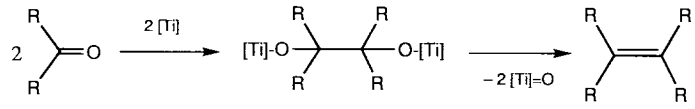
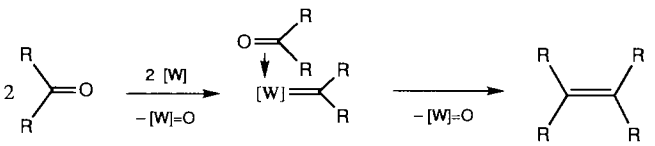
Reductive coupling of ketones to form alkenes, an extremely useful synthetic process in organic chemistry, is most often achieved with the aid of low-valent titanium reagents, according to the procedure developed by McMurry.[1] It is generally accepted that this reaction involves the intermediacy of a titanium pinacolate, which is subsequently deoxygenated to the corresponding alkene in the rate-determining step (Scheme 1). The



Scheme 1. Reductive coupling of ketones via a metallopinacol intermediate.

pinacolate could be formed by dimerization of two ketyl radicals or nucleophilic attack of the carbonyl dianion on a free ketone. In a number of instances, pinacols were indeed isolated by carrying out the reaction at low temperature; they were converted into the alkenes when resubmitted to the more forcing experimental conditions.

There are also a few examples of reductive coupling of ketones in which metallopinacols are clearly not the precursors of the alkene products. These transformations involve carbenoid species.[2, 3] In particular, reactions of ketones with W^{II} or W^{III} compounds proceed by initial cleavage of the ketonic C—O bond to give an alkylidene complex which further reacts with another ketone to afford the alkene, presumably via a metallaoxetane intermediate (Scheme 2).[2]



Scheme 2. Reductive coupling of ketones via a carbenoid species.

A clear mechanistic distinction is now recognized between these coupling reactions of ketones, depending on whether tungsten or titanium compounds are utilized. Although the possible involvement of carbenoid species in McMurry type reactions has been considered,[4] definite proof for their existence is lacking. In the course of our studies on the reductive coupling of ketones with uranium or titanium tetrachloride in the presence of alkali metal amalgam,[5] we undertook a careful analysis of the products and made observations that are not in agreement with the above ideas. We now put forward the dualistic aspects of the mechanism of these McMurry-type reactions.

Acetone reacted in tetrahydrofuran (THF) with one equivalent of $TiCl_4$ and excess Li(Hg) to give, after hydrolysis, a mixture of **1a** and **2a** as the major products; isopropanol and other

unidentified compounds, presumably products of aldol reactions, were also formed in lower yields. Total conversion of the carbonyl substrate was achieved in 10 h with three equivalents of lithium amalgam (Table 1). The formation of **2a** at 20 °C was

[a] Molar ratio 1:1:3 (M = Ti) or 1:1:2 (M = U); all reactions were carried out in THF at 20 °C followed by hydrolysis; the organic products were identified by NMR spectroscopy, GC, and GC-MS. [b] Propene and propane were not detected. [c] About 10% of the ketone was recovered.

most intriguing, since the McMurry alkene synthesis supposedly requires higher temperatures for the deoxygenation step. In fact, a very small amount of **2a**, if any, appeared to have been produced by reduction and deoxygenation of a pinacolate intermediate, as shown by control experiments. The quantity of **2a** was not significantly increased after further addition of Li(Hg) to the reaction mixture, and only 5% of the alkene was obtained after 10 h at 20 °C upon treatment of the lithium pinacolate **3a** with $TiCl_4$ (or $TiCl_3$) and Li(Hg). The results of the reactions with **3** are summarized in Table 2.

[a], [b] See footnotes in Table 1; the molar ratios are here 1:2:4 (M = Ti) or 1:2:3 (M = U). [c] Treatment of **3c** with $TiCl_4$ gave iPr_2CO quantitatively (see text).

Similar treatment of diethylketone with $TiCl_4$ and Li(Hg) afforded **1b** and **2b**, but, in contrast to the reaction of acetone, the quantity of the alkene exceeded that of the diol. Most striking, however, was the formation of 2-pentene (**4a**) and *n*-pentane, which apparently resulted from deoxygenation of the ketone. Successive treatment of **3b** with $TiCl_4$ and Li(Hg) gave **2b**, indicating that the latter could be obtained by reduction of a pinacolate intermediate; however, **4a** was also formed, showing that the pinacolic C—C bond was cleaved under these conditions.

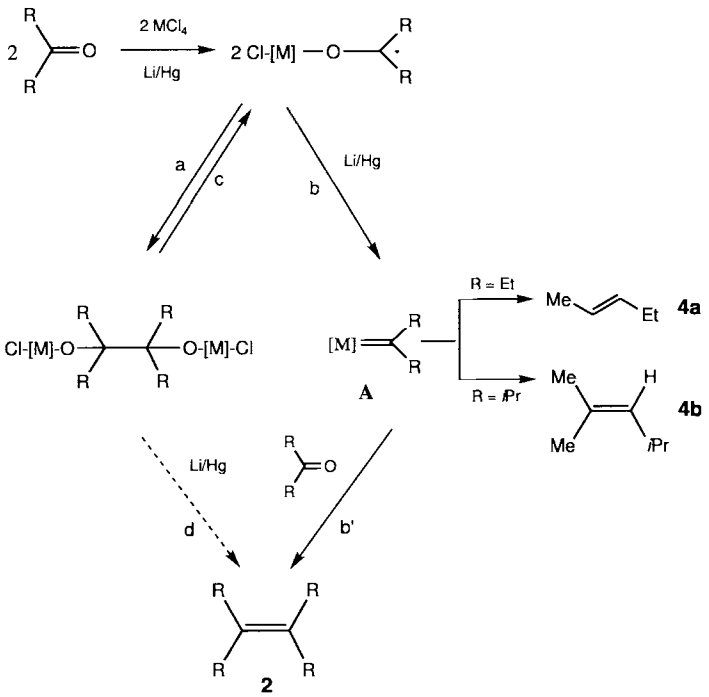
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3621-2380 $ 17.50+.50/0

The trend observed in the product distribution was greatly amplified in the case of diisopropylketone. At room temperature, no **1c** but only **2c** resulted from the reductive coupling of $i\mathrm{Pr_2CO}$, whereas 2,4-dimethyl-2-pentene (**4b**) and 2,4-dimethylpentane were formed by deoxygenation of the carbonyl substrate. The titanium pinacolate $\mathrm{Cl_3TiOC}i\mathrm{Pr_2C}i\mathrm{Pr_2OTiCl_3}$, prepared by treating **3c** with $TiCl_4$, was not stable and transformed within 5 min into a mixture of $TiCl_3$ and $i\mathrm{Pr_2CO}$. Treatment of **3c** with $TiCl_3$ also gave $i\mathrm{Pr_2CO}$ as the major product (60%) along with $i\mathrm{Pr_2CHOH}$ (12%) and **4b** (2%). It was then doubtful that alkene **2c** resulted directly from deoxygenation of a metallopinacol; the facile cleavage of the titanium pinacolates, as well as the absence of pinacol in the product mixture, indicated that reductive coupling of diisopropylketone with the $TiCl_4$/Li(Hg) system does not proceed by dimerization of ketyl radicals.

Of course, such McMurry reactions of $i\mathrm{Pr_2CO}$ were previously performed with a number of titanium reagents, and, in agreement with our results, the corresponding pinacol was never detected among the coupling products. It is nevertheless very surprising that the formation of **4b** was overlooked so far. For example, it was reported that $i\mathrm{Pr_2CO}$ reacted with $TiCl_3$ in the presence of potassium to give **2c** in 37% yield;[6] we confirmed this result but also found that **4b** was the major product of the reaction (45%). More generally, deoxygenation of a ketone $\mathrm{RCOCH_2R'}$ to form the alkene $\mathrm{RCH{=}CHR'}$ was never noticed in a McMurry reaction, while the transformation $\mathrm{RCOCH_2R'} \rightarrow \mathrm{RCH_2CH_2R'}$ was observed with several hindered ketones;[7] the origin of the alkane has not been clarified.

Reductive coupling of ketones R_2CO (R = Me, Et, *i*Pr) was achieved by using UCl_4 in place of $TiCl_4$. We already reported that acetone reacted with UCl_4 and Li(Hg) in a molar ratio of 1:1:1 to give the bimetallic pinacolate dianion $[\mathrm{Cl_4U{-}OCMe_2CMe_2O{-}UCl_4}]^{2-}$ in almost quantitative yield;[5] with two equivalents of Li(Hg), formation of tetramethylethylene could be observed only upon heating the mixture at 60 °C. These results are in accordance with the postulated mechanism of the McMurry reaction. However, reactions of Et_2CO and $i\mathrm{Pr_2CO}$ with the UCl_4/Li(Hg) system afforded the same products as those obtained with $TiCl_4$: **4a** and **4b** were formed along with alkenes **2b** and **2c**, and pinacol **1c** was not detected. Complete conversion of these ketones required two equivalents of Li(Hg), which is in agreement with the fact that U^{III} instead of Ti^{II} species were the active species in the reduction process.[8] Most interestingly, the uranium pinacolates $\mathrm{Cl_3UOCR_2CR_2OUCl_3}$ (R = Me, Et, *i*Pr) were much more stable than their titanium counterparts. Treatment with Li(Hg) led essentially to the corresponding U^{III} complexes, which in no case could be further deoxygenated at 20 °C to alkenes **2** (Table 2).

The above results indicate that reactions of aliphatic ketones R_2CO (R = Me, Et, *i*Pr) with the MCl_4/Li(Hg) system (M = Ti or U) followed two distinct routes to lead to the metallopinacol or the tetraalkylethylene, respectively (Scheme 3). The former would be formed by dimerization of two ketyl radicals; this mechanism is generally accepted for the McMurry reaction (Scheme 1). The alkene $R_2C{=}CR_2$ would come from the reaction of the ketone with a carbenoid species (**A** in Scheme 3) that results from reduction and deoxygenation of the ketyl radical; this mechanism should be similar to that represented in Scheme 2. Rearrangement of the carbenoid intermediate **A** (R = Et or *i*Pr) would give alkenes **4a** and **4b** by migration of H (it is possible that propene, which could be formed from acetone, was not detected by GLC because it escaped into the vapor phase). Formation of **4a** and **4b**, which did not result from Li(Hg) reduction of the alkoxide derivatives $\mathrm{Cl_3TiOCHR_2}$ (R = Et, *i*Pr), was reminiscent of the synthesis of alkenes by



Scheme 3. Reductive coupling of R_2CO (R = Me, Et, *i*Pr) with the MCl_4/Li(Hg) system. ([M] = UCl_2 or TiCl). a) M = Ti, U; R = Me, Et; b), b') M = Ti; R = Me, Et, *i*Pr; M = U; R = Et, *i*Pr; c) M = Ti, U; R = Et, *i*Pr; d) M = Ti; R = Et.

treatment of alicyclic ketones with chlorotrimethyl silane and zinc, a reaction which likely involves organozinc carbenoid species.[9] The Me_3SiCl/Zn system also reductively coupled aryl and α,β-unsaturated carbonyl compounds; this transformation did not proceed via pinacol-type intermediates but presumably by a carbenoid.[3]

Currently, the actual carbenoid species **A** have not been characterized; they could not be detected by NMR spectroscopy. Except for the reaction of Et_2CO with the $TiCl_4$/Li(Hg) system, the two routes in Scheme 3 would be well separated, since the metallopinacols were not the precursors of alkenes $R_2C{=}CR_2$, at least at room temperature. Acetone underwent pinacolization exclusively (M = U) or preferentially (M = Ti), whereas diisopropyl ketone reacted solely by the alternative carbenoid route regardless of the system. This great difference in reactivity between Me_2CO and $i\mathrm{Pr_2CO}$ can be accounted for by steric factors; the more sterically hindered the ketyl radicals are, the more difficult they are to dimerize. Steric hindrance would also destabilize the pinacolate intermediates with respect to rupture of their C–C bond and reverse conversion into the ketyl radicals. Such reversible cleavage of metallopinacols was already assessed in the production of the unsymmetric alkene $\mathrm{Ph_2C{=}CTol_2}$ (Tol = *p*-Me-C_6H_4) by treating a mixture of pinacols $\mathrm{HOCPh_2CPh_2OH}$ and $\mathrm{HOCTol_2CTol_2OH}$ with uranium powder,[10] and in the reactions of benzophenone[11] or acetophenone[8] with titanium compounds.

The data reported here indicate that, contrary to the generally accepted mechanism, metallopinacols are not the sole precursors to the alkene products of the McMurry reactions. If the ketyl radicals—initially formed by electron transfer from the low-valent metal complex to the carbonyl substrate—can be effectively coupled into pinacolate intermediates, they can also be reduced and deoxygenated into carbenoid species; the latter provide the alkene after further reaction with the ketone. The course of the reaction, via the metallopinacol or the carbenoid intermediates, is largely determined by the steric hindrance of

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3621-2381 $ 17.50+.50/0

the ketone; the less hindered ketones follow the pinacolization route. Even if they are formed, metallopinacols are not necessarily the precursors of the corresponding alkene, especially at room temperature, since they can be transformed back into the ketyl radicals by reversible cleavage of the pinacolic C–C bond.

Period Pieces!

Episodes from the History of the Rare Earth Elements. (Series: Chemists and Chemistry.) Edited by *C. H. Evans*. Kluwer, Dordrecht, 1996. 240 pp., hardcover £ 89.00.—ISBN 0-7923-4101-5

"I am willing to venture the opinion that the history of the rare earths is more fascinating, and illuminates more areas of chemical progress, than the history of any other group of elements." This view by C. H. Evans, the editor and a coauthor of this book, will be endorsed by many others besides rare earth enthusiasts and historians of science and technology. This 15th book in the series *Chemists and Chemistry* can also be regarded as forging links between chemistry and other sciences such as physics, medicine, biology, and geology. Eleven "episodes" from the history of the rare earth elements are described here by a team of well-chosen experts, mainly by examining the original literature and accounts of events. In the preface and in the introduction the editor gives a concise and informative explanation of the background to the two-part structure of the book (Part 1: Discovery, and Part 2: Applications). The story begins in 1787 with the discovery by the amateur mineralogist Lieutenant C. A. Arrhenius of the black mineral ytterbite (later called gadolinite). The 160-year history of the further discoveries that followed gives an impressive insight into the many technological innovations and advances in theory during that period.

As I read in Part 1 the history of how the dogged persistence and impatience of the experimental chemists were finally rewarded, I felt both pleasure and admiration. The authors of Chapters 1–5 (mostly Scandinavian) give a detailed, skillful, and sensitive account of the work leading to the discovery of the various elements. These discoveries were achieved largely without the guidance of Mendeleev's Periodic System, and were justly described by G. de Hevesy in 1926 as "one of the most brilliant accomplishments that experimental chemistry has ever produced". We learn that the fascinating history of the discoveries of cerium and of element 71 (lutecium) included fierce disputes about claims of priority. The articles include such interesting items as exchanges of letters, portraits of the chemists involved, and personal anecdotes relating to people such as C. G. Mosander, known affectionately to his friends as "Pater Moses", who was much more than a dedicated chemist. The introduction of spectrochemical analysis in 1859 not only gave a considerable new impetus to the discovery of new elements but also increased the opportunities for confusion, as the samples were seldom pure enough for the purpose. It was not until 1922 that Bohr's revolutionary theory of the atom paved the way for H. G. Moseley's development of the method of X-ray spectroscopy, eventually bringing order out of the chaos that had existed with regard to the number of rare earth elements and their structure. Although 16 of the 17 rare earth elements had already been discovered at that time, the skepticism of traditional experimental chemists towards the growing community of ambitious atomic physicists was such that the search for new rare earth elements went on regardless. However, we now read that "the new physics has changed the basis of rare earth research and stripped it of its chemical romance." The high point of this first part is undoubtedly the story of the discovery of the last (radioactive) rare earth element promethium in 1947 at the Clinton Laboratories, Oak Ridge, Tennessee, described in a lively style by its discoverer, J. A. Marinsky. The element was isolated by the ion-exchange technique that had recently been developed for separating radioactive fission products.

The second part of the book begins with a tribute to C. Auer von Welsbach who, true to his lifetime motto "plus lucis", invented the thorium–cerium incandescent mantle, and thus, in the forecourt of the café at the Viennese Opera, "illuminated" the birth of the rare earth industry. His life's work is analyzed by E. Baumgartner, a former employee of the Treibacher Chemical Works founded by von Auer. The account deals with the discovery of the elements neodymium, praseodymium, and lutecium, and the inventions of the oxide incandescent mantle, of the (osmium) metal filament lamp, and of the pyrophoric misch-metal alloys ("Auermetal" for lighter flints). In Chapter 8 two scientists from the Baotou Rare Earth Metals Research Institute report on work carried out in China to exploit 75% of the world's reserves of rare earth ores (the Baiyunebo mine in Inner Mongolia). As well as describing the raw material extraction processes and the separation and refinement of the metals by solvent extraction, the authors discuss potential areas of use. They give tables of data on production, consumption, and export quantities extending up to 1990. Unfortunately we learn nothing about the six-year plan which was mapped out by the Chinese government for the years 1990–1995. The last three "episodes" are concerned with geology, biology, and medicine, and as one with no special knowledge of these fields I found the discussions very interesting. Trace analytical methods such as neutron activation, yield reliable data about the occurrence and distribution of rare earths in nature, and thus give valuable clues concerning the formation of the earth's crust and the mantle. The cell biologist A. Weiss, one of the pioneers of this interdisciplinary field, describes the "lanthanum method", whereby the "spectroscopically inert" calcium(II) is replaced isomorphically by lanthanum(III), in order to study the biological role of calcium. In this example the method is used to investigate calcium mobilization patterns in smooth muscle. In the last chapter the editor reviews the medical applications of rare earths. These include the use of cerium nitrate for the control of vomiting and coughing, and of rare earth sulfates to treat infectious diseases such as tuberculosis. Two other compounds that are now used clinically are the anti-inflammatory

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3621-2383 $ 17.50+.50/0

agent Phlogosol (sodium disulfosalicylatosamarium anhydride) and GdDTPA, which is a contrast agent for magnetic resonance imaging.

As a collection of episodes from the history of the rare earth elements, the book makes no claim to completeness, especially in the area of applications. Although the chapters are presented as separate stories in the individual style of their authors, sometimes with overlapping of the subject matter, the overall effect is quite well-integrated. The articles emphasize the interpretation of historical connections. Thus the work can be regarded as an excellent complement to the more technologically and scientifically orientated review by K. A. Gschneidner and C. R. Eyring ("Two Hundred Year Impact of Rare Earths on Science", *Handbook on the Physics and Chemistry of Rare Earths*, Elsevier, Amsterdam, 1988). But who is likely to be willing to buy it at this rather high price?

The History of the Faraday Society. By *L. E. Sutton* and *M. M. Davies*. Royal Society, Cambridge, 1996. XV+414 pp., hardcover £ 20.00.—ISBN 0-85404-863-4

Because of the effect the Faraday Society has had on me it is difficult for me to give a dispassionate review of this book. As an undergraduate I was frequently recommended to read papers published in that Society's *Transactions* and *Discussions* and my own first research was published in the former just 60 years ago. But it was the debates, recorded *verbatim* in the *Discussions*, which really captured my attention and stimulated my imagination. The cut and thrust of the arguments of the proponents and opponents brought into sharp focus not only the scientific issues but also the personalities of some of the leading physical chemists of the time who spoke in the discussion. As I pointed out in the paper I was asked to give at celebratory 100th Faraday Discussion held at the Royal Institution on 24 April 1995, the effect on me of reading the comments in the general discussion which took place in 1921 and was published as Volume 17 of the *Transactions* "was a turning point for me because chemical kinetics came alive, the comments ... had all the excitement of a good novel, particularly when F. A. Lindemann demolished the idea separately propounded by Professor Lewis of Liverpool and Professor Perrin of Paris that "first order (gaseous) reactions were really photochemical" and "later in the discussion predicted that as the pressure was lowered such reactions would display second order kinetics" as later researchers were to verify". Thus it was I became an enthusiastic supporter of the Society and all its works and have remained so ever since; others have told me of similar experiences.

The recipe for such success was simple; circulate the page proofs of all the papers to all participants well before the meeting at which each author would be allowed only about 5–10 minutes to highlight the salient points, thereby leaving three or four times that time for discussion, and create an atmosphere and ample opportunity for informal conversations. The *Discussion* meetings have continued to flourish, to such a degree that physical chemists from other countries have not only flocked to them but invited the Society to hold their meetings overseas which is the greatest compliment they could pay. The *Transactions* have likewise prospered because they have changed to meet differing needs. Thus *Special Issues* have been published which concentrate on a particular topic and *Faraday Research Articles* have been incorporated in the *Transactions* which survey developments in a special area of current interest. Such innovations have doubtless contributed to the outstanding success of the *Transactions* as a highly regarded and popular international journal so that by 1996 an average of between four and five manuscripts were submitted each working day.

Who were the people who were influential in the society and made success possible? This book tells the story of the growth of the Faraday Society from its very modest beginnings in 1902 when a group of friends, some old and distinguished like Dr. (later Sir Joseph) Swan FRS, and C. V. Boys FRS, some young and later to become distinguished like F. G. Donnan, met and set up a committee to consider the desirability and feasibility of establishing an Electrochemical Society for which Germany in 1894 had already set an example. The first meeting of the Council of the new society which had appropriated the name "Faraday" doubtless as a means of gaining respect, as may also have been the case two years earlier when the *Elektrochemische Gesellschaft* became the *Deutsche Bunsen Gesellschaft für angewandte Chemie*, took place on 11 February 1903. For many years the Faraday Society had no rooms of its own, very few paid staff, and was administered by G. S. W. Marlow and Miss Beatrice Kornitzer who were completely devoted to its service, as I know from experience.

For me this book also has a special significance because it has two authors both of whom died before its publication. When I was an undergraduate Dr. Leslie Sutton was a young don, i.e. a lecturer, in Oxford making his name as an early skilled measurer of dipole moments and when I arrived in Cambridge Mansel Davies was a research student working on infrared spectroscopy under the supervision of G. B. B. M. Sutherland. Mansel became a life long friend and Leslie Sutton was later in life a colleague of mine at Oxford. Sutton covers the period 1903–1945 and Davies from 1945 to January 1972 when the Faraday Society became the Faraday Division of the Royal Society of Chemistry, a fusion which has been beneficial to both. The literary styles of the two authors are very different; so too are the matters they chose to emphasize. In my opinion these differences add to rather than detract from the interest of the book, and they give an enlarged and more diversified picture of the Society than either of them could have produced alone. The readers of the book will gain a fascinating insight into the way in which a society founded by a few enthusiasts became influential in the maturation of the subject of physical chemistry, how that subject interacted beneficially with biological and material sciences and was applied. I commend the book unreservedly as a vignette of social history of part of twentieth century science.

Table of Isotopes. 8th Edition, Volumes 1 and 2. Edited by *R. B. Firestone* and *V. S. Shirley*. John Wiley & Sons Ltd, New York, 1996. XXIV, 2970 pp. with 9 appendices and CD-ROM, hardcover £ 190.00.—ISBN 0-471-14918-7 (text volumes)/0-471-16405-4 (CD-ROM)

The eighth edition of this standard work has now appeared, despite the fact that in 1978 the seventh edition was announced, in its preface, as being probably the last, to be replaced in the future by other forms of data compilation. That was not good news for those who had become used to looking up data in the *Table of Isotopes*, the "Blue Bible", but the thinking behind it was understandable when one compared the still handy sixth edition with the massive seventh—where would this growth finally end?

Now we have before us the latest version of the work: two volumes in a colorful binding, grown to 3100 pages listing

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3621-2384 $ 17.50+.50/0

the nuclear properties of about 3200 isotopes and isomers of 111 elements. It is based on the combined efforts of more than 100 scientists from various countries, who have critically evaluated some 24000 publications and contributed their results to form the Evaluated Nuclear Structure Data Files (ENSDF) at the Brookhaven National Laboratory.

Despite the even greater quantity of data contained in the eighth edition, one is immediately at ease with using it, as the well proven structure has been retained. The data are arranged in mass chains with increasing mass number. Then within a given mass number the nuclear charge numbers increase, with radioactive decay schemes providing a system for quick optical orientation.

However, the details have undergone some considerable changes. Thus, only one set of data is given for each nuclide, namely that which the compilers regard as representing the current state of knowledge, instead of data from different authors being listed alongside each other. Many users will certainly regard this as an improvement. Where one wishes to consult the original sources, the well-chosen literature references given here are a useful starting point; alternatively one can obtain information from the *Nuclear Data Sheets*, from mass chains published in *Nuclear Physics*, or lastly from the actual ENSD files. In this edition greater attention has been paid to data on nuclear reactions. The excited nuclear states that they generate are now listed instead of being shown diagrammatically. Also the states that belong together within rotation bands are indicated by suitable schematic diagrams, leading to useful information about one important aspect of nuclear structure.

The appendices too have been considerably enlarged. In these, data that are scattered throughout the entire tabulation are systematically collected together under various properties headings. For example, the characteristic gamma-emissions of radioactive nuclides are arranged according to their energies, which is useful when one wishes to identify an unexpected gamma line. Various other properties of atoms, nuclei, and radiations, which users of the *Table of Isotopes* are likely to need frequently, are summarized in the form of diagrams or tables. There is even a short section on nuclear structure.

Furthermore, when you buy the *Table of Isotopes* you also receive a second copy in the form of an interactive CD-ROM edited by Frank Chu, which can be used with Windows, Macintosh, or UNIX systems. You can either load it into your desktop PC at home or carry the data around in your laptop computer. The data are exactly the same as in the printed volumes, but they are displayed in a much more spacious style and arranged in a clearly ordered manner, rather than in continuous lines as in the book version. This increases the number of pages to about 14000. Finding one's way around is helped by color codes and by "bookmarks". Data with common features can be quickly called up with a mouse click. Thus, starting from the mass chain one can easily find the radioactive decay data for a particular isotope, and proceeed from there to the decay scheme, and finally to the bibliography. There one can click on the abbreviated codes to read names of authors, titles, and short abstracts. Any details that are not sufficiently well resolved on the screen for easy reading, such as a complex decay scheme, can be magnified up to eightfold if necessary. On the whole, however, the hardcopies are beautifully sharp, even at normal size. Lastly, the CD-ROM also contains some additional information not provided in the book version, for example about the ENSDF system.

Although many users will continue to prefer the familiar printed version of the *Table of Isotopes*, especially for quickly looking up some item of information such as the half-life of a nuclide or a characteristic gamma line, the CD-ROM is undeniably the form that will prevail in the future. One quickly gets accustomed to using it. In the preface Richard Firestone assures us that there is still plenty of space on the CD-ROM, and points out that it can easily be updated from the database. For this reason he promises that updated editions will appear more frequently than in the past—the eighth edition will certainly not be the last. Users will look forward to that.

Homoleptic Metal Carbonyl Cations of the Electron-Rich Metals: Their Generation in Superacid Media Together with Their Spectroscopic and Structural Characterization**

Helge Willner* and Friedhelm Aubke*

Homoleptic carbonyl cations of the electron-rich metals in Groups 8 through 12 are the newest members of the large family of transition metal carbonyls. They can be distinguished from typical metal carbonyl complexes in several respects. Their synthesis entails carbonylation of metal salts in such superacids as fluorosulfuric acid and "magic acid" HSO_3F–SbF_5. Thermally stable salts with $[Sb_2F_{11}]^-$ as counterion are obtained with antimony pentafluoride as reaction medium. Both the $[Sb_2F_{11}]^-$ anion and superacid reaction media have previously found little application in the organometallic chemistry of d-block elements. Also unprecedented in metal carbonyl chemistry are the coordination geometries with coordination numbers 4 (square-planar coordination) and 2 (linear coordination) for the cation. Formal oxidation states of the metals, and the charges of the complex cations, extend from +1 to +3: thus CO is largely σ-bonded to the metal, and the CO bond is strongly polarized. Minimal metal → CO π-backbonding and a positive partial charge on carbon are manifested in long M–C bonds, short C–O bonds, high frequencies for C–O stretching vibrations (up to 2300 cm^{-1}), and small ^{13}C NMR chemical shifts (up to $\delta_c = 121$). Prominent examples of these unusual homoleptic carbonyl cations, which were recently the subject of a Highlight in this journal, include the first carbonyl cation of a p-block metal $[Hg(CO)_2]^{2+}$, the first trivalent carbonyl cation $[Ir(CO)_6]^{3+}$, and the first multiply charged carbonyl cation of a 3d metal $[Fe(CO)_6]^{2+}$. In this overview we propose to a) outline the historical origins of cationic metal carbonyls and their methods of synthesis; b) present a summary of the general field of carbonyl cations, which has developed over a very short period of time; c) discuss the structural and spectroscopic characteristics of metal–CO bonding; d) discuss the special significance associated with reaction media and the $[Sb_2F_{11}]^-$ anion; and e) point to the most recent results and anticipated future developments.

1. Introduction

Carbon monoxide, CO, is the most important and versatile ligand in the organometallic chemistry of transition metals.[1] This simple diatomic molecule can bind in monodentate or multidentate fashion to a host of charged and uncharged metal atoms, clusters, organometallic fragments, and surfaces of metals or ionic crystals. The products range from diverse molecular complexes, through adsorbates, to matrix-isolated molecules. The origin of this multifaceted bonding potential is to be found in a synergistic interaction between σ-donor bonding of the 5σ molecular orbital of CO to a suitable atomic orbital on the metal atom with σ symmetry, and π-backbonding of the metal atom into the π* molecular orbitals of CO. In the case of typical mononuclear homoleptic metal carbonyls, several simplifications occur as a result of: a) the bonding nature of CO, which is in this case only monodentate; b) nearly strict observance of the 18-electron rule [the 17e molecule $V(CO)_6$ constitutes an exception], which permits the prediction of molecular structures and reactivity characteristics; and c) the need for optimization of the synergistic bonding, whereby the formal charge on the metal remains low (normally 0 or ±1). Especially π-backbonding serves to stabilize the M–CO bond in the presence of a low formal charge.

As a consequence of these conditions typical carbonyl complexes are formed in the middle of the d series (Groups 5 through 9). Their molecular geometries are predictable from VSEPR theory.[2] The geometries are mainly limited to three

simple types: a) octahedral coordination, $[M(CO)_6]^m$, $m = -1$, 0, +1; b) trigonal-bipyramidal coordination, $M(CO)_5$; and c) tetrahedral coordination, $M(CO)_4$.

Thermally stable, isolable compounds do not exist for all these structural types. Until 1990, only carbonyl cations of the type $[M(CO)_6]^+$ (M = Mn, Tc, Re) were known.[3, 4] Among the neutral complexes $M(CO)_4$, only $Ni(CO)_4$, the oldest compound in the group,[5] is stable at room temperature, whereas the homologous complexes $Pd(CO)_4$ and $Pt(CO)_4$ exist exclusively at low temperature in the matrix.[6]

Very recently there have been two further developments reaching beyond the typical carbonyls:

1. Many new "highly reduced" metal carbonyl anions have been obtained through chemical reduction in basic solvents.[7] These are of the general type $[M(CO)_n]^{m-}$, where M is an element from Groups 4 through 9, the oxidation states/ionic charges m fall between -2 and -4, and the coordination numbers n are between 3 and 6. The molecular geometries are comparable to those of typical carbonyls (octahedral, trigonal bipyramidal, and tetrahedral). In addition, trigonal-planar anions of the type $[M(CO)_3]^{3-}$ (M = Co, Rh, Ir) have been described.[7] All these highly reduced carbonyl metalates obey the 18e rule, and form, together with the typical carbonyl metalates $[M(CO)_n]^-$ (M = an element of the Groups 5, 7, 9; $n = 6, 5, 4$) and $[M(CO)_4]^{2-}$ (M = Fe, Ru, Os), the largest group of mononuclear homoleptic carbonyl complexes.

2. Completely new homoleptic carbonyl cations, the subject of a recent highlight in this journal,[8] can be prepared[9] in superacid medium.[10] They are of the type $[M(CO)_n]^{m+}$, with M = an element of the Groups 8 through 11, $n = 6$ (octahedral),[11-13] $n = 4$ (square planar),[14] and $n = 2$ (linear),[15, 16] where $m = 1, 2, 3$. These cations form isolable, thermally stable salts with $[Sb_2F_{11}]^-$ as the anion. The boundary of the transition metals was crossed for the first time with $[Hg_n(CO)_2]^{2+}$, $n = 1, 2$.[15]

Metal carbonyl cations display two unique features: a) Cations with the electronic configurations d^8 and d^{10} are square planar or linear, respectively. These geometries are unprecedented in metal carbonyl chemistry. b) The number of valence electrons (16 or 14) violates the noble gas rule.

To this group can also be added the typical carbonyl cations $[M(CO)_6]^+$, M = Mn, Tc, Re, which have been known since 1961. All known mononuclear metal carbonyl complexes are listed in Table 1. They are divided into typical metal carbonyls, highly reduced carbonyl metalates,[7] and homoleptic metal carbonyl cations.[9] If one includes the carbonyl complexes with copper and silver, all the d-block metals except those in Group 3 (Sc, Y, La) form at least one type of carbonyl derivative. In addition to these mononuclear cases, two binuclear cations have so far been isolated from SbF_5 suspension or HSO_3F solution: linear $[Hg_2(CO)_2]^{2+}$ [15] and cyclic $[Pd_2(\mu\text{-}CO)_2]^{2+}$.[17] Whereas all the homoleptic carbonyl cations exist in magic acid (HSO_3F–SbF_5) the autoionization ion SO_3F^- is sufficiently

H. Willner

F. Aubke

Helge Willner, born in 1947 in Hamm, Westphalia, pursued an apprenticeship as laboratory assistant and studies at the Engineering School in Essen before embarking upon and completing in 1971 a chemistry degree at the University of Münster. In 1974 he presented a dissertation under the supervision of H. J. Becher on the subject of vibrational spectra of doped ionic crystals. He subsequently went to the University of Bochum to work on matrix-isolation spectroscopy and fluorine chemistry with A. Haas. He also acquired knowledge of special matrix techniques during 1977 in the laboratory of L. Andrews, Charlottesville, VA (USA). He then completed his habilitation in Bochum in 1981 with an investigation of binary sulfur and selenium fluorides, and in 1982 was called to a professorship in inorganic chemistry at the University of Hannover. During a sabbatical semester in 1989 with F. Aubke in Vancouver, Canada, he became interested in superacids, and there laid the groundwork for this article with the discovery of the $[Au(CO)_2]^+$ cation. His principal areas of activity are matrix-isolation spectroscopy of small, reactive molecules, especially in the fields of atmospheric and fluorine chemistry, as well as—in the past eight years—coordination chemistry in superacid media.

Friedhelm (Felix) Aubke was born in 1932 in Herne (Westphalia). He studied chemistry at the Technische Hochschule Aachen, where he received his doctorate under M. Schmeisser in 1962. After postdoctoral research in Seattle, Washington (G. H. Cady), and Hamilton, Ontario (R. J. Gillespie), he started his academic career in 1966 at the University of British Columbia, Vancouver, Canada, where he has been a full professor since 1978. His research in physical inorganic chemistry has been concerned with the development of new superacid systems, their application in the generation of unusual, highly electrophilic nonmetallic, metallic, and organometallic cations, and their subsequent spectroscopic and structural studies. Felix Aubke is the recipient of the Killam Senior Faculty Research Fellowship (1987) and the Alexander von Humboldt Research Prize (1995). He has been very active in fluorine chemistry, and has hosted in Vancouver both the 10th (1982) and the 15th (1997) International Symposia on Fluorine Chemistry

Table 1. Mononuclear homoleptic metal carbonyl species that are stable under ordinary conditions.

$[Hf(CO)_4]^{2-}$	$[Ta(CO)_5]^{3-}$	$[W(CO)_4]^{4-}$	$[Re(CO)_4]^{3-}$	[a]	$[Ir(CO)_3]^{3-}$			
metal carbonyl cations								
				$[Fe(CO)_6]^{2+}$			$[Cu(CO)_n]^+$ [b]	
				$[Ru(CO)_6]^{2+}$		$[Pd(CO)_4]^{2+}$	$[Ag(CO)_m]^+$ [c]	
				$[Os(CO)_6]^{2+}$	$[Ir(CO)_6]^{3+}$	$[Pt(CO)_4]^{2+}$	$[Au(CO)_2]^+$	$[Hg(CO)_2]^{2+}$

[a] $[M(CO)_4]^{2-}$ complexes with M = Fe, Ru, or Os are considered typical; $[M(CO)_3]^{4-}$ are anticipated. [b] $n = 1-4$, thermally unstable. [c] $m = 1-3$, thermally unstable.

nucleophilic in the protic acid HSO_3F to partially displace CO from the carbonyl cations. In this manner cationic derivatives of the general type $[M(CO)_n(SO_3F)_n]$, $n = 1, 2, 3$, are formed, in which fluorosulfate groups are covalently bonded through an oxygen atom to M. Examples include $Au(CO)SO_3F$,[16a] $M(CO)_2(SO_3F)_2$ in which M = Pd or Pt,[18] and $Ir(CO)_3(SO_3F)_3$.[19] They have been included in this overview for three reasons:

1. Their spectroscopic and bonding characteristics are similar to those of the corresponding homoleptic metal carbonyl cations.
2. The molecular structures of *cis*-$Pd(CO)_2(SO_3F)_2$,[18b] *mer*-$Ir(CO)_3(SO_3F)_3$,[19] and *cyclo*-$[Pd_2(\mu\text{-}CO)_2](SO_3F)_2$ [17] are known and provide useful structural information.
3. Most metal carbonyl fluorosulfates are easily converted by solvolysis in liquid SbF_5 under a CO atmosphere into the corresponding $[Sb_2F_{11}]^-$ salts.[14, 16b] The example of the pair $Au(CO)SO_3F$–$[Au(CO)_2][Sb_2F_{11}]$ [Eq. (a)] illustrates the relationship between the two groups.

$$Au(CO)SO_3F \underset{\text{in } HSO_3F:\ +SO_3F^-,\ -[Sb_2F_{11}]^-}{\overset{\text{in } SbF_5:\ +CO,\ -Sb_2F_9(SO_3F)}{\rightleftharpoons}} [Au(CO)_2][Sb_2F_{11}] \qquad (a)$$

Antimony pentafluoride as sole reaction medium for carbonylation,[20] and the use of binary metal fluorosulfates and halides as starting materials,[21] has in the meantime diminished the significance of metal carbonyl fluorosulfates as precursors in the synthesis of salts with metal carbonyl cations.

In certain cases, anhydrous hydrofluoric acid is used as a reaction medium for the preparation of metal carbonyl fluorides. Some of those considered here, such as $Ir(CO)_3F_3$,[22] possess fluorosulfate analogues, in this case $Ir(CO)_3(SO_3F)_3$.[19]

1.1. The History of Homoleptic Carbonyl Cations of Electron-Rich Metals

Many authors are of the opinion that the accidental discovery of $Ni(CO)_4$ by Mond, Langer, and Quincke in 1890[5] marks the beginning of metal carbonyl chemistry.[23] The organometallic chemistry of carbon monoxide was thereafter intensively developed through the contributions of W. Hieber and co-workers,[24, 25] and today constitutes an important component of modern transition metal chemistry.[1, 26, 27] Less well known is an earlier, equally fortuitous discovery in the year 1868 by Paul Schützenberger.[28, 29] During an attempt to catalyze the reaction of CO with Cl_2 to give $COCl_2$ with heated platinum Schützenberger succeeded in isolating and identifying three carbonyl chlorides of divalent platinum with the compositions $Pt(CO)_2Cl_2$, $Pt_2(CO)_4Cl_4$, and $Pt_2(CO)_3Cl_4$.[29] The compound *cis*-$[Pt(CO)_2Cl_2]$ has since been very thoroughly investigated, and it has been shown that CO is primarily σ-bonded to the Pt^{II} center.[30] Subsequent systematic studies of these compounds, which were regarded as CO adducts to transition metal chlorides, led to three important contributions by W. Manchot and co-workers:

1. Confirmation[31a] of the existence of the platinum carbonyl chlorides described by Schützenberger,[28, 29] and discovery of the first carbonyl derivative of palladium, with the composition $Pd(CO)Cl_2$.[31b]
2. The synthesis of Au(CO)Cl, the first carbonyl derivative of gold,[32] whose structure is also now known[33]—this simple four-atom molecule remained the only mononuclear gold(I) carbonyl complex for 65 years.
3. The first use of a strong protic acid (concentrated H_2SO_4) in the attempted preparation of carbonyl cations of silver.[34]

Much of this early work has been summarized by M. I. Bruce,[35] S. C. Tripathi et al.,[36a] and M. N. Vargaftik et al.[36b] More recent studies in the area of these noble metal carbonyl halides have been carried out by P. L. Goggin et al.[30] and F. Calderazzo et al.[37–39]

It has since become clear that a formal relationship[40] exists between Schützenberger's $Pt(CO)_2Cl_2$[28, 29] and the homoleptic cation $[Pt(CO)_4]^{2+}$.[14] The first thermally stable homoleptic carbonyl cations of the type $[M(CO)_6]^+$ (M = Mn,[41] Tc,[42] Re,[43]) were discovered, however, by E. O. Fischer, W. Hieber, and their co-workers in 1961. The syntheses were accomplished starting from $M(CO)_5X$, X = Cl or Br, through halide abstraction with Lewis acids at high temperature and high CO pressure [Eq. (b)].

$$M(CO)_5X + AlCl_3 + CO \xrightarrow[90°C]{\text{ca. 300 bar CO}} [M(CO)_6][AlCl_3X] \quad (b)$$

X = Cl, Br; M = Mn, Tc, Re

Detailed studies of vibrational spectra have shown that these cations have octahedral geometries.[44, 45] Subsequent attempts to extend the same synthetic methods to metal carbonyl halides of Group 8 ($M(CO)_4X_2$ where M = Fe, Os and X = Cl, Br), appeared to lead to the doubly charged cations $[M(CO)_6]^{2+}$ (M = Fe, Os) with $[AlX_4]^-$ (X = Cl, Br) as counterion.[43a] However, these as well as other reports of the synthesis of $[Fe(CO)_6]^{2+}$ [48] were repudiated within a few years.[49]

Not until 35 years later[43a] did it prove possible to obtain not only $[Os(CO)_6]^{2+}$ and $[Ru(CO)_6]^{2+}$,[11] but also $[Fe(CO)_6]^{2+}$,[12] as thermally stable $[Sb_2F_{11}]^-$ salts ($T_{decomp.} > 100\,°C$). Their synthesis required the development of a new carbonylation method in superacid media.[8] Again, as with the discovery of $Ni(CO)_4$ and the first synthesis of $Pt(CO)_2Cl_2$, the beginning was marked by an accidental discovery. Attempts to prepare the $[HCO]^+$ ion—previously discovered in interstellar space[50, 51]—by protonation of CO in the conjugated superacid HSO_3F–$Au(SO_3F)_3$[52] resulted instead in the reductive carbonylation of $Au(SO_3F)_3$ to form the first homoleptic noble metal carbonyl cation $[Au(CO)_2]^+$,[16a] initially in solution and later as the thermally stable salt $[Au(CO)_2][Sb_2F_{11}]$.[16b] The advances achieved in homoleptic metal carbonyl chemistry since that time are discussed below. The molecular ion $[HCO]^+$ has, interestingly, acquired great significance with respect to the discussion of bonding in metal carbonyl cations. Its CO force constant of $21.3 \times 10^2\ N\,m^{-1}$ [50c] can be regarded as a limiting value for the strongest C–O bond in carbonyl cations in the complete absence of π-back-bonding. The change from the ionizing protic acid HSO_3F and the magic acid HSO_3F–SbF_5 to liquid SbF_5 as sole reaction medium finally has permitted the facile preparation of such multiply charged carbonyl cations as $[M(CO)_6]^{2+}$, M = Fe,[12] Ru,[11] Os,[15] or $[Ir(CO)_6]^{3+}$,[13] none of which exist in HSO_3F.

1.2. Recent Developments in Cationic Carbonyl Complexes, and the Goal of this Article

Apart from the carbonyl cations mentioned above, the cationic carbonyl complexes of silver and copper, which display low thermal stability, are relevant to this article. The silver(I) carbonyls $[Ag(CO)_n]^+$, $n = 1-3$[53–56] exist with complex teflato counterions (teflate = $OTeF_5$) such as $[B(OTeF_5)_4]^-$ or $[Nb(OTeF_5)_6]^-$. They are formed by CO addition to the corresponding silver(I) salts, but under normal conditions are unstable and release CO spontaneously.[56] Nevertheless, it has been possible to determine two molecular structures by X-ray diffraction on single crystals at −125 °C: those of $Ag(CO)[B(OTeF_5)_4]$ and $[Ag(CO)_2][B(OTeF_5)_4]$.[53, 56]

Cationic complexes of copper(I), which are discussed elsewhere,[9b, 35] have a long history and important applications as carbonylation catalysts. It is interesting that cations such as $[Cu(CO)_n]^+$, $n = 1-4$, or $[Ag(CO)_2]^+$ are generated in strong protic acids like HSO_3F and HSO_3CF_3.[57] According to a recent study the isolable salt $[Cu(CO)][AsF_6]$,[58] which forms with the fluoro anion $[AsF_6]^-$, is capable at 0.3 bar CO pressure of accepting additional carbon monoxide up to a composition $[Cu(CO)_n]^+$, $n = 2, 3$.[59] Structural characterization in this case is so far limited to Cu(CO)Cl.[60] A comparison of the molecular structures of CO adducts for all three metals of Group 11 is possible for a series of tris(pyrazolyl)borate complexes of the type $[HB(3,5\text{-}(CF_3)_2Pz)_3]MCO$, M = Cu,[61] Ag,[62] and Au.[63] Structural comparisons with similar species from the Cambridge Data Index[64] are also useful. Observed bond lengths, for example, can be correlated with bond orders.[65, 66] Interionic and intermolecular secondary bond lengths, as defined by Alcock,[67] can also be compared with the sums of van der Waals radii.[68]

Among the homoleptic carbonyl cations, the largest group consists of the octahedral species $[M(CO)_6]^{n+}$ in which $n = 1$, (M = Mn, Tc, Re[41–43]), 2 (M = Fe,[12] Ru, Os[11]), and 3 (M = Ir[13] and Fe[12]). Both the neutral species $M(CO)_6$ (M = Cr, Mo, W) and the carbonyl metalates $[M(CO)_6]^-$ (M = V, Nb, Ta,[69, 70]) and $[M(CO)_6]^{2-}$ (M = Ti, Zr, Hf[71]) are known.

A comparison of the spectroscopic properties of these isosteric complexes is planned in this review. Since CO and the CN^- ion are isoelectronic, it is also reasonable to compare the metal carbonyl cations and the corresponding cyanometalate anions. Cyano complexes are known for almost all, but especially for the late transition metals.[72, 73] Corresponding isoelectronic and isosteric anionic cyano complexes exist for all the mononuclear homoleptic metal carbonyl cations characterized to date. Only $Hg(CN)_2$,[74] which corresponds to $[Hg(CO)_2]^{2+}$,[15] is neutral. Spectroscopic properties of the cyano complexes have been thoroughly investigated.[75]

The formation of thermally stable salts with $[M(CN)_n]^{(m-n)-}$ anions, where m is the oxidation state of the metal, is possible in numerous solvents and with many different countercations. On the other hand, it has so far been possible to stabilize homoleptic carbonyl cations only with the $[Sb_2F_{11}]^-$ anion, which is formed in SbF_5. The reasons for the special role of the $[Sb_2F_{11}]^-$ anion will be discussed in Section 2.1. There are of course many more known cyanometalate anions[72, 73] than homoleptic metal carbonyl cations. The chemical behavior of the established metal cyanide complexes has already been intensively investigated, whereas the chemistry of the new $[M(CO)_n]^{m+}$ species requires further research. Thus, the yellow ferrocyanide salt $K_4[Fe(CN)_6]\cdot 3H_2O$ has been known since 1752,[76] whereas the first successful synthesis of $[Fe(CO)_6][Sb_2F_{11}]_2$ did not occur until 1996.[12]

The common features of the two types of complexes with opposite charges relate to structural and spectroscopic characteristics. These are in turn a consequence of the similar bonding relationships of CN^- and CO to the metal ions M^{n+} ($n = 1-3$), including a largely σ-donor contribution and minimal π-back-bonding from ligand to metal ion. This is revealed especially clearly in the ν(CX) stretching frequencies (X = O, N) or in force constants, which will be compared and discussed in subsequent sections.

An overwhelmingly σ-bonded CO type of bonding is not exclusive to the metal carbonyl cations. Others have been discussed in a previous overview,[9b] including $BH_3\cdot CO$[77] and $[HCO^+]$,[50, 51] in which CO is coordinated to a main group

element. In recent years there have been numerous reports regarding CO adducts on the surface of ionic crystals and on zeolites doped with transition metal ions, in which chemisorbed CO functions as a surface probe.[78] Equally well documented is the use for carbonylation reactions of solvated Cu^I and Ag^I carbonyl cations in strong protic acids, including HSO_3F.[57] All these aspects have already been summarized,[9b] and will not be further examined here.

Recent reports concerning CO adducts with several organometallic Lewis acids should be mentioned as well: systems of the general type L_nM ($n = 2, 3$; L = Cp (η^5-C_5H_5) or Cp* (η^5-C_5Me_5); and M = d^0-metal ions, actinoides, or main group metals).[79] Among these carbonyls, $[Cp_2^*Zr(\eta^3\text{-}C_3H_5)(CO)][B(C_6H_5)_4]$[79a] is stable at room temperature. The species $[R_2Zr(\eta\text{-}COMe)(CO)][MeB(C_6F_5)_3]$ (R = Cp, Cp*)[79b] display absorption maxima in wavenumbers for CO stretching vibrations at 2105 and 2176 cm^{-1}, respectively. Based on Fenske–Hall molecular orbital calculations,[80] these metal–CO bonds are found to consist overwhelmingly of σ-donor contributions, with little π-backbonding despite the d^0 electron configurations. Noteworthy also are adducts of the type $Cp_2^*M(CO)$ (M = Si,[81] Ca[82]) and $(C_5Me_4H)_3U(CO)$, the first uranium carbonyl to be isolated.[83] These examples point to fascinating developments in metal carbonyl chemistry, and underscore the great versatility of CO as a ligand.

In contrast to the homoleptic carbonyl cations, such carbonyls are frequently of low thermal stability, the CO addition is reversible, and the M–CO bond is stabilized by other, ancillary ligands, especially Cp*. The development that has led to these new complexes[79, 81–83] began with the use of Cp*[84, 85] and followed the classical approaches and methods of organometallic chemistry. The synthesis of homoleptic carbonyl cations, on the other hand, has become possible only through the introduction of superacid media (Section 2).

2. Discussion

2.1. Superacid Reaction Media

Acidic reaction media have rarely been employed in transition metal carbonyl chemistry, with three exceptions:

1. Strong protic acids such as H_2SO_4 and CF_3SO_3H are occasionally utilized for the preparation of organometallic cations by protonation of suitable substrates.[3, 4, 86]
2. Selected Lewis acids like BF_3(g) and AlX_3 (X = Cl, Br) can serve as halide-abstracting agents.[3, 4, 41–43] Anions of stronger acids, or superacids of the type $[EF_6]^-$ (E = P, As, Sb, and others) are introduced in metathesis reactions to stabilize organometallic cations. Their use has previously been discussed.[3, 4]
3. The use of superacids as reaction media in synthetic chemistry has previously been the domain of inorganic main group chemistry and organic chemistry.[10] Superacids have been employed in metal carbonyl chemistry only occasionally in the generation of reactive cations of Ag^I and Cu^I intended as catalysts.[9b, 57] The first successful synthesis of a homoleptic metal carbonyl cation, $[Au(CO)_2]^+$,[16] became possible with use of the classical Brønsted superacid HSO_3F[10] and the molecular superacid SbF_5. This pair of superacids and the combination of the two, the conjugated superacid HSO_3F–SbF_5 or magic acid,[10a] are the only superacids we have utilized in the generation of homoleptic metal carbonyl cations.

2.1.1. *Fluorosulfuric acid, HSO_3F*

The acid–base characteristics of HSO_3F are best described by the autoionization equilibrium in Equation (c). The specific

$$2HSO_3F \rightleftharpoons H_2SO_3F^+ + SO_3F^- \quad (c)$$

conductivity of HSO_3F at 25 °C is $1.08 \times 10^{-4}\ \Omega^{-1}\,cm^{-1}$,[87a] and the limits of its application are defined by the protonation potential of the acidic ion $H_2SO_3F^+$ and the nucleophilicity of SO_3F^-. Electrophilic cations exist in HSO_3F as long as they are not further protonated by $H_2SO_3F^+$ or attacked by SO_3F^-. Fluorosulfuric acid is a very useful solvent for carbonylation reactions from both practical and chemical standpoints. Of practical importance for low-temperature studies and reactions at high temperature is the wide liquid range of the substance (f.p. −89, b.p. 163 °C). HSO_3F does not react with glass at room temperature and below. However, at elevated temperature a dissociation occurs [Eq. (d)], one consequence of which is an

$$HSO_3F \rightleftharpoons HF + SO_3 \quad (d)$$

attack on glass apparatus. The substance's high dielectric constant ε^{25} of about 120[87] causes it to be an excellent ionizing solvent. Although HSO_3F is commercially available, it must be purified before use.[87d] HSO_3F also displays certain unique features from a chemical viewpoint. For example, it is completely miscible with bis(fluorosulfuryl) peroxide, $S_2O_6F_2$. The latter reagent, first prepared in 1957 by Dudley and Cady,[88] can be obtained easily and safely by catalytic fluorination of SO_3.[89] Solutions of $S_2O_6F_2$ in HSO_3F are both strongly oxidizing and ionizing,[90] and they permit the facile synthesis of many binary fluorosulfates of the late transition metals,[91] such as that of $[Au(SO_3F)_3]_2$ [Eq. (e)].

$$2Au + 3S_2O_6F_2 \xrightarrow{HSO_3F} [Au(SO_3F)_3]_2 \quad (e)$$

The relevance to homoleptic metal carbonyl cations becomes clear when one considers that the carbonyl cations of Hg^{II},[15] Au^I,[16] and M^{II} (M = Ru, Os,[11] Pd, Pt[14]) have all been synthesized from the corresponding metal fluorosulfate precursors. These in turn arise by oxidation of the appropriate powdered metal with $HSO_3F/S_2O_6F_2$.[91] Apparently HSO_3F is also an excellent solvent for the growth of single crystals. A recently reported single-crystal study of the polymeric compounds $[SbF_2(SO_3F)]_x$, $[SbF(SO_3F)_2]_x$, and $[Sb(SO_3F)_3]_x$ underscores this point.[92] Thus, it is very convenient to use the same solvent (HSO_3F) both for the synthesis of the metal fluorosulfate as well as for its subsequent conversion into a homoleptic carbonyl cation and crystal growth. Excess $S_2O_6F_2$ is easily removed under vacuum, and remaining traces react with CO[16a] [Eq. (f)].

$$CO + S_2O_6F_2 \longrightarrow CO_2 + S_2O_5F_2 \quad (f)$$

CO_2 and $S_2O_5F_2$ arise also in the reductive carbonylation of metal fluorosulfates as a consequence of thermal decomposition of the phosgene analogue $OC(SO_3F)_2$.[93]

Although the solubility of CO in HSO_3F is low (less than 0.01 M at 1 bar CO and 25 °C[16a]), carbonylation reactions take place in superacids at 25–60 °C and CO pressures around 1 bar, usually within a few hours. These reaction conditions represent a remarkable contrast to the formation of $[M(CO)_6][AlX_4]$ (M = Mn,[41] Tc,[42] Re;[43] X = Cl, Br), which require 300–320 bar CO and temperatures around 90 °C.

In contrast to fluorosulfuric acid, the equally strong anhydrous hydrofluoric acid has found little application in synthetic transition metal carbonyl chemistry, probably for practical reasons. Two examples of synthetic applications are the oxidative carbonylation of gold with UF_6 in HF to give $[Au(CO)_2][UF_6]$[94a] and the fluorination of $Ir_4(CO)_{12}$ with XeF_2 in HF producing $Ir(CO)_3F_3$.[22]

Also of importance to this work are IR matrix studies on the isomeric molecular complexes FH···CO (**1**) and FH···OC (**2**).[94b] The observed shifts $\Delta\tilde{\nu}$(CO) of $+24\,cm^{-1}$ for **1** and $-9\,cm^{-1}$ for **2** relative to matrix-isolated CO, and the low frequency for the vibration of HF relative to that of CO (about $100\,cm^{-1}$ for both isomers) show that the hydrogen bonds are weak. This in turn makes the low solubility of CO in strong protic acids understandable. The different shifts $\Delta\tilde{\nu}$(CO) can be attributed to the different polarization of the CO bonds in **1** and **2**,[94c] analogous to HCO^+ and COH^+.[94d] The unusually high CO frequencies found for metal carbonyl cations point definitively to C-coordinated CO ligands, an interpretation also consistent with recently established structures and quantum mechanical calculations (see Section 2.5.4).

2.1.2. *Antimony Pentafluoride, SbF_5*

Among the known Lewis acidic fluorides, liquid SbF_5 is particularly favored as a reaction medium. Other Lewis acids such as BF_3, SiF_4, PF_5, and AsF_5 are gaseous under normal conditions, whereas oligomers such as TaF_5, NbF_5, and BiF_5 are solids.[95] SbF_5 displays a liquid region extending from 8 to 141 °C,[95] a range in which it is oligomeric and associated through F-bridges in a helical fashion,[96a] and hence extremely viscous.[85b] As a result of its low electrical conductivity of less than $7\times10^{-9}\,\Omega^{-1}cm^{-1}$, there is no evidence for autoionization. Consequently, nucleophiles such as $[SbF_6]^-$, like SO_3F^- in HSO_3F, are present only in very low concentration. Viewed overall, SbF_5 is a poor, exceptionally weakly ionizing solvent, and in many carbonylation reactions the starting materials and products are merely suspended rather than dissolved. Consequently, such heterogeneous reactions are frequently very time-consuming.

Whereas pure SbF_5 is seldom used as a reaction medium, it finds broad application in conjugated superacids such as $HF-SbF_5$[97] and HSO_3F-SbF_5 (magic acid),[10] in which SbF_5 is regarded as the strongest of the molecular Lewis acids.[10, 98] Many carbocations[10a, 99] and cations of the p-block elements[10b] are prepared in these systems. Earlier attempts at transforming various fluorosulfates into fluoroantimonates with SbF_5, as well as the first carbonylation reactions in SbF_5, have already been summarized.[20] A change from HSO_3F to SbF_5 as reaction medium was necessitated by the fact that many homoleptic carbonyl cations, including $[Au(CO)_2]^+$[16a] and $[M(CO)_4]^{2+}$ (M = Pd, Pt)[14] cannot be isolated from HSO_3F solution. In contrast to $[Au(CO)_2]^+$ and $[M(CO)_4]^{2+}$ (M = Pd, Pt), other homoleptic carbonyl cations such as $[Hg(CO)_2]^{2+}$,[15] $[M(CO)_6]^{2+}$ (M = Fe,[12] Ru, Os,[11] and $[Ir(CO)_6]^{3+}$[13]) do not exist in HSO_3F and can therefore be prepared only in SbF_5. Consequently, SbF_5 has been elevated to the position of sole reaction medium. An apparent disadvantage of SbF_5 consists in the difficulty of growing single crystals in this environment. The products are usually polycrystalline powders, which must then be recrystallized. The only medium that is suitable in this case is magic acid (HSO_3F-SbF_5) which will be discussed next.

2.1.3. *Magic Acid (HSO_3F-SbF_5) and the Undecafluorodiantimonate(V) Ion $[Sb_2F_{11}]^-$*

Addition of SbF_5 to HSO_3F causes the acidity to be increased by up to seven orders of magnitude as a result of the formation of a conjugated superacid.[10, 100] Simultaneously the basicity is decreased because of complexation of the fluorosulfate ion by SbF_5. This process can initially be visualized as a reaction between a Lewis acid and a Lewis base, namely SbF_5 and SO_3F^-, which shifts the autoionization equilibrium to the right [Eq. (g)].

$$2HSO_3F + SbF_5 \rightleftharpoons [H_2SO_3F]^+ + [SbF_5(SO_3F)]^- \qquad (g)$$

However, ^{19}F NMR studies on the system HSO_3F-SbF_5 show considerably greater complexity than Equation (g) suggests, and the presence of up to 15 different anions including $[Sb_2F_{11}]^-$ has subsequently been confirmed spectroscopically.[101–105] Although even at high SbF_5 concentrations (greater than 30 mol%) $[Sb_2F_{11}]^-$ is present in HSO_3F only in concentrations of a few mol%, its salts are only slightly soluble. This becomes apparent from the unexpected isolation of the oxonium salt $[H_3O][Sb_2F_{11}]$ from HSO_3F-SbF_5 and its single-crystal X-ray structure.[106] $[H_3O][Sb_2F_{11}]$ arises through a reaction between magic acid and glass. It is thus not surprising that two $[Sb_2F_{11}]^-$ salts with metal carbonyl cations, $[Hg(CO)_2][Sb_2F_{11}]$[15b] and $[Ir(CO)_5Cl][Sb_2F_{11}]_2$,[13] have been obtained as single crystals from magic acid and subsequently characterized by X-ray diffraction.

The geometry of the $[Sb_2F_{11}]^-$ anion in $[H_3O][Sb_2F_{11}]$ permits certain conclusions to be drawn about secondary interionic contacts. In $[H_3O][Sb_2F_{11}]$ three crystallographically distinct $[Sb_2F_{11}]^-$ anions are present, and they deviate in very similar ways from ideal D_{4h} symmetry (Figure 1). The three most impor-

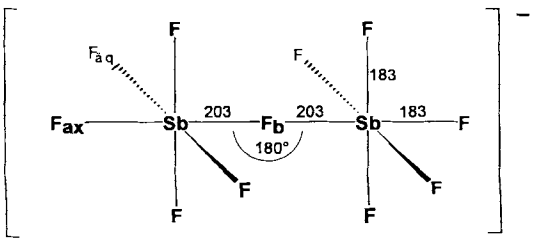

Figure 1. Geometric parameters [pm] for an undistorted $[Sb_2F_{11}]^-$ ion with D_{4h} symmetry.

tant deviations in the anion are 1) deformation of the $Sb-F_{(b)}-Sb$ bond angle from 180 through 149.4 to 145.9° in the $[H_3O]^+$ salt,[106] 2) torsion of the two planar $SbF_{4(eq)}$ groups from an eclipsed to a staggered conformation, and 3) slight changes in the $SbF_{(eq)}$ or the $SbF_{(ax)}$ bond lengths.

In addition to asymmetric hydrogen bonds of the type $O-H\cdots F$ in $[H_3O][Sb_2F_{11}]$,[106] which generate interionic contacts, similar contacts are known in compounds between $[Sb_2F_{11}]^-$ and nonmetal cations. Molecular structures have been described for a number of these salts with the cations $[I_2]^+$,[107] $[TeF_3]^+$,[108] $[IF_4]^+$,[109] $[XeF]^+$,[110] $[XeF_3]^+$,[111] $[SbCl_4]^+$,[112] and $[Se_2I_4]^{2+}$.[113]

In all cases, the $[Sb_2F_{11}]^-$ anion is distorted in a way similar to that in $[H_3O][Sb_2F_{11}]$. In $[H_3F_2][Sb_2F_{11}]$ and $[H_2F][Sb_2F_{11}]$ the $[Sb_2F_{11}]^-$ is regular.[114] A related structure is also encountered in $[Br_2][Sb_3F_{16}]$,[115] with significant $Br\cdots F$ contacts. A comparative overview of various structures containing $[Sb_2F_{11}]^-$ anions has been published.[45] Interionic contacts in these molecular structures[106-113] are manifested in two ways. First, many $F\cdots E$ distances are shorter than the sum of the corresponding van der Waal's radii.[68] In the examples presented,[106-115] acceptors in the interactions (apart from hydrogen) are the elements I, Br, Te, Xe, Sb, or Se in low oxidation states. Both Se and I function as acceptors in $[Se_2I_4]^{2+}$, the only doubly charged cation.[113] Second, the anion $[Sb_2F_{11}]^-$, or in one case $[Sb_3F_{16}]^-$,[115] is distorted relative to Figure 1. A reduced $Sb-F_b-Sb$ angle and changes in the dihedral angle $F_t-S_b-F_b-Sb$[45] are a good measure of interionic contacts in most of the structures.

The flexibility of the $[Sb_2F_{11}]^-$ anion result from weak bonding within the $(Sb-F_b-Sb)$ bridge. Since almost all thermally stable homoleptic carbonyl cations exist as $[Sb_2F_{11}]^-$ salts, the formation of significant interionic contacts is a further important characteristic of the $[Sb_2F_{11}]^-$ ion in addition to its low nucleophilicity. The extent and nature of these contacts will be discussed in detail in Section 2.4.2 for the cases $[Hg(CO)_2][Sb_2F_{11}]_2$[15b] and $[Ir(CO)_5Cl][Sb_2F_{11}]_2$.[13]

Apart from $[Sb_2F_{11}]^-$, another superacidic anion, $[Pt(SO_3F)_6]^{2-}$,[116] also exists and forms a thermally stable salt with $[Pt(CO)_4]^{2+}$ of the composition $[Pt(CO)_4][Pt(SO_3F)_6]$.[117] From ^{119}Sn Mössbauer parameters of various dimethyltin(IV) salts[118] it has been ascertained that $[Pt(SO_3F)_6]^{2-}$ is a weak nucleophile very similar in this respect to $[Sb_2F_{11}]^-$. Moreover, the $[Pt(SO_3F)_6]^{2-}$ anion is trigonally distorted as a consequence of secondary contacts between $Cs^+\cdots O$ and $Cs^+\cdots F$ in $Cs_2[Pt(SO_3F)_6]$,[106] in contrast to the regular octahedral form of the $[Sb(SO_3F)_6]^-$ anion[106,119] in $Cs[Sb(SO_3F)_6]$.

2.1.4. Alternative Solvents and Reaction Media

Apart from the superacid media, only a few other solvents find application in the synthesis and characterization of transition metal carbonyl cations. $[Au(CO)_2][Sb_2F_{11}]$ is very soluble in liquid SO_2,[16b] which is also utilized in the synthesis of $[Cu(CO)][AsF_6]$.[58] Nevertheless, $[M(CO)_4][Sb_2F_{11}]_2$ (M = Pd, Pt) are insoluble in SO_2,[14] and $[Hg(CO)_2][Sb_2F_{11}]$ decomposes in SO_2 with evolution of CO.[15] Perfluoroalkyl sulfonylfluorides, R_fSO_2F ($R_f = C_4F_9$, and higher homologues) are inert to metal carbonyl salts, but dissolve SbF_5 very well. They find limited application in purification processes.[15] Donor solvents easily displace CO, as the transformation of $[Au(CO)_2][Sb_2F_{11}]$ into $[Au(NCCH_3)_2][SbF_6]$ in acetonitrile demonstrates.[16b] The claimed formation of cations of the type $[Ag(CO)_n]^+$ ($n = 1, 2$) in the aprotic solvent 1,1,2-$C_2Cl_3F_3$ is difficult to reconcile with a postulated ionic structure for the silver carbonyl cation in the teflato complexes.[56]

2.2. Syntheses

2.2.1. General Aspects

The generation of homoleptic metal carbonyl cations and the synthesis of cationic metal carbonyl fluorosulfates and fluorides in superacid media is accomplished either by direct CO addition to highly reactive, naked metal cations, or by oxidation of neutral mono- or multinuclear metal carbonyls in the presence of CO.

Since homoleptic metal carbonyl cations of the general type $[M(CO)_n]^{m+}$ ($n = 2, 4, 6$; $m = 1, 2, 3$) exist almost exclusively with $[Sb_2F_{11}]^-$ as counterion, liquid SbF_5 is the reaction medium of choice. Similarly, metal carbonyl fluorosulfates or fluorides are best synthesized in HSO_3F or anhydrous hydrofluoric acid. Details of the most important syntheses are discussed below.

2.2.2. Carbonylations in Liquid SbF_5

Details of carbonylations in SbF_5 are summarized in Table 2. The syntheses are divided into three groups.

Table 2. Syntheses of homoleptic carbonyl cations as $[Sb_2F_{11}]^-$ salts.

Cation	[a]	Reagents	Conditions[b] $p(CO)$ [bar]	T [°C]	t	Ref.
$[Hg(CO)_2]^{2+}$	a	$Hg(SO_3F)_2$, CO, SbF_5	1	80	1 d	[11]
$[Hg_2(CO)_2]^{2+}$	a	$Hg_2(SO_3F)_2$, CO, SbF_5	0.5	60	1 d	[11]
$[Au(CO)_2]^+$	a	$Au(CO)SO_3F$, CO, SbF_5	1	60	2 h	[16b]
	b	$Au(SO_3F)_3$, CO, SbF_5	1	60	1 h	[21]
	b	$AuCl_3$, CO, SbF_5	1	60	3 d	[21]
	b	AuF_3, CO, SbF_5	1	25	3 d	[16b]
$[Pd(CO)_4]^{2+}$	a	$Pd(CO)_2(SO_3F)_2$, CO, SbF_5	1	60	5 h	[15]
	b	$Pd[Pd(SO_3F)_6]$, CO, SbF_5	0.5	80	1 d	[21]
	a	$PdCl_2$, CO, SbF_5	2	60	10 d	[21]
$[Pd_2(\mu\text{-}CO)_2]^{2+}$	d	$[Pd_2(\mu\text{-}CO)_2](SO_3F)_2$, SbF_5	–	20	20 d	[21]
$[Pt(CO)_4]^{2+}$	a	$Pt(CO)_2(SO_3F)_2$, CO, SbF_5	1	60	2 d	[15]

	b	$PtCl_2$, CO, SbF_5	2	60	14 d	[21]
$[Ir(CO)_6]^{3+}$	b	IrF_6, CO, SbF_5	1	60	10 h	[14]
$[Fe(CO)_6]^{2+}$	c	$Fe(CO)_5$, CO, SbF_5, AsF_5 oder Cl_2	1	40	1 d	[13]
$[Ru(CO)_6]^{2+}$	b	$Ru(SO_3F)_3$, CO, SbF_5	1	80	3 d	[12]
$[Os(CO)_6]^{2+}$	b	$Os(SO_3F)_3$, CO, SbF_5	1	80	3 d	[12]
$[Mn(CO)_6]^+$	c	$Mn_2(CO)_{10}$, CO, SbF_5	2	40	7 d	[21]
$[Re(CO)_6]^+$	a	$Re(CO)_5Cl$, CO, SbF_5	1	60	8 h	[21]

[a] Synthetic methods: a: Carbonylation with retention of oxidation state, in some cases with simultaneous solvolysis; b: reductive carbonylation; c: oxidative carbonylation; d: metathesis. [b] Applicable to millimolar scale preparations. SbF_5 and CO in excess.

2.2.2.1. Solvolysis and Carbonylation

In the course of such a synthesis, the oxidation state of the metal in the starting compound remains unchanged. The synthesis of $[Hg(CO)_2][Sb_2F_{11}]_2$ serves as an example [Eq. (h)].[15]

$$Hg(SO_3F)_2 + 2CO + 8SbF_5 \longrightarrow [Hg(CO)_2][Sb_2F_{11}]_2 + 2Sb_2F_9(SO_3F) \quad (h)$$

The anion $[Sb_2F_{11}]^-$ forms in the course of the solvolysis. $Sb_2F_9(SO_3F)$, the most volatile of the known fluoride–fluorosulfates of antimony(v),[120] is easily separated. In the case of the starting material $Re(CO)_5Cl$, a volatile by-product has been formulated as SbF_4Cl. It corresponds approximately to a compound described by O. Ruff et al.[121] as $3SbF_5 \cdot SbCl_5$, the structure of which is unknown.[122]

2.2.2.2. Reductive Carbonylation

Reductive carbonylation is a simple, elegant process in which solvolysis is accompanied by reduction of the metal salt. In a single synthetic step CO functions as a reducing agent and ligand, while SbF_5 plays the dual role of reaction medium and source of the counterion $[Sb_2F_{11}]^-$. As the synthesis of $[Pt(CO)_4][Sb_2F_{11}]_2$ shows, all the by-products are volatile [Eq. (i)].[21] An interesting variant is the recently reported reductive carbonylation of IrF_6 [Eq. (j)],[13] in which octahedral

$$Pt(SO_3F)_4 + 5CO + 8SbF_5 \longrightarrow [Pt(CO)_4][Sb_2F_{11}]_2 + CO_2 + S_2O_5F_2 + 2Sb_2F_9(SO_3F) \quad (i)$$

$$2IrF_6 + 15CO + 12SbF_5 \longrightarrow 2[Ir(CO)_6][Sb_2F_{11}]_3 + 3COF_2 \quad (j)$$

coordination geometry at iridium is retained, fluoride is exchanged for CO, and the positive oxidation state of iridium changes from 6 to 3. The reductive carbonylation of $AuCl_3$ in SbF_5 leads to COF_2 as by-product, since the initially formed $COCl_2$ is fluorinated by the excess SbF_5.[123]

2.2.2.3. Oxidative Carbonylation

An example in this case is the synthesis of $[Fe(CO)_6][Sb_2F_{11}]_2$ by oxidation of $Fe(CO)_5$ with AsF_5 or Cl_2 [Eq. (k)].[12] The

$$Fe(CO)_5 + AsF_5 + 5SbF_5 + CO \longrightarrow [Fe(CO)_6][Sb_2F_{11}]_2 + AsF_3 \cdot SbF_5 \quad (k)$$

solid by-product $AsF_3 \cdot SbF_5$[124] is removed by repeated washing with SO_2. In the transformation of $Mn_2(CO)_{10}$ with SbF_5 and CO into $[Mn(CO)_6][Sb_2F_{11}]$, SbF_5 serves simultaneously as oxidizing agent and reaction medium.

2.2.3. Comments Regarding Reactions in Liquid SbF_5

As can be seen from Table 2, all the homoleptic metal carbonyl cations that form thermally stable $[Sb_2F_{11}]^-$ salts can be prepared by one of the three synthetic methods described. This also includes the binuclear cations $[Hg_2(CO)_2]^{2+}$[15] and *cyclo*-$[Pd_2(\mu\text{-}CO)_2]^{2+}$.[21] Limitations of the methods are encountered where reaction of the metal salt in SbF_5 proceeds in a different way, or where the resulting metal carbonyl cations are of limited thermal stability, which interferes with their isolation. An example of a different reaction pathway is the reductive carbonylation of FeX_3 (X = Cl, SO_3F), which leads to the known $Fe[SbF_6]_2$.[125a] This product belongs to a group of compounds of the type $M[SbF_6]_2$ (M = Cr, Mn, Fe, Co, Ni, Cu, Zn, Ag, Cd, Sn),[91, 125] all of which display layered structures. The M^{2+} cations occupy every second octahedral vacancy in the $Li[SbF_6]$-analogous structure. As would be expected, no salt in this category has so far been successfully carbonylated with CO in SbF_5.

Thermally unstable cations of the type $[Ag(CO)_n]^+$ ($n = 1$ or 2) are formed through the reductive carbonylation of $Ag(SO_3F)_2$.[126] Removal of excess SbF_5 under vacuum at room temperature produces solid $Ag[Sb_2F_{11}]$. Despite this limitation, a great many new homoleptic metal carbonyl cations were prepared in liquid SbF_5 within a short period of time as thermally stable salts with $[Sb_2F_{11}]^-$ counterions. The synthesis of multiply charged cations of the type $[M(CO)_n]^{m+}$ ($n = 2, 4, 6$; $m = 2, 3$) can be accomplished in a very simple manner. This is only rarely the case with the use of traditional methods.[3, 4] Among the singly charged cations in Group 11, only $[Au(CO)_2]^+$[16b] is sufficiently stable to be separated as an $[Sb_2F_{11}]^-$ salt from SbF_5.

2.2.4. Carbonylations in Brønsted Superacids

The two protic superacids HSO_3F[86] and anhydrous hydrogen fluoride[127] are very well suited to the preparation of metal carbonyl fluorosulfates and fluorides. A report has recently appeared concerning fluorine-containing organometallic compounds of the d-block elements.[128] Selected examples relevant to homoleptic carbonyl cations are discussed below.

2.2.4.1. Carbonylations in Fluorosulfuric Acid

Reactions leading to metal carbonyl fluorosulfates are summarized in Table 3. Most of the syntheses are reductive carbonylations, with the exception of the synthesis of $Ir(CO)_3(SO_3F)_3$,[19] which occurs by the addition of CO to $Ir(SO_3F)_3$[129] in HSO_3F. In contrast to the formation of $Ir(CO)_3(SO_3F)_3$, reductive carbonylations in HSO_3F occur rapidly, often within hours. The presentation in Table 3 is limited to fully characterized metal carbonyl fluorosulfates. There are indications of a mixture of isomeric species of the type

Table 3. Syntheses of metal carbonyl fluorosulfates.

[a] Synthetic methods: a: Carbonylation with retention of oxidation state; b: reductive carbonylation; c: metathesis. [b] Applicable to millimolar scale preparations, HSO_3F and CO in excess. [c] In CH_2Cl_2.

$M(CO)_4(SO_3F)_2$ (M = Ru, Os), but separation of these isomers has not yet proven possible. Isomer separation has succeeded, however, for $Ir(CO)_3(SO_3F)_3$ through recrystallization from HSO_3F. In this case the *mer* isomer is the preferred form, and only about 15% of *fac*-$Ir(CO)_3(SO_3F)_3$ is present in solution.[19] The compounds $M(CO)_2(SO_3F)_2$ (M = Pt, Pd)[18] arise through nucleophilic substitution starting from $[M(CO)_4]^{2+}$, and are present exclusively in the *cis* form.

2.2.4.2. *Syntheses in Anhydrous Hydrogen Fluoride*

The synthesis of mononuclear metal carbonyl fluorides of the type $M(CO)_nF_m$ (*m*, *n* = 2–4; M = Mo, Mn, Re, Ru, Os, Ir) is possible through fluorination of binary mono- or multinuclear metal carbonyls with MF_6, XeF_2, or F_2, either in HF or in fluorochlorocarbons such as 1,1,2-$C_2Cl_3F_3$.[128] Reaction of $Re_2(CO)_{10}$ with ReF_6 in HF[130] leads to a cationic carbonyl derivative $Re(CO)_5(\mu\text{-}F)ReF_5$ that has been characterized structurally.[131] Subsequent carbonylation in HF produces $[Re(CO)_6][ReF_6]$,[132] and the cation $[Re(CO)_6]^+$ permits comparisons with earlier vibrational spectroscopic studies.[43] An additional structurally characterized product from the reaction of $Re_2(CO)_{10}$ with ReF_6 in HF is $[Re(CO)_6][Re_2F_{11}]$.[45] The anion $[Re_2F_{11}]^-$ is very similar structurally to the $[Sb_2F_{11}]^-$ ion. $[Re(CO)_6]^+$ is the only octahedral homoleptic carbonyl cation whose structure is so far known. The molecular structure of *fac*-$Ir(CO)_3F_3$,[22] obtained from an analysis of EXAFS data, permits limited comparisons with *mer*-$Ir(CO)_3(SO_3F)_3$.[19] *Fac*-$Ir(CO)_3F_3$ is formed from $Ir_4(CO)_{12}$ by fluorination with XeF_2 in HF.[22] Finally, carbonylation of RuF_5 at 200 °C leads to a product with the composition $Ru(CO)_3F_2 \cdot RuF_5$,[133] which also arises from treatment of $Ru_3(CO)_{12}$ with XeF_2 in HF.

In both Brønsted superacids, HSO_3F and HF, the formation of covalently bonded metal carbonyl fluorosulfates and fluorides is to be expected. Only occasionally are homoleptic metal carbonyl cations like $[Re(CO)_6]^+_{solv}$[45,132] and $[Au(CO)_2]^+_{solv}$[16a] observed. In many cases, HF can be replaced for the preparation of metal carbonyl fluorides by the aprotic solvent 1,1,2-$C_2Cl_3F_3$, which displays sufficient resistance to powerful fluorinating reagents such as F_2 and XeF_2.

2.2.5. *Alternative Synthetic Methods*

Two alternative synthetic pathways have found limited application: metathesis reactions and CO addition to metal salts with weak coordinating anions. Metatheses with $AgSO_3F$ have been used for the preparation of $M(CO)_5SO_3F$ (M = Mn, Re).[134] Both compounds are included in Table 3. Tris(pyrazolyl)borate complexes of the type $[HB(3,5\text{-}(CF_3)_2Pz)_3]MCO$ (M = Cu, Ag, Au)[61–63] can be prepared by metathesis and subsequent CO addition with the appropriate metal complexes.[61,62] For metatheses of this sort there are numerous precedents,[3,4] but also certain limitations: Suitable precursors must be available, and separation of the solid products can be difficult. Advantage is often taken of solubility differences in coordinating solvents, and yields are generally low. Nevertheless, in the case of the above-mentioned investigations single crystals can be isolated, and three useful molecular structures have been determined.[61–63] The fundamental principle is reversible CO addition to coordinatively unsaturated metal salts with large, weakly coordinating anions.[135] This concept is based on the notion that the metal ions are present as strong Lewis acids that can also bind weak donor ligands. Relevant examples are $Cu[AsF_6]$,[136] which forms CO adducts of the type $[Cu(CO)_n][AsF_6]$ ($n = 1$,[58] 2, 3[59]), and $Ag[B(OTeF_5)_4]$, which accepts up to 3 molar equivalents of CO.[53–56] Either high CO pressure or low temperature is required to prevent a reversible loss of CO. Molecular structures are known for $Ag(CO)[B(OTeF_5)_4]$[53,56] and $[Ag(CO)_2][B(OTeF_5)_4]$.[54,56] Useful starting materials have so far been limited to Cu^I [58,59] and Ag^I [53–56] salts. For Cu^I and Ag^I the existence of multiple CO-containing compounds with very similar physical and spectroscopic properties[56,59] prevents a clean separation of the thermally unstable products. Synthesis of individual homogeneous compounds on a preparative scale can be assured only by temperature and pressure control during CO addition. In cases in which the preparation of homoleptic metal carbonyl cations in SbF_5 and their subsequent isolation as $[Sb_2F_{11}]^-$ salts fails, CO addition to coordinatively unsaturated salts with weak coordinating ligands is the method of choice. Reported structures[53,54,56] and the pyrazolylborate complexes of Cu, Ag, and Au[61–63] provide insight into the nature of the M–CO bond in these thermally unstable complexes.

2.2.6. *Syntheses of Cationic Metal Carbonyl Complexes: Comparisons and an Overview*

The principle underlying all the syntheses discussed here consists of creating metal ions that function as Lewis acids and are thus in a position to bind weak Lewis bases. In the case of Cu^I and Ag^I salts with weak coordinating anions,[53–56,58,59] the Lewis acid strength of the metallic centers is noticeably reduced by significant cation–anion contacts, and CO addition is reversible. Such contacts exist in any salt. Indeed, so-called noncoordinating anions[135,137] are known to be a myth. In salts with doubly and triply charged cations, lattice energies and secondary anion–cation contacts increase in strength, so reversible CO addition to MX_2 salts is possible only under matrix-isolation conditions.[138] In pyrazolylborate complexes[61–63] the Lewis acid strength of the metal ions is reduced through contact with N atoms of the ligands, whose basicity is in turn reduced by the electron-attracting CF_3 groups. Nevertheless, weak, overwhelmingly σ-bonded CO adducts can still be synthesized with these complexes.[61–63] The synthetic method (reversible CO addition at electrophilic M^I centers for M = Cu, Ag, Au[53,54,59,62,63]), solubility in aprotic solvents like 1,1,2-$C_2Cl_3F_3$,[56] CH_2Cl_2,[63] or THF[61,62], and low thermal stability of the products is more consistent with the behavior of molecular adducts than with that of salts containing metal carbonyl cations.

In contrast, reduction or solvolysis in superacid media can be used to achieve intermediate naked metal cations of the type M^{n+} ($n = 1-3$). These highly reactive cations are present in an acidic matrix and function as strong Lewis acids with respect to CO. The acceptor strength of M^{n+} increases with increasing *n*, and carbonyl cations with classical coordination geometries

(linear, square planar, octahedral; see Table 1) are formed as a function of the d-electron configuration. Thermally stable salts arise in liquid SbF_5 exclusively with the $[Sb_2F_{11}]^-$ anion. In the superacids HF[127] and HSO_3F[87] CO and the weakly nucleophilic autoprotolysis ions F^- and SO_3F^- compete, so in most cases metal carbonyl fluorides or fluorosulfates are formed. Oxidation of mono- and multinuclear metal carbonyls in superacids[12, 128] leads to coordinatively unsaturated metal carbonyl cations, which behave as Lewis acids relative to F^-[128] or CO[12] and lead either to metal carbonyl fluorides or, in the presence of CO, to homoleptic carbonyl cations like $[Fe(CO)_6]^{2+}$.[12]

Carbonylation reactions in superacid media have in the meantime found broad application (Tables 2 and 3). CO addition to metal complexes is only sensible to apply in the case of metals that form no thermally stable carbonyl cations.

The concept presented here—preparation of naked, uncoordinated metal ions in a superacidic matrix and their subsequent reaction with CO—is analogous to the formation of binary metal carbonyls through cocondensation of naked metal atoms with CO in an inert gas matrix,[6, 139, 140] or the reaction of metal vapors with CO in the gaseous phase at high temperature.[26, 27]

2.3. Physical and Chemical Properties of Cationic Metal Carbonyl Complexes

Most of the cationic metal carbonyl complexes have been synthesized and described within the past seven years. Although an impressive number of molecular structures has been elucidated, and the thermally stable species have been largely characterized by vibrational and ^{13}C NMR spectroscopy, little else is known apart from the development of alternative synthetic pathways. In a few cases characterization of the products has remained incomplete, as with two teflate complexes, formulated as $[M(CO)][OTeF_5]$ (M = Ag, Au),[56] for which ionic structures have been suggested and $\tilde{\nu}(CO)$ values below 2200 cm^{-1} have been observed. Equally questionable and unproven is an ionic formulation for $Au(CO)SO_3F$, suggested in the same paper on account of the known physical and spectroscopic characteristics.[16]

All the cationic metal carbonyl complexes discussed here are very sensitive to hydrolysis. Their reactivities and thermal stabilities vary within a wide range. The salts of such multiply charged cations as $[Ir(CO)_6][Sb_2F_{11}]_3$[13] and $[M(CO)_6][Sb_2F_{11}]_2$ (M = Ru, Os)[11] react with HSO_3F or HSO_3F–SbF_5 with release of CO, whereas $[Hg(CO)_2][Sb_2F_{11}]_2$ can be recrystallized only from magic acid. On the other hand, compounds in the series $[M(CO)_6][Sb_2F_{11}]_2$ (M = Fe, Ru, Os) possess extraordinarily high thermal stability,[11, 12] which suggests stabilization through high lattice energies. By contrast, CO adducts of the coinage metal salts are thermally unstable, but stable to aprotic solvents.[61–63] A remarkable exception is $[Au(CO)_2][Sb_2F_{11}]$[16b] with a decomposition point of 130 °C, compared with $[Ag(CO)_2][Sb_2F_{11}]$ that is not isolable, and $[Ag(CO)_2][B(OTeT_5)_4]$[54, 56] that under normal conditions releases CO. This is not entirely unexpected, because the stability constant of $[Au(CN)_2]^-$, isoelectronic with $[Au(CO)_2]^+$, is 15 orders of magnitude higher than that for $[Ag(CN)_2]^-$.[73] The capacity of gold to form strong covalent bonds in primarily linear complexes is well documented[141] and probably a consequence of relativistic effects,[142] which are especially pronounced for gold.[142a] Expansion of the coordination from 2 to 3 and 4 for Cu^I and Ag^I is most readily recognized in the case of the cyano complexes.[72, 73] The only such complex that exists for Au^I is $[Au(CN)_2]^-$, whereas for Ag^I and Cu^I not only $[M(CN)_2]^-$ but also complexes of the type $[M(CN)_3]^{2-}$ and $[M(CN)_4]^{3-}$ are known.

A limited number of chemical reactions has been reported in which so far only Au^I takes part. A ligand-exchange reaction [Eq. (l)] was discovered in the course of attempts at recrystallization and leads to an interesting molecular structure.[16b] Exchange of PF_3 for CO[143] [Eq. (m)] makes it clear that PF_3 is a better σ-donor than CO towards Au^I. The $[Au(PF_3)_2]^+$ cation, which can also be generated in situ [Eq. (n)], is the first thermally stable cation with PF_3 as ligand.[144]

$$[Au(CO)_2][Sb_2F_{11}] + 2CH_3CN \xrightarrow{CH_3CN} [Au(NCCH_3)_2][SbF_6] + 2CO + SbF_5 \quad (l)$$

$$[Au(CO)_2][Sb_2F_{11}](s) + 2PF_3(g) \longrightarrow [Au(PF_3)_2][Sb_2F_{11}](s) + 2CO(g) \quad (m)$$

$$Au(SO_3F)_3 + 3PF_3 \xrightarrow{HSO_3F} [Au(PF_3)_2]^+ + S_2O_5F_2 + POF_3 + SO_3F^- \quad (n)$$

These reactions illustrate the synthetic potential of homoleptic metal carbonyl cations. Finally, a kinetic study involving ^{13}C NMR spectroscopy of the CO exchange between $[Au(CO)]^+_{solv}$ and $[Au(CO)_2]^+_{solv}$ in HSO_3F and HSO_3F/SbF_5 led to the suggestion of a dissociative mechanism.[145]

Because CO complexes of Cu^I and Ag^I show low thermal stability, they are more reactive and serve as carbonylation catalysts in strong protic acid solution.[9b, 53, 56, 59]

In summary, it can be concluded that the synthetic routes as well as the chemical and physical properties of the two sets of compounds (that is, the salts of homoleptic metal carbonyl cations and CO adducts of Ag^I and Cu^I complexes) differ significantly. Because in both sets a series of molecular structures is now known, it has become possible to make comparisons in order to understand the origins of these differences better. Moreover, many vibrational spectroscopic studies of CO complexes[146–149] offer good opportunities for comparisons between the two groups of cationic complexes (see Section 2.5.1).

2.4. Molecular Structures of Cationic Metal Carbonyl Complexes

The discussion in this section is limited to two structural aspects: The internal bonding parameters of cationic metal carbonyl derivatives that reflect the nature of bonding between the metal and carbon monoxide, and external secondary contacts between differently charged ions, molecular species, or adjacent layers in the case of layered structures.

2.4.1. Internal Bonding Parameters

Structural data that are the subject of this section are presented in Table 4. The entries themselves can be divided into two

Table 4. Structural data for cationic metal carbonyl species and related carbonyl derivatives.

Compound	d(M-C) [pm]	$\bar{d}$(M-C) [pm][a]	d(C-O) [pm]	$\tilde{\nu}(CO)_{IR}$ [cm^{-1}][b]	d(M-X) [pm][c]	Ref.

[a] $\bar{d}$(M–C) = average M–C distance according to ref. [64]. [b] $\tilde{\nu}(CO)_{IR}$: frequency of the IR-active CO vibration or its numerical mean value. [c] d(M–X): average M–X distance. [d] Electron diffraction data. [e] $\tilde{\nu}(F_{1u})$ for $[Ir(CO)_6]^{3+}$. [f] EXAFS data; d(C–O) not precisely determined. [g] $\bar{d}$(M–C) data for M = Pt. [h] $\bar{d}$(M–C) for μ^2CO. [i] $\bar{d}$(M–C) data for M–CN complexes; ref. [64]. [j] L_F signifies $[HB(3,5(CF_3)_2Pz)]^-$ (Pz = pyrazolyl). [k] Ref. [74b]: $Hg(CN)_2$.

groups: 1) cationic metal carbonyl derivatives drawn from element Groups 7 through 12, and 2) octahedral metal carbonyl complexes $[M(CO)_6]^-$ (M = Nb, Ta)[70c] and $M(CO)_6$ (M = Mo, W)[150] from the 4d and 5d series. These structures constitute the basis for a correlation of the spectroscopic properties of octahedral metal carbonyls of the 5d transition metal series, as discussed in the next section.

Table 4 also contains, for comparative purposes, average covalent bond lengths d(M–C), d(CM–O), and d(MM–X). Because the C–O bond lengths show little variation at higher bond orders (between 2 and 3),[1] the more informative mean vibrational frequencies $\nu(CO)_{avg}$ expressed in wavenumbers have also been tabulated from IR data. Difficulties associated with the interpretation of CO bond lengths become more apparent through an examination of data from the Cambridge Data Collection.[64] For the 10022 CO bond lengths registered for metal carbonyl complexes in that source, the mean value is 114.3, whereas the lower quartile mean value (q_l) is 113.2 and the upper quartile value (q_u) is 115.6. This means that 50%, or 5011 sets of data, fall in a narrow range of 2.4 pm, and are in fact identical within experimental error. Additional uncertainties arise in comparisons among the data in Table 4, because different measurement temperatures have been utilized, and corrections for thermal motion have not been applied uniformly. A good example is the linear cation $[Hg(CO)_2]^{2+}$ [15b] The mean vibrational frequency $\nu(CO)_{avg}$ for this cation is 2279 cm^{-1}, the highest yet reported for a metal carbonyl cation. One would therefore expect a very short CO bond. X-ray diffraction data at 195 K lead to a CO bond length of 110.4(12) pm. After correction for thermal motion, however, this becomes 112.6 pm, virtually identical with the 112.81 pm CO bond distance for gaseous CO.[151] Also problematic are structure determinations of low precision. A very short CO bond length of 107 pm is listed in Table 4 for $[Ag(CO)_2][B(OTeF_5)_4]$.[54, 56] However, the standard deviation of ± 5 makes a more detailed discussion meaningless. The data in Table 4 do support the conclusion that CO bond lengths for cationic metal carbonyl derivatives lie at the lower end of the scale, frequently below q_l,[64] whereas the ν(CO) data are comparable to or somewhat higher than the value for free CO itself (2143 cm^{-1}[149]).

If one assumes reduced π-backbonding as the cause of the short, strong CO bonds, this should be reflected in an increase in the metal–carbon bond length. It is difficult to find a solid basis for a sensible evaluation of M–C distances in Table 4, since eleven different metals are involved, and the oxidation states range from -1 to $+3$. Both metallic radii[152] and Shannon radii[153, 154] are of little help, because the latter are to some extent tabulated for other oxidation states or coordination numbers than those appearing here. We base our considerations therefore on the median $\bar{d}$(M–C) values for carbonyl compounds of known structure.[64] Unfortunately, in 1989 (date of the most recent edition of the Cambridge Data Collection[64]) distances were still missing for terminal Pd^{II}–CO bonds. In such cases we use for comparison $\bar{d}(Pt^{II}\text{–}CO)$ values in view of the similar metallic radii of 134 pm for Pd and 135 pm for Pt[152] and Shannon radii of 78 pm for Pd^{2+} and 74 pm for Pt^{2+} in a square-planar configuration.[153, 154] For the metal carbonyl derivatives of the coinage metals (Cu, Ag, Au) as well as mercury there exist in most cases more recent structural data, although these have not yet been tabulated. Recourse is therefore taken to the bond lengths in M–CN complexes,[64] although due to the greater σ-donor capacity of CN^-[72, 73] these are shorter (e.g., for $[Hg(CO)_2]^{2+}$ 208.3(10) pm,[15b] and for the isoelectronic $Hg(CN)_2$ 201.5(3) pm[74b]).

Two comments of a technical nature seem appropriate. Most of the structural data in Table 4 were obtained from X-ray diffraction on single crystals. The structure of $Hg(CN)_2$ was derived from a neutron diffraction study,[74b] and the structures of $M(CO)_6$ (M = Mo, W) from electron diffraction.[150] The molecular structure of *fac*-$Ir(CO)_3F_3$[22b] was obtained by analysis of EXAFS data. In this particular case the method permitted no reliable conclusions to be drawn about the CO distance. Moreover, the known difficulties in position determination for light atoms adjacent to heavier atoms often leads to large standard deviations.

The M–C distances for the 19 metal carbonyl derivatives in Table 4 fall between 180 and 210 pm. With the anionic and neutral octahedral species $[M(CO)_6]^-$ (M = Nb, Ta)[70b] and $M(CO)_6$ (M = Mo, W), the M–C distances are rather large relative to the average values $\bar{d}$(M–C). Similarly, long M–C bonds are also found for carbonyls in positive oxidation states. This observation appears at first unexpected, since positive charges usually cause adjacent bonds to be strengthened and shortened. The effect is particularly clear with iridium(III)

derivatives,[13, 19, 22b] where the measured M–C bonds are about 10 to 15 pm longer than the tabulated average $\bar{d}$(M–C) based on 148 structures. Even the q_1 value of 189.8 pm[64] is significantly smaller. Less pronounced differences exist for the M–C bonds in *cis*-$Pd(CO)_2(SO_3F)_2$[18b] and $[Hg(CO)_2]^{2+}$.[15b]

In all cases the ν(CO) values lie between 2200 cm^{-1} and 2279 cm^{-1}, which is consistent with a strong σ-bond and very little π-backbonding between metal and C.

For complexes with a singly positively charged metallic center only small deviations are observed from the mean $\bar{d}$(M–C) values. The M–C bond lengths for Re or Ag are greater than the tabulated mean values, and the values for Cu and Au are somewhat smaller. In complexes with a common ligand, $[HB(3,5(CF_3)_2Pz_3]^-$,[61–63] d(M–C) and $\tilde{\nu}$(CO) conform to the sequence Ag > Au > Cu. In the latter case $\tilde{\nu}$(CO) is only slightly greater than 2143 cm^{-1} (free CO[149]), which indicates only weak σ-donor bonding and π-backbonding. Even for $[Pd_2(\mu\text{-}CO)_2](SO_3F)_2$,[17] with bidentate, symmetrical bridging CO groups, the CO bond length of 113.3(6) pm is noticeably smaller than the mean length of 117.1 pm or the q_u value of 115.9 pm for this bond type.[64] In this arrangement there also appears to be reduced π-backbonding. For this compound d(Pd–C) is somewhat smaller than the $\bar{d}$(M–C) of 200.4 pm and nearly identical to the q_u value of 197.9 pm.[64]

The data presented in Table 4 support the conclusion that, in cationic metal carbonyls, the (M–C) bond length increases and the (C–O) bond becomes stronger with increasing oxidation state, as is also easily seen from vibrational frequencies. The observed, significant covalent (M–X) distances in cationic metal carbonyl complexes make it clear that homoleptic carbonyl cations are present in Table 4 in only three structurally characterized salts: $[Re(CO)_6][Re_2F_{11}]$,[130b] $[Ag(CO)_2][B(OTeF_5)_4]$,[54, 56] and $[Hg(CO)_2][Sb_2F_{11}]_2$.[15b] An ionic structure has also been established for $[Ir(CO)_5Cl][Sb_2F_{11}]_2$.[13] $Ag(CO)[B(OTeF_5)_4]$, on the other hand, contains no discrete $[Ag(CO)]^+$ cation, and is better formulated as a covalent complex.[53] The two Ag···O bonds to the teflate group ($OTeF_5$) of 232.4(6) and 243.6(7) pm[53, 54] are comparable to the two Ag···O contacts of 235.7(5) to 244.8(5) pm in Ag^I–succinimide complexes[155] as well as to the average value of 257.5 pm for Ag^I–ether complexes.[64] The coordination number of three for silver in $Ag(CO)[B(OTeF_5)_4]$ is normal,[156] as for example in $[Ag(CN)_3]^{2-}$.[72, 73] Convincing proof for the existence of the isolated cations $[Ag(CO)]^+$ and $[Au(CO)]^+$ is thus lacking.

Molecular structures for the two metal carbonyl fluorosulfates *cis*- $Pd(CO)_2(SO_3F)_2$[18b] and *mer*-$Ir(CO)_3(SO_3F)_3$[19] are reproduced in Figures 2 and 3. The noteworthy differences in stereochemistry are a consequence of the syntheses. *cis*-$Pd(CO)_2(SO_3F)_2$ arises through nucleophilic substitution of CO by SO_3F^- in the initially formed $[Pd(CO)_4]^{2+}$ [18] in HSO_3F solution. By contrast, *mer*-$Ir(CO)_3(SO_3F)_3$ is formed together with about 15% of the *fac* isomer by slow CO addition to $Ir(SO_3F)_3$[129] in HSO_3F. Both geometries are thus attributable to the *trans*-directing effects of the CO ligands.[157]

As can be seen from the two figures and the tables in publications [18b] and [19], the majority of the structural parameters, bond lengths, and bond angles for the two compounds are nearly identical. There are differences, however. Whereas the metal–oxygen bond lengths of about 200 pm in both compounds are similar, the metal–CO bond lengths differ in an interesting way. The Ir–C distance of 193.7(7) pm when the CO group is *trans* to SO_3F is very similar to the Pd–C distances of 194.5(5) and 191.9(5) pm. The Ir–C distances of 199.9(6) and 200.6(6) pm for a linear $Ir(CO)_2$ group are significantly larger. This points to less metal-to-CO π-backbonding in such groups. The FSO_2O ligands appear rather to function as weak π-electron donors. One should therefore expect a difference in the CO bond lengths: smaller CO distances are anticipated in the linear $Ir(CO)_2$ group. However, this is not the case. All five CO bond lengths are identical within experimental error. Moreover, the mean vibrational frequencies $\tilde{\nu}(CO)_{avg}$ of 2218 cm^{-1} for the two compounds are also identical.[18, 19] For this reason, other effects must influence the electron density in the π* orbitals of the CO ligands. These effects will be discussed in the following section.

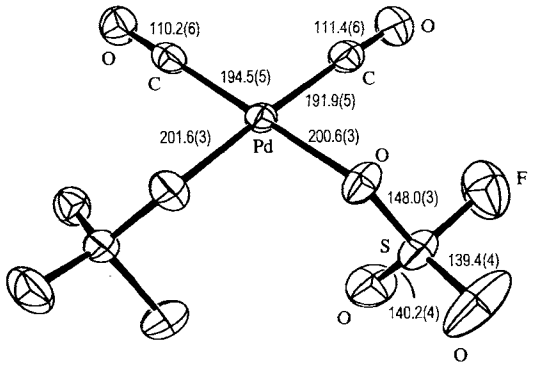

Figure 2. The molecular structure of *cis*-$Pd(CO)_2(SO_3F)_2$[18].

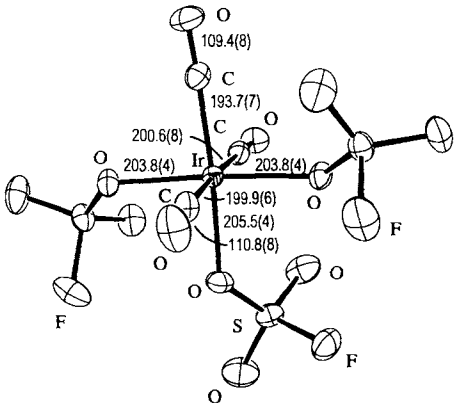

Figure 3. The molecular structure of *mer*-$Ir(CO)_3(SO_3F)_3$[19].

2.4.2. *External Bonding Parameters*

As was first established during the structure determination of *cis*-$Pd(CO)_2(SO_3F)_2$,[18b] weak but significant secondary contacts exist especially between the C atoms of the CO groups and noncoordinated terminal O atoms of FSO_2O groups, which lead apparently to small changes in the π*-electron density of the CO group. Based on a suggestion of Alcock,[67] secondary bonds can be recognized by distances that are larger than the sum of the covalent radii,[65, 152] but significantly smaller than the sum

of the van der Waal's radii.[68] In the case of the C···O and C···F contacts under consideration here, the sums of the covalent radii are 143.1 and 141.1 pm,[152] and those of the van der Waal's radii are 322 and 317 pm, respectively.[68] The observed C···O and C···F contacts fall in the approximate range of 260 to 300 pm (Table 5). In the above structures, the C atom of the carbonyl group functions as an acceptor and the O atom of the fluorosulfate group as a donor for secondary interactions. There are five such contacts per C atom for *cis*-$Pd(CO)_2(SO_3F)_2$,[18b] and an average of about four for *mer*-$Ir(CO)_3(SO_3F)_3$.[19] Details regarding the number and extent of secondary contacts can be extracted from Table 5.

Table 5. Secondary interactions in cationic metal carbonyl derivatives.

Geometry, Compound [c]	Secondary interactions			Ref.

[a] –O group *trans* to SO_3F. [b] C–O group *trans* to Cl. [c] d_w = sum of the van der Waals radii.

Only very weak interactions to the central metal atom are observed, as in the case of *cis*-$Pd(CO)_2(SO_3F)_2$ with a 300.7 pm Pd···O contact, which in view of the sum of van der Waals radii of 322 pm[68] must be regarded as weak. A weak CO···OS interaction of 286.1 pm in *cis*-$Pd(CO)_2(SO_3F)_2$ makes the distinct preference for C as acceptor quite obvious. With *mer*-$Ir(CO)_3(SO_3F)_3$[19] there are no contacts with Ir, since the central metal atom is less accessible than in square-planar *cis*-$Pd(CO)_2(SO_3F)_2$.

Secondary contacts also exist for the complexes of Group 11, as, for example, in $Ag(CO)[B(OTeF_5)_4]$,[53, 56] $[Ag(CO)_2][B(OTeF_5)_4]$,[54, 56] and even in the parent $Ag[B(OTeF_5)_4]$.[158] In the case of the two $[Sb_2F_{11}]^-$ salts of $[Hg(CO)_2]^{2+}$ [15b] and $[Ir(CO)_5Cl]^{2+}$ [13] several significant contacts are listed in Table 5. Here the interactions are largely interionic, and fluorine from the $[Sb_2F_{11}]^-$ anion functions as donor atom.

A further indication of interionic interactions exists for $[Sb_2F_{11}]^-$ salts as well. As in $[H_3O][Sb_2F_{11}]$,[106] the anion deviates from ideal D_{4h} symmetry. This is especially clear from the Sb-F_b-Sb angle, which is between 145.9(2) and 149.4(3)° in $[H_3O][Sb_2F_{11}]$[106] and 147.6(3)° in $[Hg(CO)_2][Sb_2F_{11}]_2$.[15b] In $[Ir(CO)_5Cl][Sb_2F_{11}]$[13] the deviation from linearity is less severe, and two Sb-F_b-Sb angles of 153.2(6) and 156.5(6)° are found.

On the other hand, in the structure of $[Re(CO)_6][Re_2F_{11}]$ there are no observable interionic contacts.[130b] Consequently, the $[Re_2F_{11}]^-$ anion displays D_{4h} symmetry. In $Re(CO)_5$-μ-F–ReF_5[130c] the shortest interionic C···F distance of 317.0 pm is almost identical with the sum of the van der Waals radii. Thus, in both rhenium carbonyl compounds the C atom is either less electrophilic or less accessible for secondary contacts.

In *fac*-$Ir(CO)_3F_3$,[22] two long Ir···F contacts of 339.0(7) and 356.0(8) pm have been described on the basis of EXAFS analyses.[22b] However, it is unclear whether these fluorine atoms also form intermolecular contacts to carbon. In Au(CO)Cl[33] the linear molecules are arranged antiparallel in the crystal lattice, which results in C···Cl contacts of 335 pm, slightly less than the sum of the van der Waals radii (345 pm).[68]

The contacts presented in Table 5 can be divided into four groups: 1) In molecular carbonyl derivatives one finds inter- and intramolecular interactions. 2) Mostly interionic contacts are observed for ionic derivatives. 3) Very rarely, contacts are observed between layers, as in $[Hg(CO)_2][Sb_2F_{11}]_2$.[15b] 4) Equally seldom are there C···F contacts in fluorosulfates, since in SO_3F the oxygen atom is more basic than the fluorine atom.

This observation is in good agreement with the coordination behavior of the FSO_2O group in metal fluorosulfates, in which coupling occurs over one, two, or three O atoms of the FSO_2O group, whereas coordination with the F atom is extremely rare.[159]

In most of the examples in Table 5, C atoms of the CO groups are the preferred acceptors for secondary contacts, because in cationic metal carbonyls, in which π-backbonding is significantly reduced, the carbon atom is exceptionally electrophilic. An ab initio study on carbonyl cations and isoelectronic cyano anions of the type $[M(CX)_n]^{+/-}$ (M = Ag, Au; X = O, N; n = 1–3), taking relativistic nuclear potentials into account,[160] has shown that the positive ionic charge of the cation distributes itself over the metal atoms and the carbon atoms, whereas the O atoms are negatively charged. Adjacent partial positive charges on M and C make the rather large M–C bond distances understandable, especially with metal formal charges of +2 and +3 (see Table 4). This charge distribution also explains why, apart from C, the metal center can also function as an acceptor for secondary contacts. Both centers are quite accessible in the case of linear cations. The structure of $[Hg(CO)_2][Sb_2F_{11}]_2$ offers an illustration.[15b] In a linear cation [the Hg–C–O angle is 177.7(7)°], mercury and the two C atoms all have four

interionic contacts with F atoms from the bent $[Sb_2F_{11}]^-$ anion. For the C atom there is also a supplementary C···F contact between layers. All the interionic contacts are of similar strength. Details of the very regular spatial arrangement of the fluorine atoms around Hg and C are illustrated in Figure 4.

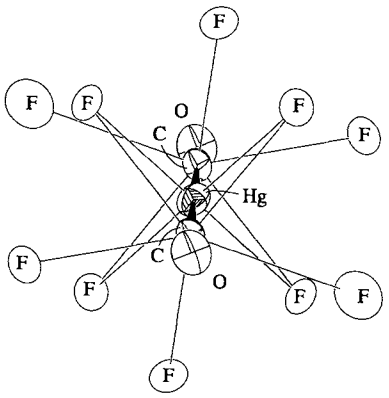

Figure 4. Excerpt from the crystal structure of $[Hg(CO)_2][Sb_2F_{11}]$[15b], in which nearest interionic contacts to the $[Hg(CO)_2]^{2+}$ cation are depicted.

Whereas the environment of Hg is distorted octahedral, the C atoms display a coordination number of 7. The resulting geometry can be approximately described as a compressed pentagonal bipyramid, with Hg and O in axial positions. All interionic contacts in $[Hg(CO)_2][Sb_2F_{11}]_2$ participate in the formation of a three-dimensional network, which includes the carbonyl groups.[15b] They further contribute significantly to the stability of the metal carbonyl cation in the solid state. Interestingly, there are similar intermolecular contacts in the isoelectronic $Hg(CN)_2$,[74b, 161] as well as in $HgCl_2$,[162] in which mercury is coordinated to N or Cl.

In contrast to $[Hg(CO)_2][Sb_2F_{11}]_2$, the structures of $[Ag(CO)_2][B(OTeF_5)_4]$[54, 56] and $Ag(CO)[B(OTeF_5)_4]$[53, 56] display interionic contacts exclusively between Ag and the O or F atoms of the anions. These Ag···O or Ag···F contacts are comparable in strength with those in the starting compound $Ag[B(OTeF_5)_4]$,[158] where they are somewhat more numerous (six Ag···F and three Ag···O contacts) than in $Ag(CO)[B(OTeF_5)_4]$[54] (four Ag···F and two covalent Ag–O distances) or $[Ag(CO)_2][B(OTeF_5)_4]$[56] (three, four, or seven Ag···F distances are found for the three $[Ag(CO)_2]$ groups). Secondary interionic contacts to the carbons of the CO groups are absent in the silver(I) carbonyl derivatives,[163] as seen in Table 5. Consequently, in the silver(I) carbonyl compounds the CO ligands do not participate in the formation of three-dimensional networks. The observed ready loss of CO thus leads to an increase in lattice energy with the formation of $Ag[B(OTeF_5)_4]$[158] or also $Ag(OTeF_5)$ and $B(OTeF_5)_3$.[56] The preferred coordination to Ag^I is explained by the fact that the positive charge of the cationic Ag(CO) complex seems to be localized primarily on Ag^I, consistent with the calculations of Veldkamp and Frenking.[160] For example, charge distributions for the linear cations $[M(CO)_2]^+$ (M = Ag, Au) have been calculated to be $Ag^{+0.82}-C^{+0.54}$ and $Au^{+0.61}-C^{+0.60}$.

As soon as the coordination number rises from 2 to 4 and 6 and the geometry is altered from linear to square planar and then octahedral, secondary contacts to the metal atom virtually disappear, whereas the carbon atom establishes an increased number of contacts. Moreover, and this is especially apparent in the molecular structure of $[Ir(CO)_5Cl][Sb_2F_{11}]_2$,[15] there is also a limited number of O···F and interanionic F···F contacts. Interionic O···F contacts up to 282 pm are significantly less than the 299 pm sum of van der Waals radii.[68] These and also the Cl···F interactions, with distances between 322 and 356 pm relative to a sum of van der Waals radii of 322 pm, are probably repulsive in nature, caused by C···F interactions. In octahedral carbonyl complexes, C···F contacts are imposed and possible only with simultaneous formation of O···F contacts. However, it is also possible that the positive partial charges in the highly charged cations (+2 or +3) distribute themselves additionally over oxygen, which should lead to weak, bonding O···F contacts.

The many weak secondary contacts exert a stabilizing effect on these molecular structures. The formation of extended three-dimensional networks is best demonstrated in $[H_3O][Sb_2F_{11}]$.[106] By contrast, $[H_3O][SbF_6]$[164] reveals an "ionic" cubic structure. These examples point to a unique role that the dioctahedral $[Sb_2F_{11}]^-$ ion plays. The absence of secondary F···C or O···C contacts in Ag^I-carbonyl complexes[53–56] is surely only one reason for their observed thermal instability. Significant also is both the Ag–C bond energy, which is actually low relative to that of Au–C,[160] and the relatively low lattice energies for salts with large, singly charged ions.[165]

In two areas the secondary contacts described here permit important conclusions to be drawn:

1) The preference for C in the CO group as acceptor for contacts shows clearly that in cationic metal carbonyls the CO group is polarized in the sense $C^{\delta+}-O^{\delta-}$. This polarization was recently confirmed through ab initio calculations as well, which provided an explanation for the high CO stretching frequencies and force constants.[166]

2) Both experiment[9b, 15b, 19] and theoretical calculations[80] suggest a low electron density in the $2\pi^*$ orbitals of CO in all carbonyl cations. For $[Hg(CO)_2][Sb_2F_{11}]_2$[15b] or $[Ir(CO)_5Cl][Sb_2F_{11}]_3$,[13] where secondary contacts are present, it is unclear whether the residual electron density originates with the metal (through π-backbonding) or with the anion (through secondary contacts).

Secondary interionic contacts are also observed with carbonyl metalates. In this case they are referred to as ion-pair effects[167] and involve the oxygen of the carbonyl group as donor and the cation as acceptor. In weakly ionizing solvents this leads to the formation of ion pairs.

2.5. Spectroscopic Properties and Bonding Relationships of Cationic Metal Carbonyl Complexes

The existing structural data, based mainly on X-ray diffraction, are of limited use for developing an intensive discussion of the bonding relationships in homoleptic metal carbonyl cations, since they are imprecise and so far available only for a small number of relevant compounds. Spectroscopic data are therefore especially important and highly informative for this class of compounds.

Table 6. Spectroscopic properties of homoleptic metal carbonyl cations, metal carbonyl fluorosulfates, and related species.

Compound [a]	$\tilde{\nu}(CO)_{IR}$ [cm^{-1}]	$\tilde{\nu}(CO)_{Raman}$ [cm^{-1}]	f_{CO} [10^2 N m^{-1}]	δ_C	$^1J_{MC}$ [Hz]	Ref.

Vibrational spectroscopic data not only permit statements regarding the symmetry of the metal carbonyl fragments, but also allow calculations of CO bond strengths. ^{13}C NMR shifts and $^1J_{M,C}$ coupling constants are helpful for characterizing the M–CO bonds. The many sets of published vibrational[146–149] and ^{13}C NMR data[168] permit a comprehensive comparison with corresponding data for cationic metal carbonyl derivatives (Table 6).

2.5.1. *Vibrational Spectra*

Three elementary conditions should apply to the assignment and interpretation of vibrational data:

1) The composition and identity of the metal carbonyl complexes should be unambiguous, and the spectroscopic data must be reproducible.
2) Because of the high symmetry of the cations (O_h, D_{4h}, $D_{\infty h}$), both IR and Raman data must be available.
3) Vibrational analyses should, where possible, extend over the entire fundamental vibration region, and isotopic data should be included for the computation of reliable force constants.

The data presented in Table 6 generally fulfill the above criteria, and the resulting CO force constants permit comparisons with other carbonyl and isoelectronic cyanide species. All f_{CO} values have been calculated according to the method of Cotton and Kraihanzel (CK).[169] The fundamental assumption of isolated CO stretching is completely valid for homoleptic metal carbonyl cations whose $\tilde{\nu}(CO)_{avg}$ values fall between 2200 and 2300 cm^{-1}, whereas the remaining fundamental vibrations of the cations lie below 600 cm^{-1}. Moreover, a normal-coordinate analysis for $[Au(CO)_2]^+$ utilizing ^{13}C and ^{18}O isotopic data, together with the G and F matrix elements of the general valence force field proposed by Jones,[75] shows that calculated CO force constants obtained in this way do not differ significantly from those determined according to the CK method.[169]

To keep the discussion within bounds, we consider below in detail only the homoleptic metal carbonyl cations. Almost all the metal carbonyl fluorosulfates have been structurally characterized. They show fundamentally lower CO force constants than the corresponding homoleptic carbonyl cations, and these vary only slightly within the group: 19.3 for *fac*-$Ir(CO)_3(SO_3F)_3$,[19] 19.5 for $Au(CO)SO_3F$,[16a] 19.6 for *cis*-$Pt(CO)_2(SO_3F)_2$,[18a] 19.9 for *cis*-$Pd(CO)_2(SO_3F)_2$,[18a] and 20.0/19.5 $\times 10^2$ N m^{-1} for *mer*-$IR(CO)_3(SO_3F)_3$.[19] The two geometric isomers of $Ir(CO)_3(SO_3F)_3$ make it clear that a CO bond *trans* to an SO_3F group is weakened.

The isoelectronic pairs CO/CN^-, CO^+/CN, and HCO^+/HCN shown in Table 7 provide a basis for our discussion. For most of these, very precise bond lengths are available from analyses of microwave[51b, 170, 171] and electronic spectra,[151, 172] and data also exist for the latter for ν(CO) and ν(NO). In the linear species HCO^+ and HCN, ν(CX) is strongly coupled with ν(CH), which means CX force constants can be calculated only with the aid of a normal-coordinate analysis

Table 7. Bond lengths d(C–X) (X = O, N), stretching vibrational frequencies $\tilde{\nu}$(CX), and force constants f_{CX} for selected CO and CN species.

Compound	d(C-X) [pm]	$\tilde{\nu}$(CX) [cm^{-1}]	f_{CX} [10^2 N m^{-1}]	d(C-X)	Ref. $\tilde{\nu}$(CX)	f_{CX}
CO	112.8	2143	18.6	[151]	[149]	[16b]

[a] See text. [b] This paper.

based on the general valence force model.[75] In contrast to CO, the choice of the available data is problematic in the case of the cyanide ion. Examination of many X-ray structures has led to an approximate bond length of 110 ± 4 pm.[173] The origin of the extreme inaccuracy associated with ionic cyanides is to be found in the corrections for thermal motion and in problems due to disorder. Moreover, the corresponding CN bond lengths in cyano complexes are insensitive to electronic influences. This is reflected in a mean CN distance of 114.6 pm, derived from 168 structures of CN complexes, for which 50% of the data lie between 113.8 and 115.4 pm.[64] Of course, the vibrational frequency $\tilde{\nu}(CN^-)$ for the cyanide ion is also influenced by the environment. We have selected a value of 2038 cm^{-1} for the "free ion", established in a detailed study by Field and Sherman,[174] and from that we have calculated f_{CN}. Slightly larger values for f_{CN} (up to 16.5×10^2 $N m^{-1}$) have been reported elsewhere.[75, 175]

If one ignores the imprecision in the bond length for the cyanide ion, all CO bond lengths in Table 8 appear to be about 5 pm shorter than those of the corresponding CN species. This may be due in part to differences in the atomic radii of O and N.

Table 8. Comparison of bonding force constants for isoelectronic pairs of metal carbonyl cations and cyano complexes.

[a] This paper; calculated according to the CK method, ref. [169]; vibrational data from the cited literature.

The sums of the covalent radii for single, double, and triple bonds[152] are all about 4–5 pm shorter for C–O than for C–N. A relatively large difference of $2.8-3.4 \times 10^2$ $N m^{-1}$ can be established between force constants for the carbonyl and cyanide species.

Figure 5 depicts a correlation between f_{CO} and bond lengths for gaseous CO derivatives, for which precise bond lengths and force constants are known.[176, 177] The exponential function used to describe the correlation is suitable for estimating CO bond strengths or lengths in carbonyl complexes, as is demonstrated, for example, with $[Au(CO)_2]^+$.[16b] The introduction of average CO bond lengths and the previously mentioned q_l and q_u values[64] for metal carbonyl compounds in Figure 5 permits a further conclusion. Exactly 50% of all the CO bond lengths in the Cambridge Index fall within a narrow range of 2.4 pm, and are virtually identical within the usual limits of error.

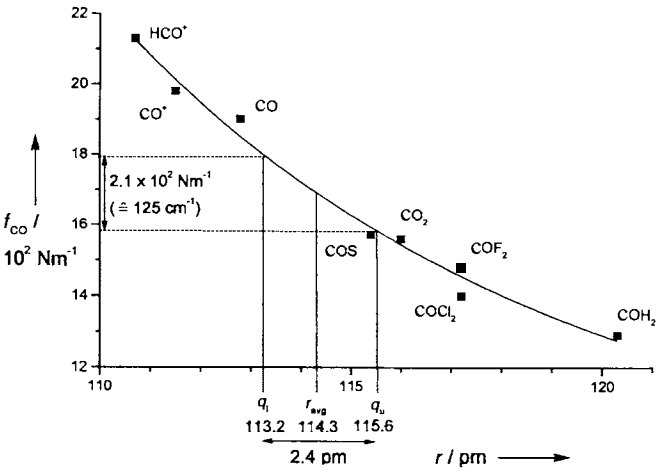

Figure 5. CO force constants as a function of CO bond lengths [$\bar{r}_{avg}$ = average CO bond length, established on the basis of 10022 sets of data (Cambridge Index)]. References for f(CO)/r(CO): HCO^+ [50c]/[51b], CO^+ ($X^2\Sigma^+$) and CO[151]/[151], COS[176a]/[176b], CO_2[176a]/[176c], COF_2[177a]/[176b], $COCl_2$[177b]/[176b], COH_2[177c]/[176c]

The extrapolated vibrational spectroscopic data extend over 2.1×10^2 $N m^{-1}$ (f_{CO}), or approximately 125 cm^{-1} (ν_{CO}), which permits a much more exact differentiation.

The usefulness of valence force constants becomes clear in Table 8 when comparing homoleptic metal carbonyl cations with the corresponding isoelectronic and isostructural cyano complexes. For both groups of compounds the force constants f_{CO} and f_{CN} are larger than those of the free ligands CO and CN^- (see Table 7). This means that in both cases the ligand-to-metal σ-bond is dominant, whereas π-backbonding in the examples presented is weak. For the protonated ligands HCO^+ and HCN, force constants of 21.3×10^2 and 18.3×10^2 $N m^{-1}$, respectively, represent limiting values for both series. The ligands are exclusively σ-bonded to H^+, since π-backbonding is impossible. Among the metal complexes cited, $[Hg(CO)_2]^{2+}$ and $Hg(CN)_2$ come closest to being *purely* σ-bonded, since the corresponding force constants of 21.0 and 18.1×10^2 $N m^{-1}$ are nearly identical to those of HCO^+ and HCN within the limits of error. The slightly smaller force constant in $[Hg(CO)_2][Sb_2F_{11}]$ relative to that of HCO^+ might be attributed to significant interionic F···C contacts (see Table 5 and Figure 4), which increase the electron density in the π* orbitals of CO and thus weaken the CO bond.

If the coordination number increases from 2 through 4 to 6 in CO and CN^- complexes, with the metal atom in the +2 oxidation state, the bond strength for CX (X = O, N) gradually decreases in both series. The decrease in f_{CX} is more pronounced for cyanometalates than for carbonyl cations.

The observed trend is a good illustration of the synergistic nature of the bonds between the metal ion and CO or CN^-. With an increasing number of ligands, the negative charge on the central atom is raised as a result of the σ-bond, and consequently π-backbonding increases. This is more prominent with CN^- than with CO, because cyanide is a better σ-donor.[1, 72, 73] In effect, bonds of the type CX (X = O, N) are weakened by increasing M-to-C π-backbonding. A second example of the synergistic nature of the metal–ligand bond in CO and CN^- complexes is found in the three pairs of isosteric complexes in

the 5d series: linear $[Au(CX)_2]^{\pm 1}$, square-planar $[Pt(CX)_4]^{\pm 2}$, and octahedral $[Ir(CX)_6]^{\pm 3}$ (X = O, N). In this series, the oxidation state of the metal increases at each step by 1, and the coordination number by 2. The values for f_{CN} decrease and those for f_{CO} increase with increasing coordination number. It appears that, for carbonyl cations, π-backbonding decreases with increasing oxidation state, whereas in the isoelectronic cyano ions it increases. Within the series of isostructural metal carbonyls and cyanometalates[178,179] in Groups 10 (Pd, Pt) and 8 (Fe, Ru, Os), all the force constants are nearly identical. This is no longer the case in Group 11, in which CX bonds in the silver complexes are clearly weaker than in the gold complexes. The f_{CO} value of 19.7×10^2 N m^{-1} for $[Ag(CO)_2]^+$ is the lowest for all the metal carbonyl cations in Table 8. Since no secondary contacts between the anions and the C atom are observed,[162] a smaller polarization of CO could be responsible for the weak CO bond in $[Ag(CO)_2]^+$.

Indications of the significance of polar components to the strength of the CN bond stem from two cationic derivatives of $Hg(CN)_2$.[180] Solvolysis of $Hg(CN)_2$ in anhydrous HF in the presence of AsF_5 or BF_3 leads to solids described as $[Hg(CN)][AsF_6]$ or $[Hg(CN)][BF_4]$ with IR bands at 2290 and 2270 cm^{-1}, respectively. This means that in the first compound the CN force constant is 19.9×10^2 N m^{-1}. As far as we know, this is the highest reported value for an isolable CN compound. In the cation $[Hg(CN)]^+$ the positive ionic charge is distributed between Hg and C, leading to a charge distribution $C^{\delta+}-N^{\delta-}$ for the ligand. Interestingly, the isoelectronic cation $[Hg(CO)]^{2+}$ remains unknown.

An additional informative correlation relates exclusively to metal hexacarbonyl complexes. Vibrational spectra in the CO stretching region for $W(CO)_6$,[75,149,168,181] $[Re(CO)_6]^+$,[44,130,132] $[Os(CO)_6]^{2+}$,[11-13] and $[Ir(CO)_6]^{3+}$[13] are reproduced in Figure 6. All three fundamental vibrations are shifted to higher frequency with increasing oxidation state of the metal. Moreover, the separation between the two Raman-active bands $\nu_1(A_{1g})$ and $\nu_3(E_g)$ becomes progressively smaller from 105 cm^{-1} for $W(CO)_6$ to 19 cm^{-1} for $[Ir(CO)_6]^{3+}$. The intensity of the totally symmetric A_{1g} band increases steadily relative to that of the E_g band. The origin of this trend is to be found in decreasing electronic vibrational coupling of the CO ligands in $W(CO)_6$ through $[Ir(CO)_6]^{3+}$.

The series of isoelectronic metal hexacarbonyl complexes is completed by the anions $[Ta(CO)_6]^-$[70c,149] and $[Hf(CO)_6]^{2-}$.[7,71b] Figure 7 shows two relationships between the force constants f_{CO} or ^{13}C chemical shifts (to be discussed in Section 3.5.2) and the nuclear charge number or oxidation state of the metal centers. Since Raman spectra for the two carbonyl metalates $[Hf(CO)_6]^{2-}$ and $[Ta(CO)_6]^-$ have apparently not been reported, the appropriate force constants were estimated to be 12.8×10^2 and 14.2×10^2 N m^{-1}, respectively, based on an extrapolation from the linear relationship between $\tilde{\nu}^2(F_{1u})$ and the f_{CO} values for the remaining four $[M(CO)_6]$ species. As can be seen in Figure 7, CO bond strength increases steadily with increasing oxidation state of the metallic center. The overall change in f_{CO} within the series amounts to 8×10^2 N m^{-1}. Since the increase in f_{CO} is only 1×10^2 N m^{-1} between $[Os(CO)_6]^{2+}$ and $[Ir(CO)_6]^{3+}$, the otherwise linear relationship becomes curved. Force constants for the osmium(II) and iridium(III) car-

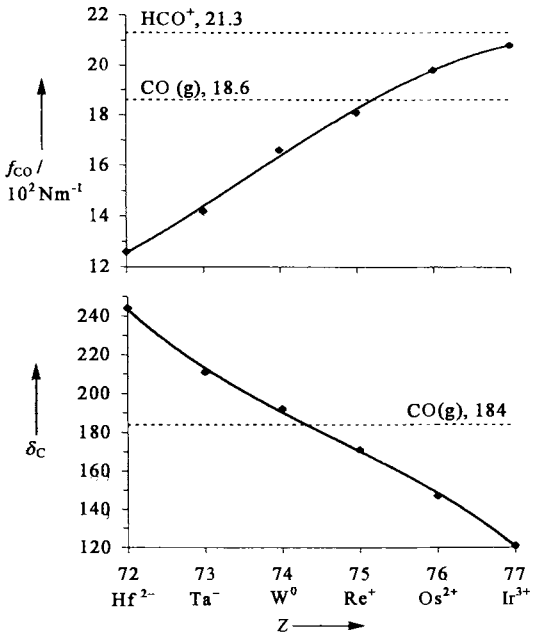

Figure 7. Relationship between CO force constants and ^{13}C NMR chemical shifts for the isosteric octahedral hexacarbonyl species $[M(CO)_6]^n$ ($n = -2$ to $+3$; M = Hf, Ta, W, Re, Os, Ir) with nuclear charges Z. The data for CO and HCO^+ define boundaries for the relevant bonding types (see text).

bonyls fall in a region defined by the f_{CO} values for CO ($f_{CO} = 18.6 \times 10^2\ N\,m^{-1}$) and HCO^+ ($f_{CO} = 21.3 \times 10^2\ N\,m^{-1}$) as upper and lower limits. The f_{CO} values for the remaining metal hexacarbonyl complexes lie outside this region. Similar relationships can also be established for other hexacarbonyls of the 4d and 3d metals, as shown in Table 9. With the exception of $[Tc(CO)_6]^+$, all the IR-active F_{1u} fundamental vibrations have been listed. Table 9 also contains ^{13}C NMR chemical shifts,

Table 9. Spectroscopic data for hexacarbonyl compounds derived from transition metals in Groups 4 through 9.

$\tilde{\nu}$ [cm^{-1}]	Group					
δ_C	4	5	6	7	8	9
	$[Ti(CO)_6]^{2-}$	$[V(CO)_6]^-$	$Cr(CO)_6$	$[Mn(CO)_6]^+$	$[Fe(CO)_6]^{2+}$	
F_{1u}	1748	1859	2000	2100	2203	
δ_C	246	224	212	195	179	
	$[Zr(CO)_6]^{2-}$	$[Nb(CO)_6]^-$	$Mo(CO)_6$	$[Tc(CO)_6]^+$	$[Ru(CO)_6]^{2+}$	
F_{1u}	1757	1860	2004	–	2198	
δ_C	245	217	204	–	166	
	$[Hf(CO)_6]^{2-}$	$[Ta(CO)_6]^-$	$W(CO)_6$	$[Re(CO)_6]^+$	$[Os(CO)_6]^{2+}$	$[Ir(CO)_6]^{3+}$
F_{1u}	1757	1850	1998	2084	2190	2254
δ_C	244	211	192	171	147	121

which will be discussed in Section 2.5.2. The 500 cm^{-1} range covered by $\tilde{\nu}$(CO) is much larger than usual for terminally bonded CO (1850 to 2125 cm^{-1}).[1, 75, 146–149] F_{1u} values for $[M(CO)_6]^{2+}$ (M = Fe, Ru, Os) and for $[Ir(CO)_6]^{3+}$ lie significantly above the limit of 2143 cm^{-1} for free CO.[149]

Comparatively high wavenumbers for the F_{1u} vibration have also recently been observed for $[Fe(CO)_6]^{3+}$ (2256 cm^{-1})[12] and $[Os(CO_6)]^{3+}$ (2252 cm^{-1}) and are currently being further investigated[181a] and subjected to theoretical calculation.[181b] As in the case of the f_{CO} and f_{CN} values for Groups 8 and 10 (see Table 8), all F_{1u} wave-number values within a group are independent (< 10 cm^{-1}) of the metal in question. In the case of all 15 species in Table 9, for identical octahedral geometry the charge on the complex is the only variable that establishes the relative proportions of σ-donor and π-acceptor contributions to the M–CO bond.

Starting from the carbonyl metalates of the early transition metals, with extensive π-backbonding, the σ bond becomes stronger with increasing oxidation state of the metal. When the charge rises to +2 and +3, the π contribution becomes smaller, whereas the σ-bonding fraction increases. This trend can be extended to Groups 10 and 11, although species such as $[Pt(CO)_6]^{4+}$ and $[Au(CO)_6]^{5+}$ appear not to exist. Instead, these metals form planar $[Pt(CO)_4]^{2+}$ (d^8) and linear $[Au(CO)_2]^+$ (d^{10}) as cations with the highest CO content.

2.5.2. ^{13}C NMR Spectra

Two sets of data are available from the ^{13}C NMR spectra of metal carbonyl complexes: chemical shifts δ_c and, in the case of metallic centers with a nuclear spin of 1/2, the coupling constants $^1J_{M,C}$. The chemical shift, which consists of a diamagnetic and a paramagnetic term, is sensitive to the σ, π, and polar contributions to bonding—as is the CO force constant, but in a different way. The coupling constant depends largely on the Fermi contact term and indicates the strength of MC σ-bonding.

As can be seen in Figure 7 for 5d $M(CO)_6$ complexes and in Tables 6 and 9 for additional metal carbonyl derivatives, trends similar to those discussed can also be established on the basis of ^{13}C chemical shifts. The chemical shift of free ^{13}CO at $\delta = 184$[16b, 168] relative to $(CH_3)_4Si$ (TMS) can be regarded as a limit for cationic carbonyl derivatives with smaller values, as well as typical of carbonyls and highly reduced carbonyl metalates with higher resonance frequencies and correspondingly higher δ values. Two exceptions to this rule are so far known. The chemical shift of $[Hg_2(CO)_2]^{2+}$ is $\delta = 189$, and the cations $[M(CO)_6]^+$ show resonances at $\delta = 195$ for M = Mn and $\delta = 171$ for M = Re, which fall on either side of ^{13}CO.

As can be seen in Table 9 for octahedral homoleptic $M(CO)_6$ complexes, the ^{13}C chemical shifts in the three *n*d series ($n = 3-5$) are dependent upon the oxidation state of the metal. With increasing charge from −2 to +3 the δ_C values decline, while the force constants rise simultaneously, as is also apparent from Figure 7 for the 5d metals. In addition, the resonance frequencies decrease with increasing atomic mass, although f_{CO} apparently does not change. Differences in the chemical shifts within Group 4 are very small, but they are larger for the remaining groups. It appears that increasing Lewis acid strength and the accompanying decrease in metal → CO π-backbonding is responsible for the "horizontal" trend, which influences δ_c and f_{CO} in similar ways. The "vertical" trend of δ_c is caused by increased shielding of the C atom with increasing atomic mass of the metal. As a consequence of the two trends, the smallest chemical shift of $\delta = 121$ is observed for $[Ir(CO)_6]^{3+}$.[13] It was shown through a recently completed density functional theory (DFT) study on 18 $[M(CO)_6]^n$ species that the paramagnetic contribution largely determines chemical shifts.[181c] The paramagnetic contribution is in turn dependent on the energy difference between the dπ orbitals of the metal and the π* orbitals of CO.

The δ_c values for $[Fe(CO)_6]^{3+}$ [12] and $[Os(CO)_6]^{3+}$ [181] are of interest in this context, but they have not yet been ascertained. For both complexes a paramagnetic ground state term is expected, which should affect the chemical shifts and cause broad resonance in the ^{13}C NMR spectrum.

A dependence is anticipated between ^{13}C chemical shift and coordination number in the 5d series $[Ir(CO)_6]^{3+}$, $[Pt(CO)_4]^{2+}$, and $[Au(CO)_2]^+$, with a common ratio (2:1) of number of CO ligands to ionic charge. The δ_C values increase from 121 through 137 to 174, whereas the f_{CO} values decrease only slightly from 20.8 through 20.6 to $20.1 \times 10^2\ N\,m^{-1}$. Substitution of CO in $[Au(CO)_2]^+$ [16] and $[M(CO)_4]^{2+}$ (M = Pd, Pt)[14] by SO_3F^- to give the metal carbonyl fluorosulfates $Au(CO)SO_3F$[16a] and *cis*-$M(CO)_2(SO_3F)_2$ (M = Pd, Pt)[18] strengthens the M → CO π-backbonding. Both f_{CO} and δ_C decrease. Interestingly, for the two Pd^{II} species $[Pd(CO)_4]^{2+}$ and *cis*-$Pd(CO)_2(SO_3F)_2$ the chemical shifts are very similar ($\delta = 144$ and 145). Much the same is true in Group 11. The ^{13}C chemical shifts for $[Ag(CO)_2]^+$ and $[Ag(CO)]^+$ are nearly identical at $\delta = 172.3$ and 171.4,[156] and slightly smaller than in the case of $[Au(CO)_2]^+$ [16b] ($\delta = 174$).

The currently known $^1J_{M,C}$ coupling constants are listed in Table 6. These include the nuclei ^{199}Hg,[15] ^{195}Pt,[181] and $^{109}Ag/^{107}Ag$.[56] All the J values are unusually large, often larger than those previously reported.[15, 56] The increase in Pt–CO bond strength is clearly evident in the transition from $[Pt(CO)_4]^{2+}$ with $^1J_{Pt,C} = 1550$ Hz to $Pt(CO)_2(SO_3F)_2$ with $^1J_{Pt,C} = 2011$ Hz. The same applies to the pair $[Hg(CO)_2]^{2+}$/$[Hg_2(CO)_2]^{2+}$ with $^1J_{Hg,C}$ values of 5220/3350 Hz. This correlates very well with thermal stabilities: $[Hg(CO)_2][Sb_2F_{11}]_2$ is thermally stable well above 100 °C, whereas $[Hg_2(CO)_2][Sb_2F_{11}]_2$ loses CO even at room temperature.

A detailed discussion of NMR data is envisioned for a later date, and appears inappropriate as part of this overview. The limited number of ^{13}C NMR data available for cyanometalates[75, 149] also eliminates the immediate possibility of a comprehensive comparison with the corresponding isoelectronic metal carbonyl cations.

2.5.3. Summary of Observed Trends in Spectroscopic Properties

The observed trends in spectroscopic properties for isosteric homoleptic metal carbonyl and cyano complexes can be summarized as follows: 1) Parameters such as the CX force constants f_{CO} or f_{CN}, selected CO vibrational frequencies, and ^{13}C chemical shifts are dependent upon the oxidation state, nuclear charge, and coordination geometry of the metal ion. 2) All spectroscopic properties change consistently and gradually with these parameters and can be extrapolated from correlations like the one shown in Figure 7. 3) The nearly constant differences in CO and CN bond strength apparent between CO/CN^-, HCO^+/HCN, and isoelectronic carbonyl/cyano complexes are a consequence of the differing bond polarities $C^{\delta+}-O^{\delta-}$ versus $C^{\delta-}-N^{\delta+}$, which strengthens the CO bond and weakens the CN bond.

2.5.4. Discussion of the Characteristics of the (M–C–O) Bond

The metal–CO bond in all metal carbonyl complexes can be described by a modified synergistic bonding model. For purposes of clarification Figure 8 has been devised to provide a schematic representation of orbital overlap in the individual (M–CO) segments with terminally bonded CO. The σ-donor bond from the 5σ molecular orbital of CO is shown as an arrow pointing in the direction of the metal atom. One component of the π-backbonding from the nd_{xz} or nd_{xy} metal orbital into the π* molecular orbitals of CO is symbolized by two curved arrows in the direction of CO. Thin lines indicate a weak bond, whereas thick lines depict the dominant bond type. Apart from these covalent bonding contributions, electrostatic effects in particular influence the CO bond, as shown by the most recent theoretical studies.[166, 181c] These electronic effects cause the indicated charges on the CO ligands (Figure 8a and c). In an analogous way, interionic contacts are directed toward the O atom in carbonyl metalates (a) and toward the C atom in carbonyl cations (c). The approximate wavelength regions for CO vibrations and oxidation states of the metal atoms are also indicated. Figures 8a and 8c represent limiting situations. In (a) π-backbonding dominates in a highly reduced carbonyl metalate, whereas in (c) a metal carbonyl cation, σ-bonding is overriding. Figure 8b

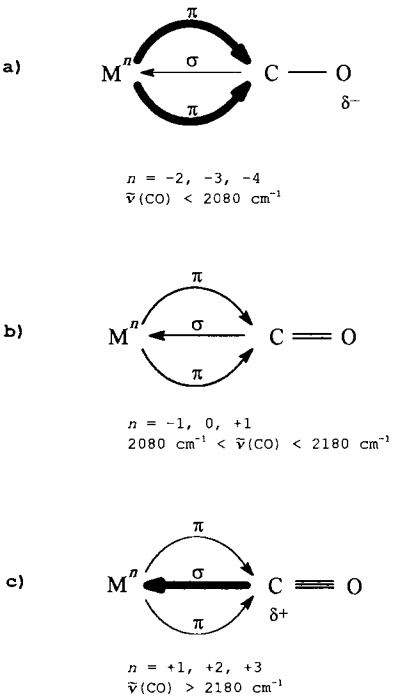

Figure 8. Schematic synergistic bonding model for a) predominantly π-bonded, highly reduced carbonyl metalates, b) typical metal carbonyls, and c) largely σ-bonded metal carbonyl cations.

characterizes the synergistic bonding in typical metal carbonyls, which may overlap with bond types (a) and (c) depending upon the oxidation state of the metal. So far, iridium is the only metal found to form a typical carbonyl complex $[Ir(CO)_4]^-$,[26, 27] a highly reduced complex $[Ir(CO)_3]^{3-}$,[7] and a homoleptic, mononuclear carbonyl complex $[Ir(CO)_6]^{3+}$,[13] where the oxidation states range from −3 to +3.

In this modified bonding model (Figure 8) that also takes into account electrostatic influences, σ- and π-bonding are regarded as complementary. Hence neither a "π-only" nor a pure "σ-only" situation exists. Although alternative bonding descriptions have been proposed,[182] the simple synergistic model according to Dewar, Chatt, and Duncanson[183–185] has not lost its appeal, thanks to its broad applicability also to a host of complexes with other π-acceptor ligands.[1, 26, 27] Many theoretical studies, only a few of which are cited here,[186–193] are based on the synergistic concept. Using various nuclear potentials and basis sets, structural parameters [d(M–C) and d(C–O)], spectroscopic properties [$\tilde{\nu}$(CO), δ_C, and electronic transitions], as well as M–CO bond energies and total energies for typical metal carbonyls have been well reproduced or predicted. There have also been many attempts to calculate relative σ- and π-contributions to overall bonding, and to compare various π-acceptor ligands. This does not apply in equal measure to the highly reduced carbonyl metalates and metal carbonyl cations. Ionic metal carbonyl species with charges of 2 or greater are to some extent stabilized by counterions through lattice energies, interionic interactions, or solvation in solution. In any case, theoretical calculations, which generally are based on gaseous free ions, become very complex if one attempts to extend them to the solid state or to solution conditions.

A comparative study of the homoleptic metal carbonyl cations $[M(CO)_n]^+$ ($n = 1, 2$) for all the 3d and 4d metals in the gaseous phase[194] apparently involves no overlap with our own work. More relevant in this context is a theoretical study taking into account relativistic nuclear potentials for metal carbonyl cations and cyano anions of the type $[M(CO)_n]^+$ and $[M(CN)_n]^{(n-1)-}$ (M = Cu, Ag, Au; $n = 1-3$)[160] and an experimental report of the determination of bond energies by mass spectrometry for the gaseous ions $[M(CO)_n]^+$ (M = Cu, Ag; $n = 1-4$).[195] There are three results in particular that coincide with our observations and conclusions: 1) linear species of the type ML_2 (M = Cu, Ag, Au; L = CO, CN^-) are more stable than species of the types ML, ML_3, ML_4;[160, 194] 2) for ML_n complexes ($n = 1-3$), stability decreases in the order $Au^I > Cu^I > Ag^I$;[160] 3) calculated partial charges for $[Au(CO)_2]^+$ and $[Ag(CN)_2]^-$ suggest differing bond polarities for the ligands.

Based on Fenske–Hall MO calculations,[80] it has been established that d^0 $[Cp_2Zr(CO)$[78, 79]] and d^{10} $[Ag(CO)$[53–56]] complexes involve significant π-backbonding. Also very promising is the most recent DFT study on octahedral $[M(CO)_6]^n$ species (M = metals of the 3d–5d series; $n = -2$ to $+3$).[181c] Apart from the frequencies of the CO vibrations and the ^{13}C NMR chemical shifts, which agree well with the experimental data in Tables 6 and 9, $(CO)_5M-CO$ dissociation energies were also calculated. The work of Ehlers, Ziegler, et al.,[181c] as well as that of Szilagyi and Frenking,[181d] suggests for $W(CO)_6$ the lowest M–CO dissociation energy of about 50 kcal mol^{-1}, and for $[Ir(CO)_6]^{3+}$ the highest of about 80 kcal mol^{-1}.

There is reason to hope that further calculations taking advantage of modern theoretical methods will permit ever deeper insights into the bonding relationships in all metal carbonyls. Moreover, the electronic spectra of certain $[M(CO)_n]^{m+}$ species are of interest as a way of ordering CO and CN^- with respect to their ligand field strengths in isoelectronic carbonyl and cyano complexes through ligand field analysis.[196]

The modified synergistic bonding model (Figure 8) suggested above permits several simple conclusions to be drawn:

1. CO is a far more versatile ligand than originally assumed.[1, 26, 27] The molecule forms thermally stable complexes with most metals apart from those of Group 3 (Sc, Y, La)[40] and a few main group metals.
2. The oxidation states of the metallic centers extend from −4 to +3. CO accommodates itself to this wide range through variation in both the σ- and π-components of overall bonding as well as through bond polarization. This variation is reflected in an enormous range for $\tilde{\nu}$(CO) for terminally bonded CO, extending from approximately 1400 to 2300 cm^{-1}, roughly three times as wide a range as previously assumed (1850 to 2125 cm^{-1} [1]).
3. Figure 8 illustrates qualitatively the synergistic M–CO bonding both in organometallic derivatives and in coordination compounds with classical linear and square-planar geometries.
4. Whereas one of the bond types (a) or (c) may dominate, the M–CO bond nevertheless remains synergistic. Strong σ-donor bonding leads to π-backbonding, and vice versa. Interpretations such as "σ-only" in cationic metal carbonyls[39, 56] are not consistent with the model, and not scientifically tenable, as the previous discussion of CO force constants demonstrates. The interpretation by Pearson,[198a] which classifies CO as a Lewis acid and M as a Lewis base, is limited to typical uncharged metal carbonyls. Extension of his interpretation (which is based on absolute electronegativities[198b]) to all three groups of carbonyl derivatives has not yet been accomplished. The dimensions of metal carbonyl chemistry have been considerably broadened with the discovery of highly reduced carbonyl metalates[7] and homoleptic metal carbonyl cations. Consequently, any description of the M–CO bond must now be seen in a wider perspective.

Strauss et al.[56] have proposed for the silver(I) CO adducts the vague, simplistic description "nonclassical" metal carbonyls,[56] and unfortunately we have also applied this designation to the $[Hg(CO)_2]^{2+}$ cation.[15b] In view of the results presented and discussed in the present publication, we are of the opinion that a distinction between classical and nonclassical carbonyls is nebulous, misleading, and unnecessary. Instead, we have adopted the terminology originally suggested by W. Hieber,[24] which combines the term "metal carbonyl cation" with the adjective "homoleptic". The designations "classical" and "nonclassical" are unfortunate from another standpoint as well: In the related field of carbocation chemistry[10a, 99] this terminology is no longer accepted by IUPAC.[199] Finally, a quotation from George Olah's Nobel Prize Lecture[200] makes the point well:

"The terms classical and nonclassical are expected, however, to fade away gradually as the general nature of bonding becomes recognized."

3. Summary and Conclusions

Superacids,[10] which were earlier used for the synthesis and investigation of very reactive cations, especially carbocations[10, 99, 200] and hetero- and homonuclear polycations of main group elements,[10b, 87c, 201, 202] have proven to be useful reaction media for the preparation of homoleptic metal carbonyl cations. In the context of the studies described here it has been observed that the Lewis superacid SbF_5[98] is an ideal reaction medium. Liquid SbF_5[20] allows preparation of highly reactive naked metal cations that are carbonylated under very mild conditions and can be isolated in the form of thermally stable salts of metal carbonyl cations with $[Sb_2F_{11}]^-$ as counterion. The ability of $[Sb_2F_{11}]^-$ to stabilize electrophilic cations is well documented,[107–115] and also becomes apparent through the three recently accomplished structure determinations of $[H_3O][Sb_2F_{11}]$,[106] $[Hg(CO)_2][Sb_2F_{11}]_2$,[15b] and $[Ir(CO)_5Cl]$-$[Sb_2F_{11}]_2$.[13] Significant secondary interionic and intermolecular contacts exist in *cis*-$Pd(CO)_2(SO_3F)_2$[18b] and *mer*-$Ir(CO)_3$-$(SO_3F)_3$[19] between the C atom of the CO group and an F[13, 15b] or O atom[18b, 19] of $[Sb_2F_{11}]^-$ or the SO_3F^- group. These contacts increase the lattice energies in salts with metal carbonyl cations,[11–16] and transform the molecular structures into three-dimensional networks.[17–19]

Species with linear[15, 16] and square-planar[14, 18] coordination geometries violate the 18e rule, and are without precedent

in metal carbonyl chemistry.[1, 26, 17] Equally unprecedented are the observed spectroscopic properties [$\tilde{\nu}$(CO), f_{CO}, δ_C, and $^1J_{M,C}$), with $\tilde{\nu}$(CO) values of up to 2300 cm^{-1}, greatly exceeding the 2143-cm^{-1} value for free CO.[84] These observations, together with closely related structural and spectroscopic properties of the isoelectronic cyanometalates,[72-75] point to a dominant OC → M σ-bond in the homoleptic metal carbonyl cations. The more the oxidation state of the metallic center decreases, the more π-backbonding of the typical metal carbonyls increases, until with the carbonyl metalates it becomes dominant. The gradual, charge-dependent change in σ/π bonding components and the CO charge polarization is reflected in gradual trends in spectroscopic properties.

With the carbonyl derivatives now known for transition metals from Groups 4 through 11, together with those of mercury and a number of main group metals,[40, 81-85] some of limited thermal stability, it becomes clear that the CO ligand, known for 130 years, is still capable of producing surprises.

The developments and results described in this review have occurred rapidly and unexpectedly. So unexpectedly, in fact, that in a future-oriented summary of metal carbonyl chemistry projected into the next century and published in 1990 in honor of the 100th anniversary of the discovery of $Ni(CO)_4$,[5] there is no mention of homoleptic metal carbonyl cations. It may therefore seem somewhat inappropriate for us now also to engage in prognoses for the future, although these are limited to homoleptic metal carbonyl cations. In the next few years we can expect:

1. The complete characterization of homoleptic metal carbonyl cations with paramagnetic ground states, so far a rarity in metal carbonyl chemistry.[1, 7, 26, 27] The most promising candidates are octahedral cations of the type $[M(CO)_6]^{3+}$ (M = Fe, Ru, Os). As previously noted, prospects are less bright for the formation of highly charged cations such as $[Pt(CO)_6]^{4+}$ and $[Au(CO)_6]^{5+}$ in the form of thermally stable salts.
2. At rhodium there still is a gap in the 4d series, although such cations as $[Ru(CO)_6]^{2+}$,[11] $[Pd(CO)_4]^{2+}$,[14] and $[Ir(CO)_6]^{3+}$[13] are known for the neighboring metals. We hope to close this gap with the square-planar $[Rh(CO)_4]^+$. A number of preliminary investigations indicate its existence (synthesis, IR, Raman, ^{13}C NMR spectra).[203] Together with the potentially analogous cations $[Ir(CO)_4]^+$ and $[Au(CO)_4]^{3+}$, as well as the known $[M(CO)_4]^{2+}$ (M = Pd, Pt),[14] comparisons within a systematic study would be possible.
3. Chemical properties of the $[M(CO)_n]^{m+}$ species have so far not been studied systematically. Attempted substitution of CO by other small molecular Lewis bases such as NO, N_2, or PF_3 would appear to be a worthwhile undertaking. A start has already been made with $[Au(PF_3)_2][Sb_2F_{11}]$.[143]
4. General opinion in the inorganic literature, as well as the modes of thought of teachers and students, is likely to change. The excessive importance previously attributed to π-backbonding and the 18-electron rule in metal carbonyl chemistry has been called into question. The homoleptic metal carbonyl cations described here make it clear that, in addition to the undoubtedly important organometallic chemistry, there exists also a much older coordination chemistry of carbon monoxide. It will be more difficult in the future to classify Schützenberger's[28, 29] pioneering efforts as laboratory curiosities. Our field of observation has been considerably widened.

We wish to express our deepest appreciation to our diplom, masters, and doctoral students for their engaged efforts over the course of many years, which constitute the basis for the developments described here. Equally important has been a collaboration with crystallographers from Simon Fraser University and the University of British Columbia, as well as discussions with numerous colleagues. All those who have participated in this work are acknowledged by name in the cited literature. We have received financial support from various sources: the Deutsche Forschungsgemeinschaft, The Fond der Chemischen Industrie (H. W.), the Natural Science and Engineering Research Council of Canada (F. A.), and the North Atlantic Treaty Organization in the form of a joint research grant. F. A. expresses his thanks to the Alexander von Humboldt Stiftung for a research prize 1995/96 and H. W. to the Degussa AG for gifts in the form of noble metal powders.

Starting from cyclodiynes one obtains cyclopropenonophanes, cyclopropenyliophanes, and cyclobutadienosuperphanes.

Their syntheses and properties are presented in the following review.

Phanes with Three- and Four-Membered Rings as Building Elements

Rolf Gleiter* and Martin Merger

Dedicated to Professor Roald Hoffmann on the occasion of his 60th birthday

The systematic integration of the small 2π- and 4π-electron systems cyclopropenylium ion, cyclopropenone, oxocyclobutenylium ion, and cyclobutadiene into phane chemistry was initiated only a few years ago. $[n_2]$Cyclopropenyliophanes, $[n_2]$cyclopropenonophanes, metal-capped $[n_4]$cyclobutadienosuperphanes, and other new families of double-decker phane species became available from cycloalkydiynes through special methods of double [2+1]cycloaddition with carbenes and metal complex induced dimerization by double [2+2]-cycloaddition. Phane-specific structural features were elucidated by X-ray structural analyses. Cyclic voltammetry and PE spectroscopy as well as MO calculations revealed considerable interactions between closely spaced π-electron systems. Decapping cyclobutadienosuperphanes formally extended the synthetic principle to threefold [2+2]cycloadditions resulting in $[n_4]$-bridged tricyclo[4.2.0.0^{3,5}]octa-3,7-dienes, which represent a new type of cage compounds. Moreover, completion to fourfold [2+2]addition was achieved with the photoinduced transformation of $[3_4]$-bridged tricyclo[4.2.0.0^{3,5}]octa-3,7-diene into propella$[3_4]$cubane.

Keywords: carbenes · cycloalkadiynes · cyclophanes · small ring systems · transition metals

1. Introduction

Phane chemistry has grown to an important discipline that attracts both synthetic and physical chemists. Bridged arenes such as [*n*]cyclophanes furnish information about the sensitivity of aromatic character with respect to deformation of the planar conjugated π system. $[n_m]$Phanes in which two or more π moieties are stacked onto each other at a fixed distance provide structures that are well suited for studying interactions between the functional groups. Furthermore, they are excellent host molecules and models for enzyme reactions.[1, 2]

Successful strategies were developed for constructing theoretically as well as aesthetically attractive target molecules to enrich our repertoire of synthetic methods and to increase our understanding of chemical bonds.[1, 2] Therefore, the original meaning of the term "phanes" was extended by several groups. It now comprises not only arenes but also nonaromatic π systems and even cycloaliphatic molecules ("aliphanes")[1] which are cyclically combined with the same or other functions, for example tricyclo[4.2.2.2^{2,5}]dodeca-1,5-diene[3] and cycloocta-1,5-diyne[4] (which are viewed as etheno- and acetylenosuperphanes)[5, 6] as well as $[2_2]$cyclooctatetraenophanes[7] and adamantanophanes.[8, 9]

However, this does not mean that the exploratory potential of phane chemistry in the area of arenes principally ebbs. Besides numerous fascinating contributions on phanes of benzenoid arenes, there has been little work done on the non-benzenoid 6π-electron arenes[1] cyclopentadienide ion, tropylium ion, and tropone, although they offer additional chances for studying charge–charge and dipole–dipole interactions when incorporated into $[n_2]$phanes.

It is even more remarkable that for decades the aromatic units used were limited to 6π and higher systems; the smallest are cyclopentadienide and five-membered heterocycles[1] such as thiophene, pyrrole, and furan. The 2π-electron species cyclopropenylium ion, an outstanding representative for Hückel aromaticity $[(4n+2)\pi, n = 0]$, was not introduced into phane chemistry until recently. Likewise, the related cyclopropenone and four-membered metal-stabilized systems oxocyclobutenyl cation and cyclobutadiene were widely neglected.

Now, however, we are able to present a first review on methods which were developed for synthesizing double-decker phanes of all these small π systems from cycloalkadiynes as well as on results of structural studies and investigations of intramolecular interactions between the π moieties. Moreover, we report some synthetically attractive transformations of cyclobutadienosuperphanes.

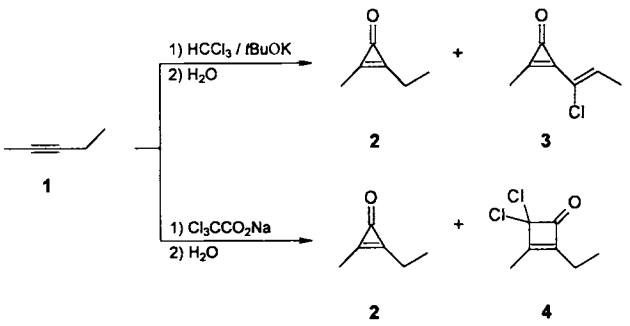
2. $[n_2]$Phanes with C_3 Cycles

2.1. Cyclopropenonophanes

At a first glance the syntheses of $[n_2]$cyclopropenono-acetyleno-phanes and $[n_2]$cyclopropenonophanes may appear feasible by simple addition of dichlorocarbene to cyclic diynes and hydrolysis. This procedure was described by Breslow et al.[10-12] and Dehmlow[13,14] for preparing monofunctional cyclopropenones from alkynes. Although this method allowed ready access to a series of dialkylcyclopropenones, it was judged as preparatively "weak"[15] until 1992. The precursors used for generating dichlorocarbene (sodium trichloroacetate in dimethoxyethane at 80 °C[10-12] or ethyl trichloroacetate/sodium methoxide,[10,16] chloroform/sodium hydroxide under phase transfer conditions,[17,18] chloroform/potassium *tert*-butoxide[13,14,19] in petroleum ether or benzene and bromotrichloromethane/methyl lithium in diethyl ether at −95 °C[20,21]) afford the desired 3,3-dichlorocyclopropenes with only low selectivity. Particularly with alkynes **1**, in which there are CH_2 groups next to the triple bond, the yields of cyclopropenones **2** obtained after hydrolysis are on average a few percent.[10-12,15] Among the numerous side products α-chloroalkenylcyclopropenones **3**[13,22] and dichlorocyclobutenones **4**,[11,14] which result from insertion of a second dichlorocarbene, were identified.



For the essentially more demanding cyclopropenation of difunctional acetylenic substrates, we turned our attention to complexes **5** ($n \leq 3$),[23-25] which are prepared from $HCCl_3$ and BuLi in THF [Eq. (1)], as an alternative source of dichlorocarbene. According to Köbrich et al.[26] and Hoeg et al.,[27] complexes **5** are considerably more stable than $LiCCl_3$ in diethyl ether.[20] They exhibit markedly reduced reactivity in alkene cyclopropanations, and, to our knowledge, have not been used in alkyne cyclopropenations. In our experiments with monoalkynes, the dichlorocarbenoid species **5** proved to be an effective cyclopropenation agent; side reactions were excluded to a large extent, and, thus, the selectivity raised in general to over 70%.[28]

$$HCCl_3 + BuLi \xrightarrow[-78\,^\circ C]{THF} Cl-\overset{Cl}{\underset{Cl}{C}}-Li \cdot 3\,THF \quad (1)$$

5

2.1.1. $[n_2]$Cyclopropenono-acetyleno-phanes

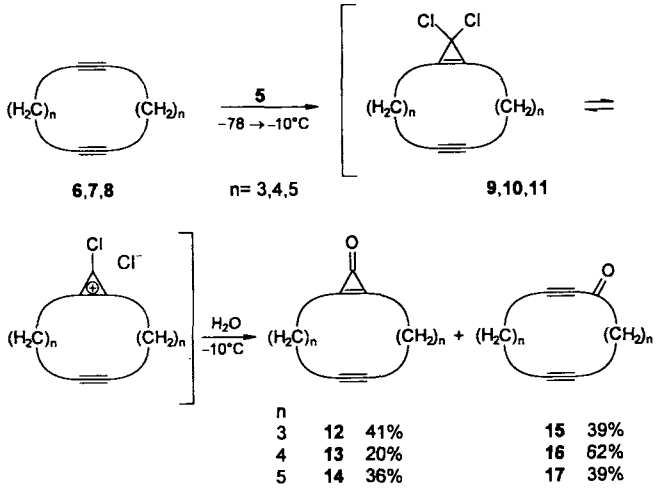
Treatment of cyclodeca-1,6-diyne (**6**), cyclododeca-1,7-diyne (**7**), and cyclotetradeca-1,8-diyne (**8**) with an equimolar amount of $LiCCl_3$ in THF at −78 to −10 °C allowed mono-dichlorocyclopropenation in about 80% yield, based on 80% conversion. Hydrolysis of the resulting dichlorobicycloalkenynes **9**–**11** in THF at −10 °C led, presumably via ambident chlorocyclopropenylium intermediates,[28] not only to the target compounds $[3_2]$-, $[4_2]$-, and $[5_2]$cyclopropenono-acetyleno-phanes **12**–**14**, but also to cycloalkadiynones **15**–**17** under ring expansion. In no case could a $[n_2]$cyclopropenonophane be detected as a by-product.

Rolf Gleiter, born in 1936 in Stuttgart, Germany, studied chemistry at the Universität Stuttgart and completed his doctoral thesis in 1964 with F. Effenberger. After postdoctoral stays in the U. S. A. with P. von R. Schleyer at Princeton University (1966) and R. Hoffmann at Cornell University (1967–1968), he went to Basel, Switzerland, and completed his habilitation in 1972. In the following year he accepted the position of professor of theoretical organic chemistry at the Technische Hochschule Darmstadt, Germany. Since 1979 he has been professor of organic chemistry at the Universität Heidelberg, Germany. His areas of interests include the interactions in nonconjugated π systems, the syntheses of model compounds, and quantum-chemical calculations.

R. Gleiter

M. Merger

Martin Merger, born in 1965 in Ludwigshafen/Rhein, Germany, studied chemistry at the Universität Heidelberg and, in addition, music (violin, concert exams) at the Hochschule Mannheim. In the group of Rolf Gleiter he completed his doctoral thesis on phanes of small π ring systems. He received a graduate fellowship from the Studienstiftung des deutschen Volkes and was a member of the Graduiertenkolleg "Selektivität und Katalyse in der organischen und metallorganischen Chemie". Since 1996 he has been working in the research department of the BASF AG.



Phanes **12**–**14** enabled us to study the mutual influence of a triple bond and a cyclopropenone moiety (which have similar basis orbital energies) as a function of their intramolecular arrangement for the first time. We recorded the PE spectra of **12**–**14**;[29] the first PE bands of **12** and **13** are shown in Figure 1. In **12** a considerable interaction between the π orbital of

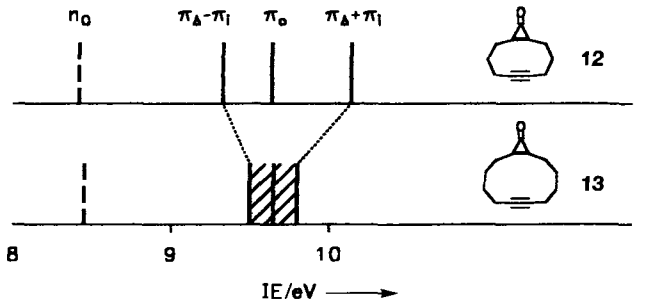


Figure 1. The first PE bands of **12** and **13**.

the cyclopropenone ring (π_A) and the in-plane π orbital of the triple bond (π_i) is observed with a split in π-bond energies of 0.81 eV. According to the corresponding wave functions (Figure 2), theinteraction occurs partly through space and partly

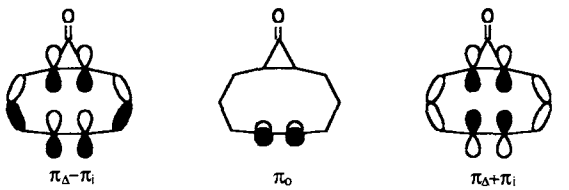

Figure 2. Schematic representation of the π wave functions of **12**.

through bonds. In **13** the distance between the π systems is considerably larger than in **12**, and hence the splitting of the π bands amounts to only 0.3 eV (Figure 1). In **14** there is no interaction, and both functional groups appear to be independent.

We successfully grew single crystals of **12**, and eludicated its molecular structure by X-ray analysis. As shown in Figure 3, **12** exists in a boat conformation in which the central CH_2 groups

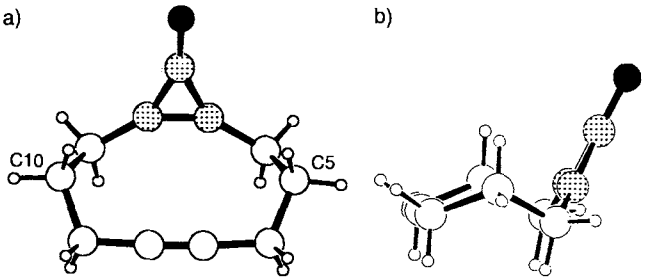

Figure 3. Molecular structure of **12** in the crystal; a) top view, b) side view. The stippled circles represent the carbon atoms of the three-membered rings, and the black circle represents the oxygen atom.

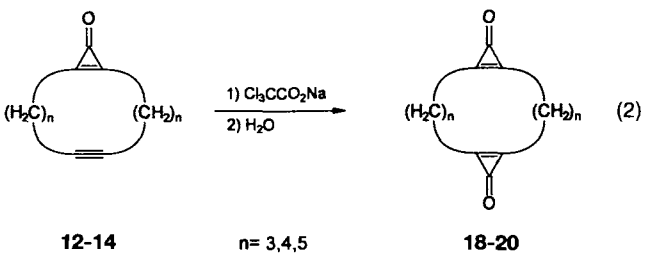
of both C_3H_6 bridges are oriented *syn* to the cyclopropenone moiety.[29] In contrast, the starting material **6** adopts a chair conformation.[30] However, molecular-mechanics calculations on **12** give evidence that a chair and an *anti*-boat conformation are close in energy to the *syn*-boat conformation found in the crystal. The transannular distance between the triple bond and the C–C double bond in **12** is 3.11 Å, which is only slightly larger than the transannular distance between the triple bonds in **6** (2.99 Å). The bond angles at the triple bond in **12** (175°) are larger than in **6** (171.7°). However, enough strain remains to pyramidalize the bridgehead carbons by 3 and 4.3°.

2.1.2. *[n_2]Cyclopropenonophanes*

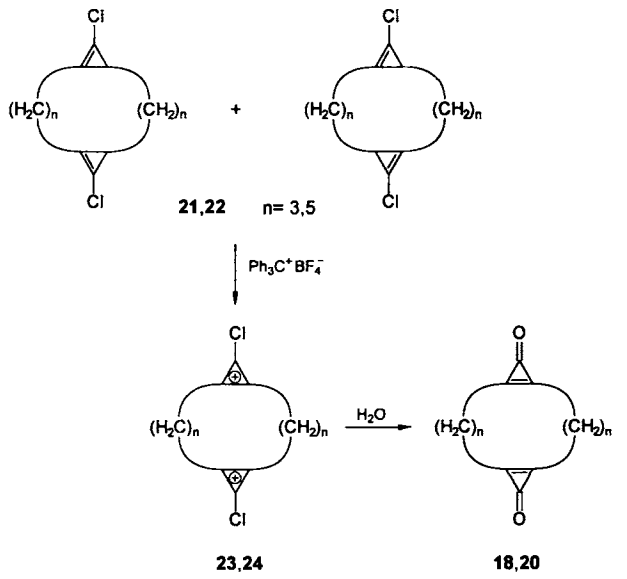
Our efforts to prepare [n_2]cyclopropenonophanes directly from the cycloalkadiynes **6**–**8** failed, even with a large excess of **5**. After hydrolysis, only **12**–**14** were found in drastically reduced yields. The dichlorocyclopropene unit in intermediates **9**–**11** apparently shields the triple bond against attack by **5** and preferably reacts with additional carbenoid. This problem could be successfully overcome by cyclopropenating the second triple bond of **12**–**14** [see Section 2.1.1; Eq. (2)]. Conventional treat-



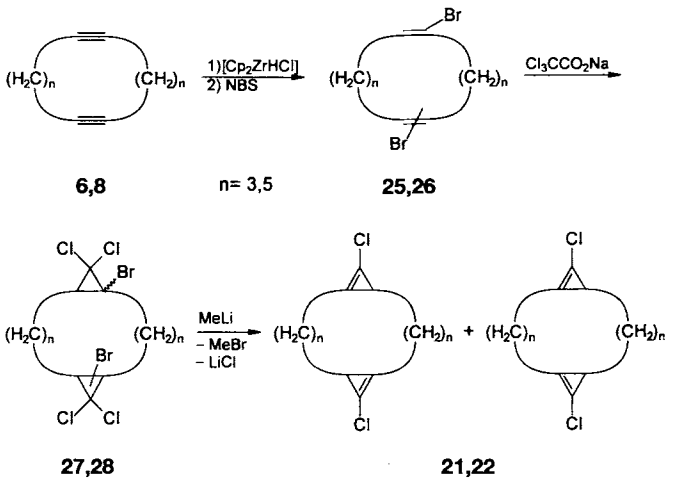
(2)

ment of **12**–**14** with one equivalent of sodium trichloroacetate followed by hydrolysis afforded [n_2]cyclopropenonophanes **18**–**20**[31] in 3–5% yields, which are within the usual range for known syntheses of monofunctional cyclopropenones.[10, 11]

To improve the preparative productivity, we designed an alternative synthesis[31] that is also based on cyclic diynes but does not involve dichlorocyclopropene intermediates. The key step consisted of hydride abstraction from dichlorotricyclodienes such as **21** and **22** to give dichloro[n_2]cyclopropenyliophanes (**23**, **24**), which were converted without isolation into [n_2]cyclopropenonophanes (**18**, **20**) by hydrolysis.



As the first representatives of a dichlorotricycloalkadiene, **21** ($n = 3$) and **22** ($n = 5$) could be prepared in a four-step sequence (Scheme 1) by applying a modified form of methods developed in the chemistry of monofunctional chlorocyclopropenes.[32]



Scheme 1. Synthesis of dichlorotricycloalkadienes **21** and **22**.

Cyclodiynes **6** and **8** were treated with Schwartz's reagent and *N*-bromosuccinimide (NBS) to provide dibromides **25** and **26** (mixtures of isomers), which were submitted to dichlorocyclopropanation with a large excess of sodium trichloroacetate in dimethoxyethane at 80 °C to afford dibromotetrachlorotricycloalkanes **27** and **28** in about 50% yield. Dehalogenation of **27** and **28** with methyl lithium gave **21** and **22** in yields exceeding 90%. Finally, hydride abstraction from **21** and **22** with triphenylmethyl tetrafluoroborate[33] (not optimized) and subsequent hydrolysis resulted in conversion into **18** (13%) and **20** (78%).

The $[n_2]$cyclopropenonophanes **18**–**20** are crystalline, fairly stable compounds that melt at 215 (**18**), 191–193 (**19**), and 131 °C (**20**). The X-ray structure analysis[31] of **18** revealed that there is an interplanar angle of 95.5° between the cyclopropenone moieties (Figure 4). The ten-membered ring adopts

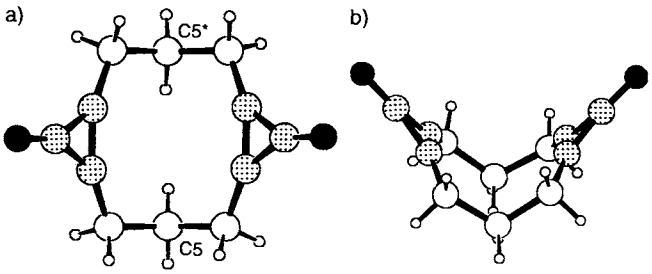


Figure 4. Molecular structure of **18** in the crystal, a) top view, b) side view. The stippled circles represent the carbon atoms of the three-membered rings, and the blacks circles the oxygen atoms.

a boat conformation, in which C5 and C5* are on the same side of the ring and opposite to the cyclopropenone moiety. In this respect **18** differs from the starting compound **12**, in which the carbon atoms C5, C10 and the cyclopropenone unit are on the same side (see Figure 3). The bridgehead atoms of **18** are pyramidalized by 8 and 9°, which indicates considerable strain and is probably partially induced by dipole–dipole interactions. The transannular distance between the bridgehead carbon atoms is 0.4 Å larger than in **12**. Nevertheless, splits of π-orbital energies from 0.53 to 0.83 eV for the low-energy conformers are indicated by ab initio calculations with a 6-31G* basis set (which reproduced remarkably well the interactions in **12** found by PE spectroscopy).[29] The interactions occur mainly through-space and only slightly through-bond (Figure 5). Preliminary MINDO/3 calculations do not indicate significant π–π interactions in **19** and **20**.

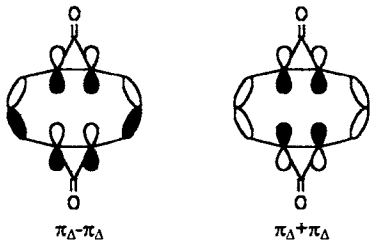

Figure 5. Schematic representation of the wave functions $\pi_\Delta - \pi_\Delta$ and $\pi_\Delta + \pi_\Delta$ of **18**.

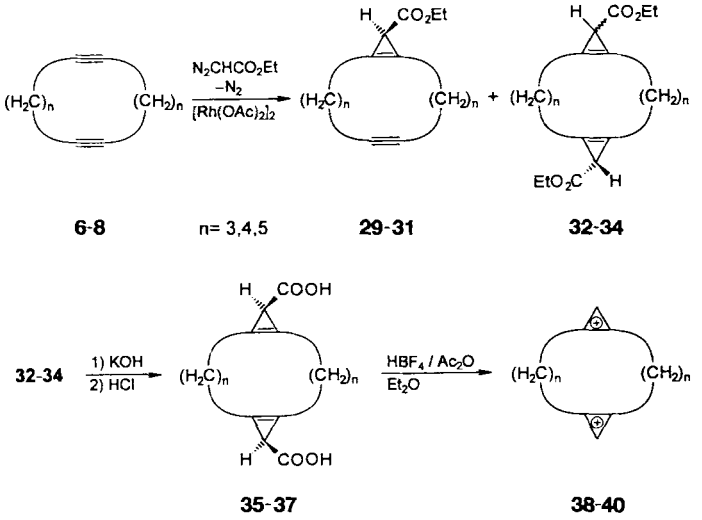
2.1.3. *[n_2]Cyclopropenyliophanes*

Although dialkylcyclopropenylium salts (tetrafluoroborates, perchlorates) and their precursors dialkylcyclopropenecarboxylic acids, derived from alkynes, have been known since the 1960s,[34] no difunctional compounds of these types were reported before 1992. Hence, to synthesize $[n_2]$cyclopropenyliophanes on the basis of cycloalkadiynes via tricycloalkadiene dicarboxylic esters and acids, new methodical requirements arose (see Scheme 2).

In the standard method of Rh-catalyzed preparation of monofunctional dialkylcyclopropene-3-ethylcarboxylates from alkynes and diazoethyl acetate,[35–43] low alkyne conversion (<50%), low temperature (0–25 °C), and long reaction times (20 h) are essential for supressing a number of undesired side reactions—such as dimerization of ethoxycarbonylcarbene,[44–46] addition of a second ethoxycarbonylcarbene,[35, 36, 44, 47–51] and ring opening to ethoxycarbonylvinylcarbenes[43, 52]—which compete with the ethoxycarbonylcar-

bene. Evidently, the restriction of conversions to low levels by using high ratios of alkyne functionality to diazoethylacetate (2:1–20:1) cannot be held in the desired double cyclopropenation of cycloalkadiynes to the tricycloalkadiene dicarboxylic esters.

Our investigations with **6–8** showed rate and selectivity of cycloaddition to be strongly dependent on the reaction medium.[53] In ethers (diethyl ether, THF) carbene dimerization predominates, whereas cycloaddition proceeds very slowly and does not exceed the stage of mono-addition.[53, 88b] Both acceleration and increase in efficiency were achieved by initiating the cyclopropenation with small amounts of CH_2Cl_2 (needed to dissolve the solid substrates **6–8**) and performing it at 50–60 °C with continuous addition of diazo ethylacetate. While the "medium" rapidly adopted ester quality, conversion of cyclodiynes approached 100% within half an hour. The *cis*- and *trans*-tricycloalkadienedicarboxylic esters **32–34** were obtained in yields of about 45% along with up to 40% of recycleable mono-adducts **29–31** (bicycloalkenynecarboxylic esters; Scheme 2).[54] Saponification of **32–34** in methanolic KOH[55]



Scheme 2. Synthesis of $[n_2]$cyclopropenyliophanes.

and acidification led to dicarboxylic acids **35–37** without difficulties. It should be pointed out that **29–37**, the "intermediates" on the way to $[n_2]$cyclopropenyliophanes, may themselves be conceived as $[n_2]$phanes, **29–31** as $[n_2]$cyclopropeno-acetylenophanes, and **32–37** as $[n_2]$cyclopropenophanes.

Our attempts to transform **35–37** into cyclopropenyliophanes **38–40** by decarbonylation with aqueous HBF_4 (48%) and acetic anhydride (analogous to the synthesis of dipropylcyclopropenylium tetrafluoroborate)[34] failed. However, the extensive decomposition observed could be decisively suppressed by replacing aqueous HBF_4 with anhydrous HBF_4 in diethylether; this reduces the amount of acetic acid in the reaction mixture.[53, 54] Crystallization from acetonitrile/diethyl ether afforded $[3_2]$-, $[4_2]$-, and $[5_2]$cyclopropenyliophanes **38–40** (tetrafluoroborates) as colorless needles in 60–70% yield. They decompose rapidly upon heating with a color change to dark brown. They may be stored in the solid state at −30 °C without decomposition, but in solution they can be handled for only a short time. Compared to dipropylcyclopropenylium tetrafluoroborate, which melts at 70 °C without decomposition,[34] **38–40** appear to be considerably destabilized phane-specifically due to intramolecular charge–charge interaction.

The ^{1}H NMR signal for the protons of the three-membered rings appears at $\delta \approx 10.4$–10.5, which is characteristic of cyclopropenylio ions.[56] The structure of $[5_2]$cyclopropenylophane **40** could be eludicated by X-ray analysis (Figure 6).[57] Like the cyclopropenone units in **18**, the cyclopropenylium moieties face each other. The angle between the rings is 41.3°.

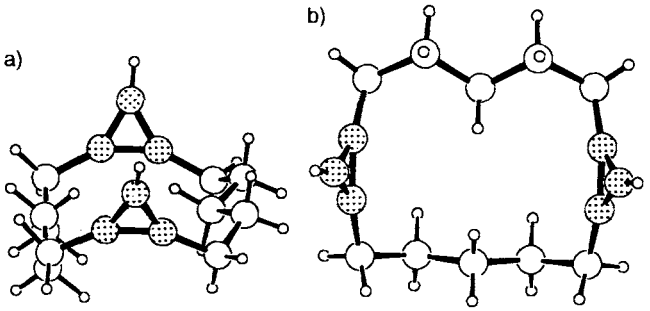


Figure 6. Molecular structure of **40** in the crystal; a) side view, b) top view. The stippled circles represent the carbon atoms of the three-membered rings.

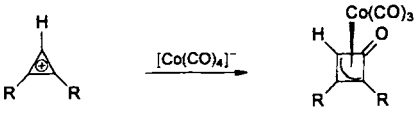
3. $[n_2]$Phanes of C_4 Cycles

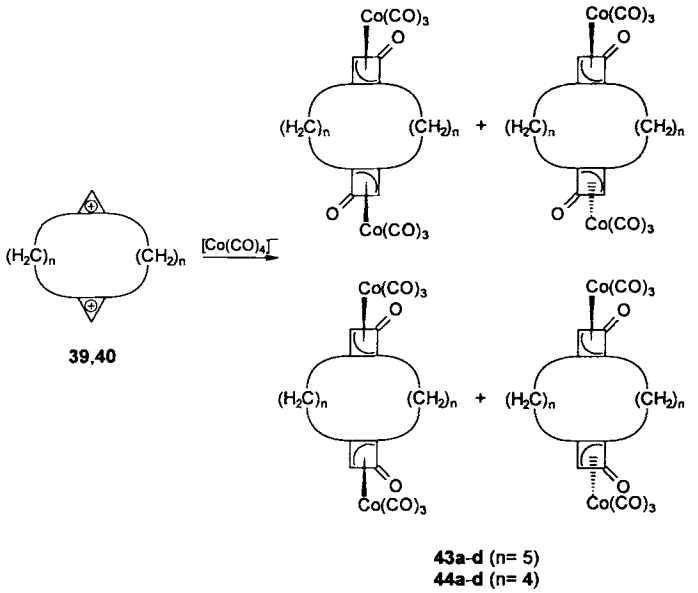
3.1. $[n_2]$Oxocyclobutenyl-tricarbonylcobalt-phanes

As outlined by Hughes et al,[58] complexation of disubstituted cyclopropenylium salts **41** with $[Co(CO)_4]^-$ involves selective CO insertion at a position vicinal to the nonsubstituted carbon atom to give 2,3-disubstituted (η^3-1-oxocyclobutenyl)tricarbonylcobalt (**42**). Having made the difunctional $[n_2]$cyclo-



propenyliophanes **38–40** (see 2.1.3), we saw chances for preparing metal-complexed oxocyclobutenylphanes for the first time. This may attract attention also with regard to metal-stabilized cyclobutadienophanes (see Section 3.2), particularly as η^3-oxocyclobutenyl complexes are reported to be useful precursors for cyclobutadiene complexes.[59–61]

We succeeded in synthesizing cobalt complexes of this type from **39** and **40**, but so far not from the $[3_2]$-species **38**[57] (Scheme 3). Differing from single symmetrically disubstituted cyclopropenylium ions, $[n_2]$cyclopropenyliophanes give rise to four isomers, since CO may insert in either of the two C–C single bonds and, thus, somewhat complicate the preparation. Nevertheless, all isomers of $[5_2]$oxocyclobutenyl-tricarbonylcobalt-phane (**43a–d**) were isolable from the product mixture resulting from the reaction of **40** with $[Co(CO)_4]^-$ in acetoni-



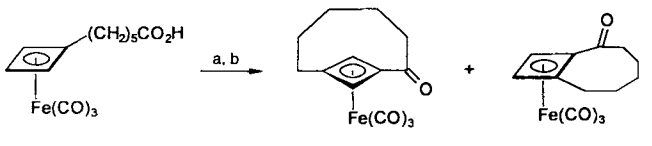
Scheme 3. Synthesis of metal-complexed oxocyclobutenylphanes.

trile. The yellow solids were obtained in an overall yield of 55%. Their IR and ^{1}H NMR data corresponded very well with those reported for the dipropyloxocyclobutenyl complex.[62]

The less stable [4$_2$]cyclopropenyliophane **39** could be complexed in an analogous fashion to yield a mixture of four isomeric [4$_2$]oxocyclobutenyl-tricarbonylcobalt-phanes (**44a–d**) in minor yield (20%). Predominating decomposition of **38** under complexation conditions inhibits transformation to [3$_2$]oxocyclobutenyl-tricarbonylcobalt-phanes in isolable amounts.

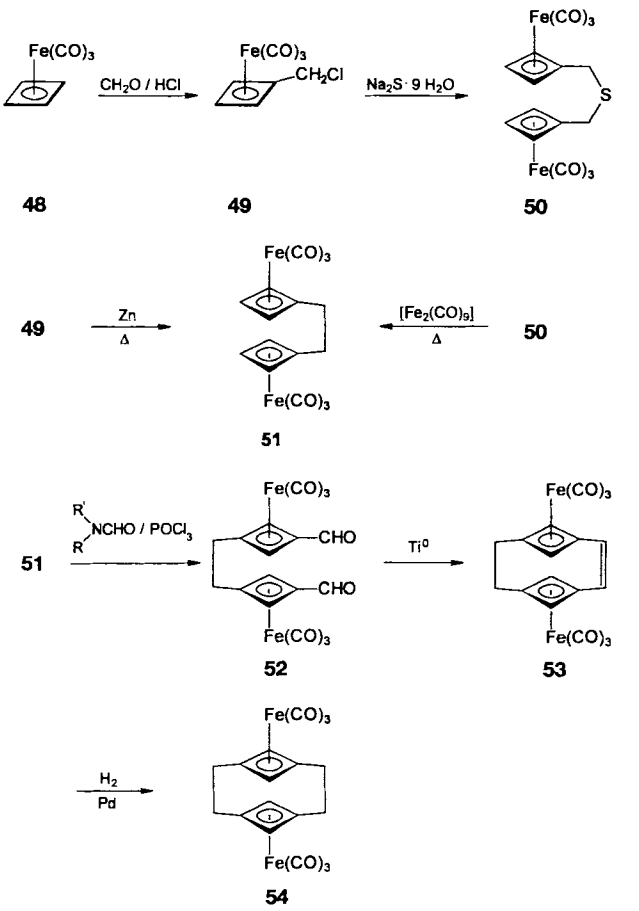
3.2. Metal-Capped Cyclobutadienophanes

The simplest single- and double-decker compounds of this type are [6]cyclobutadieno-tricarbonyliron-phane (**46**,[63] a single cyclobutadiene-complex unit 1,3-bridged with an oxohexamethylene chain, Scheme 4) and [2$_2$]1,3-cyclobutadieno-tri-



Scheme 4. a) $(COCl)_2$; b) $AlCl_3/CS_2$.

carbonyliron-phane (**54**, Scheme 5).[64] Their syntheses make use of the aromatic properties of the cyclobutadienetricarbonyliron moiety (**48**).[65] Phane **46** was obtained with its isomer **47** upon intramolecular acylation of **45**. Double bridging of two units of **48** to **54** was achieved in a multistep procedure:[64] Chloromethylation of **48** gave **49**, which was coupled directly with Zn or via sulfide **50** with [$Fe_2(CO)_9$] to yield **51**. Diformylation of **51** by the Vilsmeier procedure and coupling of the resulting **52** with Ti^0 led to phane **53**, which could be readily hydrogenated to **54**.



Scheme 5. Synthesis of cyclobutadieno-tricarbonyliron-phane **54**.

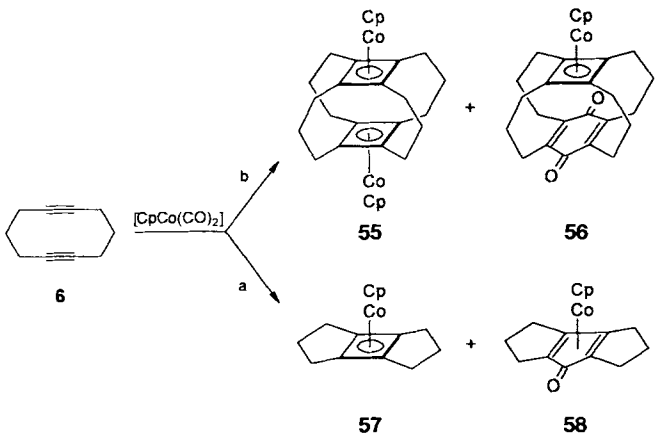
An X-ray investigation of **54** revealed that the two parallel metal-capped cyclobutadiene units are separated by 2.70 Å.[64] The methylene groups of the bridges are bent out of the cyclobutadiene planes by 20.6° away from the iron fragments.

3.2.1. Metal-Capped Cyclobutadienosuperphanes

3.2.1.1. One-Pot Synthesis

Our group entered the field of metal-capped cyclobutadienophanes "through the back door".[66] While investigating the electronic structure of cyclodeca-1,6-diyne (**6**),[30] we found that the highest occupied MO is the in-plane orbital $6a_u$. We concluded that side-on attack of an electrophilic metal fragment should be favored over a perpendicular approach. Hence, in the presence of [CpCo(CO)$_2$] (Cp = C_5H_5) **6** might undergo intermolecular reactions to yield oligomers rather than intramolecular [2+2]cycloaddition to give tricyclic metal-capped cyclobutadienes, a species which was discovered earlier by King and co-workers upon transforming higher cyclodiynes such as **7** and **8** with [CpCoL$_2$].[67–69]

Indeed, the main product isolated (12%) from the reaction mixture of **6** and [CpCo(CO)$_2$] in octane was CpCo-stabilized [3$_4$]cyclobutadienosuperphane (**55**)—which apperently results from dimerization of **6** by double [2+2]cycloaddition (Scheme 6, pathway b)—whereas the product of intramolecular [2+2]cycloaddition **57** was formed only to a minor extent (6%, Scheme 6, pathway a).[70,71] As a side product (0.7%) the

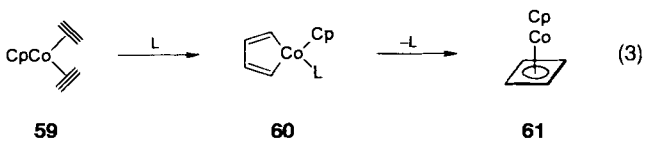


Scheme 6. Products resulting from the reaction of **6** with $[CpCo(CO)_2]$.

mixed superphane **56** was found, which is also generated by dimerization but requires additional CO insertions. On the other hand, when the reaction was carried out in toluene, ketone **58** was formed as well by intramolecular cycloaddition of **6** and CO insertion.[71]

The amazing one-pot synthesis of cyclobutadienosuperphanes inspired us to clarify the scope of its applicability and the essential features as well as to differentiate it from intramolecular reactions. With this goal set, one has to consider that superphane formation has a minor part within a complex system of cycloaddition reactions, and hence single correlations found do not allow general interpretations or definite predictions. Nevertheless, some determining features concerning structures, steric orientations, reactivity, and mechanisms could be outlined.

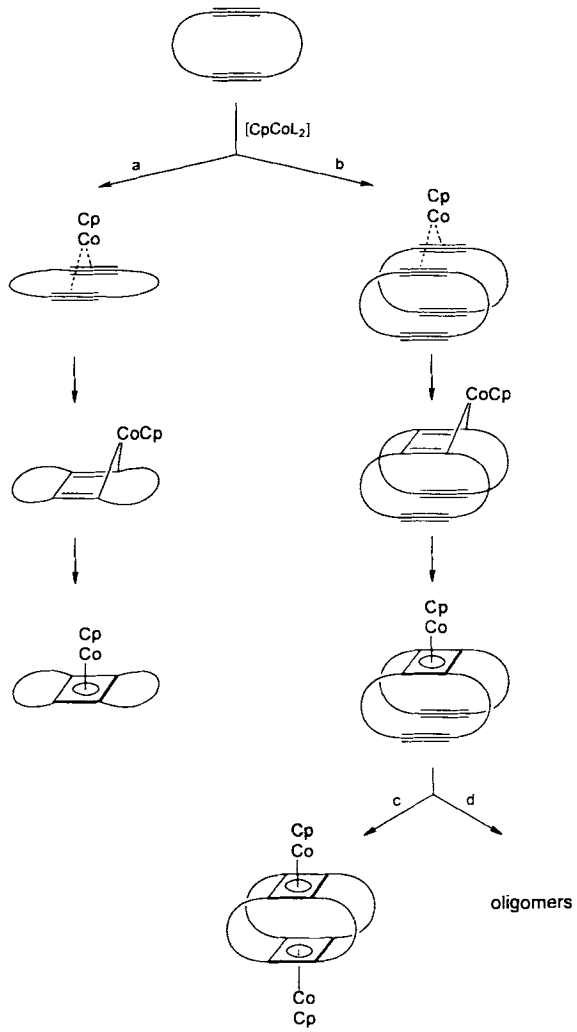
In principal, the formation of Co-complexed cyclobutadienes of general type **61** from diacetylene complexes **59**, which are made from two acetylene molecules and $[CpCoL_2]$ (similarly with $[Fe(CO)_5]$), is postulated to occur by [2+2+1]cycloaddition to metallacycle **60** and subsequent rearrangement thereof [Eq. (3)].[72] Direct transformation of **59** into **61** does not seem



(3)

likely, since molecular orbital calculations predict a high activation energy for this symmetry-forbidden process.[73] The sequence **59** → **60** → **61** is supported by the work of Wakatsuki, Yamazaki et al.,[74] who were able to isolate phosphane-stabilized cobaltoles of type **60** (L = phosphane).

Transferring this sequence to cyclic diynes, one easily recognizes two product-determining alternatives (Scheme 7) for the [2+2+1]cycloaddition: the intramolecular pathway a or the intermolecular pathway b. Along pathway b further transformation of monocyclobutadienediyne intermediates may branch into pathways c (intramolecular) and d (intermolecular) to give cyclobutadienosuperphanes and higher molecular products, respectively. In summary, superphane formation from **6** is interpreted as a result of combining an intermolecular (pathway b) and an intramolecular [2+2]cycloaddition (pathway c; see also Section 3.2.1.2).



Scheme 7. In analogy to reaction (3), possible progess of the reaction of cyclodiynes with $[CpCoL_2]$.

The structures of **55** and **56** determined by X-ray analysis are shown in Figure 7. The central carbon skeleton in **55** (Figure 7, top)[70] shows C_{4h} symmetry. The two complexed cyclobutadiene units are separated by 2.94 Å. As seen in the top view, the propano bridges adopt a pin-wheel conformation. The mixed superphane **56** (Figure 7, bottom)[71] shows a deformation of the quinone ring, in which the carbonyl groups are twisted out of the plane of the double bonds by 27°. The four propano bridges adopt C_{2v} symmetry.

The preference of pathway b/c in Scheme 7 over pathway a by **6** might not only be due to the relatively high π_i-orbital energy, which favors a side-on approach, but also to the higher activation energy of pathway a (formation of a strained cobaltol species with a double anti-Bredt structure) and to an entropically convenient orientation of the two triple bonds in the intermediate monocyclobutadienediyne of the pathway b/c. These considerations led us to study the ratio of intramolecular versus intermolecular reactions (a/b, c/d) as a function of ring size by allowing 10- to 18-membered cyclodiynes to react with $[CpCoL_2]$ (L_2 = 2CO, cod). However, the investigation of the symmetric cyclodiynes **7**,[67] **8**,[75] **65**,[76] and **67**[76] in addition to **6** (Scheme 8) did not result in a continuous but in an alternating function, which apparently indicates that the conformations of

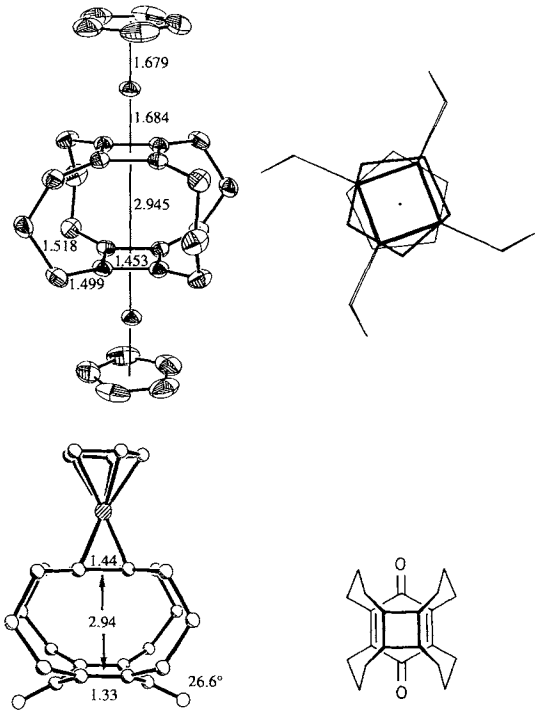


Figure 7. Molecular structure of **55** (top; side and top views) as well as of **56** (bottom; side view and the central skeleton as viewed from the top).

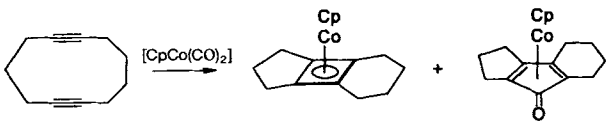
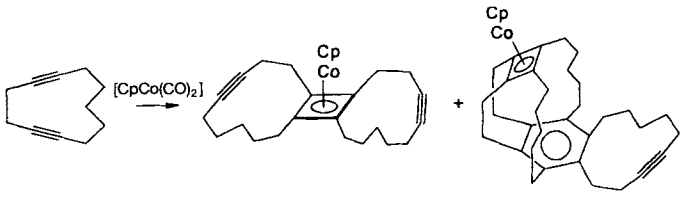
the bridges are predestinational factors. Only those symmetric diynes with an odd number of CH_2 units in the bridges (**6**, **8**, and **67**) gave cyclobutadienosuperphanes (**55**, **63**, and **68**, respectively), the yields of which decreased in the same order. In contrast, from cyclodiynes with an even number of CH_2 bridges (**7**, **65**), no superphanes were obtained. By intramolecular [2+2]cycloaddition (pathway a in Scheme 7) **7** was converted into **62** in strikingly high yield (86%), and **65** afforded tricycle **66** (70%).[75] The unsymmetric cycloundecadiyne **69** (with one odd and one even-numbered bridge)[76] behaved just like **7**, and gave no superphane in addition to the products of intramolecular [2+2]cycloaddition, **70** (32%) and **71**.

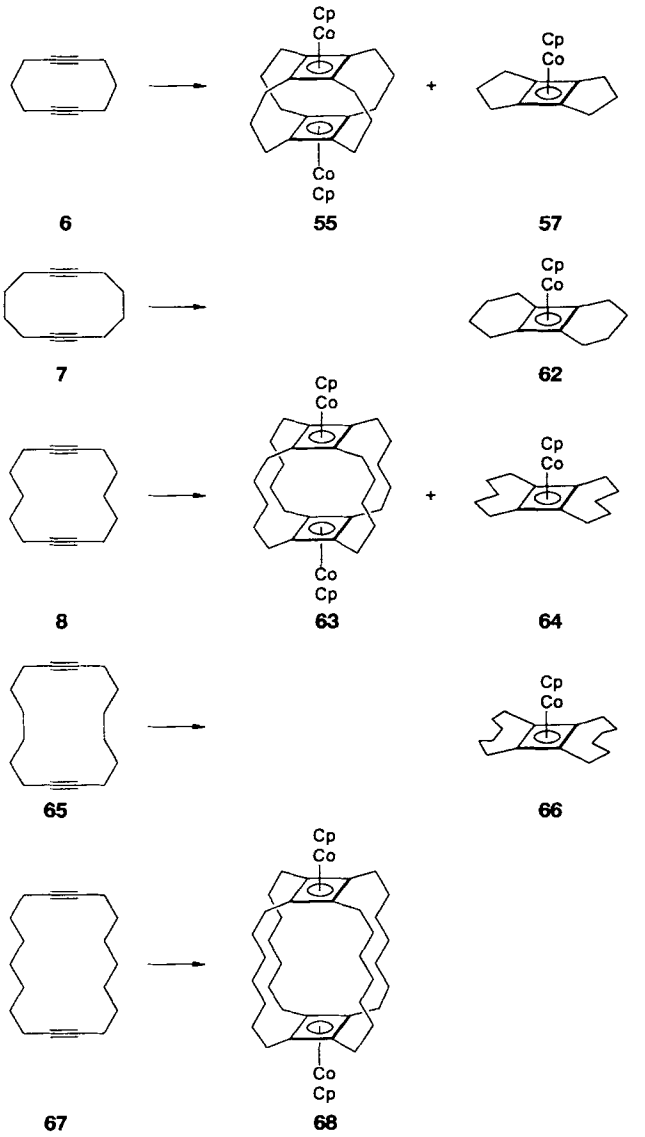


69 **70** **71**

The isomeric cycloundeca-1,5-diyne (**72**), however, follows neither pathway a nor pathway b/c.[77] It is outstanding in two respects: The complexed dimer **73** formed by intermolecular [2+2]cycloaddition (pathway b) could be readily isolated, and trimer **74** was identified as by-product. The mixed phane **74**

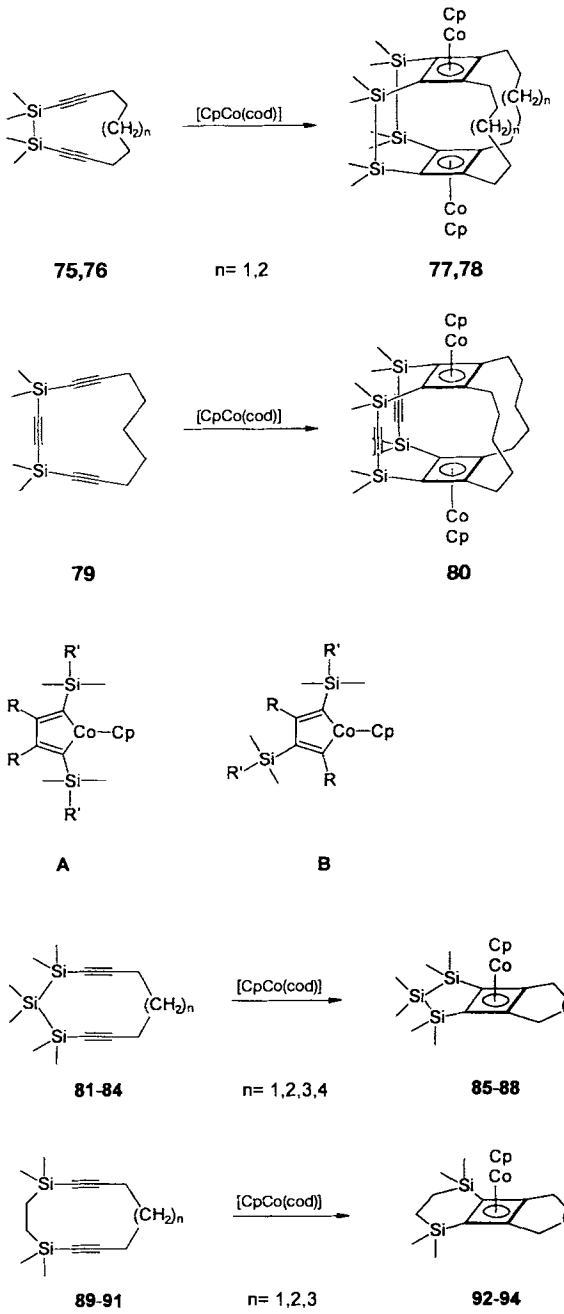


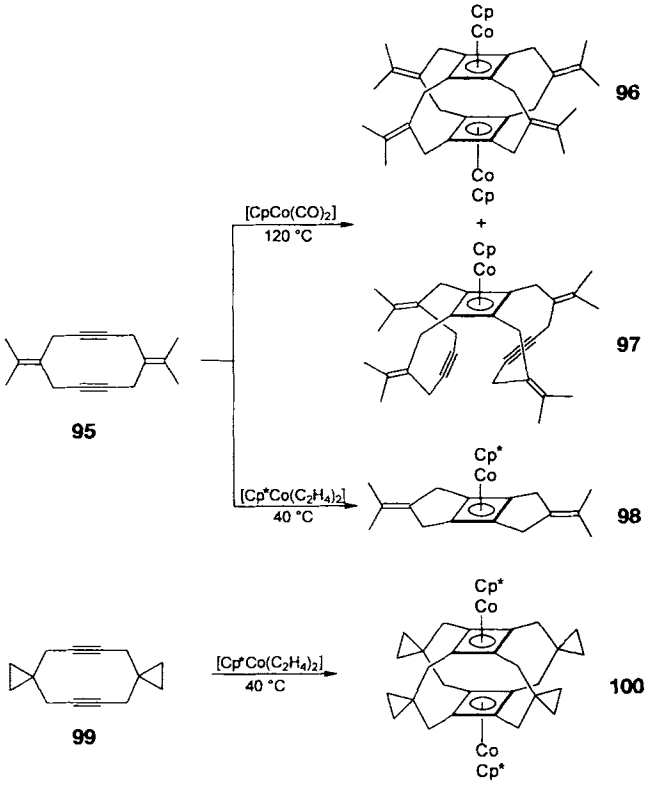
72 **73** **74**



Scheme 8. Progress of the [$CpCoL_2$]-initiated [2+2]cycloadditions of cyclodiynes as a function of their ring size.

presumably results from [2+2+2]cycloaddition (pathway b/d) of **73** and **72**. In view of the strongly steric effects of bulky α substituents in asymmetric monoalkynes which are reported to give mainly C_{2v}-symmetric cyclobutadienes,[74] we synthesized a number of analogously structured, congested cyclic diynes[78] and treated them with [$CpCoL_2$]. In the cases of **75**, **76**, and **79** we obtained superphanes **77**, **78**, and **80** in unusually high yields (40–60%).[79] Clearly, the sila bridges display extensive directing effects and not only entirely block intramolecular [2+2]cycloaddition (pathway a in Scheme 7) but also strongly suppress oligomerization (pathway b/d) in favor of dimerization (pathway b/c). Moreover, the course of CpCo-induced double [2+2]cycloaddition (pathway b/c), leading exclusively to the C_{2v}-symmetric **79**, **78**, **80**, appears to be confined to cobaltol intermediates of type **A**, which apparently are sterically favored over cobaltols of type **B** already in the first stage. If any cobaltol of type **B** is formed, it further reacts selectively along pathway b/d. In contrast to **75**, **76**, and **79**, the less rigid systems **81**–**84** and **89**–**91** react with [CpCo(cod)] along the intramolecular pathway a and yield tricycles **85**–**88** and **92**–**94**[80].





Scheme 9. Comparison of the cyclization behavior of **95** and **99**.

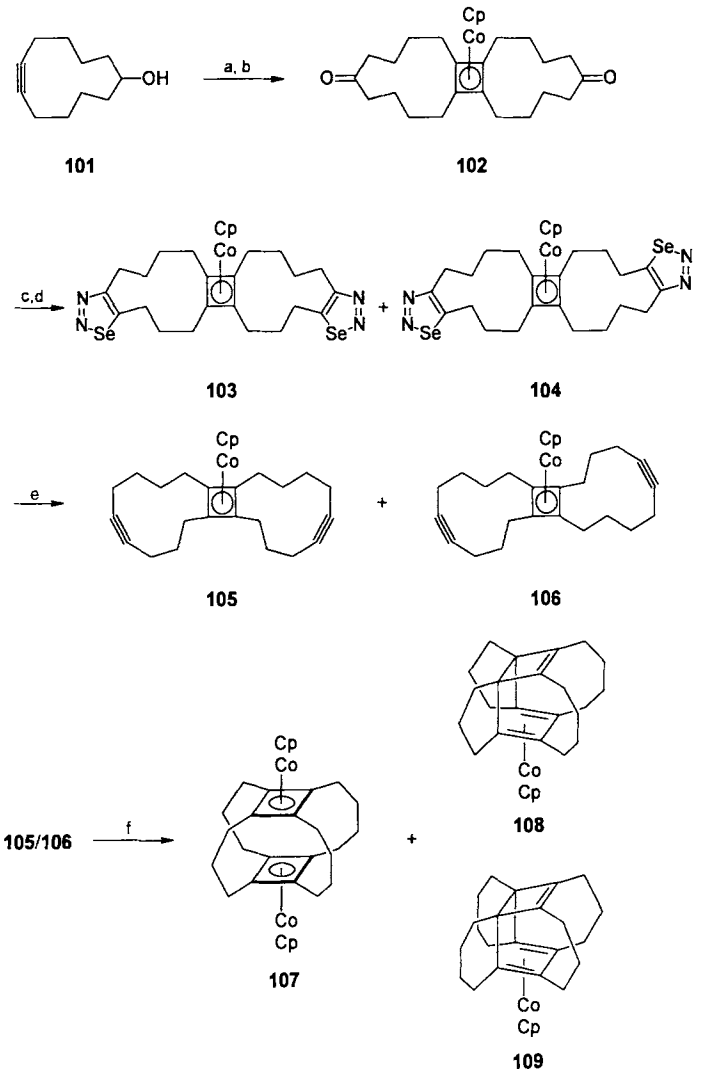
To obtain more information on sterical influences, we studied the 4,9-disubstituted cyclodeca-1,6-diynes **95**[81] and **99**[82] for comparison with the unsubstituted **6** under the assumption that in **95** the side-on approach of the complexing agent (inducing dimerization by pathway b) and in **99** the perpendicular attack (inducing intramolecular cyclization by pathway a) are disfavored. This rationalization seemed to be principally confirmed by the reactions of **99** and **95** with $[Cp^*Co(C_2H_4)_2]$ under mild conditions (40 °C, $Cp^* = C_5Me_5$, Scheme 9). Diyne **99** gave superphane **100** (10%) but no tricyclic product,[82] whereas **95** afforded the tricyclic complex **98** in nearly quantitative yield.[81] However, the reactivity of **95** proved to be strongly dependent on the properties of the complexing agent and the reaction conditions: With $[CpCo(CO)_2]$ and at 120 °C the reaction appeared to be totally reversed from pathway a to pathway b; superphane **96** (10%) and additionally **97** (2%), which is apparently the intermediate for pathway b/c[81] to **96**, were isolated.

Concerning the complexing agents, we found that the yield of superphanes of type **55** can be improved considerably by introducing electron-withdrawing substituents (formyl and carboxylic ester groups) into the Cp units of either $[CpCo(CO)_2]$ or [CpCo(cod)], thus raising the electrophilic character of the agents.[83] In summary, our investigations teach us that not only structural and electronic properties of the cycloalkadiynes as well of as the cyclobutadienediyne intermediates (pathway b in Scheme 7) but also the reactivity of the complexing agents and the reaction conditions are determining factors for cyclobutadienosuperphane synthesis.

3.2.1.2. Stepwise Synthesis of Cyclobutadienosuperphanes

Although the one-pot dimerization of cyclodiynes allows access to cyclobutadienosuperphanes and has proven to be applicable to a series of different substrates, an additional challenge arose to break its limitations, especially a) to exclude the competing intramolecular cycloadditions, b) to prepare cyclobutadienosuperphanes with even-numbered or different bridges, and c) to cap the phanes with two different metal fragments. Assuming that complexed tricyclic cyclobutadienediynes such as **97** are superphane precursors (see Section 3.2.1.1, Scheme 7, pathway b) and, furthermore, that the conformational influence of bridges is of less importance for pathways c and d than for pathways a and b, we focussed on replacing one of the triple bonds in cyclodiynes with a functional group, which after dimerization according pathway b should allow generation of this triple bond.

This concept proved to be feasible with cyclic ynols.[84] The first stepwise synthesis of a cyclobutadienosuperphane, incorporating different alkylene bridges, is briefly outlined in Scheme 10. 6-Cycloundecynol **101** was heated with [CpCo(cod)]

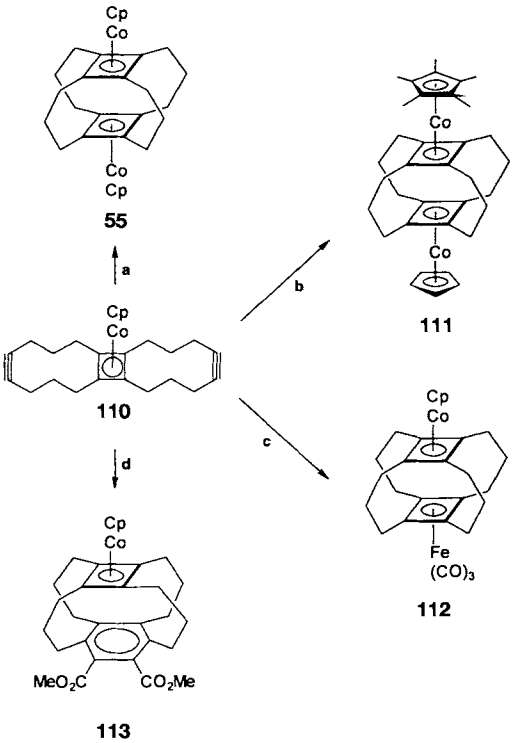


Scheme 10. Synthesis of the first cyclobutadienosuperphane **107** with various alkandiyl bridges. a) [CpCo(cod)], b) Oppenauer oxidation, c) semicarbazide acetate, d) SeO_2/HOAc, e) *n*BuLi/THF, f) $[CpCo(CO)_2]$.

and subsequently oxidized to ketone **102**. Reaction of **102** with semicarbazide followed by oxidation with SeO_2 provided an unseparable mixture of two regioisomeric bis(selenadiazoles) **103** and **104**, which were treated with *n*BuLi in THF at $-40\,^{\circ}C$ to yield a 1:1 mixture of diynes **105** and **106**. Finally, transformation of **105** and **106** with $[CpCo(CO)_2]$ gave superphane **107** and the bridged bicyclo[4.2.0]octa-2,4,7-triene complexes **108** and **109** in a 2:1:1 ratio. The unexpected formation of **108** and **109** is interpreted as resulting from a [4+2]cycloaddition of a cobaltole and a CpCo-bound cyclobutadiene unit. The structures of **107** and **109** were confirmed by X-ray investigations of single crystals. Due to the different lengths of the propano and butano bridges in **107**, the cyclobutadiene units are not parallel; their separation ranges from 3.0 to 3.4 Å.

Apparently, in the mixture **105/106**, only **105** reacts to form a phane. We ascribe this to the parallel orientation of the triple bonds in this molecule; in **106** both triple bonds are probably inclined towards each other.

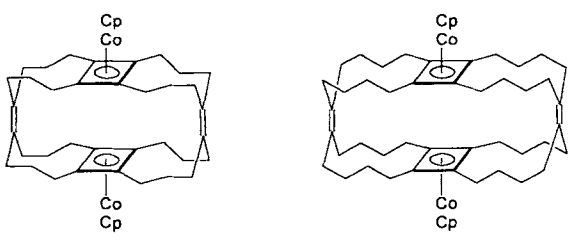
Similarly to **105** and **106**, tricyclic diyne **110** was synthesized from 5-cyclodecynol.[84] According to X-ray studies of **110**, the acetylene units are parallel to each other at a distance of 6.3 Å. Its reactions are summarized in Scheme 11. Heating **110** and



Scheme 11. Reactions of diyne **110**. a) $[CpCo(CO)_2]$, b) $[Cp^*Co(CO)_2]$, c) $[Fe(CO)_5]$, d) $MeO_2C-C\equiv C-CO_2Me$, $[CpCo(CO)_2]$.

$[CpCo(CO)_2]$ for 2 h in toluene gave superphane **55** in high yield (80%) and traces (1%) of **56** (see Scheme 6). With $[Cp^*Co(CO)_2]$ (in decalin) instead of $[CpCo(CO)_2]$, **111** was obtained in 80% yield. From **110** and $[Fe(CO)_5]$ in toluene at reflux, the mixed-capped superphane **112** was formed in only 8% yield.[84] Finally, heating **110** in the presence of dimethylacetylene dicarboxylate and $[CpCo(CO)_2]$ yielded the mixed cyclophane **113** as the minor product besides **55**. The quick formation of **55** supports our assumption that **110** is an intermediate in the synthesis of **55** from **6** (Scheme 6) according to Scheme 7, pathway b/c.

Another method that is suitable for the stepwise synthesis of (long-chain) cyclobutadienosuperphanes is the intermolecular McMurry coupling[85] of tricyclic diketocyclobutadiene complexes. In this way **114** (from **102**) and **115**, which represent cyclobutadieno- as well as ethenosuperphanes, were prepared.



3.2.1.3. Properties and Reactions of Metal-Stabilized Cyclobutadienophanes

Superphanes **55**, **63**, and **68** are ideal models for studying interactions between two CpCo-capped cyclobutadiene units stacked onto each other at different well-defined distances. Cyclic voltammetry (CV) proved to be the method of choice for establishing such interactions. Figure 8 shows the CV data[86]

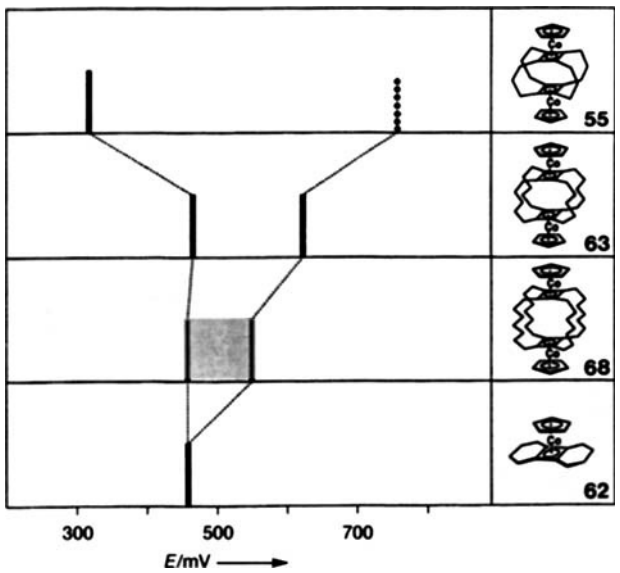


Figure 8. CV oxidation potentials of **55**, **63**, **68**, and **62**.

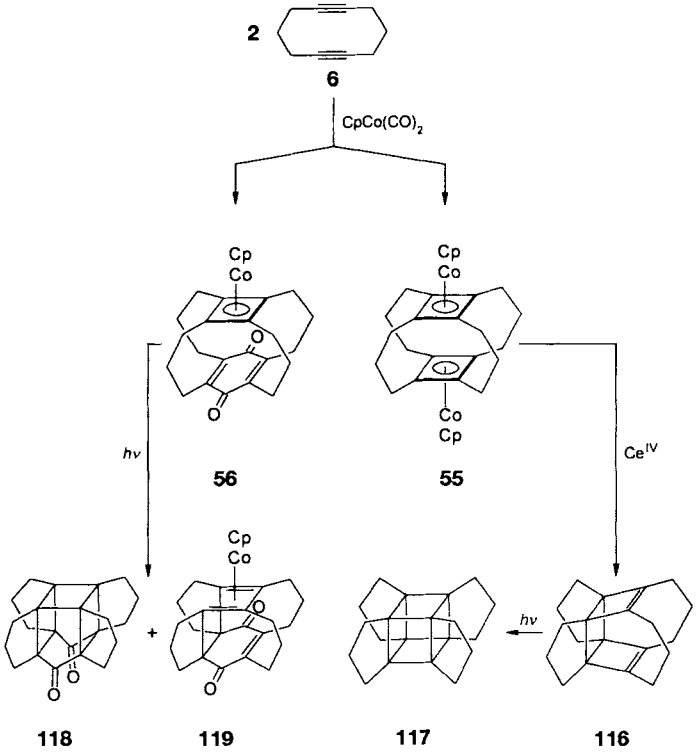
obtained for **55**, **63**, **68**, and the reference complex **62**. The first (reversible) oxidation step in **55** (E_{Ox1} = 0.31 eV), leading to a radical cation, proceedes more easily than that of **62** (E_{Ox1} = 0.46 eV); this indicates a considerable increase of the HOMO energy in the ground state of **55**. On the other hand, presumably due to delocalization of the positive charge over both π units, the second (irreversible) oxidation step in **55** needs considerably higher energy (E_{Ox2} = 0.76 eV). In the neutral compounds **63** and **68**, the less closely arranged π units appear to be independent, like that of **62**; concerning the first oxidation potentials, no significant differences are found. Nevertheless, the potentials required for the second oxidation step reveal marked interactions in the radical cation state of **63** and even of **68**, although it decreases with chain length.

Complex **56** (see Scheme 6) can be conceived as a donor–acceptor phane with the metal-stabilized cyclobutadiene unit as the donor and the quinone unit as the acceptor. This view is supported by a long wave length absorption band at 424 nm.[71]

The view of cyclobutadienosuperphanes as dimers of cyclodiynes and as products of double [2+2]cycloaddition involving all four triple bonds prompted us to investigate further synthetic application of [2+2]cycloaddition involving the four "double bonds" as well. The hypothetical, unstabilized cyclobutadienosuperphanes should provide chances for extending the coupling sequences to three- and fourfold [2+2]cycloadditions and thus make accessible fourfold-bridged *syn*-tricyclo[4.2.0.0^{2,5}]octa-3,7-dienes, a new species of cage compounds, and new representatives of propella[n_m]cubanes.

We succeeded in removing the CpCo fragments of the superphanes **55**, **96**, and **107** by oxidation with Ce^{IV} and in case of **55** (less efficiently) by irradiation.[87] The main product (80%) starting from **55** was the [3$_4$]-bridged *syn*-tricyclo[4.2.0.0^{2,5}]octa-3,7-diene **116**, as postulated according to the concept of threefold [2+2]cycloaddition (Scheme 12). The corresponding bridged *syn*-tricyclo[4.2.0.0^{2,5}]octa-3,7-dienes were obtained from **96** and **107**.[81,88a] The intramolecular cycloaddition of two cyclobutadiene moieties seems to be limited to cyclobutadienosuperphanes with up to four-membered bridges. Superphanes with longer chains, such as **63** and **68**, are not transformed to the corresponding cage compounds by oxidation or irradiation.



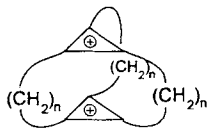
Scheme 12. Products of multiple cycloadditions starting from cyclodiyne **6**.

Finally, the last step of fourfold [2+2]cycloaddition could be achieved as well in two cases so far (Scheme 12).[87,89] Irradiation of **116** afforded the fourfold-bridged propella[3$_4$]cubane **117**, another dimer of cyclodecadiyne. Analogously, the photoinduced transformation of the mixed superphane **56** underwent two cycloaddition steps to lead to **118** accompanied by **119**.

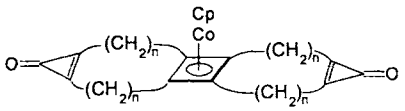
4. Outlook

The availability of [n_2]cyclopropenyliophanes (**38**–**40**), [n_2]cyclopropenonophanes (**18**–**20**), and difunctional intermediates (**12**–**14**, **21**, **22**, **32**–**34**) provides new synthetic perspectives, especially with respect to applying known transformations of monofunctional systems (cyclopropenylium ions, cyclopropenones, 3-carboxycyclopropenes, 1-chlorocyclopropenes).

Foremost, we envision further bridging for construction of $[n_3]$cyclopropenyliosuperphanes **120**, counterparts of cyclobutadienosuperphanes that are still lacking.



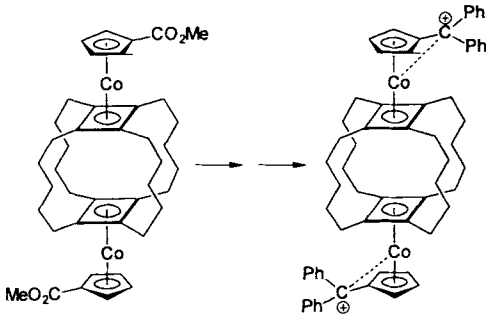
120



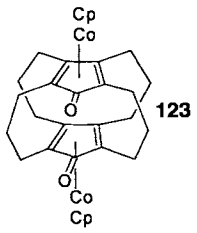
121

$[n_2]$Cyclopropenono-acetyleno-phanes such as **12**–**14**, which were successfully used for the synthesis of $[n_2]$cyclopropenone-superphanes **18**–**20** (see Section 2.1.2), and bicycloalkenyne carboxylic esters like **29**–**31** may generally serve as functionalized alkyne substrates. Thus, CpCo-induced dimerization of **12**–**14** by [2+2]cycloaddition could afford mixed phanes **121**.

In the area of cyclobutadienosuperphanes, variation of the complexing agent appears to be synthetically promising. As mentioned above, ester groups in the CpCo fragment markedly increase the selectivity of cyclodiyne dimerization by double [2+2]cycloaddition. Systematically fitting the complex ligand with substituents may not only allow an extention of the scope of superphane synthesis but also provide functionalities that are suitable for further transformations in the outer sphere. For example, the metal-stabilized dication species **122** might be derived from diester **105**.



124 **122**



123

On the other hand, side products formed by insertion (**56**, **58**, **113**) indicate variability with respect to the π centers as well. Consequently, new attractive goals such as $[3_4]$cyclopentadienonosuperphane **123** can be specifically approached.

Financial support by the Deutsche Forschungsgemeinschaft (SFB 247), the Volkswagen-Stiftung, the Fonds der Chemischen Industrie, and the BASF AG, Ludwigshafen, is gratefully acknowledged. M. M. thanks the Studienstiftung des Deutschen Volkes for a graduate fellowship. We thank all members of the group mentioned in the references for their experimental and intellectual contributions. Thanks are also due to our colleagues H. Irngartinger, B. Nuber, and M. L. Ziegler for numerous X-ray structures analyses.

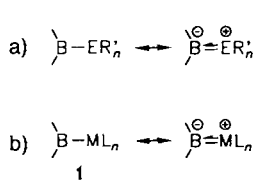
Boryl Metal Complexes, Boron Complexes, and Catalytic (Hydro)boration

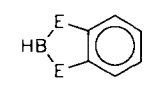
Hubert Wadepohl*

Boryl metal complexes had had a long run-up, and are now moving from the confines of boron chemistry into the spotlight of a much broader range of chemical interest. Their story began in the early 1960s, when Nöth and Schmid reported the first complexes in which a boryl group (BR_2) is directly bonded to a transition metal (M) through the boron atom.[1] In 1970 Schmid deduced that "Covalent bonds between boron and metals and boron and nonmetals are similar in character", and consequently derived a description of boryl metal complexes as simple borane derivatives $[R_2BML_n]$ (**1**).[2] Analogous to the (p → p) π contributions characteristic of many nonmetal–boron bonds (Scheme 1a), (d → p) π contributions are possible for transition metal–boron bonds (Scheme 1b), and, therefore, the BR_2 group can also be regarded as a complex-stabilized "pseudo-carbene".[3] The extent of such a π interaction between a metal and a boron atom is still disputed today, and of course it depends on the remaining ligands on the metal atom and on the substituents on the boron atom, all of which must compete with the electrophilic boron center for the π electrons.[4]



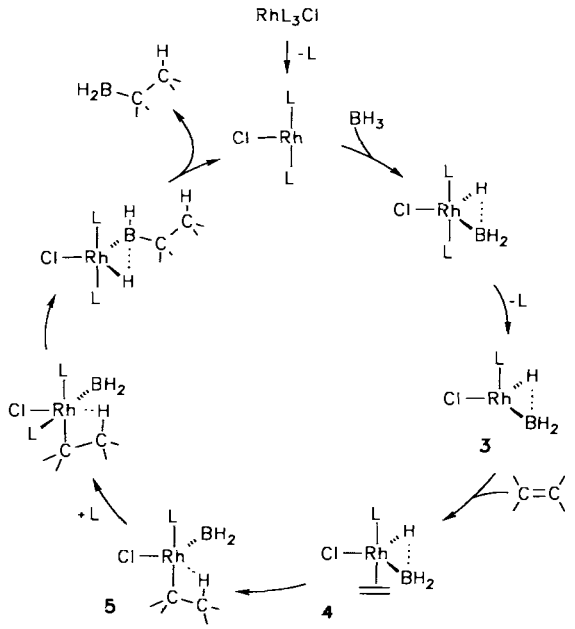
Scheme 1. a) Nonmetal–boron bonds and b) transition metal–boron bonds.

Early work soon fell into oblivion, perhaps because none of the boryl metal complexes could be crystallized and analyzed by X-ray crystallography, and because the spectroscopic methods of the time could not always characterize them to present standards.[5] It was not until 1985 that interest in boryl metal complexes was reawakened, this time as postulated intermediates, and they were reported once again by Nöth's research group.[6] Described in their contribution, a milestone of boron chemistry, is the first use of rhodium-complex catalysts to mediate the hydroboration of olefins by benzo-1,3,2-dioxaborolane (catecholborane, *H*Bcat, **2**) which otherwise reacts very sluggishly. There is no question about the importance of hydroboration in organic syntheses; the value of the catalytic variant lies not only in the activation of less reactive boranes, which are therefore easy to handle and store, but also in the controlling of the selectivity of the reaction. Already in this initial work, chemoselectivity was found: In unsaturated ketones, it is the C–C double bond and not the keto group which undergoes catalytic hydroboration. This is in contrast to the situation for the noncatalytic variant. Enantio-, regio-, and diastereoselective hydroborations are also known today.[7, 8]



HBcat **2**, E = O
HBOp **19**, E = NH

Among the catalysts, complexes of late transition metals form the major group. Of these, hydridoboryl metal complexes, formed by oxidative addition of the borane to a coordinatively unsaturated metal center, play a key role. There are extensive high-level theoretical investigations of the reactions catalyzed by Rh^I. However, there still remain some differences in opinion over certain details of the mechanism. These boil down to the question of whether the olefin inserts into the M–H or the M–B bond in the key step. Schleyer et al.[9] favor a dissociative reaction pathway (Scheme 2), with an initial transfer of a hydrogen



Scheme 2. Simplified catalytic cycle for hydroboration with the Rh^I catalyst according to calculations by Schleyer et al. [9].

atom onto the olefin (**4** → **5**). It is possible that there is an intermediate **3** with 14 valence electrons. On the other hand, Morokuma et al.[8] favor the migration of a boryl group (Scheme 3, **6** → **7**). Experimental (kinetic) results appear to be more in line with the first possibility.[10]

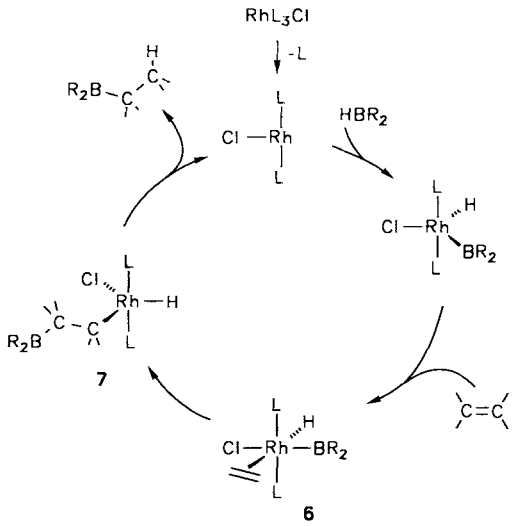
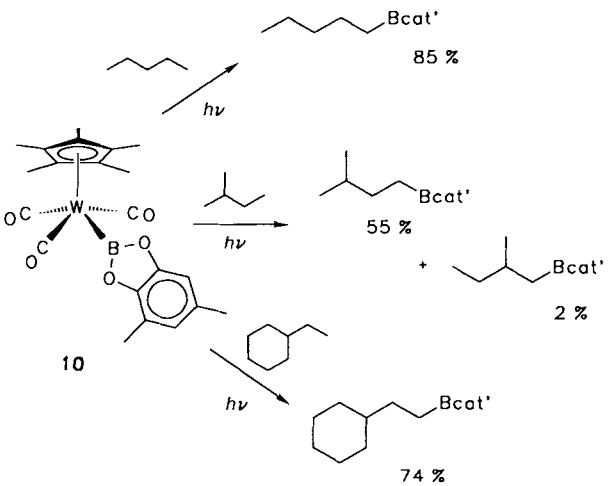


Scheme 3. Simplified catalytic cycle for hydroboration with the Rh^I catalyst according to calculations by Morokuma et al.[8].

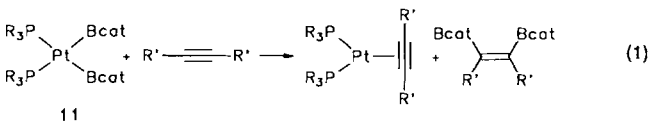
The great potential of catalytic (hydro)boration of unsaturated C–C bonds has led to intensive research in the synthesis and, above all, the chemistry of boryl metal complexes in recent years.[11] Some reactions have been discovered in which even saturated hydrocarbons can become functionalized! This was found upon irradiation of the complexes $[(C_5Me_5)M(Bcat')(CO)_2]$ (**8**, M = Fe; **9**, M = Ru), and $[(C_5Me_5)W(Bcat')(CO)_3]$ (**10**) in alkanes (Bcat' = 3,5-dimethylcatecholboryl):[12] In highly selective stoichiometric reactions with alkanes, esters of boronic acid (alkyl-Bcat') are formed in which the catecholboryl group (Bcat') has replaced a hydrogen atom in the sterically least hindered, primary position of the alkane (Scheme 4). These



Scheme 4. Functionalization of saturated hydrocarbons with complex **10**.

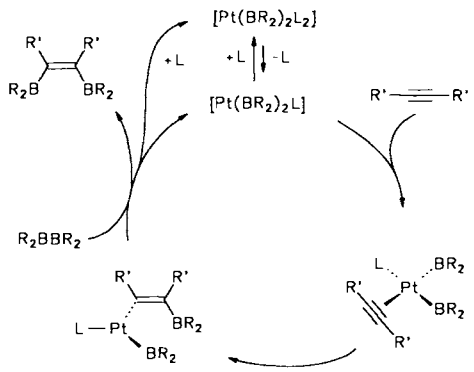
reactions probably proceed via coordinatively unsaturated intermediates $[(C_5Me_5)M(Bcat')(CO)_{n-1}]$ (M = Fe, Ru, $n = 2$; M = W, $n = 3$), which can undergo either M–B/C–H σ-bond metathesis or oxidative addition of the alkane with subsequent reductive elimination of the borylated alkane. The major primary organometallic products are the photolabile hydrido complexes $[(C_5Me_5)MH(CO)_n]$, which then react further to give the binuclear complexes $[\{(C_5Me_5)M(CO)_n\}_2]$. It is not surprising that the high selectivity of the reaction towards sp^3 C–H bonds only then occurs if, as found for the Bcat'-complexes, no sp^2 C–H bonds are sterically accessible. Therefore, with $[(C_5H_5)Fe(Bcat)(CO)_2]$ and similar complexes, the more reactive C–H bonds of arenes can be functionalized, but not those of alkanes (in the absence of other arenes the phenylene ring of the catecholboryl ligand of a second molecule is probably attacked).[13]

Upon addition of diborane(4) derivatives (R_2BBR_2) C–C multiple bonds can be diborylated. Although this reaction, also known as boraborylation, has been known for a long time,[14] its usefulness in organic synthesis is severely limited by the fact that reactive tetrahalodiboranes(4) are rather unstable and hard to come by; the more readily obtainable tetraalkoxydiboranes(4) ($(RO)_2BB(OR)_2$) do not react. Again, a transition metal center can induce the desired activation, in the form of complexes with two boryl ligands. Indeed, *cis*-diboryl metal complexes such as **11** react stoichiometrically with alkynes to give *cis*-1,2-diborylalkenes [Eq. (1)].[15] The diborylation of



(1)

alkynes, for example catBBcat also proceeds under catalytic conditions; here, **11** shows greater activity[15b,16] than $[Pt(PPh_3)_4]$,[17] from which the precatalyst **11** is formed during the reaction. The experimental results show that, in contrast to the originally proposed mechanism,[17] the dissociation of phosphane from $[Pt(BR_2)_2L_2]$ (e. g. **11**) is a critical reaction step (Scheme 5).[15,16] Initially, monoolefins could not be diborylat-



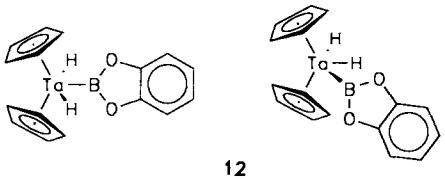
Scheme 5. Postulated catalytic cycle for the diboration of alkynes with Pt complexes.

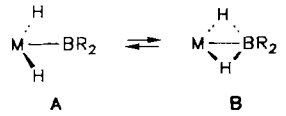
ed with platinum catalysts. With typical Rh hydroboration catalysts, such as $[RhCl(PPh_3)_3]$, only a mixture of products was obtained in which products of β-hydrogen elimination dominated.[18] The β-elimination could be suppressed with an electron-rich Au^I catalyst (obtained in situ from $[AuCl(PEt_3)]$ and two equivalents of $(cHex_2PCH_2)_2$. However, this system only functioned with a few activated alkenes, such as vinyl- or allylbenzene, as the substrates.[18] If the dissociation of a phosphane ligand from **11** is decisive for the activation of the catalyst, then phosphane-free catalyst systems should be much more active. This was confirmed for the diborylation of 1,3-dienes with Pt

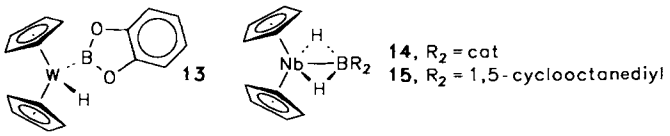
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2442 $ 17.50+.50/0

complexes as the catalysts:[19] $[Pt(dba)_2]$,[20] $[Pt(cod)_2]$,[21] and $[Pt(norbornene)_3]$[21] indeed catalyzed the diborylation of α-alkenes and some strained cycloalkenes (dba = dibenzylideneacetone, cod = (*Z*,*Z*)-1,5-cyclooctadiene)!

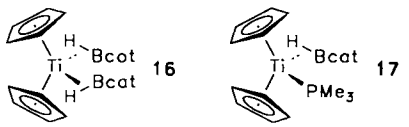
The use of organolanthanide complexes[22] and some complexes of the early transition metals[23–25] as hydroboration catalysts provide interesting perspectives for controlling selectivity. Several recent publications illustrate the particular features of the interaction of boranes with electron-poor transition metals: Whereas the oxidative addition of the B–H bond onto the metal center is characteristic of the late transition metals, in the complexes of early transition metals the type of bond between the borane and the metal center is very variable. Thus, the tantalum complexes **12** are genuine hydridoboryl complexes (structure type **A**);[26] this is also valid for tungsten complex **13**.[27] On the other hand, the NMR spectra and their changes upon deuteration of the niobium complex **14** were interpreted in terms of an equilibrium between two isomers in solution: structure type **A** (hydridoboryl complex) and **B** (hydridoborate). The crystal structure tends towards type **A**, whereas the structure of the 9-BBN derivative **15** is closer to **B** in the solid state.[27]







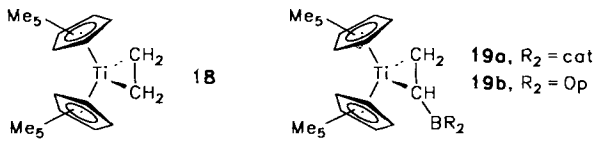
In complexes **16**[28] and **17**,[29] synthesized by Hartwig et al., the ligands are coordinated to the metal atom in a "side-on" fashion by their B–H bonds. This is shown by the spectroscopic



data measured in solution (high-field position and coupling to boron of the bridging hydrogen atoms in the ^1H NMR spectrum, low-frequency shift of the B–H stretching mode in the IR spectrum). The bridging hydrogens atoms were localized in X-ray crystal structure analyses: They are bound to both B and Ti. Acute B-Ti-H angles and large Ti–B distances indicate the presence of a (weakened) B–H bond. Until now, such σ complexes[30] were known only with η^2-H–H[31] and η^2-Si–H bonds.[32] With alkanes, there is only indirect evidence for this type of bonding, for which a role in C–H activation is ascribed.[33] However, its "intramolecular" variant, agostic C–H coordination, is wide-spread.

Based on MO calculations, the authors give a reason for the (relative) stability of the borane σ complexes: In addition to the donor function of the B–H σ bond there is the acceptor function of a p orbital on the boron atom (or better, of the LUMO of the borane, which is bonding with respect to B–H, but π-antibonding with respect to B–O).[28] The LUMO of the borane fits much better energetically than a σ* orbital of an alkane to the HOMO of the metal fragment, and allows therefore greater backbonding. This should also be valid for the (so far unknown) σ complexes with η^2-C–H(aromatic) coordination; this could be the reason for the easier activation of such bonds on the metal center. Addition of H_2SiPh_2 to **17** gives rise to an equilibrium between **17** and $[(C_5H_5)_2Ti(PMe_3)\{\eta^2\text{-}(HSi)HPh_2\}]$, which lies more on the side of the borane complex. The σ borane complex is therefore more stable than the σ silane complex, which is understandable in terms of the above-mentioned bonding mechanism and the greater Lewis acidity of boron. Likewise, it is not surprising that the borane ligands in **16** and **17** are much more active than in the free state; they stoichiometrically hydroborate alkynes and imines under very mild conditions.

In the rhodium-catalyzed hydroboration of alkenes to alkylboranes, "dehydrogenating borylation" often occurs as a side reaction, in which alkenyl boranes are formed (formal B–H/C–H bond metathesis).[34] Recently, Smith et al. succeeded in performing this reaction selectively with ethylene as the substrate and a titanium catalyst.[35] The same research group had already found that $[(C_5Me_5)_2Ti(\eta^2\text{-}CH_2{=}CH_2)]$ (**18**) reacts with catecholborane to produce **19a** with an η^2-vinyl-



borane as a ligand.[36] Apparently, β-hydrogen elimination from the postulated primary product (**20** → **21**, Scheme 6) is more favorable than reductive elimination of an alkylborane. Additional products were ethane and $[(C_5Me_5)_2Ti]$. The latter is known to react with ethylene to give **18**, so that a closed cycle of stoichiometric reactions is formed. Under catalytic conditions, however, the catalyst decomposed to give a mixture of various Ti species, which led finally to only the usual hydroboration product CH_3CH_2Bcat. Therefore, the problem was to decrease the rate of the unproductive catalyst decomposition relative to that of regeneration of the ethylene complex **18** (**19** → **18** in Scheme 6). A simple modification of the borane—exchanging the dialkoxyborane (HBcat, **2**) for the isoelectronic diaminoborane benzo-1,3,2-diazaborolane (HBOp **22**)—already gave the desired results.[35] Owing to the stronger B–N bonds and the lower B–H activity, the stability of the catalytic species should be increased and its decomposition, for example by borylation of the vinylborane ligand in **19**, should be retarded. However, along with this effect, modification of the borane caused an unexpected, drastic acceleration of the reaction of **19** with ethylene (>90% turnover in <5 min at −80 °C for **19b**

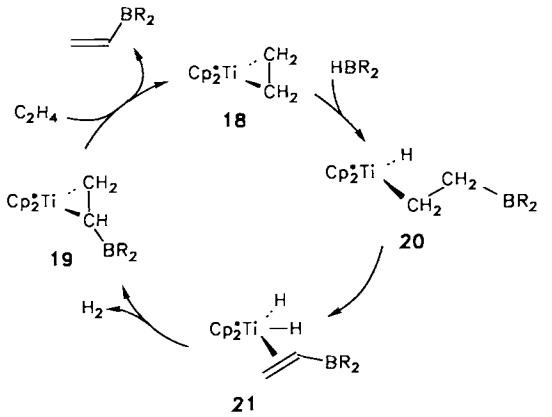

Scheme 6. Postulated catalytic cycle for the "dehydrogenative borylation" of ethene with a titanocene complex (Cp* = tetramethylcyclopentadienyl). The dihydrogen produced in step **21** → **19** reacts selectively with **18** to give ethane and "[Cp*$_2$Ti]", which reacts with ethylene to regenerate the catalyst **18**.

versus 40% turnover in 72 h at 25 °C in the case of **19a**). This very ligand exchange, in which the vinylborane is liberated and **18** regenerated, is the "bottle neck" of the catalytic cycle (Scheme 6).

These examples show, that even established reactions such as hydroboration can provide new facets if transition metals are brought into play. The end is not yet in sight. For example, Gladysz, Horváth et al. recently reported in this journal a new "environmental friendly" variation of Rh-catalyzed hydroboration, in which very high turnovers and excellent recovery of the catalyst was achieved by fluoric two-phase catalysis (with Wilkinson's catalyst modified by fluoroalkyl groups in a fluorinated solvent).[37] Numerous other novel types of reaction, related to those described here, are not usable without a catalyst. Silyl-,[38] stannyl-,[39,40] and sulfanylborations[41] as well as boron cross-couplings[42]—all of which yield valuable building blocks for organic and organometallic synthesis—may be named as examples. Boryl metal complexes play an important role as intermediates in all of them. With regard to new types of structures, the combination metal complex/borane continues to produce novelties, so that one can look forward to further developments.

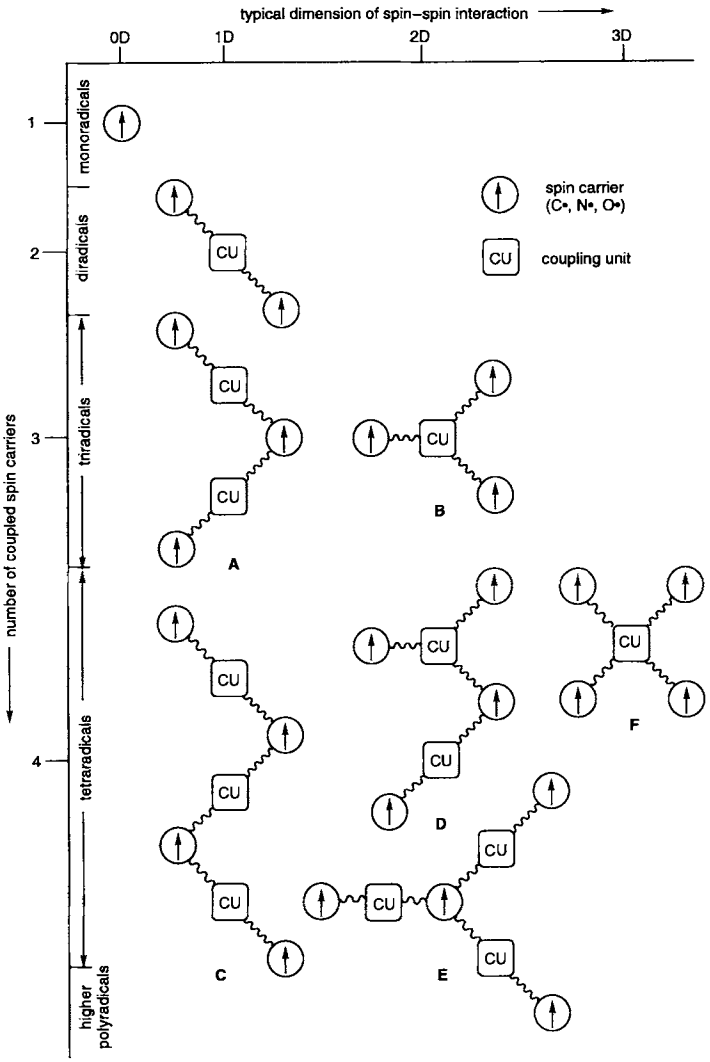
Organic Tri- and Tetraradicals with High-Spin or Low-Spin States

Werner M. Nau*

When carbon, nitrogen, or oxygen atoms carrying an unpaired electron ("spin carriers") are linked through a coupling unit (CU) and incorporated into an organic molecular framework, polyradicals result. After the appearance of the most recent reviews on polyradicals and related structures with unpaired electrons, for example polycarbenes,[1] the design of novel tri- and tetraradicals, the lowest homologues, has been actively continued.[2–11] The fascination arises not only from the idea of using them as building blocks for larger polyradicals with potential practical applications[1, 7] and the interest of ESR spectroscopists in such model systems, but also from the structural and synthetic challenges as well as the aesthetic appeal they present. The possible topologies of tri- and tetraradicals are shown in Scheme 1. The introduction of three or four spin carriers into a molecular framework allows two- or three-dimensional spin–spin interactions, which are required for desirable bulk properties such as ferromagnetism.[1]

Scheme 1 represents the spin coupler's toolbox, since the building blocks **A**–**F** contain all the relevant topological information for constructing higher polyradicals. Although the jury is still out as to which of the candidates **A**–**F** will first be a practically applicable magnetic material, examples for all but one type are known to date: Triradicals **1**[1a] and **2**[2] correspond to type **A**, triradicals **3**–**5**[3, 4a, 5] to type **B**, tetraradicals **6**–**11**[6, 7, 8a, 9–11] to type **C**, and tetraradicals **12**[1e] and **13**[1b] to types **E** and **F**, respectively. No example has been reported for **D**, the type of lowest symmetry, but it is contained as a substructure in higher polyradicals.[10] Interestingly, the simplest derivative of type **F**, the tetramethylenemethane tetraradical $C(R_2C^{\bullet})_4$, has remained elusive.

Types **A** and **C** are chain-like homologues. Open chains lead to linear structures such as **6**–**9**, whereas linking the ends of the chain results in cyclic structures (for example **10** and **11**), which display distinct properties.[1e, 2] In contrast, **B**, **D**, and **F** are derived from branching at a coupling unit. In tetraradicals there is also the possibility for branching at a spin carrier (**E**) rather than at a coupling unit (**D** and **F**). Valence considerations for type **E** restrict the maximum connectivity at a carbon or nitrogen radical center to three (one unpaired electron and three free valences for branching), whereas no branching is possible for an oxygen atom as the spin carrier. However, the use of complexing metal centers as coupling units, akin to that in compound **11**, could be employed to bypass such valence limitations.[4b, 11] On the other hand, the connectivity at the coupling units is not restricted to structures like **B** and **F** but limited only by the fantasy of the synthetically inclined polyradical engineer, who may employ higher conjugated cyclic polyenes or even fullerenes. Types **B**, **E**, and **F** constitute the core of "dendritic" polyradicals.[1e]



Scheme 1. Possible topologies of tri- and tetraradicals.

Generally speaking, the formation of structures **A**–**F** requires homolytic cleavage of three or four chemical bonds, or three or four one-electron oxidation or reduction steps. Experimentally, there appear to be four basic strategies for achieving this goal, the choice of which depends on the type of spin carrier and the coupling unit. First, oxidation of carbanions,[2, 5, 10] or amines[3] [Eqs. (1a) and (1b)] was used to access structures **2**, **3**,

analogously for introducing more than one oxygen spin carrier (structures **1**, **4**, and **13**).[1, 4] The resulting "stable free tri- and tetraradicals",[1h] like some of the Gomberg-type derivatives with triaryl-substituted spin sites,[2, 3, 5, 10] are chemically stable at ambient temperature and relatively insensitive towards oxygen, an important aspect for potential practical use.

Coupling units may promote parallel or antiparallel spin alignment by a variety of electronic mechanisms (orthogonal orbitals, superexchange, and spin-polarization).[1] A parallel alignment leads to "ferromagnetic" or "high-spin" coupling, whereas an antiparallel orientation results in "antiferromagnetic" or "low-spin" behavior. From the application point of view, high-spin polyradicals could be useful as organic ferromagnets,[1] and most of the tri- and tetraradicals **1**–**13** have been studied in this context. Conversely, some low-spin polyradicals, for example those derived from the singlet tetraradical **14**, have recently been suggested to support electric conductivity.[7]

In open-chain tri- or tetraradicals the exclusive use of ferromagnetic coupling units gives rise to quartet ($S = 3/2$) or quintet spin states ($S = 2$) as ground states, as is the case for **1** and **2** (type **A**) or **6** and **9** (type **C**). In contrast, not all coupling units need to be antiferromagnetic to produce low-spin states. For example, to construct singlet ($S = 0$) tetraradicals of type **C** (three coupling units), it is sufficient to confer antiferromagnetic character either to the two outer coupling units (**14**)[8b] or only to the central unit (**15**).[7] Analogously, in triradicals of type **A** already a single antiferromagnetic coupling unit favors low-spin doublet states ($S = 1/2$). When all three electron spins in triradicals of the *cyclic* type **A** (or of type **B**) are antiferromagnetically coupled, an interesting situation arises. At least two electrons must be aligned in a parallel fashion—despite the antiferromagnetic interaction between them— such that a "spin-frustrated" system with two virtually degenerate low-spin (doublet) ground states may result. This exceptional phenomenon was recently described for structure **4**.[4a]

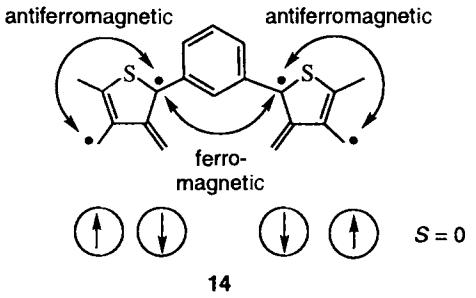
Experimental and theoretical studies[8, 12] demonstrated that the ferromagnetic or antiferromagnetic properties of various coupling units do not always follow intuitive or readily pre-

5, **10**, and **12**; the required intermediate carbanions are obtained by deprotonation of triarylmethanes,[5] or by reduction of triarylmethyl ethers with lithium in tetrahydrofuran.[2, 10] Since this procedure appears to be restricted to triaryl-substituted spin carriers, the second method, which employs photolysis of bisazoalkanes, is complementary [Eq. (2)]; the resulting hydrocarbon tetraradicals **6**–**9**,[6–9] however, are persistent only in low-temperature glasses. Third, reduction of aromatic ketones to produce ketyl radical anions [Eq. (3)] can be extended to generate tetraradicals such as **11**.[11] Of course, the well-established synthetic sequences for preparing "stable free radical" units such as nitroxide and galvinoxyl [Eq. (4)] can be used

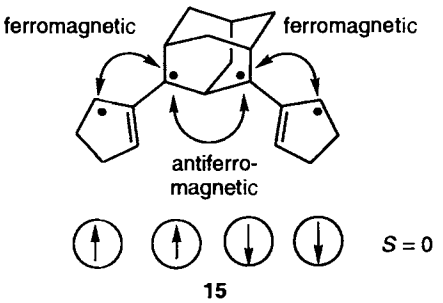
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2446 $ 17.50+.50/0

dictable trends. The methylene group is the simplest coupling unit and, depending on the conformation, may give rise to ferromagnetic or antiferromagnetic coupling;[8b] difluoro substitution of the methylene group promotes the latter.[12b] The *m*-phenylene coupling unit has been most extensively employed (see **1**–**12**) due to its robust ferromagnetic coupling properties, synthetic compatibility, and the possibility of 2D spin–spin interaction through the 1,3,5-substitution pattern (Mataga polymer).[1] Moreover, the ferromagnetic coupling of *m*-phenylene can be modified by conformational constraints,[8c] aryl substituents,[4a, 12a] and the use of heteroaromatic analogues or ionic derivatives.[8a] Such magnetic fine-tuning promises some interesting twists in the design of more sophisticated structures. While the selection of the coupling unit is crucial for controlling spin multiplicity in tri- and tetraradicals, the type of spin carrier (C˙, N˙, O˙) appears to be less important, at least for *m*-phenylene as the coupling unit. Hence, even the hetero-substituted triradical cation **3** and the tetraradical anion **11** exhibit high-spin ground states, just as their neutral analogues **5** and **10**.

Tri- and tetraradicals can be conveniently observed and identified by ESR spectroscopy, with the exception of ESR-silent singlet tetraradicals such as **14** and **15** (here, the absence of ESR signals was taken as evidence for their singlet multiplicity).[7, 8b]



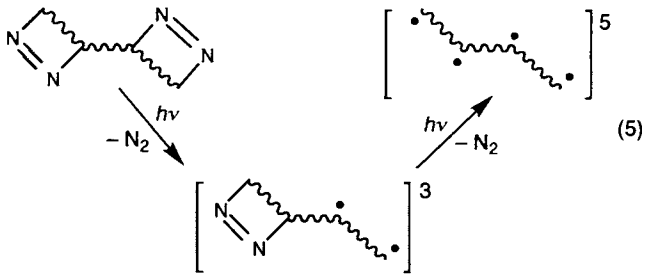
14



15

Quartet and quintet states produce very distinct ESR spectra, which yield the zero-field splitting parameters characteristic of tri- and tetraradicals, and provide a sensitive probe for their detection. In addition, the temperature dependence of the intensity of the ESR signal (Curie plot) can be employed to establish the quartet or quintet state as the ground state, and, in some cases, to estimate the energy gaps to the lower spin states (that is, the doublet of a triradical or the triplet and singlet of a tetraradical).[3, 8b]

The assignment of ESR spectra to high-spin tri- and tetraradicals is nowadays facilitated by computer simulations. Conversely, experimental high-spin ESR spectra were crucial for refining theoretical models of spin–spin interactions and accurately predicting the resulting ESR features.[6–10] The ESR spectra produced upon photolysis of bisazoalkanes[6–9] are particularly instructive, because stepwise nitrogen extrusion—that is, pairwise formation of spin carriers—produces first the triplet diradical ESR spectra [Eq. (5)], unless the diradicals have



(5)

singlet ground states.[7, 8b] Discernible spectral changes are observed upon prolonged irradiation, which can be convincingly assigned to the quintet tetraradicals; ideally, all of the intermediate triplet diradicals are converted into the tetraradicals, leaving behind the pure quintet ESR spectra.

Magnetization studies offer another means of characterizing the high-spin character of tri- and tetraradicals, and constitute the greatest hurdle for any polyradical as far as potential applications as an organic ferromagnet are concerned. Depending on the applied magnetic field, the amount and magnetic moment of paramagnetic molecules, and the temperature, the spins in a sample align and the degree of alignment can be measured as magnetization or magnetic susceptibility.[1] Plotting the data according to theoretical functional relationships allows one to extract the spin multiplicity of a tri-, tetra-, or higher polyradical. Deviations from the expected magnetization functions were interpreted in terms of 1) molecular defects, 2) thermal equilibration between different spin states, and 3) concomitant *intermolecular* coupling between the paramagnetic molecules.[1, 10] This last effect is the stumbling block for many organic tri- or tetraradicals, since intermolecular coupling is often antiferromagnetic in nature,[1a, 11] which makes their practical use as organic ferromagnets questionable. This limitation necessitates the design of higher and truly 3D polyradicals, or, as alternative, warrants suitable crystal packing[1c, 13] and metal-coordinating strategies[4b, 11] to ensure ferromagnetic coupling even in the absence of covalent molecular connectivity.

The tropidinyl (trop) group is a novel ligand that is isoelectronic with cyclopentadienyl (Cp), and is derived from a readily available natural product. It can be used to synthesize zirconium complexes that are analogous to metallocenes. When activated with methylalumoxanes they function as catalysts for ethylene polymerization. More about the synthesis and properties of this new class of complexes is reported by R. G. Bergman and G. G. Lavoie on p. 2450ff.

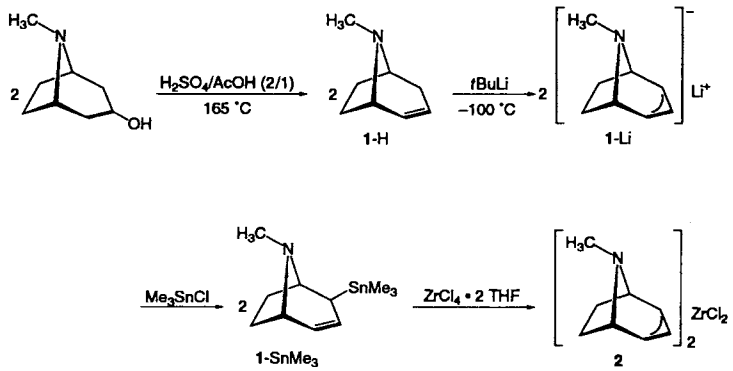
Synthesis, Structural Characterization, and Reactivity of Novel Zirconium(IV) Complexes Containing the Tropidinyl Ligand**

Gino G. Lavoie and Robert G. Bergman*

Cyclopentadienyl (Cp) and bis(cyclopentadienyl) complexes have played an enormous role in the development of fundamental and practical organometallic chemistry.[1] The use of metallocene catalysts for Ziegler–Natta polymerization of alkenes,[2] one of the most important recent advances in the latter area, has generated interest in the synthesis of ligands that are isoelectronic with Cp but might confer different properties (e. g., different rates or selectivities) on the derived metal complexes.

The conception of the Cp group as a delocalized three-electron anionic allyl ligand combined with a two-electron neutral alkene ligand raises the possibility of combining the allyl group with other two-electron donors to give complexes that would be isoelectronic with, but less symmetrical than, Cp complexes. However, allyl complexes of early transition metals often have low thermal stability.[3,4] We therefore sought a system in which an anionic allyl ligand is connected by two bridges to a neutral two-electron donor,[5] in the hope that this would make the derived organometallic materials more robust. We now report the execution of this idea in the synthesis of complexes derived from the readily available bicyclic molecule tropidine (**1**-H, Scheme 1). The advantages of **1** are that 1) the ligand derived



Scheme 1. Synthesis of **2** from tropine.

from it has separate 2σ- and 4π-electron donor sites, 2) the presence of the two-carbon bridge helps to localize the allyl functionality in a specific part of the molecule and prevents loss of the ligand by β-hydride elimination (Bredt's rule),[6–8] and 3) the ligand lacks groups that allow easy deactivation by cyclometallation (intramolecular C–H activation). To our knowledge, this is the first report of coordination of this ligand to a transition metal center.

Tropidine (**1**-H) can be readily obtained by dehydration of tropine under strongly acidic conditions (Scheme 1).[9] The allylic position was deprotonated by treating the bicyclic compound with a strong base such as *tert*-butyllithium at low temperature.[10] Subsequent addition of trimethyltin chloride to the lithium salt of the tropidinyl (trop) anion (**1**-Li) yields the stannylated compound **1**-$SnMe_3$ in good yield. Addition of two equivalents of **1**-$SnMe_3$ to a solution of $ZrCl_4 \cdot 2THF$ in dichloromethane gave the desired disubstituted zirconium complex $[(trop)_2ZrCl_2]$ (**2**) in 59% yield (Scheme 1). Other methods involving reaction of **1**-H or the corresponding silylated derivative with Zr^{IV} precursors such as $[Zr(NMe_2)_4]$, $[Zr(OtBu)_4]$, or $[Zr(CH_2Ph)_4]$ did not give the expected product, even at elevated temperature. Similarly, addition of the trop anion to Zr^{IV} starting materials led only to mixtures of unidentified complexes.

