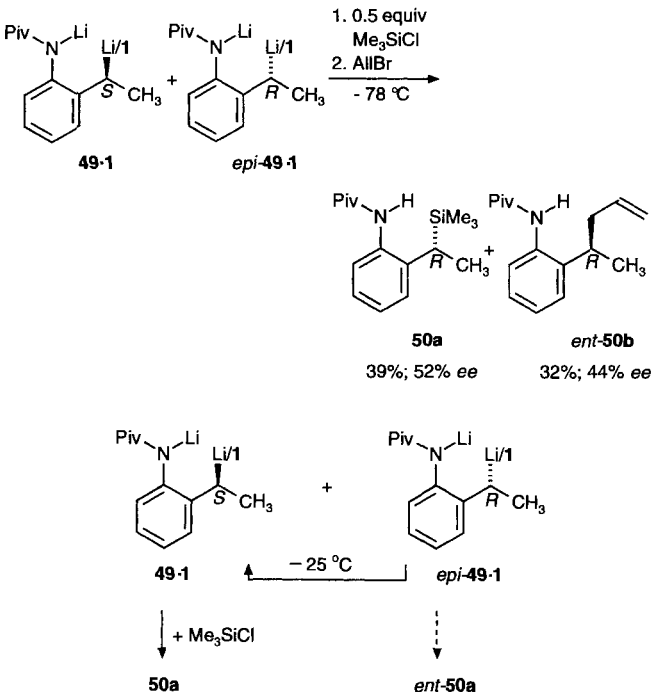
The two diastereomeric complexes **49**·**1** and *epi*-**49**·**1** are present before equilibration in roughly equal amounts. Their re-



Scheme 26. Enantioselective lithiation and substitution of 2-ethyl-*N*-pivaloylaniline [88]. El = alkyl, Me_3Si, and others.

activities toward electrophiles differ; from subsequent experiments a difference $\Delta G^{\ddagger}_{epi-49\cdot1} - \Delta G^{\ddagger}_{49\cdot1} = 3.4\ kJ\,mol^{-1}$ was established for trimethylsilylation at −78 °C.[88b] This can be exploited as follows (Scheme 27): If one adds to this mixture only half an equivalent of trimethylsilyl chloride, primarily **49**·**1** is trapped, with formation of the (*R*)-configured silane **50a**. Excess allyl bromide transforms the residual *epi*-**49**·**1** into the oppositely configured product *ent*-**50b**.

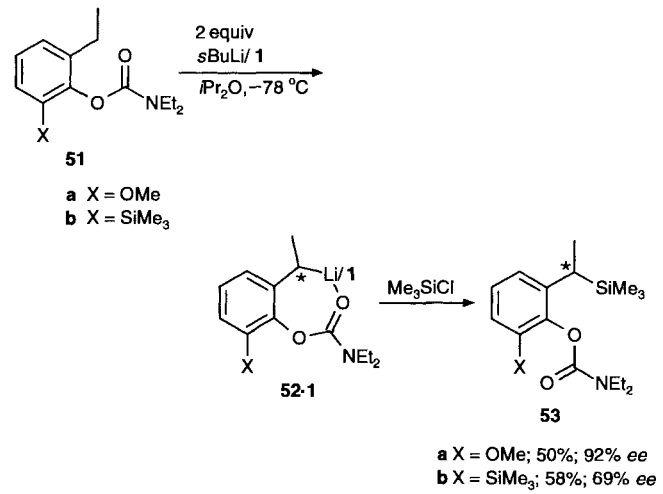
The configurational lability of lithiated intermediates at higher temperature permits recycling of the less reactive epimer into the other ("diastereomeric recycling"[88b]) through a warming and cooling sequence ("warm and cool protocol"[88b]) as a means of increasing the enantiomeric excess. As a result of warming to −25 °C, a **49**·**1**:*epi*-**49**·**1** ratio of 92:8 is established, which is then frozen by cooling the reaction mixture to −78 °C. A trapping experiment with excess trimethylsilyl chloride produces the enantiomers **50a** and *ent*-**50a** in a ratio of 92:8 (84% *ee*). However, if the electrophile is added in two portions of 0.45 equivalents each, with warming to −25 °C in between, the result is **50a** with a 98% *ee* (*e.r.* = 99:1).



Scheme 27. Differing reactivities of the diastereomeric ion pairs **49·1** and *epi*-**49·1**; "diastereomeric recycling."[88b]

α-Monosubstituted benzyllithium compounds thus assume an intermediate position with respect to their configurational stability, and in favorable cases their behavior can be prearranged by the selected reaction temperature. Configurational lability permits efficient dynamic kinetic resolution at higher temperature, whereas freezing the equilibrium between the epimers opens the possibility of thermodynamically governed reaction control.

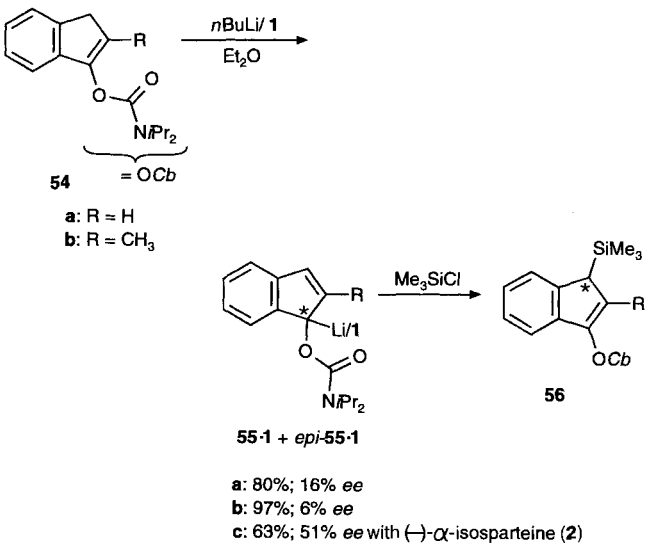
V. Snieckus et al. established a high enantiomeric excess by deprotonation of the 2-ethylphenyl carbamate **51** with subsequent silylation (Scheme 28).[90] The configuration of the dominant products **53** and intermediates **52·1**, as well as the extent of the configurational stability, are so far unknown.



Scheme 28. Enantioselective lithiation and substitution of 2-ethylphenyl *N*,*N*-diethylcarbamates [90].

3.3. Chiral Lithium Indenides

The epimeric (−)-sparteine complexes of 1-lithioindenyl *N*,*N*-diisopropylcarbamate[91] (**55a·1** and *epi*-**55a·1**) rapidly equilibrate at temperatures around 0 °C, and produce upon silylation the optically active silane (+)-**56a**[92] with only 16% *ee* (Scheme 29). In a similar way, one obtains from the 2-methylindenyl derivative **54b** via the corresponding indenides



Scheme 29. Lithiation and silylation of indenyl carbamates [91, 96].

55b·1 and *epi*-**55b·1** the silane (+)-**56b**[92] with only 6% *ee*. ^{1}H NMR spectra in [D_8]toluene could be obtained from both of the indenide complexes **55a·1** and **55b·1** (Figures 3 and 4), and

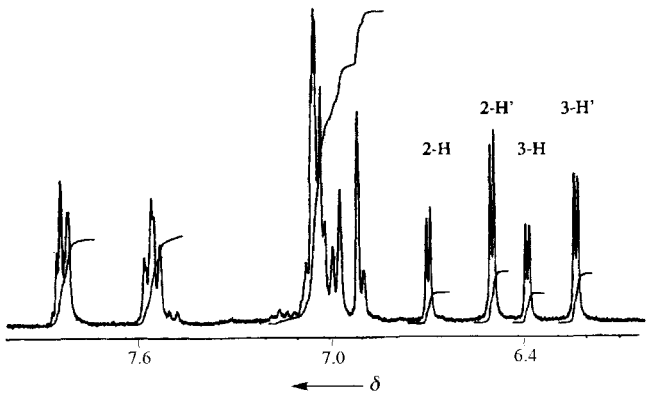


Figure 3. Excerpt from a ^{1}H NMR spectrum (300 MHz) of [1-(*N*,*N*-diisopropylcarbamoyloxy)-1*H*-inden-1-yl)lithium·(−)-sparteine (**55a·1** and *epi*-**55a·1**) in [D_8]toluene at −15 °C [91]. The spectrum indicates the presence of two diastereomers in the ratio 60:40; these interconvert only slowly, if at all.

these verify the presence in each case of two diastereomers in a ratio of roughly 60:40.[91–94] This in turn indicates an energy difference ΔG_{263} of 0.9 kJ mol^{-1}.

Semiempirical calculations (MOPAC, PM3)[95] predict for the ground state energies of the complexes **55b·2** and *epi*-**55b·2**,

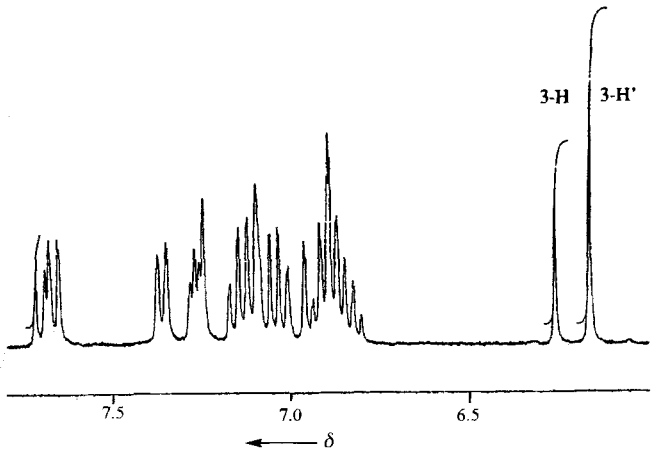

Figure 4. Excerpt from a ^{1}H NMR spectrum (300 MHz) of [1-(*N*,*N*-diisopropylcarbamoyloxy)-2-methyl-1*H*-inden-1-yl]lithium·(−)-sparteine (**55b**·**1** and *epi*-**55b**·**1**) in [D$_8$]toluene at −10 °C [91]. The sharp signals of the "cyclopentadienyl protons" H-3 and H-3′ (in the diastereomers) are $\Delta\delta \approx 0.1$ apart.

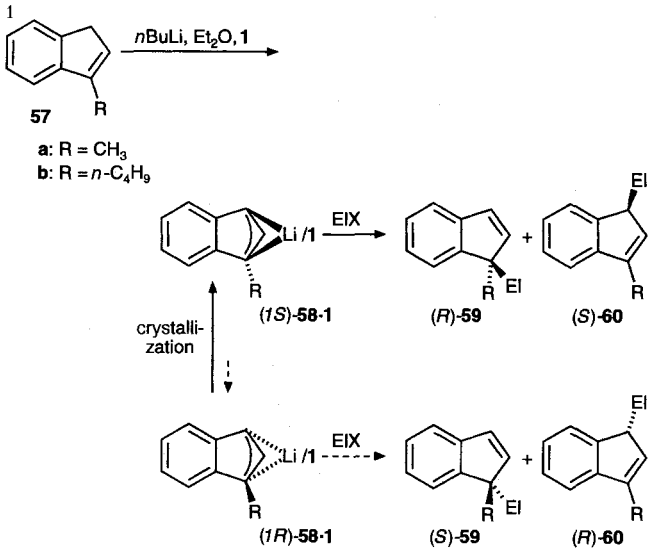
which bear the C_2-symmetric (−)-α-isosparteine as ligand, a higher difference of 2.5 kJ mol^{-1}, and the silylation experiment in fact led to (+)-**56b** with 51% *ee*.[96]

To our great surprise, the ion pairs **58**·**1** derived from 1-alkyl-3*H*-indenes **57** proved to be the most efficient representatives (Scheme 30).[97] As I. Hoppe observed as early as 1990, the



Scheme 30. Lithiation, dynamic kinetic resolution of (1*S*)-**58**·**1** by crystallization and enantioselective substitution of 1-alkyl-3*H*-indenes [97].

1-methyl derivative **57a** is rapidly deprotonated by *n*-butyllithium/(−)-sparteine in ether, and a yellow solid crystallizes upon warming the reaction mixture. After addition of an acid chloride or an aldehyde[98] the 1-substitution product (*R*)-**59** is usually isolated with an enantiomeric purity greater than 95% *ee*. Only with bulky carbonyl compounds such as 2,2-dimethylpropanal or acetone does a 3-substitution product of the type (*S*)-**60** predominate (Table 3). Similar results are provided by the 1-butyl derivative **57b**, although here the regioselectivity is reversed even sooner to the benefit of the γ-adduct (*S*)-**60h**.

Table 3. Lithiation and stereoselective substitution of 1-alkyl-3*H*-indenes [97].

Starting material	EIX	Products[a]	El	**59**:**60**	Yield [%]

[a] Unless indicated otherwise, the enantiomeric excess is greater than 95% *ee*. [b] Epimers with respect to the 1′-stereocenter. [c] The *ee* value could not be determined.

These results are best interpreted with an assumption of equilibrating dissolved ion pairs (1*S*)- and (1*R*)-**58**·**1**, from which one epimer crystallizes and reacts stereoselectively as a solid at low temperature with the carbonyl compound added as electrophile. It was long unknown which configuration applied to the crystallizing ion pair. An X-ray structural analysis[97] was ultimately successful for the dominant complex **58b**·**1** (Figure 5). This established a (1*S*)-configuration along with η^3-coordination for the indenide to the lithium cation. The C1−Li and C3−Li distances of 243.2 and 233.4 pm are unusually long.

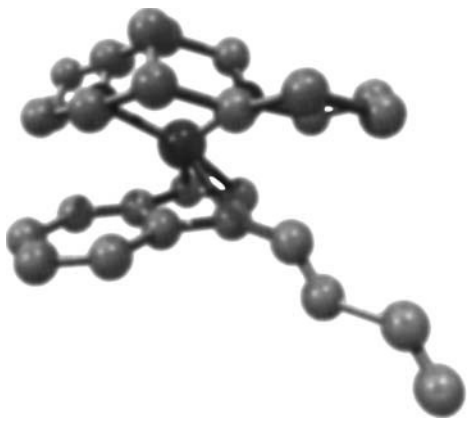

Figure 5. X-Ray crystal structure analysis of η^3-[(1*S*)-1-butylindenyl]lithium·(−)-sparteine **58b**·**1** [47]. All hydrogen atoms have been omitted.

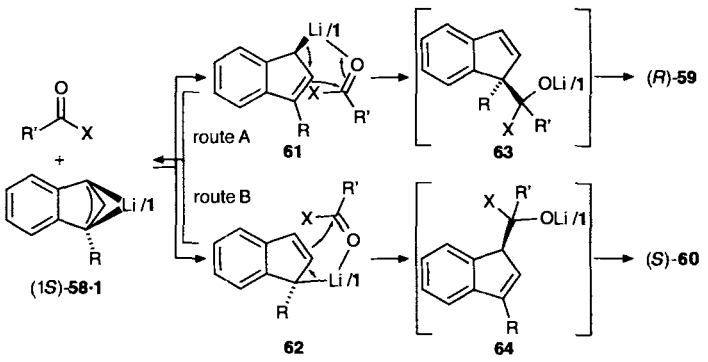
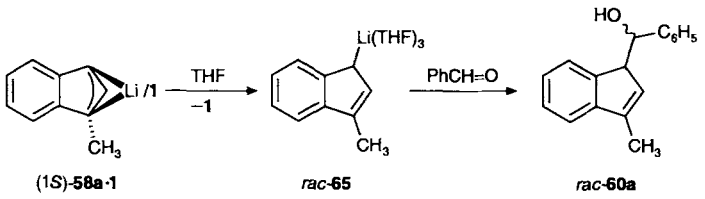
Carbonyl addition thus proceeds with retention. Apparently the attacking carbonyl group reversibly displaces one coordination site of the allyl anion with the formation of intermediates **61** or **62**, which react further by transfer of the carbonyl compound with allylic inversion to give adducts **63** or **64** (Scheme 31).[99] Route A should be favored because of the weaker C1−Li interaction. Only when the C−C bonding step leading to **63** is heavily burdened sterically should route B with formation of the γ-adduct **60** gain the upper hand.

The (−)-sparteine complexes **58**·**1** are quite labile. Addition of THF causes one coordination site of the indenide and also



Scheme 31. Formation of the α- and γ-adducts **59** and **60**.

sparteine on lithium to be displaced; (1*S*)-**58a**·**1** is transformed into the η^1-$(THF)_3$ complex *rac*-**65**, which has also been characterized by crystal structure analysis (Scheme 32, Figure 6).[97, 100] Reaction of the latter with benzaldehyde produces the completely racemic γ-adduct *rac*-**60a**. Quite generally, the regioselectivity of substitution is strongly influenced by the ligands on lithium, since in the complex **58**·TMEDA there is a considerable tendency toward γ-substitution.[101]



Scheme 32. Formation of the complex *rac*-**65** and its addition to benzaldehyde.

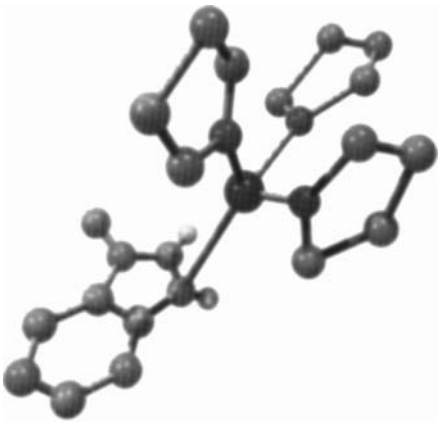


Figure 6. X-Ray crystal structure analysis of *rac*-(3-methylinden-1-yl)lithium·(3THF) (*rac*-**65**) [97]. All hydrogen atoms with the exception of those on C-1 and C-2 have been omitted.

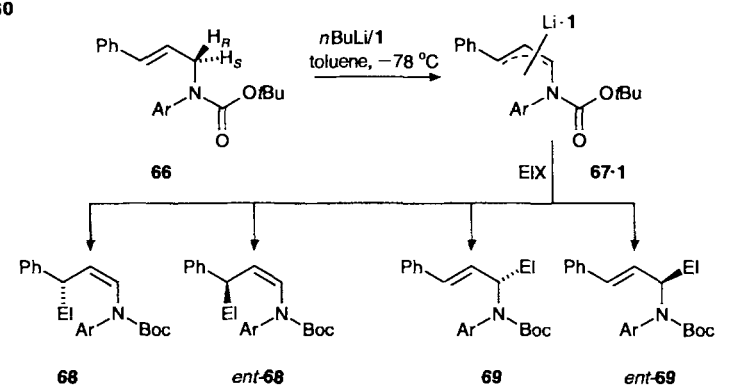
3.4 Lithiated Cinnamylamides

As P. Beak and G. A. Weisenburger recently found,[102] one of the enantiotopic methylene protons in (*E*)-*N*-(*p*-methoxyphenyl)cinnamylamide (**66**) is released with outstanding differentiation by *n*-butyllithium/(−)-sparteine (Scheme 33, Table 4). The η^3-allyllithium compound[103] **67**·**1** has been formulated as an intermediate, which can be trapped with various electrophiles to give products with high enantiomeric enrichments. Conclusive control experiments prove the configurational stability of **67**·**1** under the selected reaction conditions. The configuration of **67**·**1** was derived under the assumption that transformations with alkylating and silylating agents proceed as *anti*-E′ reactions, and hydroxyalkylations with ketones as *syn*-E′ reactions.[104]



Scheme 33. Enantioselective lithiation and substitution of *N*-Boc-*N*-(*p*-methoxyphenyl)cinnamylamine (**66**) [102]. Ar = 4-$MeOC_6H_4$, Boc = $OCOtBu$.

Table 4. Enantioselective deprotonation and substitution of **66**.

*El*X	Major product	Yield[%]	*ee*[%]

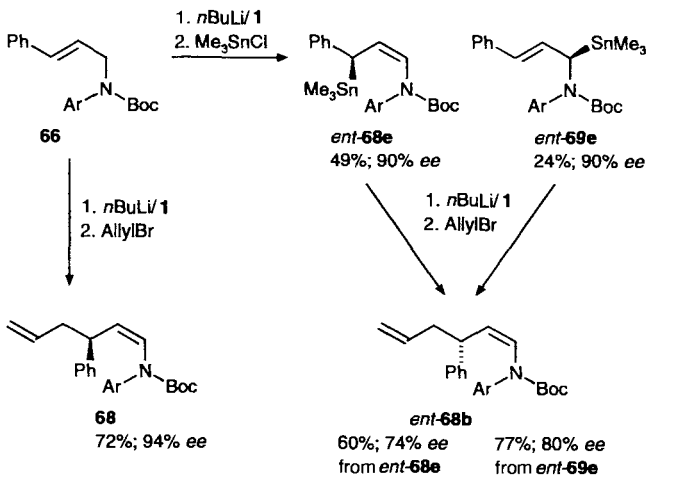
$(CH_2)_5C{=}O$	*ent*-**68f**[c]	77	98

[a] Together with 24% of the γ-silane **69d** (94% *ee*). [b] Together with 24% of the γ-stannane *ent*-**69e**. [c] El = 1-hydroxycyclohexyl.

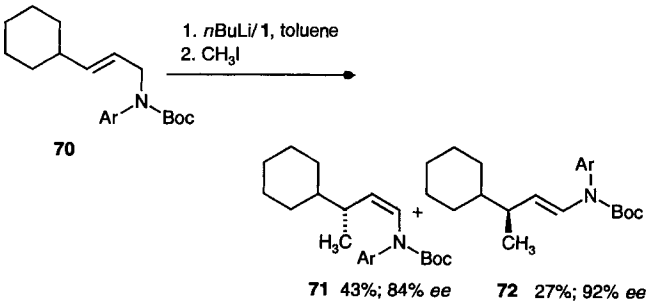
In order to gain access to the opposite series of enantiomers, the authors again utilized the sequence of stannylation of **67**·**1** followed by lithium–tin exchange,[105] which led to *ent*-**68** (Scheme 34). This lithiostannylation was carried out in the pres-



Scheme 34. Configurational inversion through stannylation and lithiodestannylation [102].

ence of (−)-sparteine, because uncomplexed **67** is configurationally labile.

The high γ-selectivity and enantioselectivity of the methylation remains intact in corresponding transformations of the cyclohexylallyl derivative **70** as well, although the result is the oppositely configured products **71** and **72**, with (*Z*)- and (*E*)-double bonds[106] (Scheme 35). Since the enamides of the corresponding aldehydes are subject to hydrolysis, these experiments demonstrate an additional route to enantiomerically enriched homoenolate equivalents.

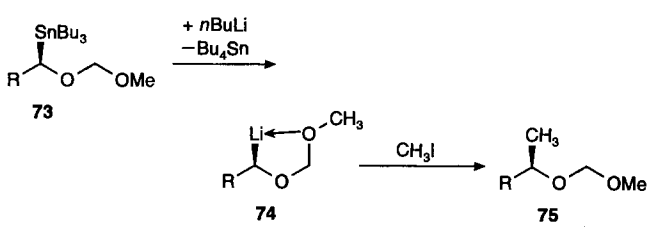


Scheme 35. Lithiation and methylation of the cyclohexyl derivative **70** [102]. Ar = 4-MeOC$_6$H$_4$.

4. Configurationally Stable Chiral Ion Pairs through Deprotonation of Achiral and Racemic Precursors

4.1. Preparations of Non-Resonance-Stabilized 1-Hydroxyalkyllithium Derivatives

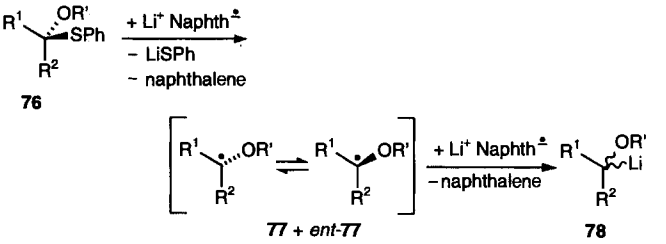
Enantiomerically enriched 1-(alkoxymethoxy)alkyllithium derivatives of the type **74** were recognized to be configurationally stable by W. C. Still and C. Streekumar in 1980; the compounds fail to racemize below −40 °C in ethereal solvents.[107, 108] They were prepared by lithium–tin exchange starting from the precursor **73**. Transmetalation is accomplished, as is the subsequent methylation to **75**, with stereoretention (Scheme 36).[107, 109, 110]



Scheme 36. Preparation of enantiomerically enriched 1-oxyalkyllithium derivatives by lithiodestannylation [107].

The tin derivative **73** was obtained through a laborious racemate resolution by way of diastereomeric esters, although simpler pathways are now known, most of which involve asymmetric reduction of acylstannanes.[111]

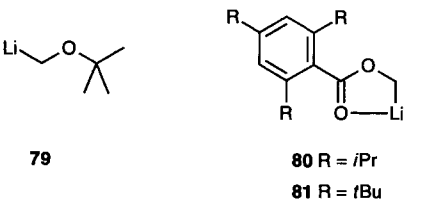
In contrast to the above-described lithiodestannylation, reductive cleavage of chiral monothioacetals **76** is not suitable for stereoselective carbanion generation (Scheme 37),[112] because



Scheme 37. Preparation of racemic α-oxyalkyllithium derivatives by reductive desulfenylation.

it proceeds via a configurationally labile radical intermediate **77** due to the single-electron transition involved. This reaction thus leads to the racemic products **78**.[113]

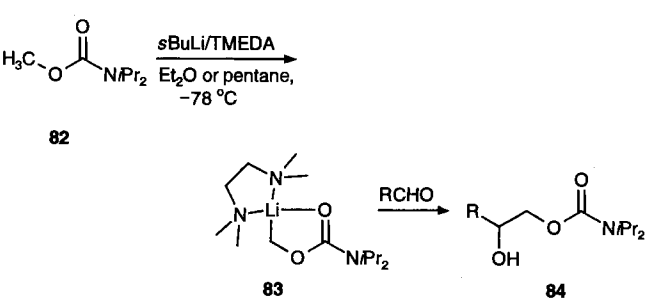
Formation via deprotonation is ruled out by the extraordinarily low CH-acidity of dialkyl ethers. The situation is more favorable for esters because of the possibility of efficient complexation of the lithium reagent[114] and the associated increase in kinetic acidity, as well as dipole stabilization of the ion pair, although a competitive nucleophilic attack is a potential threat. Thus, only lithiomethyl derivatives of a *tert*-butyl methyl ether[115] (**79**) and sterically blocked benzoic acid esters (**80**[116] and **81**[117]) could be obtained (Scheme 38); persistent homologues with primary alkyl chains cannot be generated in this way.[118]



Scheme 38. 1-Oxymethyllithium derivatives accessible by deprotonation [115, 116a, 117].

As expected, the methyl *N*,*N*-diisopropylcarbamate[119] **82** is easily deprotonated by *sec*-butyllithium/TMEDA in diethyl ether or pentane as solvent (Scheme 39); addition of the lithium intermediate **83**·**TMEDA** to aldehydes and ketones to give diol derivatives of type **84** is straightforward.[120]

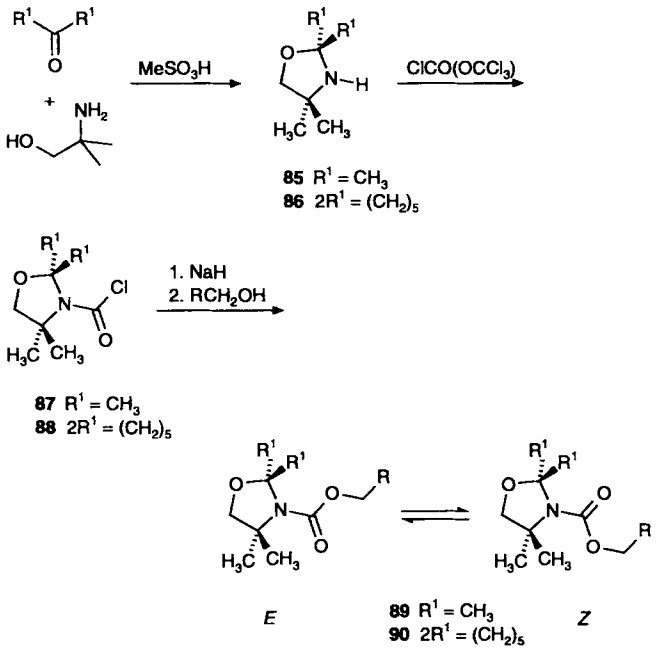
This reaction is applicable to the ethyl carbamate, although "the faithful servants" that one called upon in the case of the



Scheme 39. Preparation and carbonyl addition of 1-(*N*,*N*-diisopropylcarbamoyloxy)methyllithium (**83**) [120b].

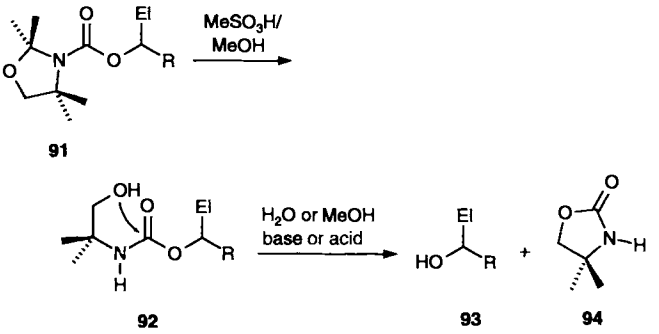
bulky carbamoyl group proved hard to dismiss; subsequent hydrolytic cleavage of *N,N*-dialkylcarbamates of saturated alcohols cause considerable difficulties, and only reductive methods with large excesses of diisobutylaluminum hydride[121] under drastic conditions have so far led to success.

A general solution to the problem was achieved with 1,3-oxazolidine-3-carboxylic esters of the types **89**[122] and **90**[123] (Scheme 40).[122] 2,2,4,4-Tetrasubstitution accomplishes extremely efficient shielding of the carbonyl group, but incorporation of an aminoketal group also ensures the presence of an acid-labile potential cleavage site. The acid chlorides **87** and **88** required for introduction of an activating *O*-protective group are obtained by condensation[124] of 2-amino-2-methylpropanol with acetone or cyclohexanone to give the distillable oxazolidines **85** and **86**, followed by chlorocarbonylation with diphosgene.[122, 123] The carbamates **89** and **90**, generally obtained by the acylation of alcohols with acid chlorides **87** and **88**, are present as *E*/*Z* mixtures, which in the time frame of ^{1}H NMR spectroscopy interconvert only slowly. The consequence is a doubling of the signals when ^{1}H NMR spectra are recorded without special precautions.[125] Spectroscopic evaluation is less hampered for *Cby*-esters of the type **89** than for the originally utilized spirocyclic *Cbx*-esters **90**.



Scheme 40. General synthesis of 1,3-oxazolidine-3-carboxylic acid esters.

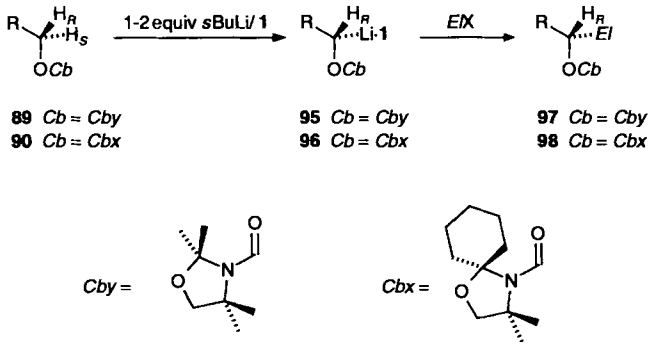
The 2,2,4,4-tetramethyl-1,3-oxazolidinyl group corresponds approximately in terms of spatial demand to a di-(*tert*-butylamino) group, so it is hardly surprising that secondary alkyl esters **91** (R and El = alkyl) usually are not attacked even by lithium aluminum hydride[126] in boiling THF. Stirring in methanol containing methanesulfonic acid releases the *N*-(β-hydroxyalkylurethane) **92** from the *N,O*-acetonide **91**. Thereafter, the hydroxy group plays an active role in base- or acid-catalyzed deblocking to alcohol **93** (Scheme 41).



Scheme 41. Stepwise cleavage of the 1,3-oxazolidine-3-carbonyl residue.

4.2. (−)-Sparteine-Induced Deprotonation of Achiral Alkyl Carbamates

The deprotonation of "ordinary" achiral primary alkyl carbamates of types **89** or **90** with *sec*-butyllithium/(−)-sparteine in diethyl ether or hydrocarbons proceeds with a reliable preference for the *pro-S*-proton to give the lithium derivatives **95**·**1** or **96**·**1**, which can be substituted with various electrophiles under stereoretention to give **97** or **98**, respectively (Scheme 42, Table 5). The resulting enantiomeric enrichment is normally



Scheme 42. Enantioselective deprotonation and substitution of "oxazolidine carbamates" **89** and **90**.

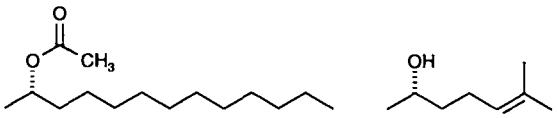
[a] The enantiomeric excess is greater than 95% *ee*. Deviations are indicated in parentheses. [b] Subsequent methylation of the carboxylic acid with diazomethane. [c] Mixture of epimers. [d] Use of 3 equivalents of *sec*-butyllithium/**1**. [e] *Fc* = ferrocenyl. [f] $(H_3C)_2C{=}CH{-}(CH_2)_2$.

more than 95% *ee*. Suitable reaction partners include methyl iodide, CO_2, alkyl chloroformates, aldehydes, ketones, carboxylic acid chlorides and esters, and trialkylsilyl and trialkyltin chlorides. Partial racemization is observed in reactions with benzylic and allylic halides, which speaks for the involvement here of single-electron transfer (SET)[127] in the substitution step, which is favored by resonance stabilization of the benzylic or allylic radical. Primary alkyl iodides can be caused to react[128] by the addition of HMPTA-substitutes such as 1,3-dimethyltetrahydro-2(1*H*)-pyrimidinone (DMPU).[129] It is especially noteworthy that acylation occurs without racemization. This points to weak kinetic basicity of the lithium compounds **95** and **96**, which presumably has its origin in the severe steric burden of the lithium cation, that in turn hinders "docking" at the ketone on the carbonyl group and thus activation of the neighboring CH-bond.

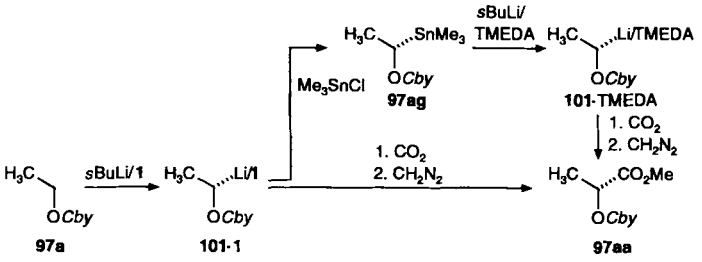
Methylation product **97fi** led, with 98% *ee*[122] after deblocking and acetylation, to (*S*)-(+)-2-tridecylacetate **99**, a pheromone of the fruit fly *Drosophila muelleri*,[133] whereas (*S*)-(−)-sulcatol (**100**),[134a] a pheromone of the beetle *Gnathotricus sulcatus*,[134b] (92% *ee*) was obtained from **97gi** (Scheme 43).[130]



99 **100**

Scheme 43. Synthetic insect pheromones **99**[122] and **100**[130].

Unlike in the case of the lithium ion pairs of resonance-stabilized α-carbamoyloxyalkanides (see Section 3.1), substitution reactions of the saturated analogues **95·1** and **96·1** always occur with retention of configuration. Thus, the synthetic ester **97aa** is identical with a sample prepared from (*R*)-lactic acid.[123] (*R*)-**97aa** was also obtained via the detour of stannylation of **101·1** to (*S*)-**97ag** and destannylation with *n*-butyllithium/TMEDA by way of the sparteine-free complex **101**·TMEDA (Scheme 44).[123]



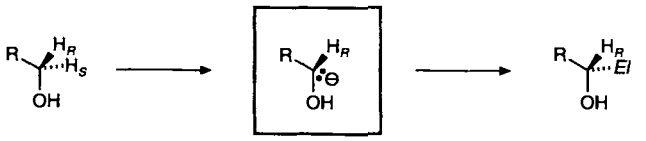
97a **101-1** **97aa**

Scheme 44. Stereochemical correlation of the metal derivatives with (*R*)-lactic acid [123].

Since according to all previous experience[109,135] the lithiodestannylation step is always accompanied by retention, stannylation must also have taken this configurative course.

Thus, the process permits a broad range of electrophilic substitution reactions of *pro-S*-protons in alkanols; the lithiated carbamates **95·1** or **96·1** correspond to the chiral synthon **I** (Scheme 45).

Irregularities can arise if the starting material contains heterosubstituents. The following causes will be discussed in Sections 4.1–4.6: 1,2- and 1,3-elimination of nucleofugic leaving groups;



I

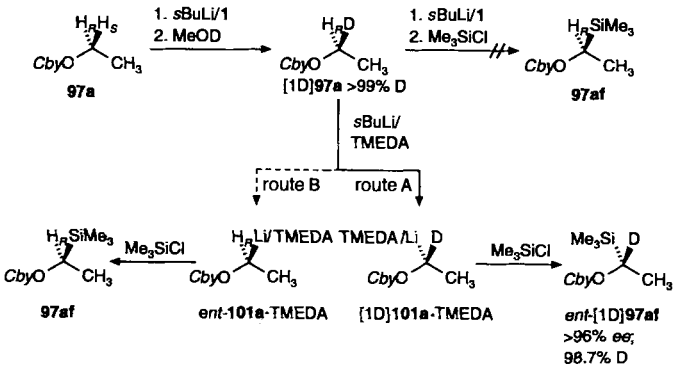
Scheme 45. General synthetic strategy.

displacement of (−)-sparteine by Lewis-basic substituents in the substrate; opposite stereochemical preferences in chiral substrates through the formation of "mismatched pairs."[56]

First, however, we discuss insights gained to date into the mechanistic pathway of (−)-sparteine-mediated deprotonation.

4.3. On the Mechanism of Kinetically Controlled Carbamate Deprotonation

A series of simple experiments[136] with the deuterium-labeled substrate [1*D*]**97a** supports the validity of the previously described interpretation (Scheme 46):[137] Through double application of the sequence (−)-sparteine-induced deprotonation



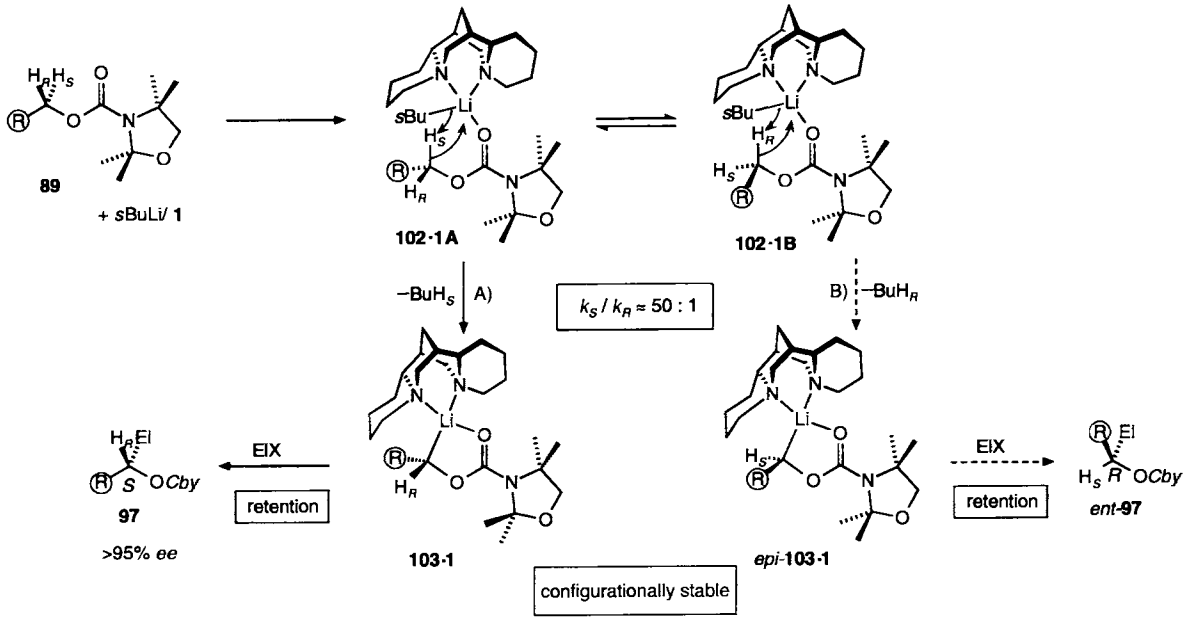
97a [1D]**97a** >99% D **97af**

ent-**101a**-TMEDA [1D]**101a**-TMEDA *ent*-[1D]**97af** >96% *ee*; 98.7% D

Scheme 46. Determination of the kinetic isotope effect k_H/k_D in the deprotonation of an alkyl carbamate [136].

and deuterolysis of the organolithium intermediate it was possible to isolate the α-deuterioethyl carbamate [1*D*]**97a** with a 1-D_1-content higher than 99%. An attempt at renewed deprotonation with *sec*-butyllithium/(−)-sparteine (**1**) and subsequent trapping with chlorotrimethylsilane failed; the anticipated silane **97af** was detectable at most in trace amounts. Deprotonation of [1*D*]**97a** with the achiral base pair *sec*-butyllithium/TMEDA, on the other hand, is not subject to any stereochemical restriction: the ratio of rates according to which reaction pathways A and B proceed is determined exclusively by the kinetic isotope effect k_H/k_D. The reaction produced, after silylation, the silane *ent*-[1*D*]**97af** with greater than 96% *ee* and a ^1H content of less than 1.3%.[138] From this one can calculate a k_H/k_D ratio of >70.[139]

The following conclusions can be drawn from these results: 1) Lithiated alkyl carbamates are completely stable configurationally in the form of TMEDA or (−)-sparteine complexes under the reaction conditions. 2) The deprotonation step is kinetically controlled, and this step determines the stereochemical course. 3) A *pro-S*-proton is abstracted with high selectivity



Scheme 47. Diastereomorphic transition states in the (−)-sparteine-mediated deprotonation of ethyl carbamate **97a** with *sec*-butyllithium.

under the influence of (−)-sparteine, and the incoming electrophile occupies its topochemical position. 4) The observed kinetic isotope effect k_H/k_D of at least 70 points to the intervention of a quantum-mechanical tunneling effect.[139, 140] Powerful H/D tunneling effects are observed when the reactants and products are separated by high, very "thin" potential barriers. This applies to proton transfer when the base and the resulting carbanion have similar basicities, and when the reacting centers are heavily shielded sterically. To our knowledge, the largest H/D kinetic isotope effect for a deprotonation reaction ($k_H/k_D = 24.3$) was determined in the deprotonation of 2-nitropropane with 2,4,6-trimethylpyridine.[140b]

Additional experimental facts are also important if one wishes to propose a solid mechanistic model: 1) Without addition of a bidentate ligand such as TMEDA or (−)-sparteine (**1**), deprotonation of "simple" alkyl carbamates is excluded. 2) A reactive alkyl carbamate like **89** or **90** added to an equimolar mixture of *sec*-butyllithium, (−)-sparteine (**1**), and the (not deprotonateable) isopropyl carbamate *i*prO*Cby* at −78 °C is also not attacked.[141] This means that prior to the deprotonation step a complex consisting of alkyllithium, the bidentate ligand, and the carbamate forms virtually irreversibly. Beak et al.[142] verified by NMR spectroscopy the presence in ethereal solution of an unsymmetrical complex of the composition $[(RLi)_2(Et_2O)_2 \cdot \mathbf{1}]$, which is, however, under the conditions applicable here for the kinetics of the deprotonation step of no significance.

Proton transfer in the aggregate **102·1** is turned in this way into an intramolecular process with differentiation between diastereotopic protons (Scheme 47). Abstraction of the *pro-S*-H from conformation **A** occurs roughly 50 times more rapidly than that of the *pro-R*-H from conformation **B**, which leads to the minor diastereomer *epi*-**103·1**. From this result a free energy difference $\Delta G^{\neq}$ of about 6.3 kJ mol^{-1} is calculated.

The limits of the deprotonation of very weak CH acids have nearly been reached; it is apparent here that the combination *sec*-alkyllithium/(−)-sparteine was a fortunate choice, and with respect to the basicity and steric demands of base and ligand an optimum has almost surely been reached: Deprotonation of nonactivated alkyl carbamates does not occur with use of *n*- or *tert*-butyllithium/(−)-sparteine (**1**) or *sec*-butyllithium/(−)-α-isosparteine (**2**).[131]

J. Haller and E.-U. Würthwein simulated the energy minima for transition states along the diastereomorphic reaction pathways **A** and **B** with the aid of semiempirical calculations (MOPAC, PM3).[95] For this process, *sec*-butyllithium was replaced by the achiral isopropyllithium,[143] and lithium parameters from Anders[95b] were utilized. In both transition structures **104·1A** and **104·1B** (Figure 7) the reaction center inserts into a "niche" that is left free by a "wing" of the ligand (−)-sparteine.

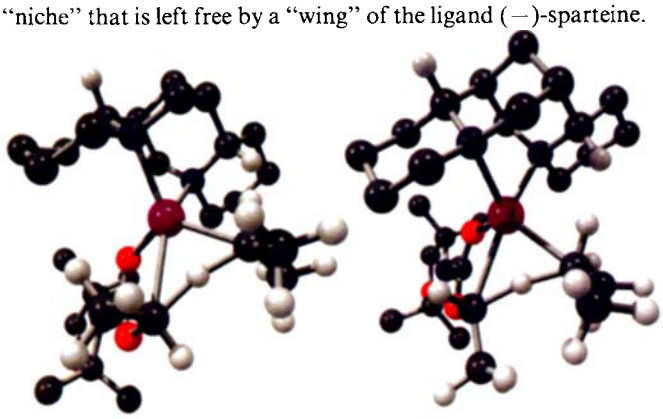


Figure 7. Models of the calculated diastereomorphic transition states (MOPAC, PM3) in the intramolecular removal of the *pro-S*-proton (left) and the *pro-R*-proton (right) in carbamate **97a** by isopropyllithium/(−)-sparteine [141]. In the case of sparteine (top of both illustrations) all hydrogen atoms have been omitted except for those at the bridgeheads; the same applies to the 2,2,4,4-tetramethyloxazolidin-3-carbonyl residue (bottom left). The view into the reaction center [the "triangle" consisting of the lithium cation (violet), C-1 of the substrate (left), the proton to be transferred (white), and C-2 of the base (right)] has been held constant. In both transition states, the bulky base (bottom right) extends into the niche left free by the *cis*-annelated outer six-membered ring of the sparteine. The *pro-S*-transition state (left) corresponds to the experimentally observed stereochemical course; here the methyl group (bottom left) extends forward. In the *pro-R*-transition state (right) it points downward; here the distance to the isopropyl group of the base is smaller, and therefore the steric interaction greater.

The structures differ from each other in that the urethane alkyl group in structure **104·1A** extends into the free space, whereas that in **104·1B** collides with the isopropyl group. The calculated energy difference $\Delta\Delta G^{\ddagger}$ of 0.8 kJ mol^{-1} is much too small in comparison to the experimental value of $\geq$6.3 kJ mol^{-1}; we suspect that the calculation method selected for the exact solution of this complex problem is, like other semiempirical methods, inadequate for the task, which is complicated further by the appearance of tunneling effects.[144]

Better agreement between experimental and calculated results is obtained when diastereotopic differentiation is established through a neighboring stereogenic center in the substrate:[145] (*R*)-2-Phenylpropyl carbamate[146] **105** leads after deprotonation and methoxycarbonylation to the diastereomeric esters **108** and **109** in a ratio of 95:5 (Scheme 48); that is, the *pro-S*-proton is removed roughly 20 times more rapidly than the *pro-R*-proton. However, in (1-tetrahydronaphthyl)methyl carbamate **110**, which has an equivalent configuration,[146] a reverse preference for **113**:**114** is registered with a ratio of 13:87.[147]

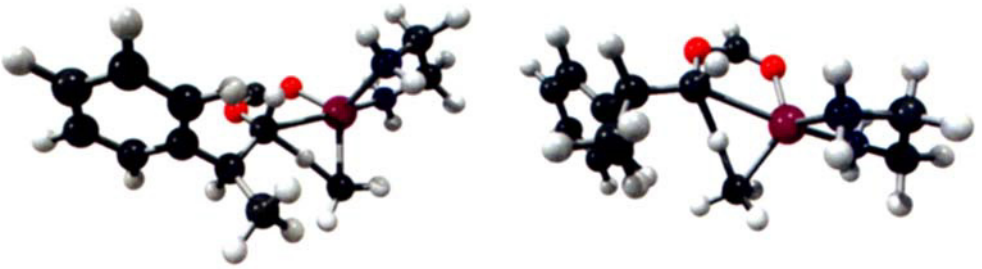

Figure 8. Models of the calculated diastereomorphic transition states (MOPAC, PM3) for removal of the *pro-R*-proton in a complex consisting of methyllithium/ethylenediamine and (*S*)-1-phenylethyl formate (left) or (*R*)-1-phenylethyl formate (right)[145]. In the transition state a triangle is formed consisting of the now pentacoordinated lithium cation (violet), the (also pentacoordinated) carbon atom of the base, and the C–H acid, on the basis of which the attacked proton wanders. The calculated energy difference $\Delta\Delta H^{\ddagger}$ in favor of the *ul*-proton (left) relative to the *lk*-process (right) amounts to 2.9 kJ mol^{-1}. In the most favorable conformations in each case the plane of the phenyl residue is parallel to the C–H bond at the stereogenic center in order to avoid 1,3-allyl strain. In the favorable *ul*-transition state (left) the C1–C2 bond can assume a completely eclipsed conformation at the expense of an interaction between an *ortho*-H atom and the remaining 1-H atom, whereas that conformation in the *lk*-transition state apparently represents a poor compromise. The two experiments are possible only by computer, since in a reaction flask the system would discover that removal of an N–H proton and subsequent attack of lithium amide on the formyl group would be the favored reaction pathway.

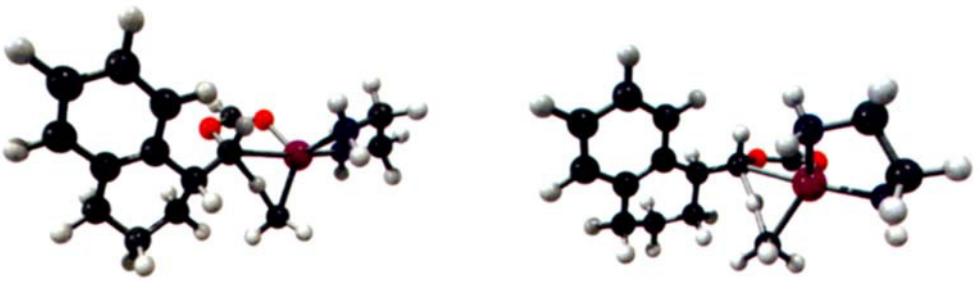

Figure 9. Models of the calculated diastereomorphic transition states (MOPAC, PM3) for removal of the *pro-R*-proton in a complex consisting of methyllithium/ethylenediamine and (*R*)-(left) or (*S*)-(1,2,3,4-tetrahydronaphth-1-yl)methyl formate (right)[145]. In this case calculations ($\Delta\Delta H^{\ddagger}$ = 2.9 kJ mol^{-1}) and experiment ($\Delta G^{\ddagger}_{-78\,^{\circ}C}$ = 2.9 kJ mol^{-1}) show the *lk*-transition state (left) to be the more favorable. Since the phenyl residue and the attached alkyl group are constrained in a plane by the ring, the conformational energies are reversed relative to the α,β-(1,1')-C–C bond. In the *ul*-transition state (right) the interaction of the C-2-methylene group of the tetrahydronaphthyl residue with the reaction center ia apparently stronger than that of the *lk*-transition state (left).

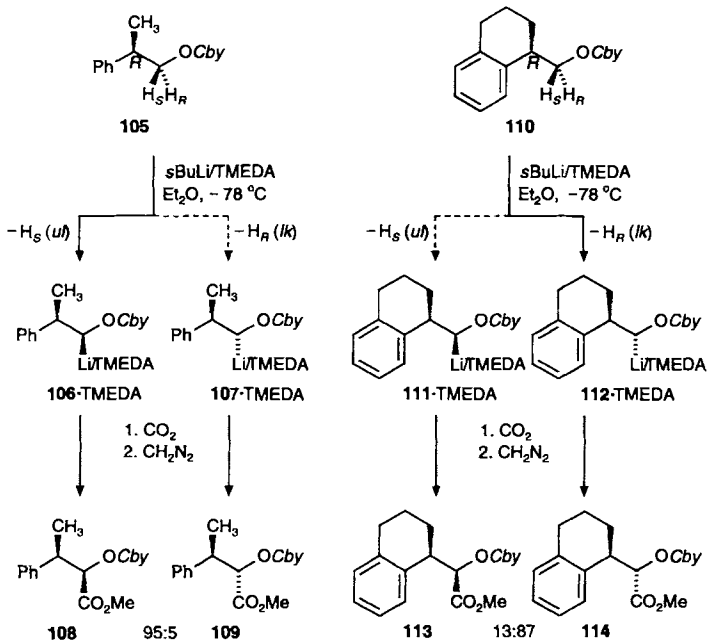
Although the PM3 calculations[95] are carried out with simplified substrates (formyl in place of oxazolidinecarbonyl) and reagents (MeLi for *sec*-BuLi and ethylenediamine for TMEDA), they correctly reflect the observed trend (Figures 8, 9).[148]



Scheme 48. Diastereotope-differentiating deprotonation of chiral alkyl carbamates [145].

Calculated energy differences $\Delta(\Delta H^{\ddagger}_{lk} - \Delta H^{\ddagger}_{ul})$ correspond well with the experimentally determined values $\Delta(\Delta G^{\ddagger}_{lk} - \Delta G^{\ddagger}_{ul}$ in parentheses): 2.5 (5.0) kJ mol^{-1} for the system **105** and −2.5 (−2.5) kJ mol^{-1} for **110**.

It is apparent that significant differences in the energies of diasteromorphic reaction pathways for a kinetic racemate resolution under the influence of the chiral base pair *sec*-butyllithium/(−)-sparteine are susceptible to exploitation.[145, 149] The enantiomer that reacts most rapidly is the one in which the *pro-S* preference of substrate matches that of the reagent, namely (*R*)-**105** and (*S*)-**110**.[145, 149]

4.4. Deprotonation of Heterosubstituted Alkyl Carbamates

As described in the preceding section, the formation of a complex consisting of alkyl carbamate, *sec*-butyllithium, and (−)-sparteine is essential for achieving highly stereoselective deprotonation. If the alkyl group bears a strong donor substituent, this may displace the sparteine.

Thus, deprotonation of the 3-(*N*,*N*-dimethylamino)propyl carbamate **117a**, followed by reaction with various electrophiles, leads to the nearly racemic product **118a** (Scheme 49).[150, 151] The bulkier *N*,*N*-dibenzylamino group on

	R^1	R^2	Yield [%]	*ee* [%]
a	CH_3	CH_3	92 [a]	<10
b	CH_3	$PhCH_2$	70	80
c	$PhCH_2$	$PhCH_2$	94	97

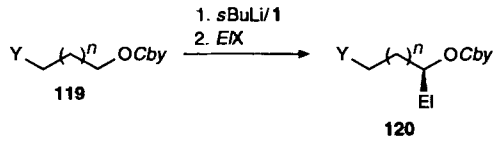
the other hand does not interfere, and the product **118c** of electrophilic substitution is obtained with the customary enantiomeric enrichment of greater than 95% *ee*.[150] In this respect the (*N*-benzyl-*N*-methylamino) group in **117b** (80% *ee*) occupies an intermediate position.[150]

The 3-, 4-, and 5-carbamoyloxy,[153] 4-methoxy or 5-silyloxy,[153a] and 2-dibenzylamino groups[154] do not disrupt the enantioselectivity of deprotonation in the presence of (−)-sparteine (Scheme 50, Table 6).



Scheme 50. Enantioselective deprotonation and substitution of ω-heterosubstituted alkyl carbamates.

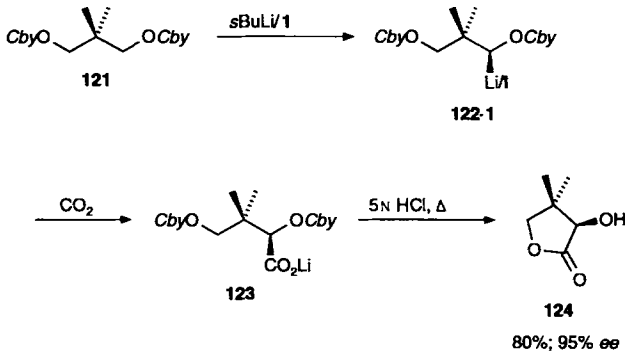
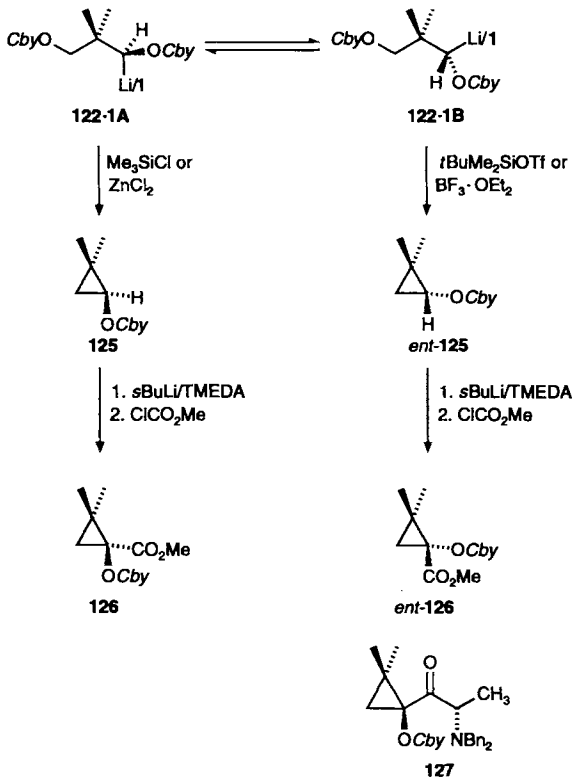
[a] Isolated as the methyl ester after treatment with diazomethane.

Compound **120g** is a protected derivative of D-isoserine.[154] Carboxylation of lithiated 1,3-dicarbamates leads in two steps to essentially enantiomerically pure γ-lactones, as illustrated in an exemplary way by the synthesis of D-pantolactone (**124**) (Scheme 51).[153a, 156]

1,3-Dicarbamates like **122·1** (Scheme 52) bear potential leaving groups that are activated by Lewis acids. In fact, we observed upon treatment with chlorotrimethylsilane the formation of the cyclopropyl carbamate **125** with 1,3-elimination of the lithium carbamate salt.[136, 153a, 157, 158] In the process the (*S*)-enantiomer **125** results with greater than 95% *ee*, as could be demonstrated by transformation into the carboxylic acid ester **126** and crystalline ketone **127** via the configurationally stable[159] intermediate lithium cyclopropanide. Investigations with the deuterium labeled, enantiomerically enriched starting material (*S*)-[1*D*]**121** proved without question that ring closure



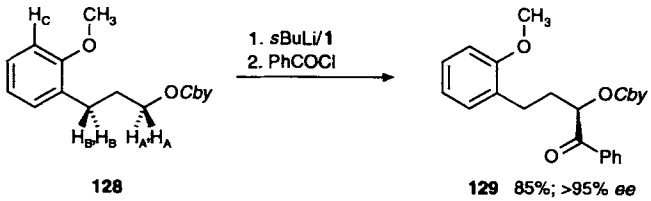
Scheme 51. Synthesis of (*R*)-pantolactone [153a].