The ^1H NMR spectrum of **2** in CD_2Cl_2 shows a very simple pattern, which suggests that the complex may have C_2 symmetry. The solid-state structure was solved on a single crystal by direct methods[11] and expanded with Fourier techniques[12] (Figure 1).[13] Surprisingly, the complex has a C_1-symmetric structure in which the trop ligands are rotated by 76.86° with respect to one other. The trop ligand labeled C1, C2, C3, C8, N1 is bound symmetrically to the metal center. In contrast, the other trop ligand is unsymmetrically bound to zirconium, as evidenced by different bond lengths for Zr1–C9 and Zr1–C11. The Cl1-Zr1-Cl2 bond angle of 100.89(3)° is slightly more obtuse than the corresponding angle of 97.1° in $[Cp_2ZrCl_2]$.[14] The Zr1–Cl1 and Zr1–Cl2 bond lengths of 2.5051(8) and 2.5089(8) Å, respectively, are somewhat longer than that of 2.44 Å in zirconocene dichloride.[14]

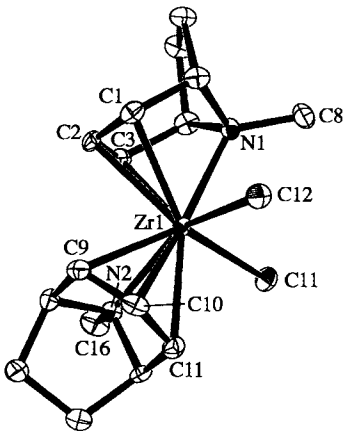


Figure 1. ORTEP plot of **2**. Selected bond lengths [Å] and angle [°]: Zr1–Cl1 2.5051(8), Zr1–Cl2 2.5089(8), Zr1–C1 2.537(3), Zr1–C2 2.518(3), Zr1–C3 2.523(3), Zr1–C9 2.493(3), Zr1–C10 2.595(3), Zr1–C11 2.595(3), Zr1–N1 2.353(3), Zr1–N2 2.369(3); Cl1-Zr1-Cl2 100.89(3).

The discrepancy between the solid-state structure and the observed ^1H NMR spectrum led us to investigate the fluxional behavior of **2**. A series of variable-temperature ^1H NMR (300 MHz) spectra were collected. These revealed strongly fluxional behavior, which resolved into a spectrum exhibiting nonequivalent trop ligands at −90 °C. The spectrum at −90 °C is consistent with the X-ray structure. The decoalescence of the central allylic protons at −48 °C indicates a free energy barrier for rotation of the trop ligands of 19 kcal mol^{-1}.

We carried out some preliminary reactivity studies on **2**. Addition of two equivalents of methyllithium gave the yellow dimethylzirconium complex $[(trop)_2ZrMe_2]$ (**3**, Scheme 2). As in the dichloride **2**, a simple pattern was observed in the room-temperature ^1H NMR spectrum of **3**. In contrast to **2**, however, no decoalescence of the signals was observed when **3** was cooled to the freezing point of dichloromethane.

Complex **3** was characterized by X-ray crystallography.[13] As in **2**, the trop ligands are related by no symmetry element, but are rotated with respect to one another by 87.71°, more than 10° greater than in **2**. We are unsure why the energy barrier for rotation of the trop ligands in **3** is substantially lower than that in the corresponding dichloride **2**. The Zr–trop bonds are also longer than those in **2**. The Zr–Me bond lengths and the Me-Zr-

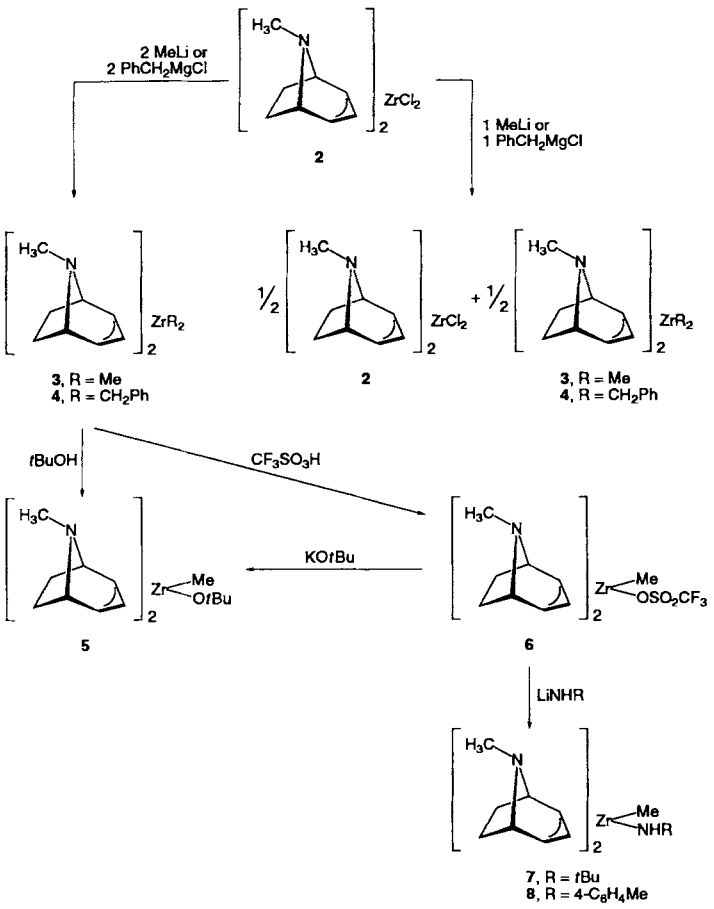

Scheme 2. Ligand-substitution reactions of **2**.

Me bond angle are 2.316(2) and 2.315(2) Å, and 95.75(9)°. These values are similar to those reported for dimethylzirconocene [2.280(5) Å and 2.275(5) Å, 95.6(12)°].[15] Complex **3** was unstable when placed under prolonged dynamic vacuum, and an uncharacterized white powder formed.

Addition of two equivalents of benzylmagnesium chloride to **2** gave the expected bis(benzyl)zirconium derivative **4**. The NMR spectrum shows apparent C_2 symmetry, but a recently determined X-ray structure of **4**[13] shows nonequivalent trop ligands analogous to those in **2** and **3**. When only one equivalent of methyllithium or benzylmagnesium chloride was added to **2**, a 1:1 mixture of **2** and the corresponding bis(alkyl)zirconium derivative was obtained.

Protonolysis of **3** with *tert*-butyl alcohol at room temperature gave the yellow complex **5** in quantitative yield. Treatment of **3** with *tert*-butylamine did not yield the corresponding *tert*-butylamido complex. Heating the reaction mixture to 77 °C led to decomposition of **3** prior to formation of the desired product **7**. The latter could, however, be prepared in 95% purity (92% yield) by protonation of **3** with one equivalent of trifluoromethanesulfonic acid to give **6** and subsequent addition of one equivalent of LiNH*t*Bu. Similarly, **8** and **5** can be synthesized by addition of the corresponding nucleophile to **6**. As was observed for **3**, placing **8** under vacuum for one hour led to decomposition to an uncharacterized white powder.

Preliminary experiments were carried out on the use of $[(trop)_2ZrX_2]$ complexes as polymerization catalysts. Addition of a large excess of methylaluminoxane (MAO) to a solution of **2** in toluene under an ethylene atmosphere gave a purple solution that was active for the polymerization of this alkene. The measured polyethylene productivity of 17 $kg\,mol^{-1}\,h^{-1}$, as determined by comparative studies, was roughly 14 times slower than ethylene polymerization by $[Cp_2ZrCl_2]$/MAO under the same conditions.[16] Further studies will be required to determine whether the trop ligands remain attached to the metal during polymerization, although the fact that $[(trop)_2ZrMe_2]$ retains these ligands on treatment with trifluoromethylsulfonic acid suggests that the trop—Zr bond is robust.

Straightforward synthetic routes can be devised for attaching substituents to the trop rings and for linking two trop ligands together to produce *ansa* analogues of the materials described here. Such studies are under way, as is the development of methods for attaching trop ligands to other metal centers.

Experimental Section

Synthesis and analytical data on complexes **1**-$SnMe_3$, **2**, **3**, and **4** are given here. Data on complexes **5**–**8** will be provided elsewhere.

Safety note: Because of the high toxicity of tin compounds and the high neurological activity of tropidine derivatives, all work must be performed in a well-ventilated working area and skin contact prevented with protective clothing and gloves.

1-$SnMe_3$: *tert*-Butyllithium (1.7 M in pentane, 52 mL, 88 mmol) was added dropwise over 15 min to tropine [9] (10.7 g, 88.9 mmol) in pentane (500 mL) at −100 °C. Deprotonation was allowed to proceed at −80 °C for 3 d. The resulting mixture was then cooled to −100 °C, and trimethyltin chloride (1 M in hexane, 104 mL, 104 mmol) was added over 15 min. The pale yellow solution immediately turned white with concomitant precipitation of white solid. The flask was warmed to room temperature over 1 h, and the mixture stirred for an additional 30 min. Water (100 mL) was carefully added, and the organic materials were extracted with pentane. The combined organic extracts were washed with brine and dried over sodium sulfate. The solvents were removed under water aspirator pressure, and the residue was distilled under vacuum (3 mtorr) at 50 °C to give 11.2 g (45%) of **1**-$SnMe_3$. ^1H NMR (C_6D_6): δ = 5.52 (m, 2H, olefinic), 3.13 (m, 1H, bridgehead), 3.04 (br s, 1H, bridgehead), 2.42 (s, 4H, N*Me* and C*H*$SnMe_3$), 2.07 (m, 2H, CH_2), 1.81 (m, 1H, CH_2), 1.46 (m, 1H, CH_2), 0.06 (s, 9H, $SnMe_3$; further split by 8.7 and 7.7% of ^{119}Sn and ^{117}Sn, respectively; J = 25.5 Hz); $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 127.3, 127.1 (olefinic), 60.1, 58.7 (bridgehead), 36.7 (C7 or C8), 34.8 (NMe), 33.1 (C7 or C8), 30.5 (*C*H$SnMe_3$), −10.1 ($SnMe_3$); HRMS: *m/z* calcd for $C_{11}H_{21}N_1Sn$: 287.0696; found: 287.0702.

2: A Schlenk flask was charged with a solution of $ZrCl_4 \cdot 2THF$ (758 mg, 2.01 mmol) in dichloromethane (25 mL). **1**-$SnMe_3$ (1.16 g, 4.02 mmol) was added over 5 min with stirring. The solution immediately turned orange and was stirred for 4 d at room temperature. The reaction mixture was filtered, and the solid washed with dichloromethane. The volatile materials were removed in vacuo, and the residue was washed thoroughly with pentane and then extracted with toluene. The solvent was removed in vacuo to give 478 mg (59%) of an analytically pure, fine orange powder. ^1H NMR (CD_2Cl_2): δ = 5.72 (dd, J = 7 Hz, 2H, central allylic), 4.31 (d, J = 7 Hz, 2H, terminal allylic), 4.29 (d, J = 7 Hz, 2H, terminal allylic), 3.73 (br s, 4H, bridgehead), 2.48 (s, 6H, NMe), 2.23 (s, 8H, CH_2); ^1H NMR (C_6D_6): δ = 5.38 (dd, J = 7.3 Hz, 2H, central allylic), 4.26 (br s, 4H, terminal allylic), 3.54 (br s, 4H, bridgehead), 2.29 (s, 6H, NMe), 1.84 (s, 4H, CH_2), 1.68 (m, 4H, CH_2); $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 132.0 (C3) 87.6 (C2 and C4), 67.0 (C1 and C5), 41.2 (NMe), 38.9 (CH_2); elemental analysis calcd for $C_{156}H_{24}N_2Cl_2Zr_1$: C 47.28, H 5.95, N 6.89; found: C 46.78, H 5.85, N 6.60; HRMS: *m/z* calcd: 404.0364; found: 404.0361.

3: Complex **2** (118 mg, 0.290 mmol) was dissolved in 10 mL of THF and cooled to −30 °C. Methyllithium (1.4 M in ether, 414 mL, 0.580 mmol) was added, and the reaction mixture stirred at room temperature for an additional 3.5 h. The solvent was evaporated under reduced pressure, and the residue extracted with pentane. The combined pentane extracts were filtered. The filtrate was recovered, and the volatile components were removed in vacuo to yield 94.6 mg (89%) of analytically pure, yellow solid. ^1H NMR (C_6D_6): δ = 4.86 (dd, J = 7.4 Hz, 2H, central allylic), 3.87 (d, J = 7.3 Hz, 2H, terminal allylic), 3.86 (d, J = 7.3 Hz, 2H, terminal allylic), 3.31 (m, 4H, bridgehead), 2.12 (m, 4H, CH_2), 2.02 (s, 6H, NMe), 1.90 (m, 4H, CH_2), 0.22 (s, 6H, $ZrMe_2$); ^1H NMR (CD_2Cl_2): δ = 4.85 (dd, J = 7.2 Hz, 2H, central allylic), 3.87 (d, J = 7.2 Hz, terminal allylic), 3.51 (br s, 4H, bridgehead), 2.30 (s, 6H, NMe), 2.23 (s, 8H, CH_2), −0.30 (s, 6H, $ZrMe_2$); $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 126.3 (central allylic), 80.4 (terminal allylic), 66.8 (bridgehead), 40.4 (NMe), 39.9 (CH_2), 25.8 ($ZrMe_2$); $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 149.7 (central allylic),

103.9 (terminal allylic), 90.1 (bridgehead), 63.9 (NMe), 63.2 (CH_2), 47.6 ($ZrMe_2$); elemental analysis calcd for $C_{18}H_{30}N_2Zr_1$: C 59.12, H 8.27, N 7.66; found: C 59.43, H 8.38, N 7.60; LRMS (EI): *m/z* calcd: 364; found: 364.

4: Complex **2** (103 mg, 0.254 mmol) was dissolved in 10 mL THF and cooled to $-30\,^{\circ}C$. Benzylmagnesium chloride (1 M in ether, 481 mL, 0.481 mmol) was added, and the solution stirred at room temperature for 2 h. The solvents were removed in vacuo. Complex **4** was recovered by extraction of the residue with toluene. The volatile materials were removed to give 110 mg (88%) of an orange solid. Analytically pure crystals of **4** can be obtained by vapor diffusion of pentane into a toluene solution of this solid at $-30\,^{\circ}C$. ^1H NMR (C_6D_6): $\delta = 7.27$ (t, $J = 7.7$ Hz, 4H, Ar), 7.12 (t, $J = 7.7$ Hz, 4H, Ar), 6.90 (t, $J = 7.2$ Hz, 2H, Ar), 5.14 (dd, $J = 7.4$ Hz, 2H, central allylic), 3.80 (d, $J = 7.3$ Hz, 2H, terminal allylic), 3.78 (d, $J = 7.3$ Hz, 2H, terminal allylic), 2.85 (br s, 4H, bridgehead), 2.05 (s, 6H, NMe), 1.95 (m, 4H, CH_2Ph), 1.72 (s, 8H, CH_2); $^{13}C\{^1H\}$ NMR (C_6D_6): $\delta = 155.8$ (C_{ipso}), 128.9 (central allylic), 128.0 (Ar), 125.7 (Ar), 119.4 (C_{para}), 83.8 (terminal allylic), 66.4 (bridgehead), 58.6 (CH_2Ph), 40.2 (NMe), 39.5 (CH_2); elemental analysis calcd for $C_{30}H_{38}N_2Zr$: C 69.58, H 7.40, N 5.41; found: C 69.56, H 7.60, N 5.21.

Polymerization of C_2H_4 by **2** and MAO: A Schlenk flask was charged with **2** (5.3 mg, 13 mmol) and 8 mL toluene and placed under 1 atm ethylene. MAO (Akzo, type 4; 3.4 mL, 13 mmol) was added over 1 min at room temperature. The yellow solution immediately turned dark orange, then blue and violet. The color vanished within 15–20 min. The solution was stirred under 1 atm ethylene for 45 min, and then the polymerization was stopped by careful addition of an acidified methanol solution (5% HCl). The mixture was filtered, and the polymer thoroughly dried in vacuo. Yield: 102 mg (17 $kg\,mol^{-1}\,h^{-1}$). Similar conditions were used for the control experiment with Cp_2ZrCl_2 (240 $kg\,mol^{-1}\,h^{-1}$).

[16] Preliminary measurements showed that the polyethylene exhibits a relatively high molecular weight but a rather broad polydispersity ($M_w = 628045$; $M_n = 14267$). We are grateful to Drs. Timothy Wenzel and Thomas Peterson, Union Carbide Co., for arranging to have these measurements made.

High La^{III} Affinity of a Bis(spirobenzopyran) Azacrown Ether and Photoinduced Switching of its Ion Selectivity between Multivalent and Monovalent Metal Ions**

Keiichi Kimura,* Tomohito Utsumi, Takashi Teranishi, Masaaki Yokoyama, Hidefumi Sakamoto, Masanori Okamoto, Ryuichi Arakawa, Hiroshi Moriguchi, and Yoko Miyaji

The photochromicity of spirobenzopyran derivatives is due to photoisomerization between their electrically neutral spiropyran and zwitterionic merocyanine forms.[1] The photochromism can often be used for controlling physical properties.[2] We are interested in macrocyclic ligands that can switch their metal ion complexing ability and/or their ion selectivity photochemically, as well as their application in materials science and analytical chemistry. We therefore designed 1,3,3-trimethylindolino-6′-nitrobenzopyrylospiran derivatives with a crown ether moiety at the 8′-position, in which the phenolate oxygen atom of the merocyanine form plays an important role in metal ion complexation by forming a six-membered ring chelate with a nitrogen atom of the azacrown ether.[3] The spirobenzopyran azacrown ethers can undergo photochemical switching upon complexing monovalent metal ions, and have been successfully applied in photoresponsive ion-conducting systems.[4]

Recently the crown ether derivative **1**, which has two spirobenzopyran moieties, was designed for photocontrol of the complexation of divalent metal ions.[5] In our studies, we found that, even in the dark, **1** binds multivalent metal ions much more strongly than its corresponding parent azacrown ether **2** (Scheme 1). Here we report the remarkably high affinity of **1** for La^{3+} and the photochemical switching of its ion selectivity between trivalent and monovalent metal ions.

Absorption spectra of solutions containing equimolar amounts of **1** and a metal ion in acetonitrile recorded in the dark showed a significant peak between 500 and 600 nm, which were assigned to the merocyanine form of the photochromic moiety; isomerization into this form was induced by complexation of the cation by the crown ether moiety. In general, the merocyanine absorption was much more intense for mulitivalent metal ions such as Ca^{2+} and La^{3+} than for monovalent ions such as Na^+ and K^+. This suggests a higher affinity of **1** for multivalent metal ions than for monovalent ones. Clear evidence for this was given by ESI mass spectrometry. Figure 1 shows a mass spectrum of **1** and **2** in acetonitrile in the presence of the nitrates of Li^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, Cd^{2+}, Pb^{2+}, La^{3+}, and Eu^{3+}. With **2**, medium-intensity peaks were observed for the Na^+ and K^+ complexes and a very small peak was seen for the Ca^{2+}

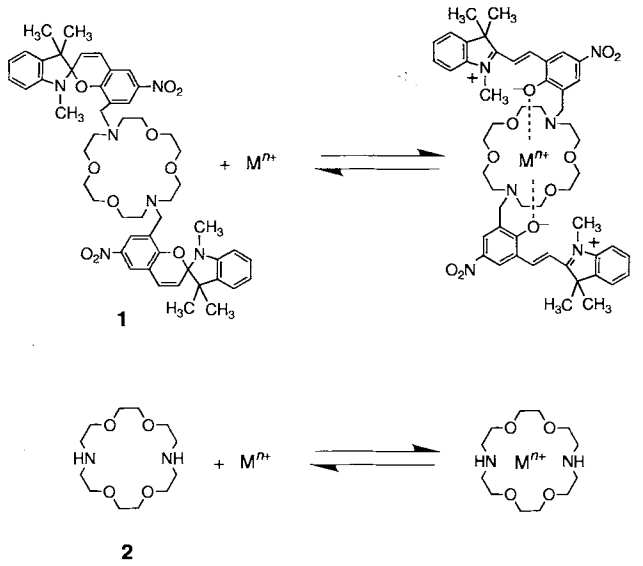

Scheme 1. Complexation of metal ions by **1** and **2**.

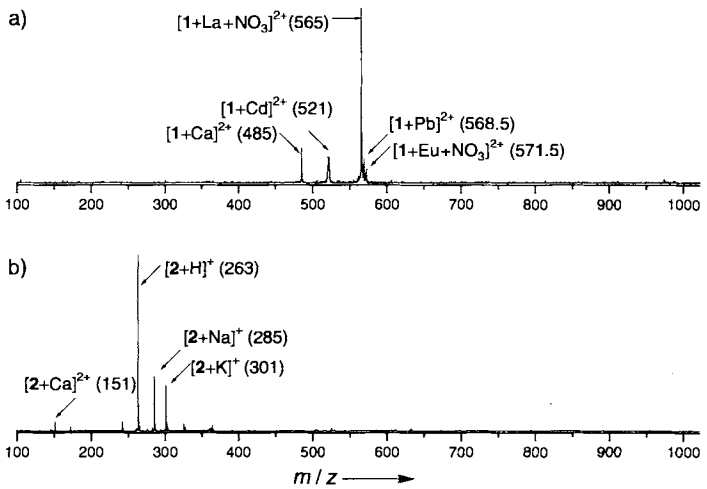

Figure 1. Mass spectra of solutions of **1** (a) and **2** (b) in acetonitrile in the presence of the nitrates of Li^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, Cd^{2+}, Pb^{2+}, La^{3+}, and Eu^{3+} in the dark. $c(\mathbf{1}) = c(\mathbf{2}) = c$(metal nitrate) $= 1 \times 10^{-4}$ mol dm^{-3}.

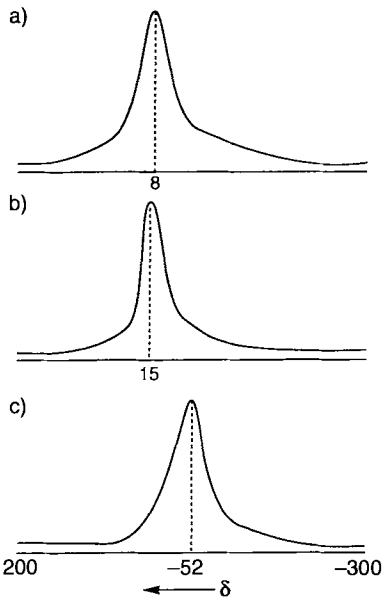

Figure 2. ^{139}La NMR spectra of a solution of $La(NO_3)_3$ in CD_3CN (a) and in the presence of **1** (b) and **2** (c) in the dark. $c[La(NO_3)_3] = 2 \times 10^{-2}$, $c(\mathbf{1}) = 1.5 \times 10^{-2}$, $c(\mathbf{2}) = 3 \times 10^{-1}$ mol dm^{-3}.

complex. There was no indication of complexation of other metal ions, especially trivalent ions, by **2**. This observation is in good accord with the general ion selectivity of the diaza-18-crown-6 ring.[6] Surprisingly, no significant peaks for the complexes of the monovalent metal ions with **1** were seen. Instead, medium-intensity peaks were observed for the complexes of divalent ions Ca^{2+}, Cd^{2+}, and Pb^{2+}. Most interestingly, the most intense peak corresponds to a complex of **1** with the trivalent ion La^{3+}.

Thus, with a preference for mulitivalent rather than monovalent metal ions, the complexation properties of **1** differ greatly from those of its parent crown ether. This suggests a strong ionic interaction of the phenolate anion of the merocyanine moiety with a metal ion in the crown ether component. Since the small cations Mg^{2+} and Eu^{3+} give no peak and a relatively small peak, respectively, for the complex with **1**, a size fit of the crown ether moiety to the metal ion is also crucial for formation of stable complexes with **1**.

^{139}La NMR spectroscopy provided important information on the strong interaction between La^{3+} and the phenolate anion in the complex **1**-La^{3+} (Figure 2). A ^{1}H NMR experiment indicated that both of the spirobenzopyran moieties in the **1**-La^{3+} complex are isomerized to the corresponding merocyanine form, even in the dark. Addition of **2** in high concentration to a solution of La^{3+} in acetonitrile led to broadening and a downfield shift of the ^{139}La NMR signal. This means that La^{3+} is complexed by the crown ether by an ion–dipole interaction, and that the complex is quite unsymmetrical. In contrast, addition of **1** gave a sharper peak and an upfield shift, indicating that the phenolate oxygen atoms of the merocyanine form of **1** act as axial ligands that interact strongly with an La^{3+} ion in the crown ether moiety. Since the La^{3+} complex of **1** gives a single peak in the mass spectrum, assigned to [**1**-$La(NO_3)$]$^{2+}$, the positive charge of La^{3+} in the crown ether moiety may be balanced not only by two phenolate anions but also by a nitrate anion. The peak sharpness also suggests that the asymmetry of the **2**-La^{3+} complex is alleviated by axial interaction with the phenolate oxygen atoms. Presumably, such strong ionic or coordinative interactions with the phenolate anions is responsible for the remarkable selectivity of **1** for multivalent metal ions, especially La^{3+}, over monovalent ones.

Since **1** and **2** differ so greatly in their selectivity for mono- and multivalent metal ions, photoisomerization of the merocyanine moiety of **1** back to its electrically neutral spiropyran form should switch the ion selectivity from multivalent to monovalent metal ions. We attempted to observe photoinduced ion selectivity switching of **1** by ESI-MS with an on-line photoirradiation apparatus.[7] As already mentioned, **1** has a much higher affinity for multivalent metal ions than for monovalent ones. However, with 100 molar equivalents of K^+ and one molar equivalent of La^{3+}, the ion peak of **1**-K^+ complex can be seen together with that of **1**-La^{3+} (Figure 3a). Mass spectra were recorded immediately after irradiation of the solution of **1** in acetonitrile with visible light (> 500 nm) in a glass capillary in the ESI interface. The peak ratio **1**-La^{3+}:**1**-K^+ was significantly lower after photoirradiation (Figure 3b). Clearly the ion selectivity of **1** can be switched from La^{3+} to K^+. When irradiation was ended, the high La^{3+} selectivity of **1** was restored.

Thus, crowned bis(spirobenzopyran) **1** has realized the extremely high affinity for La^{3+} by the powerful interaction with

Ion-Exchange Resins for Combinatorial Synthesis: 2,4-Pyrrolidinediones by Dieckmann Condensation**

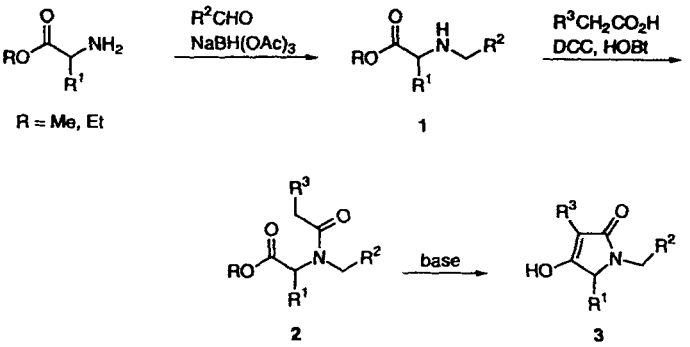
Bheemashankar A. Kulkarni and Arasu Ganesan*

Dedicated to V. R. Mamdapur on the occasion of his 60th birthday

Combinatorial organic synthesis has tremendous potential in areas which benefit from high-throughput screening of compounds for a desired property. Thus far, the emphasis has been on drug discovery,[1] although applications[2] such as molecular recognition, catalysis, and materials science are likely to increase in importance. It is now clear that few, if any, organic reactions are incompatible with library synthesis. However, as most transformations are not quantitative, the major challenge lies in purifying products from unchanged starting materials, undesired by-products, as well as catalysts and other reagents.

Current library-purification methods rely on phase separation.[3] In the solid-phase procedure, the compound is covalently attached to a resin, while reagents are removed by simple filtration. This enables the use of large excesses of reagent to drive reactions forward. However, solid-phase synthesis has a number of limitations, including the need for translation of reaction conditions optimized in solution. Recently, solution-phase methods for library generation have gained in popularity, accompanied by protocols for achieving phase separation such as acid–base extraction,[4] resin-bound scavengers,[5] and fluorous three-phase partitioning.[6] Here we report a combinatorial synthesis in which an ion-exchange resin serves as a reagent and a purification agent.

We were interested in a modular synthesis of 2,4-pyrrolidinediones (tetramic acids) as a scaffold for novel biologically active compounds. These heterocycles were envisaged to arise by the following sequence (Scheme 1): 1) reductive alkylation[7] of an



Scheme 1. Combinatorial synthesis of 2,4-pyrrolidinediones; DCC = dicyclohexyl carbodiimide, HOBt = 1-hydroxy 1*H*-benzotriazole hydrate.

α-amino acid ester, 2) acylation of product **1** with a substituted acetic acid, and 3) Dieckmann condensation[8] of amide ester **2** to yield 2,4-pyrrolidinedione **3**. The final products are thus assembled from three building blocks (amino acids, aldehydes, carboxylic acids) that are available with a high degree of diversity.

First we performed a model study: *N*-benzylglycine ethyl ester was coupled[9] with cyanoacetic acid to give amide **2a** (R^1 = H, R^2 = Ph, R^3 = CN). The desired Dieckmann condensation[10] occurred in 70–80% yield with various bases.[11] We also found that Amberlyst A-26 resin (OH^- form) promotes the cyclization. The simplicity of handling makes this the reagent of choice, and we believe this to be the first use of an ion-exchange resin for this venerable reaction.[12]

The pyrrolidinedione remains tightly bound to the resin until it is released by acid treatment (Scheme 2).[13] Only successfully cyclized material is resin-bound, whereas other components are washed away. This represents a new paradigm for solution-phase library purification. Previous applications of ion-exchange resins in combinatorial synthesis emphasized their use as activating agents[14] or scavengers.[15, 16] In this respect, our

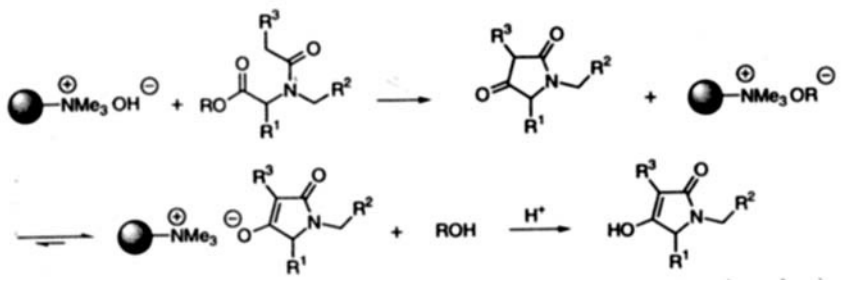

Scheme 2. A quaternary ammonium resin (OH^- form) catalyzes the Dieckmann condensation and purifies the reaction products.

positive selection of the desired product is analogous to Armstrong's[17] solid-phase resin capture.

The ion-exchange resin protocol is applicable to a variety of Dieckmann substrates (Table 1). A reasonably strong electron-withdrawing group (R^3) is required; when R^3 = Ph, no reaction was observed under the usual conditions. Upon prolonged stirring with resin, hydrolysis of the ester to the free carboxylic acid (**2**, R = H) occurred; this was also detected as a minor pathway when R^3 = SPh (**2d**).

Table 1. Yield and purity of representative examples of the Dieckmann condensation in the presence of the quaternary ammonium resin Amberlyst A-26 [a].

Amide	R^1	R^2	R^3	Product	Yield [%]	Purity [%]
2a	H	Ph	CN	**3a**	72	92
2b	H	Ph	o-$O_2NC_6H_4$	**3b**	73	89
2c	H	Ph	$P(O)(OEt)_2$	**3c**	86	87
2d	H	Ph	SPh	**3d**	87	71 [b]
2e	*i*Pr	Ph	CN	**3e**	80	94
2f	$CH_2CH_2SCH_3$	Ph	CN	**3f**	79	83
2g	CH_2Ph	Ph	CN	**3g**	77	85
2h	CH_2Ph	p-$MeOC_6H_4$	CN	**3h**	75	86
2i	CH_2Ph	p-$O_2NC_6H_4$	CN	**3i**	70	92
2j	CH_2Ph	p-*t*BuC_6H_4	CN	**3j**	71	88

[a] The yields reported are for the crude material and uncorrected for the possibility of hydrate formation. All compounds were fully characterized by NMR spectroscopy and MS. The purity was assessed by HPLC (UV detection at 254 nm). [b] The product is accompanied by the hydrolyzed ester (17%).

The selectivity of the resin-bound purification method has enabled us to carry out the overall process (**1** to **3**) with minimal purification. For example, crude **2g** was prepared from L-phenylalanine methyl ester by reductive alkylation and acylation with only aqueous washes in between, and cyclized to afford **3g** in 64% overall yield (comparable to the 68% obtained when chromatographically purified intermediates were used). We are presently adapting this methodology to the preparation of 2,4-pyrrolidinedione libraries by discrete parallel synthesis.

Experimental Section

2g: To a solution of L-*N*-benzylphenylalanine methyl ester [18] (330 mg, 1.23 mmol) in CH_2Cl_2 (10 mL) was added cyanoacetic acid (125 mg, 1.47 mmol) and 1-hydroxy 1*H*-benzotriazole hydrate (HOBt, 199 mg, 1.47 mmol). The solution was cooled to 0 °C, followed by slow addition of dicyclohexyl carbodiimide (DCC, 355 mg, 1.72 mmol). The reaction mixture was warmed to room temperature, stirred for 6 h, filtered, washed (water, saturated $NaHCO_3$, and brine), dried ($MgSO_4$), and concentrated. Flash chromatography (silica, 0–40% ethyl acetate/hexanes) yielded the amide (380 mg), which recrystallized (EtOAc/hexanes) as a white solid (360 mg, 87% yield); m.p. 90–92 °C; IR (Nujol): $\tilde{\nu}$ = 2258, 1733, 1645 cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$): δ = 3.23–3.42 (m, 4H), 3.70 (s, 3H), 3.88 (d, J = 17.1 Hz, 1H), 4.34 (d, J = 17.0 Hz, 1H), 4.45 (dd, J = 5.6, 9.9 Hz, 1H), 7.09–7.16 (m, 5H), 7.25–7.32 (m, 5H); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 25.62, 34.99, 52.45, 53.01, 62.11, 113.44, 126.97, 127.07, 128.25, 128.88, 129.05, 129.16, 134.63, 137.17, 162.74, 169.89; $[\alpha]_D^{22} = -132.4°$ (c = 0.5, $CHCl_3$); elemental analysis calcd for $C_{20}H_{20}N_2O_3$: C 71.41, H 5.99, N 8.32; found: C 71.22, H 6.11, N 8.23.

3g: To a stirred solution of **2g** (330 mg, 0.98 mmol) in MeOH (10 mL) was added Amberlyst A-26 resin [19] (450 mg, OH^- form). After 16 h the resin was filtered and washed three times with MeOH. The resin was then stirred for 30 min with MeOH (10 mL) and trifluoroacetic acid (TFA, 0.4 mL), filtered, and washed three times with MeOH. Concentration of the filtrate afforded the 2,4-pyrrolidinedione hydrate (241 mg), which recrystallized (MeOH/acetone/hexanes) as a white solid (215 mg, 68% yield); m.p. 234–237 °C; IR (Nujol): $\tilde{\nu}$ = 2214, 1678 (br), 1595 (br) cm^{-1}; ^1H NMR (300 MHz, [D_6]DMSO): δ = 2.94 (dd, J = 4.5, 14.2 Hz, 1H), 3.15 (dd, J = 4.4, 14.2 Hz, 1H), 3.89 (t, J = 4.4 Hz, 1H), 4.00 (d, J = 15.3 Hz, 1H), 4.86 (d, J = 15.3 Hz, 1H), 7.09–7.22 (m, 5H), 7.25–7.31 (m, 5H); ^{13}C NMR (75 MHz, [D_6]DMSO): δ = 34.12, 43.08, 60.95, 77.14, 115.01, 126.56, 127.12, 127.63, 128.00, 128.47, 129.36, 135.54, 137.58, 168.74, 185.63; $[\alpha]_D^{22} = -127.3°$ (c = 0.15, MeOH); HRMS (calcd/found): 304.1212/304.1234 [M^+]; elemental analysis calcd for $C_{19}H_{16}N_2O_2 \cdot H_2O$: C 70.79, H 5.62, N 8.68; found: C 70.64, H 5.49, N 8.55.

Insertion of Carbenoids into Cp–H Bonds of Ferrocenes: An Enantioselective-Catalytic Entry to Planar-Chiral Ferrocenes**

Stephan Siegel and Hans-Günther Schmalz*

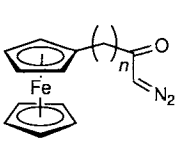
Since the epoch-making discovery of ferrocene in 1951,[1] the chemistry of this organometallic compound has been intensely investigated. Even recently, the ferrocene substructure enjoys a keen scientific interest—especially as a sound construction element for developing new catalysts and materials.[2]

In the course of our work on the preparation and synthetic application of chiral transition metal π complexes,[3] we considered whether cyclization reactions of the type shown in Equation (1) are possible, or, more generally, if ferrocenes can be

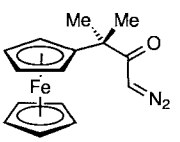
(1)

functionalized (by C–H insertion) upon reaction with carbenes. We assumed that the comparably electron-rich cyclopentadienyl rings of ferrocene could react with electron-poor carbenes (or carbenoids). We report here the success of such reactions and, thus, the first examples of carbene insertion into Cp–H bonds of ferrocene derivatives.[4] Furthermore, we show that this chemistry can be used for the enantioselective-catalytic preparation of planar-chiral ferrocenes.[5]

We employed the metal-catalyzed decomposition of α-diazo carbonyl compounds, since it is a reliable method for generating carbenoid species.[6] The (nonstabilized) electrophilic metal–carbene intermediates show a chemical behavior similar to that of free carbenes, and are well suited for insertions into aryl C–H bonds.[6, 7] As substrates we chose the diazoketones **1**–**3**.

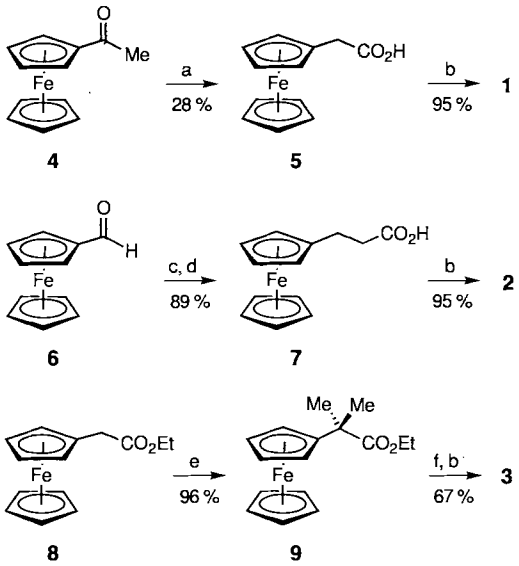


1: $n = 1$
2: $n = 2$



3

The synthesis of **1** (Scheme 1) started with acetylferrocene (**4**), which was subjected to a Willgerodt reaction to provide ferrocenyl acetic acid (**5**),[8, 9] which in turn was converted into diazoketone **1** in 95% yield by the one-pot procedure described in the Experimental Section.[10] To prepare the homologous substrate **2**, formylferrocene (**6**)[11] was first transformed by decarboxylative Knoevenagel condensation and catalytic hydrogenation into acid **7**,[11, 12] which was further converted into diazoketone **2** in high yield. Substrate **3** was synthesized by esterification of **5** to **8** (MeOH, $SOCl_2$, 83%). Two deprotonation/methylation cycles then afforded the dimethylated compound **9** in almost quantitative yields, from which diazoketone **3** was obtained after hydrolysis by the standard one-pot protocol.[9]



Scheme 1. Preparation of the cyclization precursors **1**–**3**. a) S_8, morpholine, 130 °C, 17 h, then 4N NaOH, reflux, 4 h; b) NaH, C_6H_6, room temperature (RT), then $(COCl)_2$, pyridine, 0 → 55 °C, 2 h, removal of solvent, then CH_2N_2, Et_2O, 0 °C, 30 min; c) $H_2C(CO_2H)_2$, cat. piperidine, pyridine, 100 °C, 2 h; d) H_2, Pd/C, EtOH, RT, 48 h; e) LDA, THF, −60 °C → RT, then aqueous work-up; repetition of the sequence; f) 10% NaOH, MeOH, reflux, 3 h.

We then investigated the projected cyclizations with the well-known (achiral) catalysts $[Rh_2(OAc)_4]$ and $[Rh_2(OCOCF_3)_4]$, and found suitable reaction conditions for all three substrates that allowed the preparation of the desired cyclization products (**10**, *rac*-**12**, and *rac*-**14**) in reasonable yields. The most important results are summarized in Table 1; however, here we emphasize some observations explicitly: A bridged ferrocene derivative (**11**) was obtained (as a side product) only in the case of **1**. In all reactions with $[Rh_2(OAc)_4]$ in halogenated solvents (Table 1, entries 1, 3, 6, and 7), ferrocene was isolated as a by-product in considerable amounts (10–20%).[13] Compared to reactions with $[Rh_2(OAc)_4]$, those of **1** and **2** with $[Rh_2(OCOCF_3)_4]$ proceeded much more cleanly (entries 2 and 4), and only 1 mol% of the catalyst was required to provide *rac*-**12** in acceptable yields (47% based on converted starting material). An attempt to carry out the $[Rh_2(OAc)_4]$-catalyzed reaction of **2** in benzene resulted in the formation of significant amounts of the (intermolecular) Buchner product **13**.[14] Preliminary cyclization experiments with **3**, which were carried out in an NMR tube with $[Rh_2(OAc)_4]$ or $[Rh_2(CF_3CO_2)_4]$ in C_6D_6 or

[a] See Experimental Section. [b] Yields of isolated products after chromatographic separation. [c] In this case, 24% of the starting material **2** was recovered.

$CDCl_3$, showed that the cyclization product *rac*-**14** formed only in traces when the latter was used as the solvent. In contrast, dichloromethane proved to be a more appropriate solvent, and was also better than fluorobenzene and trifluoromethylbenzene.[15] It is known that (in addition to rhodium salts) copper compounds are especially well suited as catalysts for the generation of carbenoids from diazo compounds.[6b] Therefore, we tested the cyclization of substrates **2** and **3** with $Cu(hfacac)_2$ (hfacac = hexafluoroacetylacetonate), which has proven useful for C–H insertions into electron-rich aromatic compounds (e. g. *N*-methyl pyrrol).[16] Indeed, we obtained good results with this catalyst—especially in the case of **3**, which in the presence of $Cu(hfacac)_2$ (5 mol%) afforded *rac*-**14** in 66% yield.

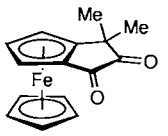
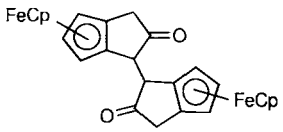
rac-**15**: IR: $\tilde{\nu}$ = 3102, 2966, 2931, 2863, 1751, 1699, 1480, 1455 cm^{-1}; ^1H NMR: δ = 1.23 (s, 3H), 1.63 (s, 3H), 4.27 (s, 5H), 4.70 (pseudo d, J = 2.5 Hz, 1H), 5.03 (pseudo t, 1H, J = 2.5 Hz), 5.15 (d, J = 2.5 Hz, 1H); ^{13}C NMR: δ = 23.1 (CH_3), 30.1 (CH_3), 42.7, 65.0 (CH), 67.8 (CH), 76.0 (CH), 76.1 (CH), 77.2, 79.8, 175.9, 204.8; HR-MS: calcd for $C_{15}H_{14}FeO_2$: 282.0343, found: 282.0347

The cyclization products **10**, *rac*-**12**, and *rac*-**14** (spectroscopic data are given in Table 2) are surprisingly sensitive towards oxidation; they decompose upon exposure to air under formation of polar, intensely colored by-products. For instance, violet 1,2-diketone *rac*-**15** was isolated from a solution of *rac*-**14** with a catalytic amount of $Cu(hfacac)_2$ in dichloromethane that was exposed to the air for several hours. Furthermore, aerobic workup of the reaction mixture from the treatment of **1** with $Cu(hfacac)_2$ in dichloromethane provided a product of constitution **16**[17] in 19% yield as a 1:1 mixture of diastereomers. This was apparently formed by oxidative dimerization of **10**.

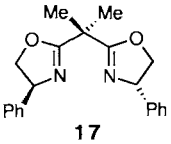


15

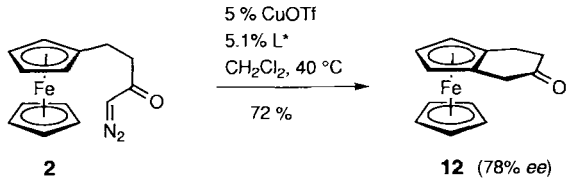


16

Because the cyclizations **2** → *rac*-**12** and **3** → *rac*-**14** represent chirogenic reactions[18] that can in general be conducted enantioselectively, it was straightforward to test these reactions with chiral catalysts.[19] Our first attempt with the prominent mepy-rhodium(II) complex[20] furnished disappointing results.[21] In contrast, cyclization experiments with the catalyst (5 mol%) prepared in situ from copper(I) triflate and **17**[22] in dichloromethane at reflux were successful. In the case of **2**, we obtained the cylization product **12**[23] in 72% yield with an enantiomeric excess of 78% *ee* (Scheme 2). Cyclization of **3**, performed under the same



17



2 **12** (78% *ee*)

Scheme 2. Enantioselective cyclization of **2**. Tf = trifluoromethanesulfonyl, L* = chiral ligand.

conditions, also furnished an optically active product (**14**)[24] in good yield (89%) with an enantiomeric purity of 62% *ee* (Scheme 3). It is remarkable that these reactions not only proceeded with significant enantioselectivity but also gave higher chemical yields than those with the achiral catalysts. Further investigations must now show if the enantioselectivity can be increased by varying the catalyst systems.

The experiments described here show for the first time that carbene insertions into Cp–H bonds of ferrocene derivatives are possible and can be used (in a preparatively attractive man-

ner) for synthesizing interesting new compounds. This extends the chemistry of ferrocene by a basic new variant, and also opens a unique opportunity for the enantioselective-catalytic synthesis of planar-chiral ferrocene derivatives.

Experimental Section

General procedure for preparing the cyclization precursors **1**–**3** from the corresponding ferrocenyl alkanoic acids: To a stirred suspension of the ferrocenyl alkanoic acid (4.1 mmol) in anhydrous benzene (60 mL) was added sodium hydride (4.18 mmol) under an argon atmosphere, and after 10 min pyridine (2.61 mmol). The mixture was cooled to 0 °C, and freshly distilled oxalyl chloride (26.5 mmol) added dropwise. After complete addition stirring was continued for 30 min at 0 °C, for 30 min at room temperature, and finally for 1 h at 55 °C. After filtration of the reaction mixture through a short pad of silica gel, the solvent and excess oxalyl chloride were completely removed in vacuo. The dark brown residue was dissolved in Et_2O (15 mL), and a solution of diazomethane (35 ml, ≈0.6 M in Et_2O) added at 0 °C. After the reaction mixture was stirred for 20 min at 0 °C excess diazomethane and solvent were completely removed in vacuo, and the residue was purified by flash chromatography (hexane/EtOAc).

General procedure for the cyclization experiments summarized in Table 1: To a solution of the catalyst (34 μmol; 5 mol%) in the anhydrous solvent (10 mL) was added dropwise at RT under an atmosphere of argon a solution of the diazoketone (0.68 mmol) in the solvent (5 mL) within about 30 min. Gas evolution (N_2) indicated the decomposition of the diazo compound. After complete addition stirring was continued until complete conversion was reached (usually about one hour). After rapid filtration of the dark brown reaction mixture through a short pad of silica gel under argon, the solvent was completely removed in vacuo. The products were separated and purified by flash chromatography or radial chromatography (using a chromatotron) under an argon atmosphere.

Enantioselective cyclizations: Ligand **17** (17.3 μmol) was added to a solution of $Cu^{I}OTf$ (17 μmol; weighed in a glove box) in CH_2Cl_2 (3 mL) under an argon atmosphere. After the reaction mixture was stirred for 2 h at RT, the green solution of the catalyst was heated to reflux, and a solution of the substrate (**2** or **3**; 0.34 mmol) in CH_2Cl_2 (10 mL) slowly added within 2 h with a syringe pump (all under argon). After complete addition the brownish solution was heated at reflux for 20 min before being subjected to work-up as described above. The enantiomeric excess of the product was determined with HPLC (Daicel, Chiralcel OJ).

Asymmetric Self-Replication of Chiral 1,2-Amino Alcohols by Highly Enantioselective Autoinductive Reduction**

Takanori Shibata, Tomohide Takahashi, Takashi Konishi, and Kenso Soai*

Dedicated to Professor Dieter Seebach on the occasion of his 60th birthday

Self-replication, like the chirality of the components, is one of the most characteristic features of living organisms. Therefore, self-replication of a chiral molecule is of much interest. The concept of self-replication, however, has not been applied in asymmetric synthesis; almost all conventional asymmetric syntheses require chiral auxiliaries with structures which differ from

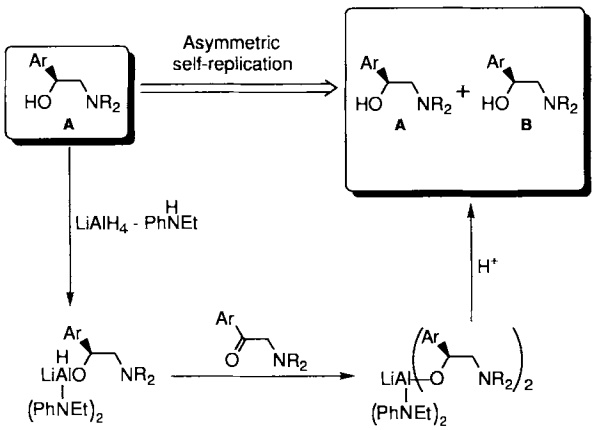
those of the chiral products. The only exceptions are the diastereoselective process with self-regeneration of a stereocenter,[1] the asymmetric autoinduction,[2] and the asymmetric autocatalytic reaction.[3] Asymmetric autoinduction has been limited to the enantioselective alkylation of aldehydes.[2] We report here the first highly enantioselective self-replication in an asymmetric autoinductive reduction in which the structure and configuration of the chiral ligand and product are identical.

We examined the asymmetric autoinductive reduction of α-amino ketones with lithium aluminum hydride[4] modified with a chiral 1,2-amino alcohol and an achiral additive[5] (Scheme 1).



Scheme 1. Asymmetric self-replication of 1,2-amino alcohols; **A** = chiral ligand, **B** = reaction product. The ligand **A** recovered at the end of the reaction and the product **B** have the same structure and configuration.

2-Morpholinoacetophenone (**1a**) was reduced with chirally modified $LiAlH_4$, which was prepared in situ from $LiAlH_4$, chiral (*S*)-2-morpholino-1-phenylethanol (**2a**),[6] and *N*-ethylaniline[5a] in Et_2O at −78 °C. The 1,2-amino alcohol (*S*)-**2a** was obtained in 95.8% *ee* (Table 1, entry 1), which means that (*S*)-**2a** was newly formed in 78.8% yield with 82.4% *ee*.[7] This result implies that **1a** was enantioselectively reduced by chiral **2a** to give new **2a** with the same (*S*) configuration. Lowering the reaction temperature (from −78 to −100 °C) improved the chemical yield, and the enantioselectivity remained high (entry 3). When the chiral ligand (*R*)-**2a** was used instead of (*S*)-**2a**, (*R*)-**2a** was formed in 88.6% yield with 84.7% *ee* (entry 4). Entries 5–9 in Table 1 demonstrate that a variety of N-heterocycles can be used as amino substituents. The reactions of (*S*)-**2c** and **2d** at −78 °C[8] were also examined (entries 6 and 7); the enantioselectivity was very high in both cases (87.9 and 90.1% *ee*, respectively).[9] The *ee* values of products **2a**–**2d** (entries 4–7) were easily improved to greater than 99.5% *ee* by a single recrystallization. This means that, by the self-replication of amino alcohols used as chiral ligands, increased amounts of chiral amino alcohols were obtained with no loss of enantiomeric purity. With (*S*)-2-(*N*,*N*-dibenzylamino)-1-phenylethan-1-ol (**2e**) as the chiral ligand, product **2e** formed in moderate optical yields (72.2% *ee*, entry 8). Entry 9 shows the results of the reaction with (*S*)-1-(4-methylphenyl)-2-pyrrolidinoethan-1-ol (**2f**).[10]

The present method demonstrates the first highly enantioselective autoinductive reduction in which the product has the same structure and configuration as the chiral ligand; a separation of the product from the chiral ligand is therefore unnecessary. This system could introduce a new concept into asymmetric reduction.

Experimental Section

In the following, a typical experiment and the method used to calculate the yield and *ee* values of the newly formed 1,2-amino alcohol (Table 1, entry 3) are described. To a suspension (1 mL) of $LiAlH_4$ (47.4 mg, 1.25 mmol) in Et_2O was added a solution (14 mL) of (*S*)-**2a** (263.0 mg, 1.27 mmol, >99.5% *ee*) in Et_2O over a period of 10 min with vigorous stirring. The mixture was heated at reflux for 1 h, treated within 5 min with a solution (2 mL) of *N*-ethylaniline (309.0 mg, 2.55 mmol) in Et_2O, and heated again at reflux for an additional hour. After the reaction mixture was cooled to −100 °C, a solution (3 mL) of **1a** (102.7 mg, 0.50 mmol) in Et_2O was added dropwise. The reaction mixture was stirred at this temperature for 3–4 h, poured into 1 M hydrochloric acid (5 mL) to quench the reaction, and neutralized with a saturated aqueous solution of $NaHCO_3$ (15 mL) at 0 °C. The mixture was filtered over celite, the precipitate thoroughly washed with CH_2Cl_2 (30 mL), and the combined filtrate extracted with CH_2Cl_2. The extract was dried over anhydrous $MgSO_4$, and the solvent removed under reduced pressure. Purification of the crude product by flash column chromatography gave **2a** (355.5 mg) as a mixture of the newly formed product **2a** and the chiral ligand **2a** (263.0 mg). HPLC analysis of the mixture using a chiral column (DAICEL Chiralcel OD-H) provided an enantiomeric purity of 95.7% *ee*. Therefore, the mixture consisted of (*S*)-**2a** (347.9 mg) and (*R*)-**2a** (7.6 mg). The amount of newly formed **2a** was 355.5 − 263.0 = 92.5 mg (0.446 mmol, 89.2% yield), consisting of (*S*)-**2a** (347.9 − 263.0 = 84.9 mg) and (*R*)-**2a** (7.6 mg). The newly formed (*S*)-enriched amino alcohol **2a** had an enantiomeric purity of 83.6% *ee*.

Table 1. Asymmetric autoinductive reduction according to Equation (1) using 1,2-amino alcohols **2a**–**f** as chiral ligands [a].

Chiral Methyl-Branched Surfactants and Phospholipids: Synthesis and Properties

Michael Morr,* Jens Fortkamp, and Stefan Rühe

The recent publication of the synthesis and unusual properties of spiro-surfactants by Menger et al.[1] prompted us to report the results of our work on chiral methyl-branched surfactants and phospholipids which are obtained by formal opening of spiro-compounds. For some time we have been engaged in the isolation of chiral methyl-branched fatty acids, for example, (2*R*,4*R*,6*R*)-2,4,6-trimethyloctanoic acid (**1**)[2] from the preen gland of the musk duck *Cairina moschata* as well as (2*R*,4*R*,6*R*,8*R*)-2,4,6,8-tetramethyldecanoic acid (**2**) and (2*R*,4*R*,6*R*,8*R*)-2,4,6,8-tetramethylundecanoic acid (**3**)[3] from

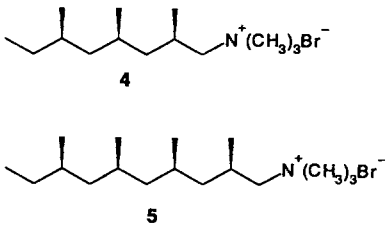
2	1	0	COOH
3	1	1	COOH
lardolure	1	1	OCHO
norlardolure	1	0	OCHO

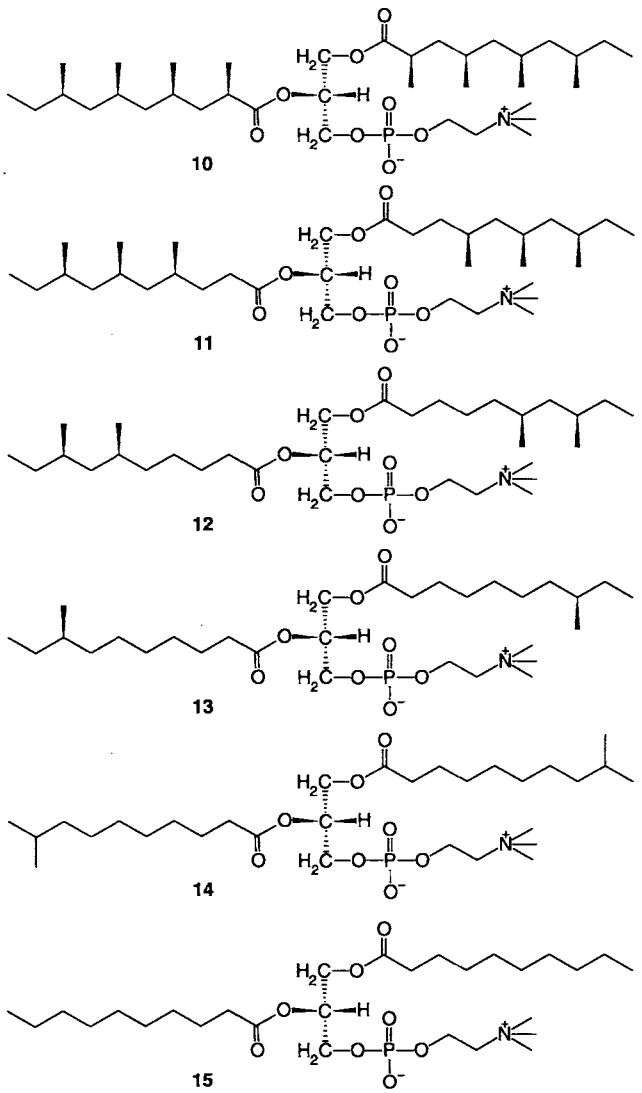
the preen gland of the domestic goose *Anser a.f. domesticus*. In addition to a number of new derivatives of these compounds—such as the mite pheromones lardolure and norlardolure[4, 5] as well as new, chiral ferro- and antiferroelectric liquid crystals with methyl side chains[6]—we were interested in the physical and chemical properties (such as critical micellization concentration (CMC)) of surfactants **4** and **5**, which are derived from



4

5

1 and **2**, respectively. We also focused our attention on the diacyl-*sn*-glcero-3-phosphatidylcholines **10**–**15**, which show high enantiomeric purity and a uniform chain length of ten carbon atoms, but varying numbers of methyl-substituted chiral



10

11

14

15

centers. Properties required for their useful applications (e. g. as membrane constituents) were analysed by differential scanning calorimetry (DSC) to determine the main phase-transition temperatures, and with a Langmuir film balance to record π-*A*-isotherms.

The methyl esters **6** of **1** and **2** were allowed to react with lithium aluminum hydride to give alcohols **7** ($n = 0, 1$; yield 95%), which were converted by tosylation (via **8**) into the bromides **9** with LiBr in acetone (85%). The reaction of **9** with trimethylamine in ethanol at 80 °C (in a pressure vessel) afforded **4** and **5** in quantitative yield.

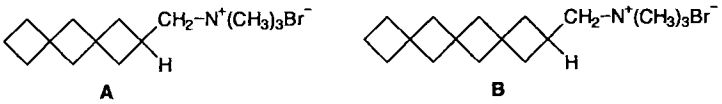
Aqueous solutions of **4** and **5** were analyzed tensiometrically at 25 °C. It is known that with common surfactants the surface tension decreases steadily until the CMC is reached. At higher surfactant concentrations surface tension does not decrease further, as there is a preferred invasion of surfactant molecules into the micelles instead of enrichment at the air–water interface. These characteristic properties were observed for **4**. The CMC is 9.12×10^{-2} M, which is comparable to that of 1.4×10^{-1} M (**A**) for the corresponding spiro-surfactant found by Menger et al.[1] Apparently, the tendency of **4** to form micelles is significantly lower than with common surfactants with the same total number of carbon atoms. Menger et al. also reported that formation of micelles seems to be inhibited by a certain rigidity of the methyl-branched aliphatic chain. They gave an estimated CMC for the spiro-compound of more than 4.4×10^{-3} M (**B**).[1] For



the corresponding compound **5** we observed a decrease in the surface tension to about 27 mN m^{-1} and a CMC of 1.5×10^{-2} M. As with the spiro-compound, the plot of the surface tension is anomalous since it is partially convex, and the surface tension changes only slightly at low concentrations.

Phospholipids **10**–**15** were synthesized according to Hermetter and Paltauf.[7, 8] When applied to the synthesis of **10**, the same method caused racemization at the 2-position of the carboxylic acid group; hence, an alternative approach had to be found. Using the method of Wood,[9] **2**, *sn*-glycero-3-phosphocholine (as the $CdCl_2$ complex), and dicyclohexyl carbodiimide (DCC)/4-dimethylamino pyridine (DMAP) in ethanol-free chloroform gave **10** in 66% yield after 10 d at room temperature. Gas-chromatographic analysis of an acidically methylated sample indicated that chirality was conserved to more than 95%. Compound **11** was synthesized by standard chain-elongation procedures (malonic ester method). (6*R*,8*R*)-6,8-Dimethyldecanoic acid, which was used to synthesize **12**, was obtained in a 16-step procedure, and (*R*)-8-methyldecanoic acid, required for **13**, required a 10-step synthesis.[2, 10]

The calorimetric analyses of the phospholipid suspensions **10**–**15** were performed on a "high-sensitivity" differential calorimeter (MC-2D, Micro Cal, Inc.), which functions according to the principle of dynamic performance differential calorimetry. No phase transitions were observed for **11**–**13** between −45 and 25 °C; Menger et al. found the same result with the spirophospholipids (Figure 1). This is in agreement with

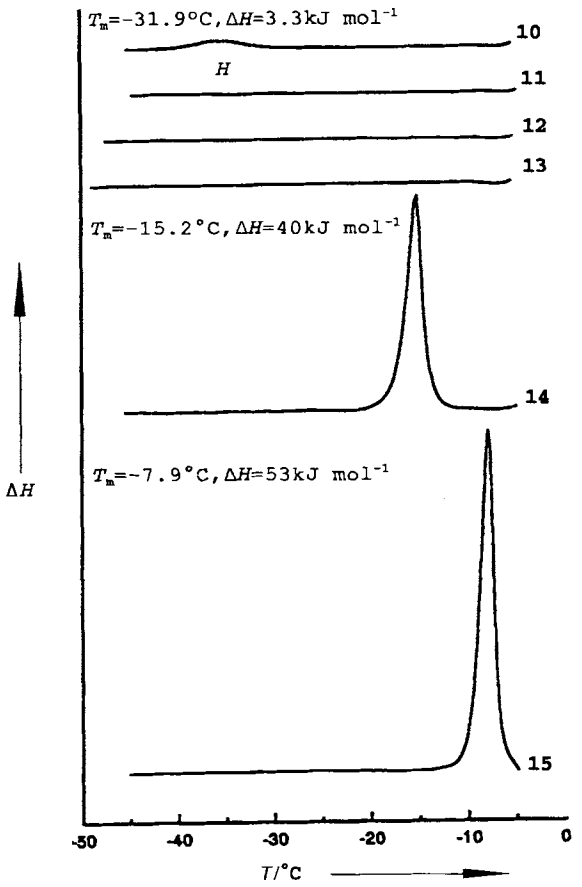


Figure 1. DSC heating thermograms of **10**–**15**, $c = 10$ mg mL^{-1} in water, heating rate = 20 °C h^{-1}.

expectations based on comparisons with the results of McElhaney et al.[11] Phospholipid **10** showed a main phase-transition temperature T_m of −31.9 °C. It is clear from the curve that it is a very broad phase transition with a relatively low transition enthalpy ΔH. Although DSC data do not provide information about processes at the molecular level, it is easy to imagine that—based on the three-dimensional structure derived from calculations of molecular dynamics[12] for **2**—the gel phase of such a compound is less ordered than that of the corresponding nonbranched compound. This is indicated by a lower transition enthalpy. The fact that **10**, in contrast to **11**–**13**, shows a phase transition within the temperature range used suggests that the acyl chains in **10** are more easily arranged, even if in a relatively unordered fashion. The chain is more bulky throughout the overall length of the molecule than the head group. This is different to the phosphatidylcholines, which show no phase transition, and is in accordance with the data from the film balance.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2461 $ 17.50+.50/0

The data for **14** ($T_m = -15.2\,°C$, $\Delta H = 40\,kJ\,mol^{-1}$) are consistent with the results of McElhaney et al.[13] for other diacylphosphatidylcholines with longer chain lengths (e. g. $T_m = -18.8\,°C$ and $\Delta H = 32.6\,kJ\,mol^{-1}$ for bis(10-methylundecanoyl)phosphatidylcholine). Comparison of our data with that for the corresponding nonbranched didecanoylphosphatidylcholine (**15**; $T_m = -7.9\,°C$, $\Delta H = 53\,kJ\,mol^{-1}$) shows that, in contrast to compounds with linear chains, a slightly disturbed gel state can be assumed for the diisoacylphosphatidylcholines.

Diacylphosphatidylcholines **10**–**15** were analyzed with a film balance (Lauda FW 2) to ascertain their behavior at the water–air interface. The shapes of the π-A-isotherms at 0 and 20 °C are almost identical and characteristic of those from expanded films (Figure 2). An increase in the surface per molecule of 50 to

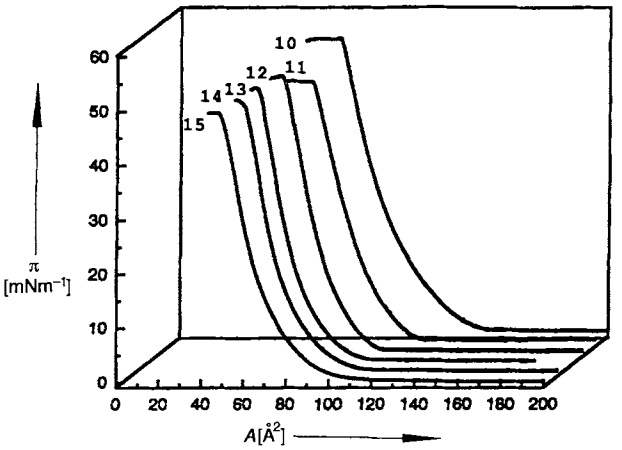

Figure 2. π-A-Isotherms of **10**–**15** on water at 0 °C, compression time = 30 min for 927 cm², A = molecule surface per molecule.

76 Å² is observed with an increasing number of methyl branches in the acyl chain. This is in accordance with the results for dipalmitoylphosphatidylcholine and the corresponding iso and anteiso compounds,[14] for which the maximum surface tensions differ only slightly (48–51 $mN\,m^{-1}$ for **11**–**14**). Surprisingly, the value for **10** is slightly higher (54 $mN\,m^{-1}$). An explanation for this could be the ratio of the steric requirements of the head group and the acyl chain. For the nonbranched compound the head group has a higher steric requirement than the acyl chains, whereas the methyl side chains in the other compounds disturb an optimized arrangement. For **10** the acyl chains are more bulky than the head group. This is supported by DSC data that show a phase transition within the investigated temperature range for **10**, but not for **11**–**13**. Further confirmation of this hypothesis is the absence of a condensed phase; phase transitions were found only for **10**, **14**, and **15**, and these were clearly below 0 °C. A pharmaceutically interesting application could be the modification of liposome properties with respect to their permeability by specific addition of branched phospholipids.

A Supercharged Anion with a Silyl-Substituted Eight-Center, Twelve-Electron π System: Synthesis and Characterization of the Tetralithium Salt of an Octasilyl-Substituted Trimethylenecyclopentene Tetraanion**

Akira Sekiguchi,* Tsukasa Matsuo, and Chizuko Kabuto

Supercharged anions with extended π-electron systems have attracted considerable interest owing to their unique structures and electronic properties.[1] The existence of a hexaanionic species in the solid state is inferred from the formation of K_6C_{60}, which was characterized by X-ray powder diffraction[2] and ^{13}C NMR spectroscopy.[3] Scott et al. recently reported on the tetralithium salt of the corannulene tetraanion ($C_{20}H_{10}$) and its derivatives.[4] The most recent, and, to our knowledge, only report on the molecular structure of a rubrene tetraanion (crystallized as a tetrasodium salt; rubrene = 5,6,11,12-tetraphenyltetracene, $C_{42}H_{28}$) that has been confirmed by X-ray crystallography was carried out by Bock et al.[5] We report here a tetraanion with a new silyl-substituted eight-center, twelve-electron π system, which was isolated as the tetralithium salt **2**.

As an appropriate precursor of the tetraanion, the octasilyl-substituted trimethylenecyclopentene **1** with an eight-electron π system was prepared as pale yellow crystals by the reaction of hexadecamethyl-3,5,8,10,13,15,18,20-octasilacycloicosa-1,6,11,16-tetrayne with $[(C_5H_4Me)Mn(CO)_3]$ under photochemical conditions. The molecular structure of **1** is shown in Figure 1.[6]

Reduction of **1** with lithium in dry, oxygen-free tetrahydrofuran at room temperature led to the formation of an orange solution of the tetraanion of **1** (Scheme 1). Crystallization from hexane afforded air- and moisture-sensitive pale orange crystals of the tetralithium salt **2**, which contains four molecules of THF.

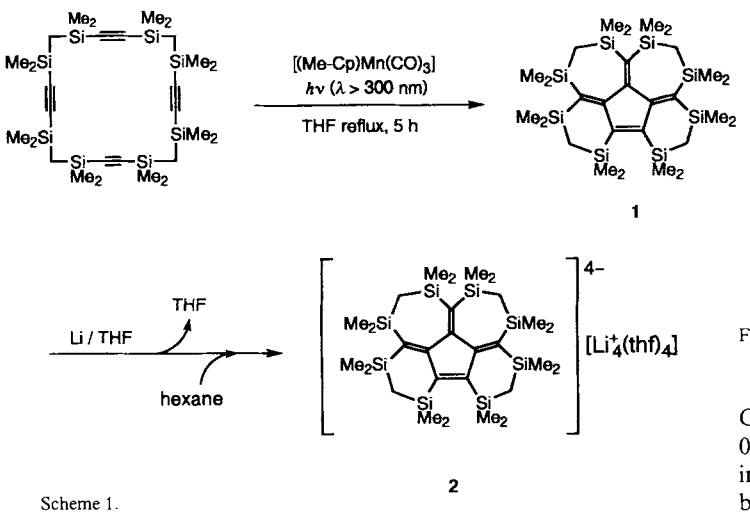

Scheme 1.

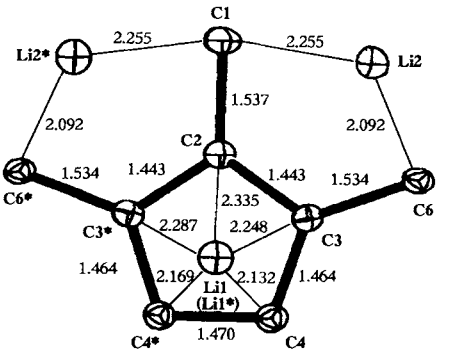

Figure 3. Section from the structure of **2** with selected distances [Å].

The molecular structure of **2** was determined by X-ray diffraction (Figure 2)[7] and shows that the molecule has C_2 symmetry and that the C1–C2 bond is a crystallographic twofold axis. The tetralithium salt **2** is monomeric and forms contact ion pairs in the crystals. One THF molecule is coordinated to each lithium atom. Li1 and Li1* are located near the center of the ring, above and below the plane of the five-membered ring. The distances between Li1 and the carbon atoms of the five-membered ring (C2, C3, C4, C4*, and C3*) range from 2.132 to 2.335 Å (av 2.234 Å). Li2 and Li2* are bonded to the two exocyclic carbon atoms (C1, C6 and C1, C6*) (Figure 3).

A comparison of the structural parameters of **1** and **2** is quite interesting. Eight carbon atoms of the π skeleton of **2** become completely coplanar by the four-electron reduction. The C3–C6, C3*–C6*, and C1–C2 distances in **2** are between 0.179 and 0.186 Å (av 0.182 Å) longer than the corresponding distances in **1**. In addition, the C4–C4* distance in **2** is elongated by 0.098 Å. By contrast, the C3–C4, C3*–C4*, C2–C3, and C2*–C3* distances in **2** are between 0.042 and 0.080 Å (av 0.062 Å) shorter than those in **1**. That is, the C–C double bonds in **1** are elongated, whereas the C–C single bonds are shortened by the reduction. The five-membered ring is planar and forms an almost equilateral pentagon, as determined by the internal bond angles of 107.4–108.8° (av 108.0°) and the sum of the bond angles (540.0°). The C–C distances in the five-membered ring range between 1.443 and 1.470 Å (av 1.457 Å). The Si–C bonds (C1–Si1, 1.832(3); C6–Si2, 1.809(4); C6–Si3, 1.832(4) Å) in **2** are considerably shorter than those in **1** (1.900(6), 1.893(6), and 1.889(6), respectively), because of the delocalization of the negative charge onto the silicon centers by pπ-σ* conjugation.

The structure of **2** in [D_6]benzene was characterized by ^{1}H, ^{13}C, ^{29}Si, and ^{6}Li NMR spectroscopy. The two methyl groups of $SiMe_2$ and the two hydrogen atoms of CH_2 are magnetically nonequivalent, which is attributed to the fixed six- or seven-membered ring and to the coordination by the lithium atoms. Thus, ^{1}H NMR spectrum of **2** in [D_6]benzene reveals the presence of eight signals for methyl groups and four doublets for methylene groups with geminal couplings of 13.2 and 13.7 Hz. In the ^{29}Si NMR spectrum, four signals are observed at $\delta = -16.1$, -15.1, -14.5, and -13.2, which are shifted to higher field in comparison to those of **1**. The ^{13}C NMR spectrum shows five signals for quaternary carbon atoms at

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2463 $ 17.50+.50/0

$\delta = 9.62$, 19.7, 107.0, 132.1, and 148.2. The signal at $\delta = 19.7$ splits into a triplet ($J(^{13}C,^{6}Li) = 6.2$ Hz) due to coupling with one ^{6}Li ($I = 1$), whereas the signal at $\delta = 9.62$ splits into a quintet ($J(^{13}C,^{6}Li) = 2.3$ Hz) due to coupling with two equivalent ^{6}Li centers. Thus, we assign the triplet to C6 and C6*, and the quintet to the C1 carbon atom. From the ^{13}C NMR spectral data, it is apparent that the negative charge is largely delocalized over the three exocyclic carbon atoms (C1, C6, and C6*) of the π-electron system of **2**. The signals of these carbon atoms in **2** are considerably shifted to higher field relative to those signals in **1** by $\Delta\delta = 169.3$ for C1 and $\Delta\delta = 152.9$ for C6 and C6*.

Interestingly, the ^{6}Li NMR spectrum of **2** yielded two signals of equal intensity at $\delta = -6.27$ and 2.47. The appreciable upfield shift at $\delta = -6.27$ is evidently caused by the strong shielding effect of the diamagnetic ring current resulting from the six π electron system. Thus, this ^{6}Li NMR signal is reasonably assigned to Li1 and Li1*, which are located above and below the five-membered ring, respectively.

On the basis of these spectroscopic data, the molecular structure of **2** in the crystal is maintained in solution. The results of the X-ray crystallographic and NMR studies presented here indicate that the tetraanion of **2** has a stable, closed-shell structure that is stabilized not only by the eight silicon atoms but also by the aromatic cyclopentadienyl anion.

Experimental Section

1: A mixture of 3,3,5,5,8,8,10,10,13,13,15,15,18,18,20,20-hexadecamethyl-3,5,8,10,13,15,18,20-octasilacycloicosa-1,6,11,16-tetrayne (201 mg, 0.33 mmol) and $[(C_5H_4Me)Mn(CO)_3]$ (93 mg, 0.43 mmol) in THF (30 mL) was irradiated with a 500 W high-pressure mercury lamp for 5 h through the cut off filter ($\lambda > 300$ nm) under the reflux in THF. After removal of the manganese complex, the reaction mixture was chromatographed on silica gel to produce pale yellow crystals of **1** in 17% yield. M.p. 229–230 °C; ^{1}H NMR ([D$_8$]toluene, TMS): $\delta = -0.28$ (d, $^{2}J(H,H) = 13.4$ Hz, 2H, CH_2), −0.16 (d, $^{2}J(H,H) = 13.4$ Hz, 2H, CH_2), 0.05 (s, 6 H, CH_3), 0.05 (d, $^{2}J(H,H) = 13.6$ Hz, 2H, CH_2), 0.18 (s, 6H, CH_3), 0.21 (s, 6H, CH_3), 0.23 (s, 6H, CH_3), 0.26 (s, 6H, CH_3), 0.29 (s, 6H, CH_3), 0.30 (s, 6H, CH_3), 0.31 (s, 6H, CH_3), 0.43 (d, $^{2}J(H,H) = 13.6$ Hz, 2H, CH_2); $^{13}C\{^{1}H\}$ NMR ([D$_1$]chloroform, TMS): $\delta = 1.00$, 1.13, 1.76, 2.54, 3.52, 3.69, 3.99, 4.77, 6.45, 12.0, 134.1, 135.7, 158.6, 172.6, 178.9; $^{29}Si\{^{1}H\}$ NMR ([D$_1$]chloroform, TMS): $\delta = -13.3$, −10.2, −10.0, −9.1.

2: Crystals of **1** (51 mg, 0.083 mmol) and lithium metal (30 mg, 4.3 mmol) were placed in a sealed tube with a magnetic stirrer. After the tube had been degassed, dry, oxygen-free THF (3 mL) was introduced by vacuum transfer, and the mixture was stirred at room temperature to give an orange solution of the tetraanion of **2** within 1 h. After the solvent had been removed in vacuo, degassed hexane was introduced by vacuum transfer. Then after the lithium had been removed, the solution was cooled to afford orange crystals of **2** in a quantitative yield. ^{1}H NMR ([D$_6$]benzene, TMS): $\delta = -0.72$ (d, $^{2}J(H,H) = 13.7$ Hz, 2H, CH_2), −0.20 (d, $^{2}J(H,H) = 13.7$ Hz, 2H, CH_2), 0.05 (s, 6H, CH_3), 0.08 (s, 6H, CH_3), 0.12 (d, $^{2}J(H,H) = 13.2$ Hz, 2H, CH_2), 0.29 (s, 6H, CH_3), 0.34 (d, $^{2}J(H,H) = 13.2$ Hz, 2H, CH_2), 0.54 (s, 6H, CH_3), 0.56 (s, 6H, CH_3), 0.61 (s, 6H, CH_3), 0.62 (s, 6H, CH_3), 0.63 (s, 6H, CH_3), 1.32 (m, 16H, THF), 3.56 (m, 16H, THF); $^{13}C\{^{1}H\}$ NMR ([D$_6$]benzene, TMS): $\delta = 5.37$, 5.67 (2CH_3), 6.65, 6.90, 6.96, 7.37, 7.53, 9.20, 9.62 (quint, $J(^{13}C,^{6}Li) = 2.3$ Hz), 11.6, 19.7 (t, $J(^{13}C,^{6}Li) = 6.2$ Hz), 25.4 (THF), 68.9 (THF), 107.0, 132.1, 148.2; $^{29}Si\{^{1}H\}$ NMR ([D$_6$]benzene, TMS): $\delta = -16.1$, −15.1, −14.5, −13.2; $^{6}Li\{^{1}H\}$ NMR ([D$_6$]benzene, LiCl in MeOH, external): $\delta = -6.27$, 2.47.

Tetradecanuclear Molybdenum (Tungsten)/Copper/Sulfur Heterobimetallic Clusters $[(n\mathrm{Bu})_4N]_4[M_4Cu_{10}S_{16}O_2E]\cdot H_2O$, (M = Mo, E = O; M = W, E = 1/2O + 1/2S)**

Jun Guo, Xintao Wu,* Wenjian Zhang, Tianlu Sheng, Qun Huang, Ping Lin, Quanming Wang, and Jiaxi Lu

The synthetic and structrual chemistry of heterometallic Mo(W)/Cu(Ag)/S clusters has developed rapidly.[1] Recently, certain clusters were found to exhibit strong nonlinear optical (NLO) properties,[2] which attracted many to synthesize more new structure types in this field. Starting from thiometalates we synthesized many Mo(W)/Cu(Ag)/S complexes such as the square-type octanuclear clusters $[Et_4N]_4[M_4Cu_4S_{12}O_4]$ (M = Mo, W),[3] the dodecanuclear clusters $[M_4Cu_4S_{12}O_4(Cu(tmen))_4]$ (tmen = tetramethylethylenediamine),[3] the eicosanuclear clusters $[Et_4N]_4[M_8Cu_{12}S_{28}O_4]\cdot DMF$ (DMF = *N*,*N*-dimethylformamide),[4] the linear-chain polymeric cluster $[WS_4Ag\cdot NH_3C(CH_2OH)\cdot 2DMF]_n$,[5] the double-chain polymeric cluster $[WS_4Ag\cdot NH_3C(CH_2OH)\cdot H_2O]_n$,[5] and the square-type octanuclear cyclic clusters $[W_4S_{16}Ag_5M(DMSO)_8]_n$ (M = Nd, La; DMSO = dimethyl sulfoxide).[6] The double incomplete cubane-like cluster compound $[Cu_6S_6W_2(SCMe_3)_2(O)_2(PPh_3)_4]$[7] is a structural model for the active center of nitrogenase.[8] Therefore, investigating the

structural characteristics of Mo(W)/Cu(Ag)/S clusters may help us to understand the structure model of the active center of nitrogenase. We recently established a synthetic route in which sulfur is introduced into the systems $[MS_nO_{4-n}]^{2-}/Cu^+$ ($n = 3, 4$) by self-assembly, and obtained the novel tetradecanuclear clusters **1** and **2**. Here we report the syntheses and structures of these two complexes.

$[(n\text{Bu})_4\text{N}]_4[\text{Mo}_4\text{Cu}_{10}\text{S}_{16}\text{O}_3]\cdot\text{H}_2\text{O}$ **1**

$[(n\text{Bu})_4\text{N}]_4[\text{W}_4\text{Cu}_{10}\text{S}_{16.5}\text{O}_{2.5}]\cdot\text{H}_2\text{O}$ **2**

All syntheses were performed at room temperature under air.[9] Complex **1** was obtained by the reaction of K_2MoS_3O, CuBr, and $(n\text{Bu})_4\text{NBr}$ (1:2:1.5) in DMF for several hours with subsequent addition of an aqueous solution of Li_2S (excess). Complex **2** was synthesized in a similar manner except that $(NH_4)_2WS_3O$ was used instead of K_2MoS_3O. The S^{2-} ion in the reaction played an important role by substituting the ligands of the M/Cu/S compounds that show a weak affinity for copper(I). This is conducive to assembling larger clusters from smaller ones, and provides an attractive synthetic route to large clusters.

The two title complexes are isomorphous and crystallize in the orthorhombic space group $Pna2_1$ with four molecules in the unit cell.[10, 11] Therefore, only the structure of **1** will be described here (Figure 1). The anion of **1** has approximately *m*

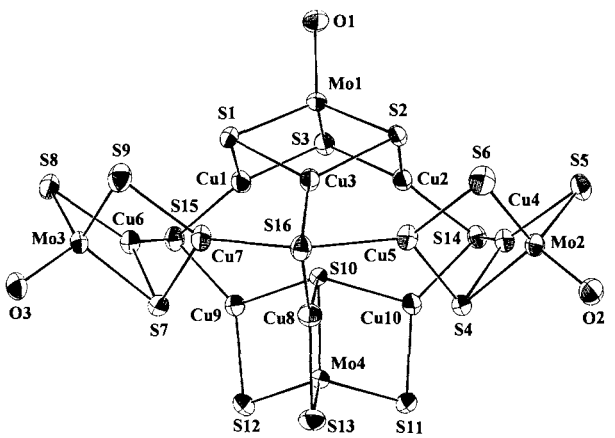

Figure 1. The structure of the anion of **1** (ORTEP representation, 20% displacement ellipsoids). Selected distances [Å] and angles [°] (range): Mo–Cu 2.660(2)–2.713(2), Cu–Cu 2.725(2)–2.953(2), Mo–O 1.697(9)–1.783(10), Mo–S 2.206(4)–2.278(3), Cu–S 2.202(4)–2.316(3); S-Mo-E (E = S, O) 106.90(11)–112.5(3), Cu-Mo-Cu 82.31(5)–94.04(6), Mo-Cu-Cu 122.03(7)–137.72(8), Mo-S-Cu 71.48(10)–75.10(12).

point group symmetry with a mirror plane through S3, O1, Mo1, Cu3, S16, Cu8, S10, S13, and Mo4 (mean deviation of 0.0073 Å). It can be viewed as consisting of one incomplete cubane-like Cu_3MoS_3O fragment, one trigonal-prism-type Cu_3MoS_4 fragment and two butterfly-type Cu_2MoOS_3 fragments that are bridged by one μ_4-S and two μ_3-S atoms. The "top" Cu_3MoS_3O subunits and the "bottom" Cu_3MoS_4 subunit are bridged by three S^{2-} ions (S14, S15, and S16); this shows some similarity to the structural characteristics of the Mo/Fe/S active center of nitrogenase,[8] whose M'_3MoS_3 and M'_4S_3 ($M' = Fe$) subunits are bridged by three S^{2-} ions. The two Cu_2MS_3O side groups (M = Mo, W) linked by the bridging sulfur atoms have a stable effect on the core (Figure 2). Apart from two Cu_2MS_3O side groups, the remaining six Cu atoms form a central trigonal prism which is capped by two M atoms;

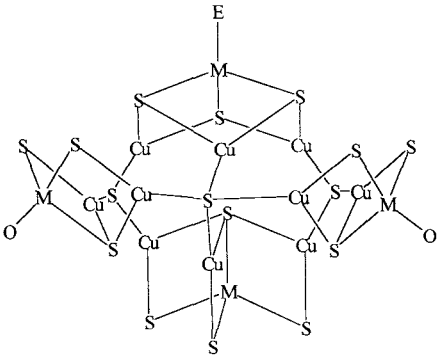

Figure 2. The framework of the anions of **1** and **2** (M = Mo. E = O; M = W, E = 1/2O + 1/2S).

the metal-connectivity pattern of $Cu_6M_2S_{10}$ core portion is similar to the structure model of the Mo/Fe/S active center of nitrogenase. We expected S10 to be outside the central unit, but it is indeed inside the core. This indicates that the present μ_4-S configuration is more stable. We reported another complex, $[Et_4N]_2[(\mu_6\text{-S})Cu_6S_6(S_2)_6Mo_6O_6]$, in which a μ_6-S atom is inside the metal core.[12] If S^{2-} ions exist, the six Fe atoms of the Mo/Fe/S active center of nitrogenase could coordinate with a μ_6-S atom.

The unconventional metal framework of the anion $[M_4Cu_{10}S_{16}O_2E]^{4-}$ (M = Mo, E = O; M = W, E = 1/2O + 1/2S) contains metal atoms in conventional trigonal-planar (Cu) and tetrahedral coordination enviroments (Mo, W). The Cu–Cu distances (2.725(2)–2.953(2) Å) in the anion of **1** are longer than 2.56 Å; Ahlrichs et al. consider this marginal covalent contribution, as a dispersion interaction of the d^{10} systems.[13] Because the Mo, Cu, and S atoms of the anion of **1** have several different coordination environments, their distances and angles vary. As is the case with Cu_2MoS_3O fragments, Mo–Cu distances in the Cu_3MoS_3E (E = O or S) fragments are 2.660(2)–2.677(2) Å and 2.682(2)–2.713(2) Å. The S14–Cu and S15–Cu bond lengths range from 2.202(4) to 2.214(4) Å, whereas the other S–Cu lengths are 2.218(4)–2.316(3) Å. With the exception of Cu-Mo4-Cu (87.66(6)–94.04(6)°), Cu-Mo-Cu angles range from 82.31(5) to 83.80(6)°. The S_M-Cu- S_M and S_M-Cu-S_b angles are 103.69(7)–107.20(13)° and 119.30(13)–136.03(15)°, respectively (S_b = S14, S15, S16; S_M represents the sulfur atoms of MoS_3O^{2-} and $MoS_4{}^{2-}$); these structureal parameters are consistent with those reported for $[Cu_6S_6W_2(SCMe_3)_2(O)_2(PPh_3)_4]$.[7]

The two title complexes crystallize in the noncentrosymmetric space group. Therefore, further research of their nonlinear optical properties is of interest.

Experimental Section

1: A solution of K_2MoS_3O (1.145 g, 4 mmol), CuBr (1.147 g, 8 mmol), and $(n\text{Bu})_4\text{NBr}$ (1.934 g, 6 mmol) in DMF (9 mL) was stirred for 12 h. A solution of Li_2S (0.45 g, 10 mmol) in water (1.5 mL) and DMF (3 mL) was then added. The reaction mixture was stirred for only one minute, the dark precipate removed by filtration, and *i*PrOH (3 mL) added. Dark crystals of **1** (0.90 g) were obtained by allowing the violet filtrate to stand at room temperature for one day.

2: A procedure similar to that used for the synthesis of **1** was employed except that $(NH_4)_2WS_3O$ (1.329 g,4 mmol) was used instead of K_2MoS_3O. Allowing the red filtrate to stand at room temperature for three days gave red crystals of **2** (0.85 g). Crystals of **2** were also obtained by allowing Et_2O to diffuse into the filtrate over four days.

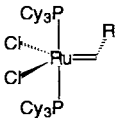
Olefin Metathesis in Compressed Carbon Dioxide**

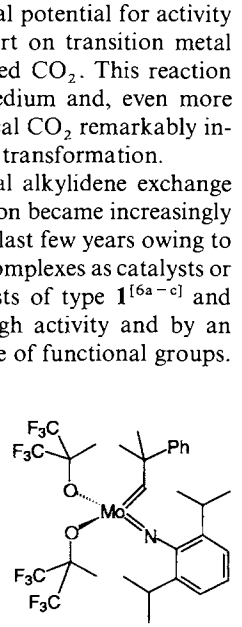
Alois Fürstner,* Daniel Koch, Klaus Langemann, Walter Leitner,* and Christian Six

Numerous advantages are associated with the use of supercritical carbon dioxide ($scCO_2$) as an ecologically benign and economically feasible reaction medium for metal-catalyzed reactions.[1] Technical aspects like its nonflammability, the lack of virtually any toxicity, the absence of a gas/liquid phase boundary, and possible simplifications in work up favor $scCO_2$ as an alternative to conventional solvents. The utilization of $scCO_2$ as solvent *and* C_1-building block offers further opportunities for homogeneous catalysis.[2] Moreover, the physiochemical properties of a supercritical fluid can be tuned within a certain range by adjusting its density and the parameters pressure and temperature. Chemical interactions of $scCO_2$ with substrates and/or catalysts[3] offer additional potential for activity and selectivity control. Herein we report on transition metal catalyzed olefin metathesis in compressed CO_2. This reaction can be performed efficiently in this medium and, even more intriguingly, the properties of supercritical CO_2 remarkably increase the scope of this well-established transformation.

Olefin metathesis refers to the mutual alkylidene exchange reaction of alkenes.[4] This type of reaction became increasingly important as a synthetic tool during the last few years owing to the application of well-defined carbene complexes as catalysts or catalyst precursors.[5] Especially catalysts of type **1**[6a–c] and type **2**[6d] are distinguished by their high activity and by an excellent compatibility with a wide range of functional groups.



1a R = CH=CPh$_2$
1b R = Ph



2

We found that both types of catalysts are suitable for ring opening metathesis polymerization (ROMP) of norbornene and cyclooctene in compressed carbon dioxide to form the technically important polymers Norsorex and Vestenamer (Table 1). The activities of these catalysts for ROMP of norbornene in compressed carbon dioxide are considerably higher than that observed with $[Ru(H_2O)_6(OTos)_2]$ in the same medium.[7] The desired polymers are obtained in excellent yields after short reaction times, both in liquid and in supercritical carbon dioxide.

[a] **A** = norbornene, **B** = *cis*-cyclooctene. **A**/Tol. = saturated solution of norbornene (85.1 %, GC) in toluene. [b] Density of reaction mixture (substrate + CO_2 + additives) based on the reactor volume V = 27 mL. [c] At reaction temperature, ± 5 bar. [d] From integration of the olefinic proton signals in the ^{1}H NMR. [e] From high-temperature GPC measurement in decalin at 423 K with polystyrene as reference. [f] Glass-temperature from DSC measurement. [g] Comparative experiment in CH_2Cl_2 (4.0 mL). [h] Not determined.

During the course of the reaction the polymers precipitate from the CO_2 phase and are readily isolated by simply venting the reactor. Under suitable reaction conditions and after removal of metallic residues by conventional methods, the products exhibit properties (molecular weight and microstructure) comparable to the materials prepared in CH_2Cl_2 by conventional means.[4] The catalyst should be injected as a solid or in dissolved form to the homogeneous solution of the monomer in CO_2 in order to avoid broad molecular weight distributions resulting from uncontrolled initiation of the polymerization reaction.

Catalysts of type **2** are known to initiate a "living" ROMP in organic solvents.[8] Complete conversion (yield 97%) of the monomer is observed if the amount of catalyst in $scCO_2$ is lowered to a ratio of norbornene/**2** of 625/1 under conditions otherwise identical to those given in Table 1, entry 6. The use of even lower catalyst loadings results in a sudden drop of the yield of polymer (norbornene/**2** 900/1: 19%; 1730/1: 6%). The reasons for this behavior are presently under investigation.

Even in the light of these very promising results on ROMP in $scCO_2$, the success of this methodology for ring-closing metathesis (RCM, Table 2) is remarkable. It may seem unfavorable at first sight to carry out a reaction that releases one equivalent of ethene at elevated pressure. However, since the total pressure in the reaction vessel is almost exclusively determined by the amount of CO_2 that does not participate in the reaction, it has little effect on the overall process.

During our investigations on the preparation of the 16-membered cyclic compound **10** by RCM of diene **9**[9a, b] in $scCO_2$ (Scheme 1), a remarkable influence of the density of the supercritical medium on product distribution was observed (Figure 1). Whereas the large ring was produced in excellent yields at densities of the compressed phase of $d \geq 0.65$ g mL^{-1}, mainly oligomers were obtained by ADMET[4] (acyclic diene metathesis) at lower densities.

This density effect on the reaction pathway may—at least in part—be attributed to the compressibility of the supercritical phase: Increasing the density at constant volume leads to an increasing number of inert solvent molecules and mimics the effect of dilution in conventional solvents ("Ziegler-Ruggli's dilution principle" [10]), favoring the intramolecular reaction pathway (Figure 2).[11] This effect has received little attention up to now and might be valid for other cyclization reactions as well.[12]

The scope of RCM in $scCO_2$ is evident from the examples for preparation of products of different ring sizes and functionalities compiled in Table 2. The five-membered ring **4** is obtained in almost quantitative yield from **3** in the form of colorless crystals after release of CO_2. The synthesis of karahanaenone **6**,

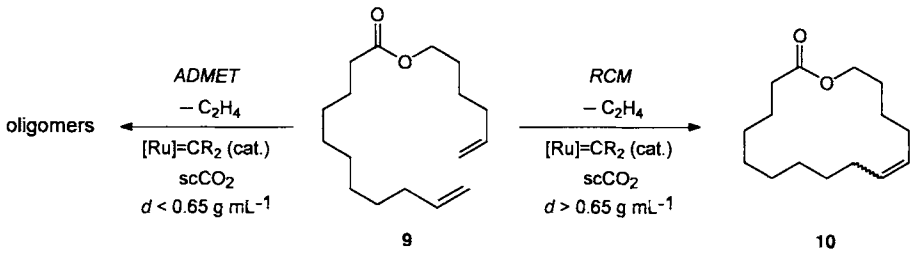

Scheme 1. Competition between RCM and ADMET during olefin metathesis of the acyclic diene **9** in compressed CO_2.

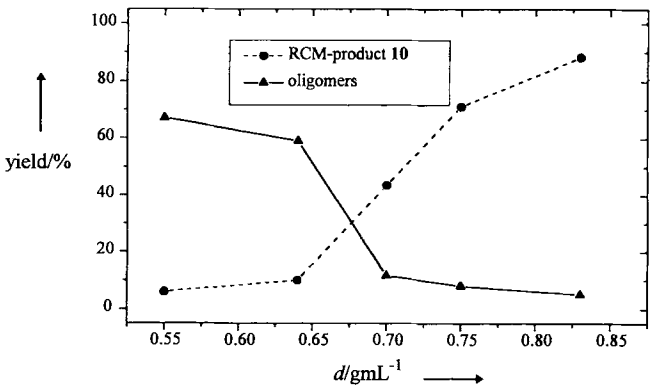

Figure 1. Effect of the density of the supercritical medium on the path of the metathesis of diene **9** leading to the formation of the macrocycle **10** or oligomeric products.

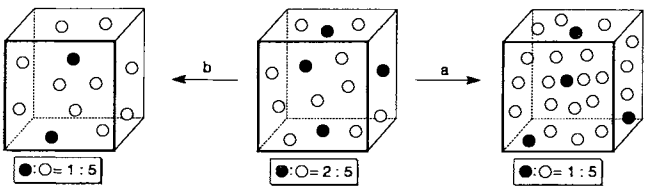

Figure 2. The dilution principle at constant volume: Increasing the density of a supercritical medium (a) or increasing the dilution in a conventional solvent (b) lead to a decreasing ratio of reactive particles (●) to inert solvent molecules (○) and thereby favor intramolecular pathways over intermolecular ones.

an olfactory substance contained in hops and cypress oil (*Cypressus sempervirens*),[13] is an example for the formation of a trisubstituted cycloalkene by using the alkylidene complex **2** in $scCO_2$. Entry 3 shows that enyne metathesis reactions[14] can also be successfully performed in $scCO_2$.

The remarkably simple syntheses of the macrocycles **10** and **12** are of special interest. These two compounds, which exhibit a strong musklike odor on their own, can be converted into the commercial perfume ingredients exaltolide and Arova 16 by hydrogenation of the C–C double bonds.[15] The products can be selectively removed from the reactor by virtue of the extractive properties of CO_2[16] and collected in cold traps. The metal residues in the autoclave are still active for RCM (entries 5 and 6) making this process potentially attractive for technical applications.

Metathesis catalysts of type **1** are deactivated by basic N–H groups; substrates containing this type of functionality can be cyclized only in protonated or otherwise protected form in conventional solvents.[17] In $scCO_2$, however, metathesis of diene **13** using catalyst **1a** forms epilachnene **14**[18] smoothly, showing that amines react without the need for protection. We attribute this to reversible formation of the corresponding carbamic acid under the reaction conditions. This example illustrates the possibility of using the reaction medium CO_2 as a "protecting group" in organic synthesis.

The results outlined above demonstrate for the first time the general applicability of olefin metathesis in compressed carbon dioxide and nicely illustrate some of the advantages related to this particular reaction medium. Although there is some experimental evidence that this transformation is homogeneously catalyzed,[19] no definite conclusion can be drawn at present. Our current efforts are directed to answering this question and to further broadening the scope of this methodology in organic synthesis.

Experimental Section

Ring opening metathesis polymerization in $scCO_2$: A stainless-steel high-pressure vessel ($V = 27$ mL) equipped with thick wall glass windows, PTFE-stirring bar, bore hole for a thermocouple, needle and ball valves was charged with norbornene (407 mg, 4.32 mmol) under argon. A dosing unit containing **1b** (5.50 mg, 0.67×10^{-2} mmol) was connected to the reactor through the ball valve. The reactor was filled through the needle valve with CO_2 (15.3 g, $d = 0.58$ gmL^{-1}) using a compressor. A colorless homogeneous supercritical phase was formed upon heating to 318 K under stirring. The dosing unit was pressurized with argon (150 bar), and by opening the ball valve the solid catalyst was introduced into the reaction vessel. After the mixture had been stirred for 14 h, the reactor was vented and the crude polymer (341 mg) was isolated. Purification of the polymer by conventional methods gave a white tacky material (316 mg, 78%). The analytical data are summarized in Table 1.

Macrocyclization by RCM in $scCO_2$: The unsaturated ester **9** (180 mg, 0.64 mmol) and the catalyst **1a** (7 mg, 7.55×10^{-3} mmol) were filled into separate compartments in a high-pressure vessel ($V = 225$ mL, equipment as above) under Ar. The reactor was pressurized with a certain amount of CO_2 using a compressor. The resulting reaction mixture was stirred for 72 h at 313 K. The volatiles were then passed through a cold trap at 233 K and the reactor was washed with acetone in order to quantitatively isolate any oligomers present. The fractions were combined and the solvent was evaporated. Low molecular weight compounds (unconverted **9** and cyclization product **10**) were separated from oligomers by column chromatography (silica gel, hexane/ethyl acetate). The results are represented graphically in Figure 1.

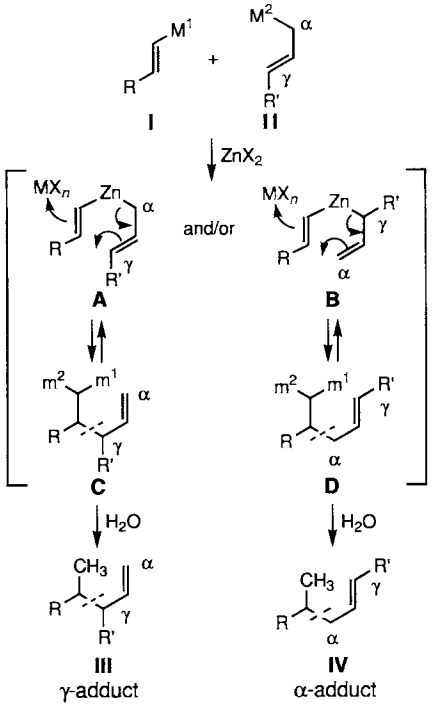
Unusual Regioselectivity in the Reductive Coupling of Alkynes and Allenes by Hydrozirconation and Zinca-Claisen Rearrangement

Keisuke Suzuki,* Takahiro Imai, Shigeo Yamanoi, Masao Chino, and Takashi Matsumoto

Dedicated to Prof. Dr. Dieter Seebach on the occasion of his 60th birthday

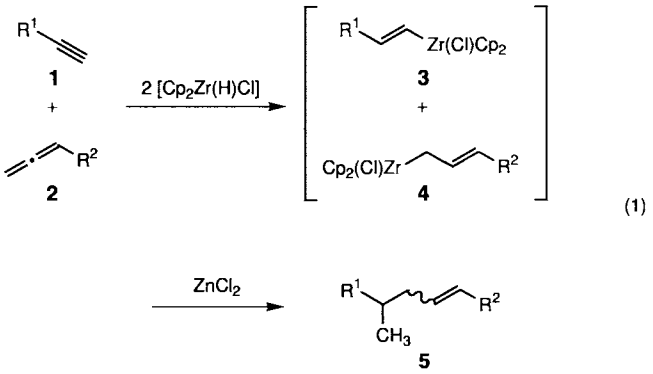
The allylmetalation of vinylmetal compounds is a new approach to C–C bond formation.[1, 2] Although the precise mechanism must still be elucidated, various features of the reaction are nicely summarized by the zinca-Claisen mechanism of Knochel and Normant and their co-workers[1d–h, 3a, 4] (Scheme 1): Coupling of vinylmetal compound **I** and allylmetal derivative **II** (M^1, M^2 = Li, MgX, ZnX, etc.) occurs by transmetalation with zinc to form **A** and/or **B**, which then undergoes bond reorganization.[4, 5] Substituted allyl–metal compounds (**II**: R′ ≠ H) tend to couple through **A** to form *gem*-bismetallic compounds **C** as the kinetically controlled products that give, upon hydrolysis, the γ-adducts **III**. Prolonged reaction results in equilibration of the organometallic species, leading to an increase in the fraction of isomeric *gem*-bismetallic compounds **D** that in turn produce the α-adducts **IV**. Unfortunately,



Scheme 1. Zinca-Claisen mechanism for the allylmetalation of vinylmetal compounds.

IV cannot be obtained selectively, because equilibration is slow and the α/γ ratio remains low even after extended reaction.[3] From an experimental standpoint, preparation of the starting organometallics **I** and **II** is sometimes troublesome as well.[6]

We report here an in situ approach to such precursors as **I** and **II** involving hydrozirconation[7, 8] [Eq. (1)], which facilitates the



(1)

reductive coupling of a series of alkynes and allenes. A noteworthy feature of this method is that the α-adduct is obtained with high selectivity. We also discuss possible explanation for the unusual regioselectivity that is observed and examine the synthetic utility of the reaction in remote asymmetric induction for synthesis of the vitamin E side chain.

Treatment of alkyne **1a** (R^1 = TrOCH$_2$) and allene **2a** (R^2 = CH_2CH_2OMOM) with the Schwartz reagent[9] in CH_2Cl_2 (−78 → 25 °C) led to a red solution that was subsequently treated with $ZnCl_2$ at 0 °C. Stirring at 25 °C for 2 h gave the α-adduct **5a** (see Table 1) as the sole product; none of the γ-adduct was detected (α:γ > 98:2).[10, 11] Under the same conditions this unusual regioselectivity proved applicable to a wide range of starting allene/alkyne combinations (Tables 1 and 2).[11] The sole exception was reaction of methyl-

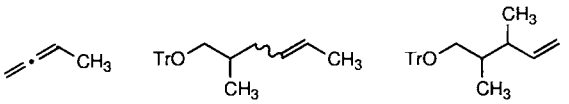
allene **6** with alkyne **1a**, which gave adduct **7** as an α/γ-mixture. This in turn provided a clue to the source of the unusual regioselectivity.



6 α-**7** γ-**7**

Figure 1 shows the time course for α-adduct content in the overall adduct mixture, which shows the existence here also of a $\gamma \rightarrow \alpha$ isomerization pathway (**C** → **D** in Scheme 1); however, in this case the isomerization is exceptionally rapid. Curve B describes the reaction of alkyne **1a** with **6**. After an initial γ-selective reaction,[12] the α/γ ratio steadily increases, reaching 83/17 after 9 h and 94/6 after 36 h (not shown). Such a rapid and complete $\gamma \rightarrow \alpha$ isomerization has not been observed previously

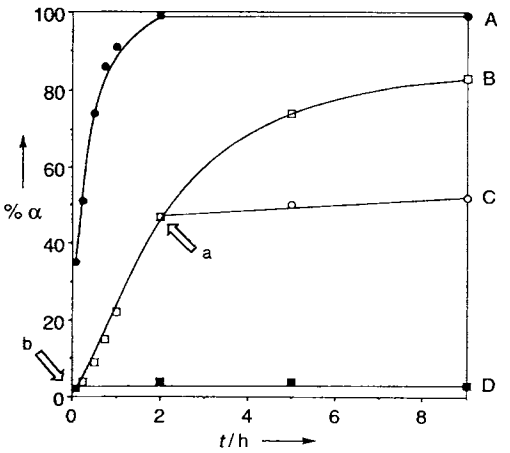


Figure 1. Time dependence of the fraction of α-adduct in the overall amount of adduct [α/(α+γ) × 100%]. A: Reaction of **1a** with **2a**. B: Reaction of **1a** with **6**. C: $MgBr_2$ addition 2 h after $ZnCl_2$ introduction (arrow a). D: $MgBr_2$ addition 5 min after $ZnCl_2$ introduction (arrow b).

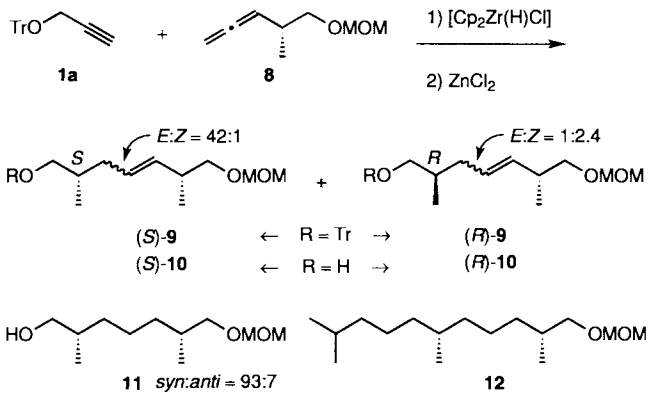
in related reactions that involve organolithium and/or -magnesium reagents (vide supra).[3] The isomerization proceeds even more rapidly in reactions of other allenes, as exemplified by the reaction of allene **2a** (curve A): the $\gamma \rightarrow \alpha$ shift is so fast here that after 2 h at 25 °C only the α-adduct **5a** is observable.[12]

Why, then, does the present isomerization rate differ so markedly from that associated with the conventional protocol? A Mg^{II} salt plays a key role.[13] Thus, in the reaction of **1a** and **6**, the $\gamma \rightarrow \alpha$ isomerization virtually ceases upon addition of $MgBr_2$, as shown by curves C and D.[12, 14] Thus, the observed γ-selectivity in the previous examples[3] can be explained through inhibition of $\gamma \rightarrow \alpha$ isomerization by a Mg^{II} salt. In contrast, the present case is "magnesium-free," so the α-adduct is obtained selectively. Nevertheless, the precise nature of the inhibitory effect remains unknown.[14]

The process described here presented an opportunity for a new vitamin E synthesis involving remote stereocontrol.[15] Reaction of homochiral allene **8**[16] and alkyne **1a** as above gave the α-adduct **9** (Scheme 2). GC-Analysis of alcohol **10**, derived



Scheme 2. Synthesis of an intermediate along the pathway to vitamin E (**12**) through the coupling of an alkyne with an allene. **9**: R = Tr; **10**: R = H.

from **9** [TsOH (cat.)/MeOH, quantitative], showed the ratio of the four isomers, (*S*,*Z*):(*S*,*E*):(*R*,*Z*):(*R*,*E*) to be 91:2:2:5, indicating a remarkable degree of selectivity *S*:*R* of 93:7 with respect to the newly formed chiral center.[17] Indeed, hydrogenation of **9** gave a 93:7 mixture of *syn*- and *anti*-**11**,[18] which could be converted (TsCl; $Me_2CH(CH_2)_2MgBr$, Cu^{2+}; H_3O^+) into **12**, a known intermediate in vitamin E synthesis.[15a] The origin of this high level of 1,5-asymmetric induction is currently under investigation.[19]

Experimental Section

In a typical experiment, a suspension of Schwartz reagent [9] was prepared by adding CH_2Cl_2 (1.0 mL) to $Cp_2Zr(H)Cl$ (603 mg, 2.34 mmol) at −78 °C [8c]. Then a mixture of alkyne **1a** (193 mg, 0.648 mmol) and allene **2a** (116 mg, 0.906 mmol) in CH_2Cl_2 (2.5 mL) was added. After gradual warming to 25 °C, the resulting red solution was chilled to 0 °C, and to this was added $ZnCl_2$ (0.69 M in ether, 1.3 mL). After 2 h at 25 °C the mixture was diluted with ether and poured into cooled, saturated aqueous $NaHCO_3$. The ether solution was extracted three times with EtOAc and the combined organic extracts were washed with saturated aqueous Na_2SO_4, dried over Na_2SO_4, and filtered through a Celite pad. Evaporation of volatile components and purification by preparative TLC (hexane/EtOAc = 9/1) gave **5a** (231 mg, 83%).

[10] Quenching the reaction with D_2O led to doubly deuterated **5a** (CHD_2 instead of CH_3).
[11] Absence of the γ-adduct was established by ^1H NMR, HPLC, and/or capillary GC. In each case, a comparison sample containing the γ-adduct was prepared by early quenching. Upon hydrogenation, each α-adduct gave a single saturated compound.
[12] The coupling reaction itself is complete within a few minutes after addition of $ZnCl_2$.
[13] Lithium salts (LiI, LiBr) also have a retarding effect, but much smaller. We originally thought that $[Cp_2ZrCl_2]$ present in the reaction mixture was responsible for the unusual regioselectivity, but this turned out not to be the case.
[14] Simple quenching by protic impurities that may have contained $MgBr_2$ was ruled out: Quenching with D_2O after addition of $MgBr_2$ produced a doubly deuterated product [10].
[15] For syntheses of the vitamin E side chain involving remote stereocontrol, see a) K.-K. Chan, N. Cohen, J. P. De Noble, A. C. Specian, Jr., G. Saucy, *J. Org. Chem.* **1976**, *41*, 3505; b) B. [16] >98% *ee*. The synthesis of **8** will be described elsewhere.
[17] Analysis is based on a comparison with the authentic stereoisomers.
[18] Based on an MTPA(= α-methoxy-α-trifluoromethylphenylacetic acid) analysis of **11** by ^{19}F NMR spectroscopy.
[19] A chelating group in the allene is essential: Stereoselectivity fell to about 1:1:1:1 if the MOM substituent in **8** was replaced by a TBDPS group. On the other hand, the protective group of the alkyne is less influential, and *S*/*R* selectivity remains 9:1 irrespective of protection. The high (*Z*)-selectivity with (*S*)-**9** is noteworthy because of the contrast with lower selectivities with (*R*)-**9** or simpler, nonstereogenic substrates.

Copper Pnictogenides as Selective Reagents: A New Access to Functionalized Phosphanes and Arsanes**

Christian Meyer, Hansjörg Grützmacher,* and Hans Pritzkow

Dedicated to Professor Gottfried Huttner on occasion of his 60th birthday

Many catalytically effective transition metal complexes contain phosphane ligands, and increasing demands concerning the reactivity and selectivity of these catalysts require the synthesis of special ligands. Phosphanes are usually prepared by allowing either a halophosphane $R_{3-n}P(Hal)_n$ to react with carbanion equivalents M^+R^- or an alkali metal phosphide $(R_{3-n}P)^-M_n^+$ (M = Li, Na, K) to react with a carbocation equivalent R^1-Z (Z = leaving group).[1] Copper reagents proved to be versatile for the selective formation of C–X bonds (X = C, Si, Sn, S, Se, Te).[2] Recently we synthesized tris(telluro)carbenium ions $[(RTe)_3C]^+[CuBr_2]^-$ by treating the copper complex [(bpy)CuTeR] (bpy = 2,2′-bipyridyl) with CBr_4.[3] We now extended these investigations to the reaction of copper phosphides and arsanides with organohalides R–Hal, which, to our knowledge, has not been reported to date.

According to the method of Caulton et al.,[4] tetrameric copper(I) *tert*-butoxide (**1**) was allowed to react with diphenyl(element) hydrides **2**–**4** to provide the partially new copper pnictogenides **5**[5]–**7** as insoluble, red-brown coordination polymers of unknown structures (Scheme 1). In the presence of the nitrogen heterocycles bpy (**8**), phenanthroline (**9**, phen), or neocuproine (**10**, neocup), deeply colored complexes such as **11**–**14**, which are relatively soluble in aromatic hydrocarbons, are formed. In the copper phosphides, the R_2P group can take either a μ_2- (three-center four-electron bond) or a μ_3-bridging position (four-center four-electron bond) between the copper centers,[6a–e] as evidenced by ^{31}P NMR spectroscopy (significant shift towards low-resonance frequencies in the case of μ_3-PR_2 units: $\delta < -50$ versus 85% H_3PO_4). Accordingly, species with μ_2-bridging Ph_2P groups dominate in solutions of **12** and **13** (^{31}P NMR: $\delta = -25$; Table 1).

The X-ray structure analysis shows that in the solid state **12** consists of a six-membered Cu_3P_3 ring in a twist conformation with alternating Cu–P distances (2.24 and 2.30 Å, Scheme 1). The Cu–Cu distances (3.9–4.1 Å) preclude significant metal–metal bonding interactions.[7] The structure of the species

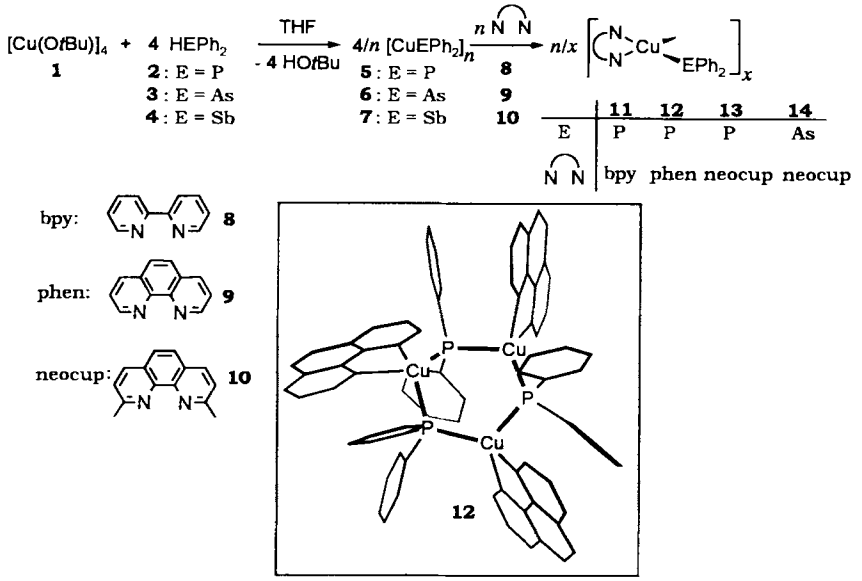

Scheme 1.

formed upon dissolving the bipyridine complex **11** is more complex: Resonances in the ^{31}P NMR spectrum are at $\delta = -15$ and -84; the latter is asigned to a μ_3-bridging Ph_2P unit.

We studied the reactivity of copper phosphide complexes **11**–**13** (E = P) and of arsanide complex **14** with respect to various organohalides containing further functional groups. Some examples are outlined in Scheme 2. The most remarkable result of this study is the selectivity and varying degrees of reactivity as a function of the nitrogen heterocycles $\widehat{NN}$, which control these reactions. Only activated chlorine or bromine centers in an allylic or benzylic position or situated α to an ester group are replaced by the Ph_2P group of **11**. The nitrile group in **15** or the ester group in **17** remain unaffected. The phosphanes **18** and **21** are thus obtained in good yields (Table 2).

Corresponding reactions employing lithium phosphide as the reagent lead to a mixture of compounds.[5c] Nonactivated alkyl halides react with the more reactive phenanthroline complex **12** to yield alkyl phosphanes. Neocuproine complexes **13** and **14** are the most reactive. In addition to all previously listed substrates, they also react with the protected brominated serine derivative **16** (which does not react with **11** or **12**). Using this method, chiral phosphanes *R,S*-**19**[8] and arsanes *R,S*-**20** are directly accessible, however, they are not enantiomerically pure. Starting with *S*-**16**, epimerization of the chiral center is observed in the course of the reaction. In addition to the products **19** or **20**, small amounts of phosphane **2** or arsane **3**, respectively, are detected.

To demonstrate the selectivity of the new reagents, we performed the sequential synthesis of the mixed (ω-phosphanyl)arsane **22** starting from 3-chloropropyl chloroacetate (**17**). In the first step the activated benzylic C–Cl functionality reacts with the less reactive copper phosphide **11** to give exclusively phosphane **21**. In the second step the more reactive neocuproine copper arsanide **14** reacts cleanly with substitution of the less reactive C–Cl unit to give **22** in good yields.

Certainly, simple phosphanes will continue to be synthesized by common methods. However, the use of copper pnictogenides $CuER_2$—whose reactivity can be fine-tuned by appropriate choice of a co-ligand—allows the relatively simple synthesis of phosphanes and, in particular, arsanes[9] bearing additional functional groups (CN, COOR, $CONR_2$). The reactions reported here are therefore a useful extension of established synthetic methods. Further optimization of the reaction conditions and variation of the nitrogen-containing ligands $\widehat{NN}$ should allow the synthesis of highly functionalized and even chiral ligands $ER^1R^2R^3$ (E = P, As, Sb).

Experimental Section

5, **6**, and **7**: A solution of **2**, **3**, or **4** (11 mmol, 1.1 equiv) in THF (10 mL) was slowly added within 30 min to a vigorously stirred solution of **1** (10 mmol) in THF (40 mL). During addition **5**, **6**, and **7** precipitated as deeply colored powders, which were filtered, washed repeatedly with Et_2O, and finally dried under high vaccum; yields 79–98%.

11–14: Copper phosphanide **5** or copper arsanide **6** (1.2×10^{-3} mol, 1 equiv) was suspended in THF (50 mL). Under vigorous stirring a solution of the ligand (**8–10**; 1.3×10^{-3} mol, 1.1 equiv) in THF (20 mL) was slowly added. The reaction mixtures were filtered over silica and then concentrated to a few milliliters. The deeply colored, air-sensitive complexes **11–14** precipitated at −20 °C as microcrystalline materials; yields 53–70%.

18–22: Freshly prepared solutions of **11–14** in THF were allowed to react with one equivalent of the organohalide (**15–17**) dissolved in THF. After complete reaction (a deep red solution over a yellow precipitate formed) the solvent was removed under vaccum, and the residue suspended in Et_2O. A saturated solution of KCN in H_2O was added until two colorless, clear phases formed. The ether phase was seperated and washed with H_2O and then 2 N HCl/H_2O. After the organic phase was dried over Na_2SO_4, the volume of the solution was reduced under vacuum. The phosphanes (arsanes) **18–22** were obtained as colorless oils. The phosphanated amino acid derivative **19** could be recrystallized from EtOH. All compounds gave satisfactory elemental analyses.

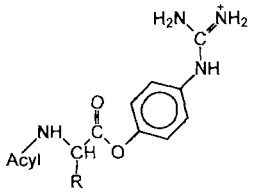
Substrate Mimetic Mediated Peptide Synthesis: An Irreversible Ligation Strategy That Is Independent of Substrate Specificity**

Frank Bordusa, Dirk Ullmann, Christian Elsner, and Hans-Dieter Jakubke*

Chemical peptide synthesis requires large experimental efforts to protect the side chains of trifunctional amino acids, and the risk of racemization cannot be entirely eliminated. There is therefore a need to explore enzyme-based alternatives.[1] Despite the undisputed advantages of enzymatic syntheses, their application is limited by the restrictive substrate specificity of enzymes and by the risk of undesired proteolysis of the starting materials or the products of segment condensations.

As early as 1991 we reported the application of 4-guanidinophenyl esters of acylated amino acids (**1**) for trypsin-catalyzed peptide syntheses in collaboration with the research group of Mitin. We could show that even acylated donor esters containing proline, D-alanine, or β-alanine in the specificity-determining P_1 position could be coupled successfully.[2] The 4-guanidinophenyl ester (OGp) leaving group of these substrates binds to the active site of trypsin in a way that mimics trypsin-specific side chains (Arg, Lys). As a result, peptide coupling occurs irreversibly and independent of specificity. We therefore consider the term "substrate mimetics" more suitable than the older "inverse substrates".[3] Recent improvements in the chemical synthesis of guanidino- and amidinophenyl esters, especially in the lab of Tanizawa, and their utilization in trypsin-catalyzed synthesis[4] initiated more intensive investigation of this ligation strategy.



1

Here we describe studies on the utility of 4-guanidinophenyl esters for segment condensations catalyzed by trypsin in comparison to reactions catalyzed by thrombin and clostripain, which had not yet been exploited for this strategy. These enzymes have a primary specificity for basic side-chain functionalities. The OGp leaving group binds in place of the specificity-determining basic side-chain functionality, as demonstrated by the program Autodock (Figure 1).[5, 6] After formation of the acylated enzyme, deacylation by the added amino component occurs independent of the primary specificity of the protease. As a result, the newly formed peptide bond cannot be recognized by the enzyme and is not subject to secondary hydrolysis. Figure 2 shows the course of a (3 + 5) segment condensation of the simple model peptide Boc-Phe-Gly-Gly-Ala-Phe-Ala-Ala-Gly-OH (Boc = *tert*-butoxycarbonyl), and demonstrates the excellent utility of substrate mimetics for the clostripain-catalyzed ligation. The maximum product concentration is reached after a few minutes and remains unchanged after 72 hours; this clearly

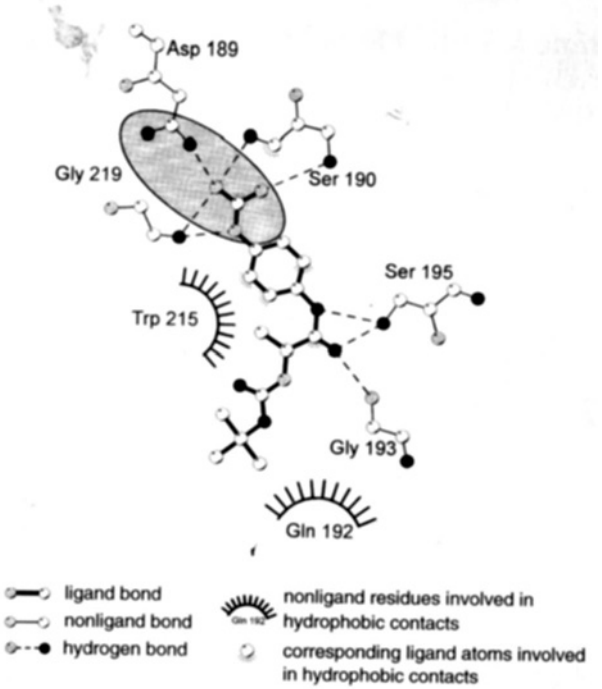

Figure 1. Ligplot drawing of the fit of Boc-Ala-OGp into the active site of the serine protease trypsin [6, 7].

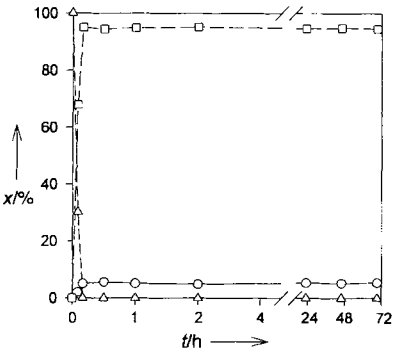

Figure 2. Course of the clostripain-catalyzed (3 + 5) segment condensation of Boc-Phe-Gly-Gly-OGp and H-Ala-Phe-Ala-Ala-Gly-OH (Boc-Phe-Gly-Gly-OGp (△); Boc-Phe-Gly-Gly-Ala-Phe-Ala-Ala-Gly-OH (□); Boc-Phe-Gly-Gly-OH (○)). Conditions were as described in ref. [8]; x = product yield.

proves the irreversibility of the ligation. In a preparative reaction with Boc-Phe-Gly-Gly-OGp (122 mg, 0.174 mmol) and H-Ala-Phe-Ala-Ala-Gly-OH (157 mg, 0.286 mmol), we obtained 177 mg (91% yield) of the Boc-protected octapeptide.[9]

Table 1 shows that all three enzymes are capable of catalyzing the (3 + 5) segment condensation, however, with largely varying yields. The highest yield was obtained with the cysteine protease clostripain, which also provided yields of over 90% for other 4-guanidinophenyl esters of acylated amino acids. Reactions of Boc-Xaa-OGp with H-Ala-Phe-Ala-Ala-Gly-OH under variation of the P_1 amino acid Xaa provided the yields given in parentheses: Gly (93%), Ala (95%), Leu (91%), Phe (91%), and Pro (90.5%).[8] A decisive advantage of clostripain in substrate mimetic mediated peptide syntheses results from its low P'_1 specificity for the N-terminal amino acid residue of the amino component. The results shown in Figure 3 clearly

Table 1. Product yield x of the thrombin-, trypsin-, and clostripain-catalyzed segment condensation of Boc-Phe-Gly-Gly-OGp (2 mM) and H-Ala-Phe-Ala-Ala-Gly-OH as a function of the concentration of the amino component [a].

AFAAG [mM]	x [%] thrombin	trypsin	clostripain
2.4	n.d. [b]	n.d. [b]	83
4	10	21	94
6	14	29	96
8	18	38	98

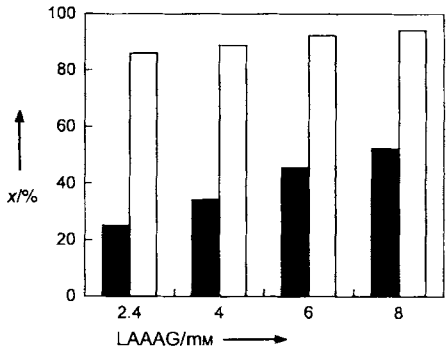

Figure 3. Product yield x for the segment condensation of Boc-Phe-Gly-Gly-OGp (2 mM) and H-Leu-Ala-Ala-Ala-Gly-OH catalyzed by clostripain (□) and trypsin (■) as a function of the concentration of amino component. Conditions were as described in ref. [8].

demonstrate that replacement of N-terminal Ala with Leu in the amino component has a less significant but positive influence on the yields of trypsin-catalyzed reactions; this is in accordance with the enzyme's known P'_1 specificity.[10] However, the high yields in clostripain-catalyzed segment condensations are nearly unaffected. A wide substrate specificity of the enzyme for the N-terminal amino acid of the amino component, which is desirable for segment condensations, can only be provided by clostipain, as demonstrated by acyl-transfer reactions with various amino components.[11]

Our results demonstrate that the serine protease thrombin can be utilized in substrate mimetic mediated segment condensations. However, the cysteine protease clostripain is of more general and practical importance for this new ligation strategy due to the high reaction yields and its low P'_1 specificity. Universal application of clostripain is only limited when using arginine-containing reagents. In these cases the residue should be placed at the N-terminus of the amino component. Alternatively, one can utilize the synthetic potential of zymogens, which are inactive in proteolysis reactions[12] and capable of accepting substrate mimetics during peptide synthesis. The current innovative method contributes to the development of practical enzymatic ligations for peptide and protein chemistry.

[6] The docking procedure was performed based on the crystal structure of trypsin 2TPN (J. Walter, W. Steigemann, T. P. Singh, H. Bartunik, W. Bode, R. Huber, *Acta Crystallogr. Sect. B* **1982**, *38*, 1462–1470) and the modeled structure of Boc-Ala-OGp. The 125 million enzyme-substrate conformations were generated in a $80 \times 72 \times 72$ Å^3 grid with a resolution of 1 Å. The conformation of lowest energy was used as the starting point for another docking procedure with 125 million enzyme-substrate conformations in a grid of $80 \times 80 \times 80$ Å^3 with a resolution of 0.35 Å. The CHARMm 23.1 template charges were used (F. A. Momany, R. Rone, H. Kunz, R. F. Frey, S. Q. Newton, L. Schäfer, *J. Mol. Strukt. (Theochem)* **1993**, *286*, 1–18). All torsion angles were allowed to rotate freely.

[7] A. C. Wallace, R. A. Laskowsy, J. M. Thornton, *Protein Eng.* **1995**, *8*, 127–132.

[8] The enzyme-catalyzed reactions were performed in 0.05 M 2-[4-(2-hydroxyethyl)]-1-piperazineethanesulfonic acid (HEPES, pH = 8.0), which was 0.1 M NaCl and 0.01 M $CaCl_2$. The concentration of Boc-Phe-Gly-Gly-OGp was 2 mM for all analytical reactions. The concentration of H-Ala-Phe-Ala-Ala-Gly-OH was 4 mM for reactions with Boc-Phe-Gly-Gly-OGp (Figure 2) and for reactions with Boc-Xaa-OGp. Enzyme concentrations used were [trypsin] = 9.6×10^{-6} M, [thrombin] = 2.2×10^{-5} M, and [clostripain] = 1.6×10^{-6} M in reactions with Boc-Phe-Gly-Gly-OGp. In the cases of Boc-Gly-OGp, Boc-Ala-OGp and Boc-Phe-OGp the same concentration of clostripain was used. In reactions with Boc-Leu-OGp or Boc-Pro-OGp the concentration of clostripain was 1.3×10^{-5} M. The reactions were analyzed under optimized conditions with reverse-phase HPLC using a RP-18 column (Vydac, 218TP54, 5 μM, 300 Å, 25×0.4 cm; The Separations Group), an SG-120 5 μm RP18 Grom Capcell column (Grom) of the same dimensions, and a 4.6×125 mm RP-4 column (Kromasil, EKA-NOBEL). Detection was carried out at 254 nm for the Phe-containing substrate mimetics Boc-Phe-Gly-Gly-OGp and Boc-Phe-OGp, and at 220 nm for all other mimetics Boc-Xaa-OGp. For the latter the yield was calibrated based on reactions in which the acylated donor ester was completely consumed.

[9] Boc-Phe-Gly-Gly-Ala-Phe-Ala-Ala-Gly-OH was synthesized in preparative amounts with 3 mM Boc-Phe-Gly-Gly-OGp and 4 mM H-Ala-Phe-Ala-Ala-Gly-OH. The total volume of the reaction mixture was 58 mL. Other reaction conditions were as described in ref. [8]. The enzymatic reaction was stopped by addition of trifluoroacetic acid (TFA, 1% solution); this led to precipitation of the desired peptide product, which was washed with water. Boc-Phe-Gly-Gly-Ala-Phe-Ala-Ala-Gly-OH·2.5 TFA·2 H_2O ($C_{43}H_{58.5}F_{7.5}N_8O_{18}$, 1117.98): calcd elemental analysis: C 46.20, H 5.27, N 10.02; found: C 45.22, H 5.80, N 10.81; MALDI-TOF: $m/z = 819.29$ $[M+Na]^+$.

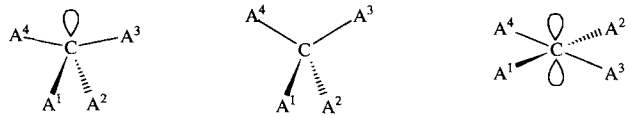
Stabilization of a C_{2v}-Distorted Methane Derivative in an Organometallic Framework**

Jörg Schottek, Gerhard Erker,* and Roland Fröhlich

Dedicated to Professor Dieter Seebach on the occasion of his 60th birthday

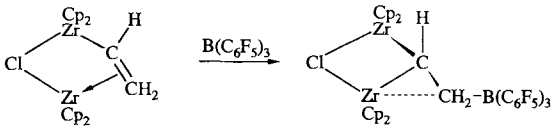
The molecular structure of tetrahedral methane can formally be distorted in different ways.[1] Opening both angles A^1-C-A^2 and A^3-C-A^4 from 109 to 180° in the same direction, to place the four substituents in one plane, leads to planar methane (D_{4h}, Scheme 1). In contrast to "natural" T_d methane, the D_{4h} species



Scheme 1. Symmetries of methane derivatives.

has an electron-deficient σ system and two electrons in the 2p orbital perpendicular to the molecular plane. It is possible to stabilize this situation electronically,[2] and there are many examples of compounds that contain a planar-tetracoordinate carbon atom.[3] Opening only the A^3-C-A^4 angle of T_d methane leads to a series of C_{2v} methane derivatives; increasing this angle to greater than 180° provides an inverted tetracoordinate carbon atom.[4] Again, this deformation results in an electron-deficient σ system, now located at the A^3-C-A^4 moiety, and increased electron density at the opposite sides of the A^1–C and A^2–C vectors.[5] As with planar-tetracoordinate carbon, C_{2v} methane derivatives should be stabilized by electron-donor substituents that compensate for the electron deficiency in the σ system and by π-acceptor substituents that show conjugation of the resulting electron pair, but with a different spatial arrangement than in D_{4h} methane.

Here we report the preparation and the structural characterization of the stable organometallic C_{2v} methane derivative **2**, which contains an internal ion-pair interaction in a rigid organometallic framework that stabilizes the unusual geometry at carbon. The strong Lewis acid tris(pentafluorophenyl)borane adds regioselectively to the dinuclear bis(zirconocene) compound **1** to yield **2** in about 60% yield with formation of a B–C



1 **2**

bond at the $=CH_2$ terminus of the bridging vinyl moiety. The starting material **1**[6] was obtained by hydrozirconation of acetylene followed by addition of the [Cp_2Zr] building block, which was generated photochemically from diphenylzirconocene.[7]

Single crystals of **2** that were suitable for X-ray structure analysis were obtained from toluene at −50 °C. The crystal structure of **2** (Figure 1) shows a dinuclear, chloro-bridged complex containing an asymmetric triangular Zr1-Cl-Zr2 framework. The Zr2–Cl bond is markedly shorter (2.5422(7) Å) than the rather long Zr1–Cl bond (2.6409(7) Å, angle Zr2-Cl-Zr1 86.05(2)°). The Zr1 ··· Zr2 separation of 3.5373(5) Å apparently precludes any direct metal–metal interaction. The two metallocene moieties are arranged in such a way (dihedral angles D1-Zr2-Cl-Zr1 117.0, D3-Zr1-Cl-Zr2 111.6°) that the Zr2-C1-Zr1 plane is the common σ-bonding plane.[8] Consequently, the carbon framework of the μ-$CHCH_2BR_3$ (R = C_6F_5) ligand is located in front of the Zr1 ··· Zr2 edge of the central Zr_2Cl triangle, as far as this is allowed by the bonding angles at the carbon atoms. The interaction of the μ-$CHCH_2$ moiety with both the transition metal centers is the main reason for the unusual and remarkable structural features of **2**. The quality of the X-ray analysis even allowed us to include the located hydrogen atoms at C1 and C2 into the structural description.

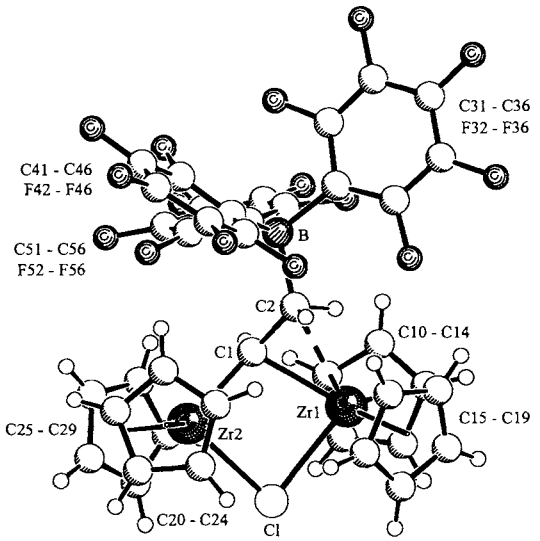

Figure 1. Molecular structure of **2**. Selected bond lengths [Å] and angles [°]: Zr1–Cl 2.6409(7), Zr2–Cl 2.5422(7), Zr1–Zr2 3.5373(5), Zr1–C1 2.396(3), Zr2–C1 2.156(3), Zr1–C2 2.600(3), C1–C2 1.502(3), C1–H1 0.98(3), C2–H2a 0.94(3), C2–H2b 0.99(3), C2–B 1.695(4), B–C31 1.669(4), B–C41 1.664(4), B–C51 1.647(4); Zr1-Cl-Zr2 86.05(2), Cl-Zr1-C1 81.89(6), Zr1-C1-Zr2 101.86(10), C1-Zr2-Cl 89.06(7), Zr2-C1-C2 145.9(2), Zr1-C1-C2 80.11(14), Zr1-C2-C1 65.22(13), Zr1-C2-B 155.0(2), C1-C2-B 119.2(2).

Carbon atom C1 is tetracoordinate and exhibits a strong distortion towards a C_{2v} structure (see Scheme 1). It is bonded to C2 (1.502(3) Å), H1 (0.98(3) Å), Zr1 (2.396(3) Å), and Zr2 (2.156(3) Å). The bonding angles of this moiety deviate considerably from tetrahedral angles. The Zr2-C1-C2 angle is 145.9(2)° (which corresponds to the increased A^3-C-A^4 angle in C_{2v} methane, Scheme 1). The angles Zr2-C1-H1 and C2-C1-H1 are 105.(2) and 109(2)°, respectively. In contrast, the remaining angles at C1 are much smaller (Zr2-C1-Zr1 101.86(10), Zr1-C1-C2 80.11(14)°); the Zr1-C1-H1 angle is 101(2)°. A noteworthy structural feature is the very short Zr2–C1 distance of 2.156(3) Å; to our knowledge, this is the shortest length for a bond from a zirconocene to a tetracoordinate carbon center.[9] This indicates the presence of an additional bonding interaction between the electron pair at the "backside" of carbon C1 in C_{2v} methane, which results from the severe distortion of the framework, and the coplanar acceptor orbital on the adjacent metallocene unit (see Figure 2). This carbon → metal donor interaction probably contributes substantially to the electronic stabilization of the distorted geometry of the tetracoordinate carbon center C1.

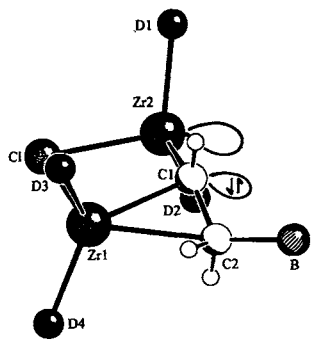

Figure 2. Partial structure of **2**. The orbitals depicted at C1 and Zr2 indicate a potential stabilizing interaction (D1—D4 denote the centroids of the Cp rings).

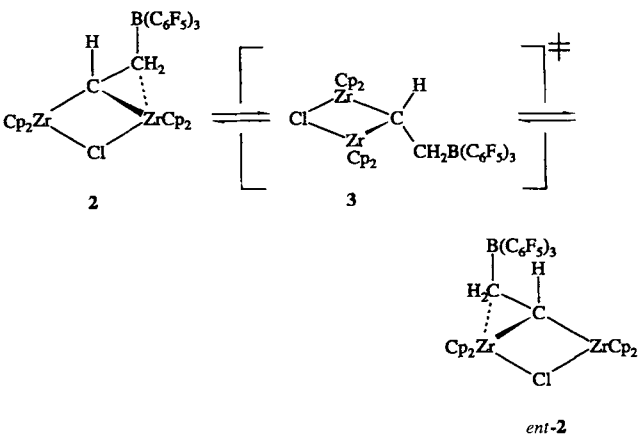
The bonding features at C2 are also unusual. Formally, C2 appears as a distorted trigonal bipyramidal pentacoordinate carbon atom.[10] However, there is only a minor distortion of the tetrahedral C1C2(H_2)BR_3 moiety (C1-C2-B 119.2(2), C1-C2-H2a 113.(2), C1-C2-H2b 110(2), B-C2-H2a 109(2), B-C2-H2b 102(2)°), which exhibits an additional bonding contact to Zr1 (C2–Zr1 2.600(3) Å). The C2–H2a and C2–H2b bonds are oriented toward Zr1, and the C2–B vector points in the opposite direction (Zr1-C2-B 155.0(2)°). The R_3B-C2 ··· Zr1 contact features properties typical of an electrostatic interaction. Complex **2** contains an internal ion-pair interaction between the cationic metallocene and the negatively polarized borate methylene group inside the dinuclear metallocene borate betaine structure.[11]

According to NMR spectroscopy, **2** shows a similar structure in solution. At 233 K **2** exhibits four resonances in both the ^{1}H and ^{13}C NMR spectra ([D_8]toluene) due to the two pairs of diastereotopic Cp ligands (δ = 5.44, 5.36, 5.26, 4.78 and 111.1, 110.2, 108.5, 107.1). There is an additional signal in each spectrum for C1H at δ = 7.12 and 174.7, respectively (^1J(C,H) = 122 Hz). The C2(H_2) signal at δ = 2.75 in the ^{1}H NMR spectrum is broad. Compound **2** shows temperature-dependent NMR spectra: Raising the temperature leads to a pairwise coalescence of the resonances for the Cp ligands. Therefore, at 298 K very simple ^{1}H and ^{13}C NMR spectra are observed, which each feature only two resonances for Cp (δ = 5.42, 5.18 and 111.6, 110.7). In the ^{13}C NMR spectrum the resonance for C2 appears at δ = 21.8.

The dynamic NMR spectra indicate an intramolecular enantiomerization process for **2**. It must be assumed that this proceeds with opening of the internal Zr1 ··· C2(H_2)BR_3 ion-pair bond. The rearrangement pathway probably passes through an intermediate structure that contains a normal tetrahedral carbon atom C1. From the temperature-dependent NMR spectra, a Gibbs activation energy for this thermally induced rearrangement was estimated to be $\Delta G^{\ddagger}_{enant} \approx 12.1 \pm 0.5$ kcal mol^{-1} for the temperature at which the signals for the Cp ligands coalesce (273 K).[12]

A qualitative estimate of the energetic properties at the C_{2v}-methane carbon atom C1 of **2** can be deduced from the dynamic behavior. In the course of the **2**⇌*ent*-**2** topomerization the inter-



nal Zr1 ··· C2(H_2)BR_3 ion pair has to be cleaved. Assuming similar energetics as for the acyclic $[Cp_2ZrR]^+/[CH_3B(fluoroaryl)_3]^-$ ion pair,[11a] the bond dissociation energy for the Zr1 ··· C2(H_2)BR_3 group can be estimated to be about 16–18 kcal mol^{-1}. By comparing this value with the magnitude of $\Delta G^{\ddagger}_{enant}$ in **2**, it can be concluded that the distorted C_{2v} geometry at C1 of complex **2** is about 5 kcal mol^{-1} less favorable than the normal tetrahedral geometry, which is probably realized in the intermediate structure **3**. The unusual, distorted coordination geometry of C1 in **2** is therefore only observable because of the additional stabilization due to formation of the internal ion-pair interaction between Zr1 and the C2(H_2)BR_3 moiety. Thus, the otherwise disfavored system **2** gains so much stabiliza-

tion energy, compared to **3**, that it becomes the global minimum and is the only observed system.

This result emphasizes that the metal–ligand ion-pair bond is an important, but often unused, structural element for the composition of organometallic frameworks. The bonding strength of these ion-pair interactions is located between the weak noncovalent interactions and the covalent bonds of corresponding metal complexes. It is likely that such interactions will play an increasingly important role in the field of organometallic chemistry and catalysis.

Experimental Section

1: Vinylzirconocene chloride (0.70 g, 2.47 mmol) and diphenylzirconocene (0.93 g, 2.48 mmol) were dissolved in toluene (20 mL) and irradiated for 6 h at −78 °C (Philips HPK 125, Pyrex filter). The solvent was then removed in vacuo, and the residue washed with pentane to give **1** (660 mg, 53 %); m.p. 204 °C (decomp, determined by differential scanning calorimetry (DSC)). ^{1}H NMR (200 MHz, 300 K, [D$_6$]benzene): δ = 7.15, 3.92, 2.64 (ABX system, ^3J = 13.5, 17.8 Hz, ^2J = 1.8 Hz, each 1 H, vinyl), 5.61, 5.32, 5.25, 5.07 (s, each 5H, Cp); ^{13}C NMR (90 MHz, 300 K, [D$_6$]benzene): δ = 178.8, 63.1 (vinyl), 106.5, 105.2, 104.5, 103.6 (Cp).

2: Complex **1** (120 mg, 0.24 mmol) was mixed with B(C$_6$F$_5$)$_3$ (122 mg, 0.24 mmol). Toluene (30 mL) was added at 0 °C, and the reaction mixture stirred for 20 min at room temperature. The product was precipitated by adding pentane (20 mL). The solvent was decanted, and the residue stirred in pentane to give **2** (150 mg, 61 %); m.p. = 100 °C (DSC). Elemental analysis calcd for C$_{40}$H$_{23}$BF$_{15}$ClZr$_2$ (1018.9): C 47.23, H 2.28; found: C 47.01, H 2.74; ^{1}H NMR ([D$_8$]toluene, 600 MHz, 223 K): δ = 7.12 (m, 1H, C1H), 5.44, 5.36, 5.26, 4.78 (s, each 5H, Cp), 2.75 (br, 2H, C2(H$_2$)); ^{13}C NMR ([D$_8$]toluene, 150 MHz, 298 K): δ = 174.7 (^1J(C,H) = 122 Hz, C1), 148.3 (^1J (C,F) = 234 Hz), 139.4 (^1J(C,F) = 244 Hz), 136.8 (^1J(C,F) = 243 Hz, *o*-, *p*-, *m*-C$_6$F$_5$), 125.1 (*ipso*-C of C$_6$F$_5$), 111.6, 110.7 (Cp), 21.8 (br, C2); ^{19}F NMR ([D$_8$]toluene, 564 MHz, 213 K): δ = −130.7, −161.4, −166.0 (*o*-, *m*-, *p*-C$_6$F$_5$); ^{11}B NMR ([D$_8$]toluene, 64 MHz, 300 K): δ = −11.3.

X-ray crystal structure analysis of **2**: Single crystals were obtained from toluene, C$_{40}$H$_{23}$BClF$_{15}$Zr$_2$·2C$_7$H$_8$, M_r = 1201.55, crystal size 0.8 × 0.6 × 0.3 mm, a = 16.256(1), b = 18.248(1), c = 16.497(1) Å, β = 98.42(1)°, V = 4840.9(5) Å^3, ρ_{calcd} = 1.649 g cm^{-3}, μ = 0.582 mm^{-1}, Z = 4, monoclinic, space group $P2_1/n$ (no. 14), λ = 0.71073 Å, T = 223 K, $\omega/2\theta$ scans, 10176 measured reflections ($\pm h$, $-k$, $+l$), [(sin θ)/λ] = 0.62 Å^{-1}, 9828 independent and 7694 observed reflections [$I \geq 2\sigma(I)$], 669 refined parameters, R = 0.032, wR^2 = 0.078, max./min. residual electron density 0.62/ − 0.38 e Å^{-3}. Hydrogen atoms at C1 and C2 were taken from the difference Fourier analysis and isotropically refined; hydrogen atoms at the Cp rings and at both toluene solvent molecules were calculated and refined as riding. The data set was collected with an Enraf Nonius MACH3 diffractometer. The following programs were used: data reduction: MolEN, structure solution: SHELXS-86, structure refinement: SHELXL-93, graphics: SCHAKAL-92. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100458. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

Intramolecular Hydrocarbonation of ε-Alkynyl Malononitriles Catalyzed by Palladium Olefin Complexes

Naofumi Tsukada and Yoshinori Yamamoto*

Addition of a carbon nucleophile to a C–C multiple bond is one of the most important methods of C–C bond formation in organic synthesis. The Michael reaction is a classic and standard procedure for this purpose, in which an anionic organometallic species (NuM) adds to an activated alkene bearing an electron-

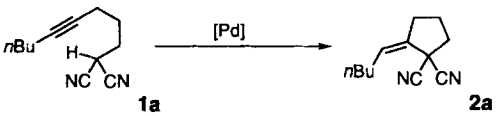
withdrawing group (a Michael acceptor).[1] Addition of an NuM to a nonactivated alkene,[2] and the addition of pronucleophiles (NuH) to Michael acceptors,[3] takes place in the presence of certain transition metal catalysts. More recently it has been found that transition metal catalysts facilitate the "hydrocarbonation" of nonactivated C–C multiple bonds through activation of C–H bonds in active methylenes and methines,[4] terminal alkynes,[5] aldehydes,[6] or aromatic rings.[7] However, to the best of our knowledge, "hydrocarbonation" of simple alkynes with active methylenes and methines has not been reported, except for Gore–Balme's carbocyclization under basic conditions.[8] We wish to report that intramolecular hydrocarbonation of alkynes with an active methine proceeds very well under neutral and mild conditions in the presence of a 1,5-cyclooctadiene–Pd catalyst.[9]

Initially we investigated the palladium-catalyzed cyclization of internal alkyne **1a**, which bears a malononitrile group at the terminus of the carbon chain [Eq. (a); Tables 1 and 3]. The



1a **2a** (a)

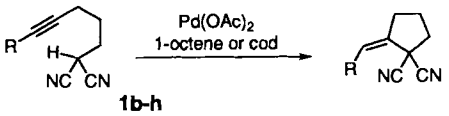
Table 1. Palladium-catalyzed cyclization of **1a** to **2a** [Eq. (a)][a].

Entry	Additive	T[°C]	Yield[%][b]
1	–	70	33
2	PPh_3	RT	35
3	1-octene	70	64[c]
4	1-octene	100	84
5	cod	RT	89
6	cod	RT	85[d]

[a] **1a** (0.3 mmol) was treated in 3 mL of ethanol over 12–36 h in the presence of $Pd(OAc)_2$ (0.06 mmol, 20 mol%) and an additive (PPh_3, 0.12 mmol, 1-octene 0.6 mmol, cod 0.12 mmol). [b] Determined by NMR spectroscopy with *p*-xylene as internal standard. [c] Significant amounts of **1a** were recovered. [d] With 5 mol% $Pd(OAc)_2$ and 20 mol% cod.

ε-alkynyl malononitrile **1a** indeed underwent cyclization in the presence of $Pd(OAc)_2$ in ethanol at 70 °C to afford alkylidenecyclopentane **2a** in 33% yield, together with unidentified products (entry 1). Use of ethanol as a solvent was essential; the reaction did not proceed at all in nonprotic solvents like toluene and THF. Cyclization of **1a** proceeded at room temperature in the presence of PPh_3, but the yield of **2a** was not improved (entry 2). Reaction at 70 °C decreased the yield to 25%. Use of 1-octene as an additive gave **2a** stereoselectively in 64% yield (entry 3). However, reaction was incomplete (entry 3), and palladium black appeared at an early stage.[10] Higher temperatures enhanced the yield of **2a** (entry 4), presumably because the reaction proceeded more rapidly and was complete before the "Pd^0" intermediate was converted into Pd-black. Finally, we discovered that use of 1,5-cyclooctadiene (cod) as an additive gave the best results (entry 5). The reaction proceeded very smoothly even at room temperature to give **2a** in 89% yield, and no Pd-black appeared during the process. The cod apparently acts as a chelate ligand for palladium(0).[11] Moreover, use of cod reduces the amount of catalyst required from 20 to 5 mol% (entry 6). The *Z*-isomer **2a** was obtained exclusively, and no *E*-isomer could be detected in any of the cases investigated. The olefin geometry was established unambiguously by NOE experiments. Use of $[Pd_2(dba)_3]\cdot CHCl_3$ and dppf gave **2a** in very low yield along with several unidentified compounds (dba = dibenzylideneacetone; dppf = 1,1-bis(diphenylphosphanyl)ferrocene). No reaction whatsoever was observed with $[Pd_2(dba)_3]\cdot CHCl_3$ and $Pd(PPh_3)_4$. Reaction of **1a** in toluene/ethanol (5/1) or THF/ethanol (5/1) in the presence of a mixture of $Pd(OAc)_2$ (5 mol%) and cod (20 mol%) also proceeded very smoothly, giving **2a** in 88 and 83% yield, respectively.

Cyclization reactions of various ε-alkynyl malononitriles **1** are summarized in Table 2 [Eq. (b)]. The reaction of **1b** which



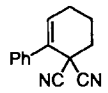
1b-h **2b-h** (b)

Table 2. Cyclization of ε-alkynyl malononitriles **1** to **2** [Eq. (b)][a].

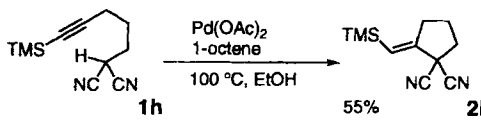
Entry	1	R	Yield[%][b]
1	**1b**	H	39
2	**1c**	Me	70
3	**1d**	$HO(CH_2)_3$	76
4	**1e**	TBDMS-$O(CH_2)_3$	80
5	**1f**	TBDMS-OCH_2	80
6	**1g**	Ph	73[c]
7	**1h**	TMS	84[d]

[a] **1** (0.3 mol) in toluene/ethanol (5/1) was teated at room temperature over 30–96 h in the presence of 5 mol% $Pd(OAc)_2$ and 20 mol% cod. TBDMS = *tert*-butyldimethylsilyl, TMS = trimethylsilyl. [b] Isolated product. [c] Mixture of **2g** and **3** (93:7, determined by NMR spectroscopy). [d] Mixture of *Z*- and *E*-isomers (91:9, determined by NMR spectroscopy).

bears a terminal alkyne unit was sluggish and gave the methylenecyclopentane **2b** in 39% yield (entry 1); the low yield and slow reaction may be due to oxidative addition of Pd^0 into the C–H bond of the terminal alkyne.[5] Methylacetylene derivative **1c** gave **2c** in good yield (entry 2). The reaction of **1d** containing a hydroxy group gave **2d** in high yield without producing furan or pyran derivatives, which are major products in palladium-catalyzed cyclization of hydroxy acetylenes (entry 3).[12] It is interesting that hydroxy-free **1d** and hydroxy-protected **1e** gave similarly high yields (entries 3 and 4). Propargyl ether **1f** afforded **2f** in high yield (entry 5). Only **1g** resulted in both *exo*- and *endo*-cyclization, affording a 93:7 mixture of benzylidenecyclopentane **2g** and phenylcyclohexene **3** (entry 6). Cyclization of **1h** gave a 91:9 mixture of the *Z*- and *E*-isomers in 84% yield. It is worth noting that cyclization of **1h** using 1-octene rather than cod as an additive afforded primarily the *E*-isomer [13] [Eq. (c)],



3



1h 55% **2h** (c)

E:*Z* = 76:24

whereas no *E*-isomer at all was obtained in the reactions of **1a** and **1c–g** under the same conditions (Table 1, entry 4). Reaction of other pronucleophiles, such as cyanoester **1i** and diester **1j**, produced no cyclization product.

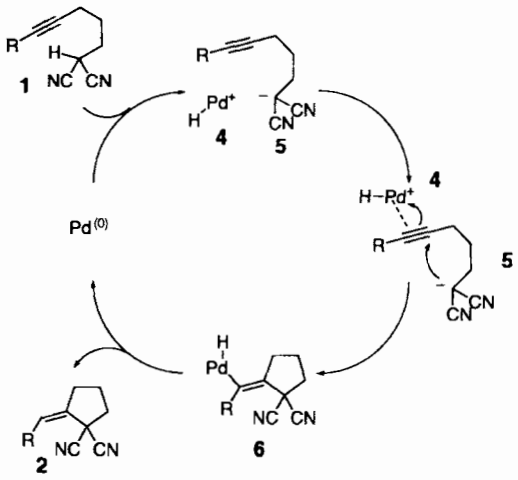
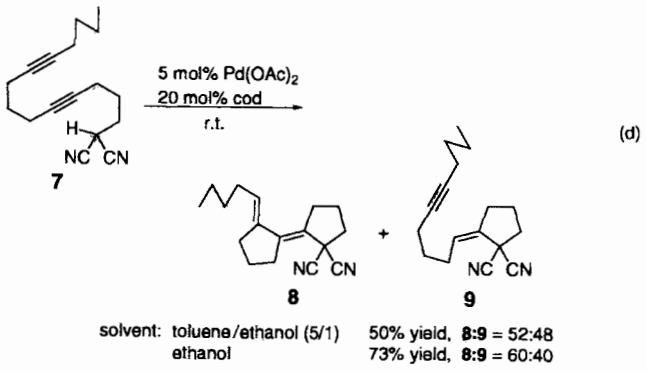
The addition of active methines and methylenes to 1,3-dienes or allenes probably proceeds by way of π-allyl palladium intermediates, which are generated by insertion of a double bond into a Pd–H bond, with subsequent addition of the pronucleophile.[4] However, the formation of **2** from **1** cannot be explained by hydride addition to the unsaturated C–C bond. A plausible mechanism is shown in Scheme 1. Cationic palladium hydride complex **4** and the carbanion **5** would be produced by abstraction of a proton from $HC(CN)_2R$ by Pd^0. Although the role of ethanol is not clear, it may assist in the formation of **4**.[14] Coordination of **4** to the triple bond of **5** would be followed by



Scheme 1. Possible mechanism for the cyclization of **1**.

rapid intramolecular cyclization of **5** from the opposite side of Pd. This addition would be more rapid than migratory insertion of alkyne into the Pd–H bond (hydropalladation), and it affords the vinylpalladium compound **6**.[15] Reductive elimination of palladium(0) from **6** leads to cyclization product **2**. The observed *Z*-geometry of **2** is in accord with this mechanism.

Cyclization of diynyl malononitrile **7** afforded the tandem cyclization product **8** along with monocyclization compound **9** [Eq. (d)]. Treatment of **9** under the reaction conditions did not



produce **8**.[14] These results support intervention of vinyl palladium species **6** in the catalytic cycle. The amount of ethanol present had no significant influence upon the ratio **8**:**9**.

Although the $[Ni(cod)_2]$ complex has been widely used as a catalyst or reagent in organic synthesis, use of a Pd^0–cod complex as a catalyst is unprecedented so far as we know.

Experimental Section

Representative procedure for the synthesis of **2e** from **1e**: To a solution of $Pd(OAc)_2$ (3.4 mg, 0.015 mmol) in toluene (1.0 mL) was added ethanol (0.5 mL) and 1,5-cyclooctadiene (7.4 mL, 0.06 mmol) under an argon atmosphere, and the mixture was stirred for 1 h at room temperature. A solution of **1e** (91 mg, 0.3 mmol) in 1.5 mL of toluene was then added. The mixture was stirred at room temperature, and the progress of the reaction was monitored by TLC. After 84 h, **1e** had been completely consumed. The reaction mixture was filtered through a short silica gel column (eluent: ethyl acetate). Concentration and purification by column chromatography over silica gel (hexane/ethyl acetate) afforded **2e** in 80% yield (73 mg).

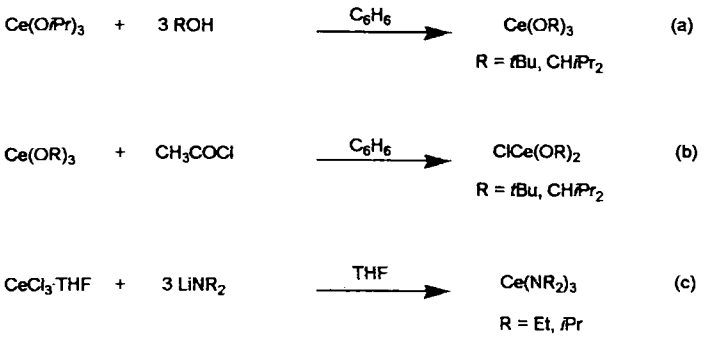
Ligand Effects in Diastereoselective Additions of Organocerium Reagents to Carbonyl Substrates**

Carmen Alcaraz and Ulrich Groth*

One of the most important contributions of lanthanide reagents to synthetic organic chemistry is the application of organocerium reagents in carbonyl addition reactions.[1] Owing to their low basicity and high nucleophilicity, organocerium reagents afford much higher yields of addition products with highly enolizable substrates than the corresponding organolithium or organomagnesium reagents from which they can be generated in situ. Furthermore, the steric bulk of organocerium reagents should make them suitable candidates for achieving high diastereoselectivity in additions to carbonyl derivatives.[2] The nature of the ligands determines the direction and extent of stereoselectivity in many carbonyl addition reactions,[3] but the sense and magnitude of diastereoselectivity achievable in the addition of organocerium reagents to chiral carbonyl substrates has to date not been explored in a systematic fashion.

We report here on the synthesis of new alkoxy- and amidocerium compounds of the general formula $ClCe(OR)_2$, $Ce(OR)_3$, and $Ce(NR_2)_3$. Cerium(III) trialkoxides were prepared by ligand exchange reactions of the known $Ce(OiPr)_3$[3c,4] with the appropriate alcohols[5] [Eq. (a)]; cerium(III) chloride dialkoxides were obtained by reaction of the relevant cerium(III) trialkoxides with one equivalent of acetyl chloride[6] [Eq. (b)]; amidocerium compounds were synthesized by reaction of the $CeCl_3 \cdot THF$ complex with three equivalents of lithium amides[7] [Eq. (c)]. All these alkoxy- and amidocerium compounds were



used without further purification; however, X-ray structures have not yet been obtained because of the low tendency of these compounds to form crystals.

For the addition reaction the cyclopentanone derivative *rac*-**1** was used as a substrate since it is well known that diastereoselectivities in the addition of organometallic reagents to cyclopentanones are lower than that to cyclohexanones. The yields are also lower because of the high tendency of cyclopentanone derivatives to undergo enolization. The organocerium reagents

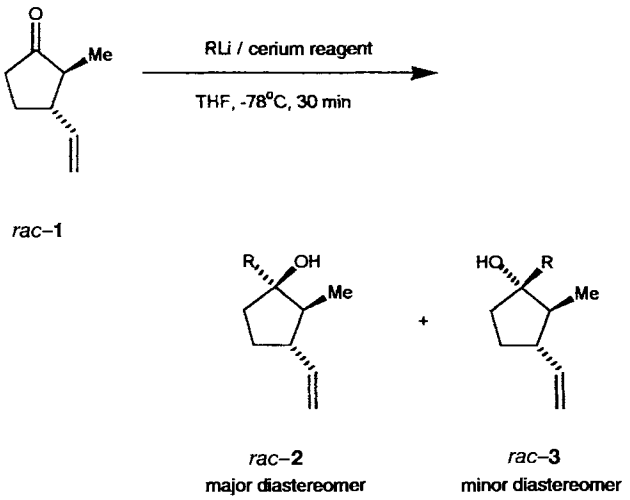
[**] Lanthanoids in Organic Synthesis, Part 2. This work was supported by the EU Commission, Directorate General XII, and the Fonds der Chemischen Industrie. C. A. thanks the EU Commission for a fellowship (Contract-No. ERBCHBI-CT94-1465). Part 1: Ref. [4b].

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2480 $ 17.50+.50/0

were formed in situ by treatment of the cerium compounds (see [Eqs. (a)–(c)]) with organolithium reagents at −78 °C for 1 h. Then 2-methyl-3-vinylcyclopentanone (*rac*-**1**)[8] was added to afford the addition products *rac*-**2** and *rac*-**3**. The results are



given in Table 1. The nature of these organocerium species is unknown and has proved resistant to study,[9] but most probably organocerium species derived from cerium chloride dialkoxides are neutral species of the type $RCe(OR')_2$ and those derived from cerium trialkoxides are ate-complexes of the type $Li[CeR(OR')_3]$.

Table 1. Stereoselective additions of organocerium reagents to 2-methyl-3-vinylcyclopentanone (*rac*-**1**)[12].

6	$MeLi/Ce(OiPr)_3$[b]	86	93	–
7	$MeLi/Ce(OiPr)_3$[c]	74	90	–
8	$MeLi/ClCe(OtBu)_2$	77	85	–
9	$MeLi/ClCe(OCHiPr_2)_2$	87	89	–
10	*n*BuLi	49	56	36
11	*n*BuLi/$ClCe(OCHiPr_2)_2$	89	90	–
12	*t*BuLi	77	35	57
13	*t*BuLi/$ClCe(OCHiPr_2)_2$	90	80	–
14	PhLi	85	70	24
15	PhLi/$ClCe(OCHiPr_2)_2$	94	95	–

[a] Determined by GC analysis. [b] Addition at −98 °C. [c] In Et_2O.

Enolization of the starting ketone was only observed with organocerium reagents derived from cerium triamides (Table 1, entries 3 and 4). The ligands have a pronounced influence on the stereoselectivity of the addition reactions. As expected, increasing steric hindrance led to increased diastereoselectivity. Unfortunately, no addition took place with the sterically most demanding compounds $Li[CeMe(OtBu)_3]$ and $Li[CeMe(OCHiPr_2)_3]$. Lowering the temperature (−98 °C) slighty improved the diastereoselectivity (entry 6) but carrying out the additions at −78 °C is more convenient. In Et_2O the diastereoselectivity obtained was lower than in THF (entry 7). The best results were achieved with $RCe(OCHiPr_2)_2$ in THF. Its addition to the cyclopentanone derivative *rac*-**1** (entries 9, 11, 13 and 15) proceeds with good to very good diastereoselectivities (87–94% *de*), which are among the best reported for the addition of organometallic reagents to simple cyclopentanones.[10, 11]

In order to establish the width of application of the new cerium derivatives in carbonyl addition reactions, the addition of organocerium reagents derived from $ClCe(OCHiPr_2)_2$ and $Ce(OCHiPr_2)_3$ to 2-methylcyclohexanone, 4-*tert*-butylcyclohexanone, and 2-phenylpropionaldehyde was investigated (Table 2).

Table 2. Stereoselective addition of organocerium reagents to selected carbonyl substrates.

Carbonyl derivative	Reagent	*de*[%][a]	Yield[%]
2-methylcyclohexanone	MeLi	63	74
2-methylcyclohexanone	$MeCeCl_2$	88	89
2-methylcyclohexanone	$MeCe(OCHiPr_2)_2$	97	91
2-methylcyclohexanone	$Li[CeMe(OCHiPr_2)_3]$	–	–[b]
2-methylcyclohexanone	*n*BuLi	78	80
2-methylcyclohexanone	$nBuCeCl_2$	94	92
2-methylcyclohexanone	$nBuCe(OCHiPr_2)_2$	98	88
4-*tert*-butylcyclohexanone	MeLi	24	50
4-*tert*-butylcyclohexanone	$MeCeCl_2$	36	93
4-*tert*-butylcyclohexanone	$Li[CeMe(OCHiPr_2)_3]$	68	88
2-phenylpropionaldehyde	MeLi	82	57
2-phenylpropionaldehyde	$MeCeCl_2$	84	85
2-phenylpropionaldehyde	$Li[CeMe(OCHiPr_2)_3]$	90	89

[a] Determined by GC analysis. [b] No addition took place, probably because of the bulky ligands.

As in the case of 2-methyl-3-vinylcyclopentanone (*rac*-**1**), no reaction took place in the addition of $Li[MeCe(OCHiPr_2)_3]$ to 2-methylcyclohexanone. In contrast, the addition of $MeCe(OCHiPr_2)_2$ and $nBuCe(OCHiPr_2)_2$ to 2-methylcyclohexanone gave the corresponding alcohols with diastereoselectivities of 97 and 98% *de*, by using the sterically less demanding organocerium compounds $MeCeCl_2$ and $nBuCeCl_2$ the selectivities dropped to 88 and 94% *de*, respectively. In the case of 4-*tert*-butylcyclohexanone and 2-phenylpropionaldehyde the addition reactions could be performed with the sterically most demanding compound $Li[MeCe(OCHiPr_2)_3]$ and gave yields between 88 and 89%. With 4-*tert*-butylcyclohexanone an increase of diastereoselectivity from 36% ($MeCeCl_2$) to 68% *de* ($Li[MeCe(OCHiPr_2)_3]$) was established. The addition of $Li[MeCe(OCHiPr_2)_3]$ to Cram's aldehyde (2-phenylpropionaldehyde) led to the corresponding alcohol with a diastereoselectivity of 90% *de*. In constrast the use of $MeCeCl_2$ (84% *de*) or MeLi (82% *de*) gave considerably lower selectivities. The application of these new organocerium reagents in natural product synthesis, for example for the enantioselective synthesis of the antifungal chokols,[10, 13] is currently under investigation.

Experimental Section

All reactions were performed with rigorous exclusion of oxygen and water under a dry nitrogen atmosphere, using Schlenk, vacuum-line, and glovebox techniques.

Preparation of cerium trialkoxides: To a solution of $Ce(OiPr)_3$ (6.0 mmol) in benzene (10 mL), the appropriate alcohol (20 mL) was added and the mixture was heated under reflux overnight. It was then cooled to room temperature and the solvent removed in vacuo (20 °C, 0.005 Torr) to afford the corresponding cerium trialkoxide in 90–95% yield.

Preparation of cerium chloride dialkoxides: Acetyl chloride (2.0 mmol) was added to a solution of the appropriate cerium trialkoxide (2.0 mmol) in benzene (20 mL), and a pale brown solid precipitated immediately. The mixture was heated to reflux for 2 h, cooled to room temperature, and the solvent removed by cannula. The solid was dried in vacuo (20 °C, 0.005 Torr) to afford the cerium chloride dialkoxide in 80–90% yield.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2481 $ 17.50+.50/0

Carbonyl addition reactions: To a solution of the cerium compound (1.5 mmol) in THF (5 mL) cooled to −78 °C, methyllithium (1.2 mmol, 0.75 mL of a 1.6 N solution in diethyl ether) was added. After 1 h the appropriate carbonyl derivative (1.0 mmol) was added slowly and the mixture was stirred at −78 °C for 30 min. Then, a saturated aqueous NH_4Cl solution (10 mL) was added, solid material was removed through a short pad of Celite, the Celite was rinsed with diethyl ether, and the ethereal solution was dried with $MgSO_4$. The solvent was removed in vacuo and the residue purified by flash chromatography.

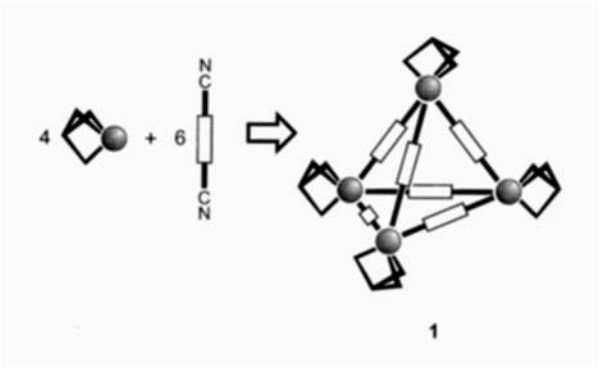
Template-Mediated Self Assembly of Six- and Eight-Membered Iron Coronates **

Rolf W. Saalfrank,* Ingo Bernt, Eveline Uller, and Frank Hampel

Dedicated to Professor Gottfried Huttner on the occasion of his 60th birthday

The "synthesis of properties"[1] is a professed goal in supramolecular chemistry. There are a large number of naturally occurring iron oxide minerals with complex structures[2] that serve as model compounds. Additionally, the iron-storage protein ferritin, which is the biological prototype of these inorganic systems,[3, 4] has been investigated comprehensively. Furthermore, discrete clusters with up to nineteen oxygen-bridged iron atoms have been synthesized and unequivocally characterized.[3] For better understanding of electron transfer processes and of magnetic properties of polynuclear iron,[3, 5] manganese,[6] and nickel complexes[7] further studies on compounds of this type are necessary. The same is true for the recently described cyclic ferrocene heptamer[8] and for metallacrown ethers with an enclosed cation[9, 10] or anion.[11] With respect to potential applications, iron(III) compounds certainly play a central role.

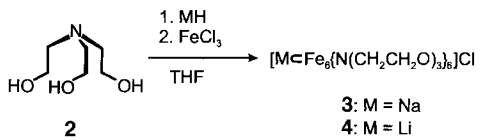
Our investigations have revealed that parallel to the family of classical crown ethers, cryptands, and their complexes there exists a class of topomerically analogous metallacrown ethers,[10] metallacryptands,[12, 13] and their inclusion compounds. In all these cases, bisbidentate ligands act as ditopic bridges. In addition we have studied the formation of one- (1D), two- (2D), and three-dimensional (3D) coordination polymers using coordinatively unsaturated, effectively linear bidentate dinitrile monomers.[14] Through a combination of both methods, we planned to construct novel adamantanoid tetranuclear chelate complexes **1**. Following the strategy for the synthesis of the tetranuclear



1

chelate complexes $[M \subset Fe_4L_6^1]$[12b] and of 1D coordination polymers $^1_\infty[NaL^2(pmedta)]$ (pmedta = pentamethyldiethylenetriamine),[14a] this objective should be accomplished by reaction of four equivalents of a tripodal metal template and six equivalents of a α,ω-dinitrile. Evidently, 1,1,1-tris(diphenylphosphinomethyl)ethane (triphos) used by Huttner et al.[15] was better suited for this purpose than the ligands triethanolamine **2** and *N*-methyldiethanolamine (**6**) that we have used.

Contrary to what was expected, treatment of triethanolamine **2** with sodium hydride, iron(III) chloride, and fumaric acid dinitrile in THF afforded the yellow solid **3**, in which the iron-to-ligand ratio was 1:1, instead of a tetranuclear chelate complex of type **1**. However, even when no dinitrile was used the same result was obtained. Since the ^1H and ^{13}C NMR spectra of product **3** do not allow an unequivocal characterization of its



2

molecular structure, we carried out an X-ray crystallographic structure analysis.[16] According to this analysis, **3** is present in the crystal as a cyclic iron(III) complex with a [12]metallacrown-6 structure, in which a sodium ion is encapsulated in the center, and chloride is the counterion (Figure 1). The six crystallo-

Selected bond lengths [Å] and angles [°] of **4**: Fe–N 2.195(6), Fe–μ_1O 1.882(5), Fe–μ_2O_{ipso} 2.030(5), Fe–$\mu_2O_{vic.}$ 1.969(5), Fe–μ_3O_{ipso} 2.082(5), Fe–$\mu_3O_{vic.}$ 2.027(5); μ_3O_{ipso}-Fe-$\mu_2O_{vic.}$ 76.2(2), $\mu_2O_{vic.}$-Fe-μ_1O 95.9(2), μ_1O-Fe-μ_2O_{ipso} 98.5(2), μ_2O_{ipso}-Fe-μ_3O_{ipso} 93.3(2).

graphically equivalent iron atoms of the centrosymmetric cation $[Na\subset Fe_6\{N(CH_2CH_2O)_3\}_6]^+$ of **3** are located in the corners of a regular hexagon. The Fe–Fe distance is 3.216 Å, the interior angles of the hexagon are 120°. The diameter of the hexagon, defined as the distance between two opposite iron atoms, is 6.431 Å. The distorted octahedral coordination sphere of the iron atoms is composed of one nitrogen donor, one μ_1-, and two μ_2- and μ_3-oxygen donors. Consequently, triethanolamine acts as a tritope tetradentate ligand and links three iron(III) ions.[11]

Three sets of six oxygen atoms are located at the corners of three pairs of regular triangles which are rotated 60° relative to each other (Figure 2, left). These trigonal faces are located parallel and equidistant in pairs, with one plane above and one below the hexagonal plane generated by the iron atoms. These six oxygen atoms are related by an S_6 axis. The sodium ion is located in the center of cation **3** and has a distorted octahedron coordination sphere from the six μ_3O atoms. The diameter (1.98 Å) of the cavity marked by opposite μ_3O atoms almost corresponds to double the ionic radius of sodium (2.04 Å). (Distances: Na–μ_3O: 2.372 = *a*;[17] Na–μ_2O: 3.504; Na–μ_1O: 4.998 Å).

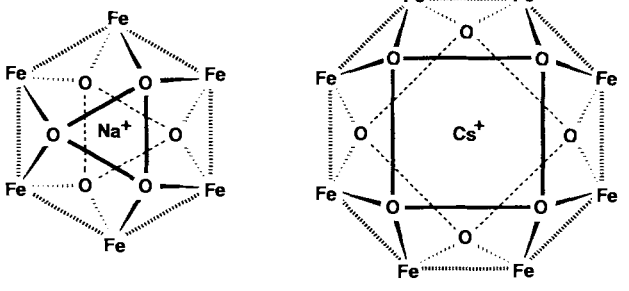

Figure 2. Left: Schematic representation of the central Fe_6O_6 backbone of **3**, showing the octahedral oxygen environment of sodium. Right: Schematic representation of the central Fe_8O_8 backbone of **5**, showing the quadratic antiprismatic oxygen environment of cesium. In both cases for reasons of clarity only the μ_3O atoms are displayed.

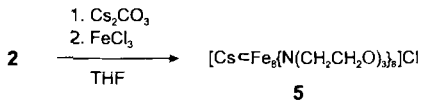
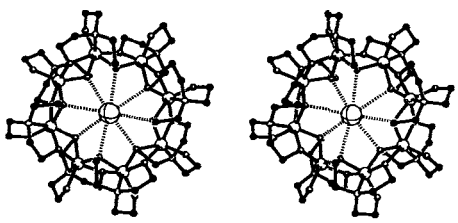
The different reactivity of the ligands triphos and triethanolamine (**2**) can be explained by the fact that the latter is a tetradentate ligand and moreover phosphorus generally does not bridge, whereas oxygen undergoes μ_2- and μ_3-linkages. According to Lehn et al.,[11a] in the case of the template-mediated self-assembly of a supramolecular system, amidst a set of possibilities the one combination of building blocks that leads to the best receptor for the substrate is realized. Therefore, *possibly* the six-membered cyclic structure **3** is exclusively selected from all the possible iron triethanolatamine oligomers when sodium ions are present. Thus, in the presence of cations with ionic radii that differ from that of sodium, variant structures are expected.

In order to test this hypothesis, we allowed triethanolamine **2** to react with lithium hydride and iron(III) chloride. The FAB-MS spectrum (FAB = fast atom bombardment) of the reaction product shows a peak at $m/z = 815$, which corresponds with the molecular ion $[Li\subset Fe_4\{N(CH_2CH_2O)_3\}_4]^+$ and indicates the formation of a tetranuclear complex.[18] The main product, however, is the hexanuclear complex $[Li\subset Fe_6\{N(CH_2CH_2O)_3\}_6]Cl$ **4** (distances: Li–μ_3O: 2.256; Li–μ_2O: 3.505; Li–μ_1O: 4.975 Å). The basic iron framework of the isostructural Li complex **4** and Na complex **3**[16] differs only slightly with respect to bond lengths and bond angles (see Figure 1).

We were more successful when we allowed triethanolamine **2** to react with cesium carbonate and iron(III) chloride. An X-ray structure analysis of the reaction product **5** revealed a cyclic



iron(III) complex with a [16]metallacrown-8 structure in which cesium was located in the center of the ring and chloride functioned as counterion (Figure 3). The eight iron atoms of the approximately centrosymmetric cation $[Cs\subset Fe_8\{N(CH_2CH_2O)_3\}_8]^+$ of **5** are located in the corners of a nearly regular octagon. The Fe–Fe distances range from 3.143 to 3.162 Å, and the interior angles of the octagon range from 135.17 to 133.33°.



= Cs, = Fe, = O, = N, • = CH_2

Figure 3. Stereoview of the cation of **5** in the crystal (PLUTON representation; view along the crystallographic S_8 axis; H atoms excluded). For reasons of clarity the chloride ion and the crystal solvents were omitted. Selected bond lengths [Å] and angles [°] (mean values) of **5**: Fe–N 2.259, Fe–μ_1O 1.885, Fe–μ_2O_{ipso} 2.007, Fe–$\mu_2O_{vic.}$ 1.989, Fe–μ_3O_{ipso} 2.018, Fe–$\mu_3O_{vic.}$ 2.005; μ_3O_{ipso}-Fe-$\mu_2O_{vic.}$ 75.37, $\mu_2O_{vic.}$-Fe-μ_1O 93.29, μ_1O-Fe-μ_2O_{ipso} 98.49, μ_2O_{ipso}-Fe-μ_3O_{ipso} 100.06.

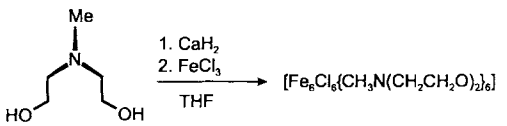
The diameter of the octagon, defined as the mean distance between opposite iron atoms, is 8.224 Å. The distorted octahedral coordination sphere of the iron atoms is composed of one nitrogen donor, one μ_1-, and two μ_2- and μ_3-oxygen donors. Three sets of eight of a total of twenty-four oxygen atoms are located in the corners of three pairs of square faces that are rotated 45°

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2483 $ 17.50+.50/0

relative to each other (Figure 2, right). The square faces are located parallel and almost equidistant in pairs, and one plane lies above and one plane lies below the octagon generated by the iron atoms; these structural elements share a common S_8 axis. The cesium ion lies directly above the center of the cation of **5**. It is shifted by about 0.5 Å towards the chloride counterion. The eight μ_3O atoms form a quadratic antiprism coordination sphere around the cesium center (mean distances: Cs–μ_3O: 3.291; Cs–μ_2O: 4.358; Cs-μ_1O 5.939). The distance between the cesium ion and the chloride ion is 3.446(9) Å.

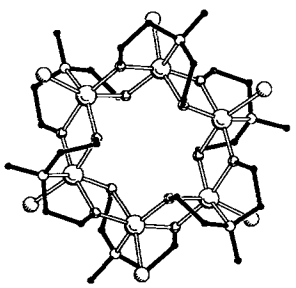
Remarkably, the formation of the cations of **3** and **5** requires the spontaneous and correct assembly of 13 or 17 components (6/8 Fe^{3+}, 6/8 $[N(CH_2CH_2O)_3]^{3-}$ and 1 Na^+/Cs^+). Consequently, the two cations obey the three fundamental criteria, namely recognition, orientation, and termination, for the formation of supramolecular systems.

Furthermore, a common feature of complexes **3** and **5** is that the μ_1O atoms do not participate in the formation of the hexa- and octanuclear structures. They solely function as ligands for the coordinative saturation of the iron atoms. However, other donors such as chloride ions could also be candidates for this function. Therefore, we allowed *N*-methyldiethanolamine **6** to



6 **7**

react with calcium hydride and iron(III) chloride and carried out an X-ray crystallographic structure analysis of the product formed.[16] According to this analysis, product **7** is present in the crystal as the unoccupied neutral iron(III) complex with [12]metallacrown-6 structure (Figure 4).



◯ = Fe, ◯ = Cl, ◎ = O, ○ = N, ● = CH_2, CH_3

Figure 4. Structure of **7** in the crystal (PLUTON representation; view along the crystallographic S_6 axis; H atoms excluded). For reasons of clarity the chloride ion and the crystal solvents are omitted. Selected bond lengths [Å] and angles [°] (mean values) of **7**: Fe–N 2.264, Fe–Cl 2.322, Fe–$\mu_2{}^i$O$_{ipso}$ 2.008, Fe–$\mu_2{}^i$O$_{vic.}$ 1.980, Fe–$\mu_2{}^a$O$_{ipso}$ 2.026, Fe–$\mu_2{}^a$O$_{vic.}$ 1.972; $\mu_2{}^i$O$_{ipso}$-Fe-$\mu_2{}^a$O$_{vic}$ 74.9, $\mu_2{}^a$O$_{vic}$-Fe-Cl 92.0, Cl-Fe-$\mu_2{}^a$O$_{ipso}$ 99.8, $\mu_2{}^a$O$_{ipso}$-Fe-$\mu_2{}^i$O$_{ipso}$ 94.9.

The six iron atoms of the centrosymmetric neutral molecule $[Fe_6\{H_3C\text{-}N(CH_2CH_2O)_2\}_6Cl_6]$ **7** are located in the corners of an almost regular hexagon. The Fe–Fe distances range from 3.167 to 3.185 Å, the interior angles of the hexagon range between 118.51 and 120.75°. The diameter of the hexagon, defined as the mean distance between two opposite iron atoms, is 6.361 Å. The distorted octahedral coordination sphere of the iron atoms comprises one nitrogen donor, one chloride ion, and four μ_2O donors.

Experimental Section

General method: To a suspension of sodium hydride (20 mmol, 0.48 g; for **3**), lithium hydride (20 mmol, 0.16 g; for **4**), cesium carbonate (15 mmol, 5.30 g; for **5**), or calcium hydride (7.5 mmol, 0.32 g; for **7**) in anhydrous THF (200 mL), triethanolamine **2** (5 mmol, 0.65 mL; for **3**, **4**, **5**) or *N*-methyldiethanolamine **6** (5 mmol, 0.60 mL; for **7**) was added. After the mixture had been stirred for 1 h at 20 °C, a solution of anhydrous iron trichloride (5 mmol, 0.81 g) was added dropwise. The reaction mixture was stirred for 4 days at 20 °C and the precipitate was subsequently collected on a glass frit. In the case of **3** and **4** the solid was extracted with dimethyl sulfoxide (150 mL). Chloroform (200 mL) and pentane (100 mL) were added, and the yellow microcrystalline precipitate was collected on a frit. In the case of **5** and **7** the solid was extracted with dichloromethane (300 mL) and upon evaporation of the solvent a yellow microcrystalline powder was isolated. Correct elemental analyses were obtained for all new compounds.

Specific Recognition of a Minimal Model of Aminoacylated tRNA by the Elongation Factor Tu of Bacterial Protein Biosynthesis**

Stefan Limmer,* Martin Vogtherr, Barbara Nawrot, Rainer Hillenbrand, and Mathias Sprinzl

In the course of protein biosynthesis the aminoacylated transfer RNA (aa-tRNA), which is correctly "charged" with its specific amino acid, has to be transported to the ribosome. In bacterial biosynthesis this function is carried out by the elongation factor Tu (EF-Tu), which must be able to recognize all aa-tRNAs as well as to reject uncharged elongator tRNAs and the initiator tRNA—in bacteria invariably fMet-tRNA (fMet = formylmethionyl), which is formylated and interacts with the initiation factor IF-2. Thus, the specific recognition of the aa-tRNAs may depend neither on variations in the sequences and the tertiary structures, nor on the nature of the attached amino acid itself.

The region common to all aa-tRNAs comprises the ubiquitous CCA terminus of the tRNA and the ester linkage at the 2′- or 3′-OH groups of the ribose of the terminal adenosine 76.[1] In solution the two isomers that have 2′- and 3′-ester bonds are in a dynamic equilibrium.[2] It was shown[3] that minihelices consisting of at least ten base pairs and an aminoacylated, single-stranded (A)CCA end are relatively tightly bound by EF-Tu·GTP. The smallest conceivable unit as a minimal model of aa-tRNA is made up of the terminal adenosine and an attached amino acid.[2] Indeed, such aminoacylated adenosines are able to compete sucessfully for the aa-tRNA binding site of a specific inhibitor of EF-Tu, namely *N*-tosyl-L-phenylalanylchloromethane.[4]

The stability of the ester bond between ribose and amino acid is rather low under conditions which are optimal for EF-Tu (pH = 7.5). Hence, we used anthranilic acid as an amino acid analogue, which has a higher stability with respect to hydrolysis of the ester bond. Its suitability for binding to EF-Tu was demonstrated for yeast $tRNA^{Phe}$ charged with anthranilic acid.[5] The transacylation rate of the anthranilic acid between the 2′ and 3′ ribose positions is drastically lower for anthraniloyladenosines **1**[6] than for corresponding aminoacylated adenosines; this

correlates with the significantly increased stability of the ester bond towards hydrolysis. Due to the lack of important regions of the aa-tRNA—with which the EF-Tu interacts in its active, GTP-bound form[7]—only a drastically diminished affinity of **1** for EF-Tu can a priori be expected. This should give rise to an exchange of **1** between free and bound forms that is fast on the NMR time scale.[8, 9] In this case the observed values of chemical shift and linewidth represent the weighted averages of the corresponding quantities in the free and bound states. The linewidths of the signal for the small ligand molecule should continuously increase with rising protein concentration. Owing to the much larger molecular weight of the protein (ca. 45 kDa) and the therefore distinctly faster T_2 relaxation, the protein contributes merely a more or less pronounced, poorly resolved background to the ^{1}H NMR spectrum of the complex.

In Figure 1 the ^{1}H NMR spectra of the complexes of EF-Tu·GTP from the eubacterium *Thermus thermophilus* with **1** in varying molar ratios are displayed. As expected for fast exchange (that is, weak binding), the linewidth rises as the relative protein fraction increases from 1:20 to 1:2.5. The resonances for the 3′ isomer are broadened to a distictly greater extent than those for the 2′ isomer, suggesting a preferred binding of the former. This confirms earlier experiments[10] from which an almost exclusive binding of the 3′ isomer of aa-tRNA to EF-Tu was deduced. By contrast, a weakened interaction of both species with EF-Tu·GTP was found upon using aa-tRNA variants in which the terminal adenosine was replaced by 3′- or 2′-deoxyadenosine.[11]

All lines in the spectrum of **1** become broadened in the presence of EF-Tu (see Table 1 and Figure 1), although not to the same degree; the 2′ and 3′ ribose resonances of the 3′ isomer are particularly broadened. From these differences, conclusions concerning the contact sites of the ligand with the protein can be derived: For the molecular regions of the ligand with the closest contacts to the protein, the most significant alterations of the relaxation behavior are due to additional relaxation pathways involving protons of the protein. Such a difference in line broadening is often characteristic of a specific ligand–protein interaction.[14]

Table 1. Linewidths[Hz][a] and chemical shifts (in parentheses) in the ^{1}H NMR spectrum of free and EF-Tu·GTP-bound[b] **1**.

Proton	3′ Isomer free	3′ Isomer bound	2′ Isomer free	2′ Isomer bound
H8	2.6 (8.409)	28.0 (8.356)	2.6 (8.437)	13.0 (8.432)
H2	2.6 (8.292)	(8.240)[c]	2.5 (8.258)	(8.240)[c]
H1′	10.8 (6.257)	33.0 (6.207)	9.9 (6.442)	17.3 (6.446)
H2′	14.7 (5.156)	47.0 (5.121)	12.9 (5.870)	19.3 (5.848)
H3′	10.8 (5.598)	53.0 (5.598)	11.4 (4.817)	16.5 (4.812)

[a] Linewidths at half-height, measured over the multiplet structure. [b] 1 mM **1**, 0.18 mM EF-Tu·GTP in borate buffer, pH = 7.5, D_2O/[D_4]methanol 7/1, 281 K. [c] Strong overlap of the resonances for both isomers.

Remarkably, the integral ratio of the signals for 3′-**1** and 2′-**1** shifts from about 2:1 for free **1** towards 1:1 with rising protein concentration. This means that with an increasing fraction of bound **1**, which preferably binds as the 3′ isomer, the relative population of the 2′ isomer grows. The same effect is achieved when the binding equilibrium is shifted by varying the temperature while keeping the concentrations of protein and ligand constant. For 1 mM **1** and 0.18 mM EF-Tu·GTP, the ratio increases from about 1:1 (3′:2′) at 281 K to about 1.8:1 at 307 K. Preferred binding of the 3′ isomer alone is not sufficient to account for this behavior. One conceivable explanation is that,

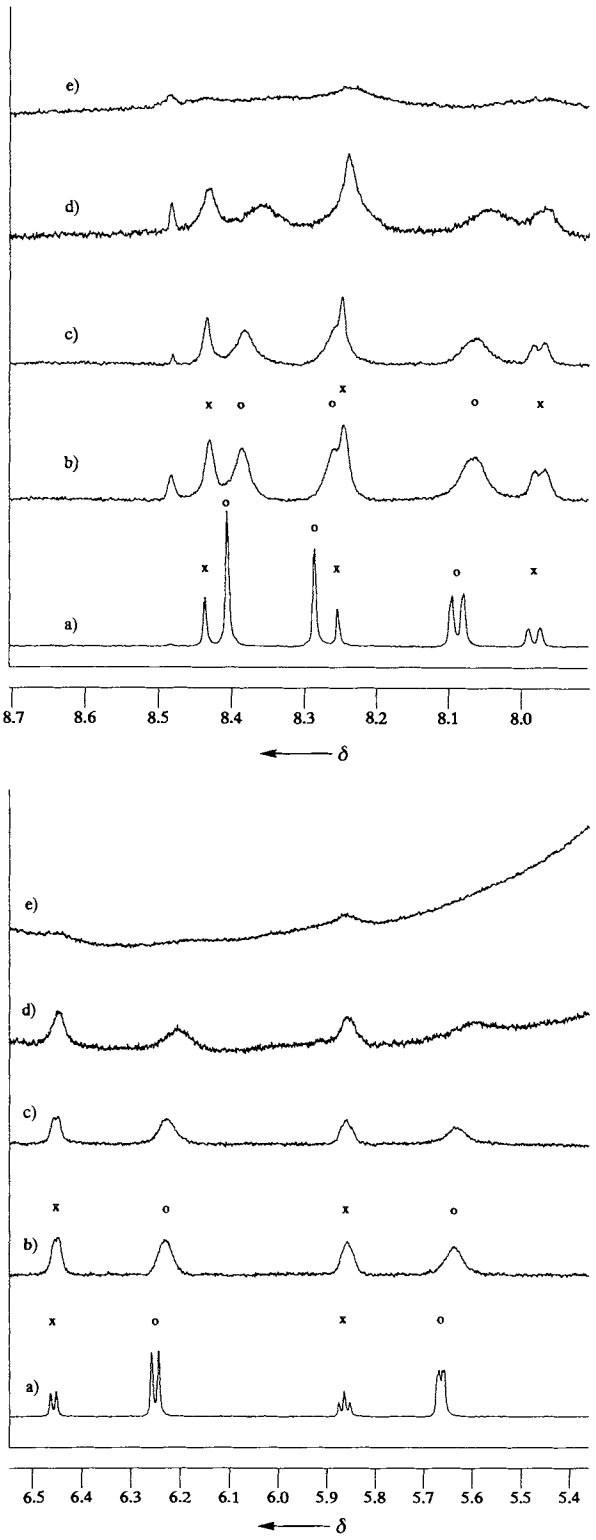

Figure 1. Portions of the ^{1}H NMR spectra with aromatic (top) and ribose 1′, 2′, and 3′ signals (bottom) of 3′(2′)-anthranyloyladenosine (**1**) in D_2O/[D_4]methanol (7/1) at 281 K. Concentration of **1** 1 mM, concentration of EF-Tu·GTP a) 0.00, b) 0.05, c) 0.08, d) 0.18, e) 0.4 mM. The signals of the 3′ and 2′ isomers are marked with o and x, respectively (for the assignment, see Table 1). The baseline distortion is due to the protein background spectrum.

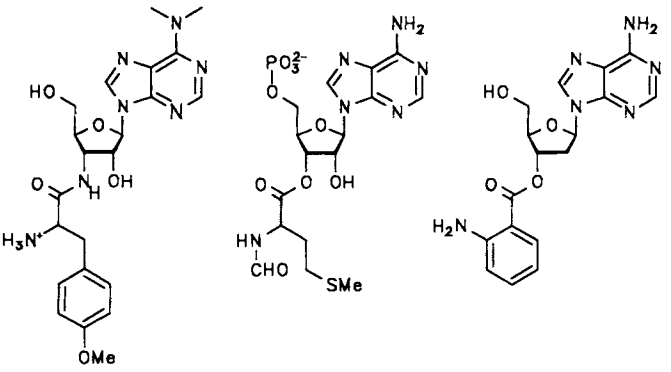
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2486 $ 17.50+.50/0

compared to free **1**, transacylation of **1** is accelerated upon binding to EF-Tu. Since EF-Tu binds the two isomers with different strengths, an equilibrium is adjusted which reflects the different affinities for the protein and leads to an accumulation of the 2′ isomer.

The observed line broadening (and hence ligand binding) is independent of the guanosine nucleotide (GTP, GPPNHP, GDP) bound to EF-Tu, which is different than in the case of complete aa-tRNA.[12] The rearrangement of the EF-Tu structure[7, 16a, b] associated with GTP binding is a prerequisite for the binding of the tRNA in a cleft formed between domains I and II, in which stabilizing interactions between EF-Tu and tRNA are enabled. Naturally, these contacts cannot take place with the small ligand **1**, which may explain both the diminished affinity and the absence of any differences between the GTP/GPPNHP- or GDP-complexed forms with respect to binding to EF-Tu. For the specific interaction of the terminal A76, the relative orientation of the three EF-Tu domains—which is determined by the nature of the bound nucleotide—plays only a minor role.

To check the specificity of the complex formation, several control experiments with structurally related compounds of low molecular weight were carried out. In the case of the antibiotic puromycin (**2**) the ester bond between ribose and amino acid is replaced by an amide bond; in formylmethionyl-AMP (**3**) the amino group of the amino acid is formylated. In both cases only negligible increases in linewidth were measured under the conditions used for the **1**·EF-Tu complex (1 mM ligand, 0.08 mM EF-Tu·GTP, 281 K; Figure 2a and b). Evidently, these molecules are not bound by the protein; with **3**, neither of the two isomers is bound.

The higher affinity of 3′-**1** immediately suggests the question of whether only the esterified 3′-OH group is required for recognition and binding, or if the 2′-OH group is also necessary. The existence of the free 2′-OH group enables transacylation, which could also be possibly relevant in the recognition process. To check this, the binding of the 2′-deoxy derivative **4** was studied.



2 **3** **4**

Under the same conditions as before, the resonances become only slightly broadened yet again (Figure 2c), which indicates a distinctly reduced binding as compared to 3′-**1**. This hints at an important role of the 2′-OH group both in **1** and in the terminal adenosine of the aa-tRNA. This conclusion is corroborated by a crystal structure analysis,[7] according to which a hydrogen bond involving a conserved glutamate 271 can be formed. Indeed, a drastically diminished aa-tRNA binding strength is found for an EF-Tu variant, in which this glutamate was replaced by aspartate (E271D). The ^{1}H NMR signals of **1** (Figure 3) in the presence of the mutant protein E271D are broadened to a much lesser extent than with the wildtype potein, thus suggesting a distinctly reduced binding strength. This substanti-

Figure 2. Figure 3. Ribose region of the ^{1}H NMR spectrum (281 K) of **1** with 0.08 mM a) EF-Tu·GTP wildtype, b) EF-Tu(E271D)·GTP, and c) EF-Tu(C82A/T394C)·GTP.

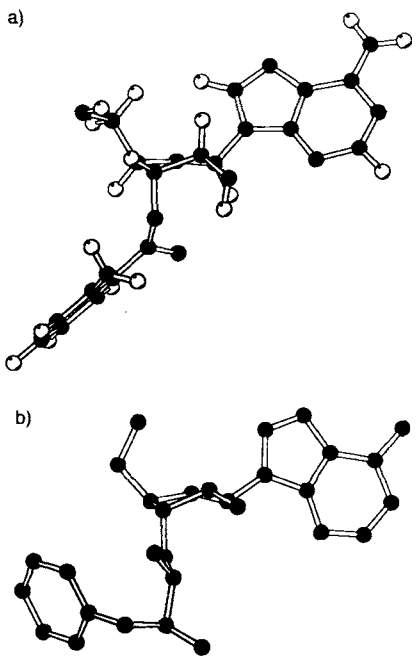

Figure 4. a) Structure in the EF-Tu·GTP bound state of **1** calculated from NMR data (MOLSCRIPT [22] representation). b) Conformation of the terminal adenosine in the aminoacylated tRNA^{Phe} from the crystal structure [7] of the ternary complex EF-Tu·GTP·Phe-tRNA^{Phe}.

ates the specificity of the interaction, also on the part of the protein, as the double mutant C82A/T394C gives rise to increases in linewidth that are comparable to those with the wildtype EF-Tu (Figure 3c). Since intact tRNA is able to make further contacts with EF-Tu,[7] aa-tRNA variants with terminal 2′- and 3′-deoxyadenosines are also bound by EF-Tu·GTP, however, with decreased affinity.[11] To rule out nonspecific interactions of **1** with proteins, in particular with those from the protein biosynthesis cycle, the interaction of **1** with the initiation factor IF-2 was investigated (again 1 mM ligand, 0.08 mM protein; Figure 2d). Here, too, no change in the spectrum as compared to that of free **1** (Figure 1a) was detected; this indicates a negligible interaction between **1** and IF-2.

The structure of free **1** was characterized recently.[6] The conformation of the EF-Tu-complexed molecule can be determined with transfer-NOE (TrNOE) measurements.[13, 14] This exploits the different signs and magnitudes of the NOE for a small molecule like **1** (slightly positive) and for a protein–ligand complex (strongly negative).[14] When the ligand (which is present in a large excess) exchanges rapidly between enzyme-bound and free forms, the NOE from the bound state is transferred into the free state and exceeds the NOE due to the free ligand by far. The measurement of the TrNOE thus permits a structure elucidation of the bound ligand. The complex of EF-Tu with the extremely slowly hydrolyzing GTP analogue GPPNHP was employed for the conformation analysis, in order to preclude any effects of the GTP hydrolysis and the concomitant conformational changes of EF-Tu[7, 16] during data acquisition. For technical reasons the spectra were measured at 298 K. In the NOESY spectrum (1 mM ligand, 0.05 mM EF-Tu) strong positive cross-peaks are observed,[8, 14] which are more intense for the 3′ isomer than for the 2′ isomer, due to the preferred binding of the former.

The structure of complexed **1** (Figure 4) was calculated using the full relaxation matrix. It differs only slightly from the structure postulated for free **1**.[6] In particular, the base is *anti* with respect to the ribose ring, and the sugar ring adopts a 2′-*endo* puckering. The structure thus obtained can be compared to that of the terminal adenosine of the aa-tRNA from the ternary complex EF-Tu·GTP·Phe-tRNA^{Phe} (Figure 4b).[7] The two structures are in fair agreement, in particular with reference to base orientation and ribose pucker. Moreover, since the amino groups of the amino acid of the aa-tRNA and of **1** are positioned similarly, they are able to interact with histidine 273 and asparagine 285 of EF-Tu.

The investigations presented here suggest that the specific recognition of EF-Tu by aminoacylated elongator tRNAs most likely occurs through contacts of the ribose of the terminal nucleotide of the tRNA, to which the amino acid is esterified. Clearly, the isomer with the amino acid attached to the 3′-OH position is bound much more strongly. The closest contact of the terminal aminoacylated adenosine with the protein is through the 2′-OH position of the ribose and the 3′-ester linkage. These findings could possibly serve as a starting point for the design of compounds based on **1**, which bind to EF-Tu even better and hence could act as specific inhibitors of the aa-tRNA–EF-Tu interaction and thus the whole bacterial protein biosynthesis.

Experimental Section

The synthesis of **1** followed the method in ref. [8]. The preparation and purification of EF-Tu [18] and IF-2 [20] from *Th. thermophilus* overproduced in *E. coli* were published previously. Compound **3** was synthesized according to ref. [19]. For solubility reasons, NMR samples of **1** and **2** were dissolved in a mixture of D_2O buffer (50 mM sodium borate pH = 7.5; 50 mM KCl) and [D_4]methanol (7/1). Methanol was not required for **3**, and [D_6]DMSO (9/1) was used instead of methanol for **4**. For final sample volumes of 500 μL, the protein was dissolved in 437.5 μL of the buffer and, after lyophilization, redissolved in the same volume of D_2O. A solution of **1** or **2** (8 mM, 62.5 μL) was subsequently added. Compounds **3** and **4** were treated in the respective solvents.

All NMR spectra were measured at 500 MHz on a Bruker DRX-500 spectrometer. The data was analyzed with the NDEE program package (Software Symbiose GmbH, Bayreuth, Germany). The NOESY spectra were recorded with 4 k data points in t_2 and 512 t_1 increments with mixing times of 70 or 150 ms. The HDO signal was suppressed by presaturation.

The XPlor program package [17] was employed to calculate the structure of protein-bound **1**. It cooled from 1200 to 50 K within 1 ps with both the geometric and a relaxation matrix (correlation time for the complex 20 ns) [21] energy terms turned on. The structures with the smallest *R* factor were selected.

Electrostatic Layering of Giant Vesicles**

Fredric M. Menger* and Jason S. Keiper

In the Langmuir–Blodgett method, a vertical plate is dipped up and down through a water-supported monolayer, thereby depositing monolayers onto the plate one at a time.[1] Thus, the thickness and constitution of a multilayered assembly can be controlled. We report here experiments in which a giant vesicle, an object of considerable recent attention,[2–6] is successfully coated with lipid bilayers. The layering is electrostatically driven and detectable under phase-contrast microscopy. Controlled layering now joins growth, fusion, undulation, excretion, and healing[5, 6] as observable phenomena with giant vesicles.

Giant anionic vesicles (20–50 μm in diameter) were prepared from a mixture of 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC), the sodium salt of 1-palmitoyl-2-oleoyl-*sn*-glycero-3-[phospho-*rac*-(1-glycerol)] (POPG), and cholesterol in a molar ratio of 79:9:12. Giant cationic vesicles were prepared from POPC, didodecyldimethylammonium bromide (DDAB), and cholesterol (molar ratio also 79:9:12). Vesicle formation was carried out with the following protocol: Lipid mixtures in $CHCl_3$/MeOH were stripped of solvent, and the resulting films vortexed with deionized water. Lyophilization gave fluffy white powders. Afterwards, the powder (0.1 mg or less) was smeared onto the microscope slide (within the confines of a Teflon O-ring cemented onto the slide). The sample was hydrated with water (≈0.5 mL) for at least 30 min to give a polydisperse array of vesicular structures.

Giant vesicles of opposite charge were brought into contact according to the following procedure: A suitable anionic vesicle was grasped with a polished holding pipet (under slight suction provided by a picoinjector device) and guided into a vesicle-free region of the microscope field. Cationic vesicles from another preparation were then withdrawn into a capillary pipet with the aid of a hand-controlled microsyringe. This pipet was emptied of its contents adjacent to the lone anionic vesicle. Finally, the held anionic vesicle was brought into contact with a "free" cationic vesicle, and the interaction between the two membranes was observed as a function of time under 400-fold magnification. Others have shown that light defracted from even a single bilayer is visible by light microscopy,[7] and that vesicle adhesion is amenable to micromechanical testing.[8]

Neutral vesicles composed only of POPC and cholesterol failed to "stick" even when repeatedly pushed into contact; the free vesicle immediately diffused away from the one held stationary by the pipet. In contrast, two vesicles of opposite charge "snapped" together (Figure 1). The cationic vesicle formed a concavity on its surface in order to enhance its contact with the neighboring anionic vesicle. The configuration was, however, unstable. After approximately 90 s the cationic vesicle departed while concurrently "peeling" lipid away from the anionic vesicle, as evidenced by a decided thinning of the anionic membrane. When the same two vesicles were forced into contact following their separation, they were unable to adhere. Apparently, the transfer of lipid from anionic to cationic vesicle generated two multilamellar vesicles, both with outer anionic shells that repelled each other.

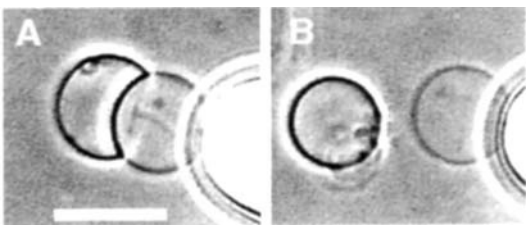

Figure 1. A) A "free" cationic vesicle that adheres to an anionic vesicle held by a micropipet. B) After about 90 s the cationic vesicle coats itself with anionic lipid from the stationary vesicle and diffuses away. Bar = 25 μm.

To confirm the above conclusions, the held vesicle from the preceding experiment was brought into contact with a new cationic vesicle. Adhesion occurred as with the first cationic vesicle (Figure 1). This is strong additional evidence that the anionic vesicle never lost its negative charge, and that lipid transfer was, therefore, unidirectional. The cationic vesicle must have thereby become coated with one or more of the anionic bilayers (the exact number is being now investigated by a newly designed Oxford Institute scanning transmission electron micropscope cryoprobe). If, instead, this receptor vesicle had actually incorporated anionic lipid within its outer cationic bilayer, its surface area would have greatly expanded; this was not observed. Moreover, such a direct transfer of lipid between bilayers should be slow as is "flip-flopping" between leaflets of a single bilayer.[9]

A cationic vesicle will frequently burst upon touching an anionic vesicle. Figures 2A and 2B show a small cationic vesicle that adhered to a larger anionic vesicle and then, upon bursting, coated only the "northern" hemisphere of the host vesicle (see the enhanced thickness of the coated region in Figure 2B). Subsequently, a second cationic vesicle fastened to an uncoated section of the anionic vesicle (Figure 2C). This cationic vesicle also burst to coat the remaining portion of the anionic vesicle (Figure 2D). When this anionic vesicle, now encapsulated with at least one cationic bilayer, was brought into contact with an anionic vesicle of nearly equal size, the latter adhered and burst (Figure 2E). The resulting lipid wrapped around the host membrane (Figure 2F), further thickening it. The twice-altered vesicle must have regained its negative charge because it could now no longer adhere to anionic vesicles.

The reproducible negative-positive-negative sequence in Figure 2 is reminiscent of the lamination possible with Langmuir–Blodgett films. The vesicle system has an operational advantage over films, however, in that films are blocked on one side by a solid support; this makes studies of diffusion through films more difficult. In any event, periodicity in vesicle membranes (as in solid films)[10] could lead to cooperative electronic effects and, thus, to systems with useful electrical, magnetic, and optical properties.

Servuss and Boroske[11] showed years ago that a membrane image can be scanned for intensity as a function of position as one passes through the membrane. We now applied this method to Figure 2 with the aid of an Image-Pro Plus processing routine. Figure 3A gives such an intensity distribution as the held vesicle (just prior to the adhesion shown in Figure 2A) is scanned along the indicated arrow. Intensities of 43 and 47 units correspond to the two points at which the arrow crosses a presumed single bilayer. After the small vesicle bursts and coats the northern hemisphere of the large vesicle (see Figure 2B), the scan changes to that in Figure 3B. The intensities are now 58 and 95 units, which correspond to single and double bilayers, respectively. The scan of Figure 2F (not shown) indicates that both crossover points are now triple bilayers (118 units).

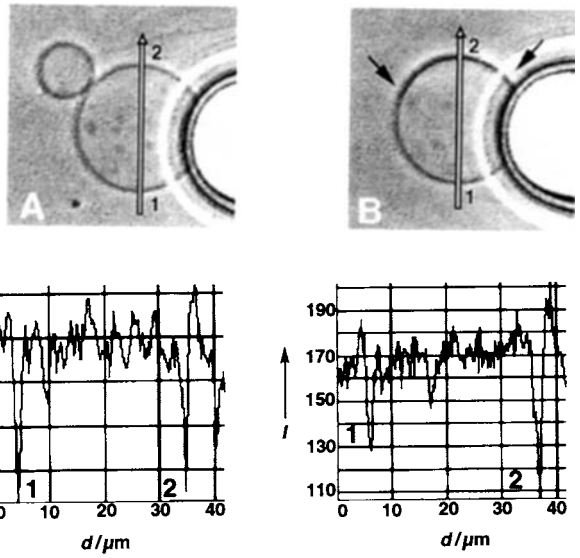

Figure 3. A) Intensity profile of the vesicle membrane prior to the adhesion shown in Figure 2A. The two minima represent the points where the white arrow in the micrograph crosses the bilayer. B) Intensity profile of the partially coated vesicle shown in Figure 2B. The intensity differences are measured from minima to adjacent maxima (representing the white "halo") and are in arbitrary units.

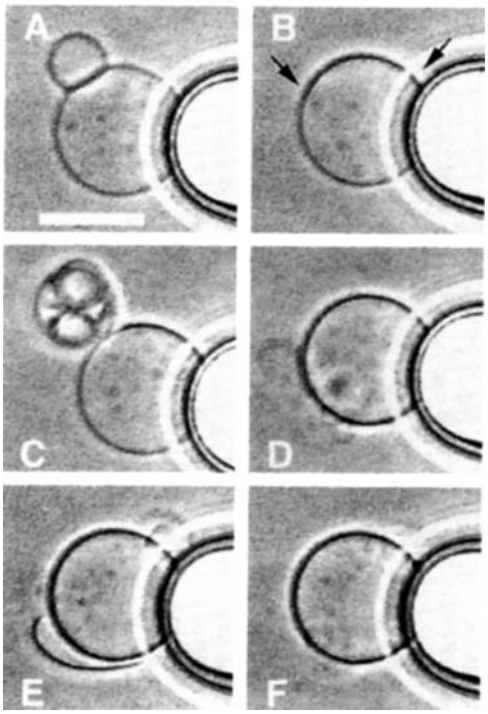

Figure 2. A) Adhesion of a small cationic vesicle to a large anionic vesicle. B) Within 10 s the cationic vesicle bursts and coats the northern region of the anionic vesicle (indicted by the arrows). C),D) A second cationic vesicle binds, bursts after 2 s, and coats the entire anionic vesicle. E),F) An anionic vesicle binds to the new cationic surface, bursts, and regenerates an anionic surface. Bar = 25 μm.

Electrostatic charge is an important feature of cell membranes,[12] and vesicles provide a useful means for evaluating this property. Most corresponding model studies in the past were carried out on submicroscopic vesicles (only 20–200 nm in diameter), for which information must be inferred spectroscopically.[13, 14] Giant vesicles, on the other hand, allow the surface charge to be controlled while the modifications are examined directly by optical methods.

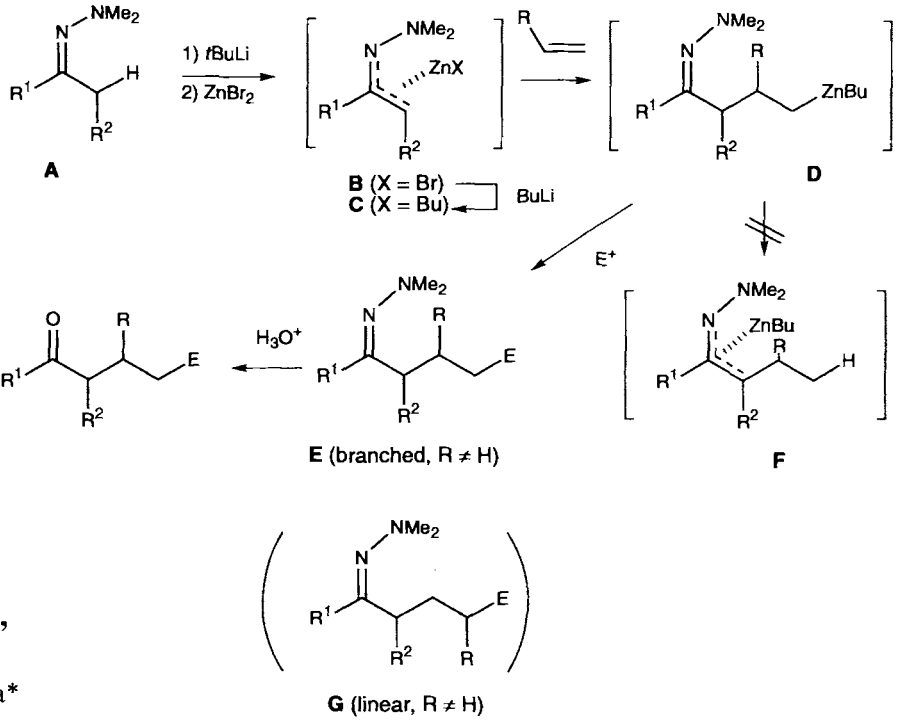

Scheme 1. Addition of a zinc hydrazone to a simple olefin; E = H, $H_2C{=}CHCH_2$, $H_2C{=}CHCH(Ph)$.

Addition of Azaenolates to Simple, Unactivated Olefins**

Katsumi Kubota and Eiichi Nakamura*

Whereas an enolate anion and its azaenolate congener readily add to a carbonyl compound,[1] they do not normally react with a simple, unactivated olefin;[2] little effort has been expended to effect such an "olefinic analogue" of the aldol reaction.[3, 4] We now found that addition of zinc hydrazone **C** to a simple olefin takes place at room temperature to afford the organozinc compound **D**, which then reacts with an added electrophile to give **E** in good yields (Scheme 1). The overall process represents a three-component synthesis of carbonyl derivatives. The key to a successful reaction is the use of the $BuZn^{II}$ species **C** instead of the $BrZn^{II}$ species **B**, with which the reaction was impractically slow.

N,*N*-Dimethylhydrazones **A** are ubiquitous synthetic substitutes of ketones, as they can be readily synthesized from and converted back into the corresponding ketones.[5] The addition reaction of the zinc hydrazone to an isolated olefin was carried out in the following manner for the *N*,*N*-dimethylhydrazone of 1,5-diphenylpentan-3-one (see Experimental Section for details): The hydrazone was treated in diethyl ether sequentially with one equivalent each of *t*BuLi, $ZnBr_2$ (to generate **B**), and BuLi (to generate **C**).[6] The solution of **C** was then placed under an ethylene atmosphere (5–10 atm) and stirred for four days at 20–35 °C. After the pressure had been released, water or D_2O was added to afford the ethylated product **E** in 88% yield (E = H or D, R = H; 100% deuterium incorporation at the terminal carbon atom; Table 1, entry 1). This indicates that the γ-zinc hydrazone **D** (a γ-enolate or "bis(homoenolate)")[7a] does not isomerize to a more stable isomer, such as **F**. We did not observe the formation of products due to addition of **D** to the C=N bond of **D** or **E**, or to further reaction of **D** with ethylene. There was no sign of butyl-group transfer from **C** in any of the reactions examined.[8] The use of the butylated species **C** is crucial, since **B** afforded **E** (E = H) in much lower yield (22%) under the same reaction conditions.[9]

Cyclic (entries 2 and 6) and acyclic ketone hydrazones (entries 1, 3–5, 7–13) reacted equally well. Deprotonation of an unsymmetrical ketone hydrazone (entry 5) took place at the less

1: R = H
2: R = C_6H_5
3: R = 4-$CH_3OC_6H_4$
4: R = 2-$CF_3C_6H_4$
5: R = $CH_3(CH_2)_5$
6: R = $(C_4H_9)_3SnCH_2$

hindered side, and the subsequent reaction with ethylene proceeded with retention of this regiochemistry.

Trapping **D** with carbon electrophiles provided a one-pot three-component coupling reaction; the results are summarized in entries 3–5 of Table 1. Allylation of **D** was achieved by an S_N2' reaction in the presence of a copper(I) salt.[10] Thus, **D** ($R^1 = PhCH_2CH_2$, $R^2 = PhCH_2$, R = H) reacts with CuCN and then with excess allyl bromide at 25 °C to afford an allylated product in 81% yield (entry 3). Reaction with cinnamyl bromide afforded exclusively an S_N2'-substituted product in 74% yield (entry 4).

Table 1. Hydrazone synthesis by a three-component coupling as an "olefinic analogue" of the aldol reaction [a].

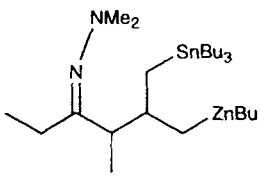
Entry	Olefin	Zinc hydrazone[b]	Electrophile[c]	Product	Yield[%] [d]
1	**1**	**7**	$H_2O(D_2O)$		90
2	**1**	**9**	H_2O		83
3	**1**	**7**	$H_2C{=}CHCH_2Br$, CuCN		81
4	**1**	**8**	$PhCH{=}CHCH_2Br$, CuCN		74[e]
5	**1**	**10**	$H_2C{=}CHCH_2Br$, CuCN		71
6	**1**	**11**	H_2O		42
7	**2**	**8**	H_2O	Ar = C_6H_5	46[e,f]
8	**3**	**8**	H_2O	Ar = p-$CH_3OC_6H_4$	33[e,g]
9	**4**	**8**	H_2O	Ar = o-$CF_3OC_6H_4$	69[e,h]
10	**2**	**7**	H_2O		39[e,i]
11	**2**	**8**	$H_2C{=}CHCH_2Br$, CuCN		45[e]
12	**5**	**7**	H_2O		30[e,j]
13	**6**	**7**	H_2O		35[e,j]

[a] All reactions were carried out in diethyl ether at 25–35 °C for 4 (ethylene (**1**)) or 7–11 days (olefins **2**–**6**). The product consisted of a single stereoisomer (the stereochemistry was not determined). [b] See the Experimental Section for details of the metalation. [c] Excess H_2O (D_2O) was used for entries 1, 2, 6–10, 12, and 13. One equiv of CuCN, and three equiv of allyl bromide or cinnamyl chloride were used for entries 3–5 and 11. [d] Isolated product. [e] A 1:1 mixture of diastereomers. The ratio was determined by ^{13}C NMR spectropscopy. [f] The branched:linear ratio (**E**:**G**, Scheme 1) was 95:5. [g] **E**:**G** = 96:4. [h] **E**:**G** = 88:12. [i] **E**:**G** = 94:6. [j] The linear isomer was not detected.

Conversion of the alkylated *N*,*N*-dimethylhydrazones back into the corresponding ketones could be performed in high yield, for instance, with $CuCl_2$ catalysis (see Experimental Section).[5d] The SAMP hydrazone,[11] which was made from cyclohexanone and optically active hydrazine (S)-(−)-amino-2(methoxymethyl)pyrrolidine (SAMP), also reacted with excess ethylene to form the allylated product in 42% yield and a diastereomer ratio of 82:18 (entry 6).[12] These results suggest a new possibility for the asymmetric synthesis of carbonyl compounds.

The reaction with substituted olefins gave us some insight into the nature of the present reaction (Scheme 1; Table 1, entries 7–10). The zinc hydrazone reacted with a substituted styrene (6 equiv) at 20–25 °C to give mainly a "branched" adduct **E** (R = Ar) rather than a "linear" adduct **G**. Thus, *p*-methoxystyrene, styrene, and *o*-trifluoromethylstyrene reacted to provide the alkylated products in moderate yields (33–69%) with a ratio of branched to linear products (**E**:**G**) of 96:4, 95:5, and 82:18, respectively. The regioselectivity is hence opposite to that expected for conjugate addition of a free anionic species, in which the aryl group acts to stabilize the anion. There was however a small increase of the reaction rate in the given order, which suggests that there is some nucleophilic character to the reaction. The corresponding lithiated hydrazone is totally inert to styrene.[13] The styrene adduct could be utilized for further carbon-chain elongation (entry 11).

Aliphatic olefins such as 1-octene (entry 12) also took part, albeit slowly, in the reaction. It is noteworthy that allylstannane, which is normally regarded as a nucleophilic reagent, also reacted with a zinc hydrazone in 35% yield (entry 13).[14] Taken together with the styrene experiments, both the nucleophilicity of the azaenolate moiety and the electrophilicity of the zinc atom play equally important roles, as predicted for this type of reaction.[15] The product of the allylstannane reaction, **12**, possesses a novel assortment of functional groups: two organometallic groups of different reactivities and an electrophilic C–N double bond.



12

We have demonstrated that azaenolates add smoothly to simple, unactivated olefins to provide ketone derivatives by one-pot coupling of three components. Elucidation of the mechanism as well as development of enantioselective reactions[16] will be the subjects of further studies.

Experimental Section

1,5-Diphenyl-2-ethyl-3-pentanone *N*,*N*-dimethylhydrazone: To a solution of the *N*,*N*-dimethylhydrazone of 1,5-diphenylpentan-3-one (0.86 mL, 3.0 mmol) in Et_2O (3.0 mL) was added *t*BuLi in pentane (1.48 M, 2.0 mL, 3.0 mmol) at −70 °C, and the mixture warmed to 0 °C. After 4 h $ZnBr_2$ in Et_2O (0.33 M, 9.0 mL, 3.0 mmol) and, after another hour, BuLi in hexane (1.67 M, 1.8 mL, 3.0 mmol) were added, and the mixture was warmed to room temperature. After 1 h the prepared zinc hydrazone was transferred to an autoclave, and stirred under ethylene (8 atm) for four days. The resulting zinc hydrazone **D** was quenched with aq 30% potassium sodium tartrate, and the mixture extracted with ethyl acetate. After the organic extract was washed with aq sodium bicarbonate and aq sodium chloride, and dried over sodium sulfate, the solvent was removed in vacuo to provide 1.5 g of an oily crude product. Purification on silica gel (20 g, eluent Et_2O/hexane (5/95) and then Et_2O/hexane (15/85)) afforded a small amount of the starting hydrazone and the title compound (0.833 g, 90%). The product was fully characterized by IR, ^1H and ^{13}C NMR spectropscopy as well as elemental analysis.

Instead of treating **D** with water, **D** was allylated in situ (81% overall yield) by addition of $CuBr \cdot Me_2S$ (1.5 equiv) and then allyl bromide (3 equiv). The mixtrure was stirred for 3 h stirring and then subjected to aqueous workup as above (Table 1, entry 3). The hydrazone product was smoothly hydrolyzed (85% yield) according to a literature procedure [5d] by stirring a mixture of the hydrazone (1 mmol), $CuCl_2$ (1 mmol), 0.05 N phosphate buffer (3 mL), water (5 mL), and THF (15 mL) at 25–35 °C for 9 h.

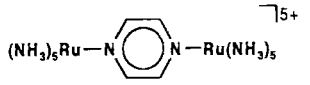
[2] The difficulty of this reaction is seen in the endothermicity of the reaction (26.5 kcal mol^{-1}, as calculated for free acetone enolate + ethylene, HF/3-21 + G).
[3] To improve the unfavorable thermodynamics a) the ring strain of a cyclic olefin was used (E. Nakamura, K. Kubota, *J. Org. Chem.* **1997**, *62*, 792–793) and b) an intramolecular reaction was carried out with an enolate bearing a $BrZn^{II}$ cation (P. Karoyan, G. Chassaing, *Tetrahedron Lett.* **1997**, *38*, 85–88; E. Lorthiois, I. Marek, J. F. Normant, *ibid.* **1997**, *38*, 89–92).
[4] Another recent (formally related) solution to the problem is the use of vinylmagnesium bromide as an "activated form" of ethylene (E. Nakamura, K. Kubota, G. Sakata, *J. Am. Chem. Soc.* **1997**, *119*, 5457–5458). This reaction, which takes place by a metalla-Claisen rearrangement, may be mechanistically unrelated to the present reaction.
[5] Utility of metalated hydrazones in the synthesis of carbonyl compounds is well documented: a) G. Stork, J. Benaim, *J. Am. Chem. Soc.* **1971**, *93*, 5938–5939; b) E. J. Corey, D. Enders, *Chem. Ber.* **1978**, *111*, 1337–1361 and **1978**, *111*, 1362–1383; c) D. E. Bergbreiter, M. Momongan, *Comprehensive Organic Synthesis, Vol. 2* (Eds.: B. M. Trost, I. Fleming), Pergamon, Oxford, **1991**, pp. 503–526; d) E. J. Corey, S. Knapp, *Tetrahedron Lett.* **1976**, *41*, 3667–3668.
[6] The structure of the zinc hydrazone is presently unknown. For the structures of lithium hydrazones, see D. B. Collum, D. Kahne, S. A. Gut, R. T. DePue, F. Mohamadi, R. A. Wanat, J. Clardy, G. V. Duyne, *J. Am. Chem. Soc.* **1984**, *106*, 4865–4869; R. A. Wanat, D. B. Collum, *ibid.* **1985**, *107*, 2078–2082; D. Enders, G. Bachstädter, K. A. M. Kremer, M. Marsch, K. Harms, G. Boche, *Angew. Chem.* **1988**, *100*, 1580–1581; *Angew. Chem. Int. Ed. Engl.* **1988**, *27*, 1522–1524.
[7] For a review of the related chemistry of homoenolates, see I. Kuwajima, E. Nakamura, *Comprehensive Organic Synthesis Vol. 2* (Eds.: B. M. Trost, I. Fleming), Pergamon, Oxford, **1991**, pp. 441–454.
[8] It is notable that the azaenolate moiety in **C**, and not the seemingly more reactive butyl group, reacts preferentially with the olefin. This lacking reactivity of the alkyl–zinc bond agrees with the fact that the product **E** does not react further with the starting olefin.
[9] The MeZn and *tert*-BuZn analogues of **C** are less reactive than **C**.
[10] See also K. Sekiya, E. Nakamura, *Tetrahedron Lett.* **1988**, *29*, 5155–5156; M. Arai, T. Kawasuji, E. Nakamura, *J. Org. Chem.* **1993**, *58*, 5121–5129, and references therein.
[11] D. Enders in *Asymmetric Synthesis, Vol. 3* (Ed.: J. M. Morrison), Academic Press, **1984**, pp. 275–339.
[12] The configuration of the new chiral center was assigned in anlogy to the reactions with SAMP hydrazones [11].
[13] Theory suggests that electrophilic activation of the olefin by the metal cation is important for the carbometalation of olefins: E. Nakamura, Y. Miyachi, N. Koga, K. Morokuma, *J. Am. Chem. Soc.* **1992**, *114*, 6686–6692; M. Nakamura, E. Nakamura, N. Koga, K. Morokuma, *J. Chem. Soc. Faraday Trans.* **1994**, *29*, 1789–1798; E. Nakamura, *Pure Appl. Chem.* **1996**, *68*, 123–130.
[14] Competition experiments indicated that 1-octene and the allylstannane react at roughly the same rate.
[15] The question still remains as to why the zinc hydrazone reacts much faster with olefins than with the polarized C=N bond.
[16] M. Nakamura, A. Hirai, E. Nakamura, *J. Am. Chem. Soc.* **1996**, *118*, 8489–8490; M. Nakamura, M. Arai, E. Nakamura, *ibid.* **1995**, *117*, 1179–1180.

Ligand-Mediated Coupling of Organometallic Reaction Centers**

Wolfgang Kaim,* Ralf Reinhardt, and Jan Fiedler

Dedicated to Professor Wolfgang Beck on the occasion of his 65th birthday

The electronic coupling of reversible single-electron transfer at individual redox centers as mediated by bridging molecules has played a pivotal role for the understanding of intra- and intermolecular electron transfer reactivity.[1] The mechanistic concepts of ligand-mediated "communication" between two or more electron-transfer-active metal sites have developed from simple systems, marked by the mixed-valent Creutz-Taube ion **1** as a molecular model for degenerate electron transfer between two separated metal ions,[1b, c, 2] to encompass a high degree of experimental and theoretical sophistication, and now extend from small molecules to large biological systems.[1a]



1

One common way[1c] to measure the metal–metal interaction in species like **1** is to determine the comproportionation constant K_c, which is defined in Equations (1) and (2) (Int: mixed-valent intermediate). However, for chemical purposes directed at synthetic transformations and eventual multielectron catalysis it would be more relevant to couple "redox reactivities" instead of mere electron transfer. Among the redox reactions beyond pure electron transfer processes, the EC-type "composite" mechanisms[3] represent the best understood examples: electron transfer (E) is followed by an elementary chemical step (C) such as a dissociation, and the thus created new species may eventually revert back to the starting compound through another set of EC steps. Composite processes such as EC or ECE (a two-electron variant) are crucial in organometallic chemistry and catalysis, for example, within reductive elimination/oxidative addition sequences.[3]

$$K_c = [Int]^2/[Ox] \times [Red] = 10^{\Delta E/59\ mV} \quad (1)$$

$$[Ox] + [Red] \rightleftharpoons 2[Int] \quad (2)$$

A well established reversible ECE process[4] involving Rh^{III} and coordinatively unsaturated Rh^{I} species has been used for some years for the catalysis of hydride transfer, for example, to H^+, NAD^+, or formate.[4a, 5] A single $\{Cp^*ClRh^+\}$ fragment ($Cp^* = C_5Me_5$) bound to an α-diimine ligand such as 2,2′-bipyridine or a 1,4-diaza-1,3-butadiene[4d, 6a] undergoes an ECE process in which the initial electron uptake is followed by a rapid dissociation of chloride as the chemical step and by a second electron acquisition. This reaction produces deeply colored neutral "Rh^{I}" compounds that are reoxidized at a significantly less

negative potential and then bind to the additional ligand.[4] In the catalytic cycle the active form Cp*Rh(α-diimine) can oxidatively add a proton to form the essential, reactive hydride intermediate [Cp*RhH(α-diimine)]$^+$.[4a, b, 5] The less reactive iridium analogues may be isolated and characterized.[6]

In a first systematic attempt to extend the coupling of electron transfer sites to the coupling of redox reaction centers through conjugated bridging ligands we have synthesized[7] the symmetrically dinuclear compounds [Cp*ClRh(μ-L)RhClCp*](PF$_6$)$_2$, L = bpip[8a] (**2**) and bptz[8b] (**3**) and studied their extended but

fully reversible electrochemistry by EPR and UV/Vis spectroscopic techniques. Whereas bpip resembles a bis-chelate modification of the familiar pyrazine ligand (see **1**), the bptz molecule was chosen because of its proven ability to promote very strong coupling between transition metal centers; for example, $K_c = 10^{15}$ for the bis(tetraammineruthenium) compound.[8b]

The results of the cyclic voltammetry of the dinuclear rhodium compounds reveal fully reversible cycles, including two separated halide dissociation/association processes and up to six electron transfer steps (Figure 1). Diagnostic criteria for the oxidation state formulation of the intermediates are the UV/Vis/NIR absorption spectra from OTTLE spectroelectrochemistry (Figure 2),[9] the release of chloride as studied by Hg polarography,[4e] and—in the case of paramagnetic compounds—the EPR signals. From this information we can derive the sequence summarized in Table 1.

In both cases (L = bpip and bptz), the first reduction is no longer an ECE process but an electrochemically reversible one-electron reduction. Absorption and EPR spectra clearly indicate L-centered spin (a radical anion ligand[10]). Chloride dissociation occurs only after the second one-electron reduction, indicating a decoupling of the ECE process[11] into an E and EC step. In other words, the ligand L acts as a remote electron storage or "reservoir"[3, 12] until the second electron triggers a

combined metal-centered two-electron reduction of Rh^{III} to yield chloride-free Rh^I. The appearance of the {Cp*Rh^I} moiety bound to a π-acceptor ligand is evident from intense long-wavelength absorptions.[4c]

Interaction between the two organometallic reaction centers[11] is evident from the fact that the loss of chloride occurs stepwise, separated by significant potential differences of more than 300 mV. The class I[13] mixed-valent species [Cp*ClRh-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2494 $ 17.50+.50/0

(μ-L)RhCp*]$^{\bullet+}$ formed in the first chloride-releasing process is reduced for L = bptz in an ECE step to neutral [Cp*Rh-(μ-bptz)RhCp*] at more negative potential; there are two more reversible one-electron steps with a paramagnetic intermediate that may be formulated[14] according to [Cp*Rh^{I}(μ-bptz^{-I})-Rh^{I}Cp*]$^{\bullet-}$ $\leftrightarrow$ [Cp*Rh^{I}(μ-bptz^{-II})Rh^{II}Cp*]$^{\bullet-}$ based on the significant g anisotropy[14] in comparison to that of [Cp*ClRh^{III}-(μ-bptz^{-I})Rh^{III}ClCp*]$^{\bullet+}$ (Table 1).

For L = bpip the second ECE step is once again decoupled but—unlike the first—in an EC process followed by an electron transfer E step. This sequence produces an unusual mixed-valent Rh^{II}/Rh^{I} intermediate with a comproportionation constant K_c of about $10^{2.4}$ and a series of fairly intense long-wavelength absorption bands in the near-infrared (NIR) region (Figure 2). This intermediate differs from the much investigated Creutz-Taube ion **1**[1c, 2] by being a d^7/d^8 [15] instead of a d^5/d^6 mixed-valent dimer. The higher reduced states of the bpip complex were too unstable for further characterization. In summary, the following general points can be made:

- The ECE processes observed for the mononuclear systems[4, 5] can be split in various ways (E + EC, EC + E).
- Acceptor ligands may act as passive electron storage sites until the necessary number of electrons is collected and then transferred to the potentially reactive site at the right potential for chemical reactivity.
- There is clearly a "communication" between the organometallic reaction sites in the dinuclear rhodium complexes bridged by bpip or bptz; the halide-releasing steps are separated by about 0.3 (L = bptz) and 0.5 V (L = bpip).

At this point the differences between the two systems are not immediately apparent, this first systematic study thus produces further questions related to the eventual construction of multielectron redox systems coupled with potentially catalytic chemical reactivity.

[7] a) General procedure: [{Cp*Cl$_2$Rh}$_2$] (250 mg, 0.4045 mmol) [4] was suspended in acetone (50 mL) and treated with $AgPF_6$ (204.5 mg, 0.809 mmol) and stirred for 30 min. The resulting AgCl was filtered off and Bu_4NPF_6 (620 mg, 1.6 mmol) was added to the filtrate. A solution of the bridging ligand (L = bpip or bptz, 0.32 mmol) in acetone (ca. 20 mL) was then added. After the mixture had been stirred for 6 h at room temperature the volume was reduced to about 20 mL and the light brown (L = bpip) or dark red (L = bptz) product was completely precipitated by addition of pentane. Filtration and washing with diethyl ether yielded about 70% of the product. Correct elemental analyses (C,H,N). b) The complexes are formed as mixtures of *cis* and *trans* isomers with respect to Cl and Cp* ligands. For L = bptz (ratio 4:1) the NMR signals of the minor component could not be completely identified due to partial overlap: ^{1}H NMR (250 MHz, CD_3NO_2, 298 K): δ = 1.98 (s, 30H; Cp*, major isomer), 1.99 (s, 30H; Cp*, minor isomer), 8.36 (ddd, 2H; H5,5'), 8.70 (td, 2H; H4,4'), 9.26 (m, 2H; H3,3'), 9.28 (m, 2H; H6,6'); J(H3,H4) 7.8, J(H4,H5) 7.8, J(H5,H6) 5.5, J(H3,H5) 1.2, J(H4,H6) 1.4 Hz. c) For L = bpip the *cis* and *trans* isomers are formed in a 1:1 ratio that can be shifted to 3:1 by fractional crystallization. As expected, cyclic voltammetry and spectroelectrochemistry are not perceptibly affected by the changing isomer ratio. ^{1}H NMR (250 MHz, CD_3NO_2, 298 K): δ = 1.65 (s, 30H; Cp*, isomer I), 1.63 (s, 30H; Cp*, isomer II), 2.94 (s, 6H; CH_3, isomer I), 2.98 (s, 6H; CH_3, isomer II), 7.65 (m, 4H; ^{o}-H,$^{o'}$-H, two isomers), 7.69 (m, 2H; ^{p}-H,$^{p'}$-H, two isomers), 7.83 (m, 4H; ^{m}-H,$^{m'}$-H, two isomers), 9.64 (s, 2H, ^{pz}-H; isomer I), 9.61 (s, 2H, ^{pz}-H; isomer II).

Isolation and X-ray Structural Determination of Both Folded and Twisted Conformers of Bis{4*H*,8*H*-4-(dicyanomethylene)-benzo[1,2-*c*:4,5-*c'*]bis[1,2,5]thiadiazol-8-ylidene}, an Overcrowded Ethylene with High Electron Affinity**

Takanori Suzuki,* Takanori Fukushima, Tsutomu Miyashi, and Takashi Tsuji

Recently much attention has been focused on optically responsive molecules, which are interesting as molecular devices or switches.[1] Overcrowded ethylenes are one of the promising candidates for this purpose,[2] because they exhibit a characteristic color change associated with their conformational isomerism. The leading compound in this area is bianthrone (**1**),[3] which adopts the doubly folded conformation **1A** in the ground state to reduce the steric repulsion in the fjord region.[4] Triggered by heating, photoexcitation, or pressure, this yellow conformer partly transforms into a green metastable form,[5] which is believed to be the twisted conformation **1B**.[6] Because the

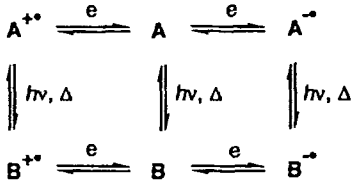
features of the analogous charged isomers are different from those of the corresponding neutral species, the conformational change can be also induced electrochemically.[7] Combination of the isomerism and electron transfer is expected to provide the multichannel response system depicted in Scheme 1, but none of



Scheme 1. Multichannel response system based on the conformational change of both the neutral and charged species.

the overcrowded ethylenes have yet afforded stable radical ion salts. We have designed and prepared the title electron acceptor **2**, whose radical anion is stable enough to be isolated. Neutral **2** exhibits the characteristic chromism involving the folded and twisted conformers. This compound is the first interconvertible overcrowded ethylene of which both conformers can be isolated and their geometries unambiguously determined by X-ray analyses.[8]

Ethylene **2** was obtained in 50% yield by oxidation of tricyclic compound **3**[9] with SeO_2 on heating under reflux in EtOH for 18 h and purification by successive recrystallization. The appearance of the crystalline sample differs in color significantly depending on the recrystallization solvents; yellow plates [m.p. 351–357 °C (decomp.)] were obtained from 1,2-dichloroethane, whereas deep violet needles [m.p. 110–112 °C (decomp.)] or cubes [m.p. 84–86 °C (decomp.)] were formed in CH_2Cl_2 or PhCN solution. Combustion analyses indicated that the latter two forms contain crystallization solvents (**2**·CH_2Cl_2 or **2**·2PhCN, respectively).[10]

X-ray analyses[11] clearly show that the molecule in the unsolvated yellow crystal adopts doubly folded geometry (**2A**) whereas the twisted conformer (**2B**) exists in the violet PhCN-solvated crystal (Figure 1). Both types of deformation are due to the

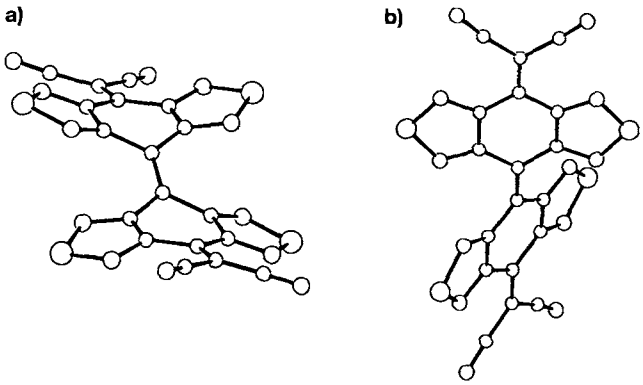


Figure 1. Two geometries of **2** determined by X-ray: a) the doubly folded conformer **2A** (in the unsolvated yellow crystal the molecule on the crystallographic center of symmetry); b) the twisted conformer **2B** in the violet PhCN-solvated crystal.

repulsive interaction through the short N···N contacts (2.67 Å in **2A**; 2.74 and 2.81 Å in **2B**) of less than the sum of van der Waals radii (3.0 Å). The central ethylene bond in **2A** [1.362(4) Å] is completely planar within only 0.01 Å deviation of six carbon atoms from the least-squares plane, yet the same bond in **2B** is twisted by 48.1° and much longer [1.388(7) Å] than in **2A**. On the other hand, the halves of the molecule containing the tricyclic moiety in violet **2B** are nearly planar (less than 0.11 Å deviation) as in **3** or **4**,[9] but the central six-membered ring in yellow **2A** deforms into the boat form with the dihedral angle of 149.8° between the fused heterocycles.

Upon heating, the solvated violet crystals turned yellow with loss of volatile CH_2Cl_2 or PhCN. The resulting solids as well as the yellow plates of **2A** did not show any indication of conformational isomerism to form violet **2B** up to the decomposition point of the **2A** crystal. These results indicate that in the solid state the doubly folded geometry is more stable at high temperature. The twisted conformer **2B** can be isolated as a solid only in the presence of suitable guest (solvent) molecules.[12] Inspection of the packing arrangement suggests that **2B**·2PhCN crystal is a clathrate complex, and the cavities formed by twisted conformers **2B** are filled with the solvent molecules (Figure 2). On the other hand, electrostatic S···N≡C interactions connect the folded conformers **2A** in the lateral direction to form an infinite "sheetlike" network, which is further stacked to form a layer structure as in **4**.[9] Such an attractive force is also at work, but less effectively, in **2B**·2PhCN; thus the stabilization by S···N≡C interaction may also contribute to the preference for the **2A** conformer in the crystalline state.

Upon grinding in a mortar, the yellow crystal of **2A** turned violet, illustrating its mechanochromic behavior. Under the FT-IR microscope a single crystal of **2A** showed a band at 1581 cm^{-1}, which is assigned to the C=C stretching mode of the dicyanomethylene groups. After grinding, this band remained at 1580 cm^{-1} in the spectrum (KBr disk) but a new and larger band appeared at 1553 cm^{-1}, a quite similar frequency to that of **2B**·CH_2Cl_2 (1551 cm^{-1}) and **2B**·2PhCN (1550 cm^{-1}) crystals. The new band disappeared concomitant with the fading of the violet color upon heating the KBr pellet at 220 °C for 5 h, and the original band grew in intensity. Such a phenomenon is best accounted for by the reversible mechano- and thermochromism involving the two conformers **2A** and **2B**.

In contrast to the solid state, in solution the twisted conformer **2B** seems to be more stable,[12] and both yellow and solvated violet crystals afforded identical violet solutions upon dissolution. The UV-Vis spectrum [λ_{max} (lg ε) = 313 (4.659), 400

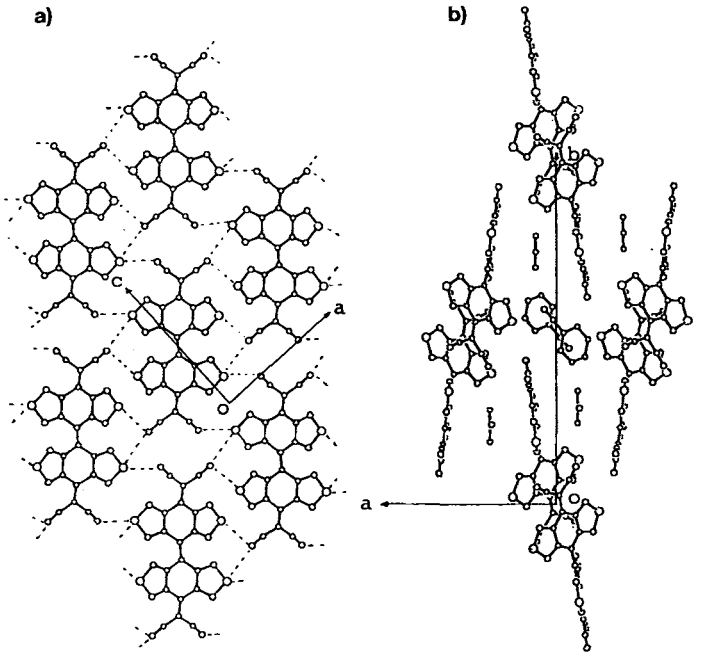

Figure 2. Arrangement of the molecules a) in the unsolvated yellow crystal (short S···N≡C contacts of 3.30, 3.32, and 3.36 Å are indicated by dotted lines) and b) in the violet PhCN-solvated crystal (two crystallographically independent PhCN molecules are included in the spatial cavity; short S···N≡C contacts (S···N = 3.01 Å) are observed along the *c* axis not shown in this view).

(4.165), 433 (sh, 4.096), 515 (sh, 4.470), 544 nm (4.513) in CH_2Cl_2 at 25 °C] closely resembles that of **2B**·CH_2Cl_2 crystal [KBr disk; λ_{max} (relative intensity) = 326 (1.00), 407 (0.28), 568 (sh, 0.84), 607 nm (0.87)]. Although the precise proportion of **2A** and **2B** in solution is not known, the cyclic voltammogram of **2** can be explained by assuming the presence of only one conformer (**2B**). Thus, four reversible, one-electron reduction waves were observed at +0.28, +0.06, −0.95, and −1.10 V vs the saturated calomel electrode (0.1 M nBu_4NBF_4 in CH_2Cl_2, Pt electrode, scan rate 100 mVs^{-1}, 25 °C). The electron affinity of **2** is similar to that of TCNQ (E_1^{red} = + 0.30 V) and much higher than those of **1** or its bis(dicyanomethylene) derivative[13] (E_p^{red} = −1.16 and −0.77 V, respectively, under the same conditions). Thus, by the reaction with iodide **2** was readily reduced to the radical anion, which could be isolated as stable salts.[14] Furthermore, **2** gave charge transfer complexes with some donors despite its severely deformed geometry. The moderate electrical conductivity ($\sigma = 3.4 \times 10^{-2}$ Scm^{-1}) of the 1:1:1 complex of **2**, tetrathiatetracene, and H_2O is noteworthy.

A Calix[4]arenoporphyrin**

Richard G. Khoury, Laurent Jaquinod, Katsuhiro Aoyagi, Marilyn M. Olmstead, Andrew J. Fisher, and Kevin M. Smith*

Due to the potential biological or other catalytic activity of supramolecular arrays,[1, 2] much interest has been focused on the synthesis and chemistry of such assemblies. Recently, large cyclic structures were obtained based on porphyrin subunits as building blocks.[3] It was shown that supramolecular arrays of porphyrins with higher order structures act not only as unique molecular recognition species but also as enzyme-mimicking catalytic sites.[4]

Among the different building blocks that were studied for the synthesis of artificial receptor molecules, calixarenes,[5] cyclodextrins, and resorcinol-based cavitands are particularly useful.[6] Recently, considerable interest has been given to the use of calixarenes as platforms for the construction of supramolecular receptor assemblies.[7] Calixarenes are readily accessible cyclic polyphenols which are chemically transformable in a selective fashion, so that they are used as building blocks for larger

and more sophisticated molecular assemblies. Calixarenes have been very actively investigated, and a great number of derivatives of different types have been synthesized which display a variety of substrate binding and reactivity features.[8]

Aiming at the synthesis and elaboration of large systems based on both calixarene and porphyrin units, we utilized calixarenes as molecular platforms that allow the synthesis of supramolecular porphyrin assemblies with well-defined, conformationally fixed superstructures. Complexation of calix[4]-arenes, which possess strong ion-bonding properties, with porphyrins, which are pH-dependent photoactive chromophores, can potentially lead to new molecular receptors for the development of efficient sensing agents. Several porphyrin–calixarene complexes have been synthesized; however, the yields were usually less than one percent, or the complex contained only one porphyrin subunit.[9]

We adopted the Zinke–Cornforth procedure,[5b, 10] with some minor modifications, for synthesizing a calix[4]porphyrin. Two main issues addressed in the planning of our synthesis were solubility and steric congestion due to the large size of the porphyrin chromophore. By careful design and molecular modeling, we determined that a porphyrin with unsubstituted peripheral positions on its upper half would minimize any steric congestion among adjacent porphyrins, but that the resulting calixarene would probably have the $\alpha,\beta,\alpha,\beta$-atropisomeric conformation. On the lower half, ethyl groups were placed at the peripheral pyrrole subunit carbon atoms to increase solubility of the final product.

The upper half of the porphyrin was prepared by condensation of *p*-anisaldehyde and pyrrole in trifluoroacetic acid (TFA), resulting in methoxyphenyldipyrromethane (**1**) in 51% yield (Scheme 1).[11] Vilsmeier bisformylation of **1** gave **2** (86% yield), which reacted with 2,3,7,8-tetraethyldipyrromethane (**3**) to afford 4-(12,13,17,18-tetraethylporphyrinyl)anisole (**4**) in 49% yield. The methoxy group was then cleaved with BBr_3 to give 4-(12,13,17,18-tetraethylporphyrinyl)phenol (**5**) in quantitative yield. Nickel was then inserted (in 97% yield) to prevent any adverse interactions of the central nitrogen atoms of the porphyrin in the subsequent reactions. Heating the nickel(II) complex of **5** at reflux in dioxane containing NaOH gave a mixture of the monobenzylalchohol porphyrin **6** (major product, 61% yield), the starting porphyrin **5**-Ni, and the bis-(benzylalcohol)porphyrin **7** (9% yield). Heating the mixture at reflux in diphenyl ether containing NaOH followed by a workup with ethyl acetate gave a precipitate, which was dissolved in DMF and subjected to chromotography on Sephadex G-25-300. The fastest running band was collected to give calix[4]-arenoporphyrin **8** in 60% yield.

^{1}H NMR spectroscopy of **8** (in $(CD_3)_2SO$) showed broad signals, which were only marginally temperature dependent, at $\delta = 9.85$ (*meso*-H), 9.11 (β-H), 7.44 (OH), 7.34 (aromatic H), and 3.98 (methylene bridge). Peaks for the ethyl substituents appeared at $\delta = 4.13$ and 1.69. The methylene bridge carbon atoms were at $\delta = 29.8$ in the ^{13}C NMR spectrum. Spectrophotometry showed a broadened Soret band at $\lambda_{max} = 404$ nm (porphyrin monomer **5**-Ni: 399 nm). The calix[4]arenoporphyrin **8** was further characterized by mass spectrometry, elemental analysis, and X-ray diffraction studies. Figure 1 shows the molecular structure of **8**.[12] Surprisingly, the molecule adopts the cone $(\alpha,\alpha,\alpha,\alpha)$ conformation. Of the four configurations possible for the calix[4]arenoporphyrin (Figure 2), we anticipated, based on molecular modeling and other energetic considerations, that the molecule would adopt the $\alpha,\beta,\alpha,\beta$ configuration; we also expected that π-π stacking of the type shown in Figure 2 would be reasponsible for the broadening in the ^{1}H NMR spectrum. Fig-

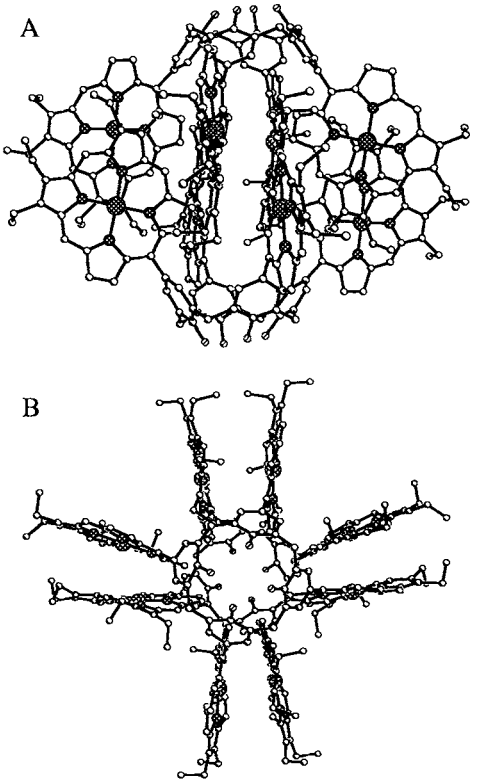

Figure 3. Molecular structure of the aggregated dimer of **8**; A: side view, B: top view. Hydrogen atoms have been omitted for clarity.

ure 3 shows the interactions which exist between two neighboring molecules of calix[4]arenoporphyrin, and fully explains the existence of the $\alpha,\alpha,\alpha,\alpha$ conformation. Aggregation between two molecules to give a cogwheel arrangement is clearly a dominating phenomenon, and this leads to a self-assembling supramolecular array which, as the nickel(II) complex, we have thus far been unable to uncog.

The unit cell in the crystal structure of **8** has the dimensions $a = b = 23.51$, $c = 100.61$ Å and a volume of 55609 Å^3. A large void exists in which methanol molecules of solvation partially occupy twelve sites; two more methanol sites exist within the cavity of each calix[4]arenoporphyrin. Inclination angles of the phenyl groups (with respect to the best plane of methylene groups) for the calixporphyrin complex are 130.1, 123.9, 118.5, and 126.2°; calix[4](*p-tert*-butylbenzene) has an inclination angle of 123°.[5b] Deviations from this value are usually caused by packing effects, or in this case, aggregation of the calix[4]-arenoporphyrin units. Another indicator of the strain placed on the calixarene by the porphyrin subunits are the larger O—O distances of 2.513, 2.872, 2.790, 2.479 Å; the average value in calix[4](*p-tert*-butylbenzene) is 2.650 Å.[5b] The asymmetric unit consists of two calix molecules, each of which forms an aggregate with its centrosymmetrically related pair. A fourfold screw axis along the *c* axis generates the packing system. Whereas one molecule occupies the space at the center of the cell, the other is positioned at the corners; this forms channels in the lattice packing model.

The structural features of **8** are unique. We consider the dimeric cogwheel compound derived from **8** to be a remarkable example of a robust, definitively structured, self-assembled supramolecular array of versatile chromophores. Further studies focus on the syntheses of calix[6]- and calix[8]arenoporphyrins, and formation of free base as well as other metal complexes. Based on the fact that the calix[8]arenoporphyrin might

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2499 $ 17.50+.50/0

afford a cyclic cogged dimer with sixteen π-stacked tetrapyrrole units, further studies are aimed at developing molecules which are potential models for systems such as the array of tetrapyrroles in the light-harvesting component of the bacterial light harvesting complex LH2.[14] Indeed, we note that the B800 and B850 components of the light-harvesting complex II in *Rhorospirillum molischianum* consist of eight and sixteen units of bacteriochlorophyll, respectively.[15]

[12] Crystallographic details for **8**: $C_{141.75}H_{128}N_{16}Ni_4O_{5.75}$, dark green, octahedral crystal ($0.15 \times 0.10 \times 0.10$ mm), tetragonal space group $P4_122$ (no. 92); $a = b = 23.510(3)$, $c = 100.61(2)$ Å, $V = 55609(16)$ Å^3, $Z = 16$. Of 33061 reflections measured, 15009 were unique and 9740 observed ($R_{int} = 0.033$, $T_{min} = 0.90$, $T_{max} = 0.85$, $\mu = 1.047$ mm^{-1}, $\rho_{calcd} = 1.138$ g cm^{-3}); $R1 = 0.1142$ (observed data, $I > 2\sigma(I)$) and $wR2 = 0.3483$ (all data) for 2571 parameters. Data were collected at 113(2) K on a Siemens Hi Star multiwire proportional counter diffractometer mounted on a Rigaku RU300 rotating anode equipped with a 3.0×0.3 mm focal cup and Göbel mirrors ($Cu_{K\alpha}$ irradiation; $\lambda = 1.54178$ Å, ω scan mode, $2\theta_{max} = 90.2°$). The structure was solved by direct methods and refined (based on F^2 with all independent data) by full-matrix least-squares methods (Siemens SHELXTL Version 5.03). A total of fourteen methanol sites were found; twelve were located in regions of void, and the other two in the calixarene cavities. All sites showed only partial occupancy summing to a total of 1.75 methanol molecules. With the exception of the solvent molecules, non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were generated by idealized geometry and treated as riding using isotropic thermal parameters (but not on the solvent molecules). The data were corrected for absorption [13]. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100523. In the course of our study on heterocyclobutanes **1**[1] bearing highly coordinated main group elements at the position adjacent to the heteroatom we have reported the syntheses and isolation of intermediates of the Wittig and Peterson-type reactions.[2] Recently we also achieved the synthesis of tetracoordinate and pentacoordinate 1,2-oxathietanes and their thermolysis to the oxirane with retention of configuration.[3] Our studies on the influence of ring size on the stability of 1,2-oxaphosphetanes led to the synthesis of **2**, the first stable pentacoordinate spirophosphorane with two 1,2-oxaphosphetane rings; the stability is attributed to the trifluoromethyl groups at the 4-position.[4, 5]

2

Unexpectedly, however, double olefin extrusion from **2** was unsuccessful, because of the electronic effect of the strong electron-withdrawing groups. Taking into consideration the bonding character of equatorial bonds in a trigonal-bipyramid (TBP) structure, an electron-releasing group such as an alkyl group at the 3-position is expected to stabilize a TBP structure sufficiently even in the absence of a strong electron-withdrawing group. The introduction of such a substituent at the 3-position may also lead to kinetic stabilization toward hydrolysis by steric protection, as observed in the tetracoordinate 1,2-oxathietanes.[3a] We now report the synthesis, crystal structures, and thermolysis of all three diastereomers of 2,2,6,6-tetrakis(4-chlorophenyl)-3,7-dimethyl derivatives **3**.

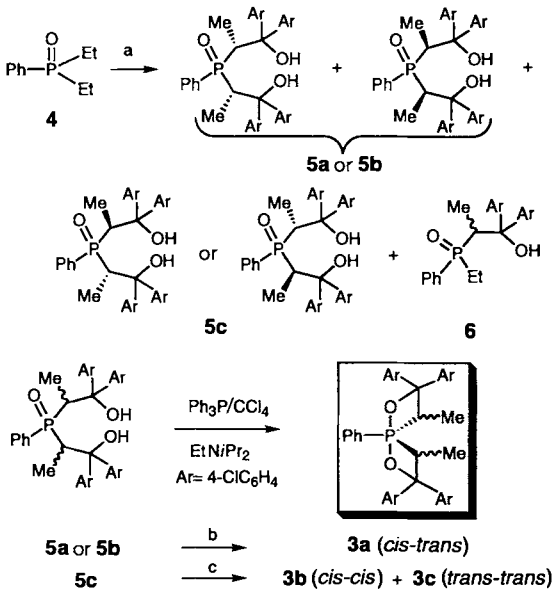
Sequential treatment of diethylphenylphosphane oxide (**4**) with *n*BuLi, 4,4′-dichlorobenzophenone, and aqueous NH_4Cl gave a diastereomeric mixture of bis(β-hydroxyalkyl)phosphane oxides (**5a–c**) along with a diastereomeric mixture of monohydroxyalkyl derivatives **6** (35%). Cyclization and dehydration of **5a** or **5b** by Appel's method[6] gave the *cis-trans* isomer **3a**, while similar treatment of **5c** provided a mixture of the *cis-cis* isomer **3b** and the *trans-trans* isomer **3c** (Scheme 1). The two oxaphosphetane rings of the *cis-trans* isomer **3a** are different from each other, while those of the *cis-cis* and *trans-trans* isomers **3b** and **3c**, respectively, were equivalent.



Scheme 1. a) 2.3 molar equiv *n*BuLi, THF, −78 → 25 °C, 10 min; 2.19 molar equiv 4,4′-dichlorobenzophenone, THF, −78 °C, 1 h; −78 → 25 °C; 25 °C, 2 h; aqueous NH_4Cl; b) **5a**: CH_3CN, 25 °C, 7 h; **5b**: CH_3CN, 40 °C, 8 h; c) CH_3CN, 25 °C, 6.5 h.

The X-ray crystallographic analysis of all three diastereomers showed that **3a** and **3b** have a distorted TBP structure with two oxygen atoms at apical positions, while **3c** has a distorted square-pyramidal (SP) structure with the phenyl carbon atom at apical and the other four atoms at basal positions, respectively (Figures 1 and 2).[7] In the crystal structure of the *cis-trans* isomer **3a** (TBP → SP[8] 19.0%) the apical bond angle deviates by 12.08(10)° from linearity. Deviations in the range between 10 and 20° are a common structural feature of hypervalent species containing a four-membered ring.[1a, b, 3b] On the other hand, in the *trans-trans* isomer **3c** (TBP → SP 73.7%) the apical P–C(Ph) bond length was 1.796(7) Å, while the basal P–C bond lengths were 1.835(7) and 1.829(7) Å, indicating that the apical bond is stronger than the basal bonds in an SP structure.

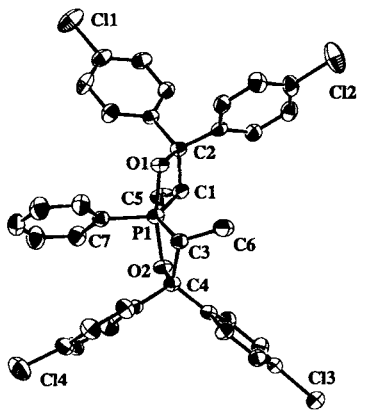


Figure 1. Structure of *cis-trans* **3a** (ORTEP drawing, thermal ellipsoid plots for 30% probability). Selected bond lengths [Å], bond angles [°], and torsion angles [°]: P1–O1 1.738(2), P1–O2 1.741(3), P1–C1 1.819(3), P1–C3 1.825(3), P1–C7 1.798(3); O1-P1-O2 167.92(10), C1-P1-C7 120.2(1), C1-P1-C3 128.0(1), C3-P1-C7 111.8(1), P1-C1-C2 89.4(2), C1-C2-O1 96.2(2), C2-O1-P1 96.4(1), O1-P1-C1 77.9(1), P1-C3-C4 87.9(2), C3-C4-O2 96.1(2), C4-O2-P1 95.1(2), O2-P1-C3 77.9(1), P1-C1-C2-O1 2.2(2), P1-C3-C4-O2 13.8(2).

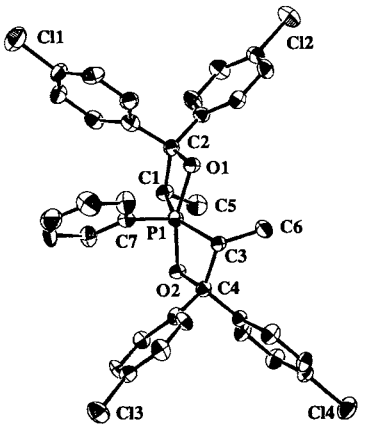

Figure 2. Structure of *trans-trans* **3c** (without Et_2O, ORTEP drawing with thermal ellipsoid plots for 30% probability). Selected bond lengths [Å], bond angles [°], and torsion angles [°]: P1–O1 1.719(4), P1–O2 1.715(4), P1–C1 1.835(7), P1–C3 1.829(7), P1–C7 1.796(7); O1-P1-O2 157.5(2), C1-P1-C7 108.8(4), C1-P1-C3 142.8(3), C3-P1-C7 108.4(4), P1-C1-C2 88.3(5), C1-C2-O1 95.6(5), C2-O1-P1 95.6(4), O1-P1-C1 76.7(3), P1-C3-C4 87.8(4), C3-C4-O2 95.6(5), C4-O2-P1 95.6(4), O2-P1-C3 77.4(3); P1-C1-C2-O1 15.2(4), P1-C3-C4-C2 14.6(4).

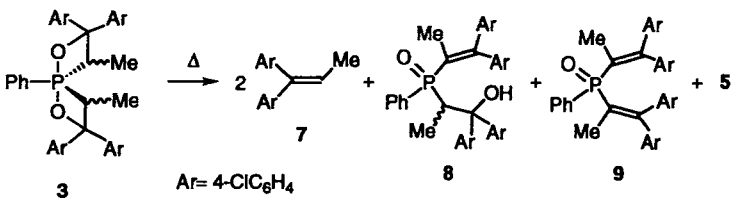
The ^{31}P NMR spectrum of **3c** in solution showed a peak at $\delta = -33.6$, which is similar to the values observed in the ^{31}P NMR spectra of **3a** ($\delta = -31.2$) and **3b** ($\delta = -32.7$), indicating that **3c** also has a TBP structure in solution.[9] Interestingly, the large difference in crystal structure between **3a,b** and **3c** is probably attributable to crystal packing forces, in other words, the energy difference between TBP and SP structures is quite small in this system as usual. Taking into consideration the high moisture sensitivity of a 3,7-unsubstituted derivative of **3**, it becomes clear that the electropositive substituents (CH_3) at the equatorial positions stabilize the TBP structure both thermodynamically and kinetically—evidently with support from the 4-chlorophenyl groups at the β-carbon atoms of the apical ligands.

Thermolysis of these compounds gave the corresponding olefin **7**, the ring-opened isomer of **3** (**8**), the dehydration product of **8** (**9**), and **5**. Interestingly, although the yields of the olefin are



only moderate, they indicate that in sharp contrast to the thermolysis of **2**, one molecule of **3** afforded two molecules of the olefin by a double olefin extrusion (Table 1). Monitoring the reaction by NMR spectroscopy showed that there is an equilibrium between **3b** and **3c** during the reaction. Such an equilibrium has previously never been observed in pentacoordinate 1,2-oxaphosphetanes with two apical oxygen atoms.[10] Fur-

Table 1. Yields of products in the thermolysis of **3**. (Solvent C_6D_6, $T = 80\,^{\circ}C$.)

Entry	3	t	Additive	Yield[%][a] 7	8 [b]	9	5
1	**3a**	6 h	–	55	49(16:33)	23	traces
2	**3b**	6 h	–	29	62(51:11)	16	7
3	**3b**	6.5 d	$EtNiPr_2$	158	–	4	–
4	**3b**	20 h	$EtNiPr_2 \cdot HCl$	127	27(>100:1)	9	–
5	**3c**	5 h	–	67	36(>100:1)	10	20

[a] Based on **3** and determined by ^1H NMR spectroscopy. [b] The ratio of two diastereomers is shown in parentheses.

thermore, the thermolysis of **3b** in the presence of $Et(iPr)_2N$ and $Et(iPr)_2N \cdot HCl$ afforded the olefin in 158 and 127% yields, respectively (Table 1, entries 3 and 4). Judging from the longer reaction time of these reactions than that without an additive (entry 2), it is conceivable that the additives do not accelerate the olefin formation reaction, but retard the side reactions. Although we have no real evidence at present it is most likely that coordination of amine or chloride ion to the phosphorus center plays an important role in reducing the acidity of the methine proton. Further investigations on the effects of additives are in progress.

Experimental Section

*n*BuLi (1.64 M solution in hexane, 14.6 mL) was added to a solution of $PhP(O)Et_2$ (**4**) (1.89 g, 10.4 mmol) in dry THF (30 mL) at $-78\,^{\circ}C$ under argon. The reaction mixture was stirred at room temperature for 10 min, and cooled again to $-78\,^{\circ}C$. A solution of 4,4'-dichlorobenzophenone (5.73 g, 22.8 mmol) in THF (30 mL) was added to the cooled solution at $-78\,^{\circ}C$. After stirring at $-78\,^{\circ}C$ for 1 h, the reaction mixture was allowed to warm to 25 °C, stirred for 2 h, and then treated with aq NH_4Cl and extracted with CH_2Cl_2. The extracts were dried over anhydrous $MgSO_4$. After removal of the solvent under reduced pressure the residue was subjected to dry column chromatography to afford diastereomeric mixtures of **5** and **6** (1.25 g, 35%). These were purified by column chromatography (SiO_2, CH_2Cl_2), flash column chromatography (SiO_2, CH_2Cl_2/hexane, 3/2), and recrystallization (CH_2Cl_2). Yields based on ^1H NMR data: **5a**, 6.9%; **5b**, 19%; **5c**, 25%.

5a: Colorless crystals; m.p. 225.0–226.0 °C (decomp); elemental analysis calcd for $C_{36}H_{31}O_3Cl_4P$ (%): C 63.18, H 4.57, Cl 20.72; found: C 63.22, H 4.77, Cl 20.71; ^1H NMR (500 MHz, $CDCl_3$, 27 °C, TMS): $\delta = 1.44$ (dd, $^3J(H,P) = 15.0$ Hz, $^3J(H,H) = 7.3$ Hz, 6H, CH_3), 3.42 (quint, $^3J(H,H) = {}^2J(H,P) = 7.3$ Hz, 2H, CH), 5.35 (s, 2H, OH), 6.76–6.79 (m, 4H, 4-ClC_6H_4), 6.96–7.04 (m, 6H, Ar), 7.09–7.14 (m, 2H, Ph), 7.17–7.20 (m, 4H, 4-ClC_6H_4), 7.26–7.29 (m, 4H, 4-ClC_6H_4), 7.33–7.38 (m, 1H, Ph); $^{31}P\{^1H\}$ NMR (109 MHz, $CDCl_3$, 27 °C, 85% H_3PO_4): $\delta = 56.7$.

To a solution of phosphane oxide **5a** (59 mg, 0.087 mmol) and Ph_3P (228 mg, 0.87 mmol) in CH_3CN (6 mL), $Et(iPr)_2N$ (0.15 mL, 0.86 mmol) and CCl_4 (0.084 mL, 0.87 mmol) were syringed at 25 °C. After the mixture had been stirred for 7 h, *cis-trans* **3a** precipitated out (24 mg). The precipitates were filtered and the filtrate was subjected to column chromatography (SiO_2, CH_2Cl_2: hexane = 1:1) to afford *cis-trans* **3a** (23 mg, total yield was 81%). A similar reaction (40 °C, 8 h) using **5b** instead of **5a** gave **3a** (42%), while the reaction (25 °C, 6.5 h) using **5c** afforded a mixture of *cis-cis* **3b** (39%) and *trans-trans* **3**) (26%). Recrystallization from CH_2Cl_2/hexane gave an analytically pure sample, and single crystals suitable for X-ray crystallographic analysis were grown in ether/hexane.

cis-trans **3a**: Colorless crystals; m.p. 119.5–120.5 °C (decomp); elemental analysis calcd for $C_{36}H_{29}O_2PCl_4$ (%): C 64.88, H 4.38, Cl 21.27; found: C 64.81, H 4.57, Cl 20.88; ^1H NMR (500 MHz, $CDCl_3$, 27 °C, TMS): $\delta = 0.94$ (dd, $^3J(H,H) = 8.4$ Hz, $^3J(H,P) = 26.3$ Hz, 3H, CH_3), 1.35 (dd, $^3J(H,H) = 8.0$ Hz, $^3J(H,P) = 27.4$ Hz, 3H, CH_3), 4.24 (dq, $^2J(H,P) = 16.7$, $^3J(H,H) = 8.4$ Hz, 1H, CH), 4.58 (dq, $^2J(H,P) = 25.6$, $^3J(H,H) = 8.0$ Hz, 1H, CH), 6.96–7.09 (m, 9H, Ar), 7.20–7.35 (m, 10H, Ar), 7.87–7.96 (m, 2H, *o*-H of Ph); $^{31}P\{^1H\}$ NMR (109 MHz, $CDCl_3$, 27 °C, 85% H_3PO_4): $\delta = -31.2$.

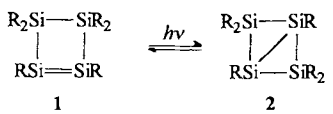
Hexaaryltetrasilabuta-1,3-diene: A Molecule with Conjugated Si–Si Double Bonds**

Manfred Weidenbruch,* Stefan Willms, Wolfgang Saak, and Gerald Henkel

Dedicated to Professor Hans Georg von Schnering

Since the isolation of the first molecular compound with an Si–Si double bond[1] the chemistry of disilenes has experienced an explosive development, which is reflected in numerous review articles.[2] However, molecules with conjugated Si–Si double bonds had not been reported previously. Recently, Kira et al. described the tetrasilacyclobutene **1**, the first compound to contain an endocyclic Si–Si double bond, which they obtained in very low yield.[3] Although **1** is thermally rather stable, on exposure to light it rearranges to the bicyclobutane derivative **2**, which, in turn, reverts back to **1** in the dark. A tetrasilabuta-1,3-diene was postulated as a feasible intermediate in the reaction sequence **1** ⇄ **2** but could not be isolated (Scheme 1).



1 2

R = *t*BuMe$_2$Si

Scheme 1.

We now report on the synthesis and characterization of the tetrasilabuta-1,3-diene **6**, which is accessible in acceptable yield by a surprisingly simple process. In the course of the synthesis of the unsymmetrically substituted disilene Mes$_2$Si=SiTip$_2$ (Mes = 2,4,6-Me$_3$C$_6$H$_2$, Tip = 2,4,6-*i*PrC$_6$H$_2$) from Mes$_2$ClSiSiClTip$_2$ and lithium[4,5] we had observed that the yield of the disilene in the dehalogenation step passed through a maximum and then decreased again continuously. At the same time increasing amounts of 1,3,5-triisopropylbenzene were obtained, indicating that the cleavage of TipLi from already formed disilene with concomitant formation of the disilenyllithium compound Mes$_2$Si=SiTipLi proceeds as a competing reaction to the elimination of chlorine at the lithium surface (Scheme 2). A similar reaction mode had previously been observed by Masamune et al. in the reaction of naphthalene/lithium with a tetraaryldigermene.[6]

In order to keep the reaction process as simple as possible, we prepared the symmetrically substituted disilene **3**[7] according to the method of West et al.[8] and used this in the first step towards the postulated disilenyllithium compound **4**. The tendency for the formation of aryllithium compounds apparently present in this system was exploited in the second step of the reaction sequence in which half of **4** reacted with mesityl bromide to give the bromodisilene **5**. The resultant product **5** did indeed react with the remaining **4** smoothly to furnish the hexaaryltetrasilabuta-1,3-diene **6**, which was isolated in the form of reddish brown crystals.

Tip = 2,4,6-*i*Pr$_3$C$_6$H$_2$; Mes = 2,4,6-Me$_3$C$_6$H$_2$

Scheme 2.

First indications on the constitution of **6** were provided by the ^{29}Si MMR spectrum, which revealed two signals shifted to low field. The singlet at $\delta = 52.3$ is typical for the Tip$_2$Si group of disilenes,[4,7,8] while the second signal at $\delta = 89.5$ is in the characteristic region for 1,2-diaryl-1,2-disilyldisilenes.[9] Additional information was furnished by the electron spectrum of **6** in which the absorption at longest wavelength at 518 nm is bathochromically shifted by about 100 nm in comparison to the signals of tetraaryldisilenes and even exceeds the absorption maxima of persilylated disilenes.[10] In a similar manner to that by which conjugation in buta-1,3-dienes effects a marked red shift of the bands in comparison to those of ethenes,[11] the lowering of the transition energy of **6** also supports a conjugation between the two double bonds in solution.

The X-ray crystallographic analysis (Figure 1)[12] not only confirmed the constitution of **6** but also revealed some noteworthy details. The conformation of the compound approaches the *cis* form; the dihedral angle between the two planes composed of the atoms Si1-Si2-Si2a and Si2-Si2a-Si1a is 51°. The molecules of **6** possess crystallographic C_2 symmetry; the C_2 axis passes through the middle of the central Si–Si bond and exactly bisects the dihedral angle. Compound **6** crystallizes with a molecule of diisopropyl ether, which merely serves to stabilize the lattice and does not interact with the silicon atoms. As in buta-1,3-dienes, the Si–Si double bonds in **6** are about 3 pm longer than those of tetraaryldisilenes such as, for example, **3**.[7] The reduction in length of the formal Si–Si single bond is more pronounced since it is markedly strained in view of the bulky substituents; it is even shorter than the Si–Si bonds lengths of 235 pm recorded for sterically inconspicuously substituted disilanes. Together with the electron spectrum, these values demonstrate that conjugation between the two double bonds of **6** exists both in solution and in the crystal.

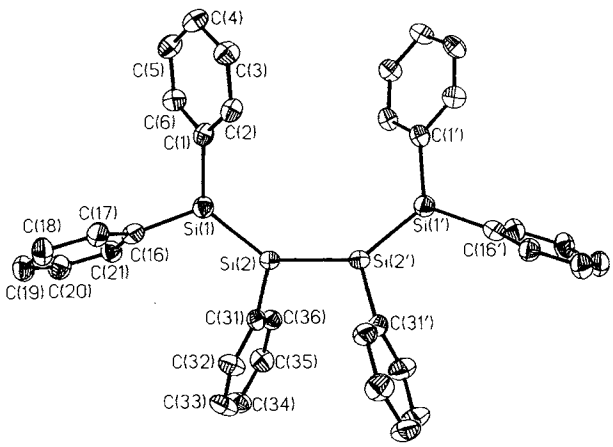

Figure 1. Structure of **6** in the crystal (50% probability, isopropyl groups and hydrogen atoms omitted). Selected bond lengths [pm] and angles [°]: Si1–Si2 217.5(2), Si2–Si2' 232.1(2), Si1–C1 189.4(4), Si1–C16 187.9(4) Si2–C31 190.4(4); Si1-Si2-Si2' 135.0(1), Si2-Si1-C1 128.9(1), Si2-Si1-C16 119.0(1), Si1-Si2-C31 117.0(1).

Even though compound **6** is extremely sensitive towards air it is thermally very stable and melts without decomposition at 237 °C. An irreversible rearrangement or decomposition reaction only occurs at above 267 °C and is indicated by a change in color from red to yellow. We will next investigate whether compound **6** can participate in typical reactions for 1,3-dienes, especially cycloadditions of the Diels–Alder type.

Experimental Section

Lithium (60 mg, 8.7 mmol) was added to a solution of **3** (700 mg, 0.81 mmol) in dimethoxyethane (30 mL) and the initially blue-green, later red, mixture was stirred for 2 h at room temperature. After separation of insoluble materials, the remaining solution was cooled to −30 °C and treated with mesityl bromide (80 mg, 0.40 mmol). After the solution had been allowed to warm to room temperature, it was stirred for 16 h. The precipitated solid was filtered off and recrystallized from toluene to furnish **6** (280 mg, 53% yield) as reddish brown crystals; m.p. 237–238 °C; ^{1}H NMR (Bruker AM 300, [D$_6$]benzene, 25 °C): $\delta = 0.16$ (d, 3H, $J = 6.6$ Hz), 0.24 (d, 3H, $J = 6.5$ Hz), 0.34 (d, 3H, $J = 6.5$ Hz), 0.45 (d, 3H, $J = 6.6$ Hz), 0.52 (d, 3H, $J = 6.5$ Hz), 0.85 (d, 3H, $J = 6.5$ Hz), 1.02 (d, 3H, $J = 7$ Hz), 1.08 (d, 3H, $J = 6.8$ Hz), 1.09 (d, 3H, $J = 6.8$ Hz), 1.14 (d, 3H, $J = 6.8$ Hz), 1.15 (d, 3H, $J = 6.8$ Hz), 1.34 (d, 3H, $J = 6.5$ Hz), 1.35 (d, 3H, $J = 6.5$ Hz), 1.37 (d, 3H, $J = 6.5$ Hz), 1.64 (d, 3H, $J = 6.5$ Hz), 1.69 (d, 3H, $J = 6.5$ Hz), 1.78 (d, 3H, $J = 6.6$ Hz), 1.88 (d, 3H, $J = 6.5$ Hz), 2.55 (sept., 1H, $J = 6.5$ Hz), 2.64 (sept., 1H, $J = 6.5$ Hz), 2.65 (sept., 1H, $J = 6.5$ Hz), 3.44 (sept., 2H, $J = 6.5$ Hz), 3,56 (sept., 1H, $J = 6.8$ Hz), 3.86 (sept., 1H, $J = 6.5$ Hz), 4.42 (sept., 1H, $J = 6.6$ Hz), 4.99 (sept., 1H, $J = 6.6$ Hz), 6.68 (d, 1H, $J = 1.5$ Hz), 6.84 (d, 1H, $J = 1.5$ Hz), 6.86 (d, 1H, $J = 1.5$ Hz), 6.94 (d, 1H, $J = 1.5$ Hz), 6.98 (d, 1H, $J = 1.5$ Hz), 7.20 (d, 1H, $J = 1.5$ Hz); ^{13}C NMR ([D$_6$]benzene, 25 °C): $\delta = 23.81$ (C$_p$), 23.90 (C$_p$), 24.09 (C$_p$), 24.22 (C$_p$), 24.48 (C$_p$), 24.66 (C$_p$), 24.79 (C$_p$), 25.12 (C$_p$), 25.31 (C$_p$), 25.50 (C$_p$), 31.12 (C$_t$), 34.21 (C$_t$), 34.47 (C$_t$), 34.85 (C$_t$), 37.46 (C$_t$), 37.79 (C$_t$), 38.08 (C$_t$), 38.31 (C$_t$), 39.41 (C$_t$), 121.74, 121.97, 122.50, 122.80, 123.69, 125.66, 129.29, 132.79, 135.64, 136.39, 150.44, 153.36, 153.84, 154.21, 154.44, 156.30; ^{29}Si NMR (Bruker AMX 300, [D$_6$]benzene, 25 °C): $\delta = 52.3$ (s), 89.5 (s); MS (CI, NH$_3$): m/z (%): 1349 (4, MNH$_4^+$), 1332 (9, MH$^+$); UV/Vis (THF): λ_{max} (lgε) = 392 (4.48), 518 (4.41) nm.

Synergism between the Guest Compound and the Host Framework in Zeolite CsNaY after Impregnation with Cesium Hydroxide**

Michael Hunger,* Udo Schenk, Beate Burger, and Jens Weitkamp

Over the past decades acid zeolites have found numerous applications as catalysts in industrial chemistry. In contrast, only scarce attention has been paid to basic zeolite catalysts, even though such materials show great potential for a number of industrially important reactions—such as dehydrogenation of alcohols, isomerization of olefins, side-chain alkylation of toluene, or the synthesis of 4-methylthiazol.[1] The chemical properties of basic zeolites are determined by the alkali metal cations, which act as weak Lewis acid sites, and the basic framework oxygen atoms. Exchanging sodium ions in the synthesized zeolites with rubidium or cesium ions brings about a decrease in the mean electronegativity of the framework, and the basicity of the oxygen atoms increases.[2] Strongly basic sites can be created by incorporating alkali metal oxides into the zeolite pores.[3, 4] Inside the zeolite host, such oxide guests can occur with a high dispersion. We have now applied multinuclear NMR spectroscopy to investigate the host–guest interactions of oxidic nanoparticles in a Y-type zeolite prepared by exchange with cesium cations followed by impregnation with cesium hydroxide and calcination (see Experimental Section).

According to Hathaway and Davis,[3] the selectivity for acetone formation in the conversion of propan-2-ol can be used as a measure of catalyst basicity. Propan-2-ol was converted at atmospheric pressure in a flow-type unit made of glass with a saturator, a fixed-bed reactor, and an on-line capillary gas chromatograph. All zeolites were first calcined in a flow of dry nitrogen for 12 h at 673 K. At this temperature and a modified residence time of $W/F_{P-2-ol} = 450$ g h mol^{-1}, conversions between 70 and 90% were achieved, and the acetone selectivities amounted to 0, 9, and 61% for NaY, CsNaY-70, and CsNaY-70/16CsOH, respectively. These figures clearly demonstrate the increase in catalyst basicity.

Prior to the NMR measurements the zeolites were heated in a glass tube at a rate of 10 K per hour and calcined for 12 h at 673 K and 10^{-2} Pa. Figure 1 shows the ^{27}Al NMR spectra of the dehydrated zeolites recorded with a spin-echo sequence.[5] The dominating solid-state interaction of the aluminum atoms in the framework of the dehydrated zeolites is that between the electric quadrupole moment Q and the z component of the electric field gradient V_{zz} at the sites of the resonating aluminum nuclei. The strength of this quadrupolar interaction is described by the quadrupole coupling constant $QCC = e\,Q\,V_{zz}/h$, where e is the elementary charge, and h Planck's constant. In a strained framework-AlO_4 tetrahedron, the charge distribution directly surrounding the resonating Al nucleus is unsymmetrical; hence, there is a high electric field gradient and a high ^{27}Al quadrupolar coupling constant. In other words, QCC furnishes information on the chemical bonds inside the zeolitic host framework, and the aluminum atoms represent internal probes for detecting changes in the framework bonds. Previous ^{27}Al NMR investiga-

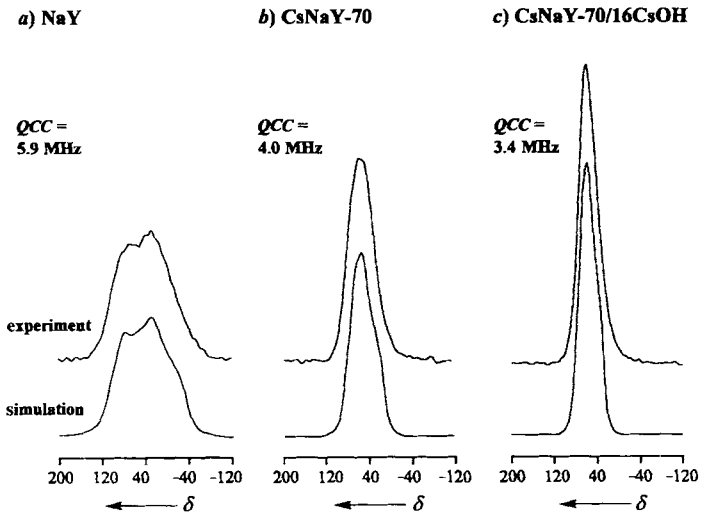

Figure 1. ^{27}Al NMR spectra (104.2 MHz) of dehydrated (673 K) zeolites a) NaY, b) CsNaY-70, and c) CsNaY-70/16CsOH. The quadrupole coupling constants QCC (see text) were determined by simulating the experimental spectra with the Bruker WINFIT software.

tions revealed a relationship between the chemical properties of dehydrated zeolites and the QCC values of the framework-AlO_4 tetrahedra.[5, 6] For acidic zeolites such as HZSM-5 ($n_{Si}/n_{Al} = 22.0$, $QCC = 15.5-16.0$ MHz),[5, 6] HMOR ($n_{Si}/n_{Al} = 8.0$, $QCC = 13.7$ MHz),[5] HY ($n_{Si}/n_{Al} = 3.1$, $QCC = 12.7-13.5$ MHz),[5, 6] and HNaX ($n_{Si}/n_{Al} = 1.4$, $QCC = 10.8$ MHz),[6] the ^{27}Al quadrupole coupling constant decreased with increasing aluminum content in the framework. Even more pronounced variations in QCC occur upon doing from an acidic form of zeolite Y ($QCC = 12.7-13.5$ MHz)[5, 6] to the basic sodium form ($QCC = 5.5$ MHz).[6] A simulation of the ^{27}Al spin-echo NMR spectra depicted in Figure 1 gives quadrupole coupling constants of 5.9 MHz, 4.0 MHz, and 3.4 MHz for zeolites NaY, CsNaY-70 and CsNaY-70/16CsOH, respectively. These values unambiguously show that the chemical bonds of the zeolite host are affected not only by ion exchange (NaY → CsNaY-70), but also by impregnation with cesium hydroxide.

The cesium oxide guest compound was directly investigated with ^{1}H and ^{133}Cs MAS NMR spectroscopy (MAS = magic angle spinning). The ^{1}H MAS NMR spectra of the three zeolites are shown in Figure 2. The concentrations of the hydroxyl groups were determined quantitatively by applying the absolute

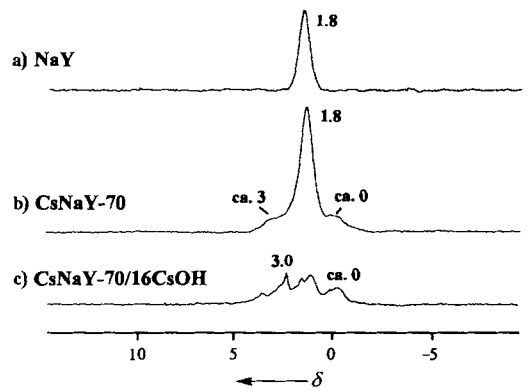

Figure 2. ^{1}H MAS NMR spectra (400.1 MHz) of dehydrated (673 K) zeolites a) NaY, b) CsNaY-70, and c) CsNaY-70/16CsOH; sample spinning rate about 10 kHz.

intensity mode with an external intensity standard (zeolite HNaY-35). The spectrum of zeolite NaY (Figure 2a) consists of one signal at $\delta = 1.8$ (referenced to TMS), which is caused by 1.4 ± 0.2 SiOH groups per unit cell (u.c.) at the framework defects and at the external surface of the zeolite crystallites.[7] Exchanging the sodium ions with cesium ions leads to an increase in the intensity of this signal (Figure 2b), corresponding now to 1.8 ± 0.2 SiOH/u.c. In addition, weak signals appear at $\delta \approx 0$ and 3, which can be assigned to undisturbed and hydrogen-bonded metal OH groups, respectively.[7] Upon impregnating zeolite CsNaY-70 with cesium hydroxide (Figure 2c), the concentration of the silanol groups drops to 0.4 ± 0.2 SiOH/u.c. However, there is no significant change in the signals at $\delta \approx 0$ and 3. Therefore, impregnation of CsNaY-70 does not result in the formation of hydroxyl groups bound to the alkali metal; that is, the guest compound exists as an oxide. On the other hand, the decrease in the concentration of the silanol groups indicates that the guest compound chemically interacts with the framework defect sites.

The ^{133}Cs MAS NMR spectra of the dehydrated zeolites CsNaY-70 and CsNaY-70/16CsOH are shown in Figure 3.

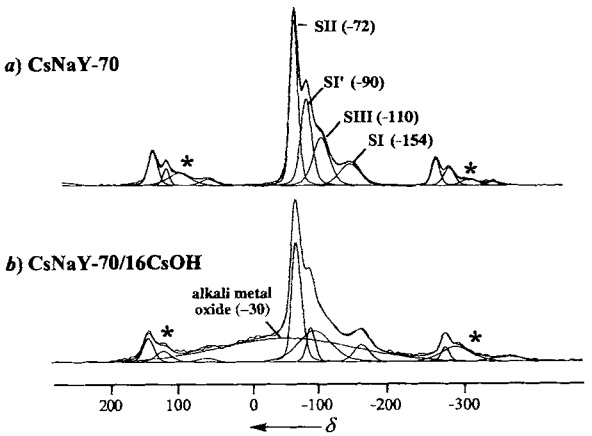

Figure 3. ^{133}Cs MAS NMR spectra (52.5 MHz) of dehydrated (673 K) zeolites a) CsNaY-70 and b) CsNaY-70/16CsOH; sample spinning rate about 10 kHz (*: MAS sidebands).

A modified 4-mm Bruker MAS NMR probe head was used. By applying a sample spinning rate of $\nu_{rot} \approx 10$ kHz ($\nu_{rot} \approx 4$ kHz was employed in earlier work),[8] the spectral resolution was significantly enhanced. This, in turn, was a prerequisite for investigating cesium oxide in zeolite CsNaY-70/16CsOH. The spectrum of dehydrated zeolite CsNaY-70 (Figure 3a) consists of signals at $\delta = -154$, -110, -90, and -72 (referenced to 1 M CsCl) due to cesium cations (37.3 Cs^+/u.c.) located at positions SI, SIII, SI', and SII, respectively.[8] For the impregnated zeolite (Figure 3b), an additional signal is observed with a linewidth of $\Delta\nu_{1/2} = 10 \pm 1$ kHz and a center of gravity at $\delta \approx -30 \pm 2$. Its intensity contribution of $30 \pm 5\%$ agrees well with the amount of cesium oxide introduced in the impregnation step (see below). To interpret the signal at $\delta = -30$, it is important to notice that pure cesium hydroxide (dehydrated for 12 h at 673 K) gives a narrow ^{133}Cs MAS NMR sideband pattern with an isotropic chemical shift of $\delta = 146$ (not shown). Consequently, the cesium oxide in CsNaY-70/16CsOH does not exist as pure isolated clusters. The strong broadening of the signal at $\delta = -30$ may originate in a distribution of chemical shifts for highly dispersed cesium oxide species bound in different ways to the framework.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2505 $ 17.50+.50/0

Bosacek recently proposed a new method for characterizing the mean electronegativity and basicity of the zeolite lattice.[9] He found a correlation between the isotropic ^{13}C NMR shift of the methoxy groups formed upon adsorption of methyl iodide on dehydrated zeolites and the mean Sanderson electronegativity, S^m, of the lattice. Varying S^m from 3.04 for zeolite HZSM-5 ($n_{Si}/n_{Al} = 21.8$) to 2.26 for zeolite CsNaX-49 ($n_{Si}/n_{Al} = 1.2$) resulted in a change in the shift for the methoxy groups from $\delta(^{13}C) = 59.4$ to 54.1 ($\delta(^{13}C)/S^m \approx 6.8$).[9] Bosacek proposed ^{13}C cross-polarization (CP)/MAS NMR spectroscopy of the methoxy groups bound to the zeolite as a new method for determining the basicity of the framework oxygen atoms in zeolites. Figure 4 shows the ^{13}C CP/MAS NMR spectra of the dehydrated zeolites NaY, CsNaY-70, and CsNaY-70/16CsOH after adsorption of $16\,CH_3I$/u.c. The signals at $\delta = -20 \pm 0.5$ are due to physisorbed CH_3I.[9] The chemical shifts of the methoxy groups in zeolites NaY ($\delta = 56.7$, Figure 4a) and CsNaY-70 ($\delta = 56.1$, Figure 4b) correlate well with their mean Sanderson electronegativities ($S^m = 2.60$ and 2.46, respectively). The spectrum of zeolite CsNaY-70/16CsOH (Figure 4c) consists of signals at $\delta = 55.4$ and 50.3 due to methoxy groups and a narrow signal at $\delta = 61.0$. This latter signal has an intensity contribution of about 10% and is due to dimethyl ether.[9] Since there is no signal at $\delta = 56.1$ (for methoxy groups in zeolite CsNaY-70), the whole framework of zeolite CsNaY-70/16CsOH must have been uniformly affected by CsOH impregnation. The change in the ^{13}C shift from $\delta = 56.1$ for methoxy groups in zeolite CsNaY-70 to $\delta = 55.4$ for methoxy groups in zeolite CsNaY-70/16CsOH corresponds to an increased framework basicity of the latter. The high-field signal at $\delta = 50.3$ (Figure 4c), with MAS sidebands comparable to those of the signal at $\delta = 55.4$, indicates the existence of an additional strongly basic compound. Apparently, the methoxy groups responsible for this signal are bound to the alkali metal guest introduced upon impregnation. The high intensity of this signal ($32 \pm 5\%$ of the total intensity) points to a large surface and, hence, to a high dispersion of this alkali metal guest compound in CsNaY-70/16CsOH.

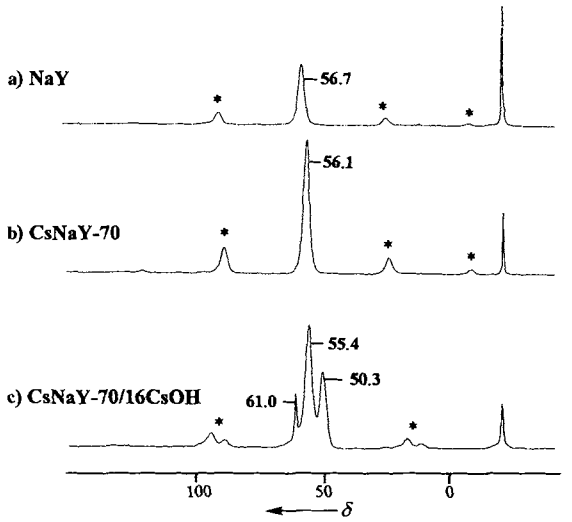

Figure 4. ^{13}C CP/MAS NMR spectra (100.6 MHz) of dehydrated (673 K) zeolites a) NaY, b) CsNaY-70, and c) CsNaY-70/16CsOH loaded with $16\,CH_3I$/u.c.; recorded with a contact time of 3 ms and a sample spinning rate of about 3 kHz (*: MAS sidebands).

In conclusion, impregnation and calcination of zeolite CsNaY-70 with cesium hydroxide not only creates a cesium oxide guest with a high dispersion, but it also affects the chemical properties of the zeolite framework. By using the methoxy groups as an NMR spectroscopic probe, a significant decrease in the mean electronegativity of the zeolite framework was detected upon impregnation with CsOH. Spin-echo NMR spectra of framework aluminum atoms functioning as internal probes revealed an impregnation-induced variation of the ^{27}Al quadrupole coupling constant and, hence, of the chemical bonding inside the dehydrated zeolite framework. A signal of the guest species was observed in the ^{133}Cs MAS NMR spectrum of the dehydrated zeolite CsNaY-70/16CsOH, which differs significantly from that of the pure dehydrated alkali metal hydroxide. The pronounced broadening of this signal points to a high dispersion of the guest inside the pores of zeolite CsNaY-70/16CsOH. The significant decrease in the intensity of the ^1H MAS NMR signal for defect SiOH groups accompanying impregnation is due to deprotonation of these sites by the alkali oxide, and possibly indicates that at least a part of the guest compound is bound to defect sites of the zeolite framework.

Experimental Section

The parent zeolite NaY (Union Carbide Corp., Tarrytown, NY, USA, $n_{Si}/n_{Al} = 2.6$) was ion-exchanged five times in a 0.4 M aqueous solution of CsCl at 353 K, which led to 70% exchange of sodium (zeolite CsNaY-70). Part of this material was then suspended in a 0.2 M solution of CsOH which contained exactly the amount of CsOH need for the final material. The suspension was stirred overnight to dryness at 353 K and calcined for 12 h at 673 K. The material coded CsNaY-70/16CsOH was impregnated with 16 CsOH/u.c. The chemical compositions of the samples were analyzed with inductively coupled plasma atomic emission spectrometry (ICPAES) and atomic absorption spectrometry (AAS). ^{27}Al and ^{29}Si MAS NMR spectroscopy (Bruker MSL 400) of the hydrated zeolites NaY, CsNaY-70 and CsNaY-70/16CsOH showed that no dealumination of the zeolite framework took place as a result of cesium exchange, impregnation with CsOH, and calcination.

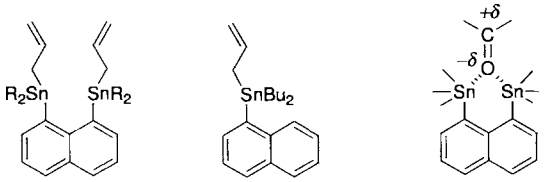
1,8-Bis(allylstannyl)naphthalene Derivatives as Neutral Allylation Agents: Rate Acceleration by Chelation-Induced Lewis Acidity**

Naoki Asao, Pingli Liu, and Keiji Maruoka*

Allylation of aldehydes and ketones with trialkylallylstannanes to form homoallylic alcohols is one of the most powerful C–C bond forming reactions in organic synthesis, and a variety of procedures have been elaborated.[1] Most of the procedures developed so far involve the effective use of Lewis acids as activating agents under mild conditions, since noncatalyzed allylations do not occur or are exceedingly slow, even at elevated temperatures.[2] Brønsted acids and basic Bu_4NF can also be employed to promote this transformation.[3,4] Allylations that are induced photchemically or by high pressure can be executed under neutral conditions.[5,6] We here report a new type of noncatalyzed allylation of aldehydes and ketones using 1,8-bis(allylstannyl)naphthalene derivatives **1**, which is based on a chelation-induced Lewis acidity of neutral, bidentate organostannane reagents, as depicted in **A**.[7,8]

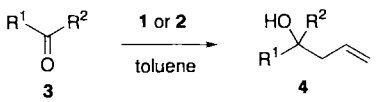


1a (R = Bu)
1b (R = Me)

2

A

The requisite 1,8-bis(allyldibutylstannyl)naphthalene (**1a**) can be prepared by treatment of 1,8-diiodonaphthalene[9] with BuLi (2 equiv), dibutyltin dichloride (2 equiv), and allylmagnesium bromide (2.2 equiv) in about 55% yield. The monostannyl compound **2** was also synthesized in analogy to **1a** from 1-bromonaphthalene. The reaction of **2** with cyclohexanone (**3**; $R^1 \cdot R^2 = -(CH_2)_5-$; 5 equiv) in toluene at 100 °C for four days proceeds very sluggishly to furnish 1-allylcyclohexanol (**4**;



3 **4**

$R^1 \cdot R^2 = -(CH_2)_5-$) in only 4% yield. In contrast, **1a** afforded the allylation product in 80% yield upon reaction with cyclohexanone under similar conditions. This rate acceleration is ascribable to the appearance of the latent Lewis acidity, which is induced by the chelation effect of neutral, bidentate bis(stannane) **1** on the carbonyl group (structure **A**).[10] A similar tendency is also observed with 2-nonanone substrate **3** (R^1 = Me, $R^2 = C_7H_{15}$; see Table 1, entry 2).

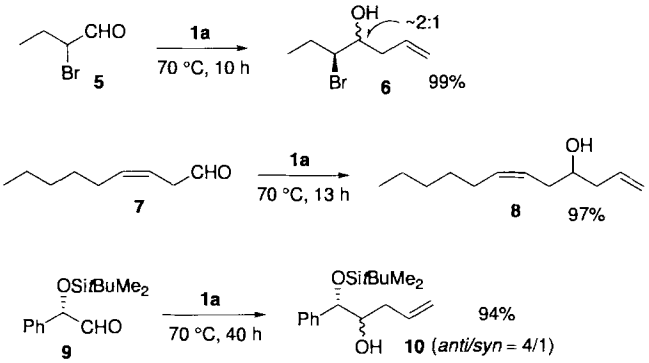
Table 1. Allylation of various carbonyl substrates **3** with **1** under neutral conditions [a].

Entry	R^1	R^2	Reagent	Conditions	Yield [%] [b]
1	$-(CH_2)_5-$		**1a**	100 °C, 4 d	80 (4)
2	C_7H_{15}	CH_3	**1a**	100 °C, 3 d	44 (2)
3	Ph	H	**1a**	50 °C, 12 d	99 (5)
4	Ph	H	**1a**	70 °C, 82 h	98 (5)
5	Ph	H	**1b**	70 °C, 53 h	99 (4)
6	cyclohexyl	H	**1a**	50 °C, 12 d	99 (5)
7	cyclohexyl	H	**1a**	70 °C, 63 h	98 (3)
8	Ph	Cl	**1a**	100 °C, 1 h	64 [c] (<1)
9	C_7H_{15}	Cl	**1a**	100 °C, 1 h	57 [c] (<1)
10	Ph	OCH_3	**1a**	100 °C, 3 d	<1
11	PhCH=CH	CH_3	**1a**	100 °C, 7 d	40 [d]

[a] The reaction was carried out with 1 equiv of **1** and 5 equiv of **3** in toluene. [b] Yield of the isolated product. Yields obtained with monostannyl analogues **2** under similar reaction conditions are given in parentheses. [c] Yields of the corresponding ketones. [d] Yield of 1,2-addition product.

The selected allylations of carbonyl substrates listed in Table 1 provide the following conclusions: 1) Reactions of aldehydes proceed smoothly to give secondary homoallylic alcohols in almost quantitative yields (entries 3–7). 2) One characteristic feature is the smooth alkylation of acid chloride with **1a** (entries 8 and 9). Such a transformation is not realized with monostannane **2**, as reported earlier.[11] 3) Esters are inert under the standard reaction conditions (entry 10). 4) 1,8-Bis(allyldimethylstannyl)naphthalene (**1b**) showed reactivity similar to that of **1a** (entry 5). 5) Although the Lewis acid promoted allylation of α,β-unsaturated ketone with an allylstannane is reported to give a conjugate adduct selectively,[12] reaction with **1a** exclusively afforded a carbonyl allylation product (entry 11).

Another characteristic feature of the allylation is its applicability to more sensitive substrates, which normally provide side products in the existing acid-catalyzed allylations with monoallylstannanes. For example, α-bromo aldehyde **5**, *cis*-β,γ-unsaturated aldehyde **7**, and optically pure α-siloxyphenylacetaldehyde **9** afforded the corresponding bromohydrine **6** without epoxide formation, the bis(allylic) product **8** without olefin migration, and the 1,2-siloxy alcohol **10** without racemization, respectively.[13]



It is noteworthy that the present allylation can be utilized even in aqueous media. Highly reactive aldehydes such as α-keto aldehydes, trifluoroacetaldehyde, and α-halo aldehydes usually exist as hydrates, hemiacetals, or aqueous solutions. Our allylation works equally well in the presence of water with such commercially available aldehydes under mild conditions.[14] This provides a new, one-pot approach to allylated α-hydroxy esters from various tartrates via the intermediary glyoxylate hydrates (Scheme 1).

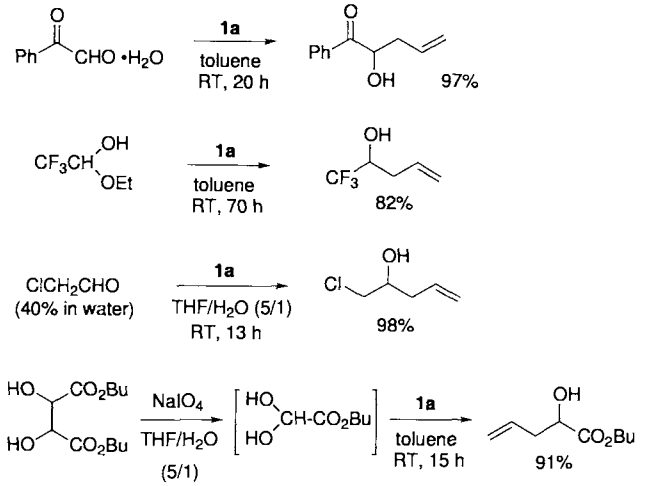
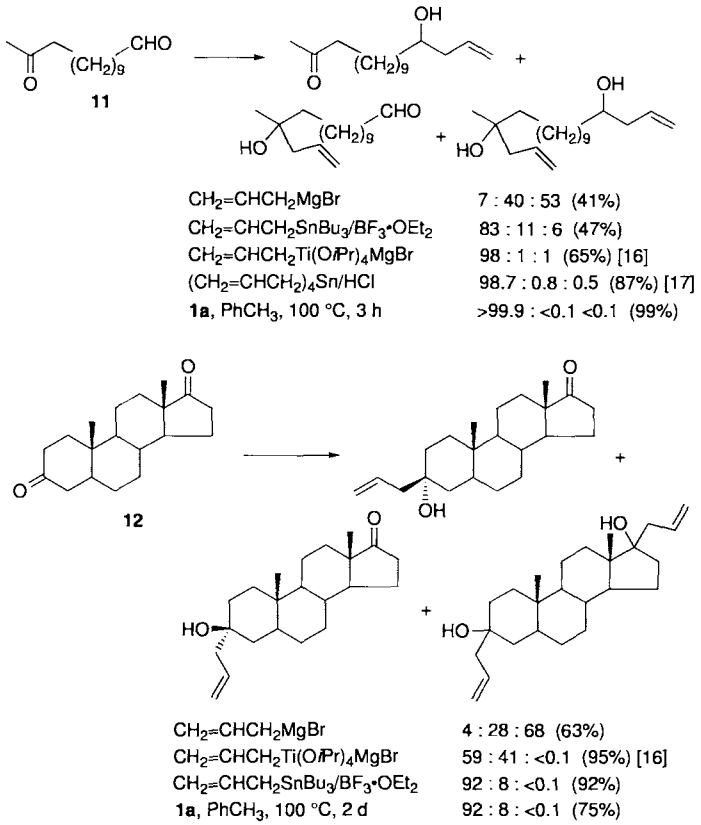


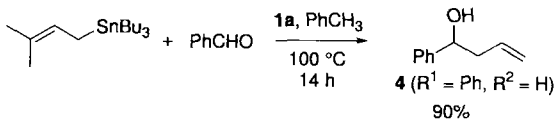
Scheme 1. Allylation with **1a** in the presence of water; RT = room temperature.

Allylation with bis(stannyl) derivatives **1** is highly chemoselective, and occurs exclusively at the less hindered carbonyl group, as demonstrated by the chemoselective allylation of dicarbonyl substrates **11** and **12**. Such ability to discrimate between two different carbonyl groups is far superior to that of conventional allylation agents (Scheme 2).[15]



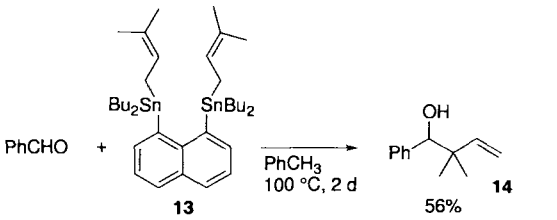
Scheme 2. Comparison of the chemoselectivity of the allylation with **1a** and other reagents [15].

The present allylation may proceed either intra- or intermolecularly. To explain the mechanism of the allylation, the cross-over reaction of **1a** and tributylprenyltin [1 equiv each, Eq. (1)] with benzaldehyde was carried out; allylation product **4**



(1)

(R^1 = Ph, R^2 = H) was furnished solely in 90% yield without any prenylation product.[18, 19] This result and that of the reaction of 1,8-bis(dibutylprenylstannyl)naphthalene (**13**) with benzaldehyde, which afforded **14** exclusively in 56% yield [Eq. (2)],



(2)

indicate that allylation with **1** takes place intramolecularly via a six-membered transition state with carbonyl substrates.

We have developed a new agent which is highly effective for the selective allylation of aldehydes and ketones under neutral conditions. The reaction proceeds without any catalyst by taking advantage of the chelation-induced Lewis acidity of bidentate bis(stannyl) compounds. More appropriate choice of metals and more sophisticated design of neutral, bidentate organometallic compounds possessing high latent Lewis acidity are the subjects of our ongoing studies.

Experimental Section

The allylation of cyclohexanecarboxaldehyde is representative: To a solution of **1a** (500 mg, 0.74 mmol) in toluene (3 mL) was added cyclohexanecarboxaldehyde (0.45 mL, 3.7 mmol) at room temperature under an argon atmosphere. The mixture was allowed to warm to 70 °C, and stirred for 63 h at this temperature. After the mixture cooled to room temperature the solvent was removed in vacuo, and the residue purified by column chromatography on basic silica gel with hexane/EtOAc (7/1) as eluent to give 1-cyclohexyl-3-buten-1-ol (110 mg, 98% yield) as a colorless oil.

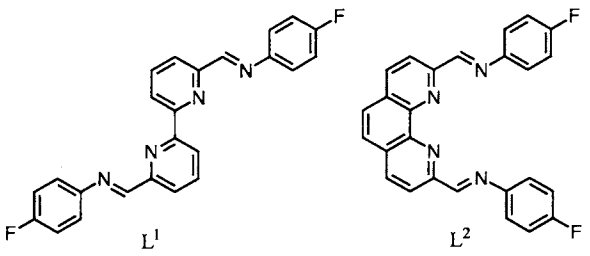
[18] Use of excess prenyltributyltin (about 2–3 equiv) also gave none of the prenylation product.
[19] The Lewis acidity of 1,8-bis(stannyl)naphthalene derivatives was also examined for the allylation of monostannane **2** with benzaldehyde in the presence of 1,8-bis(tributylstannyl)naphthalene as a bidentate Lewis acid under reaction conditions similar to those described for entry 4 of Table 1. Since the allylated product was obtained in higher yield (14%) than that in entry 4, 1,8-bis(tributylstannyl)naphthalene seems to possess only weak Lewis acidity.

Copper(I) Helicates Containing Bridging But Nonchelating Polypyridine Fragments**

Raymond Ziessel,* Anthony Harriman,* Jean Suffert, Marie-Thérèse Youinou, André De Cian, and Jean Fischer

Polypyridine ligands can complex an inordinately wide range of cations and have numerous important analytical applications. These ligands have also found prominent use in supramolecular chemistry where, by virtue of their forming stable and well-defined complexes with metal cations, they have facilitated assembly of molecular (double and triple) helicates, knots, grids, ladders, catenates, rotaxanes,[1–4] and related exotic structures.[5, 6] Such elaborate molecular architectures are made possible by incorporating several polypyridine units into oligomeric or macrocyclic multitopic ligands. Subsequent coordination with copper(I), or similar metal centers, provides the impetus for self-organization into highly ordered structures. The resulting tetrahedral complexes are sufficiently stable for the copper(I), in general, to bind selectively to the polypyridine ligand, even if the molecule possesses additional coordination sites. Indeed, there are very few examples where a polypyridine unit is bypassed in favor of other coordination sites, and where this happens, these tend to be idealized stereospecific cavities.[7]

The ligands L^1 and L^2 possess two disparate binding sites in close proximity. They were synthesized by reaction of 2,2′-



bipyridyl-6,6′-dicarbaldehyde[8] or 1,10-phenanthroline-2,9-dicarbaldehyde[9] with 4-fluoroaniline in the presence of catalytic amounts of *p*-TsOH. Both ligands react with $[Cu(CH_3CN)_4]ClO_4$[10] to afford *deep-green*, air-stable materials in almost quantitative yield. These products lack the metal-to-ligand charge-transfer (MLCT) absorption band considered to be characteristic of tetrahedral copper(I) polypyridine complexes. On the basis of FAB and ES mass spectrometry it was concluded that the isolated products were the corresponding binuclear copper(I) complexes, without contamination from mononuclear or polymeric structures. The products, therefore, may be assigned the general formula $[Cu_2L_2](ClO_4)_2$ ($L = L^1, L^2$). Direct involvement of the terminal imino groups in the coordination sphere was confirmed by solid-state and solution-phase FT-IR studies and by both ^1H and ^{13}C NMR spectroscopy. The NMR studies also indicated that the two ligands bound to each copper(I) cation were equivalent and that each ligand was symmetric about its center.

Indeed, the solid-state structures of $[Cu_2(L^1)_2](ClO_4)_2$ und $[Cu_2(L^2)_2](ClO_4)_2$ (Figure 1) are best described as double-stranded helicates with the two copper(I) cations lying at center-to-center separations of 2.885(2) and 2.748(1) Å, respectively. These separations are among the shortest metal–metal distances yet found in inorganic helicates,[11] being of the same order as observed in many copper-containing enzymes,[12] but there is no indication of a copper–copper bond. Each ligand wraps around the two copper(I) cations, and the polypyridine units become twisted (approximately 36° for $[Cu_2(L^1)_2](ClO_4)_2$) about the exocyclic central C–C bond. Interestingly, the copper(I) center is significantly closer to the imino N atom than to that of the adjacent pyridine unit, but there is no obvious indication of intramolecular π-stacking.

These crystallographic structures clearly indicate that, at least in the solid state, the two pyridine groups within a given ligand are complexed to different cations. Each copper(I) ion is coordinated to four nitrogen atoms, provided by the imine and pyridine groups of two distinct ligands, to give a distorted tetrahedron with a small angle of about 80°. It appears, therefore, that incorporation of imine groups at the α,α′ positions of a bipyridine or phenanthroline ligand causes the central unit to become nonchelating and, instead, to adopt a bridging role. This may not be too surprising for L^1, where individual pyridines can rotate freely, and is somewhat reminiscent of the double-helicates formed from sexipyridine ligands.[13] However, such behavior is unparalleled for a phenanthroline-based

ligand, and it is noteworthy that the pyridino N atoms in L^2 are well situated to form a chelate.

We were unable to isolate the mononuclear complex of L^1, and even in the presence of a 10-fold excess of ligand, $[Cu_2(L^1)_2]^{2+}$ was the only product observable by NMR spectroscopy. This was not the case with L^2 where the mononuclear complex $[Cu(L^2)_2]^+$ was isolated in low yield from reaction in the presence of excess ligand (ES-MS$^+$ in H_2O/CH_3CN: m/z 907.5). Although an X-ray structural determination remains elusive, it was firmly demonstrated by FT-IR as well as ^1H and ^{13}C NMR spectroscopy that the copper(I) cation is coordinated at the imino and adjacent pyridino binding sites. Again, the compound lacks the MLCT absorption band characteristic of a copper(I) bis(phenanthroline) complex.

Successive complexation of copper(I) with the multitopic ligands L^1 and L^2 was followed by spectrophotometric titration in deoxygenated acetonitrile/dichloromethane (4/1) containing tetraethylammonium perchlorate (0.1 M). The stability constants (K), as derived by global analysis of the titration data, are collected in Table 1. Evaluation of individual stability constants K_1, K_2, and K_3 is based on the mechanism for stepwise assembly of the metallohelicate described in Equations (1)–(3). Confidence in this model stems from our isolation of $[Cu(L^2)_2]^+$ and its subsequent conversion into $[Cu_2(L^2)_2]^{2+}$. In the case of L^2, it was possible to confirm the stability constant for the final step in helicate assembly by direct titration ($\lg K_3 = 6.08$). Furthermore, the overall stability constant (β_L) for each imino complex could be obtained by dissociative titration with 2,9-dimethyl-1,10-phenanthroline (neocuproine, L^3). This latter reaction (Eqs. 4 and 5) could be followed due to the development of the intense MLCT absorption band of $[Cu(L^3)_2]^+$. The corresponding β values can be expressed in terms of the overall stability constant for formation of copper(I) bis(neocuproine) ($\lg \beta_{L^3} = 14.2$) as follows: $\beta_4 = \beta_{L^3}^2/\beta$ where $\beta = K_1 K_2 K_3$ and $\beta_5 = \beta_{L^3}/K_1 K_2$.

$$Cu^+ + L \rightleftharpoons [CuL]^+ \quad (1)$$

$$[CuL]^+ + L \rightleftharpoons [CuL_2]^+ \quad (2)$$

$$Cu^+ + [CuL_2]^+ \rightleftharpoons [Cu_2L_2]^{2+} \quad (3)$$

Table 1. Stability constants (K) for individual steps in helicate assembly, overall association constants (β) for complex formation, and pK_A values for the free ligands L^1, L^2, and L^3. The numbers given in parentheses refer to values calculated from separate titrations.

Reaction	Ligand	$\lg K$	$\lg \beta$

$$[Cu_2L_2]^{2+} + 4L^3 \rightleftharpoons 2[Cu(L^3)_2]^+ + 2L \quad (4)$$

$$[CuL_2]^+ + 2L^3 \rightleftharpoons [Cu(L^3)_2]^+ + 2L \quad (5)$$

These stability constants contain information on both accumulation (i.e., collection) and organization (i.e., orientation).[1] The first step must involve attachment of a copper(I) fragment to a single N donor, but this species could not be isolated or resolved during titration. Molecular mechanics (MM2) simulations indicate that in the most stable conformations the free ligands are planar, due to charge transfer along the molecular axis, and have *trans* imino groups. For these conformations, SCF-MO calculations with PM3 parameters indicated that the imino N atoms possess slightly higher electron density than the pyridine N atoms. The terminal fluorine atoms do not influence the electronic properties of the ligands and are not essential for helicate formation. There appears to be little difference in the relative accessibility of these two sites towards a bulky cation such as $[Cu(CH_3CN)_4]^+$, but slight rotation of the terminal phenyl ring exposes the imino N atom to the approaching cation while, at least with L^2, blocking access to the pyridino N atoms. On this basis, we might expect the initial binding contact between copper(I) and a multitopic ligand to involve coordination at the imino function. Subsequent attachment to an adjacent pyridino N donor requires internal torsional motion, but may be driven by the chelate effect. The derived stability constants for this step (K_1) indicate that the ditopic ligands are somewhat inferior chelators than neocuproine, probably due to their increased stereochemical bulk and concomitant entropic factors. Interestingly, the order of K_1 values differs from the trend in pK_A values measured for the free ligands by potentiometric titration in a 1/1 mixture of dioxane and water (see Table 1).

Under the conditions used for the titrations (addition of copper(I) to excess ligand), coordination of a second ligand to the

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2510 $ 17.50+.50/0

mononuclear fragment [Eq. (2)] should be competitive with dimerization to form $[Cu_2L_2]^{2+}$. For neocuproine, this is a highly favorable process and is only slightly less propitious for L^1. Formation of the 1/2 complex is not so auspicious with L^2, presumably because of steric crowding, and there is a serious drop in stability constant for this step. Metallohelicate assembly, following coordination of a second copper(I) center [Eq. (3)], is considerably easier with the more flexible bipyridyl-based ligand than with its phenanthroline analogue. In part, this difference can be attributed to the relative capacity for internal rearrangement to provide a suitable binding geometry around the cation. It is during addition of the second copper(I) cation that the real differences emerge between the two multitopic ligands. It appears that L^1 exhibits positive cooperativity towards copper(I) in that $K_1 < K_2 < K_3$ and the overall stability constant for the metallohelicate ($\lg\beta_L = 26$) compares well with the only available published data for a somewhat comparable process.[14] In the case of L^2, helicate formation is not driven by positive cooperativity since $K_2 < K_1 < K_3$, and the overall stability constant ($\lg\beta_L = 16$) reflects the relative difficulty in attaining a suitable geometry. In fact, it is remarkable that this ligand supports helicate formation.

An important finding to emerge from this study is that positive cooperativity is not a prerequisite for helicate formation, although the noncooperativity found for L^2 causes the overall stability constant to decrease by ten orders of magnitude. A more remarkable aspect of this work, however, concerns our observation that the polypyridine units do not operate as single chelators for copper(I) but that individual N atoms act independently as secondary coordination sites. Self-organization into helicate structures is a multistep process, but in the case of L^2, we were able to isolate and characterize a crucial intermediary metallo fragment. In this latter system, helicate formation is restricted by thermodynamic considerations rather than kinetic factors as is the case in certain pentanuclear helicates.[15] These metallohelicates with copper(I) centers in unusually close proximity can be dismantled under mild conditions by a) oxidation, b) competitive complexation, or c) addition of excess ligand in the case of L^2. One clear advantage of these systems is that the terminal imino group is readily functionalized without disruption to the helicate structure. Thus such local molecular architectures can be readily included into organized macroscopic ensembles, such as calamitic mesophases.

Experimental Section

Synthesis and characterization of the free ligands and complexes used in this study will be reported elsewhere. All materials gave satisfactory elemental analyses and NMR, mass, and infrared spectra.

X-ray structure analyses: $[Cu_2(L^1)_2](ClO_4)_2 \cdot CH_3CN$, $M_r = 1163.9$; deep green crystals ($0.22 \times 0.18 \times 0.12$ mm^3); monoclinic space group $P2_1/c$ with $a = 13.667(5)$, $b = 25.617(8)$, $c = 15.195(6)$ Å, $\beta = 110.17(2)^\circ$, $V = 4993.6$ Å^3, $Z = 4$, $\rho_{calcd} = 1.548$ g cm^{-3}, $\mu = 27.086$ cm^{-1}. A total of 5651 reflections were collected on a Philips PW 1100/16 diffractometer at $-100\,^\circ$C with Ni-filtered $Cu_{K\alpha}$ radiation $\lambda = 1.5418$ Å. The systematic absences together with the E statistics and the NZ test suggested the space group $P2_1/c$. The structure was solved by a combination of Patterson, difference Fourier analysis, and full-matrix, least-squares methods. The final conventional residuals were $R = 0.050$ and $R_w = 0.070$ for 2820 reflections having $I > 3\sigma(I)$. $[Cu_2(L^2)_2](ClO_4)_2 \cdot H_2O$, $M_r = 1188.9$; dark green crystals ($0.32 \times 0.25 \times 0.12$ mm^3); monoclinic space group $C2/c$ with $a = 23.804(7)$, $b = 14.743(4)$, $c = 13.755(3)$ Å, $\beta = 90.68(2)^\circ$, $V = 4826.9$ Å^3, $Z = 4$, $\rho_{calcd} = 1.636$ g cm^{-3}, $\mu = 28.266$ cm^{-1}. Collected data: 2916; $R = 0.035$ and $R_w = 0.054$ for 2117 reflections having $I > 3\sigma(I)$. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100335. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

Titrations were made by adding successive aliquots of a solution of $[Cu(CH_3CN)_4](ClO_4)$ in deoxygenated acetonitrile to a solution of the ligand in deoxygenated CH_3CN/CH_2Cl_2 (4/1) containing tetraethylammonium perchlorate (0.1 M). Stability constants were calculated (30 concentrations analyzed at 60 different wavelengths) with the SPECFIT program and known spectra of the reactants and products. Similar titrations were made by addition of neocuproine to the copper(I) complexes in deoxygenated CH_3CN/CH_2Cl_2 4/1 containing tetraethylammonium perchlorate (0.1 M).

Photochemical Synthesis of Polyrotaxanes from Stilbene Polymers and Cyclodextrins**

Wolfgang Herrmann, Maria Schneider, and Gerhard Wenz*

Since the initial pioneering work the synthesis of rotaxanes[1] has been the subject of continuously increasing interest,[2] especially as it has been facilitated by supramolecular positioning of

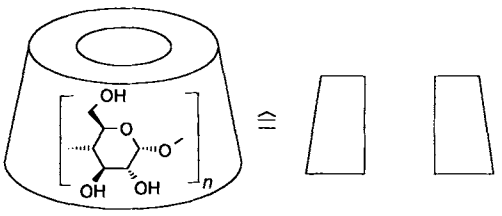
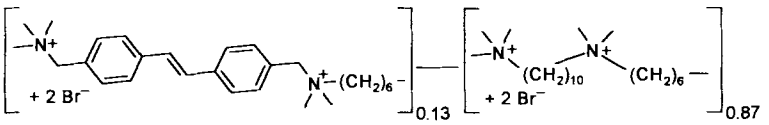
the components (template synthesis[3]).[4] In particular the ability of cyclodextrins **1a–c** to include guest molecules was exploit-



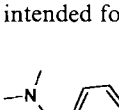
1a-c (n = 6-8)

ed for the synthesis of rotaxanes by covalent attachment of blocking groups.[5] The synthesis of polyrotaxanes by polymerization of monomeric cyclodextrin inclusion compounds[6] or by coupling of blocking groups to polymeric inclusion compounds was also described.[7] Often, choosing reaction conditions that allow both formation of the inclusion compound and attachment of blocking groups was difficult. Self organization of polymers with cyclodextrins takes place preferentially in aqueous solutions, whereas the reactions of blocking reagents with the polymers must usually be carried out in inert organic solvents.



(*E*)-**2**

With the aim of forming polyrotaxanes photochemically[8] we synthesized the stilbene polymer (*E*)-**2**, whose decamethylene segments are well suited for threading cyclodextrins.[7b, 9] In addition, the polymer contains (*E*)-stilbene segments which are intended for the photosynthetic formation of blocking groups. The model compound (*E*)-**3** was converted into the (*Z*)-isomer upon irradiation with UV light in the presence of **1b**. In contrast, the inclusion of two guest molecules (*E*)-**3** in **1c** caused [2+2]cycloaddition leading to tetraphenylcyclobutanes.[10] When irradiated, an aqueous solution of (*Z*)-**2** isomerized, as expected, to the polymer (*Z*)-**2** (Scheme 1) without degradation of the polymer chain; this was confirmed by ^{1}H NMR and UV/Vis spectroscopy. The reduction of absorption in the UV region and the shift of the maximum to shorter wavelength, which are associated with the (*E*)/(*Z*) isomerization, were also observed for monomeric stilbenes (Figure 1a).[11, 12] There was no indication of the formation of [2+2]photoaddition products.



(*E*)-**3**

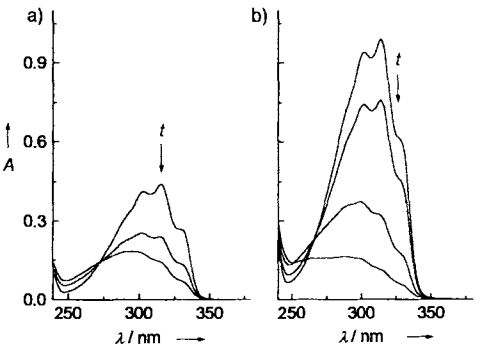


Figure 1. UV spectra of a) 0.18 mM (*E*)-**2** in water (not irradiated and after 30 and 120 min irradiation), b) 0.15 mM (*E*)-**2**·(*E*)-$\mathbf{3}_{0.13}$·$\mathbf{1b}_{0.87}$·$\mathbf{1c}_{0.13}$ in water (not irradiated, after 30 and 120 min and after 30 h irradiation). See Experimental Section for the reaction conditions.

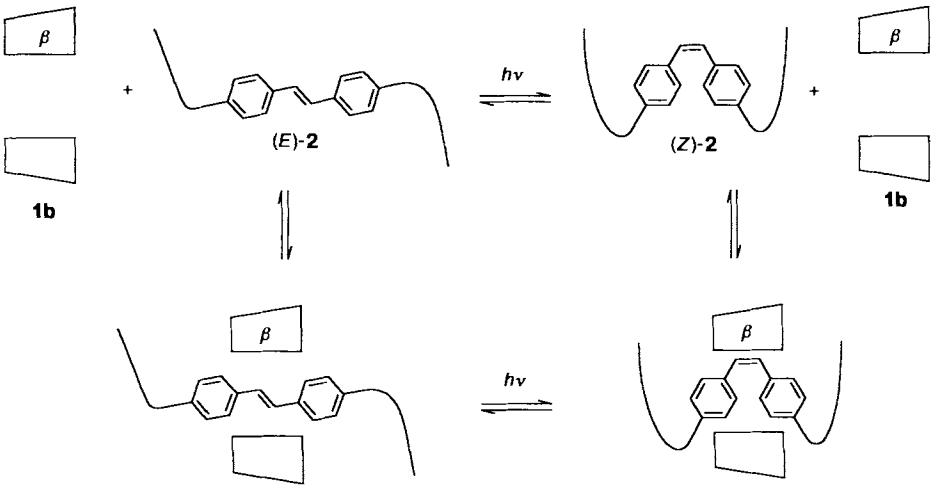
We hoped that polyrotaxanes would form after inclusion of polymer (*E*)-**2** in cyclodextrin, and subsequent photoisomerization of (*E*)-**2** took place in the presence of **1b**. The polymeric inclusion compounds and the polyrotaxanes were distinguished by gel permeation chromatography (GPC) with detection of the optical rotation. For cyclodextrins, which are permanently bound to a polymer, a rotational signal in the polymer region (V_e = 4–7 mL) was expected, whereas for dissociated systems a rotational signal for free cyclodextrin at V_e = 9 mL was expected; the latter was found for (*Z*)-**2**·**1b** (Figure 2a). Therefore, (*Z*)-stilbene segments are not suitable blocking groups for **1b**.

To check whether photochemically formed tetraphenylcyclobutane groups are effective blocking groups for **1b**, the quaternary polymeric inclusion compound (*E*)-**2**·(*E*)-$\mathbf{3}_{0.13}$·$\mathbf{1b}_{0.87}$·$\mathbf{1c}_{0.13}$ was prepared by self organization in an aqueous solution. In this supramolecular complex each cyclodextrin ring **1c** encloses a polymer-bound (*E*)-**2** and a monomeric (*E*)-**3** stilbene unit (Scheme 2). According to the results of GPC, about 12% of the cyclodextrin remained bound to the polymer (Figure 2b). In an analogous test run without the addition of (*E*)-**3** no polymer-bound cyclodextrin was detected for the ternary inclusion compound (*E*)-**2**·$\mathbf{1b}_{0.87}$·$\mathbf{1c}_{0.13}$. Therefore, in the quaternary inclusion compound (*E*)-**2**·(*E*)-$\mathbf{3}_{0.13}$·$\mathbf{1b}_{0.87}$·$\mathbf{1c}_{0.13}$ the additionally included stilbene (*E*)-**3** acts as a stabilizing splint since the space inside **1c** is completely filled.



Scheme 1. Photochemical (*E*)/(*Z*) isomerization of polymer **2** and self-organization with cyclodextrin **1b**.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2512 $ 17.50+.50/0

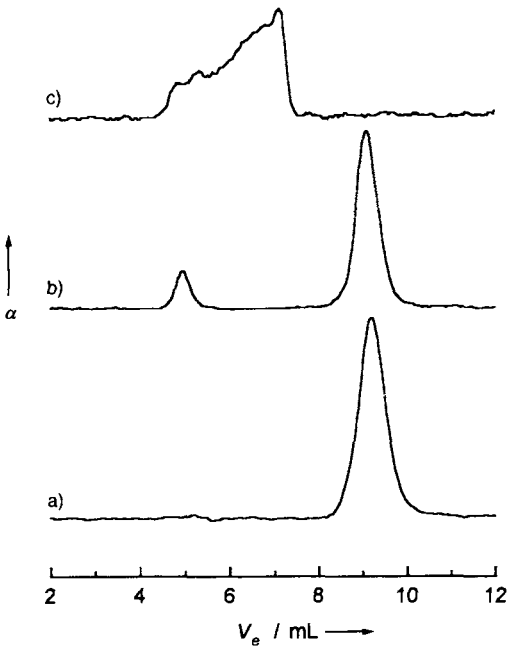


Figure 2. GPC elution curves of a) (*E*)-**2**·**1b**$_{0.87}$·**1c**$_{0.13}$, b) (*E*)-**2**·(*E*)-**3**$_{0.13}$·**1b**$_{0.87}$·**1c**$_{0.13}$, and c) **4**.

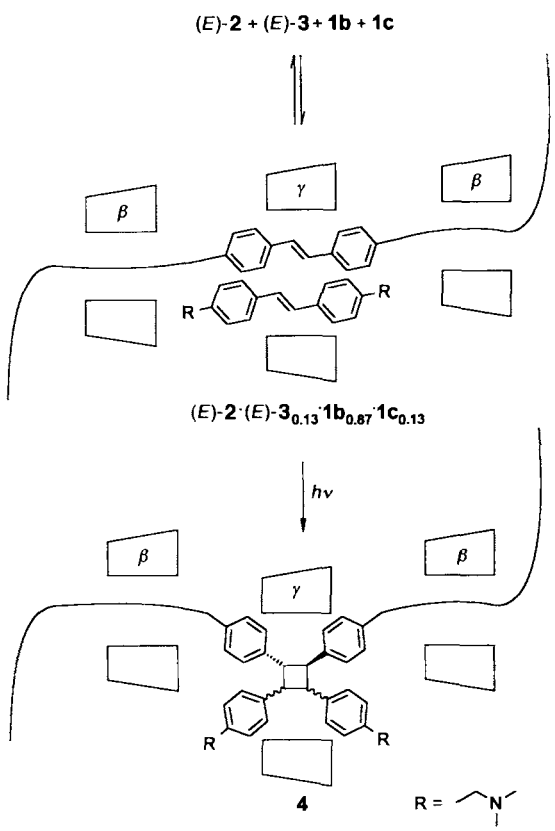

Scheme 2. Self-organization of the polymeric inclusion compounds (*E*)-**2**·(*E*)-**3**$_{0.13}$·**1b**$_{0.87}$·**1c**$_{0.13}$ and photochemical synthesis of polyrotaxane **4**.

The threaded rings and (*E*)-**3** can be completely separated from the polymer (*E*)-**2** by continuous ultrafiltration.

Irradiation of a saturated aqueous solution of (*E*)-**2**·(*E*)-**3**$_{0.13}$·**1b**$_{0.87}$·**1c**$_{0.13}$ with UV light at 312 nm for 30 h produced **4** (Scheme 2, Figure 1b). The increased absorption, especially at 250 nm, indicates isolated phenyl groups. In addition, the signals for the (*E*)- and (*Z*)-stilbene units in the ^{1}H NMR spectrum vanished. GPC of the raw product showed an increased amount (20%) of polymer-bound cyclodextrins. All free or not permanently bound cyclodextrin rings were removed by continuous ultrafiltration. In the residue **4** 20% of the repeating units remained included in cyclodextrin. GPC showed neither free cyclodextrin rings nor easily removable ones remaining in product **4** (Figure 2c). Therefore, **4** is a polyrotaxane, since unthreading of the cyclodextrin is hindered by the attached bulky tetraphenylcyclobutane groups.[13]

The additional inclusion of the monomeric stilbene (*E*)-**3** in the inclusion compound of the polymeric stilbene (*E*)-**2** not only stabilizes the supramolecular structure but makes possible further chemical modification. Therefore, to our knowledge, this is the first demonstration of the supramolecular catalysis of a polymer-analogous conversion; that is, a conversion of the repeating units without changing the chain length.

Experimental Section

GPC was performed on a HEMA-Bio column (Polymer Standards Service, Mainz, Germany, 1000 DEAE) with water/acetonitrile/glacial acetic acid 80/20/0.1. A continuous polarimeter (λ = 589 nm, Chiralyser, IBZ Messtechnik, Hannover, Germany) was used for detection. For the quantitative evaluation, equal specific-rotation values were assumed for polymer-bound and free cyclodextrins.

(*E*)-**2**: 1,10-Dibromodecane (35.100 g, 117.0 mmol) and *N*,*N*,*N*′,*N*′-tetramethyl-1,6-diaminohexane (22.400 g, 130.0 mmol) were dissolved in MeOH/*N*-methylformamide (1/1, 130 mL) and stirred at 50 °C. 4,4′-Bis(bromomethyl)-(*E*)-stilbene (4.759 g, 13.0 mmol, 0.1 equiv) was subsequently added. After two weeks at 50 °C the product was added dropwise to Et_2O (3 L) and thus precipitated. It was purified by dialysis in water with a hollow-fiber module (Allwall GFE 12, Gambro, Hechingen, Germany). The residual solution of (*E*)-**2** was freeze-dried (37.58 g, 60%). The ratio of the monomer units in the polymer (0.87:0.13) was determined from the integrals in the ^{1}H NMR spectrum. ^{1}H NMR (400 MHz, D_2O): δ = 1.33–1.45 (m, 14.4H; CH_2), 1.78 (br s, 7.5H; CH_2), 1.90 (m, 0.5H; CH_2), 3.05 (s, 12H; CH_3), 3.29 (m, 8.0H; NCH_2CH_2), 4.54 (s, 0.5H; $ArCH_2$), 7.44 (s, 0.5H; =CH), 7.61 (d, J = 7.9 Hz, 1.0H; ArH), 7.81 (d, J = 7.9 Hz, 1.0H; ArH); ^{13}C NMR (D_2O): δ = 24.64, 24.70, 27.97, 28.31, 31.01, 31.19 (CH_2), 52.41, 53.22 (CH_3), 66.64, 67.03 69.80 (NCH_2), 129.55, 130.01, 136.22, 141.87, 144.02 (=CH, Ar); UV/Vis (H_2O): λ (ε) = 304 (14600), 316 nm (16200).

(*Z*)-**2**: (*E*)-**2** (650 mg, 1.35 mmol) was dissolved in water and irradiated for 60 min with UV light (λ = 312 nm, Type-D89008 UV source, 6 W, Bioblock Scientific, Illkirch Cedex, France). (*Z*)-**2** was finally isolated in quantitative yield as a colorless powder by freeze-drying. ^{1}H NMR (400 MHz, D_2O): δ = 1.33–1.41 (m, 14.4H; CH_2), 1.74–1.88 (m, 8.0H; CH_2), 3.02 (s, 12H; CH_3), 3.26 (m, 8.0H; NCH_2), 4.43 (s, 0.5H; $ArCH_2$), 6.80 (s, 0.5H; =CH), 7.40 (s, 2.0H; ArH); UV/Vis (H_2O): λ (ε) = 293 nm (5500).

(*E*)-**2**·(*E*)-**3**$_{0.13}$·**1b**$_{0.87}$·**1c**$_{0.13}$: (*E*)-**2** (467.2 mg, 0.96 mmol), (*E*)-**3**·2HCl (46.0 mg, 0.13 mmol), **1b** (949.6 mg, 0.84 mmol), and **1c** (162.2 mg, 0.13 mmol) were dissolved in water (30 mL) and stirred for 7 d at room temperature. The product was obtained as a fine, colorless powder in quantitative yield by freeze-drying. ^{1}H NMR (400 MHz, D_2O): δ = 1.33–1.42 (*m*, 14.4H; (*E*)-**2**-CH_2), 1.76 (*m*, 8.0H; (*E*)-**2**-CH_2), 2.75 (s, 1.6H; (*E*)-**3**-CH_3), 3.04 (s, 12H; (*E*)-**2**-CH_3), 3.29 (m, 8.0H; (*E*)-**2**-CH_2), 3.58–3.70 (m, 14.3H; OH), 3.78–3.92 (m, 28.5H; OCH. OCH_2), 4.23 (br s, 0.5H; (*E*)-**3**-$ArCH_2$), 4.68 (br s, 0.5H; (*E*)-**2**-$ArCH_2$), 5.05–5.10 (m, 7.1H; OCH), 6.80 (m), 7.16 (br s), 7.34 (m), 7.53 (m), 7.61 (br s; ArH; =CH).

4: (*E*)-**2**·(*E*)-**3**$_{0.13}$·**1b**$_{0.87}$·**1c**$_{0.13}$ (150 mg, 0.089 mmol) was placed in water (2.5 mL) and irradiated for 6 h. The reaction mixture was finally diluted with water (100 mL) and purified by continuous ultrafiltration (Ultrafiltration cells Berghof, Eningen, Nadir-Polyethersulfone membrane 2000 Dalton, Hoechst, Frankfurt, Germany; 5 bar, 2.2 L water/18 h). Upon freeze-drying, **4** was obtained as a colorless powder (70 mg, 0.042 mmol). ^{1}H NMR (400 MHz, D_2O): δ = 1.33–1.41 (m, 14.4H; CH_2), 1.75 (m, 8.0H; CH_2), 2.57 (s, 1.6H; CH_3), 3.02 (s, 12H; CH_3), 3.27 (m, 8.0H; NCH_2), 3.56–3.70 (m, 2.9H; OCH), 3.79–3.86 (m, 5.7H; OCH, OCH_2), 3.98, 4.13, 4.33, 4.69 (1.6H; CH, $ArCH_2$), 5.01–5.08 (m; OCH), 7.21, 7.31, 7.41 (2.1H; ArH).

[12] The possibility of accomplishing the reverse reaction—that is, the (*Z*)/(*E*) isomerization—either photochemically or thermally was not investigated.

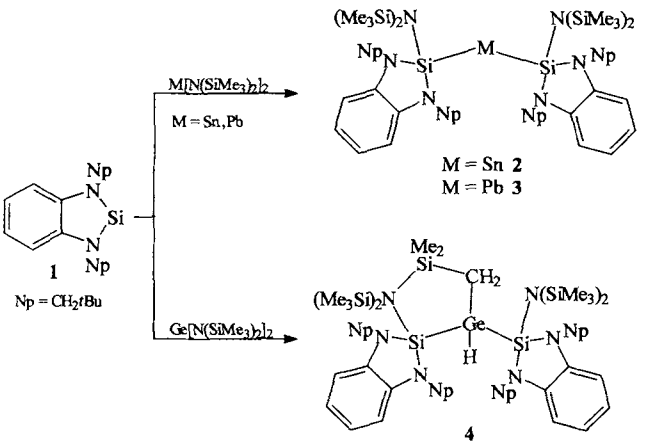
[13] The tetraphenylbutane groups probably prevent unthreading only of the **1b** rings, since monomeric tetraphenylcyclobutane is rapidly enclosed by **1c**[10]. The **1b** rings stop the **1c** rings from wandering.

New Reactions of a Silylene: Insertion into M–N Bonds of $M[N(SiMe_3)_2]_2$ (M = Ge, Sn, or Pb)**

Barbara Gehrhus, Peter B. Hitchcock, and Michael F. Lappert*

Transient silylenes SiX_2 (X^- = a monohapto ligand) are important synthons in organosilicon chemistry, being a source of unusual tetravalent silicon compounds. Typically this involves either a) reaction with an organic or inorganic unsaturated substrate,[1a] or b) insertion into a compound containing a M′–Hal (e.g. Hal = Cl and M′ = B, C, Si, or P) or M′–H (e.g. M′ = C, Si, or O) bond.[1b] In contrast, insertions into an M′–N bond are as yet unreported. We have recently shown that the thermally stable but reactive bis(amino)silylene **1**[2a] also undergoes both type a) (with a chalcogen[2a] or various C–C, C–O, and C–N multiply bonded compounds[2b]) and type b) (with CH_3–I or C_2H_5O-H[2a]) reactions. Thermally stable monomeric Group 14 metal(II) amides $M[N(SiMe_3)_2]_2$ (M = Ge, Sn, or Pb) have an extensive range of reactivity, but insertions into the M–N bonds giving rise to new divalent M(II) compounds has not previously been observed.

We now show that treatment of the pale yellow silylene **1**[2a] with the yellow-to-orange $M[N(SiMe_3)_2]_2$ compounds in *n*-hexane at ambient temperatures afforded after work-up the crystalline dark green (Sn) or black-green (Pb) bis(silyl)metal(II) compounds **2** or **3**, respectively, or the colorless azadisilagermole **4** (Scheme 1). The lead(II) compound **3** was appreciably more labile both in solution and in the solid than the isoleptic tin(II) compound **2**, and slowly deposited lead over a period of days.



Scheme 1. Reactions of the cyclic silylene **1**, Np = neopentyl, with the metal amides $M[N(SiMe_3)_2]_2$, M = Ge, Sn, Pb.

Each of the compounds **2**–**4** gave satisfactory microanalysis, EI mass and multinuclear NMR spectra (see Experimental Section). In addition, single-crystal X-ray diffraction data revealed their molecular structures, illustrated for **2** or **3** in Figure 1;

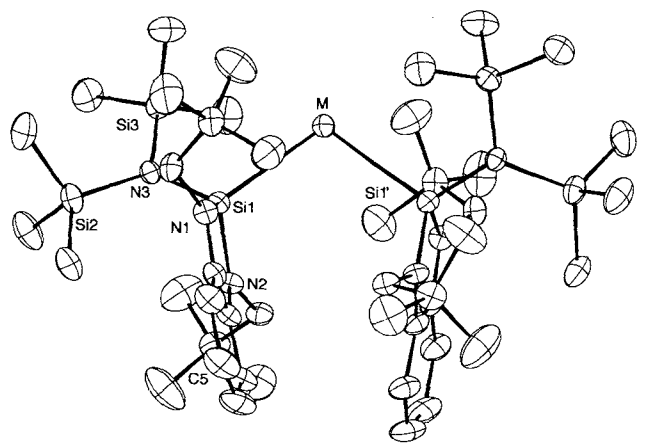


Figure 1. Crystal structures of **2** (M = Sn) and **3** [M = Pb; data shown in square brackets]. Selected bond lengths [Å] and angles [°]: M–Si1 2.712(1) [2.776(3)], Si1–N2 1.745(3) [1.751(9)], Si1–N3 1.768(3) [1.757(8)], Si1–N1 1.754(3) [1.755(8)]; Si1-M-Si1′ 106.77(5) [105.8(1)], N2-Si1-N3 115.1(2) [115.5(4)], N2-Si1-N1 92.0(2) [92.6(4)], N3-Si1-N1 111.5(2) [112.6(4)], N2-Si1-M 116.8(1) [116.1(3)], N3-Si1-M 112.5(1) [111.3(3)], N1-Si1-M 106.8(1) [107.1(3)].

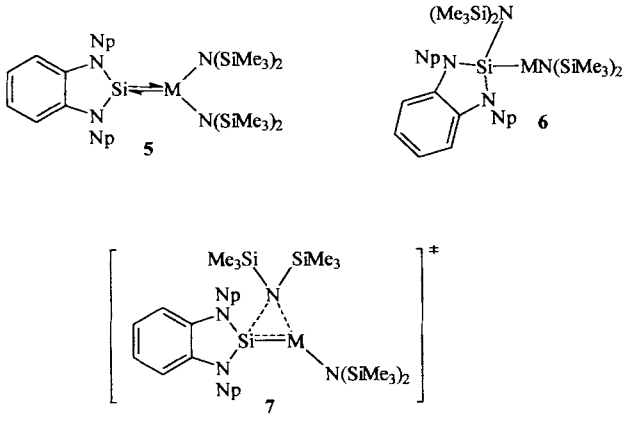
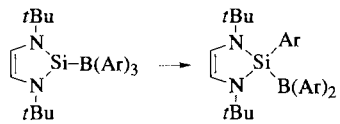
details for **4** will be published later. Compound **2** is to our knowledge the first two-coordinate tin(II) compound having the $SnSi_2$ framework, but for lead(II) there is a precedent for **3** in $Pb[Si(SiMe_3)_3]_2$.[3] The tin analogue of this lead compound is a Sn–Sn-bonded dimer, and the only other tin(II) silyl compound is $[Sn\{Si(SiMe_3)_3\}_2(\mu\text{-Cl})Li(thf)_3]$.[4]

We suggest that the reaction pathway for the conversion of **1** and $M[N(SiMe_3)_2]_2$ into the bis(silyl)metallene **2** or **3** proceeds via intermediates **5** and **6**. The cyclic transition state **7** may be



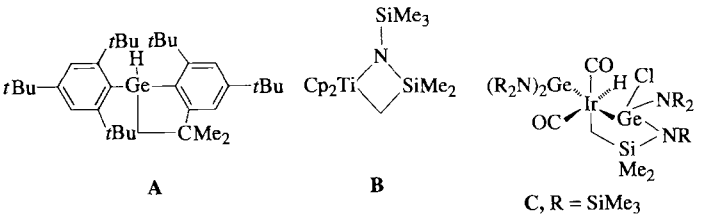
implicated in the transformation of **5** → **6** and a similar one also between **6** and the ultimate product **2** or **3**. The formation of **5** involves the notion that both **1** and $M[N(SiMe_3)_2]_2$ (M = Sn or Pb) are capable of behaving as a Lewis acid and a Lewis base. Precedents for compounds related to **5** in Group 14 element chemistry include the crystallographically characterized dinuclear M^{II}–M^{II} compounds $[M\{CH(SiMe_3)_2\}_2]_2$ (M = Ge or Sn),[5] $[Sn\{Si(SiMe_3)_3\}_2]_2$,[3] $[Sn\{2\text{-}t\text{Bu-}3,5,6\text{-}Me_3C_6H\}_2]_2$,[6] and $X_2SnSnCl_2$ [X = $CH(SiMe_3)(8\text{-}C_9H_6N)$].[7] As for **5** → **6**, 1,2-migration of a ligand from M → M′ is well documented, for example, for OMe from Si → Si (α-elimination),[8] for 2,4,6-$Me_3C_6H_2$ from Ge → Si,[9] for Cl from Sn → Sn,[7] and for C_6F_5 from B → Si [Eq. (1), Ar = C_6F_5[10]].



(1)

The synthesis of the germanium(IV) hydride **4** from **1** and $Ge[N(SiMe_3)_2]_2$ is believed to proceed through a similar pathway, except that steric acceleration caused the bis(silyl)-germylene **8** (the Ge analogue of **2** and **3**) to undergo cyclometalation. Thus **4** may be formed by insertion of the labile germylene **8** into a C–H bond of an $N(SiMe_3)_2$ group. Precedents for a related C–H activation have been described (Scheme 2), for example, the conversion of a) $Ge(2,4,6\text{-}tBu_3C_6H_2)_2$ into its Ge^{IV} isomer **A** in the presence of a Lewis acid such as $GeCl_2$,[11] b) $[Ti(\eta^5\text{-}C_5H_5)_2\{N(SiMe_3)_2\}_2]$ into **B** and $HN(SiMe_3)_2$,[12] and c) the formation of **C** from $[Ir(Cl)(CO)_3]$ generated in situ and $Ge[N(SiMe_3)_2]_2$.[13]

In the crystalline bis(silyl)tin(II) compound **2**, each molecule has a V-shaped skeletal structure and lies on a twofold rotation axis bisecting the Si1-Sn-Si1′ angle of 106.77(5)°. This value is at the upper end of the range of X-Sn-X′ angles for monomeric, crystalline Sn^{II} compounds (cf. 104.7(2)° in $Sn[N(SiMe_3)_2]_2$,[14] 109.7(2)° in $Sn[NC(Me_2)(CH_2)_3CMe_2]_2$,[15] 103.6(1)° in Sn-



Scheme 2. Examples of products of C–H insertion reactions that could be formed analogously to **4**.

$(2,4,6\text{-}tBu_3C_6H_2)_2$,[16] 88.8(2)° in $Sn[O(2,6\text{-}tBu_3\text{-}4\text{-}Me\text{-}C_6H_2)]_2$,[17] 85.4(1)° in $Sn[S(2,4,6\text{-}tBu_3C_6H_2)]_2$,[18] or 98.8(4)° in $Sn[P\{Si(tBu)F(2,4,6\text{-}iPr_3C_6H_2)\}(SiiPr_3)]_2$[19]), but is similar to those in the Sn–Sn-bonded dinuclear compounds $[Sn\{CH(SiMe_3)_2\}_2]_2$[5] and $[Sn\{Si(SiMe_3)_3\}_2]_2$[3] of 109.2(2)° and 108.25(3)°, respectively. The very long Sn–Si bond of 2.712(2) Å in **2** is a noteworthy feature, particularly when this value is compared to the sum of the Sn and Si covalent radii of 2.58 Å or the Sn–Si distances of 2.666(7) Å in $[Sn\{Si(SiMe_3)_3\}_2]_2$[3] and of 2.681(2) Å in $[Sn\{Si(SiMe_3)_2\}_2(\mu\text{-Cl})Li(thf)_3]$.[4] The closest Sn···Sn contact for **2** is about 10 Å.

The lead(II) compound **3** is isostructural with **2**, and the molecular geometric parameters for the two are very similar, except that for M = Pb the M–Si bond is longer (2.776(3) Å) and the Si1-M-Si1′ angle is narrower (105.8(1)°). These observations are consistent with the pattern previously noted when comparing M–X bond lengths and X-M-X angles for pairs of MX_2 molecules (M = Sn or Pb). For example, the corresponding values in $Pb[N(SiMe_3)_2]_2$ are 2.24(2) Å and 103.6(7)°, respectively, and in the analogous tin(II) amide 2.09(1) Å and 104.7(2)°, respectively.[14] However, it is evident that the Pb–Si bond and Si1-Pb-Si1′ angle in **3** are significantly longer and narrower than in $Pb[Si(SiMe_3)_3]_2$ for which the values 2.702(3) Å and 113.56(10)°, respectively, were observed.[3] The torsion angle N1-Si1···Si1′-N2′ is 57° (Figure 2, Si1′ is masked by Si1) in the Sn compound **2** and 55° in the Pb compound **3**.

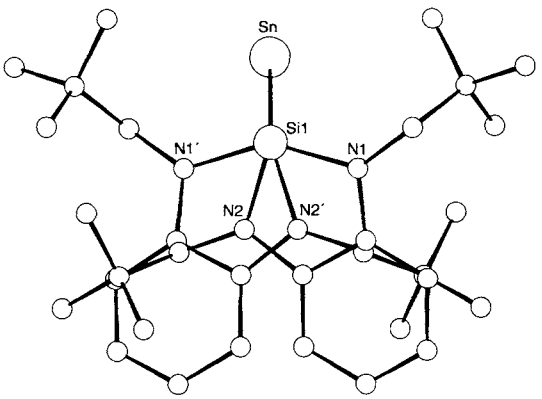


Figure 2. Side-on view of the framework of **2**, $N(SiMe_3)_2$ substituents omitted.

It is likely that in solution compounds **2** and **3** have similar structures to those in the solid; CP-MAS data, as well as UV/Vis spectra, will be discussed in a subsequent full paper.

The reactions in Scheme 1 may well be the first of a much wider series of transformations involving reactions between the stable **1** or a transient silylene and a carbene or carbene analogue (see, for instance, ref. [20]).

Experimental Section

2: A solution of **1** (0.3 g, 1.112 mmol) in *n*-hexane (10 mL) was added to a solution of $Sn[N(SiMe_3)_2]_2$ (0.49 g, 1.112 mmol) in *n*-hexane (10 mL), causing an immediate color change from orange to dark green-brown. The mixture was stirred for 4 h. The formed precipitate, which largely redissolved upon heating, was filtered hot, and the filtrate was slowly cooled to room temperature and then at −25 °C to afford compound **2** (0.48 g, 87%) as dark green crystals, m.p. 165–167 °C (decomp); correct elemental analysis; MS: *m/z* (%) 986 (4) $[M]^+$, 869 (57) $[M-119]^+$; ^{1}H NMR (300 MHz, [D$_6$][benzene], 298 K): δ = 0.16 and 0.47 ($SiMe_3$, 2s, 36H), 0.86 (CMe_3, s, 36H), 2.81, 2.86, 2.94 and 2.99 (CH_2, AB-type, broad, 8H), 6.58–6.62 and 6.82–6.86 (phenyl, m, 8H); $^{13}C\{^1H\}$ NMR (75.47 MHz, [D$_6$][benzene], 298 K): δ = 5.53 and 7.38 ($SiMe_3$), 29.31 (CMe_3), 32.52 (CMe_3), 56.88 (CH_2), 110.62, 117.76, and 142,94 (phenyl); $^{29}Si\{^1H\}$ NMR (99.33 MHz, [D$_8$][toluene], 298 K): δ = −2.00 and 9.74 ($SiMe_3$), no $^{119}Sn\{^1H\}$ signal was detected (cf. ref.[3]).

3: Compound **3** (0.45 g, 69%) was obtained as black-green crystals from $Pb[N(SiMe_3)_2]_2$ (0.32 g, 0.607 mmol) and **1** (0.33 g, 1.214 mmol) by a procedure as for **2**; m.p. 150–151 °C (decomp); correct elemental analysis; MS: *m/z* (%) 869 (7%) $[M-207]^+$; ^{1}H NMR (300 MHz, [D$_6$][benzene], 298 K): δ = 0.14 and 0.39 ($SiMe_3$, 2s, 36H), 0.89 (CMe_3, s, 36H), 2.95, 3.00, 3.34 and 3.38 (CH_2, AB-type, broad, 8H), 6.55–6.58 and 6.83–6.87 (phenyl, m, 8H); $^{13}C\{^1H\}$ NMR (75.47 MHz, [D$_6$][benzene], 298 K): δ = 5.78 and 9.37 ($SiMe_3$), 30.86 (CMe_3), 32.68 (CMe_3, broad), 57.35 (CH_2, broad), 112.60, 118.15 and 144.60 (phenyl); $^{29}Si\{^1H\}$ NMR (99.33 MHz, [D$_8$][toluene], 298 K): δ = 0.09 and 11.27 ($SiMe_3$).

4: A solution of **1** (0.68 g, 2.5 mmol) in *n*-hexane (10 mL) was added to a solution of $Ge[N(SiMe_3)_2]_2$ (0.58 g, 1.25 mmol) in *n*-hexane (20 mL). After the mixture had been stirred overnight, the solvent was removed in vacuo. The remaining white solid was recrystallized from *n*-pentane to afford **4** (0.85 g, 73%) as colorless crystals, m.p. 188–190 °C (decomp); correct elemental analysis; MS: *m/z* (%) 943 (50) $[M]^+$; ^{1}H NMR (500 MHz, [D$_6$][benzene], 298 K): δ = 0.11, 0.17 and 0.46 ($SiMe_3$, 3s, 27 H), 0.30 and 0.36 ($SiMe_2$, 2s, 12H), 0.82, 0.88, 1.09 and 1.17 (CMe_3, 4s, 36H), 0.53 (CH_2, dd, 2H, ^2J(H,H) 12.66 Hz, ^3J(H,H) 3.23 Hz), 4.00 (GeH, dd, 1H, ^3J(H,H) 3.22 and 11.94 Hz), 2.31, 2.36, 2.65, 2.68, 2.76, 2.79, 3.14, 3.17, 3.24, 3.26, 3.32, 3.35, 3.36, 3.38 (CH_2, AB type, 8H) and 6.56-6.88 (phenyl, m, 8H); $^{13}C\{^1H\}$ NMR (75.47 MHz, [D$_6$][benzene], 298 K): δ = 1.97 (CH_2), 2.90, 4.01, 5.91, 6.00 and 7.26 (SiMe), 29.25, 29.91 and 30.38 (CMe_3), 33.43, 33.92 and 34.41 (CMe_3), 57.51, 57.57, 58.31 and 58.72 (CH_2), 109.56, 110.37, 110.49, 110.68, 117.73, 118.07, 118.15, 118.29, 142.21, 142.71, 142.89 and 143.18 (phenyl); $^{29}Si\{^1H\}$ NMR (99.33 MHz, [D$_6$][benzene], 298 K): δ = 3.17, 3.71 and 4.78 ($SiMe_3$), 9.19 ($SiMe_2$), 2.06 and −10.18.

Crystal structure analysis for **2**: $C_{44}H_{88}N_6Si_6Sn$, a = 28.235(9), b = 10.856(4), c = 23.019(1) Å, β = 128.27(4)°, V = 5540(4) Å^3, Z = 4, monoclinic, space group $C2/c$ (no. 15), ρ_{calcd} = 1.19 mg m^{-1}, μ = 0.624 mm^{-1}, $R1$[for 3651 reflections with $I > 2\sigma(I)$] = 0.043, $wR2$[for all 4864 reflections] = 0.094, GOF on F^2 = 1.019. Crystal structure analysis for **3**: $C_{44}H_{88}N_6PbSi_6$, a = 28.274(12), b = 10.746(3), c = 22.784(9) Å, β = 127.96(4)°, V = 5458(4) Å^3, Z = 4, monoclinic, space group $C2/c$ (no. 15), ρ_{calcd} = 1.31 mg m^{-}, μ = 3.26 mm^{-1}, $R1$[for 3917 reflections with $I > 2\sigma(I)$] = 0.068, $wR2$[for all 4778 reflections] = 0.208, GOF on F^2 = 1.027. For both **2** and **3** the structure was solved by direct methods (SHELXS-86) and refined with full-matrix least-squares based on all F^2 (SHELXL-93). All non-H atoms were anisotropic, H atoms included in a riding mode. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository numbers CSD-407492 (**2**) and CSD-407493 (**3**).

Platinum-Catalyzed Regioselective Silaboration of Alkenes**

Michinori Suginome, Hiroshi Nakamura, and Yoshihiko Ito*

Activation of thermally stable bonds between main-group elements such as boron, silicon, and tin has recently become the subject of growing interest. Addition of these intermetallic compounds to carbon–carbon multiple bonds (bis-metallation) has been achieved by using an appropriate transition metal catalyst; bis-metallated organic compounds are obtained that are otherwise difficult to synthesize. In addition to the homometallic compounds with B–B,[1] Si–Si,[2] and Sn–Sn bonds,[3] heterometallic compounds containing B–Si,[4] B–Sn,[5] and Si–Sn[6] bonds have been employed for the transition metal catalyzed bis-metallation of alkynes. Heterometallic bis-metallation is especially interesting, because the reactions proceed not only with high stereoselectivity but also high regioselectivity. However, to our knowledge, bis-metallation of alkenes with heterometallic compounds has not been reported, although addition of the homometallic compounds to C–C double bonds has been reported for diboron[7] and disilicon[2e, 8] compounds. Here we report that, in the presence of a platinum catalyst, addition of the B–Si bond to C–C double bonds takes place with regioselective bond formation between silicon and the terminal carbon atom. This result is interesting because silaboration of terminal alkynes proceeds with the opposite regiochemistry.[4]

Dimethylphenylsilyl(pinacol)borane (**1a**) and 1-octene (1.5 equiv) in dioxane were heated at reflux in the presence of transition metal catalysts (Scheme 1). As summarized in Table 1, platinum phosphane complex catalysts promoted the addition of the B–Si bond to the C–C double bond of 1-octene to give a silaboration product. It is noteworthy that silaboration to give 2-boryl-1-silyloctane **2a** is highly regioselective and that a small amount of 1-boryl-1-silyloctane **3a** is formed.

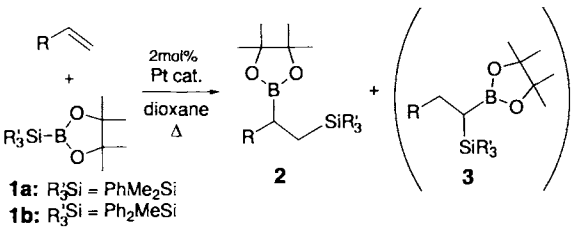


Scheme 1. Platinum-catalyzed silaboration of alkenes.

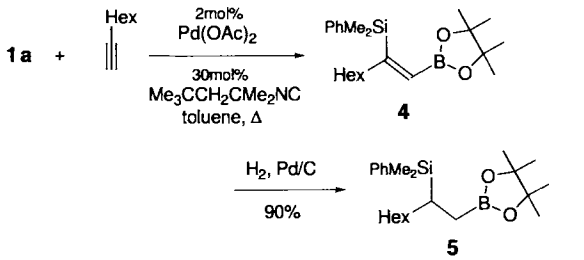
Table 1. Platinum-catalyzed silaboration of 1-octene [a].

Entry	1	Catalyst	Product	Yield[%]	Ratio 2:3
1	a	$[Pt(PPh_3)_4]$	2a	45	85:15
2	a	$[Pt(CH_2{=}CH_2)(PPh_3)_2]$	2a	53	87:13
3	b	$[Pt(CH_2{=}CH_2)(PPh_3)_2]$	2a′	65	93:7
4	a	$[Pt(PMePh_2)_4]$	2a	7	74:26

[a] Silylborane (1 equiv), 1-octene (1.5 equiv), and catalyst (0.02 equiv) were heated at reflux in dioxane for 2 h.

Triphenylphosphane (entries 1 and 2) was the ligand of choice with regard to catalytic activity and product selectivity (see entry 4). For the silaboration of 1-octene, methyldiphenylsilyl(pinacol)borane (**1b**) gave better yield and selectivity for 1,2-silaboration (entry 3), while catechol- and bis(diethylamino)borane derivatives did not afford silaboration products in the presence of the platinum catalysts.

The absence of 1-boryl-2-silyloctane **5**, the regioisomer of **2a**, in the reaction mixture of the silaboration of 1-octene was unambiguously confirmed by independent synthesis of **5** by palladium-catalyzed silaboration of 1-octyne,[4] followed by catalytic hydrogenation (Scheme 2).



Scheme 2. Synthesis of 1-bora-2-silylalkane **5** by silaboration of 1-octene to give **4**, followed by hydrogenation.

Silaboration has successfully been applied to various alkenes, including functionalized alkenes and styrene derivatives (Table 2). Ester and ketone groups on the olefinic substrates were tolerated in the reaction with **1a** to give the corresponding silaboration products (entries 1 and 2). Styrene derivatives also underwent silaboration in moderate yield and high regioselectivity without formation of the 1,1-isomers (entries 3–5). Electronic effects of substituents on the aromatic ring of the styrene derivatives did not influence the yield. For these alkenes use of **1b** resulted in considerably lower yields. The silaboration of gaseous ethylene (60 atm) in the presence of $[Pt(CH_2{=}CH_2)(PPh_3)_2]$ as catalyst furnished 2-boryl-1-silylethane in 73% yield, accompanied by the formation of 1,2-bis(dimethylphenylsilyl)ethane in 10% yield (entry 6). Use of $[Pt(PPh_3)_4]$ as catalyst completely suppressed the by-product formation and gave exclusively the desired 2-boryl-1-silylethane **2g** (entry 7).

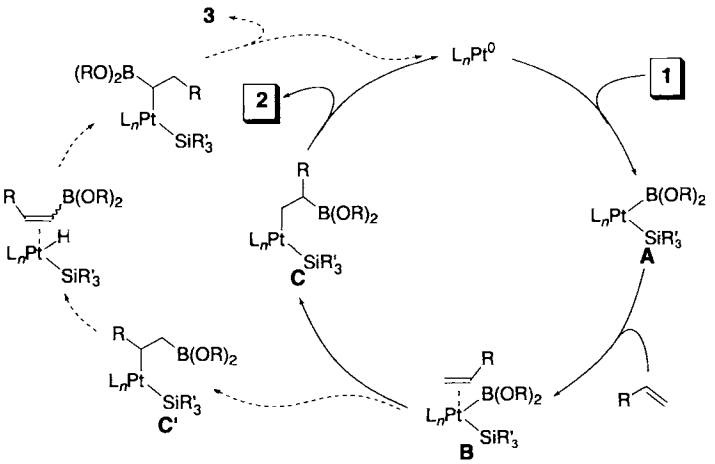
Table 2. Platinum-catalyzed silaboration of alkenes with **1a** [a].

Entry	R	Product	Yield[%]	Ratio 2:3
1	$AcOCH_2CH_2$	2b	46	84:16
2	$CH_3COCH_2CH_2$	2c	46	85:15
3	Ph	2d	51	>99:1
4	4-$MeOC_6H_4$	2e	53	>99:1
5	4-$CF_3C_6H_4$	2f	46	>99:1
6[b]	H	2g	73[c]	>99:1
7[b,d]	H	2g	74	>99:1

[a] Borane **1a** (1 equiv), alkene (1.5 equiv), and $[Pt(CH_2{=}CH_2)(PPh_3)_2]$ (0.02 equiv) were heated to reflux in dioxane for 2 h, unless otherwise noted. [b] Reaction under an ethylene pressure of 60 atm in toluene. [c] 1,2-Bis(dimethylphenylsilyl)ethane was also isolated (10%). [d] $[Pt(PPh_3)_4]$ (0.02 equiv) was used as a catalyst.

A catalyst prepared from $Pd(OAc)_2$ and 1,1,3,3-tetramethylbutyl isocyanide, which was the catalyst of choice in the silaboration of alkynes, as well as palladium phosphane catalysts such as $[Pd(PPh_3)_4]$, did not catalyze the silaboration reaction.

A possible mechanism of the silaboration of alkenes is depicted in Scheme 3. The catalytic cycle is initiated by oxidative addition of a B–Si bond of **1** to platinum to give **A**, followed by



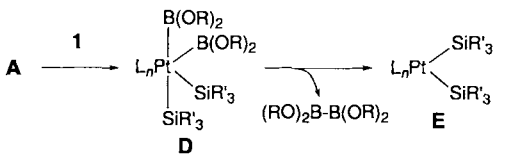
Scheme 3. Possible mechanism of the silaboration of alkenes.

alkene coordination to platinum (**B**) and then migratory insertion to give **C**. The platinum catalyst is regenerated by reductive elimination, with formation of the silaborated alkene **2**. Selective insertion of the C–C double bond into the Pt–B bond of **B**, which results in Pt–C bond formation at the terminal C atom, may be responsible for the high regioselectivity. Indeed, α-boryl-4-methoxystyrene, which may arise from β-hydride elimination from intermediate **C**, was isolated in 12% yield together with dimethylphenylsilane in the reaction of 4-methoxystyrene (Table 2, entry 4). The formation of the 1,1-isomer **3** as a by-product of the silaboration of aliphatic alkenes can be explained by another catalytic cycle, which splits from the main catalytic cycle with the regioisomeric insertion of the C–C double bond into the Pt–B bond of **B**. Intermediate **C′** thus generated produces **3** by β-hydride elimination and subsequent reinsertion of the resulting alkenylborane into the Pt–H bond, followed by reductive elimination.[9]

The formation of the bis-silylation product in the reaction of ethylene with $[Pt(CH_2{=}CH_2)(PPh_3)_2]$ as catalyst is suggestive of an intermediate bis(silyl)platinum complex **E**, which may be formed from Pt^{IV} complex **D**, which in turn is formed by double

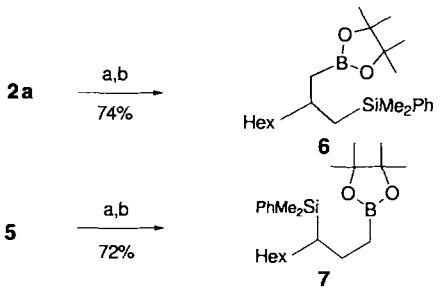
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2517 $ 17.50+.50/0

oxidative addition of **1** to the Pt^0 complex,[10] followed by reductive elimination of diborane (Scheme 4). Formation of **D** could be suppressed by using $[Pt(PPh_3)_4]$ as a catalyst, that is, in the presence of excess PPh_3.



Scheme 4. Possible route of formation of a bis(silyl)platinum complex.

The silaboration reaction made possible a regioselective C–C bond formation at the boryl-substituted C atom. For example, one-carbon homologation of **2a** and **5**, prepared from 1-octene and 1-octyne, respectively, was carried out (Scheme 5). Treatment of **2a** and **5** with chloro(trimethylsilyl)methyllithium gave the corresponding homologation products **6** and **7**, respectively, after selective removal of the trimethylsilyl group by tetrabutylammonium fluoride (TBAF).[11]



Scheme 5. Synthesis of **6** and **7**: a) Me_3SiCH_2Cl, *s*BuLi, *N,N,N',N'*-tetramethyl ethylene diamine, THF, −78 °C b) TBAF, THF, reflux.

Here we have presented preliminary results on the regioselective silaboration of simple alkenes. Optimization of the reaction conditions on the basis of the mechanism shown in Scheme 3 is currently underway.

Experimental Section

General procedure for silaboration of alkenes: To a solution of platinum catalyst (0.076 mmol) in dioxane (1 mL) were added silylborane **1** (3.9 mmol) and alkene (5.9 mmol). The mixture was heated at reflux for 2 h. Evaporation of volatile materials under reduced pressure was followed by column chromatography on silica gel to give **2** and **3** in the yields listed in Tables 1 and 2.

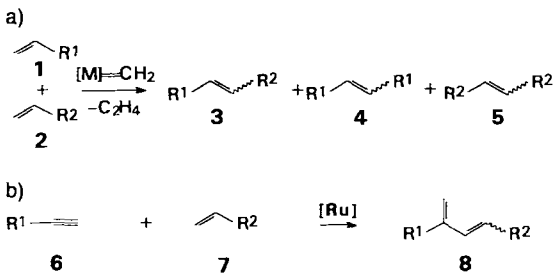
A Crossed Yne–Ene Metathesis Showing Atom Economy**

Roland Stragies, Matthias Schuster, and Siegfried Blechert*

Transition metal catalyzed olefin metathesis has recently acquired increasing significance in organic chemistry.[1] Ring-closing metatheses (RCM) have been shown especially reliable for the preparation of five- through eight-membered rings and larger systems.[2] Applications of RCM to the synthesis of fluvirucine,[3] epothilone,[4] and other natural products[5] verify the efficiency of this approach to carbon–carbon bond formation. To date, olefin metathesis has primarily been employed in organic chemistry as a synthetic method for cyclization. There are far fewer examples of the synthesis of acyclic alkenes by selective cross-metathesis of two different alkenes. In the cross-metathesis of two terminal alkenes **1** and **2** one must of necessity take into account the formation of homodimers **4** and **5** (Scheme 1a). Based on early results it is nonetheless possible to carry out highly selective couplings by the choice of suitable substituents.[6] To our knowledge, nothing has previously been



Scheme 1. a) Cross-metathesis of two terminal alkenes; b) crossed yne–ene metathesis.

reported with respect to the corresponding behavior of terminal alkynes. We describe here examples of atom economy[7] in selective cross couplings of monosubstituted alkynes with alkenes. Metatheses of alkynes are above all known from polymerizations and a few ring-closing metatheses. Thus, cyclizations of enynes to five- through seven-membered rings have been reported.[8a] This reaction principle found an elegant application in the synthesis of stemoamide.[8b] A double ring-closing metathesis to bicyclic systems has also been achieved by treatment of appropriate dienynes.[9] However, much more common than such intramolecular reactions is the intermolecular metathesis of alkynes, leading to polymers. Apart from the polymerization of simple alkynes,[10] the ring-closing metathesis polymerization of 1,6-heptadiynes has proven especially interesting.[11]

In the course of systematic studies on selective cross-metathesis we found that terminal alkynes **6** and terminal alkenes **7** were transformed selectively by ruthenium catalysis into disubstituted dienes **8** (Scheme 1b). In contrast to the cross-metathesis of two alkenes, no ethylene or other by-product is released in this case; that is, C–C bond formation occurs with atom economy. To date, catalysis of this reaction has been successful only with the Grubbs ruthenium catalyst[12] $[Cl_2(PCy_3)_2Ru{=}CHPh]$(**[Ru]**; Cy = cyclohexyl). Use of the more reactive Schrock molybdenum catalyst[13] $[PhMe_2CCH{=}Mo{=}N(2,6\text{-}iPr_2C_6H_3)\{OCMe(CF_3)_2\}_2]$ has polymerization of the alkyne component[9] as its only consequence under the same reaction conditions. Figure 1 illustrates several products of the new cross-metathesis process.[14] The reaction is carried out in dichloromethane at room temperature with 5–7 mol% **[Ru]**.

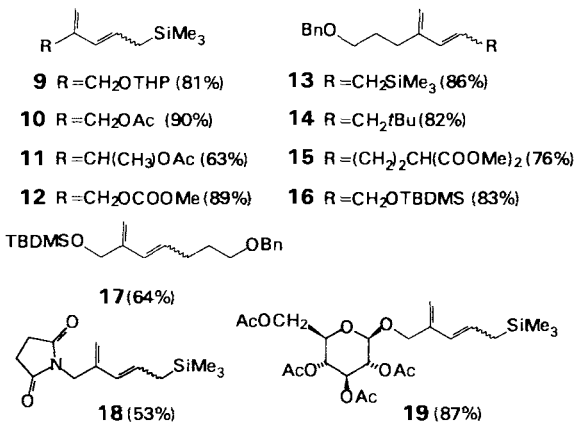

Figure 1. Products of the ruthenium-catalyzed crossed yne–ene metathesis. THP = tetrahydro-2*H*-pyran-2-yl, TBDMS = *tert*-butyldimethylsilyl.

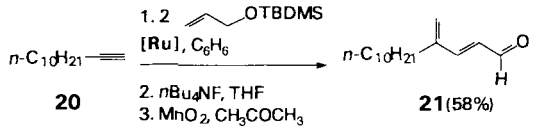
Reported yields were achieved within 12–48 h using a two- to threefold excess of the alkene component; a greater excess leads to no increase in yield. With a 1:1 mixture one does indeed obtain dienes as the main products, but in lower yield. Dimerization of the alkenes occurs only to a very limited extent.

Because of the great synthetic potential of allylsilanes, we undertook initial experiments in the reaction of allyltrimethylsilane with alkynes. Once the alkene had been coupled with THP-protected propargyl alcohol highly selectively and in acceptable yield to give the 1,3-disubstituted diene **9**, we also examined the behavior of propargyl acetate and carbonate. Compounds **10**–**12** show that coupling occurs smoothly here as well. The resulting allyl acetate structural unit offers diverse possibilities for subsequent reactions. Allylic acetates as well as the usually more reactive allylic carbonates are of interest, for example, in π-allylpalladium chemistry.[15] Due to the combination of an allylsilane with an allylic acetate or carbonate, **10**–**12** can be regarded as vinylogous trimethylenemethane precursors.[16] We are currently investigating their Pd-catalyzed reactions. The facile, selective cross-coupling reactions with allylsilanes cannot be attributed to special electronic characteristics of this particular class of compounds: comparison of **13** and **14** shows that the carbon analogue of allyltrimethylsilane, 4,4-dimethyl-1-pentene, reacts in similarly high yield. Coupling product **15** from benzyl-protected 4-pentyne-1-ol and dimethyl (3-butenyl)-malonate demonstrates the applicability of strongly CH-acidic alkenes. However, no reaction occurs with the corresponding dimethyl allylmalonate, presumably due to steric effects.

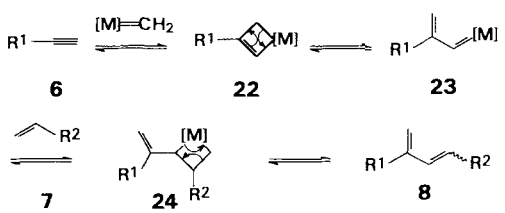
The coupling of a TBDMS-protected allylic alcohol with an alkyne to give **16** is just as successful as the inverse combination of alkene and alkyne to **17**. It is apparent from the syntheses of **18** and **19** that nitrogen-containing and highly functionalized substrates are also applicable. Yields were considerably poorer with unprotected alcohols. Disubstituted alkynes or 1,2-substituted alkenes fail to react under the conditions employed. Coupling products **9**–**19** arise as isomeric mixtures; the (*Z*)/(*E*) ratios as determined by ^{1}H NMR spectroscopy lie in a range between 1:3 in the case of **11** and about 1:2 to 1:1 with the other compounds. Because of this lack of stereoselectivity we are currently investigating techniques for (*Z*)/(*E*) isomerization. One possibility is presented in Scheme 2 with the synthesis of α-triticene[17] (**21**), an antifungal compound isolated from cereal



Scheme 2. Synthesis of α-triticene (**21**).

seeds. Because of the higher solubility of alkyne **20** this metathesis was carried out in benzene. The metathesis product was deprotected *in a one-pot reaction and oxidized* directly with MnO_2, in the course of which it was isomerized completely to the desired (*E*)-isomer, isolated in an overall yield of 58%.

Metallacyclobutenes are assumed to be intermediates in the reaction of alkynes with metathesis catalysts.[9, 11] Several mechanisms are possible for the ruthenium-catalyzed yne–ene metathesis. NMR studies have shown that the ruthenium catalyst reacts selectively with alkynes in the presence of alkenes. In the absence of alkene there occurs only a slow oligomerization, whereas in its presence a rapid subsequent reaction leads to product **8**. We therefore favor the reaction course illustrated in Scheme 3. We assume as the first step that the methylidene complex formed from the Grubbs catalyst undergoes a regioselective [2+2] cycloaddition with the triple bond of **6**. Subsequent cycloreversion leads to the stabilized, conjugated carbene complex **23**. This reacts through further [2+2] cycloaddition with alkene



Scheme 3. Proposed mechanism for the yne–ene metathesis.

component **7** to give **24**, and with subsequent cycloreversion to the conjugated diene **8**. The fact that coupling is limited to terminal alkynes may have a steric origin. Formation of the more stable and thus less reactive conjugated carbene complex **23** might explain why the yne–ene metathesis requires longer reaction times than conventional cross-metathesis between alkenes. Volatile ethylene is formed in the cross-metathesis of terminal alkenes, whereas the yne–ene metathesis takes place with atom economy. The driving force in yne–ene metathesis may be the formation of a conjugated diene.

The type of reaction described here is, to our knowledge, the first selective crossed yne–ene metathesis. Application of this cross-metathesis between terminal alkynes and alkenes has been demonstrated by the synthesis of variously functionalized dienes. The reaction opens the way to interesting structural elements: thus, conjugated allylsilanes have found a variety of applications, for example in Sakurai reactions.[18] The metathesis products are also of interest with respect to Diels–Alder reactions and cycloadditions. We are currently investigating the applications of yne–ene metathesis in natural product synthesis.

Total Synthesis of Eleutherobin**

K. C. Nicolaou,* Floris van Delft, Takashi Ohshima, Dionisios Vourloumis, Jinyou Xu, Seijiro Hosokawa, Jeffrey Pfefferkorn, Sanghee Kim, and Tianhu Li

Eleutherobin[1, 2] **1** (Figure 1) is a newly discovered antitumor agent which has a mechanism of action[3] like Taxol (**2**) and a novel molecular architecture. Its structure was based on spectroscopic results,[1, 2] although no absolute configuration was assigned. Isolated from an *Eleutherobia* species of marine soft corals (possibly *E. albiflora* Alcynacea, Alcyoniidea) collected in the Indian Ocean near Bennett's Shoal in Western Australia, this substance is extremely scarce, and yet its tubulin polymerization and microtubule-stabilizing properties and 100-fold higher potency (over the mean cytotoxicity of an NIH cell line panel) against selected breast, renal, ovarian, and lung cancer cells[2] make it (along with epothilones[4–9] A (**3**) and B (**4**), Figure 1), one of the most promising antitumor agents isolated from nature in recent years. Here we report the first total synthesis of eleutherobin (**1**) which renders the natural product (**1**) and two biologically active analogues (**33** and **34**, see Scheme 3) readily available for further studies. Furthermore, the described chemical synthesis allows assignment of the absolute stereochemistry of eleutherobin (**1**) and opens an avenue for the generation of combinatorial libraries for biological screening purposes.

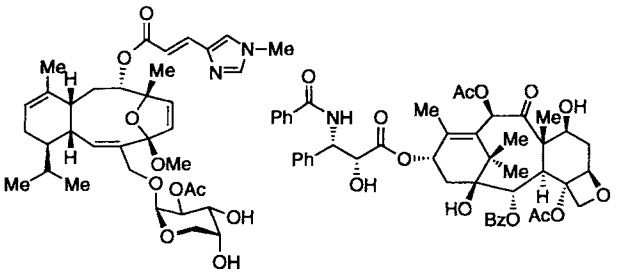
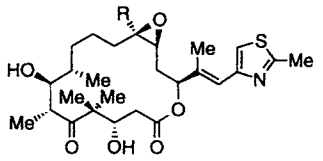
[**] We thank Dr. W. Fenical for preprints of refs. [2, 25] as well as selected spectra of eleutherobin, and Dr. D. H. Huang and Dr. G. Siuzdak for NMR spectroscopic and mass spectrometric assistance, respectively. This work was supported by The Skaggs Institute for Chemical Biology, the National Institutes of Health USA, CaP CURE, Novartis, and by fellowships from the Netherlands Organization for Scientific Research (NWO) (to F. v. D.), Novartis (to D. V.), the Japanese Society for the Promotion of Science for Young Scientists (to S. H.), and the Department of Defense, USA (to J. P.). F. v. D., T. O., D. V., J. X., and S. H. contributed equally to this project.



1: eleutherobin

2: Taxol



3: R = H : epothilone A
4: R = Me : epothilone B

Figure 1. Molecular structures of eleutherobin (**1**), Taxol (**2**), and epothilones A (**3**) and B (**4**) (Ac = acetyl, Bz = benzoyl).

The structure of eleutherobin (**1**), which is similar to those of eleuthosides[10] A and B, sarcodictyins[11–14] A and B, and valdivones[15], includes a synthetically challenging tricyclic skeleton (**ABC**, Figure 2) and two side chains, one containing an

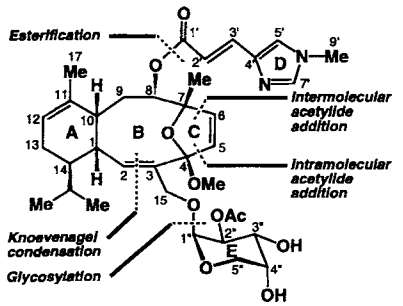


Figure 2. Numbering and strategic bond disconnections of eleutherobin (**1**) (Ac = acetyl).

(*E*)-*N*(6′)-methylurocanic acid residue (**D**) and the other a *β*-linked 2″-*O*-acetyl-D-arabinopyranose unit (**E**). The strategy for the total synthesis of this naturally occurring substance was designed based on a retrosynthetic analysis featuring the strategic bond disconnections highlighted in Figure 2. Thus, a properly functionalized ring **A** was to be derived from (+)-carvone and elaborated to a more advanced intermediate by an intermolecular acetylide addition to a ketone and a Knoevenagel condensation with an aldehyde functionality to form bonds C6–C7 and C2–C3, respectively. A glycosylation with a suitably functionalized D-arabinose derivative was then to follow, in order to introduce the carbohydrate moiety, whereas an intramolecular acetylide-aldehyde condensation was expected to form the 10-membered ring of the target molecule (bond C4–C5). Oxidation to an ynone and protecting group manipulations, followed by selective reduction of the triple bond (C5–C6) was expected to allow formation of the **BC** framework by intramolecular attack of the C7 hydroxyl function on the C4 carbonyl group. Finally, the (*E*)-*N*(6′)-methylurocanic acid moiety was to be introduced by esterification, following which eleutherobin (**1**) was expected to emerge upon deprotection.

Scheme 1 summarizes the construction of the initially targeted key ynal precursor **18**. Thus, the (+)-carvone-derived,[14, 16] TBS-protected (for abbreviations see legends) aldehyde **5** was converted to a C8 mixture (about 1.25:1) of hydroxyketones **6** by reaction with 1-ethoxyvinyllithium followed by acid hydrolysis (82% overall yield). Addition of ethynylmagnesium bromide to hydroxyketones **6** led, stereospecifically,[17] to a mixture of two acetylenic diols (C7, C8) **7** in 76% overall yield. Desilylation of **7** with TBAF afforded, after flash chromatography (silica gel, ether/hexane 3:1), pure triol **8** (52% yield) along with its C7, C8 diastereoisomer (40% yield). Triol **8** (identified by correlation with a previously synthesized sample)[14] was then converted to the primary alcohol **10** by persilylation (TES-OTf) and selective monodesilylation (PPTS-MeOH) in 98% overall yield. Oxidation of **10** with TPAP-NMO[18] then produced aldehyde **11** (98% yield) which underwent smooth Knoevenagel condensation with ethyl cyanoacetate in the presence of *β*-alanine[19] to afford, stereoselectively, the desired (*E*)-*α*,*β*-unsaturated cyanoester **12** in 95% yield. The reduction of **12** with DIBAL at −78 to −10 °C (hexanes) proceeded in high yield and with remarkable selectivity to afford the desired glycosylation acceptor, hydroxyaldehyde **13** in 75% yield.

The D-arabinose trichloroacetimidate derivative **17** required for coupling was prepared from the previously synthesized[20] phenyl thioglycoside **14**: The reaction of **14** with PMB-Cl in the presence of NaH afforded **15** (93% yield), and the acid-induced removal of the acetonide group gave the expected diol (84% yield). Subsequent silylation with TBS-OTf led to **16** (97% yield), whose reaction with NBS in acetone:H_2O (93:7) gave the corresponding lactol (80% yield), which underwent a reaction with CCl_3CN in the presence of NaH to give **17** (93% yield)[21].

Coupling of **13** with **17** (2.0 equiv) in ether proceeded smoothly in the presence of TMS-OTf at 0 °C to afford predominantly the *β*-glycoside **18** along with its *α*-anomer (**18′**) in high yield. Flash column chromatography (silica gel, Et_2O in hexanes, 1:20) led to pure *β*-glycoside **18** (54% yield) and *α*-glycoside **18′** (28% yield) (for spectroscopic data see Table 1).

The conversion of ynal **18** to eleutherobin (**1**) followed the path shown in Scheme 2. Ring closure of **18** was facilitated by the action of LiHMDS in THF at −20 °C, which furnished the 10-membered ring alcohol **19** (mixture of C4 diastereoisomers). Oxidation of **19** with Dess–Martin reagent[22] then led to the bis-conjugated ketone **20** (80% overall yield from **18**). At this stage, the acetyl group was installed on the carbohydrate ring of the molecule by removing the PMB group (DDQ, 90% yield) and acetylating the resulting secondary alcohol **21** (Ac_2O, Et_3N, 4-DMAP, 90% yield). The acetate **22** was then exposed to $Et_3N \cdot 3HF$ in THF at 25 °C, conditions which allowed the selective removal of both TES groups leading to diol **23** in 86% yield. Compound **23** was then subjected to Lindlar hydrogenation conditions, which gave crude lactol **25** in high yield. Although the postulated intermediate, bis-enone **24**, was not detected, its intermediacy in this sequence is logical and indeed required. Treatment of lactol **25** with PPTS in MeOH at 25 °C led to the isolation of its methoxy derivative **26** in 78% overall yield from **23**, as a single stereoisomer. The *β*-stereochemistry of the methoxy group in **26** was assumed on the basis of molecular models, and was confirmed by its conversion to eleutherobin (**1**).

For the purposes of esterification, the known[23] ethyl (*E*)-*N*(6′)-methylurocanate **27** (Scheme 2) was sequentially converted to sodium salt **28** (NaOH, THF, H_2O) and *tert*-butyl dride **29** [*t*BuC(O)Cl, THF, about 90% overall yield]. The at-

tachment of the (*E*)-*N*(6')-methylurocanic acid residue onto the main framework of eleutherobin was accomplished by reacting alcohol **26** with mixed anhydride **29** in the presence of Et_3N and 4-DMAP in CH_2Cl_2 at 25 °C, furnishing ester **30** in 75% yield (for spectroscopic data see Table 1). Finally, exposure of **30** to TBAF in THF generated eleutherobin (**1**) in 88% yield. Synthetic eleutherobin (**1**) exhibited identical properties to those reported[1, 2] for the natural substance (^1H and ^{13}C NMR, MS, $[\alpha]_{25}^{D}$, IR, and UV). The synthetic correlation of eleutherobin (**1**) ($[\alpha]_{25}^{D}$ = 67 (c = 0.2, MeOH)) to (+)-carvone and D-arabinose establishes its absolute stereochemistry as that shown in structure **1**.

In order to explore the structure–activity relationships of eleutherobin, two novel analogues were designed and targeted

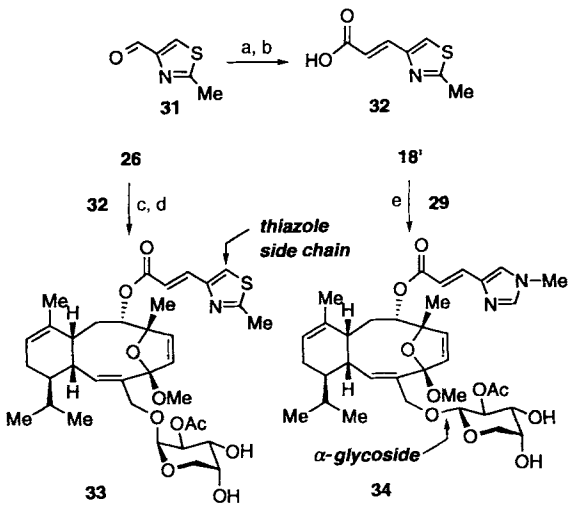
LiHMDS = lithium hexamethyldisilazide, DDQ = 2,3-dichloro-5,6-dicyano-1,4-benzoquinone, Ac = acetyl, 4-DMAP = 4-dimethylaminopyridine, PPTS = pyridinium *p*-toluenesulfonate, TBAF = tetra-*n*-butylammonium fluoride.

for synthesis (Scheme 3). The epothilone-inspired analogue **33**, which carries a thiazole-containing side chain instead of the *N*(6′)-methylurocanic acid residue, was constructed by esterification of alcohol **26** (DCC, 4-DMAP, 70% yield) with the corresponding carboxylic acid (**32**, prepared from aldehyde **31**[24] as shown in Scheme 3), followed by TBAF-induced desilylation (85% yield). The α-glycoside analogue of eleutherobin, compound **34**, was constructed from the α-glycoside **18′** (Scheme 3)



Scheme 3. Structure and synthesis of eleutherobin analogues **33** and **34**: a) $Ph_3P{=}CHCO_2Me$ (1.5 equiv), benzene, 80 °C, 85%; b) LiOH (3.0 equiv), THF:H_2O (1:1), 97%; c) DCC (1.8 equiv), 4-DMAP (0.5 equiv), **32** (2.0 equiv), CH_2Cl_2, 25 °C, 6 h, 70%; d) TBAF (5.0 equiv, 1 M in THF), THF, 25 °C, 3 h, 85% e) see legend to Scheme 2. DCC = 1,3-dicyclohexylcarbodiimide, 4-DMAP = 4-dimethylaminopyridine, TBAF = tetra-*n*-butylammonium fluoride.

by the same sequence and in similar yields as described for eleutherobin (**1**).

In the filtration-colorimetric tubulin polymerization assay[5] using MAP-rich tubulin, synthetic eleutherobin (**1**) and its analogues **33** and **34** exhibited activity comparable to that of Taxol (**2**) (**2**: 49%; **1**: 70%; **33**: 56%; **34**: 54%). The data for eleutherobin (**1**) are consistent with those obtained with the natural substance (**1**),[2, 25] whereas those for **33** and **34** establish the first important and path-pointing structure–activity relationships within the eleutherobin family.

The described chemistry opens a pathway for a practical synthesis of eleutherobin (**1**) and its analogues. Furthermore, the reported chemical synthesis allowed the assignment of the absolute stereochemistry of the natural product, and the preparation of its first biologically active analogues (**33** and **34**). Applications to the large-scale production of eleutherobin (**1**) and the generation of combinatorial libraries of this and related structures for chemical biology studies are now possible.

Fuzzy Definitions

Concepts in Chemistry—A Contemporary Challenge. Edited by *D. H. Rouvray*. John Wiley & Sons, Chichester, 1997. xvi, 420 pp., hardcover £ 65.00.—ISBN 0-86380-200-1

The sixth in the series of Mathematical Chemistry Conferences was held on July 10–14, 1995, in Pitlochry, Scotland. The title of the conference was "Are the Concepts of Chemistry all Fuzzy?" Two books on mathematical chemistry have emerged from this meeting, both edited by one of the conference organizers, Professor Dennis H. Rouvray. One of them is under review here; the other is *Fuzzy Logic in Chemistry* (Academic Press, San Diego, 1997). Although the list of contributors is different in the two books, there is considerable overlap in the contents, with a very fuzzy dividing line between them. Thus it is curious that neither of the books makes explicit mention of the other.

The original stimulus for the editor's interest came from a dust jacket comment by Martin Gardner that "outside of mathematics and logic, all definitions are fuzzy." A statement by H. A. Kramers in 1946 is repeatedly quoted: "... in physical science in particular, the most important and fruitful concepts are those to which it is impossible to attach a well-defined meaning."

The 12 chapters of the book cover a wide range of topics and vary considerably in the depth of treatment of their subject matter. The introductory chapter by the editor, "Are the Concepts of Chemistry all Fuzzy?", is followed by one on the partnership between mathematics and chemistry (N. Trinajstic). This chapter goes back to such fundamentals as the definition of science and the roots of mathematics and of chemistry, and also covers such recent events as the discovery of buckminsterfullerene. It defines mathematical chemistry as "that part of theoretical chemistry which is concerned with the application of mathematical methods in the chemical world."

The next two chapters also deal with broad conceptual topics, one with periodicity (E. V. Babaev and R. Hefferlin) and the other with chemical structure (J. L. Villaveces C. and E. E. Daza C.). The remaining eight chapters focus on more specific areas such as allotropic structures, aromaticity, ring currents, porous delocalization of superconductors, chirality (two chapters), complexity, and immunological recognition.

Lest we judge the title of the book too pretentious, we must remember that the divergence of topics and depth of discussion derive from the conference program. There are conspicuous omissions from the point of view of the interplay between mathematics and chemistry, for example combinatorial chemistry and quasicrystals, both being recent hot topics. Nonetheless, what is presented here is a rich collection of interesting contributions.

One section in the chapter "The Concept of Chemical Structure" does not do justice to the rest of the volume. There are some trivial points that could easily be corrected, for example electron diffraction is called "electronic diffraction", and neutron diffraction is described as being performed on gases. Incidentally, electron diffraction is listed as a new experimental technique, quite a compliment for this 67-year-old tool, even if only gas-phase studies are considered. However, one aspect that could be conceptually damaging is the discussion of differences in the form of structural information originating from different techniques. The authors state that "this situation has created a profusion of geometrical parameters that greatly complicate the definition of molecular geometry." However, the complication may arise only from the lack of understanding of the physical origin of differences among these geometrical parameters. Decades ago, precision was generally too low to warrant concern about the differences in the physical meaning of the structural information originating from different techniques. Nowadays, however, a precise measurement or computation needs to be qualified by additional information as to its origin, so that one can assess its accuracy. To simply compare "experimental" and "computed" data, for example, is no longer acceptable because they may have a different physical basis. In addition to the difference in the physical phenomena utilized in various techniques, the extent of motion plays an important role in this, because of the very different ways in which the motional effects are averaged. The extent of motion also greatly influences the applicability of our model of chemical structure. We have to educate ourselves to an increased degree of rigor in these aspects, whether we are providers or users of structural information. This is a conceptual question, and this book missed an important opportunity to put it in proper perspective.

All in all, however, this book, along with its companion volume, discusses contemporary questions of mathematical chemistry at a high level. It has the potential of making its topics—which to many appear esoteric—accessible to a broad circle of chemists. Therefore, I recommend it to graduate students and researchers interested in aspects of their field beyond the confines of their research projects.

Fuzzy Logic in Chemistry. Edited by *D. H. Rouvray*. Academic Press, San Diego, 1997. 364 pp., hardcover $ 80.00.—ISBN 0-12-598910-6

The review articles collected together in this book are extended versions of papers presented during a conference held in 1995 on the subject of fuzzy logic in chemistry. The contributions can be roughly divided into three categories: introductory articles of a scientific/philosophical nature, articles concerned with the intrinsic problem of uncertainty and/or with the potential applications of fuzzy methods,

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

and lastly those in which the mathematical techniques based on the theory of fuzzysets are used to solve chemical problems. Rather surprisingly, there is no contribution on fuzzy control methods.

In the first article D. H. Rouvray explains how the motivation to develop a theory that can be applied to inexact quantities is a consequence of uncertainties that are inherent in the systems under investigation. Central to this is the philosophical question of the connection between knowledge, the degree of truth of that knowledge, and uncertainty. He gives a useful compilation of various definitions of uncertainty, emphasizing that there is no general agreement on this point.

The title chosen by G. Klir for his contribution already betrays the fact that he approaches the task of giving a mathematical introduction to the subject only in a half-hearted way. Instead, his article too consists largely of a discussion of philosophical aspects. It would have been more useful to put a greater emphasis on reporting the forum discussions between mathematicians and chemists, so as to clarify the issues and concepts; for example, compare the conflicting statements of Klir and Bangov about the relationship between fuzzy set theory and probability theory.

The next two articles belong to the second of the categories mentioned above. That by A. Amman sets out to provoke thought about the concept of chemical structure. Starting from quantum-mechanical considerations, he throws up a number of questions that can be expressed generally as follows: can deviations from classical behavior in chemistry be understood by treating strict classical behavior as a limiting case that corresponds to a crispset? According to this view, quantum-mechanical deviations from that situation, which result from a finite number of degrees of freedom or from finite masses, correspond instead to fuzzy sets. K. Mislow is thoroughly committed to the fuzzy concept in chemistry, and shows that in any case one does in fact think and express ideas in terms of fuzzy theories. In the main part of his article he gives a concise summary of his work on extending the concept of chirality.

All the following articles are concerned with applications of fuzzy set theory to the solution of chemical problems. The 86-page contribution by P. Mezey begins by discussing the relationship between fuzziness and resolution, and then deals with resolution-dependent chirality, symmetry, or measures of symmetry. In considering how to develop a fuzzy way of modeling electron density, Mezey uses the analogy between α-cuts and electron density levels, and also develops a generalization of the Hausdorff distance incorporating fuzziness. From this basis he then develops fuzzy generalizations of symmetry elements, measures of symmetry, and other classical concepts, which are used to describe the degree of correspondence of molecular form and size. He ends by describing various methods for calculating fuzzy electron density fragments, which are then stored in numerical databases and can be used as building blocks for constructing macromolecular electron density maps.

J. Brickmann discusses the use of mutual matching methods for molecular recognition. The starting point for this is the classification problem involved in the lock-and-key principle. One stage of this concerns the transformation of numerical data into diagrams, which allows one to visually inspect the system under investigation. To test the compatibility of numerical data with abstract categories of human thought processes, Brickmann uses the concept of linguistic variables. Finally he applies membership functions to a description of a soft surface, and develops strategies for fuzzy pattern recognition on surfaces.

The articles by J. Xu and I. Bangov are concerned with the use of fuzzy logic for interpreting spectra, with particular emphasis on applications involving 2D NMR techniques. Both authors set out to explain how fuzzy spectroscopic data can be correlated with fuzzy molecular graphs. Xu divides his method into two stages: first one evaluates the extent of agreement between the spin–spin couplings and the molecular topology, and secondly one evaluates the degree of similarity between the graphs by a fuzzy distance measurement. However, the explanation could have been improved by a better matching between the schematic examples that are given. The article ends by touching briefly on applications to IR spectroscopy and mass spectrometry. Bangov provides some well worked out examples of the use of fuzzy methods in computer-aided structure determination. However, Equation (5) contradicts Figure 1, and also appears to contain a printing error, as it implies that the number of spectral features available for determining the structure is equal to the number of atoms. Furthermore, on the basis of this equation the author derives some generalizations that are open to question. In the main part of the article Bangov gives a breadth-frist algorithm that can be used for generating structures, and allows the risk of a combinatorial explosion to be kept under control more effectively than in depth-first procedures.

The article by D.-D. Dumitrescu is concerned with the classification of unknown samples using fuzzy cluster analysis. In the mathematical part he proposes an extension of Bezdek's "fuzzy-c-means" algorithm. His approach to the "cluster validity" problem is based on proving the existence of a hierarchical structure within the data, and for this purpose he introduces the degree of polarization of a fuzzy partition. The algorithm makes use of binary partitions (divisive hierarchical clustering) based on procedures analogous to fuzzy-c-means. Furthermore, by using fuzzy cross-classification, the author classifies the objects according to their variables and the variables according to the objects, and investigates their interrelationship in the partitions. Some examples of analytical applications of these methods are described.

The fact that D. H. Rouvray has taken on the task of collecting together, for the first time, reports of work on the applications of fuzzy methods in chemistry-related research, is very much to be welcomed. Therefore, the uniqueness of this work—at least for the present—is in itself sufficient reason for recommending *Fuzzy Logic in Chemistry*. It will be useful not only for specialists in the particular fields concerned to study how classical concepts are being extended, but also for everyone interested in these methods, as an overview showing how far the theory of fuzzy sets has already entered chemical research.

Alkyl Polyglycosides. Technology, Properties and Applications. Edited by *K. Hill, W. von Rybinski* and *G. Stoll.* VCH Verlagsgesellschaft, Weinheim, 1996. ix, 242 pp., hardcover DM 148.00.—ISBN 3-527-29451-1

The appearance of a monograph on the properties and uses of alkyl polyglycosides (APGs), a new and interesting class of surfactants, is a welcome development. It will be especially useful for chemists who are active in the field of surfactants and are seeking new areas of application. The painstaking work of compiling the first complete picture of the technology, the physical and chemical properties, and the many applications of APGs has been undertaken by 36 scientists of the Henkel research group. This

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2526 $ 17.50+.50/0

was no easy task in view of the breadth of the subject and the enormously wide range of practical applications, and success was only made possible through the powerful research resources of the Henkel group.

The monograph consists of 14 chapters. Chapter 1 reviews the history of the industrial development of APGs and their place in surfactants chemistry, then Chapter 2 describes the technology of this class of compounds and the methods whereby they are synthesized, with clearly set out process schemes which help the reader's understanding. Chapter 3 describes the methods used for the analysis of APGs (HPLC, chromatography, etc.), enlivened by many instructive examples. Chapter 4 gives a very informative discussion of the physical and chemical properties of APGs, including mixtures of two or more compounds. Phase diagrams and related aspects are covered, thus providing the basis for understanding the later chapters. As well as treating binary and multicomponent systems, this chapter deals with the rheological properties of APGs, interfacial phenomena, and phase diagrams for microemulsions. This treatment provides the first comprehensive picture of the properties of APGs in their many aspects and variations, especially for multicomponent systems. Chapter 5 moves on from the basic knowledge covered in the previous chapters by describing the cosmetic and dermatological properties of APGs, and Chapter 6 discusses the cleansing effects of APGs on "hard" surfaces. Chapter 7 is concerned with the "formulation problems" involved in the agricultural uses of APGs. Chapters 8–10 then deal with synthetic aspects of the new nonionics and with their toxicological and dermatological properties. Chapters 11 and 12 are concerned with the environmental aspects of the use of APGs. Chapter 13 contains valuable information about the patent situation with regard to APGs, and lastly Chapter 14 gives a brief survey of the position regarding feedstocks for manufacturing APGs.

This monograph is unique in its treatment of a wide range of properties of APGs that are relevant to their applications, and thus it is extremely valuable for the laboratory scientist working in this field. As a consequence of the way in which the volume has been written, a certain amount of overlapping is unavoidable. The individual chapters make effective use of diagrams and schemes to aid the reader's understanding. There is a useful bibliography at the end of each chapter, although this often includes references to company research reports that are not easily accessible for ordinary readers. A possible improvement to the book would be to introduce each chapter with a short summary.

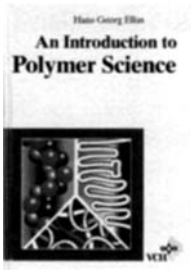
An Introduction to Polymer Science. By *H.-G. Elias*. WILEY-VCH, Weinheim, 1997. xxii, 470 pp., hardcover DM 88.00—ISBN 3-527-28790-6

This book is invaluable. It is well written, well organized, and captures the multidisciplinary nature of the field of polymer science. The book is organized into three sections with a total of fifteen chapters covering the various aspects of polymer chemistry, polymer physics, and polymer processing. It starts with a good introduction giving the reader a history lesson in the discovery/invention and subsequent development of polymer science. Then the author covers the basics of polymer structure and molecular weight distribution. Instead of separating the experimental determination of molecular weight distribution from the theoretical aspects (as commonly done in other textbooks), the author addresses both the theoretical aspect and experimental determination within the same chapter. This is an improvement over the way other authors present the subject. The remaining chapters in the "Chemistry" section cover the gamut of types of polymerization, including the usual anionic, cationic, free radical, and step growth. The chapter on free radical copolymerizations and the following appendix to Chapter 3 are especially well done. In addition, the chapter on biological polymerizations is helpful with respect to natural fiber production.



The next two sections of the book cover the physics and physical chemistry of polymers. The physical chemistry section concentrates on polymer packing, polymer chain motion, viscosity, and polymer thermodynamics. There is a strong emphasis on theoretical considerations within these sections. The section on polymer physics focuses on bulk properties of polymers. There is a particularly comprehensive chapter within this section on polymer transitions and relaxations. Finishing up this section is a chapter on solid state properties, which covers viscoelastic concepts, deformation of polymers, and failure modes of polymers. The last section of the book is entitled "Technology", meaning polymer technology. This section covers the pragmatic nuts and bolts of polymer processing, usage, disposal, and recycling.

Overall, the book is outstanding in a number of areas. The author is diligent and well organized with regard to the references at the end of every chapter, and general references for more in depth discussion of subject matter are always readily accessible. In addition, a comprehensive table of symbols and succinct appendices round off a truly excellent job of documentation. As an instructor, I found that some of the sections and some of the figures used as examples were more geared towards an intermediate audience rather than to beginning students in polymer science. As a reference source for technicians and scientists in industry who work in the polymer field, this is a "must have" book. However, most of the chapters are very well suited to instructing the novice polymer scientist, and I will use this book as a supplementary textbook for my next course.

Enzymes. A Practical Introduction to Structure, Mechanism and Data Analysis. By *R. A. Copeland*. VCH Publishers, New York, 1996. 322 pp., hardcover DM 89.00.—ISBN 1-56081-903-0

This book is intended to serve as an introduction to working methods in enzymology for beginners. Seven of the eleven chapters are mainly devoted to a meticulous treatment of kinetic methods and the analysis of the data obtained.

Chapter 1 presents a short history of enzymology, which is unfortunately too brief and contains inaccuracies. Sanger published the complete sequence of insulin in 1953, not in 1957 as stated here, and his method did not involve the Edman breakdown reaction (p. 7). Chapter 2 contains a basic summary of the knowledge of general chemistry that should be familiar to every science student who has successfully reached the pre-degree year. Chapter 3, "Structural Components of Enzymes", summarizes the standard textbook knowledge concerning protein structure. The structures of five arbitrarily chosen cofactors are described; however,

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2527 $ 17.50+.50/0

the structure shown under the heading "nicotinamide" is that of the dihydro compound.

Chapter 5 is concerned with the chemical mechanism of enzyme catalysis, and explains the most commonly cited concepts and theories, which are associated with the names of Pauling, Koshland, Jencks, and Fersht. The "three-point attachment" concept is illustrated schematically using the example of alcohol dehydrogenase, but there is no mention here of the name of Ogston. The author fails to provide a geometrical explanation for the stereoselectivity. The serine proteases are discussed as an example of a detailed enzymatic mechanism. This chapter ends with sections on acid–base, nucleophilic, and electrophilic catalytic reactions.

The part of the book that is most useful for the experimentalist begins with Chapter 5, which deals with the stationary phase kinetics of single-substrate reactions. This concentrates mainly on the classical Michaelis–Menten kinetic model, with the usual mathematical, graphical, and linearized representations and analysis. The significance of the kinetic constants such as K_m, V_{max}, and k_{cat}/K_m, and various possible cases that can arise in measurements and calculations, are discussed in detail. Unfortunately, however, the running title throughout this chapter omits the important word "steady", so that it loses its intended meaning. Chapter 6 contains very detailed laboratory procedures for isolating enzymes and testing their activity. Sometimes aspects that are obvious are explained in minute detail. For example, the advice given on page 137 that turbid solutions can be cleared by filtration or centrifuging to remove particles (with a reference to the author's own report on this) is unnecessarily elaborate. The effects of pH, temperature, and isotopes on the enzyme activity are also discussed in this chapter.

The following three chapters deal with the various types of enzyme-inhibiting effects: reversible, tight-binding (practically irreversible), and time-dependent. The author's expertise is seen to good advantage in the treatment of this topic. He presents a rigorous and thorough discussion of competitive, noncompetitive, and uncompetitive inhibition processes, illustrated by examples. The practical importance of enzyme inhibitors in the pharmaceutical and agrochemical industries is emphasized by discussing examples such as Methotrexate, Flubriprofen, Mevinolin, and DuP697 (a prostaglandin G/H synthase inhibitor). The descriptions taken from the author's own research in this field are especially effective.

The last two chapters (10 and 11) are devoted to the kinetics of enzymatic reactions involving several substrates and to cooperative phenomena in enzyme catalysis. The book ends with two appendixes listing commercial suppliers of importance to enzymologists (with addresses) and computer software.

Enzymologists with a chemical bias will find that the book contains less on the structural aspects of enzyme catalysis than the title suggests. With regard to enzyme test methods the main emphasis in the book is on the UV spectroscopic assay, which is the method of choice for kinetic studies. For structure determination much more detailed information can be obtained by NMR spectroscopy, stereospecific isotopic labeling, and the use of substrate analogs, combined with site-directed mutagenesis. To sum up, Copeland has written a book that will be very useful for the enzyme kineticist, but will have only limited value outside this relatively narrow area of interest.

Organic and Bio-organic Mechanisms. By *M. Page* and *A. Williams*. Addison-Wesley Longman, London, 1997. 298 pp., paperback £ 27.99.—ISBN 0-582-07484-3

The authors have written this book for advanced students, post-graduate students, and practicing scientists who are interested in mechanistic studies in organic and bioorganic chemistry, to provide these readers with an introduction to the subject. Some previous knowledge is assumed, and therefore the authors have not felt it necessary to include a long-winded introduction to the theory of transition states and kinetics; instead they deal with these aspects briefly and then quickly come to the main topic. The book is structured in such a way that individual readers have the choice of either going straight to the chapters that are most relevant for them, or working through the very readable chapters that explain the methodology of studying reaction mechanisms. The ease with which the authors are able to treat both conventional organic reactions and the enzymatic mechanisms of bioorganic chemistry using the same models and techniques is refreshing.

The book can be divided into three parts. The first two chapters deal with the fundamentals (transition states and kinetics). Then, in Chapters 3–6, the authors discuss the dependence of transition states on molecular structure, followed by isotope effects and solvent effects. Chapter 6, entitled "Transition State Structures—Anomalies", explains how certain situations can lead to incorrect conclusions about the mechanism. This chapter also serves to set the reader a sort of "on-line test", as the arguments are based on the fundamental principles explained earlier, allowing one to assess how well one has assimilated these ideas. In the third part, Chapters 7–10, some important aspects of enzymatic reactions and enzyme modeling systems are discussed.

The book begins, logically, with a chapter on the central idea of the transition state, factors that can stabilize it, and its importance in the progress of a reaction. Specific aspects of the transition state such as the stereoelectronic effect, energy transfer, and the principle of least movement are discussed. Chapter 2 deals with models for describing reaction kinetics, ranging from the simple rate equation to the Curtin–Hammett principle and labeling experiments. Here again the authors use examples from organic and bioorganic chemistry. The next three chapters may be grouped together under the heading of factors influencing the transition state and the reaction kinetics. Chapter 3 is concerned with the effects of structural factors on the reaction mechanism; here the important words "Hammett equation" give an indication of the chapter's contents. However, the text is not well matched to the diagrams, and as a result the reader is likely to be confused. Chapter 4 deals with the various aspects of isotope effects, then Chapter 5 describes how the reaction mechanism can be influenced by external factors such as different solvents, strongly basic or acidic media, temperature, and pressure. If this book had been a technical manual, Chapter 6 might well have been given the title "troubleshooting", as it deals with anomalies of the transition state, such as microscopic medium effects and Brönsted anomalies.

In Chapter 7 the authors consider the mechanisms by which functional groups of biological importance are transferred. Particular attention is given to the distinction between concerted and sequential mechanisms. Unfortunately, however, the treatment here is less thorough than in the previous chapters. For example, one might have expected that after explaining

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2528 $ 17.50+.50/0

(on page 13) the conclusions that can be drawn from the three-dimensional energy diagram, the authors would have cited this as evidence for a dissociative mechanism in the hydrolysis of phosphoric acid monoesters (S. J. Admiral, D. Herschlag, *Chemistry and Biology* **1995**, *2*, 729–739). In this chapter the possible reaction paths are described only in a general way, which is regrettable. Again, in Chapter 8, the important role of metal ions in the hydrolysis of acyl derivatives is not covered adequately, being limited to the Lewis acid activity and the increase in the acidity of coordinated water. Some important aspects, such as the suppression of pseudorotation in the hydrolysis of phosphates, are not mentioned.

Chapter 9 describes enzyme models, mainly involving a host–guest interaction followed by a reaction. Here the authors mention the important studies by Breslow using cyclodextrin as the guest molecule, as well as reactions involving micelles or macromolecules. Lastly, in Chapter 10, enzyme mechanisms are classified under five basic types—acyl group transfers, proton transfers, C–C bond-forming reactions, hydride transfers, and alkyl group transfers—and are discussed with the help of examples. The description of the mechanisms in this chapter gives a useful insight into enzymatic reactions, although the depth of treatment is scarcely more than one finds in a good organic chemistry textbook. Also the chapter fails to cover some important mechanisms, such as that of ribonucleotide reductase, or to discuss important techniques used to study enzymatic mechanisms, such as ESR spectroscopy.

The authors place special emphasis on the quantitative treatment of the reaction kinetics, and to this end they provide a useful appendix containing tables of various kinetic parameters, such as Hammett constants.

The book's main strength is in the descriptions of organic reactions. Although the authors cover the theoretical fundamentals for describing complex enzymatic reactions very thoroughly, the treatment of the mechanisms of such reactions in the second part of the book does not match up to the first part as regards depth and detail. As a further criticism of the book, some important methods that give only a semiquantitative or purely qualitative description of enzymatic processes are not mentioned, even though there exist many important and highly topical processes for which kinetic data alone are insufficent to determine the mechanism. The book can be recommended for readers who wish to brush up their knowledge about solvent effects and isotope effects, and about kinetic measurements for studying reaction mechanisms. However, for anyone seeking a comprehensive treatment of the details of biological reaction mechanisms, this is not a suitable book.

Fundamental Toxicology for Chemists. Edited by *J. H. Duffus* and *H. G. J. Worth*. Royal Society, Cambridge, 1996. 329 pp., paperback £ 29.50.—ISBN 0-85404-529-5

Modern toxicology is an interdisciplinary subject involving chemistry, biology, medicine, and pharmacology, with the aim of understanding the dangers caused by chemicals and identifying areas of risk. These arise in the field of university teaching just as elsewhere, and lectures on the subject are provided for science students in German universities. Attendance at these is compulsory for chemistry students. The German Chemical Society (GDCh) recently set up a new working group on "Umweltchemie und Ökotoxikologie" (Environmental Chemistry and Ecotoxicology), a choice of name which underlines the importance attached to this subject. The main purpose of ecotoxicology is to investigate the risks of environmental damage from chemicals, and to suggest preventive measures.

This book has been sponsored by the International Union of Pure and Applied Chemistry (IUPAC), and is intended to serve mainly as an introductory textbook for chemistry undergraduates in British and American universities. The 21 chapters are the work of 16 authors. An introduction to the principles and methods of toxicology is followed by chapters dealing with the following aspects in the order given: toxicological kinetics and dynamics; the interpretation of data; risk assessment; risk management; exposure and monitoring; mutagenicity; carcinogenicity; reproductive toxicology; immunotoxicology; skin toxicity; inhalation toxicity; liver toxicology; renal toxicology; neurotoxicology; behavioral toxicology and cotoxicology; a chapter on radionuclides, biocides, and pesticides; safe handling of chemicals. Finally there are two appendices containing a curriculum on toxicology for chemists, and a glossary of commonly used terms. The topics covered correspond essentially to those that make up a typical lecture series on toxicology for students of natural sciences. The book could serve both as a useful accompaniment to such a lecture course for chemists, and as an introduction to toxicology for individual study.

As always with multiauthor textbooks, there is a danger that the chapters may show large differences in the quality of the writing. It is part of the editors' role to prevent this, but in this case they have not been very successful. In fact, a few of the chapters are of a poor standard. For example, the author of the chapter on mutagenicity gives a detailed description of the structure and function of DNA and of the genetic code, but fails to devote similar attention to commonly used toxicological procedures such as the Ames test or the HPRT/TK mutagenicity test using mammalian cell cultures (V79 etc.). Also the book does not include enough discussion of the relationship between chemical structures or compound classes and their toxicological properties, an aspect that is of particular interest to the chemist.

The value of this monograph must also be measured against the several German language textbooks on toxicology that have appeared in the last few years. If we compare it, for example, with the recently published book by Greim and Deml (*Toxikologie*), it fails to reach a similar standard. Also the new book by Dekant and Vamvakis (*Toxikologie*) is considerably better as an introduction for chemists, and is more soundly planned than this English-language textbook. Thus we can, at best, only recommend this book as supplementary reading to accompany a lecture course on toxicology.

Handbook of Downstream Processing. Edited by *E. Goldberg*. Chapman & Hall, London, 1997. 720 pp., hardcover £ 149.00.—ISBN 0-7514-0364-4

One of the more complex, and at the same time fascinating, tasks of pharmaceutical biotechnology is that of isolating products from downstream processing, starting from biological sources, to provide new lead structures. There are no standard and universally applicable methodologies or strategies for isolating secondary metabolites or recombinant proteins produced by fermentation. The route from the culture solution to the pure isolated substance still depends to a large extent on the experimentalist's store of past experience and imaginative resources. Moreover, the procedure of finding new biologically active lead structures

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2529 $ 17.50+.50/0

from natural sources is made much more complicated when, in addition to the problems of isolating pure substances from fermentation products, one is constrained by the regulations and guidelines of "good manufacturing practice". One of the main aims of this book edited by E. Goldberg is to provide help with that task and to apply some systematic concepts to the complex subject of downstream processing.

The 720-page book contains 26 chapters by 33 different practitioners and experts, of whom all but two are from the USA and other parts of the English-speaking world. Many of these have a background in process technology. Thus the book is intended mainly for chemical and pharmaceutical process engineers who are involved in the design and construction of plant and buildings for biotechnology, and/or with the production and isolation of biologically active natural products, including the development and optimization of the relevant processes. Accordingly, therefore, most of the chapters deal with routine process stages such as cell disruption, filtration, solvent extraction, solid-phase extraction, membrane techniques, crystallization, and freeze-drying. However, it is unfortunate that chromatographic methods, which often serve as the key steps in work-up procedures, are not given enough space here, with no more than just a short chapter on affinity chromatography and one on the scale-up of column chromatography methods. In contrast, for example, the chapter on distillation processes is quite long. Thus the treatment of chromatographic processes is inadequate for a book with the above title.

Although the book's main emphasis is on practical aspects, some chapters also discuss the physical-chemical fundamentals of the methods concerned, and include the most important mathematical formulas that are essential for understanding the principles. Each chapter ends with a comprehensive and fairly up-to-date bibliography, covering publications up to 1992. Some chapters also include information about commercial manufacturers of equipment. However, it is regrettable that these are limited to suppliers in the USA, even in cases where the market leader in a particular field is based in Europe or Japan. Moreover, it is not very helpful that numerical data are often given in feet, inches, or gallons, so that one has to convert these to SI units. Admittedly there is a conversion table in the book, but American authors in engineering disciplines should by now be gradually becoming accustomed to internationally accepted units. Also, the usual practice internationally is to give temperatures in degrees Celsius or Kelvin rather than Fahrenheit. Also, not surprisingly, the biological safety levels used in the USA do not have quite the same meaning as those in European countries. Nevertheless, the importance of these criticisms should not be exaggerated.

Some notes and comments on a few of the chapters now follow. First there is an excellent description of the most important methods of mechanical cell disruption. The advantages and disadvantages of grinding and high-pressure homogenization are discussed. In a future revised edition it would be useful to also treat nonmechanical methods in more detail than here; such methods are becoming increasingly important, e.g. for isolating plasmid-DNA.

This is followed by chapters on filtration, extraction, and crystallization. These describe the current state of the art in these processes, although I found them too theoretically orientated. On the other hand, the chapters on drying and freeze-drying are highly informative, even for the specialist; the latter chapter is especially good. The contribution on membrane processes is also excellent, but that on electrodialysis is too long, especially since this method has only limited use in scaled-up versions.

The comprehensive treatment of methods for cleaning and sterilizing machinery, plants, and work areas is especially welcome. "Clean-in-place" and "sterilization-in-place" methods are described in detail, with examples showing how to set out protocols for these procedures. Water purification methods are also given due attention, and there is even a chapter devoted to waste treatment, an important aspect of any biotechnological process. I was especially impressed by the chapters on the planning and validation of biotechnological processes, which contain a wealth of useful information, even for the specialist. The manufacturing processes for bulk materials and for biologically active agents are compared in a chapter which makes interesting reading, even though this topic was not strictly necessary in a book on downstream processing.

The book is very attractively produced, with a clear typeface. The text is relieved by many figures and tables which contribute to the reader's understanding. These include flow charts showing biotechnological processes and plants in accurate detail.

To summarize, the book offers a great deal of useful information for readers from all disciplines concerned with the work-up of feedstocks produced by biological processes under cGMP conditions, even though the relative emphasis given to the individual topics does not always seem appropriate. For a handbook of this kind the treatment of chromatography is less than adequate. Apart from this criticism, the book will certainly be a valuable resource, especially for technologists involved in the design and setting up of biotechnological processes and plant. It also contains many useful ideas for everyone seeking mild techniques for the work-up of culture solutions, and it is a valuable addition to the literature on biotechnology.

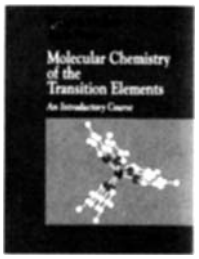
Molecular Chemistry of the Transition Elements. An Introductory Course. By *F. Mathey* and *A. Sevin*. John Wiley & Sons, Chichester, 1996. 232 pp., paperback £ 18.99.—ISBN 0-471-95687-2

A growing demand for modern textbooks in transition metal chemistry recently has led to the publication of several new textbooks covering various aspects of this vast field. Whereas some emphasize classical coordination chemistry and its concepts based on the paradigm set by Alfred Werner and his successors (e.g., M. Gerloch and E. C. Constable, *Transition Metal Chemistry*, VCH Verlagsgesellschaft), others are primarily devoted to the area of organometallic complex chemistry (and explicitly say so in their title, e.g., C. Elschenbroich and A. Salzer, *Organometallics*, 2nd edition, VCH Verlagsgesellschaft). The book by Mathey and Sevin belongs to the latter category and the choice of the title may be traced to the "unconventional approach" that the authors announce in the preface. This textbook, which is based on lecture notes and the teaching experience of both authors, is intended as a guide to the different aspects of structure and reactivity in organometallics, emphasizing a conceptual approach, in particular the molecular orbital picture.



In a very short (possibly too short!) introductory chapter the authors give an overview of the history of organometallic

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3622-2530 $ 17.50+.50/0

chemistry. Such historical chapters in textbooks tend to provoke criticism in reviews, since authors and reviewers have more or less subjective (usually disparate) views on how the history of a field of science should be presented. Nevertheless, the historical development of an area of science should be an integral part of a textbook, and the authors might consider expanding this section in a future edition of the book.

The second chapter, entitled "The fundamental concepts", aims to provide the basis of the whole didactic approach. The discussion covers formal electron counts of the most important ligands, some molecular orbital considerations, and the application of these to several important reactions, such as oxidative additions and reductive eliminations as well as nucleophilic attack at the CO ligand. My main criticism concerns the way in which molecular orbital theory is introduced. Although the students at the authors' universities may, at a very early stage of their course, have been taught the kind of fragment orbital approach to organometallic chemistry that was successfully introduced by R. Hoffmann and others, this is not generally so. Therefore an introduction to these methods, in particular the orbital perturbation approach, is absolutely necessary in a book which is explicitly aimed at the beginner in organometallic chemistry. However, this is not to deny that the fragment MO approach may be very effectively employed in the teaching of the concepts used to analyze structures and reaction pathways in organometallics.

Chapter 3 is a review of some of the most important chemical (especially structural) motifs in transition metal organometallic chemistry, introducing the basic features of metal hydrides, carbonyls and other compounds containing metal–carbon single and multiple bonds, π-coordination of olefins, and some important aspects of compounds containing metal–metal bonds. Unfortunately, several errors have crept into this section. For instance, the example given for a carbonylation on page 76 is actually a carboxylation, and the same reaction scheme is repeated one page later in the correct context. Another unnecessary duplication of reaction schemes has occurred with the reactions of Na[Mn(CO)5] on the same two pages. The section on phosphorus compounds (3.8) appears somewhat isolated and slightly misplaced in a book on transition metal chemistry.

Chapters 4 and 5 give a useful introduction to the applications of organometallic complexes in organic synthesis and homogeneous catalysis, covering both fundamental aspects and more recent developments. The authors succeed in developing the broad scope of present-day applications, and the examples they cite are well chosen.

In summary, I feel that the book could be a valuable addition to the existing introductory textbooks on transition metal organometallics if some of the theoretical fundamentals were introduced more coherently. Also some imprecise and occasionally confusing statements have crept in, although this may be due to the translation from the original French version. The book treats many aspects that have not been covered adequately by other textbooks. With some reservations as mentioned above, I can recommend it as a textbook for undergraduate chemistry students, not least because the paperback edition is very reasonably priced.

Understanding Reactivity Patterns of Radical Cations**

Michael Schmittel* and Armin Burghart

Dedicated to Professor Waldemar Adam on the occasion of his 60th birthday

Over the last 15 years electron transfer activation has emerged as a valuable concept for accomplishing novel reactions and has found widespread application in the selective transformation of increasingly complex molecules. This review presents in a conceptualized manner the vast number of radical cation reactions obtained after chemical, electrochemical, and photoinduced one-electron oxidation. To familiarize the reader with the concepts of electron transfer a simple and straightforward classification of radical cation reactions has been devised to allow the presentation of a manifold of reactions in a readily understandable manner. Whenever possible, thermochemical and kinetic data are provided.

Keywords: electron transfer · kinetics · radical ions · reaction mechanisms · thermodynamics

1. Introduction

While recent years have witnessed a steady increase in the use of complex reaction systems for accomplishing highly selective reactions, comparatively little attention has been devoted to exploiting the concepts of electron transfer in organic transformations. This is even more astounding in light of the fact that the transfer of one electron constitutes one of the simplest elemental reactions in chemistry, and is conceptually linked to photochemical activation. Although preparative photochemistry has adopted an important place in synthetic chemistry,[1] electron transfer chemistry[2] still awaits wide acceptance in the synthetic community in spite of the important merits of organic electrochemistry.[3]

Actually, only a small fraction of the plethora of preparative reactions is currently based on electron transfer processes.[4] Examples include the Birch reduction,[5] acyloin condensation,[6] Ullmann coupling,[7] formation of Grignard reagents,[8] and $S_{RN}1$ reactions.[9] Hence, most preparative chemists are still reluctant to use the concepts of electron transfer (ET) in a more general sense for designing new reactions. A reflection of this widespread neglect of ET concepts is the fact that we routinely investigate IR, NMR and UV spectroscopic data of compounds, but not their electrochemical data. A justification often quoted for this obvious neglect is the inherent complexity of ET-initiated processes and the lack of data available for making reliable predictions for new reactions. Consequently, this review was written in an attempt to provide a lucid perception of electron transfer activation concepts by, with the help of examples, juxtaposing results of preparative electron transfer chemistry and physical organic concepts.

Intriguingly, the last couple of years have shown a growing number of ET-promoted reactions that proceed with high selectivity and, in some cases, allow transformations that have never been realized before—for example Diels–Alder reactions of indoles[10] and ketenes[11] as dienophiles, or of vinylindoles as dienes[12] among others.[2] Nature also demonstrates the potential of ET activation in enzymatic processes,[13] such as in the monoamine oxidase[14] and the DNA-photolyase reaction.[15, 16] Selective ET processes and radical ion intermediates play an important role in coal chemistry,[17] photodegradation of polymers,[18] and DNA strand scission.[19] Hence, the recent progress in electron transfer chemistry prompts us to predict a much larger number of processes yet to be discovered.

Certainly one reason for the limited use of ET concepts in synthetic schemes is the aforementioned difficulty in controlling the various reaction events involving odd-electron species, regardless of whether a catalytic (Scheme 1a) or stoichiometric transformation is considered (Scheme 1b). To understand this problem better, let us have a closer look at a well-studied electron transfer process: the radical cation catalyzed Diels–Alder reaction, which has become a distinguished example for the potential of ET activation. After addition of 5–10 mol% of tris(*p*-bromophenyl)aminium hexachloroantimonate (CH_2Cl_2, room temperature, 15 min), the Diels–Alder cyclodimerization of cyclohexadiene can be

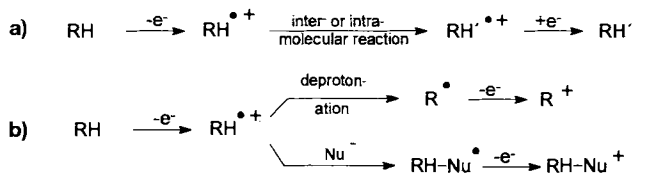
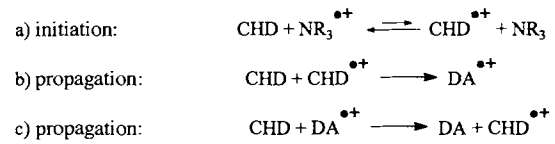


Scheme 1. Reaction of odd-radical species in catalytic (a) and stoichiometric amounts (b).

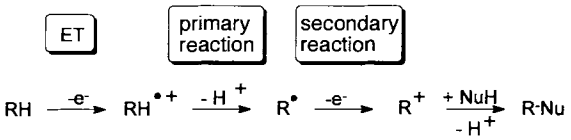
accelerated by a factor of 10^{15} with respect to the thermal reaction.[20] Based on the seminal mechanistic studies, mainly undertaken by Bauld[20] and Eberson,[21] the following mechanism may be proposed.[22] After an initiating one-electron oxidation (Scheme 2a; CHD = 1,3-cyclohexadiene, DA =



Scheme 2. Mechanism of the ET-induced Diels–Alder cyclodimerization of 1,3-cyclohexadiene (CHD); DA = Diels–Alder product.

Diels–Alder product), the endergonic equilibrium of which we can control on the basis of the redox potential data, the cycloaddition of $CHD^{\bullet+}$ with CHD to yield $DA^{\bullet+}$ takes place almost without an activation barrier ($\Delta H^{\neq} = 1.6$ kcal mol^{-1}).[22e] However, right after the cycloaddition step the highly reactive $DA^{\bullet+}$ has to be reduced in a controlled manner to make the desired overall reaction work; this can be achieved by reductive ET from either the diene or the triarylamine to the $DA^{\bullet+}$.[23] Recent work[11b] emphasized that the last reduction step may be pivotal in the reaction sequence, which underlines the importance of considering redox potentials and reorganization energies of both the reactants and the products.

In total, this cycloaddition and all following examples illustrate that we always have to control a whole series of events in order to obtain a successful reaction (Scheme 3): a) electron transfer (ET), b) primary reaction of the radical cation, c) reaction of the follow-up odd-electron species (secondary reaction), and d) trapping of the cationic intermediate.



Scheme 3. Steps of an ET-induced reaction sequence.

Due to space limitations, we will only very briefly deal with the various ways of effecting electron transfer and instead concentrate on how the fate of the radical cation is predetermined by structural features (primary reactions). Likewise, it is of crucial importance to control the follow-up reactions (secondary reactions) of odd-electron intermediates and to trap finally closed-shell species for devising a clean, preparatively useful reaction.

Although we will restrict our discussion to the one-electron oxidation chemistry of neutral molecules in the following, a similar analysis of the chemistry of radical anions will be

A. Burghart M. Schmittel

Michael Schmittel was born in 1956 and studied chemistry at the Universität Freiburg. After receiving his Diplom in 1980 he briefly switched subjects and with a scholarship from the Studienstiftung des Deutschen Volkes studied French at the Sorbonne in Paris, where he finished the Diplôme de langue et civilisation française. After returning to Freiburg he received his doctorate in 1985 under the supervision of Christoph Rüchardt with a thesis on the cis → trans isomerization of azoalkanes that was recognized with the Gödecke-Preis. A NATO postdoctoral appointment brought him to Joseph P. Dinnocenzo at the University of Rochester, were his interest in electron transfer chemistry was ignited. He received a Liebig-Stipendium from the Fonds der Chemischen Industrie, returned to the Universität Freiburg in 1987, completed his habilitation in 1992, and was appointed Professor of Organic Chemistry at the Universität Würzburg in 1993. His research interests encompass electron transfer activation, radical cation catalysis, electroanalytical chemistry, stable simple enols, new trigger mechanisms for enediyne cycloaromatizations, novel thermal biradical cyclizations, electroactive protecting groups, activation of oxygen, radical dications, redox active materials for sensors, supramolecular coordination complexes, and topology in chemistry.

Armin Burghart was born in 1968 and studied chemistry at the Universität Freiburg. After completing his Diplom in 1993, he moved to Würzburg, where he in 1997 finished his doctoral thesis in the research group of Michael Schmittel in the field of stereoselective reactions of enol radical cations. His work was recognized by a scholarship from the Fonds der Chemischen Industrie.

reported in due course. The present treatment, however, also excludes distonic radical cations[24]—odd-electron species in which the charge and the radical cannot be localized on the same atom—that by their very nature act like uncharged electrophilic radicals. In addition, we will not treat the one-electron oxidation chemistry of carboxylic acids (the Kolbe reaction); this subject has been comprehensively described in recent reviews,[25] and in many cases it is not clear whether oxidation of the neutral molecules or the carboxylates is involved. This important reaction has now successfully been used in macrocyclizations[26] and in diastereoselective couplings as well.[27] Likewise, oxidations utilizing Mn^{III} salts, which have found extensive use in synthetic schemes,[28] will not be discussed here, since the radicals are formed from inner-sphere ET via manganese enolates with no involvement of radical cation species.

2. Generation of Radical Cations in Solution

First, two remarks: In contrast to neutral molecules, radicals are much easier to oxidize,[29] except for one distinguished case: the oxidation potentials of α-carbonyl radicals of electron-poor substrates are higher than those of the parent enol precursors.[30] Normally, under conditions of chemical and anodic oxidation, neutral radicals are, however, efficiently oxidized to cationic intermediates.

Radical cation processes do not always result under oxidative conditions. Irrespective of the method for generating radical cations in solution, one should always be aware that these highly acidic species may trigger acid-promoted reactions,[31, 32] which may be mistaken for ET-catalyzed processes.[33]

2.1. Chemical Oxidation

The generation of radical cations in solution can be accomplished by different methods; chemical oxidation of neutral molecules is one of the most important modi operandi. The thermochemistry of a simple ET reaction[34] (Scheme 4) is described by $\Delta G = -nF(E^0_{A/A^{\bullet-}} - E^0_{D/D^{\bullet+}})$. As a consequence, the Gibbs energy ΔG is negative only if E^0 for the couple $A/A^{\bullet-}$ is more positive than that for $D^{\bullet+}/D$. It should be noted that although redox potentials E^0 are strictly defined as reduction potentials,[34, 35] for organic substrates oxidation potentials of neutral compounds are conveniently used.[36] Because of the high reactivity of most organic radical cations, frequently only the potentials of the anodic peak are quoted; these are thermochemically not relevant but constitute acceptable approximations (± 0.2 V) if heterogeneous electron transfer is fast. Details have been described in several textbooks.[2, 3]

$$A + D \rightleftharpoons A^{\bullet-} + D^{\bullet+}$$

Scheme 4. Simple ET reaction between an acceptor A and a donor D.

In most synthetic schemes, one-electron transfer is set up in an endergonic preequilibrium that is rapidly depleted because of the fast follow-up reactions of radical cations. High concentrations of radical cations that generally lead to undesired reactions are thus avoided.

While many oxidants (such as transition metal oxides) react by inner-sphere electron transfer and do not generate free radical cationic intermediates, stable aminium salts[37a, b] and phenanthrolineiron(III) compounds[37c, d] have frequently been used as well-behaved one-electron oxidants. Oxidants[38] such as Ce^{IV}, Cu^{II}, and Ag^{II} constitute borderline cases that are difficult to classify.[2c] Despite some uncertainties, we have not excluded them from our analysis in Section 4.

2.2. Anodic Oxidation

Radical cations can also be produced electrochemically by means of heterogeneous ET between an electrode and a substrate in solution.[3a–e] Advantageously, electrochemical methods allow the application of exactly the electrode potential desired for transformation of the reactant (controlled-potential methods). When working under constant-current conditions the electrode potential is often not constant, and therefore selectivity problems may arise. Hence, to achieve high chemo- and regioselectivities, controlled-potential methods are often preferred.

One specialty of anodic oxidation is that radical cations are formed in much higher stationary concentrations than in homogeneous solution; this often has implications on follow-up reactions. For instance, radical cation catalyzed processes are less efficient and have a lower turnover under anodic oxidation conditions. Fortunately, the scope of electroorganic methods has been significantly enhanced, in particular through the work of Steckhan,[39] by using electrochemical mediators that work in homogeneous solution and thus provide conditions that are very similar to those of chemical oxidation.

2.3. Photoinduced Electron Transfer Oxidation

Photoinduced electron transfer (PET) is a rather novel oxidation technique with a great potential.[2b, 40] This method exploits the ability a) of electronically excited acceptors A to function as strong oxidants (Scheme 5a) and b) of electronically excited donors D to lose an electron rather easily (Scheme 5b). In the case of a) the oxidant is a short-lived intermediate, which will consequently not react with other short-lived intermediates such as radicals.[41] Hence, the substrate is oxidized under locally oxidative conditions; however, reductive conditions prevail after ET. There are many ways to avoid the energy-wasting back electron transfer through the proper choice of solvents and acceptors—in particular by addition of Li^+ ions,[42] cosensitizers, and sacrificial acceptors or by complexation of excited state acceptors to Mg^{2+}.[43] The special PET literature should be consulted for details.[2b, 40]

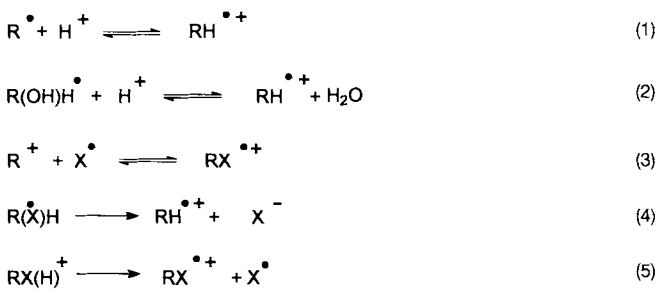
$$\text{a)}\quad D + A \xrightarrow{h\nu} D + A^{*} \longrightarrow D^{\bullet+} + A^{\bullet-}$$

$$\text{b)}\quad D + A \xrightarrow{h\nu} D^{\bullet} + A \longrightarrow D^{\bullet+} + A^{\bullet-}$$

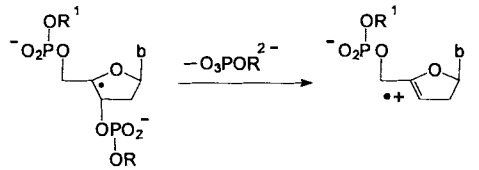
Scheme 5. Photoinduced electron transfer after excitation of the acceptor A (a) or the donor D (b).

2.4. Special Methods for Generating Radical Cations

Although less convenient, some non-oxidative methods exist to generate radical cations (Scheme 6, [Eqs. (1)–(5)]), for example, according to Equation (5) in the Hofmann-Löffler-Freytag reaction.[44] The DNA strand scission in 4′-nucleotide radicals was explained by a heterolytic C–O bond cleavage yielding the corresponding radical cation[19c] [Eq. (4) and Scheme 7].



Scheme 6. Non-oxidative processes for the formation of radical cations.



Scheme 7. Cleavage of the C–O bond of 4′-nucleotide radicals leading to DNA strand scission.

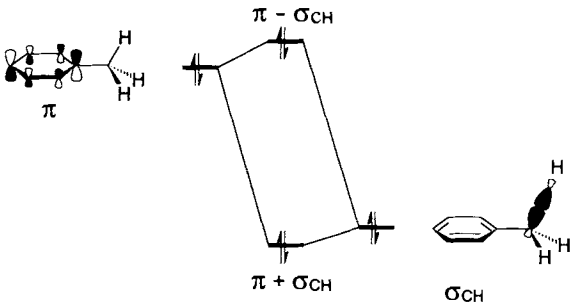
3. Our Classification Schemes—Primary and Secondary Reactions

Several monographies and reviews, in particular in electroorganic[3] and photoinduced electron transfer chemistry,[40] have conceptualized the inherent notions of electron transfer activation by using various classification schemes to arrange the manifold reactions available. In most cases the categorization illustrates the preparative aspects; for example, classification according to bond formation or the main functionality involved in the reaction was emphasized. While this approach is beneficial for selecting a suitable reaction, it does not convey the essential principles of radical cation chemistry in solution.

In contrast to earlier concepts we would like to present our analysis according to the primary reactions of the three main electrophoric systems involved in one-electron oxidation, hence conceptualizing the reactivity patterns in an insightful manner. The electrophore of the substrate to be oxidized is defined by the atom or group of atoms exhibiting the largest HOMO coefficient(s); this allows differentiation between π, n, and σ donors. Accordingly, toluene is a typical π donor, triethylamine an n donor, and cyclopropane a σ donor. To picture the bonds directly attached to the electrophore, we will use a special presentation. The benzylic hydrogens in a π donor such as toluene are therefore depicted as follows: ⓟ-C-H.

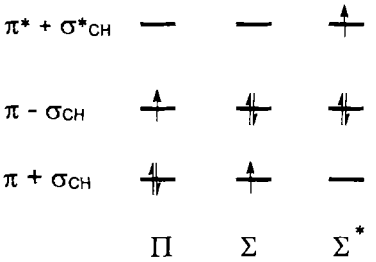
3.1. Molecular Orbital Picture of a Radical Cation

To understand some conceptual features of radical cation chemistry, a short interlude to the molecular orbital (MO) picture of toluene and the electron configuration of toluene•+ is very helpful (Scheme 8). An analysis of toluene•+ in light of



Scheme 8. Simplified orbital-interaction diagram for toluene.

the three-electron three-orbital three-configuration model[45] indicates that it possesses a Π ground state. Accordingly, one would expect that predominantly nucleophilic or radical attack at the aromatic nucleus should take place; however, deprotonation in the benzylic position is also an important reaction pathway. Clearly, excited electronic configurations, in which the C–H bond is severely weakened (Σ and Σ* configurations, Scheme 9), can mix with the Π ground state configuration to lead to an avoided crossing.

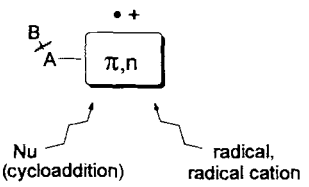


Scheme 9. Three-electron three-orbital three-configuration model[45].

With ⓞ•+ the chemistry is quite straightforward. Since the electron is removed from a scissile bond, the corresponding σ bond is cleaved basically exclusively.

3.2. Primary Reaction Pathways of π and n Radical Cations

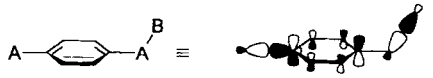
The chemistry of a radical cation in solution is mainly determined by its primary reaction, which can be easily categorized as soon as we have identified the electrophore with the lowest oxidation potential. Importantly, however, the sort of radical cation reactions observed in solution does not depend on the nature of the electrophore (that is, ⓟ•+ or ⓝ•+) but rather on the structural motifs at the periphery of the electrophore. Only a limited number of reaction modes is usually observed that are equally present in ⓟ•+ or ⓝ•+ (Scheme 10, Table 1):



Scheme 10. Schematic representation of the most important primary reaction pathways for π and n radical cations (㊀•+ and ⓝ•+).

1) A–B bond cleavage at the periphery of the electrophore (A–B = C–H, A–H, C–X, C–C, X–Y; see Table 1),
2) reactions initiated by attack of nucleophiles (including rearrangements and cycloadditions), and
3) radical-based processes (ET, dimerization, reactions with radicals, and hydrogen transfer).

In contrast to A–B bond ruptures, ㊀-A•+ and ⓝ-A•+ bond cleavage directly at the electrophore is very rarely observed. The bond to be cleaved is orthogonal to the electrophore orbitals, whereas A–B may align with p orbitals of the electrophore (Scheme 11).



Scheme 11. Views of the orbital overlapping show why A–B bond cleavage is preferred over ㊀-A•+ cleavage.

While Scheme 10 gives a rough idea of the different primary reaction pathways available to π and n radical cations, Table 1 provides a more detailed list. It should be noted, however, that quite often a variation in the substituents at one electrophore site may entail a switch from ㊀•+ to ⓝ•+ within a series of related compounds (see Section 3.4).[46]

3.3. Secondary Reaction Pathways

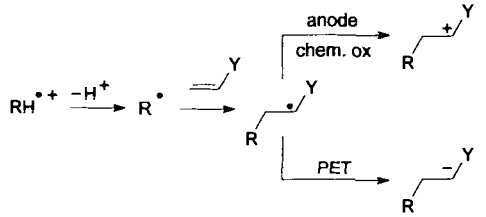
An analysis of Table 1 indicates that the majority of the primary reaction products are odd-electron or other highly reactive species; their reactions should be carefully composed in the design of a successful reaction. The secondary reaction and, thus the fate of the primary intermediate may be controlled by the appropriate choice of the initial electron transfer oxidation system. In this context, it makes a tremendous difference whether we set up a reaction under PET or chemical oxidation conditions.

3.3.1. Radicals as Primary Intermediates

When using chemical or anodic oxidation, the radicals obtained after ㊀-C-H•+ deprotonation ([→CH], see below and Tables 1–3 for the classification system) are further oxidized in most cases ([R^{+}_{ox}]), so that products derived from cationic intermediates can be expected ([→CH, R^{+}_{ox}], Scheme 12). However, under conditions of photoinduced electron transfer the radicals and radical cations as primary intermediates are often reduced by the acceptor A•−. Hence, in the first case products are derived from anionic intermediates ([→CH, R^{-}_{red}], Scheme 13). In addition, radical intermediates can efficiently be trapped by addition to unsaturated compounds when their oxidation or reduction is slower than addition. Only the resulting secondary intermediates undergo subsequent oxidation or reduction ([→CH, $R^{+}_{add,ox}$] and [→CH, $R^{-}_{add,red}$], Scheme 14).

Scheme 12. Deprotonation of a radical cation and further oxidation of the formed radical: the [→CH, R^{+}_{ox}] reaction.

Scheme 13. Radical cations obtained by photoinduced electron transfer react after deprotonation to form radicals, which are reduced to the anion by an acceptor: the [→CH, R^{-}_{red}] reaction; bet = back electron transfer.



Scheme 14. Addition of radical intermediates on unsaturated compounds and subsequent oxidation or reduction: the [→CH, $R^{+}_{add,ox}$] and [→CH, $R^{-}_{add,red}$] reactions.

To indicate the mechanism operative for radical intermediates, we designed a simple code for abbreviating the primary (Table 1) and secondary reaction pathways (Table 2). It

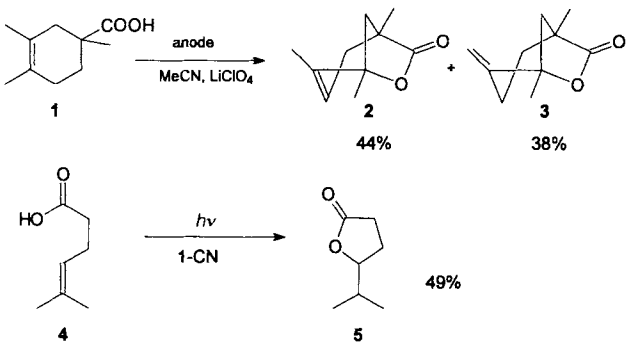
$R^{\bullet}_{red}$	$R^{\bullet} \rightarrow R^{-}$	anion	PET
$R^{\bullet}_{rad}$	typical radical reactions	various	under all conditions
$R^{\bullet}_{add,ox}$	$R^{\bullet} + C{=}C \rightarrow R{-}C{-}C^{\bullet} \rightarrow R{-}C{-}C^{+}$ [a]	cation	anode, chemical oxidation
$R^{\bullet}_{add,red}$	$R^{\bullet} + C{=}C \rightarrow R{-}C{-}C^{\bullet} \rightarrow R{-}C{-}C^{-}$ [a]	anion	PET
$R^{\bullet}_{RA}$	reaction with radical anion	anion	PET

[a] Addition to a double or triple bond.

should be noted, however, that we omitted simple heteroatom deprotonation reaction as a secondary reaction in order to focus on the more relevant follow-up reactions. Hence, the code for the reaction shown in Scheme 15 is $[\rightarrow Nu, R^{\bullet}_{ox}]$.

Scheme 15. The $[\rightarrow Nu, R^{\bullet}_{ox}]$ reaction.

Two examples (Scheme 16) shall illustrate how the outcome can be altered by controlling the secondary reaction. In both cases the primarily formed olefin radical cation is attacked intramolecularly by the carboxyl group to provide lactones **3** and **5**, respectively;[47, 48] however, in the first example the resulting radical is oxidized, and in the second it is reduced. To show the reaction steps involved in the primary and secondary processes we will use the classification system outlined in Tables 1–3. Hence, the primary reaction will be

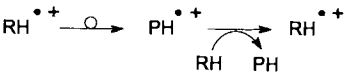


Scheme 16. The $[\rightarrow Nu, R^{\bullet}_{ox}]$ reaction according to Utley (1978, top) and the $[\rightarrow Nu, R^{\bullet}_{red}]$ reaction according to Gassman (1987, bottom).

termed $[\rightarrow Nu]$, corresponding to nucleophilic attack of the carboxyl group on the olefin radical cation. The secondary reactions are categorized as radical oxidation $[R^{\bullet}_{ox}]$[47] and radical reduction $[R^{\bullet}_{red}]$,[48] respectively.

3.3.2. *Radical Cations as Primary Intermediates*

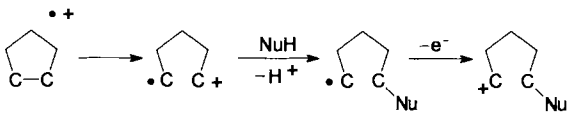
Radical cations appear as primary intermediates in radical cation catalyzed processes, such as cycloadditions or rearrangements, or after intramolecular bond cleavage. The typical situation in a radical cation catalyzed process is depicted in the following. After rearrangement $[\rightarrow R]$ of the reactant radical cation $RH^{\bullet+}$ to $PH^{\bullet+}$, the chain is further propagated by ET reduction between RH and $PH^{\bullet+}$ ($[\rightarrow R, RC_{red}]$, Scheme 17).



Scheme 17. Regeneration of the starting radical cation by radical cation catalyzed reaction with rearrangement and subsequent ET reduction.

Quite often after intramolecular bond cleavage a distonic radical cation is formed with a separated radical and cationic center. Whereas the radical center undergoes follow-up reactions similar to those of primary radicals (see Table 2), the cationic center usually reacts with added nucleophiles. The sequence of these events is for the most part not established by mechanistic investigations; the sequence chosen in the code is therefore purely arbitrary.

A simple example should demonstrate the classification. After C–C bond cleavage in the primary reaction $[\rightarrow CC]$, the distonic radical cation will be trapped by a nucleophile at the cationic center and also oxidized at the radical site (Scheme 18). The index used for trapping the nucleophile (Nu) is then combined with that for the radical oxidation: $[\rightarrow CC, RC_{Nu,ox}]$ (Table 3).



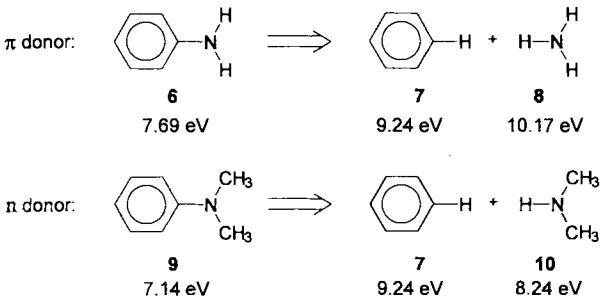
Scheme 18. Example of a $[\rightarrow CC, RC_{Nu,ox}]$ reaction.

The most important codes are provided in Table 3; the first index denominates the destiny of the cationic center, and the second the follow-up reaction of the radical site. Clearly, it will not always be possible to ascertain the sequence of events in complex reaction cascades without detailed mechanistic work. However, we consider this short classification according to primary and secondary reactions as a very helpful tool for explaining product formation without the need for detailed mechanistic discussions.

3.4. Electrophore Types

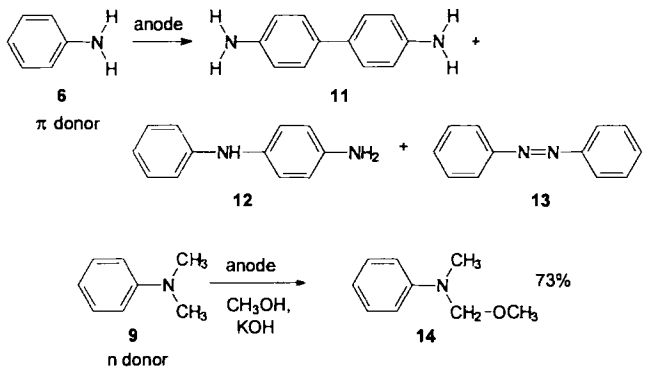
A particular difficulty in classifying the electrophoric system seems to arise when two different types of donors are linked together by a covalent bond, that is, ⓟ-ⓝ. The following procedure is therefore recommended. The bond between the two electrophore systems is cut, and hydrogen atoms are added to both fragments (ⓟ-H and ⓝ-H). The ⓟ–ⓝ system is now classified according to the isolated electrophore exhibiting the lower oxidation (or ionization) potential. Accordingly, aniline (**6**), for example, would be divided into the amine (n donor) and the phenyl part (π donor). As benzene (**7**) has the lower oxidation (or ionization) potential

(Scheme 19), aniline is classified as a π electrophore system, but *N*,*N*-dimethylaniline (**9**) as an n donor.



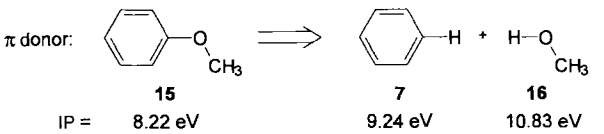
Scheme 19. Classification scheme for combined electrophore systems (see text for details); data for ionization potentials from ref. [49].

Interestingly, this simple classification scheme often allows a convincing explanation of the observed radical cation chemistry. For example, in the anodic oxidation of the n donor **9**,[50] the predominant product **14** mainly arises from side-chain functionalization, a reaction that is similar to anodic oxidations of simple aliphatic amines. In contrast, the π donor **6** affords **11**–**13** (Scheme 20) after one-electron oxidation,[51] which are coupling products typical of arene oxidations.

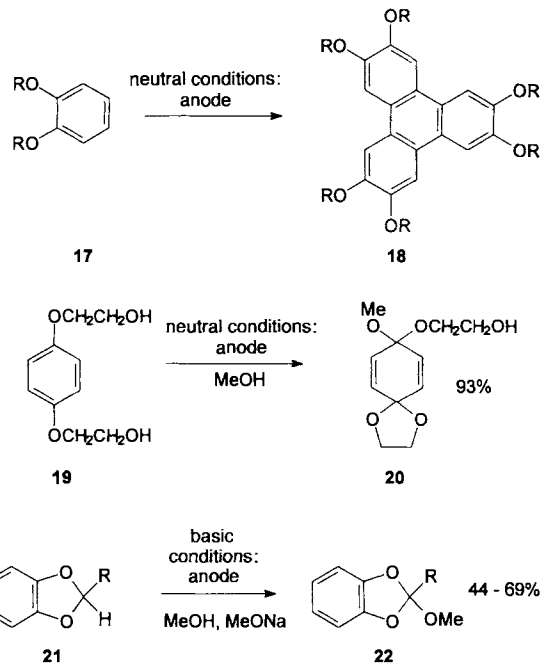


Scheme 20. The [→Nu,$R^{\bullet}_{ox}$] reaction according to Nelson (1974, top) and the [→CH,$R^{\bullet}_{ox}$] reaction according to Shono (1982, bottom).>

Clearly, this simple approach must have some limitations. For instance, there are some cases where the main reactivity patterns of the radical cation stem from the part of the electrophore with the higher oxidation potential, for example phenyl alkyl ethers. In line with the above considerations of ionization potentials, anisol (**15**) should be classified a π donor (Scheme 21). In the majority of anodic oxidation reactions of anisole under neutral conditions, typical reactions of $\textcircled{\pi}^{\bullet+}$ are indeed observed, for example coupling reactions[52] and nucleophilic attack at the aromatic nucleus.[53] However, upon changing to basic oxidation conditions, deprotonations at the position α to the oxygen atom are often encountered;[54] according to our classification that is typical for $\textcircled{n}^{\bullet+}$ (Scheme 22).



Scheme 21. Classification scheme for anisol (**15**); ionization potentials from ref. [49].



Scheme 22. The [→Nu,$R^{\bullet}_{ox}$] reactions according to Parker (1972, top) and Tissot (1975, middle) as well as the [→CH,$R^{\bullet}_{ox}$] reaction according to Thomas (1985, bottom).

Hence, the radical cation may sometimes show reactions typical for oxidation of the weaker donor; their portion in solution depends on the energy of the involved excited electronic configuration[45] and their relative reactivity. In

Table 3. The most important secondary reactions in radical cation chemistry and the oxidation systems for setting up such reactions. Part 2: Distonic and simple radical cations (RC) as primary intermediates[a].

Code	Secondary reaction	Product	Oxidation system
RC_{ox}	$RH^{\bullet+} \rightarrow RH^{2+}$	dication	anode, chemical oxidation
RC_{red}	$RH^{\bullet-} \rightarrow RH$	neutral	PET, radical cation chain
RC_{Nu}	cationic center reacts with nucleophile	radical	under all conditions
$RC_{Nu,ox}$	cationic center reacts with nucleophile, radical center will be oxidized	cation	anode, chemical oxidation
RC_{RA}	reaction with radical anion	neutral	PET
RC_{add}	radical center adds to unsaturated bond	radical cation	under all conditions
$RC_{CA,red}$	cycloaddition and reduction of reagent	neutral	under all conditions

[a] Distonic radical cations result mostly from intramolecular bond cleavage.

summary, the categorization in π or n donors will allow us to predict the reactivity mode by using the simple reactivity paradigms outlined in Section 4. However, we should always be aware of the limitations of this simplistic approach.

3.5. σ Radical Cations

Only a small selection of the molecules studied can be categorized as σ donors according to our classification. Nevertheless, σ radical cations ⓞ$^{\bullet+}$ have found wide recognition in synthetic schemes; most systems are derived from the very strong σ donors[55] of the C–Si and C–Sn type: ⓞ-C-Si$^{\bullet+}$ and ⓞ-C-Sn$^{\bullet+}$. In contrast, pure C–C electrophores show very high oxidation potentials, and they are usually not accessible with standard oxidation procedures.[56] Only strained carbocycles exhibit sufficiently low oxidation potentials, although in the meantime a PET protocol for functionalizing adamantane, cyclohexane, and 2,3-dimethylbutane has been set up as well.[57, 58] Adamantane is easier to oxidize than aliphatic ethers.[58]

Polysilanes and their radical cations have attracted much attention because of their potential utility as one-dimensional conductors.[59] According to ESR investigations, however, the unpaired electron in oligosilane radical cations is mostly confined to one elongated Si–Si bond.[60] Interestingly, the ionization potentials (IP) of allyltrimethylsilane (IP = 9.0 eV) and tetramethylsilane (IP = 9.5 eV) are even lower than that of propene (IP = 10 eV), which allows classification of both silanes as σ donors.[55] Indeed, considerations of ionization potential suggest that the donor capability of a C–Si σ bond is similar to that of a lone pair on oxygen.[55] Even stronger σ donors are germanes and stannanes, as indicated from the ionization potentials of $GeMe_4$ (IP = 9.2 eV) and $SnMe_4$ (IP = 8.76 eV).[49]

4. Reactivity Patterns in ⓟ$^{\bullet+}$, ⓝ$^{\bullet+}$, and ⓞ$^{\bullet+}$

The plethora of reactions hitherto realized after one-electron oxidation of neutral molecules has made it almost impossible to present an analysis in a sensible way. We will therefore restrict ourselves to the enumeration of a few selected examples of synthetic interest and instead try to present the typical reaction patterns operating in this chemistry. Furthermore, we will try to conceptualize structure–reactivity relationships on the basis of some recent data on the rates of reactions. There are also many possibilities for manipulating the primary reaction pathways of radical cations beyond the inherent reactivity patterns (Table 4).

Table 4. Some selected factors affecting the reactivity of radical cations.

Structural effects	External effects

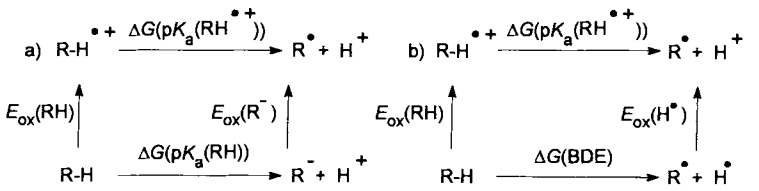
4.1. C–H Deprotonation

4.1.1. A Physical Organic Prelude

Deprotonation at C–H is a typical reaction pathway for almost all radical cations of the type ⓟ-C-H$^{\bullet+}$ and ⓝ-C-H$^{\bullet+}$. Calculations using thermochemical cycles[62, 63] show that the acidity of a radical cation is inherently augmented, with respect to that of the neutral precursor, almost independent of the nature of the electrophore. This is a consequence of the fact that for essentially all cases R^- is more readily oxidized than RH ($E_{ox}(RH) > E_{ox}(R^-)$, Scheme 23a). The change in



Scheme 23. Thermochemical cycle process for determining the acidity of radical cations.

pK_a (ΔpK_a) when switching from the neutral to the one-electron oxidized molecule can therefore be derived from $\Delta G = -nF[E_{ox}(RH) - E_{ox}(R^-)]$. Alternatively, if the pK_a of the neutral molecule is not known, that of the radical cation can nevertheless be determined through a different thermochemical cycle using the C–H homolytic bond dissociation energy and the oxidation potential of the neutral molecule (Scheme 23b). Within a series of related molecules exhibiting very similar values of ΔG(BDE) for the neutral compounds, one can expect the acidity of RH$^{\bullet+}$ to increase with the oxidation potential of RH. For instance, in the case of toluene$^{\bullet+}$, $\Delta G(pK_a^{\bullet+}) = -17$ kcal mol^{-1} in acetonitrile has been estimated, which corresponds to $pK_a = -13$.[62] Electron-donating substituents increase the stability of the arene radical cation and render the odd-electron species less acidic; for example, hexamethylbenzene$^{\bullet+}$ has a pK_a value of only 2.[64] Some representative thermodynamic acidities, mostly derived from calculations of thermochemical cycles and only rarely determined directly,[65] are listed in Table 5.

Table 5. Thermodynamic acidities of π radical cations for C–H deprotonation in DMSO.

R-H	$pK_a(RH^{\bullet+})$	$pK_a(RH)$	Ref.
$PhCH_2CN$	−32	21.9	[66]
$PhCH_2SO_2Ph$	−25	23.4	[67]
Ph_2CH_2	−25	32.2	[68]
$PhCH_3$	−20	43	[68]
indene (3-H)	−18	20.1	[69]
Cp*H*	−17	18.0	[68, 70]
fluorene (9-H)	−17	22.6	[71]
C_5Me_5H	−6.5	26.1	[70]

Fortunately, kinetic acidities of radical cations were investigated recently in some detail. From the seminal studies of Kochi,[64] Baciocchi,[72] Savéant,[73, 74] and others[75, 76] on the deprotonation rates of ⓟ-C-H$^{\bullet+}$, a linear relationship between

$\lg k_{dep}$ and pK_a is derived, which should allow rough predictions of kinetic acidities for alkyl arene radical cations (Figure 1). The Brønsted parameter $\alpha = 0.24$ suggests a reactant-like transition state with a low positive charge on the α carbon atom.[72]

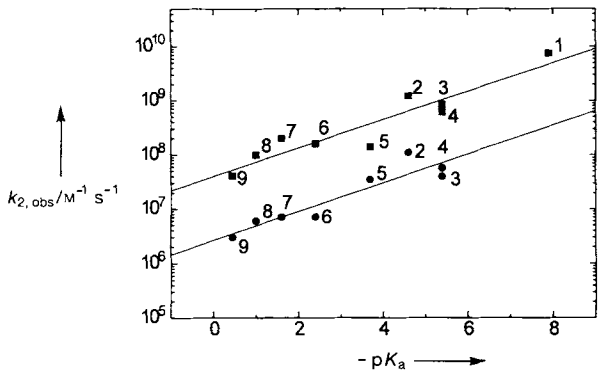


Figure 1. Brønsted plots for the deprotonation of 4-MeOPhCH$_2$X$^{\bullet+}$ by NO_3^- (■) und 2,6-lutidine (●)[72]. The numbers correspond to different compounds 4-MeOPhCH$_2$X$^{\bullet+}$:1: X = CN, 2: X = Cl, 3: X = OMe, 4: X = OH, 5: X = OAc, 6: X = Ph, 7: X = 4-MeOPh, 8: X = Me, 9: X = H.

However, this simple picture was questioned by the work of Savéant on NADH model compounds; the intrinsic barriers for deprotonation were found to correlate with homolytic bond dissociation energies but not with pK_a values.[73] Proton transfer from radical cations should therefore be viewed as concerted electron and hydrogen-atom transfer. While this controversy is far from being settled, the differences to the results presented above may be due to the fact that we are dealing with ⓝ-C=CCH$^{\bullet+}$ deprotonation in the latter case but ⓟ-C-H$^{\bullet+}$ in the former. These results on alkyl arene radical cations indicate that deprotonation at the benzylic position is often a rapid, and sometimes even a diffusion-controlled, process that depends on the acidity of the radical cation and the strength of the base used.

Somewhat less is known about the acidity of ⓝ-C-H$^{\bullet+}$; almost all data are for amine radical cations (Table 6) and only few for other systems (e. g. ether$^{\bullet+}$[77] and thioether$^{\bullet+}$[78]). In contrast to π radical cations, however, deprotonations directly at the electrophore are much better known for ⓝ-H$^{\bullet+}$ (e. g. $Me_2NH^{\bullet+}$: $pK_a = 6.5-7.5$).[79]

Table 6. C–H acidities of amine radical cations in DMSO[80].

ⓝ-C-H$^{\bullet+}$	pK_a(ⓝ-C-H$^{\bullet+}$)	pK_a(ⓝ-C-H)
	−13	27.9
	−11	27.0
	−11	24.4
	−9.4	25.6

The kinetics of proton transfer in amine radical cations is of wide interest because of the importance of such deprotonations in photochemical, electrochemical, and biochemical redox processes. Hence, their rates of α-deprotonation[81–88] and pK_a values[83–85] have been repeatedly reported. Although this complex issue is far from being settled, some major effects were identified that influence the kinetic acidity: steric and stereoelectronic effects,[87, 88] entropic factors,[84] base strength,[84] and late transition state.[84, 85]

A study of the substituent effects on C–H deprotonation in amine radical cations was recently undertaken by Mariano;[85b] this led to a scale of relative acidities. Absolute rate constants were reported for various substituents in $Ph_2NCHR^1R^{2\bullet+}$ (Table 7).[89] Importantly, the kinetic acidities parallel the thermodynamic pK_a values. It should, however, be noted that the observed substituent effects do not parallel those observed by Lewis.[88]

Table 7. Substituent effects on the deprotonation of $Ph_2NCHR^1R^{2\bullet+}$ (base: nBu$_4$NOAc in MeOH/MeCN (1/3) at 25 °C[89]).

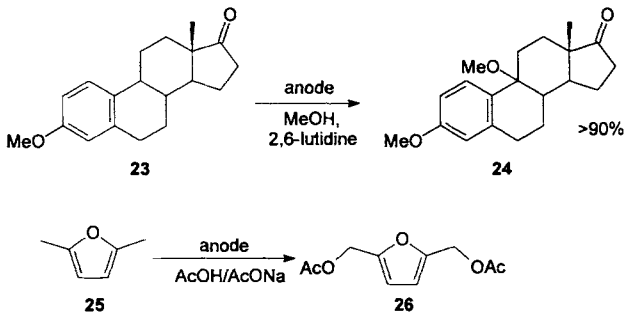
R^1	R^2	k[M^{-1}s^{-1}]
Me	H	2.3×10^5
Me	Me	1.7×10^5
Ph	H	3.2×10^6
CH=CH$_2$	H	2.6×10^6
C≡CH	H	7.0×10^7

Very little is known about ⓞ:C-H$^{\bullet+}$ deprotonation. Recently, such processes were used in the arylation of alkanes in PET reactions with TCB or CA.[57, 58] All radical cations investigated exhibit a strongly negative Gibbs energy for deprotonation with strong preferences for the tertiary C–H bond over secondary or primary bonds (e. g. $\Delta G^0 = -11.5$ and -8.0 kcal mol^{-1} for the tertiary and secondary C–H bonds in adamantane$^{\bullet+}$).[57] Here, ⓞ:C-H$^{\bullet+}$ cleavage is observed although the HOMO of such compounds is mainly governed by C–C σ bonds.[90]

4.1.2. ⓟ-C-H$^{\bullet+}$ Deprotonation

Rapid ⓟ-C-H$^{\bullet+}$ deprotonation can often be utilized for highly selective functionalizations at allylic or benzylic positions. Interestingly, it was only in the late 1960s that these technically important reactions[91] were recognized as electron transfer processes.[92, 93] In the chemical or anodic oxidation of **23**[94] or **25**,[95] the radicals formed in the primary process are further oxidized to cationic intermediates ([$\rightarrow$CH, R$^+_{ox}$]) that are readily trapped with a variety of nucleophiles (Scheme 24). The analogous reaction sequence [$\rightarrow$CH, R$^+_{ox}$] has found widespread use in protecting-group chemistry, for example in the selective deprotection of alcohols[96] and carboxylic acids[97] from substituted benzyl ethers and esters,[39] respectively.

Screening the literature clearly indicates that most of the ⓟ-C-H$^{\bullet+}$ deprotonations are for aromatic or heteroaromatic[98] systems carrying alkyl side chains, whereas for simple olefinic systems,[99, 100] this is not such a dominant pathway with respect to nucleophilic attack and cycloaddition. Never-



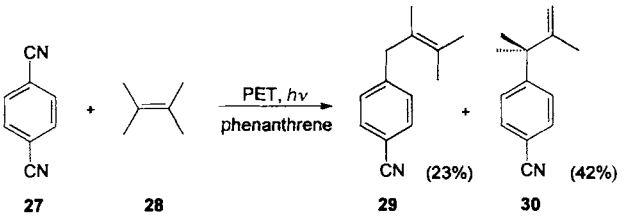
Scheme 24. The [→CH,R^{+}_{ox}] reactions according to Ponsold (1979, top) and Brettle (1966, bottom).

theless, deprotonation of various 1,4-cyclohexadiene radical cations[101] affords aromatized derivatives; this suggests that a similar mechanism may operate in the oxidation of arachidonic acid by lipoxygenase.[102]

A vast number of reactions could be listed here, which all show preferential deprotonation at the benzylic position. However, only a few examples exhibit deprotonation directly at the π electrophore, that is, involving the aromatic C–H protons. Although a pK_a of -4 was estimated for the benzene radical cation in acetonitrile,[63] deprotonation at the aromatic nucleus is in general a rare event. Since other reactions are much more preferred, for example nucleophilic attack on $ArH^{\bullet+}$, only sterically hindered bases such as di-*tert*-butyl pyridine were reported to induce deprotonation.[103]

Deprotonation of radical cations generated by PET is often too slow to compete with back electron transfer. However, when acceptors such as **27** give rise to strongly basic radical anions, deprotonation in the ion radical pair may become an efficient process (Scheme 25).[104]

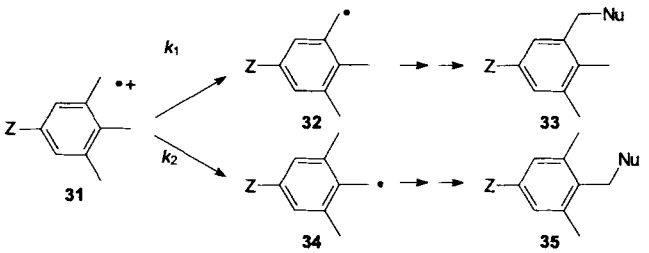
Although stereoelectronic factors in π-C-H$^{\bullet+}$ deprotonation were recently studied in depth, their role remains obscure. Since deprotonation in π-C-H$^{\bullet+}$ should be accelerated by optimum overlap of the π-SOMO with the C–H bond, preferential deprotonation in *p*-methylcumene (*p*-cymene$^{\bullet+}$) at the methyl group rather than at the more acidic isopropyl group was originally rationalized in terms of



Scheme 25. The [→CH,R^{+}_{RA}] reaction according to Arnold (1984).

conformational restraints.[105, 106] Recent investigations on the same radical cation in solution[107] and in the gas phase[108] failed to observe significant stereoelectronic effects, which however showed up in the deprotonation of α-substituted *p*-xylene$^{\bullet+}$ at CH_3 instead of CH_2tBu.[109] This discrepancy, however, may be due to the fact that free radical cations were not always formed.[110] In a detailed study on the relative C–H deprotonation reactivity as a function of different electron transfer oxidants, the secondary C–H bond was the most reactive.[111] Such a reactivity pattern can be utilized for selective functionalizations,[112] in particular in rigid systems,[109] as recently illustrated by Arnold[113] in the PET-induced *cis* → *trans* isomerization of 1-methyl-2-phenylcyclopentane$^{\bullet+}$. The photostationary state (>99% *trans*) is controlled by the relative kinetic acidities of the isomers; both display the same thermodynamic acidity ($pK_a = -15$).

An insightful review on C–H deprotonations of alkyl arenes was provided by Baciocchi that illustrates that not only radical-stabilizing effects but also the charge distribution in the radical cation contribute to the positional selectivity.[114, 115] For example, electron-donating substituents increase the *para* to *meta* deprotonation selectivity in **31** (Scheme 26, Table 8).



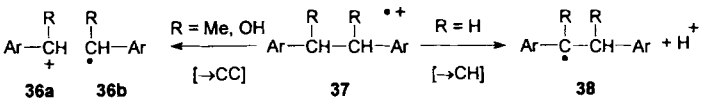
Scheme 26. Reaction pathways for the anodic functionalization of 5-Z-substituted 1,2,3-trimethylbenzenes according to Baciocchi (1986).

Table 8. Relative rates in the anodic functionalization of 5-Z-1,2,3-trimethylbenzenes (Scheme 26)[114].

Z	k_2/k_1	Z	k_2/k_1
CO_2Me	2.0	Br	42
H	3.4	Me	55
*t*Bu	24	OMe	>200

Electronic effects of α substituents on the deprotonation rates of alkylarene radical cations were also studied (see Figure 1); k_{dep} decreases with CN > Cl > OMe > OH > OAc > Ph > 4-MeOPh > Me > H.[72]

It is instructive to realize that deprotonation at the benzylic position in 1,2-diarylethane$^{\bullet+}$ is much faster than C–C bond cleavage, whereas with 2,3-dimethyl-2,3-diphenylbutane$^{\bullet+}$ C–C bond fragmentation is the predominanting process (Scheme 27). Similarly, substitution of an α-hydrogen

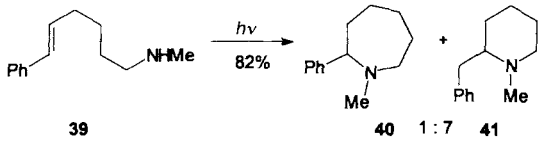


Scheme 27. Competition between deprotonation and C–C bond cleavage in 1,2-diarylethane$^{\bullet+}$.

atom by an α-hydroxy group accelerates C–C fragmentation. This is simply a consequence of the lower C–C bond dissociation energy; the acidity of the radical cations is changed less.[116]

4.1.3. ⓝ-C-H$^{\bullet+}$ and ⓝ-H$^{\bullet+}$ Deprotonation

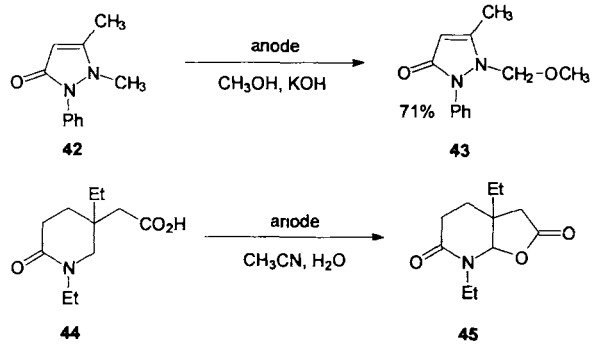
In contrast to ⓟ-H$^{\bullet+}$ deprotonation, which is almost completely unknown, ⓝ-H$^{\bullet+}$ deprotonation directly at heteroatoms such as in RNH_2[117] or RSH[118] occurs quite frequently. For instance, it plays an important role in the oxidative N–H deprotonation[119, 120] triggered after intramolecular electron transfer in the linked donor–acceptor system **39** (Scheme 28).[121] Such reactions were successfully used in the construction of heterocyclic rings (including the benzomorphan skeleton)[122] and in the photo-Smiles rearrangement.[123, 124] The mechanism is, however, not undoubtedly established in all cases.



39 **40** 1 : 7 **41**

Scheme 28. The [→ ⓝH,R$^{\bullet}_{rad}$] reaction according to Lewis (1989).

Nevertheless, ⓝ-C-H$^{\bullet+}$ deprotonation at a position α to the heteroatom is by far the more important pathway, and it has received wide attention because of its occurrence in the biologically important monoamine oxidase reaction.[14] It is also the key step in the α functionalizations of amines,[125] hydroxylamines,[126] amides,[127] lactams,[128] carbamates,[129] amino acids,[130] dipeptides,[131] sulfides,[132] ethers,[77] phosphanes, and others.[2, 3, 40, 133] The plethora[134–140] is only poorly represented by the small selection (Scheme 29).[134, 135]



42 **43**

44 **45**

Scheme 29. The [→ CH,R$^{\bullet}_{ox}$] reactions according to Kaupp (1985, top) and Irie (1980, bottom).

Under chemical and anodic oxidative conditions, the resulting α-amino radicals are readily oxidized (e. g. $E^{ox}_{1/2}$ ($Me_2NCH^{\bullet}_2$) = −1.03 V versus SCE)[29] to give iminium ion intermediates. Interestingly, even PET conditions (when selected properly, as with **46**; Scheme 30)[137] allow access to cationic intermediates.[125] A special variant uses ⓝ-C-H$^{\bullet+}$ deprotonation after intramolecular ET, for example between the amine and the enone functionality of **48**, to effect cyclization at the stage of the α-amino radical and the radical anion of the enone (Scheme 31).[139]

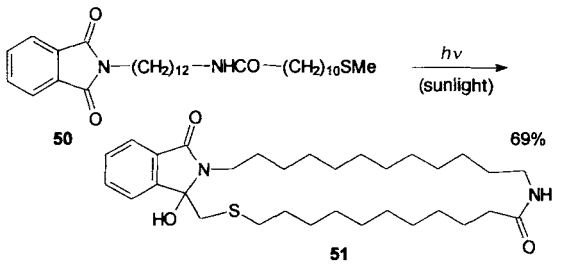
48 **49**

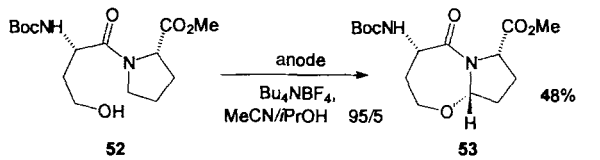
Scheme 31. The [→ CH,R$^{\bullet}_{add}$] reaction according to Kraus (1991); triton B = benzyltrimethylammonium hydroxide.

Such ⓝ-C-H$^{\bullet+}$ deprotonation reactions after intramolecular ET have found use in fascinating macrocyclizations, such as in **50** → **51** (Scheme 32),[141] and in the formation of



Scheme 32. The [→ CH,R$^{\bullet}_{rad}$] reaction according to Kanaoka (1992).

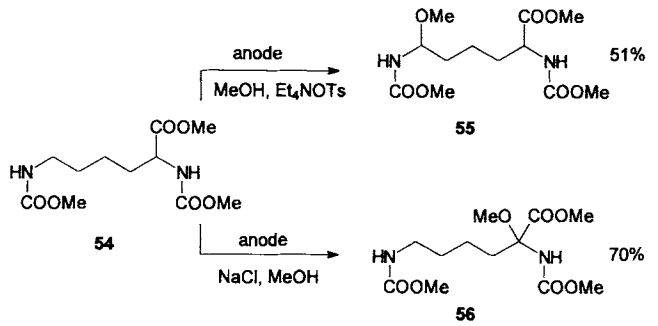
heterocyclic rings starting from amines[142] and thioethers,[143] as demonstrated through the elegant work by Kanaoka and Griesbeck. Furthermore, this strategy was used for the electrochemical preparation of the bicyclic, reverse-turn peptidomimetics **53** from dipeptide **52** (Scheme 33)[144] and in the synthesis of the berberine alkaloid chilinene.[145]



52 **53**

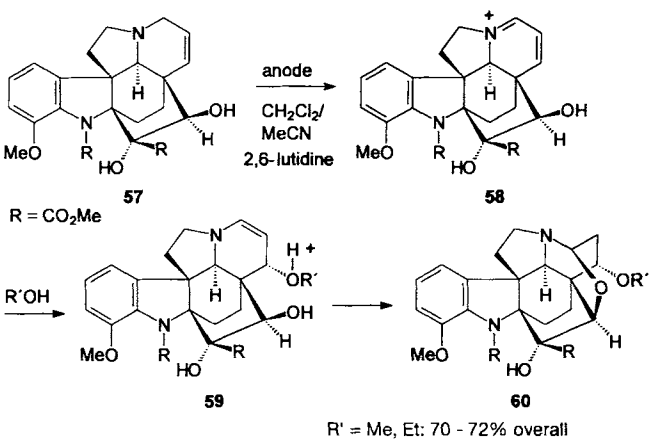
Scheme 33. The [→ CH,R$^{\bullet}_{ox}$] reaction according to Moeller (1995); Boc = *tert*-butoxycarbonyl.

In some cases the chemoselectivity can be steered by ingenious ways in anodic oxidations.[146] Direct anodic oxidation of **54** preferentially gives rise to ⓝ-C-H$^{\bullet+}$ deprotonation at the (ω − 1) position to yield **55** in 51% (Scheme 34); however, in the presence of NaCl anodically generated Cl^+ first produces N_α-chloroamine. Upon elimination of hydrogen chloride and addition of methanol, this methoxylation protocol afforded **56** in 70% yield.



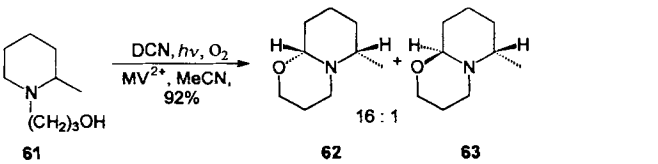
Scheme 34. Reaction **54** → **55**: the [→ CH,$R^{\bullet}_{ox}$] reaction according to Shono (1983); Ts = $H_3CC_6H_4SO_2$.

Very recently, the electrochemically mediated conversion of aspidofractinine-type alkaloids such as kopsingine to kopsidines A and B (**60**) was successfully realized (Scheme 35).[147] Likewise, anodic oxidation of 2,5-dihydro-*1H*-1-benzazepines provides a synthetic access to the rare *5H*-1-benzazepines.[148]



Scheme 35. The [→ CH,$R^{\bullet}_{ox}$] reaction according to Kam (1995).

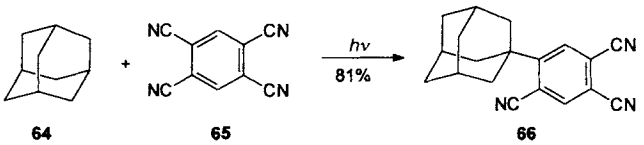
Since the deprotonation step in ⓝ-C-$H^{\bullet+}$ requires the overlap of the half vacant p orbital with the incipient carbon radical orbital,[87, 88] stereoelectronic factors often give rise to preferential deprotonation at the less substituted side group, as in **61** (Scheme 36).[125] When overlap is impossible, as in triisopropylamine$^{\bullet+}$, deprotonation is almost perfectly inhibited.[149]



Scheme 36. The [→ CH,$R^{\bullet}_{ox}$] reaction according to Pandey (1991); MV^{2+} = methyl viologen.

4.1.4. ⓞ:C-H$^{\bullet+}$ Deprotonation

Evidence for ⓞ:C-$H^{\bullet+}$ cleavage was deduced from pulse-radiolysis studies.[150] From ESR investigations it was suggested that deprotonation preferentially occurs at the C–H bond with the highest unpaired electron density.[151] It was only recently that ⓞ:C-$H^{\bullet+}$ deprotonations were observed in the arylation of alkanes upon PET with TCB (**65**) or CA (Scheme 37).[57, 58] In **64**$^{\bullet+}$ deprotonation at the tertiary C atom is always strongly favored.



Scheme 37. The [→ CH,$R^{\bullet}_{RA}$] reaction according to Albini (1995).

In a series of substituted adamantanes, deprotonation was found to dominate over C–C bond cleavage in the *tert*-butyl- and methoxymethyl-substituted derivatives. Indeed, calculations of thermochemical cycles indicate C–H bond cleavage is exergonic, as opposed to endergonic C–C bond fragmentations (Table 9). A different behavior was found for *t*Bu-Ad after photoinduced and anodic oxidation; the first method provided mainly C–H,[58] and the latter C–C[58, 152] scission products. It was proposed that anodic oxidation may proceed via the corresponding dications as a result of the high stationary concentration at the electrode.[58]

1-($MeOCH_2$)-$Ad^{\bullet+} \rightarrow 1\text{-}Ad^{\bullet} + MeOCH_2^+$	11.4

[a] Ad = adamantyl, AdH = adamantane.

4.2. A–H Deprotonation

When an AH (e. g. OH or NHR) and a CH_2R functionality are placed at the α-position of an electrophore, A–H deprotonation usually prevails over C–H deprotonation. The alternative bond cleavage—namely, formation of RA^+ and $H^{\bullet}$—is much more endergonic and does not play a role in solution.[153] For many substituted arenes the pK_a (ⓟ-A-$H^{\bullet+}$) values correlate with those for the gas phase[68] or with Brown substituent constants[157] when the solvation terms remain constant.

Unfortunately, only few kinetic data on deprotonation of ⓞ:A-$H^{\bullet+}$, ⓝ-A-$H^{\bullet+}$, and ⓟ-A-$H^{\bullet+}$ are available.[161, 162] The propensity of ⓟ-A-$H^{\bullet+}$ to undergo deprotonation may be directly related to their thermodynamic acidities (Table 10). From these data it becomes clear that ⓟ-O-$H^{\bullet+}$ species tend to be much more acidic than ⓟ-NH-$H^{\bullet+}$ species, which explains the occasionally observed reluctance of aniline radical cations to undergo deprotonations. However, this picture may be much more complex once reliable kinetic data

Table 10. Acidities of selected π-A-H$^{\bullet+}$ species.

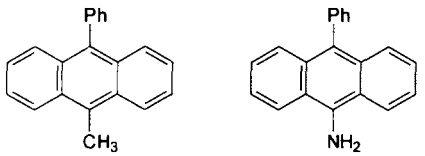
are considered, which are unfortunately not available at present. Exceptions are data for enol[161] and phenol radical cations such as methoxyphenol$^{\bullet+}$ [163, 164] ($k = 2.2 \times 10^6\ s^{-1}$).[164]

Parker observed an unexpectedly fast rate for the endergonic π-N-H deprotonation of **68**$^{\bullet+}$ with various pyridines as bases (Table 10), which could be explained by taking hydrogen bonding between the radical cation and the base into account.[162] In contrast, the thermodynamically more feasible deprotonation of **67**$^{\bullet+}$ ($pK_a = 3.0$) is much slower (Table 11).



67 **68**

Table 11. π-C-H$^{\bullet+}$ versus π-N-H$^{\bullet+}$ deprotonation in CH_3CN in the presence of 2,6-di-*tert*-butylpyridine as base [162].

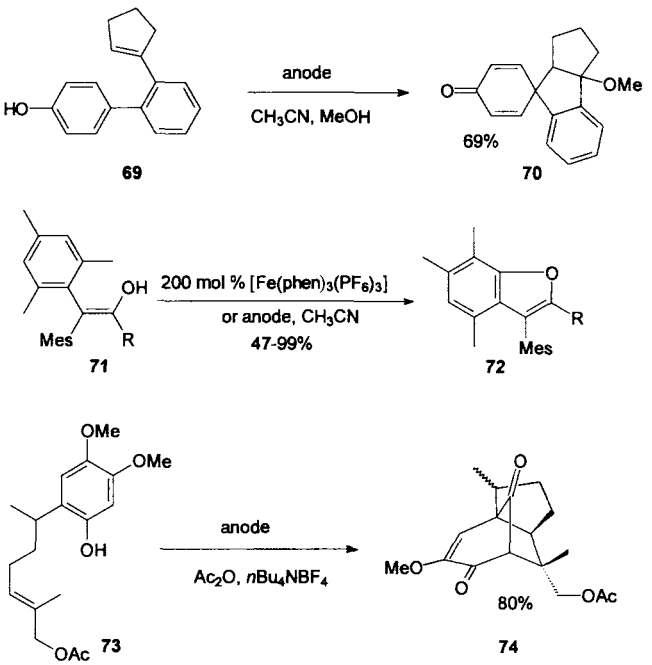
R-A-H	$pK_a(RAH^{\bullet+})$	k_{dep} [$M^{-1}s^{-1}$]
67	+3	27
68	+17	4.3×10^5

This indicates that charge distribution and the identity of the atom to which the proton is attached do play an important role in determining kinetic acidities. Thermochemical and kinetic data for deprotonation on π-A-H$^{\bullet+}$ are basically unkown with the exception of a few pK_a values for oxime radical cations (e. g. $CH_3CH{=}NOH^{\bullet+}$).[165]

4.2.1. π-A-H$^{\bullet+}$ Deprotonation

The π-A-H$^{\bullet+}$ deprotonation constitutes an extremely useful synthetic transformation, in particular for phenols,[166, 167] hydroquinones,[166] enols,[168] anilines,[169] and compounds with related functionalities.[170] In most cases, under anodic or chemical oxidation conditions the formed radicals are rapidly oxidized to intermediate cations ([$\rightarrow$AH, R^+_{ox}]), from which the observed chemistry is readily understood. The mechanistic scheme may end up being very complex when oxidation of the radicals is rather slow, since radical–neutral and radical–radical combination reactions may prevail (e. g. with phenoxyl radicals).[171]

The cations generated in a [$\rightarrow$AH, $R^{\bullet}_{ox}$] sequence were used for intriguing intramolecular reactions, for example in the synthesis of spiro compounds[172] and benzofurans,[168] the synthesis of natural products,[173] and other important transformations[166] (Scheme 38). Cations that are generated accordingly may also undergo fragmentation; this process is used in transacylation chemistry.[174]

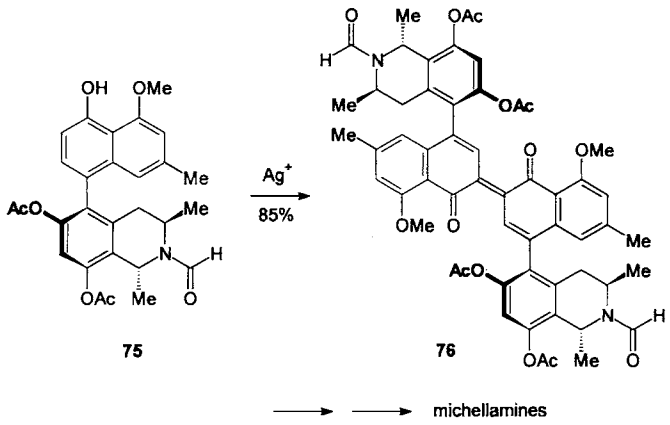


Scheme 38. The [$\rightarrow$AH, $R^{\bullet}_{ox}$] reactions according to Swenton (1991, top), Schmittel (1994, middle), and Yamamura (1991, bottom); phen = 1,10-phenanthroline; Mes = $2,4,6\text{-}Me_3C_6H_2$.

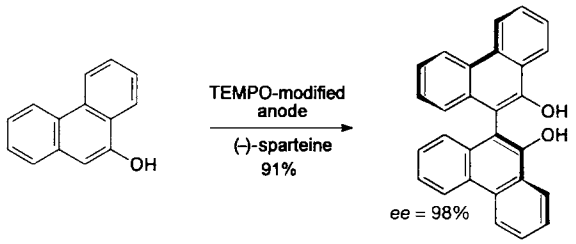
Importantly, the resulting cationic intermediates can also be trapped in intermolecular processes, such as in the synthesis of neolignan natural products.[175] The oxidation mechanism of phenols is of paramount interest in connection with biosynthetic coupling reactions,[176] with quinone and quinol[177] formation, and protecting-group chemistry.[178] Recently, this approach found intriguing use in the total synthesis of michellamines A, B, and C (Scheme 39), which are members of a biologically important class of quateraryls with outstanding activity against HIV.[179] Most importantly, such intermolecular coupling reactions can be conducted in a highly enantioselective way with chiral Cu^{II} complexes[180] or TEMPO-modified graphite electrodes in the presence of (−)-sparteine (Scheme 40).[181]

In most cases, α-carbonyl radicals are more difficult to oxidize than the parent enol precursors,[30] and mostly α-carbonyl radical chemistry is observed in such a protocol. For example, addition to unsaturated compounds led to inter-[182] and intramolecular bond formations; the latter has interesting applications in spiroannulation strategies.[183]

Whereas π-A-H$^{\bullet+}$ deprotonation reactions are often effected with π-O-H$^{\bullet+}$, they are rather rare with π-N-H$^{\bullet+}$. In the



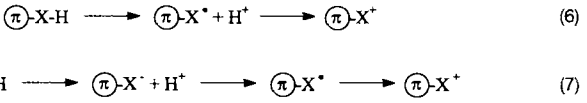
Scheme 39. The [→ AH, $R^{\bullet}_{ox}$] reaction according to Bringmann (1994).



Scheme 40. The [→ AH, $R^{\bullet}_{rad}$] or the [→ AH, $R^{\bullet}_{ox}$] reaction according to Osa (1994); TEMPO = 2,2,6,6-tetramethylpiperidin-*N*-oxyl.

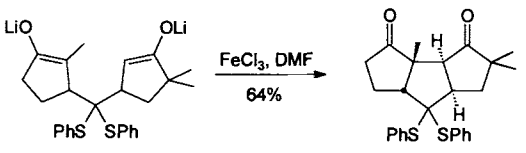
case of the latter ⓟ-C-H$^{\bullet+}$ deprotonation, if feasible, is often the dominant reaction pathway, as with the anodic dimerization of tetrahydrocarbazole.[184, 185] In contrast to the above-mentioned functionalities, enamines are most likely to be classified as ⓝ$^{\bullet+}$ [186] and will be treated in Section 4.2.2. However, the electron-deficient benzotriazole forms a π radical cation that can be arylated after ⓟ-N-H$^{\bullet+}$ deprotonation.[187]

The propensity to react via the cation formed after the secondary oxidation of the radical ([→ AH, $R^{\bullet}_{ox}$]) can be readily understood by comparing the oxidation potentials of neutral precursors and radicals. However, oxidation potentials of ⓟ-X$^{\bullet}$ are only scarcely known, except for phenols/phenoxyl radicals and enols/α-carbonyl radicals (Table 12). It is certainly helpful to recognize that the formal transformation (6) in Scheme 41 may be accessed as a function of the pH of the solution by reaction (7). This holds true in particular



Scheme 41. The formal oxidation (6) can be realized as a function of the pH value as reaction (7).

for phenols and enols/ketones even at pH values well below the pK_a value,[190] as documented in the oxidation of teniposide,[191] the coupling of (+)-verbenone,[192] and in a new synthesis of hirsutene[193] (Scheme 42). Such an approach



Scheme 42. Key step in the synthesis of hirsutene according to Cohen (1993).

allows additional control of the reaction: Radical or cationic intermediates can be generated in a defined manner, since oxidation potentials of phenolate/phenoxyl radical and enolate/α-carbonyl radical are neatly spaced.[160] Equally, such oxidative coupling can be performed with high simple and induced diastereoselectivity.[194]

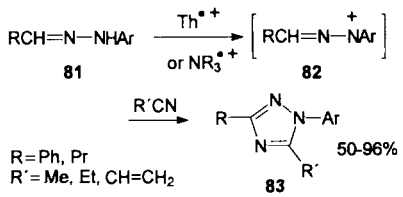
4.2.2. ⓝ-A–H$^{\bullet+}$ Deprotonation

The ⓝ-A-H$^{\bullet+}$ deprotonations known at present are limited to a small number of functionalities derived from -N–OH, -N–NH_2, -S–SH, and -P–NH_2. Their synthetic potential is therefore still restricted to a few examples.[195] Nevertheless, ⓝ-A-H$^{\bullet+}$ deprotonation plays a dominant role in the oxidative formation of 1,2,4-triazoles from arylhydrazones such as **81** (Scheme 43),[196] azo compounds from hydrazines,[197] and pyrazoles from chalcones and benzalacetones[198] in the presence of nitriles. The mechanistic scenarios of these ⓝ-A-H$^{\bullet+}$ deprotonations are not fully settled. Hence, we assume, on the basis of the high acidity (see Table 10), that loss of a proton should always be much faster than nucleophilic attack. Follow-up radical oxidation should then provide intermediate cations, from which the reactions can be understood (Scheme 43). The same radical intermediates may be prepared from one-electron oxidation of the corresponding anions at rather low potential, as demonstrated for iminoxy radicals.[199]

The situation of hydrazine$^{\bullet+}$ is representative for all ⓝ-A-H$^{\bullet+}$ systems. While numerous reports deal with the chemistry and properties of fully alkylated hydrazine radical cations,[200] very little is known about the oxidation of mono-, di-, and trialkylated systems.[201] Equally little is known about the controlled one-electron oxidation of enamines for which N–H deprotonation could play a viable role,[202] presumably

Table 12. Oxidation potentials of ⓟ-A-H and ⓟ-A$^{\bullet}$ (versus SCE).

ⓟ-A-H	E_{ox}	Ref.	ⓟ-A$^{\bullet}$	E_{ox}	Ref.
	1.33	[188]		1.02	[188]
	0.55	[189]		0.23	[189]
	1.07	[160]		0.60	[160]
	1.15	[160]		0.65	[160]

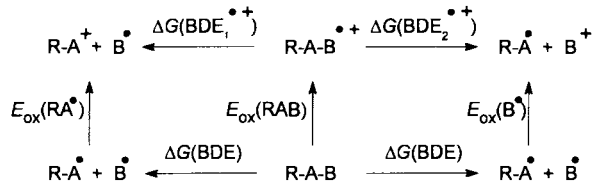


Scheme 43. The [→ AH, $R^{\bullet}_{ox}$] reaction according to Shine (1988).

because of their high reactivity with respect to oxygen.[203] Hence, such reactions have found only very limited use, for example in the formation of α,β-unsaturated imines.[204]

4.3. A–B Bond Dissociation

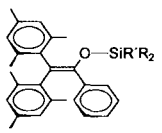
A thermochemical cycle similar to that in Scheme 23 is often used for predicting ㊀-A-B$^{\bullet+}$ or ⓝ-A-B$^{\bullet+}$ bond energies; however, two different cleavage modes are possible to yield either A or B as cationic fragments (Scheme 44). As expected, the fragment with the lower radical oxidation potential will always end up as the cation upon monomolecular bond scission. In reality, only a few combinations A–B have found use in synthesis (see below), since bond cleavage at the stage of the radical cation has to be fast to compete successfully with other pathways.



Scheme 44. Thermochemical cycle for determining the A–B bond dissociation energy (BDE) and cleavage selectivity.

Unfortunately, there is very little experimental data for the thermochemical driving force[205] and the kinetics of ㊀-A-B$^{\bullet+}$ cleavage. Fragmentations of ㊀-O-SiR$_3^{\bullet+}$ and ㊀-O-C$^{\bullet+}$ were investigated recently by Kochi[206a] and Schmittel.[206b, 207] From the few kinetic data available, it has become clear that ㊀-O-Si$^{\bullet+}$ bond cleavage is slower than that of ㊀-O-H$^{\bullet+}$, and that it can be induced by addition of nucleophiles such as alcohols and pyridines (Table 13). In accordance with the nucleophile-induced bond-cleavage mechanism,[208] the O–SiMe$_2$*t*Bu cleavage is significantly slower than that of O–SiMe$_3$.[206b]

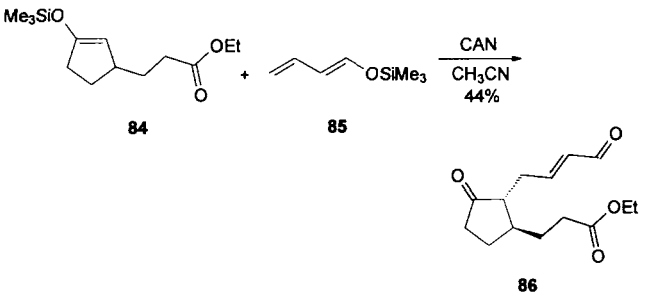
Table 13. Kinetics of ㊀-O-Si$^{\bullet+}$ bond fragmentation in CH_3CN and CH_2Cl_2 [206b].



R′	R	k_{AB} [s^{-1}] (in CH_3CN)	k_{AB} [s^{-1}] (in CH_2Cl_2)	k_{AB} [$M^{-1}s^{-1}$], induced with MeOH (in CH_2Cl_2)
Me	Me	$> 10^4$	1.3×10^2	8.7×10^5
*t*Bu	Me	6.0×10^2	1.3×10^{-1}	1.1×10^2

4.3.1. ㊀-A-B$^{\bullet+}$ Bond Dissociation

Among the numerous combinations possible for ㊀-A-B, only A–B = O–SiR$_3$ (e. g. enol and phenol silyl ethers) were studied more extensively, whereas others with A–B = O–SnR$_3$,[209] O–COR,[207] O–P(OEt)$_2$,[210] O–PO(OEt)$_2$,[210] O–TiCp$_2$Cl,[211] O–AlCl$_2$,[212] S–CHR$_2$,[205] and Si–Si[213, 214] were only recently introduced. Bond cleavage of ㊀-A-B$^{\bullet+}$ was used in enone[215] formation and in the elegant chemoselective deprotection of silyl enol ethers in the presence of siloxy substituents (developed by Gassman).[216] Otherwise, ㊀-O-SiMe$_3^{\bullet+}$ bond cleavage was utilized in various intermolecular C–C bond formation processes.[217] After chemoselective oxidation of the trimethylsilyl dienol ether **85** the formed α-carbonyl radical is not further oxidized because of its high oxidation potential[30] but instead adds to **84** (Scheme 45). The resulting radical is only thereafter further oxidized ([→ AB, $R^{\bullet}_{add.ox}$]).[218] Similarly, ketene silyl acetals react under oxidative conditions in intermolecular C–C bond formations,[219] indicating that radical cations may play an important role in the Lewis acid mediated Mukaiyama–Michael reaction.[220]



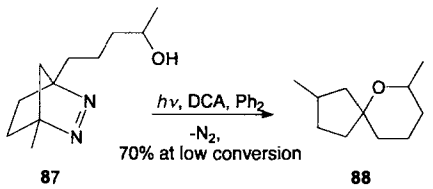
Scheme 45. The [→ AB, $R^{\bullet}_{add.ox}$] reaction according to Ruzziconi (1993).

Intermolecular reactions were accomplished with n nucleophiles, for example after desilylation of ㊀-O-SiMe$_3^{\bullet+}$ and further oxidation of the resulting radicals ([→ AB, $R^{\bullet}_{ox}$]),[221] as well as with anion radicals generated by PET.[222] Even ㊀-O-C$^{\bullet+}$ and ㊀-S-C$^{\bullet+}$ fragmentations are possible, as shown in the deprotection of aryl glycosides.[223]

4.3.2. ⓝ-A-B$^{\bullet+}$ Bond Dissociation

A particularly rich chemistry of ⓝ-A-B$^{\bullet+}$ fragmentations was reported for azoalkane radical cations. At first glance, one is led to classify such a process as bond cleavage directly at the electrophore. This, however, ought to be kinetically unfavorable in terms of the almost orthogonal arrangement of the two orbitals involved (n, σ).[224] Thus, we prefer to regard azoalkane radical cations as ⓝ=N-C$^{\bullet+}$ species in which the n electrophore is represented by the second nitrogen.

While little synthetic use has been made from acyclic azoalkane radical cations,[225] the corresponding cyclic systems give rise to distonic radical cations[226, 227] that undergo interesting rearrangements[228] with a remarkable stereochemical memory effect.[229] In addition, spiroethers were obtained after intramolecular cyclization (Scheme 46).[230]

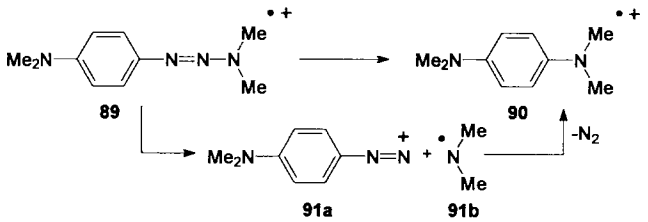


87 88

Scheme 46. The [→ AB, $RC_{Nu,red}$] reaction according to Adam (1993).

Predictions are difficult to make since only few kinetic data are available[231a] on the bond cleavage, but it seems that in bicyclic systems both strain[231b] and electronic effects[231a] are important. As expected, the efficiency of the fragmentation is determined by the stabilization of the resulting radical and cation.[224a, b] In acyclic *cis*-azoalkane radical cations, however, inversion at the nitrogen is more rapid than C–N bond cleavage.[232]

The ⓝ=N-N$^{\bullet+}$ bond cleavage that takes place in triazene radical cations with a rate constant k of about 0.01 s^{-1}[233] is much slower than the ⓝ=N-C$^{\bullet+}$ scission of azoalkane radical cations. It was indicated in several cases that clean N–N scission yielding a diazonium cation and a nitryl radical is the dominant reaction (Scheme 47);[234, 235] this may have important biochemical consequences, as triazenes are regarded as carcinogenic compounds.



Scheme 47. The [→ AB, $R^{\bullet}_{rad}$] reaction according to Speiser (1992).

4.3.3. ⓢ:A-B$^{\bullet+}$ Bond Cleavage

Recently, major interest has focused on reactions of peralkylcyclopolysilanes which contain small and medium-sized rings and exhibit rather low oxidation potentials that decrease to 0.4 V versus SCE with decreasing ring size.[236] In line with our classification, the unpaired electron in hexamethyldisilane$^{\bullet+}$ and hexamethyldigermane$^{\bullet+}$ is localized in σ orbitals between the two metals.[237] Cleavage of the Si–Si bond in cyclopolysilane$^{\bullet+}$[238] to yield synthetically interesting α-alkoxypolysilanes[239] and in linear polysilane$^{\bullet+}$ was studied (Scheme 48).[240] In **94**$^{\bullet+}$[241] the Si–Si bond cleavage is an intramolecular nucleophile-assisted process, as deduced from mass spectrometry fragmentation profiles.[242]

Cleavage of the Si–Si bond was also observed upon PET of hexamethyldisilane and aromatic nitriles to provide silylation at the aromatic ring; unfortunately, it proceeded only in very moderate yields.[243] By the same token, Sn–Sn,[244] Sn–Ge,[244] Sn–Si,[244] and Ge–Ge[245] bond ruptures were documented at the stage of the radical cation. While kinetic data on these bond cleavages are lacking, a qualitative ranking was tentatively provided: Si–Si < Ge–Ge ≪ Sn–C.[245]

94 95 96

Scheme 48. The [→ AB, $RC_{Nu,red}$] reaction according to Hirai (1986, top) and the [→ AB] reaction according to Nakadaira (1991, bottom).

4.4. C–C Bond Dissociation

Although C–C bond fragmentations play an important role in synthetic radical cation chemistry, their special significance results from fundamental and industrial aspects, that is, the oxidative break down of softwood lignin[246] and new processes for converting coal into chemicals and fuels.[247] In numerous cases C–H deprotonation competes with C–C bond dissociation, and in order to prevail C–C bond fragmentations mostly need to be exergonic. As illustrated in Scheme 44, simple calculations of thermochemical cycles and semiempirical methods[248] can be used to estimate the two-center one-electron bond strengths.

Bibenzyl$^{\bullet+}$—the prototype of a coal model compound—preferentially reacts by deprotonation,[249, 250] since the estimated C–C bond strength of 29 kcal mol^{-1} in acetonitrile is too high.[251] In many investigations it became clear that upon adding alkyl,[113, 249] aryl,[252–255] hydroxy,[256–259] siloxy,[256] or alkoxy[251, 260–263] substituents to the CH_2CH_2 unit, the barrier for ⓟ-C-C$^{\bullet+}$ scission could be lowered because of the more favorable thermodynamics.[264] Such bond dissociation energies (Table 14) are helpful for devising fast cleavage reactions; for instance, a PET-induced fragmentation is only feasible if ΔG^0 is smaller than 10 kcal mol^{-1}, otherwise it may not compete with back electron transfer.[251]

Table 14. Calculated change in enthalpy for ⓟ-C-C$^{\bullet+}$ bond scission.

Since C–C bond scissions most often proceed monomolecularly and only rarely in a nucleophile-assisted process,[267] it is possible to make reasonable predictions on the kinetics (based on the extensive work by Akaba,[268] Das,[269] and Maslak[270, 271]), as a linear correlation[272] between kinetic and thermodynamic data for ⓟ-C-C$^{\bullet+}$ rupture could be derived (Figure 2). Indeed, the activation barriers proved to be almost identical with experimental ΔG^0 values.[271] The activation data in Table 15 reveal strongly negative activation

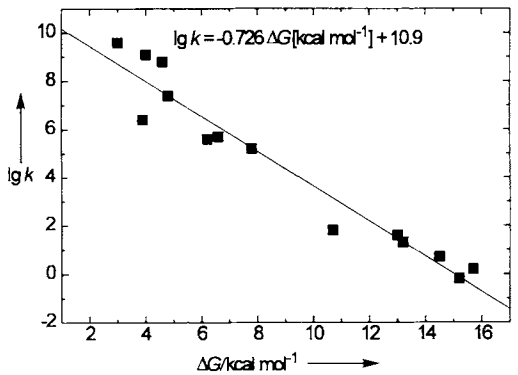

Figure 2. Linear correlation of $\lg k$ and the thermodynic driving force ΔG for the bond dissociation of substituted 1,2-biarylethanes [271].

entropies for all bicumyl$^{\bullet+}$ fragmentations, which demonstrates the importance of considering the charge localization and the concomitant changes in solvation in the transition state.[270] This charge localization in the scissile bond was verified in calculations as well,[45] whereas in the reactant radical cations (for example bibenzyl$^{\bullet+}$ [248] and aryl alkane$^{\bullet+}$ [45]) the charge and the spin density is only delocalized over one of the aromatic rings.[274] A lucid picture with regard to the role of stereoelectronic factors, charge delocalization, solvent effects etc. has been drawn in an insightful review.[275]

An aspect of high synthetic consequence was recently disclosed through the work of Dinnocenzo,[267] who demonstrated that ⓝ-C-C$^{\bullet+}$ cleavage in **97** follows a nucleophile-induced cleavage pathway. Optically active (*R*)-**97** reacted with methanol under clean inversion to the optically active methyl ether **98** (Scheme 49).[267] The inversion of configuration at C2 was rationalized by attack of the nucleophile onto the ring-closed radical cation from the backside in a three-electron S_N2 reaction; the explicit mechanistic details could be construed with the valence-bond configuration-mixing model.[276] The observed bimolecular rate constants that are dominated by electronic rather than steric factors range around $10^6 - 10^8\,M^{-1}s^{-1}$, which points to rather fast induced C–C bond cleavage.[277] So far nucleophile-induced fragmentations are apparently restricted to strained systems.[278] In contrast, thermodynamic (Table 16) and kinetic data for ⓝ-C-C$^{\bullet+}$ fragmentation are only available for few systems: Ph(PhNH)CH–CHPh(OH)$^{\bullet+}$: $k_f = 3.7 \times 10^5\,s^{-1}$,[279] Ph(*N*-morpholinyl)HC–CHPh(*N*-morpholinyl)$^{\bullet+}$: $k_f = 9.6 \times 10^7\,s^{-1}$.[280]

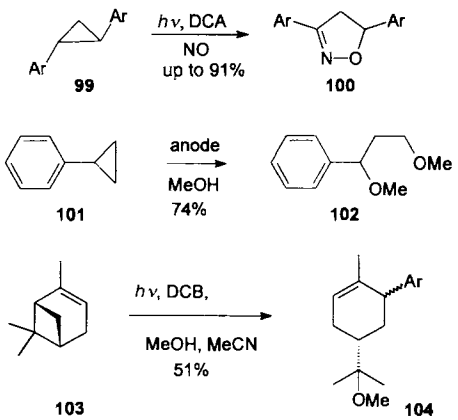
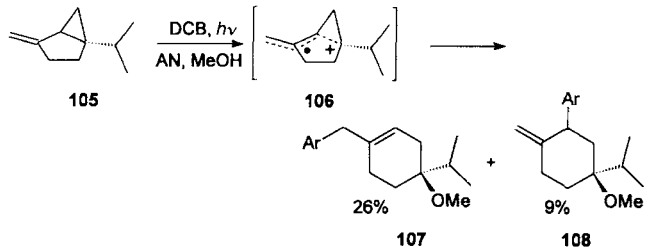
4.4.1. ⓟ-C-C$^{\bullet+}$ Bond Dissociation

The ⓟ-C-C$^{\bullet+}$ bond dissociation often has to compete with ⓟ-C-H$^{\bullet+}$ deprotonation, as long as the latter is feasible.[281] Hence, an extra driving force for ⓟ-C-C$^{\bullet+}$ bond scission may be desirable, and is often brought about in strained carbocyclic systems. A good part of the hitherto known examples stem indeed from strained cyclopropanes,[282] spiroalkanes,[283] cyclobutanes, or oxiranes.[284] Synthetically interesting reactions may subsequently be derived from trapping the ring-opened distonic radical cation with electron-rich double-bond systems,[285] oxygen,[286] NO,[287] or n nucleophiles (Scheme 50).[288, 289]



Scheme 50. The [→ CC, $RC_{Nu,rad}$] reaction according to Mizuno (1992, top), the [→ CC, $RC_{Nu,ox}$] reaction according to Shono (1970, middle), and the [→ CC, $RC_{Nu,RA}$] reaction according to Arnold (1989, bottom).

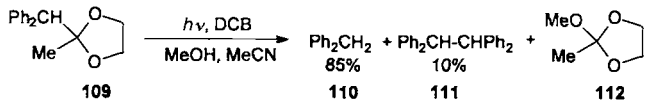
A high degree of stereo- and regioselectivity was disclosed in the PET oxidations of (1*R*,5*R*)-(+)-sabinene (**105**; Scheme 51), which emphasizes the importance of distribution



Scheme 51. The [→CC,$RC_{Nu,RA}$] reaction according to Roth (1994); AN = acetonitrile, Ar = 4-NCC_6H_4.