Scheme 52. Stereochemistry of the 1,3-elimination of a 1,3-dicarbamate [157, 160].

here occurs stereospecifically, with retention at C-1 as well as inversion at C-3, hence out of conformation **122·1a**.[136] To our great surprise, stronger Lewis acids like *tert*-butyldimethylsilyl triflate or boron trifluoride caused formation of the opposite enantiomerically enriched cyclopropane, *ent*-**125** (>95% *ee* and 74% *ee*); stereoinversion at both reactive centers was verified.[160–163]

Despite many possible complications, the carbamate group is distinguished by its unsurpassed directing effects. The following "acid test" (Scheme 53) underscores this assertion: Carbamate

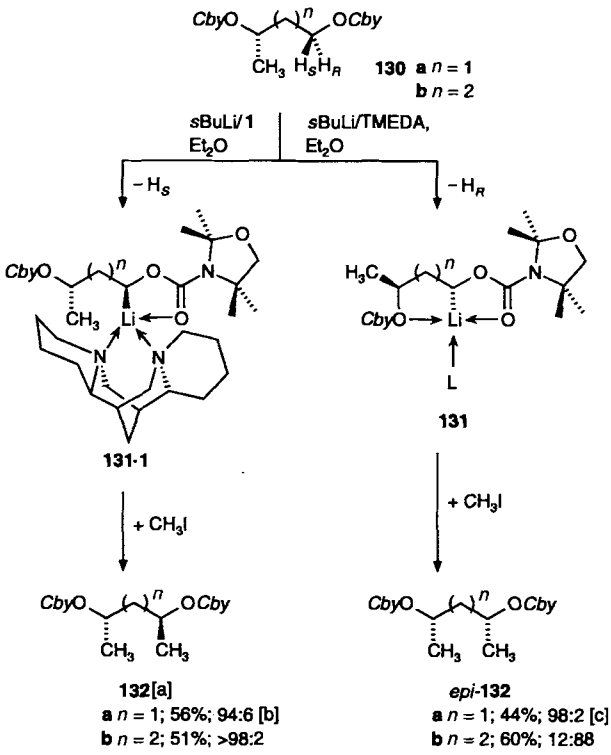


Scheme 53. Competing acidic positions in (−)-sparteine-induced lithiation [165].

128 bears three extraordinarily easily activable protons in H_C, H_B, and $H_{B'}$;[164] nevertheless, under the usual conditions of (−)-sparteine-induced deprotonation, exclusively the *pro-S*-proton H_A is released.[165]

4.4.1. Competition with Stereogenic Centers in the Substrate; Kinetic Resolution

Provided that a good donor substituent is attached to a stereogenic C atom in the γ- or δ-position, it can ensure a significant amount of chiral induction in the deprotonation step. It is useful when this chelate effect is subordinate in the competition with (−)-sparteine (**1**). In favorable cases—as with 1,3-dicarbamate **130a**—lithiation can then be directed preferentially in either of the two directions.[166] Application of the sparteine variant with subsequent methylation led to the (*S,S*)-2,4-pentanediol derivative **132a** with high selectivity, whereas in the presence of TMEDA the *meso*-compound *epi*-**132a** dominated (Scheme 54).[166] We suspect that a bicyclic chelate complex of



Scheme 54. (−)-Sparteine- vs. substrate-directed diastereoselective lithiation of 1,3- and 1,4-dicarbamates [166]. [a] Conducted with the carbamate residue *Cbx*. [b] Ratio **132**:*epi*-**132** [= (*S,S*):(*S,R*)]. [c] Ratio *epi*-**132**:**132** [= (*S,R*):(*S,S*)].

the type **131**[167] forms, and the more favorable *exo*-position of the stationary methyl group determines the transition state.[168] In the homologous (*S*)-2-methyl-1,4-butanediyl dicarbamate **130b**, reagent- and substrate-controlled deprotonations take the identical stereochemical course, and lead with differing efficiency to the (*S,S*)-diol derivative **132b**.

An effective substrate-inherent chiral induction can also be exploited with the acetonide of the (*S*)-3,4-dihydroxybutyl carbamate **133**.[169] Deprotonation in diethyl ether (without any other additive) and reaction of the resulting ion pairs **134** and *epi*-**134** with trimethyltin chloride produces mainly the (1*S*,3*S*)-diastereomer **135** (Scheme 55, Table 7). From this one can conclude that there is highly selective formation of the *anti*-annelated tricyclic chelate complex **134**.[168,170] In the presence of (−)-sparteine (**1**) the tendency toward release of the *pro-S* pro-

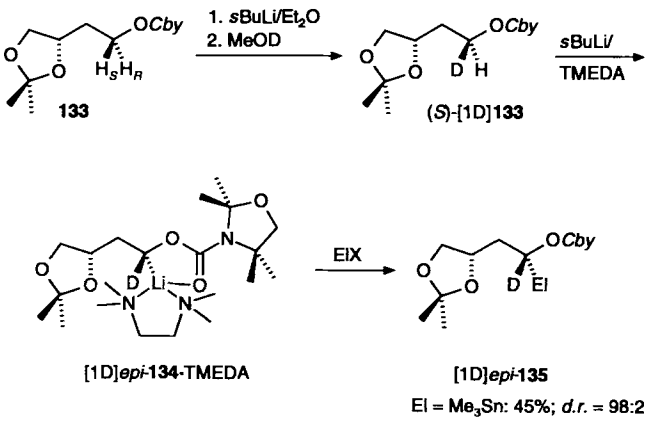
ton is further increased, because in this case *epi*-**135a** is no longer identifiable in the reaction mixture. The 2,2-dimethyl-substituted 1,3-dioxolane ring is only a weak ligand for lithium, for in the deprotonation step, as with sparteine, it is displaced by TMEDA. As Table 7 indicates, diastereoselectivity decreases

under these conditions and is reversed by means of (+)-sparteine (*ent*-**1**)[171] with its preference for the *pro-R*-proton. In other words, in the presence of a bidentate complexing ligand, intramolecular complexation is not involved, and the normal deprotonation pathway applies. Conformational rigidity in the form of the acetonide is essential for achieving high substrate-controlled stereoselectivity, for the 3,4-dimethoxy derivative **136** reacts unselectively under the above-described conditions.[169]

As Table 7 shows, the ion pair **134** reacts smoothly with a wide variety of electrophiles, and acylation also poses no problems. For this reason the substrate constitutes a valuable synthetic equivalent to the (*S*)-1,3,4-trihydroxybutanide (**K**).[172] The method should be generalizable to the transfer of longer chains and more highly functionalized analogues.

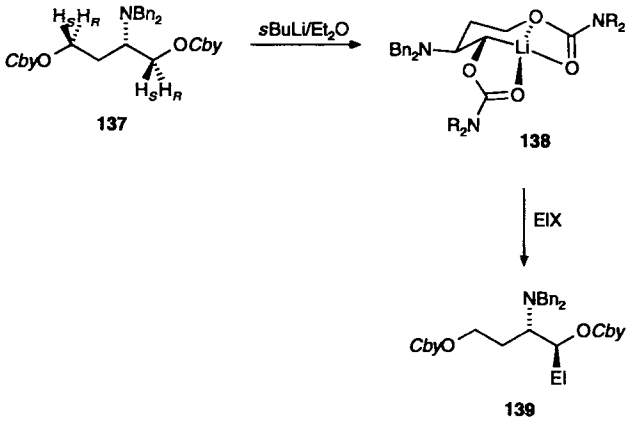
How might one now gain entrance to the epimeric series *epi*-**135** without the need for the awkwardly available (+)-sparteine? This is easy so long as a deuteration of the product can be tolerated (Scheme 56).[65e] Acetonide **133** is lithiated and



Scheme 56. Reversal of diastereoselectivity through deuteration of **133** [65e].

deuterated under substrate control. Because of the large kinetic H/D isotopic effect (see Section 4.2), TMEDA-assisted lithiation leads from (*S*)-[1*D*]**133** to the diastereomerically pure ion pair [1*D*]*epi*-**134**, which is configurationally stable and can be substituted to give [1*D*]*epi*-**135** under stereoretention.

High substrate-controlled diastereoselectivities are also achievable if the substituent capable of chelating is not itself on a stereogenic center, but rather adjacent to one. Upon deprotonation according to either the TMEDA or the (−)-sparteine variant, followed by reaction with electrophiles, dicarbamate **137** of (*S*)-2-(dibenzylamino)-1,4-butanediol,[173a,c] derived from (*S*)-asparaginic acid, leads to mixtures of regio- and diastereomers.[173b] However, if the transformation is carried out in diethyl ether (without addition of a diamine), the pure 1-substitution product **139** results (Scheme 57, Table 8). The breadth of the applicable electrophiles and the high reactivity are noteworthy. We therefore conclude that formation of the chelate complex **138** is kinetically controlled;[174,176] the cause of the highly stereoselective course of the reaction is thought to be the strong tendency of the 2-dibenzylamino and 4-carbamoyloxy groups to occupy an equatorial position in the developing six-membered ring.



Scheme 57. Substrate-directed regio- and diastereoselective deprotonation of dicarbamate **137** [173b].

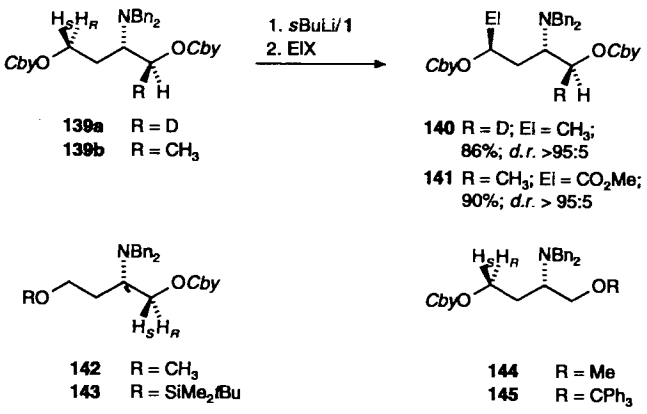
[a] In no case could a second diastereomer be verified by ^{1}H NMR, so the diastereomeric ratio was at least 97:3. [b] After esterification with diazomethane. [c] (*E*)-MeCH=CH−C=O. [d] (*E*)-MeCH=CHCOCl. [e] Ref. [175].

The 4-methyl ether **142** shows very similar selectivity,[173b,177] whereas the 4-*O*-TBDMS ether **143** is unreactive,[177] which also supports the important role played by the complexing substituent in the 4-position.

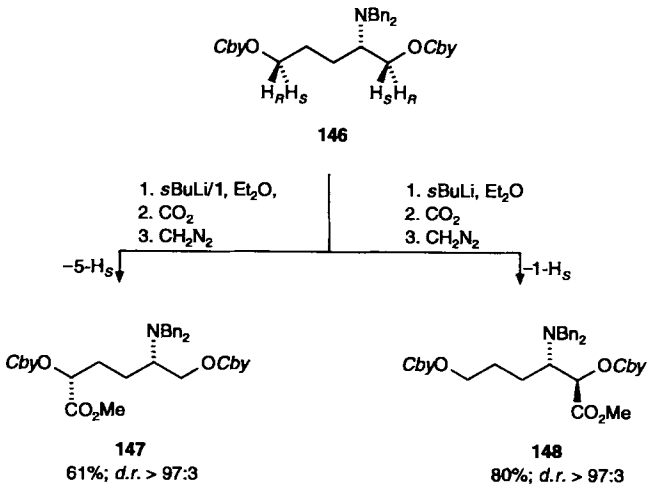
If the 1-*pro-S*-position of substrate **137** is blocked, whether by an alkyl group or deuterium,[178,179] the (−)-sparteine-mediated deprotonation "at the other end" takes its usual course, with the abstraction of *pro-S*-H-4 (Scheme 58). Obviously the 1-posi-



Scheme 58. Lithiation of 2-amino-1,4-butanediol derivatives in the 4-position [173b, 177].

tion can also be blocked in a classical way after introduction of a nonactivating protective group such as methyl or trityl at O-1 (**144** and **145**, Scheme 58), leading to regio- and stereoselective deprotonation at C-4.[177]

In the corresponding 2-amino-1,5-pentanediol derivative **146**, made from (*S*)-glutamic acid, internally assisted deprotonation is apparently retarded due to the unfavorable ring size of the resulting lithium chelate complex (Scheme 59).[173b] Thus, in



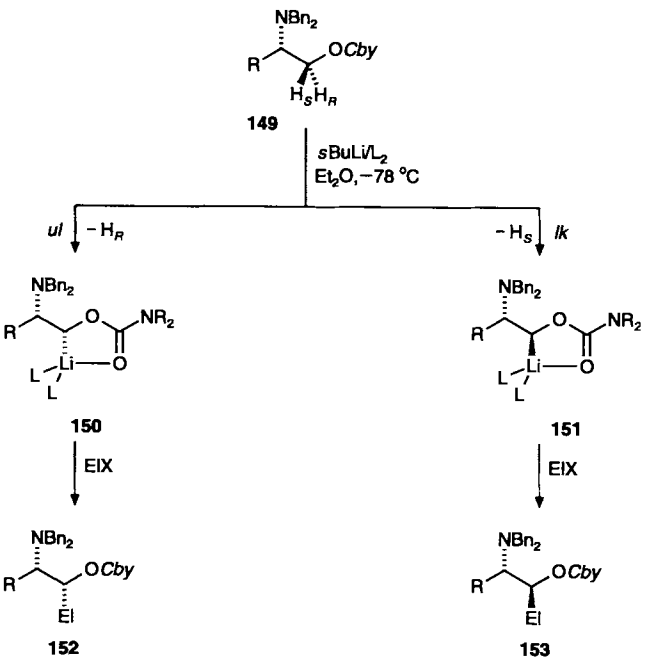
Scheme 59. Regio- and diastereoselective substitution of the 2-amino-1,5-pentanediol derivative **146** [173b].

the presence of (−)-sparteine, proton 5-H_S is abstracted almost exclusively, whereas in the absence of a diamine a slower deprotonation at C-1 is initiated; the intermediate lithium compounds produce, after trapping with carbon dioxide and *O*-methylation, the regioisomeric esters **147** and **148**.

Therefore, the procedures described offer extremely facile access to equivalents for the stereoisomerically pure carbanionic synthons **L** through **O** (Scheme 60).

Scheme 60. Carbanionic synthons accessible from 2-amino-1,ω-alkanediols [173b].

(*S*)-2-(*N*,*N*-Dibenzylamino)alkyl carbamates, accessible in a small number of steps from the natural amino acids,[180] display marked *ul*-induction[6a] in TMEDA-assisted deprotonation[154] (L_2 = TMEDA). Therefore, the *pro-R*-proton is preferentially abstracted, and one obtains after reaction, irrespective of the electrophile, an excess of the diastereomer **152** (Scheme 61, Table 9). The (*S*)-alaninol derivative **149a** constitutes an excep-



Scheme 61. Deprotonation of (*S*)-2-(*N*,*N*-dibenzylamino)alkyl carbamates. For R, see Table 9.

tion. One presumes that proton abstraction takes place in the antiperiplanar conformation, and in the normal case the *pro-R*-H is more accessible (Figure 10).[181] As described above, we have so far found no indication that the dibenzylamino group interacts as a complexing ligand.[182]

In the presence of (−)-sparteine (L_2 = 1) as complexing partner, the situation of a "mismatched pair" arises due to its preference for the *pro-S*-proton.[56] Strong substrate-directed stereoselection is directed toward the *pro-R*-H, and thus retards

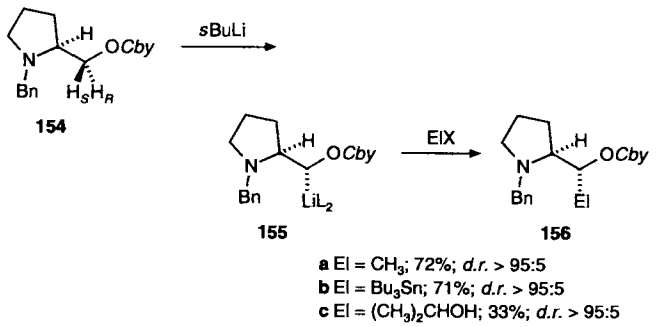
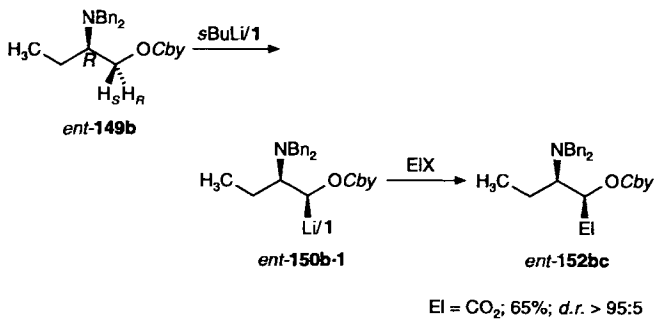
formation of the diastereomeric ion pair **151**, which in the presence of large residues R may be completely excluded.

Also with the (*S*)-prolinol derivative **154** there is a strong preference for abstraction of the *pro-R*-proton, which leads via the ion pair **155** to the diastereomerically pure substitution products **156** (Scheme 62).[154] Quite surprisingly, when deprotonation is carried out in ether solution in the presence of (−)-sparteine[154] or entirely without the addition of a diamine, the very same diastereomer results.[184] This observation permits only one conclusion: Here the less shielded amino function intervenes in the deprotonation step in an intra- or intermolecular way.



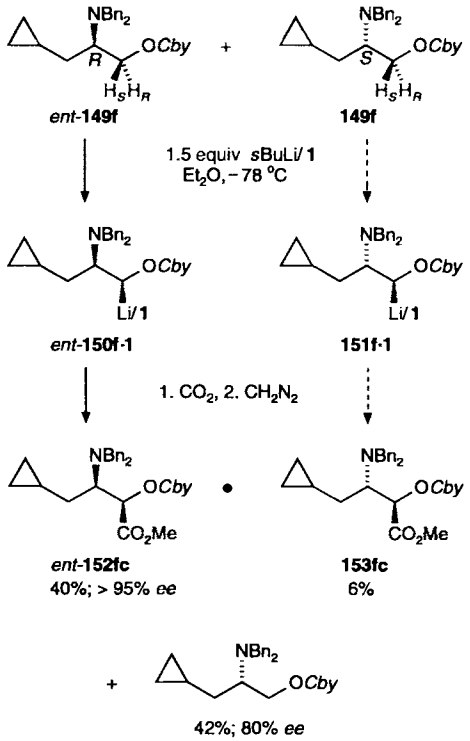
Scheme 62. Diastereoselective deprotonation of the prolinol carbamate **154** [154].

In the (−)-sparteine-induced deprotonation of (*R*)-2-(dibenzylamino)alkyl carbamates *ent*-**149**, both the substrate- and the reagent-controlled preferences point to the *pro-S*-proton. As a consequence, the reaction is rapid and stereoselectivity virtually complete (compare with *ent*-**149b** in Table 9) (Scheme 63).[183, 184] The sharply differing reactivities of the



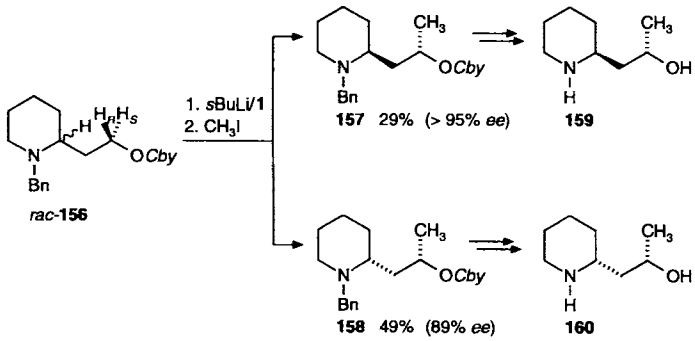
Scheme 63. Highly diastereoselective deprotonation and substitution of the (*R*)-2-(*N*,*N*-dibenzylamino)butyl carbamate *ent*-**149b** [183].

two enantiomers with respect to *sec*-butyllithium/(−)-sparteine can be exploited for efficient kinetic racemate resolution. As with all kinetic racemate resolutions with carbamates, at least one equivalent of alkyllithium is required; apparently this is irreversibly bound in a precomplex even with the less reactive enantiomer. From the racemic β-cyclopropylalaninol derivative *rac*-**149f** it was possible in this way to acquire the ester *ent*-**152fc** (>95% *ee*) and recover (*S*)-carbamate (*S*)-**149f** (Scheme 64).[128, 185] The advantage relative to classical or enzymatic racemate resolution lies in the possibility of accomplishing a highly diastereoselective C–C coupling in addition.



Scheme 64. Kinetic resolution of the carbamate *rac*-**149f** [129, 185].

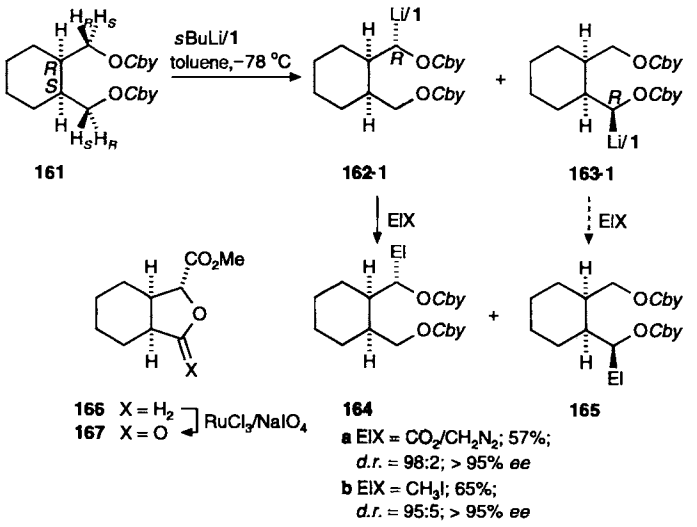
As was demonstrated with 3-(piperidine-2-yl)ethyl carbamate *rac*-**156**, the method can also prove valuable when differentiation between the enantiomers is less efficient.[186] One obtains after methylation the epimeric (2*S*)-alkyl carbamates **157** (>95% *ee*) and **158** (89% *ee*), which after deblocking lead to the alkaloids (+)-sedridine[187] (**159**) and (+)-allosedridine (**160**) (Scheme 65). The sequence possesses the character of a



Scheme 65. Synthesis of (+)-sedridine and (+)-allosedridine [186].

highly enantioselective substitution on a racemic starting material, which simplifies racemate resolution of the starting material by turning it into a separation of product diastereomers.

An interesting stereochemical problem is presented by *meso*-dicarbamate **161** (Scheme 66).[153b, 188] The compound bears two enantiotopic side groups, each with two diastereotopic protons. The chiral base *sec*-butyllithium/(−)-sparteine abstracts that *pro-S*-proton whose removal is supported by the substrate-inherent preference, namely *R*-H_S.[189] The [1*R*,1(1*R*),2*S*]-configured lithium intermediate **162**·**1** arises in excess together with the [1*S*,1(1*R*),2*R*]-diastereomer and leads to the substitution products **164** with high stereoselectivity.



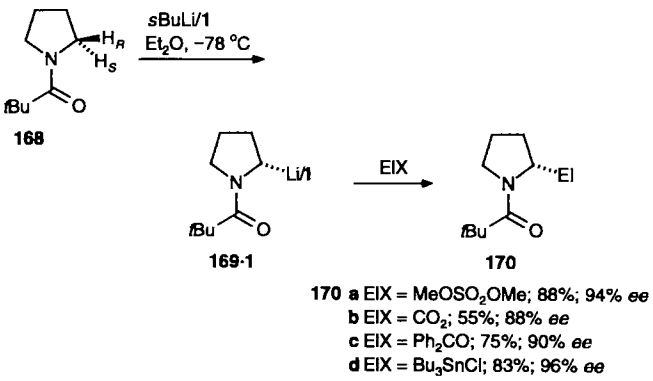
Scheme 66. Desymmetrization of a *meso*-1,4-dicarbamate [153b].

Carboxylic acid ester **164a** was transformed with 5N hydrochloric acid into the tetrahydrofuran derivative **166**, which was oxidized to the lactone acid ester **167**.[190] At this stage the expected configuration was verified by an X-ray crystal structure analysis.[191] All in all, desymmetrization of the *meso*-substrate was associated with highly diastereoselective C−C bond formation.

4.5. Enantioselective Lithiation of *N*-Boc-Pyrrolidines

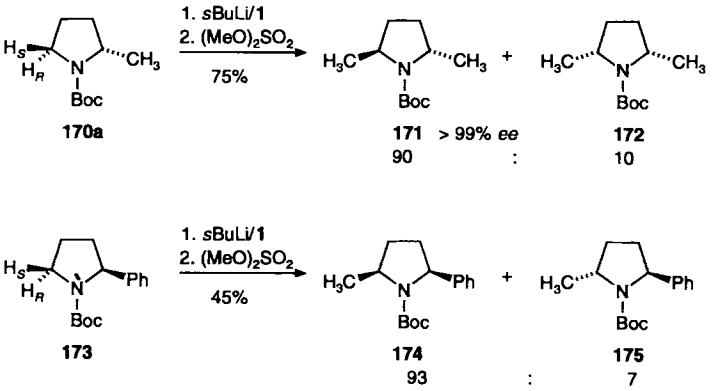
As Beak et al. were able to show as early as 1984 that *N*-(*tert*-butoxycarbonyl)pyrrolidines and -piperidines are easily deprotonated to the corresponding racemic dipole-stabilized lithium–carbanion pairs.[192] Application of *sec*-butyllithium/(−)-sparteine to *N*-Boc-pyrrolidine leads through enantiotopic differentiation, after removal of the *pro-S*-2-H atom, to the configurationally stable intermediate **169**·**1**, which can be substituted with retention by various electrophiles (Scheme 67).[193]

The (*R*)-diphenylprolinol derivative **170c** can be enriched to 99.3% *ee* by recrystallization and provides a valuable ligand for enantioselective ketone reduction according to Corey–Itsuno.[194] Tin compound **170d** is the starting material for the synthesis of enantiomerically enriched 2-lithio-*N*-methylpyrrolidines developed by R. E. Gawley.[195] Double lithiation/methylation offers easy access to the (*S*,*S*)-2,5-dimethylpyrrolidine derivative **171**; a possibility has also been worked out for separation of the roughly 10% content of *meso*-compound **172**



Scheme 67. (−)-Sparteine-controlled deprotonation of *N*-Boc-pyrrolidine [193].

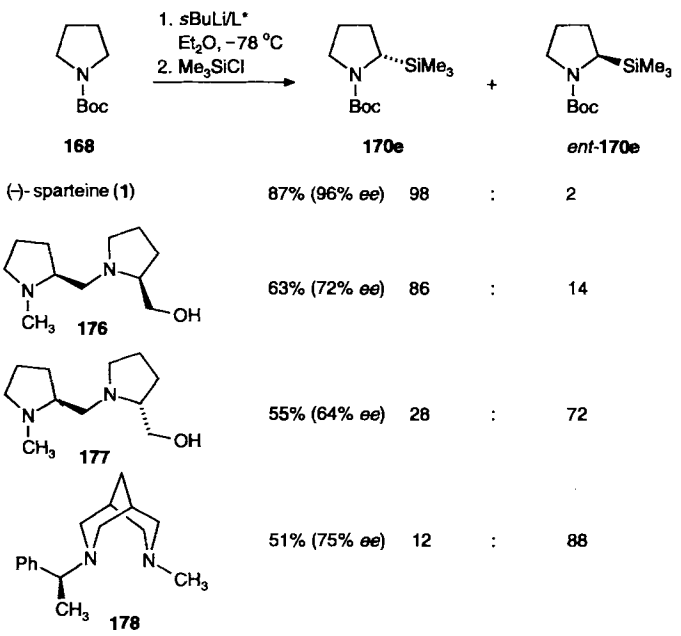
(Scheme 68).[193b] As expected, reagent-induced chiral induction dominates, as has also been shown to be the case with the 2-phenylpyrrolidine derivative **173**.[85]



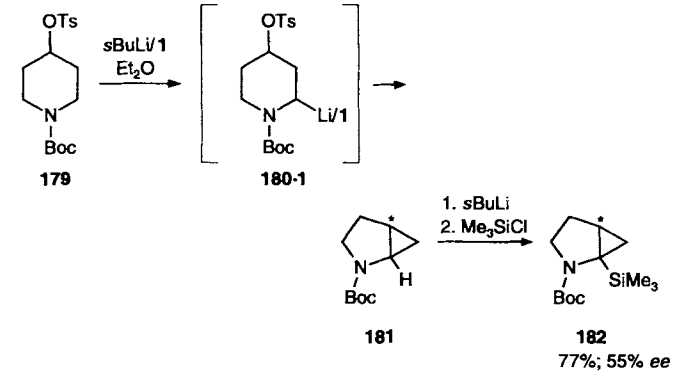
Scheme 68. Reagent-directed deprotonation of chiral 2-substituted *N*-Boc-pyrrolidines [85].

From a mechanistic standpoint there are many parallels to the deprotonation of *O*-alkyl carbamates (Sections 4.1–4.3);[196] kinetic and deuteration studies suggest rapid formation of a precomplex of the reaction partners.[142, 197] M. E. Kopach and A. I. Meyers were able to show with a conformationally biased pyrrolidine that both the deprotonation and substitution steps proceed with retention.[198] In a paper that is well worth reading, about two dozen ligands—mainly chiral diamines—were investigated to see to what extent they could replace (−)-sparteine (**1**), or even lead conveniently into the other series of enantiomers.[199] The most effective among them have been collected in Scheme 69.

Essential, sufficiently high configurational stability of the lithiated intermediates seems to be limited to pyrrolidines like **168**.[200] The greater configurational lability of the corresponding piperidines can be compensated for to some extent through a rapid, intramolecular subsequent reaction. Thus, Y. S. Park and P. Beak obtained the 1-azabicyclo[3.1.0]hexane **182** with 55% *ee* after deprotonation of *N*-Boc-4-tosylpiperidine (**179**) in the presence of (−)-sparteine by the addition of chlorotrimethylsilane; the configuration is still unknown (Scheme 70).[201] In this case, rapid 1,3-substitution of the enantiomerically enriched intermediate **180**·**1** preserves most of the chiral information.



Scheme 69. Testing of various bidentate ligands in reagent-controlled deprotonation of *N*-Boc-pyrrolidine [199].



Scheme 70. Enantioselective deprotonation and intramolecular alkylation of an *N*-Boc-piperidine [201]. Ts = 4-$MeC_6H_4SO_2$.

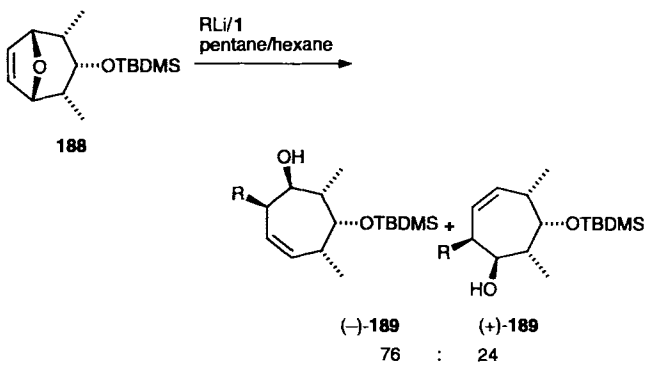
ing of the epoxide ring and insertion into the γ-*endo*-CH bond. *cis*-Epoxides of medium-sized cycloalkanes undergo similar reactions with transannular CH-insertion.[202a]

An interesting vinylogous nucleophilic ring opening of *meso*-oxabicyclic system **188** by *n*-butyllithium/(−)-sparteine was discovered by M. Lautens et al. (Scheme 72).[203] The best results [60% yield of (−)-**189** with 52% *ee*] were obtained with five equivalents of butyllithium and 15 mol% (−)-sparteine at −40 °C in pentane/hexane.



Scheme 72. Nucleophilic ring opening of *meso*-oxabicyclic compound **188**. R = Bu.

4.6. Enantiotopically Differentiating Lithiation at Other Prochiral Groups; Planar- and Axial-Chiral Intermediates

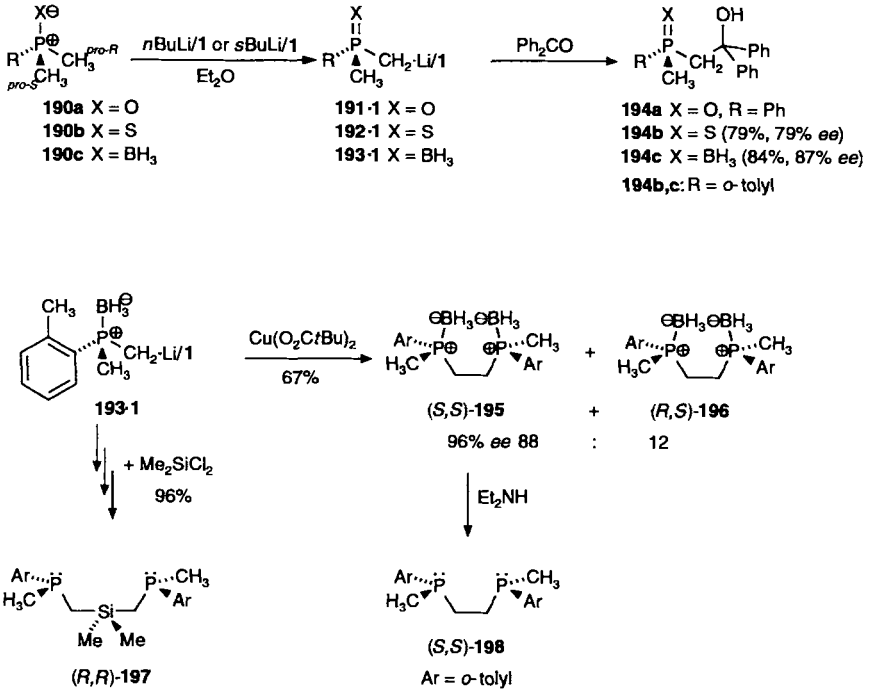
In the preceding sections, chirality was in most cases introduced through differentiation by the chiral base between enantiotopic protons of a methylene group. This means that configurational stability of the lithiated intermediate under the reaction conditions as well as a subsequent stereoselective substitution are necessary prerequisites. A few other cases in which no stereogenic carbanionic C atom is formed will now be discussed.

Hodgson et al. investigated a rearrangement of *meso*-epoxides induced by chiral bases.[202] Treatment of *exo*-norbornene epoxide (**183**) with *sec*-butyllithium/(−)-sparteine in pentane permitted the isolation of (−)-nortricyclanol[185] in 73% yield and 52% *ee* (Scheme 71).[202b] The base differentiates between the (*R*)- and (*S*)-sites on the oxirane unit during proton abstraction, and the carbenoid stabilizes immediately through open-

Both methyl groups in the dimethylphosphane derivatives **190**–**192** (Scheme 73) are enantiotopic, and the attached hydrogen atoms are acidified. During deprotonation to **191·1**–**193·1** the phosphorus atom becomes a stereogenic center. First experiments in deprotonation of dimethylphenylphosphine oxide (**190a**, R = C_6H_5) with *n*-butyllithium/(−)-sparteine were described in very brief form by Raston, White, et al.,[42] with an observed diastereomeric ratio in the range of 60:40.

Better results were obtained by D. A. Evans et al. with aryldimethylphosphine sulfides **190b** and the borane complex **190c**;[204] *ee* values of 74–94% were achieved in the capture products with benzophenone (**194b** and **194c**).

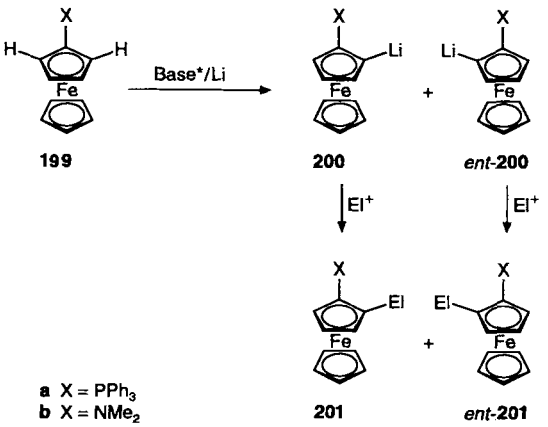
Oxidative coupling of the lithium derivative **193·1** with copper(II) pivalate to give the bis(phosphonium) complexes **195** and **196** is associated with an enhancement of the enantiomeric ratio to 98:2 (96% *ee*) (Scheme 73), because the greatest part of the epimer (P_R)-**193·1** (present to the extent of about 12%) is removed as the *meso*-diastereomer (*R*,*S*)-**196**. Deblocking of the



Scheme 73. Enantioselective, (−)-sparteine-induced deprotonation of aryldimethylphosphane derivatives [204].

borane complex (*S*,*S*)-**195** with diethylamine leads to the free diphosphane (*S*,*S*)-**198**. Just as in the case of the bis(phosphinyl)-substituted silane (*R*,*R*)-**197**, C_2-symmetric diphosphanes obtained in this way represent valuable potential ligands for enantioselective catalyst systems.

Based on the seminal work by I. Ugi and H. B. Kagan,[205] ferrocenes are extraordinarily versatile chiral auxiliaries and catalyst ligands. When one succeeds in using an enantiomerically pure base to distinguish between the enantiotopic sites of the achiral monosubstituted ferrocene **199** (Scheme 74), racemization of the enantiomerically enriched planar-chiral intermediates **200** and *ent*-**200** remains possible only through a proton transfer reaction or dissociation–recombination of the ferrocene; that is, configurational stability can be presupposed.[206]



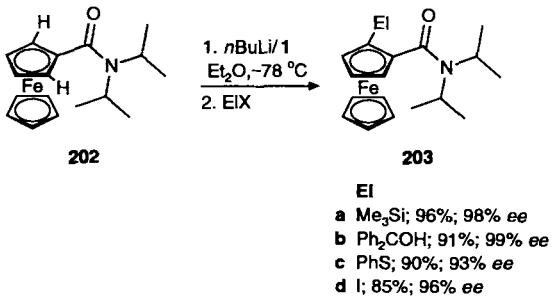
Scheme 74. (−)-Sparteine-induced *ortho*-lithiation of a ferrocene derivative [207].

Good enantiomeric enrichments have also been achieved through enantioselective deprotonation of other ferrocene derivatives: (diphenylphosphanyl)ferrocene (**201a**) with lithium (*R*,*R*)-bis(1-phenylethyl)amide, 55% *ee*,[208] and (dimethylaminomethyl)-ferrocene (**201b**) with (*R*,*R*)-*N*,*N*,*N*′,*N*′-tetramethyl-1,2-cyclohexanediamine/*n*-butyllithium,[209] 80% *ee* (Scheme 74).

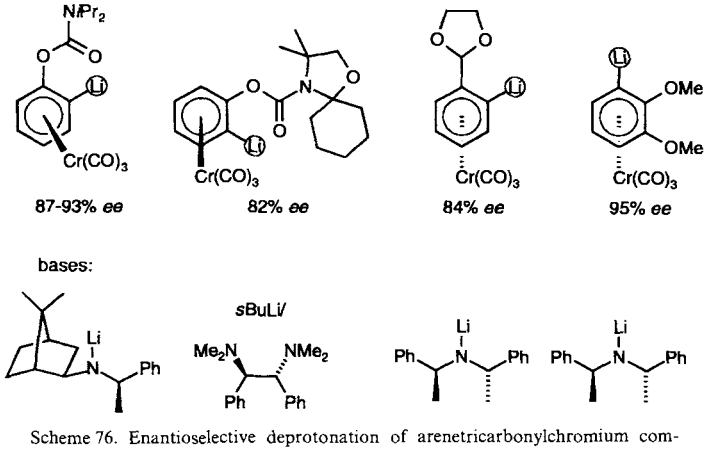
A breakthrough was achieved by V. Snieckus et al.,[207] when they subjected *N*,*N*-diisopropylferrocene carboxamide (**202**) to deprotonation with *n*-butyllithium/(−)-sparteine in diethyl ether (Scheme 75). The expected products **203** were isolated with a host of electrophiles in 62–96% yield and 81–99% *ee*.

Related stereochemical problems are posed by monosubstituted arenetricarbonylchromium complexes; in this case chiral bases other than alkyllithium/(−)-sparteine prove to be most useful. Scheme 76 collects examples from the research groups of Kündig,[210] Uemura,[211] Simpkins,[212, 213] and Schmalz.[214]

Axial chirality can also be created through enantiotopically discriminating deprotonation. The first examples, with 2,2′-dimethyl-1,1′-binaphthyl and 2,2′,6,6′-tetramethyl-1,1′-biphenyl

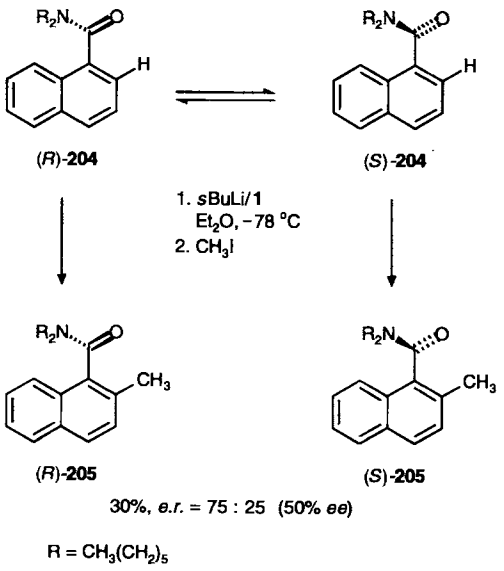


Scheme 75. Lithiation and substitution of monosubstituted ferrocenes with enantiotopic differentiation.



Scheme 76. Enantioselective deprotonation of arenetricarbonylchromium complexes [210–212, 214].

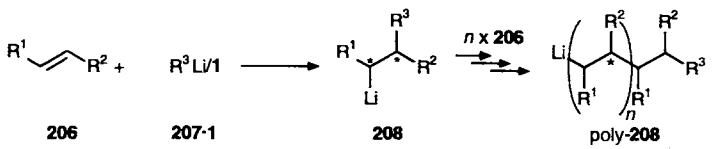
from Raston et al., are unfortunately not well documented with respect to quantitative results and configurational assignment.[215] P. Beak and D. P. Curran recently described a (−)-sparteine-induced deprotonation and methylation of the 1-naphthoic acid amide **204** with 50% *ee* (Scheme 77).[216] The yield at −78 °C amounted to only 53%, and from that one can conclude that the chiral base apparently accomplishes a kinetic racemate resolution between conformers that are interconverted only very slowly at −78 °C.[217]



Scheme 77. Induction of axial chirality through (−)-sparteine-induced deprotonation [216].

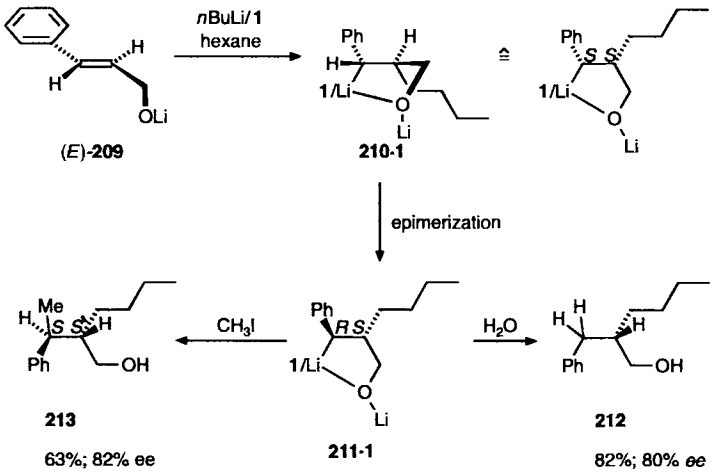
5. Sparteine-Induced Carbolithiation

So far we have discussed only the most popular route to "carbanion generation", the deprotonation of CH-acidic precursors. The addition of organolithium to C=C double bonds (carbolithiation)[218] is an attractive alternative, because it yields an additional C−C bond "gratis" (Scheme 78). This reaction represents the first step in anionic polymerization;[218] its use in organic synthesis depends upon retarding (relative to the first step) addition of the intermediate **208** to another molecule of alkene **206**. This can be accomplished, for example, by conducting carbolithiation with a 5-alkenyllithium derivative in an intramolecular way according to W. F. Bailey,[219, 220] or in a case where the adduct **208** is specially stabilized.



Scheme 78. Sparteine-induced asymmetric polymerization.

As a benefit, control is extended over two or even three (if the residue R^3 is chiral) stereogenic centers in the product. I. Marek, J.-F. Normant, and co-workers succeeded in carrying out an enantioselective (−)-sparteine-controlled addition of alkyllithium to cinnamyl alcoholates and cinnamylamines (Scheme 79).[221] Reaction of the (*E*)-alcoholate (*E*)-**209** with



Scheme 79. Enantio- and diastereoselective carbolithiation of lithium (*E*)-3-phenyl-2-propen-1-olate [221].

butyllithium/(−)-sparteine provides good insight into the course of the reaction. In a *syn*-addition, typical for carbometalation,[222] butyllithium/(−)-sparteine [presumably bonded in a precomplex to the alcoholate (*E*)-**209**] attacks the C=C double bond from the *Si*-face. The resulting five-membered ring chelate complex **210·1** bears phenyl and butyl residues in *cis*-orientation, hence the configurationally labile benzyllithium derivative epimerizes with formation of the more stable *trans*-substituted chelate **211·1**. Protonation produces the (*S*)-configured alcohol **212** with 80% *ee*, whereas methylation with inversion[223] leads to the doubly branched (*S,S*)-alkanol **213**. Locking the intermediate into the chelate and the formation of reactive, presumably hexameric[224] lithium alcoholate clusters with diminished reactivity protects adducts **210·1** and **211·1** from polymerization. Quite remarkably, 5 mol% of (−)-sparteine is sufficient to produce enantioselective reaction.[225]

Enantiofacial differentiation on the part of the (−)-sparteine reagent at C-2 of the double bond in the conformationally restricted complex determines the stereochemical course of the reaction, since a configurationally stable stereocenter is created at C-2. Consequently, the (*Z*)-alcoholate (*Z*)-**209** leads to the opposite series of enantiomers.[221a] Similarly successful additions have been realized with (*E*)-cinnamylamines and -acetals.[221b]

Kündig et al. have recently reported on enantioselective carbolithiation of the arenetricarbonylchromium complex **214** from 4,4-dimethyl-2-phenyl-1,3-oxazolidine (Scheme 80).[226] Here the (−)-sparteine reagent attacks one of the enantiotopic sites preferentially from the "upper side," and treatment of the carbanionic intermediate[227] with propargyl bromide leads to a 5,6-*trans*-disubstituted cyclohexadiene **215**. Greater enantiomeric excesses (65–93% *ee*) with somewhat lower yields (51–67%) were achieved on using (*S,S*)-1,2-dimethoxy-1,2-diphenylethane (**216**) in place of (−)-sparteine.[226]

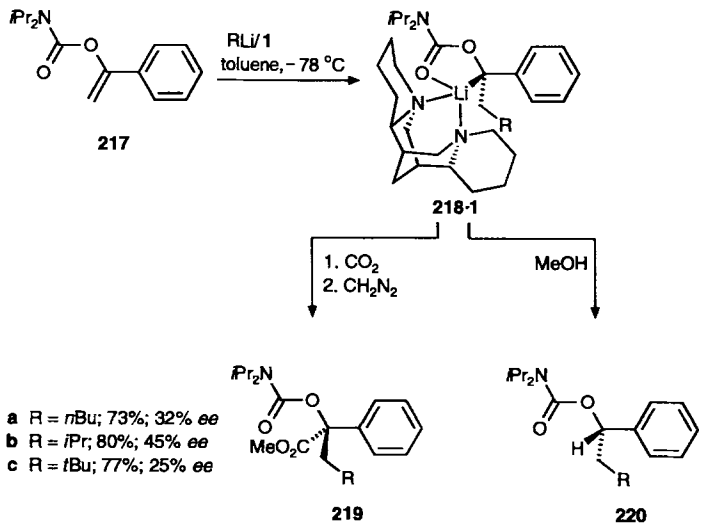
Scheme 80. Diastereo- and enantioselective reaction of the tricarbonylchromium arene complex **214** [226]. HMPA = hexamethylphosphoramide.

Orientational investigations with α-styryl-*N*,*N*-diisopropyl carbamate (**217**) reveal a pathway to enantiomerically enriched secondary benzyl alcohols (Scheme 81).[228] Attack by alkyllithium/(−)-sparteine leads—albeit with reduced enantiofacial selectivity—to the configurationally stable adducts **218**·**1**, which are carboxylated with inversion[74b] and protonated with retention of configuration.[229]

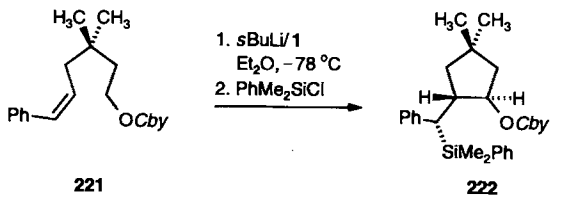


Scheme 81. Enantioselective carbolithiation of α-styryl carbamate **217** [228].

Intramolecular carbolithiations of (*E*)-alkenyllithium compounds proceed rapidly, as documented by numerous studies by Bailey et al., by 5-*exo*-*trig*-ring closure.[219, 230] However, this pathway has so far been used only to synthesize racemic or achiral cyclopentane derivatives. The gap has been closed by a highly stereoselective carbolithiation developed by us, which also assures control over the configuration of the attacking C-nucleophile; it produces in the case of the substituted cyclopentane **222**, for example, three consecutive, uniformly configured stereogenic centers (Scheme 82).[231]

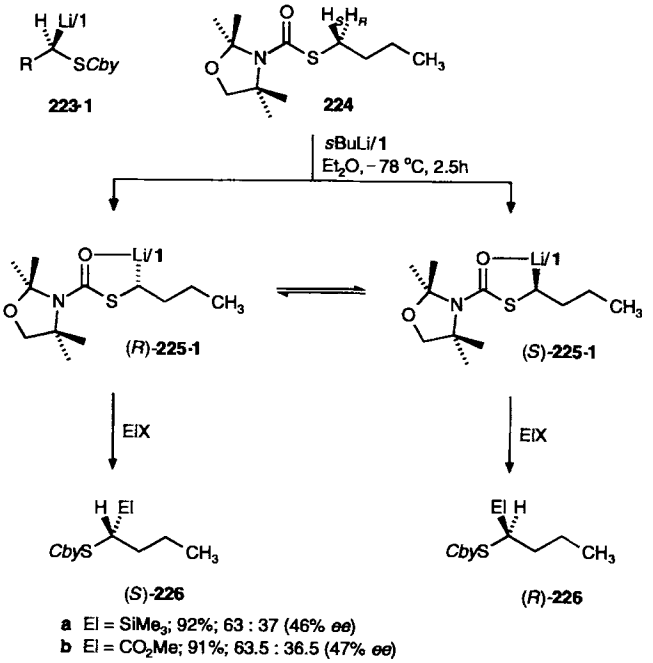
6. Ion Pairs from α-Thiocarbanions

In contrast to α-alkoxyalkyllithium derivatives, α-thio-substituted alkyllithium[232] and benzyllithium compounds[232] **223**·**1**



Scheme 82. Stereohomogeneous cyclopentyl carbamates through cyclocarbolithiation [231].

have turned out in all the relevant studies to be especially configurationally labile. Experimental results from Reich et al. point to the fact that the formation of solvent-separated ion pairs tends to increase the barrier to inversion rather than lower it.[232b] Nevertheless, we thought it might be possible that incorporation into a rigid chelate complex might lead to an increase in configurational stability. Alkyl[233] and vinyl *N*,*N*-dimethylmonothiocarbamates[234] are distinguished by high kinetic acidity. B. Kaiser thus investigated the (−)-sparteine-induced deprotonation of *S*-alkyl thiocarbamates of the type **224**;[235, 236] the reactions with *S*-butyl esters (Scheme 83) will be discussed as

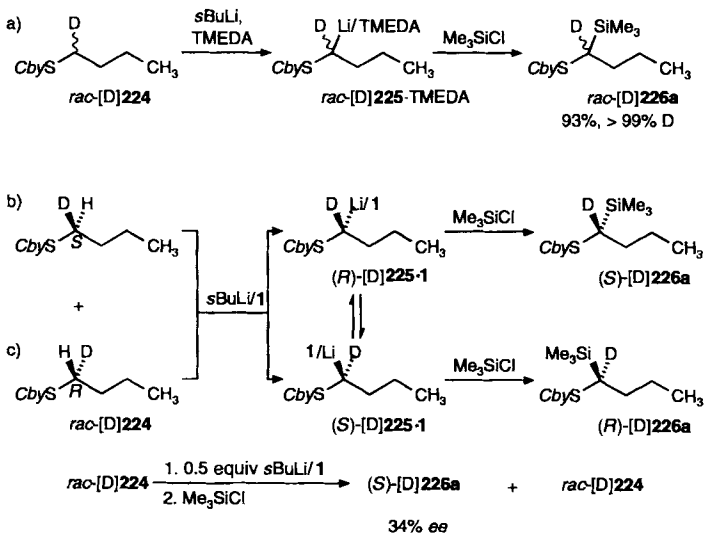


Scheme 83. (−)-Sparteine-mediated deprotonation of *S*-alkyl thiocarbamates [235].

an example of the results of this study. Deprotonation of **224a** with *sec*-butyllithium/(−)-sparteine in diethyl ether and trapping of the carbanionic intermediate with chlorotrimethylsilane led to the silane (+)-(*S*)-**226a** with 46% *ee*. A nearly identical result was recorded in carboxylation and esterification to (−)-(*S*)-**226b**.[236]

Is the cause here insufficient configurational stability of the diastereomeric intermediates (*R*)-**225**·**1** and (*S*)-**225**·**1**, which enter into equilibrium under the reaction conditions, or inadequate enantiotopic differentiation in the deprotonation step? As demonstrated by the following series of experiments with the

deuterated substrate *rac*-[*D*]**224**, in this case both factors are responsible (Scheme 84).[235] During deprotonation with *sec*-butyllithium/TMEDA (a) and capture of the intermediate ion



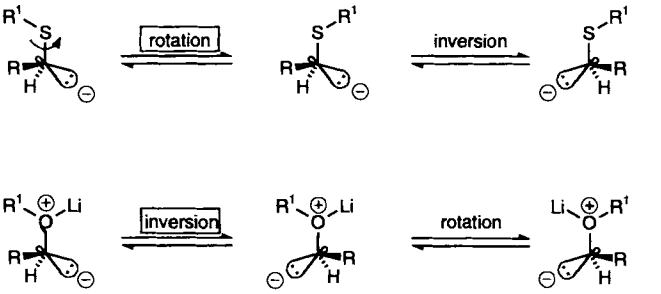
Scheme 84. Reactions with deuterium-labeled thiocarbamates.

pair *rac*-[*D*]**225** to give the silane *rac*-[*D*]**226a**, all the deuterium remains in the molecule; that is, the kinetic H/D isotope effect is on the order of about 100. In the next experiment (b), *rac*-[*D*]**224** was treated with one equivalent of the chiral base system *sec*-butyllithium/(−)-sparteine, and silylation was initiated; the result was a greater than 99% deuterated product (*S*)-[*D*]**226a** in 93% yield and 34% *ee*.[237] If there were a great preference for one of the enantiotopic protons *pro-S*-H or *pro-R*-H, one of the enantiomers would have been preferentially deprotonated, thus introducing a kinetic resolution like that observed with the corresponding *O*-alkyl carbamates (Section 4.2). However, the substrate was nearly completely deprotonated; nevertheless, an overproportional amount of enantiomerically enriched product was isolated. From this it can be concluded that the diastereomeric ion pairs (1*R*)- and (1*S*)-[*D*]**225**·**1** equilibrate under the reaction conditions. Experiment (c) solidifies this conclusion; it differs from experiment (b) only in a reduced amount of base (0.5 equivalents). Again the product was (*S*)-[*D*]**224a** with 34% *ee*, and the recovered unchanged substrate [*D*]**224** took the form of a racemate. There was thus no kinetic resolution, and the product ratio was determined thermodynamically at the stage of the ion pairs.

Also for the (−)-sparteine complex of the dilithium compound derived from *N*-methyl-3-phenylthiopropionamide, which represents a valuable homoenolate reagent, Takei et al. found evidence of configurational lability in THF at −78 °C, as well as similarly low enantiomeric enrichment in the aldehyde adducts.[238]

For an efficient utilization of chiral α-thiocarbanions, conditions and ligands must be found that lead to the largest possible energy difference between the diastereomeric lithium complexes. Corresponding investigations with (similarly configurationally labile) lithium-1-(phenylselenyl)alkanides carried out by R. W. Hoffmann et al. show through an NMR study that this is not a simple venture.[239]

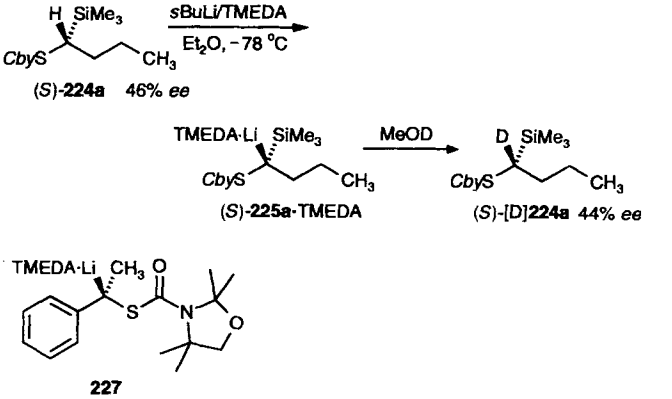
Why do *S*- and *O*-lithioalkyl derivatives behave so differently? Presumably the relatively long C(= O)−S and C−S bonds (about 180 pm compared to 140 pm for C−O) establish a less compact transition state for deprotonation, coupled with diminished enantiotopic differentiation. Moreover, the mechanisms of enantiomer interconversion differ. Evidence is increasing that rotation of the attached C−S bond from the antiperiplanar to the synperiplanar conformation is the rate-determining step in the enantiomer interconversion, whereas for α-hydroxyalkyllithium derivatives inversion at the carbanionic center appears to be the slowest step (Scheme 85).[240]



Scheme 85. The rate-determining step in enantiomer interconversion of α-heterosubstituted alkyllithium compounds.

It can be concluded from the work of R. W. Hoffmann et al. on racemic 1-(arylselenyl)alkyllithium derivatives that bulky arylthio residues increase the barrier to enantiomer interconversion.[241] An increased crowding of groups at the carbanionic center should for the same reason lead to increased configurational stability. Indeed, the lithium compound (*S*)-**225a**·TMEDA prepared from (*S*)-**224a** (46% *ee*) with *sec*-butyllithium in diethyl ether proved to be configurationally stable at −78 °C, because after standing for 2.5 h, deuterolysis produces the capture product (*S*)-[*D*]**226a** with 44% *ee* (Scheme 86).[235]

This is, to the best of our knowledge, the first enantiomerically enriched α-thioalkyllithium derivative. The world record with respect to configurational stability is held by benzyllithium derivative (*S*)-**227** (99% *ee*).[242, 243] No racemization could be demonstrated after standing for 24 h at −78 °C, and even 10 min of warming the reaction mixture to 0 °C caused less than 1% racemization.



Scheme 86. Configurationally stable α-thioalkyllithium derivatives [235, 241, 242].

7. Summary and Prospects

The interaction between a lithium ion bearing chiral ligands and a developing or previously formed carbanion forces the latter into a specific configuration, whether through a preferred diastereomorphic transition state in the course of deprotonation or because of the establishment of a state of equilibrium. In combination with a stereoselective substitution step, this provides a new and effective strategy for enantioselective synthesis. The synthetic value of the process is increased by the fact that the carbanionic reagents are obtained by simple deprotonation of the corresponding CH acids. The examples discussed above were discovered through intuition, whereby spontaneous crystallization of one of the diastereomers occasionally played a crucial role in increasing efficiency. One goal is to understand the interaction between chiral ligand, cation, and substrate or carbanion better, as well as to quantify it through quantum-mechanical calculations in order ultimately to succeed in predicting favorable ligand–carbanion combinations. We are closer to this goal with respect to estimating the relative energies of diastereomeric ion pairs than for diastereomorphic transition states.

The results described from our own research group have been achieved over the past eight years by capable and enthusiastic co-workers. Their names are included in the bibliography. Special thanks are due to Prof. Dr. E.-U. Würthwein, who convinced me (D. H.) of the value of quantum-mechanical computational methods for the solution of our problems, introduced several co-workers to the application of these methods, and stood at our side with unselfish advice and assistance. A. Deiters and Dipl.-Chem. T. Heinl gave valuable support with the presentation of the manuscript and the graphics. The work was supported for many years by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the Stiftung Volkswagenwerk, and Bayer AG.