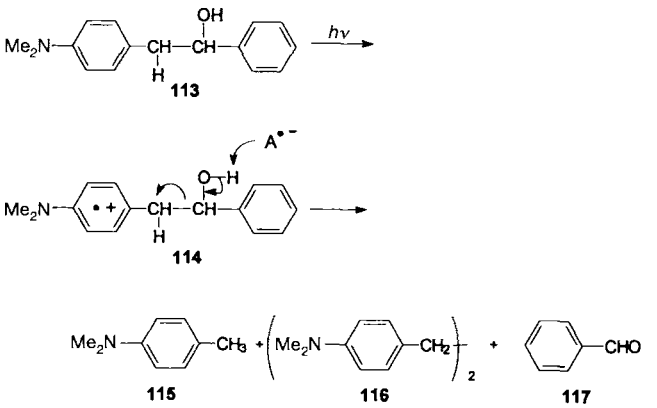
of spin and charge in the radical cation for the resulting chemistry[290] and points again to the occurrence of a nucleophile-assisted ⓟ-C-C$^{\bullet+}$ cleavage. Similarly, in the PET oxidation of (+)-carene, Arnold observed a stereo- and regioselective ⓟ-C-C$^{\bullet+}$ bond opening in the presence of methanol, whereas in acetonitrile (+)-carene$^{\bullet+}$ was partially racemized.[291] To rationalize the regioselective attack of methanol a simple rule was provided: The center with the lower oxidation potential will preferentially react as carbocation.[291]

One-electron oxidation of unstrained olefins and arenes equally leads to C–C bond cleavage if the bond dissociation energy can be lowered adequately (Scheme 52);[251, 292] the



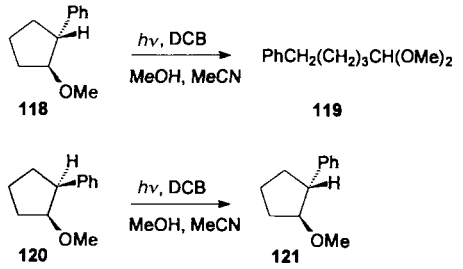
Scheme 52. The [→CC,$R^{\bullet}_{red}$] reaction according to Arnold (1989).

electron apportionment of the two cleavage fragments can be concluded by the thermodynamic stability of the two possible cations. The ⓟ-C-C$^{\bullet+}$ bond cleavage reactions of unstrained systems may also occur in a base- or nucleophile-induced mode, as demonstrated by Whitten and Baciocchi. However, only a few cases were reported so far (Scheme 53).[293]



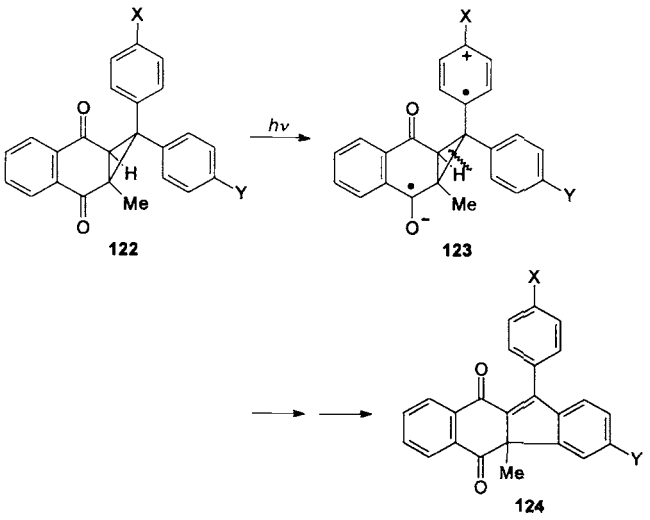
Scheme 53. The [→CC] reaction according to Whitten (1989); A = thioindigo.

Until now, only little attention has been devoted to stereoelectronic factors controlling ⓟ-C-C$^{\bullet+}$ bond scission. Clearly, the rate of fragmentation should be higher with increased overlap between the π electrophore and the scissile σ bond.[294] Conversely, a dihedral angle (defined by the plane of the π system and the C–C bond) of 90° ought to lead to slower cleavage, as demonstrated for the methyl 2-phenylcyclopentyl ether radical cation.[251, 261b] While *trans*-**118** readily underwent ⓟ-C-C$^{\bullet+}$ fragmentation, the *cis* compound **120** afforded **121** after oxidation, deprotonation, reduction, and reprotonation (Scheme 54). Similar stereoelectronic effects were detected for the ⓟ-C-C$^{\bullet+}$ cleavage of indane, 2,3-dihydrobenzofuran, and furan derivatives[262b] as well as for substituted cyclohexanes.[263]



Scheme 54. The [→CC,$RC_{Nu,red}$] reaction according to Arnold (1989, top) and the [→CH,$R^{\bullet}_{red}$] reaction according to Arnold (1991, bottom).

In PET-initiated ⓟ-C-C$^{\bullet+}$ cleavages, the rate of back electron transfer may often surpass that of the desired reaction. An efficient strategy for avoiding back electron transfer in such schemes uses rapidly fragmentable acceptors in a cofragmentation protocol[295] or "cooperative C–C fragmentation". In the latter reaction the scissile bond is flanked by a radical cation and a radical anion substituent (see for example **123** in Scheme 55).[296]

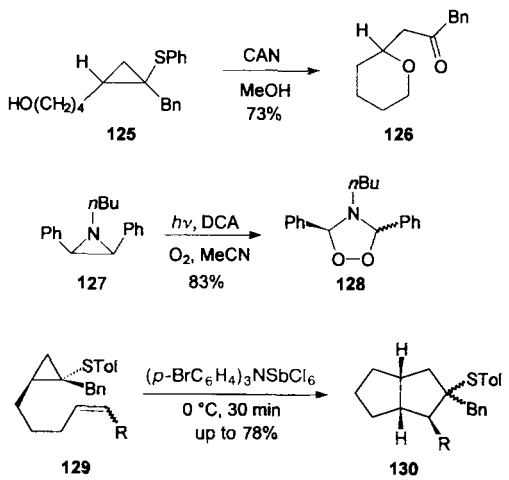


Scheme 55. The [→CC] reaction according to Oshima (1996); X = Y = H, Me, OMe.

4.4.2. ⓝ-C-C$^{\bullet+}$ Bond Dissociation

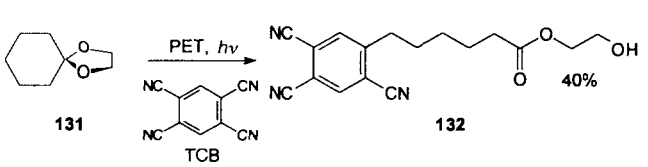
The controlled C–C bond rupture in ⓝ-C-C$^{\bullet+}$ has not been used as often as in ⓟ-C-C$^{\bullet+}$, but it was beautifully employed

in the synthesis of anhydrovinblastine.[297] Again, one has to provide the necessary thermochemical driving force, which can be accomplished by stabilizing the resulting cationic and/or radical fragments.[298, 299] Otherwise ⓝ-C-C$^{\bullet+}$ bond rupture may not compete successfully with deprotonation. As cation stabilization is the more important contributor, N, S, O, and aryl substituents are most helpful for inducing a ⓝ-C-C$^{\bullet+}$ cleavage mode, as demonstrated with amino ketones,[300] amino alcohols,[301] and β-phenylamines.[302] Fragmentations of amino alcohol radical cations may proceed by a base-assisted mechanism.[266] In addition, one finds ⓝ-C-C$^{\bullet+}$ bond scission is feasible in strained carbocyclic[303] or heterocyclic[304, 305] ring systems. In particular, substituted cyclopropyl sulfides such as **125**[303] and **129**[306c] were extensively exploited in intramolecular etherifications, spiroannulations, and diquinane synthesis (Scheme 56).[306]



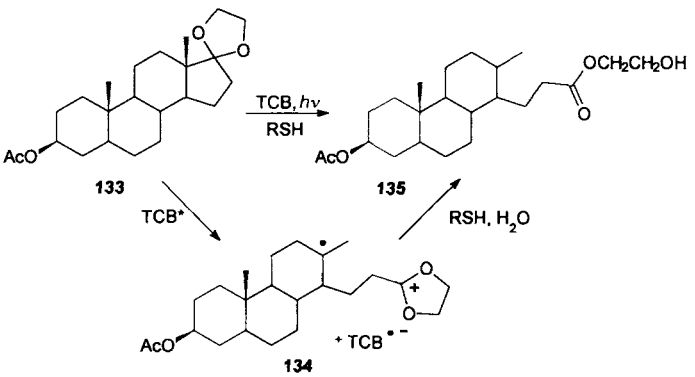
Scheme 56. The [→CC,RC$_{Nu,ox}$] reaction according to Iwata (1994, top) and the [→CC,RC$_{CA,red}$] reactions according to Schaap (1983, middle) and Iwata (1995, bottom); Tol = $H_3CC_6H_4$.

Depending on the structure ⓝ-C-C$^{\bullet+}$ cleavage can readily outrun ⓝ-C-H$^{\bullet+}$ deprotonation.[300b] Accordingly, deprotonation seems to be much less a problem with dioxolane$^{\bullet+}$, as C–C bond rupture is almost exclusively observed.[307] However, because of the high oxidation potentials of dialkyldioxolanes (> 2.7 V versus SCE), only very strong acceptors (such as excited TCB) provide enough driving force for the electron transfer. After ⓝ-C-C$^{\bullet+}$ bond cleavage in **131** the distonic radical cation couples to the TCB radical anion (Scheme 57).



Scheme 57. The [→CC,RC$_{Nu,RA}$] reaction according to Albini (1992).

Through the proper choice of reaction conditions, radical–radical anion coupling can be avoided in such PET reactions; for example, **135** was obtained from **134** in the presence of thiols by hydrogen-atom abstraction (Scheme 58).[308] Likewise, aliphatic ethers readily undergo ⓝ-C-C$^{\bullet+}$ cleavage[309] after oxidation, since a portion of the driving force stems from their high oxidation potentials.[77]

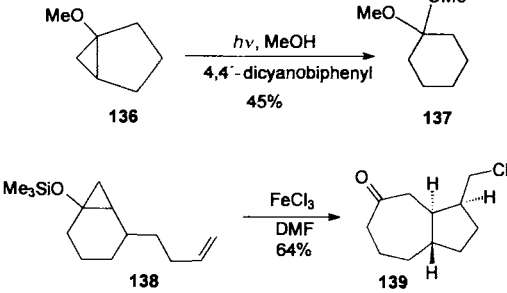


Scheme 58. The [→CC,RC$_{Nu,rad}$] reaction according to Albini (1994).

Steric and stereoelectronic effects in ⓝ-C-C$^{\bullet-}$ fragmentations were shown to be important in amino alcohols and diamines as well. The most favorable conformation for bond cleavage is that with the two heteroatomic functionalities in an antiperiplanar arrangement.[266]

4.4.3. ⓞ-C-C$^{\bullet+}$ Bond Dissociation

Important recent contributions to ⓞ:C-C$^{\bullet+}$ are derived from studies on strained carbocycles, for example cyclopropanes (Scheme 59),[310, 311] bicyclobutanes,[312] tetrahedranes,[313] and housanes.[229] ESR investigations on alkane radical cations show that in general inner C–C σ bonds are selectively weakened.[314] This is in line with cleavage selectivities observed in pulse-radiolysis experiments. Stereoelectronic factors are not expected to play an important role, as the unpaired electron is already removed directly from the scissile bond.



Scheme 59. The [→CC,RC$_{Nu,red}$] reaction according to Gassman (1988, top) and the [→CC,RC$_{-E,add}$] reaction according to Booker-Milburn (1992, bottom). RC$_{-E,add}$: radical cations result after loss of an electrofuge from a double bond.

4.5. C–X Dissociation

The C–X dissociation energies can be estimated according to the thermochemical cycle in Scheme 44 (Table 17). Unfortunately, their usefulness is not clear: Several examples of nucleophile-assisted ⓣ-C-Si$^{\bullet+}$ cleavages[208] were disclosed by Dinnocenzo, which were induced by addition of the appropriate nucleophiles. Only in light of such a mechanism can it

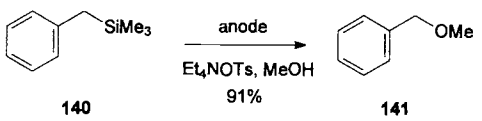
be understood that a C–Si bond worth about 30 kcal mol^{-1} in the *p*-methoxybenzyltrimethylsilane$^{\bullet+}$ is selectively cleaved at about 1×10^6 s^{-1} at room temperature.[315-317] Consonant with this proposal, the rate of C–Si bond rupture increases with more nucleophilic partners and with less crowded SiR_3 fragments.

The kinetics of n-C-X$^{\bullet+}$ cleavages were only recently studied, however only for n-C-Si$^{\bullet+}$. In the case of $PhN(Me)CH_2$–$SiMe_3^{\bullet+}$ a clear dependence of k on the concentration of MeOH, H_2O, and nBu$_4$NF indicates a silophile-induced desilylation.[89] The second-order rate constants revealed the desilylation to be a rather rapid process: 8.9×10^5 (MeOH), 1.27×10^6 (H_2O), and 3.1×10^9 M^{-1}s^{-1} (nBu$_4$NF).

4.5.1. π-C-X$^{\bullet+}$ Bond Dissociation

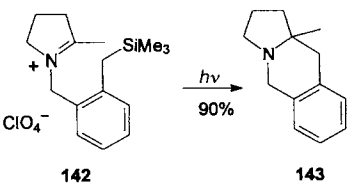
Although π-C-X$^{\bullet+}$ have not been investigated as extensively as π-C-H$^{\bullet+}$ or π-C-C$^{\bullet+}$ scissions, they have some intriguing synthetic value insofar as they allow the predetermination of the scissile bond.[320] In particular, by using the trialkylsilyl or the trialkylstannyl group as a kind of "super proton" an interesting oxidative approach to the desired radicals can be set up (Scheme 60);[321] this works even better than π-C-H$^{\bullet+}$ deprotonation.[322] Such π-C-X$^{\bullet+}$ bond cleavage reactions with stannanes have some potential for unconventional imaging systems, an idea that was first exploited by Eaton.[323]



140 141

Scheme 60. The [→ CX, R$^{\bullet}_{ox}$] reaction according to Yoshida (1986).

The synthetic potential of π-C-SiR$_3^{\bullet+}$ and π-C-SnR$_3^{\bullet+}$ bond rupture was explored by Mariano in both intermolecular and intramolecular variants using iminium salts as photooxidants.[324] High yields could be realized through intramolecular radical–radical coupling reactions, for example **142** → **143** (Scheme 61). Alternatively, other processes can be triggered after π-C-X$^{\bullet+}$ bond scission (e. g. [→ CX, R$^{\bullet}_{RA}$]), as in the photobenzylation or allylation of aromatic or heteroaromatic compounds.[325-327]



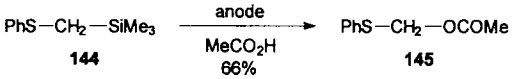
142 143

Scheme 61. The [→ CX, R$^{\bullet}_{rad}$] reaction according to Mariano (1984).

In particular, C–Si bond cleavage in benzyl and allyl silanes is so fast that substitution at the π system cannot compete.[328] As a consequence benzylsilanes were used as interesting mechanistic probes to differentiate between hydrogen-atom abstraction and electron transfer, for example in side-chain bromination.[329] Studies on silaindane$^{\bullet+}$ indicated that π-C-Si$^{\bullet+}$ bond cleavage is not dependent on stereoelectronic factors, presumably because of the strong Si–O bond formed in the nucleophile-assisted mode with ROH.[330]

4.5.2. n-C-X$^{\bullet+}$ Dissociation

Similar to the case of π-C-X$^{\bullet+}$, n-C-X$^{\bullet+}$ bond cleavage was exploited to cleave selectively a preconditioned bond (mostly in amines, sulfur, and other nitrogen-centered electrophores with X = SiR_3 and SnR_3 as superelectrofuges). For instance, α functionalization can readily be accomplished after n-C-X$^{\bullet+}$ bond scission of arylthiomethylsilane **144**[321a] as an alternative to n-C-H$^{\bullet+}$ deprotonation of sulfides (Scheme 62).[331] In some special cases the observed stereoselectivities indicate a n-C-X$^{\bullet+}$ fragmentation[332] induced by the intramolecular attack of a nucleophilic double bond. The



144 145

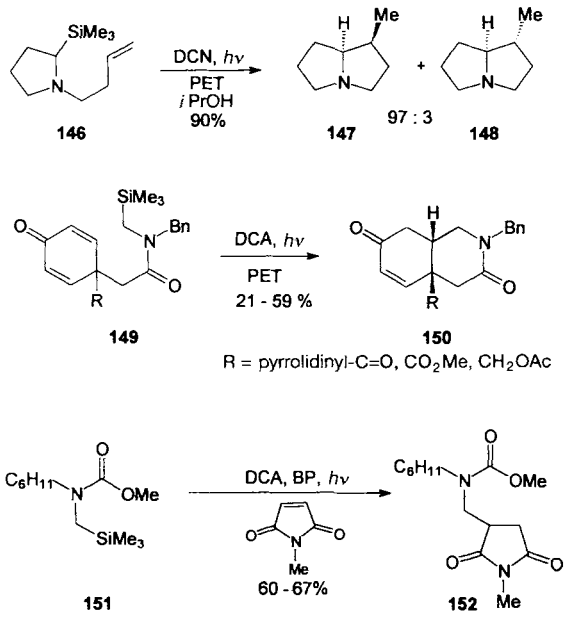
Scheme 62. The [→ CX, R$^{\bullet}_{ox}$] reaction according to Fuchigami (1989).

n-C-X$^{\bullet+}$ cleavages have efficiently been exploited in intramolecular cyclizations,[85, 332-334] for example in the synthesis of (−)-retronecanol,[332a] but only seldomly in intermolecular reactions, for example with α-silylthioethers[335] and with carbamates (Scheme 63).[336]

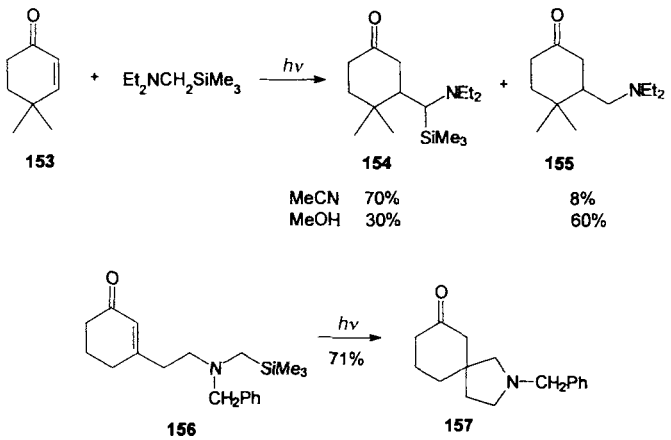
After intra- and intermolecular PET from α-silylamines onto enones, the follow-up reactions can be steered by the choice of solvent (Scheme 64). As proton transfer from the amine radical cation to the enone radical anion is fast in aprotic media (e. g. CH_3CN) almost no desilylation but mainly deprotonation is observed. In protic solvents, where a hydrogen bonding decreases the basicity, desilylation is preferred.[337] Intramolecular ET in **156** opened the way for a spiroannulation.[333] In continuation of the above strategy, a sequential double-desilylation methodology was recently devised for generating a nonstabilized azomethine ylide that could be employed in the synthesis of 1-azabicyclo[*m*.3.0]-alkanes.[338]

4.5.3. σ-C-X$^{\bullet+}$ Dissociation

Similar schemes as for π-C-X$^{\bullet+}$ and n-C-X$^{\bullet+}$ bond cleavages were set up in σ:C-X$^{\bullet+}$ reactions, in particular for silanes and stannanes such as silyl and stannyl[339] ethers as well as 2-silyl-[340] or 2-stannyl-1,3-dithianes.[341] After one-electron oxidation **158** cleaves to form the tributylstannyl

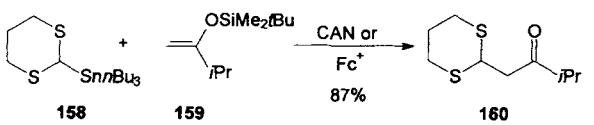


Scheme 63. The [→ CX, $R^{\bullet}_{add,red}$] reactions according to Pandey (1992, top), Mariano (1992, middle), and Steckhan (1995, bottom); BP = biphenyl.



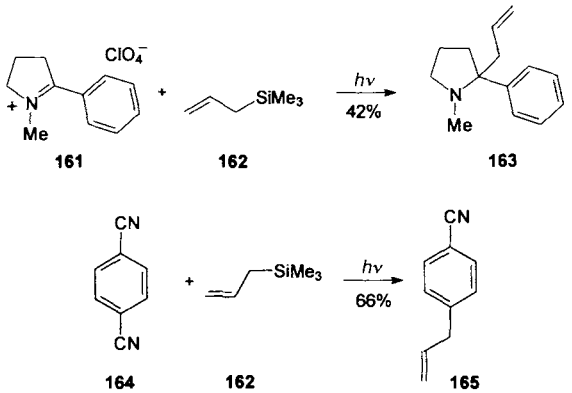
Scheme 64. The [→ CX, $R^{\bullet}_{RA}$] reactions according to Mariano (1988, top; 1989, bottom).

radical and the 1,3-dithian-2-yl cation;[342] the latter could be efficiently trapped with various unsaturated, electron-rich substrates such as olefins and silyl enol ethers (Scheme 65).



Scheme 65. The [→ CX, $R^{\bullet}_{ox}$] reaction according to Narasaka (1993); Fc^+ = ferrocenium ion.

The C–Sn unit as σ electrophore[343] and readily scissable element has found elegant use in the functionalization of stannyl ethers,[339] carbamates,[339] carboxamides,[344] benzil,[345] and carbamides.[344] Many C–X cleavages that take place after oxidation of simple allylsilanes and allylstannanes should also be categorized as ⓞ:C-$X^{\bullet+}$ reactions, for example **162** (+**161**) as [→ CX, $R^{\bullet}_{rad}$][346] and **162** (+**164**) as [→ CX, $R^{\bullet}_{RA}$] (Scheme 66).[347]



Scheme 66. The [→ CX, $R^{\bullet}_{rad}$] reaction according to Mariano (1982, top) and the [→ CX, $R^{\bullet}_{RA}$] reaction according to Otsuji (1985, bottom).

In a direct comparison it was found that ⓞ:C-$Sn^{\bullet+}$ bond cleavage is much more facile than ⓞ:C-$Si^{\bullet+}$ rupture,[342, 348] however, neither thermochemical nor absolute rate data are available.[349] In contrast to reports on π-C-$Si^{\bullet+}$ fragmentations[208], ⓞ:C-$Si^{\bullet+}$ do not undergo nucleophile-assisted cleavage.[348]

4.6. Attack of nucleophiles

In the preceeding sections, oxidative incorporation of a nucleophile was effected by trapping a cationic intermediate after cleavage (e. g. [→ CH, $R^{\bullet}_{ox}$] or [→ AB, $R^{\bullet}_{ox}$]). However, this is also possible by direct attack of a nucleophile onto a radical cation, for example in aromatic substitution.[350]

Although a large number of $RH^{\bullet+}$–Nu reactions were studied,[25] there are basically no general guidelines on how to set up an ideal system. Part of the problem arises from the complex mechanistic schemes that may be operative in seemingly identical reactions. Whereas mechanistic details were identified in singular cases, they are unknown for most reactions. Several mechanistic scenarios that depend on the nucleophile and $RH^{\bullet+}$ need to be discussed, as outlined in detail by Hammerich and Parker,[351] for example disproportionation,[352] complexation, and half-regeneration (Scheme 67). In addition, Okazaki stressed that deprotonation of the primary adduct is important for protic nucleophiles such as alcohols and water.[353]

While in the early 1980s the kinetics of radical cation–nucleophile combinations was intensely investigated, these studies were often hampered by the fact that complex mechanisms[354, 355] were operative as a consequence of using radical cations of low reactivity. A long-standing discussion on the reactivity of radical cations with nucleophiles[356–358] has taken place ever since. Although additional kinetic studies were undertaken with the advent of nanosecond and picosecond time resolved techniques, no consistent picture of this reaction mode has emerged so far.

disproportionation:

$$2\,RH^{\bullet+} \rightleftharpoons RH^{2+} + RH$$
$$RH^{2+} + Nu \longrightarrow \text{products}$$

complexation:

$$RH^{\bullet+} + Nu \rightleftharpoons (RH/Nu)^{\bullet+}$$

[a] 2,4,6-trimethylpyridine.

A controversial message resulted from considerations of the valence-bond curve-crossing model,[358] which stated that the Ⓐ$^{\bullet+}$–Nu and Ⓝ$^{\bullet+}$–Nu reactions are formally forbidden, and therefore quite slow. The apparent failure of the curve-crossing model to predict correctly the barrier to the reaction of 9-phenylanthracene$^{\bullet+}$ with pyridine emphasized the necessity of taking additional parameters into consideration, that is, the association constants of ground and excited state reactants.[359]

A large body of kinetic data was published over the last decade, especially for substituted phenylanthracenes and styrenes by Parker[360-363] and Johnston,[364, 365] respectively (see Table 18). It was demonstrated that π radical cation–nucleophile combinations may be very rapid processes, and often approach the diffusion-controlled limit in the case of anionic nucleophiles. Despite the fact that many Ⓐ$^{\bullet+}$ compounds react rather rapidly, in particular with nitrogen nucleophiles, the situation is much more complex with oxygen nucleophiles[366] since examples exhibiting slow[367] and fast[364] attack have been documented. For example, primary amines react with the 9-phenylanthracene radical cation (**166**$^{\bullet+}$) by nucleophile addition at position 10 with second-order rate constants in the range 8×10^6 to $3 \times 10^9 M^{-1}s^{-1}$. The rates increased with increasing amine basicity and decreasing steric requirements.[360] In contrast, tertiary amines and anilines react with **166**$^{\bullet+}$ only by electron transfer (1.5×10^9 to $2 \times 10^{10} M^{-1}s^{-1}$), the rates of which correlate quite well with the oxidation potentials of the amine.[360] The reaction with substituted pyridines are markedly slower ($k = 10^3 - 10^7 M^{-1}s^{-1}$).[368]

Less studied are the kinetics with protic nucleophiles, which may react according to the deprotonation mechanism (see Scheme 67). In line with tabulated nucleophilicity data[369] the reaction rates with water and alcohols are much smaller than those with amines and pyridines.[353, 364] The Arrhenius activation energies determined for a series of substituted anthracene radical cations indicate the involvement of an initial π complex prior to bond formation (Scheme 68).[368]

$$A^{\bullet+} + Nu \longrightarrow (A/Nu)^{\bullet+}$$
$$(A/Nu)^{\bullet+} \longrightarrow A^{\bullet}\text{-}Nu^{+}$$

Scheme 68. Participation of a preliminary π complex in the reaction of substituted anthracene radical cations with nucleophiles.

Unfortunately, from a mechanistic point of view it is often very difficult to differentiate between Ⓐ$^{\bullet+}$+Ⓐ reactions (*r*adical *s*ubstrate *c*oupling, RSC) and Ⓐ$^{\bullet+}$/Ⓐ$^{\bullet+}$ combinations (*r*adical *r*adical *c*oupling, RRC). Clearly, the latter mode is often realized for anodic oxidations when the stationary concentration of the radical cations is as high as for the dimerization of triphenylamine.[370] Nevertheless, RSC mechanisms were established in the anodic dimerization of 4-methoxybiphenyl,[371] tetrahydrocarbazole,[354b] 4,4′-dimethoxystilbene,[372] and 9-methoxyanthracene radical cations.[373] It should be noted that under pulse-radiolysis conditions dimerization of triphenylamine proceeds preferentially by the rapid RSC mechanism ($k = 1 - 10 \times 10^7 M^{-1}s^{-1}$).[374]

Kinetic data on Ⓝ$^{\bullet+}$–Nu reactions are very scarce, but it was demonstrated recently that phosphane radical cations react with oxygen and sulfur nucleophiles[375] ($k = 10^5 - 10^7 M^{-1}s^{-1}$) following the same reactivity pattern as with styrene$^{\bullet+}$.[364] Moreover, a looser transition state for the reaction with thiols than with alcohols was indicated.[375]

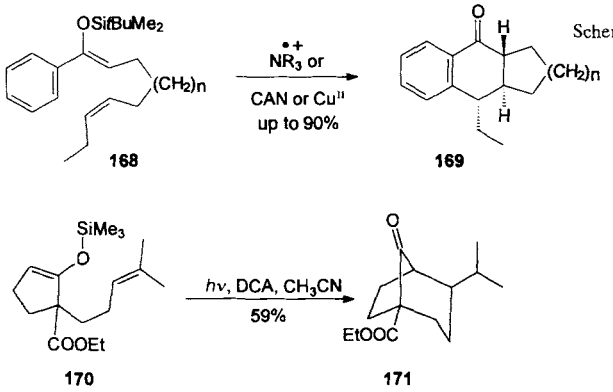
Concerning intramolecular processes, cyclization rate constants for the attack of double bonds on dialkylamine radical cations[376] ($k = 2 \times 10^7 - 1 \times 10^{10} M^{-1}s^{-1}$) were four orders of magnitude faster than those of dialkylaminyl radicals.

4.6.1. *Attack of Nucleophiles on* Ⓐ$^{\bullet+}$

Part of the large interest in the Ⓐ$^{\bullet+}$–Nu reaction derives from the importance of radical cations as intermediates in the metabolic activation of polycyclic aromatic hydrocarbons.[377]

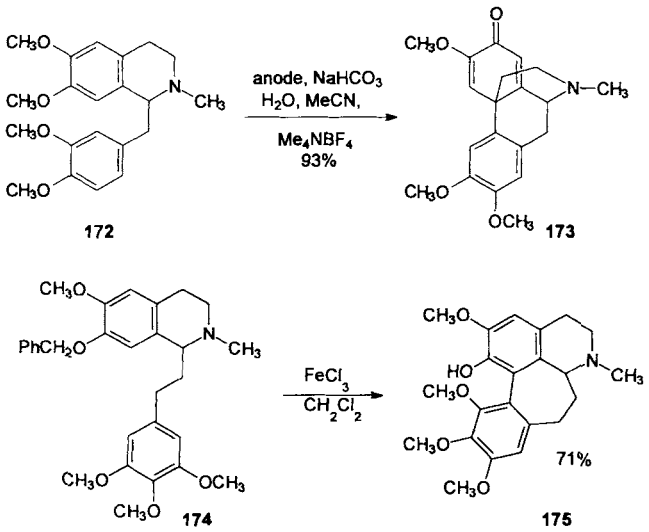
In addition, attack of nucleophiles on $\pi^{\bullet+}$ constitutes a reaction of large synthetic benefit and allows the formation of C–C, C–O, C–N, and other useful bonds.

Intramolecular reactions with π nucleophiles have attracted much attention because of their potential to construct synthetically useful five- and six-membered rings. In particular, arenes,[378, 379] alkyl enol ethers,[380, 381] enol thioethers,[381] silyl enol ethers,[378, 382–384] and enol esters[385] were used because of their low oxidation potentials (Scheme 69). According to Moeller,[386] enol ether cyclizations are best described as reversible; the outcome is controlled by the ease of oxidation of the intermediate distonic radical cation.



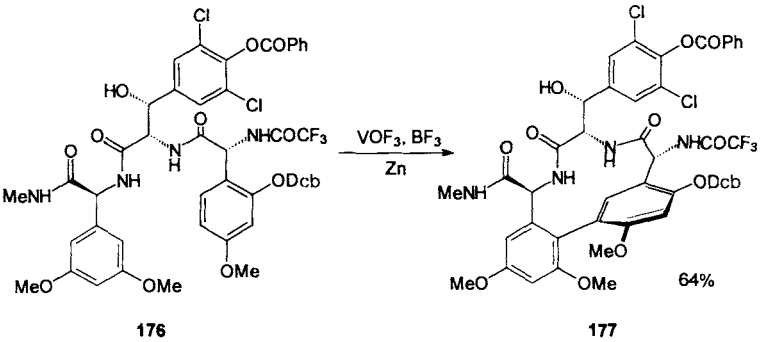
Scheme 69. The [→ Nu, $R^{\bullet}_{ox}$] reaction according to Snider (1990, top) and the [→ Nu, $R^{\bullet}_{red}$] reaction according to Mattay (1992, bottom).

The intramolecular variant with aromatic electrophores was often exploited for synthesis, for example in the transformation of the tetrahydroisoquinoline systems into alkaloids with the morphinane framework[387] and to kreysigine (**175**, Scheme 70).[388] Because of the electron-rich catechol unit, the π system of **172** and **174** is more readily oxidized



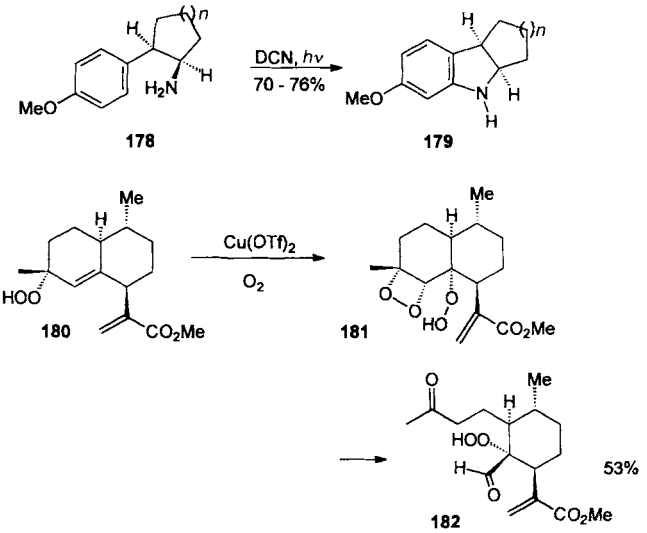
Scheme 70. The [→ Nu] reactions according to Miller (1978, top) and Herbert (1995, bottom).

than the amine functionality. Recent research focused on using this protocol for a biomimetic atropselective coupling to vancomycin antibiotics (**177**, Scheme 71),[389] as well as in the synthesis of isostegnan,[390] lignan lactones,[391] and deoxyschizandrins.[392]



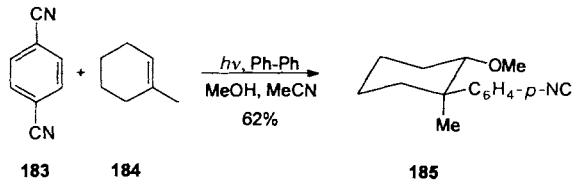
Scheme 71. The [→ Nu, $R^{\bullet}_{ox}$] reaction according to Evans (1993); Dcb = 3,4-dichlorobenzyl.

Likewise, n nucleophiles such as OH,[393, 394] COOH,[48, 395] and even NH_2[396, 397] can be applied in intramolecular cyclizations to trap olefin and arene radical cations, as demonstrated for the construction of **179** (Scheme 72).[396] Intramolecular attack of a hydroperoxy group onto an olefin radical cation is thought to constitute the key step in the synthesis of qinghaosu derivatives,[398] which makes use of the oxidant in only catalytic amounts (Scheme 72).



Scheme 72. The [→ Nu, $R^{\bullet}_{ox}$] reaction according to Pandey (1990, top) and the [→ Nu, $R^{\bullet}_{rad}$] reaction according to Haynes (1990, bottom); Tf = F_3CSO_2.

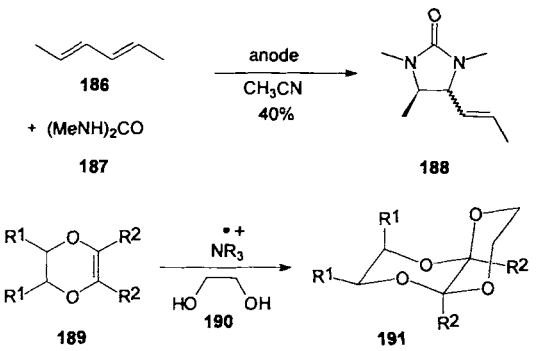
Synthetically useful intermolecular C–C bond formations were realized with π nucleophiles and cyanide, mostly under conditions of anodic oxidation (e. g. in dimerizations[399, 400] and cross couplings). As a special variant the photo-NOCAS (*n*ucleophile–*o*lefin *c*ombination *a*romatic *s*ubstitution) reaction after PET between an olefin and a cyanoaromatic acceptor was developed by Arnold (Scheme 73).[104, 401] First,



Scheme 73. The [→ Nu, $R^{\bullet}_{RA}$] reaction according to Arnold (1988).

184$^{\bullet+}$ is attacked by nucleophiles such as methanol or cyanide before the resulting radical reacts with the anion radical.

Transformations involving intermolecular attack of n nucleophiles at ⓟ$^{\bullet+}$ include reactions at olefins,[402] enol esters,[403] enol ethers (Scheme 74),[404] benzofurans,[400] dienes (Scheme 74),[405, 406] furans,[407] pyrrolidines,[408] and ketene imines.[409] In the cases where *cis* and *trans* adducts are formed, the diastereoselectivity depends on the solvent polarity and the bulkiness of the nucleophile.[402, 410] Importantly, the attack of n nucleophiles on ⓟ$^{\bullet+}$ proceeds by an *anti*-Markovnikov addition.[411]

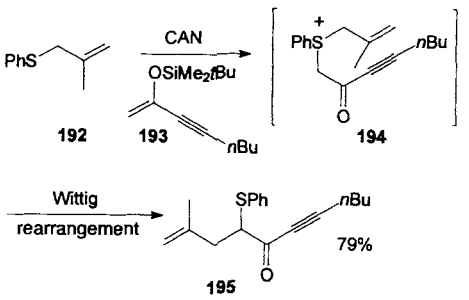


Scheme 74. The [→ Nu, $R^{\bullet}_{ox}$] reactions according to Schäfer (1979, top) and Lopez (1987, bottom).

In some instances interesting cyclizations of the resulting radical were triggered after attack by alcohols at the ⓟ$^{\bullet+}$ species.[412] Also the first enantioselective methanol addition under PET conditions was recently realized,[413] which required the enantiofacial-differentiating step to take place in a contact ion pair.[414] Further synthetic use of such ⓟ$^{\bullet+}$–Nu reactions was explored in intermolecular C–C bond formations starting from enamine[100, 415, 416] and silylated *aci*-nitroalkane radical cations.[417]

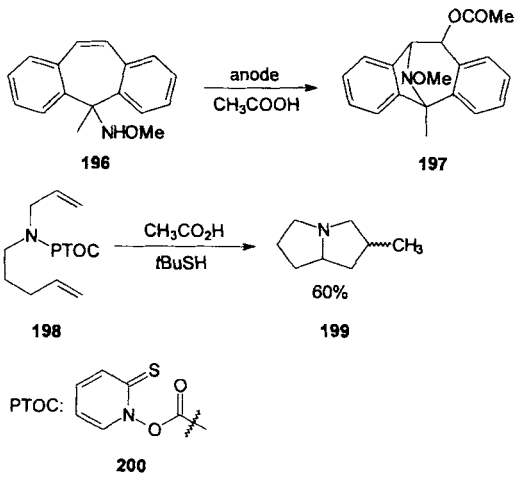
4.6.2. *Attack of Nucleophiles on* ⓝ$^{\bullet+}$

Attack of a nucleophile onto a ⓝ$^{\bullet+}$ species was observed mainly for nitrogen, phosphorous, and sulfur compounds. It plays an meaningful part in the formation of oxygenated derivatives (P,[418] S[419]) and in removing sulfur protecting groups.[420–422] In contrast to nitrogen-centered radical cations that undergo a rich chemistry with C–H and C–C bond cleavage, $R_3P^{\bullet+}$ and $R_2S^{\bullet+}$ suffer predominantly nucleophilic attack[423, 424] with only few exceptions.[425] Attack by carbon nucleophiles may also take place: For example, **192**$^{\bullet+}$ is attacked by a silyl enol ether to yield **195** by a Wittig rearrangement of the intermediate sulfonium salt (Scheme 75).[426]



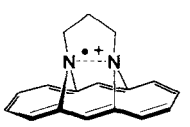
Scheme 75. The [→ Nu, $R^{\bullet}_{ox}$] reaction according to Narasaka (1991).

Intramolecular cyclizations of amine radical cations were exploited to furnish five-membered rings. In this protocol the distonic radical cation, formed after intramolecular cyclization to a π bond system, is further oxidized; this was demonstrated impressively in the anodic formation of **197** (Scheme 76).[427] A conceptually related cyclization protocol was devised by Newcomb that allows the synthesis of perhydroindoles, pyrrolizidines (for example **199**, Scheme 76), and other heterocyclic systems.[428] As an exception, the amine radical cation is generated by protonation of the neutral aminyl radical, which itself was formed from the PTOC carbamate **198**. As a pivotal point, the cyclization of the electrophilic radical cation has to be much more efficient than that of the neutral radical. The cyclized distonic radical cation is then deprotonated and trapped with RSH to afford product **199**. This strategy is related to the cyclization of *N*-chloroamines and nitrosamines in many ways.[429]



Scheme 76. The [→ Nu, $R^{\bullet}_{ox}$] reaction according to Karady (1989, top) and the [→ Nu, $R^{\bullet}_{add}$] reaction according to Newcomb (1987, bottom).

In very few cases the attack of a nucleophile can be stopped at the formation of a two-center three-electron bond.[430] An example is **201**$^{\bullet+}$, which exhibits a N–N distance of 216 pm that is shorter than in the neutral molecule (270 pm).[431]



201

4.6.3. *Attack of Nucleophiles on* ⓞ$^{\bullet+}$

Although ⓞ$^{\bullet+}$–Nu combinations may be involved in the oxidative coupling of strained carbocyclic ring systems with inert nucleophiles,[310b, 432] mechanistically it is very difficult to decide if nucleophilic attack takes place prior to ⓞ:C-C$^{\bullet+}$ cleavage. A clear cut case, however, was detected for quadricyclane$^{\bullet+}$; its C–C bond was opened by *t*BuOH with $k = 2.0 \cdot 10^6\,M^{-1}s^{-1}$.[494]

4.7. Cycloadditions and Other Pericyclic Processes

4.7.1. *A Mechanistic Interlude*

Cycloadditions and other pericyclic processes[433] such as rearrangements and cheletropic reactions have mostly been observed for ⓟ$^{\bullet+}$. These transformations provide an attractive incentive to investigate radical cation chemistry, since in the majority of cases the observed activation barriers are extremely low, and even forbidden processes can quite often be initiated. For a radical cation catalyzed pericyclic reaction the product should exhibit a higher oxidation potential than the reactant (Figure 3). Follow-up oxidation reactions of the product are thus avoided.

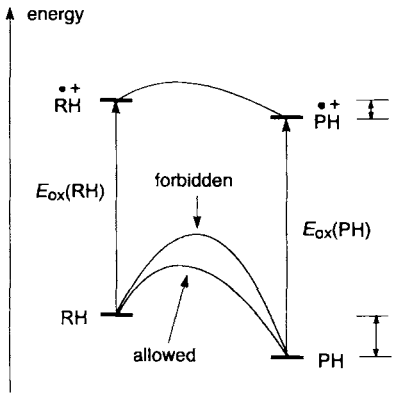


Figure 3. Energy diagramm of a radical cation catalyzed rearrangement RH → PH.

When selecting a chemical oxidant as catalyst (e. g. $NR_3^{\bullet+}$), it is advisable to generate the desired reactant radical cation in a moderately endergonic electron transfer preequilibrium with $\Delta E_{ox} = E_{ox}(RH) - E_{ox}(NR_3) \approx 0.3$–$0.6$ V (Scheme 77).

$$NR_3^{\bullet+} + RH \rightleftharpoons NR_3 + RH^{\bullet+} \qquad E_{ox}(NR_3) < E_{ox}(RH)$$

Scheme 77. The endergonic electron transfer equilibrium between RH and $NR_3^{\bullet+}$.

Since follow-up reactions of RH$^{\bullet+}$ are extremely rapid, the overall reaction rate is still reasonably fast despite the endergonic ET equilibrium. Larger differences in redox potential (ΔE_{ox}), however, slow down the overall reation too much. Kinetic studies of the Diels–Alder cycloaddition indeed revealed a curved Hammett–Brown plot, which is consistent with a mechanistic transition from reversible to rate-determining oxidation of RH.[434a] If ΔE_{ox} is too small, a very high concentration of the primary radical cations RH$^{\bullet+}$ results and leads to undesired radical cation–radical cation coupling reactions. Quite often the most critical step is the electron transfer reduction of PH$^{\bullet+}$ (Scheme 78, propagation

steps 1 and 2). Reduction can be more efficient when the neutral amine is added in excess,[435] and when neutral reductants are used instead of cationic reductants (e. g. $[Fe(phen)_3]^{2+}$).[11b] Chemical oxidation allows both modes of chain propagation, that is reduction of PH$^{\bullet+}$ by either the reduced oxidant (here NR_3) or by RH, whereas anodic initiation is limited to propagation step 2. In the case of chemical oxidation, propagation steps 1 and 2 are often parallel reactions; the former is strongly favored due to redox potential and reorganization considerations that render this mode much more efficient than anodic initiation.[436]

In PET-initiated pericyclic reactions the situation is quite different, since either an excited acceptor (Scheme 79) or—more rarely—an excited donor is used, which renders the initial ET process strongly exergonic. As reduction of PH$^{\bullet+}$ by A$^{\bullet-}$ is equally a strongly exergonic process, we usually do not see a chain process unless RH can compete as a reductant (Scheme 79). PET initiation allows for an array of additional

\end{aligned}$$

Scheme 79. Mechanism of PET-initiated pericyclic reactions.

alterations to control the outcome of the reaction; the details of this[42] exceed the limits of this review.

Despite their synthetic value, very little is known about the thermodynamics and kinetics of radical cation cycloadditions. As the barriers for the individual cycloaddition steps should be very small, even slight variations in substituent may result in drastic changes. Clearly, cross-cycloadditions are synthetically more important than cyclodimerizations. Recent studies by Johnston, Takamuku, and Brede[437, 438] have for the first time

provided an insightful picture of the rate differences for cycloaddition of various alkenes or dienes to 4-methoxystyrene and 4-methoxy-β-methylstyrene radical cations (Table 19).

Table 19. Experimental kinetic (room temperature) and activation data for radical cation cycloadditions.

	4.6×10^8		products unknown	[438]

Accordingly, steric effects at the electrophilic site as well as the ability of the added nucleophile RCH=CH_2 to stabilize radicals and cations play important roles; their importance is reflected in a rate decrease for R = Ph ≈ OR > vinyl > alkyl by a factor of 100–300.[437b] In principle, the observed trends follow those for the addition of carbocations to alkenes.[369]

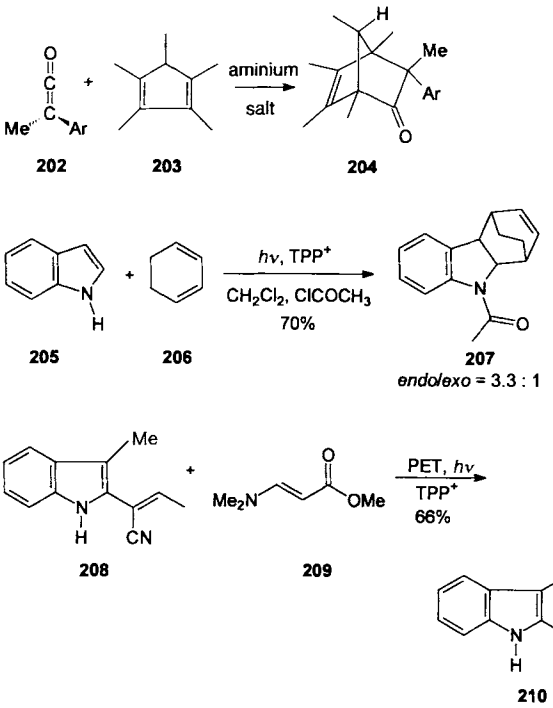
Recently, a thorough study shed some light on the details of the dimerization of stilbene$^{\bullet+}$. The reaction of stilbene$^{\bullet+}$ with stilbene proceeds with $k = 3.4 - 3.9 \times 10^8\,M^{-1}s^{-1}$ to yield first a π dimer then a σ radical cation.[439] As the dimerization proved to be very susceptible to steric effects, but not to change in the configuration at the double bond of the stilbene, it was proposed to involve initial formation of a π complex with overlap of two benzene rings.[440] Likewise, the kinetics of intramolecular radical cation Diels–Alder reactions and cyclobutanations were investigated for their use as radical cation probes. Rate constants of 10^7 to $10^9\,s^{-1}$ were found.[434b]

4.7.2. Cycloadditions and Other Pericyclic Processes

Since we would like to restrict the discussion to deliberately triggered ET processes, we will not discuss here cycloaddi tion mechanisms in which radical ion pairs form upon mixing of strong donor dienes and acceptor dienophiles or vice versa.[441]

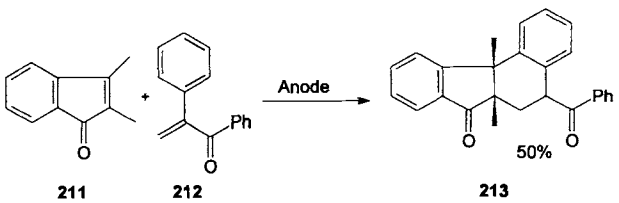
Cycloadditions and Cycloreversions

The paramount part of the literature is concerned with cycloadditions of olefins, whereas only very few contributions deal with cycloaddition on aromatic rings. After the pioneering work of Ledwith[442] and the seminal contributions of Bauld at the beginning of the 1980s,[443] numerous reports were published over the last 15 years that emphasize the synthetic value of this methodology.[444] This became particularly clear through the development of reactions that had not been realized by any other method before, for example Diels–Alder reactions of ketenes **202**[11] and indols **205**[10] as dienophiles and of vinylindoles[445] to carbazoles (such as **210**) and pyrido[1,2-*a*]indoles (Scheme 80). Since the richness of this chemistry is far beyond the scope of this article, the interested reader is refered to a recent review.[446]

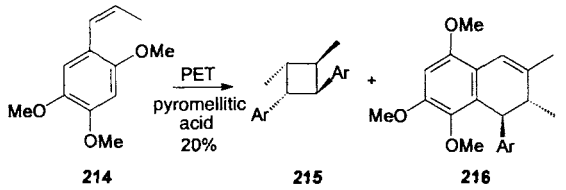


Scheme 80. The [→CA,RC_{red}] reactions according to Schmittel (1991, top), Steckhan (1990, middle) as well as Blechert and Steckhan (1994, bottom).

Although aromatic systems have a low propensity to take part in catalytic cycloadditions,[447] the driving force for the reaction of **211** and **212** is presumably due to the fact that *exo*-methylenecyclohexadiene$^{\bullet+}$ is more stable than toluene$^{\bullet+}$ (Scheme 81). Convincingly, the radical cation Diels–Alder cycloaddition was already tested in natural-product chemistry,[448] for example in the synthesis of β-selinene[449] and neolignan magnoshinin (**216**, Scheme 82).[450]



Scheme 81. The [→CA,RC_{red}] reaction according to Simonet (1986).



214 215 216

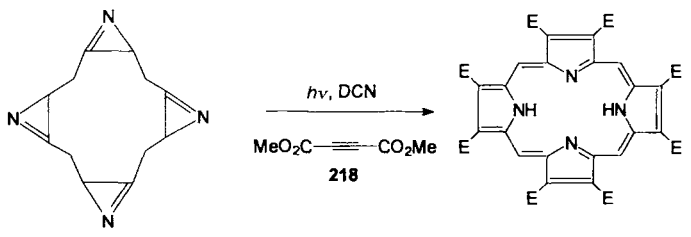
Scheme 82. The [→CA, RC_{red}] reaction according to Takeshita (1987).

The scope of radical cation catalysis was also extended to other cycloadditions, for example with diazomethane$^{\bullet+}$,[451] and to [2+2]cyclodimerizations of electron-rich alkenes.[452] Some of the PET-initiated [2+2]cycloadditions proceed stereoselectively, and others in a stepwise mode,[453] as in the case of 2,6-diarylocta-1,6-diene$^{\bullet+}$.[454]

From a mechanistic point of view, the Diels–Alder reaction can proceed via either a diene radical cation in a [3+2]cycloaddition or a dienophile radical cation in a [4+1]cycloaddition. Despite the fact that the [3+2] mechanism is formally forbidden[455] it proceeds as readily as the allowed [4+1] variant. In contrast to [4+1]cycloadditions, [3+2]cycloadditions, seem to occur by a stepwise mechanism, as recently disclosed for allene[456] and 2,3-diphenyl-1,3-butadiene[457] Diels–Alder reactions.

In other cases, radical cation catalysis was used to accelerate otherwise slow pericyclic processes. The most prominent example is the Diels–Alder cyclodimerization of cyclohexadiene,[22b] which was speeded up by a factor of 10^{15} with respect to the thermal reaction. Several other dienophiles and dienes were tested successfully as well.[446]

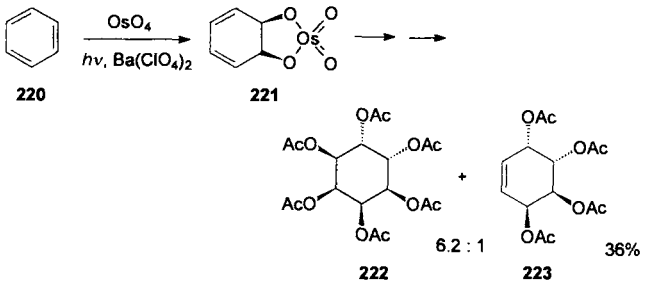
An exciting application was developed by Mattay.[458] Azirine$^{\bullet+}$ (generated by PET) can be opened to the 2-azaallenyl radical cations,[459] which readily add to various substrates such as imines and acetylenes to allow the synthesis of imidazoles,[458a, c] heterophanes,[458a, d] and even phorphyrines (Scheme 83).[458a, c] The intermediacy of an azaallene radical cation was demonstrated by an electron pulse radiolysis experiment, which indicated a lifetime in the microsecond range in the presence of imines.[458c]



217 218 219

Scheme 83. The [→CC, $RC_{CA,red}$] reaction according to Mattay (1992).

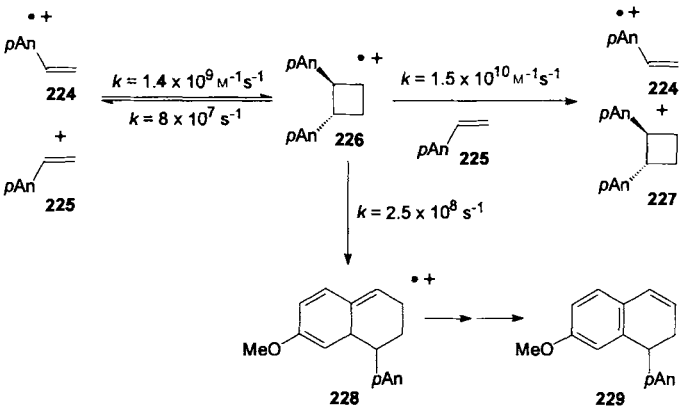
A particularly promising variant of radical cation cycloadditions can be triggered by PET from charge-transfer complexes. By using this conceptually simple method, a potent procedure—for example in the *cis*-hydroxylation of benzene and substituted analogues—was developed that allowed synthetic access to inosite and condurite derivatives (Scheme 84).[460]



220 221 222 223

Scheme 84. The [→RA] reaction according to Motherwell (1995).

Although the data in Table 19 show that the cycloaddition is very rapid, realization of a ET reaction poses a substantial challenge, since cyclodimerization may effectively compete with the desired cross-cycloaddition. Fortunately, a thorough picture of the [2+1]cycloaddition of 4-methoxystyrene (**225**) became available very recently,[365] which emphasizes the importance of the rapid one-electron reduction of intermediate **226**$^{\bullet+}$ by **225** (Scheme 85). As a consequence, the dihydronaphthalene **229** is formed at low concentrations of **225**, cyclobutane **227** is the major product while at higher concentrations.



Scheme 85. [2+1]Cycloaddition of 4-methoxystyrene (**225**) according to Johnston (1995); pAn = 4-$MeOC_6H_4$.

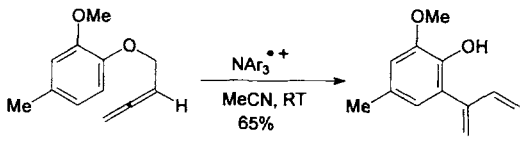
Cheletropic Reactions

Cheletropic reactions constitute a recent addition to the realm of radical cation catalysis.[461] Two processes, namely hole-catalyzed epoxidation[462] and cyclopropanation,[463] exhibit different chemoselectivities when compared to other epoxidation and cyclopropanation strategies. In particular, the more highly substituted double bond is usually attacked.

Rearrangements, Cyclizations, and Isomerizations

Rearrangements of radical cations in matrices, in the gas phase, and/or at very low temperature[464] have received much interest. While these studies—for example on the rearrangements of benzvalene$^{\bullet+}$,[465] semibullvalene$^{\bullet+}$,[466] cyclooctatetraene$^{\bullet+}$,[467] dihydropentalene$^{\bullet+}$,[468] 1,5-hexadiene$^{\bullet+}$,[469] 1,5-hexadiyne$^{\bullet+}$,[470] and many others[471]—have greatly contributed to our understanding of the low activation barriers of radical cation chemistry, only few of these processes have been translated into synthetic solution chemistry.

In recent years, radical cation catalysis has found elegant use for the acceleration of many thermally allowed and forbidden processes. Examples include the Cope,[472] Claisen[473] (Scheme 86), epoxide → ketone,[474] vinylcyclo-



230 231

Scheme 86. The [→R,RC$_{red}$] reaction according to Venkatachalam (1994).

butane,[475] vinylcyclobutanone,[11b] and vinylcyclopropane[476] rearrangements as well as the 1,16-hydrogen shift in an A/D seco corrin radical cation.[477] The stereochemical course of these rearrangements is quite diverse, and is stereospecific in the vinylcyclobutane[475, 478] and the Cope[472b] rearrangement but proceeds with retention, inversion, or partial loss of the stereochemical integrity in the rearrangement of vinylcyclopropane[479] and vinylcyclobutanone[11b] radical cations.

Although *cis* ⇌ *trans* isomerizations[480] have seldom been used in synthetic schemes, they have attracted ample interest from a mechanistic point of view[481] because of their potential in petroleum formation.[482] For a long time it was believed that olefin radical cation isomerization—stilbene$^{\bullet+}$ is a particularly well-studied representative[483]—is quite fast; however, it proved to be rather slow ($k = 10^4\ s^{-1}$).[484] As a consequence of the fast dimerization of stilbene$^{\bullet+}$, an addition–elimination mechanism may be feasible for the isomerization.[481] In contrast, derivatives of *cis*-stilbene$^{\bullet+}$ containing a *p*-MeO group isomerize much more rapidly ($k = 4.5 \times 10^6 - 1.4 \times 10^7\ s^{-1}$) by a unimolecular pathway to provide an insightful picture of the importance of separation and localization of positive charge and spin.[440] In addition, the reduction of the electron density at the unsaturated linkage is thought to accelerate the *cis* → *trans* isomerization.[485] The thermal *cis* → *trans* isomerization of polyene$^{\bullet+}$ took place within about the same time, as indicated by lifetimes of 2 μs.[486]

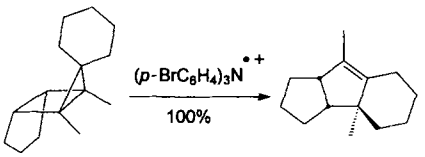
Electrocyclic Processes

Several contributions have addressed the theory governing electrocyclic reactions of open-shell systems.[455, 487] Such reactions should be very facile,[488] and their stereochemical course should in general correspond to that of the neutral molecule. This picture was indeed confirmed through the observation of conrotatory ring-opening reactions for cyclobutene$^{\bullet+}$[489] and benzocyclobutene$^{\bullet+}$.[490] The stereoselective ring opening of oxaziridines to nitrones was similarly observed in PET reactions.[491] So far, photochemical electrocyclic processes[492] of radical cations have received little attention despite the often unexpected results.

4.7.3. Pericyclic Processes of ⓝ$^{\bullet+}$ and ⓞ$^{\bullet+}$

With the exception of quadricyclane$^{\bullet+}$,[493] pericyclic reactions of pure ⓝ$^{\bullet+}$ and ⓞ$^{\bullet+}$ have rarely been investigated so far. The rapid interconversion ($k = 10^6\ s^{-1}$)[494] of quadricyclane$^{\bullet+}$ to its valence isomer, norbornadiene$^{\bullet+}$, has been the target of ample attention for almost thirty years. This is due not only to its potential to store solar energy and optical data, but also since many endeavours to observe quadricyclane$^{\bullet+}$ directly originally failed.[495] CIDNP,[496] optical spectroscopy[497] and ESR[494] evidence only recently unambiguously established it as a minimum structure. Quadricyclane$^{\bullet+}$ is about 7 kcal mol^{-1} higher in energy than norbornadiene$^{\bullet+}$ and is separated from it by an activation energy of 11 kcal mol^{-1}.[493a]

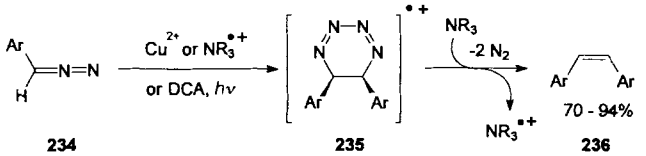
Moreover, mechanistic investigation of pagodane$^{\bullet+}$ and isopagodane$^{\bullet+}$ revealed the extreme points of [2+1]cycloreversions.[498, 499] Oxidative rearrangements of other strained carbocyclic systems were observed,[310, 500] but only few lead to synthetically useful products, for example as in the radical cation catalyzed formation of diquinane (**233**, Scheme 87).[501]



232 233

Scheme 87. The [→R,RC$_{red}$] reaction according to Adam (1995).

A rare event of a cycloaddition involving a σ radical cation was demonstrated for aryldiazomethanes **234**.[502] The radical cation chain cycloaddition ([→CA, RC$_{red}$]) could be triggered equally well by PET (DCA, *hν*) or chemical oxidation (Cu^{2+}, $NR_3^{\bullet+}$; Scheme 88).



234 235 236

Scheme 88. The [→CA,RC$_{red}$] reaction according to Sawaki (1992).

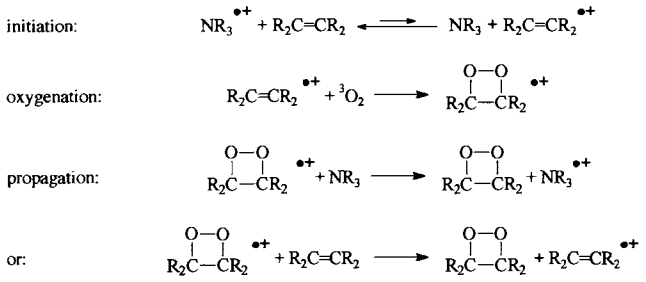
4.8. Reactions with Radicals

Reactions with short-lived radicals are not only interesting from a mechanistic point of view, but have also found use in PET processes.[503, 504] However, we focus our attention on the reaction of radical cations with stable radicals.

4.8.1. Reaction of ⓟ$^{\bullet+}$, ⓝ$^{\bullet+}$, and ⓞ$^{\bullet+}$ with Oxygen

Ever since the seminal contribution by Barton[505] on the aminium salt catalyzed oxygenation of ergosteryl acetate, this mild synthetic access to dioxetanes has attracted widespread interest. It should be noted, however, that the radical cation chain mechanism of this reaction was only recognized years later.[506] Oxygenations of radical cations were also invoked in

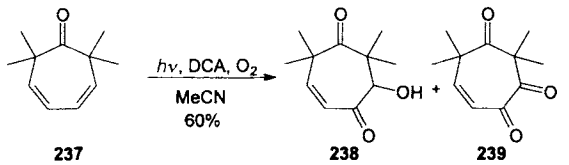
biological systems, as in the metabolic conversion of phenothiazine-based drugs.[507] Importantly, direct evidence for the occurrence of a dioxetane radical cation could be obtained;[508] it results from the stepwise addition of $^3O_2$ to a olefin radical cation (Scheme 89). Under PET conditions



Scheme 89. Mechanism of the radical cation induced addition of $^3O_2$ to olefins.

oxygenation may also proceed by two other viable mechanisms: a) reaction of the olefin radical cation with superoxide formed by ET from the radical anion to oxygen[509] or b) by an exciplex oxygenation mechanism.[510]

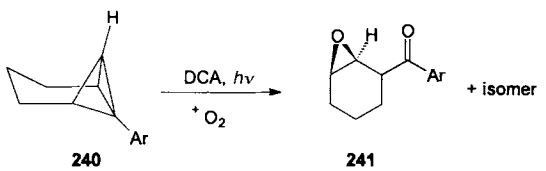
Over the last couple of years several π electrophores were oxygenated by an ET strategy: olefins,[511] dienes (Scheme 90),[505, 506, 512, 513] enol ethers,[514] arenes,[515] and others.[516] Similar conditions were applied in the oxygenation of n donors, such as with aromatic sulfides,[507, 517] 1,3-dithianes,[518] aziridines,[519] and phosphorous compounds.[520]



237 238 239

Scheme 90. The [→ Rad] reaction according to Schuster (1986).

Dioxanes and dioxolanes are accessible by oxygenation of distonic 1,4- or 1,3-radical cations. 1,2-Dioxanes, for instance, are formed after the photoinduced ET dimerization of diarylethenes[521] in the presence of oxygen via the intermediate 1,4-radical cation, which is attacked by $^3O_2$ at the radical site.[522] Furthermore, 1,4- and 1,3-radical cations obtained from C–C bond cleavage in cyclopropane$^{\bullet+}$, bicyclobutane$^{\bullet+}$ (Scheme 91),[523] and cyclobutane$^{\bullet+}$ equally react efficiently with molecular oxygen.[524, 525] Oxygenations can alternatively take place after ⓟ-C-H$^{\bullet+}$ or ⓝ-C-H$^{\bullet+}$ deprotonation to give rise to hydroperoxides[526] either with oxygen or superoxide.[527]



240 241

Scheme 91. The [→ CC,Rad] reaction according to Gollnick (1989).

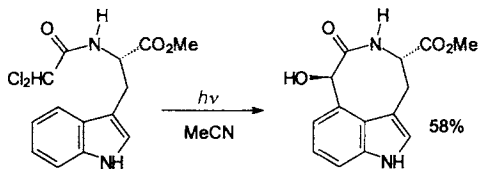
Recently, oxygenation of radical cations was also accomplished with several other reagents, for example in the epoxidation of olefin$^{\bullet+}$ with NO_2,[528] NO_3,[528] and SeO_2[462] as well as in the formation of sulfoxides from PET oxidation of sulfides with tetranitromethane.[529] Interestingly, NO_2 seems to react more efficiently with radical cations than O_2;[528] however, detailed kinetic data are not available yet.

It was demonstrated that oxygenation rates of aryl olefin radical cations are on the order of $10^6 M^{-1}s^{-1}$.[530] Since two electron-deficient radicals are combined, the reaction rates are two or three orders of magnitude lower than those for neutral radicals with oxygen.[531] In contrast, *trans*-stilbene$^{\bullet+}$ exhibits little reactivity towards oxygen, whereas derivatives with a *p*-MeO group react on the order of $k = 1.2 \times 10^7 - 4.5 \times 10^7 M^{-1}s^{-1}$. The enhancement in reactivity is most certainly due to charge–spin separation.[440]

4.8.2. *Reaction of* ⓟ$^{\bullet+}$, ⓝ$^{\bullet+}$, *and* ⓞ$^{\bullet+}$ *with Neutral Radicals*

Unfortunately, limited use is still being made of radical cation–radical reactions.[503] This reaction mode was originally postulated to be the primary reaction in the charge-transfer nitration of aromatic systems with tetranitromethane.[64] However, Eberson later demonstrated that such radical cation–NO_2 combinations may be very slow.[532] Results from the anodic nitration starting from naphthalene/nitrite mixtures[533] and ^{15}N CIDNP investigations by Lehnig[534] into the nitration of dimethoxybenzenes confirmed the mechanism of charge-transfer nitration for electron-rich arenes.

Some synthetic applications of this reaction mode are derived from PET systems by using "self-destructive" electron acceptors that can generate radicals.[535] The scope of this approach is particularly well demonstrated in PET systems leading to an intra-[536] or intermolecular[537] radical ion pair. When the site of the anion radical is designed to loose a nucleofuge, it may provide a reactive radical that can combine with the site of the radical cation.[503] This protocol opened interesting synthetic approaches to cephalotaxine,[538] pyrrolobenzazocine,[539a] and indolactam (Scheme 92).[539b] Also ⓝ$^{\bullet+}$ may react with radicals, as illustrated in the arylation of trivalent phosphorous compounds in ET reaction with aryl diazonium salts.[540]



242 243

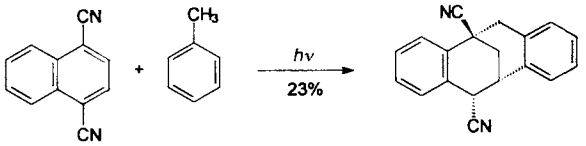
Scheme 92. The [→ Rad] reaction according to Moody (1988).

4.8.3. *Reaction of* ⓟ$^{\bullet+}$, ⓝ$^{\bullet+}$, *and* ⓞ$^{\bullet+}$ *with Anion Radicals*

Radical ion pairs may readily be generated from neutral precursors by PET. However, in most cases the only reaction

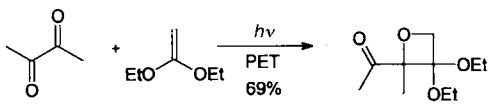
is unproductive back electron transfer of no synthetic value, except when one reactant is thus produced in the excited state. Nevertheless, there are two important reaction modes that have already found frequent use in synthetic schemes: deprotonations[503] and C–C bond formations.

In the context of deprotonation by radical anions, the reaction pathways may be controlled by choosing acceptors that produce highly basic radical anions after ET. However, in polar medium proton transfer may likewise involve the solvent as base, as elegantly demonstrated for 1,4-DCN–toluene.[154] While proton transfer within the ion radical pair provided the tetracyclic product **246** (Scheme 93), deprotonation of toluene$^{\bullet+}$ by the solvent resulted in the formation of *cis*-2-benzyl-1,2-dihydronaphthalene.[541]



Scheme 93. The [→ CH, $R^{\bullet}_{RA}$] reaction according to Albini (1982, 1984).

Although direct bond formation between radical cations and radical anions is rare, it is thought to play an important role in PET Paterno–Büchi reactions, which were studied in detail by Mattay (Scheme 94).[542] A similar cycloaddition is triggered in the PET reaction of 1,4-naphthoquinones and 1,1-diarylethenes, which exhibits a distinctly different outcome depending on the ΔG^0 of the electron transfer.[543] Moreover, the photochemical reaction of aromatic nitro compounds[544] and alkenes[545] may proceed by combination of a radical anion and a radical cation.

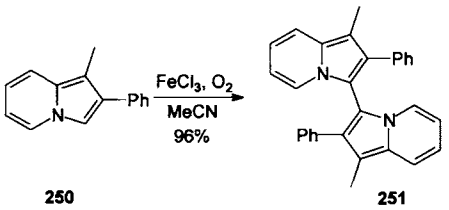


Scheme 94. The [→ RA] reaction according to Mattay (1987).

Combination of radical ions is a mechanistic borderline case in aromatic photonucleophile substitution (S_NAr^- versus S_NAr^*); it most likely takes place only in some limited cases.[546] A particular variant for combining radical ions is the reaction of ⓟ$^{\bullet+}$ with superoxide, which is generated by secondary ET from the acceptor radical anion to oxygen. Such combinations show rate constants near the diffusion limit,[530, 547] as in the case of stilbene$^{\bullet+}$ with $O_2^{\bullet-}$ ($k = 4.1 \times 10^{10}\,M^{-1}s^{-1}$).[530]

4.8.4. Dimerization of Radical Cations

As pointed out in Section 4.6, there is an unfortunate mechanistic uncertainty concerning as to whether a RSC or a RRC mechanism is operative[548] (Scheme 95) in oxidative dimerizations. Importantly, stable symmetric ⓟ$^{\bullet+}$ often undergo π dimer formation in the solid state[549] or in solution.[550]



Scheme 95. The [→ Dim] reaction according to Greci (1988).

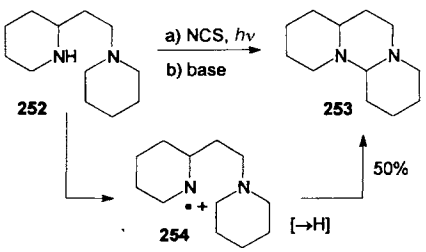
Nevertheless, dimerization of two radical cations[551] constitutes a process of utmost current interest, since it plays a key role in the industrially important electropolymerization of pyrroles and thiophenes.[552] It is, however, not clear whether the same mechanism that applies for the formation of bipyrrol is valid for the construction of a larger polymer backbone, as larger oligomers are expected to become less reactive.[553] For example, quinquethiophene radical cations[553] only dimerize with rate constants of $3 \times 10^3 - 5 \times 10^3\,M^{-1}s^{-1}$. Similarly, RRC of two Ph_2NH radical cations is the key process in the electrochemical formation of diphenylbenzidine[554] as well as with triphenylamine$^{\bullet+}$ and *N,N*-dimethylaniline$^{\bullet+}$ (Table 20).[555]

Table 20. Rates of the RRC coupling of selected aromatic amine radical cations at room temperature.

Substrate	$k\,[M^{-1}s^{-1}]$	Ref.
triphenylamine$^{\bullet+}$	3×10^3	[555]
diphenylamine$^{\bullet+}$	2.0×10^5	[554]
N,N-dimethylaniline$^{\bullet+}$	1.5×10^7	[555]

4.8.5. Atom Abstraction

Radical cations are by their very nature odd-electron species. However, atom-transfer reactions have not yet been extensively studied, although they are known to be of fundamental importance, for example in the Hofmann-Löffler-Freytag reaction,[556] and allow the synthesis of piperidine and pyrrolidine derivatives (Scheme 96). Whereas earlier data on relatively stable amine radical cations indicated that intermolecular hydrogen abstractions are very slow (1,3-cyclohexadiene and 9-anisylacridine$^{\bullet+}$: $k = 1.03 \times 10^3\,M^{-1}s^{-1}$ at



Schema 96. The [→ H, $R^{\bullet}_{rad}$] reaction according to Ban (1976); NCS = *N*-chlorosuccinimide.

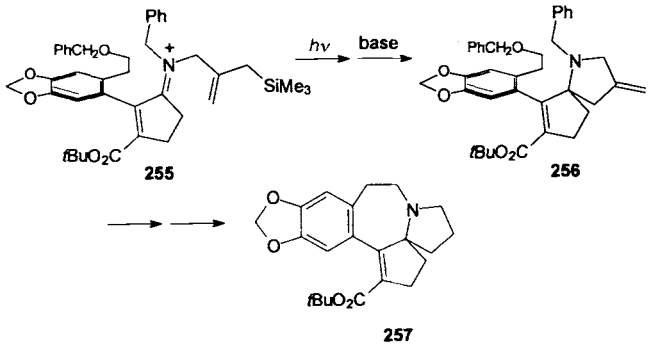
298 K),[557] recent data on more reactive aminium systems led to much higher values ($k = 10^6 - 10^8\,M^{-1}s^{-1}$).[376]

5. Conclusion

This review was written to develop a conceptually simple rationalization of radical cation chemistry in solution, independent of whether these highly reactive species were formed by chemical, electrochemical, or photochemical oxidations. The pivotal step in our procedure is to identify the main electrophore in the molecule of interest, since the overwhelming amount of reactions will occur at the electrophore itself or at its periphery by fragmentation of the ⓟ-A-B, ⓝ-A-B, or ⓞ:A-B bond. Rewardingly, all types of radical cations—either π, n, or σ systems—show very similar reactivity patterns.

For the majority of substrates, the differentiation between π, n, and σ donors can be derived in a straightforward manner; nevertheless, numerous cases remain for which this distinction remains arbitrary. In particular, it is known for several functionalities that their HOMO energies are quite similar, so that a switch between π, n, and σ donor may occur after small variations in substituents.[451]

Beyond the simple reactivity paradigms provided above, distance[558] and stereoelectronic factors should find extensive use for controlling the outcome of the reaction. In the elegant construction of the harringtonine alkaloid skeleton,[559] Mariano demonstrated how these factors were advantageously combined (Scheme 97). In an intramolecular PET the less oxidizable electrophore (ⓟ-C-Si) is oxidized, as ET from the more electron-rich aryl functionality to the excited iminium acceptor is impeded by the perpendicular arrangement.



Scheme 97. The [→CX,$R^{\bullet}_{rad}$] reaction according to Mariano (1989).

Certainly, a vital aspect of our classification system is to make reliable predictions on the chemistry of complex molecules after one-electron oxidation, which is only possible at present with some limitations. In particular, there is lack of kinetic and thermochemical data and of investigations on steric as well as stereoelectronic factors. Extensive studies on how to induce high stereoselectivities in such processes are also urgently needed. In light of the multitude of highly stereoselective radical reactions that emerged over the last couple of years,[560] radical cation chemistry holds a great promise for synthetic transformations. A nearly unknown field of chemistry will additionally develop after one-electron oxidation of short-lived intermediates, for example, such as carbenes[561] and cations.[562] Unquestionably, with all the terra incognita yet to be discovered, the design of novel radical cation reactions will continue to present an intellectual challenge for experimental and theoretical chemists for years to come.

M.S. would like to thank all his co-workers whose commitment has made possible the joint contributions in the field of electron transfer activation: Ulrich Baumann, Ingo Bohn, Armin Burghart, Andreas Haeuseler, Susanne Kiau, Anja Langels, Michael Levis, Maik Röck, Barbara Rohwedder, Heinke von Seggern, Rolf Söllner, Holger Trenkle, and Clemens Wöhrle. Generous financial support over many years from the Deutsche Forschungsgemeinschaft, the Volkswagen-Stiftung, the Fonds der Chemischen Industrie, the Wissenschaftliche Gesellschaft Freiburg, and the BASF AG is gratefully acknowledged.

[264] This trend can readily be understood based on calculations of thermochemical cycles, since the oxidation potentials of the 1,2-diarylethanes remain almost constant upon addition of the substituents at the ethylene moiety. However, the oxidation potentials of the radicals are significantly lowered, see ref. [261a].

[270] P. Maslak, S. L. Asel, *J. Am. Chem. Soc.* **1988**, *110*, 8260–8261.

[271] P. Maslak, T. M. Vallombroso, W. H. Chapman, Jr., J. N. Narvaez, *Angew. Chem.* **1994**, *106*, 110–113; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 73–75.

[272] Maslak et al. [271]) obtained a quadratic Marcus-type correlation for bond cleavages of radical cations and anion radicals; that is not detectable for radical cations only.

[273] P. Maslak, J. N. Narvaez, *Angew. Chem.* **1990**, *102*, 302–304; *Angew. Chem. Int. Ed. Engl.* **1990**, *29*, 283–285.

[274] Similarly, the unpaired electron in di(9-anthryl)methane$^{\bullet+}$ is only delocalized over one of the anthracene rings: A. Terahara, H. Ohya-Nishiguchi, N. Hirota, H. Higuchi, S. Misumi, *J. Phys. Chem.* **1986**, *90*, 4958–4961; for triptycene$^{\bullet-}$: H. Quast, H. L. Fuchsbauer, *Chem. Ber.* **1986**, *119*, 1016–1038.

[275] P. Maslak, *Top. Curr. Chem.* **1993**, *168*, 1–46.

[276] J. P. Dinnocenzo, S. S. Shaik, *J. Org. Chem.* **1990**, *55*, 3434–3436.

[277] J. P. Dinnocenzo, D. R. Lieberman, T. R. Simpson, *J. Am. Chem. Soc.* **1993**, *115*, 366–367.

[278] The rate of C–C bond fragmentation in the radical cations can in general be qualitatively predicted since it increases with increasing oxidation potential of the molecule, decreasing C–C bond strength, and decreasing oxidation potential of the fragment that ultimately appears as the carbocation. Since oxidation potentials for the starting compounds and the radicals are either available or can be estimated with reasonable accuracy, the bond dissociation energies of the radical cations can readily be calculated.

[340] Based on our criteria, 2-silyl-1,3-dithianes have an n electrophore, see ref. [341a].

[341] Since both electrophores, the lone pair on sulfur and the σ C–Sn bond, have very similar ionization potentials, the choice of a ⓞ$^{+}$ species is arbitrary. Based on cyclic voltammetry measurements, however, we prefer to describe the 2-stannyl-1,3-dithianes as σ electrophores, see also a) R. S. Glass, A. M. Radspinner, W. P. Singh, *Pure Appl. Chem.* **1996**, *68*, 853–858; b) *J. Am. Chem. Soc.* **1992**, *114*, 4921–4923.

[425] A cycloaddition of a sulfur radical cation is reported in ref. [449]. However, that system should be classified as a $\pi^{\cdot+}$ and not as $n^{\cdot+}$, which provides a rather simple rationalization for their different behavior.
[426] K. Narasaka, T. Okauchi, *Chem. Lett.* **1991**, 515–518.
[427] S. Karady, E. G. Corley, N. L. Abrahamson, J. S. Amato, L. M. Weinstock, *Tetrahedron* **1991**, *47*, 757–766; S. Karady, E. G. Corley, N. L. Abrahamson, L. M. Weinstock, *Tetrahedron Lett.* **1989**, *30*, 2191–2194. In this case, it cannot be excluded that a $\pi^{\cdot+}$ is attacked by the n nucleophile.

A Novel Methyltrioxorhenium (MTO)-Catalyzed Epoxidation of Olefins: An Impressive Example of Simplicity, Selectivity, and Efficiency

Andreas Gansäuer*

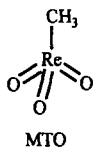
One of the main goals of research in chemistry in recent years has been the development of new efficient catalytic reactions giving the desired products in high yield and selectivity under mild conditions without the formation of by-products and with low catalyst loading. In this context epoxidations are of great interest because epoxides can be readily transformed into a wide variety of useful compounds. Their sensitivity to ring opening, however, sets limits on the acidity and basicity of the reagents used.

The most widely used epoxidation reagent in research laboratories, *meta*-chloroperoxybenzoic acid (*m*-CPBA),[1] poses a number of problems that make the need for the development of efficient catalytic systems evident. Acid-sensitive epoxides are not tolerated under typical conditions because of the acidity of *m*-chlorobenzoic acid, and the reagent is not reactive enough in certain cases, for example for electron-deficient olefins. In a more general sense *m*-CPBA is not economical because hydrogen peroxide has first to be transformed into *m*-CPBA; thus, after the epoxidation *m*-chlorobenzoic acid has to be recovered and then recycled. Also the reagent cannot be stored in pure form because of the explosion hazards. Economically favorable are therefore reactions that employ cheap, readily available stoichiometric oxidants, such as oxygen, hydrogen peroxide, or bleach in a transition metal catalyzed reaction without the production of side products that are difficult to remove or to recycle.

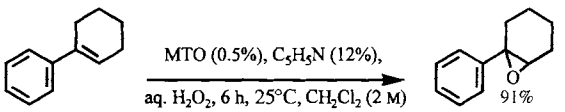
Interesting reactions in this context are nickel-[2] and vanadium-catalyzed[3] epoxidations with oxygen, and manganese-catalyzed[4] reactions with bleach as stoichiometric oxidants. However, the former reaction usually requires the presence of stoichiometric amounts of aldehydes that are oxidized to acids, and the latter is limited to a certain degree by incomplete stereoselectivity. Both reactions therefore do not fully meet the demands of an efficient transformation.

A first breakthrough with rhenium compounds as catalysts was achieved by Herrmann et al.[5] The use of methyltrioxorhenium (MTO; 0.1–1.0 mol%) as powerful epoxidation catalyst is possible with anhydrous hydrogen peroxide in *tert*-butyl alcohol as stoichiometric oxidant. Most likely the catalytically active species is a bis(peroxo) complex of rhenium.[6] Although effective for numerous substrates, this method suffers somewhat from concomitant opening of the epoxide. To a ceratin degree this problem can be overcome by using amines and pyridines[7] as additives or by employing the urea hydrogen peroxide complex[8] as stoichiometric oxidant. However, catalyst turnover is decreased significantly and sensitive epoxides are still decomposed.

An effective system that avoids the above-mentioned disadvantages and preserves high catalyst activity and chemoselectivity has recently been developed by Sharpless et al.[9] By using aqueous hydrogen peroxide instead of anhydrous hydrogen peroxide as stoichiometric oxidant in combination with catalytic amounts of pyridine (12 mol%) and MTO (0.5 mol%) a variety of epoxides can be obtained with high chemoselectivity in good to excellent yields, as exemplified in Equation (a). The reaction is run at room temperature with high concentration of substrate (1–2 M) in dichloromethane. Product isolation is simple and convenient because the only by-product of the reaction is water. No products from ring opening of the epoxide are usually detected.



MTO



(a)

The crucial role of pyridine seems to be threefold: it increases catalytic activity, prevents product decomposition, and in sufficient concentration leads to an increase of catalyst lifetime. However, pyridine has to be used in excess with respect to MTO because of N-oxidation during the course of the reaction. In this respect the two-phase system has a unique advantage as demonstrated by Herrmann et al.[10] Pyridine-N-oxides, which are detrimental to catalyst activity, are mostly dissolved in the aqueous phase. Thus only pyridine, which is responsible for high catalyst activity and selectivity, remains in the organic phase ensuring efficient complexation of MTO. Sterically demanding pyridines, such as picoline, are ineffective in accelerating the reaction.

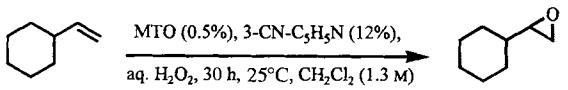
The epoxidation of terminal olefins still requires prolonged reaction times (usually longer than 92 h) under these conditions. A faster conversion of products can be achieved by ligand-tuning using sterically undemanding, electron-deficient pyridines like 3-cyanopyridine.[11] The epoxidation is usually complete in less than 30 h. Presumably, the electron deficiency of these pyridines facilitates the binding of the olefin substrate. For very acid-sensitive products, such as styrene oxide, pyridine is required additionally to prevent epoxide decomposition [Eq. (b)].



86 % (b)

In summary the novel ligand-accelerated catalytic system[12] described by the Sharpless et al. offers a simple, safe, economical, and easy to carry out epoxidation reaction that will undoubtedly find numerous applications in the synthesis of epoxides from olefins. With the recently devised efficient synthesis and recycling procedure for MTO by Herrmann et al.,[13] the reaction seems to be especially well-suited for large-scale applications and has the potential for enantioselective catalysis by using chiral pyridine derivatives as ligands.

Polyamides as Artificial Regulators of Gene Expression

Klaus Weisz*

Numerous control mechanisms in the living cell are based on the sequence-specific recognition of nucleic acids. Thus, gene expression in organisms is controlled by proteins that selectively recognize and bind to nucleic acid sequences. In addition, a number of natural low molecular weight drugs are able to interact with DNA thereby interfering with genetic processes. The prospect of using DNA-specific ligands as novel tools in molecular biology or as drugs for a directed control of gene expression has greatly stimulated the rational development of artificial DNA-binding compounds. The major as well as minor groove of a DNA double helix may serve as a specific binding site for ligands. Each of the four base pairs has a characteristic pattern of available hydrogen bond donor and acceptor sites, which allows the recognition from both grooves under formation of specific hydrogen bonds (Scheme 1). However, the nearly symmetric arrangement of the thymine O2 and adenine N3 acceptor sites precludes a distinction of AT and TA base pairs in the minor groove at least by means of hydrogen bond interactions.

Netropsin and distamycin are two natural antibiotics that preferentially bind at A/T sequences in the minor groove of a DNA double helix (Scheme 2a,b).[1] The concave shape of these oligopeptides with their structural complementarity to the convex floor of the minor groove allows maximum interactions with the DNA, which are further enforced by the narrow groove of A/T-rich DNA tracts. In addition to electrostatic and van der Waals forces, hydrogen bonds between the amide protons of the oligopeptides and the adenine N3 as well as thymine O2 acceptor sites of the base pairs contribute to the stability and A/T preference of these drugs. The best-studied minor groove binding ligand is netropsin and it has frequently been taken as the paradigm for the rational design of synthetic drugs. The conversion of one or both of the pyrrole rings in netropsin to imidazole was a first attempt to extend the recognition code to G/C base pairs.[2] The resulting netropsin analogues were expected to allow specific hydrogen bonds between the imidazole ring nitrogen atom and the exocyclic amino group of the guanine bases. Although G/C base pairs were increasingly tolerated in the binding domain, there was an overall decrease in affinity

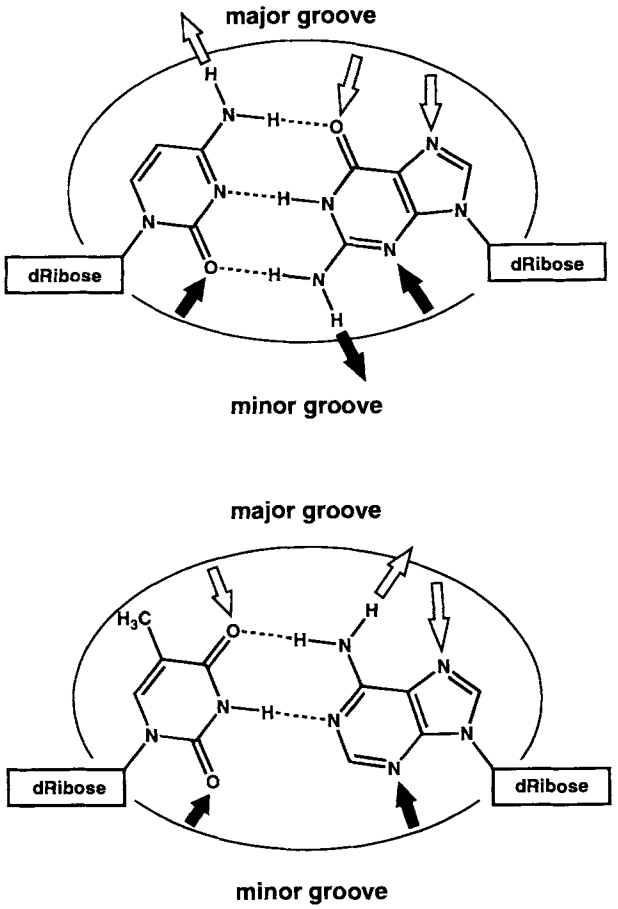
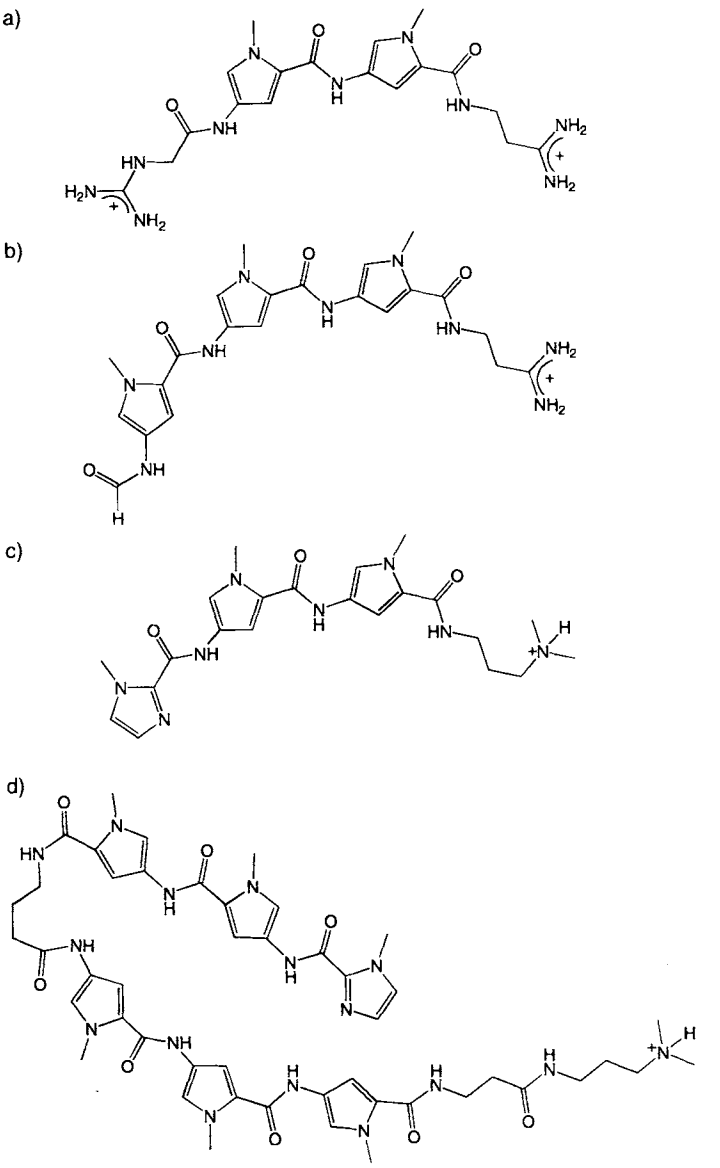


Scheme 1. GC (top) and AT base pair (bottom). Free hydrogen bond donor and acceptor sites in the major and minor groove of double-stranded DNA are indicated by white and gray arrows, respectively.



Scheme 2. Structure of DNA-binding natural and synthetic polyamides. a) Netropsin, b) distamycin, c) 1-methylimidazole-2-carboxamide-netropsin, d) hairpin polyamide ImPyPy-γ-PyPyPy-β-Dp (Im = *N*-methylimidazole, Py = *N*-methylpyrrole, γ = γ-aminobutyric acid, β = β-alanine, Dp = *N*,*N*-dimethylaminopropylamide).

and specificity of such ligands. Evidently, hydrogen bonds in these complexes are of minor importance and the decrease of other noncovalent interactions in the expanded minor groove of G/C segments impairs effective ligand binding.

Unexpected NMR results from Pelton and Wemmer on complexes of distamycin with double-helical DNA marked the turning point in the quest for netropsin derivatives with altered sequence specificity.[3] At higher concentrations of monocationic distamycin two molecules of the drug were found to be bound simultaneously in the minor groove of the central 5′-AAATT-3′ segment of a DNA double helix. Within these 2:1 complexes the two ligands are stacked antiparallel, side-by-side in the groove with each distamycin molecule preferentially forming hydrogen bonds with nucleobases of its adjacent DNA strand. Incorporation of a dimer results in the expansion of the groove favoring such a 2:1 motif in sequences with a wide minor groove.

The breakthrough in the development of netropsin analogues with an expanded recognition code was finally achieved by the groups of Dervan and Wemmer. 1-Methylimidazole-2-carboxamide-netropsin (Scheme 2c), a synthetic monocationic tripeptide with a N-terminal 1-methyl-2-carboxamide-imidazole residue and two *N*-methyl-2-carboxamide-pyrrole units recognized a 5′-TGACT-3′ sequence with high specificity.[4] Structural studies indicated the formation of a 2:1 complex with an antiparallel orientation of the two ligands in the DNA minor groove, as was found earlier for distamycin at high concentrations (Scheme 3a).[5] The specific recognition of GC and CG base pairs came as a surprise and can be attributed to the expected interaction between the N3 imidazole ring nitrogen atom and the 2-amino group of guanine protruding from the floor of the minor groove. Evidently, a binary code consisting of two polyamide units was required to distinguish GC, CG, and AT base pairs: an imidazole ring paired with a pyrrole ring of the second ligand in the dimeric motif recognizes a GC base pair; correspondingly, a pyrrole/imidazole combination targets a CG, and a pyrrole/pyrrole combination as well as N- and C-terminal alkyl residues target AT or TA base pairs. The latter are mostly degenerate. In contrast, the original netropsin ana-

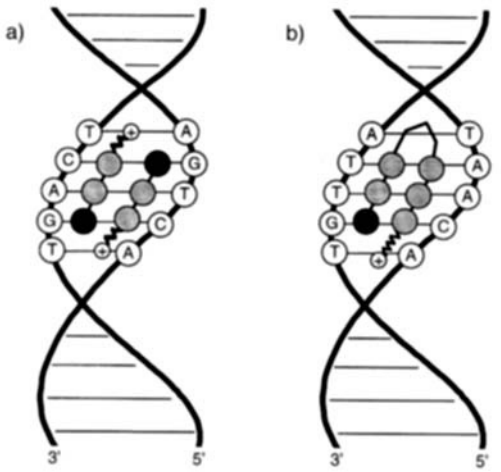
logues failed to bind in a 2:1 motif because of their dicationic structure, which resulted in repulsive electrostatic forces on dimerization. The generality of this 2:1 recognition code was subsequently confirmed on various sequences.[6] Shortly thereafter further improvements in the design of pyrrole-imidazole polyamides were introduced by Dervan et al. By covalently connecting two polyamides with a γ-aminobutyric acid linker and by introducing a C-terminal β-alanine residue, both DNA affinity and specificity were significantly increased by the formation of a hairpin motif (Scheme 2d and 3b). Also, synthesis of the polyamides was greatly facilitated by using solid-phase methods.[7,8a-c]



Scheme 3. Model of the sequence-specific binding of a) 1-methylimidazole-2-carboxamide-netropsin and b) ImPyPy-γ-PyPyPy-β-Dp in the minor groove of a DNA double helix. Gray and black circles represent pyrrole and imidazole units of the polyamide, respectively.

The recently published paper by Gottesfeld et al. adds one more chapter to the successful story of pyrrole-imidazole polyamides.[9] For the first time it was shown that polyamides are capable of selectively interfering with gene expression as artificial regulators in eukaryotic cells. An eight-ring polyamide targeted to the binding site of the transcription factor TFIIIA in the minor groove specifically inhibited transcription of the 5S RNA gene in *Xenopus* kidney cells. These experiments indicate that polyamides are capable of entering the cell and the nucleus and displacing transcription factors because of their higher affinity towards the target sequence.

However, despite these promising results the potential of synthetic polyamides to act as specific gene regulators cannot be definitely assessed yet. The majority of DNA-binding proteins interact with nucleobases in the DNA major groove. It remains to be seen whether and how minor groove binding ligands are capable of effectively modulating protein-DNA interactions and influencing the resulting regulatory mechanisms in a variety of cell types. Also, the question arises of how selectively genes are recognized by synthetic polyamides. Based on statistical arguments it can be shown that, depending on the base composition, approximately 17 base pairs must be read by a ligand to recognize a unique sequence in the human genome.[10] However, due to the degeneracy of AT and TA base pairs in the imidazole/pyrrole recognition code this number must be set even higher. Unfortunately, there are still some limitations with polyamide ligands. Polyamides having more than five rings, that is with binding sites longer than 7 base pairs, show a continuous decrease in their affinity and selectivity towards the target sequence.[11] This can be attributed to the nonperfect adjustment of the polyamide geometry to the double helix resulting in small irregularities, which, in turn, are amplified with increasing length of the binding site. By linking two three-ring polyamide subunits with a spacer like β-alanine, the recognition sequence of such an elongated ligand could be extended up to 13 base pairs.[12] However, in addition to the 2:1 binding motif with fully overlapping polyamides, "slipped" motifs with only partially overlapped monomers are formed as well. Thus, it will be important for the future to develop ligands that bind in a definite and predetermined manner also to longer base sequences with high affinity and specificity.

In contrast to polyamides, single-stranded "antigene" oligonucleotides bind in the major groove of a double helix forming a local triple helix. Recent studies on a covalently linked polyamide-oligonucleotide conjugate reveal that binding occurs simultaneously to the major and minor groove even at subnanomolar concentrations.[13] Since antigene oligonucleotides are modularly constructed from the same units as the double helix itself and are thus optimally adjusted to the target molecule, they have no limitations regarding the length of their binding site. On the other hand, only AT and GC base pairs in homopurine sequences are recognized, because an effective recognition code for TA and CG base pairs is still lacking. Combining both binding motifs in a chimeric ligand not only enhances binding affinity and specificity, but may also significantly expand the repertoire of possible target sequences. In view of this development in the design of artificial regulators of gene expression, DNA binding polyamides seem to be on their way to a promising future even with some questions still unresolved.

Molecule-Sized Gates Based on Surface-Confined Dendrimers**

Mingqi Zhao, Hideo Tokuhisa, and Richard M. Crooks*

In this report we demonstrate for the first time that surface-confined dendrimers[1-5] embedded within self-assembled monolayers (SAMs) of alkylthiols[6] can act as ion gates of molecular dimension.[7,8] These composite organic thin films are conceptually, structurally, and chemically very similar to the membrane/protein composites found in nature.[9] Molecular systems such as these are relevant for applications in electrocatalysis, chemical sensing, and separations.

Prior to the work described here, we showed that generation 0–8 (G0–G8) amine-terminated poly(amidoamine) (PAMAM) dendrimers[10] could be immobilized on surfaces by covalent attachment of the dendrimer amine groups to the acid terminus of a mercaptoundecanoic acid SAM.[1,11] Here we show that PAMAM dendrimers form high-density monolayers on Au surfaces, without the need for an intervening SAM adhesion layer, primarily as a consequence of multiple amine/Au interactions. This represents a major simplification of the previously described linking procedure. Additionally, we find evidence that single-component dendrimer monolayers result in a dendrimer conformation that is quite unlike the spherical form of G4 and higher generation PAMAM materials. In contrast, however, when a dendrimer monolayer is exposed to hexadecylthiol ($CH_3(CH_2)_{15}SH$, abbreviated C16SH), the dendrimer monolayer is compressed, and the molecule's conformation changes to that of an on-end oblate spheroid (see Scheme 1). Finally, and most significantly, of the redox probe molecules $[Ru(NH_3)_6]^{3+}$ and $[Fe(CN)_6]^{3-}$ at pH = 6.3, only the negatively charged $[Fe(CN)_6]^{3-}$ can penetrate a two-component monolayer composed of a G4 PAMAM dendrimer and C16SH and undergo electron exchange with the underlying electrode, whereas when the dendrimers are fully deprotonated at pH = 11, both redox probe molecules undergo electron transfer (Scheme 1). This effect is fully reversible as the pH is toggled between 6.3 and 11. Significantly, we provide unambiguous evidence for the first time that penetration by the redox probe molecules occurs *through* the interior of the dendrimers.[13-15]

Figure 1a shows an FTIR–external reflection (FTIR-ER) spectrum of a G4 PAMAM monolayer prepared by immersion of a Au/Ti/Si(100) substrate in a 0.1 mM ethanolic solution of the dendrimer for 20 h, followed by careful rinsing and drying in flowing N_2. The relevant peaks that confirm attachment of the dendrimer to the surface arise from the dendrimer framework: the amide I and amide II bands at 1661 and 1552 cm^{-1}, respectively, and bands resulting from the two kinds of methylene groups present in PAMAM dendrimers at 2926, 2852, and 2818 cm^{-1},[16] and the amide and amine N–H stretching modes centered around 3300 cm^{-1}. Mass titrations based on surface acoustic waves (SAWs)[17] indicate that about (88 ± 2)% of the Au surface is occupied by the dendrimers after this step. Figure 1b shows the effect of immersing the dendrimer-modified electrode in a 1 mM ethanolic solution of C16SH for 20 h: there is a dramatic increase of the band intensity in the hydrocarbon region, confirming adsorption of C16SH to the Au surface, and a slight increase in the amide bands, which probably results from the orientational change induced in the dendrimer structure by the C16SH SAM (see Scheme 1). The important point is that after exposure to C16SH, the dendrimer number density does not change significantly from its original value, but there is a shear force induced by the C16SH SAM that results in lateral compression of the dendrimers. On the basis of the mass titrations,

FTIR-ERS, and ellipsometry[18] we estimate that the percentage of the surface accessible to the thiol increases from 12% to greater than 50% after exposure to C16SH.

Figure 2 shows cyclic voltammetric data obtained from the mixed G4/C16SH monolayer corresponding to Figure 1b. At low pH (Figure 2a) the terminal amine groups of the dendrimers are protonated (pK_a about 9.5)[12] and effectively block penetration, and hence electrochemical reduction, of $[Ru(NH_3)_6]^{3+}$. In contrast, the rate of reduction of negatively charged $[Fe(CN)_6]^{3-}$ is only slightly hindered relative to that at a naked Au electrode. Contrast these results with those obtained at high pH (Figure 2b) when the amine groups are in their neutral form. In this case, both the $[Fe(CN)_6]^{3-}$ and $[Ru(NH_3)_6]^{3+}$ penetrate the dendrimer portion of the mixed SAM. This result alone, however, does not definitely prove

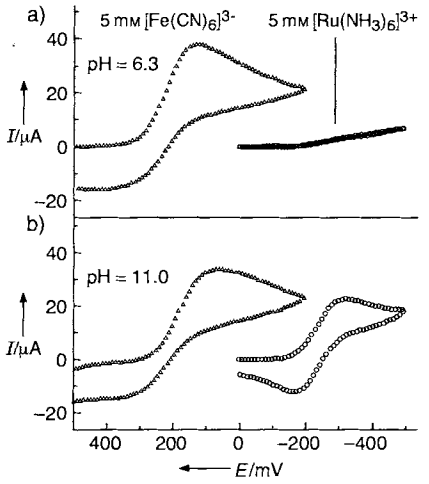

Figure 2. Cyclic voltammetry (E vs. Ag/AgCl, 3 M NaCl) of 5 mM $[Fe(CN)_6]^{3-}$ and 5 mM $[Ru(NH_3)_6]^{3+}$ in 0.5 M aqueous Na_2SO_4 electrolyte solutions at G4/C16SH-modified Au electrodes: a) pH = 6.3 (0.025 M Na_2HPO_4 + 0.025 M NaH_2PO_4), and b) pH = 11 (0.036 M NH_4Cl + 2.0 M "NH_4OH", prepared from a 28% solution of NH_3). Electrode area: 0.086 cm^2, scan rate: 50 $mV\,s^{-1}$.

intradendrimer mass transfer of the redox probes, since the observed effect could arise from probe penetration at the dendrimer/C16SH interface. Because of the strong shear force exerted on the dendrimers by C16SH, we view this as an unlikely scenario, but to show definitively that the dendrimers themselves, rather than dendrimer-induced defects in the monolayer, are acting as molecular gates we performed two additional experiments.

In the first experiment, we prepared a G4 monolayer as described previously, converted the terminal amine groups to 4-(trifluoromethyl)benzamido groups, soaked the resulting dendrimer surface in C16SH, and then examined the electrochemical response in the presence of $[Fe(CN)_6]^{3-}$ at pH 6.3. Conversion of the surface-confined dendrimer to the fluorinated derivative (G4-F), without loss of dendrimer from the surface, is confirmed by the appearance of the new CF_3 band in the FTIR-ERS spectrum at 1329 cm^{-1} and the slight increase in amide-band intensity resulting from coupling of the 4-(trifluoromethyl)benzoyl groups to the amine-terminated dendrimer (Figure 1c). Figure 3 compares the cyclic voltammetry that arises from G4/C16SH and G4-F/C16SH monolayers: the protonated amines pass $[Fe(CN)_6]^{3-}$, but the bulky and hydrophobic 4-(trifluoromethyl)benzamido groups prevent penetration. If penetration occurred primarily at defects in the G4/C16SH interface rather than through the dendrimer interior, then we might anticipate similar responses for the fluorinated and unfluorinated dendrimers.

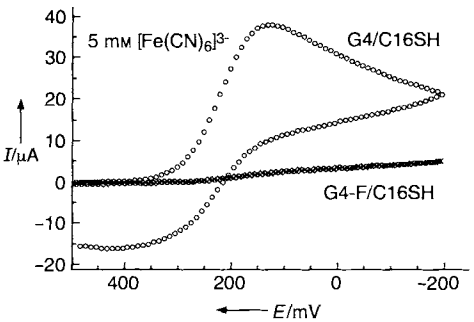

Figure 3. Cyclic voltammetry (E vs. Ag/AgCl, 3 M NaCl) of 5 mM $[Fe(CN)_6]^{3-}$ at a G4/C16SH-modified Au electrode and a G4-F/C16SH-modified Au electrode in a 0.5 M aqueous Na_2SO_4 electrolyte solution (conditions as in Figure 2a).

A second experiment provides additional evidence for intradendrimer mass transfer of the redox probes. Figure 4 shows results for cyclic voltammetric experiments obtained using electrodes prepared from mixed monolayers composed of G0, G4, or G8 dendrimers and C16SH for both positively and negatively charged redox probes at pH 6.3. Considering first the results obtained with the $[Fe(CN)_6]^{3-}$ probe (Figure 4a), we observe that the Faradaic current decreases as a

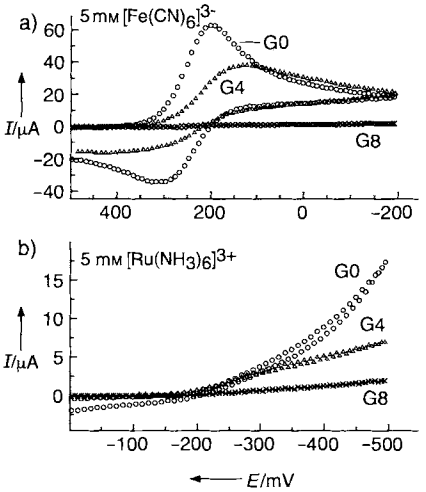

Figure 4. Cyclic voltammetry of 5 mM solutions of $[Fe(CN)_6]^{3-}$ (a) and $[Ru(NH_3)_6]^{3+}$ (b) at G0/C16SH-, G4/C16SH-, and G8/C16SH-modified Au electrodes in a 0.5 M aqueous Na_2SO_4 electrolyte solution (conditions as in Figure 2a).

function of increasing dendrimer generation. This result is a consequence of steric crowding on the exterior of the dendrimer as the number of terminal groups increases and a corresponding reduction in permeability. A similar trend is observed for $[Ru(NH_3)_6]^{3+}$ (Figure 4b), but the currents are much lower for all three dendrimer generations relative to that observed for $[Fe(CN)_6]^{3-}$, because of the electrostatic repulsion of the probe by the positively charged dendrimer surface.

In summary, we have reported four new findings. First, PAMAM dendrimers adsorb irreversibly onto Au at high

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3623-2597 $ 17.50+.50/0

surface concentrations. Second, surface-confined dendrimers undergo a dramatic conformational change upon exposure to C16SH, resulting from shear compression. Third, and most significantly, the dendrimers act as molecular gates in that they can be tailored to permit selective intradendrimer mass transfer. Finally, we have shown that the primary amines of the surface-confined dendrimers can be easily functionalized without significant desorption of dendrimer. These four key results open the door to a new generation of dendrimer-modified surfaces suitable for a range of technologically important applications.

[18] Ellipsometric measurements indicate that a G4-modified surface changes in thickness from 1.9 ± 0.2 to 3.7 ± 0.2 nm after exposure to an ethanolic C16SH solution. Ellipsometric modeling results derived from the Bruggemann effective-medium approximation data suggest a change in the calculated, single-dendrimer height from 2.8 to 5.5 nm. H. Tompkins, *A Users Guide to Ellipsometry*, Academic, New York, **1993**, Apendix B.) Previously reported theoretical calculations (see ref. [10]) are consistent with this result.

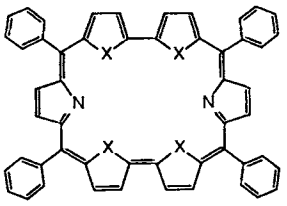
Tetrathia- and Tetraoxarubyrins: Aromatic, Core-Modified, Expanded Porphyrins**

Alagar Srinivasan, VenkatRam M. Reddy, S. Jeyaprakash Narayanan, Bashyam Sridevi, Simi K. Pushpan, Murugaeson Ravikumar, and Tavarekere K. Chandrashekar*

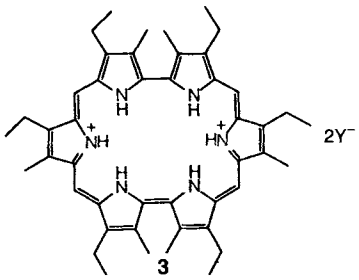
Dedicated to Professor Varadachari Krishnan on the occasion of his 60th birthday

The current trend towards broadening the basis of porphyrin chemistry by developing novel polypyrrolic systems has stimulated an immense research effort in the area of "expanded porphyrins".[1] Synthetic work in this direction has led to several classes of expanded porphyrins including sapphyrin,[2] pentaphyrin,[3] hexaphyrin,[4] rosarin,[5] rubyrin,[6] and octaphyrin.[7] These generally have more than four pyrrole units linked through three or four *meso* carbon bridges. Many related studies have provided valuable information on ring size, aromaticity, macrocyclic stability, and the ability of the compounds to act as chelating receptors for the complexation of anions, cations, and neutral substrates.[8]

Replacement of one or more pyrrole rings by other heterocycles such as thiophene or furan rings leads to core-modified, expanded porphyrins that might have properties that are substantially different to those of well-studied nitrogen analogues[9] due to altered electronic structures. We have been interested in such core modification of porphyrin systems, and our efforts in this direction have revealed many similarities and differences in electrochemical, photochemical, and optical properties relative to the corresponding nitrogen analogues.[10] Here we report the first examples of expanded porphyrins containing either two bithiophene or two bifuran units covalently linked to two pyrrole rings through four methine bridges.[11] We refer to them as tetrathia- and tetraoxarubyrins **1** and **2**, which are analogous to the hexapyrrolic homologue rubyrin **3** reported by Sessler et al.[6]



1 X = S
2 X = O



3

The synthetic method currently available for preparing five- or six-membered expanded porphyrins is based on an acid-catalyzed [3+2] or [4+2] MacDonald condensation between a dicarboxyl-substituted tripyrromethane or tetrapyrrolic unit with diformyl bipyrroles.[2b,c,6] The present method adopts a different approach based on the synthesis

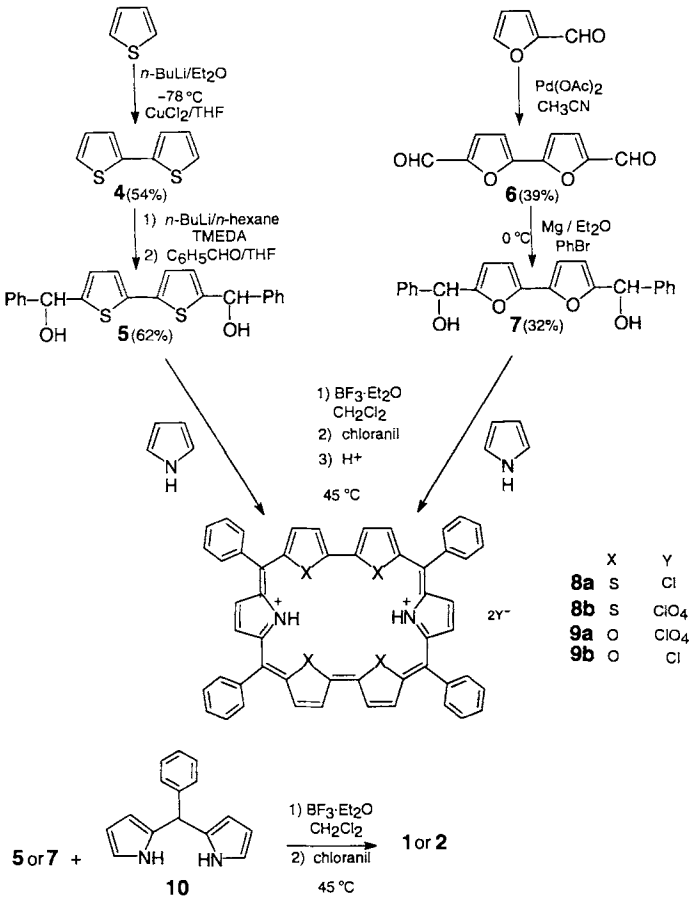
of core-modified mono- and dithiaporphyrins[9] (Scheme 1). Thus, the two key precursors bithiophenediol **5** and bifurandiol **7**—synthesized from thiophene via **4** or from furfual via



Scheme 1. Synthesis of tetraoxa- and tetrathiarubyrins **1** and **2**.

6, respectively—provide **1** and **2** as shiny green metallic solids in 28 and 15% yield, respectively, upon condensation with pyrrole under Lindsey conditions[12a] followed by oxidation with chloranil. Alternatively, reaction of **5** or **7** with dipyrromethane[12b] **10** under Lindsey conditions followed by oxidation afforded **1** or **2** in 20% yield. Treatment of **1** and **2** with HCl and $HClO_4$ gave **8a**, **8b** and **9a**, **9b**, respectively, in 85–90% yield.

The compositions of **1** and **2** were established from FAB mass spectra, which show peaks at 813 and 750, respectively, with 100% fragmentation. The electronic absorption spectra[13] of **1** and **2** in CH_2Cl_2 (Figure 1a) exhibit an intense Soret band and four Q bands. The electronic spectra generally resemble those of *meso*-tetraphenylporphyrins, but are significantly red-shifted; this is not surprising considering the larger aromatic systems (26 π electrons) in **1** and **2** relative to the 18 π electronic systems of *meso*-tetraphenylporphyrins.[14] Protonation of **1** and **2** by addition of a dilute solution of trifluoroacetic acid (TFA) in CH_2Cl_2 leads to further red shifting of both the Q and Soret bands (Figure 1b); this effect is typical of *meso*-tetraarylporphyrins. Changing the counterions in **8a** and **9a** produces only minor changes. Therefore, the similarity of the electronic absorption spectra of **1**, **2** and their protonated derivatives with that of *meso*-arylporphyrin and its protonated derivative confirms the aromatic nature of the former.

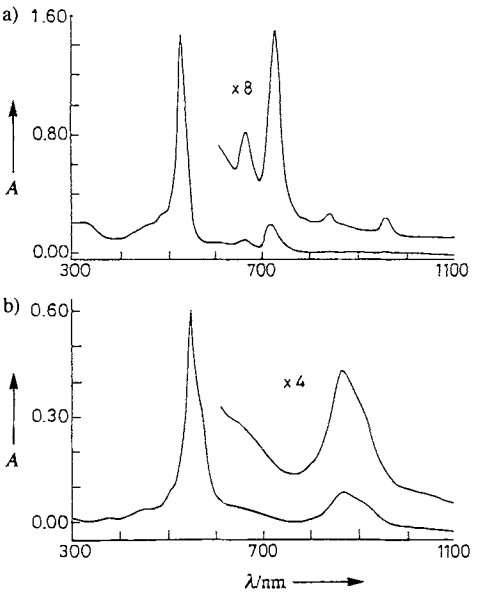


Figure 1. Electronic absorption spectra of **1** in CH_2Cl_2 (1.85×10^{-5} M) a) without TFA and b) with about 10^{-3} M TFA.

Energy-optimized structures for **1** and **2** are shown in Figure 2. It is clear from the structures of **1** and **2** that the two bithiophene/bifuran units, one containing a double bond and

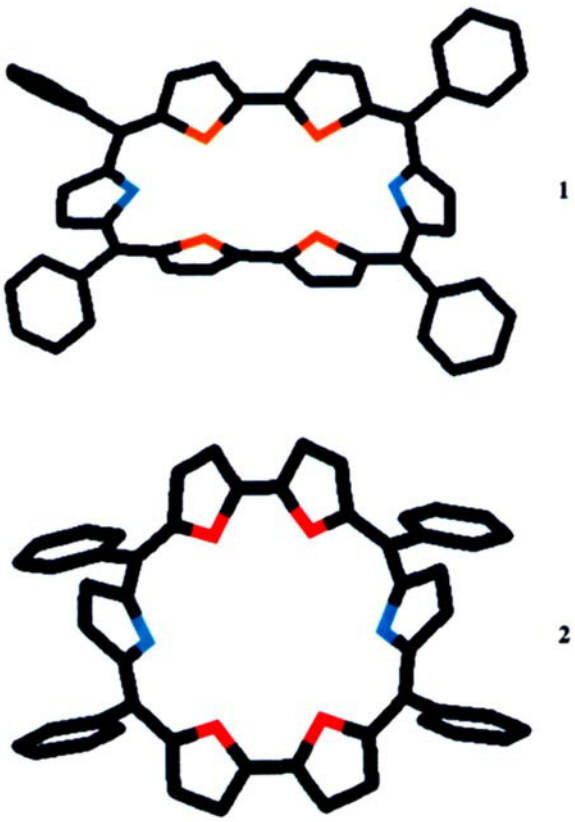

Figure 2. Geometry-optimized structures (Hyperchem 5.0 with AM1 basis set) of **1** and **2**; red: oxygen; yellow: sulfur; blue: nitrogen.

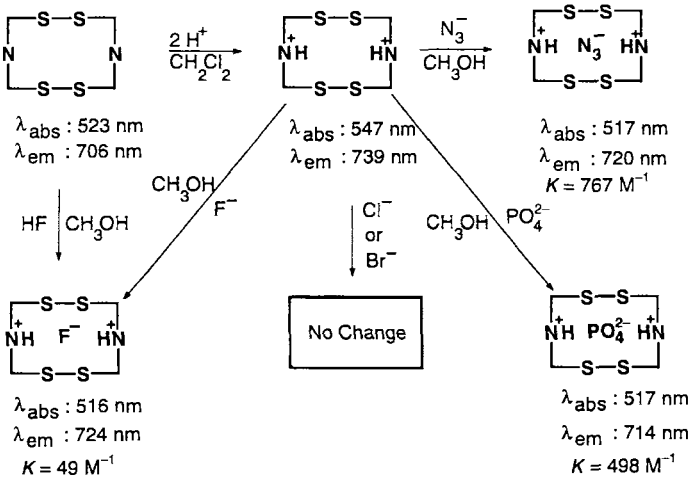
the other only a single bond, occupy different planes. This reflects their different magnetic environments. In fact, the observation of two doublets separated by 1.15 ppm for

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3623-2599 $ 17.50+.50/0

bithiophene and by 1.00 ppm for bifuran protons in the ^{1}H NMR apectrum clearly reveals their magnetic inequivalence. Compound **3** also shows a difference in the chemical shift for the bipyrrole ethyl-methyl substituents of about 2 ppm .[6] The chemical shifts for the inner NH protons of $\delta = -5.15$ and -4.82 observed for **1** and **2**, respectively, in $CDCl_3$ containing deuterated TFA further establishes their aromatic character.

Additional evidence for the aromatic character of **1**, **8a**, and **8b** comes from preliminary cyclic voltammetric studies. The two quasi- reversible ring reductions observed for **1** in CH_2Cl_2 suggest stabilization of the corresponding LUMOs relative to the LUMOs of *meso*-tetraarylporphyrins by 370 mV. An estimated HOMO–LUMO gap of 1.64 V for **8b** in CH_3CN indicates a significant reduction relative to sapphyrin (1.88 V)[14] and *meso*-tetraphenyl porphyrin (2.26 V),[10] thus explaining the large red shifts for **1** and its protonated derivatives.

Spectral titrations of a methanolic solution of **8a** and **8b** with anions (F^-, N_3^-, and adenosine 5′-monophosphate (AMP)) results in a decrease in absorbance, a blue shift of the Soret bands in the absorption spectra by about 30 nm, and a blue shift of the emission bands by about 15 nm together with enhanced emission intensity (AMP shows the greatest increase of about 200%, probably due to charge neutralization); this suggests anion binding that is similar to that observed for sapphyrins[8] (Scheme 2). Binding constants



Scheme 2. Characteristics of anion binding of tetrathiarubyrin.

evaluated by an analysis of absorption data using the Nash equation[15] vary as $N_3^- > AMP > F^-$. Transport studies[16] in U tubes reveal the transport of F^- and AMP at lower rates than observed for sapphyrins and **3**.

In summary, we have synthesized two new core-modified, expanded porphyrins with 26 π electrons by a relatively easy method under mild conditions and demonstrated their anion-binding capabilities. This method avoids the difficult synthesis of sensitive precursors such as tripyrromethanes and tetrapyrrole units required for [3+2] and [4+2] condensations. The availability of gram quantities of these materials permits detailed spectroscopic and photochemical investigations that might in turn shed more light on the suitability of these materials for medicinal applications, including their use as sensitizers for photodynamic therapy and MRI contrasting agents.

Experimental Section

1: 5,5′-Bis(phenylhydroxymethyl)-2,2′-bithiophene (1 g, 2.65 mmol) and pyrrole (0.184 mL, 2.65 mmol) in dry CH_2Cl_2 (800 mL) were stirred under a nitrogen atmosphere for 15 min at room temperature. A freshly distilled solution of $BF_3 \cdot Et_2O$ (2.5 M, 10 mol%) in dry CH_2Cl_2 was added, and the reaction mixture stirred for one additional hour. The resulting solution was opened to air, chloranil (1 g, 4 mmol) was added, and the mixture was heated at reflux in a preheated oil bath at 45 °C. After removal of solvent, the crude product was purified by column chromatography. After an initial brown fraction was eluted with CH_2Cl_2/ethyl acetate (70/30), the second dark violet fraction was identified as **1** (28% yield). Alternatively, pyrrole was replaced by dipyrromethane **10** in the above procedure to generate **1** in 20% yield. A similar procedure was followed for the synthesis of **2** using bifurandiol.

1: ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 7.98$ (m, 12H), 8.55 (m, 8H), 9.06 (s, 4H), 10.49–10.50 (d, $J = 3.00$ Hz, 4H), 11.64–11.66 (d, $J = 6$ Hz, 4H); ^{1}H NMR (300 MHz, $CDCl_3$/TFA): $\delta = -5.15$ (s, 2H), 8.32–8.34 (m, 12H), 9.02–9.04 (m, 8H), 9.41 (s, 4H), 10.96–10.98 (d, $J = 3$ Hz), 11.74–11.76 (d, $J = 6$ Hz); UV/Vis (CH_2Cl_2/1% Et_3N): λ_{max} ($\varepsilon \times 10^{-3}$) = 523 (79.81), 659 (4.88), 717 (10.18), 837 (0.55), 958 nm (0.60); emission (CH_2Cl_2): $\lambda = 706$, 768 nm; MS (FAB): m/z (%) = 813 (100); CV (CH_2Cl_2/tetrabutyl ammonium perchlorate (TBAP, 1×10^{-2}‰M)): $E_{1/2}$(R1) = −0.86 V ($\Delta E_p = 150$ mV); $E_{1/2}$(R2) = −1.05 V ($\Delta E_p = 110$ mV); ΔE(red) = 190 mV; UV/Vis (CH_2Cl_2/TFA): λ_{max} ($\varepsilon \times 10^{-3}$) = 449 (3.3), 543 (44.0), 867 nm (6.2).

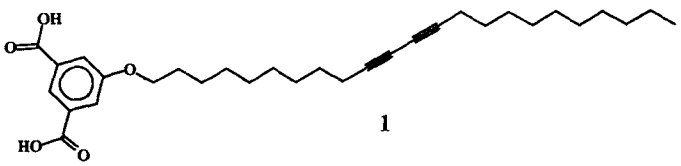
Submolecularly Resolved Polymerization of Diacetylene Molecules on the Graphite Surface Observed with Scanning Tunneling Microscopy

Petrus C. M. Grim, Steven De Feyter, André Gesquière, Peter Vanoppen, Markus Rücker, Suresh Valiyaveettil, Georg Moessner, Klaus Müllen, and Frans C. De Schryver*

Polydiacetylenes (PDA) have become an important class of materials because of their interesting optical and electronic properties. Diacetylenes can in principle polymerize in the solid, liquid crystalline, or the molten state.[1] The solid-state topochemical 1,4-polymerization was first documented by Wegner in 1969.[2] The polymerization of thin films, such as Langmuir–Blodgett[3] and chemisorbed self-assembled monolayers on gold,[4] has been reported. A few studies dealt with physisorbed self-assembling monolayers on graphite. Ozaki et al. have shown evidence of polymerization in a vapor-deposited monolayer of diacetylene molecules with Penning ionization electron spectroscopy.[5] Rabe et al. have observed a physisorbed monolayer of a diacetylene compound at the liquid/graphite interface, with scanning tunneling microscopy (STM).[6] Since the first STM related publications of physisorbed monolayers on alkanes and long-chain alcohols,[7] such self-organized monomolecular adlayers have been studied with STM for a broad range of compounds.[8] Physisorbed monolayers of organic molecules at the liquid/graphite interface containing photoactive groups were recently reported,[9] and the light induced *cis–trans* isomerization could be imaged with submolecular resolution.[10,11] In this communication, we report the photopolymerization of a physisorbed monolayer containing diacetylene moieties, self-assembled from solution at the liquid/graphite interface. The monolayer structures before and after the polymerization have been imaged with submolecular resolution by means of STM. The visualization of the transformation from diacetylene to polydiacetylene in two dimensions might lead to a better understanding of the parametrization of such a polymerization.

When a drop of the solution of the isophthalic acid derivative **1** in 1-undecanol is applied to the graphite surface, a physisorbed monolayer is spontaneously formed at the liquid/graphite interface. Figure 1 (left) shows the image of the structure of such a monolayer observed with STM. A very clear image contrast is obtained due to an increased tunneling current over specific areas of the monolayer (e.g. aromatic moieties) and good stability of the monolayer. The structure



1

consists of lamellae of the molecules of **1** interspersed by alternate lamellae of solvent molecules. Such a solvent incorporation (or solvent codeposition) has recently been reported for isophthalic acid derivatives.[11] The carboxyl functions of the isophthalic acid (ISA) head groups can form hydrogen bonds between neighboring molecules of **1** or between molecules of **1** and solvent molecules. The latter possibility leads to the incorporation of the solvent molecules into the monolayer structure. One of the solvent lamellae is indicated in Figure 1 (left, arrow labeled SOLV). The

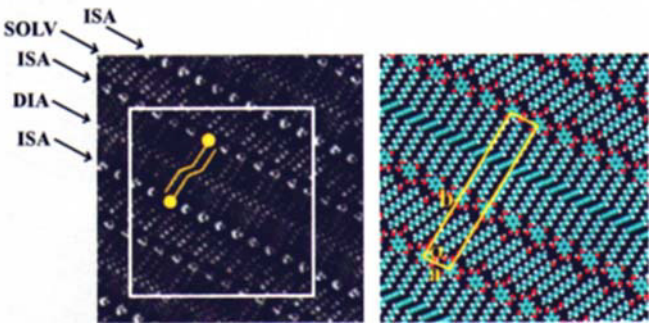


Figure 1. Left: STM image of a physisorbed monolayer of molecules of **1** from a solution in 1-undecanol (image size 12.7×12.7 nm^2). White corresponds to the highest and black to the lowest measured tunneling current in the image. Bias voltage and average tunneling current were -1.2 V and 1.0 nA, respectively. The isophthalic acid headgroups are labeled ISA, the diacetylene groups DIA and solvent molecules SOLV. Right: Model of the area indicated in the STM image, with superimposed unit cell.

undecanol molecules of the solvent lamellae are oriented at an angle of 68° relative to the direction of the lamellae. The lamellae of the molecules of **1** are characterized by the positions of the ISA headgroups and the diacetylene (DIA) moieties of the molecules. The diacetylene moieties, clearly visible in the STM image, appear as two bright spots in the

middle of the lamellae of **1**. It is possible to discern each molecule within the monolayer. For clarity, two molecules of **1** have been schematically drawn in the STM image. The headgroups of adjacent molecules of **1** point in opposite directions, thereby forming a close-packed, interdigitated lamella. The distance from one ISA headgroup to the next is 9.44 ± 0.09 Å. Comparison with the HOPG reference image (not shown), acquired immediately after the STM image of the physisorbed monolayer, shows that the alkyl chains of the molecules of **1** are lying in the direction of one of the main graphite axes. Based on these STM observations, a molecular model can be constructed for the physisorbed monolayer. Figure 1 (right) represents a model of the indicated area in Figure 1 (left), along with a unit cell of the observed structure. The unit cell parameters are $a = 9.44 \pm 0.09$, $b = 55.3 \pm 1.3$ Å and $\alpha = 82 \pm 4°$. The model suggests steric hindrance in the lamellae of **1** between the terminal methyl group of one molecule and a carboxyl function of the neighboring headgroup. In the adlayer this might be solved by a small tilt out of plane of one of these groups, but this can not be resolved in the STM image.

After the irradiation of the solution present on the graphite, the graphite surface was reexamined with the same scanning parameters as before. Monolayer structures are again observed. An example of such an image is shown in Figure 2A, where the ISA headgroups and solvent molecules can be easily recognized. The contrast in the middle of the lamellae of **1** can be described by a series of bright spots, whereas in Figure 1 (left) the direction of each diacetylene unit could easily be distinguished. The specific STM contrast in Figure 2A is more indicative of a polydiacetylene, characterized by a sequence of double, single, triple, and single bonds. This already suggests that the monolayer structure might be polymerized along the lamellar direction. An important change in the spacing between the ISA headgroups from the unpolymerized repeating distance of 9.44 ± 0.09 Å to 9.81 ± 0.05 Å is observed. The model of a polymerized monolayer also shows the unit cell (Figure 2B). The experimental value of 9.81 Å for the ISA headgroup distance is in perfect accord with the value of 9.82 Å obtained in a model optimized for the polymer chain. Consequently, the repeating distance in the polymer backbone is 4.91 Å (half of the headgroup spacing), which is in excellent agreement with the crystal structure data of polymerized diacetylenes.[12] From this it can be concluded that the monolayer structure has indeed polymerized. The unit cell parameters a', b', and α', as defined in the model for the polymerized monolayer, have been experimentally determined to be 9.81 ± 0.05, 54.8 ± 1.3 Å, and $82 \pm 4°$, respectively. These unit cell parameters are all in close agreement with the values determined from the model.

Since the polymerization is known to be topochemical,[2] it has to take place at the liquid/graphite interface, under well specified conditions. The analysis of a broad range of crystallized diacetylenes by X-ray crystallography[12] shows that topochemical polymerization can occur when the monomer stacking distance d is near 5 Å and the angle φ between the diacetylene rod and the stacking axis is around 45°. For our system, these values are 4.72 Å and 50°, respectively![12]

Scanning on a larger scale reveals the presence of domains. A domain boundary is depicted in Figure 2C: two domains are visible, pointing in slightly different directions. The domain in the lower left of the image represents an unpolymerized monolayer structure, since the ISA headgroup distance was determined to be 9.42 Å (mean value for three rows of ISA headgroups). In addition, no solvent codeposition was observed inside this domain. The other domain, rotated clockwise by 6° with respect to the first one, consists of a polymerized monolayer (ISA headgroup separation of approximately 9.81 Å). Polymerized lamellae without the incorporation of solvent are visible in the STM image in Figure 2C and are indicated by the arrows. Figure 2D shows an enlarged part of Figure 2C (as indicated) in more detail. Separated by a domain boundary, the upper, polymerized monolayer shows a bright contrast due to the polydiacetylene chains (as in Figure 2A), while in the lower, unpolymerized domain, the diacetylene groups of the individual molecules of **1** can again be distinguished. The average tunneling current at the positions of the diacetylene groups of the polymerized and the unpolymerized domain did not vary and was a factor of 1.5 higher than the average tunneling current at the positions of the alkyl chains. In principal, the diacetylene moieties can take two different orientations with respect to the lamellar direction. These two specific orientations are mirror images with respect to the lamellar direction. In the lamella in the lower left of the STM image in Figure 2D, the diacetylene groups are oriented almost horizontally, whereas in the next lamella they are oriented almost vertically. In the lamella in the lower right of the image, they are again oriented almost horizontally.

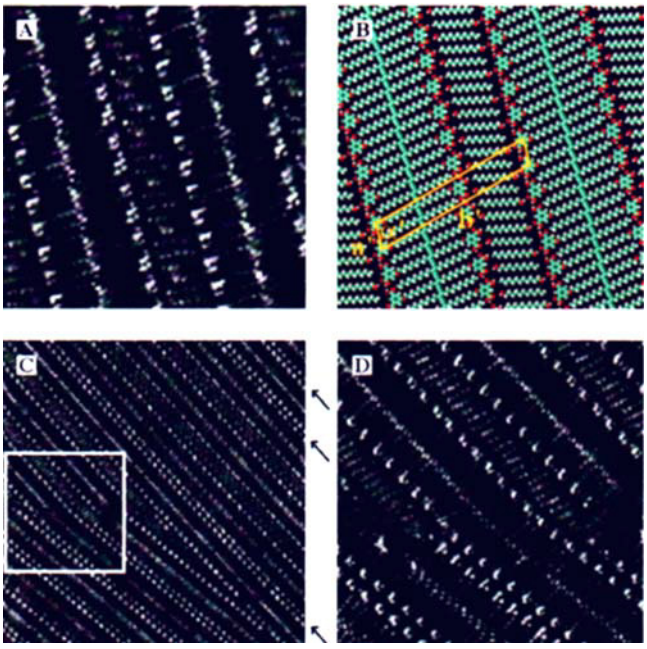

Figure 2. A) STM image of an irradiated monolayer. White corresponds to the highest and black to the lowest measured tunneling current in the image. Image size 10.8×10.8 nm^2; bias voltage -0.5 V and average tunneling current 1.0 nA. B) Model including unit cell of the imaged area in A. C) STM image of a domain boundary separating an unpolymerized (in the lower left) and a polymerized (rest of the image) region. Arrows indicate the absence of solvent codeposition inside the polymerized domain. Image size 38.5×38.5 nm^2; bias voltage -0.6 V and average tunneling current 1.0 nA. D) Zoom of the indicated area in C. Image size 15.3×15.3 nm^2; bias voltage -0.6 V and average tunneling current 1.0 nA.

Experimental Section

For the observation of the physisorbed monolayers, a commercial STM setup was used (Discoverer, Topometrix Inc., Santa Barbara, CA (USA)) operating under ambient conditions. STM tips were electrochemically etched from Pt/Ir wire (80%/20%, diameter 0.2 mm) with 6 N NaCN/2 N KOH in water as etching solution. The samples were prepared as follows: First **1** was dissolved in 1-undecanol (Aldrich, 99%), at a concentration of approximately 1 mg mL^{-1}.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3623-2602 $ 17.50+.50/0

One drop of this solution was applied to the basal plane of a piece of highly oriented pyrolytic graphite (HOPG, grade ZYB, Advanced Ceramics Inc., Cleveland, OH (USA)). The tip was immersed in the solution and brought close to the liquid/solid interface. During tip scanning the variations in the tunneling current were detected while keeping the average tunneling current at around 1 nA. Acquisition time for one image frame of 200 lines and 200 pixels per line was approximately 7 s (limits set by the Discoverer instrument). Tunneling voltages were between 0.5 and 1.5 V (sample negative). An image of the graphite surface could be obtained at low bias voltages. Immediately after each image a calibration image of the graphite surface was acquired at exactly the same position. This minimizes possible errors in the image analysis due to drift and scanner distortion effects, because these effects will appear to the same extent in the STM image of the monolayer structure as well as in the HOPG reference image. Lattice parameters of the observed monolayer can thus be determined with a high accuracy. The ISA headgroup separation was determined by averaging over a large number of repeating distances per row. The experimental values reported are mean values for many images, acquired during different experiments performed with different tips. After obtaining a HOPG reference image for calibration, the tunneling voltage could be increased to observe the physisorbed monolayer again. We have not seen any evidence that the monolayer was disturbed due to the calibration procedure described above. The STM data were not subjected to image processing. Irradiation was carried out as follows: first the tip was retracted and the STM head removed. Then the graphite, its surface still coated with solution, was irradiated by means of a CAMAG universal lamp (wavelength 254 nm) by putting it approximately 5 cm above the surface. The duration of the illumination was 20–30 minutes. After this time, the STM head was reinstalled and imaging resumed.

Comparison of the Bioactive Conformations of Sialyl Lewis^X and a Potent Sialyl Lewis^X Mimic**

Wolfgang Jahnke,* Hartmuth C. Kolb, Marcel J. J. Blommers, John L. Magnani, and Beat Ernst

Interactions of glycopeptides and glycolipids bearing sialyl Lewis^X with a family of C-type lectins, the selectins, are responsible for the "rolling" event which is the initial step in leukocyte recruitment to sites of injury or inflammation.[1] This process plays a crucial role in a number of diseases and pathological situations, for example inflammation, reperfusion injury, rheumatoid arthritis, metastasis, and angiogenesis.

Currently, great research efforts are concentrated on developing carbohydrate-derived drugs which interfere with the rolling stage of the inflammatory response by blocking the selectin binding site.[2] To design sialyl Lewis^X mimics, a thorough understanding of the structure–activity relationship as well as the bioactive conformation (that is, the conformation of the mimic bound to the selectin) is required.

A powerful method for elucidating the bioactive conformation of selectin antagonists is offered by transfer NOE NMR spectroscopic techniques. This method is ideally suited for studying ligand–protein interactions with binding affinities in the micromolar to millimolar range,[3] affinities typical of selectin antagonists. Thus, the bioactive conformation of sialyl Lewis^X **1** was recently determined by transfer NOE NMR studies on the sialyl Lewis^X/E-selectin complex.[4] Here we describe the first bioactive conformation of a potent sialyl Lewis^X mimic (**2**, Scheme 1),[5] using the same technique. our assays this mimic binds to E-selectin with an affinity that is more than ten times higher than that of sialyl Lewis^X (IC_{50} of **1**: 1.0–1.2 mM, of **2**: 0.10–0.11 mM).

The NMR resonances for the mimic **2** were assigned on the basis of two-dimensional ROESY, TOCSY, P.E.COSY, HSQC, and HSQC-TOCSY experiments. The latter two (involving the heteronucleus ^{13}C) were necessary for unambiguous assignment due to considerable overlap of resonances from the two cyclohexyl rings. The signals of the two diastereotopic exocyclic Hβ protons and (*S*)-cyclohexyllactic acid (Cyc-1) were individually assigned by analysis of homonuclear three-bond coupling constants from P.E.COSY, heteronuclear three-bond coupling constants from HMBC, and ROE intensities from ROESY. Table 1 lists the assignments for the ^1H and ^{13}C resonances for **2**.

Table 1. ^1H and ^{13}C chemical shifts of sialyl Lewis^X mimic **2** [a].

[a] At 25 °C in D_2O, 100 mM imidazole, pH = 7.4 (uncorrected). The upper numbers correspond to ^1H resonances, the lower numbers to ^{13}C resonances. All shifts are given relative to 3-(trimethylsilyl) 1-propanesulfonic acid (DSS). The symbol "a" refers to the axial protons, and "e" to the equatorial protons of the cyclohexyl rings of (*S*)-cyclohexyllactic acid (Cyc-1) or (1*R*,2*R*)-1,2-cyclohexanediol (Cyc-2).

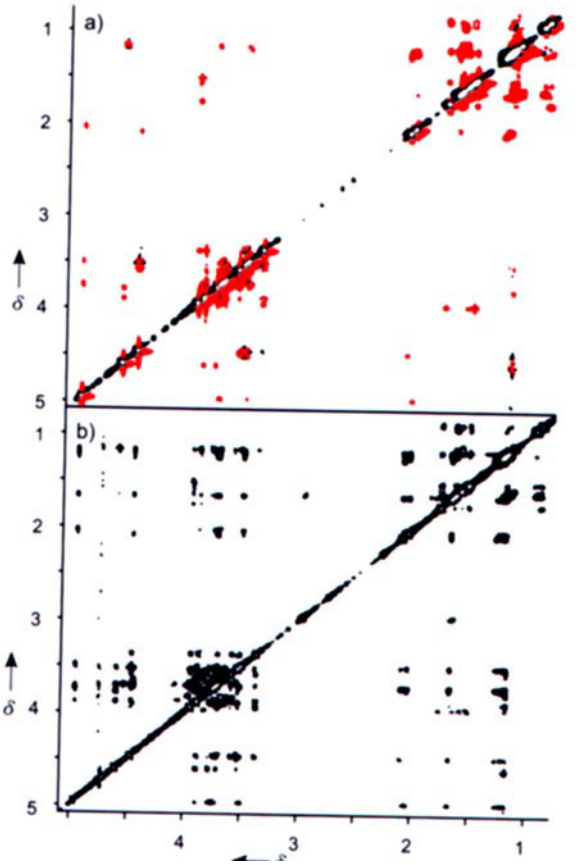

Figure 1. Two-dimensional NOESY spectra of a) free sialyl Lewis^X mimic **2** (17 mM) and b) **2** complexed to E-selectin (1.75 mM). Both spectra were acquired in the same buffer and at the same temperature (25 °C). The mixing time was 200 ms, and a $T_{1\rho}$ relaxation filter was used [6]. For experiment b) 35 μM E-selectin/IgG construct was added to yield an effective mixture of **2** to E-selectin in a ratio of 25:1.

The NOESY spectrum of unbound **2** shows weak positive NOEs (resulting in negative NOE cross-peaks, Figure 1a). When E-selectin is added, the NOESY spectrum measured with a $T_{1\rho}$ relaxation filter[6] displays intense negative NOEs. Therefore, all negative NOEs observed for the complexed mimic **2** can unambigously be attributed to transfer NOEs. This is in contrast to studies with sialyl Lewis^X **1**,[4c] for which negative NOEs were observed for both bound and unbound states. The opposite signs for NOEs measured for unbound **1** and **2** are caused by the different rates of molecular tumbling in solution, which results from their different molecular weights (**1**: M_r 991.0, **2**: M_r 578.6).

Transfer NOE spectra of the sialyl Lewis^X mimic **2** were recorded with mixing times of 25, 50, 80, 100, 150, 200, and 300 ms. In addition, a transfer ROESY spectrum was recorded with a mixing time of 80 ms. Transfer NOE intensities were extracted as cross-peak integrals and displayed as built-up curves. In total, built-up curves of 38 intramolecular distances were analyzed. On the basis of the built-up curves as well as the sign and intensities of the ROE, a total of 22 transfer NOEs were assigned as "direct NOEs", in which spin diffusion plays no dominant role. Those 22 NOEs were classified as strong, medium, or weak and translated into distances smaller than 3.5, 4.5, and 5.5 Å, respectively. Transfer NOEs that were clearly absent in transfer NOE spectra with mixing times shorter than 100 ms, and for which no NOE cross-peak was detected in the free ligand, were translated into distances larger than 4 Å. Table 2 lists the direct NOEs together with the corresponding distance constraints. These distance constraints are less rigorous than those resulting from the commonly used isolated spin pair approximation (ISPA).[7] Since the mimic **2** binds with an affinity that is more than ten times greater than that of the natural epitope sialyl Lewis^X **1**, ISPA-derived distance constraints would not give more accurate data. The large number of 22 distance constraints compensates for the lack of precision in the individual distance constraints and defines the resulting structures quite well. The structures were calculated with the distance geometry program DGII.

A superposition of 19 calculated structures of **2** bound to E-selectin is shown in Figure 2b. The position of the terminal cyclohexyl ring is not well defined, whereas the carboxylic acid clearly points out of the paper plane towards the observer. In the core the galactose and fucose ring systems,

$Ha^{Cyc\text{-}1}$-$H\alpha^{Cyc\text{-}1}$	4.0	

[a] Fuc = fucose, Gal = galactose; r_{min} = minimum distance, r_{max} = maximum distance. The two non-NOE constraints involving $H\beta^{Cyc\text{-}1}$ are applied to each of the β protons individually. If no lower limit is given, the limits are taken as the sum of the van der Waals radii.

which are linked by the (1*R*,2*R*)-1,2-cyclohexanediol spacer, are stacked. Figure 2c shows the same superposition from a slightly different angle. Here it can be seen that the Cα–C(O) bond vector of the (*S*)-cyclohexyllactic acid is rather well defined by the NMR data. Due to a lack of protons, however, the orientation of the oxygen atoms are not defined by the NMR data, and the carboxylic group appears to be freely rotatable.

A comparison of the bioactive conformations of **1** and **2** (Figures 2a and 2b) show that the core conformations of both bound sialyl Lewis^X **1**[4c] and bound mimic **2** are very similar. A characteristic feature of both compounds is the stacked arrangement of the core. The carboxylic group of *N*-acetylneuraminic acid and (*S*)-cyclohexyllactic acid also have the same orientation, whereas the residue of *N*-acetylneuraminic acid in **1** and the cyclohexyl ring in **2** clearly point in different directions.

The comparison of the bioactive conformations of **1** and **2** can be quantified by an internal coordinate plot (Figure 3). The core conformation, defined by the dihedral angle $C2^{NeuNAc}$-$O^{GlcNAc/Fuc}$-$C1^{Fuc}$-$C4^{Fuc}$, is plotted versus the orientation of the acid, defined by the dihedral angle $C1^{NeuNAc}$-$C2^{NeuNAc}$-$O^{GlcNAc/Fuc}$-$C1^{Fuc}$. In this internal coordinate system, the dihedral angle defining the core conformation of mimic **2** is $-36.4(5.8)^\circ$ and $-40.2(4.7)^\circ$ for **1**. The dihedral angle defining the acid orientation of mimic **2** is $120.5(16.1)^\circ$ and $110.7(9.0)^\circ$ for **1**. The bioactive conformations of both **1** and **2** thus occupy overlapping regions in the internal coordinate plots, and, consequently, are identical within experimental errors.

The presence of the carboxylic group is a prerequisite for biological activity.[8] Recent studies suggest that the bioactivity of a proposed mimic is related to its ability to present the carboxylic group in the required orientation.[5,8b] The results of this investigation clearly support this hypothesis by showing that the carboxylic group does indeed have the same orientation in the bioactive conformation of sialyl Lewis^X **1** and its mimic **2**. In summary, all the functional groups of **1** which are required for binding (see Scheme 1) are oriented very similarly in **2**. This suggests that both ligands have comparable binding modes.

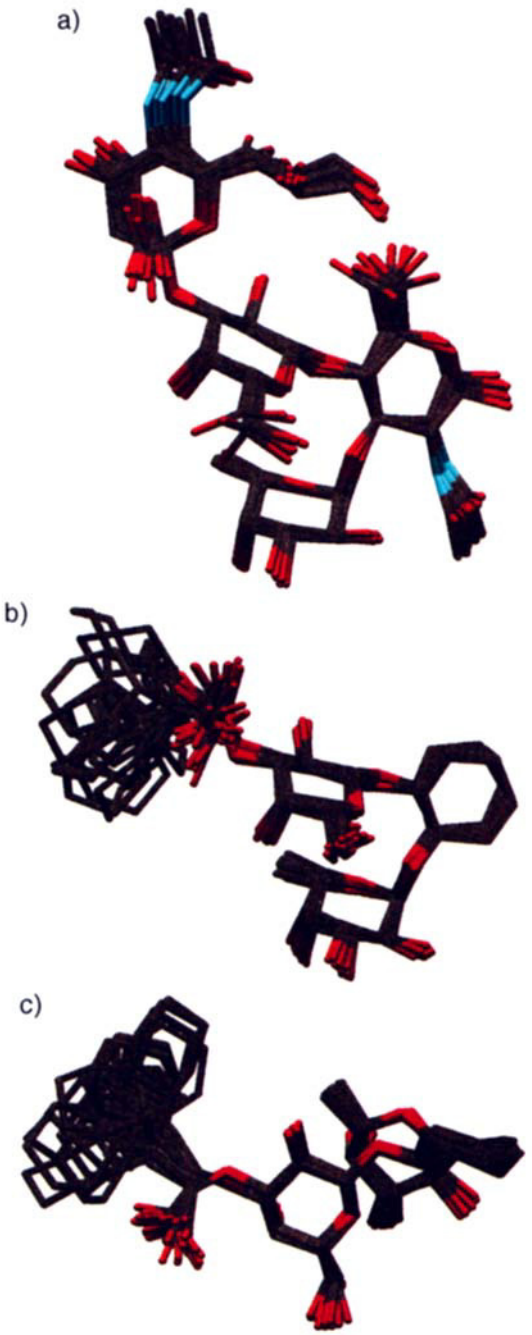

Figure 2. Bioactive conformations of E-selectin ligands: a) superposition of 10 structures of **1** bound to E-selectin [4c]; b) superposition of 19 distance geometry structures of **2** bound to E-selectin; c) portion b) viewed from a different angle.

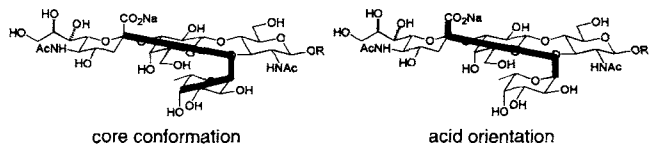
Poorly defined parts of the structures determined by NMR spectroscopy, for example the orientation of the terminal cyclohexyl ring in the present study, can have two fundamentally different causes. First, "true" flexibility in the molecule and the corresponding decrease in correlation time of interproton vectors can lead to the absence of NOE cross-peaks, even if protons are close in space at least part of the time. Second, a lack of NOE cross-peaks simply caused by the absence of neighboring protons can produce apparent flexibility in structures calculated on the basis of NOE constraints, although the region may actually be rather rigid. In the case of mimic **2**, the observed lack of NOEs for the terminal ring would then simply result from the ring being extended,



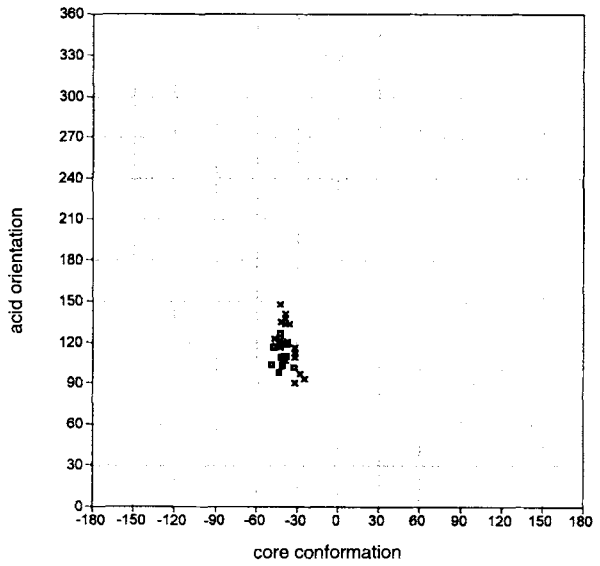


Figure 3. Internal coordinate plot [5] of the bioactive conformations of **1** (□) and **2** (×). See text for further details.

independent of flexibility. Thus, the two possibilities cannot be unequivocally distinguished for **2**. In principle the question could be resolved by measuring ^{13}C relaxation parameters and interpretating them in terms of motional models,[9] but such an analysis has not been carried out so far and seems rather challenging for *bound* sialyl Lewis^x. It should be emphasized that the disordered cyclohexyl ring does not necessarily reflect mobility in the bound form.

The rational design of sialyl Lewis^x mimics is crucially dependent on structural information of their complexes with E-selectin. Although no structure of an E-selectin/ligand complex has yet been reported, the X-ray structure of E-selectin[10] and the NMR structures of **1**[4] or **2** bound to E-selectin are now available. In addition, binding studies with sialyl Lewis^x analogues define functional groups involved in binding interactions with the receptor,[11] and point-mutation studies of E-selectin define the amino acid residues responsible for sialyl Lewis^x binding.[12] On the basis of these data, it is possible to develop a model for the E-selectin/sialyl Lewis^x complex which allows the rational design of more potent sialyl Lewis^x analogues.

Experimental Section

The ectodomains of human E-selectin were combined by means of the polymerase chain reaction (PCR) with the Fc region of human IgG1, and subcloned in the expression vector pcDNAI/neo (Invitrogen). Following transfection of CHO-K1 cells (ATCC CCL-61) and selection with G418 (Gibco), a stable cell line was obtained which secreted about 25 $\mu g\,mL^{-1}$ recombinant E-selectin/hIgG. To produce larger amounts, this cell line was cultivated in a hollow fiber bioreactor (1.1 m^2, 50 mL, Cellco) in Opti-MEM culture medium (Gibco) supplemented with 2% fetal-calf serum and 200 $mg\,mL^{-1}$ gentamycin. The supernatant of the conditioned cells was first purified by affinity chromatography on protein A/agarose (Sigma). The protein fraction obtained by elution with 20 mM glycine/HCl (pH = 3.0) was neutralized and purified by chromatography directly on an anti-human-E-selectin affinity column (2 mg monoclonal antibody 7A9 per milliliter affigel). Specifically bound E-selectin/IgG was eluted with 5 M urea in buffered salt solution and finally dialyzed against Dubeccos phosphate buffered saline (PBS) solution. The protein thus obtained showed, in sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis under reducing conditions, a single band at about 140 kDa. For NMR spectroscopic analysis about 6 mg of E-selectin hIgG were dialysed against 100 mM perdeuterated imidazol (Sigma), 1 mM $CaCl_2$ (pH = 7.4) in D_2O and concentrated by means of Centricon YM-50 (Amicon) to a final volume of 0.5 mL.

IC_{50} values were determined with a standard ELISA assay using an E-selectin IgG and biotinylated polymer containing sLe^a. Wells in a microtiter plate (plate 1, Falcon probind) were coated with E-selectin/hIg chimera by incubation of 100 µL of the purified chimeric protein at a concentration of 200 ng/well in 50 mM Tris, 0.15 M NaCl, 2 mM $CaCl_2$ (pH = 7.4; Tris-Ca^{2+}). After 2 h 100 µL of a 1:1 mixture of 1% BSA in Tris-Ca^{2+} and Stabilcoat were added to each well and incubated at 22 °C to block nonspecific binding. During this incubation, inhibitory test compounds, diluted in Tris-Ca^{2+} and 1% BSA, were titrated by a twofold serial dilution in a second U-shaped bottom low-bind microtiter plate (plate 2, Costar). An equal volume of a preformed complex of a biotinylated sLe^a polymer and horseradish peroxidase labeled streptavidin (KPL, Gathersburg, MD, USA) at 1 $mg\,mL^{-1}$ in Tris-Ca^{2+} and 1% BSA was added to each well. After 2 h at 22 °C plate 1 was washed with Tris-Ca^{2+}, and 100 µL per well were transferred from plate 2 to plate 1. The binding reaction was allowed to proceed for 2 h at 22 °C while rocking. Plate 1 was then washed with Tris-Ca^{2+}, and 100 µL of 3,3′,5,5′-tetramethylbenzidine substrate (KPL, Gathersburg, MD, USA) was added to each well. After three minutes the colorimetric reaction was stopped by adding 100 µL of 1 M H_3PO_4 per well, and the optical density was determined at 450 nm.

All NMR experiments were carried out at 25 °C on a Varian UnityPlus 600 MHz spectrometer. Susceptibility-matched NMR tubes (Shigemi) were used with a sample volume of 220 µL. The sample contained 35 µM E-selectin construct and 1750 µM sialyl Lewis^x mimic **2** in 100 mM deuterated imidazole (pH = 7.4), 1 mM $CaCl_2$ in D_2O. Since each E-selectin/IgG molecule contains two binding sites for sialyl Lewis^x or mimics, the true ratio of protein to ligand was 1:25. NOESY spectra were acquired using a spin-lock filter [6] before t_1 of 20 ms duration and 9 kHz strength. A recycle time of 1.85 s was used. Spectra were acquired with 384 complex t_1 points and 32 transients per t_1 point.

Structures were calculated with the distance geometry program DGII (INSIGHTII, MSI) on a SGI workstation. As described in the text, 22 nontrivial distance constraints derived from NOE data were used. The sugar pucker of the four carbohydrate rings was determined by homonuclear and heteronuclear coupling constants for unbound **2**, and made plausible for bound **2** by analysis of NOE intensities in transfer NOE spectra. To fix the sugar puckers, 36 constraints between carbon atoms located within a distance of 3 Å in the same ring were used. Fifty structures were smoothed using triangle smoothing, and embedded in 4-D space. The structures were refined using 10000 steps of simulated annealing. During simulated annealing, the atomic mass was multiplied by a factor of 1000. The structures were finally minimized using 250 steps of conjugate gradient minimization. The sums of van der Waals radii were used as constraints. All other nonbonded interactions were excluded from the calculations to prevent possible bias induced by force-field parameters. Thus, the structural variations within the family of structures represents the measured data and is not simply a consequence of energy minimisation. A subset of 19 structures converged to conformations which satisfied all distance constraints as well as sugar pucker constraints within 0.05 Å. The average pairwise root mean square deviation (rmsd) was 0.25 Å for superposition of the fucose heavy atoms, galactose heavy atoms, (1*R*,2*R*)-1,2-cyclohexanediol (cyc-2) heavy atoms, and Cα–C(O) atoms of the (*S*)-cyclohexyllactic acid (cyc-1). For all heavy atoms, the average pairwise rmsd was 1.16 Å.

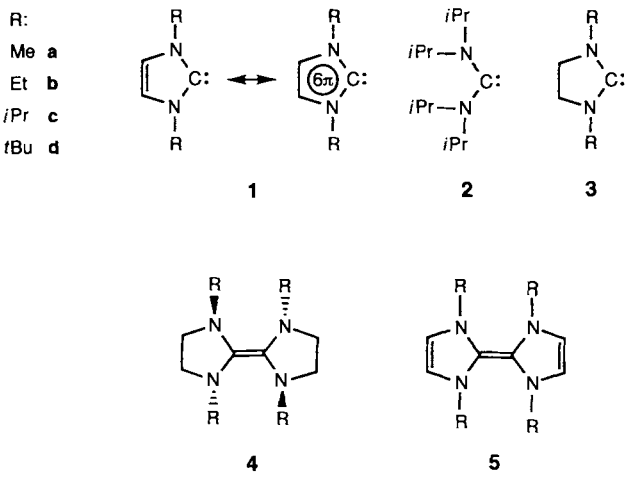
Steric Stabilization of Nucleophilic Carbenes**

Michael K. Denk,* Avinash Thadani, Ken Hatano, and Alan J. Lough

After early studies by Wanzlick,[1] the chemistry of stable carbenes [1–7] underwent a revival in 1991 with the structural characterization of **1** (R = 1-adamantyl).[2] Stable carbenes such as **1** are now easily accessible and show a rich reaction chemistry.[2–4] Computational studies have confirmed that carbenes of type **1** possess aromatic stabilization.[5] The numerous aromatic carbenes **1** currently have only two nonaromatic counterparts, compounds **2**[6] and **3** (R = mesityl).[7] The isolation of the stable bis(diisopropylamino)carbene (**2**) by Alder et al.[6a] demonstrates for the first time that neither aromatic stabilization nor the constraints resulting from ring geometry are necessary to obtain stable diaminocarbenes. The dimerization of carbenes to olefins[8–11] can prevent their isolation but is thermodynamically unfavorable for carbenes **1**, as was shown by Taton and Chen.[11]



Following studies on stable silylenes,[12] germylenes,[13] and phosphenium cations[14] isostructural to **1** and **3**, we demonstrate herein that the successful isolation of carbenes **3** has kinetic reasons (in contrast with **1**) and is critically dependent on the bulk of the substituent R. The new carbenes **3a–3d**[6b] were obtained by reductive desulfurization from the corresponding thioureas[15] with potassium in boiling THF, a method used in the aromatic series (carbenes **1**) by Kuhn et al.[16] The analogous ureas are inert even after prolonged treatment with molten potassium. Carbene **3d**, the sterically most shielded carbene in this series, is a low-melting, colorless solid that distills without decomposition and is stable indefinitely under exclusion of air and moisture. For R = Me (**3a**), Et (**3b**), and *i*Pr (**3c**), the carbenes persist in solution but slowly dimerize to give the olefins **4a–4c**. Attempted distillation of the carbenes **3a–3c** (60 °C/0.1 Torr) yields the olefins as easily sublimable, air- and moisture-sensitive colorless solids. Compound **4a** was previously obtained by other methods[17,18] but has not been structurally characterized. The slow dimerization of **3a–3c** in solution suggests a substantial activation barrier. The dimerizations obey (^{1}H NMR) a second-order rate law and, accordingly, are concentration dependent.[19] The pure carbenes **3a–3c** dimerize within minutes, but frozen solutions of **3a–3c** in benzene can be stored indefinitely at −20 °C. Olefins of type **4** can fragment to give transition metal carbene complexes.[17] The dissociation of **4** to free carbenes **3** is of interest as a possible pathway for these reactions; however, high-temperature ^{1}H NMR spectra did not show any signs of this dissociation.[20]

The additional electronic stabilization in diaminocarbenes **1** is evident, for example, in that while **3c** dimerizes, the aromatic 4,5-dimethyl-substituted analogue of **1c** is stable.[21] Indeed, not a single carbene of type **1** has been observed to dimerize and olefins of type **5** require additional covalent bridging of the substituents R to be stable, as was shown by Taton and Chen.[11] The lack of aromatic stabilization in carbenes **3** is also shown by the deshiedling of the carbene-carbon atom ($\Delta\delta(^{13}C) \approx 30$ relative to those in **1**).[2–5,21]

A single-crystal X-ray structure analysis of **3d**[22] shows the two nitrogen atoms to be in nearly planar environments (sum of bond angles: N(1) 356°, N(2) 357°; see Figure 1). The valence angle at the carbene-carbon atom is significantly larger (106.44(9)°) than the N-Si-N and N-Ge-N angles of the

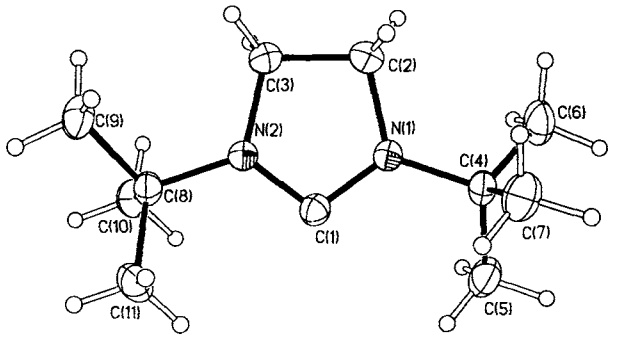

Figure 1. Molecular structure of **3d** in the solid state (ORTEP view, thermal ellipsoids are at the 50% probability level). Selected bond lengths [pm] and angles [°]: C(1)–N(1) 134.8(1), C(1)–N(2) 134.7(1), N(1)–C(2) 147.6(1), N(1)–C(4) 148.0(1), C(2)–C(3) 151.2(2), N(1)–C(1)-N(2) 106.44(9); C(1)-N(1)-C(2) 112.51(8), N(1)-C(2)-C(3) 101.34(9), C(4)-N(1)-C(2) 120.53(8), C(4)-N(1)-C(1) 123.10(8).

isostructural silylenes (95.4(1)[12] and germylenes 88.0(1).[13] The short C^{II}–N bond length (135 pm) indicates a partial double bond.

A comparison of the carbene **3d** with the olefin **4a** highlights characteristic changes in the five-membered C_2N_2C framework (Figure 1 and 2): the C–N bond lengths

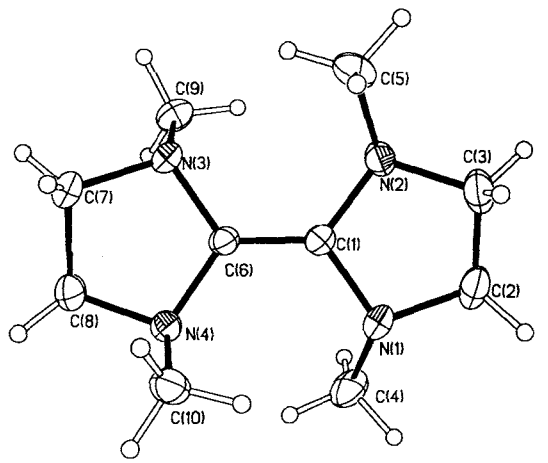

Figure 2. Molecular structure of **4a** (ORTEP view, thermal ellipsoids are at the 50% probability level). Selected bond lengths [pm], bond angles [°], and torsional angles [°]: C(1)–C(6) 134.94(11), N(1)–C(1) 142.05(11), N(2)–C(1) 141.77(11), N(3)–C(6) 143.63(11), N(4)–C(6) 144.30(10) N(2)–C(3) 146.34(12), C(3)–C(2) 150.7(2), N(4)–C(8) 147.20(11), C(8)–C(7) 152.54(14), C(7)–N(3) 147.02(12); N(1)-C(1)-N(2) 108.71(7), N(3)-C(6)-N(4) 111.29(7), N(3)-C(6)-C(1)-N(2) 5.94(13); N(3)-C(6)-C(1)-N(1) –173.57(7), N(4)-C(6)-C(1)-N(1) 8.01(13), N(4)-C(6)-C(1)-N(2) – 172.47(7).

increase from the carbene (**3d**: 135 pm) to the dimer (**4a**: 142–147 pm), and the nitrogen atoms pyramidalize (sum of the nitrogen bond angles in **4a**: 331–340°). The N-C-N bond angles of **3d** and **4a** are nearly identical. The twisting of the $N_2C{=}CN_2$ framework in **4a** (N-C-C-N torsional angles of 6 and 8°) is reproduced by calculations (AM1, MP4/6-31G*) both for **4a** and the unsubstituted derivative (R = H) and has, presumably, electronic rather than steric origins.

The structures of the open-chain carbene **2**[6] and the cyclic carbene **3d** show significant differences. The N-C-N bond angle in **3d** (106.44(9)°) is compressed compared to that in **2** (121.0(5)°) and the C^{II}–N bond length is shortened (134.8(3) pm in **3d**, 136.3(6) pm in **2**). The ^{13}C NMR shifts reflect the structural differences: the carbene–carbon atom in **3d** ($\delta = 238$) is strongly shielded compared to that in **2** ($\delta = 256$). We conclude that the ring geometry in carbenes **3** stabilizes the carbene (shortened C–N bond, shielded carbene signals) through an additional compression of the N-C-N valence angle. In support of our conclusion, diaminocarbenes and silylenes show decreased thermal stability if the ring size is increased from five (C_2N_2E:) to six (C_3N_2E:).[24]

Experimental Section

All operations were performed under argon (99.995%) with usual Schlenk techniques. The respective thiourea [15] (10 mmol), potassium (30 mmol), and THF (50 mL) were boiled under reflux for 30 min. After filtration and removal of the solvent under vacuum (–20 °C), the carbenes **3a**–**3c** were obtained as yellow, viscous oils. Distillation of **3d** (0.1 Torr, 120 °C oil bath) yielded the pure **3d** as a colorless, low-melting solid (m.p. 22–23 °C). Yields: quantitative for **3a**–**3c**, 85–95% for **3d**. Attempted distillation of **3a**–**3c** (0.1 Torr, 60 °C oilbath) led to sublimation of the olefins **4a**–**4c** as colorless, crystalline solids in quantitative yields. NMR data: C_6D_6, 20 °C,TMS.

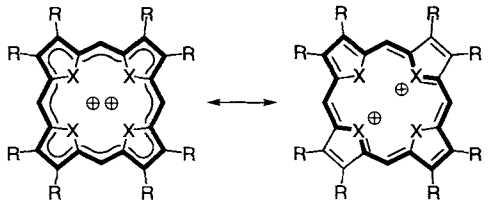
Octaethyltetraselenaporphyrin Dication**

Emanuel Vogel,* Christoph Fröde, Andreas Breihan, Hans Schmickler, and Johann Lex

Dedicated to Professor Marianne Baudler on the occasion of her 75th birthday

The oxygen analogue of porphyrin, the D_{4h} symmetrical dication **1** (as its perchlorate),[1,2] constitutes a key compound in the chemistry of nonnatural porphyrins. There exists a close relationship between **1** and porphyrin, both in terms of their synthesis and their aromaticity, as evident from spectra and molecular structure. However, the two macrocycles differ markedly in their chemical properties. Unlike porphyrin and the neutral monooxa- and dioxaporphyrins,[3] **1** is no longer able to form complexes with metal ions because of its positive charge. Central to the chemistry of **1** are nucleophilic additions (and subsequent transformations) and the tetraoxaporphyrin redox system, which is derived from the dication and is interesting from many viewpoints.[4]



1–6

R=H **1**: X=O, **2**: X=S, **3**: X=Se (in solution only)
R=C_2H_5 **4**: X=O, **5**: X=S, **6**: X=Se

The recently synthesized tetrathiaporphyrin dication **2** (as its perchlorate)[5,6] and the tetraselenaporphyrin dication **3**,[5] which has until now only been obtained in solution, both resemble **1** in terms of their reactivity and spectral characteristics, even though the ring system deviates significantly from planarity because of the steric interactions of the heteroatoms. Since the study of **1**–**3** is adversely affected by problems associated with solubility and/or crystallization, it is sensible to follow the lead of porphyrin chemistry and turn to the octaethyl compounds **4**–**6**. After the syntheses of **4**[7] and **5**,[8] that of **6**, presented here, has also been achieved, and with it the set of chalcogenaporphyrins—with the exception of the tellura compound[9]—is now complete.

The 2-(hydroxymethyl)-3,4-diethylselenophene (**7**)[10] was chosen as the starting material in the synthesis of the octaethyltetraselenaporphyrin dication **6** (as its perchlorate). This would allow use of the route already proven in the synthesis of **1**, **4**, and **5**—the tetracyclocondensation to "porphyrinogen" and its oxidation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) with addition of $HClO_4$.

Treatment of **7** with one equivalent of *p*-toluene sulfonic acid in nitromethane at 80 °C (10 min) gave the expected octaethyltetraselenaporphyrinogen **8**, albeit only in small amounts. Analogous to the cyclocondensation of 2-(hydroxymethyl)-

3,4-diethylthiophene,[8] the macrocycle **9**, which contains five selenophene units, was also formed. The complex reaction mixture was worked up conventionally in order to isolate the cyclocondensation products **8** and **9**. These were then further purified by chromatography using silica gel and *n*-hexane/dichloromethane (3/1). The first fraction contained several open-chain condensation products (all in less than 1% yield), after which **8** and **9** were eluted together.[11] It proved expedient to treat this fraction, after removal of the eluent, with *n*-hexane. This treatment left the major amount of **8** undissolved, and it could be filtered off. Chromatography of the filtrate with *n*-hexane/toluene (4/1), again on silica gel, finally allowed the remainder of **8** (first fraction) to be separated from **9**. Recrystallization of both compounds from ethanol yielded **8** as colorless needles (m.p. 220–222 °C) and **9** as an amorphous colorless powder (m.p. 130–132 °C, yield in each case 3%). The homologous compounds **8** and **9** could not be differentiated by NMR spectroscopy, and were thus assigned structurally on the basis of their mass spectra.

The tendency of **8** to form is very noticeably lower than that of its oxygen and sulfur analogues, which is probably due to the large increase in the angle between the exocyclic bonds at the α positions of the heterocycle (from 147° to 156°)[12] on going from thiophene to selenophene; such a change favors the formation of open-chain compounds. The helical effect[13] of the ethyl groups, to which the relatively high yields of porphyrinogens from 2-(hydroxymethyl)-3,4-diethylfuran and -thiophene is ascribed, evidently plays a negligible role in the case of **7**.

Oxidation of octaethyltetraselenaporphyrinogen (**8**) to give the octaethyltetraselenaporphyrin dication **6** (as its perchlorate) proceeded smoothly: **8** was heated to 80 °C in glacial acetic acid with DDQ (3 mol equiv) for 30 min and the reaction mixture was then treated with 70% perchloric acid (1:10 in HOAc; 5 mol equiv). Compound **6** was formed and separated upon cooling of the solution as a microcrystalline green powder. This was taken up in a small amount of trifluoroacetic acid, layered with three times the volume of acetic acid, and left to crystallize. After two days **6** had precipitated in the form of metallic green needles, which contained two equivalents of trifluoroacetic acid (material used for X-ray structure analysis). Heating the crystals to 50 °C under vacuum (0.01 Torr, 2 d) gave analytically pure **6** as a stable, very hydrolytically sensitive compound in 58% yield.

The ^{1}H NMR spectrum (CD_3NO_2) of **6** is very similar to the spectra of the oxygen and sulfur analogues **4** and **5**. In accord with the presence of an aromatic dicationic porphyrin, the singlet for the *meso*-protons (H_m) occurs at very low field (δ = 12.10, see Table 2). The slight high-field shift of the H_m signal in **6** compared to that in **5** ($\Delta\delta = 0.43$) most likely arises from the fact that the ring system in **6**, due to the larger van der Waals radius of the heteroatoms (S: 1.85 Å, Se: 2.0 Å), is more deformed than that in **5**. The ^{13}C NMR spectrum of **6**, which as expected contains five signals, corresponds well to that of the sulfur analogue. On the basis of Se–H coupling (^3J(Se,H_m) = 10.8 Hz), an inverse ^{1}H–^{77}Se NMR spectrum could be obtained, which indicated a chemical shift for the ^{77}Se nucleus of $\delta = 747$ (standard: $(CH_3)_2Se$). The UV/Vis spectrum of **6** in formic acid has a flattened maximum at 483 nm ($\varepsilon = 61\,800$), which can be interpreted as a bathochromically shifted Sôret band, but displays relatively high absorption ($\lambda = 700-800$ nm, $\varepsilon \approx 9000$) at longer wavelengths (in the Q band region); however, defined energy transitions cannot be recognized.

An X-ray crystallographic analysis of the octaethyltetraselenaporphyrin dication (**6**, as its perchlorate)[14] reveals that the molecule has a nonplanar ring conformation, as shown in Figure 1. In accordance with the established centrosymmetry of the dication, the four selenophene rings are twisted from the molecular plane (defined by the four *meso*-carbon atoms) in the sense of a *syn,syn,anti,anti* arrangement. The twist angles of the selenophene rings are 24.3° and 30.5°, respec-

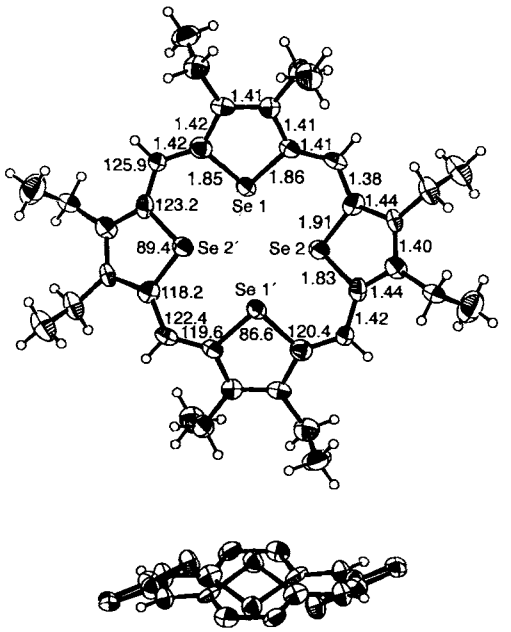

Figure 1. Structure of **6** in the crystal (top: plan view; bottom: side view; ethyl groups are omitted for clarity). Selected bond lengths [Å] and bond angles [°]; the vibrational ellipsoids represent 40% probability.

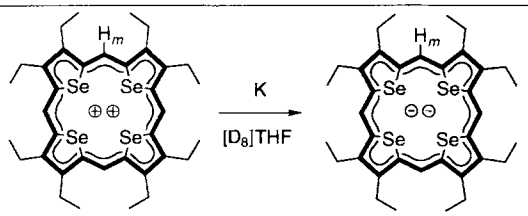
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3623-2610 $ 17.50+.50/0

tively, and thus are significantly greater than those of the thiophene rings in the corresponding sulfur compound **5** (19°), which likewise exhibits centrosymmetry. The shortest Se···Se distance in **6** is 2.9 Å, that is more than 1 Å less than double the van der Waals radius of the selenium atom. The simplicity of the NMR spectra indicates that in solution **6** (like **5**) is a dynamic molecule, in which the hetero five-membered rings exchange sites rapidly by conformational processes.

The most remarkable chemical transformation of the dication **6** is its exhaustive reduction to the dianion **11**,[15] achieved by a potassium mirror in deuterated THF at −78 °C (complete conversion after two days with formation of a brown-red solution).[16] Whereas the sulfur compound **5** reacts under these conditions to give predominantly polymeric products, **6** amazingly accepts four electrons smoothly to give the aromatic dianion **11** with 22 π electrons. This was clearly identified by the ^{1}H NMR spectrum (analogous to that of **6**), the ^{13}C NMR spectrum (five signals), and the inverse ^{1}H–^{77}Se NMR spectrum (singlet, Table 1). That the signal of the *meso* protons of **11** is only shifted by $\Delta\delta = 1$ to higher field

Table 1. Characteristic NMR data for **6**[a] and **11**[b].



6 **11**

	6	**11**
δ H$_m$	12.10	11.03
δ C$_m$	138.21	107.45
δ Se	747 (^3J(Se,H$_m$) = 10.8 Hz)	586 (^3J(Se,H$_m$) = 14.9 Hz)

[a] ^{1}H-NMR 300 MHz, ^{13}C-NMR 75.5 MHz, ^{77}Se-NMR 57.2 MHz, CD_3NO_2. [b] ^{1}H-NMR 300 MHz, ^{13}C-NMR 75.5 MHz, ^{77}Se-NMR 76.3 MHz, [D$_8$]THF.

with respect to that of **6**, indicates that despite the negative charge on **11** strong deshielding is still prevalent. Thus the dianion maintains a pronounced diamagnetic ring current. On going from dication **6** to dianion **11** the center of ^{13}C resonances of the twenty perimeter carbon atoms is shifted to higher field by $\Delta\delta = 36$. This corresponds roughly to the value of 32, which is the value expected for **6** as derived from the empirical Spiesecke–Schneider correlation[17] between charge density and chemical shift in $(4n+2)\pi$-electron systems.[18]

The cyclocondensation product **9**, which contains five selenophene rings, should be capable of being oxidized[8] to the potentially aromatic 22π-electron decaethylpentaselenapentaphyrin trication (**10**). Thus **9** was treated with antimony(v) chloride in dichloromethane. A saltlike product was obtained (green needles with a metallic luster), whose cationic component was unambiguously shown to be the desired trication by NMR spectroscopy (Table 2). Isolation of **10** with a uniform counterion remains to be accomplished, since the anionic component of the oxidation product is a mixture of different chloroantimonate ions.

After the successful synthesis of cationic oxygen, sulfur, and selenium analogues of the porphyrins (the chalcogenaporphyrins with the exception of the tellurium compound), attention is now focussed on the fascinating neutral tetraphosphaporphyrins as the remaining synthetic challenge in the field of porphyrin derivatives, which are derived from the parent tetrapyrrolic macrocycle by substitution of the nitrogen atoms for other heteroatoms.

Table 2. Selected physical data for **6**–**14**[a].

6: ^{1}H NMR (CD_3NO_2): $\delta = 12.10$ (s, 4H; H$_m$), 4.16 (q, 16H; CH_2), 1.79 (t, 24H; CH_3); ^{13}C NMR (CD_3NO_2): $\delta = 173.39, 160.72, 138.21, 25.44, 17.74$; ^{77}Se NMR ($CD_3NO_2$): $\delta = 747$; MS (FAB): *m/z* (%): 793 (100) [$M^+ - 2\,ClO_4$]; IR (CsI): $\tilde{\nu}$= 2969, 2933, 2873, 1452, 1399, 1369, 1350, 1213, 1173, 1130, 1105, 1083, 625 cm^{-1}; UV/Vis (HCOOH): λ_{max} (ε) = 483 nm (61800), 700–800 (9000)

7: ^{1}H NMR ($CDCl_3$): $\delta = 7.45$ (s, 1H; H-5), 4.74 (s, 2H; H-2a), 2.90 (s, 1H; OH), 2.50 (q, 2H; H-3a), 2.48 (q, 2H; H-4a), 1.24 (t, 3H; H-4b), 1.07 (t, 3H; H-3b); ^{13}C-NMR ($CDCl_3$): $\delta = 146.10, 143.89, 141.25, 121.85, 59.86, 23.75, 21.10, 15.00, 13.44$; MS (GC-MS, EI, 70 eV): *m/z* (%): 218 (65) [M^+], 189 (45), 137 (100); IR (film): $\tilde{\nu}$= 3334, 2964, 2931, 2872, 1460, 1375, 1305, 1185, 1143, 1100, 1004, 924, 798, 782, 728 cm^{-1}; UV/Vis (CH_2Cl_2): λ_{max} (ε) = 257 nm (7400)

8: ^{1}H NMR ($CDCl_3$): $\delta = 4.05$ (s, 8H; H$_m$), 2.42 (q, 16H; CH_2), 1.06 (t, 24H; CH_3); ^{13}C NMR ($CDCl_3$): $\delta = 143.69, 140.50, 30.40, 21.61, 15.19$; ^{77}Se-NMR ($CH_2Cl_2$): $\delta = 600$; MS (FAB): *m/z* (%): 796 (5) [M^+], 307 (30). 154 (100), 137 (60); IR (KBr): $\tilde{\nu}$= 2959, 2928, 2899, 2868, 2822, 1462, 1445, 1374, 1307, 1280, 1115, 1047, 937 cm^{-1}; UV/Vis (CH_2Cl_2): λ_{max} (ε) = 258 nm (25400)

9: ^{1}H NMR ($CDCl_3$): $\delta = 4.14$ (s, 10H; H$_m$), 2.45 (q, 20H; CH_2), 1.08 (t, 30H; CH_3); ^{13}C NMR ($CDCl_3$): $\delta = 141.71, 140.60, 30.61, 21.68, 15.16$; MS (EI, 70 eV): *m/z* (%): 996 (60) [M^+], 967 (70), 201 (100); IR (KBr): $\tilde{\nu}$= 2962, 2928, 2869, 1451, 1375, 1311, 1293, 1119, 1048, 930 cm^{-1}; UV/Vis (CH_2Cl_2): λ_{max} (ε) = 257 nm (38900)

10: ^{1}H NMR (CD_3NO_2): $\delta = 14.78$ (s, 5H; H$_m$), 5.71 (q, 20H; CH_2), 2.56 (t, 30H; CH_3); ^{13}C NMR (CD_3NO_2): $\delta = 170.43, 162.93, 136.07, 28.37, 20.07$; MS (FAB): *m/z* (%): 991 (100) [M^+]; IR (CsI): $\tilde{\nu}$= 3526, 2968, 2930, 2870, 1521, 1473, 1448, 1419, 1373, 1308, 1256, 1183, 1110, 1052, 983, 925, 838 cm^{-1}; UV/Vis (CH_2Cl_2, 0.2% $SbCl_5$): λ_{max} = 551, 778, 856 nm (ε on the basis of mixed counterions, not exactly defined)

11: ^{1}H NMR ([D$_8$]THF): $\delta = 11.03$ (s, 4H; H$_m$), 4.01 (q, 16H; CH_2), 1.98 (t, 24H; CH_3); ^{13}C NMR ([D$_8$]THF): $\delta = 131.12, 126.08, 107.45, 24.48, 18.21$; ^{77}Se-NMR ([D$_8$]THF): $\delta = 586$

12[10]: ^{1}H NMR ($CDCl_3$): $\delta = 3.64$ (s, 6H; CH_3), 3.29 (s, 4H; CH_2); ^{13}C NMR ($CDCl_3$): $\delta = 171.07, 52.24, 23.14$; MS (EI, 70 eV): *m/z* (%): 226 (15) [M^+], 194 (35), 167 (15), 152 (10), 94 (15), 74 (20), 45 (100); IR (Film): $\tilde{\nu}$= 3003, 2953, 1733, 1437, 1409, 1270, 1109, 1010, 878, 770, 669 cm^{-1}; UV/Vis (CH_2Cl_2): λ_{max} (ε) = 242 nm (900)

13[10]: ^{1}H NMR (C_6D_6): $\delta = 3.30$ (s, 3H; $COOCH_3$), 2.90 (q, 2H; H-4a), 2.81 (q, 2H; H-3a), 1.15 (t, 3H; H-4b), 1.13 (t, 3H; H-3b); ^{13}C-NMR (C_6D_6): $\delta = 169.18, 163.25, 156.74, 155.29, 137.15, 134.84, 51.73, 22.75, 22.64, 14.92, 14.85$; MS (EI, 70 eV): *m/z* (%): 290 (100) [M^+], 275 (80), 257 (95), 91 (65); IR (KBr): $\tilde{\nu}$= 2982, 2875, 1715, 1680, 1653, 1541, 1277, 1264, 1249, 1229, 1153 cm^{-1}; UV/Vis (CH_2Cl_2): λ_{max} (ε) = 294 nm (13700)

14[10]: ^{1}H NMR ($CDCl_3$): $\delta = 7.72$ (s, 1H; H-5), 3.80 (s, 3H; $COOCH_3$), 2.93 (q, 2H; H-3a), 2.50 (q, 2H; H-4a), 1.23 (t, 3H; H-4b), 1.13 (t, 3H; H-3b); ^{13}C NMR ($CDCl_3$): $\delta = 163.96, 154.08, 147.40, 130.32, 129.79, 51.65, 23.63, 22.28, 14.17, 13.59$; MS (EI, 70 eV): *m/z* (%): 246 (100) [M^+], 231 (80), 215 (90), 91 (80); IR (film): $\tilde{\nu}$= 2968, 2874, 2837, 1709, 1547, 1452, 1383, 1309, 1233, 1189, 1167, 1112, 1088, 1059, 1023 cm^{-1}; UV/Vis (CH_2Cl_2): λ_{max} (ε) = 270 nm (10800)

[a] ^{1}H NMR 300 MHz, ^{13}C NMR 75.5 MHz, ^{77}Se NMR 57.2 or 76.3 MHz. Apart from **10** (mixture of chloroantimonate counterions) and **11** (generated in an NMR experiment), correct elemental analyses were obtained for all compounds.

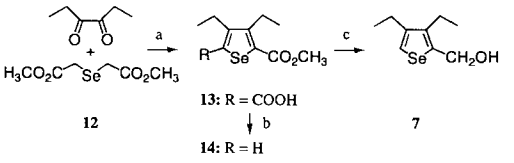
[9] Monotelluraporphyrins are already known, see refs. [2b] and [6c,i]. There should be no doubt as to the viability of the octaethyltetratelluraporphyrin dication, since octaethyl-*N,N',N'',N'''*-tetramethylporphyrin dication is both stable and aromatic, even though its ring skeleton is very strongly nonplanar.[5] Despite the advances in the chemistry of tellurium (see N. Petragnani, *Tellurium in Organic Syntheses*, Academic Press, London, **1994**), the synthetic route to the tellurium analogue of **4**, **5**, and **6** still appears to be strewn with difficulties.

[10] The new compound **7** can be obtained according to the following reaction scheme (in analogy to the corresponding thiophene [8]). For the preparation of the required **12** from Na_2Se and methyl chloroacetate see: H. Rheinboldt in *Methoden Org. Chem. (Houben-Weyl), 4th. ed. vol 9, p.* 976:



a) *t*BuOK in *t*BuOH, 1 h, 25 °C; crude **13** is sufficiently pure and is used directly; analytical sample: colorless crystals, m.p. 158 °C (*n*-hexane). b) Cu/ca. 300 °C, 0.5 h; **14** was purified by chromatography on silica gel, first with *n*-hexane (separation of diethylselenophene) then with *n*-hexane/ethyl acetate (5/1), and isolated in 38% yield; colorless crystals, m.p. 18 °C (from *n*-hexane). c) $LiAlH_4$ in THF, 1 h, 25 °C; **7** precipitated from *n*-hexane as a colorless, mother-of-pearl-like solid, m.p. 21 °C (yield 94%).

[11] The compounds **8** and **9** were identified on the basis of their characteristic violet color, which appeared on the thin layer chromatograms [*n*-hexane/toluene (4/1)] after treatment with nitric acid vapor (the color of the first fraction disappeared after a short time).

[12] Calculated from the relevant bond angles for thiophene and selenophene given in C. W. Bird, G. W. H. Cheeseman in *Comprehensive Heterocyclic Chemistry, Vol. 4, Part 3* (Eds.: A. R. Katritzky, C. W. Rees), Pergamon, Oxford, **1984**, p. 3.

[14] Crystal structure data for $\mathbf{6}\cdot 2\,CF_3COOH$: $C_{36}H_{44}Cl_2O_8Se_4\cdot 2\,CF_3COOH$, $M_r = 1219.51$, crystals from CH_3COOH/CF_3COOH (3/1); crystal dimensions $0.25\times0.18\times0.15$ mm^3, monoclinic, space group $P2_1/n$, $a = 7.9260(10)$, $b = 22.651(6)$, $c = 13.146(3)$ Å, $\beta = 98.12(2)^\circ$, $V = 2336.5(9)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.733$ g cm^{-3}; $F(000) = 1212$; $\mu_{Mo} = 3.337$ mm^{-1}; 4536 measured reflections, 3854 independent, 2038 observed reflections ($F_o^2 > 2\sigma F_o^2$); $\theta_{max} = 25^\circ$; $R1 = 0.0940$, $wR2 = 0.1868$. Enraf-Nonius CAD4 diffractometer (room temperature, $Mo_{K\alpha}$ irradiation, $\lambda = 0.71069$ Å). The structure was solved by direct methods and refined with F^2 for all independent reflections (heavy atoms with anisotropic temperature factors, the positions of the H atoms were calculated); $wR2 = \{\sigma w(F_o^2 - F_c^2)^2/\sigma w(F_o^2)^2\}^{1/2}$. Programs used: MolEN (Enraf-Nonius) for structure determination and SHELXL-93 (G. M. Sheldrick, University of Göttingen) for refinement. Calculations were carried out at the Regionales Rechenzentrum der Universität Köln. The crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100418. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge, CB21EZ, UK (fax: Int code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

[15] Cyclovoltammetric studies on **6** indicate two reduction waves, which in terms of the electron transitions cannot be interpreted unambiguously because of the strong broadening.

[16] The reduction took place under an inert atmosphere in a reaction flask that was connected through a frit to a NMR tube.

[17] H. Spiesecke, W. G. Schneider, *Tetrahedron Lett.* **1961**, 468; B. Eliasson, U. Edlund, K. Müllen, *J. Chem. Soc. Perkin Trans. 2* **1986**, 937; G. A. Olah, G. D. Mateescu, *J. Am. Chem. Soc.* **1970**, *92*, 1430.

[18] The fairly good correlation of experimental and calculated $\Delta\delta$ values is astonishing, because the possibility that the heteroatoms in both **6** and **11** could carry charge was not taken into consideration.

Contracted Porphyrins: Octaethylisocorrole**

Emanuel Vogel,* Beate Binsack, Yvonne Hellwig, Christoph Erben, Andreas Heger, Johann Lex, and Yun-Dong Wu*

Dedicated to Sir Alan Battersby

The tetrapyrrolic aromatic macrocycle corrole **1**, pioneered in the 1960s by A. W. Johnson[1] (and related structurally to vitamin B_{12}[2] through corrin), is the prototype of the "contracted porphyrins". In analogy to porphyrin, compound **1** is distinguished by an 18 π main conjugation pathway, but has three internal NH hydrogen atoms, making it a potential trianionic ligand. As has been documented by publications from a series of research groups, **1** readily undergoes complexation to yield corrolates with numerous metal ions, in particular those of trivalent metals.[3] The ability of the corrole ligand to stabilize metal ions in higher oxidation states has recently been established.[4] This, along with the most recent synthesis of bis-corroles,[5] corrole heterodimers,[5] and *meso*-phenyl-substituted metallocorrolates[6] have all played a part in bringing the chemistry of corroles out of the shadows of porphyrin chemistry.

Starting from the conceptualization of structural isomers of porphyrin with N_4 coordination, four of which—porphycene, hemiporphycene, corrphycene, and isoporphycene—have already been synthesized,[7] it is a logical step to consider the possible existence of isomers of corrole. While porphyrin has no fewer than seven isomers, the absence of one *meso* unit reduces the possible number of isomers under discussion in the case of **1** to three: compounds **2**–**4**. These are given in Table 1 in order of their relative energies (with respect to **1**), calculated by the PM3 and BLYP/6-31G**//3-21G methods; the relative energies listed refer to the most stable NH tautomer.[7,8]

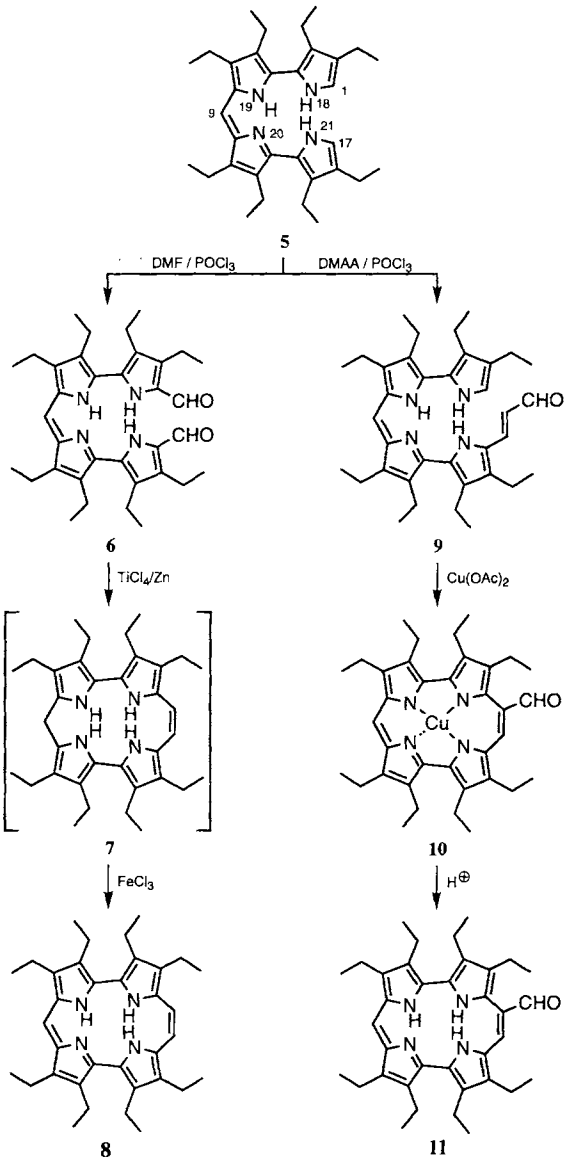
Table 1. Corrole **1** and its structural isomers **2**–**4**[a], arranged according to increasing relative energy [kcal mol^{-1}] with respect to **1**.

			[18]Corrole-(1.1.1.0)	Corrole-(2.0.1.0)	Corrole-(2.1.0.0)	Corrole-(3.0.0.0)
Corrole	**Isocorrole**		
1	**2**	**3**	**4**
0.0	3.8	15.3	35.1
0.0	3.5	15.1	39.8

[a] In each case the most stable NH tautomer is shown. Top line: PM3, bottom line: BLYP/6-31G**//3-21G.

Amongst the corrole isomers, the most likely synthetic candidate appears to be the [18]corrole-(2.0.1.0) (**2**), which will be termed as isocorrole henceforth, since this has the advantage over the other possible isomers of being only 3.5–4 kcal mol^{-1} higher in energy than **1**. Having already obtained the isocorrole derivatives 19-formyl-3,6,13,16-tetrabromo-2,7,12,17-tetrapropylisocorrole[9] and 19-formyl-2,3,6,7,12,13,16,17-octaethylisocorrole[7] (unexpectedly), we are now able to report a rational synthesis of the 2,3,6,7,12,13,16,17-octaethylisocorrole (**8**), which can be considered as a model compound for isocorrole, and the 9-formyl derivative of **8**, that is, compound **11**. An entry to **8** on a preparative scale was offered by the McMurry reductive coupling of the tetrapyrrolic α,ω-dialdehyde **6**. Compound **6** was obtained by allowing the recently described tetrapyrrole **5**[10] to react with the Vilsmeier reagent dimethylformamide/phosphoryl trichloride (in a tenfold excess) in dichloromethane at room temperature (2 h). It was purified by column chromatography on aluminum oxide (activity III) with dichloromethane/ethyl acetate and recrystallized from toluene to give a green, microcrystalline powder with a metallic luster (m.p. 130–132 °C, yield 80%). As can be shown by 2D-NMR experiments, both **5** and **6**—analogous to the simple pyrromethenes[11]—are (*Z*) configured. Reductive coupling of **6** with low-valent titanium to afford **8** was performed similiarly to the method described for the preparation of porphycene from 5,5′-diformyl-2,2′-bipyrrole (see Experimental Section).[12] Since **8** thus formed was accompanied by a dihydroisocorrole, most likely compound **7**, the coupling product which, after conventional work-up, was present in ether, was treated with a solution of iron(III) chloride. Subsequent chromatography on neutral aluminum oxide with *n*-hexane/dichloromethane, followed by recrystallization from *n*-hexane/dichloromethane, gave the desired octaethylisocorrole **8** as violet rectangles with a metallic luster (m.p. 182–183 °C, yield 23%).

The tetrapyrrole **5** is similarly well suited as a starting material for the synthesis of a useful functionalized isocorrole, the 9-formyl-2,3,6,7,12,13,16,17-octaethylisocorrole (**11**), which is a regioisomer of the above-mentioned 19-formyl octaethylisocorrole. The route to **11** involves the conversion of **5** with a slight excess (1.5 equiv) of the vinylogous Vilsmeier reagent 3-(dimethylamino)acrolein (DMAA) and phosphoryl trichloride in dichloromethane, which leads predominantly to the amorphous monoaldehyde **9** (purity ca. 95%).[10] If the crude aldehyde is allowed to react with copper(II) acetate in methanol at room temperature, an unprecedented, probably template-controlled cyclization takes place, leading to the copper complex **10** (crystals of m.p. 174–176 °C, yield 52%),



in which the metal ion is formally in the +3 oxidation state.[13] The complex was demetalated by reaction with concentrated sulfuric acid at room temperature, which liberated the free 9-formyl octaethylisocorrole **11** as a stable compound (m.p. 209–210 °C, yield 42%).

Octaethylisocorrole (**8**) is characterized by its spectra and molecular structure as an aromatic tetrapyrrolic macrocycle, closely related to its octaethylcorrole pendant. The ^{1}H NMR spectrum ($CDCl_3$, room temperature) of **8** displays the simple pattern (Table 2), expected on the basis of a rapid NH tautomerism, which increases the effective molecular symmetry: two singlets at $\delta = 8.76$ and 8.43 (for the perimeter protons H-19 and H-9,10 that are deshielded by the diamagnetic ring current), and four quartets and four triplets at $\delta =$ 3.63–3.49 and 1.61–1.47, respectively (methylene and methyl protons of the pairwise equivalent eight ethyl groups). The resonance of the NH protons required the temperature to be lowered to −50 °C before sufficiently sharp signals (singlets) were obtained; these lie at $\delta = 6.18$ (1H, shifted to low field by hydrogen bonding) and at $\delta = -1.20$ (2H). The assignments of the three NH protons to the four nitrogen atoms, along the lines of structural formula **8**—and therefore inverse in

comparison to the 19-formyl isocorrole[7,9]—were deduced from the ^{13}C resonances of rings A and D, which display low-field shifts typical of pyrrolenine units.

The UV/Vis spectrum of **8** is, like that of the octaethylcorrole, similar to those observed for the porphyrins (Figure 1, Table 2). It displays a Sôret band at $\lambda(\varepsilon) = 384$ nm (104900),

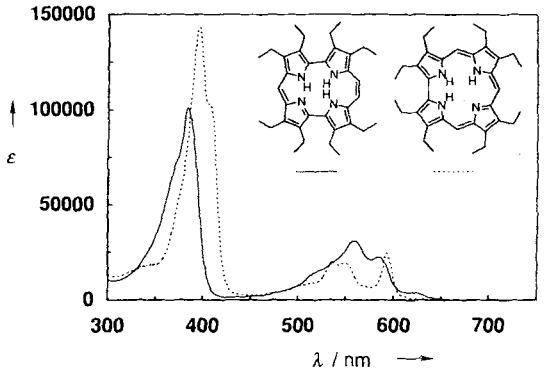

Figure 1. UV/Vis spectra of octaethylisocorrole (**8**) and octaethylcorrole (both in CH_2Cl_2).

Table 2. Selected physical data for the compounds **6**, **8**, **10**, and **11**[a].

[a] ^1H NMR 300 MHz, ^{13}C NMR 75.5 MHz; IR: CsI; UV/Vis: CH_2Cl_2.

which, compared with that of the analogous corrole [396 nm (146000)], is slightly hypsochromically shifted, and also a series of Q bands at 520–620 nm. An X-ray crystallographic analysis[14] of **8** (Figure 2) indicates that the ring framework, as a consequence of the steric interactions of the imino-hydrogen atoms, deviates slightly more from planarity (maximum distance of the C and N atoms from the mean plane of the ring structure: ±0.38 Å) than that in 8,12-diethyl-2,3,7,13,17,18-hexamethylcorrole.[15] While the pyrrole rings

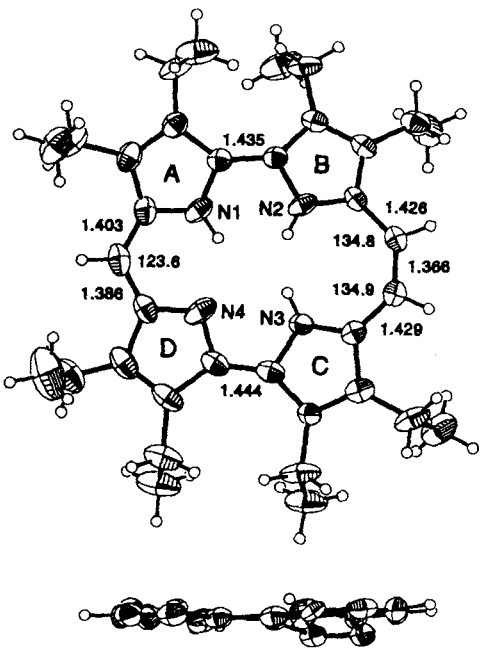

Figure 2. Structure of **8** in the crystal (top: plan view; bottom: side view, ethyl groups omitted for clarity). Vibrational ellipsoids (40% probability) and selected bond lengths [Å] and angles [°] (standard deviation ca. 0.008 Å and 0.5°, respectively). Selected distances [Å]: N1···N2 2.566, N1···N4 2.544, N2···N3 2.998, N3···N4 2.63.

A, C, and D, of which the rings A and D belong to a pyrromethene unit, are tilted from the mean plane by only 5–9°, ring B has a tilt angle of 18°. Interestingly, the imino-hydrogen atoms in **8** are not distributed, due to disorder, over the four nitrogen atoms, as is the case in the octaalkylcorroles mentioned earlier, but are localized on N1, N2, and N3, according to the molecular structure shown.

Isocorrole **2** has a coordination site, which—in a planar arrangement—is very similar to that of the parent compound **1**. In accordance with this, octaethylisocorrole (**8**) is capable of forming stable complexes with most of the metal ions that are known to give corrole complexes.[3] As is shown, particularly by the isolation of Co^{III}, Cu^{III}, Fe^{IV}, and Mn^{IV} isocorrolates[16,17] (these are still being investigated in part), **8** is a ligand that supplements the porphyrins, porphyrin isomers, and corroles as complex-forming tetrapyrrolic macrocyles.

Experimental Section

6: Anhydrous dimethylformamide (2.4 mL, 30 mmol) and freshly distilled phosphoryl trichloride (3.0 mL, 5.01 g, 33 mmol) in dichloromethane (15 mL) were added dropwise to a solution of tetrapyrrole **5** (1.5 g, 3 mmol) in dichloromethane (75 mL) at 0 °C, which caused the initially violet solution to gradually turn blue. This solution was stirred for a further 2 h, after which time the reaction

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3623-2614 $ 17.50+.50/0 *Angew. Chem. Int. Ed. Engl.* **1997**, *36*, No. 23

mixture was carefully poured onto saturated potassium carbonate solution (300 mL)(with ice cooling), and worked-up conventionally. Subsequent chromatography of the product on aluminum oxide (activity grade III) (column: 25 × 3.5 cm) with dichloromethane/ethyl acetate (1/1) delivered a magenta major fraction, which contained the dialdehyde **6**. This precipitated from toluene as a green microcrystalline powder with a metallic luster; m.p. 130–132 °C; yield 1.33 g (80 %).

8: Zinc (7.8 g, 120 mmol) and copper(I) chloride (1.2 g, 12 mmol) were added to tetrahydrofuran (160 mL). This mixture was then treated with titanium tetrachloride (6.6 mL, 60 mmol) and heated to reflux for 2 h. Over the course of 20 min a solution of dialdehyde **6** (1.1 g, 2 mmol) in tetrahydrofuran (150 mL) was added dropwise and the reaction mixture was stirred at reflux for a further 5 min. Finally, the reaction mixture was hydrolyzed by pouring it into a 10 % aqueous ammonia solution (150 mL) at 0 °C, the product extracted into ether (multiple extraction of the residue with ether was necessary) and the washed ether solution was treated with 5 % iron(III) chloride solution. After chromatography on neutral alumina (activity grade III) (column: 25 × 3 cm) with *n*-hexane/dichloromethane (2/1), **8** was obtained as an intense red-orange fluorescent main fraction. Crystallization from *n*-hexane/dichloromethane gave **8** as violet, rectangular crystals with a metallic luster; m.p. 182–183 °C; yield 240 mg (23 %).

10: A solution of **9** (552 mg, 1 mmol) in methanol (100 mL) was treated with copper(II) acetate hydrate (1.0 g, 5 mmol) and the reaction mixture was stirred at room temperature for 1 h. After removal of the solvent in vacuum, the residue was purified by chromatography on silica gel (20 × 4 cm) with dichloromethane/*n*-hexane (2/1), from which minor (violet and brown) fractions were obtained. Change of the eluent to dichloromethane yielded the major fraction (brown), which contained the copper complex **10**. Crystallization from methanol/dichloromethane (6/1) delivered **10** as black needles; m.p. 174–176 °C; yield 318 mg (52 %).

11: Copper complex **10** (611 mg, 1 mmol) was treated, with stirring, with concentrated sulfuric acid (50 mL) at room temperature. Subsequently, the reaction mixture was poured onto ice (200 g), the product was extracted into dichloromethane, and the organic phase was washed with dilute ammonia solution. The residue formed after the usual work-up was purified by chromatography on silica gel (20 × 4 cm) with dichloromethane/*n*-hexane (2/1). The first fraction to elute was the unchanged copper complex. After changing the eluent to dichloromethane a second fraction was obtained, which was blue and contained **11**. Crystallization from *n*-hexane/dichloromethane (5/1) yielded **11** as red needles; m.p. 209–210 °C; yield 231 mg (42 %).

The [18]porphyrin-(3.0.1.0), designated as isoporphycene, was recently synthesized, as the octaethyl compound, via the corresponding nickel complex. While Ni^{II}-octaethylporphycenate displays the (*Z*) configuration, the free octaethylisoporphycene ligand has an (*E*) configuration both in solution and in the crystal: E. Vogel, M. Bröring, R. Demuth, C. Erben, P. Scholz, unpublished results.

[8] Calculations of the corrole isomers were carried out independently of ourselves by A. Ghosh and K. Jynge. The method used by these authors (LDF) produced relative stabilities for the isomers that correspond qualitatively with those reported here. We thank Prof. A. Ghosh, University of Tromsø (Norway) for sending us his manuscript.

[13] The copper complex **10**, which, in agreement with the presence of Cu^{III}, is diamagnetic, has a reasonably well resolved ^1H NMR spectrum at −57 °C. At higher temperatures, line broadening occurs—an indication of developing paramagnetism. Simultaneously the signals for the peripheral vinylic protons shift to higher field, and that of the protons of a CH_2 group shift to lower field (Table 2). Such a temperature dependence of the ^1H NMR spectrum may be due to a rapid equilibrium (on the NMR time scale) between molecules in the diamagnetic Cu^{III} ground state and others in a higher, excited, triplet (paramagnetic) state [4c]. A crystal structure analysis of **10** shows that the aldehyde group is disordered, but it can be definitely stated that the copper isocorrolate ring system is almost planar.

[14] Crystal structure data for **8**: $C_{35}H_{46}N_4 \cdot 0.5\ C_6H_6$, $M_r = 561.81$; crystals from benzene; crystal dimensions 0.35 × 0.30 × 0.30 mm; triclinic, space group $P\bar{1}$, $a = 12.117(3)$, $b = 12.961(3)$, $c = 13.373(3)$ Å, $\alpha = 64.71(2)$, $\beta = 63.02(2)$, $\gamma = 66.79(2)°$, $V = 1525.0(7)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.138$ g cm^{-3}; $F(000) = 610$; $\mu_{Mo} = 0.67$ cm^{-1}; 5712 measured reflections; 4380 observed reflections. ($F_o^2 > 2\sigma F_o^2$); $\theta_{max} = 27°$; $R = 0.044$, $R_w = 0.052$. Enraf-Nonius CAD4 diffractometer (room temperature, $Mo_{K\alpha}$ radiation $\lambda = 0.71069$ Å). The structure was solved by using direct methods and subsequently refined (heavy atoms with anisotropic, H atoms with isotropic temperature factors). The calculations were carried out on a pdp-11/23-plus microcalculator using MolEN (Enraf-Nonius). The crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100426. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union road, Cambridge, CB2 1EZ, UK (fax: Int code + (1223)336-033; e-mail deposit@chemcrys.cam.ac.uk).

[17] The properties of the mono- and dinuclear Fe^{IV} isocorrolates correspond generally to those of the related Fe^{IV} corrolate pendants [4a]. However, due to disordered crystals more precise X-ray crystallographic data on these complexes are not available presently.

Twofold C–C Single Bond Activation and Cleavage in the Reaction of Octatetraynes with Titanocene and Zirconocene Complexes**

Paul-Michael Pellny, Normen Peulecke, Vladimir V. Burlakov, Annegret Tillack, Wolfgang Baumann, Anke Spannenberg, Rhett Kempe, and Uwe Rosenthal*

Dedicated to Professor Jörg Lorberth on the occasion of his 60th birthday

The synthesis of novel carbon modifications is an intensely researched area in modern acetylene chemistry.[1] Organometallic derivatives of carbon-rich polymers with conjugated π systems[2] have gained particular significance since they have facilitated the synthesis of various carbon networks, which form the basis for high-grade materials in the field of material science. We were interested in the interaction of

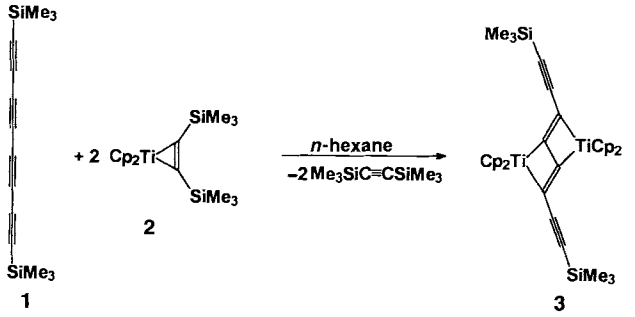
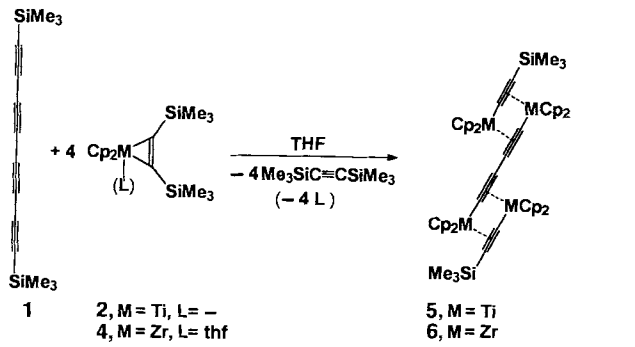
"carbyne" $(-C\equiv C-)_n$, the simplest carbon modification, with selected transition metal complexes. Since these polyalkyne carbon rods are difficult to investigate,[3] we turned our attention to the "smaller homologues", namely the butadiynes $R(-C\equiv C-)_2R$[4] and the octatetraynes $R(-C\equiv C-)_4R$, and herein report on the results of reactions of the latter with titanocene and zirconocene sources. The products obtained are highly dependent on the substituents R attached to the tetrayne and on the stoichiometry of the reaction.

The reaction of bis(trimethylsilyl)octatetrayne (**1**) with two equivalents of the $[Cp_2Ti]$ complex **2**, which readily releases bis(trimethylsilyl)acetylene and thus is a superb preparative source for the unstable titanocene "$[Cp_2Ti]$",[4] gave the dark



green complex **3** by complexation at the two middle triple bonds of **1**. According to its spectroscopic data, this complex is identical to the compound that Teuben and co-workers obtained previously from the reaction of $[Cp_2TiCl]_2$ with $Li-C\equiv C-C\equiv C-SiMe_3$, and which they then investigated with regard to reactions at the free triple bonds.[5]

Treatment of **1** with four equivalents of **2**, or reaction of **3** with two further equivalents of **2** led, under cleavage of the two outer C–C single bonds, to the dark red complex **5** in



good yields (84%). Complex **5** is soluble in THF, slightly less soluble in benzene, and only sparingly soluble in *n*-hexane. The IR spectrum of **5** shows two bands in the expected range for complexed C–C triple bonds at 1816 and 1784 cm^{-1}. The ^1H [$\delta = 5.34$ (s, 40H; Cp), 0.31 (s, 18H; $SiMe_3$)] and ^{13}C NMR spectra [$\delta = 132.7$, 140.4, 208.5, 236.6 (C≡C)] confirm a symmetrical coordination. The crystal structure analysis[6] of **5** (Figure 1) provided clear evidence for the twofold bond cleavage at the outer C–C single bonds of **1**.

The golden yellow zirconium compound **6** was synthesized from **1** and four equivalents of the zirconocene source **4**;[4] compound **6** is analogous to **5** and shows very similar spectroscopic and structural properties.[7]

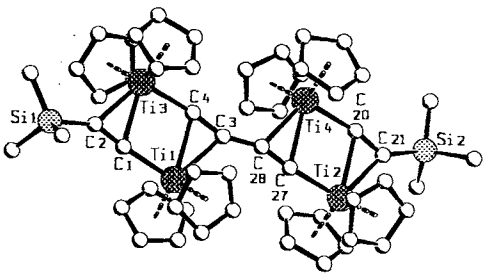


Figure 1. Molecular structure of **5** in the crystal (the structure of **6** is analogous).

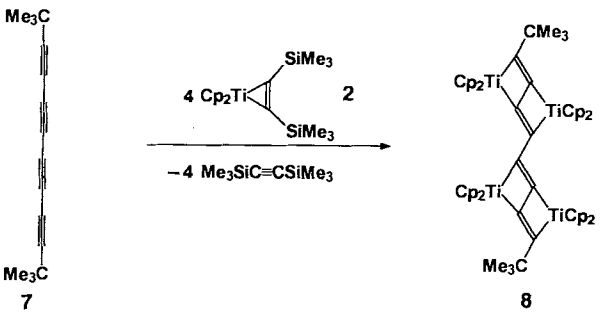
The three C–C distances in **1** that correspond to single bonds are 1.39(1), 1.33(1), and 1.38(1) Å;[8a] in **5** two of these are significantly longer: C1···C4 3.02(7) and C20···C27 3.05(7) Å; this confirms the lack of a bond between these C atoms in **5**. The C–C distances in the inner C_4 chain [**5**: C4–C3 1.26(2), C3–C28 1.41(2), C28–C27 1.29(2); **6**: C4–C3 1.30(2), C3–C28 1.43(2), C28–C27 1.25(2) Å] and the short metal–C distances strongly indicate a diacetylene structure $M-C\equiv C-C\equiv C-M$, are less supportive of a cumulene structure $M=C=C=C=C=M$,[9] and virtually rule out the bis(carbyne) form $M\equiv C-C\equiv C-C\equiv M$.[10] Nevertheless, for example, the Ti–C σ bonds in **5** [Ti3–C4 2.06(2), Ti2–C27 2.06(2), Ti1–C1 2.09(2), Ti4–C20 2.07(2) Å] are significantly shorter than usual Ti–C single bonds, which lie within the range of 2.27 to 2.16 Å. The four associated Ti-C-C angles are nearly 180°; thus, a description of the Ti–C bonds as double bonds seems justified. All distances between Ti centers and the C atoms of the triple bonds to which they coordinate are almost identical. The description of the Zr compound **6** is analogous. The Zr–C σ bonds in **6** [Zr3–C4 2.18(2), Zr2–C27 2.17(2), Zr1–C1 2.20(2), Zr4–C20 2.17(2) Å] are all about 0.1 Å longer than the corresponding Ti–C bonds in **5**.

When the bis(*tert*-butyl)octatetrayne **7** was used instead of **1**, the subsequent reaction with four equivalents of the titanium complex **2** gave compound **8**; that is, in this case there are no C–C bond activations and bond cleavages, but an almost symmetrical complexation of a total of four titanocene cores to the octatetrayne occurs. Compound **8** is soluble in



THF but only slightly soluble in *n*-hexane. The IR spectrum shows no band in the range expected for a complexed C–C triple bond; that is between 1900 and 1600 cm^{-1}. The ^1H [$\delta =$ 5.61 (s, 40H; Cp), 1.40 (s, 18H; CMe_3)] and ^{13}C NMR spectra [$\delta = 133.9$, 135.3, 210.2, 230.7 (C≡C)] confirm a symmetrical coordination of the octatetrayne.

Crystallization of **8** revealed that it occurs in two modifications. In addition to needlelike crystals (triclinic, space group $P\bar{1}$), rhombs (monoclinic, space group $C2/c$) were

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3623-2616 $ 17.50+.50/0

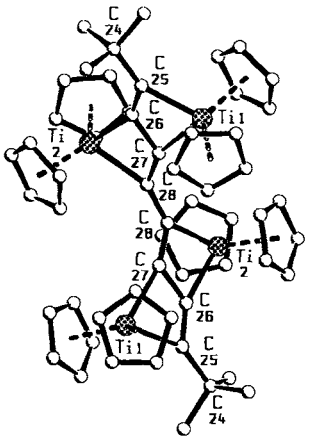


Figure 2. Molecular structure of **8** in the crystal.

observed. The crystal structure analysis[11] of the monoclinic modification of **8** (Figure 2) showed an arrangement with two intact μ-(1,3-η:2,4-η)-*trans*,-*trans*-tetradehydrobutadiene units between two titanocene cores that are both almost planar and that are connected by a C–C single bond [C28–C28 1.424(6) Å]. The angle between the two planes is about 68.6°. The ligand can be described as follows: two "zigzag butadienes" form the substituted and intact "zigzag octatetraene" with alternating C–C single and double bonds [for the two tetradehydrobutadiene units: C24–C25 1.515(5), C25–C26 1.313(5), C26–C27 1.503(5), C27–C28 1.315(4) Å]. In addition the angles correspond to those of conjugated alkenes [C24-C25-C26 130.6(4), C25-C26-C27 128.6(3), C26-C27-C28 128.2(3), C27-C28-C28 134.8(3)°]. It is remarkable that the C atoms in the middle and at the ends of the C chain show wider angles.

Investigations into the application of the reactivity pattern to other compounds such as substituted bis(σ-butadiynyl) metal complexes as well as tris- and hexakis(butadiynyl)benzene are currently in progress.

Experimental Section

All research was carried out under the exclusion of oxygen and moisture. Compound **1** was prepared according to method given in reference [8b], **7** according to that in reference [12]. The ^{1}H and ^{13}C NMR spectra of **3**, **5**, and **8** were recorded in [D$_8$]THF and those of **6** in [D$_6$]benzene on a Bruker-ARX-400 spectrometer at $T = 297$ K.

3: **1** (55 mg, 0.23 mmol) was added to a solution of **2** (161 mg, 0.46 mmol) in *n*-hexane (10 mL) at −40°C. The solution turned green and was left at −30°C. After 12 h the resulting yellow-brown solution gave compound **3** (120 mg, 87%), whose data correspond closely with those given in reference [5]: m.p. >250°C; C,H analysis for $C_{34}H_{38}Si_2Ti_2$ (598.62): calcd.: C 68.22, H 6.40; found: C 67.65, H 6.50; ^{1}H NMR: $\delta = 0.28$ (s, 18H; SiMe$_3$), 5.53 (s, 20H; Cp); ^{13}C NMR: $\delta = 108.2$ (Cp), 110.1, 113.8 (CSi), 146.0, 198.6 (C≡C); IR (Nujol): $\tilde{\nu} = 2077$ cm^{-1} (non-complexed C≡C); MS (70 eV): *m/z* 227 ([**1**−Me]$^+$), 178 ([Cp$_2$Ti]$^+$).

5: **1** (60 mg, 0.25 mmol) was added to a solution of **2** (345 mg, 0.99 mmol) in THF (20 mL). The mixture immediately turned yellow-brown, then green, and after stirring for 24 h at 40°C was red-brown. After all volatile components had been removed under vacuum, the residue was taken up in THF (5 mL) and layered with *n*-hexane (10 mL). After a few days at 0°C dark red needles precipitated, which were washed with cold *n*-hexane and dried under vacuum. Yield: 200 mg (85%). M.p. >250 C; C,H analysis for $C_{54}H_{58}Si_2Ti_4$ (954.75): calcd.: C 67.9, H 6.12; found: C 66.65, H 6.15; ^{1}H NMR: $\delta = 0.31$ (s, 18H, SiMe$_3$), 5.34 (s, 40H; Cp); ^{13}C NMR: $\delta = 1.8$ (SiMe$_3$), 104.6 (Cp), 132.7, 140.4, 208.5, 236.6 (C≡C); IR (Nujol): $\tilde{\nu} = 1816$, 1784 (coordinated C≡C), 1242 cm^{-1} (δ(SiCH$_3$)); MS (70 eV): *m/z* 275 ([Cp$_2$Ti−C$_2$SiMe$_3$]$^+$), 178 ([Cp$_2$Ti]$^+$).

6: Compound **6** was prepared analogously to **5** from **4** (461 mg, 0.99 mmol) and **1** (60 mg, 0.25 mmol) in THF. Golden yellow crystals, yield: 220 mg (79%); m.p. >250°C; C,H analysis for $C_{54}H_{58}Si_2Zr_4$ (1128.11): calcd.: C 57.49, H 5.18; found: C 57.51, H 5.28; ^{1}H NMR: $\delta = 0.44$ (s, 18H; SiMe$_3$), 5.42, 5.50 (s, each 20H; Cp); ^{13}C NMR: $\delta = 1.8$ (SiMe$_3$), 102.9, 103.6 (Cp), 143.6, 151.0, 216.8, 240.1 (C≡C); IR (Nujol): $\tilde{\nu} = 1797$, 1731 (coordinated C≡C), 1242 cm^{-1} (δ(SiCH$_3$)); MS (70 eV): *m/z* 318 ([Cp$_2$Zr−C$_2$SiMe$_3$]$^+$), 221 ([Cp$_2$Zr]$^+$).

8: A solution of **2** (697 mg, 2.00 mmol) in THF (10 mL) was allowed to react at room temperature with a solution of **7** (107 mg, 0.51 mmol) in THF (10 mL). The resulting mixture was left for a few days at room temperature, and then concentrated to 5 mL and layered with *n*-hexane (10 mL). After three days at room temperature dark green needles precipitated, which were washed with *n*-hexane and dried under vacuum. Yield: 328 mg (71%). M.p. >250°C; C,H analysis for $C_{56}H_{58}Ti_4$ (922.60): calcd.: C 72.90, H 6.34; found: C 72.13, H 6.42; ^{1}H NMR: $\delta = 1.40$ (s, 18H; CMe$_3$), 5.61 (s, 40H; Cp); ^{13}C NMR: $\delta = 33.4$ (*C*Me$_3$), 43.0 (*C*Me$_3$), 107.4 (Cp), 133.9, 135.3, 210.2, 230.7 (C≡C); MS (70 eV): *m/z* 259 ([Cp$_2$Ti−C$_2$CMe$_3$]$^+$), 178 ([Cp$_2$Ti]$^+$).

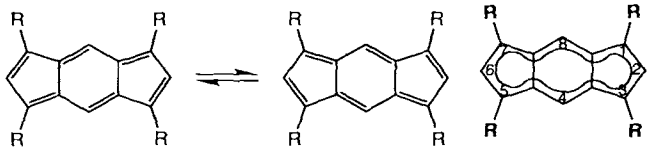
Synthetic, Structural, and Bonding Studies of Indacene Dianions**

Douglas R. Cary, Jennifer C. Green, and Dermot O'Hare*

The subject of aromaticity has been of fundamental importance to organic chemists since the early days of chemistry.[1] While numerous benzenoid compounds are known and have been studied over the years, the search for new highly conjugated molecules continues. Inorganic chemists have also been attracted to extended conjugated systems because of the potential for these ligands to promote metal–metal interaction, giving rise to materials with useful electronic properties.[2,3] It is for these reasons that the synthesis of 1,3,5,7-tetra-*tert*-butyl-*s*-indacene(**2**) by Hafner et al. has received a great deal of attention.[4] As an unusual example



1A R = H
2A R = *t*Bu

1B R = H
2B R = *t*Bu

of a stable nonalternant antiaromatic compound,[5] **2** has been carefully studied by spectroscopy and most of the data presented suggest that it can be regarded as a delocalized structure (**2B**).[4,6–11] Several theoreticians have performed calculations on *s*-indacene (**1**) and most suggest the ground-state structure consists of two interconverting isomers **1A** with C_{2h} symmetry.[8,10,12,13] More recently, some higher level ab initio and density functional theory (DFT) calculations have indicated **1B** as the favored structure.[14,15] Various substituent effects have been examined for *s*-indacene and most results agree that the interconversion barrier is quite low in the case of 1,3,5,7-*tetra*-alkyl-*s*-indacenes (≤ 8 kJ mol^{-1}); *tert*-butyl substituents give rise to structures closer to the experimentally observed D_{2h} structure than those obtained with methyl substituents.

In the course of our investigations of bimetallic transition metal complexes with indacene ligands, which are expected to facilitate interaction between metal centers,[16–18] we have been surprised by the difficulty in preparing dianions of heavily alkylated *s*-indacenes.[17,18] Prior routes to transition metal indacene complexes have generally involved the double deprotonation of dihydroindacenes and subsequent salt metathesis with metal halide sources.[19–22] Syntheses with **2** differ in that a neutral ligand is available, which can then be treated with low-valent metal sources to give bimetallic species. We have been able to prepare bis(cyclopentadienylcobalt) compounds in this manner by using $[CpCo(C_2H_4)_2]$ as the metal source.[23] Based on Jonas's work on preparing [CpFe(diene)]$^-$-species, we have attempted to extend this chemistry to the iron analogues by the reduction of ferrocene with lithium in the presence of **2**.[24] Surprisingly, this reaction did not give an iron-containing product but rather dark orange crystals of $[(Li^+)_2(\mathbf{2}^{2-})(thf)_4]$. In the same manner, reduction of **2** with potassium in the presence of [18]crown-6 gives red crystals of $[(K^+)_2(\mathbf{2}^{2-})([18]crown\text{-}6)_2]$.

The isolation of these indacene dianions is unusual in that the parent compound $[(Li^+)_2(\mathbf{1}^{2-})]$ has always been used in situ, presumably due to its insolubility and sensitivity to air and moisture. Furthermore, previous work has indicated only the spectroscopic observation of the radical anion obtained from the in situ reduction of **2** with K, without evidence for a second reduction.[11] Reduction with $LiAlH_4$ under standard organic reaction conditions results in the formation of dihydro-**2**.[4] Using inert atmosphere techniques has enabled the isolation and study of these extremely sensitive species, which can be classified as the aromatic analogues of **2** (14 π electrons).

The spectroscopic and structural properties of $[(Li^+)_2(\mathbf{2}^{2-})(thf)_4]$ and $[(K^+)_2(\mathbf{2}^{2-})([18]crown\text{-}6)_2]$ are most easily examined in comparision to **2**. In each case, the NMR data indicate a delocalized structure on the NMR timescale. The ^{1}H NMR chemical shifts for the methine protons of $[(Li^+)_2(\mathbf{2}^{2-})(thf)_4]$ are $\delta = 6.77$ and 8.28 for the *C*-2,6 and *C*-4,8 positions, respectively. Thus these protons are significantly deshielded in comparison to the corresponding shifts in **2** ($\delta =$ 5.29 and 6.90, respectively), presumably due to an increase in the ring current. This effect is also observed for the *tert*-butyl groups, but to a lesser extent ($\delta = 1.90$ for the Li complex vs. 1.18 for **2**). As expected, the $^{13}C\{^1H\}$ NMR signals for the reduced species are significantly shielded ($\delta = 103.7$, 108.4, 111.7, 122.8) with respect to those of the neutral compound ($\delta = 124.9$, 129.1, 132.0, 164.3) due to increased electron density. The NMR data for $[(K^+)_2(\mathbf{2}^{2-})([18]crown\text{-}6)_2]$ are less informative due to its poor solubility, even in $[D_8]$THF.

The crystal structures of $[(Li^+)_2(\mathbf{2}^{2-})(OEt_2)_2(thf)_2]$ and $[(K^+)_2(\mathbf{2}^{2-})([18]crown\text{-}6)_2]$ are shown in Figure 1 These are the first structural reports on the indacene dianion. Recrystallization of $[(Li^+)_2(\mathbf{2}^{2-})(thf)_4]$ from diethyl ether resulted in the formation of $[(Li^+)_2(\mathbf{2}^{2-})(OEt_2)_2(thf)_2]$, which consists of discrete molecules of $[(Li^+)_2(\mathbf{2}^{2-})(OEt_2)_4]$ and $[(Li^+)_2(\mathbf{2}^{2-})(thf)_4]$. The most important features of each molecule are the geometric parameters for the indacendiide fragment, which are very nearly the same in each case; therefore, the molecular structure of $[(Li^+)_2(\mathbf{2}^{2-})(OEt_2)_4]$ will be used as an example for the discussion. As with **2**, each $\mathbf{2}^{2-}$ fragment is planar and lies on a crystallographic inversion center. In addition, the alkali metals are bonded fairly symmetrically to all five carbon atoms of the terminal indacene rings ($Li-C_{av} = 2.34$ Å for the diethyl ether adduct). This is in contrast to nearly all previous transition metal *s*-indacene structures, in which the metal has slipped off the centroid of the five-membered ring.[16,19,20,25] This is most likely the result of the metal–ligand bonding being predominantly electrostatic in nature, although previous structures of polycyclic hydrocarbon dianions have generally shown less symmetric coordination.[26–29] The observed *trans* arrangement is to be expected because of the electrostatic repulsions between lithium cations.

A comparison of the structural data for **2** and $\mathbf{2}^{2-}$ is given in Figure 2. Perhaps the most striking feature in this comparision is the similarity between the structures of the two fragments. The most signficant difference is in the C3–C5 distances (see, for example, Figure 1b), which are approximately 0.02 Å longer in the dianion. The remaining C–C distances are slightly lengthened in $\mathbf{2}^{2-}$, but to a lesser extent; the C-C-C angles are only slightly affected. These features are in sharp

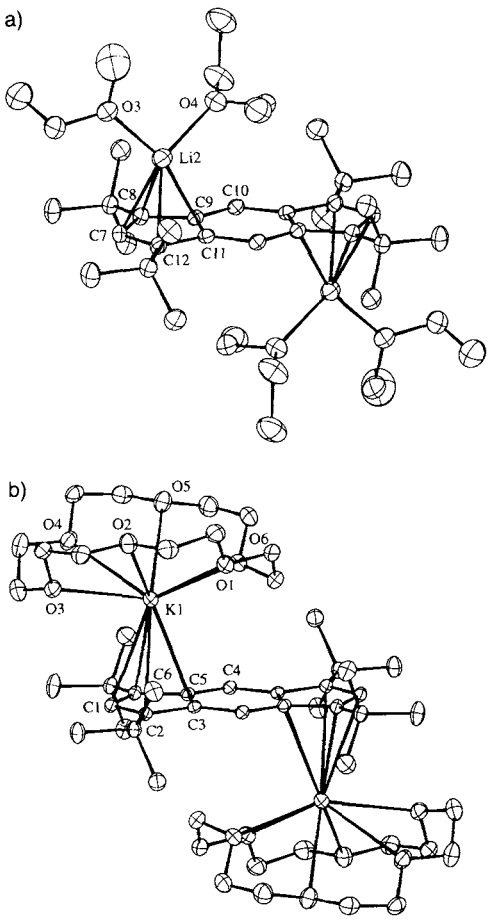

Figure 1. a) Crystal structure of $[(Li^+)_2(2^{2-})(OEt_2)_2(thf)_2]$. Selected interatomic distances [Å] and angles [°] for $[(Li^+)_2(2^{2-})(OEt_2)_4]$: Li2–O3 2.033(4), Li2–O4 2.057(4), Li2–C7 2.333(4), Li2–C8 2.337(4), Li2–C9 2.356(4), Li2–C11 2.352(4), Li2–C12 2.336(4); and for $[(Li^+)_2(2^{2-})(thf)_4]$ (not shown): Li1–O1 1.962(4), Li1–O2 1.979(4), Li1–C1 2.259(4), Li1–C2 2.269(4), Li1–C3 2.323(4), Li1–C5 2.338(4), Li1–C6 2.288(4), O1-Li1-O2 96.1(2). b) Molecular structure of $[(K^+)_2(2^{2-})([18]crown\text{-}6)_2]$. Selected interatomic distances [Å]: K1–O1 2.8836(9), K1–O2 3.1054(9), K1–O3 2.8937(9), K1–O4 3.0045(9), K1–O5 3.2372(9), K1–O6 2.7455(9), K1–C1 3.092(1), K1–C2 3.107(1), K1–C3 3.111(1), K1–C5 3.108(1), K1–C6 3.093(1).

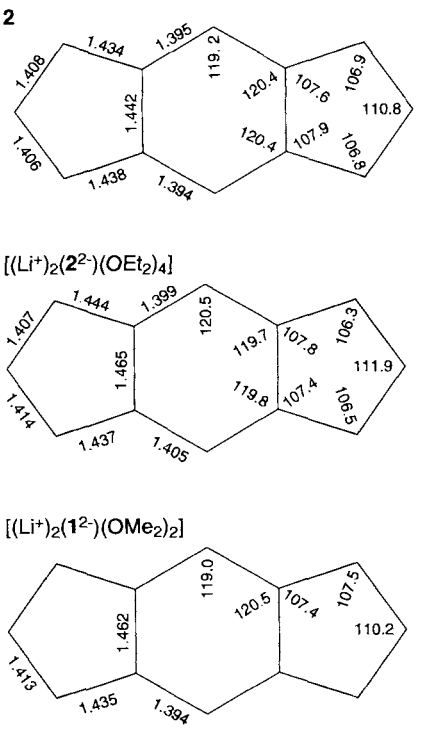

Figure 2. Selected structural data (bond lengths in Å and angles in °) for **2** (T = 100 K)[6], the indacendiide fragment of $[(Li^+)_2(2^{2-})(OEt_2)_4]$ (T = 150 K), and the calculated structure of $[(Li^+)_2(1^{2-})(OMe_2)_2]$ the estimated standard deviations for the last decimal place for bond lengths and angles of $[(Li^+)_2(2^{2-})(OEt_2)_4]$ are 3 and 2, respectively.

contrast to the transition metal structures solved in our laboratory thus far, which have invariably shown significant ring expansion (in terms of the size of the angles) as well as bending of the ligand in many cases.[16,23] The overall geometries are both essentially D_{2h}; the bond lengths are clearly not assignable to either single or double bonds. However, we cannot rule out the possibility of disorder effects.

In order to understand these surprising results, DFT calculations were carried out on $[(Li^+)_2(1^{2-})]$ and $[(Li^+)_2(1^{2-})(OMe_2)_2]$ using a generalized gradient approximation as implemented in the Amsterdam density functional code.[30] Initially, $[(Li^+)_2(1^{2-})]$ was constrained to have C_i symmetry, but the final geometry approximated C_{2h} and thus both $[(Li^+)_2(1^{2-})]$ and $[(Li^+)_2(1^{2-})(OMe_2)_2]$ were optimized with the constraint of C_{2h} symmetry. This is equivalent to D_{2h} symmetry for the 1^{2-} fragment of each molecule, indicating a delocalized ligand. Selected distances and angles obtained for $[(Li^+)_2(1^{2-})(OMe_2)_2]$ are included in Figure 2; they are in good agreement with the experimental data for 2^{2-}. Both model compounds give nearly the same geometries for the 1^{2-} fragment; the inclusion of ether groups primarily affects the metal–carbon distances (2.178 Å without OMe_2 vs. 2.305 Å with). Calculations on isolated 1^{2-} give bond lengths longer than for either molecular species. The frontier orbitals obtained are in agreement with previous extended Hückel, semiempirical, ab initio, and DFT calculations on *s*-indacene.[12,14,25] The HOMO contains π-electron density on C-1,3,4,5,7,8; the nodal planes pass through the bridgehead carbons as well as along the long axis through C-2 and C-6. The result is an almost nonbonding orbital with elongation in the direction of the short symmetry axis.

Experimental Section

$[(Li^+)_2(2^{2-})(thf)_4]$: Addition of THF (30 mL) to **2** (520 mg, 1.38 mmol) and small Li pieces (298 mg, 42.9 mmol) gave a orange solution and orange powder within 24 h. After the mixture had been stirred for 48 h, the solvent was removed under vacuum. *All of the orange solid was extracted from unconverted Li with toluene*, the mixture was concentrated, and cooled to −45 °C. Dark black-orange crystals were collected by filtration (271 mg, 29%). Satisfactory analytical data could not be obtained because of extreme air and moisture sensitivity. ^{1}H NMR (C_6D_6, 300 MHz): δ = 8.28 (s, 2H), 6.77 (s, 2H), 2.95 (m, 16H), 1.90 (s, 36H), 0.99 (s, 16H); $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6): δ = 122.8 (C-1,3,5,7 or C-3a,4a,7a,8a), 111.7 (C-2,6 or C-4,8), 108.4 (C-2,6 or C-4,8), 103.7 (C-3a,4a,7a,8a or C-1,3,5,7), 68.2 (THF), 33.4 (-C(CH_3)$_3$), 32.6 (-C(CH$_3$)$_3$), 25.3 (THF); IR (KBr/Nujol) [cm^{-1}]: $\tilde{\nu}$ = 1311 w, 1294 w, 1262 w, 1248 w, 1221 m, 1191 m, 1175 s, 1074 m, 1049 m, 1029 m, 999 m, 945 w, 917 w, 889 m, 825 s, 727 s.

$[(Li^+)_2(2^{2-})(OEt_2)_2(thf)_2]$: Dissolution of $[(Li^+)_2(2^{2-})(thf)_4]$ in diethyl ether, followed by crystallization from toluene yielded $[(Li^+)_2(2^{2-})(OEt_2)_2(thf)_2]$. ^{1}H NMR (300 MHz, C_6D_6): δ = 8.28 (s, 2H), 6.78 (s, 2H), 2.89 (m, 16H), 1.90 (s, 36H), 0.96 (m, 8H), 0.77 (t, 12H).

$[(K^+)_2(2^{2-})([18]crown\text{-}6)_2]$: Addition of THF (30 mL) to **2** (482 mg, 1.28 mmol), small K pieces (100 mg, 2.56 mmol), and [18]crown-6 (675 mg, 2.55 mmol) gave a dark red solution within 2 h. After the mixture had been stirred for 3 h, the solution was filtered and pentane was layered on top. Slow solvent diffusion resulted in the formation of dark red crystals (495 mg, 39%). Satisfactory analytical data could not be obtained because of extreme air and moisture sensitivity. ^{1}H NMR (300 Mhz, [D$_8$]THF): δ = 1.73 (s, 36H), 3.24 (s, 48H), 6.00 (s, 2H), 7.13 (s, 2H). IR (KBr/Nujol) [cm^{-1}]: $\tilde{\nu}$ = 1582 w, 1322 w, 1298 w, 1251 m, 1222 w, 1187 w, 1110 s, 960 s, 862 w, 831 m, 803 w, 723 m.

X-ray crystal structure analysis of $[(Li^+)_2(2^{2-})(OEt_2)_2(thf)_2]$: $C_{44}H_{76}Li_2O_4$, $P\bar{1}$, $a = 9.782(1)$, $b = 14.594(1)$, $c = 15.640(1)$ Å, $\alpha = 74.999(2)$, $\beta = 81.977(2)$, $\gamma = 83.417(2)°$, $V = 2128.34$ Å^3, $Z = 2$, $\rho_{calcd} = 1.07$ g cm^{-3}, $\mu = 0.060$ mm^{-1}, $T = 150$ K, crystal dimensions ca. $0.25 \times 0.50 \times 0.50$ mm^3, 90 frames, 26428 measured (8101 unique) reflections, $R = 0.0472$ and $R_w = 0.0475$ for 5823 reflections with $I > 6\sigma(I)$, maximum and minimum peak in final Fourier difference synthesis 0.58 and -0.42 e Å^{-3}. Unit weights were used in the refinements. The asymmetric unit consists of half of a molecule of $[(Li^+)_2(2^{2-})(OEt_2)_4]$ and half a molecule $[(Li^+)_2(2^{2-})(thf)_4]$, each located about an inversion center.

X-ray crystal structure analysis of $[(K^+)_2(2^{2-})([18]crown\text{-}6)_2]$: $C_{76}H_{88}K_2O_{12}$, $P2_1/n$, $a = 13.959(1)$, $b = 10.403(1)$, $c = 19.733(1)$ Å, $\beta = 107.376(1)°$, $V = 2740.31$ Å^3, $Z = 2$, $\rho_{calcd} = 1.19$ g cm^{-3}, $\mu = 0.22$ mm^{-1}, $T = 150$ K, crystal dimensions ca. $0.20 \times 0.25 \times 0.40$ mm^3, 90 frames, 29555 measured (6266 unique) reflections, $R = 0.0422$ and $R_w = 0.0464$ for 5403 reflections with $I > 3\sigma(I)$, maximum and minimum peak in final Fourier difference synthesis 0.36 and -0.23 e Å^{-3}. A weighting scheme based on an optimized three-coefficient Chebyshev polynomial was used in the refinements [31]. General crystallographic information: Data were collected on an Enraf-Nonius DIP 2000 image plate diffractometer using graphite-monochromated $Mo_{K\alpha}$ radiation (step of 2° between frames, $\theta_{max} = 26°$). Corrections were made for Lorentz and polarization effects [32]. The structures were solved by direct methods using SIR92 [33] and refined by using full-matrix least-squares. Hydrogen atoms were fixed in geometrically idealized positions and allowed to ride on their attached carbon atoms. Corrections for the effects of anomalous dispersion and isotropic extinction (through an overall extinction coefficient) [34] but not for absorption, were made in the final stages of refinement. All crystallographic calculations were performed by using the Oxford CRYSTALS system [35] running on a Silicon Graphics Indigo R4000 computer. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100693. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code + (1223) 336-033; e-mail: deposit@chemcrys.cam. ac.uk).

Highly Enantioselective Catalytic Conjugate Addition and Tandem Conjugate Addition–Aldol Reactions of Organozinc Reagents**

Ben L. Feringa,* Mauro Pineschi, Leggy A. Arnold, Rosalinde Imbos, and André H. M. de Vries

Dedicated to Professor D. Seebach on the occasion of his 60th birthday

Although efficient catalysts for a number of asymmetric carbon–carbon formations are known to date,[1] a highly enantioselective catalytic version of the conjugate addition of organometallic reagents to enones is lacking.[2] Recently chiral catalysts based on Cu^I, Ni^{II}, Zn^{II}, or Co^{II} complexes of a variety of ligands have shown enantioselectivities up to 90% in 1,4-additions of Grignard, organolithium, or dialkylzinc reagents.[3] The results so far have not revealed, however, the key elements for realization of complete stereocontrol but do reveal the rather complex nature of some of these chiral catalytic systems.[4] Previously we have demonstrated that copper complexes of chiral phosphorus amidites show relatively high *ee* values for the 1,4-adducts of R_2Zn reagents and acyclic as well as cyclic enones.[5]

In this communication both the first catalytic asymmetric 1,4-addition reactions of organometallic reagents with complete

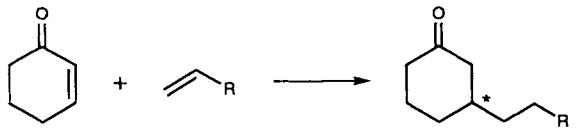
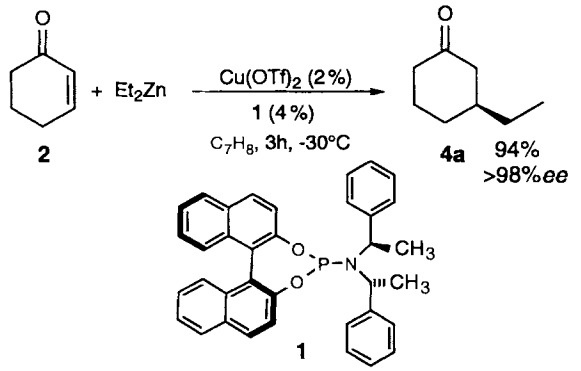
stereocontrol and highly enantioselective tandem conjugate addition-aldol reactions are reported. In our design of a catalytic asymmetric 1,4-addition the following aspects were considered: a) Can very efficient ligand-accelerated catalysis [6] be achieved? b) Is it possible to use an enone and an olefin [Eq. (a)] as starting material? c) Are functional groups tolerated?



(a)

The remarkable ligand effect of binaphthol-derived phosphorus amidites on the copper-catalyzed 1,4-addition of Et_2Zn to enones[5] was explored by a modular variation of the binaphthyl and amine moieties in these ligands. Much to our delight the incorporation of two chiral structural units, that is, the sterically demanding (*R,R*)-bis(1-phenylethyl)amine and unsubstituted (*S*)-2,2′-binaphthol (as present in C_2 symmetric ligand **1**), resulted in a *matched* combination[7] and a highly selective catalyst for the addition of Et_2Zn to cyclohexenone (Scheme 1). Thus the catalyst prepared from $Cu(OTf)_2$



Scheme 1. Enantioselective 1,4-addition of Et_2Zn to **2**, catalyzed by $Cu(OTf)_2$/**1**. Tf = trifluoromethane sulfonate.

(2 mol%) and **1** (4 mol%) provided (*S*)-**4a** in 94% yield and an *ee* value greater than 98%. Excellent yields and enantiomeric excesses ranging from 94 to greater than 98% are obtained for cyclohexenone and substituted cyclohexenones with a variety of zinc reagents (Table 1).[8] Having realized complete stereocontrol in the formation of a number of 3-substituted cyclohexanones **4** (Table 1, entries 1, 4–7),

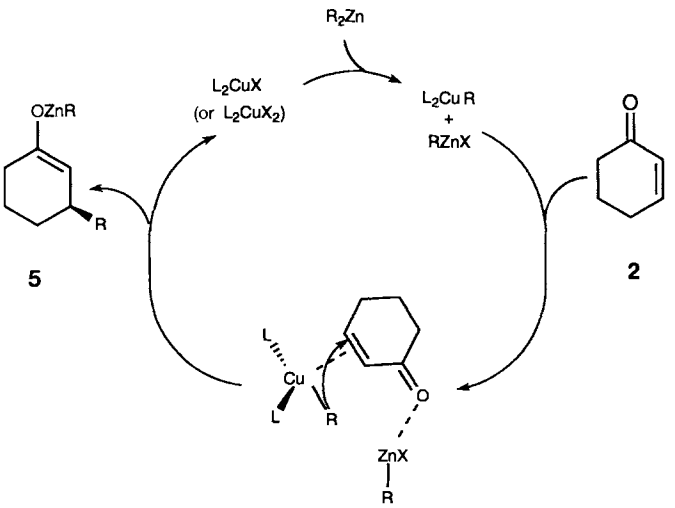
[a] Reaction conditions as in ref. [5]. [b] Yields of isolated products. [c] Determined by ^{13}C NMR spectroscopy after derivatization with 1,2-diphenyl ethylenediamine [5, 16]. [d] (*S*)-**4** could not be detected.

we examined catalytic 1,4-additions of diheptyl zinc (**3c**) and functionalized dialkylzinc reagents (**3e**–**3h**).[9] The R_2Zn reagents were prepared from the corresponding alkenes by hydroboration and subsequent zinc exchange according to Knochel[10,11] or with the corresponding Grignard reagent (Table 1, entry 9). Again excellent enantioselectivities were achieved (Table 1, entries 8–13). It is particular noteworthy that the new catalyst tolerates ester and acetal functionalities. So far the catalyst based on $Cu(OTf)_2$/ligand **1** does not show satisfactory enantioselectivities for five- and seven-membered cyclic enones (Table 1, entries 2,3). For these substrates further ligand tuning is required.

A possible pathway for the 1,4-addition could involve transfer of an alkyl fragment from R_2Zn to the copper complex,[11] followed by π-complexation of the resulting copper alkyl species to the double bond of the enone[12] and of the alkylzinc ion to the enone carbonyl (Scheme 2). Next alkyl transfer to the β-position of the enone generates alkylzinc enolate **5**, which upon protonation provides cyclohexanone **4**.



Scheme 2. Postulated catalytic cycle of the 1,4-addition.

It is anticipated that the zinc enolate **5**, resulting from the conjugate addition, might be trapped by an aldehyde in a subsequent aldol reaction.[13] The regio- and enantioselective catalytic three-component coupling was indeed achieved with

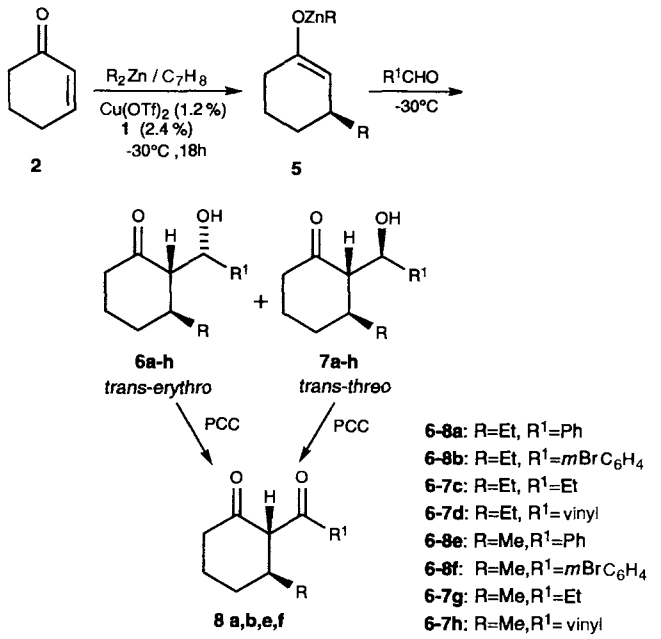
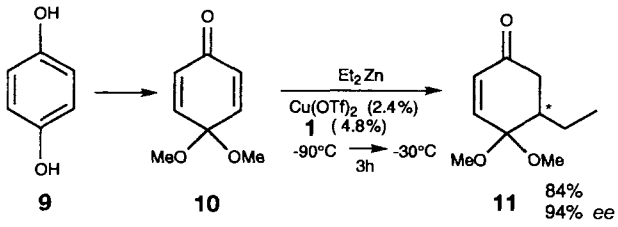
[a] 1.0 equiv of Lewis acid added. [b] Yields of isolated, pure aldols. [c] See *Experimental Section* for the determination of the *ee* values. [d] An unseparable mixture of aldols was obtained. [e] The relative configuration (*erythro*:*threo*) has not been established.

in situ generated enolate (Table 2). For example, when enolate **5**, formed from **2** and diethylzinc in the presence of $Cu(OTf)_2$ (1.2 mol%) and ligand **1** (2.4 mol%), was treated with benzaldehyde at −30°C for 10 min, an approximately 3:7 mixture of *trans,erythro*-**6a** and *trans,threo*-**7a** was obtained in 88% isolated yield (Table 2, No. 1). The aldol products were readily separated by flash chromatography (SiO_2, 30% ethyl acetate, 70% hexanes) and oxidized to a single isomer of diketone **8a** with 95% ee. The results shown in Table 2



indicate that other representative aldehydes undergo the tandem 1,4-addition–aldol reactions (in the presence or absence of Lewis acids) affording the corresponding *trans*-2,3-disubstituted cyclohexanones with enantioselectivities always exceeding 90%. In all cases small amounts of copper catalyst (1.2 mol%) lead to clean zinc enolate formation, fast and regioselective aldol reactions and *trans*-vicinal disubstituted cyclohexanones are exclusively obtained. The relative and absolute stereochemistry of (−)-*trans-erythro*-**6b** was established to be 2*S*,3*S*,1′*S* on the basis of single crystal X-ray analysis.[14] As far as we know this represents the first catalytic one-pot organozinc conjugate addition–enolate-trapping reaction that proceeds with high enantioselectivity.

The synthetic versatility of the new catalytic enantioselective C–C bond formation is further illustrated by the 1,4-addition of Et_2Zn to highly symmetrical dienone **10** readily obtained by oxidation of hydroquinone **9** (Scheme 3).[15] In



Scheme 3. Catalytic enantioselective 1,4-addition of Et_2Zn to the dienone **10**[15].

view of the potential to use various zinc reagents, the multifunctional nature of **11**, and the short, highly selective, and efficient route from hydroquinone, this new method may allow a versatile entry to a variety of optically active cyclohexenones.

Experimental Section

1: The procedure for related phosphorus amidites [5] was followed except that *n*BuLi/THF was used instead of Et_3N/toluene in the second step: chromatography (SiO_2, hexane:CH_2Cl_2 3:1), yield 40%, $[\alpha]_D = +456.0$ ($c = 0.79$, $CHCl_3$). ^1H NMR: $\delta = 7.98-8.08$ (m, 4H), 7.17–7.74 (m, 18H), 4.63 (q, $J = 7.2$ Hz, 2H), 1.85 (d, $J = 7.2$ Hz, 6H); ^{13}C NMR ($CDCl_3$): $\delta = 150.2$, 150.0, 149.6, 142.8, 132.8, 131.4, 130.5, 130.3, 129.4, 128.3, 128.1, 128.0, 127.9, 127.8, 127.2, 127.1, 126.7, 126.0, 124.7, 124.5, 122.4, 52.3, 51.1, 21.8; ^{31}P NMR: $\delta = 145.3$.

6b/7b,8b: Typical procedure for the conjugate addition–enolate-trapping reactions with **2**: A solution of $Cu(OTf)_2$ (0.0045 g, 0.012 mmol) and **1** (0.013 g, 0.024 mmol) in toluene (5.0 mL) was stirred for 1 h at room temperature under nitrogen. The colorless solution was cooled at −30°C and **2** (0.097 g, 1.0 mmol) and $ZnEt_2$ (1.0 mL of a 1.1 M solution in toluene) were added. After 18 h at −30°C *m*-bromobenzaldehyde (0.277 g, 1.5 mmol, freshly distilled) in toluene (1.0 mL) was added, and the reaction mixture was stirred for 10 min, quenched with saturated aqueous NH_4Cl (5.0 mL) and extracted with diethyl ether (2 × 30 mL). The combined organic layers were washed with brine (5.0 mL), dried over $Mg(SO_4)_2$, filtered, and evaporated to give a crude reaction product that was purified by flash chromatography (SiO_2, mixture of 20% ethyl acetate and 80% hexanes) to afford **6b** and **7b**. Yield of **6b**: 0.10 g, 32%; solid with m.p. 81.4–82.8°C; $[\alpha]_D = -50.0$ ($c = 1.52$, CH_2Cl_2); ^1H NMR (200 MHz, $CDCl_3$) δ 7.35–7.51 (m, 1H), 7.14–7.29 (m, 3H), 5.12 (t, $J = 6.1$ Hz, 1H), 3.31 (d, $J = 6.3$ Hz, OH), 2.63 (dd, $J = 6.8$ and 4.9 Hz, 1H), 2.31–2.40 (m, 2H), 1.18–1.96 (m, 7H), 0.76 (t, $J = 7.3$ Hz, 3H). ^{13}C NMR: $\delta = 214.8$, 145.0, 130.3, 129.7, 129.5, 124.9, 71.9, 60.5, 41.5, 39.3, 27.5, 26.0, 23.0, 10.4. HRMS calcd for $C_{15}H_{20}O_2$ 232.1463; found 232.1464. Yield of **7b**: 0.164 g, 53%; oil, $[\alpha]_D = -23.0$ ($c = 1.14$, CH_2Cl_2); ^1H NMR (200 MHz, $CDCl_3$): $\delta = 7.47$ (br.s, 1H), 7.14–7.37 (m, 3H), 4.83–4.89 (m, 1H), 2.61 (dd, $J = 7.8$ und 4.64 Hz, 1H), 1.20–2.38 (m, 9H), 0.88 (t, $J = 7.8$ Hz, 3H); ^{13}C NMR: $\delta = 215.0$, 145.9, 130.1, 129.7, 128.9, 124.3, 71.1, 60.9, 41.8, 41.7, 27.9, 25.5, 25.2, 10.2; HR-MS calcd for $C_{15}H_{20}O_2$ 232.1463; found 232.1467.

To a mixture of **6b/7b** (0.031 g, 0.1 mmol) in CH_2Cl_2 (2.0 mL) were added molecular sieves (4 Å, 0.10 g) and PCC (0.043 g, 0.2 mmol) at 0°C. After 2 h stirring at room temperature, the reaction mixture was diluted with diethyl ether, filtered over Celite, and evaporated to dryness. Purification by chromatography (SiO_2, mixture of 10% ethyl acetate and 90% hexanes) provided pure **8b** (0.025 g, 81%). The enantiomeric excess (93% *ee*) was determined by chiral HPLC [Regis (*R*, *R*)-Whelk-01 column, flow rate 0.5 mL min^{-1}, 5% *i*PrOH, 95% hexane, T_{ret} 34.5 min (3*S*, 2*R*), T_{ret} 37.2 min (3*R*, 2*S*)]. HPLC analysis of the recrystallized product (hexane) gave an *ee* value of > 98%. M.p. 82.5–83.2°C. $[\alpha]_D = -26.4$ ($c = 0.25$, CH_2Cl_2). ^1H NMR (200 MHz, $CDCl_3$): δ 7.98–8.00 (m, 1H), 7.65–7.77 (m, 2H), 7.29–7.37 (m, 1H), 4.09 (d, $J = 9.5$ Hz, 1H), 2.35–2.55 (m, 3H), 2.09–2.14 (m, 2H), 1.22–1.82 (m, 4H), 0.90 (t, $J = 7.3$ Hz, 3H). ^{13}C NMR: $\delta = 208.2$, 196.7, 138.9, 135.6, 130.9, 129.9, 126.4, 63.5, 41.9, 41.4, 27.7, 27.0, 23.9, 10.6. HRMS calcd for $C_{15}H_{17}O_2Br$ 308.0411; found 308.0418.

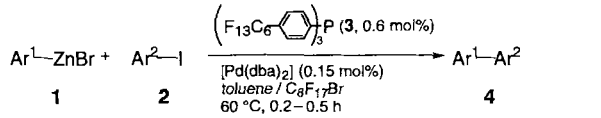
Palladium-Catalyzed Cross-Coupling of Organozinc Bromides with Aryl Iodides in Perfluorinated Solvents**

Bodo Betzemeier and Paul Knochel*

The formation of new carbon–carbon bonds by palladium-catalyzed cross-coupling has experienced a spectacular development over the past ten years.[1] Most of these reactions require relatively large quantities of a costly palladium catalyst (1–5 mol%)[2] and removal of traces of palladium compounds from the reaction products; this has hampered applications of this methodology to large-scale syntheses. Recently we showed that perfluorinated solvents are a convenient medium for transition metal catalyzed oxidations with a perfluorinated metal complex as the catalyst.[3,4] At high temperatures (ca. 60 °C) many organic solvents and reagents are soluble in perfluorinated solvents, but at room temperature organic compounds are insoluble; this leads to a two-phase system at room temperature. Fluorous biphasic catalysis, popularized by Horvárth,[5] has the advantage of easy phase separation and avoids pollution of the reaction product with the transition metal catalyst, which is only soluble in the fluorous phase and can be reused several times after simple phase separation. Here we report that palladium(0)-catalyzed cross-coupling[6] between arylzinc bromides (Ar^1ZnBr, **1**) and aryl iodides (Ar^2I, **2**) proceeds smoothly in the presence of the perfluorinated phosphane **3** (0.6 mol%) and bis(dibenzylideneacetone)palladium(0) ([Pd(dba)$_2$], 0.15 mol%)[7] with 1-bromoperfluorooctane ($C_8F_{17}Br$) and toluene as the solvent system to provide polyfunctional biphenyls of type **4** in high yields (Table 1).

Table 1. Palladium-catalyzed cross-coupling between arylzinc bromides **1** and aryl iodides **2** in a toluene/1-bromoperfluorooctane biphasic system.



1 **2** **4**

Entry	Ar^1	Ar^2	Product **4**	Yield [%] [a]
1	Ph	4-$AcOC_6H_4$	**4a**	93
2	4-ClC_6H_4	4-$NO_2C_6H_4$	**4b**	93
3	4-ClC_6H_4	3-$EtO_2CC_6H_4$	**4c**	97
4	3-$CF_3C_6H_4$	4-$MeOC_6H_4$	**4d**	89
5	3-$CF_3C_6H_4$	4-BrC_6H_4	**4e**	92
6	2-thienyl	3-$MeOC_6H_4$	**4f**	98
7	2-thienyl	4-$NO_2C_6H_4$	**4g**	87
8	4-TIPS-OC_6H_4 [b]	3-$EtO_2CC_6H_4$	**4h**	97
9	4-TIPS-OC_6H_4	4-BrC_6H_4	**4i**	99

[a] Yield of isolated product. [b] TIPS = iPr_3Si.

Arylzinc bromides **1** were prepared from the corresponding aryl bromides by bromine–lithium exchange followed by lithium–zinc transmetalation with zinc bromide.[8] 2-Thienyllithium used to prepare 2-thienylzinc bromide was obtained by deprotonation of thiophene with *n*-butyllithium.[9] The use of triarylphosphane **3**, which bears long perfluorinated chains, is essential for the success of the reaction. No activity of the palladium catalyst was observed with the previously known $(C_6F_{13}C_2H_4)_3P$.[5,10] The new phosphane **3** was prepared in three steps from 4-iodoaniline. Treatment of **3** with copper and $C_6F_{13}I$ in DMSO (120 °C, 2 h) gave the substituted aniline **5** in 86% yield.[11] Sandmeyer reaction of **5** [a) $NaNO_2$, HBr; b) CuBr] provided the corresponding aryl bromide **6** in 76% yield. Bromine–lithium exchange with *n*BuLi in THF followed by addition of PCl_3 afforded the phosphane–borane complex **7** in 37% yield after protection with borane (Scheme 1). After **7** was purified, the borane protecting group was removed with diethylamine.[12]

The free phosphane **3** was treated with [Pd(dba)$_2$] in $C_8F_{17}Br$ to afford an orange solution of [Pd{P(C_6H_4-C_6F_{13})$_3$}$_4$] (**8**). With this catalyst (0.15 mol%), the reaction between an arylzinc bromide and an aryl iodide is complete within 0.5 h at 60 °C. At this temperature, the reaction mixture is homogeneous and a two-phase system is again obtained upon cooling to room temperature. The cross-coupling product **4** is easily

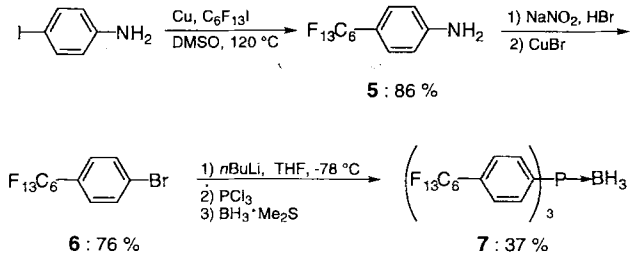
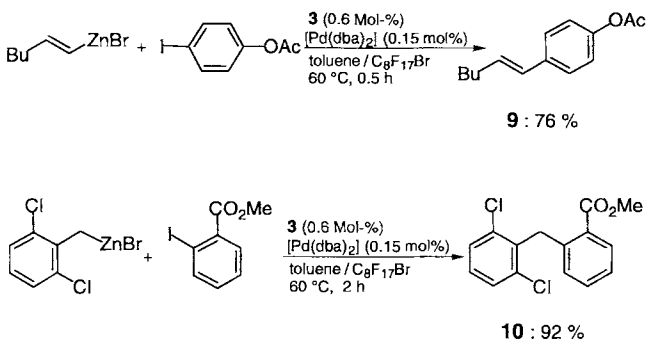


Scheme 1. Synthesis of perfluorinated phosphane **7**.

recovered from the toluene phase, whereas the palladium catalyst remains in the fluorous phase. The latter can be reused several times without significant changes in reaction yields. Thus, cross-coupling between phenylzinc bromide and 4-iodophenyl acetate in the presence of **8** (1.5 mol%) provides the biphenyl **4a** in 93% yield. Repeating the reaction four times with the same catalyst solution gave yields of 91, 90, 86, and 89%. Furthermore, **8** displays higher activity than $[Pd(PPh_3)_4]$, which may be due to the presence of the fluorinated carbon chain. It removes electron density from the phenyl ring to lead to an electron-deficient phosphane, and favors reductive elimination in these cross-couplings. The high activity of **8** allows the use of only 0.15 mol% of the catalyst under standard conditions. Upon further reducing the catalyst quantity to 0.07 mol%, a decrease in yield was observed (**4a** was obtained in only 76% yield, as opposed to 93%; Table 1, entry 1). Interestingly, these cross-coupling reactions tolerate several functional groups such as Cl, NO_2, CO_2R, CF_3, and iPr_3SiO. Furthermore, in the case of 4-bromoiodobenzene, only substitution of the iodide atom is observed; the C–Br bond is unaffected (entries 5 and 9). Cross-coupling can also be extended to alkenylzinc bromides[8] and benzylzinc bromides[13] to provide the styrene derivative **9** (76%) and diarylmethane **10** (92%), respectively (Scheme 2).



Scheme 2. Cross-coupling with an alkenyl- and a benzylzinc bromide.

We have prepared a new triarylphosphane **3** bearing perfluorinated substituents which allows efficient palladium-catalyzed cross-coupling between organozinc bromides and aryl iodides in biphasic catalysis. The simple work-up conditions and the possibility of reusing the catalyst for several reactions have been demonstrated. The performance of other transition metal catalyzed reactions of interest for organic synthesis with the new fluorous phosphane **3** is currently underway.

Experimental Section

Typical procedure: 4-acetoxybiphenyl (**4a**). A 10 mL Schlenk flask was charged with a solution of **8** (1.2 μmol, 0.15 mol%, prepared in situ) in $C_8F_{17}Br$ (2 mL). 4-Iodophenyl acetate (210 mg, 0.8 mmol) in toluene (2 mL) was added at 0°C followed by a solution of phenylzinc bromide (0.88 mmol, 1.1 equiv) in toluene (1 mL). The reaction mixture was stirred at 60°C for 0.5 h to provide a homogeneous solution. Upon cooling to 0°C, phase separation occured immediatly. The orange perfluorinated phase containing the catalyst **8** was recovered and could be used for further experiments. The organic phase was diluted with Et_2O and washed with a saturated aqueous solution of NH_4Cl. The crude product obtained after evaporation of the solvent was purified by flash chromatography (hexanes/ether 19/1) to yield pure **4a** (158 mg, 0.74 mmol, 93% yield).

Synthesis and Structure of Aluminum-Fluorine-Oxygen Clusters**

Said D. Waezsada, Feng-Quan Liu, Craig E. Barnes, Herbert W. Roesky,* Mavis L. Montero, and Isabel Usón

Dedicated to Professor Heribert Offermanns on the occasion of his 60th birthday

AlF_3 and cryolite (Na_3AlF_6) are of great importance in the exploitation of aluminum[1] and belong along with hydrogen fluoride to the most important technical inorganic fluorine products. In contrast, organic compounds with the composition $RAlF_2$ are virtually unknown. K. Ziegler mentioned the reaction of $EtAlCl_2$ with sodium fluoride; however the reaction product was not fully characterized.[2] We recently showed that $(R)(R')NAlMe_2$ compounds react with Me_3SnF under formation of Me_4Sn to give $(R)(R')NAlF_2$.[3] Structure analyses have shown that these compounds exist as trimers in the absence of donor solvents. On treatment with anhydrous THF, the trimers react as expected to give adducts with the composition $(R)(R')NAlF_2 \cdot THF$. We have now established that, depending on the substituents R and R', successive reactions can occur on recrystallizing the THF adducts from *n*-hexane. In the case of the compounds $(2,6\text{-}i\text{Pr}_2C_6H_3)[Si(i\text{Pr})Me_2]NAlF_2 \cdot THF$ (**1**) and $(2,6\text{-}i\text{Pr}_2C_6H_3)[Si(t\text{Bu})Me_2]NAlF_2 \cdot THF$ (**2**), the adducts are regenerated quantitatively. Compounds in which the substituents in the *ortho* position of the phenyl ring (group R) or the substituents on the silicon atom (group R') are smaller behave in a completely different manner; the compounds $(2,6\text{-}Me_2C_6H_3)[Si(t\text{Bu})Me_2]NAlF_2 \cdot THF$ (**3**) and $(2,6\text{-}i\text{Pr}_2C_6H_3)(SiMe_3)NAlF_2 \cdot THF$ (**4**) are converted into the aluminum clusters **3a** and **4a**, respectively, which both contain an oxygen atom in the center of the Al_6F_{12} tetrakishexahedron [Eq. (1)].

$$\underset{\mathbf{3,4}}{6\,(R)(R')NAlF_2 \cdot THF} \xrightarrow[-2\,(R)(R')NH]{n\text{-hexane}} \underset{\mathbf{3a,4a}}{[(R)(R')NAlF_2]_4[AlF_2(thf)]_2O} \qquad (1)$$

The basic framework of **1** corresponds to that of **2**, and that of **3a** corresponds to that of **4a**. It was therefore decided to dispense with a detailed discussion of the geometrical crystallographic data of **2** and **3a**. Compound **1** crystallized in the monoclinic space group $P2_1/c$.[4] Al(1) in **1** (Figure 1) is coordinated in a slightly distorted tetrahedral fashion with bond angles of between 98.6° and 118.1°. The average Al–F bond length (165.7 pm) is comparable with the terminal Al–F bond lengths in $[(2,6\text{-}i\text{Pr}_2C_6H_3)(SiMe_3)NAlF_2]_3$.[3] Compound **4a** also crystallized in the monoclinic space group $P2_1/c$.[4] Each Al atom in **4a** is six-coordinate (Figure 2). The aluminum atoms are each bonded to four fluorine atoms and to the central oxygen atom. In addition, amino groups are coordinated to Al(1) and Al(2), and a THF molecule to Al(3); the coordination sphere of these Al atoms can be described as distorted *trans*-octahedral (AlF_4ON and AlF_4O_2). The fluorine atoms each bridge two aluminum atoms; the average Al–F bond length is 182.8 pm. This value is significantly larger than the average terminal Al–F distance in **1**. The *trans*- and *cis*- F-Al-F angles at Al(3) (average value 172.0° and 89.9°, respectively) are larger than the angles at Al(1) and Al(2) (average values 150.2° and 86.5°, respectively). The O(3) atom in the center of the cage is coordinated in a distorted octahedral fashion to six aluminum atoms. The Al–O distance is shorter for Al(3) (1.903 pm) than for Al(1) and Al(2) (average value 2.267 pm).

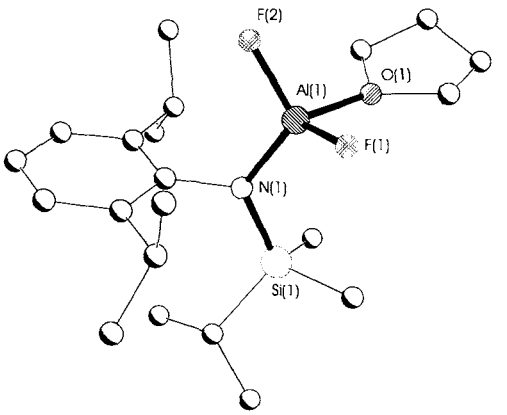

Figure 1. Structure of **1** in the crystal. Selected bond lengths [pm] and angles [°]: Al(1)–F(2) 165.3(2), Al(1)–F(1) 166.0(2), Al(1)–N(1) 180.9(2), Al(1)–O(1) 185.6(2); F(2)-Al(1)-F(1) 112.0(1), F(2)-Al(1)-N(1) 112.3(1), F(1)-Al(1)-N(1) 118.1(1), F(2)-Al(1)-O(1) 104.4(1), F(1)-Al(1)-O(1) 98.6(1), N(1)-Al(1)-O(1) 109.6(1).

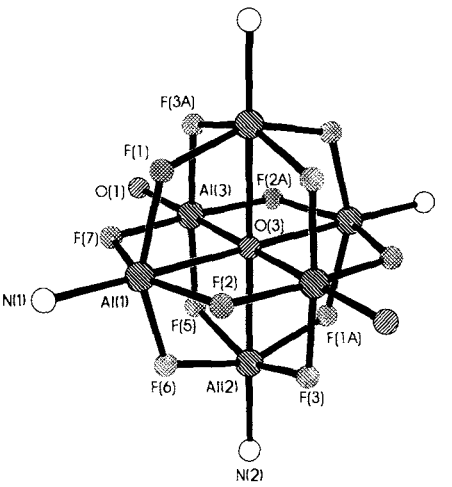

Figure 2. Structure of **4a** in the crystal. For clarity, only the atoms of the THF solvent molecules and the ligands bonding to aluminum are shown. Selected bond lengths [pm] and angles [°]: Al(2)–F(1A) 184.0(2), Al(3)–F(3A) 179.9(2), Al(3)–F(2A) 179.9(2); F(7)-Al(1)-F(1) 86.1(1), F(2)-Al(1)-F(6) 86.4(1), F(2)-Al(1)-F(1) 85.7(1), F(7)-Al(1)-F(6) 86.6(1), F(1)-Al(1)-F(6) 150.1(1), N(1)-Al(1)-O(3) 179.2(1), F(7)-Al(1)-F(2) 150.1(1), F(5)-Al(2)-F(6) 86.0(1), N(1)-Al(1)-F(6) 105.5(1), F(1)-Al(1)-O(3) 75.1(1), F(7)-Al(3)-F(5) 89.9(1), F(7)-Al(3)-O(1) 93.6(1).

The insertion of oxygen under elimination of two amine molecules could be caused by water or THF. In order to clarify this, temperature-dependent ^1H NMR and ^{19}F NMR spectra were made from solutions of **1** and **3** in $[D_8]$toluene (−90 to 0 °C). As expected, a singlet occurs in the ^{19}F NMR spectrum of **1** down to −90 °C. In contrast, the singlet in the ^{19}F NMR spectrum of **3** ($\delta = -174.3$ at room temperature) splits into three signals ($\delta = -134.2, -165.6, 172.7$) in the ratio 1:1:1 at −90 °C. Moreover, traces of the eliminated amine are evident in the ^1H NMR spectrum of **3**. The ^{19}F NMR spectrum of **3a**

([D$_6$]benzene) shows a number of resonance signals at room temperature that split into two signals in the ratio 1:2 at 70 °C. This spectrum can be unequivocally attributed to the cluster structure. The ^{1}H NMR spectra of the (R)(R′)NAlF$_2$ · THF compounds have both the expected resonance signals. No differentiation between coordinated THF and free THF is observed at −90 °C on addition of further amounts of THF to the samples. This confirms the rapid exchange of the THF molecules.

The possibility of a partial hydrolysis was ruled out by the controlled hydrolysis of a sample of **4**; the Me_3SiF signal in the ^{19}F NMR spectrum was of greater intensity after the hydrolysis. Thus, only the reaction with THF needs to be taken into consideration. Indeed, reactions of aliphatic ethers with halides of Group 13 have often been reported.[7] The reaction of R_2O with BCl_3 leads to the formation of RCl and $ROBCl_2$. In contrast, the corresponding reaction with BF_3 leads to alcohols (or water) and olefins.[8] Investigations into analogous reactions of THF with BF_3[9] and $AlCl_3$[10] have also been reported; these always led to cleavage of the THF and opening of the ring. Thus, the aluminum-fluorine-oxygen clusters obtained are dependent on the substituents R and R′ of (R)(R′)NAlF$_2$ · THF. A molecular compound of oxygen in which the oxygen atom is surrounded by six main group elements was thus obtained for the first time. This type of structure was, until now, only known for the d- and f-block elements.[1]

A Sequential Photoinduced Electron Relay Accelerated by Fullerene in a Porphyrin-Pyromellitimide-C_{60} Triad**

Hiroshi Imahori,* Koji Yamada, Masato Hasegawa, Seiji Taniguchi, Tadashi Okada,* and Yoshiteru Sakata*

Dedicated to Professor Emanuel Vogel on the occasion of his 70th birthday

In addition to displaying a variety of unique properties such as superconductivity, biological activity, and ferromagnetism,[1] C_{60} is a good electron acceptor as well as a sensitizer when employed in photophysical and photochemical processes.[2,3] We[3,4] and others[5–7] demonstrated that C_{60} can accelerate photoinduced charge separation (CS) and decelerate charge recombination (CR) in donor-linked fullerenes. Utilization of such a building block in more elaborate molecular systems seems to be promising for the construction of solar energy conversion systems. In photosynthesis the fundamental principle for converting light into chemical potential energy is photodriven CS and subsequent fast electron relay between well-arranged pigments within the reaction center.[8] Although there have been numerous attempts to mimic vectorial electron transport across the

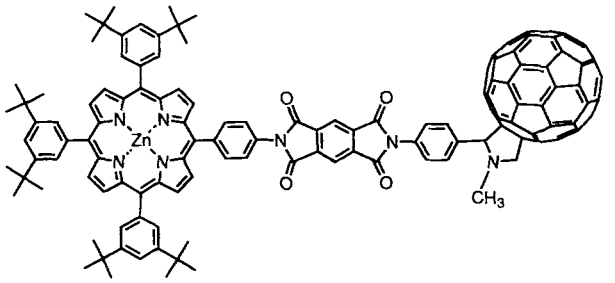
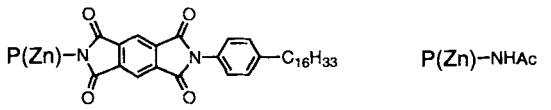
membrane using synthetic molecular arrays, it is still difficult to achieve a long-lived CS state with a high quantum yield without loss of a large amount of the input energy by the light.[9]

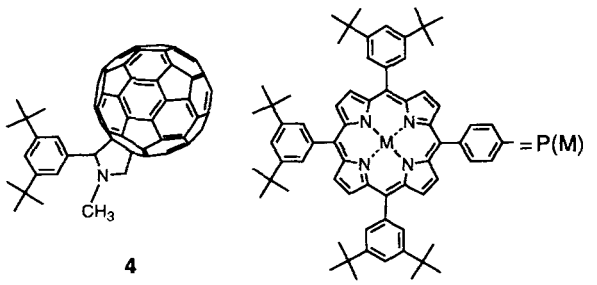
Here we report the synthesis and photophysical properties of the porphyrin-pyromellitimide-C_{60} triad **1** (P-Im-C_{60}; P = porphyrin, Im = imide). The energy gradients of each state are in the order P^*-Im-C_{60} > $P^{\bullet+}$-$Im^{\bullet-}$-C_{60} > $P^{\bullet+}$-Im-$C_{60}^{\bullet-}$. Accordingly, **1** will display a sequential electron transfer (ET) that is quite similar to primary ET events at reaction centers of photosynthesis. In addition, it is expected that the unique properties of C_{60} in ET will increase the yield of the CS state and prolong the lifetime[3,4] by storing a substantial amount of the excitation energy. The characteristic intense absorption band due to the imide anion radical as well as the conformational rigidity will be helpful for analyzing the dynamics of ET.[10]



1

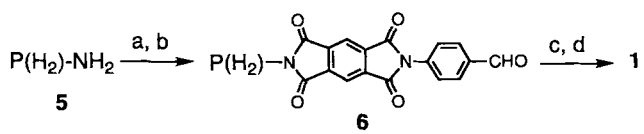


2 **3**



4

The synthesis of **1** is shown in Scheme 1. Cross-condensation of aminoporphyrin **5**, pyromellitic dianhydride, and protected formyl aniline in dimethylformamide (DMF) followed by deprotection of the formyl group gave pyromellitimide-substituted porphyrin **6** in 19% yield. The zincporphyrin-pyromellitimide-C_{60} triad **1** was obtained in 33% yield by 1,3-dipolar cycloaddition with **6**, *N*-methylglycine, and C_{60} in toluene and subsequent treatment with $Zn(OAc)_2$.[11] C_{60}-free dyads **2** as well as single-chromophore compounds **3** and **4** were also synthesized as references. Their structures were verified by analytical methods including ^1H and ^{13}C NMR spectroscopy and MALDI-TOF (matrix-assisted laser desorption/ionization time-of-flight) mass spectrometry.



5 **6**

Scheme 1. Synthesis of **1**; a) pyromellitic dianhydride, 4-(5,5-dimethyl-1,3-dioxan-2-yl)aniline, DMF, reflux, overnight; b) trifluoroacetic acid (TFA), H_2SO_4, $CHCl_3$, room temperature, overnight; c) C_{60}, *N*-methylglycine, toluene, reflux, 6 h; d) $Zn(OAc)_2$, $CHCl_3$, reflux, 30 min.

The absorption spectra of **1** in dioxane and THF are essentially a linear combination of the absorption spectra of **2** and **4**, and give no indication for strong interactions between these chromophores. The absorption due to the C_{60} unit is much weaker and broader than that of the porphyrin, whereas discernible absorption of the imide moiety appears around 250–300 nm. The redox potentials of **1** (in CH_2Cl_2 with 0.1M nBu_4NPF_6 as a supporting electrolyte and quoted relative to the ferrocene/ferrocenium potential: −1.50, −1.21, −1.13, +0.31, +0.67 V) correspond roughly to the sum of **2** (−1.22, +0.31, +0.67 V) and **4** (−1.54, −1.15 V).

The fluorescence spectra of **1** and **2** are quenched more strongly than those of **3** when excited at the Soret band at the same concentration (0.06 for **1**, 0.08 for **2** in dioxane). These results show rapid quenching of the excited singlet state of the porphyrin by the imide, because the porphyrin is excited selectively.

Before discussing the photodynamics of **1**, those of **2** are described as a simple model. The transient spectrum of **2** in dioxane 20 ps after excitation with a pulse at 590 nm shows the immediate rise of bands at 650 and 720 nm, which are assigned to the zinc porphyrin radical cation ($ZnP^{\bullet+}$)[4] and imide radical anion ($Im^{\bullet-}$), respectively. The time profile of the absorbance at 456 nm, which corresponds to the $S_n \leftarrow S_1$ absorption of the porphyrin ($^1ZnP^*$) and $ZnP^{\bullet+}$, was analyzed by a single exponential decay with a time constant of 180 ps (Figure 1). Measurement of the fluorescence lifetime of **2** was carried out by a picosecond single photon counting technique with excitation at 400 nm and monitoring at 650 nm, the wavelength at which fluorescence is due only to the porphyrin. The decay curve at 650 nm was fitted by one major exponential decay with a time constant of 160 ps, which is in good agreement with that of the absorbance decay at 456 nm.

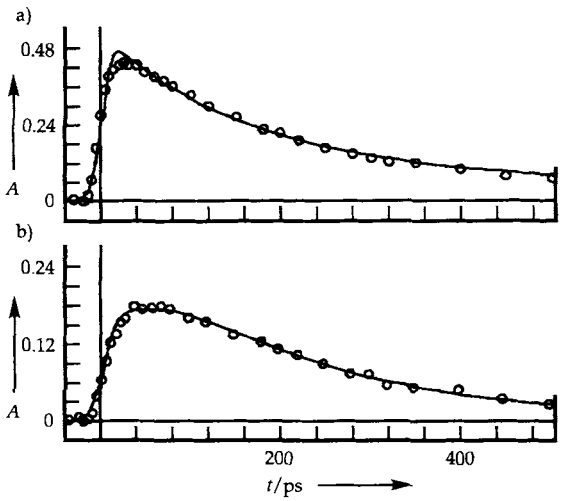


Figure 1. Time profiles of transient absorbances *A* of **2** in dioxane at a) 456 and b) 720 nm after excitation at 590 nm. The time constants for the exponential decrease in intensity is 180 ps in both cases; for b) the intensity of the absorption initially increases with a time constant of 60 ps.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3623-2627 $ 17.50+.50/0

On the other hand, the transient absorbance at 720 nm arises with a time constant of 60 ps and decays with that of 180 ps. These results indicate that CR is faster than CS, even in a nonpolar solvent like dioxane; the lifetime of the ion pair is considered to be 60 ps ($= \tau_1$).[4,10] The time-resolved transient absorption spectra for **1** in dioxane are shown in Figure 2. Immediately after excitation of **1** with a pulse at

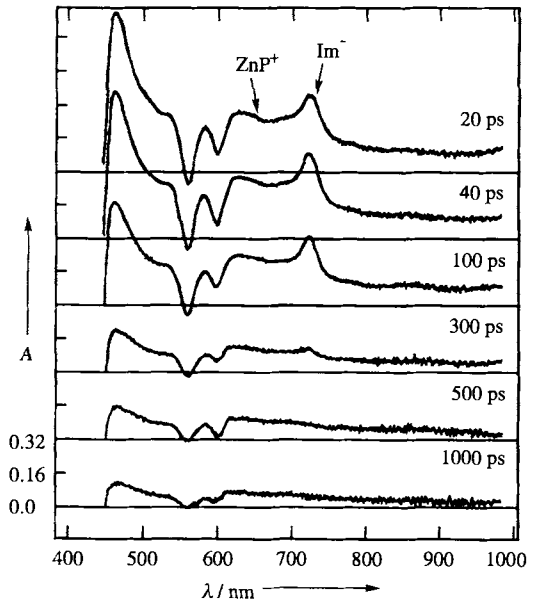

Figure 2. Absorption spectra of **1** in dioxane at different times (resolution in picosecond range) after excitation at 590 nm. The delay times between excitation and measurement are indicated on the right. A = Absorbance.

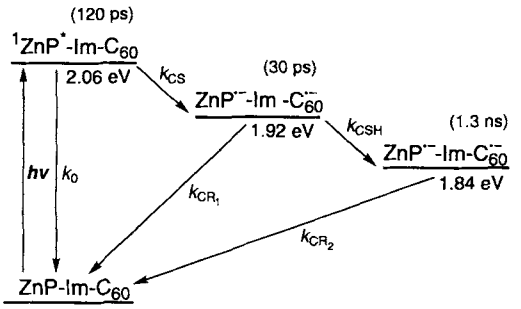
590 nm—the wavelength at which the porphyrin and the C_{60} unit absorb in a ratio of 14:1—bleaching of the ground-state porphyrin absorption of the Q bands at 560 and 600 nm, intense absorption with a maximum near 470 nm, and characteristic bands at 650 and 720 nm (attributable to $ZnP^{\bullet+}$ and $Im^{\bullet-}$, respectively) were observed. The absorbances at 460, 650, and 720 nm show biphasic decays with time constants of 120 ps and 1.3 ns; those at 650 and 720 nm display an additional rise with a time constant of 30 ps. However, the band for $Im^{\bullet-}$ decays much faster (120 ps) than that for $ZnP^{\bullet+}$. This shows the sole broad absorption due to ZnP^+, which eventually decays with a time constant of 1.3 ns. These results clearly demonstrate the initial formation of $ZnP^{\bullet+}$-$Im^{\bullet-}$-C_{60} followed by a charge shift (CSH) to produce $ZnP^{\bullet+}$-Im-$C_{60}^{\bullet-}$.[12] The photodynamic behavior of **1** in dioxane is summarized in Scheme 2.[13] The fluorescence decay of **1** at 650 nm was analyzed by one major exponential decay with a time constant of 100 ps, which is consistent with that of 120 ps for absorbance decays at 460, 650, and 720 nm. This implies that the rate constant k_{CR1} for charge recombination in **1** is larger than that for charge seperation (k_{CS}), which is similar to the situation with **2**; the lifetime of $ZnP^{\bullet+}$-$Im^{\bullet-}$-C_{60} is considered to be 30 ps ($= \tau_2$). Therefore, the rate constant for charge shift (k_{CSH}) is estimated to be $1.6 \times 10^{10}\ s^{-1}$ according to Equation (a).

$$k_{CSH} = (k_{CSH}+k_{CR1}) - k_{CR1} = 1/\tau_2 - 1/\tau_1 \qquad \text{(a)}$$

In spite of the small difference (0.08 V) in electron-accepting abilities between the imide and the C_{60} moieties, the rate



Scheme 2. Reaction scheme and energy diagram for **1** in dioxane [13]. The lifetime of each state is given in parentheses. $k_0 = 5.0 \times 10^8$, $k_{CS} = 7.8 \times 10^9$, $k_{CR1} = 1.7 \times 10^{10}$, $k_{CSH} = 1.6 \times 10^{10}$, and $k_{CR2} = 7.7 \times 10^8\ s^{-1}$.

of CSH competes well with that of CR ($k_{CR1} = 1.7 \times 10^{10}\ s^{-1}$), resulting in the formation of $ZnP^{\bullet+}$-Im-$C_{60}^{\bullet-}$ with a total quantum yield of 0.46.[10] It is remarkable that the lifetimes of the S_1 state due to the porphyrin are quite different for **1** and **2**; the lifetime of **1** is about 30% shorter than that of **2**. This may be explained by the acceleration effect of C_{60} on imide moiety mediated ET through the spacer[3,4,6] or the direct through-space ET from $^1ZnP^*$ to C_{60} concomitant with sequential ET. In the more polar solvent such as THF, excitation of **1** leads to the formation of $ZnP^{\bullet+}$-$Im^{\bullet-}$-C_{60} within 20 ps, but CR is much faster than CS, which makes formation of $ZnP^{\bullet+}$-Im-$C_{60}^{\bullet-}$ quite difficult.[10,13]

A sequential ET relay that mimicks the reaction center of photosynthesis and the resulting fairly long-lived CS state with moderate quantum yield have been realized in the triad system involving fullerene. These results show that C_{60} is a suitable building block for systems showing artificial photosynthesis. We are currently applying this strategy for the construction of solar energy conversion systems.[14]

[13] The Gibbs energy for CR and CS, $-\Delta G_{CR}$ and $-\Delta G_{CS}$, are given by Equations (b)–(d); where $\Delta E_{0\text{-}0}$ is energy of the 0–0 transition between the

$$-\Delta G_{CR} = E_{ox} - E_{red} + \Delta G_s \quad \text{(b)}$$

$$-\Delta G_{CS} = \Delta E_{0\text{-}0} - (-\Delta G_{CR}) \quad \text{(c)}$$

$$\Delta G_s = \varepsilon^2/(4\pi\varepsilon_0)[\{1/(2R^+) + 1/(2R^-) - 1/R_{CC}\}(1/\varepsilon_s) - \{1/(2R^+) + 1/(2R^-)\}(1/\varepsilon_r)] \quad \text{(d)}$$

S_1 and S_0 states for the porphyrin, E_{ox} and E_{red} are the first oxidation potential of the donor and the first reduction potential of the acceptor in CH_2Cl_2, R^+ and R^- are the radii of D and A ($R^+(P) = 5.0$, $R^-(Im) = 3.5$, $R^-(C_{60}) = 4.4$ Å). R_{cc} is the distance between the centers of the two moieties ($R_{CC}(P{-}Im) = 12.3$, $R_{CC}(P{-}C_{60}) = 23.5$ Å), and ε_s and ε_r are static dielectric constants of solvent used and, when measured, the redox potentials ($\varepsilon_s = 7.4$ in THF and $\varepsilon_r = 8.9$ in CH_2Cl_2). In dioxane the Born equation does not give correct values for ΔG_s because of an overestimation of the polarity. Therefore, the value of $\Delta G_s = 0.40$ eV in dioxane is used tentatively, assuming that the value of ΔG_s for this system is identical to that of porphyrin-linked quinones: T. Asahi, M. Ohkohchi, R. Matsusaka, N. Mataga, R. P. Zhang, A. Osuka, K. Maruyama, *J. Am. Chem. Soc.* **1993**, *115*, 5665.

Detection of Scalar $^6Li,^{15}N$ Coupling across Coordinative Li–N Bonds**

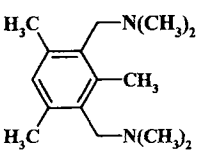
Dietmar Hüls, Harald Günther,* Gerard van Koten, P. Wijkens, and J. T. B. H. Jastrzebski

Dedicated to Professor Reiner Radeglia on the occasion of his 60th birthday

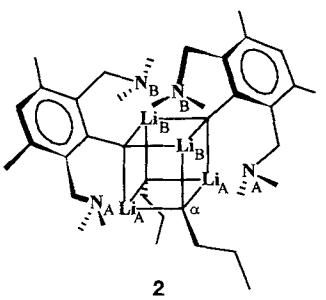
Scalar NMR spin–spin coupling constants are structural parameters characteristic for the bonding and the connectivity in molecular systems. They also play an essential part in the structural elucidation of organolithium compounds.[1] In particular $^6Li,^{13}C$ and $^6Li,^{15}N$ couplings are important indicators of aggregate size, since their magnitude depends on the aggregation state of the metalated species.[1,2]

A typical phenomenon in organolithium chemistry is the stabilization of organometallic clusters through coordination with donor ligands like ethereal solvents or amines.[3] In particular *N,N,N′,N′*-tetramethylethylenediamine (TMEDA) finds broad application. These ligands can be detected quite frequently by NMR spectroscopy through signal integration or heteronuclear Overhauser (HOESY) experiments.[4] However, scalar coupling between lithium and ligand atoms is usually not observed. An exception are scalar $^6Li,^{15}N$ couplings for Li–N chelate bonds in a chiral bidendate lithium amide,[5a] for lithium hexamethylsilazide,[5b] and in 2-(dimethylaminomethyl)phenyllithium,[6] as well as $^7Li,^{31}P$ interactions in complexes between lithium cations and hexamethylphosphoric triamide (HMPTA).[7] We report here the detection of $^6Li,^{15}N$ coupling across coordinative Li–N bonds in a 2:2 benzyl/butyllithium aggregate.

Reaction of 1,3-bis(dimethylaminomethyl)-2,4,6-trimethylbenzene (**1**) with *n*-BuLi in a 1:1 molar ratio leads to the



1



2

mixed aggregate **2**,[8] for which X-ray analysis yields relatively short Li–N distances of 212.3(6) pm for Li_A-N_A and 204.5(7) pm for Li_B-N_B.[8] A detailed NMR investigation of [^{6}Li]-**2**[9] confirms the tetrameric structure also for the compound in solution. Thus, in the region of slow exchange at 231 K, where inter- as well as intra-aggregate dynamics are "frozen" on the NMR time scale, we find two ^6Li resonances at $\delta = 0.68$ and 0.77 (relative to 0.1 M LiBr as external standard in THF, Figure 1a), which show in the $^6Li,^6Li$ INADEQUATE

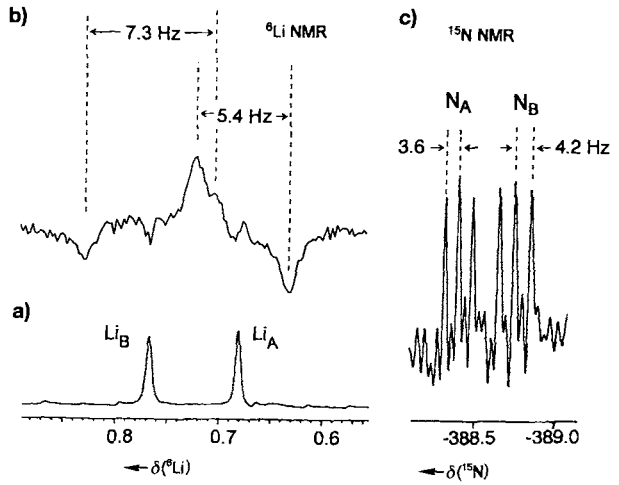

Figure 1. a) One-dimensional ^{6}Li NMR spectrum (58.88 MHz) of [^{6}Li]-**2**; δ scale relative to 0.1 M LiBr in THF. b) One-dimensional ^{6}Li,^{13}C HMQC experiment (58.88/100.13 MHz) for [^{6}Li]-**2** (0.24 M in [D_8]toluene); $T = 230$ K; $1/2J = 68.5$ ms, sweepwidth 35.3 Hz, relaxation delay 1 s; number of experiments 4 K; time for measurement 5.3 h; c) ^{15}N{^{1}H} NMR spectrum (40.54 Hz) of [^{6}Li]-**2** with ^{15}N in natural abundance (0.36%); sweepwidth 6.67 kHz; number of experiments 16 K; relaxation delay 2 s; δ scale relative to $CH_3{}^{15}NO_2$; time for measurement 11.3 h. All spectra were recorded on a Bruker AMX-400 spectrometer.

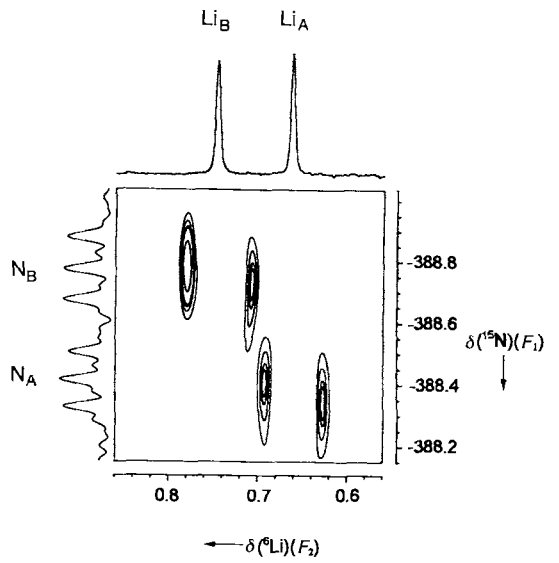

Figure 2. Two-dimensional ^{6}Li,^{15}N HMQC spectrum (55.88/40.54 MHz) of [^{6}Li]-**2** (0.24 M in [D_8]toluene) with ^{15}N in natural abundance (0.36%); $1/2J = 129.9$ ms, sweepwidths 65.9 Hz in F_1 (^{15}N) and 96 Hz in F_2 (^{6}Li); 12 t_1 experiments, 256 data points in F_2; digital resolution 5.49/0.38 Hz (F_1/F_2); 768 transients; time for measurement 6.5 h [19].

experiment[10] a homonuclear scalar ^{6}Li,^{6}Li coupling of 0.1 Hz. In the ^{13}C NMR spectrum only the lithiated carbon of the *n*-butyl residue, C_α, shows splitting by scalar ^{6}Li,^{13}C coupling. As in the majority of other benzyl lithium systems, the ^{6}Li,^{13}C coupling to the benzylic carbon is not resolved.[11]

The assignment of the two ^{6}Li resonances, which is important for the discussion below, follows from the different intensity of the ^{6}Li,$^{13}C_\alpha$ correlation signals found in the 2D ^{6}Li,^{13}C HMQC experiment[12] and of the ^{13}C satellites in the 1D ^{6}Li,^{13}C HMQC spectrum[1b] (Figure 1b). In both cases the high-field ^{6}Li signal shows the higher intensity and can thus be assigned to the Li_A positions, which are adjacent to *two* butyl residues and thus belong to a spin system with twice the ^{13}C natural abundance. From the satellite spectra as well as by line-shape analysis of the ^{13}C signal we obtained $J(^6Li_A,{}^{13}C_\alpha) = 5.4$ Hz and $J(^6Li_B,{}^{13}C_\alpha) = 7.3$ Hz.

To our surprise, the ^{15}N NMR spectrum then showed a 1:1:1 triplet splitting (Figure 1c) for the two ^{15}N resonances, expected on the basis of the C_2 symmetry of the aggregate, at $\delta = -388.4$ and -388.7 (relative to $CH_3{}^{15}NO_2$ as external standard). The coupling constants are 3.6 and 4.2 Hz for $J(Li_A,N_A)$ and $J(Li_B,N_B)$, respectively. The observed 1:1:1 multiplicity as well as the 2D ^{6}Li,^{15}N HMQC experiment[13] (Figure 2) performed in order to assign the ^{15}N resonances identify both splittings beyond doubt as ^{6}Li,^{15}N interactions. The assignment of the ^{15}N resonances and consequently also that of the observed couplings by the 2D ^{6}Li,^{15}N HMQC experiment rest on the ^{6}Li assignment discussed above.

Scalar coupling of this type has been detected so far nearly exclusively for lithium amides.[14] The scalar coupling across a coordinative bond found here can be explained by the short Li–N distances found in the solid, which are apparently maintained in solution. Remarkably, the magnitude of the coupling constants correlates with Li–N distances more typical for Li–N bonds in lithium amides[15] than for coordinative bonds of amine ligands (around 212–230 pm).[15] A correspondence between the distance of coupled nuclei and the magnitude of a scalar spin–spin interaction was also found in the case of a ^{15}N,^{107,109}Ag coupling in a bidentate silver(I) complex with amine/imine ligands.[16,17] A possible explanation of the unusual spin–spin interaction comes from the "through-space" mechanism, which is well established for ^{19}F,^{19}F and ^{1}H,^{1}H interactions in cases of steric compression.[18] Dynamic processes could be responsible for the fact that no ^{6}Li,^{15}N coupling has yet been found for TMEDA ligands.[20]

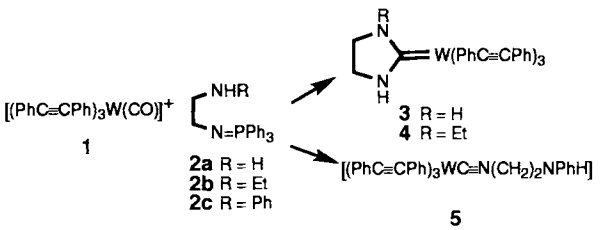
[19] We point out that the software for Bruker AMX spectrometers contains an error which may lead to mirror-image spectra and thus to erroneous signal assignments for X,Y correlations that employ the third frequency channel.
[20] **Note added in proof** (October 21, 1997): The detection of a $^{6}Li,^{15}N$ coupling (2 Hz) for the $[(\{[^{6}Li]BuLi\}_2\{[^{15}N](tmeda)_2\}]$ complex ($[D_8]$toluene, −110 °C) was recently reported: D. Waldmüller, B. J. Kotsatos, M. A. Nichols, P. G. Williard, *J. Am. Chem. Soc.* **1997**, *119*, 5479–5480.



The crystal structure of **3** confirms the presence of a carbene moiety. Figure 1 shows the molecular structure of **3**, the first tungsten complex that contains only carbene and alkyne ligands. Comparing the bond lengths and angles of **3** and **1** shows the coordination geometry at the metal center to be essentially unchanged.[7] Apparently, changing from a π-acidic carbonyl ligand to a nucleophilic carbene ligand[8] has little influence on the structure. The W–C7 bond length (2.167(8) Å) lies within the normal range for metal carbene complexes and is only slightly shorter than that reported by Dötz et al. for $[(CO)_4W{=}C(OMe)(o\text{-}C_6H_4C{\equiv}CPh)]$ [2.181(5)Å].[2a]

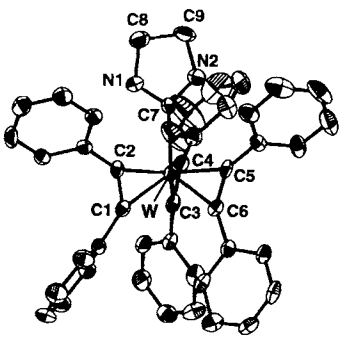


Figure 1. Molecular structure of **3** (numbering of aromatic carbon atoms omitted for clarity). Selected bond lengths [Å] and angles [°]: W–C7 2.167(8), W–C1 2.049(9), W–C2 2.064(8), W–C3 2.062(9), W–C4 2.067(9), W–C5 2.098(8), W–C6 2.053(8), C1–C2 1.32(1), C3–C4 1.31(1), C5–C6 1.30(1); W-C7-N1 124.4(6), W-C7-N2 132.9(6).

Novel Alkyne Carbene Tungsten Complexes**

Rong-Zhi Ku, Der-Yi Chen, Gene-Hsiang Lee, Shie-Ming Peng, and Shiuh-Tzung Liu*

Since the discovery of Fischer carbene complexes,[1a] numerous transition metal carbene complexes have been synthesized.[1] Among them, a few carbene complexes with coordinated alkyne ligands are known.[2–3] Such complexes are believed to be important intermediates for metal-mediated metathesis of alkynes.[2–4] Pioneering work by Dötz et al. has shown this reaction to be a versatile tool in organic synthesis.[4–5] All of these carbene complexes contain carbonyl ligands and transition metals in low oxidation states. We now report the synthesis of the first carbonyl-free alkyne carbene tungsten complexes **3** and **4**.

Treatment of **1** with an equimolar quantity of the amino-substituted iminophosphorane **2a** in dichloromethane gave the diaminocarbene complex **3** in 53% yield. The carbene group is presumably formed by deoxygenation of the carbonyl ligand by the iminophosphorane to give an isocyanide complex, which subsequently undergoes intramolecular attack by the amino group.[6] Complex **3** is stable in air and dissolves in most organic solvents. The ^{13}C NMR resonance of the carbene carbon atom at $\delta = 220.2$ is shifted downfield relative to that of $[(CO)_5W{=}C(NHCH_2)_2]$ ($\delta = 204.0$).[6]

[**] This work was supported by the National Science Council of the Republic of China (Grant No. NSC86-2113-M002-21). We thank Professor Gwo-Rong Her for help in the mass determination of polymers.

The *N*-ethyl compound **4** was prepared analogously from **1** and **2b**, but the phenyl-substituted iminophosphorane **2c** did not give the corresponding cyclic carbene species. Instead, the isocyanide complex **5** was obtained, presumably for steric reasons and because of the lower nucleophilicity of the aromatic amine. The substituents on the alkyne ligands also influenced the formation of carbene complexes. Neither $[(PhC{\equiv}CEt)_3W(CO)]$ nor $[(EtC{\equiv}CEt)_3W(CO)]$ reacted with **2a** to give the desired complex, and tungsten starting material was recovered. This illustrates the limitations of iminophosphorane in extracting the oxygen atom from coordinated carbonyl ligands.[6] Nevertheless, this approach provides another synthetic route to diaminocarbenes.[9]

Complex **3** catalyzes the polymerization of diphenylacetylene. In a typical experiment, a mixture of **3** (10 mol%) and PhC≡CPh in chlorobenzene was heated to reflux for 48 h. Polydiphenylacetylene was obtained as a yellow precipitate in 66% yield (based on the amount of diphenylacetylene consumed). The reaction solution contained pentaphenylbenzene (1.3%), pentaphenylcyclopentadiene (2.3%), and hexaphenylbenzene (3.7%). The benzene derivatives are the result of trimerization, while the pentaphenylcyclopentadiene

is believed to be formed in a manner similar to that reported by Green et al. for the reaction of $[(PhC{\equiv}CPh)_3W(NCMe)]$ with *o*-diphenylphosphanylstyrene.[10] Polydiphenylacetylene is a yellow solid, insoluble in most organic solvents, even boiling dichlorobenzene. It was characterized by solid-state ^{13}C NMR and mass spectrometry. The parent peak at $m/z = 3402$ corresponds to 19 diphenylacetylene units. The ^{13}C NMR spectrum shows signals at $\delta = 125$ and 144 for the aromatic and olefinic carbon atoms, respectively. Possible applications of this polydiphenylacetylene are currently being investigated.

Experimental Section

3: A solution of **1** [7] (300 mg, 0.4 mmol) and iminophosphorane **2a** (141 mg, 0.44 mmol) in dichloromethane (20 mL) was stirred at 25 °C for 16 h. The solvents were removed and the residue was chromatographed on silica gel (15 g) with dichloromethane/hexane (2/5, v/v) as eluent. The eluate was collected and concentrated to give **3** as a white solid. M.p. 178–180 °C (decomp); ^1H NMR (300 MHz, $CDCl_3$): $\delta = 7.48-7.13$ (m, 30H, ArH), 6.50 (s, 2H, NH), 3.47(s, 4H, CH_2); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 220.2$ (W=C), 198.9 (PhC), 181.7 (PhC), 143.9–125.5 (Ph), 45.8 (CH_2). Analysis: calcd for $C_{45}H_{36}N_2W$: C 68.53, H 4.60, N 3.55; found C 68.38, H 4.62, N 3.39.

Colorless single crystals of **3** were obtained by recrystallization from dichloromethane/hexane. Crystal data for **3**: $C_{45}H_{36}N_2W$, $M_r = 788.63$, orthorhombic, space group *Pbca*, $a = 20.589(5)$, $b = 20.463(6)$, $c = 16.503(6)$ Å, $V = 6953(4)$ Å^3, $Z = 8$, $\rho_{calcd} = 1.507$ g cm^{-3}, $\lambda = 0.7107$ Å, $\mu = 34.246$ cm^{-1}, $F(000) = 3144$, $T = 298$ K, crystal dimensions $0.30 \times 0.35 \times 0.70$ mm. All measurements were performed on a Nonius CAD-4 diffractometer and refined by a least-squares treatment. $R_F = 0.039$, $R_w = 0.040$ for 3344 reflections with $I_0 > 2.0\sigma(I_0)$ and 434 variables. The NRCVAX program was used for the computation.[11] Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100570. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (Fax: Int. code + (1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

4: White solid, m.p. 182–183 °C (decomp); ^1H NMR (300 MHz, $CDCl_3$): $\delta = 7.48-7.16$ (m, 30H), 3.81 (t, $^3J(H,H) = 9.3$ Hz, 2H), 3.26 (t, $^3J(H,H) = 9.3$ Hz, 2H), 2.27 (q, $^3J(H,H) = 7.4$ Hz, 2H), 0.03 (t, $^3J(H,H) = 7.4$ Hz, 3H); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 219.9$, 198.5, 181.6, 143.8–125.5 (PhC), 47.4, 45.4, 43.2, 11.9; analysis: calcd for $C_{47}H_{40}N_2W$: C 69.12, H 4.94, N 3.43; found C 69.10, H 4.91, N 3.38.

5: White solid, m.p. 163–164 °C (decomp); ^1H NMR (300 MHz, $CDCl_3$): $\delta = 7.53-6.35$ (m, 35H), 4.07 (t, $^3J(H,H) = 5.3$ Hz, 2H), 3.43 (t, $^3J(H,H) = 5.3$ Hz, 2H); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 193.7$, 177.9, 145.8, 142.2–112.8 (PhC), 44.2, 42.4; analysis: calcd for $C_{51}H_{40}N_2W$: C 70.84, H 4.66, N 3.24; found C 70.77, H 4.73, N 3.33.

Polydiphenylacetylene: Diphenylacetylene (225 mg) and **3** (100 mg, 0.126 mmol) in chlorobenzene were heated to reflux for 48 h. A yellow precipatate (149 mg, 66%) was collected by centrifugation with recovery of starting material (108 mg). ^{13}C NMR (solid state, 75 MHz): $\delta = 144$, 125; IR (KBr) $\tilde{\nu} = 1598$, 1578, 1492, 1441 cm^{-1}; MS (DCI): m/z 3402 ($[M+NH_4]^+$), 3224 ($[M+NH_4-178]^+$), 3046 ($[M+NH_4-2\times178]^+$), etc.

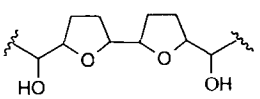
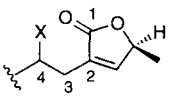
A Convergent Synthesis of (+)-Parviflorin, (+)-Squamocin K, and (+)-5*S*-Hydroxyparviflorin**

Barry M. Trost,* Trevor L. Calkins, and Christian G. Bochet

The diverse bioactivities of the annonaceous acetogenins as antitumor, immunosuppressive, pesticidal, antiprotozoal, anthelmintic, and antimicrobial agents have resulted in considerable attention being focused upon them.[1,2] The acetogenins almost invariably have the butenolide fragment **A** as a head group. Frequently, the most biologically active ones possess a hydroxyl group at C-4 of **A** and a dihydroxy bis(tetrahydrofuran) unit **B** somewhere in the chain.



B



A

Special interest accrues to those members that show remarkable differential cell cytotoxicity. For example, parviflorin (squamocin E, **1**)[3] shows ED_{50} values against human lung, breast, and colon carcinoma of 1.3×10^{-15}, 1.7, and 0.5 respectively. In trying to devise a convenient convergent general strategy to these bioactive acetogenins, we chose parviflorin as a target because of its partially hidden symmetry revealed by our retrosynthetic analysis outlined in Scheme 1. Regio- and diastereoselective introduction of the C-4 hydroxyl

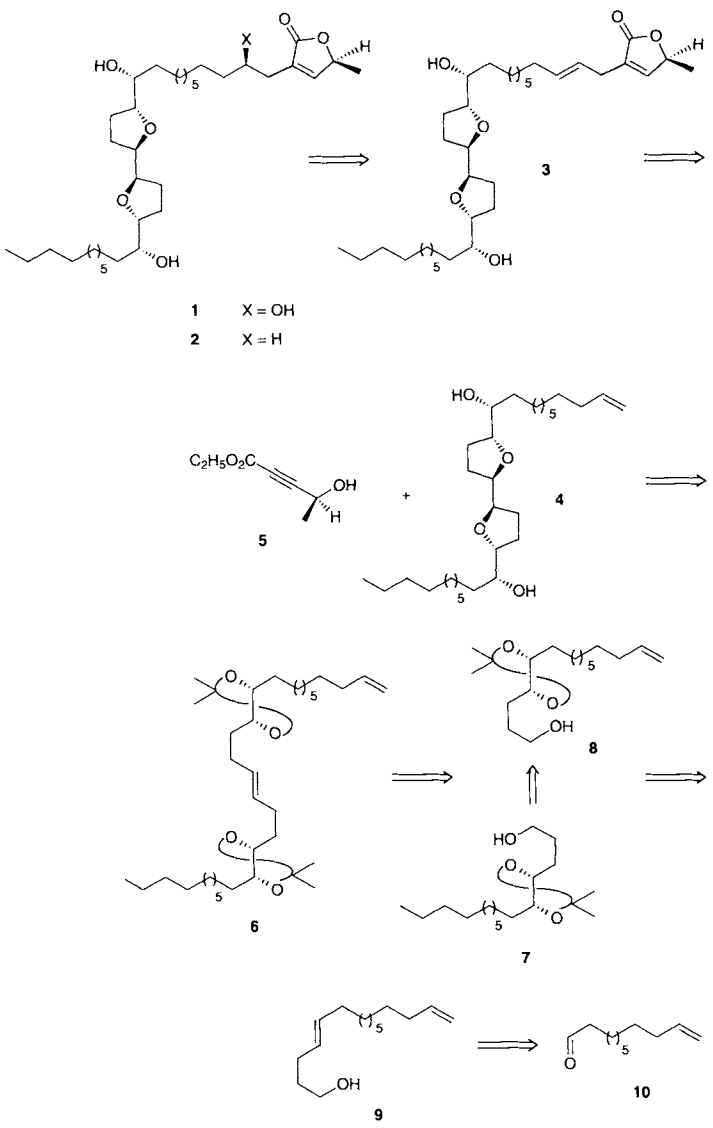


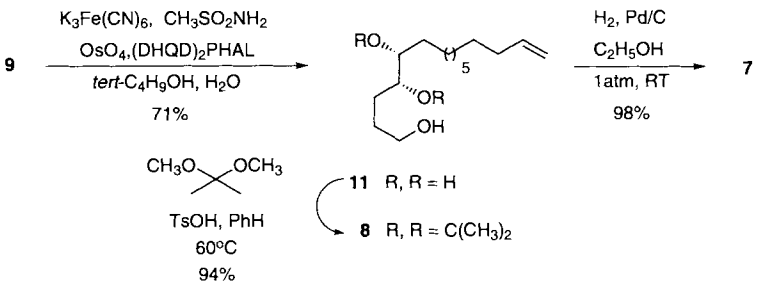
Scheme 1. Retrosynthesis of parviflorin (**1**).

group from an alkene precursor suggests that **3** may be a viable option. Such a precursor is particularly useful, since the double bond can serve as a focal point to diverge to other acetogenins such as squamocin K (**2**) or analogues by chemoselective oxidation at or adjacent to this alkene. The availability of our recently developed Ru-catalyzed Alder–ene type reaction[4] suggests as precursors the alkene **4** and alkyne **5**, which is already readily available from *S*-lactic ester.[4] The bis(tetrahydrofuran) **4** nearly possesses a C_2 symmetry axis; the presence of the terminal double bond is the only feature destroying this symmetry element. Envisioning the *trans*-alkene **6** as the precursor to **4** suggests an olefination to join **7** and **8** to create **6**. It is now obvious that since hydrogenation of **8** creates **7**, the former then becomes both halves of **4** and should readily derive from commercially available 10-undecenal (**10**) via the known **9**.[5] Thus, two units of **8** and one unit of **5** converge to create parviflorin and squamocin K.[6,7] In this paper, we report the realization of Scheme 1.

The first two nearly identical blocks **7**[8] and **8**[8] were synthesized as shown in Scheme 2 from **9**, which was prepared in three steps from **10** as previously described.[5] Dihydroxylation by the Sharpless protocol[9] required monitoring to avoid overoxidation. Stopping the reaction at approximately 2/3 conversion gave diol **11**[8] in 71% yield and 94% *ee*.[10] Protection of the diol gave the first half (**8**)[8] and subsequent catalytic hydrogenation produced the second half (**7**).[8]

The desire for the (*E*)-alkene **6** led us to choose the Julia olefination[11] for the coupling (Scheme 3). To this end, the alkene half **8** was converted straightforwardly into the sulfone **12**[8,12,13] and the alkane **7** into the aldehyde **13**.[8,14] The aldehyde **13** was added to a solution of the lithiated sulfone in THF, and the cold reaction quenched with benzoyl chloride to give adduct **14**[8] reproducibly in 74% yield. Control of the metalation time (30 min) and direct acylation were required to obtain these results. The benzoate **14** was particulary prone to undergo base-catalyzed eliminations under the reductive cleavage conditions even in the presence of numerous buffers. The best in minimizing the simple elimination proved to be boric acid. The alkene **6** was isolated in a 61% overall yield from **12** and **13** as a 3:1 *E*/*Z* mixture. It proved unnecessary to separate the *E*/*Z* mixture, since only the *E* isomer undergoes subsequent dihydroxylation.

The alkene **6** becomes a pivotal intermediate to approach a variety of diastereomeric acetogenins by both the choice of dihydroxylation protocol and hydroxyl group differentiation (in terms of which oxygen becomes the nucleophile and which oxygen the electrophile for formation of the tetrahydrofuran). For the synthesis of parviflorin, **6** was subjected to the Sharpless protocol using $(DHQ)_2PHAL$ to give diol **15**[8] (DHQ–H = dihydroquinine, PHAL = 1,3-phthalazinediyl; Scheme 4) as a single diastereomer, which formed the corresponding mesylate **16**[8] virtually quantitatively. Because hydrolysis of the acetonides was accompanied by partial cyclization, the crude hydrolysate was directly treated with base to give the bis(tetrahydrofuran) **4**. The stage is now set for the butenolide annulation: heating a 1:1 to 1:1.6 ratio of **4**:**5** in methanol at 60°C in the presence of 5 mol% [CpRu(COD)Cl][4] gave 71–98% yields of the butenolide **3**.[8] It is important to note that no protecting groups are required in this reaction. The synthesis of (+)-squamocin K (**2**) only required hydrogenation of the double bond, which proceeded quantitatively with Wilkinson's catalyst[15]



Scheme 2. Synthesis of the building blocks **7** and **8**. Ts = *p*-$CH_3C_6H_4SO_2$.

(C_2H_5OH/PhH (1/1.2), room temperature, 1 atm H_2). Comparison of the infrared and ^1H and ^{13}C NMR spectra of the synthetic and the natural product as well as rotation identified the product.

For parviflorin, we must install the C-5 hydroxyl group. The protocol began with a diastereoselective dihydroxylation to (5*S*)-hydroxyparviflorin (**17**,[8] Scheme 5).[16] Chemoselective deoxygenation of the C-5 hydroxyl group takes advantage of

the regioselective opening of an intermediate acetoxonium ion upon treatment with acetyl bromide to give bromoacetate **18**, which simultaneously acetylates the additional two hydroxyl groups. Radical debromination gave parviflorin triacetate **19**, which was readily hydrolyzed under acid conditions to give parviflorin, identical spectroscopically to the natural product.

This convergent sequence offers a flexible approach to the bis(tetrahydrofuran) acetogenins. For example, various diastereomers are easily accessed by the method of elaborating the alkene **6**. In addition to the *threo-trans-threo-trans-threo* series, the *threo-cis-threo-cis-threo*, *erythro-trans-threo-trans-*

erythro, *erythro-cis-threo-cis-erythro*, *threo-trans-erythro-trans-erythro*, and *erythro-trans-erythro-trans-threo* isomers should be available by manipulation of the oxygen pattern. To demonstrate this principle, *cis*-dihydroxylation of **6** with AD-mix β followed by the same protocol led to the *threo-cis-threo-cis-threo* isomer of **3**. The particular case of parviflorin illustrates the effectiveness of the strategy, since thirty of the carbon atoms and four stereogenic centers derive from a common building block, while the remaining five carbons and an additional stereogenic center are installed by the Ru-catalyzed Alder–ene reaction. Thus, this route should be a versatile approach to the bis(tetrahydrofuran) acetogenins.

Catalytic Asymmetric Alkylation of Nucleophiles: Asymmetric Synthesis of α-Alkylated Amino Acids**

Barry M. Trost* and Xavier Ariza

Modified peptides not only open a major avenue to understanding biological phenomena, but also offer opportunities for drug discovery.[1] Incorporating conformational constraints probes the molecular structure of receptors. By preorganizing the optimum conformation for binding, significant enhancements of biological activity can be expected. Introduction of alkyl groups at the α-carbon of amino acids introduces such conformational constraints and, furthermore, enhances metabolic stability. As a result, the synthesis of α-alkylated amino acids has attracted considerable attention.[2–6] Virtually all methods involve controlling diastereoselectivity—either by use of a chiral auxiliary[3] or by involving what is termed self-reproduction of chirality (also termed self-regeneration of stereocenters).[4] Methods in which the asymmetric inducing unit is required only catalytically are lacking. The major method for catalytic asymmetric synthesis of simple amino acids,[7a] hydrogenation of dehydroamino acids, is not applicable. We report a new strategy for the synthesis of α-alkylated amino acids, which are important building blocks for peptide synthesis.

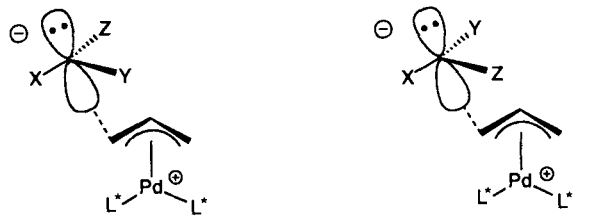
The question relates to the broader one of inducing absolute stereochemistry at an enolate carbon. No reaction is as ubiquitous as alkylations of enolates and related intermediates. The major current approach to effect such reactions asymmetrically involves use of stoichiometric amounts of chiral auxiliaries.[3] Catalytic processes, outside of aldol-like reactions, are rare.[7b,8] An approach based upon palladium-catalyzed allylic alkylations faces the difficult obstacle, illustrated in Scheme 1, that the attacking nucleophile is very remote from the chiral inducing units L*—in fact, the nucleophile is insulated from these chiral ligands by the allyl moiety. It is not surprising that examination of such



Scheme 1. Two competing arrangements for the approach in the asymmetric allylic alkylation at a nucleophilic carbon atom.

reactions to date have been disappointing.[9] Modest success stems from ligands with functional arms that appear to reach beyond the allyl barrier to help direct an incoming nucleophile. We have been exploring a different concept borrowed from the basic principles of an active site of an enzyme.[10] In this model, primary chirality in terms of structural units that contain stereogenic centers induces conformational chirality, which, in turn, creates chiral space. The ability of the reactants to "fit" into the "active site" then defines the molecular recognition and, consequently, the asymmetric induction.

One way to apply this concept to the asymmetric synthesis of α-alkylated amino acids invokes the allylation of the readily available azlactones.[11] The initial studies examined the reaction of the alanine-derived azlactone **1** (R = CH_3) and 3-acetoxycyclohexene (**2**) by using ligand **3** and a palladium complex **4** as a precatalyst (Scheme 2). On use of cesium

carbonate as base in dichloromethane at room temperature, a 2.5:1 diastereomeric ratio (d.r.) of alkylation product was obtained in 96% yield. Gratifyingly, the enantiomeric ex-

cesses (*ee*) were 94% and 92% for the major and minor diastereomers, respectively.[12] The major diastereomer is assigned as depicted in **5**, based on chemical correlation with the known amino acid **6**[13] and analogy to asymmetric alkylations of the allylic ester.[14] Variation to less polar (e.g., benzene) or more polar solvents (e.g., THF or DMSO) failed to improve the diastereomeric ratio or affect the *ee*. With dichloromethane as the standard solvent, the base was varied. Other inorganic or organometallic bases did not prove beneficial. Employing triethylamine, however, did enhance the d.r. to 2.8:1 and the *ee* to 99%. This result prompted our re-examination of the solvent effect with this base. In DMSO or DMF the diastereomeric ratio increased to greater than 4:1. The best diastereoselectivity was observed in acetonitrile. In this case a 90% yield of alkylated product with 8.7:1 d.r. and 99% *ee* of the major diastereomer was obtained. Since the minor diastereomer can be removed by column chromatography, **5** ($R = CH_3$) can be isolated diastereomerically and enantiomerically pure. Table 1 summarizes the alkylation for

Table 1. Results of the asymmetric alkylation of **1** with 3-acetoxycyclohexene (**2**).

Entry	R	Yield[%]	d.r.[a]	*ee*[%][a]
1	CH_3	90	8.7:1	99
2	CH_2Ph	74	12.4:1	99
3	$CH_2CH(CH_3)_2$	77[b]	13.3:1[c]	99[d]
4	$CH(CH_3)_2$	91	>19:1	95

[a] Determined by HPLC on a Chiralcel OD column with heptane/2-propanol mixtures unless stated otherwise. [b] Yield of pure major isomer only. [c] Determined by HPLC on a Microsorb Si 80-125-C5 column with a heptane/ethyl acetate mixture. [d] Determined by HPLC on a Chiralpak AD column.

a range of azlactones. Expectedly, as the size of the R group of the azlactone increased, the diastereoselectivity increased. 3-Acetoxycyclopentene behaved similarly. The tentative assignment of configuration is based upon analogy to that for **5** ($R = CH_3$).

An interesting approach to serine analogues is illustrated in Scheme 3. Palladium-catalyzed allylic alkylation of geminal dicarboxylates serves as a synthetic equivalent to an aldol

Scheme 3. Asymmetric alkylation of azlactones **1** with *gem*-dicarboxylate **7**.

reaction but for stablized pronucleophiles that do not normally provide stable adducts.[15] Thus, asymmetric desymmetrizations of such compounds function as the equivalent of an asymmetric addition of stabilized nucleophiles to carbonyl groups.[16] In this case the chiral recognition with respect to the allyl unit differs from that of Scheme 2, in which the attack of the nucleophile on the π-allylpalladium intermediate is the enantiodiscriminating step with respect to both partners. In Scheme 3 the configuration with respect to the allyl fragment is established in the ionization step, whereas that with respect to the nucleophiles is obviously fixed in the alkylation step. As shown in Table 2, entry 1, our standard conditions gave reasonable d.r. and *ee* values but not as high as those of Scheme 2. In our studies of desymmetrization of the geminal dicarboxylates with achiral nucleophiles, sodium hydride in DME proved to be effective.[16] Indeed, application of these conditions improved both the d.r. and *ee* value (Table 2,

Table 2. Conditions and results of the asymmetric alkylation of **1** with the *gem*-dicarboxylate **7**[a].

entry 2). Temperature also has an effect. In the case of the phenylalanine derivative (Table 2, entries 3 and 4), simply lowering temperature from room temperature to 0°C increases the diastereomeric ratio; the *ee* value also increased. Expectedly, increasing the size of the R group increases the diastereomeric ratio (entries 4–6). The configuration of these serine analogues is assigned based upon precedent in the desymmetrization reaction with achiral nucleophiles and the established configuration on alkylation of the azlactones **1** with **2**, and an X-ray crystal structure of **8** ($R = CH_2Ph$).

This new method for synthesis of α-alkylated amino acids is the first catalytic asymmetric reaction to yield members of this important family of compounds. Hydrolysis provides the amino acids (cf. Scheme 2) without danger of racemization. Furthermore, the azlactones can be used to construct constrained peptides by directly coupling them with a second amino acid unit.[11] By making available greater diversity in such novel amino acids, generation of libraries of peptidomimetics by combinatorial chemistry is facilitated. More generally, inducing chirality at a prochiral nucleophilic center by this mechanism may have broader applications. An important question to address is: why does the family of catalysts employing ligands like **3** function so well? Although detailed structural information is still lacking despite significant effort, the model in which a chiral pocket is envisioned as depicted in the cartoon of Scheme 4 does rationalize the result.[17]

Experimental Section

Alkylation of **2**: 3-Acetoxycyclohexene (**2**, 28 μg, 200 μmol) was added to a solution of Et_3N (56 μL, 400 μmol) and 4-alkyl-2-phenyl-2-oxazolin-5-one (450 μmol) in acetonitrile (1 mL, dry and oxygen free). A prepared solution of **4** (1.8 mg, 4.9 μmol) and chiral ligand **3** (10.4 mg, 15.1 μmol) in acetonitrile (1 mL) was added by cannula under N_2. The reaction mixture was quenched (2–6 h) with aqueous phosphate buffer (pH 7, 40 mL) and extracted with CH_2Cl_2 (3 × 30 mL). The combined organic layer was dried over Na_2SO_4 and concentrated in vacuo. The residue was purified by flash chromatography on silica gel (eluent: petroleum ether/EtOAc).

Alkylation of **7**: A solution of **1** (450 μmol) in DME (1 mL, dry and oxygen free) was added to NaH (95% in oil, 10.1 mg, 400 μmol) at –78°C and allowed to warm to room temperature. When gas evolution stopped, a solution of **4** (1.8 mg, 4.9 μmol) and ligand **3** (10.4 mg, 15.1 μmol) in DME (0.5 mL) was added. Finally a solution of **7** (46.9 mg, 200 μmol) in DME (1 mL) was added at the desired

A Highly Efficient Aminohydroxylation Process**

A. Erik Rubin and K. Barry Sharpless*

Dedicated to Professor Dieter Seebach on the occasion of his 60th birthday

Stereospecific transformations of olefins to 1,2-diols[1,2] and β-amino alcohols[3,4] are very important due to the ready availability of the starting materials and the significance of the products as building blocks in the syntheses of drugs and natural products, ligands for asymmetric catalysis, and chiral auxiliaries.[1–5] The recently discovered catalytic asymmetric aminohydroxylation (AA) of olefins,[4] a close "relative" of the highly reliable catalytic asymmetric dihydroxylation (AD),[1] stereospecifically provides N-protected β-amino alcohols with the added benefit of good to excellent regio- and enantioselectivities. However, in the absence of cinchona alkaloid ligands (i.e., in the achiral mode, which yields racemic products if the olefin is prochiral), the reaction is plagued by the formation of large amounts of diol and suffers from a significant decrease in regioselectivity.[4,6]

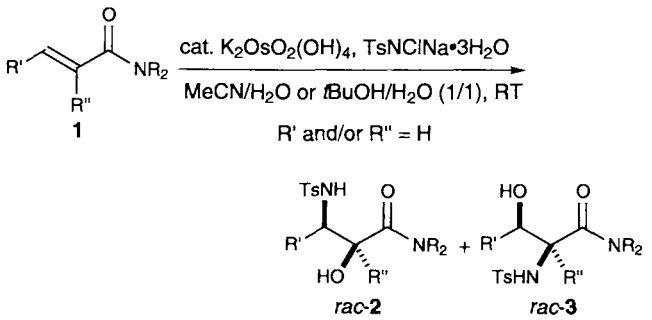
In our continuing effort to develop the AA further and to expand its scope, α,β-unsaturated amides were examined as potential substrates. Remarkably, they gave only racemic products in the AA with chloramine T.[7] On the other hand, they exhibited excellent reactivity and afforded very high yields of the hydroxysulfonamide products, whether or not ligand was added. A more detailed study of the "ligand-independent" aminohydroxylation of α,β-unsaturated amides was then undertaken (Scheme 1).



Scheme 1. Osmium-catalyzed aminohydroxylation of α,β-unsaturated amides with chloramine T; Ts = p-$MeC_6H_4SO_2$.

Aminohydroxylation of the differently N-substituted cinnamamides **1a**–**1f** gave excellent results, even though much lower amounts of the osmate catalyst, chloramine salt, and solvent were employed than are optimal for the standard AA (Table 1).[8] In all cases, the major regioisomer was **2**, in which the newly added nitrogen atom was in the benzylic position (see Scheme 1, R' = Ph).[9] This is the same, albeit weaker, regioselectivity observed for cinnamate *esters* in AA.[4] However, under otherwise identical experimental conditions, the nature of the substituents on the amide nitrogen atom had a significant effect on the extent to which **2** predominanted over **3** as well as on the reaction rates. The Weinreb methoxymethyl cinnamamide (**1a**)[10] proved to be the best substrate; it gave the highest regioselectivity and required the shortest reaction time. However, indicating that rapid turnover and high regioselectivity are not necessarily directly related, *N-tert*-butylcinnamamide (**1f**) was almost as reactive as **1a**, yet gave the poorest regioselectivity of the cinnamamides examined.

Table 1. Effect of N-substituents on the aminohydroxylation of cinnamamides [a].

Entry	Substrate	t[h][b]	**2**:**3**[c]	Yield of *rac*-**2**[%] (M.p.[°C])[d]
1	 **1a**	1	7.3:1	82 (180–181)
2	 **1b**	4	5.0:1	75 (176–177)
3	 **1c**	20	3.3:1	65 (223–225)
4	 **1d**	6	2.8:1	65 (170–171)
5	 **1e**	2	2.6:1	51 (185–186)
6	 **1f**	2	1.6:1	[e]

[a] Reaction conditions: 1.0 mol% $K_2OsO_2(OH)_4$, 1.2 equiv of TsNClNa·$3H_2O$, $MeCN/H_2O$ (1/1), RT, 0.2 M olefin. [b] Approximate reaction time required for the disappearance of the starting olefin, as determined by TLC. [c] Determined by ^1H NMR spectroscopy. [d] Yield and melting point of the pure major regioisomer (**2**) after recrystallization of the crude product (which consisted of **2**, **3**, and excess $TsNH_2$) from *i*PrOH. [e] Recrystallization from *i*PrOH afforded **2f** and **3f** (2:1) in 72% yield.

Further studies with **1b** demonstrated that higher initial concentrations of the olefin as well as much lower loadings of the catalyst could be employed without compromising either the yield or the regioselectivity of the aminohydroxylation.[11] In addition, at olefin concentrations of 0.5 M or greater and with *t*BuOH in place of MeCN as the co-solvent, the hydroxysulfonamide products derived from cinnamamides precipitated directly from the reaction solution in high yield and could be conveniently isolated by filtration. This led to the development of two procedures for aminohydroxylation of α,β-unsaturated amides: method A when the products are insoluble in the reaction mixture, and method B when they are soluble. These procedures differ only in that the former calls for a 25% excess of the chloramine salt and *t*BuOH as the co-solvent, whereas the latter requires one equivalent of the co-oxidant and MeCN as the co-solvent. The excess chloramine T used in procedure A supports better turnover near the end of the reaction. However, elimination of the necessity of removing excess *p*-toluenesulfonamide (produced in the reductive workup) from the product far outweighs the inconvenience of the slightly longer reaction times needed in procedure B because no excess chloramine salt is used. Table 2 lists the results from the aminohydroxylation of different cinnamamides, alkyl-substituted acrylamides, and a parent acrylamide (**1i**) using procedures A and B.

As can be seen in Table 2, excellent yields of the hydroxysulfonamide products were obtained from each of the olefins examined. Most importantly, these high yields and short reaction times were achieved at high substrate concentrations and at room temperature with as little as 0.10 mol% of the catalyst. In the old racemic aminohydroxylation of olefins with on chloramine T,[3a–c] 1 mol% of OsO_4, reaction times in excess of 12 h, and temperatures of 60 °C were required to obtain moderate to good yields of the hydroxysulfonamide products. The poor turnover rates in the old system are now largely attributed to the small amount of water present in the original recipes. However, as mentioned earlier, in the absence of ligands the presence of more water does lead to greater intrusion of the competing dihydroxylation cycle. With olefins other than α,β-unsaturated amides, diol can be expected to constitute up to 70% of the product mixture in some cases.[6] It is the unique ability of α,β-unsaturated amides (e. g. **1a**–**1k**) to benefit from the rapid turnover rates associated with high concentrations of water while somehow avoiding the paths leading to a diol by-product, which accounts for their unprecedented efficiency in the aminohydroxylation.

The hydroxysulfonamide products are in general highly crystalline, and, due to the regioselectivity of the aminohydroxylation, the major regioisomer is usually obtained in pure form following a single recrystallization of the mixture of isomers. However, for cases in which separation is difficult or in order to fully exploit the high combined yields in which the products are obtained, reactions which transform both regioisomers into the same product are of interest. One such

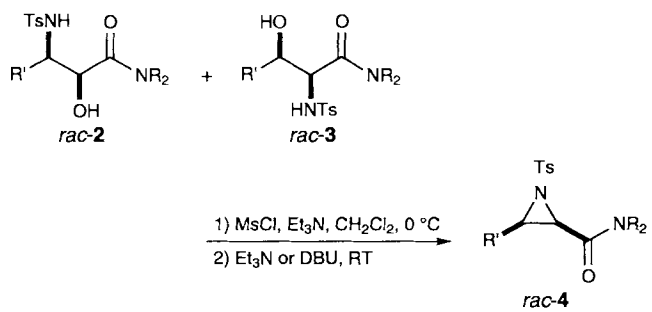
example is cyclodehydration of hydroxysulfonamides to give the corresponding aziridines (Scheme 2).[12] "Activated aziridines" such as **4** are versatile synthetic intermediates and have found wide use in the synthesis of biologically active compounds.[13]

The crude mixtures of hydroxysulfonamides **2** and **3**, obtained directly from the aminohydroxylation of olefins **1**, were cyclized to the aziridines **4** in a one-pot procedure (Scheme 2). The yields of the ring closure for several pairs of regioisomers are listed in Table 3. Thus, a highly efficient two-step synthesis of aziridines **4** from readily available



Scheme 2. Conversion of regioisomeric aminohydroxylation products **2** and **3** into the same aziridine **4**; Ms = $MeSO_2$.

olefins and without the need for purification of the intermediates is now available.

α,β-Unsaturated amides represent one of the few olefin classes for which the osmium-catalyzed aminohydroxylation is highly efficient in the absence of added ligands. The principal advantages of the method are excellent chemical yields, rapid turnover rates (enabling the use of very low loads of catalyst), the ability to use high concentrations of substrate, and the necessity for only one equivalent or a small excess of chloramine salt. The latter consideration along with the favorable "crystallinity factor" greatly simplifies product isolation and makes these processes ideal for large-scale applications. In addition, the rapid emergence of diversity chemistry[14] makes such powerful transformations, especially those yielding racemates,[15] more important than ever.

Experimental Section

Aminohydroxylation procedure A (when the products are insoluble in the reaction mixture), as described for the aminohydroxylation of *N,N*-dimethylcinnamamide (**1b**): To a mechanically stirred solution of **1b** (17.52 g, 100 mmol) and chloramine T trihydrate (35.2 g, 125 mmol) in tBuOH/water (130 mL, 1/1) was added $K_2OsO_2(OH)_4$ (73.7 mg, 0.20 mmol, 0.20 mol %). As the catalyst dissolved (20–30 min) the supernatant became orange and then darkened to deep orange-red once the solution was homogeneous. The reaction was stirred overnight at room temperature, during which time a fine precipitate appeared.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3623-2639 $ 17.50+.50/0

Subsequent thin-layer chromatography (TLC; silica, R_f(**1b**) = 0.20, R_f(products) = 0.15, EtOAc/hexane (1/1), two developments) indicated that the olefin had been completely consumed. The endpoint of the reaction was accompanied by a change in the color of the reaction solution back to yellow-orange. Water (50 mL) was added, and the reaction slurry cooled with stirring in an ice/water bath for 1 h. The solid product was collected by filtration, washed with water (2 × 50 mL), and dried under a stream of air overnight to afford the product (34.0 g, 94%) as a mixture of **2b** and **3b** (3.0:1). Recrystallization of a portion of this mixture from MeOH afforded analytically pure **2b** as colorless blocks: m.p. 176–177 °C (sealed tube); ^{1}H NMR (400 MHz, $CDCl_3$, TMS): δ = 7.56–7.53 (m, 2H), 7.24–7.20 (m, 5H), 7.16–7.13 (m, 2H), 5.52 (d, J = 6.1 Hz, 1H), 4.46 (dd, J = 6.9, 4.4 Hz, 1H), 4.42 (dd, J = 6.1, 4.4 Hz, 1H), 4.02 (d, J = 6.9 Hz, 1H), 2.84 (s, 3H), 2.67 (s, 3H), 2.36 (s, 3H); elemental analysis calcd for $C_{18}H_{22}N_2O_4S$: C 59.65, H 6.12, N 7.73; found: C 59.68, H 5.99, N 7.76.

Aminohydroxylation procedure B (when the products are soluble in the reaction mixture), as described for the aminohydroxylation of *N,N*-dimethylacrylamide (**1i**): To a magnetically stirred solution of **1i** (5.0 mL, 4.81 g, 48.5 mmol) and chloramine T trihydrate (14.0 g, 49.7 mmol) in MeCN (50 mL) and water (50 mL) was added $K_2OsO_2(OH)_4$ (89.3 mg, 0.24 mmol, 0.50 mol%). The color changes described for procedure A were noted, and the reaction mixture was stirred overnight at room temperature. TLC (silica, R_f(**1i**) = 0.27, R_f(products) = 0.40, EtOAc) revealed that the olefin had been completely consumed. Na_2SO_3 (10 g) and ethyl acetate (50 mL) were added and the triphasic mixture was vigorously stirred for a further hour, during which time the solids completely dissolved. After separating the phases and extracting the aqueous phase with ethyl acetate (2 × 50 mL), the combined organic phases were shaken with brine (50 mL), dried over Na_2SO_4, filtered, and concentrated under reduced pressure to yield an oil. Trituration of the oil with diethyl ether (ca. 30 mL) followed by filtration afforded the solid product (13.8 g, 99%) as a mixture of **2i** and **3i** (10:1). Recrystallization of a portion of this mixture from MeOH afforded analytically pure **2i** as colorless needles: m.p. 123–124 °C (sealed tube); ^{1}H NMR (400 MHz, $CDCl_3$, TMS): δ = 7.76–7.72 (m, 2H), 7.33–7.30 (m, 2H), 5.24–5.21 (m, 1H), 4.47–4.42 (m, 1H), 3.84 (d, J = 7.4 Hz, 1H), 3.28 (ddd, J = 13.2, 8.2, 3.2 Hz, 1H), 3.00 (s, 3H), 2.97 (s, 3H), 2.89 (ddd, J = 13.2, 7.4, 4.4 Hz, 1H), 2.43 (s, 3H); elemental analysis calcd for $C_{12}H_{18}N_2O_4S$: C 50.34, H 6.34, N 9.78; found: C 50.34, H 6.25, N 9.79.

Preparation of aziridines **4**, as described for *rac*-**4b**: A magnetically stirred solution of a mixture of **2b** and **3b** (5.0:1, 2.10 g, 5.8 mmol) and Et_3N (1.1 mL, 7.9 mmol) in CH_2Cl_2 (30 mL) under N_2 was cooled in an ice/H_2O bath, and methanesulfonyl chloride (0.58 mL, 7.5 mmol) was added dropwise over 30 min. After the addition was complete, stirring was continued at 0 °C for 30 min, before 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU, 2.6 mL, 17.4 mmol) was added and the ice/water bath removed. After 15 min TLC (silica, R_f(**4b**) = 0.44, EtOAc/hexane 4/1) indicated that aziridine formation was complete. The reaction mixture was extracted with 2 N aqueous HCl (30 mL) followed by saturated aqueous $NaHCO_3$ (30 mL). The organic layer was dried over anhydrous Na_2SO_4, filtered, and concentrated under reduced pressure. Flash column chromatography on silica gel with EtOAc/hexane (3/1) as the eluent and subsequent removal of solvent provided **4b** (1.90 g, 95%) as a colorless solid: m.p. 130–131 °C (sealed tube); ^{1}H NMR (400 MHz, $CDCl_3$, TMS): δ = 7.98–7.95 (m, 2H), 7.35–7.33 (m, 2H), 7.30–7.26 (m, 5H), 4.14 (d, J = 7.5 Hz, 1H), 3.79 (d, J = 7.5 Hz, 1H), 2.90 (s, 3H), 2.70 (s, 3H), 2.42 (s, 3H); elemental analysis calcd for $C_{18}H_{20}N_2O_3S$: C 62.77, H 5.85, N 8.13; found: C 62.61, H 5.69, N 8.24.

[15] Another advantage of racemates, pointed out by a reviewer, is that modern preparative chiral HPLC often enables access to both enantiomers. The pharmaceutical industry now favors this approach for quick "enantiodeconvolutiuon" of biological activity.

Di-, Tri-, and Tetranuclear Alkoxyaluminum Hydrides

Heinrich Nöth,* Andreas Schlegel, Jörg Knizek, and Holger Schwenk

Little is known about the degree of association of alkoxyalanes in the solid state or in solution. Seminal papers published in the 1960s describe reactions of short-chain alcohols with aluminum hydride.[1] Determination of the molecular mass proved that tBuOAlH$_2$ and (tBuO)$_2$AlH are dimeric in benzene. Recent X-ray structure analysis ascertained that the association occurs via an Al_2O_2 four-membered ring.[2] The syntheses of alkoxyalanes are described by Equations (1) and (2).

$$AlH_3 + HOR \longrightarrow H_2Al(OR) + H_2 \quad (1)$$

$$AlH_3 + 2\,HOR \longrightarrow HAl(OR)_2 + 2\,H_2 \quad (2)$$

Although it was demonstrated that the amount of hydrogen liberated during the reaction is equivalent to the molar amount of the alcohol, the composition of the product is dependent on the size and the branching of the alkyl

[*] Prof. Dr. H. Nöth, Dipl.-Chem. A. Schlegel, Dipl.-Chem. J. Knizek, Dr. H. Schwenk

Fax: Int. code + (89) 590-2451

group R.[1] Mono- and disubstituted alkoxyalanes containing sterically less demanding *n*-alkyl groups disproportionate according to Equations (3) and (4). In addition, association to units of higher molecular order rises as the alkyl group becomes smaller.[1]

$$2(RO)AlH_2 \xrightleftharpoons{Et_2O} AlH_3 + (RO)_2AlH \quad (3)$$

$$2(RO)_2AlH \xrightleftharpoons{Et_2O} Al(OR)_3 + (RO)AlH_2 \quad (4)$$

The electron-deficient alkoxyalanes $(RO)_{3-n}AlH_n$ are intermolecularly stabilized by dimerization, oligomerization, or polymerization with formation of oxo or hydride bridges, thus increasing the coordination at the Al centers to four or five. Mixed polymers may be formed, as suggested but not structurally proven.[1] Disproportionation and association are at first sight two independent phenomena. However, they might cooperate and, as a consequence, make the isolation of analytically pure, well-defined compounds more difficult. The use of sterically demanding alcohols reduces the tendency of the alkoxyalanes to disproportionate and to oligomerize, as demonstrated for tBuOAlH$_2$ and (tBuO)$_2$AlH.[2] Nevertheless, ROAlH$_2$ with R = 2,6-di-*tert*-butyl-4-methylphenol can be obtained as an Me$_3$N adduct which is present both as a monomer and a hydride-bridged dimer in the crystal lattice.[3]

We now demonstrate that additional structural patterns emerge depending on the steric requirement of the alkyl group R. This is documented by compounds **1**–**4**, which are obtained by allowing the corresponding alcohols to react with AlH$_3$ in diethyl ether [Eqs. (1) and (2)].

[{(tBu)$_2$(Me)COAlH$_2$}$_2$] **1** [{(tBu)(Me)(H)COAlH$_2$}$_4$] **2**

[(iPrO)$_2$AlH{(iPrO)AlH$_2$}$_2$] **3a** Li[(tBuCH$_2$O)$_5$Al$_3$H$_5$]·Et$_2$O **4**

The reaction of tBu$_2$(Me)COH with AlH$_3$ in diethyl ether [Eq. (1)] yields the respective monoalkoxyalane, which is a dimer according to its mass spectrum and X-ray structure (Figure 1). Although the product of the 1:1 reaction of

tBuMeCHOH with AlH$_3$ is dimeric in the gas phase, as ascertained from its mass spectrum, the X-ray structure analysis reveals that in **2** two dimers are associated through two hydride bridges to form a tetranuclear alkoxyalane in the solid state (see Figure 2).

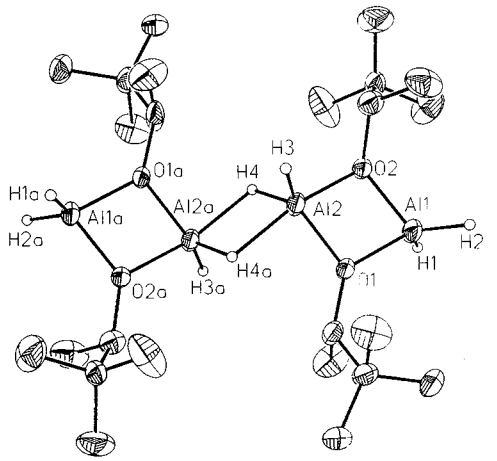

Figure 2. ORTEP representation of the molecular structure of **2**. Selected atomic distances [Å]: Al1–H1 1.38(7), Al1–H2 1.57(5), Al2–H3 1.49(5), Al2–H4 1.60(4), Al2–H4a 1.85(4), Al2 ··· Al2a 2.731(3), Al1–O1 1.837(3), Al2–O1 1.819(3), Al1–O2 1.808(3), Al2–O2 1.864(3). Selected bond angles [°]: O1-Al1-O2 80.9(1), O1-Al2-O2 79.9(1), Al1-O1-Al2 99.7(2), Al1-O2-Al2 99.1(2), H1-Al1-H2 123(2), H3-Al2-H4 116(2), H4-Al2-O2 97(2), H4-Al2-O1 120(2), H3-Al2-O1 123(2), H4a-Al2-O2 161(2).

In contrast, the analogous reaction with isopropyl alcohol does not lead to dimeric isopropoxyalane. Only part of the product can be sublimed under vacuum, and the most volatile component turned out to be the trinuclear complex **3a** (see Figure 3), which can be looked at as a mixed oligomer of two molecules of iPrOAlH$_2$ with one molecule of (iPrO)$_2$AlH. Complex **3a** is formed by partial disproportionation of iPrOAlH$_2$ in solution [Eq. (3)]. However, the sublimate not only furnishes single crystals of **3a** but also its chain polymer **3b**, in which the Al$_3$(OiPr)$_4$H$_5$ units are connected through hydride bridges (see Figure 4). Both species exhibit two identical ^{27}Al NMR signals in a 2:1 ratio for tetra- and pentacoordinated aluminum atoms. Therefore, there is only one trinuclear species present in solution. The IR spectrum shows bands for both terminal (1845 and 1824 cm^{-1}) and bridging hydrogen atoms (1785 and 1665 cm^{-1}). Complex **3a** is obtained in yields of over 90% by allowing 3 mol of AlH$_3$ to react with 4 mol of isopropyl alcohol.[4]

The solubility of ROAlH$_2$ and (RO)$_2$AlH increases when a slight excess of LiAlH$_4$ is applied in the preparation of AlH$_3$. This is particularly noticeable for the reaction of neopentyl alcohol with AlH$_3$ in diethyl ether [Eq. (2)]. Under these conditions—formally depicted in Equation (5)—compound **4** is produced, which can be formulated as Li[AlH$_3$(OCH$_2$ tBu)]·[(tBuCH$_2$O)$_2$AlH]$_2$·Et$_2$O.

$$LiAlH_4 + 2\,AlH_3 + 5\,t\text{BuCH}_2\text{OH} \longrightarrow \mathbf{4} + 5\,H_2 \quad (5)$$

The structures of the new alkoxyalanes were determined by X-ray crystallography. The structure of **1** (see Figure 1) is similar to that of *tert*-butoxyalane.[2] The molecule posesses a crystallographic center of inversion and an acute O-Al-O angle of 82.73(6)°, which corresponds to 81.0(2)° for *tert*-butoxyalane.[2] The sum of bond angles at the oxygen atoms is 359.6°, suggesting sp^2 hybridization for the oxygen atoms. Steric effects are most likely responsible for the large Al(1a)-O1-C1 bond angle of 138.6(1)°, because both *tert*-butyl groups at C1 point in the direction of Al(1a), whereas the sterically less demanding CH$_3$ group at C1 is associated with the much smaller Al1-O1-C1 bond angle of 123.7(1)°. While there are no intermolecular interactions in the lattice of **1** which exceed

those of van der Waals contacts, in the case of **2** two molecules of $[\{(t\mathrm{Bu})(\mathrm{Me})(\mathrm{H})\mathrm{COAlH_2}\}_2]$ associate through Al–H bridges to form "twin molecules" (see Figure 2). An analogous structure was recently reported by Raston et al. for $[\{t\mathrm{Bu_2}(\mathrm{H})\text{-}\mathrm{COAlH_2}\}_4]$.[5]

There are two Al atoms of coordination number 4 and two of coordination number 5 in **2**. The bonding parameters of the Al_2O_2 four-membered rings correspond closely to those of **1**; in particular, there is no noticeable elongation of the Al–O bond to the pentacoordinated Al centers. These feature a distorted trigonal-bipyramidal environment. Atoms H3, H4, and O1 are in the equatorial positions with bond angles close to 120°, while O2 and H4a occupy the axial positions. The hydrogen-brides are weak and asymmetric, similar to those in dimeric $AlH_3 \cdot THF$.[6] Consequently, for **2** only one signal for tetracoordinated Al ($\delta(^{27}\mathrm{Al}) = 121$) is observed in benzene and diethyl ether. The *tert*-butyl groups are in an anti-periplanar orientation with respect to the plane of the Al_2O_2 ring. Within the dimeric units, each asymmetrically substituted C atom posesses the same absolute stereoconfiguration: (*S*) in one unit, and (*R*) in the other. Consequently, there are double sets of ^1H and ^{13}C resonances.

$Al_3(O\mathit{i}\mathrm{Pr})_4H_5$ was isolated in two different modifications **3a** and **3b** (Figures 3 and 4, respectively). In **3a** the sum of angles for bonds from Al1 to O1, O4, and H2 is 360°, and the O2-Al1-O3 bond angle is 168°. This indicates the presence of a distorted trigonal-bipyramidal Al center. Accordingly, the Al–O bonds to the apical O atoms are longer. The Al_2O_2 four-membered rings are asymmetric inspite of their planarity. Due to the open H-Al-H bond angles (av 118.4°), there is considerable deviation from a tetrahedral geometry of the ligands. The hydrogen-bridged species **3b** (Figure 4) shows almost the same bonding parameters for the central Al1 atom as **3a**. The bond angles of Al2 and Al3, which show trigonal-bipyramidal configuration, compare well with the related coordination sphere of Al2 in **2**.

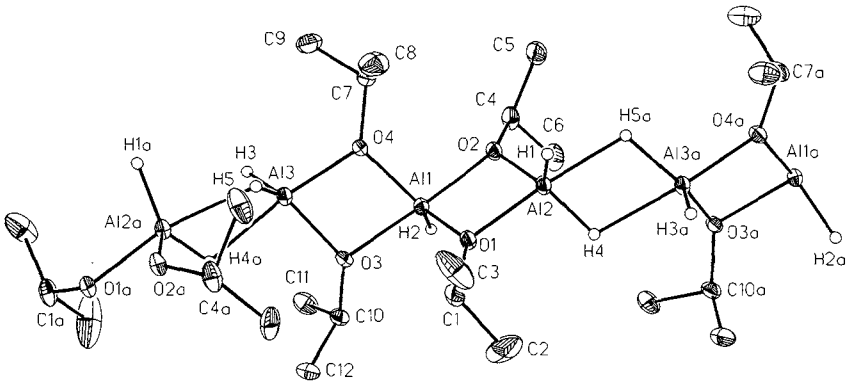

Figure 4. ORTEP representation of the molecular structure of **3b**. Selected atomic distances [Å]: Al1–H2 1.52(4), Al2–H1 1.47(4), Al2–H4 1.51(5), Al2–H5a 2.04(4), Al3–H3 1.50(4), Al3–H5 1.55(4), Al3–H4a 2.04(4), Al1–O1 1.830(3), Al2–O1 1.885(3), Al1–O4 1.827(3), Al3–O4 1.877(3), Al1–O2 1.938(3), Al2–O2 1.808(3), Al1–O3 1.952(3), Al3–O3 1.815(3), Al1 ··· Al2 2.885(1), Al1 ··· Al3 2.885(2). Selected bond angles [°]: Al1-O1-Al2 101.9(1), Al1-O2-Al2 100.7(1), Al1-O3-Al3 99.7(1), Al1-O4-Al3 102.1(1), O1-Al1-O2 77.7(1), O1-Al2-O2 79.7(1), O3-Al1-O4 77.8(1), O3-Al3-O4 80.0(1), O1-Al1-O3 97.8(1), O1-Al1-O4 114.7(1), O2-Al1-O3 171.0(1), O2-Al1-O4 96.8(1), H1-Al2-H4 119(2), H3-Al3-H5 117(2), H2-Al1-O1 122(2), H2-Al1-O2 97(1), H2-Al1-O3 92(1), H2-Al1-O4 124(2), H5a-Al2-O1 168(1), H4-Al2-O2 118(2), H1-Al2-O2 121(2), H5-Al3-H4a 72(2), H5a-Al2-H4 73(2), Al3-H5-Al2a 103(2), Al2-H4-Al3a 103(2).

The composition and the two ^{27}Al NMR signals at $\delta = 125$ and 81 indicate that **4** is an unusual compound (Figure 5). In contrast to the situation in the alkoxyalanes discussed so far, all Al atoms in **4** are pentacoordinated. This compound can be looked at as being built from one molecule of H_2AlOR with two molecules of $HAl(OR)_2$ by Al–O coordination to result

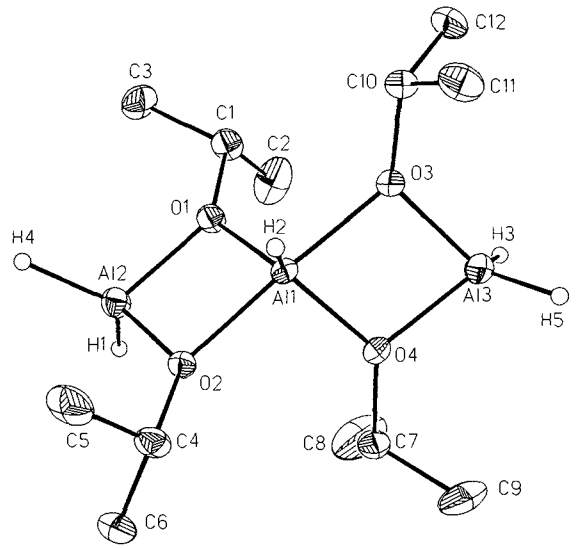

Figure 3. ORTEP representation of the molecular structure of **3a**. Selected atomic distances [Å]: Al1–H2 1.52(4), Al2–H1 1.54(4), Al2–H4 1.50(4), Al3–H3 1.52(5), Al3–H5 1.44(5), Al1–O1 1.832(3), Al2–O1 1.832(3), Al1–O4 1.839(3), Al3–O4 1.833(3), Al1–O2 1.918(3), Al2–O2 1.802(3), Al1–O3 1.925(3), Al3–O3 1.801(3), Al1 ··· Al2 2.842(2), Al1 ··· Al3 2.846(2). in a six-membered ring with chair configuration. All Al–O bridges are of almost the same length. The endocyclic O-Al-O bond angles approach that of a tetrahedron. In addition, two exocyclic OR groups coordinate through their oxygen atoms to the lithium center of a "lithium hydride molecule".

The hydride ion of the "LiH component" lies above the Al atoms of the Al_3O_3 chair. It coordinates not only to the Li center but also to all three Al atoms. As far as we are aware, this is the first molecular compound with a tetracoordinated hydridic hydrogen atom. The distortion from a tetrahedral environment is small. Since the Al–H distances are about 0.5 Å longer than those for the terminal Al–H units, these bonds are weak. Moreover, we conclude that the $H_2Al(OR)_2$ group is a weaker hydride acceptor than the $HAl(OR)_3$ group, because the Al–H distance to the central hydride is longer (2.02 Å) than that of the $HAl(OR)_3$ groups (av 1.84 Å). The ^{27}Al NMR signal at $\delta = 81$ is assigned to the latter.

The examples presented here demonstrate that the chemistry and structural chemistry of alkoxyalanes is much more variable than hitherto assumed. Mixed oligomers $Al_n(OR)_{3n-m}H_m$ may form which can bind LiH with formation of alkoxyhydrido aluminates. We assume that alkoxyalanes can be developed into useful reagents for selectively reducing functional organic groups.

Experimental Section

All reactions were performed in an atmosphere of nitrogen using dry solvents. ^{27}Al NMR spectra: 70 MHz, 25 °C, C_6D_6; IR spectra: Nujol/Hostaflon; all compounds gave correct elemental analyses.

1: A solution of $AlCl_3$ (0.57 g, 4.3 mmol) in Et_2O (10 mL) was added to a stirred solution of $LiAlH_4$ (0.49 g, 12.9 mmol) in Et_2O (10 mL) at 0 °C[7]. A solution of tBu_2MeCOH (2.71 g, 17.1 mmol) in Et_2O (15 mL) was then added dropwise to the suspension. Hydrogen gas formed. After the suspension was stirred for 2 h, the insoluble material (LiCl) was removed by filtration (G4 glass frit). Et_2O was removed from the filtrate, and the residue dried in vacuo. Compound **1** crystallized from Et_2O/pentane (4/1) at −20 °C as colorless prisms [8]; yield 2.38 g (74.3 %), m.p. 160 °C (decomp). ^{27}Al NMR: $\delta = 117$ ($h_{1/2} = 3834$ Hz); IR: $\tilde{\nu} = 1872$ (vs), 1849 cm^{-1} (vs, $\nu_{as,s}(AlH_2)$); MS (70 ev): $m/z = 372$ [M^+], 315 [$M^+ - t$Bu].

2: A solution of $AlCl_3$ (1.66 g, 12.5 mmol) in Et_2O (40 mL) was added to a stirred solution of $LiAlH_4$ (1.42 g, 37.4 mmol) in Et_2O (20 mL) at 0 °C[7]. The resulting suspension was then treated with a solution of *t*BuMeCHOH (5.09 g, 6.2 mL, 49.8 mmol) in Et_2O (20 mL). Hydrogen gas was liberated. The suspension was stirred for 5 h, the insoluble material removed by filtration (G4 glass frit), the solvent removed from the filtrate, and the colorless residue dried in vacuo. Sublimation at 45 °C (bath temperature) and $3 \cdot 10^{-9}$ bar yielded colorless crystals of **2** [8]; yield 5.12 g (78.6 %); m.p. 72–75 °C. ^{27}Al NMR: $\delta = 121$ ($h_{1/2} = 3695$ Hz); IR: $\tilde{\nu} = 1854$ (sh), 1841 (vs; $\nu_{as,s}(AlH_2)$), 1645 (w, br), 1578 (w, br), 1531 cm^{-1} (w, br; ν(AlH bridge)]; MS (70 eV): $m/z = 260$ [M^+] for the dinuclear species, 259 [$M^+ - H$], 203 [$M^+ - t$Bu], 175 [$M^+ - t$BuCHCH$_3$], 159 [203 − CH_3CHO], 117 [161 − CH_3CHO].

3a and **3b**: A solution of $AlCl_3$ (1.62 g, 12.2 mmol) in Et_2O (30 mL) was added to a stirred solution of $LiAlH_4$ (1.39 g, 36.5 mmol) in Et_2O (20 mL) at 0 °C[7]. The resulting suspension wsa treated with *i*PrOH (2.92 g, 3.72 mL, 48.6 mmol) in Et_2O (20 mL) at 10 °C. Hydrogen was liberated. After the reaction mixture was stirred for 3 h, the insoluble material was removed by filtration (G4 glass frit), and the solvent removed from the filtrate under vacuum. Product **3a** was obtained from the colorless solid residue by sublimation at 35 °C (bath temperature) and at $1 \cdot 10^{-3}$ bar [8]. Product **3b** appeared as a second fraction subliming at 40 °C and 5×10^{-3} bar [8]; total yield 1.22 g (15.5 %). Softening range of **3a** and **3b**: 49–61 °C. ^{27}Al NMR: $\delta = 126$ ($h_{1/2} = 2118$ Hz), 60 ($h_{1/2} = 1283$ Hz); IR: $\tilde{\nu} = 1842$ (vs), 1825 (vs), 1785 (s, br; $\nu_{as,s}(AlH_a)$); 1665 cm^{-1} (m, br; $\nu(AlH_b)$).

4: A solution of $AlCl_3$ (1.59 g, 11.9 mmol) in Et_2O (25 mL) was added to a stirred solution of $LiAlH_4$ (1.57 g, 41.4 mmol) in Et_2O (20 mL) at 10 °C[7], followed by $tBuCH_2OH$ (8.41 g, 95.4 mmol) in Et_2O (30 mL). Hydrogen was liberated. Stirring was continued for 4 h at ambient temperature. Then the insoluble material was separated by filtration (G4 glass frit), and extracted twice with pentane (2 × 20 mL). Fractional crystallization at 2 °C yielded colorless needles of **4** [8]; yield 2.48 g (72.5 %); m.p. 104 °C (decomp). ^{27}Al NMR: $\delta = 125$ (br), 81 (br); ^7Li NMR (105 MHz, 25 °C, C_6D_6): $\delta = 1.09$: IR: $\tilde{\nu} = 1839$ (sh), 1821 (vs; $\nu_{as,s}(AlH_t)$), 1797 (m), 1739 cm^{-1} (w; $\nu_{as,s}(AlH_b)$).

[8] Data for the X-ray structure determinations were collected with a Siemens P4 diffractometer equipped with a CCD area detector ($Mo_{K\alpha}$, $\lambda = 0.71073$ Å). The reflections were recorded in a total of 1200 frames with $\Delta\varphi = 0.3°$ at two different χ settings. The structures were solved with direct methods using the program XS (Siemens). The structure was refined with the least-squares method (program SHELXL93, G. M. Sheldrick, Göttingen, Germany, **1993**). Carbon-bound hydrogen atoms were included in the refinement with a riding model with fixed isotropic temperature parameter U, and the positions of the Al- and Li-bound hydrogen atoms were freely refined. The thermal ellipsoides in the Figures are depicted at a probability level of 25 %. Carbon-bound hydrogen atoms are omitted for clarity. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100400. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code + (1223) 336-033; e-mail: deposit@chemcrys.cam.ac.uk). **1**: $C_{20}H_{46}Al_2O_2$, colorless prism, $0.5 \times 0.4 \times 0.4$ mm^3, monoclinic, space group $P2_1/c$, $a = 8.3389(2)$, $b = 12.1377(2)$, $c = 11.7629(2)$ Å, $\beta = 106.908(1)°$, $Z = 4$, $V = 1139.12(4)$ Å^3, $\rho_{calcd} = 1.086$ g cm^{-3}, $\mu = 0.137$ mm^{-1}, $F(000) = 416$, $T = 193(2)$ K, $2\theta = 4.94 - 58.40°$; of 6394 reflections recorded, 2233 were unique (R(int) = 0.0585) and 1242 observed with $F > 4\sigma(F)$; 124 parameters were refined. $R = 0.0372$, $R2 = 0.0858$, GOF = 1.125; $\Delta\rho = 0.201$ e Å^{-3}. **2**: $C_{24}H_{60}Al_4O_4$, colorless block, $0.45 \times 0.35 \times 0.3$ mm^3, monoclinic, space group $P2_1/n$, $a = 11.6718(4)$, $b = 12.2962(4)$, $c = 12.1433(4)$ Å, $\beta = 101.291(1)°$, $Z = 4$, $V = 1709.1(1)$ Å^3, $\rho_{calcd} = 1.012$ Mg m^{-3}, $\mu = 0.159$ mm^{-1}, $F(000) = 576$, $T = 233$ K, $2\theta = 4.42 - 57.76°$; of 8992 reflections recorded, 3185 were unique (R(int) = 0.0767) and 1495 observed with $F > 4\sigma(F)$; 169 parameters were refined. $R = 0.0811$, $R2 = 0.1842$, GOF = 1.099; $\Delta\rho = 0.391$ e Å^{-3}. **3a**: $C_{12}H_{33}Al_3O_4$, colorless block, $0.37 \times 0.22 \times 0.2$ mm^3, orthorhombic, space group $P2_12_12_1$, $a = 9.405(1)$, $b = 11.492(1)$, $c = 18.845(1)$ Å, $Z = 4$, $V = 2036.8(2)$ Å^3, $\rho_{calcd} = 1.051$ Mg m^{-3}, $\mu = 0.192$ mm^{-1}, $F(000) = 704$, $T = 213(3)$ K, $2\theta = 4.16 - 54.76°$; of 6858 reflections, 3788 were unique (R(int) = 0.0518) and 3391 observed with $F > 4\sigma(F)$; 200 parameters were refined. $R = 0.0537$, $R2 = 0.1144$, GOF = 1.180; $\Delta\rho = 0.317$ e Å^{-3}. **3b**: $C_{12}H_{33}Al_3O_4$, colorless prism, $0.4 \times 0.27 \times 0.25$ mm^3, monoclinic, space group $P2_1/c$, $a = 16.7180(7)$, $b = 8.3793(4)$, $c = 15.0832(6)$ Å, $\beta = 110.625(1)°$, $Z = 4$, $V = 1977.5(2)$ Å^3, $\rho_{calcd} = 1.083$ Mg m^{-3}, $\mu = 0.197$ mm^{-1}, $F(000) = 704$, $T = 193$ K, $2\theta = 2.60 - 54.94°$; of 10011 reflections recorded, 3625 were unique (R(int) = 0.1147) and 2296 observed with $F > 4\sigma(F)$; 199 parameters refined. $R = 0.0723$, $R2 = 0.1267$, GOF = 1.203; $\Delta\rho = 0.382$ e Å^{-3}. **4**: $C_{29}H_{70}Al_3LiO_6$, colorless needles, $0.4 \times 0.24 \times 0.2$ mm^3, orthorhombic, space group $Pbca$, $a = 20.447(3)$, $b = 18.1972(1)$, $c = 21.833(6)$ Å, $Z = 8$, $V = 8123(2)$ Å^3, $\rho_{calcd} = 0.986$ Mg m^{-3}, $\mu = 0.124$ mm^{-1}, $F(000) = 2672$, $T = 203(3)$ K, $2\theta = 3.52 - 58.28°$; of 38008 reflections recorded, 8395 were unique (R(int) = 0.0765) and 4558 observed with $F > 4\sigma(F)$; 400 parameters were refined. $R = 0.0655$, $R2 = 0.1399$, GOF = 1.143; $\Delta\rho = 0.543$ e Å^{-3}.

Synthesis and Structure of a Tetragallane $[R_4Ga_4I_3]^-$ and a Polyhedral Nonagallane $[R_6Ga_9]^-$**

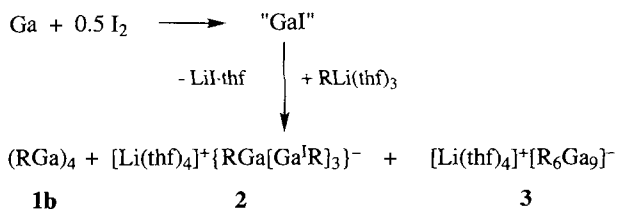
Wolfgang Köstler and Gerald Linti*

Dedicated to Professor Gottfried Huttner on the occasion of his 60th birthday

Compounds with metal–metal bonds have a special fascination and with a growing number of atoms, they provide an insight into the transition from molecules to metals. The digallanes(4) R_4Ga_2,[1] a cyclotrigallane $R_3Ga_3M_2$ ($R = 2,6\text{-}Mes_2C_6H_3$, M = Na, K),[2] a pentagallane $[Cl_2Ga(OEt_2)]_3[Cl\text{-}Ga(OEt_2)_2]Ga$,[3] and a cyclooctagallane $Ga_8I_8(PEt_3)_6$[4] represent structurally investigated electron-precise oligogallanes. The tetragallanes(4) $(RGa)_4$ [**1a**: $R = C(SiMe_3)_3$, **1b**: $R = Si(SiMe_3)_3$[5]] with a tetrahedral framework of gallium atoms are the only polyhedral molecular compounds of gallium that are considered electron deficient. The mixture (neopentyl-Ga)$_n$ ($n = 8.9-10.5$) obtained by reduction of (neopentyl)$_2$GaCl may also be classified in this group.[6]

Compounds **1a** and **1b** were prepared by reaction of gallium(II) halides $Ga_2X_4 \cdot 2$dioxane with three equivalents RLi; however, at best one third of R and half of the gallium used is found in the desired products. A more economical synthesis should be possible from gallium(I) derivatives. We describe herein the reaction of "GaI"—available from gallium and iodine in a simple manner[7]—with tris(trimethylsilyl)silyllithium (= hypersilyllithium).[8] The former has already been employed as the gallium(I) source in the preparation of $[Tp^{tBu2}]Ga$ (Tp^{tBu2} = tris(3,5-di-*tert*-butylpyrazolyl)hydroborate.[9]

Freshly prepared "GaI" was treated at −78 °C in toluene with $Li(thf)_3Si(SiMe_3)_3$ (Scheme 1), affording a dark red solution. After the reaction mixture had been concentrated to



Scheme 1. R = $Si(SiMe_3)_3$.

dryness, **1b** crystallized from a violet-colored pentane extract. Prior to that, yellow crystals of **2** can be isolated. This compound forms preferentially if the Ga:I:hypersilyl ratio is changed from 1:1:1 to 2:1:0.7. This reproducible variation in the product distribution gives a clear indication of the problem associated with the "GaI" used. Evidently, it is a mixture of gallium subiodides, the composition of which requires further study. First indications are delivered by a detailed analysis of the reaction products. If the black residue left over after filtration is washed with toluene after the extraction with pentane, a dark red solution results, from which after separation of colorless crystals of lithium iodide · thf, black crystals of diamagnetic **3** can be obtained. The X-ray crystal structure analysis of the tetragallane derivative **2**[10] shows that it crystallizes in the monoclinic space group $P2_1/c$, and exhibits a cubane-type arrangement of four Ga atoms and three iodine atoms (Figure 1). One corner of the cube

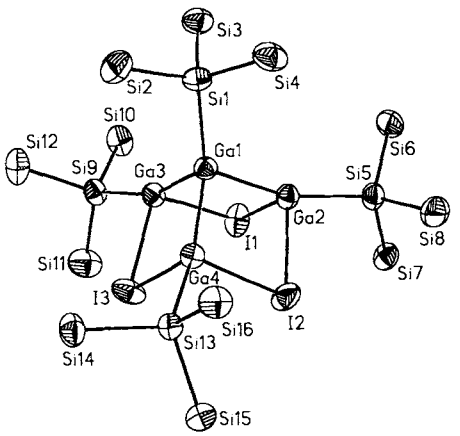


Figure 1. Crystal structure of the anion in **2**. The methyl groups have been omitted for clarity. Selected bond lengths [pm] and angles [°]: Ga1–Ga2 253.51(7), Ga1–Ga3 253.56(7), Ga1–Ga4 252.88(8), I1–Ga2 285.70(7), I1–Ga3 287.35(7), I2–Ga4 283.23(7), I2–Ga2 285.99(8), I3–Ga3 285.43(8), I3–Ga4 285.94(7), Ga1–Si1 242.23(14), Ga2–Si5 246.83(14), Ga3–Si9 246.90(14), Ga4-Si13 245.70(13), Si–Si 232.8–236.0; Ga4-Ga1-Ga2 94.05(3), Ga4-Ga1-Ga3 94.28(2), Ga2-Ga1-Ga3 94.52(2), Ga-I-Ga 81.04(2)–81.22(2), Ga1-Ga-I 91.90(2)–92.75(2), I-Ga-I 96.85(2)–99.39(3).

remains unoccupied. The three Ga–Ga edges are of equal length within the standard deviation criteria (av Ga–Ga: 253.3 pm). This value is in the typical range for Ga–Ga bonds in digallanes, for example, $[Ga_2Cl_2(hypersilyl)_2]_2$ (d_{Ga-Ga} = 250.5 pm).[11] The iodine bridges are nearly symmetric [$d_{Ga-I} = 283.2(1)-287.4(1)$ pm]. The Ga–I distances are about 30 pm longer than the terminal Ga–I bonds in $[GaI_4]^-$,[12] but are similar to the bridging ones in $Ga_8I_8(PEt_3)_6$.[4] The Ga1–Si1 distance [242.4(1) pm] is shorter than the other Ga–Si bonds (av 246.6 pm). This difference, which is accompanied by a slight reduction in the Si-Si-Si angles from 108.1° (on an average) at Si1 to 106.4° at Si5, Si9, and Si13, may be explained in part by the steric demand of the iodine atoms; however, it should not be overemphasized, because Ga–Si bond lengths are known to vary considerably.[13]

The X-ray crystal structure analysis of **3**[10] shows that it crystallizes in the monoclinic space group *C*2/*c* and verifies the composition as $[Li(thf)_4]^+$ $[(hypersilyl)_6Ga_9]^-$. The anions form channels in which the counterions are intercalated in a highly disordered manner. The C_2-symmetric cluster anion (Figure 2) is described as a slightly distorted pentagonal bipyramid of Ga atoms, two equatorial edges of which are bridged by further Ga atoms. Six of the Ga atoms, namely the apical ones, two equatorial, and the bridging ones, bear hypersilyl groups. Ga2, Ga3, and Ga4 form together with the Ga atoms at their symmetry-equivalent positions a five-membered ring, which deviates only marginally from planarity. Thus, Ga2 resides only 22 pm above the Ga3-Ga4-Ga3A plane. The bridging Ga atoms Ga5 and Ga5A also lie only slightly (11 pm) outside this plane. The distances (Figure 3) of

[**] The Chemistry of Gallium, Part 11. We thank Prof. D. Fenske and Prof. P. Klüfers for their help with the crystal structure investigations, and the Deutsche Forschungsgemeinschaft for its financial support. Part 10: G. Linti, R. Frey, *Z. Anorg. Allg. Chem.* **1997**, *623*, 531–538.

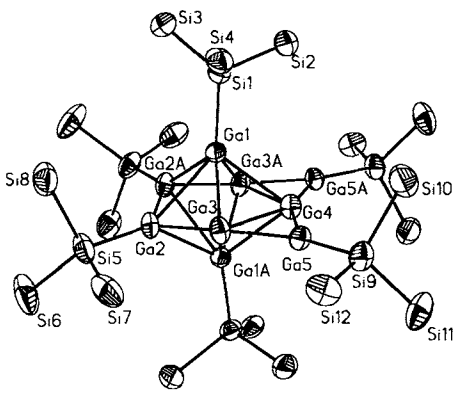

Figure 2. Crystal structure of the cluster anion in **3**. The methyl groups have been omitted for clarity.

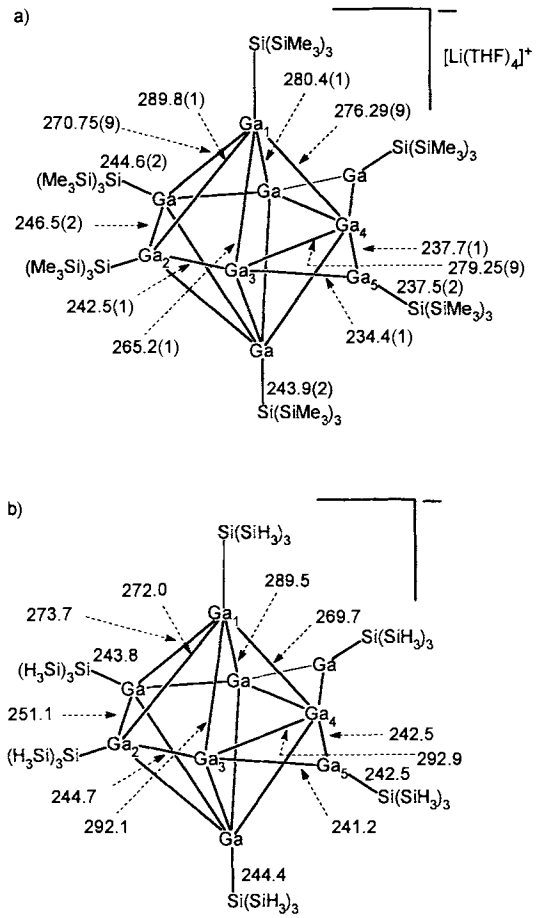

Figure 3. a) Selected distances [pm] in **3** determined by X-ray crystallography [pm]; b) results of the DFT calculation on $[\{(H_3Si)_3Si\}_6Ga_9]^-$

the apical Ga atoms to the basal ones range between 265 and 290 pm. The average distance (276.5 pm) is equivalent to the longer distances in elemental gallium. Within the five-membered ring four short distances (242.5, 246.5 pm) are found together with the long Ga3–Ga4 distance (279.2 pm). In contrast, the Ga3–Ga5 and Ga4–Ga5 distances (234.4 and 237.7 pm, respectively) to the edge-bridging gallium centers are very short. Comparatively speaking, the Ga–Ga distances in the electron-precise **2** are shorter by 16 and 6 pm, respectively, than those in the electron-deficient clusters **1a**[5a] and **1b**,[5b] which accounts for the transition from two-center, two-electron (2c–2e) bonds in **2** to multicenter bonds. The Ga–Ga distances in the nonclassical **3** (234.4–290 pm) cover a wide range, which is dependent on the varying coordination numbers 3 to 6 and the different surroundings of the gallium centers. In the Ga_{12} icosahedra present in the three-dimensional network of $Na_xMg_{5-x}Ga_9$ the Ga–Ga distances range between 269 and 273 pm.[14]

For cluster **3** ($n-1=8$) pairs of framework bonding electrons are available, if RGa is considered to contribute two electrons and the gallium atoms not bearing silyl substituents are considered to contribute one electron; thus, according to Wade–Rudolph–Mingos rules, a bicapped pentagonal bipyramid would be expected. Density functional theory (DFT) calculations[15] on $[Ga_9R_6]^-$ (R = H, SiH_3, $Si(SiH_3)_3$) show, in spite of the drastic reduction of the steric demand of the substituents, a good agreement of the structure of the Ga_9 framework with that of **3**. In Figure 3 the results of the crystal structure analysis are compared with the results of the quantum-chemical calculations. Consideration of the bonding properties with the aid of Roby–Davidson population analyses reveals that large three-center bond contributions are found on the polyhedral faces and the attached "ears". This is in accord with a description, adapted from borane clusters, with eight 2c–2e bonds and six 3c–2e bonds for the Ga_9Si_6 framework.

The synthesis of compound **3** has afforded a cluster with an unprecedented structure, in which the average oxidation state of gallium is 0.56. This shows—bearing in mind the still unknown constitution of the used "GaI"—the fine line between disproportionation to gallium and gallanes in higher oxidation states on the one hand and stabilization of lower oxidation states on the other hand. Compound **2**, which is isoelectronic to a trigallylarsane[16] $As[Ga(R)X]_3$, is a promising building block for further gallium cluster compounds with heteroatoms.

Experimental Section

a) A solution of $Li(thf)_3Si(SiMe_3)_3$ (1.42 g, 3.0 mmol) in toluene (20 mL) was added dropwise to an intensively stirred suspension of freshly prepared "GaI" (0.59 g, 3.0 mmol) in toluene (15 mL) at −78 °C. The mixture was allowed to warm to ambient temperature over a period of 3 h and was then stirred for a further 12 h. After evaporation of the reaction solution to dryness the residue was extracted with pentane (30 mL) and then with toluene (20 mL). Fractional crystallization from pentane at 0 °C afforded **1b** (0.38 g, 40%) and **2** (0.18 g, 12%). Compound 3 (0.09 g, 11%) crystallized after LiI·THF from the concentrated toluene fraction.

b) In the analogous reaction of "GaI" (0.77 g, 2.9 mmol with respect to GaI)—in the preparation of which a 100% excess of gallium was used—with $Li(thf)_3Si(SiMe_3)_3$ (0.96 g, 2.0 mmol) **1b** (0.07 g, 8%), **2** (0.55 g, 39%), and **3** (0.07 g, 9%) were isolated.

2: ^{1}H NMR (250 MHz, [D$_8$]THF, 300 K): $\delta = 0.282$, 0.276 (s each, 1:2, 81H, $SiMe_3$), 0.24 (s, 27H, $SiMe_3$); ^{1}H NMR (250 MHz, [D$_8$]THF, 323 K): $\delta = 0.297$, 0.290 (s each, 1:1, 81H, $SiMe_3$), 0.26 (s, 27H, $SiMe_3$) [This hints at an attack of THF on the Ga–I bridges]; ^{13}C NMR ([D$_8$]THF, 300 K): $\delta = 5.0$, 4.5, 3.9 ($SiMe_3$); ^{29}Si NMR ([D$_8$]THF, 300 K): $\delta = -7.5$ (3 $SiMe_3$), −9.0 (1 $SiMe_3$), −114.0 (3 Si), −121.5 (1 Si); MS(70 eV): selected, characteristic peaks: *m/z* (%): 1322 (1) [Ga_4(hypersilyl)$_4I^+$ − $SiMe_3$], 1085 (12) [Ga_3(hypersilyl)$_2I_3^+$], 73 (100) [$SiMe_3^+$].

3: ^{1}H NMR ([D$_8$]toluene, 300 K): $\delta = 3.49$ (OCH_2), 1.70 (CH_2), 0.49 ($SiMe_3$); MS(70 eV): selected, characteristic peaks: *m/z* (%): 843 (0.5) [Ga_5(hypersilyl)$_2^+$], 565 (7) [Ga(hypersilyl)$_2^+$], 232 (100) [hypersilyl$^+$ − Me].

Atomically Resolved Structure of Fracture Surfaces of a Ba/Si/O/C Glass with Atomic Force Microscopy**

Wolfgang Raberg, Volker Lansmann, Martin Jansen,* and Klaus Wandelt*

As sharp discrepancy with the importance of amorphous solids[1]—which include on one hand the oxide glasses as one of the largest and most versatile material classes and on the other the amorphous semiconductors[2] or the amorphous high performance ceramics[3] as materials of the future—the knowledge about their structures is far from complete.[4] Indeed, the highly developed repertoire of methods for structural analysis of molecules and crystalline solids fails when applied to samples which do not exhibit any translational symmetry.

Spectroscopic methods yield quite reliable information on the nearest neighbors (first coordination sphere) of a given atomic species.[5] Despite the enormous progress, for instance in nuclear magnetic resonance techniques (spin-echo and double-resonance techniques)[6] or in diffraction methods (determination of partial structure factors),[7] only averaged information about the medium- and long-range order is obtainable. For this reason only in specific cases (e.g., in the amorphous modification of elements)[8] has it been possible to develop concrete and detailed structural models that explain all experimental data.

A potential alternative to structurally sensitive probes, which reach their limits in applications on amorphous substances and therefore cannot give definite information on this topic, is the use of as many different methods as possible in order to obtain complementary as well as overlapping structural information. By combining this data with theoretical simulations concrete structural models may be developed. But again such a model gives the amorphous structure only indirectly. The better approach would be a direct imaging of the structure, which has recently become possible with scanning probe methods. In this paper we present the first image of the fracture surface of a glass with atomic resolution obtained with the atomic force microscope (AFM);[9] this image gives direct insight into the glass structure.

A barium silicate glass was chosen as test system for this investigation, since a good contrast and differentiated distance spectrum was expected from this material. Furthermore, the crystalline structures of several barium silicates are well known,[10] which may facilitate classification of the observed structural units. In order to strengthen the glass network, carbon was introduced in the melting process. That the carbon indeed was inserted into the silicate network was proved by ^{29}Si MAS-NMR spectroscopy.[11] The concomitant increase of the glass transition temperature indicates a higher degree of crosslinking in the oxycarbide glass than in the oxide glass. A

fragment of this oxycarbide glass was introduced into an ultra high vacuum chamber (UHV). The fracture surface of the sample was cleaned in an outgassing procedure and then investigated with the atomic force microscope in the contact mode.

On a 1000 nm × 1000 nm scale (Figure 1) of the untreated fracture surface one can clearly recognize a distinct granular structure comprising grains 150 nm to 200 nm in diameter.

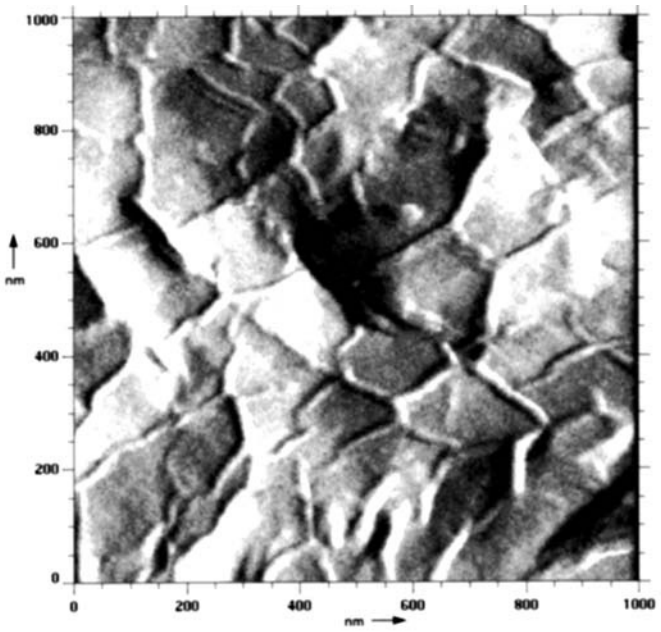

Figure 1. AFM image of the unprepared glass surface (contact force mode; maximum height difference about 50 nm).

These structures could not be observed in an earlier investigation with a conventional scanning electron microscope (usual lateral resolution in the range of 200 nm). The reason for the development of the grain boundaries and their composition is not known yet. An obvious possibility is a beginning phase separation.

Since the surface roughness between the domain walls is very small, the atomic structure of the fracture surface can be imaged. Figure 2 shows a topographic image of a 3.9 nm × 3.9 nm section after an outgasing procedure of several hours at around 400 K. The distances between the brighter regions, which correspond to elevations on the surface, are of the order of the expected interatomic distances and suggest that in this case atomic resolution was indeed obtained. There are no hints of periodic structures, only several more regular units like rings or chains.

In Figure 3 the pair distribution function corresponding to Figure 2 is shown, which in the following section is compared with the structural properties of a crystalline barium silicate, with experimental data (X-ray and neutron-scattering measurements[12]) on a barium disilicate glass, and with results from electron diffraction experiments[13] on the identical oxycarbide glass. The pair distribution function in Figure 3 is representative for the pair distribution functions corresponding to images of other areas of the fracture surface.

In the case of a totally disordered distance distribution one would expect a linear increase in the pair distribution function. This is indeed observed in Figure 3. In addition, several intensity peaks are superimposed upon the linearly

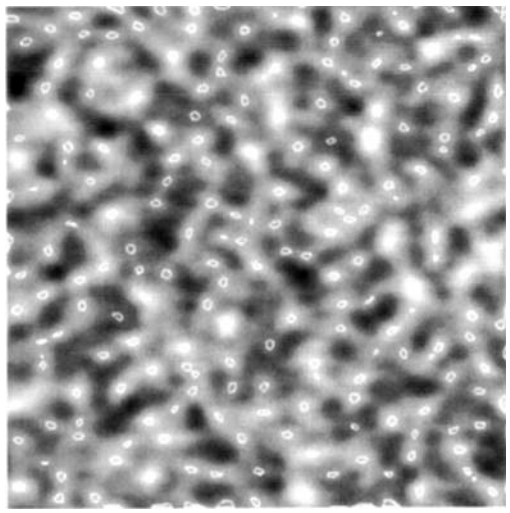

Figure 2. Topographic AFM image (constant force mode, $F = 25$ nN) of a 3.9 nm × 3.9 nm section of the Ba/Si/O/C glass after an outgasing procedure of several hours at around 400 K. The white circles indicate the atomic positions used for the calculation of the pair distance distribution. The grey scale corresponds to a height difference of 0.3 nm.

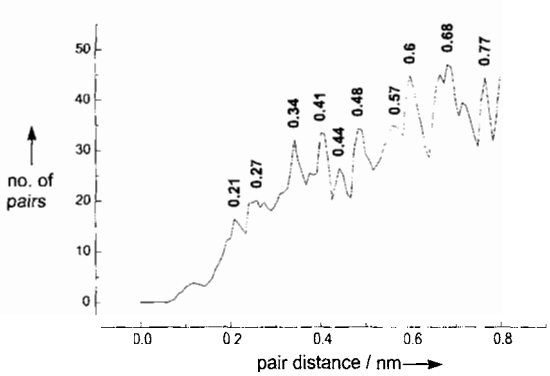

Figure 3. Interatomic pair distribution function determined from Figure 2

rising background, which indicates increased occurence of characteristic pair distances.

The shortest distance of 0.16 nm in the crystalline reference material is also observed in electron diffraction experiments with this glass, and in the X-ray and neutron scattering measurements of the barium disilicate glass, but does not appear in the AFM measurements (Table 1). Since this distance is attributed to Si–O bonding, this observation suggests that no Si atoms are on the surface and that the SiO_4 tetrahedra are intact. This is supported by the absence of a peak at 0.3 nm, corresponding to a Si–Si distance in the crystalline reference material.

The distance of 0.27 nm can be attributed to the Ba–O and the O–O distance (tetrahedral edge), in full agreement with the results from the crystalline barium disilicate and from the diffraction measurements with glasses. In contrast, the peak at 0.21 nm is not found in the reference data; this peak might represent an O–C distance (edge of an SiO_3C tetrahedron). In the same way the other distances (0.34 nm, 0.41 nm, and 0.44 nm) can be attributed to particular atomic pairs. The distance of 0.34 nm seems to be assignable only if Si atoms are considered. This is, however, not in contradiction to the interpretation that no silicon is at the surface, since this distance might result from a bond between an oxygen atom

0.68				mro
0.77	0.78	0.78	0.77	mro

[a] Distances above 0.45 nm are not assigned to a certain atomic distance pair and are attributed to medium range order effects (mro).

situated perpendicular (with respect to the surface) to a Si atom and a neighboring atom.

At larger distances further peaks clearly indicate a medium-range order in the investigated glass. However, a definite assignment has yet to be done. The appearance of the 0.77 nm peak both in AFM and diffraction measurements is particularly remarkable, since this is a lattice constant of crystalline barium disilicate.

Two possible problems arise with the direct imaging of fracture surfaces of amorphous solids by atomic force microscopy, if one wants to resolve the bulk structure of glasses. First, the structures on the fracture surface might undergo a relaxation and therefore not correspond exactly to the position of the atoms in the bulk. Second, as the fracture will take place predominantly at the weaker bonds in the glass, these areas will dominate the images. However, since the relaxation in glasses with a highly developed network and low crystallization tendency will only result in displacements and not in reconstructions one can expect that the principles (repetition of structures, ring dimension, residues of translational symmetry) of medium- and long-range order will be preserved and reproduced in the image. In the case of the Ba/Si/O/C glass the justification for this assumption is proved by the good agreement of the AFM results with data obtained from completely independent measurements.

Atomic force microscopy is superior to all other methods of studying solids without translational symmetry in that it allows direct imaging of the atomic structure and therefore can be used to develop a reliable model of the structure of glasses. In the present case the classical controversy concerning the structure of glass between the hypothesis of Zachariasen ("network hypothesis")[15] and that of Lebedew ("crystallite theory")[16] can be settled. The AFM images show unambiguously that the barium silicate glass consists of a tetrahedral network.

Experimental Section

The Ba/Si/O/C glass was made under argon atmosphere by melting a mixture of $BaCO_3$, SiO_2, and SiC in a high frequency furnace in a BN crucible placed in a carbon crucible to ensure inductive coupling. The melt was held at 1650°C for 30 min and after switching off the furnace cooled down in a strong stream of argon. The average cooling rate from maximum temperature to around 700°C was about 10 $K s^{-1}$. The cation ratio Ba:Si in the starting mixture was 37:63 with 3 atom% carbon in form of SiC.

A fragment of this sample was clamped to the sample holder with a small vice. The images were obtained under ultrahigh vacuum after an outgassing procedure of several hours at about 400 K with a combined atomic force/scanning tunneling microscope (Omicron Vakuumphysik GmbH). The AFM measurements were carried out in the contact mode immediately after transfer with single crystal silicon cantilevers (Nanosensors) and constant loading forces in the range 25 nN—50 nN [17].

Sergeants-and-Soldiers Principle in Chiral Columnar Stacks of Disc-Shaped Molecules with C_3 Symmetry**

Anja R. A. Palmans, Jef A. J. M. Vekemans, Edsko E. Havinga, and E. W. Meijer*

Seminal studies by Green and co-workers to understand the underlying principles of chirality in stiff helical polymers such as the polyisocyanates have led to observations referred to as the "Majority Rule" and the "Sergeants-and-Soldiers Principle".[1] Poly(*n*-alkyl isocyanates) adopt an extended helical conformation in which long stretches of one helical sense, *P* or *M*, are separated by high-energy reversals. To favor one

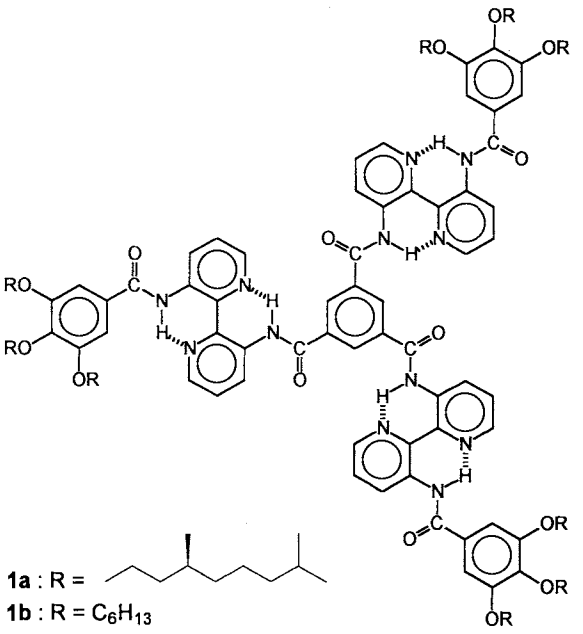
helical sense, it is only required to add a small portion of chiral units (sergeants) to the achiral units (soldiers) or to have a slight majority of *R* over *S* units in the polymer. Recently, it was shown that these effects are operative in other polymers with stiff helical backbones.[2] This is in sharp contrast to the behavior in small molecules where, for example, the optical rotation of a mixture of two enantiomers varies linearly with their ratio. Also in liquid crystals the induction of chirality is complex but seems to be predominantly linear or additive:[3] the more chiral molecules added to a nematic liquid crystal, the shorter the helical pitch of the induced cholesteric phase.[3b] In this communication we describe our results on the stereochemical issues of the associates of disc-shaped molecules **1** in diluted alkane solutions ($10^{-4}-10^{-6}$ mol L^{-1}). The molecules are stacked in highly ordered chiral columns, with a strong, cooperative response to chiral information. This amplification in chirality furnishes the first example in which the sergeants-and-soldiers principle is operative in dynamic structures of molecular aggregates.

Extended-core disc-shaped molecules are of interest, because they show liquid-crystalline properties within a broad temperature regime, and the stability of the molecular stacks is guaranteed by many secondary interactions.[4] We have studied in detail the synthesis and properties of achiral compounds **1**, in which the extended core is based on a concerted conformational preference owing to intramolecular H-bonding in the three acylated 3,3′-diamino-2,2′-bipyridine moieties.[5] Chiral analogue **1a** is synthesized starting from (*S*)-citronellol, which was successively hydrogenated, brominated, coupled to methyl 3,4,5-trihydroxybenzoate and transformed by established procedures[5] into the desired disc-shaped compound **1a**. Both **1a** and **1b** show a thermotropic



liquid crystalline D_{ho} phase, and X-ray diffraction suggests the presence of a helical superstructure. In concentrations greater than or equal to 7% w/w in apolar solvents like hexane, dodecane, and cyclohexane, molecules **1b** are organized in a columnar phase in which the 3.5 Å disc–disc distance within the columns is preserved.[6]

UV spectra of **1a,b** in different solvents show distinct differences in the $\pi-\pi^*$ transition of the bipyridine moiety (Figure 1). In $CHCl_3$ λ_{max} amounts to 351 nm ($\varepsilon = 5.3 \times 10^4$ L mol^{-1} cm^{-1}), whereas in dodecane a significant red shift of 13 nm is observed for λ_{max} to 364 nm ($\varepsilon = 3.2 \times 10^4$ L mol^{-1} cm^{-1}), and a shoulder in the spectrum in $CHCl_3$ has developed into a peak at 384 nm ($\varepsilon = 2.3 \times 10^4$ L mol^{-1} cm^{-1}) in dodecane. The spectrum in dodecane resembles the UV spectrum of a sheared film of pure **1a**, which is in a D_{ho} phase at room temperature. Heating the dodecane solution to 100°C leads to a blue shift of the λ_{max} to 357 nm and the disappearance of the fine structure. These results imply that **1a** is dissolved in $CHCl_3$ as individual molecules (and in dodecane at 100°C), while aggregation occurs in dodecane (and related alkane solvents) at room temperature in which the packing of the molecules in columns is similar to that in neat **1a**.

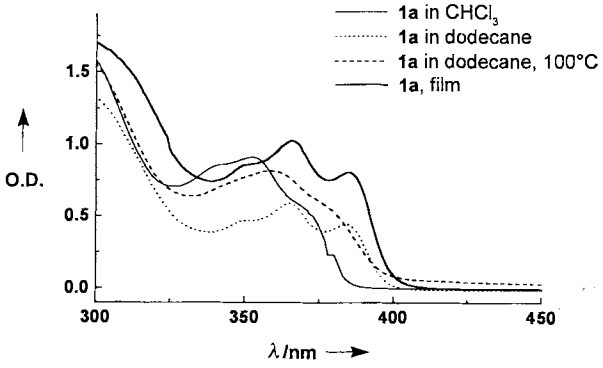


Figure 1. UV spectra of **1a** in $CHCl_3$ ($c = 1.7 \times 10^{-5}$ mol L^{-1}, $l = 1$ cm), in dodecane ($c = 1.8 \times 10^{-5}$ mol L^{-1}, $l = 1$ cm), and as a neat, sheared film.

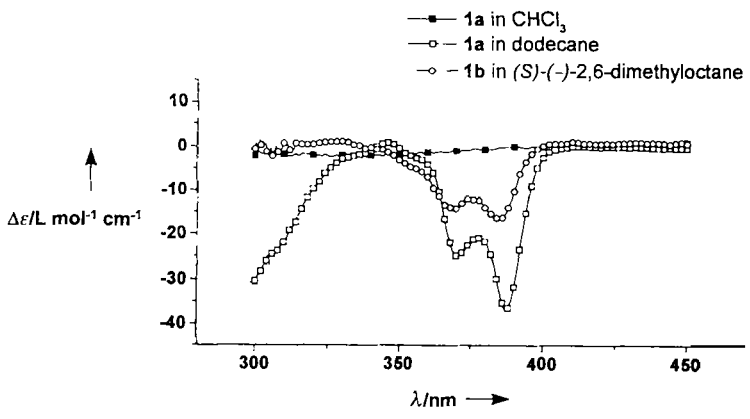
In $CHCl_3$ compounds **1a,b** do not exhibit Cotton effects in the UV/Vis range of the circular dichroism (CD) spectrum. In dodecane, however, **1a** shows a very strong, negative Cotton effect associated with the $\pi-\pi^*$ absorption band of the bipyridine moiety at $\lambda = 387$ ($\Delta\varepsilon = -35.6$ L mol^{-1} cm^{-1}) and 369 nm ($\Delta\varepsilon = -23.6$ L mol^{-1} cm^{-1}) with chiral anisotropy factors[7] g of -1.5×10^{-3} and -7.4×10^{-4}, respectively. Heating the sample leads to a gradual decrease of the Cotton effects and a complete loss at 100°C. Subsequent cooling to room temperature restores the original Cotton effects. Most remarkably, the UV and CD spectra of the achiral compound **1b** in optically active (*R*)-(−)-2,6-dimethyloctane[8] as solvent are almost identical to the spectra of chiral compound **1a** in dodecane in the $\pi-\pi^*$ absorption band of the bipyridine moiety (Figure 2). The anisotropy factors g, however, are slightly lower (-8.5×10^{-4} at $\lambda = 386$ nm and -5.3×10^{-4} at $\lambda = 367$ nm). Again, heating of this sample leads to a decrease of the Cotton effects, showing the dynamics in chiral solvation.[9]

These results on chiral solvation indicate strong cooperative effects, suggesting a tendency of the stacks to take on a helical arrangement. We therefore attempted to apply the sergeants-and-soldiers principle to mixtures of **1a** and **1b** in hexane. As expected **1b** does not show any Cotton effect in hexane. However, addition of only 2.5% of chiral **1a** to achiral **1b** in hexane generates a strong Cotton effect, especially in the bipyridine transition band, which was similar in magnitude as for pure **1a** in hexane. The remarkable observation that the

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3623-2649 $ 17.50+.50/0



Cotton effects of the mixtures of about 10% **1a** and 90% **1b** are larger than for pure **1a** is tentatively explained by a more effective packing between achiral molecules **1b** than between chiral molecules **1a**.

The mixing experiment was repeated with solutions of different concentrations of compounds **1a** and **1b** in hexane. The dependence of the g values on the amount of chiral **1a** added to a solution of achiral **1b** is depicted in Figure 3. The curves show the same trend, although the effect is smaller for the lowest concentration (1.9×10^{-6} mol L^{-1}). We also found that the Cotton effect in the bipyridine band is almost independent of the concentration of pure **1a** in hexane within the range 10^{-6} - 10^{-3} mol L^{-1}, with a slight deviation at the low concentration end (Figure 3, inset).

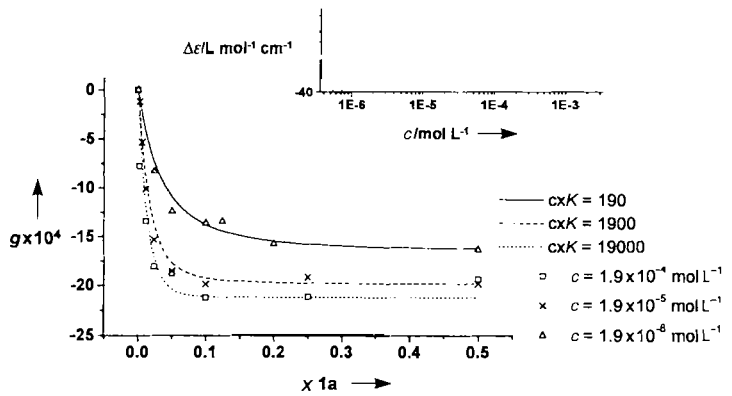


Figure 3. The anisotropy factor g as a function of the amount of **1a** (x in mol fraction) added to the achiral solution of **1b** in hexane in 1 mm (□), 1 cm (×), and 10 cm (△) cells. The fitted lines represent the theoretically predicted development of g as a function of the mol fraction of chiral compound **1a** present in the mixture (an association constant K of approximately 10^8 M and a cooperative length L_c of 81 gave the optimal fit). The inset gives

The results given above are in full agreement with the strong cooperative effect of the sergeants-and-soldiers principle, but now in a dynamic system. To quantify the experimental results presented in Figure 3, we developed a theoretical model to fit these data. In this model the association constant K and the cooperative length L_c—which is the length of that part of the stack with only one helical sense between the helix reversals—can be varied. We assume that the contributions to the Cotton effect in the bipyridine band of a stack is proportional to the number of monomeric units in the stack, and remaining nonassociated species do not contribute to the Cotton effect. Furthermore, the association constants K of chiral and achiral monomers are equal, and if a stack contains a chiral monomer, the latter will induce chirality in other molecules in the stack not further away than s units. For mixed stacks in equilibrium we can then deduce an equation to fit the experimental data points with K and s as variables.[10] A fit of this model to the experimental data leads to $K = (1 \pm 0.5) \times 10^8$ L mol^{-1} and $s = (40 \pm 2)$ which yields $L_c = 2s+1 \approx 80$.

We propose the following hypothesis to explain the cooperative response of compound **1** on external chiral information. The C_3-symmetrical molecules of type **1** adopt a propellerlike conformation in which the bipyridine wedges are tilted with respect to the central trimesic core.[11] In hexane molecules **1** are aggregated in columnar stacks, and the packing between subsequent molecules will be optimal when all bipyridine wedges are tilted in the same direction, which results in a preferred stable chiral conformation of each disc-shaped molecule.[12] This can be compared with propellers piled on top of each other. Rotating the first with respect to the second will improve the packing but will also give rise to a helix. Equal amounts of P and M helices are present within the stacks of achiral **1b**. The stack length is concentration-dependent and corresponds with $K \approx 10^8$ L mol^{-1}, while the cooperative length L_c of one helical sense between helical reversals is not concentration-dependent and has the value $L_c \approx 80$. On the other hand, the stacks of **1a** are assumed to have only one helical sense P or M. The instantaneous Cotton effect in the bipyridine band upon addition of chiral **1a** to a solution of achiral **1b** points to dynamic processes and an exchange of the molecules between different columns. By introducing on average one molecule of chiral **1a** per 80 molecules of **1b** into the stacks of **1b**, the chiral component (the sergeants) will dictate the helical sense of the total stack (of soldiers) for steric reasons. That a chiral alkane solvent can also dictate the sense of helicity of a stack of achiral molecules presumably means that the first layer of solvent organizes itself along the peripheral alkoxy chains of the molecules with precision. Again, steric factors will dictate which helical sense will lead to the most favorable interactions between subsequent molecules.

In conclusion, it is shown that the sergeants-and-soldiers principle and chiral solvation are operative in dynamic, columnar stacks of molecules **1** in alkane solvents.

[10] For mixed stacks in equilibrium we can deduce the following equation:

$$\frac{g}{g_0} = \frac{\sum_{n=2}^{\infty}[M_n]n(1-q^n)+\sum_{n=s+1}^{2s}[M_n]\left(n-\sum_{i=1}^{n/2}2q^{i+i}\right)+\sum_{n=2s+1}^{\infty}[M_n]\left(n-\sum_{i=1}^{s}2q^{n-s}-\sum_{i=s+1}^{n-s}q^{2s+1}\right)}{\sum_{n=2}^{\infty}[M_n]n}$$

in which g is the anisotropy factor for a mixture with mol fraction x of chiral **1a** in a solution of **1b**, g_0 is the anisotropy factor for the solution of pure **1a** [11], $a = K[M] = 1 + [(1 - \sqrt{1 + 4Kc})/2Kc]$ (M. B. Martin, *Chem. Rev.* **1996**, *696*, 3043), $q = 1 - x$, $t = aq$, $r = a\sqrt{q}$ and s is the number of molecules for which chirality is controlled in one direction. Evaluation gives:

$$\frac{g}{g_0} = 1 - \frac{(2-t)\left(\frac{t}{1-t}\right)^2 - \frac{s(1-t)+1}{(1-t)^2}t^{s+1} + \frac{2(t^{s+1}-t^{2s+1})}{(1-a)(1-q)} + \frac{t^{2s+1}}{(1-a)^2} - \frac{2(qr)^{s+1}(1-r)}{(1-q)(1-r)}}{(2-a)\left(\frac{a}{1-a}\right)^2}$$

[11] For the constant g_0, the g value of the 10/90 mixture **1a/1b** was used in the fit to compensate for packing effects.
[12] In (−)- and (+)-3,3′-di(camphanoylamino)-2,2′-bipyridine in MeOH and $CHCl_3$, weak Cotton effects are found in the bipyridine band, which are attributed to a small deviation from coplanarity of the bipyridine system.
[13] This packing of the molecules in columns could be stabilized by intermolecular H-bonding. See a) Y. Yasuda, E. Iishu, H. Inada, Y. Shirota, *Chem. Lett.* **1996**, 575; b) Y. Yasuda, Y. Takebe, M. Fukumoto, H. Inada, Y. Shirota, *Adv. Mater.* **1996**, *8*, 740.

$Ba_2Nd_7Si_{11}N_{23}$—A Nitridosilicate with a Zeolite-Analogous Si–N Structure**

Hubert Huppertz and Wolfgang Schnick*

In the past few decades zeolites and aluminosilicates have found important technological applications as microporous solids.[1] For the specific modification of their catalytic properties the tetrahedral centers aluminum and silicon were substituted by a large number of electropositive elements.[1,2] Recently, the replacement of the bridging atoms O by different atoms or building units in the network structures was successful.[3] For example, $Zn_6[P_{12}N_{24}]Cl_2$ with a sodalite-analogous structure of corner-sharing PN_4 tetrahedra was synthesized in our group.[4] Host–guest behavior by reversible encapsulation of molecular hydrogen was established for the analogous halogen-free nitridosodalite $Zn_6[P_{12}N_{24}]$.[5]

With regard to the material properties and the high stability of nitridosilicates, it seemed challenging to build up zeolite-analogous microporous network structures from SiN_4 tetrahedra. Typical for nearly all oxidic zeolites is a molar ratio of tetrahedral centers (T) to bridging atoms (X) of T:X = 1:2 (T = Al, Si; X = O).[6] This ratio should also hold for zeolite-analogous nitridosilicates. All nitridosilicates obtained so far by high-temperature synthesis possess Si–N substructures in the range $0.5 \leq T:X \leq 0.75$ having no open channels or large cavities.[7]

The synthesis of $Ba_2Nd_7Si_{11}N_{23}$ produced the first nitridosilicate with a zeolite-analogous Si–N network structure. The new nitridosilicate was synthesized in a high-frequency furnace[8] by reaction of stoichiometric amounts[9] of barium and neodymium with silicon diimide[10] under nitrogen atmosphere [Eq. (a)]. By this procedure $Ba_2Nd_7Si_{11}N_{23}$ is formed as a coarse crystalline, dark blue solid.[11] Like all other nitridosilicates synthesized in our group, $Ba_2Nd_7Si_{11}N_{23}$ is stable up to 1600°C and insensitive to hydrolysis.

$$2\,Ba + 7\,Nd + 11\,Si(NH)_2 + {}^1/_2\,N_2 \xrightarrow[\text{HF furnace}]{900-1650\,^\circ C,\,40\,h} Ba_2Nd_7Si_{11}N_{23} + 11\,H_2 \qquad \text{(a)}$$

The X-ray structure analysis[12] on single crystals of $Ba_2Nd_7Si_{11}N_{23}$ shows a three-dimensional network structure of corner-sharing SiN_4 tetrahedra according to $^3_\infty[(Si^{[4]}_{11}N^{[1]}_2N^{[2]}_{21})^{25-}]$. With a molar ratio of Si:N = 11:23, the degree of condensation is smaller than in most of the oxidic zeolites (Al/Si:O = 1:2).[13] Accordingly besides bridging atoms $N^{[2]}$, terminal atoms are connected to Si ($N^{[1]}$). (The superscript in square brackets in $N^{[x]}$ defines the number of Si atoms covalently bound to N, and vice versa for $Si^{[x]}$). The ratio of Q^4 and Q^2 tetrahedra in the Si–N network structure is 10:1. Thus $Ba_2Nd_7Si_{11}N_{23}$ shows the lowest degree of condensation amongst the Si–N network structures obtained so far. The network of corner-sharing SiN_4 tetrahedra in $Ba_2Nd_7Si_{11}N_{23}$ can be characterized by the specific distribution of Si_nN_n ring sizes.[14] In $Ba_2Nd_7Si_{11}N_{23}$ all ring sizes appear with the exception of $n = 2$ and 5.

Characteristic for the structure of $Ba_2Nd_7Si_{11}N_{23}$ (Figure 1) are channels along [001]. The Ba^{2+} ions are centered in the Si_8N_8 ring channels and in the Si_6N_6 ring channels along [100]. The Nd^{3+} ions are positioned in the smaller voids. The metal ions are coordinated by seven and eight nitrogen atoms of the Si–N network (Ba^{2+}–N: 273(1)–316(2) pm; Nd^{3+}–N: 229(2)–312(1) pm). The Ba^{2+} ions in the wide Si_8N_8 ring channels (Figure 2) have a markedly higher coordination number of 16 and corresponding longer distances to the nitrogen atoms (Ba^{2+}–N: 337(1)–441(2) pm).

The bond distances $Si–N^{[2]}$ in the network structure (167(1)–175.5(5) pm) are typical for simple bridging $N^{[2]}$ atoms in nitridosilicates.[7] The distances $Si–N^{[1]}$ (175.4(12) pm) correspond to the values of terminal N atoms in $Ba_5Si_2N_6$ (174–176 pm).[15]

A measure for the microporousity of a zeolite-analogous structure is the framework density (FD), which indicates the number of tetrahedral centers (T) in a volume of 1000 Å^3. With a FD of 18.5, $Ba_2Nd_7Si_{11}N_{23}$ is similar to typical zeolites (framework densities of some zeolites in T/(1000 Å^3): 17.5 ($AlPO_4$-5), 17.9 (ZSM-5), 19.3 (Nonasil)).[6]

The successful synthesis of $Ba_2Nd_7Si_{11}N_{23}$ is the first proof that not only highly condensed Si–N network structures but also open, zeolite-like networks of corner-sharing SiN_4 tetrahedra can be realized. In contrast to conventional zeolites, which are synthesized by solvothermal procedures using templates, the nitridosilicates are only accessible by high-temperature synthesis. The next aim of our efforts will be the exchange of the bulky metal ions for hydrogen atoms

Alkylrhenium Oxides from Perrhenates: A New, Economical Access to Organometallic Oxide Catalysts**

Wolfgang A. Herrmann,* Roland M. Kratzer, and Richard W. Fischer

Organometallic oxides have been thoroughly investigated, particularly because some representatives of this ever-growing class of compounds exhibit a variety of catalytic properties.[1] One of the main reasons behind our interest in rhenium is the diverse catalytic successes of methyltrioxorhenium (MTO).[2] This has recently been reported to catalyze different oxidation processes.[2–4] Twenty years after MTO was first observed,[5] two synthetic pathways have become established for access to organorhenium(VII) oxides:

1) Direct alkylation of dirhenium heptoxide (Re_2O_7) with tetraalkyltin or dialkylzinc. However, in this case 50% of the rhenium is lost in the form of unreactive trialkylstannyl- and zinc perrhenate.[6] 2) Alkylation of Re_2O_7 in the presence of trifluoroacetic anhydride. Here, the formation of rhenium-containing by-products is suppressed, but the anhydride used is expensive and rather sensitive.[7]

The disadvantage of both these methods is that the Re_2O_7 starting material is extremely moisture sensitive. Now for the first time, a simple one-pot reaction facilitates the use of a wide variety of easily accessible perrhenates as starting compounds. MTO **1**, for example, can be synthesized in excellent yields without the rigorous exclusion of air and moisture (Table 1). The perrhenates ($M[ReO_4]_n$, $n = 1$, 2 and

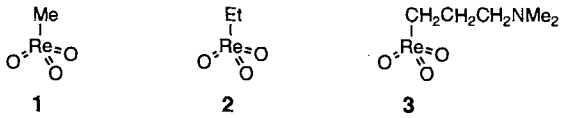

Table 1. Direct synthesis of organorhenium(VII) oxides from perrhenates (solvent: acetonitrile).

	Perrhenate	Alkylation reagent	Conditions t (h)	T (°C)	Yield $RReO_3$ (%)[a]

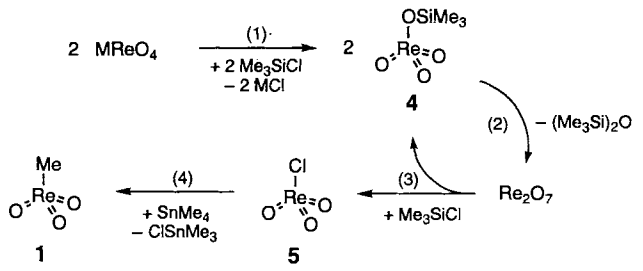
[a] Isolated yield except the marked examples 6 and 7. [b] GC yield (±5%).

$M = Ag^+$, K^+, Na^+, Zn^{2+}, Ca^{2+}, NH_4^+; $(CH_3)_3SnReO_4$) are then treated with chlorotrimethylsilane and tetramethyltin. The addition of one equivalent of H_2SO_4 is recommended if only scarcely soluble perrhenates are used. With alkylzinc compounds this new synthetic route can be extended to the preparation of homologues of **1** and to alkyl-functionalized derivatives. For instance, ethyltrioxorhenium(VII) (**2**) is produced in 36% yield.[8] In addition, the oxidation catalyst [3-(dimethylamino)propyl]trioxorhenium(VII) (**3**) could be prepared by using this new method.[9]

A key advantage of this new route is the possibility of catalyst recycling in MTO-catalyzed oxidation processes; the perrhenates can be separated from exhausted catalyst solutions through simple precipitation of the perrhenic acid from the solution. This new aspect sets the industrial application of rhenium catalysts in a realistic context.

The synthesis proceeds as exemplified for MTO **1** (Scheme 1): First perrhenate is converted to trimethylsilyl perrhenate (**4**) and the respective metal chloride (1).[10,11] The next step is a condensation of two activated perrhenates **4** (2). The resulting dirhenium heptoxide is then cleaved with (the second equivalent of) chlorotrimethylsilane to give chlorotrioxorhenium (**5**) and **4** (3); the final alkylation of **5** (4) affords MTO **1**.

This new synthetic strategy represents an economical and simple access to organorhenium oxides from a plethora of readily available, rather cheap perrhenates. An extension of this concept to the neighboring elements of the periodic table seems feasible. One of our future goals is the activation of simple oxo salts (Cr, Mo, W, Mn) with chlorotrimethylsilane[11] with the aim of synthesizing novel organometallic oxides.



Scheme 1. Synthetic steps in the formation of methyltrioxorhenium from perrhenates.

Experimental Section

The perrhenates were prepared by oxidation of rhenium with H_2O_2 (30%) and precipitation (KCl, $AgNO_3$) or neutralization (e.g., NaOH, $Ca(OH)_2$). $Zn[ReO_4]_2$ and $(CH_3)_3SnReO_4$ were formed as by-products in the synthesis of organorhenium oxides[6,8]. Unless mentioned otherwise, acetonitrile (Merck, p. A.) was used without further purification or drying procedures. Chlorotrimethylsilane (98%, Aldrich) was distilled prior to use.

CH_3ReO_3 **1**: *Attention! Tetramethyltin and trimethyltin chloride are very toxic and volatile. All transformations are therefore to be performed in a hood.* $Ag[ReO_4]$ (1.00 g, 2.79 mmol) was dissolved in CH_3CN (20 mL) in a sealable 50-mL Erlenmeyer flask. After the addition of $ClSi(CH_3)_3$ (0.78 mL, 6.14 mol), a white precipitate was formed immediately. To the suspension $Sn(CH_3)_4$ (0.43 mL, 3.07 mol) was added and the mixture was stirred for 12 h at 25 °C. It was then filtered and the resulting yellow solution was evaporated in a Schlenk tube under reduced pressure (20 mbar). Due to the volatility of the tin compounds it is recommended that a trap cooled with nitrogen is installed between the Schlenk tube and the pump. The residue was sublimed at ambient temperature under high vacuum (10^{-2} mbar). Compound **1** was obtained in 76% yield (696 mg, m.p. 108 °C).

$Na[ReO_4]$ (1.00 g, 3.66 mmol) was suspended in CH_3CN (20 mL) in a 50-mL round-bottomed flask. After the addition of $ClSi(CH_3)_3$ (1.02 mL, 8.05 mol) and $Sn(CH_3)_4$ (0.56 mL, 4.03 mol) the reaction mixture was heated to reflux for 4 h. Then the cooled mixture was filtered and the yellow-orange solution was evaporated to dryness in a Schlenk tube under reduced pressure (20 mbar). The residue was sublimed at ambient temperature under high vacuum (10^{-2} mbar). Compound **1** was obtained in 70% yield (639 mg, m.p. 108 °C).

$K[ReO_4]$ (8.70 g, 0.03 mol) was suspended in CH_3CN (150 mL) in a 250-mL flask with a faucet. Concentrated H_2SO_4 (1.6 mL, 0.03 mol), $ClSi(CH_3)_3$ (8.30 mL, 0.066 mol), and $Sn(CH_3)_4$ (4.2 mL, 0.03 mol) were added and the reaction mixture was stirred at 25 °C for 24 h. Then the solution was evaporated to dryness without filtration at 20 mbar and the black residue was extracted with *n*-pentane (4 × 50 mL) for several hours each time. The combined extracts were evaporated to about 30 mL and maintained at −35 °C for 24 h. The precipitating MTO still contained Me_3SnCl and was therefore purified by sublimation (25 °C, 10^{-2} mbar). Yield: 63% (4.71 g). If the melting point of this MTO fraction is still below 100 °C, a second sublimation must follow.

$(CH_3)_2NCH_2CH_2CH_2ReO_3$ **3**: $Na[ReO_4]$ (0.50 g, 1.83 mmol) was suspended in dry CH_3CN (10 mL) under the exclusion of air and treated at −40 °C with $ClSi(CH_3)_3$ (0.46 mL, 3.66 mmol) and $Zn[(CH_3)_2NC_3H_6]_2$ (0.43 g, 1.83 mmol). The mixture was stirred at 0 °C for 12 h. Then the solution was evaporated to dryness and the residue was extracted with *n*-pentane (3 × 5 mL). The combined extracts were evaporated and kept in a cool place. Compound **3** precipitated from the solution in 25% yield. Elemental analysis for $C_5H_{12}NO_3Re$ (320.4): calcd. C 18.69, H 3.77, N 4.36; found C 18.76, H 4.00, N 4.08; IR (KBr): $\tilde{\nu} = 960\ cm^{-1}$ (Re=O), 917 (Re=O); ^1H NMR (200 MHz, CD_3CN, 20 °C): $\delta = 2.20$ (s, 6H, NCH_3), 2.85 (t, 2H, NCH_2), 3.02 (m, 2H, $CH_2CH_2CH_2$), 3.50 (t, 2H, $ReCH_2$); $^{13}C\{^1H\}$ NMR (200 MHz, CD_3CN, 20 °C): $\delta = 57.3$ (NCH_3), 80.2 (NCH_2), 47.2 ($CH_2CH_2CH_2$), 28.4 ($ReCH_2$).

$CH_3CH_2ReO_3$ **2**: The preparation of **2** was performed with $Zn(CH_2CH_3)_2$ under analogous conditions to those employed for **3**. Yield: 36%.

Repetitive Construction of Macrocyclic Oligophenylenes**

Volker Hensel, Karola Lützow, Joel Jacob, Katrin Gessler, Wolfram Saenger, and Arnulf-Dieter Schlüter*

Cyclic oligophenylenes[1] and related compounds with conformationally rigid structures[2] have attracted the interest of chemists for issues including aromaticity, host–guest chemistry, aggregation behavior, and molecular constructions. Repetitive strategies are of importance in synthetic chemistry whenever structurally defined and monodispersive molecular objects in the nm range are targeted.[3] Recently Moore[4a] and Höger[4b] applied this concept to hexagonal macrocycles with phenylacetylene units. Stimulated by these studies and given the experience in our group with Suzuki cross-coupling reactions,[5] we decided to develop a repetitive synthesis of soluble, regular macrocyclic oligophenylenes.

Macrocycles **1** ($n = 0$, 1) were selected as initial targets because they are the smallest cyclic hexagonal oligophenylenes in which the unavoidable solubilizing groups can be attached at the sides and not the corners. This leaves the option of introducing substituents at the latter, for example, for the construction of further macrocycles. The synthesis of **1** was achieved by subjecting a variety of kinked oligophenylene telechelics (modules)[6] to Suzuki cross-coupling.[7] They may be classified as either AB-type modules consisting of six (**2**, **4**) and twelve phenylene units (**3**, **5**) or AA- and BB-type modules consisting of three (**6a**) [**6b**: five] and five phenylene units (**7a**) [**7b**: seven], respectively.[8] For each module the conditions such as solvent, kind of catalyst and its relative amount, dilution, kind of base, temperature, scale of reaction, and reaction time were systematically optimized in order to gain maximum insight into the factors which influence these ring-closing reactions.[9,10]

The optimized yields are given in Scheme 1. They allow a number of conclusion to be drawn: a) Each of the routes actually furnishes macrocycle **1**,[11] however, the yields vary considerably (13–85%); b) neither module **2** nor **3** gives satisfactory yields; c) bromide is apparently far inferior to iodide; d) yields are highest (85%) if iodo telechelics are used that already carry the required number of phenylene units (**5a,b**); e) coupling of smaller telechelics (**4a,b**) saves three steps but leads to a decrease in yield (35–40%), regardless of whether the AA/BB- or AB-type approach is chosen;[12] f) pinacole esters of boronic acids are somewhat superior to the corresponding free acids with regard to coupling efficiency (for example, see the reaction of **5b** versus that of **5a**); handling and spectroscopic characterization of esters is also more convenient; g) the best results are generally obtained under high dilution using a syringe pump.[10] Conclusion b) deserves further comment: The $Br/(BOR)_2$ substitution pattern more or less fails with regard to ring formation because deboronification is no longer a well-known side reation[5a,13] but a main reaction. For example, the attempted coupling of **3a** gave, besides a few percent of desired ring **1b**, the deboronified starting compound and a deboronified noncyclic dimer in yields of approximately 43% each (HPLC). Clearly, deboronifaction and linear growth overrides ring closure.[14]

To accumulate knowledge on conformational characteristics of these oligophenylenes, in particular with regard to the relative positioning of the corners, attempts were made to crystallize **1b**.[15] Unfortunately these failed; flexible chains introduced to enhance solubility often reduce the ability of the compound to crystallize. However, crystals of **1a** could be grown from a solution in chloroform/ethanol, and the crystal structure of **1a** was solved by X-ray diffraction.[16,17] Cycle **1a** crystallizes as a 1:1 complex with chloroform (Figure 1).[18] In contrast to inclusion complexes in which the chloroform molecule is stabilized through van der Waals interactions,[19] the guest in **1a** is fully ordered. The hydrogen atom of chloroform points to the middle of a benzene ring, which leads to an unusual chloroform–arene hydrogen bond (distances C–π: 3.53 and 3.48 Å; H–π: 2.45 and 2.44 Å; angle C-H-π: 171.2 and 159.2°, respectively, for the two molecules in the asymmetric units). This weak hydrogen bond is comparable to acetylenic CH hydrogen bonds.[20] The chloroform molecule is held in its position not only by this hydrogen bond but also by van der Waals interactions involving the chlorine atoms and the opposite benzene rings.

Suzuki cross-coupling is a feasible method for the gram-scale synthesis of cyclic oligophenylenes. With the $I/B(OH)_2$ substitution pattern, yields as high as 85% can be reproducibly obtained. In view of the considerable size of cycles **1**, it is not only the efficient coupling chemistry which is responsible for this high yield, but presumably also the rigid structure of

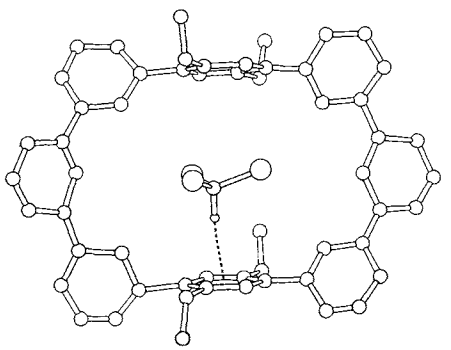

Figure 1. Molecular structure of the inclusion complex **1a**·$CHCl_3$ (one of the two molecules per unit cell). Chlorine, carbon, and hydrogen atoms are shown as big, medium, and small balls, respectively. Four carbon atoms per hexyl chain are omitted for clarity. The dashed line represents the CH–π hydrogen bond between the guest chloroform and the macrocyclic host.

the precursors to ring closure. This rigidity reduces their conformational space and, thus, the entropy costs associated with ring formation. We are now synthesizing cycles with chloride or trimethylsilyl groups at the corners in order to construct a second layer of hexagons.

Experimental Section

1b (typical procedure): A solution of **5b** (903 mg, 0.415 mmol) and [Pd{P(*o*-tol)$_3$}$_3$] (10 mg, 2.4 mol%) in dry toluene (25 mL) was added with a syringe pump within 54 h to a boiling mixture of [Pd{P(*o*-tol)$_3$}$_3$] (11 mg, 2.6 mol%) in 2N Na_2CO_3 (90 mL), dimethoxyethane (100 mL), and toluene (50 mL). The phases were then separated, and the organic phase was washed with water. Removal of the solvent in vacuo gave crude **1b** with a purity of 89% (analytical HPLC). Purification by preparative HPLC gave 678 mg of **1b** (85%).

[16] X-ray diffraction data were collected at room temperature with a CAD4 diffractometer on an FR571 rotating anode X-ray generator (Enraf-Nonius, Delft). A crystal of dimensions $0.4 \times 0.1 \times 0.1$ mm^3 was sealed in a quartz capillary. The space group and unit-cell parameters were determined from the diffraction angles of 25 reflections. The ccrystals belong to a monoclinic space group ($P2_1$, $Z = 4$), $a = 10.279(3)$, $b = 35.055(5)$, $c = 17.153(3)$, $\beta = 90.11(2)°$; two molecules in the asymmetric unit. Every molecule contains a chloroform molecule in its cavity (composition: $(C_{72}H_{80})_2 \cdot (CHCl_3)_2$). The structure was determined by direct methods (SIR92) using 4344 independent reflections and refined with full-matrix least squares. The relatively high final R value of 0.123 for 3698 data with $F \geq 2\sigma_F$ can be explained by the presence of eight hexyl chains. Two of these chains (one on every molecule) are not included in the model, since they have a high disorder which could not be resolved in the difference Fourier maps. A. Altomare, G. Cascarano, C. Solvation and the Synthesis of Self-Assembled Capsules**

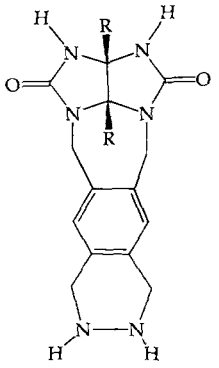
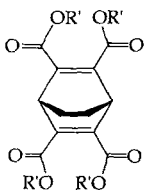
Yuji Tokunaga, Dmitry M. Rudkevich, and Julius Rebek, Jr.*

Template effects appear frequently in biology and chemistry. Transcription and translation are among the earliest recognized examples in biology, whereas in chemistry the synthesis of macrocyclic crown ethers,[1] catenanes, rotaxanes,[2] and other ring systems[3] is most often associated with template effects. That solvents can act as templates was recognized by Cram et al.[4] and Sherman et al.[5] for the synthesis of carceplexes. Here we report that template effects involving solvents can be observed in the synthesis of hydrogen-bonded capsules, and suggest that this phenomenon may be a general feature in the synthesis of reversibly formed assemblies.

The capsules (softballs) have pseudo-spherical structures formed by dimerization of self-complementary subunits.[6] The synthesis concludes with the reaction of hydrazine derivative **1** with tetraesters **2a** or **2b** (Scheme 1). The reaction



1, R = $CO_2CH_2CH_2CH(CH_3)_2$



2a, R' = C_6F_5
2b, R' = 2,4,5-$Cl_3C_6H_2$

Scheme 1. Components for the final reaction in the synthesis of molecular softballs: hydrazine **1** and tetraesters **2a** and **2b**.

generally proceeds in high yield in a number of organic solvents and is complete within a few hours for **2a** or longer for the less reactive **2b**.[7] All three possible isomers are formed: C-shaped **3**, S-shaped **4**, and W-shaped **5** (Scheme 2 and Table 1); their distribution is dependent on the solvent. The C-isomer **3** is quite soluble in benzene or toluene, and forms the well-defined dimeric capsule **6** (Scheme 3), in which two solvent molecules are enclosed.[6,8] In $CDCl_3$, however, **3** behaves differently. At concentrations greater than 5mM the ^{1}H NMR spectrum of **3** contains broad signals and shows that the presence of other aggregates, which form and dissipate on the NMR time scale, is likely. In solvents such as dimethylsulfoxide (DMSO), which compete for hydrogen-bond donors, all three isomers **3**–**5** exist as monomers.

In those solvents that favor formation of the dimeric capsule **6**, the reaction between **1** and **2** gives a significant increase in the yield of **6** (Table 1). The expected statistical distribution of **3**, **4**, and **5** is 1:2:1. This distribution was, however, never realized. In "competitive" solvents such as THF and DMSO, the distribution came closest to the theoretical one. The yields of **3** in benzene, toluene, and *p*-xylene were 1.5 to 1.6 times higher; the product distribution of **3**, **4**, and **5** reaches 2.4:2.4:1.0 in toluene. On the other hand, in $CHCl_3$ and CH_2Cl_2 the yields of **3** were even lower than those expected statistically. Instead, these solvents favored the formation of S-shaped **4**.

The data suggest that solvent and hydrogen bonding play a role in the reaction, but what and when? The sequence of reactions leading to isomers **3**–**5** is straightforwarded: Four covalent bonds are formed (irreversibly), and processes

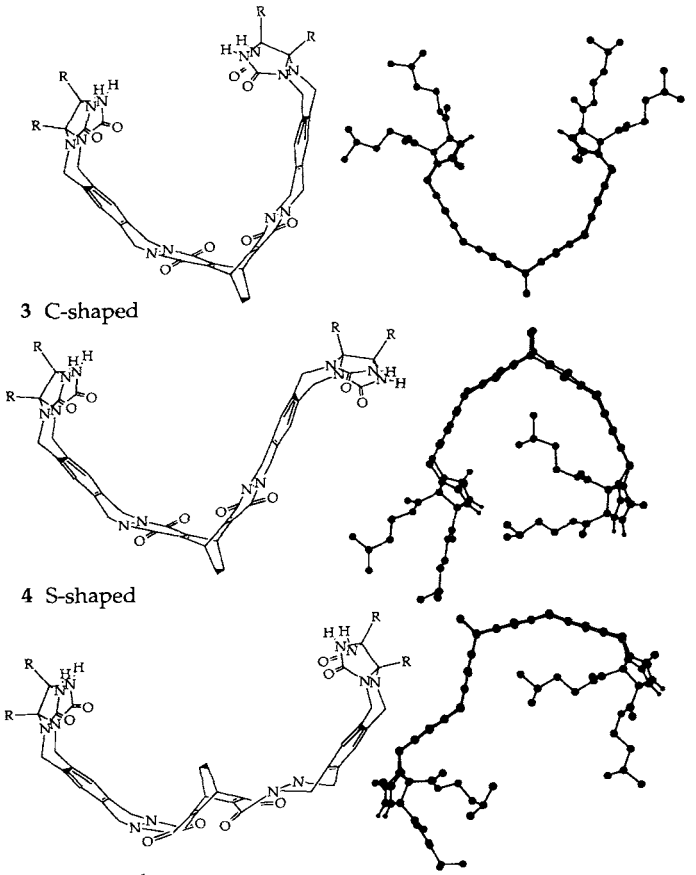
Table 1. Yields for the reactions of **1** with **2a** in different solvents [a–c].

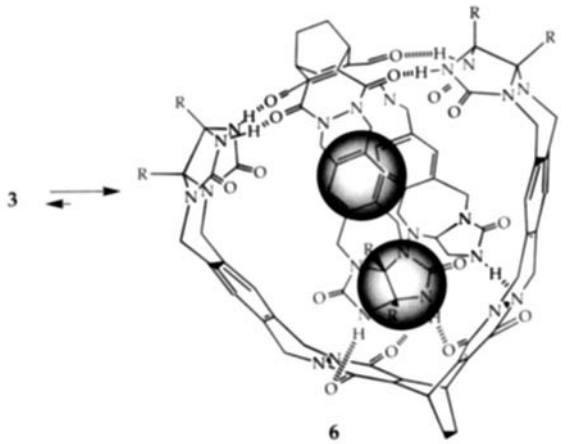
Solvent	Yield [%]			3:4:5
	3	**4**	**5**	
calculated	25	50	25	1.0:2.0:1.0
DMSO	31	44	25	1.4:1.8:1.0
THF	25	46	29	0.9:1.6:1.0
benzene	36	43	20	1.8:2.2:1.0
toluene	41	41	17	2.4:2.4:1.0
p-xylene	39	48	13	3.0:3.7:1.0
$CHCl_3$	19	66	16	1.2:4.1:1.0
CH_2Cl_2	23	62	15	1.5:4.1:1.0

[a] Averaged value from at least two independent experiments (estimated error ±5%, total yield ca. 100%). [b] The concentration of **2a** was 5×10^{-3} M in all reactions. [c] Determined by ^{1}H NMR spectroscopy in [D_6]DMSO.

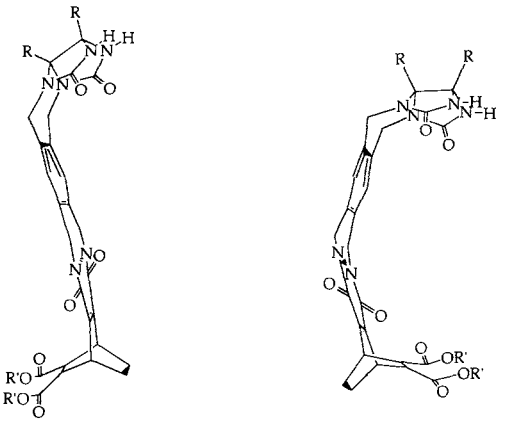


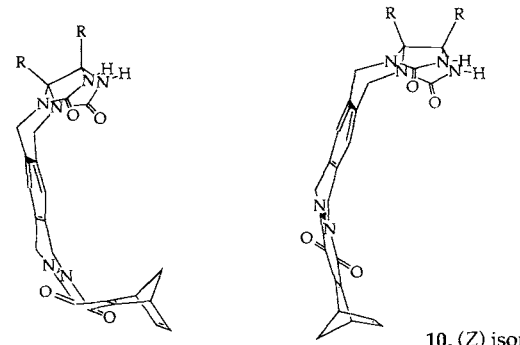
Scheme 2. Schematic representations of the three isomers **3**, **4**, and **5** (*left*) as well as their most compact energy-minimized [10] conformations (right). The carbon-bound hydrogen atoms are omitted for clarity

involving the preassociation of the reactive components should be considered.[9] Clearly, one amide bond forms slowly between **1** and, for example, **2a**. This is followed by a rapid cyclization that makes the second amide bond to produce intermediates **7** or **8**. Repitition of the sequence at the remaining two ester groups of the central unit completes the process. The first amide bond to be formed determines whether isomer **7** or **8** is the intermediate (i. e., whether the glycoluril substituents R are (*E*)- or (*Z*)-configured with respect to the bridge of the central unit). However, both isomers should form in equal amounts (Scheme 4). Indeed, the reaction of a truncated model system with **1** bears out this expectation: Equal amounts of the (*E*) isomer **9** and (*Z*) isomer **10** (Scheme 4) are formed, independent of solvent (benzene, $CHCl_3$, etc.). This places an upper limit of 50% on the yield of the C-shaped subunit **3**, since it can arise only



Scheme 3. Compound **3** forms the hydroden-bonded dimer **6** when two solvent molecules of appropriate size are encapsulated.





Scheme 4. Isolated intermediates: (*E*) isomer **7** and (*Z*) isomer **8** as well as the model compounds **9** and **10**.

from the (*Z*) isomer. Accordingly, the template effect of solvent, if any, must operate at the second stage of the reaction—namely, the partitioning of the (*E*) or (*Z*) isomers.

What accounts for the enhanced yield of **3** in aromatic solvents? Statistically, **8** is expected to give **3** and **4** in equal amounts. To test this, **7** and **8** were isolated from a preparative-scale synthesis and subjected to the second stage of the reaction in various media. When treated with one equivalent of **1** in DMSO, isomers **7** or **8** indeed gave **4** and **5** or **3** and **4**, respectively, in the expected 1:1 ratios (Table 2). This is in

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3623-2657 $ 17.50+.50/0

Table 2. Yields for the reactions of **1** with **7** or **8** in different solvents[a–c].

Solvent	(1+7) Yield[%]		4:5	(1+8) Yield[%]		3:4
calculated	50	50	1.0:1.0	50	50	1.0:1.0
DMSO	50	50	1.0:1.0	51	49	1.04:1.0
benzene	62	38	1.6:1.0	64	36	1.8:1.0
$CHCl_3$	65	35	1.9:1.0	36	64	0.6:1.0

[a] Averaged value from at least two independent experiments (estimated error ±5%, total yield ca. 100%). [b] The concentration of **1** was 5×10^{-3} M in all reactions. [c] Determined by ^{1}H NMR spectroscopy in [D_6]DMSO.

good agreement with the distribution for the overall reaction in DMSO (Table 1). Unexpectedly, in $CHCl_3$, the (*E*) isomer **7** reacted with **1** to form **4** in yields of up to 65%. The same result holds for the reaction of the (*Z*) isomer **8** with **1**: 64% of S-shaped **4** was obtained. Whatever the reason, $CHCl_3$ disfavors the formation of C- or W-shaped products (Table 2). A factor that could be responsible is that $CHCl_3$ either fits into the transition state leading to the S-shaped product, or makes an inappropriate fit into the transition state leading to the other products. The S-shaped isomer may have a uniquely compact low-energy conformation (Scheme 2),[10] in which its internal cavity can be filled by the isopentyl esters of a glycoluril unit. In benzene the product distribution was reversed, and a yield of 64% was obtained for C-shaped **3**. This is the medium in which the solvent-occupied dimeric capsule enjoys the greatest stability.

It is possible to calculate the distributions of **3**–**5** in different solvents by using the data for the second stage and assuming that the first stage gives equal amounts of (*Z*) and (*E*) intermediates. The results (Table 3) compare well with the experimental observations summarized in Table 1, and clearly

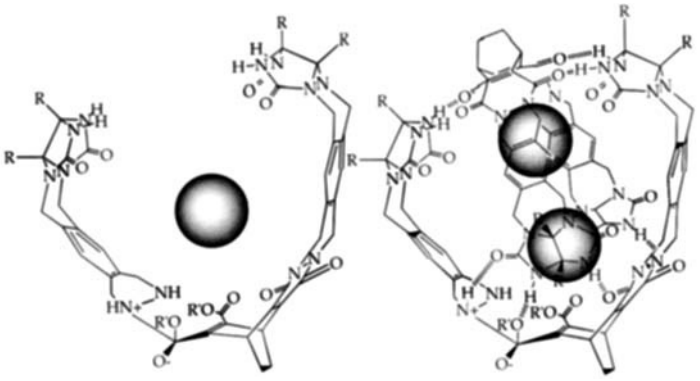
Table 3. Estimated distribution of yield[%][a] for **3**–**5** in different solvents.

	3	4	5
DMSO			
total yield	31	44	25
(*E*) isomer	0	25	25
(*Z*) isomer	26	25	0
$CHCl_3$			
total yield	19	66	16
(*E*) isomer	0	33	18
(*Z*) isomer	18	32	0
benzene			
total yield	36	43	20
(*E*) isomer	0	31	19
(*Z*) isomer	32	18	0

[a] Calculated from the results of reactions **1**+**2a**, **1**+**7**, and **1**+**8**; [total yield] = [**3**]+[**4**]$_Z$+[**4**]$_E$+[**5**], where [**3**], [**4**]$_Z$, [**4**]$_E$, and [**5**] correspond to the concentrations of isomers **3**, **4**, and **5**, which are produced from both (*Z*) and (*E*) isomers.

justify the assumption that selection occurs in the second stage of the reaction.

It is hard to imagine that solvent plays a role in the first stage of the reaction, as the stereocenters are remote from each other and only connected by a single amide: No cavities are generated in the rate-determining step. However, the curvature and the concave shapes of the (*E*) and (*Z*) intermediates invite solvation. Benzene, toluene, or *p*-xylene can be recognized by and well fit within the (*Z*)-shaped intermediate. Subsequently, the remaining exposed surface of the solvent attracts reactant **1**, and lends stability to the reversibly formed zwitterionic, tetrahedral intermediate that leads to the C-shaped product (Scheme 5, left). One of these solvent molecules must fit well within the monomeric form of **3**, since



Scheme 5. Possible tetrahedral intermediates of the reaction between **1** and **2**: left: monomer A associated with one solvent molecule; right: templated complex B.

two of these molecules are accomodated inside the dimeric capsule.[6] Alternatively, or in addition, the templated pathway involving the hydrogen-bonded tetrahedral intermediate (Scheme 5, right) is possible.[11] Since the dimerization constant of **3** in benzene is high, the concentration of monomers **3** (template) and its complex (Scheme 5, right) must be very low. Such situations were encountered by von Kiedrowski[12] for templating hexadeoxynucleotides and Ghadiri et al. for templating peptides.[13] Autocatalysis in the case presented here has yet to be established. We are confident in this respect, as template effects of products during the synthesis of self-assembled dimeric capsules have already been observed.[9,14] Meanwhile, we propose that the most commonly encountered molecular recognition phenomenon—solvation—plays an active rather than a passive role in the formation of a covalent bond.

[8] For example, the ^{1}H NMR spectrum of **3** in [D$_6$]benzene contains sharp signals and, in particular, a downfield NH-singlet at $\delta = 8.83$ that is independent of concentration; the corresponding NH-singlet in model (nondimeric) glycolurils is at $\delta \approx 5.0$ in [D$_6$]benzene. The FT-IR spectrum of **3** (benzene, $2 \times 10^{-5} - 1 \times 10^{-3}$ M) showed only the NH stretching absorption at 3229 cm^{-1}, which is about 180 cm^{-1} lower than that observed for nonassembled glycolurils. From ^{1}H NMR dilution experiments ($5 \times 10^{-4} - 1.5 \times 10^{-2}$ M), a lower limit for the dimerization constant K_D of 10^7 M^{-1} was estimated. Solutions of **3** in benzene were analyzed by electrospray mass spectrometry (ESI-MS) and showed, in addition to the signal for monomer **3** at 1268 Da, a fairly strong (ca. 20%) signal for dimer **6** at 2535 Da.

[14] 1-Adamantanecarboxyamide—known as a good guest for dimeric capsule **6** in benzene and *p*-xylene [6]—also enhanced the yields of **3** in these solvents but not in $CDCl_3$, in which the carboxamide is not encapsulated.

Synthesis and Structure of ITQ-3, the First Pure Silica Polymorph with a Two-Dimensional System of Straight Eight-Ring Channels**

Miguel A. Camblor,* Avelino Corma, Philip Lightfoot, Luis A. Villaescusa, and Paul A. Wright*

Silicon dioxide appears in nature in several crystalline forms of high density, like quartz, cristobalite, tridymite, moganite, and the high pressure polymorphs coesite, keatite, and stishovite.[1] The mineral melanophlogite also presents a framework of SiO_2, which contains cages in which gases are occluded. In the last two decades a number of new pure silica polymorphs, some of them with microporous frameworks, have been synthesized with the aid of organic structure-directing agents.[2] Microporous, pure silica polymorphs lacking Si–OH moieties arising from defects of connectivity between adjacent tetrahedra can have considerable technological interest in view of their hydrophobic properties.[3] For example, silica polymorphs with small channels (apertures formed by windows containing eight SiO_4 tetrahedra) would show shape-selectivity properties in adsorption and would find attractive potential applications in purification and separation processes. However, the only silica phases containing eight-ring (8MR) pores that are available so far, namely, decadodecasil-3R (with a two-dimensional (2D) system of sinusoidal 8MR channels) and RUB-3 (1D 8MR channels),[4] are relatively dense,[5] characterized by a framework density (*FD*, defined as the number of Si atoms per 1000 Å^3) of 17.7 and 17.4, respectively. These features limit their adsorption properties and are a clear drawback for this kind of application.

We report here on the synthesis and structure of ITQ-3,[6] the first pure silica polymorph containing a two-dimensional system of straight 8MR pores. This phase presents a very low density structure characterized by an *FD* of 16.3, which is the second lowest *FD* among silica polymorphs, the first one being that of the three-dimensional, large pore, 12-ring pure silica zeolite Beta ($FD = 15.6$).[7] Furthermore, ITQ-3 possesses the largest microporous volume as measured by N_2 adsorption (0.23 cm^{3}g^{-1}, relative to 0.22 cm^{3}g^{-1} measured for pure silica Beta).[7]

Calcined ITQ-3 consists of a three-dimensional framework of 4-connected SiO_4 tetrahedra with no Si-O-Si connectivity defects, as evidenced by its ^{29}Si MAS NMR spectrum (Figure 1), which shows no absorptions below $\delta = -105$ due to Si (3Si,1OH) species. Moreover, the spectrum shows a very high resolution of tetrahedral Si (4Si) sites, directly attributable to the crystallographically distinct Si environments in the structure. Such a high resolution is generally only observed when there is an essentially complete absence of Si–OH and Si-O-Al species.

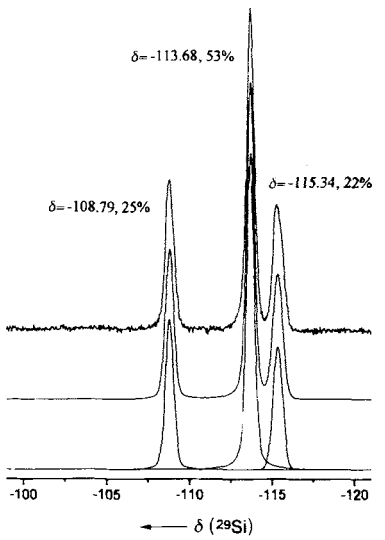

Figure 1. ^{29}Si MAS NMR spectrum of pure silica ITQ-3. From bottom to top: deconvoluted components, simulated, and experimental spectra.

The experimental synchrotron X-ray powder diffraction data of a calcined ITQ-3 sample was indexed as orthorhombic ($a = 20.622(1)$, $b = 9.7242(4)$, $c = 19.623(2)$ Å) and with symmetry *Cmcm*, *Cmc*2$_1$, or *C*2*cm* (determined by the examination of the systematic absences). These symmetries were consistent with the ^{29}Si MAS NMR spectrum of ITQ-3 (Figure 1), if the unit cell possessed four distinct crystallographic sites for silicon, each on general equivalent positions and two of the four having overlapping resonances.

The unit cell size and symmetry were observed to be consistent with a structural model that can be described as that produced by the unit cell twinning of the zeotype RUB-13

(structure code RTH).[8] A similar relationship is observed between the structure types TON and MTT.[9] To determine whether this proposed structure for ITQ-3 fits the experimental diffraction data, a model was obtained starting from the set of atomic coordinates for silicon atoms in RTH, applying *Cmcm* symmetry in the unit cell (with a doubled cell repeat along c^* relative to that in RTH, arising from the unit cell twinning), and placing oxygen atoms midway between the tetrahedral atoms. This model was refined against the diffraction data with the presence of constraints on the Si–O and Si–Si bond lengths and on the O-Si-O bond angles. Although the profile was reasonably well fitted, Bragg reflections related to the cell twinning exhibited broadening with respect to the other peaks. This broadening was matched empirically with the peak broadening options implemented within the GSAS program.[12] The fit was significantly improved if the low angle peaks (below 11°) were excluded, because the values of the peak broadening functions are largely determined by these intense peaks (if included), and these values are not accurately extrapolated over the rest of the profile. A more theoretical treatment of this peak broadening dependence on (*hkl*) is underway in terms of distances between stacking faults parallel to (001). The final fit to the diffraction profile is sufficiently close (Figure 2) to

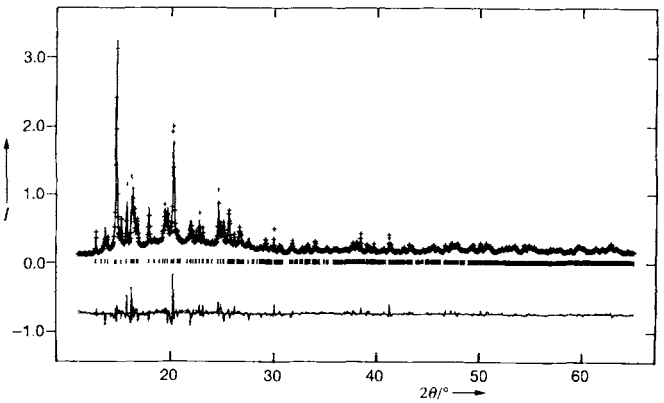

Figure 2. Observed (+) and calculated (bars) Rietveld refinement of ITQ-3, as well as the difference profile (bottom). The broad background hump arises from diffuse scattering from the silica glass capillary. I = intensity (in counts × 10^4).

indicate that the structural model is correct. No significant improvement in fit was obtained by lowering the symmetry. To demonstrate that ITQ-3 is indeed a distinct end-member of the structural series, Figure 3 compares the simulated diffraction patterns of ITQ-3 (this work) and RTH[8] with the experimental diffractogram measured on calcined ITQ-3 with a laboratory X-ray diffractometer.

A stereoplot of the ITQ-3 framework down [010] is given in Figure 4. The structure of ITQ-3 comprises a two-dimensional system of interconnected 8MR straight channels running along [010] and [001]. The intersection of both types of channels generates four large cavities per unit cell in which presumably the template cations are located (exactly one per cage, according to the chemical composition, see experimental section). These cavities, which can be denoted as $[4^65^86^48^4]$ (where n^i indicates that there are i faces of n sides in the polyhedral cage defining the cavity; Figure 5, right), are very similar to those found in the borosilicate RUB-13[8] (Figure 5, left) except for the presence of the mirror plane perpendicular to c, which RUB-13 lacks. This makes a significant difference in terms of shape of the cage (although not so in terms of

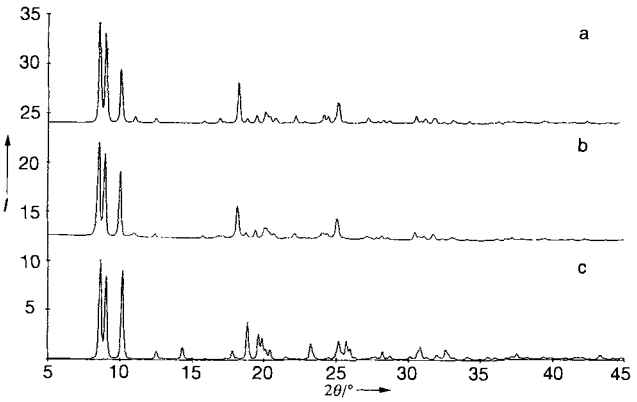

Figure 3. Comparison of the simulated X-ray diffraction pattern of ITQ-3 ($Cu_{K\alpha 1}$) (a) with experimental X-ray diffraction data (laboratory diffractometer) of calcined ITQ-3 (b). The pattern simulated from the atomic coordinates of RTH (c)[8] is also given. I = intensity (arbitary units).

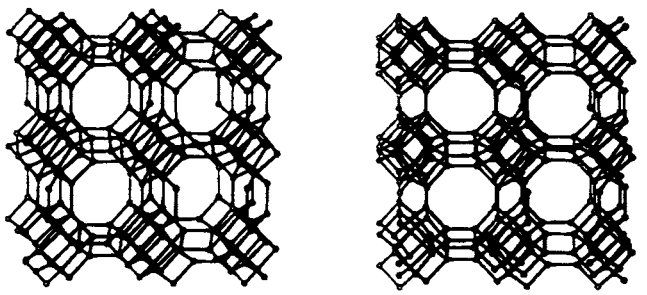

Figure 4. Stereo plot of the structure of ITQ-3 down [010]. Only tetrahedral atom connectivity is represented.

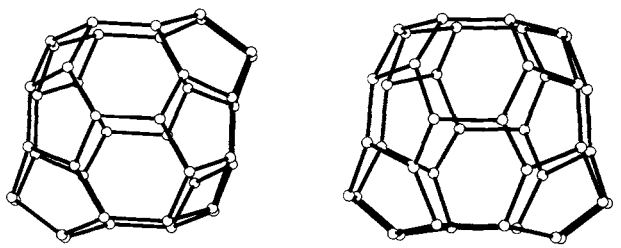

Figure 5. Comparison of the $[4^65^86^48^4]$ cages of RTH (left) and ITQ-3 (right).

volume), and presumably, the synthesis of ITQ-3 is made possible by a tight fit of the template cation in this cage. Further work to locate the exact position of the cation in as-made ITQ-3 is in progress to check this hypothesis, which would imply a true template effect in the synthesis of this new pure silica polymorph.

The incorporation of Al in framework positions of ITQ-3 is also easily achieved.[6] This allows the preparation of acid catalysts that, due to the small pore openings and the large cage present in the structure, show marked shape-selectivity properties. This catalyst can be advantageously used in several applications of high technological importance, like the selective cracking or hydrocracking of normal alkanes or alkenes, postreforming of gasoline, steam cracking, dewaxing by selective cracking of normal alkanes, and transformation of methanol to olefins.[6]

Finally, the synthetic procedure that led to the synthesis of ITQ-3 appears to show an outstanding ability to produce pure

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3623-2660 $ 17.50+.50/0

silica polymorphs of remarkable low framework density. With different structure-directing agents the method has so far produced the spontaneous nucleation and growth of the Beta (BEA),[7] ITQ-4 (IFR),[10] and ITQ-3 pure silica polymorphs. These three phases share the notable characteristic of having the lowest framework densities ever reported for pure silica polymorphs (15.6, 17.0 and 16.3, respectively; compare with 17.4 for RTE and pure silica SOD). This synthetic methodology, based on the F^- method first introduced by Flanigen and Patton, and subsequently developed by others,[11] makes use of comparatively low temperatures (below 175°C, typically a maximum of 150°C) and low F^-/SiO_2 and H_2O/SiO_2 ratios (typically about 0.5 and ≤ 15, respectively) and appears to open a promising route to the synthesis of very open pure silica frameworks.

Experimental Procedure

Synthesis: Pure silica ITQ-3 was synthesized from 1,3,3,6,6-pentamethyl-6-azoniabicyclo[3.2.1.]octane ($C_{12}H_{24}N^+$) as structure-directing agent. This cation was prepared by reaction of the corresponding amine with an excess of CH_3I and was used in its hydroxide form after anion exchange of the iodide. The hydrothermal reaction (PTFE-lined stainless steel autoclaves, 150°C, rotation (60 rpm), 19 days, pH = 7.5, composition SiO_2:0.5 $C_{12}H_{24}NOH$:0.5 HF:7.7 H_2O) yielded a white highly crystalline solid (20.9 g per 100 g of initial mixture, amounting to about 90% of the silica recovered as ITQ-3). Chemical analysis of as-made ITQ-3 reveals that the sample contains no aluminum and that the organic cation is occluded intact within its pores (elemental analysis found: C 12.48, H 2.05, N 1.20, F 1.50%; the ideal unit cell composition of $(C_{12}H_{24}NF)_4(SiO_2)_{64}$ requires C 12.40, H 2.08, N 1.20, F 1.63%). The integrity of the organic cation in as-made ITQ-3 is also evidenced by ^{13}C CPMAS NMR spectroscopy. After calcination at 580°C the organics are removed from the material.

Structure determination: A synchrotron X-ray powder diffraction pattern was collected at room temperature over the range $3 \geq 2\theta \geq 66°$, with a 0.01° step size, over 12 hours on beamline 9.1 at the Daresbury synchrotron using X-rays of wavelength 1.2513(2) Å. No special precautions were taken to remove all of the water from the sample, which was packed in a 0.7 mm diameter silica glass capillary. X-ray diffraction data on the same sample was collected on a laboratory STOE powder diffractometer in transmission mode, with monochromated $Cu_{K\alpha 1}$ radiation ($\lambda = 1.54056$ Å). In this case the sample was prepared in a disc between thin mylar sheets.

Profile refinement of the structural model was performed with the Rietveld method within the GSAS program,[12] using bond length and bond angle constraints. In the final fit the profile was matched from $11 \geq 2\theta \geq 66°$. The final refinement used 59 variables and 57 constraints and had R_{wp} and R_p values of 8.6 and 6.2%, respectively. The average values and standard deviations of Si-O bond lengths were 1.60(4) Å and of O-Si-O angles were 109.4(3.5)°; the final atomic coordinates are given in Table 1. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, on quoting the depository number CSD-407793.

1,5,7-Triazabicyclo[4.4.0]dec-5-ene Immobilized in MCM-41: A Strongly Basic Porous Catalyst**

Yarlagadda V. Subba Rao, Dirk E. De Vos, and Pierre A. Jacobs*

Basic catalysis is in general an area that is less developed than acidic catalysis; this is particularly true for highly dispersed or porous materials.[1] Zeolites or mesoporous molecular sieves can acquire basicity by exchange or impregnation with Cs^+, but the limited strength of the resulting basic sites offers perspectives for only a small range of organic syntheses.[2] Similarly, aluminophosphate nitride catalysts show low basicity, and are relevant only in Knoevenagel additions.[3] As an alternative, highly reactive entities such as Na clusters have been introduced into zeolites. Although these materials can handle difficult reactions such as side-chain alkylations, they are extremely prone to deactivation by environmental CO_2 or water.[4] These examples illustrate the continuous interest in designing new solid, basic catalysts.[5–7] To facilitate handling these materials should have an inorganic backbone structure; however, classic oxides have the disadvantage of potentially releasing OH^- ions into solution. Here we present a novel heterogeneous, strongly basic catalyst, in which a guanidine base is covalently coupled to

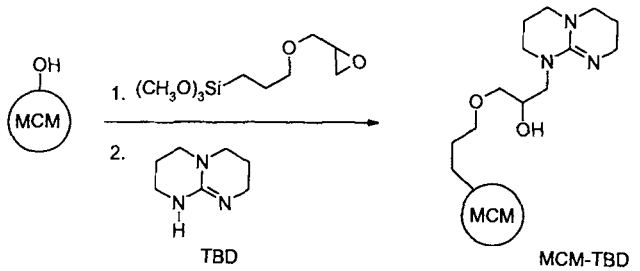
an inorganic siliceous mesoporous support. It is demonstrated that this material is truly catalytic for, for example, Michael additions under remarkably mild conditions. The pore structure influences the selectivity of the reaction, as shown by a comparison with a nonporous material. Reactions that are discussed include Michael additions, Robinson annulations, Knoevenagel condensations, and nucleophilic epoxidations.

1,5,7-Triazabicyclo[4.4.0]dec-5-ene (TBD, Scheme 1) is the prototype for a group of strong guanidine bases which can be used as stoichiometric reagents or as catalysts. The pK_B values



Scheme 1.

of these bases are about 25, ensuring a well-defined and strong basicity.[8] TBD contains a N–H group, which can be immobilized by nucleophilic attack on an immobilized electrophile. The traditional approach uses substitution of a chloro- or bromopropyl group with the amine. However, this requires harsh conditions, and the liberated acids (HCl, HBr) might poison the base sites. Furthermore, quaternization of the amine is a hardly avoidable side reaction.[5,6] Therefore, a route by surface glycidylation was designed. We previously applied this method successfully in the immobilization of an azacycloalkane epoxidation catalyst.[9] First, the mesoporous, siliceous MCM-41 support is obtained by the usual liquid crystal templated synthesis.[10] Next, its inner surface is covered with oxirane groups by reaction of the surface SiOH groups with 3-trimethoxylsilylpropoxymethyloxirane. Finally, TBD reacts under remarkably mild conditions with the epoxide group without formation of any by-products (Scheme 1).

The success of this reaction sequence was confirmed by IR and NMR spectroscopy as well as thermogravimetric analysis. For instance, the magic angle spinning solid-state NMR spectrum shows that the oxirane ring in the silane coupling agent is intact after the reaction with the surface hydroxyl groups. Measurement of the N_2-adsorption isotherm demonstrated that the pore volume with a radius smaller than 2 nm substantially decreases from 1.62 mL N_2 STP (standard temperature and pressure) to 1.2 mL per gram by the anchoring of the TBD unit. Moreover, the average pore diameter also shows a tendency to decrease, suggesting that the environment for organic reactions is spatially more constrained after surface modification.

The MCM-TBD material was used as a catalyst for Michael reactions (Scheme 2). It is critical that the catalyst accelerates only the desired 1,4-addition, and bypasses side reactions such as other condensations, dimerizations, or rearrangements. Some results are compiled in Table 1. Excellent selectivities were obtained for the reaction of typical Michael donors and enones. For instance, with ethylcyanoacetate (ECA) and cyclopentenone, the 1,4-adduct is obtained in 52% yield and

Table 1. MCM-TBD as a catalyst for Michael reactions of ethylcyano acetate (ECA) and diethyl malonate (DEM) [a].

Entry	Donor	Acceptor	T[K]	t[h]	Yield[%][b]
1	ECA	methyl vinyl ketone	338	0.5	98 (81)[c]
2	DEM	methyl vinyl ketone	338	0.5	34 (1)[c]
3	ECA	acrolein	313	0.5	100 (55)[c]
4	DEM	acrolein	313	0.5	100 (53)[d]

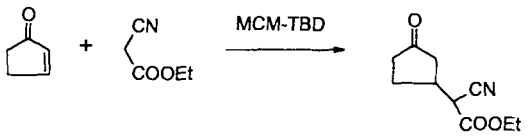
10	DEM	cyclohexenone	353	60	2.7
11	DEM	cyclohexenone	353	60	15
12	DEM	methyl vinyl ketone	338	0.5	7

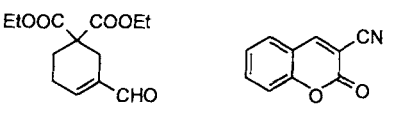
[a] Conditions: 1 mmol of donor, 1 mmol of acceptor, 20 mg of catalyst (MCM-TBD for entries 1–10 and TBD-modified SiO_2 for entries 11 and 12), 2 mL of CH_3CN under N_2. [b] Yields are based on the Michael acceptor. [c] Molar yield of di-addition product in parentheses. [d] Cyclized product **1**. [e] Knoevenagel adduct.



Scheme 2.

100% selectivity (Scheme 2). The well-defined strong basicity of the MCM-TBD catalyst ensures optimum selectivity for most reactions. Not only cyano-activated donors, but also the less acidic diethylmalonate (DEM) can be successfully used. Acrolein reacts with DEM to lead to double Michael addition of the acceptor on the donor and eventual cyclization to **1**. The preference for single or double addition can be controlled by reaction stoichiometry, time or, temperature. The previously reported Cs-MCM-41 materials only catalyze Michael reactions under much more drastic conditions (high concentrations, 24 h, 428 K).[26] In contrast, the present MCM-TBD catalyst requires 0.5–5 h at 293–353 K.

Ring formation to form **1** in the reaction of acrolein on DEM proves that the catalyst is also capable of performing the aldol condensation, which is the second stage in the



1 **2**

Robinson annulation. This was confirmed by reactions of indanedione or cyclohexan-1,3-dione with methyl vinyl ketone, in which both the primary adduct and the annulation product were obtained.

In most cases, the order of reactivity is as expected from electronic arguments. For acceptors in Michael additions the order is cyclopentenone ≈ cyclohexenone < acrylonitrile < ethyl acrylate ≈ methyl vinyl ketone < acrolein. However, anomalies are observed for the attempted formation of large Michael adducts with the MCM-TBD catalyst. This becomes most apparent when the MCM-TBD catalyst is compared with an amorphous silica on which TBD has been analogously

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3623-2662 $ 17.50+.50/0

anchored (Table 1, entries 11 and 12). Differences in reactivity can therefore be traced directly back to the steric influence of the host structure. The MCM-TBD catalyst is more active for most reactions (e. g. methyl vinyl ketone + DEM, entries 2 and 12), which is presumably due to a higher surface loading of active groups. However, this activity order is reversed for the reaction of cyclohexenone and DEM (entries 10 and 11). The large size of the adduct and the reduced pore size in the modified MCM material suggest that this might be a case of transition state shape selectivity.

Whereas Michael reactions require a pronounced basicity, Knoevenagel condensations of aromatic aldehydes are a lot easier. With the MCM-TBD catalyst they proceed smoothly and even at room temperature (Table 2). The selectivity is excellent, usually over 90%, and in several cases yields approach 100%. In the reaction of salicylaldehyde and ECA, the 1,2-addition is followed by an intramolecular esterification, leading to 3-cyanocoumarin (**2**) in a 58% yield. The remarkable stability of the catalytic activity may well be due to the fact that the anchored TBD is a tertiary amine. This avoids the formation of Schiff bases, which is a major problem with the more familiar immobilized primary or secondary amines.[6]

Table 2. Knoevenagel condensations with MCM-TBD [a].

Donor	Acceptor	Yield [%] [b]
ethylcyano acetate	PhCHO	54
	PhCHO	41 [c]
	p-NO_2-PhCHO	95
	p-CH_3O-PhCHO	9
malononitrile	PhCHO	95
	p-NO_2-PhCHO	98
	p-CH_3O-PhCHO	48

[a] Conditions: 1 mmol of donor, 1 mmol of acceptor, 5 mg of catalyst, 2 mL of toluene, 1–2 h, 343 K, N_2 atmosphere. [b] Yields are based on the aldehyde. [c] 24 h, 293 K.

Even under the aqueous conditions of epoxidation with H_2O_2, the material still exhibits its basic properties. A heterogeneous catalyst for nucleophilic epoxidation of, for example, alkenones should selectively deprotonate H_2O_2, which is considerably more acidic than water. In case of MCM-TBD, the HOO^- anion forms a hydrophobic ion pair with the protonated catalyst. The lipophilicity of the MCM-TBD catalyst favors adsorption of the olefin substrate, which reacts via a 1,4-addition intermediate. While the yields for alkenals might be lowered by acetal formation, particularly alkenones are easily epoxidized with high selectivities (Table 3). Therefore, the use of the heterogeneous catalyst avoids the need for a liquid base and facilitates work-up of the product.

Our results prove that it is feasible to introduce strong, non-hydroxide basicity into a MCM-41 structure by the covalent bonding of the active centers on MCM carriers. The mechanical stability of the inorganic support materials ensures easy separation of the solid catalyst and the liquid phase, which is a serious problem for organic polymer supported catalysts.[5] The coupling procedure itself is highly convenient, and much more simple and general than an in situ synthesis approach.[7] Finally, the pool of available guanidine bases ensures optimum adaptability of the catalyst to specific reaction requirements.

Table 3. Epoxidations with MCM-TBD [a].

Substrate	TON	*S* [%]
methyl vinyl ketone	109	63 [b]
cyclopentenone	183	> 95
cyclohexenone	80	89
trans-2-hexenal	195	31 [c]

[a] Conditions: 1 mmol of substrate, 2 mmol of H_2O_2, 5 mg of catalyst, 1 mL of methanol, 273 K, 1–2 h. Turnover numbers TON were calculated as mole of product per mole of immobilized TBD. Selectivities *S* were calculated with respect to the enone or enal. [b] The remainder was the dimer of methyl vinyl ketone. [c] The remainder was the (hemi)acetal.

Experimental Section

Siliceous MCM-41 was obtained by the procedure of Beck et al. [10], and the residual template was removed by calcination. The vacuum-dried support (3 g) was allowed to react with trimethoxysilylpropoxymethyloxirane (4.5 mmol) in dry toluene at reflux for 24 h. IR spectroscopy shows that consumption of the surface silanol groups is almost complete. The glycidylated MCM-41 (1.0 g) was allowed to react with TBD (2.2 mmol) in toluene (15 mL) at 298 K for 10 h, and excess TBD was removed by lengthy soxhlet extraction with CH_2Cl_2. The resulting MCM-TBD catalyst was stored under vacuum. Thermogravimetric analysis provided a nitrogen content of 1.05 mmol per gram, which corresponds to 0.35 mmol of TBD per gram.

In a typical Michael addition the MCM-TBD catalyst (20 mg), the donor (1 mmol), CH_3CN (2 mL), and the acceptor (1 mmol) were placed successively in a Schlenk tube under nitrogen. The reaction was followed and quantified by gas chromatography, and products were identified with GC-MS and NMR spectroscopy.

Absorption/Electron Transfer/Absorption—An Efficient Pathway to Hydrated Electrons in Laser Flash Photolysis**

Valentin Zubarev and Martin Goez*

The solvated (hydrated) electron is a key intermediate in pulse radiolysis.[1] It can also be formed in laser flash photolysis by the absorption of a single photon[2] or, more frequently, by the successive absorption of two photons.[3] In all examples of the latter pathway reported so far, the intermediate that is ionized by the second photon has invariably been an excited state produced by absorption of the first photon. In this work, we present the first instances of photoionization by an absorption/electron transfer/absorption mechanism, that is, where the second photon is absorbed by a radical ion. As we will show, this pathway to hydrated electrons is quite efficient; moreover, it could be fairly common in laser flash photolysis and thus have consequences for mechanistic interpretations.

For detection we used Fourier Transform (FT) EPR spectroscopy.[4] Most of the investigations were carried out with the system anthraquinone-1,5-disulfonate/methionine (AS/Met). The experiments were performed in aqueous solution at pH $\approx$ 11, that is, well above pK_{a2} of the amino acid.[5]

Intersystem crossing of photoexcited ^{1}AS leads to the formation of a spin-polarized triplet state ^{3}AS,[6a] which is characterized by an electron spin relaxation time of 1 ns.[6b] From experiments with varying concentration of the amino acid, the rate constant for electron transfer quenching of ^{3}As by Met was estimated to be higher than 5×10^9 M^{-1}s^{-1}. Under our experimental conditions (typically, [Met] = 0.1 M) the life of ^{3}AS is thus decreased to well below 1 ns, and at least 30% of its spin polarization is transferred to the radical ions $AS^{\bullet-}$ and $Met^{\bullet+}$, which are the primary products of electron transfer quenching. Quinone concentrations below 5×10^{-4} M were chosen to avoid self-quenching of ^{3}AS and EPR line broadening due to spin-exchange, as well as to ensure homogeneous generation of the radicals (the optical density of the samples is smaller than 0.1 at the excitation wavelength of 308 nm). It was ascertained that the light is absorbed only by the quinone despite the disparately larger concentration of the quencher.

Figure 1 shows FT-EPR spectra of this system obtained at two different delay times between laser flash and acquisition pulse. The easily identifiable emission signal[6a] of the semiquinone radical anion $AS^{\bullet-}$ is found in all these measurements, whereas no signals of methionine-derived radicals are visible.[7] The most notable feature of the spectra in Figure 1 is the occurrence of an emissively polarized singlet EPR line. This peak is only observed at low quinone concentration ($\lesssim 5 \times 10^{-4}$ M); its intensity relative to the $AS^{\bullet-}$ signal increases with decreasing quinone concentration. Its g value of 2.00055 is indicative[3] of a hydrated electron. This assignment was rendered beyond doubt by experiments with

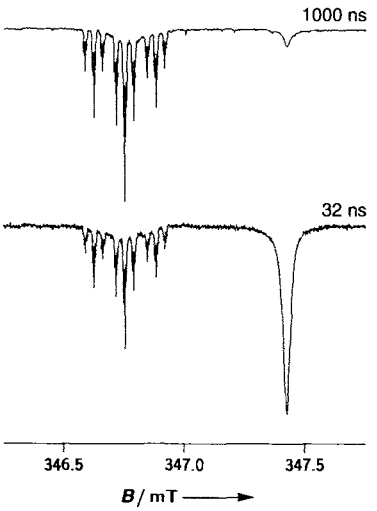

Figure 1. Spin-polarized FT-EPR signals (ν = 9.728 GHz) in the photoreaction of 1×10^{-4} M anthraquinone-1,5-disulfonate (AS) with 0.1 M methionine in H_2O at pH 11. Bottom trace: start of acquisition pulse 32 ns post flash, 100 transients; top trace: start 1000 ns post flash, 1000 transients. The intensities in both spectra are directly comparable. The multiplet is due to the semiquinone radical anion $AS^{\bullet-}$, the singlet to the hydrated electron e^-_{aq}.

the electron scavengers N_2O and $ClCH_2COO^-$, which do not undergo electron transfer with either ^{3}AS or $AS^{\bullet-}$. Saturation of the solution with N_2O completely suppressed the singlet EPR peak. The hydroxyl radical resulting from this scavenging process is unobservable owing to its fast reaction with Met.[9] When the photoreaction was carried out in the presence of 5×10^{-3} M of $ClCH_2COO^-$, the intensity of the emissive singlet was strongly reduced while the triplet of the $\cdot CH_2COO^-$ radical[10] appeared, also in emission. These experiments provide unequivocal evidence for the formation of the hydrated electron e^-_{aq} as an intermediate in the photoreaction of ^{3}AS with Met.

The FT-EPR signals of $AS^{\bullet-}$ and of e^-_{aq} exhibit an opposite time dependence (Fig. 1). From 32 ns post flash onwards (the shortest possible delay between the end of the laser flash and the start of the acquisition pulse with the spectrometer used), the polarization of e^-_{aq} decreases monotoneously to zero while the polarization of $AS^{\bullet-}$ increases by a comparable amount. By varying the reactant concentrations, it was established that these effects are due to the reaction of e^-_{aq} with ground state AS ($k \approx 2.5 \times 10^{10}$ M^{-1}s^{-1}),[11] which transfers emissive polarization from e^-_{aq} to $AS^{\bullet-}$; scavenging of e^-_{aq} by Met ($k < 1 \times 10^7$ M^{-1}s^{-1}),[12] and relaxation of e^-_{aq} ($T_1(e^-_{aq}) = 8$ μs)[3a] play only a secondary role under our experimental conditions.

The reaction of e^-_{aq} with AS provides the explanation why e^-_{aq} is not observed at quinone concentrations higher than about 5×10^{-4} M. First, in our experiments the linewidth of the e^-_{aq} singlet is determined by the chemical lifetime of this species. Hence, increasing the concentration of AS increases the linewidth of the e^-_{aq} signal and decreases its peak height proportionally. Second, the acquisition pulse (duration 48 ns) is not a δ-pulse (i.e., not infinitely short) on the timescale of the chemical decay. Sampling an exponentially decreasing magnetization with such a "long" pulse starting at a certain time after the laser flash is equivalent to sampling it with a δ-pulse that is delayed by an additional time τ;[14] under our experimental conditions, τ amounts to a constant 30 ns. Third, the rise time of the pulse (33 ns at a resonator frequency of 9.73 MHz and a Q value of 1000) acts like a further shift of the same magnitude.[14b] These delays cause a much stronger

reduction of the e^-_{aq} signal with increasing quinone concentration than would be expected at the start of the observation pulse 32 ns post flash.

The polarization ratio $P(e^-_{aq})/P(AS^{\bullet-})$ depends on the intensity I_{exc} of the excitation light, a decrease of I_{exc} leading to a decrease of this ratio. After correction for the above-mentioned polarization transfer by the reaction of spin-polarized e^-_{aq} with ground-state AS, the relationship between I_{exc} and $P(e^-_{aq})/P(AS^{\bullet-})$ is approximately linear. This clearly shows that a second photon is involved in the production of e^-_{aq}. As virtually no EPR signals are observed in the absence of a quencher,[15] the hydrated electron must be generated by two successive monophotonic steps: first excitation of AS and then photoionization of an already spin-polarized intermediate.

$AS^{\bullet-}$ is the most likely candidate for this intermediate, photoionization of radical anions being a well-known process.[2a,b,16] It absorbs strongly at 308 nm ($\varepsilon \approx 1 \times 10^4\ M^{-1}cm^{-1}$).[18] The standard redox potential E^0 for the reaction (1) is calculated to be 2.27 V from E^0 for the half reactions (2) and (3)

$$AS^{\bullet} + nH_2O \rightleftharpoons AS + e^-_{aq} \quad (1)$$

$$e^-_{aq} \rightleftharpoons nH_2O + e \qquad E^0 = 2.77\ V\ [1] \quad (2)$$

$$AS + e^- \rightleftharpoons AS^{\bullet-} \qquad E^0 = -0.50\ V\ [17] \quad (3)$$

At 308 nm (i.e., 4.0 eV), photoionization of $AS^{\bullet-}$ is thus thermodynamically feasible.

An approximate expression for $P(e^-_{aq})/P(AS^{\bullet-})$ at the end of the laser pulse (duration $\tau_L = 20$ ns) can be derived by neglecting the secondary reaction of e^-_{aq} with AS. Assuming a rectangular laser pulse, the photoionization of $AS^{\bullet-}$ is described as a first-order process. This implies optically thin samples, which is fulfilled in our case. The corresponding rate constant k_{ion} is directly proportional to I_{exc}. Furthermore, the generation rate of $AS^{\bullet-}$ can be taken as constant because τ_L is much longer than the spin-polarized lifetime of excited ^3AS. For $P(e^-_{aq})/P(AS^{\bullet-})$ one obtains Equation (4) (cf. ref. [19]), the right-hand side of which is approximately equal to $k_{ion}\tau_L/2$, because in our experiments $k_{ion}\tau_L \lesssim 1$. This is in accordance with the experimentally observed dependence of $P(e^-_{aq})/P(AS^{\bullet-})$ on I_{exc}.

$$\frac{P(e^-_{aq})}{P(AS^{\bullet-})} = \frac{k_{ion}\tau_L}{1-\exp(-k_{ion}\tau_L)} - 1 \quad (4)$$

Hydrated electrons were also found in similar chemical systems. When ^3AS was quenched by triethylamine TEA ([TEA] = 0.03 M, pH = 9) instead of Met, the ratio $P(e^-_{aq})/P(AS^{\bullet-})$ at 32 ns post flash remained essentially the same. In this system, (emissive) polarizations were also observed for the quencher-based radicals $TEA^{\bullet+}$. Likewise, with SO_3^{2-} as quencher ($[SO_3^{2-}] = 0.1$ M, pH = 11) the three intermediates $AS^{\bullet-}$, $SO_3^{\bullet-}$, and e^-_{aq} were detected, all polarized in emission. Although in this case the yields of e^-_{aq} were rather low, which we ascribe to scavenging by an impurity (presumably hydrogen peroxide formed during preparation of the solutions), the intermediacy of much larger amounts of e^-_{aq} could be confirmed by adding the scavenger $ClCH_2COO^-$, which gave a strong signal of $\cdot CH_2COO^-$.

The all-emissive polarizations in the systems AS/TEA and AS/SO_3^{2-} show that the triplet mechanism is their only source. As no new polarizations are generated at the radical pair stage, the polarizations of e^-_{aq} and of $AS^{\bullet-}$ must thus be proportional to the respective concentrations, with identical constants of proportionality. Hence, it can be concluded from integration of the signals in Figure 1 that approximately equal amounts of e^-_{aq} and $AS^{\bullet-}$ are formed under the experimental conditions (maximum light intensity about 5×10^{16} photons per cm^2, which seems to be fairly representative for other laser flash photolysis experiments as well). The absorption/electron transfer/absorption pathway to e^-_{aq} is thus quite efficient. Despite this fact, it does not seem to have been observed before in laser flash photolysis, although reported routes to solvated electrons such as pulse radiolysis/absorption[2a] or chemical reduction/absorption[2b] bear resemblance to it.[19] The reasons why e^-_{aq} could be detected in the present work are, first, that its life was increased by the use of small sensitizer concentrations, and second, that a very specific detection method, EPR spectroscopy, was employed in its much more sensitive pulsed and FT variant.

It is expected that the described pathway to solvated (hydrated) electrons by two-photon ionization via radical ions is not confined to these few examples but is a general mechanistic possibility in photoinduced electron transfer reactions studied by laser flash photolysis, especially in strongly quenched samples. While e^-_{aq} might not be observable under normal experimental conditions—namely, higher sensitizer concentrations—because it is immediately scavenged, its intermediacy would nevertheless exert an influence on the quantum yields and, owing to its high reactivity, very likely also on product distributions and rate constants.

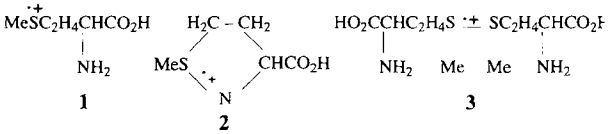
[7] There are two likely reasons for the failure to detect these intermediates. On the one hand, their polarizations are distributed over several species: the initial open-chain, sulfur-centered radical cations **1** stabilize within nanoseconds or faster by formation of cyclic structures **2** with an intramolecular two-center, three-electron bond between sulfur and nitrogen, as well as of intermolecular adducts **3** with Met molecules [8, 9]; furthermore, fast deprotonation and decarboxylation of **2** (lifetime 220 ns) lead to α-thioalkyl and α-aminoalkyl radicals [9]. On the other hand, the line widths of these



intermediates are expected to be much larger than those of $AS^{\bullet-}$ (3–5 μT), and their peak heights will thus be reduced proportionally.

[11] Pulse radiolysis experiments gave $k = 1.7 \times 10^{10}\ M^{-1}s^{-1}$ for this reaction (H. Pal, D. K. Palit, T. Mulherjee, J. P. Mittal, *Radiat. Phys. Chem.* **1991**, *37*, 227–235). We explain the difference by the higher ionic strength in our measurements.
[12] The rate constant in the literature ($k = 3.5 \times 10^7\ M^{-1}s^{-1}$ at pH 6.0) [13] is larger, because in our experiments Met is present in its deprotonated (anionic) form. For other amino acids, this deprotonation slowed down the reaction with e^-_{aq} by up to an order of magnitude [13].

The Organic Chemistry of Coordination Compounds: Unprecedented Substitution Reactions of Functionalized Polypyridine Complexes

Dimitrios Tzalis and Yitzhak Tor*

The organic chemistry of coordination complexes is largely unexplored.[1] Despite a vast interest in utilizing polypyridine-containing coordination compounds for the study of energy and electron transfer, the construction of nanostructured materials, and the fabrication of molecular devices,[2] their full potential as synthetic building blocks remains unutilized. A better understanding of the effects of the coordinated metal ion on the reactivity and reaction pathways of the bound ligands should result in the prudent and targeted use of coordination compounds in various synthetic transformations.[3]

Early examples indicated that metal ion coordination can substantially alter aromatic electrophilic substitutions of coordinated phenanthrolines.[1,4] Much less is known, however, on nucleophilic substitution reactions of coordinated polypyridine ligands.[5,6] Nucleophilic displacements of 4-halopyridines have been found to be accelerated by metal coordination[1] and have been extended to Ru^{II}-coordinated 4,4′-dichloro-2,2′-bipyridines[7] and 4′-chloro-2,2′:6′,2″-terpyridines.[8] While the 4-position of an uncoordinated pyridine ring is inherently electrophilic, the 3-position is not.[9] Metal coordination might have been expected to sufficiently activate 3-halopyridines to enable nucleophilic substitutions. Yet, $[(bpy)_2Ru(3\text{-chloropyridine})_2]^{2+}$ (bpy = 2,2′-bipyridine) failed to react with a powerful nucleophile such as methanethiolate.[1]

We report here on the efficient nucleophilic substitution reactions of Ru^{II} and Os^{II} complexes of 3-bromo-1,10-phenanthroline. Reactions with fluoride, methoxide, and methanethiolate ions as representative nucleophiles provide novel coordination compounds of hitherto unknown phenanthroline derivatives. Under identical reaction conditions, the free ligand, 3-bromo-1,10-phenanthroline, completely fails to react. Our results illustrate an unprecedented reactivity of these polypyridyl complexes and establish the activating role of the coordinated metal ion. We demonstrate that these reactions proceed with retention of configuration at the metal center and discuss mechanistic implications.

The starting materials, $[(bpy)_2M(3\text{-bromo-1,10-phenanthroline})][PF_6]_2$ (**1a**, M = Ru; **1b**, M = Os) are conveniently prepared from $[(bpy)_2MCl_2]$ and 3-bromo-1,10-phenanthroline.[10] Treating these metal complexes with sodium methanethiolate in DMF (or methanol) at room temperature, sodium methoxide in methanol at 50°C, and anhydrous potassium fluoride in DMF at 130°C readily provided the substitution products **2a,b**, **3a,b**, and **4a,b**, respectively (Scheme 1).[11] The free 3-bromo-1,10-phenanthroline is unsusceptible to these nucleophiles even under forcing conditions. Effort has been invested to confirm the identity of the substitution products in order to exclude the possible formation of isomeric complexes. The one- and two-dimensional ^1H NMR spectra of **2a,b** and **3a,b** confirm the expected *meta*-substitution pattern, showing a typical 1,3 long-range coupling ($J \approx 1.5$ Hz) for H2 and H4 of the phenanthroline ligand. The proton-coupled ^{19}F NMR spectrum of **4a,b** shows a doublet of doublets at $\delta = -65$ ($^3J = 8.5$ and 8.0 Hz) verifying the presence of a 3-fluoro substituent.[12]

2 a: M = Ru, X = SCH_3
b: M = Os, X = SCH_3
3 a: M = Ru, X = OCH_3
b: M = Os, X = OCH_3
4 a: M = Ru, X = F
b: M = Os, X = F

Scheme 1. Displacement reactions of metal-coordinated 3-bromo-1,10-phenanthroline. a) Reaction conditions: for **2**: $NaSCH_3$ in DMF (or methanol) at room temperature (2–18 h); for **3**: $NaOCH_3$ in methanol, 50°C (2–6 h); for **4**: anhydrous KF in DMF, 130°C (6–24 h).

To investigate whether the coordinated metal ion is directly involved in these substitution reactions, the enantiomerically pure Λ-**1a** was treated with the same nucleophiles.[13] The CD spectrum of the product **3a** shows the expected minor shifts in the Cotton effects and $\Delta\varepsilon$ values very similar to those in the spectrum of the starting material Λ-**1a** (Figure 1).[14] These observations confirm the retention of configuration at the metal center. Following the course of the reactions by ^1H NMR spectroscopy showed a clean conversion of the starting material into the product. Taken together, these results exclude the possible interruption of the octahedral coordination geometry and the formation of associative intermediates as a major reaction pathway. To facilitate a nucleophilic attack at the unreactive 3-bromo-1,10-phenanthroline ring system, the coordinated metal ion has to alter the electronic properties of the ligand.

Two major mechanisms may be operative in these nucleophilic displacement reactions: the elimination–addition pathway (EA) or the addition–elimination pathway

(AE).[15] The EA mechanism should involve the highly reactive (and previously unobserved) metal-coordinated dehydrophenanthroline intermediate and might lead to the formation of *cine*-substitution products. While our data cannot unequivocally exclude the EA pathway in the highly basic KF/DMF and NaOMe/MeOH media at elevated temperatures, the exclusive formation of *ipso*-substitution products and the efficient reactions observed under very mild conditions with the soft and weakly basic CH_3S^- ion strongly support the AE mechanism.

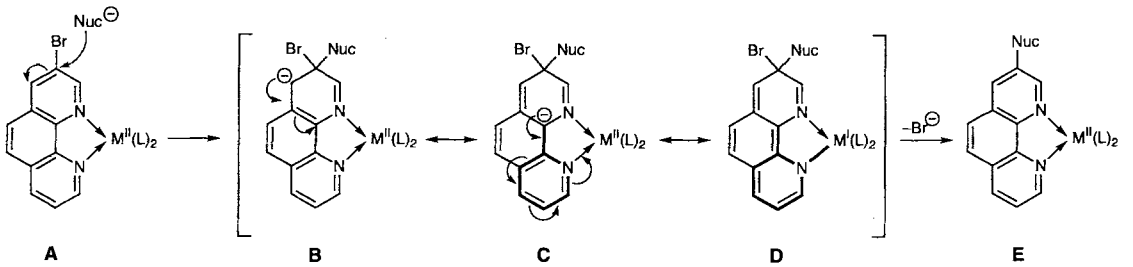
How can metal coordination facilitate the nucleophilic addition to the funtionalized phenanthroline? Metal coordination is expected to decrease the electron density on the heterocyclic ligand by induction through the σ framework, making it more susceptible to nucleophilic attack, while π backbonding may diminish this polarization.[16] In general, this metal-induced polarization enhances the reactivity at positions 2 and 4 to the nitrogen in the electron-deficient pyridines, leaving the 3-position largely unaffected.[1,9] How can the high reactivity of the complexed 3-bromo-1,10-phenanthroline then be explained? We propose to view the complexed phenanthroline ring as composed of two components: 1) the reacting ring bearing N1 and the 3-bromo substituent, and 2) the activating unsubstituted ring bearing N10 (Scheme 2). A nucleophilic attack at the *ipso* position of substrate **A** would generate the "classical" addition intermediate **B**. This "anionic" σ-complex is stabilized by delocalization of the additional charge over the neighboring ring as well as the metal ion. As shown in **C** and **D**, this delocalization is facilitated by an electron-withdrawing group, the metal-coordinated N10 pyridine ring, at position 1a, which is *para* to the attacked *ipso* position. Elimination of bromide provides the substitution product **E**.

In many respects the efficient displacement reactions observed with the soft MeS^- ion have striking similarities to typical S_NAr substitution reactions of highly electron-deficient aromatic compounds (e.g. 2,4-dinitrohalobenzenes).[17] Specifically, the reaction of the fluoro-containing complex $[(bpy)_2Ru(3\text{-fluoro-}1,10\text{-phenanthroline})][PF_6]_2$ **4a** with sodium methanethiolate in methanol was found to proceed at least ten times faster than the corresponding reactions of the bromo-containing complex **1a**.[18] In addition, the reaction of the Os^{II}-containing complex **1b** with sodium methanethiolate was found to be four times slower than the corresponding reaction of the Ru^{II}-containing complex **1a**.[19] These observations suggest that the substitution reactions are subject to both Coulombic and frontier orbital controls.[20] Assuming that the elimination step is not rate-determining, the higher reactivity of the fluoro vs. the bromo derivative is consistent with a Coulombic contribution to rate enhancement. Furthermore, better π backbonding of Os^{II} relative to that of Ru^{II} is expected to increase the electron density of the complexed phenanthroline's LUMO, decreasing its interaction with the nucleophile's HOMO, thus leading to a slower reaction as observed.

We have established a novel and powerful approach for the efficient modification of coordination compounds at a position previously assumed to be unreactive. We have demonstrated, for the first time, that metal coordination activates the position *meta* to the nitrogen atom in 1,10-phenanthroline, leading to efficient nucleophilic substitutions. This unprecedented reactivity is attributed to the increased electrophilicity of the complexed ring upon metal coordination and the effective resonance stabilization of the "anionic" addition intermediate. This simple methodology opens new routes for the fabrication of previously inaccessible complexes and provides insight into the organic chemistry of coordination compounds.

Experimental Section

All reactions were carried out in the dark under Ar atmosphere, using anhydrous solvents and salts. All complexes were isolated as their PF_6^- salts. A representative procedure and spectroscopic data: **2a**: A mixture of **1a** (23.6 mg, 2.45×10^{-5} mol) and sodium methanethiolate (7.2 mg, 1.04×10^{-4} mol) was stirred in DMF (5 mL) at room temperature for 18 h. The crude reaction mixture was evaporated to dryness. The orange solid obtained was suspended in 3 mL water and filtered to yield 19.3 mg (85% yield) of the pure product **2a**. ESI/MS: *m/z*: 785.2 [M^+]; UV/Vis (CH_3CN): λ_{max} (ε) = 246 (4.4×10^4), 286 ($7.6 \times$



Scheme 2. The proposed mechanism for the nucleophilic substitution reactions of metal-coordinated 3-bromo-1,10-phenanthroline. The novel electron-withdrawing group, the metal-coordinated N10 pyridine ring, which is *para* to the attacked *ipso* position, is in bold.

The Linking of Two Acetylide Units through a Plane of Four Iron Atoms**

John E. Davies, Martin J. Mays,* Paul R. Raithby, and Koshala Sarveswaran

There has been considerable interest in the nature of the bonding within octahedral organometallic clusters of the type *trans*-$E_2(ML_n)_4$, where M is a transition metal and E is a main group atom or conical fragment such as BH, CR, GeR, NR, PR, S, or Se.[1–4] A notable feature of the structures is that the E···E separation is short, and often lies in a range only 12–25% longer than that corresponding to a single E–E bond. Thus, for example, in $[Co_4(\mu_4\text{-}PPh)_2(\mu_2\text{-}CO)_2(CO)_8]$[5] the P···P distance of 2.537(6) Å is only 0.3 Å greater than an accepted P–P single bond length,[6] and in $[Co_5(CO)_{13}(\mu\text{-}CO)B_2H]$, which contains a Co_4B_2 core,[7] the B–B distance of 1.85 (4) Å is within the range observed for polyhedral boranes with B–B bonding.[8] These short distances have been attributed to an attractive direct E···E interaction, although the need to optimize M–M and M–E distances is also acknowledged to be an important factor.[1,5]

We now report the synthesis of **1** by thermolysis of $[Fe_2(CO)_6(\mu_2\text{-}\eta^2\text{-}C{\equiv}CPh)(\mu\text{-}PPh_2)]$ in toluene at 100°C. An

$[Fe(\mu_4\text{-}PPh_2)_2(\mu_4\text{-}\eta^2\text{-}C{\equiv}CPh)_2(CO)_8]$ **1**

X-ray crystallographic study of **1**[9] shows that the C–C separation of the two μ_4-C atoms across the Fe_4 plane is only 1.610(8) Å, less than 5% longer than a normal C–C single bond (Figure 1).

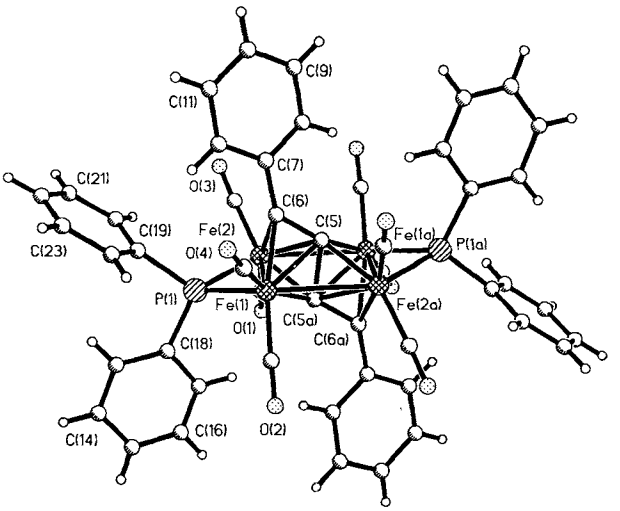

Figure 1. Molecular structure of **1**. Selected bond lengths [Å] and angles [°]: Fe(1)–C(6) 2.011(4), Fe(1)–C(5) 2.143(4), Fe(1)–Fe(2) 2.5334(9), Fe(2)–C(5A) 1.993(4), Fe(2)–C(5) 2.154(4), Fe(1)–Fe(1A) 2.8722(9), C(5)–C(5A) 1.610(8), C(5)–Fe(1A), 2.014(4), Fe(1)–C(5A) 2.014(4), Fe(1)–P(1) 2.2045(13), Fe(1)–Fe(2A) 2.8721(9), Fe(2)–C(6) 2.044(4), Fe(2)–P(1) 2.2037(13), C(5)–Fe(2A) 1.993(4), C(5)–C(6) 1.388(5); Fe(1)-Fe(2)-Fe(1A) 90.14(3), Fe(2)-P(1)-Fe(1) 70.16(4), Fe(2A)-C(5)-Fe(1A) 78.4(2), Fe(2A)-C(2)-Fe(1A) 87.9(2), Fe(1A)-C(5)-Fe(2) 87.1(2), Fe(1)-C(5)-Fe(2) 72.26(12), Fe(2)-Fe(1)-Fe(2A) 89.86(3).

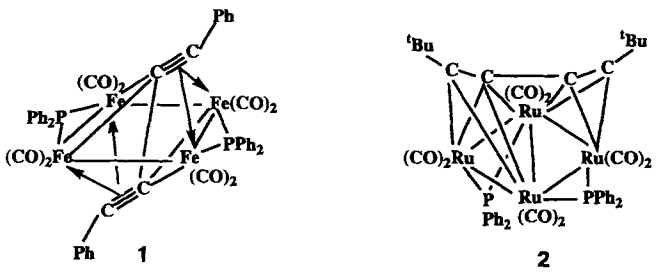
The molecule is centrosymmetric and the four iron atoms form a rectangle. Each iron atom is terminally coordinated by two carbonyl groups. The opposing Fe–Fe edges bridged by the PR_2 groups are shorter (2.5534(9) Å) than the unbridged edges (2.8722(9) Å). The μ_4-η^2 acetylide ligands on each Fe_4 face are orientated *trans* to each other such that the C-Ph carbon atoms symmetrically bridge the two Fe–Fe edges, which are also bridged by the PPh_2 groups. The μ_4-C atoms and the four iron atoms may be regarded as a distorted octahedron that is face-capped by the two CPh groups on opposing faces. Viewed in this way the cluster has a polyhedral electron count of 68, with eight skeletal electron pairs rather than the seven required for conformity with Wade–Mingos rules.[10]

The short C–C distance across the Fe_4 plane must result in part from the need to optimize the Fe–Fe and Fe–C bond lengths. Such optimization in the related octahedral cluster $[Ru_5(CO)_{13}(\mu_4\text{-}\eta^2\text{-}C{\equiv}CPh)(\mu\text{-}PPh_2)]$ with an octahedral Ru_5C core results in the μ_4-C atom being only 0.841 Å above the Ru_4 plane that is capped on the other face by the fifth Ru atom.[11] There must, however, also be a direct interaction across the Fe_4 plane in **1** between orbitals on the two carbon atoms completing the distorted octahedral core; MO calculations on related μ_4-P and μ_4-B species suggest that this interaction is likely to be bonding in character.[1–5] Accordingly the two acetylide ligands in **1** can be regarded as being coupled together to form a ten-electron donor diyne ligand, which is threaded through and bonded to the Fe_4 plane. Similar coupling of two acetylide ligands on a Ru_4 butterfly framework in the complex **2** has recently been reported, but

$[Ru_4(CO)_8(C_4tBu_2)(\mu\text{-}PPh_2)_2]$ **2**

the resulting diyne ligand was bonded to one face only of the butterfly as shown in Scheme 1.[12] Complex **2** has the same



Scheme 1. Line drawings of the structures of **1** and **2**.

polyhedral electron count as **1** but there is an extra metal–metal bond and the diyne ligand acts as an eight- rather than a ten-electron donor to the metal framework.

The C–C distances within the C_4 diyne unit of **1** are 1.388(5) (outer) and 1.610(8) Å (inner); the corresponding distances in **2** are 1.332(7), 1.321(7) (outer) and 1.366(7) Å (inner). The fact that the inner, formally single, C–C bond in **1** is longer than that in **2** can be rationalized as being due to the need to accommodate the Fe_4 ring around the C–C axis. On the other hand the coupling of two acetylide ligands in dinuclear titanium and zirconium complexes to give C–C bonds longer than that in **1** is well known.[13] Long single C–C bonds have also been reported in a range of other molecules and have been the subject of theoretical investigations.[14]

The reactivity of **1** and the possibility of synthesizing related polycarbon ligands threaded through metal atom frameworks are under investigation.

Experimental Section

1: A stirred solution of $[Fe_2(CO)_6(\mu_2\text{-}\eta^2\text{-}C{\equiv}CPh)(\mu\text{-}PPh_2)]$ (0.80 g, 1.41 mmol) in toluene (50 mL) was heated at 100 °C for 24 h. The solvent was then removed on a rotary evaporator, the residue taken up in the minimum amount of CH_2Cl_2 and adsorbed onto silica. The silica was pumped dry and added to the top of a silica chromatography column. Elution with *n*-hexane/CH_2Cl_2 (4/1) and removal of solvent gave **1** as a brown powder (0.35 g, 21 %). Crystals suitable for the X-ray analysis were grown by slow evaporation of a 1/1 *n*-hexane/CH_2Cl_2 solution of the complex. Selected spectroscopic data for **1**: IR (CH_2Cl_2 solution) major bands: $\tilde{\nu}_{CO}$ = 2003 vs, 1976 s cm^{-1}; ^1H NMR (400.16 MHz, 25 °C, $CDCl_3$, $SiMe_4$): δ = 8.16(m, 3H; aryl C-H), 7.62(m, 6H; aryl C-H), 7.33(m, 3H; aryl C-H), 7.20(m, 3H; aryl C-H), 7.03(m, 6H; aryl C-H), 6.88(m, 3H; aryl C-H), 6.65(m, 6H; aryl C-H); ^{31}P NMR (162.000 MHz, 25 °C, $CDCl_3$, relative to $P(OMe)_3$ with upfield shifts negative): δ = 95.5 (μ-PPh_2); ^{13}C NMR (100.614 MHz, 20 °C, $CDCl_3$): δ = 212.4(s; FeCO), 211.0 (s; FeCO), 143.2 (d, $^2J(^{31}P^{13}C)$ = 22.4 Hz; -*C*CPh), 135.7–127.5 (m, 36C; aryl-C), 95.6 (s, 1C; C*C*Ph); MS (FAB): *m/z*: 1020 (M^+).

Enantioselective Diels–Alder Cycloaddition by Preorganization on a Chiral Lewis Acid Template**

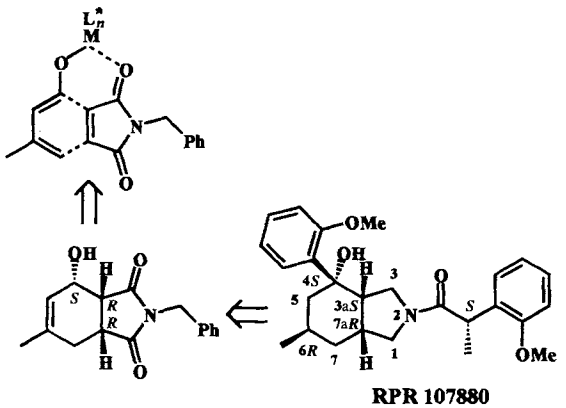
Hugues Bienaymé*

In memory of Wolfgang Oppolzer

Recent years have witnessed impressive advances in catalytic asymmetric [4+2]cycloadditions.[1] But tailoring an efficient chiral catalyst designed for a specific transformation is by no means an easy task: several parameters, such as the reactive conformation of the dienophile (s-*cis* or s-*trans*), the basic lone pair of the carbonyl to be coordinated, the degree of freedom, and the bonding mode of the Lewis acid/carbonyl complex,[2] just to mention a few, need to be carefully controlled. As a consequence of a potentially great number of thermally accessible reactive conformers, catalysts for enantioselective cycloadditions are always time-consuming to develop and often very substrate specific. Herein we disclose our preliminary results on "internally promoted" asymmetric Diels–Alder cycloadditions in connection with the synthesis of the potent, non-peptidic, NK1-selective, substance P antagonist RPR 107880.[3]

Preliminary work from our laboratory shows that dienes covalently connected to a Lewis acid, for example dimethylaluminum dienolates, are able to undergo extremely rapid and (regio/stereo)selective [4+2]cycloadditions with various dienophiles.[4] By virtue of their rigid bicyclic [6.6] transition states, these entropically favored cycloadditions were thought to overcome most of the impediments commonly associated with the design of an efficient chiral catalyst.

As depicted in Scheme 1, our plan for the industrial synthesis of RPR 107880 relies on a ligand-controlled asymmetric Diels–Alder cycloaddition between *N*-benzylmaleimide (NBM) and a chiral prenal enolate at an early stage. The *endo*-(3a*R*,4*S*,7a*R*) perhydroisoindole cycloadduct could then be easily manipulated by conventional chemistry to yield the target compound, (3a*S*,4*S*,6*R*,7a*R*)-4-(2-methoxyphenyl)-2-[(*S*)-2-(2-methoxyphenyl)propionyl]-6-methyl-perhydroisoindol-4-ol. Only the first key step of this synthesis will be reported here.



Scheme 1. Retrosynthesis of RPR 107880.

Titanium was identified as the best potential catalyst on the following considerations: a) Titanium dienolates can be prepared easily from available 1-acetoxybutadienes by an alkoxide transesterification reaction.[5] b) Chiral titanium alkoxide species are easily prepared by mixing chiral diols and titanium tetraalkoxides.[12b] c) Most of the chiral diol ligands known are reasonably accessible (derived from the natural pool or by short syntheses). d) Catalytic asymmetric cycloaddition is theoretically possible if the ligand exchange reaction is fast enough. e) Titanium tetraalkoxides are nontoxic, cheap, and nonpyrophoric.

To clarify the major kinetic parameters the nonasymmetric cycloaddition between 1-acetoxyisoprene and *N*-benzylmaleimide was first studied with titanium tetraisopropylate as the promoter (Scheme 2, Table 1). Two *endo* cycloadducts were isolated: alcohol *rac*-**1a** resulting from the expected titanium-catalyzed transesterification/cycloaddition process, and acetate *rac*-**2** from the thermal (or externally catalyzed) process. The product ratios varied with the amount of $Ti(OiPr)_4$ used; however, with a stoichiometric amount of $Ti(OiPr)_4$ the transesterification reaction (which is expected to be the rate-limiting step[4] in the process leading to *rac*-**1a**) was quite competitive with the easy thermal cycloaddition (entry 1). A marked temperature dependance was also noted: when 1.2 equiv $Ti(OiPr)_4$ was employed but the reaction was conducted at 0°C instead of 25°C, *rac*-**2** was formed as the major compound (240 min, *rac*-**2**/*rac*-**1a** $\approx$ 80/20). This is likely due to the occurrence of unreactive $Ti(OiPr)_4$ oligomers at lower temperatures.[6] Under these reaction conditions **1a** was not acylated to **2** or vice versa (however, on prolonged reaction time or heating at 60°C, **2** was partly transesterified to **1a**).

Various homochiral diols were then evaluated. Among commonly used ligands (+)-diisopropyltartrate and (+)-1,1-binaphthol either completely inhibited or slowed down the transesterification reaction, resulting in the formation of **2** as the exclusive or major product. The $\alpha,\alpha,\alpha',\alpha'$-tetraaryl-1,3-dioxolane-4,5-dimethanol (TADDOL)[7] ligands gave better results. They led to an overall substantial kinetic enhancement and a useful level of enantiocontrol (Table 1, entries 2–11). In a first set of experiments the isopropyl alcohol generated upon mixing $Ti(OiPr)_4$ and (−)-TADDOL ((*R*,*R*)-$\alpha,\alpha,\alpha',\alpha'$-tetraphenyl-1,3-dioxolane-4,5-dimethanol) was removed by distillation in vacuo as a toluene azeotrope. The expected oily (−)-TADDOL diisopropyltitanate was dissolved in a solvent and cooled before 1-acetoxyisoprene and NBM were added successively. Cycloadducts **1a** (and **2**) were purified by flash chromatography, and the enantiomer ratio (e.r.) of **1a** was determined by HPLC on a chiral stationary phase. Very interestingly, isopropropyl alcohol may not be removed from the reaction mixture, since cycloaddition is apparently faster than protonation of the dienolate. Furthermore, a slight increase in enantioselectivity was observed in that case (cf. entries 2 and 3). The main improvement came upon changing the $Ti(OiPr)_4$/(−)-TADDOL ratio. The optimum was found to be 2:1, whereas at higher ratios the selectivity dropped (entries 3–5). A marginal improvement was noted when the slightly more sterically demanding (−)-NpTADDOL ligand[8] was used (entry 6). Under optimized conditions an enantiomer ratio of 95:5 was reached, but the amount of **2** was also increased (entry 8). For the synthesis of RPR 107880 optically

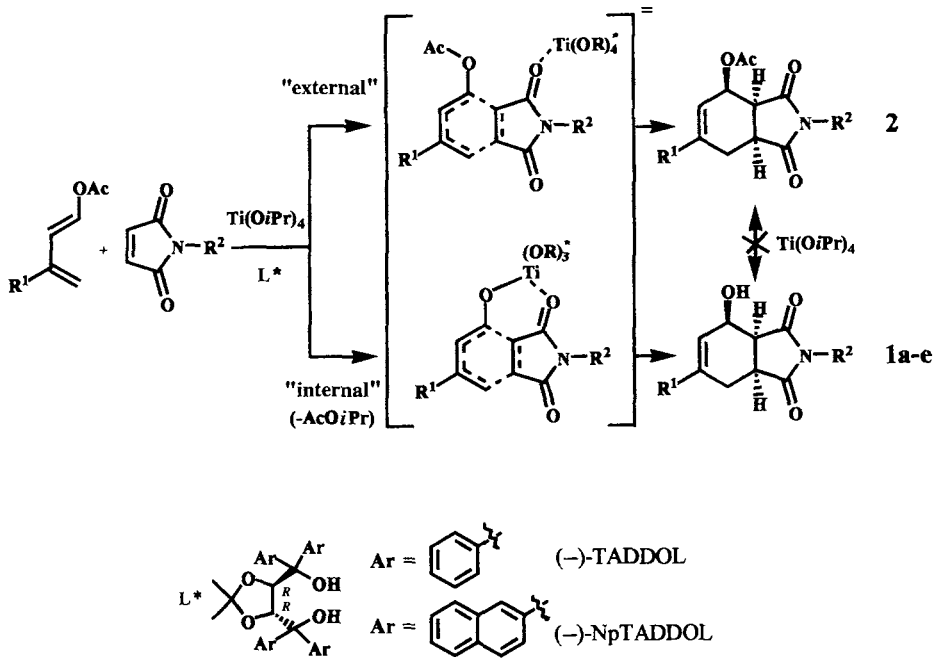
[a] Determined by HPLC with a chiral column (Diacel Chiralpak AD, 250 × 4.6 mm; heptane/isopropyl alcohol 70/30). [b] Isopropyl alcohol generated from Ti(O*i*Pr)4 was left in the reaction mixture. [c] Yield for **1** only. [d] Diastereomer ratio. [e] 14% *exo* cycloadduct also present. [f] Not determined.



Scheme 2. Postulated transition states for the externally promoted (top) and internally promoted cycloadditions (bottom) of maleimides.

pure (–)-**1a** could be obtained from a single recrystallization (isopropanol, e.r. = 95:5 → 99:1; 75% overall isolated yield).

As we believed that internal coordination was key to the high enantioselectivity, the small amount of acetate **2** coproduced in optimized experiment 8 was isolated and saponified to **1a** (2 equiv $Ti(OiPr)_4$, *i*PrOH, 65°C, 10 h), which was found to be almost racemic (e.r. = 48:52). Apparently, neither of the two putative chiral species present, [(–)-TADDOL]$Ti(OiPr)_2$ and [(–)-TADDOL]Ti(O*i*Pr)-(O-isoprenyl), were efficient in promoting the asymmetric, externally catalyzed cycloaddition leading to **2**. This observation clearly illustrates the important role of reagent preorganization in this internally promoted cycloaddition.

Some experiments were also carried out to determine whether a catalytic amount of ligand would yield similar results (entry 7). Unfortunately, the enantiomer ratio of this cycloaddition dropped as the amount of ligand decreased. Apparently the (–)-TADDOL ligand remained strongly bound to the titanium nucleus and did not exchange with excess $Ti(OiPr)_4$ to regenerate the chiral catalyst.

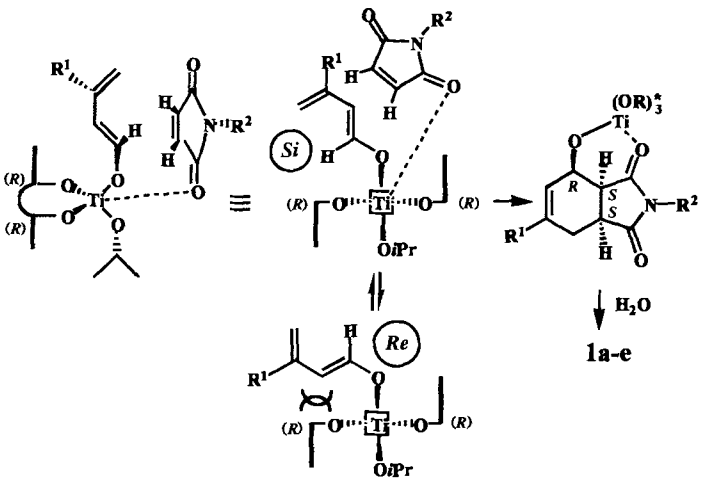
We probed the scope and limitation of this reaction by changing the substituents on the diene and dienophile. Gratifyingly, the previously optimized protocol afforded high yields and enantiomer ratios in each case. These (limited) modifications to the diene and dienophile did not appear to alter the stereochemical outcome of the cycloaddition. This observation is important, since maleimides are monodentate C_{2v}-symmetric dienophiles (i.e. difficult dienophiles) and is also in sharp contrast with earlier results where low substrate diversity was the rule.[9]

The lack of published analytical data for enantiomerically pure structures of type **1** prompted us to obtain the X-ray crystal structure to ascertain the absolute configuration. We were not able to produce suitable crystals of either alcohol **1a**,

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3623-2671 $ 17.50+.50/0

1b, or derivatized esters of **1a**. Only cycloadduct **1c** (from the cycloaddition with (*R*)-α-methylbenzylmaleimide) gave satisfactory crystals, the absolute stereochemistry of which proved to be (3a*S*,4*R*,7a*S*).[10,13] A favored ligand-controlled *endo-Si* approach (with (−)-TADDOLs) was thus postulated for all maleimides studied here.[11]

We propose the following model for the stereochemical outcome of the TADDOL–titanate internally promoted cycloadditions. TADDOL-based titanium catalysts have been used with success in various enantioselective transformations,[12] a certain amount of stereochemical information is thus available. Our rationale for the high enantioselectivities observed here is illustrated in Scheme 3 and parallels that proposed by Seebach et al. for the enantioselective *Si* addition of dialkylzinc reagents to aldehydes.[8] The well-documented



Scheme 3. Model for enantioface selection in internally promoted cycloadditions.

propeller-type arrangement of TADDOL titanates impose two quasi-axial aryl substituents to fill the top right and bottom left front octants around the titanium nucleus (this holds for the (−)-(*R*,*R*)-TADDOLs). These substituents are schematized by bold vertical bars in Scheme 3. The (substituted) butadienyloxy fragment will likely occupy the "free" octant in an extended conformation to minimize steric interactions with the ligand aryl rings, thus exposing its *Si* face to the dienophile. Another possible important feature in this cycloaddition, although not readily quantified, is a change in the coordination geometry of the metal center during the cycloaddition process (from tetrahedral in the starting titanium dienolate to trigonal-bipyramidal upon coordination with the dienophile). This change would push the butadienyl moiety further into the ligand sphere and thus reinforce potential nonbonding interactions. Lastly, our simplistic model does not account for the important role of the ligand/$Ti(OiPr)_4$ ratio, which still remains unclear.

We thus have developed a new potent coordination mode for the Diels–Alder cycloaddition, where cooperativity between enthalpic and entropic factors is likely responsible for the high enantioselectivities (and reactivities) observed. Though only stoichiometric for the moment, this method enables the reaction of difficult dienophiles such as maleimides with high selectivities and under very mild conditions. This type of catalysis, in which the Lewis acid and one of the reactants are chemically linked, should find new synthetic applications.