[3] Reviews of the structure of organolithium compounds: a) P. von R. Schleyer, *Pure Appl. Chem.* **1984**, *56*, 151; b) G. Boche, F. Haller, K. Harms, D. Hoppe, W. Koch, J. Lorenz, M. Marsch, A. Opel, C. Tümmler, O. Zschage, "Crystal Structure and Reactivity (Selectivity) of Oxygen (Aryloxy; Carbamoyloxy; Silyloxy)-Substituted Lithium Compounds" in *New Aspects of Organic Chemistry II*, Kodansha, Tokyo, **1992**, pp. 159–179; c) E. Weiss, *Angew. Chem.* **1993**, *105*, 1565; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1501; d) C. Lambert, P. von R. Schleyer, *ibid.* **1994**, *106*, 1187 and **1994**, *33*, 1129; e) C. Lambert, P. von R. Schleyer, "Carbanionen - Polare Organometall-Verbindungen," in *Methoden Org. Chem.* 1952– *(Houben–Weyl), Carbanionen*, 4th ed., Vol. E19d, **1993**, pp. 1–106.

[4] Regarding the advantages of C_2-symmetric ligands, see the following reviews: a) J. K. Whitesell, *Chem. Rev.* **1989**, *89*, 1581; b) H. Waldmann, *Nachr. Chem. Tech. Lab.* **1991**, *39*, 1142.

[5] In the preceding example, a nonsymmetric C_2 ligand would have had the consequence that an additional stereogenic center would have been established at the lithium cation, and it would have been necessary for us to consider twice as many diastereomers.

[6] The term "two-dimensional stereogen" has been considered better defined: a) D. Seebach, V. Prelog, *Angew. Chem.* **1982**, *94*, 696; *Angew. Chem. Int. Ed. Engl.* **1982**, *21*, *654*. Although not as well defined, we continue to use the simpler designation "prochiral": b) E. L. Eliel, S. H. Wilen, *Stereochemistry of Organic Compounds*, 1st ed., Wiley, New York, **1994**.

[7] On applying the term "cation" rather generously and even including covalently bonded metal substituents (e.g., magnesium, boron, zinc, and titanium), this simple concept has been shown to be exceptionally successful. Magnesium: a) R. Noyori, M. Kitamura, *Angew. Chem.* **1991**, *103*, 34; *Angew. Chem. Int. Ed. Engl.* **1991**, *31*, 49; b) B. Weber, D. Seebach, *Tetrahedron* **1994**, *50*, 6117; Boron: c) H. C. Brown, P. V. Ramachandran, *J. Organomet. Chem.* **1995**, *500*, 1; d) D. S. Matteson, *Chem. Rev.* **1989**, *89*, 1535; e) W. R. [75] Information on the stereochemical course of electrophilic substitution of chiral benzyllithium compounds is still quite fragmentary. Only in the case of (1-lithio-1-phenylethyl)-*N*,*N*-diisopropyl carbamate [74a,b] and 2,4,6-triisopropyl benzoate,[74c] which are accessible in enantiomerically enriched form with known configuration through deprotonation of optically active precursors, do there exist firm correlations between the configurations of starting materials and products. The trend toward stereoinversion in reactions with alkyl and acyl halides, carbon dioxide, carbon disulfide, and silyl and stannyl chlorides is strong. Protonation with alcohols and carboxylic acids, hydroxyalkylation with aliphatic aldehydes, and acylation with esters occur with retention; in these cases one can assume a preassociation of the reagent at the cation. The experimental basis is too small for solid generalization; moreover, a strong dependence on individual factors is to be anticipated.
[76] Zhang and Gawley carried out similar experiments in THF and isolated racemic products. This once again verifies that (–)-sparteine is easily displaced from the lithium cation by THF: P. Zhang, R. E. Gawley, *J. Org. Chem.* **1993**, *58*, 3223.

[84] We refrain here from providing an interpretation in depth. If the individual lithiation and substitution steps are subject to the same stereochemical course as was proven to be the case for the lithium derivatives of secondary benzyl carbamates [75], **38**·**1** must possess the (*R*)-configuration [83b].

[89] Configurational assignment is based on the assumption of stereoinversion in the course of silylation.
[90] V. Snieckus, lecture on December 16, 1996, in Münster.
[91] S. Retzow, dissertation, Universität Kiel, **1993**.
[92] The absolute configuration of the predominant stereoisomer is unknown.
[93] For **55a**·**1**/*epi*-**55a**·**1**, a free energy of epimerization $\Delta G^{\ddagger}_{epi}$ of about 67 kJ mol^{-1} was estimated from the coalescence temperature, whereas for the pair **55b**·**1**/*epi*-**55b**·**1** a value of >78 kJ mol^{-1} results in the same way.
[94] An additional problem will be touched upon only briefly: Since (−)-sparteine is not C_2-symmetric, a stereogenic center is also created at the tetrahedrally coordinated lithium cation. In this way four diastereomers compete. All experimental indications are consistent with the view that epimerization at lithium is much more rapid than that at the carbanionic C atom.

[98] The addition of tetra(isopropoxy)titanium leads to increases in the yield and product purity of the resulting carbinols, but does not change either the enantio- or the diastereoselectivity. From this we conclude that metal exchange does not arise in the carbanionic intermediate. Rather, we suspect that the lithium alcoholate is bound as a titanate, and hence possible subsequent and retroreactions are prevented.
[99] In a general sense, and with the same consequences with respect to regioselectivity, intermediates can be formulated in which the carbonyl oxygen atom has displaced one coordination site of (−)-sparteine.
[100] A lithium–sparteine contact has also been demonstrated by NMR spectroscopy in diethyl ether solution, whereas in THF solution no such evidence was discovered; S. Gessler, Diplomarbeit, Universität Marburg, **1996**.

[102] G. A. Weisenburger, P. Beak, *J. Am. Chem. Soc.* **1996**, *118*, 12218.
[103] The authors suggest a η^3-structure **67**·**1** and not a η^1-α-lithio ion pair [102]. Presumably the marked γ-selectivity of the substitution reaction serves as an argument. We were able to show that related η^1-α-lithioallyl ion pairs (for which the α-chelate structure was established) display a strong tendency toward γ-alkylation [46a, 64, 65d].
[104] Only the (*S*)-configuration of **68d** was rigorously proven [102].
[105] The authors claim that the provisional assignments of absolute configuration for the stannanes *ent*-**68e** and *ent*-**69e** are based on analogies to our results [102]. On this basis we come to the reverse conclusion (**68e** and **69e**), but then encounter contradictions with respect to the configurational assignment of the alkylation products **68b** and *ent*-**68b**.
[106] The high enantioselectivity is only useful in a preparative sense if the (*E*)- and (*Z*)-enamides **71** and **72** are separated and they do not interconvert during workup and separation.

[143] In this way the useless stereogenic center in the base is avoided. It follows from studies by Beak that this exchange has virtually no influence on the stereoselectivity [142].
[144] We believe that despite the small calculated energy difference the calculated structures portray the decisive distinction. It is very likely that the "true" transition states are more compact than the calculated ones. For the ground state of the lithium–sparteine–methylindenide complex **58a**·**1**: Li–N distances measured in the crystal structure (209.5 pm and 214.1 pm) are noticeably shorter than the calculated distances (225.2 pm und 226.4 pm). T. Heinl, Diplomarbeit, Universität Münster, **1996**.
[145] J. Haller, T. Hense, D. Hoppe, *Liebigs Ann. Chem.* **1996**, 489.
[146] These investigations were carried out with racemic mixtures; for greater clarity, one enantiomer has been singled out.
[147] T. Hense, Diplomarbeit, Universität Münster, **1993**.
[148] Those with little practice in stereochemistry are asked to forgive us for the confusion we may have perpetrated. For reasons of clarity we have held constant the configurational arrangement at the reaction center in the calculations, and instead varied the configuration at the stationary center. This is legitimate, since all such transformations that obey the relative topicity *lk* (*like*) [6a]—irrespective whether *R,Re*, *S,Si* or *R*,Re**—must overcome the same energy barrier. The same applies in principle to the *ul* (*unlike*) series.

[166] H. Ahrens, M. Paetow, D. Hoppe, *Tetrahedron Lett.* **1992**, *33*, 5327.

[167] We do not know the precise structure of bis-chelate complexes like **131**. It is also possible that the more effectively donating carbonyl group of the γ- or δ-carbamoyloxy residue binds, but then a seven- or eight-membered ring would need to form. We can also only speculate about the fourth ligand L; Et_2O or $Me_2NCH_2CH_2NMe_2$ (TMEDA) bound in monodentate fashion are possible candidates.

[168] Irrespective of the fact that the deprotonation step is kinetically directed, the energetically more favorable bicyclic chelate complex is formed in excess.

[169] H. Helmke, D. Hoppe, *Synlett 1995*, 978.

[170] Based on MOPAC calculations [65e], there is an energy difference of 4.6 kJ mol^{-1} between the simplified complexes **134** and *epi*-**134** ($Me_2NC{=}O$ for *Cby*, L = Me_2O).

[171] For the preparation of (+)-sparteine from *rac*-lupinane, which is obtained from the seeds of *Lupinus alba*, see ref. [26a].

[172] Another elegant route for diastereoselective generation of protected 1,3-dihydroxyalkanides was developed by S. E. Rychnovsky: a) [113b]; b) T. I. Richardson, S. D. Rychnovsky, *J. Org. Chem.* **1996**, *61*, 4219; review: c) S. D. Rychnovsky, *Chem. Rev.* **1995**, *95*, 2021.

[173] a) W. Guarnieri, Diplomarbeit, Universität Kiel, **1992**; b) W. Guarnieri, M. Grehl, D. Hoppe, *Angew. Chem.* **1994**, *106*, 1815; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 1734; c) P. Gmeiner, A. Kärtner, *Synthesis* **1995**, 83.

[174] The energy difference in the ground state between the complexes (1*S*)-**138** and (1*R*)-**138** is apparently smaller than the relevant free energies of activation, because the addition of lithium bromide initiates an epimerization that leads to a 1:2 mixture [175]. Nevertheless, the possibility that a further LiBr-containing aggregate enters into competition cannot be ruled out [175].

[175] M. Sendzik, Diplomarbeit, Universität Kiel, **1995**.

[176] We do not know the structure of **138**; our suggestion offers one plausible interpretation of the experimental findings. In particular, it remains unclear in what way the 4-O*Cby* group is bound to the lithium cation, and whether an additional ligand L (here Et_2O) is acquired.

[177] M. Sendzik, dissertation, Universität Münster, **1997**.

[178] This experiment proves that there is a kinetically determined deprotonation.

[179] As demonstrated here, the high H/D kinetic isotope effect permits a very general utilization of deuterium as protective group in the deprotonation of alkyl carbamates.

[180] Preparation of 2-(dibenzylamino)alkanols: a) L. Velluz, D. Amiard, R. Heymes, *Bull. Soc. Chim. Fr.* **1954**, 1012; b) M. T. Reetz, M. W. Drewes, A. Schmidt, *Angew. Chem.* **1987**, *99*, 1186; *Angew. Chem. Int. Ed. Engl.* **1987**, *26*, 1141; c) ref. [173c].

[181] The following problem has been avoided in Figure 10: With the exception of two energetically unfavorable conformational arrangements, the pyramidal dibenzylamino group contributes to varying degree to the shielding of the front and rear faces. It is quite conceivable that the influence of the "small" methyl group is overcompensated in this way.

Charge Transfer in DNA: A Controversy

Ulf Diederichsen*

Interest has increased in the scrutiny of linear molecular structures with regard to their conductivity, and several models that define charge propagation have evolved; one concept describes a molecular wire in which an electron tunnels through a valence-bound, linear, saturated carbon chain.[1] Thus, the probability that the charge remains within the chain is very low. A new model, which was developed for positive charge transfer in small peptides in the gas phase, follows a stepwise charge transport through energetically varied intermediate states.[2] Various amino acids in the peptide backbone function to control the mechanism of charge transfer. However, for large, complex folded proteins electron transfer in solution is described as a tunneling process that proceeds along the peptide backbone and passes through space.[3]

A well-defined linear helix and repetitive structure is found in the DNA double strand. It consists of a stack of purine–pyrimidine base pairs which are topologically stabilized by a ribosyl phosphodiester double strand. The interaction of the π electrons, which are 3.4 Å apart, provides an important contribution to DNA double strand stability. The question of whether DNA has a structurally inherent potential for transport of electrons over greater distances has been discussed for some time.[4] An early experiment that points out electron migration in DNA defines the photoinduced interaction between intercalating ethidium donors with acceptors that are unspecifically bound to the DNA backbone.[5] In recent years experiments by Barton et al., which confirm indications that efficient charge migration within the DNA duplex might be possible over distances up to 40 Å, have raised attention.[6] Initially, a fast hopping mechanism through the stack of base pairs (π way) was suggested.[6] An alternate model is based on quantum mechanical tunneling, which is supported by the valence orbitals of the π stack; however only moderate electron-transport properties can be expected.[7] Another approach based on conductivity measurements suggests electron transport through the outer sphere of the ribosyl phosphodiester backbone with tightly bound water molecules.[8]

Due to original difficulties in the synthesis of DNA strands with covalently linked metal-complex intercalators (1% yield) and the high concentration necessary for determining electron-transport rates, some of the electron-transport studies were carried out with *noncovalently linked intercalators*. (Figure 1a).[9]

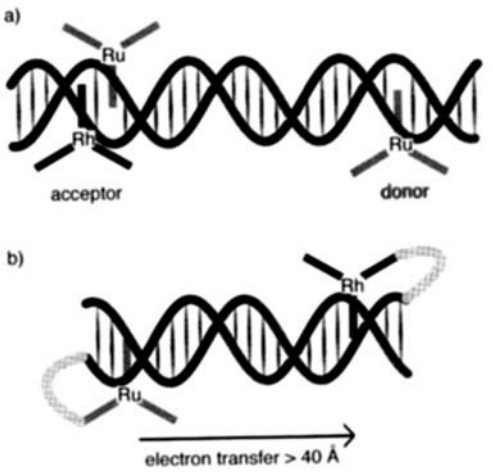

Figure 1. a) Intercalation of nontethered ruthenium and rhodium complexes to DNA takes place without a defined distance between electron donors and acceptors. The high rates observed for electron transport most likely result from clustering of the intercalators. b) DNA double strands with metal intercalators covalently tethered to the 5'-termini ensure electron transfer between separated donor and acceptor complexes.

These experiments provide limited information, primarily because the real distance of electron transport with unspecifically bound intercalators is unknown. In some instances cooperative binding of donor and acceptor intercalators in clusters could explain the rapid exchange of electrons. Circular dichroism (CD) spectra indicate cooperative binding of the intercalators, thus suggesting the influence of the neighboring intercalators.[10] Furthermore, by simulating electron transport as a function of the distance between the metal complex, the experiment with noncovalently linked intercalators is correlated advantageously by the pairing of donor–acceptor complexes.[11]

On the other hand, the stoichiometry of DNA and intercalator has no kinetic effect, and the rate of electron transport is clearly dependent on the sequence, which is in contrast to a direct exchange between donor and acceptor intercalator; electron exchange on poly d(AT) is 30 times faster than on poly d(GC).[6] As long as the distances between the intercalators are not defined, it is difficult to determine which effect

influences electron transport. This requires a system in which the *intercalators are covalenty bound* to the DNA strands.

When a DNA double strand consisting of 15 base pairs is covalently linked through the 5′-terminus to the electron-donating metal intercalator $[Ru(phen)_2(dppz)]^{2+}$ and through the opposite 5′-position to the acceptor $[Rh(phen)(phi)_2]^{3+}$ (phen = 1,10-phenanthroline, dppz = dipyrido[2,3-*a*:2′,3′-*c*]phenazine, phi = 9,10-phenanthrenequinonediimine), intercalation of the metal ligands over a distance of 40 Å is possible (Figure 1b); the luminescence usually present in intercalated ruthenium complexes is not observed.[12] This luminescence quenching is interpreted as electron transfer from the activated ruthenium to the rhodium complex and back at a rate of at least $3 \times 10^9\ s^{-1}$. Control experiments on photochemical DNA cleavage at the intercalation site proved that the positions of intercalation are usually two base pairs away from the ends. Furthermore, at least 85% of the quenching of the ruthenium-complex emission is due to an intramolecular process.[12] The dependence of electron transport on the distance between donor and acceptor remains an important issue. Recently, Lewis et al. described photoinduced electron transport between a stilbene molecule, which functions as a loop for two DNA strands forming a double helix, and a guanine residue of a G–C base pair.[13] Decreasing fluoresence quenching with increasing distance between the G–C base pair and stillbene was established. Also Tanaka et al. observed a distance-dependent electron transfer between an acridine derivative that is covalently anchored into an internucleotide site in DNA and a guanine residue.[14] Furthermore, experiments are expected in the near future from Meade[15] and Barton et al.[6] The latter use covalenty bound ethidium instead of ruthenium donors with donor–acceptor distances of 17–36 Å, and observe a negligible distance dependency for fluorenscence quenching.

Because of the great biological significance of charge transport, the development of artificial electron transfer systems for simulating biologically relevant functions has received much attention. The Barton group investigated DNA mutation by electron transfer for a guanine residue oxidized at C8[16] and the repair of thymine-dimer damage resulting from [2+2]cycloaddition.[17] These experiments support the concept of electron transport through the stack of DNA base pairs. In addition, they indicate a new principle for the formation and possible repair of DNA damage, because, in contrast to the position of electron transfer, the mutation location can be precisely established. Photochemical activation (365 nm) of the electron acceptor $[Rh(bpy')(phi)_2]^{3+}$ (bpy′ = 4-butyric acid 4′-methylbipyridine) that is covalently linked to the DNA duplex at the 5′-terminus (Figure 2) generates an electron hole that might equilibrate in the DNA base pair stack. Positions such as GG or GGG sequences are susceptible to oxidation because of the electron-donor properties of the adjacent guanine residue; therefore, oxidation at C8 of the 5′-terminal guanine residue proceeds with a low quantum yield of 10^{-7}. When several GG sequences are present, the more distant ones are more easily oxidized.[16]

Quantitative repair of the damaged thymine dimer is achieved through photochemical activation of the statistically intercalated metal complex $[Rh(phi)_2(dmb)]^{3+}$ (dmb = 4,4′-dimethyl-2,2′-bipyridine). The reaction is catalytic, since only substoichiometric amounts of intercalator are required.[17] Full

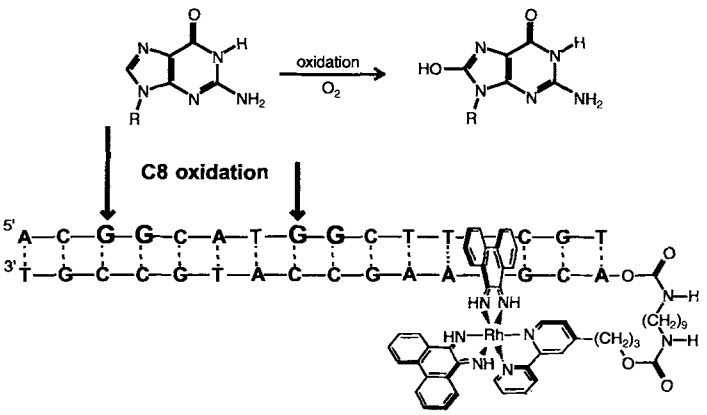

Figure 2. Electron transport initiated by photochemical activation of a covalently tethered rhodium-complex intercalator selectively oxidizes the 5′-guanine residue of a G–G dimer.

repair is observed even when $[Rh(phi)_2(dmb)]^{3+}$ is covalently tethered to the 5′-terminus of the DNA (Figure 3). The yields strongly depend on how the base pairs stack and how closely the intercalator interacts with the nucleobases. In this manner, effective damage repair of a less than ideally stacked thymine dimer is indicated, in which a thymine dimer projects out of the helix; this provides better contact with the nontethered inter-

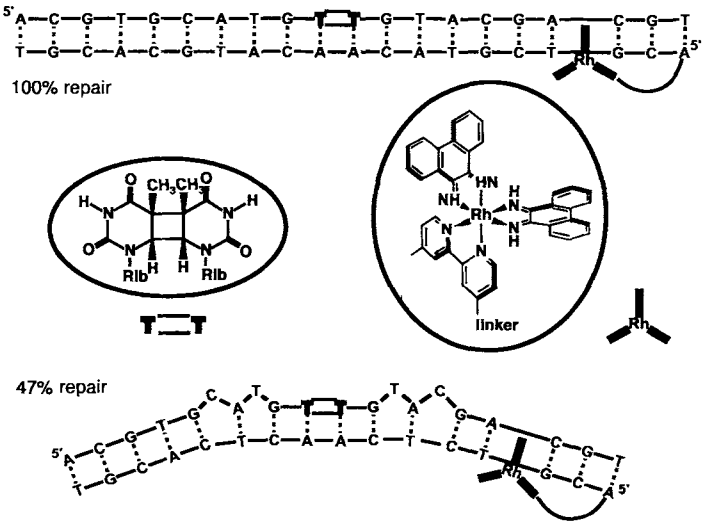

Figure 3. Photochemical activation of a rhodium-complex intercalator covalently tethered to the 5′-position of DNA initiates complete repair of the damage to a thymine dimer. Perfect stacking of the nucleobases is required for most effective repair.

calator. Control experiments show that repair of the T–T dimer with covalently bound metal complex does not result from an intermolecular reaction between DNA double strands. Furthermore, the repair efficiency is independent of the distance or the binding of the intercalator to either end of the double strand.[17]

The investigated DNA electron transfer systems are controversial with respect to the distance dependency of electron transport. In contrast to studies on systems clearly showing distance-dependent electron transport,[13, 14] Barton's results indicate that with ideal DNA geometry the electron transfer is virtually distance independent.[6, 16, 17] Effective stacking of arenes in-

volved in the transport process (intercalator, base pairs, thymine dimers) seems to be neccessary for uninterrupted electron transport. Mismatched base pairs, bulges that disturb the strand geometry, and loosely bound intercalators with weak stacking interaction have negative effects on the transport.[6] Sequence dependency of electron transport also seems reasonable, because nucleobases contribute differently to double-strand stability through stacking. Interference in base stacking could be important for regulating usually unrestricted electron transfer within the DNA stack.

Investigations based on past results are already in progress using DNA electron transport as a sensor. To detect a DNA sequence, one could advantageously use the fact that a single DNA strand has low and a helical double strand high conductivity. The presence of a sought after DNA sequence can be clarified by a great increase in conductivity when bound to a complementary DNA strand which is placed in a conducting matrix.[18] The efficiency of electron transport provides an additional measurement of the structural interference of a DNA double helix through base-pair mismatch, DNA damage, or bulges.

The present interesting experiments concerning electron transport in DNA raise many questions, which call for a mechanistic understanding of the electronic properties of DNA. The development of satisfactory theories and prognosis requires cooperation between bioorganic chemistry for the molecular design of and experiments with appropriate test systems, physical chemistry for diagnostics (transport rates), and theoretical chemistry for mechanistic interpretation.

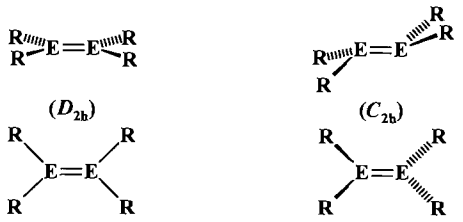
How Can One Recognize a Triple Bond between Main Group Elements?

Karl Wilhelm Klinkhammer*

The synthesis of compounds containing a double bond between heavy main group elements has challenged chemists since the double-bond rule was established by Goubeau in 1957. According to this rule, no double bond, which is stable towards polymerization, should exist between elements for which the sum of their electronegativities exceeds a certain amount (approximately 5).[1] Thus—with the exception of the combinations P/S, S/S, P/Cl, S/Cl, and Cl/Cl—a double bond is stable only if at least one of the atoms is a second-row element.

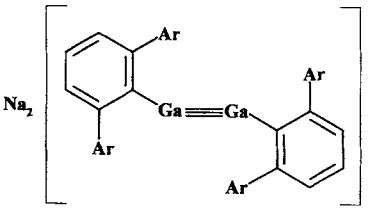
The ingenuity of some chemists, however, canceled out this rule with a trick called *kinetic stabilization*.[2] By using very bulky substituents a few dozen compounds containing formal double bonds between heavy electropositive elements were synthesized.[3] Compounds with corresponding triple bonds remained unknown. Some of the synthesized alkene homologues, however, show unexpected differences to "ordinary" double bonds: a) The four substituents no longer lie in a plane with the double-bonded atoms (idealized D_{2h} symmetry), but rather show a typical *trans*-bent orientation (idealized C_{2h} symmetry). b) The double bond is only marginally shorter and, in a few cases, even longer than the corresponding single bond. c) Cleaving the double bond requires less energy than cleaving the corresponding single bond; the compound and its carbene-type fragments are often in thermal equilibrium in solution.



In accordance with Goubeau's rule, these "abnormalities" become more important for elements of low electronegativity. Therefore, no (isolable) molecular compound is known to date containing homonuclear double bonds between the heaviest elements of Group 14, 15, or 16. Molecules showing multiple bonds between the more electropositive heavier elements of Group 13 were unknown until very recently, when the research groups of Uhl, Pörschke, and Power reported the syntheses of radical anions such as $[Al_2R_4]^-$ or $[Ga_2R_4]^-$ (bond order 3/2), and Robinson et al. described the anionic cyclotrigallenes $[R_3Ga_3]^{2-}$ (bond order 4/3).[4] These compounds display the expected shortening of Al–Al and Ga–Ga bond lengths compared to dialanes and digallanes, Al_2H_4 and Ga_2H_4. However, for dimeric cyclopentadienyl derivatives of indium(I) and thallium(I)—which, from a classical point of view, may be double-bonded species (R–E=E–R)—only very long E–E distances (> 350 pm) are observed. Moreover, only monomers are present in solution.[5]

What are then the typical features which unambiguously define a multiple bond? Is a short E–E bond imperative? A recent paper by Robinson et al. allowed us to ask this question again. They reported a compound they call "the first gallyne", that is, the first species showing a triple bond between heavy main group elements.[6] The synthesis was accomplished by using an extremely bulky *m*-terphenyl substituent. During the last years substituents of this type had been frequently used, mainly by the groups of Power and Robinson, to stabilize molecules with atoms of unusually low coordination.[4, 7]

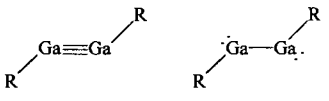
"How short is a –Ga≡Ga– triple bond?" is the question posed at the beginning of the paper on the synthesis and characterization of gallyne **1**, a compound containing two-coordinate



1

Ar = 2,4,6-*i*Pr$_3$C$_6$H$_2$

gallium and an almost planar but nonlinear C-Ga-Ga-C framework.[8] This question possibly reflects a preliminary discussion with Power, who thinks that a Ga–Ga distance of 2.32 Å is too long to be called a triple bond. In his opinion, the observed C-Ga-Ga angles of 129–134° seem to fit better the alternative description of a digallane with one lone pair at each gallium atom (**B**) than a formulation as a triply bonded system (**A**).[9] How can one verify the presence of a multiple bond? Classical criteria are short bond distances, high bond energies, and large force constants as well as a characteristic geometry. Thus, C–C double bonds within alkenes are always shorter than corresponding single bonds within alkanes, much more energy is needed to cleave them, and both carbon atoms exhibit trigonal-planar coordination. On the other hand, the C–C triple bond is shorter and stronger than a double bond, and both carbon atoms are linearly coordinated.



A **B**

Theoretical analyses with ab initio methods show that the elements from the second row of the periodic table have an exceptional position, and the criteria mentioned above are not imperative for multiple bonds between heavy main group elements.[3, 10] This is caused by the different radial extension of

the s and p valence orbitals, which corresponds to a lower inclination to hybridize, and by markedly lower E–E bond energies. Simply said: The amount of energy gained by the hypothetical formation of a double bond from the corresponding carbene homologues is diminished by the energy needed to promote the fragments R_2E from their singlet ground state to their triplet valence state. The same holds for the formation of a triple bond from carbyne- or borylene-homologous fragments.

For most of the carbene fragments R_2C, the sum of the promotion energies is much lower than the C=C bond energy and may even be zero in certain cases. In the case of the analogous silylene, germylene, and stannylene fragments, however, the promotion energy often amounts to more than half of the bond energy of the E–E double bond.[3] In the case of lead, the heaviest Group 14 element, as well as the corresponding EH fragments of Group 13 (E = Al, Ga, In, Tl), promotion energies are even higher, and, at least for this simple model, dimerization is totally inhibited. Lowering the energy of dimerization also results in geometrical changes. The trigonal-planar and linear coordination of the double or triple bonded atoms is distorted. The E–E bond is lengthened, and pyramidalization or tilting of the $E-EH_2$ and E–EH fragments, respectively, occurs.

That means that neither the bond length, nor the bond strength or the topology are reliable criteria for determining the bond order of bonds between heavy main group elements. How can one find a way out of this dilemma? If there are no reliable experimental criteria for a multiple bond, we have to go back to the original definition of a bond and analyze the mode of bonding with quantum mechanics: A *covalent* bond consists of an electron pair which is *localized* on only two atoms, and a *triple* bond is defined by *three* covalent bonds connecting two atoms.

Quantum mechanical calculations are nowadays mainly performed with the widespread LCAO (*l*inear *c*ombination of *a*tomic *o*rbitals) method, which leads to canonical molecular orbitals, that is, delocalized orbitals with coefficients on all atoms. By using the NBO (*n*atural *b*ond *o*rbitals) analysis, however, one may easily transform the canonical orbitals into orbitals which are localized at one or two centers, corresponding to lone pairs or bonds, respectively.[11, 12] The derived model is virtually the same as the simple picture obtained using the octet rule. In the cases of ethylene and acetylene, two and three bonds between the carbon atoms, one σ bond and one or two π bonds, are obtained. Applying this method to gallyne $[Ga_2H_2]^{2-}$, which differs from acetylene by a nonlinear *trans*-bent H-Ga-Ga group, three bonds are also obtained: a) a σ bond, b) an "ordinary" π bond constructed from p orbitals perpendicular to the molecular plane, and c) a "slipped" π bond in which the maxima of electron density is shifted towards the gallium atoms (Figure 1).[13] Closer inspection reveals that this view is equivalent to a model with two donor–acceptor bonds, which was proposed as early as 1976 by Lappert et al. for describing bonding within the distannene $[(Me_3Si)_2CH]_2Sn{=}Sn[CH(SiMe_3)_2]_2$ (Figure 2).[14] In the present gallyne, the donor-acceptor bonds are augmented by an additional π bond to yield a Ga–Ga triple bond.[15]

A pure quantum mechanical definition of a multiple bond which is not further verified by experimental data may or may not be accepted. However, the very existence of compounds such as the gallyne remains exciting, because established, apparently unique conceptions and models lead to ambiguous statements and, therefore, have to be modified. The principle of kinetic stabilization supported by extremely bulky substituents will hopefully yield further thrilling compounds.

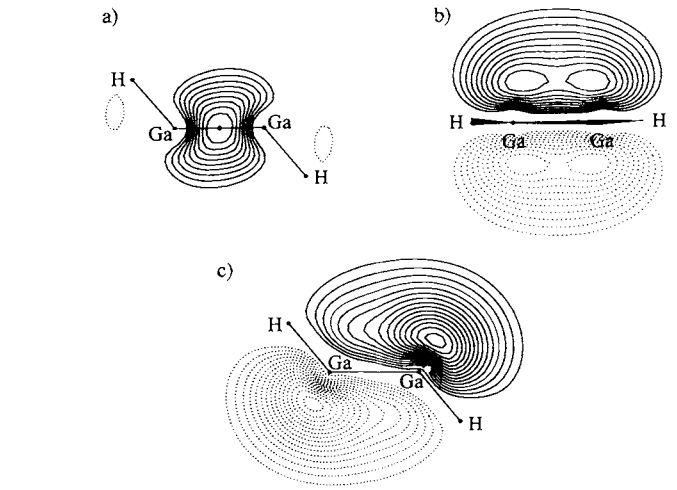

Figure 1. Ga≡Ga bond orbitals derived from NBO analysis. The different signs of the wave functions are represented by solid and dotted contours; a) σ bond, b) π bond, c) "slipped" π bond.

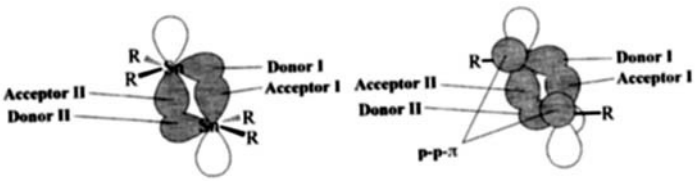

Figure 2. Description of the bonding situation in Sn_2R_4 (left) and $[Ga_2R_2]^{2-}$ (right) according to the model of donor–acceptor bonds [14].

[2] From the point of view of physics, the term "kinetic stabilization" should not be used because it intermingles kinetics and thermodynamics. The effects which are described by this term, however, do consist of both a kinetic and a thermodynamic contribution in many cases: On the one hand, the oligomerization reactions are slowed down, and, on the other, the oligomerization products are thermodynamically destabilized.

[12] The ELF (*e*lectron *l*ocalization *f*unction) is a further suitable tool for interpreting results of quantum chemical calculations in terms of such vivid concepts as "lone pair" or "bond": B. Silvi, A. Savin, *Nature* **1994**, *371*, 683; A. D. Becke, E. Edgecombe, *J. Chem. Phys.* **1990**, *92*, 5397; A. Savin, A. D. Becke, J. Flad, R. Nesper, H. G. von Schnering, *Angew. Chem.* **1991**, *103*, 421; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 409; A. Savin, R. Nesper, S. Wengert, T. F. Fässler, *ibid.* **1997**, *109*, 1892 and **1997**, *36*, 1808. This function, which measures the probability of finding two electrons of opposite spin in the same space, is in accordance with a triple bond within gallyne $[Ga_2H_2]^{2-}$.
[13] I carried out the NBO analyses employing the NBO module implemented in Gaussian 94: NBO Version 3.1, E. D. Glendening, A. E. Reed, J. E. Carpenter, F. Weinhold implemented in Gaussian 94, Revision D.1: M. J. Frisch, G. W. Trucks, H. B. Schlegel, P. M. W. Gill, B. G. Johnson, M. A. Robb, J. R. Cheeseman, T. Keith, G. A. Petersson, J. A. Montgomery, K. Raghavachari, M. A. Al-Laham, V. G. Zakrzewski, J. V. Ortiz, J. B. Foresman, J. Cioslowski, B. B. Stefanov, A. Nanayakkara, M. Challacombe, C. Y. Peng, P. Y. Ayala, W. Chen, M. W. Wong, J. L. Andres, E. S. Replogle, R. Gomperts, R. L. Martin, D. J. Fox, J. S. Binkley, D. J. Defrees, J. Baker, J. P. Stewart, M. Head-Gordon, C. Gonzalez, J. A. Pople, Gaussian, Pittsburgh (PA), **1995**. The gallium atoms were described by LANL2 pseudopotentials. Basis sets of double-zeta quality were used for hydrogen, carbon, and gallium.
[14] P. J. Davidson, D. H. Harris, M. F. Lappert, *J. Chem. Soc. Dalton Trans.* **1976**, 2268; D. E. Goldberg, P. B. Hitchcock, M. F. Lappert, K. M. Thomas, A. J. Thorne, T. Fjeldberg, A. Haaland, *J. Chem. Soc. Dalton Trans.* **1986**, 2387. Double or triple bond models with equivalent "banana bonds" instead of σ and π bonds are obtained by unitary transformations. An analogous relationship exists between the bonding model for gallyne $[Ga_2H_2]^{2-}$ derived here and the model by Lappert of two donor–acceptor bonds (augmented by a further π bond)
[15] Quantum chemical investigations of the bonding within homologues systems of alkenes and alkines, E_2H_4 and E_2H_2, yield analogous results. A survey is given in ref. [3] as well as in K. Kobayashi, S. Nagase, *Organometallics* **1997**, *16*, 2489, and references therein. The latter demonstrates that the introduction of bulky ligands further stabilizes the *trans*-bent form of disilynes (R_2Si_2), which are isolelectronic to Robinson's gallyne.

EVENTS

Announcing the

XXIII International Symposium on Macrocyclic Chemistry

Macrocycles in Academe and Industry

June 7th–12th, 1998
Turtle Bay, Hawai

Imaging, Chelation, Catalysis, Molecular Recognition, Sensing.
Poster Presentations Currently Being Accepted.

Site of symposium is the Turtel Bay Hilton on the North Shore of the Island of Oahu. Activities of interest include golf, surfing, and tennis. An excursion to the Polynesian Center is planned. Organized by Jonathan Sessler, Eric Anslyn, and Eiichi Kimura.

To acquire registration and poster contribution forms please write: Eric V. Anslyn, Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin TX 78712, or e-mail anslyn@ccwf.cc.utexas.edu.

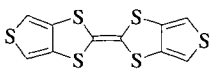
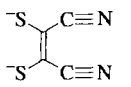
An Organic Spin-Ladder Molecular Material**

Concepció Rovira,* Jaume Veciana, Elisabet Ribera, Judit Tarrés, Enric Canadell, Roger Rousseau, Montserrat Mas, Elies Molins, Manuel Almeida, Rui T. Henriques, Jorge Morgado, Jean-Philippe Schoeffel, and Jean-Paul Pouget

Materials with a ladder type arrangement of the spins ("spin-ladder compounds") have brought a lot of excitement to the quantum magnets community.[1] The initial expectations concerning these materials have been fully confirmed by recent findings of a puzzling dependence of the bulk magnetic properties with the even/odd number of legs in the ladder. Recent results on metal-based compounds (mainly oxides) indicate that while odd-leg ladders are gapless and have magnetic behavior similar to one-dimensional chains, even-leg ladders have only short-range order and a finite spin gap. In addition, holes injected into even-leg ladders are predicted to pair and possibly show superconductivity.[2] Until now only very few two-leg and three-leg ladder compounds formed by connected chains of transition metal atoms have been studied.[2a, 3] Because of their structural flexibility molecular solids offer many possiblities to finely tune interesting physical situations such as those exhibited by spin-ladder materials. Molecular organic solids with this kind of behavior could be obtained by assembling a finite number of molecular chains one next to the other to form "ladder-structures" of increasing width. We have succeeded in preparing and characterizing $[(DT\text{-}TTF)_2][Au(mnt)_2]$ (**1**, DT-TTF = "dithiophentetrathiafulvalene", mnt = maleonitrile dithiolate), one of these wide spin-ladder organic solids.



DT-TTF



mnt

By analogy with the metallic α phases of the $(Per)_2M(mnt)_2$ family (Per = perylene, M = metal), which crystallize in a structure containing pairs of perylene chains surrounded by $M(mnt)_2$ chains,[4] we sought to construct a ladder molecular organic compound by replacing perylene by an appropriate aromatic donor. As electron donor we chose DT-TTF, [5] which tends to stack to form chainlike structures and which contains sulfur atoms on the periphery that are able to promote close contacts between the chains,[6] to provide the rungs of the spin ladder system. As counterion we chose the closed-shell monoanion $[Au(mnt)_2]^-$,[7] which might magnetically isolate the ladder chains.

The target compound $[(DT\text{-}TTF)_2][Au(mnt)_2]$ (**1**) was obtained as dark needles by electrocrystallization from a dichloromethane solution containing the donor and the tetrabutylammonium salt of $[Au(mnt)_2]^-$. The mixed valence character of this salt was confirmed by the presence in the near infrared (NIR) spectrum of the characteristic "A" band of the mixed valence states centered at 2700 nm.[8] Compound **1** crystallizes in the monoclinic system,[9] and the asymmetric unit comprises one molecule of DT-TTF and 0.5 molecule of $[Au(mnt)_2]$. At room temperature the DT-TTF and $[Au(mnt)_2]$ molecules form segregated regular stacks of donors and acceptors along *b* in a herringbone pattern (Figure 1). Inside each stack, donors **D** (DT-TTF) and acceptors **A** ($[Au(mnt)_2]$) slip parallel to the shortest axis of the molecule and have interplanar distances of 3.555(3) and 3.581(4) Å, respectively. The DT-TTF stacks are arranged in pairs related by a twofold screw axis, and they alternate with single stacks of $[Au(mnt)_2]$ along the $a-c$ direction. Apparently the pairs of organic donor stacks form a structural two-leg ladder, since they are strongly linked by three interstack S···S close contacts (Figure 1b). As shown later, the double donor stacks form a two-leg spin ladder below 225 K due

to the localization of unpaired electrons in $(DT\text{-}TTF)_2^{+}$ dimeric units.

The electrical conductivity along the chain axis b is thermally activated and is about 8 $S\,cm^{-1}$ at room temperature. Its temperature dependence (Figure 2) has an inflexion point at about 220 K, denoting that the gap increases significantly below this temperature. The thermopower $S(T)$ is positive (about 40 $\mu v\,K^{-1}$ at 300 K), indicating a hole transport as expected in a partially oxidized (quarter empty) donor band.

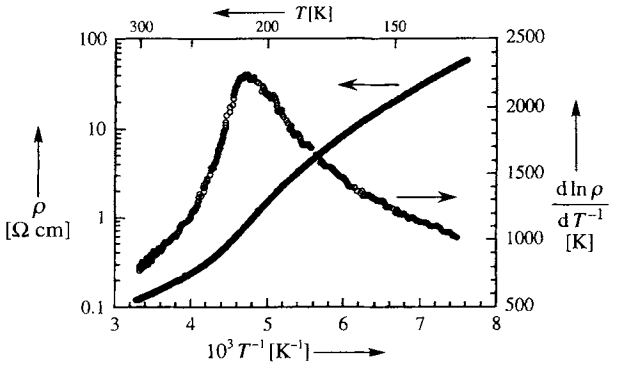

Figure 2. Electrical resistivity ρ of $[(DT\text{-}TTF)_2][Au(mnt)_2]$ as a function of the reciprocal temperature (left) and its first derivative, $d\ln\rho/dT^{-1}$ (right), measured along the needle axis b by the standard four-probe method.

Taken together, the 2:1 stoichiometry, the closed-shell character of $[Au(mnt)_2]^{-}$, and the electrical transport measurements clearly show that below 220 K the unpaired electrons are quite localized in the organic, DT-TTF, interacting double chains. Consequently, depending on the strength of the interactions within and between the double chains, this organic system could well fulfill the requirements for spin-ladder behavior. In order to quantify this point we have calculated the HOMO–HOMO transfer integrals for the different donor $\cdots$ donor interactions of the lattice.[10] There are only three types of DT-TTF interactions (Figure 1): 1) those within the DT-TTF molecular chains (I), 2) those connecting the two molecular chains that form the pair (II), and 3) those between the extremities of the molecules in different paired chains (III). The calculated $t_{HOMO-HOMO}$ transfer integrals are 36 meV for t_I, 21 meV for t_{II}, and 6 meV for t_{III}. Three important implications may be drawn from these values. First, the transfer integral t_{III} between the pairs of chains is quite small relative to those within chains (t_I and t_{II}). Thus, the different pairs of chains of the lattice are probably quite isolated. Second, the transfer integrals up the chain (t_I) and coupling the two paired chains (t_{II}) are nonnegligible. Third, these transfer integrals within chains (t_I and t_{II}), although nonnegligible, are smaller than those of related molecular metals. This agrees with the relatively high but activated conductivity. These three observations suggested a possible spin-ladder behavior for **1** in which the paired chains constitute the ladder. However, before pursuing along this line, we must consider additional structural features that explain more clearly the observed electronic localization.

In order to study this point, X-ray diffuse scattering experiments were performed.[11] X-ray patterns taken at 15 K reveal a weak scattering consisting of single diffuse lines located midway between successive layers of main Bragg reflections perpendicular to the chain direction b. Its reduced wave vector ($0.5b^*$) shows that a dimerization is achieved in the chain direction. These lines are broader than the experimental resolution, which means that the dimerization takes place only on a local scale. At 15 K their half width at half maximum (HWHM) along b is of $\Delta Q = 0.035$ Å^{-1}. The inverse of this quantity, corrected by the (gaussian) resolution, leads to an intrachain correlation length ξ_b of 60(40) Å, if one assumes an intrinsic Lorentzian (gaussian) profile for the diffuse scattering. As shown in Figure 3 (top) these diffuse lines begin to broaden substantially above about 225 K and at 295 K ξ_b amounts to about 20 Å.

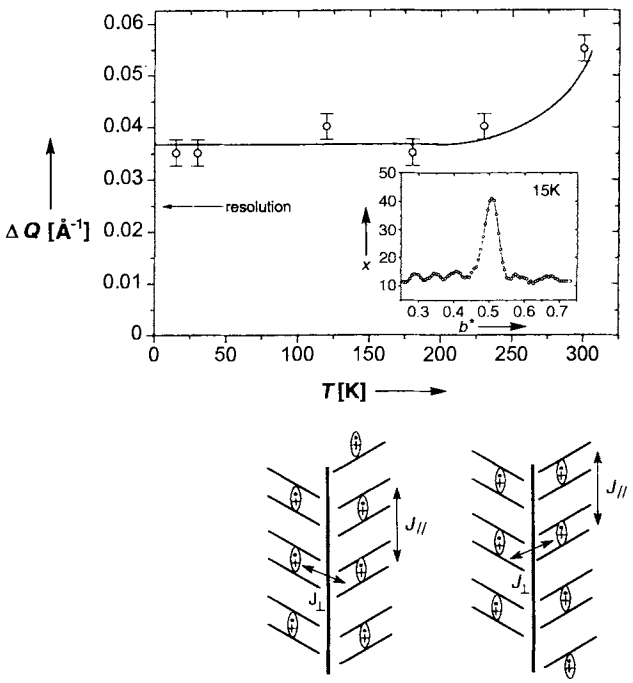

Figure 3. Top: Thermal dependence of the HWHM along the b axis of the $1/2b^*$ diffuse lines of **1**. The inset shows the profile along b^* of such a line (χ is the number of counts in arbitary units). Bottom: Schematic illustration of the two possible two-leg ladders formed by the dimerization of DT-TTF stacks, where $J_{\parallel}$ is the exchange coupling along the chains, and $J_{\perp}$ is the coupling along the rungs.

The weakness of the scattering suggests that the dimerization occurs on the pairs of strongly linked DT-TTF stacks. The observation of diffuse lines means that there is no sizable phase relation between the dimerization of first pairs of adjacent stacks. Their finite width shows that the dimerization locally breaks the twofold screw axis symmetry, which relates the two stacks that form the ladder. As there are two ways to break this symmetry (see Figure 3, bottom), it can be easily understood that their simultaneous realization on a given pair of stacks will limit the intrachain correlation length. From the previous determination of ξ_b, one can estimate an average domain size at low temperature of about $L_b (= \pi\xi_b) = 150$ Å (i.e. $40b$). Therefore, this structural study indicates that at low temperature (15–225 K) this molecular system consists of isolated ladders with a finite number (about 40) of rungs. The decrease of this number above 225 K leads to a better conducting state.

In this picture each dimer has one localized electron (Figure 3, bottom). Since $[Au(mnt)_2]^{-}$ has a closed-shell nature, the magnetic properties of this compound arise only from the spins located in the organic $(DT\text{-}TTF)_2^{+}$ units of the ladders, in agreement with the observed ESR g factor. Thus the ESR g factor of the radical cation $[DT\text{-}TTF]^{\cdot+}$ in solution,[5] is very close to the average g value of the crystals of **1**. As expected, the minimum g value is observed when the magnetic field is applied parallel to the stacking b axis.[12] The relatively large paramagnetism thus associated with these $[(DT\text{-}TTF)_2]^{\cdot+}$ units does not show any significant anomaly around 220 K, where the trans-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3621-2325 $ 17.50+.50/0

port properties displayed anomalies; this fact indicates that, due to electronic correlations, the spin and charge degrees of freedom in the DT-TTF chains are separated. The most important result (Figure 4) is that the static magnetic susceptibility[13] $\chi(T)$

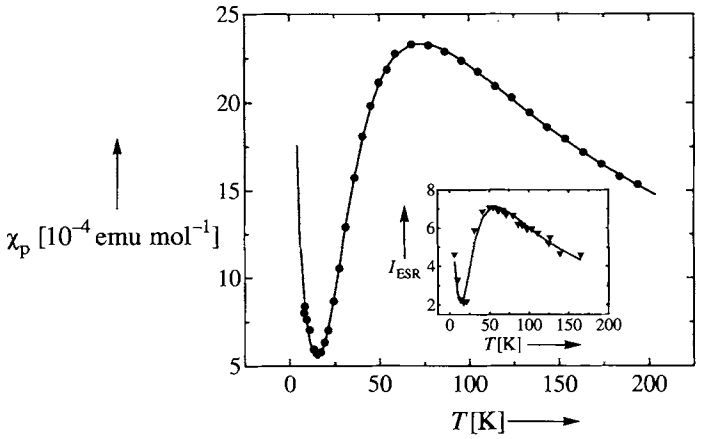

Figure 4. Temperature dependence of the paramagnetic susceptibility. The solid line is the fit to the expression (2) of reference [2c] (see text). Inset shows the temperature dependence of paramagnetic susceptibility measured by ESR on a single crystal.

shows an activated behavior above 70 K together with a Curie–Weiss behavior at higher temperatures. This is characteristic of a system having localized spins with strong antiferromagnetic interactions, which displays a spin gap. In this respect the experimental data from 8 to 45 K can be fitted to the low temperature expression for the susceptibility of a two-leg ladder model found by Troyer et al. [Eq. (1)],[14] where α is a constant corresponding

$$\chi_{ladder} = \alpha T^{-1/2} \exp(-\Delta/kT) \quad (1)$$

to the dispersion of the excitation energy, and Δ is the finite energy gap in the spin-excitation spectrum. For such a fit Equation (2), which takes into account the Curie contribution due

$$\chi = f\chi_{ladder} + (1-f)\chi_{Curie} \quad (2)$$

both to the finite sizes of the ladders and to the magnetic defects present in the crystals, was used. In Equation (2) f is the molar fraction of $[(DT\text{-}TTF)_2]^{\bullet+}$ units forming the regular ladder. The resulting parameters of this fit were $f = 0.98$, $\alpha = 7.22 \times 10^{-4}$ emu $K^{1/2}$ mol^{-1}, and $\Delta/k = 78$ K ($r^2 = 0.9972$). The experimental susceptibility was also fitted with the expression (2) given by Barnes and Riera,[2c] for a two-leg ladder model (solid line in Figure 4), which provides the exchange coupling parameters $J_{\parallel}$ and $J_{\perp}$, of the ladder spin configuration. The resulting parameters of such a fit were $f = 0.980$, $J_{\parallel}/k = -83$ K and $J_{\perp}/k = -142$ K ($r^2 = 0.9989$). The ratio between $J_{\parallel}$ and $J_{\perp}$ is in good agreement with the ratio between the transfer integrals evaluated from the t_I and t_{II} values once the dimeric nature of the elementary building block of the ladder is taken into account. The spin gap has also been calculated from the resulting values of $J_{\parallel}$ and $J_{\perp}$ by using the expression $\Delta = |J_{\perp}| - |J_{\parallel}| + J_{\parallel}^2/2J_{\perp}$,[14] to give $\Delta/k = 83$ K, in good agreement with the previous value. The intensity of the ESR signal, which is proportional to the paramagnetic spin susceptibility, also exhibits the same thermal dependence as the static spin susceptibility (inset of Figure 4), confirming that the spin-ladder behavior occurs on the organic $[(DT\text{-}TTF)_2]^{\bullet+}$ stacks.

The results presented here characterize $[(DT\text{-}TTF)_2][Au(mnt)_2]$ as the first example of a purely organic system with a ladder spin configuration that shows this magnetic behavior below 225 K. This result opens new possibilities to apply supramolecular chemistry for tailoring ladder architectures with different structural characteristics and promising magnetic properties.

[9] Crystallographic data for $C_{28}H_{16}N_4S_{16}Au$: crystal dimensions $0.37 \times 0.23 \times 0.065$ mm; $M_r = 1110.31$, monoclinic, space group $P2_1/n$, $a = 16.334(1)$, $b = 3.912(1)$, $c = 27.348(2)$ Å, $\beta = 101.787(6)°$; $Z = 2$; $V = 1710.7(2)$ Å^3, $\rho_{calcd} = 2.16$ g cm^{-3}. Data were collected at 293 K on an Enraf-Nonius CAD4 diffractometer equipped with a Mo X-ray tube, and a graphite monochromator selected $Mo_{K\alpha}$ radiation (absorption coefficient $\mu = 5.31$ mm^{-1}. Data collection up to $2\theta = 62°$ and $-23 \le h \le 23$, $0 \le k \le 5$, $-39 \le l \le 0$ affords 7898 reflections measured with $\omega - 2\theta$ scans. Lorentz, polarization, and absorption (DIFABS: max/min absoption factors 1.254/0.793) effects were corrected. The structure was refined using full-matrix least-squares methods (SHELXL-93). The minimized function was $\omega(F_o^2 - F_c^2)^2$ with $\omega = 1/\sigma^2F^2 + (AP)^2 + BP$ and $A = 0.0419$, $B = 0.57$, $P = [\mathrm{Max}(0 \cdot F_o) + 2F_c]/3$ and s, the standard deviation estimated from counting statistics. At convergence the final R indices were $R_1 = 0.068$, $wR_2 = 0.078$ (for all data) and $R_1 = 0.027$, $wR_2 = 0.066$ (for $I > 2\sigma(I)$ reflections). The final max/min residuals were $1.11/-0.91$ e Å^{-3}. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100375. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

[10] As in previous studies of related materials (L. F. Veiros, M. J. Calhorda, E. Canadell, *Inorg. Chem.* **1994**, *33*, 4290–4294), the calculations use an extended Hückel type hamiltonian (R. Hoffmann, *J. Chem. Phys.* **1963**, *39*, 1397-1412) and a modified Wolfsberg–Helmholz formula (J. H. Ammeter, H.-B. Bürgi, J. Thibeault, R. Hoffmann, *J. Am. Chem. Soc.* **1978**, *100*, 3686–3692) to calculate the nondiagonal H_{ij} matrix elements and a single-ζ atomic orbital basis set.

[11] The experiment was performed with the so-called "fixed film-fixed crystal" method with a monochromatized $Cu_{K\alpha}$ ($\lambda = 1.542$ Å) beam.

[12] The ESR spectra consists in a single Lorentzian line in all the orientations of the crystal with respect to the external magnetic field. The room temperature line-widths measured in the three orthogonal orientations of the crystal are $\Delta H_{pp} = 42$, 25, and 26 G, with g factors of 2.0127, 2.0050, and 2.0020, respectively.

[13] Magnetic susceptibility was measured by the Faraday method in the range 4–300 K in a polycrystalline sample with an applied magnetic field of 1 T. A correction for the diamagnetic contribution estimated as 4.6×10^{-4} emu mol^{-1} from tabulated Pascal constants was applied.

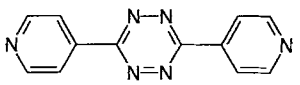
Anion Control in Bipyridylsilver(I) Networks: A Helical Polymeric Array**

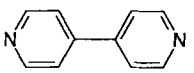
Matthew A. Withersby, Alexander J. Blake, Neil R. Champness, Peter Hubberstey,* Wan-Sheung Li, and Martin Schröder*

The construction of inorganic supramolecular arrays based on covalent interactions[1] or hydrogen bonding[2] is a rapidly developing area of research that has implications for the rational design of functional materials. A variety of architectures have been reported including adamantoid,[3-5] octahedral,[6] ladder,[7] honeycomb,[8] and "brick wall".[9] We have been investigating the effect of ligand functionality in the construction of arrays based on Cu^I and Ag^I,[4] and report here what we believe to be a unique helical structural motif in inorganic supramolecular architectures. Furthermore, the structure of $[Ag(pytz)(X)]_\infty$[10] is both anion-controlled for $X = NO_3^-$—the structure contrasts markedly with that of the corresponding $X = PF_6^-$ and BF_4^- analogues—and dependent upon ligand functionality. This gives a completely different structural motif from that of the corresponding 4,4′-bipyridyl complex, $[Ag(4,4'\text{-bpy})(NO_3)]_\infty$.[11]



3,6-di(4-pyridyl)-1,2,4,5-tetrazine

pytz



4,4′-bipyridine

4,4′-bpy

$[Ag(pytz)(NO_3)]_\infty$ was prepared as scarlet-red hexagonal crystals by layering a solution of $AgNO_3$ in MeCN over a solution of pytz in CH_2Cl_2. The crystals grew over a period of two days, and could be prepared from the reaction of either one or two equivalents of ligand per equivalent of $AgNO_3$. The single-crystal X-ray structure of the product[12] shows that each Ag^I ion is coordinated to two pytz ligands in a linear arrangement (Ag–N11 2.154(3), Ag–N21 2.151(3) Å, N11-Ag-N21 180°) to give linear chains of alternating Ag^I ions, separated by 15.34 Å, and pytz ligands. As in $[Ag(4,4'\text{-bpy})(NO_3)]_\infty$, the chains align in a parallel fashion to form two-dimensional sheets. In the 4,4′-bpy complex alternate sheets, which are linked by Ag···Ag interactions, are oriented at 90° with respect to each other. In the pytz complex, however, the sheets stack along a 6_1 screw axis to give a helical staircase motif. In fact, each Ag^I center interacts weakly with two NO_3^- ions (d(Ag–O31) = d(Ag–O32) = 2.787(2) Å),[16] which adopt positions perpendicular to the pytz-Ag-pytz axis, to give a pseudo square planar geometry at the Ag^I center (Figure 1). The NO_3^- ions bridge adjacent chains through two of their oxygen atoms; each chain is related to the next by a 60° rotation and by a step of 5.18 Å to generate the helical staircase motif (Figure 2). Thus, despite their weakness, the resultant 3D structure is controlled by $Ag^I \cdots NO_3^-$ interactions. The points at which the chains cross—one may consider these as the center of the helix—correspond to overlapping pyridine units (Figures 2 and 3). We believe this helical motif to be unique in inorganic supramolecular architectures, and, significantly, it contrasts markedly with the structure observed for $[Ag(4,4'\text{-bpy})(NO_3)]_\infty$,[11] which consists of linear Ag^I–bpy chains linked in a T-shape through Ag···Ag interactions (Ag–Ag 2.970(2) Å). This confirms the importance of ligand functionality in determining the structure of these types of inorganic supramolecular arrays.

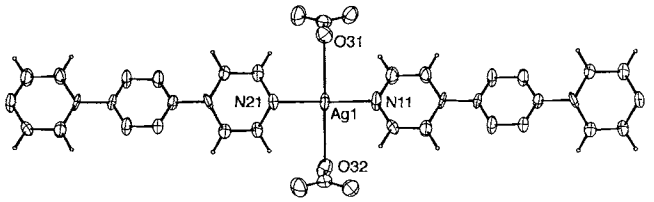


Figure 1. View of the pseudo square planar environment at the Ag centers in $[Ag(pytz)(NO_3)]_\infty$.

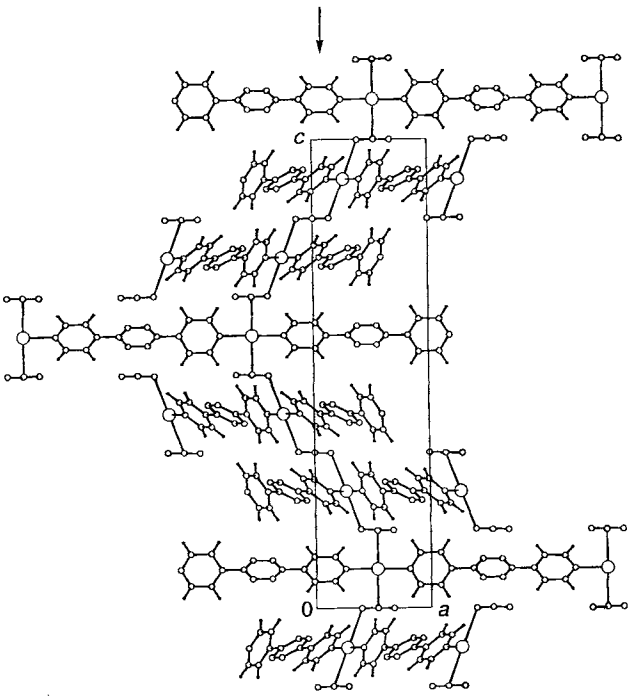

Figure 2. View of the helical structure of $[Ag(pytz)(NO_3)]_\infty$ from the side, which illustrates the pivotal role of the NO_3^- ions. The 6_1 screw axis is marked with an arrow.