Experimental Section

Typical procedure for the internally promoted cycloaddition of 1-acetoxybutadienes with maleimides. (3a*S*,4*R*,7a*S*)-2-Benzyl-4-hydroxy-6-methyl-1,3,3a,4,7,7a-hexahydro-1*H*-isoindole (**1a**): (−)-NpTADDOL[7] (6.18 g, 9.27 mmol) was suspended in dry toluene (40 mL). The clear solution obtained upon addition of $Ti(OiPr)_4$ (5.50 mL, 18.5 mmol) was cooled to −15/−10°C, and freshly distilled 1-acetoxyisoprene (1.72 g, 13.6 mmol, Rhône-Poulenc Animal-Nutrition) and *N*-benzylmaleimide (1.68 g, 8.97 mmol) were added successively. After the dienophile had been consumed (TLC, Et_2O/pentane 70/30), 2N HCl (30 mL) and ice were added. The crude reaction mixture was extracted twice with Et_2O (60 mL) and the organic phase washed with saturated $NaHCO_3$ (50 mL). Flash chromatography (Et_2O/pentane (1/1) → Et_2O) furnished (in order): (−)-NpTADDOL (5.68 g after recrystallization, 92% recovered), acetate **2** (0.266 g, 9.5%) and alcohol **1a** (2.122 g, 87%, e.r. = 95:5). **1a** was recrystallized from isopropropyl alcohol (15 mL) to give 1.82 g of analytically and optically pure crystals (75% overall yield). **1a:** M_r = 271.31; m.p. 104.5–105°C; $[\alpha]_D$ = −27.4 (29°C, c = 1.7 in CH_2Cl_2); ^1H NMR (300 MHz, [D$_6$]DMSO, 25°C, HMDS): δ = 1.63 (br. s, 3H), 2.17 (dd, 1H, J = 16.4, 9.1 Hz), 2.33 (dd, 1H, J = 16.4, 5.5 Hz), 2.93 (dd, 1H, 9.1, 4.8 Hz), 3.18 (dt, 1H, J = 9.1, 5.5 Hz), 4.32 (m, 1H), 4.43–4.52 (m, 2H), 5.66 (m, 1H), 7.19 (m, 5H); IR (KBr): $\tilde{\nu}$ = 3512, 3091, 1772, 1698, 1606, 1586, 1497, 1401, 733, 704 cm^{-1}; HRMS: m/z calcd for $C_{16}H_{17}NO_3$: 271.1208; found: 271.1198. C,H,N analysis calcd for $C_{16}H_{17}NO_3$: C 70.83, H 6.31, N 5.16; found: C 71.60, H 6.30, N 5.30.

[8] Np-TADDOL is a highly efficient ligand for the asymmetric addition of organozinc reagents to aldehydes: a) D. Seebach, D. A. Plattner, A. K. Beck, Y. M. Wang, D. Hunziker, W. Petter, *Helv. Chim. Acta* **1992**, *75*, 2171–2209; b) Y. N. Ito, X. Ariza, A. K. Beck, A. Bohac, C. Ganter, R. E. Gaw, Y. N. Ito, X. Ariza, A. K. Beck, A. Bohac, C. Ganter, R. E. Gawler, F. N. M. Kühnle, J. Tuleja, Y. M. Wang, D. Seebach, *Helv. Chim. Acta* **1994**, *77*, 2071–2110.

[9] The scope of the first efficient asymmetric cycloadditions involving N-substituted maleimides was narrow, and the maleimide N-substituents are not easily removed: E. J. Corey, S. Sarshar, D. H. Lee, *J. Am. Chem. Soc.* **1994**, *116*, 12089–12090.

[10] The absolute configuration was determined based on the known configuration of the side chain. Since the problem of double stereoinduction arises with this homochiral substrate (substrate and ligand-controlled Diels–Alder cycloaddition), several controls were performed with (*R*)-α-methylbenzylmaleimide and acetoxyisoprene under conditions for the nonasymmetric reaction with internal promotion ($Ti(OiPr)_4$ or $Ti(OiPr)_4$/*rac*-TADDOL). None of these controls exhibited a diastereomer ratio exceeding 60:40, a result indicating that (*R*)-α-methylbenzylmaleimide is not responsible for the enantiocontrol in cycloaddition leading to **4**. Furthermore, (*R*)-α-methylbenzylmaleimide is known to be a weakly diastereoselective dienophile in substrate-controlled Diels–Alder cycloadditions: S. W. Baldwin, P. Greenspan, C. Alaimo, A. T. McPhail, *Tetrahedron Lett.* **1991**, *32*, 5877–5880.

[11] The absolute stereochemistry shown in Scheme 2 is opposite to that required for the construction of the RPR 107880 core. However, this is of little concern, since both antipodal forms of TADDOL ligands are equally available from tartrate esters.

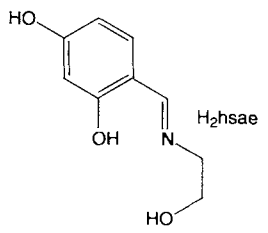
Cluster Assembly by Hydrogen Bonds: Channel Structure of Cu_4L_4 Cubanes

Hiroki Oshio,* Yuki Saito, and Tasuku Ito

Supramolecular chemistry of coordination compounds and organic solids is the subject of intense research.[1] It has been known for several years that self-assembly through hydrogen bonds leads to well-organized organic and inorganic supramolecular structures, and that channel structures, which are formed by self-assembly, can be applied in areas such as selective enclathration, microporosity, and catalysis.[2] On the other hand, transition metal complexes with a cubane structure, in which four metal ions are linked by hydroxo, alkoxo, azido, sulfido, or iminato bridges,[3] are a very important class of compounds (M_4L_4).[4] Among them, alkoxo-bridged copper(II) cubanes, many of which exhibit a quintet ground state because of weak intracluster ferromagnetic interactions, have been extensively studied from magneto-structural viewpoints.[5] We report here that introduction of a hydroxy group into the bridging ligand of a cubane core leads to the formation of a hydrogen-bond network with a channel structure.

The reaction of copper(II) acetate monohydrate with H_2hase (2-(4-hydroxysalicylideneamino)ethanol) in methanol followed by the recrystallization in acetonitrile gave dark blue crystals of **1**, , which crystallize in the monoclinic space group



$[Cu_4(hsae)_4)] \cdot 2H_2O \cdot 4CH_3CN$ **1**

*C*2/*c*.[6] The structure of **1** contains a tetranuclear cubane core (Figure 1), which sits on a crystallographic twofold axis that passes through the middle of the Cu1 ··· Cu1′ and Cu2 ··· Cu2′ vectors. The asymmetric unit, thus, consists of half of the tetramer.

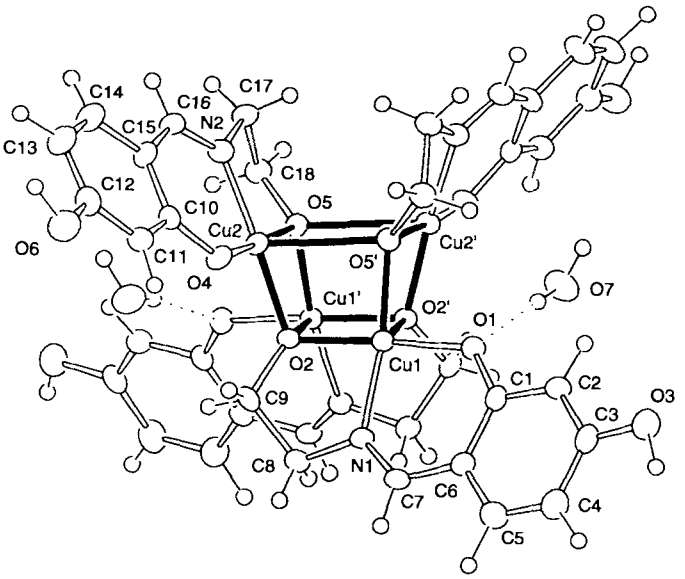

Figure 1. Crystal structure of **1** (ORTEP diagram; ellipsoids at the 50% probability level). Selected distances [Å] and angles with standard deviation in parentheses: Cu1–O1 1.894(3), Cu1–O2 1.959(3), Cu1–O2′ 2.467(3), Cu1–O5′ 1.956(3), Cu1–N1 1.925(4), Cu2–O2 1.930(3), Cu2–O4 1.939(3), Cu2–O5′ 2.562(3), Cu2–N2 1.914(4), Cu2–O5 2.000(3); Cu1-O2-Cu1′ 101.5(1), Cu1-O2-Cu2 106.1(1), Cu1′-O2-Cu2 90.1(1), Cu1-O5′-Cu2 85.8(1), Cu1-O5′-Cu2′ 104.8(1), Cu2-O5-Cu2′,104.2(1); key to symmetry operation for primed atoms: $1-x, y, 3/2-z$.

The cubane core of **1** is based on an approximately cubic array of alternating copper and oxygen atoms. The intracluster metal–metal separations are 3.108(1) (Cu1 ··· Cu2), 3.443(1) (Cu1 ··· Cu1′), 3.134(1) (Cu1 ··· Cu2′), and 3.6154(9) Å (Cu2 ··· Cu2′). Each copper atom resides in a square pyramidal coordination environment with one nitrogen and two oxygen atoms from the ligand and two oxygen atoms from neighboring units of the cubane. According to the four short and one long bond lengths (see Figure 1) between the copper and coordinating atoms, basal planes for Cu1 and Cu2 are O1-N1-O2-O5′ and O4-N2-O5-O2, in which the copper ions are displaced by 0.053(1) and 0.041(1) Å above the plane, respectively. The magnetic orbitals ($d_{x^2-y^2}$) of the Cu1 and Cu2 ions, which are perpendicular to each other, are parallel to the basal planes (Figure 2a).

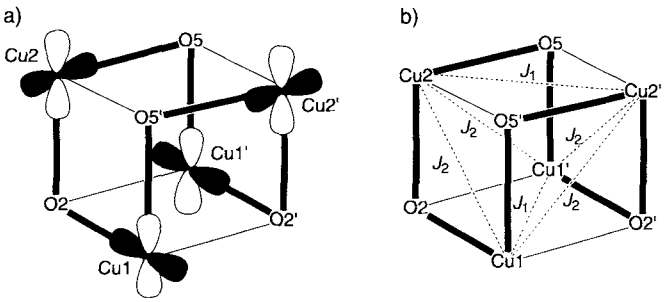

Figure 2. a) Arrangement of magnetic orbitals of **1**, b) magnetic interactions in **1**. Short bonds are represented by thick lines.

In **1**, water molecules (O7) and hydroxyl groups (O3 and O6) play an important role in constructing a network structure of hydrogen bonds; simple translations lead to the formation of a layer structure in the *ac* plane in which the hydrogen bonds are O(7)-H ··· O(1) 2.693(5) Å, O(3)-H ··· O(4) 2.710, and O(6)-H ··· O(7) 2.692 Å. The additional

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3623-2673 $ 17.50+.50/0

hydrogen bond between the water molecule(O7) and the hydroxyl group (O6) requires an offset between successive layers that is generated by a twofold screw axis. Consequently, the hydrogen network forms a channel structure along the *b* axis (Figure 3).

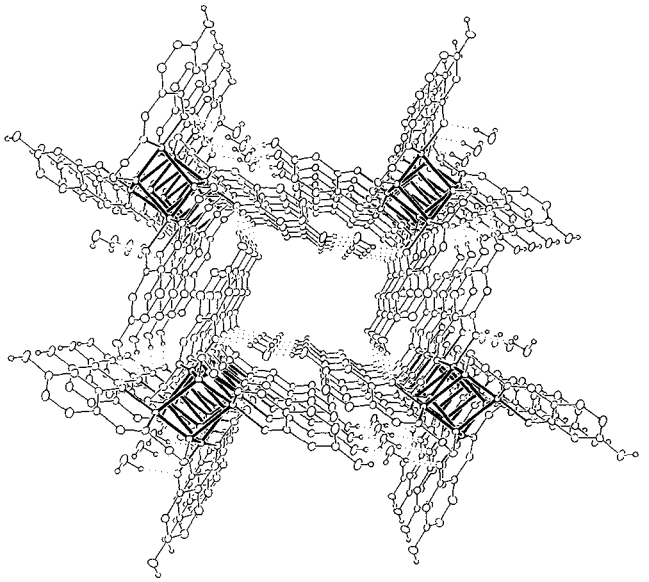

Figure 3. Channel structure of **1**.

The temperature dependence of the magnetic susceptibility of **1** was measured in the temperature range between 2.0 and 300 K (Figure 4). At room temperature the value of $\chi_m T$ is

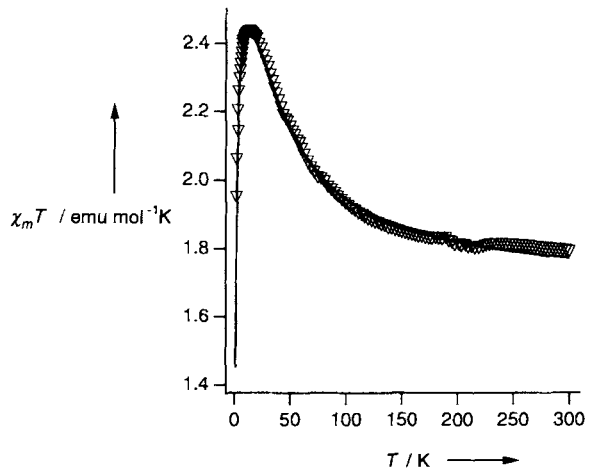

Figure 4. Plot of $\chi_m T$ as a function of T for **1**. The solid line was calculated with the parameters given in the text.

1.8 emu K mol^{-1} per molecule, as expected for four noncorrelated spins. Upon cooling the sample, $\chi_m T$ increases to a maximum value of 2.44 emu K mol^{-1} at 14 K, then decreases. This is indicative of an intracluster ferromagnetic interaction, since the intercluster metal–metal distances are over 7.0 Å these would only give rise to very weak magnetic interactions. The axial bonds Cu1–O2′ and Cu2–O5′ are elongated due to a pseudo Jahn–Teller effect, which leads to weaker magnetic interactions within the Cu2 ··· Cu2′ and Cu1 ··· Cu1′ pairs. The magnitudes of the magnetic interactions within the Cu1 ··· Cu2 and Cu1 ··· Cu2′ pairs are considered to be comparable, because the bridging angles and spacings for Cu1-O2-Cu2 and Cu1-O5′-Cu2′ are similar. The two exchange parameters J_1 and J_2 were, therefore, introduced for the analysis of the magnetic data and a schematic drawing of the magnetic pathways is depicted in Figure 2b. The experimental magnetic data were analyzed with the Hamiltonian operator $\mathscr{H}$ [Eq. (1)] and the intercluster interaction was

$$\mathscr{H} = -2J_1(S_{Cu1}S_{Cu1'} + S_{Cu2}S_{Cu2'}) - 2J_2(S_{Cu1}S_{Cu2} + S_{Cu1}S_{Cu2'} + S_{Cu1'}S_{Cu2} + S_{Cu1'}S_{Cu2'}) \quad (1)$$

included as a mean field correction θ. The least squares calculation yielded the best fit parameters of $g = 2.02(1)$, $J_1 = -17.6(1)$ cm^{-1}, $J_2 = +36.0(9)$ cm^{-1}, and $\theta = -1.0(1)$ K. The propagation of intracluster magnetic interactions occurs according to the known dependence of J versus bridging angles.[7] The magnetic orbital overlap through oxygen p-orbitals becomes nearly zero for the bridging angles Cu1-O2-Cu2 and Cu1-O5′-Cu2′ of 106.1(1) and 104.8(1)°, respectively.[8] Furthermore, the perpendicular arrangement of the magnetic metal orbitals (Figure 2a) results in zero orbital overlap leading to ferromagnetic interactions (J_2), while the parallel orientation results in antiferromagnetic interactions (J_1).

The present compound is an example of how the introduction of hydroxyl groups can be useful for assembling clusters. Furthermore, the compound is soluble not only in acetonitrile but also in water, which indicates that the compound has potential to clathrate organic molecules while still maintaining its hydrogen-bonding network.

Experimental Section

H_2hsae (0.138 g, 1 mmol), prepared by condensation of 2,4-dihydroxybenzaldehyde with 2-aminoethanol, was added to a solution of copper(II) acetate monohydrate (0. 199 g, 1 mmol) in methanol (80 mL). The resulting dark green pprecipitate was filtered, and recrystallization in acetonitrile gave dark blue tabletlike crystals, one of which was subjected to the X-ray structural analysis. Elemental analysis: found (calcd) C 45.25 (45.13), H 4.62 (4.48), N 9.40 (9.57).

[6] Crystal data of **1** ($C_{44}H_{52}Cu_4N_8O_{14}$): dark blue tablet ($0.2 \times 0.2 \times 0.3$ mm^3), $M_r = 1171.13$, monoclinic $C2/c$ with $a = 25.355(4)$, $b = 9.211(4)$, $c = 21.460(3)$ Å, $\beta = 98.23(1)°$, $V = 4960(2)$ Å^3 (by least-square refinement of 20 reflections ($25° < 2\theta < 30°$)), $Z = 4$, $\rho_{calcd} = 1.568$ g cm^{-3}, $F(000) = 2399$, $\mu(Mo_{K\alpha}) = 17.73$ cm^{-1}. Data collection: Rigaku AFC5S diffractometer, ω-2θ mode, scan width $1.45 + 0.40\tan\theta$, scan speed 4° min^{-1}, $Mo_{K\alpha}$ ($\lambda = 0.71073$ Å) radiation; $T = -120$ °C; 4325 reflections measured($3° < 2\theta < 55°$), 4325 unique reflections, of which 3519 ($I_0 > 3.0\sigma I_0$) were used for the calculation. Data were corrected for Lorentz and polarization and an empirical absorption correction (ψ-scan) was applied, which resulted in transmission factors ranging from 0.575 to 0.760. The structure was solved by a conventional heavy-atom method and refined by full-matrix least-squares by using Xtal 3.2 (*XTAL 3.2 User's Manual*, The University of Western Australia and Maryland). All non-hydrogen atoms were readily located and refined with anisotropic thermal parameters, and hydrogen atoms were located from difference Fourier maps and refined with isotropic thermal parameters. Final $R = 0.040$, $R_w = 0.032$ for 316 parameters. The final Fourier difference synthesis showed minimum and maximum peaks of -0.77 and $+0.67$ e Å^3.

Synthesis of a Small-Pore Microporous Material Using a Computationally Designed Template**

Dewi W. Lewis,* Gopinathan Sankar, Joanna K. Wyles, John Meurig Thomas,* C. Richard A. Catlow,* and David J. Willock

The ability to design and synthesize materials, with predetermined physical and catalytic properties is an oft-aspired goal of the chemist. Recent progress has demonstrated how this may well be viable in the field of microporous solids, particularly in the case of syntheses mediated by the use of structure-directing templates.[1–3] Here we demonstrate how we are able to design, using computational methods, an organic template suitable to form a targeted microporous material, which results not only in the formation of that crystalline structure, but also manifests a number of other predefined physical properties.

Microporous materials, both aluminosilicate and aluminophosphate based, with the Chabazite structure (IZA code CHA) act as catalysts for a number of important reactions. For example SAPO-34 is an effective catalyst for the conversion of methanol to light olefins.[4] However, there are a number of problems in the synthesis of such materials, which we believe arise from the choice of the organic species used as the structure-directing agent. These molecules facilitate the formation of the structure, being encapsulated in the resulting porous framework; the framework structure is a reflection, to varying degrees, of the size and shape of the organic species. Typically, small amines are used to form the chabazitic materials (for example, triethylamine, cyclohexylamine, and *N,N*-diethyl-2-aminoethanol).[5] Both experimentally[5] and computationally[6] it is generally noted that two such molecules can fit inside the CHA cage,[7] although full occupancy of all template sites is not a prerequisite of crystal formation. Such a templating regime requires first relatively high concentrations of aliovalent metal substituents (either M^{2+} on Al^{3+} sites or Si^{4+} on P^{5+} sites) as a result of the need to compensate for the 2+ charge of the protonated templates, per cage, and second the ordering of the templates in a close-packed configuration which requires relatively slow kinetics. The latter requirement results in the competitive formation of other microporous phases where template ordering is not as crucial—an effect particularly significant in aluminophosphate preparations where phases with the $AlPO_4$-5 (AFI) structure are readily formed.[8,9] Although the presence of aliovalent metal in the framework gives rise to catalytic centers, high concentrations can have a deleterious effect on the stability and performance of the material.

Our aim was therefore to synthesize an aluminophosphate-based material with the CHA structure which, by the use of a new template, would circumvent the above problems. Such a template would be designed computationally with our recently developed de novo design methodology.[3] We determined that the following properties would be crucial in our synthesis strategy: a) The selected template would form a CHA material quickly and in a phase pure form, with little or no extraneous microporous phases. b) The template would be present at a concentration of one molecule per unit cell and must fully occupy the CHA cage. c) The charge on the template would be able to be varied to accommodate a range of metal concentrations in the framework and thus allow a degree of control over the catalytic behavior arising from the presence of these substituents.

Once we had identified a suitable candidate template, a program of synthesis was undertaken, and the resulting products were characterized by a combination of XRD and EXAFS studies.

We applied de novo molecular design methods, as embodied in our ZEBEDDE code,[3] to computationally design a template to meet the above criteria. The method allows molecular entities to be grown from a so-called seed molecule, to which new molecular fragments are added from a library. A number of actions are possible, which under the control of a cost function based on van der Waals overlap, minimize the nonbonded contacts between the framework and the template.[3,10] Resulting species are subsequently ranked according to their binding energy (a measure of effective fit inside the pore), which can provide a guide to the likely efficacy of that molecule as a successful template for the structure in question.[11]

We performed a number of simulations, described in more detail elsewhere,[10] using seeds from C_1 (methane) to C_4 (*n*-butane). In each case the concentration of the resultant organic molecule was restricted to one per unit cell (or cage). Typical templates included branched hydrocarbons and amines (for example, 3,3,6-trimethyloctylamine and 6-ethyloctylamine) which are similar in structure and geometry to

two triethylamine molecules—the common template used in Chabazitic MeAPO syntheses—linked across the cage.[10] However, although these may be suitable as templates from a space-filling point of view, their flexibility might lead to a large number of conformations, which will reduce the likelihood of the formation of a crystalline microporous material.

Another molecule generated by the code, bicyclohexane, is more rigid and therefore does not suffer this drawback. Furthermore, the symmetry of the molecule is such that any disorder of the molecule, both rotational and by inversion through the bridge between the cyclohexane rings, does not significantly alter the interactions between the template and the framework.

We therefore used this molecule as a basis for our synthetic strategy. Bicyclohexane is, however, incompatible with typical hydrothermal conditions, being insoluble in water. We therefore modified the molecule by introducing nitrogen centers: templates are typically amines. Although nitrogen can be included automatically by ZEBEDDE as part of a molecular fragment, its position is controlled by the order in which random actions occur, and therefore, post-growth modification is the most effective method of fine-tuning the suggested templates. Furthermore, there is little distinction between C and N in our cost function, since the function is based on van der Waals radii. However, with each modification, energy minimization calculations with the Discover code[12] were performed to ensure that the new template remained a suitable candidate. At the same time, we had to consider the availability and possible synthesis routes for the organic species. Bearing in mind that previous syntheses of CHA-structured cobalt aluminophosphate materials have proved most successful with Co concentrations equivalent to two Co atoms per unit cell, we identified 4-piperidinopiperidine as a suitable candidate for initial evaluation of templates based on the bicyclohexane motif; the commercial availability of this material is also important. The generation of 4-piperidinopiperidine from an ethane seed within the CHA structure is illustrated in Figure 1a, and Figure 1b depicts the energy-minimized geometry of the molecule in a siliceous unit cell of chabazite. We calculate the binding energy of 4-piperidinopiperidine to be $-54\ kJ\,mol^{-1}$, which compares favorably with that found for templates known to form CHA-structured materials,[6] for example, cyclohexylamine ($-61\ kJ\,mol^{-1}$).

Preparations with a typical gel composition of $0.2\,CoO:0.9\,Al_2O_3:1.5\,P_2O_5:30\,H_2O:2.0\,C_{10}H_{20}N_2$ yielded a single blue crystalline phase, which we designate DAF-5 (*D*avy *F*araday 5). Crystallization was carried out in a stainless steel autoclave in the temperature range 150–165°C, and DAF-5 was obtained after subjecting the gel to these hydrothermal conditions for about 4 hours. The resulting X-ray powder diffraction pattern (Figure 2a) can be readily indexed with the auto-indexing program TREOR[13] to a hexagonal cell (cell parameters: $a=b=13.537$ Å, $c=15.480$ Å; $\alpha=\beta=90.0$, $\gamma=120°$; cell volume $=2457$ Å^3) and is similar to that of the mineral chabazite and other related chabazitic materials (Figure 2).[14] The presence of the organic template, which is not ordered, makes a full structure determination from the powder pattern difficult, although a good model can be produced for the inorganic lattice, which results in a chabazitic cage structure. A more detailed structure determination is in progress from single crystal data. The influence of the template on the relative intensities of the diffraction patterns is illustrated in Figure 2b and c, demonstrating that the intensity differences between a typical calcined CHA-structured material[14] and the as-prepared

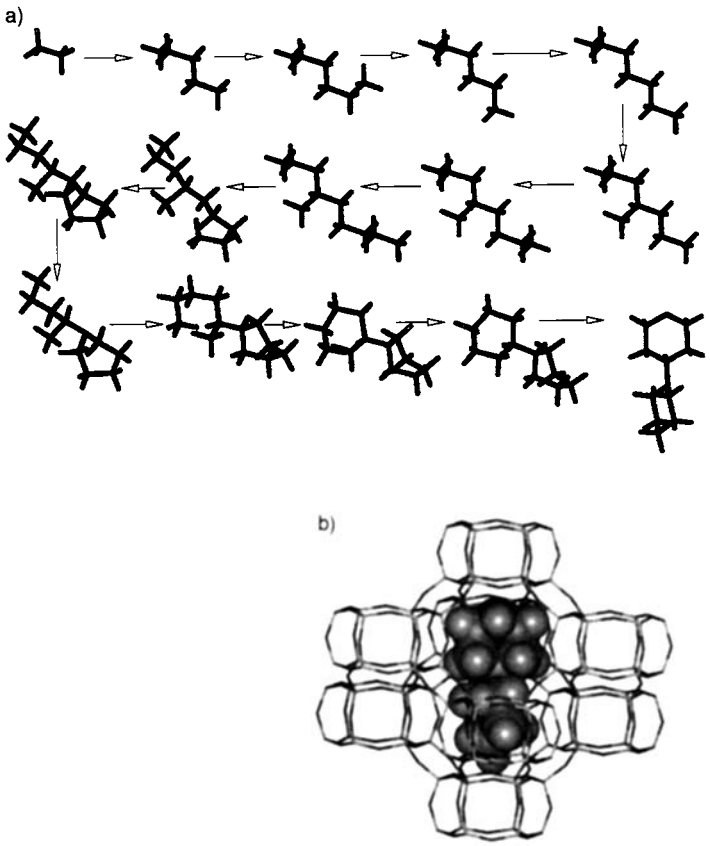

Figure 1. a) Generation of 4-piperidinopiperidine from an ethane seed in a siliceous CHA unit cell with the program ZEBEDDE [3]. Note that the molecule is oriented to best illustrate the growth process rather than its true position in the CHA cage. Further details are given elsewhere [10]. b) Energy-minimized location of 4-piperidinopiperidine in the CHA cage.

DAF-5 sample are consistent with the presence of the template. Elemental analysis gives a framework composition of $Co_{0.28}Al_{0.72}PO_4$, which is in close agreement with a theoretical composition of $Co_{0.25}Al_{0.75}PO_4$ for a material with 2 Co atoms per unit cell that compensate for the template's 2+ charge. Analysis of the Co K-edge EXAFS data (Figure 3) reveals that the cobalt is incorporated into the framework by substitution at tetrahedral sites. The Co–O and Co–P distances and the Co-O-P bond angle obtained from the analysis of the EXAFS data (multiple scattering methodology[15,16]) are given in Table 1 and are typical of many other Co-substituted aluminophosphate materials.[17]

The synthesis of DAF-5, a Chabazitic cobalt aluminophosphate has been achieved by the computational design of a new template. We have thereby again demonstrated that the computational method of de novo template design is viable as a tool for designing templates. Furthermore, the synthesis has achieved a number of other goals set out as objectives for the study and as such can be considered an example of a priori materials design. In particular, the disadvantages of small templates present at a concentration of two per unit cell—long preparation times and concomitant poor sample purity—were avoided with a larger template, which can only be present at a concentration of one per unit cell: the target structure was synthesized in less than 4 hours at reasonably low temperatures, and without interference from the formation of other microporous phases. A further goal was to provide control of the metal content of the framework by a

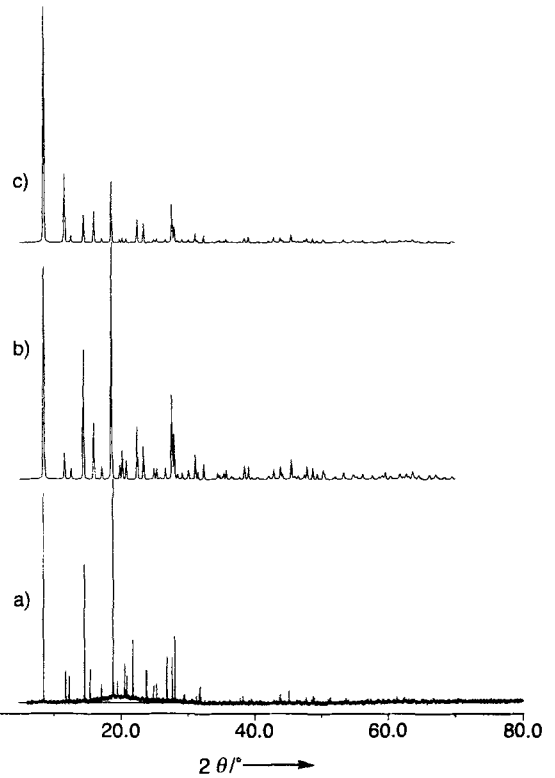

Figure 2. a) Experimental powder X-ray diffraction patterns for DAF-5, and for comparison the calculated diffraction patterns[19] for a CHA-structured aluminiumphosphate unit cell (space group $P1$) in the presence of (b) and in the absence of the template (c). The calculated pattern for the templated system is in excellent agreement with the peak positions and relative intensities of the experimental data, although only one unique template geometry was used to calculate the simulated pattern whereas other orientations are present in the experimental sample. Note that the peak width used in the simulated patterns is larger than that for the high-resolution powder pattern obtained from synchrotron radiation.

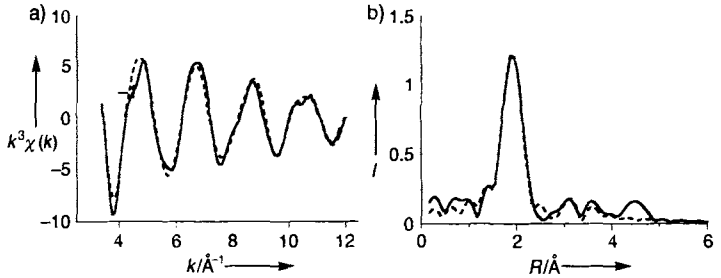

Figure 3. Co k-edge EXAFS (a) and the associated Fourier transform (I = FT magnitude) of the as-synthesized DAF-5 (b). In each case the solid line shows the experimental data and the dotted curve was calculated from the parameters given in Table 1.

template "tuneable" in terms of charge. Although we have considered only a 2+-charged template, given suitable synthesis conditions 4-cyclohexylpiperidine (which will have a charge of 1+ in the gel) is also likely to form a CHA-structured material. We should also note that if bicyclohexane could be incorporated into a nonpolar synthesis gel, such a gel may also be conducive to forming the siliceous or aluminophosphate end-members of this structural type. We note that gallophosphates (analogues of AlPOs) have been formed from such nonpolar gels, although with different templates to those used here.[18]

Table 1. Structural parameters DAF-5 obtained from Co K-edge EXAFS data; N is the coordination number, R the interatomic distance and σ^2 the Debye–Waller factor. The fit index is 14.18.

Atom pair	N	R[Å]	σ^2[Å]	Co-O-P bond angle
Co–O	4.1	1.94	0.0045	–
Co–P	2.6	3.17	0.006	133
Co–P	1.5	3.33	0.006	150

In this work we have demonstrated the successful application of computer-aided materials design, through the identification of critical parameters in the synthesis and the computational design of a suitable template, to the formation of a microporous material possessing predefined structural and physical properties. We believe that such an approach provides an effective route to the synthesis of novel microporous materials.

Experimental Section

DAF-5 was prepared from a gel with a typical composition of $0.2\,CoO : 0.9\,Al_2O_3 : 1.5\,P_2O_5 : 30\,H_2O : 2.0\,C_{10}H_{20}N_2$ in a Teflon lined stainless steel autoclave at between 150 and 165°C for a maximum of six hours. The gel was prepared from phosphoric acid, aluminium hydroxide, cobalt(II) acetate, and 4-piperidinopiperidine (all Aldrich). X-ray diffraction data were collected at room temperature on station 2.3 at the Daresbury Synchrotron source (operates at 2 GeV with typical currents between 120–250 mA) at $\lambda = 1.3999$ Å in capillary mode. Co K-edge EXAFS were collected at room temperature on station 7.1 at the Daresbury laboratory, and the data analyzed with the suite of programs available there (EXCALIB, EXBROOK, and EXCURV92).

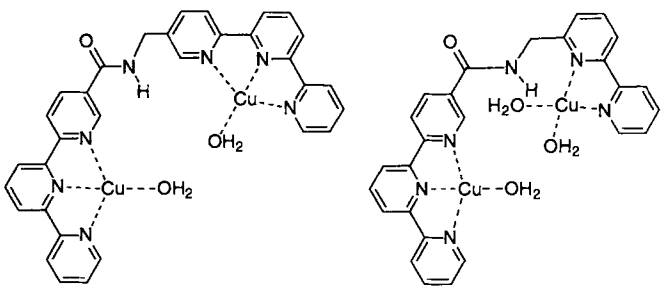
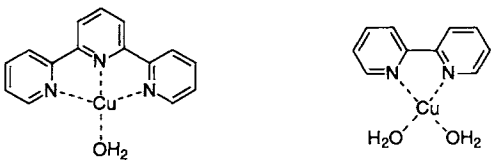
Rapid and Highly Selective Cleavage of Ribonucleoside 2′,3′-Cyclic Monophosphates by Dinuclear Cu^{II} Complexes**

Shanghao Liu, Zhiyong Luo, and Andrew D. Hamilton*

Recently there has been increasing interest in the design of catalysts for the hydrolysis of phosphodiester groups in DNA and RNA.[1,2] These artificial nucleases have many potential applications as anticancer or antiviral drugs[2f-i,3-5] and as artificial restriction nucleases.[1,6] Since metal ions are found in the active sites of many natural nucleases,[6,7] it is not surprising that metal complexes constitute a major class of artificial catalysts for phosphodiester hydrolysis.[1,2] Inspired by natural nucleases that exploit two metal ions in their active sites, several research groups developed dinuclear metal complexes that show significantly higher activity than mononuclear metal complexes.[2a,b,d-g,8-11] We recently showed that dinuclear Cu^{II} complexes **1** and **2** are more active than mononuclear Cu^{II} complexes **3** and **4** in catalyzing transesterification of the RNA model compound 2-hydroxypropyl-*p*-nitrophenylphosphate (HPNPP).[12] Here we report that **1** and **2** are also more effective than **3** and **4** in promoting base- and regioselective hydrolysis of ribonucleoside 2′,3′-cyclic monophosphates **5**,[13] intermediates in the hydrolysis of RNA (Scheme 1).[14]



1 **2**



3 **4**

Hydrolysis of **5a–d** in the presence of excess **1–4** was conveniently monitored by HPLC; all reactions followed first-order kinetics. The pH–rate profiles for the hydrolysis of **5a** in the presence of **1** and **2** (Figure 1) show that maximal activities are reached at pH 7.5. Consequently, all other reactions were also carried out at pH 7.5. Table 1 summarizes rate constants and regioselectivities for the hydrolysis of **5a–d** catalyzed by **1–4**. Dinuclear complexes **1** and **2** are indeed more active than mononuclear complexes **3** and **4**. For example, **1** is almost 500 times more active than **3** in catalyzing the hydrolysis of **5b** (Table 1, entries 6 and 8). Similarly, although not as remarkably, **2** is about 35 times more active than **3** and about 22 times more active than **4** in catalyzing the

hydrolysis of **5a** (Table 1, entries 2–4). These results demonstrate that the two Cu^{II} ions in **1** and **2** are highly cooperative in promoting hydrolysis of **5a–d**.

More interestingly, the dinuclear complexes show markedly higher, and in some cases opposite, base and regioselectivities relative to the mononuclear complexes. For example, **5b** is hydrolyzed about six times faster than **5a** when **1** is the catalyst but slightly *more slowly* than **5a** when **3** is the catalyst (Table 1, entries 1, 3, 6, and 8). Dinuclear complex **1** is not only the most active but also the most regioselective catalyst among the four complexes. For example, **1** cleaves the P–O (3′) bond in **5c** more than 17 times faster than the P–O (2′) bond (Figure 2 and Table 1, entry 11). In contrast, **2–4** cleave one P-O bond in **5c** no more than twice as fast as the other P–O bond (Figure 2 and Table 1, entry 12–14). Similarly, **1** is far more regioselective than **2–4** in hydrolyzing **5d** (Table 1, entries 16–19). Although not as active or regioselective as **1**, **2** is more base-selective than **1** and mononuclear complexes **3** and **4**. Dinuclear complex **2** hydrolyzes **5a** faster than the other three substrates with a maximun rate difference of 31-fold between **5a** and **5b** (Table 1, entries 2 and 7).

Natural ribonucleases hydrolyze RNA not only rapidly but also base-selectively. Furthermore, they hydrolyze **5a–d**, the intermediates in RNA hydrolysis, regiospecifically and produce only **6**.[14] Although a number of metal complexes were developed that cleave RNA and **5** rapidly,[1,2] few show significant base or regioselectivity.[2c,e,16] On the other hand, several catalysts, most having cyclodextrins as binding sites, show remarkable regioselectivities in catalyzing the hydrolysis of **5a–d**. However, the rate enhancements are usually less than ten times higher than the background rate of hydrolysis.[15,17,18] Dinuclear Cu^{II} complexes **1** and **2** cleave **5a–d** with both high activity (up to 10^6 rate enhancement over the background hydrolysis; Table 1, entries 6 and 10) and remarkable base and regioselectivities. In this regard, **1** and **2** resemble natural nucleases more closely than most nuclease mimics. Interestingly, the selectivity of **1** in cleaving **5c** and **5d** to produce more nucleoside 2′-monophosphate (**7c** and **7d**) than nucleoside 3′-monophosphate (**6c** and **6d**) is opposite to that of natural nucleases or the few nuclease mimics that show some regioselectivity. This reversed regioselectivity may be useful, since the 2′- and 3′-hydroxyl groups have quite different reactivities in enzymatic manipulation of RNA.

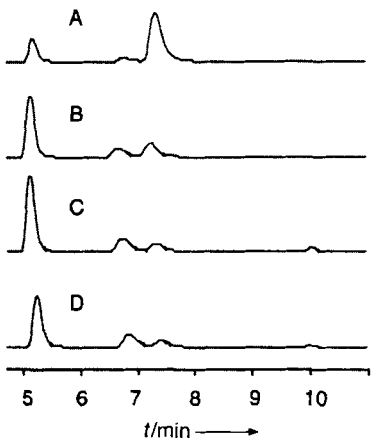

Figure 2. HPLC traces for the regioselective hydrolysis of **5c** (2′,3′-cUMP) in the presence of **1–4** in HEPES (0.05 M, pH 7.5) at 25 °C. [**5c**] = 0.2 mM; [**1**,**2**] = 1.0 mM; [**3**,**4**] = 2.0 mM. A: **1**, after 1.5 h; B: **2**, after 22.5 h; C: **3**, after 119 h; D: **4**, after 120 h. Retention times are as follows: 2′,3′-cUMP 5.2 min, 3′-UMP 6.8 min, 2′-UMP 7.4 min, uracil 10.1 min.

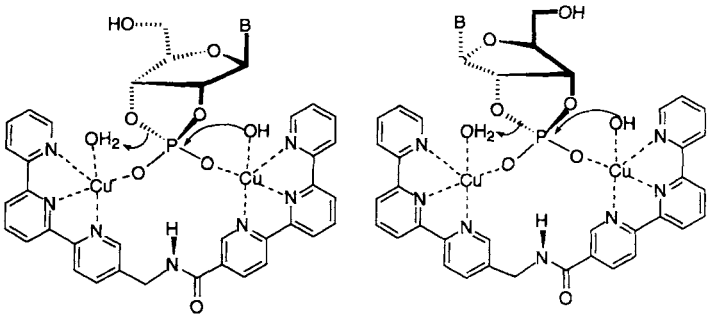
Natural nucleases achieve high base- and regioselectivities by recognizing and binding to nucleotide bases in the scissile region of RNA. We believe that **1** and **2** operate by similar mechanisms, based on an analysis of the data in Table 1. First, the high base and regioselectivities observed for **1** and **2** are likely due to active participation of the base groups in catalyst–substrate binding rather than steric effects, since the observed base- and regioselectivities do not correlate with the size or shape of the bases. For example, adenine and guanine in **5a** and **5b** are of similar size but show very different reactivities and regioselectivities. Second, the bases probably interact with the ligands instead of the Cu^{II} ions, since the observed base and regioselectivities do not correlate with known affinities of the nucleotide bases for metal ions.[19,20] For example, uracil and cytosine have very different affinities for metal ions, but both **5c** and **5d** show high regioselectivities with catalyst **1** (Table 1, entries 11 and 16).

Nucleotide bases can interact with the dinucleating ligands by hydrogen bonding to the amide linker or stacking to the π surface of the terpyridine or bipyridine subunits.[19,20] Scheme 2 shows two possible mechanisms by which **1** may hydrolyze **5**. Both mechanisms are consistent with a high degree of cooperativity between the two Cu^{II} ions in **1** (Table 1), which supports a double Lewis acid activation, and the bell-shaped pH–rate profile (Figure 1), which indicates both general base and general acid catalysis. The two mechanisms differ in the orientation of substrate with respect to the two Cu^{II} ions in **1**. As a result, the amide linker can potentially form a hydrogen bond in one but not the other orientation of the nucleotide base in the substrate–catalyst complex. Asymmetry of this type in substrate–catalyst interaction is required for there to be any difference in reactivity of the P–O (2′) and P–O (3′) bonds. Models show that the carbonyl group of uracil or cytosine in **5c** and **5d** is well positioned to form a hydrogen bond to the amide linker in **1** in only one catalyst–substrate complex. This suggests differential substrate–catalyst complex formation as a possible origin for the regioselectivities of **1**/**5c** and **1**/**5d**.



Scheme 2. Regioselective binding between the unsymmetric dinuclear metal complex **1** and **5a–d** as well as the resulting cleavage reactions. Since the two possible binding modes should have different binding energies, the left one is favored over the other and regioselective hydrolysis results.

Unlike **1**, the two Cu^{II} ions in **2** show only a moderate degree of cooperativity (Table 1), indicating a one Lewis acid–one general acid/base mechanism[12] and a reason for low regioselectivity. However, **2** shows higher selectivity for adenine relative to the other nucleotide bases. Sigel et al.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3623-2679 $ 17.50+.50/0

reported that the adenine group in 5′-AMP forms a stronger stacking interaction to bipyridinecopper(II) complexes than the uracil group in 5′-UMP.[19] Such a stacking interaction between adenine and bipyridine may account for the high selectivity of **2** for **5a** over **5b–d** (Table 1).

Dinuclear complexes **1** and **2** are highly active in promoting hydrolytic cleavage of nucleoside 2′,3′-cyclic monophosphates. Furthermore, **1** is highly regioselective and cleaves **5c** and **5d** predominantly to nucleoside 2′-monophosphates. On the other hand, **2** shows remarkable base selectivity and hydrolyzes **5a** much faster than **5b–d**. Presumably, **1** achieves high regioselectivity by regioselectively binding to the bases in the substrates, while **2** attains base selectivity by a preferential $\pi-\pi$ stacking interaction between the bipyridine unit in **2** and the bases in the substrates. More experiments are in progress to probe the exact nature of interactions that give rise to the high reactivities and base and regioselectivities shown by **1** and **2**.

Experimental Section

The preparation of **1–4** has been described previously [12]. Cleavage of **5** by **1–4** was followed by HPLC (Ranin). The following procedure is typical: **1** (1.1 mM, 4.5 mL) in a buffer was mixed with **5a** (2.0 mM, 0.5 mL) in the same buffer. Aliquots (200 μL) of the reaction mixture were quenched with ethylenediaminetetraacetate (EDTA, 20 mM, 200 μL). After any solid that formed was filtered, the quenched solution (20 μL) was injected onto a C-18 reversed-phase column and eluted for 10 min with 1–10% CH_3CN in H_2O containing 0.1% CF_3COOH (flow rate 1.0 mL min^{-1}). The eluent was monitored at λ_{max} of the nucleobase (260 nm for adenine and uracil, 252 nm for guanine, and 268 nm for cytosine) by a Rainin UV-C detector. The first-order rate constants k were obtained as slopes of plots of $\ln(A_0/A_t)$ versus t, where A_0 and A_t are integrations of the areas of the HPLC peaks for **5** at $t=0$ and t, respectively. Selectivities for the formation of 3′-monophosphate (**6**) with respect to 2′-monophosphate (**7**) were calculated from the ratios of integrations of the areas of the HPLC peaks for **6** and **7**. The identities of **6** and **7** were established with authetic samples (Sigma). The two isomers have nearly identical extinction coefficients at λ_{max} of the nucleobase. Therefore, the ratio of the HPLC peaks for **6** and **7** is equal to the ratio of the amounts of **6** and **7** produced (i. e., the regioselectivity). In all cases the ratios remained constant throughout the entire course of hydrolysis. For slow reactions ($k < 5\times10^{-6}$ s^{-1}), appreciable amounts of **6** and **7** were further hydrolyzed to give inorganic phosphate and the correponding nucleosides before **5** was completely hydrolyzed. However, the ratio of **6** to **7** in the reaction mixture remained unchanged. Duplicate runs showed measurement errors of less than ±15% for k and less than ±3% for the regioselectivity.

A Calixarene with Four Peptide Loops: An Antibody Mimic for Recognition of Protein Surfaces**

Yoshitomo Hamuro, Mercedes Crego Calama, Hyung Soon Park, and Andrew D. Hamilton*

The design of synthetic hosts that can recognize protein surfaces and disrupt biologically important protein–protein interactions remains a major unsolved problem in bioorganic chemistry.[1] In contrast, the immune system offers numerous antibodies that show high sequence and structural selectivity in binding to a wide range of protein surfaces.[2] This diversity of recognition is even more remarkable, because all antibody fragment antigen binding (FAB) regions share a common structural motif of six hypervariable loops held in place by the closely packed constant and variable regions of the light and heavy chains. Four of these loops (L2, L3, H2, and H3) generally take up a hairpin conformation and the remaining two form more extended loops.[2] X-ray analyses of protein–antibody complexes show that strong binding is achieved by the formation of a large and open interfacial surface (> 600 Å) composed primarily of residues that are capable of mutual hydrophobic, electrostatic, and hydrogen bonding interactions.[3–5] The majority of antibody complementary

determining regions (CDRs) contact the antigen with four to six of the hypervariable loops.[4]

In recent years there has been considerable interest in the design of novel antibody-like recognition motifs.[6] Approaches have included the randomization of known CDR loops[7] or of two interhelix loops in a protein with four-helix bundles,[8] de novo protein design of loops based on a protein template,[9] or non-peptide artificial receptors.[10] However, the search for antibody mimics has not yet yielded compact and robust frameworks that reproduce the essential features of the CDRs.[11] Our strategy is to use a macrocyclic scaffold to which multiple peptide loops in stable hairpin-turn conformations can be attached. In this paper we report the synthesis of an antibody mimic based on calix[4]arene linked to four constrained peptide loops (Figure 1). The resulting host binds to the surface of cytochrome c in a manner similar to the natural protein partners.

Calix[4]arene was chosen as the core scaffold, as it is readily available[12,13] and can be locked into the semirigid cone conformation by alkylation of the phenol groups. This results in a projection of the *para*-substituents onto the same side of the ring to form a potential binding domain.[14] The required tetracarboxylic acid **1** was prepared by alkylation of calix[4]-arene[12c] (*n*-butyl bromide, NaH) followed by formylation (Cl_2CHOCH_3, $TiCl_4$) and oxidation ($NaClO_2$, H_2NSO_3H).[15]

3

The peptide loop was based on a cyclic hexapeptide in which two residues were replaced by a 3-aminomethylbenzoyl (3amb) dipeptide analogue[16] containing a 5-amino substituent for facile linkage to the scaffold. Von Itzstein et al. and DeGrado et al. had previously shown that cyclic peptides of this type take up intramolecularly hydrogen-bonded β-turn conformations.[17] The 5-nitro substituted dipeptide analogue was formed by selective reduction (BH_3) of methyl 3-amidocarbonyl-5-nitrobenzoate, followed by deesterification (LiOH in THF) and reaction sequentially with Fmoc-Asp-(*t*Bu)-OH and H-Gly-Asp(*t*Bu)-Gly-OH (dicyclohexyl carbodiimide (DCC), *N*-hydroxysuccinimide) to yield Fmoc-Asp(*t*Bu)-5$NO_2$3amb-Gly-Asp(*t*Bu)-GlyOH. Cyclization with 4-dimethylaminopyridine (DMAP) and 2-(1*H*-benzotriazole-1-yl-1,1,3,3,-tetramethyluronium tetrafluoroborate (TBTU) was achieved in 70% yield, followed by reduction (H_2, Pd/C) to give the amino-substituted peptide loop **2**. Amine **2** was coupled to the tetraacid chloride derivative of **1** ($(COCl)_2$, DMF) and deprotected with trifluoroacetic acid (TFA) to give the tetraloop structure **3**. The molecular structure of this host (Figure 1) resembles that of the antigen

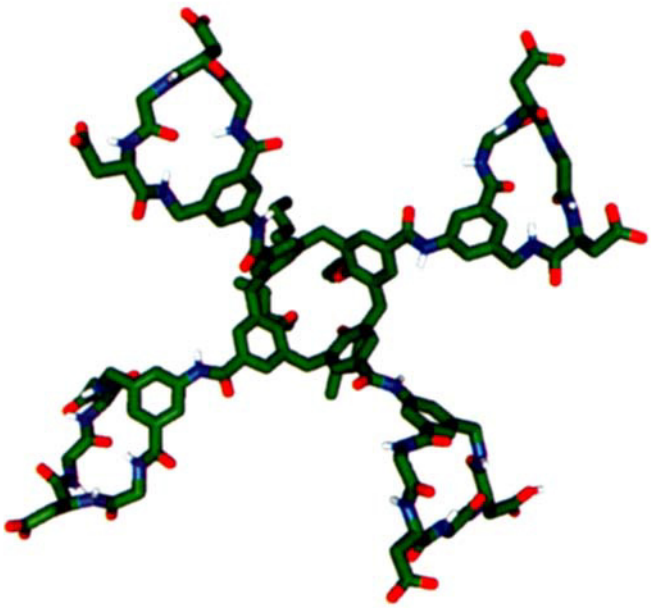

Figure 1. Representation of the structure of host **3** with four peptide loops [24].

binding region of an antibody but is based on four loops rather than six.[3] We chose cytochrome c as the initial protein target, since it is structurally well-characterized and contains a positively charged surface made up of several lysine and arginine residues.[18] In this study the negatively charged GlyAspGlyAsp sequence was used in the loops of **3**[19] to complement the charge distribution on the protein. However, the synthetic strategy permits the use of other sequences to generate antibody mimics with different recognition characteristics.

The special binding affinity afforded by the multiloop structure in **3** for cytochrome c (cyt c) was clearly seen by affinity chromatography. A mixture of **3** and single peptide loop diacid **4** in tris(hydroxylmethyl)aminomethane (Tris) buffer was added to a column containing agarose-linked cyt c followed by increasing concentrations of NaCl.[20] The monoloop derivative **4** eluted without NaCl, whereas the tetraloop receptor **3** required NaCl concentrations of 2 M before it passed through the column. This affinity compares well with cytochrome oxidase which was reported to elute from a similar column at NaCl concentrations of 100 mM.[21] Further support for a strong and discreet interaction came from gel permeation chromatography on Sephadex G-50 in 5 mM phosphate buffer at pH 7.4. A 2:1 mixture of **3** and cyt c gave a sharp band with a shorter retention time (reflecting larger

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3623-2681 $ 17.50+.50/0

molecular size) than pure cyt c (Figure 2). Furthermore, a corresponding 1:2 mixture showed both bands in the chromatogram, confirming the presence of both complexed and free cytochrome c in solution.

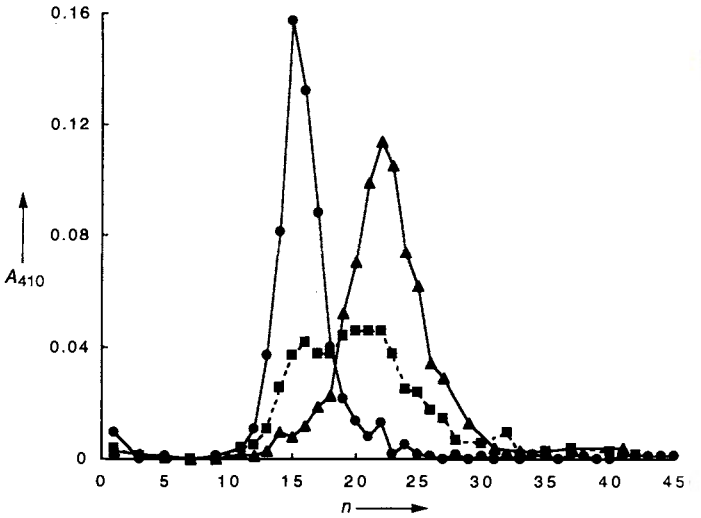

Figure 2. Gel permeation chromatography on Sephadex G-50 with phosphate buffer (5 mM, pH = 7.4) of cytochrome c (▲), 1:2 cytochrome c:**3** (●), and 2:1 cytochrome c:**3** (■). A_{410} is the absorbance at 410 nm; n is the fraction number.

The exact site on the surface of cytochrome that binds **3** has not yet been established. One likely possibility is the region close to the heme edge surrounded by the group of positively charged residues (Lys-17, 18, 21, 77, and 88),[22] which forms the primary interaction surface with electron transfer partners such as cytochrome c peroxidase and cytochrome oxidase.[23] Support for this binding arrangement came from ^{1}H NMR titration experiments: changes in the position of the hyperfine shifted heme-CH_3 resonances were followed as a function of increasing concentration of **3**.[25] The heme 8-CH_3 and 3-CH_3 resonances shifted upfield ($\Delta\delta = -0.27$) and downfield ($\Delta\delta = +0.25$), respectively, broadened, and reached saturation at approximately one equivalent of added **3**. The direction and the size of the shifts (-0.5 and $+0.5$) are similar to those seen in the equivalent titration between cyt c and cytochrome c peroxidase.[26] Docking a calculated structure for **3** with this region on the X-ray structure of cyt c[18] (Figure 3) confirms that the four peptide loops can contact four of the five lysine residues and cover a large area of the protein surface.[24]

A key goal in this work is to use our antibody mimics to disrupt the normal function of the protein. We have investigated the effect of complexation with **3** on the interaction of Fe^{III}-cyt c with reducing agents.[27,28] In phosphate buffer Fe^{III}-cyt c (1.57×10^{-5} M) is rapidly reduced by excess ascorbate (2.0×10^{-3} M) with a pseudo-first-order rate constant 0.1090 ± 0.001 (Figure 4). In the presence of **3** (1.91×10^{-5} M) the rate of cyt c reduction is diminished tenfold ($k_{obs} = 0.010 \pm 0.001\ s^{-1}$), consistent with the calixarene derivative's binding to the protein surface and inhibiting approach of ascorbate to the heme edge (Figure 3). A very similar inhibition of ascorbate reduction is seen with the cytochrome c/cytochrome c peroxidase complex,[27] further suggesting that **3** binds to a similar region of cyt c as its natural protein partners. A plot of k_{obs} vs. [**3**] shows a saturation curve that fits well to a 1:1 binding model and from which an association

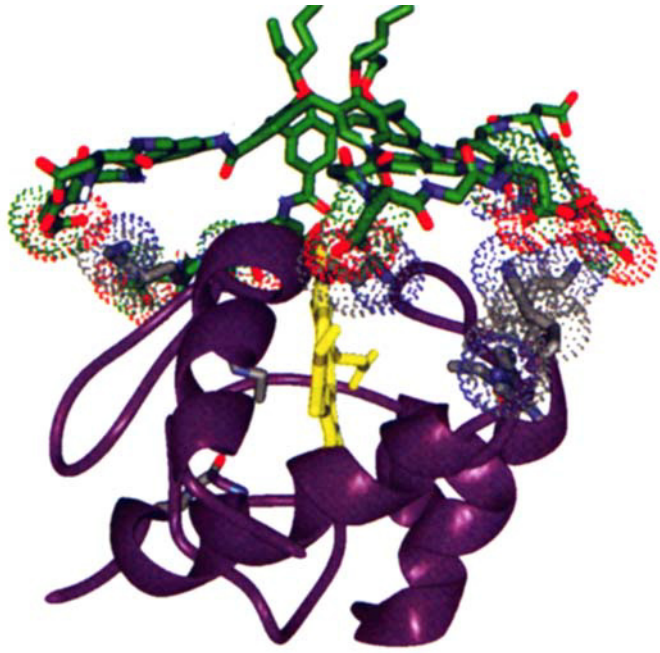

Figure 3. Proposed structure for the complex between cytochrome c and **3** [24].

constant of $(3.05 \pm 0.20) \times 10^6\ M^{-1}$ was calculated. The importance of the four loops in the design of **3** is seen by the minimal effect that even large concentrations of single loop **4** (5.36×10^{-4} M) had on the ascorbate reduction. Also, the interaction between **3** and cyt c is not simply a polyanion effect as excess concentrations of inositol hexaphosphate (Figure 4) or polyglutamate (at glutamate concentrations of 2.60×10^{-3} M) had only modest effect on the rate of ascorbate reduction.[28]

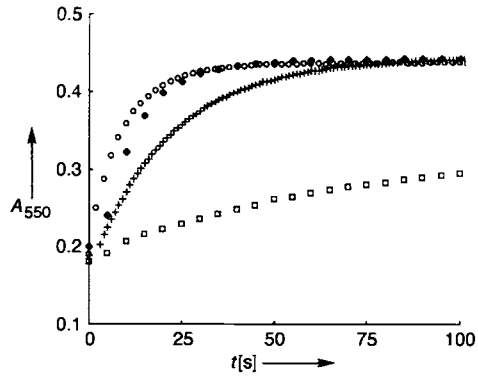

Figure 4. Kinetics of reduction of Fe^{III}-cyt c (1.57×10^{-5} M) by ascorbate in the presence of no receptor (○), **3** (1.91×10^{-5} M, □), **4** (5.36×10^{-4} M, ◆), and inositol hexaphosphate (2.55×10^{-4} M, +). A_{550} is the absorbance at 550 nm.

The new type of synthetic host **3** thus mimics antibody combining sites in having several peptide loops arrayed around a central binding region. The large surface area in the molecule allows strong binding to a complementary surface on cytochrome c and disrupts, in a similar way to cytochrome c peroxidase, the approach of reducing agents to the active site of the protein. We are currently preparing libraries of antibody mimics from different peptide loop sequences and screening their binding to a range of protein targets.

Experimental Section

3: To a solution of **1** [14,15] (86 mg, 0.10 mmol) and oxalyl chloride (254 mg, 2.0 mmol) in dry CH_2Cl_2 (10 mL) was added DMF (0.025 mL) through a silica gel filter, and the mixture was stirred at room temperature for 8 h. The reaction mixture was evaporated in vacuo to obtain the acid chloride (102 mg). A solution of **2** [17] (266 mg, 0.44 mmol) and diisopropylethylamine (DIEA, 80 mg, 0.60 mmol) in dry CH_2Cl_2 (10 mL) was added to the evaporated residue. The mixture was stirred at room temperature for 14 h. The reaction mixture was purified by preparative thin-layer chromatography (SiO_2; eluted with MeOH/CH_2Cl_2, first 1/9 and later 1/4) to afford the octa-*tert*-butyl ester derivative of **3** as a yellow powder (281 mg, 89%): m.p. > 350°C; ^{1}H NMR (300 MHz, [D$_6$]DMSO): $\delta = 10.10$ (br. s, 4H), 8.95 (br., 4H), 8.49 (br., 4H), 8.25 (d, $J = 8.7$ Hz, 4H), 8.09 (br., 4H), 7.99 (m, 8H), 7.67 (s, 4H), 7.60 (s, 8H), 7.37 (s, 4H), 4.81 (m, 8H), 4.51 (m, 8H), 3.99 (m, 20H), 3.63 (m, 8H), 3.46 (m, 4H), 2.79 (m, 4H), 2.62 (m, 4H), 2.31 (m, 8H), 1.97 (m, 8H), 1.47 (m, 8H), 1.35 (m, 72H), 1.02 (t, $J = 8.4$ Hz, 12H); ^{13}C NMR (75 MHz, [D$_6$]DMSO): $\delta = 120.1$, 117.8, 80.0 (2C), 75.0, 49.1, 48.8, 44.2, 42.3, 41.4, 37.5, 36.9, 31.9, 30.5, 27.6 (2C), 18.9, 14.0.

The octaester (298 mg, 0.093 mmol) was added to TFA (3 mL) and dry CH_2Cl_2 (3 mL), and the mixture was stirred at room temperature for 1 h. The mixture was evaporated under reduced pressure. The crude product was passed through anion exchange resin (Amberlite IRA-400(OH), water) and cation exchange resin (Amberlite IR 120 (plus), water) to remove ions. Water was lyophilized to give **3** (229 mg, 90%): m.p. > 350°C; ^{1}H NMR (300 MHz, [D$_6$]DMSO): $\delta = 10.02$ (s, 4H), 8.81 (s, 4H), 8.48 (s, 4H), 8.31 (d, $J = 8.7$ Hz, 4H), 7.97 (m, 12H), 7.64 (s, 4H), 7.55 (s, 8H), 7.30 (s, 4H), 4.76 (m, 8H), 4.52 (m, 8H), 4.0–3.4 (m, 32H), 2.8–2.6 (m, 8H), 2.5–2.3 (m, 8H), 1.97 (m, 8H), 1.50 (m, 8H), 1.01 (t, 8H); ^{13}C NMR (75 MHz, [D$_6$]DMSO): $\delta = 172.2$, 171.7, 170.9, 170.4, 169.3, 168.5 (2C), 165.1, 159.0, 140.2, 138.8, 134.4, 134.2, 128.7, 128.3, 121.4, 119.9, 117.7, 75.0, 49.1 (2C), 44.3, 42.2, 41.3, 36.1 (2C), 31.9, 30.5, 18.9, 14.0; high-resolution fast-atom-bombardment mass spectrometry (matrix: 3-nitrobenzyl alcohol): *m/z* calcd for $C_{128}H_{145}N_{24}O_{44}$ (M+H$^+$) 2721.9767; found 2721.985.

$BaSn_3$: A Superconductor at the Border of Zintl Phases and Intermetallic Compounds. Real-Space Analysis of Band Structures**

Thomas F. Fässler* and Christian Kronseder

In memory of Jeremy Burdett

Superconducting intermetallic compounds that are rich in main group elements, especially the alloys that crystallize in the Cu_3Au structure type, have been a focus of research owing to the interesting dependence of their critical temperature T_c on their valence electron counts.[1] In the course of our investigations on phases rich in germanium, tin, and lead, we discovered superconducting compounds in the latter two systems. We report here the pure-phase synthesis, magnetic properties, and electronic structure of $BaSn_3$, which crystallizes in the Ni_3Sn structure type (hexagonal variant of Cu_3Au). Results of band-structure calculations on $BaSn_3$ that predict anisotropic conductivity and show very flat bands at the Fermi edge E_F were the impetus for our magnetic studies. The coincident appearance of quasi-molecular states (localization)—and therefore a high density of states at E_F—with steep, disperse bands crossing the Fermi level (delocalization) may be viewed as a "fingerprint" in the search for new superconductors.[2] The hypothesis that pairing localization of conducting electrons occurs in superconductors[3] was successfully tested with several model systems, for example $(RE)_2X_2C_2$ (RE = rare earth metal, X = halogen) and $La_9Br_5(CBC)_3$.[2,4] Note that even in the case of the superconducting cuprates, the maximum transition temperature corresponds to a high density of states at E_F (van Hove singularity).[5]

$BaSn_3$ is a model superconducting compound, as it is the first material discovered at the border of intermetallic compounds and Zintl phases that exhibits these characteristics. In this work the electronic properties of $BaSn_3$ are rationalized using calculations of band structure and the electron localization function (ELF).[6] A real-space analysis of the band structure is accomplished with the aid of direction-dependent partial electron density (PED).[7] Such a depiction of the crystal-orbital densities allows an analysis of the band structure in real space that is unachievable with other methods,[11] and provides intuitive pictures for solid-state compounds that are similar to those provided by the popular orbital concept for molecular systems.

$BaSn_3$ was synthesized as a pure phase by the stoichiometric combination of the elements.[14–16] $BaSn_3$ crystallizes in the primitive hexagonal Ni_3Sn structure type (space group $P6_3/mmc$, $a=b=7.253(2)$, $c=5.496(2)$ Å) with the tin atoms at the nickel positions.[16] This structure type, which is common for intermetallic compounds, occurs by a 1:3 distribution of the Sn and Ba atoms within hexagonal layers (small and large circles in Figure 1a) that stack in an ABAB sequence (Figures 1a and 1b). The distortion within the layers of Sn atoms (Wyckoff site: $(6h)\,x$, $2x$, 1/4; $x=0.8594$) with respect to the corresponding sites in the aristotype structure ($x=0.8333$) leads to shorter contacts between Sn atoms within a layer (Sn–Sn 3.058 Å)[17] and longer distances between Sn and Ba centers (Sn–Ba 3.663 Å). The compression along the c axis ($c/a=0.758$) manifests itself in short interlayer distances between Ba and Sn atoms (Ba–Sn 3.641 Å); however, the Sn–Sn interlayer contacts (3.266 Å) are longer than the intralayer contacts.

The topology of the tin framework (Figure 1g) emphasizes the relationship to the hexagonal perovskite structure ($BaNiO_3$) and a description according to the concept of Zintl, Klemm, and Busmann. $BaSn_3$ may be described as a defect structure in which tin atoms are at the oxygen positions, and the centers of the octahedra are unoccupied ($Ba\square Sn_3$). The one-dimensional chains running along the c axis are constructed from elongated face-sharing octahedra and may be described as $^1_\infty[Sn_6^{4-}]$, a formula that invokes the transfer of Ba valence electrons to the Sn polyanion. If only the shortest Sn–Sn contacts are considered to be bonding, the tin atoms may be viewed as forming triangular Sn_3^{2-} ions (Scheme 1).[17] Such units are isoelectronic with aromatic 2π-electron cyclopropanyl cations ($C_3R_3^+$). Therefore, the chains of face-sharing octahedra may also be viewed as a stacking of triangular units with strong interactions between the component π systems.

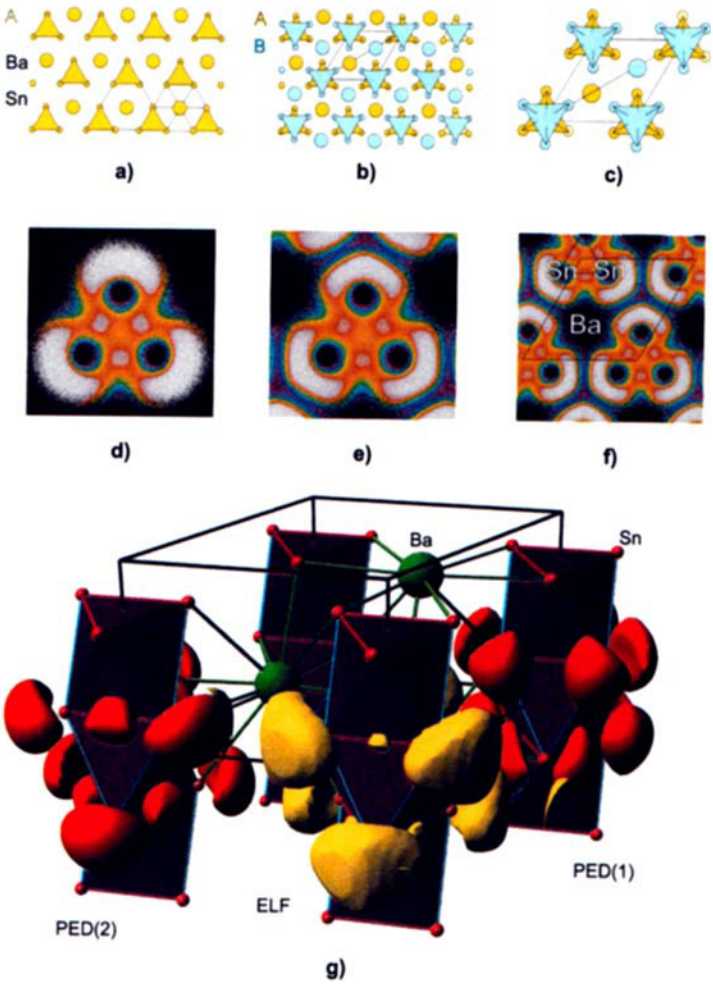

Figure 1. Structure and graphical analysis of the electronic structure of $BaSn_3$. a) A hexagonal layer with a 1:3 distribution of the atoms, b) AB stacking of two such layers ($z=1/4$ and 3/4), c) distortion from ideal hexagonal packing, d) the ELF in a plane through the atoms of an isolated one-dimensional $^1_\infty[Sn_6^{4-}]$ chain of octahedra, e) the ELF in $BaSn_3$ (same plane as in d)), f) a larger cross-section from the $BaSn_3$ structure, g) 3D representation of the face-sharing tin octahedra. ELF = 0.80 (yellow); the PED (red) isosurfaces of the band sections **1** (right) and **2** (left) have been added. The PED was calculated for the thick part of the flat bands near the Fermi level (between M and Γ) in Figure 3.

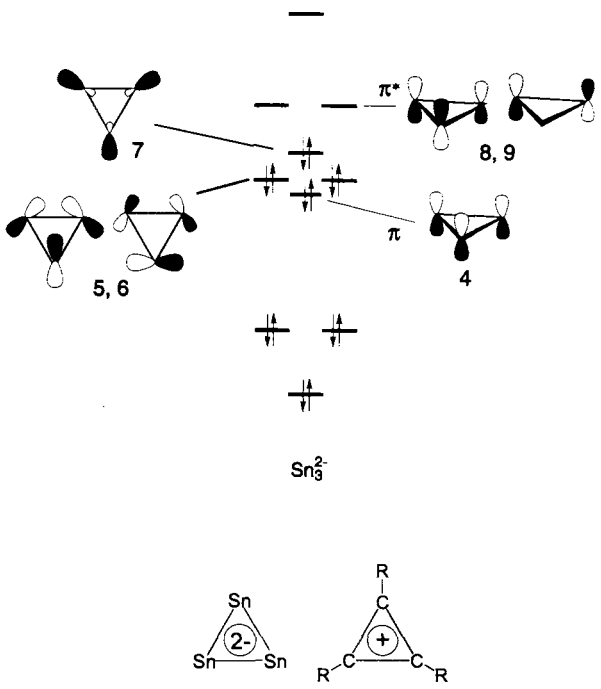

Scheme 1. MO scheme of a Sn_3^{2-} Zintl anion.

Measurements of the magnetic suseptibility at low field and at various temperatures showed the typical curves for diamagnetic shielding and the Meissner effect ($T_c=4.3$ K, Figure 2).[18] The transition temperature of $BaSn_3$ can be clearly differentiated from that of tin (3.7 K), as proven by similar measurements on elemental Sn and a simultaneous measurement of a mixture of Sn and $BaSn_3$ (inset of Figure 2).

The density of states and a section of the band structure obtained from LMTO calculations are shown in Figure 3.[19] The band structure of $BaSn_3$ (Figure 3a) features a large

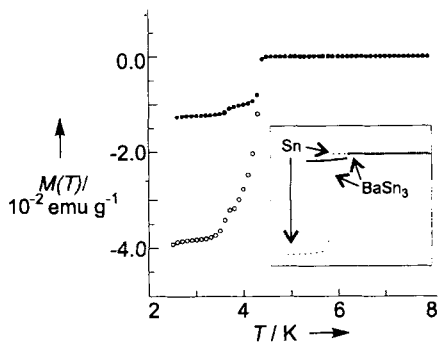

Figure 2. Diamagnetic shielding (○) and Meissner effect (●) in $BaSn_3$ as a function of temperature. The inset shows the results of a similar measurement on elemental tin.

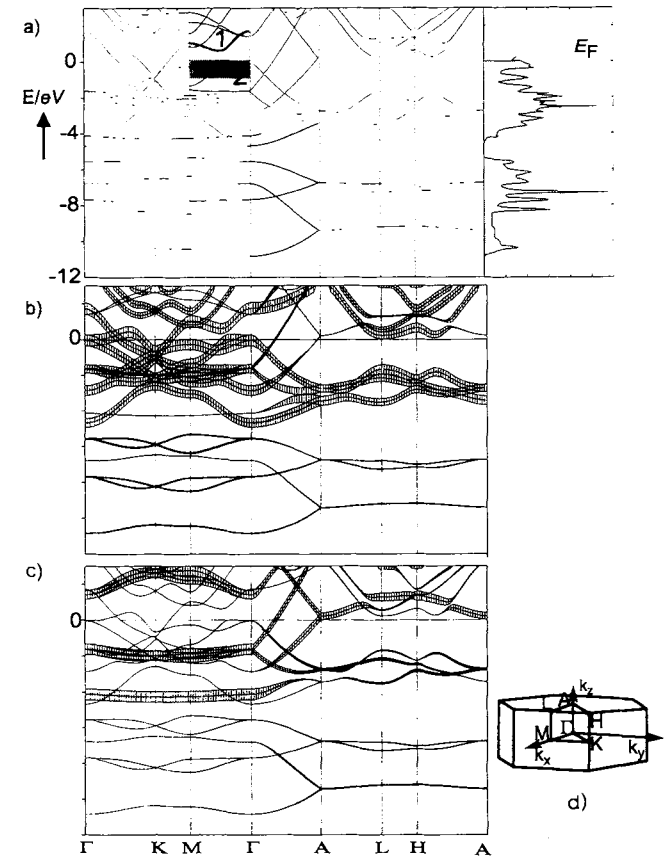

Figure 3. Band structure and density of states of $BaSn_3$. The contributions of the b) p_x, p_y and c) p_z orbitals the tin atom are plotted. The Fermi level is taken as the point of zero energy. The Brillouin zone is shown in d).

dispersion in the bands along the symmetry lines perpendicular to the distorted hexagonal layers; the bands parallel to the layers are comparatively flat. An anisotropic metallic conductivity is apparent in $BaSn_3$ with the special situation that flat bands and a degeneracy (in the zone center Γ) appear at the Fermi level. This leads to an increased density of states at E_F (Figure 3a, right). A "fat-band" analysis, in which the thickness of the band represents the corresponding orbital contribution, shows that the flat portions of the bands in the vicinity of E_F originate from p_x and p_y orbitals of the Sn atom (Figure 3b). Conversely, in the sections featuring steep bands, such as from Γ to A (i. e. parallel to the octahedral chains, z direction), increased mixing with the p_z orbital is observed (Figure 3c). From real-space PED plots, sections **1** and **2** of the band structure depicted in Figure 3a may be assigned to the molecular orbitals of the triangular Sn_3 unit shown in Scheme 1.

The result of the graphical analysis[20] of an extended-Hückel calculation,[21] which enables a qualitative analysis of the LMTO band structure, is shown in Figure 1g. Here the PED isosurface of the flat band from section **1** (along the M – Γ line) is shown on the right octahedral chain, and that of section **2** on the left.[22] The analysis shows that the bands below E_F arise from the lone electron pairs (MO 7, Scheme 1) with mixing of the "tangential orbitals" of the tin triangle (see MOs 5 and 6); above E_F, only the tangential orbitals are apparent. It is remarkable that the "MO-like" pictures in Figure 1g were obtained from calculations of band structures with the underlying symmetry of the k points in reciprocal space, and not calculated from points of higher symmetry (e. g. only at Γ), which is the usual method for depicting the wave function.[23] This enables consideration of anisotropic properties in real space.

To pinpoint the interaction between the free electron pairs at the Fermi level,[24] ELF analyses were performed.[20] Figure 1d shows the ELF of a layer parallel to the xy plane through three tin atoms of an isolated $^1_\infty[Sn_6^{4-}]$ octahedral chain. One can clearly discern three small bright areas, which are consistent with the Sn–Sn bond lengths that are about 0.2 Å shorter; this supports the formulation as a Sn_3^{2-} Zintl ion.[17] Three outer areas with half-moon shapes correspond to the free electron lone pairs of the tin atoms. The same cross-section from the full $BaSn_3$ structure is shown in Figure 1e, and a magnification of a unit in Figure 1f. The lone pairs are clearly flattened owing to interactions with neighboring electron pairs. This correlates with the strong lowering of the bands at the Fermi level (section **2**) that is observed in calculations for which a larger separation of the octahedral chains is effected by increasing the unit-cell parameters but retaining the same Sn–Sn bond lengths. The "compression" of the lone pairs in $BaSn_3$ may also be seen in three-dimensional ELF plots (yellow isosurface in Figure 1g).

The results obtained with PED and ELF demonstrate that the interaction of the lone pairs parallel to the layers are responsible for the band dispersion and for the elevation of certain bands at the Fermi level. The following qualitative picture of the electron – phonon interactions may be deduced: Lattice vibrations have a strong effect on the interactions between the lone pairs. Raising the states of the free electron pairs above the Fermi level results in electron transfer to the conduction band (and vice versa), that is, transitions between localized and conducting electrons may be dependent on lattice vibrations.

$BaSn_3$ may certainly be viewed as a borderline Zintl phase. Strong "interanionic" interactions between the π systems of the anionic units and weak interactions between the lone pairs must be considered. Similar situations were also found in other compounds. Interactions leading to 1D metallic properties were seen between the π systems of the central Si_6 rings in the stacked planar $[Si_{12}]^{20.5-}$ anions of $Ca_7Mg_{7.25}Si_4$.[25] Parabolic arrangements of lone pairs were observed in the intermetallic compound $RhBi_4$[26] and in the caverns of the lead substructure of K_5Pb_{24}.[8] Both $RhBi_4$[27] and K_5Pb_{24}[8] exhibit superconductivity. Superconductivity is also observed in the silicides $(Na,Ba)_xSi_{46}$.[28] The silicon atoms are tetravalent in the basic clathrate(I) structure type A_4Si_{23} where A = K, Na.[29] Assigning the composition of some compounds of this structure type as $A_4E_{22}\square_1$ (A = alkali metal, E = Si, Ge)

requires that one of the sites in the 3D network of E atoms is vacant.[30] Since sites adjacent to the empty position contain three-bonded atoms (that are isosteric to the Group 15 elements), these compounds may also be described as Zintl phases with interacting electron pairs. A strong interdependent influence of neighboring electron pairs of three-bonded atoms can also be found in the Zintl phase $K_6Sn_{23}Bi_2$.[8,31]

These observations can be interpreted as evidence for a correlation between the presence of localized states in the form of lone pairs in metallic conductors and superconductivity. Further examples and analyses may lend support to this theory. For $BaSn_3$, which resides on the border of intermetallic compounds, it appears that a balanced interplay of interactions between localized and delocalized structural components leads to the development of specific metallic properties.

[7] The PED was calculated by summing the square of the wave function at respective k points lying inside a selected energy window. This can be accomplished using a k point set standardized over the first Brillouin zone [9] or, as done here, by choosing k points along selected symmetry lines. Using the former method to calculate the PED over an energy window either above or below E_F leads to a density of states around the Fermi level that may be used to simulate tunneling electron microscope images [8–10].

[14] Stoichiometric amounts of barium (0.538 g, surface impurities were removed immediately before loading) and tin powder (1.512 g) were heated in niobium ampoules at 150 degress per hour to 720 °C. The ampoules were held at 720 °C for 48 h and then cooled at 50 degrees per hour to 640 °C. They where then held at this temperature for 16 d. $BaSn_3$ was isolated as a microcrystalline, shiny silver powder. Resistivity measurements on pressed pellets show a linear increase with temperature in the region from −200 to 25 °C. A stable phase with this composition was identified in 1930 from thermal studies on the Ba/Sn system [15], and a single crystal isolated from investigations in a ternary system (Ba/Al/Sn) was structurally characterized [16]. We obtained single crystals of $BaSn_3$ in the investigation of the ternary K/Ba/Sn system.

[18] The magnetic susceptibility was measured with a SQUID magnetometer (MPMS 5, Quantum Design). The samples were cooled in the absence of a magnetic field. After introducing a field of 10 G, the sample was warmed ("shielding") and then cooled ("Meissner"). Suprasil quartz capillaries (5 mm diameter) served as sample holders. The shoulder at 3.7 K in the plot in Figure 2 can be assigned to trace amounts of elemental tin. As no lines characteristic of tin can be seen in an X-ray powder pattern, an impurity level of less than 5% tin can be estimated.
[19] Calculations were performed with the program TB-LMTO-ASA[12] without the addition of interstitial spheres with s-, p-, and ("down-folded") d-partial waves for Ba and Sn.
[20] The analyses were carried out with the program MEHMACC (U. Häusermann, S. Wengert, R. Nesper, T. F. Fässler, ETH Zürich, **1993**); the pictures were created with the program COLTURE for the isosurfaces (P. Hofmann, R. Nesper, ETH Zürich, **1993**) and GRAPA for the cross-sections (J. Flad, F.-X. Fraschio, B. Miehlich, Institut für Theoretische Chemie der Universität, Stuttgart, **1989**). The programs are available under mehmacc@inorg.chem.ethz.ch. MEHMACC is based on the QCPE extended-Hückel program EHMACC [21].
[21] Program EHMACC: M.-H. Whangbo, M. Evain, T. Hughbanks, M. Kertes, S. Wijeyesekera, C. Wilker, C. Zheng, R. Hoffmann, **1990**; relevant parameters (H_{ii}, ξ): Sn 5s −16.16 eV, 2.12, 6p −8.32 eV, 1.82; Ba 6s −4.76 eV, 1.263, 6p −2.64, 1.263.
[22] In the extended-Hückel band structures of band section **1**, no crossing of the next-highest band is observed between M and Γ.

Carbohydrates Coordinated to Platinum(IV) through Hydroxyl Groups: A New Class of Platinum Complexes with Bioactive Ligands**

Dirk Steinborn,* Henrik Junicke, and Clemens Bruhn

The discovery of the carcinostatic effect of *cis*-$[PtCl_2(NH_3)_2]$ by Rosenberg et al.[1] and investigations on the mechanism of action of platinum compounds in chemotherapy[2] promoted the developement of the coordination chemistry of platinum(II) with biologically important ligands.[3–5] Nowadays attention is focused on platinum(IV) complexes with bioactive ligands, because of the lower toxicity of platinum(IV) and the possibility of oral administration of some potent platinum(IV) compounds as well as the

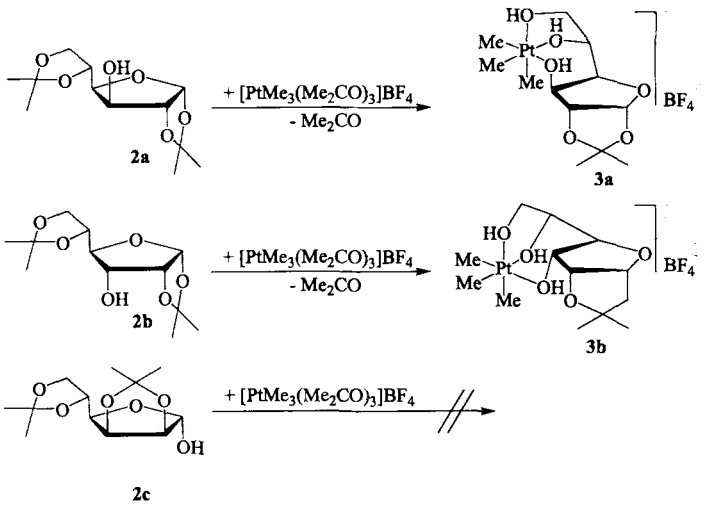
[**] This work was promoted by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie, and supported by gifts of chemicals from Degussa and Merck.

fact that they can coordinate to DNA without prior reduction to platinum(II) compounds.[3,6,7] In general, they have been less thoroughly investigated than platinum(II) complexes. Although binding of metal ions to carbohydrates is essential in numerous biological processes,[8] complexes of platinum(IV) with carbohydrates have not yet been described, probably due to the reducing properties of the latter. Here we report on the coordination of 1,2-*O*-isopropylidene-protected α-D-gluco- and α-D-allofuranose to a trimethylplatinum cation to give the first carbohydrate platinum(IV) complexes.

$[(PtMe_3I)_4]$[9] reacts with $AgBF_4$ in acetone to give *fac*-$[PtMe_3(Me_2CO)_3]BF_4$ (**1**),[10] which is monomeric and highly moisture-sensitive in the solid state. Solutions of **1** in acetone react with stoichiometric amounts of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**2a**) and -α-D-allofuranose (**2b**) within a few hours to give trimethylplatinum(IV)-*O*-isopropylidene-α-D-glucofuranose (**3a**) and -α-D-allofuranose (**3b**) complexes (conversion 60–65%, yield ca. 40%; Scheme 1).



Scheme 1. Synthesis of complexes **3a** and **3b**.

One of the two isopropylidene protecting groups is removed as acetone by traces of water. With an excess of **2** (n(**1**):n(**2**) = 1:2), the protecting group of the surplus sugar is not cleaved, even if the reaction mixture is treated with 3–10 equivalents of water. This proves that the elimination of a protecting group is assisted by platinum. The higher (Brønsted) acidity of the aqua platinum complex (formed by H_2O–Me_2CO exchange in **1**) and/or coordination of a ketal oxygen atom to the platinum center could be decisive.

2,3:5,6-Di-*O*-isopropylidene-α-D-mannofuranose (**2c**) neither reacts with **1** to give a platinum complex according to Scheme 1 nor does it lose a protecting group. The first steps in the formation of **3a** and **3b** are probably coordination of the unprotected hydroxyl group (C3–OH) to platinum and formation of a chelate complex, followed by (platinum-assisted) elimination of an isopropylidene protecting group. Complex **3a** is also obtained in a reaction analogous to Scheme 1, with the singly protected sugar 1,2-*O*-isopropylidene-α-D-glucofuranose (**2a′**) instead of the doubly isopropylidene protected carbohydrate (yield 95%). However, using a small excess of **2a′** (n(**1**):n(**2a′**) = 1:1.1) led to decomposition.

Complexes **3a** and **3b** were fully characterized by ^1H, ^{13}C, and ^{195}Pt NMR spectroscopy.[11] The ^1H and ^{13}C NMR resonances were assigned on the basis of HETCOR experiments. In [D$_6$]acetone differences in the chemical shifts of up to $\Delta\delta = 3.0$ (**3a**) and 11.0 (**3b**) occur for the carbon atoms of the coordinated and noncoordinated ligands. Relative to the starting material **1**, the ^1H resonances for methyl ligands in **3a** and **3b** are shifted to higher field by $\Delta\delta = 0.11$, and the ^{195}Pt NMR resonances by 364 and 176, respectively. These results confirm complex formation in acetone. Since this is not observed in [D$_4$]methanol, it must be concluded that the complexes are largely dissociated in this solvent.

The single-crystal X-ray structure of **3a**[12] is shown in Figure 1. 1,2-*O*-Isopropylidene-α-D-glucofuranose acts as neutral tridentate ligand which is coordinated only through three hydroxyl groups ($\kappa^3O^{3,5,6}$ coordination). The five-, six-, and seven-membered 1,3,2-dioxaplatina rings exhibit envelope, distorted chair, and twist-boat conformations, respectively. The cyclic system is not free of angle strain, as revealed by the O-Pt-O angles in particular, two of which are distinctly smaller than 90° (O5-Pt-O6 75.7(6), O3-Pt-O5 78.6(4)°). The three Pt–O bonds are equal within the limits of error (223 pm). They are among the longest Pt–O bonds[13] being a consequence of the strong *trans* influence of the methyl groups.[14]

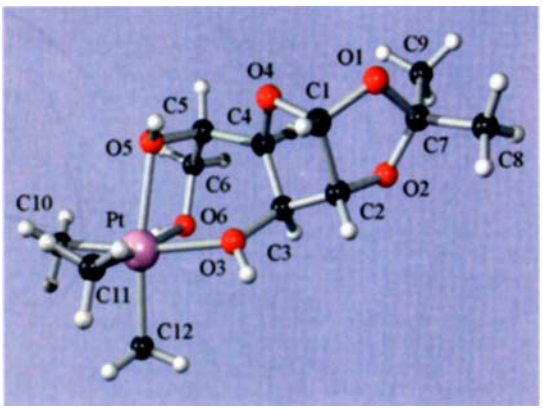


Figure 1. Molecular structure of the cation in **3a**. Selected bond lengths [pm] and angles [°]: Pt–C10 202(1), Pt–C11 202(2), Pt–C12 207(2), Pt–O3 222.7(7), Pt–O5 224(1), Pt–O6 223(1), O3–C3 147(2), O5–C5 147(3), O6–C6 145(2), C3–C4 147(2), C4–C5 153(2), C5–C6 149(3); C10-Pt-C11 91(1), C10-Pt-C12 90.5(9), C11-Pt-C12 89.3(7), O3-Pt-O5 78.6(4), O3-Pt-O6 87.5(6), O5-Pt-O6 75.7(6), C10-Pt-O3 172.5(8), C10-Pt-O5 93.9(7), C10-Pt-O6 91.2(8), C11-Pt-O3 90.0(8), C11-Pt-O5 99.1(6), C11-Pt-O6 174.6(7), C12-Pt-O3 97.0(7), C12-Pt-O5 170.4(6), C12-Pt-O6 95.7(7), Pt-O3-C3 123.5(8), Pt-O5-C5 107(1), Pt-O6-C6 113.0(9), O3-C3-C4 110(1), O5-C5-C6 108(1), O5-C5-C4 113(1), O6-C6-C5 110(1), C3-C4-C5 123.4(9), C4-C5-C6 115(2).

Complexes **3a** and **3b** belong to the less investigated transition metal complexes with "pure" polyalcohol ligands (i. e., coordinated only through hydroxyl groups).[15] They are not only the first carbohydrate complexes of platinum(IV) but also the only complexes of platinum that contain neutral carbohydrate ligands without anchor groups. Since these ligands play an important role under physiological conditions, **3a** and **3b** open a new class of platinum(IV) complexes with bioactive ligands, which are not only important for coordination chemistry but might also be of pharmacological interest.

Experimental Section

3a,b: [$(PtMe_3I)_4$] [9] (230 mg, 0.14 mmol) was added to a stirred solution of $AgBF_4$ (100 mg, 0.51 mmol) in dry acetone (20 mL) in the dark. After 30 min AgI was removed by filtration, and the colorless solution of **1** was added to a solution of **2a** or **2b** (141 mg, 0.54 mmol) in acetone (5 mL) and stirred for 12 h. The solvent was then removed, and the white residue extracted with chloroform (2 mL). The filtered extract was freed of solvent to give **3a** and **3b** as colorless

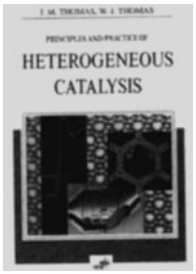
For a Heterogeneous Readership

Principles and Practice of Heterogeneous Catalysis. By *J. M. Thomas* and *W. J. Thomas*. WILEY-VCH, Weinheim, 1997. 669 pp., hardcover 128.00 DM—ISBN 3-527-29288-8

In their preface to this impressive book, the authors remark that "catalysis occupies a pivotal position in the physical and biological sciences" and that it is also "the mainstay of the chemical industry". The truth of these statements is itself sufficient justification as to why, in the absence of contemporary competitors, a book dealing with the "Principles and Practice of Heterogeneous Catalysis" should be warmly welcomed by all who work in the field of catalytic science. Yet, although the title of this book refers explicity to heterogeneous catalysis, and much of what the authors have to say concerns the nature, structure, and use of solid catalysts and the molecular mechanisms driving catalytic cycles, the book will nevertheless be of value to those whose main aim is to learn about the nature and behavior of catalysts in general. The authors of the present book correctly point out that the recent two or three decades have seen a revolution in our detailed understanding of the surface structure of solid materials, especially large single crystals with adsorbed layers. Such progress has been made through the use of sophisticated physical techniques, a number of which have also allowed the surface of catalysts to be studied in the working state.



This is a substantial book covering some 669 pages of text in eight chapters, which are: 1. "Setting the Scene" (perhaps best described by the title of one of the sections, "Perspectives in Catalysis: Past, Present, Future"); 2. "The Fundamentals of Adsorption: Structural and Dynamic Considerations, Isotherms, and Energetics"; 3. Characterizing Catalysts and Their Surfaces"; 4. "The Significance of Pore Structure and Surface Area in Heterogeneous Catalysis"; 5. "The Solid-State and Surface Chemistry of Catalysts"; 6. "Poisoning, Promotion, Deactivation and Selectivity of Catalysts"; 7. "Catalytic Process Engineering"; 8. "Heterogeneous Catalysis: Examples and Case Histories".

In broad terms, these eight chapters cover the topic in adequate detail, but we particularly commend the authors for the inclusion of a chapter on "Catalytic Process Engineering" (Chapter 7) together with related material in Chapter 4 on diffusional effects in porous catalysts. These matters are so often ignored by chemists, yet even in laboratory-scale catalytic work, failure to appreciate heat- and mass-transport factors can lead to grossly misleading conclusions. Chapter 7 also describes a number of experimental and industrial reactors in a clear and instructive manner.

Each of the eight chapters is provided with a set of problem questions (typically 10–25 or so in number) with which readers may test their understanding of the material presented. These problems are seldom trivial, and any reader who is able to provide satisfactory answers to most of them would indeed be knowledgeable in the subject. Despite the authors' comments attached to the problems of Chapters 1 and 2, we suggest that a problem-solving reader would be best advised to use the entire book as source material, rather than relying only on the content of an individual chapter.

It is probably quite unreasonable to expect any book of the size and complexity of the present one to be without sins of commission and omission. We only draw attention to the following points in the hope that our comments may be of assistance to the readers.

In general, the authors have gone to a great deal of trouble to provide some historical background to the various topics which are then discussed in detail. This is certainly to be welcomed, and it will be of considerable value to readers whose main aim is to gain an overall view of the subject. Nevertheless, their historical approach needs to be used with caution. Thus (cf. Chapter 1) the emphasis of Balandin and others on the matching between the geometry of benzene and that of certain planes of transition metals should now be treated only as an interesting historical anecdote rather than a matter of real relevance to a reaction mechanism for, for example, benzene hydrogenation.

On page 27 there is some confusion in the definition of turnover frequency (TOF). This ought to be unambiguously defined as the reaction rate (i.e., dn/dt) per active site, as recommended by IUPAC and as is given on page 27 in eqn. (3). However, except in special circumstances (e.g., degree of conversion $\rightarrow 0$ or a zero-order reaction), dn/dt is not the same as the number of molecules reacting in time t as given in the text immediately preceding eqn. (3): this is not a TOF but a site–time yield. As the authors correctly point out, it is generally quite difficult to know the number of active sites per unit quantity of a heterogeneous catalyst: even so, we do not believe it is reasonable to recommend the use of a sort of TOF expressed per unit area or per unit volume of catalyst. The IUPAC definition for TOF is the number of times the catalytic cycle turns over per second. In fact, one of its main virtues is that it is expressed with only one unit—the second. In the discussion around this point on page 27, the authors correctly point out that chemisorption is a useful method by which, at least in some cases, the problem of estimating the active site concentration may be approached, and the text refers the reader to Chapter 3 for chemisorption methodology. In fact, Chapter 3 says almost nothing about this method (cf. a one-line entry in Table 3.1). The well-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for reviews will not be returned.

known importance of chemisorption methods for catalyst characterization mandates more detail than is contained in a one-line-entry.

Chapter 8 ("Heterogeneous Catalysis: Examples and Case Histories") analyzes important and best-understood catalytic processes: Synthesis of Methanol, Fischer–Tropsch Catalysis, Synthesis of Ammonia, Oxidation of Ammonia, In-Situ Catalytic Reaction and Separation, Automobile Exhaust Catalysts, Photocatalytic Breakdown of Water and the Harnessing of Solar Energy, Catalysis Using Microporous or Mesoporous Solids and Modified Clays, Catalytic Processes in the Petroleum Industry, and The Role of Catalysis in Energy-Related Environmental Technology. In most instances, these topics are reasonably well treated, given the amount of space that could be made available and the huge quantity of technical detail which could be drawn upon. Chapter 8 also discusses reactor types for several large-scale processes, as well as some promising new multipurpose catalytic reactors involving simultaneous distillation, membrane permeation, or combustion. In two cases, the authors include a numerical example that is most instructive. Nevertheless, we have two critical comments. Firstly we believe it to be a pity that the authors did not deal with metal-catalyzed carbon–carbon bond rupture (i.e., hydrogenolysis) reactions since these are of considerable industrial significance and also provide some of the best available examples of catalytic selectivity control. Secondly we believe that in some aspects of their treatment of ammonia synthesis, the authors have done less than justice to what is known about this important catalytic process. In particular, it is now reasonably well established that the predominant active sites for this reaction are the so-called C_7 sites. Such sites occur on the (111) and (211) surface planes of iron. This is inadequately dealt with, and is not made clear that these active sites can be counted by the use of high-temperature nitrogen chemisorption.

When dealing with the book as a whole, we find we must take the authors to task over the matter of referencing for material in the text. Material (e.g., figures) taken unaltered from pre-existing literature is, of course, acknowledged in detail. However, in the text itself (i.e., as written by the authors), citations to the relevant literature are in general either not provided at all (e.g., an author's name may be cited but without *any* reference leading to the original literature), or else an author's name may be cited, together with a date, in which case the appropriate literature reference is likely to be found in the section "Further Reading" at the end of the chapter. The problem then is that the author's name which is cited in the text is not necessarily the name of the lead author in the reference, so that a frustrating search becomes necessary. Of course, the extent to which referencing to the literature is necessary in the text is dependent on who is going to read it. In our opinion, the usefulness of the book to researchers and advanced teachers is substantially diminished by the inadequate and idiosyncratic referencing to the relevant original literature. Furthermore, if the generally accepted practice had been followed, it would have been possible for appropriate credit to have been given to authors deserving of priority. As it now stands, these referencing deficiencies make it difficult for us fully to recommend the book as a reference work. In addition, the index is less than adequate.

Nevertheless, despite our reservations, the community in catalysis must be most grateful to the authors for writing a book which illustrates the vitality in the field in a readable manner. Anyone who has heard it said that catalysis is a mature field will be easily convinced, even after only a cursory perusal of this book, that scientists and engineers working in the theory and practice of catalysis are poised to discover, invent, and innovate. With this in mind, we suggest the book should be on the list of required reading for people such as university deans, industrial managers, foundation directors, and government officials in science policy. To this end, an executive summary would have been a valuable addition to each chapter. We also highly recommend the book as a "get acquainted" resource for senior chemistry and chemical engineering students and their advisors. The upbeat and inspirational style of the book will broaden the horizon of those looking for a challenging graduate program and an exciting professional career. Thank you, J. M. and W. J. Thomas, for your labor of love.

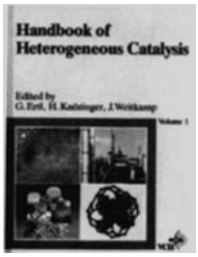
Handbook of Heterogeneous Catalysis. By *G. Ertl, H. Knözinger,* and *J. Weitkamp.* WILEY-VCH, Weinheim, 1997. 2500 pp., 2030 fig., 500 tab., hardcover 2490.00 DM—ISBN 3-527-29212-8

This five-volume compendium follows in the spirit of those edited by Schwab in the 1940s and Emmett in the 1950s, and the editors state that this handbook is the first to describe comprehensively all facets of heterogeneous catalysis from scientific fundamentals to industrial processes. Although an ambitious undertaking involving more than 200 authors and requiring several years, as evidenced by the variation in the most recent references cited at the end of each chapter, the result is remarkably successful and coherent. In most cases, the editors have obtained some of the most knowledgeable and active scientists in each area to author or coauthor a review of that subject. At the very least, this handbook verifies the enormous impact heterogeneous catalysis has on our society through improvements in commercial processes.



Volume 1 begins by stating general principles related to heterogeneous catalysis, then it provides historical perspectives of catalytic science as well as industrial catalysis. The remainder of the volume is devoted to describing the preparation of both unsupported and supported catalysts, with an emphasis on those catalysts, most important commercially, that is, metallic and bimetallic systems and zeolites. The chapters on zeolite acidity and basicity and on carbons are especially thorough (over 50 pages) with an excellent set of references provided in each case.

Volume 2 focuses on the characterization of both industrial-type high surface area catalysts as well as model systems. The standard methods for measuring physical properties are reviewed, and essentially all the various techniques that can provide information about chemical properties are discussed. Although a detailed introduction of the scientific fundamentals pertaining to each spectroscopic method could not be given due to space constraints, sufficient background is provided along with applications to allow the reader to understand the capability of the technique.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/10923-2690 $ 17.50+.50/0

References to allow a more thorough understanding of the principles involved are invariably provided. The chapters on vibrational spectroscopy and the use of IR spectroscopy to characterize surface acidity and basicity are especially informative and contain extensive citations. The various UHV surface science technique are enumerated, and their applications to various single-crystal surfaces of metals, oxides, and bimetallic systems, as well as ultrathin oxide films, are described.

Volume 3 deals with core issues related to catalytic reactions and their economic industrial utilization. These include elementary steps, mechanisms and modeling, the effect of transport processes, deactivation and regeneration, types of laboratory reactors, and reaction engineering. Chemisorption in theory and practice is addressed initially. Fundamentals of catalytic rates are reviewed, theoretical modeling of surface reactions is discussed, and various approaches to kinetic modeling are then covered, as well as means to evaluate the validity of the model chosen. Although not lengthy, these treatises are sufficient when coupled with the references cited to provide guidance for those interested in kinetic modeling. Various experimental techniques for probing reaction mechanisms are reviewed, and the reader is also introduced to some of the conceptual aspects of heterogeneous catalysis such as structure sensitivity, promoters and poisons, and effects due to ensembles and ligands, spillover, and substituent groups. The importance of heat- and mass-transfer limitations on reaction rates is emphasized in a thorough mathematical approach, and criteria are provided to estimate the influence of these effects on experimental reaction rate data. The use of different laboratory test reactors is analyzed, and the utilization of commercial-type fixed-bed, fluidized-bed, and slurry reactors is described in some detail. Finally, special catalytic systems, including chemical sensors, electrocatalysis, and supercritical media, are discussed.

Volume 4 is devoted to processes of industrial interest and addresses environmental catalysis, inorganic reactions, and energy-related catalytic reactions. Consequently, the status of catalytic pollutant control from both gasoline and diesel engines as well as that related to stationary sources is summarized. The principal current problem of NO_x emissions is emphasized and one new technology applicable to the latter source—gas turbine catalytic combustion—is described. Up-to-date reviews are provided for six industrial inorganic reactions, the most important of which are NH_3 synthesis, NH_3 oxidation, SO_2 oxidation, and the Claus process to form sulfur. Reviews of the last group of reactions include those for steam and CO_2 reforming along with the water gas shift reaction and COS removal, CO and CO_2 hydrogenation, methanol synthesis, methanol to hydrocarbons, catalytic cracking, hydrocracking and dewaxing, catalytic reforming of gasoline, alkane isomerization, synthesis of gasoline additives (MTBE), hydrotreating reactions including demetalation, isobutane alkylation, alkane aromatization, coal gasification, and coal liquefaction. Reactions associated with fuel cells and photocatalysis are also addressed. The sections on methanol synthesis and catalytic cracking are particularly informative and the former has an especially good reference list.

Volume 5 concludes the series by giving detailed information about almost thirty types of catalytic organic reactions of industrial significance. Although all cannot be listed here, they encompass reactions dealing with hydrogenation/dehydrogenation, aromatic alkylation, hydroformylation, selective oxidation (including ammoxidation), amination, halogenation, metathesis, oligomerization, and polymerization. Enantioselective and immobilized enzyme catalyst systems are also covered. These chapters provide a summary of the chemistry involved as well as mentioning the principal catalysts used in each process.

In summary, the 2500 pages contained in these volumes provide a tremendous amount of information. The most recent citations at the end of each section range from 1992 to 1997 with most being 1994 or later; consequently, the reviews typically represent an up-to-date perspective on each topic. Unfortunately, a few of the chapters do not measure up to the high standards set by the remainder, and one chapter provides an inconvenience by listing references alphabetically, rather than numerically, as done in other chapters. Nevertheless, I consider this series to be a resource that will be invaluable to those in academia as well as to scientists in industrial and governmental laboratories and perhaps indispensable to researchers working in small industrial laboratories that have limited library facilities. The price of DM 2490 (or $1,740) is steep; however, when viewed relative to the annual subscription cost of a typical scientific journal, it is much more reasonable, particularly when the contents of this handbook will be valuable to scientists and students for years to come.

Encyclopedia of Molecular Biology and Molecular Medicine. Edited by *R. A. Meyers.* WILEY-VCH, Weinheim, 1996/97. 6 volumes, hardcover DM 2940.00, 6 Vol. Set—ISBN 3-527-28478-8—single volumes DM 590.00 each., Vol. 1: 462 pp., ISBN 3-527-28471-0; Vol. 2: 480 pp., ISBN 3-527-28472-9; Vol. 3: 522 pp., ISBN 3-527-28473-7; Vol. 4: 508 pp., ISBN 3-527-28474-5; Vol. 5: 516 pp., ISBN 3-527-28475-3; Vol. 6: 495 pp., ISBN 3-527-28476-1

The first volume of this six-volume encyclopedia appeared at the beginning of 1996, and only 18 months later, in early summer 1997, the work was completed with the publication of Volume 6. It is intended to serve as a comprehensive reference source on molecular aspects of biology and medicine. The complete work of 3000 pages (including the index) contains almost 300 articles on the molecular biology of living organisms.

The encyclopedia sets a new standard in the field of molecular biology, especially in the areas of genome research and the molecular basis of genetically caused diseases. Several articles are devoted to the human genome. Important analytical techniques used in biochemistry, molecular biology, and genetic engineering are described in detail, including the latest developments. Diagnostic techniques for diseases, and in some cases also therapeutic methods, are described. As well as purely scientific articles there are others dealing with important practical aspects, as for example in the contribution on "Transgenic Animal Patents". However, although the encyclopedia partly covers the molecular mechanisms of both well-established and modern drugs, such as enzyme inhibitors, receptor agonists and antagonists, transport blockers (uptake inhibitors), and ion channel ligands, the treatment of these aspects is rather brief and is limited to a few articles, such as the excellent but quite short contribution on "Medicinal Chemistry". Also the highly

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/10923-2691 $ 17.50+.50/0

topical subject of "Drug Targeting and Delivery" merited more than the mere two pages allowed here. However, the shortness of many of the articles is perhaps unavoidable in view of the broad conception of the work and the great variety of topics covered.

The first volume of this encyclopedia has already been reviewed in this journal (*Angew. Chem.* **1996,** *108,* 1218; *Angew. Chem. Int. Ed. Engl.* **1996**, *35*, 1578. The very favorable impression reported then is further reinforced on examining the complete work. The appearance of all six volumes within a short space of time has ensured that all the articles are similarly up-to-date. It is pleasing to find that the literature references extend up to 1996 in many cases. For example, the article on "Yeast Genetics" (Vol. 6, p. 305) mentions the complete sequencing of the yeast genome published in April 1996. The cross-references to related articles in the encyclopedia are especially useful; by following these through one can quickly find one's way around the available information on a particular area of interest. As an example, in the article on "Receptor Biochemistry" (although there is also an entry for "Other Receptors") we find that only membrane-bound receptors are mentioned there. However, information about soluble receptors can be found in the articles on "Endocrinology, Molecular" and "Steroid Hormones and Receptors", both of which are listed as cross-references. On the other hand, the articles "Vitamin Receptors" and "Zinc Finger DNA-Binding Motifs", which also contain information about important aspects of soluble receptors, are not mentioned.

Volume 6 contains a comprehensive index (127 three-column pages) listing all the subjects that are treated in more or less detail in the text but do not necessarily have a separate article devoted to them.

Much care has been devoted to the copy-editing, and the number of errors has been kept very low. To mention particular errors would probably convey a misleading impression of the whole. However, just one should be picked out because of its unintentional humor: on page 347 of Volume 2 the text refers throughout to "glucocerebrosidase" instead of distinguishing between this and "glucocerebroside", an error which is amusing rather than serious. As in Volume 1 reviewed earlier, the later volumes too contain a few incorrect structural formulas (e.g., those of estrone on p. 165 of Vol. 2 and of cyproterone acetate on p. 484 of Vol. 5).

There are a few omissions and other shortcomings that one would wish to see remedied in a revised edition, but their number is small. For example, there is no entry under the important heading "Proteome". Also there are a few minor weaknesses, which is almost inevitable in any multiauthor work. Thus, for example, combinatorial chemistry—perhaps as a result of its rapidly growing importance—appears in several different places, sometimes with identical figures (as in the illustration of the split-and-combine technique). However, a redundancy of this kind does no serious harm.

In agreement with the earlier verdict based on Volume 1, the *Encyclopedia of Molecular Biology and Molecular Medicine* is without a competitor in this field, and it is an important and valuable resource for one's daily work. Every chemist, biochemist, biologist, or medical scientist who is interested in a new topic in molecular biology or genome research will find this encyclopedia useful in providing a rapid overview of the subject of interest. It is an essential addition to the libraries of university departments, research institutes, and industry engaged in research in these areas. In most cases the high price will, of course, prevent individuals from buying their own copy. However, the publishers have devised an elegant solution to this problem, in the form of a shortened version entitled *Molecular Biology and Biotechnology. A Comprehensive Desk Reference* (VCH Publishers, New York, 1995. 1024 pp., hardcover DM 275.00; paperback DM 89.00.—ISBN 1-56081-569-8/1-56081-925-1). This should prove useful when the library copy that you so urgently need turns out (yet again) to have been lent out to a colleague.

Hugo Kubinyi
BASF AG, Ludwigshafen (Germany)

A Lifetime of Synergy with Theory and Experiment. (Series: Profiles, Pathways, and Dreams. Series editor: J. I. Seeman.) By *A. Streitwieser.* American Chemical Society, Washington, DC, 1996. 310 pp., hardcover $ 34.95—ISBN 0-8412-1836-6

In general, chemists have little inclination to study history, and the history of their own subject is no exception. Brought up to appreciate practical skills and used to learning by pictorial presentations, they often acquire a dislike of pure text ("when will there finally be a formula scheme"), which stands right at the heart of humanities, and therefore also of historical sciences. It is therefore not surprising that compared with the large number of biographical and historical works in the neighboring disciplines, there are only a few in the area of chemistry. Biographical material is likely to be found in obituaries, which naturally are meant to present the deceased from the most favorable point of view possible.

Several years ago, J. I. Seeman, himself active in the area of physical organic chemistry, asked a number of well-known chemists—the vast majority of whom come from the Anglo-American realm—to present essays on the development of organic chemistry over the past 30–40 years using their personal research work. The project, initially planned to be a terse one-volume compilation not including autobiographical material, has grown since 1990 to the proportions of 22 full-fledged autobiographies of prominent chemists. Andrew Streitwieser, one of the chosen authors, now presents his life's work. The external circumstances of this can be presented as a paradigm of the dynamics of American society: while his parents were not "dishwashers", they nevertheless were German immigrants struggling with the disaster of the Depression; so their son Andrew had to earn extra money to enable him to attend a science-oriented high school. He, like many others, had been won over to chemistry by his first chemistry set (which is no longer possible these days, as he deplores, because "all but the most innocuous chemicals are considered too dangerous—or perhaps too subject to lawsuits—for children to form part of their play and learning"). His career advanced steadily via the studies at Columbia and the post-doctorate at MIT to the tenured position at Berkeley, overshadowed only by the illness and death of his first wife. Accordingly, he does not report on any strife, let alone personal adversaries that might have impeded his progress. He only deplores the contemporary widespread disrespect for physical organic chemistry, and the problems that arise from ever fiercer competition for grant money, while funding through the department becomes ever more marginal—a situation that has become a threat to the freedom of research and teaching. Central to this book however is Streitwieser's chemical research, which began with solvolysis reactions, and

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/10923-2692 $ 17.50+.50/0

focused on CH-acidities, theoretical and organometallic (uranocene-)chemistry, and polycations. His commitments as the author of well-known textbooks and his role as an editor of *J. Org. Chem.* are also mentioned. Many references to the primary literature, a collection of short biographies of the chemists mentioned in the text, and an index are testimony of the author's diligent approach. The reader who expects a collection of "funny" anecdotes will therefore be disappointed, although there are references here and there to hobbies like fly fishing, and the author includes information about all of his students who are mentioned. Rather, Streitwieser endeavors to show how the mutual fertilization of theory and experiment have contributed to his scientific success. This book will therefore be of great value to those who wish to be informed about the research of Streitwieser's group and, moreover, about the development of physical organic chemistry in the USA over the past three to four decades.

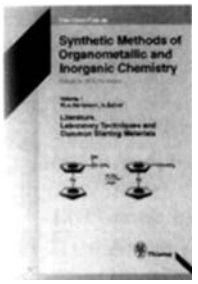
der Universität Heidelberg (Germany)

Synthetic Methods of Organometallic and Inorganic Chemistry. Vol. 6. Lanthanides and Actinides. Edited by *F. T. Edelmann.* (Series editor: W. A. Herrmann). Georg Thieme Verlag, Stuttgart, 1997. 226 pp., hardcover DM 124.00.—ISBN 3-13-103071-2

This book is the best current source of preparative information on lanthanide and actinide complexes. It is an important resource for anyone involved in the chemistry of these metals.

The decision to update the classic *Handbook of Preparative Inorganic Chemistry* by G. Brauer, and to include organometallic as well as inorganic information, is an excellent one. In the past, "Brauer" has been extremely valuable as a concise source of detailed preparative information in the inorganic area. A single source of this type is useful not only to obtain specific information, but also to get an overview of an area, its techniques, and its potential applicability to a problem. The Herrmann/Brauer update of this series will be even more useful since it will extend the coverage to modern organometallic chemistry. This is a daunting task, however, and requires eight volumes!



The decision to include in this series one volume on lanthanide and actinide chemistry was also an excellent choice. Lanthanide and actinide chemistry has been one of the most rapidly developing areas of inorganic and organometallic chemistry in recent years. Since this is a rather modern area, no single source of preparative information is available. Currently, this information must be obtained either from the primary literature or from review articles. As the field has grown, recent review articles must report only the latest results in order to maintain a manageable size. As a result, several sources must be examined sequentially to get synthetic information and to be to certain that it is up-to-date. The Edelmann volume of the Herrmann/Brauer series provides in a single book the information currently available on lanthanide and actinide synthesis.

Professor Edelmann did an excellent job in organizing this volume. Initially, he surveyed the lanthanide and actinide community for suggestions and contributions and used this input to select the specific syntheses to be included. All of the major types of compounds are represented in this volume, which is an outstanding achievement considering the space limitations. With the growth rate of this field, the volume could easily double in size in the next revision. Users of this volume should realize that the coverage is necessarily representative rather than comprehensive.

Professor Edelmann has also written introductions to each of the chapters, briefly surveying the synthetic aspects of each sub-category. These introductions are very valuable since this type of summary information on preparations is not readily available elsewhere. Occasionally, introductions to some of the specific syntheses have also been written to put the chemistry in context. These are stimulating since they sometimes include statements not universally accepted by the lanthanide and actinide community. For example, syntheses of some bimetallic compounds traditionally thought to have no metal–metal bonding are prefaced by comments that the distances suggest metal–metal interactions. Similarly, prefaces to some sections make statements about the relative sizes of cyclopentadienyl ligands for which there is not complete agreement among specialists.

The individual synthetic sections of the book are generally taken directly from the literature. As such, different syntheses have different levels of detail. For example, in some cases all of the infrared data on a series of analogous compounds is given, whereas in other cases no such information is included. Similarly, cell constants from X-ray crystallographic studies are sometimes, but not always, given when a structural study has been done. In the case of the syntheses taken from the older literature, some of the formulas for the starting materials are antiquated, particularly in terms of alkoxide precursors which have subsequently been found to have structures more complicated than $Ln(OR)_3$ or $Ln(OR)_4$. Hence, it must be remembered that this book is neither a critical review nor a publication such as *Inorganic Synthesis*, in which the preparations have been independently tested. In addition, since this field is moving quickly, the book already unavoidably contains some dated material. For example, it is stated in one section that the introduction of a third π ligand to a $(C_5Me_5)_2U$ unit is impossible.

The four chapters divide the book into lanthanide (inorganic and organometallic) and actinide (inorganic and organometallic) sections. The inorganic chapters are also valuable to organometallic researchers since they describe the preparation of starting materials. For example, since it is somewhat difficult to obtain truly anhydrous lanthanide starting materials, and the descriptions of the drying methods are in very early literature, it is particularly useful to have a modern analysis of this topic.

In summary, this lanthanide/actinide inorganic/organometallic volume is a unique resource in the field. This information has not previously been available in a single place and no modern compilation of these details is available. For someone interested in starting a project in lanthanide or actinide chemistry, this volume provides the information on how to begin experimentally. For any active lanthanide/actinide laboratory this book is an essential resource. It should be required reading for all new students in lanthanide/actinide laboratories, and I found that it can stimulate thought in the experienced researcher as well.

William J. Evans
Department of Chemistry,
University of California
Irvine, CA (USA)

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/10923-2693 $ 17.50+.50/0

Inorganic and Organometallic Reaction Mechanisms. Second Edition. By *J. D. Atwood.* WILEY-VCH, Weinheim, 1997. xiv, 312 pp., hardcover DM 98.00.—ISBN 0-471-18897-2

The material presented in this text (which is intended for students at the graduate level) encompasses kinetics and mechanisms of both "classical" inorganic reactions and organometallic transformations. While the book does cover the essentials of inorganic reaction mechanisms, the emphasis is clearly on organometallic reactions, which are treated in considerable detail. The material is arranged in eight chapters, each of which concludes with a list of references and a substantial collection of exercise problems. References have been included up to 1995, and about 40% of the problems have been taken from the primary literature.

Chapter 1 provides the grounding in chemical kinetics, discussing basic rate laws, activation parameters, the principle of microscopic reversibility, linear free energy relationships, a variety of techniques for following kinetic experiments, and schemes for the classification of reaction mechanisms. For more thorough coverage the reader is referred to a number of seminal texts in the references section, but will miss the recent work by R. B. Jordan (*Reaction Mechanisms of Inorganic and Organometallic Systems*, Oxford University Press, New York, 1991) which is not cited until Chapter 3. Chapters 2 and 3 deal with the stereochemistry, reactivity, and mechanisms of substitution of square-planar complexes and octahedral Werner-type complexes, respectively. Chapter 4 is the largest in the book, and discusses organometallic substitution reactions, the emphasis being on metal carbonyl complexes and hydride complexes. Oxidative addition/reductive elimination reactions, the centerpiece of organometallic synthesis, are covered in Chapter 5, which gives an overview of stereochemical and mechanistic investigations, including a brief section on free radical mechanisms. Chapter 6 provides further coverage of these reactions as applied in homogeneous catalysis (hydrogenation, hydroformylation, hydrocyanation, olefin metathesis, alkene polymerization, and methanol carbonylation). Chapter 7 is concerned with stereochemical nonrigidity of inorganic and organometallic systems, covering the topics of coordination number isomerization, migration of a metal around an unsaturated ring, and rearrangements in metal clusters. The final chapter deals with electron transfer reactions including long-range and multielectron transfer. A comparatively brief index concludes the book.

Most readers, in common with this reviewer, will probably compare *Inorganic and Organometallic Reaction Mechanisms* with Jordan's *Reaction Mechanisms of Inorganic and Organometallic Systems.* While both books nominally cover the same ground, there are considerable differences in emphasis. A strong point of the title under review is the detailed treatment of organometallic reactions which, amongst other aspects, emphasizes the importance of NMR techniques in mechanistic studies of fluxional systems and provides sample spectra. This emphasis comes at the expense of topics such as chelate formation, where the coverage is not nearly as comprehensive as in Jordan's work, or other subjects such as inorganic photochemistry and enzyme kinetics, which are not covered at all. Still, the book does provide a good introduction to the study of kinetics and reaction mechanisms and takes the reader with more "inorganic" leanings to a point where he or she can probe further with the aid of the excellent compilation of references. The problems are extensive and provide the reader with many an opportunity to practice newly acquired concepts on experimental data. While the book has generally been carefully produced, there are occasional inconsistencies in the labeling of figures (e.g., no units given in Fig. 1.18, and no specification of the "different mechanistic possibilities"), and minor errors in some of the derived functions (e.g., Eqs. 1.68–1.70, where the exponents are not recognizable as such). Also, phrases such as "Since NH_3 does not have an electron pair ..." (p. 85) are less than to the point. Overall, however, if it were not for the high list price, this book could be recommended as a worthy addition to the library of any graduate student with an interest in inorganic, and especially organometallic, reaction mechanisms.

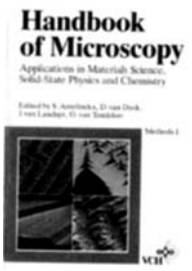
Handbook of Microscopy. Applications in Materials Science, Solid-State Physics and Chemistry. Edited by *S. Amelinckx, D. van Dyck, J. van Landuyt* and *G. van Tendeloo.* VCH Verlagsgesellschaft, Weinheim, 1996. Three volumes, hardcover DM 1197.00 (complete set); individual volumes DM 498.00 each. Vol. 1, 536 pp.—ISBN 3-527-29280-2; Vol. 2, 450 pp.—ISBN 3-527-29473-2; Vol. 3, 833 pp.—ISBN 3-527-29293-4



Editing a handbook of microscopy is a very ambitious project, even though its coverage is limited in this case to applications in materials science, solid state physics, and chemistry (thereby excluding the biological and medical sciences, two other major fields of application). Although it is not immediately obvious from the title whether "chemistry" here means chemistry in general or solid state chemistry in particular, one may assume the latter. The many authors of the individual chapters and sections of this three-volume handbook, who also include the editors themselves, are all well recognized experts in their fields.

The first two volumes ("Methods: I" and "Methods: II") are devoted to the various methods of microscopy, and form a single integrated unit. As explained in the preface, these volumes deal with all those methods that yield localized information about microstructure and/or composition. Their objektive is to enable the reader to choose the best method for a particular purpose and to understand its capabilities and limitations. The main topics covered in "Methods: I" are light microscopy (Raman, near-field optical, infrared, etc.), X-ray microscopy, acoustic microscopy, and the stationary beam methods of electron microscopy (transmission EM, high voltage EM, Lorentz microscopy, electron holography methods, and convergent beam electron diffraction—the latter being a departure from the handbook's main subject area). "Methods: II" begins with the scanning electron microscopy methods (SEM in the conventional reflection mode, scanning transmission EM, electron probe microanalysis, etc.). It continues with magnetic methods, emission methodes (photo-

electron emission, field emission and field ion microscopy), and scanning near-field probe methods (scanning tunneling, scanning force, and magnetic force microscopy). Finally there is a supplement which includes, along with other material, a very useful chapter on image recording and image processing.

It is already evident from the above (incomplete) list of topics that it is quite difficult to find suitable names for all the methods of interest, while avoiding creating verbal monstrosities. In striving to achieve a coherent system of nomenclature the editors have certainly been quite creative. For example, the chapter on scanning near-field probe methods is entitled "Scanning Point Probe Techniques", but this expression does not reappear thereafter.

The chapter on light microscopy begins with a historical outline, but a little more detail on this would have been welcome. In a handbook as comprehensive as this, it would have been desirable to include a separate short chapter on the history of microscopy as a whole.

The section on imaging by the scanning electron microscopy methods is agreeable to read, being clearly written and largely avoiding formulas and derivations, but one would have expected more than a mere 23 pages on this, which is probably the most widely used of the electron microscopy methods (including its use in the chemical industry). In contrast one finds, for example, that ballistic electron emission microscopy, a modern but comparatively exotic method, is treated in detail with 28 pages. It is surprising that scanning electron microscopy, a long-established and powerful method with some 20 thousand instruments installed worldwide, seems to deserve less space than that. Perhaps it is thought that exactly because it is so much more widely used than the other methods it involves less scientific depth.

Volume 3, "Applications", is divided according to areas of use, namely materials science, solid state physics, and chemistry. Its purpose is to explain which microscopy techniques are most appropriate for the various types of materials and problems, and thus this volume can be used independently. The following types of materials are discussed in turn: metals and alloys, rocks and minerals, semiconductors and semiconducting devices, optoelectronic materials, ferroic materials, structural ceramics, gemmological materials, superconducting ceramics, nonperiodic structures (amorphous materials and quasicrystals), medical and dental materials, carbon (graphite, diamond, buckminsterfullerene and related forms, nanotubes), engineering composites, polymers and their monomeric analogs, nuclear materials, and magnetic materials. There are special chapters on topics such as small particles, structural phase transformations, environmental problems, quantitative analysis from microscopic images, and (last but not least) the preparation of samples for transmission electron microscopy. Obviously the choice of types of materials to be included can never be completely exhaustive, and subjective preferences have certainly played a part. Moreover, there is undoubtedly a tendency, especially in this volume, to emphasize the authors' own publications or those in their own fields of research.

A single reviewer cannot, of course, pretend to be able to judge the scientific quality of the whole of such an extensive, wide-ranging, and detailed handbook with absolute reliability. I have carefully studied those chapters that deal with the areas most familiar to me, whereas other chapters were only skimmed through. Some random checks on the literature references revealed only trivial shortcomings, and although there were contradictions concerning the attribution of chapters or sections to the authors envolved, these too can be dismissed as unimportant. However, the work contains too many small inconsistencies and errors for my taste. One expects a handbook of microscopy to remain useful for a good number of years, and therefore it would have been worthwhile to devote more care to the editing. For example, very early on in the work ("Methods: I", p. 6) it is surprising to find that one of the pioneers of microscopy, Professor Henry F. W. Siedentopf of Jena (1872–1940), is credited with having received a Nobel Prize; although such an honor may well have been deserved, the world knows nothing of it. Many of the printing errors can be blamed on the computerized typesetting that is usual nowadays, but these ought to have been corrected by the publisher's copy editors (do such people still exist?). Just a few of these typos are listed below. "Silicium" instead of silicon and "Schockley" instead of Shockley ("Methods: I", pp. 353, 385, resp.) would hardly cause misunderstanding, but Ti_2O instead of NiO, and "stair red dislocations" for stair-rod dislocations (same volume, pp. 379, 384, resp.) could present difficulties. "Electromechanical" instead of electrochemical and "Heydenreich" instead of Heidenreich ("Applications", pp. 12, 5, resp.) will confuse. Surely it is already well known that the two important scientists with these rather similar names are unrelated. In the section on high-resolution transmission electron microscopy, which I read with special interest, the symbols ψ and φ for the object and image wave-functions are sometimes confused, in both the formulas and the figures (e.g., p. 358 of "Methods: I"), and the word "phase" is used quite loosely. In these cases experts will easily guess what was intended, but for other readers it is essential to be absolutely accurate to avoid misunderstandings.

However, although these shortcomings had to be mentioned in the interest of completeness, readers of *Angewandte Chemie* will be interested in other qualities of the handbook, insofar as it also aims to cover applications in chemistry and solid state chemistry. In this context, of course, we are not concerned with "Methods: I" and "Methods: II". But even in the "Applications" volume chemical aspects are only touched on in passing, and this applies to the chapters on superconductors, polymers, small particles, and medical and dental materials. This only serves to emphasize the general observation that microscopists working in the area of chemistry are not sufficiently assertive in bringing their achievements to the notice of the scientific world.

There is at present no other available work that is comparable to this *Handbook of Microscopy*, and for this reason alone it will certainly find buyers, especially libraries. In a limited sense it can be regarded as a successor to *Electron Microscopy in Solid State Physics*, by Bethge and Heydenreich, which was published ten years earlier. However, a more detailed comparison is not possible, as the present handbook covers a much wider range of subject matter, especially in the parts concerned with methods. Science libraries should certainly buy it. Prospective individual buyers should, in view of the high cost, try to take a look at a copy before deciding whether it meets their needs.

The major target of oxidative damage of nucleic acid within the cell is guanine (G). Metal intercalators which are strong photooxidants and attached to the DNA at a well-defined separation from a GG doublet can initiate selective oxidation of 5´-guanine from a distance.

Long-range charge transfer is mediated by the DNA base paired stack. Metal complexes whose ligands have an extended "aromatic surface" for intercalation in DNA can function as electron donors (red) and acceptors (yellow) to probe photoinduced electron transfer through the DNA base stack.

Charge Transfer through the DNA Base Stack

R. Erik Holmlin, Peter J. Dandliker, and Jacqueline K. Barton*

Whether the DNA base pair stack might serve as a medium for efficient, long-range charge transfer has been debated almost since the first proposal of the double-helical structure of DNA. The consequences of long-range radical migration through DNA are important with respect to understanding carcinogenesis and mutagenesis. Double-helical DNA has in its core a stacked array of aromatic heterocyclic base pairs, and this molecular π stack represents a unique system in which to explore the chemistry of electron transfer. We designed a family of metal complexes which bind to DNA by intercalative stacking within the helix; these metallointercalators may be usefully applied in probing DNA-mediated electron transfer. Here we describe a range of electron transfer reactions we carried out which are mediated by the DNA base paired stack. In some cases, DNA serves as a bridge, and spectroscopic analyses permit us to probe how the π stack couples DNA-bound donors and acceptors. These studies point to the sensitivity of coupling to DNA intercalation. However, if the DNA π stack effectively bridges donors and acceptors, the base-pair stack itself might serve not only as a conduit for electron transfer in DNA, but also in reactions initiated from a remote position. We carried out a series of reactions involving oxidative damage to DNA arising from the remotely positioned oxidant on the helix. The implications of long-range charge migration through DNA to effect damage are substantial. As in other DNA-mediated charge transfers, these reactions are highly dependent on DNA intercalation and the integrity of the intervening base-pair stack, but not on molecular distance. Furthermore, a physiologically important DNA lesion, the thymine dimers, can be reversed in a reaction initiated by electron transfer. This repair reaction can also be promoted from a distance as a result of long-range charge migration through the DNA base pair stack.

1. Introduction

The biochemist perceives double-helical DNA primarily as a target for molecular recognition. As the molecular library of the cell, double-helical DNA must access genetic information and express it through an array of noncovalent interactions between proteins and nucleic acids.[1] The rational design of drugs targeted to DNA depends on determining general principles that govern the selective recognition of a nucleic acid site.[2] To understand in detail the remarkable variety of reactions involving the double helix within the cell, such as repair of DNA damage, coordination of the transcription of different genes, or screening of the fidelity of the DNA library, it becomes important to explore and consider the rich chemistry of DNA.[3]

Here we focused on the DNA double helix as a medium for charge transfer. From this perspective, the DNA polymer in its double-helical form may be viewed as an extended array of stacked, electronically coupled, aromatic heterocycles within a polyanionic sugar–phosphate backbone (Figure 1). Extended π systems in the solid state facilitate charge transport and are a major focus of study in materials research.[4, 5] The DNA double helix is a molecular π-stacked array, and may therefore represent a unique, structurally well-defined system to explore. We may ask, then, whether the DNA double helix facilitates charge transfer over long distances, and indeed, whether the base-pair stack can act as a conduit for chemistry at a distance.

Over the forty years since Watson and Crick first proposed the double-helical structure for DNA, scientists have considered the possibility of charge transfer through the base stack. Early theoretical models predicted that electron hopping from base to base might occur on the picosecond time scale.[6] Conductivity measurements on DNA fibers bracketed a "DNA band gap" of about 2 eV.[7] The question of whether radicals generated by high-energy irradiation of DNA migrate over distances of 2 or 200 base pairs has been the subject of intense debate amongst radiation biologists.[8] In the last decade, experimental studies by chemists of DNA as a

medium for charge transfer have centered on photoinduced electron transfer between donors and acceptors bound to DNA in solution.[9, 10]

We designed small, coordinatively saturated transition metal complexes to interrogate the structure and function of nucleic acids.[11] To study DNA-mediated charge transfer, we exploited the well-characterized chemical and photophysical properties of polypyridyl metal complexes.[9, 12] Our first investigations revealed that the presence of the DNA polymer enhanced the efficiency of photoinduced electron transfer between complexes bound weakly to DNA;[13] the rate of luminescence quenching of photoexcited $[Ru(phen)_3]^{2+}$ by tris(phenanthroline) complexes of Co^{III} and Rh^{III} is enhanced by two orders of magnitude in the presence of DNA (phen = phenanthroline). Moreover, this electron transfer can be enantioselective. It is more efficient for Δ-$[Ru(phen)_3]^{2+}$, which binds to DNA somewhat more tightly, than for the Λ isomer. These studies demonstrated the utility of chiral, octahedral metal complexes in probing electron transfer through the DNA π stack. However, since DNA binding by tris(phenanthroline) metal complexes is not restricted to intercalation, several factors could contribute to the enhanced reactivity in the presence of DNA: a) the increased local concentration of reactants near the helix, b) the possibility of facilitated diffusion of species along the polymer, and, perhaps most intriguingly, c) the possibility that electron transfer may occur over a long range through the π stack.

Since these early studies, we have focused our attention on metallointercalators—complexes which bind to DNA by classical intercalation—to explore charge transfer through

R. Erik Holmlin was born in 1967 and received a Bachelor of Arts degree in chemistry from Occidental College in Los Angeles. He began graduate studies as an National Science Foundation Graduate Research Fellow under Jacqueline Barton at the California Institute of Technology in 1993. His doctoral research has focused on applications of metallointercalators in DNA-mediated charge transfer.

Peter Dandliker was born in 1967 and received his Bachelor of Arts degree in chemistry at the University of California at Berkeley in 1990. In 1995 he earned his Ph.D. in organic chemistry with François Diederich at UCLA. He joined the research group of Jacqueline Barton as a Damon Runyon-Walter Winchell Cancer Fund Postdoctoral Fellow in 1995, where he has used intercalators to photochemically repair pyrimidine dimers in DNA. This past summer he joined Abbott Laboratories in Illinois as a research scientist.

Jacqueline K. Barton is the Hanisch Memorial Professor of Chemistry at the California Institute of Technology (Caltech). She received her Ph.D. in inorganic chemistry at Columbia University in 1979 with S. J. Lippard. After a postdoctoral fellowship at Bell Laboratories and Yale University, she became an assistant professor at Hunter College, City University of New York. In 1983 she returned to Columbia University, becoming an associate professor of chemistry and biological science in 1985 and professor in 1986. In the fall of 1989 she moved to Caltech. Barton has pioneered the application of transition metal complexes as tools to probe recognition and reactions of double-helical DNA. She has designed octahedral metal complexes which recognize nucleic acid sites with high affinities and specificities. These synthetic transition metal complexes have been useful in elucidating chemical principles which govern the recognition of nucleic acids, and in developing luminescent and photochemical reagents as new diagnostic tools. With these transition metal probes, studies to eludicate the chemistry of electron transfer mediated by the DNA double helix have also been carried out. Barton is the author of more than 100 publications and has received numerous awards, including the Paul Karrer Medal in 1996.

the π stack.[9] Tight binding and rigid association of the complexes with the helix restricts diffusion along the DNA polymer on the time scale of the reaction. Moreover, intercalative stacking of the donors and acceptors in the DNA helix provides a direct probe of the DNA π stack. In each system charge transfer mediated by the DNA is most affected by how the donors and acceptors are coupled into the DNA π stack. Therefore, DNA-mediated electron transfer depends strongly on π stacking.

Here we describe our recent investigations of DNA-mediated electron transfer with metallointercalators. We do not provide an exhaustive review of the literature, but instead present some of our experiments, which serve to illustrate principles we have learned and issues we need to understand better in delineating this chemistry. The study of DNA-mediated electron transfer is a challenging one, and requires a mix of bioinorganic chemistry, fast photophysics, and the chemistry of nucleic acid modification. The challenge, however, is worthwhile, since the DNA double helix is not simply a passive surface for reactions but instead a remarkable medium through which chemistry is carried out at a distance.

2. Metallointercalators as Probes for DNA-Mediated Electron Transfer

In probing DNA-mediated electron transfer, we focused on octahedral metal complexes which bind tightly to DNA by intercalation. NMR spectroscopy was useful for structurally characterizing the noncovalent association of these metal complexes with the DNA duplex, while photophysical and photochemical studies were exploited to determine the position and the factors affecting association of the complexes along the helical polymer. These companion experiments have proven to be powerful tools in defining the chemistry of charge transfer. Figures 2 and 3 schematically illustrate some of the complexes we may employ as donors and acceptors for photoinduced electron transfer.

2.1. Dipyridophenazine Complexes of Ruthenium and Osmium

The family of mixed-ligand complexes of type $[M(L)_2(dppz)]^{2+}$ (M = Ru, Os; L = phen, 2,2′-bipyridyl (bpy); dppz = dypyrido[3,2-*a*:2′,3′-*c*]phenazine) which contains the dppz ligand represents a straightforward extension of tris(phenanthroline) metal complexes; the "aromatic surface" of the dppz ligand provides an expansive platform for intercalation (Figure 2). The dppz complexes of ruthenium, osmium, and more recently cobalt, nickel, and rhenium, were shown to bind to DNA by preferential intercalation of the dppz ligand within the helical stack.[14–17] Binding affinities for duplex DNA are $\geq 10^7\ M^{-1}$, approximately three orders of magnitude higher than those of the simple tris(phenanthroline) metal complexes. NMR spectoscopic studies of selectively deuterated $[Ru(phen)_2(dppz)]^{2+}$ isomers bound to a DNA hexamer indicated intercalation from the major-groove side of the DNA helix with a family of orientations.[18] Although some sequence preferences are evident in the binding of the complexes to DNA, as determined from NMR spectroscopic studies, high sequence selectivity is not apparent; this is consistent with biophysical studies which indicate that classical intercalation occurs essentially randomly along a helical polymer. Because of the low sequence selectivity, however, a detailed structural determination of how these complexes stack in a helix is precluded.

The utility of the dppz complexes for our studies rests not only in the tight intercalative binding by the complexes but also in their unique photophysical properties. Irradiation of these complexes with visible light leads to efficient population of a metal-to-ligand charge-transfer (MLCT) excited state that is localized on the dppz ligand.[14, 19, 20] Although luminescence can be readily detected upon excitation in organic solvents, that in aqueous solution is quenched by proton transfer from solvent to the nitrogen atoms of phenazine.[19, 20] The DNA π stack provides protection from this quenching. Therefore, when the dppz ligand intercalates into the base-pair stack, the nitrogen atoms of phenazine are protected from water, and the complex is again emissive. This effect has proven to be a sensitive diagnostic for nucleic acids, and the term "molecular light switch" was adopted to describe this interesting luminescence property. Moreover, these molecules

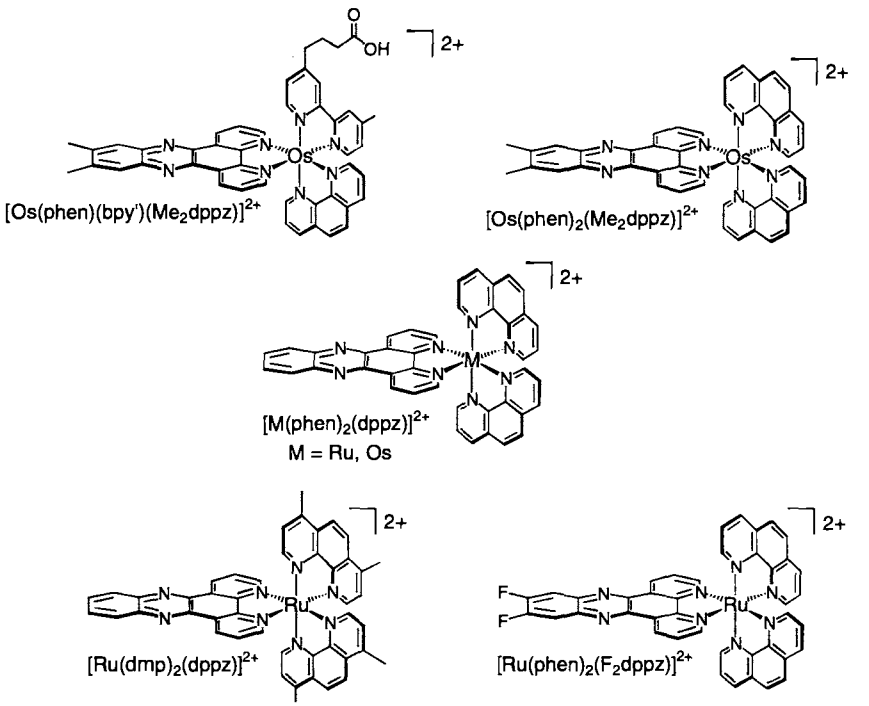

Figure 2. Derivatives of Δ-$[M(phen)_2(dppz)]^{2+}$ that bind DNA by preferential stacking of the dppz ligand between adjacent DNA base pairs (bpy′ = derivative of 2,2′-bipyridyl). In the MLCT excited state, these complexes direct an electron into the DNA π stack.

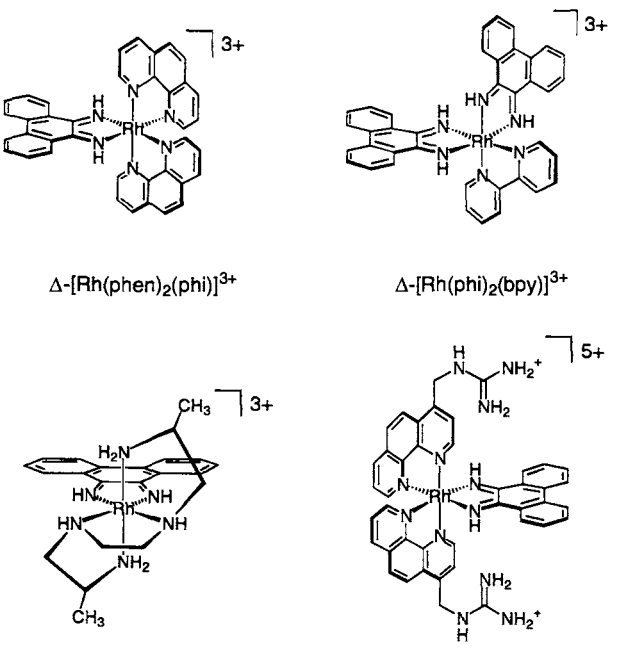
are generally useful for characterizing hydrophobic matrices, for example sodium dodecylsulfate (SDS) micelles[21] and Nafion films.[22]

Owing to the light-switch character of the $[Ru(L)_2(dppz)]^{2+}$ complexes, the steady-state and time-resolved emission profiles are particularly sensitive to the orientation of the metal complex within the DNA π stack.[14] For *rac*-$[Ru(phen)_2(dppz)]^{2+}$ bound to mixed-sequence *B*-form DNA (nucleotide:Ru = 100:1), the emission follows a biexponential decay with $\tau_1 = 130$ ns (80%) and $\tau_2 = 730$ ns (20%). Biexponential decays are also observed for the pure isomers Δ- and Λ-$[Ru(phen)_2(dppz)]^{2+}$ bound to DNA,[23] which likely reflects the population of binding orientations observed by NMR spectroscopy.[18] For Δ-$[Ru(phen)_2(dppz)]^{2+}$ bound to DNA, the emission decay is described by $\tau_1 = 150$ ns (80%) and $\tau_2 = 800$ ns (20%), whereas for Λ-$[Ru(phen)_2(dppz)]^{2+}$ bound to mixed-sequence DNA, the luminescence decays with $\tau_1 = 30$ ns (80%) and $\tau_2 = 160$ ns (20%). This difference in emission decay, manifested as an increase in the yield of steady-state emission for the DNA-bound Δ enantiomer, reflects greater protection of the intercalating ligand from the solvent. Such a propensity for intimate association between Δ-$[Ru(phen)_2(dppz)]^{2+}$ and double-helical DNA follows from the matching of symmetry between the right-handed DNA duplex and the right-handed metal complex.[24] The lifetimes and relative distributions of the excited state vary with the concentration of the bound species; this may reflect the sensitivity of these decay parameters to the rigidity of the helix, which increases with intercalator loading.

Substitution of ruthenium by osmium in $[M(phen)_2(dppz)]^{2+}$ does not alter the light-switch character or the DNA-binding properties of the complex, but provides an isostructural analogue for $[Ru(phen)_2(dppz)]^{2+}$ with distinct photophysical and electrochemical properties. Like the ruthenium analogue, no photoluminescence is detected upon irradiation of $[Os(phen)_2(dppz)]^{2+}$ in aqueous solution in the absence of DNA.[15, 25] In the presence of DNA, however, excitation of the complex affords significant, long-wavelength emission ($\lambda_{max} = 738$ nm). A biexponential decay in emission is observed for DNA-bound Δ-$[Os(phen)_2(dppz)]^{2+}$ with excited-state lifetimes below 10 ns. The osmium center stabilizes the 3+ oxidation state of the complex by about 500 mV relative to ruthenium, causing the oxidation of the osmium excited state ($E_{1/2}(*Os^{II}/Os^{III}) = 0.78$ V vs. NHE) to be about 200 mV more favorable than that of ruthenium ($E_{1/2}(*Ru^{II}/Ru^{III}) = 0.60$ V vs. NHE). We are also able to utilize phen or bpy analogues bearing electron-donating or electron-withdrawing substituents to tune further the electrochemical properties of these complexes over a range of potentials. Substitution of methyl groups onto positions 7 and 8 of the dppz ligand increases the excited-state lifetimes for both osmium and ruthenium derivatives bound to DNA (M = Ru: $\tau_1 = 370$ ns (65%), $\tau_2 = 1170$ ns (35%); M = Os: $\tau_1 = 2.18$ ns (50%), $\tau_2 = 10.1$ ns (50%)). This preferential charge transfer onto the dppz ligand is an important characteristic, which we exploited in our studies of DNA-mediated electron transfer, in that for the intercalated complex charge transfer upon excitation is directed into the π stack. These complexes are therefore particularly well-suited for probing DNA-mediated charge transfer.

2.2. Phenanthrenequinone Diimine Complexes of Rh^{III}

The rhodium intercalators we employed all contain the phenanthrenequinone diimine (phi) ligand. Several of the Rh^{III} complexes we constructed are schematically illustrated in Figure 3. For these complexes, too, one ligand provides an



Δ-$[Rh(phen)_2(phi)]^{3+}$ Δ-$[Rh(phi)_2(bpy)]^{3+}$

Δ-α-$[Rh\{(R,R)\text{-}Me_2trien\}(phi)]^{3+}$ Λ-1-$[Rh(mgp)_2(phi)]^{5+}$

Figure 3. Illustrations of phi complexes of Rh^{III} which bind to DNA by intercalation (mgp = 4-guanidiummethyl-1,10-phenanthroline). The common feature in this family of metallointercalators is the phi ligand, which serves to anchor the complex in the major groove of DNA. Systematic variations in the ancillary ligands permit tuning of binding affinity and site selectivity.

extended aromatic surface for intercalation. Indeed, all the phi complexes of rhodium we prepared thus far bind tightly to DNA by preferential intercalation of the phi ligand. Affinities range from 10^6 to 10^8 M^{-1}, and the sites recognized may be tuned selectively by varying substitutents on the ancillary, nonintercalating ligands.[26, 27] Some of these complexes display DNA affinities and specificities rivaling those of DNA-binding proteins.[27]

NMR spectroscopy has been particularly valuable in determining how these complexes are associated with DNA.[28, 29] The complexes all appear to bind DNA from the major groove. When the complex is anchored by intercalation, functional groups incorporated on the ancillary ligands can interact with sites on the major groove to determine binding-site selectivity.[26, 27] Indeed, in the case of Δ-α-$[Rh\{(R,R)\text{-}Me_2(trien)\}(phi)]^{3+}$ (trien = triethylene tetraamine), we constructed the complex so as to specify an ensemble of noncovalent contacts in the major groove for predictive targeting of the sequence 5′-TGCA-3′. Recently, a high-

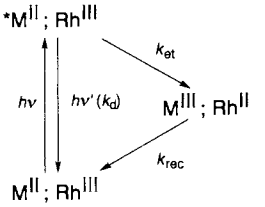
resolution structural model of this complex bound site specifically to a decamer was determined using NMR spectroscopy.[29] In this structure, the metal complex is well stacked and bound symmetrically to the double helix; the different noncovalent contacts between the ancillary ligand and major groove site 5′-TGCA-3′ are apparent. Importantly, the DNA helix is unwound to accomodate the intercalator, but otherwise little perturbation in the DNA base stack is evident.[29]

In studying DNA-mediated electron transfer between metallointercalators, we frequently employed $[Rh(phi)_2(L)]^{3+}$ complexes as ground-state electron acceptors. These complexes are primarily sequence neutral in association with DNA and therefore bind randomly to the duplex.[30] Characterization of the electrochemical properties of $[Rh(phi)_2(L)]^{3+}$ by cyclic voltammetry reveals that in DMF the formal $Rh^{III} \rightarrow Rh^{II}$ reduction occurs at about 0 V vs. NHE.[31] Hence, electron transfer from photoexcited $[M(phen)_2(dppz)]^{2+}$ to DNA-bound $[Rh(phi)_2(L)]^{3+}$ is thermodynamically favorable ($M = Ru$: $\Delta G^\circ = 0.56$ V; $M = Os$: $\Delta G^\circ = 0.73$ V).

The photochemistry of these phi complexes of rhodium has proven to be quite valuable first in determining where the metal complex is bound along the helical polymer in a given electron transfer reaction and in providing potent photooxidants which are intercalated in DNA. Therefore, given the rich photochemistry of these complexes, we are able to utilize light of different wavelengths to induce selectively different chemical reactions.[30, 32] Irradiation of the DNA-bound complexes with UV light ($\lambda = 313$ nm) leads to direct scission of the DNA sugar–phosphate backbone by a reaction consistent with hydrogen abstraction of the C3′-H atom from the deoxyribose moiety by the activated phi ligand at the intercalation site.[30] This strand scission marks the site of intercalation. This photochemical reaction has been used profitably for establishing the site selectivities of a range of complexes. If instead the $[Rh(phi)_2(L)]^{3+}$ complexes are excited with visible light ($\lambda \geq 365$ nm), a powerfully oxidizing intraligand excited state is populated.[32] Based on quenching studies in solution in the absence of DNA, the reduction potential of the excited state of $[Rh(phi)_2(phen)]^{3+}$ ($E_{1/2}(*Rh^{III}/Rh^{II})$) is estimated to be about 2 V vs. NHE. We can therefore exploit these rhodium intercalators not only as ground-state but also as excited-state electron acceptors.

3. DNA as a Bridge for Electron Transfer

Scheme 1 illustrates the cycle of electron transfer reactions between DNA-bound metallointercalators. Irradiation of the M^{II} complex with visible light leads to the formation of the photoexcited donor, which in the absence of acceptor may return to the ground state by emission of a photon. In the presence of an acceptor with the appropriate reduction potential, the photoexcited donor may transfer an electron to the ground-state acceptor (rate constant k_{et}), which results in quenching of the donor emission. The products of this forward electron transfer then undergo thermal recombination (rate constant k_{rec}) to regenerate the ground-state pair. We may therefore monitor electron transfer between metallointercalators with the DNA π stack as the intervening bridge.



Scheme 1. Cycle of electron transfer reactions between DNA-bound metallointercalators.

3.1. Intercalative Coupling into the π Stack

We first compared the quenching of DNA-bound, photoexcited $[Ru(phen)_2(dppz)]^{2+}$ by two acceptors—namely, $[Rh(phi)_2(phen)]^{3+}$, which binds to DNA by intercalation, and $[Ru(NH_3)_6]^{3+}$, which binds to the surface of the double helix (Figure 4).[31] Since the $Rh^{III} \rightarrow Rh^{II}$ reduction potential of

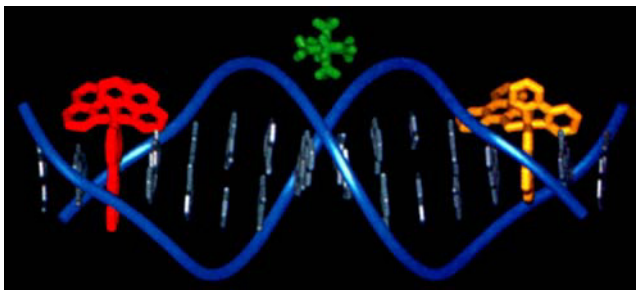


Figure 4. Schematic representation of transition metal complexes bound to DNA. Shown are Δ-$[Ru(phen)_2(dppz)]^{2+}$ (red), Δ-$[Rh(phi)_2(bpy)]^{3+}$ (yellow), and $[Ru(NH_3)_6]^{3+}$ (green). Δ-$[Ru(phen)_2(dppz)]^{2+}$ and Δ-$[Rh(phi)_2(bpy)]^{3+}$ are metallointercalators and probe the DNA base stack directly. $[Ru(NH_3)_6]^{3+}$, which does not have the ligand framework to support intercalation, binds only by surface association and therefore cannot access the π stack.

$[Rh(phi)_2(phen)]^{3+}$ ($E_{1/2}(Rh^{III}/Rh^{II}) = -0.03$ V vs. NHE) is nearly identical to that of $[Ru(NH_3)_6]^{3+}$ (0.01 V), the driving force for the reaction does not differ significantly between the two donor–acceptor pairs. When the intercalator $[Rh(phi)_2(phen)]^{3+}$ or $[Rh(phi)_2(bpy)]^{3+}$ is titrated into solutions of DNA-bound $[Ru(phen)_2(dppz)]^{2+}$, fast and efficient quenching of the ruthenium emission on the subnanosecond time scale is observed. Over a similar concentration range, $[Ru(NH_3)_6]^{3+}$ also quenches the luminescence of DNA-bound $[Ru(phen)_2(dppz)]^{2+}$. However, this quenching is less efficient and proceeds on the nanosecond time scale. In contrast to the intercalating acceptor, $[Ru(NH_3)_6]^{3+}$ exhibits a quenching profile that is consistent with a reaction which requires diffusion. Here, electron transfer does not proceed through the DNA, rather the DNA merely facilitates diffusion of the acceptor.

The distinction between electron transfer reactions involving intercalated donors and acceptors and those involving reactants bound in the groove is also evident in data emerging from other research groups.[10] For example, quenching of intercalated ethidium by *N*,*N*′-dimethyl-2,7-diazapyrenium dichloride (DAP) is enhanced compared to the reaction in the absence of DNA.[10] On the other hand, quenching of ethidium by groove-bound methyl viologen or palladium

porphyrins does not exhibit the remarkable efficiency and rate observed with the metallointercalators.[10] When methyl viologen is used to quench DNA-bound, photoexcited $[Ru(phen)_2(dppz)]^{2+}$, the quenching is also slow relative to reactions between molecules which access the π stack directly by intercalation.[10]

In fact, coupling into the π stack is so important, that even for molecules which intercalate in the DNA, the nature of the stacking interaction seems to affect the reactivity by electron transfer. For example, when $[Rh(phen)_2(phi)]^{3+}$ is titrated into solutions of DNA-bound $[Ru(phen)_2(dppz)]^{2+}$, we observe no quenching of the ruthenium photoluminescence, despite sufficient driving force for the reaction.[33] Based on photocleavage studies, $[Rh(phen)_2(phi)]^{3+}$ prefers to intercalate shape selectively at sites with an open major groove, and hence exhibits a greater sequence selectivity in binding to DNA than $[Rh(phi)_2(L)]^{3+}$.[33] Even though the complex binds by intercalation, the depth to which the complex intercalates is limited by steric clash between the ancillary phenanthroline ligands and the sugar–phosphate backbone of the DNA. Therefore, $[Rh(phen)_2(phi)]^{3+}$ appears unable to couple effectively into the DNA π stack and fails to quench the ruthenium emission.

The effect of stacking on quenching efficiency is also important for the electron donor. Owing to symmetry matching between the right-handed octahedral metal complexes and the right-handed DNA duplex,[24] the Δ enantimomer binds more deeply within the DNA base stack. It is not surprising then that Δ-$[Ru(phen)_2(dppz)]^{2+}$ is quenched more efficiently than Λ-$[Ru(phen)_2(dppz)]^{2+}$ by $[Rh(phi)_2(bpy)]^{3+}$.[33, 34] We also observed significant differences in quenching efficiency for photoinduced reactions with $[Ru(phen)_2(dppz)]^{2+}$ versus ethidium as donor when all donors and acceptors were fully bound. Here too we estimate no difference in the driving force for the two redox couples; yet, the intercalators appear to vary in how they stack in the DNA duplex, which affects the electron transfer. It is therefore clear that effective stacking is requisite for coupling into the DNA duplex. A challenge to us is to develop a good understanding of what characterizes this effective stacking and how we may develop quantitative parameters to assess this stacking and its effect on coupling into the helix.

Experiments with $[Os(phen)_2(dppz)]^{2+}$ as the photoexcited donor were valuable in characterizing the fast, static quenching, and have ruled out energy transfer and metal-complex diffusion as mechanisms for the efficient quenching between metallointercalators.[25] Just as with ruthenium, we observe efficient quenching of the osmium emission in reactions with $[Rh(phi)_2(bpy)]^{3+}$. In fact, over a range of acceptor concentrations, the osmium and ruthenium quenching profiles are remarkably similar. This is inconsistent with diffusional quenching. If molecular diffusion were important, one would predict a reduction in quenching efficiency for the osmium donor, since it has a significantly shorter excited-state lifetime than the ruthenium donor. Moreover, the red-shifted emission spectrum of the osmium complex does not overlap the acceptor absorption, which precludes energy transfer as the quenching mechanism. The correlation between the ruthenium and osmium reaction profiles also rules out participation of energy transfer in the quenching of either osmium or ruthenium by $[Rh(phi)_2(bpy)]^{3+}$.

A comparison of the quenching of ruthenium donors by DNA-bound rhodium acceptors bound to DNA and SDS micelles further illustrates the importance of the DNA π stack in mediating fast and efficient electron transfer (Figure 5).[33] The DNA double helix and the micelle both provide anionic

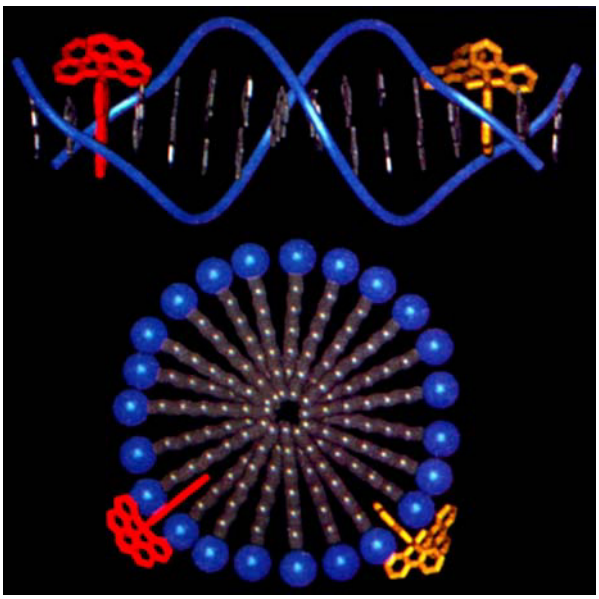

Figure 5. Illustration of the electron donor Δ-$[Ru(phen)_2(dppz)]^{2+}$ (red) and the electron acceptor Δ-$[Rh(phi)_2(bpy)]^{3+}$ (yellow) bound to double-helical DNA (top) and a SDS micelle (bottom).

surfaces to which the cationic donors and acceptors bind and a hydrophobic core region which accomodates their large, intercalating ligands. The primary difference between these two microheterogeneous environments is that the SDS micelle does not contain an organized pathway for electron transfer like the DNA. Accordingly, in the micellar system rhodium complexes do quench the ruthenium luminescence, but the electron transfer is much less efficient than the DNA-mediated reaction and proceeds on the nanosecond time scale. In fact, the quenching reaction in the micelle is diffusion-dependent and requires a collision between donor and acceptor. This in contrast to DNA-mediated electron transfer between metallointercalators, in which diffusion is clearly not required for quenching.

3.2. Rates of DNA-Mediated Electron Transfer

To deepen our understanding of electron transfer between metallointercalators, we sought to utilize ultrafast laser spectroscopy to monitor the reaction on the picosecond time scale, and, in so doing, hopefully determine the rates for these fast, photoinduced quenching processes.[34] To examine the rate of forward electron transfer (k_{et}, see Scheme 1), we employed time-correlated single-photon counting (TCSPC; resolution about 50 ps), with which the decay of the excited

state of the photoexcited $[M(phen)_2(dppz)]^{2+}$ donors could be monitored. Remarkably, when quenching of photoexcited $[Ru(phen)_2(dppz)]^{2+}$ by DNA-bound $[Rh(phi)_2(bpy)]^{3+}$ is followed by ultrafast TCSPC, no change in the kinetics of excited-state decay was detected as a function of quencher despite the significant intensity of the quenching. Instead, the quenching was manifested primarily as a loss of luminescence intensity at zero time; this intensity loss increased with increasing concentration of $[Rh(phi)_2(bpy)]^{3+}$. The same observation was made for the isostructural analogue $[Os(phen)_2(dppz)]^{2+}$. Such behavior implies that quenching by electron transfer proceeds faster than the time resolution of the instrument. Hence, we assigned a lower limit by $3 \times 10^{10}\ s^{-1}$ to the rate constant k_{et} describing this ultrafast reaction.

To monitor the back electron transfer we utilized ultrafast transient absorption spectroscopy. Following excitation of $[M(phen)_2(dppz)]^{2+}$ complexes at 390 nm, we monitored the change in the absorbance of the sample at 420 nm as a function of time. In the absence of acceptor, the kinetics of ground-state recovery match the luminescence lifetimes of the donors bound to DNA. As $[Rh(phi)_2(bpy)]^{3+}$ is titrated into solutions of DNA-bound donor, a new component is observed, which increases in intensity with increasing amounts of rhodium. Analysis of the transient absorption kinetics reveals that this fast phase is well described by $k_{rec} = 9.0 \times 10^{10}\ s^{-1}$ for M = Ru and $1.1 \times 10^{11}\ s^{-1}$ for M = Os. Since such a rate constant could not be detected in the kinetics of luminescence decay, we are confident in our assignment of this rate constant to the recombination reaction.

Transient absorption data for seven donor–acceptor pairs taken on the picosecond time scale are given in Table 1.[34]

Table 1. Rate constants for ground-state recombination following electron transfer from DNA-bound, photoexcited donors to Δ-$[Rh(phi)_2(bpy)]^{3+}$ [a, b].

Donor	DNA	k_{rec} [c] [$10^9\ s^{-1}$]	$-\Delta G°$ [d] [V]
Δ-$[Ru(phen)_2(dppz)]^{2+}$	calf thymus	9.2	1.66
rac-$[Ru(bpy)_2(dppz)]^{2+}$	calf thymus	7.1	1.69
Δ-$[Ru(dmp)_2(dppz)]^{2+}$	calf thymus	11	1.59
Δ-$[Ru(phen)_2(F_2dppz)]^{2+}$	calf thymus	7.7	1.68
rac-$[Ru(phen)_2(Me_2dppz)]^{2+}$	calf thymus	9.2	1.67
Δ-$[Os(phen)_2(dppz)]^{2+}$	calf thymus	11	1.21
Λ-$[Ru(phen)_2(dppz)]^{2+}$	calf thymus	4.5	
Δ-$[Ru(phen)_2(dppz)]^{2+}$	poly-d(AT)	7.4	
Δ-$[Ru(phen)_2(dppz)]^{2+}$	poly-d(GC)	0.21	

[a] Based on ref. [34]. The data were obtained by transient absorption spectroscopy. [b] Experimental conditions: [Ru], [Os] = 20 μM, [DNA] = 2 mM nucleotides (M:Nuc = 1:100), 5 mM tris(hydroxymethyl)aminomethane (Tris), 50 mM NaCl, pH = 8.5. [c] The error in k_{rec} was estimated to be ±10%. [d] $-\Delta G° = [E_{1/2}(M^{III}/M^{II}) - E_{1/2}(Rh^{III}/Rh^{II})]$. The error in $\Delta G°$ was estimated to be ± 50 mV.

Within this series, the reactants vary with respect to intercalating ligand, ancillary ligands, relative hydrophobicity, chirality, and metal center. Despite such a range of chemical properties, the rate observed for transient absorption is centered around $10^{10}\ s^{-1}$. Even for the osmium complex, in which the 3+ oxidation state is stabilized by about 500 mV relative to that of the ruthenium complex, the recombination rate is not significantly perturbed. A significant difference in rate is observed, however, when the absolute configuration of the donor is varied. For the right-handed Δ-$[Ru(phen)_2(dppz)]^{2+}$ $k_{rec} = 9.0 \times 10^{10}\ s^{-1}$, whereas for the left-handed enantiomer k_{rec} is diminished by a factor of 2.5. The faster electron transfer observed for Δ-$[Ru(phen)_2(dppz)]^{2+}$ is consistent with the deeper stacking of this enantiomer into the double helix.

Of particular interest is that these recombination reactions are relatively insensitive to the loading of acceptor on the helix. As the concentration of acceptor is increased throughout a titration, one expects (given random occupation of the helix) that the distribution of donor–acceptor separations should decrease. However, we observe in these experiments that, although the number of recombinations on the picosecond time scale increases with increasing amount of acceptor, the rate constant does not change as a function of acceptor concentration. This could indicate a reaction rate that exhibits a low dependence on distance.

These fast rates of reaction and insensitivity of fast recombination to loading could also be interpreted by a model in which the donor and acceptor bind cooperatively on the DNA helix.[34–36] With such a clustering model, the distances between metal complexes would be short, and, hence, the rates of reaction would be high and appear to be independent of loading. For the titration of DNA-bound $[Ru(phen)_2(dppz)]^{2+}$ with the rhodium quencher, such a clustering model can be fit but would require a cooperativity in binding of more than 1 kcal.[35] A perturbation in the circular dichroism (CD) spectrum of Δ-$[Ru(phen)_2(dppz)]^{2+}$ and Δ-$[Rh(phi)_2(bpy)]^{3+}$ bound to poly d(AT) at high loadings was interpreted as evidence for preferential binding of the rhodium complex near Δ-$[Ru(phen)_2(dppz)]^{2+}$.[36] It is difficult, however, to reconcile this clustering with several observations: a) the absence of fast quenching in the micelles where clustering should be encouraged, b) the presence of loading-independent kinetics for the full range of donors examined, and c) the random binding to DNA without conformational distortions of the donors and acceptors individually. In addition, there is no apparent structural basis for cooperative binding between ruthenium and rhodium to satisfy this model.

It is noteworthy that the largest change in electron transfer is observed as a function of the sequence of the DNA bridge.[34, 37] Evident in Table 1 are the rates of recombination k_{rec} from reduced acceptor to oxidized donor for poly d(AT) and poly d(GC): k_{rec} is 30 times higher with poly d(AT) than with poly d(GC). In addition, the yield of electron transfer from photoexcited $[M(phen)_2(dppz)]^{2+}$ to DNA-bound $[Rh(phi)_2(bpy)]^{3+}$ depends strongly on the nucleic acid sequence. For donors bound to poly d(AT) the fraction of excited states (M = Os or Ru) which undergo electron transfer resembles closely the yield of electron transfer for donors bound to mixed-sequence (calf-thymus) DNA. For the same donors bound to poly d(GC), however, the fraction quenched is significantly reduced. Nonetheless, while the yield of photoinduced electron transfer decreases for $[M(phen)_2(dppz)]^{2+}$ bound to poly d(GC) relative to mixed-sequence calf-thymus DNA and poly d(AT), the rate k_{et} of the forward reaction remains greater than $3 \times 10^{10}\ s^{-1}$.[34] These findings are also hard to reconcile with a clustering model, because both the

rate of recombination and yield of electron transfer appear to depend upon the DNA sequence between donor and acceptor.

Given these discrepancies, we reinvestigated the CD of Δ-$[Ru(phen)_2(dppz)]^{2+}$ and Δ-$[Rh(phi)_2(bpy)]^{3+}$ bound to different DNA polymers as a function of concentration to explore more fully the parameters affecting any possible clustering.[38] We found no systematic change in the CD as a function of loading on the helix nor as a function of polymer sequence. The induced CD observed with each intercalator upon addition of DNA arises whether they are bound together or separately. It is a function of binding to the chiral interbase pair site, and observed even with achiral intercalators. We also tested the clustering model more directly in an NMR experiment. Here, we examined the site selectivity of intercalation in DNA by monitoring perturbations in the signals for the exchangeable imino protons within each DNA base pair of a DNA decamer upon binding the ruthenium and rhodium intercalator separately or together. If anything, the NMR data indicate that the complexes bind anticooperatively to the decamer, and primarily at sites separated on the helix by four base pairs.

Nonetheless, this whole discussion of cooperative versus anticooperative binding on the helix teaches us some lessons. For all of these studies of electron transfer, a fundamental understanding of structure—that is, of how the donors and acceptors are associated with the helix—is essential. Moreover, to examine in detail the distance dependence of electron transfer, it is important to carry out such studies with donors and acceptors bound at a fixed separation and with a fixed intervening DNA sequence. With molecules bound noncovalently to DNA, a distribution of distances and sites occurs, and deconvoluting these different parameters becomes problematic.

3.3. Characterizing the Products of Electron Transfer

Can we provide more evidence that this fast quenching reaction is indeed electron transfer? The fraction of recombination reactions that occur on the picosecond time scale accounts for the majority of excited states which undergo electron transfer. However, a small fraction of reduced acceptor and oxidized donor appear to recombine on a longer time scale. To identify and characterize any long-lived intermediates of electron transfer between metallointercalators, we monitored the photoinduced electron transfer by transient absorption spectroscopy on the microsecond time scale. For $[Ru(dmp)_2(dppz)]^{2+}$ (dmp = 4,7-dimethyl-1,10-phenanthroline) and $[Os(phen)_2(dppz)]^{2+}$ donors, we actually observed rhodium-induced transients which persisted well into the microsecond regime.[25, 39] Owing to the stability of the osmium complex in the 3+ oxidation state, we were able to measure the wavelength dependence of the long-lived transient. The resulting difference spectrum ($Os^{III} - Os^{II}$) is nearly identical to those obtained either by chemical oxidation of $[Os(phen)_2(dppz)]^{2+}$ in solution or photochemical oxidation of DNA-bound, photoexcited $[Os(phen)_2(dppz)]^{2+}$. Thus, this long-lived intermediate was unambiguously identified as the oxidized donor, which establishes unequivocally that the reaction proceeds by electron transfer.

3.4. Electron Transfer over a Fixed Donor–Acceptor Separation

Experiments in which the donors and acceptors are bound noncovalently to the DNA duplex were all carried out at low reactant loadings in order to maximize donor–acceptor separation. In a typical experiment, a 1:1 ratio of donor to acceptor corresponds to an average separation of 25 base pairs. Remarkably, 50% of the Δ-$[M(phen)_2(dppz)]^{2+}$ excited states undergo electron transfer, indicating that the reaction is very efficient even at low loading. Under these conditions, however, a distribution of donor–acceptor separations is always present. Moreover, as discussed above, we cannot eliminate the possibility of clustering with metal complexes noncovalently bound to the helix. To establish definitively that photoinduced electron transfer may proceed over some distance, we needed to tether the donor and acceptor intercalators to opposite ends of a DNA duplex to provide an assembly in which the donor–acceptor separation might be fixed.

We constructed a DNA duplex in which $[Ru(phen)_2(dppz)]^{2+}$ and $[Rh(phi)_2phen]^{3+}$ derivatives were tethered by flexible linkers to opposite ends of a 15 base pair oligonucleotide (Figure 6).[40] The complexes were free to intercalate but

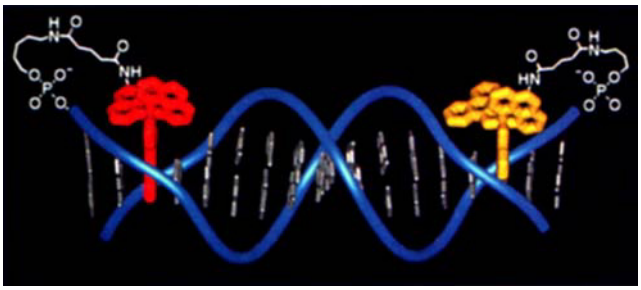

Figure 6. Schematic representation of a 15 base pair DNA duplex with Δ-$[Ru(phen)_2(dppz)]^{2+}$ as electron donor (red) and Δ-$[Rh(phi)_2(phen)]^{3+}$ as electron acceptor (yellow) tethered to opposite ends of the assembly; the complexes are intercalated but separated by a fixed distance. Shown is the most probable separation of 11 base pairs (41 Å).

separated by about 40 Å. Companion experiments with duplexes bearing either a tethered ruthenium or rhodium complex (but not both) allowed us to examine the integrity of the metal-modified DNA duplex and the intercalation sites. Owing to the sensitivity of the ruthenium luminescence to the local environment, we could characterize intercalation by the tethered ruthenium within the helix. In the conjugate assembly containing only a rhodium complex, a photocleavage experiment could be used to mark the site of intercalation.

In the 15 base pair assembly shown, intercalation of the metal complexes can occur either one or two base pairs from the end of the duplex, leading to a most probable separation of 41 Å between donor and acceptor.[40] Remarkably, no ruthenium luminescence was detected in the mixed-metal assembly upon excitation. Hence, as suggested by experiments with noncovalently bound donors and acceptors, photoinduced electron transfer through the double helix can proceed efficiently between metallointercalators over a long

molecular distance. A lower limit of $3 \times 10^9\ s^{-1}$ was set for the rate constant describing the photoinduced reaction. Therefore, the DNA double helix does indeed provide a bridge for long-range electron transfer.

Viewed in the context of classical studies of electron transfer through σ-bonded networks,[41] such long-range electron transfer through DNA was surprising. Chemists are now beginning to devote attention to developing a theoretical foundation for the consideration of charge transfer mediated by the DNA base stack.[42] Our studies point to stacking as a critical element in determining the efficiency of the reaction. An efficient reaction mediated by the DNA π stack requires full intercalation of donors and acceptors. Indeed significant differences in electron transfer are evident not only between groove-bound versus intercalated redox pairs, but also among intercalators which stack in the helix to differing extents. Our results highlight the importance of addressing this stacking parameter explicitly when constructing theoretical models of DNA-mediated charge transfer.

Other research groups have since constructed different DNA assemblies with covalently bound donors and acceptors. At first, the results with these different assemblies appear quite disparate. Meade and Kayyem developed a system in which a nonintercalating ruthenium complex is coordinated directly to amino-modified sugars at the terminal position of oligonucleotides.[43] They assert that electron transfer in this system is protein-like. Most recently, Lewis and co-workers[44] measured rates of photooxidation of a guanine base in a DNA hairpin by an associated stilbene unit bound at the top of the hairpin. By systematically varying the position of the guanine base within the hairpin and measuring the rate of electron transfer, a value for the electronic coupling parameter β could be estimated. Here, β was $0.64\ Å^{-1}$, which is intermediate between that for proteins with σ-bonded arrays and that expected for a highly coupled π-bonded array.

Most recently, we began to expand the scope of our studies to include organic intercalators such as ethidium.[45] With ethidium tethered and intercalated at one end of DNA oligonucleotides and a $[Rh(phi)_2(bpy)]^{3+}$ derivative covalently bound and intercalated at the opposite end, we also observed fast ($\geq 10^{10}\ s^{-1}$) photoinduced electron transfer. It is interesting that with excited ethidium as donor, either noncovalently or covalently bound, the efficiency of the reaction is reduced compared to that with ruthenium, despite similar driving forces. This difference in yield may reflect differences in intercalative stacking between the two donors. Importantly, systematic variation of the separation between donor and acceptor over distances ranging from 17–36 Å yields fluorescence quenching irrespective of distance, and the dependence of the quenching yield on distance is low. Although little sensitivity to distance is apparent, experiments carried out as a function of temperature and with intervening mismatches have underscored the remarkable dependence of these reactions on how the base pairs are stacked within the DNA duplex. Photoinduced quenching is apparent in an 11 base pair duplex containing tethered ethidium and rhodium (Table 2). However, if a single, intervening cytosine–adenine mismatch (C–A) is introduced, the long-range charge transfer is abolished. A guanine–adenine mismatch (G–A), which is known to be well stacked within *B*-form DNA, actually enhances quenching of electron transfer. These results certainly suggest the application of long-range electron transfer in developing new biosensors that sensitively report on the DNA bridge.

Table 2. Flourescence quenching in ethidium–Rh DNA duplexes with mismatched pairing [a].

Assembly	F_g[b]
Et'-5'-C-T-A-T-C-**T**A-T-C-G-T G-A-T-A-G-**A**-T-A-G-C-A-5'-Λ-Rh	0.21
Et'-5'-C-T-A-T-C-**C**A-T-C-G-T G-A-T-A-G-**A**-T-A-G-C-A-5'-Λ-Rh	0.04
Et'-5'-C-T-A-T-C-**G**A-T-C-G-T G-A-T-A-G-**A**-T-A-G-C-A-5'-Λ-Rh	0.26

[a] Based on ref. [45]. [b] F_g = fraction quenched: Fluorescence of duplexes containing ethidium (Et) and Rh compared to that of duplexes containing only ethidium.

Thus, we may begin to reconcile studies in our laboratory and elsewhere on DNA-mediated electron transfer in covalently bound assemblies by focusing on the issue of stacking. We find that electron transfer is most sensitive to the intervening base-pair stack. How the donor and acceptor are coupled into this stack varies in each system. In proteins for which the energetic differences in coupling depend upon σ-bonded interactions, small energetic differences between systems do not cause large differences in electronic coupling. In the DNA double helix, however, in which electronic coupling is mediated by π stacking, small energetic differences could lead to large differences in coupling efficiency. Hence, with donors and acceptors coordinated to sugar moieties, charge transfer first through a σ-bonded network could be rate-limiting. In the case of the stilbene-modified DNA hairpin, the stilbene group is closely associated but unstacked with the DNA base pairs, and hence, intermediate coupling might be expected. With well-intercalated donors and acceptors, coupling into the base-pair array should be optimum.

4. DNA-Mediated Electron Transfer Involving DNA Bases

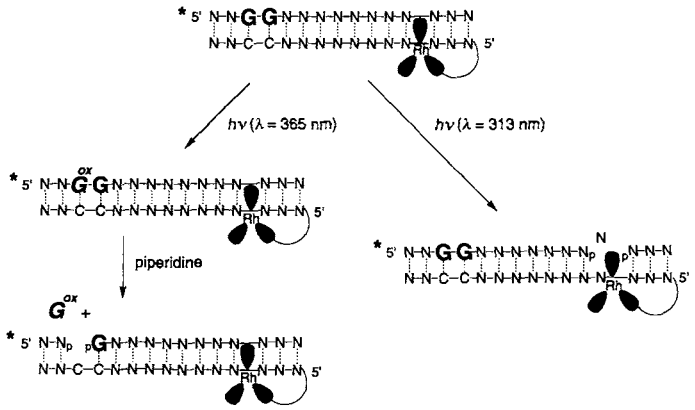
In our studies of DNA as a bridge for electron transfer, we focused on the chemistry of DNA and put aside all considerations of the DNA helix as a biologically important entity. With metallointercalators as donor and acceptor, the DNA π stack can promote photoinduced electron transfer at long range. But can the DNA helix serve not only as a conduit for electron transfer but also as a reactant? Are there reactions within the cell in which radicals migrate through the DNA π stack to damage DNA? The chemistry of the DNA π stack could indeed be an issue in carcinogenesis and mutagenesis. Moreover, might this long-range chemistry be exploited by nature in sensing or repairing DNA damage, or even more generally in transmitting information over long molecular distances with modulation by the DNA π stack? These

intriguing questions were suggested by our studies on DNA as a bridge for electron transfer and some were ready to be investigated using chemistry we developed. Most importantly, it appeared that the sensitivity of electron transfer to the DNA π stack provided a route for exploring and exploiting DNA chemistry over large distances.

4.1. Oxidative DNA Damage by Long-Range Charge Transfer

The major target of oxidative damage of nucleic acid within the cell is guanine (G).[46] Experimental studies and calculations reveal guanine to be the most easily oxidized of the nucleic acid bases.[47,48] A variety of DNA-binding agents including riboflavin, anthraquinone derivatives, and napthalimides are known for inducing, with photoactivation, oxidative damage specifically at the 5′-G of 5′-GG-3′ doublets.[48] $[Rh(phi)_2(L)]^{3+}$ metallointercalators, which serve as potent photoxidants ($E_{1/2}(*Rh^{III}/Rh^{II}) > 2.0$ eV vs. NHE) upon irradiation with low-energy light ($\lambda \geq 365$ nm),[32] might be useful in the study of long-range, DNA-mediated oxidative damage to DNA.

We implemented the strategy outlined in Scheme 2 to investigate DNA damage by long-range oxidation.[49] We prepared DNA duplexes containing 5′-GG-3′ doublet sites and a rhodium intercalator, the oxidant, tethered to one end of the



Scheme 2. Irradiation of a duplex DNA to which a rhodium complex is tethered with UV light permits determination of the site of intercalation (right) as well as the site and extent of long-range oxidation (left).

duplex. In this DNA assembly, the rhodium is separated in a well-defined manner from potential sites of oxidation. Direct strand cleavage of the DNA promoted by irradiation ($\lambda =$ 313 nm) of the rhodium-modified duplex marks the site of intercalation, and permits determination of the distance separating the rhodium complex from potential sites of damage. In contrast, irradiation of the assembly with low-energy light (365 nm) introduces a photoexcited site-specific hole into the DNA base stack and effects oxidation to yield a modified base site. The position and yield of damage is revealed subsequently by treatment of the modified DNA with piperidine, which promotes strand cleavage at the damaged site.

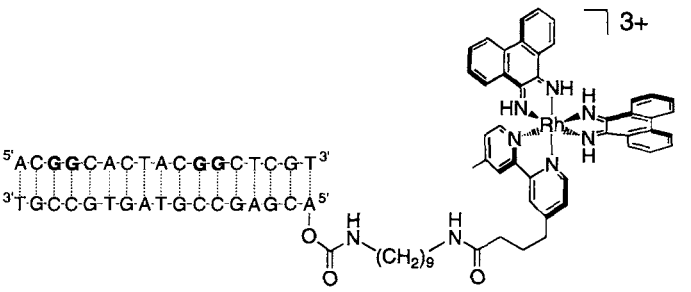


Figure 7. Rhodium-modified DNA duplex assembly constructed for investigating long-range oxidative DNA damage. The sequence shown contains two 5′-GG-3′ doublets (in bold face), potential oxidation sites, which are separated from the intercalated Rh complex by 17 Å and 34 Å [49]. For clarity the Rh complex is not shown intercalated.

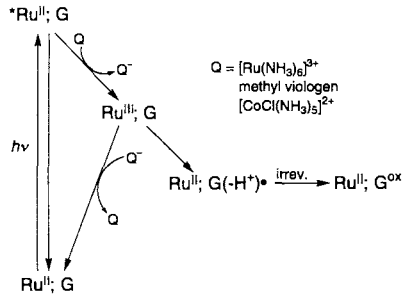
An example of a rhodium-modified assembly containing 5′-GG-3′ doublets is illustrated in Figure 7.[49] In this modified duplex, there is significant oxidative DNA damage specifically at 5′-G of the 5′-GG-3′ sites upon irradiation at 365 nm. Remarkably, this oxidative damage must occur *from a distance*. With the rhodium intercalator tethered to the 5′ end, photocleavage ($\lambda = 313$ nm) indicates intercalation primarily three base pairs from the modified terminus. In fact, for the duplex shown in Figure 7, damage is observed at both 5′-GG-3′ sites located 17 and 34 Å from the rhodium intercalator. Moreover, the intensity of oxidative damage at the site distal to the rhodium complex is comparable to (or even higher than) that of the proximal 5′-GG-3′ doublet; this suggests that the yield of damage is not strongly dependent on distance. If we examine an assembly containing only the distal 5′-GG-3′ doublet, we still see comparable damage; this demonstrates that long-range oxidation of the 5′-GG-3′ doublet does not require the intervening oxidation site.

Although the yield of oxidative damage does not vary significantly with distance, it does depend strongly on sequence, which is known to modulate oxidation potential of the base.[48] A rhodium-modified duplex containing a 5′-GGG-3′ triplet was also constructed.[49] Molecular orbital calculations of the ionization potentials of the DNA bases indicated that 5′-G of the 5′-GGG-3′ triplet is even easier to oxidize than 5′-G of the 5′-GG-3′ doublet.[48b,e] In this assembly, oxidation was observed at the 5′- and central guanine bases of the triplet and, consistent with the calculated ionization potentials, was greatest at 5′-G.

Following enzymatic digestion of the damaged duplex, 8-oxo-G was isolated as the oxidative product. 8-Oxo-G is the primary lesion in cellular oxidative DNA damage. Formation of this product requires O_2. Therefore, while the oxidative reaction in our synthetic system employs rhodium photochemistry, one might consider alternative, perhaps more physiologically relevant means to introduce a hole into the π stack. Our results appear to indicate that, irrespective of the oxidant, once such a hole is introduced into the DNA π stack, it may migrate, leading effectively to oxidative DNA damage from a distance. This characteristic of double-helical DNA—the extended base-paired π stack which facilitates long-range charge transport—is therefore not simply one of chemical novelty. It is instead a characteristic with important implications for DNA mutagenesis and carcinogenesis within the cell.

In fact, many research groups have shown that a range of oxidants can be used to promote guanine damage in DNA; whether these oxidants can also promote damage at long range needs to be established.[48]

We recently found that ruthenium intercalators can also be employed to effect long-range oxidative DNA damage.[50] Scheme 3 illustrates the flash-quench experiment used to oxidize guanines in DNA with ground-state Ru^{III} generated in situ as oxidant. An analogous flash-quench method was employed in classic studies of protein-mediated electron transfer.[51]



Scheme 3. Flash-quench experiment in which Ru^{III} prepared in situ oxidizes guanine in duplex DNA.

This flash-quench chemistry was exciting to us, since it offered another possibility for probing oxidative reactions on DNA from a distance. Moreover, the rhodium photochemistry is exceedingly inefficient and involves an excited-state oxidant. With ruthenium(III) generated in situ, more than a thousandfold increase in quantum yield occurs; the ruthenium complex represents a ground-state oxidant. Moreover, this methodology is particularly well suited for spectroscopic studies; for instance, the neutral guanine radical was identified within DNA by its characteristic transient absorption spectrum.[50a] Furthermore, with ruthenium tethered to a DNA duplex, we also find oxidative damage to DNA from a distance.[50b] Figure 8 illustrates a particularly interesting observation made using this chemistry. As with the rhodium photooxidant, reaction occurs preferentially at a 5′-GG-3′ doublet. But what if the 5′-GG-3′ doublet is removed by mutation? In that case we observed essentially equal oxidative damage distributed over all single G sites. This finding illustrates quite graphically that migration and equilibration of the oxidizing hole across the duplex must occur on a time scale which is fast compared to the trapping reaction. Our finding of damage at a distance with this system also highlights the likely generality of long-range oxidation through DNA. This chemistry may allow us to link the kinetics of these reactions (determined with spectroscopy) and the yield of products of the reaction (determined with biochemical methods) in a detailed mechanistic investigation.

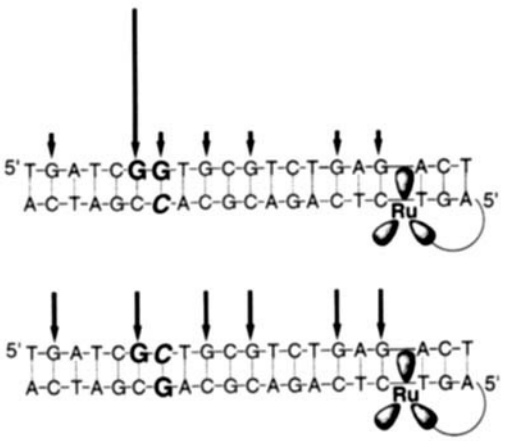


Figure 8. Long-range oxidative damage at guanine bases by tethered Ru^{III} in modified DNA duplexes with (top) and without a 5′-GG-3′ guanine doublet (bottom). With the 5′-GG-3′ site, oxidative damage is observed primarily at the 5′-G of the doublet. Without the 5′-GG-3′ site, oxidative damage is observed to an equivalent extent (indicated by the length of the arrows) at each guanine accross the duplex.

4.2. Sensitivity of Long-Range Oxidative DNA Damage to the Intervening Base-Paired Stack

Like electron transfer between metallointercalators, long-range oxidative damage is remarkably sensitive to stacking. For rhodium-modified oligonucleotides with tethered Δ-$[Rh(phi)_2(bpy)]^{3+}$, the yield of oxidized product is consistently higher than for conjugates with the rhodium center in the Λ configuration.[49] Hence, the deeper stacking of the right-handed metal complex in the DNA appears to enhance the efficiency of the damage.

We wanted to probe the sensitivity of the DNA-mediated reaction to stacking more generally by exploring whether perturbations in the intervening π stack between the donor and the acceptor also affect the oxidation.[52] The assemblies shown in Figure 9 are representative of a family of assemblies

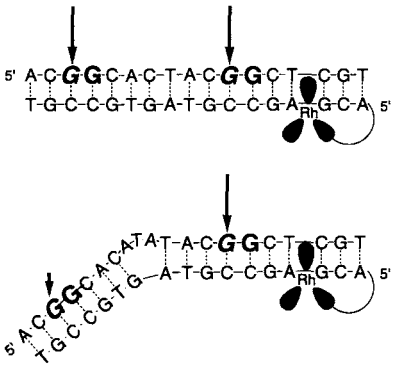

Figure 9. Long-range oxidative damage in rhodium-modified duplexes with a fully base-paired and stacked region (top) or a 5′-ATA-3′ bulged region (bottom) separating two 5′-GG-3′ potential oxidation sites. For the fully stacked duplex, the extent of damage (indicated by the length of the arrows) is nearly identical at both oxidation sites. With the 5′-ATA-3′ bulge, which disrupts the stacking between the distal 5′-GG-3′ site and the Rh intercalator but not the proximal, substantial diminution in the extent of damage at the distal site is observed [52].

prepared; each contains a rhodium oxidant and two 5′-GG-3′ doublets separated by a bulged base region. By comparing the extent of damage at the distal and proximal 5′-GG-3′ doublets in the presence and absence of the intervening bulged region, we could examine the effect of the intervening disruption in base stacking on long-range electron transfer.

Figure 9 shows the assembly containing the ATA bulge, one of the few bulges which has been characterized with high-resolution NMR spectroscopy.[53] From these structural studies it was apparent that the bulge leads to substantial but not complete disruption of the base stack: There is about 75% diminution in oxidation of the distal 5′-GG-3′ doublet compared to the proximal 5′-GG-3′ doublet. Hence, perturbations in the intervening π stack do indeed affect DNA-mediated electron transfer. In fact, these results indicate directly that the long-range hole transfer proceeds through the π stack.

These results also highlight a novel application of this chemistry. Long-range oxidation provides a means for probing the integrity of the base stack in solution. Base-pair stacking is not easily assayed by other techniques. What effects on long-range oxidation would be expected in the presence of covalent lesions to DNA, or if an intervening base were flipped out of the stack, or simply if a DNA-binding protein such as the TATA-box binding protein (which substantially distorts the duplex) were associated? Experiments that address these questions are currently underway.

Lastly, these results not only illustrate oxidative reactions on DNA from a remote site, but also suggest strategies for protecting DNA sequences within the cell from long-range damage by radicals. Oxidative damage to DNA from remote sites may be modulated by the intervening base-pair stack. For example, disruptions in the π stack, caused either by transient openings encoded by sequence or by protein binding, could actually provide a method for protecting DNA.

4.3. Remote Repair of the Thymine Dimer mediated by the DNA Base Stack

The chemistry of electron transfer may be exploited not only in effecting DNA damage but also in initiating the repair of a common light-induced DNA lesion, the thymine dimer.[54] Bacteria such as *E. coli* utilize photolyase enzymes to repair the thymine dimer photochemically.[55] In the key step of this process, visible light ($\lambda = 350-450$ nm) induces an electron transfer from an enzyme-bound flavin to the dimer, initiating repair. In model studies using photoexcited reductants, repair of the thymine dimer in duplex DNA was observed with high-energy irradiation ($\lambda \leq 300$ nm).[56] Excited-state oxidants which remove an electron from the dimer were shown to repair pyrimidine dimer model compounds when ultraviolet light (≤ 300 nm) was used to start the process.[57] Based on these results, we expected that excited-state rhodium metallointercalators, as powerful oxidants, might trigger repair of the thymine dimer in duplex DNA by injecting a photoexcited hole directly into the DNA base stack. Moreover, the thymine dimer and its repair, initiated simply by electron transfer, offered an attractive trapping reaction for characterizing parameters of DNA-mediated chemistry.

We found first that upon excitation with visible light ($\lambda = 400$ nm), $[Rh(phi)_2(dmb)]^{3+}$ (dmb = 4,4′-dimethyl-2,2′-bipyridine) initiated repair of a thymine dimer incorporated site-specifically in the center of a synthetic 16-mer oligonucleotide duplex ([duplex]:[$[Rh(phi)_2(dmb)]^{3+}$] = 1:1).[54] The repair mechanism is thought to proceed by oxidation of the dimer ($E_{1/2}(^{+}\widehat{TT}/\widehat{TT}) \approx 2.0$ V vs. NHE)[55] by the intraligand excited state of the rhodium complex, in which an electron deficiency (hole) is localized on the intercalated phi ligand.[32] Quantitative repair was also observed with concentrations of the rhodium complex as low as 500 nM and a 16-fold excess of DNA duplex (6.25 mol% $[Rh(phi)_2(dmb)]^{3+}$), indicating that the process is catalytic in rhodium. Treatment of damaged DNA with the rhodium catalyst and bright sunshine also removed the lesion completely. In these experiments, the noncovalently bound rhodium intercalator is free to sample all intercalation sites along the length of the duplex.

We next considered whether the DNA helix might facilitate oxidative repair over long ranges. We prepared dimer-containing duplexes possessing a Rh^{III} intercalator covalently tethered to one end to examine repair of the thymine dimer from a distance (Figure 10). Photocleavage of these rhodium-modified duplexes upon irradiation ($\lambda = 313$ nm) indicated

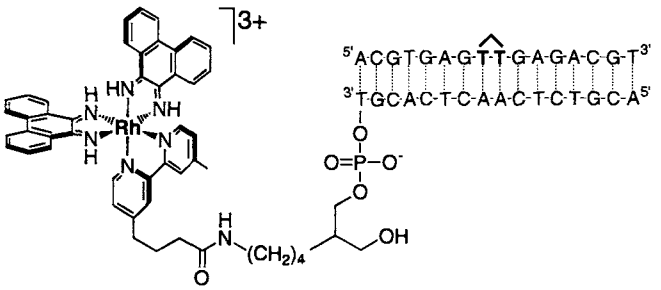

Figure 10. Rhodium-modified DNA duplex bearing a thymine dimer ($\widehat{TT}$) [54]. In the assembly shown, the Rh complex is tethered to the 3′-terminus of the modified oligonucleotide, which places the oxidant on 5′-side of the dimer. Application of oligonucleotides bearing the Rh photooxidant at either the 3′- or the 5′-terminus permits evaluation of the importance of directionality in the electron transfer.

intercalation up to four base steps from the end of the duplex, establishing that the metal center and the thymine dimer are separated by 19–26 Å through the DNA base stack. Irradiation with visible light ($\lambda = 400$ nm) also initiated dimer repair in these tethered assemblies (Table 3). Moreover, dilution and mixing experiments confirmed that the long-range repair reaction was intraduplex, and not catalyzed by rhodium tethered to a separate assembly.

How does repair efficiency vary as a function of distance and stacking? As seen in Table 3, increasing the separation between the thymine dimer from 19 to 26 Å produces only small changes in repair efficiency. As with guanine oxidation, the repair reaction is not very dependent on distance (over this range of distance), but is quite sensitive to stacking. In fact, repair efficiency is not only affected by the stacking of the catalyst but also that of the dimer and the intervening base pairs within the helix. We observed first the consistently greater repair efficiency with Δ than with Λ isomers, reflecting the deeper stacking of the right-handed metal complex into the right-handed DNA helix. We also see comparable repair efficiency in reactions with rhodium tethered to the 3′- or 5′-side of the dimer, and consequently infer that stacking on the 3′- and 5′-sides of the thymine dimer within the helix is not

Table 3. Long-range repair of thymine dimers in DNA duplexes modified with Δ-Rh [a].

[a] Based on ref. [54]. [b] Distances between catalyst and thymine dimer were based on intercalation at the sites indicated. There is a separation of 3.4 Å adjacent base pairs as well as between the intercalated phi ligand and the first base step. [c] Expressed as the percentage of thymine dimer repaired after six hours of irradiation ($\lambda = 400$ nm).

substantially different. Importantly, as expected for a π stack mediated reaction, the repair is sensitive to the stacking of base pairs between the rhodium and the dimer. The decrease in repair efficiency caused by intervening bulges in the DNA illustrates this sensitivity dramatically and confirms that the DNA base stack mediates the reaction (Table 3).

Based on these data, it is interesting to compare repair efficiency by rhodium, tethered or bound noncovalently to DNA. Repair with the tethered complex is substantially (about 30-fold) reduced compared to the noncovalently bound catalyst. Given that the efficiency does not appear to be very sensitive to the distance separating the rhodium complex and dimer, the difference in efficiency may instead reflect features of how the thymine dimer is stacked within the duplex or perhaps also how the tethered rhodium is intercalated in the helix. The lower repair efficiency in rhodium-modified duplexes may indicate that the thymine dimer is not fully stacked in the helix to either its 3′- or 5′-side. Indeed, while our studies show that long-range oxidative repair through DNA is possible, the decreased efficiency of reactions with tethered rhodium (which are mediated by the helix) actually suggest that it may be advantageous in an enzymatic repair to project the thymine dimer fully out of the helix for efficient reaction. This was proposed based on the crystal structure of DNA photolyase.[55]

These results illustrate how a physiologically important reaction of DNA may be carried out using electron transfer, and, if mediated by the DNA base stack, how it may proceed upon activation from a distance. Reactions on DNA initiated from a remote site and modulated by base-pair stacking need to be considered in evaluating charge-transfer processes involving DNA within the cell and may actually be powerfully exploited.

5. Questions Concerning DNA-Mediated Charge Transfer

Although the concept of long-range charge transfer through DNA was recognized by many researchers, DNA is not seen as a remarkable electron transfer medium by all. The fact that studies of photoinduced electron transfer on DNA appear so different from analogous studies with proteins as a medium is surprising to some. On the other hand, given the chemical differences between the π-stacked DNA helix and largely σ-bonded network of a protein, such differences might be expected. Our understanding of DNA-mediated electron transfer is certainly less well developed at this point than that of proteins as a medium.

As in studies with proteins, experiments on DNA began with noncovalently bound donors and acceptors;[58] the results obtained here varied enormously depending upon the donors and acceptors employed. While with tightly bound metallointercalators we often saw fast, efficient luminescence quenching,[9, 25, 31, 33, 34, 38, 40] with some organic DNA-binding agents, notably with ethidium as photoinduced donor and DAP as acceptor, fast quenching was not observed.[10] We have attributed such variations in rates and efficiency to the efficacy of donor and acceptor coupling into the π stack. The comparison of photoinduced quenching of $[Ru(phen)_2(dppz)]^{2+}$ luminescence by $[Rh(phi)_2(bpy)]^{3+}$, an avid intercalator, with quenching by $[Ru(NH_3)_6]^{3+}$, a groove-binding agent, is a clear cut example.[31] With $[Rh(phi)_2(bpy)]^{3+}$ photoinduced quenching is faster than expected for a collisional mechanism, while dynamic quenching by $[Ru(NH_3)_6]^{3+}$ is consistent with such a mechanism. We also find differences in rates of electron transfer between enantiomeric metal complexes bound to the helix,[9, 34] which reveal that the reaction is sensitive to subtle variations in stacking. However, not all observations may be so neatly categorized. For example, we see no substantive quenching with $[Rh(phen)_2(phi)]^{3+}$, and we have ascribed the absence of fast quenching to poor overlap of the shape-selective DNA-binding agent with the π stack.[33] Using a metalloporphyrin as donor, Brun and Harriman also showed that the kinetics of electron transfer mediated by DNA need not be fast.[10h] Here too one may ascribe the lack of a fast reaction to poor overlap of the metal complex with the DNA base pair stack; the subsequent crystallographic analysis of a metalloporphyrin bound to DNA shows base displacement rather than stacking.[59] Certainly, based on the range of results obtained thus far, a clear quantitative parameter that one might use to gauge whether fast DNA-mediated electron transfer should arise has not yet emerged.

As noted earlier, some research groups have indicated that the fast quenching we observed might be explained more simply in terms of clustering.[35, 36] A straightforward explanation for static quenching on a time scale which is fast compared to diffusion is that no diffusion is necessary; if the metal complexes bind cooperatively on the helix, they would be placed in a manner to facilitate rapid electron transfer. Barbara and co-workers[35] offered an extensive analysis of the ultrafast quenching data for Δ-$[Ru(phen)_2(dppz)]^{2+}$ and Δ-$[Rh(phi)_2(bpy)]^{3+}$ bound to calf-thymus DNA, and show

that these data may be explained based on cooperative clustering. However, no analysis is provided for Λ-$[Ru(phen)_2(dppz)]^{2+}$, which shows a different, albeit fast, quenching profile. Nor are data provided for any of the other metal complexes, which differ with respect to hydrophobicity in the ancillary ligands and hence might be expected also to differ with respect to cooperativity.

There are many other questions raised by such a model, as noted earlier. Why should there be differences in rates of recombination with the same donor and acceptor but on different DNA sequences? Why is cooperative clustering supposed to occur between ruthenium and rhodium but not for each separately? What is the basis for clustering between ethidium (which lacks ancillary bulk) and rhodium, since such clustering must be invoked here as well to account for the fast quenching observed? What is the structural basis for this supposed cooperative association? In fact, the only experimental observation provided to support a clustering model is an ill-defined perturbation in the circular dichroism of Δ-$[Ru(phen)_2(dppz)]^{2+}$ and Δ-$[Rh(phi)_2(bpy)]^{3+}$ bound to poly d(AT) at high loadings.[36] Our more recent investigation of CD shows this earlier study to be incomplete. Both a more extensive CD study and an examination of DNA binding by NMR spectroscopy show that the metallointercalators bind noncooperatively, perhaps even anticooperatively, to the DNA duplex. Nonetheless, this whole issue underscores the importance of structural characterizations of DNA-bound donors and acceptors. Our results establish, at the very least, the striking sensitivity of DNA-mediated electron transfer to how donors and acceptors are bound to the helix.

Clearly, a clustering model can never be definitively ruled out for different species bound noncovalently to DNA, but it cannot be applied in reconciling data for systems in which electron donors and acceptors are tethered to DNA duplexes at known, fixed positions. With tethered intercalators, we examined electron transfer between metallointercalators tethered to a 15-mer DNA duplex,[40] and between ethidium and $[Rh(phi)_2(bpy)]^{3+}$ tethered to a series of DNA duplexes.[43] These results clearly support quenching of long-range electron transfer and are fully consistent with observations made with noncovalently bound complexes. However, in these studies we are able to measure only quenching (that is, the absence of luminescence), and therefore the interpretation of a striking long-range electron transfer rests primarily on a series of negative results. It is important to carry out ultrafast transient absorption experiments on these tethered DNA assemblies to measure rates of electron transfer. These studies will be challenging, however, since fast time resolution and low concentrations (to insure intramolecularity) are needed. In this context, experiments with noncovalently bound intercalators provide a valuable foundation.

In fact, it was because of the possible ambiguity in interpreting quenching studies that we first turned to studies with DNA as a reactant.[48–50, 52, 54] If we can measure a product of electron transfer at a distance away from the source of charge transport, then, irrespective of the time scale, one can document definitively a long-range effect. Hence, from this perspective, as well as in a biological context, our studies of oxidative damage to DNA over a long range using tethered oxidants have been important. Here, critics question the poor efficiency of the reaction. The quantum yield for oxidative damage is 10^{-7} for the rhodium oxidants; in fact, all photochemistry with these rhodium complexes is inefficient ((photoaquation) $= 10^{-4}$), owing in part to other overlapping transitions. With ruthenium(III) as oxidant, using the flash-quench methodology,[50] we found a quantum yield for damage over a distance of >30 Å of 0.002 with methyl viologen as quencher; this yield seems reasonably high considering the alternate reaction pathways available to ruthenium. Given this increased yield and the completely parallel observations made with the ruthenium and rhodium photochemistry, it becomes difficult to characterize these studies as merely the result of statistical fluctuations or "leakage". As shown by spectroscopic studies, these long-range reactions depend sensitively on stacking of the donor and the acceptor, and on structural perturbations in the intervening DNA helix. Moreover, in the case of long-range oxidative repair of thymine dimers in DNA,[54] conversion into repaired product is quantitative and triggered simply by electron transfer (requiring no additional, diffusing species). While it is still important to emphasize that these experiments do not provide a measurement of the rate of long-range electron transfer, they unambiguously establish chemistry over a distance.

Few theoretical treatments of DNA as a medium for electron transfer have been described, and here too there is much to debate. Beretan and co-workers[42c–d] described calculations which indicate that DNA is protein-like and serves as an insulator. These calculations show agreement with some kinetic data reported by Meade[39] and Harriman,[10] and show differerences of several orders of magnitude to our measurements of the quenching of electron transfer with covalently bound metallointercalators. The calculations, however, do not take into account any coupling that arises due to stacking, either of the bases or intercalators. Furthermore, no variations were made in sequence or base structure to establish a sensitivity in parameters to such changes, as was seen experimentally. Using calculations based upon Redfield theory, Friesner and co-workers[42a] suggested how base stacking could give rise to a delocalized "band", which might facilitate long-range charge transfer without a significant distance dependence. In fact, this work provides a prediction for experimentalists to pursue, namely that low temperatures should eliminate thermal access to this band and shut down the electron transfer. Calculations made more than twenty years ago[6] also led to substantial debate regarding both the energetics and mechanisms of long-range electron transfer. It is our view that more experimental data are needed to provide a firm foundation upon which theorists may build. At this stage hopping models, charge delocalization, and band theory all offer interesting perspectives from which our experiments may be interpreted, but experiments to distinguish between these models have not yet been established.

6. Summary and Outlook

Here we have described a range of charge-transfer reactions mediated by the DNA base pair stack. The reactions

proceed quickly and efficiently between donors and acceptors which are well coupled into the π stack. These reactions do not appear to depend sensitively upon the molecular distances between reactants but are exquisitely sensitive to stacking, the stacking of donor and acceptor, also the stacking of the bases which intervene.

These results provoke a host of questions and new experiments. Over what molecular distances can charge effectively be transported through DNA? We need to develop assays to examine reactions over 50–100 base pairs, not 10–20, as explored thus far. What are the rates of these reactions? Our instrumentation has allowed us only to place limits on rates for photoinduced quenching, and no systematic determination of how rates vary with distance and sequence was made. Such data are essential in developing a theoretical framework to describe this chemistry. We need also to understand how these reactions vary with temperature and with changes in nucleic acid conformation. Importantly, we need to develop quantitative parameters to describe stacking within the double helix and how such stacking affects electronic coupling in DNA.

Perhaps most intriguing are some of the biological consequences of this chemistry. Does radical damage to DNA arise from a distance within the cell? Are there cellular mechanisms which insulate sequences from such damage or through which the positioning of damage is controlled? Might such long range chemistry be exploited in new chemotherapeutic design or in the development of novel nucleic acid based sensors? Is long-range charge transport through DNA exploited within the cell for long range transmission of information across the DNA library? These questions are certainly provocative. They nonetheless represent important challenges for the future and, based upon future work, should become implicit to our understanding of the chemistry of DNA.

We are grateful to the National Institutes of Health (NIH) for their financial support of this work. We are also most grateful to our co-workers for their efforts in elucidating this chemistry. Their scientific contributions have been referenced throughout this review. This work began as a collaboration with C. V. Kumar and N. J. Turro, and it has been a most rewarding journey from those first experiments.

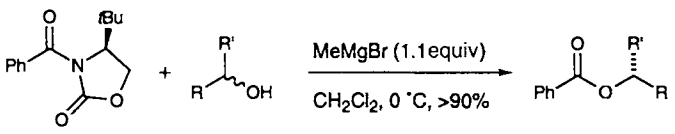
Nonenzymatic Kinetic Resolution of Secondary Alcohols

Peter Somfai*

Secondary alcohols are an important class of readily derivatizable compounds that can be incorporated into a variety of synthetic strategies. The kinetic resolution of these compounds, or more often of their corresponding acetates, has traditionally been achieved by using esterases and often with excellent results.[1] Recent developments of this approach, in which metal catalysts were used to racemize the substrate, led in combination with appropriate enzymes to efficient dynamic kinetic resolutions.[2] The nonenzymatic kinetic resolution of racemic alcohols has proven to be more difficult, the only prominent example being the Sharpless resolution of allylic alcohols;[3] recently, however, several impressive results have been documented. In principle, four strategies have been pursued with varying degrees of success. In the most straightforward one a preformed enantiomerically pure acylating agent, such as an acyl halide[4] or *N*-benzoyl oxazolidinone **1**,[5] is treated with a racemic secondary alcohol **2** to give the acylated product **3** and recovered starting material (Scheme 1). The inherent drawbacks with this

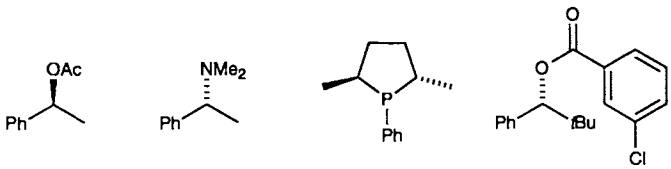


1 (1equiv) **2** (10equiv) **3a** *ee*=95%
a R=Ph, R'=Me **b** *ee*=65%
b R=Ph, R'=*i*Pr **c** *ee*=5%
c R, R'=*c*-C_6H_{11}, Me

Scheme 1. Kinetic resolution of **2** with oxazolidinone **1**[5].

method are that a stoichiometric amount of the chiral reagent is required and, in the case of the acyl halide, that the acylated product will be formed as a mixture of diastereomers unless the dynamic resolution reaction proceeds with complete selectivity.

Alternatively, advantage can be taken of the fact that the acylation of secondary alcohols is subjected to nucleophilic catalysis. In a pioneering study more than 60 years ago Wegler investigated the acylation of several racemic secondary alcohols mediated by brucine and strychnine.[6] For example, when racemic **2a** was treated with acetic anhydride in the presence of stoichiometric amounts of brucine, (*S*)-α-methylbenzyl acetate ((*S*)-**4**) was formed, although its optical purity cannot be ascertained from the data given. More recently the efficiency of other tertiary amines as acylation promoters have been investigated; the best result for the acylation of **2a** was obtained with amine **5** (**2a**:AcCl:**5**=2:1:1) and yielded (*S*)-**4** with an optical purity of 68%.[7]



(*S*)-**4** **5** **6** **7**

The first example of a chiral nucleophilic promoter that is also capable of catalytic turnover was described by Vedejs et al.,[8] who showed that acylation of **2a** with Ac_2O in the presence of the C_2-symmetric phospholane **6** (**2a**:Ac_2O:**6**=1:2.5:0.16) gave **4** with an *ee* of 34% (44% conversion, $s=k_{fast}/k_{slow}=2.7$), while racemic 2,2-dimethyl-1-phenylpropanol was acylated with *m*-chlorobenzoic anhydride under the same reaction conditions to yield the corresponding ester **7** (*ee*=81%, 25% conversion, $s=12-15$).

In a continuation of these studies the enantiomerically pure DMAP analogue **8** (*ee*>99%, DMAP=4-dimethylaminopyridine) was prepared by the same group and converted into the pyridinium salt **9** (Scheme 2), which for steric reasons is not sufficiently reactive to promote acyl transfers to alcohol **2** by itself.[9] However, in the presence Lewis acids ($ZnBr_2$ or $MgBr_2$) and Et_3N, neither of which can be omitted, a slow acylation ensues to give the mixed carbonates **10** with high *ee* and impressively high *s* values.

The inherent problem with these resolutions is that the starting material becomes continuously enriched in the isomer that reacts more slowly as the reaction proceeds. Exceptionally large differences in rate between the enantiomers are thus required to obtain high *ee* values of the product, as well as of the enriched isomer in recovered starting material, together with high conversion (e.g. at 50% conversion, $s=200$, *ee*=96%; $s=500$, *ee*=98%). In an attempt to overcome this

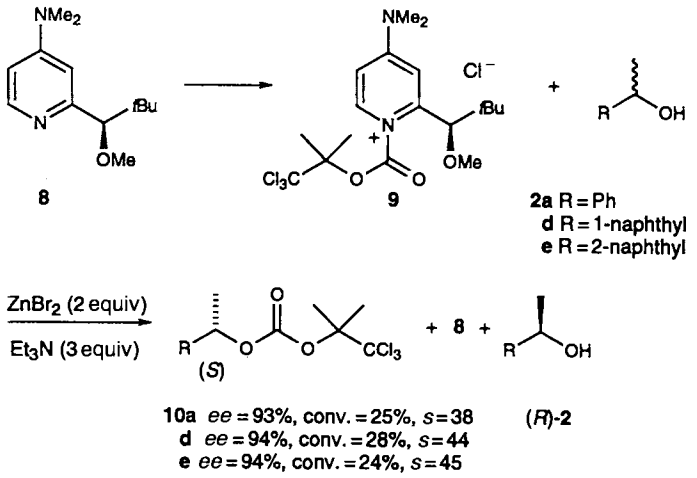
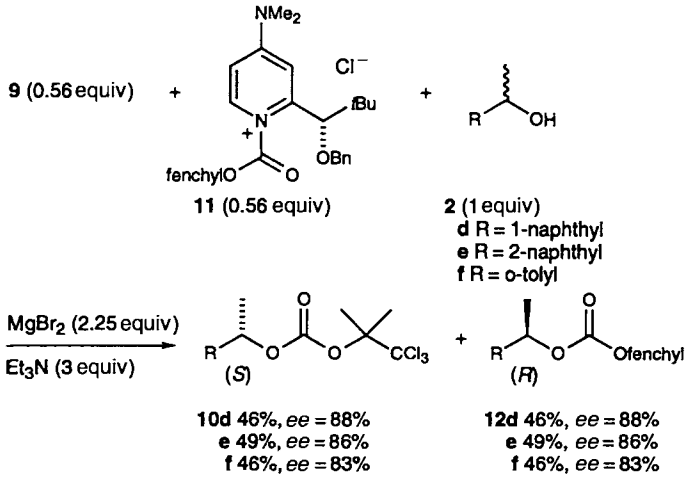


Scheme 2. Kinetic resolution of **2** with pyridinium salt **9**[9]. $s = k_{fast}/k_{slow}$.

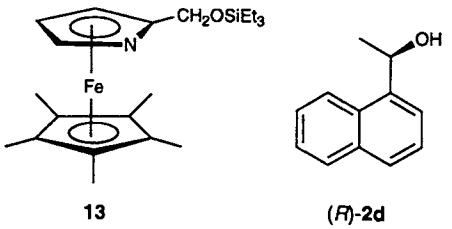
difficulty, an ingenious protocol was developed by Vedejs and Chen in which two competing processes, with similar rates and selectivities but for opposite enantiomers, are run in parallel (parallel kinetic resolution, PKR), so that the optimal 1:1 ratio between the stereoisomers is maintained throughout the experiment.[10] The advantages can be appreciated by considering a PKR experiment in which two simultaneous reactions with selectivities for opposite isomers, each with $s = 49$ (100% conversion): ideally, this system would give both products with an *ee* value of 96%. In contrast, in order to equal this result a simple kinetic resolution would need to have $s = 200$ (50% conversion). Reagents **9** and **11** were selected as they were expected to behave as quasi-enantiomers and acylate opposite enantiomers of racemic secondary alcohols to give products that could be readily separated. In the event, when **9** and **11** were treated with three different aromatic secondary alcohols the corresponding carbonates were formed in high yield and *ee*, clearly demonstrating the potential of the method (Scheme 3).

In addition, two other research groups have described useful nucleophilic catalysts for the kinetic resolution of secondary alcohols. Ruble and Fu showed that azaferrocene **13**, which has a stereochemical environment in the proximity



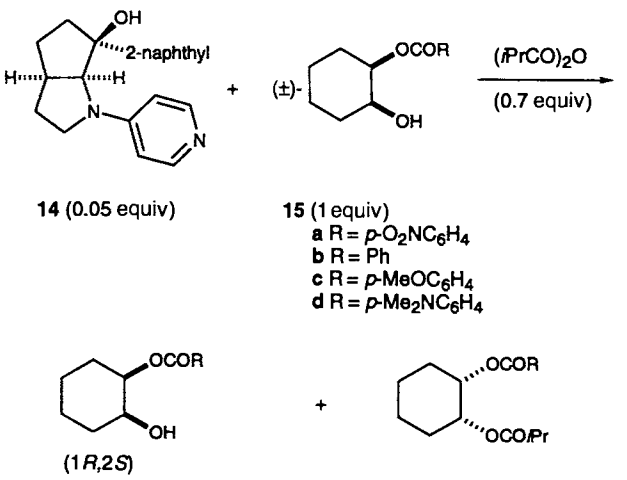
Scheme 3. Parallel kinetic resolution of **2**[10].

of the nitrogen atom quite different from that of **8**, catalyzes the acylation of **2d** with diketene (**2d**:diketene:**13** = 1:1.2:0.1) to give (*R*)-**2d** with *ee* = 87% (67% conversion, $s = 6.5$).[11] In



addition, compound **13** and derivatives thereof were shown to be promising catalysts for other transformations requiring nucleophilic promoters.

A completely different approach was pursued by Fuji and co-workers.[12] They prepared enantiomerically pure pyridine derivative **14**, reasoning that the reduced steric hindrance in the proximity of the nitrogen nucleus should result in efficient catalytic turnover and that chiral recognition might be possible by remote asymmetric induction in a process similar to the "induced fit" mechanism in enzymes. When **14** was treated with racemic **15b** and isobutyric anhydride, (1*R*,2*S*)-**15b** was recovered with *ee* = 81% (71% conversion, $s = 4.5$, Scheme 4). Interestingly, the optical purity of the recovered



15a *ee* = 54%, conv. = 73%, $s = 2.4$
b *ee* = 81%, conv. = 71%, $s = 4.5$
c *ee* ≥ 85%, conv. = 70%, $s = 5.3$
d *ee* ≥ 99%, conv. = 72%, $s > 10.1$

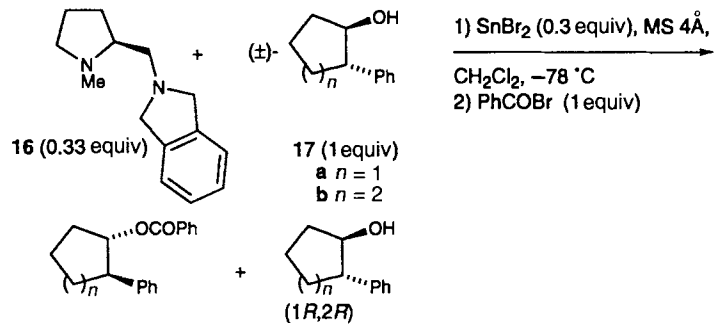
Scheme 4. Kinetic resolution of **15** with pyridine derivative **14**[12].

alcohol is dependent on the electron-donating ability of the aromatic nuclei in the substrate, possibly indicating that $\pi-\pi$ stacking plays a pivotal role in the enantiodifferentiating event. It was also shown that the pyridinium ion derived from **14** and isobutyric anhydride adopts a "closed conformation", in contrast to **14** itself, in which the naphthyl moiety is situated over the pyridine ring, thus shielding the *si* face of the carbonyl group and supporting the "induced fit" concept.

The kinetic resolution of secondary alcohols is also subjected to asymmetric Lewis acid catalysis, as described in

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2732 $ 17.50+.50/0 *Angew. Chem. Int. Ed. Engl.* **1997**, *36*, No. 24

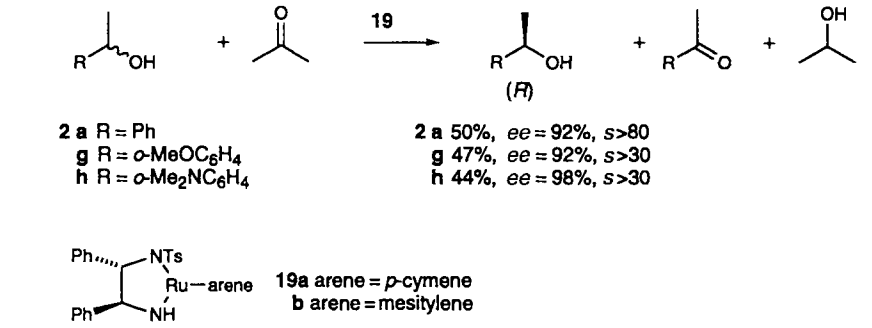
a recent elegant study by Oriyama et al.[13] The complex formed by mixing $SnBr_2$ and amine **16** derived from proline in the presence of molecular sieves catalyzed the benzoylation of racemic **17** to give benzoate **18** along with recovered (1*R*,2*R*)-**17** in exceptional yields and selectivities (Scheme 5). In the investigation with several other alcohols, the cyclic species generally performed better than the acyclic ones.



18a $n = 1$; 44%, $ee = 86\%$ **17a** 46%, $ee = 86\%$, $s = 27$
b $n = 2$; 44%, $ee = 97\%$ **b** 49%, $ee = 84\%$, $s > 100$

Scheme 5. Lewis acid catalyzed kinetic resolution of **17**[13].

Finally, Noyori and coworkers have shown that chiral Ru^{II}–diamine complexes are efficient catalysts for the enantioselective transfer hydrogenation of several prochiral ketones, using 2-propanol as the hydrogen source, to give the corresponding alcohols with high *ee* values.[14a] The reaction is microscopically reversible and the faster formed stereoisomer of the product is also the one that is most readily oxidized in the reverse process. Consequently, secondary alcohols with a high reduction potential should be eligible for kinetic resolution with these types of catalysts.[14a,b] That this is indeed the case was elegantly demonstrated with the Ru^{II} complex **19a**, or the mesitylene derivative **19b** (Scheme 6).



2a R = Ph **2a** 50%, $ee = 92\%$, $s > 80$
g R = o-MeOC$_6$H$_4$ **g** 47%, $ee = 92\%$, $s > 30$
h R = o-Me$_2$NC$_6$H$_4$ **h** 44%, $ee = 98\%$, $s > 30$

19a arene = *p*-cymene
b arene = mesitylene

Scheme 6. Ru^{II}-catalyzed kinetic resolution[14b].

Several alkyl aryl carbinols were successfully resolved by using **19** with excellent recovery of unchanged substrate with high *ee* values. Two cyclic allylic alcohols, 2-cyclohexen-1-ol and 3-methyl-2-cyclohexen-1-ol, were also suitable substrates in this resolution, both of which are particularly valuable substrates in organic synthesis. Although this transformation superficially bears resemblance to the Oppenauer oxidation it has unequivocally been shown that the Ru^{II}-catalyzed kinetic resolution proceeds by an 18-electron metal hydride species and not by a metal alkoxide intermediate, as is the case for the latter transformation.[14c]

In summary, scalemic secondary alcohols can be obtained by nonenzymatic kinetic resolution and in some cases with excellent selectivities. Although these results in general fall short when compared with those obtained with the esterase-promoted resolutions, it is expected that a more thorough understanding of the enantiodiscriminating event in these processes will result in the development of even more efficient catalysts.

Valence Tautomeric Interconversion in Transition Metal 1,2-Benzoquinone Complexes

Philipp Gütlich* and Andrea Dei

Transition metal complexes with electronically labile ground states exhibiting interconversion between states of similar energy have been subject to extensive study in recent years. Mixed valency,[1] spin crossover,[2] and valence tautomerism[3,4] are some of the dynamic electronic processes that have attracted the attention of many research groups. One of their goals is to explore the factors inducing and affecting intramolecular electron transfer between metal centers in mixed-valence complexes, between different spin states in spin-crossover systems, or between the metal center and redox-active ligands in valence tautomers. There is, in fact, also hope that these electronic switching processes will provide the foundation for application in molecule-based devices.[5]

The concept of valence tautomerism was introduced to define the properties of a molecular adduct $A-D^+$ (A = acceptor, D = donor) whose electronic ground state is described by two or more isomers with different charge distributions. The interconversion between the different valence tautomers is accomplished by an intramolecular electron transfer according to Equation (a).

$$A-(D^+) \rightleftharpoons (A^+)-D \qquad (a)$$

To obtain molecular adducts characterized as valence tautomers, two conditions must be simultaneously satisfied: The degree of covalency in the interaction between A and D must be low, and the energy of the frontier orbitals of the two counterparts must be similar. The coexistence of both these conditions is hard to achieve, and, to our knowledge, only a few transition metal complexes of 1,2-benzoquinone exhibit this unusual property.[3,4] The behavior of this class of metal complexes originates from the small changes in free energy associated with the semiquinonato/catecholato (sq/cat) couples and from the fact that the electronic structures of the metal–1,2-benzoquinone complexes can often be described with localized electronic structures. Therefore, due to the low orbital mixing, there is a possibility for the existence of isomers differing in charge distribution. Consequently, when the energy difference between two electronic tautomers is small, intramolecular electron transfer between the metal and the ligand may occur to give rise to a valence tautomeric equilibrium.[6] From a phenomenological point of view the process is associated with large changes in structural, optical, and magnetic properties of the molecular systems.

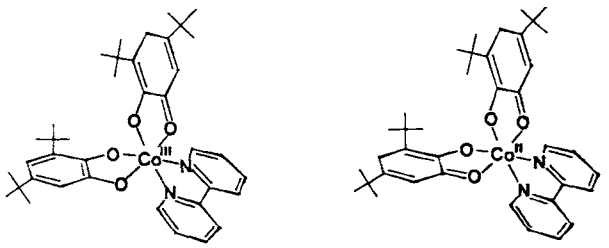
Prof. Dr. A. Dei
Dipartimento di Chimica, Università di Firenze (Italy)

The first report of this fascinating chemical phenomenon appeared in 1980.[7] The complex [Co(bpy)(dbsq)(dbcat)] (where bpy is 2,2′-bipyridine, and dbsq and dbcat are the semiquinonate and catecholate forms of 3,5-di-*tert*-butyl-1,2-benzoquinone) was shown to contain low-spin cobalt(III) in the solid state. However, the unusual temperature dependence of the magnetic and spectral properties of this complex in solution led to the postulation that the equilibrium shown in Scheme 1 exists.



Scheme 1.

The two tautomers are related by an intramolecular one-electron transfer between the catecholate ligand and the cobalt(III) ion as well as a spin change $S=0 \rightarrow S=3/2$ at the cobalt center. This is in agreement with the change in the magnetic moment of the complex from 2.3 μ_B at low temperatures, at which the low-spin (ls) cobalt(III) tautomer with one unpaired electron at the sq ligand predominates, to 4.3 μ_B at higher temperatures, at which the complex is in the high-spin (hs) cobalt(II) form with one unpaired electron at each of the two sq ligands.

Following this first example, other metal–1,2-benzoquinone derivatives were found to undergo valence tautomerism. To date, however, the cobalt–1,2-benzoquinone complex is the only system involving valence tautomers whose electronic ground states are characterized by different spin multiplicities. For possible application it is necessary that the transition between two different electronic states is sharp and exhibits hysteresis effects. Therefore, attention has been focused on the molecular control of valence tautomerism of cobalt–1,2-benzoquinone complexes in the solid state.

The simple idea of controlling the interconversion equilibrium by systematically varying the redox potential of the cobalt acceptor offered the first significant breakthrough. In the family of $[Co(N-N)(diox)_2]$ complexes (N–N = diimine ligand, diox = 1,2-benzoquinone derivative) the solution critical temperature T_c (at 50% concentration of either tautomer) of the interconversion is systematically shifted depending on the donor ability of the N–N ligand.[8,9] Solid samples containing either pure $[Co^{III}(N-N)(dbcat)(dbsq)]$ or

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2734 $ 17.50+.50/0

$[Co^{II}(N-N)(dbsq)_2]$ at room temperature were isolated. Finally, it was established that valence tautomeric equilibrium can be thermally induced in the solid state. Data on magnetic susceptibility obtained at various temperatures showed that toluene-solvated $[Co(phen)(dbsq)_2]\cdot C_6H_5CH_3$ (phen = 1,10-phenanthroline) undergoes a reversible conversion between hs-Co^{II} and ls-Co^{III} tautomers, and that this interconversion occurs abruptly in the temperature range 220–260 K with a small hysteresis of 5 K. The X-ray structure analysis of this complex at 295, 238, and 137 K fully supports this hypothesis; the pattern of bond lengths indicates $[Co^{II}(phen)(dbsq)_2]$ at high temperatures and $[Co^{III}(phen)(dbcat)(dbsq)]$ at low temperatures.[9] The change in the average metal–ligand bond length is 0.18 Å as a consequence of the drastic change in the population of the antibonding e_g^* orbitals: $(t_{2g})^6$(ls-Co^{III}) $\rightarrow (t_{2g})^5(e_g^*)^2$(hs-$Co^{II}$). The presence of the toluene molecule is rather critical. The nonsolvated complex remains in the Co^{II} tautomeric form from 320 to 2 K. Studies on similar cobalt–1,2-benzoquinone complexes revealed the existence of valence tautomeric interconversion in the solid state.[10–12]

Very recently it was found that the interconversion can be driven by pressure as well as by changes in temperature.[13] Samples of both the nonsolvated and toluene-solvated complexes discussed above were subjected to increasing pressures at room temperature, and XANES (X-ray absorption near-edge spectroscopy) revealed the occurrence of valence tautomeric interconversion. This occurred at relatively low pressures for the toluene-solvated derivative, that is, in the range of 0.075 to 0.700 Gpa ($P_C\uparrow = 0.370$ Gpa; P_C is concentration of 50% of either tautomer). A much higher pressure was required for the conversion of the nonsolvated derivative ($P_C\uparrow = 1.1$ Gpa), which at ambient pressure exists in the Co^{II} form down to 2 K.

Further experiments showed that the interconversion may also be photoinduced. The photoelectron spectrum of solid $[Co^{III}(bpy)(dbsq)(dbcat)]$ was recorded during irradiation with a mercury lamp.[4] In the absence of light the expected Co^{III} spectrum was obtained. When the sample was irradiated, multiple satellites indicating the presence of the Co^{II} form were detected. Furthermore, a polymeric pyrazine-bridged $[Co^{III}(cat)(sq)]$ complex was prepared and characterized.[14] This compound exhibits, like all these Co^{III} complexes, an intense transition at 2500 nm, which was attributed to a ligand-to-metal charge transfer (LMCT); however, it is more likely due to a metal-mediated intervalence transition of the 1,2-benzoquinone ligands. When thin crystals of these compounds were irradiated with a tungsten lamp, rare photomechanical effects were observed. This behavior was attributed to cumulative structural changes associated with the valence interconversion, which propagate along the chain length of the polymer. Similar photomechanical effects were observed in crystals of [Co(bpy)(3,6-dbsq)(3,6-dbcat)].[10]

Picosecond laser flash photolysis studies on these cobalt complexes provided more detailed information on the nature of this interconversion.[15] A pump laser pulse into a LMCT band of the Co^{III} tautomer in the visible spectrum induces a transient absorption of a Co^{II} band and a corresponding transient bleaching of the Co^{III} band. Since the two transients are characterized by identical kinetics, it was suggested that the tautomerization is described by a first-order reaction. Apparently, there is no evidence for the existence of a ls-Co^{II} form, which in principle may be expected to be the reasonable intermediate species in the electron transfer.

All the available data indicate that the interconversion between the cobalt valence tautomers is similar to that associated with spin-crossover complexes.[2] The thermodynamic quantities ΔH and ΔS of the equilibrium involving [Co(bpy)(dbsq)(dbcat)] in the solid state are 32 kJ mol^{-1} and 98 J mol^{-1} K^{-1}, respectively.[16] These values, which were obtained from measurement of magnetic susceptibility, are in good agreement with those for the same equilibrium in toluene ($\Delta H = 33.9$ kJ mol^{-1} and $\delta S = 124$ J mol^{-1} K^{-1}). The process is characterized by a positive change in entropy due to the increase in spin multiplicity on passing from $[Co^{III}(cat)(sq)]$ to $[Co^{II}(sq)_2]$ and especially the increase in low-frequency vibrational activity according to the weakened metal–ligand bond in Co^{II} complexes.[9,11,16] The Co^{III} species lies at lower enthalpy with respect to the Co^{II} species and is therefore favored at low temperatures. However, if the entropy term is large, the Co^{II} species becomes stabilized at higher temperatures, similar to the high-spin state in spin-crossover systems.[17]

These considerations led to more sophisticated control of the phenomenon. It was convincingly demonstrated that the charge distribution depends on subtle co-ligand bonding effects. It was first established that the interconversion also occurs with pseudooctahedral complexes containing *trans* nitrogen donor atoms, for example pyridine ligands.[18] The change in geometry results in no substantial difference in behavior. The interconversion temperature in a series of $[Co(N-N)(diox)_2]$ complexes, where N–N is an aliphatic tertiary diamine, changes drastically upon varying the basicity of the bidentate ligand.[19] The T_c value of the propylene derivative is about 200 K lower than that of the corresponding ethylene complex. Furthermore, a large hysteresis effect ($T_c\uparrow = 340$ K vs. $T_c\downarrow = 100$ K) was observed in the bis(pyridine) ether derivative of the bis(1,2-benzoquinone)cobalt moiety.[20] Structural characterization of the two redox isomers at room temperature showed that the hysteresis effect is due to an alteration in the co-ligand structure as a consequence of the change in radius of the metal. At 273 K the metastable Co^{III} species can be converted into the Co^{II} isomer by optical excitation of the LMCT transition.

Valence tautomers were also observed for manganese–1,2-benzoquinone complexes. In this case three oxidation states of the metal ion (i.e., II, III, and IV) can be involved in the intramolecular electron transfer with the coordinated 1,2-benzoquinone ligand. However, since all the manganese ions have high-spin electronic ground states, and antiferromagnetic coupling occurs between the metal and the ligand spins,[4,21] the electronic ground states of a pair of valence tautomers (for example, Mn^{II}(sq) and Mn^{III}(cat) or Mn^{III}(sq) and Mn^{IV}(cat)) have the same spin multiplicity (quintet and quartet, respectively, for the two pairs considered). Therefore magnetic measurements fail to provide information on tautomeric equilibria. Nevertheless, $[Mn(N-N)(diox)_2]$ complexes show behavior similar to that of the cobalt complexes.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2735 $ 17.50+.50/0

Shortly after the detection of the first valence tautomeric equilibrium, it was shown that the temperature-dependent solution electronic spectrum of the structurally characterized $[Mn^{IV}(py)_2(dbcat)_2]$complex was consistent with Equation (b).[22]

$$[Mn^{IV}(py)_2(dbcat)_2] \rightleftharpoons [Mn^{II}(py)_2(dbsq)_2] \quad (b)$$

This tautomeric equilibrium involves the simultaneous transfer of two electrons, but it probably proceeds via $[Mn^{III}(py)_2(dbcat)(dbsq)]$ as intermediate and in a stepwise fashion, as recently suggested.[23] Here manganese complexes of formula $[Mn(N-N)(diox)_2]$ were shown to contain the metal ion in the three oxidation states II, III, and IV depending on the donor ability of the ancillary ligand. In addition, the structural parameters of the *o*-phenanthroline complex were consistent with the presence of both the Mn^{III} and Mn^{IV} tautomers in the crystal lattice. As with the 1,2-benzoquinone complexes containing cobalt in different oxidation states, the presence of the Mn^{III} species is evidenced by a strong transition in the region of 2100–2200 nm. The intensity of the transition is temperature-dependent, which indicates the existence of interconversion equilibria between Mn^{IV} and Mn^{III} tautomers as well as between Mn^{III} and Mn^{II} tautomers. Again, in both equilibria the species with the metal in the higher oxidation state is stabilized at low temperature, therefore suggesting that both interconversions are driven by entropy.

On the basis of these results, one could reasonably expect that the conditions for the occurrence of valence tautomerism might also be achieved for bis(1,2-benzoquinone)iron analogues. Unfortunately, efforts in this regard were unsuccessful.[10,24] A series of $[Fe^{III}(N-N)(dbcat)(dbsq)]$ was prepared and characterized, but no evidence for interconversion to the corresponding $[Fe^{II}(N-N)(dbsq)_2]$ was found, although the latter was expected to be thermodynamically favored at high temperatures.

The different behavior of the three metal ions can be reasonably explained by taking into account the change in electronic configuration occurring during the intramolecular redox process. All these complexes are six-coordinate, and for the $Mn^{IV} \rightarrow Mn^{II}$ and $Co^{III} \rightarrow Co^{II}$ interconversions electrons are placed into e_g^* orbitals. Since these orbitals are σ-antibonding in character, a significant weakening of the metal–ligand bonds occurs and, thus, the intramolecular processes have large positive changes in enthalpy and entropy. This does not occur for the $Fe^{III} \rightarrow Fe^{II}$ system, since both are high or low spin and the change in electronic configuration does not involve a change in the population of the e_g^* orbitals. Hence the interconversion is expected to be characterized by a much smaller positive change in enthalpy with respect to those associated with the manganese and cobalt complexes. This is also reflected by the small differences (≈ 0.03 Å) in the metal–oxygen bond length in iron(III)– and iron(II)–1,2-benzoquinone complexes; the changess in bond lengths for the $Mn^{IV} \rightarrow Mn^{II}$ and $Co^{III} \rightarrow Co^{II}$ complexes are quite large (≈ 0.20 Å).[23,24]

Cobalt and manganese complexes 1,2-benzoquinones have provided the most fruitful examples for the investigation of this unusual phenomenon of electronic lability, and, as mentioned above, they are of relevant interest for the design of molecule-based switching devices. Nevertheless, there is evidence that other metal ions may be used to obtain 1,2-benzoquinone complexes characterized by valence tautomeric interconversion. The solution behavior of some nickel,[25] copper,[26] rhodium, and iridium[27] complexes can be correctly explained by valence tautomeric equilibria. Finally, the unusual photomechanical behavior exhibited by crystals of $[Rh(CO)_2(3,6\text{-dbsq})]$, which were reported to bend reversibly when exposed isothermally to low-energy light,[28] can likely be ascribed to an optically driven intramolecular electron transfer.[29]

Enantioselective Synthesis of Altohyrtin C (Spongistatin 2): Synthesis of the AB- and CD-Spiroketal Subunits**

David A. Evans,* Paul J. Coleman, and Luiz Carlos Dias

Dedicated to Professor Dieter Seebach and Professor Yoshito Kishi on the occasion of their 60th birthdays

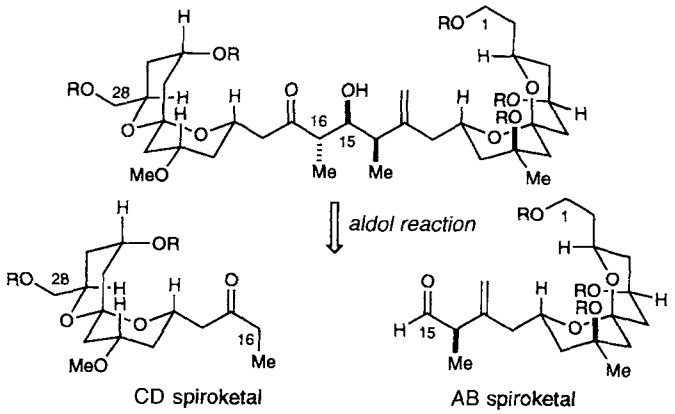
The spongipyran macrolides, a new class of marine natural products, exhibit subnanomolar antitumor activities against a number of human cancer cell lines. Independent bioassay-guided isolation and structure elucidation efforts by the Pettit, Fusetani, and Kitagawa groups have recently identified the structurally related macrolides spongistatins (*Spongia* family),[1] cinachyrolide A (*Cinachyra* family),[2] and the altohyrtins (*Hyrtios* and *Spirastrella* families).[3] The structures of the major constituents in each study, spongistatin 1, cinachyrolide A, and altohyrtin A, were determined on the basis of NMR[4] spectroscopic investigations. While each of these structures has been assigned the same carbon skeleton, the proposed structures differ in the relative stereochemical relationships among the AB and CD spiroketals, rings E and F, and at the C_{15} and C_{16} stereocenters (Figure 1). Since only the Kitagawa altohyrtin structure elucidation included

	X	IC_{50} (KB cell line)
Altohyrtin A	Cl	0.01 ng mL^{-1}
Altohyrtin B	Br	0.02 ng mL^{-1}
Altohyrtin C	H	0.40 ng mL^{-1}

Figure 1. Structures of altohyrtins A–C [3] and their antitumor activities.

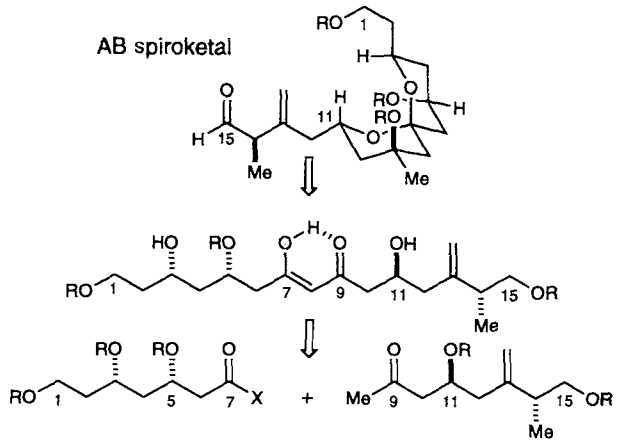
an absolute configuration assignment,[3c,d] it is possible that, because of the lack of an adequate correlation of relative stereochemical assignments between subunits, the stereochemical configurations of some of the indicated skeletal subunits in both spongistatin 1 and cinachyrolide A could be antipodal. This raises the prospect that all three molecules could possess identical stereostructures. On the basis of the preceding discussion, we undertook an enantioselective synthesis of the proposed altohyrtin structure.

The total synthesis of altohyrtin C[3b] described in this and the following two communications verifies the Kitagawa altohyrtin structural assignment, and establishes the identity of altohyrtin C and the independently isolated spongistatin 2.[1b] In this communication, we describe the synthesis of the C_1-C_{15} AB-spiroketal and $C_{16}-C_{28}$ CD-spiroketal altohyrtin subunits, which will be joined through the illustrated aldol fragment coupling reaction (Scheme 1).



Scheme 1. Projected aldol coupling of the altohyrtin AB and CD spiroketals.

The synthesis plan for the C_1-C_{15} AB spiroketal[5] is outlined in Scheme 2. After the illustrated internal deketalization, disconnection of the simplified acyclic precursor at the C_7-C_8 bond affords two fragments of similar complexity, the synthesis and assembly of which is now described.



Scheme 2. Retrosynthesis of the AB spiroketal.

Synthesis of C_1-C_7 fragment **6** (Scheme 3) began from (*S*) alcohol **1**,[6] prepared from TBS-protected glutaric anhydride.[7] Successive trityl protection and DIBALH reduction afforded aldehyde **2** (81%) along with recovered (*S*)-2-naphthylethanol. Wittig homologation[8] and removal of the silyl protecting group afforded **4**, which was subjected to base-

[4] for abbreviations.)

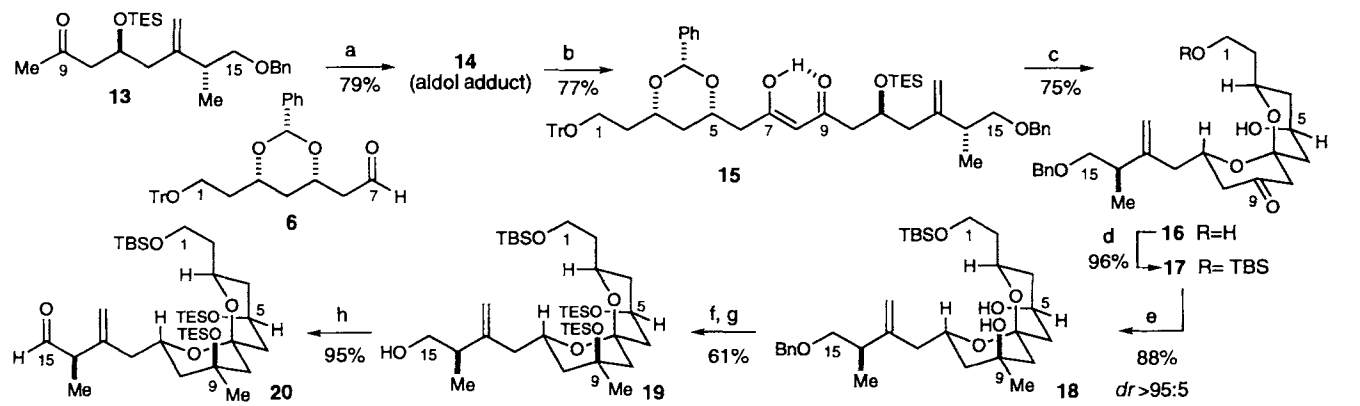
induced, intramolecular heteroconjugate 1,4-addition of the derived benzaldehyde hemiacetal to afford the 1,3-*syn* acetal **5** (83%, *dr* > 95:5).[9] DIBALH reduction provided aldehyde **6** in 56% overall yield for the six-step sequence.

The synthesis of the C_8-C_{15} fragment began with the chiral synthon **8**, readily derived from the oxazolidinone-mediated titanium enolate alkylation product **7** (Scheme 4).[10] Transformation of methyl ester **8** to the derived allylsilane **9** was achieved with (trimethylsilylmethyl)magnesium chloride and cerium(III) chloride, followed by elimination induced by acidic silica gel.[11] The optimal conditions for the allylsilane addition to aldehyde **10**[12] involved pretreatment of **9** with $SnCl_4$ followed by addition of **10**. This protocol provided **11** in 98% yield (*dr* = 94:6). Mitsunobu inversion of the C_{11} alcohol[13] (79%) and subsequent methanolysis (99%) provided **12** possessing the desired absolute stereochemical relationships at both C_{11} and C_{14}. Successive ketal hydrolysis and silyl protection afforded the C_8-C_{15} methyl ketone fragment **13** in 53% overall yield for the seven-step sequence.

Union of the C_1-C_7 and C_8-C_{15} fragments was initiated by treatment of methyl ketone **13** with dibutylboron triflate and iPr_2NEt[14] followed by addition of aldehyde **6** to provide aldol adduct **14** (79%) as a 1:1 mixture of C_7 diastereomers (Scheme 5). Oxidation of this mixture with chromium trioxide/pyridine/Celite[15] gave β-diketone **15** in 77% yield along with 12% recovered **14**. Multiple deprotection and spiroketalization of this substrate was achieved by treatment with $HF/H_2O/CH_3CN$. As anticipated, the only spiroketal diastereomer obtained (75%) from this transformation was the thermodynamically favored anomer **16**.[16]

With the AB-spiroketal framework in hand, the construction of the stereocenter at the tertiary atom C_9 was achieved by treatment of **17** with methyllithium/cerium trichloride in THF to provide axial alcohol **18** as a single diastereomer (Scheme 5; 86%; *dr* = > 95:5).[17] Silyl protection was followed by debenzylation (LDBB)[4,18] to afford the primary alcohol **19** in 61% yield (two steps). Oxidation (Dess–Martin periodinane, pyridine, 95%) to aldehyde **20** proceeded without epimerization of the C_{14} stereocenter. This oxidant is unique in its ability to execute this transformation without conjugating the proximal olefin. Aldehyde **20**, which is too labile for chromatographic purification, must be used immediately in the critical aldol coupling to the CD spiroketal.[19]

If the CD-spiroketal fragment is assembled from an acyclic precursor, the possibility exists for the formation of two diastereomeric structures, designated as CD_1 and CD_2 (Figure 2). Unlike the "axial–axial" AB spiroketal (analogous to CD_2, Figure 2), the CD spiroketal is disposed in an "axial–equatorial" configuration (CD_1, Figure 2), which is disfavored in isolated systems on stereoelectronic and steric grounds.[20] While the stabilization of diastereomer CD_1 in the altohyrtin



Scheme 5. Construction of the AB spiroketal **20**. a) 1. (See ref. [4] for abbreviations.)

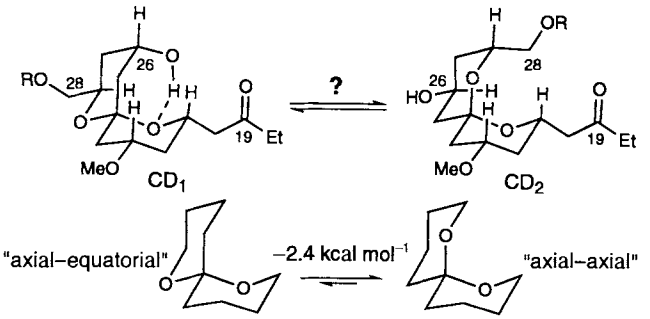


Figure 2. Possible CD-spiroketal configurations.

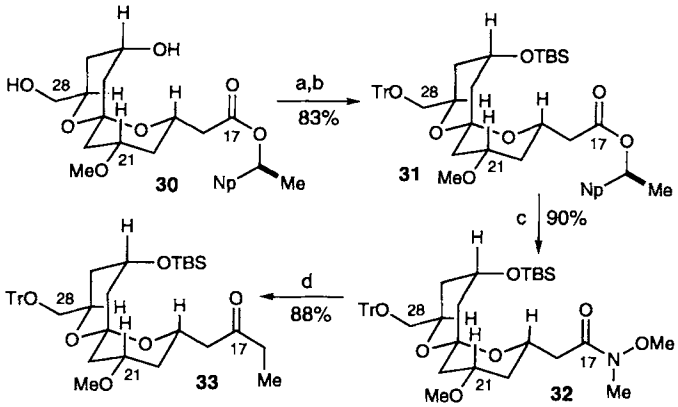
skeleton may be due to macrocyclic conformational constraints, structural features of the isolated CD system might also aid in enforcing this configuration. In this regard, the potential for an internal hydrogen bond between the C_{26} hydroxyl moiety and the ring-C skeletal oxygen (Figure 2) in spiroketal CD_1 was noted.

The synthesis of the CD spiroketal[21] was initiated by the regioselective opening of (*R*)-trityl glycidol[22] (**21**) with divinylcuprate (Scheme 6). The resulting alcohol (**22**) was transformed to methyl ketone **25** by a series of reactions presented in the preceding discussion (cf. Scheme 3). Aldol union of **25**, through its derived boron enolate,[14] with aldehyde **26**[6] afforded the adduct possessing the desired *S* configuration at C_{21} ($dr = 96{:}4$). Previous work from this laboratory has established that the dominant stereocontrol element in this reaction is the C_{25} alkoxy substituent on the enolate coupling partner and that the trend toward 1,5-*anti* induction is general.[23,24]

Several conventional refunctionalization steps were next carried out prior to spirocyclization. Methylation[25] of aldol adduct **27** afforded spirocyclization substrate **28**. The subsequent deprotection of the four oxygen protecting groups (at C_{19}, C_{25}, C_{27}, and C_{28}) and concomitant spirocyclization were achieved upon treatment of **28** with camphorsulfonic acid in a methanol/dichloromethane solution (1/15, 13 h, 25°C).[26] Two separable isomeric spiroketal products **29** and **30** (ratio 6:1) were isolated in 70% yield. A by-product that incorporated a second methyl ether at C_{25} was also identified (18%).[27] Diagnostic NOE experiments provided unequivocal stereochemical assignments for both spiroketal diastereomers.[28] The major isomer **29** possesses the undesired spirane ring fusion (CD_2, Figure 2). Equilibration[29] with three equivalents of $Mg(O_2CCF_3)_2$ in CF_3CO_2H/CH_2Cl_2 gave a 2.2:1 mixture of isomers **30** and **29**. We believe that the derived magnesium complexes of the two spiroketals are the species undergoing equilibration, thus altering the equilibrium ratio of spiroketal diastereomers.[30] Other conditions afforded higher ratios but lower yields of the isolated spiroketal ($ZnCl_2$, CH_2Cl_2, 22°C; **30**:**29** = 4.3:1).

Transformation of **30** to the desired CD-spiroketal ethyl ketone **33** (Scheme 7) was achieved by selective protection of the C_{28} hydroxyl group of **30** as its trityl ether, TBS-silylation



Scheme 7. Synthesis of CD-spiroketal ethyl ketone **33**. a) TrCl, pyridine, 60°C; b) TBSOTf, 2,6-lutidine; c) MeO(Me)NH·HCl, EtMgBr, THF, –10°C; d) EtMgBr, THF, 0°C. (See ref. [4] for abbreviations.)

at C_{25}, and transformation of the C_{17} ester functionality to an ethyl ketone through its corresponding Weinreb amide **32**.[31] Attempted transamidation of ester **31** under Lewis acidic conditions (MeONHMe·HCl, $AlMe_3$)[32] afforded none of the desired amide and led to appreciable epimerization of the spiroketal stereocenter.

The described syntheses of the AB- and CD-spiroketal subunits provide efficient routes to significant quantities of these portions of the spongipyran architecture. Realization of the aldol coupling of these fragments and further elaboration to altohyrtin C are discussed in a subsequent communication.[19]

[22] (*R*)-Trityl glycidol was prepared in 95% *ee* by Sharpless asymmetric epoxidation of allyl alcohol and in situ tritylation. Recrystallization provided the enantiomerically enriched compound: H. S. Hendrickson, E. K. Hendrickson, *Chemistry and Physics of Lipids*, **1990**, *53*, 115–120.

[23] Under these reaction conditions, aldehyde **26** has no preferred diastereoface. Coupling of methyl ketone **25** with the antipode of **26** under the same reaction conditions also gives a 1,5-*anti* product.

[24] The diastereoselectivity for this methyl ketone aldol coupling is 9.6:1 at −78°C. At −110°C, the diastereoselectivity increases to 22:1. a) D. A. Evans, P. J. Coleman, B. Cote, *J. Org. Chem.* **1997**, *62*, 788–789; b) I. Paterson, K. R. Gibson, R. M. Oballa, *Tetrahedron Lett.* **1996**, *37*, 8585–8588.

[25] a) D. A. Evans, A. M. Ratz, B. E. Huff, G. S. Sheppard, *Tetrahedron Lett.* **1994**, *35*, 7171–7172; b) H. Meerwein, G. Hinz, E. Kronig, E. Pfeil, *J. Prakt. Chem.* **1937**, 147, 257–285.

[26] Attempted spiroketalization of **28** in the absence of MeOH led to rapid β-elimination of the C_{21} methyl ether to give an α,β unsaturated ketone.

[27] Related case of methanol incorporation in a spirocyclization product: I. Paterson, S. Bower, M. D. McLeod, *Tetrahedron Lett.* **1995**, *36*, 175–178.

[28] Stereochemical assignments were supported by NOE experiments (1D and 2D) and ^{1}H NMR measurements. An NOE enhancement between H_{19} and H_{27} was observed in the axial–equatorial isomer **30**. The NMR signal for H_{25} was illuminating as well: **29**: $\delta = 3.9$ (m, $J(H_{25}, H_{26ax}) = 11$ Hz); **30**: $\delta = 3.9$ ppm (t, $J = 3.2$ Hz).

[29] Due to the sensitivity of spiroketal substrate **29** to acidic media, equilibration experiments were kept short (1–3 h). In dichloromethane/CSA, **29** equilibrated to a 1:1 (29:30) mixture of spiroisomers after 3 h.

[30] Presumably, the C_{25} hydroxyl is assisting in the equilibration to afford **30** by participating in an internal chelate with the metal cation and proximally positioned anomeric oxygen. For related cases see a) D. R. Williams, P. A. Jass, R. D. Gaston, *Tetrahedron Lett.* **1993**, *34*, 3231–3234; b) M. J. Kurth, E. G. Brown, E. Hendra, H. Hope, *J. Org. Enantioselective Synthesis of Altohyrtin C (Spongistatin 2): Synthesis of the EF-Bis(pyran) Subunit**

David A. Evans,* B. Wesley Trotter, Bernard Côté, and Paul J. Coleman

Dedicated to Professor Dieter Seebach and Professor Yoshito Kishi on the occasion of their 60th birthdays

Concurrent with the syntheses of the AB- and CD-spiroketal subunits of the altohyrtin skeleton,[1] the synthesis of the altohyrtin C_{29}–C_{51} EF-bis(pyran) fragment was addressed. The principal subunits for this portion of the altohyrtin skeleton are illustrated in Figure 1. The retrosynthetic proposal focuses on the incorporation of the C_{44}–C_{51} side chains (X = H, Cl, Br) as allylmetal nucleophiles into the illustrated F-ring epoxide at a late stage in the synthesis. In turn, this bis(pyran) is assembled through acylation of the illustrated E-ring sulfonyl anion with an F-ring[2] carboxylic

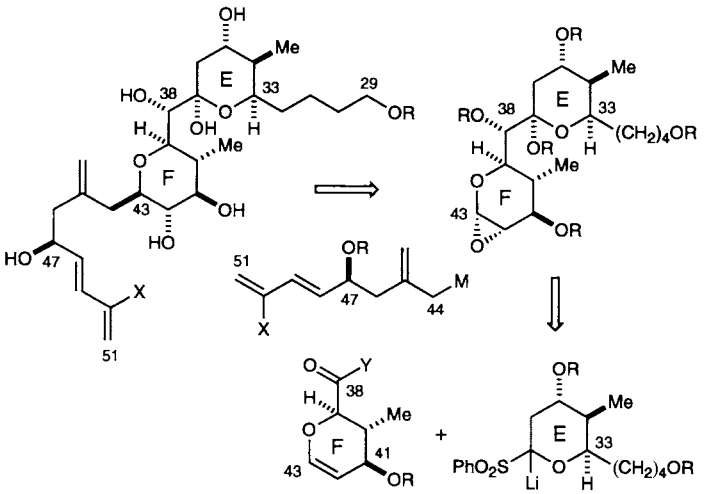

Figure 1. Retrosynthesis of the EF-bis(pyran) subunit.

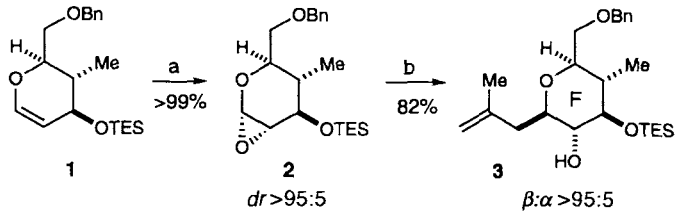
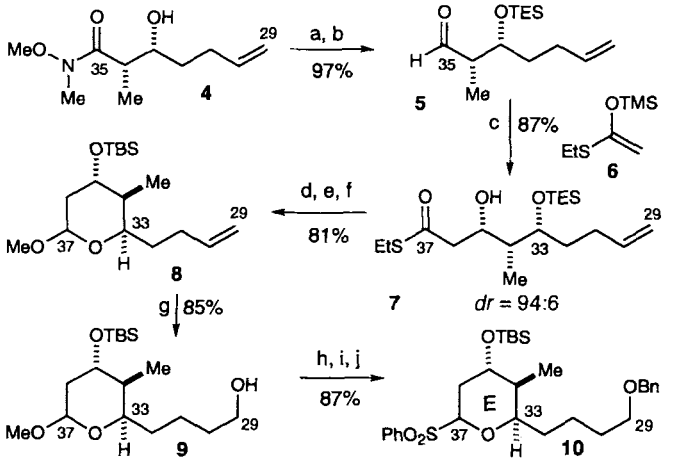
acid derivative. This strategy accommodates the use of either antipode of the E- or F-ring subunits in the event of a stereochemical discrepancy in this portion of the structure.[3]

In conjunction with this plan, a practical solution for β-*C*-glycosidation through the allylstannane-mediated cleavage of glycal epoxides has been developed (Scheme 1).[4] Dihydropyran **1** was found to undergo highly stereoselective epoxidation by dimethyldioxirane in full accord with extensive precedent.[5] The resulting glycal epoxide **2**, when treated with tributylmethallylstannane and tributylstannyl triflate, was transformed to the F-ring analogue **3** with high diastereoselectivity. Tributylstannyl triflate was unique among the surveyed Lewis acid activators in providing exclusively the β isomer; other Lewis acids afforded significant amounts of diastereomeric addition products, presumably through the intervention of an oxocarbenium ion intermediate.



Scheme 1. β-*C*-glycosylation mediated by tributylstannyl triflate. a) Dimethyldioxirane, acetone, CH_2Cl_2, 0°C; b) 5 equiv of tributylmethallylstannane, 2 equiv of Bu_3SnOTf, CH_2Cl_2, −78°C. (See ref. [4] for abbreviations.)

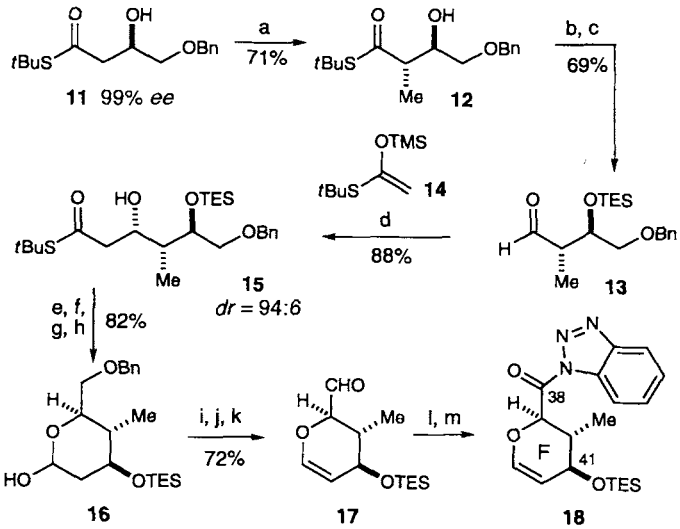
Application of this methodology to a more highly functionalized system was next investigated. Synthesis of the $C_{29}-C_{37}$ E-ring fragment was initiated from the enantiomerically pure boron aldol adduct **4**[6] (Scheme 2). Sequential alcohol protection and amide reduction provided aldehyde **5**, which was subjected to a Felkin-selective Lewis acid catalyzed ($BF_3\cdot Et_2O$) aldol addition with thioketene acetal **6** to afford thioester **7** (87%; *dr* = 94:6). Fukuyama reduction to the derived aldehyde[7] and acid-catalyzed deprotection–acetalization followed by silyl protection of the remaining secondary alcohol afforded the E-ring methyl ketal **8** (81%, three steps).