The degree of anion control observed in the structure of $[Ag(pytz)(NO_3)]_\infty$ is illustrated by the structure of the isomorphous PF_6^- and BF_4^- complexes, $[Ag(pytz)(PF_6)(MeCN)]_\infty$ and $[Ag(pytz)(BF_4)(MeCN)]_\infty$. Both were prepared analogously to the NO_3^- complex, and deep-red crystals were obtained over similar time periods. The single-crystal X-ray structure of these complexes[17,18] revealed a completely different and comparatively simple structure based on linear chains of alternating Ag^I ions and pytz ligands which align themselves along the [101] direction. However, the 3D structure is different to that of the 4,4′-bpy analogue in that the chains formed pairs which were joined through Ag···Ag interactions (3.230(1) Å (PF_6^- compound) and 3.312(1) Å (BF_4^- compound)) and $\pi-\pi$ interactions between adjacent pytz ligands (Figure 4). In addition, each Ag^I ion in these structures interacts with a MeCN solvent mole-

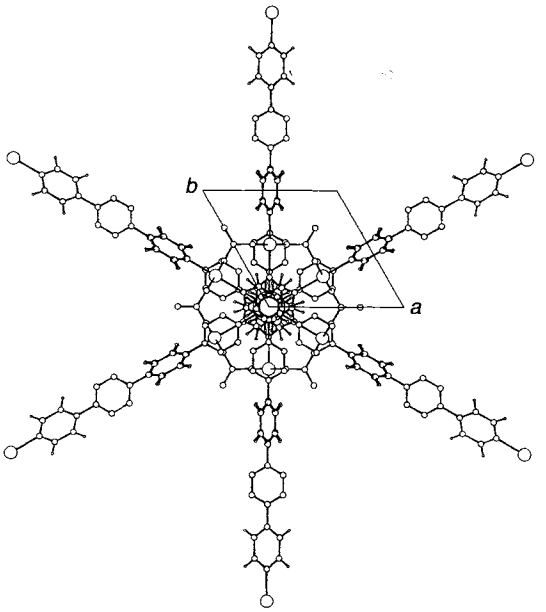

Figure 3. View of $[Ag(pytz)(NO_3)]_\infty$ along the helical axis that illustrates the hexagonal arrangement of the polymeric chains.

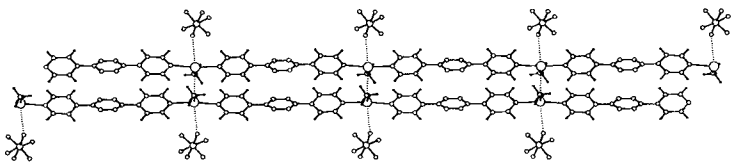

Figure 4. View of the linear chain pairs formed by $[Ag(pytz)(X)(MeCN)]_\infty$ ($X = PF_6^-$, BF_4^-).

cule (Ag–N 2.648(4) Å (PF_6^- compound) and 2.637(2) Å (BF_4^- compound)). However, these pairs of Ag–bpy chains are all parallel to each other, in contrast to the those in NO_3^- complex, and there are no significant interactions between adjacent pairs of chains, most significantly not even through the anion.

These results not only represent the first example of a helical staircase structural motif but also a remarkable case of anion control of supramolecular architecture construction. We are currently investigating whether this control can be transferred to other metal–ligand arrays and indeed to other anions.[20]

Experimental Section

$[Ag(pytz)(NO_3)]_\infty$: A solution of $AgNO_3$ (0.0365 g, 0.2 mmol) in MeCN (3 mL) was layered onto a solution of pytz (0.0505 g , 0.214 mmol) in CH_2Cl_2 (10 mL). The solutions were left for two days at room temperature, and red hexagonal crystals were obtained. Elemental analysis calcd for $C_{12}H_8AgN_7O_3$: C 35.49, H 1.99, N 24.14; found: C 35.42, H 1.81, N 23.98; IR (KBr): $\tilde{\nu}$ = 3048 (w), 2952 (w), 2905 (w), 1616 (m), 1589 (m), 1558 (m), 1411 (m), 1384 (s), 1262 (m), 1111 (m), 1055 (m), 917 (m), 833 (m), 716 (m), 599 (s) cm^{-1}.

$[Ag(pytz)(PF_6)(MeCN)]_\infty$ was prepared analogously to $[Ag(pytz)(NO_3)]_\infty$ but with $AgPF_6$ (0.0522 g, 0.207 mmol) in place of $AgNO_3$. Elemental analysis calcd for $C_{14}H_{11}AgF_6N_7P$: C 31.72, H 2.09, N 18.50; found: C 32.21, H 2.00, N 18.81; IR (KBr): $\tilde{\nu}$ = 3086 (w), 3003 (w), 2952 (w), 1616 (m), 1590 (m), 1560 (m), 1411 (m), 1391 (s), 1262 (m), 1112 (m), 1056 (m), 917 (m), 833 (s), 717 (m), 599 (s), 560 (m) cm^{-1}.

$[Ag(pytz)(BF_4)(MeCN)]_\infty$ was prepared analogously to $[Ag(pytz)(NO_3)]_\infty$ but with $AgBF_4$ (0.0406 g, 0.209 mmol) in place of $AgNO_3$. Elemental analysis calcd for $C_{14}H_{11}AgBF_4N_7$: C 35.63, H 2.35, N 20.77; found: C 35.52, H 2.18, N 20.67; IR (KBr): $\tilde{\nu}$ = 3090 (w), 3009 (w), 2953 (w), 1611 (m), 1589 (m), 1559 (m), 1411 (m), 1391 (s), 1263 (w), 1221 (w), 1055 (s), 919 (m), 834 (m), 717 (m), 599 (s) cm^{-1}.

[16] The Ag–O distances of 2.787(2)Å are typical for such interactions between Ag^I centers and NO_3^- ions [11].

[17] X-ray crystal structure analysis of $[Ag(pytz)(PF_6)(MeCN)]_\infty$: $C_{14}H_{11}AgF_6N_7P$, red plates, crystal dimensions $0.62 \times 0.54 \times 0.27$ mm^3, monoclinic, space group $P2_1/n$ (no. 14), $a = 9.242(3)$, $b = 13.695(2)$, $c = 14.010(2)$ Å, $\beta = 99.68(3)°$, $V = 1747.9(8)$ Å^3, $Z = 4$, $F(000) = 1040$, $\rho_{calcd} = 2.014$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 1.31$ mm^{-1}, $T = 220.0(2)$ K. Data were collected on a Stoe Stadi-4 four-circle diffractometer with graphite-monochromated $Mo_{K\alpha}$ radiation in the $\omega-\theta$ scan mode with a scan width of $(4.0+0.347\tan\theta)°$ ($5.7 \le 2\theta \le 50.1°$, $-10 \le h \le +11$, $0 \le k \le +16$, $-5 \le l \le +16$). A ψ-scan absorption correction was applied to the data (T_{min} 0.521, T_{max} 0.628); 2914 unique reflections ($R_{int} = 0.0567$), of which 2385 had $I \ge 2\sigma(I)$, were used in all calculations. The structure was solved by direct methods [13] and refined using full-matrix least squares on F^2 [14]. All non-hydrogen atoms were refined anisotropically, and hydrogen atoms were treated with a riding model (d(C–H) = 1.00 Å, U_{iso} = 0.03 Å^2), except those on methyl groups (d(C–H) = 1.00 Å, U_{iso} = 0.06 Å^2). A three-term Chebychev weighting scheme was adopted [15]. Final R values: $R = 0.0738$, wR_2 (all data) = 0.0414 [19].

[18] X-ray crystal structure analysis of $[Ag(pytz)(BF_4)(MeCN)]_\infty$: $C_{14}H_{11}AgBF_4N_7$, red plates, crystal dimensions $0.55 \times 0.33 \times 0.16$ mm^3, monoclinic, space group $P2_1/n$ (no. 14), $a = 8.754(3)$, $b = 13.565(3)$, $c = 14.049(5)$ Å, $\beta = 98.46(3)°$, $V = 1650.1(7)$ Å^3, $Z = 4$, $F(000) = 928$, $\rho_{calcd} = 1.813$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 1.254$ mm^{-1}, $T = 220.0(2)$ K. Data were collected on a Stoe Stadi-4 four circle diffractometer with graphite-monochromated $Mo_{K\alpha}$ radiation in the $\omega-\theta$ scan mode with scan width of $(1.50+0.347\tan\theta)°$ ($5.2 \le 2\theta \le 50.0°$, $-10 \le h \le +10$, $-16 \le k \le +16$, $-16 \le l \le +16$). A numerical absorption correction was applied to the data (T_{min} 0.653, T_{max} 0.799); 5494 unique reflections ($R_{int} = 0.1252$), of which 4394 had $I \ge 2\sigma(I)$, were used in all calculations. The structure was solved by direct methods [13] and refined using full-matrix least squares on F^2 [14]. The structure was disordered along the direction of the Ag-pytz-Ag chains, and all atoms with the exception of the BF_4^- anion and the MeCN molecule were affected. The relative occupancies were 0.8 and 0.2; the geometry of the lower-occupancy ligand was restrained to the average geometry of the higheroccupancy ligand. All higher occupancy

atoms were refined anisotropically, and all lower-occupancy atoms isotropically. No hydrogen atoms were modelled on atoms of the lower occupancy ligand. Hydrogen atoms were treated with a riding model (d(C–H) = 1.00 Å, U_{iso} = 0.03 Å^2). A two-term Chebychev weighting scheme was adopted [15]. Final R values: R = 0.1065, wR_2(all data) = 0.1095 [19].

[19] Further details of the crystal structure investigations can be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, Germany upon quoting the deposit numbers CSD-407272 ([Ag(pytz)$(NO_3)]_x$), CSD-407273 ([Ag(pytz)(BF_4)(MeCN)]$_x$), and CSD-407274 ([Ag(pytz)-(PF_6)(MeCN)]$_x$).

Electronic Structure of Manganese(III) Compounds from High-Frequency EPR Spectra

Anne-Laure Barra, Dante Gatteschi,* Roberta Sessoli, Gian Luca Abbati, Andrea Cornia, Antonio C. Fabretti, and Myriam G. Uytterhoeven

EPR spectra of transition metal ions with an even number of unpaired electrons are very difficult to obtain, principally because the ground state spin multiplet is largely split in a zero magnetic field by the low symmetry components of the crystal field. When the zero field splitting is much larger than the microwave quantum used in the spectrometer, transitions can be observed only at extremely high fields, much larger than usually available. This is a very unfortunate situation, because EPR spectroscopy can, in principle, provide a great deal of information on the geometrical and electronic structure of the transition metal ion. This situation is changing rapidly following the introduction of high-frequency–high-field EPR spectrometers (HF-EPR),[1] which allow the detection of spectra of integer spin multiplets with very large zero field splittings.

Manganese(III) is certainly one of the unfavorable metal ions for EPR studies. In an octahedral ligand environment, its four unpaired electrons result in a ^5E_g ground state, which is unstable to Jahn–Teller distortions. The inherent low symmetry of the complexes gives rise to large zero field splitting and to date the reports of EPR spectra of manganese(III) are exceedingly rare[2] and most of them refer to forbidden transitions within the non-Kramers doublets.[3] Far-IR techniques have been used to characterize manganese(III)-doped rutile[4] and some porphyrins;[5] however, no HF-EPR spectrum of simple complexes has to our knowledge been reported so far. Given the large interest in the electronic structure of manganese(III), which is relevant to such diverse topics as photosystem II,[6] colossal magneto-resistance,[7] and single-molecule magnets,[8] we decided to investigate simple manganese(III) complexes by using the high-field EPR spectrometer at Grenoble, which can reach 500 GHz and 30 T. We report here the HF-EPR spectra of [Mn(dbm)$_3$] (Hdbm = 1,3-diphenyl-1,3-propanedione) to illustrate how EPR spectra can be easily detected and reproduced with ligand field models. This work opens exciting perspectives for the investigation of manganese(III) compounds.

A low-quality X-ray crystal structure analysis of [Mn(dbm)$_3$] was previously reported.[9] As the coordination geometry of the manganese ion needs to be determined precisely for a detailed analysis of the HF-EPR results, we collected a new data set[10] and refined the structure. The coordination polyhedron is tetragonally elongated as a result of Jahn–Teller distortion and thus shows significant deviation from idealized D_{4h} symmetry.[11]

Powder EPR spectra of polycrystalline [Mn(dbm)$_3$] were recorded at 245.0 and 349.3 G Hz in the range between 4.2 and 30 K on a laboratory-made spectrometer by using a far-IR laser as radiation source.[12] The spectra recorded at 349.3 GHz at 15 K are shown in Figure 1. The relative intensities changed markedly on varying the temperature because the Zeeman energy is similar to the thermal energy. This allows the determination of the sign of the zero field splitting. At least eleven features are observed in the range 0–12 T; the strongest absorption bands appear at low field. The corresponding spectra recorded at 245.0 GHz (Figure 2) show fewer features (only nine are clearly observed), and also the pattern of intensities of the transitions changes dramatically. The spectra of [Mn(dbm)$_3$] clearly indicate that the amount of energy required for the zero field splitting is similar in size to the radiation used in the experiments (8.17 and 11.65 cm^{-1}, respectively). Therefore, it is very difficult to perform even a qualitative assignment of the transitions, because in this case many "forbidden" transitions may be present. The fit of the spectra was performed with a program written by H. Weihe et al.,[13] which diagonalizes the full Hamiltonian matrix within the basis of five $S = 2$ spin functions [Eq. (a)].

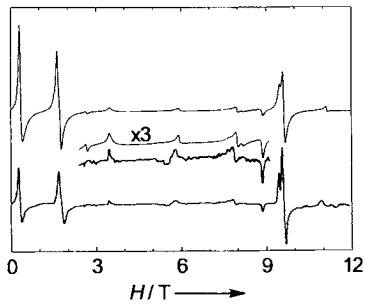

Figure 1. Experimental (bold) and simulated powder HF-EPR spectrum of polycrystalline [Mn(dbm)$_3$] at 349.3 GHz and 15 K. The free electron resonates at about 12.46 T.

$$H = \boldsymbol{B}\cdot\boldsymbol{g}\cdot\boldsymbol{S} + \boldsymbol{S}\cdot\boldsymbol{D}\cdot\boldsymbol{S} \quad \text{(a)}$$

The calculated transitions are very sensitive to the zero field splitting parameters D and E, which are therefore accurately determined, both in terms of their size and sign; however, these transitions are much less sensitive to the g values, which therefore are determined with less accuracy. To avoid over-parameterization we assumed $g_x = g_y$. The best fit calculated spectra are shown in Figures 1 and 2. The agreement is very good both in terms of the position and the intensity of the bands. The best fit parameters are: $g_x = g_y = 1.99$; $g_z = 1.97$; $D = -4.35$ cm^{-1}, $E = 0.26$ cm^{-1}. Attempts were also made at including fourth-order crystal field terms that are symmetry-allowed,[14] but no significant improvement on the fit was found, therefore we neglect these terms here.

The assignment of the features to the transitions can be performed by using pseudo-rotation plots and the high-field labeling of the energy levels. The resonance fields of the transitions are calculated in the three principal planes of the $\boldsymbol{g}$ tensor, which is assumed to be parallel to the $\boldsymbol{D}$ tensor. The intense feature observed at the lowest fields in Figure 1 is associated with the z component of the forbidden $M = +2 \rightarrow M = -1$ transition, which is partially allowed by the mixing of the $M = +1$ and $M = -1$ states, while the feature at about 1.8 T is attributed to the y component of the $1 \rightarrow 0$ transition and the z component of the $2 \rightarrow 1$ transition. The other intense and structured feature at about 9.8 T corresponds to the x and y components of the $0 \rightarrow 1$ transition. In Figure 2 the strongest absorptions at 6.1 T and 6.8 T are attributed to y and x components, respectively, of the allowed $0 \rightarrow 1$ transition.

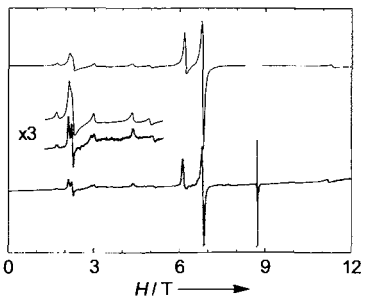

Figure 2. Experimental (bold) and simulated powder HF-EPR spectrum of polycrystalline [Mn(dbm)$_3$] at 245.0 GHz and 15 K. The narrow line at about 8.75 T is attributed to the standard (α,α-diphenyl-β-picrylhydrazyl, dpph).

At the simplest level the parameters for an elongated octahedral complex with rhombic distortion are related to the electronic structure [15] according to Equation (b), in which g_e is the free

$$g_z = g_e - \frac{8\lambda}{\Delta E(xy \rightarrow x^2 - y^2)};\quad g_x = g_e - \frac{2\lambda}{\Delta E(yz \rightarrow x^2 - y^2)};\quad g_y = g_e - \frac{2\lambda}{\Delta E(xz \rightarrow x^2 - y^2)}; \qquad \text{(b)}$$

electron value, and the energy differences ΔE refer to the indicated d orbitals; $\lambda = \zeta/2S$, where ζ, the spin-orbit coupling constant, is about 90 cm^{-1} for the free manganese(III) ion.

The zero field splitting parameters can be evaluated by general relations [Eq. (c)], which are expected to be valid if only the states belonging to the same Russell–Saunders manifold $^{2S+1}$L are included.

$$D = 1/2\,\lambda[g_z - 1/2\,(g_x + g_y)];\ E = 1/4\,\lambda[g_x - g_y] \qquad \text{(c)}$$

The ΔE energy differences of the transitions can be obtained from the electronic spectra. Spectra recorded in toluene solution showed a maximum at 9000 cm^{-1} and shoulders at about 18000 and 21000 cm^{-1}. In analogy to [Mn(acac)$_3$][16] (Hacac = 2,4-pentanedione) we assign the lowest energy band to $^5A_1 \leftarrow {}^5B_1$, that is the transition between the two split levels of the ^5E_g ground state in octahedral symmetry. The other two bands correspond to $^5B_2 \leftarrow {}^5B_1$ and $^5E \leftarrow {}^5B_1$. We assume that the ground state of [Mn(dbm)$_3$] is $^5B_1$ in agreement with the elongated octahedral geometry experimentally observed; thus, $\Delta E(xy \rightarrow x^2 - y^2) = 18000$ cm^{-1} and $\Delta E(xz,yz \rightarrow x^2 - y^2) = 21000$ cm^{-1}. Using these values and the free ion spin orbit coupling constant we calculate $g_{\parallel} = 1.96$ and $g_{\perp} = 1.99$, which are in fair agreement with the experimental data. Using Equation (c) we obtain the zero field splitting parameter $D = -1.4$ cm^{-1}. The agreement is good for the sign, but not acceptable for the value. A similar discrepancy was previously observed for the spectra of manganese(III)-doped rutile.[4] The disagreement between experiment and calculation was attributed to the neglect of the $^3T_{2g}$ excited state, formed by placing the four electrons in the t_{2g} orbitals, which at the simplest level of approximation contributes to the zero field splitting parameter with an additive term [Eq. (d)]. B and C are electron repulsion terms, which in

$$D' = -\frac{\zeta^2}{6B + 5C + \Delta E(xz,\ yz \rightarrow z^2)} \qquad \text{(d)}$$

the free ion take the values $B = 1140$ cm^{-1} and $C = 3675$ cm^{-1}. Using Equations (c) and (d), the calculated zero field splitting parameter becomes $D = -4.9$ cm^{-1}, which is in good agreement with the experiment.

We calculated the parameters of the spin Hamiltonian operator also in a more general way by developing a suitable computer program that uses the angular overlap model (AOM) for the ligand field.[17] The energies of the states appropriate to the d^4 configuration are calculated within the weak field formalism by a full matrix diagonalization. The computed electronic energies and eigenfunctions are therefore correct to all orders in perturbation theory. Details of the computer program and its applications to selected systems will be published elsewhere. The parameters of the spin Hamiltonian operator obtained in this way can be considered as the best improvement to the perturbative approach [Eqs. (a)–(c)].

The fitting strategy was that of finding the AOM parameters from the electronic spectra and then calculating the parameters of the spin Hamiltonian operator. The structure of [Mn(dbm)$_3$] is essentially orthoaxial; the O-Mn-O angles are close to 90° or 180°. Therefore we assumed that the differences in bond lengths are primarily responsible for the electronic structure of the complex. In an orthoaxial complex the energies of the d levels can be described as reported in reference [18]. By using these values the energies of the electronic transitions can be expressed by Equations (e)–(g).

$$E(^5A_1 \leftarrow {}^5B_1) = \nu_1 = e_\sigma^x + e_\sigma^y - 2e_\sigma^z \qquad \text{(e)}$$

$$E(^5B_2 \leftarrow {}^5B_1) = \nu_2 = 3/2\ e_\sigma^x + 3/2\ e_\sigma^y - 2\ e_\pi^x - 2\ e_\pi^y \qquad \text{(f)}$$

$$E(^5E \leftarrow {}^5B_1) = \nu_3 = 3/2\ e_\sigma^x + 3/2\ e_\sigma^y - 2\ e_\pi^x - 2\ e_\pi^z \qquad \text{(g)}$$

Since we have no evidence of symmetry lower than axial from the electronic spectra we first set $e_{\sigma,\pi}^x = e_{\sigma,\pi}^y$. With this approach the three electronic transitions can be fitted with four parameters. By using the appropriate values for the observed transitions, and fixing for instance e_π^z to 1000 cm^{-1}, the other parameters are calculated as $e_\sigma^z = 4833$ cm^{-1}, $e_\sigma^x = 9333$ cm^{-1}, and $e_\pi^x = 2500$ cm^{-1}. Translating the AOM parameters into the usual crystal field parameter Dq, by applying the relation Dq = 3/10 e_σ − 4/10 e_π the calculated Dq value for the axial ligands is 1050 cm^{-1} and for the equatorial ligands 1800 cm^{-1}.

These values were used to calculate the parameters of the spin Hamiltonian operator by using the procedure described above. First the parameters were calculated by neglecting the contribution from the excited Russell–Saunders multiplets with $S < 2$. The calculated D value of -1.35 cm^{-1} corresponds nicely to that obtained with the perturbative formulas in Equations (b) and (c). The same calculations were repeated with the inclusion of all the excited Russell–Saunders terms, and the results are

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3621-2330 $ 17.50+.50/0

$g_x = g_y = 1.99$, $g_z = 1.96$, and $D = -4.57\ cm^{-1}$. In this case the agreement between observed and calculated zero field splitting can be considered as very satisfactory. Interestingly, non-zero fourth-order parameters of the order of $10^{-4}\ cm^{-1}$ are calculated. This can have a large significance for the interpretation of the magnetic properties of clusters that show quantum tunneling of the magnetization at low temperature.[19]

Improvements to the fit can be achieved by taking into consideration the difference in the ligand field parameters of the equatorial ligands. The average Mn–O distance on the x axis is 1.913 Å, and that for the ligands on the y axis is 1.933 Å; thus some anisotropy may be anticipated. If we assume that the calculated difference in the Dq values for the axial and equatorial ligands is due to an exponential decrease of the parameter with the metal–ligand distance, the Dq parameters for the ligands on the x and y axes can be calculated as 1850 and $1750\ cm^{-1}$, respectively. By setting $e_\sigma^x = 9595\ cm^{-1}$, $e_\pi^x = 2570\ cm^{-1}$, $e_\sigma^y = 9080\ cm^{-1}$, $e_\pi^y = 2430\ cm^{-1}$, and leaving the parameters of the axial ligand at the previously determined value, we calculate $g_x = 1.99$, $g_y = 1.99$, $g_z = 1.96$, $D = -4.55\ cm^{-1}$, and $E = 0.28\ cm^{-1}$, in good agreement with the experimental data.

$[Mn(dbm)_3]$ is the first molecular manganese(III) complex for which a detailed analysis of the EPR parameters could be performed. The results given here show that HF-EPR can easily provide the g factors and the zero field splitting of manganese(I–II) complexes. The success of the ligand field analysis confirms that structural information can be readily obtained from the spectra. Furthermore, we have shown how reasonable estimates of the $\boldsymbol{g}$ and $\boldsymbol{D}$ tensors in pseudo-octahedral manganese(III) complexes can be made simply by recording the electronic spectra in solution. We have not observed hyperfine splittings in our sample, but, given the success in the interpretation of the other tensors it is reasonable to assume that the ligand field analysis is applicable also for the **A** tensor. This is of great significance for the current efforts in the understanding of the structure of photosystem II.

Experimental Section

$[Mn(dbm)_3]$ was obtained by an alternative procedure to those already reported for the synthesis of manganese(III) tris(β-diketonate) complexes [20]. A solution of Hdbm (4.4 mmol) and triethylamine (12 mmol) in anhydrous, oxygen-free CH_3CN (40 mL) was prepared under dinitrogen. Solid $MnBr_2 \cdot 4H_2O$ (2 mmol) was then added, and the solution was stirred for 1.5 h under dinitrogen. The yellow precipitate was collected by filtration and suspended in CH_3CN with stirring. Upon contact with air, the precipitate progressively dissolved and the mixture turned brown; black lustrous crystals of $[Mn(dbm)_3]$ formed quickly. The purity of the samples was checked by microanalysis: Calcd. for $MnC_{45}H_{33}O_6$ (%): C 74.58, H 4.59; found: C 74.84, H 4.57.

Controlling Microstructure in Polymeric Molecular Shuttles: Solvent-Induced Localization of Macrocycles in Poly(urethane/crown ether) Rotaxanes**

Caiguo Gong and Harry W. Gibson*

Polyrotaxanes, which are formed by threading macrocycles onto polymeric backbones or side chains, have been studied extensively in the last decades.[1–6] Cyclodextrins[2–4] and crown ethers[5, 6] are often used as the cyclic components. In poly(ester rotaxane)s, crown ether can freely translate along the backbone and aggregate into a separate phase, because no significant interaction between the ester linkages and the cycles exists.[5c, 5d] However, the crown ether is influenced by blocking groups (BG) bearing tetraphenylmethyl moieties in the chain.[6] While small molecular shuttles have been widely studied,[1b, 1c] oligomeric[7] and polymeric[8, 9] counterparts based on paraquat charge transfer systems, in which the cycles shuttle between solvent and backbone, have only recently been addressed. We now report the preparation of novel polymeric molecular shuttles with polyurethanes containing BG units as backbones and [30]crown-10 (30C10) as the cyclic unit; the latter only move on the chain. Furthermore, we demonstrate for the first time the ability to control the locus of the macrocycles in these polyrotaxanes with solvent effects.

Copoly(urethane/30C10 rotaxane)s **4a–c** and homopoly(urethane/30C10 rotaxane) **4d** were prepared from diol BG **1**,

[a] Polymerization at 95 °C for 7 h.

While free 30C10 has a chemical shift of $\delta = 3.67$ in $CDCl_3$,[6a] threaded 30C10 in **4a–d** only displays one signal at $\delta = 3.51$ (Figure 1). However, for copoly(ester rotaxane)s made from **1**, 1,10-decanediol, and sebacoyl chloride, threaded 30C10 showed a range of chemical shifts.[6b] What causes the difference in the ^{1}H NMR spectra of these two polyrotaxanes? In the polyesters, threaded 30C10 is shielded by the phenyl groups of the BG units and shifted upfield. It displays different time-averaged chemical shifts corresponding to the various sequence structures in which it is constrained; in the sequences with longer distances between the BG units, the crown ether is less shielded.[6b] Nuclear Overhauser effect spectroscopy (NOESY) revealed the correlation between 30C10 and the phenyl groups of the BG moieties,[6] and it is believed that 30C10 tends to stay close to these phenyl groups. With polyurethane as the backbone, hydrogen bonding between the in-chain NH groups and the crown ethers takes place,[10] and, therefore, 30C10 is localized at the NH groups. Such hydrogen bonding induces the well-defined polymeric microstructure **5** (Scheme 2), in which

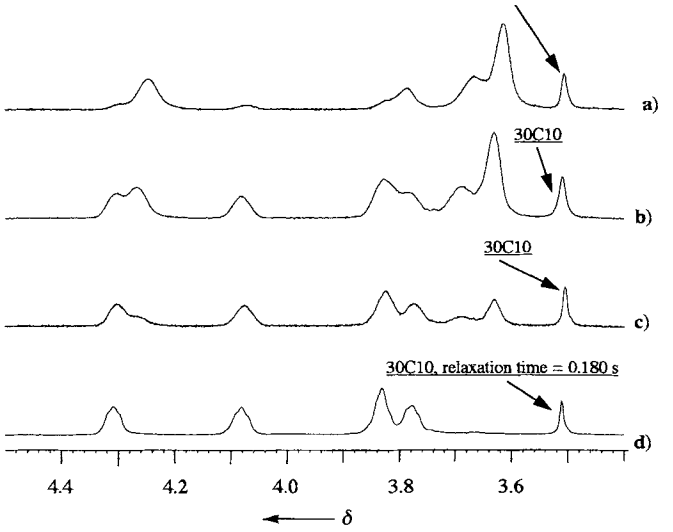

Figure 1. Section from the aliphatic region in the 400-MHz ^{1}H NMR spectra of a) **4a**, b) **4b**, c) **4c**, and d) **4d** in $CDCl_3$ at 30 °C.

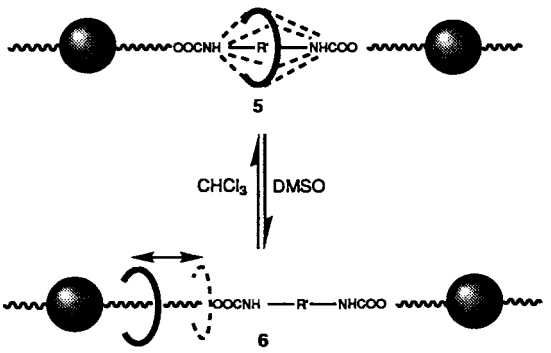

Scheme 2. Polymeric molecular shuttles: solvent-induced localization of 30C10 in **4a–d**.

30C10 is confined near the phenyl groups of the MDI units. The upfield shift for threaded 30C10 in the polyurethanes is caused by these phenyl rings. Therefore, in $CDCl_3$ threaded 30C10 in **4a–d** display the same chemical shift, even in different sequence structures.

To confirm the above hypothesis, ^{1}H NMR studies of poly(urethane rotaxane)s were also performed in [D_6]DMSO. As shown in Figure 2, threaded 30C10 in copolyurethanes **4a–c** indeed displays a range of chemical shifts from $\delta = 3.33$ to 3.38, while free 30C10 has a chemical shift at $\delta = 3.52$. DMSO is a very good solvent for displacing hydrogen bonding between NH groups and crown ethers, and, therefore, the macrocycles in polyurethanes are no longer localized at the NH groups but are instead forced away and move along the rest of the backbone between the BGs (structure **6** in Scheme 2). The signal for 30C10 is shifted upfield because it is shielded in a time-averaged man-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3621-2332 $ 17.50+.50/0

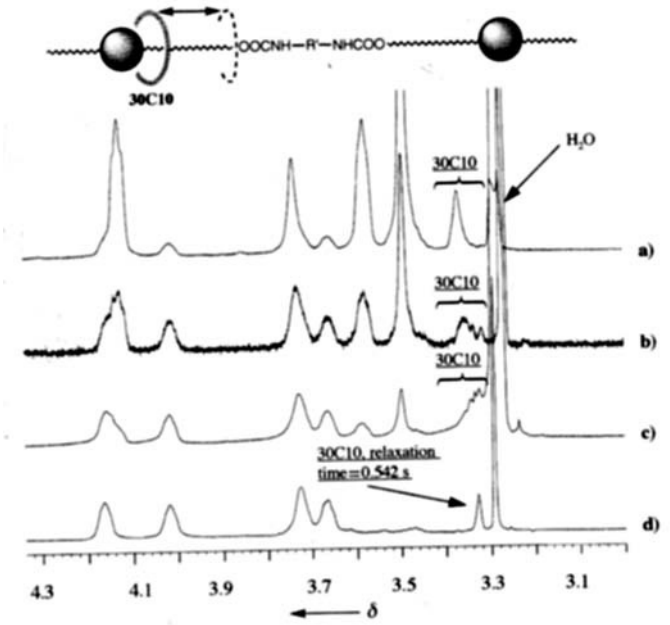

Figure 2. Section from the aliphatic region in the 400-MHz ^{1}H NMR spectra of a) **4a**, b) **b**, c) **4c**, and d) **4d** in [D$_6$]DMSO at 30 °C.

ner by the phenyl groups of the BG units and the MDI units; this is the same reason as for polyesters.[6] Since the copolyurethanes have different sequence structures with different lengths between the BG units, a range of chemical shifts for threaded 30C10 reflecting these sequence structures was observed (Figure 2). Therefore, 30C10 tends to be more mobile in DMSO and spend most of its time away from the NH group which interacts strongly with the solvent.

All these observations are supported by the measurements of spin-lattice relaxation times (T_1). Threaded 30C10 in **4d** has a T_1 of 0.178 and 0.542 s in chloroform and DMSO, respectively.[11] The smaller value in chloroform confirms the restriction of ring movement (both translation and rotation) due to hydrogen bonding (**5** in Scheme 2), while the larger T_1 in DMSO indicates relatively free translational and rotational movement of the macrocycle (**6** in Scheme 2). However, the macrocycle in **4d** is still restricted to a large extent even in DMSO, since its T_1 is smaller than that of unthreaded 30C10 (1.78 s). The large difference in T_1 values between threaded and unthreaded macrocycles provides a novel, easy, and reliable method for characterizing the formation of polyrotaxanes, and augments chemical-shift changes and NOESY.[6]

Polymeric shuttles were successfully prepared with polyurethanes as backbones and the crown ethers as macrocycles, and a novel method for controlling microstructures of the polymeric materials in solution was demonstrated. The crown ethers in **4a**–**d** are localized at the NH groups by hydrogen bonding in $CHCl_3$, in which both rotation and translation are restricted, while they are delocalized (mobile) but removed from the NH groups in DMSO. In principal, this concept can be used for other polymers bearing similar functional groups, for example polyamides.

Experimental Section

The diols (1 equiv **1** and **2**) were dissolved in 30C10 (3 equiv) at 95 °C, and the solution was stirred for 0.5 h. After addition of **3**, polymerization proceeded for 7 h under a nitrogen atmosphere. The product was precipitated from DMF into methanol three times to remove unthreaded 30C10. The specific feed compositions for **4a**–**d** are detailed in Table 1. Their threading efficiencies and molecular weights are summarized in Table 2.

Table 2. Threading efficiencies and results of gel permeation chromatography (GPC) of **4a**–**d**.

Products	x	m/n[a]	M_n[b] [kg mol^{-1}]	M_w[b] [kg mol^{-1}]
4a	0.10	0.036	22.6	39.4
4b	0.40	0.040	12.4	18.0
4c	0.70	0.045	18.7	52.9
4d	1.00	0.049	23.5	37.8

[a] Threading efficiencies (m/n, the average number of cycles per repeat unit) were measured by ^{1}H NMR spectroscopy[6]. [b] Measured by GPC with universal calibration in *N*-methylpyrrolidone (NMP) at 60 °C.

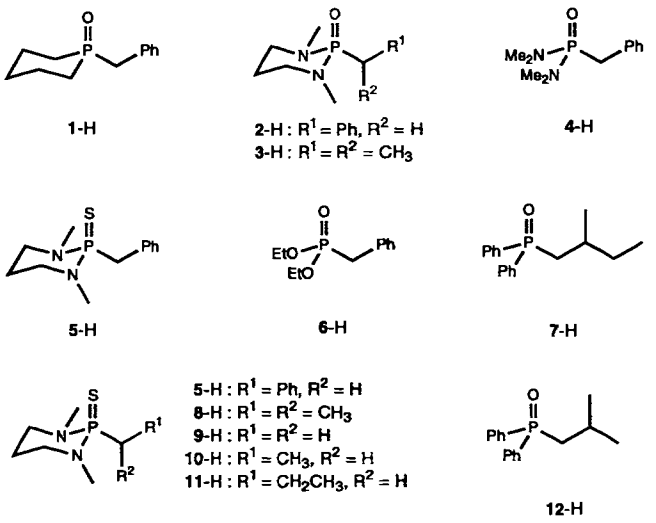
The First Lithiated Phosphane Oxide with Li–C Bonds: Synthesis and Structure of $[\{Ph_2P(O)CHLiC(H)MeEt\}_4]$**

John E. Davies, Robert P. Davies, Lorraine Dunbar, Paul R. Raithby, Matthew G. Russell, Ronald Snaith,* Stuart Warren, and Andrew E. H. Wheatley

Lithiated phosphane oxides, Horner–Wittig reagents,[1] are extremely important in synthetic organic chemistry, for example in the stereoselective syntheses of alkenes[2] and the asymmetric synthesis of chiral compounds.[2, 3] Despite such importance, relatively little is known about the detailed structures of these reagents. Six solid-state, THF-complexed structures have been solved; five are dimers obtained by lithiation of *P*-benzylphosphorinane-1-oxide (**1**-H),[4] phosphonamides **2**-H, **3**-H, and **4**-H,[5a–c] and thiophosphonamide **5**-H.[5d] The structures of all



five are similar. They contain planar $(LiX)_2$ rings (X = O, S) with two THF ligands solvating each Li^+ center. There are no Li–C contacts, and, reflecting this coordinative inactivity, the carbanionic carbon centers are nearly planar and formally sp^2-hybridized. Similar features are seen in the DABCO complex (DABCO = $N(CH_2CH_2)_3N$) of the lithiated phosphonate ester **6**-H, except that here the $(LiO)_2$ rings are connected by DABCO ligands to give an infinite layered network.[6] Here we describe the very different structure of a lithiated phosphane oxide, tetrameric $[\{Ph_2P(O)CHLiC(H)MeEt\}_4]$ (**7**-Li). It is the first uncomplexed lithiated phosphane oxide and the first that is not a monomer or a dimer. Each unit of the tetramer contains two stereogenic centers, a feature which, as far as we are aware, has not been seen before in any lithiated organic molecule. Most importantly, each unit has a Li–C bond and, hence, an sp^3-hybridized, pyramidalized carbanionic center.

Our investigation was prompted by solution studies on lithiated thiophosphonamides derived from **5**-H and **8**-H to **11**-H. In THF **5**-Li (a dimer in the solid state, as noted above) and **8**-Li (a tris(THF)-complexed monomer in the solid state)[5e] are monomeric, solvent-separated ion pairs with nearly planar sp^2-hybridized carbanionic centers.[5d] In marked contrast, however, in solutions at low temperatures **9**-Li to **11**-Li have sp^3-carbanionic centers and Li–C contacts, as shown by NMR spectroscopy (^1H, $^{6,7}Li$, ^{13}C, ^{31}P); direct ^6Li–^{13}C coupling was observed.[7] This dramatic structural switch was attributed to two main factors: a) the accessibility of localized charge to metal cation contact and b) the degree of solvation of the attendant cation. We reasoned that a C–Li contact, and thus an sp^3-hybridized carbon center, could best be encouraged by lithiating a phosphane oxide with small and/or flat substituents in, above all, non-Lewis base media. By excluding such solvent molecules, the P-bound carbanionic center should be primed to act, in effect, as a donor to the lithium atom. Our initial efforts concentrated on lithiating $Ph_2P(O)CH_3$[2b] in toluene, but this gave only microcrystalline material.[8] We therefore switched to **7**-H. A suspension of **7**-H in toluene at −78°C gave a yellow solution after treatment with one equivalent of *n*BuLi in hexane. At room temperature a yellow solid precipitated which could best be dissolved for crystallization by heating after addition of one-third of an equivalent of HMPA ($O=P(NMe_2)_3$). Subsequent cooling afforded crystals identified as **7**-Li by elemental analyses as well as ^1H and ^{13}C NMR spectroscopy in THF (see Experimental Section). It was readily apparent that HMPA had not been incorporated; presumably, it merely aids dissolution of the precipitated product by increasing the polarity of the solvent mixture. Furthermore, the position of the ^{13}C NMR resonance due to the P-CH_2 group in **7**-H (δ = 36.92) had barely changed after lithiation to **7**-Li (δ(P-CHLi) = 36.78). This strongly indicates retention of sp^3 hybridization at this carbon center.

The crystal structure of **7**-Li [9] revealed a tetramer (Figure 1). In crystallographic terms the structure is not good. It has a high *R* value (R_1 = 0.1316) as a result of the poor quality of the crystals, which is consistent with the presence of highly disor-

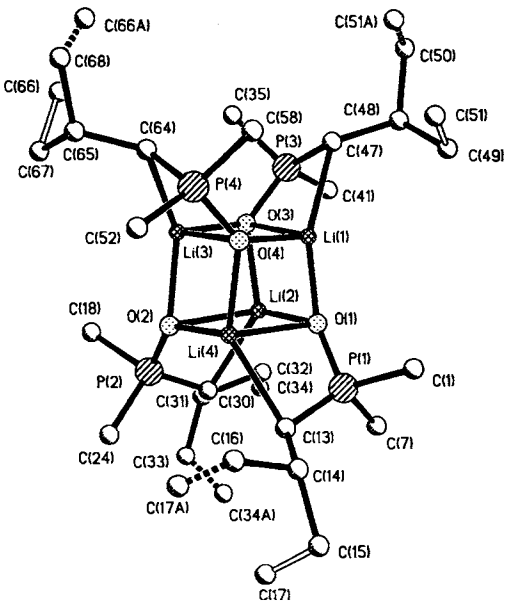


Figure 1. The molecular structure of **7**-Li. The toluene solvent molecules, H atoms, and C atoms of the phenyl group (except for the α-C atoms) have been omitted for clarity. The methyl and ethyl groups were disordered, and two positions are shown for the ethyl β-C atoms.

dered toluene solvate molecules (one per tetramer) in the lattice. Inspection of the structure shows that two of the new stereogenic centers of the PCH(R)Li groups are *R* (C(13) and C(30)) and two are *S* (C(47) and C(64)). However, it is impossible to decide which diastereoisomers are present because of the uncertainty of the positions of the PCHLi·CHMe·CH_2*Me* methyl groups (C(17), C(51), C(66), and C(34)). Nonetheless, the key features of **7**-Li in the solid state are clear. The core consists of a $(LiO)_4$ pseudo-cubane formed by stacking two dimeric rings, Li(3)-O(3)-Li(1)-O(4) and Li(2)-O(2)-Li(4)-O(1). Such a $(LiX)_4$ unit is common in complexes of the type $(RLi \cdot L)_n$, where the R^- anion is alkoxide, enolato (X = O), alkyl, aryl (X = C), or imide (X = N) and L is an added monodentate Lewis base such as THF, HMPA, or an internal single-base center (e. g. MeO, Me_2N) within the anion.[10] In **7**-Li the internal Lewis base is the carbanionic center of the $^-$CHC(H)MeEt unit. Within each monomeric unit, this carbanionic center has a contact with a Li^+ center to give an O-P-C-Li ring. The Li–C distances (av 2.23 Å, range 2.21(3)–2.26(3) Å) can be compared with those in lithiated phosphonamides **2**-Li , **3**-Li, and **4**-Li, in which the Li···C distances (3.83(1), 3.778(10), and 3.678(6) Å respectively) exceed the sum of the van der Waals radii, and with those in typical lithium alkyls such as $(EtLi)_4$ (av Li–C 2.25 Å)[11] and $(t$BuLi$)_4$ (av Li–C 2.246 Å).[12] The Li–O distance (av 2.27 Å, range 2.25(2)–2.28(2) Å) within each chelated monomeric unit is similar to the Li–C distance, and rather longer than the Li–O contacts which connect these units together in the cube (av 1.91 Å, range 1.85(3)–1.95(3) Å). The Li–O(P) distances are similar to those in THF complexes **1**-Li to **4**-Li, as are the P–O and P–C(H) distances in **7**-Li (av 1.541 Å, range 1.525(10)–1.555(9) Å, and av 1.682 Å, range 1.669(14)–1.702(13) Å, respectively).

Without question, the above structural features for tetrameric **7**-Li prove that it contains sp^3-hybridized carbanionic centers with contacts to lithium. We also lithiated the related but achiral phosphane oxide **12**-H in toluene. The X-ray analysis of **12**-Li was also plagued with disordered toluene solvent molecules, but the basic structure is akin to that of **7**-Li, that is, a tetrameric cubane with both Li–O and Li–C bonds. Given such disorder, **7**-Li and related systems are being synthesized (starting from enantiomerically pure precursors) in benzene in the hope of obtaining more accurate structures. These should provide good stereochemical information on the effect an extant and adjacent stereogenic center exerts on the new stereogenic center produced by lithiation. Finally, lithiation of **7**-H in toluene gives a solution at −78°C that persists until close to ambient temperature, and the then precipitated **7**-Li can be recrystallized from toluene/HMPA without incorporation of HMPA (an exceptionally good complexant for lithium). In a similar vein, it is clear from ^{13}C NMR spectroscopic data that solid **7**-Li dissolves in [D_8]THF with retention of its Li–C bonds. These results indicate that it will be profitable to examine the reactivity and selectivity of solutions of reagents such as **7**-Li in solvents such as toluene, HMPA, and THF.

Experimental Section

7-Li: *n*BuLi in hexane (5 mmol) was added to a suspension of **7**-H (1.36 g, 5 mmol) in toluene (6 mL) at −78 °C. Warming the yellow solution to room temperature caused precipitation of a yellow powder, which dissolved upon heating after addition of HMPA (0.29 mL, 1.67 mmol). Cooling the ensuing red solution afforded cubic yellow crystals of **7**-Li, $[\{Ph_2P(O)CH(Li)C(H)MeEt\}_4] \cdot C_6H_5CH_3$, $C_{75}H_{88}Li_4O_4P_4$. The yield of the first batch was 18%; m.p. decomp (loss of toluene) from 98 °C; calcd elemental analysis: C 74.7, H 7.4, Li 2.3, P 10.3; found: C 74.0, H 7.4, Li 2.1, P 10.3; ^{1}H NMR ([D_8]THF, 400.136 MHz, 25 °C): δ = 7.91 (m, 4H, Ph), 7.15 (m, 6H. Ph), 1.93 (m, 1H, CH), 1.76 (m, 1H, P-CH), 1.41 (m, 1H, CH_AH_B), 1.25 (m, 1H, CH_AH_B), 0.98 (d, 3H, CH_3), 0.86 (t, 3H, CH_2CH_3); toluene resonances have been excluded; ^{13}C/APT NMR ([D_8]THF, 100.614 MHz, 25 °C): δ = 143.77 (d, *ipso*-C, Ph), 133.35 (d, *meta*-C, Ph), 128.77 (s, *para*-C, Ph), 127.58 (d, *ortho*-C, Ph), 37.24 (d, CH_2, ^3J(C,P) = 11.1 Hz), 36.78 (d, P-CH, J(C,P) = 138.4 Hz), 34.50 (d, CH, ^2J(C,P) = 6.5 Hz), 27.62 (d, CH_3, ^3J(C,P) = 9.3 Hz), 12.68 (s, CH_2CH_3); toluene resonances have been excluded.

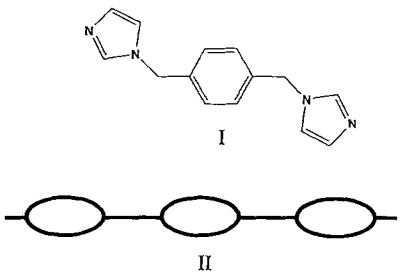
The Structure of $[Zn(bix)_2(NO_3)_2]\cdot 4.5H_2O$ (bix = 1,4-Bis(imidazol-1-ylmethyl)benzene): A New Type of Two-Dimensional Polyrotaxane**

Bernard F. Hoskins, Richard Robson,* and Damian A. Slizys

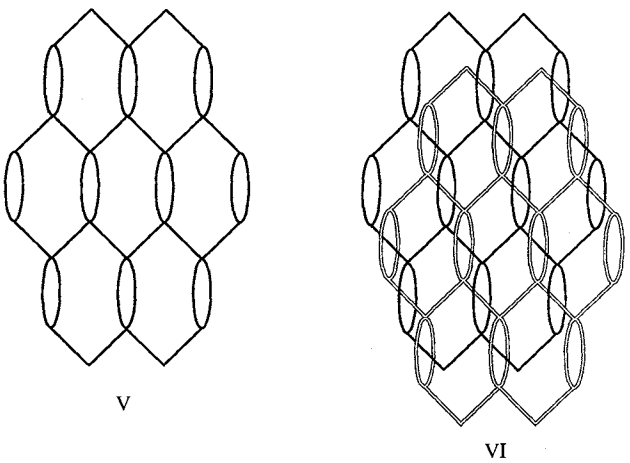
Rotaxanes and polyrotaxanes currently attract considerable interest.[1] Polyrotaxanes resembling strings of beads have been reported, in which macrocycles such as cyclodextrins and cyclic polyethers provide the beads and polymers of various sorts act as the string; however, these have generally been structurally irregular. The first three examples of structurally regular polyrotaxanes amenable to single-crystal X-ray diffraction study were reported very recently within a short time by Kim et al[2] and by ourselves.[3] The examples from Kim et al. consist of a one-dimensional Cu^{II} coordination polymer and an analogous 2D Ag^{I} derivative of the same ligand with a macrocyclic cucurbituril bead encircling every repeat unit; in both cases the beads are secured in place by hydrogen bonds between their oxygen atoms and NH_2^+ groups incorporated into the polymer for this purpose. The 2D polyrotaxane that we reported[3] is also a coordination polymer, but it differs fundamentally from that of Kim et al. in that the rings associated with the rotaxane are themselves part of a 1D polymeric chain. It has the composition $[Ag_2(bix)_3(NO_3)_2]$ (bix = 1,4-bis(imidazol-1-ylmethyl)benzene, **I**; Scheme 1) and consists of 1D polymeric chains of the type represented schematically by **II**, in which the threefold connecting nodes are provided by three-coordinate Ag^{I}. The metal centers are connected by two types of bridging bix units: those forming $Ag_2(bix)_2$ rings and those that connect the rings with each other (referred to here as "rods"). Each polymeric chain is entangled through rotaxane interactions with an infinite number of other chains, so that every one of its $Ag_2(bix)_2$ rings encircles an Ag-bix-Ag rod of another chain and every one of its Ag-bix-Ag rods passes through an $Ag_2(bix)_2$ ring of another chain. This generates the 2D polyrotaxane sheet represented by **III**.



Scheme 1.

We report here the structure of $[Zn(bix)_2(NO_3)_2]\cdot 4.5H_2O$, which, like the silver derivative, has a 2D polyrotaxane structure. Its topology, however, is entirely different. The outstanding structural features are polyrotaxane columns of the type represented schematically by **IV**.

Crystals suitable for single crystal X-ray diffraction studies were obtained directly from reaction mixtures containing zinc nitrate and bix in aqueous methanol. The zinc centers are all equivalent and in a distorted tetrahedral N_4 coordination environment. The N-Zn-N angles vary from 96.2(1) to 125.0(1)°, and the Zn–N bond lengths from 1.994(3) to 2.056(4) Å. There are two independent 2D polymeric sheets of the type represented schematically by **V** (Scheme 2), in which the fourfold connecting nodes are provided by zinc; two such sheets interpenetrate as shown by **VI**. Therefore, three types of bridging bix ligands are present: those that form the macrocyclic $Zn_2(bix)_2$ rings (Zn···Zn 11.902(2) Å), the rods that pass through these rings (Zn···Zn 15.037(2) Å), and those that connect columns of type **IV** (Zn···Zn 14.146(2) Å). The C/N/Zn arrangement within columns of type **IV**, which are oriented parallel to the *a* axis, is shown in Figure 1, and that within an entire interpenetrating double sheet in Figure 2. Water molecules and nitrate ions located largely within the double-sheet structure are highly disordered.



Scheme 2.

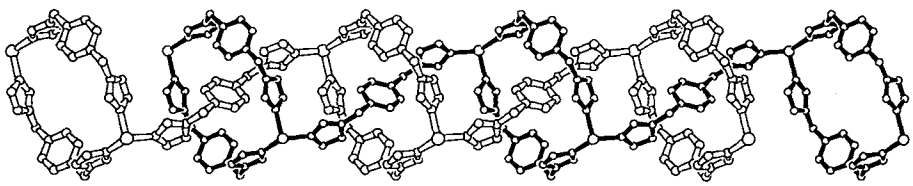


Figure 1. A polyrotaxane column present in the $\{Zn(bix)_2^{2+}\}_n$ framework structure. Small circles represent C and N atoms, and large circles Zn atoms. The components of two independent networks are indicated by filled and open connections.

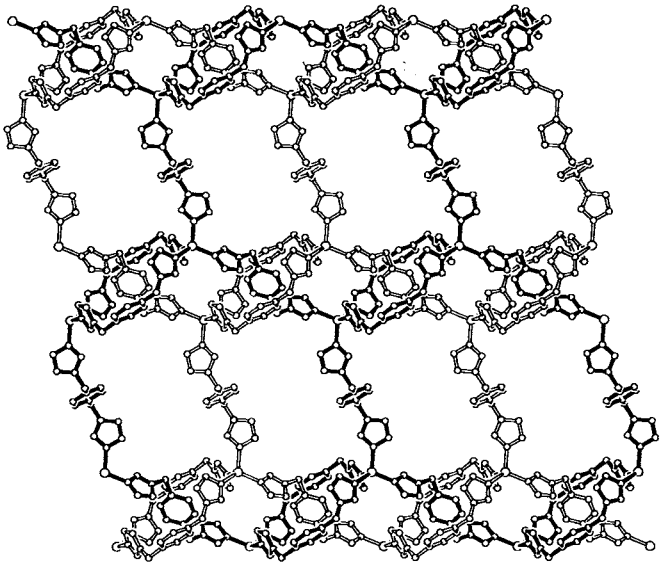

Figure 2. A view of the pair of independent and interpenetrating extended 2D $\{Zn(bix)_2^{2+}\}_n$ networks.

The stereochemical relationships between the $M_2(bix)_2$ ring and the bix rod passing through it are contrasted for the silver and zinc derivatives in Figure 3. In both cases the macrocyclic ring is arranged around a center of symmetry, but the two differ

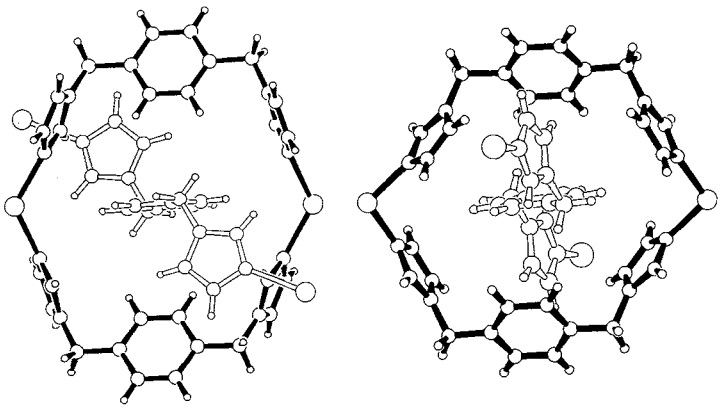

Figure 3. Comparison of the stereochemical relationships between a metal-bix-metal rod and the $metal_2(bix)_2$ ring through which it passes for $[Ag_2(bix)_3(NO_3)_2]$ (left) and $[Zn(bix)_2(NO_3)_2]\cdot 4.5H_2O$ (right).

in conformation. The Ag···Ag separation across the ring (10.503(1) Å) is significantly smaller than the Zn···Zn separation (11.902(2) Å), mainly as a result of the larger N-M-N angle for trigonal silver (127.3(1)° internal to the ring) than for tetrahedral zinc (103.2(1)° internal to the ring). Another conformational difference arises in the direction of inclination for the phenylene units of the macrocycle. In the case of zinc, the C–C edge of the phenylene units that appears on the same side of the macrocycle as the C–C edges of the two adjacent imidazoles is oriented outwards, away from the center of the macrocycle, whereas in the case of silver it is oriented inwards. As is apparent in Figure 3, the central phenylene unit of the rod relative to the surrounding macrocycle is much the same in the two cases. However, the orientation of the rod metal–metal vector relative to the macrocyclic average plane is significantly different: it is inclined away from the perpendicular to the ring much more in the case of silver, as can be clearly seen in Figure 3. In both cases many contacts between H atoms and aromatic C or N atoms in the range of 2.9 to 3.2 Å participate in the rod-to-ring interaction; in the case of silver there are also two shorter interactions (2.684(4) and 2.772(5) Å), both involving coordinated N atoms. The shortest interaction in the case of zinc (2.954(4) Å) also involves a coordinated N atom of the macrocycle, but no particular rod-to-ring interaction appears to be of significance.

Bridging ligands derived from 1,4-xylyl appear to have some propensity for forming catenanes and rotaxanes by penetrating parts of independent components through $M_2(ligand)_2$ rings. Thus, in addition to the two bix-based polyrotaxanes described here, the related 1,4-xylyl-derived ligands, 1,4-bis(4-pyridylmethyl)benzene and *N,N'-p*-phenylenedimethylenebis(pyridin-4-one) were reported to form discrete molecular catenanes[4] and infinite polycatenanes,[5] respectively. Related cyclophanes derived from 1,4-xylyl involving C–C and C–N covalent bonds rather than metal–ligand bonds have also been extensively used by Stoddart et al. to generate a wide range of catenanes and rotaxanes.[6]

Experimental Section

Hydrated $[Zn(bix)_2(NO_3)_2]$ was obtained by adding a solution of bix dihydrate [3] (58.8 mg, 0.214 mmol) in methanol (5 mL) to a solution of zinc nitrate hexahydrate (21.3 mg, 0.072 mmol) in water (5 mL). The crystals that separated after 18 h were collected, washed with aqueous methanol, and dried under air. Elemental analysis calcd for $C_{28}H_{33}N_{10}O_{8.5}Zn$ ($[Zn(bix)_2(NO_3)_2]\cdot 2.5H_2O$): C 47.3, H 4.7, N 19.7, Zn 9.2; found: C 47.4, H 4.5, N 19.8, Zn 9.2. Crystal data: $[Zn(bix)_2(NO_3)_2]\cdot 4.5H_2O$, $M_r = 747.04$, triclinic, space group $P\bar{1}$ (no. 2), $a = 10.489(1)$, $b = 13.539(2)$, $c = 13.659(2)$ Å, $\alpha = 70.53(1)$, $\beta = 83.21(1)$, $\gamma = 77.27(1)°$, $U = 1781(4)$, $Z = 2$, $\rho_{calcd} = 1.39\ g\,cm^{-3}$, $\rho_{found} = 1.44(2)\ g\,cm^{-3}$, $\mu(Mo_{K\alpha}) = 7.6\ cm^{-1}$, $F(000) = 778$. Intensity data for 7145 reflections, yielding 6280 independant reflections ($R_{int} = 0.0124$), were measured at 295(1) K with $Mo_{K\alpha}$ radiation (graphite monochromator) using an Enraf-Nonius CAD-4 MachS diffractometer and employing the $\omega/2\theta$ scan method; absorption corrections were applied [7]. All non-hydrogen atoms of the polymeric cation, together with oxygen atoms attributed to two of the waters of solvation, were located using the Patterson interpretation routine of the SHELXS-86 program [8]. Subsequent cycles of least-squares refinement and difference syntheses (SHELXL-93) [9] indicated that both of the crystallographically independent anions and the remainder of the water structure were extensively disordered; these features were incorporated in the model. The ligand hydrogen atoms, all of which were revealed in the difference syntheses during the last stages of refinement, were included in the refinement at their geometrically constrained positions. Anisotropic displacement parameters were applied to all non-hydrogen atoms of the coordination polymer and the full-weight oxygen atoms of the water structure. Full-matrix least-squares refinement based on F^2 converged with $R_1 = 0.0716$, $wR_2 = 0.2163$, and goodness of fit = 1.041; minimum and maximum residual electron density were -0.733 and $0.881\ e\,Å^{-3}$. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100 532. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code +(1223) 336-033; e-mail: deposit@chemcrys.cam.ac.uk).

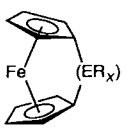
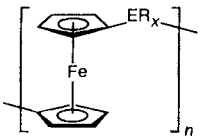
Incorporation of a First Row Element into the Bridge of a Strained Metallocenophane: Synthesis of a Boron-Bridged [1]Ferrocenophane**

Holger Braunschweig,* Regina Dirk, Matthias Müller, Paul Nguyen, Rui Resendes, Derek P. Gates, and Ian Manners*

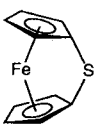
[1]Ferrocenophanes **1** are unusual, strained organometallic species that have attracted considerable interest with respect to their structures, reactivity, and, more recently, their propensity to undergo ring-opening polymerization (ROP) reactions.[1–5] The latter provide access to novel, high molecular weight poly(ferrocene)s **2**.[3] The first [1]ferrocenophane, the silicon-bridged



1



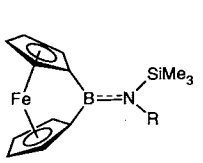
2



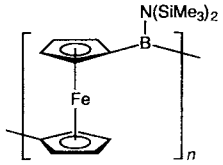
3

species **1** (ER$_x$ = SiPh$_2$), was prepared in 1975 by the reaction of dilithioferrocene·TMEDA (TMEDA = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine) with Ph_2SiCl_2 and was shown to possess a strained structure in which the tilt angle between the planes of the cyclopentadienyl ligands is about 19°.[6] The range of [1]ferrocenophanes has subsequently been extended to include compounds whose bridges contain other main group elements of the second period and below from Group 14 (Ge and Sn; tilt angles 14–19°),[7] Group 15 (P and As; tilt angles 23–27°),[8] and also Group 4 transition metals (Ti, Zr, Hf; tilt angles = ca. 6°).[9] In general, the smaller the covalent radius of the atom in the bridge, the larger the tilt angle, and the higher the ring strain present. With this in mind, one of our groups recently reported the preparation of a sulfur-bridged [1]ferrocenophane **3**, the first ferrocenophane with a Group 16 element in the bridge.[10] This species possessed the highest tilt angle recorded to date for a strained [1]ferrocenophane (31.05(10)°).[11] As the covalent radii of first row elements are even smaller than that of sulfur their incorporation into the bridged structure would be expected to provide access to even more highly strained species. We have investigated the preparation of such compounds because of our interests concerning the use of ROP to access new metal-based polymers,[3] possible interactions between the iron and the bridging element,[12] and the opportunity of accessing novel species with bonds between transition metals and main group elements by insertion reactions.[13, 14] In the case of a bridging boranediyl moiety, insertion processes might provide a new synthetic route to transition metal boryl complexes, which, to date, are mainly restricted to the use of the 1,2-phenylenedioxy group as the boron bound ligand.[15] With this in mind, we report here the first [1]ferrocenophane containing a first row element in the bridge, a boron-bridged [1]ferrocenophane.[16]

Reaction of a suspension of dilithioferrocene·TMEDA with $(Me_3Si)_2NBCl_2$[17] in benzene or toluene at 25 °C, followed by recrystallization from hexanes at −30 °C afforded dark red crystals. NMR spectroscopic data were consistent with the formation of the highly strained [1]boraferrocenophane **4a**. For example, a characteristically large separation ($\Delta\delta = 0.50$ ppm) of the α and β protons of the cyclopentadienyl groups was detected by ^{1}H NMR spectroscopy, and the ^{13}C NMR signal ([D$_8$]toluene, −30 °C) of the *ipso*-C atom was detected at δ = 45.0 and is upfield shifted compared to the signal for unstrained systems (ferrocene, $\delta = 68.0$). Surprisingly though, it is shifted much further downfield with respect to those of compound **3** ($\delta = 14.3$) and other less strained [1]ferrocenophanes.[18] The ^{11}B NMR signal ($\delta = 48.3$) was in the range expected for a planar three-coordinate boron atom. In hexanes, **4a** exhibits a UV/Vis absorbance at 479 nm which is considerably red-shifted with respect to ferrocene (λ_{max} = 440 nm); however, interestingly, it is not as low energy as that of **3** (λ_{max} = 504 nm). The [1]boraferrocenophane **4b** was prepared by a method analogous to that employed for **4a** and was characterized similarly.



4a, R = SiMe$_3$
4b, R = *t*Bu



5

In order to completely characterize and probe the strain present in **4a**, a single-crystal X-ray diffraction study was undertaken.[19] This indicated that molecules of **4a** are highly strained with a tilt angle of 32.4(2)°, the largest reported to date for a [*n*]metallocenophane (Figure 1). The large ring tilting in **4a** is accompanied by a Cp$_c$1-Fe-Cp$_c$2 angle (Cp$_c$ = ring centroid) of 155.2(2)° (ferrocene: 180°), which is smaller than that in **3** [156.9(1)°]. The cyclopentadienyl rings are in an eclipsed conformation with a C(10)-Cp$_c$1-Cp$_c$2-C(20) torsion angle of 1.0(2)°. Additional structural distortions include angles of 33.7(2)° and 34.0(2)° between the cyclopentadienyl ring planes and the exo-

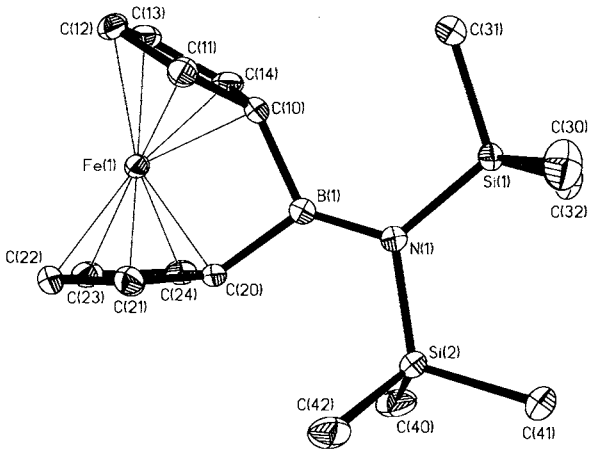

Figure 1. Molecular structure of **4a** in the crystal (ellipsoids drawn at 50% level).

cyclic C–B bonds. The B–N bond length is 1.399(2) Å, which is typical for a B–N double bond (1.41 Å).[20] The Fe(1) and B(1) atoms do not appear to show a substantial interaction; the Fe(1)–B(1) distance is 2.590(2) Å, which is significantly longer than for a single bond (in $[CpFe(BPh_2)(CO)_2]$, d(Fe–B) = 2.034(3) Å[15c]) and longer than the sum of the covalent radii (2.15 Å).[21]

In order to explore the polymerization behavior of **4a** a differential scanning calorimetry (DSC) investigation was undertaken. A DSC thermogram of **4a** (Figure 2) showed a melt

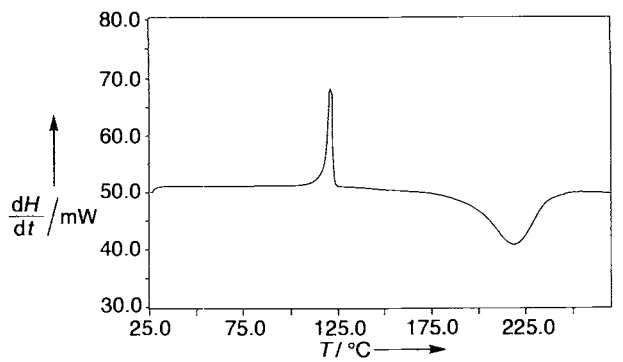

Figure 2. DSC thermogram of **4a**.

endotherm at about 115 °C, followed by a ROP exotherm at about 190 °C. Similar behavior has been detected by DSC for strained silicon-bridged [1]ferrocenophanes. In the case of **4a** the ΔH for the ROP was 95 kJ mol^{-1}, which is significantly greater than for silicon-bridged [1]ferrocenophanes (70–80 kJ mol^{-1}) (tilt angles 16–21°).[22]

The product **5** formed from heating **4a** at 180 °C for 2 h was found to be mainly insoluble in organic solvents. However, ^{1}H NMR analysis of a soluble extract in C_6D_6 showed the presence of oligomers. Pyrolysis mass spectrometry of **5** confirmed the presence of the ferrocenylborane repeat unit, and peaks were observed that could be assigned to cyclic oligomers **5** ($n = 2$) and **5** ($n = 3$).

We are now carrying out detailed studies on the chemical behavior of **4a** and **4b**. As mentioned above, the possibility of the insertion of transition metals into the strained *ipso*-C–B bond is of particular interest. Work aimed at the preparation and characterization of soluble poly(boraferrocene)s is also in progress.

Experimental Section

4a: $[Fe(\eta^5\text{-}C_5H_4Li)_2]\cdot$TMEDA (1.20 g, 2.79 mmol) was suspended in benzene (70 mL) at room temperature and $[(Me_3Si)_2N]BCl_2$ (0.67 g, 2.79 mmol) was added dropwise by a syringe. After the mixture had been stirred for 6 h, all volatile components were removed in high vacuum (25 °C/0.001 Torr) and the residue was taken up in hexane (30 mL). After filtration, **4a** (0.35 g; 35%) was obtained at −30 °C as dark red crystals. NMR spectra in C_6D_6 at 25 °C: ^{1}H NMR (500 MHz, TMS): $\delta = 0.37$ (s, 18H; $SiMe_3$), 3.91, 4.41 (2m, 8H; C_5H_4); ^{11}B NMR (160 MHz, $Et_2O\cdot BF_3$): $\delta = 48.3$; ^{13}C NMR (126 MHz, TMS): $\delta = 5.1$ ($SiMe_3$), 45.0 (*ipso*-C), 72.4, 77.1 (C_5H_4); UV/Vis (hexanes): λ_{max} (ε) = 479 nm (593 L mol^{-1} cm^{-1}); MS (70 eV): m/z (%): 355 (100) [M^+], 340 (80) [$M^+ - CH_3$], 299 (70) [$M^+ - Fe$], 73 (30) [$SiMe_3$] (the calculated isotopic distribution for each ion was in agreement with experimental values); elemental analysis (%): calcd for $C_{16}H_{26}BFeNSi_2$: C 54.10, N 3.94, H 7.38; found C 53.43, N 4.13, H 7.79.

4b: As described for **4a**, $[Fe(\eta^5\text{-}C_5H_4Li)_2]\cdot$TMEDA (1.38 g, 3.21 mmol) suspended in benzene (70 mL) was treated with [*t*Bu(Me_3Si)N]BCl_2 [17] (0.73 g, 3.21 mmol), and **4b** (0.48 g; 44%) was obtained as dark red crystals. NMR spectra (same conditions as for **4a**); ^{1}H NMR: $\delta = 0.43$ (s, 9H; $SiMe_3$), 1.50 (s, 9H, *t*Bu), 3.92, 3.94, 4.40, 4.42 (4m, 8H; C_5H_4); ^{11}B NMR: $\delta = 44.7$; ^{13}C NMR: $\delta = 7.5$ ($SiMe_3$), 34.6 (CMe_3), 44.3, 46.1 (*ipso*-C), 57.9 (CMe_3), 72.0, 72.8, 76.6, 76.7 ($2C_5H_4$); elemental analysis (%): calcd for $C_{17}H_{26}BFeNSi$: C 60.21, N 4.13, H 7.73; found C 58.70, N 4.00, H 7.89.

5: **4a** (80 mg) was heated at 180 °C in a sealed, evacuated Pyrex tube. After about 15 min. the contents of the tube melted and became increasingly viscous, becoming immobile after 2 h. The red glassy material obtained quantitatively was found to be essentially insoluble in common organic solvents. A small amount was extracted with C_6D_6. ^{1}H NMR (400 MHz): $\delta = 0.25$, 0.33, 0.46 (3s, $SiMe_3$), 4.19, 4.26, 4.38, 4.53, 4.66, 4.94 (6t, C_5H_4). Pyrolysis MS of the crude product **5** (70 eV, 450 °C): m/z (%): 1065 (45) [$n = 3$], 710 (100) [$n = 2$], 355 (78) [$n = 1$], 73 (80) [$SiMe_3$] (the calculated isotopic distribution for each ion was in agreement with experimental values).

[19] Crystallographic data for **4a** ($C_{16}H_{26}BFeNSi_2$): monoclinic, $P2_1/c$, $a = 11.614(1)$, $b = 11.506(1)$, $c = 13.601(1)$ Å, $\beta = 98.526(2)°$, $V = 1797$ Å^3, $Z = 4$, $\mu = 9.62$ cm^{-1}, $Mo_{K\alpha}$ ($\lambda = 0.71069$ Å), $\rho_{calcd} = 1.31$ g cm^{-3}, 100 K, Enraf-Nonius DIP2020 image plate diffractometer with graphite monochromator, dark red crystal (dimensions $0.21 \times 0.26 \times 0.31$ mm^3). Of 18806 reflections recorded ($1 < \theta < 27°$, $-13 \le h \le 13$, $-14 \le k \le 14$, $-16 \le l \le 16$), 3605 were unique and 3186 were observed with $I > 3\sigma(I)$. The images were processed with the DENZO and SCALEPACK programs [23]. Solution by direct methods and refinement by the full-matrix least-squares method. Subsequent difference Fourier analysis revealed that one of the $Si(CH_3)_3$ groups was disordered over two sites with 80% and 20% fractional occupancy. In the final stages of the structure determination all methyl hydrogen atoms were added geometrically after each refinement cycle and included in the structure factor calculations: 235 refined parameters for 3189 observations. Corrections for Lorentz and polarization effects, secondary extinction and anomalous scattering were applied. Refinement was completed by using Chebyshev weighting scheme with three parameters [24]. Refinement on F, $R = 0.028$, $R_w = 0.035$, GOF = 1.056, $\Delta\rho_{max} = 0.46$ e Å^{-3}, and $\Delta\rho_{min} = 0.46$ e Å^{-3}. All crystallographic calculations were carried out using the CRYSTALS package [25]. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication no. CCDC-100378. Recognition of Anions through NH–π Hydrogen Bonds in a Bicyclic Cyclophane—Selectivity for Nitrate**

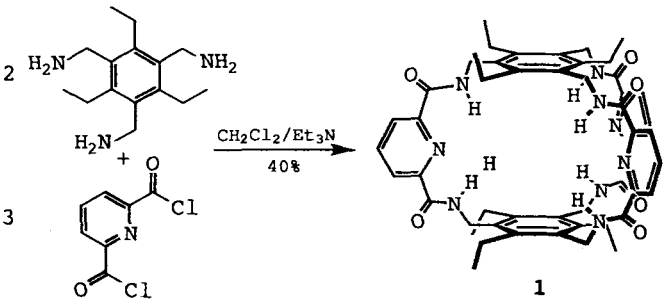
Adrian P. Bisson, Vincent M. Lynch, Mary-Katherine C. Monahan, and Eric V. Anslyn*

The molecular recognition of anions with synthetic receptors is an expanding field of research. Synthetic anion receptors to date have typically employed various combinations of Lewis acids,[1] protonated polyammonium macrocycles,[2] pyrroles,[3] guanidiniums,[4] and amides.[5] The selectivity these hosts exhibit comes from both size and shape complementarity as well as anion basicity.[6] With anions such as carboxylates and phosphates, hydrogen bonding from these receptors is typically targeted to the guest heteroatom's lone pairs. Herein we introduce a novel C_3-symmetric host capable of hydrogen bonding to the anion's π systems. The combination of geometric and electrostatic complementarity leads to stronger binding of nitrate than might be expected based upon its basicity.

Nature in part uses amide hydrogen bonding for the binding of sulfate and phosphate when they are bound within proteins.[7] With this in mind, we designed an amide-linked C_3-symmetric bicyclic cyclophane (**1**, Scheme 1) capable of



Scheme 1. Synthesis of the bicyclic cyclophane **1**.

recognizing anions exclusively through neutral hydrogen bonding.[8] The C_3 symmetry comes from two rigid building blocks, 2,6-pyridine dicarbonyl dichloride and 1,3,5-triaminomethyl-2,4,6-triethylbenzene.[9] Amides formed by 2,6-pyridine dicarbonyl dichloride are oriented such that the amide NH protons are hydrogen bonded to the pyridine nitrogen, forcing a converged geometry.[10] Also the alternating steric interactions in 1,3,5-triaminomethyl-2,4,6-triethylbenzene ensure that the amine groups are oriented on the same face of the aromatic ring.[11] The bicyclic cyclophane produced converges six amide hydrogens into the center of a binding pocket. Due to the geometry imposed by the cyclophane, a host–guest complex with nitrate or acetate would involve hydrogen bonding to π electrons in preference to lone pair electrons.

The preorganization of both building blocks for **1** greatly facilitated the synthesis (Figure 1). On treatment of two equivalents of 1,3,5-triaminomethyl-2,4,6-triethylbenzene with three equivalents of 2,6-pyridine dicarbonyl dichloride the rigid bicyclic cyclophane is formed in surprisingly high yield (40%).

X-ray quality crystals of the host were grown from a CH_2Cl_2/CH_3CN solution (Figure 1a).[12a] As expected, the cavity is lined by six hydrogens all oriented toward the center. The cavity size measures 78.3 Å^3; the aromatic rings are separated by 7.0 Å. The cavity of the free receptor is occupied by two water molecules and one molecule of CH_3CN. The latter forms hydrogen bonds with the amides of one of the acyl pyridine units and π–π stacks between the faces of the aromatics.

X-ray quality crystals of the chloride complex were also grown from the same solvent mixture in the presence of excess tetrabutylammonium chloride (Figure 1b).[12b] In this case, a 2:1 stoichiometry of guest to host was found; each chloride forms hydrogen bonds with the amides of one acyl pyridine. The remaining space within the cavity is occupied by a water molecule which is hydrogen bonded to each chloride and to the last acyl pyridine unit, forming a cooperative network of eight hydrogen bonds.

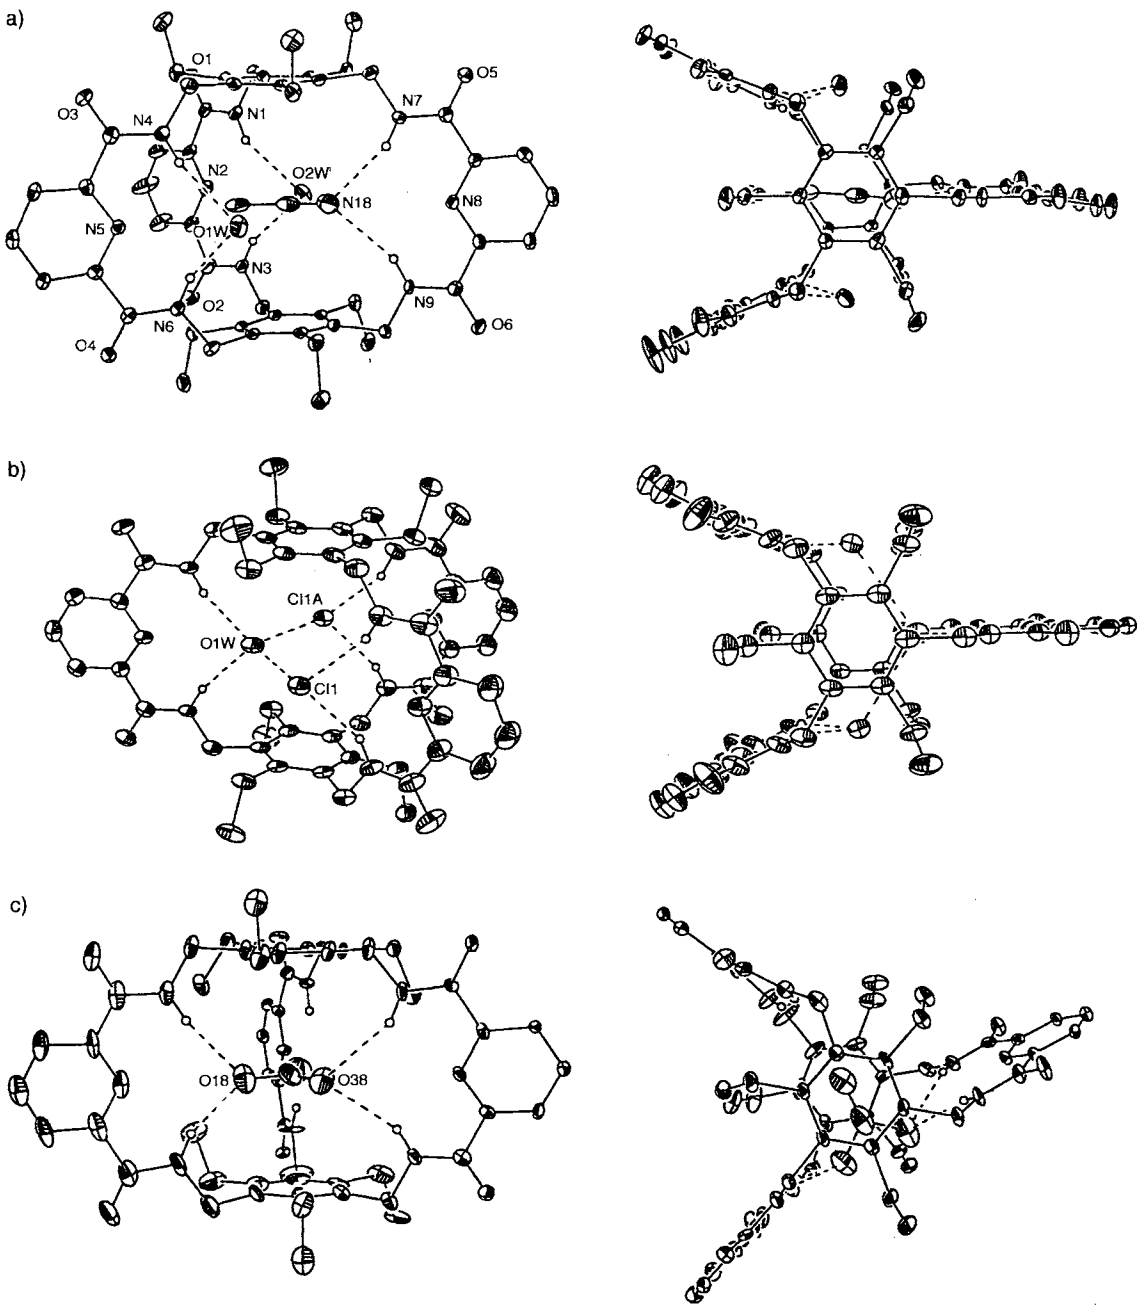

Figure 1. Two views of the crystal structures of a) free host **1** (thermal ellipsoids scaled to 30%), b) $2\,Bu_4NCl\cdot\mathbf{1}$ (thermal ellipsoids scaled to 20%) c) $2\,Bu_4NOAc\cdot\mathbf{1}$ (thermal ellipsoids scaled to 20%).

Crystals of the acetate complex suitable for X-ray analysis were grown from a $H_2O/EtOH/CH_2Cl_2$ solution in the presence of excess ammonium acetate (Figure 1c).[12c] In this case, the acetate is bound within the cavity to form a 1:1 complex. The anion is bound by two hydrogen bonds from the amides of two acyl pyridines.

The solution state anion binding properties of **1** were determined both by Job plots[13] and ^1H NMR titration experiments, the latter being analyzed with EQNMR[14] (Table 1). In all experiments the change in chemical shift of the amide NH resonances was followed. These signals shifted downfield, indicative of hydrogen bonding. Initial studies were carried out in CD_2Cl_2. However, the association constants were too large to determine at NMR concentrations, suggesting values in excess of

Table 1. Association constants K [M^{-1}] determined by ^1H NMR titration experiments[a] in 25% CD_2Cl_2/CD_3CN (1/3 v/v) at 298 K and pK_a values of the acids corresponding to the anion X^-.

Anion X^-	K [M^{-1}]	pK_a of HX
AcO^-	770±120	4.6
NO_3^-	300±30	−1.4
CN^-	115±10	9.2
Cl^-	40±8	−7
$H_2PO_4^-$	25±5	2
Br^-	15±8	−9
HSO_4^-	<5	−9

[a] Titrations were typically run at 10 mM host concentrations with aliquots of a 0.3 M tetrabutylammonium salt solution added. Association constants were determined by EQNMR[14].

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3621-2341 $ 17.50+.50/0

$10^4-10^5\,M^{-1}$. Increasing the polarity of the solvent to 25% CD_2Cl_2 in CD_3CN (v/v) allowed association constants to be determined. In all cases the stoichiometry of the solution state complexes was determined to be 1:1.

The host was found to exhibit enhanced binding of acetate and nitrate over cyanide, chloride, dihydrogen phosphate and bromide, while the binding of hydrogen sulfate was negligible. This enhanced binding is most likely due to encapsulation of these geometrically equivalent guests and the formation of several hydrogen bonds from both above and below the plane defined by the anions.

Several pieces of data lead to the conclusion that the host/guest complex with nitrate involves the encapsulation of this anion in the cavity with six hydrogen bonds. First is the comparison of the geometry of acetate and nitrate, and the fact that acetate is encapsulated. Moreover, acetate binds only a factor of 2.6 times better than nitrate, although it is 10^6 times more basic. Further, dihydrogen phosphate is also significantly more basic than nitrate, yet it is precluded from the cavity due to size and therefore has a much lower affinity.

The results presented here demonstrate that amide NH proton donors are effective for hydrogen bonding to planar anions. Although acetate had the largest association constant of all the anions studied, hydrogen bonding between the geometrically matched host and nitrate led to enhanced binding, overcoming the weak coordinative ability of this anion.

Tetraethylammonium Trichloride: A Versatile Reagent for Chlorinations and Oxidations**

Thierry Schlama, Kiroubagaranne Gabriel, Véronique Gouverneur, and Charles Mioskowski*

Functional-group manipulation is fundamental to synthetic organic chemistry, and the development of new reagents remains of great interest. Organic polyhalide salts have established themselves as useful reagents for halogenations.[1] Solid organic tribromides are a practical source of electrophilic bromine. However, the development of new reagents for chlorination is still unexplored, and only a few organic salts have been studied.[2] Here we demonstrate the efficiency of tetraethylammonium trichloride, a new organic salt that is a practical source of chlorine. This reagent was easily prepared by bubbling

chlorine through a solution of tetraethylammonium chloride in dichloromethane. The content of active chloride was 3.2 mmol g^{-1}, and no decrease in activity was observed upon storage for several months at room temperature.

Several substrates including alkynes, alkenes, aldehydes, ketones, esters, acetals, and arenes were easily chlorinated under mild conditions (Scheme 1, Table 1). Alkenes and alkynes were converted into vicinal dichloroalkanes and dichloroalkenes, respectively, in good yields (entries 1–13). All reactions of the alkynes afforded the (*E*) stereoisomer exclusively, as determined from ^{1}H NMR spectra of the crude mixtures and confirmed by comparison with authentic samples. The reagent is equally compatible with alkynols (entry 4) or silylated alcohols (entry 5). THP-protected alkynols gave the desired product in low yields (entry 6, THP = tetrahydro-2*H*-pyran-2-yl), since side products probably arose from chlorination of the acetal group (entries 21 and 22).

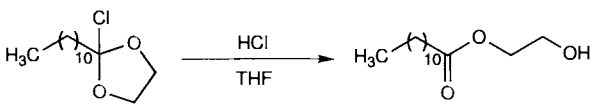
Direct dichlorination of saturated aldehydes at the α-position was achieved under mild conditions with two equivalents of tetraethylammonium trichloride (entry 14). Even with one equivalent of reagent, the reaction proceeded beyond the monochlorinated product. Ketones were selectively monochlorinated at the α-position (entry 15), but, unlike in the case of aldehydes, the reactions did not proceed to di- or trichloro derivatives. α,β-Unsaturated ketones (entries 16 and 17) were converted into the corresponding α,β-unsaturated α-chloroketones, probably via vicinal α,β-dichloroketones which underwent spontaneous dehydrohalogenation. Esters, with the exception of activated β-keto esters, failed to react (entry 18). Aromatic compounds activated with an electron-donating group were easily chlorinated at the *para* position (entry 19), and a bifunctional compound with both an activated aromatic ring and an alkyne functionality was preferentially chlorinated at the *para* ring position (entry 20).

Interestingly, the diethylene acetal of *n*-dodecanal was successfully chlorinated; the chlorine atom is on the dioxy carbon atom (entries 21 and 22). Treating this compound with 10% aqueous HCl afforded the corresponding ester in quantitative yield (Scheme 2). This is an unusual transformation, because the product usually isolated from the reaction of acetals with halogens is an α-halogenated acetal.[3] However, it was reported that acetals derived from non-enolizable aldehydes can be oxidized to the corresponding ester with *N*-bromosuccinimide under photolytic conditions[4] or in the presence of a radical initiator such as azobis(isobutyronitrile) (AIBN) or *t*-butyl peroxide.[5] However, in contrast to our chlorinated acetal derivatives, the intermediate brominated acetal could not be isolated.



Scheme 2. Hydrolysis of the chlorinated acetal.

In the presence of pyridine/1,4-diazabicyclo[2.2.2]octane (DABCO) in acetonitrile, tetraethylammonium trichloride oxidizes secondary and benzylic alcohols to the corresponding ketones or aldehydes (Table 2). The oxidation failed when dichloromethane was used instead of acetonitrile, or triethylamine in place of pyridine. Secondary alcohols were selectively

Table 2. Oxidations with tetraethylammonium trichloride.

oxidized over primary alcohols (entry 7). Allyl alcohols were not oxidized, but chlorinated at the double bond (entry 4).

Compared to other reagents,[2] tetraethylammonium trichloride has several advantages as a chlorinating or oxidizing agent. This stable, crystalline solid is more convenient to handle, and—unlike in the case of iodoperchloride salts—the reaction times are greatly reduced, and no iodine is produced that can give rise to by-products. In general, chlorination of alkenes or alkynes proceeded stereoselectively in excellent yields. Interesting results were obtained with acetals, which afforded stable chloroacetals in which the chlorine atom is located on the dioxy carbon atom.

Experimental Section

Synthesis of $Et_4N^+(Cl_3)^-$: A solution of Et_4NCl in CH_2Cl_2 was saturated with Cl_2. The solvent was then removed in vacuo to afford a yellow solid which can be stored for months under an argon atmosphere.

Chlorination: $Et_4N^+(Cl_3)^-$ (1.5–3 equiv) was added in one portion under an argon atmosphere at −78 or 0 °C to a solution of the substrate (1 equiv) in CH_2Cl_2 (0.3 M). After addition of water, the organic phases were dried over $MgSO_4$ and filtered on celite. The solvent was removed in vacuo, and the crude compound purified by column chromatography.

Oxidation: $Et_4N^+(Cl_3)^-$ (1–3 equiv) was added to a solution of the alcohol in CH_3CN (0.3 M) and pyridine (4 equiv) at room temperature. After disappearance of the yellow color, DABCO (1 equiv) was added. After completion of the reaction, the crude mixture was concentrated in vacuo, and the residue was purified by column chromatography.

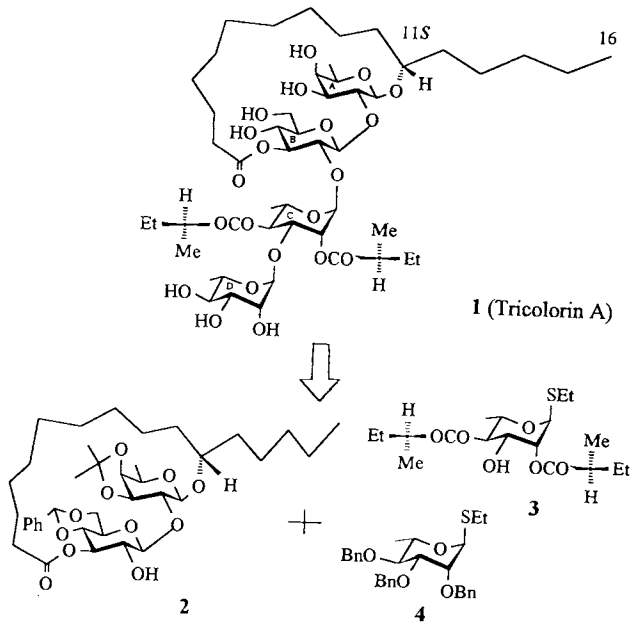
The First Total Synthesis of Tricolorin A

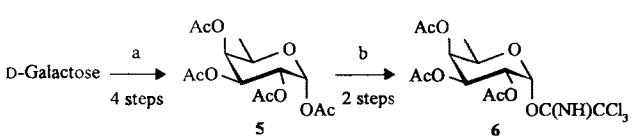
Shou-Fu Lu, QinQin O'yang, Zhong-Wu Guo, Biao Yu,* and Yong-Zheng Hui*

Tricolorin A, a member of the resin glycoside family, was first isolated by Pereda-Miranda et al. in 1993 from *Ipomoea tricolor cav.* (convolvulaceae), a plant used in traditional Mexican agriculture as a weed controller.[1] Bioassays showed that tricolorin A was not only largely responsible for weed-growth inhibition by the plant, but it also possessed significant cytotoxic activity against cultured P-388 and human breast cancer cells ($ED_{50} = 2.2\ \mu g\,mL^{-1}$).[1a] What attracted us most was the beauty of the structure of tricolorin A, which, bearing a disaccharide containing a 19-membered macrolactone, represents a perfect balance between hydrophobicity and hydrophilicity. We therefore directed our efforts towards the total synthesis of this interesting molecule, during the course of which Schmidt et al. accomplished a first total synthesis of another molecule of the resin glycoside family (calonyctin A).[2] Heathcock recently reported the synthesis of a macrolactone disaccharide subunit (**2**) of tricolorin A.[3] Coincidentally, we employed a similar strategy for assembling **2** in our total synthesis. Here we describe this total synthesis of tricolorin A. Of particular interest is the regioselective macrolactonization of a 1-hydroxycarbonyl-pentadec-10(s)-yl disaccharide to form the macrolactone disaccharide **2**, and a one-pot assembly of two monosaccharide donors (**3** and **4**, Scheme 1).[4]



Scheme 1. Retrosynthesis of tricolorin A.

First, four monosaccharide building blocks (**6**,[5] **8**,[6] **3**,[7] and **4**[4c]) were prepared as shown in Schemes 2–4. All are glycosyl donors either with a neighboring participating group (**6**, **8**, **3**) or with a strong anomeric effect (**3**, **4**) that is sufficient to cause highly selective β-glycosidation (for **6**, **8**) or α-glycosidation (for **3**, **4**). Methyl 11(s)-jalapinolate [methyl 11(s)-hydroxyhexadecanoate (**14**)][8] was prepared by employing a chiral-pool approach starting from D-(+)-mannitol (Scheme 5).[9]



Scheme 2. Preparation of monosaccharide synthon **6**: a) 1. anhydrous Cu_2SO_4, acetone, H_2SO_4 (concd, cat.), RT, 29 h, 62%; 2. *p*-TsCl (Ts = $H_3CC_6H_4SO_2$), pyridine (Py), 55 °C, 4 h, 94%; 3) $NaBH_4$, Me_2SO (DMSO), 120 °C, 5 h, 75%; 4. Ac_2O/HOAc (2/1), H_2SO_4 (concd, cat.), −15 °C, 4 h, 20%; b) 1. NH_3 in MeOH/THF (3:7), 0 °C, 3 h, 50%; 2. $CNCCl_3$, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), CH_2Cl_2, RT, 14 h, 79%.

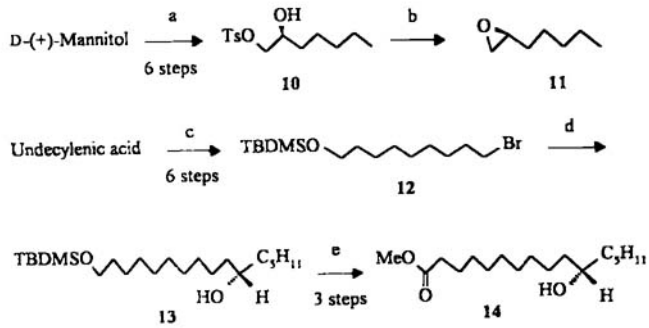
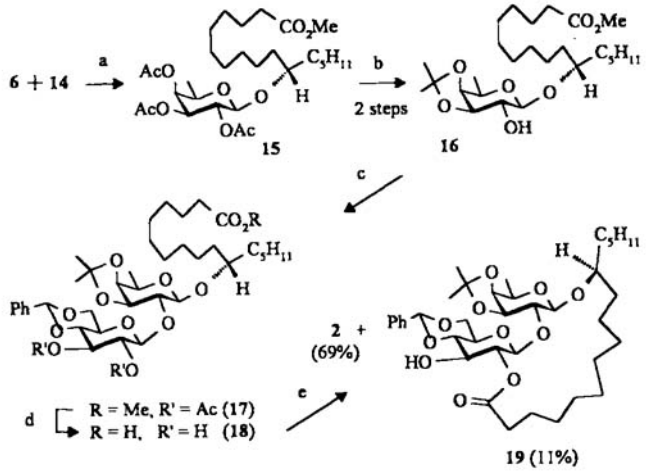
Bu_2SnO, toluene, reflux, 1 h, then *p*-$MeOC_6H_4CH_2Cl$ (PMBCl), CsF, Bu_4NI, DMF, RT, 33 h, 79%; 2. 2(*s*)-methylbutyric anhydride (2.0 equiv), 4-(dimethylamino)pyridine (DMAP), Py, RT, 27 h, 70%; 3. ceric ammonium nitrate (CAN, 2.0 equiv), CH_3CN/H_2O (9:1), 25 min, 97%; b) BnBr, NaH, DMSO, 0°C, 11 h, 52%.



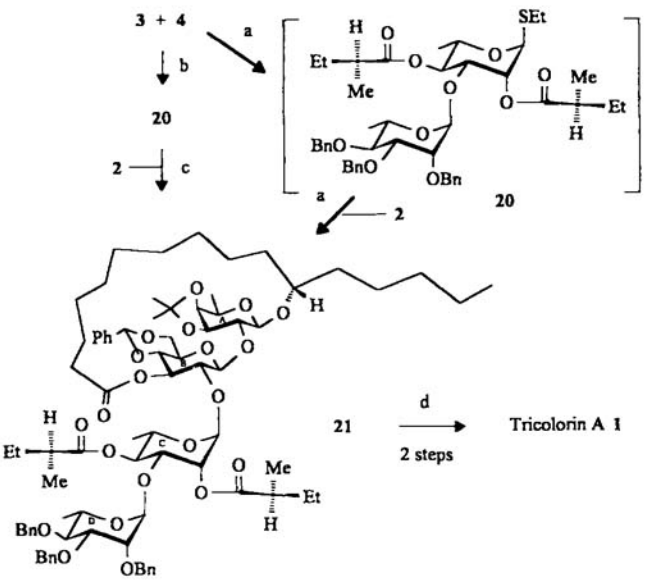
Scheme 5. Synthesis of methyl 11(*s*)-jalapinolate (**14**): a) 1. $ZnCl_2$, acetone, RT, 21 h, 32%; 2. $NaIO_4$, CH_2Cl_2/H_2O (20:1), RT, 1 h, 97%; 3. $Ph_3P^+(CH_2)_3CH_3Br^-$, THF, *n*BuLi/hexane, −78°C → 0°C, 2.5 h, 64%; 4. H_2, 10% Pd/C (cat.), 3 d; 5. 80% HOAc, 40°C, 20 h, 77% (2 steps); 6. *p*-TsCl, CH_2Cl_2, 0°C, 16 h, 44%; b) *t*BuLi/pentane (1.5 mol mL^{-1}), −30°C → RT, 1 h, 70%; c) 1. $LiAlH_4$, THF, reflux, 12 h, 95%; 2. Ac_2O, Py, RT, 2 h, 95%; 3. $KMnO_4$, benzene/H_2O/HOAc (4/4/1), Bu_4NI, RT, 14 h, 91%; 4. Br_2, HgO, CCl_4, reflux, 5 h, 83%; 5. *p*-TsOH (cat.), CH_3OH, reflux, 1.5 h, 92%; 6. *t*$BuMe_2SiCl$ (TBDMSCl), imidazole, RT, 3 h, 97%; d) Mg, THF, reflux, 2 h, then CuI (cat.), **11** (1.0 equiv), −78°C → RT, 2.5 h, 66%; e) 1. Ac_2O, Py, RT, 14 h, 91%; 2. Jones reagent, acetone, RT, 1.5 h, 89%; 3. $BF_3 \cdot OEt_2$ (3.0 equiv), MeOH, 40°C, 4 h, 97%.

With methyl 11(*s*)-jalapinolate (**14**) and monosaccharide donors **6** and **8** at hand, we sought to construct the macrolactone disaccharide **2** (Scheme 6). Alcohol **14** was readily glycosylated by imidate **6** using the procedure of Schmidt et al.[10] to afford **15**, which was sequentially subjected to deacetylation and isopropylidenization to give **16** with only the 2′-OH group free. Treatment of alcohol **16** with thioglycoside donor **8** in the presence of *N*-iodosuccinimide (NIS) and AgOTf (Tf = F_3CSO_2) in CH_2Cl_2 at −15°C led to disaccharide **17** in 76% yield, which was saponified with 3% KOH in MeOH/H_2O (9:1) to provide acid **18** with the 2″- and 3″-OH groups free. Regioselective macrolactonization of **18** by the Corey–Nicolaou protocol[11] gave the desired 3″-OH macrolactonized product **2** in 69% yield, together with the 2″-OH macrolactonized product **19** in 11% yield.[12]

Macrolactone tetrasaccharide **21** was finally assembled in 43% yield (based on consumed **2**) by a facile one-pot, two-step glycosylation of **2** with thioglycoside donors **3** and **4** using NIS/TfOH (cat., Scheme 7).[4] Alternatively, **21** was also constructed stepwise; disaccharide synthon **20**, the intermediate in the above



Scheme 6. Synthesis of macrolactone disaccharide **2**: a) **6** (0.9 equiv), $BF_3 \cdot OEt_2$ (1.2 equiv), CH_2Cl_2, −15°C, 1 h, 66%; b) 1. 1% NaOMe in MeOH, −15°C, 25 min; 2. $Me_2C(OMe)_2$, *p*-TsOH, acetone, 14 h, 82% (2 steps); c) **8** (1.6 equiv), NIS (3.0 equiv), AgOTf (1.0 equiv), 4-Å molecular seives, CH_2Cl_2, −15°C, 0.5 h, 76%; d) 3% KOH, MeOH/H_2O (9/1), reflux, 24 h, 91%; e) $(PyS)_2$, Ph_3P, toluene, reflux, 7 d, 69% for **2**, 11% for **19**.



Scheme 7. Synthesis of tricolorin A (**1**): a) **3** (1.2 equiv), **4** (1.0 equiv), NIS (1.4 equiv), TfOH (cat.), 4-Å molecular seives, Et_2O/DCE (1:1; DCE = 1,2-dichloroethane), −15°C, 15 min, then **2** (1.6 equiv), NIS (1.4 equiv), TfOH (cat.), 4-Å molecular seives, RT, 1 h, 43% (based on **2**); b) IDCP (2.3 equiv), 4-Å molecular seives, CH_2Cl_2, RT, 0.5 h, 98%; c) NIS (4.5 equiv), AgOTf (0.5 equiv), 4-Å molecular seive, CH_2Cl_2, RT, 1 h, 86%; d) 1. DDQ (3.0 equiv), CH_3CN/H_2O (9/1), reflux, 4 h, 80%; 2. H_2 (6 MPa), 10% Pd/C, 60°C, 7 h, 88%.

one-pot protocol, was efficiently synthesized by a reaction of thioglycosides **3** and **4** involving the well-known "armed–disarmed" glycosidation approach[13] in the presence of iodium di-*sym*-collidine perchlorate (IDCP).[14] Glycosylation of macrolactone disaccharide **2** by disaccharide donor **20** in the presence of a promoter (NIS/AgOTf)[15] afforded the important precursor (**21**) of tricolorin A in good yield (86%). Final deprotection of the 3′,4′-*O*-isopropylidene and 4″,6″-*O*-benzylidene of **21** by DDQ[16] followed by removal of the benzyl groups by hydrogenation provided tricolorin A in 70.4% yield. The physical data obtained were essentially identical to those reported.[1, 17]

We have achieved the first total synthesis of tricolorin A in a total of 45 steps, where the longest linear sequence consists of

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3621-2345 $ 17.50+.50/0

20 steps, and the overall yield is 0.65% starting from D-(+)-mannitol. The synthetic route features regioselective macrolactonization of a disaccharide bearing a 19-membered ring and a one-pot glycosidation for construction of a macrolactone tetrasaccharide.

Fluorous Biphasic Catalysis: Complexation of 1,4,7-[$C_8F_{17}(CH_2)_3$]$_3$-1,4,7-Triazacyclononane with [$M(C_8F_{17}(CH_2)_2CO_2)_2$] (M = Mn, Co) To Provide Perfluoroheptane-Soluble Catalysts for Alkane and Alkene Functionalization in the Presence of *t*-BuOOH and O_2**

Jean-Marc Vincent, Alain Rabion, Vittal K. Yachandra, and Richard H. Fish*

Recently, Horváth and Rábai published a seminal paper on a new homogeneous catalysis concept—Fluorous Biphasic Catalysis (FBC)—that entailed the use of a fluorocarbon as one phase containing a modified catalyst with polyfluorinated alkyl side chains (fluoroponytails), while the substrate and the product were soluble in a second hydrocarbon phase.[1] It is also important to note that low-boiling, perfluorinated solvents are immiscible both in water and many organic solvents.[2] Therefore, separation of the product from the catalyst occurred by solubility differences between the hydrocarbon and fluorocarbon phases; this process thus represents a potentially interesting new concept for the industrial synthesis of important chemicals.[1, 3, 4]

In this communication, we present the synthesis of a new fluoroponytailed ligand (**4**), namely, tris-*N*-(4,4,5,5,6,6,7,7,8,8,9,9,10,10,11,11,11-heptadecafluoroundecyl)-1,4,7-triazacy-

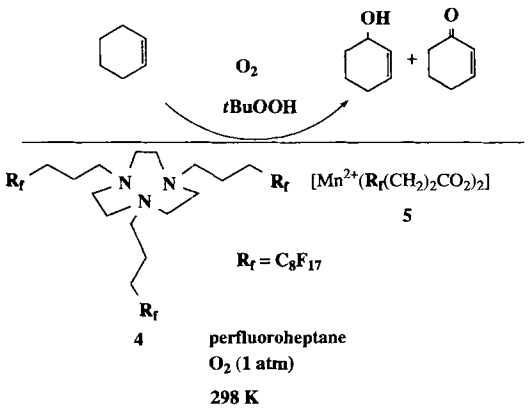
$[Co(O_2C(CH_2)_2C_8F_{17})_2]$ **6**

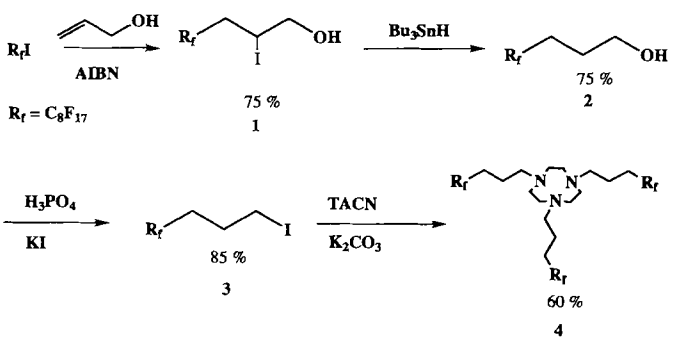
tion of alkanes and alkenes, using in situ generated $[R_fMn^{2+}(R_fTACN)]$ and $[R_fCo^{2+}(R_fTACN)]$ complexes (**7** and **8**, respectively) as catalysts that are totally soluble in the fluorous phase (Scheme 1). In contrast to the new FBC concept, the oxidation



Scheme 1. Fluorous biphasic oxidation catalysis with cyclohexene as the substrate and complex **7** formed in situ with **4** and **5**.

of alkanes with *tert*-butyl hydroperoxide (TBHP) in acetonitrile and epoxidation of alkenes with H_2O_2 in acetone were previously achieved in one homogeneous phase by the in situ preparation of Mn^{2+} catalysts containing 2,2′-bipyridine and tris-N-methyl-TACN ligands, respectively, and separation of the Mn catalyst from the product is relatively difficult or impossible.[5] We will demonstrate that this novel FBC approach for separation of the catalyst from the substrate appears viable for oxidation of alkanes and alkenes in the presence of the necessary oxidants, TBHP and O_2 gas, and that these oxidation reactions occur by an autoxidation mechanism under our FBC conditions.[6, 7]

One key component of the FBC approach includes the new fluoroponytailed ligand **4**, synthesized by the sequence of reactions shown in Scheme 2. It is important to note that the three-methylene spacer in **3** is necessary, not only to insulate the amine from the powerful electron-withdrawing effect of the perfluoroalkyl group, but also to avoid a facile elimination reaction of HI that predominately occurs when a two-carbon spacer is used



Scheme 2. Synthesis of **4**.

during the formation of **4**. The first step to the new perfluoroalkyl iodide **3** proceeds by a free radical addition of a perfluoroalkyl iodide (R_fI) to allyl alcohol that was initiated with AIBN to provide the perfluoroalkylated iodohydrin **1**.[8] Compound **1** was then reduced to the perfluoroalkyl alcohol **2** by using tributyltin hydride in dry benzotrifluoride.[9] Iodination of **2** to form **3** was achieved with 85% phosphoric acid in the presence of phosphorous pentaoxide and potassium iodide in 85% yield.[10] Finally, ligand **4** was obtained from TACN and **3** in $DMSO/K_2CO_3$ in 60% yield after recrystallization (Scheme 2; see Experimental Section). Compound **4** is soluble in cold perfluorohexane and perfluoromethylcyclohexane, and represents, to our knowledge, the first example of an R_f-amine ligand that is soluble in a perfluorocarbon solvent.

The other important components were the new R_fMn^{2+} and R_fCo^{2+} complexes **5** and **6** synthesized by reaction of $Mn(ClO_4)_2 \cdot 6H_2O$ or $Co(ClO_4)_2 \cdot 6H_2O$ in acetone with two equivalents of the triethylammonium salt of the 3-R_f-alkylpropanoic acid, $C_8F_{17}CH_2CH_2CO_2H$; elemental analysis of **5** and **6** provide a metal-to-carboxylate ligand ratio of 1:2, while **5** was found to be slightly soluble in perfluorocarbons, exhibits an intense and broad ESR signal at $g = 2$ (9 K), and displays the characteristic 6-line hyperfine structure ($J = 90$ G) of a mononuclear Mn^{2+} complex.[11] Interestingly, when one equivalent of **4** was added to a solution of **5** in perfluoroheptane, a UV absorption band appears at 320 nm, tentatively suggesting that a new $[R_fMn(R_fTACN)]^{2+}$ complex (**7**) was formed in situ. Similarly, when ligand **4** and complex **6** were combined the complex $[R_fCo(R_fTACN)]^{2+}$ (**8**) resulted.

The FBC oxidation results for several substrates are presented in Table 1. All the experiments were carried out under biphasic conditions, generating complexes **7** or **8** in situ in perfluoroheptane (Scheme 1), while the upper phase was the substrate itself. Importantly, the oxidation products were detected only in the colorless upper phase after decantation (GC), while the colored perfluoroheptane lower phase contains only traces (< 5%) of product. Clearly, a facile and rapid separation of the products from the catalyst was achieved with this FBC approach.

Table 1 demonstrates that the olefin with allylic hydrogens, cyclohexene, provides the highest yield of oxidation products (650% with TBHP in 3 h), while alkane oxidation was much lower (cyclohexane: 12% cyclohexanol (CyOH)/cyclohexanone (CyONE) with TBHP in 24 h; toluene: 65% $PhCH_2OH/PhCHO$ with TBHP in 24 h). In the presence of a vigorously stirred mixture of **7**, TBHP, and oxygen gas (1 atm), cyclohexene was converted into a product ratio of 2-cyclohexen-1-one (CyenONE, about 65%), 2-cyclohexen-1-ol (CyenOH, about

Table 1. Functionalization of alkenes and alkanes under fluorous biphasic catalysis conditions [a].

Cat.	Substrate	Oxidant	Product (μmol)	Yield [b] [%]	Time [h]
7	cyclohexene	$TBHP/O_2$	CyenOH (160), CyenONE (300)	650	3
7	cyclohexene	TBHP	CyenOH (<2), CyenONE (<2)		7
7	cyclohexene	O_2	CyenOH (<1), CyenONE (<1)		24
5	cyclohexene	$TBHP/O_2$	CyenOH (130), CyenONE (160)	360	12
7	styrene	$TBHP/O_2$	no epoxide		24
7	toluene	$TBHP/O_2$	PhCHO (15), $PhCH_2OH$ (30)	65	24
7	cyclohexane	$TBHP/O_2$	CyOH (5), CyONE (3.5)	12	24
8	cyclohexene	$TBHP/O_2$	CyenOH (185), CyenONE (360)	750	20
8	cyclohexane	$TBHP/O_2$	CyOH (7), CyONE (5.5)	17	24

[a] Conditions: **5** or **6** (3.5 μmol) and **4** (3.5 μmol) were dissolved in hot perfluoroheptane (3 mL) and then the substrate (2 mL) was added. The reaction starts after the addition of TBHP (90%, 72 μmol) under an O_2 atmosphere when required. [b] Total yield was based on TBHP added.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3621-2347 $ 17.50+.50/0

35%), and a small amount of cyclohexene oxide (<2%), while with complex **8** similar oxidation results were obtained. Styrene, with no allylic hydrogens, is not converted into styrene epoxide under these biphasic conditions. In the absence of O_2 or TBHP, only negligible amounts of 2-cyclohexen-1-ol and 2-cyclohexen-1-one were detected, indicative of an autoxidation reaction; that is, *both* were necessary for oxidation to proceed. At the end of the reaction the upper phase was removed, and new aliquots of cyclohexene and TBHP were added to provide a 400% yield after 5 h, showing that the catalyst, after decantation, was only present in the lower fluorocarbon phase.

These results were in agreement with an autoxidation mechanism involving alkoxy (RO$^\cdot$) or alkylperoxy (ROO$^\cdot$) radicals,[12] where the reaction was initiated by tBuO$^\cdot$ or tBuO$_2^\cdot$ radicals produced from redox reactions (Haber–Weiss Process, Equations 2 and 3 with Mn^{2+}/Mn^{3+}). In the case of the substrate

$$Mn^{2+} + RO\text{-}OH \xrightarrow{\text{Reduction}} RO^\cdot + Mn^{3+} + HO^- \quad (1)$$

$$Mn^{3+} + ROO\text{-}H \xrightarrow{\text{Oxidation}} RO_2^\cdot + Mn^{2+} + H^+ \quad (2)$$

cyclohexene, the allylic radical formed was then trapped by O_2 ($k > 10^9\,M^{-1}sec^{-1}$) to provide cyclohexenylperoxy radicals, which were able to homolytically remove a hydrogen (bond energy of RCOO–H 90 kcal mol^{-1}) from benzylic or allylic C–H bonds (85 kcal mol^{-1}), and hence, propagate the radical reactions. The secondary cyclohexenyl hydroperoxide that was formed then decomposes catalytically in the presence of the Mn catalyst to give the alcohol and the ketone products.[13]

The lower yields observed in the case of cyclohexane are consistent with the stronger C–H bond strength (95 kcal mol^{-1}),[12] which implicates the cyclohexylperoxy radical and thus causes a lowering of the rate of the propagation step. The chain termination step presumably comes mainly from the coupling of two cyclohexenylperoxy radicals to give alcohol, ketone, and O_2 (Russell-type mechanism).[12]

The R_fMn complex, formed during the oxidation of **7**, was plausibly a $R_fMn^{3+}Mn^{4+}$ dimer. Therefore, when TBHP was added to the reaction mixture, the solution turns brown and exhibits intense UV-Vis absorptions (ε per Mn atom is approximately 9000 and 1130 $M^{-1}cm^{-1}$ at 300 and 500 nm, respectively, after 1 h) characteristic of dinuclear $Mn^{3+}Mn^{3+}$, $Mn^{3+}Mn^{4+}$, or $Mn^{4+}Mn^{4+}$ complexes.[14] The occurrence of such a putative $R_fMn^{3+}Mn^{4+}$ dimer from starting complex **7**, under oxidation conditions, was unambiguously confirmed by ESR studies at 9 K. Thus, a strong, distinctive 16-line signal of an antiferromagnetically coupled $R_fMn^{3+}Mn^{4+}$ dimer complex at $g = 2$ was observed in the perfluoroheptane phase, after 1 h of reaction. Indeed, it has recently been shown that the decomposition of TBHP in the presence of a dinuclear Mn_2^{3+}(2-OHsalpn)$_2$ complex (salpn = bis(salicylidene)propylenediamine dianion) resulted in the formation of tBuO$^\cdot$ radicals and a dinuclear $Mn^{3+}(\mu\text{-}O)_2Mn^{4+}$ complex.[15]

Furthermore, reaction 2 was favored over reaction 3 with complex **7** for two important reasons: 1) It has been previously shown that in nonpolar solvents equation 3 was very slow,[16] and 2) the $R_fMn^{3+}Mn^{4+}$ dimeric species formed upon the addition of TBHP to complex **7** was not very efficient in the oxidation of TBHP. Interestingly, after three hours, the 16-line ESR signal had almost disappeared, which suggests that this $R_fMn^{3+}Mn^{4+}$ dinuclear mixed valent species might be involved in the catalytic decomposition of the cyclohexenyl hydroperoxide intermediate to provide the alcohol and ketone products.

Finally, as pointed out recently by Pozzi et al.,[17] despite the apparent simplicity of the FBC concept the concrete demonstration of this strategy is still a difficult challenge, since the solubilization of the fluoroponytailed metal complexes used in perfluorocarbons is one limiting step along with catalyst stability and the favorable recycling of the catalyst system. We now have been able to solubilize complexes **7** and **8** successfully in perfluoroheptane, using both the new R_fTACN ligand **4** and the new R_fMn^{2+} and R_fCo^{2+} complexes **5** and **6**, with fluoroponytailed carboxylate ligands. Moreover, we have been able to perform alkane and alkene oxidations under FBC conditions in the presence of TBHP and O_2 as oxidant, and hence, separate the products from the catalyst by a simple decantation process. The oxidation process occurs by an autoxidation mechanism, with formation of alkenyl or alkyl hydroperoxides as the key intermediates, which then are catalytically decomposed by the R_fMn- or R_fCoR_fTACN catalyst, probably at the solvent interface, to provide the alcohol and ketone products. Future studies will attempt to ascertain the unequivocal structures of complexes **5**–**8** by single-crystal X-ray crystallography, define the role of the dinuclear $R_fMn^{3+}Mn^{4+}$ complex in the decomposition of the alkyl and alkenyl hydroperoxide intermediates and determine its full structure, as well as further the scope of the FBC approach to oxidation chemistry.

Experimental Section

4: TACN (88.4 mg, 0.73 mmol), K_2CO_3 (423 mg, 3.1 mmol), and $R_fCH_2CH_2CH_2I$ (1.41 g, 2.41 mmol) were dissolved in DMSO (10 mL, distilled over CaH_2) and heated at 90 °C for 24 h. Then perfluoroheptane (20 mL) was added to the reaction mixture, and the brown fluorous lower phase was separated and then filtered. After removing the solvent, compound **4** was obtained as a brown oil. After crystallization from hot hexane, compound **4** was isolated as a yellowish powder in 60% yield. FAB/MS: m/z 1510 [$M+H^+$]. Elemental analysis calcd for $C_{39}H_{30}F_{51}N_3$: C 31.03, F 64.20, H 1.98, N 2.78; found: C 30.74, F 64.31, H 2.02, N 2.70. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta = 2.71$ (s, 12H, NCH_2CH_2N), 2.55 (t, 6H, NCH_2CH_2), 2.17 (m, 6H, $CH_2CH_2CH_2$), 1.58 (m, 6H, $CH_2CH_2R_f$).

5: $CF_3(CF_2)_7CH_2CH_2CO_2H$ (1.35 g, 2.80 mmol) was dissolved in acetone (15 mL) and to this solution was added triethylamine (380 mL, 2.80 mmol). This resulting solution was added dropwise to $Mn(ClO_4)_2\cdot 6H_2O$ (500 mg, 1.37 mmol) dissolved in acetone (30 mL). The sticky precipitate that formed was vigorously stirred for 2 h. After filtration, **5** was obtained as a white powder in 75% yield. Elemental analysis calcd for $C_{22}F_{34}H_{12}O_6Mn$: C 24.61, F 60.19, H 1.12, Mn 5.12; found: C 25.37, F 59.77, H 0.94, Mn 5.50.

6: The same procedure as for complex **5** was used for the synthesis of **6**, except with $Co(ClO_4)_2\cdot 6H_2O$. A pink precipitate formed immediately, and after filtration, a pink powder was obtained in 100% yield. Elemental analysis calcd for $C_{22}H_{12}F_{34}CoO_6$: C 24.53, H 1.11, F 59.98, Co 5.46; found: C 25.05, H 1.27, F 60.15, Co 5.35.