Scheme 2. Synthesis of E-ring phenylsulfone **10**. a) TESOTf, 2,6-lutidine; b) DIBALH, −78°C; c) **6**, $BF_3\cdot Et_2O$, CH_2Cl_2, −78°C; d) Lindlar catalyst, Et_3SiH, 1-hexene, acetone; e) CSA, MeOH; f) TBSCl, imidazole, DMF; g) 9-BBN, then H_2O_2; h) $TMSSPh$, ZnI_2; i) NaH, BnBr, Bu_4NI; j) *m*-CPBA, $NaHCO_3$. (See ref. [4] for abbreviations.)

Hydroboration of **8** with 9-BBN then afforded alcohol **9** (85%). Preparation of the E-ring phenylsulfone **10** was completed by anomeric sulfide formation ($TMSSPh$, ZnI_2),[8] C_{29} alcohol benzylation (NaH, BnBr, Bu_4NI, 90% from **9**), and sulfide oxidation (*m*-CPBA, $NaHCO_3$, 97%).

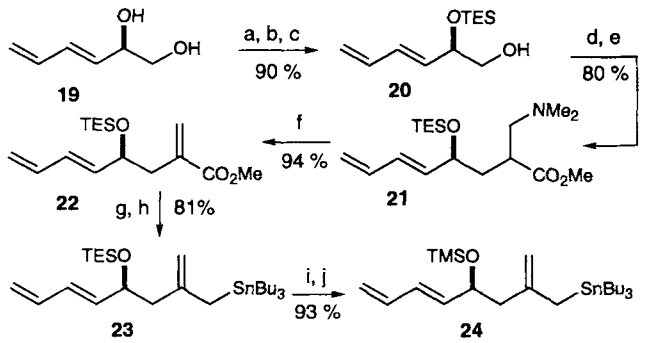
Synthesis of the F-ring dihydropyran began from our previously reported aldol adduct **11** (99% ee, *R* configuration; Scheme 3).[9] Fräter–Seebach alkylation (71% yield; *dr* = 5–8:1)[10] was followed by successive alcohol protection (TESCl, imidazole, 80%) and thioester reduction (DIBALH, 86%) to give aldehyde **13**. A Felkin-selective, 1,3-*anti* aldol reaction[11] with thioketene acetal **14** ($BF_3\cdot Et_2O$, toluene, −93°C) provided thioester **15** (88%; *dr* = 94:6). Silyl deprotection and Ag(I)-mediated lactonization (88%, two steps) followed by TES protection and DIBALH reduction (93%, two steps) afforded lactol **16**. $POCl_3$-mediated dehydration (81%), removal of the C_{38} benzyl group (LDBB, 99%), and Parikh–Doering oxidation (90%)[12] provided the F-ring dihydropyran aldehyde **17**. Buffered Kraus oxidation[13] of this intermediate provided a carboxylic acid that could be transformed to the activated benzotriazolyl amide **18** through the corresponding acid chloride.[14] In our subsequent sulfonyl carbanion acylation studies (vide infra), it was found that **18** is superior to the analogous acid chloride, which readily undergoes competitive carbanion-initiated proton transfer.



Scheme 3. Synthesis of the activated F-ring amide **18**. a) LDA, HMPA, MeI, THF, −55°C; b) TESCl, imidazole; c) DIBALH, −78°C; d) **14**, $BF_3\cdot Et_2O$, toluene, −93°C; e) PPTS, MeOH; f) AgO_2CCF_3, benzene; g)TESCl, imidazole; h) DIBALH, −78°C; i) $POCl_3$, pyridine, 80°C; j) LDBB, THF, −78°C; k) $SO_3\cdot$pyridine, DMSO, Et_3N; l) $NaClO_2$, 2-methyl-2-butene, ethyl-1-propenyl ether, *t*-BuOH, pH 5.5; m) 1. 1-chloro-*N*,*N*-trimethylpropenylamine; 2. benzotriazole, pyridine, DMAP. (See ref. [4] for abbreviations.)

Synthesis of the requisite allylstannane side chain began with the known (2*S*,3*E*)-hexa-3,5-diene-1,2-diol (**19**)[15] (Scheme 4). A three-step sequence provided monosilylated ether **20** in 90% overall yield without intervening purifications. Conversion of **20** into the corresponding alkyl triflate followed by treatment with the lithium enolate of methyl β-dimethylaminopropionate[16] provided **21** (80%). Quaternization and elimination of the dimethylamino group (MeI, Na_2CO_3, 94%) was followed by ester reduction (DIBALH, 95%) to give the corresponding allylic alcohol. In situ mesylation and displacement with tributylstannyllithium[17] gave TES-protected allylstannane **23** in 85% yield. Basic

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2742 $ 17.50+.50/0 *Angew. Chem. Int. Ed. Engl.* **1997**, *36*, No. 24



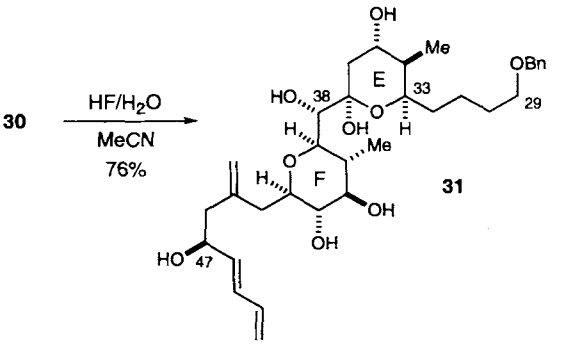
Scheme 4. Synthesis of altohyrtin C side chain **24**. a) AcCl, 2,6-lutidine, CH_2Cl_2, −78°C; b) TESCl, *imidazole*, CH_2Cl_2; c) DIBALH, toluene, −78°C; d) Tf_2O, pyridine, CH_2Cl_2, −10°C; e) methyl β-dimethylaminopropionate, LDA, THF, −78°C; f) MeI, Na_2CO_3, MeOH; g) DIBALH, CH_2Cl_2, −78°C; h) BuLi, MsCl, THF, −78°C, then Bu_3SnLi; i) NaOH, EtOH; j) *N,O*-bis(trimethylsilyl) acetamide. (See ref. [4] for abbreviations.)

deprotection and resilylation then provided TMS-protected allylstannane **24** in 93% yield.

At this stage, acylation of the E-ring phenylsulfone[18] with the activated F-ring amide was addressed (Scheme 5). While the use of F-ring derivatives including the C_{38} aldehyde **17**, activated esters, and acid chlorides engendered problems ranging from sulfone elimination to unwanted proton transfer, lithiation of 1.1 equivalents of sulfone **10** followed by addition of 1 equivalent of amide **18** provided the EF bis(pyran) **25** in 60% yield (four steps from **17**). Methanolysis of **25** provided ketone **26** isolated in 48% yield.[19] Of the hydride reducing agents surveyed, $KBHEt_3$ proved most effective in securing the desired configuration at C_{38} (90%; $dr > 99{:}1$). At this juncture, a single-crystal X-ray analysis of alcohol **27** unequivocally confirmed the structure of this advanced intermediate.[20]

After silylation of **27**, epoxidation of **28** with dimethyldioxirane again proceeded stereoselectively (100%; $dr > 95{:}5$) to afford **29**. Treatment of this epoxide with allylstannane **24** and tributylstannyl triflate provided the desired adduct **30** in 80% yield as a single diastereomer. The excess allylstannane from this experiment was recovered quantitatively after chromatography. The size of the C_{47} alcohol protecting group appears to play a significant role in this reaction; use of allylstannanes containing larger silyl protecting groups (e.g. **23**) resulted in lower yields of isolated **30** due to competitive decomposition of starting epoxide.

At this juncture, acidic catalysts were evaluated for the deprotection of the EF bis(pyran) **30**. Prior experience had revealed that ring-E Δ^{36} dihydropyran formation was to be avoided, since rehydration of this intermediate was problematic. Treatment of **30** with aqueous HF resulted in removal of all four silyl protecting groups as well as hydrolysis of the C_{37} methyl ether to the corresponding lactol [Eq. (1)]. This experiment allayed concerns that the unwanted elimination



(1)

to the dihydropyran would complicate the projected final deprotection sequence leading to the target structure. In addition, ^1H NMR chemical shifts and coupling constants of **31** correlated very well with those reported for altohyrtin C (Table 1).[21] The union of the EF bis(pyran) **28** with the

Table 1. Chemical shifts (δ), multiplicities, and coupling constants [Hz] in [D6]DMSO.

Proton	Altohyrtin C[21]	**31**

[19] The two anomers of **25** underwent methanolysis at different rates. The mixture of anomers was subjected to ZnI_2/MeOH at room temperature, which converted the major anomer into **26** (> 95:5 α). The minor anomer of **25** was then separated and treated with $MgBr_2 \cdot Et_2O$ in refluxing MeOH to provide additional **26** (2:1 α). The major side product in these reactions was the enone product of sulfone elimination: D. S. Brown, S. V. Ley, S. Vile, M. Thompson, *Tetrahedron* **1991**, *47*, 1329–1342.

Enantioselective Synthesis of Altohyrtin C (Spongistatin 2): Fragment Assembly and Revision of the Spongistatin 2 Stereochemical Assignment**

David A. Evans,* B. Wesley Trotter, Bernard Côté, Paul J. Coleman, Luiz Carlos Dias, and Andrew N. Tyler

Dedicated to Professor Dieter Seebach and Professor Yoshito Kishi on the occasion of their 60th birthdays

With convergent syntheses of the AB,[1] CD,[1] and EF[2] spongipyran fragments in hand, the assembly of these subunits to the altohyrtin C skeleton was addressed (Figure 1). While the C_{44}–C_{51} side chain had been successfully

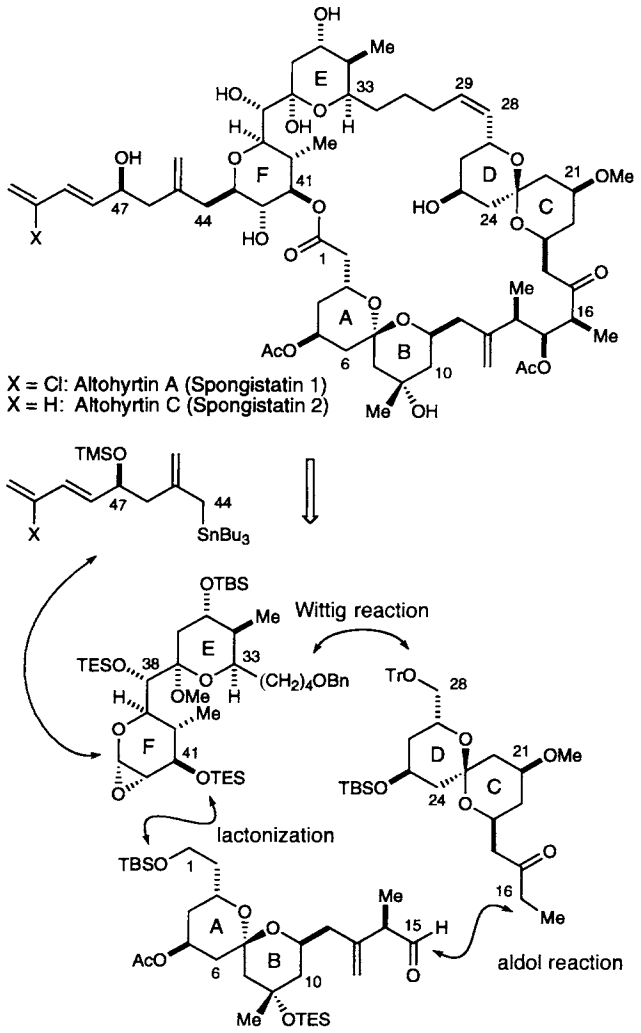

Figure 1. Assembly of the altohyrtin subunits. (See ref. [4] for abbreviations.)

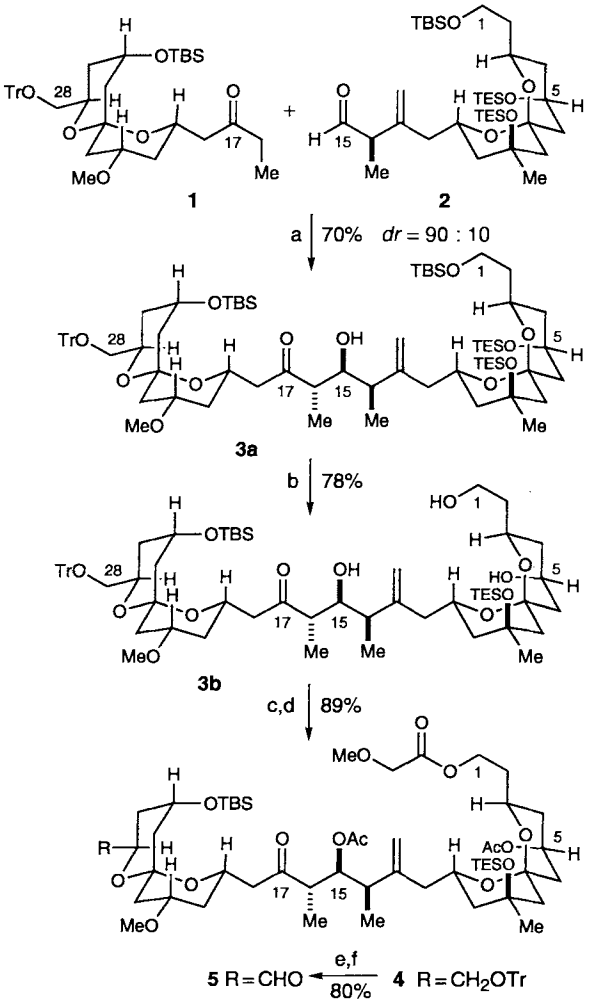
incorporated into the isolated EF bis(pyran),[2] we planned to delay the introduction of this fragment until later in the assembly process. Since data obtained for the altohyrtins and spongistatins reveal that the identity of the side-chain substituent X exhibits a significant influence on the cytotoxic potency of these molecules,[3] we intend to develop syntheses of other side-chain analogues of these macrolides in forthcoming investigations. We report here the completion of the total synthesis of altohyrtin C (spongistatin 2), which employs a diastereoselective aldol union of the AB- and CD-spiroketal subunits, a Wittig coupling of the ABCD and EF fragments, a late-stage addition of the $C_{44}-C_{51}$ side chain to the fully elaborated ABCDEF system, and a regioselective macrolactonization, which exhibits fortuitous discrimination between the unprotected C_{41} and C_{42} diol functionalities of the F ring.

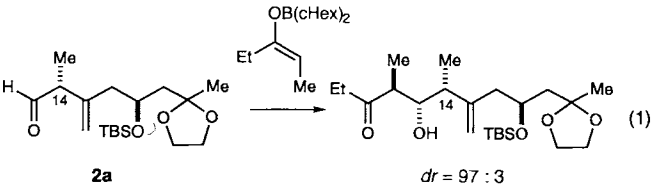
The aldol coupling of CD-spiroketal ethyl ketone **1**[1] with AB-spiroketal aldehyde **2**[1] was first addressed (Scheme 1).[4]



Scheme 1. AB/CD aldol fragment coupling. a) $(cHex)_2BCl$, Et_3N, pentane, 0°C, 90 min, then −78°C, addition of **2**; b) HF·pyridine, THF, 0°C; c) $(MeOCH_2CO)_2O$, iPr_2EtN, CH_2Cl_2; d) Ac_2O, DMAP, pyridine, 22°C; e) Me_2AlCl, CH_2Cl_2, −78°C; f) Dess–Martin periodinane, CH_2Cl_2. (See ref. [4] for abbreviations.)

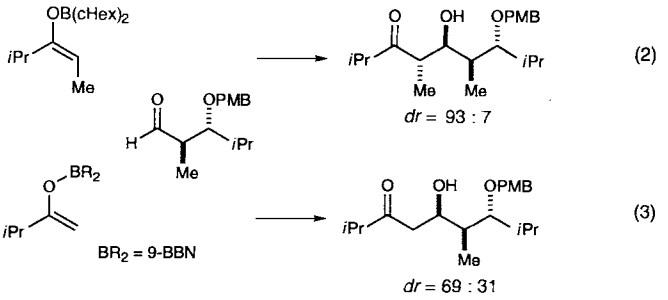
Ample precedent exists for establishment of the 1,2-*anti* relationship between C_{15} and C_{16} through the use of *E* boron enolates;[5] however, control of the incipient C_{15}-hydroxyl configuration was a concern. Because each reacting partner in this proposed aldol reaction has stereocenters that can potentially influence the stereochemical outcome of the reaction, the stereochemical preferences of each fragment were separately examined.

An investigation of the intrinsic diastereofacial bias of the *E* boron enolate derived from **1** indicated that remote chirality on **1** would not significantly influence the stereochemical outcome of the proposed aldol union.[6] In contrast, treatment of model aldehyde **2a** with the *E* boron enolate of 3-pentanone gave the corresponding Felkin *anti* aldol adduct in 97:3 diastereoselectivity [Eq. (1); the *dr* value gives the ratio



(1)

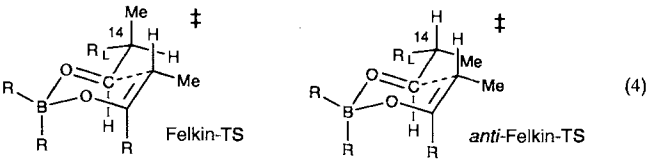
of the given isomer to all other isomers].[7] Control experiments demonstrate that *E* substituted boron enolates [Eq. (2)] exhibit enhanced Felkin selectivities in additions to chiral α-substituted aldehydes relative to their unsubstituted counterparts [Eq. (3)]. This increased selectivity can be



(2)

(3)

attributed to destabilization of the Felkin *anti* transition state by a developing *syn* pentane interaction [Eq. (4)].[8]



(4)

In the event, selective formation of the *E* boron enolate of ethyl ketone **1** with dicyclohexylchloroborane,[9] followed by the addition of aldehyde **2**[10] afforded a 9:1 mixture of product diastereomers (Scheme 1) favoring the desired Felkin adduct **3a** (70%). At this point in the synthesis, incorporation of the C_5 and C_{15} acetate residues present in the altohyrtin structure was addressed. Selective desilylation of **3a** at C_1 and C_5 with buffered HF·pyridine proceeded in good yield to give triol **3b** (78%).[11] Selective monoacetylation at the C_1-hydroxyl with methoxyacetic anhydride was followed by bis(acylation) at C_5 and C_{15} with acetic anhydride to afford **4** (89%). The selection of the methoxyacetyl residue for interim protection of the C_1 (carboxyl) terminus was made after difficulties were encountered in the selective hydrolysis of the corresponding C_1 acetate, which required extended reaction times. Under these conditions significant β-elimination of the C_{15} acetate residue was noted.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2745 $ 17.50+.50/0

Refunctionalization of the C_1-C_{28} bis(spiroketal) **4** in preparation for the Wittig reaction was then undertaken. Removal of the C_{28} trityl ether with Me_2AlCl[12] under carefully controlled conditions afforded the corresponding alcohol,[13] which was oxidized with the Dess–Martin periodinane to give aldehyde **5**, the substrate required for the projected Wittig reaction. The requisite phosphonium salt **7** was prepared from EF-bis(pyran) benzyl ether **6**[2] (Scheme 2) by successive debenzylation (LDBB, 96%), mesylation (MsCl, Et_3N, 99%), sodium iodide displacement (NaI, acetone, 94%), and displacement by triphenylphosphane (PPh_3, MeCN, 91%). Deprotonation of **7** (1.26 equiv) with LiHMDS followed by addition of aldehyde **5** provided the desired Wittig product **8** in 64% yield (>95:5 *Z*:*E*).[14] Removal of the methoxyacetate C_1 protecting group was accomplished with NH_3/MeOH in 82% yield. While hydrolysis of the secondary acetates at C_5 and C_{15} was not observed, a minor by-product resulting from β-elimination of the C_{15}

ester was isolated. Dess–Martin oxidation (92%) followed by buffered Kraus oxidation[2] and silyl protection (TIPSCl, Et_3N) provided TIPS ester **9** (72%, two steps).

At this stage, introduction of the $C_{44}-C_{51}$ side chain was undertaken. Epoxidation of the $C_{42}-C_{43}$ dihydropyran was accomplished with complete chemo- and stereoselectivity (as judged by ^1H NMR analysis) by addition of approximately 1.5 equivalents of dimethyldioxirane. Immediate treatment of the resulting epoxide with allylstannane **10**[2] (16 equiv) and tributylstannyl triflate (2 equiv) afforded the desired adduct **11**, comprising the full altohyrtin carbon skeleton, in 80–94% yield of isolated product as a single diastereomer. The excess allylstannane was recovered in quantitative yield after column chromatography.

As a prelude to macrocycle formation, a complex series of silyl deprotection operations on ester **11** was implemented. Treatment of this intermediate with buffered HF·pyridine (THF, 0°C), afforded selective deprotection of the TIPS ester at the C-terminus, the C_{47} TMS ether, and the C_{41} TES ether,[15] while retaining the four silyl protecting groups at C_9, C_{25}, C_{35}, and C_{38} (Scheme 2). Subjection of acid triol **12** to Yamaguchi macrolactonization conditions (2,4,6-trichlorobenzoyl chloride, iPr_2NEt, DMAP)[16] provided a product tentatively identified as the desired cyclization product bearing a trichlorobenzoyl group at the C_{47} oxygen. Accordingly, selective protection of acid triol **12** at the C_{47} hydroxyl was performed prior to macrolactonization to give TES ether **13** (TESCl, imidazole, 0°C, 61% from **11**).[17]

Exposure of **13** to Yamaguchi conditions provided a single regioisomeric lactone **14** in 86% yield. Deprotection (HF/H_2O/MeCN) provided the desired natural product, which was isolated in 85% yield after reverse phase HPLC. The regiochemical outcome of the macrocyclization was unambiguously established by observation of the coupling patterns among the $C_{40}-C_{44}$ protons in the COSY spectrum of the deprotected compound ([D_6]DMSO). This allowed an unambiguous assignment of resonances of hydrogen atoms at the C_{41} and C_{42} atoms; both the diagnostic downfield shift of the $C_{41}H$ resonance ($\delta = 4.68$ for $C_{41}H$, 3.04 for $C_{42}H$) and the presence of a $C_{42}H-C_{42}OH$ coupling verified that macrolactonization had occurred at the C_{41}-hydroxyl group. Our observation that the seco acid **13**, carrying an unprotected hydroxyl function at C_{42}, may be cyclized directly to the macrolactone **14** simplifies the later stages of the synthesis plan. The motivation for attempting this cyclization as part of the original plan was based on the conviction that any protecting group appended to the C_{42}-hydroxyl would add sufficient steric hindrance to the C_{41}-hydroxyl group to impair the macrolactonization process.

The synthetic material was identical to a sample of natural spongistatin 2[18] as judged by ^1H NMR (500 MHz, CD_3CN), HPLC, electrospray mass spectroscopy, and ultraviolet spectroscopy. Comparison of optical rotations confirmed that the synthetic and natural compounds possessed the same absolute stereochemistry (synthetic: $[\alpha]_D^{24}$ +21.3° ($c = 0.03$ in MeOH); natural: $[\alpha]_D^{24}$ +29.2° ($c = 0.12$ in MeOH)). Further, detailed comparison of one-dimensional ^1H NMR and two-dimensional COSY spectra (500 MHz, [D_6]DMSO) confirmed that our synthetic material was also identical to natural altohyrtin C.[19] We thus conclude that spongistatin 2 and altohyrtin C are identical compounds and speculate that the altohyrtin stereochemical assignment can be extended to the remaining members of the spongipyran family.

The route to altohyrtin C outlined here should be readily applicable to the side-chain congeners altohyrtin A (spongistatin 1) and altohyrtin B,[3] with dihydropyran **9** serving as a common intermediate for the synthesis of these compounds and additional unnatural analogues.[20]

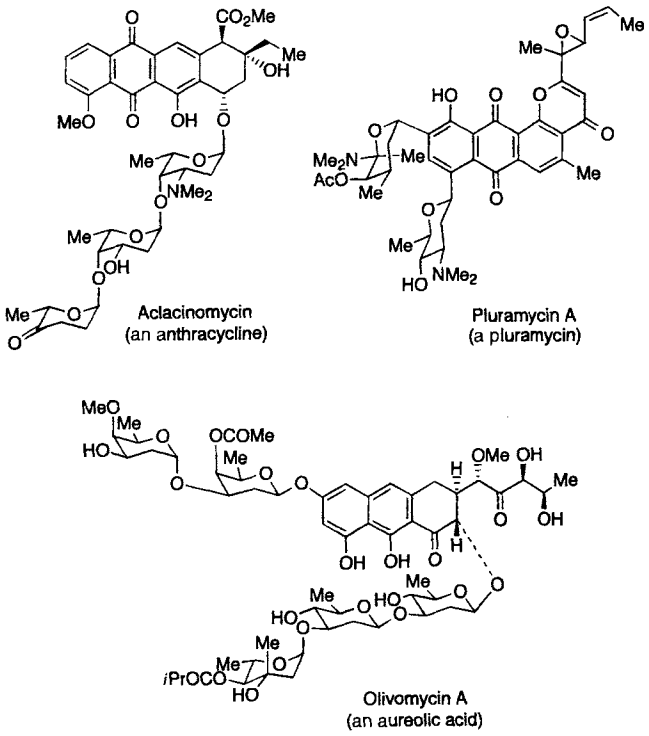
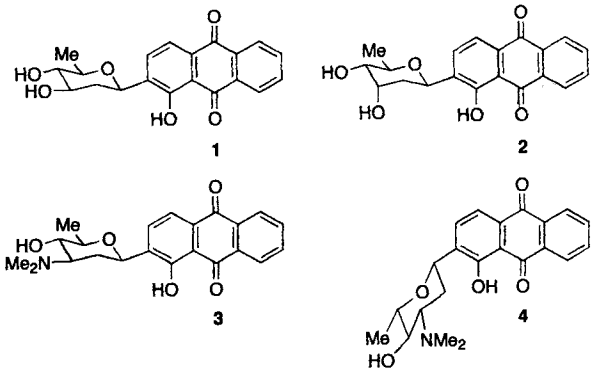
Artificial Anthraquinone–Carbohydrate Hybrids: Design, Synthesis, DNA Binding, and Cytotoxicity**

Kazunobu Toshima,* Hiromi Ouchi, Yoriko Okazaki, Takaaki Kano, Makoto Moriguchi, Akira Asai, and Shuichi Matsumura

Novel DNA-binding molecules, particularly those with high efficiency and sequence-specificity, are very interesting from the chemical and biological standpoint and offer considerable potential in medicine.[1-7] The design and synthesis of artificial molecules that exhibit such interactions with DNA is therefore an important goal in contemporary chemistry. Certain clinically important antitumor antibiotics such as anthracyclines,[8] aureolic acids,[9] and pluramycins,[10] which strongly bind to DNA in a sequence-selective manner, have already been found in nature (Scheme 1). Although these various agents have been regarded as belonging to distinct classes of antibiotics, from a chemical standpoint they are commonly found to contain arene and carbohydrate domains. In their DNA-binding activity the aromatic moieties function as DNA intercalators, whereas the carbohydrate residues bind to the DNA grooves. Even the active forms of enediyne antibiotics, which efficiently cleave DNA, can be viewed as aromatic–carbohydrate hybrids.[1] Based on these facts concerning compounds of natural origin, we considered the possibility of creating artificial DNA-binding molecules that consist of aromatic and carbohydrate domains. In this communication we discuss the molecular design, chemical synthesis, DNA-binding properties, and cytotoxicity of the novel and artificial anthraquinone–carbohydrate hybrids **1**–**4**.[11]



Scheme 1. Representative naturally occurring DNA-binding antitumor antibiotics constructed from arene and carbohydrate building blocks.



In our approach to DNA-binding hybrids we selected anthraquinone as the aromatic building block, because this is an aromatic skeleton present in many DNA-binding antitumor antibiotics. Certain 2,6-dideoxy sugars seemed appropriate as the carbohydrate source, since these are also found in many naturally occurring DNA-binding antitumor antibiotics, and the hydrophobicity[12-14] of 2,6-dideoxy sugars appeared advantageous for binding to the DNA groove.

The anthraquinone–carbohydrate hybrids **1**–**4** were synthesized by a short reaction sequence. The key step is an aryl C-glycosylation reaction with an unprotected sugar, recently developed in our laboratory (Scheme 2).[15] Aryl C-glycosylation of 9,10-dimethoxy-1-hydroxyanthracene (**5**) and the unprotected 2,6-dideoxy sugars D-olivose (**6**) and D-digitoxose (**7**) in the presence of a catalytic amount of trimethylsilyl trifluoromethanesulfonate (TMSOTf)/silver perchlorate in MeCN proceeded at room temperature to afford the unprotected aryl β-C-glycosides **10** and **11**, respectively, in a regio- and stereospecific fashion. Analogous transformations of **5** with **8** or its enantiomer **9** under TMSOTf catalysis in CH_2Cl_2 at 40 °C gave regio- and stereospecifically the unprotected aryl β-C-glycoside **12** and its enantiomer **13**, respectively. Subsequent oxidation of glycosides **10**–**13** with cerium(IV) ammonium nitrate (CAN) in MeCN/H_2O at −17 °C furnished the desired anthraquinone–carbohydrate hybrids **1**–**4**.

The DNA-binding characteristics of **1**–**4** were first assayed by the DNase I footprinting method with double-stranded M13mp18 DNA singly labeled with ^{32}P at the 5′ end. In the case of hybrids **1** and **2**, which both contain neutral sugars, no significant change from the cleavage pattern of the control was observed. By contrast, the cleavage patterns differ substantially from the control experiment with hybrids **3** and **4**, both of which contain an amino sugar, since cleavage in the 5′-TGC regions by DNase I is significantly diminished (Figure 1). This demonstrates convincingly that hybrids **3** and **4** bind to DNA in a sequence-selective fashion.[16] Interestingly, the DNA-binding ability of D-amino sugar hybrid **3** is stronger than that of L-amino sugar hybrid **4**. Furthermore, no

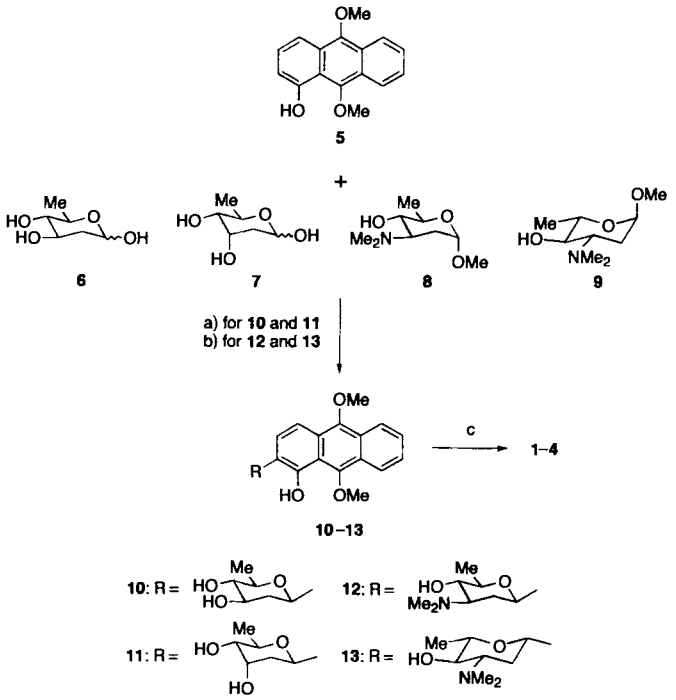

Scheme 2. Synthesis of **1**–**4**. a) TMSOTf (0.2 equiv), $AgClO_4$ (0.2 equiv), MeCN, 25 °C, 0.5 h, 75% (**10**), 25% (**11**); b) TMSOTf (1.2 equiv), CH_2Cl_2, 40 °C, 18 h, 63% (**12**), 64% (**13**); c) CAN (2.5 equiv), $MeCN/H_2O$, −17 °C, 0.5 h, 42% (**1**), 36% (**2**), 44% (**3**), 44% (**4**).

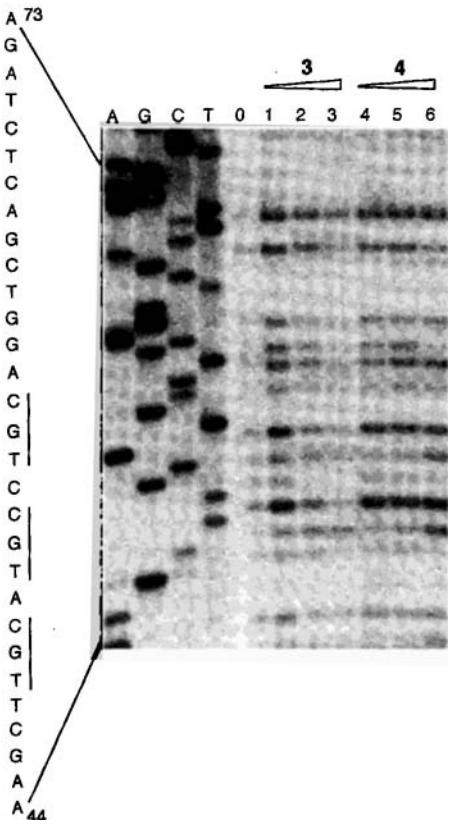

Figure 1. DNase I footprinting of 5'-end labeled M13mp18ds DNA bound to the hybrids **3** and **4**. DNase I digestion was carried out at room temperature for 1 min. Samples were assayed by electrophoresis on 15% polyacrylamide/8 M urea slab gel (bases 44–73 are shown). Lanes A, G, C and T: Sanger reactions of A, G, C and T, respectively; lane 0: control in the absence of added chemicals; lanes 1–6: **3** (20, 200, 2000 μM), **4** (20, 200, 2000 μM).

DNA binding could be demonstrated for the components of hybrid **3**, 1-hydroxyanthraquinone and amino sugar **8**, based on the DNase I footprinting assay. These results clearly indicate the importance of the hybrid structure constructed from anthraquinone and the amino sugar for DNA binding.

Confirmation that hybrids **3** and **4** bind to DNA with intercalation was obtained from a DNA unwinding assay with linearized pBR322 DNA and T4 DNA ligase.[17] The DNA intercalator first unwinds linearized DNA, which results in a change in the amount of twist in the double helix. Through formation by T4 ligase of a cyclic DNA from DNA bound to the intercalating compound, the linking number of the unwound DNA is frozen. Removal of the intercalating compound results in restoration of the normal degree of twist, while the linking number remains constant. This in turn leads to the introduction of negative superhelicity into the DNA. Figure 2 shows the product separation on an agarose gel for the DNA unwinding assay with DNA-binding hybrids **3** and **4**. Control DNA molecules appear as a lightly positively supercoiled population of topoisomers (lane 2). Upon ligation in the presence of an increasing concentration of intercalator, the molecular population becomes increasingly negatively supercoiled relative to the control. On the gel the topoisomers initially appear more relaxed and then progressively more negatively supercoiled. Under these assay conditions, **3** and **4** converted the topoisomers into more relaxed forms at low concentration and then to the completely negatively supercoiled form at high concentration. Furthermore, the intercalation potential of **3** is about five times greater than that of **4**. This result demonstrates that DNA intercalation activity is definitely dependent on the configuration of the sugar moiety in the hybrid.

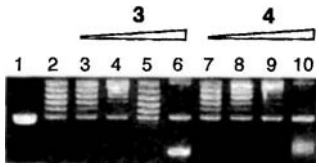

Figure 2. Effects of **3** and **4** on a DNA unwinding assay with T4 ligase. Unwinding mesurements were carried out as described in ref. [17]. Linearized plasmid DNA was incubated with T4 DNA ligase in the presence of the hybrids at various concentrations. Hybrid-induced DNA unwinding was detected on an agarose gel containing no ethidium bromide. Lane 1: linear DNA; lane 2: control in the absence of added chemicals; lanes 3–10: **3** (0.4, 2.0, 10, 50 μM), **4** (0.4, 2.0, 10, 50 μM).

The cytotoxicity of DNA-binding hybrids **3** and **4** was examined by using HeLa S3 cells exposed to each agent for 72 h.[18] The IC_{50} values of **3** and **4** were 9 and 58 μM, respectively. Hybrid **3** was about six times more cytotoxic than **4**, a result which is undoubtedly associated with the fivefold greater intercalation potential of **3** than of **4**. The cytotoxic activity of the anthraquinone–carbohydrate hybrids is thus correlated with their capacity to bind DNA.[19]

The present work demonstrates not only the molecular design and chemical synthesis of novel anthraquinone–carbohydrate hybrids, but also their DNA-binding profiles and cytotoxic activities. It has been shown that even a simple designed molecule can have strong DNA-binding properties in a sequence-selective fashion. The chemistry and biological evaluation presented provide significant information about the molecular design of novel and artificial DNA binding agents based on an intercalator–carbohydrate hybrid system.

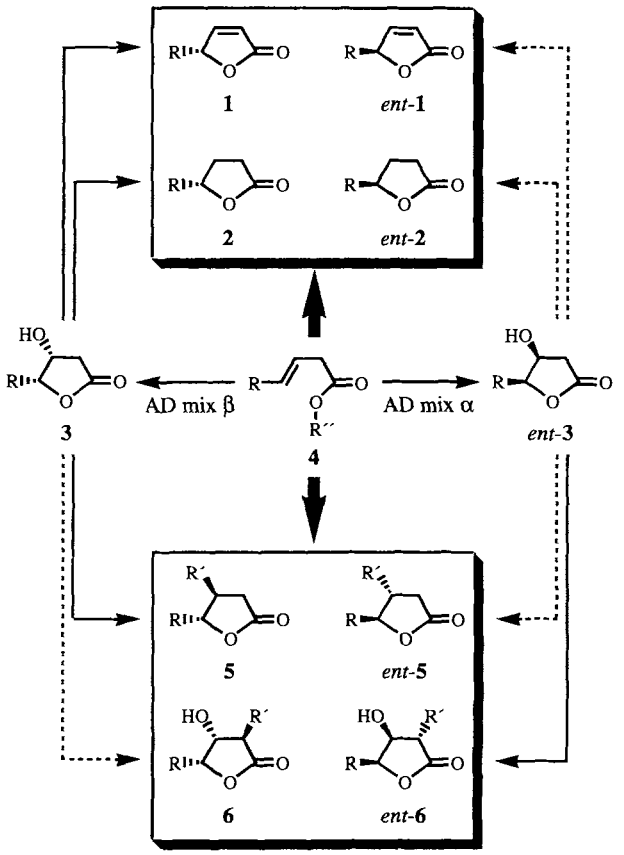
Synthesis of Optically Active Butenolides and γ-Lactones by the Sharpless Asymmetric Dihydroxylation of β,γ-Unsaturated Carboxylic Esters**

Christian Harcken and Reinhard Brückner*

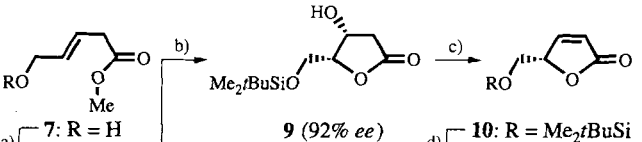
The Sharpless asymmetric dihydroxylation ("AD") of olefins is an indispensable tool for contemporary organic synthesis.[1] Frequently, the obtained 1,2-diols are not yet the desired target molecules. Rather, they are so profoundly modified by follow-up reactions that it may no longer be clear from the structures of the final products how well an AD served in their construction. The present study reveals that enantiomerically pure or enantiomerically enriched γ-chiral butenolides and γ-chiral γ-lactones—for which many syntheses are known, but more efficient ones are continuously being sought[2,3]—must be considered interesting products of the AD, too (Scheme 1). Specifically, ADs of β,γ-unsaturated esters **4** provided (in accordance with the scarce literature precedence[4,5]) lactonized dihydroxylation products, that is,



Scheme 1. Furanone derivatives accessible in two or three steps from **4**. Concrete examples for the reactions marked with solid arrows are given in Schemes 2–5. The dashed arrows refer to analogous transformations in the respective enantiomeric series that, however, have not yet been performed.

the compounds **3** or their enantiomers *ent*-**3** (78% ≤ *ee* ≤ 97%). From these, we have prepared to date chiral butenolides **1**/*ent*-**1**, monosubstituted γ-lactones **2**/*ent*-**2**, disubstituted γ-lactones **5**/*ent*-**5**, and trisubstituted γ-lactones **6**/*ent*-**6**. The transformations used are exemplified by enantioselective syntheses of the ranunculin aglycon (**11**; 92% *ee*; Scheme 2), the pheromone dodecanolide (**16**; 95% *ee*; Scheme 3), *trans* quercus lactone (**21**; 97% *ee*; Scheme 4), and one of the *epi*-blastmycinones (**25**; 78% *ee*; Scheme 5).

Our novel approach to γ-chiral butenolides **1** on the basis of the transformation type-**4**-ester → type-**3**-lactone is shown in Scheme 2. First, the known hydroxyester **7**[6] was O-silylated



Scheme 2. a) *t*BuMe$_2$SiCl (1.5 equiv), imidazole (3.0 equiv), CH_2Cl_2, 0°C, 30 min; 84%. b) AD mix β (1.40 g per mmol of **8**), methanesulfonyl amide (1.0 equiv), *t*BuOH/H_2O (1/1), addition of **8**, 0°C, 36 h; 88%. c) NEt_3 (2.1 equiv), methanesulfonyl chloride (1.1 equiv), CH_2Cl_2, 0°C, 1 h; 72%. d) HF/pyridine complex (70%, 0.50 mL per mmol of **10**), THF, 0°C, 16 h; silica gel, 15 min; 85%.

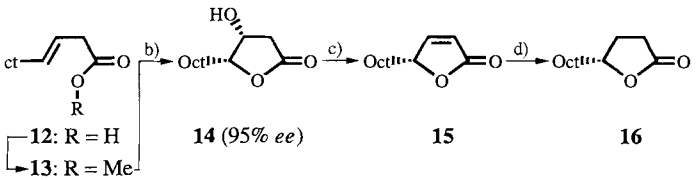
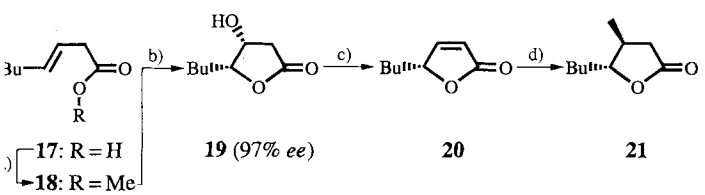
to form the β,γ-unsaturated ester **8**.[7] Then the compound was asymmetrically dihydroxylated by treatment with AD mix β to provide after purification by flash chromatography on silica gel[8] the *tert*-butyldimethylsilylated γ-lactone **9**[9] with 92% *ee*.[10] Mesylation with mesyl chloride/triethylamine followed by the spontaneous β-elimination of methanesulfonic acid introduced the C=C bond of the silylated butenolide **10**. Deprotection with HF/pyridine gave the ranunculin aglycon **11**.[11,12]

Our type-**4**-ester →type-**3**-lactone approach to chiral monosubstituted γ-lactones **2** is illustrated in Scheme 3 by an enantioselective synthesis of the rove beetle pheromone (+)-dodecanolide (**16**).[13] We started with a decarboxylative deconjugating Knoevenagel condensation between decanal and malonic acid; this provided the β,γ-unsaturated acid **12** predominantly as the desired *trans* isomer.[14] Four more steps (62% yield) led to the target structure **16**. They were: 1) esterification (→methyl ester **13**), 2) AD with AD mix β (→lactone **14**; 95% *ee*[10]), 3) mesylation/β-elimination (→butenolide **15**), and 4) Pd-catalyzed hydrogenation.[15]



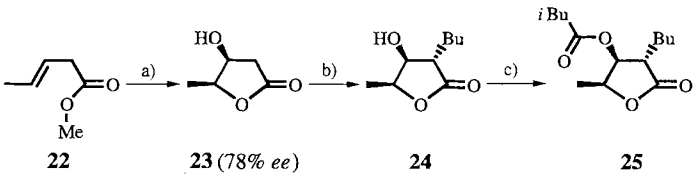
Scheme 3. a) MeOH (3.0 equiv), camphorsulfonic acid (1.0 mol%), $CHCl_3$, removal of water by azeotropic distillation, 12 h; 90%. b) AD mix β (1.40 g per mmol of **13**), methanesulfonyl amide (1.0 equiv), *t*BuOH/H_2O (1/1), addition of **13**, 0°C, 48 h; 81%. c) NEt_3 (2.1 equiv), methanesulfonyl chloride (1.1 equiv), CH_2Cl_2, 0°C, 15 min; 91%. d) Pd (10% on charcoal, 5 mol%), H_2 (3 bar), EtOAc, room temperature, 12 h; 94%.

Scheme 4 illustrates the AD-mediated type-**4**-ester →type-**3**-lactone approach to chiral disubstituted γ-lactones **5** by the hitherto shortest enantioselective synthesis[16] of *trans* quercus lactone (**21**).[17] This compound is formed in whisky barrels manufactured from oak-wood and contributes to the taste of the liquors stored therein. Acid **17**[14] was condensed with methanol and the resulting methyl ester **18** treated with AD mix β. Lactone **19** was obtained in 92% yield and with 97% *ee*.[18] Dehydration with the mesyl chloride/triethylamine mixture, which was also used in the **9**→**10** and **14**→**15** conversions, yielded butenolide **20**. Me_2CuLi added to this compound exclusively from the less hindered face, and we isolated the desired *trans*-configured 1,4-addition product **21** (the *trans* quercus lactone, also termed *trans* oak lactone or *trans* whisky lactone) and none of its *cis* isomer. The overall yield of this sequence was 47%.



Scheme 4. a) MeOH (3.0 equiv), camphorsulfonic acid (1.0 mol%), $CHCl_3$, removal of water by azeotropic distillation, 6 h; 76%. b) AD mix β (1.40 g per mmol of **18**), methanesulfonyl amide (1.0 equiv), *t*BuOH/H_2O (1/1), addition of **18**, 0°C, 36 h; 92%. c) NEt_3 (2.1 equiv), methanesulfonyl chloride (1.1 equiv), CH_2Cl_2, 0°C, 15 min; 87%. d) CuI (1.5 equiv), Et_2O, 0°C; addition of MeLi (3.0 equiv); cooling to −78°C; addition of **20** in Et_2O, 1.5 h; 77% of **21**.

Scheme 5 shows how treatment of the commercially available methyl pentenoate **22** with AD mix α makes the type-**4**-ester →type-**3**-lactone conversion a remarkably efficient synthesis of chiral trisubstituted γ-lactones **6**. Not



Scheme 5. a) AD mix α (1.40 g per mmol of **22**), *t*BuOH/H_2O (1/1), addition of **22**, 0°C, 5 d; 40%. b) LDA (3.0 equiv), THF, −78°C, 2 h; BuI (1.5 equiv) in THF/DMPU 1/1 (3 mL per mmol of BuI), −35°C, 20 h; 53% of **24**. c) 3-Methylbutanoyl chloride (1.5 equiv), CH_2Cl_2/pyridine 5/1, room temperature, 6 h; 83%.

unexpectedly,[19] the dihydroxylation product **23** exhibited only 78% *ee*.[10] With reference to the next step, it is known that in HMPA-containing THF (HMPA = hexamethyl phosphoric triamide) the α-alkylation of dilithiated β-hydroxy-γ-lactones akin to compound **23** occurs such that the α-substituent is oriented almost exclusively *trans* with respect to the β-OH group.[20] We were pleased to find that in 4:1 THF/DMPU[21] (DMPU = dimethylpropyleneurea) the butylation of the dilithiated β-hydroxylactone **23** itself also delivered only the *trans*-alkylated lactone **24** (53% yield) and no *cis* isomer at all. Acylation with isovaleroyl chloride led to the isovalerate **25**. As an epimer of blastmycinone, the antimycin A_3 degradation product, compound **25** had previously been synthesized several times, but with less rigorous stereocontrol.[22]

Several other AD-mediated butenolide and butyrolactone syntheses that exploit the ready availability of type-**4** esters[14] and employ type-**4**-ester →type-**3**-lactone conversions are under investigation in our laboratory.

A Hexaimidazole Ligand Binding Six Octahedral Metal Ions To Give an Infinite 3D α-Po-Like Network Through Which Two Independent 2D Hydrogen-Bonded Networks Interweave**

Bernard F. Hoskins, Richard Robson,* and Damian A. Slizys

The current intense activity in the area of crystal engineering can be traced back to a number of pioneering studies, an important one of which concerns the hexa-host clathrates introduced and elaborated by MacNicol et al. about twenty years ago.[1] This approach, which offered a very appealing element of deliberate design, led to the isolation and structural characterization of a wide range of new crystalline inclusion compounds by the use of host molecules based on benzene rings hexasubstituted by flexible but bulky side arms such as arylthio-, aryloxy-, and arylmethyl- groups. Weak van der Waals interactions were responsible in these cases for binding the hexa-host molecules together into a crystal lattice that left large cavities for guest molecules. Herein we make use of the hexa-host approach, but the six benzene substituents are terminated by outwardly directed imidazole donor ligands which can then, in principle, be bound together into a crystalline lattice by coordinate bonds to metal ions. Metal–ligand bonding in these systems may provide much better control and strength in assembling the hexa-hosts into lattices with larger cavities than could possibly be achieved by using the weaker and less predictable van der Waals interactions.

The ligand used here is hexakis(imidazol-1-ylmethyl)benzene (hkimb; **1**). Imidazole termini were deliberately chosen because they provide strong coordinate bonds and are small enough to allow six to assemble around an octahedrally coordinated metal ion (in contrast, for example, to pyridine donors).

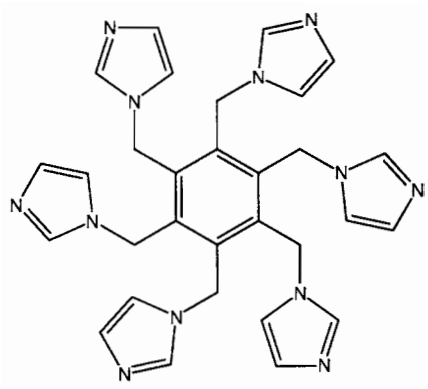
Another fruitful approach introduced by MacNicol et al. was based on the so-called Piedfort concept, in which two centrosymmetrically related 1,3,5-trisubstituted six-membered aromatic systems bound together by face-to-face π interactions mimic a single hexa-host molecule.[2] The ligand **1**



1

was arrived at, in part, by reverse Piedfort thinking as follows. The ligand 2,4,6-tri(4-pyridyl)-1,3,5-triazine (tpt) has recently been found to provide a number of highly symmetrical infinite coordination networks with unprecedented structures,[3–5] one in particular of which generates enormous sealed-off cavities.[3] The tpt ligands in these cases appear as closely associated centrosymmetrically related pairs that behave almost like single six-connecting units. A single hkimb ligand may be able to mimic these versatile $(tpt)_2$ pairs.

Compound **1** was synthesized by the reaction between hexakis(bromomethyl)benzene and sodium imidazolate and was structurally characterized as the hexahydrate by X-ray crystallography. To our surprise the molecule, in the crystal lattice, does not adopt the "1,3,5-up/2,4,6-down" conformation, but rather the "1,2,3-up/4,5,6-down" conformation (Figure 1). Hydrogen bonding of the exposed imidazole lone pairs to lattice water is responsible for this conformation. The closely related ligand hexakis(pyrazol-1-ylmethyl)benzene was reported recently and this does adopt the "1,3,5-up/2,4,6-down" conformation in the solid phase.[6]

The heavily hydrated $Cd(hkimb)F_2 \cdot 14H_2O$ was obtained by maintaining a hot aqueous solution containing CdF_2 and hkimb at 80 °C in an enclosed vessel for four days during which time colorless rhombohedral crystals separated. The structure was determined by X-ray crystallography, which revealed that every ligand, as intended, was attached to six cadmium centers and every cadmium was surrounded octahedrally by imidazole donors from six separate hkimb ligands (Figure 2). An infinite α-Po-related (or NaCl-related) coordination network is thereby formed in which alternating Cd center and benzene rings provide the six-connecting nodes (Figure 3). All ligands are equivalent as are all side arms

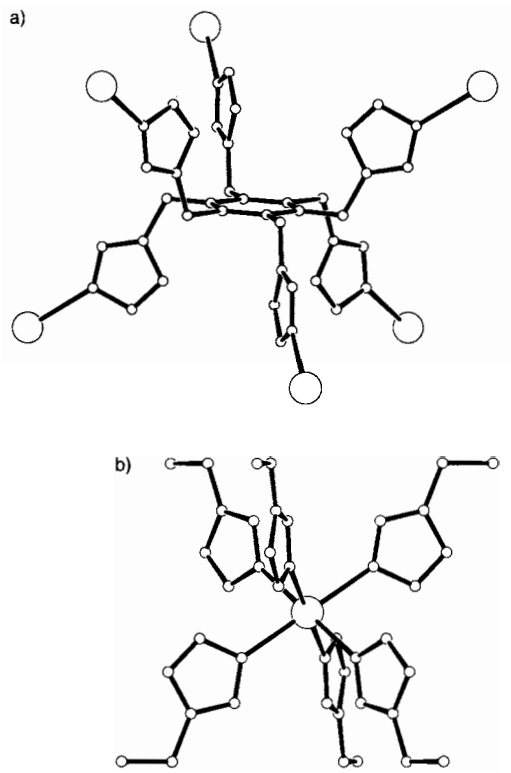


Figure. 2. Sections from the crystal structure of **2.** a) Six cadmium centers are attached to each imidazole ring of **1**. b) Each cadmium center is surrounded by six imidazole donors from six separate hkimb ligands. Cd – N, 2.350(3) Å.

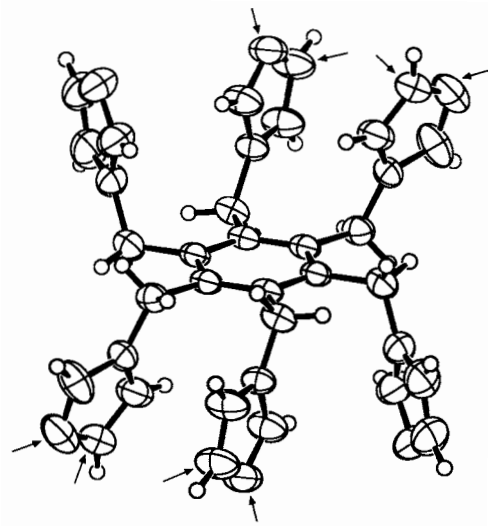

Figure 1. The structure of the centrosymmetric **1** in the $hkimb \cdot 6H_2O$ crystal. The symmetry-related imidazole residues at the top left and bottom right have the well-defined orientations shown, but the other two pairs show orientational disorder around the CH_2–N bond which interchanges N3 and C4–H.

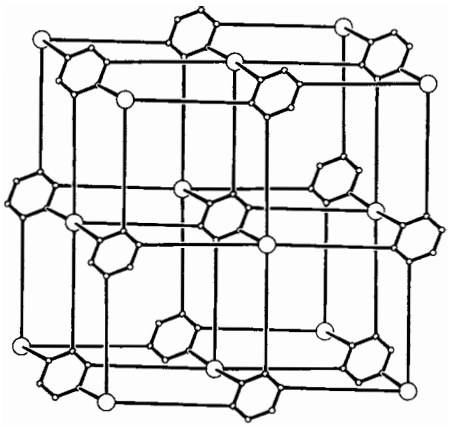

Figure. 3. Schematic representation of the infinite α-Po-related 3D net. The imidazolylmethyl links between Cd and the C_6 ring are represented by heavy lines.

within a ligand; all cadmium centers also are equivalent. The mean planes of all the benzene rings are parallel, the rhombohedral $\bar{3}$ axis passing perpendicularly through the center of the ring.

The fourteen molecules of water per cadmium arrange themselves into two independent undulating H-bonded 2D sheets. One of these, sheet A, includes the fluoride ion and the other, sheet B, consists entirely of water (Figure 4). The

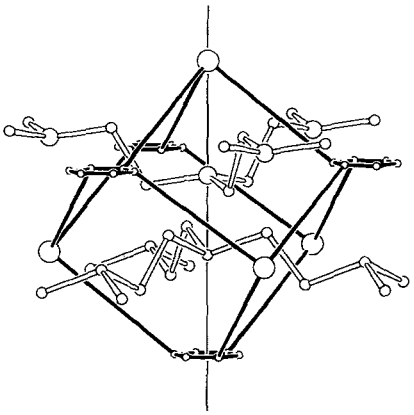

Figure. 4. Representation of the two independent H-bonded 2D sheets that weave through the 3D coordination polymer network of **2**. Circles in order of decreasing radius represent Cd, F, O, and C, respectively. "Open" connections represent H bonds. The fine vertical line passing through Cd, F, a water O atom, and the center of the C_6 ring represents the rhombohedral $\bar{3}$ axis. Sheet A is the upper one, sheet B the lower.

normals to the mean planes of the sheets are parallel with the $\bar{3}$ rhombohedral axis which is indicated in Figure 4 passing through a cadmium, a fluorine, and an oxygen center of one H_2O molecule belonging to sheet B and the center of the benzene ring. Within each cubelike rhomb of the sort represented by heavy lines in Figure 4 is found one F^- ion which is H-bonded to three symmetry-related water molecules of sheet A (F···O 2.634(9) Å). Each rhomb also contains an independent group of four water molecules of sheet B, consisting of a central water molecule located on the $\bar{3}$ axis, H-bonded to three symmetry-related water molecules (O···O 2.700(12) Å). These separate $F^-(H_2O)_3$ and $(H_2O)(H_2O)_3$ groups then connect to identical groups in adjacent rhombs by hydrogen bonds passing through the shared rhomb "windows" (Figure 4; O···O through the windows 2.99(2) Å for sheet A and 2.78(2) Å for sheet B). The closest oxygen-to-oxygen contact between the two sheets is 3.234(11) Å.

A large number of coordination networks have been generated recently by the use of two-, three-, and four-connecting ligands and the general area offers realistic promise of new materials with interesting and useful properties.[7] The easily synthesized six-connecting hkimb ligand reported here will undoubtedly afford many new types of framework materials.

Experimental Section

1: To a suspension under dinitrogen of NaH (3.159 g of a 60% dispersion in oil, 78.9 mmol) in THF (100 mL) was added a solution of imidazole (4,241 g, 62.3 mmol) in THF (200 mL). The resulting suspension was stirred for 30 minutes at which point hexakis(bromomethyl)benzene (5.815 g, 9.1 mmol) was added and washed into the suspension with THF (200 mL). The slurry was heated to 60 °C and was maintained at this temperature with stirring overnight. After the mixture had cooled the THF-insoluble solid was collected, washed with THF (20 mL), and then dissolved in water (30 mL). Aqueous HBr (2 M) was added dropwise until the pH had decreased to 6.5. A white precipitate formed during the addition. The solid was collected and recrystallized, with a hot filtration, from water to give the presumed the hexahydrobromide salt [3.723 g (39%)]. This was converted to the free base by passing an aqueous solution down an anion exchange column (Amberlite IRA 400) in the hydroxide form. The eluate was evaporated to dryness under reduced pressure and the residue was recrystallized from water to give hkimb·$6H_2O$ (2.168 g, 36%). ^{1}H NMR (CD_3OD) $\delta = 4.90$ (s, 2H; water), 5.48 (s, 2H; CH_2), 6.74 (1H, 4- or 5-imidazole), 6.86 (1H, 4- or 5-imidazole), 7.35 (1H, 2-imidazole); ^{13}C NMR (CD_3OD) $\delta = 45.82$, 120.06, 129.76, 137.93, 139.58. Elemental analysis for $C_{30}H_{30}N_{12}\cdot 5.7H_2O$: Calcd: C 54.5, H 6.3, N 25.4; found: C 54.5, H 6.1, N 25.5.

2: A solution of CdF_2 (22.1 mg, 0.147 mmol) in hot water (80 °C, 50 mL) was added to a solution of hkimb·$6H_2O$ (82.8 mg, 0.124 mmol) in hot water (80 °C, 50 mL). The initially clear solution was maintained at 80 °C in an enclosed vessel for four days during which time colorless rhombohedral crystals separated. The crystals of Cd(hkimb)$F_2\cdot 14H_2O$ (26.0 mg, 22%) were collected from the hot solution. Elemental analysis for $C_{30}H_{56}CdF_2N_{12}O_{13}$ (Cd(hkimb)$F_2\cdot 13H_2O$): Calcd: C 38.2, H 6.0, N 17.8, Cd 11.9, F 4.0; found: C 38.6, H 5.3, N 17.5, Cd 11.5, F 3.9.

Crystal data for hkimb·$6H_2O$. $M_r = 666.74$, monoclinic, space group $P2_1/c$ (No. 14), $a = 10.353(1)$, $b = 14.010(1)$, $c = 11.432(1)$ Å, $\beta = 97.32(1)°$, $V = 1644.6(2)$, $Z = 2$, $\rho_{calcd.} = 1.346$ g cm^{-3}, $\rho_{exp.} = 1.36(1)$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 8.1$ cm^{-1}, $F(000) = 708$. Intensity data for 4133 reflections, yielding 3326 independent reflections ($R_{int} = 0.0227$), were measured at 295(2) K with $Cu_{K\alpha}$ radiation (graphite monochromator) using an Enraf-Nonius CAD-4 MachS diffractometer and employing the $\omega/2\theta$ method; absorption corrections were applied [8]. All non-hydrogen atoms were located by using direct methods [9]. Subsequent cycles of least-squares refinement and difference syntheses (SHELXL-93) [10] indicated disorder in the location of carbon and nitrogen atoms within the imidazole rings and in the position of the oxygen atoms of two of the water molecules; these features were incorporated in the model. All the hydrogen atoms of the hkimb molecule, including those associated with the partially occupied carbon/nitrogen sites, were revealed in difference syntheses during the final stages of refinement and they were included in the refinement at their geometrically constrained positions. Anisotropic displacement parameters were applied to all non-hydrogen atoms. Full-matrix least-squares refinement based on F^2 converged with $R1 = 0.0506$, $wR2 = 0.1445$ and GOF = 1.081; values of minimum and maximum residual electron density 0.376 and -0.210 e Å^{-3}. Crystal data for Cd(hkimb)$F_2\cdot 14H_2O$. $M_r = 961.29$, rhombohedral, space group $R\bar{3}m$ (hexagonal setting of No. 166), $a = 11.989(2)$, $c = 25.362(5)$, $V = 3157(1)$, $Z = 3$, $\rho_{calcd.} = 1.517$ g cm^{-3}, $\rho_{exp.} = 1.54(1)$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 49.0$ cm^{-1}, $F(000) = 1500$. Intensity data for 1889 reflections, yielding 833 independent reflections ($R_{int} = 0.0340$), were measured at 295(2) K with $Cu_{K\alpha}$ radiation (graphite monochromator) using an Enraf-Nonius CAD-4 MachS diffractometer and employing the $\omega/2\theta$ method; absorption corrections were applied [8]. All non-hydrogen atoms were located by using the Patterson interpretation routine of SHELXS-86 program [9]. The ligand hydrogen atoms, all of which were revealed in the difference syntheses during the last stages of refinement [10], were included in the refinement at their geometrically constrained positions. Anisotropic displacement parameters were applied to all non-hydrogen atoms. Full-matrix least-squares refinement based on F^2 converged with $R1 = 0.0433$, $wR2 = 0.1184$ and GOF = 1.111; values of minimum and maximum residual electron density 0.905 and -0.989 e Å^{-3}. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication no. CCDC-100665. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ (fax: Int. code + (1223) 336-033; e-mail: deposit@chemcrys.cam.ac.uk).

Periodic Structure of a Single Sheet of a Clothlike Macromolecule (Atomic Cloth) Studied by Scanning Tunneling Microscopy**

Tomohide Takami,* Hiroyuki Ozaki,* Mayumi Kasuga, Takao Tsuchiya, Yasuhiro Mazaki, Daiji Fukushi, Ayumi Ogawa, Masayuki Uda, and Masakazu Aono

Recently we prepared a single sheet of a sashlike or clothlike macromolecule (atomic sash or atomic cloth) by photopolymerization of alkadiyne or alkatetrayne molecules that were laid flat and closely packed in a vapor-deposited monolayer on a cooled graphite substrate. The process was monitored by Penning ionization electron spectroscopy (PIES).[1-3] Particularly the atomic cloth, which is composed of flatly lying alkyl chains cross-linked alternately by polydiacetylene (PD) and polyacetylene (PA) chains as shown in Figure 1, triggered our interest because of its molecular structure, electronic structure, and electrical properties. It is expected that the unit mesh of the atomic cloth is forced to have a parallelogram structure because of the peculiar clothlike configuration supported by the substrate. This is in spite of considerable strain mainly due to the overcrowding of hydrogen atoms at the crossing points of alkyl and PA chains.

[**] We thank Dr. Naoaki Kanada and Mr. Takeharu Sekiguchi (The University of Tokyo), Dr. Toru Egawa (Hokkaido University), Prof. Toshimasa Ishida (University of Shizuoka), and Dr. Hideki Katagiri (Electrotechnical Laboratory) for helpful discussions. This work was partly supported by the Special Researchers' Basic Science Program in RIKEN, and a grant-in-aid for Scientific Research on Priority Areas "Molecular Superstructure—Design and Creation" (no. 262/08231219) from the Ministry of Education, Science, Sports, and Culture, Japan. For a definition of "atomic cloth", see ref. [2, 3] and Y. Harada, S. Masuda, H. Ozaki, *Chem. Rev.* **1997**, *97*, 1897–1952.

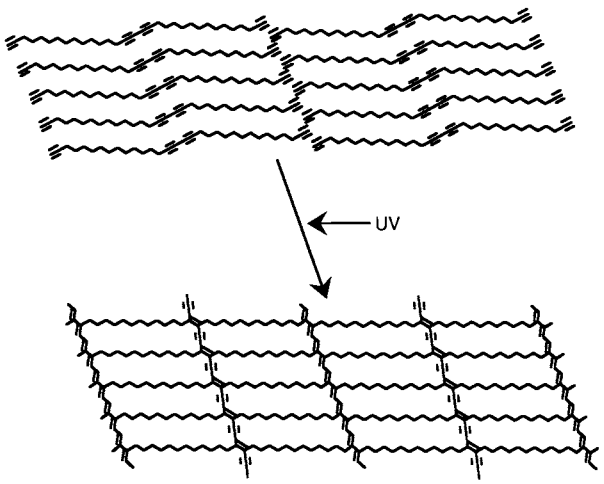

Figure 1. Schematic drawing of the atomic cloth prepared by photopolymerization of 1,15,17,31-dotriacontatetrayne molecules that were laid flat and closely packed in a monolayer.

The atomic cloth can also be regarded as a two-dimensional anisotropic sheet or an array of one-dimensional π-electron systems with fixed configuration, which cannot be easily obtained by ordinary preparative methods. Thus, it is of fundamental importance to prove and explain the periodic structure of the atomic cloth for studies on this fascinating material.

It was confirmed by PIES that 1) the graphite surface was just covered with the flatly lying alkyl chains, and the orientation was maintained throughout UV irradiation, 2) the π MOs of the diacetylene and acetylene units of the monomer (1,15,17,31-dotriacontatetrayne (DTTY)) were altered to the long conjugated systems of the PD and PA chains, and 3) unlike an unirradiated monolayer, the irradiated monolayer did not sublime under ultrahigh vacuum (UHV) upon heating to room temperature.[2] To obtain direct evidence for the formation of the clothlike structure, scanning tunneling microscopy (STM) was applied. We found the unit vectors of the atomic cloth by analyzing the periodic modulation of the STM image contrast due to the coincidence of the structure of the atomic cloth and that of the graphite substrate.

The specimen was prepared on a cleavage plane of highly oriented pyrolytic graphite (HOPG) in an UHV electron spectrometer, as previously described.[2,3] The atomic cloth did not show a different PIE spectrum after it was temporarily exposed to the air at room temperature and then returned to the spectrometer. The STM equipment (from WA Technology) was in another UHV chamber.[4] An STM tip made of tungsten wire (diameter 0.5 mm) was sharpened by electrochemical etching. STM images were obtained at room temperature in the constant-current topograph mode and calibrated with the images of HOPG and Si(111) 7×7 surfaces obtained immediately before and after the measurements of the atomic cloth. The scanning time was about 30 s for one image of 256×256 points.

The STM topograph of the atomic cloth is shown in Figure 2. This image was obtained at a sample bias voltage of +0.2 V, which corresponds to the unoccupied states. Sixteen bright lines running diagonally from the upper left to the lower right are observed; their brightness changes alternately.[5-7] The distance between the adjacent brighter and darker

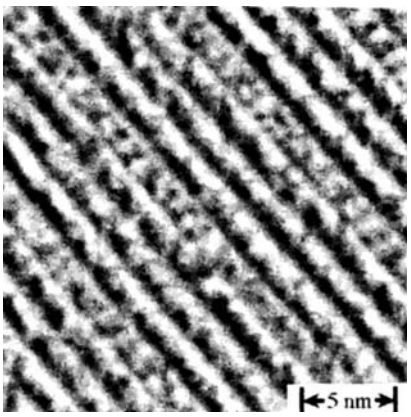

Figure 2. UHV-STM image of the atomic cloth on graphite. Sample bias voltage: +0.2 V, tunneling current: 0.1 nA, image sizes: 20.0 × 20.0 nm.

lines is 1.7 ± 0.1 nm. Taking into account the chemical structure of the atomic cloth, it is natural to ascribe this value to the distance between the neighboring PD and PA chains; this results in a distance D of 3.4 nm between two nearest PD or PA chains. It is noteworthy that there is a modulation in the STM image contrast at every fourth lines, that is, with a periodicity of $2D = 6.8$ nm. Moreover, an internal structure is observed between two of the four lines: runglike features are placed at an average rung–rung separation of $d = 1.4$ nm. This value is close to three times the width of an alkyl chain (0.47 nm). The peak–peak height of the topograph is about 0.4 nm, which is in agreement with the thickness of the atomic cloth. However, the real thickness cannot be estimated by STM.

Figures 3a and 3b show a Fourier-transformed power spectrum of the STM image (Figure 2) and its schematic interpretation, respectively. From the analysis of the Fourier transform we can make the following four findings: First, intense spots in Figure 3a (large spots in Figure 3b) result in the main interval in Figure 2 ($D/2 = 1.7$ nm), the distance between a PD chain and its neighboring PA chain. Second, additional spots in Figure 3a (small spots in Figure 3b) are

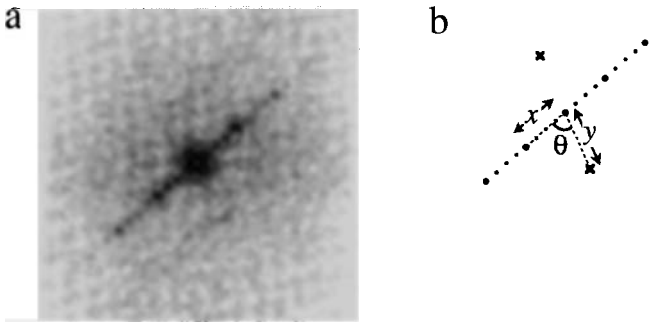

Figure 3. a) Fourier-transformed power spectrum of the STM image shown in Figure 2; b) schematic interpretation of the power spectrum.

lined up with the quartered interval of distance $2D = 6.8$ nm. This periodicity is observed as the four-line modulation pattern of the STM image contrast in Figure 2. Third, two diffuse spots (crosses in Figure 3b) are also observed in Figure 3a. Half of the distance between the diffuse spots corresponds to the spacing for the twisted features in Figure 2 ($d = 1.4$ nm), which is three times the width of the alkyl chain. Fourth, angle θ between the two lines drawn on the spots in Figure 3b is 71.7°, and ratio y/x is 1.18.

These results are explained by lattice matching between the atomic cloth and graphite according to Equation (a);

$$p \cdot \mathbf{a} = i \cdot \mathbf{a}_g + j \cdot \mathbf{b}_g,\ q \cdot \mathbf{b} = k \cdot \mathbf{a}_g + l \cdot \mathbf{b}_g \qquad \text{(a)}$$

$\mathbf{a}_g$ and $\mathbf{b}_g$ are the unit vectors of graphite, $\mathbf{a}$ and $\mathbf{b}$ vectors for the repeating units of the atomic cloth along a PD or PA chain and $-(\overset{|}{C}{=}\overset{|}{C}\text{-}C_{12}H_{24})_{2n}-$ chain, respectively, and $p\mathbf{a}$ and $q\mathbf{b}$ the unit vectors of the total system comprising the atomic cloth and graphite. Periodicities $2D$ and d (corresponding to $x/4$ and y in the Fourier transformation) imply $q = 2$ and $p = 3$. Using the values of $2D$, d, and θ, we can find the approximate commensuration $\begin{pmatrix} i & j \\ k & l \end{pmatrix} = \begin{pmatrix} 7 & -4 \\ 13 & -20 \end{pmatrix}$, as shown schematically in Figure 4. Furthermore, if the one-dimensional modulation of

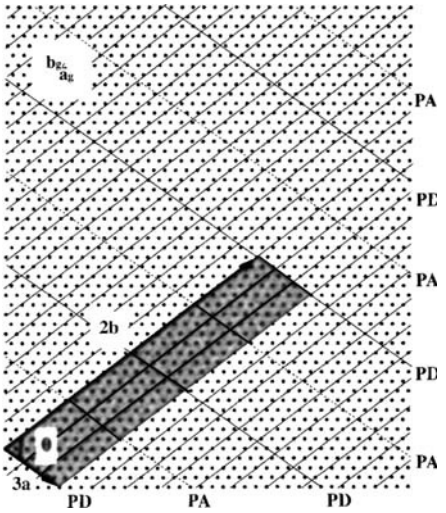

Figure 4. Proposed periodic structure of the atomic cloth on a graphite lattice (black circles). Solid and dashed lines show the PD and PA chains, respectively.

the STM image contrast with periodicity $2D$ is ascribed to the point-on-line coincidence,[8] which occurs when only j and l (or i and k) are integers and places all the lattice points of the organic layer on the (1,0) (or (0,1)) lines of graphite, values i and k are modified as 7.01 and 12.9 by introducing $m = |\mathbf{b}|/|\mathbf{a}| = (1/|\mathbf{a}|)/(1/|\mathbf{b}|) = (3y \sin\theta)/(x \sin\theta/2) = 6y/x = 7.07$ in Equation (b).

$$\begin{pmatrix} \frac{i}{p} \\ \frac{\sqrt{3}k}{2mq} \end{pmatrix} = \frac{1}{\sin\theta} \begin{pmatrix} -\sin\left(\theta + \frac{\pi}{3}\right) & 1 \\ -\frac{3}{4} & -\sin\left(\theta - \frac{\pi}{3}\right) \end{pmatrix} \begin{pmatrix} \frac{j}{p} \\ \frac{\sqrt{3}l}{2mq} \end{pmatrix} \qquad \text{(b)}$$

Equation (b) can be derived from the geometry of an adlayer whose structure on a hexagonal substrate is expressed by Equation (a). Thus, one obtains $|\mathbf{a}| = 0.499$ and $|\mathbf{b}| = 3.54$ nm; the former is comparable to the length of the repeating unit of various PDs (ca. 0.49 nm).[9]

Eichhorst-Gerner et al. prepared a one-dimensional hydrogen-bonded network with a donor–acceptor complex of 5-alkoxyisophthalic acid and 2,5-dimethylpyrazine at a liquid–graphite interface, and obtained the STM image with submolecular resolution.[10] In this network, the hydrogen bonds were introduced without altering the alkyl skeletons, and the methyl ends remained free. As a consequence, the direction of the zigzag coincides with that of vector $\mathbf{a}_g$, and the

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2756 $ 17.50+.50/0

length of the repeating unit nearly matches $|\mathbf{a}_g|$, which is responsible for the resolved STM pictures of the chains. This is usually the case for STM images of, for example, alkanes, alkanols, fatty acids, and dialkylbenzenes adsorbed on HOPG and observed with submolecular or atomic resolution.[11-13] In contrast, we introduced the new covalent bonds among molecules in a vapor-deposited monolayer and prepared a single sheet of a two-dimensional macromolecule: The centers and ends of chain molecules were transfixed with PD chains and stitched with PA chains, respectively, to afford condensed parallelograms without free methyl ends but with changes in the bond lengths and angles of the alkyl chains (see Figure 1). We consider that the drastic rearrangement of the covalent bonds detected by PIES[2] leads to the following results.

First, the atomic cloth is not commensurate with graphite in all directions. In fact, since i is very close to an integer (7)—to say nothing of j—the atomic cloth is almost point-on-point coincident with graphite along the **a** axis. On the other hand, since k is considerably different from an integer (13), there is no point-on-point but only point-on-line coincidence along the **b** axis. In other words, the periodicities of the PD and PA chains are approximately commensurate with that of graphite, while that of the $-(C{=}C_i-C_{12}H_{24})_{2n}-$ chains is not. It should be noted that neither the direction nor the periodicity of $-C_{12}H_{24}-$ matches that of graphite ($\mathbf{a}_g$ and $|\mathbf{a}_g|$). Second, the two-dimensionality of the atomic cloth may bring about slight local fluctuation or irregularity in the periodicity: The two-dimensional macromolecular network on a graphite lattice probably distorts the flexible portions in order to reduce the total energy of the system. Third, it is likely that these situations lead to the obviously observed periodicity $2D$ ($x/4$), but rather ambiguous periodicity d (y) in Figure 2 (Figure 3). It is surprising that the commensuration between PD/PA and graphite is present after such a drastic reaction. Studies on the structure of the DTTY monolayer are desired to elucidate the details. However, they are difficult, because the monomer monolayer is very liable to sublime under UHV at room temperature; furthermore, DTTY undergoes photopolymerization in the room light.

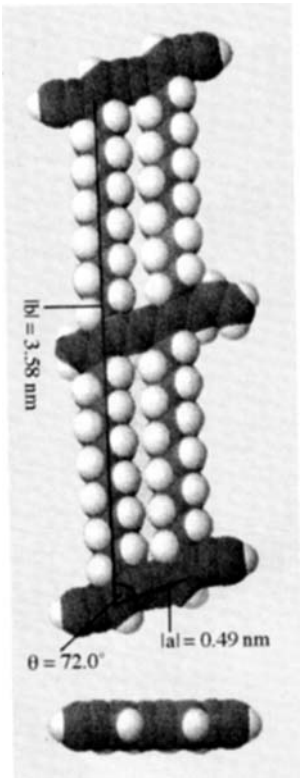

Figure 5. Structure of a model oligomer corresponding to the unit mesh of the atomic cloth obtained by MM2 calculation.

The periodic structure of the atomic cloth determined by STM can be supported by an MM2 calculation. Figure 5 shows the calculated structure of a model oligomer molecule corresponding to the unit mesh of the atomic cloth. The values of $|\mathbf{a}|$, $|\mathbf{b}|$, and θ are in good agreement with those observed.

We have observed the atomic cloth, a single sheet of a clothlike macromolecule, by STM. The periodic features and contrast modulation of the STM images are explained by lattice matching between the atomic cloth and graphite. The lengths of the unit vectors of the atomic cloth are 0.499 and 3.54 nm, and the angle between the vectors is 71.7°. These results show the great promise of STM in determining the structure of a two-dimensional macromolecule (organic monoatomic layer) prepared on a crystallographical surface.

[5] We carried out ab initio calculations on some oligomeric models of the atomic cloth. The results showed that the LUMO is mainly distributed on the PD chains, whereas the HOMO is on the PA chains. If the picture presented in Figure 2 is assumed to be due to the LUMO, the brighter lines correspond to the PD chains, and the darker lines to the PA chains. However, this tentative assignment does not matter for the following discussion on the structure of the atomic cloth.
[6] We compared our STM images with the artifact images reported in C. R. Clemmer, T. P. Beebe, Jr., *Science* **1991**, *251*, 640–642 and H. Chang, A. J. Bard, Langmuir **1991**, *7*, 1143–1153, which were ascribed to the cleavage steps, strands, and small particles of HOPG. Our STM image, however, has a long periodicity and is different from the artifact images.
[7] Reversed STM images were observed upon changing the bias voltage; that is, PD and PA chains were dark, and alkyl chains bright. Nevertheless, there was no distinct feature corresponding to the latter chains but the undulation of contrast due to the former chains with periodicity $2D$. The image due to graphite was not observed either.

Conformation Control in Polymetallic Mesocycles by Metal–Metal Bonding: The First Example of an Hg–Cu Interaction**

Marc Bénard, Ulf Bodensieck, Pierre Braunstein,* Michael Knorr, Martin Strampfer, and Carsten Strohmann

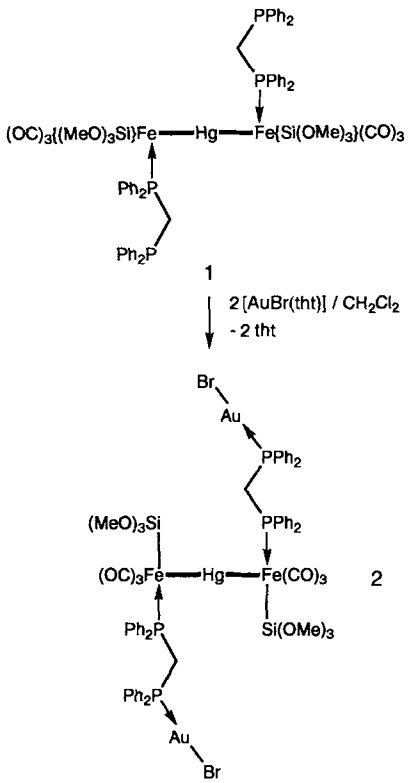
Dedicated to Professor The Lord Lewis on the occasion of his 70th birthday

Seven- to ten-membered inorganic rings (mesocycles) in which two or more *consecutive* atoms are transition metals are relatively few, and heterometallic examples are even rarer.[1] By analogy with cyclic structures consisting of isolated metal centers connected by bridging ligands,[2] their structure, conformation, and topology should depend not only on the nature of the organic backbone, but also on the nature of the metal–ligand interactions. In addition, unique properties may result when metal–metal bonds are introduced,[3] and novel features can be anticipated when these interactions occur in directions different from those of the covalent bonding, as shown by the chemistry of gold.[4] Although this element exhibits the most pronounced relativistic effects, interactions involving other d^{10} closed-shell ions (such as Hg^{II}) are also expected to influence the structure and properties of complexes.[5] Here we report the first example of an attractive Cu–Hg interaction and show how its transannular orientation determines the conformation of an unprecedented cyclic polymetallic complex.

The central d^{10} ion in the heterotrinuclear complex **1** (dppm = $Ph_2PCH_2PPh_2$)[6] confers rigidity to the Fe-Hg-Fe chain and allows free rotation about the metal–metal bonds. We have now used this molecule as a large trimetallaphosphane ligand for the synthesis of unusual heterometallic ring and chain complexes. To our knowledge, only metallaphosphanes containing one[7] or two metal centers have been used previously.[8]

The reaction of **1** with two equivalents of [AuBr(tht)] (tht = tetrahydrothiophene) gave the yellow, air-stable chain complex **2**, whose spectroscopic data (see Experimental Section) are consistent with the structure shown in Scheme 1.

Upon mixing **1** with slightly more than two equivalents of $[Cu(NCMe)_4]PF_6$ in cold CH_2Cl_2, yellow complex **3** formed quantitatively. The ν(CO) region of its IR spectrum is very similar to that of **2**, and the presence of acetonitrile coordinated to copper is indicated by very weak bands at



Scheme 1.

2314 and 2278 cm^{-1}. When crystals of **3** were dissolved in CH_2Cl_2/CD_2Cl_2 at room temperature, two sets of $^{31}P\{^1H\}$ NMR resonances were observed with approximately equal integral intensities. The first set comprised two broad signals at $\delta = 50.1$ and -13.1 for the open-chain complex **3**, while the second set consisted of a well-resolved multiplet at $\delta = 46.2$ and a broad multiplet at $\delta = -9.9$, which were assigned to the cyclic species **4**. On cooling to 223 K, the resonances assigned to **3** became two well-resolved doublets centered at $\delta = 48.0$ and -15.6 with $^2J(P,P) = 8$ Hz. The signals of **4** now appeared at $\delta = 46.2$ and -10.3, and their integral intensities were diminished to about 5–10% of those of **3**. No significant change was observed upon further cooling to 213 K. Orange **4** was independently synthesized in high yield by the reaction of **1** with only one equivalent of $[Cu(NCMe)_4]PF_6$ in CH_2Cl_2 (Scheme 2).

The structure of the cation of **4** is shown in Figure 1.[9] The Fe-Hg-Fe unit is linked to the Cu atom by dppm ligands. A C_2 axis passes through the Cu and Hg atoms. The geometry around Fe could be regarded as distorted octahedral, although the angle C2-Fe-C3 is only 162.2(3)°, as is observed in other complexes of the type $[MFe(SiR_3)(CO)_3(PR_3)]$.[10] The alternative description as trigonal bipyramidal, for which the Fe–Hg bond is neglected, is therefore more consistent with a formal d^8 Fe^0 center. The Fe–Hg distance of 2.611(4) Å is in the normal range.[6,11] The most unusual feature of this structure is the presence of an attractive Cu–Hg interaction, which results in a coordination number of three for both metal centers. The Cu–Hg bond appears to be the first of its kind, and the metal–metal distance of 2.689(2) Å can be compared to the sum of the Pauling covalent radii (1.17 (Cu) + 1.44 (Hg) = 2.61 Å). The P2-Cu-P2a angle of 160.16(9)° reflects the bonding interaction between the two d^{10} ions and illustrates the capacity of **1** to behave as a *trans* bridging

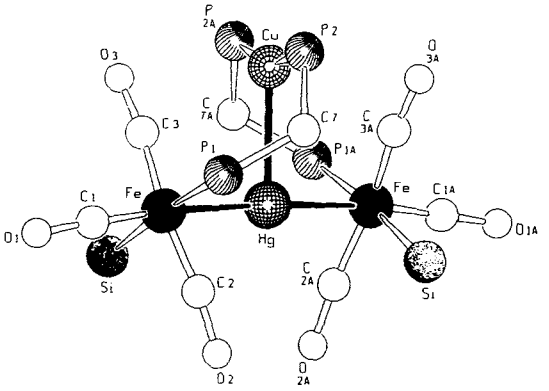
+ $[Cu(NCMe)_4]PF_6$

Scheme 2.



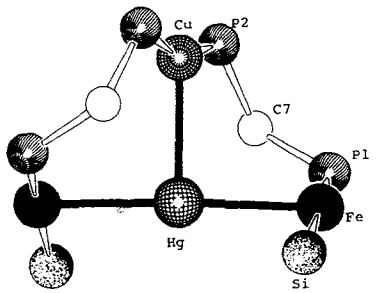


Figure 1. a) Top: Structure of the cation $[Hg\{Fe[Si(OMe)_3](CO)_3(\mu\text{-dppm})\}_2Cu]^+$ in $4\cdot 4CH_2Cl_2$ (SCHAKAL plot). Selected interatomic distances [Å] and angles [°]: Hg–Fe 2.613(2), Hg–Cu 2.689(2), Fe–Si 2.330(2), Fe–P1 2.260(2), Fe–C1 1.775(6), Fe–C2 1.794(7), Fe–C3 1.784(7), Cu–P2 2.228(2); Fe-Hg-Fe(a) 176.62(4), Fe-Hg-Cu 91.96(2), Hg-Fe-Si 82.97(6), Hg-Fe-P1 95.92(6), P1-Fe-Si 175.49(7), P2-Cu-P2a 160.16(9); b) Bottom: view of the heavy-atom core.

ligand. The linearity of the Fe-Hg-Fe chain is maintained in **4** and confers a T-shaped structure to the metal core.[12]

Extended Hückel calculations[13] on the model system **5** yielded the orbital interaction diagram shown in Figure 2.

$[Hg\{Fe[Si(OMe)_3](CO)_3(dppm\text{-}P)\}_2]$ **1**

$[Hg\{Fe[Si(OMe)_3](CO)_3(\mu\text{-dppm})AuBr\}_2]$ **2**

$[Hg\{Fe[Si(OMe)_3](CO)_3(\mu\text{-dppm})\}_2\{Cu(NCMe)_2\}_2][PF_6]_2$ **3**

$[Hg\{Fe[Si(OMe)_3](CO)_3(\mu\text{-dppm})\}_2Cu]PF_6$ **4**

On the left, the interaction diagram between the valence orbitals of an Hg atom and those of the $\{Fe[Si(OH)_3](CO)_3PR_3\}_2$ dimer (both fragments are assumed to be neutral) shows the origin of the Fe–Hg bonding interactions. The bonding orbital of lowest energy (−14.1 eV) is equally shared between the 6s orbital of mercury and an in-phase combination of the d_{z^2} orbitals of Fe (the z axis is parallel to the Fe-Hg-Fe direction). The antibonding counterpart of this interaction (−6.1 eV) is mainly centered on Fe, but still contains an important contribution (22%) from the s orbital of Hg. The second Fe-Hg-Fe bonding orbital (−12.1 eV) results from the favorable interaction between the out-of-phase combination of the d_{z^2} orbitals of iron with the p_z orbital of Hg. The latter orbital is not affected by the incoming $[Cu(PR_3)_2]^+$ cation and represents, practically unchanged, the HOMO of complex **5**. A cluster of eight orbitals with strongly dominant Fe character (−12.7 to −13.3 eV) also remains unperturbed by the approaching copper complex fragment.

$[Hg\{Fe[Si(OH)_3](CO)_3(\mu\text{-}H_2PCH_2PH_2)\}_2Cu]^+$ **5**

The Cu–Hg bonding orbital of lowest energy arises from the favorable overlap between the unoccupied p_x orbitals of both metal atoms, which point towards each other. However, the stabilized combination is too high in energy to be occupied (−9.3 eV). This orbital represents the LUMO of **5**. The only effective interaction between Cu and Hg involves the 6s orbital of Hg (stabilized by the d_{z^2} orbitals of Fe) and the d_{x^2} orbital of the copper fragment (the x axis is parallel to the Cu–Hg axis). The orbitals of both fragments are doubly occupied and generate a four-electron interaction, which is often considered to be unfavorable. However, the upper term of this interaction is only moderately destabilized due to contributions from energetically high-lying orbitals such as

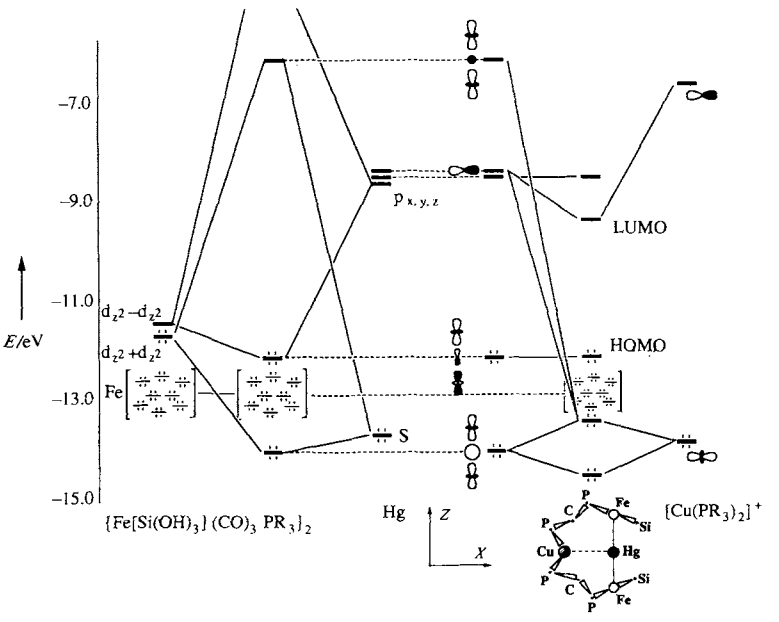

Figure 2. Simplified orbital interaction diagram between a $\{Fe[Si(OH)_3](CO)_3(PR_3)\}_2$ dimer and a Hg atom (left). Both fragments are assumed to be neutral. The orbitals of the resulting heterotrinuclear complex fragment are then allowed to interact with $[Cu(PR_3)_2]^+$, which yields $[Hg\{Fe[Si(OH)_3](CO)_3(\cdot\text{-}H_2PCH_2PH_2)\}_2Cu]^+$ (**5**; right).

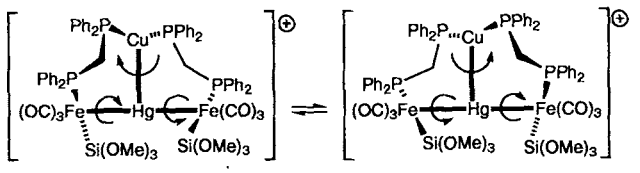
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2759 $ 17.50+.50/0

the p_x orbital of Hg and the antibonding orbital of the trinuclear fragment referred to as $d_{z^2}(Fe_1) - s(Hg) + d_{z^2}(Fe_2)$. The four-electron interaction yields a moderate energy splitting of about 1 eV between the resulting orbitals, and should be considered as globally devoid of any repulsive character (Figure 2, right).

Although the short Cu–Hg distance cannot be ascribed to a definite metal–metal bond, the T shape of the complex allows the two metal atoms to approach each other to the limits of their covalent radii without developing the repulsion characteristic of pair–pair interactions. This is somewhat reminiscent of 1,6-transannular interactions in ten-membered organic rings. We believe the structure of complex **4** and the Cu–Hg distance to result, at least in part, from steric and strain factors that are expected to develop in the mesocycle constructed around the T-shaped metal framework, and from the van der Waals interactions between heavy-metal atoms with closed-shell configurations.[14]

The dynamic behavior observed for the PCH_2 protons of the dissymmetric molecule **4** (broad ^1H NMR signals at $\delta =$ 3.76 and 3.48), together with the successful simulation of the $^{31}P\{^1H\}$ NMR spectrum at 300 K as an AA′XX′ spin system, indicates the existence of an average plane of symmetry. This can be achieved by torsion along the Cu–Hg bond (Scheme 3), which can be compared to a "molecular torsion pendulum".



Scheme 3. The dynamic behavior of **4** in solution which accounts for the occurrence of an average mirror plane containing the four metal centers.

Owing to the lability of the P→Cu bond, the "locking/unlocking" equilibrium between the chain **3** and the ring **4** (Scheme 2) can be shifted towards **3** by lowering the temperature, which favors nitrile over phosphane coordination to Cu^I, and by increasing the MeCN and/or the Cu^+ concentration. The absence of MeCN ligand(s) on the copper atom of **4** supports the presence of a Cu–Hg bonding interaction, which decreases the coordinative unsaturation of the Cu atom.[15]

Experimental Section

All experiments were carried out under nitrogen by using Schlenk-tube techniques. Satisfactory elemental analyses were obtained for all complexes. NMR spectra were recorded on Bruker SY200 and AC300 instruments, and mass spectra were measured on a Fisons ZAB-HF spectrometer (Université Louis Pasteur, R. Hueber). Unless otherwise specified, the pure complexes are air-stable in the solid-state for prolonged periods of time.

2: Solid **1** (0.200 g, 0.134 mmol) and [AuBr(tht)] (0.050 g, 0.137 mmol) were mixed and cooled to −78 °C, and then CH_2Cl_2 (5 mL) was added. After the solution warmed to room temperature it was stirred for 1 h under exclusion of light. The resulting yellow solution was filtered, evaporated to 1 mL, and layered with 10 mL of hexane. The mixture was allowed to stand at 0 °C, and bright yellow crystals formed after one week (0.200 g, 75%). IR (KBr): ν(CO) = 2012 (vw), 1994 (s), 1943 (m), 1921 cm^{-1} (vs); FIR (polyethylene): ν(Au–Br) = 239 cm^{-1} (vs); ^1H NMR (200 MHz, $CDCl_3$, 323 K): $\delta = 3.54$ (s, 18H, OCH_3), 3.61 (br m, 4H, CH_2), 7.26–7.66 (m, 40H, C_6H_5); $^{31}P\{^1H\}$ NMR (81.02 MHz, CH_2Cl_2/C_6D_6, 303 K): $\delta = 48.3$ (br s, 2P, P(Fe), $^2J(P,^{199}Hg) \approx 170$ Hz), 21.8 (d, 2P, P(Au), $^2J(P,P) = 19$ Hz); (263 K): $\delta = 46.5$ (d, 2P, P(Fe), $^2J(P,P) = 19$, $^2J(P,^{199}Hg) = 180$ Hz), 21.0 (d, 2P, P(Au)).

3: Solid **1** (0.200 g, 0.134 mmol) was added at 0 °C to a solution of $[Cu(NCMe)_4]PF_6$ (0.100 g, 0.268 mmol) in CH_2Cl_2 (10 mL). The clear solution was stirred for 0.5 h, and then the volume reduced to about 5 mL. After layering the solution with hexane, yellow, air-stable crystals of **3** formed after a few days at 5 °C (0.26 g, 90%). IR (KBr): ν(CN) = 2314 (vw), 2278 (vw); ν(CO) = 1994 (s), 1935 (sh), 1929 (vs); ν(PF) = 840 cm^{-1} (vs); $^{31}P\{^1H\}$ NMR (81.02 MHz, CH_2Cl_2/CD_2Cl_2, 223 K): $\delta = 48.0$ (d, 2P, P(Fe), $^2J(P,P) = 8$ Hz), −15.6 (d, 2P, P(Cu)); (CH_2Cl_2/CD_3CN, 304 K): $\delta = 53.0$ (s, 2P, P(Fe), $^2J(P,^{199}Hg) \approx 170$ Hz), −13.5 (br s, 2P, P(Cu)).

4: Solid **1** (0.298 g, 0.200 mmol) was dissolved in CH_2Cl_2 (10 mL), and $[Cu(NCMe)_4]PF_6$ (0.075 g, 0.200 mmol) was added. The solution was stirred for 15 min and then layered with hexane. Large orange crystals of $4 \cdot 4CH_2Cl_2$ were isolated after one day. IR (KBr): 1999 (s), 1931 cm^{-1} (vs, br); $^{31}P\{^1H\}$ NMR (121.1 MHz, $CDCl_3$, 300 K): $\delta = 47.7$ (AA′XX′ spin system, 2P, P(Fe), $N =$ 51 Hz), −9.9 (br, 2P, P(Cu)).

Theoretical Studies of the Structure, Aromaticity, and Magnetic Properties of *o*-Benzyne**

Haijun Jiao, Paul von Ragué Schleyer,* Brett R. Beno, Kendall N. Houk,* and Ralf Warmuth*

In memory of Georg Wittig

o-Benzyne (1,2-didehydrobenzene, **1**) was postulated as an unstable intermediate by Wittig 57 years ago.[1] The distorted structure and the ability of **1** to participate in a wide variety of organic reactions have elicited intense interest in this reactive species.[2] The nature of **1** has been investigated extensively with both experimental[3–6] and theoretical methods.[7,8]

Warmuth recently reported the first ^{1}H and ^{13}C NMR spectra of **1** trapped within a hemicarcerand host.[9] Here we compare calculated ^{1}H and ^{13}C NMR chemical shifts as well as ^{13}C–^{13}C coupling constants to the experimental values, and report aromatic stabilization energies, magnetic susceptibilities, magnetic susceptibility exaltations, and nucleus-independent chemical shifts for **1**. These properties are used to probe the nature of **1**, and to address the possibility of bond localization induced by the in-plane π bond.

Benzene adopts its experimental geometry because the energetic preference for a σ bonding array with equal C–C bond lengths and D_{6h} symmetry is larger than the destabilization of the π system, which favors a bond-localized D_{3h} geometry.[10] Since the in-plane π bond in **1** distorts the molecule away from D_{6h} symmetry, reducing the σ stabilization, does bond localization of the π system result? If so, to what extent, and is **1** best described as a cyclohexadienyne (**1a**), a cyclic cumulene (**1b**), or a delocalized aryne (**1c**)?

[**] This work was supported by the Deutsche Forschungsgemeinschaft in Erlangen, and by the National Science Foundation and the Alexander von Humboldt Foundation (Feodor-Lynen fellowship for R.W.) in Los Angeles.

Recent experimental studies provided structural information for **1**. Radziszewski et al.[5d] measured a C≡C stretching vibration of 1846 cm^{-1} in a neon matrix. This is consistent with the value of (1860 ± 15) cm^{-1} given by an earlier laser photodetachment study.[6a] This frequency is closer to the C≡C stretching vibration in acetylene (1974 cm^{-1}) than to the C=C stretch in ethylene (1623 cm^{-1}).[11] Based on a dipolar ^{13}C NMR spectrum of 1,2-$^{13}C_2$-**1** in an argon matrix, Orendt et al.[12] deduced a C1–C2 length of (1.24 ± 0.02) Å, which is also indicative of partial triple bond character.

In the present study geometries were optimized with density functional theory (DFT) using the Becke3LYP[13] and BLYP[14] functionals and several basis sets with the Gaussian 94 program.[15] Magnetic susceptibilities (χ) were calculated at the Becke3LYP/6-31G* level with the CSGT method,[16] and nucleus-independent chemical shifts[17] at GIAO-SCF/6-31 + G*//Becke3LYP/6-31G*.[18] NBO analyses[19] provided the Wiberg bond indices (WBI) on the Becke3LYP/6-31G* geometries. The CSGT, GIAO, and NBO methods are implemented in Gaussian 94. The ^{1}H and ^{13}C NMR chemical shifts as well as the ^{13}C–^{13}C coupling constants were calculated using the PW91 (Perdew-Wang-91) exchange correlation potential and the IGLO-III basis set with the SOS-DFPT method (SOS-DFPT = *s*um *o*ver *s*tates *d*ensity *f*unctional *p*erturbation *t*heory)[20] in the deMon program.[21]

Table 1 summarizes the optimized C–C bond lengths of **1** at various computational levels. Most of the methods listed give C1–C2 bond lengths within 0.02 Å of the experimental value

Table 1. Optimized bond lengths [Å] for **1** at various computational levels.

Level	C1–C2	C2–C3	C3–C4	C4–C5

exptl[12]	1.24 ± 0.02			

of (1.24 ± 0.02) Å, but the Becke3LYP bond lengths are slightly closer.[12] The CASSCF structures have C2–C3, C3–C4, and C4–C5 bond lengths which alternate in the pattern long-short-long, while the those at the Becke3LYP level have bond lengths that follow the pattern short-long-short. On the basis of bond lengths alone, the CASSCF structures resemble **1a**, while the Becke3LYP geometries are closer to **1b**. Which more accurately describes the nature and electronic structure of **1**? To model the strain effects and bonding in **1** as closely as possible, we optimized the geometries of a set of reference molecules (**2**–**9**).

As shown in Figure 1, the bond length and the WBI of the triple bond in **1** are close to the mean of the corresponding values for 2-butyne (**2**) and the central C=C bond in

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2761 $ 17.50+.50/0

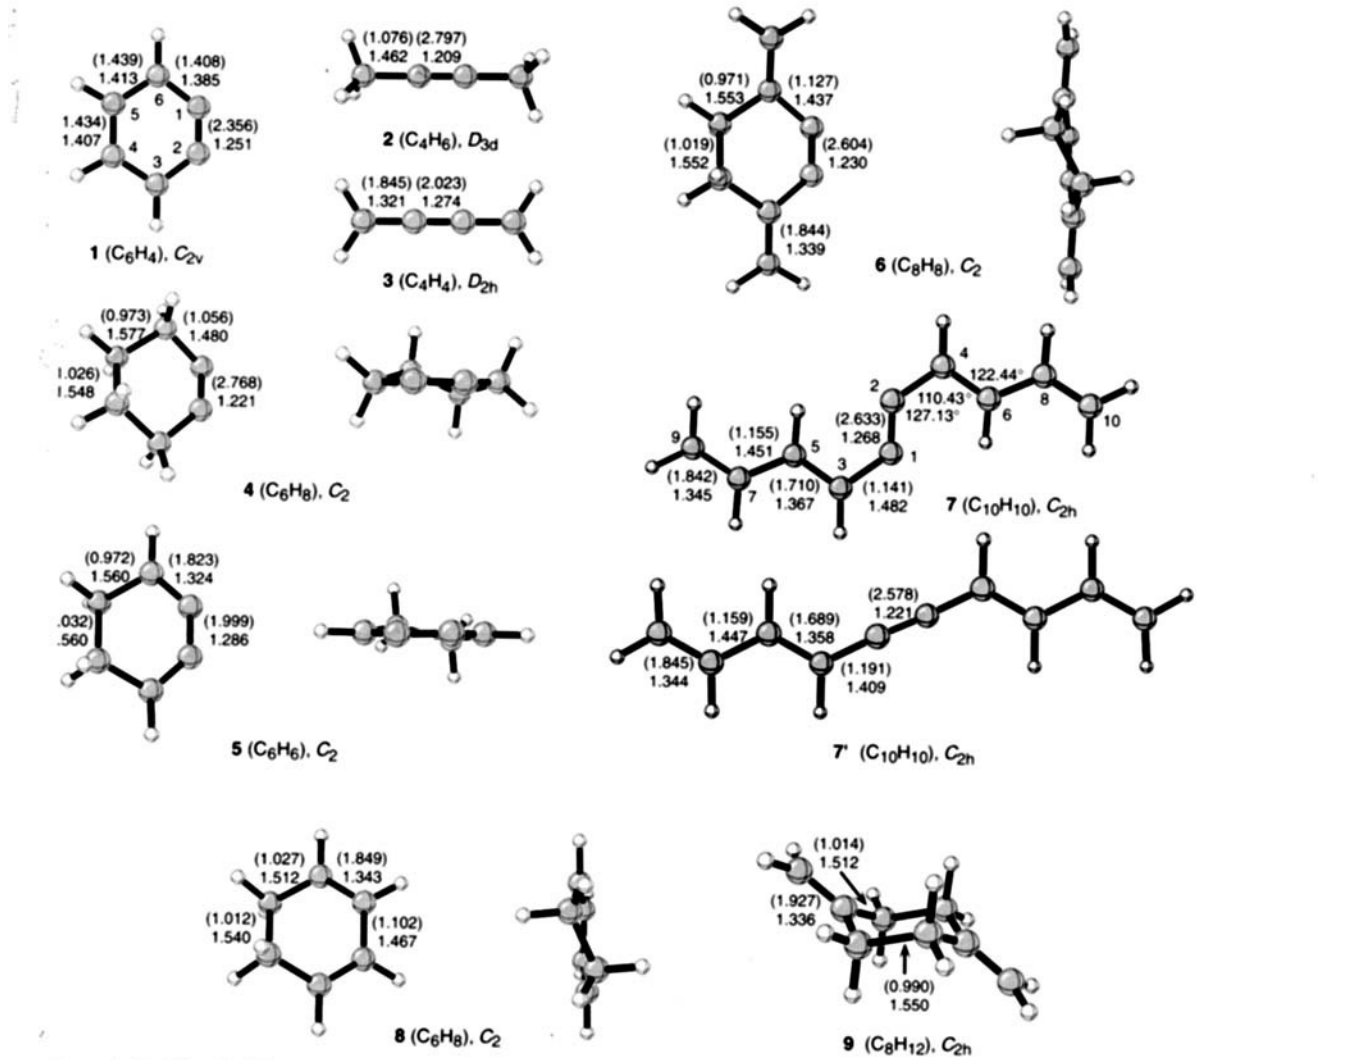

Figure 1. Bond lengths [Å] and corresponding Wiberg bond indices (in parentheses) for **1**–**9** optimized at the Becke3LYP/6-31G* level (**7** is partially optimized with bond angles fixed as in **1**).

butatriene (**3**). However, both **2** and **3** lack the strain present in **1**. Indeed, strain elongates the triple and cumulene bonds by 0.012 Å in both cyclohexyne (**4**) and 1,2,3-cyclohexatriene (**5**); the corresponding WBIs are smaller as well. However, neither **4** nor **5** are the best reference molecules. The triple bond in **1** is connected to two formally sp^2 carbon atoms, and this situation is not present in **4**. The most appropriate model compound, 1,4-dimethylene-2-cyclohexyne (**6**), has a longer C≡C bond length and a smaller WBI than **2**; both strain and conjugation effects are responsible. The strain effects were evaluated by comparing the distorted (partially optimized) reference molecule **7** (all-*trans*-1,3,7,9-decatetraene-5-yne) with the fully optimized **7′**, in which the bond angles are fixed as in **1**. The C≡C bond in **7** (1.268 Å) is longer than in **7′** (1.221 Å), and the corresponding WBI in **7** (2.633) is larger than in **7′** (2.578). Strain also elongates C1–C3 from 1.409 Å in **7′** to 1.482 Å in **7**.

At the Becke3LYP/6-31G* level, the WBI calculated for the triple bond in **1** (2.356) is smaller than that in **7** (2.633). The other WBIs are intermediate between those for the double and single bonds in **7**, and are close to the value for benzene (1.437). Although the geometry of **1** is distorted due to strain, the electron delocalization still resembles that of benzene. When the benzene WBI is subtracted, the net WBI of 0.919 for C1–C2 in **1** corresponds to a single bond (compare the difference in WBI (0.923) between the C1–C2 triple bond and the C3–C5 double bond in **7**. Thus, **1** is more acetylene-like (**1a**) than cumulene-like (**1b**).

Alternatively, the correct structure of **1** can be addressed by comparing the experimental and computed NMR chemical shifts based upon different (e. g. CASSCF(8,8), CCSD(T), and Becke3LYP) geometries. As shown in Table 2, the calculated ^{1}H NMR chemical shifts agree well with the experimental values.[9] However, discrepancies were found for the ^{13}C NMR chemical shifts, especially for C1 and C2. The best agreement with the experimental values is obtained using

Table 2. ^{1}H and ^{13}C NMR chemical shifts calculated at the SOS-DFPT-PW91/III level and determined experimentally; the differences $\delta_{calcd} - \delta_{exptl} = \Delta\delta$ are given in parentheses.

Nucleus	δ_{exptl} [9]	δ_{calcd} [a]	δ_{calcd} [b]	δ_{calcd} [c]
H(C3,C6)	7.6	7.9 (0.3)	7.8 (0.2)	7.9 (0.3)
H(C4,C5)	7.0	7.1 (0.1)	7.0 (0.1)	7.2 (0.2)
C1,C2	182.7	186.4 (3.7)	193.7 (11.0)	195.1 (12.4)

C4,C5	138.2	142.3 (4.1)	143.3 (5.1)	143.2 (5.0)

[a] With Becke3LYP/6-311 + G** geometry. [b] With CASSCF(8,8)/DZP geometry. [c] With CCSD(T)/6-31G** geometry.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2762 $ 17.50+.50/0

the Becke3LYP/6-311 + G** geometry (C1–C2 1.245 Å; deviation of $\Delta\delta = 3.7$ for C1 and C2). The calculated ^{13}C NMR chemical shifts for C1 and C2 obtained using CASSCF(8,8)/DZP (C1–C2 1.262 Å) and CCSD(T)/6-31G** geometries (C1–C2 1.269 Å) are 11.0 and 12.4 ppm larger than the experimental value. The calculated $^{13}C-^{13}C$ coupling constants obtained using the Becke3LYP/6-311 + G** geometry agree well with the experimentally deduced values (Table 3). That the ^1H chemical shifts of **1** are close to that for benzene

Table 3. $^{13}C-^{13}C$ coupling constants [Hz] for **1** calculated at the SOS-DFPT-PW91/III//Becke3LYP/6-311 + G** level.

	C1–C2	C2–C3	C3–C4	C4–C5
^1J	191.9	72.8	49.8	69.0
$^1J_{expt}$ [9]	(177.9 ± 0.7)	(75.7 ± 0.9)	(50.9 ± 0.8)	(71.0 ± 0.8)
	C1–C3	C1–C5	C3–C5	
^2J	−10.9	3.4	−1.3	
	C1–C4	C3–C6		
^3J	10.8	2.1		

($\delta = 7.37$) also indicates a comparable degree of aromaticity. Hence, the geometry optimized for **1** at the Becke3LYP/6-311 + G** level should be reasonably accurate. We also predicted the ^2J and ^3J coupling constants to assist further experimental investigations (Table 3).

Does the in-plane π bond affect the aromaticity of **1**? The criteria of aromaticity—for example aromatic stabilization energy (ASE),[22] magnetic susceptibility exaltation (Λ),[23] and nucleus-independent chemical shifts (NICS)[17]—provide evidence for the degree of electron delocalization in **1**. The ASE of **1** can be estimated by using homodesmotic reactions [Eqs. (1) and (2)].[24] In Equation (1), angle strain corrected **7**

$$\mathbf{7} - \textit{trans}\text{-butadiene} = \mathbf{1} \quad (1)$$

$$\mathbf{6}+\mathbf{8} = \mathbf{9}+\mathbf{1} \quad (2)$$

and *trans*-butadiene are used as the reference molecules. Reference molecule **6**, 1,3-cyclohexadiene (**8**), and 1,4-dimethylene cyclohexane (**9**) are used in Equation (2); all molecules are the most stable isomers, and the strain contributions cancel to a large extent. The ASE of benzene, computed by using Equation (3), provides the most direct comparison.[25]

$$\text{all-}\textit{trans}\text{-decapentaene} - \textit{trans}\text{-butadiene} = \text{benzene} \quad (3)$$

The ASEs calculated for **1** using Equations (1) and (2) are larger than that obtained for benzene with Equation (3) (Table 4).[25] The considerable strain energy of **1** (53.6 kcal mol^{-1}), approximated by the energy difference between the partially optimized **7** and fully optimized **7'**, is responsible for its high reactivity. The aromaticity of **1** does not overcome the strain energy; the net destabilization of **1** is 35.0 kcal mol^{-1}. Despite the large strain, the singlet state of **1** is still 31.8 kcal mol^{-1} lower in energy than the triplet state (Becke3LYP/6-311 + G*). The value at this level is somewhat smaller than the experimental results based on photoelectron spectroscopy (e. g. 37.6 kcal mol^{-1} [6a] and (38.5 ± 2.4) kcal mol^{-1} [6b]) as well as high-level ab initio calculations (33.3 kcal mol^{-1} [7f] and (36 ± 2) kcal mol^{-1} [7n]). The Becke3-LYP/6-311 + G** C≡C stretching vibration at 1948 cm^{-1} (after scaling)[26] is larger than the value for the neon matrix (1846 cm^{-1}).[5d]

Table 4. Becke3LYP/6-31G* total energies E_{tot} in Hartree, ASE values in kcal mol^{-1}, and χ and Λ values in ppm cgs (at the CSGT-Becke3LYP/6-31G*// Becke3LYP/6-31G* level) for **1** and some important comparison compounds.

	E_{tot}	ASE [a]	χ	Λ [a]
1	−230.90996 [b]	−18.6 (1), −18.7 (2)	−46.4	−23.4 (1)
6	309.50726			
7 [c]	−386.87239		−45.8	
8	233.41892			
9	−312.04609			
trans-butadiene	−155.99216		−22.8	
all-*trans*-decapentaene	−388.21302		−51.7	
benzene	−232.24870	−17.5 (3)	−46.1	−16.7 (3)

[a] The homodesmotic Equation used for calculating the value is given in parentheses. [b] The Becke3LYP/6-311 + G* total energies for the singlet and triplet states of **1** are −230.96566 and −230.91499, respectively. [c] The total energy for fully optimized **7'** is −386.95777.

Like ASE, the magnetic susceptibility exaltation Λ[23] can also be estimated easily from homodesmotic equations, for example, from Equation (1). The calculated Λ value for **1** is greater than that for benzene (Table 4). The calculated NICS (which is proving to be a simple and efficient criterion of aromaticity)[17] of **1** is also much larger than that of benzene (Table 5). However, the local shielding of the in-plane π bond in **1** also contributes.

Table 5. The calculated NICS values for **1** and **6** as well as their difference (ΔNICS(**1** − **6**)) compared with those for benzene at the GIAO-SCF/6-31 + G*// Becke3LYP/6-31G* level.

R [Å] [a]	NICS(**1**)	NICS(**6**) [b]	NICS(**1**) − NICS(**6**)	NICS(benzene)
0.0	−20.8	−9.5	−11.3	−9.7
0.5	−19.1	−7.7	−11.4	−11.5
1.0	−14.3	−4.5	−9.8	−11.5
1.5	−9.1	−2.1	−7.0	−8.4
2.0	−5.4	−0.9	−4.5	−5.3
2.5	−3.3	−0.4	−2.9	−3.4
3.0	−2.1	−0.2	−1.9	−2.2

[a] Distance from the geometrical center and perpendicular to the ring plane. [b] Computed at the same distance (1.133 Å) as in **1** between the molecule center and the midpoint of the triple bond.

Reference molecule **6** was used to evaluate this in-plane contribution. The NICS value for **6** is −9.5 when computed at the same position in **6** as in **1** (i. e. using the same distance, (1.133 Å) between the center of the heavy atom and the midpoint of the triple bond). Taking this correction into account, the net NICS for **1** of −11.3 is still somewhat larger than that for benzene. Furthermore, the NICS values for the points perpendicular to the molecular plane of **1** are close to the corresponding values for benzene after correction (see Table 5).

The standard heat of formation ΔH_f(298 K) of **1** can be computed from Equation (4). From the Becke3LYP/6-311 + G** energy including the thermal correction at 298 K

$$\mathbf{1}+\textit{trans}\text{-2-butene} = \text{benzene} + \textit{trans}\text{-butadiene} \quad (4)$$

and the experimental heats of formation of the reference molecules in Equation (4),[27] ΔH_f(298 K) is 113.5 kcal mol^{-1}. This is higher than the experimental estimate of (106 ± 3) kcal mol^{-1} [3d, 7q] and the highest level ab initio result (106.0 kcal mol^{-1}).[7q]

In conclusion, *o*-benzyne is aromatic according to the geometric, energetic, and magnetic criteria. However, the in-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2763 $ 17.50+.50/0

plane π bond induces a small amount of bond localization, resulting in a structure with more acetylenic (**1a**) than cumulenic (**1b**) character. The large angle strain in **1** is responsible for its high reactivity. Agreement between the computed and experimental ^{1}H and ^{13}C NMR chemical shifts as well as the $^1J(^{13}C,^{13}C)$ values supports the observation of **1** in a hemicarcerand strongly.[9] The Becke3LYP/6-311 + G** optimized structure of *o*-benzyne should be reasonably accurate.

[25] The computed ASE for benzene decreases when the length of the open-chain polyene used as the reference is increased. The ASE for benzene is −21.7 kcal mol^{-1} based on the homodesmotic equation: 3 × (*trans*-butadiene − ethylene) = benzene (see ref. [22c]).

[26] The correlation used for benzene was $y_{expt} = 19.9 + 0.96x$ (Becke3LYP/6-311 + G**).

[27] The standard heats of formation ΔH_f(298 K) are −(2.7 ± 0.2) kcal mol^{-1} for *trans*-2-butene, (19.8 ± 0.2) kcal mol^{-1} for benzene, and (26.3 ± 0.2) kcal mol^{-1} for *trans*-butadiene; see J. B. Pedley, R. D. Naylor, S. P. Kirby, *Thermochemical Data of Organic Compounds*, 2nd ed., Chapman and Hall, London, **1986**. The Becke3LYP/6-311 + G** total energies including thermal correction at 298 K are −230.89237 for **1**, −157.16078 for *trans*-2-butene, −232.20578 for benzene, and −155.95047 for *trans*-butadiene.

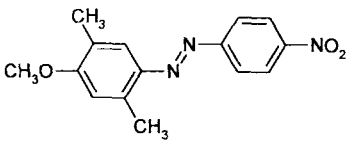
Merocyanine Dyes in the Cyanine Limit: A New Class of Chromophores for Photorefractive Materials**

Frank Würthner,* Rüdiger Wortmann,* Ralf Matschiner, Katarzyna Lukaszuk, Klaus Meerholz,* Yessika DeNardin, Reinhard Bittner, Christoph Bräuchle, and Rüdiger Sens

With the rapid progress in information and telecommunication technologies ("multimedia") faster methods for transmitting, storing, and processing data are required.[1] While fast optical data transmission through glass fibers is already well established, there is a need to develop high-speed storage and switching devices based on photons instead of electrons. A new promising method for reversible data storage is based on the photorefractive (PR) effect, whose "parallel character" allows optical processing of large amounts of data by holography.

Photorefractivity has been demonstrated only recently in amorphous organic materials.[2] Here, research is confronted with the difficult task of developing a complex functional material that provides photoconductivity and refractive-index modulation in films of high optical quality and stability against dielectric breakdown. The materials investigated so far are mostly composites consisting of a charge-transport agent (e. g. triarylamine or carbazole-based photoconductors[3]), an electrooptic (EO) chromophore with high second-order polarizability β,[4] small amounts of a sensitizer, and variable amounts of additives (plasticizer, polymeric binder).

Among the EO chromophores the azo dye 2,5-dimethyl-(4-nitrophenylazo)anisole (DMNPAA) dominates the scene



DMNPAA

because of its outstanding compatibility with carbazole charge-transport polymers.[5] With DMNPAA-doped polymers holographic gratings with almost 100% diffraction efficiency were achieved for the first time. To get such a strong PR effect, however, DMNPAA concentrations as high as 50 wt% and high electric fields of $50-100\ V\,\mu m^{-1}$ are required. For applications improved chromophores are needed to reduce the chromophore content and, thus, avoid problems with phase separation and to operate the devices at lower field strength. Here we introduce a conceptionally new class of dyes which represent a significant step towards this goal.

Our work was triggered by the fact that the refractive-index modulation in organic materials with a low glass-transition temperature is predominantly due to the Kerr and not the Pockels effect as in inorganic crystals.[7a] This difference is because in these composites the dipolar chromophores are able to reorient in the light-induced space-charge field.[6] As a result, a new figure-of-merit F_0 for photorefractive chromophores was derived which is approximated fairly well by Equation (1).[7a,8] Here M is the molecular weight, μ_g is the

$$F_0 = [9\mu_g\beta_0 + 2\mu_g^2\alpha_0/(kT)]/M \quad (1)$$

dipole moment, and α_0 and β_0 are two-level approximations for the static first- and second-order polarizabilities of the chromophore.[8] For "one-dimensional" chromophores consisting of a π system with donor and acceptor substitutents these polarizabilities can be reasonably approximated by considering the transition dipole μ_{ag}, the transition wavelength λ_{ag}, and the difference in dipole $\Delta\mu$ between the ground (g) and excited states (a) [Eqs. (2) and (3)].[7,8]

$$\alpha_0 = 2\mu_{ag}^2\lambda_{ag}/(hc) \quad (2)$$

$$\beta_0 = 6\mu_{ag}^2\Delta\mu\lambda_{ag}^2/(hc)^2 \quad (3)$$

Estimations for typical chromophores used in nonlinear optics (NLO) demonstrate that the main contribution in Equation (1) originates from the α term ("birefringence contribution"), whereas the β term ("electrooptical contribution") is only of minor importance.[7a,d] Therefore, design strategies should focus on the optimization of the α term, unlike in previously established concepts. According to a two-center charge-transfer model, the birefringence term is optimized when the ground and excited states display the same charge separation. For this *charge-resonance limit* the transition dipole μ_{ag} and therefore (according to Equation (2)) α_0 are maximized, whereas the change of dipole moment $\Delta\mu$ and therefore (according to Equation (3)) β_0 become zero.[7a] The first successful utilization of chromophores in the charge-resonance limit in PR polymers was demonstrated only recently.[7a-c]

According to Dähne et al.[9] and Marder et al.[10] merocyanines may be fine-tuned to become such a borderline case ("cyanine limit") with a 50% contribution each of the neutral and the zwitterionic resonance structures (Scheme 1). At this

Scheme 1.

point, the polymethine chain reaches the highest possible degree of conjugation with high values of μ_g and α, but a vanishing β.[9,10] Accordingly, we expected optimized neutrocyanines to be the best candidates for obtaining highly improved photorefractive materials.

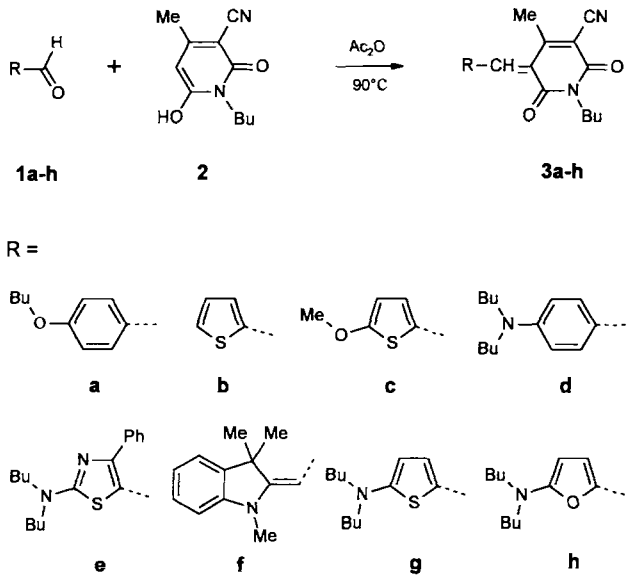
In contrast to the cationic cyanine and anionic oxonol dyes, little is known about the ideal charge-resonance state in uncharged merocyanines. Based on our experience with functional dyes for NLO[11] and thermal transfer printing,[12] monomethine dyes with electron-rich donor arenes and heterocyclic acceptors seemed most promising. Using 1-butyl-4-methyl-2,6-dioxo-1,2,5,6-tetrahydro-pyridine-3-carbonitrile (**2**)[13] as the acceptor unit, dyes **3** were synthesized in yields of over 80% (Scheme 2).[14]



Scheme 2.

Based on the UV/Vis absorption spectra (Table 1 and Figure 1) a classification of merocyanines **3** in polyene-like and cyanine-like chromophores is possible. With increasing donor strength the absorption maximum is shifted to longer wavelengths, and the intensity of the transition increases. However, sharp and intense spectra which are typical for cyanine chromophores are observed only for the best donor units (**3f–h**).[15] In the *cyanine limit* both ground and excited states are characterized by equal contributions of the two resonance forms. As a consequence only small displacements of the nuclear coordinates occur upon excitation.

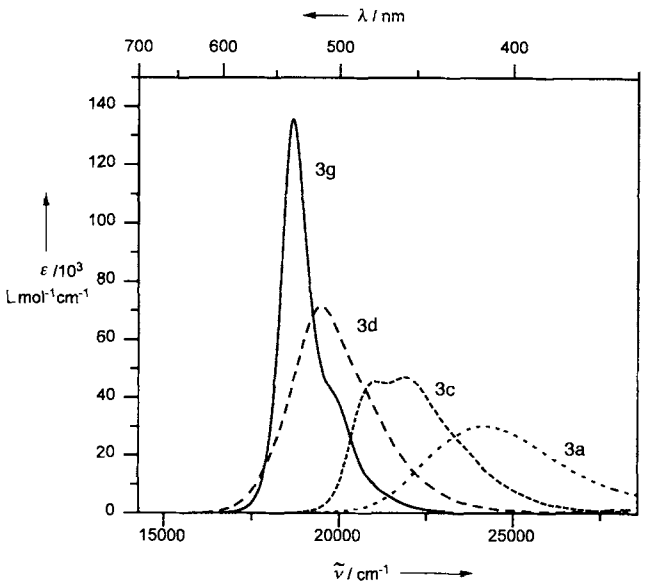


Figure 1. UV/Vis absorption spectra of the merocyanine dyes **3a**, **3c**, **3d**, and **3g** in dioxane.

To gain a more detailed insight into the electronic structure of these chromophores, we determined the dipole moments of the ground and excited states by means of electrooptic absorption measurements (EOAM; Table 1)[16] and estimated the values of α_0, β_0, and F_0 for the PR chromophores according to Equations (1)–(3). Based on these data the merocyanines **3a–d** are appropriately described as polyene-like compounds which are characterized by a large increase of their dipole moment upon excitation. Those compounds show also pronounced solvatochromism[17] and high β values, which are desired for applications in NLO.[11] The highest change in dipole moment (and also the highest β value) is observed for **3d.** From this it becomes clear that the cyanine limit is not accessible with benzene donor groups. This is due to the high aromaticity of the benzene ring, which counteracts the conjugation along the polymethine chain. Hence, the transition to cyanine-like chromophores is only possible with less aromatic heterocyclic donor groups. The series of five-membered heterocycles **3b**, **3c**, **3e**, **3g**, and **3h** illustrates this gradual change from a polyene-like to a cyanine-like dye system. Compounds **3f–h** exhibit negligible dipole changes of $\Delta\mu < 2$ D and thus represent cyanine dyes with optimized conjugation. Their PR figures-of-merit F_0 calculated accord-

Table 1. Optical[a] and electrical[b] properties of chromophores **3a–h** and DMNPAA, determined by UV/Vis and electrooptical absorption measurements in dioxane, and calculated PR figures-of merit F_0[c].

ing to Equation (1) are almost ten times higher than those of DMNPAA, which raised our expectation of observing large photorefractive effects.

To demonstrate the validity of our concept and the utility of the new chromophores under conditions similar to those used for applications, we prepared PR composites consisting of the chromophores **3e** and **3g**, the charge-transport polymer poly(*N*-vinylcarbazole) (PVK), the IR sensitizer (2,4,7-trinitro-9-fluorenyliden)malononitrile (TNFM), and the plasticizer *N*-ethylcarbazole (ECZ). Despite their rather large dipole moments both chromophores exhibit excellent compatibility with the PVK matrix, allowing a chromophore content of up to 50% in the composite without problems of phase separation. The PR properties were investigated by two-beam coupling and four-wave mixing experiments at 790 nm (the samples were 105 μm thick). This yielded the gain coefficient Γ for the asymmetric energy transfer between the two beams writing the hologram and the diffraction efficiency η for the readout of the hologram by an independent probe beam.[5,7] These experiments revealed an additional advantage of the cyanine chromophores over traditional NLO chromophores: The shape of the absorption curve at the low energy side is rather steep (compare **3d** and **3g** in Figure 1), enabling the use of laser wavelengths closer to the wavelength of the absorption maximum and, thus, dispersive enhancement of the refractive-index modulation.

Figure 2 shows the results of our holographic investigation on the composite containing the thiophene chromophore **3g** (20 wt%). The field-dependent diffraction efficiency first

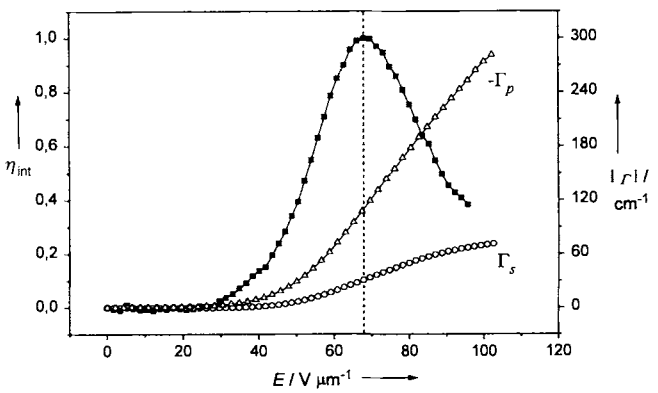

Figure 2. Dependence of the internal diffraction efficiency η_{int} for *s*-polarized writing beams ($I_1 \approx I_2 = 0.1$ W cm^{-2}) and *p*-polarized reading beam ($I_3 \ll I_1, I_2$) (■) as well as the absolute value of the gain coefficient Γ_s (○) and Γ_p (△) for *s*- or *p*-polarized writing beams ($I_1 = 100 \times I_2$) on the external applied electric field E. The composition of the material is **3g**:PVK:ECZ:TNFM = 20:45:33:2 (wt%). The experiments were performed with a tilted geometry (tilt angle $\Psi_{ext} = 60°$); the angle between the writing beams was $2\theta_{ext} = 20°$.

increases and reaches a maximum at $E_{max} = 68$ V μm^{-1}. This corresponds to complete internal diffraction of the readout beam ($\eta_{int} \approx 1$); externally, however, the achievable diffraction is limited to $\eta_{ext} \approx 0.3$ by the absorption of the material at the laser wavelength of 790 nm.[18] For even higher fields the diffraction efficiency decreases due to its $\sin^2$ dependency on the index-modulation amplitude Δn.[19] The maximum index-modulation amplitude achieved was $\Delta n \approx 5.2 \times 10^{-3}$ at 95 V μm^{-1}. The gain coefficient Γ increases monotonously with increasing field and finally reaches -280 cm^{-1} for *p*-polarized and $+70$ cm^{-1} for *s*-polarized beams. These values are among the largest ever reported for PR polymers, in particular in view of the long wavelength of 790 nm. The response time of the grating build-up was about 2800 ms at $E = 68$ V μm^{-1}.

For comparison, we also investigated a composite containing 50 wt% DMNPAA[5] under identical conditions. In this case complete internal diffraction was observed at slightly higher field ($E_{max} = 75$ V μm^{-1}). Assuming a quadratic dependence of Δn on the strength of the applied electric field,[6] this corresponds to a value for Δn that is 1.3 times larger in the composite using **3g**, even though the chromophore content is significantly lower.

Figure 3 shows the strengths of the electric fields which have to be applied to the device in order to achieve complete internal diffraction as a function of the chromophore content for **3e**, **3g**, and DMNPAA. The almost parallel shape of the

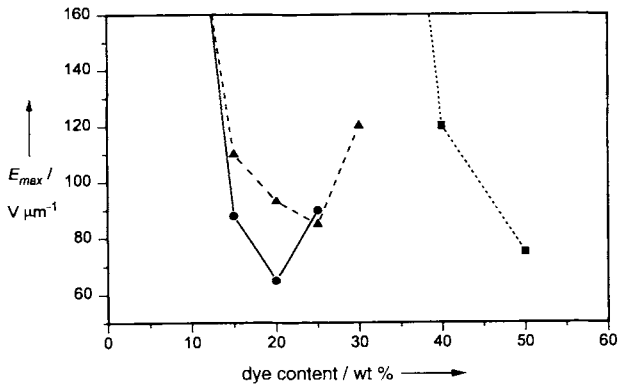

Figure 3. Dependence of the applied external field for achieving complete internal diffraction E_{max} on the chromophore content: **3g** (●), **3e** (▲), DMNPAA (■). By varying the ratio of PVK to ECZ the glass-transition temperature was adjusted to about 25 °C in all cases.

curves at low dye concentration agrees well with our expectations based on the electrooptic investigations. The thiophene chromophore **3g** was expected to show better photorefractive properties than **3e**, whereas both were considered to be much superior to the reference chromophore DMNPAA. However, by going to higher concentrations (≈ 50 wt%) an improvement in performance (reduction of E_{max}) is only observed for DMNPAA. By contrast, a significant drop in performance is observed already at a concentration of 25 wt% for the best chromophore of the series, the thiophene derivative **3g**. For loading above 40 wt%, no photorefractive effect could be observed.

To exploit the full potential of the new methine chromophores **3**, we are currently trying to solve the problems encountered at higher dye concentrations. These are possibly due to the formation of dye aggregates with antiparallel alignment of the dipoles which cannot be poled by the electric field. Therefore, we are attempting to reduce aggregation by attaching sterically demanding substituents to the chromophore core.

In conclusion, a material with excellent photorefractive performance was obtained with only 20% of **3g**. The new merocyanine dyes in the cyanine limit clearly demonstrate the benefit of optimizing chromophores according to Equation (1). The development of further new chromophores according to this design strategy will push forward the field of organic photorefractive materials.

[17] Solvatochromism (= displacement of the absorption bands under the influence of a solvent) is a direct consequence of the change in dipole upon excitation. Consequently, we observe a pronounced shift of the absorption maximum of 23 nm for **3d** ($\Delta\mu = 9$ D) in dimethylformamide compared to dioxane. On the other hand, **3g** has an absorption maximum at the same wavelength in both solvents.

[18] We assume that the somewhat high absorption is caused by complex formation between **3g** and TNFM. By reducing the amount of TNFM or by using a different sensitizer we hope to reduce the absorption losses.

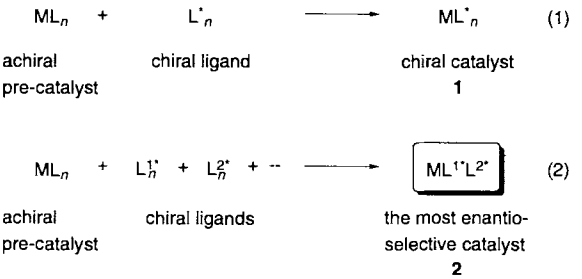
Self-Assembly of Several Components into a Highly Enantioselective Ti Catalyst for Carbonyl-Ene Reactions**

Koichi Mikami,* Satoru Matsukawa, Thorsten Volk, and Masahiro Terada

Dedicated to Professor Dieter Seebach on occasion of his 60th birthday

Asymmetric catalysis of organic reactions has become the focus of a great deal of research.[1] Berrisford, Bolm, and Sharpless recently emphasized the significance of "chiral ligand acceleration" in asymmetric catalysis.[2] Ligand-accelerated catalysis occurs when a more effective chiral catalyst for a particular reaction is obtained by the exchange of an achiral ligand for a chiral one [Reaction (1) in Scheme 1]; the reaction can thus proceed highly enantioselectively.[2] The combination of an achiral pre-catalyst with several chiral ligands or ligand components (L^{1*}, L^{2*},..) may selectively assemble into the most active and most enantioselective chiral catalyst among the possible catalysts derived from these ligand components in a quasi-combinatorial way [Reaction (2)].[3,4] Hill and Zhang recently reported the results of



Scheme 1. General principle of the ligand exchange.

an elegant study in which such a "smart" self-assembly resulted in the creation of an achiral "immortal catalyst".[5] We here report on the first example of the formation of a chiral catalyst by virtue of the cooperation of several chiral ligands and an achiral complex by such a "smart" self-assembly. The application of this catalyst in the asymmetric catalysis of the carbonyl-ene reaction shows it to be not only the most enantioselective catalyst but also the most stable and therefore exclusively formed species. Thus, the present work can be considered in part as a "chiral evolution" of the studies by Hill and Zhang on an achiral system.

The self-assembly of a chiral titanium catalyst from an achiral precursor such as $Ti(OR)_4$ and two different chiral diol components is exemplified for two catalysts (Scheme 2), each of which was prepared by three routes. The combination of "acidic" (*R*)-binaphthol [(*R*)-BINOL][6] and the relatively basic diol (*R*)-$\alpha,\alpha,\alpha',\alpha'$-tetraphenyl-2,2-dimethyl-1,3-dioxo-

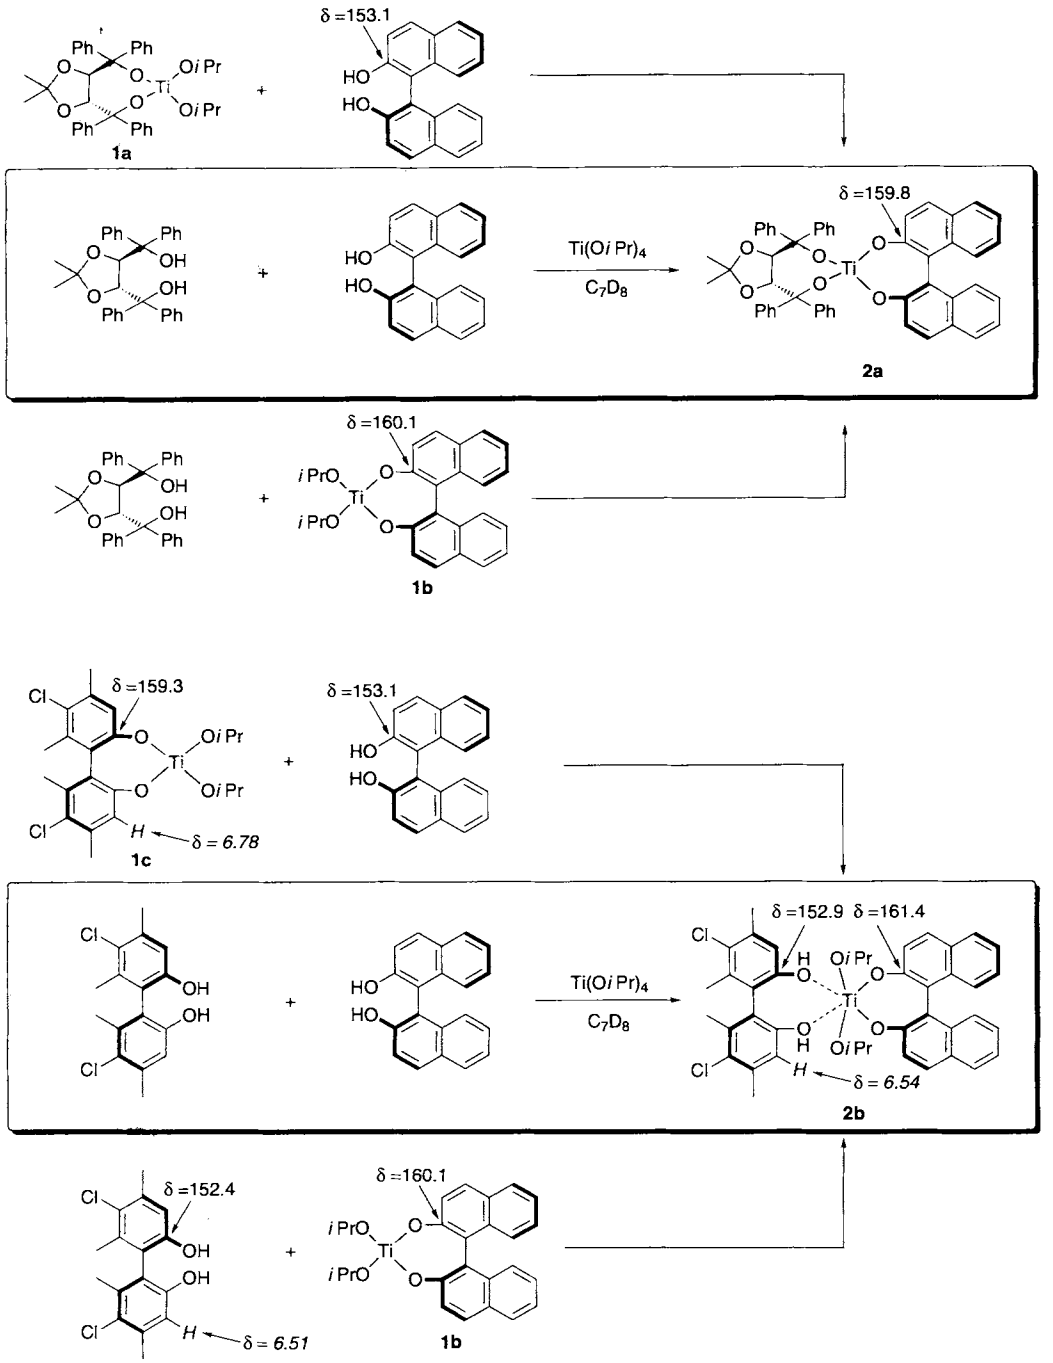


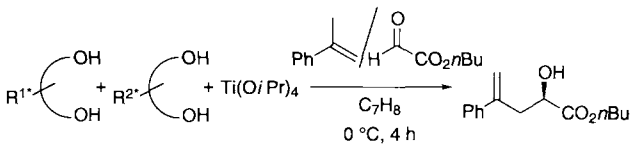
Scheme 2. "Smart" self-assembly of the highly active Ti catalysts **2a** and **2b**. The ^{1}H NMR spectrum of complex **2a** shows no *i*PrOH signals.

lane-4,5-dimethanol [(*R*)-TADDOL][7] with Ti(O*i*Pr)$_4$ in a molar ratio of 1:1:1 yielded a single chiral titanium complex by "push–pull" assembly of the TADDOL–BINOL combination. The [Ti{(*R*)-BINOLate}{(*R*)-TADDOLate}] complex (**2a**) was identified by ^{13}C and ^{1}H NMR spectroscopy in [D$_8$]toluene; these NMR spectroscopic studies also confirmed the absence of any other complexes, especially the symmetrically substituted [Ti{(*R*)-TADDOLate}$_2$] and [Ti{(*R*)-BINOLate}$_2$]. However, complex **2a** can also be obtained from [Ti{(*R*)-TADDOLate}(O*i*Pr)$_2$](**1a**)[8] by addition of (*R*)-BINOL and from [Ti{(*R*)-BINOLate}(O*i*Pr)$_2$](**1b**)[9] by addition of (*R*)-TADDOL as has been shown in separate sets of experiments.

Likewise, [{(*R*)-BINOLate}{(*R*)-5-Cl-BIPOL}(O*i*Pr)$_2$] (**2b**) (5-Cl-BIPOL = 5,5′-dichloro-4,4′,6,6′-tetramethyl-2,2′-biphenol) can be synthesized from Ti(O*i*Pr)$_4$ by reaction with (*R*)-BINOL and a more acidic diol such as (*R*)-5-Cl-BINOL.[10] Both the addition of (*R*)-5-Cl-BIPOL to [Ti{(*R*)-BIPOLate}(O*i*Pr)$_2$] (**1b**) and the addition of (*R*)-BINOL to [Ti{(*R*)-5-Cl-BIPOLate}(O*i*Pr)$_2$](**1c**)[11] afforded the complex **2b**, whose formation as the sole product of the reaction was confirmed by ^{13}C and ^{1}H NMR spectroscopy.

The importance of this selective multicomponent self-assembly is exemplified by attempts at the enantioselective catalysis of the carbonyl-ene reaction;[12,13] the results clearly show that a highly enantioselective catalyst is formed. The

catalyst was prepared in each case by mixing the components in a molar ratio of 1:1:1 (vide supra) and used in situ (10 mol% were employed with respect to olefin and glyoxylate) (Scheme 3 and Table 1).



Scheme 3. General scheme for the Ti-catalyzed asymmetric glyoxylate-ene reaction.

Table 1. Asymmetric catalysis of the reaction of α-methylstyrene and *n*-butyl glyoxylate (Scheme 3), in which the catalysts are produced from $Ti(OiPr)_4$ and $R^{1*}(OH)_2$ and $R^{2*}(OH)_2$.

Entry	$R^{1*}(OH)_2$	$R^{2*}(OH)_2$	Yield [%] [a]	*ee* [%]
1			50	91
2		–	0	–
3			15	40
4		–	4	0
5			66	97
6		–	13	75
7		–	20	95

[a] The yield was determined by gas chromatography (OV-1701, benzophennone as internal standard).

The complex **1a** did not afford any of the carbonyl-ene product (Table 1, entry 2), in contrast, **2a** gave a yield of 50% with an enantiomeric excess (*ee*) of 91% [(*R*)-product; entry 1]. Similarly with $[Ti\{(R)\text{-}(OCHCO_2iPr)_2\}(OiPr)_2]$ virtually none of the product was obtained (entry 4),[14] whereas 15% of the coupling product was formed when $[Ti\{(R)\text{-}(OCHCO_2iPr)_2\}(OiPr)_2\{(R)\text{-BINOL}\}]$, with only 40% *ee* (entry 3). The use of (*R*)-5-Cl-BIPOL and (*R*)-BINOL proved to be the best combination for the self-assembly of a highly selective catalyst. The carbonyl-ene reaction proceeded quite smoothly to produce the highest enantioselectivity of 97% *ee* along with the highest yield (66%, entry 5). Significantly lower enantiomeric excesses and yields were obtained by using the catalyst **1c** (yield: 13%, 75% *ee*) or the catalyst **1b** (yield: 20%, 95% *ee*) (entries 6 and 7, respectively).

In summary, the "smart" self-assembly of a highly enantioselective catalyst from a pre-catalyst and *several* ligands has been achieved. The most effective and enatioselective catalyst among the possible combinations forms exclusively regardless of the starting conditions, thus facilitating a simple experimental procedure. The selective assembly of complexes to give systems containing several ligands might prove a powerful tool for the development of catalysts for asymmetric synthesis.

Experimental Section

The catalyst was prepared on a 0.1-mmol scale by mixing achiral $Ti(OiPr)_4$, (*R*)-BINOL, and a further chiral diol such as (*R*)-TADDOL or (*R*)-5-Cl-BIPOL in a molar ratio of 1:1:1 in toluene at 0°C under an argon atmosphere. The carbonyl-ene reaction was then carried out in situ by addition of α-methylstyrene (1 mmol) and *n*-butyl glyoxylate (1 mmol, freshly distilled prior to use) to the solution in toluene and was monitored by TLC. Standard workup (hydrolysis with H_2O, extraction with EtOAc, washing with 1N HCl, and drying over $MgSO_4$) followed by flash chromatography on silica afforded the carbonyl-ene product. Yields and enantiomeric excesses were determined by gas chromatography (OV-1701, standard: benzophenone) or with HPLC (Daicel CHIRALPAK AS column, hexane/2-propanol (3/1), 0.5 mL min^{-1}, $t_R = 9.48$ min (*S*), 12.60 min (*R*), respectively (Table 1).

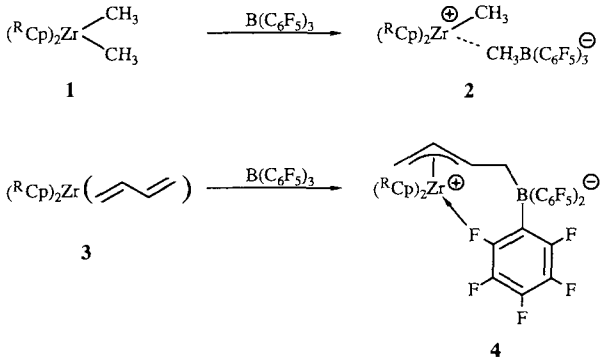
Noncovalent Interactions in Organometallic Compounds: Formation of an Intramolecular Metal–Carbon Ion Pair in Zirconium Borate Betaines**

Jörn Karl, Gerhard Erker,* Roland Fröhlich, Frank Zippel, Friedrich Bickelhaupt, Marcel Schreuder Goedheijt, Otto S. Akkerman, Paul Binger, and Jörg Stannek

Noncovalent metal–ligand interactions and ion pairing will probably be of increasing importance as structural elements and latent functionalities in the organometallic chemistry of transition metals.[1] It will become necessary to learn about the factors that govern the formation of such bonding features. We now found that for a class of metallocene borate betaines geometric parameters of the allyl unit constitute the structural element that determines whether the electron-deficient metal center is stabilized by an intramolecular M···CH_2[B] ([B] = $B(C_6F_5)_3$) ion pair[2] or by M···F-C coordination.[3]

T. J. Marks et al. demonstrated that dimethylzirconocenes **1** (^{R}Cp = substituted cyclopentadienyl) are able to transfer a methyl anion to the strong Lewis acid tris(pentafluorophenyl)borane. The resulting products **2** favor structures with a rather stable ion pair in the solid state as well as in solution (Zr···CH_3[B] ≈ 2.55 Å, $\Delta G^{\neq}_{dis} \approx 16-18$ kcal mol^{-1}). Only the onset of polymerization upon treatment of these active Ziegler catalysts with α-olefins seems to cleave these ion pairs effectively.[4]

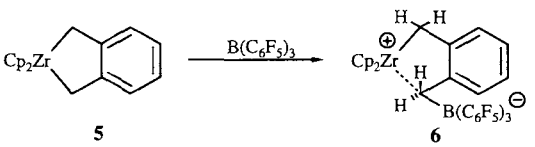
We recently found that (butadiene)zirconocene complexes **3**[5a] add $B(C_6F_5)_3$ at the terminal CH_2 group of the conjugated diene ligand to yield the metallocene borate betaines **4**.[6] The resulting substituted π-allyl moiety in **4** is *E*-configurated. This geometrically prohibits intramolecular Zr···CH_2[B] ion pairing in **4** analogous to the favorable Zr···CH_3[B] interaction in **2**. Instead, **4** is stabilized by



coordination of an *ortho*-F atom of a C_6F_5 substituent on boron to the electrophilic metal center. The strength of this Zr···F interaction was determined to be about 8.5 kcal mol^{-1}.[7] Addition of a reactive α-olefin again removes this "protecting group" from the catalytically active Zr^+ center, and complexes **4** serve as active single-component metallocene Ziegler catalysts.[6]

If the interpretation is correct that intramolecular Zr···CH_2[B] ion pairing in **4** is disfavored due to the geometrically prohibitive *E* position of the CH_2[B] substituent at the π-allyl ligand, then the intramolecular Zr–C ion pairs of the metallocene borate betaine system should be observed again in cases where the isomeric *Z*-allyl-CH_2[B] arrangements are favored. We have synthesized two such betaine systems, and characterized them stereochemically and with regard to the intramolecular interaction between allyl-CH_2[B] and Zr.

As a first substrate we employed (*ortho*-quinodimethane)-zirconocene (**5**).[5b] This complex marks the metallacyclic extreme of the (s-*cis*-diene)metallocene family of complexes: the π interaction between Zr and carbon atoms C2 and C3 is



only marginally pronounced. Nevertheless, this complex, in which the cisoid arrangement of the C1–C2 and C3–C4 vectors has become fixed by the anellated phenylene moiety, exhibits a variety of chemical features typical of the (s-*cis*-1,3-diene)zirconium complexes.[5]

Complex **5** reacts instantaneously with one molar equivalent of $B(C_6F_5)_3$ at room temperature in toluene to form the 1:1 addition product **6**. Adding a layer of pentane above the solution of the product in toluene furnished single crystals of **6** within three days that were suited for an X-ray structure analysis. This confirmed that the $B(C_6F_5)_3$ moiety had added to the C4 atom. Compound **6** constitutes an internal ion pair that

contains a $[Cp_2ZrR]^+$ cation and a $[RB(C_6F_5)_3]^-$ anion in a single molecule (Figure 1). The Cp_2Zr moiety of **6** exhibits the usual structural parameters of Group 4 bent metallocenes.[8] The Zr–C1 bond is very short (2.264(3) as opposed to 2.776(3) for Zr–C2 and 2.898(3) Å for Zr–C3). It is the coordination

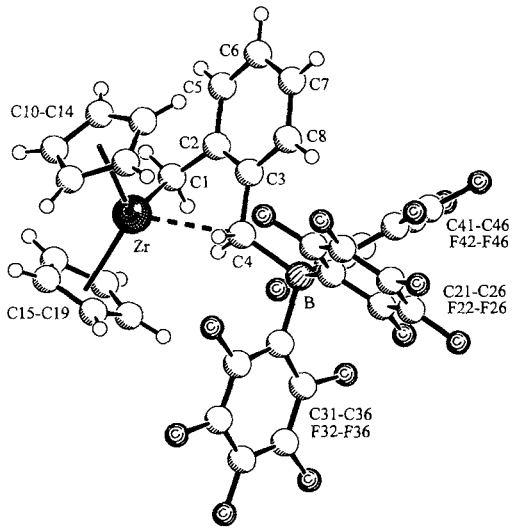

Figure 1. Molecular structure of betaine **6**. The ion-pair interaction between Zr and C4 is indicated by a dashed line. Selected bond lengths [Å] and angles [°]: Zr–C1 2.264(3), Zr–C4 2.595(3), Zr–C_{Cp} (av) 2.508(4), C1–C2 1.472(5), C2–C3 1.414(4), C2–C5 1.406(5), C5–C6 1.358(5), C6–C7 1.395(5), C7–C8 1.370(5), C3–C8 1.401(4), C3–C4 1.517(4), C4–B 1.682(3), B–21 1.655(4), B–C31 1.663(5), B–C41 1.646(5); C1-C2-C5 119.7(3), C2-C5-C6 122.3(3), C5-C6-C7 119.5(4), C6-C7-C8 119.9(4), C7-C8-C3 121.6(3), C8-C3-C4 119.8(3), C3-C4-B 119.1(3), C4-B-C21 117.4(2), C4-B-C31 108.1(3), C4-B-C41 103.3(2), C21-B-C31 102.3(2), C21-B-C41 112.1(3), C31-B-C41 114.0(2); see text for additional values.

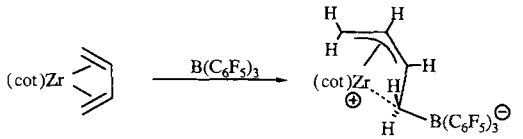
pattern of the sp^3-hybridized carbon atom C4, which bears the $B(C_6F_5)_3$ substituent, that makes **6** structurally noteworthy. Atom C4 exhibits a rather short distance to the zirconium atom (2.595(3) Å), and the Zr-C4-B angle is 155.3(2)°. The C4–Zr vector points in a direction opposite to the C4–B vector. We regard the Zr–C4 bond as an electrostatic ion pair. Consequently, both C–H bonds at C4 are oriented toward the transition metal (C3-C4-B 119.1(3)°), which is different from the situation at the distorted-tetrahedrally tetracoordinated C1. The resulting "ion-paired five-membered metallacycle" is nonplanar and structurally resembles the "envelope" geometry of the starting material **5**; its folding angle (i. e., the angle between the Zr/C1/C4 and C2/C3/C5 – C8 planes in **6**) amounts to 68.6°.[9] Some of the bond angles inside the five-membered ring are quite different than normal (C1-Zr-C4 75.41(11), Zr-C1-C2 93.5(2), Zr-C4-C3 85.4(2), C1-C2-C3 121.7(3), C2-C3-C4 121.6(3)°). The heavy atoms at C4 (Zr, C3, B) are almost coplanar (sum of angles 359.8°). Thus, the C4–B vector attains an almost *gauche* orientation to its neighboring aromatic ring (dihedral angles C8-C3-C4-B −47.9(4), C2-C3-C4-B 135.0(3)°). The internal ion pair formed between Zr and C4 apparently leads to an optimal situation with regard to steric interaction and electrostatic stabilization of **6**.

In solution at 253 K **6** exhibits NMR signals for a pair of diastereotopic Cp ligands ($\delta(^1H/^{13}C) = 5.41/112.0$, 4.48/111.1 at 600/150 MHz) as well as C1 ($\delta(^1H) = 2.17$, 1.80) and C4 protons ($\delta(^1H) = 0.89$, 0.30).[9] The ^{13}C NMR resonance for C1 appears at $\delta = 57.6$; the signal for C4 is probably very broad due to the adjacent boron nucleus and could not be located. Complex **6** exhibits temperature-dependent ^{19}F NMR spectra. Already at 253 K 14 resonances are observed (two of the *ortho*-F resonances are accidentally isochronous). These spectra also clearly rule out the presence of any coordination of F to the electrophilic Zr center in solution. The observed characteristic splitting pattern originates from hindered rotation of the $B(C_6F_5)_3$ "propeller" on the NMR time scale, which is similar to the situation in several other $R\text{-}B(C_6F_5)_3$ systems.[10]

The formation of an internal ion pair in **6** is not unique, but apparently in general present as soon as the metallocene borate betaine features the sterically favorable *Z*-allyl arrangement.[11] Therefore, we treated the (η^4-butadiene)(η^8-cyclooctatetraene)zirconium complex **7**[12] with $B(C_6F_5)_3$. At ambient temperature the Lewis acidic borane adds instantaneously and with complete regioselectivity to the C4 atom of the butadiene ligand to form **8**. Again we obtained single



7 **8**

crystals from a solution in toluene within three days after cautiously adding a layer of pentane. The X-ray structure analysis of **8** shows the presence of a η^8-cot ligand (Zr–C(cot) 2.371(5) – 2.433(5) Å) and a *Z*-configured CH_2[B]-substituted allyl ligand at zirconium (Figure 2). The coordination of

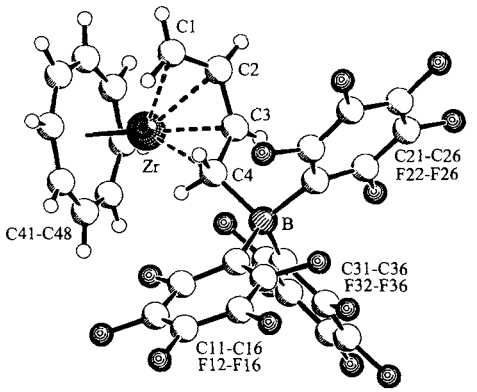


Figure 2. Molecular geometry of **8**. Selected bond lengths [Å] and angles [°]: Zr–C_{cot} (av) 2.403(3), B–C11 1.656(5), B–C21 1.645(5), B–C31 1.656(6); C1-Zr-C2 31.1(2), C1-Zr-C3 59.7(2), C1-Zr-C4 69.8(2), C2-Zr-C3 34.4(2), C2-Zr-C4 60.1(1), C3-Zr-C4 34.7(1), Zr-C1-C2 68.8(3), Zr-C2-C1 80.0(3), Zr-C2-C3 65.6(2), Zr-C3-C2 80.0(2), Zr-C3-C4 85.5(2), Zr-C4-C3 59.8(2), C1-C2-C3 123.2(4), C2-C3-C4 122.2(4), C3-C4-B 114.7(3); see text for additional values.

the allyl ligand to zirconium is rather unsymmetrical. The Zr–C3 bond is the shortest (2.266(4) Å), whereas the Zr–C2 and Zr–C1 bonds are markedly longer (2.450(4) and 2.588(5) Å, respectively). Accordingly, there is a short – long sequence of the C–C bond lengths in the allyl unit (C1–C2 1.359(8), C2–C3 1.407(6) Å). The C3–C4 bond length is 1.493(5) Å. Atom C4 again has distorted trigonal-bipyramidal coordination (C4–B 1.665(5), C4–Zr 2.614(4) Å; Zr-C4-B 148.8(3)°). The dihedral angle C2-C3-C4-B amounts to −139.6(4)°. The hydrogen atoms at C4 are apparently oriented in the direction of the metal atom. We conclude that **8** also forms an internal ion pair to give rise to a five-membered metallacycle. The essential structural features of the complexes **8** and **6** are closely related in this respect.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2772 $ 17.50+.50/0

In solution **8** shows ^{1}H and ^{13}C NMR resonances for the η^8-cot ligand at $\delta = 5.94$ and 96.9, respectively ($^1J_{CH} = 169$ Hz). The ^{13}C NMR signals for the carbon atoms of the allyl ligand appear at $\delta = 79.9$ ($^1J_{CH} = 166$, 158 Hz), 127.1 (154 Hz), and 103.1 (172 Hz); the corresponding ^{1}H NMR resonances are at $\delta = 2.80$, 2.05 (*syn,anti*-1-H), 4.75 ("*meso*"-2-H), and 2.08 (*syn*-3-H).[13] The *gauche* orientation of the $B(C_6F_5)_3$ substituent at C4 (see above) together with the Zr–C4 ion pair make the hydrogen atoms 4-H and 4-H′ diastereotopic. Consequently two ^{1}H NMR resonances are found at $\delta = 0.07$ and -1.00. The ^{13}C NMR signal for C4 appears at $\delta = 14.1$ ($^1J_{CB} = 37$ Hz); this is typical for a CH_2[B] carbon atom that has a direct contact to zirconium. The ^{19}F NMR spectrum of **8** shows three sharp resonances for the *ortho*-, *meta*-, and *para*-F atoms of the $B(C_6F_5)_3$ substituent down to 193 K. There is no indication of C–F coordination in solution.

The results described here show that the intramolecular stabilization of Group 4 metallocene borate betaines is controlled by the geometrical features of their CH_2[B]-substituted allyl moiety. The *E* configuration leads to favored coordination of an *ortho*-C-F moiety to the zirconium center, whereas the respective *Z* orientation results in the formation of a stable ion pair interaction between the transition metal and the CH_2[B] unit.[14]

Experimental Section

All reactions were carried out under argon.

6: Complex **5** [5] (326 mg, 1.00 mmol) and $B(C_6F_5)_3$ (520 mg, 1.01 mmol) were suspended in toluene (2 mL), and a layer of pentane was carefully added. After three days the betaine was isolated as red crystals; yield 585 mg (70%); m.p. 104 °C (decomp). ^{1}H NMR (599.9 MHz, 253 K, [D$_8$]toluene): $\delta = 7.59$ (d, $^3J(H,H) = 8.1$ Hz, 1H, 5-H), 6.78 (pseudo t, 1H, 7-H), 6.73 (pseudo t, 1H, 6-H), 6.26 (d, $^3J(H,H) = 8.1$ Hz, 1H, 8-H), 5.41, 4.48 (each s, each 5H, Cp), 2.17 (d, $^2J(H,H) = 12.7$ Hz, 1H, 1-H′), 1.80 (d, $^2J(H,H) = 12.7$ Hz, 1H, 1-H), 0.89 (br, 1H, 4-H′), 0.30 (br, 1H, 4-H); ^{13}C NMR (150.8 MHz, 253 K, [D$_8$]toluene): $\delta = 148.3$ (d, $^1J(C,F) = 250$ Hz, *o*-$B(C_6F_5)_3$), 140.6, 140.3 (each C, C-2, C-3), 139.4 (d, $^1J(C,F) = 250$ Hz, *p*-$B(C_6F_5)_3$), 137.5 (d, $^1J(C,F) = 250$ Hz, *m*-$B(C_6F_5)_3$), 131.0 (CH, C-5), 130.6 (CH, C-7), 129.8 (CH, C-8), 126.3 (CH, C-6), 112.0, 111.1 (each CH, Cp), 57.6 (CH_2, C-1), signals for the *ipso*-C of C_6F_5 and C4 were not detected at 253 K (assignments were supported by the results of GCOSY, GHSQC, and GHMBC experiments [16]); ^{19}F NMR (564.3 MHz, 253 K, [D$_8$]toluene): $\delta = -167.3$, -166.1 (2 ×), -165.3, -164.7, -162.0 (br, 6F, *m*-F), -160.5, -159.6, -159.4 (br, 3F, *p*-F), -141.7, -137.3, -134.3, -130.6, -129.5, -128.8 (br, 6F, *o*-F); IR (KBr): $\tilde{\nu} = 3119$, 2963, 2921, 1642, 1513, 1458, 1382, 1281, 1085, 981, 825 cm^{-1}; elemental analysis calcd for $C_{36}H_{18}BF_{15}Zr$ (837.5): C 51.63, H 2.17; found: C 50.93, H 2.75.

8: Complex **7** [12] (250 mg, 1.00 mmol) and $B(C_6F_5)_3$ (520 mg, 1.02 mmol) were allowed to react in toluene (2 mL). The color of the solution changed from blue-green to red-brown. A layer of pentane (6 mL) was carefully added. After three days at ambient temperature the product was obtained as red crystals; yield 530 mg (70%); m.p. 54 °C (decomp). ^{1}H NMR (599.9 MHz, 298 K, [D$_8$]toluene): $\delta = 5.94$ (s, 8H, cot), 4.75 (m, 1H, 2-H), 2.80 (dd, $^{2/3}J(H,H) = 9.8$, 2.0 Hz, 1H, 1-H′), 2.08 (m, 1H, 3-H), 2.05 (d, $^2J(H,H) = 9.8$ Hz, 1H, 1-H), 0.07 (br, 1H, 4-H′), -1.00 (br, 1H, 4-H); ^{13}C NMR (150.8 MHz, 298 K, [D$_8$]toluene): $\delta = 148.4$ (d, $^1J(C,F) = 240$ Hz, *o*-$B(C_6F_5)_3$), 139.0 (d, $^1J(C,F) = 240$ Hz, *p*-$B(C_6F_5)_3$), 137.3 (d, $^1J(C,F) = 240$ Hz, *m*-$B(C_6F_5)_3$), 127.1 (CH, $^1J(C,H) = 154$ Hz, C-2), 103.1 (CH, $^1J(C,H) = 172$ Hz, C-3), 96.9 (CH, $^1J(C,H) = 169$ Hz, COT), 79.9 (CH_2, $^1J(C,H) = 166$, 158 Hz, $^3J(C,H) = 9$ Hz, C-1), 14.1 (CH_2, $^1J(C,B) = 37$ Hz, C-4), the signal for the *ipso*-C of C_6F_5 was not observed (the assignments were supported by GCOSY and GHSQC experiments [16]); ^{19}F NMR (564.3 MHz, 298 K, [D$_6$]benzene): $\delta = -165.7$ (t, $^3J(F,F) = 21$ Hz, 6F, *m*-F), -161.1 (t, $^3J(F,F) = 20$ Hz, 3F, *p*-F), -135.0 (d, $^3J(F,F) = 21$ Hz, 6F, *o*-F); IR (KBr): $\tilde{\nu} = 3086$, 2963, 2922, 1645, 1516, 1454, 1274, 1086, 976, 814, 757 cm^{-1}; elemental analysis calcd for $C_{30}H_{14}BF_{15}Zr$ (761.4): C 47.32, H 1.85; found: C 47.11, H 2.12.

X-ray crystal structure analysis of **6**: $0.60 \times 0.50 \times 0.08$ mm, $a = 27.026(2)$, $b = 12.785(1)$, $c = 20.425(1)$ Å, $\beta = 117.54(1)$, $V = 6256.7(7)$ Å^3, $\rho_{calcd} = 1.778$ g cm^{-3}, $\mu = 4.70$ cm^{-1}, empirical absorption correction with φ-scan data ($0.968 \le C \le 0.999$), $Z = 8$, monoclinic, space group $C2/c$ (no. 15), $\lambda = 0.71073$ Å, $T = 223$ K, $\omega/2\theta$ scans, 6543 measured reflections ($\pm h, -k, +l$), $[(\sin\theta)/\lambda] = 0.62$ Å^{-1}, 6357 independent and 3905 observed reflections [$I \ge 2\sigma(I)$], 478 refined parameters, $R = 0.038$, $wR^2 = 0.084$, max./min. residual electron density 0.69/−0.37 e Å^{-3}. Hydrogen atoms were calculated and refined as riding atoms.

X-ray crystal structure analysis of **8**: $0.60 \times 0.50 \times 0.40$ mm, $a = 11.365(1)$, $b = 17.676(1)$, $c = 14.047(3)$ Å, $\beta = 99.10(1)$, $V = 2786.4(7)$ Å^3, $\rho_{calcd} = 1.815$ g cm^{-3}, $\mu = 5.17$ cm^{-1}, empirical absorption correction with φ-scan data ($0.878 \le C \le 0.998$), $Z = 4$, monoclinic, space group $P2_1/n$ (no. 14), $\lambda = 0.71073$ Å, $T = 223$ K, $\omega/2\theta$ scans, 5889 measured reflections ($\pm h, -k, +l$), $[(\sin\theta)/\lambda] = 0.62$ Å^{-1}, 5661 independent and 4003 observed reflections [$I \ge 2\sigma(I)$], 424 refined parameter, $R = 0.046$, $wR^2 = 0.122$, max./min. residual electron density 0.83/−0.77 e Å^{-3}. Hydrogen atoms were calculated and refined as riding atoms.

Both data sets were measured on an Enraf Nonius MACH3-diffractometer. The following computer programs were used: MolEN for data reduction, SHELXS-86 for structure solution, SHELXL-93 for structure refinement, SCHAKAL-92 for graphics. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100478. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code + (1223) 336-033; e-mail: deposit@chemcrys.cam.ac.uk).

[9] Compound **5** is dynamic and shows a rapid flipping of the nonplanar metallacyclic five-membered ring, thereby interconverting the isoenergetic envelope conformations. The internal organometallic ion pair of **6** features an analogous automerization reaction, albeit with a substantially increased activation barrier ($T_{coalesence}$(Cp) ≈ room temperature).

A Cyclic Octadecairon(III) Complex, the Molecular 18-Wheeler**

Stephen P. Watton, Peter Fuhrmann, Laura E. Pence, Andrea Caneschi, Andrea Cornia, Gian Luca Abbati, and Stephen J. Lippard*

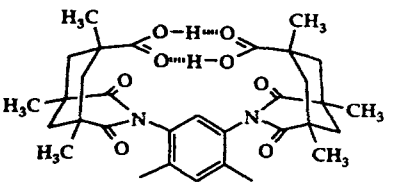
The development of strategies for the synthesis of high-nuclearity metal clusters has provided substantial impetus to in several different fields, including materials chemistry,[1] bioinorganic chemistry,[2] and solid-state physics.[3,4] The architecture of large transition metal clusters can often result in novel chemical and physical properties. For example, polyiron and polymanganese complexes of nanometer size and with high-spin ground states afford single-domain magnetic particles, which may display hysteresis effects of purely molecular origin.[1,3] It is of interest to investigate the properties of increasingly larger assemblies of interacting metal ions, because they are expected to evolve gradually towards those of bulk materials.[1a,1c] Furthermore, large cyclic polymetallic clusters are also valued for their ability to mimic the properties of linear coordination polymers.[5]

Previously we described a cyclic decairon(III) complex having the composition $[Fe(OCH_3)_2(O_2CCH_2Cl)]_{10}$, referred to as a molecular ferric wheel, the solid-state properties of which were thoroughly investigated.[5] A number of related circular clusters have been synthesized, the latest of which contains seven linked ferrocene rings and has been called a molecular scoop wheel.[6] In the present communication we report the synthesis, solid-state structure, and magnetic behavior of the compound **1** (where XDK is the dianion of *m*-xylylenediamine bis(Kemp's triacid imide)).[7] This complex, which we designate the "molecular 18-wheeler", is the largest cyclic ferric cluster reported so far, containing 18 iron(III) atoms in a ring.[8]

$[Fe(OH)(XDK)Fe_2(OCH_3)_4(O_2CCH_3)_2]_6$ **1**

The title compound was obtained in the presence of tetraalkylammonium carboxylate salts from slightly alkaline methanolic solutions of the diiron(III) complex **2** (see Experimental Section). This material was previously employed in

$[Fe_2O(XDK)(CH_3OH)_5(H_2O)](NO_3)_2 \cdot 4H_2O$ **2**



XDKH$_2$

our laboratories to prepare models of the carboxylate-bridged diiron cores present in a variety of non-heme proteins.[9] The composition of the crystalline compound, a double salt having the formula $\mathbf{1} \cdot 6Et_4N(NO_3) \cdot 15CH_3OH \cdot 6Et_2O \cdot 24H_2O$, was established by elemental analysis and a single-crystal X-ray diffraction investigation. Figure 1 displays the structure of the molecular 18-wheeler viewed perpendicular to the plane of the ring.

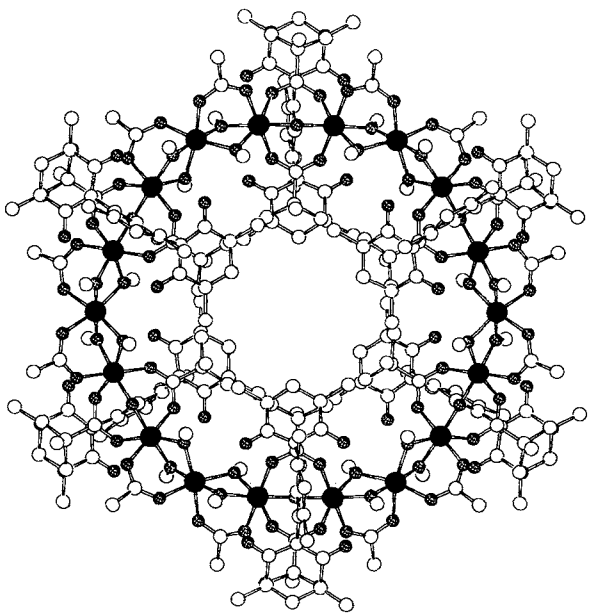


Figure 1. Ball-and-stick representation of **1**, viewed perpendicular to the plane of the ring. Iron atoms are drawn in black, oxygen atoms are shaded, carbon and nitrogen atoms are depicted as open circles, and hydrogen atoms are omitted for clarity.

The octadecairon cluster in **1** has idealized D_{3d} symmetry. The repeating unit comprises a (μ-hydroxo)bis(μ-carboxylato)-diiron(III) moiety linked by an acetate and two methoxide ions to a third iron atom (Figure 2). An acetate and two additional

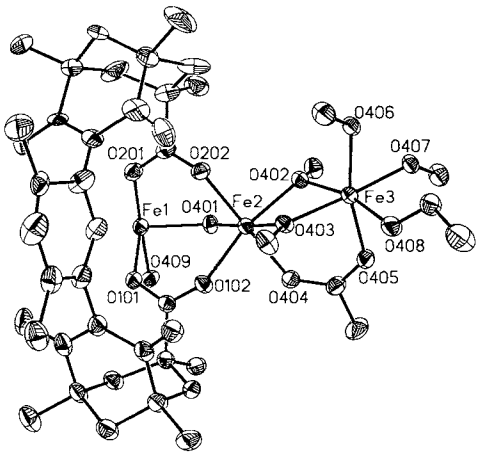

Figure 2. ORTEP view of the asymmetric unit of **1** showing 30% probability thermal ellipsoids and the labeling scheme for the iron and oxygen atoms. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å]: Fe1–O401 1.975(3), Fe1–O407′ 1.977(3), Fe1–O406′ 1.985(3), Fe1–O201 2.011(4), Fe1–O101 2.031(3), Fe1–O409 2.054(4), Fe2–O403 1.968(3), Fe2–O401 1.971(3), Fe2–O402 1.989(3), Fe2–O202 2.025(3), Fe2–O102 2.037(3), Fe2–O404 2.060(3), Fe3–O403 1.965(3), Fe3–O407 1.967(3), Fe3–O406 1.999(3), Fe3–O402 2.005(3), Fe3–O405 2.050(3), Fe3–O408 2.063(4). Bond angles [°]: Fe2-O401-Fe1 123.7(2), Fe2-O402-Fe3 99.18(14), Fe3-O403-Fe2 101.29(14), Fe1′-O406-Fe3 99.50(14), Fe3-O407-Fe1′ 100.9(2). Nonbonded distances [Å]: Fe1···Fe2 3.479(1), Fe2···Fe3 3.041(1), Fe3···Fe1′ 3.041(1).

methoxide ligands on this iron center form bridges to the next trinuclear repeating unit in the cluster. The (μ-acetato)bis(μ-alkoxo)diiron(III) center in the cluster is relatively rare, appearing mainly in oligomeric structures such as the ferric wheel[5] and similar compounds.[10] A discrete complex having the related (μ-carboxylato)(μ-hydroxo)(μ-aqua)diiron(III) or (μ-carboxylato)bis(μ-hydroxo)diiron(III) core would be of great value, since this Fe_2 core occurs in the resting state of the hydroxylase enzyme of soluble methane monooxygenase.[11]

Each iron atom in **1** has distorted octahedral symmetry. The assignment of the bridging oxygen atom O401 (Figure 2) as a hydroxide ion is supported by the Fe–O bond distances of 1.971(3) and 1.975(1) Å, the charge neutrality, and the magnetic behavior of **1**. A plot of the magnetic susceptibility per iron atom, χ_{Fe}, versus temperature T measured on a microcrystalline sample at an applied field of 1 T in the range $2.2 < T < 260$ K displays a broad maximum at about 60 K (Figure 3). This behavior is indicative of antiferromagnetic interactions between the high-spin iron(III) ions ($S = 5/2$). In antiferromagnetically coupled rings containing an even number of equivalent metal ions, the position of the maximum and the corresponding value of the susceptibility per metal ion are expected to scale linearly with the isotropic coupling constant J between nearest neighbors. Comparison of the χ_{Fe} vs. T curves for **1** with those for related complexes containing six- or ten-membered rings (Figure 3)[5,12] suggests the presence of more than one kind of magnetic interaction in **1**. This result presumably reflects the presence of two different types of bridging units. In order to explore this issue in a more quantitative manner, we introduced a simplified six-sided

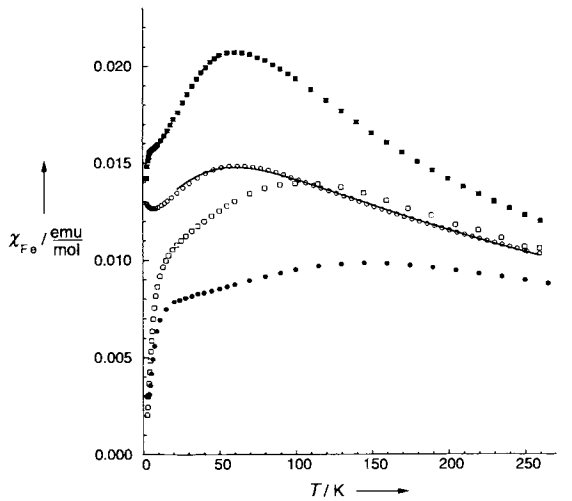

Figure 3. Observed magnetic susceptibility per iron atom versus temperature data for solid samples of **1** (○), $[NaFe_6(OCH_3)_{12}(dbm)_6]^+$ (●, $J = 20.4$ cm^{-1}), $[LiFe_6(OCH_3)_{12}(dbm)_6]^+$ (□, $J = 14.3$ cm^{-1}), and $[Fe_{10}(OCH_3)_{20}(O_2CCH_2Cl)_{10}]$ (■, $J = 9.6$ cm^{-1}) at 1 T. The solid line represents the curve calculated with the parameters given in the text for a solid sample of **1**. dbm = 1,3-diphenylpropane-1,3-dione.

polygon model to simulate the magnetic properties of **1**. The pattern of nearest-neighbor Heisenberg interactions was described by the Hamiltonian given in Equation (1), which matches the alternation of chemically different bridging units (Figures 1 and 2).

$$\mathcal{H} = \Sigma_i J_i (S_i \cdot S_{i+1}) \quad (1)$$

where $S_7 = S_1$, and J_i varies as $\ldots J_A, J_A, J_B, J_A, J_A, J_B \ldots$

The best fit parameters with a fixed g of 2.00 were $J_A = 19.9$ cm^{-1} and $J_B = 6.8$ cm^{-1}. The calculated susceptibility versus temperature plot (solid line in Figure 3) is in fairly good agreement with the experimental data. The values of the coupling constants are in the range expected for bis(methoxide) and mono(hydroxide)bis(carboxylate) bridging units[13,14] and eliminate the possibility of oxo bridges, which would lead to much stronger antiferromagnetic interactions ($J = 80 - 120$ cm^{-1}).[14] The magnetic properties of **1** render it an important addition to the class of antiferromagnetically coupled cyclic metal complexes.[4] Ferromagnetically coupled cyclic complexes containing metal ions other than iron(III) are available and illustrate the effect of metal d electron count on magnetic exchange.[15]

The self-assembly of an octadecanuclear iron(III) complex provides further evidence for the tendency of metal atoms linked by alkoxide or hydroxide ligands (monoatomic bridges) and *syn,syn* η^2-carboxylate bridges to form large cyclic structures. The bending module afforded by two one-atom and one η^2-carboxylate bridge leading to the decanuclear ferric wheel was discussed previously.[5] The repeating unit in the 18-wheeler consists of the XDK ligand attached to one of these bending modules at either end (Figures 1 and 2). The mean deviation of the 18 iron atoms from the calculated best plane through them is 0.388 Å. To compare the contributions of the different iron sites to the total bend of the molecule, the iron atoms were projected onto this plane and the bend angles determined. The main bend of 32.8° occurs at Fe3 and is more than twice those at Fe1 and Fe2 (12.4° and 14.8°, respectively). These values satisfy the relationship in

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2775 $ 17.50+.50/0

Equation (2). The two pairs of methoxide bridges at Fe3 allow

$$\begin{aligned} &6[180^\circ - \sphericalangle(\text{Fe1–Fe2–Fe3})] \\ &+6[180^\circ - \sphericalangle(\text{Fe2–Fe3–Fe1})] \\ &+6[180^\circ - \sphericalangle(\text{Fe2–Fe1–Fe3})] = 360^\circ \end{aligned} \quad (2)$$

a much higher bending modulus within the circle than the three carboxylate bridges for Fe1 and Fe2. Examination of a space-filling model of the structure reveals that it has a central hole with an approximate inside diameter of 4–5 Å. The hydrophobic environment afforded by the XDK ligand on the inner surface of the wheel is incompatible with occupancy by cations, as occurs in smaller metallocycles lacking this feature.[12]

In conclusion, the molecular architecture of **1** underscores the ability of chemical synthesis to enrich our visual world with objects of beauty.[16] Once again the tendency of complex molecules to form highly symmetrical structures is manifest.

Experimental Section

1: **2** (0.05 g, 0.046 mmol), synthesized as described in ref. [9], was mixed with solid $Et_4N(O_2CCH_3)\cdot 4H_2O$ (0.024 g, 0.093 mmol, 2 equiv). Methanol (1 mL) was added to afford a golden brown solution. Upon addition of 8 μL (0.100 mmol, 2 equiv) of 1-methylimidazole the solution turned a darker brown. Careful layering of diethyl ether on the resulting solution provided large golden-yellow, well-shaped cubic crystals of **1** in low yield (about 10%) within several days. The crystals are extremely sensitive to solvent loss, cracking immediately upon exposure to air. Elemental analysis found for a sample flushed extensively with Ar: C 45.15, H 6.28, N 4.38, Fe 13.25. Calcd. for $\mathbf{1}\cdot 6Et_4N(NO_3)\cdot 24H_2O$: C 45.40, H 6.75, N 4.41, Fe 13.19. IR (Nujol, NaCl): $\tilde{\nu}$ = 1732, 1694, 1537, 1364, 1335, 1195, 1047, 958, 850 cm^{-1}. Crystal structure data for **1**: $C_{327}H_{522}Fe_{18}N_{20}O_{142}$, M_r = 8010.95, trigonal, space group $R\bar{3}$ (hexagonal axes), $a = b = 29.841(2)$, c = 41.085(6) Å, $V = 31684(6)$ $Å^3$, $Z = 3$, $F(000) = 12684$, $\lambda = 0.71073$ Å, T = 188(2) K, $\mu(Mo_{K\alpha}) = 0.681$ mm^{-1}. The intensities were measured by a Siemens SMART-CCD system on a golden-yellow crystal with the dimensions 0.44 × 0.4 × 0.4 mm^3, which was mounted under a stream of nitrogen on the tip of a quartz glass capillary with Paratone N. The data were integrated to a resolution of 0.9 Å. Of 45106 reflections, 10145 were independent and 10141 were used in the structure refinement. The structure was solved by direct methods and refined by using the SHELXTL program package[17]. During subsequent refinement cycles all of the non-hydrogen atoms could be located. Hydrogen atoms were added in idealized positions. Twelve non-hydrogen atoms in the asymmetric unit for the XDK ligand were disordered, and an appropriate model was introduced and refined; restraints for the anisotropic thermal parameters were applied for these atoms. A tetraethylammonium ion was treated similarly. One molecule of diethyl ether was also located, and its non-hydrogen atoms were refined anisotropically. The values for $R1$ and $wR2$ were 0.0628 and 0.1893, respectively, and the maximum and minimum residual electron density was 0.622 and −0.451 e $Å^{-3}$. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data centre as supplementary publication no. CCDC-100663. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code + (1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

Scission of DNA with Bis(1,10-phenanthroline)copper without Intramolecular Hydrogen Migration**

Ottilie Zelenko, James Gallagher, and David S. Sigman*

The principal products of the chemical cleavage of DNA by bis(1,10-phenanthroline)copper ($[Cu(phen)_2]^+$) and hydrogen peroxide are 5′- and 3′-phosphomonoesters, free purines and pyrimidines, and 5-methylene furanone (5-MF; Scheme 1).[1] Since 5-MF is a cyclic lactone whose carbonyl oxygen atom does not exchange with solvent once it is formed,[2] the source of this atom is solvent water.[3] The reaction proceeds rapidly under physiological conditions and does not require base to catalyze the elimination reactions which cause breaks in the phosphodiester backbone.[3] Isolation of 5-MF,[4] the 3′-displacement in the scission sites of the two strands of duplex DNA,[4–6] and the protection from scission by minor-groove ligands such as netropsin[7] strongly suggest that the reaction of the tetrahedral chelate complexes occurs from a binding site within the minor groove.

We initiated a series of studies using DNA with deuterium-substituted deoxyriboses to probe the detailed mechanism of the chemical cleavage.[8] The elegant studies by Sugiyama, Fujimoto, and Saito—who prepared C-2′ radicals by photo-

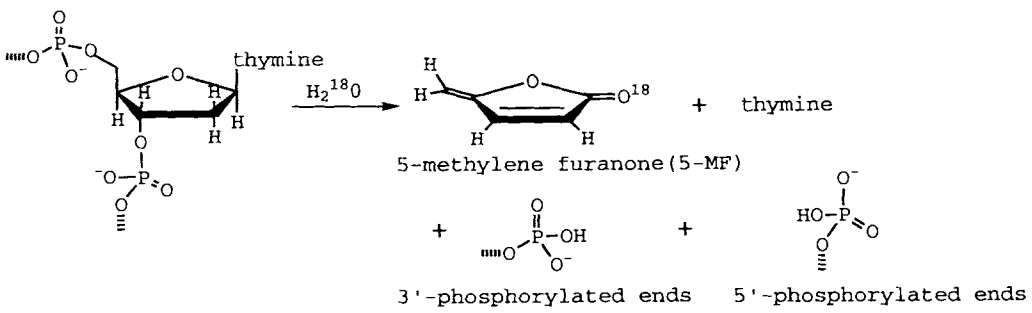
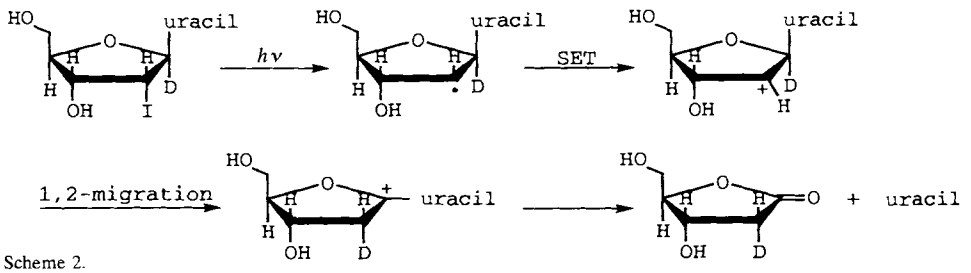


Scheme 1. SET = one-electron transfer



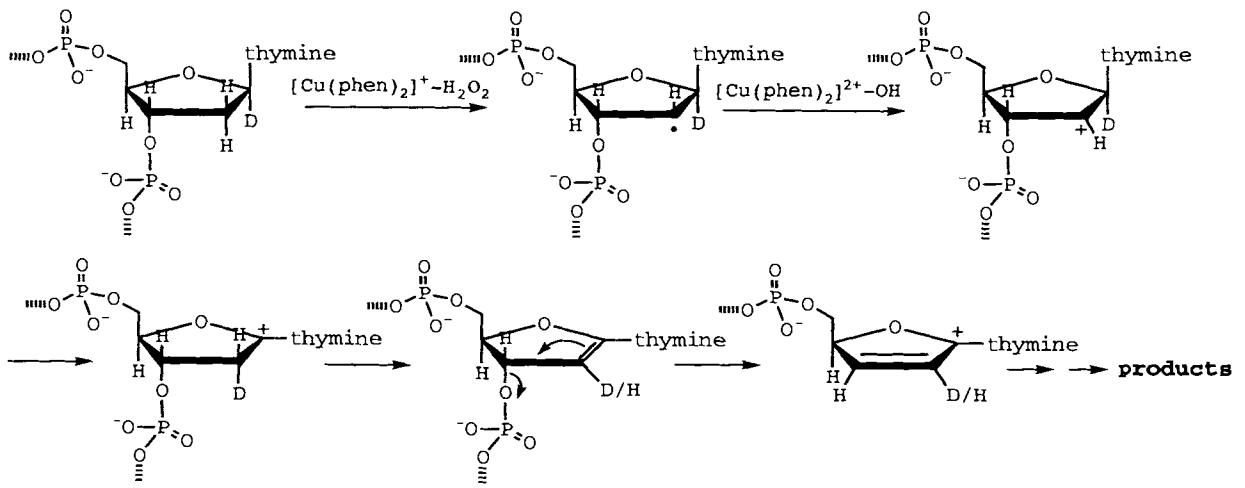
Scheme 2.

lysis of 5-iodouridine and 2'-deoxy-2-iodouridine—suggested a novel mechanism for initiating scission of the phosphodiester backbone[9] which we had not previously considered. Sugiyama et al demonstrated that photolysis of C-1'D-2'-deoxy-2-iodouridine yields the corresponding 2-deoxyribolactone with greater than 90% retention of deuterium at C-2' of the deoxyribose moiety (Scheme 2). The yield of 5-MF accompanying this reaction is variable and depends on solvent polarity.[9] The authors suggested that the presence of a 3'-phosphate group would facilitate heterolytic scission of the carbon–oxygen bond.[9]

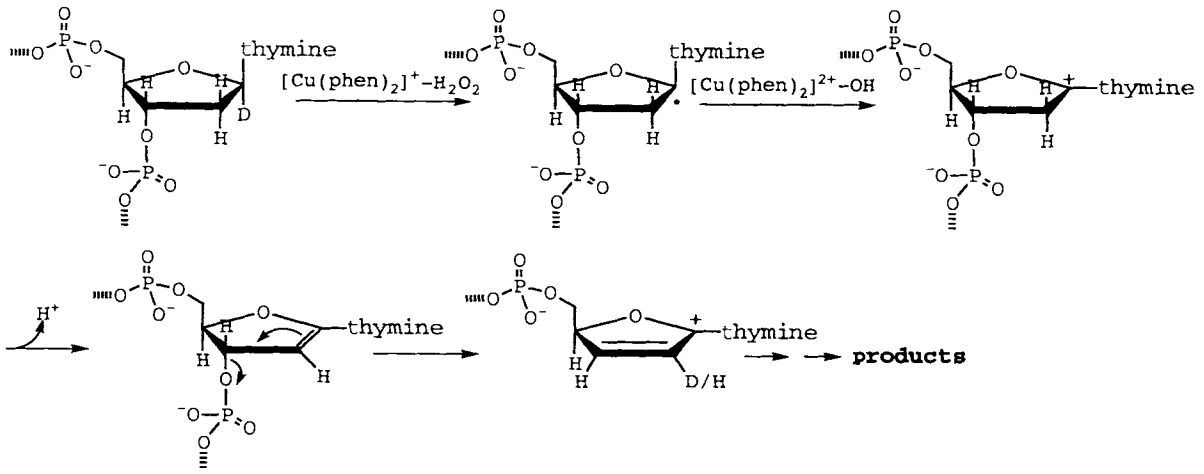
Based on these studies, one possible pathway for the scission of DNA would be hydrogen-atom abstraction from C-2'H in the minor groove formed by oxidation of $[Cu(phen)_2]^+$ by hydrogen peroxide via an intermediate whose precise structure is under investigation (Scheme 3). Following hydrogen-atom abstraction the C-2' radical would be subjected to one-electron oxidation by the DNA-bound $[Cu(phen)_2]^{2+}$-OH leading to a C-2' carbocation. A 1,2-hydride shift would then generate a C-1' carbocation. A series of nonstereospecific elimination reactions could then proceed to give the anticipated products with oxygen atoms from water incorporated into 5-MF, as previously demonstrated.[3]

We tested the possibility of C-2' hydrogen abstraction and an intramolecular 1,2-hydrogen shift for scission by $[Cu(phen)_2]^+$ using DNA containing C-1'D-thymidine. This specifically labeled DNA, which corresponds to sequence positions from −40 to +40 of the *E. coli* lac UV-5 fragment, was synthesized with C-1'-deuterated thymidine in both strands. Following digestion by $[Cu(phen)_2]^+$, 5-MF was isolated and analyzed by mass spectrometry using the same methods previously employed to identify the source of the oxygen atom in 5-MF.[3] Analysis of 5-MF isolated from unlabeled DNA according to Grundmann and Kober[10] demonstrated that the isotopic ratio *m/z* 97:96 reflecting the natural occurrence of deuterium and ^{13}C was 4.5 ± 0.4% (5.6% was expected). The isotopic ratio of *m/z* 97:96 for 5-MF isolated from DNA prepared with C-1'-deuterated thymidine following cleavage was 5.3%. We conclude that 5-MF isolated is not enriched in deuterium under these experimental conditions.

These findings rule out initial C-2'H abstraction (first step in Scheme 3) but are consistent with the reaction mechanism that we postulated involving initial C-1'H abstraction (Scheme 4) followed by one-electron oxidation by $[Cu(phen)_2]^{2+}$-OH to give the C-1' carbocation. Since spontaneous scission of the DNA backbone occurs in the absence of heat and base, we proposed that this intermediate does not react to give a deoxyribonolactone. Rather, it loses a proton



Scheme 3.



Scheme 4.

(Scheme 4) in a step which could be favored electrostatically by the neighboring 3′-phosphate. Elimination of the 3′phosphate ensues, resulting in the formation of the resonance-stabilized carbocation, which is then subjected to nucleophilic attack by water, the source of oxygen for 5-MF. Based on the studies of Sugiyama et al.[9] the intramolecular 1,2-hydride shift is stereospecific, but the loss of C-2′H should not exhibit a strong stereochemical preference. Since approximately 30% of the nucleotides cleaved in the DNA were thymidine groups, and the scission is effectively "nucleotide neutral" with a modest preference for guanine, a reduced preference for cytosine, and no preference for adenine and thymine,[5,6], the isotopic ratio of *m/z* 97:96 would have been an easily observable 19%.

The use of isotope scrambling in DNA prepared from nucleotides that are specifically deuterated in the deoxyribose moiety provides a method for studying intermediates not formed in a kinetically slow step. The formation of 5-MF as a result of the chemical cleavage of DNA by $[Cu(phen)_2]^+$ and H_2O_2 requires the loss of a C-2′ hydrogen atom. If there had been migration of C-1′D to the C-2 position, as expected from mechanistic studies on the photolysis of C-1′D-2′-deoxy-2-iodouridine, the *m/z* 97:96 of 5-MF should have been enhanced. Our inability to observe migration of the C-1′ deuterium atom strongly argues against initial oxidative attack of the pro *R* hydrogen atom of C-2′ by the DNA-bound oxidative species formed in the reaction of hydrogen peroxide and cuprous ion. Our data are consistent with the initial abstraction of the C-1′ hydrogen atom by the chemical nuclease that is reactive in the minor groove.

Experimental Section

All chemicals for the synthesis of organic products were obtained from Aldrich. The phosphoramidite building blocks for the synthesis of oligonucleotides were purchased from Glen Research. The thymidine phosphoramidite labeled with deuterium at the C-1′ position of the deoxyribose was synthesized according to published procedures [11,12]. The structure of the compound was verified by ^{1}H NMR and ^{31}P NMR spectroscopy (Bruker, 400 MHz). The deuterium content was determined to be $\geq 95\%$ by ^{1}H NMR spectroscopy. The single strands of the lac UV5 fragment (−40 to +40) were synthesized on a Pharmacia LKB Gene Assembler using standard methods for phosphoramidites. The oligonucleotide were purified by polyacrylamide gel electrophoresis (PAGE, 15%) under denaturing conditions.

In a typical cleavage experiment, $[Cu(phen)_2]^+$ (10:1 phen:$CuSO_4$) was added until a final concentration of 10 μM Cu^{2+} to the double-stranded lac UV5 fragment (250 μg, 15 μM) in 50 mM Tris/HCl (pH = 8.0) and 5 mM ascorbic acid. The reaction was performed at room temperature for 40 min. After heating the mixture at 90 °C for 40 min 5-MF was isolated by extraction into Et_2O. The concentrated ether extract was analyzed by GC-MS as previously described [3]. Under these conditions, DNA was complete cleaved, as shown by the analysis of reactions in which ^{33}P-labeled DNA was used. Using 20% PAGE, no parent band was left, and only one major band corresponding to a fragment ≤ 2 bases long was obtained.

Rhenium Complexes with a Photochemically Variable Anthracene Subunit: A Molecular Switch**

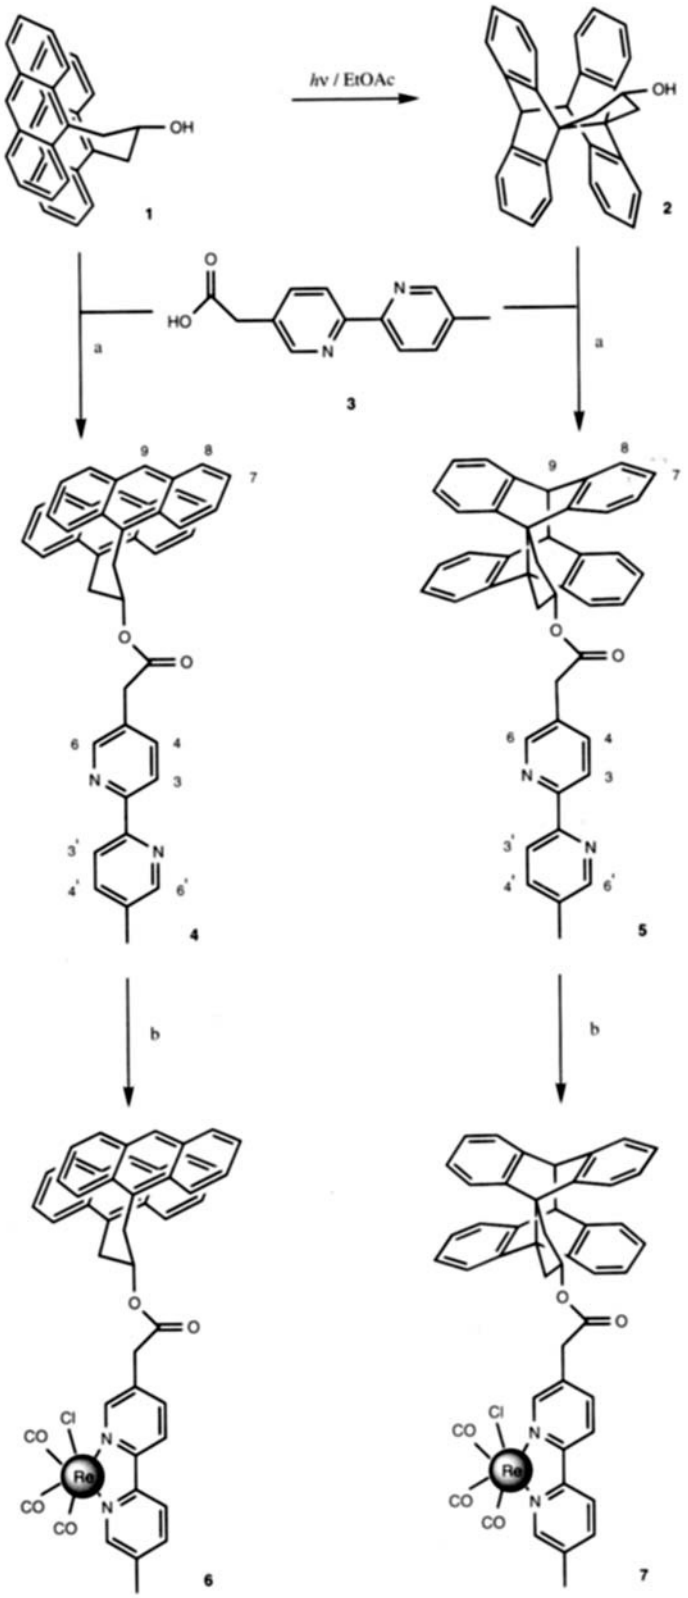
Andreas Beyeler, Peter Belser,* and Luisa De Cola

The outstanding feature of supramolecular systems, as compared to simple compounds, is their ability to perform more complex functions. As molecular devices they can, according to the type of system, also be used in practical applications. The molecular switches belong to a particularly interesting group, and can be used for data storage in computers.[1,2] In the case of a simple yes/no switch,[3] those triggered by light differ from redox and pH switches[4] in that they do not have to be in solution, but can also be used in a solid matrix.

The system described here is an example of such a photoswitch. It consists of two separate subunits: the switch and the detector. The latter is influenced by the switching subunit in that it indicates the state of the switch. For the molecular device reported here, a subunit has been chosen for the switch which has already been reported[5] and which consists of two parallel anthracenes linked by a C_3 bridge. On irradiation with visible light, intramolecular dimerization takes place (**1**→**2**). The back reaction (**2**→**1**) is triggered by irradiation with UV light (254 nm). Linkage of this switching unit to a 2,2′-bipyridine (bpy) ligand makes it accessible for complexation. The complexed metal center can then act as a detector, because the intensity of the emissions from the metal center differ according to the state of the switching unit.

Since alcohol **1** is rather inert towards chemical reactions for steric reasons, esterification was the only possible way to link the switching unit to the ligand. The choice of the acid employed was also decisive for the formation of the product. Diisopropylcarbodiimide was used for the esterification instead of the usual dicyclohexylcarbodiimide (DCC),[6] since the latter gives a 1:1 adduct with the resulting ester **4**. In order to investigate the separate switching processes, both types of ligand, **4** and **5**, were synthesized from the alcohols **1** and **2**, respectively. The rhenium complexes **6** and **7** were both synthesized by known methods (Scheme 1).[7]

The switching process **4**→**5** is triggered by irradiation with visible light, and the back reaction **5**→**4** with UV light. The change in the spectrum on irradiation is easily monitored by the changes in the absorption , for example, at 256 and 388 nm (see arrows in Figure 1). Since the anthracenes not only undergo the desired 4π+4π-cyclization, but also the irreversible photoaddition of singlet oxygen to give a 9,10-μ-peroxo bridge, the irradiation experiments had to be performed under the exclusion of oxygen. Therefore, all the investigated solutions were saturated with argon. In order to investigate the reversibility of the switch, a cyclohexane solution of the closed ligand **5** was irradiated (5 min) with a UV lamp, followed by irradiation (10 min) with visible light. After this cycle, the initial state was nearly reached (insert in Figure 1). For both the forward and backward reactions, the changes in the signals observed were constant. In order to investigate the reaction accurately, measurements were carried out in shorter intervals during the first cycle, but not for the subsequent cycles.



Scheme 1. Synthesis of the anthracene–rhenium complex switch: a) diisopropylcarbodiimide, DMAP, CH_2Cl_2; b) $[Re(CO)_5Cl]$, toluene.

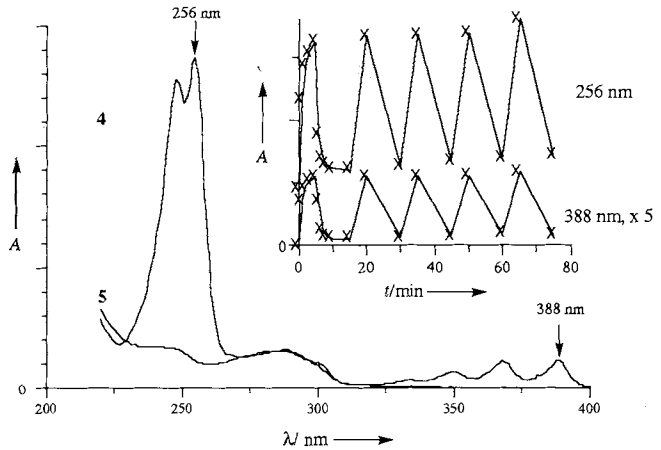

Figure 1. Absorption spectra of ligands **4** (open form) and **5** (closed form) as well as a diagram for the reversibility of the switching process (insert).

The separately synthesized rhenium complexes **6** and **7** exhibited markedly different emissions. While the emission of **7** was as expected, that of **6** was almost completely quenched (Figure 2). The two anthracenes quench the emission in the

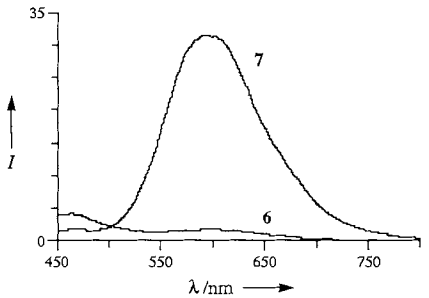

Figure 2. Emission spectra of the rhenium complexes **6** (open form) and **7** (closed form).

complexed subunit very effectively; this has also been observed in other complexes. In this case there is a fast transfer of energy from the metal complex unit to the anthracene unit.

The combination of a photochemically variable anthracene subunit with the observed emission from the rhenium subunit makes it possible for this switch to function. A further important condition is the reversibility of such systems, which is ensured in the investigated compounds.

Because of the photoinduced $4\pi+4\pi$-cyclization of the parallel anthracenes, the extended π systems are disrupted and can therefore no longer act as quenchers. On continuous irradiation of **6** with visible light, there should be a rhenium emission that increases with the irradiation time; this was confirmed experimentally. A corresponding decrease of the emission was observed for **7** as soon as its solution was irradiated with UV light. Preliminary experiments showed that solvation effects strongly influence the reaction rate of the switching process. Depending upon the choice of the solvent, side-reactions may appear.

This system provides a new, efficient photoswitch, which permits a reversible change in the emission of a spatially separated subunit of the molecule. Further experiments on the photophysical and photochemical properties of the rhenium complexes as well as the analogous ruthenium complexes are currently in progress.

Experimental Section

1: The synthesis was carried out according to the method applied by Becker and Amin[5]; however, the product was purified by Soxhlet extraction with hot *n*-hexane until no more anthracene could be detected in the tube (14 h) (SiO_2, hexane/ethyl acetate (8/2), $R_f = 0.82$). The residue in the Soxhlet tube was extracted with hot dichloromethane (100 mL). The mixture was cooled and the yellow crystals filtered off (41 % yield).

3: 5,5′-dimethyl-2,2′-bipyridine (3.68 g, 20 mmol) was dissolved in anhydrous THF (50 mL) and cooled to −78 °C under Ar. This solution was treated with LDA solution (13.3 mL, 20 mmol of a 1.5 M solution in cyclohexane) by slow dropwise addition through a septum, and the mixture was stirred for 2 h. Anhydrous gaseous CO_2 was bubbled through the black solution, which gave rise to an increase in the temperature and eventually a clear yellow solution was formed. The mixture was stirred for 1 h at −78 °C under a flow of CO_2 gas, then it was gradually allowed to warm to room temperature to produce a yellowish precipitate. After addition of several drops of water, the solvents were evaporated. The residue was taken up in 1 M NaOH (200 mL), extracted with hexane (200 mL), and the organic phase washed with 1 M NaOH (2 × 100 mL). The acidity of the combined aqueous phases was adjusted to pH = 5 by the addition of 3 M HCl, and the mixture was then concentrated until crystallization commenced. The crystals were dried at 50 °C and 200 mbar to give **3** (2.38 g, 10.4 mmol, 52 %). ^{1}H NMR (300 MHz, [D$_6$]DMSO, 25 °C, TMS): $\delta = 12.50$ (br. s, 1 H, COOH), 8.53 and 8.51 (both s, 1 H, CH(6 and 6′, respectively)), 8.29 and 8.25 (both d, 1 H, CH(3 and 3′, respectively)), 7.80 and 7.74 (both dd, 1 H, CH(4 and 4′, respectively)), 3.70 (s, 2 H, CH_2), 2.35 (s, 3 H, CH_3); MS (EI): *m/z*: 228 (M^+), 183 (M^+ − COOH), 155 (M^+ − CH_2COOH), 141 (bpy), 128, 115, 102, 92, 65, 51, 45; HR-MS: calcd. for $C_{13}H_{12}N_2O_2$: 228.0899, found: 228.0891.

4: **3** (133 mg, 0.58 mmol), **1** (240 mg, 0.58 mmol), and a spatula tip of 4-(dimethylamino)pyridine (DMAP) were dissolved in anhydrous dichloromethane (40 mL). After addition of diisopropylcarbodiimide (120 mg, 0.95 mmol), the apparatus was closed with a drying tube and the mixture was stirred at room temperature for 36 h. The reaction mixture was filtered through celite and washed with dichloromethane (40 mL). The filtrate was extracted with 1 M HCl (2 × 50 mL), 1 M NaOH (2 × 50 mL), and water (50 mL), then it was dried over $MgSO_4$, and evaporated to dryness. The crude yellow product was dissolved in THF, mixed with an equal amount of silica gel, and evaporated to dryness. The residue was applied to a silica gel column and eluted with hexane/ethyl acetate (8:2) until unconverted **1** had been completely removed. Subsequently, the column was eluted with THF. The powder obtained after evaporation was purified over a Sephadex column (LH-20, eluent THF), to remove the urea by-product. Yield: 200 mg (0.32 mmol, 55 %) **4**. M.p. 233–235 °C; ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 8.50$ (d, 1 H, CH(6′)), 8.36 (s, 2 H, CH(9)), 8.24 (d, 1 H, CH(3′)), 8.22 (d, 1 H, s, CH(6)), 8.08 (d, 1 H, CH(3)), 7.96 (d, 8 H, CH(8)),7.61 (dd, 1 H, CH(4′)), 7.40–7.25 (m, 8 H, CH(7)), 7.09 (dd, 1 H, CH(4)), 5.78 (quint., 1 H, CHO), 4.14 and 3.79 (both dd, 2 H, CH_2), 3.29 (s, 2 H, CH_2COO), 2.38 (s, 3 H, CH_3); MS (FAB): *m/z*: 623 (M^+), 530, 485, 438, 423, 394 (**1** − OH), 229 (**3**), 184 (**3** − COOH), 155 (Me-bpy); correct elemental analysis for $C_{44}H_{34}N_2O_2 \cdot 0.75\,H_2O$.

The ester **5** was synthesized analogously from **2**[5] and **3**. M.p. 226–227 °C; ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 8.72$ (d, 1 H, CH(6′)), 8.53 (d, 1 H, CH(6)), 8.46 (d, 1 H, CH(3′)), 8.34 (d, 1 H, CH(3)), 7.92 (dd, 1 H, CH(4′)), 7.66 (dd, 1 H, CH(4)), 7.22 (m, 2 H, CH(7,8)), 7.13 (m, 2 H, CH(7,8)), 6.94 (m, 2 H, CH(7,8)), 6.90–6.77 (m, 10 H, CH(7,8)), 5.98 (quint., 1 H, CHO), 4.53 (s, 2 H, CH(9)), 3.90 (s, 2 H, CH_2COO), 2.99 („t", 2 H, CH_2), 2.88 (dd, 2 H, CH_2), 2.41 (s, 3 H, CH_3); MS (FAB): *m/z*: 623 (M^+), 394 (**1** − OH), 329, 307, 289, 229 (**3**); correct elemental analysis for $C_{44}H_{34}N_2O_2 \cdot 0.5\,H_2O$.

Rhenium complex[7]: **6**: Under argon, [Re(CO)$_5$Cl] (27.3 mg, 0.075 mmol) was dissolved in anhydrous toluene (10 mL). At 60 °C **4** (47 mg, 0.075 mmol) was added in a countercurrent of argon. The reaction mixture was heated to 80 °C for 15 h to give a yellow precipitate. The cooled solution was filtered, and the solid washed with toluene (1 mL) and ether (15 mL). The crude product was taken up in chloroform (20 mL), mixed with silica gel (ca. 400 mg), and evaporated. The yellow granular powder was applied to a column (SiO_2, 11 × 1 cm) and eluted with ethyl acetate until the first contaminant was washed off. The mobile phase was washed with dichloromethane until the product was eluted. After evaporation of the solvent, **6** (50 mg, 0.054 mmol, 72 %) was obtained as a pale yellow powder. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 8.84$ (d, 1 H, CH(6′)), 8.53 (d, 1 H, CH(6)), 8.40 and 9.37 (both s, 1 H, CH(9)), 7.97 (td, 8 H, CH(8)), 7.91 (d, 1 H, CH(3′)), 7.81 (dt, 1 H, CH(4′)), 7.60 (d, 1 H, CH(3)), 7.43–7.29 (m, 8 H, CH(7)), 7.00 (dd, 1 H, CH(4)), 5.87 (quint., 1 H, CHO), 4.20 (m, 2 H, CH_2), 3.91 (dm, 2 H, CH_2), 3.27 (s, 2 H, CH_2COO), 2.49 (s, 3 H, CH_3); MS (FAB): *m/z*:

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2780 $ 17.50+.50/0

928 (M^+), 893 ($M^+ - Cl$), 844 ($M^+ - 3CO$), 809 ($M^+ - 3CO - Cl$), 499, 454, 426, 307.

Rhenium complex **7**: Under argon, $[Re(CO)_5Cl]$ (27.3 mg, 0.075 mmol) was dissolved in anhydrous toluene (10 mL). At 60 °C, **5** (47 mg, 0.075 mmol) was added in a countercurrent of argon and the reaction mixture heated to 80 °C for 15 h. The cooled solution was filtered, washed with toluene (1 mL), suspended in ether, filtered, and dried in a high vacuum to give **7** (66 mg, 0.071 mmol, 94%) as a yellow powder. ^1H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 9.04$ (s, 1H, CH(6')), 8.88 (d, 1H, CH(6)), 8.21 (dd, 1H, CH(4')), 8.17 (d, 1H, CH(3')), 8.08 (dd, 1H, CH(3)), 7.86 (dd, 1H, CH(4)), 7.22 (m, 2H, CH(7,8)), 7.12 (m, 2H, CH(7,8)), 6.96 (m, 2H, CH(7,8)), 6.90–6.78 (m, 10H, CH(7,8)), 6.00 (quint., 1H, CHO), 4.54 (s, 2H, CH(9)), 3.99 (s, 2H, CH_2COO), 3.06 („t"d, 2H, CH_2), 2.85 (dd, 2H, CH_2), 2.52 (s, 3H, CH_3); MS (FAB): *m/z*: 928 (M^+), 893 ($M^+ - Cl$), 844 ($M^+ - 3CO$), 499 ($M^+ - \mathbf{1}$), 471, 454, 307.

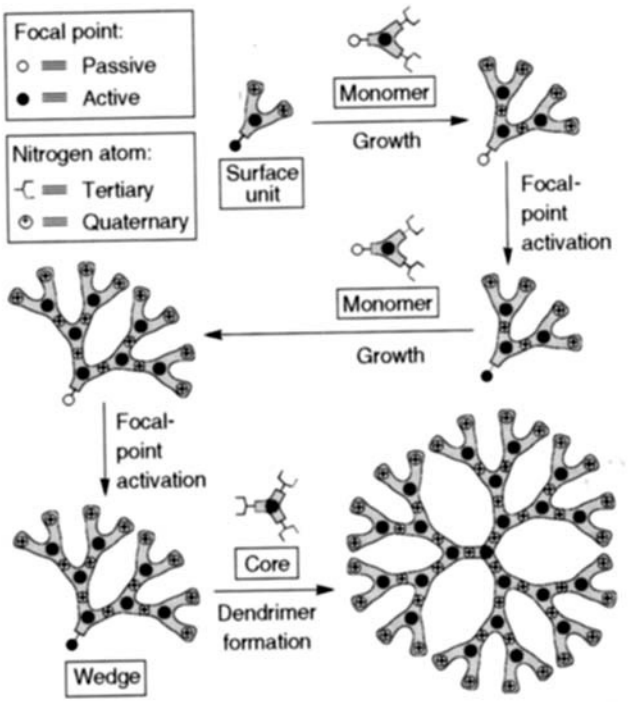

Scheme 1. Schematic representation of the convergent approach to the synthesis of a third-generation polycationic dendrimer with quaternary ammonium linkages.

Polycationic Dendrimers**

Peter R. Ashton, Kazusato Shibata, Andrew N. Shipway, and J. Fraser Stoddart*

Dedicated to Professor Achim Müller on the occasion of his 60th birthday

Dendritic molecules[1] carrying multiple cationic sites are—unlike their polyanionic counterparts[2]—still very rare.[3] The catalytic activity of a dendrimer coated with quaternary ammonium centers on its surface has been investigated,[4] and a series of dendrimers in which the core and branch points are either ammonium[5] or phosphonium sites[6] have been reported. However, the potential applications of dendrimers might be hindered by the low yields of their syntheses.

We are interested in creating dendritic microenvironments, in which a wide range of different chemical reactions can be carried out.[7] It is not unlikely that dendrimers with cavities that are splattered with positive charges and yet largely lipophilic should be able to bind simultaneously counterions—in the shape of reactive nucleophiles[8]—and organic substrates.[9]

Here we present a particularly attractive and efficient convergent approach (Scheme 1) to gram quantities of polycationic wedges and dendrimers.[10] The core and branching points are based on a mesitylene framework. Generation growth is achieved by using the high-yielding Menschutkin reaction, in which the growing dendritic wedge bearing a reactive benzylic CH_2Br group at the focal point is attached to the benzylic CH_2NEt_2 functionalities in a monomer unit, thereby producing new cationic sites.[11] The larger "passive" wedge is isolated, and the new benzylic CH_2OH group then converted into the reactive CH_2Br group to afford a larger "active" wedge. The series of first-, second-, and third-generation wedges are incorporated into the corresponding dendrimers by allowing the active wedges to react with the core, namely, 1,3,5-tris(diethylaminomethyl)benzene (**C**). To ensure that the Menschutkin reaction is high-yielding, the amines (i. e., the monomer **M** and the core **C**) must be of extremely high purity. As new cationic sites are created, the "soft" PF_6^- anion is introduced to aid the solubility of the positively charged macromolecules in organic solvents.

The synthesis[12] of the monomer **M**, the core **C**, the first-generation ($g = 1$) wedge **1GW**·$2PF_6$, and the zero-generation ($g = 0$) dendrimer **0GD**·$3PF_6$ are summarized in Scheme 2. 1,3,5-Tris(bromomethyl)benzene (**2**), which was obtained by bromination of 1,3,5-tris(hydroxymethyl)benzene[13] (**1**) with three equivalents of Ph_3P/CBr_4 in THF, was treated with an excess of Et_2NH to give the core **C** (97% yield). Reaction of **1** with two equivalents of Ph_3P/CBr_4 in THF afforded 3,5-bis(bromomethyl)phenylmethanol (**3**, 55% yield), which was converted into the monomer **M** (86% yield) by treatment with excess Et_2NH. Reaction of **3** with excess Et_3N yielded **4**·2Br quantitatively. After counterion exchange with NH_4PF_6/H_2O to produce **4**·$2PF_6$, the CH_2OH group in $\mathbf{4}^{2+}$ was converted into a CH_2Br group with HBr/HOAc to afford, after counterion exchange, the wedge **1GW**·$2PF_6$ ($g = 1$, 89% yield). Successive treatment of **2** with an excess of NEt_3 and NH_4PF_6 yielded the dendrimer

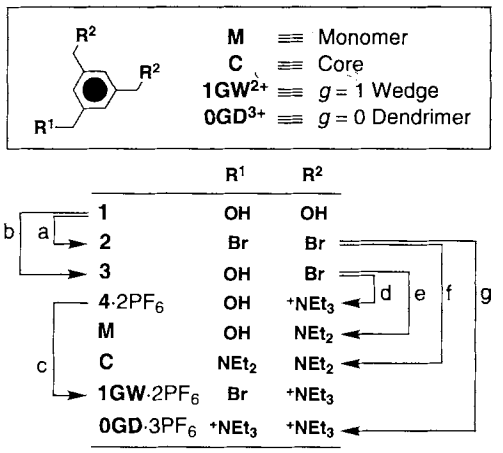
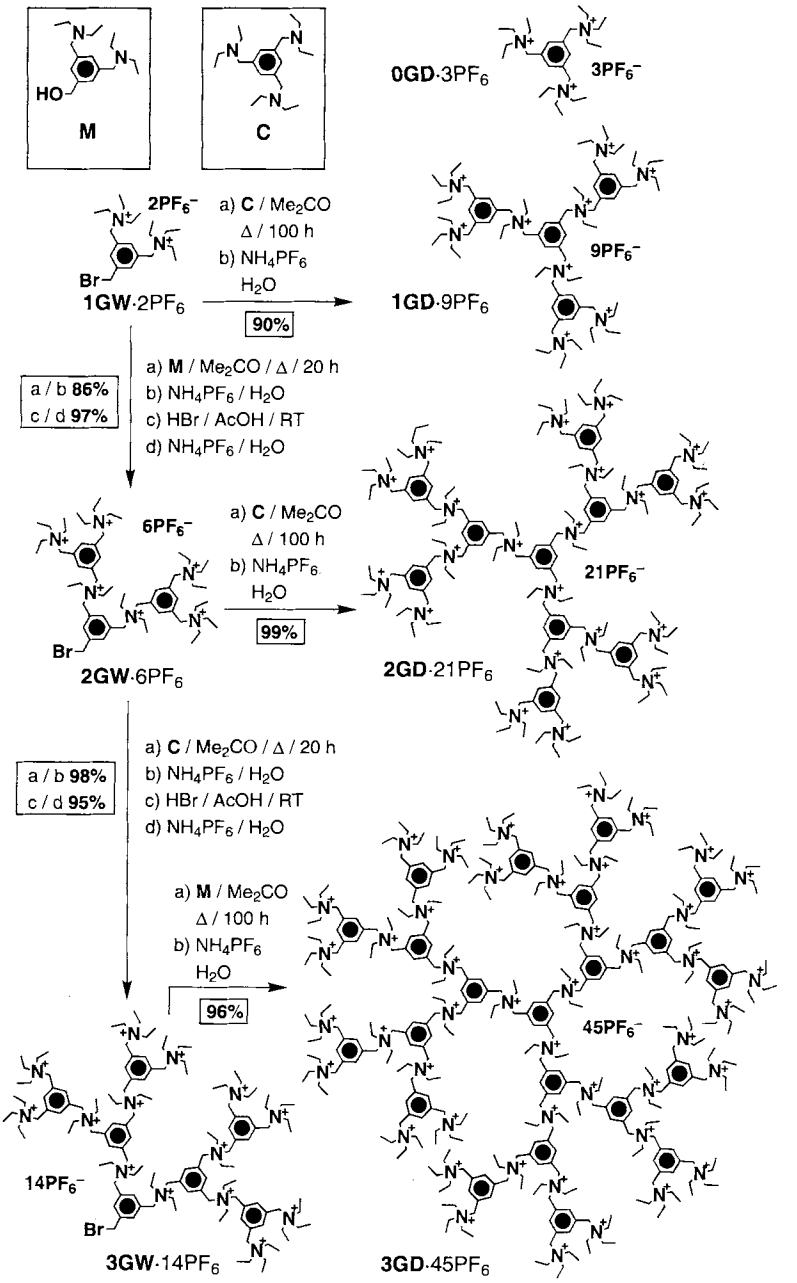


Scheme 2. Synthesis of the key building blocks—namely, the monomer **M**, the core **C**, the first-generation wedge **1GW**·2PF$_6$ ($g=1$), and the zero-generation dendrimer **0GD**·3PF$_6$ ($g=0$)—from 1,3,5-tris(hydroxymethyl)benzene (**1**). a) 45% HBr in AcOH, 20°C, 46 h, 98%; b) CBr_4/PPh_3/THF, 20°C, 2 h, 55%; c) 1. 45%. HBr in AcOH, 20°C, 20 h; 2. NH_4PF_6/H_2O, 100%; d) Et_3N/Me_2CO/MeOH, 20°C, 2 h, 100%; e) Et_2NH, 20°C, 4 h, 86%; f) Et_2NH/Et_2O, 20°C, 23 h, 97%; g) Et_3N/MeOH, 20°C, 2 h, 49%.



Scheme 3. Synthesis of up to third-generation dendrimers and wedges from the monomer **M**, the core **C**, and the first-generation wedge **1GW**·2PF$_6$.

0GD·3PF$_6$ ($g=0$, 67% yield), which is stable[14] upon heating in CD_3SOCD_3 at 100°C in the presence of about ten equivalents of NaOMe.

Wedge growth (Scheme 3) as far as the third-generation wedge ($g=3$, **3GW**$^{14+}$) was achieved by a repetitive sequence of steps: a) successive Menschutkin reactions between **M** and wedges **1GW**·2PF$_6$ ($g=1$) and **2GW**·6PF$_6$ ($g=2$) in Me_2CO, b) subsequent counterion exchange, c) treatment of the benzylic alcohol functionality with HBr/HOAc to give the benzylic bromide, and d) counterion exchange with aqueous NH_4PF_6. All the steps proceeded with better than 90% yields. Dendrimers **1GD**·9PF$_6$ ($g=1$), **2GD**·21PF$_6$ ($g=2$), and **3GD**·45PF$_6$ ($g=3$) with 9, 21, and 45 cationic sites, respectively, were synthesized in yields of 90, 99, and 96% by allowing the core **C** to react with the wedges **1GW**·2PF$_6$, **2GW**·6PF$_6$, and **3GW**·14PF$_6$ in turn in Me_2CO to effect the three necessary Menschutkin reactions followed by counterion exchange. They are all stable white solids which decompose without melting above 200°C; they are very soluble in organic solvents such as Me_2CO, DMF, DMSO, $MeNO_2$, and MeOH. The constitutions and purities of all the wedges and dendrimers were established by LSI mass spectrometry, ^1H and ^{13}C NMR spectroscopy, and elemental analysis. The LSI mass spectra of **1GW**·2PF$_6$, **2GW**·6PF$_6$, **3GW**·14PF$_6$, **0GD**·3PF$_6$, and **1GD**·9PF$_6$ display peaks at $m/z=543$, 1706, 4027, 710, and 2451, respectively, corresponding to $[M-PF_6]^+$. **2GD**·21PF$_6$ and **3GD**·45PF$_6$ do not exhibit $[M-PF_6]^+$ ions, possibly as a result of their highly charged character.

An extremely efficient synthetic route to polycationic dendrimers has been established. There is every reason to believe that further growth of the dendrimers beyond the third generation will be possible using, for example a "double-stage" approach.[15] This simple and very high-yielding synthetic methodology for constructing monodisperse macromolecular polyelectrolytes, whose solubility can be influenced by the nature of the counterions, has important implications when it comes, for example, to investigating interfacial phenomena and devising new analytical procedures[16] and catalytic processes.

Experimental Section

3: m.p. 94–95°C; MS(EI): $m/z=294$ [M^+], 213 [M^+-Br], 134 [M^+-2Br]; ^1H NMR ($CDCl_3$, 300 MHz): $\delta=1.80$ (br s, 1H), 4.45 (s, 4H), 4.68 (s, 2H), 7.32 (s, 3H); ^{13}C NMR ($CDCl_3$, 75 MHz): $\delta=32.7$, 64.4, 127.3, 128.7, 138.6, 142.2; elemental analysis calcd for $C_9H_{10}Br_2O$: C 36.77, H 3.43; found: C 36.85, H 3.32.

C: b.p. 129°C (0.40 torr); MS (EI): $m/z=333$ [M^+]; ^1H NMR ($CDCl_3$, 300 MHz): $\delta=1.02$ (t, 18H, $J=7$ Hz), 2.49 (q, 12H, $J=7$ Hz), 3.53 (s, 6H), 7.14 (s, 3H); ^{13}C NMR ($CDCl_3$, 75 MHz): $\delta=11.7$, 46.6, 57.4, 128.0, 139.3; elemental analysis calcd for $C_{21}H_{39}N_3$: C 75.62, H 11.78, N 12.60; found: C 75.50, H 11.86, N 12.86.

M: b.p. 129°C (0.10 torr); MS (EI): $m/z=278$ [M^+]; ^1H NMR ($CDCl_3$, 300 MHz): $\delta=1.02$ (t, 12H, $J=7$ Hz), 2.49 (q, 8H, $J=7$ Hz), 3.53 (s, 4H), 4.63 (s, 2H),

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2782 $ 17.50+.50/0

7.15–7.22 (m, 3H); ^{13}C NMR ($CDCl_3$, 75 MHz): δ = 11.4, 46.5, 57.3, 64.7, 126.1, 128.8, 139.5, 141.2; elemental analysis calcd for $C_{17}H_{30}N_2O$: C 73.33, H 10.86, N 10.06; found: C 73.40, H 10.86, N 9.92.

4·2 PF_6: m.p. 185–187 °C (decomp); MS (LSI): *m/z*: 481 [$M^+ - PF_6$]; ^{1}H NMR (CD_3SOCD_3, 300 MHz): δ = 1.31 (t, 18H, *J* = 7 Hz), 3.17 (q, 12H, *J* = 7 Hz), 4.49 (s, 4H), 4.60 (d, 2H, *J* = 6 Hz), 5.46 (t, 1H, *J* = 6 Hz), 7.40 (s, 1H), 7.56 (s, 2H); ^{13}C NMR (CD_3SOCD_3, 75 MHz): 7.4, 52.0, 58.9, 62.0, 128.4, 132.0, 134.5, 144.4; elemental analysis calcd for $C_{21}H_{40}F_{12}N_2OP_2$: C 40.26, H 6.44, N 4.47; found: C 40.32, H 6.39, N 4.34.

1GW·2 PF_6: **4**·2 PF_6 (14.1 g, 22.4 mmol) was added to 45%. HBr in HOAc (60 mL). The reaction mixture was stirred for 65 h before being concentrated under vacuum to yield a brown oil, which was treated with aqueous NH_4PF_6 to afford **1GW**·2 PF_6 as a white solid (13.8 g, 20.0 mmol, 89%); m.p. 183–185 °C (decomp); MS (LSI): *m/z* = 543 [$M^- - PF_6$]; ^{1}H NMR (CD_3SOCD_3, 300 MHz): δ = 1.31 (t, 18H, *J* = 7 Hz), 3.17 (q, 12H, *J* = 7 Hz), 4.50 (s, 4H), 4.83 (s, 2H), 7.48 (s, 1H), 7.72 (s, 2H); ^{13}C NMR (CD_3SOCD_3, 75 MHz): δ = 7.4, 32.9, 52.0, 58.5, 129.1, 135.0, 136.1, 139.9; elemental analysis calcd for $C_{21}H_{39}BrF_{12}N_2P_2$: C 36.59, H 5.70, N 4.06; found: C 36.33, H 5.50, N 3.88.

2GW·6 PF_6 and **3GW**·14 PF_6: Wedge **1GW**·2 PF_6 or **2GW**·6 PF_6 and the monomer **M** (0.45 mol%) were heated at reflux in Me_2CO. After removal of the solvent under vacuum, the residue was treated with an excess of NH_4PF_6 in aqueous Me_2CO. The precipitated PF_6^- salts were isolated by filtration, washed with H_2O, and dried before being stirred with 45% HBr in HOAc at room temperature for 65 h. Concentration of the solution under vacuum afforded a brown oil, which was treated with aqueous NH_4PF_6 to yield the appropriate second- or third-generation wedge

2GW·6 PF_6: white solid (97% yield); decomposition without melting above 130 °C; MS (LSI): *m/z* = 1706 [$M^- - PF_6$]; ^{1}H NMR (CD_3SOCD_3, 300 MHz): δ = 1.33 (t, 36H, *J* = 7 Hz), 1.45 (t, 12H, *J* = 7 Hz), 3.19 (m, 32H), 4.53 (s, 8H), 4.66 (br s, 8H), 4.80 (s, 2H), 7.69 (s, 3H), 7.76 (s, 4H), 7.82 (s, 2H); ^{13}C NMR (CD_3SOCD_3, 75 MHz): δ = 7.4, 8.4, 32.6, 52.0, 52.7, 58.2, 60.3, 129.2, 129.3, 129.4, 135.6, 136.5, 138.2, 138.6, 140.0; elemental analysis calcd for $C_{59}H_{107}BrF_{36}N_6P_6$: C 38.30, H 5.83, N 4.54; found: C 38.28, H 5.89, N 4.59.

3GW·14 PF_6: white solid (95% yield); decomposition without melting above 100 °C; MS (LSI): *m/z* = 4027 [$M^+ - PF_6$]; ^{1}H NMR (CD_3SOCD_3, 300 MHz): δ = 1.33 (br s, 72H), 1.50 (m, 36H), 3.20 (br s, 72H), 4.52 (br s, 16H), 4.68 (br s, 24H), 4.80 (s, 2H), 7.60–7.95 (m, 21H); ^{13}C NMR (CD_3SOCD_3, 75 MHz): δ = 7.4, 8.4, 52.0, 52.7, 58.2, 59.8, 129.2, 129.5, 138.5, 139.0; elemental analysis calcd for $C_{135}H_{243}BrF_{84}N_{14}P_{14}$: C 38.87, H 5.87, N 4.70; found: C 38.78, H 6.08, N 4.75.

0GD·3 PF_6: Et_3N (5 mL) was added with constant stirring to a solution of **2** (0.13 g, 0.39 mmol) and NH_4PF_6 (0.15 g, 1.3 mmol) in Me_2CO (5 mL), and then the reaction was stirred for 3 h. The solution was filtered and dried over K_2CO_3, and the solvent removed. The product was purified by recrystallization from Me_2CO/hexane to give **0GD**·3 PF_6 (white solid, 67% yield); MS(EI): *m/z* = 710 [$M^- - PF_6$]; ^{1}H NMR (CD_3COCD_3, 300 MHz): δ = 1.56 (t, 27H, *J* = 7 Hz), 3.51 (q, 18H, *J* = 7 Hz), 4.79 (s, 6H), 8.08 (s, 3H); ^{13}C NMR (CD_3COCD_3, 75 MHz): δ = 8.0, 53.5, 59.9, 130.8, 139.6.

1GD·9 PF_6, **2GD**·21 PF_6, and **3GD**·45 PF_6: Wedge **1GW**·2 PF_6, **2GW**·6 PF_6, or **3GW**·14 PF_6 (3.1 equiv) and the core **C** were heated at reflux in Me_2CO for 100 h. The solution was then added to an excess of aqueous NH_4PF_6, and the mixture stirred for 10 min. The resulting precipitate was filtered, washed with H_2O, and dried.

1GD·9 PF_6: white solid (90% yield); decomposition without melting above 200 °C; ^{1}H NMR (CD_3SOCD_3, 300 MHz): δ = 1.33 (br s, 54H), 1.50 (br s, 18H), 3.18 (br s, 48H), 4.51 (br s, 12H), 4.68 (brs, 12H), 7.60–8.00 (m, 12H); ^{13}C NMR (CD_3SOCD_3, 75 MHz): δ = 7.4, 8.4, 52.0, 52.7, 58.1, 59.8, 129.2, 129.5, 138.4; elemental analysis calcd for $C_{84}H_{156}F_{54}N_9P_9$: C 38.85, H 6.05, N 4.85; found: C 38.64, H 6.46, N 4.52.

2GD·21 PF_6: white solid (99% yield); decomposition without melting above 200 °C; ^{1}H NMR (CD_3SOCD_3, 300 MHz): δ = 1.33 (br s, 108H), 1.47 (m, 54H), 3.19 (m, 108H), 4.53 (br s, 24H), 4.65 (br s, 36H), 7.60–8.00 (m, 30H); ^{13}C NMR (CD_3SOCD_3, 75 MHz): δ = 7.4, 8.4, 52.0, 52.7, 58.2, 60.2, 129.2, 129.3, 129.4, 138.2, 138.3, 138.4, 138.5; elemental analysis calcd for $C_{198}H_{360}F_{126}N_{21}P_{21}$: C 39.12, H 5.97, N 4.84; found: C 39.12, H 5.84, N 4.92.

3GD·45 PF_6: white solid (96% yield); decomposition without melting above 200 °C; ^{1}H NMR (CD_3SOCD_3, 300 MHz): δ = 1.33 (br s, 216H), 1.51 (br s, 126H), 3.18 (br s, 228H), 4.52 (br s, 48H), 4.67 (br s, 84H), 7.70–7.90 (m, 66H); ^{13}C NMR (CD_3SOCD_3, 75 MHz): δ = 7.4, 8.4, 52.0, 52.7, 58.2, 59.8, 129.2, 129.5, 138.4; elemental analysis calcd for $C_{426}H_{768}F_{270}N_{45}P_{45}$: C 39.22, H 5.93, N 4.83; found: C 39.09, H 5.94, N 4.78.

[1] a) D. A. Tomalia, A. M. Naylor, W. A. Goddard III, *Angew. Chem.* **1990**, *102*, 119–157; *Angew. Chem. Int. Ed. Engl.* **1990**, *29*, 138–175; b) G. R. Newkome, C. N. Moorefield, F. Vögtle, *Dendritic Molecules*, VCH, Weinheim, **1996**; c) O. A. Matthews, A. N. Shipway, J. F. Stoddart, *Prog. Polym. Sci.*, **1998**, *23*, 1–56.

[2] Many dendrimers with polyanionic surfaces have been synthesized, see for example a) K. R. Gopidas, A. R. Leheny, G. Caminati, N. J. Turro, D. A. Tomalia, *J. Am. Chem. Soc.* **1991**, *113*, 7335–7342; b) C. J. Hawker, K. L. Wooley, J. M. J. Fréchet, *J. Chem. Soc. Perkin Trans. 1* **1993**, 1287–1297.

[3] Apart from cationic sites being introduced into an organic compound during its synthesis, polycationic dendrimers have been produced by a) modification of neutral dendrimers (see for example C. Larré, A.-M. Caminade, J.-P. Majoral, *Angew. Chem.* **1997**, *109*, 614–617; *Angew. Chem. Int. Ed. Engl.* **1997**, *36*, 596–599) and b) incorporating transition matals into the dendritic structure (see for example S. Campagna, G. Dendti, S. Serroni, A. Juris, M. Venturi, V. Ricevuto, V. Balzani, *Chem. Eur. J.* **1995** *1*, 211–221; S. Achar, J. Puddephatt, *J. Chem. Soc. Chem. Commun.* **1994**, 1895–1896).

[6] K. Rengan, R. Engel, *J. Chem. Soc. Perkin Trans. 1* **1991**, 987–990.

[7] Although many diverse examples of catalytic dendrimers have been reported, they rely upon the incorporation of a known catalytic site inside or on the surface of the dendritic structure rather than upon the unique dendritic microenvironment itself, see for example a) J. W. J. Knapen, A. W. van der Made, J. C. de Wilde, P. W. N. M. van Leeuwen, P. Wijkens, D. M. Grove, G. van Koten, *Nature* **1994**, *372*, 659–663; b) A. Miedaner, C. J. Curtis, R. M. Barkley, D. L. DuBois, *Inorg. Chem.* **1994**, *33*, 5482–5490; c) P. J. Dandliker, F. Diederich, J.-P. Gisselbrecht, A. Louati, M. Gross, *Angew. Chem.* **1995**, *107*, 2906–2909; *Angew. Chem. Int. Ed. Engl.* **1995**, *34*, 2725–2727.

[8] For examples of the encapsulation of guest molecules inside dendritic structures, see a) A. M. Taylor, W. M. Goddard III, G. E. Keifer, D. A. Tomalia, *J. Am. Chem. Soc.* **1989**, *111*, 2339–2341; b) G. R. Newkome, C. N. Moorefield, G. R. Baker, M. J. Saunders, S. H. Grossman, *Angew. Chem.* **1991**, *103*, 1207–1209; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 1178–1180; c) C. J. Hawker, K. L. Wooley, J. M. J. Fréchet, *J. Chem. Soc. Perkin Trans. 1* **1993**, 1287–1297; d) J. F. G. A. Jansen, E. M. M. de Brabander-van den Berg, E. W. Meijer, *Science* **1994**, *266*, 1226–1229; e) J. F. G. A. Jansen, E. W. Meijer, E. M. M. de Brabander-van den Berg, *J. Am. Chem. Soc.* **1995**, *117*, 4417–4418.

[9] Examples of catalyses have been observed in cationic micelles (F. M. Menger, L. G. Whitesell, *J. Am. Chem. Soc.* **1985**, *107*, 707–708) and in polymerized micelles (A. Kumar, G. Oehme, J. P. Roque, M. Schwarze, R. Selke, *Angew. Chem.* **1994**, *106*, 2272–2274; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 2197–2199).

[10] C. J. Hawker, J. M. J. Fréchet, *J. Am. Chem. Soc.* **1990**, *112*, 7638–7647.

[11] The formation of this polycationic dendrimer is exactly analogous to that of the Fréchet dendrimers, except that the nucleophile in this case is an $ArCH_2NEt_2$ rather than a phenoxide group. For this reason, the two systems should be compatible in the construction of mixed-monomer dendritic architectures.

[12] The nomenclature employed for describing the wedges and dendrimers: a number (**0**, **1**, **2**, or **3**) denoting the generation followed by the letter **G** for generation, and thereafter by the letter **W** or **D** for a wedge or a dendrimer, respectively.

[13] Although **1** is commercially available, it is convenient and economical to make on a 100-g scale. Esterification of 1,3,5-tribenzenecarboxylic acid (trimesic acid) with $MeOH/H_2SO_4$ followed by reduction of the triester affords 1,3,5-tris(hydroxymethyl)benzene in quantitative yield.

[14] The ^{1}H NMR spectrum of a mixture of **0GD**·3 PF_6 (10 mg) and NaOMe (5 mg) in CD_3SOCD_3 (0.7 mL) was essentially unchanged after heating at 100 °C for 72 h.

[15] K. L. Wooley, C. J. Hawker, J. M. J. Fréchet, *J. Am. Chem. Soc.* **1991**, *113*, 4252–4261.

[16] S. A. Kuzdzal, C. A. Monnig, G. R. Newkome, C. N. Moorefield, *J. Am. Chem. Soc.* **1997**, *119*, 2255–2261.

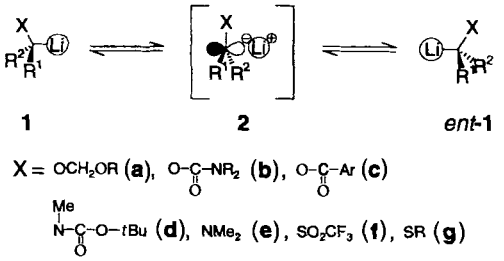
A Highly Enantiomerically Enriched α-Thiobenzyl Derivative with Unusual Configurational Stability**

Dieter Hoppe,* Bernd Kaiser, Oliver Stratmann, and Roland Fröhlich

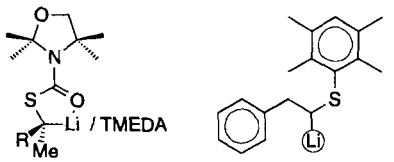
Dedicated to Professor Waldemar Adam on the occasion of his 60th birthday

α-Heterosubstituted, enantiomerically enriched alkyllithium compounds **1** have gained importance in the field of enantioselective synthesis.[1-4] Electrophilic reagents react with retention of configuration (R^1, R^2 = alkyl, H), whereas inversion of configuration takes place at the benzylic position.[2n-p,3h] The configurational stability reaches a synthetically useful level and provides the possibility of handling **1** or *ent*-**1** without racemization for only a few α-oxy-[2] or α-amino-substituted[3] species (**1a**–**1e**) and for lithiated alkyl trifluoromethyl sulfones[4] (**1f**) between −80 and −30 °C (Scheme 1).



Scheme 1. Inversion of the configuration of alkyllithium compounds **1**.

However, α-thio-substituted alkyllithium derivatives **1g** are characterized by a notorious lability of configuration.[5] As far as we know, the only exception is the lithiated *S*-(α-trimethylsilylalkyl) thiocarbamate **3b**.[6] It can be kept in diethyl ether at −78 °C for several hours without noticeable racemization, whereas non-silylated **3a** shows configurational

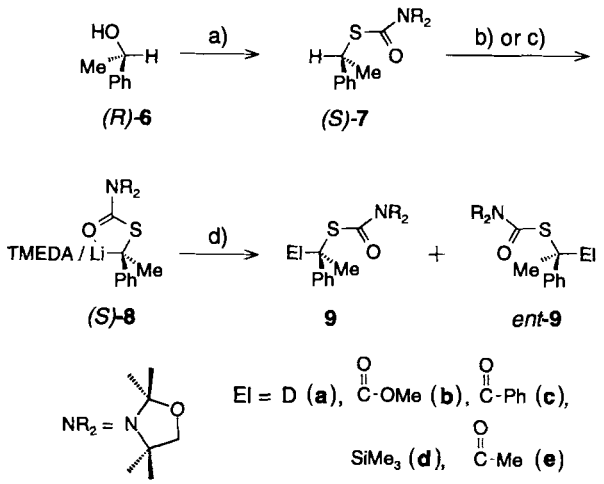


lability under these conditions (TMEDA = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine).[7] Based on work by H. J. Reich et al.[5a-e] and R. W. Hoffmann et al.,[5f-l] this is caused by a different mechanism of racemization. Neither formation of a solvent-separated ion pair nor inversion of configuration at the carbanionic center but rotation of the hyperconjugated S–C bond seems to be the rate-determining step (Scheme 2). In this case the barrier of racemization should be enhanced by

Scheme 2. Proposed mechanism for the inversion of configuration in **2g**.

bulky substituents R at the sulfur atom (as for **4**)[5k-l] and by branching at the carbanionic center.

With respect to these results we investigated the lithium compound (*S*)-**8**, which can be expected to have a larger tendency to form solvent-separated ion pairs than **3a** because of the additional resonance stabilization of the anion. Thiocarbamate (*S*)-**7**[8] (>99% *ee*)[9] was synthesized from (*R*)-1-phenylethanol[10] [(*R*)-**6**, Scheme 3], which was ob-



Scheme 3. Synthesis of (*S*)-**8**, **9**, and *ent*-**9**. a) 1. Diisopropyl azodicarboxylate (DIAD)/Ph_3P/MeCOSH (THF), 70%; 2. $LiAlH_4$ (Et_2O), 99%; 3. NaH/$ClCONR_2$ (THF) 92%; b) *sec*-BuLi/TMEDA (Et_2O, −78 °C; c) *sec*-BuLi/TMEDA (Et_2O, −78 °C–0 °C; d) ElX.

tained by the classical method of resolution. Deprotonation[11] was achieved by adding *sec*-butyllithium/TMEDA to a solution of (*S*)-**7** in diethyl ether at −78 °C. At this temperature the solution was quenched with several electrophilic reagents (method A). We obtained the substitution products (*S*)-**7** (reprotonation with MeOH or AcOH), **9a**, and *ent*-**9b**–*ent*-**9e** with 97% to greater than 99% *ee* (Table 1).

Table 1. Lithiation and substitution of (*S*)-**7**.

Electrophile (ElX)	Method	Product [a]	Yield [%]	*ee* [%]	$[\alpha]_D^T$ [b]
H*OMe*	A	(*S*)-**7**	95	99	−127.2
H*OMe*	B	(*S*)-**7**	91	≥99	−128.6
H*OAc*	A	(*S*)-**7**	98	≥99	−133.5
D*OMe*	A	**9a** [c]	94	98	−129.1
MeO(CO)*Cl*	A	*ent*-**9b**	98	≥99	−24.6
MeO(CO)*Cl*	B	*ent*-**9b**	98	≥99	−25.5
CO_2 [d]	A	*ent*-**9b**	90	99	−22.5
Ph(CO)*Cl*	A	*ent*-**9c**	82	99	+116.5
Me_3SiCl	A	*ent*-**9d**	93	≥97	−90.7
Me(CO)*Cl*	A	*ent*-**9e**	95	≥99	−22.5
Me(CO)*Cl*	B	*ent*-**9e**	98	≥99	−21.8
Ac*OAc*	A	**9e**	75	57	+12.3

[a] All products were obtained analytically pure (C ± 0.4%, H ± 0.3%, N 0.3%). [b] $T = 20-27$ °C, $c = 1.06-1.93$ g(100 mL)$^{-1}$ in CH_2Cl_2. [c] Degree of deuteration 86%. [d] Without deacidification, followed by esterification of the carboxylic acid with diazomethane.

The absolute configuration of compounds *ent*-**9b** to *ent*-**9d** was confirmed by single-crystal X-ray diffraction analysis with anomalous dispersion.[12]

In further experiments a solution of (*S*)-**8** was maintained at -2 to 0 °C for ten minutes and then cooled again to -78 °C before the electrophile was added (method B). The products (*S*)-**7**, *ent*-**9b**, and *ent*-**9e** still had the high enantiomeric purity of $\geq 99\%$ *ee*.[13] Therefore, the half-life of racemization of **8** can be extrapolated to several hours.[14] As observed for the corresponding benzylcarbamate (O instead of S in **8**), substitution mainly takes place with inversion of configuration.[2n-p] Only electrophilic reagents that tend to coordinate the lithium cation react suprafacially with retention of configuration; examples are protonic acids or acid anhydrides as shown for **9e** in Table 1. The combination of effective kinetic acidification of the optically active precursor **7** by an *S*-carbamoyl group with hindrance of rotation of the adjacent C–S bond in the ion pair provided the first, and probably generalizable, access to highly enantiomerically enriched α-thiocarbanions.

Experimental Section

Method A: Salt-free *sec*-butyllithium (1.25 mmol, $\approx$1.3 M in isopentane/cyclohexane) was added to a solution of TMEDA (174 mg, 1.50 mmol) and (*S*)-**7** (293 mg, 1.00 mmol) in diethyl ether (10.0 mL) at -78 °C. After 2 h of stirring the electrophile was injected, and the reaction mixture stirred for a further 2–5 h. The cool solution was poured into a mixture of diethyl ether (10 mL) and 2 N HCl (10 mL). The aqueous phase was extracted three times with diethyl ether. After the combined organic phases were dried and deacidified with Na_2SO_4/$NaHCO_3$, the crude product was purified by flash chromatography on silica gel.

Method B: After lithiation and 1 h of stirring at -78 °C the reaction mixture was warmed to -2 to 0 °C (internal thermometer) in an ice/water bath within 2–5 min, kept at this temperature for 10 min, and cooled to -78 °C with a dry ice/acetone bath within about 10 min. The electrophile was added, and the reaction mixture treated as described for method A.

[7] An α-(phenylselenoalkyl)magnesium compound that is configurationally stable at -78 °C was prepared by kinetic resolution: W. Klute, M. Krüger, R. W. Hoffmann, *Chem. Ber.* **1996**, *129*, 633–638.

[8] (*S*)-**7**: M.p. 96 °C; ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.45-1.64$ (m, 12H), 1.70 (d, 3H), 3.72 (s, 2H), 4.79 (q, 1H), 7.20–7.40 (m, 5H); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 23.0$ (CH_3), 24.8 (CH_3), 25.8 (CH_3), 44.0 (C), 60.9 (C), 76.7 (CH_2), 97.3 (C), 127.0 (CH), 127.4 (CH), 129.0 (CH), 143.0 (C), 163.2 (C); IR (KBr): $\tilde{\nu} = 1610\ cm^{-1}$ (C=O); $[\alpha]_D^{25} = -133.1$ ($c = 1.22$, CH_2Cl_2, >99% *ee*); addition of (+)-Eu(hfc)$_3$ (40 mol%) leads to splitting of the down field shifted singlet for the CH_2 group in the ^{1}H NMR spectrum (300 MHz) by $\Delta\delta = 0.03$.

[9] All experiments were also carried out with the racemic starting material *rac*-**7**. The enantiomeric excesses were determined with ^{1}H NMR spectroscopy (300 MHz) by addition of (+)-Eu(hfc)$_3$ or (+)-Pr(hfc)$_3$ (11–56 mol%) in $CDCl_3$ (0.8 mL) and comparison with corresponding spectra of the racemic compounds. Usually the highly enantiomerically enriched products showed only the signal for one enantiomer. In these cases the given enantiomeric excesses and detection limits were confirmed by addition of the racemic compounds.

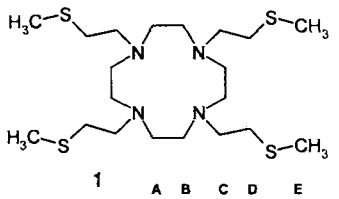
[13] Reproduction of these results requires salt-free *sec*-butyllithium and highly pure, and in particular disulfide-free, **7**; otherwise lower yields and enantiomeric excesses are registered.
[14] An experiment in which (*S*)-**8** is warmed to −2 to 0 °C for 1 h and quenching with methyl chloroformate leads to *ent*-**9b** in 58% yield with 73% *ee*. A longer reaction time at 0 °C causes severe decomposition.

A Highly Stable Silver(I) Complex of a Macrocycle Derived from Tetraazatetrathiacyclen**

Thomas Gyr, Helmut R. Mäcke,* and Michael Hennig

The chemistry of the coinage metals is of special interest in many diverse fields; one notable example is the medical application of gold(I) complexes for treating rheumatoid arthritis and as cytotoxic agents.[1] Another promising application is the use of the β-ray-emittig radionuclides ^{111}Ag[2] and ^{198}Au[3] in selective internal radiotherapy of tumors as radiometal-based bioconjugates. To reach their biological target intact, the radiometal is generally immobilized with a chelating ligand to withstand attack of the metal ions from body fluids and to avoid transfer of these metals to proteins. There has been great progress along these lines with other metallic radionuclides for radiotherapy, for example with ^{67}Cu[4] and ^{90}Y.[5] However, the considerable efforts expended in synthesizing complexes of silver(I) with sufficient stability to allow their use in vivo[2,6] have not been successful.

Here we describe the initial results of a study directed at synthesizing stable Ag(I) complexes. Preliminary results indicated that the macrocyclic chelating ligand 1,4,7,10-tetrakis[2-methylsulfanyl)ethyl]-1,4,7,10-tetraazacyclododecane (dotete, **1**; the letters A–E identify carbon atoms whose



1 A B C D E

resonances appear in the ^{13}C NMR spectra in Figure 3) shows a very high affinity for Ag^+, which is strongly preferred over Pb^{2+}; the two ions are found together in nature.[7] Moreover, it was of interest to ascertain if the coordination number for Ag^+ could be extended to eight by a strong electronic interaction between Ag^+ and the thioether functional groups,[8] utilizing the conformational rigidity and potential preorganization of cyclen-like macrocycles with side chains (cyclen = 1,4,7,10-tetraazacyclododecane).[9] Despite the preference of Ag^+ for coordination numbers two and four,[10] the use of crown thioether ligands produced complexes with coordination number six.[11] We report here the synthesis, characterization, and X-ray crystal structure of a novel N4S4 macrocycle as well as the crystal and solution structures of its new extraordinarily stable Ag^+ complex. Its stability is also compared to that of the Pb^{2+} complex.

The reaction of cyclen with 2-chloroethyl methyl sulfide in CH_3CN and in the presence of K_2CO_3 as base readily yields dotete. A solution of dotete in CH_2CL_2 was mixed with an equimolar amount of silver nitrate in CH_3CN; addition of ammonium hexafluorophosphate gave colorless crystals of $[Ag(dotete)]PF_6$ (**2**). The effective encapsulation of Ag^+ by dotete was confirmed by two qualitative observations: 1) $[Ag(dotete)]^+$ is stable in phosphate-buffered saline for 24 h, and 2) a slight excess of dotete readily dissolves AgI.

By using pH titrations and argentometric methods the protonation constants for dotete and complexation constants with Ag^+ in MeOH/H_2O (1/1) were determined to $pK_{a1} = 11.26$ and $pK_{a2} = 6.02$; the complexation constant is $\lg K_{[Ag(dotete)^+]} = 19.63$. This is by far the highest binding constant reported for silver(I) ions.

The high stability is preserved at lower pH values; the protonated species $[Ag(Hdotete)]^{2+}$ was formed with $\lg K_{[Ag(Hdotete)^{2+}]} = 2.8$. Measurements on the concentration of free silver ion gave values of 0.3% at pH = 2.2, which is consistent with that obtained from pH titrations. The extraordinary stability of $[Ag(dotete)]^+$ was confirmed by a competition experiment with the strong Ag^+-chelating ligand [18]aneS6 ([18]aneS6 = 1,4,7,10,13,16-hexathiacyclooctadecane). An equimolar amount of Ag^+ with traces of $^{110m}Ag^+$ was added to a 90% methanolic, neutral, phosphate-buffered solution of [18]aneS6 and dotete [10:1, Eq. (a)]. The mixture was investigated with HPLC and TLC using radiometric detection methods.

$$^{110m}Ag^+ + \text{dotete (1 equiv)} + \text{[18]aneS6 (10 equiv)} \rightarrow [^{110m}Ag(dotete)]^+ + \text{[18]aneS6} \quad \text{(a)}$$

Both methods showed exclusive formation of $[^{110m}Ag(dotete)]^+$, indicating that this complex possesses a stability constant that is at least three orders of magnitude higher than that for $[Ag([18]aneS6)]^+$ under these conditions. For $[Pb(dotete)]^{2+}$ stability constants of $\lg K_{[Pb(dotete)^{2+}]} = 8.8$ and $\lg K_{[Pb(Hdotete)^{3+}]} = 3.0$ were found.

The X-ray structures were determined for the uncomplexed monoprotonated dotete (counter ion PF_6^-) and for $[Ag(dotete)]PF_6$ (**2**).[15] In the case of **2**, there are two molecules in the asymmetric unit. They possess similar conformations with the exception of a disordered side chain in one molecule, which was refined for two slightly different conformations. The molecule without disorder is shown in Figure 1. Both independent cations show the same coordination geometry: The Ag^+ ion is hexacoordinated to the four nitrogen and two of the four possible sulfur donor atoms. The molecules are chemically equivalent but differ in the orientation of the terminal methyl group on the coordinated sulfur atoms. The four nitrogen atoms are nearly coplanar (maximum deviation 0.018 Å), and the silver ion is located 1.346 and 1.329 Å above the best N_4 plane. The Ag–N (av 2.53(3) Å) and Ag–S bond lengths (av 2.72(3) Å) are not unusual. Two opposite noncoordinating sulfur atoms are more than 5.0 Å from Ag. The structure of the free protonated ligand is shown in Figure 2. Its preorganization is clear even in the solid state. The N4 plane is intact (maximum deviation 0.055 Å), and the side chains are all *syn* to the N4 plane.

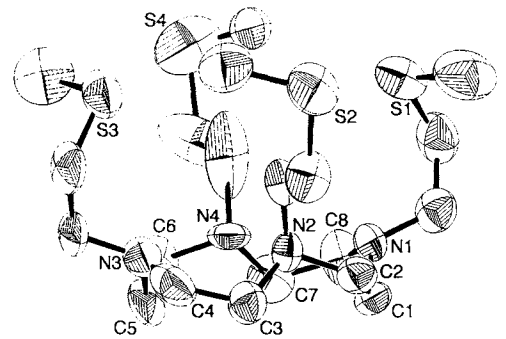

Figure 2. ORTEP representation of the crystal structure of Hdotete$^+$ (thermal ellipsoids at the 50% probability level). Selected bond lengths [Å] and angles [°]: N(1)–C(1) 1.428(13), N(1)–C(8) 1.450(2), N(4)–C(6) 1.540(2), N(4)–C(7) 1.478(14); C(1)-N(1)-C(8) 114.7(10), C(3)-N(2)-C(2) 111.1(9), C(5)-N(3)-C(4) 112.0(11), C(7)-N(4)-C(6) 109.5(9).