A 1,3,5-Triphosphinantriium Ion**

Ekaterina Gorbunowa, Gernot Heckmann, Ekkehard Fluck,* Matthias Westerhausen, and Rudolf Janoschek

Dedicated to Professor Hans Georg von Schnering

In 1976 we prepared the spherical, negatively charged $[P_{12}S_{12}N_{14}]^{6-}$ ion by reaction of P_4S_{10} with potassium cyanate.[1] In spite of the spatial proximity of the charge carriers, the anion is both thermally stable and stable to hydrolysis. The 1,1,3,3,5,5-hexakis(dimethylamino)-1λ^5,3λ^5,5λ^5-triphosphinantriium cation **2** has also proved to be thermally stable. The charge carriers in the six-membered ring are separated from one another by just a single CH_2 group. Cyclic phosphonium salts with two positively charged phosphorus atoms and symmetrically arranged phosphorus–carbon units have been described previously.[2–7] However, in the quadruply charged P–C heterocycles known to date, three or four methylene groups separate the individual phosphorus atoms and thus 16-membered or 20-membered rings are present.[4] A cyclic dication prepared by Karsch that contains two phosphonium centers and a phosphane center in the 1,3,5 positions could not be quaternized to the 1,3,5-trication; instead, ring-opening occurred.[8]

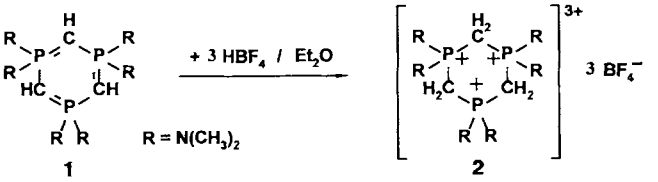
[**] This work was supported by the Fonds der Chemischen Industrie.

Compound **2** is formed by the reaction of 1,1,3,3,5,5-hexakis(dimethylamino)-1,3,5-triphosphinine (**1**) with $HBF_4 \cdot Et_2O$ in diethyl ether with a yield of 79.3 %. The colorless crystalline compound melts at 211–212 °C and is soluble in acetonitrile.



The singlet at δ = 45.21 in the $^{31}P\{^1H\}$ NMR spectrum of **2** indicates that a planar ring is present within the scope of the NMR time scale. The position of the singlet is—compared with the position of the signal of the ylidic PCP triad of the starting material **1**—shifted upfield by 20.2 ppm in the region of the λ^5-1,3-diphosphetes.[9] The base of the singlet has a narrow line width and is flanked by two pairs of ^{13}C satellites.[10] Together with the triplet observed in the $^{13}C\{^1H\}$ NMR spectrum at δ = 18.26, which displays individual lines with different structures, these four ^{13}C satellites permit the full evaluation of the A_2BX spin system of the [$^{13}C_1$] isotopomer of **2**. A ^{13}C-DEPT experiment confirmed unequivocally the presence of the endocyclic CH_2 groups. The small geminal P–P coupling constant of 4.0 Hz is characteristic for a P–CH_2–P group.[11] The ^2J(P,P) coupling constant of the P=C–P triad in the starting material **1** was determined to be 73 Hz. As is the case in **1**, a small negative vicinal P–C coupling constant is found in the ring (−1.8 Hz).[12]

The crystal structure analysis of **2** in the solid state revealed a six-membered heterocycle; the atoms P1, P3, C2, and C3 lie almost in a plane (Figure 1). P2 and C1 are both located above

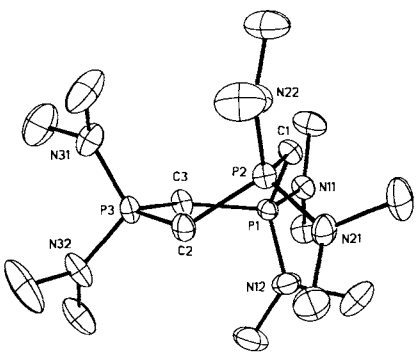


Figure. 1. Molecular structure of the cation **2** in the crystal (thermal ellipsoids at 50 % probability, H atoms not shown for clarity). Selected distances [pm] and angles [°]: P1–C1 178.9 (3), P1–C3 180.6(3), P2–C1 180.2(3), P2–C2 181.2(3), P3–C2 180.7(3), P3–C3 181.7(3); P1-C1-P2 114.3(2), P1-C3-P3 117.4(2), C1-P2-C2 108.32(13), P2-C2-P3 119.9(2), C2-P3-C3 108.90(14), C3-P1-C1 103.8(2).

this plane; their positions in the ring are characterized by greatly different bond angles (P2-C2-P3: 119.9°, C1-P1-C3: 103.8°) and by distances between 178.9 and 181.2 pm, which are typical for P–C single bonds.[13] The nitrogen atom environments are approximately planar. The P–N bond lengths (160.7–162.0 pm) are about 7 pm shorter than those found in the starting material **1** and in 1λ^5,3λ^5-diphosphinines.[14, 15] There are no interactions between the triply positively charged six-membered ring and the tetrafluoroborate ions, and there is no H···F bridging. The peaks of the singly and doubly charged cations

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3621-2349 $ 17.50+.50/0

can be found in the positive-ion FAB mass spectrum of **2** with the corresponding ^{13}C peaks. The signal of the triply charged cation was not detected. Density function calculations (B3LYP/6-31G*) on the more simple ion $[\{P(NH_2)_2\}_3\{CH_2\}_3]^{3+}$ showed a puckered ring at the energy minimum for C_1 symmetry with an average P–C bond length of 185 pm.[16]

Experimental Section

A solution of $HBF_4 \cdot Et_2O$ (1.12 mL, 8.4 mmol, $\rho = 1.19\ g mL^{-1}$) in diethyl ether (10 mL) was slowly added to a cooled (−20 °C) solution of **1** (0.67 g, 1.69 mmol) in diethyl ether (10 mL). Compound **2** began to precipitate immediately. The pale pink colored reaction solution was warmed to room temperature and stirred for a further 12 h. After the mixture had been filtered, the resulting crystalline precipitate of **2** was analytically pure. Clear, colorless crystals were obtained by recrystallization from an acetonitrile/diethyl ether solution at room temperature. Yield: 0.91 g (79.3 %). $M = 659.8\ g mol^{-1}$. MS (positive-ion FAB, NBA) *m/z* (%): 398 (16) $[M^* - 2H^+, {}^{13}C]$, 397 (100) $[M^* - 2H^+]$, 199.6 (2) $[M^* - H^+, {}^{13}C]$, 199.1 (18) $[M^* - H^+]$; $M^* = M - 3BF_4^-$; ^1H NMR (250 MHz, CD_3CN, 300 K, TMS): δ = 4.06 (t, $^2J(H,P) = 17.7$ Hz, $^4J(H,P) < 0.3$ Hz, 6H; CH_2,), 2.97 (d, $^3J(H,P) = 12.2$ Hz, 36H; CH_3); $^{31}P\{^1H\}$ NMR (161.978 MHz, CD_3CN, 305 K, 85% H_3PO_4): $\delta = 45.21$ (s, $^2J(P,P) = 4.0$ Hz according to A_2BX simulation); ^{13}C NMR (100.614 MHz, CD_3CN, 305 K, TMS): $\delta = 18.26$ (A_2BX simulation: $^1J(P,C) = 80.0$ Hz, $^3J(P,C) = -1.8$ Hz, $^1J(C,H) = 130.2$ Hz; CH_2), 38.45 (s; CH_3); ^{19}F NMR (235.360 MHz, CD_3CN, 300 K, $CFCl_3$): $\delta = -149.31$ (s); IR (Nujol, CsBr plates): $\tilde{\nu}$ = 1301 (s), 1213 (m), 1168 (m), 1061 (vs), 1053 (sh), 998 (m), 991 (sh), 838 (m), 722 (vw), 521 (vw) cm^{-1}.

$[CH(Me)P(Et)_2NSiMe_3]^-$—A Carbanion That Functions as a Bridging Ligand**

Anita Müller, Bernhard Neumüller, and Kurt Dehnicke*

In the solid state the lithiation products of *N*-(trimethylsilyl)phosphanimines, for example the tetrameric methyl derivative **1**[1] and the dimeric compounds **2**[1] and **3**,[2] are aggregated to oligomers, in which the N atoms participate by internal solvation. Their preparative potential has scarcely been made use of to date. Compound **1** reacts with chlorotrimethylsilane under elimination of LiCl to form the corresponding silylation product,[3a] whereas the reaction of **1** with zinc chloride, in which the latter functions primarily as a catalyst, the carbadianionic Li_{14} cluster **4** is obtained.[4] Very recently the formation of trimethylsilyliminophosphoranylenamidolithium complexes by treatment of α-lithiated phosphanimines of type **1** with benzonitrile was reported.[3b]

$[\{LiCH_2P(Me)_2NSiMe_3\}_4]$ **1**

$[\{LiC(Me)_2P(iPr_2)NSiMe_3\}_2]$ **2**

$[\{Li(C_6H_4)P(Ph)_2NSiMe_3\}_2(Et_2O)]$ **3**

$[\{Li_7[CHP(Me)_2NSiMe_3]_3[OSi(Me)_2nBu]\}_2]$ **4**

We have now established that the ethyl derivative **5**, the crystal structure of which[5] is analogous to that of the tetrameric **1**, is an attractive reagent. Its carbanionic C atom is asymmetrically substituted and, as a consequence of the internal solvation of the Li atoms, it forms strained Li-C-P-N four-membered rings; thus, it is extraordinarily reactive. Compound **5** is readily obtained from $Me_3SiNPEt_3$ and *n*-butyllithium in *n*-hexane; it is a viscous oil, which crystallizes slowly at −30 °C. With copper(I) iodide and with zinc chloride, **5** reacts according to Equations (1) and (2) forming the well-defined metal derivatives **6** and **7**, respectively, with unusual structures.

$$\underset{\mathbf{5}}{[\{LiCH(Me)P(Et)_2NSiMe_3\}_4]} + 2\,CuI \longrightarrow \underset{\mathbf{6}}{2[CuLi\{CH(Me)P(Et)_2NSiMe_3\}_2]} + 2\,LiI \quad (1)$$

$$3\,\mathbf{5} + 12\,ZnCl_2 \rightarrow \underset{\mathbf{7}}{[\{ClZnCH(Me)P(Et)_2NSiMe_3\}_{12}]} + 12\,LiCl \quad (2)$$

Addition of **5** to suspensions of the metal halides in diethyl ether causes rapid dissolution of the solids; after a rather long crystallization period **6** and $7 \cdot 4Et_2O$ are obtained as colorless single crystals. According to the crystal structure analysis[6] **6** is a lithium cuprate whose carbanionic atoms C1 and C10 are asymmetrically substituted and in which both copper and lithium exhibit almost linear coordination (Figure 1). The two metal atoms link the two carbanions $[CH(Me)P(Et)_2NSiMe_3]^-$ to form an undulated eight-membered ring with approximate C_2 symmetry. The Li-N-P bond angles in **5** (94.6°) are smaller than in **6** (mean 112.3°), and the N-P-C angles of 108.8° in **5** are increased to 112.2° in **6**, indicating a practically unstrained eight-membered ring. A similar eight-membered ring structure to that in **6** occurs in the dimeric ylidic copper complex $[\{CuMe_2P(CH_2)_2\}_2]$ (**8**).[7]

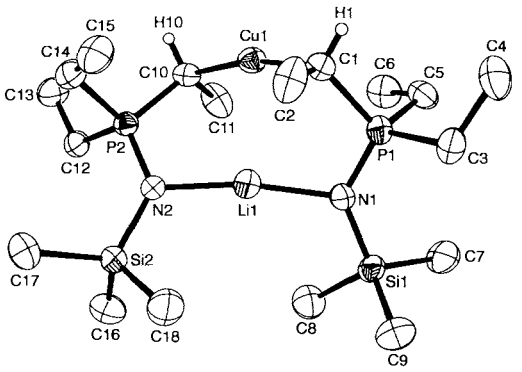

Figure 1. Molecular structure of **6** in the crystal. Selected (in some cases average) bond lengths [pm] and angles [°]: Cu–C 195.4(2), Li–N 194.2(4), P–C1,10 176.7(2), P–N 159.6(2); C1-Cu1-C10 167.2(1), N1-Li1-N2 169.9(3), Cu-C-P 108.5(2), Li-N-P 112.3(2), N-P-C1,10 112.2(1).

Figure 1 shows the (*S*,*S*) configurated molecule, which in the given centrosymmetric space group $P\bar{1}$ requires a (*R*,*R*) configurated molecule as counterpart. The Cu–C bond lengths of 195.1 and 195.6 pm agree well with those in other organocopper compounds in which the copper atom adopts a coordination number (CN) of 2.[8] In spite of the low coordination number at the lithium atom of **6** there is no tendency towards solvation with diethyl ether. This has recently been established for a series of lithium cuprates in THF solutions by accurate cryoscopic measurements, and leads to cleavage of higher aggregated structures.[9] We attribute this behavior of **6** to the shielding effect of the methyl groups of the $SiMe_3$ moieties. The two Li–N bonds in **6** are the same length within standard deviations; the average Li–N bond length of 194.2 pm in **6** is thus significantly shorter than that in trimeric lithium amides like $[\{LiN(SiMe_3)_2\}_3]$[10] and in the trimeric *N*-lithio-*N*-trimethylsilyl-9-amino-9-borabicyclo[3.3.1]nonane.[11] In these compounds, in which CN = 2 at Li and CN = 4 at the N atoms, the Li–N bond lengths range from 197 to 200 pm. Because of their ylidic character the P–C bonds of the carbanionic atoms C1 and C10 (176.7 pm) are, as in **5**, significantly shorter than the P–C(Et) bonds of 182.6 pm.

Likewise in the zinc compound **7**, the main feature of the structure[12] is the heterocyclic undulated eight-membered rings, in which pairs of zinc atoms are linked by the two carbanions $[CH(Me)P(Et)_2NSiMe_3]^-$ (Figure 2). Compared with simple dialkylzinc complexes that contain N-donor molecules, in which the Zn–C distances range between 197.5 and 200.0 pm and the Zn–N distances between 227 and 241 pm,[13] the average Zn–C bond lengths in **7** are slightly longer (204.9 pm), whereas the Zn–N distances of 203.2 pm are considerably shorter. Along with the relatively short P–C and P–N distances in the carbanionic bridging ligand this suggests electron delocalization within the CPN fragment. The eight-membered rings in **7** are additionally capped by a chlorine atom that bridges the two zinc atoms, forming acute Zn-Cl-Zn bond angles of 82.7°. The eight-memebered rings are organized to a cyclic dodecamer through the formation of μ_2-chloro bridges with obtuse Zn-Cl-Zn bond angles of 127.4° (Figure 3). Despite the different bond angles at the chlorine atoms all Zn–Cl distances are equal within standard deviations. The result is a 24-membered ring structure with an outer diameter of 2.5 nm, consisting of twelve Zn and twelve Cl atoms. The asymmetric unit contains six chiral centers at the zinc atoms and six at the carbanionic C atoms. Owing to the centrosymmetry of the dodecamer the entire molecule is a racemate. Considering the van der Waals radii the cavity in the interior of the ring has elliptic diameters of 140 and 430 pm, which is thus too narrow even for a H_2 molecule. Hence, a template effect similar to that considered responsible for the formation of some abiotic macrocycles[14] can be excluded for the synthesis of **7**.

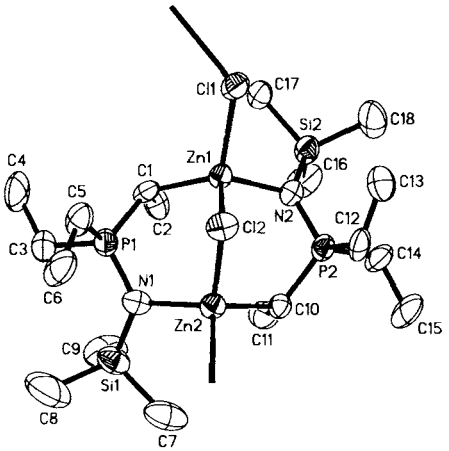

Figure 2. Section of the dodecameric structure of **7**. The average bond lengths [pm] and angles [°] refer to all atoms of the asymmetric unit: Zn–C 204.9(7), Zn–N 203.2(6), Zn–Cl 239.5(2), P–C(carbanion) 176.7(8), P–N 162.1(6); C-Zn-N 120.4(3), Cl-Zn-Cl 94.7(1), Zn-Cl[a]-Zn 82.7(1), Zn-Cl[b]-Zn 127.4(1), Zn-C-P 114.6(4), Zn-N-P 115.5(3), N-P-C 112.5(3). Cl[a]: inside dimeric units; Cl[b]: between dimeric units.

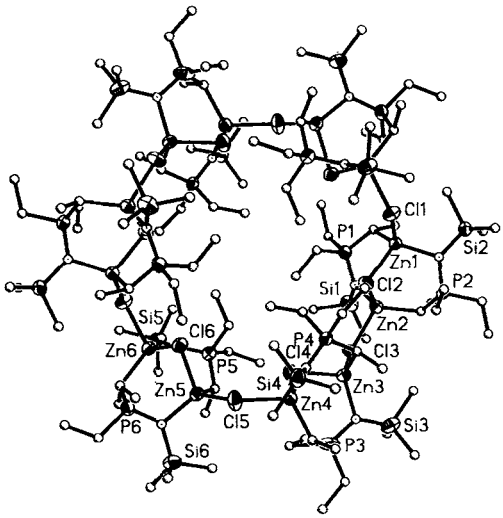

Figure 3. Dodecameric ring structure of **7** in the crystal; the atoms of the asymmetric unit are numbered.

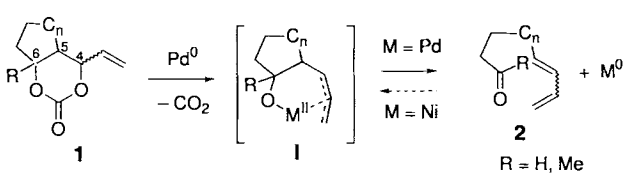
Synthesis of Doubly Unsaturated Aldehydes and Ketones by a Novel β-Decarbopalladation**

Hiroto Harayama, Toshitsugu Kuroki, Masanari Kimura, Shuji Tanaka, and Yoshinao Tamaru*

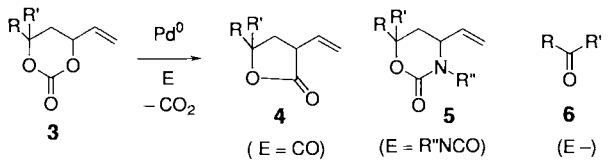
Owing to their synthetic importance and mechanistic interest, transition metal catalyzed or promoted cyclizations of 1,ω isomers of enals,[1] enecarboxylic esters,[2] dienals,[3] dienes,[4] and enynes[5]—which provide vicinally difunctionalized cycloalkanes and heterocycles—have been rapidly developed and extensively studied. Interestingly, however, the reverse process, a ring-opening reaction, has received less attention. Here we report a novel Pd^0-catalyzed ring opening of 4-vinyl cyclic carbonates **1**, furnishing a variety of dienals and dienones **2** in excellent



1 **I** **2**

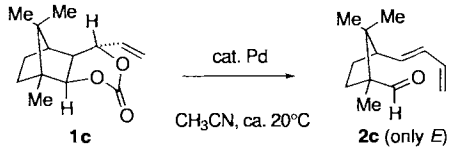
yields. The reaction most likely proceeds by β-decarbopalladation of the π-allylpalladium intermediate **I** (M = Pd), which is formally the reverse process of the Ni^0-catalyzed cyclization of **2** to **I** (M = Ni) reported by Mori et al.[3]

We studied the Pd^0-catalyzed decarboxylative carbonylation (providing **4**, E = CO)[6] and the carbonate–carbamate transformation (providing **5**, E = TsNCO or ArNCO)[7] of monocyclic carbonates **3**. In the absence of electrophilic reagents E, **3** yielded aldehydes (e. g. benzaldehyde in 88% yield) and ketones **6** (e. g. dibenzyl ketone in 80% yield) upon treatment with $[Pd_2(dba)_3] \cdot CHCl_3$ (0.05 equiv, dba = dibenzylideneacetone) in dry acetonitrile at room temperature.



3 **4** **5** **6**

To test the generality of this fragmentation reaction, we examined tricyclic carbonate **1c** under various conditions (Scheme 1).



1c **2c** (only *E*)

1 $[Pd_2(dba)_3] \cdot CHCl_3$ / 72 h / 70%
2 $[Pd_2(dba)_3] \cdot CHCl_3$ + $P(OMe)_3$ (0.4 equiv) / 7 h / 82%
3 $[Pd(PPh)_4]$ / 72 h / 75%
4 $[PdCl_2\{P(o\text{-}Tol)_3\}_2]$ / 72 h / 0%
5 $Pd(OAc)_2$ / 120 h / 0%

Scheme 1. Yield of isolated **2c** depending on the reaction conditions. For each entry the palladium catalyst (0.1 equiv), reaction time, and yield of **2c** are given. In the case of entry 4 there was no reaction, and for entry 5 almost no reaction.

Irrespective of the presence or absence of phosphane and phosphite ligands, Pd^0 complexes cleanly promoted ring opening (entries 1–3). All reactions proceeded at room temperature and provided stereochemically homogeneous *cis*-1,2,2-trimethyl-3-(1,3-butadienyl)cyclopentanecarbaldehyde ((*E*)-**2c**) in good yields. The *E* isomer was identified from the coupling constant of the olefinic protons (J(H1,H2) = 15.4 Hz, 400-MHz ^{1}H NMR). Palladium(II) complexes were totally ineffective (entries 4 and 5).

Table 1 summarizes the results obtained for a variety of bi- and tricyclic carbonates **1**. It is apparent that the reaction tolerates a wide structural variety of **1**, and is independent of the length of the carbon chain between C5 and C6 ($n = 0, 1, 2, 4, 8$) and the substitution pattern of the olefinic portion. Furthermore, not only dienals, but also dienones (entries 5 and 9) were obtained in good yields.

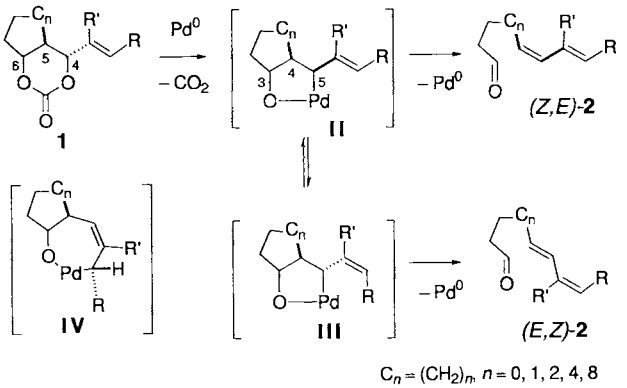
[a] Reaction conditions: **1** (1 mmol) and $[Pd_2(dba)_3]\cdot CHCl_3$ (0.05 mmol) in dry acetonitrile (5 mL) at ambient temperature under N_2. [b] Only the major isomer is shown. [c] Total yield of spectroscopically homogeneous **2** obtained after column chromatography over silica gel. [d] Ratios determined by ^1H NMR spectroscopy (400 MHz). [e] At room temperature for 30 h, then at 55 °C for 0.5 h. [f] At room temperature for 52 h, then at 55 °C for 1 h. [g] Complex diastereomeric mixture. [h] At room temperature for 24 h, then at 55 °C for 3 h.

The stereochemical outcome of the dienyl moiety of **2** may be rationalized according to Scheme 2. We postulate that *cis*-4,5-disubstituted 2-oxa-1-palladacyclopentane **II** is generated by oxidative addition of Pd^0 on the O3–C4 bond of **1** with inversion of configuration, and isomerizes to the corresponding *trans* isomer **III** via **IV** (a σ-π-σ interconversion that accompanies isomerization of the double bond (R ≠ H)). The thus formed



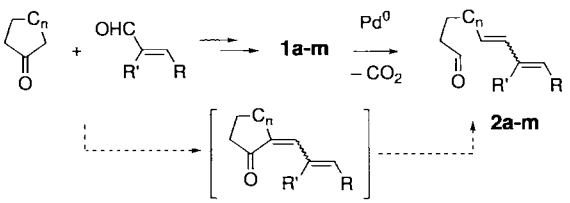
Scheme 2. Possible explanation for the stereochemical progress of reaction **1** → **2**.

intermediates **II** and **III** undergo C3–C4 bond fission (*cis*-β-decarbopalladation) to give (*Z*,*E*)-**2** and (*E*,*Z*)-**2**, respectively.

Intermediates **II**, generated from **1a** and **1b**, possess such strained cyclobutane C3–C4 bonds that they would readily fragment to provide (*Z*)-**2a** and (*Z*,*E*)-**2b** (entries 1 and 2 in Table 1). In the case of **1d** (entry 3), on the other hand, **II** possesses a less strained C3–C4 bond, but suffers from steric repulsion between *cis*-oriented C_n (= CH–CMe_2) and 1-propenyl groups (R = Me, R′ = H). Accordingly, it would rather isomerize to the thermodynamically more stable intermediate **III** to provide (*E*,*Z*)-**2** than fragment to (*Z*,*E*)-**2**. The exclusive formation of *E*-configurated double bonds in (*E*)-**2c**, (*E*,*Z*)-**2e**, and (*E*)-**2f** (Scheme 1 and entries 4 and 5 in Table 1) may be similarly rationalized. The *E*-selective formation of **2m** (entry 12), as opposed to the *Z*-selective formation of **2l** (entry 11), seems to be a natural consequence of steric repulsion between the C_n chain $(CH_2)_8$ and the isopropenyl groups in **II** (R = H, R′ = Me).

The clean and facile β-decarbopalladation[8] of **II** and **III** may primarily owe its origin to the C3–C4 bonds, which are weakened by the negatively charged O2,[9] and to their five-membered structures, which render an alternative β-dehydropalladation providing 2-alkenylidenecycloalkanols conformationally less favorable.[10] The ring opening of 2-oxa-1-palladacyclopentanes **II** and **III** to olefins and aldehydes contrasts the cyclization of some titanium–olefin complexes and aldehydes providing 2-oxa-1-titanacyclopentanes.[1, 11]

We have demonstrated that dienals and dienones **2** can be obtained from bi- and tricyclic carbonates **1** in excellent yields and stereoselectivities. Cyclic carbonates **1a**–**m** were prepared from cyclic ketones and α,β-unsaturated aldehydes.[12] Accordingly, as illustrated in Scheme 3, the overall transformation formally comprises aldol condensation of cyclic ketones with unsaturated aldehydes and hydrogenolysis of the C1–C2 bonds of thus formed α-alkenylidenecycloalkanones. The synthetic utility of this reaction may be augmented by the usefulness of **2** as synthetic intermediates, the ready availability of **1** with a wide structural variety,[12] and the mild reaction conditions under which the reaction can be easily performed.



Scheme 3. Formal mechanism for the synthesis of **2** from cyclic ketones and α,β-unsaturated aldehydes.

Experimental Section

2d: A solution of **1d** (250 mg, 1 mmol: m. p. 79.0–80.0 °C (hexane)) [12] in dry acetonitrile (5 mL) was added with a syringe to a nitrogen-purged flask containing $[Pd_2(dba)_3]\cdot CHCl_3$ (51.8 mg, 0.05 mmol). After stirring for 55 h at room temperature, the reaction mixture was diluted with ether and filtered through a Celite pad with suction. The filtrate (30 mL) was washed with saturated $NaHCO_3$ (10 mL) and dried over magnesium sulfate. Removal of the solvent in vacuo followed by column chromatography over silica gel (hexane/ethyl acetate 64/1, v/v) gave **2d** as an oil (155 mg, 73% yield). IR (neat): $\tilde{\nu} = 1720$ (s) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$, TMS): $\delta = 0.79$ (s, 3H), 0.97 (s, 3H), 1.08 (s, 3H), 1.38 (ddd, $J = 5.5, 9.9, 13.9$ Hz, 1H), 1.68 (dddd, $J = 5.5, 9.9, 11.7, 13.9$ Hz, 1H), 1.75 (dd, $J = 1.8, 7.0$ Hz, 3H), 1.92 (ddt, $J = 4.7, 13.9, 9.9$ Hz, 1H), 2.42 (ddd, $J = 4.7, 11.7, 13.9$ Hz, 1H), 2.52 (dd, $J = 8.4, 9.9$ Hz, 1H), 5.42 (dq, $J = 11.0, 7.0$ Hz, 1H), 5.52 (dd, $J = 8.4, 15.0$ Hz, 1H), 6.00 (ddd, $J = 1.8, 11.0, 15.0$ Hz, 1H), 6.32 (dd, $J = 11.0, 15.0$ Hz, 1H), 9.65 (s, 1H); HR MS calcd for $C_{14}H_{22}O$: 206.1671; found (%): 206.1678 (75) [M^+], 191 (9), 122 (15), 95 (100).

[12] Precursors **1a–m** were obtained in the following yields (aldol addition, reduction with $LiAlH_4$ or addition of MeLi, cyclocarbonation with methyl chloroformate [6b]: **1a**: 98%, 25% (as a single diastereomer, column chromatography, silica gel, hexane/ethyl acetate gradient), 54%; **1b**: 95%, 25% (as a single diastereomer, column chromatography, silica gel, hexane/ethyl acetate gradient), 40%; **1c**: 98%, 98%, 37% (recrystallization from hexane); **1d**: 97%, 85%, 32% (recrystallization from hexane); **1e**: 98%, 98%, 20% (column chromatography, silica gel, hexane/ethyl acetate gradient); **1f**: 98%, 20%, 38% (recrystallization from hexane); **1g**: 95%, 12% (as a single diastereomer, column chromatography, silica gel, hexane/ethyl acetate gradient), 50% (recrystallization from benzene/hexane); **1h**: 70%, 98%, 14% (recrystallization from ethyl acetate/hexane); **1i**: 88%, 91%, 47% (recrystallization from benzene-hexane); **1j**: 88%, 74%, 61%; **1k**: 98%, 80%, 83%; **1l**: 95%, 80%, 20% (recrystallization from benzene/hexane; **1m**: 95%, 70%, 34% (recrystallization from benzene/hexane. All new compounds were characterized by NMR and IR spectrscopy as well as elemental analysis or high-resolution mass spectrometry.

Efficient Enzymatic Synthesis of the Core Trisaccharide of *N*-Glycans with a Recombinant β-Mannosyltransferase**

Gregory M. Watt, Leigh Revers, Matthew C. Webberley, Iain B. H. Wilson, and Sabine L. Flitsch*

The β-1,4-mannosidic linkage is common to most asparagine-linked oligosaccharides (*N*-glycans) in glycoproteins as part of their pentasaccharide core structure. Because of its importance and the difficulty of chemical synthesis, it has provided a challenge to organic chemists for some time and has resulted in a number of very elegant synthetic strategies.[1–10]

The β-mannosidic linkage is a good target for enzymatic methods. Unprotected chitobiosyl acceptor substrates can be used since regio- and stereoselectivity of the coupling reaction is ensured by the enzyme. Thus, glycosidases (β-mannosidases) have been used to catalyze the mannosylation,[11–13] but they suffer from low yields, especially where the chitobiosyl acceptor substrate is concerned, which has to be added in excess. As an alternative enzyme system, we therefore report the use of glycosyltransferases, in particular the β-1,4-mannosyltransferase from yeast, which catalyzes the mannosyl transfer from GDP-mannose to chitobiosyl-lipids **1** and **2** (Scheme 1).

The gene for the yeast enzyme *ALG1* (ALG = *A*sparagine-*L*inked *G*lycosylation) has been isolated and sequenced by Robbins and colleagues.[14, 15] The enzyme uses a complex, dolichol-linked acceptor substrate (**1**), which can be efficiently replaced by phytanol derivative **2**, obtainable in 70% yield from chitobiose octaacetate.[16–18] More simple chitobiosyl phosphate and alkyl chitobiosides were not accepted as substrates.[19] Expression of the mannosyltransferase in a heterologous host (*E. coli*) was possible,[14] but the yield was poor and purification proved difficult. Our aim was therefore to obtain a more practical biocatalyst by modifying *ALG1* and then inserting the modified gene into a suitable overexpression vector.

First the enzyme was made soluble by deleting a hydrophobic N-terminal sequence of amino acids 2–35 (generating AlgΔTM),[20] thus overcoming problems with expression, isolation, and stability of the enzyme. Second the highly immunogenic Myc polypeptide sequence (EQKLISEEDL) was fused to

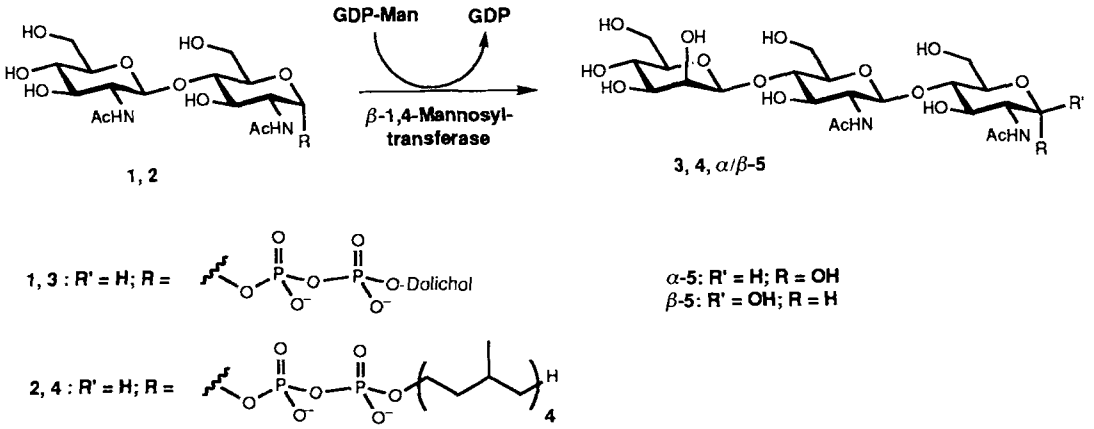

Scheme 1. Transferase-catalyzed mannosylation of **1** and **2** using GDP-mannose.

the N-terminus to aid detection of the enzyme by Western blotting with the commercially available anti-Myc monoclonal antibody.[21] Third a N-terminal decahistidine sequence (His_{10}) allows metal affinity chromatography of the protein.[22] The new *His10mycALG1ΔTM* gene was inserted into a variety of commercially available overexpression vectors, of which the pET-16b (AMS Biotechnology, Whitney, Oxon UK) proved to be the most successful. The new plasmid (pLR36) thus generated is shown in Figure 1.

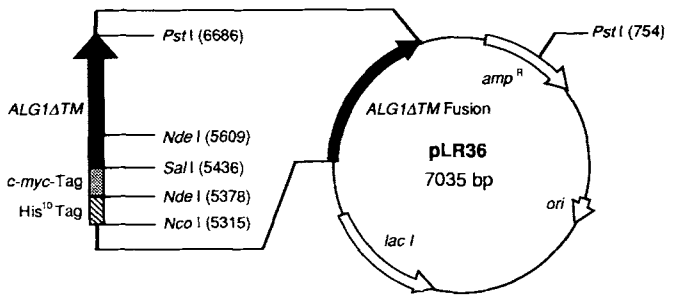

Figure 1. The new plasmid (pLR36).

Transformation of *E. coli* (BL21(DE3)pLysS) with the plasmid pLR36 yielded mannosyltransferase activity of about 0.2 U per gram of wet cells. Functionally pure, immobilized biocatalyst could be prepared by simply passing the crude cell lysate (obtained by a freeze–thaw cycle) through an affinity column charged with nickel(II) ions, followed by washing to remove impurities. This immobilization appeared to stabilize the enzyme, which can be stored at 4 °C for several days. Incubation with **2** and GDP-mannose yielded **4**, which after acid hydrolysis and purification by gel-permeation chromatography afforded the trisaccharide α/β-**5** as a mixture of C-1 anomers in 80% yield. Although alkaline phosphatase[23] was used in this reaction, assays showed that it provided no significant increase in GDP-mannose turnover. The ^{1}H NMR spectra showed that the trisaccharide was identical to that derived from a natural source.

In summary, the enzymatic formation of the β-1,4-mannosidic linkage was achieved both regio- and stereoselectively in good yield from the synthetic chitobiosyl phospholipid **2**. We are convinced that this approach will be particularly useful for providing biosynthetic intermediates for the studies of subsequent glycosyltransferases of the biosynthetic pathway of N-linked oligosaccharides[24] and for in vitro protein glycosylation.[25, 26] Further elongation of the Manβ1-4GlcNAcβ1-4GlcNAc lipid (**4**) with other transferases can also lead to short chemoenzymatic syntheses of the pentasaccharide core and of more complex *N*-glycans.[27]

Experimental Section

Enzymatic synthesis of Manβ1-4GlcNAcβ1-4GlcNAc (α/β-**5**): Phytanylpyrophosphoryl-α-*N*,*N*'-diacetylchitobioside **2**[18] (2.8 mg, 3.2 μmol) was incubated at 37 °C with GDP-mannose (2.4 mg, 4.0 μmol) with 50% (v/v) enzyme-charged resin (prepared from 5 g wet *E. coli* cells) in buffer (50 mM Tris-HCl, 5 mM $MgCl_2$, 0.25% Triton-X-100 (v/v), pH 7.5; 20 mL). Final concentrations were 160 μM **2** and 200 μM GDP-mannose. The reaction was shaken at 100 rpm for 30 min. and alkaline phosphatase (8 U) was added; shaking was continued for a further 1 h, whereafter the resin was filtered and washed exhaustively with chloroform/methanol/water (10/10/3). The combined organic and aqueous phases were evaporated to dryness, and the residue treated with 20 mM HCl (25 mL) at 100 °C for 1 h. The aqueous phase was subjected to Bio-Gel P4 gel-filtration chromatography, and fractions containing oligosaccharides corresponding to a hydrodynamic volume of 5 glucose units were pooled and lyophilized to give the target compound α/β-**5** as a mixture (α/β = 2/1) of anomers at the C-1 position (1.5 mg; yield 80% from **2**, 65% from GDP-mannose). Selected ^{1}H NMR data (600 MHz, D_2O): δ = 2.08, 2.10 (2 × s, 6H; 2 × $NHCOCH_3$), 3.44 (1H, m; H-5''), 4.08 (d, ^3J(H2'',H3'') = 3 Hz, 1H; H-2''), 4.62 (d, ^3J(H1',H2') = 8 Hz; H1'β), 4.63 (d, ^3J(H1',H2') = 8 Hz; H1'α), 4.72 (d, ^3J(H1,H2) = 8 Hz; H1β), 4.80 (s, 1H; H1''), 5.21 (d, ^3J(H1,H2) = 3 Hz; H1α).

Artificial Phototropism: Reversible Photoseparation of Self-Assembled Interlocking Conjugates**

Andrew C. Benniston,* Anthony Harriman,* and Dimitri S. Yufit

Supramolecular structures, especially those constructed by interlocking redox-active host–guest species, offer the possibility for devising artificial phototropic systems.[1–4] The key feature of such units is the large light-induced conformational change along a preferred trajectory, which allows reversible cycling of the energy and information stored in the superstructure. Special interest should be given to systems in which the primary binding mode involves electron donor–acceptor interactions, since the association constant for self-assembly of the supramolecular structure can be modified dramatically and spontaneously by laser excitation.[1] In particular, interaction between a dicationic acceptor A^{2+} and a neutral donor D is often characterized by the development of a colored charge-transfer (CT) complex $D \cdot A^{2+}$. Direct excitation into the CT absorption band causes electron transfer from donor to acceptor and formation of a radical ion pair (RIP). Mutual electrostatic repulsion facilitates separation of the RIP into solvated radical cations,[4] provided charge recombination is not too fast (Figure 1).

Charge recombination is controlled by the amount of energy to be dissipated by vibrational modes, and the rate decreases with increasing energy of the RIP.[5] The energy-gap dependence is shallow, however, and, to benefit from such circumstances, donor–acceptor pairs displaying extreme redox potential difference must be used. A different strategy for stabilizing the RIP against rapid charge recombination involves extending the size of the overlapping π electron clouds.[6] This introduces additional CT states into the excited-state manifold and stabilizes the ground state of the CT complex by mixing with higher energy states.[6, 7] Indeed, the rate of charge recombination within RIPs decreases with increasing delocalization of HOMO or LUMO states.[8, 9] We now explored the idea that artificial phototropic systems can be devised by encapsulating a large dicationic electron acceptor inside the cavity of an electron-rich crown ether.[10]

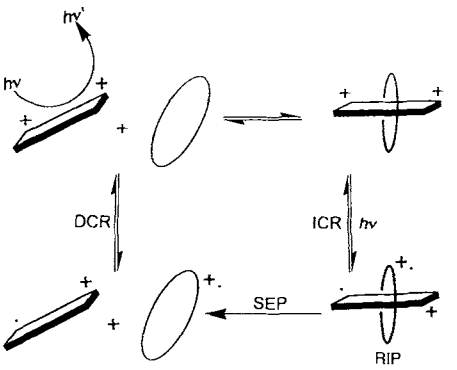

Figure 1. Pictorial representation of the events that follow from excitation of a CT complex formed by encapsulating a dicationic electron acceptor inside a macrocyclic receptor; ICR = intracomplex charge recombination, SEP = separation, DCR = diffusive charge recombination.

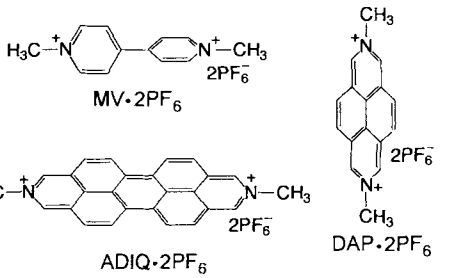
Mixing *N*,*N*′-dimethyl-2,7-diazapyrenium bis(hexafluorophosphate) ($DAP \cdot 2PF_6$) with dibenzo[34]crown-10 (CE10) in acetonitrile causes the appearance of a broad CT absorption band ($\lambda_{max} \approx 430$ nm) which is partially obscured on the high-energy side by local absorption bands. Progressive addition of CE10 to a solution of $DAP \cdot 2PF_6$ in acetonitrile is accompanied



1 = $DAP \cdot 2PF_6$/CE10 1/1
2 = $MV \cdot 2PF_6$/CE10 1/1

by extinction of fluorescence from the pyrene derivative ($\Phi_F = 0.67$, $\tau_S = 10.1$ ns)[11] without formation of new fluorescent species. The fluorescence titration was consistent with the formation of a nonfluorescent 1:1 complex (**1**) with a binding constant K_A of $3900 \pm 360\,M^{-1}$ at 18 °C. Therefore, $DAP \cdot 2PF_6$ shows greater affinity for binding to CE10 than to the smaller dibenzo[24]crown-8 ($K_A = 840\,M^{-1}$).[12] *N*,*N*′-dimethyl-4,4′-bipyridinium bis(hexafluorophosphate) ($MV \cdot 2PF_6$) also binds to CE10 ($K_A = 50 \pm 10\,M^{-1}$),[10, 13] whereas a binding constant of $K_A = 425 \pm 40\,M^{-1}$ was found for the larger *N*,*N*′-dimethylanthra[2,1,9-*def*:6,5,10-*d*′*e*′*f*′]diisoquinoline bis(hexafluorophosphate) ($ADIQ \cdot 2PF_6$).

FAB mass spectra recorded for solutions containing different mole fractions of $DAP \cdot 2PF_6$ and CE10 in acetonitrile displayed a cluster of peaks at $m/z = 915$ ($[\mathbf{1} - PF_6]^+$) and $m/z = 770$ ($[\mathbf{1} - 2PF_6]^+$), which correspond uniquely to the 1:1 complex. Molecular ions attributable to 1:2, 2:1, or 2:2 supramolecular assemblies were not detected, even with a large molar excess of CE10. ^1H NMR spectroscopic titrations in which aliquots of CE10 were added to a solution of $DAP \cdot 2PF_6$ in [D_6]acetone showed pronounced upfield shifts for the α (− 0.34 ppm) and γ protons (− 0.36 ppm) on the $DAP \cdot 2PF_6$ moiety concomitant with the appearance of a resonance at $\delta = 5.57$ due to CE10.

The magnitude of the induced shifts are taken as firm evidence for the formation of an intimate CT complex in which there is strong overlap of π orbitals on donor and acceptor.[4] Analysis of the ^{1}H NMR spectral data with Job's method[14] indicates that the predominant species in acetone is the 1:1 complex, but there are hints that an unstable 1:2 complex might be formed at very high mole fractions of CE10.[15] Similar studies with MV·2PF$_6$ showed only the 1:1 complex, whereas ADIQ·2PF$_6$ formed both 1:1 and 1:2 complexes.[15]

According to X-ray diffraction studies of **1**, the dication is centered in the cavity of the crown and closely aligned with the two hydroquinol units. The separation between the parallel benzene rings of the crown host is 6.88 Å, but the rings are shifted so that each half of the guest interacts with only a single hydroquinol unit (Figure 2). The mean host–guest separation is

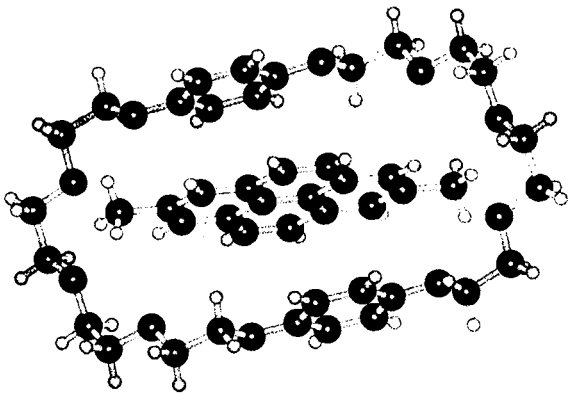

Figure 2. ORTEP representation of the crystal structure of the CT complex **1**. Hexafluorophosphate anions are omitted for clarity.

3.46 Å, and there is an angle of 3.9° between the planes of the benzene rings and the dication. The N(1)–N(1a) axis of the dication is tilted by about 21° with respect to the C(9)–C(12) axis of the macrocycle. Room-temperature NMR studies indicate fast rocking of the DAP·2PF$_6$ subunit about a perpendicular axis passing through the complex. Similar structural facets have been reported for complex **2** formed between MV·2PF$_6$ and CE10.[13]

Laser excitation of **1** in acetonitrile at 18 °C results in rapid establishment of the RIP, as detected by transient absorption spectroscopy.[5, 10] The RIP, which shows a similar differential absorption spectrum to that of the π radical cation formed upon one-electron reduction of DAP·2PF$_6$,[11] evolves from the initially formed Franck–Condon state on the timescale of a few picoseconds (Figure 3). Absorption due to the corresponding π radical cation of the crown ether is too weak to contribute appreciably to the observed signal. Deactivation of the RIP occurs by first-order kinetics with a rate constant k_{obs} of $7.7\times10^9\ s^{-1}$. This decay process partially (to 90%) restores the ground state of the complex; the approximately 10% of the initial signal that does not return to the prepulse baseline on the picosecond timescale is attributed to the formation of solvated π radical cations. On this basis it is possible to assign individual rate constants[5] for charge recombination ($k_{CR}\approx7\times10^9\ s^{-1}$) and separation ($k_{sep}\approx7\times10^8\ s^{-1}$). The solvated π radical cations recombine through diffusional contact over tens of microseconds. Under identical conditions, the RIP derived from **2** decays rapidly ($k_{obs}=1.82\times10^{10}\ s^{-1}$) without observable separation. Therefore, for **2** $k_{CR}\approx1.8\times10^{10}\ s^{-1}$ and $k_{sep}<1\times10^9\ s^{-1}$. It was not possible to excite selectively the

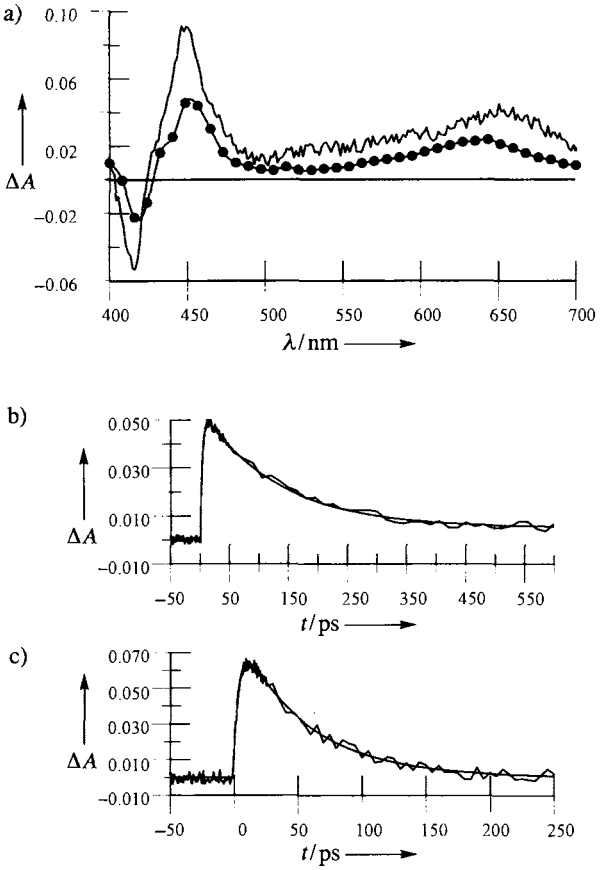

Figure 3. a) Transient differential absorption spectra recorded 25 ps (solid line) and 25 ns (-●-) after laser excitation of the CT complex **1**. b) Decay profile recorded at 630 nm for the CT complex **1**. c) Decay profile recorded at 610 nm for the CT complex **2**.

CT complex formed between ADIQ·2PF$_6$ and CE10 due to overlapping absorption bands localized on the acceptor.

Comparable amounts of vibrational energy have to be dissipated during charge recombination in the RIPs formed from **1** and **2**. This is evident by the similar maxima for CT absorption bands formed upon encapsulation of DAP·2PF$_6$ ($\lambda_{max}\approx430$ nm) and MV·2PF$_6$ ($\lambda_{max}\approx440$ nm) into CE10 and by the respective redox potentials. Cyclic voltammetry studies of **1** in butyronitrile showed two quasi-reversible one-electron reductions, with half-wave potentials of −0.60 and −1.30 V versus SCE, and an irreversible oxidation at +1.45 V versus SCE. Successive reductions occur at the diazapyrenium dication, first forming the π radical cation and then the neutral species, while oxidation takes place at the hydroquinol units. Complex **2** displayed one-electron reductions at −0.60 and −1.01 V versus SCE and an irreversible oxidation at +1.39 V versus SCE. Therefore, differences in the rates of charge recombination cannot be ascribed to either thermodynamic or stereochemical factors.

The main difference between diazapyrenium and viologen acceptors concerns the energy level of localized π–π* states. Indeed, the relatively low energy of π–π* states localized on the acceptor in **1**, compared to those in **2**,[16] facilitates mixing of these states with the CT state.[6, 7] Such an interaction, which introduces some π–π* character into the CT state, stabilizes the ground state of the complex[6] and decreases the rate of charge recombination in the RIP.[7, 8] It is this relatively slow rate of charge recombination (provided by interstate mixing), together with electrostatic repulsion between the partners within the RIP, that permits photoseparation of complex **1**.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3621-2357 $ 17.50+.50/0

Without interstate mixing the conjugate does not function as a phototropic assembly, and absorbed photons are converted into heat within about 50 ps. Interstate mixing extends the overall timescale for charge recombination to about 40 μs, but the phototropic process itself continues for milliseconds. This is because diffusional charge recombination occurs between separated π radical cations, and is followed by slower reinsertion of the dication into the receptor (see Figure 1). In contrast to the case with MV·2PF$_6$, where the acceptor is nonfluorescent and separation of the RIP is minimal, formation of free DAP·2PF$_6$ as a transitory species can be followed by fluorescence spectroscopy using two-color (or delayed pulse) excitation. Background fluorescence, being set by the amount of free DAP·2PF$_6$, can be suppressed with excess CE10, while the rate of reinsertion of DAP·2PF$_6$ into the cavity is solvent-dependent. Similar behavior is found for ADIQ·2PF$_6$, but the level of background fluorescence is too high for practical application. With complex **1**, however, laser-induced fluorescence selectively tracks the evolution and disappearance of free diazapyrenium dications.

Experimental Section

DAP·2PF$_6$ [11] and CE10 [17] were prepared by literature methods. ADIQ·2PF$_6$ was available from earlier work [11]. All compounds gave satisfactory analytical data that were consistent with their assigned structures. Fast kinetic measurements were made with nanosecond and sub-picosecond laser flash photolysis equipment, built for this purpose, similar to that described previously [11]. The excitation wavelength was 440 nm. Decay kinetics were obtained by collecting transient differential absorption spectral profiles at about 50 delay times. Binding constants were determined by fluorescence spectroscopy with about 50 different concentrations of crown ether being added to a solution of fluorophore in acetonitrile.

X-ray structure analysis of **1**: $C_{48}H_{54}F_{12}N_3O_{10}P_2$, $M_r = 1122.88$, yellow prisms, $0.15 \times 0.20 \times 0.45$ mm, measured at 293(2) K; triclinic, $P\bar{1}$, $a = 11.284(2)$, $b = 11.211(2)$, $c = 12.043(2)$ Å, $\alpha = 99.95(3)$, $\beta = 106.28(3)$, $\gamma = 107.15(3)°$, $V = 1342(4)$ Å^3, $\rho_{calcd} = 1.389$ mg m^{-3}, Enraf-Nonius CAD-4 diffractometer, $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å), $\mu = 0.179$ mm^{-1}, $\omega/2\theta$ scan, $2\theta \leq 60°$; of 7524 reflections measured, 6509 were independent; ψ-scan absorption correction, $T_{min} = 0.94$, $T_{max} = 1.00$. The structure was solved with direct methods (SHELXS-86), and refined on F^2 (SHELXL-93; non-hydrogen atoms, except disordered F atoms, were refined anisotropically, and H atoms at calculated positions in riding mode). $R_1 = 0.0959$ for 6494 reflections ($F_0 \geq 4\sigma(F)$), $wR_2 = 0.2949$ for all data, GOF = 1.0086, 330 parameters, $\Delta\rho_{max} = 1.042$ e Å^{-3} in the vicinity of a severely disordered solvent molecule. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100343. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code +(1223) 336-033; e-mail: deposit@chemcrys.cam.ac.uk).

[15] Complexation of higher order causes a slight curvature of the plateau region at high mole fractions of CE10. Such behavior is not seen in the mass-spectral studies. Formation of a 1:1 complex for ADIQ·2PF$_6$ in [D$_6$]acetone causes upfield shifts of −0.15, −0.13, and −0.022 ppm for the α, β, δ protons, respectively. Formation of a 1:2 complex causes further upfield shifts of −0.083 (α), −0.070 (β), and −0.012 ppm (δ). Both complexes are observed by FAB mass spectrometry in acetonitrile.
[16] These energy gaps, which are crudely estimated from absorption maxima of the lowest-energy π–π* transition localized on the acceptor and the CT transition are 1.6, 0.15, and −0.3 eV for MV·2PF$_6$, DAP·2PF$_6$, and ADIQ·2PF$_6$, respectively. For the latter, the CT band lies at higher energy than the lowest-energy π–π* transition.

Novel Zwitterionic Diallylzirconium Complexes: Synthesis, Structure, Polymerization Activity, and Deactivation Pathways**

Gerardo Jiménez Pindado, Mark Thornton-Pett, Marco Bouwkamp, Auke Meetsma, Bart Hessen,* and Manfred Bochmann*

Group 4 metallocene complexes are becoming increasingly important as "single-site" catalysts for the polymerization of α-olefins,[1] and the number of industrial processes based on Cp complexes is growing rapidly.[2] The catalytically active species are electron-deficient complexes of the type $[Cp_2MR]^+$ (M = Ti, Zr, Hf), which are usually generated in situ by reacting a neutral metal alkyl complex with cation-generating activators such as methylaluminoxane (MAO) or, in aluminum-free systems, $M^+[B(C_6F_5)_4]^-$ ($M = HNMe_2Ph$, CPh_3), to give ion pairs $[Cp_2MR]^+X^-$ [X = Me-MAO, $B(C_6F_5)_4$].[1] Zwitterionic complexes such as $[Cp^*_2Zr(m\text{-}C_6H_3Et)B(C_6H_4Et)_3]$, $[Cp_2ZrMe(\mu\text{-}Me)B(C_6F_5)_3]$, $[Cp^*TiMe_2(\mu\text{-}Me)B(C_6F_5)_3]$ (Cp^* = tetramethylcyclopentadienyl), $[Zr(CH_2Ph)_3(\eta\text{-}Ph)BPh_3]$, and $[Zr(CH_2Ph)_3(\eta^6\text{-}PhCH_2)B(C_6F_5)_3]$ have proved to be useful catalyst precursors;[3–7] here the active species is generated by dissociation into ion pairs. More recently Erker et al. prepared zwitterionic allylic complexes $[Cp_2M(\eta^3\text{-}C_3H_4CH_2)B(C_6F_5)_3]$ by treating zirconocene and hafnocene butadiene complexes with $B(C_6F_5)_3$. These compounds are less electron-deficient than the alkyl complexes mentioned above and achieve an electron count of 18 through a weak Zr–F coordination.[8]

Structural and catalytic studies have so far mainly concentrated on the chemistry of highly reactive 14-electron alkyl complexes $[Cp_2MMe]^+$ (M = Ti, Zr, Hf). The isoelectronic cationic

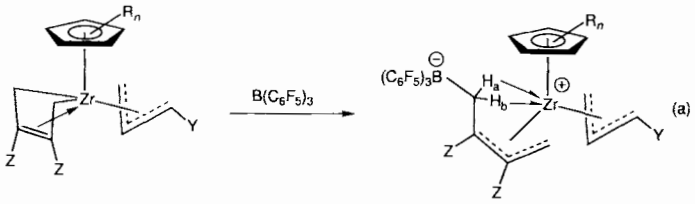
diallyl complexes of the type $[CpM(\eta^3\text{-allyl})_2]^+$ should exhibit a similarly promising reactivity. We describe here the synthesis, catalytic activity, and structural characterization of the first zwitterionic diallylzirconium complexes. The ability of these species to undergo unusually facile C–H activation illustrates the remarkable difference in reactivity between mono-Cp $[CpM(allyl)_2]^+$ ions and the more familiar metallocene analogues $[Cp_2MR]^+$ (R = alkyl, allyl).

Treatment of a solution of $[Cp''Zr(\eta^3\text{-}C_3H_5)\{\eta^4\text{-}CH_2C(Me)C(Me)CH_2\}]$ (**1a**) [Cp'' = 1,3-$(SiMe_3)_2C_5H_3$] in toluene with $B(C_6F_5)_3$ at −78 °C leads to a color change from red to orange. Monitoring this reaction by NMR spectroscopy in CD_2Cl_2 between −70 and 20 °C reveals the formation of a single chiral complex; seven ^{1}H NMR resonances for allylic ligands (five from the η^3-C_3H_5 ligand, two from the η^3-dienyl unit) appear together with two broadened doublets for the -CH_2-B moiety at $\delta = -0.33$ and −1.78 (Table 1). These data are consistent with an attack by $B(C_6F_5)_3$ exclusively on one of the terminal carbon atoms of the diene ligand to give the zwitterionic diallyl complex **2a** [Eq. (a)]. The unusually high-field shifted ^{1}H NMR resonances for the CH_2–B moiety suggest possible C–H···Zr bonding.



1a, R_n = 1,3-$(SiMe_3)_2$; Y = H, Z = Me
1b, R_n = 1,3-$(SiMe_3)_2$; Y = Me, Z = H
1c, R_n = Me_5; Y = Me, Z = H

2a - c

The ^{11}B NMR singlet of **2a** at $\delta = -12.0$ confirms the formation of a triarylborate. The ^{19}F NMR spectrum shows six resonances for the *ortho*-F atoms of three inequivalent C_6F_5 groups, whose rotation about the B–C_6 and B–CH_2 bonds is evidently highly hindered. All six *o*-F signals have chemical shifts between $\delta = -129$ and −135 and remain unchanged on cooling to −85 °C; a high-field shift of one of the *o*-F signals, which might indicate a metal–fluorine coordination,[9] is not observed.

Compound **2a** is isolated as air-sensitive orange crystals (83% yield) that are thermally stable at room temperature. Cooling solutions of **2a** in toluene to −16 °C afforded orange-yellow crystals of **2a**·toluene suitable for X-ray diffraction.[10] The sterically demanding ligands of the zwitterionic molecule (Figure 1) prevent any close intra- or intermolecular M···F interactions. The Zr–C distances in the $[Cp'Zr(allyl)_2]^+$ core correspond closely to the values of the neutral allyl precursor. The cationic 14-electron fragment is stabilized by two agostic interactions with the B–CH_2 group [Zr···H 2.29(5) and 2.30(5) Å].[11]

Compound **2a** crystallizes with one molecule of toluene, which in the crystal is associated with one of pentafluorophenyl rings; the distances between the plane of the six-membered ring of the toluene molecule and the best least-squares plane through the C_6F_5 group are relatively short (3.17–3.45 Å). This solvent binding is reminiscent of the well known 1:1 stacking phases formed between benzene and hexafluorobenzene.[12]

Mixtures of **1a** activated with one equivalent $B(C_6F_5)_3$ in toluene catalyze the polymerization of ethene under mild conditions (Table 2). While the M_w values are within the expected range, the broadening of the polydispersities with rising poly-

Table 1. Selected spectroscopic data.

2a: ^{1}H NMR (300 MHz, CD_2Cl_2, −40 °C; C atom numbering as in Figure 1): $\delta = -1.78$, −0.33 (br s, 1H each; H_2CB), 0.19, 0.36 (s, 9H each; SiMe), 1.41, 2.52 (d, $J = 8.3$ Hz, 1H each; CCH_2), 1.68, 1.76 (s, 3H each, diene-Me); 1.96 (m, 2H), 2.66 (br. d, 1H), 3.19 (d, $J = 15.3$ Hz 1H; 14 or 16-CH_2), 5.96 (m, 1H, 15-CH), 6.51, 6.96 (m, 1H, 4,5-C_5H_3), 6.44 (m, 1H, 2-C_5H_3); ^{13}C NMR (75.4 MHz, CD_2Cl_2, −40 °C): $\delta = -0.55$, −0.23 (q, $J = 119.1$, 119.6 Hz; SiMe), 16.93, 23.77 (q, $J = 129.5$, 127.8 Hz, diene-Me), 31.09 (vbr. t, CH_2B), 59.64 (t, $J = 150.1$ Hz, CCH_2), 67.12, 71.03 (t, $J = 155.9$, 158.6 Hz; CH_2 of C_3H_5), 112.91 (m, 8-C), 117.53 (d, $J = 170.5$ Hz; 2-C_5H_3), 124.0, 131.45 (d, $J = 169.8$, 172.0 Hz; 4,5-C_5H_3), 125.28, 129.26 (m, 1,3-C_5H_3), 138.06 (m, 7-C), 140.77 (d, $J = 153.2$ Hz, 11-CH); ^{11}B NMR (96.2 MHz, CD_2Cl_2, −40 °C): $\delta = -11.99$; ^{19}F NMR (CD_2Cl_2, −50 °C): $\delta = -129.6$, −132.2, −130.0, −132.6, −134.0, −134.7 (d, ^3J(F,F) = 19.6 Hz, 1F each; *o*-F), −159.9, −160.1, −160.6 (t, ^3J(F,F) = 19.7 Hz, 1F each; *p*-F); −164.2, −165.1, −165.6, −167.0 (m, 2F, 1F, 2F, 1F; *m*-F)

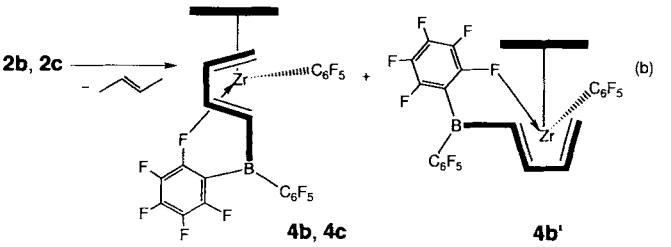
44	10	0.180	43.2	107	5.2
60	10	0.190	45.6	77.3	7.6

[a] Conditions: **1a** (25 μmol), $B(C_6F_5)_3$ (25 μmol), toluene (20 mL), ethene 1 bar. [b] In 10^3 g PE (mol Zr)$^{-1}$ h^{-1}.

merization temperature to values significiantly higher than those typically obtained for metallocenes may suggest the loss of active site uniformity. Such behavior may offer advantages where the desired polymer properties or processing parameters favor broader polydispersities.[13, 14]

Treatment of **2a** with excess *tert*-butylisocyanide at 0 °C leads to the immediate formation of the adduct **3a** as yellow microcrystals. Rather unexpectedly, warming the reaction mixture did not lead to an isocyanide insertion product but to the quantitative regeneration of **1a**, together with *t*BuNC·$B(C_6F_5)_3$ ($\tilde{\nu}_{C\equiv N}$ = 2300 cm^{-1}), which, to our knowledge, is the first example of a fully reversible formation of a $[RB(C_6F_5)_3]^-$ borate unit. By contrast, di-Cp complexes such as $[Cp_2Zr\{C_3H_4CH_2{-}B(C_6F_5)_3\}]$ readily give the expected isocyanide insertion products.[8b]

The reaction of $B(C_6F_5)_3$ with the butadiene complexes **1b** and **1c** gives the corresponding zwitterionic complexes **2b** and **2c**, respectively. The spectroscopic data of these compounds are very similar to those of **2a**. Both catalyze the polymerization of ethene but are thermally less stable than the sterically more hindered **2a** and decompose by an unexpected C–H activation pathway, in which 2-butene is eliminated and a C_6F_5 group migrates from boron to zirconium to give **4** [Eq. (b)]. In the case



of **2b**, this reaction sequence is very facile even at −60 °C.[15] The transformation of the four-coordinate borate in **2b** into a three-coordinate boryl in **4b** is reflected in the change in the ^{11}B NMR signal from about $\delta = -12$ to $\delta = +43$. Compound **4b** is accompanied by a second, fluxional isomer **4b'**. The C_5Me_5 complex **2c** is more stable and rearranges to **4c** with $\tau_{1/2} \approx 20$ min in C_6D_6 and 2–3 min in C_6D_5Br at room temperature.

The X-ray structure analysis of **4c**·0.5 Et_2O (Figure 2)[16] shows a trigonal-planar $B(C_6F_5)_2$ unit; one *o*-F atom is coordinated to the metal center ($\delta(^{19}F) = -179.8$). The ZrC_4 core has the familiar metallacyclopentene envelope conformation.

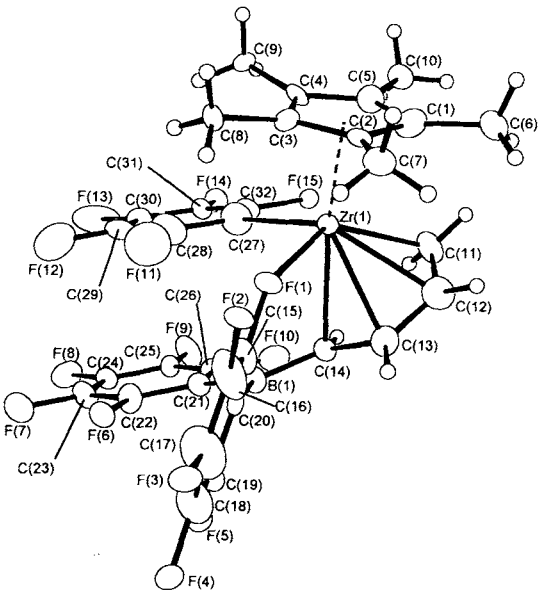


Figure 2. Structure of **4c**. Selected bond lengths [Å] and angles [°]: Zr(1)–C(11) 2.314(3), Zr(1)–C(12) 2.451(3), Zr(1)–C(13) 2.458(3), Zr(1)–C(14) 2.481(2), Zr(1)–C(27) 2.315(2), Zr(1)–F(1) 2.4292(15), C(11)–C(12) 1.414(4), C(12)–C(13) 1.375(4), C(13)–C(14) 1.454(3), B(1)–C(14) 1.488(3), B(1)–C(20) 1.582(4), B(1)–C(21) 1.590(3), C(15)–F(1) 1.380(3), C(19)–F(5) 1.351(3); F(1)-Zr(1)–C(27) 100.47(7), B(1)-C(14)-C(13) 126.3(2), C(11)-C(12)-C(13) 121.8(2), C(12)-C(13)-C(14) 120.5(2).

Surprisingly, the diene unit is oriented approximately orthogonal to the Cp ring and does not fall into either of the usual "prone" and "supine" categories.[17] The distribution of the bond lengths in the ZrC_4B unit, in particular the relatively short B–C(H) bond (1.485 Å), suggests that the zwitterionic resonance structure **B** may dominate over formulation **A**.[18]

The results establish cationic 14-electron mono-Cp complexes as a new class of polymerization catalysts; their reactivity patterns, however, differ markedly from the behavior of the better-known di-Cp systems.

Experimental Section

All synthetic procedures were carried out under dry nitrogen using Schlenk techniques. NMR spectra were recorded on Bruker 300 and 500 MHz instruments. Compounds **1a**–**1c** were synthesized according to literature procedures [19].

2a: $B(C_6F_5)_3$ (0.89 g, 1.73 mmol) in toluene (20 mL) was added to a solution of **1a** (0.73 g, 1.72 mmol) in toluene (30 mL) at −78 °C. The mixture was stirred at this temperature for 30 min and then allowed to warm to room temperature. The color of the mixture changed instantaneously from red to dark orange. Concentration of the solution to 20 mL followed by cooling to −16 °C afforded orange crystals of **2a**·toluene (1.29 g, 1.38 mmol, 80%). Elemental analysis (%): Calcd for $C_{38}H_{36}BF_{15}Si_2Zr\cdot C_7H_8$: C 52.6, H 4.3; found: C 51.8, H 4.5.

3a: *t*BuNC (0.21 mL, 1.86 mmol) was added to a solution of **2a** (0.96 g, 0.93 mmol) in toluene (10 mL) at 0 °C. The resulting yellow mixture was concentrated and cooled to −16 °C to give yellow crystals of **3a** (0.79 g, 0.77 mmol, 83%). Elemental analysis (%): Calcd for $C_{43}H_{45}BF_{15}NSi_2Zr$: C 50.4, H 4.5, N 1.4; found: C 50.6, H 4.7, N 1.3. IR (Nujol): $\tilde{\nu}$ = 2179 cm^{-1} (C≡N).

2b: This compound is thermally sensitive and was therefore generated in solution and characterized spectroscopically. $B(C_6F_5)_3$ (52 mg, 0.1 mmol) in [D_8]toluene (0.2 mL) was added to a solution of **1b** (42 mg, 0.1 mmol) in [D_8]toluene (0.3 mL) at −60 °C. The orange solution contained **2b**, together with some **4b** and **4b′**.

4b: The compound was generated in situ from **1b** and $B(C_6F_5)_3$ (1 equiv) in [D_8]toluene at 0 °C; it slowly decomposed in solution at room temperature.

4c: A solution of $B(C_6F_5)_3$ (0.228 g, 0.44 mmol) in benzene (5 mL) was added to a solution of **1c** (0.148 g, 0.44 mmol) in benzene (5 mL) at room temperature. The resulting orange solution was stirred at ambient temperature for 40 min during which the solution turned red. The solvent was removed in vacuo and the residue was extracted with diethyl ether. Concentration and cooling of the solution to −70 °C yielded **4c**·0.5 Et_2O as a red crystalline solid (0.141 g, 0.20 mmol, 46%). Elemental analysis (%): Calcd for $C_{32}H_{20}BF_{15}Zr\cdot 0.5(C_2H_5)_2O$: C 48.8, H 3.0, Zr 10.9; found: C 48.5, H 3.0, Zr 10.8.

[9] The coordinated *ortho*-F in [$Cp_2Zr\{C_3H_4CH_2B(C_6F_5)_3\}$] experiences an upfield shift of about 80 ppm to δ = −213.2 [8a].

[10] X-ray structure analysis of **2a**·toluene: An orange prism with dimensions 0.65 × 0.42 × 0.25 mm was grown from toluene and coated in perfluoropolyether RS3000 oil (Riedel De-Haën). $C_{38}H_{36}BF_{15}Si_2Zr\cdot C_7H_8$, M_r = 1028.01 (includes toluene molecule), triclinic, space group $P\bar{1}$, a = 10.4955(12), b = 13.538(2), c = 16.650(2) Å, α = 77.695(11), β = 83.542(10), γ = 78.945(14)°, Z = 2, V = 2262.2(5) Å^3, ρ_{calcd} = 1.509 Mg m^{-3}, μ = 3.344 mm^{-1}, $F(000)$ = 1044. Data collection was carried out at 160 K on a Stoe STADI4 four-circle diffractometer operating in the ω-θ scan mode using graphite-monochromated $Cu_{K\alpha}$ radiation (λ = 1.54184 Å). 7130 unique reflections were measured in the range 2.72 ≤ θ ≤ 64.54° (−12 ≤ h ≤ 12, −15 ≤ k ≤ 15, 0 ≤ l ≤ 18). The structure was solved by heavy atom methods using SHELXS-86 [20] and refined by full-matrix least-squares (against all the unique F^2 data) using SHELXL-93 [21]. Non-hydrogen atoms (including those of the toluene solvate molecule) were refined with anisotropic displacement parameters; hydrogen atoms were constrained to idealized positions by using a riding model with free rotation for methyl groups and fixed isotropic displacement parameters. Final $wR_2 = \{\sum[w(F_o^2 - F_c^2)^2]/\sum(F_o^2)^2]\}^{-1} = 0.1542$, conventional R = 0.0530 for F values of 6699 reflections with $F_o^2 > 2\sigma(F_o^2)$. Weighting scheme $w = [\sigma^2(F_o^2) + (0.0584P)^2 + 12.2995P]^{-1}$, where $P = (F_o^2 + 2F_c^2)/3$, goodness of fit = 1.069 for all F^2 values and 618 parameters. Maximum and minimum residual electron density 1.13 and −1.15 e Å^3, respectively [16b].

[11] Similar agostic interactions of two of the three methyl hydrogen atoms are found in $[(1,2\text{-}C_5H_3Me_2)_2ZrMe(\mu\text{-}Me)B(C_6F_5)_3]$ [Zr···H = 2.25(3) and 2.30(3) Å], while $[Cp_2ZrMe(\mu\text{-}Me)B(C_6F_5)_3]$ shows rather weaker agostic interactions [Zr···H 2.44(3) and 2.47(3) Å] [4].

[13] The "constraint geometry" complexes $[(C_5Me_4SiMe_2NtBu)Ti(C_4H_4R_2)]$ in the presence of $B(C_6F_5)_3$ are highly active for the copolymerization of ethene with 1-octene: D. D. Devore, F. J. Timmers, D. L. Hasha, R. K. Rosen, T. J. Marks, P. A. Deck, C. L. Stern, *Organometallics* **1995**, *14*, 3132. The living ethene oligomerization with activator-free $[(C_5Me_5)ZrR(2.3\text{-}Me_2C_4H_4)]$ has recently been reported: B. Hessen and H. van der Heijden, *J. Am. Chem. Soc.* **1996**, *118*, 11670.

[14] By contrast, propene polymerizations with $[Cp^*TiMe_3]/B(C_6F_8)_3$ give polymers with very narrow polydispersities and living characteristics: J. Sassmannshausen, M. Bochmann, J. Rösch, D. Lilge, *J. Organomet. Chem.*, in press.

[15] In contrast to the facile transfer of a C_6F_5 substituent from $B(C_6F_5)_3$ to a Zr atom, $B(C_6F_5)_3$ is inert towards electrophiles such as BBr_3 or Br_2. C_6F_5 transfer has been observed before at higher temperature and prolonged reaction times: R. Gomez, M. L. H. Green, J. L. Haggit, *J. Chem. Soc. Dalton Trans.* **1996**, 939.

[16] a) X-ray structure analysis of **4c**·0.5 Et_2O: an orange-red parallelepiped with dimensions 0.15 × 0.17 × 0.50 mm was grown from diethyl ether. Data were collected at 130 K. $C_{32}H_{20}BF_{15}Zr\cdot 0.5(C_2H_5)_2O$, M_r = 828.58, monoclinic $P2_1/n$, a = 12.903(1), b = 18.430(1), c = 13.389(1) Å, β = 96.08(1)°, V = 3166.0(4) Å^3, Z = 4, ρ_{calcd} = 1.738 Mg m^{-3}, μ = 4.64 cm^{-1}, 5128 reflections with $F_o \geq 4.0\sigma(F_o)$, 566 refined parameters. Data collection was carried out on an Enraf-Nonius CAD-4F^2 diffractometer using graphite-monochromated $Mo_{K\alpha}$ radiation (λ = 0.71073 Å; $\Delta\omega$ = 0.90 + 0.34tanθ). 6264 Unique reflections were measured in the range 2.2 ≤ 2θ ≤ 56.0° (−15 ≤ h ≤ 8, −1 ≤ k ≤ 20, 0 ≤ l ≤ 17). The structure was solved by Patterson methods and extension of the model was accomplished by direct methods applied to differene structure factors using the program DIRDIF [23]. The structure was refined by full-matrix least-squares (SHELXL93 [21]). Non-hydrogen atoms were refined with anisotropic displacement parameters. The diethyl ether solvent molecule was highly disordered over an inversion center. The programs PLATON [24] (calculation of geometric data) and PLUTO [25] (structure diagram) were used. Final $wR_2 = \{\sum[w(F_o^2 - F_c^2)^2]/\sum(F_o^2)^2]\}^{-1} = 0.0783$, conventional R = 0.0318 for F values of 5128 reflections with $F_o^2 > 2\sigma(F_o^2)$. Weighting scheme $w = [\sigma^2(F_o^2) + (0.0429P)^2 + 1.6097P]^{-1}$, where $P = (F_o^2 + 2F_c^2)/3$, goodness of fit = 1.066 for all F^2 values and 566 parameters. Maximum and minimum residual electron density 0.54 and −0.48 e Å^3, respectively. b) Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100329. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: Int. code +(1223) 336-033; e-mail: deposit@chemcrys.cam.ac.uk).

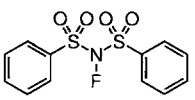
Regio- and Enantioselective Synthesis of α-Fluoroketones by Electrophilic Fluorination of α-Silylketone Enolates with *N*-Fluorobenzosulfonimide**

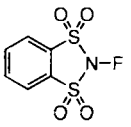
Dieter Enders,* Marcus Potthoff, Gerhard Raabe, and Jan Runsink

Dedicated to Professor Dieter Seebach on the ocassion of his 60th birthday

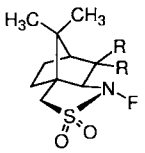
Over the last twenty years scientific and economic interest in organofluorine compounds has grown immensely due to their rapidly increasing practical use in plant protection, medicine, and other applications.[1, 2] The development of modern synthetic methods for electrophilic fluorination by substitution or addition with NF reagents has aided this advance, and various user-friendly NF fluorinating reagents are now available.[3] They provide a selective source of electrophilic fluorine that can be used in many ways. For this purpose *N*-fluorosulfonimides (**A**, **B**), *N*-fluorosulfonamides (**C**), and ammonium salts of type **D** were used. Davis et al.[4] reported the use of *N*-fluorobenzo-1,2-sulfonimide (**B**) for synthesizing fluorinated ketones, aldehydes, and esters. Differding et al. described the development and diverse application possibilities of *N*-fluoro-*N*,*N*-bis(phenyl)sulfonylamine (**A**, NFSI),[5] which was used for the electrophilic fluorinations presented here.



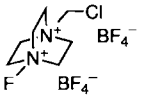
A (NFSI)



B



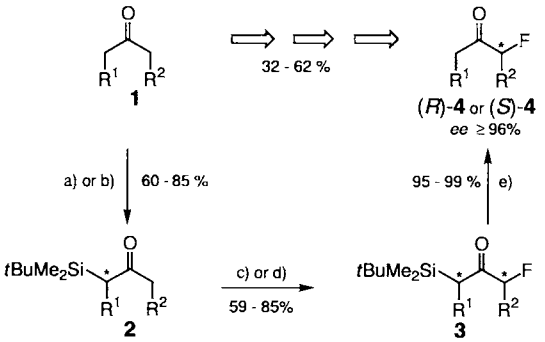
C (R=H,Cl)



D

Until now the enantioselective synthesis of α-fluoroketones was only occasionally found in the literature. Differding et al.[5] reported the first enantioselective synthesis of α-fluorocarbonyl compounds using camphorsultam derivatives **C** (R = H, *ee* = 10–70%), and Davis et al.[4] described the fluorination of various carbonyl compounds with **C** (R = Cl, *ee* = 10–75% and R = H, *ee* = 25–70%). The enantiomeric excesses, however, reached no practical values. Kabat[6] recently published an enantioselective synthesis of α-fluoroketones by nucleophilic fluorination of allene oxides, which were synthesized by a Sharpless epoxidation. We have now, for the first time, obtained the title compounds in high yields, few steps, and very good enantiomeric excesses by a general synthetic route starting from simple ketones.

As shown in Scheme 1, α-silylketones (*R*)-**2a**, **b**, **d**, **e** and (*S*)-**2c** were converted with high enantiomeric purity (≥98%) in three



Scheme 1. Enantioselective synthesis of α-fluoroketones. a) Symmetrical ketones [(*R*)-**2**]: 1. SAMP, 12 h; 2. LDA, Et_2O, 0 °C, 4 h; 3. *t*$BuMe_2SiOTf$, −78 °C → RT; 4. O_3, CH_2Cl_2, −78 °C; b) unsymmetrical ketones (*S*)-**2** (R^1 = H): 1. SAMP, 12 h; 2. LDA, THF, 0 °C, 4 h; 3. *t*$BuMe_2SiCl$, −78 °C → RT; 4. *n*BuLi, Et_2O, 0 °C, 4 h; 5. diisopropylamine, EtBr, −78 °C → RT; 6. O_3, CH_2Cl_2, −78 °C; c) diastereoisomers **3c**–**e**: 1. LDA, THF, 0 °C, 4 h; 2. NFSI, −78 °C → RT, flash chromatography; d) diastereoisomers **3a**–**c**: 1. LHMDS, THF, 0 °C, 16 h; 2. NFSI, −78 °C → RT, flash chromatography; e) NH_4F (10 equiv), KH_2PO_4 (10 equiv), HF (aq, 1 equiv), nBu_4NF (1 equiv), THF, −78 °C → RT.

or four steps by the reaction of ketones **1a**–**e** with (*S*)-1-amino-2-methoxymethylpyrrolidine (SAMP) followed by silylation/α-alkylation and ozonolysis. Symmetric and unsymmetric (control of regiochemistry) as well as cyclic and acyclic ketones can be used as precursors.[7] After metalation with 1.1 equivalents of lithium diisopropylamide (LDA) in THF at 0 °C, electrophilic fluorination with NFSI at −78 °C led to α-fluoro-α′-silylketones (*S*,*S*)-**3c** or (*R*,*R*)-**3d**,**e** in good to very good diastereoselectivities (*de* from 67 to greater than 98%) and good yields (59–85%). After flash column chromatography the practically diastereomerically pure products (*de* greater than 98%) were obtained (Table 1). The *de* values of (*S*,*S*)-**3c** and (*R*,*R*)-**3d**,**e** were determined by ^{13}C NMR spectroscopy. For the synthesis of the product with the epimeric fluorinated center, the α-silylketones were converted into the enolates by treatment with 1.1 equivalents of lithium hexamethyldisilazide (LHMDS) at 0 °C in THF. The enolates were then fluorinated at −78 °C with NFSI to the appropriate α-fluoro-α′-silylketones (*S*,*R*)-**3a**,**b** and (*R*,*S*)-**3c** in good to high diastereoselectivities (*de* = 78–89%) and good yields (70–80%). Again, flash column chromatogra-

Table 1. Yields, base used, and diastereoisomeric excesses for the synthesis of α-fluoro-α′-silyl-ketones **3**.

3	R^1	R^2	Base [a]	Yield [%]	*de* [%] [b, c]
(*S*,*R*)-**3a**	Et	Et	LHMDS	80	89 (≥98)

We would like to thank the following companies for the donation of chemicals: Degussa, BASF, Hoechst, Bayer, and Wacker Chemie. We would particularly like to thank Allied Signal Inc., Buffalo, USA, for *N*-fluorobenzosulfonimide.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3621-2362 $ 17.50+.50/0

phy provided the practically diastereomerically pure products (*de* from 96 to greater than 98%, ^{13}C NMR). As for all acyclic ketones, alternative employment of lithium amide bases LDA and LHMDS allowed the formation of both α-fluorine epimers and finally both enantiomers, as shown for **3c**. This is rationalized by the differing enolate geometries [LDA (*E*), LHMDS (*Z*)]. This was confirmed by NMR spectroscopic analysis for the synthesis of the appropriate silylenol ether at both −78 and 0 °C according to Heathcock and Evans.[8]

Comparison of the ^1H NMR spectra of (*R*,*S*)-**3c**, (*S*,*S*)-**3c**, and (*R*,*R*)-**3e** (NOE measurements) supplied the preferred conformation in solution, with which the relative and absolute configuration of the newly generated stereocenter could be determined. This result was confirmed by an X-ray crystal structure analysis of (*R*,*R*)-**3e** (Figure 1);[9, 10] the fluorinating reagent approaches the enolate from the side opposite to that of the sterically demanding silyl group.

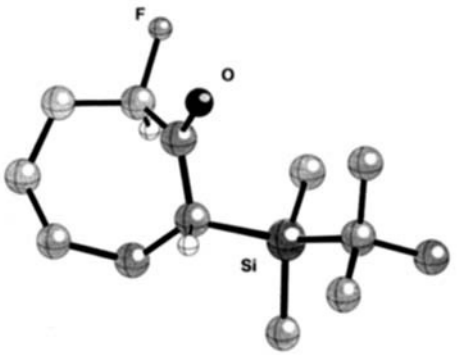

Figure 1. Crystal structure of α-fluoro-α′-silylketone **3e** [11].

For the racemization-free desilylation of α-fluoro-α′-silylketones **3a**–**e**, hydrofluoric acid and tetrabutylammonium fluoride were added to a suspension of ammonium fluoride and potassium dihydrogenphosphate in THF at −78 °C followed by the α-fluoro-α′-silylketone, and the reaction mixture was warmed.[12] Flash column chromatography provided α-fluoroketones **4a**–**e** in very good yields (95–99%) and high enantiomeric excesses (*ee* from 96 to greater than 98%), which were assigned by ^1H NMR spectroscopy with addition of a chiral co-solvent (Table 2).[13]

The regio- and enantioselective route described here presents the first general method for preparing practically enantiomerically pure α-fluoroketones from simple ketone precursors. By appropriate choice of base or starting ketone, both enantiomers of this important class of compounds can be obtained in good yield.[14]

Table 2. Yield, rotational value, and enantiomeric excesses of α-fluoroketones **4**.

(*R*)-**4d**	$(CH_2)_3$		99	+54.78 (1.0)	≥96
(*R*)-**4e**	$(CH_2)_4$		99	+72.87 (0.7)	≥96

[a] The *ee* values were determined by ^1H NMR spectroscopy (Varian Gemini 300 MHz spectrometer) with (−)-(*R*)-1-(9-anthryl)-2,2,2-trifluoroethanol as the co-solvent.

Experimental Section

Silylketones (*R*)-**2a**, **b**, **d**, **e** and (*S*)-**2c** were synthesized by the SAMP/RAMP-hydrazone method [7, 12].

Synthesis of **3a**–**e**: a) diastereoisomers (*S*,*S*)-**3c** and (*R*,*R*)-**3d**,**e**: To a solution of diisopropylamine (0.8 mL, 5.5 mmol) in THF (25 mL) at 0 °C was added *n*BuLi (3.7 mL, 1.5 N in *n*-hexane). After 30 min **2** (5 mmol) dissolved in THF (5 mL/mmol) was added. After 4 h the solution was cooled to −78 °C, and NFSI (1.58 g, 5 mmol) in THF (20 mL) was added dropwise. The reaction mixture was slowly warmed to room temperature, and the reaction quenched with an aqueous solution of NH_4Cl. The reaction mixture was then poured into water (10 mL), extracted three times with CH_2Cl_2 (15 mL), and dried over Na_2SO_4. The solvent was removed in vacuo. The crude oily solid was purified by distillation and then by column chromatography (SiO_2, ether/pentane 1/100), the remaining starting material was removed, and the diastereoisomers were separated to give (*S*,*S*)-**3c** and (*R*,*R*)-**3d** as colorless liquids and (*R*,*R*)-**3e** as a solid. b) Diastereoisomers (*S*,*R*)-**3a**,**b** and (*R*,*S*)-**3c**: To hexamethyldisilazane (1.15 mL, 5.5 mmol) in diethyl ether (10 mL) was added *n*BuLi (3.7 mL, 1.5 N in *n*-hexane) at 0 °C. The solution was warmed to room temperature, and the solvent removed under high vacuum. The remaining colorless solid was dissolved in THF (25 mL), cooled to 0 °C, and treated dropwise with **2** (5 mmol) dissolved in THF (5 mL/mmol). After 16 h the reaction mixture was cooled to −78 °C, and NFSI (1.58 g, 5 mmol) in THF (20 mL) was added. After the reaction mixture was slowly warmed to room temperature, it was quenched with an aqueous solution of NH_4Cl. The mixture was then poured into water (10 mL), extracted three times with CH_2Cl_2 (15 mL), and dried over Na_2SO_4. The solvent was removed in vacuo. The crude oily solid was purified by distillation and then by column chromatography (SiO_2, ether/pentane 1/100), the remaining starting material was removed, and the diastereoisomers were separated to give (*R*,*S*)-**3a**,**b** and (*R*,*S*)-**3c** as colorless liquids.

Desilylation of **3a**–**e**: NH_4F (10 equiv), KH_2PO_4 (10 equiv), Bu_4NF (1 mL, 1 M in THF), and HF (1 equiv of 40% solution in water) were added to THF (25 mL), and the solution was cooled to −78 °C. Then **3a**–**e** (1 mmol) in THF (10 mL) was added dropwise. After the mixture was slowly warmed to room temperature, it was quenched with a saturated solution of NH_4F. The reaction mixture was then poured into water (10 mL), extracted three times with of CH_2Cl_2 (10 mL), and dried over Na_2SO_4. The solvent was removed in vacuo. The crude brown-red products were purified by flash column chromatography (SiO_2, ether/pentane 1/40) to give **4a**–**e**. These colorless liquids can be stored at −20 °C under argon without racemization.

[9] Suitable crystals were obtained from pentane at −20 °C. $C_{13}H_{25}OFSi$, $M_r = 244.43$, crystal dimensions about $0.3 \times 0.3 \times 0.5$ mm, orthorhombic, $P2_12_12$ (no. 18), $a = 19.753(1)$, $b = 10.916(6)$, $c = 7.0199(9)$ Å, $V = 1513.7$ Å^3, $Z = 4$, $\rho_{calcd} = 1.073$ g cm^{-3}. Data were collected with an Enraf–Nonius CAD4 four-circle diffractometer with graphite-monochromated $Cu_{K\alpha}$ radiation ($\lambda = 1.54179$ Å). The structure was solved with direct methods (Gensin, Gentan, from Xtal3.2) [10]. Some of the hydrogen positions could be localized, and the remainder were calculated. There were 1461 observed reflexions [$I > 2\sigma(I)$], and 145 parameters refined; $R = 0.095$, $R_w = 0.061$; min./max. residual electron density −1.7/ + 0.6e Å^{-3}. The configuration at CF was determined by using the well-known configuration at CSi. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100579. The Use of a Ten-Membered Tetraphosphole Macrocycle to Increase the Lifetime of a Palladium Catalyst

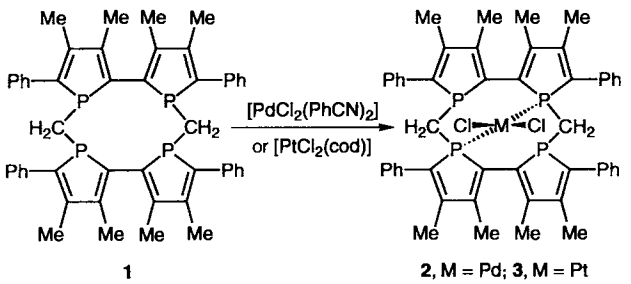
François Mercier, Frank Laporte, Louis Ricard, François Mathey,* Marc Schröder, and Manfred Regitz

Transient [PdL_2] complexes (L = phosphane) are the active intermediates in a number of reactions and processes[1] such as the Heck reaction[2] and the Stille cross-coupling reaction.[3] In some cases, the catalyst is lost at the end of the process as an insoluble precipitate, especially when the reaction is performed at relatively high temperature as in the case of the Heck reaction.[4] Recently we described a series of readily accessible tetraphosphole macrocycles of variable ring sizes (9–16 atoms).[5] The phosphorus atoms in these macrocycles are characterized by a low inversion barrier (about 16 kcal mol^{-1}) because of their incorporation into phosphole rings.[6] This means that a mixture of the various stereoisomers of each macrocycle behaves as the single stereoisomer that is the best adapted to coordinate to any given transition metal center.

In view of the importance of palladium catalysts in organic synthesis, we decided to study the properties of the palladium complexes of one of the most accessible tetraphosphole macrocycles, the ten-membered tetraphosphane **1**. The reaction of **1** with [$PdCl_2(PhCN)_2$] in dichloromethane immediately affords the red 1:1 complex **2** (Scheme 1), which was characterized by X-ray crystal structure analysis (Figure 1).



Scheme 1.

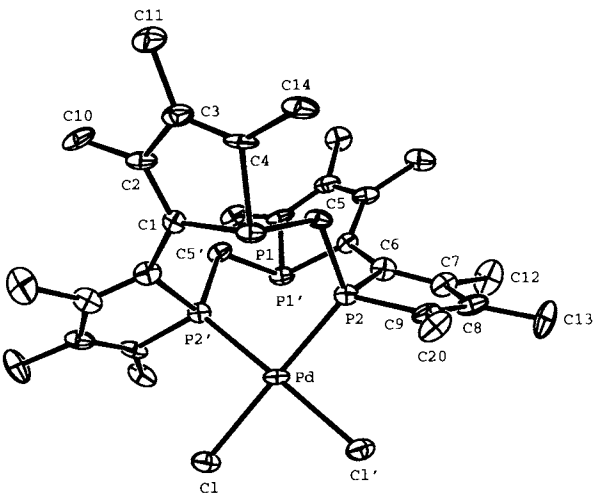


Figure 1. Crystal structure of **2**. Phenyl groups have been omitted for clarity. Important distances [Å] and angles [°]: Pd–Cl 2.344(2), Pd–Cl′ 2.346(2), Pd–P2 2.261(2), Pd–P2′ 2.264(2), Pd···P1 3.78; Cl-Pd-Cl′ 89.0(1), Cl-Pd-P2′ 89.18(6), Cl′-Pd-P2 89.16(6), P2-Pd-P2′ 93.2(1).

The structure shows a diagonal chelation of the palladium atom. The metal resides in a square-planar coordination environment with a *cis* arrangement of the phosphorus and chlorine atoms. The Pd···P1 separations are relatively short (3.79 Å). The angle between the lone pair at P1(P′1) and the P1(P′1)–Pd bond is calculated to lie around 72°. Thus, some through-space interaction probably exists between the noncoordinated phosphorus atoms and palladium. The ^{31}P NMR spectrum reveals the presence of two nonequivalent P atoms that show a large coupling (^2J(P,P) = 79 Hz). The analogous platinum complex **3** is similar (^2J(P,P) = 65 Hz), but additional Pt–P couplings are seen (^1J(Pt,P) = 3149 Hz). A simulation also indicates some coupling between the Pt and the noncoordinated P atoms (J(Pt,P) ≈ 127 Hz).

The structural characteristics of the Pd^{II} complex **2** suggested that some stabilization of a [Pd^0(**1**)] intermediate could be achieved because of the cradle conformation of **1** in the complex and because of the through-space interactions of the noncom-

plexed lone pairs of electrons of **1** with the 14-electron palladium center. To test this hypothesis, we decided to compare the performance of **1** against the well-studied trifurylphosphane ligand Fu_3P in the palladium-catalyzed Stille cross-coupling reaction.[7, 8] Two types of catalytic systems were used for the comparison. The first, classical one used a mixture of one equivalent of $Pd(OAc)_2$ with four P donors (corresponding to one molar equivalent for **1**). In the second system, two equivalents of CuI were added.[8] The lifetime of the catalyst was evaluated by running the coupling of PhI with $CH_2=CHSnBu_3$ until the reaction stopped, then recharging the used catalyst with further batches of the same reagents. This process was repeated several times. The results are collected in Table 1. An inspection of these

Table 1. Stille coupling of iodobenzene with tributylvinyltin.

Entry	Phosphane	Catalyst (mol%)	T[°C]	t[h]	Conversion [%][a]
1	Fu_3P	Pd(5)	50	3	100
2	**1**	Pd(5)	50	3	85
3	Fu_3P	Pd(1)	80–90	3	100 [b]
4	**1**	Pd(1)	80–90	3	95
5a	Fu_3P	Pd/Cu(1)	80–90	3	100 [b]
5b	Fu_3P	Pd/Cu(1)	80–90	3	66
6	**1**	Pd/Cu(1)	80–90	3	100
7	Fu_3P	Pd/Cu(0.25)	60	5	85
	Fu_3P	Pd/Cu(0.25)	60	18	85
8a	**1**	Pd/Cu(0.25)	60	5	50
	1	Pd/Cu(0.25)	60	20	90
	1	Pd/Cu(0.25)	60	40	100
8b	**1**	Pd/Cu(0.25)	60	24	94
8c	**1**	Pd/Cu(0.25)	60	24	95

[a] Determined by gas chromatography. [b] Pd precipitate observed.

data clearly shows that the macrocycle **1** gives a slightly less active catalyst than with Fu_3P (compare entries 1 and 2 as well as 7 and 8a), which is consistent with the suspected higher stability of the [Pd(**1**)] system. In contrast, the lifetime of the [Pd(**1**)] catalyst is much longer than that of the $[Pd(Fu_3P)_2]$ species. Indeed, a precipitate is often observed at the end of the catalytic cycle with Fu_3P (entries 3 and 5a) and the activity of the catalyst drops sharply with time (entry 7). Recycling the catalyst is possible with **1**, even at low concentration (entries 8a–c) but this is not possible with Fu_3P (entries 5a, b). Consequently, the [Pd(**1**)] catalyst is much more cost-effective than $[Pd(Fu_3P)_2]$.

Similar results to those for the Stille coupling have been obtained in the Pd-catalyzed allylation of the malonate anion[9] (Table 2). In this case, the palladium complex of **1** is the best catalyst, especially at low concentration (entries 1 and 6). It is noteworthy that diagonal complexation of two of the four lone pairs of electrons of **1** by a $[Mo(CO)_4]$[5] fragment drastically decreases the efficiency of the catalyst (Table 2, entries 1 and 5).

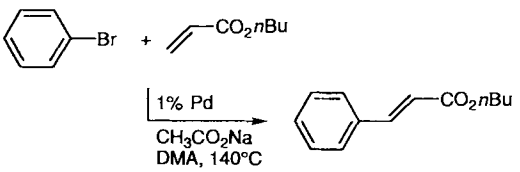
Table 2. Palladium-catalyzed reaction of $PhCH=CHCH_2OAc$ with $NaCH(COOMe)_2$ [a].

Entry	Phosphane	Pd [mol%]	t[h]	Conversion [%][b]
1	**1**	0.5	3	95
2	Fu_3P	0.5	3	60
3	Ph_3P	0.5	3	10
4	$(Ph_2PCH_2)_2$	0.5	3	98
5	**1**·$Mo(CO)_4$	0.5	3	72
6	**1**	0.05	48	100
7	$(Ph_2PCH_2)_2$	0.05	48	93

[a] In THF at room temperature. [b] Traces of $(PhCH=CHCH_2)_2C(CO_2Me)_2$ are always formed.

This observation confirms the positive effect of the noncomplexed P atoms of **2** on the catalytic activity.

Finally, a comparison has been drawn with the palladacycles proposed by Herrmann et al.[4] for the Heck reaction (Scheme 2). After 48 h, we observed a 89% conversion; a 96%



Scheme 2.

conversion was achieved with the catalyst from Herrmann et al.[4] However, our catalyst was still active, since quantitative conversion was observed after additional heating for 48 h. Thus, the extraordinary resistance of our system toward degradation is clearly established.

Experimental Section

2: **1** (0.39 g, 0.5 mmol) was dissolved under argon in CH_2Cl_2 (20 mL) and a solution of $[PdCl_2(PhCN)_2]$ (0.20 g, 0.5 mmol) in CH_2Cl_2 (5 mL) was added dropwise. After the mixture had been stirred at room temperature for 15 min, the solvent was evaporated under vacuum, and the residue was extracted with hot C_6H_6 (2 × 1 mL). The extracts were cooled to room temperature and allowed to stand to give dark red monocrystals of **2**. Yield: 0.43 g (90%). ^{31}P NMR (CD_2Cl_2): $\delta = -11.50$, 22.76 (AB system, $^2J(A,B) = 79.4$ Hz); ^1H NMR (CD_2Cl_2): $\delta = 1.82$ (s, 6H; CH_3), 1.94 (s, 6H; CH_3), 2.07 (d, $^4J(H,P) = 3.1$ Hz, 6H; CH_3), 2.11 (br., 4H; CH_2), 2.19 (d, $^4J(H,P) = 1.4$ Hz, 6H; CH_3), 6.60–7.90(m, 20H; Ph); ^{13}C NMR (CD_2Cl_2): $\delta = 13.3$, 15.52, 15.71, 17.64 (s; CH_3), 21.97 (pseudo-t; CH_2); elemental analysis (%): calcd for $\mathbf{2}\cdot 0.5\,C_6H_6$: C 64.35, H 5.20, P 12.53, Cl 10.76; found: C 64.47, H 5.35, P 13.20, Cl 10.67.

3: **1** (0.039 g, 0.05 mmol) was dissolved under argon in CH_2Cl_2 (2 mL) and a solution of $[PtCl_2(cod)]$ (0.020 g, 0.05 mmol) in CH_2Cl_2 (5 mL) was added dropwise. The mixture was heated for 15 min at 40 °C. After the solution had been allowed to cool, it was concentrated under vacuum, and Et_2O (5 mL) was added. The precipitate was washed with Et_2O and dried under vacuum. Yield 0.040 g (80%). ^{31}P NMR ([D$_6$]DMSO): $\delta = -8.50$, 9.17 (AB system, $^1J(P_A,Pt) = 3149$ Hz, $^1J(P_B,Pt) = 127$ Hz, $^2J(P_A,P_B) = 65.0$ Hz); ^1H NMR ([D$_6$]DMSO): $\delta = 1.34$ (s, 6H; CH_3), 1.46 (s, 6H; CH_3), 1.61 (s, 6H; CH_3), 1.73 (s, 6H; CH_3), 2.05 (d, $^2J(H,P) = 1.7$ Hz, 4H; CH_2), 6.11–7.40 (m, 20H; Ph); ^{13}C NMR ([D$_6$]DMSO): $\delta = 14.17$, 15.84, 16.04, 16.34 (s; CH_3), 20.0 (pseudo-t; CH_2).

Stille coupling: An appropriate amount of catalyst was preformed under argon in a dry schlenk flask equipped with a magnetic stirring bar in freshly degassed DMF (3 mL) at room temperature. It was prepared from either $Pd(OAc)_2$ (1 equiv) and tri-2-furylphosphane (4 equiv) or from $Pd(OAc)_2$ (1 equiv) and **1** (1 equiv) by stirring at 40 °C for 15 min. Iodobenzene (0.112 mL, 1 mmol) was added to the preformed catalyst and, after a period of 15 min at room temperature, tributylvinyltin (0.292 mL, 1 mmol) was introduced. Thereafter, in specific cases CuI (2 equiv) was added. The flask was then immersed in a thermostated bath, and the evolution of the crude reaction mixture was monitored by GC on a Varian 3400 apparatus equipped with a WCOT (25 m, 0.25 mm) capillary column, CP-SiP-SCB stationary phase between 40 °C and 220 °C.

Palladium catalyzed allylic substitution: A mineral oil dispersion of NaH (60% NaH, 1.25 mmol) was washed free of oil with dry *n*-pentane (2 × 5 mL). The oil-free NaH was suspended in THF (4 mL), stirred, cooled to 0 °C, and treated dropwise with a solution of dimethyl malonate (1.2 equiv). After the reaction was complete, the resulting solution of sodium dimethyl malonate was transferred by cannula under argon into a 50 mL flask containing 1-acetoxy-3-phenyl-2-propene (1.2 mmol), and the catalyst, which had been previously prepared by mixing solutions containing $[Pd(dba)_2]$ (1 equiv; dba = dibenzylidenacetone) in THF (1 mL) and the phosphane (4 equiv) in THF (1 mL,) and stirring under argon at room temperature (in the cases of **1** and **1**·$Mo(CO)_4$, the catalyst was prepared as above from tetraphosphole (1 equiv); the reaction was stirred for 15 min at 50 °C). The reaction mixture was stirred at room temperature and the degree of conversion was calculated from the crude reaction mixture by ^1H NMR spectroscopy. The work up involved dilution in glacial acetic acid, extraction with Et_2O, and washing with brine. Subsequent evaporation of the solvents gave the crude product as a yellow oil, which was purified by chromatography on alumina by using hexane/ethyl acetate (80/20).

Heck coupling: Aryl bromide (5 mmol), *N*,*N*-dimethyl acetamide (DMA) (5 mL), *n*-butyl acrylate (5.5 mmol), and anhydrous sodium acetate (0.5 g) were placed

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3621-2365 $ 17.50+.50/0

under argon in a 50 mL double-necked flask equipped with a reflux condenser. The flask was heated at 140 °C and the solution of freshly prepared catalyst (1 equiv, 1 mL DMA) (see above), was added rapidly. The conversion of the aryl bromide was monitored by GC on 50 μL samples of the crude mixture dissolved in acetone (2 mL).

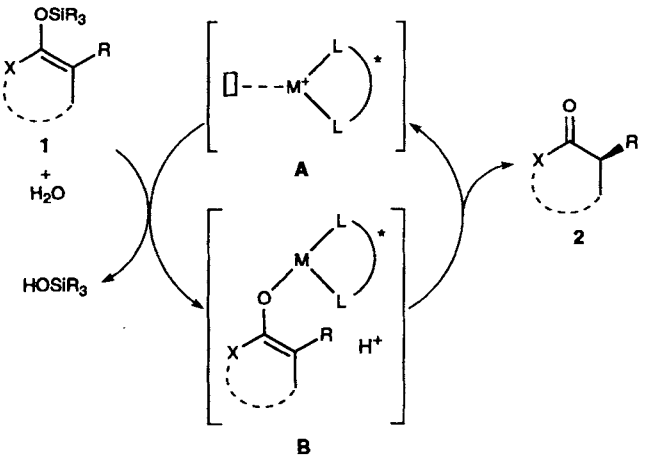
Asymmetric Catalytic Protonation of Silyl Enol Ethers with Chiral Palladium Complexes**

Masaharu Sugiura and Takeshi Nakai*

The enantioselective protonation of prochiral enolates with a chiral proton source has attracted much attention as a general methodology for the asymmetric synthesis of α-substituted carbonyl compounds.[1] While most of the methods reported so far require the use of more than a stoichiometric amount of a chiral Brønsted acid, the catalytic use of a chiral acid, combined with a stoichiometric amount of an achiral proton source, has also been successful.[2] Disclosed here is a conceptually new approach to the asymmetric catalytic protonation of enol silyl ethers, which employs water as the proton source and a chiral palladium complex as the catalyst.

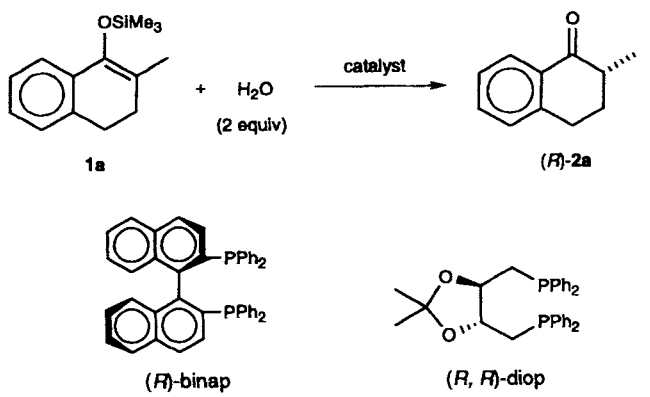
Scheme 1 illustrates our working hypothesis.[3] Chiral transition metal complex **A**, if coordinatively unsaturated, should activate silyl enol ether **1** and promote attack by water onto the silyl group to afford chiral metal enolate **B** and a silanol. Enolate **B** would then be diastereoselectively protonated by water to



Scheme 1. The working hypothesis.

afford the enantiomerically enriched ketone **2** with regeneration of **A**. To realize this new concept, the chiral transition metal catalyst should be capable of preferentially activating the enol ether over the coexisting water and product ketone. Based on these considerations, we selected chiral cationic Pd complexes as the catalyst. Shibasaki et al. recently reported that the chiral cationic Pd complex prepared from [$PdCl_2$\{(*R*)-binap\}] (binap = 2,2′-bis(diphenylphosphanyl)-1,1′-binaphthyl) and AgOTf (1:1) in the presence of 4-Å molecular sieves (MS) in wet DMF serves as an efficient asymmetric catalyst for aldol reactions due to the intermediacy of a chiral Pd enolate.[4]

Therefore, we focused on the two chiral cationic Pd species generated from [$PdCl_2$\{(*R*)-binap\}] (**3a**) or [$PdCl_2$\{(*R*,*R*)-diop\}] (**3b**) and silver salts for the protonation of cyclic enol ether **1a** with water (Scheme 2). Whereas the Pd species generated by



Scheme 2. Protonation of cyclic enol ether **1a** by water in the presence of chiral, cationic Pd complexes generated from [$PdCl_2$\{(*R*)-binap\}] (**3a**) or [$PdCl_2$\{(*R*)-diop\}] (**3b**) and silver salts.

mixing **3a** and two equivalents of $AgPF_6$ showed high catalytic activity but low enantioselectivity (Table 1, entry 1), that generated by the method of Shibasaki et al.[4] provided higher enantiomeric excesses; however, the reproducibility was very poor (entry 2). We therefore suspected that a contaminant plays a vital role in this reaction. Significantly enough, when a small amount of diisopropylamine—a possible contaminant of **1a**—was added to the catalyst solution, the enantioselectivity remarkably improved to 79% *ee*; the reproducibility was also very good (entry 3).[5] Analogous use of the diop complex **3b**

Table 1. Optimization of asymmetric catalysis for the protonation of **1a** with water [a].

Entry	Catalyst	Conditions	Yield [%][b]	*ee*[%][c] (Config.[d])
1	$[PdCl_2\{(R)$-binap$\}]$ (**3a**, 5 mol%) $AgPF_6$ (10 mol%) CH_2Cl_2/MeOH	RT 0.5 h	95	4–13 (*S*)
2	**3a** (5 mol%) AgOTf (5 mol%) 4-Å MS, DMF/H_2O	RT–30 °C 84–5 h	25–85	44–73 (*R*)
3	**3a** (5 mol%) AgOTf (5 mol%) 4-Å MS, DMF/H_2O then iPr_2NH (0.5 mol%)	50 °C 18 h	83	79 (*R*)
4	$[PdCl_2\{(R,R)$-diop$\}]$ (**3b**, 5 mol%) AgOTf (5 mol%) 4-Å MS, DMF/H_2O then iPr_2NH (0.5 mol%)	50 °C 5 h	78	3 (*S*)
5	$[PtCl_2\{(R)$-binap$\}]$ (5 mol%) AgOTf (5 mol%) 4-Å MS, DMF/H_2O then iPr_2NH (0.5 mol%)	50 °C 118 h	62	4 (*R*)

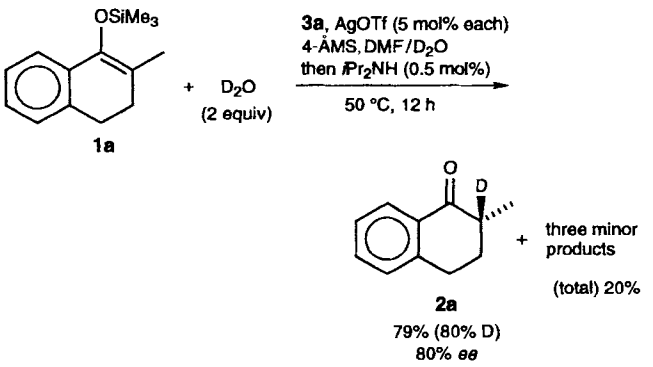
[a] All reactions were carried out with **1a** (0.5 mmol, see Experimental Section). [b] Yield of isolated product. [c] Determined by HPLC analysis on CHIRALCEL OD. [d] Assigned by comparing the optical rotation with literature values [6].

provided a lower enantiomeric excess (entry 4). A similar Pt–binap complex was also inferior to **3a** in both activity and enantioselectivity (entry 5). Furthermore, using $AgPF_6$ instead of AgOTf afforded **2a** in 81% yield and 76% *ee* (*R*), and using basic alumina instead of 4-Å molecular sieves resulted in 91% yield and 63% *ee*.

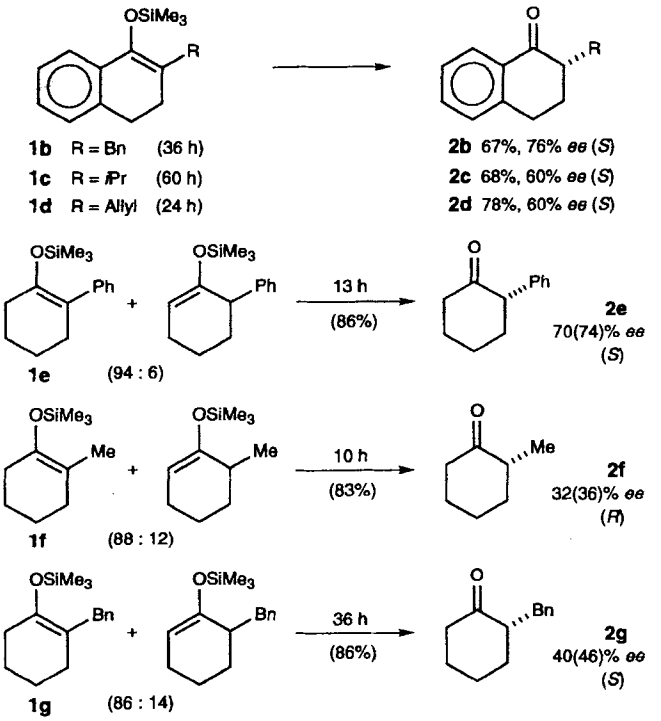
The question of what role the added diisopropylamine plays arises. Interestingly, addition of triethylamine gave essentially the same results (84% yield and 76% *ee*), indicating that the amine might act as a Lewis base, and not as a proton source. Moreover, ^{31}P NMR spectroscopic measurements of the catalyst solutions before and after addition of diisopropylamine[7] suggest that the amine might selectively deactivate one of the binap-bound Pd species initially formed. In other words, it appears that upon addition of the amine, the surviving Pd species act as the predominant catalyst(s), thus making the reaction slower but providing enhanced enantiomeric selectivity.

To gain further insight into the reaction mechanism, a labeling experiment with D_2O was carried out (Scheme 3).[8] Ketone **2a**, with 80% deuterium content at the α-position, was obtained together with traces of unexpected by-products,[9] implying that the reaction is more complicated than anticipated. More detailed studies must be awaited.

Finally, the present asymmetric catalysis was also applied to silyl enol ethers **1b–g**[5] under optimized conditions (Scheme 4).



Scheme 3. Labeling experiments with D_2O.



Scheme 4. Asymmetric catalytic protonation of various silyl enol ethers under optimal conditions. Values for **2e–g** that are corrected for the regioisomeric purity of the silyl enol ethers are given in parentheses.

While comparably high levels of enantiomeric selectivity were obtained with **2b–e**,[10] **1f** and **1g** gave moderate enantiomeric selectivity.

Experimental Section

In a typical reaction a mixture of **3a** (20 mg, 0.025 mmol), AgOTf (6.4 mg, 0.025 mmol), 4-Å MS powder (150 mg), DMF (1 mL), and water (36 μL) was stirred at room temperature for 2 h under an argon atmosphere. The resulting mixture was filtrated through a short Celite column to provide a red solution. An aliquot (10 μL) of a solution containing iPr_2NH (33 μL) and DMF (1 mL) was added along with water (18 μL), and the mixture stirred at room temperature for 30 min. Then, **1a** (116 mg, 0.5 mmol) was added, and the resulting solution stirred at 50 °C for 18 h. After dilution with ether (40 mL), addition of water (10 mL), and filtration through a Celite pad, the organic layer was washed with brine, dried over magnesium sulfate, and freed of solvent under reduced pressure. Purification by preparative thin-layer chromatography afforded **2a** (66 mg, 83%).

Selective Enhancement of NMR Signals for α-Cyclodextrin with Laser-Polarized Xenon**

Yi-Qiao Song, Boyd M. Goodson, Rebecca E. Taylor, David D. Laws, Gil Navon, and Alexander Pines*

Xenon, hydrophobic and chemically inert, has been widely used as an NMR probe of chemical environments, both in solution and in the solid state.[1] With the application of optical pumping,[2] a large (> 10%) ^{129}Xe nuclear-spin polarization can be generated. This polarization has been used to increase the sensitivity of ^{129}Xe NMR spectroscopy[3, 4] and magnetic resonance imaging (MRI),[5] and to supply polarization to neighboring spins on surfaces.[6] It was recently shown that enhanced xenon polarization can also be transferred to molecules in solution[7] by cross-relaxation, a process dubbed the *s*pin *p*olarization *i*nduced *n*uclear *O*verhauser *e*ffect (SPINOE). Because the SPINOE depends on the proximity of ^{129}Xe atoms to neighboring spins, as well as their relative motion, more rapid transfer of polarization is expected when xenon is temporarily bound, thereby permitting selective enhancement of NMR signals of nuclear spins near xenon binding sites.

Here we report polarization transfer from laser-polarized ^{129}Xe to ^{1}H spins in two molecular systems in solution: *p*-nitrotoluene (*p*-NT), which couples mainly diffusively to xenon, and α-cyclodextrin (α-CD, Figure 1), a cyclic oligosaccharide with a hydrophobic pocket known to bind xenon[8, 9] and other guest species.[10] Binding of xenon to α-CD gives rise to cross-relaxation rates up to 150 times greater than those between xenon and *p*-NT; this results in more rapid transfer of polarization. Furthermore, enhancements of ^{1}H spins adjacent to the xenon binding site in α-CD are greater than those of ^{1}H spins further away.

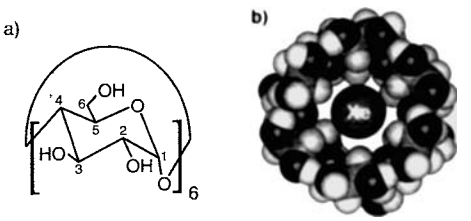

Figure 1. a) Structural formula of α-cyclodextrin. b) CPK model of α-cyclodextrin [16] in which a xenon atom is placed within the hydrophobic pocket containing the hydrogen atoms H3 and H5.

The change in the ^{1}H magnetization due to the presence of highly polarized xenon is well approximated by Equation (1).[7]

$$\frac{\Delta M^{H}}{M_{eq}^{H}} = -\sigma_n n^{Xe} T_1^{H} \frac{\gamma^{Xe}}{\gamma^{H}} \frac{\Delta M^{Xe}}{M_{eq}^{Xe}} (1-e^{-t/T_1^{H}}) \quad (1)$$

$$\sigma_n n^{Xe}, \quad \frac{1}{T_1^{Xe}} \ll \frac{1}{T_1^{H}} \quad (2)$$

Here, σ_n is the partial millimolar cross-relaxation rate, n^{Xe} is the concentration of ^{129}Xe in the solution, γ^{Xe}, γ^{H} are the magnetogyric ratios, M^{Xe}, M^{H} and M_{eq}^{Xe}, M_{eq}^{H} are the enhanced and equilibrium magnetization of ^{129}Xe and ^{1}H, respectively, T_1^{Xe}, T_1^{H} (under condition (2)) are the ^{129}Xe and ^{1}H spin-lattice relaxation times, and $\Delta M = M - M_{eq}$. In the absence of laser polarization, the ^{129}Xe–^{1}H NOE enhancement is minuscule ($\approx 10^{-5}$) due to low xenon concentration and weak ^{129}Xe–^{1}H coupling. In previous work[9, 11] ^{129}Xe–^{1}H interactions were indirectly observed by detecting changes in the xenon signal during proton saturation. With the use of laser-polarized xenon, however, the ^{129}Xe–^{1}H NOE enhancement ($\approx 10^{-2}$)[12] is detected directly in the resolved ^{1}H NMR spectrum.