To probe the nature of Ag coordination in solution and to understand the high solution stability of **2**, $^{13}C\{^1H\}$ NMR spectra were measured at different temperatures in acetone. The room-temperature spectra in various solvents indicate the equivalence of the four side chains. The spectra consist of four resonances at $\delta = 53.69$ (C), 50.99 (A,B), 32.65 (D), and 16.32 (E; see formula drawing of **1** and Scheme 1). This is somewhat surprising considering the hexacoordination of Ag^+ in the solid state with binding to two transannular sulfur atoms. Therefore, in order for all four side chains to be equivalent in solution, either all S-donor atoms are bound to Ag^+, or there is rapid interchange between the different bound and unbound states at room temperature on the NMR time scale. The equivalence of ^{13}C NMR signals for carbon atoms C, D, and E (101 MHz) holds to 183 K, the lowest temperature we could achieve. However, the resonance for ring carbon atoms A and B, arising as a singlet around $\delta = 51$ at room temperature (Figure 3), broadens at lower temperatures and splits into a doublet below 253 K. This fluxionality indicates inequivalence of the ring carbon atoms at lower temperature, and was found with cyclen derivatives with side chains as ligand in octacoordinate complexes (i.e., $[M(dotam)]^{2+}$; dotam = 1,4,7,10-tetrakis(acetamido)-1,4,7,10-cyclododecane; M = Ca^{2+}, Cd^{2+}, Pb^{2+}, Zn^{2+}). These observations are attributed to rapid interconversion of the helical arrangement of the side chains in a square-antiprismatic complex as shown in Scheme 1.[9,12] The rate of interconversion and the Gibbs energy of activation for this process at the coalescence temperature (270 K) were estimated to be 240 s^{-1} and $\Delta G^{\ddagger} = 53.5$ kJ mol^{-1}, respectively.

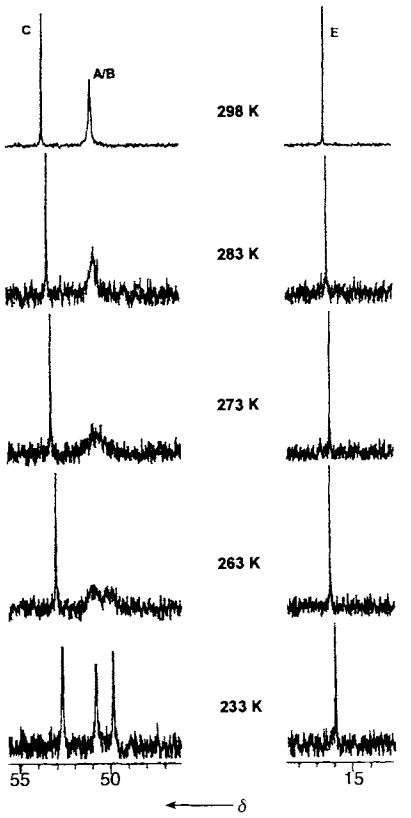

Figure 3. Sections of ^1H-decoupled ^{13}C NMR spectra (101 MHz) of 4×10^{-2} M [Ag(dotete)]PF_6 in acetone at different temperatures. See the formula drawing of **1** and Scheme 1 for assignment of the signals.

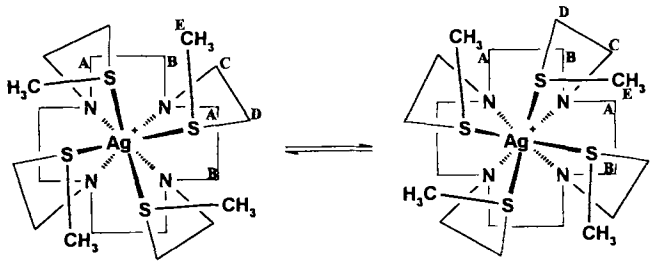

Scheme 1. Helicity reversal of the side chains in [Ag(dotete)]$^+$ leading to equivalence of the ring carbon atoms A and B on the NMR time scale.

Our results obtained with dotete serve as a useful guide for the design of bifunctional ligands by functionalizing the carbon backbone of the macrocycle along the lines already published.[4a,b,5a] It appears that, despite the high degree of preorganization of dotete, the soft Ag^+ ion prefers the tertiary amine donors over the soft S-donor atoms. Nevertheless, our data indicate that all four S-donor atoms contribute to the highest stability found for a silver(I) complex in solution. Finally, we achieved very high discrimination between silver(I) and lead(II), with the former being favored by more than a factor of $10^{10.8}$; this is the highest value reported.[13]

Experimental Section

1: The reaction of cyclen (1.00 g, 5.8 mmol) with 2-chloroethyl methyl sulfide (2.95 mL, 29.0 mmol, 5 equiv) in CH_3CN and excess K_2CO_3 at 40 °C for 24 h affords dotete (1.72 g, 72% yield). FAB-MS: $m/z = 469.0$ $[M+H]^+$; ^1H NMR (400 MHz, CD_3OD, 25 °C): $\delta = 2.12$ (s, 12H), 2.54–2.71 (m, 32H); $^{13}C\{^1H\}$ NMR (101 MHz, CD_3OD, 25 °C): $\delta = 15.80$, 32.48, 53.07, 56.47. Hdotete$^+BF_4^-$ was obtained by adding HBF_4 in Et_2O to dotete in $CHCl_3$. After 4 h at room temperature the mass was triturated, filtrated, and dried for 24 h under high vacuum; yield 94%. Elemental analysis calcd for $C_{20}H_{46}S_4F_8N_4B_2$: C 36.98, H 7.14, F 23.41, N 8.63, B 3.33; found: C 36.28, H 7.00, F 23.77, N 8.51, B 3.32. The PF_6 salt prooved to be more suitable for crystallization.

2: The dotete (149.2 mg, 0.318 mmol) was dissolved in CH_2Cl_2 (4 mL), and a solution of $AgNO_3$ (54 mg, 0.318 mmol) in CH_3CN (4 mL) added. The colorless mixture was stirred for 30 min at room temperature to afford a clear solution of the Ag^+ complex. Removal of the solvent under vacuum and redissolution of the residue in CH_3OH followed by the addition of NH_4PF_6 (51.8 mg, 0.317 mmol) produced colorless crystals of **2**; yield 54.2 mg (23.6%). EI-MS: $m/z = 575.3/577.3$ $[^{107,109}Ag(dotete)]^+$; ^1H NMR (400 MHz, CD_3OD, 25 °C): $\delta = 2.21$ (d, 12H), 2.48–2.85 (br m, 32H); $^{13}C\{^1H\}$ NMR (101 MHz, CD_3OD, 25 °C): $\delta = 15.80$, 32.48, 53.07, 56.47; elemental analysis calcd for $C_{20}H_{44}AgS_4PF_6N_4$: C 34.17, H 6.44, Ag 14.50, N 7.66, found: C 33.29, H 6.15, Ag 14.95, N 7.76.

pH and argentometric titration: Due to the low solubility of dotete in water at pH > 10, the titration was performed in 50% aqueous methanol ($I = 0.1$ (KNO_3), 2.1×10^{-3} M dotete, 2.05×10^{-3} M Ag^+, 0.5 M $(CH_3)_4NOH$). An automatic titration system consisting of a Metrohm-654 potentiometer and a Metrohm-665 dosimat with a pH electrode (Metrohm 6.0726.100; saturated KCl solution as the inner electrolyte, and 0.1 M KNO_3 in 50% aqueous methanol as the outer electrolyte) was used. Data was acquired with a 386 computer using TITFIT software [14]. The concentration of free Ag^+ ions was determined using a silver electrode with a Ag/AgCl reference electrode (Metrohm 6.0133.100) calibrated against six solutions of known Ag^+ concentrations (10^{-3}–10^{-6} M).

[15] Crystal structure analyses. a) General: All measurements were made on a Nicolet P3 diffractometer with graphite-monochromated $Mo_{K\alpha}$ radiation. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100510. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code + (1223) 336-033; e-mail: deposit@chemcrys.cam.ac.uk). b) Hdotete$^+PF_6^-$: $C_{20}H_{45}F_6N_4PS_4$, monoclinic $P2_1/n$, $a = 14.487(3)$, $b = 14.225(3)$, $c = 14.848(3)$ Å, $\beta = 95.81(3)°$, $V = 3044.2(11)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.339$ g cm^{-3}, $T = 293$ K. The structure was solved using direct methods, expanded by fourier techniques, and refined against F^2 by full-matrix least-squares methods using the Shelx 93 crystallographic software package [16]. Anisotropic temperature factors were refined with restraints because of the weak data. Of 2390 reflections collected (maximum $2\Theta = 35°$), 1886 were unique. The final residuals for 317 parameters and 93 restraints refined against 1457 unique data with $I > 2\sigma(I)$ were $R = 0.117$ and $R_w = 0.249$. c) **2**: $C_{40}H_{88}Ag_2N_8S_8P_2F_{12}$, monoclinic, $P2_1/a$, $a = 14.330(4)$, $b = 25.350(5)$, $c = 17.932(3)$ Å, $\beta = 107.66(3)°$, $V = 6207.1(24)$ Å^3, $Z = 8$, $\rho_{calcd} = 1.539$ g cm^{-3}, $T = 293$ K. The structure was solved using Patterson methods, expanded by fourier techniques, and refined against F^2 by full-matrix least-squares methods using the Shelx 93 crystallographic software package [16]. There are two molecular units in the asymmetric unit. The disordered side chain of one molecule was refined isotropically in two conformations. No hydrogen atoms were included for atoms involved in the disorder. All other atoms were refined anisotropically, and hydrogen atoms were included and refined using a riding model. Of 11351 reflections collected (maximum $2\Theta = 50°$), 10876 were unique. The final residuals for 649 parameters and 4 restraints refined against 7701 unique data with $I > 2\sigma(I)$ were $R = 0.0558$ and $R_w = 0.1467$.

A New Technique for Assembling Thin, Defined Multilayers**

André Laschewsky,* Bernd Mayer, Erik Wischerhoff, Xavier Arys, Alain Jonas, Martti Kauranen, and André Persoons

Three principal techniques are used presently to prepare ultrathin multilayer films by self-organization: the Langmuir–Blodgett technique,[1] chemical self-assembly with stepwise activation of the surface,[1,2] and alternating physisorption of oppositely charged polyelectrolytes.[3] All these techniques have their advantages and disadvantages.[4] Recently, we presented a new multilayer technique combining features of the "classical" methods, which has the potential to profit from their strong points and to avoid some of their drawbacks. The method is physisorption of a reactive polyion by electrostatic interactions (alike physisorption of oppositely charged polyelectrolytes), followed by chemical activation (alike chemical self-assembly) with a reagent of low molar mass in order to reverse the charge at the surface (*Co*atings by *M*ultiple *P*olyelectrolyte *A*dsorption/*S*urface Activation, CoMPAS, Figure 1).[5] The use of a polymeric adsorbate distinguishes CoMPAS from the related techniques of step-

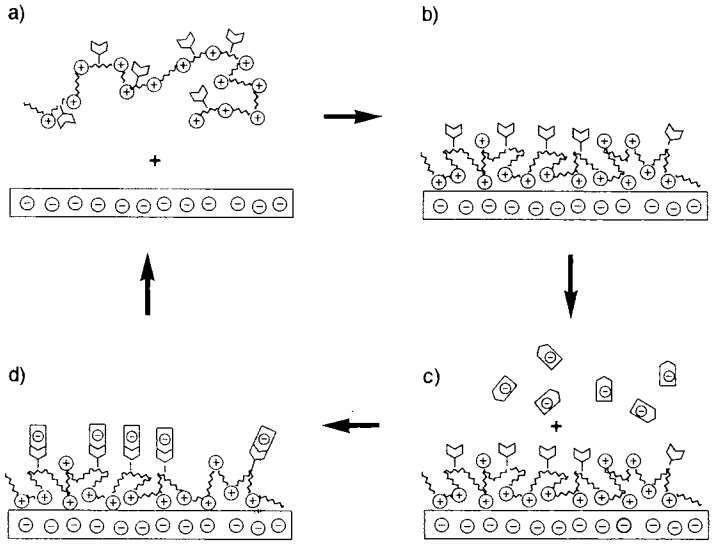

Figure 1. Schematic representation of the CoMPAS technique. a) Physisorption: A support having a negatively charged surface is dipped into a solution of a polycation containing reactive groups. b) Adsorption of the polycation; reactive groups are presented at the surface. c) Activation: The assembly is dipped into a solution of a negatively charged reagent. d) After the interfacial reaction the negative surface charge is restored, and the sample is ready for the next cycle.

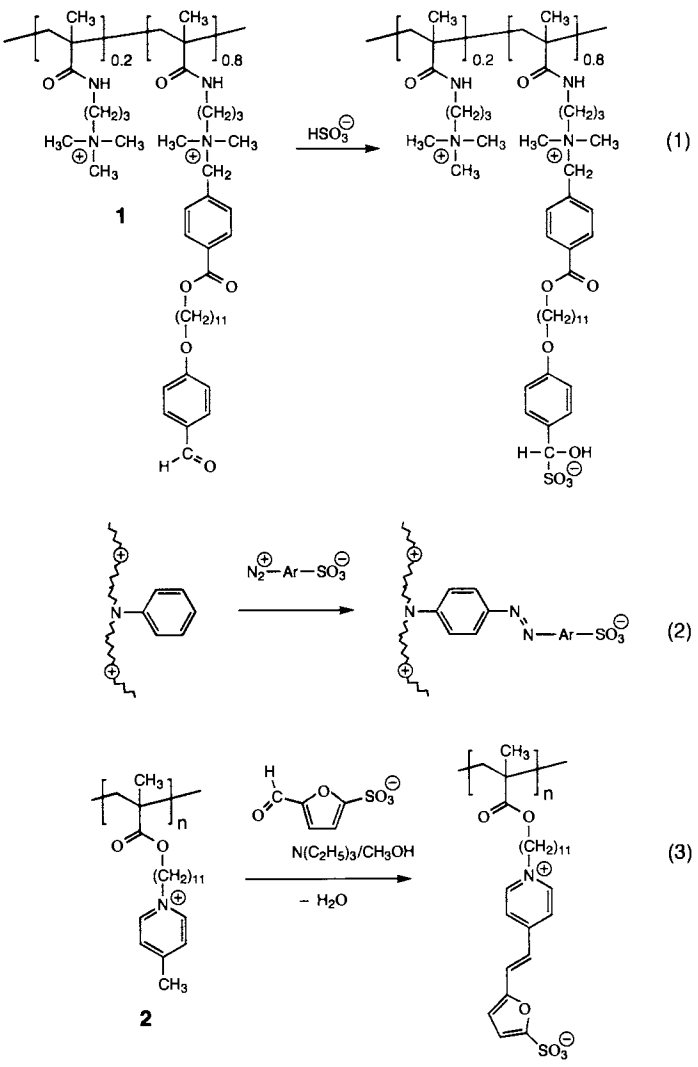


wise chemisorption/activation by H. Katz et al.[6] or chemisorption/polymerization by T. Marks et al.[7] The polymeric character of the adsorbate makes the method less prone to defect propagation in higher layers. Furthermore, CoMPAS requires only a minimum of equipment and is rather fast (< 1 h per layer).

The reactive polymers have to be designed properly for CoMPAS: besides the essential ionic fragments and polar reactive groups, spacer groups separating the two seem to be necessary.[8] Presumably, the spacers enable the reactive groups to accumulate at the film surface, as required for obtaining charge reversal at the surface.

A variety of reactive polyions and complementary reagents of low molar mass proved to be useful for CoMPAS. Under standard conditions[3,5] polycations bearing aldehyde groups can be activated by the bisulfite anion at ambient temperature in water [Eq. (1)].[9] Under similarly mild conditions, polycations with aniline residues can be activated by coupling with diazonium salts bearing negative charges [Eq. (2)].[9] However, the good stability and adhesion of the multilayers due to the electrostatic interactions also allow for activation under harsher conditions: Polymers with γ-picolinium residues (e. g. **2**) can be condensed with a negatively charged aldehyde by heating at reflux in methanol [Eq. (3)].[10]

The success of the activation step is evidenced by characteristic fragments of the coupling products seen in secondary ion mass spectrometry,[5] as well as by UV/Vis spectroscopy. The systems were chosen such that the activation step induces a change in the electronic spectra of the films. Therefore, the chemical reaction and the layer-by-layer growth are easily monitored (see Figure 2). As condensation of picolinium salts with aldehydes and azo coupling lead to strong chromophores, the evolution of color during the reaction allows verification of the macroscopic homogeneity of the assemblies, which often is a crucial point in the analysis of thin films. In fact, the multilayers obtained are homogeneous to the naked eye and the optical microscope.

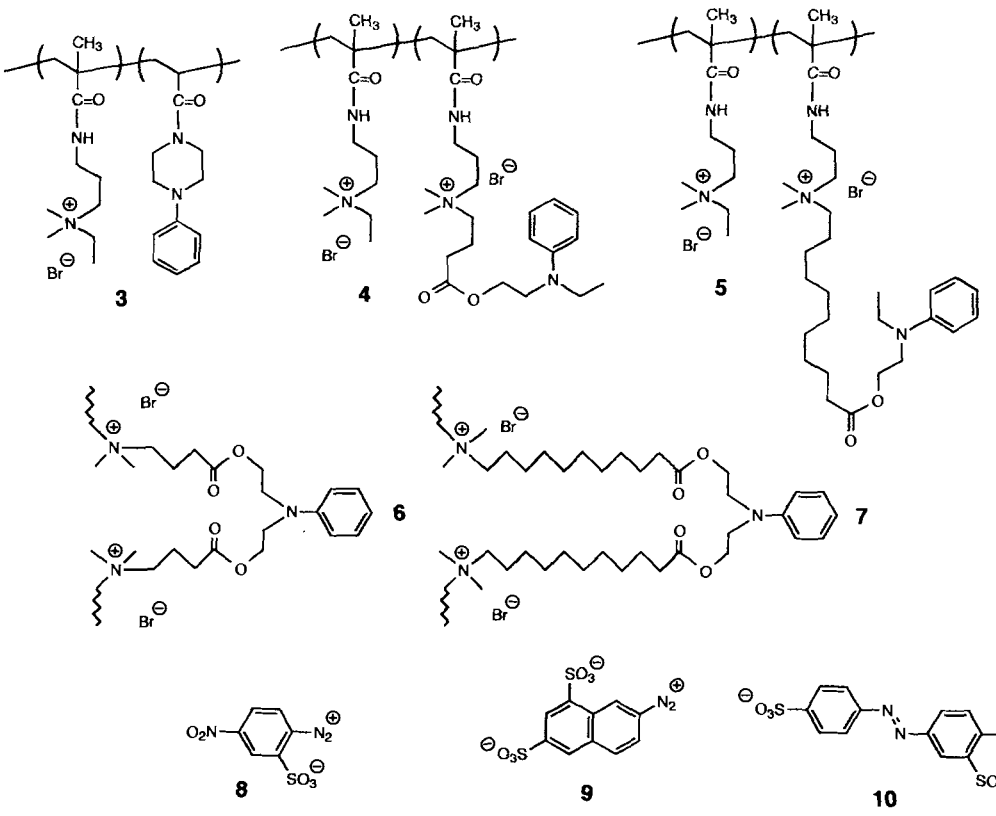
Whereas the success of CoMPAS depended sensitively on the detailed systems for reactive polycations bearing aldehyde or picolinium moieties, generally good results were obtained so far with polycations bearing aniline residues activated by azo coupling. The aniline residue can be located in the side chains (**3**–**5**) as well as in the main chain (**6**, **7**) with different contents of hydrophobic groups. Also, a variety of diazonium salts could be used for the activation step, including bulky **9** and **10**.

UV/Vis spectroscopic studies on multilayer films are exemplified for polycation **2**, which is activated by 5-formyl-2-furanesulfonic acid [Eq. (3)], and for assemblies of polycations **4** or **6**, which are activated by the diazonium salt **8**. The plots of absorbance versus the number of deposition cycles are linear, pointing to a regular and reproducible assembly process (Figure 2).

However, several analytical techniques must be employed to judge unambiguosly the quality of the films. Though UV/Vis spectroscopy indicates a regular increase in deposited material with every cycle in assemblies of polymers **4** and **6** activated with **8**, X-ray reflectivity reveals that the average thickness of the assembly made up of **4** is as low as 0.6 nm. Furthermore, the roughness of the film increases with ongoing growth, suggesting incoherent layers. In contrast, rather smooth films with an average thickness of 1.32 nm per layer are obtained with polycation **6** (Figure 3).

The success of the CoMPAS technique implies a basic noncentrosymmetric film structure. Therefore, this process

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2789 $ 17.50+.50/0



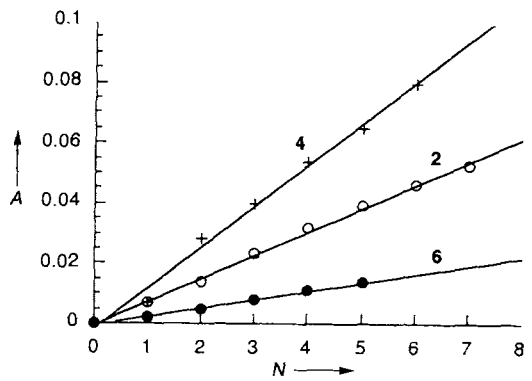


Figure 2. Plot of absorbance A versus the number of deposition cycles N for polymer **2** activated with 5-formyl-2-furansulfonic acid ($\lambda_{max} = 385$ nm) and for polymers **4** ($\lambda_{max} = 498$ nm) and **6** ($\lambda_{max} = 450$ nm) activated with diazonium salt **8**. The lines give the best linear fits.

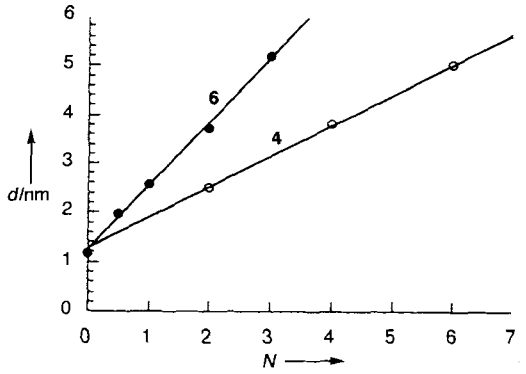

Figure 3. Dependence of thickness d, as determined by X-ray reflectivity, on the number of deposition cycles N for assemblies made from polycations **4** and **6** activated with diazonium salt **8**. The offset at zero is due to a primary layer pair of poly(ethyleneimine)/poly(vinylsulfate). The lines give the best fits to the data.

may allow the preparation of functional noncentrosymmetric films, which is notoriously difficult to achieve. A noncentrosymmetric orientation of the chromophores formed in the deposition process—alike the forced noncentrosymmetric orientation of chromophores in self-assembled multilayers[6,7]—is not compulsory, but should be possible. As activation of the aniline-bearing polycations and the polymeric picolinium salts yields chromophores with strong nonlinear optical properties, these assemblies were analyzed by second harmonic generation (SHG) experiments.

For coatings made up of the picolinium salt **2** activated with 5-formyl-2-furansulfonic acid, no second-harmonic signal could be detected. Possibly, the elevated temperatures of the activation reaction lead to a randomization of the orientations of the chromophores. In contrast, multilayer assemblies of polycations **4** and **7** activated with **8** showed significant SHG activity. It is important to notice that the SHG intensity of the signal increases with the number of layers (Figure 4); this demonstrates a noncentrosymmetric orientation of the chromophores not only in the first, but also in the subsequent layers. Nevertheless, the increase in intensity is not quadratic, as is expected for assemblies with the same orientation for each layer. Therefore, the degree of orientation must be lower for higher layers, but the noncentrosymmetric character still persists.

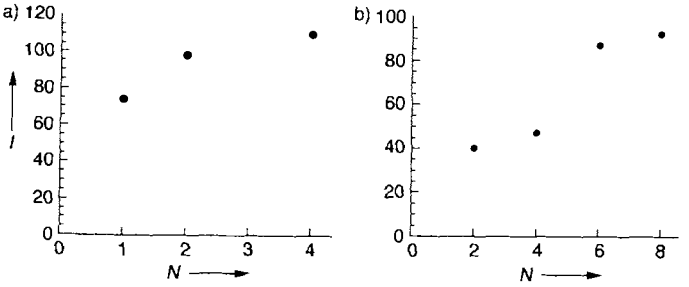

Figure 4. Second-harmonic intensity I (arbitrary units) in dependence of the number of deposition cycles N for polycations a) **4** and b) **7** activated with diazonium salt **8**.

The methodologies to fabricate thin, defined multilayers are enriched by the new CoMPAS technique. A particularly interesting feature is the possible access to noncentrosymmetric films. Still, the problem of reproducible orientation of the chromophores with ongoing film growth needs to be addressed in the future.

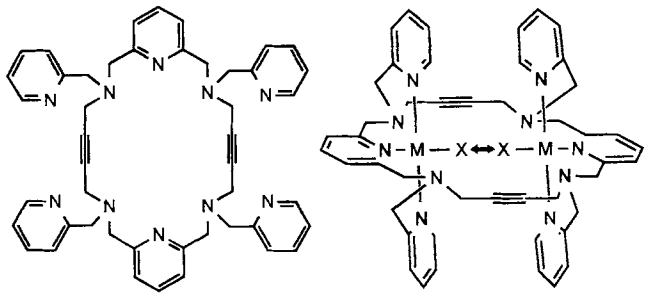
Interchangeable Coordination Geometries: pH-Controlled Change of Trigonal-Prismatic to Octahedral Metal Coordination in a Dinuclear Cobalt(II) Complex**

Carsten Wendelstorf and Roland Krämer*

The coordination geometry of metal complexes has substantial influence on their physical and chemical properties. There is considerable interest both in a detailed understanding of the factors that determine the coordination geometry and in the control of complex structure by ligand design.[1] Transition metal ions with coordination number (CN) 6 are octahedrally coordinated in most cases. A trigonal-prismatic arrangement of donor atoms is less common. Intramolecular repulsion of donor atoms and ligand field stabilization are two important parameters which energetically favor an octahedral geometry.[2]

Although trigonal-prismatic structures are considered as intermediates of intramolecular rearrangement processes of octahedral complexes, it is usually not possible to isolate the two geometrical isomers ("allogons").[3] To our knowledge, switching the octahedral to the trigonal-prismatic structure of a metal complex in a controlled and reversible fashion has never been reported. We have now observed this feature for the first time on a macrocyclic dicobalt(II) complex, $[(\mathbf{L})Co_2]^{4+}$.

The novel decaaza macrocycle **L** was prepared by N-alkylation of a previously described hexaaza macrocycle[4] with 2-(chloromethyl)pyridine. Ligands that are structurally related to the pentadentate 2,6-bis(*N*-picolylaminomethyl)-pyridine subunit of **L** form octahedral transition metal complexes with coordination of, for example, a solvent molecule at the sixth coordination site.[5] In $[(\mathbf{L})Co_2(X)_2]^{n+}$ such a behavior would result in substantial steric repulsion of solvent ligands X according to molecular models.



In the dicopper(II) complex of a related, bis(tetradentate) ligand such steric stress generates vacant coordination sites at the metal centers.[6] $[(\mathbf{L})Co_2(X)_2]^{n+}$ obviously finds another way out with retention of CN 6: the metal ions switch to trigonal-prismatic coordination! Usually cobalt(II) adopts the latter geometry only with rigid chelate ligands in which the donor atoms are more or less preorientated in a trigonal-prismatic fashion.[7] Figure 1 shows the crystal structure[8] of the purple complex $[(\mathbf{L})Co_2(CH_3CN)_2](ClO_4)_4$ (**1**), which was prepared by reaction of **L** with two equivalents of $Co(ClO_4)_2 \cdot 6H_2O$ in acetonitrile. The complex cation is located on a

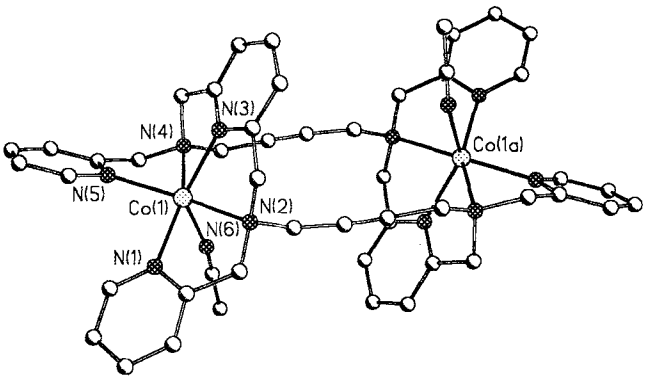


Figure 1. Structure of the $[(\mathbf{L})Co_2(CH_3CN)_2]^{4+}$ ion of **1**. Hydrogen atoms not shown. Selected distances [Å] and angles [°]:Co(1)–N(1) 2.184(5), Co(1)–N(2) 2.312(4), Co(1)–N(3) 2.082(5), Co(1)–N(4) 2.417(5), Co(1)–N(5) 2.138(4), Co(1)–N(6) 2.096(6), Co···Co 7.78; N(6)-Co(1)-N(1) 84.0(2), N(6)-Co(1)-N(2) 91.1(2), N(2)-Co(1)-N(1) 74.6(2), N(5)-Co(1)-N(3) 103.1(2), N(5)-Co(1)-N(4) 72.2(2), N(4)-Co(1)-N(3) 103.1(2), N(6)-Co(1)-N(4) 80.0(2), N(3)-Co(1)-N(2) 74.8(2), N(5)-Co(1)-N(1) 90.4(2), N(6)-Co(1)-N(5) 111.0(2), N(4)-Co(1)-N(2) 130.5(1), N(3)-Co(1)-N(1) 136.7(2).

crystallographic center of symmetry. The Co^{II} ion displays near trigonal-prismatic coordination. The triangles N(1)-N(2)-N(6) and N(3)-N(4)-N(5) (see Figure 3) are twisted along the axis defined by the triangle centers by an average angle of $\theta = 12°$ (perfect trigonal prism 0°; perfect octahedron = trigonal antiprism 60°). It is evident from Figure 1 that the trigonal prismatic coordination avoids any steric repulsion of acetonitrile ligands.

The color of an aqueous solution of $[(\mathbf{L})Co_2](NO_3)_4$, prepared in situ from **L** and $Co(NO_3)_2 \cdot 6H_2O$, immediately turns from purple to yellow-green on addition of one equivalent of NaOH. The reaction product was isolated by addition of $NaClO_4$. From acetonitrile/diethyl ether yellow-green single crystals of $[(\mathbf{L})Co_2(\mu\text{-}OH)](ClO_4)_3$ (**2**) were grown.[8] Both cobalt(II) ions display a distorted octahedral

geometry. They are cristallographically nonequivalent, but bonding parameters within the coordination polyhedron are similar (Figure 2). Both in **2** and in **1** the Co–N distances are

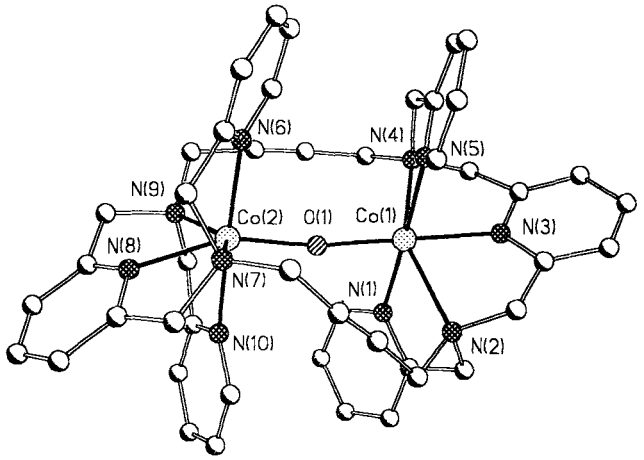

Figure 2. Structure of the $[(\mathbf{L})Co_2(\mu\text{-}OH)]^{3+}$ cation of **2**. Hydrogen atoms not shown. Selected distances [Å] and angles [°]: Co(1)–O(1) 1.951(2), Co(1)–N(1) 2.210(2), Co(1)–N(2) 2.335(2), Co(1)–N(3) 2.090(2), Co(1)–N(4) 2.276(2), Co(1)–N(5) 2.183(2), Co(2)–O(1) 1.975(2), Co(2)–N(6) 2.169(2), Co(2)–N(7) 2.322(2), Co(2)–N(8) 2.103(2), Co(2)–N(9) 2.257(2), Co(2)–N(10) 2.304(2), Co···Co 3.91; Co(2)-O(1)-Co(1) 170.7(2), O(1)-Co(1)-N(3) 168.6(1), N(5)-Co(1)-N(1) 177.46(9), N(4)-Co(1)-N(2) 148.26(8), O(1)-Co(2)-N(8) 157.9(1), N(10)-Co(2)-N(6) 175.6(1), N(9)-Co(2)-N(7) 147.15(8).

consistent with high-spin electron configuration, which is expected for Co^{II} complexes with CN 6.[9] Incorporation of a bridging hydroxide ligand enables the metals in **2** to switch to octahedral geometry. The hydroxo bridge is almost linear (Co-O-Co-angle of 170.8°). The average twist angles θ of the triangles N(1)-N(2)-O(1) and N(3)-N(4)-N(5) at Co(1) and of triangles N(6)-N(7)-O(1) and N(8)-N(9)-N(10) at Co(2), respectively, are 42° and 38° (Figure 2). Thus, cobalt coordination is not perfectly octahedral, but distorted towards a trigonal-prismatic geometry—as it is often observed for transition metal ions of CN 6. The change from the trigonal prism in **1** to the octahedron in **2** is not a simple twist of the triangles represented in Figure 3. Additionally, the configuration of one of the chiral nitrogen atoms is inverted. Consequently, the picolyl substituents of the mononuclear subunit are *trans*-oriented relative to the macrocyclic framework in **2** but *cis*-oriented in **1**.

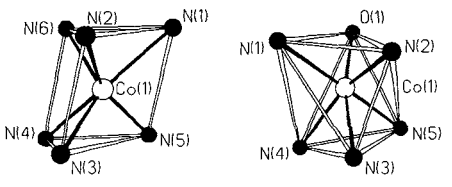

Figure 3. Cobalt(II) coordination polyhedra in **1** and **2**.

In solution the interconversion of the trigonal-prismatic and the octahedral complex was followed by spectrophotometric titration. An aqueous solution of $[(\mathbf{L})Co_2](NO_3)_4$ is acidic (pH 4.0), purple in color, and displays an optical band at $\lambda_{max} = 530$ nm, $\varepsilon = 39\,M^{-1}cm^{-1}$. A solution of a crystalline sample of **1** in acetonitrile has a comparable spectrum ($\lambda_{max} = 530$ nm, $\varepsilon = 59\,M^{-1}cm^{-1}$). It is obvious that $[(\mathbf{L})Co_2]$ is trigonal-prismatically coordinated in aqueous solution, with a H_2O molecule in the sixth site of each metal. On titration with NaOH the color of the solution turns yellow-green (Figure 4). After addition of 1.0 equivalent of NaOH (pH 6.5)

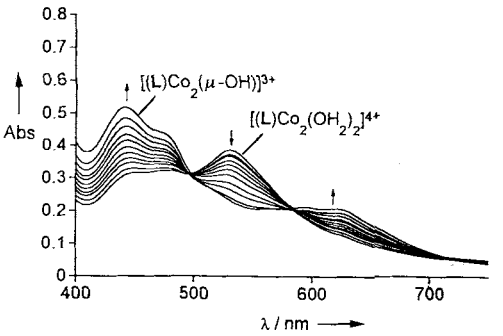

Figure 4. Spectrophotometric titration of $[(\mathbf{L})Co_2(OH_2)_2](NO_3)_4$ (10 mM in H_2O), prepared in situ from **L** and $2\,Co(NO_3)_2 \cdot 6H_2O$, with NaOH (0–1 equiv). Spectra correspond to NaOH addition in steps of 0.1 equiv.

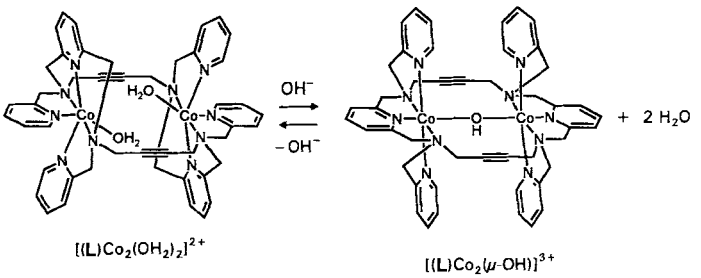
the optical spectrum ($\lambda_{max} = 441$ nm, $\varepsilon = 60\,M^{-1}cm^{-1}$; $\lambda(sh) = 475$ nm; $\lambda_{max} = 595$ and 623 nm, $\varepsilon = 21$ and $22\,M^{-1}cm^{-1}$) corresponds to the spectrum of a solution of crystalline **2** in acetonitrile ($\lambda_{max} = 443$ nm, $\varepsilon = 57\,M^{-1}cm^{-1}$; $\lambda(sh) = 475$ nm; $\lambda_{max} = 597$ and 625 nm, $\varepsilon = 24$ and $24\,M^{-1}cm^{-1}$). Isosbestic points at 500 nm and 585 nm indicate smooth conversion of $[(\mathbf{L})Co_2(OH_2)_2]^{4+}$ into $[(\mathbf{L})Co_2(\mu\text{-}OH)]^{3+}$. Addition of one equivalent of HNO_3 to $[(\mathbf{L})Co_2(\mu\text{-}OH)]^{3+}$ regenerates the spectrum of $[(\mathbf{L})Co_2(OH_2)_2]^{4+}$, and titration with NaOH is reproducible. By addition of 0.5 equivalents of NaOH to $[(\mathbf{L})Co_2(OH_2)_2]^{4+}$ a 1:1 mixture of aqua and hydroxo complex is obtained at pH 4.5. This allows a rough estimate of the hydroxide binding constant of $[(\mathbf{L})Co_2]^{4+}$, which is rather large relative to that of other macrocyclic dicobalt(II) complexes.[10]



It is evident from the spectrophotometric titrations that a simple variation of pH effects reversible switching from trigonal-prismatic to octahedral state of the metal ions in $[(\mathbf{L})Co_2]^{4+}$. $[(\mathbf{L})Co_2(OH_2)_2]^{4+}$ and $[(\mathbf{L})Co_2(\mu\text{-}OH)]^{3+}$ are not isomeric, but the donor environments of the metal ions differ only marginally ($-OH_2$ ligand is replaced by "OHM ligand").

The observations described above are not specific for cobalt(II). Preliminary studies indicate that switching the coordination geometries of the Mn^{II}, Ni^{II}, and Zn^{II} complexes of **L** is possible in a similar fashion.

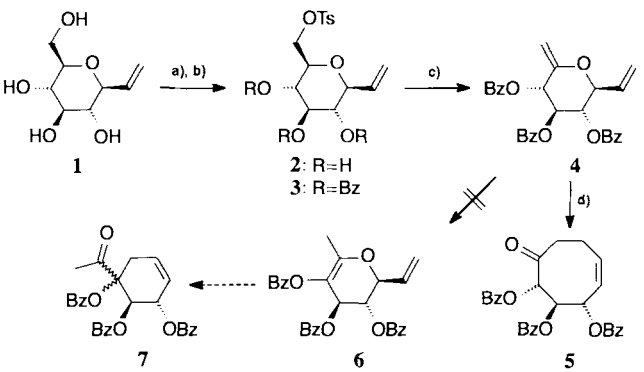
From D-Glucose to a New Chiral Cyclooctenone**

Barbara Werschkun and Joachim Thiem*

Eight-membered carbocycles have increasingly attracted the interest of natural product chemists in recent years. The discovery of a growing number of naturally occurring compounds with eight-membered rings as a structural feature especially among the diterpenes, of which particularly the highly functionalized taxane derivatives show exceptional biological activity, has led to a significant increase in synthetic efforts in this area. The formation of eight-membered rings is a special problem in organic chemistry: owing to the unfavorable energetic relations that are caused by Pitzer strain and transannular interactions, the usual ring-closing methods can often only be applied with low product yields, if at all.[1] Thus alternative synthetic routes such as fragmentations or ring enlargements are of great importance. An elegant variation of the latter reaction is the Claisen rearrangement of 2-methylene-6-vinyl-tetrahydropyrans to cyclooctenone derivatives used by Paquette et al. in the synthesis of several natural products.[2,3]

The tetrahydropyran structure of the starting material and the complex oxygen-rich chiral eight-membered rings that are difficult to obtain by other methods, which were expected as products of the rearrangement, made it seem reasonable to apply the reaction to carbohydrates. The Claisen rearrangement has been used in carbohydrate chemistry as an efficient C–C coupling method for a long time, but its application was restricted to the introduction of alkyl branches and the synthesis of C glycosides.[4] A skeletal rearrangement with loss of the sugar structure was hitherto unknown as was the synthesis of 5,6-unsaturated *C*-vinylglycosides such as **4**, which we have achieved by a simple sequence of well-known reactions (Scheme 1).



Scheme 1. Synthesis and rearrangement of **4**. a) TsCl, pyridine, 62%; b) BzCl, pyridine, 89%; c) DMSO, 80 °C, 1. NaI, Bu_4NI, 2. 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), 52%; d) xylene, reflux, 60%.

The β-*C*-vinylglycoside **1** is available as a pure anomer from the Grignard reaction of acetobromoglucose with vinylmagnesium bromide in approximately 30% yield.[5] The selective reaction of the primary hydroxy group with tosyl chloride (TsCl) to give **2**, and the subsequent perbenzoylation with benzoyl chloride (BzCl) to afford the protected tosylate **3** are standard methods. In a one-pot reaction introduced by Sato et al.,[6] the sulfonate moiety is first replaced by an iodine substituent, followed by base-catalyzed elimination of hydrogen iodide, during which the exocyclic double bond is formed. The allyl enol ether **4**, which is obtained in 50% yield, is stable enough to be purified on silica gel and kept for several weeks at -18 °C.

Simple heating of a solution of **4** in boiling xylene leads to the carbocycle **5** in 60% yield after 12 h, as the expected product of the sigmatropic rearrangement. In spite of the well-known tendency of 2-methylene-substituted tetrahydropyrans to isomerize under conversion of the exo- into an endocyclic double bond,[7] neither the derivative **6** nor its hypothetical reaction product **7** was found. It has to be emphasized that due to the β configuration of the C-glycosidic vinyl group a

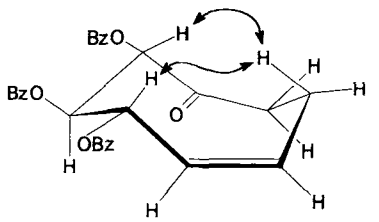
sigmatropic rearrangement can only occur out of the $^1C_4$ conformation of the carbohydrate ring, and that this is the first example of a Claisen rearrangement of such a configured compound. The boat–chair conformation of **5** shown in Figure 1 can be deduced from the ^3J couplings in the ^{1}H NMR



5

Figure 1. Boat–chair conformation of **5** deduced from NMR data. The arrows reproduce the observed NO effects.

spectrum and is supported by the transannular NOEs observed in the two-dimensional experiment. The very sharp signals point to the fact that the flexibility is strongly reduced by the three sp^2 carbon centers, which for less substituted systems has already led to remarkable stereoselectivity in follow-up reactions.[8]

This fact together with the three defined chiral centers from the original carbohydrate framework and the high density of oxygen-containing substituents, which can be readily modified synthetically, make compounds like **5** attractive as useful synthetic building blocks, particularly since they are now available from the simple and common starting material D-glucose in few steps.

Experimental Section

5: A solution of **4** (52 mg, 0.11 mmol) in dry xylene (5 mL) was heated to reflux for 12 h. After evaporation of the solvent the residue was purified by chromatography on silica gel with petroleum ether/ethyl acetate (5/1) as eluent. This afforded **5** (31 mg, 60%) as a colorless syrup. $[\alpha]_{20}^{D} = -49.5$ ($c = 1$, chloroform). ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 2.43-2.50$ (m, H-7eq), 2.60 (ddd, H-8ax, $J = 4.6$, 12.7, 13.2 Hz), 2.85–2.95 (m, H-7ax), 3.13 (ddd, H-8eq, $J = 4.1$, 12.7 Hz), 5.53 (d, H-2, $J = 8.6$ Hz), 5.62 (dd, H-5, $J = 7.1$, 11.2 Hz), 5.71 (dd, H-3, $J = 8.6$, 10.7 Hz), 5.92 (m, H-6), 6.22 (ddd, H-4, $J = 1.5$, 7.1, 10.2 Hz), 7.20–7.47, 7.79–7.85 (2 × m, 9H, 6 H, aryl). ^{13}C NMR (100 MHz, $CDCl_3$): $\delta = 22.01$ (C-7), 42.08 (C-8), 68.91 (C-4), 69.51 (C-3), 76.32 (C-2), 126.88–132.63 (C-5, C-6, aryl-C), 164.45, 164.48, 164.74 (3 × CO_2), 203.78 (C-1).

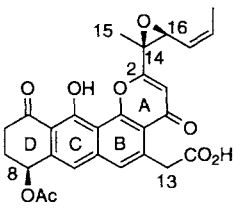
Synthesis of an ABC Ring Analogue of Kapurimycin A_3 as an Effective DNA Alkylating Agent**

Kazuhiko Nakatani,* Akimitsu Okamoto, and Isao Saito*

The antitumor antibiotic kapurimycin A_3 (**1**),[1] whose structure is closely related to that of pluramycins,[2] alkylates DNA by attacking the epoxide subunit on guanine at N7 to form a kapurimycin–DNA adduct.[3] The high efficiency of the selective alkylation of guanine at N7 implies that the epoxide subunit is placed in the major groove of DNA with an appropriate alignment to N7 of guanine through precovalent intercalation of the aromatic moiety, as previously suggested for aflatoxin B_1[4] and altromycin B.[5,6] To identify the factors responsible for such an efficient and selective guanine alkylation and to devise new DNA-alkylating agents possessing an epoxide subunit, we synthesized the truncated kapurimycin analogues **2** and **3** as well as their epoxy alcohol and



kapurimycin A_3 **1**

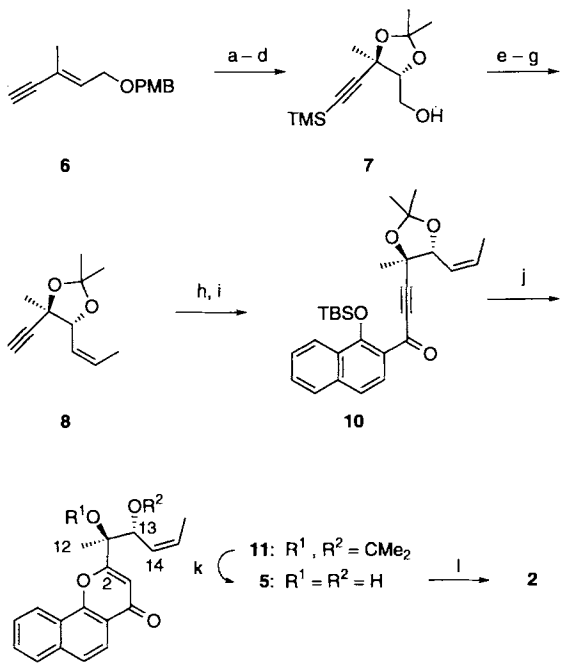
[**] Special thanks are due to Drs. Y. Uosaki, M. Hara, and H. Saito (Kyowa Hakko Kogyo CO., LTD.) for valuable discussions and a generous gift of kapurimycin A_3.

diol derivatives **4** and **5**, respectively, and examined their activity toward DNA alkylation. We report here that the ABC ring analogue **2** of kapurimycin A_3 fulfills a minimal structural requirement for this antibiotic in terms of efficiency and sequence selectivity for guanine alkylation.

The ABC ring analogue **2**, which has the same absolute configuration as **1** (14*S*, 16*S*),[7] was synthesized by a highly convergent route that features coupling of 1-*tert*-butyldimethylsilyloxy-2-naphthoaldehyde (**9**) with the precursor for the chiral side chain **8** followed by efficient pyranone formation (ring A, Scheme 1). Asymmetric dihydroxylation of *p*-methoxybenzyl ether **6**, obtained from a commercially available alcohol with AD-mix-β,[8] produced the corresponding diol, which was converted into alcohol **7**. After recrystallization, **7** had an enantiomeric purity of 93% *ee*, as determined by ^{1}H NMR spectroscopy of the α-methoxy-α-(trifluoromethyl)-phenylacetic acid (MTPA) ester. Oxidation of **7** followed by Wittig olefination with ethylidene triphenylphosphorane provided the alkene (Z:E = 5:1),[9] which was desilylated to **8**. Addition of **9** to lithiated **8** provided the corresponding coupling product, which was subsequently oxidized with manganese dioxide to ketone **10**. Selective formation of the pyranone ring was achieved by treating **10** with KF and [18]crown-6 in anhydrous DMF[10] to give the tricyclic compound **11** in high yield.[11] Hydrolysis of the acetal produced diol **5**, which was further subjected to intramolecular Mitsunobu reaction[12] to furnish the desired (11*S*,13*S*)-**2**.[13] Kapurimycin analogues **3** and **4** were synthesized by similar routes.



Scheme 1. Synthesis of the ABC ring analogue **2**. a) AD-mix-β, 76%; b) $Me_2C(OMe)_2$, 95%; c) lithium 1,1,1,3,3,3-hexamethyldisilazane (LiHMDS), Me_3SiCl, 89%; d) 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ), 99%; e) Dess–Martin oxidation, 94%; f) $Ph_3P{=}CHCH_3$, 78%, Z:E = 5:1; g) NaOMe, 80%; h) LiHMDS, $CeCl_3$, 1-*tert*-butyldimethylsilyloxy-2-naphthoaldehyde (**9**), 47%; i) MnO_2, 76%; j) KF, [18]crown-6, DMF, 80%; k) cat. HCl, AcOH, 98%; l) diethylazodicarboxylate (DEAD), Ph_3P, 76%.

The activity of these kapurimycin analogues with respect to DNA cleavage was examined by a relaxation assay of supercoiled plasmid DNA (Figure 1). Supercoiled plasmid DNA was treated with the kapurimycin analogue (5 h, 37 °C) and then incubated for 24 h at 37 °C to complete heat-induced strand breaks at alkylated guanine residues. A distinct cleavage band was observed when DNA was treated with **2** and further incubated for 24 h at 37 °C (lane 3). Analysis of the nucleosides in calf-thymus DNA treated with **2** followed by enzymatic digestion showed that the content of 2′-deoxyguanosine decreased considerably (28%), while other nucleosides remained unchanged. These results strongly suggest that the ABC ring analogue **2** induced DNA cleavage by selective modification of the guanine base.

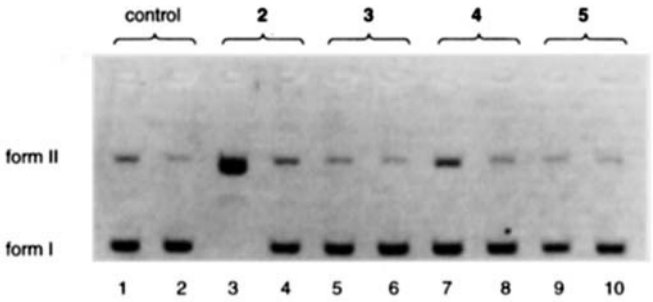


Figure 1. Cleavage of supercoiled circular pBR322 DNA (form I) by kapurimycin analogues **2**–**5** into nicked circular DNA (form II). Supercoiled pBR322 DNA (40 μM) in Tris/HCl buffer (5 mM, pH = 7.6) was incubated in the presence of **2**, **3**, **4**, or **5** (10 μM) for 5 h at 37 °C. Unbound drugs were removed by precipitation with ethanol, and the recovered DNA was dissolved in Tris/HCl buffer (condition A). To complete strand cleavage, the solution of DNA was further incubated for 24 h at 37 °C (condition B). DNA treated under condition A (even-numbered lanes) and condition B (odd-numbered lanes) were analyzed by electrophoresis on 1% agarose gel containing ethidium bromide (0.2 μg mL^{-1}). Lane 1, control for condition B; lane 2: control for condition A; lanes 3 and 4: **2**; lanes 5 and 6: **3**; lanes 7 and 8: **4**; lanes 9 and 10: **5**.

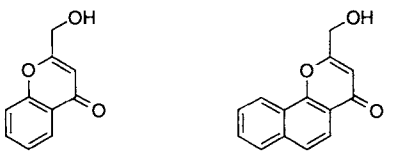
The complete lack of the DNA-cleavage activity of diol **5** (lanes 9 and 10) indicated that the epoxide subunit of **2** would be the site for DNA alkylation.[3b] A weak cleavage band detected for DNA treated with epoxy alcohol **4** (lane 7 in comparison with lane 3) suggested that the alkenyl group directly attached to the epoxide ring remarkably accelerates the rate of nucleophilic ring opening of the epoxide moiety. While the observed rates for hydrolytic cleavage of the epoxide moieties in tris(hydroxymethyl)aminomethane (Tris)/HCl buffer (pH = 7.5) at 37 °C were comparable for **1**, **2**, and **3** (half lives ($t_{1/2}$) of 3.5, 5.6, and 5.9 h, respectively) it was substantially longer for **4** under these conditions ($t_{1/2}$ > 150 h).[15] These observations may explain the extremely low DNA-cleavage activity of **4**. Of special interest is the large difference in activity between **2** and **3** (lanes 3 and 5), which is caused only by the presence or absence of ring C; this suggests stronger intercalation of the ABC rings of **2** into the DNA duplex. This assumption was proved by DNA-unwinding assays[16] with **12** and **13**; both lack an epoxide subunit for DNA alkylation. Figure 2 clearly indicates more enhanced DNA unwinding of supercoiled pBR322 DNA when treated with **13**.



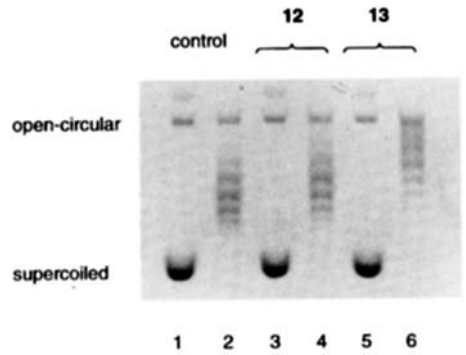


Figure 2. Unwinding of DNA by kapurimycin analogues **12** and **13**. Supercoiled pBR322 DNA (40 μM; lane 1) was first treated with topoisomerase I (topo I; 4 units) for 30 min in a buffer (10 mM Tris/HCl, pH = 7.9, 1 mM ethylenediaminetetraacetic acid (EDTA), 150 mM NaCl, 0.1 mM spermidine, 5% glycerol, 0.1% bovine serum albumin (BSA)), and further incubated for 30 min in the absence (lane 2) and presence of **12** and **13** (100 μM; lanes 4 and 6, respectively). In lanes 3 and 5 the DNA was incubated with **12** and **13**, respectively, in the absence of topo I. The resulting DNA sequences were analyzed by electrophoresis on 1% native agarose gel at 1.3 V cm^{-1} for 15 h. Lane 1: supercoiled DNA; lane 2: DNA treated with topo I; lane 3: **12**; lane 4: **12** plus topo I; lane 5: **13**; lane 6: **13** plus topo I.

DNA cleavage by the ABC ring analogue **2** was compared with that of natural kapurimycin A_3 (**1**) with respect to the efficiency and sequence selectivity for guanine alkylation (Figures 3 and 4). As shown in Figure 3, **1** cleaves DNA even

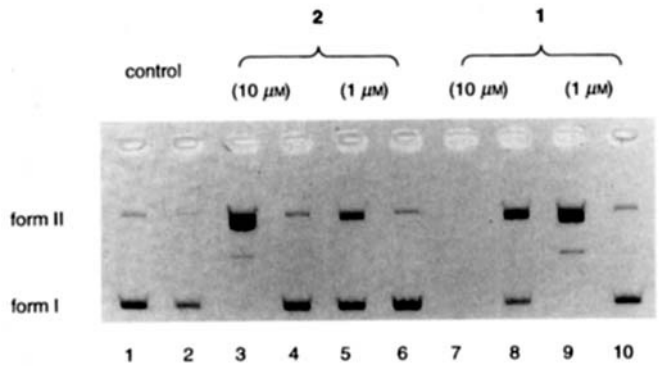

Figure 3. Cleavage of supercoiled circular pBR322 DNA by kapurimycin A_3 (**1**) and the ABC ring analogue **2**. The DNA was treated with the drugs for 5 h at 37 °C (even-numbered lanes) and further incubated for 24 h as described for Figure 1 (odd-numbered lanes). Lanes 1 and 2: controls; lanes 3 and 4: **2** (10 μM); lanes 5 and 6: **2** (1 μM); lanes 7 and 8: **1** (10 μM); lanes 9 and 10, **1** (1 μM). DNA bands in lane 7 disappeared due to the excessive cleavage by **1** under the given conditions.

at a concentration of 1 μM (lane 9), whereas **2** requires 10 μM for comparable cleavage (lanes 3 and 9). In contrast, the sequence selectivity for guanine alkylation observed for **2** shows a strong preference for the guanine group on the 5′-end of the 5′-GPu-3′ sequences, which was very similar to that observed for **1** (Figure 4).[17] These results suggest that despite the lack of ring D and other functional groups, the highly simplified analogue **2** could exhibit a very similar 5′-selectivity for guanine alkylation of duplex DNA.

We thus established a highly stereoselective and convergent synthetic route for a series of truncated analogues of kapurimycin A_3 of defined absolute configurations. We also demonstrated that the simplified analogue **2** with a minimal structure for kapurimycin A_3 can serve as an effective guanine alkylating agent for duplex DNA with a strong preference for 5′-GPu-3′.

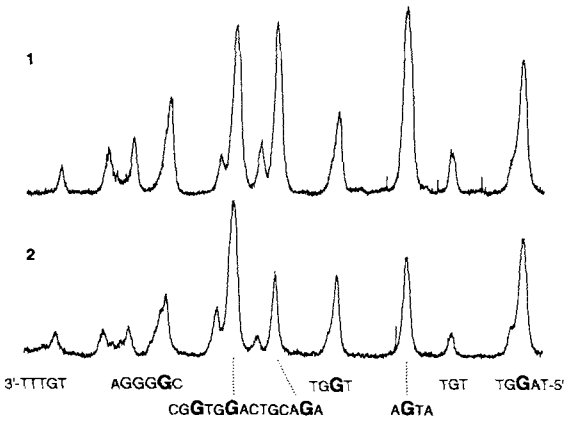

Figure 4. Sequence selectivity for guanine alkylation by natural kapurimycin A_3 (**1**, top) and the ABC ring analogue **2** (bottom). The DNA sequences including strong G-cleavage bands (bold face) are shown.

Experimental Section

Analysis of the nucleosides in calf-thymus DNA: Calf-thymus DNA (200 μM) was treated with **2** (1 mM) in Tris/HCl (pH = 7.5) for 24 h at 37 °C, and the mixture digested with snake-venom phosphodiesterase and alkaline phosphatase. The resulting mixture of nucleosides was analyzed by HPLC (Cosmosil C18-AR column, elution with 2 → 5% acetonitrile in 50 mM ammonium formate (linear gradient) over 30 min).

Rates of hydrolytic cleavage: Solutions of **1**–**4** (each 100 μM) in Tris/HCl buffer (50 mM, pH = 7.5) were incubated at 37 °C. The amounts of unchanged starting materials after a certain time interval were determined by HPLC.

Analysis of the sequence selectivity for guanine alkylation: A ^{32}P-5′-end-labeled DNA fragment (513 bp *Eco*R I-*Rsa* I fragment of pBR322 DNA) was incubated in the presence of **1** (1 μM) and **2** (10 μM) for 24 h at 37 °C in Tris/HCl buffer (pH = 7.6). DNA recovered by precipitation with ethanol was heated (90 °C, 30 min) in the presence of 10% piperidine and analyzed by electrophoresis with 8% polyacrylamide and 7 M urea (1900 v for 1.5 h). The gel was dried and exposed to a X-ray film with an intensifying sheet at −70 °C. The intensity of the cleavage bands was determined by densitometeric analysis. The DNA sequence shown in Figure 4 is as follows: 3′-TTTGT TTATC CCCAA GGCGC GTGTA AAGGG GCTTT TCACG GTGGA CTGCA GATTC TTTGG TAATA ATAGT ACTGT AATTG GTA-5′.

[17] Further evidence for alkylation of guanine by **2** was obtained by sequencing analysis. Thus, smear cleavage bands obtained by heating DNA treated with **2** did not co-migrate with Maxam–Gilbert G bands, whereas the clear G bands in Figure 4 were obtained by heating the same samples with piperidine. The observed band shift is a typical indication for alkylation of guanine at N7.

Synthesis and Crystal Structure of $[Cd_{10}Se_4(SePh)_{12}(PPh_3)_4]$ and $[Cd_{16}(SePh)_{32}(PPh_3)_2]$**

Silke Behrens, Marco Bettenhausen, Andreas Eichhöfer, and Dieter Fenske*

The synthesis of nanoclusters and colloids of II/VI compounds is of interest with regard to their size-dependent optical and electronic properties. If the radius of the particles exceeds the excitonic Bohr radius of the bulk material, a size-quantization effect occurs, and the band gap increases relative to that of the bulk material.[1,2,3] Measurements on cluster molecules of defined size could therefore lead to an exact interpretation of the observed effects. Dance et al. have already prepared a number of cadmium chalcogenide clusters.[4] Recently we synthesized the largest structurally characterized cadmium chalcogenide cluster $[Cd_{32}Se_{14}(SePh)_{36}(PPh_3)_4]$ by reaction of $[CdCl_2(PPh_3)_2]$ with $PhSeSiMe_3$ with elimination of chlorosilane.[5] This compound is isostructural with the sulfur derivatives characterized by Herron and Weller.[6,7] Further application of this synthetic principle led to the synthesis and structural characterization of the clusters **1** and **2** (Figures 1 and 2).[8]

$[Cd_{10}Se_4(SePh)_{12}(PPh_3)_4]$ **1**

$[Cd_{16}(SePh)_{32}(PPh_3)_2]$ **2**

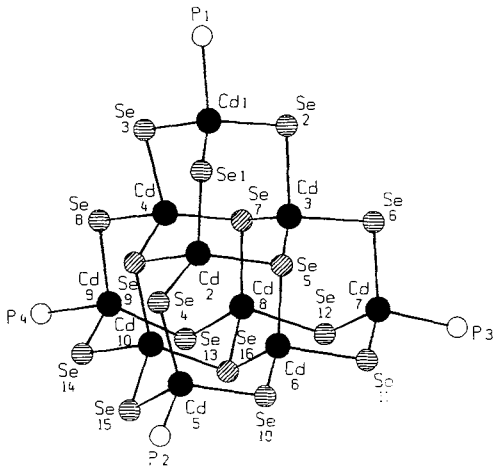

Figure 1. Molecular structure of **1**. The phenyl groups of the $SePh^-$ ligands (Se1–Se4, Se6, Se8, Se10–Se15 (●)) are omitted). Se5, Se7, Se9 and Se16 (◍) are Se^{2-} ligands.

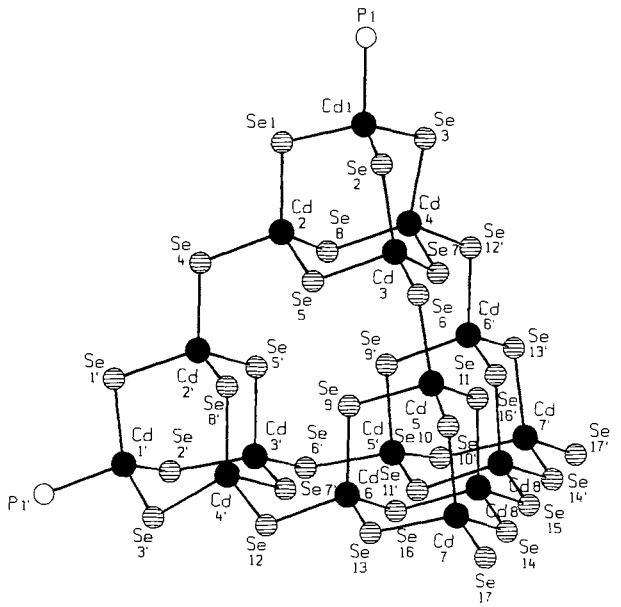

Figure 2. Molecular structure of **2** [12]. The phenyl groups of the $SePh^-$ ligands are omitted for clarity.

The reaction of $[CdCl_2(PPh_3)_2]$ with $PhSeSiMe_3$ in diethyl ether afforded colorless crystals of **1** [Eq. (a)], which crystal-

$$[CdCl_2(PPh_3)_2] \xrightarrow[Et_2O]{PhSeSiMe_3} [Cd_{10}Se_4(SePh)_{12}(PPh_3)_4] \quad \textbf{1} \qquad (a)$$

lizes in the triclinic space group $P\bar{1}$. The cluster core is composed of four fused adamantanoid cages. It is a section of the sphalerite structure, which is also found in CdSe.[9] The $[Cd_{10}Se_{16}P_4]$ cluster core forms a tetrahedron with an average edge length of 1.3 nm. The Cd atoms are coordinated in a distorted tetrahedral fashion by the Se atoms of the μ_2-$SePh^-$ (Se1–Se4, Se6, Se8, Se10–Se15) and μ_3-Se^{2-} ligands (Se5, Se7, Se9, Se16) and by the P atoms of the PPh_3 ligands [Se-Cd-Se 95.56(7)–130.23(7)°, Se-Cd-P 100.88(11)–115.70(12)°].

[**] We thank Dr. A. Deveson for correcting the English of this article. This work was supported by the Deutsche Forschungsgemeinschaft (SFB195) and the Bundesministerium für Bildung, Wissenschaft, Forschung und Technologie.

The Cd–Se bond lengths vary between 256.9(2) and 275.0(2) pm. In CdSe (zinc blende structure) the bond length is 262 pm.[7] Shorter distances [256.9(2)–261.3(2) pm] correspond to the bonds between the μ_3-Se^{2-} ligands and the Cd atoms. The four outer Cd atoms (Cd1, Cd5, Cd7, Cd9) are coordinated by the PPh_3 ligands. The structure is thus analogous to that of $[Cd_{10}Se_4(SePh)_{16}]^{4-}$, characterized by Dance et al.,[4] which contains terminal $SePh^-$ ligands in place of the PPh_3 ligands. Whereas this compound is a cluster anion, **1** is a neutral compound.

In diglyme $[CdCl_2(PPh_3)_2]$ reacts with $PhSeSiMe_3$ to give a colorless solution, from which colorless crystals of **2** are formed [Eq. (b)]. In contrast to **1**, the four adamantanoid

$$[CdCl_2(PPh_3)_2] \xrightarrow[\text{Diglyme}]{PhSeSiMe_3} \underset{\mathbf{2}}{[Cd_{16}(SePh)_{32}(PPh_3)_2]} \qquad \text{(b)}$$

$[Cd_4Se_6]$ cages of **2** are not directly fused together, but are linked by $SePh^-$ ligands to form a $[Cd_{16}Se_{30}]$ skeleton. The two phosphorus ligands (P1, P1′) are bound to Cd1 and Cd1′. In addition Cd7 and Cd7′ also form bonds to terminal $SePh^-$ ligands (Se17, Se17′). All Cd atoms have a distorted tetrahedral coordination geometry involving the Se atoms of the $SePh^-$ and the P atoms of the PPh_3 ligands [Se-Cd-Se 96.63(8)–122.83(6)°, Se-Cd-P 105.41(9)–106.62(9)°]. The Cd–Se bond lengths range between 249.4(3) and 279.6(4) pm.

Since the phenyl groups of the $SePh^-$ ligands all lie at the surface of the cluster, the center of the cluster contains a cavity of about 420 pm diameter. The space-filling model of **2** (Figure 3) shows that this cavity is completely shielded from

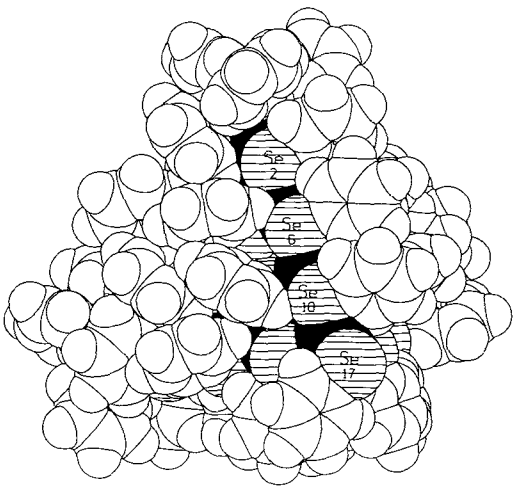

Figure 3. Space-filling model of **2**; the view corresponds to the orientation in Figure 2. Hydrogen atoms were generated by the program SCHAKAL92 [13].

the outside by the phenyl rings of the $SePh^-$ ligands. This cavity could be suitable for interstitial inclusion of other transition metal ions, but such experiments have not yet been successful. Elimination of twelve phenyl rings of the $SePh^-$ ligands and insertion of a further $[SeCd_4]$ tetrahedron into the cavity would lead to a $[Cd_{20}Se_{13}(SePh)_{20}(PPh_3)_2]^{6-}$ cluster consisting of ten fused adamantanoid cages. However, the formation of such a cluster might be unfavorable because of its high charge.

In **2** the $[Cd_{16}Se_{30}P_2]$ cluster forms a tetrahedron with an average edge length of 1.7 nm. This outer tetrahedron can be divided into four corner-sharing tetrahedra which contain the $[Cd_4Se_6]$ cages. Such corner-sharing tetrahedra also form the structural principle of nonmolecular compounds such as $Cd(SPh)_2$.[10] It is noteworthy that Dance et al. have already postulated the possible existence of a structurally analogous compound, namely, $[Cd_{16}(SPh)_{32}(dmf)_2]$, on the basis of ^{113}Cd and ^{13}C NMR data.[11]

The size-dependent optical absorption spectra of **1** and **2** are currently the subject of further investigations, and we are are extending the work presented here to the Hg/Te system. The reaction of $HgCl_2$ with $PtBu_3$ and $PhTeSiMe_3$ yields yellow crystals. Preliminary single crystal X-ray structure analysis indicates the formula $[Hg_{16}(TePh)_{32}(PtBu_3)_2]$, which is analogous to that of **2**.

Experimental Section

All steps were performed under a nitrogen atmosphere in absolute solvents.

1: $PhSeSiMe_3$ (0.96 mL, 3.8 mmol) was added to a suspension of $[CdCl_2(PPh_3)_2]$ (0.68 g, 0.96 mmol) in diethyl ether (50 mL). After a few hours colorless platelets of **1** and a yellow precipitate of unknown composition were obtained (yield 15%).

2: $PhSeSiMe_3$ (0.54 mL, 2.18 mmol) was added to a suspension of $[CdCl_2(PPh_3)_2]$ (0.77 g, 1.08 mmol) in diglyme (100 mL) to give a colorless solution, from which colorless needlelike crystals of **2** formed (yield 40%).

Structural Evolution from the Solid State to the Molecule for BaI_2: Synthesis and Crystal Structures of $[BaI_2(\mu_2\text{-}OH_2)_2]_{3/\infty}$, $[BaI_2(\mu_2\text{-}OH_2)(OC_3H_6)]_{2/\infty}$, $[BaI_2(thf)_3]_{1/\infty}$, and $[BaI_2(thf)_5]\cdot THF$ **

Katharina M. Fromm*

For chemists in all disciplines it is becoming more and more important to study and understand the region between infinite, extended structures and molecules, and this area of research has become more significant in the last few years. However, surprisingly few results have been obtained for relatively simple binary compounds such as the alkaline and alkaline earth metal halides,[1] which can in part be attributed to the difficult handling of such products. We here report herein on the synthesis of a series of donor ligand stabilized structural units that can be derived from the solid-state structure of BaI_2.

Barium iodide dissolves better than most other alkaline and alkaline earth metal halides in organic N- and O-donor solvents. In most cases yellow solutions are obtained, which indicate that the solid state structure has decomposed. Solvation with water, acetone, and THF gave rise to different BaI_2 adducts, which were isolated and characterized. The structural features of these adducts can be derived from the solid-state structure of BaI_2. On the one hand, these adducts are structurally related, and on the other hand, they build up different aggregations such as three-dimensional nets, two-dimensional layers, one-dimensional strands, or even molecular species. On solvation with water, the compounds **1** and, with additional acetone, **2** can be isolated. Compounds **3** and **4** crystallize from THF.

$[BaI_2(\mu_2\text{-}OH_2)_2]_{3/\infty}$ **1**

$[BaI_2(\mu_2\text{-}OH_2)(OC_3H_6)]_{2/\infty}$ **2**

$[BaI_2(thf)_3]_{1/\infty}$ **3**

$[BaI_2(thf)_5]\cdot THF$ **4**

Anhydrous, white barium iodide crystallises, as does $BaCl_2$ and $BaBr_2$, in the $PbCl_2$ structure type (Figure 1).[2] The barium center is surrounded by six iodine atoms in the form of a distorted trigonal prism. The rectangular faces of the prism

are capped by three additional halide atoms. These three iodine atoms lie approximately in the same plane as the barium atom, which leads to approximate D_{3h} symmetry. The distortion of the structure is clearly evident from the different Ba–I bond lengths, which can be divided into seven shorter (3.38–3.63 Å) and two longer bonds (4.10 Å); the coordination number for iodine is four and five, respectively. BaI_2 is not air stable but reacts hygroscopically with water. This solvation process affords compound **1**, which can be isolated and structurally characterized.[3]

Compound **1** forms a three-dimensional structure that contains a structural unit of BaI_2, namely a trigonal prism of I atoms (Figure 1). The barium-centered prisms of I atoms share common edges, and two of the rectangular faces are each bridged by two μ_2-oxygen atoms. Since the third rectangular face is not bridged by oxygen atoms, cavities

[a] Distances in [Å]; CN = coordination number.

occur here in the structure. The coordination number of barium increases from nine in BaI_2 to ten in **1**, whereas the coordination number for iodine decreases to three.

Compound **2**[4] is obtained in the form of pale yellow crystals from a solution of BaI_2 in acetone. The target compound **2** can be prepared by two synthetic pathways, one starting from **1** and absolute acetone, the other from dried BaI_2 and technical grade acetone. Compound **2** forms a two-dimensional layered structure that is unique for alkaline earth metal halides (Figure 1). As in the three-dimensional grid of BaI_2 and **1**, **2** also contains a trigonal prism of I atoms. The Ba-centered I prisms are condensed through two edges of the triangular faces as well as perpendicular to these through two parallel edges of one rectangular face to form a two-dimensional layered structure. In the direction of the rectangular faces, the barium centers are additionally linked through μ_2-bridging water molecules. The structure growth into the third dimension is inhibited by terminally bound acetone molecules. The Ba–I distances (3.5895(7)–3.6672(9) Å) are in the range found for the shorter Ba–I bonds in BaI_2. The coordination number for the barium atom remains the same as in BaI_2, whereas the I atoms act as μ_3-bridging ligands.

The Ba–O(H_2O) distances in **1** and **2** are 2.833–2.894 Å and 2.868 Å, respectively, and thereby shorter than those in comparable structures (2.948 Å in $[Ba(ClO_4)_2(OH_2)(py)]$ and 2.918 Å in $\{[(phen)_2BaCl(OH_2)_2(\mu\text{-}OH_2)_2(H_2O)_2ClBa(phen)_2]Cl_2 \cdot phen \cdot 4H_2O\}$[5]).

Compound **3** has a one-dimensional structure in which the barium atoms are each bridged by two μ_2-I atoms, leading to the formation of strands. The Ba_2I_2 rhombs are inclined by 74.35° toward each other and can be derived from compounds **1** and **2**; two Ba centers are bridged by two I atoms that belong to the triangular faces of the prisms. As in the solid-state structure of $[BaI_2]_\infty$, the Ba_2I_2 rings in **3** are arranged *cisoid* to the Ba center. The coordination sphere around the alkaline earth metal cation in **3** is completed by three terminally bound THF molecules. Thus, the barium center achieves a coordination number of seven and C_{2v} symmetry; the three O atoms and two of the I ligands occupy approximate equatorial positions and the other two I atoms occupy axial positions of a distorted pentagonal bipyramid.

$[BaI_2(bpy)_2]_{1/\infty}$(bpy = bipyridine) exhibits a similar one-dimensional infinite structure,[7] which is also based on Ba-vertex-linked Ba_2I_2 rhombs. The Ba–I distances in $[BaI_2(bpy)_2]_{1/\infty}$ and **3** are similar. In comparison to **3**, three THF donor molecules have formally been replaced by two bidentate N-donor ligands. Owing to the chelating effect $[BaI_2(bpy)_2]_{1/\infty}$ is thermodynamically more stable than **3**, and can easily be handled at room temperature, whereas **3** decomposes under elimination of THF molecules.

In addition to the three- (**1**), two- (**2**), and one-dimensional compounds (**3**), the zero-dimensional THF adduct **4**[8] was isolated and structurally characterized, thus completing the set of compounds based on BaI_2. In compound **4** molecular BaI_2 is stabilized by five THF molecules (Figure 1). The barium center is nearly linearly surrounded by two halide atoms, whereas in the gas phase free molecular BaI_2 has an I-Ba-I angle of between 102° and 105°.[9] The THF donor ligands complete the coordination sphere to form a pentagonal bipyramid; they occupy the equatorial positions. The coordination number for barium is seven and that for iodine is one.

These results reveal that the coordination number of iodine is influenced by the kind and number of O-donor ligands. Thus, the transition from the BaI_2 solid-state structure to **1** and **2** is accompanied by a decrease in the coordination number for iodine from four and five in BaI_2 to three in **1** and **2**, respectively. The distortion of the trigonal prisms disappears in **1** and **2**. Aggregation of the solid-state structure of $[BaI_2]_\infty$ seems to be stopped by breaking the longest Ba–I bonds. Formally, the iodine atoms capping the prism are replaced by O-donor ligands. The bridging to give a three-dimensional structure is suppressed in **2** and layers are formed by terminally bound O-donor molecules. The coordination number is three for all halogen atoms. The loss of a further dimension (as for **3**) results in a coordination number of two for all halogen atoms, and thus one-dimensional strands are observed. The series is completed by compound **4** with a zero-dimensional structure—molecular BaI_2 stabilized by donor ligands. In particular the Ba–I distances become shorter as the dimensionality decreases (Table 1), thus supporting the covalent character of the Ba–I bond.

In summary we have clearly shown the similarities of compounds **1**–**4** with the solid-state structure of BaI_2. Thus, a "genealogy tree" can be elaborated in which the influence of the number and size of donor ligands is given. The aim of future investigations will be to find out if this behavior can be extended to other ligand systems as well as other alkaline and alkaline earth metal compounds. Furthermore, studies are also required to determine whether the compounds can be combined to produce new structures.

Experimental Section

1: Anhydrous barium iodide reacted in air with water to yield colorless crystals of **1**.

2: $BaI_2(\mu_2\text{-}OH_2)_2$ (0.5 g, 1.17 mmol) was dissolved in dried and freshly distilled acetone (30 mL). After 48 h at −30 °C, pale yellow cubic crystals of **2** were isolated from the yellow solution. The crystals decomposed above −10 °C, and on contact with air they quickly lost solvent molecules.

Another synthetic pathway involved the use of dry BaI_2 with technical acetone. The desired product was isolated from this solution at −30 °C.

3: BaI_2 (0.5 g,1.28 mmol) (dried in high vacuum at 500 °C) was dissolved under nitrogen in dried and freshly distilled THF (50 mL). The yellow solution was concentrated to half the volume and layered with diethyl ether (10 mL). Pale yellow blocks of **3** crystallized at −30 °C. The compound is sensitive to air and reacts at room temperature under elimination of solvent molecules.

4: BaI_2 (0.4 g, 1 mmol; dried (see **3**)) was dissolved with heating in dried and freshly distilled THF (30 mL) under nitrogen. Pale yellow rhombs of **4** resulted after the solution was kept at −30 °C. The compound decomposed rapidly above this temperature.

Rate Enhancement of the Pauson–Khand Reaction by Primary Amines**

Takumichi Sugihara,* Mamiko Yamada, Hitoshi Ban, Masahiko Yamaguchi,* and Chikara Kaneko

The Pauson–Khand reaction is one of the most powerful methods for constructing cyclopentenones[1,2] and has been widely utilized for the synthesis of a variety of natural products.[3] "Hard" ligands, which usually contain an N or O atom, in metal-carbonyl complexes labilize the CO ligands and therefore facilitate the ligand substitution reaction.[4,5] If the "hard" ligands react with $Co_2(CO)_6$(alkyne) complexes in the presence of olefins, the substitution of CO ligands by the olefins might be facilitated. Since the coordinated alkyne is also made reactive by the labilizing effect of the "hard" ligands, the Pauson–Khand reaction might be promoted.[6] To confirm our hypothesis, we first investigated the use of "hard" ligands as solvents to study their effect on the Pauson–Khand reaction. The results are shown in Table 1. In the aprotic solvents usually used in the Pauson–Khand reaction, the desired cyclization did not proceed at 35°C even after three days (Nos. 1–4). Complex **1a** was also recovered almost quantitatively when ethanol or triethylamine, either of which might act as "hard" ligands, was used as solvent (No. 5 and 6). However, whereas the cyclization proceeded slowly in diethylamine (No. 7), it was complete within 5 min in cyclohexylamine to give **2a** in good yield (No. 10).[7,8] Comparison

Table 1. The Pauson–Khand reaction of **1a** in different solvents[a].

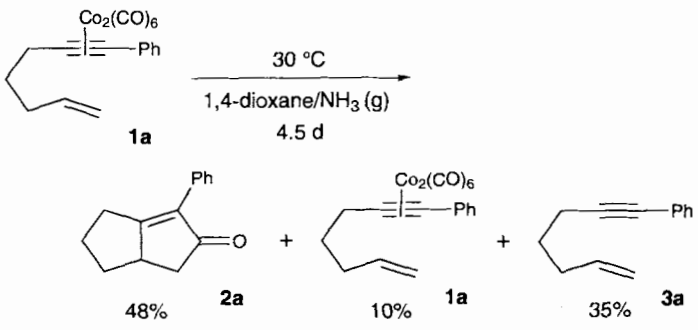
of Nos. 6–11 shows that the use of primary amines as solvents dramatically enhanced the rate of the reaction. The alkyl group on the primary amines also has a great influence on the course of the reaction. The moderately hindered primary amines, such as the ones containing secondary alkyl groups, seem to promote the Pauson–Khand reaction most effectively. The yield of **2a** reduced when an amine with a primary alkyl group was employed (No. 8). The tertiary alkyl substituted amine retarded the reaction (No. 11).

Since cyclohexylamine seemed to be the best promoter for the Pauson–Khand reaction, we varied the amount used to optimize the conditions. The results are also shown in Table 1. When the reaction of **1a** was carried out with 10 equivalents of the amine in 1,2-dichloroethane at 25°C, the desired cyclization was slow and decomplexation reduced the yield of **2a** (No. 12). In contrast, the cyclized product **2a** was produced in quantitative yield at 83°C (No. 13). No. 12–17 shows that more than three equivalents of the amine and the higher reaction temperature were both necessary to perform the desired cyclization in a short time as well as in quantitative yield. Various solvents were examined, such as *n*-hexane, toluene, 1,2-dimethoxyethane, THF, 1,4-dioxane, 2-propanol, acetonitrile, and *N*,*N*-dimethylformamide, but so far 1,2-dichloroethane remains the best solvent to obtain clean reactions and quantitative yields in this reaction system. The present conditions are a new and convenient method to promote the Pauson–Khand reaction without using oxidants.

Since primary amines were effective as promoter, we felt that ammonia should not be an exception. When **1a** was dissolved in 1,4-dioxane that was saturated with ammonia gas at 0°C and stirred in a sealed tube at 30°C for 4.5 days, the desired **2a** was produced along with **3a**. Since the use of a



sealed tube is not convenient especially on a large scale, we decided to use a biphasic system[9] in which an aqueous solution of ammonium hydroxide would be the source of ammonia. The results under different conditions are summarized in Table 2. When 16M aqueous solution of ammonium hydroxide was used as cosolvent, the cyclization proceeded

Table 2. The Pauson–Khand reaction of **1a** in a biphasic system under different conditions[a].

even at 25°C (No. 1), although the enyne **3a** released from the complex was also produced. Comparison of No. 1 with the reaction of **1a** with gaseous ammonia in 1,4-dioxane suggests that water also affects the course of the reaction. Water itself, however, is not an effective promoter, since the reaction did not occur even at 100°C (No. 2 and 3). Moreover, higher temperatures favor cyclization over decomplexation (No. 1, 4, and 5). Even less concentrated solutions of ammonium hydroxide promoted the cyclization reaction (No. 6 and 7)

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2802 $ 17.50+.50/0

until a threshold dilution of about 1M at which the reaction slowed down (No. 8). Moderate concentrations of ammonium hydroxide are apparently important. In addition, when an aqueous solution of sodium hydroxide was used instead of ammonium hydroxide, the desired cyclization did not proceed cleanly but afforded a complex reaction mixture (No. 9). Furthermore, aqueous ammonium chloride slowed down the reaction (No. 10). Therefore, neither hydroxide anions nor ammonium cations but ammonia itself is essential to enhance the rate of the Pauson–Khand reaction in this biphasic system. It is worth pointing out that aqueous ammonium hydroxide is the cheapest and the most convenient promoter for the Pauson–Khand reaction and that a simple extraction workup gave the spectroscopically pure samples of the product in the present system.[10] To our knowledge, this method is the first report of the Pauson–Khand type cyclization[1,2,11] in the presence of water.[12]

Two sets of conditions to promote the Pauson–Khand reaction, namely, 3.5 equivalents of cyclohexylamine in 1,2-dichloroethane at 83°C (conditions A) and a 1:3 mixture (v/v) of 1,4-dioxane and 2M aqueous solution of ammonium hydroxide at 100°C (conditions B), were applied to various substrates. The results are summarized in Table 3. In all cases the reaction was complete in short times and afforded the desired cyclopentenones in good yield. The two methods gave comparable results in terms of the rates and yields.

Table 3. The Pauson–Khand reaction of **1b–j** under different conditions

No.	Starting material 1	4	Product 2	Conditions A [a] t[min]	Yield[%]	Conditions B [b] t[min]	Yield[%]
1	**b**		**b**	10	89[c]	30	92
2	**c**		**c**	30	90[d]	30	90
3	**d**		**d**	10	60	10	78
4	**e**		**e**	30	71[e]	45	75[f]
5	**f**		**f**	10	62	30	67
6	**g**		**g**	20	89	30	90
7	**h**	**a**[g]	**h**	10	98[h]	10	100[h]
8	**h**	**b**[g]	**i**	10	83[h]	30	50[h,i]
9	**i**	**a**[g]	**j**	15	94[h]	10	92[j]
10	**j**	**a**[g]	**k**	10	45[h]	135	42[h]

[a] Reactions were carried out in 0.2M solution of 1,2-dichloroethane at 83°C in the presence of 3.5 equiv of cyclohexylamine under argon atmosphere. [b] Reactions were carried out in 0.1M solution of 1,4-dioxane/2M aqueous solution of NH_4OH (1:3 v/v) at 100°C under argon atmosphere. [c] Cyclopentenones **2c** and **2l** were also produced in 5% and 5% yield, respectively. [d] Cyclopentenones **2b** and **2l** were also produced in 5% and 2% yield, respectively. [e] Cyclopentenone **2m** was also produced in 14% yield. [f] Cyclopentenones **2m** was also produced in 12% yield. [g] A 1.5 equiv of **4a** or **4b** was used. [h] No regio- or stereoisomer was detected. [i] The reaction of **1h** with **4b** (10 equiv) for 30 min under conditions B gave **2i** in 91% yield. [j] Cyclopentenone **2n** was also produced in 4% yield.

In conclusion, convenient and economical promoters for the Pauson–Khand reaction have been developed. We are now trying to clarify the reaction mechanism and studying the reaction of the $Co_2(CO)_6$(alkyne) complexes with primary amines in more detail.

Experimental Section

For conditions A: Synthesis of **2a**: Under an argon atmosphere, a solution of **1a** (456 mg, 1.00 mmol) and cyclohexylamine (0.395 mL, 3.49 mmol) in 1,2-dichloroethane (5 mL) was stirred at 83°C for 5 min. After cooling, Et_2O was added, and the resulting suspension was filtered. The filtrate was washed successively with 5% aqueous HCl, H_2O, and saturated aqueous $NaHCO_3$, dried over $MgSO_4$, and concentrated in vacuo. Purification by silica gel column chromatography (Et_2O/*n*-hexane 15/85) gave 197 mg (99%) of **2a**. M.p. 65°C (Et_2O/*n*-hexane); IR (neat): $\tilde{\nu}$ = 1693, 740, 700 cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$, 25°C, TMS): δ = 1.0–1.25 (m, 1H), 2.0–2.15 (m, 2H), 2.15–2.35 (m, 2H), 2.55–2.75 (m, 1H), 2.75–3.0 (m, 3H), 7.2–7.35 (m, 1H), 7.35–7.45 (m, 2H), 7.55–7.65 (m, 2H); ^{13}C NMR (75 MHz, $CDCl_3$, 25°C): δ = 25.57, 26.98, 30.61, 42.61, 44.29, 127.50, 128.05, 128.08, 131.66, 134.14, 185.50, 208.58; C,H analysis (%) calcd. for $C_{14}H_{14}O$ (198.26): C 84.81, H 7.12; found: C 84.53, H 7.12.

For conditions B: Synthesis of **2h**: Under an argon atmosphere, a solution of **1h** (440 mg, 1.13 mmol) and norbornene (**4a**; 160 mg, 1.70 mmol) in 1,4-dioxane (3.0 mL) and 2M aqueous solution of NH_4OH (9.0 mL) was stirred at 100°C for 10 min. After cooling, Et_2O was added, and the resulting suspension was filtered. The filtrate was washed successively with H_2O, 5% aqueous HCl, and saturated aqueous $NaHCO_3$, dried over $MgSO_4$, and concentrated in vacuo. Purification by silica gel column chromatography (Et_2O/*n*-hexane 15/85) gave 253 mg (100%) of **2h**. M.p. 95°C (Et_2O/*n*-hexane); IR (neat): $\tilde{\nu}$ = 1693 cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$, 25°C, TMS): δ = 0.95–1.05 (m, 1H), 1.05–1.2 (m, 1H), 1.25–1.45 (m, 2H), 1.55–1.8 (m, 2H), 2.28 (br. d, J = 3.8 Hz, 1H), 2.37 (d, J = 5.2 Hz, 1H), 2.50 (br. d, J = 3.8 Hz, 1H), 2.65–2.75 (m, 1H), 7.25–7.45 (m, 3H), 7.64 (d, J = 2.7 Hz, 1H), 7.65–7.75 (m, 2H); ^{13}C NMR (75 MHz, $CDCl_3$, 25°C): δ = 28.24, 28.99, 31.13, 38.22, 39.33, 39.52, 47.59, 54.83, 127.06, 128.40, 131.57, 146.07, 160.31, 209.12; C,H analysis (%) calcd. for $C_{16}H_{16}O$ (198.26): C 86.45, H 6.35; found: C 86.33, H 6.55.

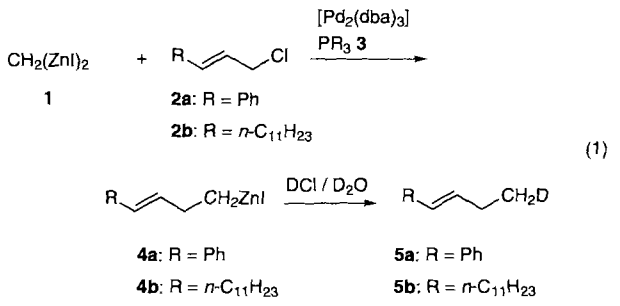
Stepwise Reaction of Bis(iodozincio)methane with Two Different Electrophiles**

Kiitiro Utimoto,* Narihiro Toda, Takeshi Mizuno, Masami Kobata, and Seijiro Matsubara

Geminal dimetallic reagents have attracted considerable attention as versatile reagents in organic synthesis,[1] and consequently their preparation has been extensively studied.[2] Application of the reagents has focused on regioselective olefination of carbonyl compounds[3] and coupling with two different electrophilic building blocks.[4] We have developed a method for preparing *gem*-bis(halozincio)alkanes from the corresponding dihalides and have used the organozinc compounds for the olefination of aldehydes and ketones.[5] We have also observed that one of the two C–Zn bonds of bis(iodozincio)methane is much more reactive than the other in the reaction with water or iodine.[5b] These results suggested that the two C–Zn bonds could be used separately. We describe here a stepwise reaction of *gem*-dizinc compounds with two different electrophiles under palladium catalysis.

We initially examined the Pd-catalyzed coupling of bis(iodozincio)methane (**1**) with allyl chlorides. As shown in Equation (1), an allyl chloride **2** (1.0 mmol) was treated with



1 (1.0 mmol) in the presence of $[Pd_2(dba)_3]\cdot CHCl_3$ (0.025 mmol) and a phosphane **3** (0.1 mmol) as a ligand in THF (dba = dibenzylideneacetone). After 30 min the resulting mixture was quenched with DCl–D_2O to give the deuterated product **5**. Combinations of allyl chlorides and ligands, as well as yields of coupling products **5** are summarized in Table 1. Excellent results were obtained by ligand tuning; phosphane ligands with electron-withdrawing groups such as tris[3,5-bis(trifluoromethyl)phenyl]phosphane (**3c**) and tris(2-furanyl)phosphane (**3d**) afforded the coupling products in good-to-excellent yields. Quantitative formation of iodozinciomethylated products **4a** was confirmed by ^1H NMR spectroscopy in $[D_8]$THF; the spectra showed the

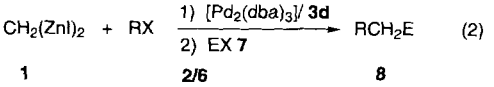
exclusive formation of (*E*)-4-phenyl-3-butenylzinc iodide when **3d** is employed as a ligand.

The intermediary organozinc compounds **4a** and **4b** reacted with other electrophiles such as allyl or acyl halides under the same palladium catalysis as shown in Equation (1).[6,7] This reaction permits a sequential coupling of bis(iodozincio)methane with two different electrophiles [Eq. (2)]



to give the three-component-coupling products in excellent yields. The results of such sequential reactions are shown in Table 2. The formation of **8d** and **8e** can be explained by Equation (3).

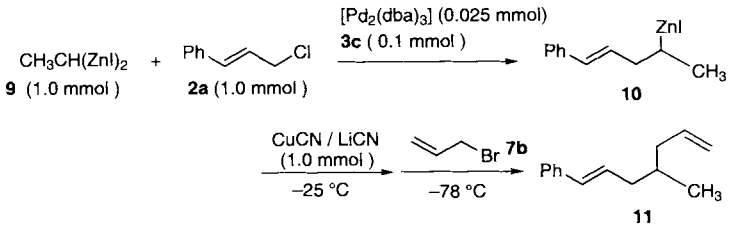
(3)

1,1-Bis(iodozincio)ethane (**9**) reacted with cinnamyl chloride (**2a**) to give the organozinc intermediate **10**, which yielded the deuteriodezincated product (**10**, D in place of ZnI) in 65% yield. The direct coupling of **10** with the allyl bromide **7b** did not occur. In this case, the copper-mediated reaction[8] gave the double coupled product **11** in 66% yield [Eq. (4)].



(4)

Experimental Section

THF (2 mL) was added to a mixture of $[Pd_2(dba)_3]\cdot CHCl_3$ (0.025 g, 0.025 mmol) and **3d** (0.023 g, 0.1 mmol) and the mixture was stirred for 5 min at 20°C. A solution of **2a** (0.15 g, 1.0 mmol) in THF (1 mL) was added to the mixture at 20°C, then a solution of **1a** (0.5 M, 2 mL, 1.0 mmol) in THF was added at 20°C and the resulting mixture was stirred for 30 min at 20°C. Thereafter a solution of **7b** (0.15 g, 1.2 mmol) in THF (1 mL) was added at 20°C, and the resulting mixture was stirred for 2 h and then poured into 1 M HCl (20 mL) and extracted with ether. The combined organic layers were washed with brine and dried over Na_2SO_4. Purification by column chromatography (silica gel) gave 1-phenyl-1,6-heptadiene (**8a**) in 87% yield.

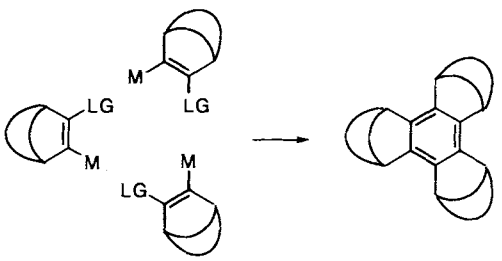
Trisannelated Benzenes by Cyclotrimerization of Bromostannylalkenes**

Richard Durr, Sergio Cossu, Vittorio Lucchini, and Ottorino De Lucchi*

Trisannelated benzenes are enjoying growing interest both as aromatic molecules with alternating bond lengths [1] and as potential precursors of significant fullerene fragments.[2] Except for the simplest cases (triphenylene and tricycloalkyl derivatives),[3] trisannelated benzenes of polycyclic molecules are prepared by two routes: from chloroalkenes with a strong base[4] or from dibromoalkene derivatives by metal–halogen exchange reactions.[5] In both cases the yields are very low—usually 10% or less—and substantial amounts of polymers are formed. The use of metal templates such as nickel[6] also leads to unpredictable and erratic results. Because of poor yields, the real utility of these molecules as precursors to fullerene substructures and eventually to fullerenes themselves can be seriously questioned, and new reactions for the aromatic cyclotrimerization of suitable precursors have clearly become necessary for the development of routes to these molecules. Here we present a method that is readily carried out under very mild reaction conditions, and consistently and reproducibly affords high yields of trimers.

We planned to apply the Stille coupling[7] to olefins containing a suitable metal atom M at one carbon and a leaving group X at the other, in the hope that it would result in trimerization to a trisannelated aromatic product rather than uncontrolled polymerization. Eventually we found that olefins containing the trimethylstannyl group as "metal" along with bromine as a leaving group smoothly afford good yields of cyclotrimers upon reaction with $Cu(NO_3)_2\cdot 3H_2O$ (Scheme 1).

The starting materials for the cyclotrimerization reactions are bromo(trimethylstannyl)alkenes. We chose the norbornene derivatives **1a–c** because such five- and six-membered



Scheme 1. Stille coupling of polycyclic olefins leading to trisannelated benzenes. M = metal, organometallic group; LG = leaving group.

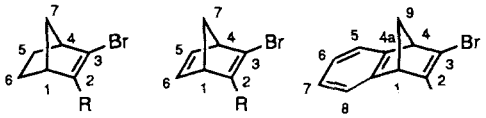
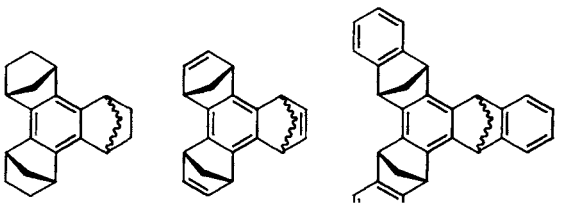
ring-containing compounds would be precursors for fullerene substructures if the cyclotrimers could be properly rearranged.

Bromo(stannyl) derivatives **1a–c**[8] were obtained in high yield under standard conditions from dibromo compounds **2a–c**[9] by metal–halogen exchange with *n*-butyllithium in THF followed by treatment with trimethyltin chloride. When



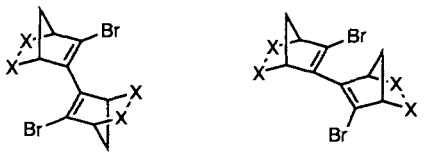
1, R = $SnMe_3$
2, R = Br
3, R = H
4, R = Cl

a THF solution of **1a–c** was added to an equimolar amount of $Cu(NO_3)_2 \cdot 3H_2O$ in THF, a rapid reaction occurred, as shown by a color change from blue to brown. Cyclotrimerized products **5a–c**[10] were obtained as a statistical (3:1) mixture of the *anti* and *syn* isomers in yields up to 80%.



Minor differences were noticed in reactions leading to **5a–c**. Although **5a** and **5b** were obtained essentially pure from **1a** and **1b**, minor amounts of dimers **6c** and **6′c**[11] (15%) arose from **1c**. However, in contrast to other cyclotrimerization procedures, no polymeric material whatsoever was formed.[4,5]

Isomeric dimers **6c** and **6′c** form as an approximately 1:1 mixture. The centrosymmetric structure of **6c** and the C_2-symmetric structure of **6′c** prevented assignment of NMR signals by the usual methods (NOE differential spectroscopy). No crystals suitable for X-ray analysis could be grown. According to literature reports, the dimers were indeed the only products to be expected.[12]



6a-c **6′a-c**

a, X-X = CH_2-CH_2
b, X-X = CH=CH
c, X-X = C_6H_4

Reaction conditions have some influence on the product composition. For example, in the case of **1c** high dilution affords predominantly the protodestannylated compounds **3c**[13] (0–10%) and a smaller amount of dimers **6c/6′c**, while high concentration favors dimers **6c/6′c** relative to the trimers. Higher temperature also favors the formation of dimers. Based on our experiments, the highest proportion of annelated compounds is obtained by adding copper(II) nitrate at room temperature to a roughly 0.1M solution of the appropriate bromo(stannyl) compound in THF.

It is also possible to carry out the reaction in a single pot starting from the dibromo compounds **2a–c**. Sequential addition of *n*BuLi, Me_3SnCl, and $Cu(NO_3)_2 \cdot 3H_2O$ affords a 50–60% yield of trimers **5a–c**, although the product is contaminated with small amounts of the chlorobromo derivatives **4a–c** (5–15%) and the protodestannylated compounds **3a–c** (0–15%). The formation of **3a–c** is not surprising because of the presence of water in the copper salt. Formation of the chlorine-containing derivative may be a result of chloride ion liberated from trimethyltin chloride.

The reaction with other copper salts takes other paths. For example, **1b** and **1c** under similar reaction conditions afford quantitatively with $CuCl_2$ the tin-chloride substitution products **4b** and **4c**, respectively.[14] No cyclotrimers or dimers could be detected in this case. Reaction of **1c** with copper(I) chloride in DMF[15] leads quantitatively to the corresponding substitution product **4c**.[14] Iron(III) chloride gives exclusively **3a–c**, whereas Pd^0[16] under standard Stille conditions is ineffective, since only starting material was recovered from the experiments in question.[7]

The mechanism of cyclotrimer formation under the catalytic influence of copper(II) nitrate is still unclear. Based on similar experiments and literature reports[13] it is possible to conjecture tin–copper transmetalation with formation of an organocopper species that evolves into a vinyl radical. At ambient temperature the intermediate radical is sufficiently reactive to displace bromine from another molecule repeatedly until the trisannelated product **5** is formed. At lower temperature it does not possess sufficient energy, so it can only react with water or dimerize. Dimerization is further encouraged by high concentration. For maximum cyclotrimerization efficiency, the concentration of radicals along the entire reaction path must not become too high (to avoid coupling). Therefore, C–Cu bond cleavage should not occur too rapidly. The formation of chloro derivatives with $CuCl_2$ might well be accounted for by internal nucleophilic substitution by a ligand coupling mechanism[17] of the hypervalent species formed by attack of chloride ion on the tin atom.

β-Donor Bonds in Compounds Containing SiON Fragments**

Norbert W. Mitzel* and Udo Losehand

Dedicated to Professor Evelyn A. V. Ebsworth

We investigated $H_3SiONMe_2$ and $H_2Si(ONMe_2)_2$, which unequivocally show the formation of Si–N β-donor bonds and are probably the simplest isolable compounds containing a SiON fragment. Recently we reported (4+4) coordination at the silicon center in $Si(ONMe_2)_4$.[1] This compound has an Si-O-N angle that is compressed by more than 16° with respect to the Si-O-C angle in the isoelectronic $Si(OCHMe_2)_4$. Ab initio calculations on $H_3SiONMe_2$ and $FH_2SiONMe_2$ predicted narrow Si-O-N angles (102.5 and 90°, respectively) and short Si–N distances.[1]. So far there has been no experimental evidence for these postulated extreme bonding situations in the SiON unit. The knowledge of the formation of Si–N β-donor interactions in SiON compounds is important for understanding the effect of *O*-silylated hydroxylamines and oximes as cross-linking agents[2] and cold-curing catalysts[3] in the synthesis of silicon polymers with low molecular weights, which can be used in electronics, construction, and medical applications. Acceleration of hydrolysis and alcoholysis of Si–H bonds in the presence of catalytic amounts of R_2NOH-type compounds was only recently established.[4] It can be explained by this interaction, which is unusual in the chemistry of p-block elements.

Numerous attempts to prepare $H_3SiONMe_2$ by condensation of H_3SiCl or H_3SiBr with $HONMe_2$ in the presence of auxiliary bases as well as reactions of $HONMe_2$ with silylamines failed. Despite the high reactivity of the agents, the reaction of H_3SiBr with $LiONMe_2$ proved to be the best synthetic method [Eq. (1)]. $H_2Si(ONMe_2)_2$ was prepared in a similar way from dichlorosilane [Eq. (2)]. Both products are

$$H_3SiBr + LiONMe_2 \longrightarrow H_3SiONMe_2 + LiBr \quad (1)$$

$$H_2SiCl_2 + 2\,LiONMe_2 \longrightarrow H_2Si(ONMe_2)_2 + 2\,LiBr \quad (2)$$

extremely sensitive to moisture, but are not pyrophoric. Although isomerization of $H_3SiONMe_2$ and $H_2Si(ONMe_2)_2$ to the aminosilanoles is thermodynamically favored, they can be heated to about 100 °C.

The identity of the compounds was proven by ^1H, ^{13}C, ^{15}N, ^{17}O, and ^{29}Si NMR spectroscopy, gas-phase IR spectroscopy, and mass spectrometry. Since $H_3SiONMe_2$ melts at low temperatures (≈ -60 °C), a single crystal for X-ray diffraction analysis had to be grown by in situ methods.[5] The molecules contain a crystallographically imposed mirror plane with an Si-O-N angle of only 102.63(5)° and short Si···N distances of 2.453(1) Å (Figure 1; the sum of the van der Waals radii of Si and N is 3.54 Å[6]). This is in excellent agreement with the

O-Si-H(1)	110.4(6)	111.5	109.3(7)–110.5(7)	110.2
O-Si-H(2)	101.7(8)	104.4		

results of quantum-chemical calculations (Table 1). The aggregation of the molecules through O···Si contacts (2.92 Å) rather than N···Si contacts (Figure 2) indicates that

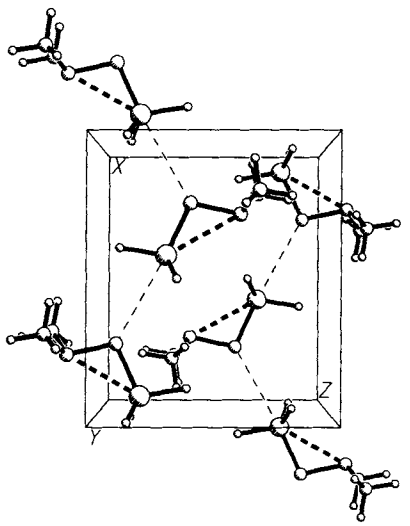

Figure 2. Intermolecular O···Si contacts between $H_3SiONMe_2$ molecules in the crystal.

the oxygen atoms are more basic than the nitrogen atoms. This implies the involvement of the electron lone pair on nitrogen in the β-donor bond to the silicon atom and the increase of basicity at the oxygen atom through a narrow Si-O-N angle. Taking the Si···O contacts into consideration, the coordination geometry at the oxygen atoms is crystallographically planar (similar to the case in $MeOSiH_3$,[7] $(H_3Si)_2O$,[8] and $(H_3Si)_2NOMe$[9]), and the electronic situation at the oxygen centers can neither be described properly with an sp^3 nor an sp^2 hybridization model (narrow Si-O-N angle).

To get an idea of the strength of a Si–N β-donor bond, several geometrical optimizations[10] at the MP2/6-31G* level of theory were peformed with successive alteration of fixed Si-O-N angles (Figure 3). Based on a comparison with

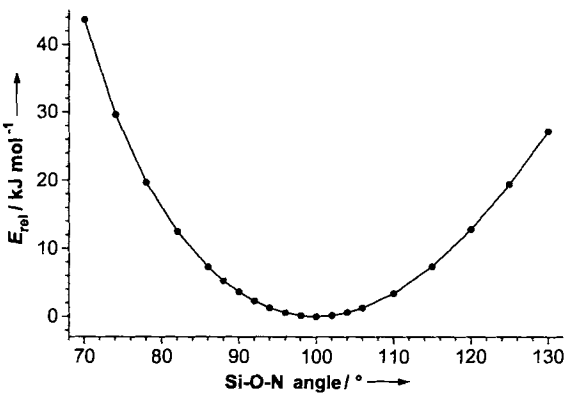

Figure 3. Relative energies (MP2/6-31G*) of $H_2SiONMe_2$ at different fixed Si-O-N bond angles.

Si-O-C angles of isoelectronic SiOCH compounds that are not capable of forming Si–N β-donor bonds (e. g. H_3SiOMe: 120.1,[7] $Si(OCHMe_2)_4$: 124.7°)[1] the Si-O-N angle can be estimated to be 120° in the hypothetical absence of a β-donor interaction. This results in an estimated bond energy of 15 kJ mol^{-1}.

The β-donor bond in $H_2Si(ONMe_2)_2$ is even stronger, as shown by an X-ray diffraction analysis of a single crystal prepared by in situ methods (Figure 4).[5] The Si-O-N angle is

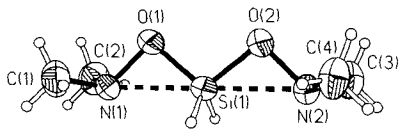

Figure 4. Molecular structure of $H_2Si(ONMe_2)_2$.

on average as small as 95.1°, and the Si···N distances of 2.300(1) and 2.336(1) Å are about 0.1 Å shorter than in $H_3SiONMe_2$. The increased coordination number at silicon (4+2) leads to a compressed O-Si-O angle of only 100.95(5)°. The N–O bonds in $H_3SiONMe_2$ and $H_2Si(ONMe_2)_2$ are more than 0.02 Å longer than that in $HONMe_2$. No intermolecular Si···O contacts were found in crystals of $H_2Si(ONMe_2)_2$.

These results show that the formation of relatively strong β-donor bonds are possible even between p-block elements. For a deeper understanding further investigations of this and related classes of compounds are necessary. Kinetic studies on $ClH_2SiONMe_2$, which we also isolated, will show to what extent the increased coordination number accelerates nucleophilic substitution.

Experimental Section

All NMR spectra were recorded at 21 °C with solutions in C_6D_6.

$H_3SiONMe_2$: *n*-Butyllithium (1.8 g, 28 mmol, 1.8 M in hexane) was added dropwise to a solution of Me_2NOH (1.7 g, 28 mmol) in pentane (50 mL). The mixture was stirred for 1 h at room temperature, and the solvent removed in vacuo. Dimethyl ether (5 mL) and bromosilane (3.1 g, 28 mmol) were added at −196 °C by condensation. The mixture was warmed to −30 °C and stirred for 2 h. All volatile products were condensed into a trap at −196 °C. Distillation through a series of traps (−50, −78, −100, and −196 °C) resulted in condensation of $H_3SiONMe_2$ in the −78 °C trap. ^1H NMR: $\delta = 2.32$ (s, 6H, H_3C), 4.58 (s, 3H, H_3Si); ^{13}C NMR: $\delta = 49.1$ (qq, $^1J(C,H) = 135.4$ Hz, $^3J(C,H) = 5.4$ Hz, CH_3); $^{15}N\{^1H\}$ NMR (DEPT): $\delta = -234.0$ (s); $^{17}O\{^1H\}$ NMR: $\delta = 112.1$ (s); ^{29}Si NMR (DEPT): $\delta = -49.5$ (q, $^1J(Si,H) = 219.3$ Hz); IR (gas): $\tilde{\nu} = 2177$ cm^{-1} (s, ν(Si–H)).

$H_2Si(ONMe_2)_2$: Methyllithium (2.5 g, 0.11 mol, 1.60 M in diethyl ether) was added dropwise to a solution of Me_2NOH (6.9 g, 0.11 mol) in diethyl ether (25 mL) at

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2808 $ 17.50+.50/0

0 °C and then stirred for 1 h at room temperature. At −196 °C dichlorosilane (5.7 g, 56 mmol) was condensed onto the mixture, which was then stirred for 1 h at −78 °C. After the mixture was warmed to room temperature all volatile components were separated from the salt by condensation. $H_2Si(ONMe_2)_2$ (4.2 g, 28 mmol, 50%) could be isolated at −35 °C as an air-sensitive, colorless liquid (m.p. 0 °C) by condensation through a series of traps (−35, −35, −78, and −196 °C). ^1H NMR: $\delta = 2.42$ (s, 12H, H_3C), 4.70 (s, 2H, H_2Si); ^{13}C NMR: $\delta = 49.7$ (qq, $^1J(C,H) = 135.4$ Hz, $^3J(C,H) = 5.4$ Hz, CH_3); $^{15}N\{^1H\}$ NMR (DEPT): $\delta = -249.2$ (s); $^{17}O\{^1H\}$ NMR: $\delta = 141.1$ (s); ^{29}Si NMR (DEPT): $\delta = -49.8$ (q, $^1J(Si,H) = 219.3$ Hz); IR (gas): $\tilde{\nu} = 2193$ cm^{-1} (s, ν(Si–H)); MS (CI): $m/z = 149$ [$M^+ - 1$].

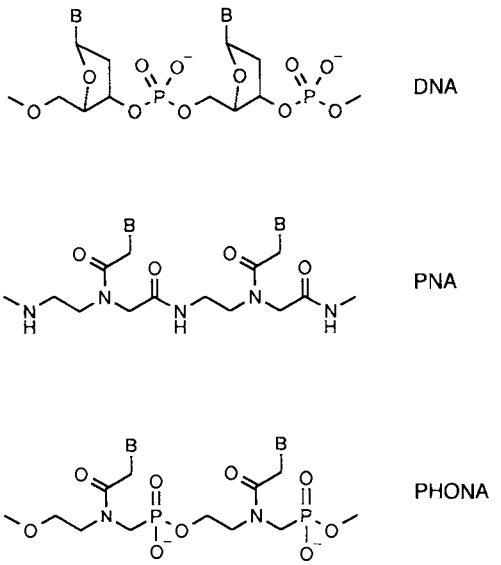
PHONA–PNA Co-Oligomers: Nucleic Acid Mimetics with Interesting Properties

Anusch Peyman,* Eugen Uhlmann, Konrad Wagner, Sascha Augustin, Caroline Weiser, David W. Will, and Gerhard Breipohl

Oligonucleotide analogues are of special interest in molecular biology and medicinal chemistry because of their use as diagnostic agents and their potential application as therapeutics.[1,2] PNAs are nucleic acid mimetics in which the sugar–phosphate backbone is completely replaced by an *N*-(2-aminoethyl)glycine scaffold. The nucleobases are attached to this backbone through methylenecarbonyl linkers (Scheme 1).[3–5] PNAs bind remarkably strongly to complementary DNA and RNA sequences.[5] This is partly due to the



Scheme 1. Structures of DNA, PNA, and PHONA.

lack of negative charges on the PNA backbone, which, however, results in poor water solubility and inadequate cellular uptake.[5,6] The reintroduction of negative charges into PNAs is possible by, for example, the synthesis of PNA–DNA chimeras,[7] or by the synthesis of a further structural variant, the PHONAs (Scheme 1).[8] PHONAs are analogues of PNAs in which the peptide bond is replaced by a phosphonic acid ester bridge.

The abundance of available nucleic acid mimetic structures offers the organic chemist the possibility of combining appropriate building blocks to create oligomers with customized properties. On the other hand prediction of the binding properties of chimeric oligomers is fraught with uncertainty, as the structures of the complexes of different nucleic acid analogues with their complementary DNA can vary widely. This is illustrated by a comparison of the structures of DNA · DNA and PNA · DNA duplexes.[9] Here we report the synthesis and binding properties of alternating PHONA–PNA

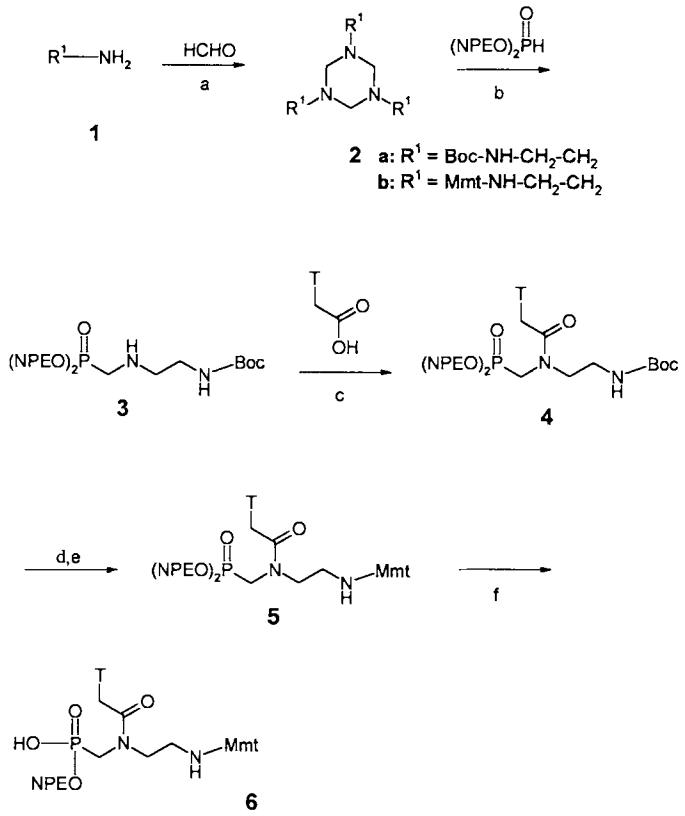
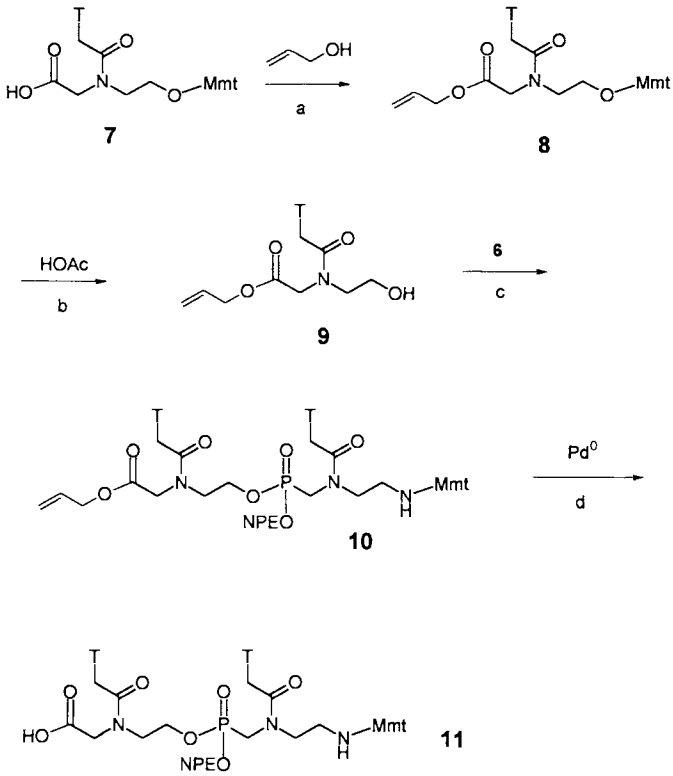
oligomers. The oligomers contain only the nucleobase thymine, as protection of exocyclic amino functions is unnecessary.

The central building block for the synthesis of PHONA–PNA oligomers is the dimer block **11** (see Scheme 3), which carries two orthogonal protecting groups: the acid-labile 4-methoxytriphenylmethyl (Mmt) protecting group for the amino function and the 4-nitrophenylethyl (NPE) phosphonic acid ester,[10] which can be cleaved by β-elimination. The synthesis of the amino-PHONA building block is shown in Scheme 2. The strategy is largely analogous to the previously



Scheme 2. Synthesis of the PHONA monomer; T = 1-thyminyl: a) 1.5 equiv HCHO, methanol, room temperature (RT), 1 h, 37%; b) 1 equiv phosphite, 2.5 h, 100°C, 23%; c) 1 equiv 1-thyminylacetic acid, 3 equiv *N*-ethylmorpholine, 1.1 equiv HATU, DMF, 24 h, RT, 66%; d) 100% trifluoroacetic acid, 0–10°C, 100%; e) 1.1 equiv MmtCl, 3 equiv diisopropylethylamine, 12 h, 0–5°C, 100%; f) 0.1M diazabicycloundecene (DBU) in acetonitrile, 24 h, 0°C, 77%.

described synthesis of the corresponding hydroxy-PHONA building block.[8] However, it was necessary to use the *tert*-butyloxycarbonyl (Boc) protecting group for the amino function. This could be exchanged for the Mmt group after attachment of the phosphonic acid. The addition of the phosphite to the corresponding Mmt-protected imine **2b** did not give the desired phosphonic acid, presumably because partially released formaldehyde reacted with both secondary amino functions. The hydroxyethylglycine-based building block **7** [7a,b] (Scheme 3) was converted into its allyl ester, and after cleavage of the Mmt protecting group, was coupled with PHONA monomer **6** by using the coupling reagent 3-nitro-1-(*p*-toluenesulfonyl)-1H-1,2,4-triazole (TSNT).[11] The allyl ester of dimer block **10** can be cleaved selectively[12] with Pd^0, which leaves the Mmt and NPE protecting groups intact.



Scheme 3. Synthesis of mixed PHONA–PNA building block **11**: a) 2 equiv allyl alcohol, 3 equiv TSNT, pyridine, 24 h, 0°C, 86%; b) 80% acetic acid, 3 h, RT, 100%; c) 1 equiv **6**, pyridine, 4 equiv TSNT, 14 h, 0°C, 65%; d) $Pd[(PPh_3)]_4$, PPh_3, diethylammonium hydrogen carbonate, CH_2Cl_2, 1 h, 70%.

The assembly of the oligomer was carried out on aminohexylsuccinyl–CPG solid support analogously to PNA synthesis.[7f] The synthesis cycle (Scheme 4) consists of

removal of the Mmt group with 80% acetic acid and coupling of the dimer block **11**. The use of a fourfold excess of **11** and HATU as the coupling reagent[13] resulted in coupling efficiencies of greater than 90%. After completion of oligomer assembly the N-terminus was acetylated with acetic anhydride, and the NPE groups were removed by treatment with 0.5 M DBU in acetonitrile. The oligomer **12** was then cleaved from the solid support by treatment with concentrated NH_4OH and purified by polyacrylamide gel electrophoresis. The highly water-soluble oligomer **12** was characterized by HPLC and electrospray-MS; its mass is 3575.7 (calculated: 3576.0).

The binding properties of alternating PHONA-PNA co-oligomer **12** were investigated by hybridization with complementary $(dA)_{12}$. On heating the hybrid gives a clear phase transition (Figure 1), with a melting temperature of 62.6°C.

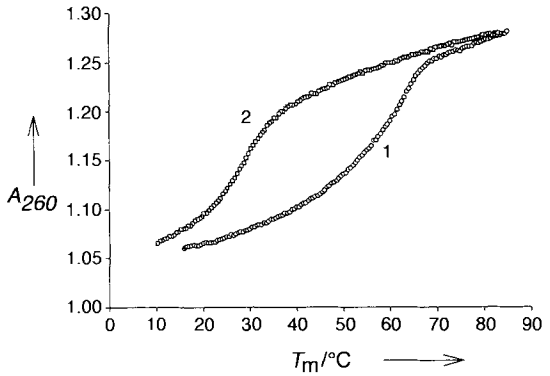

Figure 1. Determination of the melting temperature of the hybrid formed by $d(A)_{12}$ and **12** in the ratio 1:1 by UV spectroscopy at 270 nm. Buffer: 140 mM KCl, 10 mM NaH_2PO_4, 0.1 M EDTA, pH = 7.4; heating and cooling rate: 1 K min^{-1}.

As with PNAs, however, the cooling curve displays a marked hysteresis, with a melting temperature of 29.0°C. The sequence specificity of the binding is clearly demonstrated by the drastic drop in melting temperature on introduction of a mismatch in the complementary DNA strand. Replacement of just one (dA) by (dG) to give **14** results in a drop in T_m to 52.3°C. Replacement of two neighboring (dA)'s by $(dG)_2$ to give **15** gives twice as large a drop in T_m to 39.5°C, and replacement of two nonneighboring (dA)'s to give **16** reduces the T_m to 36.9°C. In this case no phase transition could be observed on cooling. Under the same conditions the corresponding DNA·DNA duplex had a melting temperature of 29.3°C (Table 1).

Comparison with the UV-melting properties of DNA·DNA and PNA·DNA complexes (the T_m of the complex of PNA-T_{10} with $(dA)_{10}$ is 73°C[14]) indicates that PHONA-PNA co-oligomers resemble the latter more closely. The prediction that in this case, as with PNAs, triple-helical structures are formed was confirmed by measurement of a Job plot.[15] (Figure 2; 2:1 ratio of **12** to $(dA)_{12}$). In addition the UV-melting behavior of a 1:1 and a 2:1 ratio of **12** to $(dA)_{12}$ are identical, the only difference being a doubling of the

Table 1. Melting temperatures T_m of **12** with completely or partially complementary DNA (ratio 1:1; buffer 140 mM KCl, 10 mM NaH_2PO_4, 0.1 M EDTA, pH = 7.4).

Strand 1	Strand 2	T_m[°C][a]	T_m[°C][b]
$(dA)_{12}$ **13**	**12**	62.6	29.0
$(dA)_6dG(dA)_5$ **14**	**12**	52.3	17.1
$(dA)_5(dG)_2(dA)_5$ **15**	**12**	39.5	15.0
$(dA)_3dG(dA)_3dG(dA)_4$ **16**	**12**	36.9	–
$(dA)_{12}$ **13**	$(dT)_{12}$	29.3	29.0

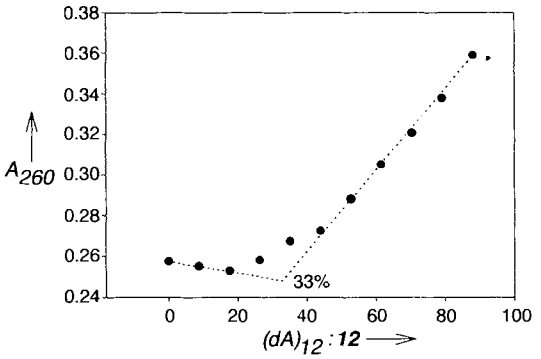

Figure 2. Job plot (continuous titration) of the interaction between **12** and $d(A)_{12}$: UV absorption at 260 nm versus mole ratio $d(A)_{12}$/**12** at 20°C, 500 mM NaCl, 10 mM HEPES, pH 7.5; 2 h equilibration before each measurement.

change in absorbance at the phase transition. Presumably half of the $(dA)_{12}$ present is bound in a $(\mathbf{12})_2 \cdot (dA)_{12}$ complex, and the other half is unbound. The hysteresis observed on cooling is possibly due to formation of the $\mathbf{12} \cdot (dA)_{12}$ duplex, which would suggest relatively slow kinetics for the formation of the triple helix.[16]

The high melting temperature of 62.6°C shows that the PHONA-PNA transitions cause very little structural perturbation in the triple helix. The somewhat lower melting temperature relative to that of $(PNA)_2 \cdot DNA$ triple helices is easily explained by the repulsion of the negative charges of the phosphate and phosphonate groups. These charges reverse the dependence of the melting temperature on salt concentration that is observed for PNAs. Changing the buffer salt concentration from 140 mM KCl to 500 mM NaCl had very little effect on the melting temperature (T_m = 64.7°C).

We have described the synthesis of new nucleic acid mimetics, the alternating PHONA-PNA co-oligomers. Their binding properties with complementary DNA are very similar to those of PNAs, but they have a much better water solubility. The synthesis and binding properties of mixed sequences, as well as the evaluation of cellular uptake and stability under biological conditions, will be reported separately.

Cylindrical Molecular Brushes**

Peter Dziezok, Sergei S. Sheiko, Karl Fischer, Manfred Schmidt,* and Martin Möller

Regular brush- or comblike macromolecules are principally accessible by homopolymerization of macromonomers. Until recently, however, the degree of polymerization of the main chain did not significantly exceed the length of the macromonomer itself, and almost spherical or starlike structures were obtained. The work presented here was initiated by a report from Tsukahara et al., who successfully polymerized methacryloyl end functionalized polystyrene macromonomers with extremely high degrees of polymerization ($P_w \approx 1000$).[1] The subsequent characterization clearly demonstrated that such molecules adopt the structure of a cylindrical brush with an extremely stiff main chain and a Kuhn statistical segment length of $l_k \approx 1000-2000$ Å.[2] The stiffness of the normally flexible polymethacrylic main chain originates from overcrowding of the side chains; a polystyrene chain with a molar mass of 2000–4000 g mol^{-1} is attached to the main chain every 2.5 Å.[3–5]

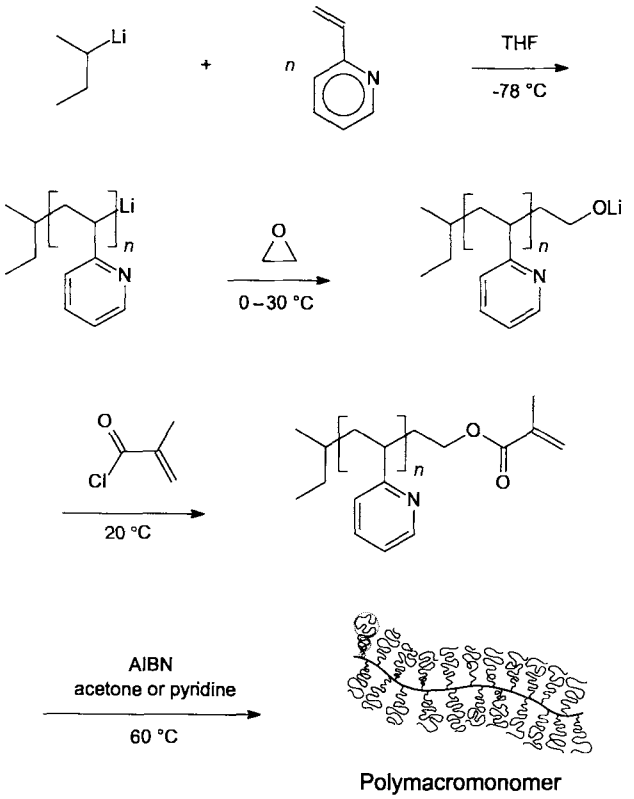
We report here on the synthesis and structure of a polymacromonomer consisting of poly-2-vinylpyridine (PVP). Compared to polystyrene (PS), polyvinylpyridine has many advantages: It is easily converted into a polyelectrolyte brush, complexed by heavy metal ions, and undergoes strong interactions with various polar substrates. The PVP macromonomer was prepared according to Scheme 1. The



Scheme 1. Synthesis of the PVP polymacromonomer; AIBN = azobis(isobutyronitrile).

success of the synthesis was monitored by matrix-assisted laser-desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry (Figure 1). Free radical polymerization

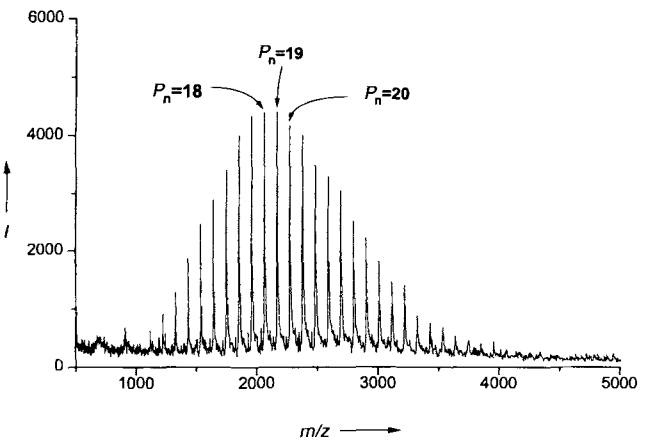


Figure 1. MALDI-TOF mass spectrum of a PVP macromonomer (intensity I in arbitrary units). The signals indicate different degrees of polymerization (P_n). The molar masses for the individual peaks are within ±0.5 Dalton of the expected molar masses of the end-functionalized PVP.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2812 $ 17.50+.50/0

of the PVP macromonomers ($M_n = 2.350\,g\,mol^{-1}$, $M_w/M_n = 1.07$) yields the polymacromonomer with high degrees of polymerization (see Table 1). To achieve high molar masses the macromonomer has to be very clean, and the polymerization has to be conducted at high concentrations (i. e., 70% macromonomer in acetone or pyridine) to form a highly viscous solution which strongly decreases the diffusion of the growing chain even at low conversion. In contrast to PS polymacromonomers, PVP polymacromonomers could not yet be characterized by multi-angle light-scattering gel permeation chromatography (GPC), because of bleeding of particles (80–100 nm in size) from the column in DMF, the solvent of choice for PVP.

Table 1. Results of light-scattering experiments with cylindrical PVP brushes.

Sample	M_w [g mol^{-1}]	R_g [nm]	R_h [nm]	l_k [a]
PVP-PMA	2.7×10^6	70	34	900

[a] Calculated from R_g and R_h by assuming a Schulz–Flory distribution of the molar mass.

The PVP polymacromonomers were deposited from a dilute solution on freshly cleaved mica. To visualize single molecules a highly diluted solution ($c = 0.02\,g\,L^{-1}$) of PVP polymacromonomers in chloroform was sprayed onto mica (Figure 2). Owing to the strong interaction of PVP with mica the molecules are "squeezed" onto the surface, as their width $d = 10 \pm 1$ nm is significantly larger than their height $h = 2.3 \pm 0.1$ nm. The width was estimated by considering the radius of the AFM tip (AFM = atomic force micro), which was determined to be $r_a = 8-10$ nm as described before.[10] In addition, the width can be determined from the lateral periodicity in the condensed films (see Figures 4–6). Both values agree fairly well. Assuming an ellipsoidal cross section with $h = 2.3 \pm 0.1$ nm and $d = 10 \pm 1$ nm and taking into account the known ratio of mass to length, the density within a single macromolecule is determined to be $\rho = 0.87 \pm 0.2\,g\,cm^{-3}$. This value is consistent within experimental uncertainty with the bulk density of PVP. As shown in Figure 2b, the diameter of the molecules vary within one molecule to resemble a caterpillar. The periodicity along the contour line is roughly 20 nm. The uneven thickness of the molecules is consistent with laterally inhomogeneous structures observed for planar polymer brushes at intermediate grafting densities.[11–13]

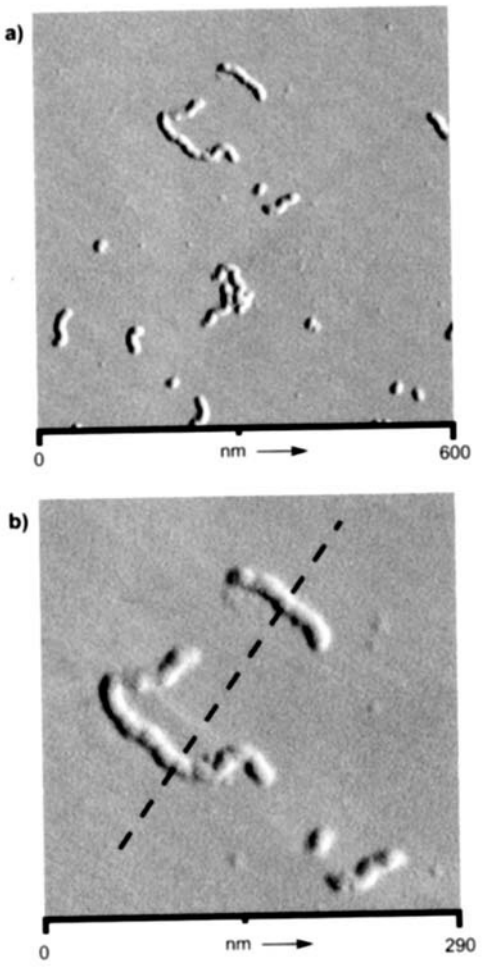

Figure 2. a), b) AFM images of cylindrical brushes of polyvinylpyridine prepared by spraying a solution in chloroform ($0.02\,g\,L^{-1}$) onto the surface of mica. b) The enlargement makes clear the caterpillarlike shape of the brushes. The thickness of the adsorbed molecules was determined to 2.2 nm from the cross-sectional profile recorded along the dashed line.

To exclude the possibility that the caterpillarlike structures consist of end-to-end aggregated short segments, we compared the mean length of the molecules with the absolute molar mass determined by static light-scattering experiments. The lengths of 278 molecules were averaged to yield a number average contour length of $L_n^{AFM} = 57$ nm and a weight average contour length of $L_w^{AFM} = 89$ nm. A histogram of the chain-length distribution is given in Figure 3. The value of L_w^{AFM} has

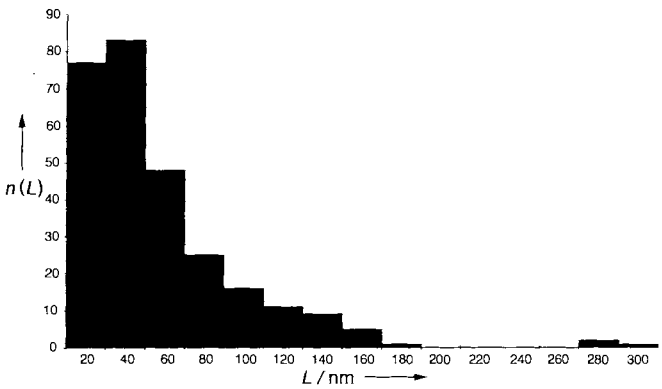

Figure 3. Histogram of the chain-length distribution measured by AFM.

to be related to the molar mass $M_w = 2.7 \pm 0.1 \times 10^6\,g\,mol^{-1}$, which was determined by light-scattering experiments in ethyl methyl ketone (MEK). Assuming an all-*trans* conformation for the main chain, a value of $L_w^{LS} = 287$ nm results, which is clearly larger. This comparison qualitatively demonstrates that the AFM technique provides images of "real" cylindrical brushes and not end-associated short fragments. However, the problem is to how to account quantitatively for the difference between L_w^{AFM} and L_w^{LS}; this seems to be beyond the experimental error of either technique.

Owing to the lack of good solvents for PVP, aggregation could falsely increase the molar mass determined by light-scattering experiments in MEK. Comparison with data on PS cylindrical brushes dissolved in the excellent solvent toluene render this possibility as extremely improbable, as both cylindrical brushes exhibit almost identical molecular characteristics (i. e., identical Kuhn statistical segment lengths). This

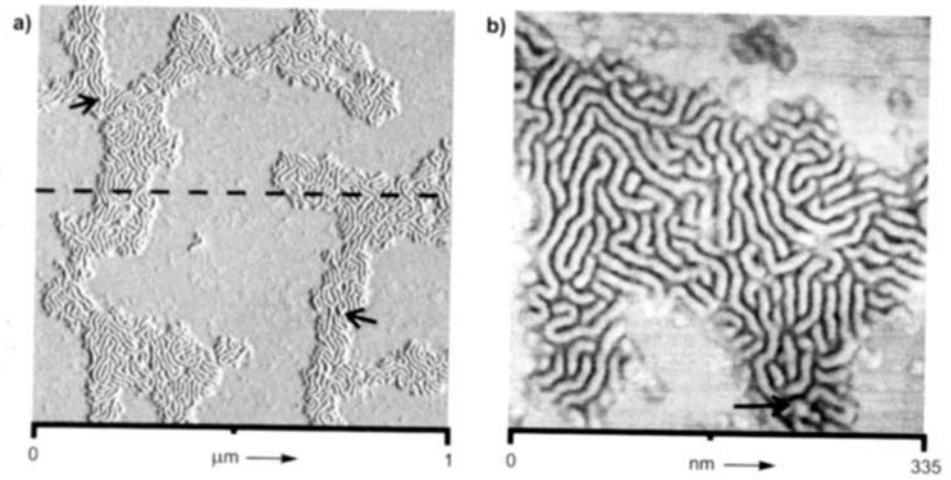

Figure 4. a) Amplitude and b) phase AFM images of a thin film prepared by spin-casting the polyvinylpyridine brushes onto the surface of mica from a solution in chloroform (0.07 $g L^{-1}$). The phase image of the enlarged area (bottom left in a) allows complete resolution of single molecules with clear discrimination of the chain ends. The cross-sectional profile recorded along the dashed line in a) yields a monolayer thickness of 2.2 ± 0.2 nm. The two arrows in a) indicate crossed molecules which are shown in detail in Figure 5.

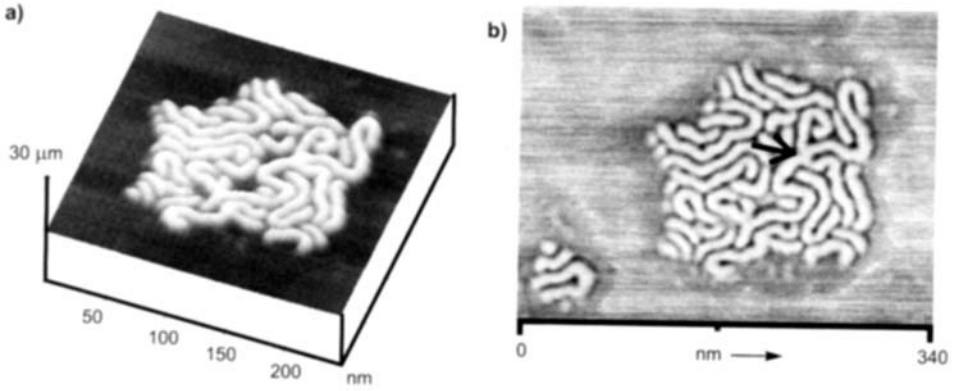

Figure 5. a) Three-dimensional and b) phase AFM images of a monolayer island obtained by spin-casting a solution in chloroform (0.04 $g L^{-1}$) onto mica. Two crossed molecules are marked by the arrow in b). The enlarged topographic image in a) clearly shows that one molecule lies above the other.

agreement is expected, because the chain stiffness should not depend on the chemical nature of the monomer units but rather on the degree of spatial overcrowding of the side chains, which is comparable for both samples. Alternatively, the contour length per monomer unit could be less than 2.5 Å (the value for an all-*trans* chain) due to a helical conformation of the main chain. This would yield the contour length per monomer unit to be only 0.8 Å, which seems to be too small. Even in the most extended rodlike conformation a radius of gyration of $R_g \approx 45$ nm would result; this is much smaller than the measured value of $R_g \approx 70$ nm. We are currently investigating this discrepancy.

To prepare monolayers a drop of a solution of polymer in chloroform (concentrations between 0.02 and 1 $g L^{-1}$) was typically spin-casted onto mica. Depending on the concentrations the polymer forms a more or less incomplete monolayer with an uniform thickness of about 2.2 nm (Figure 4, $c = 0.07\ g L^{-1}$). The small depositions in the dewetted areas of the substrate are attributed to a small fraction of unchanged PVP macromonomers. The topographic and phase images in Figure 4 demonstrate remarkable contrast and resolution of the densely packed brushes. Apparently, individual molecules do not overlap; that is, the side chains of adjacent molecules do not interdigitate. The formation of hairpins (tight backfolds) might be explained by the dewetting process in which capillary forces as well as adsorption are effective.[14]

At higher magnification it can be seen that some molecules in the monolayer lie across others (marked by arrows in Figure 4, 5). The height at the intersections shown in Figure 5a is about 3.2 nm, which is smaller than twice the thickness of the monolayer (4.4 nm). This might indicate either some deformation or molecular interdigitation of the side chains of the two polymers at the crossing point. Crossed and backfolded molecules are also depicted in Figure 6, which shows a fragment of a sample where the substrate was covered completely by a monolayer prepared by spin-casting a solution of concentration 0.14 $g L^{-1}$. Again, the irregularly but densely packed molecules hardly overlap with the exception of the crossed molecules, which are seen in the micrograph in Figure 6 as protrusions above the film surface. When the samples were annealed above the glass-transition temperature, the observed structures do not change.

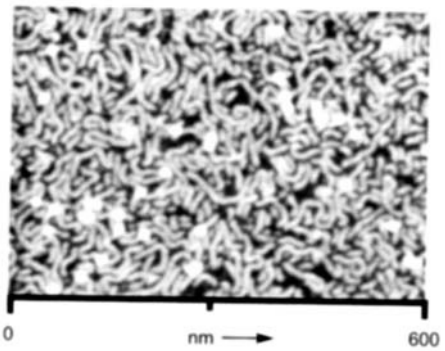

Figure 6. A height AFM image of a complete monolayer prepared by spin-casting a solution in chloroform (0.14 $g L^{-1}$). The white areas correspond to elevations due either to crossed molecules or protruding chain ends.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2814 $ 17.50+.50/0

In conclusion, intersections and hairpins are rather typical defects in the regular packing or ordering of the brushes in monolayers. This documents the essential differences in the adsorption behavior of linear flexible macromolecules and stiff brushes;[15-17] the latter are more likely to form trains rather than loops on the surface. A more perfect order—that is, straightening and disentangling of the brushes—may be enforced by charging the vinylpyridine units chemically. Therefore, such polyelectrolyte brushes may constitute a unique system for preparing striped patterns whose periodicity is defined on a sub 10 nm scale.

Experimental Section

The PVP macromonomer with a methacrylate end group was prepared by anionic polymerization as shown in Scheme 1. Tetrahydrofuran was dried over $LiAlH_4$, degassed by three freeze–thaw cycles on a vacuum line, and then destilled directly into the reaction vessel. 2-Vinylpyridine (2-VP) was dried over calcium hydride for 24 h, degassed, and destilled under reduced pressure. 2-VP (20–25 g) was dissolved in THF (≈500 mL), and the polymerization started at about −90 °C by *sec*-BuLi. The solution was dark red. After completion of the polymerization the "living" anions were terminated with excess ethylene oxide. Subsequently, the chains with terminal hydroxy groups were esterified with excess methacryloyl chloride at room temperature for 12 h. The resulting macromonomer was purified three times by precipitation of a solution of 2-propanol with petroleum ether (40–60 °C) and then freeze-dried in benzene.

For the free radical polymerization AIBN (20 mg; purified by recrystallization from methanol), was dissolved in 20 mL of acetone or pyridine and carefully degassed. The macromonomer (5 g) was then dissolved in a solution of the initiator (2.5 mL) for 12 h to yield an extremely viscous solution, which was kept at 60 °C in a thermostate bath for one week. During polymerization a phase separation occured into a polymacromonomer rich gel phase and a liquid phase; towards the end of the reaction only the gel phase was present. Addition of more acetone or pyridine resulted in a homogeneous solution, from which the polymer was precipitated with petroleum ether. The maximum yield of polymer was on the order of 70%. The unchanged macromonomer was fractionated off by precipitation with 2-propanol/petroleum ether (1/2).

The atomic force micrographs were recorded at ambient conditions with a Nanoscope III instrument (Digital Instruments, St. Barbara, USA) operating in the tapping mode [6] at a resonance frequency of about 300 kHz. The Si probes had a spring constant of about 50 $N m^{-1}$. In this mode a cantilever with a sharp tip is oscillated by a piezo driver near its resonance frequency. As the tip taps the surface both the amplitude and the phase of the oscillation change, which allows recording of images with a topographic or viscoelastic contrast [7–9].

The First Structurally Authenticated σ-Bonded Organosamarium(II) Derivative and Its Reaction with Benzophenone

William Clegg, Colin Eaborn, Keith Izod,* Paul O'Shaughnessy, and J. David Smith

Until recently the organometallic chemistry of the three lanthanide elements stable in the +2 oxidation state (Sm, Eu, Yb) was confined to compounds containing cyclopentadienyl-type ligands.[1] Despite much progress in the synthesis of σ-alkyl derivatives of ytterbium(II) and europium(II),[1b] such as the dialkyl compounds $Yb\{C(SiMe_3)_3\}_2$ and $Eu\{C(SiMe_3)_3\}_2$,[2,3] the isolation of a σ-bonded organosamarium(II) complex has remained an elusive goal. We now describe the synthesis and molecular structure of **1**, which contains Sm–C σ bonds, and report its reaction with benzophenone to give the ketyl radical anion complex **2.** Compound **1** was obtained in high yield from the reaction of $[SmI_2(thf)_2]$ with two equivalents of $K\{C(SiMe_3)_2(SiMe_2OMe)\}$ in THF and isolated as air-sensitive, deep green-black crystals.

$[Sm\{C(SiMe_3)_2(SiMe_2OMe)\}_2(thf)]$ **1**

$[Sm\{C(SiMe_3)_2(SiMe_2OMe)\}_2(OCPh_2)]$ **2**

An X-ray diffraction study[4] of **1** revealed that the samarium atom lies in a distorted square pyramidal environment with each alkyl ligand bound through both its carbanion center and the oxygen atom of its methoxy substituent to give a four-membered chelate ring. The coordination sphere of samarium is completed by a molecule of THF at the apex of the pyramid (Figure 1). The Sm–C1 and Sm–C2 distances of 2.787(5) and 2.845(5) Å, respectively, are the first Sm^{II}–C σ bonds lengths to be measured. These values are about 0.3–0.5 Å larger than those found for the Sm^{III}–$C(sp^3)$ bonds in $Sm\{CH(SiMe_3)_2\}_3$ (2.33(2) Å)[5] and for the terminal alkyl group in $[(thf)Li(\mu\text{-}CH_2SiMe_3)(\mu\text{-}OAr)Sm(CH_2SiMe_3)(\mu\text{-}OAr)_2Li(thf)]$ (2.451(10) Å; Ar = 2,6-$iPrC_6H_3$).[6] A smaller difference of about 0.19 Å between the Sm^{II}–C and the Sm^{III}–C σ bonds would be expected from consideration of the reported ionic radii for Sm^{II} and Sm^{III}.[7] The Sm–O1, Sm–O2, and Sm–O(thf) distances in **1** are similar to several previously determined Sm^{II}–O(thf) distances.[8,9]

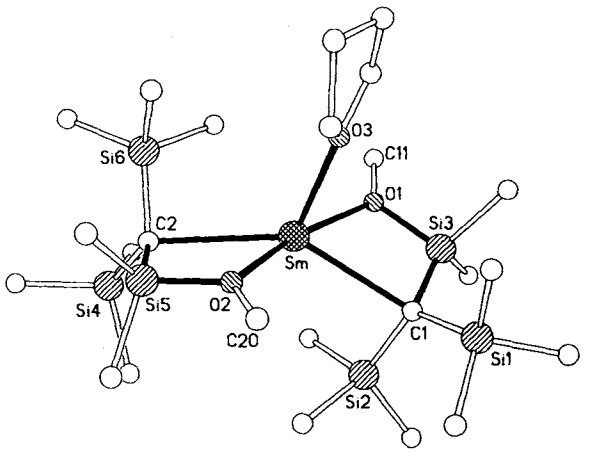

Figure. 1. Molecular structure of **1**. Selected bond lengths [Å] and angles [°]: Sm–C1 2.787(5), Sm–C2 2.845(5), Sm–O1 2.570(3), Sm–O2 2.520(3), Sm–O3 2.545(4); C1-Sm-O1 62.11(12), C1-Sm-C2 144.67(12), C1-Sm-O3 101.06(13), O3-Sm-O1 90.40(13), C2-Sm-O3 110.43(13), O2-Sm-O3 84.55(12).

Samarium diiodide is widely used as a reagent in organic synthesis and is believed to give organosamarium intermediates in Barbier-type SmI_2-mediated additions of alkyl halides to ketones.[10,11] We were interested to see whether ketones would undergo a Grignard-type reaction with **1** or give a ketyl radical anion complex similar to the recently described $[Sm^{III}(OC_6H_3\text{-}2,6\text{-}t\text{Bu-}4\text{-}Me)_2(OC_{13}H_8)(thf)_2]$ (**3**), isolated as an intermediate in the pinacol coupling of fluorenone.[12]

Reaction of **1** with one equivalent of benzophenone in light petroleum resulted in an immediate color change from dark green to deep purple. Crystallization of the resulting compound **2** from methylcyclohexane gave dark purple crystals, which exhibited broad peaks in their ^1H NMR spectrum that could be assigned to the alkyl ligands, but no signals for the benzophenone.

An X-ray crystallographic study revealed that **2** has a very similar molecular structure to **1**,[13] but with a molecule of benzophenone bound through its oxygen atom in place of the THF (Figure 2). The essentially isostructural nature and identical coordination numbers of **1** and **2** allow the bond lengths and angles within the two molecules to be compared directly and provide a method for determining whether the benzophenone is bound as a neutral ketone or as a ketyl radical anion. The Sm–C1 and Sm–C2 distances in **2** are 2.625(5) and 2.631(5) Å, respectively, approximately 0.19 Å shorter than the corresponding bond lengths in **1** (consistent with a change in oxidation state from Sm^{II} to Sm^{III}).[7] Similarly, the Sm–O1 and Sm–O2 distances of 2.367(3) and 2.387(3) Å in **2** are approximately 0.17 Å shorter than the corresponding distances in **1**. This strongly indicates that **2** is a Sm^{III} complex of a ketyl radical anion. In support of this, bond lengths and angles within the benzophenone fragment are very similar to those found for fluorenone in **3**.[12] The absence of signals due to benzophenone in the ^1H NMR spectrum of **2** is also consistent with its being bound as a delocalized ketyl radical anion.

In contrast to the behavior observed for **3**, we observed no change upon dissolution of **2** in noncoordinating solvents such as light petroleum or methylcyclohexane. This may be because the sterically demanding alkyl ligands in **2** impede further reaction.

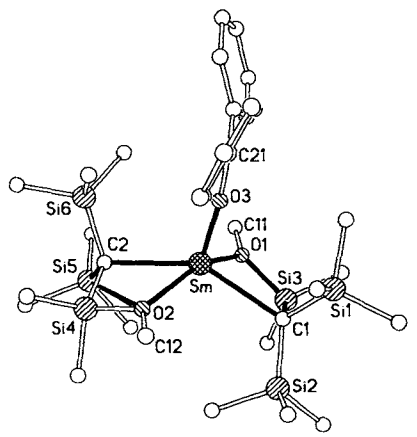

Figure. 2. Molecular structure of **2**. Selected bond lengths [Å] and angles [°]: Sm–C1 2.625(5), Sm–C2 2.631(5), Sm–O1 2.367(3), Sm–O2 2.387(3), Sm–O3 2.093(3), C21–O3 1.346(6); C1-Sm-O1 66.10(13), C1-Sm-C2 142.33(15), C1-Sm-O3 105.81(14), O3-Sm-O1 107.93(13), C2-Sm-O3 111.67(14), O2-Sm-O3 99.12(12).

Experimental Section

1: A solution of $[K\{C(SiMe_3)_2(SiMe_2OMe)\}]$ (0.99 g, 3.45 mmol) in THF (30 mL) was added to a solution of $[SmI_2(thf)_2]$ (0.97 g, 1.77 mmol) in THF (20 mL). The mixture was stirred at room temperature for three days, the solvent then removed under reduced pressure, and the residue extracted with methylcyclohexane (40 mL). The extract was filtered and the filtrate concentrated to 10 mL, then kept at −30 °C for 12 h to give dark green crystals of **1**. Yield 0.90 g (71 %), m.p. 120 °C (decomp); elemental analysis calcd. for $C_{24}H_{62}O_3Si_6Sm$: C 40.14, H 8.71;. found C 39.23, H 8.81; ^1H NMR (500 MHz, C_6D_6, 25 °C): $\delta = -9.22$ (s, 6H; $SiMe_3$), −7.06 (s, 3H; MeO), 4.28 (s, 18H; $SiMe_3$), 6.94 (s, br, 2H; THF), 19.29 (s, br, 2H, THF); EIMS (70 eV): *m/z* (%): 648 (18) $[M^+ - THF]$, 249 (20) $[C(SiMe_3)_2(SiMe_2OMe)$ (R)], 233 (100) [RH − Me], 217 (30) [RH − MeO], 73 (90) $[Me_3Si]$.

2: A solution of benzophenone (0.01 g, 0.2 mmol) in light petroleum (b.p. 40–60 °C, 5 mL) was added to a solution of **1** (0.15 g, 0.21 mmol) in the same solvent (15 mL). The mixture was stirred for 1 h and the solvent then removed under vacuum. The residue was crystallized from cold (−30 °C) methylcyclohexane (2 mL) to give deep purple crystals of **2**. Yield 0.08 g (69 %), m.p. 105 °C (decomp); ^1H NMR (500 MHz, C_6D_6, 25 °C): $\delta = -1.81$ (s, 3H; OMe), −0.12 (s, br, 18H; $SiMe_3$), 3.25 (s, br, 6H; $SiMe_2$).

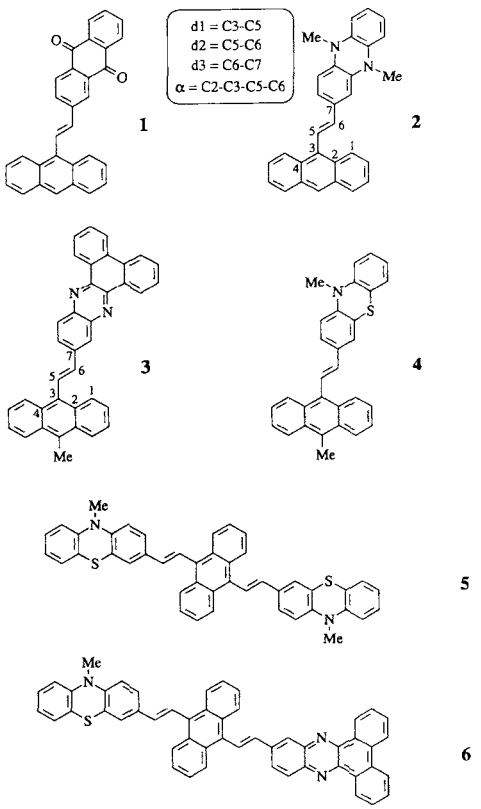
Stuctural Reorganization of Anthracene-Bridged Stilbenoids by Oxidation and Reduction**

Andreas Knorr and Jörg Daub*

Compounds with conjugated extended π-electron systems are most promising for generating new optoelectronic materials and models for energy and electron transfer as well as for mimicking charge separation. Furthermore, there are additional conceivable applications in display and optical storage devices, electrochromic materials, and systems for optoelectronic switching.[1] Simple stilbenoid pyrenes and anthracenes were recently studied due to their electrochemically generated luminescence (ECL) and application in organic light-emitting diodes (OLEDs).[2] Here we report the oxidation and reduction properties of anthracene systems **5** and **6**, which are composed of electron transfer active stilbenoid subunits that are covalently linked through the 9,10-positions of anthracene. The investigations by cyclic voltammetry and spectroelectrochemical combination techniques were supplemented by semiempirical quantum mechanical calculations.

Derivatives **1**, **4**, and **5** was synthesized by a Wittig reaction of [2-(anthraquinone)methyl]triphenylphosphonium bromide with anthracene-9-carbaldehyde (formation of **1**) or from [3-(10-methyl-10*H*-phenothiazinyl)methyl]triphenylphosphonium bromide with 10-methyl-9-anthracenecarbaldehyde (formation of **4**) or anthracene-9,10-dicarbaldehyde (formation of **5**). Compound **2** was obtained by the reaction of 5,10-dihydro-5,10-dimethyl-2-phenazincarbaldehyde with (9-anthrylmethyl)triphenylphosphonium bromide, and **6** was synthesized by a random 1:1 Wittig reaction of anthracene-9,10-dicarbaldehyde with [11-(dibenzo[*a*,*c*]phenazinyl)methyl]triphenylphosphonium bromide followed by treatment of the formed monoaldehyde with [3-(10-methyl-10*H*-phenothiazinyl)methyl]triphenylphosphonium bromide. Compound **3** was obtained by the reaction of 10-methyl-9-anthracenecarbaldehyde with [11-(dibenzo[*a*,*c*]phenazinyl)methyl]triphenylphosphonium bromide. All reactions, except for the synthesis of **1** (in EtOH/NEt_3), were carried out in THF under an N_2 atmosphere with *n*BuLi as base,[3] and led exclusively to (*E*)-stilbenes; the analogous (*Z*)-stilbenes could never be detected.[4]



Investigations of **1**–**6** by cyclic voltammetry show reversible oxidations and/or reductions. With the exception of the two-electron wave for the oxidation of **5**, all redox reactions involve the transfer of one electron. The electrochemical processes take place at significantly lower potential than for the corresponding basis compounds (Table 1), which indicates an interaction between the functional groups and the anthracene unit. Even the comparison of the oxidations of **4** and **5** as well as of the second reduction steps of **3** and **6** demonstrates the effect of this interaction (Table 1).

Spectroelectrochemistry confirms the findings of cyclic voltammetry and provides insight into the absorption characteristics of the radical ions and respective dications and dianions. Compounds **1**–**6** show a significant red shift of the lowest energy absorption bands when compared with the corresponding absorption bands for radical ions of the basis compounds (Table 1). Doubly charged species such as dianions $\mathbf{1}^{2-}$, $\mathbf{3}^{2-}$, and $\mathbf{6}^{2-}$ or dications $\mathbf{2}^{2+}$ and $\mathbf{5}^{2+}$ exhibit strong absorptions in the near-infrared region, which is in agreement with the presence of a highly delocalized quinoid species (Table 1 as well as Figures 1 and 2).

[a] A standard one-compartment, three-electrode arrangement was used with a platinium-disc working electrode and a pseudo Ag/AgCl reference. The reversible oxidation signal of ferrocene/ferrocenium (FOC) was used as an internal standard. Tetra-*n*-butylammonium hexafluorophosphate (TBAHFP) was the supporting electrolyte in all measurements, and the scan rates were 250 mV s^{-1}. All experiments were carried out under N_2. [b] The number of transferred electrons was obtained by referencing against ferrocene. [c] After cyclic voltammetry the solutions of substrate were transferred with a syringe into the previously described spectroelectrochemical cell [7]. [d] Reference compounds: anthraquinone red 1 −1320 mV/980 nm, red 2 −1920 mV/638 nm (MeCN); 9,10-dimethylphenazine ox 1 −245 mV/724 nm, ox 2 509 mV/538 nm (MeCN); phenothiazine ox 325 mV/846 nm (MeCN); 11-methyldibenzo[*a*,*c*]-phenazine red 1 −1920 mV/928 nm, red 2 /590 nm, anthracene red −2415 mV, ox E_{pa} 900.

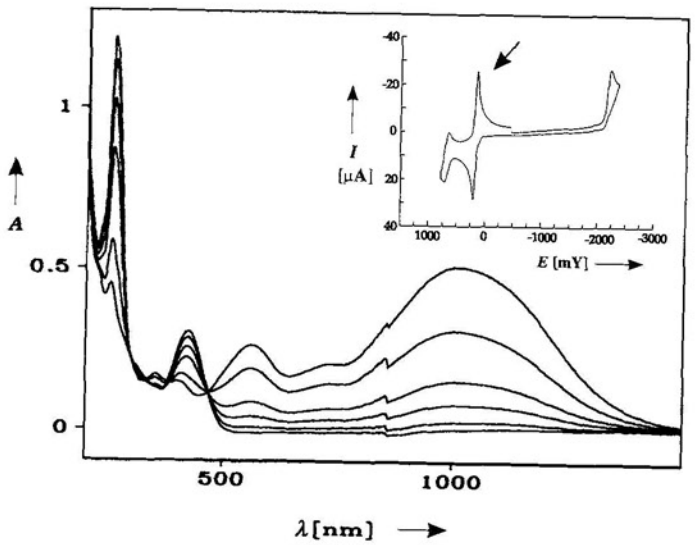

Figure 1. Spectroelectrochemistry of the oxidation of **5** to 5^{2+}; inset: the cyclovoltammogram.

To clarify the molecular and electronic structures of the species obtained by reduction and oxidation, semiempirical quantum mechanical calculations with the programs AM1 and PM3 were carried out for **2** and **3**.[5] The calculated bond lengths and dihedral angles (Table 2) allow the following conclusions: The neutral compounds show a basically decoupled set of chromophores, whereas the corresponding radical cations or anions exhibit increased interaction between the stilbenoid subunits. This is indicated by a decrease in the dihedral angles and by changes in the bond length (Table 2).

Table 2. Calculated bond lengths and dihedral angles for **2** and **3**.

	Compound	d1 [Å]	d2 [Å]	d3 [Å]	α [°]
AM1 calculations	**2**	1.460	1.342	1.453	61
	$2^{\bullet+}$	1.458	1.345	1.449	56
	2^{2+}	1.368	1.433	1.367	8
	3	1.461	1.341	1.455	64
	$3^{\bullet-}$	1.452	1.352	1.434	56
	3^{2-}	1.365	1.430	1.366	7
PM3 calculations	**2**	1.466	1.339	1.460	72
	$2^{\bullet+}$	1.463	1.343	1.455	65
	2^{2+}	1.371	1.430	1.369	5
	3	1.467	1.338	1.461	81
	$3^{\bullet-}$	1.461	1.344	1.449	66
	3^{2-}	1.367	1.432	1.366	7

The doubly charged ions of **2** and **3** have almost planar quinoid structures; comparable results were obtained for **1**, **5**, and **6** (Figure 2).[6] The lowest energy UV transitions for the

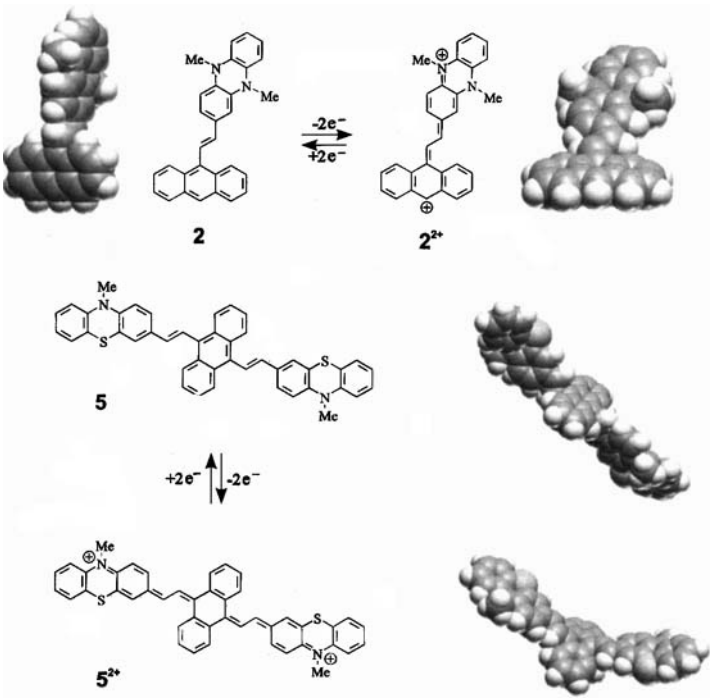

Figure 2. Calculated structures (AM1) of the neutral molecules as well as the dications of **2** and **5**.

dications and dianions of **2** and **3** evaluated by semiempirical limited-CI calculations using a continuum solvent model[8] and the predicted planar quinoid structure are in good agreement with the experimental data: For 2^{2+} the HOMO–LUMO-dominated allowed transitions at 854 (AM1, MeCN) and 1096 nm (PM3, MeCN) were obtained (experimental: 1035 nm, MeCN). For 3^{2-} the calculation yields HOMO–LUMO-dominated allowed transitions at 915 (AM1, CH_2Cl_2) and 1332 nm (PM3, CH_2Cl_2; experimental: 1020 nm, THF.)

The experimental and theoretical findings show that one-electron transfer results in increased coupling of the subunits which do not interact in the neutral forms. The formation of the doubly charged species is accompanied with even more

[5] a) AM1: M. J. S. Dewar, E. G. Zoebisch, E. F. Healy, J. J. P. Stewart, *J. Am. Chem. Soc.* **1985**, *107*, 3902; b) PM3: J. J. P. Stewart, *J. Comput. Chem.* **1989**, *10*, 209; c) G. Rauhut, A. Alex, J. Chandrasekhar, T. Steinke, T. Clark, VAMP5.01, Oxford Molecular Ltd., Oxford, **1993**. d) The geometries of closed-shell species were optimized using the RHF formalism, and those of open-shell species were treated with the AUHF formalism. All obtained structures were characterized as stationary points on the energy surface by vibrational analysis.

[6] The calculations of the neutral species showed that rotation about bond d1 leads to two transition states with dihedral angles α of 10° and 90°: **2** (10°): 8.80 (AM1), 4.20 kcal mol^{-1} (PM3); **3** (10°): 8.53 (AM1), 4.46 kcal mol^{-1} (PM3); **2**: (90°): 0.34 (AM1), 0.05 kcal mol^{-1} (PM3); **3** (90°): 0.25 (AM1), 0.03 kcal mol^{-1} (PM3). Activation enthalpies of 1.63 to 1.26 kcal mol^{-1} were found for rotation about bond d3 depending on the model system and the hamiltonian used. An analagous calculation for the correponding dication of **2** and dianion of **3** showed that rotation about bonds d1, d2, and d3 have activation barriers between 21.18 and 26.25 kcal mol^{-1}, again depending on the compound and the semiempirical method applied. It is remarkable that rotation about bond d2 (a formal single bond) leads to such high energy barriers. Furthermore, according to the semiempirical calculations the s-*cis* conformation of these doubly charged species represents a transition state and not a minimum on the energy surface of the rotation process (all transition states were characterized by vibrational analysis).

[8] For the limited-CI calculation the four highest occupied and four lowest unoccupied orbitals using only single and pairwise double excitation microstates were considered. Implementation of a perpendicular geometry for 2^{2+} and 3^{2} in the calculation of the UV transitions yields numbers that significantly deviate from the experimental findings. For computational details, see ref. [5c].

Complexes with Sb_2 and *cyclo*-Sb_3 Ligands: The Tetrahedranes $[\{C_5H_5(CO)_2Mo\}_2Sb_2]$, $[C_5H_5(CO)_2MoSb_3]$, and $[C_5Me_5(CO)_2MoSb_3]$**

Hans Joachim Breunig,* Roland Rösler, and Enno Lork

Dedicated to Professor Ionel Haiduc on the occasion of his 60th birthday

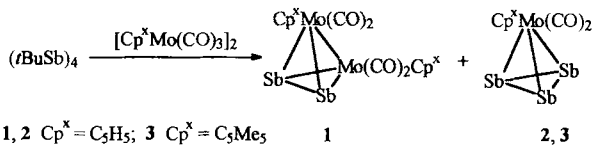
Although complexes with organosubstituent-free *cyclo*-P_n or *cyclo*-As_n ligands ($n = 3-6$) have been investigated intensively,[1] analogous compounds with *cyclo*-Sb_n ligands have not yet been described. Known complexes contain Sb_1,[1] Sb_2,[2] Sb_3^{3-},[3] Sb_7^{3-}[4] or organoantimony rings[5] as ligands. An interesting example of an Sb_2 complex is the tetrahedrane derivative **1**,[2] described by Rheingold, which can be considered an analogue of Sb_4. We report here on a favorable synthesis of **1** and on the preparation and the structure of **2** and **3**, the first complexes with *cyclo*-Sb_n ligands.

$[\{C_5H_5(CO)_2Mo\}_2Sb_2]$ **1**

$[C_5H_5(CO)_2MoSb_3]$ **2**

$[C_5Me_5(CO)_2MoSb_3]$ **3**

Compounds **1** and **2** are formed by the reaction[6] of $(t\mathrm{BuSb})_4$[7] with $[\{C_5H_5Mo(CO)_3\}_2]$ in boiling toluene. Although the Sb:Mo molar ratio of approximately 3:1 should favor the formation of **2**, the main product is **1**. Complex **2** forms in 2.3% yield as dark red, crystal needles with a metallic luster. Solutions of **2** in toluene or benzene are yellow. The crystals decompose at 110 °C and turn black. The analogous reaction of $(t\mathrm{BuSb})_4$ with $[\{C_5Me_5Mo(CO)_3\}_2]$ produced red needles of **3** in 27% yield. All three compounds are air-sensitive. The identity of the compounds was confirmed by elemental analysis and by ^{1}H NMR, IR and mass spectra. The structures of **2** and **3** were determined by X-ray structure



1, 2 $Cp^x = C_5H_5$; **3** $Cp^x = C_5Me_5$ **1** **2, 3**

analysis.[8] Complex **2** crystallizes with two independent molecules in the asymmetric unit. Both molecules contain slightly distorted tetraehedral $MoSb_3$ units in which the antimony atoms form an almost equilateral triangle. The average Sb–Sb bond length in **2** is 274.94(10) pm. This is considerably shorter than the Sb–Sb single bond lengths in $MeC(CH_2Sb)_3$ (280–282 pm),[9] $(t\mathrm{BuSb})_4$ (281.8(2) pm),[8b] or Sb_7^{3-} (287.6–290.6 pm),[3] but longer than Sb–Sb multiple bond lengths (double bond in $[\{C_5H_5Mo(CO)_2\}_2Sb_2]$

267.8(1) pm,[2] triple bond in $[Sb_2\{W(CO)_5\}_3]$ 266.3(3) pm[10]). The average Mo–Sb bond length in **2** is 290.25(10) pm, which is longer than those in **1** (276.2(1), 285.4(1) pm).[2]

The molecular structure of **3** is shown in Figure 1. The distorted tetrahedral $MoSb_3$ unit resembles very closely the

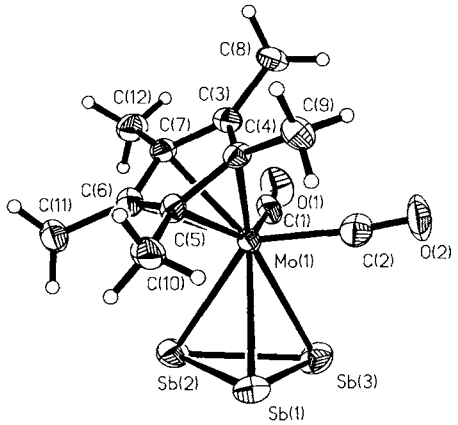

Figure 1. Molecular structure of **3** in the crystal. Selected bond lengths [pm] and mean angles [°]: Sb(1)–Sb(2) 276.82(8), Sb(1)–Sb(3) 274.25(10), Sb(2)–Sb(3) 273.97(9), Mo(1)–Sb(1) 285.12(8), Mo(1)–Sb(2) 286.00(9), Mo(1)–Sb(3) 292.52(9); Sb-Sb-Sb 60.00(2), Sb-Sb-Mo 61.47(2), Sb-Mo-Sb 56.06(2).

$MoSb_3$ unit in **2**. The crystal packing of **2** and **3** is, however, different (Figures 2 and 3). In both cases the molecules

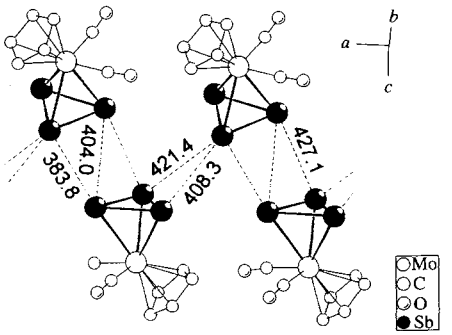

Figure 2. Selected contacts between the molecules in the crystal of **2** with Sb–Sb contact distances smaller than 440 pm.

associate through close intermolecular Sb···Sb contacts to form supramolecular units. In the case of **2** the relevant intermolecular contact distances range from 383.8–427.1 pm, within the van der Waals limit of 440 pm. Similar short Sb···Sb contact distances are also found in thermochromic organo distibanes Me_4Sb_2 (368 pm)[11] and $(Me_3Si)_4Sb_2$ (399 pm),[12] and the organo cyclostibanes $(2,4,6\text{-}Me_3C_6H_2Sb)_4$ (390 pm)[13] and $MeC(CH_2Sb)_3$ (397-401 pm).[9] The molecules in **2** associate to form to corrugated bands, which overlap like roofing tiles. The $[C_5H_5Mo(CO)_2]$ units lie above and below the antimony layers. In the crystal of **3** the molecules are associated through intermolecular Sb···Sb interactions with distances of 374.5 and 383.4 pm. The number of contacts between the molecules is smaller, because the pentamethylcyclopentadienyl groups shield the tetrahedrane molecules more thoroughly.

Experimental Section

1 and **2**: $(t\text{BuSb})_4$ (2.00 g) and $[\{C_5H_5(CO)_3Mo\}_2]$ (2.00 g) are stirred under reflux in 70 mL toluene for about 6 h. The dark red solution is decanted, and the black precipitate washed with 50 mL toluene. The solvent is removed from the combined extracts under reduced pressure, and the residue washed with 2 × 80 mL petroleum ether. The purple red powder that was not dissolved by petroleum ether was taken up in toluene (20 mL), combined with Al_2O_3 (10 g), dried to a flowing powder under reduced pressure, and placed on a chromatography column (3 × 10 cm neutral Al_2O_3 according to Brockmann, particle size 0.063–0.200 mm, degree of activity II). Compound **2** is eluted as a yellow fraction with petroleum ether/toluene (10/1) and crystallizes after concentration of the solution. Yield 50 mg (2.3%). ^1H NMR (360 MHz, C_6D_6, 25 °C): $\delta = 4.22$ (s, C_5H_5); IR (toluene): $\tilde{\nu} = 1962$, 1910 cm^{-1} (C≡O); MS (EI, 70 eV): *m/z*: 584 (90) $[M^+]$, 556 (50) $[M^+ - CO]$, 528 (100) $[M^+ - 2CO]$. Thereafter a broad red fraction is obtained with toluene giving crystals of **1** upon concentration. Yield 0.96 g, 76%. The ^1H NMR, IR and MS data are in accordance with the literature. [2]

3: The reaction of $(t\text{BuSb})_4$ (1.63 g) with $[\{C_5Me_5(CO)_3Mo\}_2]$ (0.85 g) and subsequent work-up are performed analogously. However, the crude material is not washed with petroleum ether. By successive chromatography with petroleum ether, petroleum ether/toluene (12/1), petroleum ether/toluene (8/1), and petroleum ether/toluene (2/1) four fractions are obtained. The first fraction contains 65 mg $(t\text{BuSb})_4$, the third (0.37 g $[\{C_5Me_5Mo(CO)_2\}_2]$). Concentration of the fourth fraction and cooling to −20 °C yields red needles of **3** (0.47 g, 27%). m.p. 198–199 °C (decomp.); ^1H NMR (360 MHz, C_6D_6, 25 °C) $\delta = 1.70$ (s, CH_3); IR (toluene): $\tilde{\nu} = 1951$, 1897 cm^{-1} (C≡O); MS (EI, 70 eV): *m/z*: 654 (40) $[M^+]$, 626 (20) $[M^+ - CO]$, 596 (100) $[M^+ - 2CO]$.

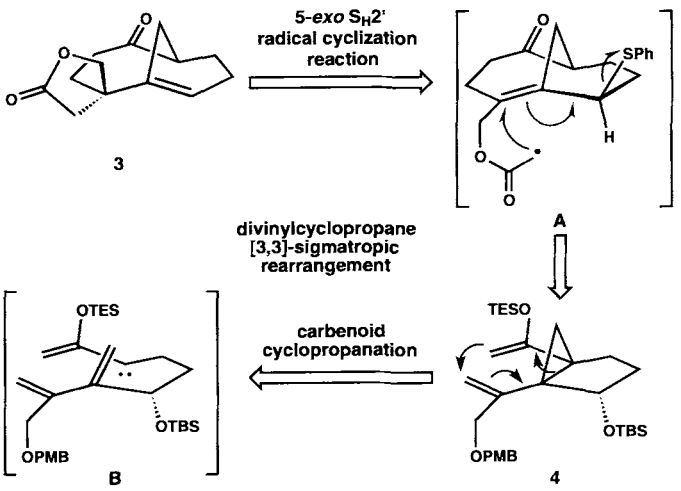
A Novel Approach to the CP-225,917 and CP-263,114 Core**

K. C. Nicolaou,* Maarten H. D. Postema, Neil D. Miller, and Guang Yang

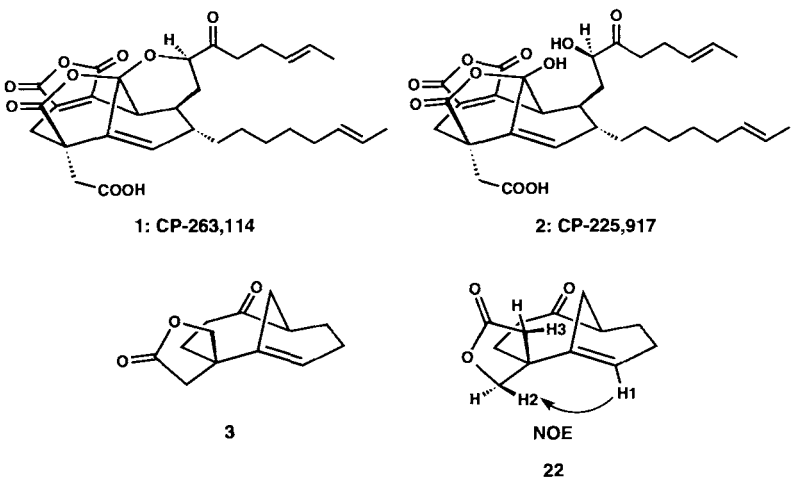
The naturally occurring substances CP-263,114 (**1**) and CP-225,917(**2**) possess intriguing molecular architecture,[1] important biological properties, and an interesting mechanism of action.[2] As inhibitors of squalene synthase and farnesyl transferase, these substances are attractive from the pharmaceutical point of view, particularly with regards to lowering cholesterol levels and to treating cancer. Isolated from an unidentified species of fungi, these compounds include within their structures a novel bicyclo[4.3.1]dec-1(9),4-dien-10-one framework onto which a variety of substituents are attached. We have previously reported on an approach to the central core of these molecules relying on an intramolecular Diels–Alder reaction.[3]

In preliminary studies designed to explore the feasibility of a strategy towards the total synthesis of the CP molecules involving a rhodium-catalyzed carbenoid generation and intramolecular trapping, followed by a divinylcyclopropane rearrangement[4] and a radical cyclization (Scheme 1) the core



Scheme 1. Retrosynthetic analysis of the CP core model system **3**.

model system **3** was defined as a target. We wish to report here the execution of this strategy, which culminated in the construction of racemic **22** which has the opposite stereochemistry at the quaternary center.



The synthesis of the requisite ketocyclopropane **15** proceeded as summarized in Scheme 2. Thus, methyl vinyl ketone (**5**) was treated with formaldehyde under Baylis–Hillman[5] conditions to afford, after *p*-methyoxybenzylation,[6] compound **6** in 25% overall yield. Formation of the enol triflate from **6** (60% yield), followed by palladium-catalyzed coupling with $Me_3SnSnMe_3$ resulted in the formation of vinyltin compound **7** (73% yield). Metal exchange followed by reaction with $TBSO(CH_2)_4CHO$ and silylation furnished bis(silyl)ether **8** in 80% overall yield. Sequential deprotection, Swern and $NaClO_2/NaH_2PO_4$/2-methyl-2-butene oxidations, followed by exposure of the resulting carboxylic acid to

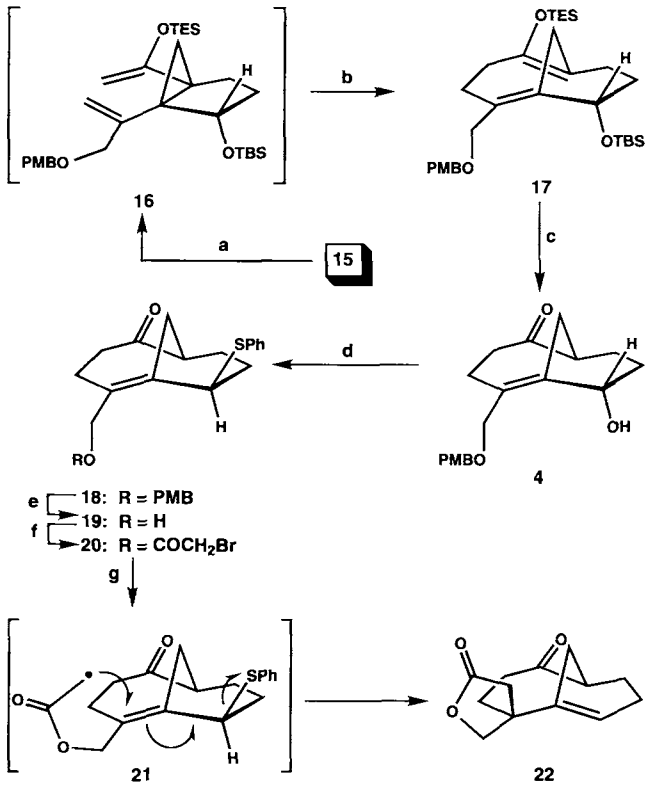
CSA = (+)-camphorsulfonic acid; DABCO = 1,4-diazabicyclo[2.2.2]octane; DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene; DEAD = diethyl azodicarboxylate; DIBAL = diisobutylaluminum hydride; DMSO = dimethyl sulfoxide; HMDS = hexamethyldisilazanide; NMO = *N*-methylmorpholine *N*-oxide; TBAF = tetrabutylammonium fluoride; Tf = trifluoromethanesulfonyl; TPAP = tetra-*n*-propylammonium perruthenate.

diazomethane led to methyl ester **9** in 87% overall yield. The diazo ester **10** (Table 1) was synthesized from **9** by a modified Taber procedure.[7] The crucial carbenoid generation and intramolecular trapping[8] was achieved by treatment of diazo compound **10** with catalytic amounts of $Rh_2(OAc)_4$ in CH_2Cl_2 at 0°C, and led predominantly to vinylcyclopropane **11** together with its C-2 diastereoisomer **14** (ca. 6.7:1 by ^1H NMR).[9] The configuration of **11** was inverted by: 1. desilylation (95% yield for **12** and its C-2 diastereoisomer) and 2 chromatographic separation, followed by Mitsunobu inversion[10] of **12** (DEAD-Ph_3P-PhCOOH, 95% yield), leading to benzoate **13**. The inversion was deemed necessary for the pending 5-*exo*-S_H2' radical cyclization, although the stereochemical requirement for this process has not been fully established. Removal of the benzoate group from **13** generated the corresponding alcohol, which was silylated by treatment with TBSOTf/2,6-lutidine to afford compound **14** (98% yield; the minor C-2 diastereoisomer corresponding to **12** was directly converted to **14** by silylation). Finally, the desired ketocyclopropane **15** (Table 1) was reached from **14** by the following sequence: 1. DIBAL reduction (86% yield), 2. NMO/TPAP oxidation,[11] 3. MeMgCl addition, and 4. a second NMO/TPAP oxidation (93% for three steps).

Treatment of **15** with an excess of KHMDS and Et_3N/TESCl at −78°C as prescribed by Ireland[12] gave the intermediate silyl enol ether **16**, which underwent divinylcyclopropane rearrangement[13] at 45°C to give, after removal of both silyl groups, alcohol **4** in 95% overall yield (Scheme 3,



Scheme 3. Synthesis of **22**. a) KHMDS (3.1 equiv), TESCl:Et_3N:THF (3:1:1) (5.1 equiv), THF −78°C, 1 h; b) THF, −78→45°C, 4 h; c) TBAF (3.5 equiv), THF, 0→23°C, 2 h, 95% over two steps; d) PhSSPh (2.0 equiv), nBu_3P (2.0 equiv), C_6H_6, 23°C, 30 min, then **4**, 23°C, 12 h, 65% based on 50% conversion; e) DDQ (1.3 equiv), CH_2Cl_2:H_2O (10:1), 23°C, 6 h, 85%; f) $BrCH_2CO_2H$ (1.5 equiv), DCC (1.6 equiv), 4-DMAP, (0.1 equiv), CH_2Cl_2, 23°C, 1 h, 81%; g) $Me_3SnSnMe_3$ (5.0 equiv), C_6H_6, *hν*, 35°C, 8 h, 61%. DCC = dicyclohexylcarbodiimide; DDQ = 2,3-dichloro-5,6-dicyano-1,4-dibenzoquinone; 4-DMAP = 4-dimethylaminopyridine.

Table 1). The structure of **4** was rigorously assigned by a combination of 2D NMR experiments. Alcohol **4** was then converted to phenyl sulfide **18** (65% based on 50% conversion) by a modified Mitsunobu-type reaction,[14] and the PMB group was exchanged for an α-bromoacetate moiety, furnishing compound **20** via **19** (69% yield over two steps). Exposure of bromosulfide **20** to $Me_3SnSnMe_3$ and irradiation (hv) in degassed benzene led to lactone **22** (61%) by means of radical intermediates (e.g. **21**) and ring closure with concomitant expulsion of sulfenyl radical (see Scheme 3).[15] This last operation served admirably to simultaneously generate the required quaternary center (albeit

with the opposite stereochemistry to that of **3**) and the bridgehead olefin, two of the most challenging structural elements in **1** and **2**. The structure of this cyclization product was assigned by spectroscopic means (see also Table 1). Thus, ^1H NMR spectroscopy (1D-GOESY) showed NOE of the H2 signal upon irradiation of H1, whereas molecular dynamics and minimization calculations (CV Force Field)[16] revealed interatomic distances of 2.5 and 4.3 Å for H1–H2 and H1–H3, respectively, supporting structure **22** rather than **3**.

The described chemistry demonstrates an efficient entry into the unusual carbon skeleton found in the CP core by combining three powerful synthetic operations (intramolecular cyclopropanation, divinylcyclopropane rearrangement, and radical cyclization). Although modifications are required, this strategy should facilitate the chemical synthesis of both natural products and relatives thereof for chemical biology investigations.

Five-Coordinate Silicon in Zeolites: Probing $SiO_{4/2}F^-$ Sites in Nonasil and ZSM-5 with ^{29}Si Solid-State NMR Spectroscopy**

Hubert Koller,* Axel Wölker, Hellmut Eckert, Christian Panz, and Peter Behrens

The primary building blocks in a wide variety of tectosilicates are corner-sharing $SiO_{4/2}$ tetrahedra.[1] Silicon typically has a coordination number of four in inorganic silicates, and only a few structures are known with other coordination numbers. Six-coordinate silicon has been found in a variety of minerals and silicon phosphates.[2] Recently, van de Goor et al. found a five-coordinate silicon site ($SiO_{4/2}F^-$) by single-crystal X-ray structure analysis of the clathrasil nonasil, which was hydrothermally crystallized from a silica gel in the presence of cobaltocenium cations and fluoride anions.[3] This nonasil will be designated as [Cp_2Co]-F-[Si-NON].[4]

Fluoride ions can be used as a substitute for OH^- in the syntheses of zeolites and clathrasils. Both F^- and OH^- are

called "mineralizing agents" since they solubilize the silica components in hydrothermal syntheses. The synthesis with fluoride results in zeolite structures containing only few defect sites;[5,6] however, the structural rationale for this phenomenon is not known. In contrast, high-silica zeolites (that is, those that have a high silicon content) made in the presence of OH^- have many defect sites which form $SiO^- \cdots HOSi$ hydrogen bonds.[6]

Since the first clathrasils and zeolites were crystallized by the fluoride route,[7] the range of structures that are synthesized in the presence of F^- (instead of OH^-) keeps increasing.[8] Aside from the aforementioned case of nonasil,[3] the structural role of fluoride was only clarified for the clathrasil octadecasil, in which F^- is located in double four ring units.[9] In the case of the high-silica zeolite ZSM-5, which is made with tetrapropylammonium cations and fluoride ions (designated as [TPA]-F-[Si-MFI]), the location of the fluoride ions was investigated by X-ray diffraction experiments on powders[10] and twinned crystals.[11] However, the results of the two studies provide different fluoride positions, and neither implies five-coordinate silicon. Apparently, the disorder of the tetrapropylammonium cations, the lack of good single crystals, and (as will be shown below) a motion of the fluoride ions caused some difficulties for the use of diffraction techniques. Here we show with ^{29}Si magic-angle spinning (MAS) NMR experiments that five-coordinate silicon in the form of $SiO_{4/2}F^-$ exists in [Cp_2Co]-F-[Si-NON] and [TPA]-F-[Si-MFI]. ^{29}Si NMR spectroscopy is a suitable method for distinguishing between four-, five- and six-coordinate silicon sites by considering their chemical shifts.[2]

Specifically, the cross-polarization (CP) technique, which relies on heteronuclear dipole–dipole interactions, allows one to probe the spatial proximity among spins. ^{29}Si NMR signals for silicon sites near fluorine can be selectively enhanced by polarization transfer from ^{19}F in $^{29}Si\{^{19}F\}$ CPMAS NMR experiments. Therefore, $SiO_{4/2}F^-$ sites will give a relatively strong signal due to the short Si–F distance.

Figure 1a shows the ^{29}Si NMR spectrum of [Cp_2Co]-F-[Si-NON]. There is partial overlapping of the resonances for ten distinct crystallographic silicon sites[3] between $\delta = -104$ and -116. Particularly interesting is a weak additional signal at $\delta = -145$, which we assign to the five-coordinate silicon in the structure of [Cp_2Co]-F-[Si-NON]. A similar chemical shift by

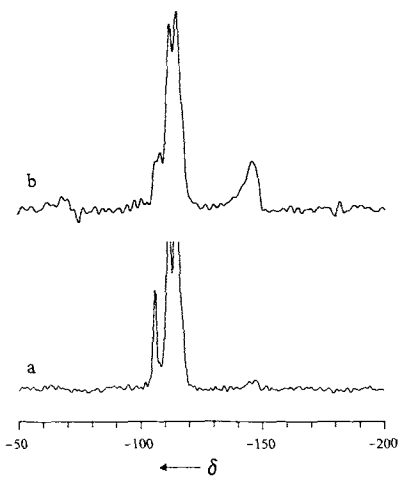

Figure 1. Nonasil sample [Cp_2Co]-F-[Si-NON]: a) $^{29}Si\{^1H\}$ CPMAS NMR spectrum, $B_0 = 7.05$ T, contact time 10 ms; b) $^{29}Si\{^{19}F\}$ CPMAS NMR spectrum, $B_0 = 4.7$ T, contact time 5 ms.

$\delta = -150$ for five-coordinate silicon was observed by solid-state ^{29}Si NMR spectroscopy in a quenched potassium silicate glass by Stebbins.[12] Figure 1b shows that the line at $\delta = -145$ in the $^{29}Si\{^{19}F\}$ CPMAS NMR spectrum is dramatically enhanced, hence confirming the assignment to a $SiO_{4/2}F^-$ species.

The $^{29}Si\{^1H\}$ CPMAS NMR spectrum of [TPA]-F-[Si-MFI] at 298 K is shown in Figure 2a. In the range of chemical shifts for four-coordinate silicon ($\delta = -107$ to -117) there are narrow signals for distinct crystallographic $SiO_{4/2}$ tetrahedra.

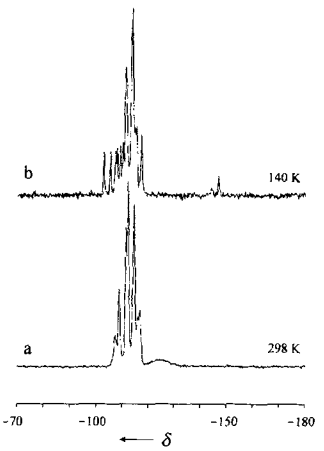

Figure 2. $^{29}Si\{^1H\}$ CPMAS NMR spectra of the ZSM-5 sample [TPA]-F-[Si-MFI], $B_0 = 7.05$ T, contact time 10 ms: a) $T = 298$ K, $\delta = -107.4, -108.9, -111.6, -112.3, -114.5, -116.2, -116.8, -125.0$; b) $T = 140$ K, $\delta = -103.0, -105.5, -107.5, -108.1, -109.3, -110.3, -111.4, -113.7, -114.8, -115.4, -117.3, -144.1, -147.0$.

However, not all of the expected signals are resolved due to overlapping of some lines. A significantly broader line is observed at $\delta \approx -125$. Although several groups obtained similar ^{29}Si NMR spectra of [TPA]-F-[Si-MFI], this broad signal at $\delta = -125$ has not been commented on before. The intensity of this signal is greatly enhanced in the $^{29}Si\{^{19}F\}$ CPMAS NMR spectrum of [TPA]-F-[Si-MFI]. Therefore, we conclude that this signal must be due to silicon sites that are in close proximity to fluorine. The chemical shift at $\delta = -125$ falls between that expected for a $SiO_{4/2}F^-$ site ($\delta \approx -145$) and the range for four-coordinate silicon ($\delta = -107$ to -117). In the following it will be shown that the line at $\delta = -125$ corresponds to an averaged signal due to dynamic exchange between four- and five-coordinate silicon.

[TPA]-F-[Si-MFI] has a phase transition at 175 K that is associated with a change in the space-group symmetry.[13] Figure 2b shows the $^{29}Si\{^1H\}$ CPMAS NMR spectrum of [TPA]-F-[Si-MFI] below this phase-transition temperature. In this spectrum the broad line at $\delta = -125$ is not observed, and instead two sharp lines for at least two distinct $SiO_{4/2}F^-$ sites are found at $\delta = -144.1$ and -147.0. The strong dipolar interaction between the ^{29}Si and ^{19}F nuclei, which would result in broader lines, is effectively averaged out by the MAS technique. Therefore, ^{19}F decoupling was not necessary to obtain the narrow lines in Figure 2b. At room temperature the fluoride ion exchanges between different $SiO_{4/2}$ tetrahedra of the MFI structure, which leads to the broad feature at $\delta = -125$. This motion is frozen out at 140 K, producing the sharp lines for the $SiO_{4/2}F^-$ sites. These observations clearly show that five-coordinate silicon exists in [TPA]-F-[Si-MFI], that is,

high-silica ZSM-5 made with fluoride as the mineralizing agent.

When crystals of [TPA]-F-[Si-MFI] are calcined, then tetrapropylammonium cations and fluoride anions are removed from the structure to leave behind a bare microporous SiO_2 framework of ZSM-5 without five-coordinate silicon. This calcined zeolite was studied in detail by others.[2,14] Work is now in progress to identify in more detail the fluoride binding sites, to characterize the motional process of the fluoride ions, and to measure the relevant ^{19}F–^{29}Si distances.

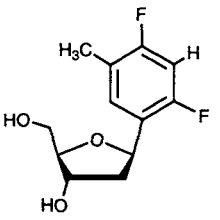
Highly Precise Shape Mimicry by a Difluorotoluene Deoxynucleoside, a Replication-Competent Substitute for Thymidine**

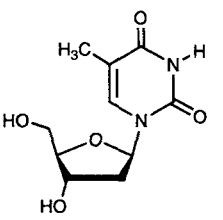
Kevin M. Guckian and Eric T. Kool*

Until recently, the large majority of studies of the origins of DNA replication fidelity have concluded that complementarity of hydrogen bonding is the chief source of energetic selectivity between the four nucleotides at the transition state for initial insertion.[1,2] As part of this field of study, a wide number of modified nucleoside analogues have been incorporated into DNA in an effort to study the origins of mutagenesis and mechanisms for the fidelity of DNA replication.[3] Virtually all of these differed from natural nucleosides both in their hydrogen bonding arrangement and in their size and shape. While such approaches have led to valuable insights, with such analogues it is extremely difficult to distinguish between steric and hydrogen bonding effects as sources of observed differences in replication properties.[4,5]

To address this problem we proposed the structures of four nucleoside analogues designed to mimic as closely as possible the structure of natural nucleosides, but lacking standard polar hydrogen bonding functionality. For example, compound **1**, a difluorotoluene deoxynucleoside, was designed to



1



2

mimic the shape of the natural deoxynucleoside thymidine (**2**). Its difluorotoluene "base" is isoelectronic with thymine, and through the replacement of the carbonyl groups with C–F and the polar N–H group with C–H the two compounds are isosteric as well.[4]

Studies of the properties of nucleoside **1** have indicated that the compound is quite nonpolar and that the difluorotoluene moiety shows no measurable hydrogen bonding tendency in aqueous and organic solutions. For example, titration of **1** with adenine derivatives in chloroform does not lead to measurable complex formation. Further, replacement of thymine with difluorotoluene in the center of a DNA duplex 12 base pairs in length causes strong destabilization, and the difluorotoluene shows no preferential pairing with adenine over the other three bases; in contrast, thymine shows a 3–4 kcal mol^{-1} preference.[6,7] Based on the hydrogen bonding complementarity model of DNA replication fidelity, it was expected that during replication this analogue would serve as a very poor enzyme substrate and would show very little

selectivity for inserting any one of the natural bases over another.

Despite this expectation, a recent study, in which the difluorotoluene analogue replaces thymidine in template DNA strands, has shown that it serves as an excellent and highly specific template for replication. The Klenow fragment (KF) of *E. coli* DNA polymerase I accepts this compound in the template with efficiency nearly matching that of thymine, and the enzyme specifically inserts adenine opposite it.[5] Thus, despite the poor hydrogen bonding abilities of the nucleoside isostere, the enzyme treats it almost as if it were thymidine. If the size, shape, and conformation of the analogue are assumed to be the same as those of thymidine, then one is led to conclude that hydrogen bonding may be less important in the fidelity of replication than previously believed, and that steric effects may play a more direct role. This argument depends strongly, however, on the similarity of the size, shape, and conformation of **1** and thymidine. We now report the results of detailed structural studies of compound **1**, with comparison to natural thymidine. We have obtained X-ray structural data for **1** and have carried out solution studies of it and thymidine by ^{1}H NMR spectroscopy as well.

We were able to obtain X-ray quality crystals of deoxynucleoside **1** from ethanol. Analysis of the solid-state structure reveals that the nucleoside analogue is a remarkably good structural mimic of thymidine. The C-nucleoside crystallized in the $P2_1$ space group and has three molecules in the asymmetric unit. All three molecules have the *anti*-glycosidic conformation; two have *S*-type (C2′-*endo*) puckers in the sugar moiety; the third has an *N*/*S* intermediate conformation (C4′-*exo*). The average bond lengths for **1** and published structural data for thymidine are given in Figure 1.[8,9] In addition, dihedral torsion angles for one of the molecules in the asymmetric unit are given in Table 1 (C6-C(N)1-C1′-C2′ is referred to as C6-C2′), again along with the analogous angles for thymidine (C(N)1-C1′). Examination of the data shows that the conformations of the five-membered rings in the two compounds are essentially identical. The glycosidic torsion angles are also similar, only 18° apart. Bond lengths for the thymine base and difluorotoluene base mimic are nearly all within 0.07 Å of each other. The chief difference is the C=O bond lengths (1.23 and 1.21 Å) as compared to the analoguous C–F bond lengths (averaging 1.37 Å and 1.37 Å, respectively).

Table 1. Structural data for **1** and thymidine obtained by X-ray crystallographic analysis.

Nucleoside	Dihedral angles[°][d]					
	C6-C2′	O4′-C3′	C1′-C4′	C2′-C5′	C(N)1-C3′	C3′-C1′
1[a]	−97.6	+32.2	−36.7	−91.5	+153.2	−9.0
thymidine[b]	−79.5	+28.4	−37.2	−87.3	+147.8	−16.8
H1′-H2′	H1′-H2″	H2′-H3′	H2″-H3′	H3′-H4′	C(N)1-H2′	
1[c]	+157.2	+35.5	−73.4	+84.2	−93.9	+34.0
thymidine[c]	+149.2	+21.9	−41.7	+87.2	−88.5	+33.8

[a] Data for one of the three molecules in the asymmetric unit (see Figure 1). [b] Data from ref.[9]. [c] The H–H dihedral angles were obtained from the crystal structures with atoms added to give normal sp^3 and sp^2 geometries. [d] Only those atoms at the end of the sequence forming the dihedral angle are given. For example, C6-C2′ refers to C6-C(N)1-C1′-C2′.

Also of interest are the noncovalent interactions found in the crystal structure of difluorotoluene deoxynucleoside and those of thymidine (Figure 2). In both structures the 3′ and 5′ hydroxyl groups form intermolecular hydrogen bonds. For compound **1**, the sugar hydroxyls are hydrogen bonded to other sugar hydroxyl groups. For thymidine, the carbonyl and N–H groups, which undergo Watson–Crick hydrogen bonding in DNA, are found to be hydrogen bonded to the sugar hydroxyl groups of neighboring molecules.[9] For deoxynucleoside **1**, no hydrogen bonds or other close contacts[10] are observed with the fluorines on the aromatic ring (the nearest contacts are several F–H contacts of 2.49–2.79 Å).[10,11] In the crystal packing array, the nonpolar difluorotoluenes are segregated from the more polar, H-bonding furanose groups (Figure 2B). Finally, in the thymidine crystal structure the heterocyclic bases are stacked in a linear array; in contrast, the difluorotoluene rings do not form stacks.

To examine these structural details in solution we carried out a conformational analysis of the difluorotoluene deoxynucleoside and of thymidine in D_2O by measuring the furanose coupling constants (Table 2).[12,13] The sugar ring protons for both molecules were completely assigned, and the coupling constants were measured at 500 MHz. The chief difference in furanose resonances for the two compounds is found in the H1′ signals; that for thymidine is $\delta = 0.93$ downfield of that for **1**, consistent with the strong difference in glycosidic bond polarities.

Despite the large difference in polarity of the glycosidic bonds, the sugar ring conformations of **1** and **2** are very similar. Analysis using published methods[13] allowed us to assign the overall conformation of the two deoxynucleosides in both cases as *S* type; thymidine is classified as 70% *S*, while the difluorotoluene compound is 90–100% *S*. In addition, NOE studies carried out on the two structures provided evidence as to the preferred glycosidic conformations in solution. Selective irradiation at the frequency of the H6 signal led to qualitatively larger enhancements of the C-5 methyl signal than of the H1′ signal, and the ratios of these two enhancements were similar for compound **1** and thymidine. This is consistent with predominantly *anti*- glycosidic conformations for both compounds in solution. Thus, we

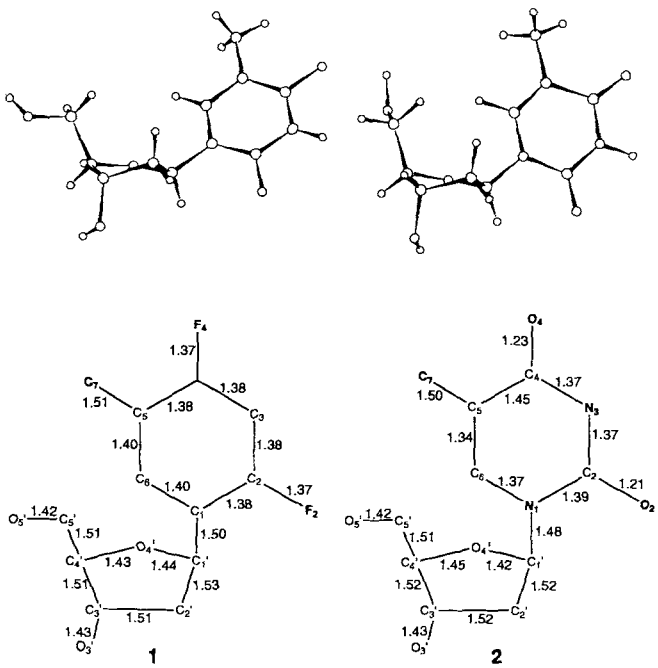

Figure 1. Single-crystal X-ray structure of difluorotoluene deoxynucleoside **1** compared to the published structure of thymidine **2**[8,9]. Top: Structures of the isolated nucleosides. Note that **1** has three different molecules in the asymmetric unit. Bottom: Bond lengths [Å] for **1** (averaged over the three molecules in the asymmetric unit) and thymidine.

[a] Not determined.

conclude that in solution the difluorotoluene nucleoside adopts an overall conformation virtually the same as that of thymidine, despite the replacement of the natural (and more polarized) C–N glycosidic bond by a C–C bond.

These structural studies have relevance to the question of how DNA is synthesized with high specificity. We have shown that the difluorotoluene nucleoside is replicated by KF polymerase with efficiency and specificity almost identical to that with thymidine when placed in synthetic DNA templates.[5] It is clear that the fluorines in **1**, which replace carbonyl groups in thymidine, have very little (if any) tendency to form hydrogen bonds, especially in aqueous solution, and this is further supported by the lack of such noncovalent contacts in the crystal structure. Moreover, the thymine heterocycle and difluorotoluene have very different electrostatic charge localizations; octanol/water partioning studies showed **1** to be highly nonpolar while thymidine is very polar.[7] These data support the notion that the structural, rather than electrostatic, mimicry of **1** may lead to its specific replication.

As a result of these studies we are developing a new model for the physical origins of the fidelity of DNA synthesis. The KF enzyme initially selects an incorrect nucleotide in DNA synthesis only once in 10^3-10^4 times, and virtually the same selectivity is seen for insertion of A (rather than C, T, G) opposite compound **1**.[5] We propose that the primary factor in this selectivity is steric exclusion of incorrect nucleotides. In this model the active site is a tightly restricted pocket defined by the surrounding enzyme and the DNA base in the template strand. The presence of thymine (or an isosteric replacement) in a template excludes guanine, cytosine, and thymine nucleotides by steric clashes with their DNA bases or with the molecules of water solvating them. Adenine is allowed because its shape and size fit perfectly into the active site cavity. This shape-selection hypothesis is currently being examined further in a number of ongoing studies.

In summary, we have analyzed the steric shape and conformation of the C-nucleoside **1** both in solution and in the solid state. The findings indicate that the difluorotoluene nucleoside is a nearly perfect isostere of the natural compound, both in bond lengths and in overall conformation. This nonpolar isostere may be therefore generally useful in the study of molecular recognition and catalytic events that involve the natural structure thymidine, such as protein–DNA recognition and enzymatic synthesis of nucleic acids.

Experimental Section

Crystal structure analysis: Single crystals of the complex were grown from a concentrated ethanol solution. A colorless crystal of approximate dimensions 0.56 × 0.24 × 0.08 mm was mounted on a glass fiber with epoxy and placed on the X-ray diffractometer for data collection at room temperature. The X-ray intensity data were collected on a standard Siemens SMART CCD Area Detector System equipped with a normal focus molybdenum-target X-ray tube operated at 1.5 kW (50 kV, 30 mA). A total of 1321 frames of data (1.3 hemispheres) were collected using a narrow-frame method with scan widths of 0.3° in ω and exposure times of 10 s per frame; the detector-to-crystal distance was 5.094 cm ($2\theta_{max} = 56.52°$). Frames were integrated with the Siemens SAINT program to yield a total of 10400 reflections, of which 6606 were independent ($R_{int} = 0.0425$, $R_{sigma} = 0.0614$ with $R_{int} = \Sigma|F_o^2 - F_c^2(\text{mean})|/\Sigma[F_o^2]$ and $R_{sigma} = \Sigma[\sigma(F_o^2)]/\Sigma[F_o^2]$). Crystal structure data: monoclinic, $a = 13.9262(2)$, $b = 6.4932(0)$, and $c = 19.8156(5)$ Å, $\beta = 104.574(1)°$, and $V = 1753.18(5)$ Å^3 ($T = 23°C$); least-squares refinement of three-dimensional centroids of >1000 reflections. (The integration program SAINT produces unreasonably cell constant errors, since systematic error is not included.) The space group was assigned as $P2_1$ on the basis of systematic absences and intensity statistics by using the XPREP program (Siemens, *SHELXTL 5.04*). The structure was solved with direct methods included in the SHELXTL program package and refined by full-matrix least-squares on F^2. For $Z = 6$, there are three independent molecules in the asymmetric unit. Although the frames were integrated to a $2\theta_{max} = 56.52°$, there were essentially no observed data >45°. Therefore these data were omitted from the refinement yielding a total of 7118 reflections, of which 4101 were independent ($R_{int} = 0.0368$, $R_{sigma} = 0.0437$) and 3548 reflections had $>2\sigma(I)$. All non-hydrogen atoms were refined anisotropically with hydrogens included in idealized positions giving a data:parameter ratio of approximately 10:1. The structure refined to a goodness of fit (GOF) of 1.157 and final residuals of $R_1 =$

Jürgen Pfeiffer and Karl Heinz Dötz*

Dedicated to Professor Dieter Seebach on the occasion of his 60th birthday

Reactions of aliphatic diazo compounds with alkenes catalyzed by transition metal complexes are among the most important methods for obtaining cyclopropanes.[1] The generally accepted mechanism involves the formation of a reactive carbene complex intermediate, resulting from electrophilic attack at the carbon atom of the diazo group and subsequent elimination of N_2. Transfer of the carbene fragment to the alkene regenerates the catalytically active species and the catalytic cycle starts again. Although a carbene complex intermediate has not yet been observed directly, convincing experimental results support this model:

1. The high asymmetric induction observed when chiral metal complexes are used requires strong steric interactions between alkene, metal complex, and carbene during the face-selective reaction step.[2]
2. Reactivity/selectivity correlations between reactions catalyzed by $[Rh_2(OAc)_4]$ and stoichiometric reactions with $[(CO)_5W{=}C(H)Ph]$ indicate a similar mechanism for the two types of reactions.[3]
3. The synthesis of stable carbene complexes from diazoalkanes[4,5] as well as that of cyclopropanes from carbene complexes support the mechanism outlined above.[1a,6] Furthermore, a chiral ruthenium complex that catalyzes the [2+1] cycloaddition of ethyl diazoacetate and styrene in high enantiomeric excess was obtained recently; the corresponding carbene complex, which also catalyzes the reaction, is isolable in the absence of styrene.[7]

The ability of chromium(0) complexes to catalyze [2+1] cycloadditions was hitherto studied in less detail.[8] During our research aimed at the synthesis of stable chromium carbene complexes from diazoalkanes and chromium complexes of the type $[(CO)_5CrL]$ (L = THF, *cis*-cyclooctene), we became interested in the utiliziation of these compounds for catalytic cyclopropanations of alkenes with diazoalkanes.

intermediate during these reactions have not been successful.

Reactions of equimolar amounts of 9-(9*H*)-diazofluorene (**7**) with enol ethers in the presence of **2** (2 mol%) also afford the corresponding spirocyclopropanes **8**[13]–**11** in good to very good yields (Scheme 2, Table 2).[14] Again, no [2+1] cycloaddition was observed with alkyl-substituted alkenes.[11] A control experiment with ethyl acrylate in the absence of **2** indicates that **12** is formed by an uncatalyzed [2+1] cycloaddition.[15] All catalyzed reactions occur with darkening of the reaction mixture; thin-layer chromatography (TLC) shows the typical violet spot for pentacarbonyl[9-(9*H*)-fluorenylidene]chromium(0) (**13**), which, in the absence of alkenes, is isolable from stoichiometric reactions of **2** with **7**.[9]

Direct evidence for **13** during the reaction of **7** with ethyl vinyl ether in the presence of **2** (5 mol%) by ^{13}C NMR spectroscopy is provided by "freezing" the reaction by cooling to -30 °C. In the range between $\delta = 200$ and 380, the ^{13}C NMR spectrum (Figure 1) exhibits the signals of **13** ($\delta =$ 217.58, 238.92, 361.32), **2** ($\delta = 216.04$, 224.31), and of hexacarbonylchromium(0). In addition, further signals are observed which could not be assigned.

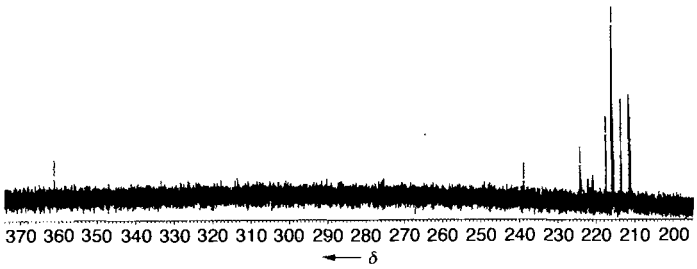

Figure 1. Section of the ^{13}C NMR spectrum (125.6 MHz, $CDCl_3$, 243 K) recorded during the reaction of **7** with ethyl vinyl ether catalyzed by **2**.

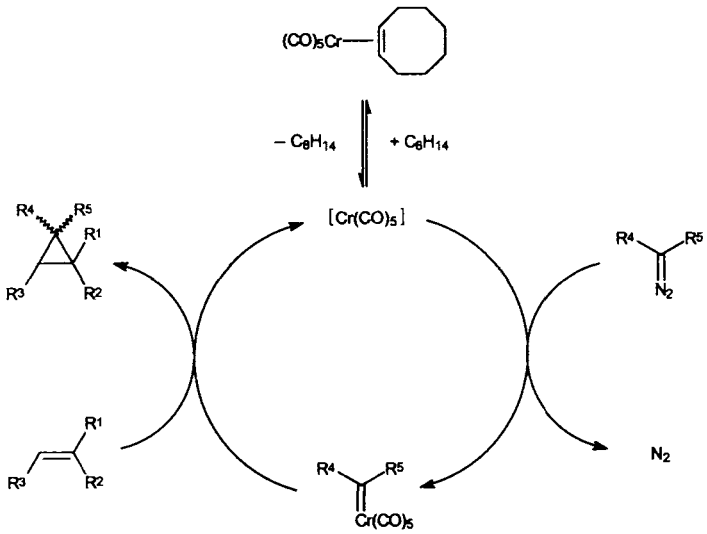
Scheme 3 presents a catalytic cycle that is consistent with the experimental results; however, the detailed mechanism of the carbene transfer from the carbene complex to the alkene remains unclear.



Scheme 3. Catalytic cycle of the chromium complex catalyzed [2+1] cycloadditions.

The chromium-catalyzed reactions of **1** and **7** with alkenes proceed with pronounced chemoselectivity with regard to the electronic properties of the olefin substituents. The preference of electron-rich C–C double bonds can be rationalized in terms of the electrophilic character of the postulated or detected intermediates $[(CO)_5Cr{=}C(H)CO_2Et]$ and **13**, respectively.

We have demonstrated that chromium(0) complexes can efficiently catalyze cyclopropanations. The presence of a weakly coordinated ligand such as *cis*-cyclooctene, which dissociates under mild conditions, generating the catalytically active species "$Cr(CO)_5$", is crucial. Furthermore, the observation of **13** by ^{13}C NMR spectroscopy represents the first

direct evidence for a carbene complex intermediate during a [2+1] cycloaddition catalyzed by a transition metal complex. Further studies on the mechanism and the stereochemical course of the reactions are in progress.

Experimental Section

General procedures: All reactions were performed under argon. Solvents were dried and degassed according to standard procedures. Yields refer to products isolated after column chromatography. Compounds **1** [16], **2** [17], and **7** [18] were synthesized according to literature methods.

3–6: A solution of **1** (1.14 g, 10 mmol) in CH_2Cl_2 (20 mL) was added dropwise over 4 h to a stirred solution of **2** (0.15 g, 0.5 mmol, 5 mol%) in the corresponding alkene (50 mmol), precooled to 5 °C. The reaction mixture changed color from yellow to green-brown under evolution of N_2. After the mixture had been stirred for a further 8 h at 20 °C and the solvent and excess alkene had been removed under reduced pressure, the residue was purified by column chromatography (petroleum ether (40/60)/Et_2O 2:1).

8–11: A solution of **7** (0.57 g, 3 mmol) in CH_2Cl_2 (30 mL) was added dropwise over 8 h to a stirred solution of the corresponding alkene (3 mmol) and **2** (0.02 g, 0.06 mmol, 2 mol%) in CH_2Cl_2 (10 mL). The reaction mixture changed color from yellow to brown-violet under the evolution of N_2. After the mixture had been stirred for a further 8 h at 20 °C and the solvent had been removed under reduced pressure, workup was performed according to one of the following procedures (see Table 2).

A: Workup by column chromatography.

B: The residue was washed several times with portions of petroleum ether(40/60) (10 mL) and filtered until only bis[9-(9*H*)-fluorenylidene]azine could be detected in the solution (TLC-control, petroleum ether (40/60)/CH_2Cl_2 1:1, $R_f = 0.35$). The combined filtrates were concentrated, and purified by column chromatographic workup.

9: ^{1}H NMR (500 MHz, $CDCl_3$): $\delta = 7.89$ (d, 1H), 7.88 (d, 1H), 7.52 (d, 1H), 7.41 (t, 1H), 7.39 (t, 1H), 7.34 (t, 1H), 7.32 (t, 1H), 7.18 (d, 1H), 3.04 (s, 3H), 2.27 (dd, $^2J = 6.15$ Hz, $^4J = 0.55$ Hz, 1H; H-3), 1.91 (d, $^2J = 6.15$ Hz, 1H; H-3), 1.82 (d, $^4J = 0.49$ Hz, 3H; CH_3); ^{13}C NMR (125.6 MHz, $CDCl_3$): $\delta = 144.9$, 144.7, 141.1, 139.9 (4quart. C), 126.5 (CH), 126.0 (CH), 125.82 (CH), 125.78 (CH), 122.7 (CH), 121.5 (CH), 119.9 (CH), 119.5 (CH), 70.3 (s, 1C; C-2), 54.8 (q, 1C; OCH_3), 41.5 (s, 1C; C-1), 30.4 (t, $^1J = 160.8$ Hz, 1C; C-3), 16.8 (q, 1C, CH_3); IR (KBr): $\tilde{\nu}$(cm^{-1}) = 3059 (m), 2962 (m), 1473 (s), 1442 (s), 1240 (vs), 1065 (vs), 813 (s), 736 (vs); MS (EI, 70 eV): *m/z* (%): 236 (95) [M^+], 221 (100) [$M^+ - CH_3$], 205 (35) [$M^+ - OCH_3$], 178 (50) [$C_{14}H_{10}^+$], 165 (44) [$C_{13}H_9^+$], 152 (25) [$C_{12}H_8^+$]; elemental analysis calcd for $C_{17}H_{16}O$ (236.31): C 86.41, H 6.82; found: C 86.11, H 6.82.

Creation of Enantioselective Biocatalysts for Organic Chemistry by In Vitro Evolution

Manfred T. Reetz,* Albin Zonta, Klaus Schimossek, Klaus Liebeton, and Karl-Erich Jaeger*

The development of chiral catalysts for the enantioselective synthesis of optically active compounds is of great academic[1] and industrial interest.[2] Inspite of worldwide intensive research in the area of homogeneous transition metal catalysis, the number of really efficient enantioselective catalysts is limited. Owing to a lack of general principles, the development of a single highly effective chiral catalyst requires laborious preparation and testing of many ligands. Alternatively, biocatalysts can be used, but by nature the problem of limited substrate specificity persists.[3] In some cases site-directed mutagenesis can be applied to improve enzyme activity and selectivity but not in a general way,

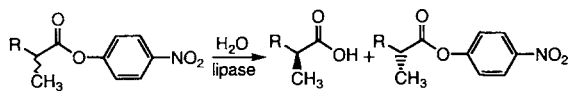
because the process requires detailed knowledge of the three-dimensional structure of the enzyme and its catalytic mechanism as well as a certain degree of intuition concerning the choice of the amino acid to be substituted.[4] Here we describe a new approach to developing enantioselective catalysts, namely in vitro evolution as a method to increase stepwise the enantioselectivity of a given unselective biocatalyst.[5] The underlying principle—"evolution in the test tube"—does not require any knowledge of the enzyme structure or of its catalytic mechanism. In vitro evolution[6] was already used successfully in efforts directed towards increasing the thermal stability and activity of enzymes.[7,8] Proper molecular-biological methods for random mutagenesis and expression of genes coupled with an efficient screening system for the rapid identification of enantioselective mutants form the basis of our strategy.[5]

The enantioselective hydrolysis of racemic *p*-nitrophenyl 2-methyldecanoate (**1**) was chosen as the test reaction. The free (*S*)-configurated acid belongs to a class of chiral compounds which are useful as drugs, plant-protecting agents, and chiral building blocks in organic synthesis.[2] The lipase from the



1, R = *n*-C_8H_{17} **2** (*R*)-**1**

bacterium *Pseudomonas aeruginosa* PAO1, which in its mature form is composed of 285 amino acids, was used as the biocatalyst.[9] The wild-type enzyme shows an enantioselectivity (*ee*) of only 2% in favor of the (*S*)-configurated acid **2**.

The number of mutants for a given enzyme in which one amino acid per enzyme molecule was substituted by one of the remaining 19 amino acids is given by Equation (a): N is the

$$N = 19^M X!/[(X-M)!M!] \quad \text{(a)}$$

number of mutants, M the number of substituted amino acids per enzyme (in this case 1), and X the total number of amino acids per enzyme. Therefore, the corresponding library of *P. aeruginosa* lipase mutants would contain 5415 members. Although such a library is already relatively small, our studies show that upon screening an even smaller number of mutants, catalysts with clearly improved enantioselectivity can be obtained.

Using the "error-prone polymerase chain reaction" (epPCR),[10] the lipase gene consisting of 933 base pairs was subjected to random mutagenesis.[11a] By changing the PCR reaction components and conditions, for example variation of the Mg^{2+} concentration, the mutation frequency was empirically adjusted so that statistically one to two base substitutions per lipase gene were introduced; this could lead to substitution of up to two amino acids per lipase molecule. This low number of mutations per lipase molecule was chosen on the assumption that the identification of the rarely occurring mutations with a positive effect would not be prevented by the more commonly occurring mutations with a negative effect. The mutated genes were ligated into a suitable expression vector, amplified in *E. coli*, and transformed into *P. aeruginosa*.[5,11b] The bacterial clones were then cultivated, each theoretically producing a mutant lipase.

About 1000 mutants isolated in this manner had to be screened for their enantioselectivity in the test reaction. To accomplish this difficult feat within a reasonable period of time, an efficient test system had to be developed; conventional separation based on liquid or gas chromatography was unsuitable due to the expected number of samples. Accordingly, the 96 wells of commercially available microtiter plates were loaded pairwise with the culture supernatants of the lipase mutants together with 0.01M Tris/HCl buffer (pH 7.5; Tris = tris(hydroxymethyl)aminomethane) followed by the addition of enantiomerically pure (*R*) and (*S*) substrates dissolved separately in DMF. Thus, up to 48 mutants per microtiter plate could be screened. The enzyme-catalyzed hydrolysis of each (*R*)/(*S*) hydrolysis pair was monitored by measuring the absorption of the *p*-nitrophenolate anion at 410 nm as a function of time. Figure 1 shows the effect of the

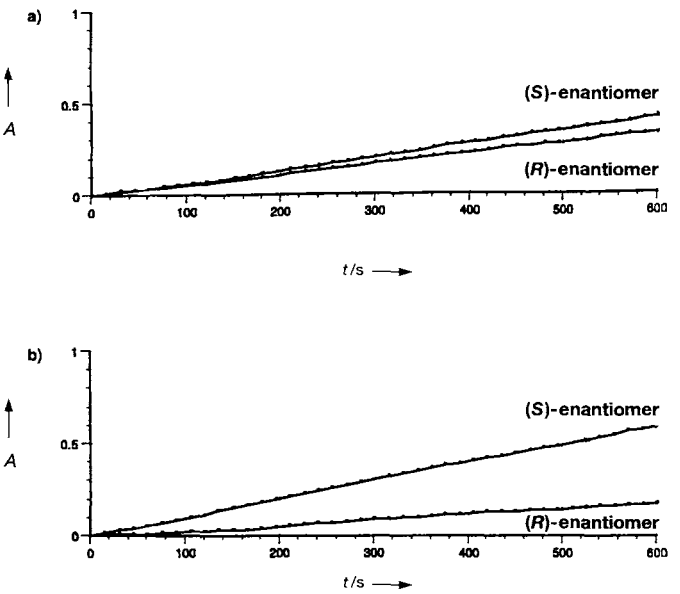


Figure 1. Course of the lipase-catalyzed hydrolysis of the *R*- and *S*-ester **1** as a function of time. a) Wild-type lipase from *P. aeruginosa*, b) improved mutant in the first generation.

original wild-type lipase as well as the typical reaction profile of an improved mutant. Although the relative slopes of the two straight lines can serve as a basis for calculating the corresponding enantioselectivity, we used them only to obtain a qualitative indication due to the possibility of various sources of error. Of 1000 mutants of the first generation tested, 12 showed an increase in enantioselectivity. The exact enantioselectivity was determined by hydrolyzing the racemate **1** in the presence of the corresponding mutant lipases and analyzing the reaction products by gas chromatography on chirally modified capillary columns. The best mutant, P1B01-E4, showed an enantioselecivity of 31% *ee*.

In each generation the clone with the highest enantioselectivity was chosen for the subsequent mutagenesis cycle (Table 1). Figure 2 shows that it was possible to increase the enantioselectivity from 2% *ee* (wild-type enzyme) to 81% *ee* in only four generations.

Table 1. Results of screening.

Generation	Number of clones tested	Number of positive clones	Designation of the chosen clone
1	1000	12	P1B01-E4
2	2200	10	P2B08-H3
3	2400	1	P3B13-D10

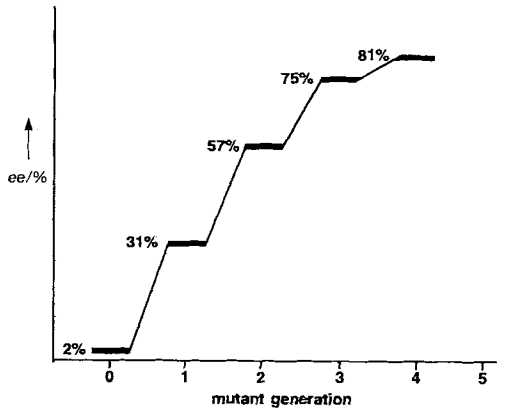

Figure 2. Sequential increase of enantioselectivity in the test reaction of **1** in the course of the mutagenesis experiments. (The *ee* values refer to the corresponding best mutant in a reaction with a conversion range of 20–30%; corresponding *E* values: 1.00, 2.10, 4.40, 9.40, and 11.3, respectively.)

In view of the fact that only four mutant generations were produced and only relatively few mutants were actually screened, the results obtained so far are remarkable. To increase the enantioselectivity even more we are currently exploring four possibilities: 1) more comprehensive screening, 2) production of further generations, 3) DNA-shuffling[6b,7] as an alternative mutagenesis method, and 4) saturation mutagenesis[12] (systematic substitution at the mutated positions with the remaining amino acids). At present it is not possible to predict which of the four strategies will lead most rapidly to an even further increase in enantioselectivity.[13] Investigations concerning sequence determination of the mutant genes as well as modelling the three-dimensional structure of the mutant proteins are also under way.

Lipases from different organisms serve routinely as catalysts in the enantioselective synthesis of chiral esters, alcohols, amines, diols, diesters, diamines, amino alcohols, α- and β-amino acid derivatives, and cyanohydrins, albeit not always with acceptable *ee* values.[3,14] Therefore, our method, which is presumably not restricted to lipases, opens up new perspectives in organic chemistry. The evolutive optimization of enantioselectivity described here can now be combined with the search for higher enzyme stability and activity.[15] All efforts in this new area depend upon the development of further screening methods.[5,16]

[11] a) The lipase gene cloned into pBluescript II KS (Stratagene) was mutagenized by epPCR[6a,9] using the following primers: A: 5′-GCG CAA TTA ACC CTC ACT AAA GGG AAC AAA-3′ and B: 5′-GCG TAA TAC GAC TCA CTA TAG GGC GAA-3′. PCR was performed under the following conditions: 2 min at 98 °C (1 ×); 1 min at 94 °C, 2 min at 64 °C, 1 min at 72 °C (25 ×); 7 min 72 °C (1 ×); b) PCR products were ligated into plasmid pUCPL6A derived from pUCPKS (A. A. Watson, R. A. Alm, J. S. Mattick, *Gene* **1996**, *172*, 163–164). Plasmids were propagated in *E. coli* JM 109, isolated, and used to transform *P. aeruginosa* PABST7.1 (K.-E. Jaeger, B. Schneidinger, F. Rosenau, M. Werner, D. Lang, B. W. Dijkstra, K. Schimossek, A. Zonta, M. T. Reetz, *J. Mol. Catal. B: Enzym.* **1997**, *3*, 3–12). For each new cycle of mutagenesis the lipase gene of the best perfoming clone for a given mutant generation was isolated and recloned into pBluescript II KS.

Dennis), Academic Press, San Diego, **1997** (*Methods Enzymol.* **1997**, *284*); d) *Lipases, Part B: Enzyme Characterization and Utilization* (Eds.: B. Rubin, E. A. Dennis), Academic Press, San Diego, **1997** (*Methods Enzymol.* **1997**, *286*); e) E. N. Vulfson in *Lipases* (Eds.: P. Woolley, S. B. Petersen), Cambridge University Press, Cambridge, **1994**, pp. 271–288; f) *Engineering of/with Lipases* (Ed.: F. X. Malcata), Kluwer, Dordrecht, **1996** (*NATO ASI Ser. Ser. E.* **1996**, *317*).

[15] In our studies this also occurred to some extent, since the mutants having a low activity (which in some cases may lead to higher enantioselectivities) are "sorted out" upon screening. Only those mutants are considered which induce a notable conversion within ten minutes under the reaction conditions. Indeed, many mutants show practically no activity, which is not surprising.

Shape-Selective Hydrogenation and Oxidation over a Platinum-Containing Ultramicroporous Heteropolyoxometallic Compound**

Yusuke Yoshinaga, Kohei Seki, Teruyuki Nakato, and Toshio Okuhara*

Shape-selective catalysis like that typically demonstrated by zeolites is of great interest from a scientific as well as an industrial viewpoint.[1-6] However, certain factors restrict the general application of zeolites: their acid strength is not very great,[7] their pore sizes are not sufficiently variable, and the choice of constituent elements is limited. Various alternative microporous inorganic materials have been synthesized for possible use as catalysts. Thus, Toba et al.[8] prepared microporous SiO_2/Al_2O_3 by a sol–gel method, and Maier et al.[9,10] described a series of microporous oxides, including SiO_2, TiO_2, ZrO_2, Al_2O_3, and related mixed oxides.

Heteropolyacids can be regarded as cluster models for mixed oxides. They are also fascinating and important catalysts from a practical standpoint, because they and their acidic cesium salts are very acidic and much more active than such zeolites like H-ZSM-5 in various acid-catalyzed reactions.[7,11-13] It is known that ammonium and cesium salts of the Keggin heteropolyacid $H_3PW_{12}O_{40}$ have porous secondary structures.[14-17] Recently Hölderich and co-workers[18] claimed that an organic salt of a Dawson heteropolyacid ($H_6P_2W_{18}O_{62}$) with 1,6-hexanediyldiamine has pores in its crystal structure. In addition, Müller et al. synthesized a supramolecular molybdenum oxide cluster with the form of a ferris wheel and thus with an opening in the center.[19] More recently, it was found that the cesium salt $Cs_{2.2}H_{0.8}PW_{12}O_{40}$ is microporous.[20] We have now succeeded in synthesizing a novel platinum-containing compound (5 wt% Pt), $Pt/Cs_{2.1}H_{0.9}PW_{12}O_{40}$ (**1**), in which all of the ultramicropores have diameters smaller than benzene (5.9 Å). Ultramicropores are defined as pores with widths less than 7 Å.[21] Here we report that **1** is an efficient catalyst for shape-selective hydrogenation of alkenes and complete oxidation of alkanes.

The adsorption isotherms of **1** are Type I isotherms[22] characteristic of microporous materials (Figure 1). On the other hand, $Pt/Cs_{2.5}H_{0.5}PW_{12}O_{40}$ (**2**) gave a Type IV isotherm in which a hysteresis was observed. A Type IV isotherm is usually associated with mesoporous materials.[22] In addition, the steep increase in adsorbed amount of gas in the low-pressure region ($p/p_0 < 0.1$) of this isotherm indicates the presence of both micropores and mesopores. The inset of Figure 1 shows Horváth–Kawazoe plots for N_2 adsorption[23] that reveal sharp peaks for **1** and **2** at 5.5 Å and 5.9 Å, respectively. Thus, **1** is microporous, while **2** contains both micro- and mesopores. However, pore diameters estimated with the Horváth–Kawazoe method are not necessarily reliable, because the analysis is performed with parameters based on the interaction between N_2 and graphite,[23] not between N_2 and an oxide.

To determine the pore size for **1**, adsorption experiments were carried out for molecules of different sizes with the aid of a microbalance (Shimadzu TG-30) connected directly to a high-vacuum system (molecular probe method). The results are summarized in Table 1. It should be noted that N_2 adsorption was measured at 77 K, and the other adsorption experiments were carried out at room temperature at a relative pressure $p/p_0 = 0.2$ (exception: 2,2-dimethylpropane $p/p_0 = 0.1$). Benzene, 2,2-dimethylpropane, CCl_4, and 1,3,5-trimethylbenzene were adsorbed on **2**. On the other hand, **1** adsorbed only small amounts of these compounds, but large amounts of N_2. This demonstrates that **1** possesses only ultramicropores with a diameter of 3.6–5.9 Å. and that the external surface area is negligibly small. By contrast, **2** has pores with a diameter of at least 7.5 Å (Table 1).

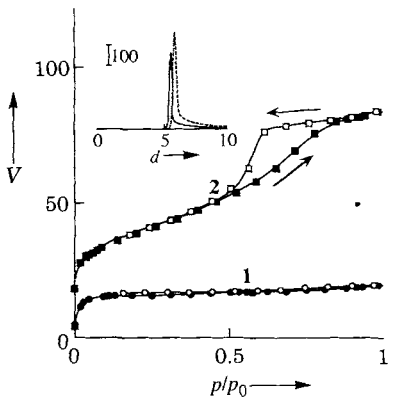

Figure 1. N_2 adsorption/desorption isotherms for **1** (black/white circles) and **2** (black/white squares) at 77 K. The samples were pretreated at 573 K in vacuum. Inset: Horváth–Kawazoe analysis [23] for **1** (solid line) and **2** (dotted line), calculated from the N_2 adsorption isotherms from standard parameters [23]. p/p_0 = relative pressure, V = adsorbed volume (in $cm^3 g^{-1}$ at standard temperature and pressure), d = pore diameter in Å; the ordinate of the inset represents $\Delta V/\Delta d$ in $mm^3 Å^{-1} g^{-1}$.

Table 1. Adsorption of various molecules on **1**, **2**, and Pt/SiO_2 (each with 0.5 wt% Pt).

Molecule	Diameter [Å]	Amount adsorbed [μmol g^{-1}] [a]		
		1 [57 $m^2 g^{-1}$]	**2** [130 $m^2 g^{-1}$]	Pt/SiO_2 [274 $m^2 g^{-1}$]
N_2	3.6	659 (64)	1679 (164)	3530 (344)
Benzene	5.9 [24]	10 (2)	507 (93)	845 (155)
2,2-DMP [b]	6.2 [24]	5 (1)	302 (68)	393 (88)
CCl_4	6.9 [24]	5 (1)	436 (85)	484 (94)
1,3,5-TMB [c]	7.5 [1]	6 (2)	566 (140)	1196 (296)

[a] Measurements were carried out at room temperature under a relative pressure (p/p_0) of 0.2 (exceptions: 77 K for N_2; $p/p_0 = 0.1$ for 2,2-dimethylpropane). Prior to measurement, samples were pretreated at 573 K in vacuum. The figures in square brackets are BET surface areas, and those in parentheses are adsorption areas [$m^2 g^{-1}$], calculated from the amount adsorbed and the molecular cross section. [b] 2,2-dimethylpropane. [c] 1,3,5-trimethylbenzene.

Figure 2 depicts the pore-size distribution for **1** and **2** in the range of mesopores, as derived from the desorption branch of the N_2 isotherm on use of the Dollimore–Heal method.[25] No mesopores are present in **1**, whereas **2** contains mesopores with a diameter of about 40 Å, consistent with the results presented in Table 1.

Catalytic activities of **1**, **2**, and a Pt/SiO_2 with respect to hydrogenation and oxidation are summarized in Table 2. In the case of hydrogenation of ethene, conversions decreased gradually with time; the conversions leveled off for all

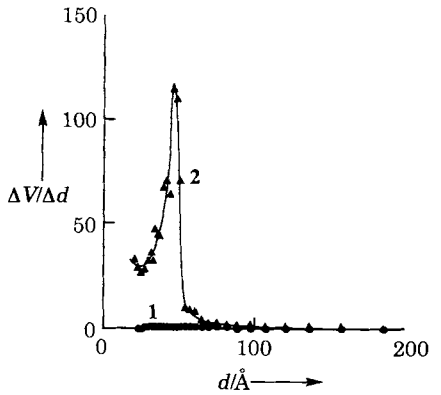

Figure 2. Pore-size distributions derived by the Dollimore–Heal method [25] for **1** (circles) and **2** (triangles) from the N_2 isotherms in Figure 1. The analysis was performed using the desorption data.

Table 2. Relative catalytic activities of **1**, **2**, and Pt/SiO_2 (each with 0.5 wt % Pt) toward hydrogenation and oxidation [a].

Reaction	T[K]	Catalytic activity [b]		
		1	**2**	Pt/SiO_2
Hydrogenation of				
ethene	320	0.9	1.9	12.7
		(7.1)	(15.0)	(100)
cyclohexene	273	0.1	18.8	52.1
		(0.2)	(36.1)	(100)
Oxidation of				
methane	573	22.5	34.5	23.0
		(97.8)	(150.0)	(100)
2,2-dimethylpropane	493	2.6	103.5	28.6
		(9.1)	(361.9)	(100)

[a] The activity is given in $mmol\,g^{-1}\,min^{-1}$ for ethene and in $\mu mol\,g^{-1}\,min^{-1}$ for the other compounds. [b] Numbers in parentheses are activities relative to those of the Pt/SiO_2 catalyst.

catalysts after about two hours under the reaction conditions employed (see Experimental Section). The activity of **1** for ethene hydrogenation (reported per unit catalyst weight) at this stationary conversion was about half that of **2**, while Pt/SiO_2 was more active than these heteropolyoxometallic catalysts. In contrast, the conversion for the hydrogenation of cyclohexene was 0.2% for **1** and 0.5% for both **2** and Pt/SiO_2. As a matter of fact, cyclohexene (which has a diameter of about 6 Å) was not adsorbed on **1** at room temperature (less than 5 $\mu mol\,g^{-1}$), whereas it was appreciably adsorbed on **2** (1300 $\mu mol\,g^{-1}$). These results indicate that **1** exhibits shape selectivity for the hydrogenation of alkenes. The amount of cyclohexene adsorbed on **2** was larger than the corresponding amounts of benzene or CCl_4. A probable explanation is that some dimerization of cyclohexene occurred on **2** as a result of superacidity [11,12] and the mesoporous structure. Another cause may be the conformational flexibility of cyclohexene.

Catalytic activities are also compared in Table 2 for oxidation of methane and 2,2-dimethylpropane; the collected data refer to the stationary states attained after about two hours. In these reactions, the decreases in conversion as a function of time were small. For methane oxidation, all the catalysts exhibited similar activities; the relative activities of Pt/SiO_2, **1**, and **2** were 1.0, 1.0, and 1.5, respectively. However, the activity of **1** for oxidation of 2,2-dimethylpropane was less than 3% that of **2** and 9% that of Pt/SiO_2. As can be seen in Table 1, 2,2-dimethylpropane was adsorbed on both **2** and Pt/SiO_2, but not on **1**. Therefore, the low activity of **1** in this reaction is due to limited adsorption and/or diffusion of the reactant molecules in the constrained pores of **1**. This is an example of shape-selective oxidation of alkanes, which is of interest for applications in catalysis and sensor materials for gas detection.

The line widths in X-ray diffractograms reveal that these cesium–hydrogen salts consist of primary crystallites with a size of about 120 Å. The primary crystallites, which are themselves nonporous,[12,15] aggregate to produce secondary particles. It is reasonable to assume that the close-packed aggregates resulting from the primary crystallites are responsible for the voids with diameters of about 40 Å. This represents a possible mechanism for the formation of mesopores in **2**. In the case of **1**, most of the mesopores might be filled with molecules of the acidic form ($H_3PW_{12}O_{40}$) during preparation. After heat treatment this salt is probably converted into a material with nearly uniform composition.[16] In both salts, pores are present between the primary crystallites. We currently speculate that micropores in **1** are generated by crystallographic mismatching of the facets.

An attempt was made to detect platinum particles in **1** and **2** by the use of transmission electron microscopy (TEM) and X-ray diffraction (XRD). TEM produced images of aggregates of fine primary crystallites of the Cs salts, but no platinum particles could be localized, even with a resolution of about 1 nm. XRD results also failed to show peaks attributable to platinum particles. These results suggest that the platinum centers are highly dispersed, with crystallite (particle) size less than 1 nm. While the surface area of **1** was about 50% that of **2**, the activity of **1** was only 0.6% and 2.5% that of **2** for cyclohexene hydrogenation and 2,2-dimethylpropane oxidation, respectively (Table 2). These results indicate that platinum particles are located exclusively within the pores of **1**.

In conclusion, a novel catalyst ($Cs_{2.1}H_{0.9}PW_{12}O_{40}$ containing 0.5 wt % platinum) exhibited shape-selective catalysis in the hydrogenation of alkenes and the oxidation of alkanes and preferentially catalyzed reactions of smaller molecules. This is the first example of shape selectivity by an ultramicroporous heteropolyoxometallic compound containing an additional metal, and it may lead to novel applications in the field of shape-selective catalysis.

Experimental Section

Both **1** and **2** were prepared by a titration method. For each an aqueous solution of $[Pt(NH_3)_4]\cdot(OH)_2$ ($0.03\,mol\,L^{-1}$) was added to an aqueous solution of $H_3PW_{12}O_{40}$ ($0.08\,mol\,L^{-1}$) at room temperature. An aqueous solution of Cs_2CO_3 ($0.10\,mol\,L^{-1}$) was then added dropwise at a rate of $1\,mL\,min^{-1}$ with vigorous stirring at room temperature. The cesium content was controlled by the amount of Cs_2CO_3 added. The platinum content was adjusted to 0.5 wt %. A pale yellow precipitate was obtained, the color of which was due to the presence of Pt. The solution was allowed to stand overnight at room temperature. The solid obtained by drying at 318 K was pretreated in a flow of O_2 at 573 K for 2 h. A Pt/SiO_2 catalyst (0.5 wt % Pt), prepared from $[Pt(NH_3)_4]\cdot(OH)_2$ and SiO_2 (AEROSIL 300, $274\,m^2\,g^{-1}$) by an impregnation method and then calcined at 773 K in air, was used as a reference. Nitrogen adsorption/desorption isotherms were measured with a BELSORP 28SA apparatus (BEL Japan, Inc.).

Catalytic reactions were carried out in a flow reactor (Pyrex, 12 mm inside diameter) at atmospheric pressure. Conditions for ethene hydrogenation: ethene 9%, H_2 91% (He diluent gas), flow rate $27.5\,mL\,min^{-1}$, 320 K, catalyst 20 mg (in powdered quartz, 200 mg); for cyclohexene hydrogenation: cyclohexene 1.5%, H_2 82% (He diluent gas 16.5%), flow rate $30.5\,mL\,min^{-1}$, 273 K, catalyst 200 mg (in powdered quartz, 200 mg); for methane oxidation: methane 30%, O_2 20% (He diluent gas 50%), flow rate $20\,mL\,min^{-1}$, 573 K, catalyst 100 mg (in powdered quartz, 300 mg); for 2,2-dimethylpropane oxidation: 2,2-dimethylpropane 4%, O_2 40% (He diluent gas 56%), flow rate $50\,mL\,min^{-1}$, 493 K, catalyst weight 20–100 mg (in powdered quartz, 100 mg). Prior to the reactions, catalysts were pretreated in a flow of O_2 at 573 K for 1 h, and then in a flow of H_2 at 573 K

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2834 $ 17.50+.50/0

for 1 h in the case of hydrogenation, or in a flow of He at 573 K for 1 h for oxidation. The catalytic test was conducted with fine powders (μm range) of the catalysts.

Stabilization of Atomic Nitrogen Inside C_{60}**

Harald Mauser, Nicolaas J. R. van Eikema Hommes, Timothy Clark, Andreas Hirsch,* Björn Pietzak, Alois Weidinger, and Lothar Dunsch

Until now only electropositive metal cations[1,2] or noble gas atoms[3,4] were incorporated into fullerenes. The first member of a new class of endohedral complexes in which the guest is a very reactive nonmetal is the recently described $N@C_{60}$.[5] ESR and electron nuclear double resonance (ENDOR) spectroscopic analyses of this system show an astonishing and unprecedented situation: Nitrogen is in its atomic ground state ($^4S_{3/2}$) and not covalently bound to the carbon atoms of the fullerene cage.[5] Therefore, the concave inner face of C_{60} must be extraordinarily inert. We now investigated the influence of the shape of a carbon network on its reactivity, and present here a topological explanation for this result. Moreover, we predict that the energy barrier for the penetration of nitrogen through the cage is comparatively low, and confirm this experimentally.

To prove that nitrogen is atomic in $N@C_{60}$ and not covalently bound to the cage atoms we performed semiempirical (PM3-UHF[6a,b]/RHF) and density functional calculations (UB3LYP/D95*//PM3[6c]) on the system N/C_{60} with the programs VAMP 6.1[7a] and Gaussian 94.[7b] The structure of $N@C_{60}$ with nitrogen in the center of the cage is the global minimum for endohedral complexation (Tables 1 and 2, Figure 1). The formation of $N@C_{60}$ from the free components is more or less thermoneutral. PM3-UHF calculations give a relative binding enthalpy of $+10.5$ kcal mol^{-1}; the UB3LYP/D95* value for the PM3-UHF geometry is -0.9 kcal mol^{-1} (Table 2). The Coulson and Mulliken charges on the nitrogen atom are both negligible according to PM3 and density functional calculations. The spin density is almost exclusively

[a] Optimized geometry. [b] Based on free C_{60} and N in the ground state (ΔH_f^0). [c] Based on the PM3-UHF geometry. [d] To reach SCF convergence faster, we calculated with five instead of six d functions. [e] Atomic units a.u. [f] TS = transition state.

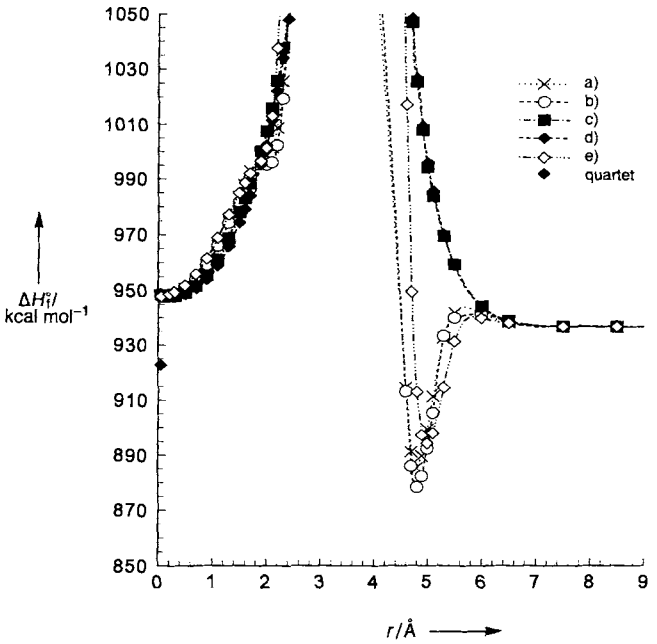

Figure 1. Enthalpies of formation ΔH_f^0 (according to PM3-UHF calculations) for N/C_{60} complexes as a function of the distance r from N to the cage center with retention of a rigid cage geometry. Displacement of the cage center towards a) a [5,6] bond, b) a [6,6] bond, c) the center of a pentagon, d) the center of a hexagon, and e) a C atom.

localized at the nitrogen atom. The fact that no charge transfer from the nitrogen atom to the fullerene takes place is due to the low, even slightly negative, electron affinity[8] of N (−0.32 eV), which is comparable with that of He (−0.59 eV). The transition from the quartet to the doublet state of the encapsulated N atom needs 22 kcal mol^{-1} (PM3-UHF). The endohedral complexation causes a lowering of the differences in energy between the doublet and the quartet state by about 20 kcal mol^{-1}.

The reaction coordinates for the endo- and exohedral approach of the N atom to a C atom, a [6,6] double bond, a [5,6] single bond, the center of a six-membered ring, and the center of a five-membered ring of fixed or optimized fullerene cage structures are shown in Figures 1 and 2. To obtain useful results, all calculations were performed for the doublet states to allow a comparison of the energies of the bound and unbound structures. With a fixed cage geometry the energy increases continuously when the N atom moves from the center to the cage, independent of the direction of approach (Figure 1). In contrast, there are strong attractive interactions if the N atom approaches a C atom, a [6,6] bond, or a [5,6] bond from the outside. This can be explained with the pyramidalization of the C atoms of C_{60}. Thus, the π orbitals do not have pure p character. The π orbital axis vector (POAV) analysis of Haddon[9] gives an average σ-bond hybridization of $sp^{2.278}$ for C_{60} and a fractional s character of the "p orbitals" of 0.085. Due to electron-pair repulsion the charge density on the outside of the fullerenes is higher than on the inside. This means that, in contrast to the reactive exterior, the orbital overlap between the fullerene and a N atom is essentially unfavorable inside C_{60}; at the same time there is a repulsion of the valence electron pairs (Figure 3).

If the fullerene cage is allowed to relax during the approach of the N atom to a C Atom, a [6,6] bond, or a [5,6] bond (Figure 2), there are local minima for the endohedral complexes corresponding to covalently bound structures with a C–N bond, an aza bridge over a closed [6,6] bond, and an aza bridge over a closed [5,6] bond (Figure 4). These local minima are about 20–50 kcal mol^{-1} higher in energy than the global minimum of N@C60 with N in the center of the cage (Table 2, Figure 3). In contrast to the corresponding exohedral complexes, no energy gain is accompanied with covalent endohedral binding and subsequent relaxation of the cage geometry (Table 2, Figure 2). This is because endohedral addition at the relatively rigid cage structure of C_{60} leads to very unfavorable geometries, such as distortion of the tetrahedral angles and untypical bond lengths near the bound addends (Figure 4b, Table 1). In the case of the corresponding exohedral adducts the opposite effect takes place. Here the cage geometry supports the formation of normal, less strained geometries in the region of the addend (Figure 4d, Table 1). For endohedral additions the considerable σ strain of the fullerene cage would be enlarged, but if the addition is exohedral the strain of the cage would decrease. The tendency of the outside surface of fullerenes to undergo addition reactions easily is confirmed by many experimental examples of exohedral adduct formation.[10,11]

The energy barriers for the penetration of nitrogen from the interior through a [5,6] or a [6,6] bond in the doublet state are 49 and 41 kcal mol^{-1}, respectively, according to PM3-UHF calculations (Figure 2), and therefore significantly lower than the most favorable value (225 kcal mol^{-1}) calculated for the penetration of He out of He@C_{60} by a one- or two-window mechanism.[3,12] Even the escape of N starting from the quartet state costs little more than 60 (PM3) or 67 kcal mol^{-1}

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2836 $ 17.50+.50/0 *Angew. Chem. Int. Ed. Engl.* **1997**, *36*, No. 24

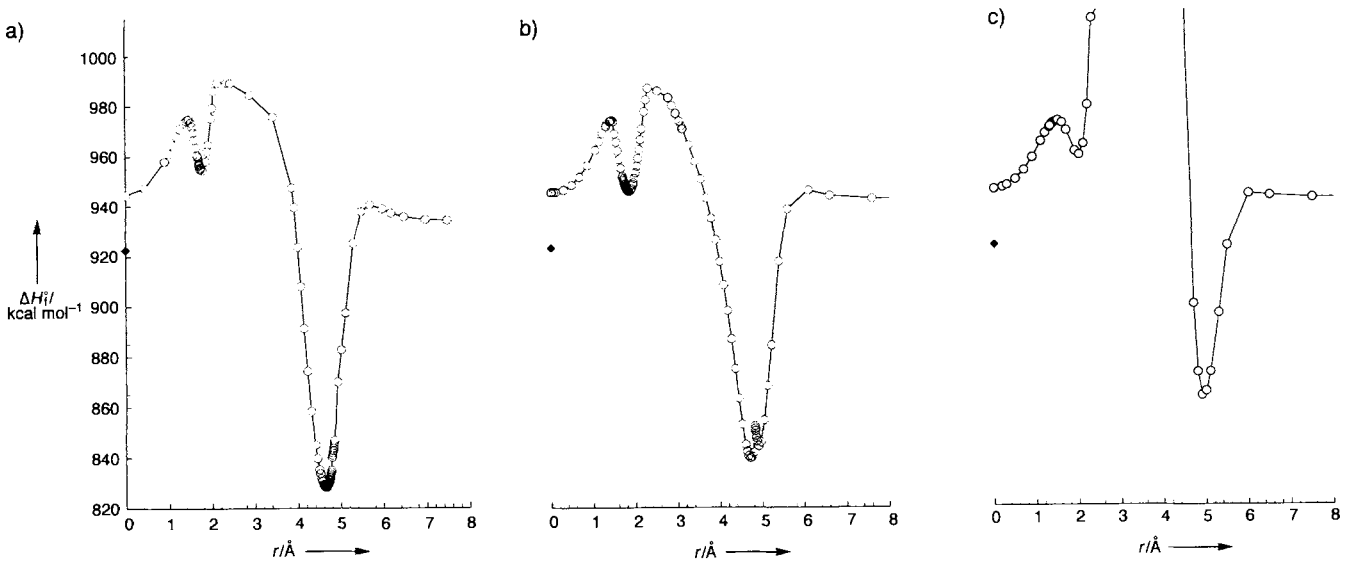

Figure 2. Enthalpies of formation ΔH_f^0 (PM3-UHF) of N/C_{60} complexes with relaxed (optimized) geometry as a function of the distance r from N to the cage center. Displacement of N from the cage center towards a) the center of a [5,6] bond, b) the center of a [6,6] bond, and c) a C atom; ◆ represents the quartet minimum. The calculations were performed for N in the doublet state. Analysis of the reaction coordinates with configuration-interaction (CI) calculations showed that the ground state is very close to the excited states of the same multiplicity. Thus, points of discontinuity of the reaction coordinates in a) and b) are due to internal crossing between different energy surfaces. The discontinuity of the reaction coordinate in b) next to the exohedral minima corresponds to the opening of the bridged [6,6] bond (Tables 1 and 2). As expected [10], this opening does not occur for the analogous bridged C_{60}NH compounds.

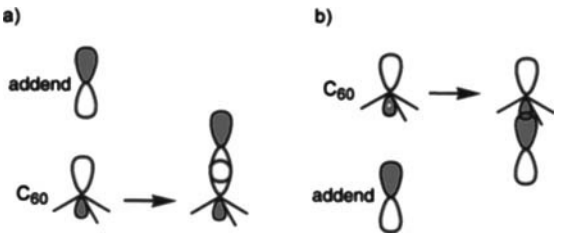

Figure 3. Schematic representation of a) exohedral and b) endohedral addition of the p orbital of the addend to the fullerene with fixed cage geometry.

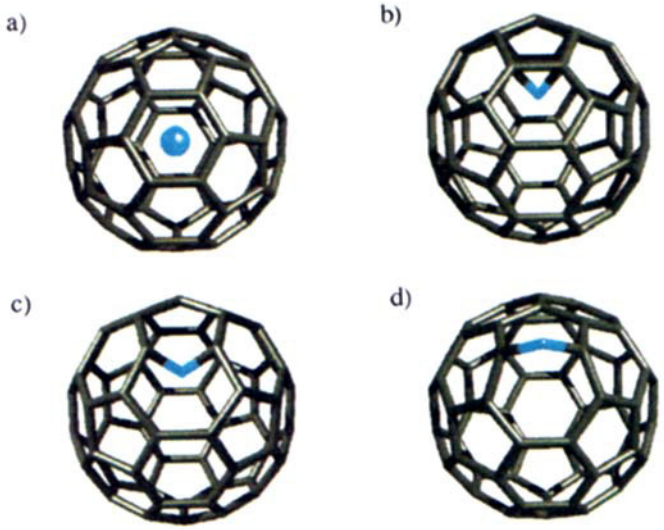

Figure 4. PM3-UHF geometries of the stationary points for the movement of an N atom from the cage center through a [5,6] bond (see also Figure 2). a) Structure of the global minimum of N@C_{60} with N in the center of the cage, b) structure of the local minimum of N@C_{60} with a covalent [5,6] aza bridge, c) transition structure for the penetration of N through a [5,6] bond, and d) structure of the minimum with an open [5,6] bond.

(UB3LYP). This is reasonable, because in the case of N@C_{60} nitrogen penetrates after formation of covalently bound adducts with endohedral [5,6] or [6,6] aza bridges (Figures 2 and 4). This bridging elongates the C–C bond (Table 1), and the penetration of the N atom through the cluster (Figure 4) and subsequent dissociation is favored. This autocatalytic bond breakage requires less energy than the considerable cage distortion needed for penetration by He. Experimentally He is able to leave C_{60} only after thermal treatment for hours at 600 to 850 °C; this process is accompanied by irreversible destruction of the fullerene cage.[3] In contrast, we showed in this study that N escapes from N@C_{60} under considerably milder conditions. In the ESR spectra of N@C_{60} at 260 °C (Figure 5) the intensity of the signals decreases continuously during the measurement. When the sample is then cooled to 220 °C, the spectrum shows the same symmetric triplet but with significantly decreased intensity. This indicates that under thermal treatment N@C_{60} leads to diamagnetic prod-

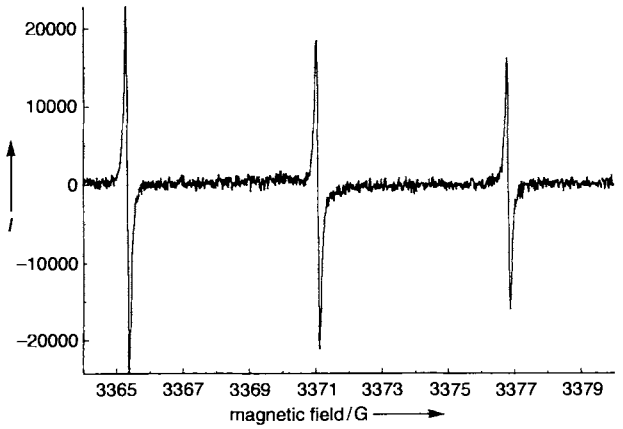

Figure 5. ESR spectra of N@C_{60} at 260 °C; sweep time 84 s for 16 G, intensity I in arbitrary units. The concentration of N@C_{60} decreased to 68% in the time between the first and the third peak (59.2 s).

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1997 0570-0833/97/3624-2837 $ 17.50+.50/0

ucts. Thus, the N atom must have penetrated the fullerene cage, because free or bound radicals can only be stabilized on the outside by subsequent reactions. According to the observed decrease in the intensity of the ESR peaks with time, it is possible to determine the lifetime of the N atoms in $N@C_{60}$ at 260 °C. With an attempt frequency of 10^{13} Hz the activation energy for N extrusion can be estimated with the Arrhenius equation to be about 40 kcal mol^{-1}.

We have now given evidence that the rigid concave shape of the interior of C_{60} is responsible for the astonishing inertness towards N atoms. The reactivity of a carbon network characteristically depends on its shape. In an upcoming theoretical study we will demonstrate that C_{60} is also a "chemical Faraday cage" for other reactive substances such as F and H atoms or the methyl radical.

Although the numerical value of S^2 is very high for adducts of fullerene radicals (and also for C_{60} itself), the energetic and geometric effects of spin contamination are small because of the very high multiplicities of the principal spin contaminants; c) B3LYP: P.