The technique used for optically pumping xenon has been described elsewhere;[4] ^{129}Xe polarizations are typically 5–10%. To detect the SPINOE signals, we used a heteronuclear difference NOE pulse sequence (Figure 2), which suppresses the equilibrium ^{1}H magnetization and is therefore directly sensitive to the SPINOE. The ^{1}H SPINOE NMR spectra for 0.1 M *p*-NT in [D$_6$]benzene with laser-polarized xenon are shown in Figure 3. Equation (1) was used to determine values of σ_n for *p*-NT by assuming a linear dependence of the cross-relaxation rate on the concentration of polarized xenon (Table 1). The values are similar to that for the hydrogen atom of [D$_5$]benzene, which is in agreement with a rough theoretical

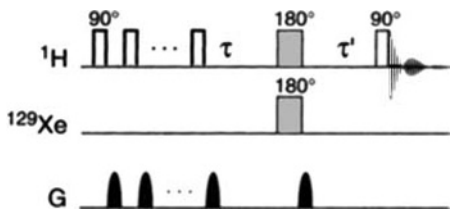

Figure 2. Heteronuclear difference NOE pulse sequence for ^{129}Xe–^{1}H SPINOE NMR spectroscopy based on sequences developed by Shaka [13]. The equilibrium ^{1}H NMR signal is saturated by 90° and gradient pulses (G); the saturation is maintained by a 180° pulse followed immediately by a gradient pulse. A xenon 180° pulse allows SPINOE signals to accumulate during the mixing periods τ and τ'. Each spectrum represents the difference of two scans.

	OH(3)	0.86 ± 0.18	1.0
	OH(6)	0.36 ± 0.14	1.1

[a] The error range for the T_1 measurements is about ±5%. [b] Data for [D_5]benzene signals in the *p*-NT spectra.

estimate of the cross-relaxation rate based on dipolar coupling modulated by molecular diffusion.[7]

The first indication of stronger couplings for laser-polarized xenon in α-CD is the reduced ^{129}Xe relaxation time T_1 (≈20 s in 0.1 M α-CD/[D_6]DMSO), which is short compared to that for xenon in 0.1 M *p*-NT/[D_6]benzene (>500 s). The equilibrium ^{1}H NMR spectrum of α-CD is shown in Figure 4a; the chemical shifts were assigned by means of a 2D COSY spectrum. After introduction of laser-polarized ^{129}Xe into the solution, SPINOE NMR spectra (Figure 4b–d) were obtained by using the pulse sequence of Figure 2. Values of σ_n for the ^{1}H spins in α-CD were obtained by fitting the data to Equation (1) (Table 1). The increase in couplings between xenon and α-CD arising from xenon binding[14] demonstrates the sensitivity of σ_n to the binding of xenon with molecules in solution.

In the case of α-CD, variation of signal enhancements is observed in the ^{1}H NMR spectrum: The strongest SPINOEs are observed from the H3 and H5 atoms located inside the hydrophobic pocket. Differences in the xenon coupling to various protons is expected when binding occurs, because dipolar relaxation is sensitive to the distances between spins and varies as $\sigma_n \propto r^{-6}$.[15] For example, from this relationship a ratio of 1:1.5 can be estimated for the range of relative distances between Xe–H5 and Xe–H1, neglecting transferred NOEs.[17] According to the X-ray structure of α-CD,[16] a ratio between 1:1.2 and 1:2, corresponding to Xe–H5 distances of about 3 to 6 Å and Xe–H1 distances of about 6 to 8 Å, is consistent with a distribution of xenon locations within the hydrophobic pocket.

These results show the potential of ^{129}Xe–^{1}H SPINOE experiments for probing the structure and dynamics of molecules in solution. Furthermore, they may have implications for NMR studies of hydrophobic potentials in systems involved in hydrophobic binding, for example, inclusion compounds, membranes, and proteins.

Reducible Nanoscale Molecular Rods Based on Diacetylene-Linked Poly(phenylthio)-Substituted Benzenes**

Marcel Mayor, Jean-Marie Lehn,*
Katharina M. Fromm, and Dieter Fenske

Structures of defined geometry and nanometric size containing electron-accepting subunits are of much interest as reducible molecular wires for the development of molecular and supramolecular electronic and photonic devices.[1–3] They may serve as connectors between components, and also possess marked nonlinear optical properties due to extended π conjugation.[4] Whereas the very actively studied entities built from conjugated electron-rich groups (such as thiophene, pyrrole[5]) lead to electronic conduction upon oxidation (p-doping), reducible wires are susceptible to n-doping through reduction and may show higher electronic mobility.

Molecular wires based on pyridinium end groups and carotenoid-type conjugated chains (termed caroviologens), which we investigated earlier, induce electron transport through lipid membranes.[5] Poly(phenylthio) aromatic systems such as **1** are well known for their host–guest chemistry in the solid state[6] and also display remarkably low reduction potentials.[7] They thus appeared to be promising candidates for incorporation into conjugated systems chosen for the development of novel types of reducible molecular wires.

We present here the synthesis, the structural characterization and some physicochemical properties of **2** and **3**, in which two

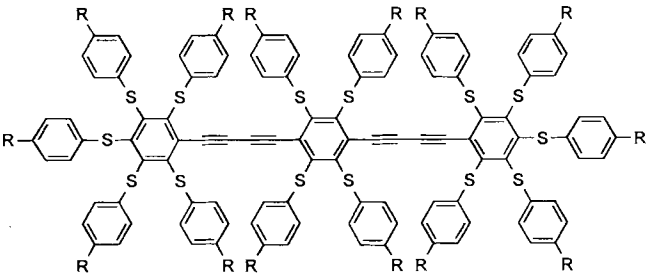
2a, R=H
2b, R=*t*Bu



3, R=*t*Bu

and three poly(phenylthio)benzene subunits are linked by diacetylene bridges as efficient π-conjugation connectors. Starting from the corresponding halogenated benzaldehydes, the acetylene-functionalized phenylthio-substituted benzenes were synthesized in three steps (Scheme 1). Aromatic nucleophilic

substitution of the halogens by thiophenyl anions in 1,3-dimethyl-2-imidazolidinone (DMI) yielded the phenylsulfanyl-substituted benzaldehydes **4** and **7** in yields of over 70%. Treatment with CBr_4/PPh_3 in CH_2Cl_2 gave the dibromoethylene derivatives **5** and **8** in good yields.[8] Reduction with excess lithium diisopropylamide (LDA) in THF led to acetylenes **6** and **9**, which were oxidatively coupled to provide poly(phenylthio)benzenes **2** and **3**.

Coupling[9] of pentakis(phenylthio)ethynyl benzene (**6a**) with copper acetate in pyridine at 45 °C gave **2a** as an orange crystalline solid in 65% yield.[10] Diacetylene **2a** is fairly soluble in organic solvents such as $CHCl_3$, CH_2Cl_2, toluene, or THF. Crystallization of **2a** from hot toluene gave single crystals suitable for X-ray analysis.[11] The solid-state structure shows that the molecule consists of two pentakis(phenylthio)benzene units linked by a diacetylene bridge, and presents a crystallographic inversion center at the middle of the C8–C8′ central bond (Figure 1) The two diacetylene-connected benzene rings lie in parallel planes and are separated by 0.75 Å. The bond lengths in the diacetylene bridge (C6C7≡C8C8′≡C7′C6′) are 1.436 (C6–C7),

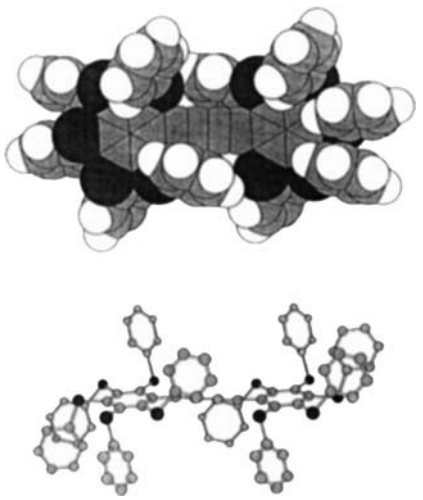

Figure 1. Crystal structure of **2a**. Top: plan view of the space-filling representation; bottom: side view of the ball-and-stick representation.

1.202 (C7–C8), and 1.372 Å (C8–C8′). The bridge angles of 175.5 (C6-C7-C8) and 178.2° (C7-C8-C8′) show slight deviation from linearity. The molecule is 15.8 Å long (distance between the two sulfur atoms that are *para* to the diacetylene linker). In analogy to the parent hexakis(phenylthio)benzene, an alternating up and down pattern (ababa) was expected for the phenylthio substituents.[14] In fact, **2a** presents a conformation in which the three phenylthio groups in *para* and *ortho* positions to the diacetylene bridge point to the same side of the benzene ring (abbba); the sulfur angles are, however, in the expected range (104–106°).

Oxidative coupling[15] of a mixture of **9** and nine equivalents of mono-acetylene **6b** in $CHCl_3$ with CuCl and *N,N,N′,N′*-tetramethyl 1,2-ethanediamine (TMEDA) under an oxygen atmosphere[16a] yielded diacetylenes **2b** and **3**, which were isolated in 45% and 16% yield, respectively, by size-exclusion chromatography. Both are intense dark orange solids and fairly soluble in organic solvents such as $CHCl_3$, CH_2Cl_2, or toluene; this allowed their characterization by ^1H and ^{13}C NMR spectroscopy as well as FAB mass spectrometry.[10, 16b]

Compounds **2** and **3** represent π-conjugated, rigid molecular rods of nanoscale dimensions with distances of 9.4 Å between the centers of the benzene cores and 15.8 Å and 25.2 Å, respectively, between the terminal sulfur atoms. The lateral phenyl groups may be considered to provide an insulating molecular sheath that protects the central functional component (see Figure 1).

UV/Vis spectra of **1b**, **2b**, and **3** (Figure 2) display an absorption maximum at about 255 nm, which may be attributed to the allowed π–π* transition in the peripheral *tert*-butylphenylthio moieties. Accordingly, the relative extinction coefficients of **1b**,

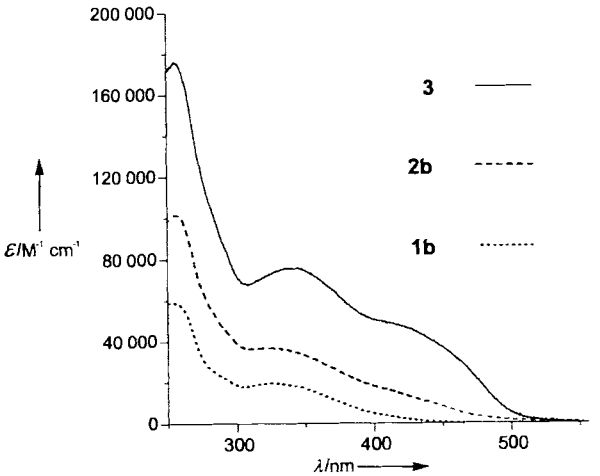

Figure 2. UV/Vis spectra of **1b**, **2b**, and **3** in CH_2Cl_2; $T = 298$ K.

2b, and **3** at 255 nm are proportional to the number of these substituents. Additional transitions are observed at 325–340 nm and, in the case of **2** and **3**, at about 430 nm. These longer wavelength transitions presumably arise from electronic interaction between poly(phenylthio)benzene and diacetylene units. Excitation of **1**–**3** in CH_2Cl_2 at 400 nm results in a moderately intense, structureless fluorescence which is not affected by oxygen. Whereas the presence of *tert*-butyl substituents in **1b** has little effect on the emission maximum (515 versus 520 nm for **1a** and **1b**, respectively), it produces a large hypsochromic shift in **2b** with respect to **2a** (560 versus 515 nm, respectively). This could reflect an alternative conformational preference that is induced by the steric requirements of the *tert*-butyl groups. Introduction of an additional dialkynephenylene unit results in further displacement of the emission to longer wavelengths in **3** ($\lambda_{max} = 600$ nm).

Of particular interest are the redox properties of **1**–**3**, which form a series with increasing conjugation. The cyclic voltammetry data are summarized in Table 1. None of the compounds **1**–**3** is oxidized up to +1.25 V. Monomeric **1a** and **1b** show a reversible one-electron reduction at −1.56 and −1.7 V, respectively. Dimeric **2a** and **2b** have two reversible one-electron re-

Table 1. Cyclic voltammetry data for **1**–**3** [a].

Compound	E_1^0 [V][b]	E_2^0 [V][b]
1a	−1.56	
1b	−1.7	
2a	−1.12	−1.38
2b	−1.17	−1.44
3	−0.98	−1.19[c]

[a] Platinum working electrode in 0.1 M $TBAPF_6$/DMF. [b] Versus ferrocene/ferrocenium, formal reduction potential $E^0 = (E_{pa} + E_{pc})/2$. [c] Two-electron reduction.

ductions at $-1.12/-1.38$ V and $-1.17/-1.44$ V, respectively; both processes are at less negative potential than the reduction of the corresponding monomeric units **1a** and **1b**. Trimeric **3** shows a reversible one-electron reduction at -0.98 V and a reversible two-electron reduction at -1.19 V.[17] The pronounced trend towards more positive reduction potentials with increasing molecular length (not only for addition of the first electron) confers the potential for very interesting electronic conductivity properties to this type of molecular wire.

The solubility and stability of the molecular rods **2** and **3** combined with their structural, optical, and electrochemical properties makes them promising candidates for the design of nanoscale molecular devices for molecular electronics and photonics.[1] The alkyne group allows connection of the rods with other alkyne-bearing components, and the peripheral phenylthio substituents can be functionalized to convey specific physical properties. We are currently investigating longer linear rods, *meta-* and *ortho-* dialkyne poly(phenylthio)benzene building blocks, and the corresponding cyclic structures.

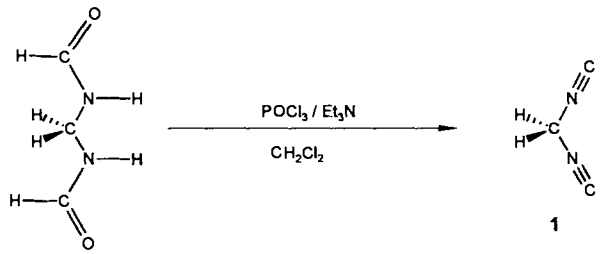
Synthesis, Structure, and Coordination Chemistry of Diisocyanomethane**

Jürgen Buschmann, Thilo Bartolmäs, Dieter Lentz,* Peter Luger, Ingo Neubert, and Matthias Röttger

About 30 years ago Neidlein reported the synthesis of diisocyanomethane (**1**).[1] However, its existence in solution could only be proved by derivatization. The isolation of this compound, which is isomeric with the long known malonodinitrile[2] and with isocyanoacetonitrile, which we recently synthesized in an analytically pure form and structurally characterized by X-ray crystal crystallography,[3] has thus far been unsuccessful. Although Neidlein reported that **1** is extremly unstable even in solution, we were able to isolate this first geminal diisocyanide by fractional condensation of a dichloromethane solution under high vacuum. Compound **1** was obtained as colorless crystals in a cooling trap at -55 °C; it melts at -15 °C and turning brown, and decomposes explosively at -10 °C to give a brown-black, virtually insoluble polymer. Since this polymer exhibits a strong fluorescence even in the NIR region, we were unable to record a Raman spectrum.



1

By using a gas IR cell that allowed **1** to be sublimed into a directly connected trap it was possible to record an IR spectrum of **1** in the gaseous state. The vibrational spectroscopic data were completed by a low-temperature FT Raman spectrum. In accord with the C_{2v} symmetry of **1**, two N≡C stretching modes were observed at 2173 and 2157 cm^{-1}. In the IR spectrum the symmetric stretching mode appears as a weak shoulder on the high frequency side in accordance with the results of an ab initio calculation.[4] The ^{1}H NMR ($\delta = 4.99$ (CH_2)), the ^{13}C {^{1}H} NMR ($\delta = 46.8$ (CH_2), 162.5 (NC)), and the ^{14}N NMR spectra ($\delta = -215.3$ (NC) ($\nu_{1/2} = 20$ Hz, due to the small electric field gradient at the nitrogen atom) exhibit chemical shift values typical for isocyanides.

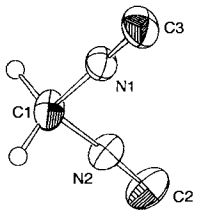

Figure 1. Molecular structure (ORTEP plot [7]) of diisocyanomethane **1** in the crystal.

Crystals suitable for an X-ray crystal structure analysis were obtained by slowly cooling a solution of **1** in diethyl ether/pentane from $-20\,^{\circ}C$ to $-90\,^{\circ}C$ in steps of 5 K per day (Figure 1). Although the studied crystal was nonmetrically twinned (2.22(2):1) the analysis of the orientation matrices showed a perfect superposition of the $0kl$ reflections, which could be scaled. A few superimposed $5kl$ and $7kl$ reflections were removed from the data file. The structure was solved by direct methods and refined in the monoclinic space group $P2_1/n$ (Table 1).[5] Interestingly, all three isomers crystallize in the monoclinic crystal system and show very similar lattice constants. Equivalent bond lengths are equal within 3σ. According to a comparison of the structure of **1** with the structures of isocyanides in the gas phase[6] and the structure obtained from the ab initio calculation, the N≡C bond length in **1** seems to be shortened due to libration effects.

Table 1. Bond lengths [pm] and angles [°] in **1** in comparison to those values obtained from an ab initio calculation.

Parameter	Crystal structure	MP2 6-31G**
C–N	142.7(1), 142.5(1)	142.2
C≡N	115.5(1), 115.1(1)	119.0
C–H	94.6(20), 97.7(19)	109.3
N-C-N	110.4(1)	110.5
C≡N-C	177.7(1), 175.9(1)	178.6

The stability of **1** increases considerably by coordination to a metal center. Reaction of **1** with $[Cr(CO)_5(thf)]$ or $[CpMn(CO)_2(thf)]$ results in the formation of monocoordinated products **2** and **4** and dicoordinated products **3** and **5**, in which **1** functions as a bridging ligand. The structures of **2** and **4** were elucidated by X-ray crystallography (Figure 2).[5] The striking differences in the C–N bond lengths of the free and coordinated isocyanide function in **2** and **4** might also be due to libration effects. The most significant differences are evident in the ^{13}C chemical shift values of the free ($\delta = 162.0$) and the coordinated

Experimental Section

1: Bis(formylamino)methane (1.02 g, 10 mmol) was suspended in dichloromethane (25 mL). Triethylamine (5.1 g, 50 mmol) was added and the mixture was cooled to $-60\,^{\circ}C$. Phosphoryl chloride (2 mL, 22 mmol) was added dropwise. After the mixture had been slowly warmed to $-20\,^{\circ}C$, it was stirred for an additional 30 min. After addition of saturated aqueous Na_2CO_3 solution the organic phase was washed twice with water (20 mL) and dried over KOH. Fractional condensation under vacuum (10^{-3} mbar) yielded **1** (500 mg, 75.8%) as colorless crystals in a trap maintained at $-55\,^{\circ}C$. M.p. $-15\,^{\circ}C$; ^1H NMR ($CDCl_3$, $-40\,^{\circ}C$): $\delta = 4.99$ (CH_2); $^{13}C\{^1H\}$ NMR ($CDCl_3$, $-40\,^{\circ}C$): $\delta = 46.8$ (CH_2), 162.5 (NC); ^{14}N NMR ($CDCl_3$, $-40\,^{\circ}C$, NH_4NO_3 ext. reference): $\delta = -215.3$ (NC); IR(g): $\tilde{\nu} = 2987$ (vw), 2170 (sh), 2132 (vs), 1380 (m), 996 (m), 941 (w), 712 (m) cm^{-1}. Raman: $\tilde{\nu} = 2997$ (m), 2956 (s), 2173 (s), 2157 (m), 1444 (m), 1361 (m), 1263 (m), 984 (w), 924 (m), 269 (m), 253 (w), 150 (w), 100 (w) cm^{-1}. MS (70 eV): *m/z*: 66 [M^+], 40 [CH_2NC^+], 28 [CH_2N^+].

2,3: $[Cr(CO)_6]$ (770 mg, 3.5 mmol) was dissolved in dry THF (50 mL) and irradiated for 6 h with a high-pressure Hg lamp. The CO that was released was removed under vacuum several times. Compound **1** (500 mg, 7.6 mmol) in dry THF (10 mL) was added to this solution at $-40\,^{\circ}C$. The reaction mixture was heated to ambient temperature, stirred for 30 min, and purified by column chromatography using dichloromethane/pentane 3:1 as eluent. Colorless crystals of **3** (200 mg, 12.7%) were obtained from the first fraction. M.p. 162 °C; ^1H NMR (CD_2Cl_2): $\delta = 5.28$ (CH_2); $^{13}C\{^1H\}$ NMR (CD_2Cl_2): $\delta = 51.2$ (CH_2), 177.6 (NC), 214.1 (CO_{cis}), 215.6 (CO_{trans}); IR (CH_2Cl_2): $\tilde{\nu} = 2160$ (w), 2132 (m), 2069 (m), 2042 (s), 1957 (vs) cm^{-1}; MS (70 eV): *m/z*: 450 [M^+], 422 [$M^+ - CO$], 394 [$M^+ - 2CO$], 366 [$M^+ - 3CO$], 338 [$M^+ - 4CO$], 310 [$M^+ - 5CO$], 282 [$M^+ - 6CO$], 254 [$M^+ - 7CO$], 232 [$[Cr(CO)_5(CNCH_2)]^+$], 226 [$M^+ - 8CO$], 204 [$[Cr(CO)_4(CNCH_2)]^+$], 198 [$M^+ - 9CO$], 176 [$[Cr(CO)_3(CNCH_2)]^+$], 170 [$M^+ - 10CO$], 148 [$[Cr(CO)_2(CNCH_2)]^+$], 130 ([$[Cr(CO)(CNCH_2)]^+$), 92 [$[Cr(CNCH_2)]^+$], 52 [Cr^+]; 28 [CO^+]. The second fraction yielded **2** (580 mg (64.2%) as pale yellow crystals. M.p. 101 °C; ^1H NMR (CD_2Cl_2): $\delta = 5.13$ (CH_2); IR (CH_2Cl_2): $\tilde{\nu} = 2160$ (w), 2136 (m), 2059 (m), 1962 (vs) cm^{-1}; MS (70 eV): *m/z* : 258 [M^+], 230 [$M^+ - CO$], 204 [$M^+ - 2CO$], 174 [$M^+ - 3CO$], 146 [$M^+ - 4CO$], 118 [$M^+ - 5CO$], 52 [Cr^+].

4,5: $[CpMn(CO)_3]$ (780 mg, 3.8 mmol) was dissolved in THF (80 mL) and irradiated for 6 h with a high-pressure Hg lamp. The CO that was released was removed under vacuum several times. Compound **1** (250 mg, 3.8 mmol) in dichloromethane

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3621-2373 $ 17.50+.50/0

(10 mL) was added to this solution at −40 °C. The reaction mixture was allowed to warm to ambient temperature, stirred for 30 min, and the products were purified by chromatography on silica using dichloromethane/pentane 1:1 as eluent. Compound **5** (60 mg, 3.8%) was isolated from the first fraction as yellow crystals. M.p. 85 °C; IR (pentane): $\tilde{\nu}$ = 2028 (vs), 1942 (vs), 1919 (m) cm^{-1}; MS (70 eV): *m/z*: 418 [M^+], 362 [$M^+ - 2CO$] 216 [[$CpMn(CO)_2(CNCH_2)$]$^+$], 160 [[$CpMn(CNCH_2)$]$^+$], 120 [[CpMn]$^+$], 55 [Mn^+]. The second fraction gave **4** (180 mg, 19.6%) as yellow crystals. M.p. 76 °C; ^1H NMR (CD_2Cl_2): δ = 4.71 (C_5H_5, 5H), 5.01 (CH_2, 2H); $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 50.1 (CH_2), 83.4 (C_5H_5), 162.0 (NC), 210.5 (NC), 228.1 (CO); IR (CH_2Cl_2): $\tilde{\nu}$ = 2147 (m), 2086 (m), 2010 (m), 1903 (vs) cm^{-1}; MS (70 eV): *m/z*: 242 [M^+], 186 [$M^+ - 2CO$], 120 [[CpMn]$^+$], 55 [Mn^+].

Catalytic Conversion of Methane into Aromatic Hydrocarbons over Iron Oxide Loaded ZSM-5 Zeolites**

Bert M. Weckhuysen, Dingjun Wang, Michael P. Rosynek, and Jack H. Lunsford*

The catalytic conversion of methane to desirable commodity chemicals is a challenging approach to the utilization of natural gas resources; consequently, considerable effort has been devoted to the development of novel catalytic systems. Oxygen has generally been used to activate the methane, even at the expense of losing some of the feedstock as carbon dioxide. The most extensively studied processes are oxidative coupling of methane,[1, 2] partial oxidation of methane to synthesis gas,[3] and the formation of such oxygenated compounds as methanol.[4] Recent studies have demonstrated that methane can be selectively converted into benzene over Mo/H-ZSM-5 catalysts in the absence of an oxidant such as O_2.[5–10]

We report here on a stable and selective bifunctional catalyst for the conversion of methane into aromatic hydrocarbons such as benzene, toluene, and naphthalene in the absence of an oxidant. The catalyst consists of iron oxides dispersed on the surface of an acidic ZSM-5 zeolite. Methane activation occurs on supported iron oxide clusters, and the primary product, ethylene, undergoes subsequent oligomerization and cyclization reactions at Brønsted-acidic sites to form the aromatic products. The Fe/H-ZSM-5 catalyst is typically prepared by incipient wetness impregnation through addition of an aqueous iron(III) nitrate solution to the H-ZSM-5 zeolite, followed by drying at 90 °C and calcination in oxygen at 500 °C. The resulting orange material is characterized by a broad electron paramagnetic resonance (EPR) signal with a g-value of 2.47 and a peak-to-peak width (ppw) of 1515 G (Figure 1A). The signal broadens upon

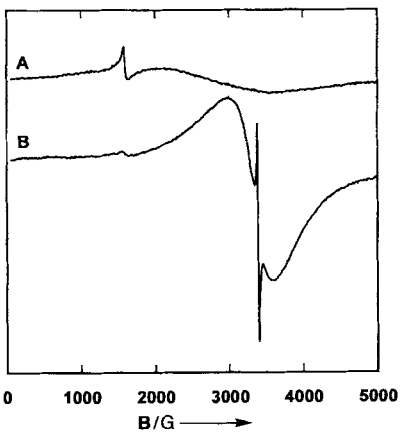

Figure 1. EPR spectra of A) a 0.6 wt% Fe/H-ZSM-5 catalyst calcined at 500 °C for 1 h, and B) an active 0.6 wt% Fe/H-ZSM-5 catalyst prereduced in CO and treated for 1 h in methane at 700 °C. The spectra were measured at 120 K, and the signal at g = 4.3 is due to distorted tetrahedral Fe^{3+} ions from the parent H-ZSM-5 material[12].

cooling and does not follow the Curie–Weiss law. Such behavior is typical for Fe_2O_3 clusters.[11, 12] The presence of iron(III) was further confirmed by X-ray photoelectron spectroscopy (XPS). The corresponding $2p_{3/2}$ and $2p_{1/2}$ binding energies (BE) of iron(III) were obtained at 710.7 eV and 724.5 eV, respectively. The spin-orbital splitting was 13.8 eV, and an accompanying weak 3d → 4s shake-up satellite peak was detected at 718.7 eV, all typical for iron(III).[13]

The calcined material was first reduced with CO at 500 °C for 6 h, heated to 700 °C in He, and then subjected to a continuous methane flow at 700 °C. Conversion and product formation were monitored by on-line gas chromatography. As an example, we will discuss the catalytic performance of a 2 wt% Fe/H-ZSM-5 catalyst in some detail (Figure 2). Similar results were

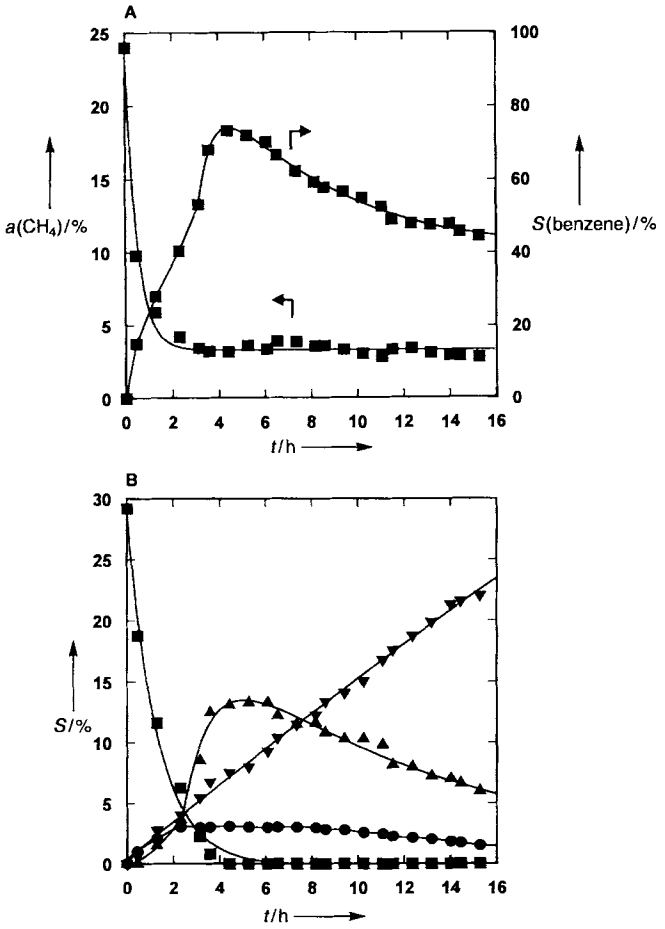

Figure 2. The catalytic performance of a Fe/H-ZSM-5 catalyst with 2 wt% iron: A) overall conversion $a(CH_4)$ [%] and benzene selectivity S(benzene) [%], and B) selectivities S [%] toward CO (■), napthalene(▲), toluene (●) and C2–C3 hydrocarbons (▼).

obtained for a 0.6 wt% Fe/H-ZSM-5 material. After an initial activation period of 4 h, a benzene selectivity of 74% was reached at a methane conversion of about 4%. During the first half-hour on stream, virtually no hydrocarbon products were formed, and the major gas-phase products were CO, CO_2, and H_2O. Because the catalyst was pretreated in He at high temperature before initiating the reaction, the only oxygen source for formation of oxygen-containing products is lattice oxygen from the catalyst. In addition to benzene, toluene and naphthalene were also formed, but with much lower selectivities. Naphthalene selectivity reached a value of 13% immediately following the initial activation period, but then declined slowly with increasing time on stream. For toluene, a maximum selectivity of 3% was observed. Thus, after a sufficiently long reaction time, mainly benzene was produced, along with some toluene and naphthalene, and the maximum selectivity toward aromatic hydrocarbons exceeded 85%. On the other hand, selectivity toward C_2 and C_3 hydrocarbons (mainly ethylene) increased continuously with increasing reaction time, as coke deposition gradually deactivated acidic sites in the zeolite where the ethylene undergoes secondary reaction. It is also remarkable that a stable conversion of 4% could be sustained even after 16 h on stream. The catalyst could be regenerated by heating the material in O_2 at 500 °C for 8 h; however, the resulting maximum methane conversion was only 3.5% at a benzene selectivity of 65%.

The black active catalyst had the typical EPR spectrum shown in Figure 1 B. Besides the sharp isotropic signal at $g \approx 2$ with ppw = 11.5 G, a broad EPR signal was observed with $g = 2.06$ and ppw = 600 G. The former signal followed the Curie–Weiss law, indicating the presence of organic radicals; that is, the formation of coke. This signal gradually increased in intensity during the course of reaction. The other EPR signal, centered at $g \approx 2.06$, broadened upon cooling and did not follow the Curie–Weiss law.[14] The nature of the species responsible for this signal was further analyzed by XPS. After passing methane gas over the catalyst, the Fe $2p_{3/2}$ and $2p_{1/2}$ BE values were determined to be 710.5 eV and 724.4 eV, respectively, and no other peaks were observed. In addition, no weak 3d → 4s shake-up satellite peak was detected at 718.7 eV. Thus, upon methane activation, the catalyst is partially reduced from Fe_2O_3 to Fe_3O_4.[13] Furthermore, the C 1s signal at 283.5 eV increased in intensity. This was due to coke formation during methane activation. Such coke may explain the decrease in selectivity toward aromatics.

By changing the CO prereduction time and temperature we were able to change the extent of the EPR-active Fe clusters. This resulted in materials with different catalytic activities, as shown in Figure 3. It is clear that an almost linear relationship exists between the level of EPR-active Fe clusters and methane-conversion activity of the catalyst at maximum benzene selectivity. This in turn suggests that such clusters may be involved in the activation of methane.

The primary products of methane activation, mainly ethylene, undergo further reaction at zeolitic acidic sites, result-

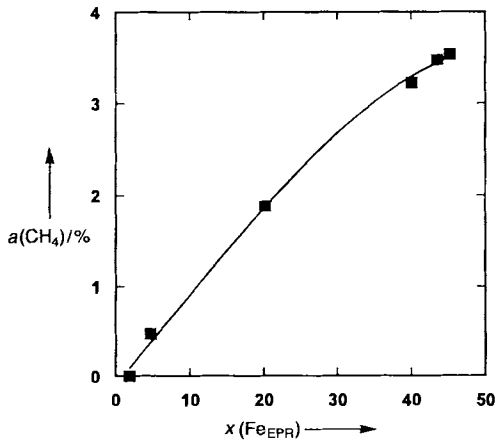

Figure 3. Methane activation behavior of Fe/H-ZSM-5 catalysts as a function of the extent of EPR-active Fe clusters, $x(Fe_{EPR})$ (in arbitrary units). The extent of such Fe clusters was determined by double integration of the recorded EPR spectra and subtraction of the contribution from a sharp isotropic signal at $g \approx 2$. Methane conversions refer to conversions at maximum benzene selectivity.

ing in the formation of benzene, toluene, and napthalene. The occurrence of such oligomerization and cyclization reactions has been demonstrated by partially and even fully exchanging the Brønsted acid sites of the starting H-ZSM-5 material with Na^+ ions. Treatment in this way resulted in a gradual decrease in the number of Brønsted acid sites, as evidenced by FT-IR spectroscopy, as well as a decrease in catalytic activity and selectivity of the catalyst. Thus, Brønsted acid sites play a crucial role in the catalytic performance of these materials. In another experiment we prepared solid-state, ion-exchanged Fe/H-ZSM-5 zeolites by using $Fe^{III}Cl_3$. The freshly prepared materials were totally inactive for methane activation. Only after CO treatment at relatively high temperatures was some activity detected. However, such materials were always catalytically inferior to those prepared by impregnation, and no naphthalene could be detected.

In conclusion, we have found that iron oxides supported on H-ZSM-5 zeolites are able to convert methane into aromatic hydrocarbons with a selectivity greater than 85%. The activity is based on a unique balance between formation of iron clusters on the surface of the zeolite and the presence of a sufficient number of Brønsted acid sites. It is also worth mentioning here that unsupported iron oxides are used industrially for the dehydrogenation of ethylbenzene to styrene under conditions similar to those applied in this study.[15] The XPS results confirm that neither metallic iron nor iron carbides are formed on this catalyst, which is significant in view of the fact that similar activation of CH_4 over an Mo/H-ZSM-5 catalyst has been proposed to involve Mo_2C, the presence of which was confirmed by XPS.[9, 10] Recently, Marczewski et al. have shown that methane can be converted into aromatics under nonoxidative conditions in a two-stage catalytic system.[16] Methane was converted into ethylene over a $Mn/Na/SiO_2$ catalyst (10% Mn, 3.4% Na) at 800 °C. The initially formed ethylene was then further converted into benzene and toluene over an H-ZSM-5 catalyst at 600 °C. Further studies on the mechanism of methane activation in the absence of oxygen, and extension to other transition metal oxides such as Cr_2O_3, V_2O_3, and WO_2 are in progress and should increase our understanding of these novel catalytic materials.

Experimental Section

Fe/H-ZSM-5 catalysts were prepared by impregnation with an aqueous solution of iron (III) nitrate onto commercial PQ Corp. H-ZSM-5 (CBU 5020E, with a Si/Al ratio of 25/1). The resulting materials were dried at 90 °C overnight (14 h) and calcined at 500 °C for 5 h. Reactions were carried out in a flow system, in reactors constructed from alumina tubes. The flow reactor had an internal diameter of 6.4 mm, and the amount of catalyst used was 1.0 g. To minimize contributions from possible gas-phase reactions, quartz chips filled the space above and below the catalyst beds in the flow reactors. A thermocouple in a smaller alumina tube was attached to the outside wall of each of the reactors. The gases, which included 10% N_2/CH_4 (UHP), O_2 (UHP), He (UHP), and CO (UHP) were obtained from Matheson and used without further purification. Gas flows were regulated by mass flow controllers (MKS Model 1159A). In the flow system the catalyst was heated in a 50 mL min^{-1} flow of O_2 to 500 °C, calcined for 1 h, and flushed in a 50 mL min^{-1} flow of He for 30 min. Reduction treatments were carried out at 500 or 700 °C for several hours in a 25 mL min^{-1} flow of CO. The total GHSV (gas hour space velocity) during methane conversion was 800 h^{-1}. The gas feed consisted of CH_4 that contained 10% N_2. The N_2 was used as an internal standard so that CH_4 conversion could be determined accurately. Coke formation during the reaction could be evaluated from a carbon mass balance. The mass balance indicated that about 5–10% of the CH_4 was converted into coke during methane activation. Reaction mixtures were analyzed by on-line gas chromatography (HP 5890A) using a 5% Bentone-34 on Chromosorb W-AW column and a HayeSep D column. All studies were carried out at atmospheric pressure. FT-IR spectra were obtained on a Perkin Elmer 2000 FT-IR spectrometer. Self-supporting wafers of 10–15 mg cm^{-2} were pressed from the powdered catalysts. Wafers were mounted on a fused-quartz bracket placed in an IR cell. The cell was equipped with KBr windows and a heated region into which the wafer could be raised and pretreated. For EPR spectroscopy, a Bruker ESP300 spectrometer at X-band (ca. 9.5 GHz) was used. EPR spectra of the active catalysts were obtained with a specially designed quartz reactor tube with a side-arm for EPR measurements. XPS spectra were acquired on a Perkin Elmer (PHI) model 5500 spectrometer. A quartz reactor system with in situ transfer capability made it possible to duplicate the conditions present in the catalytic reaction experiments.

[14] Temperature-dependence EPR spectroscopy shows that the $g = 2.06$ and $g = 4.3$ signals correspond to different iron species. In addition, the two EPR signals respond differently toward different microwave powers, and the $g = 2.06$ signal saturates more readily at liquid N_2 temperature than the $g = 4.3$ signal. The behavior of the $g = 2.06$ signal must be due to cooperative magnetic phenomena (e.g., ferro-anti-ferromagnetism and dipole–dipole interaction).

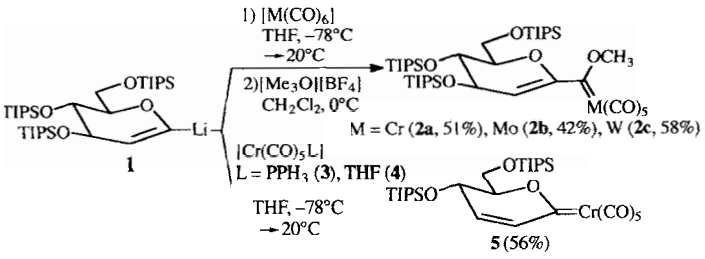
anomeric center are restricted nearly exclusively to the main group metals lithium and tin. Glycosyl complexes are known for the transition metals manganese,[2a, b] iron,[2c] and cobalt.[2d] Synthetic applications, however, have been limited to manganese compounds, which, under high pressure conditions, have been applied occasionally to the synthesis of C-glycosides.[3] We set out to incorporate the anomeric center into an electrophilic metal carbene moiety,[4] which favors the addition of nucleophiles and as such may offer a novel approach to C- and heteroatom-glycosides. Recently, we reported on the synthesis of acyclic C-1 carbene complex functionalized sugars, which are accessible by a combination of a sugar electrophile and a carbonylmetalate nucleophile.[5] Subsequently, we applied a metal-assisted cycloisomerization of sugar alkynols to the preparation of spiroketal glycoside carbene complexes and their monocyclic

Herein we describe the synthesis of and first reactivity studies on two novel types of carbene complex modified carbohydrates derived from the lithioglucal **1**.[7] According to the classical Fischer route, **1** adds to a *carbonyl ligand* of the hexacarbonyl complexes of chromium, molybdenum, and tungsten to give pentacarbonyl acylmetalates, which undergo subsequent alkylation to give the glucal carbene complexes **2a–c** (Scheme 1). The

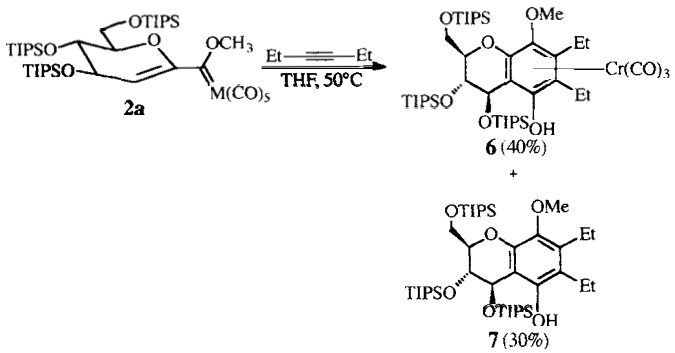


Scheme 1. Synthesis of complexes **2a–c** and **5**.

course of the reaction of the carbonyl complex with the glucal nucleophile is dependent on its substitution pattern. The presence of a good donor and leaving group ligand such as PPh_3 or THF in pentacarbonyl chromium complexes **3**[8] and **4**[9] favors the formation of the α,β-unsaturated glycosylidene complex **5**. This may be rationalized in terms of an addition/elimination sequence along which, with prior or concomitant elimination of the phosphane or THF ligand, the lithioglucal **1** first adds to the *metal* center to give an alkyl chromate intermediate,[10, 11] which subsequently, reminiscent of a Ferrier rearrangement,[12] undergoes elimination of the silyloxy group and generates the vinylcarbene complex **5**.

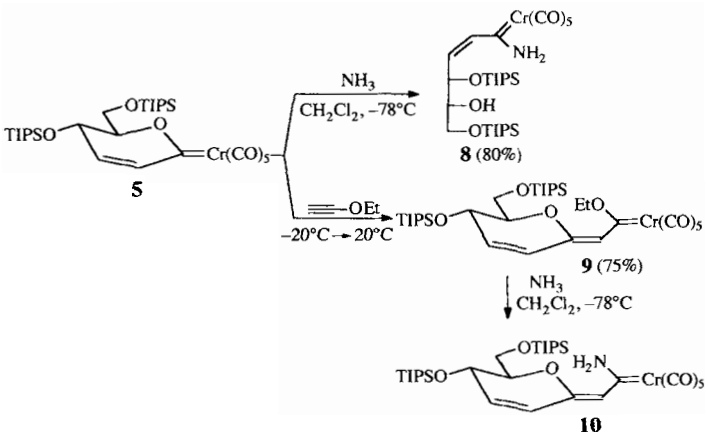
The synthetic potential of these carbene complexes is characterized by the vinyl carbene moiety and by the pronounced electrophilicity of the metal-coordinated carbene-carbon atom as evident from the ^{13}C NMR chemical shifts [δ = 338.0 (**2a**), 328.3 (**2b**), 310.9 (**2c**), and 325.7 (**5**)]. The glucal carbene complex **2a** undergoes a benzannulation reaction with 3-hexyne to give benzoglucals **6** and **7** (Scheme 2). After chromatographic work-up the hydroquinone complex **6** was obtained as a single diastereomer. However, this is not yet indicative of a diastereoselective carbene annulation since comparable yields of the uncoordinated hydroquinone derivative **7** were also isolated; thus, so far, it cannot be excluded that **7** is formed from the other diastereomer by decomplexation assisted by the bulky TIPS protecting groups.

The electrophilicity of the glycosylidene-carbon atom is evident from the ammonolysis of **5**. Ring-opening generates the



Scheme 2. Benzannulation of **2a**

α,β-unsaturated aminocarbene complex **8**, which is selectively deprotected in the 5-position. In comparison with its oxacyclic precursor **5**, complex **8** is distinctly less electrophilic (^{13}C NMR: δ = 268.9). Michael addition across the electron-deficient C=C bond, which generally occurs in vinyl carbene complexes as a competing pathway, is blocked by the adjacent sterically demanding silyl protecting group. The addition of nucleophiles can be exploited in the C_2-homologization of the glycosylidene ligand. This is demonstrated by the reaction with ethoxyethyne,[13, 14] which results in alkyne insertion, and stereoselectively affords the (*Z*)-isomer of **9** [15] (Scheme 3), whose dienyl



Scheme 3. Ammonolysis and C_2-homologization of **5**.

carbene ligand as a vinylogous Michael acceptor offers three alternatives for the addition of nucleophiles. A relatively hard nucleophile such as ammonia adds regioselectively to the carbene-carbon atom under the formation of the aminocarbene complex **10**.

The glycosylidene complexes described provide a novel strategy for modifying the anomeric center of carbohydrates by exploiting the metal carbene methodology. This approach offers a promising access to nonnatural sugar analogues as well as to unconventional synthetic routes to C- and heteroatom-glycosides.

Experimental Section

All operations were performed under argon. Solvents were dried by using standard methods. Yields reported refer to products purified by column chromatography.

2a: For the preparation of lithioglucal **1**, *n*BuLi (0.78 mL, 1.25 mmol, 1.6 M solution in hexane) was added slowly at −78 °C to a solution of 1,5-anhydro-3,4,6-tri-*O*-(triisopropylsilyl)-2-deoxy-1-tri-*n*-butyl-stannyl-D-arabino-hex-1-enitol (**11**) (0.94 g, 1.04 mmol) in THF (15 mL). The solution was stirred for 1 h at −78 °C. After

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3621-2377 $ 17.50+.50/0

addition of hexacarbonylchromium (0.28 g, 1.25 mmol) the resulting suspension was allowed to warm to room temperature over a period of 4 h. The solvent was removed in vacuo, and the residue was dissolved in dichloromethane (50 mL). After addition of $[Me_3O][BF_4]$ (0.18 g, 1.25 mmol) at 0 °C, the mixture was stirred for 1 h. Yield: 0.45 g (0.52 mmol, 51%). ^{13}C NMR (100 MHz, $CDCl_3$): δ = 338.0 (C=Cr), 225.2 (*trans*-CO), 216.5 (*cis*-CO), 156.1 (C-1), 97.0 (C-2), 81.8 (C-3), 69.1 (C-4), 66.8 (C-5), 66.4 (OCH_3), 61.2 (C-6), 18.2–18.0 ($SiCH(CH_3)_2$), 12.5–12.0 ($SiCH(CH_3)_2$).

2b (42%) and **2c** (58%) were obtained similarly.

5: *n*BuLi (0.7 mL, 1.12 mmol) was added to a solution of **11** (0.92 g, 1.02 mmol) in THF (5 mL) at −78 °C. The solution was stirred at this temperature for 1 h and then added to a suspension of **3** (0.51 g, 1.12 mmol) in THF precooled to −78 °C or, alternatively, to a solution of **4** (18.6 mL, 1.12 mmol, 0.06 M in THF). The solution was stirred for 14 h and allowed to warm to room temperature. Yield: 0.36 g (0.57 mmol, 56%) from the reaction with **3**; 0.26 g (0.41 mmol, 40%) from **4**. ^{13}C NMR (62.5 MHz, $CDCl_3$): δ = 325.7 (C-1), 225.7 (*trans*-CO), 216.5 (*cis*-CO), 136.0 (C-2), 125.5 (C-3), 86.3 (C-4), 62.1 (C-5), 61.7 (C-6), 18.3–18.1 ($SiCH(CH_3)_2$), 12.7–12.0 ($SiCH(CH_3)_2$). HR-MS: Calcd. for $C_{29}H_{48}CrO_8Si_2$: 632.2293; found: 632.2284.

6: A solution of **2a** (0.32 g, 0.32 mmol) and 3-hexyne (0.5 mL, 4.0 mmol) in THF (4 mL) was degassed (three cycles "pump, freeze, thaw") and then warmed to 50 °C for 6 h. Work-up by column chromatography afforded **6** (0.14 g, 0.16 mmol, 40%) and **7** (0.09 g, 0.11 mmol, 30%). ^{13}C NMR (100 MHz, $CDCl_3$): δ = 234.4 ($Cr(CO)_3$), 134.1, 132.7, 118.6, 112.0, 90.14, 86.9 (C-5–C-10), 83.4, 67.7, 65.6, 64.8, 62.2 (C-2, C-3, C-4, C-1, OCH_3), 21.8 ($ArCH_2CH_3$), 19.6 ($ArCH_2CH_3$), 18.3–17.7 ($SiCH(CH_3)_2$), 16.0 ($ArCH_2CH_3$), 14.8 ($ArCH_2CH_3$), 13.0–11.8 ($SiCH(CH_3)_2$).

8: A 10 s flow of ammonia was condensed at −78 °C into a solution of **5** (0.29 g, 0.46 mmol) in dichloromethane (20 mL). The solution was stirred at this temperature for 1 min. Work-up by column chromatography afforded **8** (0.24 g, 0.37 mmol, 80%). ^{13}C NMR (100 MHz, $CDCl_3$): δ = 276.6 (C=Cr), 223.0 (*trans*-CO), 217.4 (*cis*-CO), 141.0 (C-2), 126.5 (C-3), 73.8, 70.5 (C-4, C-5), 65.7 (C-6), 18.1-17.8 ($SiCH(CH_3)_2$), 12.5, 11.8 ($SiCH(CH_3)_2$). HR-MS: Calcd. for $C_{24}H_{51}NCrO_3Si_2$ (M^+ − 5CO): 509.2825; found: 509.2819.

9: A solution of ethoxyethyne (0.59 mmol) in petroleum ether (1 mL, 40/60) was added to **5** (0.31 g, 0.49 mmol) in petroleum ether (20 mL, 40/60) at −20 °C. The solution was stirred for 24 h at room temperature, (0.26 g, 0.37 mmol, 75%). ^{13}C NMR (100 MHz, C_6D_6): δ = 322.9 (C=Cr), 224.6 (*trans*-CO), 217.8 (*cis*-CO), 148.6 (C-1), 143.5, 125.0, 121.4 (alkene-C), 81.6 (C-4), 76.2 (OCH_2CH_3) , 63.23 (C-5), 61.8 (C-6), 18.2–18.0 ($SiCH(CH_3)_2$), 14.9 (OCH_2CH_3), 12.8, 12.3 ($SiCH(CH_3)_2$). HR-MS: Calcd. for $C_{28}H_{54}O_4Si_2Cr$ (M^+ − 5CO): 562.2933; found: 562.2949.

Ammonolysis of **9** was carried out similarly to that of **5**.

Stabilization of the (π-Indenyl)–Lead Bond: The First Structurally Authenticated Bis(η^5-indenyl) Complex of a Post-Transition Element, $[Pb\{1,3\text{-}(SiMe_3)_2C_9H_5\}_2]$**

Jason S. Overby, Timothy P. Hanusa,* and Paul D. Boyle

Although they are often considered as analogues of metallocenes, bis(π-indenyl) metal complexes, particularly those of main group elements, are not documented as well.[1] In complexes of post-transition metals, for example, the indenyl ligand is almost always σ-bonded (e. g., $M(\sigma\text{-}C_9H_7)_3$, M = B, Tl and $M(\sigma\text{-}C_9H_7)_nX_{4-n}$, M = Ge, Sn, Pb).[2–7] Two divalent Group 14 metal complexes of indenyl have been reported, $[Ge\{(SiMe_3)_2C_9H_5\}_2]$ and $[Ge(C_5Me_5)\{(SiMe_3)_2C_9H_5\}]$,[8] but only the latter was crystallographically characterized and shown to contain a π-bound indenyl ligand. We now report the synthesis of the first lead(II) indenyl complex, which highlights the sensitivity of such complexes to the steric and electron-donor properties of the indenyl group. The X-ray crystal structure is the first for a complex between a post-transition metal and two π-bound indenyl ligands.

Not all indenyl ligands are equally compatible with the redox-sensitive Pb^{II} center. For example, the reaction of potassium indenide, $K(C_9H_7)$, with PbI_2 in THF leads to deposition of elemental lead after several minutes. The more sterically demanding 1,3-diisopropylindenyl (Ind^{2i}) ligand was successfully used to prepare heavy alkaline earth derivatives.[1] Rapid workup (< 5 min) of the reaction between $K(Ind^{2i})$ and PbI_2 in THF or DME permits isolation of a red–orange solid that is tentatively identified as $[Pb(Ind^{2i})_2]$ (^1H NMR singlet at δ = 5.54 with $^2J(Pb,H)$ = 38.4 Hz).[9] However, even in the solid state, substantial decomposition to lead and the coupled ligand $(Ind^{2i})_2$ is apparent after several minutes at room temperature.

In contrast, the reaction of two equivalents of $K(Ind^{2Si})$ (Ind^{2Si} = 1,3-bis(trimethylsilyl)indenyl) with PbI_2 in DME provides the deep-red bis(indenyl) complex in moderate yield. Rapid workup of the reaction mixture is nevertheless required, as decomposition products (the coupled ligand and metallic lead) form if the reaction is stirred for more than 30 min at room temperature. Solid samples of $[Pb(Ind^{2Si})_2]$ are reasonably stable at room temperature, although slow decomposition oc-

curs over several months. Immediate decomposition takes place upon heating the complex to 160 °C under high vacuum. The complex disintegrates within one minute upon exposure to air or moisture, and displays high solubility in both polar and nonpolar solvents (including alkanes).

$[Pb(Ind^{2Si})_2]$ was spectroscopically characterized by ^1H and ^{13}C NMR as well as IR spectroscopy. In the ^1H NMR spectrum, there is a substantial downfield shift of the C_5-ring proton to $\delta = 6.28$, which is consistent with a highly delocalized ring system. This shift is comparable to those observed for Ge^{II} complexes of Ind^{2Si} ($\delta = 6.42, 6.32$)[8] and for related Ca^{II}, Sr^{II}, and Ba^{II} complexes.[9] Furthermore, the ^{13}C spectrum of $[Pb(Ind^{2Si})_2]$ is nearly identical to that of the Ge^{II} complexes, which is another indication of π-bound indenyl ligands. Although the molecular ion is not observed in the mass spectrum (EI, CI, or FAB techniques), fragments corresponding to the loss of methyl groups and lead could be identified.

$[Pb(Ind^{2Si})_2]$ crystallizes with two independent enantiomeric molecules in the unit cell; one of them is shown in Figure 1.[10]

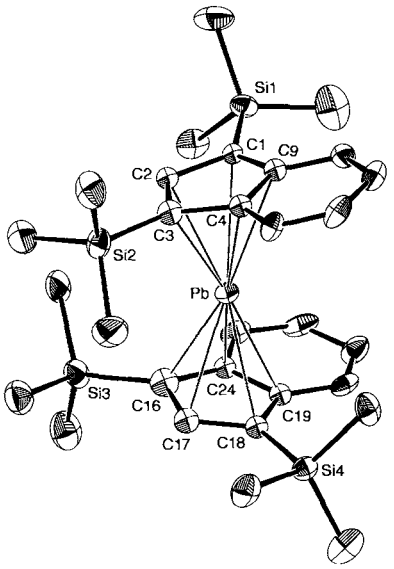

Figure 1. ORTEP plot of $[Pb\{1,3\text{-}(SiMe_3)_2C_9H_5\}_2]$; only non-hydrogen atoms are shown. Selected bond lengths [Å]: Pb–C1 2.793(11), Pb–C2 2.653(11), Pb–C3 2.669(12). Pb–C4 2.828(11), Pb–C9 2.910(12), Pb–C16 2.720(14), Pb–C17 2.736(13), Pb–C18 2.798(11), Pb–C19 2.813(11), Pb–C24 2.772(11).

The C_5 ring of each indenyl ligand is η^5-bound to the metal center; the average Pb–C distance in both complexes is 2.77(4) Å. The relevance of this value is lessened in view of the wide spread in individual bond distances [2.693(11)–2.873(12), 2.653(11)—2.910(12) Å]. Similarly broad ranges of metal—carbon distances were found in structurally characterized plumbocenes, for example, 2.69–2.90 Å in $[Pb(C_5Me_5)_2]$,[11] 2.680–2.871 Å in $[Pb\{C_5(PhCH_2)_5\}_2]$,[12] and 2.73—3.03 Å in $[Pb(C_5H_5)_2]$.[13] This demonstrates that somewhat asymmetric bonding is typical for η^5-bound rings on lead centers.

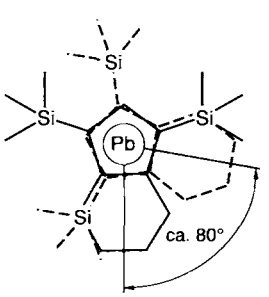

Figure 2. Gauche-eclipsed orientation of the indenyl ligands in $[Pb\{1,3\text{-}(SiMe_3)_2C_9H_5\}_2]$. Two of the C–$SiMe_3$ bonds of one indenyl ligand are aligned along the edges of the C_6 ring of the other ligand.

Interestingly, the structures display ring centroid–Pb–ring centroid angles of 173.3 and 172.9°, which represent only slight deviations from linearity. The two indenyl ligands are rotated by 83.3 and 78.7° relative to each other (Figure 2); this places the closest interligand methyl–methyl contacts at over 3.9 Å. The observed ligand orientations may serve to minimize unfavorable nonbonding interactions between the indenyl substituents. There is little evidence for stereochemical activity on the part of the metal-centered pair of valence electrons.

The synthetic restrictions detailed here concerning the isolation of bis(indenyl) complexes of Pb^{II} substantially limit the number of complexes that can be successfully prepared. Careful consideration must be given to the electronic and steric nature of the substituents on the indenyl ligand if other complexes of this nature are to be isolated. Our search for suitable ligands for use with lead and other Group 14 metals continues.

Experimental Section

Lead(II) iodide (0.24 g, 0.52 mmol) was dissolved in DME (50 mL). $K(Ind^{2Si})$ [14] (0.50 g, 0.83 mmol) was added in one portion to the orange–yellow solution; the mixture immediately turned red–orange. After the reaction mixture was stirred for 15 min, the solvent was removed under vacuum, and the residue extracted with hexane (50 mL). Filtration through a medium-porosity glass frit to remove KI followed by removal of the solvent from the filtrate provided dark red–orange $[Pb(Ind^{2Si})_2]$ in 63% yield (0.14 g, 0.19 mmol). ^1H NMR (300 MHz, C_6D_6, 20 °C): $\delta = 0.33$ (br s, 36H, $Si(CH_3)_3$), 6.28 (s, 2H, C_5-ring H; $^2J(Pb,H) = 13.0$ Hz), 7.01–6.98 (m, 4H, C_6-ring H), 7.49–7.46 (m, 4H, C_6-ring H); ^{13}C NMR (75.5 MHz, C_6D_6, 20 °C): $\delta = 1.3$ ($Si(CH_3)_3$), 114.2 ($CSiMe_3$), 122.3 (bridgehead C), 123.0 (C_5-ring CH), 130.3 (C_6-ring CH), 138.8 (C_6-ring CH); IR (KBr): $\tilde{\nu} = 3064$ (m), 2955 (s), 2895 (m), 1447 (m), 1407 (w), 1253 (vs), 1023 (m), 974 (w), 901 (vs), 838 (vs), 757 (s), 689 (m), 449 (m) cm^{-1}; MS (CI) $m/z = 561$ ($M^+ - 11$ Me), 518 ($M_+ - Pb$).
